e) Potential for accelerating the ions to the electric-magnetic field: 8 kV,
f) Temperature measurement: 400—840 °C by the use of a W5Re/W26Re thermocouple.

A glass sample of about 0.5 g was set in the Knudsen cell and heated step by step, such as: room temperature $\xrightarrow{1.5h}$ 400 °C(1h) $\xrightarrow{40m}$ 500 °C(1h) $\xrightarrow{40m}$ 600 °C(1h) $\xrightarrow{20m}$ 650 °C(1h) $\xrightarrow{20m}$ 700 °C(1h) $\xrightarrow{20m}$ 750 °C(1h) $\xrightarrow{20m}$ 800 °C(1h), or as: room temperature $\xrightarrow{40m}$ arbitrary temperature(1.5h). The steady ion currents were confirmed even after 150m at 700 °C. The weight loss of the glass between before and after heating was 1.5 mg.

Results and Discussion

The Shape of Mass Peak and Correction of the Peak Height. A mass spectrum is constituted of the background (BG) peaks and the sample peaks. Since the BG peaks appear at the positions of almost all the mass numbers, the mass spectrum of BG was used as the mass marker. As the BG molecules are composed of carbon, hydrogen and oxygen, the sample peak appears at a lower mass position than the BG peak when the mass number is the same. The typical shape of a mass peak is illustrated in Fig. 1. It can be seen that the peak height of ^{39}K started to grow at 650 °C and then continued to grow exponentially as the temperature was raised.

The heights of the BG peaks are quite different because of the change in the instrumental constant. Thus, the BG peak heights at every temperatures were normalized at constant values, and the observed heights of the sample peaks were corrected using the normalizing factor.

Establishment of the Steady Flow. The ion currents became constant after 10 min when the temperature of the sample reached the arbitrary value. This means that a steady flow from the Knudsen chamber to the ionizing chamber was established. The difference in pressure between inside and outside the Knudsen cell is calculated by means of Eq. 1, itself derived from the molecular corrision theory and the Maxwellian distribution of velocities[10,11]

$$P - P_{out} = G(2\pi RT/M)^{1/2}/(Ut), \quad (1)$$

where P: Pressure inside the Knudsen cell,
P_{out}: Pressure outside the Knudsen cell, i.e., in the ionizing chamber,
G: Effusion loss through the orifice of area U in an experimental time t,
T: Temperature in the Knudsen cell,
M: Molar weight of the effusion species.

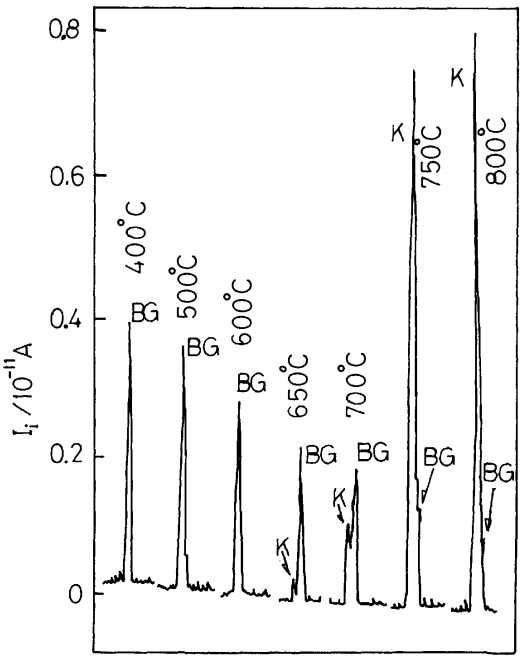

Fig. 1. Change of the mass peak pattern at m=39 for P6 glass matrix. BG: Back Ground, K: Potassium.

In view of the facts that the mean molar weight of various effusing species M is 100 g/mole and that t=4h because the effusion rate G/t increases steeply beyond 700 °C, and using the experimental values of G=1.5 mg, T=1000 K, U=0.25² π mm² and P_{out}=2×10⁻⁵ Pa, P=0.38 Pa was obtained. P=0.38 Pa corresponds to 3.1×10⁻⁹ mol from the ideal gas law, and it is comparable with the effusing rate per second G/t=1.0×10⁻⁹ mol s⁻¹. Thus a rapid but steady effusion and a similar vaporization were recognized.

Vaporizing Species and the Volatilities. The assignment of the chemical species was based on the agreement of the ion-beam current ratio with the natural abundance of isotopes. No parent-daughter relation was found between Na, NaO, Na_2O, and Na_2, or between Cs, CsO, and Cs_2O, by recording the ionization efficiency curves in the range of the ionizing voltage from 4 to 33 kV. Thus, it is presumed that the chemical formulae of the assigned ions are identical with those of the evaporating species.

The species vaporizing from every glass were Na, K, Rb, and Cs, but Li was not vaporized from any glass. Nickel and Zinc were vaporized from the P5 and P7 glasses, but not from the P6 glass. Tellurium was vaporized as Te from the P5, P6 and S4, while it was vaporized as Te and TeO_2 from the P7 and P8 glasses. The other modifier ions were not detected in the vapor phase of any glass. None of the network-former ions (Al, B, or their oxides) were detected in the vapor phase below 840 °C. The vaporizing species and the ion-beam currents observed are summarized in Table 3.

The ratios of the ion-beam current IT vs. the molar fractions of the positive ion in the glass matrix X are

shown in Table 4. The IT/X varies by several orders in magnitude with the different ions in the same glass. This means that the vaporization is incongruent. Supposing that the IT/X is a scale of the volatility, and that the species are confined to monovalent ions, silver is the most volatile; subsequently volatility order of Cs>Rb>K>Na follows silver. The exptremely high value of IT/X for silver is attributably to the rapid diffusion. The volatility of alkali metal ions is correlated with the ionic radius.

Thermodynamic Considerations. The total vapor pressure in the Knudsen cell was previously estimated as P=0.38 Pa. The partial pressure of the i-th ion P_i is proportional to the ion current I_i.[11]

$$P_i = I_i Tk/(\sigma_i S_i), \quad (2)$$

where k: Istrumental coefficient,
σ_i: Ionization cross-section,
S_i: Sensitivity coefficient of the secondary-electron multiplier.

In practice, the I_i and T are observed by means of mass spectrometry, but the estimation of the σ_i and S_i is impossible. Accordingly, the values of P_i are not

determined by the use of Eq. 2.

Suppose that an *i*-th component in the glass matrix has an activation energy of vaporization, ΔH_i^*. The ΔH_i^* is, as well known, a coefficient of the Arrhenius plot of the vapor pressure:

$$\frac{d \ln P_i}{d(1/T)} = \frac{-\Delta H_i^*}{R} \tag{3}$$

By substituting Eq. 2 in Eq. 3, we obtain:

$$\frac{d \ln(I_i T)}{d(1/T)} = \frac{-\Delta H_i^*}{R} \tag{4}$$

The plots of $\ln(I_iT)$ vs. $1/T$ showed linear lines. The coefficients of lines *a* and *b* were calculated by means of the least-squares method, they are summarized in Table 5. The ΔH_i^* values were evaluated from the *a* value and Eq. 4. They were listed in Table 6. Tables 4 and 6 indicate that the volatility of Na, Te, or Cs in the S2, S3, and S4 (S-series) glasses is obviously smaller than in the P5, P6, P7, and P8 (P-series) glasses. This is attributable to the fact that the network-former ions in the S-series glass are richer than in the P-series glass: i.e., the sum of the molar fractions of Si, B, and Al in the S-series glass was about 78 mol%, while that in the P-series glass was 61—68 mol%.

From another point of view, the activation energies of monovalent modifier ions in the same glass decrease and then increase as the ionic radius increases. If the activation energy were exactly the energy needed for release from the electrostatic force between M^+ and O^{2-}, the activation energy would decrease monotonously as the ionic radius increased. Thus, another energy which increases with the increase in the ionic radius must be included in the activation energy. The high registivity of Cs against movement has been reported after the measurement of the self-diffusion coefficient. For instance, the values in $M_2O \cdot SiO_2$ glass at 500 °C are 5.8×10^{-10} cm^2 s^{-1} for M=Cs, while 2.3×10^{-8} cm^2 s^{-1} for M=Na.[13,14] It was assumed that the additional energy is elastic energy and is proportional to the cube of the ionic radius;

$$\Delta H_i^* = \Delta H_{i,\text{coul}}^* + \Delta H_{i,\text{elas}}^*, \tag{5}$$

$$\Delta H_{i,\text{coul}}^* = N\frac{2e^2\alpha}{r_o + r_i} = \frac{A}{r_o + r_i}, \tag{6}$$

$$\Delta H_{i,\text{elas}}^* = Dr_i^3. \tag{7}$$

As the Madelung constant is used to calculate the lattice energy, $\Delta H_{i,\text{coul}}^*$ is a product of $2e^2/(r_o+r_i)$ by a constant α. Thus, a simple expression, $A/(r_o+r_i)$, was obtained. It was previously noted that the observed

a) Shannon's effective ionic radius of 6-coordinated ion; $r_o=0.140$ nm.[15]

ΔH_i^* showed different values depending on the mol% of the network-former ion: Si, B, and Al. The total mol% of the modifier cations and the middle ions in the P-series glasses were 32—39 mol%. This quantity is sufficient to determine the values of $\Delta H_{i,coul}^*$. It follows that a more precise chemical composition may also be effective. The A and D constants were calculated for the respective glass by the least-squares method, using the data of ΔH_i^* and Shannon's effective ionic radius.[15] The contributions of the electrostatic energy and the elastic energy to the total activation energy was summarized in Table 7. Almost all the $\Delta H_{i,calc'd}$ values are in agreement with the $\Delta H_{i,obs'd}$ values, but (1) the $\Delta H_{i,calc'd}$ values for every glass showed a monotonously decreasing curve with increase in r_o+r_i, and (2) the negative sign of D for the P5 and P6 glasses is unreasonable physically. The other functions, such as $A/(r_o+r_i)+B\exp[-(r_o+r_i)C]+Dr_i^3$ and $A/(r_o+r_i)+Dr_i^2$, gave quite unreasonable values of A, B, or C. The calculation based on the simple assumption suggested that the electrostatic energy is the major portion, while the elastic energy is a minor portion, of the activation energy.

Conclusion

When an aluminoborosilicate glass matrix is heated up to near the softening point, Na, K, Ni, Zn, Rb, Ag, Te, TeO_2, and Cs are detected in the vapor phase. The activation energy of vaporization was calculated from the Arrhenius plot of the observed ion currents.

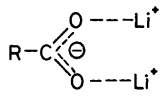
The Polarographic Reduction of Acids in Pyridine. The Cause of the Differences in Half-Wave Potentials with Various Supporting Electrolytes

Masashi Hojo,* Yoshihiro Akita, Kazukiyo Nishikawa, and Yoshihiko Imai
Department of Chemistry, Faculty of Science, Kochi University, Kochi 780
(Received April 22, 1986)

The polarographic reductions of acetic, benzoic, *p*-toluenesulfonic, and perchloric acids have been examined in pyridine solutions with tetrabutylammonium, tetraethylammonium, sodium, and lithium perchlorate as the supporting electrolytes. The difference in the half-wave potentials of the acids was explained in terms of the difference in the degree of interaction between the pyridinium ion and the conjugate bases (e.g., CH_3COO^-) made of the acids. The alkali-metal ions interact with the acetate or benzoate ion to form $RCOO^-(M^+)_2$ (M=Li and Na). The formation constants of $RCOO^-(M^+)_2$ were evaluated by means of the positive shift in the half-wave potential of the pyridinium ion in the presence of a large excess of the alkali metal ions. Substituted acetic and benzoic acids and phenols were also examined so as to ascertain the effect of the substituent groups.

Hickey et al.[1] reported very interesting behavior in the polarographic reduction of some acids in pyridine: the pyridinium ion produced in 0.1 M† $LiClO_4$ is reduced at a more positive potential than that of the wave produced in 0.1 M Et_4NClO_4. The half-wave potential ($E_{1/2}$) of the pyridinium wave in Et_4NClO_4 depends on the acids from which the pyridinium ion is produced, whereas that in $LiClO_4$ is essentially independent of the acids (leveling effect). In spite of their great efforts to clarify the cause of the difference in $E_{1/2}$ between Et_4NClO_4 and $LiClO_4$, they were not able to reach the conclusion, probably because they not only lacked knowledge about the key chemical species but had also failed in preparing the compound ($C_6H_5COONEt_4$) essential for the study in a pure form. Tsuji and Elving[2] explained the leveling effect qualitatively in terms of the ion-association and ion-exchange reactions.

We have developed a polarographic method[3,4] to obtain a complex formation constant using the anodic (mercury dissolution) wave induced from a base. By the method, we have confirmed some new species, including the $RCOO^-(M^+)_2$ (M=Li and Na)-type species for the acetate and benzoate ions in acetonitrile.[4]



The formation of the $[CH_3COOLi_2]^+$ species in acetonitrile was first proposed by Itabashi in 1972.[5]

In the present investigation, the polarographic behavior of acetic, benzoic, *p*-toluenesulfonic, and perchloric acids in pyridine is examined using several supporting electrolytes. The leveling effect of the acids caused by Li^+ and Na^+ will be accounted for by the formation of the $RCOO^-(M^+)_2$ species. Methyl- and chloro-substituted acetic acids, and chloro-substituted benzoic acids and phenols will also be examined.

The reduction of the hydrogen ion at the dropping mercury electrode is usually accompanied by a high overvoltage in aqueous solutions. Mairanovskii,[6] however, assumed that some protonated bases (e.g., protonated pyridine) might be reduced reversibly, and he confirmed a normal reversible process for the catalytic hydrogen wave caused by pyridine in a 0.1 M borate buffer containing tetraethylammonium phenylmethanesulfonate.

† 1 M=1 mol dm^{-3}.

Experimental

Pyridine from Wako Pure Chemicals (GR grade) was dried with molecular sieves 4A.[7,8] The method of preparing pure tetraethylammonium benzoate was described in a previous paper.[4] The supporting electrolytes were prepared and dried by the methods described elsewhere.[9] Benzoic and *p*-toluenesulfonic acids were dried as has been described previously.[10] Commercial acetic acid (Wako, GR grade) and perchloric acid (Wako, GR grade, 60%) were used as received. The other acids and phenols, commercially obtained GR or EP grade, were used without further purification.

All the polarograms were recorded with a Yanagimoto polarograph, Model P-1000 and a Watanabe X-Y recorder, Model WX-4401-L0, with the potential sweep rate of 5 mV s^{-1}, at (25±0.2)°C. Two dropping mercury electrodes were used: the open-circuit characteristics of the electrodes at h=50 cm were m=2.02 mg s^{-1} and τ= ca. 4 s (capillary A), and m=1.79 mg s^{-1} and τ=4.0 s (capillary B), in 0.1 M Et_4NClO_4-pyridine. The drop time was regulated at 1.0 s for all the polarographic measurements. The reference electrode was a silver-silver perchlorate electrode, Ag/0.1 M $AgClO_4$-pyridine. Pure nitrogen was used for the deoxygenation of polarographic solutions.

Results and Discussion

Acetic, Benzoic, *p*-Toluenesulfonic, and Perchloric Acids. Benzoic acid gave a single cathodic wave at ca. −1.57 V in pyridine containing 0.1 M Et_4NClO_4 as the supporting electrolyte, as is shown in Fig. 1. The wave height was linear to the concentration of benzoic acid over the range of 0.1—1 mM. The wave was found to be diffusion-controlled, as is indicated by the relation of $i_l \propto \sqrt{h}$. With 0.1 M n-Bu_4NClO_4, a similar wave was observed at almost the same potential. With 0.1 M

a) 0.1 M perchlorate salts. b) vs. Ag/0.1 M $AgClO_4$–pyridine. c) $-E$ vs. $\log[i/(i_d-i)]$. Capillary A was used for measuring the data in Table 1.

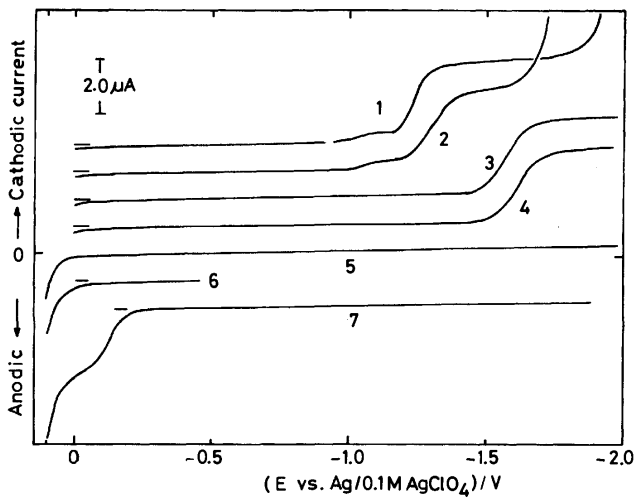

Fig. 1. D.c. polarograms of benzoic acid and the benzoate ion in pyridine containing various supporting electrolytes at 25°C.
[Benzoic acid]=1.0 mM for 1—4.
1: 0.1 M $LiClO_4$, 2: 0.1 M $NaClO_4$, 3: 0.1 M Et_4NClO_4, 4: 0.1 M Bu_4NClO_4, 5: the base current with 0.1 M Et_4NClO_4, 6: $[C_6H_5COOEt_4N]=0.99$ mM, 0.1 M $LiClO_4$ or $NaClO_4$, 7: $[C_6H_5COOEt_4N]=0.99$ mM, 0.1 M Et_4ClO_4.

$LiClO_4$ and $NaClO_4$, however, the wave was shifted to more positive potentials and the wave was accompanied by a prewave (Table 1). Similar behavior has been reported by Hickey et al.:[1] they attributed the main wave to the reduction of the pyridinium ion formed from benzoic acid and pyridine. Acetic acid gave a less reversible cathodic wave at a more negative potential than benzoic acid. The half-wave potential of the wave depended on the supporting electrolyte cation. On the other hand, the main waves for perchloric or *p*-toluenesulfonic acid (*p*-TOs) were observed at more positive potentials (−1.20—−1.245 V), being almost indifferent to the kind of supporting electrolyte cations.

The half-wave potentials of the main wave for the acids in the presence of the tetraalkylammonium ions are in this order: $HClO_4 \simeq p$-TOs>benzoic acid>acetic acid. The negative shift for the weaker acids may be accounted for by the interaction between the pyridinium ion and the conjugate-base anion ($PyH^+ \wedge\!\wedge\, RCOO^-$). Therefore, the effect of the benzoate ion on the $E_{1/2}$ for benzoic acid was examined. A ten-fold concentration increase (from 10 to 100 mM) of tetraethylammonium benzoate shifted the $E_{1/2}$ for benzoic acid (1 mM) ca. 120 mV negatively and decreased the wave height linearly down to half of the initial height at 100 mM of the salt. This shows a strong interaction between the pyridinium cation and the benzoate anion. The potential shift of ca. 120 mV with a 10-fold increase in the benzoate concentration suggested that the compound formed by the pyridinium ion and a large excess of the benzoate ion might be a 1:2 complex (pyridinium dibenzoate; cf. $[Li^+(C_6H_5COO^-)_2]$ in Ref. 4). At any rate, the benzoate and acetate ions seemed to be bound to the pyridinium ion so tightly because neither pyridinium benzoate nor acetate gave any anodic wave, although tetraethylammonium benzoate gave a well-defined anodic wave at −0.12 V with 0.1 M Et_4NClO_4 (Fig. 1).

The half-wave potentials of the reduction waves for

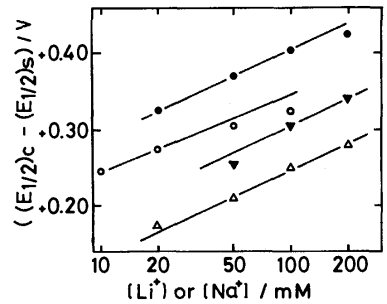

Fig. 2. Shifts of the half-wave potentials of the cathodic waves of acetic and benzoic acids (1 mM) with the addition of alkali metal ions. (●): Acetic acid, Li^+, (○): benzoic acid, Li^+, (▼): acetic acid, Na^+, (△): benzoic acid, Na^+. The total ionic strength is kept to be 0.1 M with Et_4NClO_4, except for 200 mM solutions of Li^+ and Na^+. See the text for $(E_{1/2})_c$ and $(E_{1/2})_s$.

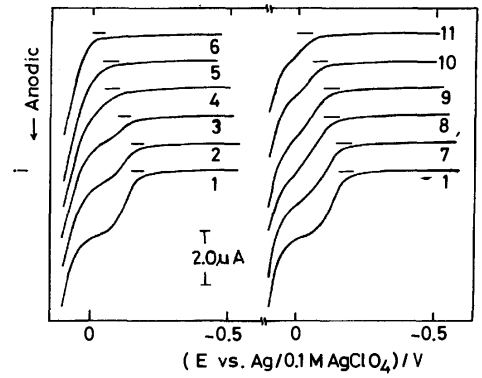

Fig. 3. Changes in the anodic wave from the benzoate ion in 0.1 M Et_4NClO_4-pyridine with the addition of $LiClO_4$ and $NaClO_4$.
$[C_6H_5COOEt_4N]$=0.99 mM.
1: Li^+ and Na^+ free, 2: 0.4, 3: 0.6, 4: 0.8, 5: 1.0, 6: 2.0 mM of Li^+, 7: 0.4, 8: 0.8, 9: 1.0, 10: 1.4, 11: 2.0 mM of Na^+.

acetic and benzoic acids were shifted positively by the supporting electrolyte cation in this order: $Li^+ > Na^+ > Et_4N^+ \simeq n\text{-}Bu_4N^+$. The positive shift by alkali metal cations suggested that the interaction between the pyridinium ion and the acetate or benzoate ion would be weakened by the interaction between the acetate or benzoate ion and the alkali-metal cations. Figure 2 shows the shifts in the $E_{1/2}$ for acetic and benzoic acids with the concentration changes in Li^+ and Na^+. The $E_{1/2}$ shifted ca. 120 mV positively upon a 10-fold increase in the concentration of the alkali-metal ions, except in the case of benzoic acid with Li^+ (ca. 100 mV). The waves became reversible and diffusion-controlled at higher concentrations of Li^+ or Na^+ ($\geqslant$ 20 mM) in most cases. However, for acetic acid, more than 50 mM of Na^+ was needed to obtain the reversible and diffusion-controlled wave.

The following equation was used to analyze the above data:

$$(E_{1/2})_c = (E_{1/2})_s + \frac{0.059}{n}\log K + \frac{0.059}{n} p \log [M^+], \quad (1)$$

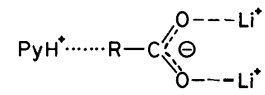
where n is the number of electrons and p is the number of M^+ bound to a carboxylate ion. The term of $(E_{1/2})_c$ means the $E_{1/2}$ of an acid in the presence of an alkali-metal ion. As the standard ($(E_{1/2})_s$), the $E_{1/2}$ of the acid in the absence of alkali-metal ions (with 0.1 M Et_4NClO_4) was taken. K stands for the overall formation constant. The other conditions for Eq. 1 are similar to those given in Refs. 3, 4, or 11. In Eq. 1, we get p=2, since the pyridinium ion is reduced by one electron (n=1)[2,12,13] and the slope of $\Delta E_{1/2}/\Delta\log[M^+]$ is ca. 120 mV, as has been mentioned above.

Thus, the reaction for acetic acid is as follows:

$$PyH^+ \wedge\wedge\wedge\wedge CH_3COO^- + 2\,M^+ \overset{K}{\rightleftharpoons} PyH^+ \cdots\cdots CH_3COO^-(M^+)_2. \quad (2)$$

The formation constants of the ion pair (or complex) between the acetate ion and the lithium and sodium ions were found to be log (K/M^2)=ca. 8.8 and ca. 7.1 respectively. We ignored the irreversibility of the wave for acetic acid in the absence of an alkali-metal ion. For the benzoate ion, the values were log (K/M^2)= ca. 7.8 and ca. 6.2 with Li^+ and Na^+ respectively. In acetonitrile,[4] the formation constants of $CH_3COO^-(Li^+)_2$ and $C_6H_5COO^-(Li^+)_2$ in the reactions between $RCOONEt_4$ and Li^+ were obtained as log (K/M^2)=11.0 and ca. 9.0 respectively. The values of the formation constants are only approximate, however, because of some irreversibility in the waves and an incomplete dissociation of $M^+ClO_4^-$ in pyridine solutions.

In this study, the cathodic wave of the pyridinium ion was used as the indicator. The pyridinium ion is not bound to the alkali-metal ion directly, but through the acetate (or benzoate) ion.



The relatively positive and constant values of the $E_{1/2}$ of $HClO_4$ and p-TOs with various supporting electrolytes indicate that the perchlorate and p-toluenesulfonate ions should interact only weakly with the pyridinium ion ($PyH^+ \cdots\cdots ClO_4^-$). If the interaction between the pyridinium ion and the conjugate base anion (from acetic or benzic acid) were completely removed by any interaction, the reduction potential of the weak acid would approach the positive value of $HClO_4$ or p-TOs.

Figure 3 shows the change in the anodic (mercury dissolution) wave from the benzoate ion (1 mM) in pyridine-0.1 M Et_4NClO_4 upon the addition of Li^+ and Na^+. The wave height of the anodic wave from the benzoate ion decreased linearly with the increase in the concentration of Li^+, and the wave disappeared completely at 1 mM of Li^+. Upon the addition of Na^+, a positive shift of the anodic wave was observed because

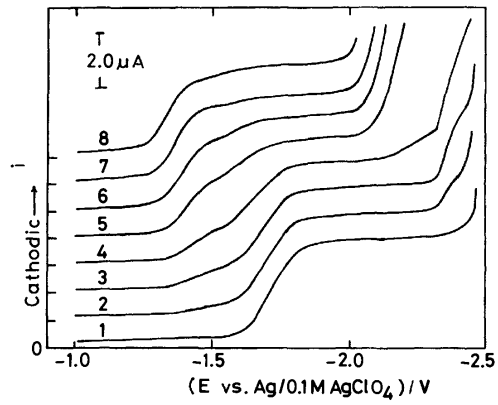


Fig. 4. Changes in the polarographic wave of 1 mM acetic acid (10 ml) with the addition of 0.1 M $LiClO_4$. The supporting electrolyte is 0.1 M Et_4NClO_4. 1: Li^+ free, 2: 40, 3: 100, 4: 200, 5: 500 μl, 6: 1, 7: 2, 8: 5 ml of 0.1 M $LiClO_4$ added. The total volume changes are not corrected.

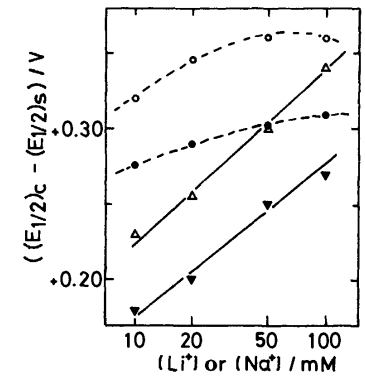

Fig. 5. Shifts in the half-wave potentials of cathodic waves of chloro-substituted benzoic acids (1 mM) with the addition of alkali metal ions.
(○): *p*-Chlorobenzoic, Li^+, (△): *p*-chlorobenzoic, Na^+, (●): 2,4-dichlorobenzoic, Li^+, (▼): 2,4-dichlorobenzoic acid, Na^+. The total ionic strength is kept to be 0.1 M with Et_4NClO_4. See Fig. 2 for $(E_{1/2})_c$ and $(E_{1/2})_s$.

the wave was not completely depressed, even at 2 mM of Na^+. In acetonitrile,[4] although the anodic wave from the benzoate ion disappeared at the equivalence point as a result of the formation of the white precipitate of lithium or sodium benzoate, the anodic wave was recovered again at a much more positive potential by the addition of a large excess of Li^+ or Na^+ (the formation of $C_6H_5COO^-(M^+)_2$). Unfortunately, the reappearance of the anodic wave was not observed, even at 0.1 M Li^+ or Na^+, in the pyridine solution, for the potential of the anodic wave was too close to the positive potential limit in the absence of any complex-forming agent (ca. +0.05 V). Thus, the formation of $C_6H_5COO^-(M^+)_2$ was not directly proved by the anodic wave from the benzoate ion in pyridine, unlike as in acetonitrile.

Figure 4 shows the change in the polarographic wave of acetic acid upon the addition of $LiClO_4$. Upon the addition of a small amount of $LiClO_4$, a small cathodic wave appeared at a more positive potential than that of the initial wave in 0.1 M Et_4NClO_4 as the supporting electrolyte. The wave height of the more positive wave increased with the increase in the concentration of $LiClO_4$. At last, the wave merged into the initial wave at high concentrations of $LiClO_4$. These experimental results suggest the successive formation of $RCOO^-Li^+$ and $RCOO^-(Li^+)_2$ from PyH^+ ∧∧∧ $RCOO^-$ and $LiClO_4$.

Hickey et al. described that specific differences in the effects of supporting-electrolyte cations appeared to be due to electrocapillary phenomena and perhaps also to the extent of the solvation of the ions.[1] However, the present study as well as the work by Tsuji and Elving[2] shows that the interaction between the pyridinium ion and the conjugate base from a weak acid plays an important role in the reduction potential of the acid in pyridine solutions.

In conclusion, the leveling effect of the carboxylic acids with Li^+ or Na^+ can be explained quantitatively by the formation of $RCOO^-(M^+)_2$-type species, instead of in terms of simple ion-exchange reactions, i.e., $PyH^+A^-+M^+ClO_4^- \rightleftarrows PyH^+ClO_4^-+M^+A^-$ (A^-=the conjugate base of an acid) proposed by Tsuji and Elving,[2] in pyridine solutions.

Methyl- or Chloro-Substituted Acetic and Benzoic Acids and Phenols. The polarographic data for propionic and pivalic ($(CH_3)_3CCOOH$) acids and for chloro-substituted acetic and benzoic acids in pyridine solutions are listed in Table 2. The polarographic behavior of these compounds was very similar to that of acetic and benzoic acids, except that trichloroacetic acid gave a very large wave (6 μA, cf. 3 μA for 1 mM acetic acid) with Et_4N^+ or n-Bu_4N^+ as the supporting-electrolyte cation. The large wave-height for trichloroacetic acid can be explained by the immediate reduction of a chlorine atom in the substituent group, besides the reduction of the pyridinium ion. Only the reduction of the pyridinium ion with one electron (n= 1) occurred for the other acids.

With Et_4N^+ or n-Bu_4N^+ as the supporting-electrolyte cation, the half-wave potential of an acid depends on its acid strength. The linear relation between $E_{1/2}$ and pK_a^{aq} (dissociation constant in water) for acids in pyridine has been reported by Tsuji and Elving.[13] With Li^+ or Na^+ as the supporting-electrolyte cation, however, the half-wave potentials of chloro-substituted acetic and benzoic acids were rather constant in value (−1.2—−1.4 V).

The effects of the concentrations of alkali-metal ions on the half-wave potentials of substituted acetic and benzoic acids were also examined. Figure 5 shows the effects of Li^+ and Na^+ on the reduction of *p*-chlorobenzoic and 2,4-dichlorobenzoic acids. The half-wave potential of *p*-chlorobenzoic and 2,4-dichlorobenzoic acids were shifted ca. 120 mV posi-

a) The formation constant, $K(M^{-2})$, in $RCOO^- + 2M^+ \rightleftarrows RCOO^-(M^+)_2$. b) The wave height was decreased by the addition of Na^+. c) The curve was separated into two parts, as is shown in Fig. 6. d) Another reaction seems to occur; see the text. e) The slope became smaller at higher concentrations of M^+.

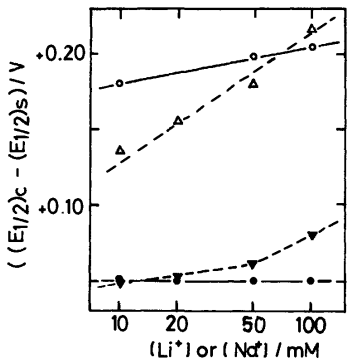

Fig. 6. Shifts in the half-wave potentials of cathodic waves of chloro-substituted acetic acids (1 mM) with the addition of alkali metal ions.
(○): Chloroacetic, Li^+, (△): chloroacetic, Na^+, (●): dichloroacetic, Li^+, (▼): dichloroacetic acid. Na^+. The total ionic strength is kept to be 0.1 M with Et_4NClO_4. See Fig. 2 for $(E_{1/2})_c$ and $(E_{1/2})_s$.

values of $\Delta E_{1/2}/\Delta\log[Li^+]$ are much smaller (40 or 50 mV) than 120 mV. Therefore, the species formed by the reaction between Li^+ and the conjugate base ($RCOO^-$) seems to be, at most, $RCOO^-Li^+$.

The slope of $\Delta E_{1/2}/\Delta\log[M^+]$ (M=Li and Na) were also small in value for chloro-substituted acetic acids, as Table 3 shows. Figure 6 illustrates the effect of Li^+ and Na^+ on the half-wave potentials of chloroacetic and dichloroacetic acids. In the case of dichloroacetic acid, the effect of Li^+ seems to be smaller than that of Na^+, judging from the potential at each concentration of M^+ and from the slope of $\Delta E_{1/2}/\Delta\log[M^+]$. Apparently, the interaction of Na^+ with the dichloroacetate ion is stronger than that of Li^+. This phenomenon may be explained by the difference in the degree of solvation between Li^+ and Na^+, and also by the weakness of the interaction of the dichloroacetate ion with the alkali-metal ions. A lithium ion will be solvated by pyridine more strongly than a sodium ion. We have found interaction between Li^+ and a monoamine as well as acyclic[14] and cyclic[15] polyamines in acetonitrile. The complexing of the lithium ion with pyridine was confirmed in acetonitrile.[16] It seems that the solvation of Li^+ by pyridine is so strong that the dichloroacetate ion cannot interact with Li^+ interact with Li^+ any more, for the basicity of the (dichloro)acetate ion is weakened by the substituted chlorine atoms.

Even the half-wave potentials of phenols were affected by the supporting-electrolyte cations (see Table 2). The interaction between a lithium ion and the anion from substituted phenol has been suggested on the basis of the UV and visible absorption spectra.[13]

We wish to express our thanks to Dr. Keiichi Tsuji of the Institute of Physical and Chemical Research for his helpful discussion. We would also like to thank Professor Kosuke Izutsu of Shinshu University for kind looking over the manuscript and for his valuable suggestions.

The Solubility of Benzene-Hydrocarbon Binary Mixtures in Water

Isao SANEMASA,* Yoshiko MIYAZAKI, Seiji ARAKAWA, Masaya KUMAMARU, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received July 21, 1986)

The solubility in water at 25.0 °C of benzene-hydrocarbon binary mixtures has been studied for different ratios between benzene and toluene, ethylbenzene, (*o*-, *m*-, *p*-)xylene, propylbenzene, chlorobenzene, and cyclohexane. Aqueous solutions saturated with mixed solutes were prepared by making use of the solute vapor. The solubility of individual constituent in the binary mixture was found to change linearly with mole fraction over a whole range of the composition. This is not the case for the benzene-cyclohexane system: the solubility of each component deviates positively from the linear change of solubility with composition. The solubility of each component of benzene-1-octanol mixture in water was also measured by adding the mixture of various compositions directly to water. The positive deviation for the solubility of each component was observed. The relationship between the 1-octanol/water partition coefficient of a solute and the aqueous solubility of pure liquid solute which forms a nonideal solution in 1-octanol was discussed.

We have previously reported a method of preparing aqueous solutions saturated with a solute such as benzene and alkylbenzenes.[1] The solute vapor in equilibrium with liquid solute is introduced into water and circulated in a closed system. The experimental characteristic of this method is that the equilibrium of the solute at different desired concentrations can be attained rapidly by adjusting the temperature of solute phase separated from aqueous phase, while the temperature of the aqueous phase is kept constant. We have demonstrated by this technique that the equilibrium solubility of sparingly soluble solutes in water changes linerly with the solute vapor pressure, in other words, the solubility obeys Henry's law.[1-3]

We will report further application of the method. Instead of changing the temperature of single liquid solute, mixed binary solutes of various compositions are used. The vapor pressure of the constituent solute varies with mole fraction in the mixed solute phase. The equilibrium solubility of each constituent is measured as a function of the mole fraction. We assume that Henry's law is applied to individual solute, because the concentration of solute in aqueous phase is usually very low. When Raoult's ideal solution law is held to mixed solute, the equilibrium solubility of the constituent solute in water is expected to be proportional to the mole fraction of solute mixture.

The solubility of a large variety of hydrocarbons has been extensively studied to accumulate data. There are, however, only a few reports concerning the aqueous solubility of mixed solutes in different composition. It is important to know what is the critical factor in determining the aqueous solubility of the constituent solute, because mixture of organic compounds rather than a solute is what we encounter in the natural aqueous environment, e.g., spilled oil on water surface.

The study of aqueous solubility of binary organic solutes is also important in considering partition of an organic solute in aqueous and organic phases. Partition coefficients of a number of chemicals in organic solvent and water, especially in 1-octanol/water system, have been extensively studied. The partition coefficient of the molecule is a measure of its relative solubility in two solvents; the coefficient has been determined under the condition that the solute concentration is extreamely low. When the solute forms a nonideal solution with organic solvent, we need to know how aqueous solubility of the solute changes with its concentration in the organic layer and what is the dominant factor in the aqueous solubility. Is there any solubilization effect of 1-octanol dissolved in water? The effect is probable only when there is an appreciable octanol-solute interaction in aqueous solution.[4] The benzene-1-octanol binary mixture was studied from interest in these problems.

Experimental

Materials. Deionized re-distilled water was used throughout this work. Benzene (99.5%), toluene (99%), ethylbenzene (98%), (*o*-, *m*-, and *p*-)xylene (each 98%), propylbenzene (97%), chlorobenzene (99%), cyclohexane (98%), and 1-octanol (95%) of analytical reagent grade with the minimum purity in the parentheses were used as solutes without further purification. When 1-octanol was used to prepare calibration curves for determining its concentrations in aqueous and benzene-1-octanol phases after equilibrium, 1-octanol was purified by distillation under reduced pressure.

Apparatus and Procedures. The apparatus used for preparing aqueous solutions saturated with solute vapor was essentially the same as that previously reported.[1]

The apparatus is composed of two main parts: A separatory funnel (300 cm^3) with a surrounding jacket and a pear-shaped flask (50 cm^3) which is immersed in a thermostated bath. We will call the former "solubility flask," and the latter "solute reservoir." These were connected to each other with Teflon or glass tubes. Water of 100 cm^3 and a binary liquid hydrocarbon mixture of 10 cm^3 were placed in the solubility flask and in the solute reservoir, respectively. The temperature of thermostated bath was kept at 25.0±0.1 °C, and that of solubility flask was also held at the same temperature by circulating water from the bath through surrounding jacket. The assembled apparatus was placed in a chamber, whose temperature was kept a little higher than 25 °C to avoid condensation of the solute vapor inside the apparatus. The solute vapor generated by bubbling air

through the solute reservoir via a sintered glass ball was introduced into the solubility flask by a Viton diaphragm airpump and was circulated at 1.5 dm^3 min^{-1}.

After the solubility equilibrium was attained (it takes 10 min), each 30 cm^3 portion of the aqueous solution was transferred successively by a stopcock attached to the bottom of solubility flask into three cylindrical separatory funnels of 50 cm^3 capacity, to which each 5 cm^3 volume of an extractant had been placed in advance. The organic extracts were analyzed by a Hitachi 164 gas chromatograph (column packing, PEG-1000; detector, hydrogen flame ionization). Cyclohexane or benzene was used as extractant; the latter was used only in the case of analyzing cyclohexane in benzene-cyclohexane system. A suitable volume of internal standard had been previously added to the extractant; *p*-xylene was used in benzene-toluene and benzene-cyclohexane systems, toluene in other systems.

The composition of mixed solute in the solute reservoir was analyzed in the following way. After the solubility equilibrium had been attained, a 5 cm^3 portion was pipetted off from the solute reservoir, diluted to 25 cm^3 with the same solvent used in extracting the solute from aqueous phase, and analyzed by gas chromatography. In this case, the solvent itself serves as an internal standard.

In the case of benzene-1-octanol system, an aqueous solution saturated with 1-octanol was not obtaied by the solute vapor circulation technique mentioned above. Then, each 60 cm^3 of mixed solute of various compositions was added to water (200 cm^3) in a 360 cm^3 glass bottle with a stopper and equilibrated by stirring overnight with a Teflon-enclosed magnet in a thermostated bath at 25.0±0.1 °C. The bottle was designed to make it easy to take out the aqueous solution through a stopcock attached to bottle side near the bottom. The solutes in 20 cm^3 portions of the aqueous solution were extracted with cyclohexane containing an internal standard and analyzed by gas chromatography. As the internal standard, toluene was used to analyze benzene and 1-hexanol to analyze 1-octanol. The solute phase after equilibrium was also analyzed by gas chromatography to determine the composition. A 5 cm^3 portion of the solute phase was taken out of the bottle and diluted to 25 cm^3 with cyclohexane which serves as internal standard.

Results

The Time Required for Attaining the Solubility Equilibrium. Aqueous solution to be saturated with solute vapor reached equilibrium with each solute of the binary mixture after 10 min at a circulation rate of vapor of 1.5 dm^3 min^{-1} (Fig. 1). In the case of benzene-1-octanol system, it was also confirmed that overnight stirring of the aqueous phase with the mixed solute solution is sufficient to attain equilibrium with each solute.

The Composition of Binary Solute Mixture and Solubility of Component Solutes in Water. The solubility of component solutes of binary mixture in water at 25.0 °C is given in Tables 1 to 3 and shown in Figs. 2 to 5 as a function of mole fraction of the component.

A single component solubility in water at 25.0 °C determined by circulating the solute vapor was 2.07×10^{-2} (benzene), 5.65×10^{-3} (toluene), 1.37×10^{-3} (ethylbenzene), 1.68×10^{-3} (*o*-xylene), 1.33×10^{-3} (*m*-xylene), 1.51×10^{-3} (*p*-xylene), 4.15×10^{-4} (propylbenzene), 3.78×10^{-3} (chlorobenzene), and 6.27×10^{-4} mol dm^{-3} (cyclohexane) and that determined by adding liquid solute directly to water was 2.22×10^{-2} (benzene) and 4.11×10^{-3} mol dm^{-3} (1-octanol). These values are in reasonable agreement with our previous estimations and with literature values.[1,5,6]

Discussion

The Technique to Prepare Aqueous Solutions Saturated with Solutes. Two techniques were used to prepare aqueous solutions saturated with solute: the circulation of solute vapor and the direct addition of liquid solute into water. The solubility of benzene determined by the latter technique was about 10% higher than that obtained by the former one. It is difficult at present to explain this discrepancy, but we suppose that the direct contact of liquid solute with water is liable to overestimated solubility due to formation of solute micro-emulsion dispersed in aqueous solution. The former technique being applied to the benzene-1-octanol system, the aqueous phase was saturated with benzene after circulation for 15 min, while the 1-octanol-saturated solution was not obtained even after 5 h at the same circulation rate. We first thought that the vapor circulation technique is inadequate for this system, because water dissolved in 1-octanol during circulation may prevent vaporization of 1-octanol (the solubility of water in 1-octanol is considerably high). Then, we tried to saturate water with 1-octanol vapor as follows; nitrogen gas was made to flow through the reservoir containing 1-octanol purified by distillation via a sintered glass ball or a glass capillary and introduced into the solubility flask. This technique, which we call the open method, gave aqueous solutions saturated with various solutes in the previous work.[1] In the case of 1-octanol, however, the

aqueous solution obtained in this manner was far from saturation even after 6 h at the aeration rate ranging from 0.02 to 1.5 dm^3 min^{-1}. Thus, the possibility that water in 1-octanol may prevent 1-octanol from vaporizing can be excluded. Different cause should be sought.

Concerning with the vapor circulation technique, it should be mentioned that, as was pointed out in the previous paper,[2] the liquid solute in the reservoir will gradually be in equilibrium with water during the

vapor circulation, and hence, the solute phase is no longer "pure" binary system. Yet we can neglect the contribution of water to the partial vapor pressure of constituent solute in the binary mixture, because the solubility of water in liquid hydrocarbons used in this study is as low as 3×10^{-3} in mole fraction.[7]

The Aqueous Solubility of Two Solutes Which Form Ideal or Near-Ideal Binary Mixtures. The solubility of the constituent solutes in the seven binary mixtures, benzene-toluene, -ethylbenzene, -(*o*-, *m*-, *p*-) xylene, -propylbenzene, and -chlorobenzene, changed almost linearly with its mole fraction over a whole range of the composition. Assuming that Henry's law holds for the dissolution of each component in water, the linear relationship between the aqueous solubility and the solute mole fraction indicates that the solute forms an ideal or nearly ideal solution with benzene.[8] In such a system, the solubility of the solute at any composition can be easily estimated by multiplying unit solubility by mole fraction of the component. It should be emphasized, however, that the mixed solute solution cannot be taken at once as being ideal, because an experimental error of 5% or so is inevitable in the solubility determinations. For instance, chlorobenzene does not form ideal solution with benzene.[9,10] Data in the literature[10] on the relationship between vapor pressure and mole fraction at 25 °C are plotted for each component in Fig. 3. The maximum deviations of vapor pressure from Raoult's law, 1.65% for chlorobenzene and 0.65% for benzene, both positive, occur at 0.5 mole fraction. The same positive deviations cannot be expected from the present study unless the accuracy of solubility measurements is improved.

The Aqueous Solubility of Two Solutes Which Form Non-Ideal Binary Mixtures. In the cases of benzene–cyclohexane and -1-octanol, the plots of the aqueous solubility of a component vs. the composition of binary solute mixture exhibit noticeable deviations from linear relationship. This arises from nonideality of these mixed solute solutions. It is well-known that benzene forms nonideal solution with cyclohexane.[11,12] We can evaluate the activity coefficients for cyclohexane, γ_a, and for benzene, γ_b, at respective mole fraction, X_a and X_b, by the equation,[13] $RT \ln \gamma_{a(b)} = X_{b(a)}^2[A_0 - A_1(1-4X_{a(b)}) + A_2(1-8X_{a(b)}+12X_{a(b)}^2)]$; the constants, A_0, A_1, and A_2 for each component are determined from the data presented in Ref. 12 to be 1318.8, −42.95, and 38.31 (cyclohexane) and 1312.9, −44.19, and 54.77 (benzene), respectively. The partial vapor pressure of the component, P_i, is expressed as $P_i = X_i\gamma_i P_i^\circ$, where X_i, γ_i, and P_i° is the mole fraction of component in the liquid solute mixture, the activity coefficient, and the pure solute vapor pressure, respectively. Figure 4 shows the partial vapor pressure as a function of the mole fraction. The solubility curve appears to be similar in shape to the corresponding vapor pressure curve. For a quantitative consideration, the ratio of the partial pressure to the equilibrium solubility in water for each component at the same mole fraction in binary mixture was determined (the ratio refers to Henry's law coefficient). We can see from Table 2 that the ratio is almost constant over a whole range of the mixed solute composition. This indicates that Henry's law is valid to the aqueous solubility of the constituent.

With respect to the benzene–1-octanol binary system, the activity of each component at 20 °C is available,[14] and literature data are plotted in Fig. 5. The activity and solubility curves for the corresponding component appear to resemble each other: both the activity and the solubility of 1-octanol change almost linearly in higher mole fraction region of 1-octanol and decrease steeply in its lower mole fraction region, while those of benzene exhibit large positive deviations from the postulated ideal linear lines in higher mole fraction region of benzene. However, as can be seen from Table 3 where ratios of the activity at 20 °C to the solubility at 25 °C are given, large discrepancies are noticeable for benzene and 1-octanol in each lower mole fraction region. These discrepancies may be attributable partly to inaccuracy of solubility measurements. It is doubtful, however, whether the activity determined in the absence of water is applicable to the present case. The water content in 1-octanol amounts to 0.25 mole fraction.[6] Yet the activity of each solute seems to dominate the aqueous solubility of benzene–1-octanol binary mixture.

The 1-Octanol/Water Partition and Aqueous Solubility of the Solute Which Forms Non-Ideal Solution with 1-Octanol. Chiou et al. have suggested a "solubilization" effect of 1-octanol;[15] the solubility of a solute in water which has been saturated with 1-octanol is larger than that in 1-octanol-free water. Miller et al., on the other hand, have demonstrated using polynuclear aromatic hydrocarbons and polychlorinated biphenyls that the presence of dissolved 1-octanol in water has little effect on the solubility of the substances in water.[4] Considerably low solubility in 1-octanol-saturated water is apparent in their data, though the authors did not mention it. This is presumably caused by the state of organic substances. The 1-octanol present saturated in water is transferred in part to the organic substances in the solid state. Then, the organic substance is no longer pure one-component system, that is, the mole fraction becomes lower than unity. This may be responsible for low solubility of the organic substances in 1-octanol-saturated water.

Our present results support Miller et al. The positive deviation of solubility of benzene in water from the ideal solubility line observed for the benzene–1-octanol system is not due to the solubilization effect by 1-octanol, but is caused by the formation of a nonideal solution from benzene and 1-octanol.

The 1-octanol/water partition coefficient, $K_{o/w}$, is commonly defined as

$$k_{o/w} = C_o/C_w, \tag{1}$$

where C_o and C_w denote the molar concentration of solute in 1-octanol saturated with water and that in water saturated with 1-octanol, respectively. Considering mutual solubility of 1-octanol and water, an equation which correlates the partition coefficient with the solubility of pure liquid solute in water, S, was proposed by Chiou et al.[15] as follows:

$$\log K_{o/w} = -\log S - \log \bar{V}^{o*} - \log \gamma_o^* + \log(\gamma_w^*/\gamma_w), \tag{2}$$

where $\bar{V}^{o*}$ is the partial molar volume of 1-octanol saturated with water, γ_o^* is the activity coefficient of the solute in 1-octanol saturated with water, and γ_w^* and γ_w refer to the activity coefficient of the solute in water saturated with 1-octanol and that in pure water, respectively. This equation is derived based on the assumption that the solute concentrations both in aqueous and 1-octanol phases are sufficiently low.

For various liquid solutes, especially for homologous series, the log $K_{o/w}$ vs. −log S plots have been found to be linear with inclinatios close to unity.[16] There have been published, however, some experimental data which clearly display the slopes significantly lower than unity.[4,15,16] Chiou et al. assumed that the solubilization effect of 1-octanol in water is one of the reasons of significantly lower inclination than the ideal value of −1.[15] We will propose the viewpoint that the liquid solute forms a nonideal mixed solution with 1-octanol. Let us consider the case of benzene–1-octanol. The $K_{o/w}$ of benzene, which is the reverse of tangent of aqueous solubility vs. solute concentration

in 1-octanol curve at infinitely diluted with 1-octanol, is not constant, but depends on the composition of octanol phase. In practice, $K_{o/w}$ is to be measured at a definite solute composition, and $K_{o/w}$ value thus determined is always larger than that expected under infinitely diluted condition. This causes the inclination of log $K_{o/w}$ vs. $-\log S$ plot to be smaller than unity. The circumstances are reversed when the solubility of the solute in water deviates negatively from the ideal solubility. The solute composition in 1-octanol should, therefore, be as low as possible, especially in such a case that the solute-1-octanol mixed solution is far from being ideal.

The Solvent Extraction and Aqueous Solubility of the Solute to be Extracted. When the solvent extraction is considered in general under the conditions that mutual solubility of extractant and water is low and further that the solute concentration in extractant and in water is sufficiently low, Eq. 2 can be written in the form;

$$\log K_{org/w} = -\log S - \log V^{org} - \log \gamma_{org}, \quad (3)$$

where $K_{org/w}$ is the partition coefficient of the solute between organic extractant and aqueous phase, V^{org} is the molar volume of pure extractant, and γ_{org} refers to the activity coefficient of the solute in pure extractant. Combining Eq. 1 with Eq. 3, we can derive $\%E$, the extraction percentage of the solute from an aqueous phase of v_w dm^3 to an organic phase of v_{org} dm^3,

$$\%E = 100/(1 + S\, V^{org} \gamma_{org} v_w v_{org}^{-1}). \quad (4)$$

This equation is useful in predicting the degree of extraction of the solute at a definite volume ratio of aqueous phase to organic phase with known values of solubility in water of pure solute to be extracted, the molar volume of pure extractant, and the solute activity coefficient in extractant. It should be emphasized that the $\%E$ depends on whether the extractant-solute system deviates positively or negatively from Raoult's law.

Synthesis, Characterization, and Optical Resolution of Electrically Neutral Octahedral Cobalt(III) Complexes Containing the Tetradentate Ligand

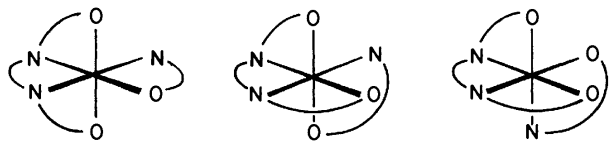
Hiroshi NAKAZAWA, Hisaka OHTSURU, and Hayami YONEDA*
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received July 28, 1986)

Three geometrical isomers of [Co(edda)(aa)] where edda=*N',N*-ethylenediaminediacetato, aa=glycinato (gly), β-alaninato (β-ala), have been synthesized and characterized. They have been completely resolved into the enantiomers, except *unsym-cis-fac*-[Co(edda)(β-ala)], by the bis(μ-*d*-tartrato)diantimonate(III) anion, $[Sb_2(d\text{-tart})_2]^{2-}$, form of QAE-Sephadex resin with water as the eluent, and their absolute configurations have been determined based upon the circular dichroism spectra. It has been revealed that the Δ enantiomer is favored more by $[Sb_2(d\text{-tart})_2]^{2-}$ than the Λ enantiomer irrespective of the kind of the geometrical isomers. Consideration on the mechanism of the optical resolution has been presented.

The optical resolution of electrically neutral transition metal complexes is difficult, compared with that of cationic or anionic metal complexes, because they do not form diastereomers with an optically active resolving agent. Chromatographic technique is very effective to achieve the optical resolution of such neutral complexes.[1] Some neutral complexes have been reported to be partially resolved into the enantiomers; *cis*-[Co(dimethylglyoximato)$_2$(NH_3)Cl] by using a quartz powder column,[2] *mer*- and *fac*-[Co(gly)$_3$], and *s-cis-mer*-[Co(edda)(gly)] by using a potato starch column,[3] where gly and edda stand for glycinato and *N,N'*-ethylenediaminediacetato, respectively. The first complete resolution of neutral complexes was reported in 1976 by Yoneda for *fac*-[Co(β-ala)$_3$] (β-ala=β-alaninato) on the Na^+ form of CM-Sephadex cation exchanger with an ethanol-water solution of sodium *d*-tartrate, Na_2(d-tart), as the eluent.[4] Thereafter, the complete resolution of a series of enantiomeric pairs of *fac*-[Co(D/L-ser)$_{3-n}$(β-ala)$_n$] (n=0 to 3, ser=serinato) was achieved on Na^+ form of TSK-211 cation exchanger with sodium bis(μ-*d*-tartrato)diantimonate(III), Na_2-$[Sb_2(d\text{-tart})_2]$, aqueous solution as the eluent.[5] An anion-exchange column has also been indicated to be useful to resolve neutral complexes into enantiomers. Two series of enantiomeric pairs of *fac*-[Co(gly)$_{3-n}$(β-ala)$_n$] and *fac*-[Co(D/L-α-ala)$_{3-n}$(β-ala)$_n$] were completely resolved on the $[Sb_2(d\text{-tart})_2]^{2-}$ form of TSK-220 anion exchanger with water as the eluent.[6] Complete resolution of the meridional isomer of tris(amino acidato)-cobalt(III) complexes has also been achieved. After success of optical resolution of *mer*-[Co(β-ala)$_3$],[7] enantiomeric pairs of *mer*-[Co(gly)$_3$] and *mer*-[Co(D/L-α-ala)$_3$] were resolved on the $[Sb_2(d\text{-tart})_2]^{2-}$ form of QAE-Sephadex resin with water as the eluent.[8]

Neutral complexes, other than tris(amino acidato)-complexes, have also been tried to be resolved. Tris-(acetylacetonato)transition-metal complexes, [M-(acac)$_3$] (M=Cr, Co, Rh, Ru) were partially resolved by the use of a *d*-lactose column[9] or a quartz column[10] and [M(acac)$_3$] (M=Cr, Co, Ru) and [M(gly)$_{3-n}$(acac)$_n$] (n=3 to 1) were also partially resoluved on a Δ-[Ni(phen)$_3$]-montmorillonite column (phen=1,10-phenanthroline).[11] Recently, [Co(acac)$_3$] and [Cr-(acac)$_3$] were completely resoluved by HPLC on a (+)-poly(triphenylmethyl methacrylate) column.[12]

Neutral complexes completely resolved so far into enantiomers are limited only to tris-chelates. We report here the complete resolution of neutral complexes containing a tetradentate ligand by column chromatography. As such complexes, we chose [Co(edda)(gly)] and [Co(edda)(β-ala)]. For both complexes, there are three geometrical isomers shown in Scheme 1.



Scheme 1.

Experimental

General Remarks. *N,N'*-Ethylenediaminediacetic acid (H_2edda), glycine (Hgly), β-alanine (H-β-ala) were commercially available and were used without further purification. Na[Co(edda)(CO_3)]·1.5H_2O,[13] Co^{II}(edda),[14] and *s-cis-mer*-[Co(edda)(gly)][15] were prepared according to the literature methods. Absorption (AB) and circular dichroism (CD) spectra were recorded on a Shimadzu UV 200 and a JASCO J-40CS, respectively.

Synthesis and Separation of the Isomers of *u-cis-mer* and *u-cis-fac*-[Co(edda)(gly)]. To a solution of 4.00 g (0.012 mol) of Na[Co(edda)(CO_3)]·1.5H_2O in 30 cm^3 of water was added 0.90 g (0.012 mol) of glycine. The solution was heated to 50 °C, and 7.5 cm^3 of HCl aqueous solution containing 1.0 cm^3 of concentrated HCl was added dropwise. The heating was continued for 5 h. Then, the solution was filtered. The filtrate was placed on an anion-exchange column (Dowex 1-X8, Cl^- form) and eluted with water to remove any residual starting material or anionic products. The eluate was evaporated under an air stream to 10 cm^3 and again filtered to remove the s-cis-mer isomer. The filtrate was placed on a cation-exchange column (SP-Sephadex C-25, Na^+ form) and

washed through with water. The color materials separated into two bands, a blue-violet band and a slower moving red-violet band. The u-cis-mer isomer (1.2 g, 32%) and u-cis-fac isomer (1.0 g, 24%) were obtained from the first and the second eluted bands as crystals by concentration, respectively.

Found: C, 29.55; H, 5.09; N, 13.34%. Calcd for *u-cis-mer*-$[CoC_8H_{14}N_3O_6]\cdot 0.5H_2O$: C, 30.39; H, 4.78; N, 13.29%.

Found: C, 27.82; H, 5.07; N, 12.39%. Calcd for *u-cis-fac*-$[CoC_8H_{14}N_3O_6]\cdot 2H_2O$: C, 27.99; H, 5.29; N, 12.24%.

Synthesis of *s-cis-mer*-[Co(edda)(β-ala)]. The complex was prepared in the manner similar to that of the glycine analog. To 500 cm^3 of an aqueous solution containing 4.66 g (0.020 mol) of Co^{II}(edda) were added 2.00 g of activated charcoal and 1.78 g (0.020 mol) of β-alanine. A stream of air was passed through the suspended solution for ca. 8 h. Then, the solution was heated at 60 °C for 30 min. The charcoal was removed by filtration and washed with hot water several times. The filtrate and washings were combined, which were heated on a stream bath almost to dryness. Purple crystals were deposited as a crude product (2.3 g, 35%). The purple product (1.1 g, 17%) for elemantal analysis was obtained by recrystallization from hot water.

Found: C, 32.26; H, 5.16; N, 12.79%. Calcd for $[CoC_9H_{16}N_3O_6]\cdot 0.5H_2O$: C, 32.74; H, 5.19; N, 12.73%.

Synthesis and Separation of the Isomers of *u-cis-mer* and *u-cis-fac*-[Co(edda)(β-ala)]. The synthesis and separation were identical with that of the glycine analog except it was carried out using 1.13 g (0.013 mol) of β-alanine. Yield of the u-cis-mer isomer was 1.2 g (18%), and that of the u-cis-fac isomer was 1.0 g (15%).

Found: C, 32.56; H, 5.37; N, 12.57%. Calcd for *u-cis-mer*-$[CoC_9H_{16}N_3O_6]\cdot 0.5H_2O$: C, 32.74; H, 5.19; N, 12.73%.

Found: C, 32.20; H, 4.75; N, 12.48%. Calcd for *u-cis-fac*-$[CoC_9H_{16}N_3O_6]\cdot 0.5H_2O$: C, 32.74; H, 5.19; N, 12.73%.

Optical Resolution by Ion-Exchange Chromatography. A column of 1.0 cm inner diameter was filled with 82.5 cm length of QAE-Sephadex A-25 (anion exchanger) which had been treated with 0.1 mol aqueous solution of $K_2[Sb_2(d\text{-tart})_2]$. About 20 mg of each sample prepared in this paper was dissolved in ca. 2 cm^3 of water and the solution was loaded on the column. The elution was done with water at a flow rate 7.8×10^{-2} $cm^3\,min^{-1}$. The void volume was measured to be 30.9 cm^3 by using $[Fe(phen)_3]Cl_2$ (phen=1,10-phenanthroline) as a marker. An automatic fraction collector was connected to the end of the column to divide the eluate into fractions of 4 cm^3. The AB spectrum of each fraction was measured. Thus, the retention volumes were determined. Two fractions in which the concentration of the separated enantiomers was highest were passed through QAE-Sephadex A-25 (Cl^- form) with water as the eluent to remove $[Sb_2(d\text{-tart})_2]^{2-}$. The eluates obtained were subjected to AB and CD measurments.

Results and Discussion

Preparation and Assignment of Geometrical Isomers. *s-cis-mer*-[Co(edda)(gly)] complex was prepared from Co^{II}(edda), obtained from $CoCO_3$ and Ba(edda), and glycine according to the literature method.[15] The geometrical isomers of [Co(edda)(diamine)]$^+$ and [Co(edda)(L)] (L=gly, L-ala) prepared from Co^{II}(edda) were assigned exclusively to trans and s-cis-mer, respectively according to the absorption spectra and ^1H NMR spectra.[14,15] Therefore, [Co(edda)(β-ala)] prepared from Co^{II}(edda) and β-alanine can be thought to have s-cis-mer configuration. The similar absorption spectrum to that of *s-cis-mer*-[Co(edda)(gly)] also supports the s-cis-mer configuration. The purity was checked by elemental analysis and column chromatography.

The reaction of $Na[Co(edda)(CO_3)]$, prepared from $Na_3[Co(CO_3)_3]$ and H_2edda, with glycine produced the mixture of u-cis-mer and u-cis-fac isomers of [Co(edda)(gly)]. Although s-cis-mer isomer was also formed in this reaction as a minor product, it could be readily removed by filtration because of its low solubility in water. The two u-cis isomers were separated by pass-

Table 1. Absorption and Circular Dichroism Data of [Co(edda)(aa)]

Complex	Absorption Max./nm (ε)	Circular Dichroism Max./nm ($\Delta\varepsilon$)[a]
s-cis-mer-[Co(edda)(gly)]	542 (116) 470 sh 372 (133)	542 (−5.35) 465 (+2.17)
u-cis-mer-[Co(edda)(gly)]	525 (94) 370 (128)	543 (−2.48) 465 (+0.97)
u-cis-fac-[Co(edda)(gly)]	520 (223) 374 (167)	523 (−1.12)

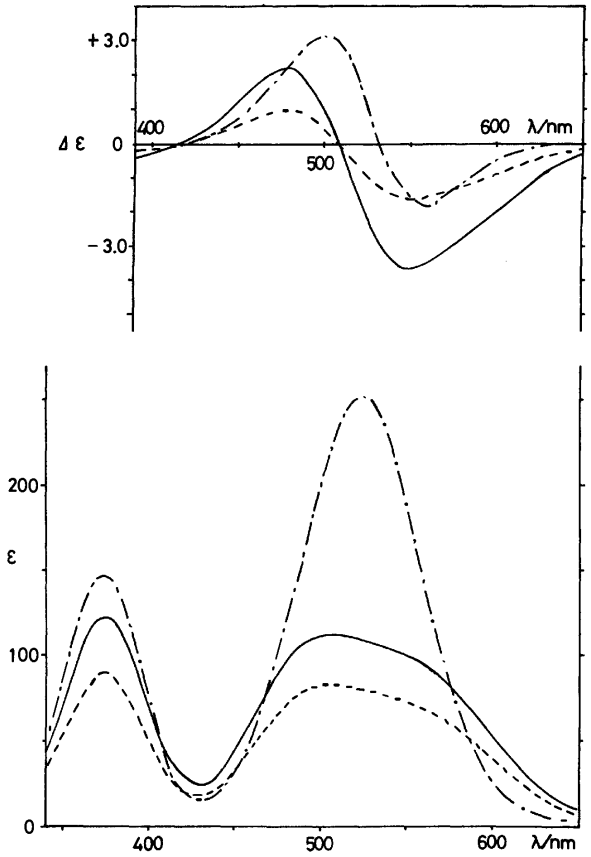

Fig. 2. Absorption spectra (below) and circular dichroism spectra (above) of *Δ*-[Co(edda)(β-ala)]; s-cis-mer (——), u-cis-mer (----), u-cis-fac(-·-·-). The scale is arbitrary for the u-cis-fac isomer due to the partial resolution.

ing through the SP-Sephadex C-25 column. The first eluted isomer was assigned to u-cis-mer and the second one to u-cis-fac, according to the reason mentioned below. The u-cis-mer and u-cis-fac isomers of [Co(edda)(β-ala)] were obtained in the manner identical with that of [Co(edda)(gly)].

The absorption (AB) and circular dichroism (CD) data of the neutral complexes prepared in this paper are given in Table 1. Figures 1 and 2 show the AB and CD spectra. The ligand field symmetry of the u-cis-fac isomer is higher than that of the u-cis-mer isomer. The decrease in symmetry from facial to meridional is expected to cause a splitting or at least a broadening of the lowest energy absorption band in the visible spectra. In [Co(edda)(gly)], broadening is obviously observed in the low-energy absorption band for the first eluted isomer. In [Co(edda)(β-ala)], a marginal shoulder is found for the first eluted isomers. In contrast, the second eluted isomers of [Co(edda)(gly)] and [Co(edda)-(β-ala)] exhibit a relatively sharp absorption band. Therefore, the first and the second eluted isomers for both [Co(edda)(gly)] and [Co(edda)(β-ala)] can be assigned to the u-cis-mer and u-cis-fac isomers, respectively. The similar assignment based upon the absorption spectra was done with respect to *u-cis-fac* and *u-cis-mer*-[Co(edda)(L-ala)] isomers.[13]

The assignment is consistent with the chromatographic behavior. Although both isomers are electrically neutral, the facial isomer has a greater dipole moment than the meridional isomer. Thus, the former is considered to interact more effectively with the functional group of SP-Sephadex C-25 cation exchanger than the later. Therefore, the facial isomer is expected to be eluted later than the meridional one. Such tendency has been actually observed (vide infra, see Table 2).

Circular Dichroism Spectra and Absolute Configurations. The partial optical resolution of *s-cis-mer*-[Co(edda)(gly)] has been attained and its absolute configuration has been established.[15] The CD spectrum of the *Λ* configuration consists of a dominant positive band at lower energy and a minor negative band at higher energy in the first d-d transition region. The sign of the dominant peak in the first d-d transition region of the CD spectrum can generally be related to the net chirality of the complex.[16,17] A *Δ* configuration of chelate rings is expected to produce a negative dominant peak in the d-d transition region while a *Λ* configuration would produce a positive dominant peak.[16] This argument has been applied to [Co(edda)(diamine)]$^{+}$[13] and *s-cis-mer*-[Co(edda)(aa)] (aa=gly, L-ala).[15] The CD spectra shown in Figs. 1 and 2 are

Table 2. Adjusted Retention Volumes and Separation Factors

Complex	Adjusted Retention Volume/cm³ First	Second	Separation Factor
s-cis-mer-[Co(edda)(gly)]	55.6 (*Λ*)[a]	63.6 (*Λ*)	1.14
u-cis-mer-[Co(edda)(gly)]	56.1 (*Λ*)	64.6 (*Λ*)	1.15
u-cis-fac-[Co(edda)(gly)]	197.1 (*Λ*)	221.1 (*Λ*)	1.12
s-cis-mer-[Co(edda)(*β*-ala)]	47.9 (*Λ*)	53.1 (*Λ*)	1.13
u-cis-mer-[Co(edda)(*β*-ala)]	45.1 (*Λ*)	53.1 (*Λ*)	1.17
u-cis-fac-[Co(edda)(*β*-ala)]	151.6[b]		—

a) Absolute configuration. b) Partial separation.

quite resemble to those of $[Co(edda)(diamine)]^+$ and *s-cis-mer*-[Co(edda)(aa)] (aa=gly, L-ala), although a minor positive band at higher energy is not observed in the case of *u-cis-fac*-[Co(edda)(gly)]. Therefore, the criterion to assign the absolute configuration from the sign of the CD spectra in the first d-d transition region should also be applicable to the u-cis-mer and u-cis-fac isomers of [Co(edda)(gly)] and [Co(edda)(*β*-ala)].

The CD spectra in Figs. 1 and 2 are for the second eluted enantiomers in the chromatographic separation. Since these CD spectra except that for *u-cis-fac*-[Co(edda)(*β*-ala)] comprise a dominant negative peak at lower energy and a minor positive peak at higher energy, the absolute configuration can be assigned to *Λ*. In the case of *u-cis-fac*-[Co(edda)(*β*-ala)], although the positive peak at higher energy is slightly greater than the negative peak at lower energy in intensity in its CD spectrum, it is highly likely that the absolute configuration is *Λ* from the quite similar CD pattern to those for the other complexes shown in Figs. 1 and 2.

Optical Resolution by Chromatography. The optical resolution was carried out by passing the neutral complexes through the $[Sb_2(d\text{-tart})_2]^{2-}$ form of QAE-Sephadex resin with water as the eluent. We chose $[Sb_2(d\text{-tart})_2]^{2-}$ as a resolving agent because $[Sb_2(d\text{-tart})_2]^{2-}$ is known to a very effective chiral selector not only for cationic transition metal complexes[1,18] but also for neutral complexes.[5-8] Water was used as the eluent in the present experiment. To obtain a good results, attention should be paid to the flow rate when neutral complexes are subjected to column chromatography in order to be resolved into enantiomers; the small flow rate seems to cause the better resolution. In the present experiment about 12 to 47 h, depending on complexes, were spent for each run. Two bands were clearly separated for every complex except for *u-cis-fac*-[Co(edda)(*β*-ala)]. The examination of the CD spectra of the eluates proved that the first eluted enantiomers have the *Λ* configurations (vide supra). In the case of *u-cis-fac*-[Co(edda)(*β*-ala)], though only one peak was obtained in the elution curve, the front and the rear fractions exhibited the enantiomeric CD spectra, indicating that the partial resolution was attained. The enantiomer in the front fraction had the *Λ* configuration. In the present chromatographic run, the chiral selector, $[Sb_2(d\text{-tart})_2]^{2-}$, was held in the stationary phase. Thus the second eluted enantiomer can be considered to have the greater affinity to $[Sb_2(d\text{-tart})_2]^{2-}$ than the first eluted enantiomer. For all neutral complexes examined in this paper, the *Λ* isomer is favored more by $[Sb_2(d\text{-tart})_2]^{2-}$ than the *Λ* isomer.

Before obtaining the adjusted retention volumes, the void volume of the column should be determined. Selection of a marker for determining the void volume is sometime difficult.[19] At first, we chose Blue Dextran 2000 as a marker since it is generally used for cation-exchange resin. However, it proved to be unsuitable because the band of Blue Dextran 2000 broadened considerably. Since QAE-Sephadex anion exchanger prevents to select anionic compounds as a marker, a cationic complex, $[Co(en)_3]Cl_3$, was used. This trial was, however, unsuccessful because it caused precipitation. The use of $[Cu(en)_2]Cl_2$ caused the greater retention volume than those of the neutral complexes. Finally, $[Fe(phen)_3]Cl_2$ proved to be a good marker to determine the retention volume of the QAE-Sephadex column. Since Sephadex contains many hydrophilic functional groups, $[Fe(phen)_3]^{2+}$ having hydrophobic ligands is presumed to have no significant interaction with the stationary phase. The resulting void volume, 30.9 cm³, may be a reasonable value, because the same void volume was obtained for SP-Sephadex-C25 cation-exchange column with the same diameter and length by using Blue Dextran as a marker, where QAE-Sephadex and SP-Sephadex resin used here have the same particle size.

The adjusted retention volumes and separation factors are listed in Table 2. For both the glycine and the *β*-alanine complexes, the retention volumes of the facial isomers are three to four times as large as those of the meridional isomers. This can be attributed to the greater dipole moment of the fac isomers. Between s-cis-mer and u-cis-mer isomers, there is no significant difference in the retention volumes. Comparison with the glycine and the *β*-alanine complexes in the same geometrical isomers reveals that the value for the glycine complex is greater than that for the *β*-alanine complex without exception. This tendency may be general because of the observation of the trend among tris(amino acidato)cobalt(III) complexes.[6,8] The

a) Λ and D stand for the configuration around Co(III) metal and of the amino acid ligand, respectively. This chromatographic separation was carried out for the enantiomeric pair of Λ-D and Δ-L. b) The values were calculated based upon the original data though these data are not shown in the literature. c) Brief chromatographic conditions: on Na^+ form of TSK-211 cation exchanger with $Na_2[Sb_2(d\text{-tart})_2]$ aqueous solution for Ref. 5; on $[Sb_2(d\text{-tart})_2]^{2-}$ form of TSK-220 anion exchanger with water for Ref 6; on $[Sb_2(d\text{-tart})_2]^{2-}$ form of QAE-Sephadex anion exchanger with water for Refs. 7, 8, and this work.

comparison among the separation factors in Table 2 reveals that there is no obvious defference (from 1.12 to 1.17).

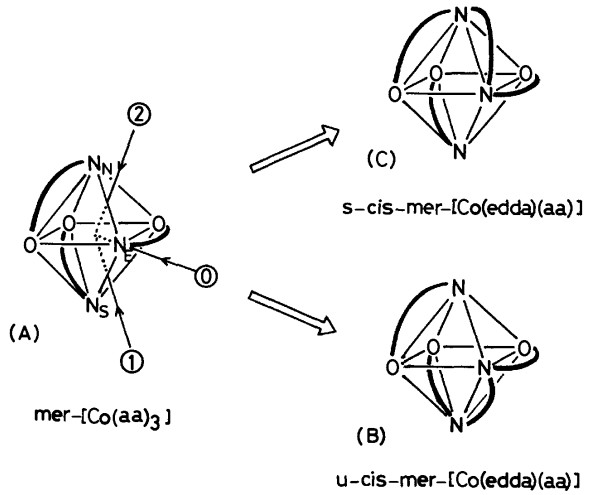
Mechanistic Consideration of Optical Resolution. Table 3 summarizes the neutral complexes completely resolved so far with $[Sb_2(d\text{-tart})_2]^{2-}$, together with the absolute configuration of the favorable enantiomer with the chiral anion, and the separation factors. As can be seen, with respect to the facial tris(amino acidato)-cobalt(III) complexes, the Λ enantiomers are favored unless two or more functional groups (hydroxyl groups) exist in the chelate rings, while the Δ enantiomers are favored in the case of the meridional complexes. This trend is kept for *mer*-[Co(edda)(aa)] complexes. However, it is not held for *fac*-[Co(edda)(aa)].

We have proposed the L-J model as a stereoselective ion-association model between a metal complex cation and $[Sb_2(d\text{-tart})_2]^{2-}$ anion.[1,20] The L-shaped channel was defined in the previous papers as the L-shaped opening between chelate rings, and the J-shaped channel as the mirror images of the L-shaped chennel. The optically active $[Sb_2(d\text{-tart})_2]^{2-}$ anion can associate intimately with that enantiomer of a metal complex cation that has the L-shaped channel, but cannot associate closely with the enantiomer that has only the J-shaped channel. In the case of *fac*-[Co(aa)$_3$], the Λ enantiomer has L-shaped channels in a position where $[Sb_2(d\text{-tart})_2]^{2-}$ anion is able to access electrostatically. Recently, the stereoselective ion-association model which is modefied and refined the L-J model has been proposed.[21] The model also suggests that the $[Sb_2(d\text{-tart})_2]^{2-}$ anion produces a favorable pair with the Λ enantiomer of the tris-chelate than with the Δ enantiomer. Thus, it is clear that the Λ enantiomer is favored by $[Sb_2(d\text{-tart})_2]^{2-}$ in homo and hetero facial tris(amino acidato)cobalt(III) neutral complexes. The chromatographic behaviour of *u-cis-fac*-[Co(edda)(aa)] that the Δ enantiomer makes an intimate pair with $[Sb_2(d\text{-tart})_2]^{2-}$ seems to be peculiar. However, the complex has neither L-shaped nor J-shaped channel. Although why the Δ enantiomer is favored more with the chiral anion and how the anion discriminates the enantiomers are not clear at present, we think this result is providing some clues about the chiral discrimination.

In meridional isomers, the Δ enantiomer is favored more by $[Sb_2(d\text{-tart})_2]^{2-}$ exclusively. Let us consider the reason. *mer*-[Co(aa)$_3$] is electrically neutral as a whole, but there is charge localization. It can be thought that the oxgen donor atom possesses a slightly negative charge and nitrogen donor atom does a slightly positive charge. From the pure electrostatic point of view, the most probable direction of the access

toward *mer*-[Co(aa)$_3$] for the [Sb$_2$(*d*-tart)$_2$]$^{2-}$ is considered to be the one indicated by arrow 0 in Scheme 2(A). However, the anion coming along this direction can not recognize the chirality of the complex because it touches the complex at only NH_2 group shown as N_E in Scheme 2(A). Next electrostatically favored access for the [Sb$_2$(*d*-tart)$_2$]$^{2-}$ is either one of the directions indicated by arrow 1 and 2. Although the two approaches are slightly different, they allow the anion to touch the complex at two NH_2 groups, N_E-N_S for arrow 1 and N_E-N_N for arrow 2. Then the anion can discriminate the absolute configuration of the complex. We consider that either one or both these two association modes 1 and 2, seem to play an important role in chiral discrimination.

u-cis-mer-[Co(edda)(aa)], Scheme 2(B), corresponds to the complex that N_E and N_S of the *mer*-[Co(aa)$_3$] are connected by a CH_2CH_2 bridge. The bridging of CH_2CH_2 group between N_E and N_N of complex (A) produces *s-cis-mer*-[Co(edda)(aa)], complex (C). The ethylene bridge between N_E and N_S precludes the access of [Sb$_2$(*d*-tart)$_2$]$^{2-}$ from the direction of arrow 1, and that between N_E and N_N prevents the access of the chiral selector from the direction of arrow 2. The two isomers, *u-cis-mer* and *s-cis-mer*-[Co(edda)(aa)], are presumed to accept the oncoming anion only through either one of the two association modes 1 and 2.



Scheme 2.

The retention volumes and the separation factors of the two isomers for both the glycine and β-alanine complexes exhibit no significant difference. Moreover, these separation factors are almost equal to those of *mer*-[Co(gly)$_3$] and *mer*-[Co(β-ala)$_3$]. Therefore, we can conclude that the two association models 1 and 2 are equally effecive on the chiral discrimination in *mer*-[Co(aa)$_3$] with using [Sb$_2$(*d*-tart)$_2$]$^{2-}$ as a resolving agent and only one mode is enough for complete resolution.

Calorimetric and Spectrophotometric Studies of Chloro Complexes of Nickel(II) and Zinc(II) Ions in *N,N*-Dimethylformamide

Shin-ichi Ishiguro,* Kazuhiko Ozutsumi, and Hitoshi Ohtaki†
Coordination Chemistry Laboratories, Institute for Molecular Science, Myodaiji, Okazaki 444
†Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta, Midori-ku, Yokohama 227
(Received August 4, 1986)

Complexation of Ni(II) and Zn(II) with Cl^- ions has been studied by calorimetry and spectrophotometry in *N,N*-dimethylformamide (DMF) containing 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ as a constant ionic medium at 25 °C. Calorimetric titration curves obtained in each system were well-explained in terms of formation of $[MCl_n]^{(2-n)+}$ (n=1—4 and M^{2+}=Ni^{2+} or Zn^{2+}), and their formation constants, enthalpies and entropies were determined. Formation of the nickel(II) chloro complexes in DMF was also supported by spectrophotometry. In the nickel(II) chloride system, the stepwise enthalpy ΔH_3° and entropy ΔS_3° values are remarkably large and positive as compared with the ΔH_n° and ΔS_n° (n=1, 2, and 4) values. Individual electronic spectra of nickel(II) ion, $[NiCl]^+$ and $[NiCl_2]$ are significantly different in both intensities and peak positions from those of $[NiCl_3]^-$ and $[NiCl_4]^{2-}$ over the range 300—850 nm. These thermodynamic and spectrophotometric results were explained in terms of formation of the octahedral $[NiCl]^+$ complex as well as $[Ni(dmf)_6]^{2+}$ and of formation of the tetrahedral $[NiCl_3]^-$ and $[NiCl_4]^{2-}$ complexes in DMF. On the other hand, in the zinc(II) chloride system, the ΔS_n° (n=1 and 2) values are large and positive, but the ΔS_n° (n=3 and 4) values are significantly small. The corresponding ΔH_n° (n=1 and 2) values are positive but the ΔH_n° (n=3 and 4) values are significantly negative. It is thus postulated that the $[ZnCl_n]^{(2-n)+}$ (n=2 and 3) complexes have the tetrahedral coordination structure as well as the $[ZnCl_4]^{2-}$ complex in DMF.

In previous papers, we reported complexation between copper(II) and chloride ions in *N,N*-dimethylformamide (DMF),[1] acetonitrile[2] and dimethyl sulfoxide (DMSO),[3] and in acetonitrile-DMF mixtures[4] by calorimetry and spectrophotometry. The complexation between copper(II) and chloride ions is markedly enhanced in these aprotic solvents as compared with that in water, which may mainly be ascribed to weaker solvent-solvent interactions in the former solvents than in the latter, as already noted by Ahrland.[5] The coordination structure around copper(II) ion changes in the course of the complexation of the metal ion with chloride ions, and the distorted octahedral $[Cu(dmf)_6]^{2+}$ and $[CuCl(dmf)_5]^+$ complexes and the distorted tetrahedral $[CuCl_3(dmf)]^-$ and $[CuCl_4]^{2-}$ complexes are formed in DMF according to an X-ray diffraction study.[6]

It has been established from measurements of electronic spectra of the tetrahalogenonickelate(II) complexes that they have the tetrahedral structure both in crystal and in solution.[7-9] The tetrahedral $[NiCl_4]^{2-}$ ion is slightly distorted in $(R_4N)_2NiCl_4$ (R=CH_3 or C_2H_5) but almost regular in the triphenylmethylarsonium compound.[10,11] The tetrahedral $[ZnCl_4]^{2-}$ entity has also been found in M_2ZnCl_4 (M^+=K^+, Rb^+ and Cs^+) crystals,[12-16] in $ZnCl_2$-KCl melts[17] and in a highly concentrated zinc(II) chloride aqueous solution.[18] Complexation between nickel(II) and halide ions has so far been studied by spectrophotometry in some aprotic solvents.[19,22] However, no quantitative result of their formation constants and enthalpies has been obtained in aprotic solvents. On the other hand, complexation of zinc(II) with halide ions has been well studied by potentiometry and calorimetry in DMSO,[23,24] although no reliable result has been reported in other aprotic solvents.[25]

Although the donicity of DMF and DMSO is not significantly different,[26] we pointed out in a previous paper[3] that the complexation of copper(II) with chloride ions is markedly weaker in DMSO than in DMF due to stronger solvent-solvent interactions in the bulk of the former. In this respect, DMF can be a better solvent than DMSO for studying weak complexation of metal ions such as nickel(II) and zinc(II) with chloride ions.

In this work, we therefore investigated complexation of Ni(II) and Zn(II) with chloride ions in DMF by calorimetry and spectrophotometry using similar procedures to those employed in previous works,[1-4] and thermodynamic quantities of formation of the metal chloro complexes were determined. Electronic spectra of individual nickel(II) chloro complexes in DMF were also estimated. On the basis of the thermodynamic and spectrophotometric results, changes in the coordination structure around nickel(II) and zinc(II) ions in the course of the complexation in DMF are discussed.

Experimental

Reagent. *Nickel(II) perchlorate DMF solvate* was obtained by dissolving nickel(II) perchlorate hexahydrate crystals in DMF and then by repeatedly recrystallizing from DMF in order to remove water, and was finally isolated by recrystallizing them from a 50% v/v DMF-acetone mixture. *Zinc(II) perchlorate DMF solvate* was prepared from zinc(II) perchlorate hexahydrate crystals by the similar procedure to that used for preparing nickel(II) perchlorate DMF solvate and was finally obtained by recrystallizing them from acetone. Each of nickel(II) and zinc(II) perchlorate DMF solvates thus prepared was dried at about 40 °C in a vacuum oven for several days and kept in a desiccator over P_2O_5. The value of x within $[M(ClO_4)_2 \cdot (dmf)_x]$ (M^{2+}=Ni^{2+} or Zn^{2+}) was found to be 6, as already noted by Schneider,[27] which

was confirmed by gravimetry using dimethylglyoxime and by titration with EDTA for nickel(II) and zinc(II) perchlorate DMF solvates, respectively.

Tetraethylammonium perchlorate and *tetraethylammonium chloride* of reagent grade were once recrystallized from water and dried at 100 °C.

N,N-Dimethylformamide was dried for several weeks over molecular sieves 4A 1/16 and then distilled at 40 °C under a reduced pressure (260 Pa) and stored over the molecular sieves in a dark bottle with a P_2O_5 drying-tube.

Measurements. Calorimetric and spectrophotometric measurements were carried out in a room thermostated at (25.0±0.2) °C. All test solutions prepared contained 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ as a constant ionic medium.

Calorimetric measurements were performed in a thermostated water-bath controlled at (25.000±0.007) °C. 100 cm^3 of a metal perchlorate DMF solution was placed in a Dewar vessel which was filled with dry nitrogen gas and prevented from moisture with a P_2O_5 drying-tube, and then it was titrated with 0.4 mol dm^{-3} $(C_2H_5)_4NCl$ DMF solution. The concentration of metal ions in the initial test solution was varied over the range 5—15 and 5—20 mmol dm^{-3} for nickel(II) and zinc(II) ions, respectively. Heats of complexation observed at each titration point were ranged 1—5 J with a certainty ±0.05 J and were corrected for heats of dilution of the titrant which were determined in advance by separate experiments by titrating a 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution with the 0.4 mol dm^{-3} $(C_2H_5)_4NCl$ titrant solution. All of the measurements were carried out by using a fully automatic on-line system for calorimetry developed in our laboratory.[28] Details of the data treatment have been described elsewhere.[2,3]

Electronic spectra were measured with a HITACHI 340 spectrophotometer (HITACHI) equipped with a PC-9801F2 computer (NEC) which recorded data every 2 nm over the wavelength range 300—850 nm. A flow cell with a light-path length of 0.5 cm was connected with a titration vessel through Teflon and glass tubes. 20 cm^3 of a metal perchlorate solution was placed in a vessel under a dry nitrogen atmosphere and then titrated with the 0.4 mol dm^{-3} $(C_2H_5)_4NCl$ titrant solution.

Results and Discussion

Nickel(II) Chloro Complexes. Calorimetric titration curves obtained in the nickel(II) chloride system with varying concentrations of the metal ion are depicted in Fig. 1. In the figure, enthalpies $\Delta H^\circ = -q/(\delta v C_{X,tit})$ were plotted against C_X/C_M, where q, δv, C_X and C_M stand for the heat evolved, the volume of an aliquot of the titrant added and the concentrations of chloride and nickel(II) ions in solution, respectively, at each titration point, and $C_{X,tit}$ denotes the concentration of chloride ion in the titrant solution.

Complexation between nickel(II) and chloride ions in DMF is rather weak because, as seen in Fig. 1, the titration curves were strongly dependent on the concentration of nickel(II) ion in the solutions and appreciable endothermicities were still observed at $C_X/C_M>10$. The enthalpy ΔH° in each titration curve first decreased with increasing C_X/C_M and then increased after passing through a minimum. Each titration curve showed a maximum value around $C_X/C_M=3—7$ and then decreased to approach $\Delta H^\circ=0$.

The calorimetric data were analyzed by assuming the formation of plausible sets of nickel(II) chloro complexes and by simultaneously optimizing their formation constants and enthalpies by the least-squares method, the results being summarized in

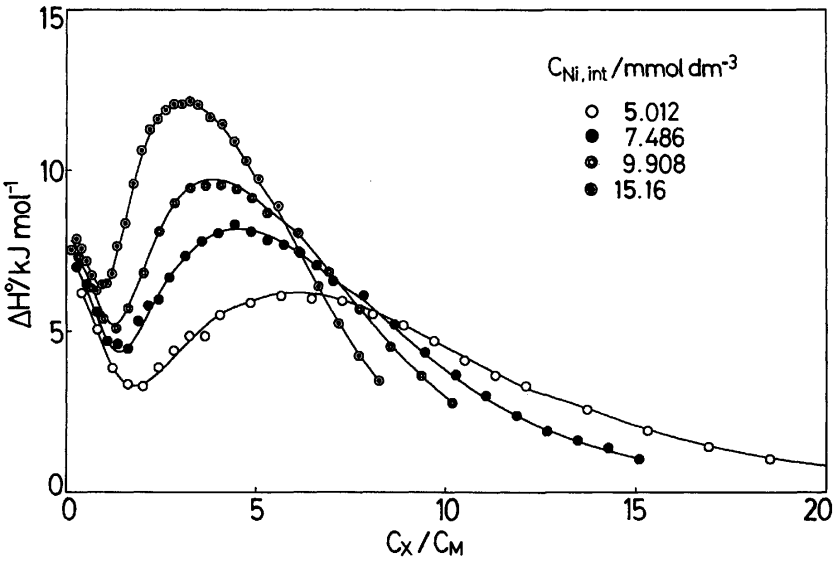

Fig. 1. Calorimetric titration curves of nickel(II) chloride DMF solutions containing 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25°C. Concentrations of nickel(II) ions, $C_{Ni,int}$/mmol dm^{-3}, in initial test solutions are given in the figure. The solid lines show the theoretical curves calculated by using the constants of the set (1—4) by calorimetry in Table 1.

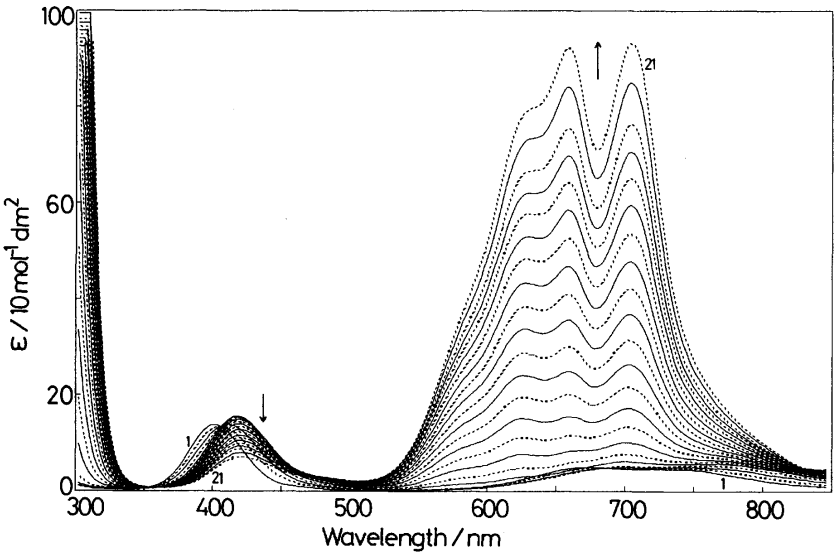

Fig. 2. Electronic spectra of nickel(II) chloride DMF solutions in the range 300—850 nm. Intensities are normalized with a unit concentration of the metal ion in solution. The spectra changed along the direction of the arrows with increasing C_X/C_M, the C_X/C_M value being varied from 0 of the solution No. 1 to 3.78 of the solution No. 21.

Table 1.

Among various sets examined, the set (1—4) assuming the formation of $[NiCl_n]^{(2-n)+}$ (n=1—4) and the set (1,3,4) eliminating $[NiCl_2]$ from the set (1—4) gave relatively small Hamilton *R*-factors (calculated by $\{\sum(q_{i,obsd}-q_{i,calcd})^2/\sum(q_{i,obsd})^2\}^{1/2}$), 0.0129 and 0.0146, respectively. Other sets such as (1, 2), (1, 3), (1, 4), (1, 2, 3), and (1, 2, 4) gave much larger values of the Hamilton *R*-factor. As seen in Fig. 1 by the solid lines, theoretical titration curves calculated by using the constants of the set (1—4) in Table 1 well reproduced the experimental points over the whole range of C_X/C_M examined. However, the set (1, 3, 4) could also reproduce the experimental points rather satisfactorily because the Hamilton *R*-factor of the set (1, 3, 4) was close to that of the set (1—4), and therefore, the $\Delta H^\circ_{\beta 2}$ and $\Delta H^\circ_{\beta 3}$ values evaluated from the calculation by using the set (1—4) contained relatively large uncertainties.

Electronic spectra of nickel(II) chloride DMF solutions measured with varying concentrations of the ligand ion are depicted in Fig. 2. Each spectrum should be represented as the sum of electronic spectra of individual nickel(II) chloro complexes by taking into account the distribution of species in solution. Therefore, absorbance data obtained at selected 30 wavelengths in the range 300—850 nm were analyzed by assuming the formation of plausible sets of nickel(II) chloro complexes and their formation constants and molar extincition coefficients of each complex at relevant wavelengths were optimized by the least-squares method. Among various sets of complexes

examined, again the sets (1—4) and (1, 3, 4), as seen in Table 1, gave relatively small Hamilton R-factors, 0.0123 and 0.0138, respectively. The same analysis was performed by using absorbance data at differently chosen 30 wavelengths in the range 300—850 nm in order to check the reproducibility of the formation constants thus evaluated, and the formation constants of each complex obtained by using the second set of data gave practically the same values as those evaluated by using the first set of absorbance data.

Since the formation constant log β_2 of the $[NiCl_2]$ complex, as well as the log β_n (n=1, 3, and 4) values of the other three nickel(II) chloro complexes obtained by calorimetry and spectrophotometry is in very good agreement with each other, as seen in Table 1, we concluded that the formation of the $[NiCl_2]$ complex should be taken into account together with the other three complexes in DMF. Consequently, we finally propose the formation of $[NiCl_n]^{(2-n)+}$ (n=1—4) in DMF. Distribution of the nickel(II) chloro complexes in DMF is depicted in Fig. 3, which was calculated by using the formation constants of the set (1—4) by calorimetry in Table 1.

Zinc(II) Chloro Complexes. Calorimetric titration curves for the zinc(II) chloride system obtained by using similar procedure to that employed in the previous section are depicted in Fig. 4. In contrast to the nickel(II) chloride system, the titration curves showed only a slight dependence on the concentration of zinc(II) ion in solution. In addition, the $\Delta H°$ values approached zero at C_X/C_M>4, indicating that the zinc(II) chloro complexes are more stable than the nickel(II) chloro complexes in DMF.

The calorimetric data were analyzed by assuming the formation of plausible sets of mononuclear $[ZnCl_n]^{(2-n)+}$($n\leq4$) complexes, and their formation constants and enthalpies were simultaneously refined. Among them, the sets (1—4) and (2—4) gave relatively small Hamilton R-factors, 0.0359 and 0.0500, respectively. The results of overall formation constants and enthalpies thus optimized for both sets are summarized

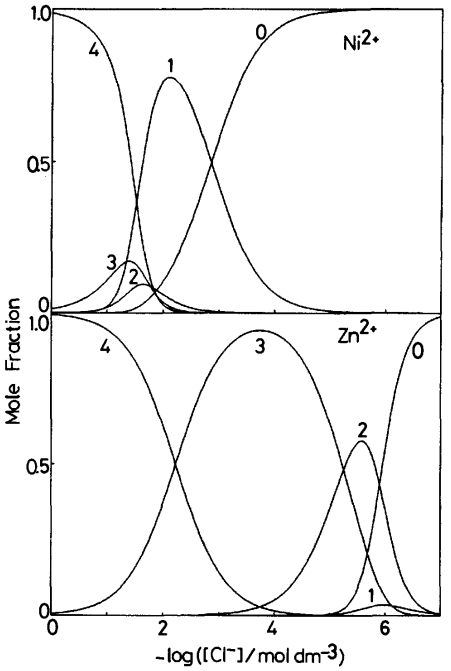

Fig. 3. Distribution of species of the chloro complexes of nickel(II) and zinc(II) ions in 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution. The numbers represent n within $[MCl_n]^{(2-n)+}$ (M^{2+}=Ni^{2+} and Zn^{2+}).

a) Ref. 24. b) Values of the overall formation of $[MCl_4]^{2-}$ (M^{2+}=Ni^{2+} and Zn^{2+}).

in Table 2. Considering the appreciably smaller Hamilton *R*-factor of the set (1—4) than that of the set (2—4), we finally propose the formation of $[ZnCl_n]^{(2-n)+}$ (n=1—4) in DMF. Distribution of species of the zinc(II) chloro complexes in DMF calculated by using the formation constants of the set (1—4) in Table 2 is also depicted in Fig. 3. As seen in Fig. 3, the formation of $[ZnCl]^+$ is so weak that the $\Delta H^\circ_{\beta1}$ value evaluated involves a rather large uncertainty.

Stepwise Thermodynamic Quantities. Stepwise formation constants, $\log(K_n/\text{mol}^{-1}\,\text{dm}^3)$, Gibbs energies, ΔG°_n/kJ mol^{-1}, enthalpies, ΔH°_n/kJ mol^{-1}, and entropies, ΔS°_n/J K^{-1} mol^{-1}, were then calculated, the results being summarized in Table 3.

Nickel(II) ion may be primarily coordinated with six DMF molecules in DMF as has been observed within the $Ni(ClO_4)_2\cdot(dmf)_6$ solvate crystal,[27] because the absorption spectrum of nickel(II) perchlorate DMF solutions showed practically the same spectral profile as the reflectance spectrum of the solvate crystal. Zinc(II) ion is suggested to be coordinated with six solvent molecules in zinc(II) perchlorate DMSO solutions and in the $Zn(ClO_4)_2\cdot(dmso)_6$ crystal.[29,30] Similarly, zinc(II) ion may be coordinated with six DMF molecules in zinc(II) perchlorate DMF solution as well as in the $Zn(ClO_4)_2\cdot(dmf)_6$ crystal.[27] Chloride ions stepwise coordinate to Ni(II) or Zn(II) ion to yield the tetrahedral $[MCl_4]^{2-}$ (M^{2+}=Ni^{2+} or Zn^{2+}) complex in the solutions[7,8] and thus all solvent molecules coordinating to the metal ions are liberated at the formation of the $[MCl_4]^{2-}$ complex. The structural change around Ni(II) and Zn(II) ions from octahedral to tetrahedral must thus take place at a certain step of complexation between the metal and chloride ions.

DMF molecules coordinating to metal ions lose their freedom of motion to a great extent. On the contrary, as the result of complexation between a metal and ligand ions, DMF molecules coordinating to the ions are liberated, the process being accompanied by an increase in the degree of freedom of the DMF molecules, i.e., the entropy change associated with the liberation of solvent molecules must be large and positive.

As seen in Table 3, the ΔH°_3 and ΔS°_3 values of stepwise formation of $[NiCl_3]^-$ are extremely large and positive as compared with the corresponding values of the $[NiCl_n]^{(2-n)+}$ (n=1, 2, and 4). Thus, DMF molecules coordinating to nickel(II) ion must be extensively liberated and the coordination number around the metal ion may be decreased at the formation of $[NiCl_3]^-$. Individual electronic spectra of $[NiCl_3]^-$ and $[NiCl_4]^{2-}$ in DMF show strong absorption bands over the range 550—750 nm which are not observed in the spectra of $[NiCl_n]^{(2-n)+}$ (n=0—2) as will be discussed in a later section. Thus, we propose the tetrahedral structure for the $[NiCl_3]^-$ complex as well as the tetrahedral $[NiCl_4]^{2-}$ complex. The trichloronickelate(II) complex may thus involve one DMF molecule within the coordination shell of the metal ion as represented by $[NiCl_3(dmf)]^-$. The metal-solvent bond within the complex may be weak because the subsequent stepwise formation of $[NiCl_4]^{2-}$ shows even negative enthalpy and entropy changes.

On the other hand, in the zinc(II) chloride system, an extensive liberation of solvent molecules may take place at the formation of the $[ZnCl]^+$ complex because

both ΔS_1° and ΔH_1° values shown in Table 3 are large and positive, and thus the coordination number around zinc(II) ion might be decreased within the $[ZnCl]^+$ complex. However, it is hard to conclude the coordination structure of $[ZnCl]^+$ (four-, five- or six-coordination) because the ΔS_n° (n=1 and 2) values involve rather large uncertainties due to the weak formation of the $[ZnCl]^+$ complex in DMF. The formation of $[ZnCl(dmso)_3]^+$ in DMSO[23,24] and of $[ZnCl(CH_3OH)_5]^+$ in methanol[31] has been suggested.

In contrast to large and positive ΔS_n° (n=1 and 2) values of formation of the $[ZnCl]^+$ and $[ZnCl_2]$ complexes, the ΔS_n° (n=3 and 4) values of $[ZnCl_3]^-$ and $[ZnCl_4]^{2-}$ are significantly small. The corresponding ΔH_n° (n=1 and 2) values are positive but the ΔH_n° (n=3 and 4) values are negative. The result indicates that the liberation of DMF molecules takes place to a great extent at each consecutive step of the formation of $[ZnCl]^+$ and $[ZnCl_2]$ but only to a small extent at the formation of $[ZnCl_3]^-$ and $[ZnCl_4]^{2-}$. It is thus expected that the $[ZnCl_2]$ and $[ZnCl_3]^-$ complexes may have a smaller coordination number than the $[Zn(dmf)_6]^{2+}$ and $[ZnCl]^+$ complexes in DMF. We therefore propose that the di- and trichloro complexes of Zn(II) have the tetrahedral four-coordinate structure in DMF, as represented by $[ZnCl_2(dmf)_2]$ and $[ZnCl_3(dmf)]^-$, respectively, which are similar to the tetrahedral $[ZnCl_4]^{2-}$ complex.

The metal-solvent interaction may be very weak within the $[ZnCl_n]^{(2-n)+}$ (n=2 and 3) complexes as indicated by negative ΔH_n° (n=3 and 4) values in spite of weaker metal-chloride bonds within higher complexes. The negative ΔH_n° value has also been observed at the stepwise formation of $[CuCl_4]^{2-}$,[1-4] as well as $[NiCl_4]^{2-}$ as discussed in a preceding section. The weakening of metal-solvent interactions may lead to an elongation of metal-solvent bonds within a metal complex. Structural evidence of elongation of a metal-solvent bond with an increase in the number of a ligand atom in the coordination shell which has a larger electron donicity than the solvent molecules has been obtained for the copper(II) chloro complexes in DMF[6] and the copper(II) and nickel(II) glycinato complexes in water[32-34] by means of X-ray diffraction.

Comparison between Formation of $[ZnCl_n]^{(2-n)+}$ in DMF and in DMSO. Complexation of zinc(II) with chloride ions has been studied in DMSO by Ahrland et al.,[23,24] and the formation of $[ZnCl_n]^{(2-n)+}$ (n=1—3) was indicated. According to their formation constants, the formation of $[ZnCl]^+$ is suppressed in DMSO as well as in DMF. It is noted that, as seen in Table 3, the formation constants of the zinc(II) chloro complexes in DMSO are markedly smaller than those in DMF, the result being mainly ascribed to smaller entropy changes in the former solvent than in the latter. When solvent molecules are liberated from the coordination sphere of an ion to enter the bulk solvent in the course of complexation, it is expected that the entropy of formation of a complex is positive. However, the positive entropy at the liberation of solvent molecules may be compensated for the structure formation of the solvent molecules in the bulk, if the solvent has rather strong solvent-solvent interactions. Since the donicity of DMF and DMSO is not largely different, the entropy increase at the liberation of solvent molecules from zinc(II) ion may be to a similar extent in both solvents. However, as described in a preceding paper,[3] DMSO has a long-range solvent-solvent interactions in the bulk than DMF has. Therefore, when solvent molecules subsequently enter the bulk phase, their degrees of freedom decrease more extensively in DMSO than in DMF, and thus, a less net entropy change of formation of a zinc(II) chloro complex results.

Electronic Spectra of Individual $[NiCl_n]^{(2-n)+}$ Complexes. Electronic spectra of individual nickel(II) chloro complexes were extracted from measured electronic spectra at varying concentrations of chloride ion in nickel(II) chloride DMF solutions over the wavelength range 300—850 nm, and the result is depicted in Fig. 5.

The nickel(II) DMF solvate complex shows an absorption peak at about 400 nm and very broad and very weak bands at 500—800 nm. The monochloronickel(II) complex shows a spectrum similar to that of the solvate complex, but the absorption peak at ca. 400 nm slightly shifted to a longer wavelength by ca. 20 nm than that of the solvate complex. The electronic spectra of these species are significantly different from the spectrum of $[NiCl_4]^{2-}$ which has the tetrahedral structure. Therefore, the $[NiCl]^+$ complex may have the octahedral type structure as well as $[Ni(dmf)_6]^{2+}$. The distorted octahedral structure of $[NiCl]^+$ in water has been suggested by X-ray diffraction.[35]

Although the spectrum of the dichloronickel(II) complex obtained is rather uncertain due to the weak formation of the complex in DMF, weak absorption bands ranging 400—600 nm are attributed to the complex, the spectrum being even slightly different from the spectra of $[Ni(dmf)_6]^{2+}$ or $[NiCl]^+$. It may be difficult to conclude the structure of the $[NiCl_2]$ complex from the spectral profile obtained here, but the different shape of the spectrum of the $[NiCl_2]$ complex suggests a different structure (a largely distorted six-coordinate or even a five-coordinate structure) of the complex from that of $[Ni(dmf)_6]^{2+}$ or $[NiCl(dmf)_5]^+$.

In the spectra of the tri- and tetrachloronickelate(II) complexes, absorption peaks appearing at 400—500 nm in the spectra of $[Ni(dmf)_6]^{2+}$, $[NiCl]^+$, and $[NiCl_2]$ almost disappear, while intense absorption peaks appear in the range 500—800 nm. The electronic spectrum of $[NiCl_4]^{2-}$ obtained has been ascribed to the absorption bands arising from the complex with the tetrahedral structure.[7-9] On the other hand, the electronic spectrum of trichloronickelate(II) complex has not been discussed in detail because overlapped spectra

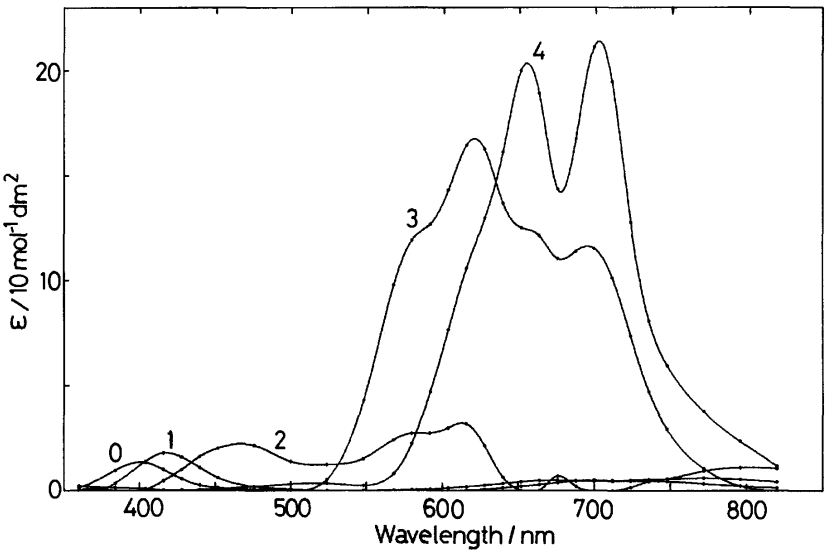

Fig. 5. Electronic spectra of individual nickel(II) chloro complexes in the range 350–850 nm obtained in 0.4 mol dm^{-2} $(C_2H_5)_4NClO_4$ DMF solution. The numbers represent n within $[NiCl_n]^{(2-n)+}$.

of $[NiCl_3]^-$ and $[NiCl_4]^{2-}$ are usually obtained in solution and it is difficult to extract the sole spectrum of $[NiCl_3]^-$. The electronic spectrum of $[NiCl_3]^-$ extracted in this work shows two peaks (ca. 620 and 695 nm) and two shoulders (ca. 575 and 660 nm). The similar intensities and peak positions of the bands of $[NiCl_3]^-$ to those of $[NiCl_4]^{2-}$ indicate that these complexes have the same type of coordination structure, i.e., the tetrahedral type structure, around the metal ion.

The similar spectrum to that of $[NiCl_3]^-$ in DMF has been observed for a nickel(II) chloride acetonitrile solution with the C_X/C_M ratio of 4,[21] the $[NiCl_3]^-$ complex probably being present as the main species in the acetonitrile solution. Similar electronic spectra of $[NiCl_3]^-$ observed in DMF and in acetonitrile in spite of a stronger donicity of DMF than that of acetonitrile suggest that the metal-solvent bonds within the $[NiCl_3(dmf)]^-$ and $[NiCl_3(acetonitrile)]^-$ complexes are so weak that the electronic spectra of the complex may not be appreciably influenced by the difference of the solvent molecules. Similar electronic spectra have also been obtained for the $[CuCl_3]^-$ complex in DMF and in acetonitrile.[1,2]

(Received August 6, 1986)

1 : 3-Cobalt(III) complexes of 3-substituted 1-phenyl-1,3-propanediones (C_6H_5-CO-CH_2-CO-R) have been synthesized, and their stereoselectivities were studied with 400 MHz proton NMR spectroscopy. When the substituent (R) was ethyl, propyl, isopropyl, butyl, or isobutyl, the complexes were obtained in a mixture of fac and mer isomers with the fac/mer ratio of 1/3, demonstrating statistical distribution. When the substituent was *t*-butoxymethyl or cyclohexyloxymethyl the fac isomer was predominantly formed. The stereoselectivity in the geometrical isomer formation of the complexes was ascribed to the interligand CH/π-interaction occuring between the R group and the phenyl ring. The stereoselectivities of the complexes [Co(*l*-moba-X)$_3$] (*l*-moba-X^-=4-(*l*-menthyloxy)-1-(*p*-X-phenyl)-1,3-butanedionate ion; X=H, Br, CH_3) were also examined by means of ^{1}H NMR spectroscopy and compared with the CD spectral result previously reported.

Previously we reported the stereoselective formation of the fac-Δ isomer of tris{4-(*l*-menthyloxy)-1-phenyl-1,3-butanedionato}M(III) complexes, [M(*l*-moba)$_3$] (M=Co, Cr, Mn) (Fig. 1(a); X=H).[2] This stereoselectivity was presumed to be due to the intramolecular, interligand CH/π-interaction[3] operating between the phenyl group and the *l*-menthyl group (Fig. 2). This presumption is supported by the facts that (1) the stereoselectivity in tris{4-(*l*-menthyloxy)-1-(2-naphthyl)-1,3-butanedionato}M(III) [M(*l*-mona)$_3$] (Fig. 1(b)) is higher than that of [Co(*l*-moba)$_3$] because of the larger π-system of the naphthyl group compared with the phenyl group[4] and (2) the stereoselectivity of [M(*l*-moba-Br)$_3$], [M(*l*-moba)$_3$], and [M(*l*-moba-Me)$_3$] (see Fig. 1(a)) is enhanced in this order because the π-electron density of the ring increases in the order 4-BrC_6H_4<C_6H_5<4-$CH_3C_6H_4$.[5]

So far we have inspected the stereoselectivities of the complexes based on circular dichroism induced at d-d transition bands. In this study we aimed to obtain direct evidences for the stereoselectivities of cobalt(III) complexes by means of high-resolution (400 MHz) proton NMR spectroscopy. We have synthesized 1 : 3-cobalt(III) complexes of various 3-substituted 1-phenyl-1,3-propanediones (Fig. 1(c)). The stereoselectivity in the formation of geometrical isomers (fac and mer) of the complexes was examined by ^{1}H NMR spectroscopy and discussed in terms of intramolecular, interligand interaction. Further, the stereoselectivities of [Co(*l*-moba-X)$_3$] (X=H, Br, Me) were examined by means of ^{1}H NMR spectroscopy, and compared with the CD spectral result previously reported.[4]

this study are given in Table 1, together with their abbreviations.

Experimental

Materials. Methyl ethyl ketone, methyl *n*-propyl ketone, methyl *i*-propyl ketone, methyl *n*-butyl ketone, methyl *i*-butyl ketone, acetophenone, *p*-bromoacetophenone, and *p*-methylacetophenone were purchased from Nakarai Chemical Co. *l*-Menthyloxyacetic acid was purchased from Tokyo Kasei Chemical Co. *t*-Butoxyacetic acid and cyclohexyloxyacetic acid were synthesized by the reaction of chloroacetic acid with *t*-butyl alcohol and cyclohexanol, respectively.[6)] Ethyl benzoate, ethyl *t*-butoxyacetate, and ethyl cyclohexyloxyacetate were synthesized by the esterification of the corresponding carboxylic acids.

Preparation. 3-Substituted 1-phenyl-1,3-propanediones (generally represented by H(L-R)) were synthesized by the Claisen condensation reaction[7)] between corresponding ester and ketone in the presence of sodium hydride as the base. The synthetic methods for H(*l*-moba-X) (X=H, Br, Me) have been described in the preceding papers.[2,5)]

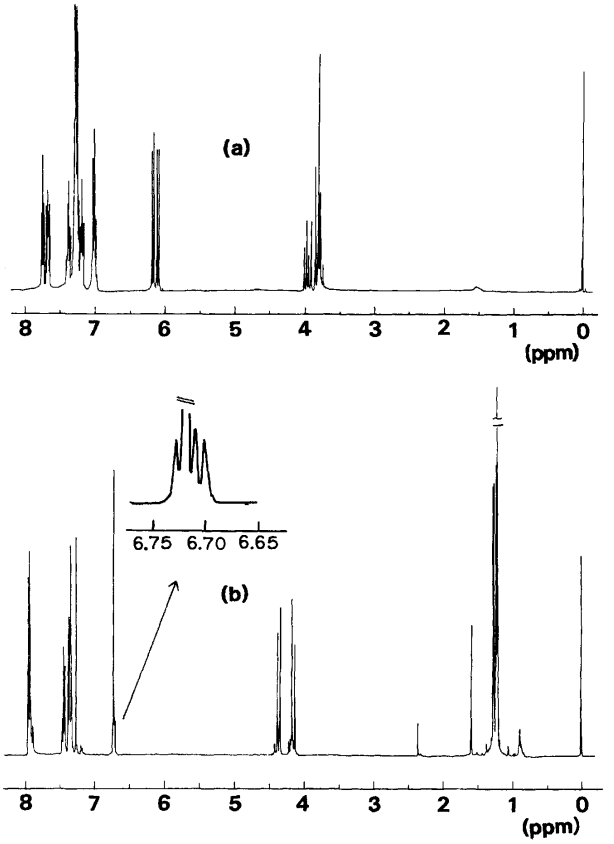

Fig. 3. Proton NMR spectra of (a) [Co(L-Bz)$_3$] and (b) [Co(L-BuO)$_3$].

Cobalt(III) complexes were obtained by the reaction of $Na_3[Co(CO_3)_3]\cdot 3H_2O$ and H(L-R)), in a way similar to that for tris(benzoylacetonato)cobalt(III).[8)] All the [Co(L-R)$_3$] complexes were obtained as green oily substances. They were purified by eluting through an alumina column (10 mm×100 mm) and identified by ^{1}H NMR spectra.

Measurements. ^{1}H NMR spectra were measured on a JEOL Fourier Transform NMR Spectrometer JNM GX-400 in $CDCl_3$. Tetramethylsilane was used as an internal standard.

Results and Discussion

For 1 : 3-cobalt(III) complexes of unsymmetrical 1,3-diketones, there are two geometrical isomers, fac and mer. The statistical ratio for the fac/mer isomers is 1/3. In the fac isomer three ligands are equivalent, whereas in the mer isomer no ligands are equivalent to each other.[9)] Therefore, in ^{1}H NMR spectra of tris(1,3-diketonato)cobalt(III) complexes, the methine proton in the chelate ring, for example, should be observed as four singlets with the same intensity (one from fac isomer and three from mer isomer) if there is no stereoselectivity in the formation of the complexes. When the interligand CH/π-interaction operates in the molecule to produce predominantly the fac isomer,

a) See Fig. 1 and Table 1. Abbreviations: met=methine proton, s=singlet, d=doublet, t=triplet, qa=quartet, qi=quintet, mc=multiplet center, CH_3=three methyl groups of the *l*=menthyl group. b) Four peaks with nearly the same intensity. c) Weak peaks in parentheses. d) AB quartet.

only one singlet of the methine signal (or one intense and three weak singlets) should be observed. Thus, the stereoselectivity in tris(1,3-diketonato)cobalt(III) complexes can be inspected by the number of the methine proton signals and their relative intensities.

Each ^{1}H NMR spectrum of the free ligands H(L-R) shows a singlet peak in the 6.1—6.7 ppm which can be assigned to the methine proton on the chelate ring. The integrated intensity of this signal corresponds to one proton, clearly indicating that the diketones assume the enol form. The assignment of main ^{1}H NMR signals of the ligands are given in Table 2.

As shown in Fig. 3(a), the spectrum of [Co(L-Bz)$_3$] shows four singlets with the equal intensity in the 6.08—6.18 ppm region, attributable to the methine protons. Evidently the fac/mer ratio is the statistical one, indicating no stereoselectivity in this case. A similar ^{1}H NMR spectral feature (four methine signals)

was observed for [Co(L-Et)$_3$], [Co(L-*n*Pr)$_3$], [Co(L-*i*Pr)$_3$], [Co(L-*n*Bu)$_3$], and [Co(L-*i*Bu)$_3$] (Table 2). On the other hand, the NMR spectrum of [Co(L-BuO)$_3$] showed a strong peak at 6.72 ppm attributable to the methine proton of the fac isomer, together with three very weak peaks at 6.70, 6.71, and 6.73 ppm attributable to the methine proton of the mer isomer (Fig. 3(b)). The methine proton intensity of the fac isomer is about 10 times that of each peak for the mer isomer, indicating the fac/mer ratio of ca. 10/3 for this complex. The fac/mer ratio was also estimated by the proton signal intensities of *t*-butyl groups; the 1.21 ppm signal attributable to the fac isomer is about 10 times as strong as the signals at 1.23, 1.25, and 1.27 ppm attributable to the mer isomer. [Co(L-CyO)$_3$] also showed a similar spectral pattern in the methine signal region, demonstrating the predominant formation of the fac isomer (Table 2). The fac/mer ratio for this complex was estimated at ca. 3 from the methine peak intensities. The stereoselectivities found for [Co(L-BuO)$_3$] and [Co(L-CyO)$_3$] may be attributed to the intramolecular, interligand CH/π-interaction as supposed for [M(*l*-moba-X)$_3$][2,5] and [M(*l*-mona)$_3$][4] (see Fig. 2).

The Dreiding model considerations suggest that the substistuent R with a carbon chain longer than two-carbon chain (C_2) may come into contact with the neighbouring phenyl ring in [Co(L-R)$_3$] but such a contact is not feasible in the complex with the substituent of C_2 chain. No stereoselectivity in [Co(L-Et)$_3$] and [Co(L-*i*Pr)$_3$], therefore, is easily understandable. However, [Co(L-*n*Pr)$_3$], [Co(L-*n*Bu)$_3$], [Co(L-*i*Bu)$_3$], and [Co(L-Bz)$_3$] also showed no stereoselectivity in spite of their substituent longer than C_2 chain. In the case of [Co(L-Bz)$_3$], the phenyl and the benzyl rings cannot stack with each other from the steric requirement of the molecule, and this may be a reason for no stereoselectivity of this complex. In contrast to the above complexes, [Co(L-BuO)$_3$] and [Co(L-CyO)$_3$] showed a high stereoselectivity.

It is not straightforward to explain the marked difference in stereoselectivities between the two classes, ([Co(L-*n*Pr)$_3$], [Co(L-*n*Bu)$_3$], and [Co(L-*i*Bu)$_3$]) and ([Co(L-BuO)$_3$] and [Co(L-CyO)$_3$]). At the moment we only point out two geometrical features which might relate to the different stereoselectivity between the two classes; (1) the latter class contains the ether group at the β-position of the substituent whereas the β-group for the former class is the methylene group, and (2) the latter class contains an inflexible hydrophobic group (*t*-butyl or cyclohexyl) in the R substituent whereas former class contains a rather flexible group in the substituent.

Proton NMR technique was applied to the analysis of the stereoselectivities of [Co(*l*-moba-Br)$_3$], [Co(*l*-moba)$_3$], and [Co(*l*-moba-Me)$_3$]. The spectra in the methine proton region are given in Fig. 4. In the spectra of [Co(*l*-moba-Br)$_3$] and [Co(*l*-moba)$_3$], four

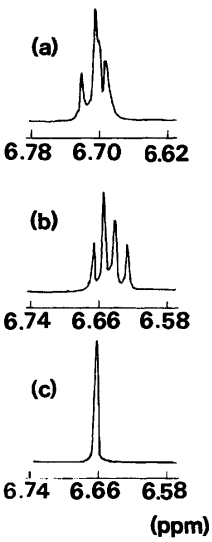

Fig. 4. NMR spectra (methine proton region) of (a) [Co(*l*-moba)$_3$], (b) [Co(*l*-moba-Br)$_3$], and (c) [Co(*l*-moba-Me)$_3$].

signals were observed. The result clearly indicates that each complex obtained is not of a pure isomer but a mixture of isomers. Since our CD spectral investigations have shown the predominant formation of the fac-isomer for these complexes,[5] the highest methine signal (6.65 ppm of [Co(*l*-moba-Br)$_3$] and 6.71 ppm of [Co(*l*-moba)$_3$]) may be assigned to this isomer. In the spectrum of [Co(*l*-moba-Me)$_3$], on the other hand, only one methine signal was observed at 6.66 ppm, clearly demonstrating that the fac-Δ isomer was selectively formed in this case. It is revealed from the present NMR spectral study that the stereoselectivity of [Co(*l*-moba-Br)$_3$], [Co(*l*-moba)$_3$], and [Co(*l*-moba-Me)$_3$] increases in this order, in accordance with the CD spectral result previously reported.[4]

It should be noted that the circular dichroism of [Co(*l*-moba-Me)$_3$], which is proved to be optically pure in this study, is 2.5 times as intense as that of optically pure [Co(acac)$_3$].[10,11] Judging from the fact that optical activity arising from the vicinal effect is at least two orders of magnitude smaller than that from the configurational effect,[12] it is suggested that the interligand CH/π-interaction enhances the distortion about the three-fold axis of the [Co(*l*-moba-Me)$_3$] molecule and thence increases the optical activity at the metal.

(Received August 11, 1986)

Extraction behavior of alkali and alkaline earth metal cations was investigated with a new extractant derived from polyethylene glycol mono[4-(1,1,3,3-tetramethylbutyl)phenyl]ether (Triton X-100; average number of oxyethylene group, 10) by introducing a phenolic(2-hydroxy-5-nitrobenzyl) group at the hydroxyl terminal of the polyethylene glycol chain. Alkali metal cations were extracted into 1,2-dichloroethane by forming 1 : 1 complex with the extractant. The overall extraction constant sequence was $K^+(10^{-9.15})>Rb^+(10^{-9.26})>Cs^+(10^{-9.28})>Na^+(10^{-10.08})>Li^+(10^{-10.36})$. The selectivity for K^+, Na^+, and Li^+ was discussed by comparing the extraction behavior with a mixture of nonionic surfactant or dicyclohexano-18-crown-6 and a proton-dissociable lipophilic dye. For alkaline earth metal cations, the extractability decreased in the order $Ba^{2+}>Sr^{2+}>Ca^{2+}\gg Mg^{2+}$. The metal extractability strongly depended on the nature of the anion in the aqueous phase.

In a previous paper,[1] we have reported the extraction behavior of alkaline earth metal cations with nonionic surfactants having a poly(oxyethylene) chain in the presence of lipophilic anions. Alkaline earth metal cations form cationic complexes with a poly(oxyethylene) chain, and the complexes are easily extractable into 1,2-dichloroethane together with lipophilic anions. The lipophilicity of the surfactant complexes seems to arise from the formation of a lipophilic shell around the cation. The extraction efficiency is strongly dependent on the lipophilicity of the counter anion.

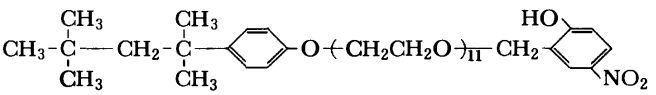
Similar to alkaline earth metal cations, alkali metal cations also form cationic complexes with a poly(oxyethylene) chain.[2-4] Yanagida et al.[5] reported that potassium ions were extracted with poly(oxyethylene) compounds together with an anion in the aqueous phase and the extractability depended on the nature of the counter anion. The interaction between the poly(oxyethylene) chain and cations has been applied not only to the photometric determination of the nonionic surfactant using the potassium ion and such a colored lipophilic anion as picrate,[6,7] but also to the sensors based on ionic-selective electrodes.[8,9]

From the standpoint of metal separation, the introduction of an anionic group into a poly(oxyethylene) chain can be expected to give a new series of extractants similar to those reported for crown ethers.[10] Yamazaki et al.[11] synthesized some poly(oxyethylene) derivatives with a hydroxyl group and a carboxyl group at each end of the poly(oxyethylene) chain and studied a carrier mediated transport of alkali metal ions.

In the present study, an integration of a nonionic surfactant (Triton X-100) and a proton-dissociable dye is attempted in the hope to obtain a new extraction-photometric reagent for alkali and alkaline earth metal cations. The basic features of the metal extraction with the extractant have been investigated.

Experimental

Reagent. The extractant (TP) which contains both Triton X-100 and phenolic structures was synthesized from Triton X-100, ethylene glycol, and 2-hydroxy-5-nitrobenzyl bromide (known as Koshland-I reagent, Dojin Labs. Inc.) as described below.



(TP)

Nonionic surfactants, Triton X-100 and polyethylene glycol mono(*p*-nonylphenyl)ethers (5PEGP, 10PEGP; 5 and 10 indicate the number of oxyethylene groups) were purchased from Tokyo Chemical Industry Co., Ltd. and used without further purification. Dicyclohexano-18-crown-6 (DCH18C6) was purchased from Nakarai Chemicals Co., Ltd. 2,5-Dinitro-4-(1,1,3,3-tetramethylbutyl)phenol (DNP) was synthesized by the method described in the preceding paper.[1] 1,2-Dichloroethane and metal salts were purchased from Wako Pure Chemical Industries, Ltd.. These reagents used were of best available grade.

2-(2-Hydroxy-5-nitrobenzyloxy)ethanol. 2-Hydroxy-5-nitrobenzyl bromide (3g, 13 mmol) was dissolved in 60 ml of ethylene glycol and stirred for 5 h at 60 °C. After the unreacted ethylene glycol was removed under reduced pressure, the resulting precipitates were recrystallized from a water–methanol mixture to give white crystals. The product was identified by means of IR and NMR spectrometry. Yield 2.53 g (93%), mp=132—133 °C. ^{1}H NMR ($CDCl_3$), 7.8—8.2 (2H, m, aromatic H), 6.9 (1H, s, aromatic H), 4.4 (2H, s, $ArCH_2$–), 3.6 (4H, s, OCH_2CH_2).

Synthesis of TP. Triton X-100 tosylate (6.5 g, 10 mmol), which was synthesized from tosyl chloride and Triton X-100 in a usual manner, was added to a suspension of sodium hydride (60% in oil; 1 g, 25 mmol) in DMF (13 ml) under nitrogen. To this solution, the DMF solution (13 ml) of 2-(2-hydroxy-5-nitrobenzyloxy)ethanol (2.1 g, 10 mmol) was slowly added at 0 °C and stirred for 24 h at room temperature. The temperature was then raised to 50—58 °C and after 2 h stirring, the mixture was concentrated under reduced pressure. The residue was taken up into chloroform and washed with water. The chloroform solution was con-

centrated and the residue was purified by column chromatography on silica gel (Wakogel C-200) with chloroform. Yield 57%. Yellow viscous oil. Found: C, 61.17; H, 8.95; N, 1.13%. Calcd for $C_{43}H_{71}O_{15}N$: C, 61.33; H, 8.50; N, 1.66%. ^1H NMR ($CDCl_3$), 8.0—8.2 (2H, m, aromatic H), 6.8—7.4 (5H, m, aromatic H), 4.8 (2H, s, $ArCH_2$-), 4.1—4.4 (2H, m, $ArOCH_2$-), 3.7—3.9 (44H, m, OCH_2CH_2), 1.85 (2H, s, $-CH_2-$), 1.5 (6H, s, $-C(CH_3)_2-$), 0.9 (9H, s, $-C(CH_3)_3$).

Determination of Acid Dissociation Constant of TP. The acid dissociation constant of TP in 20% dioxane was determined photometrically. An aliquot (20 ml) of dioxane solution of TP (4.0×10^{-4} mol dm^{-3}) was transferred to a 100 ml standard flask and an aliquot (7—10 ml) of aqueous alkali metal hydroxide or tetraethylammonium hydroxide solution (1.0 mol dm^{-3}) was added. After the mixture was diluted to 100 ml with water, the whole solution was transferred to a beaker and titrated with 1.0 mol dm^{-3} hydrochloric acid. The pH and the optical absorbance at 412 nm which corresponded to the absorption maximum of deprotonated TP were measured at 25 °C. The ionic strength was in the range 0.07—0.1.

Extraction Study. A pH-buffered aqueous solution (6 ml) of alkali or alkaline earth metal salt (0.1 mol dm^{-3}) was equilibrated with 1,2-dichloroethane solution (6 ml) of TP (10^{-4} mol dm^{-3}) or of mixture of PEGP and DNP by shaking mechanically for 20 min at 20 °C using a 50-ml centrifuge tube. After centrifuging for phase separation, the absorbances of both organic and aqueous phases at 300—450 nm and the pH of the aqueous phase were measured. When necessary, the concentration of metal ion in organic phase was determined by flame photometry (Nippon Jarrell Ash Co. Ltd., model AA-855) after back extraction with dilute hydrochloric acid.

Results and Discussion

The solubility of TP in 20% dioxane was so small that there appeared faintly milky turbidity even at 8×10^{-5} mol dm^{-3} TP concentration. The solubility increased with increasing pH of the solution. The increase is due to the proton dissociation of TP. On the other hand, TP was readily soluble in ordinary water-immiscible organic solvents. The distribution ratio of TP between water and 1,2-dichloroethane was more than 200. The deprotonated TP anion in 20% dioxane showed an absorption maximum at 412 nm, where a molar absorptivity was 14000 dm^3 mol^{-1} cm^{-1}. The acid dissociation constant was photometrically determined to be $10^{-6.90\pm0.05}$. The effect of a variety of alkali metal cations, including lithium, sodium and potassium, on the constant was investigated. However, the values obtained were similar to each other, suggesting that there were not appreciable interactions between TP (or TP anion) and alkali metal cations in this medium.

Alkali metal cations were extracted with TP into 1,2-dichloroethane. The extractability decreased in the order $K^+>Rb^+>Cs^+>Na^+>Li^+$. In preliminary experiments, it was found that the extraction was dependent only little on the concentration as well as the nature of the anion in the aqueous phase. Hence, the extraction equilibrium can be represented by the following equation:

$$M^+ + (HL)_o = (ML)_o + H^+,$$

where M^+ and HL represent alkali metal cation and TP, respectively, and the subscript "o" refers to the species in the organic phase. The extraction constant K_{ex} is defined by

$$K_{ex} = \frac{[ML]_o[H^+]}{[HL]_o[M^+]}. \quad (1)$$

In the present study, since a large excess of alkali metal cations is used as compared with the amount of the extractant, the concentration of M^+ in the aqueous phase remains constant before and after the extraction. In addition, the ratio of the concentration of complexed TP (TP anion) to that of free TP in the organic phase can be readily obtained from spectrophotometrical data. Under these conditions, it is possible to establish the stoichiometry of metal extraction by looking at the dependence of the ratio $[ML]_o/[HL]_o$ on pH, which also allows the evaluation of the extraction constant defined by Eq. 1.

The spectral parameters of alkali metal cation-TP complexes used for the calculation of extraction constants are summarized in Table 1. The molar absorptivities were calculated from the absorbance of organic phase and the concentration of extracted metal ion, which was obtained by flame photometry. All of these values, except for lithium, are similar to each other. The plots of logarithmic value of the ratio ($\log [ML]_o/[HL]_o$) against pH (which was assumed to be equal to $-\log [H^+]$) are shown in Fig. 1. Linear relationships with a slope of about 1 were obtained, indicating the validity of the proposed extraction equilibrium.

The validity of the proposed extraction reaction was also justified from the experiment on the effect of TP concentration on the metal distribution ratio (D=total concentration of metal in organic phase/total concentration of metal in aqueous phase). The results obtained are shown in Fig. 2. The plots of log D against $\log [TP]_o$ under constant pH conditions show a linear relationship with a slope of about 1.0, which indicates that TP extracts alkali metal ions by forming 1 : 1 complexes as assumed before.

Based on these results, the extraction constants were calculated and summarized in Table 1. It is noticeable that the extraction constants for potassium, rubidium and cesium are almost the same at about $10^{-9.2}$, while those of sodium and lithium are lower by one order at $10^{-10.08}$ and $10^{-10.36}$, respectively.

A similar selectivity for alkali metal cations was observed for the ion-pair extraction with noncyclic linear poly(oxyethylene) ligands and lipophilic anionic dye. Table 2 indicates the extraction constants for potassium and sodium with a combined use of such neutral ligands (5PEGP, 10PEGP, and DCH18C6) and

Concentration before equilibration:
organic phase, $[HL]_o=2.18\times10^{-5}-4.36\times10^{-4}$ mol dm^{-3}. Aqueous phase, $[MCl]=0.100$ mol dm^{-3}. KCl(pH=9.79), ●: RbCl(9.88), △: CsCl(9.44), Φ: NaCl(10.73), □: LiCl(10.91).

DNP. The extraction constants are given by the following equation;

$$M^+ + (E)_o + A^- = (MEA)_o$$

$$K_{ex} = \frac{[MEA]_o}{[M^+][E]_o[A^-]}, \quad (2)$$

where $(E)_o$ and A^- represent the neutral ligand in organic phase and DNP anion in aqueous phase, respectively.

From Table 2, the extraction constant of potassium with DCH18C6 is about hundred times larger than that for sodium. This difference in the constants does not seem to depend much on the nature of anion and solvent used.[12,13]

As to PEGP system, Table 2 shows that the difference in extraction constant between potassium and sodium increases with increasing number of oxyethylene unit of nonionic surfactants. The constant with 10PEGP for potassium ($10^{5.55}$), for which the length of poly(oxyethylene) chain is close to that of TP, is by about one order of magnitude larger than that for sodium ($10^{4.64}$). The difference (0.91 in log unit) is consistent with that (0.93) of TP. Thus, it may be concluded from the comparison that an extractant having noncyclic-poly(oxyethylene) chain has inherently higher extraction preference toward potassium over sodium and that the selectivity constant (the ratio of extraction constant) between of potassium and

sodium with 10PEGP and TP is one tenth of that with DCH18C6.

If the acid dissociation constant and distribution ratio of the extractant remain the same on change in extractant structure, a selectivity of metal extraction can generally be related to both the stability constant of the complex formation in aqueous phase and the distribution ratio of the resultant complex between aqueous and organic phases.

Ono et al.[3,4] investigated the complexation between alkali metal cations and open-chain poly(oxyethylene) conductometrically in methanol and found that the stability constants for sodium ($10^{1.43}$) are by one order of magnitude smaller than that for potassium ($10^{2.72}$). The difference in the stability constants is close to those of the extraction constants in the present study, which suggests that the difference in sodium- and potassium-extractability is related to the complex-stability characteristics inherent to poly(oxyethylene) type ligands. This in turn suggests that the difference in distribution ratio among the alkali metal complexes of PEGP and TP is rather small. This seems reasonable, since a poly(oxyethylene) chain adopts a helical conformation[14,15] in its complex with alkali metals and such a solvation shell-type around the cation is thought to show similar lipophilicity.

It is generally accepted that small-size cations such as sodium and lithium are strongly hydrated in water, which makes it difficult to form stable complexes with PEGP. It is also reported that lithium ion does not bind with poly(oxyethylene) chain in methanol because of its strong solvation.[3,4] However, lithium was considerably extracted with TP in the present study. The extractability can be interpreted by a strong ionic interaction between lithium and *p*-nitrophenolate anion of TP. The extraction of potassium, sodium, and lithium with DNP was studied in strongly alkaline media (alkali metal hydroxide solution) to give the metal extraction constant in the absence of a neutral ligand; the constants (K'_{ex}= $[MA]_o/[M^+][A^-]$) obtained were $10^{-0.62}$, $10^{-0.94}$ and $10^{1.01}$, respectively. The extractability decreases in the following order; $Li^+ \gg K^+ > Na^+$. Takagi et al.[12] reported that the crown ether compounds having an anionic side chain interact favorably with sodium and lithium ions through ionic interaction, resulting in a net decrease in the alkali metal extraction selectivity based on the "size effect" of crown ethers. The same trend obviously holds for the extraction with the present noncyclic poly(oxyethylene) extractant having a proton dissociable site within the molecule.

Unlike the extraction of alkali metal cations, the extraction of alkaline earth metals by TP is considerably affected by the nature of inorganic anions present in the aqueous phase (Fig. 3). As shown in Fig. 3, the extactability of barium decreases with anions in the order, $ClO_4^- > SCN^- > Cl^-$. The sequence of the anions is compatible with the hydrophobicity of these anions.

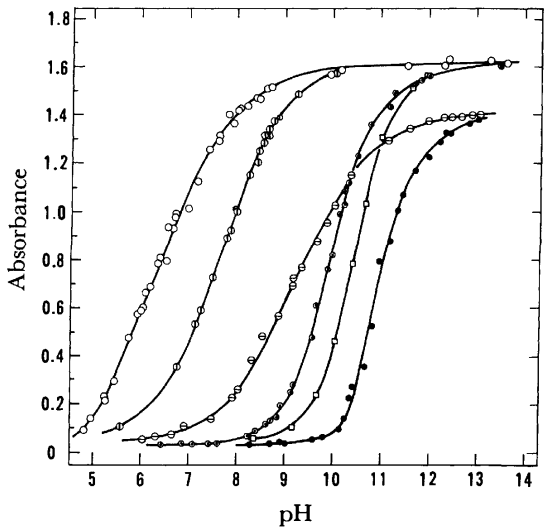

Fig. 3. Influence of pH on the extraction of alkaline earth metal ions with TP.
Concentration before equilibration:
organic phase, $[HL]_o = 1.00 \times 10^{-4}$ mol dm^{-3}
aqueous phase, $[MX_2] = 0.10$ mol dm^{-3}
○: $Ba(ClO_4)_2$ (absorbance measured at 403 nm), ◑: $Ba(SCN)_2$ (405 nm), ◉: $BaCl_2$ (410 nm), □: $SrCl_2$ (407 nm), ⊖: $Ca(ClO_4)_2$ (388 nm), ●: $CaCl_2$ (400 nm).

A similar effect was observed in the extraction of barium with a mixture of PEGP and DNP.[1] In the previous study, it was described that barium was extracted by forming a complex having a composition of Ba^{2+} : PEGP : DNP^- : inorganic anion = 1 : 1 : 1 : 1. In the present system, it is also possible that the TP anion extracts barium together with an inorganic anion in order to neutralize the charge on barium ion. However, there is a difference between the two systems (Ba^{2+}-PEGP-DNP^--X^- and Ba^{2+}-TP^--X^-) with regard to the effect of the inorganic anion on the distribution ratio of barium ion, i.e., the dependence of the extraction on the nature of the inorganic anion is much larger in the TP system than in the PEGP-DNP system. As shown in Fig. 3, the extractions of barium perchlorate and chloride with TP take place at pH 5.0 and 8.5, respectively, while corresponding pHs with PEGP and DNP were 6.0 and 7.0 (the ratio of extraction constants for barium perchlorate and barium chloride was about ten for the PEGP-DNP system[1]). This appears to arise from the dissociation of barium complex to the inorganic anion and the cationic barium complex in the organic phase, which is favorable for improving the extractability. This presumption is partly supported from the result of electric conductivity measurement on a barium-loaded organic phase. The apparent conductivity of organic phase increases in the order, $ClO_4^- > SCN^- > Cl^-$. This suggests that the dissociation constant of the barium complexes in the organic phase increases in the same order for these anions.

As to the selectivity of TP among alkaline earth metal cations, the following sequence was observed as

shown in Fig. 3: $Ba^{2+} > Sr^{2+} > Ca^{2+} \gg Mg^{2+}$. The extraction of magnesium ion is negligibly small and hence is not shown in Fig. 3. A detailed study on the extraction equilibrium and related constants is in progress.

In conclusion, the introduction of a proton-dissociable group into a poly(oxyethylene)-type surfactant molecule gave an efficient extractant for alkali and alkaline earth metal ions. The metal ions could be extracted into and back-extracted from organic solvents simply by changing the pH of the contacting aqueous solution, while the extractant stayed essentially in organic solution. This makes the extractant useful both in ordinary solvent extraction and in carrier-mediated liquid membrane separation processes. Unlike crown ether-based reagents, poly(oxyethylene)-based extractants are easy to prepare at low costs, and could be a candidate for a large scale separation of certain alkali metals in the future. On the other hand, poly(oxyethylene)-based extractants obviously can not be expected to offer a variety of metal extraction selectivity as has been proved possible with crown ether-based reagents. However, it is becoming increasingly clear that the extraction of alkali and alkaline earth metal ions depends remarkably on the nature of the incorporated anionic group (which is to make a direct interaction with the extracted metal ion), basicity and the extent of anionic charge delocalization within the proton-dissociating functional group.[16] In this sense, it would deserve further study to look at the effect of the nature of the anionic group on the extraction selectivity of metal ions.

(Received August 14, 1986)

The title complex was synthesized, and its crystal and molecular structures were determined by the single-crystal X-ray-diffraction method. It is triclinic, with the space group of $P\bar{1}$; the cell constants are a=20.621 (4), b=22.288 (5), c=7.724 (1) Å, α=93.30 (2), β=96.78 (2), γ=107.43 (2)°, Z=4, and the final R value is 0.048. Although there are two kinds of crystallographically independent complexes, their structures are almost the same, with only a slight difference in the orientations of the naphthalene rings of the ligands. Both of the central metal atoms are ennea-coordinated and are in the tricapped trigonal-prism geometry: two carboxylato ligands make four-membered chelate rings, and they are also ligated five water oxygen atoms. No carboxylate ions bridge the metal atoms, but the oxygen atoms of the ligands, isolated carboxylate ions, and the crystalline water molecules are linked through hydrogen bondings along the bc-plane. The metal atoms lie on a plane parallel to (100), and the planes are separated by the layers of the naphthalene rings of the naphthoate ions.

The structures of many lanthanoid carboxylates have already been reported, and it has been found that almost all of them are in dimeric or polymeric forms, bridged by carboxylato ligands in various modes.[1-8] The present authors were interested especially in the structure of the lanthanoid carboxylates, whose ligands have some bulky substituents, such as phenyl or naphthyl rings. In crystals of such a type of complex, the large hydrophobic parts and the hydrophilic central metal-core parts are apt to take separate positions. For example, the lanthanoid(III) 2-naphthalenesulfonates, although they are not carboxylates, have been found to have an accumulated layer structure where the naphthalene-ring part and the metal-core part form hydrophobic and hydrophilic layers alternately.[9] We have previously obtained neodymium(III) 1-hydroxy-2-naphthoate from an ethanol-water mixed solution, where the ethanol and the water molecules are both coordinated to the same metal atom, and where the metal cores are surrounded by the naphthyl groups of the carboxylato ligands.[10]

When a 2-propanol-water solvent was used instead of ethanol-water, we could obtain alcohol-free neodymium(III) 1-hydroxy-2-naphthoate. This compound is stable in air, unlike the ethanol-coordinated complex, which effloresced quite rapidly.[10] To clarify this difference, we have determined its crystal structure using the single-crystal X-ray-diffraction method.

Experimental

Synthesis of [Pentaaquabis(1-hydroxy-2-naphthoato)-neodymium(III)] (1-Hydroxy-2-naphthoate) Dihydrate. An aqueous solution of neodymium(III) chloride hexahydrate (0.38 g, 1.0_5 mmol) was mixed with an excess of a solution of sodium hydroxide. The hydroxide thus precipitated was washed with water and then dissolved into 20 cm^3 of a warm 2-propanol-water mixture (2:1=v/v) together with 1-hydroxy-2-naphthoic acid (0.59 g, 3.1 mmol); some residue subsequently filtered off. The filtrate was left standing for several days; the crystalline salt was thus precipitated. Yield: 0.36 g, 0.43 mmol, 41%. Found: Nd, 17.30; C, 47.21; H, 4.13%. Calcd for $NdC_{33}H_{35}O_{16}$: Nd, 17.34; C, 47.65; H, 4.24%.

Single-Crystal X-Ray Analysis. A crystal 0.5×0.32×0.10 mm^3 in size was used as the sample without any shaping. The crystallographic data: $NdC_{33}H_{35}O_{16}$, F.W.=831.87, triclinic, space group $P\bar{1}$, a=20.621 (4), b=22.288 (5), c=7.724 (1) Å, α=93.30 (2), β=96.78 (2), γ=107.43 (2)°, U=3347.2 (12) $Å^3$, Z=4, D_m=1.63 (3), D_x=1.65 $Mg\,m^{-3}$, μ(Mo$K\alpha$)=1.65 mm^{-1}. The reflections were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo$K\alpha$ radiation (0.7107 Å), in the range of $3°<2\theta<55°$, the ω scan technique being employed (scan speed: 4° min^{-1} (θ)); scan width: 1.27+0.5 tan θ (θ/°)). Of the 15417 independent reflections observed, 7579 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the refinement. The intensities were corrected for the Lorentz and polarization factors, as well as for the absorption.

Structure Determination. The structure was solved by the heavy-atom method. Because all the k-odd reflections were very weak, it was assumed that the crystal is formed by the alternate pile of almost identical structures along the b-axis. At first, the average positions of the metal atoms and some coordinated oxygen atoms were deduced from a Patterson map. The other non-hydrogen atoms were located by means of successive Fourier syntheses. The atomic parameters were refined successively by the block-diagonal least-squares method.

At this stage, the structure of the complex was almost converged, but the naphthalene rings parallel to (010) plane were quite deformed, and the difference Fourier synthesis showed the presence of another orientation of the ring. Therefore, the structure was refined with two independent structures, using all the reflections. At the end of the refinement, all the naphthalene rings were found to be in the normal form. The final R value was 0.048.[11]

All the calculations were carried out on a HITAC M-280H apparatus at the Computer Center of the University of Tokyo, using the local version of the UNICS program.[12] The atomic scattering factors were taken from Ref. 13.

a) The equivalent isotropic temperature factors were computed using the following expression:
$B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The b_{ij}'s are defined by:
$T=\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

Results and Discussion

The final atomic parameters and their equivalent isotropic temperature factors are listed in Table 1, while some bond lengths and bond angles, as well as some interatomic distances which are thought to be the hydrogen-bonding ones, are tabulated in Table 2. The projection of the two unit cells along the c-axis, along with the notation of the naphthalene rings, and the perspective drawings of the complex around the metal atoms, Nd(1) and Nd(2), are shown in Figs. 1, 2, and 3, respectively.[14]

Both the metal complexes have almost the same structure: the central metal atoms are ennea-coordinated and are in the tricapped trigonal-prism geometry, where four oxygen atoms of two chelating

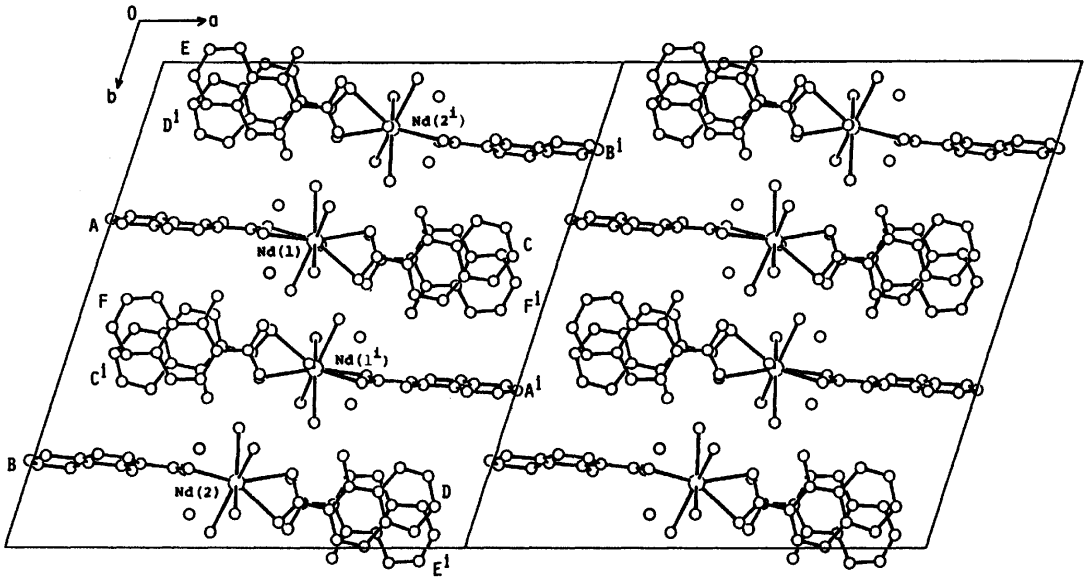

Fig. 1. Projection along the c-axis of the two unit cells with the notations of the naphthalene rings.[16]

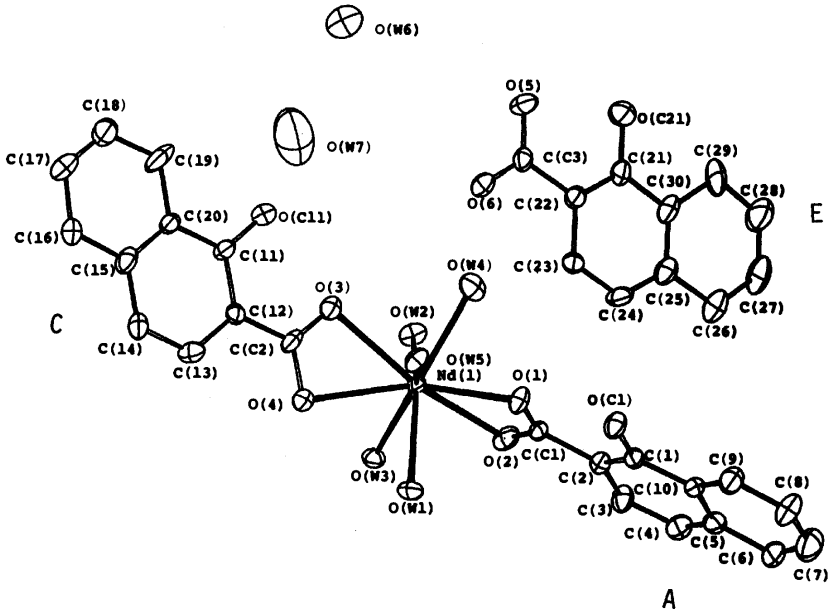

Fig. 2. Perspective drawing of the complex around Nd(1) atom and a non-coordinated naphthoate ion (**E**) with the numbering scheme.

ligands (forming four-membered rings) and five water oxygen atoms are coordinated. The main distinction between the geometries around the two metal atoms lies in the orientations of the A and B naphthoato ligands. As is shown by the schematic presentation in Fig. 4, around Nd(1) and Nd(2) both chelating ligands span the apexes of the trigonal prism and the cap positions respectively; such chelating positions are usual with this type of complex, because the distance between an apex and its nearest cap point is shorter than the edge between two apexes of the prism.[10]

No bridging by the carboxylate ions is found between metal atoms, and this type of the isolated complex is rather rare among lanthanoid carboxylates. The Nd-O bond lengths of the two carboxyl oxygen atoms of the same chelating ligand are not equal. The average lengths of the long and short bonds are 2.57 (2) and 2.49 (2) Å, respectively. However, there is no tendency for either the longer Nd-O bond to join the shorter C-O bond, or the reverse; that is, all the C-O bond lengths are not much different from the delocalized carboxyl C-O bond length. The Nd-O bond lengths in this compound are rather affected by the respective coordinating positions; generally, the Nd-O bonds at the cap positions are longer than those at the apexes of the trigonal prism. The average Nd-O bond

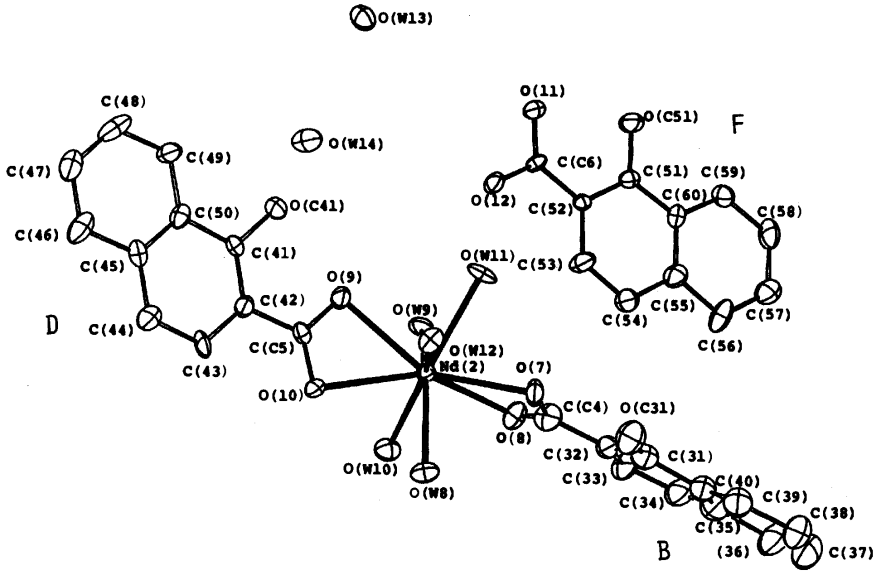

Fig. 3. Perspective drawing of the complex around Nd(2) atom and a non-coordinated naphthoate ion (**F**) with the numbering scheme.

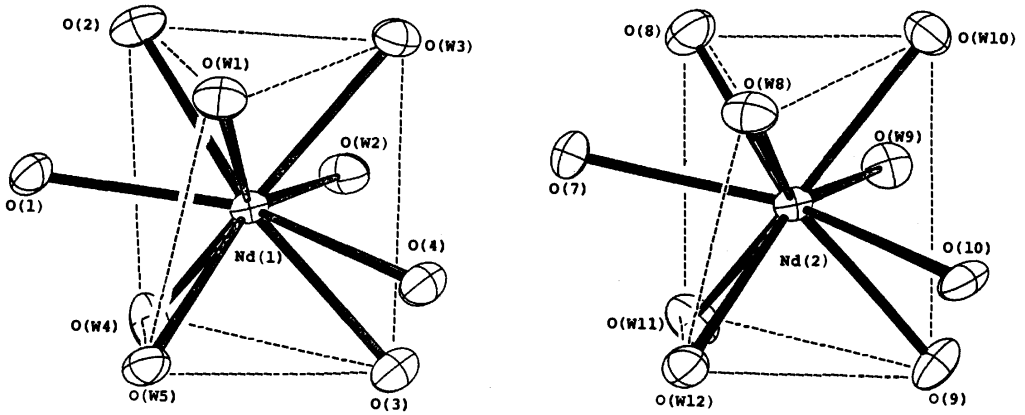

Fig. 4. Schematic presentation to show the coordination geometries around Nd(1) and Nd(2) atoms.

lengths of the water ligands are 2.48 (4) Å, which is a little shorter than that of the carboxylate oxygen atoms, 2.53 (5) Å.

The sum of the Shannon's ionic radii is 2.51 Å for the Nd-O bond (r_{Nd}(Valence(Val)=3+, Coordination Number (CN)=9)=1.163, and r_O(Val=2−, CN=2)=1.35 Å),[15] and both types of Nd-O bond lengths of this complex are not much different.

The other carboxylate anions (**E** and **F**) are not coordinated to the metal atom, and there are two more water molecules per metal atom which are not coordinated. Judging from the interatomic distances, it seems that there are some hydrogen bondings between the carboxyl and hydroxyl-group-oxygen atoms of the carboxylate ions, as well as between the coordinated and non-coordinated water oxygen atoms; many such bondings form a kind of network. Such interatomic distances are shown in Table 2.

As is shown in Fig. 1, the central metal atoms are arrayed almost entirely on (200). Both of the naphthalene rings of the chelate ligands extend to the direction approximately perpendicular to this plane. The naphthalene-ring planes of the ligands on both sides

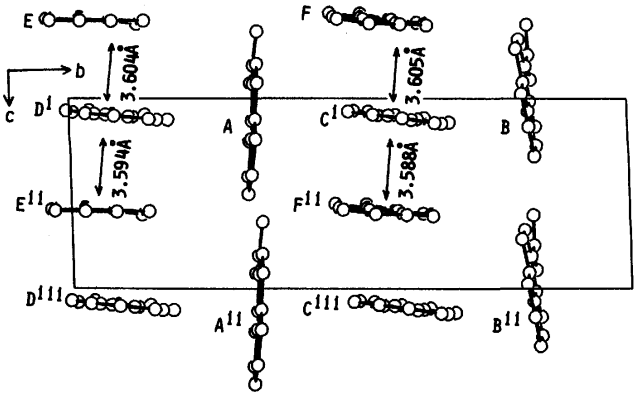

Fig. 5. Packing projection of the naphthalene rings on the plane perpendicular to the $\mathbf{D}^{i}$ ring plane, which is also approximately perpendicular to all the other naphthalene rings.[16]

of one metal atom, **A** and **C**, or **B** and **D**, are approximately orthogonal to each other, while those of the non-coordinated naphthoate ions are almost parallel to one of them, **F** and $\mathbf{C}^{i}$, or **E** and $\mathbf{D}^{i}$, with their hydroxyl groups directed in opposite directions. Thus, as is shown in Fig. 5, the series of naphthalene-ring planes, **E**, $\mathbf{D}^{i}$, $\mathbf{E}^{ii}$, ··· and **F**, $\mathbf{C}^{i}$, $\mathbf{F}^{ii}$, ··· are almost paralle:[16] the maximum dihedral angle between them is 4.7°. They are accumulated approximately in the c-direction. Their inter-planar distances are slightly longer than the thickness of an aromatic ring: $\mathbf{C}^{i}$-**F**, 3.605; $\mathbf{C}^{i}$-$\mathbf{F}^{ii}$, 3.588; **E**-$\mathbf{D}^{i}$, 3.604; and $\mathbf{D}^{i}$-$\mathbf{E}^{ii}$, 3.594 Å.[16] The overlappings of the naphthalene rings of **E**-$\mathbf{D}^{i}$, $\mathbf{D}^{i}$-$\mathbf{E}^{ii}$, **F**-$\mathbf{C}^{i}$, and $\mathbf{C}^{i}$-$\mathbf{F}^{ii}$ are 43, 50, 44, and 51% respectively.[b]

It is of interest to compare this structure with that of lanthanoid(III) 2-naphthalenesulfonate.[9] The latter is also two-dimensional network formed of hydrogen bonds between the coordinated and non-coordinated water molecules and sulfonato group, and the naphthalene rings are intercalated between the hydrophilic layers to form hydrophobic sheets. Naphthalene rings dangling from both sides of the hydrophilic sheets interlock with each other to form only one layer of naphthalene rings, and they are packed very closely, as is shown by the distances between the naphthalene rings, which are almost the thickness of the aromatic rings. In the case of the title complex, the naphthalene rings protruding from the hydrophilic layers do not interlock with each other, but form two sheets of naphthalene layers back to back. These differences may be due to the difference in the bulkiness of the sulfonato group and the carboxylato groups, and also to the participation of hydroxyl groups in the hydrogen bondings of the title complex.

The authors wish to thank the Shin-Etsu Chemical Ind. Co., Ltd., for presenting to them the highly pure lanthanoid oxides.

[b] When a naphthalene ring is projected on another naphthalene ring which is approximately parallel, the percentage of the overlapping area to the ring area is adopted.

ESR Studies of a New $3d_{z^2}$-Type Copper(II)-Crown Ether Complex with Pentagonal Bipyramidal Geometry

Yong Li, Kunihiko Tajima, Kazuhiko Ishizu,* and Nagao Azuma†
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
†Faculty of General Education, Ehime University, Matsuyama 790
(Received August 15, 1986)

In the presence of the optimum amount of water, the copper(II) ion and 15-crown-5 (15C5) derivatives gave the dihydrated complex in boron trifluoride–diethyl ether (BF_3-ether). Based on optical and ESR spectrometric titrations, we found that the crown ether captures the copper(II) ion in the equivalent metal/ligand molar ratio. The d-d band absorptions of the complexes were detected in the near-infrared region. The complexes revealed the characteristic ESR g-anisotropies ($g_z<g_x$, g_y) which are typical of the copper(II) complexes with a $3d_{z^2}$ ground-state doublet. The superhyperfine splittings due to the ^{17}O isotope was successfully detected, and the fact of the axial ligation of the water molecule was demonstrated. The ESR parameters were determined by means of the computer simulation of the line shape, while the copper-ligand bonding parameters were estimated from the ESR parameters by means of Bleaney's calculation.

The crown ether showed a pronounced ability to bind various cations and anions, with marked conformational changes in the polyether-ring moiety upon the metal chelations. Their hydrophobic exterior allows them to solubilize ionic substances in non-aqueous solvents.[1] These novel properties of crown ethers have resulted in their use as ligands in the molecular design of a metal complex with an unusual metal coordination and a distinctive electronic structure.

For example, the first successful preparation of a Cu(II) complex with a $3d_{z^2}$ ground state has been reported for the systems composed of $CuCl_2$ and crown ethers containing five oxygen atoms. In this case, the ESR measurement clearly demonstrated that the unpaired electron occupies the $3d_{z^2}$ metal orbital, as judged from the typical g-anisotropies, $g_z<g_x$, g_y.[2] The positive detection of a superhyperfine splitting ascribed to the axially ligated two chlorine atoms ($I=3/2$) suggested that the coordination geometry of the complex is a pentagonal bipyramid.[3,4] The subsequent X-ray analysis of the Benzo-15-crown-5(B15C5)-$CuCl_2$ complex visualized the detailed molecular structure, in which the complex takes the pentagonal bipyramidal geometry with the five ethereal oxygen atoms in the equatorial positions and with the two chlorine atoms at the apical positions.[5]

One of the distinct characteristics of the bonding scheme of the complex is the shorter Cu-Cl distances (2.254 and 2.242 Å) seen in the axial bond length, in comparison with the equatorial bond length (2.240—2.337 Å) between the metal and the ethereal oxygen atoms. In contrast to the case of the 5-*O*-membered crown ether, the Cu(II) complexes of 4-*O*- and 6-*O*-membered crown ethers reveal the ESR anisotropies assigned to those of the $3d_{x^2-y^2}$ or $3d_{xy}$-type ground state. In this case, the copper atom binds with the two chlorine atoms at the equatorial positions, thus forming a distorted octahedral geometry, in which the apical Cu-O distances (2.343 and 2.403 Å) are much longer than the equatorial bond length (Cu-Cl=2.214 Å, Cu-O=2.218 and 2.113 Å).[6]

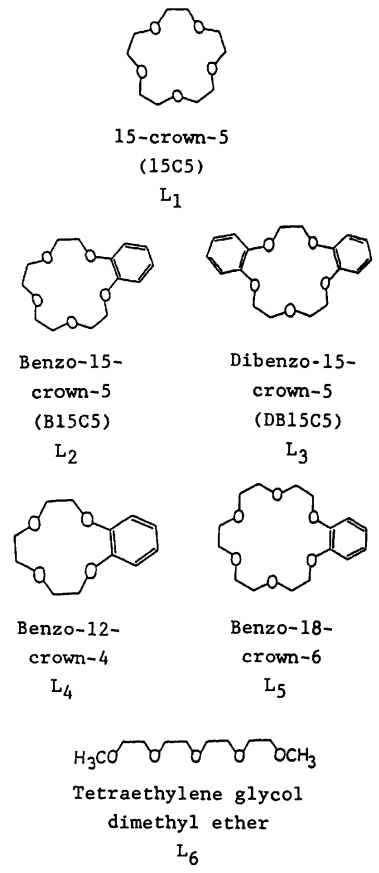

Fig. 1. Chemical structures of polyethers.

In order to elucidate in more detail the coordination chemistry with regard to the Cu(II) complex of 5-*O*-membered crown ether, we continued our efforts to obtain a similar Cu(II) complex generated in a BF_3-ether solution containing a small amount of water. Based on the spectrophotometric titration, we confirmed that the complex is a monomeric copper(II) complex, in which the Cu(II) ion is incorporated into the crown ether in the equivalent metal/ligand molar ratio. In the present paper, we wish to report the

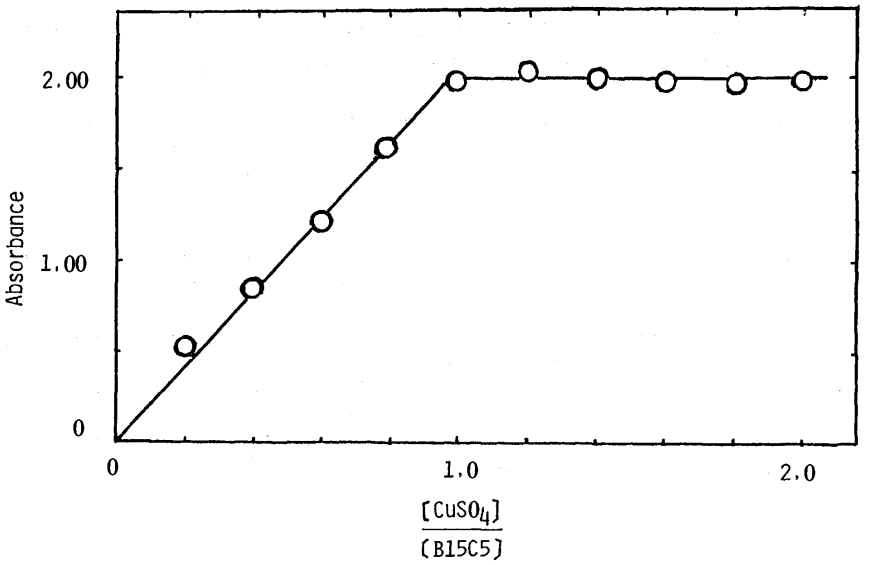

Fig. 2. Plot of the absorbance vs. the molar ratio of Cu(II) ion added to B15C5 solution.

spectroscopic properties of a new Cu(II)-5-*O*-membered crown ether complex in which two water molecules coordinate to the axial positions. The *g*-anisotropies measured, $g_z<g_x$, g_y, were indeed typical of Cu(II) complexes with the $3d_{z^2}$ ground state. The positive evidence for the axial ligation of the water molecule was successfully demonstrated by observing the ^{17}O-superhyperfine splitting, which is overlapped with each copper nuclear hyperfine splitting occurring at the g_z-component. By the aid of the MO scheme, the copper-ligand bonding nature was discussed in terms of the ^{17}O spin density.

Under the same reaction conditions, the complex formation was investigated between the Cu(II) ion and a crown ether with an even oxygen number, such as Benzo-12-crown-4(**L**$_4$) and Benzo-18-crown-6(**L**$_5$); the same experiment was also carried out for the 5-*O*-membered polyether with an open-chain structure(**L**$_6$, Fig. 1). In these cases, however, no experimental evidence to support the existence of a $3d_{z^2}$-type complex was obtained anywhere. It was thus confirmed that only 5-*O*-membered crown ethers gave the $3d_{z^2}$-type copper(II) complex in solution.

Experimental

The crown ethers used in this experiment were synthesized and purified according to Pedersen's procedure.[7] The tetraethylene glycol dimethyl ether and copper(II) salts were purchased at Wako Chemicals, Ltd., and they were used without further purification. A commercial grade of 47% BF_3-ether was used after dehydration and distillation.[8]

The electronic spectra were recorded with a JASCO UVIDEC-1 spectrometer and a JASCO UVIDEC-590 NIR spectrometer at room temperature. The ESR measurements were carried out at 77 K by using a JEOL-FE-2XG X-band spectrometer operating with a 100-KHz magnetic-field modulation. The *g*-values were determined by taking Li-TCNQ (g=2.0025) as a standard. The magnetic fields were calibrated based on the hyperfine splitting of Mn(II) in MgO (8.69 mT). All the measurements were performed at the Advanced Instrumental Center for Chemical Analysis, Ehime University.

Results and Discussion

Electronic Spectra. A 1.04×10^{-2} mol dm^{-3} solution (2.5 ml) of B15C5 dissolved in BF_3-ether was titrated with a 0.13 M $CuSO_4$ aqueous solution. By a step-by-step addition (0.04 ml) of the $CuSO_4$ solution, the growth in the absorption intensity was observed in the visible region of the electronic spectrum. An excellent linear increase in the visible absorption (λ_{max}=430 nm, ε=202 mol^{-1} dm^3 cm^{-1}) can be seen with an increase in the amount of $CuSO_4$ added, until the molar ratio of $CuSO_4$ to B15C5, [$CuSO_4$]/[B15C5], reaches unity (Fig. 2). When the total molar concentration of $CuSO_4$ exceeds that of B15C5, a sharp turning occurred on the linear plot, and no important changes in the absorption intensities were detected with a further increase in the [$CuSO_4$]/[B15C5] ratio. Based on the titration behavior between the B15C5 and the $CuSO_4$ solution, the Cu(II) complex formed in the present system is identified as a mononuclear copper(II) complex composed of the Cu(II) ion and the crown ether in an equivalent molar ratio. A similar titration behavior is obtained for the Dibenzo-15-crown-5(DB15C5)-Cu(II) complex by monitoring the characteristic absorption at λ_{max}=448 nm (ε=258 mol^{-1} dm^3 cm^{-1}).

The visible absorption bands thus characterized for DB15C5- and B15C5-Cu(II) complexes are probably to be attributed to the charge transfer between the benzene molecular orbital and the copper 3d atomic orbital, because no important absorption band can be detected for the 15C5-Cu(II) complex in the visible

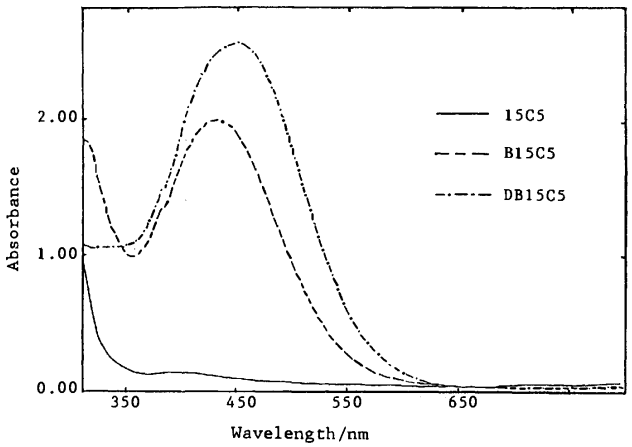

Fig. 3. Visible absorption spectra observed at room temperature for Cu(II)-complexes of L_1, L_2, and L_3.

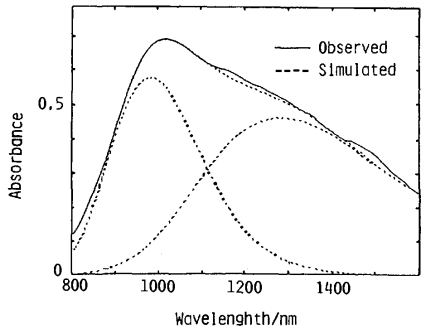

Fig. 4. Near infrared electronic absorption spectra observed at room temperature.

region of the electronic-absorption spectrum (Fig. 3). On the other hand, at the near-infrared band, broad, weak bands were found in the range from 850 to 1600 nm for all the Cu(II) complexes. The computer simulations show that the observed bands are resolved into two characteristic absorptions, occurring at 980 and 1300 nm, respectively (Fig. 4). The molar-extinction coefficients of the bands determined are of the order of 10; we thus assigned these bands to the copper d-d transition absorptions. Based on the ESR parameters (Table 2), the d-d transition energies, ΔE_{zx} and ΔE_{yz}, can be theoretically estimated as follows:

$$\Delta g_x = \frac{6\lambda'}{\Delta E_{zx}}, \quad \Delta g_y = \frac{6\lambda'}{\Delta E_{yz}}, \quad \lambda' = \alpha^2\lambda_0 \qquad (1)$$

where λ_0 (-828 cm^{-1}) is the spin-orbital interaction parameter of a copper(II)-free ion. The calculated wavelengths of the corresponding d-d absorptions (800 and 1000 nm) thus support the fact that the observed optical spectrum of each complex occurs at the near-infrared region, as is shown in Table 1.

ESR Spectra. In the same manner, the Cu(II) complexes were prepared by mixing the crown ethers (L_1, L_2, L_3) with $CuSO_4$ in BF_3-ether in the equivalent molar ratio. The ESR spectra were recorded at 77 K, as

Table 1. Absorption Spectral Data of the Crown Ether-Cu(II) Complexes

a) λ_{max} in nm and ε in mol^{-1}dm^{3}cm^{-1}.

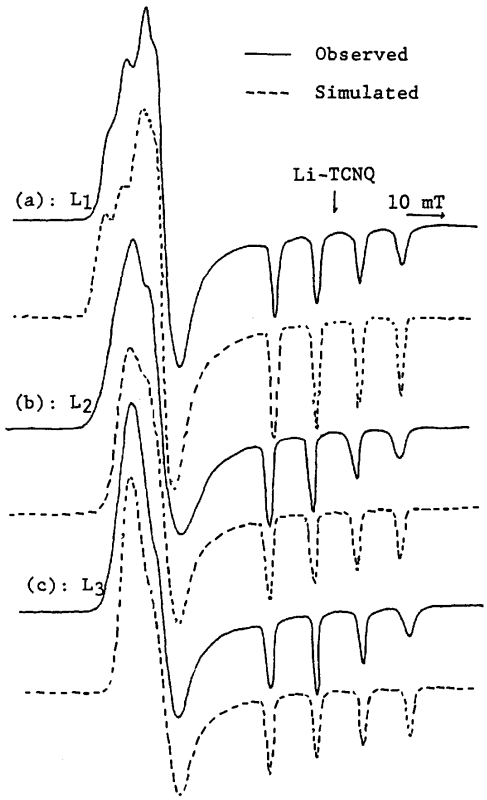

Fig. 5. ESR spectra observed at 77 K and simulated for the crown ether-copper(II) complexes in BF_3-ether. The simulations were carried out by taking the line width as follows: (a): σ_x=1.9 mT, σ_y=3.1 mT, σ_z=0.7 mT; (b): σ_x=2.8 mT, σ_y=2.7 mT, σ_z=0.7 mT; and (c): σ_x=2.2 mT, σ_y=2.8 mT, σ_z= 0.7 mT.

is shown in Fig. 5. The observed spectra together exhibit the rhombic g-anisotropies as are featured in the Cu(II) complexes with the $3d_{z^2}$ ground-state doublet. The computer simulation of the line shape (broken line) showed an excellent agreement with those of the observed spectra based on the ESR parameters summarized in Table 2. Based on the ESR intensity measured at 77 K, the complex formation between 15C5 and the Cu(II) ion was also investigated. A linear growth of the apparent ESR intensity was confirmed within the range in which the total concentration of Cu(II) ions added is less than the equivalent molar concentration of the crown ether (Fig. 6). When an excess amount of the Cu(II) ion is present in the reaction mixture, the ESR of another Cu(II) complex, which reveals the g-anisotropies typical of the $3d_{x^2-y^2}$ or

a) A in 10^{-4} cm^{-1}.

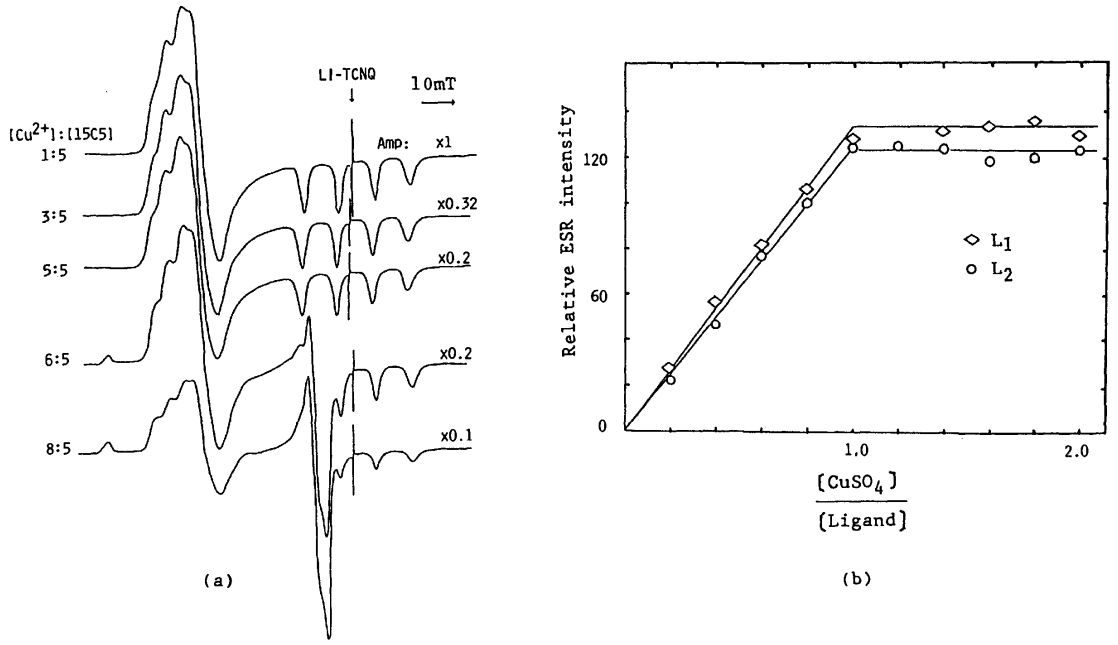

Fig. 6. ESR titration behavior observed for 15C5-Cu(II) systems. (a) ESR spectra observed at 77 K for 15C5-Cu(II) complex generated in the different copper(II) ion/ligand ratio. (b) Relation between the observed ESR intensities of 15C5-Cu(II) complex and the metal/ligand ratio during a titration.

$3d_{xy}$-type ground state, began to overlap with the ESR hyperfine structure of the 15C5-Cu(II) complex, as may be seen in Fig. 6(a). Further, we confirmed that the ESR hyperfine structure ascribed to the $3d_{z^2}$ ground state and that their intensities were not affected by the addition of another ether, 4-*O*-, 6-*O*-membered crown ether (L_4 and L_5) or 5-*O*-membered open-chain ether (L_6), in a large excess. The ESR spectra of the L_4, L_5, and L_6-Cu(II) complexes revealed the *g*-anisotropies, $g_z > g_x$, g_y, appreciate to the $3d_{x^2-y^2}$ or $3d_{xy}$ ground state. One can now conclude that the complexation between the polyether and the Cu(II) ion to give the $3d_{z^2}$ ground-state doublet is strictly limited to the case of the 5-*O*-membered crown ether.

In order to confirm the fact that the water molecules are coordinated to the Cu(II) ion at the apical positions, the L_1, L_2, and L_3-Cu(II) complexes have been obtained by using a $CuSO_4$ aqueous solution containing $H_2{}^{17}O$ (^{17}O atom%=10). The second derivative ESR spectra of the g_z-component measured are shown in Fig. 7, where the ligand superhyperfine splitting due to the ^{17}O isotope (I=5/2) may clearly be seen; the positive evidence of the water ligation is thus successfully demonstrated. Because of the lower concentration of the ^{17}O isotope contained in the H_2O used here, the possibility of the observation of superhyperfine interactions ascribed to the two ^{17}O atoms can be safely disregarded. The superhyperfine coupling constants, A_z°, are listed in Table 2.

With reference to the X-ray analysis of the molecular structure of the L_2-$CuCl_2$ complex,[5] one can now assume that the present complex has two water molecules axially coordinated above and below the pentagonal crown ring.

Calculation of Bonding Parameters. The appropriate molecular orbital occupied by an unpaired electron, which involves the metal $3d_{z^2}$ orbital and also the ligand orbital, can be expressed as follows, provided that the complexes take the pentagonal bipyramidal geometry, D_{5h}:

$$\psi_{z^2} = \alpha d_{3z^2} - \frac{\alpha'}{2\sqrt{10}}(\sqrt{10}\,Z_1 + \sqrt{10}\,Z_2 - 2\,Z_3 - 2\,Z_4 - 2\,Z_5 - 2\,Z_6 - 2\,Z_7) \quad (2)$$

Table 3. Bonding Parameters of the Crown Ether-Cu(II) Complexes

	α^2	$P^{a)}$	κ	β^2	α^2	P	κ	β^2
L_1	0.763	275	0.1003	0.0806	0.914	329	0.1561	0.0875
L_2	0.771	277	0.0904	0.0859	0.914	329	0.1235	0.0995
L_3	0.777	280	0.0700	0.0950	0.916	330	0.0995	0.1085

a) P in 10^{-4} cm^{-1}.

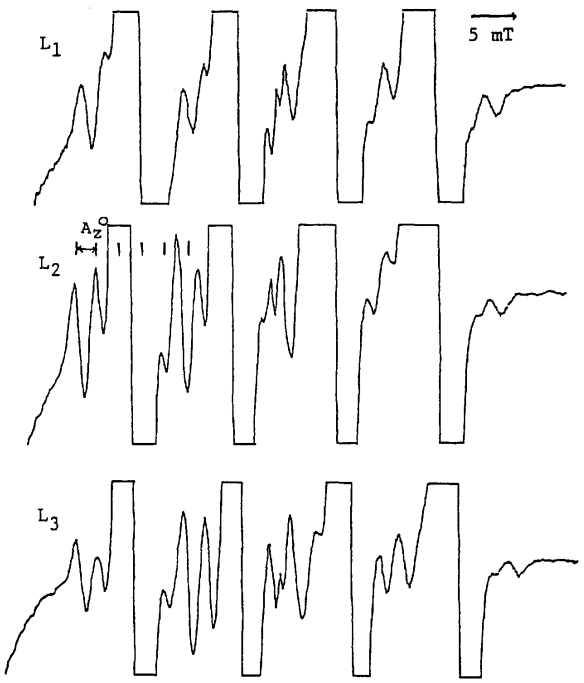

Fig. 7. Enlarged second derivative ESR spectra observed at 77 K for the g_z-components. The six-line superhyperfine structure is attributed to the ^{17}O atom of $H_2{}^{17}O$ which is axially coordinated to the Cu(II) complex.

where Z_1 and Z_2 denote the atomic orbitals in the axial ligands, where Z_3—Z_7 are those in the equatorial ligands, and where the atomic orbitals of the oxygen atoms axially coordinated are described in terms of the sp^3 hybridization, expressed as:

$$Z_i = np \pm \sqrt{1-n^2}\, s \quad (n^2 = 3/4) \tag{3}$$

The spin density on the apical ligand ^{17}O, ρ_0, was thus calculated by means of the following equation:

$$A_z^{\circ} = \rho_o(1-n^2)(A_f + 2A_p) \tag{4}$$

where A_f (-1544×10^{-4} cm^{-1}) and A_p (-48×10^{-4} cm^{-1}) are the isotropic and anisotropic hyperfine constants respectively for the unit spin density on a ^{17}O atom.[9] The total ligand spin densities thus obtained are 0.223—0.237 for the complexes, The magnitude of the spin density on the $3d_{z^2}$ copper atomic orbital, α^2, was estimated by neglecting the overlap integral between the copper and ligand orbitals. Based on the α^2 value thus determined, the Fermi contact term, κ, was calculated from the A_z value using Bleaney's equation,[10] expressed as:

$$A_x = P_0(-\kappa\alpha^2 + \Delta g_x + \frac{1}{14}\Delta g_y - \frac{2}{7}\alpha^2) \tag{5}$$

$$A_y = P_0(-\kappa\alpha^2 + \Delta g_y + \frac{1}{14}\Delta g_x - \frac{2}{7}\alpha^2) \tag{6}$$

$$A_z = P_0(-\kappa\alpha^2 + \Delta g_z - \frac{1}{14}(\Delta g_x + \Delta g_y) + \frac{4}{7}\alpha^2) \tag{7}$$

$$(\Delta g_x = g_x - g_e,\ \Delta g_y = g_y - g_e,\ \Delta g_z = g_z - g_e)$$

where P_0 (360×10^{-4} cm^{-1}) is the dipolar-term of a Cu(II)-free ion. The calculated bonding parameters of the Cu(II) complexes are summarized in Table 3. The magnitude of the calculated A_x and A_y values show an excellent accordance with the experimental tendency, $A_x > A_y$, which was determined by a computer simulation of the observed line shapes, (cf. Table 2). The anomalously small κ values estimated here may be attributed to the mixing of the 4s orbital into the $3d_{z^2}$ atomic orbital, in the correct symmetry, A_{1g}. The isotropic-interaction term measures the sum of the spin polarization attributable to the $3d_{z^2}$ and 4s electrons, written as:

$$-P_0\kappa = A_{3d}\alpha^2 + A_{4s}\beta^2 \tag{8}$$

where A_{3d}=-142×10^{-4} cm^{-1} and A_{4s}=896×10^{-4} cm^{-1}.[11]

In Table 3, the bonding parameters of the dihydrated crown ether-Cu(II) complexes are compared with those of the dichlorinated crown ether-Cu(II) complexes previously reported.[3] It was again confirmed that the contribution of about 8—9.5% from 4s reduces the κ values to a large extent. In both cases, one may see a common tendency for the Δg_z values, a measure of the admixture of $3d_{x^2-y^2}$ into the ground state, to approach that of the pure $3d_{z^2}$ ground state, Δg_z=-0.021,[10] with an increase in the number of fused benzene rings. A concomitant increase in the A_z value can be noted with the increase in the Δg_z and β^2 values. These findings imply that the planar-fused benzene restricts a conformational change in the crown ring upon the optimum metal coordination at the equatorial positions.

For the spin densities on the copper $3d_{z^2}$ orbital, however, one may note a large discrepancy between the values of the dichlorinated crown ether-Cu(II) complexes and those of the dihydrated crown ether-Cu(II) complexes. The considerable reduction in α^2 values noted for the dihydrated Cu(II) complexes means that

the covalent bonding nature between the copper and the axial ligand is more dominant in the present complexes than in the dichlorinated-Cu(II) complexes.

Finally, we would like to consider the reason why the formation of the Cu(II) complex with the $3d_{z^2}$ ground state is limited to cyclic 5-*O*-membered crown ether, not including either the cyclic 4-*O*-, 6-*O*-membered crown ethers or the open-chain 5-*O*-membered polyether. One of the ways to solve the puzzle is by a comparison of the metal-ion radii, which would give the best fit in the cavity of the 15C5. Of interest is the fact that the molecular structure of the dichlorinated B15C5-Cu(II) complex is very much like that of the B15C5-$Mg(NCS)_2$ complex, taking a pentagonal bipyramidal structure.[5,12] The effective radius reported for the Cu(II) ion (0.87 Å) is, indeed, close to that of the Mg(II) ion (0.86 Å).[13] On the other hand, the unpaired copper $3d_{z^2}$ orbital, A_{1g}, would be effectively stabilized in the pentagonal bipyramidal ligand field (D_{5h}), which has the proper symmetry with a metal atomic orbital in terms of the Jahn-Teller distortion.

It has been believed that a strict annihilation of all aerial moisture from the reaction mixture is necessary for the preparation of the crown ether-Cu(II) complex revealing the $3d_{z^2}$ ground state in solution.[3,4] In the present paper, however, the existence of a new dihydrated crown ether-Cu(II) complex with the $3d_{z^2}$ ground state has successfully been demonstrated. Thereafter, we could confirm that the ground-state electronic configuration of the crown ether-Cu(II) complex is greatly dependent on the number of ethereal oxygen donors of the crown ether, and that the $3d_{z^2}$ ground state is exactly limited to the case of the Cu(II) complex of 5-*O*-membered crown ether. In order to put our proposal on a more rigorous experimental base, ESR studies of the Cu(II) complexes with 3-*O*- and 7-*O*-membered crown ethers are now under way.

Redox Reactions of *cis*-Dialkylcobalt(III) Complexes with Benzyl and Allyl Bromides, Induced by Thermal Cleavage of the Cobalt-Carbon Bond

Kunio Ishikawa, Shunichi Fukuzumi, and Toshio Tanaka*
Department of Applied Chemistry, Faculty of Engineering, Osaka Univeristy, Suita, Osaka 565
(Received August 25, 1986)

The thermal cleavage of the cobalt-carbon bond of *cis*-dialkylcobalt(III) complexes, *cis*-$[R_2Co(bpy)_2]^+$(R=Me, Et, and $PhCH_2$; bpy=2,2′-bipyridine), was enhanced by the presence of benzyl and allyl bromide, inducing the C-C bond formation to yield mainly 1,2-diphenylethane and 1,5-hexadiene, respectively. In the *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$-allyl bromide system, a comparable amount of the cross-coupling product (4-phenyl-1-butene) was obtained together with the homo-coupling products (1,2-diphenylethane and 1,5-hexadiene). The enhancement of the thermal cleavage of the cobalt-carbon bond of *cis*-$[R_2Co(bpy)_2]^+$ by the reactions with benzyl and allyl bromides is caused by the high reactivity of the carbanion ligand of $[RCo(bpy)_2]^+$ produced by the homolytic cleavage of the cobalt-carbon bond of *cis*-$[R_2Co(bpy)_2]^+$, which undergoes the exchange, coupling, and cross-coupling reactions with benzyl and allyl groups of the bromides. Based on the kinetics and the activation parameters, the cobalt-carbon bond dissociation enthalpy of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ has been estimated to be 92 kJ mol^{-1}.

The mechanisms of thermal decomposition of organotransition-metals[1,2] as well as the bond dissociation energies of the metal-carbon bonds[3] have been subjects of much interest, since the application of transition-metal reagents to organic, organometallic, and biochemical synthesis, stoichiometric or catalytic, requires the cleavage of metal-carbon bonds. Significant attention has been devoted to mono-organocobalt complexes, which relate to the naturally occurring coenzyme, vitamin B_{12}.[4-8] Although cobalt-carbon bonds of many mono- and di-organocobalt(III) complexes are thermally stable at moderate temperatures, the cleavage of cobalt-carbon bonds is known to be enhanced significantly by redox reactions with organic and inorganic oxidants.[9-13] The cleavage of cobalt-carbon bonds of di-organocobalt(III) complexes, which has been much less studied than mono-organocobalt(III) complexes, is of particular interest, since the cleavage of the cobalt-carbon bond may produce coordinately unsaturated mono-organocobalt(II) complexes which may be much more reactive than di-organocobalt complexes.[14,15]

We have previously reported that the photocleavage of cobalt-carbon bonds of *cis*-dialkylcobalt(III) complexes, *cis*-$[R_2Co(bpy)_2]^+$ (R=Me, Et, and $PhCH_2$; bpy=2,2′-bipyridine), induces C-C bond formation via the redox reactions with benzyl and allyl bromides to yield 1,2-diphenylethane and 1,5-hexadiene, respectively, as the main products.[16] In this study, we report that the thermal cleavage of the cobalt-carbon bond of *cis*-$[R_2Co(bpy)_2]^+$ also induces the C-C bond formation in redox reactions with benzyl and allyl bromides. The present study provides a nice opportunity to compare the thermal and photochemical redox reactions of *cis*-dialkylcobalt(III) complexes with organic halides, revealing both the common and the different aspects in mechanisms between the thermal and photochemical redox reactions.

Experimental

Materials. *cis*-Dialkylcobalt(III) complexes, *cis*-$[R_2Co(bpy)_2]^+$ (R=Me, Et, and $PhCH_2$), were prepared by the reaction of $CoCl_2 \cdot 6H_2O$ with an excess of $NaBH_4$ in the presence of the corresponding alkyl halides and the ligand bpy.[16,17] They were isolated as the perchlorate salts and recrystallized from methanol/water. The purity of the complexes was checked by the elemental analysis; *cis*-$[Me_2Co(bpy)_2]ClO_4$: Found: C, 52.7; H, 4.6; N, 11.1. Calcd for $C_{22}H_{22}N_4O_4CoCl$: C, 52.8; H, 4.4; N, 11.2. *cis*-$[Et_2Co(bpy)_2]ClO_4$ H_2O: Found: C, 52.1; H, 5.1; N, 10.0. Calcd for $C_{24}H_{28}N_4O_5CoCl$: C, 52.7; H, 5.2; N, 10.2. *cis*-$[(PhCH_2)_2Co(bpy)_2]ClO_4$: Found: C, 62.0; H, 4.6; N, 8.5. Calcd for $C_{34}H_{30}N_4O_4CoCl$: C, 63.0; H, 4.7; N, 8.7. Both $[Co(bpy)_3](ClO_4)_2$ and $[Co(bpy)_3]ClO_4$ were prepared by following the literature method.[18] Benzyl or allyl bromide obtained from Wako Pure Chemicals was washed with a 5% aqueous $NaHCO_3$ solution and water successively. After the solution was dried with $MgSO_4$, it was fractionally distilled in the dark under reduced pressure before use. Reagent grade acetonitrile was purified by the standard procedure,[19] followed by redistillation from calcium hydride. Acetonitrile-d_3 was stirred with freshly activated Molecular Sieve 4A (Wako Pure Chemicals) and then transferred in vacuum. Other reagents used for the product analyses were obtained commercially.

Analytical Procedure. Thermal decomposition of *cis*-$[R_2Co(bpy)_2]^+$ was carried out in a Pyrex tube (8 mm I.D.) which contained an MeCN solution (0.5 cm^3) of *cis*-$[R_2Co(bpy)_2]^+$ (1.0×10^{-2} mol dm^{-3}). The solution in the tube was thoroughly degassed by the repeated freeze-pump-thaw cycles before sealing. The top of sealed tube was covered with a reflux condenser and the bottom containing the solution was immersed in an oil bath which was thermostated at 353 K. After the reaction for 52 h, an atmospheric pressure of nitrogen was introduced to the tube, and the gaseous products were analysed by glc using a Unibeads 1S column (1 m).

The redox reactions of *cis*-$[R_2Co(bpy)_2]^+$ with benzyl and allyl bromides were monitored using a Japan Electron Optics JNM-PS-100 ^1H NMR spectrometer (100 MHz). Typically, *cis*-$[R_2Co(bpy)_2]^+$ (0.05 mmol) and benzyl bromide

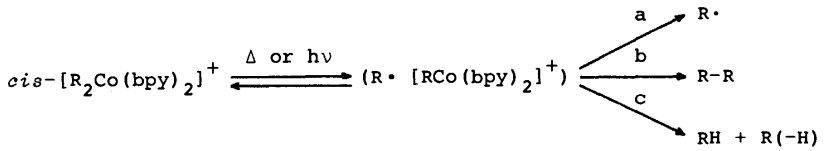
a) 1.0×10^{-2} mol dm^{-3}. b) 4.5×10^{-2} mol dm^{-3}. c) Thermolysis at 353 K. d) Photolysis was carried out under irradiation with visible light from a Xenon lamp through a Toshiba glass filter (O-36) which transmits light of $\lambda>360$ nm at 298 K (Ref. 16).



Scheme 1.

(0.05 mmol) was added to an NMR tube which contained 0.5 cm^3 CD_3CN. After the solution was degassed, the sealed NMR tube with a reflux condenser was immersed in an oil bath at 353 K. The NMR spectra were measured periodically at 298 K and the products were identified by comparing the spectra with those of authentic samples. The conversion of *cis*-$[R_2Co(bpy)_2]^+$ to $[Co(bpy)_3]^{2+}$ was confirmed by the appearance of the down field signals of the 2,2′-bipyridine ligand.[18] The organic products were analysed by glc using an OV-17 column (2 m).

Kinetic Measurements. Kinetic data were obtained by using a Union SM-401 spectrophotometer equipped with thermostated cell holders. Reaction rates were determined by the disappearance of the absorption band due to *cis*-$[R_2Co(bpy)_2]^+$ in MeCN (λ_{max}=472, 495, and 502 nm for R=Me, Et, and $PhCH_2$, respectively) under a degassed condition using a Schlenk tube equipped with a side arm fused to a square cuvette (1 or 10 mm I.D.). All the data followed pseudo-first-order kinetics, from which rate constants were determined by least-squares curve fitting using an NEC 9801F microcomputer.

Results and Discussion

Thermal Decomposition of *cis*-$[R_2Co(bpy)_2]^+$. *cis*-Dialkylcobalt(III) complexes are stable in MeCN at 298 K. When the temperature was raised to 353 K, *cis*-$[R_2Co(bpy)_2]^+$ decomposed slowly to undergo the dealkylation reaction. The product distributions are shown in Table 1, together with the data of the corresponding photodecomposition[16] for comparison. The product distributions between thermal and photodecomposition of *cis*-$[R_2Co(bpy)_2]^+$ are similar to each other, except for the ratio of the coupling products of the alkyl groups. For example, both the thermolysis and photolysis of *cis*-$[Me_2Co(bpy)_2]^+$ give methane and ethane, but the mol ratio of ethane to methane in the thermolysis at 353 K (34/66) is significantly larger than that in the photolysis at 298 K (9/91). In the case of *cis*-$[Et_2Co(bpy)_2]^+$ as well, an appreciable amount of the coupling product (butane) is obtained only in the thermolysis (Table 1). On the other hands, thermolysis of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ gives a smaller amount of the coupling product (1,2-diphenylethane) than the photolysis (Table 1).

Such product distributions between the thermolysis and photolysis may be explained by Scheme 1, where both the thermolysis and photolysis of *cis*-$[R_2Co(bpy)_2]^+$ results in the homolytic cleavage of the cobalt-carbon bond to produce a geminate radical pair (R· $[RCo(bpy)_2]^+$) which undergoes (a) free radical reactions out of the cage to yield RH and R-R, (b) a coupling reaction in the cage to yield R-R, or (c) a β-hydrogen transfer in the cage to give RH and R(-H) with a 1 : 1 ratio when the alkyl group contains a β hydrogen. Such a homolytic cleavage of the Co-C bond in the photolysis of *cis*-$[R_2Co(bpy)_2]^+$ has been confirmed by the detection of alkyl radicals in the ESR measurements at 77 K.[16] In the case of R=Me or Et, the alkyl radical formed in the geminate radical pair may be reactive enough to undergo the coupling reaction in the cage at a high temperature (e.g., 353 K) to yield more coupling product R-R than the case of photolysis at 298 K. On the other hand, the activation barrier of hydrogen abstraction by benzyl radical from a solvent is known to be higher than that of bimolecular coupling reaction of benzyl radicals.[20] Thus, in the case of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$, the former becomes a major process in the thermolysis at 353 K to yield mainly toluene (Table 1). Although the stepwise homolytic processes (Scheme 1) appear to account for the product distribution in both the thermal and photochemical decomposition of *cis*-$[R_2Co(bpy)_2]^+$ in the absence and presence of benzyl or allyl bromide as discussed later in more detail, the present conclusion that the coupling R-R and olefin R(-H) products arise

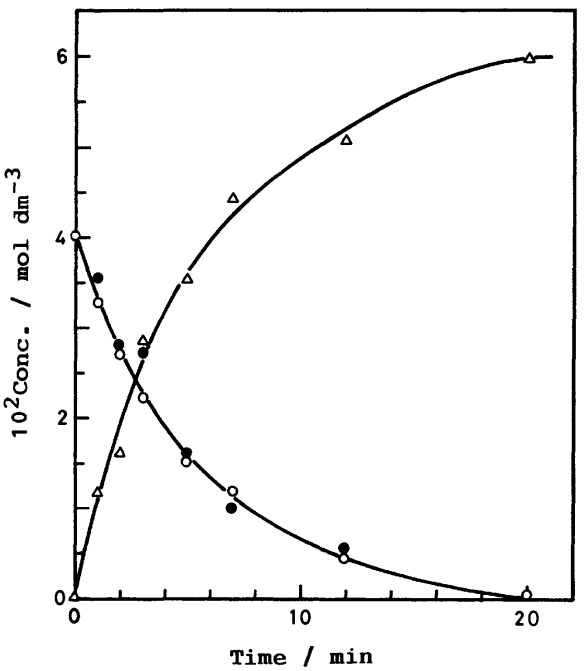


Fig. 1. Time course of the thermal reaction of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ (4.0×10^{-2} mol dm^{-3}) with benzyl bromide (4.0×10^{-2} mol dm^{-3}) under a degassed condition in CD_3CN at 353 K; *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ (○), $PhCH_2Br$ (●), and PhC_2H_4Ph (△).

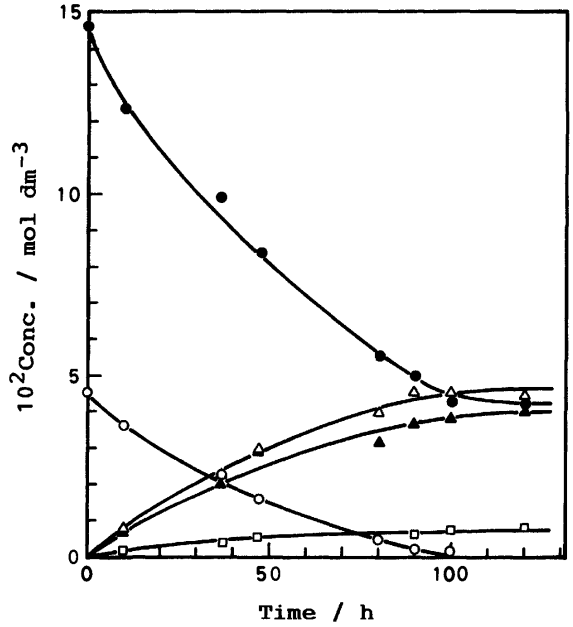

Fig. 2. Time course of the thermal reaction of *cis*-$[Me_2Co(bpy)_2]^+$ (4.5×10^{-2} mol dm^{-3}) with benzyl bromide (1.46×10^{-1} mol dm^{-3}) under a degassed condition in CD_3CN at 353 K; *cis*-$[Me_2Co(bpy)_2]^+$ (○), $PhCH_2Br$ (●), MeBr (△), PhC_2H_4Ph (△), and C_2H_6 (□).

via the homolytic cleavage of the cobalt-carbon bond must be accepted with reservation, since the concerted processes for the reductive coupling and β-elimination pathways are difficult to distinguish from the stepwise, homolytic processes.[21-24]

Redox Reactions of *cis*-$[R_2Co(bpy)_2]^+$ with Benzyl and Allyl Bromides. When the thermal decomposition of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ is carried out in the presence of benzyl bromide at 353 K, the rate is enhanced significantly as shown in Fig. 1, where the reaction is completed in 20 min. In addition, the product distribution is changed drastically from toluene as a main product in the absence of benzyl bromide to 1,2-diphenylethane in the presence of benzyl bromide (Fig. 1). The approximate stoichiometry of the reaction is given by Eq. 1,

$$cis\text{-}[(PhCH_2)_2Co(bpy)_2]^+ + PhCH_2Br \xrightarrow{\Delta} \frac{3}{2}PhC_2H_4Ph + [Co(bpy)_2Br]^+ \quad (1)$$

which is the same as the corresponding photochemical reaction.[16]

Thermolysis rate of *cis*-$[Me_2Co(bpy)_2]^+$ is also enhanced by the presence of benzyl bromide, although the rate is much slower than that of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$, as shown in Fig. 2. The presence of benzyl bromide suppresses completely the formation of methane observed in the absence of benzyl bromide (Table 1), instead methyl bromide is formed as well as 1,2-diphenylethane as a main product, while the ethane formation is not suppressed completely (Fig. 2). The apparent stoichiometry of the reaction between *cis*-$[Me_2Co(bpy)_2]^+$ and benzyl bromide is 1 : 2.3. Such a stoichiometry in Fig. 2 may be explained by considering the occurrence of two different reactions; one is the same as the corresponding photochemical reaction (Eq. 2),[16]

$$cis\text{-}[Me_2Co(bpy)_2]^+ + 3PhCH_2Br \longrightarrow \frac{3}{2}PhC_2H_4Ph + 2MeBr + [Co(bpy)_2Br]^+, \quad (2)$$

where *cis*-$[Me_2Co(bpy)_2]^+$ reacts with three equivalent amounts of benzyl bromide to yield 1,2-diphenylethane and methyl bromide, and the other is the reaction with a 1 : 1 stoichiometry to yield ethane (Eq. 3),

$$cis\text{-}[Me_2Co(bpy)_2]^+ + PhCH_2Br \longrightarrow \frac{1}{2}PhC_2H_4Ph + [Co(bpy)_2Br]^+ + C_2H_6, \quad (3)$$

where benzyl bromide may be reduced by $[Co(bpy)_2]^+$ following the coupling reaction in the cage (Scheme 1-b). The occurrence of two different reactions (Eqs. 2 and 3) can also account for the product distribution in the thermolysis of *cis*-$[Et_2Co(bpy)_2]^+$ in the presence of benzyl bromide (Fig. 3), where one mol of *cis*-$[Et_2Co(bpy)_2]^+$ reacts with 1.4 mol of benzyl bromide to yield 1,2-diphenylethane, ethyl bromide, and butane with small amounts of toluene and ethylene.

Similar results are obtained in the thermolysis of *cis*-$[R_2Co(bpy)_2]^+$ in the presence of allyl bromide. Table 2 summarizes the product distribution includ-

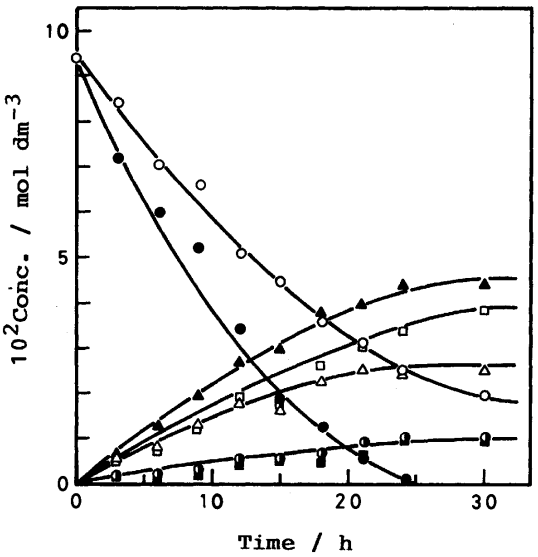

Fig. 3. Time course of the thermal reaction of *cis*-$[Et_2Co(bpy)_2]^+$ (9.4×10^{-2} mol dm^{-3}) with benzyl bromide (9.4×10^{-2} mol dm^{-3}) under a degassed condition in CD_3CN at 353 K; *cis*-$[Et_2Co(bpy)_2]^+$ (○), $PhCH_2Br$ (●), EtBr (△), PhC_2H_4Ph (▲), C_4H_{10} (□), C_2H_4 (■), and $PhCH_3$ (◑).

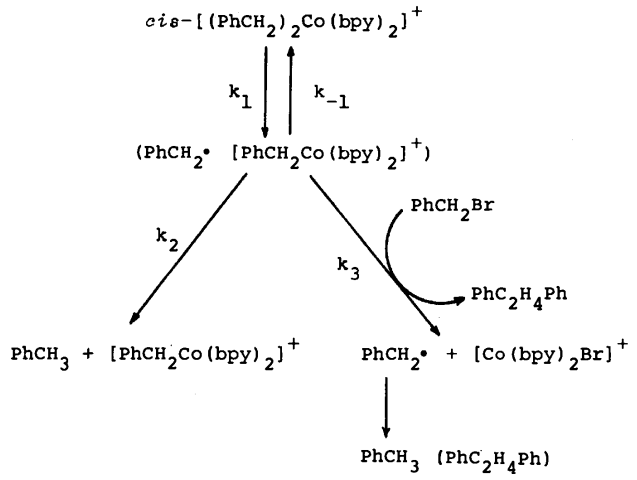
ing the minor products. In the reactions of *cis*-$[Me_2Co(bpy)_2]^+$ and *cis*-$[Et_2Co(bpy)_2]^+$ with benzyl and allyl bromides, the coupling products of the organic groups of the bromides (1,2-diphenylethane and 1,5-hexadiene, respectively) are obtained, and small amounts of cross-coupling products between the alkyl group of *cis*-$[R_2Co(bpy)_2]^+$ and the organic group of the bromides (e.g., ethylbenzene in the *cis*-$[Me_2Co(bpy)_2]^+$–benzyl bromide system) are formed as well as the products derived from hydrogen abstraction by benzyl and allyl radicals from a solvent (i.e., toluene and propene, respectively). The stoichiometry of these reactions is between 1 and 3 on the degree of the contribution of two different reactions (Eqs. 2 and 3). In the case of the reactions of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ with benzyl bromide, however, the stoichiometry is 1 : 1 (Eq. 1) to yield mainly the homo-coupling product (1,2-diphenylethane) together with a small amount of toluene. When benzyl bromide is replaced by allyl bromide in the reaction with *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$, the cross-coupling product between benzyl and allyl group, i.e., 4-phenyl-1-butene is formed together with the homo-coupling products (1,2-diphenylethane and 1,5-hexadiene) as shown in Table 2. Thus, the thermolysis of all the *cis*-dialkylcobalt(III) complexes in the presence of benzyl or allyl bromide results in the C–C bond formation to yield the homo- or cross-coupling products of benzyl and allyl groups as the main products together with small amounts of products derived from hydrogen abstraction by benzyl or allyl radical from a solvent.

Kinetics and Mechanism. The rate of thermal decomposition of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ at 353 K is the fastest among *cis*-$[R_2Co(bpy)_2]^+$, and decreases in the order R=$PhCH_2$>Et>Me. The detailed kinetic study has been limited to the thermolysis of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$, since only *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ decomposed at measurable rates at relatively low temperatures (e.g., 323 K). The decomposition rates in both the absence and presence of benzyl bromide obeyed the pseudo-first-order kinetics, and the observed rate constant was increased significantly by the presence of benzyl bromide. Such enhancement of the rate by the presence of benzyl bromide may be explained by Scheme 2, where the cleavage of the cobalt–carbon bond (k_1 in Scheme 2) occurs to give a geminate radical pair ($PhCH_2\cdot[PhCH_2Co(bpy)_2]^+$). In the absence of benzyl bromide, the overall decomposition rate may be much lowered owing to the facile recombination of benzyl radical with $[PhCH_2Co(bpy)_2]^+$ in the cage (k_{-1}).[24] The recombination between free benzyl radical and $[PhCH_2Co(bpy)_2]^+$, which are escaped from the cage, may be neglected compared with the recombination of the geminate radical pair in Scheme 2, since the former unimolecular process may be much faster than the latter bimolecular process. Applying the steady-state approximation



Scheme 2.

to the intermediate ($PhCH_2 \cdot [PhCH_2Co(bpy)_2]^+$) in Scheme 2, the observed rate constant k_0 in the absence of benzyl bromide is expressed by Eq. 4,

$$k_0 = k_1k_2/(k_{-1}+k_2), \quad (4)$$

where k_2 is the rate constant for hydrogen abstraction by benzyl radical from a solvent to yield toluene. Since the recombination process (k_{-1}) may be highly exothermic, k_{-1} may be much larger than k_2; $k_{-1} \gg k_2$, when Eq. 4 is reduced to Eq. 5.

$$k_0 = k_1k_2/k_{-1} \quad (5)$$

The benzyl group of $[PhCH_2Co(bpy)_2]^+$ produced by the homolytic cleavage of the cobalt-carbon bond of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ is regarded as the benzyl anion ligand on the basis of the ESR spectrum of $[PhCH_2Co(bpy)_2]^+$ observed in the photolysis of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ at 77 K.[15,16] Thus, in the presence of benzyl bromide, the benzyl anion ligand of $[PhCH_2Co(bpy)_2]^+$ may undergo the facile coupling reaction with benzyl bromide (k_3) to yield 1,2-diphenylethane as the case of the photoredox reaction of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ with benzyl bromide.[16] Then, the observed rate constant k_{obsd} in the presence of benzyl bromide may be given by Eq. 6. Under the

$$k_{obsd} = \frac{k_1(k_2 + k_3[PhCH_2Br])}{k_{-1} + k_2 + k_3[PhCH_2Br]} \quad (6)$$

condition that $k_{-1} \gg k_2$, from Eqs. 5 and 6 is derived Eq. 7.

$$\frac{1}{k_{obsd} - k_0} = \frac{1}{k_1} + \frac{k_{-1}}{k_1k_3[PhCH_2Br]} \quad (7)$$

The validity of Eq. 7 is confirmed by the linear plots between $(k_{obsd}-k_0)^{-1}$ and $[PhCH_2Br]^{-1}$ at various temperatures as shown in Fig. 4. The rate constant k_1 and k_3k_1/k_{-1} at 323 are obtained as $7.7\times10^{-4}\,s^{-1}$ and $1.1\times10^{-2}\,dm^3\,mol^{-1}\,s^{-1}$, respectively. The rate constant k_{-1} for the cage recombination of an alkyl radical and cob(II)alamin has been reported to be $1.39\times10^9\,s^{-1}$.[5b] By using this value, the rate constant k_3 for the redox

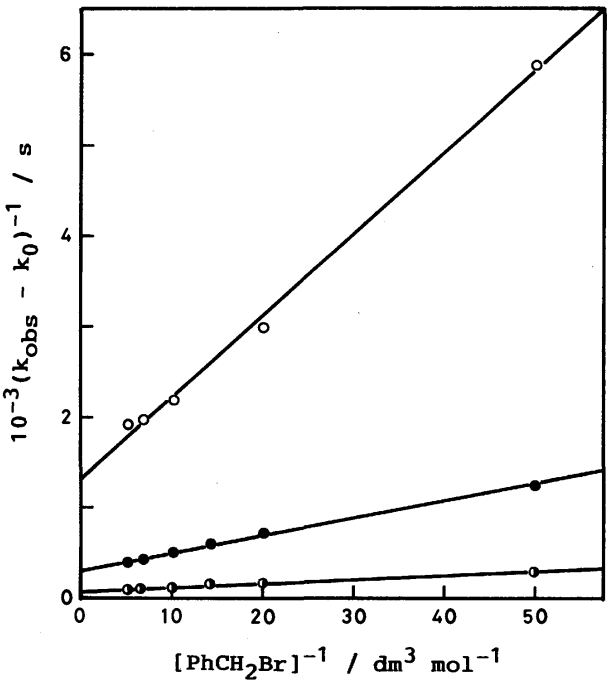


Fig. 4. Plots of $(k_{obsd}-k_0)^{-1}$ vs. $[PhCH_2Br]^{-1}$ for the thermal reaction of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ (1.1×10^{-2} mol dm^{-3}) with benzyl bromide in MeCN at 323 (○), 338 (●), and 353 K (◑); see Eq. 7 in text.

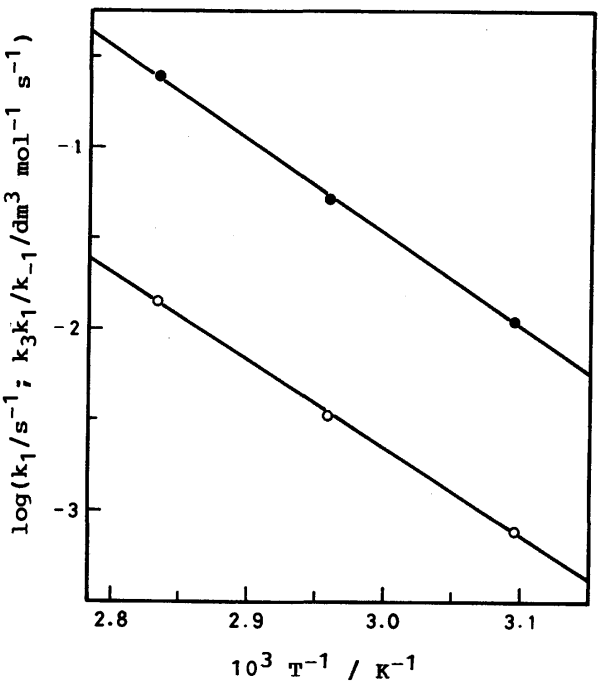

Fig. 5. Arrhenius plots of k_1 (○) and k_3k_1/k_{-1} (●) for the thermal reaction of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ with benzyl bromide in MeCN.

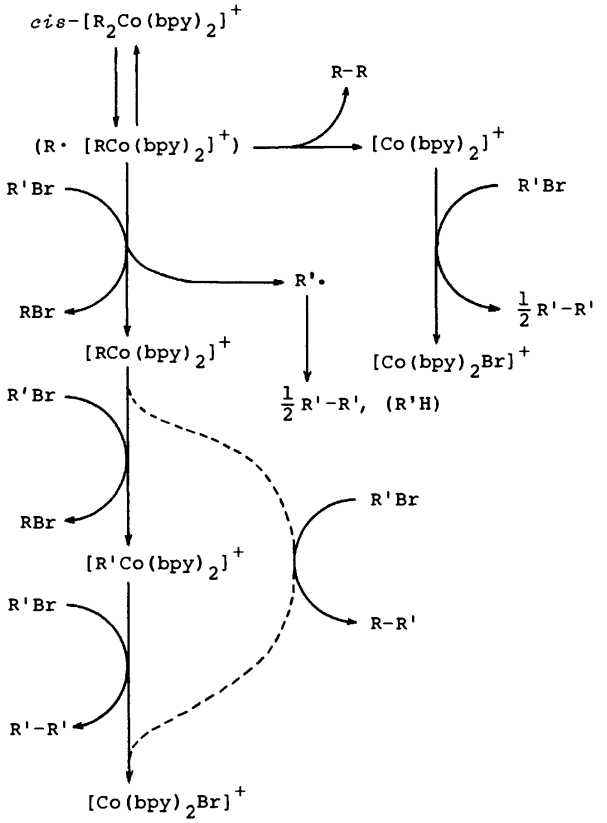
reaction of $[PhCH_2Co(bpy)_2]^+$ with benzyl bromide is estimated as $2.0\times10^{10}\,dm^3\,mol^{-1}\,s^{-1}$, which is identical with the diffusion rate constant in MeCN.[25] Arrhenius plots of both k_1 and k_3k_1/k_{-1} give good straight lines with similar slopes to each other (Fig. 5), from which

the values of $\Delta H_1^{\neq}$ and $\Delta H_3^{\neq}+\Delta H_1$ are obtained as 92±4 and 96±4 kJ mol^{-1}, respectively.

Thus, the cobalt-carbon bond dissociation enthalpy ΔH_1 is estimated as 92±4 kJ mol^{-1} by assuming that $\Delta H_1^{\neq} \cong 0$, which is a reasonable approximation for the highly exothermic radical recombination process.[5,6,24] The ΔH_1 value obtained here is similar to those of many organocobalt(III) complexes reported in the literatures.[3a,5,6] The $\Delta H_3^{\neq}$ value may also be estimated as 4±4 kJ mol^{-1} from the values of ΔH_1 and $\Delta H_3^{\neq}+\Delta H_1$. Such a small $\Delta H_3^{\neq}$ value is compatible with the rate constant k_3 being diffusion controlled as described above. The facile reaction of $[PhCH_2Co(bpy)_2]^+$ with benzyl bromide may be responsible for the efficient C-C bond formation from *cis*-$[R_2Co(bpy)_2]^+$ and benzyl bromide, induced by the thermal cleavage of the cobalt-carbon bond. A cobalt-containing product $[Co(bpy)_2Br]^+$, which may be the initial product by the reaction of $[PhCH_2Co(bpy)_2]^+$ with benzyl bromide as confirmed by the ESR spectrum in the photolysis of the *cis*-$[R_2Co(bpy)_2]^+$-benzyl bromide system at 77 K,[16] is converted to $[Co(bpy)_3]^{2+}$ being the most stable form among the mono-, bis-, and tris(2,2′-bipyridine)-cobalt(II) complexes (see Experimental).[26] On the other hand, benzyl radicals produced by the homolytic cleavage of the cobalt-carbon bond of *cis*-$[R_2Co(bpy)_2]^+$ give 1,2-diphenylethane and a small amount of toluene (Table 2).[27] According to Scheme 2, the stoichiometry of the thermal reaction of *cis*-$[R_2Co(bpy)_2]^+$ with benzyl bromide is 1 : 1, agreeing with the observation in Fig. 1 (Eq. 2).

When the alkyl groups of the reactants (*cis*-$[R_2Co(bpy)_2]^+$ and R′Br) are different, the reaction scheme becomes more complicated as shown in Scheme 3, where the thermolysis of *cis*-$[R_2Co(bpy)_2]^+$ (R=Me and Et) also leads to the homolytic cleavage of the cobalt-carbon bond to produce the geminate radical pair ($R\cdot[RCo(bpy)_2]^+$). In the presence of R′Br (R′=$PhCH_2$ and C_3H_5), the alkyl radical (Me· and Et·) may be converted to the more stable radical ($PhCH_2\cdot$ and $C_3H_5\cdot$) by the reaction with R′Br as confirmed by the ESR spectrum in the photolysis of the *cis*-$[R_2Co(bpy)_2]^+$-R′Br system at 77 K.[16] The benzyl and allyl radicals give the homo-coupling products (1,2-diphenylethane and 1,5-hexadiene, respectively) with small amounts of by-products derived from the hydrogen abstraction from a solvent (toluene and propene, respectively) as shown in Table 2. The carbanion ligand in $[RCo(bpy)_2]^+$ may react readily with R′Br to produce the more stable carbanion ligand, and $[R'Co(bpy)_2]^+$ thus formed by the exchange reaction may undergo the homo-coupling reaction with R′Br to yield R′-R′ and $[Co(bpy)_2Br]^+$, while $[RCo(bpy)_2]^+$ may proceed also to the cross-coupling reaction with R′Br, which is shown by the broken line in Scheme 3, yielding R-R′ as a minor product in Table 2 (ethylbenzene, propylbenzene, 1-butene, and 1-pentene for the *cis*-$[Me_2Co(bpy)_2]^+$-$PhCH_2Br$, *cis*-$[Et_2Co(bpy)_2]^+$-$PhCH_2Br$, *cis*-$[Me_2Co(bpy)_2]^+$-C_3H_5Br, and *cis*-$[Et_2Co(bpy)_2]^+$-C_3H_5Br systems, respectively). In this case, the stoichiometry of the reaction of *cis*-$[R_2Co(bpy)_2]^+$ with R′Br is 1 : 3 (Eq. 2), in contrast with the case in Scheme 2.



Scheme 3.

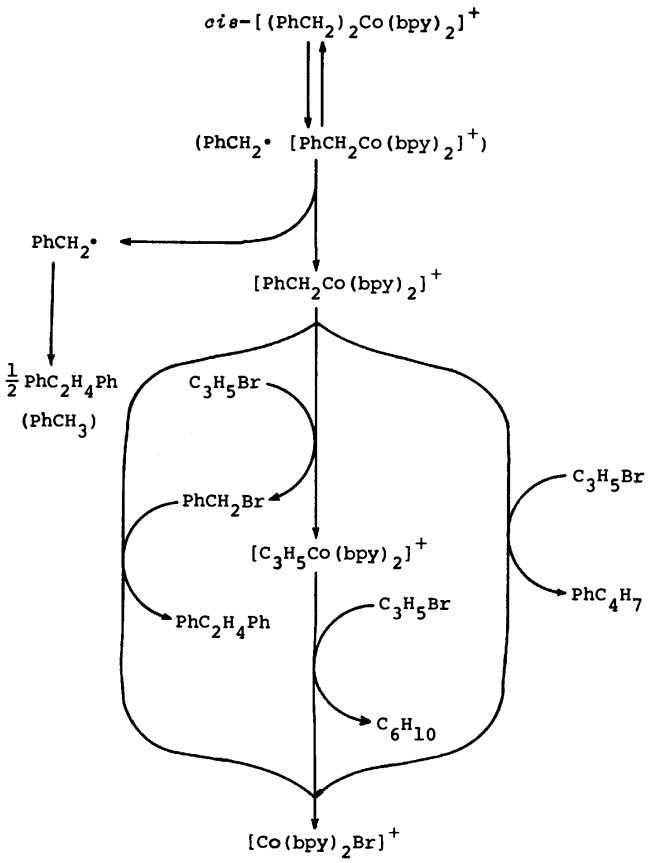
On the other hand, a coupling reaction in the geminate radical pair produced by the homolytic cleavage of the cobalt-carbon bond of *cis*-$[R_2Co(bpy)_2]^+$ may occur in the case of R=Me and Et to yield R-R and $[Co(bpy)_2]^+$ (Scheme 1-b).[28] A β-hydrogen transfer in the geminate radical pair may also occur in the case of R=Et which has a β-hydrogen to yield ethane and ethylene as well as $[Co(bpy)_2]^+$ (Scheme 1-c). In the presence of R′Br, such processes are suppressed by the facile reaction of $[RCo(bpy)_2]^+$ in the geminate radical pair with R′Br, but the reductive coupling process is not suppressed completely to yield R-R as well as $[Co(bpy)_2]^+$ which may readily reduce R′Br to give R′-R′ (Scheme 3). Although the reaction mechanism for the reduction of R′Br by $[Co(bpy)_2]^+$ is less clear than that for the reduction of R′Br by $[RCo(bpy)_2]^+$, a likely pathway may be proposed as shown by Eqs. 8—10, since the facile reduction of

$$[Co(bpy)_2]^+ + R'Br \longrightarrow [Co(bpy)_2Br]^+ + R', \quad (8)$$

$$R'\cdot + [Co(bpy)_2Br]^+ \longrightarrow [R'Co(bpy)_2Br]^+, \quad (9)$$

$$R'\cdot + [R'Co(bpy)_2Br]^+ \longrightarrow R'-R' + [Co(bpy)_2Br]^+, \quad (10)$$

alkyl halides by Co(I) complexes is known to occur to yield alkyl radicals and Co(II) complexes Eq. 8,[29] and



Scheme 4.

the coupling reaction of alkyl radicals may be enhanced in the presence of $[Co(bpy)_2Br]^+$ by the fast recombination with alkyl radicals (Eq. 9),[5,6,24] followed by the bimolecular homolytic displacement reactions (Eq. 10).[23,30] In this case, the stoichiometry is 1 : 1 (Eq. 3). Thus, these two different processes (Eqs. 2 and 3) in Scheme 3 can account for the observed stoichiometry as well as the product distribution in the reaction with R'Br (Figs. 2, 3, and Table 2).

Although the thermal reaction of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ with allyl bromide (Scheme 4) is the most complicated case, the reaction scheme is identical with that for the corresponding photochemical reaction reported in the previous paper,[16] except that the thermal cleavage of the cobalt-carbon bond occurs instead of the photocleavage. The monobenzylcobalt(II) complex $[PhCH_2Co(bpy)_2]^+$ produced by the thermal cleavage of the cobalt-carbon bond of *cis*-$[(PhCH_2)_2Co(bpy)_2]^+$ can undergo the exchange, homo- coupling, and cross-coupling reactions with comparable rates, because of similar stabilities between benzyl and allyl anions, yielding 1,2-diphenylethane and 1,5-hexadiene as the homo-coupling products as well as 4-phenyl-1-butene as the cross-coupling product (Table 2). The benzyl radicals which are also produced by the thermal cleavage of the cobalt-carbon bond give 1,2-diphenylethane and toluene by the bimolecular coupling reaction and the hydrogen abstraction from a solvent, respectively (Table 2).[27,31]

In conclusion, the present study has demonstrated that monoalkylcobalt(II) complexes produced by the thermal cleavage of the cobalt-carbon bond of *cis*-dialkylcobalt(III) complexes are highly reactive in the reduction of benzyl and allyl bromides, undergoing the C-C bond formation to yield the homo- and cross-coupling products depending on the stability of the carbanion ligand. In addition to this process which is essentially the same as employed in the corresponding photoredox reaction, the reductive elimination process, where the pair of cobalt-carbon bonds of *cis*-$[R_2Co(bpy)_2]^+$ is cleaved thermally, is also involved in the reduction of benzyl and allyl bromides.

Atmospheric Concentrations of Halocarbons in Japan in 1979—1986

Yoshihiro MAKIDE,* Akihito YOKOHATA, Yuji KUBO, and Takeshi TOMINAGA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 5, 1986)

The average atmospheric concentrations of halocarbons in the mid-latitude Northern Hemisphere have been measured accurately for 7 years from 1979 to 1986. Atmospheric samples were collected in summer and winter in Hokkaido (40—45°N), and the halocarbons at 10—400 pptv (pptv=10^{-12} v/v) concentrations were determined with 0.5% precision. The concentrations of halocarbons with long lifetimes have been increasing steadily (CCl_2F_2: 18 pptv/year, CCl_3F: 8—9 pptv/year, CH_3CCl_3: 4 pptv/year, CCl_4: 2 pptv/year); those of short-lived halocarbons ($CHCl=CCl_2$ and $CCl_2=CCl_2$) are low (<25 pptv) and show only seasonal variations.

A great concern has been shown for the change in the Earth's environment caused by increasing atmospheric concentrations of trace gases released by human activities. Among them, two groups of compounds should be watched most carefully: CO_2 which causes "greenhouse effect" as released in huge amounts,[1] and halocarbons (halogenated hydrocarbons) with extremely long atmospheric lifetimes, which cause depletion of the stratospheric ozone.[2]

Since the possibility of stratospheric ozone depletion by chlorofluoromethanes (CCl_2F_2 and CCl_3F) was pointed out in 1974,[3] extensive efforts have been made to assess the effect in the future.[2,4] The depletion of ozone in the middle and upper stratosphere has been detected recently.[4]

Halocarbon concentrations in the atmosphere were measured since 1978 at ALE (Atmospheric Lifetime Experiment) stations in Ireland (52°N, 10°W); Oregon, USA (1980—, 45°N, 124°W); the Barbados (13°N, 59°W); American Samoa (14°S, 171°W); and Tasmania (41°S, 145°E), and the data observed up to 1981 have been published.[5] However, such measurements had calibration problems,[6] and no systematic measurement of the atmospheric concentrations has been attempted in Asia. Furthermore, reliable statistics of the world production and emission of halocarbons is hardly available.[7] Since the comparison of models and measurements has shown some disagreements,[4] accurate monitoring of the atmospheric halocarbon concentrations has become more and more important.

In view of such a situation, we started measuring the average atmospheric concentrations of halocarbons in 1979 by analyzing atmospheric samples collected in Hokkaido in summer and winter. The preparation of primary standards was improved, and calibration was repeated carefully. In this paper we wish to report definite atmospheric halocarbon concentrations based on carefully established calibration standards and the trends in their concentrations over the 7 years from 1979 to 1986.

Experimental

Analytical System and Calibration. We have developed an extremely clean, all-metal analytical system for accurate measurement of ultratrace amounts of CCl_2F_2, CCl_3F, CH_3CCl_3, CCl_4, $CHCl=CCl_2$, and $CCl_2=CCl_2$ at 10—400 pptv (pptv: parts per trillion by volume, 10^{-12} v/v) concentration level in the atmosphere.[8,9] A new technique of preparing primary calibration standards was developed for relatively unstable compounds, such as CH_3CCl_3 and CCl_4.[10]

A portion of the atmospheric sample or the standard sample was introduced into an evacuated sample loop (50 ml) up to a pressure of about 1/3 atm and then transferred into a gas chromatograph. A Silicone OV-101 column was used as the preconcentration/separation column with the temperature programmed from −40 to 70 °C. Each halocarbon thus separated was determined by means of an electron capture detector. Methane was mixed into the extremely pure nitrogen carrier gas flow as a make-up gas just before the detector in order to improve the S/N ratio.

The primary calibration standard for each compound was carefully prepared by three-step static dilution with highly purified zero air to a concentration close to the atmospheric concentration. Zero air saturated with water vapor at room temperature was introduced into the flask before the final dilution step so that the water-vapor pressure in the primary standards eventually became about 1 kPa. Several ambient air samples stored in large sample containers were calibrated for all components against each primary standard; they were then used as the secondary standards in routine analysis.

Atmospheric Sampling. All samples were collected by grab-sampling in highly evacuated, extremely clean, all-stainless steel canisters (of two-liter volume and equipped with a stainless-steel bellows valve). In the field, sample air was introduced into the canister up to the ambient pressure by simply opening the valve; no pump or compressor, which would inevitably cause contamination, was employed.

Sampling locations in Japan were extensively surveyed in 1979: in the main and southern parts of Japan, it was found difficult to avoid the influence of regionally polluted air from Japan or Korea.[8] Thus we have collected well-mixed air free from local pollution (called averaged-concentration air, or background air) on a remote coast or point of land mainly in Hokkaido (but occasionally on the west coast of the Tohoku area) every summer (late July to early August) and winter (late January to early February) since 1979. Typical sampling locations are Wakkasakanai in Moor Sarobetsugenya (45°N, 142°E), Nosappu-misaki Point (43°N, 146°E), Setana in Oshima Peninsula (42°N, 140°E), and Nyudozaki Point (40°N, 140°E). Samples were collected against the wind blowing from the ocean.

While the weather conditions are relatively stable in winter (i.e., a high atmospheric pressure overlying Siberia and a low atmospheric pressure overlying the North-west Pacific

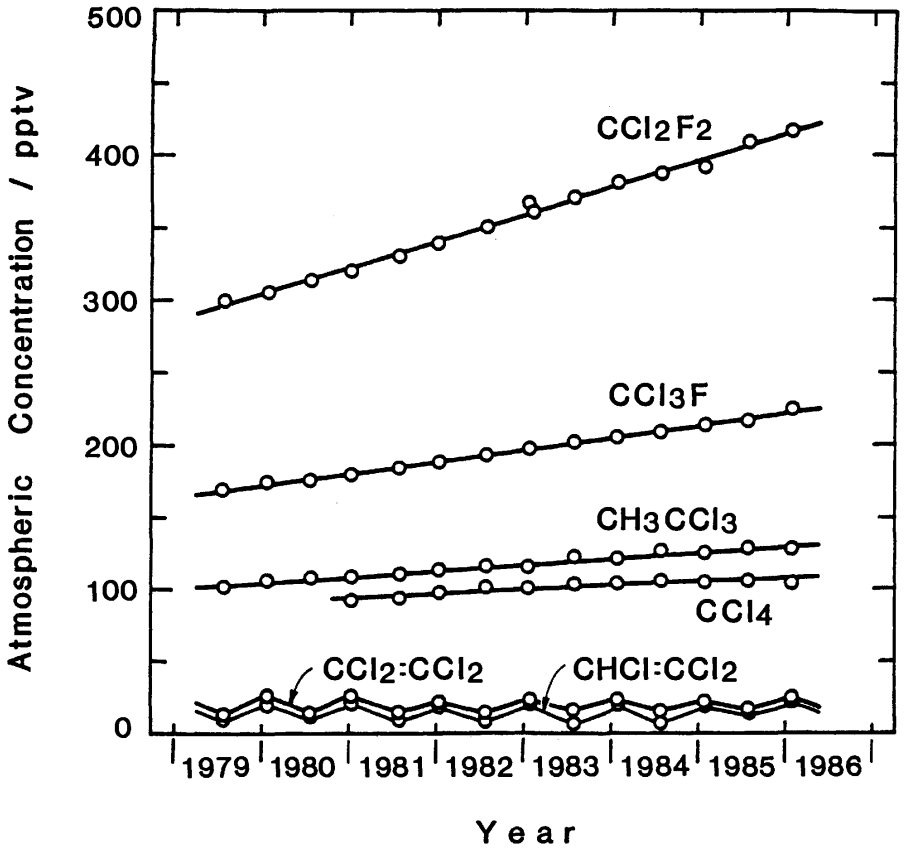

Fig. 1. Atmospheric concentrations of halocarbons in the mid-latitude Northern Hemisphere observed in Hokkaido (40—45°N) in 1979—1986. (pptv=10^{-12} v/v in dry air).

Ocean, causing strong west wind), they are changeable in summer according to the strength of the high atmospheric pressure over the Pacific Ocean. Thus, higher- or lower-latitude air was sometimes collected depending on the distribution of atmospheric pressure. All the collected samples were analyzed in our laboratory at the University of Tokyo within a few weeks of sampling.

Results and Discussion

Analysis. The primary standards for CCl_2F_2, CCl_3F, CH_3CCl_3, and CCl_4 were carefully prepared in different ways and repeatedly, and the concentration of each compound in a secondary standard was determined one by one. The calibration values for these compounds were determined definitely.

The precision of the measurement was within 0.5% at 100 pptv concentration level. The constancy of the calibration was often checked by using the same vacuum-line system and by analyzing several stored ambient air samples which contained enough water vapor to keep most components unchanged.

Trend of Halocarbon Concentrations Observed in Hokkaido. The atmospheric concentrations of CCl_2F_2, CCl_3F, CH_3CCl_3, CCl_4, $CHCl=CCl_2$, and $CCl_2=CCl_2$ observed in Hokkaido since 1979 are shown in Fig. 1.

The concentrations of CCl_2F_2, CCl_3F, and CH_3CCl_3 have been increasing almost linearly during the present period except for small fluctuations depending on the year, possibly due to the meteorological conditions and the limited number of samples. It is not clear whether or not such 2—3-year trends really reflect the variation in emission in the corresponding period.

The observed concentrations of CCl_2F_2 and CCl_3F at the end of January, 1986, were 417 and 225 pptv respectively. Our data of CCl_2F_2 and CCl_3F concentrations in 1980 agree reasonably well (within a possible range of accuracy: 4—5%) with those of the ALE measurements.[5] The increments of the CCl_2F_2 and CCl_3F concentrations we observed in the 6.5-year period were about 117 pptv (i.e., 18 pptv/year) and 56 pptv (i.e., 8.6 pptv/year) respectively; these values correspond to annual increase rates of 6.0 and 5.1% of the 1979 concentrations, or to those of 4.4 and 3.8% of the 1986 concentrations.

While the Chemical Manufacturers Association (CMA) gave estimates of world production and emission for CCl_2F_2 and CCl_3F up to 1982, it then discontinued the world estimates because of the alleged difficulty in estimating the production in the USSR and in Eastern European countries. The CMA data on CCl_2F_2 reported in 1981 were, however, revised upward in the

following year,[7] corresponding to the comments that the observed atmospheric concentrations were much higher than those expected from the 1981 CMA emission values.[11] The CMA attributed the revised amount mainly to unknown USSR emission.

In the 1980's, the world production of CCl_2F_2 and CCl_3F appears to have been roughly constant, or to be gradually increasing.[12] Even if the current emission level is maintained constant in the future (a very conservative assumption), the atmospheric concentrations of CCl_2F_2 and CCl_3F will keep increasing up to above 3000 and 1000 pptv respectively. If the emission of these halocarbons increases, as has been reported recently, the concentrations will become extremely high in the future[13] and a catastrophic change in the ozone layer can be anticipated.[14] The greenhouse effect is also predicted as a result of the strong IR absorption of halocarbons not overlapping with CO_2 absorption bands.[15]

The atmospheric concentration of CH_3CCl_3 has been increasing by about 4 pptv/year, reaching about 130 pptv in 1986. While the production and atmospheric release of CH_3CCl_3 (about 500 kilotons/year) exceed those of CCl_2F_2 and CCl_3F, the increment in its atmospheric concentration is smaller because CH_3CCl_3 is decomposed, mainly by the reaction with OH in the troposphere, and so has only a 6—7 year lifetime.[16]

The atmospheric concentration of CCl_4 increases rather slowly (about 2 pptv/year) because of its large accumulation in the atmosphere as a result of prolonged use since the 1920's, a smaller amount of release (about 100 kilotons/year) in recent years, and its lifetime of about 30 years.[10]

While our data on CCl_2F_2 and CCl_3F concentrations for the 1979—1981 period are similar to the ALE data, the CH_3CCl_3 and CCl_4 values were both about 30% lower than the ALE's.[5] Such large discrepancies in the observed CH_3CCl_3 and CCl_4 concentrations may be attributed to the calibration difficulties in their data, as we have previously pointed out.[6,10] Our new calibration method has solved the problem by adding water vapor in the preparation of standards for CH_3CCl_3 and CCl_4: otherwise, these compounds are readily adsorbed on the vessel's inner wall in extremely pure, dry gases in primary standards, thus mistakenly leading to apparently low concentrations in the standards and, consequently, high atmospheric concentrations, as might be the case with the ALE measurements.

While the $CHCl{=}CCl_2$ and $CCl_2{=}CCl_2$ concentrations in Tokyo often exceed 1000 pptv, those observed in Hokkaido were below 25 pptv, according to their short lifetimes (of a few weeks to a few months) in the troposphere; also, they showed seasonal variation (i.e., they were high in winter and low in summer). This seasonal variation in concentrations may reflect the seasonal difference in the photochemical activity (i.e., the higher OH radical concentration and faster reaction rate in summer) or a difference in the longitudinal transport of air masses from Europe to Hokkaido in the mid-latitude Northern Hemisphere (i.e., faster in winter than in summer). Such an obvious seasonal variation in $CHCl{=}CCl_2$ and $CCl_2{=}CCl_2$ concentrations has not been reported before. By analyzing the seasonal variation coupled with meteorological data, useful information regarding the photochemical activity and/or the global circulation of air masses can be obtained.

In addition to the halocarbons mentioned above, we have also observed other halocarbons, such as $CClF_2CClF_2$, CCl_2FCClF_2, and $CHCl_3$, in the same analytical run,[8,9] although their concentrations have not been determined quantitatively (because of the low concentration, contamination, or instability). CCl_2FCClF_2 has recently been increasingly used for cleaning fine electronic parts, etc. The stainless steel bellows valves of our sample canisters (Nupro SS-4H) had also been washed with this solvent (a standard procedure for meeting NASA specifications). Since we noticed that the CCl_2FCClF_2 concentration increased gradually and slightly in stored samples, even in carefully prepared sample canisters, we discontinued the quantitative determination of the CCl_2FCClF_2 concentration. However, its concentration in freshly collected samples has also been increasing because of its long atmospheric lifetime exceeding several decades.

The contamination of underground water with $CHCl{=}CCl_2$ and $CCl_2{=}CCl_2$ released by the semiconductor industry or dry cleaning has recently been observed in the USA and Japan, and more stable chlorofluorocarbons (e.g., CCl_2FCClF_2) have been proposed as substitutes for such unstable chlorocarbons. Although CCl_2FCClF_2 might be less toxic for human bodies if uptaken, it will instead contribute to the depletion of stratospheric ozone, as does CCl_2F_2. Accordingly, the use of halocarbons with extremely long lifetimes should be strictly checked for the protection of the Earth's atmosphere.

Synthesis, Characterization, and Isomerization of *trans*- and *cis*-$[CoCl_2(1,2\text{- or }1,3\text{-diphosphine})_2]^+$ and Related Complexes

Tomoji Ohishi, Kazuo Kashiwabara, and Junnosuke Fujita*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 25, 1986)

A number of new diphosphine complexes of cobalt(III), *trans*- and *cis*-$[CoCl_2$(dmpe, dmpp, dbpe, or dpee$)_2]^+$, *trans*- and *cis*-$[CoBr_2(dmpe)_2]^+$, *trans*- and *cis*-$[CoCl(H_2O)(dmpe)_2]^{2+}$, *trans*-$[Co(I_2$ or BrI$)(dmpe)_2]^+$, and $[Co(CO_3)$(dmpp or dbpe)$]^+$ have been prepared and characterized, where dmpe, dmpp, dbpe, and dpee denote 1,2-bis(dimethylphosphino)ethane, 1,3-bis(dimethylphosphino)propane, 1,2-bis(dibutylphosphino)-ethane, and *cis*-1,2-bis(diphenylphosphino)ethylene, respectively. The trans isomers of the dihalogeno complexes are stable to aquation, while the cis isomers release one of the halide ions in water fairly rapidly to yield *cis*-$[CoX(H_2O)$(diphosphine$)_2]^+$ which isomerizes to the trans isomer on exposure of ultraviolet light. The *cis*-$[CoCl_2$(diphosphine$)_2]^+$ complexes in methanol or ethanol solution isomerize to the trans isomer, and the rates were followed spectrophotometrically in the temperature range of 39.0—65.0 °C. The rates have a first-order dependence on the complex concentration. Both the ΔH^* and ΔS^* values for the isomerization increase in the order diphosphine=dmpe<dmpp<dbpe<dpee. This order coincides with the increasing order in cone angle of phosphine ligands, and suggests that the difference in rates among the complexes comes from a steric factor. Absorption spectra of all the complexes have been recorded and the results compared with those of the corresponding ethylenediamine complexes.

Since the first synthesis of cobalt(III)-diphosphine complexes, *trans*-$[CoX_2\{(C_2H_5)_2PCH_2CH_2P(C_2H_5)_2\}_2]^+$ (X=Cl^-, Br^-, and I^-) by Wymore and Bailar,[1] several complexes of this type have been prepared with $(CH_3)_2PCH_2CH_2P(CH_3)_2$,[2,3] $(CH_3)_2PCH_2CH_2CH_2P(CH_3)_2$,[4] *o*-$C_6H_4[P(CH_3)_2]_2$,[5] *o*-$C_6H_4[P(C_6H_5)_2]_2$,[6] and *cis*-$(C_6H_5)_2PCHCHP(C_6H_5)_2$.[7] To our knowledge, however, no cis isomer of those complexes is known. This paper reports the first examples of *cis*-$[CoX_2$(diphosphine$)_2]^+$, where X is Cl^- or Br^-, and diphosphine is $(CH_3)_2PCH_2CH_2P(CH_3)_2$=dmpe, $(CH_3)_2PCH_2CH_2CH_2P(CH_3)_2$=dmpp, $(C_4H_9)_2PCH_2CH_2P(C_4H_9)_2$=dbpe, or *cis*-$(C_6H_5)_2PCHCHP(C_6H_5)_2$=dpee. A pair of trans and cis isomers of $[CoX_2$(diphosphine$)_2]^+$ will be useful for studying physical and chemical properties of a cobalt(III)-phosphine complex which consists of a hard Lewis acid and a soft Lewis base. In this paper we report synthesis, absorption spectra and cis to trans isomerization of the new complexes, and compare the results with those of the corresponding ethylenediamine (en) complexes.

Experimental

Phosphine ligands were handled under an atmosphere of nitrogen until they formed cobalt(III) complexes. All solvents used for preparing ligands and complexes were deoxygenated by bubbling nitrogen for 20 min immediately before use. Absorption and ^1H NMR spectra were recorded on a Hitachi 323 spectrophotometer and a Jeol-PMX 60 spectrometer, respectively.

Phosphine Ligands. The dpee ligand was obtained from Strem Chemicals, Inc. and used as received. The dmpe[8] and dmpp[4] ligands were prepared according to literature methods, and dbpe was prepared by the following method. To $(C_4H_9)_2PH$[9] (11.4 g, 78 mmol) in dry THF (400 cm^3) was added dropwise LiC_4H_9 (15% hexane solution, 39.94 g) with stirring. After 1 h 1,2-dichloroethane (3.86 g, 39 mmol) was added to the resulting orange solution. Stirring was continued for 3 h to give a colorless solution. The solvent was removed under reduced pressure, and the oily residue was shaken with a mixture of chloroform (100 cm^3) and water (100 cm^3) to extract LiCl into water. The chloroform layer was separated, dried over Na_2SO_4 (3 g), and evaporated under reduced pressure to yield a light yellow oil of dbpe, which was used for preparing complexes without further purification.

Preparation of Complexes.† *trans*-$[CoCl_2(dmpe)_2]ClO_4$. The complex was prepared by the published method.[2]

***trans*-$[CoBr_2(dmpe)_2]ClO_4$.** An ethanol solution (5 cm^3) of dmpe (2.06 g, 14 mmol) was added to an ethanol solution (250 cm^3) of $CoBr_2\cdot 6H_2O$ (2.02 g, 6.2 mmol) with stirring. After 1 h concd HBr (1 cm^3) was added, and air was bubbled through the solution for 10 h. The resulting green solution was concentrated to 100 cm^3 under reduced pressure. On addition of $NaClO_4$ (1 g) in ethanol (5 cm^3) the concentrate gave green crystals, which were filtered and recrystallized from hot methanol. Yield: 2.1 g (55%). Found: C, 23.45; H, 4.99%. Calcd for $C_{12}H_{32}Br_2ClCoO_4P_4$: C, 23.30; H, 5.21%. The complex is soluble in methanol, ethanol, and acetonitrile.

***trans*-$[CoI_2(dmpe)_2]ClO_4\cdot 0.5CH_3OH$.** This complex was prepared by a method similar to that for *trans*-$[CoBr_2(dmpe)_2]^+$. A methanol solution (100 cm^3) containing dmpe (240 mg, 1.6 mmol) and $CoI_2\cdot 6H_2O$ (337 mg, 0.8 mmol) was stirred for 20 min and then was mixed with concd HI (1 cm^3) and $NaClO_4$ (150 mg). Air was bubbled through the solution for 6 h. The resulting dark brown solution was concentrated to 50 cm^3 under reduced pressure. The concentrate was cooled at −5 °C for 10 h to give brownish-violet crystals, which were filtered, washed with a mixture (20 cm^3) of methanol and diethyl ether (2:1), and air-dried. Yield: 200 mg (33%). Found: C, 21.02; H, 4.59%. Calcd for $C_{12.5}H_{34}ClCoI_2O_{4.5}P_4$: C, 20.61; H, 4.84%. The complex is soluble in DMF and DMSO.

***cis*-$[CoCl_2(dmpe)_2]ClO_4$.** Crystals of $[Co(CO_3)(dmpe)_2]ClO_4\cdot 1.5NaClO_4\cdot H_2O$[10] (736 mg, 1.15 mmol) were soaked in ice-cold concd HCl (20 cm^3) at 0 °C. After 1 h the result-

†All of the perchlorate salts of cobalt(III)-phosphine complexes described below are potentially explosive, and should be handled carefully.

ing red solution was mixed with an ice-cold aqueous solution (3 cm^3) of $NaClO_4$ (300 mg) and was cooled at −5 °C for 10 h. Red crystals deposited were filtered and recrystallized from acetonitrile (20 cm^3) by adding diethyl ether (50 cm^3). Yield: 340 mg (52%). Found: C, 27.23; H, 6.45%. Calcd for $C_{12}H_{32}C_{13}CoO_4P_4$: C, 27.21; H, 6.09%. The complex is soluble in methanol and acetonitrile.

***cis*-[CoBr$_2$(dmpe)$_2$]ClO$_4$·0.5CH$_3$CN·H$_2$O.** The complex was prepared by the same method as for *cis*-$[CoCl_2(dmpe)_2]^+$ using concd HBr instead of concd HCl. Yield: 38%. Found: C, 21.71; H, 5.32, N, 1.21%. Calcd for $C_{13}H_{35.5}N_{0.5}Br_2ClCoO_5P_4$: C, 21.76; H, 5.45; N, 1.07%. The complex is soluble in methanol and acetonitrile.

***trans*-[CoCl$_2$(dmpp)$_2$]ClO$_4$·0.5H$_2$O.** The complex was prepared by the method of Cloyd and Meek.[4]

[Co(CO$_3$)(dmpp)$_2$]ClO$_4$·H$_2$O. To a solution of *trans*-$[CoCl_2(dmpp)_2]ClO_4 \cdot 0.5H_2O$ (200 mg, 0.35 mmol) in a mixture (100 cm^3) of acetonitrile and water (4:1) were added K_2CO_3 (97.6 mg, 0.7 mmol) in water (3 cm^3) and active charcoal (100 mg). The mixture was stirred for 30 min and filtered. The filtrate was evaporated to dryness under reduced pressure, and the complex was extracted with methanol (20 cm^3). On addition of diethyl ether (50 cm^3) the extract gave a yellow precipitate, which was filtered, washed with a mixture (50 cm^3) of methanol and diethyl ether (1:5), and air-dried. Yield: 150 mg (78%). Found: C, 31.74; H, 6.78%. Calcd for $C_{15}H_{38}ClCoO_8P_4$: C, 31.94; H, 6.17%. The complex is soluble in methanol and ethanol.

***cis*-[CoCl$_2$(dmpp)$_2$]ClO$_4$·0.5H$_2$O.** The complex was prepared from $[Co(CO_3)(dmpp)_2]ClO_4 \cdot H_2O$ and concd HCl by a method similar to that for *cis*-$[CoCl_2(dmpe)_2]^+$. Yield: 48%. Found: C, 29.54; H, 6.19%. Calcd for $C_{14}H_{37}Cl_3CoO_{4.5}P_4$: C, 29.67; H, 6.58%. The complex is soluble in methanol and acetonitrile.

***trans*-[CoCl$_2$(dbpe)$_2$]PF$_6$·H$_2$O.** An ethanol solution (100 cm^3) containing $CoCl_2 \cdot 6H_2O$ (193 mg, 0.81 mmol) and dbpe (684 mg, 1.62 mmol) was stirred for 40 min, and then concd HCl (1 cm^3) was added. Air was bubbled through the solution for 10 h. The resulting dark green solution was evaporated to dryness under reduced pressure, and the residue was dissolved in methanol (50 cm^3). The methanol solution was shaken with hexane (100 cm^3) to extract free dbpe into hexane. This procedure was repeated several times, and the methanol layer was separated and concentrated to 20 cm^3 under reduced pressure. To the concentrate were added water (10 cm^3) and NH_4PF_6 (500 mg) dissolved in a mixture (3 cm^3) of water and methanol (1:1). The mixture was stored in a refrigerator for 10 h to yield green crystals, which were filtered, washed with a mixture (30 cm^3) of water and ethanol (4:1), and air-dried. Yield: 110 mg (15%). Found: C, 46.46; H, 9.47%. Calcd for $C_{36}H_{82}Cl_2CoF_6OP_5$: C, 46.50; H, 8.89%. The complex is soluble in methanol, ethanol, chloroform, and diethyl ether.

[Co(CO$_3$)(dbpe)$_2$]PF$_6$·1.5H$_2$O. To *trans*-$[CoCl_2(dbpe)_2]PF_6 \cdot H_2O$ (200 mg, 0.22 mmol) in a mixture (100 cm^3) of methanol and water (4:1) were added K_2CO_3 (100 mg, 0.72 mmol) in water (5 cm^3) and active charcoal (ca. 100 mg). The mixture was stirred for 4 h and filtered. The filtrate was evaporated to dryness under reduced pressure, and the complex was extracted with ethanol (20 cm^3). The extract was concentrated to 10 cm^3 and mixed with a solution of NH_4PF_6 (500 mg) in a mixture (3 cm^3) of water and ethanol (4:1). The mixture was stored in a refrigerator for 10 h to yield orange crystals, which were filtered, washed with a mixture (30 cm^3) of water and ethanol (4:1), and air-dried. Yield: 80 mg (41%). Found: C, 47.89; H, 9.04%. Calcd for $C_{37}H_{83}CoF_6O_{4.5}P_5$: C, 47.89; H, 9.02%. The complex is soluble in methanol and ethanol.

***cis*-[CoCl$_2$(dbpe)$_2$]PF$_6$·H$_2$O.** Ice-cold concd HCl (1 cm^3) was added to an ethanol solution (2 cm^3) of $[Co(CO_3)(dbpe)_2]PF_6 \cdot 1.5H_2O$ (70 mg, 0.075 mmol) at 0 °C, the color of the solution changing slowly from yellow to red. To the red solution was added NH_4PF_6 (200 mg) in water (0.5 cm^3), and the mixture was stored in a refrigerator for 10 h to give red-violet crystals, which were filtered, washed with a mixture (10 cm^3) of ethanol and water (1:5), and air-dried. Yield: 20 mg (29%). Found: C, 46.83; H, 9.56%. Calcd for $C_{36}H_{82}Cl_2CoF_6OP_5$: C, 46.50; H, 8.89%. The complex is soluble in methanol and ethanol.

***trans*-[CoCl$_2$(dpee)$_2$]ClO$_4$.** The complex was prepared according to the literature method.[7]

***cis*-[CoCl$_2$(dpee)$_2$]BF$_4$.** Ice-cold concd HCl (1 cm^3) was added dropwise to an ethanol solution (6 cm^3) of $[Co(O_2)(dpee)_2]BF_4$[7] (100 mg, 0.103 mmol) at 0 °C. After a while the resulting red-violet solution was mixed with $NaBF_4$ (200 mg) in water (1 cm^3), and was allowed to stand at 5 °C for 10 h to yield red-violet crystals, which were filtered and dissolved in a minimum amount of ethanol–dichloromethane (5:1). The solution was applied on a column (ϕ 2.5×20 cm) of Toyopearl TSK-GEL, and the adsorbed products were eluted with ethanol. An yellow-green (major product) and a red-violet (minor product) band appeared. The eluate of the red-violet band was collected and evaporated to dryness under reduced pressure below 30 °C. The residue was dissolved in ethanol (5 cm^3), and diethyl ether (5 cm^3) was added. The solution was allowed to stand at 5 °C for 10 h to give violet crystals, which were filtered, washed with a mixture (20 cm^3) of diethyl ether and ethanol (5:1), and air-dried. Yield: 20 mg (19%). Found: C, 62.68; H, 4.62%. Calcd for $C_{52}H_{44}BCl_2CoF_4P_4$: C, 61.87; 4.39%. The complex is soluble in ethanol and dichloromethane.

***trans*-[CoBrI(dmpe)$_2$]ClO$_4$.** To a methanol solution (50 cm^3) of *trans*-$[CoBr_2(dmpe)_2]ClO_4$ (200 mg, 0.32 mmol) was added dropwise a methanol solution (3 cm^3) of NaI (50 mg, 0.33 mmol) with stirring. The solution was stirred for 3 h at 45 °C, and then concentrated under reduced pressure to 5 cm^3. On cooling at 0 °C brown crystals were precipitated, filtered, washed with a mixture (30 cm^3) of methanol and diethyl ether (1:1), and air-dried. Yield: 150 mg (70%). Found: C, 21.71; H, 4.87%. Calcd for $C_{12}H_{32}BrClCoIO_4P_4$: C, 21.66; H, 4.84%. The complex is soluble in methanol and ethanol.

***cis*-[CoCl(H$_2$O)(dmpe)$_2$](PF$_6$)$_2$·CH$_3$CN.** To an acetonitrile solution (3 cm^3) of *cis*-$[CoCl_2(dmpe)_2]ClO_4$ (100 mg, 0.19 mmol) was added water (40 cm^3). The solution was stirred at room temperature for 15 min, the color of the solution changing from red to yellow. On addition of NH_4PF_6 (500 mg) in water (3 cm^3) a yellow precipitate was obtained. It was filtered, washed with water (50 cm^3), and air-dried. Yield: 110 mg (85%). Found: C, 23.07; H, 5.01; N, 1.88%. Calcd for $C_{14}H_{37}NClCoF_{12}OP_6$: C, 22.61; H, 4.84; N, 2.04%. The complex is soluble in acetonitrile. The perchlorate of the complex can be obtained by use of $NaClO_4$ instead of NH_4PF_6, but tends to explode by mechanical shock.

***trans*-[CoCl(H$_2$O)(dmpe)$_2$](PF$_6$)$_2$·CH$_3$CN.** An acetonitrile solution (50 cm^3) of *cis*-$[CoCl(H_2O)(dmpe)_2](PF_6)_2 \cdot CH_3CN$ (50 mg, 0.067 mmol) was allowed to stand at room tempera-

ture. The color of the solution changed very slowly from yellow to red-orange in the dark, but the change was remarkably accelerated by sunlight. With slow evaporation of acetonitrile red-orange crystals were precipitated, filtered, and air-dried. Yield: 45 mg (90%). Found: C, 23.18; H, 4.92; N, 2.02%. Calcd for $C_{14}H_{37}NClCoF_{12}OP_6$: C, 22.61; H, 4.84; N, 2.04%. The complex is soluble in acetonitrile.

Kinetic Measurements. Isomerization reactions of *cis*-$[CoCl_2(L)_2]^+$ (L=dmpe, dmpp, dbpe, and dpee) and *cis*-$[CoBr_2(dmpe)_2]^+$ to the trans isomers in methanol or ethanol solution were monitored spectrophotometrically with a Jasco UNIDEC 610 spectrophotometer equipped with a thermostated cell compartment. The solvents of spectroscopic grade methanol and ethanol were dried over Molecular Sieves, and the complex concentrations were ca. 4×10^{-4}—1×10^{-3} mol dm^{-3}. The temperature of the solutions was in the range of 39.0—65.0 °C and kept constant within ±0.3 °C by use of a temperature-controlled circulating bath, Yamato-Komatsu CET-24W. Suitable wavelengths for following the isomerization reactions were in the range of 485—556 nm where the complexes show the first absorption band. In each kinetic run, the plot of $\ln(D_t-D_\infty)$ vs. time gave a straight line until at least five half-lives, where D_t and D_∞ denote the absorbance at time t and at infinite time, respectively. The slope gave the first-order rate constant of isomerization k, and Eyring treatment of $\log(k/T)$ vs. T^{-1} yielded the activation parameter. All the experiments should be carried out in the dark, because the isomerization reactions were accelerated by sunlight.

Results and Discussion

Preparation and Characterization of the Complexes. All the *trans*-$[CoX_2(diphosphine)_2]^+$ (X=Cl^-, Br^-, or I^-) complexes in this study can be easily prepared by oxidation of the cobalt(II)-diphosphine species in methanol or ethanol with air in moderate yields, although the yield of the dbpe complex was rather poor because of its high solubility. For *cis*-$[CoX_2(diphosphine)_2]^+$ (X=Cl^- or Br^-), the dmpe, dmpp, and dbpe complexes were prepared by treating the corresponding carbonato complexes with concd HX, while *cis*-$[CoCl_2(dpee)_2]^+$ was obtained by the reaction of $[Co(O_2)(dpee)_2]^+$ with concd HCl, the reaction with $[Co(CO_3)(dpee)_2]^+$ giving only the trans isomer. The former three complexes can also be prepared from the corresponding peroxo complexes.[10] The reactions with concd HX should be carried out at a low temperature, since the trans isomer is formed in larger amounts with an increasing reaction temperature. The $[Co(O_2)(dpee)_2]^+$ complex afforded a mixture of the cis and trans isomers by the reaction even at a low temperature. The formation of the trans isomer will be attributable to the following properties of the dpee complex; the $[Co(O_2)(dpee)_2]^+$ complex has less reactivity toward HX compared with other diphosphine-peroxo complexes,[10] and *cis*-$[CoCl_2(dpee)_2]^+$ isomerizes to the trans isomer much faster than other *cis*-$[CoCl_2(diphosphine)_2]^+$ do (vide infra). The reaction of $[CoCO_3(dmpe)_2]^+$ with concd HI yielded only the *trans*-diiodo complex. The cis isomer in which two large I^- ions are in the cis positions will be sterically unstable.

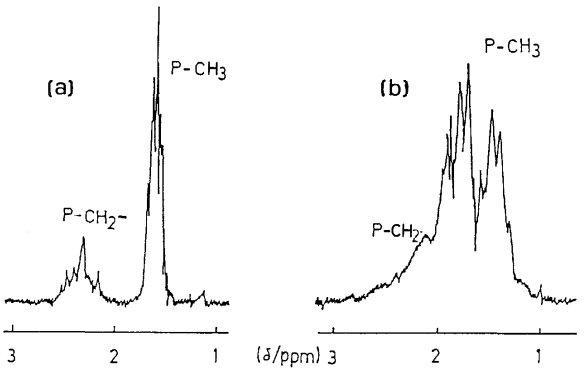

Fig. 1. ^1H NMR spectra of (a) *trans*-$[CoCl_2(dmpe)_2]^+$ and (b) *cis*-$[CoCl_2(dmpe)_2]^+$ (in CD_3CN, TMS reference).

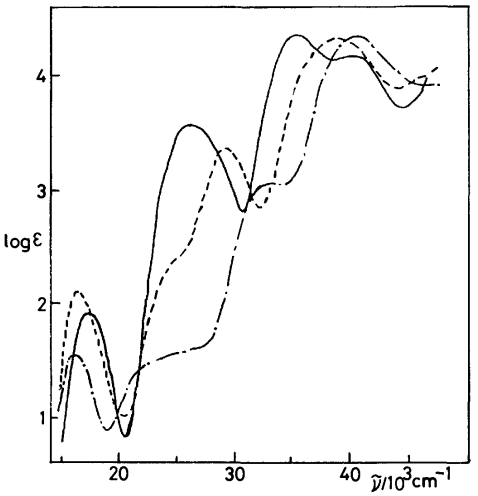

Fig. 2. Absorption spectra of *trans*-$[CoCl_2(dmpe)_2]^+$ (——), *trans*-$[CoCl_2(edmp)_2]^+$ (----), and *trans*-$[CoCl_2(en)_2]^+$ (-·-·-).

All the *cis*-$[CoX_2(diphosphine)_2]^+$ complexes in nonaqueous solvents are fairly stable in the dark, but easily isomerize to the trans isomer on exposure of ultraviolet light. The *cis*-$[CoCl_2(dmpe)_2]^+$ complex in acetonitrile afforded *cis*-$[CoCl(H_2O)(dmpe)_2]^+$ by the addition of water. The aqua complex in acetonitrile was stable in the dark, but isomerized to the trans aqua complex on exposure of ultraviolet light. Both cis and trans aqua complexes were isolated as the hexafluorophosphate. Detailed studies on these photochemical reactions are in progress.

Geometrical structures of the complexes were assigned from the ^1H NMR spectra, and from comparisons of the absorption spectra with those of other phosphine and ethylenediamine complexes. In the ^1H NMR spectrum, for example, *trans*-$[CoCl_2(dmpe)_2]^+$ shows a multiplet methyl signal at δ ca. 1.6, while the cis isomer gives many signals in the region of δ 1.5—2.0 (Fig. 1). The spectral pattern of the cis isomer is quite similar to those of $[CoCO_3(dmpe)_2]^+$ and

$[CoC_2O_4(dmpe)_2]^+$,[11] which have necessarily a cis geometry.

Figure 2 compares the absorption spectra of *trans*-$[CoCl_2(L)_2]^+$ (L= dmpe, edmp, and en), where edmp denotes $NH_2CH_2CH_2P(CH_3)_2$. For *trans*(Cl, Cl), *cis*(P, P)-$[CoCl_2(edmp)_2]^+$, we have assigned the peak at 16600 cm^{-1} to the Ia component of the first absorption band, the shoulder at ca. 23800 cm^{-1} to the second absorption band overlapped the Ib component of the first absorption band, the bands at 29500 and 39700 cm^{-1} to the Co-Cl charge-transfer band, and the shoulder at ca. 36500 cm^{-1} to the Co-P charge-transfer band, by comparing the spectrum with that of the en complex.[12] The spectrum of *trans*-$[CoCl_2(dmpe)_2]^+$ may be assigned in a similar manner; the band at 17300 cm^{-1} can be assigned to the Ia component of the first absorption band, the broad band at 26100 cm^{-1} to that involving three components, the second absorption band, the Ib component of the first absorption band, and the Co-Cl charge-transfer band, the band at 35400 cm^{-1} to the Co-P charge-transfer band, and the band at 40500 cm^{-1} to the Co-Cl charge-transfer band. In Fig. 3 the spectra of *trans*-$[CoX_2(dmpe)_2]^+$ (X=Br^- and I^-) are compared with that of *trans*-$[CoCl_2(dmpe)_2]^+$. The spectrum of the dibromo complex is similar to that of the dichloro complex, but that of the diiodo complex differs from those of other halogeno complexes. For *trans*-$[CoX_2(en)_2]^+$, the spectra of the dichloro and dibromo complexes are similar, but that of the diiodo complex also differs from others.[13] Other phosphine complexes, *trans*-$[CoCl_2(L)_2]^+$ (L=dmpp and dbpe), give spectra similar to that of the dmpe complex (Fig. 4(a)). The Ia band shifts to higher energy in the order L=dpee<dbpe<dmpp<dmpe (Table 1). This order coincides with the decreasing order in cone angle of

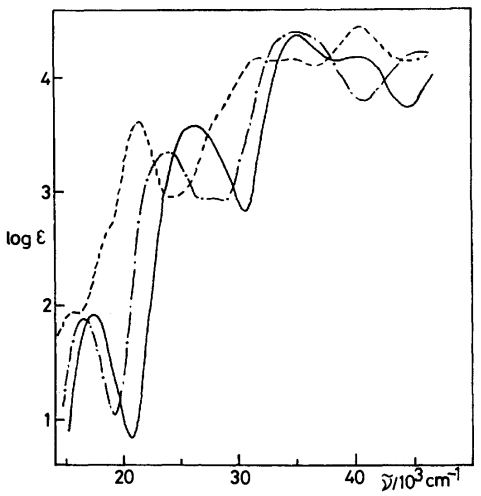

Fig. 3. Absorption spectra of *trans*-$[CoCl_2(dmpe)_2]^+$ in CH_3OH (——), *trans*-$[CoBr_2(dmpe)_2]^+$ in CH_3OH (-·-·-), and *trans*-$[CoI_2(dmpe)_2]^+$ in CH_3CN (----).

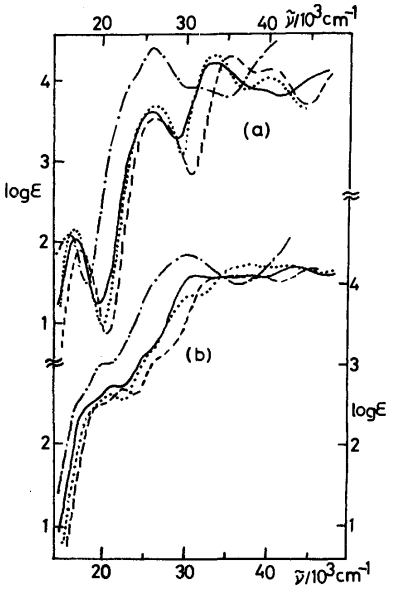

Fig. 4. Absorption spectra of (a) *trans*-$[CoCl_2(dmpe)_2]^+$ (----), *trans*-$[CoCl_2(dmpp)_2]^+$ (·····), *trans*-$[CoCl_2(dbpe)_2]^+$ (——), and *trans*-$[CoCl_2(dpee)_2]^+$ (-·-·-), and (b) *cis*-$[CoCl_2(dmpe)_2]^+$ (----), *cis*-$[CoCl_2(dmpp)_2]^+$ (·····), *cis*-$[CoCl_2(dbpe)_2]^+$ (——), and *cis*-$[CoCl_2(dpee)_2]^+$ (-·-·-). Solvent: CH_3OH except for the dpee complexes (CH_2Cl_2).

Table 1. Absorption Spectral Data[a]

Complex	$\tilde{\nu}/10^3\,cm^{-1}(\log\varepsilon)$			
trans-$[CoCl_2(dmpe)_2]^+$	17.30(1.92)	26.10(3.70)	35.40(4.35)	40.50(4.16)
cis-$[CoCl_2(dmpe)_2]^+$	19.7 (2.5)[b]	22.30(2.69)	26.60(3.06)	
trans-$[CoCl_2(dmpp)_2]^+$	16.66(2.19)	26.50(3.50)	33.50(4.34)	40.30(4.06)

	31.70(4.15)	34.50(4.14)	40.40(4.43)	

a) Solvent: CH_3OH except for *trans*- and *cis*-$[CoCl_2(dpee)_2]^+$ (CH_2Cl_2) and *trans*-$[CoI_2(dmpe)_2]^+$ (CH_3CN).
b) Shoulder.

phosphine ligands.[14]

Figure 4(b) shows absorption spectra of *cis*-$[CoCl_2(L)_2]^+$ (L=dmpe, dmpp, dbpe, and dpee). The spectra in the region of 15000—25000 cm^{-1} are similar among the four complexes and have three bands or shoulders. These absorptions can be assigned to the first and second bands from a comparison with the spectrum of *cis*-$[CoCl_2(en)_2]^+$. This complex shows the first absorption band at 18600 cm^{-1} with a shoulder at ca. 17000 cm^{-1} and the second absorption band at 25500 cm^{-1}.[15] In a previous paper,[16] we reported that the first absorption band of the $[Co(N)_n(P)_{6-n}]^{3+}$-type complexes shifts to higher energy by replacing N with P, while the energy of the second absorption band remains almost unchanged. Thus the bands and shoulders in the region of 17000—22000 cm^{-1} of *cis*-$[CoCl_2(diphosphine)_2]^+$ are assigned to the first absorption band split into two components,[17] and the shoulders in the region of 25000—26000 cm^{-1} to the second absorption band. The higher energy first absorption band shifts to higher energy in the order diphosphine=dpee<dbpe<dmpp<dmpe. This order is the same as that observed for the corresponding trans isomer. The spectral patterns in the ligand field absorption band region of these *trans*- and *cis*-$[CoCl_2(diphosphine)_2]^+$ complexes are very similar to those of *trans*- and *cis*-$[CoCl_2(diarsine)_2]^+$, respectively, to which similar band assignments have been made.[18,19]

The chloride ions in *trans*-$[CoCl_2(diphosphine)_2]^+$ are quite inert to aquation compared with those in *trans*-$[CoCl_2(en)_2]^+$. For example, *trans*-$[CoCl_2(dmpe)_2]^+$ is stable in neutral water at room temperature for at least several days, while *trans*-$[CoCl_2(en)_2]^+$ liberates one chloride ion to aquate with the half-life time of 361 min (25 °C, pH 1).[20] The *trans*-$[CoCl_2\{NH_2CH_2CH_2P(CH_3)_2\}_2]^+$ complex is also stable to aquation.[12] The reactivity of *trans*-$[CoCl_2(diphosphine)_2]^+$ to the substitution reaction of CO_3^{2-} for the two chloride ions depends on the kind of phosphines. The reaction of the dmpe complex with K_2CO_3 occurs instantly at room temperature to yield $[CoCO_3(dmpe)_2]^+$, whereas those of the dmpp and dbpe complexes proceed at a higher temperature or the addition of active charcoal. Miskowski et al.[7] used Ag_2CO_3 to prepare $[CoCO_3(dpee)_2]^+$, from *trans*-$[CoCl_2(dpee)_2]^+$, the breaking of the Co–Cl bond being assisted by Ag^+. The *trans*-dichloro complexes containing bulky phosphine ligands seem to have less reactivity to substitution reactions for the chloride ions.

In contrast to *trans*-$[CoCl_2(diphosphine)_2]^+$, the corresponding cis isomers liberate rapidly one chloride ion in aqueous solution to yield *cis*-$[CoCl(H_2O)(diphosphine)_2]^{2+}$. The reaction of *cis*-$[CoCl_2(dmpe)_2]^+$ is complete within 15 min in neutral water at 25 °C, which is much faster than that of *cis*-$[CoCl_2(en)_2]^+$ ($t_{1/2}$=ca. 46 min, 25 °C, pH 1).[20] The lability of Cl^- in *cis*-$[CoCl_2(dmpe)_2]^+$ may be brought about by the strong trans effect of the phosphine ligand.[21] However, the subsequent reaction to liberate the second chloride ion is so slow that *cis*-$[CoCl(H_2O)(dmpe)_2]^{2+}$ can be isolated. A similar aquation reaction has been reported for *cis*-$[RuCl_2\{(C_2H_5)_2PCH_2CH_2P(C_2H_5)_2\}_2]$.[22]

The *trans*-$[CoI_2(dmpe)_2]^+$ complex, which was prepared from $[CoCO_3(dmpe)_2]^+$ and concd HI, can also be obtained by metathesis of *trans*-$[CoX_2(dmpe)_2]ClO_4$ (X=Cl^-, Br^-) and NaI. The mixed halogeno complexes, *trans*-$[CoXI(dmpe)_2]^+$ (X=Cl^-, Br^-), were isolated by similar reactions, although the pure chloroiodo complex was not obtained. Reverse reactions yielding the chloro and bromo complexes from the diiodo complex do not take place. These results indicate that the cobalt(III) ion in the dmpe complex has stronger affinity to I^- than to Cl^- and Br^-. The cobalt(III) ion which belongs to a hard acid may be softened by coordination of phosphine ligands, and may have stronger affinity to a more soft base I^- than Cl^- and Br^- as predicted by the principle of "Hard and Soft Acids and Bases."[23]

Isomerization Reactions. All the *cis*-$[CoX_2(diphosphine)_2]^+$ complexes prepared in this study isomerize in methanol or ethanol to the trans isomer. Figure 5 shows the change in absorption spectrum at intervals during the isomerization of *cis*-$[CoCl_2(dpee)_2]^+$ in methanol at 50 °C. Three isosbestic points were found at 363, 488, and 634 nm and the final spectrum was identical with that of a freshly prepared solution of *trans*-$[CoCl_2(dpee)_2]^+$. These results indicate that the cis isomer isomerizes to the trans isomer, and no reverse reaction occurs. The cis isomers of other phosphine complexes gave similar results. The rates of the isomerization were followed by measuring the change in absorbance at a given wavelength, and from

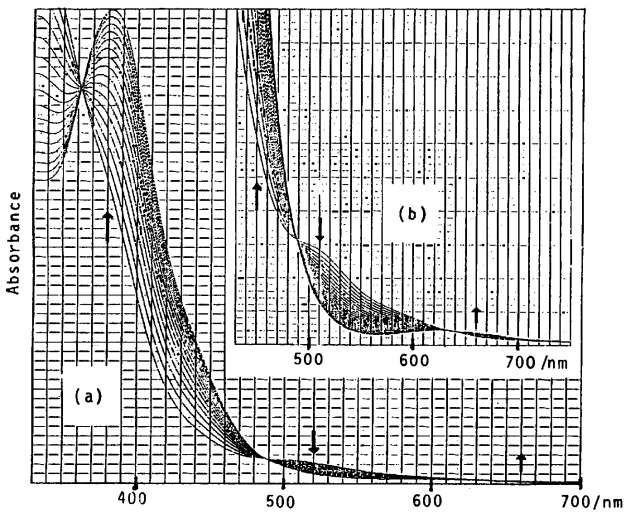

Fig. 5. Change in absorption spectrum of *cis*-$[CoCl_2(dpee)_2]BF_4$ in methanol at 50°C (recorded intervals: 30 min). Trends of spectral changes with time are shown by arrows.. In (b), the scale of absorbance is expanded.

the data the first-order rate constants were obtained (Experimental, Fig. 6, and Table 2). For *cis*-$[CoCl_2(dbpe)_2]^+$, the isomerization was also studied at 39 °C in the presence of 200 times as many moles of LiCl, but the rate was the same within the experimental error.

The mechanism for isomerization of the present complexes is not clear at present. However, the fact that the rate of isomerization of *cis*-$[CoCl_2(dbpe)_2]^+$ is not affected by the addition of LiCl suggests that the complex isomerizes by an intramolecular mechanism. Peloso and Tobe[24] proposed an intramolecular mechanism for the isomerization of *cis*-$[CoCl_2(diars)_2]^+$ (diars=*o*-phenylenebis(dimethylarsine)). This complex isomerizes to the trans isomer in methanol with a similar rate (1.67×10^{-6} s^{-1}, 55 °C) to that of *cis*-$[CoCl_2(dmpe)_2]^+$, and the rate increases only a little by the addition of LiCl. The *cis*-$[CoCl_2\{(CH_3)_2AsCH_2CH_2CH_2As(CH_3)_2\}_2]^+$ complex gives similar results in the isomerization to the trans isomer.[19] The *cis*-$[CoX_2(L)_2]^+$-type complexes (L=diphosphine and diarsine) in methanol seem to isomerize to the trans isomer intramolecularly by a similar mechanism. The *cis*-$[CoCl_2(en)_2]^+$ complex in methanol isomerizes to the trans isomer faster ($t_{1/2}$=3.6 h, 35 °C) than do the diphosphine and diarsine complexes, and the rate is dependent upon the LiCl concentration, for which a unimolecular mechanism involving a five-coordinate intermediate was proposed.[25]

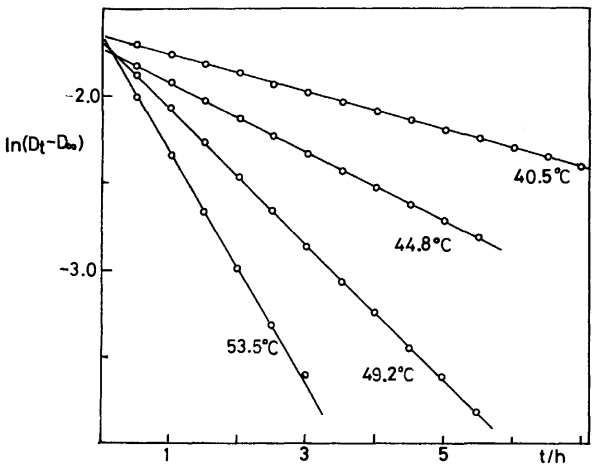

Fig. 6. Plots of $\ln(D_t-D_\infty)$ against time at 40.5, 44.8, 49.2, and 53.5°C for *cis*-$[CoCl_2(dpee)_2]BF_4$.

Table 2. Rate Constants for Isomerization of the Complexes

Complex	*t* / °C	*k* / $s^{-1}\times10^{-5}$
cis-$[CoCl_2(dpee)_2]BF_4$	40.5	2.91±0.01
	44.8	5.38±0.02
	49.2	10.72±0.02
	53.5	18.03±0.02
cis-$[CoCl_2(dbpe)_2]PF_6$	39.0	1.10±0.02
	43.3	2.06±0.03
	49.3	4.65±0.03
	52.3	7.29±0.05
cis-$[CoCl_2(dmpp)_2]BF_4$	46.4	3.27±0.02
	49.1	4.60±0.02
	51.7	6.48±0.02
	54.0	8.47±0.03
cis-$[CoCl_2(dmpe)_2]ClO_4$	55.0	0.13±0.02
	60.0	0.25±0.02
	62.3	0.28±0.04
	65.0	0.40±0.03
cis-$[CoBr_2(dmpe)_2]ClO_4$	50.0	1.15±0.03

Solvent: CH_3OH except for *cis*-$[CoCl_2(dmpe)_2]ClO_4$ (C_2H_5OH).

Table 3 lists the activation parameters for the isomerization. The ΔH^* values increase in the order, the dmpe < dmpp < dbpe < dpee complexes. However, the ΔG^* (25 °C) values are similar because of the positive ΔS^* values increasing in the same order as for the ΔH^* values. The orders in the ΔH^* and ΔS^* values coincide with the increasing order in cone angle of phosphine ligands, and suggest that the difference in rates among the complexes comes from a steric factor. If the isomerization is assumed to proceed intramolecularly , the increasing ΔH^* values with increasing bulkiness of a phosphine ligand may be conceivable, since the complex with a bulky phosphine ligand would require larger energy to reach a transition state by twisting the octahedral structure of the complex. For the change in ΔS^*, however, no appropriate explanation can be given at present, although there are fairly large differences among the complexes. More data are needed to discuss in detail.

The rate constant 1.15×10^{-5} s^{-1} at 50 °C of *cis*-$[CoBr_2(dmpe)_2]^+$ is larger by a factor of about 10 than that of *cis*-$[CoCl_2(dmpe)_2]^+$ at the same temperature. As stated previously, $[CoI_2(dmpe)_2]^+$ formed only the trans isomer by the reaction of $[CoCO_3(dmpe)_2]^+$ with HI. The cis isomer may isomerize very rapidly to the trans isomer during the reaction. The stability of *cis*-$[CoX_2(dmpe)_2]^+$ depends largely on the kind of halide ions and becomes low rapidly on going from a small Cl^- to a large I^- ion.

Table 3. Thermodynamic Parameters for Isomerization of the Complexes

Complex	ΔH^* / kJ mol^{-1}	ΔS^* / J mol^{-1} K^{-1}	$\Delta G^*_{25\,°C}$ / kJ mol^{-1}

Preparation and Properties of Cobalt(III)-1,2-Bis(dimethylphosphino)-ethane (dmpe) Complexes of the $[Co(L)(dmpe)_2]^{n+}$ Type

Tomoji Ohishi, Kazuo Kashiwabara, and Junnosuke Fujita*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received September 8, 1986)

Seven new cobalt(III)-phosphine complexes of the type $[Co(L)(dmpe)_2]^{n+}$ were prepared from *trans*-[Co(Cl or Br)$_2$(dmpe)$_2$]$^+$, where dmpe denotes $(CH_3)_2PCH_2CH_2P(CH_3)_2$, and L is $C_2O_4^{2-}$, $NH_2CH_2COO^-$(gly), $NH_2CH(CH_3)COO^-$(ala), $(C_2H_5)_2NCS_2^-$(dtc), $(NCS^-)_2$, $(NCO^-)_2$, or $(CN^-)_2$. Reactions of *cis*-$[CoCl_2(dmpe)_2]^+$ with X^- (X^-=CN^-, NCS^-, and NCO^-) yielded only *trans*-$[CoX_2(dmpe)_2]^+$. Qualitative stabilities of the complexes containing a bidentate ligand in aqueous solution were found to decrease in the order L= $CH(CH_3CO)_2^-$(acac), $C_2O_4^{2-}$, dtc>CO_3^{2-}≫gly, ala>$NH_2CH_2CH_2NH_2$(en); the complexes containing O or S donor atoms are thermally more stable than those containing an amino donor group. The d-d absorption bands of the complexes were assigned by comparing the spectra with those of related Co(III)-phosphine and -en complexes. The IR and visible absorption spectra of the NCS^- and NCO^- complexes indicate an N coordination mode of these ambidentate ligands.

In a previous paper,[1] we have prepared all complexes of the series $[Co(acac)_x(en)_y(dmpe)_z]^{(3-x)+}$ and found that $[Co(acac)_{3-n}(dmpe)_n]^{n+}$ (n=1, 2) were more stable than $[Co(en)_{3-n}(dmpe)_n]^{3+}$ (n=1, 2), where acac, en and dmpe denote an acetylacetonate ion, ethylenediamine and 1,2-bis(dimethylphosphino)ethane, respectively. The en complexes in water are reduced to Co(II) on heating over 60 °C, and $[Co(en)(dmpe)_2]^{3+}$ in water containing excess chloride ions affords *trans*-$[CoCl_2(dmpe)_2]^+$ by heating, whereas the acac complexes remain unchanged under the same conditions. The acac ligand seems to stabilize the cobalt(III)-dmpe system.

To examine properties of cobalt(III)-phosphine complexes in more detail, we attempted to prepare cobalt(III)-dmpe complexes containing a variety of ligands. This paper reports the preparation and some properties of the $[Co(L)(dmpe)_2]^{n+}$-type complexes, where L denotes a bidentate ligand such as CO_3^{2-}, $C_2O_4^{2-}$, $NH_2CH_2COO^-$(gly), (*S*)-$NH_2CH(CH_3)COO^-$(*S*-ala) or $(C_2H_5)_2NCS_2^-$(dtc), and two unidentate ions such as NCS^-, NCO^-, CN^-, or H_2O.

Experimental

The dmpe ligand[2] was handled under an atmosphere of nitrogen until it formed cobalt(III) complexes. All solvents used for the preparation of dmpe and the complexes were deoxygenated by bubbling nitrogen for 20 min immediately before use. ^{1}H NMR, absorption, circular dichroism and IR spectra were recorded on a Jeol JNM-PMX 60 spectrometer, a Hitachi 323 spectrophotometer, a Jasco J-40CS spectropolarimeter, and a Jasco A-3 infrared spectrometer, respectively.

Preparation of the Complexes.† $[Co(CO_3)(dmpe)_2]ClO_4 \cdot 1.5NaClO_4 \cdot H_2O$[3] and *trans*-$[Co(H_2O)_2(dmpe)_2](ClO_4)_3 \cdot 2H_2O$[3] were prepared from *trans*-$[CoBr_2(dmpe)_2]ClO_4$[4] and the carbonato complex, respectively by reported methods.

$[Co(C_2O_4)(dmpe)_2]PF_6 \cdot 0.5NaPF_6$. An aqueous solution (5 cm^3) of $(NH_4)_2C_2O_4$ (5.36 mg, 0.38 mmol) was added to a solution of *trans*-$[CoCl_2(dmpe)_2]ClO_4$[5] (100 mg, 0.19 mmol) in a mixture of water and methanol (1 : 1, 50 cm^3), and the mixture was stirred for 10 h at room temperature. The resulting yellow solution was diluted with water (1 dm^3) and applied on a column (ϕ 3 cm×120 cm) of SP-Sephadex C-25. The adsorbed products were eluted with 0.1 mol dm^{-3} NaCl, giving a minor green and a major yellow band. The yellow eluate was collected and evaporated to dryness under reduced pressure. A yellow complex was extracted from the residue with methanol, and the extract was mixed with an aqueous solution (5 cm^3) of $NaPF_6$ (300 mg). The mixture was concentrated in a desiccator over P_4O_{10}, yielding yellow crystals, which were filtered, washed with a mixture (30 cm^3) of methanol and diethyl ether (1 : 1), and air-dried. Yield: 80 mg (72%). Found: C, 24.89; H, 5.30%. Calcd for $C_{14}H_{32}O_4F_9P_{5.5}Na_{0.5}Co$: C, 24.86; H, 4.76%. The complex is soluble in water, methanol and ethanol.

$[Co(dtc)(dmpe)_2](ClO_4)_2$. A methanol solution (30 cm^3) containing *trans*-$[CoBr_2(dmpe)_2]ClO_4$[4] (100 mg, 0.16 mmol) and sodium diethyldithiocarbamate (36.4 mg, 0.16 mmol) was stirred for 10 h at room temperature. The yellow crystals which precipitated were filtered, washed with a mixture (20 cm^3) of methanol and diethyl ether (1 : 1) and air-dried. Yield: 52 mg (72%). Found: C, 29.10; H, 6.00; N, 1.97%. Calcd for $C_{17}H_{42}NO_8P_4S_2Cl_2Co$: C, 28.91; H, 5.99; N, 1.98%. The complex is soluble in methanol, ethanol and acetonitrile.

$[Co(gly)(dmpe)_2](ClO_4)_2 \cdot 0.5NaClO_4 \cdot H_2O$. To *trans*-$[CoCl_2(dmpe)_2]ClO_4$[5] (100 mg, 0.19 mmol) in a mixture (50 cm^3) of water and methanol (1 : 1) were added an aqueous solution (5 cm^3) of sodium glycinate (37 mg, 0.38 mmol) and a small amount of active charcoal. The mixture was stirred for 10 h at room temperature, and then filtered to remove active charcoal. The filtrate was diluted with water (1 dm^3) and applied on a column (ϕ 3 cm×120 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, a small red (probably $[Co(gly)_2(dmpe)]^+$) and then a yellow band appeared. The eluate of the yellow band was collected and evaporated to dryness under reduced pressure. The residue was treated with methanol (100 cm^3) to extract the complex. To the extract was added an aqueous solution (2 cm^3) of $NaClO_4$ (300 mg), and the mixture was concentrated in a vacuum desiccator over P_4O_{10}, yielding yellow crystals. The crystals were filtered, washed with cold methanol (10 cm^3) and air-dried. Yield: 67 mg (18%). Found: C, 26.10; H, 5.70; N, 2.24%. Calcd for $C_{14}H_{38}NO_{13}P_4Cl_{2.5}Na_{0.5}Co$: C, 26.21; H, 5.97; N, 2.18%. The complex is soluble in water and

†All of the perchlorate salts of cobalt(III)-phosphine complexes described below are potentially explosive, and should be handled carefully.

methanol.

[Co(*S*-ala)(dmpe)$_2$](ClO$_4$)$_2$·0.5NaClO$_4$. The complex was prepared by a method similar to that for the glycinato complex, using sodium (*S*)-alaninate. The separation of two diastereomers was not achieved by SP-Sephadex column chromatography. Yield: 10%. Found: C, 23.71; H, 4.97; N, 1.95%. Calcd for $C_{15}H_{38}NO_{12}P_4Cl_{2.5}Na_{0.5}Co$: C, 23.45; H, 4.95; N, 1.82%. The solubility of the complex is similar to that of the glycinato complex.

***trans*-[Co(CN)$_2$(dmpe)$_2$]ClO$_4$.** To a solution of *trans*-[CoBr$_2$(dmpe)$_2$]ClO$_4$ (480 mg, 0.776 mmol) in a mixture (15 cm^3) of acetonitrile and water (2 : 1) was added an aqueous solution (3 cm^3) of NaCN (100 mg, 2.04 mmol), and the mixture was stirred at room temperature. After 1 h the solution was concentrated to 5 cm^3 under reduced pressure and cooled at 0 °C. The white crystals which precipitated were filtered, washed with a small amount of cold methanol and air-dried. Yield: 205 mg (52%). Found: C, 32.93; H, 6.32; N, 5.49%. Calcd for $C_{14}H_{32}N_2O_4P_4ClCo$: C, 32.68; H, 6.29; N, 5.44%. The complex is soluble in water and methanol.

***trans*-[Co(NCS)$_2$(dmpe)$_2$]ClO$_4$·2NaClO$_4$.** A solution (50 cm^3) containing *trans*-[CoCl$_2$(dmpe)$_2$]ClO$_4$ (100 mg, 0.19 mmol) and KNCS (36.7 mg, 0.38 mmol) in a mixture of methanol and water (1 : 1) was stirred at 50 °C for 1 h, and then at room temperature for 10 h. The resulting orange solution was evaporated to dryness under reduced pressure, and the residue was dissolved in acetonitrile (10 cm^3). The solution was chromatographed by a column (ϕ 3 cm×40 cm) of Sephadex LH-20. By elution with a mixture of hexane and acetonitrile (1 : 1), a green (the starting dichloro complex) and an orange band appeared. The orange eluate was collected, evaporated to dryness under reduced pressure, and the residue was dissolved again in acetonitrile (5 cm^3). The solution was mixed with an acetonitrile solution (2 cm^3) of NaClO$_4$ (200 mg) and concentrated in a vaccum desiccator over P_4O_{10}. The orange crystals which were formed were filtered, washed with cold methanol (10 cm^3) and air-dried. Yield: 33 mg (21%). Found: C, 20.40; H, 4.06; N, 3.45%. Calcd for $C_{14}H_{32}N_2O_{12}P_4S_2Cl_3Na_2Co$: C, 20.51; H, 3.93; N, 3.41%. The complex is soluble in acetonitrile.

***trans*-[Co(NCO)$_2$(dmpe)$_2$]ClO$_4$·H$_2$O.** A solution containing *trans*-[CoBr$_2$(dmpe)$_2$]ClO$_4$ (300 mg, 0.49 mmol) and KNCO (119 mg, 1.47 mmol) in a mixture (100 cm^3) of methanol and water (2 : 1) was stirred for 3 h at room temperature. The resulting orange solution was diluted with water (1 dm^3) and applied on a column (ϕ 3 cm×120 cm) of SP-Sephadex C-25. By elution with 0.1 mol dm^{-3} NaCl, a green (the starting dibromo complex) and a yellow eluate were obtained. The yellow eluate was concentrated to dryness under reduced pressure, and the residue was dissolved in methanol (30 cm^3). The methanol solution was diluted with water (1 dm^3) and applied on a small column (ϕ 3cm×20 cm) of SP-Sephadex C-25. The adsorbed complex was eluted with 1 mol dm^{-3} NaClO$_4$, and the eluate was concentrated in a desiccator over P_4O_{10} to give yellow-orange crystals. The crystals were filtered, washed with a mixture (20 cm^3) of methanol and diethyl ether (1 : 1), and air-dried. Yield: 200 mg (72%). Found: C, 30.04; H, 5.80; N, 5.35%. Calcd for $C_{14}H_{34}N_2O_7P_4ClCo$: C, 29.99; H, 6.11; N, 5.00%. The complex is soluble in methanol and acetonitrile.

Optical Resolution of [Co(CO$_3$)(dmpe)$_2$]+. One g of [Co(CO$_3$)(dmpe)$_2$]ClO$_4$·1.5NaClO$_4$·H$_2$O in water (1 cm^3) was charged on the top of a column (ϕ 3 cm×30 cm) of SP-Sephadex C-25, and the complex was eluted with an aqueous solution of 0.1 mol dm^{-3} disodium (−)-di-*O*-benzoyltartrate. No resolution of the complex was achieved by this method. The yellow eluate was collected and concentrated to ca. 20 cm^3 under reduced pressure. Excess disodium (−)-di-*O*-benzoyltartrate was removed by chromatography with a column (ϕ 2.5 cm×30 cm) of Toyopearl TSK-GEL and an eluent water. The eluate was evaporated to dryness under reduced pressure, and the residue was dissolved in ethanol (20 cm^3). On addition of diethyl ether (20 cm^3) the solution gave a yellow precipitate. It was recrystallized three times from a mixture of ethanol and diethyl ether (1 : 4). Yield: 36 mg. The product was dissolved in water and the solution was applied on a column (ϕ 1.5 cm×10 cm) of SP-Sephadex C-25. The column was washed with water, and then the complex was eluted with 0.1 mol dm^{-3} NaClO$_4$. The eluate was concentrated to a small volume under reduced pressure, and the concentrate was used for CD measurements. The complex concentration was determined by reference to the ε values of the racemate.

Results and Discussion

The ease of preparation of [Co(L)(dmpe)$_2$]$^{n+}$ from *trans*-[Co(Cl or Br)$_2$(dmpe)$_2$]$^+$ and a bidentate ligand L differs appreciably by the kind of L. Reactions of *trans*-[Co(Cl or Br)$_2$(dmpe)$_2$]$^+$ with acac, CO_3^{2-}, $C_2O_4^{2-}$ or dtc proceeded smoothly at room temperature and the complexes were obtained in 70—90% yields, while those with gly or *S*-ala did not take place even at 50 °C and resulted in decomposition of the *trans*-dihalogeno complex to cobalt(II) species at a higher temperature. The gly and *S*-ala complexes were obtained in a poor yield, 18 and 10%, respectively by the reactions in the presence of active charcoal. The *trans*-[Co(Cl or Br)$_2$(dmpe)$_2$]$^+$ complex did not react with more bulky (*S*)-proline under similar conditions. The [Co(en)(dmpe)$_2$]$^{3+}$ complex is also obtained in a poor yield (18%) by a similar reaction with en.[1] The poor yield of [Co(L)(dmpe)$_2$]$^{n+}$ in which L has an amino donor group may be attributable to instability of the complex shown later.

The *trans*-[Co(Cl or Br)$_2$(dmpe)$_2$]$^+$ complex afforded only *trans*-[CoX$_2$(dmpe)$_2$]$^+$ by reactions with MX (M=Na$^+$ or K$^+$, X=CN$^-$, NCO$^-$ or NCS$^-$) at room temperature. Attempts to prepare the corresponding cis isomers were unsuccessful. The reaction of *cis*-[CoCl$_2$(dmpe)$_2$]$^+$ [4] with CN$^-$ took place easily at 0 °C, but only the trans isomer was formed, no fraction indicative of the cis isomer being obtained in column chromatography. The reactions with NCO$^-$ and NCS$^-$ proceeded hardly at 0 °C, and yielded the trans isomer at a higher temperature. Since cis-[CoX$_2$(dmpe)$_2$]$^+$ (X=Cl, Br) can be prepared from [Co(CO$_3$)(dmpe)$_2$]$^+$ by treating with HX at 0 °C,[4] no formation of cis-isomers of these pseudo-halogeno complexes would be due to kinetic reasons. When [Co(CO$_3$)(dmpe)$_2$]$^+$ is treated with HClO$_4$, instead of HX, *trans*-[Co(H$_2$O)$_2$(dmpe)$_2$]$^{3+}$ is formed.[3] For the dinitro complex, neither cis nor trans isomer was formed by the

Table 1. Absorption Spectral Data of $[Co(L)(dmpe)_2]^{n+}$

Complex	$\tilde{\nu}_1/10^3\,cm^{-1}$ (log ε)	$\tilde{\nu}_2/10^3\,cm^{-1}$ (log ε)	$\tilde{\nu}_2-\tilde{\nu}_1$	Solvent
$[Co(dtc)(dmpe)_2]^{2+}$	22.5(2.85)	25.1(3.02)	2600	CH_3CN
$[Co(CO_3)(dmpe)_2]^{+}$	23.5(2.96)	27.1(2.98)	3600	CH_3OH
$[Co(C_2O_4)(dmpe)_2]^{+}$	23.9(2.90)	27.4(2.93)	3500	CH_3OH
[Co(*S*-ala)$(dmpe)_2]^{2+}$	24.1(2.93)	28.4(3.00)	4300	H_2O
$[Co(gly)(dmpe)_2]^{2+}$	24.3(2.92)	28.4(3.01)	4100	H_2O
$[Co(en)(dmpe)_2]^{3+}$	24.8(2.86)	29.4(2.84)	4600	H_2O

reaction of *trans*-$[Co(Cl\text{ or }Br)_2(dmpe)_2]^{+}$ with $NaNO_2$. The result will be attributable to steric interactions between the NO_2^- and dmpe ligands as suggested by Miskowski et al.[6] for the corresponding *cis*-1,2-bis(diphenylphosphino)ethylene complex. The $[CoX_2(diars)_2]^{n+}$ (diars=*o*-phenylenebis(dimethylarsine)) complexes have somewhat different properties in chemical reactions. Although *cis*-$[CoCl_2(diars)_2]^{+}$ yields *trans*- $[Co(NCS)_2(diars)_2]^{+}$ by the reaction with KNCS,[7] the reaction of $[Co(CO_3)(diars)_2]^{+}$ with $HClO_4$ affords *cis*-$[Co(H_2O)_2(diars)_2]^{3+}$, from which various *cis*-$[CoX_2(diars)_2]^{n+}$ ($X=Cl^-$, NO_2^-, NO_3^-, CH_3CN) can be derived.[8]

Geometrical structures of $[CoX_2(dmpe)_2]^{n+}$can be easily assigned by comparing the ^1H NMR spectra with those of *cis*- and *trans*-$[CoX_2(dmpe)_2]^{+}$ ($X=Cl^-$, Br^-).[3]

The $C_2O_4^{2-}$ and dtc complexes appear to have stability similar to that of the acac complexes.[1] The complexes in water in the absence or presence of excess NaCl remain unchanged by heating (60—70 °C). The CO_3^{2-} complex is also stable in hot water, but gives a small amount of *trans*-$[CoCl_2(dmpe)_2]^{+}$ in the presence of excess NaCl by prolonged heating. On the other hand, the gly and *S*-ala complexes decompose to cobalt(II) species or yield *trans*-$[CoCl_2(dmpe)_2]^{+}$ under the same conditions. However, these complexes seem to be more stable than $[Co(en)(dmpe)_2]^{3+}$.[1] Thus it can be concluded qualitatively that $[Co(L)(dmpe)_2]^{n+}$ (L=a bidentate ligand) decreases the stability in the order acac, $C_2O_4^{2-}$, dtc > CO_3^{2-} ≫ gly, *S*-ala > en; the complexes containing an amino group are less stable than those with O or S donor atoms.

The NCS^- and NCO^- ligands are an ambidentate ligand to be able to coordinate to a metal ion through N or S, and N or O, respectively. In the IR spectrum *trans*-$[Co(NCS)_2(dmpe)_2]^{+}$ shows the C-S stretching band at 839 cm^{-1}, indicating the N-bonding of NCS^-.[9] Related complexes *cis*(NCS,NCS),*trans*(P,P)- and *trans* (NCS,NCS), *cis* (P,P)-$[Co(NCS)_2\{NH_2CH_2CH_2P(C_6H_5)_2\}_2]^{+}$[10] and *trans*-$[Co(NCS)_2\{cis\text{-}(C_6H_5)_2PCHCHP(C_6H_5)_2\}_2]^{+}$[6] have also been reported to have the N-bonding of NCS^-. For the coordination mode of NCS^-, Norbury et al.[11,12] pointed out that the NCS^- ligand in a hard metal complex containing π-acceptor ligands tends to coordinate through the S atom. A cobalt(III)-phosphine complex should be the case, but no S-bonding of NCS^- has been reported except for the so-called cobaloxime complexes.[13] The preference of N-bonding may come from a steric factor. The Co-NCS moiety is usually nearly linear (∠CoNC=170—180°), whereas the Co-SCN moiety is bent (∠CoSC=≈105°).[10,11] The atomic (ionic) radius of N should be much smaller than that of S. Thus the S-bonding of NCS^- will require greater space and will be unfavorable in a complex containing bulky ligands such as tertiary phosphines. The coordination mode of NCO^- in *trans*-$[Co(NCO)_2(dmpe)_2]^{+}$ could not be assigned from the IR spectrum, but will be the N-bonding, since the complex shows the absorption spectrum very similar to that of *trans*-$[Co(NCS)_2(dmpe)_2]^{+}$ in the first d-d band region (vide post).

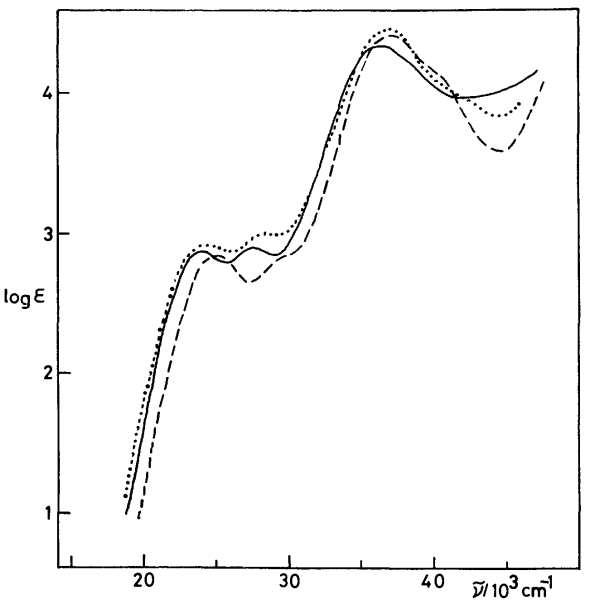

Fig. 1. Absorption spectra of $[Co(C_2O_4)(dmpe)_2]^{+}$ in methanol (——), $[Co(gly)(dmpe)_2]^{2+}$ in water (·····), and $[Co(en)(dmpe)_2]^{3+}$ in water (----).

Absorption spectra of $[Co(L)(dmpe)_2]^{n+}$ ($L=C_2O_4^{2-}$, gly, en) are shown in Fig. 1 and the data in Table 1. In a previous paper,[1] we assigned the band at 24750 cm^{-1} and the shoulder at 29400 cm^{-1} of the en complex to the first and the second d-d bands, respectively. The $C_2O_4^{2-}$ and gly complexes give two d-d bands similar to those of the en complex. The spectrum of the CO_3^{2-} complex is quite similar to that of the $C_2O_4^{2-}$ complex. These d-d bands shift to the low energy side with an increase in number of the O donor atom according to

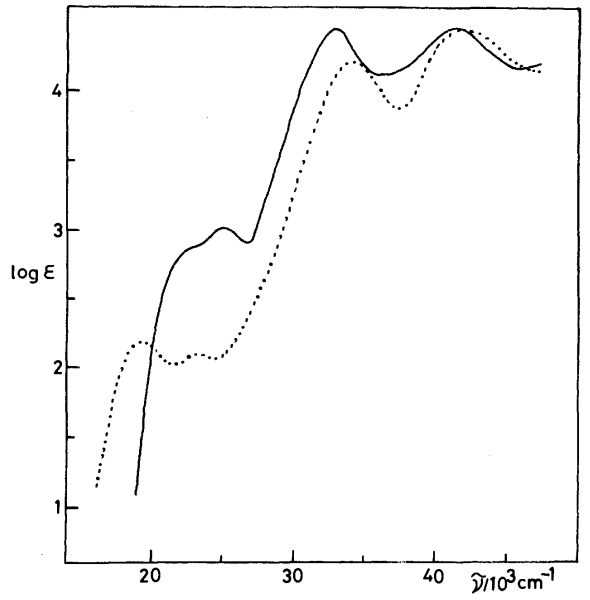

Fig. 2. Absorption spectra of $[Co(dtc)(dmpe)_2]^{2+}$ in acetonitrile (——) and $[Co(dtc)(en)_2]^{2+}$ in water (·····).

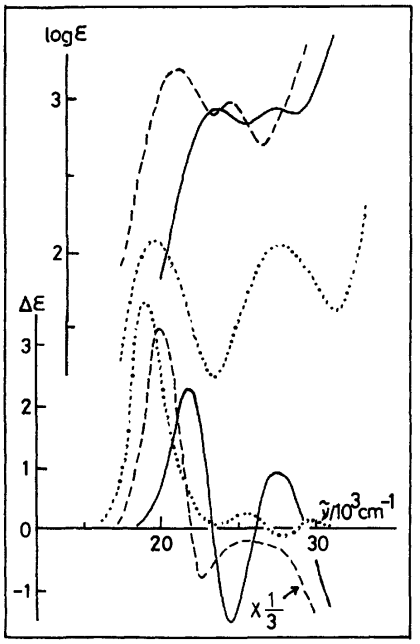

Fig. 3. Absorption and CD spectra of $(+)_{589}$-$[Co(CO_3)(dmpe)_2]^+$ in methanol (——), $(+)_{589}$-$[Co(CO_3)(diars)_2]^+$ in methanol (----),[16] and $(+)_{589}$-$[Co(CO_3)(en)_2]^+$ in water (·····).

the spectrochemical series.[14] However, the extent of shift is larger for the second d-d band than that for the first d-d band. As a result, the energy separation between the first and the second d-d bands becomes small with an increase in number of the O donor atom (Table 1). For $[Co(L)(en)_2]^{n+}$, the values of the energy separation are much larger than those of the dmpe complexes and are nearly the same among the L=en (8100 cm^{-1}), gly (8400 cm^{-1}), and $C_2O_4^{2-}$ (8100 cm^{-1}) complexes.[14]

The absorption spectrum of $[Co(dtc)(dmpe)_2]^{2+}$ is compared with that of $[Co(dtc)(en)_2]^{2+}$ [15] in Fig. 2. The bands at 19600 cm^{-1} ($\log\varepsilon$=2.21) and 23300 cm^{-1} ($\log\varepsilon$=2.11) of the en complex have been assigned to the first and the second d-d bands, respectively on the basis of the magnetic circular dichroism study.[15] The energy separation between these two bands (3700 cm^{-1}) is much smaller than that of $[Co(en)_3]^{3+}$ (8100 cm^{-1}), indicating largely reduced interelectronic repulsions between the ligand field levels. It is known that many dtc complexes show large reduction of the interelectronic repulsion.[15] Thus the shoulder at 22500 cm^{-1} and the band at 25100 cm^{-1} of $[Co(dtc)(dmpe)_2]^{2+}$ can be assigned to the first and the second d-d bands, respectively, although the energy separation between them is extremely small (2600 cm^{-1}) as a cobalt(III) complex.

Absorption and circular dichroism (CD) spectra of $(+)_{589}$-$[Co(CO_3)(dmpe)_2]^+$ are compared with those of the corresponding diars[16] and en[17] complexes in Fig. 3. The decreasing order in energy of the first d-d band is dmpe (23500 cm^{-1})>diars (21000 cm^{-1})> en (19600 cm^{-1}), while that of the second d-d band en (27900 cm^{-1})>dmpe (27100 cm^{-1})>diars (25000 cm^{-1}). From the data the ligand field splitting parameter (Δ) was estimated by assuming C=4B; 24400 cm^{-1} for dmpe, 22000 cm^{-1} for diars, and 21680 cm^{-1} for en complexes. The Δ values of the en and diars complexes are similar. However, en is a primary diamine and its ligand field strength is known to be much stronger than that of a tertiary diamine *N,N,N',N'*-tetramethylethylenediamine corresponding to dmpe and diars.[18] Thus it can be concluded that the spectrochemical series for group 5B elements is P>As>N. The same conclusion has been obtained by spectral studies of *trans*-$[CoCl_2(L)_2]^+$ (L=en, dmpe, 1,2-bis(dimethylarsino)ethane).[19]

The CD strength of $(+)_{589}$-$[Co(CO_3)(dmpe)_2]^+$ in Fig. 3 appears to be weak as compared with those of the en and diars complexes. It is not clear whether the weak strength is attributable to incomplete resolution. The $(+)_{589}$-$[Co(CO_3)(dmpe)_2]^+$ isomer exhibits a positive (21800 cm^{-1}, $\Delta\varepsilon$=+2.29) and a negative (24400 cm^{-1}, $\Delta\varepsilon$=−1.55) CD peaks in the first d-d band region. The absolute configurations of $(+)_{589}$-$[Co(CO_3)(en)_2]^+$ [17] and $(+)_{589}$-$[Co(CO_3)(diars)_2]^+$ [16] have been reported to be Λ. From a comparison of three CD spectra in Fig. 3, the $(+)_{589}$-isomer of the dmpe complex can also be assigned to the Λ configuration. The dmpe complex shows a relatively strong negative CD band in the first d-d band region. Similar strong negative bands have been observed for cobalt(III)-phosphine complexes such as Λ-$[Co(en)_n(dmpe)_{3-n}]^{3+}$ (n=1, 2)[1] or Λ-$[Co(en)_n(edmp)_{3-n}]^{3+}$ (n=0, 1; edmp=$NH_2CH_2CH_2P(CH_3)_2$).[20]

Figure 4 shows absorption spectra of *trans*-$[CoX_2(dmpe)_2]^{n+}$(X=H_2O, CN^-, NCO^-, NCS^-) and Table 2 lists the data. For *trans*-$[Co(H_2O)_2(dmpe)_2]^{3+}$, the

a) Shoulder. b) 0.5 mol dm^{-3} $HClO_4$.

shoulder around 20000 cm^{-1} and the band at 23300 cm^{-1} can be assigned to two components of the splitting first d-d band, and the band at 27300 cm^{-1} to the second d-d band, since *trans*-$[Co(H_2O)_2(en)_2]^{3+}$ shows similar d-d bands with three peaks at 18200, 22500, and 29000 cm^{-1}.[21] The *trans*-$[Co(CN)_2(dmpe)_2]^+$ complex shows a single d-d band assignable to the first d-d band. The band is rather broad and appears to involve another band. However, it remains unknown whether the band consists of two components of the splitting first d-d band or of the first and second d-d bands with a very small energy difference. The *trans*-$[Co(CN)_2(en)_2]^+$ complex shows a clear splitting in the first d-d band, giving a shoulder around 21000 cm^{-1} and a band at 24400 cm^{-1}.[22] Neither *trans*-$[Co(NCO)_2(dmpe)_2]^+$ nor *trans*-$[Co(NCS)_2(dmpe)_2]^+$ shows splittings on the first d-d band. The *trans*-$[Co(NCS)_2(en)_2]^+$ complex does not exhibit splitting either, giving a single first d-d band at 19700 cm^{-1}.[23] The NCO^- complex gives the first d-d band at nearly the same position as that of the NCS^- complex, and can be assigned to the N-bonding isomer for NCO^-, since the NCS^- ligand in the latter complex has been indicated to coordinate through the N atom by the IR spectrum (vide ante). The energies of the first d-d bands of the NCO^- and NCS^- complexes are rather lower than that of the aqua complex, although the rankings of NCO^-, NCS^- and H_2O are similar in the spectrochemical series.[14] The phosphine[6] and arsine[24] complexes of cobalt(III) containing NCS^- bonded through the N atom have been reported to give the first d-d band at a lower wavenumber than that expected from the ranking of NCS^- in the spectrochemical series.

(Received September 25, 1986)

Both racemic and optically active $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ (bpdo=2,2′-bipyridine *N,N′*-dioxide) were found to crystallize in the $lel_2 \cdot ob(\Delta(\lambda\lambda\delta), \Lambda(\delta\delta\lambda))$ isomer. The complexes isomerized spontaneously to the $lel_3(\Delta(\lambda\lambda\lambda), \Lambda(\delta\delta\delta))$ isomer upon dissolution in water with a rapid absorption spectral change, and then racemized ($\Delta \rightleftarrows \Lambda$) slowly. The rate constant for isomerization was 5.33×10^{-3} s^{-1} at 303.2 K, and that for racemization 1.93×10^{-4} s^{-1} at the same temperature. An intramolecular conformational inversion of the bpdo chelate ring ($\delta \rightleftarrows \lambda$) and an intramolecular twist mechanism were proposed for the isomerization and the racemization of the complex, respectively. Neither isomerization nor racemization was observed for $[Cr(en)(bpdo)_2]^{3+}$ in aqueous solution.

2,2′-Bipyridine *N,N′*-dioxide (bpdo) forms a skew seven-membered chelate ring upon coordination to a metal ion.[1,2] The skew chelate ring of bpdo was confirmed by X-ray analysis of $[La(bpdo)_4](ClO_4)_3$.[3] Since the skew conformation can exist in a pair of enantiomers, δ and λ as shown in Fig. 1, a tris-bpdo complex has four possible racemic pairs of diastereomers. By analogy with the stereoisomerism in $[M(en)_3]^{n+}$ (en= ethylenediamine),[4] these diastereomers can be designated as lel_3 ($\Delta(\lambda\lambda\lambda)$, $\Lambda(\delta\delta\delta)$), $lel_2 \cdot ob(\Delta(\lambda\lambda\delta), \Lambda(\delta\delta\lambda))$, $lel \cdot ob_2(\Delta(\lambda\delta\delta), \Lambda(\delta\lambda\lambda))$, and $ob_3(\Delta(\delta\delta\delta), \Lambda(\lambda\lambda\lambda))$. Bertini et al. reported that the dominant isomer of $[M(bpdo)_3](PF_6)_2$ ($M=Co^{2+}$, Ni^{2+}) in acetonitrile will be either the lel_3 or ob_3 one from ^1H NMR studies.[5] They also suggested that a rapid chelate ring interconversion ($\delta \rightleftarrows \lambda$) seems unlikely because of the anticipated high barrier to chelated bpdo interconversion.[5]

In previous papers, we reported that $[Cr(bpdo)_3]^{3+}$ [6] and $[Cr(mbdo)_3]^{3+}$ [7] (mbdo=3,3′-dimethyl-2,2′-bipyridine *N,N′*-dioxide) give one and three racemic pairs of diastereomers, respectively, and that the former complex racemizes spontaneously in aqueous solution. These results indicate that the bpdo chelate ring is flexible and changes its conformation ($\delta \rightleftarrows \lambda$) very easily. On the other hand, the mbdo chelate ring can not change its conformation because of the steric hindrance due to the methyl groups.[7] Recently, we also found that both racemic and $(-)_{589}$-$[Cr(acac)(bpdo)_2](ClO_4)_2 \cdot H_2O$ (acac=acetylacetonate(1−)) crystallize in the lel_2 ($\Delta(\lambda\lambda)$, $\Lambda(\delta\delta)$) isomer, but isomerize spontaneously to the $lel \cdot ob(\Delta(\lambda\delta), \Lambda(\delta\lambda))$ isomer and racemize in aqueous solution.[8] From kinetic studies, the isomerization of $[Cr(acac)(bpdo)_2]^{2+}$ was suggested to occur by intramolecular conformational inversion ($\delta \rightleftarrows \lambda$) of the bpdo chelate ring.[8] This result indicates that in some metal complexes, a favorable bpdo chelate ring conformation in a crystal is different from that in solution. Such a conformational change due to environment is known for $[Cr(en)_3]^{3+}$,[9] but the kinetics of conformational inversion of the en chelate ring can not be studied because of the very rapid interconversion in solution. This paper reports spontaneous isomerization of the tris-bpdo chromium(III) complex in aqueous solution sudied by absorption and circular dichroism (CD) spectroscopy. This paper also reports the results of reinvestigation on racemization of this complex.[6]

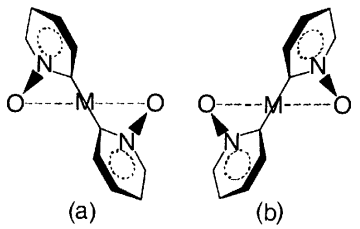

Fig. 1. The conformation of bpdo, (a) δ- and (b) λ-skew form.

Experimental

Materials. The bpdo ligand was prepared according to the literature.[10] The complexes, $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ and $[Cr(en)(bpdo)_2](ClO_4)_3 \cdot 1.5H_2O$ were prepared and resolved by the method reported previously.[6]

Kinetic Runs. Both racemic and optically active $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution show a rapid absorption spectral change. The change in absorbance at 620 nm was continuously recorded on a Shimadzu MPS-50L spectrophotometer in the temperature range of 15.0 to 35.0 °C using a 1 cm quartz cell with a cell jacket to maintain the temperature constant within ±0.1 °C. The pH and ionic strength (I=0.1) of solutions were adjusted with an aqueous solution of NaCl-HCl. Because of insufficient solubility of $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in water for the measurement (ca. 1.5 mmol dm^{-3} at 20 °C), the complex was converted into the chloride by the following method. A mixture of a Dowex 1-x8 anion exchanger in the chloride form (1 g) and an aqueous solution of NaCl (0.1 mol dm^{-3}, 20 cm^3) was kept at a constant temperature in a water bath. To the mixture, the finely ground complex (ca. 0.13 g) was added. After being stirred for 1 min, the Dowex anion exchanger was filtered off using a glass filter immersed in the same water bath. The complex concentrations were in the range of 5.0 to 7.6 mmol dm^{-3}. The rate of spectral change obeyed the first order kinetic law and the observed rate constant (k_{obsd}) is expressed as follows:

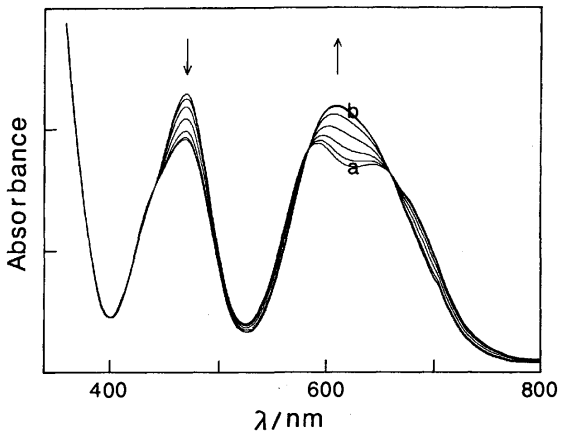

Fig. 2. Absorption spectral change in the visible region of $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution at 15.0°C. Trends of the spectral change with time are shown by arrows. Reaction time (min): 2.5(a), 4, 8, 16, 32, 64, ∞(b).

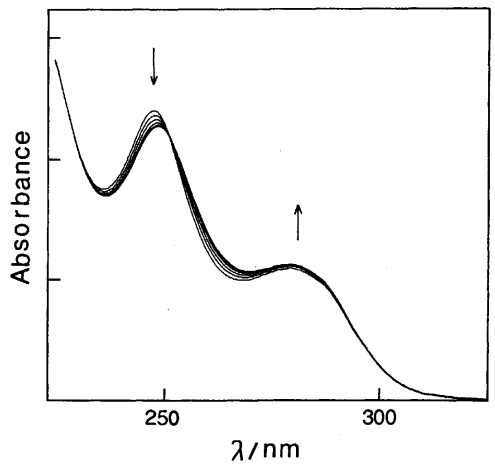

Fig. 3. Absorption spectral change in the ultraviolet region of $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution at 18.0°C. Reaction time (min): 2, 4, 8, 16, 32, ∞.

$$k_{obsd} = -\ln[(A_t - A_\infty)/(A_0 - A_\infty)]/t,$$

where A's are absorbances at the time denoted by suffixes. For a comparison, the measurements were also carried out for the perchlorate of the complex without exchanging it into the chloride. The rate observed for the perchlorate agreed with that for the chloride within the experimental error.

A decrease in optical activity at 589 nm of $(-)_{589}$-$[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution was observed by similar procedures as described above using a Union PM-101 digital polarimeter and a 5 cm quartz cell. The perchlorate of the complex was used for the measurements. The temperatures and the complex concentrations were in the range of 25.0 to 45.0 °C and 1.0 to 1.5 mmol dm^{-3}, respectively. The complex lost the optical activity in two steps with different rates, the first rapid and the subsequent slow steps (vide post). In the latter step, the rate of decrease obeyed the first order kinetic law and the observed rate constant (k_{obsd}) is also expressed by the above equation, where A's are degrees of optical rotation.

For $[Cr(en)(bpdo)_2](ClO_4)_3$, the same experiments were carried out as those for $[Cr(bpdo)_3]^{3+}$ in the dark so as to avoid photoinduced reactions.[6] Neither absorption spectral change nor loss of optical activity was observed in acidic solution. However, the complex in neutral aqueous solution showed a slight decrease in absorbance (< 1% at 530 nm) after 2 h. The resulting solution contained a very small amount of a hydrolyzed product as detected by column chromatography.

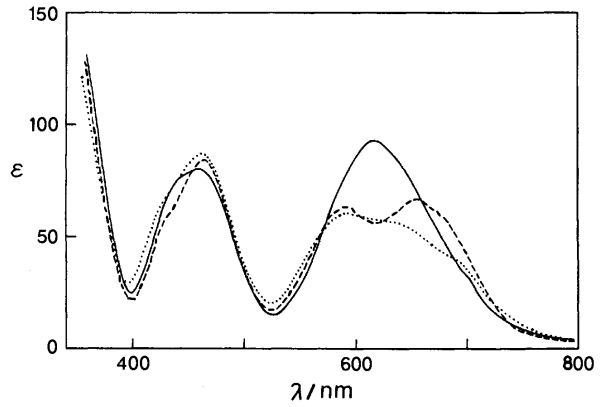

Fig. 4. Absorption spectra of three diastereomers of $[Cr(rac\text{-}mbdo)_3]^{3+}$ in the visible region in aqueous solution; *lel*$_3$ (——), *lel*$_2$·*ob* (----), and *lel*·*ob*$_2$ (·····).[7]

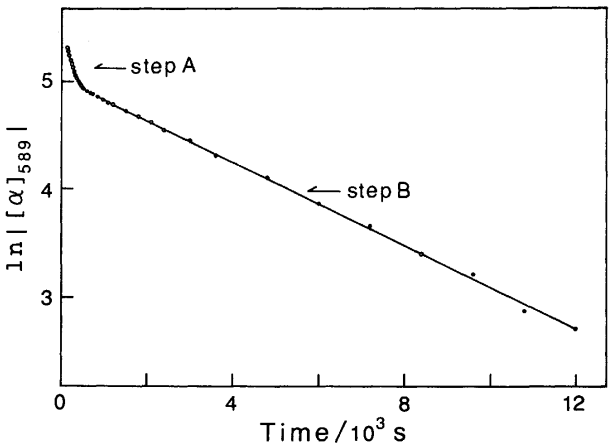

Fig. 5. Decrease in optical rotation (at 589 nm) of $(-)_{589}$-$[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ with time in aqueous solution at 30.0°C. [Complex]=1.17×10^{-3} mol dm^{-3}; I=0.1.

Other Measurements. Absorption and circular dichroism spectra were recorded on a Shimadzu MPS-50L spectrophotometer and a Jasco J-500 spectropolarimeter, respectively. Optical rotations were measured with a Union PM-101 digital polarimeter.

Results and Discussion

Properties of the Complexes. Quagliano et al. first prepared bpdo complexes with a variety of metal ions including chromium(III).[2] As we reported previously,[6] $[Cr(bpdo)_3]^{3+}$ gives only one racemic pair of diastereomers of four possible ones. No indication for the formation of the other isomers was found by SP-Sephadex column chromatography. The optical resolution of the complex[6] was achieved by a chemical

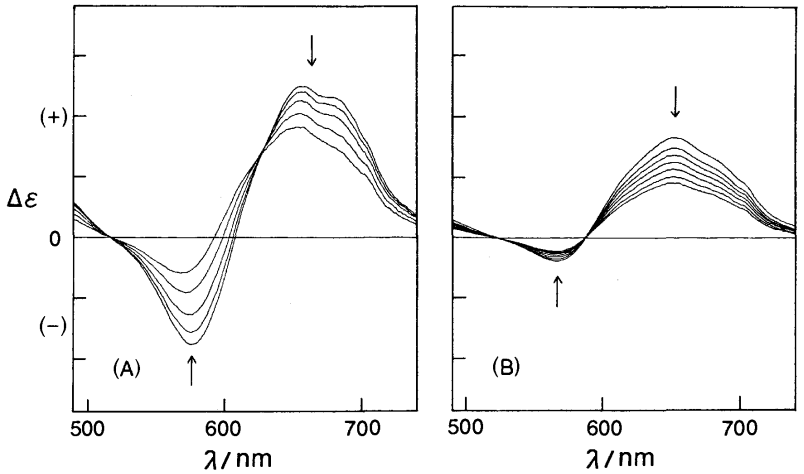

Fig. 6. CD spectral change in the region of the first absorption band of $(-)_{589}$-$[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution at 15.0°C. Trends of the spectral change with time are shown by arrows. Reaction time (min): (A): 2.5, 4, 7, 13, 25; (B): 50, 80, 110, 140, 170, 200, 230.

method using $(+)_{589}$-[Co(L-cysteinesulfinato(2−)-$S,N)_3]^{3-}$.[11] The optically active complex loses gradually its activity in aqueous solution at room temperature.

Both racemic and optically active $[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution show a rapid absorption spectral change with isosbestic points at 660, 584, 442, and 251 nm as shown in Figs. 2 and 3. The complexes are not hydrolyzed during the spectral change, no hydrolyzed product such as $[Cr(bpdo)_2(H_2O)_2]^{3+}$ [12] being detected on column chromatograms. These results suggest that the spectral change is caused by isomerization between two isomers of four possible ones of the complex. As Fig. 2 shows, the splitting first absorption band ($^4T_{2g} \leftarrow {}^4A_{2g}$) around 610 nm becomes a single peak with passage of time. All of the possible isomers of the complex have a $[CrO_6]$ chromophore in which the coordinated oxygen atoms are the same kind. However, actual symmetries of the lel_3 and ob_3 isomers will be D_3, and those of the $lel_2 \cdot ob$ and $lel \cdot ob_2$ isomers will lower to C_2. In the fields of D_3 and C_2 symmetries, the first absorption band of an octahedral parentage ($^4T_{2g}$) will split into two ($^4A_1$, ^4E) and three (2^4A, ^4B) components, respectively.[13] Figure 4 shows the absorption spectra of the isomers of $[Cr(rac\text{-mbdo})_3]^{3+}$.[7] The complex gives three racemic pairs of diastereomers, the lel_3, $lel_2 \cdot ob$, and $lel \cdot ob_2$ isomers. The ob_3 isomer will not be formed because of its extremely crowded structure.[6,7] By comparing the spectra in Figs. 2 and 4, it is seen that spectra a and b of the bpdo complex quite resemble those of the $lel_2 \cdot ob$ and lel_3 isomers of the mbdo complex, respectively. Thus the isomers corresponding to spectra a and b in Fig. 2 can be assigned to have the $lel_2 \cdot ob$ and lel_3 structures, respectively, and it is concluded that the spectral change in the bpdo complex is caused by isomerization of the complex, $lel_2 \cdot ob \rightleftarrows lel_3$. In the ultraviolet region, the spectra of the

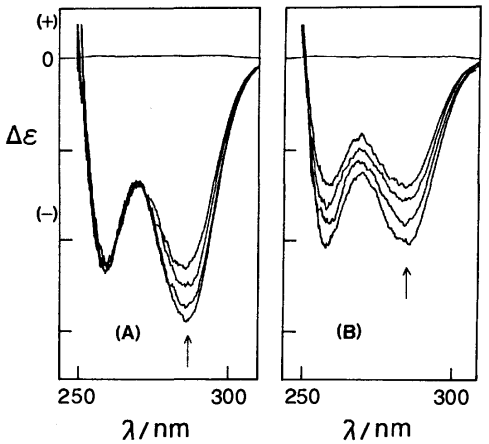

Fig. 7. CD spectral change in the ultraviolet region of $(-)_{589}$-$[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ in aqueous solution at 18.0°C. Reaction time (min): (A): 2, 5, 11, 23; (B): 50, 80, 110, 140.

three isomers of the mbdo complex are similar.[7] The spectral change in the bpdo complex is also very small as shown in Fig. 3. Molecular models indicate that the $lel_2 \cdot ob$ isomer of the bpdo complex isomerizes to the lel_3 one without difficulty and vice versa, since the bpdo chelate ring is flexible and changes its comformation, $\delta \rightleftarrows \lambda$, very easily.[6-8]

As shown in Fig. 5, an aqueous solution of $(-)_{589}$-$[Cr(bpdo)_3](ClO_4)_3 \cdot 1.5H_2O$ loses the optical activity in two steps with different rates, the first rapid (step A) and the subsequent slow (step B) steps. In the former step, the decrease in activity accompanies the absorption spectral change stated above, while no spectral change was observed in the latter step. These results suggest that step A involves the isomerization reaction between the diastereomers, $lel_2 \cdot ob \rightleftarrows lel_3$, and step B the racemization reaction between the enantiomers, $\Delta \rightleftarrows \Lambda$, of the complex. Figures 6 and 7 show the CD

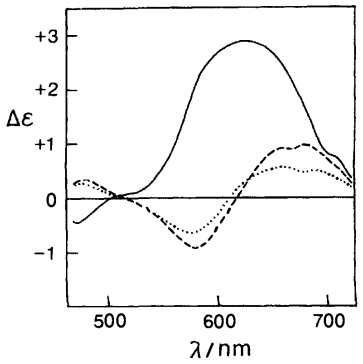

Fig. 8. CD spectra of three diastereomers of $(-)_{589}$-[Cr(rac-mbdo)$_3$]$^{3+}$ in the region of the first absorption band in aqueous solution; *lel*$_3$($\Lambda(\lambda\lambda\lambda)$) (——), *lel*$_2$·*ob*($\Lambda(\lambda\lambda\delta)$) (----), and *lel*·*ob*$_2$($\Lambda(\delta\lambda\lambda)$) (·····).[7]

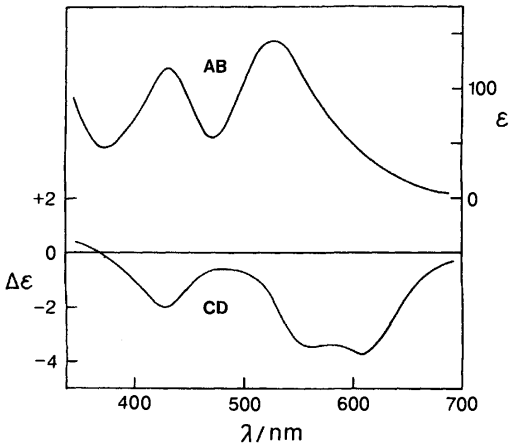

Fig. 9. Absorption and CD spectra in the visible region of $(+)_{589}$-[Cr(en)(bpdo)$_2$](ClO$_4$)$_3$·H$_2$O in 10^{-2} mol dm^{-3} hydrochloric acid.

spectral change of the $(-)_{589}$-isomer in the region of the first absorption band and in the ultraviolet region, respectively. In both regions, the spectrum varies in two steps. In the first rapid step (Figs. 6 (A) and 7 (A)), the spectrum shows a change in both magnitude and pattern and accompanies the absorption spectral change, while in the subsequent slow step (Figs. 6 (B) and 7 (B)), it only shows a decrease in magnitude and neither change in CD pattern nor in absorption spectrum was observed. In the region of the first absorption band, the complex exhibits two CD components of similar strength with opposite signs at the beginning of the reaction, but the negative component diminishes more rapidly than the positive component does. Figure 8 shows the CD spectra of the three isomers of $(-)_{589}$-[Cr(*rac*-mbdo)$_3$]$^{3+}$, *lel*$_3$($\Lambda(\lambda\lambda\lambda)$), *lel*$_2$·*ob*($\Lambda(\lambda\lambda\delta)$), and *lel*·*ob*$_2$($\Lambda(\delta\lambda\lambda)$), in the region of the first absorption band.[7] Both isomers of the *lel*$_2$·*ob* and *lel*·*ob*$_2$ show two CD components of similar strength with opposite signs, while the *lel*$_3$ one exhibits only one positive CD component. The CD spectra of these isomers suggest that the CD spectral change of the bpdo complex in the first rapid step is caused by isomerization of the complex, *lel*$_2$·*ob*($\Lambda(\lambda\lambda\delta)$)$\rightleftarrows$*lel*$_3$($\Lambda(\lambda\lambda\lambda)$). Although it is not clear from the CD spectra whether the initial isomer of the bpdo complex is *lel*$_2$·*ob* or *lel*·*ob*$_2$, it is assigned to the *lel*$_2$·*ob* isomer from the previous absorption spectral and kinetic studies (vide post). Thus it is concluded that $(-)_{589}$-[Cr(bpdo)$_3$](ClO$_4$)$_3$·1.5H$_2$O crystallizes in the $\Lambda(\lambda\lambda\delta)$(*lel*$_2$·*ob*) structure and rapidly isomerizes in aqueous solution to the $\Lambda(\lambda\lambda\lambda)$(*lel*$_3$) structure and then slowly racemizes, $\Lambda \rightleftarrows \Lambda$.

The [Cr(en)(bpdo)$_2$]$^{3+}$ complex[6] gives only one pair of diastereomers which was resolved by a chemical method using $(-)_{589}$-[As(1,2-benzenediolate(2−))$_3$]$^-$,[14] although the complex can have three possible racemic pairs of diastereomers, *lel*$_2$, *lel*·*ob*, and *ob*$_2$. Both racemic and $(+)_{589}$-[Cr(en)(bpdo)$_2$](ClO$_4$)$_3$ show no absorption and CD spectral changes in acidic solution (pH ca. 2) at room temperature, but they are slowly hydrolyzed in neutral aqueous solution (see Experimental). The slow loss of optical activity of the complex described in our previous paper[6] is attributable to the hydrolysis of the complex. Figure 9 shows the absorption and CD spectra of $(+)_{589}$-[Cr(en)(bpdo)$_2$]$^{3+}$ in the visible region recorded in this work. In the region of the first absorption band, the complex exhibits two positive CD components. In our previous work, the CD component on the low energy side could not be observed because it lies outside the region measurable by our instrument.[6] The corrected CD spectral data of the $(+)_{589}$-isomer in the visible region are as follows in $\tilde{\nu}$/cm^{-1} ($\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1}); 16500 (−3.72), 17860 (−3.49), and 23360 (−1.99). The absolute configuration of the complex including chirality of bpdo could not be assigned from the CD spectrum, because its pattern is quite different from those of analogous complexes.[6] However, examination with molecular models indicates that in the *lel*·*ob* structure of the complex, the amino or methylene protons of the puckered en chelate ring comes very close to the pyridine ring of the *ob*-form bpdo ligand, whereas there is no such proximity among the ligands in the *lel*$_2$ structure. The *ob*$_2$ isomer will not be formed because of its extremely crowded structure. Thus [Cr(en)(bpdo)$_2$](ClO$_4$)$_3$ will be stabilized in the *lel*$_2$ structure and shows no isomerization in solution. The complex does not racemize either under the same conditions as for [Cr(bpdo)$_3$]$^{3+}$ and [Cr(acac)(bpdo)$_2$]$^{2+}$ described below. Although the reason for this remains unknown at the moment, racemization of the bpdo complex seems to take place with conformational inversion of the bpdo chelate ring, i.e. the isomerization of the complex. The stereoselective formation of *lel*$_2$-[Cr(en)(bpdo)$_2$]$^{3+}$ is in contrast to that of [Cr(acac)(bpdo)$_2$](ClO$_4$)$_2$ which was found to crystallize in the *lel*$_2$ isomer but isomerize to the *lel*·*ob* one and racemize in aqueous solution.[8] Molecular models indicate that

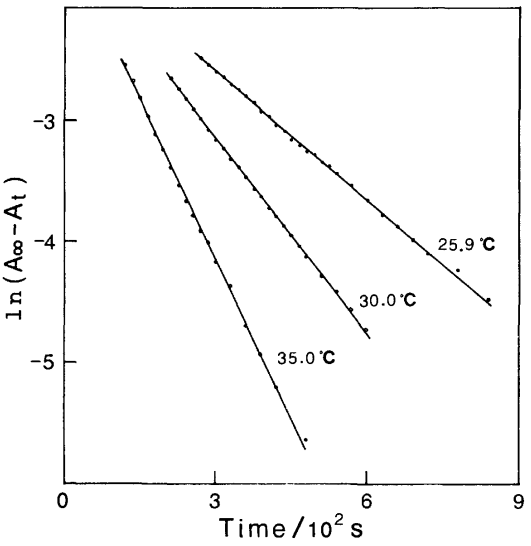

Fig. 10. Plots of $\ln(A_\infty - A_t)$ vs. time for change of absorbance (at 620 nm) of $[Cr(bpdo)_3]^{3+}$ in aqueous solution. [complex]=6.45×10^{-3} mol dm^{-3}; I=0.1.

there is no extreme proximity between the acac and bpdo ligands in these isomers. The difference in reactivity between the en and acac bis-bpdo complexes will be also attributable to such steric conditions. Recently, we found that the conformations of bpdo in mixed-ligand chromium(III) complexes are greatly influenced by other ligands in the complex.[6,8,15] For example, $[Cr(acac)_2(bpdo)]^+$ gives only a $lel(\Delta(\lambda), \Lambda(\delta))$ isomer,[8] whereas $[Cr(bpy)_2(bpdo)]^{3+}$ (bpy=2,2′-bipyridine) only an $ob(\Delta(\delta), \Lambda(\lambda))$ isomer.[15] Thus the bpdo chelate ligand changes its conformation very easily depending upon steric conditions in a complex.

Kinetics of Isomerization and Racemization of $[Cr(bpdo)_3]^{3+}$. The rate of isomerization of $[Cr(bpdo)_3]^{3+}$ in aqueous solution, $lel_2 \cdot ob \rightleftarrows lel_3$, was followed by monitoring the change in absorbance at 620 nm with time under the conditions described in Experimental part. As Fig. 10 shows, the rate of the spectral change obeyed the first order kinetic law for at least four half-lives, and the observed rate constant (k_{obsd}) was obtained from the slope of log ($A_\infty - A_t$) vs. time, where A's are absorbances at the time denoted by suffixes. The rate for the optically active complex agreed with that for the racemate within the experimental error. The values of k_{obsd} are listed in Table 1. Arrhenius treatment of log(k_{obsd}) vs. T^{-1} yielded an activation energy of (82.1±1.3) kJ mol^{-1} and Eyring treatment of log(k_{obsd}/T) vs. T^{-1} gave an activation enthalpy of (79.6±1.3) kJ mol^{-1} and an activation entropy of (−26.1± 4.3) J K^{-1} mol^{-1}. The rate was independent of concentrations of H^+ and the free ligand (bpdo). Hence it is suggested that the isomerization proceeds by an intramolecular mechanism. In a previous paper,[8] we have reported that $\Delta(\lambda\lambda)(lel_2)$-$[Cr(acac)(bpdo)_2]^{2+}$ isomerized to the $\Delta(\lambda\delta)(lel \cdot ob)$ isomer at a rate 3.31×10^{-3} s^{-1} (22.0 °C), and that the activation energy, enthalpy, and entropy values were 77.3 kJ mol^{-1}, 74.9 kJ mol^{-1}, and −38.5 J K^{-1} mol^{-1}, respectively. The rate and kinetic parameters of $[Cr(bpdo)_3]^{3+}$ are similar to those of $[Cr(acac)(bpdo)_2]^{2+}$ ($\lambda\lambda \rightleftarrows \lambda\delta$). Thus the isomerization reactions of these two complexes would proceed by the same mechanism, and the isomerization of $[Cr(bpdo)_3]^{3+}$ will not involve the reaction, $lel \cdot ob_2(\Delta(\lambda\delta\delta)) \rightleftarrows lel_3(\Delta(\lambda\lambda\lambda))$, in which simultaneous inversion of two bpdo chelate rings $\delta\delta \rightleftarrows \lambda\lambda$ takes place.

Our previous study on racemization of $[Cr(bpdo)_3]^{3+}$ in aqueous solution[6] was reinvestigated in this paper. The rate of loss of activity of $(-)_{589}$-$[Cr(bpdo)_3]^{3+}$ was followed by monitoring the change in optical rotation at 589 nm with time under the conditions described in Experimental part. As Fig. 5 shows, the rate in step B obeyed the first order kinetic law at least three half-lives, and the rate constant (k_{obsd}) was obtained from the slope of log$|\alpha_t|$ vs. time, where α is degrees of optical rotation. The values of k_{obsd} are given in Table 2. The rate of racemization was independent of concentrations of H^+ and the free ligand (bpdo). Hence the racemization ($\Delta \rightleftarrows \Lambda$) will also proceed by an intramolecular mechanism. The estimated values of activation energy, enthalpy, and entropy are (79.0±0.3)

kJ mol^{-1}, (76.5±0.3) kJ mol^{-1}, and (−64.0±1.0) J K^{-1} mol^{-1}, respectively, which agree with those estimated in our previous work.[6] From a comparison of these kinetic parameters with those of other complexes such as $[Cr(phen)_3]^{3+}$,[16] the racemization of $[Cr(bpdo)_3]^{3+}$ is suggested to proceed via an intramolecular twist mechanism. The small negative activation entropy value for the racemization of $[Cr(bpdo)_3]^{3+}$ seems to be consistent with such a mechanism.[17] In our previous work,[8] the rate of racemization of $(-)_{589}$-$[Cr(acac)(bpdo)_2]^{2+}$ in aqueous solution was found to be 1.51×10^{-4} s^{-1} at 25.0 °C with the activation energy, enthalpy, and entropy of 84.8 kJ mol^{-1}, 82.4 kJ mol^{-1}, and −41.7 J K^{-1} mol^{-1}, respectively. The rate and kinetic parameters of $[Cr(bpdo)_3]^{3+}$ are very similar to those of $[Cr(acac)(bpdo)_2]^{2+}$, and the racemization reactions of these two complexes would proceed by the same mechanism. For the intramolecular racemization of a tris(chelate)-type complex, several different twist mechanisms have been proposed.[18] However, it is difficult to determine which mechanism is the most probable for the present complexes.

(Received September 9, 1986)

Four geometrical isomers possible in each of $[Co(edma)(dien)]^{2+}$ and $[Co(edma)(mdien)]^{2+}$, where edma, dien, and mdien denote ethylenediamine-*N*-acetate, 3-azapentane-1,5-diamine, and 3-methyl-3-azapentane-1,5-diamine respectively, and facial isomer of $[Co(edma)(NH_3)_3]^{2+}$ were prepared and resolved into optically active isomers by a column-chromatographic method. The structural assignments of these geometrical isomers were carried out on the basis of the absorption, ^1H NMR, and ^{13}C NMR spectral data. The absolute configurations of the optically active isomers containing facially coordinated edma were determined by ^1H NMR measurements of the glycinate-ring methylene (-CHD-) of edma stereospecifically deuterated in a weak basic D_2O. The relationship between the absolute configurations and the CD spectral behaviors of these isomers is also discussed.

The octahedral complexes of cobalt(III) with terdentate ligands, such as iminodiacetate (ida), *N*-methyliminodiacetate (mida), 3-azapentane-1,5-diamine (dien), 3-methyl-3-azapentane-1,5-diamine (mdien), and ethylenediamine-*N*-acetate (edma), provide varieties of geometrical and optical isomers. Therefore, the complexes with these ligands are useful for the investigations of spectroscopic properties, stereochemistry, and reactivity (isomerization and racemization reactions). Keene and coworkers first isolated three geometrical isomers (u-fac, s-fac, and mer) possible for $[Co(dien)_2]^{3+}$.[1] Thereafter, a complete series of geometrical isomers have been reported for the complexes of $[Co(ida)_2]^-$,[2] $[Co(mida)_2]^-$,[2] $[Co(ida)(mida)]^-$,[3] $[Co(ida)(dien)]^+$,[4] $[Co(mida)(dien)]^+$,[5] $[Co(ida)(mdien)]^+$,[5] $[Co(mida)(mdien)]^+$,[5] $[Co(dien)(mdien)]^{3+}$[6,7] (three isomers), $[Co(edma)_2]^+$ (six isomers),[8-10] [Co(ida)(edma)],[9,10] and [Co(mida)(edma)][11] (four isomers). However, there is no report for the mixed-ligand complexes of $[Co(edma)(dien)]^{2+}$ and $[Co(edma)(mdien)]^{2+}$. Both the complexes provide four geometrical isomers with chiral structure, as shown in Fig. 1.

In the present paper, the preparation and optical resolution of $[Co(edma)(dien)]^{2+}$, $[Co(edma)(mdien)]^{2+}$ and $[Co(edma)(NH_3)_3]^{2+}$ will be described, and the stereochemistry will be discussed on the basis of their absorption, ^1H NMR, ^{13}C NMR, and CD spectral data.

Experimental

Preparation and Optical Resolution of the Complexes. Preparation of Four Geometrical Isomers of [Co(edma)(mdien)]$^{2+}$: An aqueous solution containing 2.27 g (0.01 mol) of ethylenediamine-*N*-acetic acid dihydrochloride dihydrate[12] (Hedma·2HCl·$2H_2O$) and 2.26 g (0.01 mol) of 3-methyl-3-azapentane-1,5-diamine trihydrochloride[13] (mdien·3HCl) in 60 cm^3 of water was passed through an anion-exchange resin (Dowex 1×8, ClO_4^- form) column to convert the chloride ions to the perchlorate ions, and then the solution was evaporated to a volume of 20 cm^3. Similarly, an aqueous solution containing 2.23 g (0.01 mol) of $CoCl_2·6H_2O$ in 30 cm^3 of water was passed through an anion-exchange resin column of ClO_4^- form. These two solutions were mixed and the solution was adjusted to pH 6.5—6.9 with 1 mol dm^{-3} NaOH solution. Lead dioxide (8.0 g) was stirred into the solution in small portions at 40 °C over a 1 h period, the pH of the solution being kept at 6.5—6.9. After insoluble materials had then been removed by filtration, the filtrate (red-purple) was charged on an SP-Sephadex C-25 column (ϕ 4.7 cm×90 cm, NH_4^+ form). The adsorbed band was developed with 0.2 mol dm^{-3} $(NH_4)_2SO_4$ solution. The band was separated into several bands by recyclic developement: red-orange (a mixture of four isomers of $[Co(edma)_2]^+$), red (a mixture of two isomers of $[Co(edma)_2]^+$), orange (desired isomer, el 1), red-orange (el 2), orange (el 3), violet (unidentified complex), orange (el 4), and orange ($[Co(mdien)_2]^{3+}$) bands (formation ratio of el 1, el 2, el 3, and el 4 was 39 : 48 : 2 : 11). The eluate from each band of el 1—el 4 was evaporated under reduced pressure, and methanol was added to the concentrated solution. Ammonium sulfate deposited was removed by filtration and the filtrate was again evaporated. A crude complex was obtained from the concentrated solution by addition of methanol. The isomers of el 1, el 3, and el 4 were isolated in a crystal by recrystallizing the crude complexes from water-methanol

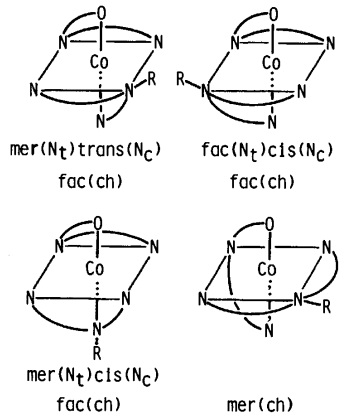

Fig. 1. Four geometrical isomers of $[Co(edma)(dien)]^{2+}$ (R=H) or $[Co(edma)(mdien)]^{2+}$ (R=CH_3). N_t and N_c denote terminal and central nitrogens, respectively, and fac(ch) and mer(ch) represent the isomers with facially and meridionally chelated ligands, respectively.

solvent. The isomer of el 2 was obtained as a crystal of bromide salt by converting the sulfate salt to the bromide salt using a short QAE-Sephadex (Br^- form) column. Found for el 1: C, 25.51; H, 6.45; N, 16.42%. Calcd for $[Co(edma)(mdien)]SO_4 \cdot 2H_2O = C_9H_{28}N_5O_8SCo$: C, 25.41; H, 6.64; N, 16.47%. Found for el 2: C, 23.60; H, 5.42; N, 14.97%. Calcd for $[Co(edma)(mdien)]Br_2 \cdot 0.5H_2O = C_9H_{25}N_5O_{2.5}Br_2Co$: C, 23.39; H, 5.45; N, 15.16%. Found for el 3: C, 24.96; H, 6.50; N, 16.15%. Calcd for $[Co(edma)(mdien)]SO_4 \cdot 2.5H_2O = C_9H_{29}N_5O_{8.5}SCo$: C, 24.89; H, 6.73; N, 16.12%. Found for el 4: C, 26.19; H, 6.76; N, 16.53%. Calcd for $[Co(edma)(mdien)]SO_4 \cdot 1.5H_2O = C_9H_{27}N_5O_{7.5}SCo$: C, 25.96; H, 6.54; N, 16.82%.

Resolution of $[Co(edma)(mdien)]^{2+}$: The racemates of el 1—el 4 were resolved into optically active isomers by a column-chromatographic method.

A solution containing ca. 1 g of each racemate of el 1—el 4 in a small amount of water was poured onto an SP-Sephadex column (ϕ 4.7 cm×50 cm, Na^+ form), and the adsorbed band was developed with a 0.2 mol dm^{-3} $Na_2Sb_2(d\text{-tart})_2$ solution. On each chromatographic run of el 1, el 3, and el 4, the adsorbed band separated completely into two bands by repeating recyclic developement 5—6 times, and each band was eluted out from the column. Whereas on the run of el 2, the band separation was incomplete. The front and rear fractions of the broadening band, which showed enantiomeric CD curves with (+) and (−) signs at 528 nm respectively, were eluted out. Each eluate was evaporated, and a saturated KCl solution was added to the concentrated solution to make deposit $K_2Sb_2(d\text{-tart})_2$ salt, which was removed by filtration. The filtrate was again evaporated, and methanol was added to the concentrated solution to eliminate KCl. The methanolic solution was evaporated, and the concentrated solution was charged on a short QAE-Sephadex (Br^- form) column to convert Cl^- ion to Br^- ion. The solution eluted with water was evaporated and methanol was added to the concentrated solution. A crude complex obtained was recrystallized from water by addition of methanol. Found for the early eluted $(-)^{CD}_{509}$ isomer of el 1: C, 23.22; H, 5.63; N, 14.95%. Found for the $(-)^{CD}_{528}$ isomer (from rear fraction) of el 2: C, 23.18; H, 5.65; N, 14.64%. Found for the early eluted $(-)^{CD}_{540}$ isomer of el 4: C, 22.92; H, 5.59; N, 15.03%. Calcd for $[Co(edma)(mdien)]Br_2 \cdot H_2O = C_9H_{26}N_5O_3Br_2Co$: C, 22.95; H, 5.56; N, 14.85%. Found for the early eluted $(+)^{CD}_{514}$ isomer of el 3: C, 23.65; H, 6.01; N, 14.30%. Calcd for $[Co(edma)(mdien)]Br_2 \cdot H_2O \cdot 0.5CH_3OH = C_{9.5}H_{28}N_5O_{3.5}Br_2Co$: C, 23.42; H, 5.79; N, 14.38%.

Preparation and Resolution of $[Co(edma)(dien)]^{2+}$: The crude isomers (el 1—el 4) of $[Co(edma)(dien)]SO_4$ were obtained by the same method as that used for the isomers of $[Co(edma)(mdien)]SO_4$. Formation ratio of el 1, el 2, el 3, and el 4 was 18 : 55 : 12 : 15. The sulfate salts were converted to the chloride salts using a QAE-Sephadex A-25 (Cl^- form) column. The crude complexes obtained were recrystallized from water by addition of methanol. The isomers of el 1 and el 3 were obtained in orange crystals and the isomers of el 2 and el 4 in red-orange crystals. Found for el 1: C, 27.03; H, 6.36; N, 19.34%. Calcd for $[Co(edma)(dien)]Cl_2 \cdot 0.5H_2O = C_8H_{23}N_5O_{2.5}Cl_2Co$: C, 26.75; H, 6.46; N, 19.50%. Found for el 2: C, 25.70; H, 6.67; N, 18.69%. Found for el 4: C, 25.44; H, 6.58; N, 18.54%. Calcd for $[Co(edma)(dien)]Cl_2 \cdot 1.5H_2O = C_8H_{25}N_5O_{3.5}Cl_2Co$: C, 25.48; H, 6.68; N, 18.57%. Found for el 3: C, 24.96; H, 6.78; N, 17.85%. Calcd for $[Co(edma)(dien)]Cl_2 \cdot 2H_2O = C_8H_{26}N_5O_4Cl_2Co$: C, 24.88; H, 6.79; N, 18.14%.

The optical resolutions of these isomers were carried out by the same method as that used for the four isomers of $[Co(edma)(mdien)]^{2+}$. Found for the late eluted $(+)^{CD}_{504}$ isomer of el 1: C, 25.70; H, 6.55; N, 18.27%. Calcd for $[Co(edma)(dien)]Cl_2 \cdot 1.5H_2O = C_8H_{25}N_5O_{3.5}Cl_2Co$: C, 25.48; H, 6.68; N, 18.57%. Found for the late eluted $(-)^{CD}_{514}$ isomer of el 2: C, 20.87; H, 5.33; N, 15.13%. Calcd for $[Co(edma)(dien)]Br_2 \cdot H_2O = C_8H_{24}N_5O_3Br_2Co$: C, 21.02; H, 5.29; N, 15.32%. Found for the early eluted $(-)^{CD}_{500}$ isomer of el 3: C, 22.61; H, 5.66; N, 15.08%. Calcd for $[Co(edma)(dien)]Br_2 \cdot CH_3OH = C_9H_{26}N_5O_3Br_2Co$: C, 22.95; H, 5.56; N, 14.86%. Found for the late eluted $(-)^{CD}_{527}$ isomer of el 4: C, 27.07; H, 6.41; N, 19.58%. Calcd for $[Co(edma)(dien)]Cl_2 \cdot 0.5H_2O = C_8H_{23}N_5O_{2.5}Cl_2Co$: C, 26.75; H, 6.46; N, 19.50%.

Preparation and Resolution of *fac*-$[Co(edma)(NH_3)_3]^{2+}$: Although the geometrical structure of this complex has been reported in the preceding paper,[14] the preparative method was not described. A solution containing 4.0 g of Hedma · 2HCl · $2H_2O$ in 40 cm^3 of water was poured onto a column containing anion-exchange resin (Dowex 1×8, NO_3^- form) and eluted out with water, in order to exchange Cl^- ion to NO_3^- ion. The eluate was evaporated to ca. 3 cm^3 and then added to a solution containing 6.0 g of $[Co(NH_3)_5(H_2O)](NO_3)_3$ in 250 cm^3 of 25% aqueous NH_3. The mixed solution was heated at 80 °C for 3 h and then cooled to room temperature. The resultant solution was evaporated to ca. 20 cm^3 to charge again on an SP-Sephadex column (ϕ 4.7 cm×50 cm, Na^+ form). The adsorbed band was developed with 0.5 mol dm^{-3} $NaNO_3$ solution. The second band of red-orange color was eluted out, and then the eluate was concentrated. Methanol was added to the concentrated eluate to make deposit $NaNO_3$ salt, which was removed by filtration. Red-orange complex was obtained from the filtrate by evaporation and by addition of methanol. This complex was used for the resolution without further purification.

The racemate obtained above was dissolved into 50 cm^3 of water to charge on an SP-Sephadex column (ϕ4.7 cm×50 cm, K^+ form). The adsorbed band was completely separated into two bands by developing it with a 0.1 mol dm^{-3} $K_2Sb_2(d\text{-tart})_2$ solution. Each band was eluted out with a 0.2 mol dm^{-3} KCl solution. The first and second eluates which exhibited (+) and (−) CD signs at 512 nm, respectively, were evaporated to ca. 5 cm^3 and 100 cm^3 of methanol was added to the concentrated solutions. Potassium chloride deposited was removed by filtration. Ethanol was added to the filtrates to obtain crude complexes, which were recrystallized from water by addition of ethanol. Found for the $(-)^{CD}_{512}$ isomer: C, 15.40; H, 6.35; N, 22.34%. Calcd for $[Co(edma)(NH_3)_3]Cl_2 \cdot H_2O = C_4H_{20}N_5O_3Cl_2Co$: C, 15.20; H, 6.38; N, 22.16%.

Determination of Absolute Configurations of the Complexes by ^1H NMR Technique. Determination of the absolute configurations of the optically active *fac*-$[Co(edma)(dien)]^{2+}$ and *fac*-$[Co(edma)(NH_3)_3]^{2+}$ complexes was carried out by the method modified that used for the $[Co(edma)_2]^+$ complex in our previous study.[8]

About 0.2 g of $(+)^{CD}_{504}$ el 1 $[Co(edma)(dien)]Cl_2 \cdot 1.5H_2O$ was dissolved into a buffer solution (pH 10), and the solution was allowed to stand at 40 °C for ca. 1 h to deuterate one of the two methylene protons on the edma glycinate ring (G-ring) (Fig. 2). The deuteration reaction was stopped by acidifing the solution (pH 5—6) with 1 mol dm^{-3} HCl, and zinc powder (2 g) was added to the solution. After stirring the mixture for 5 min at ca. 25 °C, unreacted zinc was removed

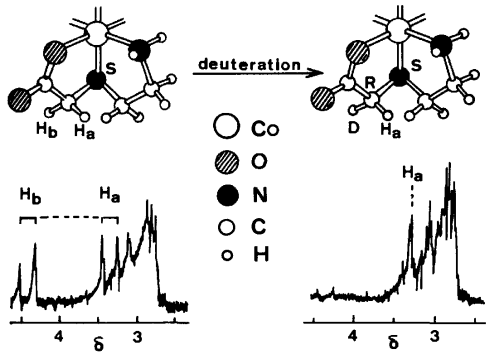

Fig. 2. Stereospecific deuteration on the G-ring $-CH_2-$ of coordinated edma in $(+)^{CD}_{504}$ el 1 of $[Co(edma)(dien)]^{2+}$

by filtration. To the filtrate, 52 mg of $CuSO_4 \cdot 5H_2O$ (to make produce a blue copper(II) complex of dien) and 95 mg of Hedma·2HCl·$2H_2O$ were added, and the solution was adjusted to pH 7.0—7.5 with 1 mol dm^{-3} NaOH. Lead dioxide (1.5 g) was added to the solution and the mixture was stirred for 15 min at ca. 25 °C. The reactant solution was filtered, and the filtrate was poured onto an SP-Sephadex column (ϕ 3 cm×35 cm, Na^+ form). The adsorbed band was separated into red, orange-red, and blue bands by elution with a 0.2 mol dm^{-3} NaCl solution. The red band including C_2- and C_1-*trans(O)*-$[Co(edma)_2]^+$ isomers was transfered to another SP-Sephadex column and developed with a 0.1 mol dm^{-3} Na_2Sb_2(d-tart)$_2$ solution. The band separated into three bands of $(-)^{CD}_{543}$ C_2-, C_1-, and $(+)^{CD}_{543}$ C_2-*trans(O)*-$[Co(edma)_2]^+$. Each band was eluted out and crystals of $(-)^{CD}_{543}$ and $(+)^{CD}_{543}$ isomers were obtained by the same procedure as that described in our previous paper,[9] and their ^{1}H NMR were measured.

Deuterations of the $(+)^{CD}_{514}$ el 2 and $(-)^{CD}_{527}$ el 4 isomers of $[Co(edma)(dien)]^{2+}$ and the $(-)^{CD}_{512}$ isomer of *fac*-$[Co(edma)(NH_3)_3]^{2+}$ were also carried out by the same method as that described for $(+)^{CD}_{504}$ el 1, except that $CuSO_4 \cdot 5H_2O$ was not used for the last isomer. The ^{1}H NMR spectra of the C_2-*trans(O)*-$[Co(edma)_2]^+$ (E-1) enantiomers obtained from the deuterated isomers are shown in Fig. 3.

Spectral Measurements. The absorption and CD spectra were measured by a Hitachi 557-type spectrometer and a JASCO J-22 spectropolarimeter, respectively. The ^{1}H NMR spectra were recorded on a JEOL MH-100 NMR spectrometer using DSS as an internal standard. The ^{13}C NMR spectra at 25 MHz were recorded on a JEOL JNM-FX 100 spectrometer. The peak positions were measured relative to internal dioxane (δ=67.40). The signals of the G-ring $-CH_2-$ carbons in coordinated edma were assigned by a ^{1}H selective decoupling method.

Results and Discussion

Assignments of Geometrical Isomers. As Fig. 1 shows, each of the mixed-ligand complexes, $[Co(edma)(mdien)]^{2+}$ and $[Co(edma)(dien)]^{2+}$, provides three facially chelated [fac(ch)] isomers of mer(N_t)-trans(N_c), fac(N_t)cis(N_c), and mer(N_t)cis(N_c) and one meridionally chelated [mer(ch)] isomer. All these isomers are chiral complexes which can be resolved into

optically active isomers. The four geometrical isomers have the same chromophore of the [Co N_5O] type, but they show spectral behaviors slightly different from each other, especially in the d-d absorption region (Fig. 4 and Table 1). The structures of these isomers can be assigned on the basis of the absorption, ^1H and ^{13}C NMR spectral data.

It is known that the molar absorption coefficient of the first absorption band is larger in a mer(ch) isomer than in a fac(ch) isomer of the terdentate ligand complexes, such as $[Co(ida)_2]^-$,[2] $[Co(edma)_2]^+$,[8] and $[Co(dien)_2]^{3+}$.[1,15] In the present complexes the band intensities of el 3 are more enhanced than those of the other isomers, suggesting that the structure of the former isomer may be assigned to mer(ch) and those of the latter isomers to fac(ch). These assignments are consistent with those done on the basis of the ^1H and ^{13}C NMR data (vide infra).

The ^1H NMR spectra of the four isomers of $[Co(edma)(mdien)]^{2+}$ are illustrated in Fig. 5 and their chemical shifts are given in Table 2, together with those of $[Co(edma)(dien)]^{2+}$. The G-ring methylene protons of el 3 resonate as a singlet-like peak at 3.73 ppm, while those of el 1, el 2, and el 4 do as four peaks of a AB quartet. Such a difference in signal pattern has also been observed between the mer(ch) and fac(ch) isomers of $[Co(edma)_2]^+$.[9] A comparison in signal pattern between the $[Co(edma)(mdien)]^{2+}$ complex and the $[Co(edma)_2]^+$ complex leads to assign el 3 to mer(ch) and el 1, el 2, and el 4 to fac(ch). Similarly, the mer(ch) and fac(ch) structures for the four isomers of $[Co(edma)(dien)]^{2+}$ are assigned from the ^1H NMR data of the G-ring methylene protons.

The el 1, el 2, and el 4 isomers of $[Co(edma)(mdien)]^{2+}$ show the methyl proton signals in the range of 2.5—2.8 ppm (Fig. 5). Previously, in the study of the (*S*)-alaninato cobalt(III) complex Berends and Brushmiller suggested that the methyl signal shifts to the lower-field side when the methyl group lies at the position deshielded by an anisotropic effect arising from the C-O bond.[16] The molecular model examinations of the three fac(ch) isomers of $[Co(edma)(mdien)]^{2+}$ show that the methyl group attaching to the central nitrogen of mdien lies at the deshielded position only in the mer(N_t)trans(N_c) structure. The methyl signal of el 1 (δ= 2.81) locates at a lower magnetic field than those of el 2 (2.63) and el 4 (2.54), which leads to assign the structure of el 1 to mer(N_t)trans(N_c).

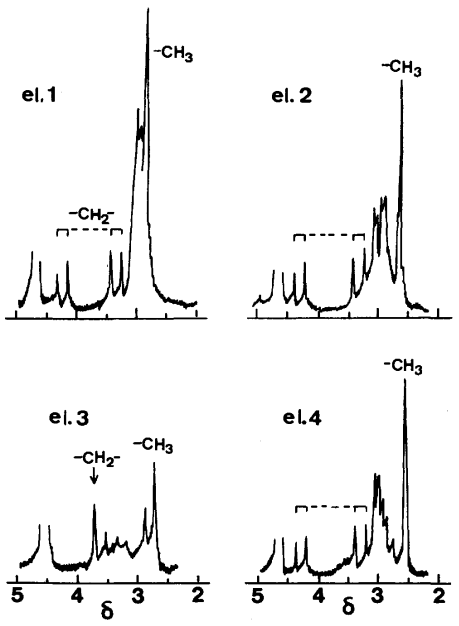

Fig. 5. ^1H NMR spectra of four geometrical isomers in $[Co(edma)(mdien)]^{2+}$.

The structural assignment of el 4 can be made on the basis of the ^{13}C NMR data. In our previous work[10] for the $[Co(edma)_2]^+$ and [Co(ida)(edma)] complexes, their geometrical structures were determined from the ^{13}C chemical shifts; the carbon neighboring to the central nitrogen (N_c) of a terdentate ligand resonates at a lower magnetic field when the trans position to N_c was occupied with oxygen atom than when the position was occupied with nitrogen atom. Figure 6(b) shows the ^{13}C NMR shift patterns of the four isomers of $[Co(edma)(mdien)]^{2+}$, and their shift data are summa-

a) δ Values from DSS (^{1}H) and TMS (^{13}C). b) Labeling of carbons is given in Fig. 6. The marked (*) signal were determined by the selective decoupling method. (s): Singlet-like peak. (d): Doublet peak.

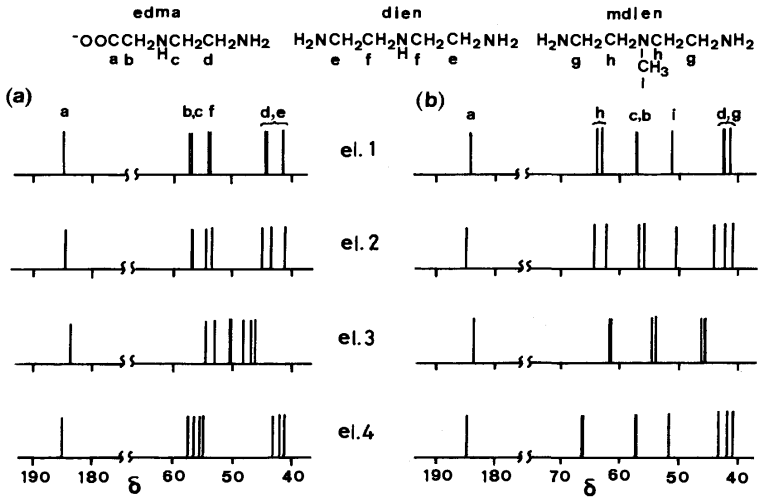

Fig. 6. ^{13}C NMR signal patterns of four geometrical isomers in (a) [Co(edma)(dien)]$^{2+}$ and in (b) [Co(edma)(mdien)]$^{2+}$.

rized in Table 2. Among three fac(ch) isomers, el 4 exhibited resonance peaks of h carbons at the lowest field: δ values for el 4, 66.08 and 66.27; for el 1, 62.96 and 63.93; for el 2, 62.38 and 64.47. Accordingly, the structure of el 4 is assigned to mer(N_t)cis(N_c), in which the trans position to N_c is occupied with oxygen atom.

The geometrical structure of el 2 was assigned on the basis of shift behavior of methyl carbon resonance. In our previous ^{13}C NMR study of [Co(ida)(mida)]$^{-}$, the higher-field shift of methyl carbon resonance observed for the u-fac isomer was ascribed to a steric interaction between the methyl group of the mida ligand and the G-ring methylene of the ida ligand.[3] Steric interaction is also expected to occur between the methyl group of mdien and the G-ring methylene of edma in [Co(edma)(mdien)]$^{2+}$ with fac(N_t)cis(N_c) structure. As given in Table 2, the methyl carbon of el 2 (δ=50.53) resonates at a higher-field relative to those of el 1

(51.26) and el 4 (51.61) with the same facially chelated form. From this result we can assign the structure of el 2 to fac(N_t)cis(N_c).

The geometrical structures of el 1, el 2, and el 4 of $[Co(edma)(dien)]^{2+}$ were assigned by comparing their absorption and CD spectra in the d-d absorption region with those of el 1, el 2, and el 4 of $[Co(edma)(mdien)]^{2+}$.

Absolute Configurations of the fac(ch) Isomers. When unsymmetrical edma was facially coordinated to a cobalt(III) ion as a terdentate ligand, the secondary nitrogen becomes an asymmetric center. In the case that a geometrical structure is given for the edma complex, the configurational chirality around the cobalt(III) is restricted by the chirality (N_R or N_S) of the asymmetric nitrogen (vice versa).

In the previous works,[9,11] it has been shown that one of the G-ring -CH_2- protons of facially chelated edma is stereospecifically deuterated in basic D_2O. For example, when the secondary nitrogen of chelated edma takes N_S chirality, the outside proton (H_b in Fig. 2) is deuterated before the inside proton (H_a) is deuterated, and the methylene carbon becomes an asymmetric center (-CHD-) with C_R chirality. In this case NMR signal of the undeuterated G-ring methylene-proton is observed as a single peak in a higher magnetic field.

Stereospecific deuteration method was also applied to the fac(ch) isomers of $[Co(edma)(dien)]^{2+}$ and $[Co(edma)(NH_3)_3]^{2+}$ (detailed deuteration procedures are described in the Experimental section). Figure 3 shows the ^1H NMR spectra of $(-)^{CD}_{543}$ E-1 and $(+)^{CD}_{543}$ E-1 (of which the absolute configurations are $\Delta\Lambda\Delta(N_R, N_R)$ and $\Lambda\Delta\Lambda(N_S, N_S)$,[9] respectively) obtained from the deuterated $(+)^{CD}_{504}$ el 1, $(+)^{CD}_{514}$ el 2, and $(-)^{CD}_{527}$ el 4 isomers of $[Co(edma)(dien)]^{2+}$ and the deuterated $(-)^{CD}_{517}$ isomer of *fac*-$[Co(edma)(NH_3)_3]^{2+}$

When the deuterated $(+)^{CD}_{504}$ el 1 isomer was used as a starting material, a single peak (marked with *) due to G-ring -CHD- was observed at δ ca. 4.3 (lower-field side) for $(-)^{CD}_{543}$ E-1 and at δ ca. 3.35 (higher-field side) for $(+)^{CD}_{543}$ E-1. As described above (Fig. 2), the single peak at lower-field is assigned to outside proton (H_b) and the single peak at higher-field to inside proton (H_a). This indicates that the chirality of the deuterated methylene carbon is C_R. As the starting isomer containing C_R exhibited a single peak in the higher-field side, the absolute configuration should be assigned to $\Lambda(GE)\Delta(EE)(N_S)$ (where G and E denote glycinate ring and ethylenediamine ring, respectively). Similar considerations for the ^1H NMR spectral data of the $(+)^{CD}_{512}$ el 2 and $(-)^{CD}_{527}$ el 4 isomers lead to conclude that their absolute configurations are $\Lambda(EE)\Delta(GE)\Lambda(GE)(N_S)$ and $\Delta(GE)\Lambda(EE)\Delta(EE)(N_S)$, respectively, as given in Table 3.

When the deuterated $(-)^{CD}_{512}$ isomer of *fac*-$[Co(edma)(NH_3)_3]^{2+}$ was used as a starting material, a single peak appeared in the higher-field side for $(-)^{CD}_{543}$ E-1 and in the lower-field side for $(+)^{CD}_{543}$ E-1 (Fig. 3). Such signal patterns suggest that the chiralities of asymmetric nitrogens and carbons in $(-)^{CD}_{543}$ and $(+)^{CD}_{543}$ E-1 are N_RC_S and N_SC_S, respectively. Accordingly, the absolute con-

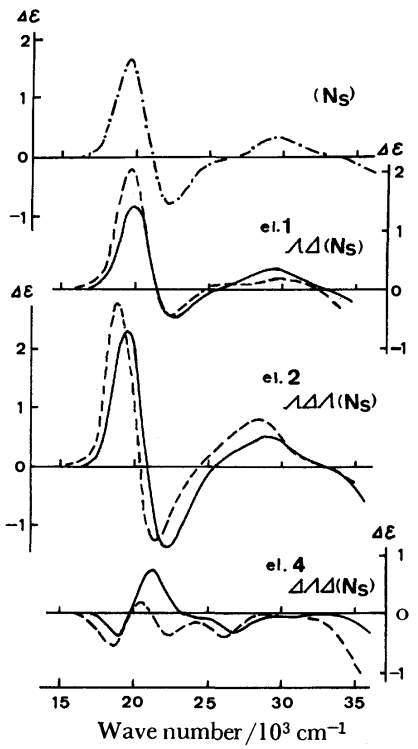

Fig. 7. The absolute configurations and CD spectra of the fac(ch) isomers in [Co(edma)-$(NH_3)_3]^{2+}$ (-·-·-), [Co(edma)(dien)]$^{2+}$ (——), and [Co(edma)(mdien)]$^{2+}$ (----).

figuration of the starting $(-)^{CD}_{512}$ isomer, which exhibited a single peak in the higher-field side, is assigned to N_R.

Absolute configurations for the optically active fac(ch) isomers of [Co(edma)(mdien)]$^{2+}$ were determined by comparing their CD spectral behaviors in the d-d absorption region with those of the corresponding fac(ch) isomers of [Co(edma)(dien)]$^{2+}$ (Table 3).

CD Spectra. The CD spectra and numerical data of the present edma complexes are shown in Figs. 4 and 7 and Table 3. The optical activities of the fac(ch) isomers of [Co(edma)(dien)]$^{2+}$ and [Co(edma)(mdien)]$^{2+}$ arise dominantly from two effects of configurational chirality due to skew pairs of the chelate rings and chirality due to the secondary nitrogen of coordinated edma. In the [Co(edma)(dien)]$^{2+}$ complex, the CD curve of $(+)^{CD}_{504}$ el 1 with Λ(GE)Δ(EE)(N_S) configuration is quite similar in pattern and intensity to that of $(+)^{CD}_{512}$ *fac*-[Co(edma)$(NH_3)_3]^{2+}$ with only N_S chirality (Fig. 7). This similarity suggests that the CD contributions from the configurational chiralities of Λ(GE) and Δ(EE) cancellate to each other. Similar considerations are also made on el 2 and el 4; the higher intense CD of $(+)^{CD}_{514}$ el 2 with ΛΔΛ(N_S) [net Λ(N_S)] is ascribed to the additive contribution from the Λ and N_S chiralities, while the lower intense CD of $(-)^{CD}_{527}$ el 4 with ΔΛΔ(N_S) [net Δ(N_S)] is ascribed to the differential contribution from the Δ and N_S chiralities.

The CD spectra of the mer(ch) isomers (el 3) of the dien and mdien complexes were measured in an acidic solution because their rapid racemization occurred in water.

The optical activity of the mer(ch) isomers arises from two effects due to chiral disposition of the nonplanar ligands and N chirality of coordinated edma. The relatively intense CD observed for two el 3, compared with the mer isomers of [Co$(dien)_2]^{3+}$,[17] [Co(mida)(dien)]$^{+}$,[18] and [Co(dien)(mdien)]$^{3+}$,[6] is ascribed to the summed effect of such two chiralities.

Pressure and Temperature Effects on Octahedral-Tetrahedral Equilibria in 3-Methylpyridine Solutions of Some Cobalt(II) Halides

Kazuo KOJIMA
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received September 11, 1986)

The visible absorption spectra of CoX_2 (X=Cl, Br) in 3-methylpyridine (3-Me-py) solutions have been measured in the pressure range of 1 bar—3 kbar at room temperature, and in the temperature range of ≈5—≈76 °C at 1 bar. The equilibrium, $[CoX_2(3\text{-Me-py})_2]$ (tetrahedral) + 2(3-Me-py) ⇄ $[CoX_2(3\text{-Me-py})_4]$ (octahedral), is found to be followed over this pressure range. Higher pressures favor the octahedral species with the volume changes −18—−19 $cm^3\,mol^{-1}$ at 1 bar. On the other hand, the above equilibrium holds fairly well at temperatures up to about 40 °C. Higher temperatures favor the tetrahedral species, the heats of reaction, being 56.7 $kJ\,mol^{-1}$ (5.0—44.8 °C) and 58.6 $kJ\,mol^{-1}$ (4.8—34.2 °C) for the chloro and bromo complexes, respectively. An intense and broad band appears around 400 nm at elevated temperatures especially for the bromo complex solution. This band may be assigned to a charge-transfer band occurring in a contact ion pair of solvent molecule 3-Me-py with X^- arising from the dissociation of the tetrahedral species $[CoX_2(3\text{-Me-py})_2]$.

King et al.[1,2] and Sawada et al.[3,4] have studied in detail the configurational equilibria between the octahedral $[CoX_2(R\text{-py})_4]$ and tetrahedral $[CoX_2(R\text{-py})_2]$ complexes in nonaqueous solvents such as nitromethane and 1,2-dichloroethane, where X=Cl, Br, or I and R-py=pyridine or methylpyridines. However, the pressure and temperature effects on the equilibria have not been discussed.

In the previous papers,[5,6] the effects of pressure and temperature on the octahedral-tetrahedral equilibria in pyridine solutions of Co(II) halides have been reported. From the variations in the visible absorption spectra with pressure and temperature, the values of ΔV and ΔH, the volume and the heat of the following reaction, were obtained

$$\underset{\text{(tetrahedral)}}{[CoX_2(py)_2]} + 2py \rightleftharpoons \underset{\text{(octahedral)}}{[CoX_2(py)_4]},$$

where X=Cl, Br, or I. Higher pressures favored the octahedral species but higher temperatures did the tetrahedral species. The ΔV values were −41, −29, and −6 $cm^3\,mol^{-1}$ at 1 bar and the ΔH values were 57.3, 60.7, and 65.3 $kJ\,mol^{-1}$ for X=Cl, Br, and I, respectively.

As a part of a series of the study, the present paper describes the spectrochemical investigations of the pressure and temperature dependence of the following equilibrium

$$\underset{\text{(tetrahedral)}}{[CoX_2(3\text{-Me-py})_2]} + 2(3\text{-Me-py}) \overset{K}{\rightleftharpoons} \underset{\text{(octahedral)}}{[CoX_2(3\text{-Me-py})_4]}, \quad (1)$$

where X=Cl or Br, and K is the equilibrium constant. Moreover, the above reaction may be accompanied by another reaction and the possibility will be also discussed.

Experimental

$CoCl_2$ and $CoBr_2 \cdot 6H_2O$ were used after drying and 3-Me-py was used after drying and distillation. Sample solutions of CoX_2 in 3-Me-py were prepared just before spectroscopic measurements.

High-pressure spectra were recorded on a Hitachi 340 spectrophotometer equipped with a clamp-type optical cell[7] and high-temperature spectra on a Shimadzu MPS-2000 instrument equipped with a pair of thermostated quartz cells.

The experimental details have been described in the previous paper.[5]

Results and Discussion

Spectra at Atmospheric Pressure and Room Temperature. The changes in the absorption spectra of CoX_2 solutions in 3-Me-py with pressure and temperature are shown in Figs. 1—4. The spectra are composed of the two main bands due to d-d transitions. The one is the O-band due to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ electronic transition of the octahedral complex $[CoX_2(3\text{-Me-py})_4]$ and the other the T-band due to the $^4A_2(F) \rightarrow {}^4T_1(P)$ transition of the tetrahedral complex $[CoX_2(3\text{-Me-py})_2]$.

At atmospheric pressure and room temperature, the O-band comprises the two peaks (503, 530 nm) and the shoulder (≈560 nm) for the chloro complex, and the two peaks (526, 543 nm) and shoulders (≈490, ≈570 nm) for the bromo complex. All of the peaks for both halo complexes lie in longer wavelength by 3—6 nm than those of the complexes $[CoX_2(py)_4]$ (X=Cl, Br) in pyridine solutions.[5]

Under atmospheric pressure and room temperature, the T-band comprises the three peaks (578, 613, and 640 nm) and the shoulder (≈665 nm) for the chloro complex, and the two peaks (597, 648 nm) and shoulders (≈626, ≈675 nm) for the bromo complex. All of these peaks for both halo complexes shift to longer wavelength by 3—7 nm in comparison with those of the $[CoX_2(py)_2]$ complexes in pyridine solutions.[5] This finding is in contrast to the results of Sawada et al.[3,4] They have found that the positions of the peaks for the tetrahedral complexes $[CoX_2(R\text{-py})_2]$ remain almost unchanged in 1,2-dichloroethane or in 1,2-dibromoethane regardless of pyridine and 3-Me-py. This

contrast may be assumed to be caused by the solute-solvent interaction.

For both halo complexes, the intensity ratio of the T-band to the O-band is larger for the CoX_2-3-Me-py system in the present study than for the CoX_2-pyridine system[5] at atmospheric pressure and room temperature. This result suggests that the equilibrium constant of Eq. 1, K, is smaller in the 3-Me-py solutions than in the pyridine ones, being in agreement with the other results.[1-4]

Pressure Effect. Figures 1 and 2 show the pressure dependence of the spectra. The intensities of the T-bands decrease with increasing pressure. Because of an enhancement of the intensities in the shorter wavelength region than about 460 nm with increasing pressure, the changes in the O-bands are more obscure in this system than in the pyridine system.[5] However, for the chloro complex the O-band intensity is found to increase slightly with pressure. This is likely for the bromo complex, judging from a comparison with the result of the $CoBr_2$-pyridine system.[5] From the facts presented above, it can be concluded that the equilibrium of Eq. 1 shifts toward the octahedral species $[CoX_2(3\text{-Me-py})_4]$ with increasing pressure.[8]

Regarding $[CoX_2(3\text{-Me-py})_4]$ as the product, the volume change, ΔV, is estimated. As shown in Ref. 5, ΔV is calculated by

$$\Delta V = -RT\frac{d}{dP}\ln(I_o/I_t), \qquad (2)$$

where R is the gas constant, and I_o and I_t are the integrated intensities of the O-band and T-band, respectively.

Figure 5 shows the plots of $\ln(I_o/I_t)$ vs. pressure. These plots are fitted to the following equations by the least-squares method:

$$\ln(I_o/I_t) = -0.0960 + 0.765P + 0.125P^2,$$

for the chloro complex, and

$$\ln(I_o/I_t) = -0.463 + 0.772P, \text{ for the bromo complex.} \qquad (3)$$

From Eqs. 2 and 3, the values of ΔV are estimated for the chloro complex as −18, −21, −24, −27, −29, −32, −34 $cm^3\,mol^{-1}$ in the order of pressure from 1 bar to 3.0 kbar at intervals of 0.5 kbar, and for the bromo complex as −19 $cm^3\,mol^{-1}$ over the range of 1 bar −1.5 kbar. No reliable datum is obtained for the bromo complex at high pressures above 1.5 kbar.

ΔV equals $V_{oct}-(V_{tet}+2V_{sol})$, where V_{oct}, V_{tet}, and V_{sol} are the intrinsic volumes of the octahedral species, the tetrahedral species, and the solvent molecule, respectively. Moreover, the ΔV values are always negative in the CoX_2-3-Me-py and CoX_2-pyridine systems. Therefore, the larger the value of $V_{oct}-V_{tet}$ or the smaller that of $V_{tet}+2V_{sol}$ becomes, the smaller $|\Delta V|$ is obtained. $|\Delta V|$, at 1 bar, is 18 $cm^3\,mol^{-1}$ for the chloro complex and is 19 $cm^3\,mol^{-1}$ for the bromo complex in the CoX_2-3-Me-py system. On the other hand, in the

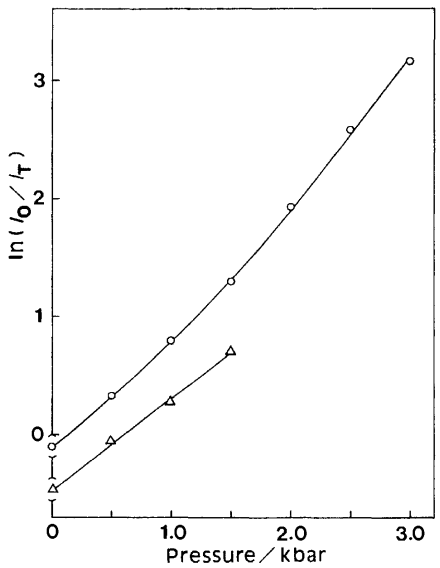

Fig. 5. Logarithm of the integrated-intensity ratio of the O-band to the T-band (I_o/I_t) vs. pressure.
O: $CoCl_2$, Δ: $CoBr_2$, ——: calculated fitting lines.

CoX_2-pyridine system, the $|\Delta V|$ values were 41 and 29 $cm^3\,mol^{-1}$ for the chloro and bromo complexes, respectively, as reported previously.[5] The values of $|\Delta V|$ for both halo complexes are found to be smaller in the CoX_2-3-Me-py system than in the CoX_2-pyridine system. This fact may imply that replacement of ligand pyridine molecules by ligand 3-Me-py ones makes the value of $V_{oct}-V_{tet}$ larger or makes the value of $V_{tet}+2V_{sol}$ smaller. For the 3-Me-py system, there is little difference in $|\Delta V|$ between the two halo complexes in contrast with the CoX_2-pyridine system. This fact may suggest that the contribution of X to V_{oct} and V_{tet} becomes relatively small in the CoX_2-3-Me-py system regardless of Cl and Br.

When the values of V_{oct} and V_{tet} are obtained, the quantitative interpretation upon ΔV can be formulated.

Temperature Effect. The variations in the spectra with temperature are shown in Figs. 3 and 4. The intensities of the T-bands increase steeply with increasing temperature. Although the changes in the O-bands with temperature are obscured due to the intense T-bands, the equilibrium of Eq. 1 probably shifts toward the tetrahedral species $[CoX_2(3\text{-Me-py})_2]$ with increasing temperature contrary to the pressure effect described above. This tendency is very similar to the CoX_2-pyridine system.[5]

However, a marked difference between the two systems should be pointed out here, that is, absorption bands at about 400 nm are observed only in the CoX_2-3-Me-py system. These bands show the following features: (i) They can be observed even at low temperatures. Those peak positions are not clear, but can be estimated at about 390 nm in the chloro complex solution and at about 400 nm in the bromo com-

plex solution. Another peak seems to lie around 430 nm in the latter. Anyway, there is little difference in the peak positions between these two halo complex systems. (ii) For the bromo complex system, the intensity of the 400-nm band increases markedly with increasing temperature simultaneously with suppression of the enhancement of the T-band intensity. The intensity of the T-band becomes smaller at 76.6 °C than at 64.8 °C. Even if the bromo complex solution heated to 76.6 °C is cooled to room temperature, the 400-nm band intensity remains almost unchanged, but the T-band intensity is reduced to a value slightly smaller than that at room temperature before heat of the solution (not shown); the variation in the intensity of the 400-nm band as a function of temperature is irreversible, but that of the T-band is almost reversible. For the chloro complex system, the similar trend for the spectral changes with temperature is observed but not significantly. These facts suggest that the 400-nm band occurs more easily for the bromo complex system than for the chloro complex one and that this band is the more strengthened, the T-band is the more suppressed. (iii) In relation to the 400-nm band, a weak and broad absorption is observed in the region of ≈350—≈440 nm in each of the spectrum of the 3-Me-py solution of KBr, $N(CH_3)_4Br$, $ZnBr_2$, or $NiBr_2$.[9]

By the way, Cabral et al.[2] have concluded that for the tetrahedral complex $[CoBr_2(3\text{-Me-py})_2]$ in nitromethane in the presence of an excess of 3-Me-py, the reaction of exchanging Br^- by 3-Me-py occurs at room temperature. Therefore, from the results of this investigation in addition to the conclusion of Cabral et al.,[2] besides the main reaction of Eq. 1, the following dissociation reaction of the tetrahedral complex occurs in the 3-Me-py solutions and shifts toward a new octahedral species with increasing temperature

$$\underset{\text{(tetrahedral)}}{[CoX_2(3\text{-Me-py})_2]} + (4-x)(3\text{-Me-py}) \longrightarrow \underset{\text{(octahedral)}}{[CoX_x(3\text{-Me-py})_{6-x}]^{(2-x)+}} + (2-x)X^-, \quad (4)$$

where x=0 or 1. The reaction of Eq. 4 is greatly dependent on the temperature for the bromo complex system, but is little for the chloro complex system.

Although any spectral evidence for the presence of the octahedral $[CoX_x(3\text{-Me-py})_{6-x}]^{(2-x)+}$ complex can not be obtained, a free X^- ion in 3-Me-py solutions is probably related to the appearance of the 400-nm band. That is, from the facts (i)—(iii) described above, the 400-nm band may be assigned to a charge-transfer band occurring in a contact ion pair of X^- with a solvent molecule of 3-Me-py.

To our knowledge, there have been some reports on the charge-transfer spectra of ion pairs between halide ions and another ions or molecules the absorption maxima of which lie in relatively long wavelength such as 400 nm. Briegleb et al.[10] have reported that in the interaction of halides e.g. LiI or LiBr (electron donor is I^- or Br^-) with trinitrobenzene in different kinds of solvents, the absorption maximum lies in 385—476 nm for the iodo complex and in 294—370 nm for the bromo complex. Dwivedi and Rao[11] have found that for the $(C_7H_{15})_4N^+X^-$-trinitrobenzene systems in CCl_4, $CHCl_3$, or CH_2Cl_2, the charge-transfer bands appear at 323 nm for X=Cl, at 371—383 nm for X=Br, and at 450—475 nm for X=I. In comparison with these authors' results, the assignment of the 400-nm band in the present study may be reasonable.

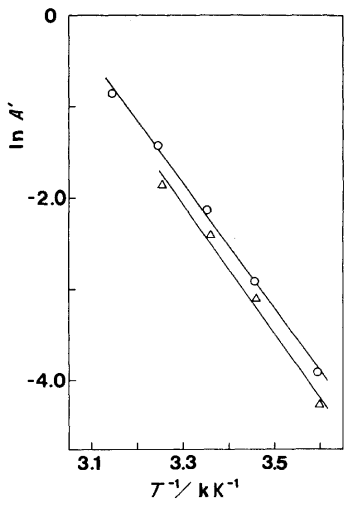

Fig. 6. Logarithm of the corrected absorbance A' vs. reciprocal of absolute temperature.
○: $CoCl_2$, △: $CoBr_2$, ——: calculated fitting lines.

The heat of reaction, ΔH, is estimated in the lower-temperature range (the tetrahedral $[CoX_2(3\text{-Me-py})_2]$ species is regarded as the product). As described in Ref. 5, the change in the equilibrium constant with temperature can be followed by the absorbance change of the 665-nm shoulder for the chloro complex and the 648-nm peak for the bromo complex. In Fig. 6, the logarithm of the corrected absorbance A' is plotted against the reciprocal of absolute temperature. As the thermal expansion coefficient of 3-Me-py has never been estimated, the corresponding value of pyridine ($0.001\ K^{-1}$)[12] is used as the approximate value for 3-Me-py over the temperature range in order to obtain the corrected absorbance A'.

As shown in Fig. 6, the plots are fitted to straight lines, indicating that ΔH is constant for each of the halo complex reaction of Eq. 1 over the lower-temperature range. From the slopes of the lines, ΔH is estimated for the chloro complex as 56.7 kJ mol^{-1} over the range of 5.0—44.8 °C and for the bromo complex as 58.6 kJ mol^{-1} between 4.8 and 34.2 °C.

The value of 56.7 kJ mol^{-1} for the chloro complex is compatible with 56.1 kJ mol^{-1} of Cabral et al.[2] Like the CoX_2-pyridine system,[5] ΔH is also larger for the bromo complex (58.6 kJ mol^{-1}) than for the chloro complex (56.7 kJ mol^{-1}) in this CoX_2-3-Me-py system.

This tendency is consistent with the proposal of King et al.[1] that ΔH is a measure of Co(II)-pyridine base dative π-bonding which increases with decrease in the electronegativity of X. For the chloro complexes, ΔH is larger for the pyridine system (57.3 kJ mol^{-1}) than for the 3-Me-py one (56.7 kJ mol^{-1}). The similar relation can be found between the two bromo complexes (60.7 and 58.6 kJ mol^{-1}). This tendency may be accounted for by the result of Cabral et al.[2] that ligand pyridine is a better π-accepter compared with ligand 3-Me-py.

The author would like to express his sincere thanks to Professor Jiro Matsuda of Ritsumeikan University for valuable discussions, critical reading of the manuscript, and continuous encouragements. The author also wishes to thank Professor Ikuji Tsujikawa of Kyoto University for his encouragements. Thanks are due to Mr. Masao Yoshikawa for his support in the experiment. This work was partially supported by a Grant-in-Aid for Scientific Research No. 59470038 from the Ministry of Education, Science and Culture.

8) As will be described below in the temperature effect, an appearance of a 400-nm band is probably related to the existence of another kind of reaction besides the equilibrium of Eq. 1. However, it is observed that the 400-nm band scarcely changes with pressure and is also not the cause of the enhancement of the intensity below about 460 nm described above. Therefore, it is thought to be reasonable that only the equilibrium of Eq. 1 is influenced by pressure.

9) The experiment has been done as follows: The four kinds of bromide were dried under reduced pressure at about 105 °C to constant weight. After dried with anhydrous $CaSO_4$, 3-Me-py was distilled. Each salt was sealed with 3-Me-py into a glass tube, and then kept for a month at about 70 °C in a drying box. The spectra were recorded at room temperature. If the experiment for the salts of chloride is done, similar results with the bromide will be expected.

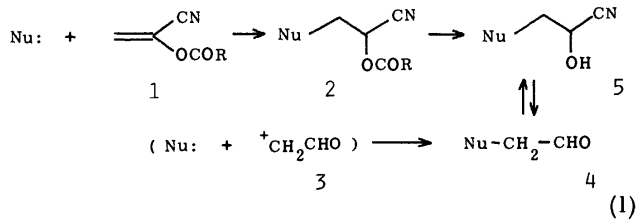
A Formylcarbonium Ion Synthon. Synthesis of 3-Thio-Substituted 2-Amino Acids and Thio-Substituted Enamines from 2-Acyloxyacrylonitriles[1)]

Akira Oku,* Naofumi Hori-ie, and Toshiro Harada
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received May 26, 1986)

The utilization of 2-acyloxy-3-phenylthiopropionitriles (**2**) which were prepared by the Michael addition of thiophenol to 2-acyloxyacrylonitriles (CH_2=C(CN)OCOR), as a formylcarbonium ion synthon, was demonstrated by the transformation of **2** into *S*-phenylcysteine and 2-phenylthio enamines.

2-Acyloxyacrylonitriles (**1**) are useful equivalents of ketenes utilizable as dienophiles,[2)] carbene acceptors and 1,3-dipolarophiles.[3)] Structures of **1** also tell us that they can be used as Michael acceptors to give **2**-substituted acetaldehyde cyanohydrins **5** which are equivalents of the corresponding **2**-substituted aldehydes **4**. In this regard, we have investigated the addition of thiols to **1** and verified that **1** can play a role of formylcarbonium ion synthon **3** (Eq. 1) as being demonstrated in the conversion of the adduct to 3-thio-2-amino acids, such as *S*-phenylcysteine, and also to 2-phenylthio enamines.



(1)

Results and Discussion

The polar addition of thiophenol to 2-benzoyloxyacrylonitrile (**1a**) in methanol at 0 °C in the presence of benzyltrimethylammonium hydroxide (Triton B, 40% in MeOH) gave 2-benzoyloxy-3-phenylthiopropionitrile.[4)] Results are summarized in Table 1 (see Eq. 2). Displacement at the carbonyl group also took place concomitantly besides the desired Michael addition. This side reaction, however, can be minimized by changing the acyloxy group: among three esters examined (benzoate **1a**, pivalate **1b**, and acetate **1c**), benzoate **1a** apparently favors the Michael addition more than the other esters.[5)] In addition, the phenyl group of **1a** may also suppress the displacement and eventually adduct **2a** predominates.[6)] The difference between **1b** and **1c** may be due to the steric effect of the *t*-butyl group that retards the displacement at the carbonyl group.

Free radical addition of thiophenol to **1c** under high-dilution conditions also yielded adduct **2c** in a better yield (55%) when pentane was the solvent. In cyclohexane, side reactions were suppressed and the isolation of **2c** was easier.

a, R^1 = Ph; b, R^1 = *t*-Bu; c, R^1 = CH_3
R^2 = Ph (a, b, c), R^2 = Et (d, e)

Adducts **2** were transformed effectively by the reaction with amines into 2-amino-3-phenylthiopropionitriles (**7**) (see Table 2 and Eq. 3) which are common intermediates for the synthesis of both title compounds. Pyrrolidine reacted with **2** exothermically and a diluent (ether) was required to control the reaction. Diethylamine reacted slowly at an ambient

temperature without solvent but effectively in boiling methanol. Both ethylamine and ammonia reacted effectively with any compound of **2** but products were thermally too labile to be isolated by distillation. Eventually, reaction mixtures were subjected directly to the following hydrolysis. When the product mixture containing **7f** was chromatographed through a silica-gel column, 2-(phenylthio)acetaldehyde cyanohydrin (**8**, ca. 10%) was isolated, which readily reacted with diethylamine independently in methanol to give **7g** (92%). This finding is indicative of the intermediacy of **8** in the main reaction channel that leads **2** to **7**.

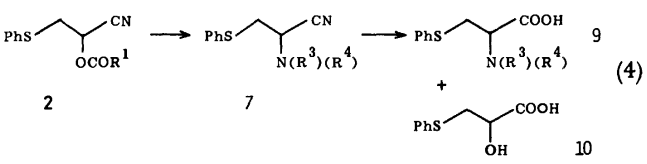
h, R^3 = Et, R^4 = H; **i**, $R^3 = R^4$ = H

The acid-catalyzed hydrolysis of **7i**[7] in aqueous HBr or H_2SO_4 gave *S*-phenylcysteine (**9**), the overall yield from **2** was 60—63% (Eq. 4). This procedure for the synthesis of **9** seems better than the reported not only in yield but also in simplicity.[8] The hydrolysis of 2-(1-pyrrolidinyl)nitrile (**7f**), however, did not give the expected amino acid, but a hydrolytic deamination took place to give 2-hydroxy-3-(phenylthio)propionic acid (**10**).[9] This is because the pyrrolidinyl group has a higher basicity than the $-NH_2$ group and hence it is protonated more easily and substituted by water.



(4)

2 7 9 10

In addition to the synthesis of 3-substituted 2-amino acids such as **9**, amino nitriles **7** exhibited an interesting behavior which can be synthetically utilizable to the preparation of thio-substituted enamines. We found that, in general, propionitriles **7** are thermally labile and unable to be isolated or purified by distillation.[10] We thought this deserves to be explored and the pyrolysis of **7** was independently investigated.[11]

When a benzene solution of **7f** was heated at 240 °C, 1-phenylthio-2-(1-pyrrolidinyl)ethene (**11f**) was obtained as a mixture of cis and trans isomers in 83% yield (conversion 71%) (Eq. 5). Analogously **7g** gave the diethylamino enamine **11g**. The same pyrolytic behaviors of both **7f** and **7g** were also observed in their VPC analysis when the injection temperatures were above 200 °C. It is noteworthy that the cyano group is the most preferable leaving group to the other potentially removable ones (phenylthio and amino group).

To summarize, 2-acyloxy-substituted acrylonitriles (**1**) have been proved to be a viable formylcarbonium ion synthon and they seem to provide us with easy access to several 2-substituted aldehyde derivatives.

Experimental

General Procedures. Boiling points are uncorrected. ^1H NMR spectra (chemical shifts are given in δ units in $CDCl_3$ solution) were recorded on Varian T-60A and IR spectra on JASCO IRA-1 spectrometers. Elemental Analyses were performed by Microanalysis Center of Kyoto University. Mass spectra including exact mass analyses were measured on a Hitachi M-80A mass spectrometer, and VPC anal ysis on Shimadzu GC-4CIT gas chromatograph (glass column; 10% Apiezon L on Chromosorb unless otherwise noted).

2-Acyloxyacrylonitriles (1). 2-Benzoyloxy- (**1a**), 2-pivaloyloxy- (**1b**), and 2-acetoxyacrylonitrile (**1c**) were synthesized from the corresponding acyl chlorides and acetyl cyanide according to our previous study.[12] Spectroscopic data of **1b** (for **1a**, **1c**, and **1d**, see Ref. 12) are as follows. ^1H NMR 1.27 (s, 9H), 5.65 (d×2, 2H, J=2.0 Hz). IR (liq film) 2960 (m), 1760 (s), 1630 (m), 1095 (s) cm^{-1}. $P^+(m/z)$ 153 (M^+).

Preparation of 3-Thio-substituted 2-Acyloxypropio-

a) Chemical shifts are in δ units and J values in Hz. b) Chemical shifts of Ph groups of **7** are abbreviated.

nitriles (2). Method A: To a mixture of acrylonitrile **1** (4 mmol) and thiol (R=Ph or Et, 5 to 6 mmol) in a solvent (MeOH, EtOH, *t*-BuOH, or Et_2O) was added a 40% MeOH solution of benzyltrimethylammonium hydroxide (Triton B, 40—80 μL) or K_2CO_3 (4 mmol). After stirring for a period at a desired temperature, the reaction mixture was extracted by a mixture of Et_2O and water, and the ethereal solution was dried ($MgSO_4$). Product **2** was separated after a silica-gel column chromatography.

Method B: Sodium metal (0.5 g, 20 mmol) was slowly added to a solution of PhSH (9.0 g, 90 mmol) and the mixture was warmed at 40 °C until sodium dissolved. The solution was cooled at −7 °C, **1c** (2.24 g, 20 mmol) was added, and the mixture was stirred for 1.5 h. The workup procedure was analogous to that of Method A.

Method C: In a photolysis apparatus equipped with a Pyrex filter and a medium pressure mercury lamp, a diluted pentane solution (200 mL) of PhSH (7.0 g) was charged and to which, under irradiation, a mixture of **1c** (3.9 g, 35 mmol) and PhSH (7.0 g) was added slowly over 2 h. After 20 h, **1c** disappeared. Adduct **2c** was isolated by a vacuum distillation. Bp 115—125 °C/1.5 mmHg (1 mmHg=133.3 Pa). Yield 55%.

Results are summarized in Table **1** and the spectroscopic data for **2** in Table 3. Exact mass of **2a**: Found, 283.0670. Calcd for $C_{16}H_{13}NO_2S$, 283.0667. **2b**: Found, 263.0978. Calcd for $C_{14}H_{17}NO_2S$, 263.0981. **2c**: Found, 221.0512. Calcd for $C_{11}H_{11}NO_2S$, 221.0511. Anal. of **2d**: Found: C, 61.53; H, 5.62; N, 5.93%. Calcd for $C_{12}H_{13}O_2NS$: C, 61.25; H, 5.57; N, 5.95%.

2-Amino-3-phenylthiopropionitriles (7). 2-Acyloxy-3-phenylthiopropionitrile (2, 1 mmol) in a solvent (Et_2O or MeOH) was mixed with an excess amount of amine (pyrrolidine, Et_2NH, 30% MeOH solution of $EtNH_2$, or NH_3 in MeOH; 3 to 20 equivalents), and the total mixture was stirred at an ambient temperature or 70 °C. 2-Amino-substituted 3-phenylthiopropionitriles (**7**) were obtained by distillation except the reactions with $EtNH_2$ and NH_3. In the latter cases products were thermally too labile to be distilled and, therefore, used directly in subsequent reactions. Results are listed in Table 2 and the spectroscopic data for **7** in Table 3.

Exact Mass of 7f: Found, 232.1038. Calcd for $C_{13}H_{16}N_2S$, 232.1036. Exact mass of the fragment peak corresponding to **11f**: Found, 205.0904. Calcd for $C_{12}H_{15}NS$, 205.0927. **7g**: Found, 234.1186. Calcd for $C_{13}H_{18}N_2S$, 234.1192. Exact mass of the fragment peak corresponding to **11g**: Found, 207.1065. Calcd for $C_{12}H_{17}NS$, 207.1083.

Acid-Hydrolysis of 2-Amino-3-phenylthiopropionitrile (7i). Nitrile **7i** (1.1 mmol) prepared quantitatively from **2c** and aqueous ammonia by the above procedure, but not isolated, was mixed with 0.2 mL of concd H_2SO_4 and 2 mL of water. The mixture was warmed at 120 °C for 24 h, cooled down to 20 °C, 2 mL of water was added, and neutralized by 28% aqueous ammonia to pH 8, After a small amount of charcoal was added, the solution was filtered, slightly acidified by diluted H_2SO_4 to pH 5, and cooled in dark to separate

S-phenylcysteine **9** in 63—70% yields. ^{1}H NMR 3.70 (br d, 2H, J=6.0 Hz), 4.50 (br q or t, 1H), 7.5 (m, 3H), 7.4 (m, 5H), 11.5 (s). IR (KBr) 2800 (broad), 1600 (s), 1500 (m), 1400 (s), 1360 (s), 720 (m) cm^{-1}.

Acid-Hydrolysis of 2-(1-Pyrrolidinyl)-3-phenylthiopropionitrile (7f). A mixture of **7f** (0.22 g, 0.95 mmol), water (0.5 mL), and 0.5 mL of 47% HBr was heated for 24 h under refluxing conditions. After the removal of water in vacuo, the residue was washed with a mixture of water and Et_2O, and the ethereal solution was analyzed to find that it consisted of only one product. The solution was esterified in MeOH by the Fischer method to give methyl 2-hydroxy-3-(phenylthio)-propionate **12** (30%). ^{1}H NMR 3.35 (s, 1H), 3.60 (s, 3H), 3.65 (br d, 2H, J=5.0 Hz), 4.37 (t, 1 H, J=5.0 Hz), 7.5 (m, 5H). IR (liq film) 3500 (broad, m), 1750 (s), 1595 (m), 1230 (broad, m), 1100 (s), 750 (m), 700 (m) cm^{-1}.

Pyrolysis of 2-(1-Pyrrolidinyl)-3-phenylthiopropionitrile (7f): Preparation of 1-Phenylthio-2-(1-pyrrolidinyl)ethene (11). A vertically fixed Pyrex column (30 cm length×10 mm i.d.) packed with glass beads was heated at 240 °C under a N_2 stream at 50 mmHg. A benzene solution (2 mL) of **7f** (0.4 mmol) was slowly injected from the top of the column and a product mixture was collected at −70 °C. 1-Phenylthio-2-(1-pyrrolidinyl)ethene (**11f**) was formed in 82% (conversion 71%). ^{1}H NMR 1.8 (m, 4H), 2.6 (m, 4H), 4.38 (d, 1H, J=12.8 Hz), 6.83 (d, 1H, J=12.8 Hz), 7.3 (m, 5H). For the exact mass of **11f**, see Experimental section corresponding to the preparation of **7f**. The same pyrolysis procedure on **7g** gave the thio enamine **11g** in 22% yield (conversion 49%). Mass spectrum of **11g**, m/z (relative intensity): 207 (M^+, 68), 174 (26), 116 (55), 91 (49), 56 (100). Exact mass: Found, 207.1070. Calcd for $C_{12}H_{17}NS$, 207.1083.

4) Thiol esters **6** (benzoate, pivalate) and thiol acetate were also formed as byproducts.

5) Not only the acidity constants of the acids corresponding to the respective ester but also the NMR chemical shift of the CH_2=proton of **1** may tell the relative reactivity toward Michael addition. Thus, the observed decreasing order in δ values of CH_2 (**1a** 5.87>**1c** 5.74>**1b** 5.67) may correspond to the reactivity order in the Michael addition. So does the IR(C=O) frequency the carbonyl reactivity toward thiolate ion, and the order in frequencies (**1c** 1765>**1b** 1760>**1a** 1740 cm^{-1}) may correspond to the reactivity in the displacement at the carbonyl.

6) Alcoholic solvents (MeOH, EtOH, *t*-BuOH) are more suitable for the reaction than ethers. When potassium carbonate was used instead of Triton B in the reaction of **1a**, the yield of **2a** slightly increased from 62 to 65% while **6a** decreased from 29 to 13%.

7) The reaction mixture of **2b** and NH_3 was directly hydrolyzed without isolating the intermediate **7i** (R^3=R^4=H)

8) L. Goodman, R. M. Moss, and B. R. Baker, *J. Org. Chem.*, **23**, 1251 (1958).

9) Product **10** was isolated as the Me ester after the treatment with MeOH.

10) Nitrile **7i** was also thermally labile under a VPC condition (injection 250 °C column 220 °C).

11) It was reported that 2-amino-2,3-diphenylpropionitrile was thermally unstable and underwent a dehydrocyanation to give the corresponding enamine. C. H. Hauser, A. M. Taylor, and T. G. Ledford, *J. Am. Chem. Soc.*, **82**, 1786 (1960).

(Received June 5, 1986)

The ^{13}CNMR spectra of diastereomeric pairs of the title compounds together with some tetrahydrofurans were examined and the chemical shifts were compared with those for the corresponding bicyclo[2.2.1]heptanes and -heptenes. The intramolecular interaction between the n-orbital of an oxygen atom and the π-orbital of an olefinic bond was found in 2-methylene-7-oxabicyclo[2.2.1]heptane. Intramolecular hydrogen bonding between the 7-oxygen and the hydroxyl group occurs in *exo*-7-oxabicyclo[2.2.1]heptane-2-methanol.

The ^{13}CNMR spectra of substituted 7-oxabicyclo[2.2.1]heptanes (**1**—**6**) and -heptenes (**7** and **8**) and some tetrahydrofurans (**9** and **10**) were examined. The chemical shifts were compared with those for analogous carbocyclic compounds. Some intramolecular interactions were expected between the oxygen atom introduced at the 7-position of a bicyclo[2.2.1]heptane skeleton and the functional group in the molecule. The hydrogen bonding in 7-oxabicyclo[2.2.1]heptane-2-methanol (**4**) and the n-π interaction in 2-methylene-7-oxabicyclo[2.2.1]heptane (**6**) were also studied.

Results and Discussion

The new compounds employed in this study were **6** and 2-methyl-7-oxabicyclo[2.2.1]hept-2-ene (**8**). The former was prepared by the thermal decomposition of 7-oxabicyclo[2.2.1]heptane-2-methanol acetate (**5**) over Pyrex chips at 450 °C and the latter was obtained by a Diels-Alder reaction of 3-methylfuran with ethylene.

Table 1 summarized the ^{13}C chemical shifts of **1**—**10**. The introduction of an oxygen atom to the 7-position of a bicyclo[2.2.1]heptane skeleton caused a downfield shift of 38 ppm for the carbon α to the oxygen atom,[1] but no appreciable shift was observed on the carbon β to the oxygen atom. The γ carbons, which are the carbons of the substituents attached to the 7-oxabicyclo[2.2.1]heptane skeleton, showed small upfield shifts compared to those for the corresponding bicyclo[2.2.1]heptanes.[1] Considerable shielding differences were observed in two diastereomeric 7-oxabicyclo[2.2.1]heptane derivatives. The signals for C2, C6, and the carbon of the substituent attached to the ring skeleton of endo-isomers always appeared at higher fields than those for exo-isomers. The resonances for C2, C6, and the methyl group of *endo*-2-methyl-7-oxabicyclo[2.2.1]heptane (*endo*-**2**) were shielded by 4.0, 6.1 and 5.3 ppm, respectively, compared to those for *exo*-**2**. The signals for other ring carbons of endo-isomers did not always appear at higher fields than those for exo-isomers. No significant shielding difference between the two diastereoisomers was found for carbons which were not directly bonded to the bicyclic skeleton. The shielding difference of the methyls between stereoisomeric methoxycarbonyl groups was 0.2 ppm and that for the acetoxyl groups was only 0.1 ppm. The resonances for the methyl carbons of diastereomers **2** appeared at δ 21.3 (exo) and 16.0 (endo). These values are comparable with those of the equatorial and axial methyls on a cyclohexane ring in a chair conformation.[2]

In the 7-oxabicyclo[2.2.1]hept-2-ene series (**7** and **8**), the introduction of a methyl group into an sp^2 carbon causes an upfield shift of the other sp^2 carbon compared to the parent compound. The methyl carbon signal for the sp^2 carbon also appeared at a higher field than that for the sp^3 carbon of compound **2**, as experienced on bicyclo[2.2.1]hept-2-enes.[1]

a) The carbon numbering is as follows:

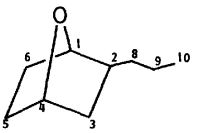

Table 2. Differences in β- and γ-Carbon Resonances between Unsaturated Compounds and between the Corresponding Saturated Ones (ppm)

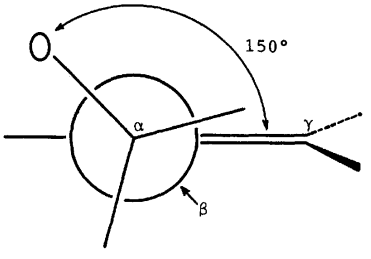
Unsaturated compound	β	γ	Saturated compound	β	γ
 6 – 11	−4.7	+0.7	 endo-2 – endo-13	+1.5	−1.5
 9 – 12	−0.5	+0.6	 14 – 15	−1.5	−3.0

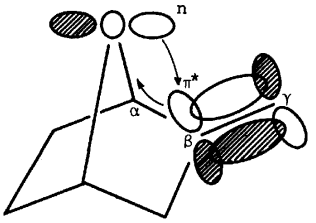
The chemical shifts were taken from[a)] Ref. 1. b) S. H. Grover and J. B. Stothers, *Can. J. Chem.*, **53**, 589 (1975). c) E. L. Eliel, V. S. Rao and K. M. Pietrusiewicz, *Org. Magn. Reson.*, **12**, 461 (1979). d) M. Christl, H. J. Reich and J. D. Roberts, *J. Am. Chem. Soc.*, **93**, 3463 (1971).

The ^{13}C chemical shifts for sp^2 carbons of **6** and 3-methylenetetrahydrofuran (**9**) were compared with those for the corresponding hydrocarbons (Table 2). The shielding differences, thus obtained, were compared with those for saturated compounds. The $\Delta\delta$ value for the carbon β to the oxygen atom between *endo*-**2** or 3-methyltetrahydrofuran (**14**) and the corresponding hydrocarbons (**13** or **15**) are +1.5 or −1.5, respectively, and that for the carbon γ to the oxygen atom being −1.5 or −3.0 ppm, respectively. On the other hand, the $\Delta\delta$ value between **6** or **9** and the corresponding hydrocarbon (**11** or **12**) are −4.7 and −0.5 for the β-carbon, and +0.7 and 0.6 ppm for the γ-carbon, respectively. The β carbon resonances for the unsaturated system which contains an oxygen atom were located at a higher field than those for the corresponding hydrocarbons. The γ carbon resonances, on the contrary, moved downfield compared to those for the corresponding hydrocarbons.

Molecular orbital interactions have been found between a nonbonding orbital of an oxygen and the π-orbital of the olefinic bond in a series of cyclic allylic ethers and alcohols in which the oxygen is placed at the anticlinal position with respect to the double bond.[3)] The Newman projection formula, viewed from C1 along the C1-C2 bond of **6** indicates that the dihedral angle between the O7-C1 bond and the C2-C8 (*exo*-methylene carbon) double bond is approximately 150°. This suggests the presence of the previously mentioned intramolecular orbital interac-

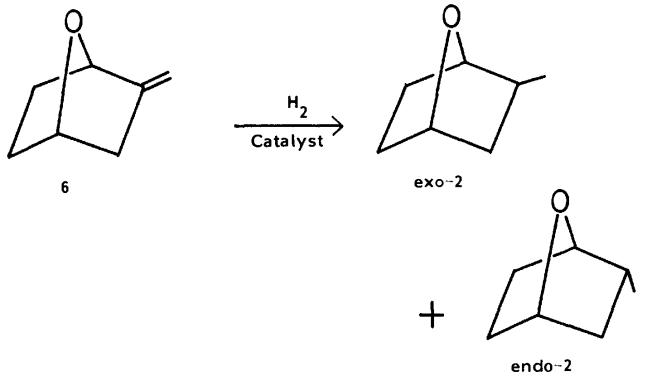


tion in this compound. The through-space interaction between the π-type n-orbital in the oxygen atom and the vacant p-π^*-orbital results in a decrease in the electron density at the oxygen atom. The enhanced effective electronegativity of the oxygen atom, therefore, induces a homoconjugative through-bond interaction between the C–O σ-orbital and the p-π-orbital.



The electron delocalization of the π-orbital by such through-space and through-bond interaction results in an upfield shift of the β carbon resonances and a downfield shift of γ carbon resonances. The shielding differences observed in a series of **9** infer the presence of an analogous orbital interaction.

The stereochemistry of the hydrogenation of 2-substituted 5-methylene-1,3-dioxanes over Group-VIII transition metals made a sharp contrast with that of 4-substituted 1-methylenecyclohexanes.[3b] A high cis selectivity was observed with the former, while the latter exhibited a wide variety of diastereomeric product distributions. The stereochemistry of the reaction was interpreted in terms of the n–π orbital interaction. The hydrogenation of **6** and 2-methylenebicyclo[2.2.1]-heptane (**11**) was performed over Group-VIII noble-metal catalysts in order to examine the stereochemistry of the reaction. In this case, the steric factor was always predominant, giving more than 58% endo-isomer (Table 3). The introduction of an oxygen atom into the 7-position of the bicyclo[2.2.1]heptane skeleton resulted in an increase in the attack of the hydrogen from the endo side, which is the opposite side of the oxygen atom. This also supports the presence of the n–π orbital interaction in **6**.[3b]



No evidence of intramolecular hydrogen bonding has been found in either *endo*- or *exo*-**4** by proton NMR spectroscopy.[4] In this work, the ν_{OH} vibration was carefully examined in these two diastereomers together with tetrahydrofuran-2-methanol (**10**) which corresponds to the partial structure of **4**. The spectra

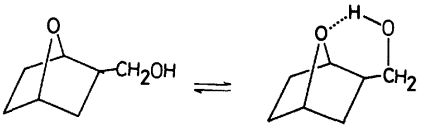
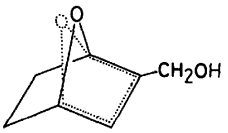
were obtained under such conditions as suppress intermolecular hydrogen bonding (in carbon tetrachloride at 4×10^{-3} M). Table 4 shows the infrared absorption frequencies in a hydroxyl stretching region. Alcohol **10** showed absorption for a free hydroxyl group at 3639 cm^{-1} and a bonded hydroxyl group at 3610 cm^{-1} as a shoulder of the main absorption. The absorption of *endo*-**4** at 3653 cm^{-1} could be associated with a free hydroxyl group, while the absorptions of *exo*-**4** appeared at 3654 and 3533 cm^{-1} corresponded to a free and a bonded hydroxyl group, respectively. Since the apparent areas of the absorption of both bonded and free hydroxyl bands of *exo*-**4**



are roughly equal, the hydrogen bonded conformers and the alternative seem to be of equal population. Such an equilibrium between the bonded and free hydroxyl species in the system may make it difficult to determine the hydrogen bonding in an NMR time scale. Essentially, free pseudo-rotation occurs between the half-chair (C_2) and the envelope (C_s) conformation of the tetrahydrofuran skeleton of **10**, with the former form slightly preferred.[5] In some conformations intramolecular hydrogen-bond formation is possible, but the bonded conformation is insufficiently stabilized by the formation of the hydrogen bond. Consequently, only a very weak absorption of a bonded hydroxyl appears. As expected, no hydrogen bond is formed in *endo*-**4** in which the C1–O7 and C2–CH_2OH bonds are in opposite direction. The tetrahydrofuran ring in **4** has a fixed C_s form with the oxygen atom out of the five-membered ring plane.[5] The structural

analysis of tetrahydrofuran and 7-oxabicyclo[2.2.1]-heptane homologs by X-ray diffraction,[6] electron diffraction[7] and microwave analysis[8] suggests that the degree of puckering of the tetrahydrofuran moiety of 7-oxabicyclo[2.2.1]heptane skeleton is a little greater than that of tetrahydrofuran itself. Consequently, the distance between O7 and the hydroxyl oxygen becomes smaller than that for **10**. This also supports the formation of stronger hydrogen bonding in the bicyclic system. Using either the equation derived by Kuhn[9] or the modified equation by Brutcher and Bauer[10] relating the $\Delta\nu$ to the hydrogen bonded distance, the distance between O7 and hydroxyl hydrogen in *exo*-**4** was estimated to be 1.28 or 1.74 Å, respectively. Since Ouellette et al. reported that the minimum O7-hydroxyl oxygen distance is 2.6 Å from the examination of the model,[4] the distance between the hydroxyl hydrogen and O7 was estimated to be 1.64 Å by assuming that the distance between the hydrogen and the oxygen of a hydroxyl group is 0.96 Å. This is in fair agreement with the results obtained in the present work. If it is possible to apply the enthalpy vs. shift difference of the ν_{OH} band relationship ($-\Delta H$ (kcal mol^{-1})$=0.016\ \Delta\nu_{OH}+0.63$)[11] to this system, $-\Delta H$ between the free and bonded species is then 10.7 kJ mol^{-1}. In this connection, $-\Delta H$ of the hydrogen bonding between benzyl alcohol and dioxane is 8.8 kJ mol^{-1}.[12]



Experimental

Materials. Diels-Alder reaction of furan and methyl acrylate by refluxing for 5 weeks followed by hydrogenation over Pd-C gave 7-oxabicyclo[2.2.1]heptane-2-carboxylic acid methyl ester (**3**) in a yield of 19%.[13] The two diastereomers of **3** were separated by fractional distillation. Ester **3** was reduced with LAH in ether to give **4**, (72%)[13] which was treated with acetic anhydride in pyridine to give **5** (70%).[13] The tosylate of **4** was reduced with LAH to give **2** (60%).[13] 1,4-Cyclohexanediol was heated over Al_2O_3 to give 7-oxabicyclo[2.2.1]heptane (**1**) (45%).[14] Diels-Alder reaction of furan with ethylene at 155 °C for 6 h gave 7-oxabicyclo[2.2.1]-hept-2-ene (**7**) (5%).[15] A Wittig reaction of tetrahydrofuran-3-one and of bicyclo[2.2.1]heptan-2-one with methyltriphenylphosphonium bromide gave **9** (65%)[16] and **11** (65%),[17] respectively. Tetrahydrofuran-3-carboxylate was reduced with LAH to give **10** (65%).[18]

2-Methylene-7-oxabicyclo[2.2.1]heptane (6). The acetate (18 g, 0.106 mol) was passed through a heated (440—450 °C) Pyrex tube (50 cm×10 mm) packed with Pyrex chips. The crude mixture was digested with pentane which was washed with a saturated $NaHCO_3$ solution and a saturated NaCl solution and then dried over $CaCl_2$. Distillation yielded **6** (3.2 g, 0.029 mol, 27%), bp 37 °C/40 mmHg. Found: C, 76.56; H, 9.58%. Calcd for $C_7H_{10}O$: C, 76.33; H, 9.15%. ^{1}H NMR (100 MHz, $CDCl_3$) δ=1.49—2.16 (6H), 4.73 (3H, m), 4.89 (1H, brs).

2-Methyl-7-oxabicyclo[2.2.1]hept-2-ene (8). After the mixture of 3-methylfuran (20 g, 0.244 mol) and ethylene (40 kg cm^{-2}) was stirred in a 200-ml autoclave at 150 °C for 24 h, the crude product was extracted with pentane. Distillation gave **8** (2 g, 0.018 mol, 7%), bp 115—120 °C. Found: C, 76.53; H, 9.53%. Calcd for $C_7H_{10}O$: C, 76.33; H, 9.15%. ^{1}H NMR (100 MHz, $CDCl_3$) δ=1.17 (2H, m), 1.27 (2H, m), 1.80 (3H, d, J=1.4 Hz), 4.69 (1H, brd, J=3.7 Hz), 4.87 (1H, brs), and 5.75 (1H, brs).

Catalytic Hydrogenation. The substrate (0.5 mmol) and the catalyst (5 mg) in ethanol (3 ml) were stirred with hydrogen at atmospheric pressure and room temperature. After the reaction was completed the catalyst was removed by the centrifugal method and the mixture was analyzed by GLC.

Spectra. ^{1}H NMR spectra were obtained with a Jeol FX-100 spectrometer and ^{13}C NMR spectra were obtained with a Jeol MH-100 and FX-100 spectrometers in an FT-mode using TMS as an internal standard. $CDCl_3$ was used as a solvent. IR spectra were measured with a Hitachi model 260-10 spectrometer using a 30-mm optical-length quartz cell. CCl_4 was used as a solvent.

We are grateful to Professor Kaoru Hanaya and Mr. Takashi Muramatsu, Miyagi University of Education, for measurements of IR spectra at high dilution.

Ethylene Glycol from Synthesis Gas by Homogeneous Ruthenium and Ruthenium-Rhodium Catalysts

Yoshihisa KISO* and Kenji SAEKI
Research Center, Mitsui Petrochemical Industries, Ltd., Waki-cho, Kuga-gun, Yamaguchi 740
(Received June 6, 1986)

In the formation of ethylene glycol from synthesis gas, amines (especially imidazole and its derivatives) enhanced the catalytic activity of a ruthenium carbonyl mixed with alkali metal halides. A rhodium carbonyl complex further promoted the activity and selectivity of a ruthenium-alkali metal halide-imidazole catalyst.

The direct formation of ethylene glycol from synthesis gas has been expected to be one of the most attractive new methods for ethylene glycol production on a commercial scale.[1,2] A number of homogeneous catalysts have been reported, such as rhodium, ruthenium, cobalt and iridium complexes.[3-10] Although some promoters, such as halides (alkali metal salt.[6] iminium salt[10] etc.) or carboxylic acids,[6,7] for ruthenium catalyst were reported, research concerning other types of promoters has scarcely been reported. In the course of our research regarding the formation of methanol and ethylene glycol from synthesis gas by ruthenium-alkali metal halide catalysts, we found that organic amines (especially imidazole compounds) promoted the activity of a ruthenium catalyst for ethylene glycol formation.[11] We also found that a rhodium carbonyl complex further enhanced the activity and selectivity of a ruthenium-halide-imidazole catalyst for ethylene glycol formation. In this paper, we report on the direct formation of ethylene glycol from synthesis gas by these ruthenium and ruthenium-rhodium bimetallic catalysts.

Results and Discussion

Ruthenium Catalyst Promoted by Halide and Amine. Dombek[6] reported that methanol and ethylene glycol are formed from synthesis gas when using a ruthenium-alkali metal halide catalyst. We examined the effect of organic amines on this ruthenium-halide catalyst (Eq. 1.).

$$CO + H_2 \xrightarrow{\text{Ru-halide-amine}} CH_3OH + HOCH_2CH_2OH \quad (1)$$

Table 1 summarizes the results for the synthesis of ethylene glycol and methanol in the presence of $[Ru_3(CO)_{12}]$, halide and amine. It was shown that *N*-methylmorpholine, pyridine, 2-pyridinol, benzimidazole, imidazole, and its methyl derivatives promoted the activity of a $[Ru_3(CO)_{12}]$-CsI catalyst for ethylene glycol formation. Of these amines, imidaozle derivatives and 2-pyridinol were especially effective. Furthermore, imidazole promoted the formation of ethylene glycol using a $[Ru_3(CO)_{12}]$ catalyst combined with several types of halide compounds (CsBr, CsCl, KI, Me_4NI, Ph_4NI). On the contrary, 2,2′-bipyridyl, pyrazole and triazole supressed the formation of ethylene glycol.

The activities for ethylene glycol and methanol formation were influenced by the molar ratio of amine to ruthenium. The molar ratio suitable for ethylene glycol formation increased in the following order; *N*-methylmorpholine<imidazole<pyridine≪2-pyridinol. This sequence shows that the more basic the amine, the lower the suitable molar ratio (pK_a at 25 °C: *N*-methylmorpholine 7.38, imidazole 6.95, pyridine 5.21, 2-pyridinol 1.25).[12] This result suggests that the amine acts as a base for the ruthenium catalyst. On the other hand, methanol formation increased with an increasing molar ratio of imidazole to ruthenium; however in the case of other amines, the activities did not greatly depend on the molar ratio of amine to ruthenium. We examined the IR spectra of a recovered reaction mixture started from $[Ru_3(CO)_{12}]$-CsI-imidazole catalyst system under a synthesis-gas atmosphere at room temperature. The spectra were similar to those started from a $[Ru_3(CO)_{12}]$-CsI catalyst system which result in the formation of $[HRu_3(CO)_{11}]^-$(ν(CO) 2020s, 1985s, 1950m cm^{-1}),[6] although the catalytic activities were different from each other. This result suggests that active species of both catalyst systems are similar; also, the ruthenium cluster anion is thought to play an important role in active species, as shown by Dombek in ruthenium-iodide catalyst system.[6] Probably, the amine is converted to an ammonium ion which acts as a cation against the ruthenium anion in the active species **1** (Eq. 2). A similar effect of amine as a cation has been proposed by Kaplan in ethylene glycol formation with a rhodium-amine catalyst:[6]

$$[HRu_x] + R_3N \rightleftharpoons \underset{\mathbf{1}}{[R_3NH]^+[Ru_x]^-}. \quad (2)$$

In ethylene glycol formation from synthesis gas, formaldehyde and glycolaldehyde are thought to be important intermediates; the formation of hydroxymethyl complex **3** from a formaldehyde complex **2** is an important step.[13] It is thought that amine promotes the formation of **3** by a proton transfer from the ammonium ion to **2** (Scheme 1). Without the aid of the ammonium ion, the formation of the methoxy complex **4** from **2** may be favored; this will produce methanol, not ethylene glycol.

Effect of Imidazole on Rhodium and Cobalt Catalysts. Rhodium carbonyls and cobalt carbonyls have

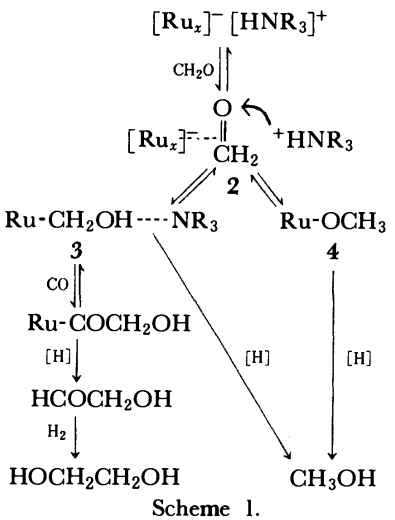
a) Charge: $[Ru_3(CO)_{12}]$ 0.10 mmol, halide 1.80 mmol, sulfolane 7.5 cm^3; run conditions: CO/H_2 (1:1) 300 kg cm^{-2}, 200 °C, 4 h. b) $100\times(HOCH_2H_2OH)\,mol/(CH_3OH+HOCH_2CH_2OH)\,mol$. c) Molar ratio of amine against Ru atom.



Scheme 1.

been known to be active catalysts for ethylene glycol formation from synthesis gas.[6)] Although the effect of amines on cobalt catalysts has scarcely been examined, amines such as alkylamines and pyridine derivatives have been reported to promote the activity of rhodium catalysts.[6)] In our research of ruthenium catalysts, imidazole derivatives were found to be effective promoters. Since the effect of imidazole derivatives on other metal catalysts has not been reported, we examined the effect of imidazole on a rhodium catalyst ($[Rh(CO)_2$(acac)] (acac=acetylacetonato) in sulfolane solvent) and a cobalt catalyst ($[Co_2(CO)_8]$ in toluene solvent), respectively (Table 2). These results showed that imidazole promoted the activity of a rhodium catalyst, though the level of activity was very low. On the contrary, a cobalt catalyst became deactivated upon adding imidazole.

Ruthenium-Rhodium Bimetallic Catalysts.[14)] As shown for ruthenium catalysts, the activity for ethylene glycol formation was promoted by amines. However, the selectivity to ethylene glycol was still low for the formation of a large amount of methanol. In order to increase the selectivity of the ruthenium catalyst, we examined the effect of a small amount of $[Rh(CO)_2$(acac)] on a ruthenium-CsI catalyst system, since several rhodium catalysts have been known to show a high selectivity to ethylene glycol. Table 3 summarizes the results of ruthenium-rhodium-CsI-imidazole catalyst. Although, rhodium itself did not show catalytic activity under the condition given in Table 3, it promoted the activity and selectivity of a ruthenium

Table 2. Effect of Imidazole on Rhodium or Cobalt Catalyst

Table 4. Synthesis Gas Reaction in the Presence of $[Ru_3(CO)_{12}]$-$Rh(CO)_2(acac)]$ Catalyst Promoted by CsI and Imidazole[a]

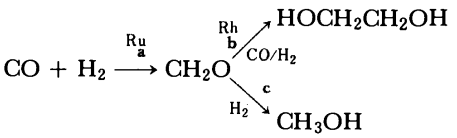
mol% of metal		mmol h^{-1}[b]	
Ru	Rh	CH_3OH	$HOCH_2CH_2OH$
100	0	6.51	0.97
86	14	4.07	2.18
75	25	2.65	2.16
50	50	1.84	1.86
0	100	0.05	0.11

a) Charge: Ru+Rh 0.4 mmol, CsI 2.4 mmol, Imidazole 2.0 mmol, *N*-methyl-2-pyrrolidone 10 cm^3; run conditions: CO/H_2 (1:1) 500 kg cm^{-2}, 200°C, 2 h. b) In addition to methanol and ethylene glycol, small amounts of other products were formed. For example in the case of catalyst Ru/Rh=75/25, methylformate 0.01 mmol h^{-1}, ethanol 0.08 mmol h^{-1} and 1,2-propanediol 0.22 mmol h^{-1} were formed.

catalyst for ethylene glycol formation. Furthermore, promotion by imidazole was also observed in ruthenium-rhodium-CsI catalysis.

In order to analyze the functions of ruthenium and rhodium metal centers, we examined the activity of ruthenium-rhodium bimetallic catalysts with various molar ratios of ruthenium/rhodium. Table 4 summarizes the results from synthesis gas reactions in the presence of $[Ru_3(CO)_{12}]$, $[Rh(CO)_2(acac)]$, CsI and imidazole. In these reactions, the total number of ruthenium and rhodium atoms were kept constant. Ethylene glycol and methanol were the main products, and small amounts of other products (methylformate, ethanol and 1,2-propanediol) were formed. The rate of ethylene glycol formation was maximum at a molar ratio of ruthenium to rhodium around 6:1—3:1.

As mentioned in the prior section, ethylene glycol and methanol are thought to be formed through the common intermediate, formaldehyde (Scheme 2).[15] Since little or no formaldehyde (or its derivatives) was detected by GC analyses, steps **b** and **c** may be faster than step **a**; therefore, the total rate of ethylene glycol and methanol formation may depend upon the rate of step **a**. This total rate (mol h^{-1}) was found to increase with increasing concentration of ruthenium (Fig. 1). This result suggests that step **a** is catalyzed mainly by ruthenium in ruthenium-rhodium bimetallic catalyst. The molar ratio of ethylene glycol to methanol, which depends upon the relative rate of step **b**/step **c**, increased upon increasing the concentration of rhodium (Fig. 1). Rhodium may promote the formation of ethylene glycol from formaldehyde. Thus, ruthenium and rhodium play important independent roles in bimetallic catalyst.



Scheme 2.

We analyzed the catalysts with IR spectra under a synthesis-gas atomsphere at room temperature. Rhodium anion species, $[Rh(CO)_4]^-$ (ν(CO) 1895s cm^{-1})[16] and minor $[Rh(CO)_2I_2]^-$ (ν(CO) 2010, 1975 cm^{-1})[17] were observed in the reaction mixture starting from rhodium-CsI-imidazole catalyst. An IR analysis of the reaction mixture starting from ruthenium-rhodium-CsI-imidazole catalyst showed the existance of $[HRu_3$-

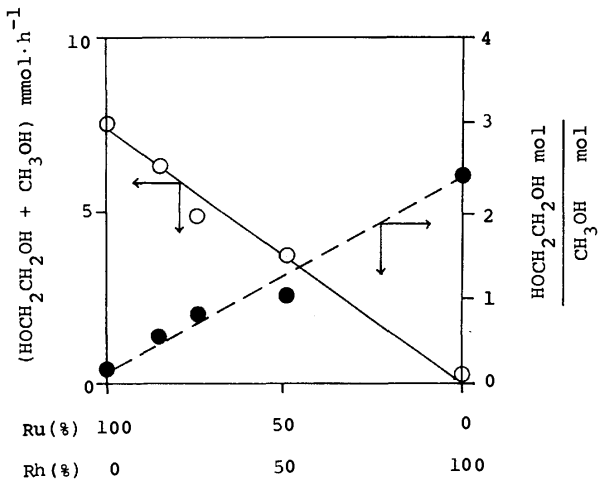


Fig. 1. Effect of molar ratio of ruthenium/rhodium on activities and selectivities of catalysts. ——○——, ($HOCH_2CH_2OH+CH_3OH$) mmol h^{-1}; ——●——, molar ratio of $HOCH_2CH_2OH$ against CH_3OH. Conditions; see Table 4.

$(CO)_{11}]^-$, $[Rh(CO)_4]^-$, and $[Rh(CO)_2I_2]^-$. No other species (such as mixed metal clusters) were observed. These results support Scheme 2 in which ruthenium and rhodium act independently.

Experimental

Catalytic expreiments were carried out in a 60-ml autoclave made of Hastelloy C-276. The reactor was charged with metal carbonyl ($[Ru_3(CO)_{12}]$, $[Rh(CO)_2(acac)]$, $[Co_2(CO)_8]$), an additive (halide, amine) and a solvent and was pressurized with CO/H_2 (1 : 1) gas and heated under stirring with a magnetic stirrer (300—600 kg cm^{-2}, 200—240 °C, 2—4 h). An analysis of the products was performed by gas chromatography (column; 10% PEG20M TPA/Chromosorb 102). Infrared spectra were recorded with a Shimadzu IR-420 spectrometer under a synthesis-gas atomsphere at room temperature.

This work was one part of the "C_1 Chemistry Project," a National Research and Development Program of Agency of Industrial Science and Technology, Ministry of International Trade and Industry (M. I. T. I.), Japan. We wish to thank Mr. Tetsuo Hayashi, Mr. Hideto Matsuoka, and Mr. Hiroyoshi Tarumoto for experimental assistance, and are grateful to Mr. Masahide Tanaka and the members of Ethylene Glycol Group of the Project for valuable discussions.

(Received June 20, 1986)

Sensitized photoreactions of 2-pyrones with chloroethylenes gave two kinds of [2+2]cycloadducts, 2-oxabicyclo[4.2.0]oct-4-en-3-ones (**4**, **8**) and across the C_3–C_4 double bond in 2-pyrone, benzene derivatives, and/or cyclobutanecarboxylic acids: Their relative yields greatly depended upon the nature of the reactants. The dehydrochlorination of the cycloadducts **4** and **8** across the C_5–C_6 double bonds in the pyrones with triethylamine in ethanol gave 5-ethenyl-2-pyrones, whose structures were previously incorrectly assigned as oxocinones, via a symmetry-allowed ring opening of 2-oxabicyclo[4.2.0]octa-4,6-dien-3-ones. Some 5-ethenyl-2-pyrones possessing a chlorinated ethenyl group finally affords 5-ethynyl-2-pyrones by an anti-elimination of hydrogen chloride. The X-ray crystallographic analyses of 5-ethenyl- and 5-ethynyl-2-pyrones are also described.

Although much attention has been denoted to the thermal cycloaddition reactions of 2-pyrones,[1] the investigation of their photochemical ones has not been extended beyond our reports[2,3] except dimerization.[4] The sensitized photochemical reaction of 4,6-dimethyl-2-pyrone (**1**) with such electron-deficient olefins as acrylonitrile and methyl acrylate gave two stereoisomeric [2+2]cycloadducts, as major products, across the C_5–C_6 double bond in **1**,[2] while methyl 2-pyrone-5-carboxylate afforded two stereoisomeric [4+2]cycloadducts in the reaction with acrylonitrile under similar conditions.[3]

Hanifin and Cohen[5] have first reported the formation of an eight-membered oxygen heterocycle, oxacyclooctatrienone (oxocinone) ring system, by the pyrolysis of a 3-chlorocoumarin photodimer with the elimination of hydrogen chloride. It was demonstrated, however, that the pyrolysis of photochemical [2+2]-cycloadducts between 2,6-dimethyl-4-pyrone with acetylenes gave no expected monocyclic oxocinones, but instead the adducts underwent a symmetry-allowed bicyclic Claisen rearrangement followed by aromatization to substituted phenols.[6] Thus, it has not been known monocyclic oxocinone ring system up to date. If [2+2]cycloadducts are again formed in the photochemical reaction of such 2-pyrones bearing an electron-donating group as **1** with halogen-substituted olefins, the halogenated cycloadducts would be expected to give monocyclic oxocinones by dehydrohalogenation with a concurrent ring expansion.

The purpose of this work was to prepare halogenated [2+2]cycloadducts to 2-pyrones in hope that they would serve as useful intermediates in the preparation of monocyclic oxocinones. This paper describes the sensitized photochemical reaction of 4,6-dimethyl- (**1**) and 4-methoxy-6-methyl-2-pyrone (**2**) with chlorinated olefins, and the dehydrochlorination of [2+2]cycloadducts. The previously proposed structures for dehydrochlorinated products[7] are also revised.

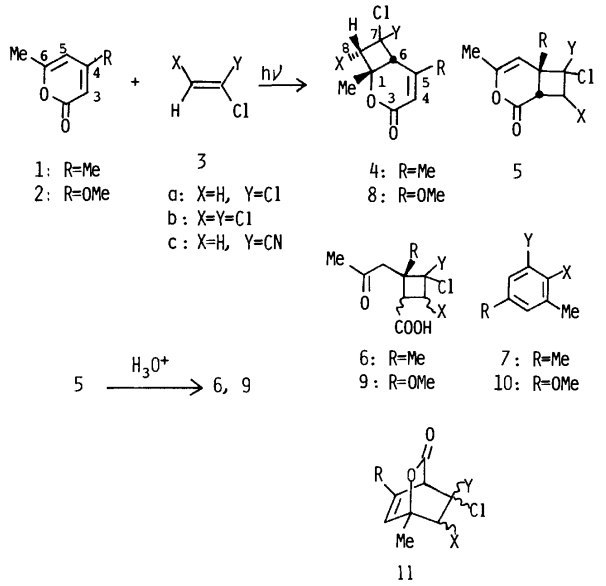
Results and Discussion

Photochemical Reactions. A solution of 4,6-dimethyl-2-pyrone (**1**) and 1,1-dichloroethylene (**3a**), trichloroethylene (**3b**), or 2-chloroacrylonitrile (**3c**), in the presence of benzophenone as a sensitizer, in acetonitrile was irradiated, through a Pyrex vessel, with a 400W high-pressure mercury lamp under nitrogen. As expected, [2+2]cycloadducts **4** were obtained in all reactions together with other products, **5**, **6** and/or **7**: Their relative yields greatly depended upon the nature of olefins (Table 1).

The products, **4a—c**, formed in all cases were assigned as regioselective [2+2]cycloadducts, 2-oxabicyclo-[4.2.0]oct-4-en-3-ones, across the C_5–C_6 double bond in **1**, and two isomers, **4c**-1 (major) and **4c**-2 (minor), which were formed in the reaction with **3c**, were deduced to be *endo*- and *exo*-7-cyano derivatives, respectively, on the basis of spectral data. Since two isomers, **4c**-1 and **4c**-2, as well as **4a** and **4b** did not change on treatment with basic alumina, which was used to infer the stereochemistry of ring junctions in photochemical [2+2]cycloadducts,[2,8] all the adducts **4** could be assigned as *cis*-fused. And, it seemed reasonable to assume that the configurations between hydrogens at 6- and 8-positions in all **4** are *cis*, because of showing a large value (2.0 Hz) of long range coupling.[9]

On the basis of comparison of spectral data of similar corresponding compounds,[2] the other products, **5**, **6**, and **7**, were easily assigned as the corresponding 3-oxabicyclo[4.2.0]oct-4-en-2-one, 2-acetonyl-2-methyl-1-cyclobutane carboxylic acids, and *m*-xylene derivatives, respectively (Scheme 1).

The photochemical reaction of 4-methoxy-6-methyl-2-pyrone (**2**) with **3a** under similar conditions gave the corresponding [2+2]cycloadduct **8a**, together with a cyclobutanecarboxylic acid **9a** as the major product. In the reaction with **3b**, **2** gave three products, [2+2]cycloadduct **8b**, cyclobutanecarboxylic acid **9b**, and 2,3-dichloro-5-methoxytoluene (**10b**). The results



Scheme 1.

Table 1. Photochemical Reaction of 2-Pyrones with Chlorinated Ethylenes[a)]

2-Pyrone	Ethylene	Products (yield/%)
1	**3a**	**4a** (17), **5a** (34)
1	**3b**	**4b** (10), **6b** (5), **7b** (4)
1	**3c**	**4c** (23),[b)] **7c** (13)
2	**3a**	**8a** (16), **9a** (56)
2	**3b**	**8b** (23), **9b** (8), **10b** (17)

a) A solution of 2-pyrone and ethylene was irradiated in the presence of benzophenone. b) Two stereoisomers, **4c**-1 and **4c**-2, were isolated in 17 and 6% yields.

are also given in Table 1.

The [2+2]cycloadducts, **8a** and **8b**, were again assigned as regio- and stereoselective adducts, like **4a** and **4b**, across the C_5–C_6 double bond in **2**, respectively.

The cyclobutanecarboxylic acids, **6** and **9**, correspond to hydrolyzed products of [2+2]cycloadducts **5** across the C_3–C_4 double bonds in **1** and **2**, respectively. In fact, the cycloadduct **5a** (R=Me, X=H, Y=Cl) was quantitatively hydrolyzed to **6a** at room temperature. On the other hand, it is evident that toluene derivatives, **7** and **10** are formed from [4+2]cycloadducts like **11** with the decarboxylation followed by dehydrochlorination (Scheme 1).

Dehydrochlorination of the 2-Oxabicyclo[4.2.0]oct-4-en-3-ones. Dehydrochlorination of the [2+2]cycloadducts, **4** and **8**, with triethylamine in ethanol under reflux afforded three types of dehydrochlorinated products depending upon the nature of substituents on the adducts as well as the reaction conditions.

The reaction of dichloro-substituted adduct **4a** with triethylamine for 30 h afforded a product **14a** with the elimination of two moles of hydrogen chloride, while trichloro- **4b** and monochloro-substituted adduct **4c** (a mixture of two isomers) gave high yields of monodehydrochlorinated products, **13b** and **13c**, under similar conditions for 15 h. Similar treatment of the dichloro-substituted adduct **8a** with triethylamine afforded a mono- **16a** and di-dehydrochlorinated product **17a** depending upon the reaction conditions (Table 2).

Table 2. Dehydrochlorination of [2+2]Cycloadducts

[2+2]Cycloadduct	Conditions[a)] Time/h	Product Yield/%
4a	Et_3N 30	**14a** 41
4b	Et_3N 15	**13b** 97
4c[b)]	Et_3N 15	**13c** 89
8a	Et_3N 2	**16a** 95
8a	Et_3N 38	**17a** 89
8b	Et_3N 1.5	**12b** 82
12b[c)]	100 °C 2	**16b** 80

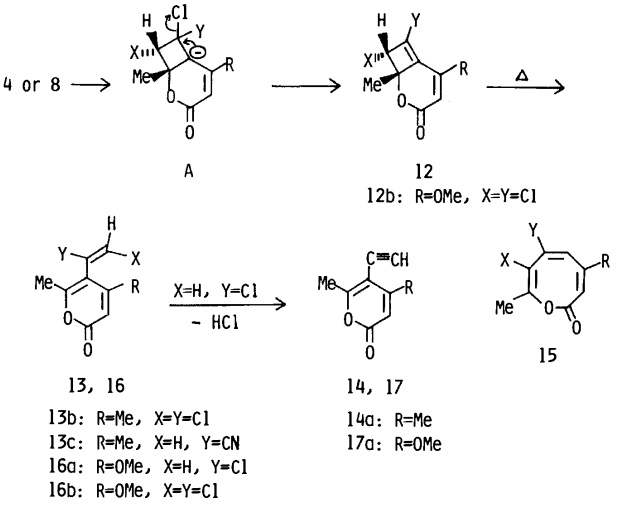
a) The reactions with Et_3N were carried out in EtOH under reflux. b) A mixture of **4c**-1 and **4c**-2 was used. c) Heated in DMSO.

The spectral data indicated that the products, **13b**, **13c**, **16a**, have similar structures each other. Although we have previously proposed the 2*H*-oxocin-2-one structures (**15**) for the compounds, **13b** and **13c**,[7)] they should be now revised to 5-ethenyl-2-pyrones on the basis of further inspection of spectral data. In addition, **13b** was finally confirmed to be 5-(*trans*-1,2-dichloroethenyl)-4,6-dimethyl-2-pyrone by the X-ray crystallographic analysis.

The di-dehydrochlorinated products, **14a** and **17a**, could be assigned as the corresponding 5-ethynyl-2-pyrones, respectively, on the basis of spectral data, and finally of X-ray crystallographic analysis of **14a**.

The X-ray crystallographic data of **13b** and **14a** will be shown in the next section.

On the other hand, the reaction of trichloro-substituted adduct **8b** with triethylamine for 1.5 h afforded another type of mono-dehydrochlorinated product **12b**, which was easily converted into an isomeric 5-ethenyl-2-pyrone (**16b**) on heating at 100 °C for 2 h (Table 2).



Scheme 2.

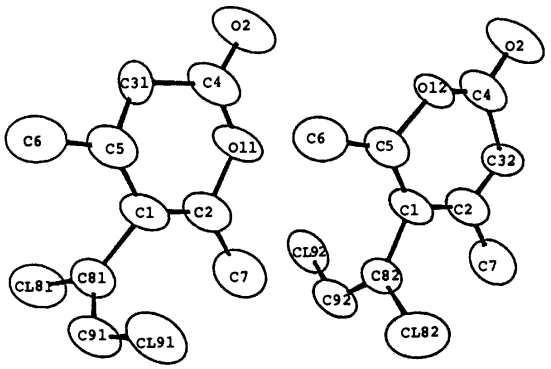


Fig. 1. Two possible molecules, **13b**, at a crystallographically equivalent site.

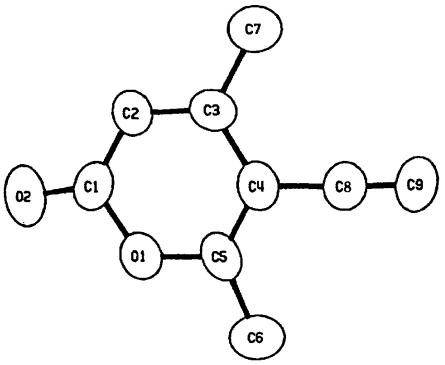

Fig. 2. Molecular structure of **14a**.

On the basis of spectral data the compound **12b** was deduced to be 7,8-dichloro-5-methoxy-1-methyl-2-oxabicyclo[4.2.0]octa-4,6-dien-3-one. Both its IR and ^{1}H NMR spectra are very similar to those of the starting [2+2]cycloadduct **8b**, except for an additional double bond absorption (1580 cm^{-1}) in the IR and a lack of a methine proton at 6-position in the ^{1}H NMR spectra. In the ^{13}C NMR spectrum, **12b** has two additional sp^2 carbons (δ 135.3 and 131.3) assigned to 6-and 7-C, accompanying lacks of sp^3 carbons (δ 53.5 and 85.3) in **8b**.

These dehydrochlorinations are summarized as follows; dichloro-**4a** → **14a**, trichloro-**4b** → **13b**, monochloro-**4c** → **13c**, dichloro-**8a** → **16a** → **17a**, trichloro-**8b** → **12b** → **16b**. The formation of **12b** from **8b** was effective in ethanol solvent, but not in benzene.

On the basis of the above results, the transformation sequence, **4** or **8** → **12** → **13** or **16** → **14** or **17**, can be illustrated as shown in Scheme 2. The elimination of a proton from **4** or **8** with triethylamine occurs at the 6-position but not at the 8-position, and generates an anionic intermediate A which is stabilized by the conjugated enone and by solvation in ethanol. Subsequent elimination of a chloride ion from A gives **12**, which then undergoes a symmetry-allowed ring opening to afford **13** or **16**. Finally, the chlorinated ethenyl-2-pyrones (**13**, **16**) (X=H, Y=Cl) give **14** and **17** by an anti-elimination of hydrogen chloride.

X-Ray Crystal Structures of 5-Ethenyl- (13b) and 5-Ethynyl-2-pyrone (14a). The molecular structures of **13b** and **14a** are illustrated in Figs. 1 and 2, respectively. Bond lengths and angles for **13b** and **14a** are also listed in Tables 3 and 4, respectively.

The compound **13b** has some interesting and unusual features in its molecular geometry. The length of the bond C_1-C_{81} (1.54 Å) is fairly longer than that for a normal conjugated single bond (ca. 1.47 Å), while the double bond C_{81}-C_{91} is fairly short (1.30 Å) (Table 3). As shown in Fig. 1, the sp^2 face of the dichloroethenyl group (C_{81}-C_{91}-CL_{91}) is distorted against the 2-pyrone face (torsional angle of C_2-C_1-C_{81}-C_{91}=94.4°) (Table 5). The characteristic geometry can be easily explained on the basis of the steric repulsion between the 5-(1,2-dichloroethenyl) group and 4,6-dimethyl groups.

Experimental

General and Materials. All melting points were uncorrected. UV spectra were recorded on a Hitachi EPS-3 spectrometer and IR spectra were determined with JASCO A-3 spectrometer. ^{1}H and ^{13}C NMR spectra were measured for $CDCl_3$ solutions on a JEOL JNM-MH-100 (100 MHz) and JEOL FX-100 (25 MHz) spectrometers using TMS as the internal reference. Mass spectra were measured with a JEOL

JMS-0lSG spectrometer. The X-ray diffraction data were obtained on an Enraf-Nonius CAD-4 automated four-circle diffractometer with a SDP program package. All the photoaddition and synthetic application reactions were monitored by the use of GC, which was performed at 170 °C (column temp) on a Yanagimoto G80 instrument using a column of Silicone SE-30 (10%)/Chromosorb W (AW). Wakogel C200 was used for preparative column chromatography.

4,6-Dimethyl-2-pyrone (**1**)[10] and 4-methoxy-6-methyl-2-pyrone (**2**)[11] were prepared according to methods previously descrived in the literature.

Photoreaction of 1 with 3a. A solution of **1** (3.0 g, 24 mmol), **3a** (23 ml, 240 mmol), and benzophenone (0.5 g, 2.7 mmol) as a sensitizer in 200 ml of acetonitrile under nitrogen atmosphere was irradiated with a Riko immersion-type 400W high-pressure mercury lamp through a Pyrex vessel at 0—5 °C for 2.5 h. The solvent was removed by the use of a rotary evaporator. The residue was chromatographed on a silica-gel column with benzene-acetone (40 : 1) gave 1.81 g (34%) of **5a** (R=Me, X=H, Y=Cl), and with (20 : 1) gave 0.90 g (17%) of **4a**. Adding one drop of water to 11 mg of **5a** and left 10d at room temperature to give 12 mg (100%) of **6a**. Compound **5a** was detected by GC analysis at 1.8 min when **4a** was at 2.6 min.

4a: Colorless oil; IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.62 (3H, s, Me), 2.06 (3H, br. s, Me), 3.24 (1H, dd, J_{gem}=16.0, $J_{8,6}$=2.0 Hz, 8-*exo*-H), 3.40 (1H, d, J_{gem}=16.0 Hz, 8-*endo*-H), 3.62 (1H, br. s, 6-H), 6.14 (1H, br. s, 4-H); MS *m/z* (220 M^+, 0.3%), 105 (base peak).

Found: C, 49.34; H, 4.56%. Calcd for $C_9H_{10}O_2Cl_2$: C, 48.90; H, 4.56%.

5a: Colorless plates from hexane; mp 78—79 °C; IR (KBr) 1765 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.43, 2.04 (each 3H, s, Me), 3.22 (3H, m, 1-H, 8-CH_2), 5.12 (1H, br. s, 5-H); MS *m/z* 220 (M^+, 2%), 82 (base peak).

Found: C, 48.80; H, 4.56%. Calcd for $C_9H_{10}O_2Cl_2$: C, 48.89; H, 4.53%.

6a: Colorless solid from acetone; mp 115—116 °C; IR (KBr) 1720, 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.58, 2.15 (each 3H, s, Me), 2.82, 3.10 (each 1H, d, J_{gem}=18.5 Hz, 5-CH_2), 3.08—3.3 (2H, m, 1-, 4-H), 10.20 (1H, br. s, COOH); MS *m/z* 238 (M^+, 0.3%), 82 (base peack).

Found: C, 45.39; H, 5.08%. Calcd for $C_9H_{12}O_3Cl_2$: C, 45.21; H, 5.06%.

Photoreaction of 1 with 3b. A solution of **1** (5.0 g, 40 mmol), **3b** (28 ml, 310 mmol), and benzophenone (1.6 g, 9 mmol) in 200 ml of acetonitrile was irradiated for 28 h. The solvent was then removed to give 1.0 g (10%) of **4b**. The residue was chromatographed with benzene to afford 0.11 g (4%) of 4,5-dichloro-*m*-xylene (**7b**). The continued elution with benzene-acetone (5 : 1) gave 0.51 g (5%) of **6b**.

4b: Colorless needles from benzene; mp 192—193 °C; IR (KBr) 1722 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.55 (3H, s, Me), 2.03 (3H, d, Me), 3.48 (1H, d, $J_{6,8}$=2.0 Hz, 6-H), 4.76 (1H, d, $J_{8,6}$=2.0 Hz, 8-H), 6.00 (1H, br. s, 4-H); MS *m/z* 219 (M-Cl, 6%), 124 (base peak).

Found: C, 42.27; H, 3.52%. Calcd for $C_9H_9O_2Cl_3$: C, 42.30; H, 3.57%.

6b: Colorless needles from benzene-acetone (5 : 1); mp 132—135 °C; IR (KBr) 1738, 1698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.60, 2.16 (each 3H, s, Me), 2.82, 3.14 (each 1H, d, J_{gem}=19.0 Hz, CH_2), 3.02 (1H, d, $J_{1,4}$=10.0 Hz, 1-H), 4.90 (1H, d, $J_{4,1}$=10.0 Hz, 4-H), 10.0 (1H, br. s, COOH); MS *m/z* 272 (M^+, 0.1%), 148 (base peak).

Found: C, 39.76; H, 4.13%. Calcd for $C_9H_{11}O_3Cl_3$: C, 39.53; H, 4.03%.

Photoreaction of 1 with 3c. A solution of **1** (3.0 g, 24 mmol), **3c** (9.5 ml, 120 mmol), and benzophenone (0.5 g, 2.7 mmol) in 200 ml of acetonitrile was irradiated for 1.5 h and the solvent was then removed. The chromatography of the residue with benzene gave 0.41 g (13%) of 3,5-dimethylbenzonitrile (**7c**). The continued elution with benzene-acetone (10 : 1) afforded 1.16 g of a mixture between **4c**-1 (17%) and **4c**-2 (6%), from which both of them were isolated by repeated chromatography.

4c-1: Colorless plates from diethyl ether; mp 100—102 °C; IR (KBr) 2250, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.64 (3H, s, Me), 2.10 (3H, br. s, Me), 2.92 (1H, dd, J_{gem}=14.0, $J_{8,6}$=2.0 Hz, 8-*exo*-H), 3.36 (1H, d, J_{gem}=14.0 Hz, 8-*endo*-H), 3.36 (1H, br.s, 6-H), 6.12 (1H, br.s, 4-H); MS *m/z* 212 (M^++1, 11%), 96 (base peak).

Found: C, 56.76; H, 4.88; N, 6.65%. Calcd for $C_{10}H_{10}NO_2Cl$: C, 56.75; H, 4.76; N, 6.62%.

4c-2: Colorless plates from diethyl ether; mp 110—113 °C; IR (KBr) 2250, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.64 (3H, s, Me), 2.05 (3H, br. s, Me), 3.10 (1H, d, J_{gem}=14.0 Hz, 8-*endo*-H), 3.30 (1H, dd, J_{gem}=14.0, $J_{8,6}$=2.0 Hz, 8-*exo*-H), 3.68 (1H, br. s, 6-H), 6.35 (1H, br. s, 4-H); MS *m/z* 212 (M^++1, 3%), 96 (base peak).

Found: C, 56.69; H, 4.78; N, 6.48%. Calcd for $C_{10}H_{10}NO_2Cl$: C, 56.75; H, 4.76; N, 6.62%.

Photoreaction of 2 with 3a. A solution of **2** (7.0 g, 50 mmol), **3a** (48 ml, 500 mmol), benzophenone (1.0 g, 5.4 mmol), and acetonitrile (500 ml) was irradiated at 0—5 °C for 4 h, the same work-up as mentioned above to give 7.2 g (56%) of **9a** from concentration and 1.7 g (16%) of **8a** from column chromatography with benzene-acetone (10 : 1). The precursor of **9a** was detected by GC analysis at 3.0 min when **8a** was at 5.5 min.

8a: Colorless leaflets from acetone-hexane (1 : 3); mp 98—99 °C; IR (KBr) 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.66 (3H, s, Me), 3.20 (1H, dd, J_{gem}=15.0, $J_{8,6}$=2.0 Hz, 8-*exo*-H), 3.36 (1H, d, J_{gem}=15.0 Hz, 8-*endo*-H), 3.68 (1H, d, $J_{6,8}$=2.0 Hz, 6-H), 3.80 (3H, s, OMe), 5.36 (1H, s, 4-H); MS *m/z* 236 (M^+, 2%), 112 (base peak).

Found: C, 45.63; H, 4.22%. Calcd for $C_9H_{10}O_3Cl_2$: C, 45.60; H, 4.25%.

9a: Colorless prisms from acetone; mp 121—122 °C; IR (KBr) 1730, 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.18 (3H, s, Me), 2.76 (2H, d, $J_{4,1}$=8.5 Hz, 4-CH_2), 3.19 (2H, s, 5-CH_2), 3.40 (3H, s, OMe), 3.44 (1H, t, $J_{1,4}$=8.5 Hz, 1-H), 10.5 (1H, br. s, COOH); MS *m/z* 237 (M−H_2O+1, 0.2%), 98 (base peak).

Found: C, 42.39; H, 4.76%. Calcd for $C_9H_{12}O_4Cl_2$: C, 42.54; H, 4.74%.

Photoreaction of 2 with 3b. A solution of **2** (5.1 g, 36 mmol), **3b** (38 ml, 430 mmol), benzophenone (2.0 g, 11 mmol), and acetonitrile (450 ml) was irradiated for 10 h and then removed the solvent to afford 2.3 g (23%) of **8b**. The column chromatography of the filtrate with benzene gave 1.2 g (17%) of 2,3-dichloro-5-methoxytoluene (**10b**) and with benzene-acetone (1 : 1) gave 0.9 g (8%) of **9b**. The precursor of **9b** was detected by GC analysis at 2.1 min when **8b** was at 11.0 min.

8b: Colorless plates from diethyl ether-hexane (2 : 1); mp 210—212 °C; IR (KBr) 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.60

(3H, s, Me), 3.26 (1H, d, $J_{6,8}$=2.0 Hz, 6-H), 3.81 (3H, s, OMe), 4.77 (1H, d, $J_{8,6}$=2.0 Hz, 8-*exo*-H), 5.35 (1H, s, 4-H); MS *m/z* 270 (M^+, 0.2%), 112 (base peak).

Found: C, 39.87; H, 3.33%. Calcd for $C_9H_9O_3Cl_3$: C, 39.81; H, 3.34%.

9b: Colorless plates from chloroform-hexane (1 : 1); mp 156—157 °C; IR (KBr) 1720, 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.24 (3H, s, Me), 3.12, 3.40 (each 1H, d, J_{gem}=19.0 Hz, CH_2), 3.42 (1H, d, $J_{4,1}$=10.0 Hz, 4-H), 3.43 (3H, s, OMe), 4.61 (1H, d, $J_{1,4}$=10.0 Hz, 1-H), 8.14 (1H, br.s, COOH); MS *m/z* 273 ($M-H_2O+1$, 0.1%), 98 (base peak).

Found: C, 37.33; H, 3.83%. Calcd for $C_9H_{11}O_4Cl_3$: C, 37.50; H, 3.80%.

Dehydrochlorination of 4a. A mixture of **4a** (0.28 g, 1.3 mmol), triethylamine (0.6 ml, 4.4 mmol), and ethanol (5 ml) was refluxed for 30 h. After concentration the residue was extracted with benzene to give 0.08 g (41%) of **14a**.

14a: Colorless prisms from chloroform; mp 139—140 °C; UV (MeOH) 309 (ε 3000), 245 nm (5000); IR (KBr) 3260, 2250, 1744 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.24, 2.44 (each 3H, s, Me), 3.40 (1H, s, 8-H), 6.04 (1H, s, 3-H); ^{13}C NMR ($CDCl_3$) δ=19.2, 20.9 (each q, Me), 75.9 (s, 7-C), 85.3 (d, 8-C), 102.6 (s, 5-C), 110.7 (d, 3-C), 156.3 (s, 4-C), 160.6 (s, 2-C), 166.8 (s, 6-C); MS *m/z* 148 (M^+, 87%), 120 (base peak).

Found: C, 73.04; H, 5.58%. Calcd for $C_9H_8O_2$: C, 72.99; H, 5.44%.

Dehydrochlorination of 4b. A mixture of **4b** (0.26 g, 1.0 mmol), triethylamine (0.2 ml, 1.5 mmol), and ethanol (5 ml) was refluxed for 15 h. After concentration the residue was extracted with diethyl ether to give 0.21 g (97%) of **13b**.

13b: Colorless prisms from hexane; mp 130—132 °C; UV (MeOH) 296 (ε 5930), 237 nm (6040); IR (KBr) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.13 (3H, d, Me), 2.25 (3H, s, Me), 6.05 (1H, br. s, 3-H), 6.60 (1H, s, 8-H); ^{13}C NMR ($CDCl_3$) δ=17.9, 19.3 (each q, Me), 111.5 (d, 3-C), 113.5 (s, 5-C), 120.8 (d, 8-C), 127.3 (s, 7-C), 154.5 (s, 4-C), 161.1, 161.2 (each s, 2-, 6-C); MS *m/z* 218 (M^+, 29%), 43 (base peak).

Found: C, 49.46; H, 3.67%. Calcd for $C_9H_8O_2Cl_2$: C, 49.32; H, 3.65%.

Dehydrochlorination of 4c. A mixture of **4c**-1 and **4c**-2 (4 : 1 mix. 0.32 g, 1.5 mmol), triethylamine (0.4 ml, 3.0 mmol), and ethanol (5 ml) was refluxed for 15 h. After concentration the residue was column chromatographed using benzene to afford 0.23 g (89%) of **13c**.

13c: White crystal; mp 63—64 °C; UV (MeOH) 296 (ε 7200), 214 nm (7700); IR (KBr) 2250, 1740, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20, 2.30 (each 3H, s, Me), 5.96, 6.42 (each 1H, $=CH_2$), 6.06 (1H, br. s, 3-H), ^{13}C NMR ($CDCl_3$) δ=18.4, 20.3 (each q, Me), 111.8 (d, 3-C), 113.1, 116.1 (each s, 5-, 7-C), 116.8 (s, CN), 138.3 (t, 8-C), 154.4 (s, 4-, 6-C), 160.7 (s, 2-C); MS *m/z* 175 (M^+, 44%), 147 (base peak).

Found: C, 68.42; H, 5.19; N, 8.00%. Calcd for $C_{10}H_9NO_2$: C, 68.56; H, 5.17; N, 8.00%.

Dehydrochlorination of 8a. The refluxing of a mixture of **8a** (0.5 g, 2.1 mmol) and triethylamine (0.9 ml, 6.3 mmol) in 10 ml of ethanol for 2 h, followed by extraction with diethyl ether to give 0.4 g (95%) of **16a**. On the other hand, a mixture of **8a** (0.28 g, 1.2 mmol), triethylamine (0.8 ml, 6.0 mmol), and ethanol (5 ml) was refluxed for 38 h, and the same work-up as mentioned above afforded 0.17 g (89%) of **17a**.

16a: Colorless prisms from chloroform; mp 110—112 °C; UV (MeOH) 283 (ε 6500), 228 nm (8000); IR (KBr) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.28 (3H, s, Me), 3.84 (3H, s, OMe), 5.40, 5.74 (each 1H, d, J_{gem}=1.5 Hz, $=CH_2$), 5.46 (1H, s, 3-H); ^{13}C NMR ($CDCl_3$) δ=17.9, 56.4 (each q, Me), 87.5 (d, 3-C), 112.7 (s, 5-C), 121.1 (t, 8-C), 130.7 (s, 7-C), 161.2 (s, 2-C), 163.1 (s, 6-C), 168.7 (s, 4-C); MS *m/z* 200 (M^+, 84%), 165 (base peak).

Found: C, 53.94; H, 4.54%. Calcd for $C_9H_9O_3Cl$: C, 53.88; H, 4.52%.

17a: Colorless needles from chloroform-diethyl ether (1 : 1); mp 140—141 °C; UV (MeOH) 290 (ε 4300), 240 nm (7900); IR (KBr) 3300, 1745, 1723 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.42 (3H, s, Me), 3.37 (1H, s, 8-H), 3.87 (3H, s, OMe), 5.44 (1H, s, 3-H); ^{13}C NMR ($CDCl_3$) δ=19.2, 56.6 (each q, Me), 73.5 (s, 7-C), 85.3 (d, 8-C), 87.2 (d, 3-C), 97.7 (s, 5-C), 162.3 (s, 2-C), 167.9 (s, 6-C), 169.3 (s, 4-C); MS *m/z* 164 (M^+, base peak).

Found: C, 65.79; H, 4.93%. Calcd for $C_9H_8O_3$: C, 65.85; H, 4.91%.

Dehydrochlorination of 8b. The refluxing of a mixture of **8b** (0.82 g, 3.0 mmol) and triethylamine (1.6 ml, 12 mmol) in 30 ml of ethanol for 1.5 h and washing the residue with water to give the water-insoluble product **12b** (0.58 g, 82%). A solution of **12b** (15 mg, 0.06 mmol) in 0.3 ml of DMSO-d_6 was heated in the NMR sample tube at 100 °C for 2 h to give 11 mg (80%) of **16b**.

12b: Colorless prisms from chloroform; mp 124—126 °C; UV (MeOH) 281 nm (ε 2100); IR (KBr) 1720, 1670, 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.61 (3H, s, Me), 3.81 (3H, s, OMe), 4.80 (1H, s, 8-H), 5.28 (1H, s, 4-H); ^{13}C NMR ($CDCl_3$) δ=21.7, 56.6 (each q, Me), 67.3 (d, 8-C), 78.3 (s, 1-C), 96.1 (d, 4-C), 131.3, 135.3 (each s, 6-, 7-C), 159.2 (s, 3-C), 164.6 (s, 5-C); MS *m/z* 234 (M^+, 2%), 199 (base peak).

Found: C, 46.07; H, 3.42%. Calcd for $C_9H_8O_3Cl_2$: C, 45.99; H, 3.43%.

16b: Colorless prisms from diethyl ether-hexane (2 : 1); mp 124—127 °C; UV (MeOH) 284 (ε 3020), 228 nm (6200); IR (KBr) 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.24 (3H, s, Me), 3.84 (3H, s, OMe), 5.48 (1H, s, 3-H), 6.57 (1H, s, 8-H); ^{13}C NMR ($CDCl_3$) δ=18.6, 56.5 (each q, Me), 87.7 (d, 3-C), 107.5 (s, 5-C), 120.1 (d, 8-C), 126.4 (s, 7-C), 160.5 (s, 2-C), 163.7 (s, 6-C), 169.5 (s, 4-C); MS *m/z* 234 (M^+, 16%), 199 (base peak).

Found: C, 46.08; H, 3.42%. Calcd for $C_9H_8O_3Cl_2$: C, 45.99; H, 3.43%.

X-Ray Analyses of Compounds 13b and 14a. Compounds **13b** and **14a** were recrystallized from diethyl ether-hexane (1 : 1) and diethyl ether solutions as colorless prisms, respectively. Crystal size: **13b** 0.56×0.35×0.42 mm^3, **14a** 0.56×0.35×0.21 mm^3. All data sets were measured by the ω—2θ scan method on a CAD4 diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). SDP Program package[12] with the tables of atomic scattering factors[13] was used.

13b: Triclinic, space group $P\bar{1}$, a=7.405(4) Å, b=7.408 (4) Å, c=10.133(3) Å, α=71.44(7)°, β=71.44(7)°, γ=81.36(7)°, V=498.8(4) $Å^3$, d (calcd)=1.458 g cm^{-3} for z=2, μ (Mo $K\alpha$)= 11.90 cm^{-1}; 2911 unique reflections, solution by direct method (MULTAN 82),[14] and refined by least-squares method with full matrix, R=0.050, R_w=0.050, unit weights, for 172 variables and 1308 reflections with $I \geq 3.0 \times \sigma$ (I). All non-H atoms anisotropic with H atoms isotropic.

14a: Monoclinic, space group $P2_1/n$, a=9.854(12) Å, b=11.444(1) Å, c=20.439(2) Å, β=85.14(5)°, V=2297(3) $Å^3$, d (calcd)=1.285 g cm^{-3} for Z=4 (12 molecules), μ (Mo $K\alpha$)=0.846

cm^{-1}; 4158 unique reflections, solution by direct method (MULTAN 82),[14] and refined by least-squares method with full matrix, R=0.106, R_w=0.106, unit weights, for 298 variables and 2076 reflections with $I \geq 3.0 \times \sigma(I)$. All non-H atoms anisotropic with H atoms isotropic. The unsymmetric unit consists of three identical molecules of **14a**. Crystal data, positional and thermal parameters, bond distances and angles as well as ORTEP drawings[15] and structure factors for compounds **13b** and **14a** are kept in the office of the Chemical Society of Japan (Document No. 8721).

The authors appreciate to the Research Center for Material Analysis in Miyazaki University for the X-ray crystallographic analysis.

(Received June 23, 1986)

Alcohols and phenols adsorbed on silica gel react with diazomethane and quantitatively afford the corresponding methyl ethers. Alumina and titanium dioxide are also effective adsorbents for the reaction.

Carboxylic acids are easily *O*-methylated with diazomethane to give the corresponding esters. Alcohols, however, do not react with diazomethane because of their weak acidity. The methylation of alcohols with diazomethane requires a Lewis acid catalyst such as boron trifluoride,[1] tetrafluoroboric acid,[2] zinc chloride[3] and aluminum chloride[4] in solution. Mineral acids are not suitable for the catalyst because they react with the reagent. Recently, silica gel suspended in ether was found to be effective for the methylation of unstable alcohols with diazomethane.[5] However, these types of catalysts are not always effective for a complete methylation of alcohols.

The use of solid adsorbents as a reaction medium is becoming increasingly widespread in organic syntheses[6] involving oxidation,[7] alkylation,[8] and condensation.[9] We have successfully utilized solid adsorbents in the acetylation of alcohols and phenols by ketene,[10] and a selective monomethyl esterification of dicarboxylic acids by diazomethane[11] or by dimethyl sulfate.[12] The advantages of solid adsorbents are simpler work-ups, milder reaction conditions and higher selectivities.

Recent spectroscopic studies[13] have proved that alcohols are chemisorbed on alumina or silica as alkoxides or a species in which O–H bonds are strongly polarized. These facts persuaded us to use these oxides as a reaction medium as well as the catalyst for the methylation of alcohols with diazomethane. We report here that gaseous diazomethane easily reacts with alcohols and phenols adsorbed on oxides to quantitatively give the corresponding methyl ethers.

Results and Discussion

Methylation of 1-Decanol. 1-Decanol, which had been adsorbed on silica gel, was treated with gaseous diazomethane. The reaction profile of the methylation of 1-decanol is shown in Fig. 1. 1-Decanol was methylated in proportion to the amounts of diazomethane introduced, and 1-methoxydecane was quantitatively obtained when about 20 molar equivalents of diazomethane were used.

In the absence of silica gel, 1-decanol in ether was hardly methylated even by the addition of 200 molar equivalents of diazomethane. Clearly, silica gel is essential for this reaction.

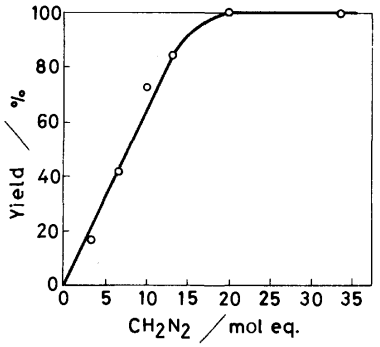

Fig. 1. Reaction profile of methylation of 1-decanol on silica gel.

Table 1. Methylation of Alcohols and Phenols on Silica Gel[a]

Substrate	CH_2N_2/mol equiv	Yield/%[b]
1-Decanol	34	99
1-Decanol[c]	159	83
1-Decanol[d]	200	< 1
Geraniol	34	96
Benzyl alcohol	34	99
1-Methyl-1-hexanol	68	99
Cyclohexanol	68	99
2-Methyl-2-hexanol	68	99
2-Methyl-2-butanol	68	99
Phenol	34	99
2-*t*-Butylphenol	34	93
2,6-Diisopropylphenol	34	79
2,6-di-t-Butylphenol	68	< 1
1-Naphthol	34	98
2-Naphthol	34	93

a) To a 1.0 g of silica gel 0.32 mmol of alcohol or phenol was added. b) Determined by GLC and/or HPLC. c) Silica gel suspended in ether. d) In an ether solution in the absence of silica gel.

Methylation of Alcohols and Phenols. Various kinds of alcohols and phenols were tested; the results are summarized in Table 1. As well as primary and secondary alcohols and phenol, tertiary alcohols and hindered phenols were quantitatively methylated. Geraniol, which holds two olefinic double bonds, was also methylated in a high yield with the bonds intact. However, 2,6-di-*t*-butylphenol was not methylated, even with 300 molar equivalents of diazomethane. On the basis of molecular models, 2,6-di-*t*-butylphenol could not be adsorbed on the silica gel surface with the hydroxyl group on account of a steric hindrance

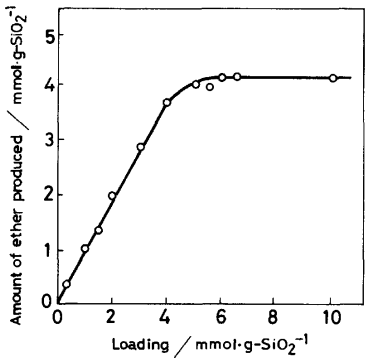

Fig. 2. Formation of 1-methoxydecane from the different amount of 1-decanol adsorbed on silica gel. The reaction was carried out with 34 molar equivalents of diazomethane.

involving the two *t*-butyl groups. These results suggest that the methylation requires the adsorption of hydroxyl group on the oxide.

While using silica gel suspended in ether, 1-decanol could not be quantitatively methylated and the product, 1-methoxydecane, was obtained in an 83% yield with a large excess of diazomethane (159 molar equivalents). Ohno et al.[5] reported that the maximum values of conversion for some alcohols such as geraniol, benzyl alcohol, and 2-methyl-2-butanol were no more than 25—54%. These less reactive alcohols could be exhaustively methylated by using our method.

Effect of Surface Coverage on Methylation. Adsorbed samples of 1-decanol with various amounts of loading were prepared and treated with diazomethane. As shown in Fig. 2, the amount of produced 1-methoxydecane was proportional to the amount of loading. Beyond the value of 4.0 mmol g^{-1}-SiO_2, however, the amount of 1-methoxydecane did not increase even upon the addition of large excess amounts of diazomethane.

The limiting value of loading (4.0 mmol g^{-1}-SiO_2) appears to be the saturation amount of 1-decanol on the silica gel surface. The surface area of the silica gel used was found to be 371 $m^2 g^{-1}$ by a BET measurement. Thus, one molecule of 1-decanol occupies 0.15 nm^2 on the silica gel surface. The critical cross section for aliphatic alcohols determined from their monomolecular layers spread over a flat surface of water is 0.216 nm^2.[14] The agreement between these two cross-sectional values implies that 1-decanol molecules are adsorbed as a monomolecular layer on silica gel. The methylation seems to occur on the silica gel surface by a reaction of diazomethane with the 1-decanol adsorbed as the monomolecular layer.

Effective Adsorbents. Various kinds of solid adsorbents were tested in the methylation of 1-decanol. A small amount of diazomethane was introduced into the reaction vessel in order to estimate the effectiveness of each adsorbent. Table 2 shows that the yields of 1-methoxydecane decreased in the following order:

Table 2. Effect of Adsorbent[a]

Adsorbent[b]	Yield/%[c]	Relative value
SiO_2	41.4	1
Al_2O_3	11.5	0.28
TiO_2	6.5	0.16
Zeolite(Na-Y type)	2.1	0.05
SiO_2–Al_2O_3[d]	2.0	0.05
Celite 545	1.3	0.03
ZnO	0.4	0.01
MgO	0.0	0.00
Non	0.0[e]	0.00

a) To a 1.0 g of adsorbent 0.32 mmol of 1-decanol was added. b) Dried at 110°C for one hour in a stream of N_2 before adsorption of 1-decanol. c) Yield of 1-methoxydecane, when 6.8 molar equivalents of diazomethane was introduced at room temperature. d) 28.6% Al_2O_3. e) In an ethyl ether solution in the absence of any additives.

$$SiO_2 > Al_2O_3 > TiO_2.$$

A sufficient amount of diazomethane resulted in a complete conversion on Al_2O_3 and/or TiO_2. On zeolite, silica-alumina, Celite 545, and zinc oxide the methylation occurred slightly. Magnesium oxide did not cause a reaction.

IR and inelastic electron tunneling spectroscopy clearly showed that surface-bound alkoxides or strongly polarized O–H bonds were formed when alcohols were introduced to silica or alumina.[13] The chemisorption of alcohol on the oxides undoubtedly facilitates a dissociation of protons from the hydroxyl group. It has been reported that methylation of alcohols is initiated by the portonation of diazomethane with the aid of a Lewis acid.[4] Probably, the protonation of diazomethane occurs on the oxides by accepting protons released from the adsorbed alcohol and the protonated diazomethane attacks the resulting alkoxide to form the methyl ether.

Experimental

Materials. A modified method was adopted for the preparation of diazomethane from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide.[15] Diazomethane is toxic and potentially explosive. All the operations were performed in a well ventilated hood and behind a safety screen. The following preparation of diazomethane is illustrative. In a 25 ml distillation flask, 2 g of potassium hydroxide, 3.2 ml of water and 11 ml of diethylene glycol dimethyl ether were placed. A stream of dry nitrogen (10 ml min^{-1}) was passed through the flask and led to a drying tube containing potassium hydroxide pellets. The flask was kept at 30°C and 6.88 g (31 mmol) of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide was added by small portions over 20 min. Nitrogen was passed for an additional 30 min in order to carry the diazomethane thoroughly into the reaction vessel for methylation. The total amount of dry diazomethane was measured to be 22 mmol (70% yield) by a GLC analysis instead of titration.[16] The amount of diazomethane was controlled by the amount of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide used.

Silica gel (Wako Chemicals; 200 mesh, for column chro-

matographic use), alumina (the reference catalyst of the Catalysis Society of Japan (JRC-ALO-5; 60—200 mesh) and titanium dioxide (JRC-TIO-1; powder), zeolite (JRC-Z-Y4.8; powder, Na-Y type), silica-alumina (JRC-SAH-1; powder, 38% alumina), Celite 545 (Johns-Manville), zinc oxide (Kokusan Chemicals), and Magnesium oxide (Kamishima Chemicals) were used. These solids were dried at 110 °C for a day and stored in a desiccator.

Other materials were commercial products and were used without further purification.

Reaction Procedure. Typically, 51 mg (0.32 mmol) of 1-decanol was added into a reaction vessel of a glass column (15-mm i.d.) containing 1.0 g of silica-gel powders. The reaction vessel was allowed to stand for a day, although lumps of silica gel usually disappeared within an hour. Then, a calculated amount of diazomethane was introduced into the reaction vessel in a stream of nitrogen at room temperature. After passage of the diazomethane through the vessel, the adsorbate was immediately eluted with ethyl acetate. The eluate was condensed and the product was analyzed by GLC and/or HPLC. 1-Methoxydecane was obtained in a 99% yield and no reaction other than methylation was observed.

The amount of diazomethane necessary for a complete methylation of 1-decanol could be reduced by the following method. The 3 molar equivalents of diazomethane were introduced into a reaction vessel maintained at −78 °C. The color of the silica gel near the entrance end of the reaction vessel changed to yellow. The vessel, sealed with septum, was allowed to stand for 12 h at room temperature to ensure a complete conversion.

Functionalization of 2-Deoxy-2,3-dehydro-*N*-acetylneuraminic Acid Methyl Ester[1)]

Kaoru Okamoto,† Tadao Kondo,††,* and Toshio Goto*
Laboratory of Organic Chemistry, Faculty of Agriculture, Nagoya University, Chikusa-ku, Nagoya 464
††Chemical Instrument Center, Nagoya University, Chikusa-ku, Nagoya 464
(Received July 3, 1986)

The acetyl protected 2-deoxy-2,3-dehydroneuraminic acid methyl ester was functionalized by modifying its 2,3-double bond to convert it into new glycosyl donors such as 2,3-dibromo-, 2,3-epoxy-, and 2-halo-3-hydroxyneuraminic acid derivatives.

In the glycosylation of *N*-acetylneuraminic acid (NeuAc), most reactions have so far been carried out by use of 2-chloro derivative of the pentaacetylated neuraminic acid methyl ester **1** first prepared by Kuhn et al.[2)] The largest problem in these reactions is that the main product is the 2-deoxy-2,3-dehydro-NeuAc derivative **2**[3)] generated by the competitive elimination of hydrogen chloride when the reactivity of the glycosyl acceptor is low. As it was difficult to prevent the elimination of hydrogen chloride in the 2-chloro derivative **1**, we have tried to utilize **2** having the 2,3-double bond to prepare new and useful glycosyl donors. The paucity of reports on reactivity of the 2,3-dehydro compound **2** prompted us to investigate it. We report here some functionalizations of **2**, which was easily prepared in 81% yield by treatment of **1** with DBU in benzene and by crystallization from hexane-ethyl acetate.

Reactivity of the 2,3-Double Bond of 2. First we carried out bromination of **2** by treatment with bromine in dichloromethane or by electrochemical oxidation of sodium bromide[4)] in acetonitrile-water (Pt-Pt electrodes) to give the 2β,3α-dibromide **3a**[5)] as white crystals in 93 or 98% yield, respectively (Table 1, Entries 1, 2). In ^{1}H NMR sepctrum the $J_{3eq,4}$ coupling constant of **3a** is 3.4 Hz, indicating that the configuration of the bromo groups is trans diaxial. The dibromide **3a** is a useful glycosyl donor for the glycosylation since the 3-axial position is blocked by the bromo group to prevent the elimination reaction.[5)]

Treatment of **2** with *N*-bromosuccinimide (NBS) in acetonitrile-water at 20 °C gave in 98% yield two bromohydrins which were separated by silica-gel column chromatography (Entry 3). The more mobile isomer was adduct **4b** having a trans diequatorial bromine (59% yield), and the slower was trans diaxial adduct **3b** (39% yield), which showed 11.0 and 3.7 Hz of $J_{3,4}$ coupling constant, respectively, in ^{1}H NMR spectra. Interestingly in this bromohydration, the product ratio was variable according to the reaction temperature. Thus, at a low temperature (−20 °C) the diequatorial adduct **4b** was obtained predominantly (dimethyl sulfoxide was used as the solvent since the reaction was very slow when acetonitrile was used), whereas at a high temperature (60—80 °C) the thermodynamically more stable diaxial isomer **3b** was formed in preference to **4b** (Entries 4, 5, 6). The use of *N*-iodosuccinimide (NIS) instead of NBS gave similar results but no adduct was obtained with *N*-chlorosuccinimide (NCS) (Entries 7, 8, 9).

Bromoacetoxylation of **2** was effective with NBS-sodium acetate-acetic acid system to give **3d** (41% yield) and **4d** (41% yield) (Entry 10). Without sodium acetate this reaction required a longer reaction time. Similar result was obtained in iodoacetoxylation of **2** except the ratio of yields of **3e** (80%) and **4e** (11%) (Entry 11). Chloroacetoxylation of **2** did not proceed similarly to the above chlorohydrin reaction (Entry 12). Treatment of **2** with NBS or 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one (TBCD) in methanol gave in quantitative yield a mixture of methyl 3-bromo glycosides **3f** and **4f** (Entries 13, 14), which was separated and the both glycosides were debrominated with tributylstannane to give methyl β-glycoside **5**[6)] (**3**: X=H, Y=OMe) and α-glycoside **6**[6)] (**4**: X=H, Y=OMe) in 96% yield. Iodomethoxylation was failed owing to decomposition of NIS with methanol (Entry 15). Attempts of haloglycosylation of **2** with NXS (X=Br, I)-sugar derivative combinations[7)] were unsuccessful.

Conversion of 3b and 3c to Glycosyl Donors 7 and 8a—c. Since direct epoxidation of **2** with various peroxides was unsuccessful, we have examined conversion of **3b** and **3c** to the epoxide **7**. Treatment of the

bromohydrin **3b** with *N*,*N*-diisopropylethylamine in anhydrous acetonitrile for 4 h gave the β-epoxide **7** as white crystals in 83% yield (Scheme 3). As some decomposition products were detected during the period of the reaction, **3b** was treated with DBU for 10 min to afford **7** in 92% yield. Similarly, the iodohydrin **3c** was converted with *N*,*N*-diisopropylethylamine to the epoxide **7** in 76% yield. In ^{1}H NMR spectrum of the epoxide **7**, the $J_{3,4}$ coupling constant was 0 Hz, and in mass (FAB) spectrum of **7**, molecular ion *m*/*z* 490 (M+1) was observed. On the other hand the diequatorial bromohydrins **4b** and **4c** were unreactive to the above epoxidation conditions.

We found that the epoxide **7** was very sensitive to the Lewis acids such as boron trifluoride–ether complex, titanium(IV) chloride, and titanium(IV) bromide. When the epoxide **7** was treated with boron trifluoride–ether complex in 1,2-dichloroethane, a single product was obtained. The vicinal coupling constant between H-3ax and fluoro group of the product was 22.6 Hz in ^{1}H NMR spectrum and the molecular ion *m*/*z* 510 was observed in mass (FAB) spectrum. From these data structure of the product was deduced as the fluorohydrin **8a** shown in Scheme 4. The treatment of **7** with titanium(IV) chloride or titanium(IV) bromide in 1,2-dichloroethane gave the 2-chloro compound **8b** or 2-bromo compound **8c** quantitatively. As the question still remained in the configuration of the anomeric position of **8b** and **8c**, the bromo derivative **8c** was treated with silver fluoride in acetonitrile to give the fluoride **8d** in concomitance with the epoxide **7**. The $J_{3ax,F}$ coupling constant of **8d** was 15.0 Hz and this value agreed with α configuration[8] of the fluorine atom, different from the β isomer **8a**.

The epoxide **7**, fluoride **8a**, chloride **8b**, and bromide **8c** are well-suited to be the glycosyl donors for the glycosylation reaction, since these derivatives are no longer the deoxysugar at **3** position and the competitive elimination reaction is suppressed.[9]

Experimental

General. Melting points were taken on a Mitamura Riken flat-bulb thermometer with a heating metal block and uncorrected. Elemental analyses were done on a Perkin-Elmer 240C elemental analyzer. Nuclear magnetic resonance spectra (NMR) were obtained with a JEOL GX-500 instrument in the FT mode. Chemical shifts were expressed in parts per million from internal tetramethylsilane (δ). Coupling constants are in hertz(Hz) and splitting pattern abbreviations are: s, singlet; d, doublet; dd, doublet of doublets; ddd, doublet of double doublets; br, broad. Mass spectra (MS) were obtained on a JEOL DX-300 spectrometer. Infrared spectra (IR) were recorded on a JASCO A-3 spectrophotometer. Optical rotations $[\alpha]_D$ were recorded on a JASCO DIP-181 digital polarimeter.

a) Measured at 40 °C. b) Multiplicity: dd. c) Multiplicity: ddd.

Analytical thin-layer chromatography (TLC) was conducted on precoated TLC glass sheets (silica gel 60F-254, layer thickness 0.25 mm) manufactured by E. Merck. Detection was effected with 2% concentrated sulfuric acid in ethanol.

^{1}H NMR data were summarized in Table 2 and MS, elemental analyses, mp, R_f, $[\alpha]_D$, and IR data in Table 3.

Methyl 5-Acetamido-4,7,8,9-tetra-*O*-acetyl-2,3,5-trideoxy-D-*glycero*-D-*galacto*-non-2-enopyranosonate (2). Compound **1** (7.7 g, 15.1 mmol), freshly prepared by Kuhn's method,[2] was dissolved in dry benzene (70 ml). After addition of DBU (2.7 ml, 18.1 mmol), the mixture was stirred for 1 h at room temperature under argon atmosphere, washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene-acetone, 3:2) to give a syrup. This syrup was crystallized from hexane-ethyl acetate to give **2** (5.8 g, 81%) as white needles.

Methyl 5-Acetamido-4,7,8,9-tetra-*O*-acetyl-2,3-dibromo-2,3,5-trideoxy-β-D-*erythro*-L-*manno*-2-nonulopyranosonate (3a). Method A. To a solution of **2** (280 mg, 0.59 mmol) in dichloromethane (5 ml) was added bromine (0.04 ml, 0.78 mmol) at 0 °C under argon atmosphere. After stirring for 10 min, the mixture was evaporated in vacuo to give a syrup, which was crystallized from hexane-ethyl acetate to give **3a** (350 mg, 93%) as white needles.

Method B. A mixture of **2** (50 mg, 0.11 mmol) and sodium bromide (250 mg, 2.4 mmol) in acetonitrile (8 ml)-water (2 ml) was electrolyzed with platinum electrodes (1×2 cm^2) 5 mm apart under a constant current density of 5 mA cm^{-2} for 2 h. The mixture was evaporated to dryness and the residue was partitioned between ethyl acetate and water. The organic layer was washed with brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was treated in a similar manner as above.

Reaction of 2 with NXS (X=Br, I) in Acetonitrile (or Dimethyl Sulfoxide)-Water. To a solution of **2** (200 mg, 0.42 mmol) in acetonitrile (or dimethyl sulfoxide) (2 ml)-water (0.8 ml) was added NXS (0.48 mmol) at the temperature shown in Table 1. The mixture was stirred for 0.2—8 h

a) Fast atom bombardment method. b) Recrystallized from hexane–ethyl acetate. c) Solvent system is benzene–acetone (3:2). d) Measured in chloroform. e) Viscous syrup.

and dried up, and the residue was chromatographed on a silica-gel column (benzene–acetone, gradient elution from 3:1 to 3:2). The fast migrating zone was a 2,3-diequatorial isomer, methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3-bromo-3,5-dideoxy-α-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**4b**) or methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-3-iodo-α-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**4c**), as a syrup and the slower migrating zone was a 2,3-diaxial isomer, methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3-bromo-3,5-dideoxy-β-D-*erythro*-L-*manno*-2-nonulopyranosonate (**3b**) or methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-3-iodo-β-D-*erythro*-L-*manno*-2-nonulopyranosonate (**3c**), which was recrystallized from hexane–ethyl acetate.

Reaction of 2 with NXS (X=Br, I) in Sodium Acetate–Acetic Acid. A solution of **2** (200 mg, 0.42 mmol), NXS (0.48 mmol), and sodium acetate (200 mg) in glacial acetic acid (2 ml) was stirred for 1—1.5 h at 20 °C under argon atmosphere. After evaporation, the residue was partitioned between ethyl acetate and water. The organic layer was washed with 5% $NaHCO_3$, water, and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene–acetone, gradient elution from 3:1 to 2:1). The fast migrating zone was a 2,3-diequatorial isomer, methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3-bromo-3,5-dideoxy-α-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**4d**) or methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3,5-dideoxy-3-iodo-α-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**4e**), as a syrup and the slower migrating zone was a 2,3-diaxial isomer, methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3-bromo-3,5-dideoxy-β-D-*erythro*-L-*manno*-2-nonulopyranosonate (**3d**) or methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3,5-dideoxy-3-iodo-β-D-*erythro*-L-*manno*-2-nonulopyranosonate (**3e**), which was recrystallized from hexane–ethyl acetate.

Reaction of 2 with NBS or 2,4,4,6-Tetrabromo-2,5-cyclohexadien-1-one (TBCD) in Methanol. To a stirred solution of **2** (100 mg, 0.21 mmol) in absolute methanol (1.5 ml) was added NBS or TBCD (0.23 mmol) at 20 °C under argon atmosphere. The mixture was stirred for 0.2—2.0 h and evaporated in vacuo to give a residue. The residue was dissolved in ethyl acetate and the solution was washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a syrup, which was chromatographed on a silica-gel column (benzene–acetone, 2:1). The fast migrating zone was a 2,3-diequatorial isomer, methyl (methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3-bromo-3,5-di-

deoxy-α-D-*erythro*-L-*gluco*-2-nonulopyranosid)onate (**4f**) and the slower migrating zone was a 2,3-diaxial isomer, methyl (methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3-bromo-3,5-dideoxy-β-D-*erythro*-L-*manno*-2-nonulopyranosid)onate (**3f**), which was recrystallized from hexane–ethyl acetate.

Methyl (Methyl 5-Acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-β-D-*glycero*-D-*galacto*-2-nonulopyranosid)onate (5). To a solution of **3f** (30 mg, 0.05 mmol) in anhydrous tetrahydrofuran (0.6 ml) was added tributylstannane (0.034 ml, 0.13 mmol). The mixture was heated for 2 h at 60 °C with stirring under argon atmosphere and evaporated in vacuo to give a syrup, which was chromatographed on a silica-gel column (benzene–acetone, 3 : 2) to give **5** (25 mg, 96%) as a syrup.

Methyl (Methyl 5-Acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-α-*glycero*-D-*galacto*-2-nonulopyranosid)onate (6). To a solution of **4f** (48 mg, 0.08 mmol) in anhydrous tetrahydrofuran (1 ml) was added tributylstannane (0.05 ml, 0.19 mmol). The mixture was worked up in a similar manner as **3f** and recrystallized from hexane–ethyl acetate to give **6** (40 mg, 96%) as a white amorphous powder.

Epoxidation of 3b. To a stirred solution of **3b** (500 mg, 0.88 mmol) in anhydrous acetonitrile (4 ml) was added *N,N*-diisopropylethylamine (0.22 ml, 1.26 mmol) or DBU (0.16 ml, 1.07 mmol). The mixture was stirred for 4 h or 10 min, respectively, at room temperature and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene–acetone, 3 : 2) and crystallized from hexane–ethyl acetate to give methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2,3-anhydro-5-deoxy-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**7**) (83 or 92%) as white needles.

Epoxidation of 3c. To a solution of **3c** (50 mg, 0.08 mmol) in anhydrous acetonitrile (0.6 ml) was added *N,N*-diisopropylethylamine (0.02 ml, 0.11 mmol). The mixture was stirred for 2 h at room temperature and worked up in a similar manner as **3b** to give **7** (30 mg, 76%) as white needles.

Reaction of 7 with Halogenating Agents ($BF_3 \cdot OEt_2$, $TiCl_4$, and $TiBr_4$). To a solution of **7** (200 mg, 0.41 mmol) in 1,2-dichloroethane (3 ml) was added boron trifluoride–ether complex, titanium(IV) chloride, or titanium(IV) bromide (0.45 mmol). The mixture was stirred for 10 min at room temperature and evaporated in vacuo to give a residue, which was dissolved in ethyl acetate. The organic layer was washed with saturated Na_2SO_4 solution (when boron trifluoride–ether complex was used, this operation was not required), 5% $NaHCO_3$, and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude syrup, which was purified by chromatography on a silica-gel column (benzene–acetone, 1 : 1) to give methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2-fluoro-, chloro-, or bromo-2,5-dideoxy-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**8a**), (**8b**), and (**8c**), respectively, in yields as shown in Scheme 4.

Fluorination of 8c with Silver Fluoride. A mixture of **8c** (150 mg, 0.26 mmol) and silver fluoride (130 mg, 1.0 mmol) in anhydrous acetonitrile was stirred for 40 min at room temperature in the dark. The mixture was filtered through a Celite 545 bed and the solid was washed with ethyl acetate. The combined filtrates and washings were evaporated to give a residue. The residue was dissolved in ethyl acetate, washed with 5% sodium thiosulfate and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene–acetone, gradient elution from 3 : 2 to 1 : 1). The fast migrating zone was the epoxide **7** (36 mg, 28%), which was obtained as white needle crystals, and the slow migrating zone was the α-fluoride, methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2,5-dideoxy-2-fluoro-α-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**8d**) (86 mg, 64%) which was obtained as a syrup.

(Received July 3, 1986)

Reaction of the 2β,3β-epoxyneuraminic acid derivative prepared from 2,3-dehydroneuraminic acid derivative with primary or secondary alcohol gave the corresponding glycoside(s) or ortho ester.

In the course of our glycosylation study on *N*-acetylneuraminic acid we have prepared some new glycosyl donors such as 2,3-dibromo-, 2,3-epoxy-, and 2-halo-3-hydroxy-*N*-acetylneuraminic acid derivatives from tetra-*O*-acetyl-2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid methyl ester (**1**).[2)] We have already reported that the 2,3-dibromo compound is well-suited for the stereoselective β-glycosylation since the bromo group prevents the elimination reaction.[3)] We report here glycosylation of the 2,3-epoxy ccmpound **2**[2)] whose epoxy ring is β-oriented (Scheme 1). If the glycosylation reaction occurs in S_N2 type, **2** is suited to give α-glycosides.

Treatment of **2** with methanol in the presence of *d*-camphor-10-sulfonic acid or Amberlyst 15 catalyst (catalytic amount) gave only methyl α-glycoside **3** in nearly quantitative yield. To determine the anomeric configuration the glycoside **3** was treated with phenyl chlorocarbonothioate[4)] in the presence of 4-dimethylaminopyridine (DMAP) to give **5**, which was reduced with tributylstannane to the known α-glycoside **6**[5)] quantitatively. Antimony pentachloride (1.0 equiv) in methanol was also effective catalyst for this glycosylation. By use of 2 equivalents of methanol in the presence of antimony pentachloride or trimethylsilyl triflate (TMSOTf) catalyst, however, an inseparable mixture of α- and β-glycosides was obtained.

Treatment of **2** with methyl 2,3,4-tri-*O*-benzyl-α-D-glucoside (**8**)[6)] in the presence of boron trifluoride–ether complex or titanium(IV) chloride gave methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2,5-dideoxy-2-fluoro-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**12**)[2)] or methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2-chloro-2,5-dideoxy-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**7**)[2)] without any glycosides. The hydroxy-β-glycoside **9** was

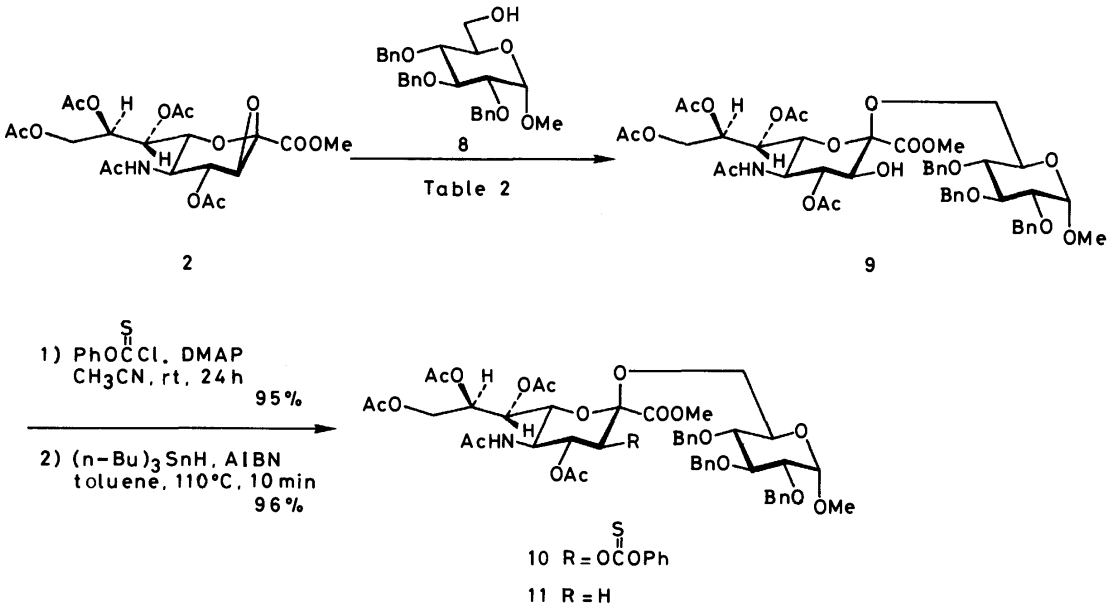
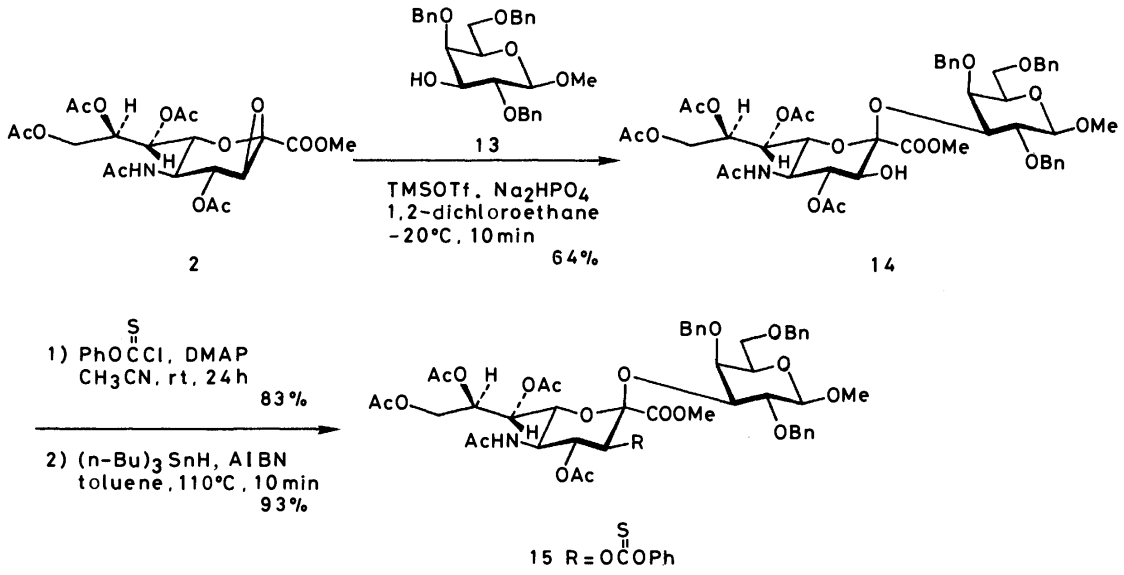
a) Two equivalents of **8** were used. b) Isolated yield. c) Methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2,5-dideoxy-2-fluoro-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**12**) was obtained in 80% yield. d) Methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2-chloro-2,5-dideoxy-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**7**) was obtained in 80% yield. e) Na_2HPO_4 was used as a buffer.

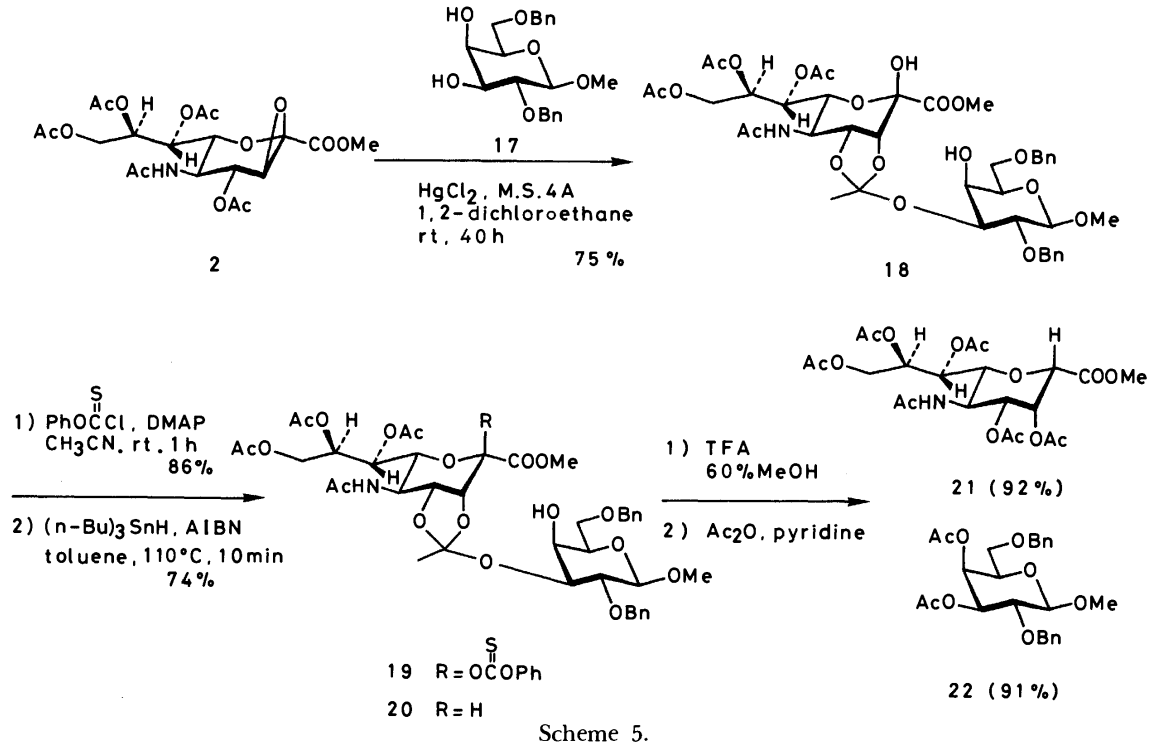


Scheme 3.

obtained in a moderate yield by the use of either antimony pentachloride or trimethylsilyl triflate. In the ^1H NMR spectrum of **9**, the coupling constant $J_{7,8}$ was 1.5 Hz and the $\Delta\delta$|H-9′-H-9| value was 0.94 ppm. In cases of the carbonothioate **10** and the glycoside **11**, the $J_{7,8}$ values were 1.5 and 2.2 Hz and the $\Delta\delta$|H-9′-H-9| values were 0.94 and 0.94 ppm, respectively. As **11** was determined to be a β-glycoside by comparing its physical data with those of the authentic sample,[3] it is safe to deduce the anomeric configuration of **9** from the $J_{7,8}$ and $\Delta\delta$|H-9′-H-9| values in ^1H NMR spectrum.[7,8] Similarly, reaction of **2** with methyl 2,4,6-tri-*O*-benzyl-β-D-galactopyranoside (**13**)[9] afforded in 64% yield only β-glycoside **14**, whose $J_{7,8}$ was 1.8 Hz and $\Delta\delta$|H-9′-H-9| value was 1.02 ppm. To make sure that the anomeric position was β configuration, the hydroxy-glycoside **14** was carbonothioated and reduced in the same manner as above to give the protected 3-*O*-(2β-neuraminyl)galactoside **16**, which was identical with the authentic sample.[3] Although the reaction of **2** with the acceptor **13** in the presence of mercury(II) chloride catalyst gave no glycosides, treatment of **2**



Scheme 4.



Scheme 5.

with a less sterically hindered acceptor **17** afforded an unstable product **18** in 75% yield. In its ^1H NMR spectrum, the coupling constant $J_{7,8}$ was 4.2 Hz and the $\Delta\delta|$H-9′-H-9$|$ value was 0.89 ppm, which were fit for neither α- nor β-glycoside. The product **18** was treated with phenyl chlorocarbonothioate to determine the structure. In spite of the presence of a carbonothioate group in **19** as evident from its ^1H NMR spectrum, the signal corresponding to H-3 of **19** was not shifted toward lower field. The carbonothioated **19** was reduced with tributylstannane to give **20**, which exhibited $J_{2ax,3eq}$ coupling constant as 2.4 Hz. From these data a series of compounds obtained by the reaction of **2** with **17** was revealed to be the ortho esters as illustrated in Scheme 5. Treatment of **20** with dilute trifluoroacetic acid in aqueous methanol gave almost instantaneously two degradation products, which were treated with acetic anhydride in pyridine to afford the acetylated compounds **21** and **22**. These compounds were characterized by IR, ^1H NMR, and mass spectra.

In summary, the epoxide **2** gave α-glycosides by the use of highly reactive acceptors such as methanol, and

β-glycosides by sugar derivatives such as a 6-unprotected glucoside and a 3-unprotected galactoside in the presence of antimony pentachloride or trimethylsilyl triflate. On the other hand, the ortho ester was yielded in the presence of mercury(II) chloride catalyst. The anomeric configuration of neuraminic acid derivatives was able to be determined from the $J_{7,8}$ coupling constant and the $\Delta\delta|$H-9′-H-9$|$ value in ^{1}H NMR spectrum. For example, 2β-glycosides showed ca. 2 Hz in $J_{7,8}$ and ca. 1 ppm of $\Delta\delta|$H-9′-H-9$|$ value, whereas 2α-glycosides showed more than 7 Hz in $J_{7,8}$ coupling constant and less than 0.5 ppm of $\Delta\delta|$H-9′-H-9$|$ value. These values in glycosides remain unaltered even if 3 position of NeuAc unit is substituted by any group.

Experimental

General. Melting points were taken on a Mitamura Riken flat-bulb thermometer with a heating metal block and uncorrected. Elemental analyses were done on a Perkin-Elmer 240C elemental analyzer. Nuclear magnetic resonance spectra (NMR) were obtained with a JEOL GX-500 instrument in the FT mode. Chemical shifts were expressed in parts per million from internal tetramethylsilane (δ). Coupling constants are in hertz(Hz) and splitting pattern abbreviations are: s, singlet; d, doublet; dd, doublet of doublets; ddd, doublet of double doublets; m, mutiplet; br, broad. Mass spectra (MS) were obtained on a JEOL DX-300 spectrometer. Infrared spectra (IR) were recorded on a JASCO A-3 spectrophotometer. Optical rotations $[\alpha]_D$ were recorded on a JASCO DIP-181 digital polarimeter.

Analytical thin-layer chromatography (TLC) was conducted on precoated TLC glass sheets (silica gel 60F·254, layer thickness 0.25 mm) manufactured by E. Merck. Detection was effected with 2% concentrated sulfuric acid in ethanol.

^{1}H NMR data were summarized in Tables 3, 4, and 5, and MS, elemental analyses, mp, R_f, $[\alpha]_D$, and IR data in Table 6.

Reaction of the Epoxide 2 and Methanol. Procedure A

a) Fast atom bombardment method. b) Measured in chloroform. c) Viscous syrup. d) Solvent system is benzene-acetone (3:2). e) Recrystallized from hexane-ethyl acetate. f) Solvent system is benzene-acetone (2:1). g) Solvent system is benzene-ethyl acetate (6:1).

(*d*-camphor-10-sulfonic acid or $SbCl_5$ catalyst in the presence of large excess methanol). To a solution of **2** (100 mg, 0.20 mmol) in absolute methanol (2.5 ml) was added *d*-camphor-10-sulfonic acid (cat. amount) or antimony pentachloride (26 μl, 0.20 mmol) at room temperature under argon atmosphere. After stirring for 15 min, the mixture was evaporated to dryness, and the residue was dissolved in ethyl acetate. The solution was washed with 5% $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4. The solvent was removed in vacuo to give a syrupy residue, which was chromatographed on a silica-gel column (benzene-acetone, 1:1) to give methyl glycoside of methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-5-deoxy-α-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**3**) as a syrup.

Procedure B (Amberlyst 15 catalyst in the presence of large excess methanol). A mixture of **2** (100 mg, 0.20 mmol) and Amberlyst 15 (cat. amount) in absolute methanol (2.5 ml) was stirred for 15 min under argon atmosphere. It was filtered and the resin was washed well with methanol. The combined filtrate and washings were evaporated to a syrup, which was purified in the same manner as procedure A.

Procedure C ($SbCl_5$ catalyst in the presence of 2 equiv of methanol). To a solution of **2** (100 mg, 0.20 mmol) in 1,2-dichloroethane (2.0 ml) containing 0.2 M (1M=1 mol dm^{-3}) methanol (2.0 ml) was added antimony pentachloride (26 μl, 0.20 mmol) at 0 °C under argon atmosphere. The mixture was stirred for 15 min, diluted with chloroform, washed with 5% $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and evaporated to dryness. The residue was purified in the same manner as procedure A. The fast migrating zone was methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2-chloro-2,5-dideoxy-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**7**)[2] (40 mg, 37%) and the slow migrating zone was an inseparable mixture of **3** (41%) and **4** (20%).

Procedure D (TMSOTf catalyst in the presence of 2 equiv of methanol). To a solution of **2** (100 mg, 0.20 mmol) in 1,2-dichloroethane (2.0 ml) containing 0.2 M methanol was added trimethylsilyl triflate (40 μl, 0.20 mmol) at 0 °C under argon atmosphere. The mixture was worked up in the same manner as above to give **3** (62%) and **4** (29%).

Methyl (Methyl 5-Acetamido-4,7,8,9-tetra-*O*-acetyl-5-deoxy-3-*O*-[phenoxy(thiocarbonyl)]-α-D-*erythro*-L-*gluco*-2-nonulopyranosid)onate (5). A solution of **3** (50 mg, 0.096 mmol), 4-dimethylaminopyridine (50 mg, 0.41 mmol), and phenyl chlorocarbonothioate (27 μl, 0.20 mmol) in anhydrous acetonitrile (1.0 ml) was stirred for 1.5 h at room temperature under argon atmosphere. The mixture was evaporated to dryness and the residue, which was partitioned between ethyl acetate and water. The organic layer was separated, washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene-acetone, 5:2) to give **5** (64 mg, 98%) as a colorless syrup.

Methyl (Methyl 5-Acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-α-D-*glycero*-D-*galacto*-2-nonulopyranosid)onate (6). To a solution of **5** (20 mg, 0.030 mmol) in toluene (1.0 ml) were added tributylstannane (20 μl, 0.074 mmol) and AIBN (cat. amount) under argon atmosphere. The mixture was heated at 110 °C for 10 min, evaporated to dryness and the residue was chromatographed on a silica-gel column (benzene-acetone, 2:1) to give crystals. Recrystallization from hexane-ethyl acetate gave **6** (15 mg, 98%) as white needles.

Reaction of the Epoxide 2 and 8. Procedure A ($BF_3 \cdot OEt_2$ catalyst). To a stirred solution of **2** (20 mg, 0.041 mmol) and **8**[6] (40 mg, 0.086 mmol) in tetrahydrofuran (0.6 ml) was added boron trifluoride-ether complex (5.2 μl, 0.041 mmol) at room temperature under argon atmosphere. After stirring for 0.2 h, the solvent was removed and the residue was dissolved in ethyl acetate. The solution was washed with 5% $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude syrup, which was chromatographed on a silica-gel column (benzene-acetone, 1:1). Unreacted **8** (35 mg) was recovered and then methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2,5-dideoxy-2-fluoro-β-D-*erythro*-L-*gluco*-2-nonulopyranosonate (**12**)[2] (16.7 mg, 80%) was obtained.

Procedure B ($TiCl_4$ catalyst). To a solution of **2** (20 mg, 0.041 mmol) and **8** (40 mg, 0.086 mmol) in 1,2-dichloroethane (0.6 ml) was added titanium(IV) chloride (4.5 μl, 0.041 mmol) at room temperature under argon atmosphere. The mixture was stirred for 0.2 h, diluted with ethyl acetate, washed with saturated Na_2SO_4 and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a residue, which was treated in the same manner as procedure A to give **8** (30 mg) and **7** (17.3 mg, 80%).

Procedure C ($SbCl_5$ catalyst). To a solution of **2** (20 mg, 0.041 mmol) and **8** (40 mg, 0.086 mmol) in 1,2-di chloroethane (0.6 ml) was added antimony pentachloride (5.2 μl, 0.041 mmol) at room temperature under argon atmosphere. The mixture was stirred for 0.2 h, diluted with ethyl acetate, washed with 5% $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene-acetone, 2:1) to give methyl 2,3,4-tri-*O*-benzyl-6-*O*-[methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-5-deox -β-D-*erythro*-L-*gluco*-2-nonulopyranosyl)onate]-α-D-glucopyranoside (**9**) (19 mg, 49%) as a syrup.

Procedure D (TMSOTf catalyst). To a mixture of **2** (20 mg, 0.041 mmol), **8** (40 mg, 0.086 mmol), anhydrous disodium hydrogenphosphate (20 mg), and 1,2-dichloroethane (0.6 ml) was added trimethylsilyl triflate (8 μl, 0.041 mmol) at 0 °C under argon atmosphere. It was stirred for 0.2 h at the same temperature and worked up in the same manner as above to give **9** (22 mg, 56%).

Methyl 2,3,4-Tri-*O*-benzyl-6-*O*-[methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-5-deoxy-3-*O*-[phenoxy(thiocarbonyl)]-β-D-*erythro*-L-*gluco*-2-nonulopyranosyl)onate]-α-D-glucopyranoside (10). A solution of **9** (22 mg, 0.023 mmol), 4-dimethylaminopyridine (6 mg, 0.049 mmol), and phenyl chlorocarbonothioate (7 μl, 0.051 mmol) in anhydrous acetonitrile (0.3 ml) was stirred for 24 h at room temperature under argon. The mixture was evaporated to dryness, and the residue was dissolved in ethyl acetate, washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material. This was chromatographed on a silica-gel column (benzene-acetone, 5:2), triturated with hexane-ethyl acetate, and washed with hexane to give **10** (24 mg, 95%).

Methyl 2,3,4-Tri-*O*-benzyl-6-*O*-[methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-β-D-*glycero*-D-*galacto*-2-nonulopyranosyl)onate]-α-D-glucopyranoside (11). To a solution of **10** (20 mg, 0.018 mmol) in toluene (1 ml) were added tributylstannane (10 μl, 0.037 mmol) and AIBN (cat. amout) under argon atmosphere. The mixture was heated at 100 °C for 15 min and the solvent was removed in vacuo to give a crude material, which was chromatographed on a silica-gel

column (benzene–acetone, 2 : 1) to give **11** (16.5 mg, 96%) as a syrup.

Methyl 2,4,6-Tri-*O*-benzyl-3-*O*-[methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-5-deoxy-β-D-*erythro*-L-*gluco*-2-nonulopyranosyl)-onate]-β-D-galactopyranoside (14). To a mixture of **2** (20 mg, 0.041 mmol), **13**[10] (40 mg, 0.086 mmol), anhydrous disodium hydrogenphosphate (20 mg), and 1,2-dichloroethane (0.3 ml) was added trimethylsilyl triflate (8 μl, 0.041 mmol) at −20 °C under argon atmosphere. It was stirred for 10 min, diluted with ethyl acetate, washed with 5% $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and evaporated to dryness. The residue was chromatographed on a silica-gel column (benzene–acetone, 2 : 1) to give **14** (25 mg, 64%) as a syrup.

Methyl 2,4,6-Tri-*O*-benzyl-3-*O*-[methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-5-deoxy-3-*O*-[phenoxy(thiocarbonyl)]-β-D-*erythro*-L-*gluco*-2-nonulopyranosyl)onate]-β-D-galactopyranoside (15). A solution of **14** (18 mg, 0.019 mmol), 4-dimethylaminopyridine (6 mg, 0.049 mmol), and phenyl chlorocarbonothioate (5 μl, 0.036 mmol) in anhydrous acetonitrile (0.3 ml) was stirred for 24 h at room temperature under argon atmosphere. After evaporation, the residue was partitioned between ethyl acetate and water. The organic layer was separated, washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a crude material, which was chromatographed on a silica-gel column (benzene–acetone, 4 : 1) to give **15** as a syrup.

Methyl 2,4,6-Tri-*O*-benzyl-3-*O*-[methyl(5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-β-D-*glycero*-D-*galacto*-2-nonulopyranosyl)onate]-β-D-galactopyranoside (16). To a solution of **15** (15 mg, 0.014 mmol) in toluene (1 ml) were added tributylstannane (7 μl, 0.026 mmol) and AIBN (cat. amount) under argon atmosphere. The mixture was heated at 110 °C for 10 min and evaporated to dryness. The residue was chromatographed on a silica-gel column (benzene–acetone, 4 : 1) to give a syrup. This was triturated with hexane–ethyl acetate and washed with hexane to give **16** (12 mg, 93%).

Reaction of the Epoxide 2 with 17. A mixture of **2** (100 mg, 0.20 mmol), **17**[10] (160 mg, 0.43 mmol), mercury(II) chloride (60 mg, 0.22 mmol), powdered molecular sieves 4A (200 mg), and 1,2-dichloroethane (3 ml) was stirred for 40 h. The reaction mixture was filtered and the solid was washed with chloroform. The combined filtrate and washings were washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a residue, which was chromatographed on a silica-gel column (benzene–acetone, 3 : 2) to give the ortho ester **18** (132 mg, 75%).

To a solution of **18** (100 mg, 0.12 mmol) and 4-dimethylaminopyridine (60 mg, 0.49 mmol) in anhydrous acetonitrile (1.5 ml) was added phenyl chlorocarbonothioate (18 μl, 0.13 mmol) under argon atmosphere. The mixture was stirred for 1 h at room temperature, evaporated to dryness, and the residue was partitioned between ethyl acetate and water. The ethyl acetate layer was separated, washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a syrup, which was chromatographed on a silica-gel column (benzene–acetone, 3 : 2) to give **19** (100 mg, 86%).

To a mixture of **19** (80 mg, 0.08 mmol), anhydrous sodium acetate (40 mg), and toluene (3 ml) was added tributylstannane (43 μl, 0.16 mmol) under argon atmosphere. The mixture was heated at 110 °C for 10 min, diluted with ethyl acetate, washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated to dryness. The residue was chromatographed on a silica-gel cloumn (benzene–acetone, 3 : 2), triturated with hexane–ethyl acetate, and washed with hexane to give **20** (50 mg, 74%).

To a solution of **20** (100 mg, 0.12 mmol) in 60% aq methanol (3 ml) was added trifluoroacetic acid (1 drop) at room temperature. After stirring for 10 min, the mixture was evaporated to dryness and the residue was treated with acetic anhydride (0.4 ml) and pyridine (0.8 ml) for 10 h at room temperature under argon atmosphere. The resulting mixture was evaporated to a syrup, which was chromatographed on a silica-gel column (benzene–ethyl acetate, 6 : 1, followed by benzene–acetone, 1 : 1) to give methyl 3,4-di-*O*-acetyl-2,6-di-*O*-benzyl-β-D-galactopyranoside (**22**) (50 mg, 92%) and methyl 5-acetamido-3,4,7,8,9-penta-*O*-acetyl-2,5-dideoxy-D-*erythro*-L-*manno*-2-nonulopyranosonate (**21**) (51 mg, 91%) as a syrup.

A Synthesis of Optically Active 4-Diethoxyphosphinyl-3-(1-hydroxyethyl)-2-azetidinone: A Potential Precursor to (1-Aminoalkyl)-phosphonic Acid Derivatives

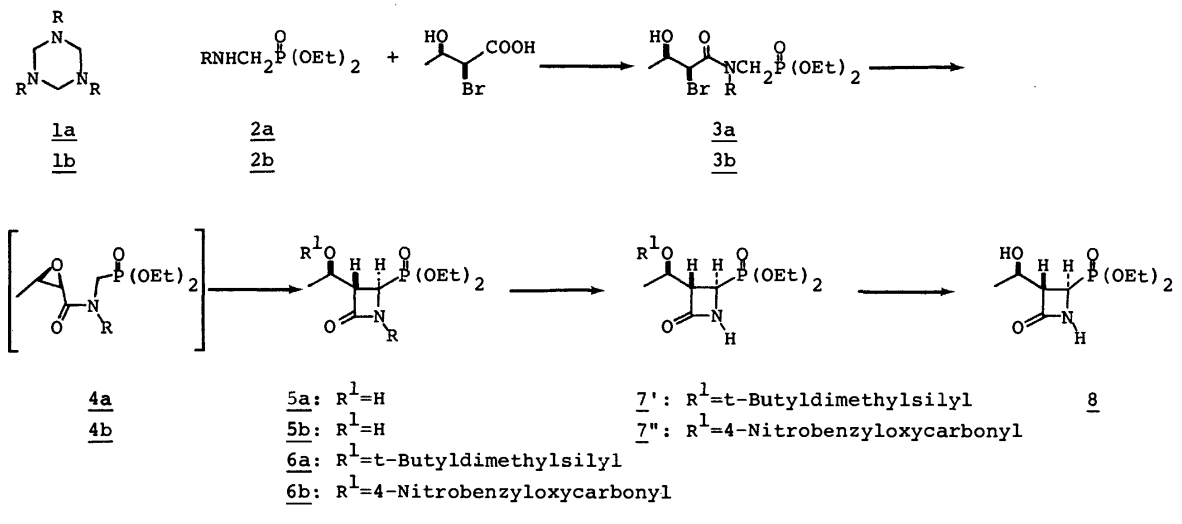
Masao SHIOZAKI* and Hidekazu MASUKO
Chemical Research Laboratories, Sankyo Co., Ltd. Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140
(Received July 10, 1986)

Optically active 4-diethoxyphosphinyl-3-(1-hydroxyethyl)-2-azetidinone (**8**) was synthesized from (2*R*,3*R*)-*N*-diethoxyphosphinylmethyl-2,3-epoxybutyramide derivatives, and compound **8** was alternatively synthesized from (3*R*,4*R*)-4-acetoxy-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)ethyl]-2-azetidinone via 3-[1-(*t*-butyldimethylsilyloxy)-ethyl] derivative.

4-Dialkoxyphosphinyl-2-azetidinone derivatives obtained by a treatment of the corresponding 4-acetoxy-2-azetidinone derivatives with trialkyl phosphites have already been reported by Campbell[1] as the starting material of alanyl dipeptide-containing organophosphorus moiety via β-phosphono-β-alanine derivatives. Such organophosphorus-containing molecules as the (1-aminoalkyl)phosphonic acid dipeptide (for example: alaphosphine–an inhibitor of alanine racemase) are becoming increasingly important for pharmaceutical use.

In this paper we wish to describe a new synthetic procedure for optically active 4-diethoxyphosphinyl-3-(1-hydroxyethyl)-2-azetidinone (**8**), as a potential precursor to one of the (1-aminoalkyl)phosphonic acid derivatives, by a ring closure of 2-bromo-3-hydroxybutyramides via the corresponding 2,3-epoxybutyramides which possess an activated methylene adjoining the amide nitrogen. This type of intramolecular concerted ring-closure reaction accompanied by an epoxide cleavage reaction to form a β-lactam derivative has already been reported.[2] On the other hand, (3*R*,4*R*)-4-acetoxy-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)-ethyl]-2-azetidinone (**9**) is one of the key intermediates to carbapenem antibiotics,[3] and **9** may become a commercially available material. Therefore, we attempted to utilize compound **9** for the synthesis of **8**. As a result, it was revealed that **9** is a promising intermediate for the synthesis of **8**. Thus, we also wish to report here this alternative procedure.

The starting phosphorus-containing butyramides were synthesized as follows: A treatment of 4-methoxybenzylamine or *p*-anisidine with paraformaldehyde according to the procedure reported by Ratcliffe et al.[4] gave hexahydro-1,3,5-triazines, **1a** (95% yield; mp 113—115 °C) or **1b** (72% yield; mp 128—130 °C). A reaction of the hexahydro-1,3,5-triazines (**1a** and **1b**) with diethyl phosphite at 100 °C for 4—6 h gave secondery amines (**2a** and **2b**: 65 and 61% yields, respectively). An amide-formation reaction of the amines (**2a** and **2b**) with 1 equivalent of (2*S*,3*R*)-2-bromo-3-hydroxybutyric acid[5] in tetrahydrofuran



Scheme 1.

(THF) in the presence of 1 equivalent of dicyclohexylcarbodiimide (DCC) gave **3a** (77% yield) and **3b** (21% yield).

Next, these phosphorus-containing butyramides were cyclized to β-lactams in a stereospecific manner. A treatment of **3a** and **3b** with 1 equivalent of lithium hexamethyldisilazanide in tetrahydrofuran at ice-cooling temperature for 5 min, and then another 1 equivalent of $LiN(SiMe_3)_2$ at 24 °C gave chiral 4-diethoxyphosphinyl-3-(1-hydroxyethyl)-2-azetidinone derivatives (**5a** (37% yield) and **5b** (61% yield) via *cis*-epoxides, **4a** and **4b**); *cis*-β-lactams were not isolated. The protection of the hydroxyl group of **5b** with 4-nitrobenzyl chloroformate by use of 4-dimethylaminopyridine (DMAP) as a base in CH_2Cl_2 gave **6b** (79% yield) as a foam. The deprotection of the methoxyphenyl group of **6b** with 3 equivalents of cerium(IV) ammonium nitrite (CAN) in acetone-H_2O (3 : 2) gave **7″** (81% yield) as a crystalline solid; mp 74—76 °C. The hydrogenolysis of **7″** with 5% Pd-C/H_2 at room temperature gave **8** (92% yield); mp 70—71 °C; $[\alpha]_D^{24}$ −4.9° (*c* 0.59, $CHCl_3$). Similarly, protection of the hydroxyl group of **5a** with *t*-butyldimethylsilyl chloride by use of 4-dimethylaminopyridine (DMAP) as a base in *N*,*N*-dimethylformamide (DMF) gave **6a** (67%). Deprotection of the methoxybenzyl group of **6a** with $K_2S_2O_8$-K_2HPO_4 in MeCN-H_2O (1 : 1) at 70—75 °C under argon for 30 min gave *N*-unsubstituted β-lactam **7′** (57% yield) as a gum. This 3,4-trans compound (**7′**) was also alternatively synthesized in good yield without detecting the 3,4-cis isomer[1b] by a treatment of (3*R*,4*R*)-4-acetoxy-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)-ethyl]-2-azetidinone (**9**) with triethyl phosphite according to Campbell's method,[1] and **7′**, obtained from both routes was identical in all respects. Compound **7′** was converted to **8** in 72% yield by a treatment with a tetrabutylammonium fluoride solution in tetrahydrofuran.

These compounds **5a**, **b**, **6a**, **b**, **7′**, **7″**, and **8** should be potential precursors to new 1-aminoalkylphosphonic acid analogues.

Experimental

Melting points were determined on a Yanagimoto micro-melting point apparatus and were uncorrected. Optical rotations were obtained by the use of a Perkin-Elmer 241 polarimeter. ^1H NMR spectra were recorded at 60 MHz with a Varian T-60 spectrometer using tetramethylsilane as an internal standard (δ value). The IR absorption spectra were determined on a Jasco IR A-2 spectrophotometer. Mass spectra were obtained on a JMS-01SG mass spectrometer. Preparative TLC was performed on silica-gel plates (Merck 60 PF_{245}), and column chromatography was carried out on columns packed with Merck silica-gel 60 using slightly increased pressure (1.5 atm) for elution. Elemental analyses were performed by the Analytical Center of the Analytical and Metabolic Research Laboratories, Sankyo Co., Ltd.

1,3,5-Tris(4-methoxybenzyl)hexahydro-1,3,5-triazine (1a). To a solution of 4-methoxybenzylamine (13.72 g, 0.10 mol) in dry ethanol (10 ml) was added formaldehyde (37 wt% solution in water, 7.5 ml) at room temperature with stirring. After 15 min, the reaction mixture was dissolved in EtOAc (100 ml). The solution was washed with water and brine, dried over $MgSO_4$, and concentrated in vacuo to give a triazine (14.22 g, 95% yield) as a crystalline solid; mp 113—115 °C. ^1H NMR ($CDCl_3$) δ=3.35 (6H, s), 3.55 (6H, s), 3.75 (9H, s), 6.65—7.25 (12H, m). MS *m/z* 447 (M^+). Found: C, 72.48; H, 7.38; N, 9.39%. Calcd for $C_{27}H_{33}O_3N_3$: C, 72.00; H, 7.40; N, 9.15%.

1,3,5-Tris(4-methoxyphenyl)hexahydro-1,3,5-triazine (1b). Treatment of *p*-anisidine and formaldehyde as described above gave **1b** in 72% yield as a crystalline solid; mp 128—130 °C. ^1H NMR ($CDCl_3$) δ=3.73 (3H, s), 4.65 (2H, s), 6.65—7.15 (4H, m). MS *m/z* 405 (M^+). Found: C, 70.63; H, 6.65; N, 10.22%. Calcd for $C_{24}H_{27}N_3O_3$: C, 71.09; H, 6.71; N, 10.36%.

***N*-(Diethoxyphosphinylmethyl)-4-methoxybenzylamine (2a).** A solution of the triazine **1a** (6.27 g, 14 mmol) in diethyl phosphite (5.4 ml, 42 mmol) was stirred for 6 h at 100 °C. After cooling, the reaction mixture was diluted with EtOAc (100 ml), which was washed with sat. $NaHCO_3$ aq and brine, dried over $MgSO_4$, and concentrated in vacuo to give an oily residue. Chromatography of the remaining residue on a silica-gel column (elution with cyclohexane-EtOAc (1 : 4)) gave an amine (7.30 g, 60.1%) as a viscous oil. ^1H NMR ($CDCl_3$) δ=1.25 (6H, t, *J*=6 Hz), 1.65 (1H, bs), 2.85 (2H, d, *J*=13 Hz), 3.65 (3H, s), 3.8—4.3 (6H, m), 6.6—7.25 (4H, m).

***N*-(Diethoxyphosphinylmethyl)-4-methoxyaniline (2b).** The same treatment of **1b** as described above in the formation of **2a** from **1a** gave **2b** in 61% yield as an oil. ^1H NMR ($CDCl_3$) δ=1.16 (6H, t, *J*=6 Hz), 3.30 (2H, d, *J*=6 Hz), 3.67 (3H, s), 3.8—4.3 (4H, m), 6.68 (4H, s). IR ν_{max}(film) cm^{-1}; 3300, 1520, 1260. MS *m/z* 273 (M^+).

(2*S*,3*R*)-*N*-(Diethoxyphosphinylmethyl)-*N*-(4-methoxybenzyl)-2-bromo-3-hydroxybutyramide (3a). To a solution of the amine **2a** (6.88 g, 24 mmol) and (2*S*,3*R*)-2-bromo-3-hydroxybutyric acid (4.39 g, 24 mmol) in THF (50 ml) was added DCC (4.66 g, 24 mmol) with stirring at room temperature. After 10 min, the reaction mixture was filtered to remove the precipitated DCC-H_2O. The filtrate was concentrated in vacuo to give an oily mixture, which was chromatographed on a silica-gel column. Elution with EtOAc gave an amide **3a** (8.32 g, 77% yield). ^1H NMR ($CDCl_3$) δ=1.1—1.4 (9H, m), 3.80 (3H, s), 3.85—4.45 (8H, m), 4.5—4.8 (2H, m), 6.85—7.20 (4H, m). MS *m/z* 451 (M^+).

(2*S*,3*R*)-*N*-(Diethoxyphosphinylmethyl)-*N*-(4-methoxyphenyl)-2-bromo-3-hydroxybutyramide (3b). The same treatment of **2b** as described above in the formation of **3a** from **2a** gave **3b** in 21% yield as a crystalline solid; mp 76—79 °C (from diisopropyl ether). ^1H NMR ($CDCl_3$) δ=1.22 (3H, t, *J*=8 Hz), 1.28 (6H, t, *J*=8 Hz), 3.78 (3H, s), 3.88—4.28 (8H, m), 6.74—7.30 (4H, m). MS *m/z* 437 (M^+). Found: C, 44.00; H, 5.78; N, 3.14; Br, 18.43; P, 7.70%. Calcd for $C_{16}H_{25}NO_6BrP$: C, 43.81; H, 5.70; N, 3.19; Br, 18.23; P, 7.16%.

(3*S*,4*R*)-4-Diethoxyphosphinyl-3-[(*R*)-1-hydroxyethyl]-1-(4-methoxybenzyl)-2-azetidinone (5a). To a solution of the amide **3a** (2.26 g, 5 mmol) in THF (10 ml) was added dropwise a solution of lithium hexamethyldisilazanide (15 mmol), which was prepared from hexamethyldisilazane (2.42 g) in THF (10 ml) and butyllithium (1.6 M in hexane, 9.38 ml), under nitrogen with stirring at 0—5 °C. After 30 min, the reaction mixture was diluted with EtOAc (100 ml), which was washed with 5% HCl, sat. $NaHCO_3$ and brine,

dried over Na_2SO_4, and concentrated in vacuo to give an oily mixture. Chromatography of the mixture on preparative silica-gel plates (developed with EtOAc) gave a β-lactam **5a** (0.68 g, 36.6% yield). IR ν_{max}(film) 1750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15—1.45 (9H, m), 2.95 (1H, bs), 3.20—3.55 (1H, m), 3.6—4.4 (7H, m), 4.75 (1H, d, J=15 Hz), 6.65—7.35 (4H, m). MS m/z 371 (M^+).

(3*S*,4*R*)-4-Diethoxyphosphinyl-3-[(*R*)-1-hydroxyethyl]-1-(4-methoxyphenyl)-2-azetidinone (5b). Treatment of **3b** with lithium hexamethyldisilazanide as described above in the formation of **5a** from **3a** gave **5b** in 61% yield as an oil. IR ν_{max}(film) cm^{-1}; 3400, 1760, 1260, 1520. ^1H NMR ($CDCl_3$) δ=1.20 (3H, d, J=6 Hz), 1.22 (6H, t, J=6 Hz), 2.15 (1H, bs), 3.70 (3H, s), 3.28—4.45 (7H, m), 6.68—7.48 (4H, m). MS m/z 357 (M^+).

(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-diethoxyphosphinyl-1-(4-methoxybenzyl)-2-azetidinone (6a). To a solution of **5a** (520 mg, 1.4 mmol) and *t*-butyldimethylsilyl chloride (320 mg, 2.1 mmol) in DMF (2 ml) was added DMAP (260 mg, 2.1 mmol) at room temperature with stirring. After 15 h, the reaction mixture was diluted with EtOAc (100 ml), which was washed with 5% HCl aq, sat. $NaHCO_3$ and brine, dried over Na_2SO_4, and filtered. The filtrate was concentrated in vacuo to give an oily product which was chromatographed on a silica-gel column. Elution with cyclohexane-EtOAc (1 : 1) gave a silyl ether (**6a**, 451 mg, 67.2% yield). ^1H NMR ($CDCl_3$) δ=0.05 (6H, s), 0.75 (9H, s), 1.05—1.40 (6H, dt, J=8, 2 Hz; 3H, d, J=6 Hz), 3.27 (1H, dt, J=8, 3 Hz), 3.73 (3H, s), 3.73—4.30 (7H, m), 4.57 (1H, d, J=14 Hz), 6.65—7.30 (4H, m). IR ν_{max}(film) 1760, 1260 cm^{-1}. MS m/z 485 (M^+).

(3*S*,4*R*)-4-Diethoxyphosphinyl-1-(4-methoxyphenyl)-3-[(*R*)-1-(4-nitrobenzyloxycarbonyloxy)ethyl]-2-azetidinone (6b). To a solution of **5b** (140 mg, 0.4 mmol), 4-nitobenzyloxycarbonyl chloride (260 mg, 1.2 mmol) in dichloromethane (4 ml) was added DMAP (150 mg, 1.2 mmol) with stirring at room temperature. After 2 h, the reaction mixture was diluted with EtOAc, which was washed with dil. HCl, water, sat. $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated in vacuo to give a residual oil. Preparative TLC of the residue on silica-gel plates gave **6b** (210 mg, 97% yield) as an oil. IR ν_{max}(film) cm^{-1}; 1760, 1610, 1520, 1260. ^1H NMR ($CDCl_3$) δ=1.24 (6H, dt, J=6, 2 Hz), 1.49 (3H, d, J=4 Hz), 3.48—3.68 (1H, m), 3.79 (3H, s), 3.84—4.38 (6H, m), 5.20 (2H, s), 6.78—8.25 (8H, m). MS m/z 536 (M^+).

(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-diethoxyphosphinyl-2-azetidinone (7′). (a) To a solution of **6a** (140 mg, 0.3 mmol) in MeCN-H_2O (1 : 1, 20 ml) was added K_2HPO_4 (490 mg, 2.8 mmol) and $K_2S_2O_8$ (900 mg, 3.3 mmol) under argon. The mixture was heated at 73 °C for 30 min with stirring. After concentration in vacuo, the residue was diluted with water (50 ml), and extracted with EtOAc (100 ml×2). The combined organic layer was washed with sat. $NaHCO_3$ and brine, dried over Na_2SO_4, filtered and concentrated in vacuo to give an oily residue. Chromatography on a preparative TLC plate (developed with cyclohexane-EtOAc (1 : 2) gave *N*-unsubstituted product **7′** (60 mg, 57% yield) as a gum. ^1H NMR ($CDCl_3$) δ=0.05 (6H, s), 0.85 (9H, s), 1.15 (3H, d, J=6 Hz), 1.35 (6H, t, J=8 Hz), 3.35 (1H, dt, J=8, 3 Hz), 3.7—4.5 (7H, m), 6.30 (1H, bs). MS m/z 366 (M^+).

(b) A mixture of (3*R*,4*R*)-4-acetoxy-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)ethyl]-2-azetidinone (**9**, 1.2 g) and triethyl phosphite (4 ml) was heated to 100 °C for 1 h. The reaction mixture was concentrated in vacuo with a pump, and chromatographed on a silica-gel column. Elution with EtOAc-cyclohexane (1 : 1) gave **7′** in 92% yield, which was identical with that obtained in (a).

(3*S*,4*R*)-4-Diethoxyphosphinyl-3-[(*R*)-1-(4-nitrobenzyloxycarbonyloxy)ethyl]-2-azetidinone (7″). To a solution of **6b** (110 mg, 0.2 mmol) in acetone (1.5 ml) and water (1 ml) was added CAN (330 mg, 0.6 mmol) at 0 °C with magnetic stirring. After 30 min at 0 °C, the reaction mixture was diluted with EtOAc, which was washed with sat. $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated in vacuo to give an oily residue. The residue was chromatographed on a silica-gel column to give **7″** (88 mg, 81% yield) as a crystalline solid: Mp 77—78 °C. ^1H NMR ($CDCl_3$) δ=1.25 (3H, d, J=6 Hz), 1.42 (6H, t, J=6 Hz), 3.41—3.70 (1H, m), 3.84 (1H, dd, J=8, 2 Hz), 4.12 (2H, dq, J=16, 2 Hz), 4.28 (2H, dq, J=16, 2 Hz), 5.26 (2H, s), 7.00 (1H, bs), 7.49—8.35 (4H, A_2B_2-quartet). MS m/z 430 (M^+). Found: C, 47.48; H, 5.27; N, 6.39; P, 7.09%. Calcd for $C_{17}H_{23}N_2O_9P$: C, 47.44; H, 5.35; N, 6.51; P, 7.21%.

(3*S*,4*R*)-4-Diethoxyphosphinyl-3-[(*R*)-1-hydroxyethyl]-2-azetidinone (8). (a) A solution of **7″** (106 mg, 0.246 mmol) in MeOH (5 ml) and 5% Pd-C (100 mg) was stirred for 2 h at room temperature under hydrogen. Filtration, concentration and column chromatography on silica gel (eluted with EtOAc-EtOH=19 : 1) gave **8** (56 mg, 91% yield) as a crystalline solid; mp 70—71 °C (from EtOAc-cyclohexane). $[\alpha]_D^{24}$ —4.9° (*c* 0.59, $CHCl_3$). IR ν_{max}(KBr) cm^{-1}; 3350, 3200, 1750. ^1H NMR δ=1.24 (3H, d, J=6 Hz), 1.32 (6H, t, J=8 Hz), 3.29 (1H, dt, 9, 3 Hz, C_3-H)), 3.61—4.41 (7H, m, containing OH), 7.40 (1H, bs, NH). MS m/z 233 (M^+−18). Found: C, 43.03; H, 7.12; N, 5.67; P, 11.53%. Calcd for $C_9H_{18}NO_5P$: C, 43.02; H, 7.16; N, 5.57; P, 12.34%.

(b) A solution of **7′** (140 mg, 0.383 mmol) in THF (2 ml) and *n*-Bu_4NF (1.0 M solution in THF, 0.6 ml) was allowed to stand overnight at room temperature. The solution was concentrated in vacuo to give an oily mixture which was chromatographed on a silica-gel column. Elution with EtOAc and then 10% EtOH in EtOAc gave **8** (70 mg, 72% yield), which was identical with that obtained from **7″** in procedure (a).

The Optical Resolution and Asymmetric Transformation of DL-*p*-Hydroxyphenylglycine with (+)-1-Phenylethanesulfonic Acid

Ryuzo YOSHIOKA,* Masanori TOHYAMA,† Osamu OHTSUKI, Shigeki YAMADA,†† and Ichiro CHIBATA†††
Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd.,
16-89, Kashima 3-Chome, Yodogawa-ku, Osaka 532
(Received July 18, 1986)

Optically active 1-phenylethanesulfonic acid was found to be an efficient resolving agent for the optical resolution and asymmetric transformation of DL-*p*-hydroxyphenylglycine. When DL-*p*-hydroxyphenylglycine was resolved by the fractional crystallization of its diastereomeric salt with (+)-1-phenylethanesulfonic acid, less soluble D-*p*-hydroxyphenylglycine (+)-1-phenylethanesulfonate [D-HPG·(+)-PES] was obtained in a good yield. Soluble L-HPG·(+)-PES was easily epimerized into DL-HPG·(+)-PES by heating it at 100 °C in glacial acetic acid in the presence of a small amount of salicylaldehyde. Under such epimerizing conditions, the asymmetric transformation of DL-HPG·(+)-PES was attempted by simultaneously combining the fractional crystallization of the less soluble D-HPG·(+)-PES and the epimerization of the soluble L-HPG·(+)-PES. This asymmetric transformation was achieved successfully; that is, 80% of the DL-HPG used as the starting material was converted into D-HPG.

D-*p*-Hydroxyphenylglycine is a starting material in the production of β-lactam antibiotics, such as semi-synthetic penicillins or cephalosporins. In order to develop a practical method for the production of this D-*p*-hydroxyphenylglycine (D-HPG), we have been studying the optical resolution of synthetic DL-HPG[1,2] by several techniques, for instance, preferential crystallization,[3] diastereomer salt formation,[4] and asymmetric transformation.

In our recent studies of asymmetric transformation,[5–8] it was reported that D-HPG was successfully prepared by asymmetric transformation combined with preferential crystallization and simultaneous racemization.[8] Besides this convenient procedure, if a suitable resolving agent of DL-HPG through diastereomer salt formation can be found, it will also provide an advantageous resolution method (i.e., asymmetric transformation) for the preparation of D-HPG. In the present work, we could find that optically active 1-phenylethanesulfonic acid was a favorable resolving agent for this purpose. In this paper, we wish to describe particularly a unique method for the preparation of D-HPG by asymmetric transformation between two diastereomeric salts of DL-HPG with (+)-1-phenylethanesulfonic acid.

In general, free neutral amino acids can not form diastereomeric salts directly with ordinary weak basic or weak acidic resolving agents. For the formation of these diastereomeric salts, it has usually employed such strongly acidic resolving agents[9,13] as the camphorsulfonic acids and also, rarely, the terpenesulfonic acids or cholestenonesulfonic acid. However, these chiral sulfonic acids derived from naturally occurring products are not necessarily satisfactory for practical production because they are expensive, are somewhat optically or chemically labile, and are not available in large amounts. Therefore, we have carried out the screening of resolving agents aimed at discovering one without these disadvantages; this led to the finding of 1-phenylethanesulfonic acid.

The synthesis and optical resolution of racemic 1-phenylethanesulfonic acid [(±)-PES] has been fairly well described in the literature.[10] According to the previously reported synthetic method, however, (±)-PES could not be easily prepared.[11] In the course of our further researches, it was found that (±)-PES synthesized by sulfonating (±)-1-phenylethyl bromide[11] could be resolved into the (+)-isomer through its diastereomeric salt with D-HPG in an aqueous solvent. On the contrary, DL-HPG could be easily resolved in the same manner into the D-isomer by using the (+)-PES as the resolving agent. In Table 1, the physical properties of D-*p*-hydroxyphenylglycine (+)-1-phenylethanesulfonate (D-HPG·(+)-PES) and L-HPG·(+)-PES are shown. Since the difference in solubility between the two diastereomeric salts in water (20 °C) was very large, the fractional crystallization of DL-HPG with less than an equivalent amount of (+)-PES in water afforded almost optically pure D-HPG·(+)-PES in a good yield (43.8% based on DL-HPG·(+)-PES).

On the other hand, we previously reported that the racemization of optically active amino acid salts (e.g., achiral sulfonates) was accomplished by heating them in an acetic acid solution in the presence of a catalytic amount of an aldehyde and free DL-amino acid.[6] This racemization method prompted us to study the asymmetric transformation of DL-HPG with (+)-PES.

In order to apply the asymmetric transformation to DL-HPG·(+)-PES, (+)-PES must be chemically and optically stable under the conditions for the above racemization (epimerization for diastereomer). The optical stability of (+)-PES was tested under the pre-

Table 2. Optical Stability of (+)-PES in Various Solvents

Solvent	Racemization degree/%		
	2h	5h	10h
Water	0	0	0
1M-H_2SO_4	0	0	0
AcOH	0	0	0
2M-NaOH	8	17	31

The solutions of (+)-PES (0.2 g) dissolved in solv. (6 ml) were stirred at 100°C for 10 h.

sent heating conditions in various solvents. As shown in Table 2, (+)-PES was quite stable at 100 °C for 10 h in water, 1 M H_2SO_4 (1 M=1 mol dm^{-3}) and in acetic acid, but in 2 M NaOH it was gradually racemized. Since (+)-PES was optically stable in acetic acid, it was preferable to accelerate the epimerization of the soluble L-HPG·(+)-PES (i.e., the racemization of the L-HPG moiety). As can be seen in Fig. 1, L-HPG·(±)-PES was easily epimerized into DL-HPG·(±)-PES by heating it at 100 °C for ca. 4 h in acetic acid containing a 0.2 molar equivalent of salicylaldehyde. In addition, the crystals of D-HPG·(+)-PES were also confirmed to be rather insoluble in acetic acid (Table 1) and to precipitate without changing, even under the above epimerizing conditions.

Thus, the characteristics of the foregoing HPG·(+)-PES satisfied the most essential requirement for the intended asymmetric transformation via diastereomer salt formation. Therefore, using the optical resolution and the epimerization method described above, the asymmetric transformation of DL-HPG·(+)-PES was examined in a system. For instance, a mixture of DL-HPG (10.0 g), (+)-PES (11.2 g), glacial acetic acid (200 ml), and salicylaldehyde (0.63 ml) (added for accelerating the epimerization) was stirred at 100 °C for 5 h. The reaction proceeded continuously in a slurry state of the solid-liquid heterogeneous system. After this reaction mixture had then been cooled at 20 °C, precipitated crystals were collected to give D-HPG·(+)-PES

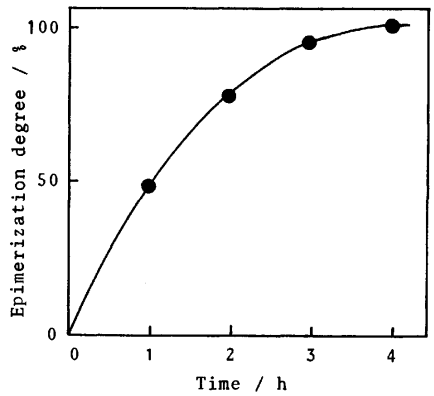

Fig. 1. Time course on epimerization of L-HPG·(±)-PES. The reactions were carried out at 100°C in L-HPG·(±)-PES/AcOH in the presence of salicylaldehyde (0.2 molar equivalent).

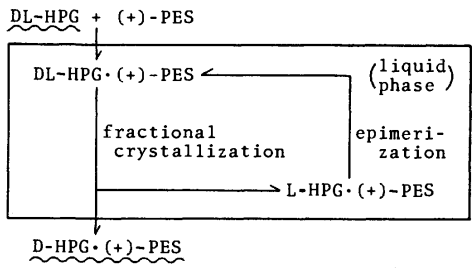

Fig. 2. Asymmetric transformation of DL-HPG with (+)-PES. ~~~, solid state.

(18.0 g); $[\alpha]_D^{25}$ −74.5° (*c* 1, MeOH); optical purity, 95.0%; yield, 85.1% (based on DL-HPG·(+)-PES). The pathway of the asymmetric transformation described here is considered to be that shown in Fig. 2: When the crystals of D-HPG·(+)-PES were fractionally precipitated from a salt solution consisting of DL-HPG and (+)-PES, the epimerization of the soluble L-HPG·(+)-PES proceeded simultaneously in the liquid phase, and D-HPG·(+)-PES was also thereupon immediately precipitated from the epimerizing solution. Since

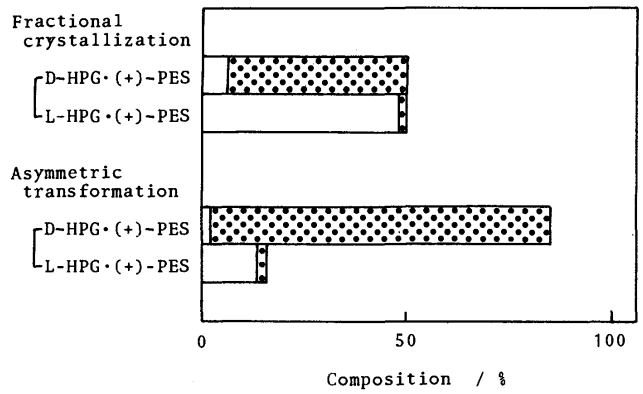

Fig. 3. The change in the composition of D- or L-HPG·(+)-PES by fractional crystallization and asymmetric transformation.
▩: Crystals of (+)-PES salt, □: (+)-PES salt in solution.

these steps were repeated continuously in the reaction system, the equilibrium finally shifted in favor of D-HPG·(+)-PES as a whole. As a result, 80% of the DL-HPG·(+)-PES was transformed into D-HPG·(+)-PES. Figure 3 shows a comparison of the results of the ordinary fractional crystallization and of the asymmetric transformation.

Among the various techniques for optical resolution, the fractional crystallization of the diastereomeric salts with a chiral resolving agent under simultaneous epimerizing conditions is known as an asymmetric transformation of the second order.[12,13] This method is very attractive, particularly when separations for industrial applications are contemplated, because it is possible to transform the racemate to the desired isomer in a nearly quantitative yield through a simple operation. The asymmetric transformation of DL-HPG with (+)-PES is, therefor, expected to be a very promising procedure for the industrial production of D-HPG.

Experimental

Materials and Analyses. D-, L-, and DL-HPG manufactured by our company, Tanabe Seiyaku Co., Ltd. were used. The (±)- and (+)-1-phenylethanesulfonic acids (PES) were prepared by the method shown below. Other chemicals were obtained from Tokyo Kasei Kogyo Co., Ltd. All samples were dried overnight in vacuo at 40 °C. Melting points were measured with a Yamato MP-21 melting point apparatus in an unsealed capillary tube; they are uncorrected. Optical rotations were measured with a Perkin-Elmer 141 automatic polarimeter. IR spectra were recorded on a Shimadzu infrared spectrophotometer, Model IR-420. ^{1}H NMR spectra were obtained using a Hitachi Perkin-Elmer R-40 High Resolution ^{1}H NMR spectrometer, with tetramethylsilane as an internal standard. Elemental analyses were performed with a Perkin-Elmer 240 elemental analyzer. Solubility was determined by approaching saturation equilibrium from both undersaturation and supersaturation. Solute concentration was measured with a Karl Zeiss immersion refractometer.

Preparation of Barium (±)-1-Phenylethanesulfonate. (±)-1-Phenylethanesulfonic acid [(±)-PES] was prepared from commercially available (±)-1-phenylethyl bromide in the manner described by Kharasch et al.[11] That is, a mixture of (±)-1-phenylethyl bromide (70 g), a 50% ammonium hydrogensulfite solution (75 g), and 28% aqueous ammonia (30 ml) was stirred at room temperature overnight. After the oil part of the reaction mixture had been removed, barium hydroxide octahydrate (60 g) was added and the ammonia was boiled out. The aqueous solution was then adjusted to neutrality with sulfuric acid, and the insoluble barium salts were filtered off and washed with water. The filtrates were partly concentrated under reduced pressure, and the precipitated crystals were filtered, washed with cold water, and dried to give (±)-PES·1/2Ba·1/2H_2O (44 g) in a 44% yield; IR (nujol) 3475, 1630, 1185, and 1065 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=1.48 (3H, d, J=7 Hz, CH_3), 3.72 (1H, q, J=7 Hz, CH), and 7.1—7.4 (5H, m, aromatic).

Optical Resolution of (±)-1-Phenylethanesulfonic Acid. To a solution of (±)-PES·1/2Ba·1/2H_2O (42.1 g) in hot 10% HCl (590 ml) was added D-HPG (26.7 g). After it had then been cooled slowly to room temperature, the mixture was stirred at 25 °C for 2 h. The resulting crystals were filtered, washed with a small amount of cold water, and dried to give crude (+)-PES·D-HPG; $[\alpha]_D^{25}$ −79.5° (*c* 1, MeOH). The crude salt (26.0 g) was recrystallized from 0.1% sulfuric acid (430 ml) to afford the pure (+)-PES·D-HPG (23.0 g); $[\alpha]_D^{25}$ −78.9° (*c* 1, MeOH); mp 262—263 °C (decomp); IR (nujol) 3050, 1740, 1600, and 1140 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=1.48 (3H, d, J=7 Hz, CH_3), 3.72 (1H, q, J=7 Hz, CH), 4.97 (1H, s, CH), 6.8—7.5 (9H, m, aromatic), and 8.7 (2H, br, NH_2).

Found: C, 54.39; H, 5.51; N, 3.99; S, 8.98%. Calcd for $C_{16}H_{19}NO_6S$: C, 54.38; H, 5.42; N, 3.96; S, 9.07%. This product was optically and chemically pure. The specific rotation of a mixture of (±)-PES and an equivalent amount of D-HPG was $[\alpha]_D^{25}$ −87.1° (*c* 1, MeOH), and that of an authentic (+)-PES·D-HPG was $[\alpha]_D^{25}$ −78.9° (*c* 1, MeOH).

The pure (+)-PES·D-HPG (22.0 g) obtained above was suspended in water (22 ml) at 50—60 °C. The solution was adjusted to pH 5.5 with 6M NaOH (ca. 10.4 ml) and then stirred at 20 °C for 2 h. The crystals thus precipitated were filtered, washed with cold water, and dried to obtain D-HPG (9.5 g). The mother liquor filtered was passed through a column of Amberlite IR-120 (100 ml, H^+ form), after which the column was washed with water. The aqueous solution passed through was treated with activated charcoal and concentrated to dryness in vacuo at 40 °C to give (+)-PES (free acid 11.5 g) as pasty crystals; $[\alpha]_D^{25}$ +21.9° (*c* 3, DMSO); ^{1}H NMR (D_2O) δ=1.71 (3H, d, J=7 Hz, CH_3), 4.24 (1H, q, J=7 Hz, CH), and 7.55 (5H, s, aromatic).

Optical Stability of (+)-1-Phenylethanesulfonic Acid. A solution of (+)-PES (free acid 0.2 g) in various solvents (6 ml) was sealed in a glass tube and shaken at 100 °C for 10 h. After the solution had then been cooled and diluted with water (4 ml), the optical rotation was measured. The racemization degree was calculated from the following formula:

$$\frac{\text{initial optical rotation} - \text{final optical rotation}}{\text{initial optical rotation}} \times 100$$

The optical stability of (+)-PES was judged from the resulting racemization degree in the various solvents shown in Table 2.

Optical Resolution of DL-*p*-Hydroxyphenylglycine. DL-HPG was resolved with (+)-PES in the same manner as in

the optical resolution of (±)-PES described above: A mixture of DL-HPG (10.0 g), (+)-PES (free acid 10.0 g), and water (200 ml) was heated until clear and then allowed to cool to 25 °C with stirring. After 2 h, the product was collected, washed with cold water, and dried to give crude D-HPG·(+)-PES (9.7 g); $[\alpha]_D^{25}$ −74.8° (*c* 1, MeOH); optical purity, 95.4% [based on D-(+) salt $[\alpha]_D^{25}$ −78.9° (*c* 1, MeOH) and DL-(+) salt $[\alpha]_D^{25}$ +9.8° (*c* 1, MeOH)]; yield, 43.8% (based on DL-HPG·(+)-PES). The change in the composition of the diastereomeric salts is shown in Fig. 3.

Epimerization of L-HPG·(+)-PES. The epimerization study of the soluble L-HPG·(+)-PES was carried out by using L-HPG·(±)-PES in order to determine the racemization degree of the L-HPG moiety. A mixture of L-HPG·(±)-PES (0.2 g), a 0.2 molar equivalent of salicylaldehyde (6.8 μl), and glacial acetic acid (6 ml) was heated in a sealed tube at 100 °C for the prescribed time interval. The reaction mixture was then diluted with acetic acid (10 ml), and the optical rotation was measured. The epimerization degree was calculated from the decrease in the optical rotation according to the above-noted formula. The results are shown in Fig. 1.

Asymmetric Transformation of DL-*p*-Hydroxyphenylglycine. A mixture of DL-HPG (10.0 g), (+)-PES (11.2 g), salicylaldehyde (0.63 ml), and glacial acetic acid (200 ml) in a flask fitted with a mechanical stirrer and a condenser was continued at 100 °C for 5 h, during which period the reaction system was heterogeneous. The reaction mixture was cooled to 20 °C, and the precipitated crystals were quickly collected by filtration, washed with a small amount of acetic acid, and dried to give crude D-HPG·(+)-PES (18.0 g); $[\alpha]_D^{25}$ −74.5° (*c* 1, MeOH); optical purity, 95.0%; yield, 85.1% (based on DL-HPG·(+)-PES). This ^{1}H NMR and the IR spectra were in accord with an authentic sample of D-HPG·(+)-PES. The change in the composition of both diastereomeric salts by the present asymmetric transformation is shown in Fig. 3.

Preparation of D-*p*-Hydroxyphenylglycine. The crude D-HPG·(+)-PES (17.0 g) obtained above was recrystallized from hot water (300 ml) to give optically pure D-HPG·(+)-PES (14.5 g); $[\alpha]_D^{25}$ −78.9° (*c* 1, MeOH). The pure salt (14.0 g) was suspended in water (15 ml) at 50—60 °C, and the mixture was adjusted to pH 5.5 by the dropwise addition of 6 M NaOH (ca. 6.6 ml), after which it was stirred at 20 °C for 2 h. The crystals thus precipitated were collected, washed with water, and dried to give D-HPG (6.0 g); $[\alpha]_D^{25}$ −158.4° (*c* 1, 1 mol dm^{-3} HCl).

Found : C, 57.50; H, 5.51; N, 8.33%. Calcd for $C_8H_9NO_3$: 57.48; H, 5.43; N, 8.38%.

The Effects of Catalysts on the Mean Structure of Solvent-Refined Coal in Coal Liquefaction

Koji CHIBA,* Hideyuki TAGAYA, Shimio SATO, and Shinya OHGI
Department of Chemical Engineering, Faculty of Engineering, Yamagata University, Johnan, Yonezawa 992
(Received July 23, 1986)

The effects of MoO_3, Fe_2O_3, or SnO on the conversion and the solvent-refined coal (SRC) yield of Taiheiyo coal were small, whereas their effects on the structure of SRC were large. SRC was separated into four fractions by successive extraction in order to clarify the differences in SRC's among the catalysts. The formation of SnO_2 after the liquefaction was confirmed. It was considered that the oxygen-abstraction ability and the radical-stabilization ability of SnO prevented the retrogressive reaction of coal, SRC, and model compounds. MoO_3 and Fe_2O_3 have a higher ability to hydrogenate and accelerate the hydrocracking of coal and coal-model compounds than does SnO, but their ability to suppress the retrogressive reaction producing heavier compounds is small.

Although many attempts have been made to find more effective coal-liquefaction catalysts, most of them have been limited to the purpose of increasing the conversion to the liquid products of coal.[1,2] However, in order to evaluate a coal-liquefaction reaction and the use of its products, the difference in the structure of the liquefaction products obtained by the use of the different catalysts needs also to be investigated.

In this paper, three different metal oxides, MoO_3, Fe_2O_3, and SnO, were used as catalysts for Taiheiyo-coal liquefaction in tetralin or decalin under a hydrogen or nitrogen atmosphere. In order to clarify the differences in the structures of the products, solvent-refined coal (SRC) was separated into four fractions by successive extraction and their structural parameters were calculated using the Brown-Ladner method.[3]

SRC was treated in the presence of a catalyst in order to correlate the results with the results of coal liquefaction. Further, the reactions of coal model compounds were also examined in order to obtain information about the roles of the catalysts.

Experimental

Taiheiyo coal-1, -2, and -D (Table 1) were ground, passed through a 100-mesh (149 μm) screen and then dried at 107 °C under a nitrogen atmosphere. Taiheiyo coal-2 was deashed to prepare Taiheiyo coal-D by the method of Fan et al.[4] The ash content decreased from 14.4 to 2.2%. For coal liquefaction, a mixture of coal (5 g), a solvent (15 g), and a catalyst (0.5 g) was placed in a Pyrex glass liner, inserted into a 100-ml magnetdriven autoclave; this autoclave was then pressurized to 5.1 MPa at room temperature with hydrogen or nitrogen. It is well-known that the autoclave wall acts as a catalyst. So a Pyrex glass liner was used. The nominal reaction time was 60 min at 400 °C. The materials remaining in the autoclave after the liquefaction were extracted with benzene. A benzene-insoluble material was weighed after drying and then further extracted with THF. The liquefaction solvent was recovered from the benzene extract by vacuum distillation. The distillation residue was weighed as SRC.[5] The conversions to a benzene-soluble material (BC) and to a THF-soluble material (TC) were calculated according to the following equation:

$$\text{Conversion to BC or TC (wt\% daf coal basis)} = \frac{(\text{Coal-charged} - \text{benzene or THF-insoluble material}) \times 100}{\text{daf coal}}$$

The SRC was separated into four fractions by successive extractions; when benzene 4%–heptane 96% (Solvent 1), benzene 15%–heptane 85% (Solvent 2), benzene 50%–hexane 50% (Solvent 3), benzene 60%–methanol 40% (Solvent 4) were used successively as the extraction solvents, Fractions 1—4 were thus obtained.

The ^{1}H NMR spectra were recorded at 90MHz on a Hitachi R 22 apparatus. The solution for the measurements of the ^{1}H NMR spectra was prepared by dissolving 40 mg of a sample in 0.4 ml of chloroform-*d*, using tetramethylsilane as the internal standard.

Results

The liquefaction reactions of Taiheiyo coal-1, -2, and -D in tetralin under a hydrogen atmosphere using different catalysts at 400 °C are shown in Table 2. When no catalyst was used, the conversions to BC and the SRC yields were in the following order: Taiheiyo-D>Taiheiyo-2>Taiheiyo-1. The same order was observed when MoO_3, Fe_2O_3, or SnO was used as the catalyst. The use of catalysts was effective for coal liquefaction, and the conversions to BC with catalysts were from 12 to 18% higher than those without catalysts, even in tetralin. Although SnO was a more effec-

tive catalyst than MoO_3 and Fe_2O_3, the differences between them were only from 4 to 6%. The highest conversion to BC was always obtained with Taiheiyo-D, and the tendency of conversion to BC with catalysts was not affected by the removal of coal minerals. On the other hand, the differences in the conversions to TC among the catalysts used were relatively small. This indicated that the interaction between coal minerals of Taiheiyo coal and the added catalyst was small. Taiheiyo coal-1 was exclusively used in the latter part of this study.

Taiheiyo coal-1 was liquefied at 400 °C for 60 min in tetralin or decalin under a hydrogen or nitrogen atmosphere using three different kind of catalysts, as is shown in Table 3. Irrespective of the catalyst, the conversion to BC, the TC, and the SRC yields were in the following order:

in tetralin under hydrogen > in tetralin under nitrogen > in decalin under hydrogen > in decalin under nitrogen.

From Table 3, it may seem that two important factors in the conversion to BC, and to TC, and in the SRC yield were the solvent and the atmosphere. To quantify the effects of the liquefaction conditions, variance analysis[6] was applied to these results. The conversions on repeated runs at 440 °C in tetralin were 64.5 and 66.4% for conversion to BC, and 92.1, and 91.9% for conversion to TC. These runs indicated that the experimental data were applicable to the analysis. In the three-way model, we investigated the effects of sixteen different combinations of four catalysts (none, MoO_3, Fe_2O_3, SnO), two solvents (tetralin, decalin), and two atmospheres (hydrogen, nitrogen). The significance at the α=0.01 level showed that the main effects of the conversion and the SRC yields were due to the solvent and the atmosphere, not to the catalyst. The SRC's were analyzed by the use of ^1H NMR, and the structural parameters of the SRC's were then calculated. The three-way variance analysis was also applied to the structural parameter, fa (aromaticity), of

SRC. In this case, even with catalysts, a significance at the α=0.01 level was observed. It was concluded that, under these liquefaction conditions, the effects of catalysts on the conversion and the SRC yield were small, whereas the effects of the catalysts on the structure of SRC were large and important.

To obtain information about the difference in the SRC structure, the molecular-weight distributions of the SRC's were measured by means of GPC; the results are shown in Fig. 1. When a catalyst, especially Fe_2O_3, was used, the heavier compounds (with molecular weights of around 10000) were larger than those with no catalyst. Moreover, when SnO was used, the compounds whose molecular weights were around 1000 were larger than those of the SRC with other catalysts. However, we could not clarify the differences in distribution among them and the difference in the role of the catalyst in the course of coal liquefaction, for the SRC contains many compounds. Therefore, the SRC was separated into four fractions by means of successive extractions.

The SRC yields of Taiheiyo coal in tetralin under a hydrogen atmosphere were 39, 39, and 44% with MoO_3, Fe_2O_3, and SnO, respectively. They were extracted successively using Solvents 1—4, whose compositions have already been described in the Experimental section. The fraction yields based on daf coal are shown in Fig. 2.

The SRC yield without a catalyst was 32%, approximately 12% smaller than that with SnO, but the distributions of the SRC without a catalyst were almost identical with those with SnO; the yields were in the following order: Fraction 4>Fraction 3≥Fraction 1> Fraction 2.

When MoO_3 or Fe_2O_3 was used, both the lighter (Fraction 1) and the heavier (Fraction 4) components were larger than those in the SRC with no catalyst.

To compare the structure of the SRC, all fractions were analyzed by means of ^1H NMR. The results of the elemental analysis and their structural parameters are shown in Table 4. The hydrogen/carbon ratio (H/C) decreased, and the oxygen content, the carbon aromaticity (fa), and the number of rings (Ra, Rn, Rt) increased, with an increase in the fraction number, irrespective of the kind of catalyst. The oxygen contents of Fractions 1—4 which were obtained using SnO were smaller than those obtained using no catalyst or Fe_2O_3. When MoO_3 was used, the oxygen contents of Fractions 1 and 2 were smaller than those obtained using SnO, but those of Fractions 3 and 4 were larger. Not only the smallest number of aromatic rings (Ra), but also the smallest number of non-aromatic rings (Rn), of all fractions were obtained when SnO was used. When MoO_3 or Fe_2O_3 was used, the numbers of total rings of Fractions 3 and 4 were 4.94 and 7.01, and 4.98 and 5.39, respectively; these numbers were larger than those when no catalyst or SnO was used. The yield of Fraction 3 was from 8.5 to 10.5 wt%, and the effect of the kind of catalyst used on the yield was relatively small. The mean molecular weight of Fraction 3 was measured by means of VPO. Values of 420 with MoO_3 and 520 with Fe_2O_3 were obtained; these values were larger than those of 320 without a catalyst and 350 with SnO.

In this way, we can clarify the differences among catalysts in the structure of SRC; when SnO was used, lighter compounds than those with other catalysts were obtained, despite the larger SRC yield.

To obtain further information on the liquefaction products, SRC was treated in the presence of a catalyst. The SRC had been obtained by the liquefaction of Taiheiyo coal without a catalyst at 420 °C for 60 min under a hydrogen atmosphere. In the reaction of SRC,

few gaseous compounds were produced during the treatment, and most of the SRC was recovered as benzene-soluble. The structural parameters are shown in Table 5. Without a catalyst, the H/C ratio of SRC decreased from 1.2 to 1.1, and the chain length decreased from 3.1 to 2.6; this indicates the presence of a slight retrogressive reaction. When MoO_3 or Fe_2O_3 was used, the retrogressive reaction was confirmed by the increases in the total rings per structural unit and in the mean molecular weight. On the other hand, when SnO was used, the mean molecular weight and the total number of rings decreased from 320 to 250, and from 4.48 to 3.76, respectively.

The retrogressive reaction for MoO_3 and Fe_2O_3 was also confirmed from model-compound studies. MoO_3 and Fe_2O_3 were more effective than was SnO for the hydrogenation reaction of naphthalene and benzophenone to tetralin and diphenylmethane. The results were identical with those reported previously.[7] Furthermore, the reactions of dibenzyl ether at 360 °C and of biphenyl at 400 °C were accelerated in the presence of MoO_3 or Fe_2O_3, as is shown in Table 6. However, the yields of unknown compounds were larger with MoO_3 or Fe_2O_3 than with no catalyst or with SnO. For example, although DBE reacted completely in the presence of MoO_3, 78.2% of the products were unknown, and some of them were insoluble to a solvent like acetone. The GPC data showed that most of the unknown products were compounds whose molecular weights were larger than that of DBE, indicating the presence of a retrogressive reaction.

Discussion

It is well-known that coal minerals catalyze liquefaction and hydrogenation in coal-conversion processes.[8-10] Guin et al. reported that certain coal minerals, particularly iron compounds, catalyze hydrogenation.[9] Atomic-absorption analysis has shown that the content of iron in Taiheiyo coal is 0.65 wt%, based on dry coal. The hydrogenation ability of coal minerals was affected by the degree of their dispersion in the coal. Therefore, we could not estimate the degree of

Table 6. Effects of Catalysts on the Decomposition Reaction of Dibenzyl Ether (DBE) at 360°C and Biphenyl (DP) at 400°C

coal-mineral effects only from the content,[11] 0.65 wt%. Conversions to BC and TC with no catalyst in decalin were larger under a hydrogen atmosphere than under a nitrogen atmosphere, as is shown in Table 3. This suggests that the participation of hydrogen molecules in coal liquefaction promotes the coal conversion. Namely, in a non-donor solvent like decalin, organic radicals react directly with hydrogen molecules.[12] Other explanation that coal minerals, the autoclave wall or the blade catalyze the liquefaction is also possible. Wall participation has been called the "memory effect."[13,14] We could not clarify this situation. However, from the liquefaction results of Taiheiyo-D, which consisted of deashed coal of Taiheiyo-2, the interaction between coal minerals and the catalyst added might be small, for the effects of an added catalyst on conversion and on the SRC yields were not affected by the deashing. Therefore, the effects of coal minerals on the following catalyst study were excluded.

The composition of the recycle solvent is an important factor in the liquefaction of coal.[15,16] One of the functions of a liquefaction solvent is to donate hydrogen to the coal.

Under a hydrogen atmosphere, the conversions to TC in the donor solvent, tetralin, were from 30 to 40% larger than those in the non-donor solvent, decalin, irrespective of the kind of catalyst. The contribution of the donor solvent to conversion was large even in the presence of a catalyst. Under a nitrogen atmosphere, the contribution of the donor solvent increased, and the differences in the conversion to TC between solvents were from 40 to 50%. These results indicated that the catalyst suppressed somewhat the contribution of the solvent donor. The structure of Taiheiyo coal SRC was directly affected by coal conversion; we have previously reported that the aromaticity, fa, of SRC tended to increase with an increase in the conversion.[17] Therefore, we could not ascertain the relationship between the solvent used and the structure of SRC.

Variance analysis was very helpful in clarifying the relationship between them. Statistical analysis, such as variance analysis, has been applied to coal chemistry, usually, applying multiple-regression analysis to coal liquefaction.[17-19] Statistical analysis gives quantitative considerations, and intuitive conclusions could be excluded. That the effects of the catalysts on the structure of SRC were large and important was concluded from the variance analysis. In order to evaluate coal liquefaction, information about the effects of catalysts on liquid-product structures was essential. Because SRC contains many compounds,[20] the fractionation of SRC before structure analysis is effective. Figure 3 shows the molecular-weight distribution of Fractions 1—4 of SRC with no catalyst; it indicates that SRC is effectively fractionated. In our fractionation method, heavier compounds were extracted increasingly with the extract solvent numbered from 1 to 4. Although the yields of Fractions 2 and 3 without a catalyst were almost identical with those with MoO_3 or Fe_2O_3, their structures were different, as is shown in Table 4. Such a difference was caused by the difference in the catalytic action of the catalysts.

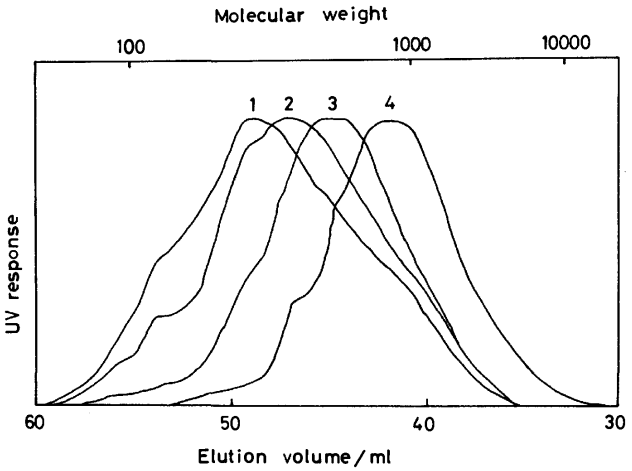

Fig. 3. Molecular weight distribution of Fractions 1—4 of SRC with no catalyst. Number in the Figure shows fraction number.

The oxygen content and ring numbers of the extract were mostly affected by the catalyst used. Lower oxygen contents were obtained with SnO. This indicates the greater ability of SnO to disrupt a linkage such as

ether bonding efficiently. DBE was decomposed more with SnO than with no catalyst, as is shown in Table 6. The yield of toluene was 51.5%, and it was the main product of the reaction. It also showed an imbalance of oxygen content between reactant and products. The oxygen contents of the products were less than that of DBE. The solution of this imbalance was obtained by means of the X-ray diffraction pattern of the liquefaction residue. SnO was oxidized to SnO_2 in the course of liquefaction. The oxygen abstraction of SnO caused the lower oxygen content of the SRC extract. On the other hand, α-Fe_2O_3 (hematite) changed to γ-Fe_2O_3 (maghemite) in the course of liquefaction, but the oxygen content of the catalyst did not change. Although the X-ray diffraction pattern of the residue with MoO_3 was not very clear because of the overlapping of plural compounds, the presence of MoO_2 after the liquefaction was confirmed. Oxygen functional groups related to hydrogen bonding between coal molecules and the extractability of coal was highly affected by the hydrogen bonding.[21] The removal of the oxygen might mean the acceleration of the dissociation of the association molecules. Furthermore, it has been reported that phenolic OH condensed to form an ether linkage, eliminating water.[22] It is possible that the oxygen release of MoO_3 to MoO_2 causes the condensation reaction. The oxygen contents of the extract with MoO_3 were not very large, but the condensation reaction produced an insoluble residue.

SRC was chosen as the more appropriate coal model. It is well-known that the reactivity of liquefaction products like SRC was less than that of coal itself,[23] but it was possible to observe the structure change in the whole compounds. In coal liquefaction, the smallest number of aromatic and nonaromatic rings was obtained with SnO. The ring number of SRC decreased when SnO was used, as is shown in Table 5. The ability of SnO to hydrogenate aromatic rings was less than that of MoO_3; this was confirmed by the hydrogenation of naphthalene.

These results indicate that SnO is effective for the cleavage reaction of a linkage like an ether bond and that, further, it possesses the ability to suppress the condensation reaction. The oxygen-removal reaction relates to the latter ability. Bacand et al. has reported that Al_2O_3 could stabilize free radicals by means of adsorption.[24] SnO could possess such a radical stabilization ability to suppress condensation reactions.

MoO_3 and Fe_2O_3, especially MoO_3, have higher abilities to hydrogenate or accelerate the hydrocracking of coal structures similar to coal-model compounds, as is shown in Table 6. However, they could not prevent the retrogressive reactions of coal, which were confirmed by the structures of the SRC extracts and by model-compound studies.

The difference in SRC structure appears to result from the inherent ability of a catalyst to liquefy coal.

Conclusions

From the three-way variance analysis, it was concluded that the effects of catalysts on conversion and on the SRC yield were small, whereas the effects of catalysts on the structure of SRC were large and important. The fractionation of SRC into four fractions was very effective for comparing the structures of SRC. The oxygen content and ring numbers of the extracts were mostly affected by the catalyst used. The formation of SnO_2 after the liquefaction shows the oxygen-abstraction reaction of SnO, which cause the oxygen content of the extract to be lower. The decomposition of SRC, dibenzyl ether, and biphenyl as coal-model compounds was also accelerated by the catalysts, but retrogressive reactions were observed when MoO_3 or Fe_2O_3 was used.

More effective catalysts for coal liquefaction can be prepared by investigating the structures of liquid products obtained with other catalysts and by selecting combinations of catalysts suitable for producing the desired liquid products. Studies of this point are under way.

The authors are grateful to Mr. Katsumi Watanabe and Mr. Hiroshi Nakamura for their technical assistance, and to Mr. Tohru Suzuki for the analyses of coal and SRC.

Optical Resolution by Preferential Crystallization of 1,1,3,3-Tetramethylbutylammonium Salt of *N*-Formyl-DL-α-phenylglycine

Tadashi SHIRAIWA,* Hideya MIYAZAKI, Tomoki IMAI, Michio SUNAMI, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received July 29, 1986)

Infrared spectrum, solubility, and ternary phase diagram of solubility indicated that 1,1,3,3-tetramethylbutylammonium salt (DL-TMB salt) of *N*-formyl-DL-α-phenylglycine is a conglomerate. In order to resolve DL-TMB salt efficiently, crystallization of D- and L-TMB salts was examined by free energy of critical nucleation in supersaturated solutions. Successive preferential crystallization of DL-TMB salt was experimented at 10 °C for racemic solution in ethanol with the degree of supersaturation of 130%, and D- and L-α-phenylglycine with 100% optical purity were obtained from pure D- and L-TMB salts.

D-α-Phenylglycine (abbreviated as D-Phg) as a useful material of ampicillin has been chemically synthesyzed,[1] because Phg is not found in natural amino acids. Synthetic DL-Phg is then subjected to optical resolution by preferential crystallization[2-4] and diastereomeric procedures[5-7] to obtain D-Phg. For the optical resolution of DL-amino acids, their *N*-acyl derivatives have been purposely used. In the case of *N*-acetyl- or *N*-benzoyl-DL-α-phenylglycine, the Phg obtained is partially racemized during hydrolysis of the derivatives,[8] because Phg is apt to racemize on heating in an acid solution. It is expected that *N*-formyl-α-phenylglycine (FrPhg) is easier to be hydrolyzed under mild conditions than *N*-acetyl and *N*-benzoyl derivatives. It was attempted, therefore, to resolve organic ammonium salts of DL-FrPhg.

The organic ammonium salts of DL-FrPhg examined are propylammonium, isopropylammonium, butylammonium, *t*-butylammonium, 1,1,3,3-tetramethylbutylammonium (DL-TMB salt), cyclohexylammonium, benzylammonium, and dibenzylammonium salts. The racemic structure of organic ammonium salts of *N*-acyl-DL-amino acids has been determined from calculated values of free energy of formation by enthalpy of fusion and melting point described in our previous papers.[3,4,9] Since the salts of DL- and D-FrPhg decompose on heating, the racemic structure of these compounds was determined by comparing infrared spectra and solubility values of the DL-salts with those of the corresponding D-salts. The TMB salt of DL-FrPhg which seems to be in a conglomerate was subjected to resolution by a preferential crystallization. Conditions of hydrolysis of the D- and L-TMB salts resolved was examined to obtain D- and L-Phg without racemization. The optical resolution by preferential crystallization needs that unseeded enantiomer remains in the solution as a supersaturation state during crystallization. Although Hongo et al. reported on the stability of solution of DL-serine *m*-xylene-4-sulfonate dihydrate,[10] such problem has not been fully studied. Therefore, crystallization of D- and L-TMB salts was examined by free energy of critical nucleation to find appropriate conditions for optical resolution of DL-TMB salt.

Table 1. Preparation of Supersaturated Solutions of 1,1,3,3-Tetramethylbutylammonium Salt of *N*-Formyl-DL-α-phenylglycine[a]

Solvent	Degree of supersaturation[b]/%	Amount/g
Methanol	110	12.855
Methanol	120	14.024
Methanol	130	15.192
Ethanol	110	3.341
Ethanol	120	3.645
Ethanol	130	3.949

a) Solvent: 50 cm³. b) Temperature: 10 °C.

Experimental

Materials. DL- and D-Phg were purchased from Sigma Chemicals Co., and amines from Wako Pure Chemicals Ind.

***N*-Formylation.** DL- and D-FrPhg were prepared by formylating DL- and D-Phg, respectively, as usual as the preparation of ordinary amino acids.[11] DL-FrPhg: Mp 175 °C. D-FrPhg: Mp 178 °C; $[\alpha]_D^{20}$ −252° (*c* 1.00, methanol).

Preparation of Organic Ammonium Salts. A solution of 0.01 mol of DL- or D-FrPhg and equimolar amine in 150 cm³ of acetone was allowed to stand overnight at 5 °C. The salt formed was filtered and recrystallized from ethanol.

D-TMB salt: C, 66.02; H, 9.08; N, 9.08% (Calcd for $C_{17}H_{28}N_2O_3$: C, 66.20; H, 9.15; N, 9.08%); mp 176—179 °C (decomp); $[\alpha]_D^{20}$ −124° (*c* 1.00, water) and $[\alpha]_D^{20}$ −109° (*c* 1.00, ethanol); solubility 14.964 g/(100 cm³ methanol), 3.571 g/(100 cm³ ethanol) at 10 °C. DL-TMB salt: C, 66.21; H, 9.07; N, 9.12%; mp 157—160 °C (decomp); solubility 23.373 g/(100 cm³ methanol), 6.075 g/(100 cm³ ethanol) at 10 °C.

L-TMB salt obtained from mother liquor in the optical resolution of DL-salt was recrystallized twice from ethanol to give L-salt with 100% optical purity; mp 177—179 °C (decomp); $[\alpha]_D^{20}$ +124° (*c* 1.00, water).

Optical Resolution. DL-TMB salt was dissolved in 50 cm³ of ethanol or methanol at approximately 40 °C to give racemic solutions with the degree of supersaturation of 110, 120, and 130% at 10 °C; results of preparation of these supersaturated solutions were summarized in Table 1. The solution was slowly cooled to 10 °C and seeded with 0.050 g of D-TMB salt. After stirring the solution at 30 rpm and 10 °C,

the precipitated salt was collected by filtration, washed with a small amount of diethyl ether, and dried. The optical purity, yield of optically pure modification (YOPM), and degree of resolution of the salt were determined by the equations described in a previous paper.[3]

Successive Preferential Crystallization. DL-TMB salt (3.949 g) was dissolved in 50 cm^3 of ethanol at 40 °C. After being cooled to 10 °C, the solution was seeded with 0.050 g of D-TMB salt and stirred for 15 min. The precipitated salt was collected by filtration, washed with a small amount of diethyl ether, and dried. DL-TMB salt (0.319 g) was dissolved in the filtrate at 40 °C. After being seeded with 0.050 g of the L-TMB salt at 10 °C, the mixture was treated similarly to the case of D-TMB salt. The degree of resolution of D- and L-TMB salts was calculated by

$$\text{Degree of resolution}/\% = [\text{YOPM}/g \times 100]/[(\text{Operation amount of D- or L-salt}/g) - 1.519/g]. \quad (1)$$

Preparation of Optically Active α-Phenylglycine. D- or L-TMB salt (8.00 g) with optical purity of approximately 95% was dissolved in 30 cm^3 of ethanol at an elevated temperature. The solution was allowed to stand overnight at 5 °C. The precipitated salt was collected by filtration to give the D- and L-TMB salts with 100% optical purity in 90% yield.

D- or L-TMB salt (3.08 g) was dissolved in a mixture of 8 cm^3 of 5 mol dm^{-3} hydrochloric acid, 22 cm^3 of water, and 20 cm^3 of ethanol. After being stirred for 2 h at 50 °C, the solution was allowed to stand overnight at room temperature, and dried under reduced pressure at 50 °C. The residue was dissolved in 40 cm^3 of methanol and pH was adjusted to 6 with concentrated aqueous ammonia. Precipitated Phg was filtered, washed with a small amount of each water and methanol, and dried. **D-Phg**: Yield 1.253 g; $[\alpha]_D^{20}$ −158° (*c* 1.00, 1 mol dm^{-3} HCl) (lit,[12] $[\alpha]_D$ −157.8°(dil HCl)). **L-Phg**: Yield 1.249 g; $[\alpha]_D$ +158° (*c* 1.00, 1 mol dm^{-3} HCl).

Measurements. The specific rotation was measured by a Union Giken PM-101 digital polarimeter with a quartz cell of 0.5 dm path length. Infrared spectra were obtained in the range 4000—400 cm^{-1} with a JASCO A-102 infrared spectrophotometer by the KBr disk method.

Saturated methanol or ethanol solutions of DL- and D-TMB salts were prepared at 10 °C and diluted appropriately. The absorbance was measured at 260 nm with a Shimadzu double-beam spectrophotometer UV-150-02 by using a quartz cell of 0.1 dm path length. Solubility values of the salts were determined from calibration curves.

Results and Discussion

Racemic Structure. Infrared spectra of DL-FrPhg ammonium salts were compared with those of the corresponding D-salts. DL-TMB salt shows infrared spectrum identical with that of D-salt, whereas the spectra of other DL-salts are different from those of D-salts. This result indicates that DL-TMB salt is either a conglomerate or a racemic solid solution but other DL-salts form racemic compounds.[13] Further, DL-TMB salt is more soluble than the D-salt as described in the experimental section, and the ternary phase diagram in Fig. 1 illustrates the patterns of a conglomerate.[14]

The above results lead to the conclusion that only DL-TMB salt exists in a conglomerate at room temperature.

Preferential Crystallization and Free Energy of Critical Nucleation. Free Energy of Critical Nucleation: The crystallization of unseeded enantiomer from a supersaturated solution is relevant to the primary nucleation; therefore the crystallization is influenced by a free energy of critical nucleation (Δg_{max}/J nucleus^{-1}).[15-17] On the other hand, the crystallization of seeded enantiomer cannot be elucidated by the Δg_{max}, but is to be related to the secondary nucleation.[17] It is, however, estimated that Δg_{max} has some influence on the crystallization of seeded enantiomer, because the growth of critical nucleus is accelerated by seeding.[17] On the assumptions that no interaction exists between D- and L-TMB salts in a supersaturated solution and that the critical nucleus of TMB salt is spherical, the Δg_{max}[17] is calculated by

$$\Delta g_{max} = 4\pi r_{cr}^2 \sigma_{cr} - (4\pi r_{cr}^3 \kappa T/3V_0) \cdot \ln(C/C^*), \quad (2)$$

where r_{cr}/m is the radius of critical nucleus, σ_{cr}/J m^{-2} the interfacial energy, T/K the temperature, V_0[18]/m^3 the molecular volume of TMB salt, κ the Boltzmann constant, C^* the solubility of TMB salt at temperature T/K, and C the amount of TMB salt in supersaturated solution. The r_{cr} and σ_{cr} were calculated by Eqs. 3 and 4.[17,19]

$$r_{cr} = 2V_0 A/\kappa T \cdot \ln(C/C^*) - 2r_0, \quad (3)$$

$$\sigma_{cr} = r_{cr} A/(r_{cr} + 2r_0), \quad (4)$$

where r_0 is the molecular radius[18] and A is a constant. The constant A was calculated from a relationship between r and σ of nucleus;[19] $\sigma_{cr}(1+2r_0/r_{cr})$=constant $(A)=\sigma_{sa}(1+2r_0/r_{sa})$, where r_{sa} and σ_{sa} are the radius and interfacial energy of embryo in saturated solution, respectively.[20] The r_{cr}, σ_{cr}, and Δg_{max} in methanol and ethanol solutions with degrees of supersaturation of 110, 120, and 130% were calculated, and listed in Table 2. The optical resolution by preferential crystallization of DL-TMB salt was carried out in methanol and

Ethanol	120	65	3.82
Ethanol	130	20	22.8

a) Salt: 1,1,3,3-Tetramethylbutylammonium salt of *N*-formyl-α-phenylglycine. b) The retardation time for crystallization of L-salt was estimated from Figs. 2 and 3. c) The amount of crystallization per time for D-salt was calculated from linear plots in Figs. 2 and 3.

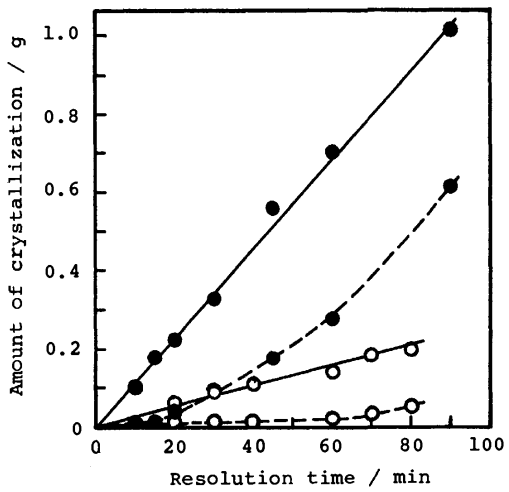

Fig. 2. Relationships between amounts of crystallization and resolution times in methanol. Temperature: 10°C. ——: D-Salt. ----: L-Salt. ○: Degree of supersaturation of 110%. ●: Degree of supersaturation of 120%.

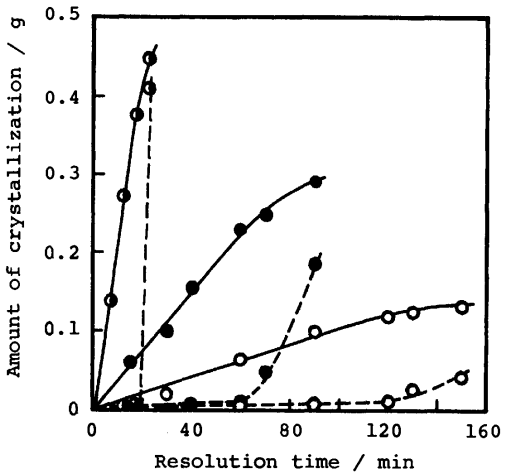

Fig. 3. Relationships between amounts of crystallization and resolution times in ethanol. Temperature: 10°C. ——: D-Salt. ----: L-Salt. ○: Degree of supersaturation of 110%. ●: Degree of supersaturation of 120%. ◑: Degree of supersaturation of 130%.

ethanol with D-salt as seed crystals; results are listed in Tables 3 and 4. From the results, amounts of crystallization[21] of D- and L-TMB salts were calculated, and the relationships between amount and resolution time are shown in Figs. 2 and 3.

Since Δg_{max} is regarded as energy barrier for growth of the primary nucleus, it is predictable that the unseeded enantiomer tends to crystallize with a decrease in Δg_{max}.[17] This is supported by the retardation time for crystallization of L-TMB salt. The retardation time is defined as the resolution time until L-TMB salt begins to crystallize; the results estimated from Figs. 2 and 3 are listed in Table 5. Although Figs. 2 and 3 indicate the presence of L-TMB salt in the D-salt crystallized in short times, it will be due to the DL-salt adhered on filtration. Rapid crystallization of L-TMB salt requires longer retardation time with an increase in Δg_{max} values. The relationship between the retardation time (θ/min) and Δg_{max} was obtained by

$$\log \theta = -0.8913 \log(1/\Delta g_{max}) + 16.18, \quad (5)$$

where the correlation coefficient is 0.972.

Figures 2 and 3 also suggest that seeded D-TMB salt tends to crystallize rapidly with a decrease in Δg_{max}. The amount of crystallization of D-TMB salt per time (R_D/g min^{-1}) listed in Table 5 was calculated from linear plots in Figs. 2 and 3. Since the Δg_{max} values of D-TMB salt are equal to those of L-salt, the relationship between R_D and Δg_{max} was examined and is expressed by

$$\log R_D = 1.275 \log(1/\Delta g_{max}) - 23.09, \quad (6)$$

where the correlation coefficient is 0.959. This result shows that the crystallization of seeded D-TMB salt is strongly influenced by Δg_{max}.

Conditions of Optical Resolution: It is possible to estimate factors on crystallization of D- and L-TMB salts from Eqs. 5 and 6. In the optical resolution for methanol solution with a degree of supersaturation of 130%, the θ and R_D values calculated from Eqs. 5 and 6 are 10.2 min and 4.11×10^{-2} g min^{-1}, respectively. L-TMB salt begins to crystallize rapidly after 10 min, and

Table 6. Optical Resolution by Successive Preferential Crystallization of 1,1,3,3-Tetramethylbutylammonium Salt of *N*-Formyl-DL-α-phenylglycine[a)]

Run	Added amount of DL-salt	Operation amount[b)]/g		Salt obtained			
				Yield	Optical purity	YOPM[c)]	Degree of resolution
	g	D-Salt	L-Salt	g	%	g	%
1	3.949	1.975	1.975	0.369	D 95.5	0.302	66.2
2	0.319	1.823	2.125	0.577	L 95.1	0.499	82.3
3	0.527	2.173	1.876	0.584	D 93.3	0.495	75.7
4	0.534	1.915	2.123	0.495	L 96.7	0.429	71.0

a) Solvent: 50 cm^3 of ethanol. Degree of supersaturation of initial racemic solution: 130%. Seed crystals: 0.050 g of D- or L-salt. Temperature: 10 °C. b) The operation amounts of D- and L-salts in solutions were calculated on the basis of analyses of the salts obtained in runs 1—3. c) YOPM: See note b) in Table 3.

the amount of D-salt crystallized at a resolution time of 10.2 min is 0.419 g; this amount corresponds to 23.5% of theoretical value. This agrees well with the results shown in Table 3; D-salt with optical purity of 71.4% was obtained in degree of resolution of 20.5% at resolution time of 10 min, the amount of crystallization of D-salt was 0.441 g, and further, the optical resolution at 15 min gave D-salt with low optical purity (20.2%). However, the above result suggests that the optical resolution for methanol solution with degree of supersaturation of 130% is not favorable for obtaining D-TMB salt with high optical purity in high degree of resolution.

The optical resolution for ethanol solution with the degree of supersaturation of 130% gave D-TMB salt with optical purity of 96.4% and degree of resolution of 76.8% at the resolution time of 17 min. The resolution for 15 min seems to be more favorable for stable optical resolution than 17 min, because it is estimated by θ values that L-TMB salt begins to crystallize rapidly after 20 min. We can estimate from R_D that 0.342 g of D-TMB salt crystallizes at resolution time of 15 min and the amount corresponds to 75.0% of theoretical value. This optical resolution gives D-TMB salt with high optical purity in relatively high degree of resolution.

Optical Resolution of Successive Preferential Crystallization. Successive Preferential Crystallization: According to the above suggestion, the successive preferential crystallization of DL-TMB salt was carried out at 10 °C at resolution time of 15 min for the ethanol solution with degree of supersaturation of 130%, as shown in Table 6. The D-TMB salt with 95.5% optical purity was obtained in degree of resolution of 66.2% from the initial solution. Since the amount of crystallized D-salt was 0.310 g, this result supports the preceding suggestion.

The successive preferential crystallization gave D- and L-TMB salts with optical purity of approximately 95% in degree of resolution of 66—82%.

Purification of Salt Partially Resolved: The D- and L-TMB slats obtained by successive preferential crystallization were easily purified by recrystallization from ethanol as described in the experimental section. TMB salt with low optical purity was purified to optically pure salt in high yield with the optimum amount of ethanol calculated from the solubility of DL-TMB salt in ethanol.[22,23)] For example, D-TMB salt with optical purity of 40.9% (1.477 g) was recrystallized from 15 cm^3 of ethanol; the optimum amount calculated is 14.37 cm^3. Solution of D-TMB salt dissolved at 40 °C was stirred for 30 min at 10 °C to crystallize 0.548 g of the D-salt with 100% optical purity; the theoretical yield of the optically pure D-salt is 0.604 g.

Hydrolysis of *N*-Formyl-α-phenylglycine: The D- or L-FrPhg with 100% optical purity was hydrolyzed by refluxing in 1 mol dm^{-3} hydrochloric acid for 2 h to give D- and L-Phg with optical purity of approximately 95%. This result indicates that these Phg were partially racemized by refluxing in hydrochloric acid. The hydrolysis of D- and L-salts with 100% optical purities was carried out by the procedure described in the experimental section. The D- and L-Phg were not racemized under these conditions, and obtained in 83% yields. Although the hydrolysis of *N*-acetyl-D-α-phenylglycine (D-AcPhg) was also attempted under similar conditions, D-Phg did not crystallize from a methanol solution at pH 6 adjusted with concentrated aqueous ammonia. AcPhg is not hydrolyzed under such conditions. This result suggests that DL-FrPhg is more favorable for the optical resolution than DL-AcPhg.

The above results indicate suitable conditions for the optical resolution of DL-TMB salt on the basis of Δg_{max} in supersaturated solutions and procedures to give optically pure D- and L-Phg by successive preferential crystallization of DL-TMB salt.

Stereoselective Formation of Allyl Ethers by Reaction of Epoxides with Organic Chlorides under Liquid-Solid Phase-Transfer Catalysis

Xue-Ping Gu, Isao Ikeda, and Mitsuo Okahara*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565
(Received August 1, 1986)

A series of *trans*-3-chloroallyl ethers and *trans*-3-thioallyl ethers were stereoselectively synthesized in one step by the reaction of 1-chloro-2,3-epoxypropane or 2,3-epoxypropyl sulfides with alkyl chlorides in the presence of solid sodium hydroxide and quaternary ammonium salt as a phase-transfer catalyst. Phase-transfer catalytic hydroxide ion-initiation followed by stereoselective isomerization of the epoxide ring through β-elimination is postulated as the important part of the reaction pathway.

Epoxy compounds have been utilized extensively in organic synthesis and industry as synthetic intermediates because of their facile preparation, and their high chemical reactivity attributable to the ring strain of the small-ring.[1,2] The reactions of various nucleophilic species with these compounds have been developed for synthetic applications.[1,3] Also, the isomerization of epoxides to allylic alcohols under the influence of strong, non-nucleophilic bases such as lithium dialkylamide attracted attention.[4] Since the formation of *trans*-3-chloroallyl alcohol through the stereoselective ring-opening of 1-chloro-2,3-epoxypropane with butyllithium was reported in 1964 (Scheme 1),[5] much work has been reported in this field,[6-9] and the crucial mechanistic point concerning the stereochemistry of β-elimination in the isomerization was indicated by deuterium-labelled experiments.[10]

Phase-transfer (PT) catalytic reaction in organic chemistry has been developed extensively in the last two decades and many synthetic techniques[11-15] have been established, which include hydroxide ion-initiated reactions due to the strong basicity of quaternary ammonium hydroxide under PT catalytic conditions. Recently, during the course of an investigation regarding the reactivity of 1-chloro-2,3-epoxypropane under PT catalytic conditions, we found a simple synthetic method for the preparation of oligoethylene glycol di-2,3-epoxypropyl ethers in good yields.[16] In this reaction, the formation of a small amount of a by-product (compound **1**) was always observed which could be isolated by fractional distillation.

By identifying the compound **1** as *trans*-3-chloroallyl 2,3-epoxypropyl ether, a new reaction of epoxy compounds which can directly and stereoselectively afford *trans*-allyl ethers under PT catalytic conditions was disclosed. Based on the postulated reaction mechanism, we anticipated this new PT catalytic reaction would have utility for the synthesis of various kinds of *trans*-3-substituted allyl ethers.

In this paper, we report the development of this finding to the synthesis of *trans*-3-chloroallyl and *trans*-3-thioallyl ethers under PT catalytic conditions (Scheme 2).

It is reported that 3-chloroallyl ethers are useful materials because of their dual functionality, and accordingly have attracted some attention.[17-22]

Results and Discussion

The structure of compound **1** was ascertained by spectral and elemental analyses. Absorptions due to the carbon-carbon double bond and ether linkages were observed in the infrared spectrum (1640 and 1110 cm^{-1}), and the presence of an epoxy ring and an olefinic moiety in trans form were confirmed from values of chemical shifts and coupling constants in the ^1H NMR. The existence of the *trans*-3-chloroallyloxy moiety was confirmed by ^1H NMR and ^{13}C NMR. Mass spectral and elemental analyses are also consist-

ent with this structure. This structure was separately confirmed by the reaction of 1,3-dichloropropene (34% cis, 66% trans) with 2,3-epoxy-1-propanol, which afforded a mixture of about 30% *cis*- and 70% *trans*-3-chloroallyl 2,3-epoxypropyl ethers (**1'**and **1**, respectively) (The cis : trans ratios of raw chlorides and products were estimated by ^{1}H NMR). Compound **1** was synthesized easily in one step from 1-chloro-2,3-epoxypropane in the presence of solid sodium hydroxide under the PT catalytic conditions as described in the experimental section. The proposed mechanism for the formation of **1** is represented in Scheme 3.

It is rational to consider that the reaction is initiated by the abstraction of a proton geminal to the chlorine atom from 1-chloro-2,3-epoxypropane with a hydroxide ion paired with the PT catalyst ammonium ion (Q^+OH^-). The carbanion **I** thus generated rearranges stereoselectively with ring-opening to the more stable and more nucleophilic alkoxide **II**,[4,23] which then reacts with another 1-chloro-2,3-epoxypropane molecule to afford **1**. Of course, the concerted route leading to **II** directly from proton abstraction can not be excluded. In the presence of alcohol, the hydroxide ion of Q^+OH^- gives mainly alkoxide, which further forms the alkyl 2,3-epoxy-1-propyl ethers by the nucleophilic substitution reaction.[16] However, in the absence of alcohol, owing to its poor nucleophilicity, the hydroxide ion acts as a base and gives a 1-chloro-2,3-epoxypropane anion **I** rather than 2,3-epoxy-1-propanol by the nucleophilic substitution reaction. This can be deduced from the fact that di-2,3-epoxypropyl ether was not detected (lower route in Scheme 3).

The above mechanism was supported by the formation of benzyl and 2-methylallyl *trans*-3-chloroallyl ethers (**2** and **3**) via the reaction of 1-chloro-2,3-epoxypropane in the presence of 2-methylallyl chloride or benzyl chloride, respectively (Table 1). The reaction of 1-chloro-2,3-epoxypropane with benzyl chloride (2 : 1 molar ratio) afforded **2** in 50% yield based on benzyl chloride together with **1** (22% based on 1-chloro-2,3-epoxypropane); reaction with 2-methylallyl chloride (2 : 1 molar ratio) gave **3** in 27% yield based on 2-methylallyl chloride together with **1** (15% based on 1-chloro-2,3-epoxypropane). Accordingly, this procedure using liquid-solid PT catalysis may lead to a general synthetic method for the preparation of *trans*-3-chloroallyl ethers.

This reaction did not proceed in the absence of PT catalyst, and the raw material, 1-chloro-2,3-epoxypropane, was recovered almost quantitatively.

In the case of 1-bromo-2,3-epoxypropane, the corresponding *trans*-3-bromoallyl ether was obtained in low yield (about 6%) under the same PT catalytic conditions as those for 1-chloro-2,3-epoxypropane. The major product was light brownish powder which is probably a polymeric substance.

So far as we know, the direct synthesis of *trans*-3-chloroallyl ethers from 1-chloro-2,3-epoxypropane is not recorded in the literature. Although 1-chloro-2,3-epoxypropane is usually reactive to nucleophiles under basic conditions, di-2,3-epoxypropyl ether (**4**) could not be detected in the products of the present reactions. On the other hand, in a separate reaction, it was confirmed that 2,3-epoxy-1-propanol gives di-2,3-epoxypropyl ether (**4**) in 23% yield by the reaction with 1-chloro-2,3-epoxypropane under the same reaction conditions. From these facts, this reaction can be considered to reveal an interesting phenomenon based on the strong basicity and weak nucleophilicity of Q^+OH^-.

This epoxide ring-opening reaction was also applied to 2,3-epoxypropyl sulfide **5**, **13** affording the corresponding *trans*-3-thioallyl ethers. The results of the reaction of phenyl and alkyl 2,3-epoxypropyl sulfide with various chlorides are shown in Table 1.

Although the reaction conditions were not optimized, it is clear that the yield of *trans*-3-thioallyl ethers decreased with less reactive chlorides. The yield of the corresponding octyl ether **10** from octyl chloride was relatively low (22%) compared with more reactive chlorides, such as 2,3-epoxypropyl (**6**, 85%), 2-methylallyl (**9**, 80%) or benzyl chloride (**7**, 73%). Although the reactivity of benzyl chloride toward S_N2 reactions is usually

Table 1. Reactions of Epoxides with Organic Chlorides

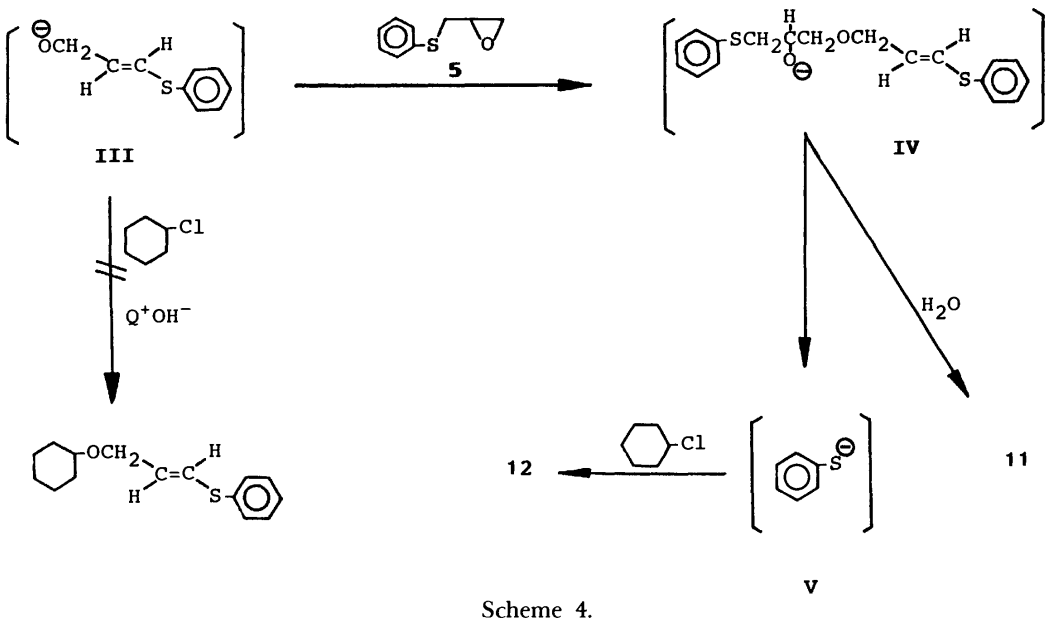
a) Isolated yield.

higher than that of 2-methylallyl chloride, the yield from the former was a little less than that from the latter. Apparently a competitive reaction occurred forming dibenzyl ether by the nucleophilic displacement to form benzyl alcohol under the PT catalytic alkaline conditions in the reaction using benzyl chloride. No noticeable competitive reaction occurred in the case of 2-methylallyl chloride.

In the case of a secondary chloride, cyclohexyl chloride, which has the poorest reactivity among the chlorides used, the major products obtained were *trans*-1,7-bis(phenylthio)-4-oxa-6-hepten-2-ol (**11**) and cyclohexyl phenyl sulfide (**12**) rather than the corresponding cyclohexyl *trans*-3-(octylthio)allyl ether.

It is difficult to deduce the reaction path to **12**, since the formation of the expected oxirane compound **6** or its derivatives has not been confirmed. However, from the fact that the reaction of **11** with cyclohexyl chloride in the presence of solid sodium hydroxide and PT catalyst afforded **12**, it may be reasonable to consider that the nucleophilic attack by certain species (including **III**) on **5** may give rise to the formation of a stable



Scheme 4.

benzenethiolate ion (**V**) and **6** (when **III** included) by the intramolecular displacement reaction. The resulting **V** then further reacts with cyclohexyl chloride to produce **12**, as proposed in Scheme 4.

In any reaction of 1-chloro-2,3-epoxypropane with phenyl 2,3-epoxypropyl ether, alkyl 2,3-epoxypropyl ether, 1,2-epoxytetradecane or *N*-benzyl-*N*-methyl-2,3-epoxypropylamine, the corresponding allyl ethers could not be obtained. In these cases, only *trans*-3-chloroallyl 2,3-epoxypropyl ether (**1**) was isolated, and the 2,3-epoxypropyl compounds were recovered almost quantitatively, although it has been reported that 1,2-epoxyalkane afforded the corresponding allylic alcohol by the reaction with butyllithium.[4)]

Experimental

^{1}H NMR spectra were recorded on a JEOL JNM-PS-100 instrument in $CDCl_3$ with Me_4Si as internal standard. ^{13}C NMR spectra were obtained on a JEOL JNM-FX-60S Fourier transform spectrometer operating at 15.04 MHz with $CDCl_3$ as solvent. Mass spectra were measured on a Hitachi RMU-6E spectrometer. Infrared spectra were obtained on a Hitachi 260-10 spectrometer.

The reagents were all of reagent grade and were used without further purification. Evaporative distillation was performed from bulb to bulb using a glass tube oven model GTO-250RS.

Preparation of *trans*-3-Chloroallyl 2,3-Epoxypropyl Ether (1): Into a solution of 1-chloro-2,3-epoxypropane (92.5 g, 1.0 mol) and tetrabutylammonium hydrogensulfate (8.3 g, 0.025 mol) in dioxane (50 ml), sodium hydroxide (32 g, 0.8 mol, pellet) was carefully added maintaining the temperature between 70—80 °C over a period of 30 min with efficient stirring. Stirring was continued for an additional 2.5 h at 70 °C. The solid material was removed by filtration through a short column filled with silica gel. Product **1** was isolated by fractional distillation at reduced pressure as a colorless oil, 28.2 g, yield 38%; bp 110—111 °C/30 Torr (1 Torr= 133.322 Pa). The purity of the product was ascertained by GLC (5% Silicone SE-30 on Celite 545, 1m) as one peak. ^{1}H NMR ($CDCl_3$) δ=2.50—2.70 (m, 1H), 2.70—2.85 (m, 1H), 3.00—3.25 (m, 1H), 3.30—3.50 (m, 1H), 3.64—3.90 (m, 1H), 3.95—4.15 (d, 2H), 5.90—6.15 (m, J=14 Hz, 1H), 6.20—6.40 (m, J=14 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=43.0, 50.0, 68.4, 70.4, 120.0, 129.5; MS *m/z* (rel intensity) 148 (M^+), 91 (65), 75 (100), 57 (78), 39 (47), 31 (45), 29 (63); IR (liquid film) 2875, 1640, 1110, 930, 800 cm^{-1}. Found: C, 48.51; H, 6.20; Cl, 23.58%. Calcd for $C_6H_9ClO_2$: C, 48.50; H, 6.10; Cl, 23.86%.

Alternative Synthesis of 1 as a Mixture with 1′: Into a Mixture of 1,3-dichloropropene (about 34% cis, 66% trans estimated by ^{1}H NMR) (7.7 g, 0.07 mol), sodium hydroxide (6 g, 0.15 mol, pellet), tetrabutylammonium hydrogensulfate (0.85 g, 0.0025 mol) in dioxane (15 ml), 2,3-epoxy-1-propanol (3.7 g, 0.05 mol) was added dropwise at 30 °C, and stirred at 40 °C for 2 h. After the workup, the mixture of **1** and **1′** was isolated by Kugelrohr distillation at reduced pressure as a colorless oil, 3.9 g, yield 53%; bp 110 °C/30 Torr. The spectral data are the same as **1** expect for ^{1}H NMR ($CDCl_3$) δ=3.90—4.10 (d, 1.2H, *trans*-OCH_2CH=$CHCl$, 70%), 4.10—4.30 (m, 0.8H, *cis*-OCH_2CH=$CHCl$, 30%).

***trans*-3-Chloroallyl Benzyl Ether (2):** A mixture of benzyl chloride (12.7 g, 0.1 mol) and 1-chloro-2,3-epoxypropane (18.4 g, 0.2 mol) was treated with sodium hydroxide under the PT catalytic conditions similar to the procedure for **1**. After the workup, compound **2** was isolated as a colorless oil by distillation at reduced pressure, 9.1 g, yield 50%, together with **1** (3.3 g, 22%); bp 55—56 °C/0.08 Torr. ^{1}H NMR ($CDCl_3$) δ=3.90—4.08 (d, 2H), 4.50 (s, 2H), 5.90—6.20 (m, J=14 Hz, 1H), 6.20—6.36 (d, J=14 Hz, 1H), 7.32 (s, H); MS *m/z* (rel intensity) 182 (M^+), 92 (48), 91 (100), 79 (12), 77 (12), 65 (10); IR (liquid film) 2850, 1640, 1450, 1350, 1110, 930, 800, 730, 700 cm^{-1}. Found: C, 65.72; H, 6.23; Cl, 19,13%. Calcd for $C_{10}H_{11}ClO$: C, 65.78; H, 6.07; Cl, 19.41%.

***trans*-3-Chloroallyl 2-Methylallyl Ether (3):** By the same procedure as used for the benzyl ether **2**, the 2-methylallyl ether **3** was obtained as a colorless oil in 27% yield (4.0 g) together with **1** (2.2 g, 15%) from the reaction of 2-methylallyl chloride (9 g, 0.1 mol) and 1-chloro-2,3-

epoxypropane (18.4 g, 0.2 mol); bp 75—76 °C/30 Torr. ^{1}H NMR ($CDCl_3$) δ=1.74 (s, 3H), 3.85—4.04 (t, 4H), 4.84—5.00 (m, 2H), 5.90—6.15 (m, J=14 Hz, 1H), 6.15—6.35 (d, J=14 Hz, 1H); MS m/z (rel intensity) 146 (M^+), 75 (100), 56 (56), 55 (93), 43 (59), 41 (85), 39 (89); IR (liquid film) 2925, 2860, 1642, 1450, 1120 cm^{-1}. Found: C, 56,98; H, 7.72; Cl, 23.91%. Calcd for $C_7H_{11}ClO$: C, 57.38; H, 7.56; Cl, 24.21%.

Di-2,3-epoxypropyl Ether (4): Into a mixture of 1-chloro-2,3-epoxypropane (13.8 g, 0.15 mol), tetrabutylammonium hydrogensulfate (0.85 g, 5% based on 2,3-epoxy-1-propanol) and potassium hydroxide (5.6 g, 0.1 mol, pellet), 2,3-epoxy-1-propanol (3.7 g, 0.05 mol) was added at 40 °C over 30 min with rapid stirring. Stirring was continued for an additional 30 min at 40 °C. The solid material was removed by filtration. Compound **4** was isolated by Kugelrohr distillation at reduced pressure as a colorless liquid, 1.5 g, yield 23%; bp 100 °C/30 Torr. ^{1}H NMR ($CDCl_3$) δ=2.54—2.70 (m, 2H), 2.70—2.90 (m, 2H), 3.04—3.28 (m, 2H), 3.28—3.60 (m, 2H), 3.70—4.00 (m, 2H); MS m/z (rel intensity) 130 (M^+), 57 (66), 31 (72), 29 (100); IR (liquid film) 2950, 1280, 1120, 940, 880, 780 cm^{-1}.

Phenyl 2,3-Epoxypropyl Sulfide (5): Benzenethiol (11 g, 0.1 mol) in dioxane (50 ml) was added to a suspension of 1-chloro-2,3-epoxypropane (27.7 g, 0.3 mol), sodium hydroxide (12 g, 0.3 mol, pellet) in dioxane (50 ml) at room temperature over 20 min with stirring. Stirring was continued for another 4 h. The solid material was removed by filtration, and compound **5** was isolated by Kugelrohr distillation at reduced pressure as a colorless liquid, 16.2 g, yield 98%; bp 90 °C/0.02 Torr. ^{1}H NMR ($CDCl_3$) δ=2.40—2.56 (m, 1H), 2.65—3.25 (m, 4H), 7.16—7.50 (m, 5H); MS m/z (rel intensity) 166 (M^+), 123 (50), 110 (100). Found: C, 64.66; H, 6.09; S, 19.44%. Calcd for $C_9H_{10}OS$: C, 65.03; H, 6.06; S, 19.28%.

Preparation of *trans*-1-Phenylthio-6,7-epoxy-4-oxahept-1-ene (6): A suspension of phenyl 2,3-epoxypropyl sulfide (**5**) (8.3 g, 0.05 mol), 1-chloro-2,3-epoxypropane (9.2 g, 0.1 mol), sodium hydroxide (6.0 g, 0.15 mol, pellet) and tetrabutylammonium hydrogensulfate (0.85 g, 5% based on **5**) in dioxane (20 ml) was stirred rapidly at 70 °C for 2 h. After separation of the solid material by filtration, compound **6** was isolated by Kugelrohr distillation at reduced pressure as a colorless oil, 9.4 g, yield 85%; bp 100 °C/0.05 Torr. ^{1}H NMR ($CDCl_3$) δ=2.52—2.70 (m, 1H), 2.70—2.85 (m, 1H), 3.00—3.24 (m, 1H), 3.24—3.36 (m, 1H), 3.36—3.88 (m, 1H), 3.88—4.40 (m, 2H), 5.68—6.10 (m, J=15 Hz, 1H), 6.30—6.56 (m, J=15 Hz, 1H), 7.10—7.50 (m, 5H); MS m/z (rel intensity) 222 (M^+), 113 (100), 57 (100); IR (liquid film) 2900, 1650, 1580, 1475, 1430, 1100, 640, 580 cm^{-1}. Found: C, 64.48; H, 6.39; S, 14.17%. Calcd for $C_{12}H_{14}O_2S$: C, 64.84; H, 6.35; S, 14.42%.

Compound **1** was also obtained in yield of 24% (1.7 g).

***trans*-1-Phenyl-5-phenylthio-2-oxapent-4-ene (7):** A mixture of **5** (8.3 g, 0.05 mol) and benzyl chloride (12.6 g, 0.1 mol) was treated with sodium hydroxide under the PT catalytic conditions in dioxane similar to the procedure for **6** at 90 °C for 2 h. After the workup, product **7** was isolated by Kugelrohr distillation at reduced pressure as a colorless liquid, 9.0 g, yield 73%; bp 135 °C/0.03 Torr. ^{1}H NMR ($CDCl_3$) δ=3.95—4.25 (m, 2H), 4.48 (s, 2H), 5.70—6.04 (m, J=15 Hz, 1H), 6.30—6.62 (m, J=15 Hz, 1H), 7.28 (s, 10H); MS m/z (rel intensity) 256 (M^+), 165 (30), 137 (50), 91 (100); IR (liquid film) 3050, 2860, 1600, 1500, 1120, 760, 720 cm^{-1}. Found: C, 74.67; H, 6.55; S, 12.52%. Calcd for $C_{16}H_{16}OS$: C, 74.96; H, 6.29; S, 12.51%.

In this reaction, dibenzyl ether **8** was also obtained as a by-product in 62% yield (6.3 g) based on benzyl chloride (0.1 mol).

***trans*-6-Methyl-1-phenylthio-4-oxahept-1,6-diene (9):** By the same procedure as used for **6**, the corresponding compound **9** was obtained in 80% yield (8.8 g) from phenyl 2,3-epoxypropyl sulfide (8.3 g, 0.05 mol) and 2-methylallyl chloride (9.05 g, 0.1 mol); bp 100 °C/0.02 Torr. ^{1}H NMR ($CDCl_3$) δ=1.76 (s, 3H), 3.60—4.24 (m, 4H), 4.90—5.10 (m, 2H), 5.75—6.10 (m, J=15 Hz, 1H), 6.30—6.56 (m, J=15 Hz, 1H), 7.10—7.50 (m, 5H); MS m/z (rel intensity) 220 (M^+), 111 (42), 109 (33), 55 (100); IR (liquid film) 2900, 1670, 1600, 1120, 910, 750, 700 cm^{-1}. Found: C, 70.62; H, 7.40; S, 14.34%. Calcd for $C_{13}H_{16}OS$: C, 70.87; H, 7.32; S, 14.45%.

***trans*-1-Phenylthio-4-oxadodec-1-ene (10):** By the same procedure as used for **6**, the corresponding compound **10** was obtained in 22% yield (3.1 g) from phenyl 2,3-epoxypropyl sulfide (8.3 g, 0.05 mol) and octyl chloride (14.9 g, 0.1 mol); bp 120 °C/0.05 Torr. ^{1}H NMR ($CDCl_3$) δ=0.80—1.04 (t, 3H), 1.20—1.80 (m, 12H), 3.36—3.60 (m, 2H), 3.95—4.26 (m, 2H), 5.75—6.08 (m, J=15 Hz, 1H), 6.34—6.60 (m, J=15 Hz, 1H), 7.20—7.50 (m, 5H); MS m/z (rel intensity) 278 (M^+), 169 (28), 71 (45), 57 (100); IR (liquid film) 2950, 2875, 1590, 1480, 1100, 740, 700 cm^{-1}.

***trans*-1,7-Bis(phenylthio)-4-oxa-6-hepten-2-ol (11):** After treating phenyl 2,3-epoxypropyl sulfide (8.3 g, 0.05 mol) with cyclohexyl chloride (11.8 g, 0.1 mol) at 100 °C for 2 h under PT catalytic conditions, solid materials were removed by filtration through a short column filled with silica gel, and the reaction mixture was separated by Kugelrohr distillation at reduced pressure. Compound **11** as a colorless oil, 1.7 g, yield 20%; bp 180 °C/0.05 Torr, and phenyl cyclohexyl sulfide (**12**) as a colorless liquid, 0.85 g, yield 9%; bp 60 °C/0.05 Torr, were isolated respectively. Spectral analysis for **11**: ^{1}H NMR ($CDCl_3$) δ=2.80—3.10 (m, 3H), 3.40—3.70 (m, 2H), 3.70—4.10 (m, 2H), 4.10—4.30 (m, 1H), 5.70—6.00 (m, J=15 Hz, 1H), 6.30-6.50 (m, J=15 Hz, 1H), 7.10—7.60 (m, 10H); MS m/z (rel intensity) 332 (M^+), 167 (100), 149 (83), 123 (100); IR (liquid film) 3500, 2900, 1600, 1500, 1460, 1100, 1040, 760, 700 cm^{-1}. Found: C, 64.66; H, 6.09; S, 19.02%. Calcd for $C_{18}H_{20}O_2S_2$: C, 65.03; H, 6.06; S, 19.29%. (Received August 4, 1986)

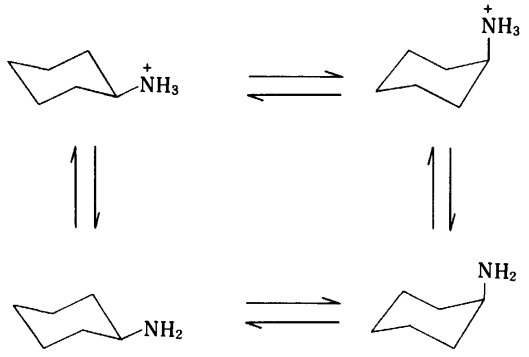
The pK_a' values of the trifluoroacetate salts of the title compounds were determined in THF–water (3 : 2) solution at 25 °C by potentiometric titration: in every compound examined, basicity of the *ap* rotamer was higher than that of the *sp* rotamer. Differences in pK_a' values (ΔpK_a) between the rotamers are in the range of 0.55 to 1.14 pK_a units, depending upon the substituents on the nitrogen atom. The ΔpK_a values in chloroform-*d* solution at 80.1 °C determined by taking advantage of the equilibrium constants of the salts and the free amines were larger than those obtained in aqueous THF solutions and were nearly independent of the substituents. The results were explained in terms of the intramolecular NH-π interactions in the *ap* salts, which are not possible in the *sp*. ^{1}H and ^{13}C NMR spectral data were in conformity with the presence of the interactions. Examination of the population ratios in various solvents revealed that *sp* conformers of the free amines are generally favored over the *ap* in polar, proton-accepting solvents, but the reverse is true for the trifluoroacetate salts. As the results, ΔpK_a values are large in toluene and chloroform but are rather small in tetrahydrofuran, acetonitrile, and nitromethane. Possible causes for the differences including solvation and hydrogen bond formation are discussed.

Physical properties of an organic compound are often the weighted means of those of several conformers of the molecule, since the interconversion among conformers usually takes place very rapidly. Acidities and basiciteis of organic compounds are examples of those cases. Taking cyclohexylamine, we notice that four processes are involved, as shown in Scheme 1, in the dissociation of this conjugate acid.



Scheme 1. Equilibria involved in dissociation of the conjugate acid of cyclohexylamine.

A common method of access to the true pK_a values of the equatorial and the axial conformers of the compound is that we use a pair of model compounds in which inversion and consequently the conformational change in the amine moiety is practically prohibited:[3] 4-*t*-Butylcyclohexylamine is a typical example, the cis isomer modelling the axial isomer and the trans the equatorial isomer.[4] Equations to obtain pK_a values of equatorial and axial isomers of the cyclohexane derivative were derived and were used in determining the pK_a values of axial and equatorial cyclohexylamines from those of cis and trans 4-*t*-butylcyclohexylamines.[4] However, such models possess inherent limitations. If we could directly determine acidities and basicities of respective rotamers, the values would be more reliable than those derived from the models.

Since we were able to isolate rotational isomers at room temperature,[5,6] we have been interested in the reactivities of those isomers.[7] The acidity or basicity is one of the examples in which we can see the respective properties of rotational isomers. The understanding of the acid-base properties of rotational isomers should contribute to get further insight into the bulk properties of organic compounds. Thus we launched a project of determining the acid-base properties of rotational isomers. This paper firstly presents some of the results obtained with 9-[2-(dialkylaminomethyl)-6-methylphenyl]fluorene rotamers both in aqueous THF and in chloroform-*d* and discusses the origin for the difference in basicities of the rotameric amines. The second point presented in this paper is the solvent effects on the base properties which can partly be interpreted on the molecular basis.

Syntheses of Amines

General procedure for the syntheses of the rotational isomers of the amines are shown in Scheme 2. The *sp* rotamer or a mixture of *sp* and *ap* rotamers of 9-(2-bromomethyl-6-methylphenyl)fluorene (**1**) was treated with the excess of the corresponding amines in THF solutions to give *sp*-[2-(dialkylaminomethyl)-6-methylphenyl]fluorenes (**2**—**5**) as a sole product after recrystallization. This stereospecific formation of the *sp* rotamer is interesting. There are two possible reasons for this phenomenon.

The first is kinetic control. Deprotonation reactions of 9-(2-methoxy-1-naphthyl)fluorene[8] and 9-(2-methoxymethyl-6-methylphenyl)fluorene and its analogs[9] with butyllithium followed by protonation with water have been known to produce the corresponding *sp* forms only. This phenomenon is attributed to the structure of the intermediate lithio com-

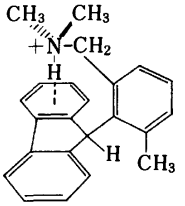
pound which is stabilized by ligation with the heteroatom in the 2-position of the naphthalene or the phenyl nucleus, and protonation of the lithio compound with retention of configuration.[10] However, it is difficult to find this type of factors for the selectivity of the reaction.

The second is the thermodynamic effect which may favor the *sp* forms. Isomerization of the 9-arylfluorene rotamers takes place when an amine is present:[11] Under the reaction conditions the *sp* and *ap* amines can isomerize and thermal equilibrium may be reached. When we treated a mixture of *sp* and *ap* rotamers of compound **1** (*sp* : *ap*=1 : 2.7) with excess of dimethylamine in a THF solution and quenched with dilute hydrochloric acid after 30 min, we found that *sp* and *ap* amines were obtained in a 6.1 : 1 ratio. This ratio increased to 10 : 1 if the reaction period was lengthened. We conclude from this together with the similar results obtained for the diethylamine and dipropylamine cases that the overwhelming formation of the *sp*-amines is due to thermodynamic control. The equilibrium data obtained here are a little different from those in THF, as discussed later, but the results can be attributed to the presence of excess of amines which are polar and favor the solvation of the *sp* forms.

According to the above results, we have to use another independent way of synthesis to prepare the *ap*-amines. We found, however, that the *ap*-amine trifluoroacetate salts were much more stable than the *sp* in chloroform. Thus heating a chloroform solution of the *sp*-salt at 80.1 °C for 7 d afforded a mixture of rotational isomers, in which the ratio *ap*/*sp* reached nearly 10 or more. The pure *ap* salts were then obtained by recrystallization of the mixture from ether. Treatment of the salts with aqueous sodium hydrogencarbonate produced pure *ap*-amines. The predominance of the *ap* form over the *sp* in chloroform must be derived by the presence of NH-π interactions in the *ap* form, which will be discussed below in more detail.

9-[2-(Dimethylaminomethyl)-6-methylphenyl]fluorene

At the outset of the project, we measured the pK_a' values of rotameric 9-[2-(dimethylaminomethyl)-6-methylphenyl]fluorene trifluoroacetate in 3 : 2 THF-water. The pK_a' values were 5.85 and 6.45 for the *sp* and *ap* forms, respectively. The results were rather unusual in the sense that the amine moiety which is located in a more crowded site is more basic than that in a less crowded site: The general tendency, that is, less crowded amines are more basic than crowded amines, is explained on the basis of the unfavorable solvation of the crowded ammonium moiety.[4,12] There can be various reasons for the anomaly but we wished to focus our attention to the possible presence of the NH-π interactions (**10**), which are possible for



10

the *ap* salt but impossible for the *sp* due to the unfavorable approach of the NH group to the π-system of the fluorene, as the main cause.

Although the OH-π interactions are well documented,[13] the NH-π interactions are rarely reported.[14–16] From the available data, however, the presence of the NH-π interactions is clearly favored when the NH groups becomes electronegative, as is expected from the charge transfer theory. Since the electronegativity of the $^{+}$NH group is very high, it will be reasonable to assume the presence of the NH-π interactions here.

If the NH-π interactions play an important role in stabilizing the *ap* form of the salt relative to the *sp*, then the relative stability should be enhanced in less electron-donating solvents in hydrogen-bond formation, since the competition of the intramolecular NH-π interactions with the hydrogen-bond formation with such solvents will become favorable for the former. Being one of those solvents, chloroform is expected to show a large difference in pK_a values of the rotational isomers of **6**. However, it is very difficult to measure pK_a values in chloroform in the usual sense.

If one is allowed to discuss the difference only, not the absolute values, then there is a trick. The K_a values of the respective rotamers can be expressed by Eqs. 1 and 2.

$$K_a(sp) = \frac{[sp\text{-amine}][CF_3COOH]}{[sp\text{-salt}]} \quad (1)$$

$$K_a(ap) = \frac{[ap\text{-amine}][CF_3COOH]}{[ap\text{-salt}]} \quad (2)$$

Dividing Eq. 1 by Eq. 2, we obtain

$$\frac{K_a(sp)}{K_a(ap)} = \frac{K(\text{salt})}{K(\text{amine})} \quad (3)$$

where K(salt) and K(amine) are equilibrium constants (*ap*/*sp*) of the salt and the free amine, respectively, in chloroform at a given temperature. Then the ΔpK_a values ($\Delta pK_a = pK_a(ap) - pK_a(sp)$) can be obtained by taking the logarithm of Eq. 3, because K(salt) and K(amine) are measurable quantities.

Before getting into discussion of the ratios of the dissociation constants in chloroform, there is one thing which we should not overlook. Due to poor solvation in chloroform, dissociation of trifluoroacetic acid in this solvent should be greatly depressed,[17] or the ammonium salt **6** should be unstable. There is a chance that **6** dissociates into the free amine **2** and trifluoroacetic acid in chloroform to some extent. In order to find out if this is the case, we observed the chemical shifts of the NMR signals due to the benzylic methylene protons and 9-H by gradually adding trifluoroacetic acid to a solution of *sp*-**2** in chloroform-*d*. The results are shown in Fig. 1. As is clear from the Figure, the methylene proton signal at δ 3.69 for the free amine moved to a lower magnetic field on addition of the acid until it reached, on addition of 1.0 equivalent of the acid, at δ 4.63, where it stayed on further addition of the acid. The 9-H signal showed the similar behavior though it moved to a higher magnetic field on protonation of the amine. These clearly indicate that the ammonium salt *sp*-**6** exists without appreciable dissociation into the free amine and the acid under the conditions.

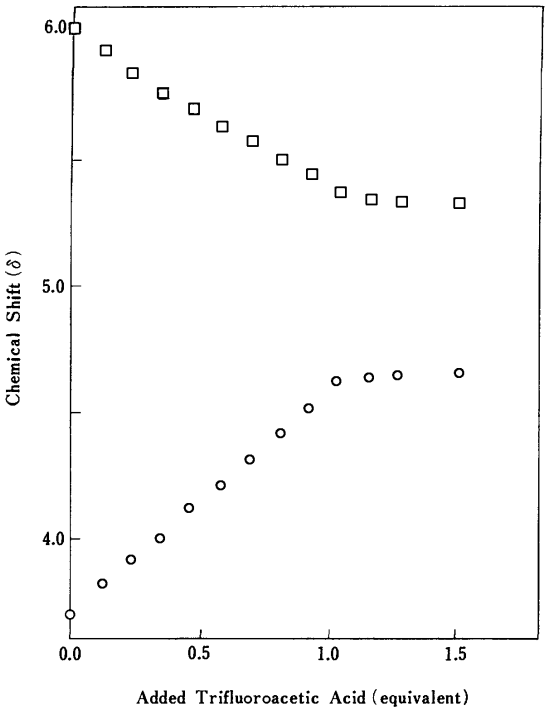


Fig. 1. Dependence of chemical shifts of benzylic protons and 9-H of *sp*-9-[2-(dimethylaminomethyl)-6-methylphenyl]fluorene in $CDCl_3$ on the amount of added trifluoroacetic acid.

In chloroform-*d*, the population ratio (*ap*/*sp*) of the rotamers of the free amine **2** was found to be 1/3.66, whereas that of the ammonium salt **6** was 9.70. Thus the ΔpK_a value in $CDCl_3$ is calculated to be 1.55. This enhancement of the difference in pK_a values of the rotamers in chloroform relative to the value in THF–water supports the idea of the presence of the NH-π interactions in the *ap* form of the salt.

9-[2-(Dialkylaminomethyl)-6-methylphenyl]fluorenes

Since the solvation effects are found to be very important in determining the pK_a values, we have extended the work to see the effects of the alkyl chain length in 9-[2-(dialkylaminomethyl)-6-methylphenyl]fluorenes (**2—5**) and their salts **6—9**. Since the alkyl chain should affect the solvation energy, there should be a chance that enhanced difference in pK_a values is observed. They may as well provide additional evidence for the presence of the NH-π interactions in the *ap* forms, when we compare the data in the series of compounds.

^{1}H and ^{13}C NMR Spectra. The ^{1}H NMR spectral data are given in Table 1. The free amines show fea-

a) α, β, and γ denote the position from the N atom in the alkyl chain. b) Multiplets centering at δ 1.7 (1 H) and 2.3 (3 H) that are not assigned.

tures that are common for the 9-arylfluorene series: The aromatic methyl and benzylic methylene signals are placed at high fields when the groups are located over the fluorene ring. Even the protons involved in the alkyl groups show similar tendency, though the effect becomes smaller as the protons are located remote from the nitrogen atom.

The change in the chemical shifts on protonation is very large especially for the protons of the methylene (methyl) groups which are attached directly to nitrogen. Inspection of the data in detail reveals that the extent of the low field shifts is different in *sp* series from that in the *ap* for some protons. Whereas the benzylic methylene signals of both *sp* and *ap* amines are similarly shifted to a low field by 0.8—0.9 ppm when the amines are protonated, the proton signals ascribable to the methylene (hereafter *N*-methylene) or the methyl group which is directly bonded to the nitrogen are shifted differently in the *sp* form from those in the *ap*. In every compound examined, the change in chemical shifts of the *N*-substituent protons is smaller in the *ap* form than in the *sp* on protonation. The dipropylamino compound **5** and its conjugate acid **9** are typical examples. The difference in the chemical shifts of the *N*-methylene proton signals is 0.77 ppm on protonation of the *sp* rotamer, while that of the *ap* rotamer is 0.44 ppm. These results may be explained on the basis of the freedom of motion of the propyl group. On one hand, the location of the benzylic methylene group is more or less fixed because of the rigidity of the part of the molecule. On the other, the *N*-methylene group can take various positions due to the conformational change in the free amine, while the position is rather fixed in the salt because of the presence of the NH-π interactions. Thus in the *ap* salt, the *N*-methylene protons are placed in the shielding region of the fluorene nucleus to counterbalance the effect of protonation to some extent and to make the smaller shifts to the low field on protonation. A similar tendency is observed in the 2-methylene protons and the methyl protons in the propyl group, though the extent of the difference becomes smaller as the protons become more remote from the nitrogen, the phenomenon being again in conformity with the freedom of motion of the propyl group.

The ammonium NH protons, though not listed in Table 1, show signals at δ ca. 11.5 and 12.5 for the *ap* and the *sp* conformers, respectively. The placement of the NH protons of the *ap* form at a higher magnetic field than that of the *sp* is another support for the presence of the NH-π interactions: The ring current effect of the fluorene ring should bring the chemical

shift of the NH protons in the *ap* forms to a high field.

It deserves mention here that the *N*-methylene protons of the *ap* forms of **7** and **9** exhibit AB pattern signals, if we neglect couplings with methylene or methyl protons, at room temperature to indicate that they are diastereotopic. It is also characteristic that the benzylic methylene protons in the *ap* forms give doublet signals. These should mean that the proton attached to the nitrogen atom dissociates slowly on the NMR time scale. Since the *N*-methylene protons of the *sp* forms do not show the diastereotopic nature nor the benzylic protons doublet signals at this temperature, the dissociation of the NH proton must be taking place much faster in the *sp* than in the *ap* form. The slow dissociation of the ammonium proton in the *ap* forms offers additional evidence for the presence of the intramolecular NH-π interactions. The details of the dynamic behavior will be described elsewhere.

The ^{13}C NMR spectral data shown in Table 2 indicate that the difference in chemical shifts between *sp* and *ap* rotamers are in most cases very small, less than 1.5 ppm. The exceptions are the benzylic methylene and aromatic methyl carbons of which differences amounted to 3.5—5.5 ppm in free amines. Although the presence of the ring current effect in ^{13}C NMR spectra is controversial,[18] it is tempting to consider that the ring current effect is operative in this case because of the proximity concerned. The most striking feature of the ^{13}C NMR spectra is the change in chemical shifts of the benzylic methylene carbons when the amine is protonated. In the case of *sp* amines, these carbons moved toward a high magnetic field by at least 5 ppm, while shifts were less than 0.8 ppm except for one case, a pair of **2** and **6**, in the *ap* forms. Since the protonation of amines usually causes a 3—5 ppm high field shift of the carbon signals alpha to the amino group,[19] the change in chemical shifts observed in the *sp* series is normal but that for the *ap* series abnormal. The contrast must be attributed to some effects of the substituents peculiar to the *ap* series.

We wish to attribute again the difference to the conformational change in the salt from that in the free amine. The repulsive interactions between lone-pair electrons and the aromatic π-system seem to be great. For example, the *sp* rotamer of 9-(2-methoxy-1-naphthyl)fluorene predominates over the *ap* form, although the half thickness of a benzo group is larger than the van der Waals radius of the oxygen atom in a methoxyl group.[20] Thus the conformation in which the amino-nitrogen is located closely to the fluorene ring is strongly disfavored. The preferred conformation must be such that the amino moiety takes a position away from the fluorene ring. This will necessarily result in the placement of the benzylic methylene protons, where they face the fluorene ring. This will cause the van der Waals shift for both hydrogens and

carbons,[21] by which carbon signals are shifted to a high field. In *ap* salts, the conformation is such that the NH-π interactions are possible in it: This requires that at least one of the methylene protons is placed away from the fluorene ring.

Rotational Barriers and Rotamer Populations. Mere consideration of the rotamer populations in equilibrium in discussing the stability of rotamers can lead to an erroneous conclusion, because one rotamer can be rich in population for two reasons; its enhanced stability relative to others and the enhanced instability of the counterparts. In order to diagnose the two possibilities, determination of rotational barriers should lend help, if the transition state for rotation can be assumed nearly equal. Thus we determined the rotational barriers and equilibrium constants in chloroform-*d* at 80.1 °C. The results are shown in Tables 3 and 4.

As is seen in Table 3, the equilibrium constants show a remarkable contrast for every compound examined: In amines, the *sp* forms are favorable species, being consistent with the general tendency that a bulkier substituent takes a position close to the 9-H in 9-(2,6-disubstituted phenyl)fluorenes,[6] while in the salts *ap* forms predominate by a factor of 10—20. The results are in conformity with the presence of the NH-π interactions in the *ap* forms of the salt.

As to the kinetics of internal rotation in amines, the rates of rotation as well as the free energy of activation for rotation are by and large the same irrespective of the alkyl chain, although a slight enhancement of the barrier is observed when one goes from methyl to ethyl and then to propyl (Table 4). This will mean that we may assume that both the ground states and the transition states for rotation are almost the same in their energy in these amines, as far as the molecular interactions are concerned. On protonation of the amine, the transition state energy of rotation will be slightly enhanced, if not the same with the amine, but the degree of the enhancement will be very small. Kinetic data in Table 4 then show that the ground state of the *sp* salt is destabilized to a small extent: This will probably because of the unfavorable steric effects on solvation. In contrast, the barrier to rotation for the process *ap*→*sp* is clearly enhanced in the salt relative to the free amine. If one takes the unfavorable solvation effects seen in the *sp* form of the salt and that the situation is even enhanced in the *ap* salt into consideration, the natural conclusion is that the *ap* form of the salt is stabilized relative to the *sp* forms due to the presence of the NH-π interactions in the former.

Difference in pK_a Values. The ΔpK_a values in chloroform-*d* are given in the last column of Table 3. Generally the difference is invariant. However, if one takes a careful look at the individual data, one notices that both *K*(amine) and *K*(salt) change as the alkyl group changes: Both the *K*(amine) and *K*(salt) values increase as the alkyl chain is lengthened. As a result, the ΔpK_a values appear to be not affected by the chain length. However, the population ratios of the salt change significantly when the alkyl chain becomes long. This is probably because the solvation becomes inefficient for the *sp* forms of the salt as the alkyl chain is lengthened, while the NH-π interactions are still

Table 5. pK_a' Values and Concentrations of the Conjugate Acids **6—9** in 3:2 THF-Water at 25°

Compound	pK_a'	*sp* Concentration / mol L^{-1}	pK_a'	*ap* Concentration / mol L^{-1}	ΔpK_a
6	5.90	0.0071	6.45	0.0059	0.55
7	5.70	0.0059	6.80	0.0072	1.10
8	5.22	0.0059	6.15	0.0059	0.93
9	4.98	0.0059	6.12	0.0077	1.14

efficient in the *ap* salt. In the free amine, the solvation effect is as well important: The solvation energy becomes small as the alkyl chain is lengthened, thus making the unfavorable steric situation for the *ap*-amine less effective.

The pK_a' values of the conjugate acids **6—9** were measured in 3:2 tetrahydrofuran-water. The results are given in Table 5. It is interesting to note that the ΔpK_a value of the methyl compound **6** is now doubled when we go to the ethyl compound **7**, whereas the ΔpK_a values do not change on further lengthening of the alkyl chain. The pK_a' values of the *sp* conjugate acids decrease monotonously when one goes from the short alkyl chains to long alkyl chains, while those of the *ap* forms show a maximum at the ethyl compound. Literature search reveals that the series of *N,N*-dialkylanilines shows the maximum basicity at the ethyl compound,[22] and the diethyl compound is more basic than the dimethyl compound in the series of *N,N*-dialkylbenzylamines,[22] though the exact cause for this phenomenon is not yet identified. It is possible that the monotonous decrease in the pK_a' values in the *sp* series is due to the steric hindrance for solvation, whereas in the *ap* the trend is normal because of the presence of the NH-π interactions. The stable conformation of the dimethylammonio group in the *sp* form of **6** will be such that the dimethylammonio group is perpendicular to the benzene ring of the 2,6-disubstituted phenyl group, as is the case of neopentylbenzene derivatives.[23] In this conformation, a water molecule can approach the ammonio-proton to form a hydrogen bond without much steric hindrance from the direction which is perpendicular to the phenyl ring. By contrast, the conformation of the diethylammonio group in the *sp* form of **7** will be such that the diethylammonio group takes a position in which the group opposes the 3-H of the phenyl ring. This is caused by severe steric interactions of the methyl group in the diethylammonio with the hydrogens at 1 and 8 positions of the fluorene ring. This conformation is unfavorable for solvation due to the steric effect, because the most stable conformation in this frame will be such that the hydrogen on the nitrogen atom of the ammonio group is located closely to the 3-H of the phenyl ring.

The sudden jump in the ΔpK_a value of the diethyl compound from the dimethyl may be ascribed to the NH-π interactions again. Due to the intramolecular interactions, the unfavorable steric effects on solvation are somewhat erased in the *ap* form relative to that of the *sp* form to make the *ap* amine more basic than the *sp*. The same factor operates in compounds with long alkyl chains (**8** and **9**) but the effect of solvation energy must be leveled off to make the apparent ΔpK_a almost the same.

Solvent Effects

The discussion presented above emphasizes that the NH-π interactions are important in affecting the difference in basicities of the rotamers in question. Chloroform is a solvent which does not donate electrons in hydrogen bond formation,[24] while the THF-water system may be taken as that NH-O hydrogen bond formation is possible between the solute and the solvent. Thus in THF-water a competition exists between the NH-O hydrogen bond and the NH-π, the former being more favored in terms of enthalpy at least than the latter. Thus it becomes of interest to examine the generality of the effect of hydrogen bond formation on the basicity difference of the rotamers. In this connection, we have examined the pK_a differences in various solvents.

The selected solvents are toluene, tetrahydrofuran, acetonitrile, and nitromethane. Toluene was assumed to be only weakly active in hydrogen bond formation and nonpolar, whereas latter three are capable of hydrogen bonding and polar. The results of the equilibrium constants and $\Delta pK_a'$ s are shown in Tables 6 and 7, respectively.

Table 7. Differences in pK_a Values (ΔpK_a) in Various Solvents at 80.1 °C

a) R and R' in Scheme 2.

As to the populations of free amines, every solvent used here favors the *sp* forms relative to chloroform. As far as the polar solvents are concerned, the results may be attributed to the favorable steric situation of the *sp* forms for solvation. The population ratios in chloroform and toluene are not explainable in a straightforward manner but they may well be due to the solvation effect again: While toluene is a large molecule which should suffer from the steric effects in solvating the *ap* form, the largest solvation effect by the chloroform molecule should be given by hydrogen-bond formation, where chloroform acts as proton donor[25] and steric requirement is rather small. Close examination of Table 6 reveals that in every solvent examined, the *ap*/*sp* ratios decrease as the chain length of the alkyl group becomes longer. The long alkyl chain seems to disfavor the stabilization due to solvation of the *sp*-amines relative to the *ap*-amines, because intrinsic steric hindrance is larger in the latter than in the former even in the short chain case: The solvation energy becomes relatively less in the *sp* form as the alkyl chain becomes long. Although dielectric constant does not seem to play any role in the population ratio in the proton-accepting solvents, the reason for this phenomenon is not well-understood at the present.

By contrast, the *ap* forms of the amine salts are favored over the *sp* forms except for **5** in THF and acetonitrile, for which the equilibrium constants are 1.0, still a larger value than any of the amines examined. It is reasonable that the equilibrium constants are rather small in polar, hydrogen-bond accepting solvents. Because of the competition between the solute-solvent hydrogen bond and the intramolecular NH-π hydrogen-bond, the former being favored in terms of enthalpy, at least some fractions of the solute molecules will take conformations which are favorable for the intermolecular hydrogen bond but disfavor the intramolecular one. Since the entropic effect is not favorable for the intermolecular hydrogen bond, the intramolecular NH-π bond may still be present in the *ap* form in proton-accepting solvents. It is possible that this effect is partially responsible to the favorable population of the *ap* form relative to the *sp*. The slight increase in the *ap*/*sp* values of every compound in THF, acetonitrile, and nitromethane as the chain is lengthened may be explained similarly as above by the steric effect on solvation.

Toluene gives interesting but puzzling results. If the polarity of the solvent were important in determining the equlibrium constants, this solvent should have given larger *ap*/*sp* values for the salts than chloroform. Since the *ap*/*sp* values of the salts were all smaller in toluene than in chloroform, there must be other factors to be considered. First is the fact that toluene is a π-base. There must be a competition between intramolecular and intermolecular NH-π hydrogen bonds. Even though the entropy effect is not favorable for the intermolecular hydrogen bond, the solute-solvent interaction, such interactions should exist at least to some extent. Second is the fact that chloroform is capable of forming a hydrogen bond. This ability will contribute to stabilizing the *ap* salts by forming a hydrogen bond with the carboxylate anion in addition to the NH-π bond relative to the *sp* salts which exist as tight ion pairs, forming a hydrogen bond between the ammonium ion and the carboxylate anion.

As the results of these factors including the NH-π interaction and the solvation of the free amines and the salts, the differences in pK_a values must be derived (Table 7). It is interesting that in proton accepting solvents the ΔpK_a values are very close to 1.0 pK_a unit, whereas the solvents which cannot form a strong hydrogen bond with the NH group give large differences. The largest ΔpK_a value was obtained for the dipropylamino-compound in $CDCl_3$ with the close second of the same compound in toluene. The results suggest that in nonpolar aprotic solvents, the ΔpK_a values of rotational isomers can be great under certain conditions.

In summary, the results described here clearly demonstrate that the acidity or basicity is different from one rotamer to another and that the solvent effect on the difference is important. The causes for the differences can be the steric effects on solvation and intramolecular interactions such as the NH-π. Although it has not been explicitly discussed in this paper, the steric hindrance to proton abstraction may be a factor to be considered. It is necessary to interpret the pK_a value of a compound by taking the following factors into consideration in addition to the solvation or the intermolecular interactions: The populations and basicities of rotamers concerned which may be affected by intramolecular interactions.

Experimental

Syntheses of Amines 2—5 and Their Trifluoroacetates

a) These compounds had been prepared in alternative ways.[9] b) The yield of the amine prepared by the method described in this paper. c) These compounds seem to contain 0.04—0.09 equivalent excess of trifluoroacetic acid, of which presence was confirmed by ^{19}F NMR spectra. The trifluoroacetic acid could not be removed by heating at 80°C in vacuo for several hours.

6—9. General procedures for the syntheses are described by taking the diethyl compound **3** and **7** as examples. The melting points, yields, and analytical data are given in Table 8.

***sp*-9-[2-(Diethylaminomethyl)-6-methylphenyl]fluorene (*sp*-3).** To a solution of 245 mg (0.70 mmol) of a rotameric mixture of 9-(2-bromomethyl-6-methylphenyl)fluorene (**1**)[26] (*sp*/*ap*=2) in 20 mL of tetrahydrofuran, was added 2.0 g (27.3 mmol) of diethylamine. The solution was stirred at 40 °C for 24 h and then the reaction mixture was poured into 30 mL of water. The mixture was extracted with ether and the ether extracts were dried over sodium sulfate. After evaporation of the solvent, the residue, of which ^1H NMR spectrum showed to be a 10:1 mixture of *sp* and *ap* amines, was submitted to silica-gel TLC. Elution with dichloromethane-ethanol (10:1) afforded 163 mg (68%) of *sp*-**3**. Recrystallization from methanol afforded pure samples.

sp-**3** trifluoroacetate (*sp*-**7**) was prepared by adding 1 mL of trifluoroacetic acid to a solution of 80 mg of *sp*-**3** in 10 mL of ether followed by stirring for 10 min. Evaporation of the solvent together with excess of trifluoroacetic acid in vacuo and then two successive recrystallizations of the residue from ether afforded a pure sample.

ap-**3** trifluoroacetate (*ap*-**7**) was obtained by heating a solution of 30 mg of *sp*-**7** in 0.5 mL of chloroform-*d* in a sealed tube at 80.1 °C by immersing the tube in a boiling benzene bath for 7 d. The ratio *ap*/*sp* of the trifluoroacetate was 12 at this stage. The product was recrystallized from ether to give pure *ap*-**7**.

ap-**3** was obtained by treating a solution of *ap*-**7** in dichloromethane with 3% aqueous sodium hydrogencarbonate. The product was purified by recrystallization from methanol.

Preparation of the dimethylamino compound **2** has been reported[9] but *ap*-**2** was more conveniently prepared by the analogous procedure described above. The results are also included in Table 8.

Some of the *ap* amines had low melting points. In these cases, the free amines were purified by chromatography on silica gel, thoroughly dried in vacuo and submitted to elemental analyses.

pK_a' Measurements. In a typical experiment, 66.9 mg of *sp*-**7** was dissolved in a 25 mL volumetric flask in 3:2 THF-water to make a 0.0059 mol L^{-1} solution. By the use of a pipet, 10 mL of this solution was placed in a two-necked flask and was titrated with a 0.083 mol L^{-1} sodium hydroxide solution in 3:2 THF-water. Evaporation of THF was prevented as much as possible by using small inlets for the buret and for a glass electrode. After a small portion of the sodium hydroxide was added, the pH value of the solution was read by the glass electrode. In one experiment, 20 to 30 points were obtained. The curve which shows the relationship between the added sodium hydroxide and the pH values is simulated by the use of a computer program[27] to get a best fit. The pK_a' values are tabulated in Table 5.

NMR Measurements. ^1H and ^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer operating at 89.55 and 22.49 MHz for proton and carbon, respectively. Some of the ^{13}C signals were assigned on the basis of off-resonance experiments and comparison of the peak intensities of the spectra obtained by the gated decoupling mode.

Kinetic Measurements. The rates of isomerization were

determined by monitoring the increase or decrease of the ^{1}H NMR signals due to each isomer in chloroform-*d* solutions. Plots of $\ln[1-(1+1/K)(a/X)]$ vs. time gave a straight line and the first order rate constants were obtained by the conventional method. In some salts in $CDCl_3$, the equilibrium constants seemed too large to afford reliable values by the NMR method. In such cases, the equilibrium constants were determined by treating them as variables starting from the NMR values: They were obtained as values which gave the best straight line in the plots of $\ln[1-(1+1/K)(a/X)]$ vs. time. Agreement between the calculated values and the observed ones by the NMR method was fairly good.

Determination of the Equilibrium Constants in Various Solvents. The amine or the salt was dissolved in a pure solvent under nitrogen and the solution was sealed in a tube, which was immersed in a boiling benzene bath (80.1 °C). It took 7 d to reach equilibrium at that temperature. The sealed tube was opened and the solvent was evaporated in vacuo. The population ratio, *ap*/*sp*, was determined by the integrated intensities in the ^{1}H NMR signals of the product in $CDCl_3$. In the case of salts, a small quantity of trifluoroacetic acid (0.05—0.10 equivalent) was added to avoid the presence of a free amine which would affect the equilibrium constant to a great extent. The effect of the presence of trifluoroacetic acid on the equilibrium was negligible, because changing the quantity of the acid within the range mentioned above did not show any significant difference in the equilibrium constants.

This work was supported by a Grant-in-Aid for Scientific Research administered by the Ministry of Education, Science and Culture, to which our thanks are due.

Preparation, 1,3-Dipolar Cycloaddition, and Thermal and Photochemical Reactions of 3,5-*exo*- and 3,5-*endo*-7-Methylene-4-azatetracyclo[4.2.1.0.^{2,8}0^{3,5}]nona-9-ones[1]

Nobuhiro KANOMATA, Tadashi KOBAYASHI, Takashi UETAKE, Shuji OKADA, and Makoto NITTA*

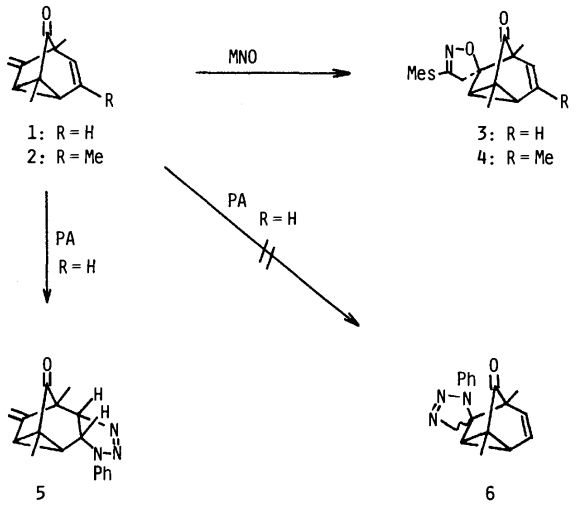
(Received August 6, 1986)

The 1,3-Dipolar cycloaddition of phenyl azide with 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one occurred onto the endocyclic double bond to give the *exo*- and *endo*-adducts (**7** and **8**) in a similar ratio. Upon photoirradiation, **7** and **8** eliminated a nitrogen molecule to give 3,5-*exo*- and 3,5-*endo*-1,3,6-trimethyl-7-methylene-4-azatetracyclo[4.2.1.0.^{2,8}0^{3,5}]nona-9-ones (**9** and **10**) in good yields. The 1,3-Dipolar cycloaddition of 2,4,6-trimethylbenzonitrile oxide with **9** and **10** occurred onto the exocyclic double bond to give two stereoisomers in each case. The stereoselectivity of the reactions is discussed on the basis of the stereoelectronic factor of the aziridine ring. The thermal reaction of **9** and **10** as well as photoirradiation of **9** caused a simple C–N bond cleavage of the aziridine ring. However, photoirradiation of **10** or its dimethyl analogue caused an unusual skeletal rearrangement resulting in the formation of 9-methylene-6-phenyl-6-azatricyclo[3.3.1.0^{2,8}]nona-3-en-7-one ring system. Mechanistic pathways of the rearrangement were postulated.

Previous work in this series has included studies concerning the stereoselectivity and site selectivity of the electrophilic reactions, such as solvomercuration, bromination,[2] 1,3-dipolar cycloaddition,[3] and dichlorocarbene addition[4] of 1,5-diemthyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (**1**)[5] and its related compounds. Among these reactions, the 1,3-dipolar cycloaddition of **1** and 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (**2**)[5] with 2,4,6-trimethylbenzonitrile oxide (mesitonitrile oxide, MNO) exhibited remarkable stereoselectivity or site selectivity to give cycloadducts **3** and **4**, while **1** with phenyl azide (PA) afforded adduct **5** (Scheme 1). The formation of the *exo*(to the carbonyl group)-adducts **3** and **4** can been explained by the preferential LUMO(MNO)-HOMO(exocyclic double bond of **1** or **2**) interaction. The prohibited endo attack of MNO onto the exocyclic double bond was ascribed to the repulsive orbital interaction, which could be experienced with the endocyclic double bond as depicted in Fig. 1. In the cycloaddition of PA, on the other hand, the LUMO(PA)-HOMO (exocyclic double bond of **1**) interaction to give *endo*- or *exo*- adduct **6** was prohibited by a repulsive orbital interaction or a large van der Waals nonbonded interaction of the phenyl group. Thus, the cycloaddition occurred onto the endocyclic double bond from the endo side to give **5**.



Scheme 1.

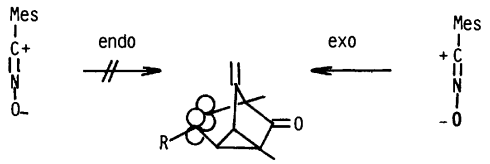


Fig. 1.

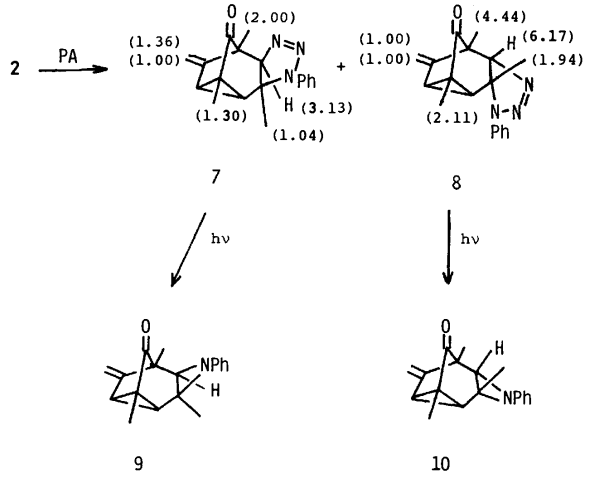
In this paper, the 1,3-dipolar cycloaddition of **2** with PA was clarified as occuring onto the endocyclic double bond from the exo and endo sides. These two adducts could eliminate a nitrogen molecule, resulting in the formation of 3,5-*exo*-1,3,5-trimethyl- and 3,5-*endo*-1,3,5-trimethyl-4-azatetracyclo[4.2.1.0.^{3,5}0^{2,8}]nona-9-ones (**9** and **10**) under photoirradiation. The 1,3-dipolar cycloaddition of MNO with the exocyclic double bond of **9** and **10** was interesting from the viewpoint of a comparison of the electronic effect of the aziridine ring of **9** and **10** with that of endocyclic double bond of **1** and **2**, in both of these the endo attack of MNO was completely prohibited (Fig. 1).[3] Furthermore, thermal and photochemical reactions of **9** and **10** were studied in order to clarify the chemical behaviors, which would be affected by stereochemical arrangements of the aziridine ring. The results are described in this paper.

Results and Discussion

The reaction of **2** with PA under reflux in cyclohexane for 50 h gave an *exo*-adduct **7** and an *endo*-adduct **8** in 32 and 31% yields, respectively. The structural proof was based on elemental analyses and spectroscopic data (see Experimental). Especially, the chemical shifts of the protons on the triazoline moieties of **7** (δ 4.12) and **8** (δ 4.14) are suggestive of the assigned

regioselectivity.[6] The stereochemical arrangement of the triazoline moiety of **7** and **8** was deduced from the pseudo-contact NMR spectra observed by using $Eu(fod)_3$.[7] The relative down-field shifts of δ's of typical protons are give in parentheses in the structural formulae **7** and **8** in Scheme 2. The small values of



Scheme 2.

3.13 and 1.04 for a proton and a methyl group on the triazoline moiety of **7**, as compared with the corresponding values of 6.17 and 1.94 of **8**, suggest the coordination of $Eu(fod)_3$ occurs on the carbonyl-oxygen and support the structural assignment of **7** and **8**. Since the terminus of the methyl-substituted endocyclic double bond (possibly with a large HOMO coefficient) was bound to a nitrogen atom bearing no phenyl group (large LUMO coefficient), the regioselectivity of the adducts **7** and **8** appears to be controlled by the PA(LUMO)-**3**(HOMO) interaction.[3,8] The carbonyl group and the exocyclic double bond of **1** and **2** exist in a similar stereochemical situation in the molecular framework (as depicted in Fig. 2). In the case of **1**, exo (to the carbonyl group) attack of PA was considered to be prohibited, probably by a steric hindrance between the phenyl group of PA and C_1-methyl group.[3] Thus, an addition occurred from the less-hindered side to give only **5**. Similarly, an exo attack in **2** also expected to be sterically hindered. However, the introduction of a C_3-methyl group in **2** resulted in the competition of exo and endo attack to give **7** and **8**. The effect of the methyl group on the stereoselectivity still remained unclear.

The photoirradiation of **7** and **8** with RPR-350 nm lamps underwent a clear elimination of a nitrogen molecule to give aziridine **9** or **10**, respectively (Scheme 2).[9,10] The structures of **9** and **10** were also confirmed on the basis of the spectral data.

Compounds **9** and **10** contain an aziridine ring instead of a π bond of **2**, the cycloaddition of which occured to give only an *exo*-adduct **4**.[3] Thus, the cycloaddition of MNO with **9** and **10** was investigated in order to gain a further insight into the stereoelectronic control of the aziridine ring, as compared with the endocyclic π bond (Fig. 1). The reaction of **9** with MNO afforded *exo*-adduct **11** and *endo*-adduct **12** in 58 and 23% yields. Similarly, a reaction of **10** afforded two adducts (**13** and **14**) in 79 and 10% yields. The structures of these adducts were deduced from the spectroscopic data. Especially, the chemcial shifts of the

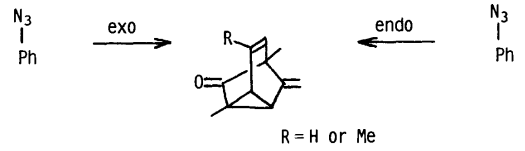


Fig. 2.

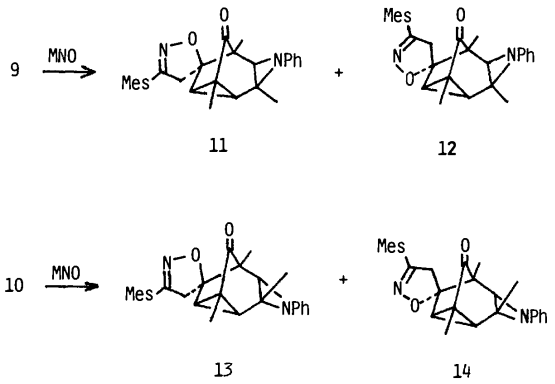


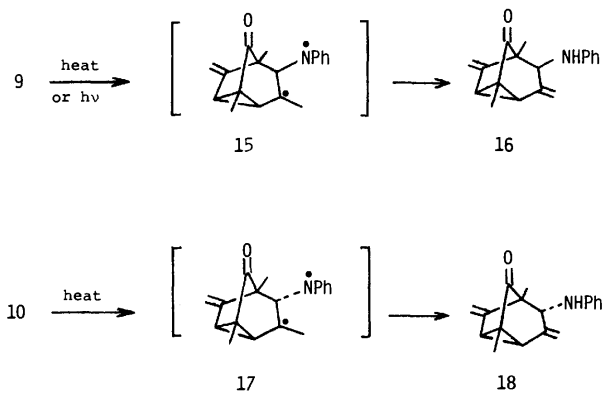
Scheme 3.

methylene group on the isoxazoline moieties were helpful in determining the stereochemistry. In the cases of *endo*-adducts **12** (δ 3.22, 3.29) and **13** (δ 3.03, 3.14), chemical shifts of these protons appeared at higher fields compared with those of *exo*-adducts, **11** (δ 3.24, 3.34) and **13** (δ 3.23, 3.29). This fact could be ascribed to the anisotropy effect of the carbonyl group. Thus, the stereochemical arrangement of the isoxazoline moieties of **11**—**14** were established.

Consequently, in the cycloaddition of MNO with **9**, the stereoelectronic control of the aziridine bent bond seemed to be much reduced compared with that of the endocyclic double bond in **2** (Fig. 1). Thus, the *endo*-adduct **12** was obtained in an appreciable amount. The steric hindrance of the methyl group at C_3 does not seem so significant in the cycloaddition of **9**. The product ratio of **13**/**14** was larger than that of **11**/**12**. This fact is suggestive of a repulsive interaction of MNO with the bent σ (C-N) bonds of the aziridine ring of **10**.

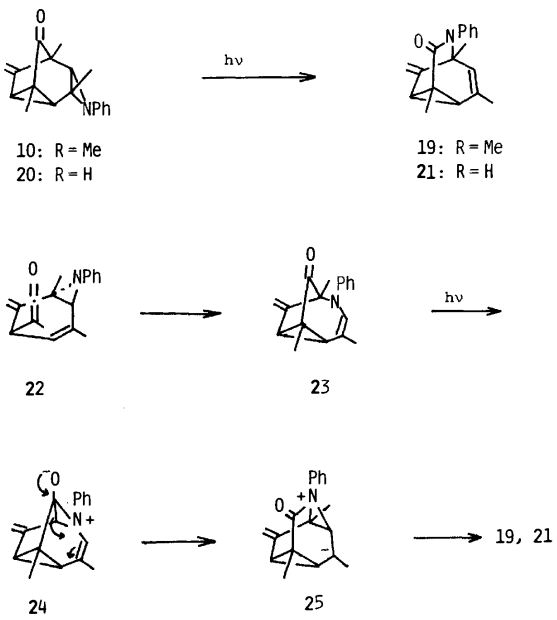
Studies of the thermal reaction[10] of **9** and **10** in 1,2-dimethylbenzene indicated that this fragmentation of the aziridine ring gave the corresponding exo and endo amino compounds **16** and **18** in 15 and 21% yields, leaving unreacted starting materials **9** and **10** in 85 and 79% yields. The structures of products **16** and **18** were unequivocally assigned on the basis of the spectral data. Similarly, a photoirradiation of **9** with RPR-254 nm lamps afforded **16** in a 35% yield. Thus, the reaction seems to proceed via diradical intermediates

15 and **17** formed by homolytic rupture of the C-N bond.[11]



Scheme 4.

However, a similar photoreaction of **10** gave only **19** in an 18% yield, in addition to large amounts of extremely decomposed materials. Similarly, the irradiation of the dimethyl derivative **20**[3] also gave **21** in a 30% yield. The structures of **19** and **21** were assigned on the basis of the spectral data. The ^{1}H NMR spectra of **19** and **21** exhibited typical chemical shifts and coupling patterns of the divinylcyclopropane moiety observed in compounds **1**, **2**,[5] and 5,8-dimethyl-9-methylenetricyclo[3.3.1.0^{2,8}]non-3-en-7-one.[12] The IR spectra suggest the existence of a six-membered amide function. Furthermore, the mass spectra of **19** and **21** exhibited an ion with *m/z* 119 (phenyl isocyanate). Thus, the structures of **19** and **21** could be deduced.



Scheme 5.

Compounds **10** and **20** have a skeleton similar to photolabile tricyclo[3.2.1.0^{2,7}]oct-3-en-8-one derivatives, which have been shown to photoisomerize to ketene derivatives.[13] Therefore, a ketene **22** is postulated to be a possible intermediate. Then, the addition of the ketene to the vinylaziridine moiety gives **23**, the photoreaction of which possibly gives zwitter ion **24**. The photoreaction initiated by the attack of a lone pair electron on nitrogen onto the carbonyl group has been previously reported regarding the rearrangement of the 8-azabicyclo[3.2.1]octa-3,6-dien-2-one ring system.[14] The reaction pathway of **24** may involve a formal intermediate **25** to give **19** and **21**. The reaction sequences postulated above are purely speculative, and evidence has not been obtained. The exo isomer **9** gives only **16** possibly via a diradical intermediate. This fact and the photorearrangement of endo isomers **10** or **20** to give **19** or **21** may stand in contrast to a thermal rearrangement of 3-arylsulfonyl-3-azatricyclo-[3.2.1.0^{2,4}]oct-6-ens.[15]

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The mass spectral studies were conducted using a Shimadzu GCMS-QP1000 and JEOL JMS-DX300 mass spectrometers. The ^{1}H NMR spectra (60 MHz) were recorded on a Hitachi R-24 spectrometer using Me_4Si as internal standard. The photoirradiations were carried out using Rayonet photoreactor fitted with appropriate lamps. All of the thermal and photochemical reactions were carried out under nitrogen atmosphere. Mesitonitrile oxide (MNO)[16] and phenyl azide (PA)[17] were prepared by the standard methods. All of the melting points are uncorrected.

Cycloaddition of 2 with PA. A solution of **2** (2.36 g, 13.6 mmol) and PA (2.78 g, 23.4 mmol) in cyclohexane (12 cm^3) was heated under reflux for 50 h. After the solvent was evaporated, the residue was separated by column chromatography on alumina. The fractions eluted with hexane afforded **2** (377 mg, 16%). The fractions eluted with benzene afforded **7** (1.28 g, 32%). The fractions eluted with dichloromethane afforded **8** (1.25 g, 31%). For **7**: Mp 86—87 °C (from hexane); IR ($CHCl_3$) 1733 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.26 (6H, s), 1.44 (3H, s), 2.10 (1H, d, J=7.2 Hz), 2.37 (1H, d, J=7.2 Hz), 4.12 (1H, s), 4.67 (1H, s), 4.86 (1H, s), 6.80—7.32 (5H, m); MS *m/z* (rel intensity) 265 (M^+-N_2, 9), 77 (100). Found: C, 73.77; H, 6.38; N, 14.41%. Calcd for $C_{18}H_{19}N_3O$: C, 73.69; H, 6.53; N, 14.33%. For **8**: Mp 114—115 °C (from hexane); IR ($CHCl_3$) 1736 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.00 (3H, s), 1.36 (3H, s), 1.52 (3H, s), 2.17 (1H, d, J=7.8 Hz), 2.64 (1H, d, J=7.8 Hz), 4.14 (1H, s), 4.90 (1H, s), 5.03 (1H, s), 6.8—7.5 (5H, m); MS *m/z* (rel intensity) 265 (M^+-N_2, 6), 118 (100). Found: C, 73.84; H, 6.46; N, 14.24%. Calcd for $C_{18}H_{19}N_3O$: C, 73.69; H, 6.53; N, 14.33%.

Photoirradiation of 7. A solution of **7** (2.0 g, 6.83 mmol) in anhydrous acetonitrile (200 cm^3) was irradiated with RPR-350-nm lamps through a Pyrex filter for 5 h. After the solvent was evaporated, the resulting residue was crystallized from ethanol to give colorless crystals of **9** (1.32 g, 73%): Mp 105—106 °C (from EtOH); IR ($CHCl_3$) 1736 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.14 (3H, s), 1.25 (3H, s), 1.27 (3H, s), 1.94 (1H, dXd, J=7.4, 0.8 Hz), 2.04 (1H, d, J=0.8 Hz), 2.40 (1H, d, J=7.4 Hz), 4.53 (1H, s), 4.79 (1H, s), 6.42—7.22 (5H, m); UV (EtOH) 244 (ε 11700) and 291 (2300). Found: *m/z* 265.1472. Calcd for $C_{18}H_{19}NO$: M, 265.1467.

Photoirradiation of 8. A solution of **8** (947 mg, 3.3 mmol) in anhydrous acetonitrile (200 cm^3) was irradiated

with RPR-350 nm lamps through a Pyrex filter. After the solvent was evaporated, the resulting residue was crystallized from hexane to give colorless crystals of **10** (760 mg, 88%): Mp 118—119 °C (from hexane); IR ($CHCl_3$) 1739 cm^{-1}; ^1H NMR (CCl_4) δ=1.19 (3H, s), 1.26 (6H, s), 1.98 (1H, d, J=1.8 Hz), 2.01 (1H, d×d, J=8.0, 1.8 Hz), 2.43 (1H, d, J=8.0 Hz), 4.72 (1H, s), 4.84 (1H, s), 6.54—7.28 (5H, m); UV (EtOH) 236 (ε 14800), 275 (sh, 2120), and 284 (sh, 1480). Found: m/z 265, 1451. Calcd for $C_{18}H_{19}NO$: M, 265.1467.

Cycloaddition of 9 with MNO. A solution of **9** (200 mg, 0.78 mmol) and MNO (122 mg, 0.78 mmol) in anhydrous benzene (5 cm^3) was heated under reflux for 6 h. After the solvent was evaporated, the residue was separated by TLC on silica gel using chloroform-benzene (1/1) as developer. The first band from the TLC plates contained 186 mg (58%) of the adduct **11**. The second band from the TLC plates gave 75 mg (23%) of the adduct **12**. For **11**: Mp 162—163 °C (from EtOH); IR ($CHCl_3$) 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (3H, s), 1.36 (3H, s), 1.37 (3H, s), 1.50 (1H, s), 2.05 (1H, d, J=2.5 Hz), 2.07 (1H, d, J=2.5 Hz), 2.25 (9H, s), 3.24 (1H, d, J=19.4 Hz), 3.34 (1H, d, J=19.4 Hz), 6.56—7.17 (7H, m); MS m/z (rel intensity) 426 (M^+, 62), 77 (100). Found: C, 78.84; H, 7.04; N, 6.70%. Calcd for $C_{28}H_{30}N_2O_2$: C, 78.84; H, 7.09; N, 6.57%. For **12**: Mp 214—216 °C (from EtOH); IR ($CHCl_3$) 1747 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23 (3H, s), 1.34 (3H, s), 1.37 (3H, s), 1.57 (1H, s), 2.08 (1H, d, J=1.8 Hz), 2.17 (1H, d, J=1.8 Hz), 2.32 (9H, s), 3.22 (1H, d, J=17.4 Hz), 3.29 (1H, d, J=17.4 Hz), 6.60—7.24 (7H, m); MS m/z (rel intensity) 426 (M^+, 19), 118 (100). Found: m/z 426. 2338. Calcd for $C_{28}H_{30}N_2O_2$: M, 426.2307.

Cycloaddition of 10 with MNO. A solution of **10** (265 mg, 1 mmol) and MNO (161 mg, 1 mmol) in anhydrous benzene (5 cm^3) was heated under reflux for 5 h. After the solvent was evaporated, the resulting residue was separated by TLC on silica gel using dichloromethane-benzene (2/1) as developer to give the adducts, **13** (323 mg, 76%) and **14** (43 mg, 10%). For **13**: Mp 196—198 °C (from EtOH); IR ($CHCl_3$) 1744 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (3H, s), 1.34 (3H, s), 1.38 (3H, s), 1.61 (1H, s), 2.09 (1H, d, J=2.0 Hz), 2.17 (1H, d, J=2.0 Hz), 2.32 (9H, s), 3.23 (1H, d, J=17.6 Hz), 3.29 (1H, d, J=17.6 Hz), 6.69—7.42 (7H, m) Found: m/z 426.2314. Calcd for $C_{28}H_{30}N_2O_2$: M, 426.2307. For **14**: Mp 191—192 °C (from EtOH); IR ($CHCl_3$) 1738 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28 (3H, s), 1.37 (3H, s), 1.41 (3H, s), 1.69 (1H, s), 2.28 (9H, s), 2.21—2.45 (2H, m), 3.03 (1H, d, J=17.4 Hz), 3.14 (1H, d, J=17.4 Hz), 6.72—7.41 (7H, m). Found: m/z 426.2314. Calcd for $C_{28}H_{30}N_2O_2$: M, 426.2307.

Thermal Reaction of 9. A solution of **9** (100 mg, 0.38 mmol) in 1,2-dimethylbenzene (2 cm^3) was heated under reflux for 20 min. After the solvent was evaporated, the mixture was then separated by TLC on alumina using hexane as developer. The first band from the TLC plates contained **16** (15 mg, 15%). The second band from the TLC plates contained **9** (77 mg, 77%). For **16**: Mp 105—106 °C (from Et_2O); IR (CCl_4) 1742 cm^{-1}; ^1H NMR (CCl_4) δ=1.03 (3H, s), 1.35 (3H, s), 2.33 (1H, d, J=7.3 Hz), 2.71 (1H, d, J=7.3 Hz), 3.51 (1H, d, J=10.3 Hz), 4.12 (1H, d×d×d, J=10.3, 3.2, 2.0 Hz), 4.75 (1H, s), 4.97 (1H, s), 5.06 (1H, d, J=3.2 Hz), 5.10 (1H, d, J=2.0 Hz), 6.35—7.25 (5H, m). Found: m/z 265.1440. Calcd for $C_{18}H_{19}NO$: M, 265.1467.

Thermal Reaction of 10. A solution of **10** (100 mg, 0.38 mmol) in 1,2-dimethylbenzene (1.5 cm^3) was heated under reflux for 2.5 h. After the solvent was evaporated, the residue was separated by TLC on alumina using hexane-benzene (2/1). The first band from the TLC plates gave **18** (21 mg, 21%). The second band from the TLC plates contained **10** (79 mg, 79%). For **18**: Mp 119—120 °C (from Et_2O); IR ($CHCl_3$) 1735 cm^{-1}; ^1H NMR (CCl_4) δ=1.06 (3H, s), 1.36 (3H, s), 2.39 (1H, d, J=7.2 Hz), 2.70 (1H, d, J=7.2 Hz), 3.35 (1H, broad d, J=10.8 Hz), 4.08 (1H, broad d, J=10.8 Hz), 4.79 (1H, s), 4.92 (1H, s), 5.12 (2H, m), 6.34—7.28 (5H, m). Found: m/z 265.1451. Calcd for $C_{18}H_{19}NO$: M, 265.1467.

Photochemical Reaction of 9. A solution of **9** (810 mg, 3.06 mmol) in anhydrous acetonitrile (50 cm^3) was irradiated with RPR-254 nm lamps in a quartz tube for 4 h. After the solvent was evaporated, the residue was separated by TLC on alumina using hexane-dichloromethane (2/1) as developer to give **16** (285 mg, 35%), the spectral data of which was identical with those of the authentic specimen.

Photochemical Reaction of 10. A solution of **10** (62 mg, 0.23 mmol) in anhydrous acetonitrile (10 cm^3) was irradiated with RPR-254 nm lamps in a quartz tube for 3 h. After the solvent was evaporated, the residue was separated by TLC on silica gel using chloroform-ethyl acetate (5/1) as developer to give **19** (11 mg, 18%): Bp 94 °C (bath temp)/93 Pa; IR (CCl_4) 2978, 2926, 1691, 1601, 1503, 1382, 1143, 900, 700 cm^{-1}; ^1H NMR (CCl_4) δ=1.49 (3H, s), 1.51 (3H, s), 1.85 (3H, d, J=1.6 Hz), 1.94—2.10 (2H, m), 5.27—5.50 (3H, m), 6.67—7.74 (5H, m); MS. m/z (rel intensity) 265 (M^+ 12), 250 (14), 146 (22), 119 (15), 77 (100). Found: m/z 265.1491. Calcd for $C_{18}H_{19}NO$: M, 265.1467.

Photochmeical Reaction of 20. A solution of **20** (100 mg, 0.4 mmol) in anhydrous acetonitrile (10 cm^3) was irradiated with RPR-254 nm lamps in a quartz tube for 14 h. After the solvent was evaporated, the residue was separated by TLC on silica gel using benzene-ethyl acetate (2/1) as developer to give **20** (53 mg, 53%) and **21** (30 mg, 30%). For **21**: Bp 110 °C (bath temp)/528 Pa; IR (CCl_4) 3030, 2985, 2915, 1656, 1597, 1492, 1385, 1121, 891 cm^{-1}; ^1H NMR (CCl_4) δ=1.02 (3H, s), 1.33 (3H, s), 1.86—2.13 (1H, m), 2.36 (1H, d, J=6.0 Hz), 4.71 (1H, s), 4.76 (1H, s), 5.54 (1H, d, J=8.0 Hz), 5.70 (1H, d×d, J=8.0, 6.0 Hz), 6.51—7.11 (5H, m); MS, m/z (rel intensity), 251 (M^+, 100), 236 (74), 132 (65), 119 (79). Found: m/z 251.1328. Calcd for $C_{17}H_{16}NO$: M, 251.1310.

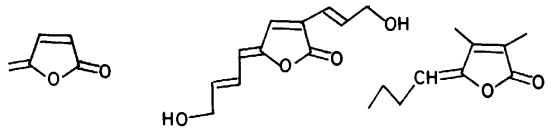
(Received August 11, 1986)

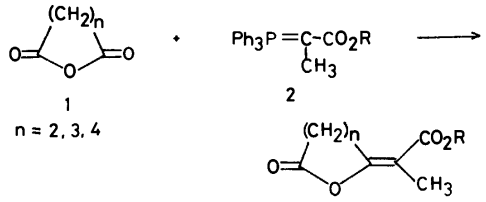
Reactions of glutaric anhydride and methyl- or phenyl-substituted ones with (α-alkoxycarbonylethylidene)-triphenylphosphorane (**2a**, ethoxy; **2b**, *t*-butoxy) gave the corresponding 6-alkoxycarbonyl-5-hepten-5-olides (**3**) and 6-alkoxycarbonyl-4-hepten-5-olides in good yields. The reaction proceeded highly stereoselectively to give (*E*)-**3**. The stereochemistry of **3** was determined by an X-ray crystallographic analysis. The reaction of adipic anhydride with **2a** afforded 7-ethoxycarbonyl-5-octen-6-olide, 7-ethoxycarbonyl-5,6-octadienoic acid, and (4*E*, 6*E*)-7-ethoxycarbonyl-4,6-octadienoic acid. A treatment of nonanedioic anhydride with **2a** gave 10-ethoxycarbonyl-8,9-undecadienoic acid, (7*E*,9*E*)-10-ethoxycarbonyl-7,9-undecadienoic acid, and diethyl 2-methyl-2,4-undecadienedioate in low yields.

Enol lactones as well as α-methylene lactones exhibit strong biological activities such as antibiotic activity, carcinogenic properties, and control activity of plant growth.[1] Many naturally occuring enol lactones have been isolated. For example, protoanemonin,[2] tetrenolin,[3] and bovolide[4] are well-known.



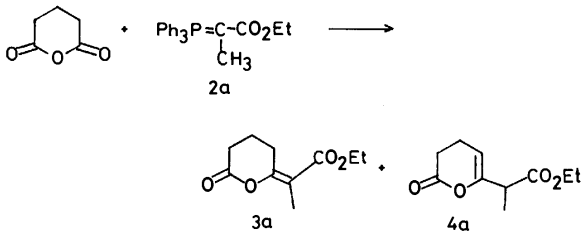
Protoanemonin Tetrenolin Bovolide

Recently, some synthetic methods of enol lactones have been developed.[5-8] We have also reported a facile, highly stereoselective synthesis of (*E*)-enol δ-lactones by the Wittig reaction of glutaric anhydrides (**1**, n=3) with (α-alkoxycarbonylethylidene)triphenylphosphorane (**2**).[9] Here, we report a full description of the previous communication[9] and its further extention to other cyclic anhydrides.



A typical method for the synthesis of enol lactones is the Wittig reaction between stabilized phosphoranes and cyclic anhydrides.[1b] The Wittig reaction of stable phosphoranes with phthalic anhydride or succinic anhydride provides enol γ-lactones in good yield;[1b,10] it has been successfully applied to the syntheses of naturally occuring enol γ-lactones.[11-14] However, Wittig reactions of glutaric anhydrides and acid anhydrides of larger ring with phosphoranes have remained almost uninvestigated. Only Chopard et al. reported that an attempt to prepare enol δ-lactones by the Wittig reaction failed, but resulted in the formation of the ring-opened products.[15]

Recently, we found that a reaction of glutaric anhydride with (α-ethoxycarbonylethylidene)triphenylphosphorane (**2a**) gives 6-ethoxycarbonyl-5-hepten-5-olide (**3a**) (13%) and its *endo*-enol lactone (**4a**) (20%), in contrast to the above result.[15]



The generality of this Wittig reaction was examined by a reaction of various methyl- or phenyl-substituted glutaric anhydrides with phosphorane **2**; the results are shown in Table 1. Most of the reactions gave mixtures of *exo*-enol δ-lactone **3** and *endo*-enol δ-lactone **4**. The geometry of **3** was tentatively assigned as *E*-configuration by a ^{1}H NMR analysis.[9] Namely, the coupling constant between methylene protons of C_4 and methyl protons of the ethylidene group showed a small value (J=1.5 Hz).[16] The reaction of **2** with β-substituted glutaric anhydrides gave predominantly *exo*-enol δ-lactone **3** in good yields. Especially, the reaction of 3-methylglutaric anhydride (**1e**) with **2b** yielded *exo*-enol δ-lactone **3f** in a high yield (86%) along with *endo*-enol δ-lactone **4f** (6%). On the other hand, a reaction of **2** with glutaric anhydride and α-substituted ones afforded *exo*-enol δ-lactone **4** as the major product (except for the reaction of **1d** with **2b**). Treatments of 2-methylglutaric anhydride with **2** provided (*E*)-6-alkoxycarbonyl-2-methyl-5-hepten-5-olide regioselectively. All of the reactions proceeded highly stereoselectively to give only (*E*)-*exo*-enol δ-lactone **3**. A trace amount of the other stereoisomer, (*Z*)-enol δ-lactone, could not be detected.

In order to definitely determine the stereochemistry of *exo*-enol δ-lactone **3**, an X-ray crystallographic analysis of **3d** was carried out representatively; this

a) Isolated yield unless otherwise indicated. b) Estimated by GLC. Analytical sample was purified by preparative GLC (column, 200 °C carrier gas, He, 25 ml min^{-1}): **3a**, R_t 2.6 min; **4a**, R_t 1.6 min. c) Produced together with **5**.

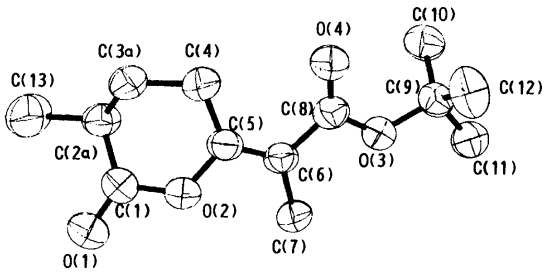

Fig. 1. Perspective view of **3d** drawn by DCMS-3.[17] Only one of the two conformations is shown for the sake of clarity.

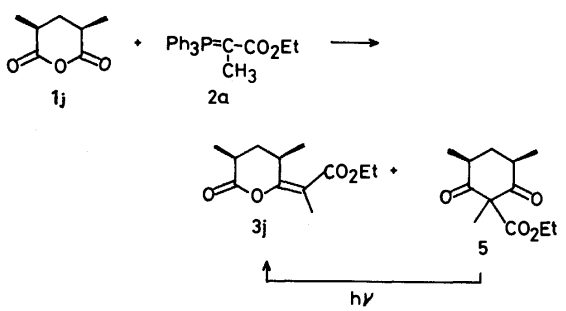
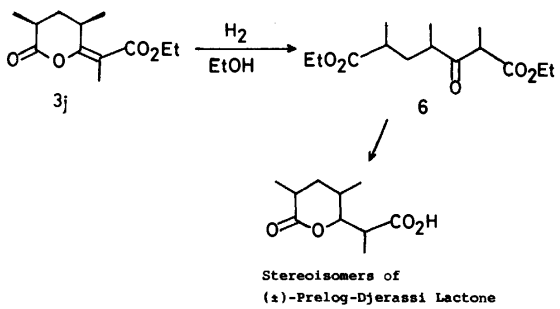
revealed that it has an (*E*)-configuration. A perspective view of **3d** drawn by DCMS-3[17] is shown in Fig. 1.

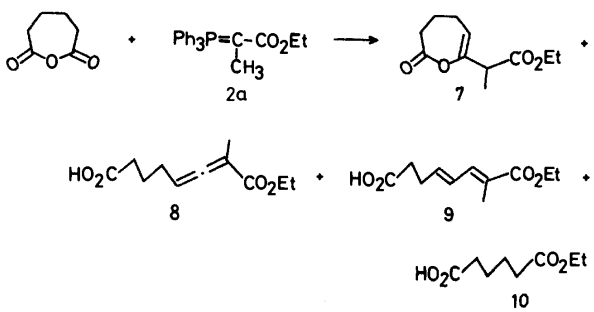
The reaction of *meso*-2,4-dimethylglutaric anhydride (**1j**) with **2a** also afforded a mixture of *exo*-enol δ-lactone **3j** (21%) and 2,6-dioxocyclohexanecarboxylate **5** (7%). The photochemical rearrangement of 1,3-cyclohexanedione to enol δ-lactone is well-known.[18] Irradiation of **5** with a high-pressure Hg lamp in benzene provided **3j** although in a low yield (10%).



Attempted conversion of **3j** to Prelog-Djerassi lactone or its stereoisomers by hydrogenation resulted in the formation of ring-opened product **6** in 91% yield. ^{13}C NMR analysis revealed that it consists of three stereoisomers. It has been reported that the reduction of β-keto ester **6** affords stereoisomers of the racemic Prelog-Djerassi lactone although the stereochemistry could not be evaluated.[19]

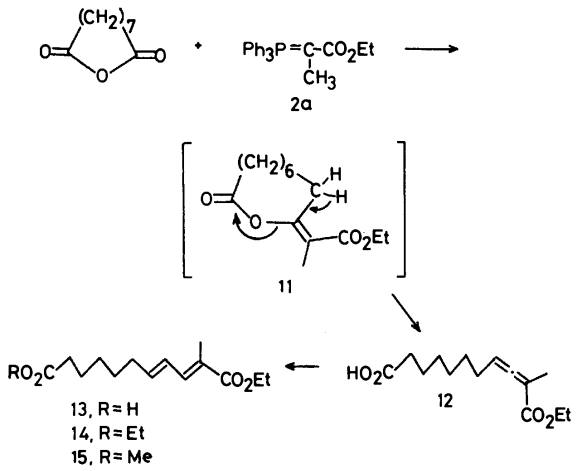


A further extention of the present reaction to other cyclic anhydrides was attempted. The reaction of adipic anhydride with **2a** gave *endo*-enol ε-lactone **7** in 13% yield, accompanied by the formation of ring-opened products, α-allenic ester **8** (4.2% yield) and its isomer **9** (6.3% yield), and ethyl hydrogen adipate (**10**). The structural elucidation of half esters **8** and

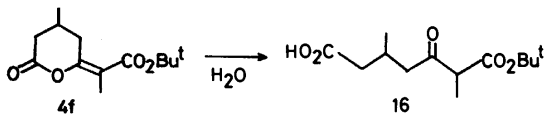


9 was carried out by an analysis of the spectral data of the corresponding methyl ethyl esters. The stereochemistry of **9** was determined by ^{1}H NMR spectral data. Namely, the signal due to C_β H which appeared considerably down field (7.25 ppm) showed α,β-trans geometry.[20] A large coupling constant (J=15.3 Hz) between C_γ H and C_δ H revealed the γ,δ-trans geometry.

A treatment of nonanedioic anhydride with **2a** gave 10-ethoxycarbonyl-8,9-undecadienoic acid (**12**) unexpectedly, although in a low yield. Allene **12** is produced by a prototropic rearrangement of the initially formed *exo*-enol η-lactone **11**. The prolonged reaction gave (7*E*,9*E*)-10-ethoxycarbonyl-7,9-undecadienoic acid (**13**) (20% yield) and its diethyl ester **14** (23% yield), both of which can be produced by a prototropic rearrangement of **12**. The structural assignment of **13** was carried out after a conversion to its methyl ester **15** with diazomethane.



Enol lactones **3** and **4** prepared in this study gradually decomposed with moisture to yield an acid ester. For example, compound **4f** produced 6-*t*-butoxycarbonyl-3,6-dimethyl-5-oxoheptanoic acid (**16**) as a 1 : 1 diastereomeric mixture after 40 days at room temperature.



The structural assignment of the products obtained in the present study was made on the basis of IR and NMR data (Tables 2—5). IR absorptions of *exo*-enol δ-lactone **3** at 1770, 1705, and 1640 cm^{-1} indicate the presence of a δ-lactone ring and a α,β-unsaturated ester group. The *exo*-enol lactone skeleton is also supported by the ^{1}H NMR spectra in which a singlet or a triplet (J=1.5 Hz) at 1.80—1.92 ppm due to methyl group attached to the double bond was exhibited. IR absorptions of *endo*-enol δ-lactone **4** at 1770 and 1740 cm^{-1} indicate the presence of a δ-lactone ring and an isolated ester carbonyl group. The structure of **4** was also supported by ^{1}H NMR data, which exhibited a doublet at δ=1.38 due to the methyl group attached to α-carbon of the ester group and a signal at δ=5.23 due to a olefinic proton of endo enol structure. As a part of a continuing ^{13}C NMR study of organic compounds, the ^{13}C NMR spectra of enol δ-lactones **3** and **4** were measured and assigned with the aid of an off-resonance decoupling technique. For the assignment of ^{13}C NMR spectra of **3h**, two peaks due to secondary

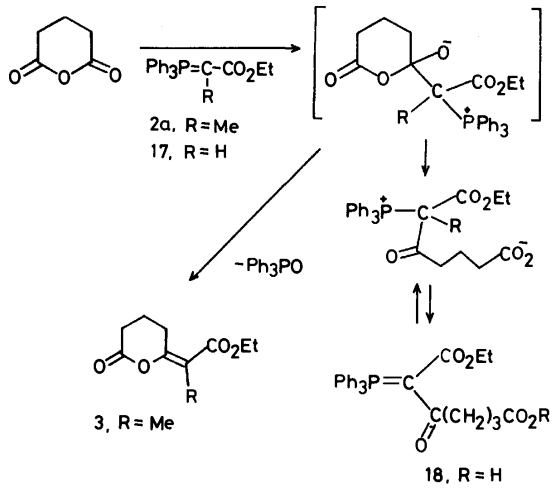
a) Diastereomeric mixture. b) May be interchangeable.

carbon could be assigned using a selective-decoupling technique. The ^{13}C NMR data summarized in Tables 4 and 5 are apparently the first reported for substituted enol δ-lactones, making structural assignments unambiguous.

We briefly discuss the reaction mechanism regarding the present reaction. In contrast to our results, the reaction of (ethoxycarbonylmethylene)triphenylphosphorane (**17**) with glutaric anhydride gave a ring-opened product **18**,[15] which would be stabilized by prototropic rearrangement. Therefore, it would be



necessary for the formation of the desired enol δ-lactones that an alkylidenephosphorane has no hydrogen atom on the α-position. The present reaction is the first synthesis of enol δ- and ε-lactones, and 2,3- or 2,4-dienedioic esters by the Wittig reaction. It will be useful for the synthesis of these derivatives.

Experimental

The melting and boiling points are uncorrected. Elemental analyses were carried out by Eiichiro Amano of our laboratory. IR spectra were obtained with a JASCO Model A-102 infrared spectrophotometer. ^1H NMR spectra (60 MHz) were recorded with a JEOL JNM-PMX60SI apparatus. ^1H NMR (100 MHz) and ^{13}C NMR spectra (25 MHz) were obtained with a JEOL JNM-FX100 apparatus, with $CDCl_3$ as a solvent. All chemical shifts are reported in δ units downfield from the internal Me_4Si; *J* values are given in hertz. Analytical determinations by GLC were performed on a Hitachi Model 163 gas chromatograph fitted with 10% Apiezone Grease L on Chromosorb W column (3 mm o.d.×1 m). Preparative GLC was performed on a Yanagimoto Model G-80 gas chromatograph fitted with 10% Apiezone Grease L on Chromosorb W column (3 mm o.d.×1 m). Column chromatography was accomplished with a 100—200 mesh Wakogel C-200. Chloroform was dried over $CaCl_2$ and distilled prier to use. The Wittig reaction was carried out under dry conditions.

(α-Ethoxycarbonylethylidene)triphenylphosphorane (**2a**) and (α-*t*-buthoxycarbonylethylidene)triphenylphosphorane (**2b**) were prepared by the method described in the literature.[21] Glutaric anhydride was purchased from Tokyo Kasei Kogyo Co., LTD. Substituted glutaric anhydrides were obtained by the known methods:[22-27] 2-methylglutaric anhydride, bp 130 °C/10 Torr (1 Torr=133.322 Pa) (lit,[24] 180—182 °C/25 Torr); 3,3-dimethylglutaric anhydride, bp 122 °C/12 Torr (lit,[25] 181 °C/25 Torr); 2,4-dimethylglutaric anhydride, bp 117—119 °C/4.5 Torr (lit,[26] 154—158 °C/20 Torr); mp 91—92 °C (lit,[26] 91.5 °C); ^{13}C NMR ($CDCl_3$) δ=15.8 (q), 33.0 (t), 36.8 (d), 170.4 (s); 3-phenylglutaric anhydride, mp 104—105 °C (lit,[27] 105 °C).

Some Wittig reactions were shown representatively.

6-*t*-Butoxycarbonyl-4-hepten-5-olide (4b). To a mixture of glutaric anhydride (0.50 g, 4.39 mmol) and **2b** (2.1 g, 5.49 mmol) was added 4 ml of dry $CHCl_3$ under N_2 and the solution was heated at the reflux temperature for 21 h. After removing the solvent, 30 ml of petroleum ether was added and the mixture was stirred at 40 °C for 3 h and then cooled. After filtration, concentration of the filtrate gave 0.962 g of crude **4b**, which was distilled to give 0.342 g (35%) of **4b**: Bp 135—155 °C/0.22 Torr. Spectral and analytical data are shown in Tables 3 and 5.

(5*E*)-6-*t*-Butoxycarbonyl-2-methyl-5-hepten-5-olide (3c) and 6-*t*-Butoxycarbonyl-2-methyl-4-hepten-5-olide (4c). A solution of 2-methylglutaric anhydride (0.50 g, 3.91 mmol) and **2b** (1.50 g, 3.92 mmol) in 7 ml of dry $CHCl_3$ was heated at the reflux temperatere for 12 h. After concentration, the residue was mixed with petroleum ether. After filtration, the filtrate was concentrated to give 0.938 g of crude product; this was chromatographed on SiO_2 (hexane/ether (20:1—1:1)) to give 0.355 g (38%) of **3c** as crystals (mp 71—72 °C) from the early fraction and 0.307 g (33%) of **4c** as a clean oil from the later fraction. Spectral and analytical data are shown in Tables 2, 3, 4, and 5.

(5*E*)-6-*t*-Butoxycarbonyl-2-methyl-5-hepten-5-olide (3f) and 6-*t*-Butoxycarbonyl-2-methyl-4-hepten-5-olide (4f). A solution of 3-methylglutaric anhydride (0.22 g, 1.72 mmol) and **2b** (0.85 g, 2.18 mmol) in 2 ml of dry $CHCl_3$ was heated at the reflux temperature for 12 h. After concentration, the residue was mixed with petroleum ether and then filtered. After filtration, the filtrate was concentrated and the residue was chromatographed on SiO_2 (hexane/ether (20:1—2:1)) to give 0.354 g (86%) of **3f** from the early fraction and 25 mg (6%) of **4f** from the later fraction. Spectral and analytical data are shown in Tables 2, 3, 4, and 5.

(5*E*)-2,4-Dimethyl-6-ethoxycarbonyl-5-hepten-5-olide (3j) and Ethyl 1,3,5-Trimethyl-2,6-dioxocyclohexanecarboxylate (5). A solution of 2,4-dimethylglutaric anhydride (0.50 g, 3.52 mmol) and **2a** (1.30 g, 3.59 mmol) in 4 ml of $CHCl_3$ was heated at the reflux temperature for 13 h. After removing the solvent, the residue was mixed with petroleum ether and filtered. The filtrate was concentrated to give 0.434 g of the residue. Preparative TLC (SiO_2, hexane/ether (3:1)) gave 0.169 g (21%) of **3j** as an oil at R_f value 0.31. Spectral and analytical data are shown in Tables 2 and 4. The component of R_f value 0.18 gave 53 mg (7%) of **5** as an oil: IR (neat)1760, 1740, 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (6H, d, *J*=7 Hz), 1.24 (3H, t, *J*=7 Hz), 1.47 (3H, s), 1.62—2.50 (2H, m), 2.5—3.28 (2H, m), and 4.22 (2H, q, *J*=7 Hz); ^{13}C NMR ($CDCl_3$) δ=13.7 (q), 14.2 (q), 14.5 (q), 20.1 (q), 35.1 (t), 43.1 (d), 62.4 (t), 71.0 (s), 168.9 (s), 202.4 (s). Found: C, 63.41; H, 7.78%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

X-Ray Crystallographic Analysis of 3d. The unit-cell constants and intensities were measured at room temperature using Ni-filtered Cu *Kα* radiation on a Rigaku four-circle diffractometer. Crystal data are as follows: $C_{13}H_{20}O_4$, M=

240.3, monoclinic, space group $P2_1/a$, a=24.452(5), b=6.089(2), c=9.206(3) Å, β=99.72(3)°, V=1351.0 Å^3, Z=4, D_c=1.18 g cm^{-3}. Due to broad diffraction profiles ω-scan technique was applied with a scan width of 2.0°+0.15°tanθ. The backgrounds were counted for 4 s at the start and end points of the scan. Of the 2001 independent reflections measured up to 2θ=120°, 1579 reflections with $F>3\sigma$ were used for the structure analysis. The intensities were corrected for the Lorentz and polarization factors. The structure was solved by the direct method,[28] and refined by the block-diagonal least-squares method.[29] Each of the two carbon atoms (C(2) and C(3)) has two sites, and their occupancies were fixed to be 0.5 during the refinement. Most of the hydrogen atoms were located in the difference Fourier synthesis calculated after the refinement with anisotropic temperature factors for the non-hydrogen atoms; the electron density distribution around C(13) was too broad to locate hydrogen atoms. The two positions were calculated for each hydrogen atom bonded to C(2), C(3), and C(4), and their occupancies given 0.5. The contribution of these hydrogen atoms were included in the refinement with their parameters being fixed. The other hydrogen atoms were refined with isotropic temperature factors. The unit weight was given for all reflections. The final R value was 0.066 for 1579 reflections. The atomic-scattering factors were taken from the International Tables for X-ray Crystallography.[30] The final atomic parameters are given in Table 6.[31]

$B_{eq} = \frac{4}{3}\sum_i\sum_j \beta_{ij} a_i a_j$.

Photochemical Rearrangement of 5 to 3j. Following a procedure described in the literature,[18] a solution of **5** (0.20 g, 0.83 mmol) in 10 ml of benzene was irradiated with a 200-W high-pressure Hg lamp (quartz jacket) from a distance of 4 cm under an N_2 atmosphere at room temperature for 65 h. After evaporating the solvent, the residual oil was purified with preparative TLC (SiO_2, hexane/ether (3 : 1)) to give 21 mg (10%) of **3j**: R_f value 0.31. Spectral data were identical with those of an authentic sample. The fraction of R_f value 0—0.2 gave a mixture of unidentified materials.

Preparation of Diethyl 3-Oxo-2,4,6-trimethylheptanedioate (6)[19] by the Hydrogenation of 3j. A mixture of **3j** (0.10 g, 0.42 mmol), dry ethanol (3 ml), Pd/$BaSO_4$ (14 mg),[32] and $FeCl_3$ (60 mg) was stirred under H_2 atmosphere for 8 h at room temperature. After filtration, the organic materials were extracted with ether. The combined extracts were washed with water, and dried over $MgSO_4$. Removal of the solvent gave a pale brown oil, which was purified by preparative TLC (SiO_2, hexane/ethyl acetate (4 : 1), R_f value 0.47) to give 74 mg of **6**:[19] IR (neat) 1740, 1720, 1182, 760 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.1 (9H, m), 1.20 (6H, t, J=7 Hz), 1.5—3.0 (4H, m), 3.6 (1H, q, J=7 Hz), 4.07 (2H, q, J=7 Hz), 4.12 (2H, q, J=7 Hz); ^{13}C NMR ($CDCl_3$) δ=12.8 (q), 13.0 (q), 14.0 (q), 14.2 (q), 15.9 (q), 16.4 (q), 17.2 (q), 17.5 (q), 17.6 (q), 17.8 (q), 17.9 (q), 35.9 (t), 36.1 (t), 36.5 (t), 36.9 (d), 37.1 (d), 37.3 (d), 43.2 (d), 43.5 (d), 43.7 (d), 51.0 (d), 51.3 (d), 52.0 (d), 60.3 (q), 60.4 (q), 170.3 (s), 175.9 (s), 176.1 (s), 176.2 (s). Found: C, 61.47; H, 8.91%. Calcd for $C_{14}H_{24}O_5$: C, 61.74: H, 8.88%.

Reaction of Adipic Anhydride with 2a. Synthesis of 7-Ethoxycarbonyl-5-octen-6-olide (7), 7-Ethoxycarbonyl-5,6-octadienoic Acid (8), and (4*E*,6*E*)-7-Ethoxycarbonyl-4,6-octadienoic Acid (9). A solution of adipic anhydride (0.90 g, 7 mmol) and **2a** (2.69 g, 7.4 mmol) in 7 ml of dry $CHCl_3$ was heated at the reflux temperature for 13 h. After concentration, the residue was chromatographed on SiO_2 (hexane/ethyl acetate (10 : 1–1 : 1)). Concentration of the early fraction gave 0.187 g (13%) of **7**: IR (neat) 1760, 1735, 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.23 (3H, t, J=7 Hz), 1.38 (3H, d, J=6 Hz), 1.6—3.0 (6H, m), 3.25 (1H, q, J=5 Hz), 4.12 (2H, q, J=7 Hz), 5.42 (1H, t, J=6 Hz). Found: C, 62.42; H, 7.46%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%. Concentration of the second fraction gave 0.246 g of carboxylic acids which were treated with diazomethane. HPLC analysis [SA-I, 6ϕ×250; hexane/ethyl acetate (2 : 1)] of the methylated products showed 4 peaks. The peaks, retention times (min), and integrated percentages are as follow: 1, 12.6, 25%; 2, 13.7, 38%; 3, 15.2, 19%; 4, 16.6, 16%. Each component was collected by preparative HPLC and identified.

1-Ethyl 8-Methyl 2-Methyl-2,3-octadienedioate (Methyl Ester of 8): Peak 1; 4.2% yield; IR (neat) 1961, 1740, 1710, 1270, 1110 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, t, J=7 Hz), 1.86 (3H, d, J=3.5 Hz), 1.60—1.92 (2H, m), 2.12 (2H, t, J=7 Hz), 2.36 (2H, t, J=7 Hz), 3.67 (3H, s), 4.18 (2H, q, J=7 Hz), and 5.40 (1H, m). Found: C, 63.55; H, 7.78%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

(2*E*,4*E*)-1-Ethyl 8-Methyl 2-Methyl-2,4-octadienedioate (Methyl Ester of 9): Peak 2; 6.3% yield; IR (neat) 1740, 1710, 1640, 1240, 760 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.29 (3H, t, J=7 Hz), 1.92 (3H, s), 2.46 (4H, s), 3.67 (3H, s), 4.18 (2H, q, J=7 Hz), 6.0 (1H, m), 6.39 (1H, dd, J=10.6 and 15 Hz), 7.25 (1H, d, J=10.6 Hz). Found: C, 63.64; H, 8.11%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

Peak 3: *N*-Methyl-*N*-nitroso-*p*-toluenesulfonamide (diazomethane source). IR and ^{1}H NMR spectra were identical with those of an authentic sample.

Ethyl Methyl Adipate (Methyl Ester of 10):[33] Peak 4: 3.2% yield: IR and ^{1}H NMR spectra were identical with those of an authentic sample.

10-Ethoxycarbonyl-8,9-undecadienoic Acid (12). A solution of azelaic anhydride (2.26 g, 0.0133 mol) and **2a** (4.88 g, 0.0133 mol) in 14 ml of dry $CHCl_3$ was heated at the reflux temperature for 12 h. After removing the solvent, 40 ml of petroleum ether was added and the mixture was stirred for 3 h and then filtered. The concentration of the filtrate gave an

oil (0.706 g) which was chromatographed on SiO_2 (hexane/ether (20 : 1–1 : 1)). Concentration of the early fraction gave 0.255 g of a mixture of unidentified products. The later fraction gave 0.338 g (10%) of **12** as an oil: IR (neat) 3700—2200, 1960, 1740, 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.6—1.8 (10H, m), 1.83 (3H, d, J=3 Hz), 2.02—2.60 (4H, m), 4.19 (2H, q, J=7 Hz), 5.40 (1H, m), 10.2 (1H, s); ^{13}C NMR ($CDCl_3$) δ=14.3 (q), 15.2 (q), 24.6 (t), 24.9 (t), 27.9 (t), 28.6 (t), 28.9 (t), 34.0 (t), 60.8 (t), 93.7 (d), 95.7 (s). Found: C, 65.98; H, 8.68%. Calcd for $C_{14}H_{22}O_4$: C, 66.12; H, 8.72%.

(7*E*,9*E*)-10-Ethoxycarbonyl-7,9-undecadienoic Acid (13) and 1-Ethyl 11-Methyl (2*E*,4*E*)-2-Methyl-2,4-undecadienedioate (14). A solution of azelaic anhydride (0.172 g, 1.01 mmol) and **2a** (0.366 g, 1.01 mmol) in 2 ml of dry $CHCl_3$ was heated at the reflux temperature for 21 h. After removing the solvent, 30 ml of petroleum ether was added and the mixture was stirred for 1 h and then filtered. Concentration of the filtrate gave a semisolid (0.445 g) which was separated by preparative TLC [SiO_2, hexane/ethyl acetate (1 : 1)]. **14**: 64 mg (23% yield); R_f 0.90; IR (neat) 1730, 1702, 1640, 1235, 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23 (3H, t, J=6 Hz), 1.30 (3H, t, J=6 Hz), 1.2—1.8 (6H, m), 1.92 (3H, s), 2.0—2.5 (4H, m), 4.13 (4H, m), 5.9—6.6 (2H, m), 7.10 (1H, d, J=11 Hz). The component of the carboxylic acid (R_f 0.37—0.63) was treated with diazomethane to give 172 mg of a clean oil which was chromatographed on preparative HPLC [column, SA-I, 6ϕ×250 mm; eluent, hexane/ethyl acetate (5 : 1), 1.3 ml min^{-1}].

(2*E*,4*E*)-1-Ethyl 11-Methyl 2-Methylundeca-2,4-dienedioate (15) (Methyl Ester of 13): R_t 10.0 min; 52 mg (19% yield); IR (neat) 1740, 1703, 1640, 1235, 1102, 970, 750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (3H, t, J=7 Hz), 1.58 (6H, s), 2.24 (4H, m), 3.66 (3H, s), 4.18 (2H, q, J=7 Hz), 6.33 (1H, dd, J=11 and 14.7 Hz). Found: C, 67.15; H, 8.81%. Calcd for $C_{15}H_{24}O_4$: C, 67.14; H, 9.01%.

Ethyl Methyl Nonanedioate:[34] R_t 10.5 min; 43 mg; IR (neat) 1740, 1175, 1100, 1035 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.24 (3H, t, J=6 Hz), 1.60 (10H, m), 2.32 (4H, m), 3.67 (3H, s), 4.12 (2H, q, J=6 Hz). The other component (55 mg, R_t 15 min) was identified as *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide by a comparison of the spectral data with that of an authentic sample.

6-*t*-Butoxycarbonyl-3,6-dimethyl-5-oxoheptanoic Acid (16). Compound **4f** (25 mg) was left at room temperature for 40 days to give 26 mg (97% yield) of **16** as a mixture of two diastereomers: IR (neat) 3500—2500, 1740, 1715 cm^{-1}; ^1H NMR (CCl_4) δ=0.95 (3H, d, J=6 Hz), 1.20 (3H, d, J=7 Hz), 1.42 (9H, s), 1.6—2.6 (5H, m), 3.25 (1H, q, J=6 Hz), 7.40 (1H, s); ^{13}C NMR ($CDCl_3$) δ=12.5 (q), 19.8 (q), 25.7 (d), 27.8 (q), 40.2 (t), 47.3 (t), 53.9 (d), 54.1 (d), 81.8 (s), 169.5 (s), 178.0 (s), 204.9 (s), 205.0 (s). Compound **16** was converted to its methyl ester with diazomethane, purified by preparative TLC [hexane/ethyl acetate (3 : 1), R_f 0.37], and analyzed.

1-*t*-Butyl 7-Methyl 2,5-Dimethyl-3-oxoheptanedioate: IR (neat) 1730, 1705, 1365, 1155, 1010, 845 cm^{-1}; ^1H NMR (CCl_4) δ=0.98 (3H, d, J=6 Hz), 1.19 (3H, d, J=6 Hz), 1.43 (9H, s), 2.06—2.78 (5H, m), 3.30 (1H, q, J=7 Hz), 3.59 (3H, s). Found: C, 61.83; H, 8.96%. Calcd for $C_{14}H_{24}O_5$: C, 61.74; H, 8.88%.

We thank the whole staff of the Crystallographic Research Center of Osaka University for permitting us to use the fourcircle diffractometer.

(Received August 12, 1986)

Twelve peptides having 4 to 6 basic amino acid residues in the hydrophobic amino acid sequence were designed and synthesized by the solution method to find peptides with potential activity against Gram-positive and -negative bacteria. CD study of the peptides demonstrated that they formed α-helical structures in the presence of phospholipid liposomes consequently to have amphiphilic property along the axis of helix. The peptides also induced the leakage of the dye carboxyfluorescein from phospholipid vesicles, indicating that the peptides possess the ability to perturb the membrane structure. These peptides showed antibacterial activity against Gram-positive bacteria, and some of them were also active against Gram-negative bacteria. Relationships between the structure and antibacterial activity of the synthetic peptides were discussed.

Recently, an amphiphilic α-helical structure, especially that containing basic amino acids, has been found to be a common factor in several biologically active peptides, e.g., plasma apolipoproteins,[1,2] calmodulin-binding peptides,[3,4] bee venom toxins[5,6] and antibacterial peptides.[7-10] Previously, we reported[11,12] that the basic model peptides, e.g., Ac-(Leu-Ala-Lys-Leu)$_{3,4}$-NHCH$_3$ ($\mathbf{4}_3$, $\mathbf{4}_4$), which were designed from the common feature of extension peptides of mitochondrial protein precursors, showed inhibition of import of the precursors to mitochondria, antibacterial activity against Gram-positive bacteria and perturbation of mitochondrial membrane and phospholipid bilayer. Their antibacterial activities were also correlated to the secondary structure of the peptides.[12] Thus, simple model peptides designed can be used as an effective tool to clarify the structure proposed for biological activity.

DeGrado reported[13] that a simple amphiphilic α-helical peptide, Fmoc-(Leu-Lys-Lys-Leu-Leu-Lys-Leu)$_{2\bar{7}}$OH (F),[14] which was designed from cecropin,[7,8] a naturally occurring cationic amphiphilic antibiotic, showed the same strong antibacterial activity as cecropin against Gram-positive and -negative bacteria. Ando et al.[15] reported that an analog of gramicidin S (GS), [D-2,3-diaminopropionic acid (D-Dpr)$^{4,4'}$]GS, had an activity against Gram-positive and -negative bacteria, although GS which has a cationic amphiphilic structure with antiparallel β-sheet and β-turn is only active against Gram-positive bacteria. The reason of the difference in the activity against Gram-negative bacteria between the model peptide $\mathbf{4}_3$ or GS and peptide F or [D-Dpr$^{4,4'}$]GS should be due to the num-

ber of basic amino acids and the secondary structure, i.e., amphiphilicity. In order to study the relationships between the activity against Gram-positive or -negative bacteria and the property of amphiphilic peptides, we have designed and synthesized several basic peptides as shown in Fig. 1, and examined antibacterial activities of the peptides and their secondary structures by CD measurements. Phase-transition release experiment of carboxyfluorescein from DPPC vesicles using the peptides was also performed in order to examine whether the ability to perturb bacterial membrane relates to the antimicrobial activity.

Results

Design. The model peptides (Fig. 1) were designed on the basis of the structures of 4_3 and 4_4 showing the strongest antimicrobial activity among the previously synthesized model peptides[12] and of peptide F taking amphiphilic α-helical structure and having the activity against Gram-positive and -negative bacteria.[13] The structural differences between 4_4 and F are just the number of basic amino acids and distribution of the Lys residues in hydrophobic sequences. Therefore, to develop peptides active against Gram-negative bacteria, the number and distribution of basic amino acid Lys were altered in the peptides. In compounds **1**—**8**, one or two additional Lys residues are distributed into 4_3 or 4_4 to keep amphiphilicity postulating that these peptides take α-helices. The sequence of **5** is almost the same as that of peptide F except for the acetyl group and the Ala residues in **5** instead of the Fmoc group and the Leu residues in F, respectively. Peptides **9** and **10** were designed to disturb the amphiphilic

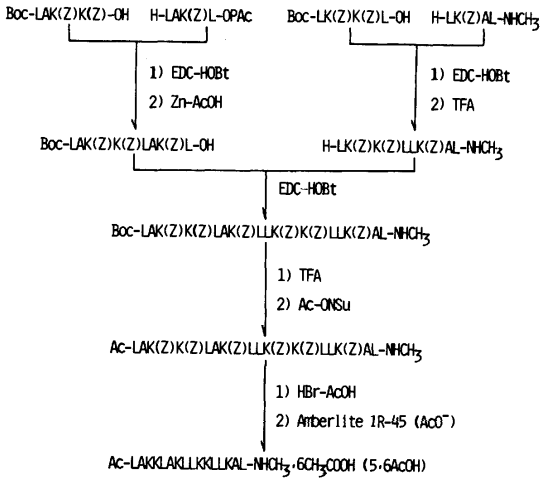

Fig. 3. Synthetic route for Ac-hexadecapeptide-$NHCH_3$ (**5**).

property by the substitution of Lys for the Leu residues in hydrophobic cluster. Orientation of the Lys residues in peptide **11** with α-helical structure is topologically similar to that of four basic amino acid residues in [D-Dpr$^{4,4'}$]GS. α-Helical nets and wheels of representative peptides are shown in Fig. 2. In peptide **12**, the Leu and Lys residues lie straight along the axis of the α-helix. Moreover, peptide L-4_3 containing Leu residues instead of Ala residues in 4_3 and peptide F were also synthesized.

Synthesis. The synthetic route for **5** is shown in Fig. 3. The tetrapeptides were prepared by stepwise elongation of the Boc-amino acid active esters.[16] The Boc-dipeptide-OPac was prepared by the mixed anhydride method.[17] After the cleavage of phenacyl ester

or Boc group, the tetrapeptides were coupled by the EDC-HOBt method[18] to give Boc-octapeptide-OPac or $-NHCH_3$. The phenacyl ester and Boc group were removed with Zn powder in acetic acid and with TFA, respectively. The resulting acid and amine components were coupled by the EDC-HOBt method to give Boc-hexadecapeptide-$NHCH_3$. The Boc group was cleaved with TFA followed by acetylation with Ac-ONSu to give Ac-peptide-$NHCH_3$. The Z groups were removed with 25% HBr in AcOH and peptide hydrobromide obtained was passed through a column of Amberlite IR-45 (acetate form) to give **5** as a tetraacetate. The purity was confirmed by TLC, paper electrophoresis, amino acid analysis and elemental analysis. Other peptides were prepared similarly. Yields and physical constants of protected peptides and final products are shown in Tables 1 and 2.

Antibacterial Activity. Antibacterial assays were

carried out by both agar dilution[19] and serial dilution method in solution medium.[20] The results of antibacterial assay of the peptides are listed in terms of minimum inhibitory concentration of growth (MIC) in Table 3 compared with that of peptide $\mathbf{4}_3$, $\mathbf{4}_4$, GS, [D-Dpr$^{4,4'}$]GS and polymyxin B (PM). In agar dilution method, present model peptides (**1**—**12** and L-$\mathbf{4}_3$) revealed weak activity against Gram-positive bacteria as compared with peptide $\mathbf{4}_3$ and GS. On the other hand, peptides with the increased number of the Lys residues (**1** and **9**) showed weak but substantial activity against Gram-negative bacteria such as *E. coli*. On the contrary, by means of serial dilution method in solution medium, all the peptides examined were active against both Gram-positive and -negative bacteria. Especially peptides **1** and **5** showed stronger activity against *E. coli* than GS did. These results indicate that increase in the number of the Lys residues leads to decrease in the activity against Gram-positive bacteria and increase in that against Gram-negative bacteria. It is noteworthy that the decrease in activity of the peptides against *S. aureus* was more marked than that against *B. subtilis*, this fact being comparable to the result that PM was inactive against *S. aureus* although strongly active against Gram-negative bacteria. Non-amphiphilic peptides (**9** and **10**) showed fairly high activity, suggesting that amphiphilic character is indeed important, but not essential for the activity against Gram-positive bacteria, especially *B. subtilis*. Deviation in distribution of the Lys residues from pep-

tide **4**$_4$ resulted in decreased activity **12**, indicating that the specific sequence and secondary structure in **4**$_3$ (Figs. 1 and 2) are important to show strong activity against Gram-positive bacteria. It is interesting that the [D-Dpr$^{4,4'}$]GS-resembling peptide (**11**) showed the same activity against Gram-positive and -negative bacteria as peptide **4**$_4$, also indicating the significance of the specific structure. Replacement of the Ala residues in peptide **4**$_3$ by the Leu residues (L-**4**$_3$) caused marked decrease in the activity, indicating that increase of the hydrophobicity in the peptide is not important to show the activity, but the Ala residues are important to show the activity. Generally, the peptides with the length of 12 residues showed higher activity against Gram-positive bacteria than those with 16 residues. This finding is comparable to the fact that peptide **4**$_3$ (n=12) was more active than **4**$_4$ (n=16).[12] The chain length of a peptide is important for its activity as described previously.[12] Peptide F did not show strong activity against Gram-positive and -negative bacteria on our assay systems contrary to DeGrado's results.[13] This might be due to the different bacterial assay systems, e.g., difference in media and conditions of bacteria.

CD Study. CD spectra of peptide **5** in H_2O and in the presence of phospholipid liposomes are shown in Fig. 4, representatively. Although peptide **5** showed the negative band at 200 nm in H_2O attributable to disordered structure, the spectra in the presence of liposomes showed marked increase in ellipticities of the negative bands at 208 and 222 nm, indicating the formation of α-helical structure in the presence of liposomes. A slight difference was observed between the spectra in the presence of neutral DPPC and acidic DPPC-DPPG (3 : 1) liposomes. α-Helicity of the peptides under various conditions was calculated from the ellipticity at 222 nm[21] and is shown in Table 4. All the peptides took the α-helical structure which was amphiphilic (except for peptides **9** and **10**) along the axis of helix in the presence of liposomes in contrast with the disordered structure in H_2O. These findings are similar to those described for peptides **4**$_3$ and **4**$_4$.[12]

a) Values are intensities of fluorescence at scanning time of 5 min (see Fig. 5 and Experimental). Concentrations of peptides are 0.2 μg ml^{-1} (0.1 μg ml^{-1} in parentheses). b) In the presence of DPPC or DPPC-DPPG (3:1). c) Disordered structure. d) Concentrations are 1.0 μg ml^{-1}.

membrane and the ability of the peptides to perturb membrane, the effect on phase-transition release of carboxyfluorescein from phospholipid vesicles was measured.[22,23] Profiles of fluorescence leakage from the DPPC vesicles by the action of peptides are shown in Fig. 5. The degrees of the leakage of the dye by the peptides are listed in terms of a relative value in Table 4. The peptides leaked the dye effectively at the phase-transition temperature of DPPC vesicles, but the degree of the leakage was lower as compared with $\mathbf{4}_3$. These results indicate that the peptides taking the α-helical structure in the presence of the phospholipid have the ability to perturb the phospholipid bilayer structure at the liquid-crystalline state of the membrane. The perturbing effect of the peptides on acidic DPPC-DPPG (3:1) vesicles was larger than that on neutral DPPC vesicles, indicating the electrostatic interaction of the cationic peptides with the acidic vesicles. It should be noted that cyclic peptides GS and PM have only the low degree of the leakage in contrast with the α-helical peptides.

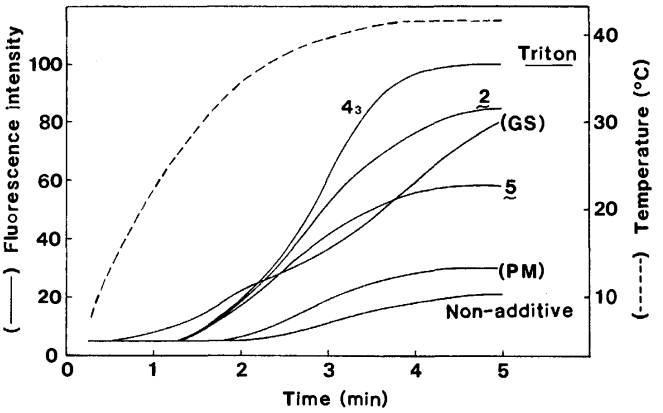

Fig. 5. Profiles of carboxyfluorescein leakage from DPPC vesicles induced by the peptides, GS and PM. Individual peptides were incubated in 2 ml of 0.1 M NaCl/20 mM phosphate buffer (pH 7.4) containing 20 μM DPPC vesicles at temperatures from 0 to 42°C for the indicated scanning time. Peptide concentration: peptide $\mathbf{4}_3$, **2**, and **5** (0.2 μg ml^{-1}); GS and PM (1.0 μg ml^{-1}).

Discussion

Previously,[12] we proposed that α-helical amphiphilicity of the whole peptide molecule, i.e., appropriate positioning of cationic and hydrophobic groups constructed in the stable α-helical structure as shown in the peptides $\mathbf{4}_3$ and $\mathbf{4}_4$, is a significant factor requisite to perturb the membrane of Gram-positive bacteria and to exhibit antibacterial activity against Gram-positive bacteria. We have postulated[12] that the peptide $\mathbf{4}_3$ takes an amphiphilic α-helix on the surface of the membrane of Gram-positive bacteria and the hydrophilic (cationic) side in the helix interacts with the acidic moiety of phospholipid in the membrane and the hydrophobic surface penetrates into the membrane to reveal the antibiosis. Here, the peptides **1**—**12** showed high ability to take α-helical structure in the presence of model membrane (Fig. 4 and Table 4) and to perturb the membrane (Fig. 5 and Table 4), though the abilities were slightly weaker than those of $\mathbf{4}_3$. Antimicrobial activity of the peptides against Gram-positive bacteria was also weaker than that of peptide $\mathbf{4}_3$ (Table 3). The ability of the peptides

and $\mathbf{4}_3$ to interact with model membrane is parallel to the activity against Gram-positive bacteria.

The increase of one or two Lys residues into $\mathbf{4}_3$ and $\mathbf{4}_4$ leads to the increase in the activity against Gram-negative bacteria, and to the decrease in the activity against Gram-positive bacteria, especially against *S. aureus* (Table 3). Polylysine and cecropins are active against both Gram-positive and -negative bacteria.[7,8,24] Polylysine capable to take a helical structure in the presence of phosphatidylserine[25] revealed antimicrobial activity against Gram-negative bacteria, though it has no amphiphilic character. These results indicate that the amphiphilic character of the peptides is not important for the activity against Gram-negative bacteria, but important for the strong activity against Gram-positive bacteria.

The peptide **11** resembling [D-Dpr$^{4,4'}$]GS has four Lys residues in the hexadecapeptide sequence in which distribution of the Lys residues is different from that of peptide $\mathbf{4}_4$ (Fig. 2) and showed the same activity against Gram-positive bacteria as peptide $\mathbf{4}_4$. In view of the low activity of peptide **12** having four Lys residues, the sequence of peptides $\mathbf{4}_3$ and $\mathbf{4}_4$ and another one of peptide **11** are important for the strong activity. However, peptide **11** did not show the activity against Gram-negative bacteria different from [D-Dpr$^{4,4'}$]GS.[15] It is noteworthy that GS has cyclic β-structure which is more rigid than the α-helical structure.

Peptide **12** was designed for the Lys and Leu residues to arrange straight along the axis of helix (Fig. 2) according to repeating heptad sequences $(a\text{-}b\text{-}c\text{-}d\text{-}e\text{-}f\text{-}g)_n$ in which a and e are hydrophobic, and c and g are hydrophilic residues.[26] This peptide showed the low activity against Gram-positive bacteria. Lau et al.[27] reported that the peptides with repeating heptad sequences were inclined to aggregate by forming double-stranded α-helical coiled-coils. The fact that the ability of the fluorescence leakage of peptide **12** was relatively low (Table 4) suggests the presence of such a self-aggregation which weakens the degree of the interaction of the peptide with bacterial membrane resulting in low activity.

It was surprising that replacement of the Ala residues in peptide $\mathbf{4}_3$ by the Leu residue (L-$\mathbf{4}_3$) resulted in 4 and 8 times decrease in activity against *S. aureus* and *B. subtilis*, respectively. This indicates the significance of the Ala residues in the sequence of $\mathbf{4}_3$. α-Helical content also decreased by substituting Leu for Ala (Table 4). These results suggest that the Ala residues in $\mathbf{4}_3$ contribute to the stabilization of α-helix.

It was found that peptide $\mathbf{4}_3$ with specific structure in which the Lys residues twist along the helix (Fig. 2) showed the strongest activity against Gram-positive bacteria, the highest helicity in the presence of liposomes and ability to leak the dye from phospholipid vesicles among the peptides examined.

Experimental

Synthesis of Peptides. TLC was carried out on Merck silica gel G with the following solvent systems: R_f^1, $CHCl_3$-MeOH (5:1); R_f^2, *n*-BuOH-pyridine-AcOH-H_2O (4:1:1:2). Paper electrophoresis was performed on a Toyo Roshi No. 52 paper with the solvent system of HCOOH-AcOH-MeOH-H_2O (1:3:6:10, v/v, pH 1.8) for 3 h at 600 V, the mobility of the peptides being given relative to Lys (R_{Lys}). Optical rotations were measured with a Union high sensitivity polarimeter PM-71. Amino acid analyses were performed on a Hitachi KLA-5 amino acid analyzer after the hydrolysis in 6 M HCl (1 M=1 mol dm^{-3}) in sealed tubes at 110 °C for 24 h.

Representative procedures are described here, and yields and physical constants are summarized in Tables 1 and 2.

Boc-Ala-Lys(Z)-OPac (14). To a mixed anhydride prepared from Boc-Ala-OH (1.52 g, 8.0 mmol), isobutyl chloroformate (1.04 ml, 8.0 mmol) and Et_3N (1.12 ml, 8.0 mmol) in THF (20 ml) was added a solution of H-Lys(Z)-OPac (3.48 g, 8.0 ml) and Et_3N (1.12 ml) in $CHCl_3$ (20 ml) at −10 °C. The mixture was stirred at room temperature for 4 h and evaporated in vacuo. The residue was dissolved in EtOAc, and the solution was washed with 10% citric acid, 4% $NaHCO_3$ and water, and dried over Na_2SO_4. After evaporation, the residue was recrystallized from EtOAc-ether-petroleum ether.

Boc-Ala-Leu-NHCH$_3$ (17). To a chilled solution of H-Leu-NHCH$_3$·HCl (3.05 g, 17 mmol) and Et_3N (2.38 ml, 17 mmol) in DMF (20 ml) was added Boc-Ala-ONSu (4.86 g, 17 mmol). The mixture was stirred at room temperature for 6 h. After evaporation, the residue was dissolved in EtOAc, and washed with 10% citric acid, 4% $NaHCO_3$ and water, and dried over Na_2SO_4. After removal of the solvent, the residue was recrystallized from EtOAc-petroleum ether.

Deprotection of Boc Group in Boc-Ala-Lys(Z)-OPac (14). Compound **14** (5.7 g, 10 mmol) was dissolved in 4 M HCl in dioxane (25 ml) at room temperature for 2 h or in TFA (10 ml) at 0 °C for 30 min. After evaporation, the residue was crystallized by the addition of ether. This was used for the next step without further purification.

Boc-Leu-Ala-Ala-Lys(Z)-OH (41). To a solution of Boc-Leu-Ala-Ala-Lys(Z)-OPac (**32**) (640 mg, 0.85 mmol) in 90% AcOH (10 ml) was added Zn powder (0.6 g) at room temperature. The mixture was stirred at room temperature for 6 h. After filtration, the filtrate was evaporated. To the residue was added 10% citric acid, and the separated oil was extracted with EtOAc and washed with water, and dried over Na_2SO_4. After evaporation, the residue was recrystallized from EtOAc-ether.

Boc-Leu-Ala-Ala-Lys(Z)-Leu-Ala-Lys(Z)-Leu-OPac (59). To a chilled solution of Boc-Leu-Ala-Ala-Lys(Z)-OH (**41**) (636 mg, 1.0 mmol), TFA·H-Leu-Ala-Lys(Z)-Leu-OPac (810 mg, 1.0 mmol), HOBt (270 mg, 2.0 mmol) and Et_3N (0.14 ml, 1.0 mmol) in DMF (10 ml) was added EDC·HCl (288 mg, 1.5 mmol). The mixture was stirred at 0 °C overnight. After evaporation, the residue was solidified by the addition of water. The solid was collected and washed 10% citric acid, 4% $NaHCO_3$ and water, and dried in vacuo.

Ac-Leu-Ala-Lys(Z)-Lys(Z)-Leu-Ala-Lys(Z)-Leu-Leu-Lys(Z)-Lys(Z)-Leu-NHCH$_3$ (93). Boc group in Boc-dodecapeptide-NHCH$_3$ (**79**) (450 mg, 0.21 mmol) was deprotected with TFA (3 ml) at 0 °C for 40 min. To a solution of the TFA salt (430

mg, 0.2 mmol) and Et_3N (0.028 ml, 0.2 mmol) in the mixture of DMF (5 ml) and DMSO (5 ml) was added Ac-ONSu (63 mg, 0.4 mmol) at room temperature. The mixture was stirred at room temperature for 1 d. After removal of the solvent, the residue was solidified by the addition of water. The solid was collected and washed with water, and dried in vacuo.

Ac-Leu-Ala-Lys-Lys-Leu-Ala-Lys-Leu-Leu-Lys-Lys-Leu-$NHCH_3$·5AcOH (1·5AcOH). Compound **93** (300 mg, 0.14 mmol) was dissolved in 25% HBr in AcOH (8 ml) at room temperature. The solution was allowed to stand at room temperature for 4 h. After evaporation, the residue was solidified by the addition of ether and decantated several times with ether. The HBr salt was dissolved in water (5 ml) and passed through a column (0.9×10 cm) of Amberlite IR-45 (AcO^- form), and eluted with water. The fraction was lyophilyzed to give a white powder.

Antimicrobial Assay. Agar dilution method.[19] The minimum inhibitory concentration (MIC) was determined by the standard agar dilution method using Trypticase soy agar. About 5 μl of bacterial suspension containing about 10^7 colony forming units ml^{-1} was inoculated with a multiple inoculator onto agar plates containing twofold serial dilution of each antibiotic. The plates were incubated at 37 °C for 18 h, and the MIC was defined as the lowest concentration of the peptide on which there was either no visible growth or less than four colonies per spot.

Serial dilution method in solution medium.[20] The cell suspension was diluted with the medium to 2×10^6 cells ml^{-1}. Various concentrations of the peptide solution were placed in the test tubes, made up to 1 ml with medium, and the cell suspension (1 ml) was added. After incubation at 30 °C for 17 h, distilled water (1 ml) was added, and the absorbance at 620 nm was measured.

Results of both assays are shown in terms of MIC in Table 3.

Preparation of Phospholipid Liposomes. DPPC and DPPG were purchased from Sigma. Phospholipid (37 mg, 50 μmol) was dissolved in chloroform (2 ml) and dried by breathing of nitrogen in a conical glass tube. The dried lipid was hydrated in 3 ml of 20 mM Tris·HCl buffer (pH 7.4) with repeated vortexed-mixing at 50 °C for 30 min. The suspension was sonicated at 50 °C for 60 min using a TOMY SEIKO ultrasonic disruptor model UR-200P and diluted to 50 ml with the same buffer (lipid concentration, 1.0 mM). The mixture of uni- and multilamellar vesicles was used for the CD measurement without further purification. When the unilamellar vesicles trapping carboxyfluorescein were prepared, the same method as described above was used except that the dried lipid (27 μmol) was hydrated in 2.0 ml of 0.1 M NaCl/20 mM phosphate buffer (pH 7.4) containing 100 mM carboxyfluorescein. The mixture of uni- and multilamellar vesicles trapping carboxyfluorescein was subjected to gel-filtration through a Sephadex 4B column (1×20 cm) in 0.1 M NaCl/20 mM phosphate buffer (pH 7.4). The separated small unilamellar vesicles were utilized in phase-transition release measurements.

CD Measurements. CD spectra were recorded on a JASCO J-40A spectropolarimeter with a JASCO data processor Model J-DPY using quartz cell of 1 mm pathlength. Spectra in water and 2,2,2-trifluoroethanol were measured at a peptide concentration of 100 μM. Spectra in the presence of phospholipid liposomes were measured at a peptide concentration of 10 μM in 20 mM Tris·HCl buffer (pH 7.4) solution containing 0.9 mM vesicles. All the measurements were carried out at 20 °C. The CD data were expressed as mean residue ellipticities as shown in Fig. 3.

Phase-Transition Release. The phase-transition release experiment was carried out according to the procedure of Utsumi et al.[22] Phospholipid vesicles, the peptides and 0.1 M NaCl/20 mM phosphate buffer (pH 7.4) were individually pre-chilled on ice. To 2 ml of phosphate buffer in the cuvette on ice was added 50 μl of the vesicles containing 100 mM carboxyfluorescein to give a final concentration of 20 μM lipid. To the mixture was added 20 μl of an appropriate dilution of the peptide in phosphate buffer. The cuvette was placed in the heated (42 °C) cuvette holder of the fluorometer, and both the fluorescence intensity and the temperature were continuously recorded. For determination of the fluorescence intensity derived from 100% dye-release, 10 μl of Triton X-100 solution (20% in phosphate buffer) was added to dissolve the vesicles. The percentage of dye-release caused by the peptide was evaluated by equation, $100\ (F-F_o)/(F_t-F_o)$, where F is the fluorescence intensity achieved by the peptides, F_o and F_t are intensities of post-transition fluorescence without the peptides and post-Triton X-100 treatment, respectively. Results are shown in Fig. 5 and Table 4.

We thank Prof. Hiroshi Nishikawa of Fukuoka University for CD measurement, and Prof. Nobuyuki Yamasaki of Kyushu University for phase-transition release experiment. We also thank Dr. Hiroo Yonezawa of Kagoshima University and the staff of Takeda Chemical Ind. Ltd. for the microbial assay.

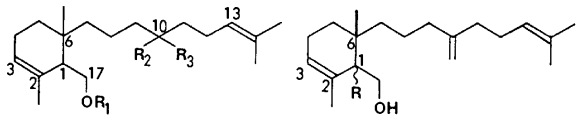
Synthesis of 2,6-Dimethyl-6-(8-methyl-4-methylene-7-nonenyl)-2-cyclohexene-1-methanols from α-Santonin[1)]

Hajime NAGANO,* Yukari MASUNAGA (née ISHIKAWA), Yukiko MATSUO, and Michio SHIOTA
Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received August 13, 1986)

α-Santonin was converted to 2,6-dimethyl-6-(8-methyl-4-methylene-7-nonenyl)-2-cyclohexene-1-methanols (**1a** and **1b**). Both spectral data of **1a** and **1b** were found to be different from those reported for magydar-2,10(20),13-trien-17-ol, a diterpene isolated from *Magydaris panacifolia* (Vahl) Lange. This indicates that the structure of the natural diterpene should be revised; the structure was later revised to *t*-6-hydroxymethyl-1, *t*-3-dimethyl-*t*-2-(3-methyl-2-butenyl)-3-(4-methyl-3-pentenyl)-*r*-1-cyclohexanol.

In 1978 J. de Pascual Teresa and co-workers reported the isolation and the structural elucidation of three new diterpenes, magydar-2,10(20),13-trien-17-ol(I), its acetate(II), and magydar-2,13-diene-10,17-diol(III), from *Magydaris panacifolia* (Vahl) Lange (Umbelliferae).[2)] The stereochemistry of these diterpenes with a novel carbon skeleton was however left undetermined. With the object of determining the stereochemistry of these diterpenes including the absolute configuration we synthesized a pair of diastereomers of 2,6-dimethyl-6-(8-methyl-4-methylene-7-nonenyl)-2-cyclohexene-1-methanols, (**1a**) and (**1b**), namely the two possible stereoisomers for the structure of magydar-2,10(20), 13-trien-17-ol (I) or its enantiomer.



I R_1 = H R_2, R_3 = CH_2
II R_1 = $COCH_3$ R_2, R_3 = CH_2
III R_1 = H R_2 = OH, R_3 = CH_3

1a α-H
1b β-H

In this work we chose α-santonin (**2**), easily available sesquiterpene, as the starting material and converted it into **1a** and **1b** via 6,7-secoeudesmane derivatives. Following the known procedures α-santonin (**2**) was transformed into 5α*H*- (**3a**)[3)] and 5β*H*-eudesmanolide (**3b**),[4)] which have the cyclohexene ring moiety in the diterpene.

In order to convert **3a** into a 6,7-seco derivative functionalization at C-7 was first carried out. Hydroxylation of the enolate of 5α*H*-eudesmanolide (**3a**) with MoO_5·pyridine·HMPT complex[5)] gave the hydroxy lactone **4a**[6)] in 58% yield. The configuration of the hydroxyl group at C-11 was assigned to be β on the basis of the precedents[7)] similar to this case. Reduction of **4a** with lithium aluminium hydride (LAH) in tetrahydrofuran (THF) under reflux afforded the triol **5a** in quantitative yield. Oxidative cleavage of the triol **5a** with sodium periodate in aqueous THF gave the β-hydroxy ketone **6a** in 98% yield. 5β*H*-Eudesmanolide (**3b**) was also converted similarly into the β-hydroxy ketone **6b** in 55% overall yield.

Althogh the Beckmann rearrangement of *O*-mesitylsulfonyloxime **7a**, which was prepared from **6a** and *O*-mesitylsulfonylhydroxylamine, was first attempted using basic alumina (Merck, activity I),[8)] the desired amide **8a** was obtained only in 35% yield together with a less polar product. The latter was assumed to be the oxazoline derivative **9** (27% yield) from its spectral data (ν_{max}. 1643 cm^{-1} (C=N); δ=1.98 (d, *J*=1.5 Hz, Me), 3.17 (m, 7α-H), and 3.26 (dd like, *J*=13 and 11 Hz, 6β-H).[9)] However, treatment of the oximes, **7a** and **7b**, with activated alumina (Wako) gave the amides, **8a** and **8b**, in 80 and 63% yields, respectively.

The hydroxy amides, **8a** and **8b**, were then reduced with LAH to afford hydroxy amines, **10a** (90% yield) and **10b** (88% yield), respectively. Oxidative cleavage of **10a** and **10b** with sodium periodate in aqueous THF followed by reduction with sodium borohydride gave the 6,7-seco derivatives, **11a** (62% yield) and **11b** (74% yield), respectively.

Completion of the side chain transformation was brought as follows. The diol **11a** was transformed into the monoiodide **13a** via the monotosylate **12a** in 46% overall yield. After tetrahydropyranylation of **13a**, the resulting iodide **14a** was treated with 2-lithio-1,3-dithiane at 0 °C to give the dithiane **15a** in 73% yield. The carbanion generated from **15a** with butyllithium was then treated with 4-methyl-3-pentenyl iodide[10)] to give compound **16a** in 60% yield.[11)] Hydrolysis of **16a** with copper(II) chloride-copper(II) oxide in acetone[12)] gave the hydroxy ketone **17a** in 40% yield. Finally the Wittig reaction of **17a** with methylenetriphenylphosphorane ($Ph_3P=CH_2$) afforded **1a** in ca. 30% yield. The ^1H NMR spectral data of **1a** were found to differ from those reported for the diterpene (I) (see Table).

The diol **11b** was converted similarly to the monoiodide **14b** in 26% overall yield. Treatment of **14b** with 2-lithio-2-(4-methyl-3-pentenyl)-1,3 dithiane gave compound **16b** in 52% yield.[11)] Hydrolysis of **16b** gave the hydroxy ketone **17b** in 40% yield.[12)] The Wittig reaction of **17b** with $Ph_3P=CH_2$ gave **1b** in 30% yield. The ^1H NMR spectral data of **1a** were obviously different from those reported for magydar-2,10(20),13-trien-17-ol (I) (see Table).

Since the two stereoisomers, **1a** and **1b**, are found to

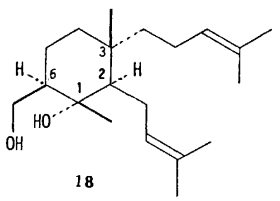
differ from magydar-2,10(20),13-trien-17-ol, the structure of the natural diterpene should be revised.

We therefore reinvestigated the structure of magydar-2,13-diene-10,17-diol (II) and established the structure of the diterpene, renamed magydardienediol, to be *t*-6-hydroxymethyl-1,*t*-3-dimethyl-*t*-2-(3-methyl-2-butenyl)-3-(4-methyl-3-pentenyl)-*r*-1-cyclohexanol (**18**) on the basis of the detailed analysis of its 400 MHz ^{1}H NMR spectrum.[13] The structure of the diterpene was also elucidated by J. de Pascual Teresa and co-workers. They proposed the structure **18** including the absolute configuration (1*S*, 2*R*, 3*S*, 6*R*).[14]

M. Bruno et al. have recently reported the isolation and the structure elucidation of a diterpene of *Bonannia graeca* (L.) Halacsy (Umbelliferae).[15] The diterpene, named bonandiol, is identical with magydardienediol (**18**).



18

Experimental

Melting points were determined on a hot block melting point apparatus and are uncorrected. ^{1}H NMR spectra of all the compounds except for **1a** and **1b** were recorded on a JEOL C-60 (60 MHz) spectrometer and those of **1a** and **1b**

were recorded on a JEOL FX-90Q spectrometer. Chloroform-*d* and tetramethylsilane were used as solvent and internal standard, respectively. IR spectra were taken on a JASCO A-3 spectrometer. Mass spectra were obtained on JEOL DX-300, Hitachi 50-GC, or Hitachi M80-A mass spectrometer using electron impact (70 ev) mode. Optical rotations were determined on a JASCO DIP-181 polarimeter. Pre-coated Merck Kieselgel 60 F_{254} was used for general analytical purposes and silica gel (Wakogel C-200) was used for column chromatography.

Hydroxylation of 3a. To a solution of lithium diisopropylamide, prepared from diisopropylamine (1.5 ml) and butyllithium (1.7 mol dm^{-3} hexane solution, 6.5 ml) in THF (6 ml) under a nitrogen atmosphere, was added a solution of **3a** (2.17 g) in dry tetrahydrofuran (18 ml) at −78 °C. The reaction mixture was stirred for 1 h at this temperature. To the solution was then added Mo_5 · pyridine · HMPT complex (6.0 g) in one portion. The suspension was stirred for 2 h at −78 °C and then warmed to room temperature. Usual work-up gave a yellow residue, which was chromatographed on silica gel (30 g; eluant: hexane–ethyl acetate 10 : 1 v/v) to give 11β-hydroxy-5αH-eudesmanolide (**4a**) (1.36 g) in 58% yield. Recrystallization of the product from diethyl ether gave colorless needles; mp 185.0—186.5 °C; $[\alpha]_D^{34}$ +132°(*c* 0.33, $CHCl_3$); IR (KBr): 3470 and 1755 cm^{-1}; ^1H NMR δ=0.92 (3H, s, 10-Me), 1.44 (3H, s, 11-Me), 1.81 (3H, m, 4-Me), 4.37 (1H, dd, *J*=12 and 9 Hz, 6-H), and 5.37 (1H, m, 3-H); MS: *m/z* 250 (rel intensity 9%, M^+) and 43 (100). Found: *m/z* 250.1555. Calcd for $C_{15}H_{22}O_3$: M, 250.1569.

5βH-Eudesmanolide (**3b**) was similarly hydroxylated to give **4b** in 75% yield. **4b**: colorless needles; mp 131.0—132.5 °C (from diethyl ether); $[\alpha]_D^{34}$ 0° (*c* 0.45, $CHCl_3$); IR: 3430 and 1755 cm^{-1}; ^1H NMR δ=1.11 (3H, s, 10-Me), 1.42 (3H, s, 11-Me), 1.64 (3H, m, 4-Me), 4.73 (1H, dd, *J*=10.5 and 4.5 Hz, 6-H), and 5.45 (1H, broad(br) s, 3-H); MS: *m/z* 250 (4%), 109 (100), and 43 (100). Found: *m/z* 250.1594.

Reduction of 4a with Lithium Aluminium Hydride. To a suspension of lithium aluminium hydride (280 mg) in dry THF (10 ml) was added a solution of **4a** in dry THF (20 ml). The reaction mixture was heated at reflux temperature under a nitrogen atmosphere for 4 h. After work-up as usual the crude product was chromatographed on silica gel (40 g; diethyl ether) to give the triol **5a** (885 mg) together with the partially reduced hemiacetal (545 mg). The hemiacetal was again reduced to **5a** in quantitative yield. **5a**: Colorless viscous oil; $[\alpha]_D^{34}$ +59° (*c* 0.91, $CHCl_3$); IR (neat): 3350 cm^{-1}; ^1H NMR δ=0.76 (3H, s, 10-Me), 1.18 (3H, s, 11-Me), 1.90 (3H, br s, 4-Me), 3.37 (1H, A part of an AB-type quartet, *J*=(−)12 Hz, 12-H), 3.53 (1H, B part of an AB-type quartet, *J*=(−)12 Hz, 12-H), 3.92 (1H, t, *J*=10 Hz, 6-H), and 5.36 (1H, m, 3-H); MS: *m/z* 254 (1%, M^+), 236 (4, M^+-H_2O) 218 (21, M^+-2H_2O), and 43 (100); Found: *m/z* 236.1707. (Calcd for $C_{15}H_{24}O_2$, *m/z* 236.1775).

The hydroxy lactone **4b** was also reduced with lithium aluminium hydride to give the triol **5b** in 75% yield. **5b**: Colorless needles; mp 129.0—129.5 °C (from hexane–diethyl ether); $[\alpha]_D^{34}$ −44° (*c* 0.5, $CHCl_3$); IR (KBr): 3300 cm^{-1}; ^1H NMR δ=0.93 (3H, s, 10-Me), 1.14 (3H, s, 11-Me), 1.80 (3H, br s, 4-Me), 2.60 (3H, br s, OH), 3.37 (1H, A part of an AB-type quartet, *J*=(−)10.5 Hz, 12-H), 3.47 (1H, B part of an AB-type quartet, *J*=(−)10.5 Hz, 12-H), 4.25 (1H, m, 6-H), and 5.55 (1H, m, 3-H); MS: *m/z* 254 (0.1%), 236 (14), 218 (62), and 109 (100).

Oxidative Cleavage of 5a with Sodium Periodate. To a solution of **5a** (615 mg) in THF (30 ml)–H_2O (10 ml) was added dropwise a solution of sodium periodate (623 mg) in water (5 ml). The reaction mixture was stirred for 1.2 h at room temperature. After work-up as usual the crude product was chromatographed (3 g; hexane–ethyl acetate 1 : 1) to give the hydroxy ketone **6a** (527 mg, 98% yield); colorless needles; mp 66.0—67.0 °C (from hexane); $[\alpha]_D^{34}$ +35° (*c* 0.34, $CHCl_3$); IR (KBr): 3420 and 1708 cm^{-1}; ^1H NMR δ=0.82 (3H, s, 10-Me), 1.88 (3H, br s, 4-Me), 2.18 (3H, s, COMe), 4.00 (1H, t, *J*=ca. 10 Hz, 6-H), and 5.35 (1H, m, 3-H); MS: *m/z* 222 (9%, M^+), 204 (10, M^+-H_2O), 189 (15, M^+-H_2O–Me), 161 (62, M^+-H_2O–MeCO), and 43 (100). Found: *m/z* 222.1622. Calcd for $C_{14}H_{22}O_2$: M, 222.1620.

The triol **5b** (201 mg) was also oxidized with sodium periodate (190 mg) to yield the hydroxy ketone **6b** in 98% yield. **5b**: Colorless oil; IR (neat): 3550 and 1710 cm^{-1}; ^1H NMR δ=0.80 (3H, s, 10-Me), 1.74 (3H, d, *J*=1.5 Hz, 4-Me), 2.18 (3H, s, COMe), 2.85 (1H, m, 7-H), 4.20 (1H, t, *J*=3.5 Hz, 6-H), and 5.65 (1H, m, 3-H); MS: *m/z* 222 (0.9%), 204 (68), 189 (30), 161 (100), and 145 (57); Found: *m/z* 204.1542. (Calcd for $C_{14}H_{20}O$, *m/z* 204.1515).

Beckmann Rearrangement of 6a. To a solution of **6a** (485 mg) in dichloromethane (15 ml), stirred at 0 °C, was added *O*-mesitylsulfonylhydroxylamine (813 mg) and the solution was stirred for 30 min at room temperature. The reaction mixture was absorbed on a column of activated alumina (Wako, for column chromatography, 50 g) and allowed to stand for 2 h. The eluate from methanol (200 ml) was evaporated under reduced pressure. Ethyl acetate was added and the resulting suspension was put on a column of silica gel (20 g). Elution with ethyl acetate gave the hydroxy amide **8a** (402 mg, 80% yield). The formation of **9** was not detected. **8a**: Mp 125.0—127.0 °C (from acetone); IR (KBr): 3400, 3330, 1655, and 1545 cm^{-1}; ^1H NMR δ=0.82 (3H, s, 10-Me), 1.78 (3H, br s, 4-Me), 2.01 (3H, s, COMe), 3.0—3.8 (3H, OH, 6-H, and 7-H), 5.34 (1H, m, 3-H), and 6.00 (1H, br s, NH); MS: *m/z* 237 (33%, M), 219 (100, M^+-H_2O), 178 (52), 163 (52), 145 (69), 109 (85). Found: *m/z* 237.1722. Calcd for $C_{14}H_{23}NO_2$: M, 237.1727.

The Beckmann rearrangement of the hydroxy ketone **6b** was similarly performed to yield the hydroxy amide **8b** in 63% yield. The formation of the corresponding oxazoline derivative was not detected. **8b**: Colorless oil; IR (neat): 3320, 1745, 1645, and 1545 cm^{-1}; ^1H NMR δ=0.87 (3H, s, 10-Me), 1.70 (3H, d, *J*=ca. 1 Hz, 4-Me), 2.02 (3H, s, COMe), 3.83 (1H, t, *J*=3.5 Hz, 6-H), 4.23 (1H, m, 7-H), 5.70 (1H, m, 3-H), and 6.00 (1H, br s, NH); MS: *m/z* 237 (0.3%), 219 (6), and 83 (100). Found: *m/z* 237.1797.

The Beckmann rearrangement of **6a** (59 mg) using basic alumina (Merck, activity I, 3 g) gave **8a** (22 mg) together with **9** (16 mg). **9**: Colorless oil; IR (neat): 1643 cm^{-1}; ^1H NMR δ=0.88 (3H, s, 10-Me), 1.78 (3H, m, 4-Me), 1.98 (3H, d, *J*=1.5 Hz, Me), 3.17 (1H, m, 7-H), 3.26 (1H, dd like, *J*=13 and 11 Hz, 6-H), and 5.33 (1H, m, 3-H).

Reduction of 8a with Lithium Aluminium Hydride. A mixture of **8a** (390 mg) and lithium aluminium hydride (470 mg) in dry diethyl ether (30 ml) was heated at reflux temperature for 3 h under a nitrogen atmosphere. Usual work-up gave the hydroxy amine **10a** (90% yield), which was recrystallized to give colorless needles; mp 64.0—65.0 °C; IR (KBr): 3400 cm^{-1}; ^1H NMR δ=0.82 (3H, s, 10-Me), 1.07 (3H, t, *J*=7 Hz, $CH_2C\underline{H}_3$), 1.88 (3H, br s, 4-Me), 2.3—2.9 (3H, m, 7-H and

$C\underline{H}_2CH_3$), 3.24 (1H, dd, J=10 and 8 Hz, 6-H), and 5.31 (1H, br s, 3-H); MS: m/z 223 (2%, M^+), 205 (18, M^+-H_2O), and 84 (100). Found: m/z 223.1910. Calcd for $C_{14}H_{23}NO$: M, 223.1935.

The amide **8b** (93 mg) was similarly reduced with lithium aluminium hydride (177 mg) to yield the hydroxy amine **10b** in 88% yield. Although the product solidified in a refrigerator, its recrystallization was not successful. **10b**: IR (neat): 3400 cm^{-1}; ^1H NMR δ=0.85 (3H, s, 10-Me), 1.12 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.67 (2H, br s, OH and NH), 1.72 (3H, d, J=1.5 Hz, 4-Me), 2.69 (2H, q, J=7 Hz, $C\underline{H}_2CH_3$), 2.95 (1H, q, J=3 Hz, 7-H), 3.77 (1H, t, J=ca. 3 Hz, 6-H), and 5.68 (1H, br s, 3-H); MS: m/z 223 (M^+).

Conversion of 10a to 11a. To a solution of **10a** (238 mg) in THF (6 ml), stirred at 0 °C, was added a solution of sodium periodate (516 mg) in water (6 ml). The solution was stirred at this temperature for 1 h under a nitrogen atmosphere. A solution of sodium borohydride (371 mg) in water (5 ml) was then added and the resulting solution was stirred for 45 min. The product was extracted with diethyl ether. The ethereal solution was washed successively with water, dilute hydrochloric acid, 5% aqueous sodium hydrogencarbonate, water, and saturated brine, and dried over anhydrous sodium sulfate. Evaporation of the solvent followed by column chromatography (8 g; hexane-ethyl acetate 1:1) gave the diol **11a** (99 mg) and the hydroxy amine **10a** (58 mg). **11a**: Colorless oil; $[\alpha]_D^{34}$ +97° (c 0.86, $CHCl_3$); IR (neat): 3340 cm^{-1}; ^1H NMR δ=1.00 (3H, s, 6-Me), 1.23 (3H, m, 2-Me), 3.5—3.8 (4H, m, two $C\underline{H}_2OH$), and 5.62 (1H, m, 3-H); MS: m/z 198 (nil, M^+), 180 (3%, M^+-H_2O), and 121 (100, $M^+-H_2O-(CH_2)_3OH$); Found: m/z 180.1448. (Calcd for $C_{12}H_{20}O$: m/z 180.1513).

The hydroxy amine **10b** (70 mg) was similarly transformed into the diol **11b** (46 mg; 74% overall yield), colorless oil; IR (neat): 3350 cm^{-1}; ^1H NMR δ=0.85 (3H, s, 6-Me), 1.73 (3H, d, J=1.5 Hz, 2-Me), 2.27 (2H, br s, OH), 3.65 (4H, m, two $C\underline{H}_2OH$), and 5.55 (1H, m, 3-H).

Conversion of 11a to 14a. A solution of **11a** (33 mg) and p-toluenesulfonyl chloride (39 mg) in pyridine (1 ml) was allowed to stand overnight at 4 °C. Then dilute hydrochloric acid was added and the product was extracted with diethyl ether. The crude product (60 mg), containing the monotosylates, the ditosylate, and **11a**, was dissolved in acetone (4 ml). To the solution was added a solution of sodium iodide (34 mg) in acetone (1 ml) and reaction mixture was heated under reflux for 2.2 h. After evaporation of the solvent the residue was chromatographed to yield the monoiodide **13a** (18 mg; 46% yield). The diol **11a** (8.6 mg) was recovered. **13a**: Colorless oil; IR (neat): 3400 cm^{-1}; ^1H NMR δ=1.00 (3H, s, 6-Me), 1.75 (3H, m, 2-Me), 3.13 (2H, t, J=7 Hz, CH_2I), 3.72 (2H, d, J=3 Hz, $C\underline{H}_2OH$), and 5.60 (1H, m, 3-H); MS: m/z 308 (4%, M^+), 290 (8, M^+-H_2O), 277 (51, M^+-CH_2OH), 121 (64), 93 (94), and 81 (100). Found: m/z 308.0541. Calcd for $C_{12}H_{21}IO$: M, 308.0638.

A solution of **13a** (56 mg) and freshly distilled dihydropyran (6 mg) in dry THF (3 ml) was stirred in the presence of a catalytic amount of p-toluenesulfonic acid. Purification of the product using a column of Florisil (10 g; hexane-diethyl ether 80:3) gave **14a** in 82% yield. **14a**: Colorless oil; ^1H NMR δ=0.93 (3H, s, 6-Me), 1.73 (3H, br s, 2-Me), 3.11 (2H, t, J=7 Hz, CH_2I), 3.2—4.0 (4H, m, CH_2OCH_2), 4.52 (1H, m, O-CH-O), and 5.40 (1H, m, 3-H).

Tosylation of the diol **11b** (39 mg) with p-toluenesulfonyl chloride (38 mg) in pyridine (0.5 ml) gave the monotosylate **12b** (22 mg; 31% yield), which was then converted to the monoiodide in quantitative yield. **13b**: Colorless oil; IR (neat): 3420 cm^{-1}; ^1H NMR δ=0.86 (3H, s, 6-Me), 1.75 (3H, br s, 2-Me), 3.19 (2H, t, J=6.5 Hz, CH_2I), 3.72 (2H, d, J=3.5 Hz, $C\underline{H}_2OH$), and 5.61 (1H, m, 3-H). The alcohol **13b** was then treated with dihydropyran in the presence of p-toluenesulfonic acid to give **14b** in 84% yield. **14b**: Colorless oil, MS: m/z 392 (0.1%, M^+), 290 (4), 201 (18), and 85 (100); Found: m/z 290.0501 (Calcd for $C_{12}H_{19}I$: $M^+-C_5H_{10}O_2$, 290.0532).

Treatment of 14a with 2-Lithio-1,3-dithiane. To a solution of **14a** (42 mg; 0.11 mmol) in dry ether (2 ml), stirred at 0 °C, was added a solution of 2-lithio-1,3-dithiane (0.4 mmol) under a nitrogen atmosphere. The crude product was chromatographed on Florisil (4 g; hexane-ether 60:3) to yield the dithiane **15a** (30 mg; 73% yield); colorless oil; ^1H NMR δ=0.94 (3H, s, 6-Me), 2.7—3.0 (4H, m, SCH_2), 3.1—4.2 (6H, m), 4.52 (1H, m, O-CH-O), and 5.39 (1H, m, 3-H); MS: m/z 384 (nil, M^+), 282 (15%, $M^+-C_5H_{10}O_2$), and 85 (100).

4-Methyl-3-pentenylation of 15a. To a solution of **15a** (17 mg; 0.044 mmol) in dry THF (0.8 ml), stirred at −30 °C, was added butyllithium (0.27 mmol) under a nitrogen atmosphere. The solution was stirred for 2 h at this temperature. A solution of 4-methyl-3-pentenyl iodide (57 mg; 0.27 mmol) in dry THF (0.5 ml) was added and the reaction mixture was stirred at 0 °C for 2 h. After work-up as usual, the crude product was passed through a column of Florisil (1 g; hexane-ether 30:1) to yield **16a** (12 mg; 60% yield); colorless oil; ^1H NMR δ=0.95 (3H, s, 6-Me), 1.5—1.8 (9H, m, three olefinic methyls), 2.6—2.9 (4H, m, SCH_2), 3.0—4.1 (4H, m, $C\underline{H}_2O$), 4.55 (1H, m, O-CH-O), 5.10 (1H, m, CH=), and 5.40 (1H, m, 3-H); MS: m/z 466 (0.6%, M), 364 (5, $M^+-C_5H_{10}O_2$), 229 (23), 85 (83), and 71 (100).

Hydrolysis of 16a with Copper(II) Chloride-Copper(II) Oxide. A suspension of **16a** (12 mg) and $CuCl_2\cdot 2H_2O$ (17 mg), and CuO (16 mg) in acetone (4 ml) was heated under reflux for 20 min. The reaction mixture was filtered and the filtrate was evaporated. The residue was chromatographed on silica gel (0.5 g; hexane-ether 10:1) to yield the hydroxy ketone **17a** (3 mg); colorless oil; IR (neat): 3450 and 1710 cm^{-1}; ^1H NMR δ=1.00 (3H, s, 6-Me), 1.5—1.75 (9H, m, three olefinic methyls), 2.34 (4H, m, CH_2COCH_2), 3.72 (2H, d, J=3 Hz, $C\underline{H}_2OH$), 5.05 (1H, m, CH=), and 5.60 (1H, m, 3-H); MS: m/z 292 (nil, M^+), 274 (1.7%, M^+-H_2O), 205 (3), 121 (100), and 69 (82); Found: m/z 205.1676 (Calcd for $C_{14}H_{21}O$: $M^+-H_2O-C_5H_9$, m/z 205.1593).

Treatment of 14b with 2-Lithio-2-(4-methyl-3-pentenyl)-1,3-dithiane. To a solution of 2-lithio-1,3-dithiane (ca. 1 mmol) in dry THF (2.5 ml), stirred at −6 °C under a nitrogen atmosphere, was added a solution of 4-methyl-3-pentenyl iodide (221 mg) in dry THF (0.2 ml). The solution was stirred at 0 °C for 3 h and then cooled to −30 °C. Butyllithium (ca. 1 mmol) was added. A part of the solution (1.5 ml) was added to a solution of **14b** (26 mg) in dry THF (1.5 ml) at −5 °C under a nitrogen atmosphere. The solution was stirred overnight at −5—0 °C. After work-up as usual the crude product was chromatographed on silica gel (2.5 g; hexane-diethyl ether 97:3) to yield the dithiane **16b** (16 mg); colorless oil; MS: m/z 466 (0.6%, M^+), 381 (4), 364 (2, $M^+-C_5H_{10}O_2$), and 69 (100).

Hydrolysis of 16b with Copper(II) Chloride-Copper(II) Oxide. The dithiane **16b** was hydrloyzed with $CuCl_2\cdot$

$2H_2O$-Cu_2O in acetone to give the hydroxy ketone **17b** in 39% yield. **17b**: Colorless oil; IR (neat): 3470 and 1710 cm^{-1}; ^1H NMR δ=0.87 (3H, s, 6 Me), 1.70 (9H, m, three olefinic methyls), 2.38 (4H, m, CH_2COCH_2), 3.73 (2H, d, J=3 Hz, $C\underline{H}_2OH$), 5.08 (1H, m, CH=), and 5.60 (1H, m, 3-H); MS: m/z 292 (nil, M^+), 274 (3%, M^+-H_2O), 109 (100), 107 (46), and 69 (99); Found: m/z 205.1660 (Calcd for $C_{14}H_{21}O$: $M^+-H_2O-C_5H_9$, m/z 205.1593).

Wittig Reaction of 17a with Methylenetriphenylphosphorane. To a solution of methylenetriphenylphosphorane, prepared from methyltriphenylphosphonium bromide (73 mg) and butyllithium (ca. 0.3 mmol) in dry diethyl ether (1 ml), was added a solution of **17a** (3 mg) in dry ether (1 ml) under a nitrogen atmosphere. The reaction mixture was then stirred for 2 h at room temperature. After work-up as usual the product was purified using column chromatography to yield **1a** (ca. 1 mg); colorless oil; IR (neat): 3400 and 890 cm^{-1}; ^1H NMR (90 MHz) δ=0.99 (3H, s, 6-Me), 1.61 (3H, s, Me), 1.69 (3H, s, Me), 1.74 (3H, d, J=1.5 Hz, Me), 3.74 (2H, m, $C\underline{H}_2OH$), 4.71 (2H, br s, $=CH_2$), 5.16 (1H, m, CH=), and 5.62 (1H, m, 3-H); MS: m/z 290 (5%, M^+), 272 (12, M^+-H_2O), 149 (26), 135 (27), 122 (52), 121 (48), 119 (27), 109 (94), 95 (48), 93 (54), 91 (23), 81 (57), 79 (23), and 69 (100). Found: m/z 290.2629. Calcd for $C_{20}H_{34}O$: M, 290.2610.

The hydroxy ketone **17b** (3 mg) was similarly methylenated with $PH_3P=CH_2$ to yield **1b** (ca. 1 mg); colorless oil; IR (neat): 3450 and 885 cm^{-1}; ^1H NMR (90 MHz) δ=0.85 (3H, s, 6-Me), 1.62 (3H, br s, Me), 1.70 (3H, br s, Me), 1.74 (3H, br s, Me), 3.73 (2H, m, $C\underline{H}_2OH$), 4.72 (2H, br s, $=CH_2$), 5.16 (1H, m, CH=), and 5.62 (1H, m, 3-H); MS: 290 (7%, M^+), 272 (8), 135 (23), 123 (20), 122 (38), 121 (38), 110 (24), 109 (83), 107 (54), 95 (37), 93 (46), 81 (46), 79 (20), and 69 (100). Found: m/z 290.2620.

Gas chromatography (20% Carbowax 20M, 3 mm×2 m, N_2 (1.2 kg cm^{-2})) of the final products showed that the contamination due to a more volatile component (t_R=4.5 min) was less than 10%; t_R(**1a**)=9.2 min and t_R(**1b**)=9.0 min.

We wish to thank Professor Akio Kobayashi, Ochanomizu University, for the mass spectral measurements (in part), and Dr. Hiroshi Hirota, The University of Tokyo, for the 90 MHz NMR measurements.

(Received August 19, 1986)

2′,3′-Dideoxykanamycin A has been prepared via two ways. 2″-*O*-Acetyl-4″,6″-*O*-benzylidene-6′-*N*,4′-*O*-carbonyl-1,3,3″-tri-*N*-tosylkanamycin A was converted to a 2′,3′-unsaturated compound by a modified Tipson and Cohen method. Hydrogenation followed by deblocking gave 2′,3′-dideoxykanamycin A (**12**). Another route for **12** was through 2′,3′-anhydro-4′,2″,4″,6″-tetra-*O*-benzoyl-2′-epi-1,3,6′,3″-tetrakis(*N*-ethoxycarbonyl)kanamycin A (**16**). Epoxide-ring opening of **16** with hydrogen iodide gave the 3′,2′-iodohydrin, which, after 2′-*O*-mesylation, led to the 2′,3′-unsaturated compound (**19**). Deblocking and hydrogenation of **19** gave **12**. 2′,3′-Dideoxykanamycin A thus synthesized was led to 2′,3′-dideoxyamikacin and other related compounds by amino protection of **12** other than the 1-amino group by zinc acetate–ethyl trifluoroacetate method followed by 1-*N*-acyl or 1-urethane formation with appropriate reagents. Their antibacterial activities were described.

Due to the lack of the hydroxyl group at C-3′, 3′-deoxykanamycin A[1] inhibits the growth of resistant bacteria producing 3′-*O*-phosphotransferases or 3′-*O*-adenylyltransferases. Attachment of (*S*)-4-amino-2-hydroxybutyryl residue at the 1-amino group of 3′-deoxykanamycin A gave 3′-deoxyamikacin,[2] which was more active than 3′-deoxykanamycin A and amikacin (1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]kanamycin A). 2′-Deoxyamikacin[3] prepared from 2′-deoxykanamycin A[4] had been found more active than amikacin against a variety of resistant bacteria. This suggests the possibility that the lack of 2′-hydroxyl group of kanamycin A may deprive the hydrogen-bond formation between 5- and 2′-hydroxyl groups and cause changes of the angles (ψ and ϕ[5]) between 2-deoxystreptamine and 6-amino-6-deoxy-α-D-glucopyranose moiety to improve the antibacterial activity. The results and the assumption described above let us to prepare 2′,3′-dideoxyamikacin.

2′,3′-Dideoxykanamycin A was prepared by two different ways. 6′-*N*-Benzyloxycarbonyl-1,3,3″-tri-*N*-tosylkanamycin A[6] (**1**) was treated with benzaldehyde dimethyl acetal in an acidic medium to give the 4″,6″-*O*-benzylidene derivative (**2**) in high yield. No benzylidenation of other hydroxyl groups of **1** was observed. Treatment of **2** with sodium hydride[7] in *N*,*N*-dimethylformamide (DMF) gave the 4′,6′-cyclic carbamate (**3**), the structure being confirmed by the IR spectrum (1700 cm^{-1}[7]). Protection of the hydroxyl groups of **3** with 1,1-dimethoxycyclohexane in the presence of trifluoroacetic acid in DMF gave the 2′,3′-*O*-cyclohexylidene derivative (**4**) in high yield. In this reaction, no formation of the 5,2′-*O*-cyclohexylidene derivative as experienced in the isopropylidenation of 6′-*N*,4′-*O*-carbonyl-4″,6″-*O*-cyclohexylidene-1,3,3″-tri-*N*-tosylkanamycin A[6] was observed. Attempts to prepare 2′,3′:4″,6″-di-*O*-cyclohexylidene derivative, instead of **4**, by one-pot cyclohexylidenation of 6′-*N*,4′-*O*-carbonyl-1,3,3″-tri-*N*-tosylkanamycin A gave no desired product in pure state. In the reaction to make **4** from **3**, conversion of the benzylidene to a cyclohexylidene group was not observed, but in strongly acidic conditions some conversion was observed. After acetylation, the 2″-*O*-acetyl derivative (**5**) was hydrolyzed with 80% aqueous acetic acid (40 °C for 3.5 h) to give the decyclohexylidene derivative (**6**) in a moderate yield (57%) with the starting material (**5**) and the debenzylidene-decyclohexylidene derivative (**7**). However, removal of the both protecting groups of **5** (to give **7**) followed by rebenzylidenation gave **6** in high yield (>90%).

Double bond between C-2′ and C-3′ of **6** was created by a modified Tipson-Cohen procedure.[8] Treatment of **6** with trifluoromethanesulfonic anhydride in pyridine gave the bis(trifluoromethanesulfonate) (**8**), that was treated with sodium iodide in DMF in the absence[8] of zinc dust to give the 2′,3′-unsaturated compound **9** almost quantitatively, the yield being unexpectedly high in comparison to the yields for 2,3-unsatunation (≈50%) using other usual 2,3-bis(sulfonic ester). If zinc dust was added in the above reaction, the yield of **9** fairly decreased. In the ^1H NMR spectrum of **9**, resonances of H-2′ and H-3′ appeared at δ 5.93 and 5.80 with the $J_{2',3'}$=10 Hz (see Experimental), the shifts and the coupling being typical for 2,3-unsaturated sugars.[9] From the ^1H-shift-correlated 2-D spectrum of **9**, the sequence of H-1-H-2-H-3 was confirmed. Catalytic hydrogenation of **9** in the presence of platinum oxide gave the 2′,3′-dideoxy derivative (**10**). Alkaline treatment of **10** cleaved the both 4′,6′-carbamate and the 2″-*O*-acetyl groups to give the ninhydrin-positive derivative (**11**), which was treated with sodium in liquid ammonia to cleave the *N*-tosyl and 4″,6″-*O*-benzylidene groups to give the final product, 2′,3′-dideoxykanamycin A (**12**).

Another route for **12** was started from 3′,4′,2″,4″,6″-penta-*O*-benzoyl-1,3,6′,3″-tetrakis(*N*-ethoxycarbonyl)-kanamycin A[4] (**13**). Treatment of **13** with methanesul-

fonyl chloride in pyridine gave the 2′-*O*-mesylate (**14**). Selective removal of the benzoyl groups of **14** with sodium methoxide in methanol with the mesyloxy group remained intact gave the debenzoyl-2′-*O*-mesylate (**15**). Treatment of **14** with sodium methoxide in 1,4-dioxane-methanol gave the 2′,3′-epoxide, which, without purification, was benzoylated to afford the tetrabenzoate (**16**). Epoxide-ring opening of **16** with sodium iodide in acetone gave the 3′,2′-iodohydrin (**17**). Presence of the 3′-iodo and 2′-hydroxyl (axial) groups were determined by the ^1H NMR spectrum of the reduction product **18** pro-

duced by treating **17** with tributylstannane and 2,2′-azobis(isobutyronitrile) (AIBN). The structure of **18** was further confirmed by giving, after deprotection, 3′-deoxy-2′-epikanamycin A.[10]

Mesylation of **17** with methanesulfonyl chloride in pyridine in the presence of 4-dimethylaminopyridine and triethylamine readily gave the 2′,3′-unsaturated product **19**, possively through the 2′-*O*-mesylate and subsequent 2′,3′-trans-diaxial elimination. It is interesting to note that in the epoxide-ring opening of 3′,4′-anhydro-2′,2″-di-*O*-benzoyl-4″,6″-*O*-cyclohexylidene-4′-epi-tetrakis(*N*-*t*-butoxycarbonyl)kanamycin A,[11] the 4′,3′-diequatorial-iodohydrin was produced, and the iodohydrin gave the 3′,4′-unsaturated compound by a similar procedure as described, but only at an elevated temperature (90 °C). Deblocking of **19** gave 2′,3′-dideoxy-2′-enokanamycin A (**20**). Catalytic hydrogenation of **20** gave 2′,3′-dideoxykanamycin A (**12**) identical with the specimen obtained by the previous route. Total yields of **12** starting from kanamycin A via the former and the latter routes were 17 (12 steps) and 10% (10 steps), respectively.

Couplings of (*S*)-4-amino-2-hydroxybutyric acid and the related acids to the 1-amino group of 2′,3′-dideoxykanamycin A were performed by utilizing zinc acetate-ethyl trifluoroacetate method.[12] Treatment of **12** with *N*-(benzyloxycarbonyloxy)succinimide[13] in dimethyl sulfoxide (DMSO) or DMF-water (10 : 1) in the presence of zinc acetate gave the 3,6′-bis(*N*-benzyloxycarbonyl) derivative (**21**) in 88 and 79% yields, the latter procedure being superior to the former in easy removal of the solvent. After trifluoroacetylation[12] of the 3″-amino group with ethyl trifluoroacetate in DMF (DMSO was used in the original procedure[12]), the free 1-amino group of the resulting product **22** was acylated with the active ester[13] of (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid. Removal of the *N*-trifluoroacetyl group of the coupling product with aqueous ammonia, followed by removal of benzyloxycarbonyl groups by catalytic hydrogenolysis gave the final product 2′,3′-dideoxyamikacin (**23**). Similarly, 1-*N*-[(*S*)-3-amino-2-hydroxypropionyl]- (**24**) and 1-*N*-[(*S*)-4-amino-2-methoxybutyryl]-2′,3′-dideoxykanamycin A (**25**) were prepared, the latter being prepared to check the biological role of the free 2‴-hydroxyl group of **23**. (*S*)-4-Benzyloxycarbonylamino-2-methoxybutyric acid (**28**) required for the synthesis of **25** was prepared from (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid[13] (**26**) by methylation (to give **27**) and hydrolysis.

Since it was reported[14,15] that 1-*N*-(2-aminoethoxycarbonyl)kanamycin A and 1-*N*-(3-aminopropoxycarbonyl)kanamycin A, both prepared readily, showed significant antibacterial activities, 2′,3′-dideoxykanamycin A derivatives having the same 1-*N*-residues were also prepared. Treatment of **22** with *N*-[2-(benzyloxycarbonylamino)ethoxycarbonyloxy]succinimide[14] or *N*-[3-(benzyloxycarbonylamino)propoxycarbonyloxy]succinimde[14] gave the corresponding 1-*N*-alkoxycarbonyl derivatives, which, after deblocking, were led to the 1-*N*-(2-aminoethoxycarbonyl)- (**29**) and 1-*N*-(3-aminopropoxycarbonyl)-2′,3′-dideoxykanamycin A (**30**).

Antibacterial activities of the final products prepared are shown in Table 1. Both 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]- (**23**) and 1-*N*-[(*S*)-3-amino-2-hydroxypropionyl]-2′,3′-dideoxykanamycin A (**24**) showed slightly enhanced antibacterial activities in comparison to the activity of amikacin, and the two analogues (**29** and **30**) having the urethane residue at C-1 showed slightly decreased activities. The derivative (**25**) having the 2‴-*O*-methyl substituent, however, showed very weak antibacterial activity suggesting the importance of the 2‴-hydroxyl group in terms of antibacterial activity.

Experimental

Melting points were determined with a Kofler block and are uncorrected. Optical rotations were measured with a Perkin-Elmer 241 polarimeter. TLC was carried out on Wakogel B-5 silica gel with detection by spraying with sulfuric acid, followed by slight heating. Column chromatography was performed on Wakogel C-200. IR Spectra were measured with a JASCO A-202 grating spectrophotometer. ^{1}H NMR Spectra were recorded at 250 (unless otherwise

stated), 200, and 90 MHz with a Bruker WM 250, JEOL FX200, and Varian EM-390 spectrometers, respectively. The chemical shifts (δ by ppm) of the spectra were measured downfield from internal TMS.

4″,6″-*O*-Benzylidene-6′-*N*-benzyloxycarbonyl-1,3,3″-tri-*N*-tosylkanamycin A (2). A solution of the mixture of **1**[1] (1.58 g), benzaldehyde dimethyl acetal (0.27 ml) and *p*-toluenesulfonic acid (55 mg of monohydrate was dried in vacuo at 100 °C for 1 h) in DMF (8 ml) was kept at room temperature. After 7 h, another acetal (0.13 ml) was added and the solution was kept for further 30 h. The solution was poured into aqueous sodium hydrogencarbonate (saturated, 320 ml) and the precipitates were thoroughly washed with water and ether to give, after drying, a solid of **2**, 1.60 g (94%), $[\alpha]_D^{23}$ −22° (*c* 0.5, oxolane).

Found: C, 55.30; H, 5.49; N, 4.84; S, 8.28%. Calcd for $C_{54}H_{64}N_4O_{19}S_3$: C, 55.47; H, 5.52; N, 4.79; S, 8.23%.

4″,6″-*O*-Benzylidene-6′-*N*,4′-*O*-carbonyl-1,3,3″-tri-*N*-tosylkanamycin A (3). To an ice-cold solution of **2** (4.65 g) in dry DMF (93 ml) was added 50% (in oil) sodium hydride (1.72 g, 9 mol equiv. for **2** as net NaH), and the mixture was vigorously stirred in the cold for 1 h under an atmosphere of nitrogen, and then overnight at room temperature. TLC (chloroform–ethanol=6:1) of the solution showed a single spot (R_f 0.15; cf **2**: 0.5). Addition of 25% acetic acid (15 ml) and evaporation in vacuo, with occasional additions of toluene, gave a residue, that was washed with ether, then thoroughly with water, and dried to give a solid of **3**, 3.97 g (94%), $[\alpha]_D^{22}$ −37° (*c* 1, acetone); IR (KBr): 1700 cm^{-1} (carbamate); ^1H NMR (pyridine-d_5) δ=2.09, 2.27, and 2.35 (each 3H, s, TsX3), 5.48 (1H, s, PhCH), 5.52 (1H, d, *J*=3.5 Hz, H-1′or H-1″), 5.59 (1H, d, *J*=3.5 Hz, H-1″ or H-1′).

Found: C, 52.85; H, 5.39; N, 5.26; S, 8.81%. Calcd for $C_{47}H_{56}N_4O_{18}S_3 \cdot 0.5H_2O$: C, 52.75; H, 5.37; N, 5.24; S, 8.99%.

4″,6″-*O*-Benzylidene-6′-*N*,4′-*O*-carbonyl-2′,3′-*O*-cyclohexylidene-1,3,3″-tri-*N*-tosylkanamycin A (4). A reaction flask containing **3** (3.97 g), 1,1-dimethoxycyclohexane (10.8 ml), trifluoroacetic acid (2.1 ml), dry DMF (20 ml), and dichloromethane (400 ml) was connected to a Soxlhet type of apparatus[2] fitted with a reflux condenser, the Soxhlet extractor being filled with molecular sieves 5A (120 ml, activated at 350 °C under a stream of nitrogen), and the mixture was refluxed for 6 h. Methanol liberated during the reaction was effectively removed by the sieves. TLC (chloroform–ethanol=5:1) of the solution showed a single spot (R_f 0.4; cf **3**: 0.18). The reaction mixture was concentrated to a small volume (≈20 ml), and poured into an ice-cold aqueous sodium hydrogencarbonate solution (saturated). The resulting precipitates were filtered, washed with water and ether alternately several times, to give, after drying, a solid of **4**, 4.15 g (97%), $[\alpha]_D^{23}$ −33° (*c* 0.6, acetone); IR (KBr): 1700 cm^{-1}; ^1H NMR (pyridine-d_5 at 90 MHz) δ=2.12, 2.24, and 2.35 (each 3H, s, TsX3).

Found: C, 55.47; H, 5.77; N, 4.88; S, 8.30%. Calcd for $C_{53}H_{64}N_4O_{18}S_3$: C, 55.78; H, 5.65; N, 4.91; S, 8.43%.

2″-*O*-Acetyl-4″,6″-*O*-benzylidene-6′-*N*,4′-*O*-carbonyl-2′,3′-*O*-cyclohexylidene-1,3,3″-tri-*N*-tosylkanamycin A (5). To an ice-cold solution of **4** (5.26 g) in dry pyridine (105 ml) was added acetic anhydride (4.8 ml) and the solution was kept at room temperature overnight. TLC (chloroform–ethanol=10:1) of the solution showed a main (**5**, R_f 0.25; cf **4**: 0.18) and trace spots (R_f 0.34 and 0.38). The reaction mixture was poured, with vigorous stirring, into an ice-cold aqueous sodium hydrogencarbonate solution (saturated, 1 l). After standing for 1 h, the resulting precipitates were filtered and dried (5.52 g). Column chromatographty of the products with chloroform–acetone (10:7→10:9, gradually changed) gave a glass, 3.15 g (64%), $[\alpha]_D^{22}$ +40° (*c* 1, acetone); IR (KBr):

1730 cm^{-1}; ^1H NMR (pyridine-d_5) δ=2.16, 2.22, and 2.34 (each 3H, s, Ts ×3), 2.52 (3H, s, Ac).

Found: C, 55.47; H, 5.75; N, 4.75; S, 7.92%. Cacld for $C_{55}H_{66}N_4O_{19}S_3 \cdot 0.5H_2O$: C, 55.40; H, 5.66; N, 4.70; S, 8.07%.

2″-*O*-Acetyl-4″,6″-*O*-benzylidene-6′-*N*,4′-*O*-carbonyl-1,3,3″-tri-*N*-tosylkanamycin A (6). A suspension of **5** (1.88 g) in 80% aqueous acetic acid (38 ml) was vigorously stirred at 40 °C for 3.5 h. TLC (chloroform–acetone=1 : 2) of the resulting solution showed spots of R_f 0.44 (**5**, slight), 0.12 (**6**, major), and 0.02 (**7**). The solution was gradually poured into an ice-cold aqueous sodium hydrogencarbonate solution (saturated, 1 l), and the precipitates were filtered, washed with water, and dried (1.44 g). Column chromatography of the products with chroloform–acetone (1 : 1→1 : 2→ acetone, gradually changed) gave a thick syrup of **6**, 0.99 g (57%), recovered **5**, 0.22 g (12%), and a solid of **7**, 0.37 g. Benzylidenation of **7** (0.37 g) in the same manner as described later (see the preparation of **6** from **7**; $C_6H_5CH(OMe)_2$ 66 μl, TosOH 14 mg, and DMF 1.9 ml, room temperature, 40 h) gave another crop of **6**, 0.35 g (totally 77%), $[\alpha]_D^{22}$ −5° (*c* 1, acetone); IR (KBr): 1700 cm^{-1}; ^1H NMR (pyridine-d_5): δ=2.14, 2.26, and 2.30 (each 3H, s, Ts×3), 2.46 (3H, s, Ac), 5.50 (1H, d, *J*=3.5 H, H-1′), 5.55 (1H, s, PhCH), 5.60 (1H, dd, *J*=3.5 and 10 Hz, H-2″), 5.97 (1H, d, *J*=3.5 Hz, H-1″). Irradiation of H-1″ collapsed the doublets of H-2″ to a doublet.

Found: C, 53.34; H, 5.21; N, 5.13; S, 8.66%. Calcd for $C_{49}H_{58}N_4O_{19}S_3$: C, 53.35; H, 5.30; N, 5.08; S, 8.72%.

2″-*O*-Acetyl-6′-*N*,4′-*O*-carbonyl-1,3,3″-tri-*N*-tosylkanamycin A (7). A suspension of **5** (1.70 g) in 80% aqueous acetic acid (34 ml) was vigorously stirred at 80 °C, whereupon clear solution was obtained after ≈5 min. After 1 h (at the same temperature), the solution was concentrated. The residue suspended in toluene was evaporated, and the residual solid was dried (60 °C, 36 h in vacuo) to give **7**, 1.48 g (quant.), $[\alpha]_D^{23}$ 0° (*c* 1, acetone); IR (KBr): 1690 cm^{-1}; ^1H NMR (pyridine-d_5 at 90 MHz) δ=2.16, 2.28, and 2.32 (each 3H, s, Ts×3), 2.51 (3H, s, Ac).

Found: C, 48.81; H, 5.41; N, 5.34%. Calcd for $C_{42}H_{54}N_4O_{19}S_3 \cdot H_2O$: C, 48.83; H, 5.46; N, 5.42%.

Benzylidenation of 7 to Give 6. Compound **7** (2.53 g) was treated with benzaldehyde dimethyl acetal (0.76 ml) in DMF (12.6 ml) in the presence of *p*-toluenesulfonic acid (190 mg) similarly as described for **2** to give a solid of **6**, 2.51 g (91%).

2″-*O*-Acetyl-4″,6″,-*O*-benzylidene-6′-*N*,4′-*O*-carbonyl-1,3,3″-tri-*N*-tosyl-2′,3′-bis(*O*-trifluoromethylsulfonyl)kanamycin A (8). To an ice-cold solution of **6** (887 mg) in dry pyridine (17.7 ml) was added trifluoromethanesulfonic anhydride (1.13 ml) and the solution was kept at the temperature for 4.5 h. TLC (chloroform–acetone=1 : 1) of the solution showed a single spot (R_f 0.25; cf **6**: 0.03). The red solution was poured into excess ice-cold aqueous sodium hydrogencarbonate and the precipitates were filtered, washed thoroughly with water, and dried (in vacuo at room temperature) to give a pale yellow solid of **8**, 1.01 g (quant.); analytical sample was purified by column chromatography with chloroform–acetone (1 : 1), $[\alpha]_D^{23}$ −32° (*c* 1, acetone); IR (KBr): 1730, 1420 cm^{-1}; ^1H NMR (pyridine-d_5) δ=2.15, 2.32, and 2.38 (each 3H, s, Ts ×3), 2.47 (3H, s, Ac).

Found: C, 44.94; H, 4.32; N, 4.21; S, 11.42%. Calcd for $C_{51}H_{56}N_4O_{23}S_5F_6$: C, 44.80; H, 4.13; N, 4.10; S, 11.72%.

2″-*O*-Acetyl-4″,6″-*O*-benzylidene-6′-*N*,4′-*O*-carbonyl-2′,3′-dideoxy-2′-eno-1,3,3″-tri-*N*-tosylkanamycin A (9). A mixture of **8** (60 mg), sodium iodide (600 mg) and imidazole (21 mg) in dry DMF (dried over molecular sieves 3A, 1.2 ml) was stirred at 100 °C for 45 min. TLC (chloroform–acetone=1 : 2) of the resulting deep red solution showed a single spot (**9**, R_f 0.58; cf **8**: 0.7). To the solution, while hot (when cooled, all contents solidified hard), was added hot chloroform (20 ml), and, after shaking for a while, the organic solution isolated was washed successively with water (10 ml×3), 0.1M (1 M= mol dm^{-3}) aqueous sodium thiosulfate (10 ml×2; to remove iodine liberated), and water (10 ml×3), dried (Na_2SO_4) and concentrated to give a glass, 46 mg (98%), $[\alpha]_D^{22}$ −12.5° (*c* 1, acetone); IR (KBr): 1710 cm^{-1}; ^1H NMR (pyridine-d_5 at 70 °C) δ=2.16, 2.25, and 2.30 (each 3H, s, Ts×3), 2.36 (3H, s, Ac), 5.73 (1H, br s, H-1′), 5.80 (1H, dt, *J*=2.5, 2.5, and 10 Hz, H-3′), 5.93 (1H, d, *J*=10 Hz, H-2′).

Found: C, 54.99; H, 5.56; N, 5.15%. Calcd for $C_{49}H_{56}N_4O_{17}S_3$: C, 55.04; H, 5.28; N, 5.24%.

2″-*O*-Acetyl-4″,6″-*O*-benzylidene-6′-*N*,4′-*O*-carbonyl-2′,3′-dideoxy-1,3,3″-tri-*N*-tosylkanamycin A (10). Platinum oxide (PtO_2, 21 mg) in oxolane–water (2 : 1, 2 ml) was activated with hydrogen (3 kg cm^{-2}, 30 min). Compound **9** (100 mg) was added and the mixture was shaken at room temperature under the same hydrogen pressure for 45 min. TLC (chloroform–acetone=1 : 1) of the solution showed a single spot (**10**, R_f 0.24; cf **9**: 0.28). The mixture was filtered and evaporated to give a glass, 97.5 mg (98%), $[\alpha]_D^{23}$ +10° (*c* 1, acetone); IR (KBr); 1700 cm^{-1}; ^1H NMR (pyridine-d_5): δ=1.6—1.85 (4H), 2.04 (1H, m), and 2.50 (1H, m)(H-2_{ax}, 2_{eq}, $2'_{ax}$, $2'_{eq}$, $3'_{ax}$, $3'_{eq}$); 2.17, 2.26, and 2.34 (each 3H, s, Ts×3), 2.51 (3H, s, Ac), 5.57 (1H, s, PhCH), 5.67 (1H, dd, *J*=3.5 and 10 Hz, H-2″), 5.73 (1H, slightly unresolved s, H-1′), 6.28 (1H, d, *J*=3.5 Hz, H-1″).

Found: C, 54.58; H, 5.54; N, 5.02; S, 8.70%. Calcd for $C_{49}H_{58}N_4O_{17}S_3$: C, 54.94; H, 5.46; N, 5.23; S, 8.98%.

2′,3′-Dideoxykanamycin A (12). From 10. To a solution of **10** (178 mg) in oxolane (2.4 ml) was added 3M aqueous sodium hydroxide (1.2 ml), and the mixture was vigorously stirred at 50 °C for 2.5 h. Concentration of the two-phase mixture gave a residue, the methanol solution of which was mixed with Dowex 50W×2 resin (NH_4^+ form, 10 ml, pretreated with methanol–water=2 : 1), and the whole mixture was poured into a column containing the same resin (1 ml). Development of the column with 3M aqueous ammonia–methanol (1 : 2) gave a ninhydrin-positive deacyl product (**11**, 167 mg). The product was purified by passing the solution in acetone through a column of Sephadex LH-20 (16 ml), that was pretreated with acetone to swell and washed with 0.5% hydrochloric acid in acetone and then with acetone. To a solution of the purified product (**11**) in liquid ammonia (≈17 ml) at −50 °C was added sodium metal (≈280 mg), and the deep-blue solution was kept for 1 h at the temperature. Addition of oxolane–water (99 : 1) until the solution became colorless, followed by gradual warming to room temperature, and evaporation under diminished pressure gave a glassy residue. To an aqueous solution of the residue was added Dowex 50W×2 resin (NH_4^+ form, 50 ml), and the mixture, after shaking for a while, was poured into a column containing the same resin (10 ml). The column was washed with water, eluted with 1M aqueous ammonia, and the eluate evaporated to give a residue (63.4 mg). The residue was chromatographed on a column of CM-Sephadex C-25 (NH_4^+ form, 32 ml) with, after washing with water, aqueous ammonia (0.01→0.15M, gradually changed) to give

a solid of **12**, 43.3 mg (51% monocarbonate), $[\alpha]_D^{23}$ +114° (*c* 1, water); $R_{\text{kanamycin A}}$ 2.0 (PPC with 1-butanol-pyridine-water-acetic acid=6:4:3:1, descending), and $R_{\text{kanamycin A}}$ 1.9 (TLC with 1-butanol-ethanol-chloroform-17% aqueous ammonia=4:7:2:7); ^{1}H NMR (20% ND_3 in D_2O) δ=1.23 (1H, q, J=12.5 Hz, H-2_{ax}), 1.6—2.05 (5H, H-2_{eq}, -$2'_{ax}$, -$2'_{eq}$, -$3'_{ax}$, -$3'_{eq}$), 5.02 (1H, d, J=3.5 Hz, H-1''), 5.31 (1H, slightly br s, H-1').

Found: C, 44.08; H, 7.33; N, 10.72%. Calcd for $C_{18}H_{36}N_4O_9 \cdot H_2CO_3$: C, 44.35; H, 7.44; N, 10.89%.

From 20. An aqueous solution (5 ml) of **20** (100 mg, monohydrate) was hydrogenated in the presence of platinum oxide (10 mg) under atmospheric pressure of hydrogen at room temperature for 3 h. After filtration, the product was purified by column chromatography of Amberlite CG-50 (NH_4^+ form, 3 ml) with 0.3M aqueous ammonia to give a solid of **12**, 91 mg (83% monocarbonate).

3',4',2'',4'',6''-Penta-*O*-benzoyl-1,3,6',3''-tetrakis(*N*-ethoxycarbonyl)-2'-*O*-methylsulfonylkanamycin A (14). To a solution of **13**[5] (3.00 g) in pyridine (30 ml) was added methanesulfonyl chloride (0.63 ml) and the solution was kept at room temperature for 1 h. After addition of water (0.2 ml) and standing for 30 min, the solution was concentrated in vacuo to dryness. The solution of the residue in ethyl acetate (100 ml) was washed with aqueous sodium hydrogencarbonate (saturated) and water, dried ($MgSO_4$), and concentrated. The residue was purified by silica-gel column chromatography (60 g) with chloroform-ethanol (50:1) to give a solid of **14**, 2.98 g (94%), $[\alpha]_D^{24}$ +102° (*c* 1, chloroform); ^{1}H NMR ($CDCl_3$ at 200 MHz) δ=2.70 (3H, s, Ms).

Found: C, 57.82; H, 5.44; N, 4.01; S, 2.39%. Calcd for $C_{66}H_{74}N_4O_{26}S$: C, 57.79; H, 5.45; N, 4.09; S, 2.33%.

1,3,6',3''-Tetrakis(*N*-ethoxycarbonyl)-2'-*O*-methylsulfonylkanamycin A (15). To a solution of **14** (137 mg) in dry methanol (5 ml) was added 28% sodium methoxide in methanol (0.1 ml) and the solution was kept at room temperature for 3 d. Resulting precipitates were filtered, washed with methanol, and dried to give a solid of **15**, 69 mg (81%), $[\alpha]_D^{20}$ +79° (*c* 1, DMF); ^{1}H NMR (pyridine-d_5-D_2O=10:1) δ=1.03 (3H), 1.12 (6H), and 1.23 (3H) (each t, $CO_2CH_2CH_3$×4); 3.42 (3H, s, SO_2CH_3), 4.83 (1H, dd, J=3.8 and 10 Hz, H-2'), 5.45 (1H, d, J=3.5 Hz, H-1''), 6.17 (1H, d, H-1'); H-1' and H-2' were confirmed by the shift-correlated 2-D spectrum.

Found: C, 42.99; H, 6.66; N, 6.17%. Calcd for $C_{31}H_{54}N_4O_{21}S \cdot H_2O$: C, 42.85; H, 6.50; N, 6.45%.

2',3'-Anhydro-4',2'',4'',6''-tetra-*O*-benzoyl-2'-epi-1,3,6',3''-tetrakis(*N*-ethoxycarbonyl)kanamycin A (16). To a solution of **14** (2.84 g) in dry 1,4-dioxane-methanol (1:1, 120 ml) was added 28% sodium methoxide in methanol (4 ml) and the solution was kept at room temperature overnight. After neutralization with 1M aqueous hydrochloric acid, the solution was concentrated to dryness. To a solution of the residue in pyridine (100 ml) was added benzoyl chloride (2.5 ml) and the solution was kept at room temperature for 1 h. Successive isolation then followed as described for **14** to give the crude product, that was purified by silica-gel column chromatography (50 g) with chloroform-ethanol (50:1) to give a solid of **16**, 1.98 g (82%), $[\alpha]_D^{20}$ +75° (*c* 1, chloroform).

Found: C, 59.66; H, 5.71; N, 4.56%. Calcd for $C_{58}H_{66}N_4O_{22}$: C, 59.47; H, 5.69; N, 4.78%.

4',2'',4'',6''-Tetra-*O*-benzoyl-3'-deoxy-2',3'-diepi-1,3,6',3''-tetrakis(*N*-ethoxycarbonyl)-3'-iodokanamycin A (17). To a solution of **16** (1.85 g) in acetone (45 ml) were added sodium iodide (1.36 g) and acetic acid (1.26 ml) and the solution was refluxed for 8 h. Concentration of the solution gave a residue, that was extracted with ethyl acetate. The solution was washed with water, dried ($MgSO_4$), and concentrated to dryness. The residue was purified by silica-gel column (50 g) with chloroform-methanol=45:1 to give a solid of **17**, 1.54 g (75%), $[\alpha]_D^{20}$ +33° (*c* 0.8, chloroform).

Found: C, 53.46; H, 5.20; N, 4.23; I, 10.01%. Calcd for $C_{58}H_{67}N_4O_{22}I$: C, 53.61; H, 5.21; N, 4.31; I, 9.78%.

4',2'',4'',6''-Tetra-*O*-benzoyl-3'-deoxy-2'-epi-1,3,6',3''-tetrakis(*N*-ethoxycarbonyl)kanamycin A (18). To a solution of **17** (300 mg) in toluene (10 ml) were added tributylstannane (0.35 ml) and AIBN (10 mg), and the mixture was heated at 70 °C for 30 min under the nitrogen atmosphere. TLC (chloroform-methanol=50:1) of the solution showed a single spot (R_f 0.07; cf **17**: 0.1). Concentration of the solution gave a syrup, that was thoroughly washed with ligroine. The syrup was purified by silica-gel column chromatography with chloroform-methanol (40:1) to give a solid of **18**, 242 mg (90%), $[\alpha]_D^{21}$ +89° (*c* 1, chloroform); ^{1}H NMR (pyridine-d_5) δ=0.75 (3H), 1.04 (6H), and 1.28 (3H) (each t, $CO_2CH_2CH_3$ ×4); 2.45 (1H, m, H-$3'_{ax}$), 2.68 (1H, m, H-$3'_{eq}$), 4.61 (1H, br, s, H-2'), 6.15 (1H, br s, H-1').

4',2'',4'',6''-Tetra-*O*-benzoyl-2',3'-dideoxy-2'-eno-1,3,6',3''-tetrakis(*N*-ethoxycarbonyl)kanamycin A (19). To a solution of **17** (1.00 g) in pyridine (20 ml) were added methanesulfonyl chloride (0.3 ml), 4-dimethylaminopyridine (90 mg), and triethylamine (1 ml), and the mixture was stirred at room temperature for 5 h. The mixture was poured into ice-water (50 g) and the precipitates were extracted with ethyl acetate. The organic solution was washed successively with 1M aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate (saturated), and water, dried ($MgSO_4$), and concentrated. The residue was purified by silica-gel column chromatography with chloroform-methanol (50:1) to give a solid of **19**, 650 mg (73%), $[\alpha]_D^{22}$ +78° (*c* 0.8, chloroform).

Found: C, 60.11; H, 5.76; N, 4.80%. Calcd for $C_{58}H_{66}N_4O_{21}$: C, 60.30; H, 5.77; N, 4.85%.

2',3'-Dideoxy-2'-enokanamycin A (20). To a solution of **19** (500 mg) in methanol (10 ml) was added 28% sodium methoxide in methanol (0.3 ml) and the solution was kept at room temperature for 30 min. Concentration in vacuo gave a residue, that was dissolved in water (6 ml) containing sodium hydroxide (1.5 g). The alkaline solution was heated at 100 °C for 3 h, then neutralized with aqueous hydrochloric acid. The reaction mixture was poured into a column of Amberlite CG-50 (NH_4^+ form, 20 ml) and, after washing with water, developed with 0.3M aqueous ammonia. Ninhydrin-positive fractions were collected and concentrated to give a solid of **20**, 135 mg (67% hydrate), $[\alpha]_D^{22}$ +106° (*c* 0.7, water); ^{1}H NMR (D_2O at 200 MHz) δ=1.18 (1H, q, J=12.5 Hz, H-2_{ax}), 1.93 (1H, dt, J=4.5, 4.5, and 12.5 Hz, H-2_{eq}), 5.00 (1H, d, J=4 Hz, H-1''), 5.43 (1H, fairly narrow and unresolved m, H-1'), 5.85 (1H, apparently ddd, the lower triplet being intense, J=2.3, 2.3, and 10 Hz, H-3'), 5.98 (1H, d, the high-field signal being intense, J=10 Hz, H-2').

Found: C, 46.25; H, 7.77; N, 11.82%. Calcd for $C_{18}H_{34}N_4O_9 \cdot H_2O$: C, 46.14; H, 7.76; N, 11.96%.

3,6'-Bis(*N*-benzyloxycarbonyl)-2',3'-dideoxykanamycin A (21). Method A. A mixture of **12** (37.7 mg, monocarbo-

nate) and zinc acetate dihydrate (56.3 mg, 3.5 molar equiv for **12**) in dry dimethyl sulfoxide (0.4 ml) was stirred at room temperature overnight. To the resulting clear solution was added *N*-(benzyloxycarbonyloxy)succinimide[13] (40.2 mg, 2.2 molar equiv for **12**) and the solution was kept at room temperature for 40 min. Addition of excess ether gave precipitates, that was filtered and washed thoroughly with ether. A solution of the precipitates in 50% aqueous oxolane was poured into a column of Amberlite CG-50 resin (7 ml, 100—200 mesh, prewashed with 1M aqueous ammonia and water, then with 50% aqueous oxolane). The column was washed with 50% aqueous oxolane (35 ml) and developed with the same solvent mixture containing ammonia (0→1M, gradually changed). The ninhydrin-positive product **21** was eluted by the procedure; zinc ion accompanied remained in the column. The eluate was evaporated to dryness to give a solid of **21**, 47.5 mg (88% hydrate), $[\alpha]_D^{22}$ +76° (*c* 0.7, DMF), R_f 0.3 (TLC with chloroform–methanol–28% aqueous ammonia=1 : 1 : 1, lower layer was used).

Found: C, 55.48; H, 6.61; N, 7.44%. Calcd for $C_{34}H_{48}N_4O_{13}\cdot H_2O$: C, 55.26; H, 6.83; N, 7.58%.

Compound **21** obtained by the above procedure was rather unstable on account of its own basicity and on storage it was liable to change to an undesirable 1,3-ureylene derivative.[16] Therefore when stable **21** was desirable, carbon dioxide was introduced to neutralize the basicity before concentration at the final stage and **21** was isolated as the carbonate salt.

Method B. To an ice-cold solution of **12** (9.84 g, monocabonate) and zinc acetate dihydrate (24.0 g, 5.7 molar equiv for **12**) in DMF–water (10 : 1, 170 ml) was added *N*-(benzyloxycarbonyloxy)succinimide (11.88 g, 2.5 molar equiv for **12**) and the solution was kept at the temperature for 1 h, then at room temperature overnight. Concentration of the solution in vacuo gave a residue, that was chromatographed on a column of Amberlite CG-50 resin (600 ml, pretreated as described for Method A) with, after washing the column with 50% aqueous 1,4-dioxane (2.7 l), 1M ammonia in the same solvent system to give a solid of **21**, 11.20 g (79% hydrate).

3,6′-Bis(*N*-benzyloxycarbonyl)-2′,3′-dideoxy-3″-*N*-trifluoroacetylkanamycin A (22). To a solution of **21** (5.10 g, monohydrate) in DMF (70 ml) was added ethyl trifluoroacetate (2.0 ml) and the solution was kept at room temperature for 20 min. TLC (lower layer of chloroform–methanol–28% aqueous ammonia=1 : 1 : 1) of the solution showed a single spot (R_f 0.5; cf **21**: 0.3). Concentration of the solution gave a syrup, that was washed with ether to give a solid of **22**, 5.9 g.

1-*N*-[(*S*)-4-Amino-2-hydroxybutyryl]-2′,3′-dideoxykanamycin A (2′,3′-Dideoxyamikacin) (23). To a mixture of **22** (5.8 g) and anhydrous sodiom carbonate (0.6 g) in 50% aqueous oxolane (170 ml) was added *N*-[(*S*)-4-benzyloxycarbonylamino-2-hydroxybutyryloxy]succinimide[3] (3.2 g) and the resulting clear solution was kept at room temperature for 2.5 h. TLC (the same solvent system as described above for **22** was used) of the solution showed a single spot (R_f 0.63). Concentration of the solution in vacuo gave a syrup, that was thoroughly washed with water to give a solid. A solution of the solid (6.07 g) in oxolane-2.2M aqueous ammonia (1 : 1, 360 ml) was kept at room temperature overnight. TLC of the solution showed a single spot (R_f 0.43). Concentration gave a residue, that was dissolved in 50% aqueous oxolane (150 ml). After addition of palladium black (360 mg) and acetic acid (6.5 ml), the solution was hydrogenated under atmospheric pressure of hydrogen for 4 h. Filtraion and neutralization of the solution with aqueous sodium hydroxide were followed by chromatography on a column of Amberlite CG-50 resin (NH_4^+ form, 150 ml). Elution with aqueous ammonia (0→0.5M, gradually changed) gave a solid of **23**, 2.89 g (69% based on **21**, monocarbonate), $[\alpha]_D^{22}$ +87° (*c* 0.9, water); IR (KBr): 1650, 950 cm^{-1}; ^1H NMR (20% ND_3 in D_2O) δ=1.43 (1H, q, *J*=12.5 Hz, H-2_{ax}), 1.6—2.05 (7H, H-2_{eq}, -2′$_{ax}$, -2′$_{eq}$, -3′$_{ax}$, -3′$_{eq}$ and COCH(OH)CH_2CH_2–), 4.17 [1H, q, *J*=3.8 and 9.5 Hz, COC*H*(OH)], 5.07 (1H, d, *J*=3.5 Hz, H-1″), 5.30 (1H, slightly br s, H-1′).

Found: C, 44.85; H, 7.43; N, 11.38%. Calcd for $C_{22}H_{43}N_5O_{11}\cdot H_2CO_3$: C, 44.87; H, 7.37; N, 11.38%.

1-*N*-[(*S*)-3-Amino-2-hydroxypropionyl]-2′,3′-dideoxykanamycin A (24). Compound **22** (5.0 g) was treated in the same manner as described for **23** only changing the succinimide reagent to *N*-[(*S*)-3-benzyloxycarbonylamino-2-hydroxypropionyloxy]succinimide (3.6 g) (prepared in a usual manner[15] from (*S*)-3-benzyloxycarbonylamino-2-hydroxypropionic acid,[16] *N*-hydroxysuccinimide, and dicyclohexylcarbodiimide) to give a solid of **24**, 1.30 g (40% based on **21**, hydrate), $[\alpha]_D^{22}$ +97° (*c* 0.7, water); ^1H NMR (D_2O at 200 MHz) δ=1.40 (1H, q, H-2_{ax}), 1.6—2.05 (5H, H-2_{eq}, -2′$_{ax}$, -2′$_{eq}$, -3′$_{ax}$, -3′$_{eq}$), 4.15 [1H, q, *J*=5 and 8 Hz, COC*H*(OH)], 5.04 (1H, d, *J*=3.5 Hz, H-1″), 5.29 (1H, slightly br s, H-1′).

Found: C, 45.44; H, 7.61; N, 12.66%. Calcd for $C_{21}H_{41}N_5O_{11}\cdot H_2O$: C, 45.22; H, 7.79; N, 12.56%.

1-*N*-(2-Aminoethoxycarbonyl)-2′,3′-dideoxykanamycin A (29). To a solution of **22** (100 mg) and anhydrous sodium carbonate (10.5 mg) in 50% aqueous oxolane (3.3 ml) was added *N*-[2-(benzyloxycarbonylamino)ethoxycarbonyloxy]-succinimide[14] (54 mg) in oxolane (1.7 ml) and the mixture was kept at room temperature for 2 h. TLC (chloroform–methanol–28% aqueous ammonia=1 : 1 : 1, lower layer) of the solution showed a single spot (R_f 0.67; cf **22**: 0.52). Evaporation gave a residue, that was washed with water and ether, and dried to give a solid (120 mg). A solution of the solid in 1,4-dioxane–2.5M aqueous ammonia (3 : 2, 6 ml) was kept at room temperature for 30 h. The slightly turbid solution showed, on TLC, a single spot (R_f 0.53). Concentration gave a residue, that was thoroughly washed with water and dried to give a solid (75 mg). A mixture of the solid and palladium black in 1,4-dioxane–water (2 : 1, 15 ml) was hydrogenated under atmospheric pressure of hydrogen for 3 h. The crude product obtained was purified by chromatography of CM-Sephadex C-25 column (NH_4^+ form, 16 ml) with, after washing with water, aqueous ammonia (0.01→0.5M) to give a solid of **29**, 33.0 mg [43% based on **21**, bis(carbonate)], $[\alpha]_D^{21}$ +85° (*c* 1, water); IR (KBr): 1700 cm^{-1}; ^1H NMR (20% ND_3 in D_2O) δ=1.43 (1H, q, *J*=13 Hz, H-2_{ax}), 1.65—2.15 (5H, H-2_{eq}, -2′$_{ax}$, -2′$_{eq}$, -3′$_{ax}$, -3′$_{eq}$), 5.11 (1H, d, *J*=3.8 Hz, H-1″), 5.35 (1H, br s, H-1′).

Found: C, 41.95; H, 7.09; N, 10.48%. Calcd for $C_{21}H_{41}N_5O_{11}\cdot 2H_2CO_3$: C, 41.62; H, 6.84; N, 10.55%.

1-*N*-(3-Aminopropoxycarbonyl)-2′,3′-dideoxykanamycin A (30). A solution of **22** (100 mg) and anhydrous sodium carbonate (10.5 mg) in 50% aqueous oxolane (3.3 ml) was treated with *N*-[3-(benzyloxycarbonylamino)propoxycarbonyloxy]-succinimide[14] (56 mg) in oxolane (1.7 ml) in a manner as described for **29** to give a solid, which was then led to **30**, 32.0 mg [40% based on **21**, bis(carbonate)], $[\alpha]_D^{21}$ +76° (*c* 2.8, water); ^1H NMR (20% ND_3 in D_2O) δ=1.43 (1H, q, *J*=12.5 Hz, H-2_{ax}), 1.65—2.15 (7H, H-2_{eq}, -2′$_{ax}$, -2′$_{eq}$, -3′$_{ax}$, -3′$_{eq}$ and

C(O)OCH$_2$C*H$_2$*CH$_2$NH$_2$), 5.11 (1H, d, J=3.8 Hz, H-1''), 5.35 (1H, br s, H-1').

Found: C, 42.46; H, 7.08; N, 9.94%. Calcd for $C_{22}H_{43}N_5O_{11}\cdot 2H_2CO_3$: C, 42.53; H, 6.99; N, 10.34%.

(*S*)-4-Benzyloxycarbonylamino-2-methoxybutyric Acid Methyl Ester (27). To a solution of (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid[13] (**26**, 2.5 g) in DMF (26 ml) were added silver oxide (4.6 g) and methyl iodide (1.9 ml), and the mixture was stirred in the dark at 5 °C overnight. After addition of methanol (0.5 ml) and ethyl acetate (50 ml), the mixture was filtered, and the filtrate was evaporated. The residue was chromatographed on silica gel with benzene–ethyl acetate (3 : 1) to give an oil of **27**, 1.42 g (51%), $[\alpha]_D^{20}$ −17° (*c* .1, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.75—2.1 (2H, m, CH_2-3), 3.25 (2H, t, J=6 Hz, CH_2-4), 3.35 (3H, s, OCH_3), 3.70 (3H, s, CO_2CH_3), 3.82 (1H, q, J=5 and 7 Hz, H-2), 5.05 (2H, s, $PhCH_2O$), 7.30 (5H, s, C_6H_5).

(*S*)-4-Benzyloxycarbonylamino-2-methoxybutyric Acid (28). To a solution of **27** (1.4 g) in acetone (40 ml) was added 1M aqueous sodium hydroxide (7.5 ml) and the mixture was kept at room temperature for 40 min. After neutralization to pH 9 with aqueous hydrochloric acid, the solution was concentrated. The concentrate was washed with ether and, after addition of aqueous hydrochloric acid (to pH 6), extracted with ethyl acetate. The organic solution was dried (Na_2SO_4) and concentrated to give an oil, that was purified by a charcoal column developed by methanol to give an oil of **28**, 0.85 g (64%), $[\alpha]_D^{22}$ −16° (*c* 1, chloroform); *m/z* 267.11269 (M^+), Calcd for $C_{13}H_{17}NO_5$: 267.11290; ^{1}H NMR ($CDCl_3$) δ=2.00 (2H, m, CH_2-3), 3.27 (2H, t, J=6 Hz, CH_2-4), 3.37 (3H, s, OCH_3), 3.81 (1H, t, J=6 Hz, H-2), 5.07 (2H, s, $PhCH_2O$), 7.30 (5H, s, C_6H_5).

1-*N*-[(*S*)-4-Amino-2-methoxybutyryl]-2',3'-dideoxykanamycin A (25). Compound **22** (360 mg) was treated in a similar manner as described for **23** with *N*-[(*S*)-4-benzyloxycarbonylamino-2-methoxybutyryloxy]succinimide (255 mg), prepared from **28** in a ususl manner, to give a solid of **25**, 100 mg (41% based on **21**), $[\alpha]_D^{22}$ +87° (*c* 0.7, water) and **12**, 105 mg (48%). **25**: ^{1}H NMR (D_2O at 200 MHz) δ=1.40 (1H, q, H-2$_{ax}$), 1.6—2.02 (7H, H-2$_{eq}$, -2'$_{ax}$, -2'$_{eq}$, -3'$_{ax}$, -3'$_{eq}$ and COCH(OCH$_3$)-C*H*$_2$CH$_2$-), 3.37 (3H, s, OCH_3), 5.06 (1H, d, J=3.5 Hz, H-1''), 5.28 (1H, slightly br s, H-1').

Found: C, 47.13; H, 8.00; N, 12.13%. Calcd for $C_{23}H_{45}N_5O_{11}\cdot H_2O$: C, 47.16; H, 8.10; N, 11.96%.

Chlorination of Acyclic β-Diketones. Formation and Stability of β-Chloro-β,γ-unsaturated Ketones[1]

Toshio SUGITA,* Hiroshi ITO, Akihiko NAKAJIMA, Motoshi SUNAMI, Atsushi KAWAKATSU, Masakazu SUAMA, and Katsuhiko ICHIKAWA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received August 22, 1986)

Chlorination of acyclic β-diketones with triphenylphosphine–carbon tetrachloride and the other chlorinating reagents predominantly afforded β-chloro-β,γ-unsaturated ketones except the cases of the terminal alkyl group of the diketones was methyl or *t*-butyl. In these reactions, the isomerization of the β-chloro-α,β-unsaturated ketones to the β,γ-unsaturated isomers was involved; the isomerization was achieved by triphenylphosphine–carbon tetrachloride as well as by some acid catalysts.

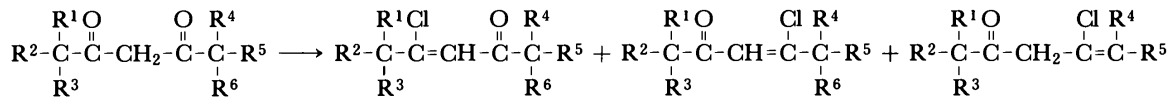
In our series of studies concerning reactions of β-diketones, the chlorination of β-diketones giving β-chloro-α,β-unsaturated ketones has attracted our attention. β-Chloro-α,β-unsaturated carbonyl compounds have become increasingly useful as intermediates in organic syntheses. For example, β-chloro-α,β-unsaturated ketones react with a zinc-silver couple in methanol,[2] active methylene compounds,[3] dimethylsulfoxonium methylide,[4] and a nitrogen compound[5] to produce a series of structurally diverse and potentially fruitful synthetic intermediates.

These β-chloro-α,β-unsaturated ketones were prepared by the chlorination of the corresponding β-diketones. However, the reactions hitherto reported were limited to those of cyclic β-diketones and 2,4-pentanedione.[2-13] Thus, we were prompted to investigate the chlorination of some acyclic β-diketones. As the chlorinating reagents of β-diketones, a variety of reagents, phosphorus trichloride,[6-8] phosgene,[9] acetyl chloride,[10] thionyl chloride,[7] phosphoryl chloride,[6] oxalyl dichloride,[2] and dichlorotriphenylphosphorane,[12] have been employed; however, triphenylphosphine in carbon tetrachloride was advantageously used to substitute the enol-hydroxyl group of β-diketones with a chlorine atom.[13] This procedure is regarded as being superior to the others since the formation of hydrogen chloride is not involved; thus, essentially neutral conditions can be maintained throughout the reaction. We examined the chlorination of several acyclic β-diketones using this procedure with some modification.

Results and Disccusion

The β-diketones were treated with triphenylphosphine and carbon tetrachloride in chloroform or in an excess of carbon tetrachloride to give β-chloro-α,β-unsaturated and/or β-chloro-β,γ-unsaturated ketones (Table 1).

Table 1. Chlorination of β-Diketones



Run	Diketone							Reagent	Solvent	Chloro ketone[a]			
		R^1	R^2	R^3	R^4	R^5	R^6			Yield/%	2	3	4
1	**1a**	H	H	H	H	H	H	Ph_3P-CCl_4	CCl_4	96	100		0
2[b]	**1a**							$(COCl)_2$	$CHCl_3$	50	100		0
3	**1a**							PCl_3	$CHCl_3$	25	100		0
4	**1b**	Me	H	H	Me	H	H	Ph_3P-CCl_4	$CHCl_3$	46(76)	20		80
5	**1b**							Ph_3P-CCl_4	CCl_4	27	17		83
6	**1b**							$(COCl)_2$	C_6H_6	36	27		73

13	**1f**	H	H	H	Me	Me	H	Ph_3P-CCl_4	CCl_4	(56)	67	4	29
14	**1g**	H	H	H	Me	Me	Me	Ph_3P-CCl_4	CCl_4	(29)[e,g]	100	0	0

a) Yields are isolated yields, values indicated in parentheses are obtained by GLPC, and the isomer distributions are obtained from the crude products by GLPC. b) Lit.[2] c) Unreacted diketone was recovered. d) Many unidentified products were obtained. e) Refluxed for 7 d. f) 26% of unreacted **1d** was recovered. g) 15% of **1g** was recovered.

Table 2. Isomerization between **2b** and **4b** in Chloroform

Catalyst	Starting material **2b** : **4b**	After 6 h at 60 °C **2b** : **4b**	After standing at room temp. overnight **2b** : **4b**
None	100 : 0	100 : 0	
Ph_3P-CCl_4	89 : 11	23 : 77	17 : 83
Ph_3P-CCl_4	2 : 98	12 : 88	14 : 86
Ph_3P	85 : 15	77 : 23	74 : 26
CF_3COOH	100 : 0	80 : 20	58 : 42
$AlCl_3$	100 : 0		57 : 43

4-Chloro-3-penten-2-one (**2a**) obtained from 2,4-pentanedione (**1a**) was a mixture of geometrical isomers (*E* : *Z*=85 : 15), which was confirmed by comparisons of their ^1H NMR spectra with the reported data.[14] Although β-chloro-α,β-unsaturated ketones were obtained from the corresponding β-diketones when the terminal alkyl group was methyl or *t*-butyl, 3,5-heptanedione (**1b**) and 2,6-dimethyl-3,5-heptanedione (**1c**) predominantly afforded unexpected β-chloro-β,γ-unsaturated ketones, 5-chloro-5-hepten-3-one (**4b**) and 5-chloro-2,6-dimethyl-5-hepten-3-one (**4c**) respectively. These ketones did not show the signal of a vinyl proton of the α,β-unsaturated ketone at around δ=6.5, but a singlet of methylene protons at δ=3.5 in their NMR spectra. These characteristic data, as well as their other NMR signals, indicate that the products are β-chloro-β,γ-unsaturated ketones. The **4b** obtained here was mainly a *Z* isomer, *Z* : *E*=89 : 11; its ^{13}C NMR spectrum indicated central methylene carbon signal at δ=52.60 and the γ-methyl signal at δ=14.27. These chemical shifts of the product were down-field compared with the respective values of its isomer (47.44 and 12.33), a small amount of which was detected in the product mixture in some cases but, unfortunately, could not be isolated. In a preliminary communication, we reported that the β-chloro-β,γ-unsaturated ketones were the exclusive product in these cases;[1] however, we later confirmed the formation of the α,β-unsaturated isomers (even in small amounts). There were some difficulties to separate the α,β-unsaturated isomers from the unreacted β-diketones. On the contrary, the β,γ-unsaturated ketones could be easily separated by column chromatography as well as GLPC. By increasing the steric bulkiness of the terminal alkyl groups of diketones, the reaction became very slow. The chlorination of **1d** resulted in only a product/unreacted diketone=7/12 after refluxing for 7 d.

In order to investigate the regioselectivity of the chlorination, unsymmetrical β-diketones were treated with triphenylphosphine and carbon tetrachloride in the same fashion. 2,4-Hexanedione (**1e**) gave a mixture of 5-chloro-4-hexen-3-one (**2e**), 4-chloro-3-hexen-2-one (**3e**) and 4-chloro-4-hexen-2-one (**4e**) in a ratio of 35 : 12 : 53. **4e** was mainly the *Z* isomer containing small amount of the *E* isomer similarly to **4b**. The chlorination of 5,5-dimethyl-2,4-hexanedione (**1g**) afforded a sole kind of α,β-unsaturated ketone. The ^1H NMR chemical shift of *t*-butyl group of the product (δ=1.14) was the same as that of the starting diketone (δ=1.14), and a long-range coupling (*J*=1.2 Hz) was observed between the methyl and the vinyl protons. Thus, the chlorination product was confirmed to be (*E*)-5-chloro-2,2-dimethyl-4-hexen-3-one (*E*-**2g**). The fact that the chlorination occurred at the acetyl moiety may be due to the steric bulkiness of the *t*-butyl group. The results obtained from these unsymmetrical diketones were comparable in the product distributions to that of symmetrical diketones. The chlorination of acetyl moiety gave only α,β-unsaturated ketones; however, the propionyl and isobutyryl groups were chlorinated, giving a mixtures of α,β- and β,γ-unsaturated isomers. Furthermore, the product ratios of α,β- and β,γ-unsaturated isomers, **3e** : **4e**=18 : 82 for propionyl group and **3f** : **4f**=12 : 88 for isobutyryl group, were quite equal to those obtained from symmetrical diketones, **2b** : **4b**=20 : 80 and **2c** : **4c**=10 : 90.

As control experiments, chlorination with oxalyl dichloride or phosphorus trichloride was pursued in the same way as reported.[2,3,7] The differences on isomeric ratio of the products in each preparation method was not so quite pronounced (Table 1), but triphenylphosphine-carbon tetrachloride system is superior to the other reagents regarding chemical yields.

As the enol form of β-diketones is considered to take an α,β-unsaturated ketone structure, the substitution of enol hydroxyl group of β-diketone by chlorine was expected to afford β-chloro-α,β-unsaturated ketone. In fact, **2b** was predominated over **4b** during an early stage of the chlorination reaction of **1b**; then, **4b** became superior as the reaction progresses. Thus, we undertook to examine the isomerization of the chlorinated products. The results are summarized in Table 2. When **2b** was heated at 60—65 °C in chloroform for 6 h, no isomerization could be observed at all. The isomerization from the α,β-unsaturated ketone **2b** to the β,γ-unsaturated isomer **4b**; however, it readily took place in the presence of triphenylphosphine and carbon tetrachloride, i.e. under the chlorination conditions, giving a mixture of 17% of **2b** and 83% of **4b**. A mixture of 14% of **2b** and 86% of **4b** was also obtained from **4b**. These values were almost identical with the isomeric ratio of the chlorination product. A slow isomerization was also achieved with acid catalysts,

CF_3COOH or $AlCl_3$, and triphenylphosphine alone. As a result of these experiments, it became clear that the β-chloro-β,γ-unsaturated ketone is thermodynamically more stable than its α,β-unsaturated isomer when a methyl group is substituted at the γ-position. The relative stabilities of the α,β- and β,γ-unsaturated carbonyl compounds have been discussed in terms of the conjugative and inductive contributions of substituents located on the three-carbon allylic chain;[15] however, very little is known about β-chloro-β,γ-unsaturated ketones and esters. Martin and Kirschleger indicated that the β-chloro-β,γ-unsaturated ketones preponderated over the α,β-unsaturated isomers in the Friedel-Crafts acylation products of alkylacetylenes with acetyl chloride.[16] Although the equilibrium between the α,β- and β,γ-unsaturated forms of the three-carbon allylic chain is not sensitive to the nature of the adjacent activating group as well as the alkyl substituents at the β-position, the alkyl substitution, particularly methyl substitution, at the γ-position increases the relative thermodynamic stability of the β,γ-unsaturated isomer.[15,17] More recently, Rhoads et al.[18] and Taskinen and Mukkala[19] reported that the introduction of a methoxyl group at the β-position strongly shifted the equilibrium towards the side of β,γ-unsaturated isomers.

In the present case, although the thermodynamic stability of β,γ-unsaturated ketones (**4**) may be primarily due to the γ-methyl substituent,[15] the similar effects to the β-methoxyl substituent would be expected for β-chloro substituent because the equilibration so strongly favored the β,γ-unsaturated isomer that would not have been expected on the basis of earlier analyses.[15] The initially formed β-chloro α,β-unsaturated ketones favored the *E* isomer. This fact may indicate a repulsive *cis* dipole-dipole interaction of the two polar functions, chloride and carbonyl, in the *Z* isomer is quite large. If the *Z* isomer exists in *s-trans* conformation, the repulsive dipole-dipole interaction would be diminished, but the steric repulsion between chlorine and the alkyl group attached to the carbonyl would contrary become prominent. In the *E* isomer of α,β-unsaturated ketones, a large steric repulsion between the ethyl or isopropyl group adjacent to the olefinic linkage and the acyl group destabilizes the *E* isomer. These steric and dipole-dipole interactions are relieved in the β,γ-unsaturated isomer. Thus, the chlorination products of **1b** and **1c** are favored β,γ-unsaturated ketone structures. On the other hand, as **2a** lacks γ-methyl substituent and also as the destabilizing *cis* steric interaction between methyl and acetyl groups would be overcome by the conjugative stabilization of α,β-unsaturated carbonyl system, **1a** gives only α,β-unsaturated **2a**.

Experimental

All bps were uncorrected. ^1H and ^{13}C NMR spectra were taken on JEOL PMX-60 and JNM-FX100 spectrometers respectively in $CDCl_3$ using TMS as an internal standard. IR spectra were measured with a Hitachi EPI-G2 spectrometer. MS spectra were taken on Hitachi M-80 mass spectrometer. GLPC analyses were performed on Hitachi 163 and 263 gas chromatographs using 3 mm×2 m columns packed with Silicone SE-30 30% on Shimalite or PEG-20M 20% on Chromosorb-W. Purifications of products were conducted by medium-pressure column chromatography on silica gel (Merck Kieselgel 60) or by atmospheric-pressure column chromatography on silica gel (Wakogel C-200).

Commercial GR grade 2,4-pentanedione was used after distillation, and the other β-diketones were prepared by reported methods.[20]

General Procedure for the Chlorination of β-Diketones. To a stirred mixture of 3,5-heptanedione (**1b**; 3.85 g, 30 mmol) and triphenylphosphine (15.7 g, 60 mmol), a solution of carbon tetrachloride (7.23 g, 47 mmol) in 55 ml of chloroform was added over a 5-min period. After the addition, the mixture was stirred at 60 °C for 6 h, then allowed to stand overnight at room temperature. The solvent was removed on a rotary evaporator under moderately reduced pressure. The residual viscous matter was extracted four times by grinding with 80 ml of pentane in a mortar finally leaving triphenylphosphine oxide and (dichloromethyl)triphenylphosphonium chloride as white crystalline powder. The extracts were combined and distilled to give a crude product, bp 95—104 °C/50 mmHg (1 mmHg=133.322 Pa), 3.5 g, which was a mixture of **1b** (4.1%), *E*-**2b** (16.3%), **4b** (77.2%), and *Z*-**2b** (2.4%) in order of GLPC retention times. The crude product was purified by moderate pressure column chromatography using hexane and hexane-ethyl acetate (98:2) as the eluent to obtain pure **2b** (0.27 g) and **4b** (1.74 g).

When the chlorination was pursued in excess carbon tetrachloride instead of chloroform solution, the GLPC-determined yields were almost comparable with the reaction in chloroform, however, we suffered some difficulties in the separation of products from the phosphonium salt and triphenylphosphine oxide.

(*Z*)-5-Chloro-5-hepten-3-one (*Z*-4b). Bp 86 °C/19 mmHg; ^1H NMR δ=1.07 (t, *J*=8 Hz, 3H), 1.78 (d, *J*=7 Hz, 1H), 2.57 (q, *J*=8 Hz, 2H), 3.39 (s, 2H), 5.72 (q, *J*=7 Hz, 1H); ^{13}C NMR δ=7.63 (q), 14.27 (q), 35.17 (t), 52.60 (t), 125.05 (s), 127.81 (d), 206.77 (s); IR (neat): 1660, 1720 cm^{-1}; MS: *m/z* 148 (M+2),

Bp 78 °C/20 mmHg; ^{13}C NMR δ=7.63 (q), 12.33 (q), 34.76 (t), 47.44 (t), 126.28 (s), 205.83 (s), a peak derived from C^5 could not be identified; Found: C, 57.54; H, 7.75; Cl, 24.35% (values obtained from the mixture).

(*E*)-5-Chloro-4-hepten-3-one (*E*-2b). ^1H NMR δ=1.06 (t, *J*=7 Hz, 3H), 1.16 (t, *J*=7 Hz, 3H), 2.49 (q, *J*=7 Hz, 2H), 2.96 (q, *J*=7 Hz, 2H), 6.35 (s, 1H); ^{13}C NMR δ=7.87 (q), 12.77 (q), 29.77 (t), 37.70 (t), 124.70 (d), 157.60 (s), 199.32 (s); IR (neat): 1600, 1690 cm^{-1}; Found: C, 57.16; H, 7.60; Cl, 23.99%.

(*Z*)-5-Chloro-4-hepten-3-one (*Z*-2b). ^1H NMR δ=1.20 (t, *J*=7 Hz, 3H), 1.30 (t, *J*=6 Hz, 3H), 2.47 (q, *J*=7 Hz, 2H), 2.60 (q, *J*=6 Hz, 2H), 6.21 (s, 1H); ^{13}C NMR δ=7.81 (q), 12.27 (q), 34.76 (t), 37.22 (t), 123.06 (d), 147.83 (s), 198.40 (s); IR (neat): 1610, 1705 cm^{-1}; Found: C, 57.40; H, 7.73; Cl, 24.29% (values obtained from a mixture of *Z*-**2b** and *Z*-**4b** (33 : 67)).

4-Chloro-3-penten-2-one (2a). Bp 63 °C/170 mmHg; ^1H NMR (*E*) δ=2.21 (s, 3H), 2.56 (d, *J*=1.1 Hz, 3H), 6.48 (q, *J*=1.1 Hz, 1H), (lit,[14] δ=2.20, 2.52, 6.47); (*Z*) δ=2.26 (s, 3H), 2.33 (s, 3H), 6.27 (s, 1H), (lit,[14] δ=2.26, 2.33, 6.27); IR (neat): 1610, 1700 cm^{-1} (lit,[14] 1610, 1705 cm^{-1}). The ratio *E* : *Z*= 85 : 15 was estimated from the peak area of GLPC.

5-Chloro-2,6-dimethyl-5-hepten-3-one (4c). Bp 113 °C/34 mmHg; ^1H NMR δ=1.13 (d, *J*=7 Hz, 6H), 1.71 (s, 3H), 1.84 (s, 3H), 2.64 (m, 1H), 3.57 (s, 2H); ^{13}C NMR δ=18.14 (q), 20.99 (q), 21.72 (q), 39.92 (d), 47.32 (t), 131.57 (s), 152.99 (s), 209.54 (s); Found: C, 61.92; H, 8.65; Cl, 19.82%. Calcd for $C_9H_{15}OCl$: C, 61.89; H, 8.66; Cl, 20.30%.

5-Chloro-2,6-dimethyl-4-hepten-3-one (2c). ^1H NMR δ= 1.25 (d, *J*=8 Hz, 6H), 1.30 (d, *J*=8 Hz, 6H), 2.60 (m, 2H), 2.75 (m, 2H), 6.38 (s, 1H); ^{13}C NMR δ=19.08 (q), 19.32 (q), 36.64 (d), 41.33 (d), 120.41 (d), 202.26 (s), a peak derived from C^5 could not be identified, (values obtained from a mixture with **4c**).

5-Chloro-2,2,6,6-tetramethyl-4-hepten-3-one (2d). ^1H NMR δ=1.17 (s, 9H), 1.26 (s, 9H), 6.57 (s, 1H); IR (neat): 1595, 1695 cm^{-1}; MS: *m/z* 204 (M+2), 202 (M^+), 147, 145, 117, 57.

5-Chloro-4-hexen-3-one (2e). ^1H NMR δ=1.07 (t, *J*=7 Hz, 3H), 2.48 (q, *J*=7 Hz, 2H), 2.54 (s, 3H), 6.39 (s, 1H); ^{13}C NMR δ=7.87 (q), 24.12 (q), 37.75 (t), 125.41 (d), 151.18 (s), 198.50 (s); IR (neat): 1605, 1695 cm^{-1}; Found: C, 54.21; H, 6.88; Cl, 26.87%. Calcd for C_6H_9OCl: C, 54.35; H, 6.84; Cl, 26.74%.

(*E*)-4-Chloro-3-hexen-2-one (*E*-3e). ^1H NMR δ=1.06 (t, *J*=7 Hz, 3H), 2.23 (s, 3H), 2.58 (q, *J*=7 Hz, 2H), 6.27 (s, 1H); ^{13}C NMR δ=7.81 (q), 28.30 (q), 37.10 (t), 124.64 (d), 142.08 (s), 198.85 (s); IR (neat): 1615, 1700 cm^{-1}. Acetyl proton signal, δ=2.23, was observed at almost the same chemical shift with *E*-**2a**, and very weak but clear signals expected to be derived from its *Z* isomer were observed in the ^{13}C NMR spectrum at δ=9.5, 29.2, and 138.4, thus the product was estimated to be *E* isomer.

(*Z*)-4-Chloro-4-hexen-2-one (*Z*-4e). ^1H NMR δ=1.78 (d, *J*=7 Hz, 3H), 2.14 (s, 3H), 3.37 (s, 2H), 5.69 (q, *J*=7 Hz, 1H); ^{13}C NMR δ=14.27 (q), 28.94 (q), 53.66 (t), 125.29 (d), 127.87 (s), 204.08 (s); IR (neat): 1660, 1725 cm^{-1}; Found: C, 54.45; H, 7.00; Cl, 26.51%. Calcd for C_6H_9OCl: C, 54.35; H, 6.84; Cl, 26.74% (values obtained from a mixture of **4e** and **3e** (92 : 8)). The product was almost a single isomer, estimated as a *Z* isomer by compairing its ^1H and ^{13}C NMR spectra with those of **4b**. Weak absorptions at δ=1.64 (d), 2.17 (s), 3.41 (s), 5.87 (s) (^1H NMR) and at δ=37.80, 47.61 (^{13}C NMR) indicated the contamination of small amount of the *E* isomer.

(*E*)-5-Chloro-2-methyl-4-hexen-3-one (*E*-2f). ^1H NMR δ= 1.13 (d, *J*=7 Hz, 6H), 2.28—2.83 (m, 1H), 2.58 (s, 3H), 6.54 (s, 1H); ^{13}C NMR δ=18.02 (q), 24.18 (q), 41.98 (d), 124.58 (d), 151.94 (s), 201.90 (s); IR (neat): 1605, 1695 cm^{-1}; Found: C, 57.55; H, 7.53; Cl, 23.89%. Calcd for $C_7H_{11}OCl$: C, 57.34; H, 7.56; Cl, 24.18%.

(*Z*)-5-Chloro-2-methyl-4-hexen-3-one (*Z*-2f). ^1H NMR δ= 1.13 (d, *J*=7 Hz, 6H), 2.77 (m, 1H), 2.28 (s, 3H), 6.39 (s, 1H); ^{13}C NMR δ=18.02 (q), 28.36 (q), 41.27 (d), 122.88 (d), 142.27 (s), 201.66 (s); IR (neat): 1610, 1695 cm^{-1}; Found: C, 57.29; H, 7.66; Cl, 23.90%.

4-Chloro-5-methyl-4-hexen-2-one (4f). ^1H NMR δ=1.78 (s, 3H), 1.89 (s, 3H), 2.17 (s, 3H), 3.46 (s, 2H); IR (neat): 1670, 1720 cm^{-1}; Found: C, 57.59; H, 7.72; Cl, 23.91%. Calcd for $C_7H_{11}OCl$: C, 57.34; H, 7.56; Cl, 24.18%.

(*E*)-5-Chloro-2,2-dimethyl-4-hexen-3-one (*E*-2g). ^1H NMR δ=1.15 (s, 9H), 2.52 (d, *J*=1.2 Hz, 3H), 6.62 (q, *J*=1.2 Hz, 1H); IR (neat): 1605, 1695 cm^{-1}; Found: C, 59.77; H, 8.22; Cl, 22.02%. Calcd for $C_8H_{13}OCl$: C, 59.81; H, 8.16; Cl, 22.07%.

Isomerization between 2b and 4b. A solution of **2b** (*E* : *Z*=55 : 1; 230 mg, 1.57 mmol), triphenylphosphine (828 mg, 3.14 mmol), carbon tetrachloride (490 mg, 3.14 mmol), tetralin (internal standard, 72 mg) in 5 ml of chloroform was kept at 57—60 °C for 6 h, then at room temperature overnight. The products distribution was analyzed by GLPC, giving the ratio of **2b** : **4b**=17 : 83. **4b** (contained 3% of **2b**, 168 mg, 1.15 mmol) was also treated as same as mentioned above yielding a mixture of **2b** : **4b**=14 : 86.

In the case of trifluoroacetic acid-catalyzed isomerization experiment, *E*-**2b** (147 mg, 1.0 mmol) and trifluoroacetic acid (104 mg, 0.91 mmol) was dissolved in 0.5 ml of $CDCl_3$, the solution in a NMR tube was kept at 53—57 °C for 5 h, and the ratio of **2b** and **4b** was obtained from the peak integrals of δ=6.35 (*E*-**2b**, 1H), 6.21 (*Z*-**2b**, 1H), and 3.39 (**4b**, 2H).

The pertial contribution of Mr. Kazuaki Abe and Mr. Mitsuru Eida to the experimental work is appreciated. The authors are grateful to Dr. Tamio Ueno of the Pesticide Research Institute for measurements of the MS spectra.

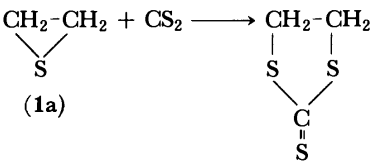
The Synthesis of 1,3-Dithiolane-2-thione Derivatives

Yoichi TAGUCHI,* Koshin YANAGIYA, Isao SHIBUYA, and Yasuo SUHARA
National Chemical Laboratory for Industry, Higashi 1-1, Yatabe, Tsukuba, Ibaraki 305
(Received August 23, 1986)

The reaction of 2,2-dimethylthiirane with carbon disulfide in the presence of triethylamine was accelerated under high pressure to give 4,4-dimethyl-1,3-dithiolane-2-thione nearly quantitatively. The activation volume of this reaction at 40 °C was estimated to be −41 ml mol^{-1}. The rate of the reaction was proportional to the amount of triethylamine when a limited amount of triethylamine was used. The reaction of 2-methylthiirane, 2-hexylthiirane, 1,2-epithiocyclohexane, and 2-phenylthiirane with carbon disulfide gave the corresponding 1,3-dithiolane-2-thione derivatives in good yields. 2-Chloromethylthiirane was less reactive to carbon disulfide than other thiiranes under high pressure. Tertiary amines such as *N*,*N*-dimethylethylamine, pyridine, and *N*-methylmorpholine were good catalysts of the reaction.

Thiiranes react with various compounds to form the open-ring products.[1,2] It has been known that five-membered heterocyclic compounds are obtained by the reaction of thiiranes with methyl cyanoacetate,[3] malononitrile,[4] acetonitrile,[5] diethyl malonate,[6] and ethyl acetoacetate.[6] Although the reaction of thiirane (**1a**) with carbon disulfide gave 1,3-dithiolane-2-thione in a good yield, the reaction of substituted thiiranes with carbon disulfide showed lower yield.[7] On the other hand, high pressure accelerates many organic reactions[8] including those of carbon disulfide.[9,10] However, there has been no report on the reaction of thiiranes under high pressure.



We will report that the reaction of substituted thiiranes with carbon disulfide is accelerated under high pressure to give the corresponding 1,3-dithiolane-2-thione derivatives in good yields. The effects of pressure, reaction temperature, and amount and kind of catalysts on the reaction of 2,2-dimethylthiirane (**1b**) with carbon disulfide were investigated and the reactions of various thiiranes with carbon disulfide attempted.

Results and Discussion

Under 1 kg cm^{-2} pressure, the reaction of **1b** with carbon disulfide at 80—100 °C in the presence of triethylamine as a catalyst gave 4,4-dimethyl-1,3-dithiolane-2-thione (**2**) in 2—12% yield. At a higher temperature (120 °C) the yield was still lower (10%)

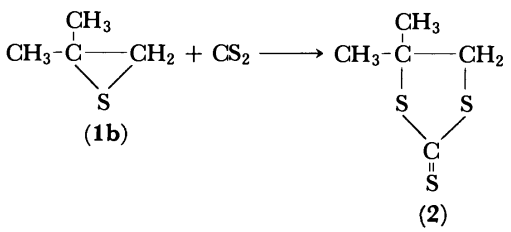


Table 1. Effect of Reaction Conditions on the Reaction of **1b** with CS_2[a]

Run	Temp	Press.[b]	Yield
	°C	kg cm^{-2}	%
1	80	1	2
2	100	1	12
3	120	1	10
4	40	5000	92
5	70	2000	96
6	100	2000	87
7	100	8000	91

a) **1b**: 10 mmol, CS_2: 50 mmol, Et_3N: 0.10 g, reaction time: 20 h. b) 1 kg cm^{-2}=0.9806×10^5 Pa.

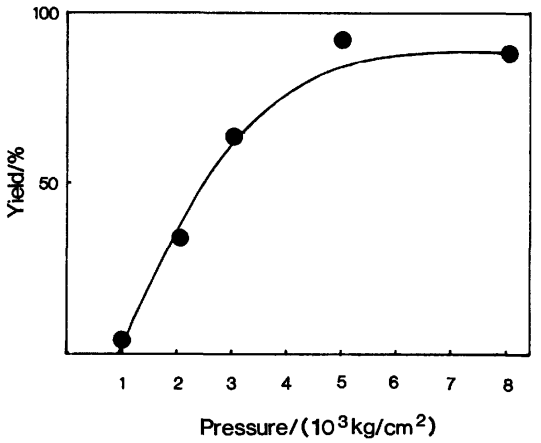

Fig. 1. Effect of pressure on the reaction of **1b** with CS_2; Reaction temperature: 40°C, reaction time: 20 h, **1b**: 10 mmol, CS_2: 50 mmol, Et_3N: 1 mmol.

and various by-products were contained in **2** (Table 1, Runs 1—3). When the reaction was carried out under high pressures (2000—8000 kg cm^{-2}), the yield of **2** increased to over 90% (Runs 4—7). As the pressure was increased to 5000 kg cm^{-2}, the rate of the formation of **2** was enhanced satisfactorily even at 40 °C (Run 4).

The effect of pressure on the reaction of **1b** with carbon disulfide is shown in Fig. 1. The reaction is regarded as a first-order reaction with respect to **1b**, because carbon disulfide is excessive. The reaction-velocity constant k is calculated from the data in Fig. 1.

The activation volume $\Delta V^{\neq}$ at 40 °C estimated by Eq. 1 was −41 ml mol^{-1}. This value suggests that the reaction is considerably accelerated by the pressure.

$$\Delta V^{\neq} = RT(\partial \ln k/\partial P)_T \quad (1)$$

Figure 2 shows that the rate of reaction of **1b** with carbon disulfide is proportional to the amount of triethyamine catalyst when a limited amount of triethylamine is used.

Table 2 shows the products and yields of reactions of various thiiranes with carbon disulfide. The reaction of 2-methylthiirane, 2,2-dimethythiirane, 2-hexylthiirane, 2-phenylthiirane, and 1,2-epithiocyclohexane with carbon disulfide gave the corresponding 1,3-dithiolane-2-thiones in good yields. The yield of the reaction of **1a** with carbon disulfide was 53%. This fact is considered to be due to a tendency of **1a** to polymerize. 2-Chloromethylthiirane showed low reactivity and selectivity toward carbon disulfide in comparison with other thiiranes.

Table 3 shows the effects of various catalysts on the reaction of **1b** with carbon disulfide. *N*,*N*-Dimethylethylamine, triethylamine, *N*-methylmorpholine, and pyridine were good catalysts under high pressure, the catalytic activity decreasing in this order. *N*,*N*-Dimethylaniline had no catalytic activity even under high pressure. The catalytic activity of tertiary amines, therefore, would be influenced by basicity as well as steric factor. Tetramethylammonium bromide, which has been reported to have catalytic activity on the reaction of oxiranes with carbon disulfide,[7] showed low activity under 8000 kg cm^{-2}. Lithium chloride was used as a catalyst of the reaction of thiiranes or oxiranes with various heterocumulenes,[8,11,12] but it had no catalytic activity on the reaction of **1b** with carbon disulfide under 8000 kg cm^{-2} at 100 °C.

The reaction of thiiranes or oxiranes with various heterocumulenes under ordinary pressure has been reported to give five-membered products.[8,11,12] The reactions of **1b** with methyl isothiocyanate, phenyl

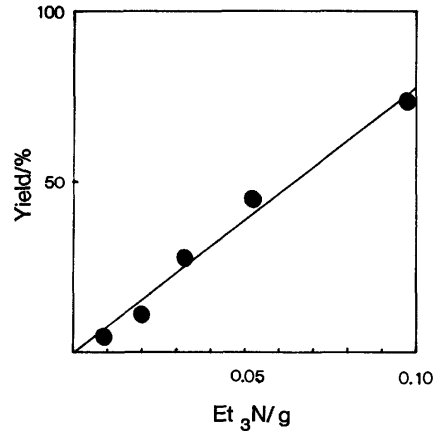

Fig. 2. Effect of amount of Et_3N on the reaction of **1b** with CS_2; Reaction temperature: 40°C, reaction time: 20 h, pressure: 3000 kg cm^{-2}, **1b**: 10 mmol, CS_2: 50 mmol.

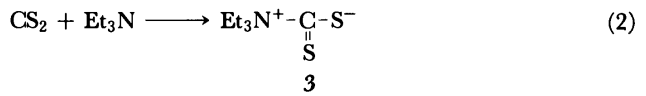
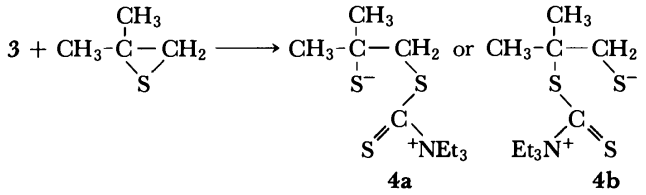
a) **1b**: 10 mmol, CS_2: 50 mmol, catalyst: 1 mmol, reaction time: 20 h.

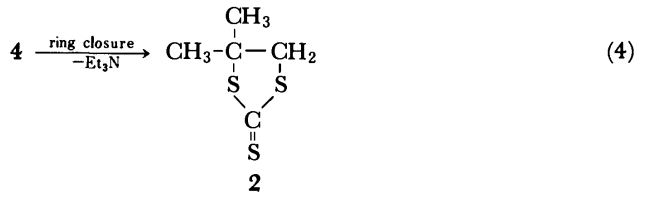
isocyanate, and dicyclohexylcarbodiimide under high pressure were tried, but no effect of the compression appeared in any cases. Accordingly, highly selective reaction of thiiranes under high pressure seems to be characteristic of carbon disulfide; it is carbon disulfide that is activated under high pressure but not **1b**. On the other hand, the reaction of **1b** with carbon disulfide without catalyst under high pressure gave various by-products and only a trace of **2** (Table 3, Run 13). It is well-known that carbon disulfide reacts with amines easily.[14]



(2)



(3)



(4)

The reaction of **1b** with carbon disulfide in the presence of triethylamine seems to proceed succesively with the first step of adduct **3** formation from carbon disulfide and triethylamine (Eq. 2), then addition of **3** to **1b** yielding **4** (Eq. 3), and ring closing of **4** (Eq. 4). Whether the structure of **4** is **4a** or **4b** is ambiguous, because both **4a** and **4b** lead to the same product **2** by rapidly succeeding ring closure. But **4a** is more likely, because active methylene compounds[6] and secondary amines[15] are apt to attack the less-hindered carbon atom of thiirane ring. Equation 4 is a reaction in which two molecules (**2** and Et_3N) are formed from one molecule, and it is unlikely that compression accelerates such a reaction. Therefore, the compression seemes to be effective on a step of Eq. 2 or 3.

Experimental

Apparatus. The apparatus used for the reaction under high pressure was the same as that described previousyl.[16]

Measurement. GLC was carried out by a JEOL 20KF chromatograph with 20% SE-30 columns. ^{1}H NMR spectra were measured by a Hitachi R-40 spectrometer. Mass spectra were measured by a JEOL D-300 GC-MS spectrometer using the CI (chemical ion) method with isobutane. IR spectra were obtained by a JASCO A-302 spectrophotometer.

Materials. Thiirane and 2-methylthiirane were purchased from Aldrich Chem. Co. 2,2-Dimethylthiirane, 2-hexylthiirane, 2-phenylthiirane, and 1,2-epithiocyclohexane were prepared as previously described.[6] 2-Chloromethylthiirane was obtained by the method of Culvenor.[17]

Reaction of Thiiranes with Carbon Disulfide. A typical procedure is as follows: A homogeneous mixture of **1b** (10 mmol), carbon disulfide (50 mmol), and triethylamine (1 mmol) in a sealed teflon tube was compressed to 5000 kg cm^{-2}, heated at 40 °C, and maintained for 20 h in a high pressure equipment. The resulting mixture was subjected to evaporation and the residue was purified by distillation with Kugelrohr to give 1.50 g (92%) of **2**. IR: 1054, 1089 cm^{-1}; ^{1}H NMR δ=1.74 (s, 6H, $2CH_3$), 3.76 (s, 2H, CH_2); QM^+: 165.

Thiirane, 2-methylthiirane, 2-hexylthiirane, 1,2-epithiocyclohexane, 2-phenylthiirane, and 2-chloromethylthiirane were treated with carbon disulfide in a similar manner to the reaction of **1b** with carbon disulfide. The spectral data of products of these reactions are as follows:

1,3-dithiolane-2-thione. IR: 1057 cm^{-1}; ^{1}H NMR δ=4.00 (s, 4H, $2CH_2$); QM^+: 137.

4-methyl-1,3-dithiolane-2-thione. IR: 1076, 1050, 1033 cm^{-1}; ^{1}H NMR δ=1.64 (d, 3H, CH_3), 3.55—3.85 (dd, 1H, one proton of CH_2), 3.95—4.20 (dd, 1H, one proton of CH_2), 4.35—4.75 (m, 1H, CH); QM^+: 151.

4-hexyl-1,3-dithiolane-2-thione. IR: 1064 cm^{-1}; ^{1}H NMR δ=0.88 (t, 3H, CH_3), 1.34 (s, 8H, $\{CH_2\}_4$), 1.70—2.10 (m, 2H, CH_2), 4.25—4.60 (m, 1H, CH); QM^+: 221.

4,5-Tetramethylene-1,3-dithiolane-2-thione. IR: 1033, 1058 cm^{-1}; ^{1}H NMR δ=1.00—2.40 (m, 8H, $\{CH_2\}_4$), 3.90—4.40 (m, 2H, CH_2); QM^+: 191.

4-Phenyl-1,3-dithiolane-2-thione. IR: 1047 cm^{-1}; ^{1}H NMR δ=3.90—4.40 (m, 2H, CH_2), 5.55—5.80 (dd, 1H, CH), 7.25—7.70 (m, 5H, C_6H_5); QM^+: 213.

4-Chloromethyl-1,3-dithiolane-2-thione was purified by column chromatography on silica gel using a mixture of hexane and chloroform (7 : 3 v/v) as an eluent. IR: 1067, 1039 cm^{-1}, ^{1}H NMR δ=3.55—4.05 (m, 2H, CH_2), 4.05—4.30 (m, 2H, CH_2), 4.30—4.65 (m, 1H, CH); QM^+: 185.

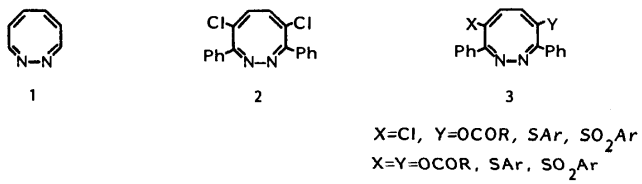
(Received August 23, 1986)

Nucleophilic substitution of 4,7-dichloro-3,8-diphenyl-1,2-diazocine with succinimide, phthalimide, *N*-methyl-*p*-toluenesulfonamide, and *o*-benzosulfimide, in the presence of silver oxide, gave the corresponding 4-mono(imido)- and 4,7-di(imido)-1,2-diazocines. 4-Acetoxy-7-phthalimido- and 4-phenylthio-7-phthalimido-1,2-diazocine were also prepared. Thermolysis of the mono(imido)-1,2-diazocines in xylene under reflux afforded the corresponding di(imido)-1,2-diazocine and/or five pyridine derivatives, whose relative yields depended upon the nature of imido substitutents in the diazocines. However, 4,7-di(imido)-1,2-diazocines did not decompose in xylene under reflux. Thermolysis of 4,7-bis(phthalimido)-1,2-diazocine at 300—310 °C gave 3,6-bis(phthalimido)-2-phenylpyridine with the extrusion of benzonitrile. In the thermolysis of the acetoxy- (230—240 °C) or phenylthio-substituted 1,2-diazocine (240—260 °C), 6-acetoxy- and 6-benzoyl-3-phthalimido-2-phenylpyridine, or 6(and 3)-phenylthio-3(and 6)-phthalimido-2-phenylpyridines were isolated together with benzonitrile, respectively. The feature of thermolysis was also discussed.

Although 1,2-diazacycloocta-2,4,6,8-tetraenes (1,2-diazocines) free of benzo groups were not known until Trost et al.[1] succeeded in an elegant synthesis of the parent 1,2-diazocine (**1**), we have recently reported a convenient method for the synthesis of 4,7-dichloro-3,8-diphenyl-1,2-diazocine (**2**), which is the first example for stable substituted monocyclic 1,2-diazocine.[2] The 1,2-diazocine **2** can be readily converted into other 4,7-disubstituted 1,2-diazocines: Thus, stable acyloxy-,[2] arylthio-,[3] and arylsulfonyl-substituted[4] 1,2-diazocines **3** were prepared by the reaction of **2** with appropriate nucleophiles. It has also been found that in contrast to the parent 1,2-diazocine (**1**), which decomposed slowly in solution at room temperature and rapidly neat to benzene and pyridine with comparable rates,[1] these stable 1,2-diazocines, **2** and **3**, had been pyrolyzed to give only pyridines accompanied by the extrusion of benzonitrile in almost all cases.



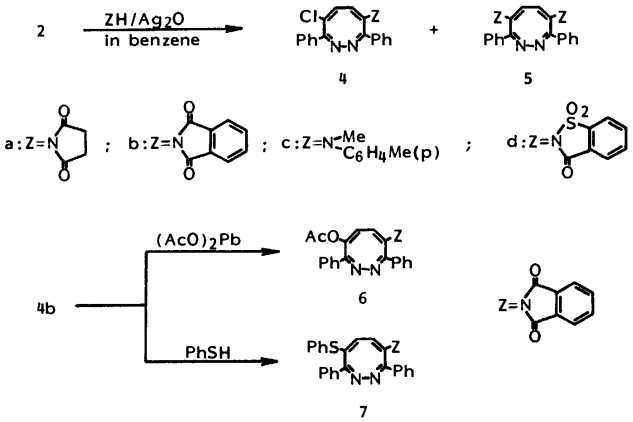
This paper describes the synthesis of stable imido-substituted 1,2-diazocines from **2**, and their thermolysis leading to pyridines. The feature of the thermolysis is also discussed.

Results and Discussion

Synthesis of Imido-Substituted 1,2-Diazocines. Although the dichloro-1,2-diazocine (**2**) did not react with succinimide in benzene under reflux, the reaction of **2** with silver succinimide (5 equiv) in benzene under reflux for 10 h afforded mono(succinimido)- **4a** and bis(succinimido)-1,2-diazocine **5a** in 39 and 34% yields, respectively. However, the succinimido-substituted 1,2-diazocines **4a** and **5a** could be also obtained in 41 and 11% yields respectively, together with unidentified viscous materials, by the reaction of **2** with succinimide (2 equiv) in the presence of silver oxide (2 equiv) in refluxing benzene for 6 h. This procedure was applied to the synthesis of other imido-substituted 1,2-diazocines.

The reaction of **2** with phthalimide, *N*-methyl-*p*-toluenesulfonamide, or *o*-benzosulfimide (saccharin) in the presence of silver oxide under the same conditions gave the corresponding mono(imido)-1,2-diazocines, **4b** (25%), **4c** (47%) or **4d** (47%), and di(imido)-1,2-diazocine, **5b** (36%), **5c** (16%), or **5d** (16%), respectively.

Moreover, in the reaction of mono(phthalimido)-1,2-diazocine (**4b**) with lead acetate or benzenethiol (each 3 equiv) in benzene under reflux for 20 or 10 h, 4-acetoxy-7-phthalimido-(**6**) or 4-phenylthio-7-phthalimido-1,2-diazocine (**7**) was obtained in 47 or 65% yield, respectively (Scheme 1).



Scheme 1.

Structural elucidation of all the imido-substituted 1,2-diazocines, **4**—**7**, was accomplished on the basis of spectral data.

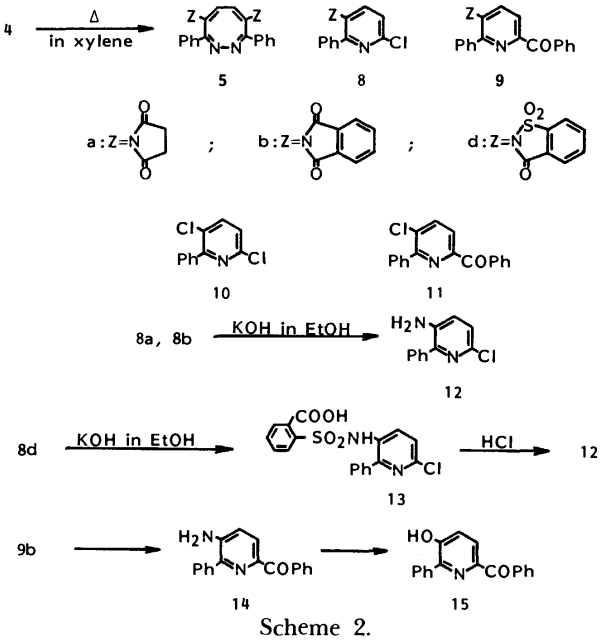
Thermolysis of Imido-Substituted 1,2-Diazocines. When the mono(succinimido)-1,2-diazocine (**4a**) was heated in dry xylene under reflux for 5 h, the bis-(succinimido)-1,2-diazocine (**5a**), 6-chloro-2-phenyl-

3-succinimidopyridine (**8a**) and 6-benzoyl-2-phenyl-3-succinimidopyridine (**9a**) were isolated in 35, 15, and 8% yields, respectively. The similar thermolysis of the mono(phthalimido)-1,2-diazocine (**4b**) gave 6-chloro-2-phenyl-3-phthalimidopyridine (**8b**) and 6-benzoyl-2-phenyl-3-phthalimidopyridine (**9b**) in 42 and 32% yields, respectively; in this case the bis(phthalimido)-1,2-diazocine (**5b**) was not formed, but benzonitrile was isolated in 17% yield.

The thermolysis of the mono(*N*-methyl-*p*-toluenesulfonamido) (**4c**) and mono(*o*-benzosulfimido)-1,2-diazocine (**4d**) was somewhat complex. The 1,2-diazocine **4c** gave only a complex mixture, from which any identified pyrolysates could not be isolated. In the thermolysis of **4d** under similar conditions, however, the bis(*o*-benzosulfimido)-1,2-diazocine (**5d**), 3-(*o*-benzosulfimido)-6-chloro-2-phenylpyridine (**8d**) and 6-benzoyl-3-(*o*-benzosulfimido)-2-phenylpyridine (**9d**) were isolated in 29, 9, and 11% yields respectively, together with 3,6-dichloro-2-phenylpyridine (**10**)[2] (17%) and 6-benzoyl-3-chloro-2-phenylpyridine (**11**)[2] (5%) (Scheme 2).

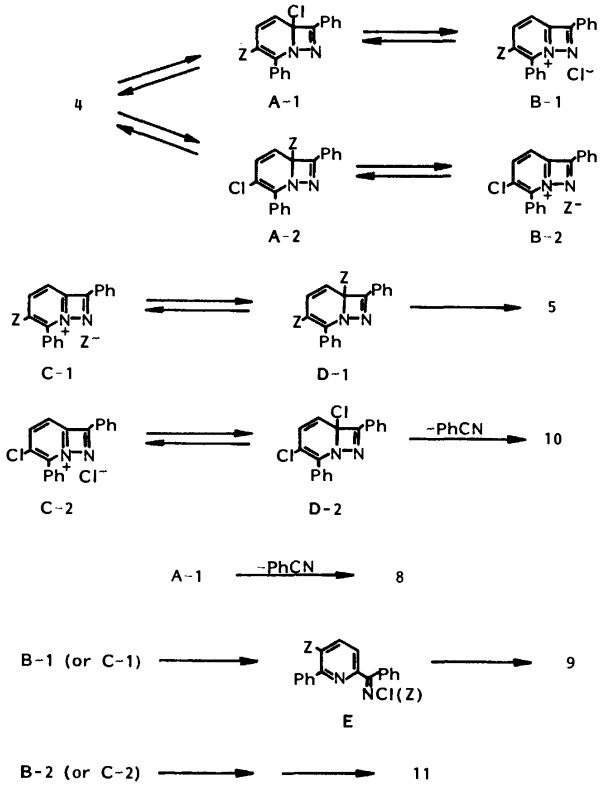
The structures of the pyridines, **8** and **9**, were assigned on the basis of spectral data as well as of the chemical conversions.

Treatment of the pyridines **8a** and **8b** with an ethanolic alkali solution under reflux gave the same product, 3-amino-6-chloro-2-phenylpyridine (**12**). The similar treatment of the pyridine **8d** gave an intermediary pyridine **13**, which was then converted into **12** on heating with hydrochloric acid. On the other hand, the treatment of **9b** with an ethanolic alkali solution under reflux afforded 3-amino-6-benzoyl-2-phenylpyridine (**14**), which was then converted, by diazotization, into known 6-benzoyl-3-hydroxy-2-phenylpyridine (**15**)[2] (Scheme 2).



Scheme 2.

As reported previously,[2-4] 4,7-disubstituted 1,2-diazocines, **2** and **3**, thermally isomerize into their valence isomers, diazabicyclooctatrienes, which are in equilibrium with azonia intermediates. Although thermolysis of the mono(imido)-1,2-diazocines (**4**) seemed somewhat more complex than that of the other stable 1,2-diazocines, **2** and **3**, the formation of products, **5** and **8**—**11**, in the thermolysis of **4** can be again explained by the intervention of diazabicyclooctatrienes and azonia intermediates (Scheme 3).



Scheme 3.

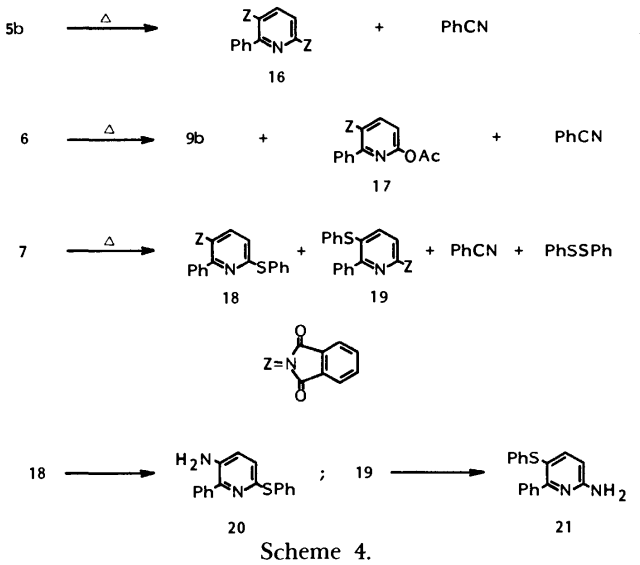
The 1,2-diazocine **4** is thermally isomerized into two valence isomers, **A-1** and **A-2**. The valence isomer **A-1** is in equilibrium with the azonia intermediate **B-1**, while **A-2** with **B-2**. The exchange of counter anion between **B-1** and **B-2** yields new azonia intermediates **C-1** and **C-2**, which are, of course, in equilibrium with the diazabicyclooctatrienes **D-1** and **D-2**, respectively. The pyridine **8** is formed from **A-1** with the extrusion of benzonitrile, whereas the ring opening of **B-1** (and/or **C-1**) to an imidoylpyridine **E**, followed by hydrolysis gives the pyridine **9**. The pyridines **10** and **11** are formed from **D-2** and **B-2** (and/or **C-2**) via similar processes, respectively. As mentioned below, di-(imido)-1,2-diazocines (**5**) are stable in xylene under reflux. Thus, **5** formed via a valence isomerization of **D-1** is unchanged under the conditions.

Next, thermolysis of 1,2-diazocines **5**—**7** was investigated. Since the 1,2-diazocines **5**—**7** did not decompose in xylene under reflux, thermolysis was performed without solvent. When the bis(phthalimido)-1,2-diazocine (**5b**) was heated at 300—310 °C (bath temp) for 15 min, benzonitrile and 3,6-bis(phthalimido)-2-phenylpyridine (**16**) were obtained in 43 and 20%

yields, respectively, together with unidentified viscous materials.

Thermolysis of the 4-acetoxy-7-phthalimido-1,2-diazocine (**6**) at 230—240 °C (bath temp) for 15 min gave the benzoylpyridine **9b** and 6-acetoxy-2-phenyl-3-phthalimidopyridine (**17**) in 11 and 10% yields respectively, together with traces of benzonitrile. When 4-phthalimido-7-phenylthio-1,2-diazocine (**7**) was heated at 240—260 °C (bath temp) for 15 min, 2-phenyl-6-phenylthio-3-phthalimidopyridine (**18**) and 2-phenyl-3-phenylthio-6-phthalimidopyridine (**19**) were isolated in 25 and 7% yields respectively, accompanied by benzonitrile (16%) and diphenyl disulfide (trace). Unidentified viscous materials were formed in thermolysis of **6** and **7**.

Structural elucidation of the pyridines **16**—**19** was accomplished on the basis of spectral data. Treatments of the pyridines **18** and **19** with an ethanolic alkali solution under reflux gave 3-amino-2-phenyl-6-phenylthiopyridine (**20**) and 6-amino-2-phenyl-3-phenylthiopyridine (**21**),[3] respectively (Scheme 4). The pathways for the thermolysis of the 1,2-diazocines **5**—**7** can be readily understood.



Scheme 4.

Experimental

IR spectra were obtained on a JASCO A-302 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-24 or a JEOL FX-100 instrument, and chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were taken with a Hitachi RMU-6L spectrometer at 70 eV ionization energy. Elemental analyses were performed on a Yanaco MT 2 CHN corder instrument.

Reaction of the Dichloro-1,2-diazocine (2) with Silver Succinimide. A mixture of **2** (0.65 g, 2.0 mmol) and silver succinimide (2.0 g, 10 mmol) in benzene (50 ml) was refluxed for 10 h. The reaction mixture was filtered, and the precipitate was washed with chloroform (50 ml). The combined filtrate was concentrated in vacuo, and the residue was chromatographed on silica gel to give 0.30 g (39%) of 4-chloro-3,8-diphenyl-7-succinimido-1,2-diazocine (**4a**) (from benzene elution) and 0.30 g (34%) of 4,7-bis(succinimido)-3,8-diphenyl-1,2-diazocine (**5a**) (from chloroform elution).

4a: Mp 179—180 °C (decomp); colorless needles; IR (KBr) 1779, 1703, 1697 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.51 (4H, s, CH_2), 6.68, 6.81 (each 1H, d, =CH, J=4.2 Hz), 7.2—7.6 (4H, m), 7.6—7.9 (4H, m); MS m/z 391, 389 (M^+). Found: C, 67.66; H, 4.01; N, 10.69%. Calcd for $C_{22}H_{16}N_3O_2Cl$: C, 67.78; H, 4.14; N, 10.78%.

5a: Mp 271—273 °C (decomp); colorless prisms; IR (KBr) 1778, 1715 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.56 (8H, s, CH_2), 7.00 (2H, s, =CH), 7.1—7.6 (10 H, m); MS m/z 452 (M^+). Found: C, 69.23; H, 4.35; N, 12.24%. Calcd for $C_{26}H_{20}O_4N_4O_4$: C, 69.02; H, 4.46; N, 12.38%.

Reaction of the Dichloro-1,2-diazocine (2) with Succinimide in the Presence of Silver Oxide. A mixture of **2** (0.65 g, 2.0 mmol), succinimide (0.4 g, 4 mmol) and silver oxide (0.9 g, 4.0 mmol) in benzene (50 ml) was refluxed for 6 h. Similar work-up of the reaction mixture and chromatography of the residue on silica gel gave 0.32 g (41%) of the mono(succinimido)-1,2-diazocine (**4a**) (from benzene elution) and 0.1 g (11%) of the bis(succinimido)-1,2-diazocine (**5a**) (from chloroform elution), together with unidentified viscous materials (0.1 g).

Reaction of the Dichloro-1,2-diazocine (2) with Phthalimide in the Presence of Silver Oxide. A mixture of **2** (0.65 g, 2.0 mmol), phthalimide (0.6 g, 4 mmol) and silver oxide (0.9 g, 4.0 mmol) in benzene (50 ml) was refluxed for 3 h. Similar work-up of the reaction mixture and the residue was chromatographed on silica gel to give 0.19 g (29%) of unchanged **2**, 0.38 g (43%) of 4-chloro-3,8-diphenyl-7-phthalimido-1,2-diazocine (**4b**) (each from benzene elution), and 0.18 g (16%) of 4,7-bis(phthalimido)-3,8-diphenyl-1,2-diazocine (**5b**) (from chloroform elution).

The reaction for 6 h under similar conditions afforded 0.21 g (25%) of **4b** and 0.38 g (36%) of **5b**, together with viscous materials (0.1 g).

4b: Mp 178—180 °C (decomp); colorless needles; IR (KBr) 1787, 1719 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.76, 6.96 (each 1H, d, =CH, J=4.2 Hz), 7.2—7.5 (6H, m), 7.5—7.9 (8H, m); MS m/z 439, 437 (M^+). Found: C, 71.35; H, 3.48; N, 9.57%. Calcd for $C_{26}H_{16}N_3O_2Cl$: C, 71.31; H, 3.68; N, 9.60%.

5b: Mp 285—287 °C (decomp); colorless needles; IR (KBr) 1779, 1713 cm^{-1}; MS m/z 548 (M^+). Found: C, 74.19; H, 3.95; N, 10.33%. Calcd for $C_{34}H_{20}N_4O_4$: C, 74.44; H, 3.68; N, 10.22%.

The ^{1}H NMR spectrum did not measured owing to its insolubility in ordinary solvents.

Reaction of the Dichloro-1,2-diazocine (2) with *N*-Methyl-*p*-toluenesulfonamide in the Presence of Silver Oxide. A mixture of **2** (0.65 g, 2.0 mmol), *N*-methyl-*p*-toluenesulfonamide (0.74 g, 4 mmol) and silver oxide (0.9 g, 4.0 mmol) in benzene (50 ml) was refluxed for 6 h. Similar work-up of the reaction mixture and chromatography of the residue on silica gel gave 0.45 g (47%) of 4-chloro-3,8-diphenyl-7-(*N*-methyl-*p*-toluenesulfonamido)-1,2-diazocine (**4c**) (from benzene elution) and 0.21 g (16%) of 4,7-bis(*N*-methyl-*p*-toluenesulfonamido)-3,8-diphenyl-1,2-diazocine (**5c**) (from chloroform elution), together with viscous materials (60 mg).

4c: Mp 168—170 °C (decomp); colorless prisms; IR (KBr) 1605, 1360, 1345 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.09 (3H, s, CH_3), 2.83 (3H, s, N-CH_3), 5.53, 6.51 (each 1H, d, =CH, J=4.2 Hz), 6.4—7.8 (14H, m); MS m/z 477, 475 (M^+). Found: C, 65.31; H, 4.54; N, 8.99%. Calcd for $C_{26}H_{22}N_3O_2Cl$: C, 65.60; H, 4.66; N, 8.83%.

5c: Mp 244—246 °C (decomp); colorless needles; IR (KBr) 1600, 1355 cm^{-1}; MS m/z 624 (M^+). Found: C, 65.28; H, 5.22; N, 9.06%. Calcd for $C_{34}H_{32}N_4O_4S_2$: C, 65.36; H, 5.16; N, 8.97%.

The ^1H NMR spectrum did not measured owing to its insolubility in ordinary solvents.

Reaction of the Dichloro-1,2-diazocine (2) with *o*-Benzosulfimide in the Presence of Silver Oxide. A mixture of **2** (0.65 g, 2.0 mmol), *o*-benzosulfimide (0.73 g, 4 mmol) and silver oxide (0.9 g, 4.0 mmol) in benzene (50 ml) was refluxed for 6 h. Similar work-up of the reaction mixture and the residue was chromatographed on silica gel to give 0.44 g (47%) of 4-chloro-3,8-diphenyl-7-(*o*-benzosulfimido)-1,2-diazocine (**4d**) (from benzene elution) and 0.20 g (16%) of 4,7-bis(*o*-benzosulfimido)-3,8-diphenyl-1,2-diazocine (**5d**) (from chloroform elution), together with viscous materials (40 mg).

4d: Mp 186—187 °C (decomp); colorless prisms; IR (KBr) 1740, 1350, 1335 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.74, 6.98 (each 1H, d, =CH, J=4.2 Hz), 7.2—7.6 (8H, m), 7.6—8.0 (6H, m); MS m/z 475, 473 (M^+). Found: C, 63.28; H, 3.51; N, 8.76%. Calcd for $C_{25}H_{16}N_3O_3Cl$: C, 63.35; H, 3.40; N, 8.87%.

5d: Mp 275—277 °C (decomp); colorless needles; IR (KBr) 1740, 1350 cm^{-1}; MS m/z 620 (M^+). Found: C, 61.77; H, 3.51; N, 8.87%. Calcd for $C_{32}H_{20}N_4O_6S_2$: C, 61.92; H, 3.25; N, 9.03%.

4-Acetoxy-3,8-diphenyl-7-phthalimido-1,2-diazocine (6). A mixture of 1.30 g (3.0 mmol) of the chloro-phthalimido-1,2-diazocine (**4b**) and 2.9 g (9 mmol) of lead acetate in benzene (60 ml) was refluxed for 20 h. The reaction mixture was filtered, and the precipitate was washed with chloroform (50 ml). The combined filtrate was concentrated in vacuo, and the residue was chromatographed on silica gel to give 0.20 g (15%) of the unchanged **4b** (from benzene elution) and 0.65 g (47%) of the acetoxy-phthalimido-1,2-diazocine (**6**) (from chloroform elution).

6: Mp 195—196 °C (decomp); colorless prisms; IR (KBr) 1760, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.93 (3H, s, CH_3), 6.38, 6.91 (each 1H, d, =CH, δ=4.2 Hz), 7.1—7.4 (6H, m), 7.4—7.8 (8H, m); MS m/z 461 (M^+). Found: C, 72.61; H, 3.91; N, 9.02%. Calcd for $C_{28}H_{19}N_3O_4$: C, 72.87; H, 4.15; N, 9.11%.

3,8-Diphenyl-4-phenylthio-7-phthalimido-1,2-diazocine (7). A mixture of 1.30 g (3.0 mmol) of the chloro-phthalimido-1,2-diazocine (**4b**) and benzenethiol (1.0 ml, 9 mmol) in benzene (60 ml) was refluxed for 10 h. After the reaction mixture was washed with a 10% aqueous sodium hydroxide solution, the benzene solution was concentrated in vacuo to leave a residue. The residue was chromatographed on silica gel to give 70 mg (5%) of the unchanged **4b** (from benzene elution) and 0.98 g (65%) of the phenylthio-phthalimido-1,2-diazocine (**7**) (from chloroform elution).

7: Mp 222—223 °C (decomp); colorless prisms; IR (KBr) 1780, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.44, 6.95 (each 1H, d, =CH, J=4.2 Hz), 7.1—7.5 (12H, m), 7.5—7.8 (7H, m); MS m/z 511 (M^+). Found: C, 75.33; H, 4.11; N, 8.29%. Calcd for $C_{32}H_{21}N_3O_2S$: C, 75.12; H, 4.14; N, 8.22%.

Thermolysis of the Mono(succinimido)-1,2-diazocine (4a). A suspension of **4a** (1.0 g, 2.6 mmol) in dry xylene (20 ml) was refluxed for 5 h; the reaction mixture turned to a clear solution after 30 min, and then a precipitate gradually formed. After the reaction mixture had been cooled to room temperature, it was filtered to give 0.41 g (35%) of the bis(succinimido)-1,2-diazocine (**5a**). The filtrate was concentrated in vacuo, and the residue was chromatographed on silica gel to give 0.11 g (15%) of 6-chloro-2-phenyl-3-succinimidopyridine (**8a**) and 70 mg (8%) of 6-benzoyl-2-phenyl-3-succinimidopyridine (**9a**) (each from benzene elution), together with 0.15 g of viscous materials (from chloroform and ethyl acetate elutions).

8a: Mp 187—188 °C; yellow prisms; IR (KBr) 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.2—2.8 (4H, m, CH_2), 7.40, 7.49 (each 1H, d, PyH, J=8.0 Hz), 7.43 (5H, s); MS m/z 288, 286 (M^+). Found: C, 62.80; H, 3.93; N, 9.86%. Calcd for $C_{15}H_{11}N_2O_2Cl$: C, 62.84; H, 3.87; N, 9.77%.

9a: Mp 140—142 °C; yellow prisms; IR (KBr) 1700, 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.3—2.9 (4H, m, CH_2), 7.35—7.7 (8H, m), 7.80, 8.16 (each 1H, d, PyH, J=8.2 Hz), 8.0—8.4 (2H, m); MS m/z 356 (M^+). Found: C, 74.29; H, 4.39; N, 7.54%. Calcd for $C_{22}H_{16}N_2O_3$: C, 74.14; H, 4.53; N, 7.86%.

Thermolysis of the Mono(phthalimido)-1,2-diazocine (4b). A suspension of **4b** (1.0 g, 2.3 mmol) in dry xylene (20 ml) was refluxed for 5 h; during which time the reaction mixture turned to a clear solution. The reaction mixture was concentrated in vacuo, and the residue was chromatographed (silica gel, benzene) to give 40 mg (17%) of benzonitrile, 0.32 g (42%) of 6-chloro-2-phenyl-3-phthaliminopyridine (**8b**) and 0.28 g (30%) of 6-benzoyl-2-phenyl-3-phthaliminopyridine (**9b**). In this case, any bis(phthalimido)-1,2-diazocine (**5b**) did not formed.

8b: Mp 139—140 °C; yellow prisms; IR (KBr) 1780, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.2—7.7 (7H, m), 7.7—7.9 (4H, m); MS m/z 336, 334 (M^+). Found: C, 68.33; H, 3.21; N, 8.10%. Calcd for $C_{19}H_{11}N_2O_2Cl$: C, 68.17; H, 3.31; N, 8.37%.

9b: Mp 173—174 °C; yellow prisms; IR (KBr) 1780, 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.2—8.3 (14H, m), 7.87, 8.11 (each 1H, d, PyH, J=8.2 Hz); MS m/z 404 (M^+). Found: C, 77.27; H, 3.45; N, 6.77%. Calcd for $C_{26}H_{16}N_2O_3$: C, 77.21; H, 3.39; N, 6.93%.

Thermolysis of the Mono(*o*-benzosulfimido)-1,2-diazocine (4d). A suspension of **4d** (1.0 g, 2.1 mmol) in dry xylene (20 ml) was refluxed for 5 h; the reaction mixture turned to a clear solution after 30 min, and then a precipitate gradually separated out. After the mixture had been cooled, filtration gave 0.38 g (29%) of the bis(*o*-benzosulfimido)-1,2-diazocine (**5d**). The filtrate was concentrated in vacuo, and the residue was chromatographed on silica gel to give trace amounts of benzonitrile, 70 mg (9%) of 3-(*o*-benzosulfimido)-6-chloro-2-phenylpyridine (**8d**), 0.10 g (11%) of 6-benzoyl-3-(*o*-benzosulfimido)-2-phenylpyridine (**9d**), 80 mg (17%) of 3,6-dichloro-2-phenylpyridine (**10**), mp 100—101 °C (lit,[2] mp 100—101 °C), and 30 mg (5%) of 6-benzoyl-3-chloro-2-phenylpyridine (**11**), mp 119—120 °C (lit,[2] mp 119—120 °C) (each from benzene elution), together with 0.2 g of viscous materials (from chloroform and ethyl acetate elutions).

8d: Mp 196—197 °C; yellow prisms; IR (KBr) 1730, 1340, 1305 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.1—7.5 (6H, m), 7.5—8.0 (5H, m); MS m/z 372, 370 (M^+). Found: C, 58.11; H, 3.06; N, 7.77%. Calcd for $C_{18}H_{11}N_2O_3SCl$: C, 58.30; H, 2.99; N, 7.56%.

9d: Mp 103—104 °C; yellow prisms; IR (KBr) 1730, 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.12—7.57 (8H, m), 7.57—7.97 (5H, m), 7.97—8.27 (3H, m); MS m/z 440 (M^+). Found: C, 67.99; H, 3.76; N, 6.57%. Calcd for $C_{25}H_{16}N_2O_4S$: C, 68.17; H, 3.66; N, 6.36%.

3-Amino-6-chloro-2-phenylpyridine (12). i) A solution of 0.1 g of the succinimidopyridine (**8a**) in ethanol (30 ml) containing potassium hydroxide (0.5 g) was refluxed for 3 h.

The reaction mixture was concentrated in vacuo, and water (30 ml) was added to the residue which was extracted with chloroform (50 ml×2). The chloroform extract was concentrated in vacuo, and the residue was chromatographed (silica gel, chloroform) to give 30 mg (42%) of the aminopyridine (**12**).

12: Mp 98—99 °C; yellow prisms; IR (KBr) 3450, 3400, 3350, 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.7 (2H, broad, NH_2), 7.04 (2H, s, PyH), 7.36—7.76 (5H, m); MS *m/z* 206, 204 (M^+). Found: C, 64.57; H, 4.51; N, 13.77%. Calcd for $C_{11}H_9N_2Cl$: C, 64.55; H, 4.43; N, 13.69%.

ii) A solution of 0.1 g of the *o*-benzosulfimidopyridine (**8d**) in ethanol (30 ml) containing potassium hydroxide (0.5 g) was refluxed for 3 h. The reaction mixture was concentrated in vacuo, and the residue was triturated with water (30 ml) to turn a solution. The aqueous solution was acidified with hydrochloric acid, and then extracted with chloroform (30 ml×2). The extract was concentrated in vacuo to leave 70 mg (67%) of *o*-[(6-chloro-2-phenyl-3-pyridyl)sulfamoyl]benzoic acid (**13**) (mp 184—186 °C; IR (KBr) 2400—3200, 1705, 1340 cm^{-1}; MS *m/z* 390 (M^+)). The pyridine **13** (70 mg) was heated in concd hydrochloric acid (20 ml) under reflux, and then the reaction mixture was concentrated in vacuo. The obtained residue was triturated with a 10% aqueous potassium hydroxide solution (15 ml), and then extracted with chloroform (30 ml×2). The extract was concentrated in vacuo, and the residue was chromatographed (silica gel, benzene) to give 20 mg (54%) of **12**.

Conversion of the Pyridine (9b) into 6-Benzoyl-3-hydroxy-2-phenylpyridine (15). A solution of **9b** (0.8 g) in ethanol (50 ml) containing potassium hydroxide (1.0 g) was refluxed for 4 h. The reaction mixture was poured into water (200 ml), and then extracted with benzene (100 ml×2). The benzene extract was concentrated in vacuo, and the residue was chromatographed (silica gel, chloroform) to give 0.41 g (78%) of 3-amino-6-benzoyl-2-phenylpyridine (**14**).

14: Mp 172—173 °C; yellow prisms; IR (KBr) 3500, 3400, 3350, 1640, 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.33 (2H, broad, NH_2), 7.10, 7.99 (each 1H, d, PyH, *J*=8.2 Hz), 7.33—7.93 (6H, m), 8.03—8.33 (4H, m); MS *m/z* 274 (M^+). Found: C, 78.90; H, 5.11; N, 10.40%. Calcd for $C_{18}H_{14}N_2O$: C, 78.81; H, 5.15; N, 10.21%.

After diazotization of 0.27 g of the pyridine (**14**) with sodium nitrite in aqueous sufluric acid (concd sufuric acid (4 ml) and water (30 ml)) at 0—5 °C, the reaction mixture was heated at 60 °C for 2 h. The mixture was extracted with chloroform (50 ml×2) and the extract was concentrated in vacuo to leave 0.11 g (41%) of the pyridine (**15**),[2] mp 172—173 °C, which was identical with an authentic sample prepared from hydrolysis of 3-acetoxy-6-benzoyl-2-phenylpyridine.

Thermolysis of the Bis(phthalimido)-1,2-diazocine (5b). The diazocine **5b** (1.0 g) in a test tube was heated at 300—310 °C (bath temp) for 15 min. The pyrolysate was chromatographed on silica gel to give 80 mg (43%) of benzonitrile and 0.16 g (20%) of 3,6-bis(phthalimido)-2-phenylpyridine (**16**) (each from benzene elution), together with 0.5 g of viscous materials (from chloroform and ethyl acetate elution).

16: Mp 303—305 °C; yellow prisms; IR (KBr) 1780, 1720 cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.15—7.35 (5H, m), 7.71, 8.23 (each 1H, d, PyH, *J*=8.2 Hz), 7.8—8.0 (8H, m); MS *m/z* 445 (M^+). Found: C, 72.56; H, 3.54; N, 9.62%. Calcd for $C_{27}H_{15}N_3O_4$: C, 72.80; H, 3.39; N, 9.43%.

Thermolysis of the Acetoxy-phthalimido-1,2-diazocine (6). The diazocine **6** (1.0 g) in test tube was heated at 230—240 °C (bath temp) for 15 min. The pyrolysate was chromatographed on silica gel to give 10 mg of benzonitrile, 0.10 g (11%) of the benzoylpyridine (**9b**) and 80 mg (10%) of 6-acetoxy-2-phenyl-3-phthalimidopyridine (**17**) (each from benzene elution), together with 0.5 g of viscous materials (from chloroform and ethyl acetate elution).

17: Mp 228—230 °C; yellow prisms; IR (KBr) 1780, 1760, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.37 (3H, s), 7.1—7.7 (7H, m), 7.7—8.0 (4H, m); MS *m/z* 358 (M^+). Found: C, 70.64; H, 3.83; N, 7.64%. Calcd for $C_{21}H_{14}N_2O_4$: C, 70.38; H, 3.94; N, 7.82%.

Thermolysis of the Phenylthio-1,2-diazocine (7). The diazocine **7** (0.9 g) in a test tube was heated at 240—260 °C (bath temp) for 15 min. Chromatography (silica gel) of the pyrolysate afforded 30 mg (16%) of benzonitrile, trace amounts of diphenyl disulfide, 0.18 g (25%) of 2-phenyl-6-phenylthio-3-phthalimidopyridine (**18**) and 50 mg (7%) of 2-phenyl-3-phenylthio-6-phthalimidopyridine (**19**) (each from benzene elution), together with 0.4 g of viscous materials (from chloroform and ethyl acetate elution).

18: Mp 193—194 °C; colorless needles; IR (KBr) 1780, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.87 (1H, d, PyH, *J*=8.2 Hz), 7.0—7.8 (15H, m); MS *m/z* 408 (M^+). Found: C, 73.74; H, 3.69; N, 6.62%. Calcd for $C_{25}H_{16}N_2O_2S$: C, 73.51; H, 3.95; N, 6.86%.

19: Mp 174—176 °C; colorless needles; IR (KBr) 1780, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.05—7.65 (10H, m), 7.65—8.0 (6H, m); MS *m/z* 408 (M^+). Found: C, 73.40; H, 3.87; N, 6.66%. Calcd for $C_{25}H_{16}N_2O_2S$: C, 73.51; H, 3.95; N, 6.86%.

Hydrolysis of the Pyridine (18). A solution of **18** (0.15 g) in ethanol (30 ml) containing potassium hydroxide (0.5 g) was refluxed for 3 h. After the reaction mixture was concentrated in vacuo, the residue was triturated with water (50 ml) which was extracted with chloroform (30 ml×2). The extract was concentrated in vacuo, and the residue was chromatographed (silica gel, chloroform) to give 60 mg (60%) of 3-amino-2-phenyl-6-phenylthiopyridine (**20**).

20: Mp 119—120 °C; colorless prisms; IR (KBr) 3460, 3300, 3150, 1635 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.80 (2H, broad s, NH_2), 6.88 (2H, s, PyH), 7.1—7.7 (10H, m); MS *m/z* 278 (M^+). Found: C, 73.11; H, 5.31; N, 10.22%. Calcd for $C_{17}H_{14}N_2S$: C, 73.35; H, 5.07; N, 10.06%.

Hydrolysis of the Pyridine (19). A solution of **19** (0.1 g) in ethanol (30 ml) containing potassium hydroxide (0.5 g) was refluxed for 3 h. Similar work-up of the reaction mixture, and chromatography (silica gel, chloroform) of the residue gave 40 mg (57%) of 6-amino-2-phenyl-3-phenylthiopyridine (**21**), mp 177—178 °C (lit,[3] mp 177—178 °C).

In Situ Generation and Synthetic Application of 2-Phenylbenzimidazoline to the Selective Reduction of Carbon-Carbon Double Bonds of Electron-Deficient Olefins

Hidenori CHIKASHITA,* Shuichi NISHIDA, Makoto MIYAZAKI,
Yasuhiro MORITA, and Kazuyoshi ITOH

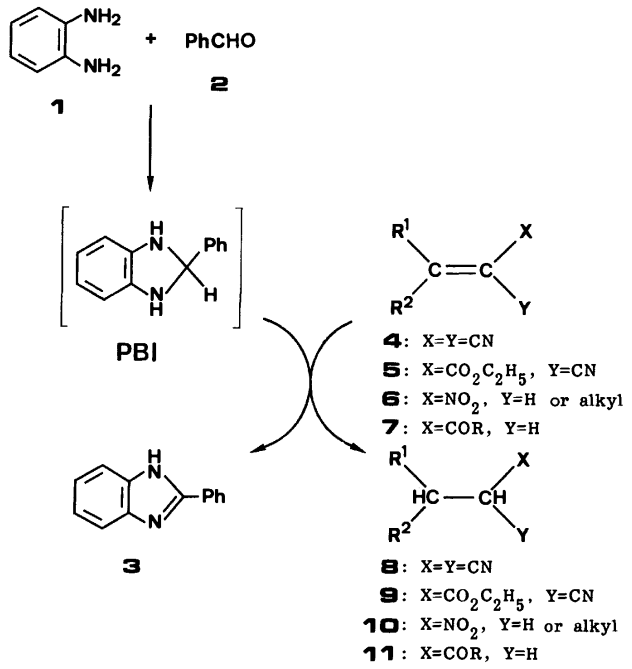
(Received September 2, 1986)

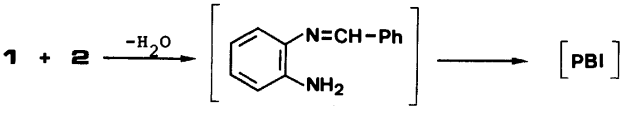
2-Phenylbenzimidazoline (PBI) as a mild, selective, and convenient reducing agent was efficiently generated in situ from *o*-phenylenediamine and benzaldehyde in alcohols. A generally applicable method for the selective reduction of carbon-carbon double bonds of a variety of electron-deficient olefins with an alcoholic solution of PBI is described. The reduction of α,β-unsaturated ketones to the corresponding saturated ketones could also be accomplished (but, less effectively) with PBI with the aid of a Lewis-acid catalyst. 1-Methyl-2-(*o*-nitrophenyl)benzimidazoline prepared and isolated by the reaction of *o*-nitrobenzaldehyde with *N*-methyl-*o*-phenylenediamine reduced benzylidenemalononitrile to give benzylmalononitrile and 1-methyl-2-(*o*-nitrophenyl)benzimidazole in high yields. This shows the validity of PBI to be the actual reducing species in the present reduction system. From a mechanistic study, the present reductions could be interpreted in terms of a mechanism involving a synchronous transport of a pair of hydrogens or a sequential transfer of a hydride and a proton from PBI to the olefins.

The selective reduction of organic functional groups is an important and frequently encountered synthetic operation in organic syntheses. Many methods have been developed toward this goal and many types of "selective reductions" have been accepted as being synthetically useful. In recent years, heterocyclic compounds having a hydrogen-donating ability, such as dihydrobenzazoles[1,2] or 1,4-dihydropyridines,[3] have been shown to be useful as such selective reducing agents. One such reagent developed in our laboratory is 2-phenylbenzimidazoline (PBI). The development of methods applicable to the selective reductions of carbon-carbon double bonds conjugated with electron-withdrawing groups such as cyano, nitro, or carbonyl group has been a synthetic subject. We have recently indicated the reducing and selective properties of PBI in the reduction of benzylidenemalononitriles and β-nitrostyrenes.[1a] However, the initial reaction mode has been shown to be disadvantageous from a synthetic viewpoint since a half molar amount of the olefins is consumed to form PBI. Due to this disadvantage, a convenient alternative method for in situ generation of PBI has been reported in a previous communication.[1b] This method includes the use of *o*-phenylenediamine (**1**) and benzaldehyde (**2**) in ethanol. In this paper, we report on details regarding the selective reduction of carbon-carbon double bonds of a variety of electron-deficient olefins with a reagent system of diamine (**1**) and aldehyde (**2**); discuss the scope, limitations, and general applicability of this simple reduction method, and show the mechanistic features of these reactions together with evidence that PBI is the actual reducing species (Scheme 1).



Scheme 1.

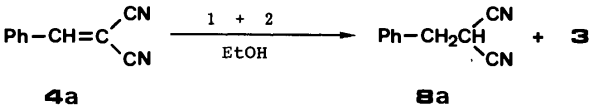
In Situ Generation and Properties of PBI. Recently, we have found that benzylmalononitriles or (2-nitroethyl)benzenes were obtained in good yields by a reaction of benzylidenemalononitriles or β-nitrostyrenes with a half molar amount of diamine (**1**); we indicated that the products resulted from a reduction of the olefins by PBI which was formed by the reaction of the olefins with equimolar amount of diamine (**1**).[1a] However, in order to synthetically utilize the reducing ability of PBI to the selective reduction of carbon-carbon double bonds of electron-deficient olefins, PBI should be prepared independently. In our attempts to prepare PBI conveniently, we have found that diamine (**1**) rapidly reacts with aldehyde (**2**) in ethanol at room



Scheme 2.

temperature to produce a mixture of *N*-benzylidene-*o*-phenylenediamine (**12**) and PBI, expected to be formed through the intramolecular cyclization of **12** (Scheme 2). Although these compounds could not be isolated, the formation of **12** and PBI were indicated by the appearance of signals at 8.57 and 5.74 ppm, assigned to methine protons of **12** and PBI, respectively, in the ^{1}H NMR spectra of an equimolar mixture of diamine (**1**) and aldehyde (**2**) in methanol-d_4 at room temperature. When the reaction mixture was allowed to warm to 50 °C, the complete disappearance of the above mentioned methine signals was observed after 24 h; also 2-phenylbenzimidazole (**3**) was isolated from the reaction mixture in 95% yield. This indicates that PBI is an unstable intermediate and is readily oxidized automatically to benzimidazole (**3**) in the absence of an appropriate hydrogen acceptor. The unstability of PBI is in sharp contrast to the high stability of *N*,*N*′-dimethylated PBI.[1f,h] In addition, Schiff's base (**12**), formed simultaneously, was inert to PBI in this mild reaction system, in contrast to the system reported by Smith et al.[4]

Upon a treatment of diamine (**1**) and aldehyde (**2**) in ethanol at room temperature, when benzylidenemalononitrile (**4a**) coexisted in the reaction system, a mixture of benzylmalononitrile (**8a**) and benzimidazole (**3**) was obtained in high yields (Scheme 3). As shown in



Scheme 3.

Table 1, this reduction also occurred by the treatment of the olefin (**4a**) with diamine (**1**) and other aldehydes under the same reaction conditions to give the same reduced product **8a** in good yields, although it is apparent that aldehyde (**2**) is the most effective among the aldehydes employed. In these reactions, benzimidazolines could not be isolated as well as PBI but the corresponding benzimidazoles were obtained in practically quantitative yields. These results indicate that the olefin (**4a**) was effectively reduced by benzimidazolines produced in situ from diamine (**1**) and aldehydes, and that compensating reactions are oxidations of benzimidazolines to benzimidazoles.

General Applicability of the PBI-Reduction to a Variety of Electron-Deficient Olefins. We have extended this simple reduction technique to a variety of electron-deficient olefins (**4—6**) which have a carbon–carbon double bond conjugated with one or two highly electron-withdrawing groups such as -CN, -NO_2, or -CO_2Et. The results are summarized in Table 2. In general, the yields of products (**8—10**) were consistently high and no other by-products were obtained at all. Benzimidazole (**3**) formed by the reactions is almost insoluble in low-polar organic solvents and could be easily removed from the reaction mixture by simple filtration after removing the solvent. A characteristic feature of the reduction is the steric effect at the β-position on the rate of reduction (Fig. 1). The results obtained by the reduction of a series of α-cyano-β-substituted cinnamonitriles (**4a—d**, **4h**, **4i**) indicate that the reduction was sensitive to a steric hinderance at the β-position associated with group R^1, revealing the following order:

$$R^1 = H > CH_3 > C_2H_5 > n\text{-}C_3H_7 > i\text{-}C_3H_7 \sim t\text{-}C_4H_9 \quad \text{(no reaction)}$$

Table 1. The Reduction of **4a** to **8a** with Diamine (**1**) and Aldehyde[a]

Aldehyde	Yield of **8a**/%[b]
Benzaldehyde (**2**)	96
Acetaldehyde	88
Propionaldehyde	90
Butyraldehyde	89
2-Phenylpropionaldehyde	87
2-Furaldehyde	61

a) All the reactions were carried out in ethanol at room temperature using the reagent system; **4a**: diamine (**1**): aldehyde = 1:1:1 (molar ratio). b) All yields were determined by GLC using benzyl cyanide as an internal standard.

Table 2. Reduction of Electron-Deficient Olefins (**4—6**) with Diamine (**1**) and Aldehyde (**2**)[a]

Product	R^1	R^2	X	Y	Reaction time/h	Yield/%[b]
8b	CH_3	C_6H_5	CN	CN	9	88
8c	C_2H_5	C_6H_5	CN	CN	9.5	88
8d	n-C_3H_7	C_6H_5	CN	CN	12	72
8e	CH_3	CH_3	CN	CN	7	80
8f	CH_3	C_2H_5	CN	CN	8	63
8g	-$(CH_2)_5$-		CN	CN	5	71
9	H	C_6H_5	$CO_2C_2H_5$	CN	11	90
10a	H	C_6H_5	NO_2	H	24	72
10c	H	p-ClC_6H_4	NO_2	H	24	65
10d	H	p-$CH_3C_6H_4$	NO_2	H	24	50
10e	H	p-$CH_3OC_6H_4$	NO_2	H	24	61

a) All the reactions were carried out in ethanol at room temperature using the reagent system; olefin: diamine (**1**): aldehyde (**2**) = 1:1:1 (molar ratio). b) Yield of isolated, pure product.

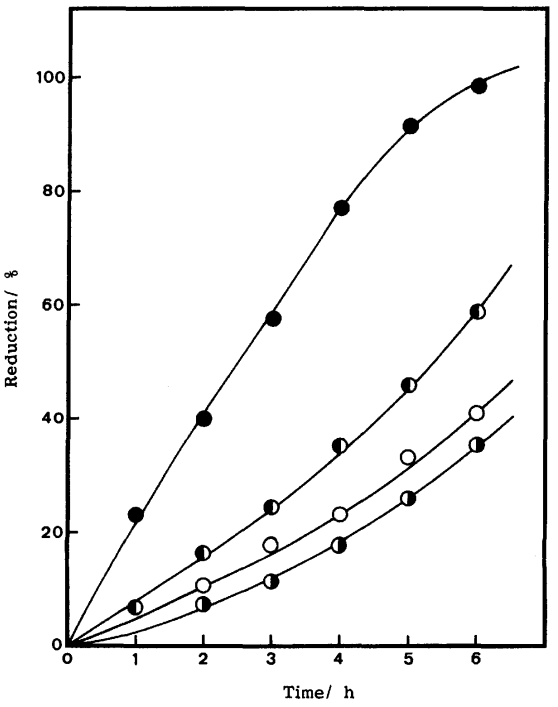


Fig. 1. Rate of reduction of β-substituted benzylidenemalononitriles with **1** and **2** in ethanol at room temperature. Olefins: **4a**(●), **4b**(◐), **4c**(○), and **4d**(◑).

Thus, a highly hindered olefin such as α-cyano-β-isopropylcinnamonitrile (**4h**) or α-cyano-β-(*t*-butyl)-cinnamonitrile (**4i**) could not be reduced at all in the present reduction system. The another feature is the electronic effect of groups X and Y on the reactivity of the olefins. Increasing the sum of the electron-withdrawing abilities of the groups X and Y resulted in a substantial increase in the reactivity of the olefin, revealing the following order:

$$X, Y = CN, CN > CN, CO_2C_2H_5 > NO_2, H > CO_2C_2H_5, CO_2C_2H_5 \text{ (no reaction)}$$

Thus, diethyl benzylidenemalonate (**13**) could not be reduced at all.

Scheme 4.

Nitroalkanes have recently been demonstrated to be useful synthetic intermediates for a variety of transformations of the nitro functionality to other functional groups.[5] Especially, aromatic nitroalkanes are of importance in connection with the synthesis of a variety of biochemically and pharmacologically interesting compounds.[6] They also have been used as a synthetically equivalent to enamines and enolates.[7] A combination of preparation of nitroalkenes from aldehydes by the Knoevenagel condensation and subsequent reduction of them to the corresponding nitroalkanes is the most desirable method for the synthesis of nitroalkanes; this is useful in connection with the elongation of aldehydes or the elongating transformation of aldehydes to ketones.[8] A widely employed method[9] for the reduction of nitroalkenes to the corresponding nitroalkanes involves a $NaBH_4$ reduction. Although this type of reduction of nitroalkenes derived from aliphatic aldehydes[9b] or ketones[10] usually proceeds smoothly in good yields, the reduction of aromatic nitroalkenes (**6**) with $NaBH_4$ produces low yields of products due to undesired side reactions such as dimerization.[9] With these considerations in mind, we studied the general applicability of the PBI-reduction method to the selective reduction of a variety of aromatic nitroalkenes (**6**).

Although the reduction of aromatic nitroalkenes (**6**) with diamine (**1**) and aldehyde (**2**) proceeded in ethanol at room temperature (Table 2), it is desirable to optimalize the reaction conditions in order to obtain the products in higher yields. Thus, the reduction of β-nitrostyrene (**6a**) with diamine (**1**) and aldehyde (**2**) was preliminary examined in a variety of solvents. As shown in Table 3, the reduction with PBI could be accelerated by the use of an alcoholic solvent; however, the kind of alcohol used did not influence the rate of reduction at 65 °C. The change in solvent does not change the specificity of the reduction, as no products other than the (2-nitroethyl)benzene (**10a**) was detected. However, the reaction in 1-butanol at reflux temperature gave the best results in terms of rapidity, due to a rise in the reaction temperature. Thus, the reduction of various aromatic nitroalkenes (**6**) were demonstrated with diamine (**1**) and aldehyde (**2**) in 1-butanol at reflux temperature. The results are summarized in Table 4. Although the kind of aromatic substituent in nitroalkenes (**6**) influenced the rate of the reduction, a variety of nitroalkenes employed here were reduced to the corresponding nitroalkanes (**10**) in excellent yields. In particular, the successful conversion of 3-(2-nitrovinyl)indole (**6k**) to the corresponding 3-(2-nitroethyl)indole (**10k**) is of interest in connection with the synthesis of substituted 3-(2-nitroethyl)-indoles which have proven to be valuable as intermediates in the synthesis of functionalized polycyclic indoles and natural products of the ergoline class.[11b] Similarly, β-nitrostyrenes (**6a—h**) without or with a substituent of nitro, chloro, methyl, methoxyl, or hydroxyl group were effectively converted to the corresponding (2-nitroethyl)benzenes (**10a—h**) in high yields by the same method. In addition, the reduction of β-nitrostyrenes (**6m—o**) possessing alkyl substitution at the α-carbon was more sluggish than that of **6a** but afforded high yields of 1-phenyl-2-nitroalkanes (**10m—o**) after the reaction time of 6—9 h. In all cases, carbon-carbon double bonds of nitroalkenes (**6**) were reduced with complete selectivity and no formation of dimer or other by-products could be observed. The use

Table 3. Rates of Reduction of β-Nitrostyrene (**6a**) with Diamine (**1**) and Aldehyde (**2**) in Various Solvents[a,b]

a) All the reactions were carried out in 1-butanol at reflux temperature using the reagent system; nitroalkene (**6**): diamine (**1**): aldehyde (**2**) = 1:1.2:1.2 (molar ratio). b) Yield of isolated, pure product.

of 1.2 equivalent of diamine (**1**) and aldehyde (**2**) was sufficient to conduct the reduction, and benzimidazole (**3**) formed by the reaction could be easily removed from the reaction mixture as described previously. Compared with several other methods[11] currently used for the reduction of aromatic nitroalkenes, the present method is advantageous on account of its simplicity and general applicability to a wide range of aromatic nitroalkenes.

Recently, 2-phenylbenzothiazoline has been reported to be a good reducing agent with the aid of $AlCl_3$ for the conjugate reduction of α,β-unsaturated carbonyl compounds.[1c,g] Using this reagent, olefins **4a—c**, **5**, and **6a** could also be reduced to the corresponding reduced products **8a—c**, **9**, and **10a** in 80—98% yields.[1g] However, these reductions with 2-phenylbenzothiazoline were apparently more sluggish than that involving the PBI-reduction method.

Throughout the reductions (Tables 2 and 4), the cyano, nitro, alkoxycarbonyl, hydroxyl, and arylic

chloro groups were inert to the PBI-reduction. In addition, we have found that other functional groups such as carbonyl, unactivated carbon-carbon double bond, carbon-carbon triple bond, and common carbon-halogen bond are inert under the present reduction conditions. These high chemoselectivities are of great importance and enhance the utility of the present reagent.

Lewis Acid-Promoted Conjugate Reduction of α,β-Unsaturated Ketones (7) with PBI. In order to demonstrate the propensity of PBI regarding a reduction of carbon-carbon double bond systems conjugated with electron-withdrawing groups, we finally examined the reduction of α,β-unsaturated ketones (**7**) to the corresponding saturated ketones (**11**). When benzylideneacetone (**7a**) was dissolved in methanol and allowed to react with 2 equivalents of the reagents, **1** and **2**, at 50 °C, no trace of reduction occurred even after 24 h. However, when the same reaction was carried out in the presence of a Lewis acid, the reduction to 4-phenyl-2-butanone (**11a**) proceeded in 6% ($AlCl_3$)—64% ($ZnCl_2$) yields (Table 5). Among the solvent tested, methanol gave the best results while the reduction in acetonitrile, which is recognized as a good medium in the reduction with 1,3-dimethyl-2-phenylbenzimidazoline[1f] or NAD(P)H-model compounds,[3] gave low yield of the product. Thus, although the enone (**7a**) itself should resist a reduction, the increased electron-deficiency of the enone due to the coordination of the carbonyl group with a Lewis acid allowed the reaction to be possible. It should be noted that the catalytic efficiency is not proportional to the efficiency in forming a complex with a carbonyl group, in contrast to the similar Lewis acid-promoted conjugate reduction with 2-phenylbenzothiazoline[1c,g] or 1,3-dimethyl-2-phenylbenzimidazoline.[1f] The latter efficiency denotes the intensity of a Lewis acid and increases in the order $ZnCl_2<FeCl_3<AlCl_3$.[12] This is probably due to the complex action of a Lewis acid on both the producing step of PBI from **1** and **2** and the actual reduction step. To survey the generality, a series of representative enones (**7b—e**) were treated in the same fashion with the reagent system of diamine (**1**), aldehyde (**2**), and $ZnCl_2$. The results are summarized in Table 6. Although conjugate reductions were accomplished in 11—44% yields with complete regiospecificity, these reactions were apparently more sluggish and less effective compared with similar reductions with 2-phenylbenzothiazoline[1c,g] or 1,3-dimethyl-2-phenylbenzimidazoline.[1f] Accordingly, the synthetic utility of PBI in the conjugate reduction of α,β-unsaturated ketones seems to be rather low.

Table 5. Conjugate Reduction of Benzylideneacetone (**7a**) with Diamine (**1**) and Aldehyde (**2**) in the Presence or Absence of Lewis Acid[a]

Lewis acid	Solvent	Yield/%[b]
None	Methanol	0
$AlCl_3$	Methanol	6
$FeCl_3$	Methanol	12
$ZnCl_2$	Methanol	64
$ZnCl_2$	Acetonitrile	10

a) All the reactions were carried out at 50°C for 24 h by using the reagent system; **7a**: Lewis acid: diamine (**1**): aldehyde (**2**)=1:1:2:2 (molar ratio). b) Yield determined by GLC.

Mechanisms. In order to obtain clear evidence of the reducing ability of PBI to electron-deficient olefins, we tried to prepare and isolate the structurally related benzimidazoline (**17**) according to the Scheme 5. When *N*-methyl-*o*-phenylenediamine (**14**) was treated under stirring with the same molar amount of *o*-nitrobenzaldehyde (**15**) in methanol at room temperature, Schiff's base (**16**) could be separated soon from the reaction mixture as orange colored needles. This compound could be directly isolated in high purity by a simple filtration from the reaction mixture; any attempt to purify it was unsuccessful due to its unstability. When **16** was heterogeneously stirred in methanol at room temperature, the orange color of **16** turned to pale brown. This was indicative of the formation of imidazoline (**17**) by the intramolecular cyclization of **16**. This compound, which was isolated by filtration, was also unstable; the continuous stirring of its methanol solution at room temperature led to the formation of a stable benzimidazole (**18**) by autoxida-

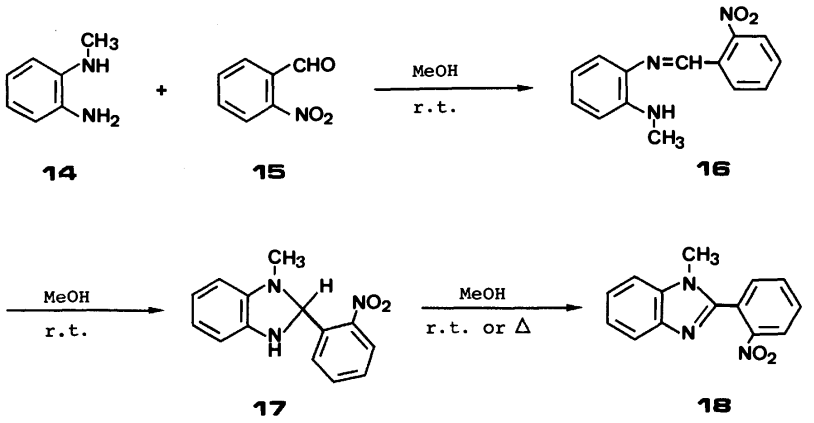
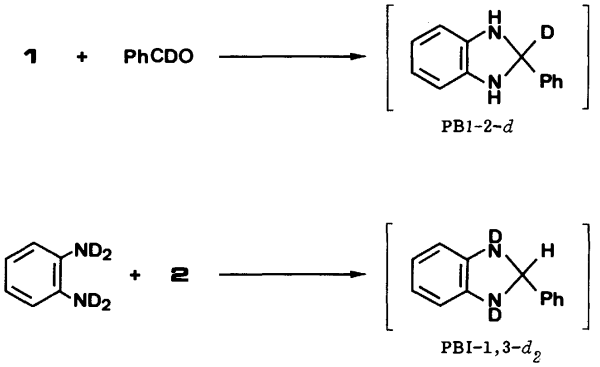


Scheme 5.

tion. The spectral and analytical data of these compounds (**16**—**18**) were entirely consistent with the proposed structures. For an examination of the reducing ability of **17**, a reaction with same molar amount of the olefin (**4a**) was carried out in ethanol at room temperature. Expectedly, the reduced product (**8a**) was obtained in 85% yield together with **18** (97% yield). This result strongly supports the validity of the existence of the reducing ability of PBI to an electron-deficient olefin.

When an ethanol solution of an equimolar mixture of **4a** and **17** was kept standing at room temperature for 12 h, a spectral change gradually occurred in which a new spectrum was reached with four clear isosbestic points at 207, 225, 291, and 331 nm (Fig. 2). The presence of these points indicates that no intermediate is present during a reaction in sufficient concentration for its own spectrum to become apparent, superimposed on those of reactants and products.

In an attempt to determine the destination of a hydrogen atom at the C-2 carbon of PBI, we reduced the olefin **6a** with PBI-2-*d* and PBI-1,3-d_2, which were prepared with the reagent system of diamine (**1**) and benzaldehyde-*d* or *o*-phenylenediamine-d_4 and aldehyde (**2**), respectively (Scheme 6). The product of the



Scheme 6.

reduction with PBI-2-*d* in 1-butanol was found to be (2-nitroethyl)benzene (**19**); it contained one deuterium atom at its β-carbon (Scheme 7). This result shows that the hydrogen atom at the C-2 carbon of PBI surely transfers to the β-carbon of the olefin as a hydride,

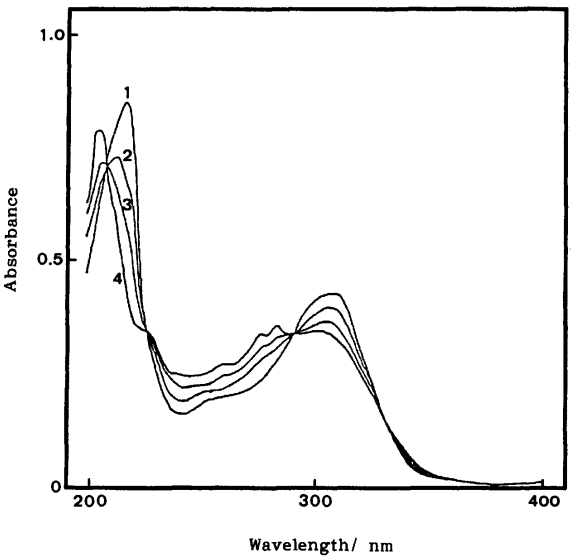


Fig. 2. Spectral change as a function of time for reaction between olefin **4a** and imidazoline **17** in ethanol at 25°C. $[\mathbf{4a}]_0=[\mathbf{17}]_0=2\times10^{-5}$ mol dm^{-3}. Time (h): 1, 0; 2, 4; 3, 8; 4, 12.

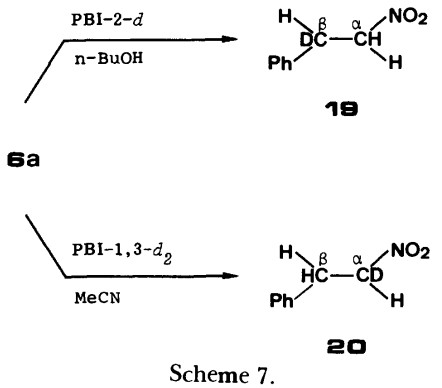


Scheme 7.

since the carbon at the β-position of **6a** is very electrophilic. When the same olefin was reduced in acetonitrile with PBI-1,3-d_2, the α-deuterated product (**20**) was selectively obtained in 83% yield (Scheme 7). This shows that the olefin incorporated the hydrogen atom at the nitrogen of PBI at its α-position probably as a proton.

Table 7. Rates of Reduction of β-Nitrostyrene (**6a**) with diamine (**1**) and *p*-Substituted Benzaldehyde in Refluxing 1-Butanol[a)]

Substituent	Reduction/%[b)]		
	1 h	3 h	5 h
NO_2	63	81	100
Cl	77	100	—
H	100	—	—
CH_3	78	100	—
CH_3O	70	85	100

a) In all cases, solutions were 0.20 M in the substrate and 0.24 M in diamine (**1**) and *p*-substituted benzaldehyde. b) All yields were determined by GLC using pentylbenzene as an internal standard.

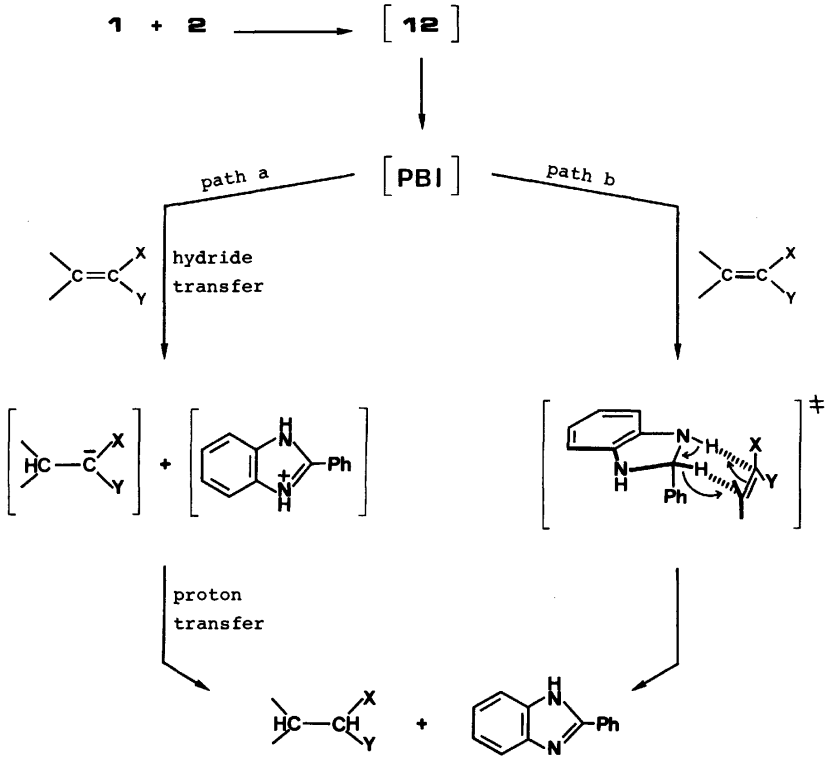
The substituent effect on the reduction of the olefin (**6a**) by PBI was studied with the reagent system of diamine (**1**) and *p*-substituted benzaldehyde. Thus, the reaction was monitored by GLC at a reflux temperature of 1-butanol. As shown in Table 7, when the aldehyde (**2**) was substituted by an electron-donating group, the rate of the reduction decreased in proportion to electron-donating ability of the substituent. On the other hand, the rate also decreased with an increase in the electron-withdrawing ability of the substituent. These results well match with a mechanism including a hydride transfer followed by a proton transfer from PBI to the olefin, since the rate of formation of PBI should decrease with an increase in electron-donating ability of the substituent and the rate on the actual reduction stage (hydride transfer) should also decrease with an increase in electron-withdrawing ability of the substituent.

Considering these facts, two possible reaction mechanisms for the present PBI-reduction can be proposed as shown in Scheme 8. They involve the sequential transfer of a pair of hydrogens of PBI (shown as path **a**) and a cyclic addition of two hydrogens of PBI in either exact or nearly exact concurrence (shown as path **b**). We consider that only the stereochemistry of the transfer of a pair of hydrogens of PBI to the carbon-carbon multiple bond of the conjugate olefin system can distinguish between path **a** and **b**. However, all of our attempts to determine such a stereochemical course were unsuccessful. Thus, paths **a** and **b** are, as yet, both candidates for the present PBI-reduction; however, path **b** seems to be more likely in light of the forementioned observation on UV-spectral change in the reduction of **4a** with **17** together with the previous results[1g)] that the hydrogen shift from 2-phenylbenzothiazoline to electron-deficient carbon-carbon double bonds of α,β-unsaturated carbonyl system is a synchronous transport of a pair of hydrogens.

Conclusion. The present study clearly reveals that PBI is a mild, selective and useful reducing agent for the reduction of carbon-carbon double bonds of electron-deficient olefins, and provides a unique and convenient method for this type of reaction. The advantages of the present method are summarized as follows:

(1) Easy preparation (in situ generation) of the reducing agent,

(2) operational simplicity,



Scheme 8.

(3) mild reaction conditions (moderate temperature, nonbasic, nonacidic, and no active ionic species present),
(4) complete selectivity,
(5) no side reactions,
(6) high chemoselectivity.

Experimental

Melting points were recorded on a Yanagimoto micro melting-point apparatus and are uncorrected. ^{1}H NMR spectra were measured with a JEOL PMX-60 spectrometer at 60 MHz using tetramethylsilane as an internal reference. IR and UV spectra were recorded on a JASCO A-202 and a Simadzu UV-240 spectrophotometers, respectively. Mass spectra were obtained on a JEOL JMS-0lSG mass spectrometer. GLC analyses were carried out on a Shimadzu Gas Chromatograph GC-6AM equipped with a hydrogen flame ionization detector using glass columns (1.5 m) packed with 2% Silicone OV-7 on Uniport HP (60—80 mesh). The yields by quantitative GLC were measured on the same columns by internal standard method. Silica gel (Wakogel C-300) was used for short-column chromatography.

Materials. *o*-Phenylenediamine was purified by recrystallization from ethanol. *o*-Phenylenediamine-d_4 was prepared by continual recrystallization of pure *o*-phenylenediamine from D_2O, that was pure *o*-phenylenediamine-d_4 by ^{1}H NMR; no amino proton absorption was detected. Aldehydes were commercially supplied and purified by distillation or recrystallization. Benzaldehyde-*d* was prepared via deuteration of 2-lithio-2-phenyl-1,3-dithiane with D_2O,[13] that was pure benzaldehyde-*d* by ^{1}H NMR; no aldehyde proton absorption was detected. Commercially available $ZnCl_2$, $FeCl_3$, and $AlCl_3$ were used without purification. Alkylidenemalononitriles,[14] ethyl α-cyanocinnamate,[15] diethyl benzylidenemalonate,[16] and aromatic nitroalkenes[17] were prepared by a Knoevenagel condensation of the corresponding aldehydes or ketones with malononitrile, ethyl cianoacetate, diethyl malonate, or nitroalkanes, respectively. Benzylideneacetone[18] and (*E*)-1,2-dibenzoylethylene[19] were prepared according to methods described in the literature. Other α,β-unsaturated ketones and solvents were commercial materials which were purified by the usual methods.

General Procedure for the Reduction of Electron-Deficient Olefins (4 and 5) with PBI. To a stirred solution of the olefin (2.0 mmol) and benzaldehyde (0.21 g, 2.0 mmol) in ethanol (20 ml) under nitrogen at room temperature, *o*-phenylenediamine (0.22 g, 2.0 mmol) was added. After completion of the reaction (monitored by TLC; see Table 2), the solvent was evaporated under reduced pressure. Dichloromethane was added to the residue and insoluble imidazole (**3**) was filtered off. After removing dichloromethane under reduced pressure, the crude product was purified by short-column chromatography on silica gel to give the pure reduced product (**8** and **9**). In a large-scale synthesis, purification by distillation or recrystallization was also effective. Some physical and spectral data of the products are given as follows: **8a**: Mp 91—92 °C; IR (KBr) 2252 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=3.16 (d, 2H, CH_2, *J*=7 Hz), 3.70 (t, 1H, CH, *J*=7 Hz), and 7.18 (s, 5H, Ar); MS *m/z* 156 (M^+). **8b**: Bp 117—119 °C/6 mmHg (1 mmHg=133.322 Pa); IR (neat) 2250 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=1.49 (d, 3H, CH_3, *J*=7 Hz), 3.31 (m, 1H, CH), 3.71 (d, 1H, CH, *J*=6 Hz), and 7.15 (s, 5H, Ar); MS *m/z* 170 (M^+). **8c**: Bp 128—130 °C/5 mmHg; IR (neat) 2250 and 2230 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=0.83 (t, 3H, CH_3, *J*=6.2 Hz), 1.91 (m, 2H, CH_2), 2.98 (q, 1H, CH), 3.83 (d, 1H, CH, *J*=6 Hz), and 7.15 (s, 5H, Ar); MS *m/z* 184 (M^+). **8d**: Bp 108—111 °C/3 mmHg; IR (neat) 2249 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=0.88 (t, 3H, CH_3, *J*=5.6 Hz), 1.20 (m, 2H, CH_2), 1.87 (q, 2H, CH_2), 3.07 (q, 1H, CH), 3.73 (d, 1H, CH, *J*=6 Hz), and 7.15 (s, 5H, Ar); MS *m/z* 198 (M^+). **8e**: Bp 85—86 °C/5 mmHg; IR (neat) 2245 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=1.21 (d, 6H, $2CH_3$, *J*=7 Hz), 2.25 (m, 1H, CH), and 3.62 (d, 1H, CH, *J*=5 Hz); MS *m/z* 107 (M^+−1). **8f**: Bp 77—78 °C/7 mmHg; IR (neat) 2246 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=0.70—1.24 (m, 6H, $2CH_3$), 1.54 (m, 2H, CH_2), 2.02 (m, 1H, CH), and 3.72 (d, 1H, CH, *J*=4.6 Hz); MS *m/z* 121 (M^+−1). **8g**: Colorless oil; IR (neat) 2251 cm^{-1} (CN); ^{1}H NMR (CCl_4) δ=0.80—2.28 (br, 11H, *c*-C_6H_{11}) and 3.42 (d, 1H, CH, *J*=5.2 Hz); MS *m/z* 147 (M^+−1). **9**: Colorless oil; IR (neat) 2240 (CN) and 1740 (CO) cm^{-1}; ^{1}H NMR (CCl_4) δ=1.14 (t, 3H, CH_3, *J*=7 Hz), 3.10 (d, 2H, CH_2, *J*=6 Hz), 3.48 (t, 1H, CH, *J*=6 Hz), 4.05 (q, 2H, CH_2), and 7.10 (s, 5H, Ar); MS *m/z* 203 (M^+).

General Procedure for the Reduction of Aromatic Nitroalkenes (6) with PBI. To a stirred solution of nitroalkene (**6**) (5.0 mmol) and benzaldehyde (0.64 g, 6.0 mmol) in 1-butanol (25 ml) under nitrogen at room temperature, *o*-phenylenediamine (0.65 g, 6.0 mmol) was added. After refluxing for the appropriate time (monitored by TLC; see Table 4), the solvent was evaporated under reduced pressure. Dichloromethane was added to the residue and insoluble imidazole (**3**) was filtered off. The dichloromethane solution was thoroughly washed with 0.1M HCl, dried with $MgSO_4$, and concentrated to give a crude product. The crude product was purified by short-column chromatography on silica gel to give the pure reduced product (**10**). In a large-scale synthesis, purification by distillation or recrystallization was also effective. Some physical and spectral data of the products are given as follows: **10a**: Bp 78 °C/1 mmHg; ^{1}H NMR ($CDCl_3$) δ=3.00 (t, 2H, β-CH_2, *J*=7 Hz), 4.27 (t, 2H, α-CH_2, *J*=7 Hz), and 6.97 (s, 5H, Ar). **10b**: Mp 96—97 °C; ^{1}H NMR ($CDCl_3$) δ=3.39 (t, 2H, β-CH_2, *J*=7 Hz), 4.63 (t, 2H, α-CH_2, *J*=7 Hz), 7.35 (d, 2H, Ar, *J*=8 Hz), and 8.09 (d, 2H, Ar, *J*=8Hz). **10c**: Bp 136 °C/3 mmHg; ^{1}H NMR ($CDCl_3$) δ=3.17 (t, 2H, β-CH_2, *J*=7 Hz), 4.43 (t, 2H, α-CH_2, *J*=7 Hz), and 7.07 (m, 4H, Ar). **10d**: Bp 96 °C/2 mmHg; ^{1}H NMR ($CDCl_3$) δ=2.25 (s, 3H, CH_3), 3.07 (t, 2H, β-CH_2, *J*=7 Hz), 4.30 (t, 2H, α-CH_2, *J*=7 Hz), and 6.90 (s, 4H, Ar). **10e**: Bp 123 °C/2 mmHg; ^{1}H NMR ($CDCl_3$) δ=3.03 (t, 2H, β-CH_2, *J*=7 Hz), 3.57 (s, 3H, OCH_3), 4.33 (t, 2H, α-CH_2, *J*=7 Hz), 6.93 (d, 4H, Ar). **10f**: Colorless oil; ^{1}H NMR (DMSO-d_6) δ=3.09 (t, 2H, β-CH_2, *J*=7 Hz), 4.43 (t, 2H, α-CH_2, *J*=7 Hz), 6.60 (d, 2H, Ar, *J*=8 Hz), and 6.86 (d, 2H, Ar, *J*=8 Hz). **10g**: Mp 50—51 °C; ^{1}H NMR ($CDCl_3$) δ=3.23 (t, 2H, β-CH_2, *J*=7 Hz), 3.80 (s, 6H, $2OCH_3$), 4.53 (t, 2H, α-CH_2, *J*=7 Hz), and 6.67 (s, 3H, Ar). **10h**: Colorless oil; ^{1}H NMR ($CDCl_3$) δ=3.13 (t, 2H, β-CH_2, *J*=7 Hz), 4.50 (t, 2H, α-CH_2, *J*=7 Hz), 5.80 (s, 2H, OCH_2O), and 6.57 (s, 3H, Ar). **10i**: Bp 61—63 °C/2 mmHg; ^{1}H NMR ($CDCl_3$) δ=3.30 (t, 2H, β-CH_2, *J*=7 Hz), 4.50 (t, 2H, α-CH_2, *J*=7 Hz), 5.97 (m, 2H, Ar), 6.13 (m, 1H, Ar), and 7.17 (s, 1H, Ar). **10j**: Bp 99—101 °C/3 mmHg; ^{1}H NMR ($CDCl_3$) δ=3.33 (t, 2H, β-CH_2, *J*=7 Hz), 4.30 (t, 2H, α-CH_2, *J*=7 Hz), and 6.80—7.03 (m, 3H, Ar). **10k**: Colorless oil; ^{1}H NMR ($CDCl_3$) δ=3.13 (t, 2H, β-CH_2, *J*=7 Hz), 4.30 (t, 2H, α-CH_2, *J*=7 Hz), 6.57 (d, 1H, Ar, *J*=4Hz), 6.97 (m, 3H, Ar), and 7.57 (br, 1H, NH). **10l**: Mp

45—46 °C; ^{1}H NMR ($CDCl_3$) δ=4.43 (t, 2H, β-CH_2, J=7 Hz), 5.30 (t, 2H, α-CH_2, J=7Hz), and 7.80—8.70 (m, 7H, Ar). **10m**: Bp 85 °C/2 mmHg; ^{1}H NMR ($CDCl_3$) δ=1.43 (d, 3H, CH_3, J=7 Hz), 3.00 (m, 2H, β-CH_2), 4.50 (m, 1H, α-CH), and 7.07 (s, 5H, Ar). **10n**: Bp 100 °C/2 mmHg; ^{1}H NMR ($CDCl_3$) δ=0.97 (t, 3H, CH_3, J=7.4 Hz), 1.90 (m, 2H, CH_2), 3.13 (q, 2H, β-CH_2), 4.60 (m, 1H, α-CH), and 7.17 (s, 5H, Ar). **10o**: Bp 81—82 °C/1 mmHg; ^{1}H NMR ($CDCl_3$) δ=0.70—2.20 (m, 7H, C_3H_7), 3.06 (m, 2H, β-CH_2), 4.67 (m, 1H, α-CH), and 7.06 (s, 5H, Ar).

Conjugate Reduction of α,β-Unsaturated Ketones (7) with PBI in the Presence of $ZnCl_2$. A solution of enone (**7**) (1.0 mmol) in dry methanol (3 ml) and $ZnCl_2$ (0.14 g, 1.0 mmol) were mixed in a glass tube under ice-water cooling. After the $ZnCl_2$ was completely dissolved, a solution of *o*-phenylenediamine (0.22 g, 2.0 mmol) and benzaldehyde (0.21 g, 2.0 mmol) in dry methanol (4 ml) was added and the mixture was degassed several times in vacuo. The tube was sealed in vacuo and kept at 50 °C for 24 h. After 0.1M HCl (15 ml) was added to the mixture in the tube under ice-water cooling, the aqueous mixture was extracted with dichloromethane. The dichloromethane solution was thoroughly washed with water, dried with $MgSO_4$, and analyzed by quantitative GLC. The results are given in Table 6. An identification of the products isolated by short-column chromatography on silica gel was performed by spectroscopic (NMR, IR, and MS) methods. These spectral data were in satisfactory agreement with those of the corresponding authentic samples or expected values.

Preparation of 1-Methyl-2-(*o*-nitrophenyl)benzimidazoline (17). A solution of *o*-nitrobenzaldehyde (0.15 g, 1 mmol) and *N*-methyl-*o*-phenylenediamine (0.12 g, 1 mmol) in methanol was stirred at room temperature. After ca. 5 min, precipitated orange-colored needles were separated out, which were collected by filtration, washed with cold methanol, and dried in vacuo to give an almost pure Schiff's base (**16**) (0.22 g, 85%); mp 89—93 °C; IR (KBr) 1590 cm^{-1} (N=C); ^{1}H NMR ($CDCl_3$) δ=2.67 (s, 3H, CH_3), 8.93 (s, 1H, CH), and 7.00—8.00 (m, 8H, Ar).

Found: C, 65.59; H, 5.05; N, 16.41%. Calcd for $C_{14}H_{13}N_3O_2$: C, 65.87; H, 5.13; N, 16.46%.

Without further purification, Schiff's base (**16**) (0.26 g, 1 mmol) was added in methanol and heterogeneously stirred at room temperature for 6 h. During this period, the orange-color of the needles turned to light brown. Filtration, washing with cold methanol, and drying in vacuo gave almost pure benzimidazoline (**17**) as brown needles (0.24 g, 92%); mp 134—136 °C; IR (KBr) 1495 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$) δ=2.97 (s, 3H, CH_3), 6.07 (s, 1H, CH), and 6.20—8.00 (m, 8H, Ar).

Found: C, 65.46; H, 5.06; N, 16.38%. Calcd for $C_{14}H_{13}N_3O_2$: C, 65.87; H, 5.13; N, 16.46%.

Reduction of Benzylidenemalononitrile (4a) with Benzimidazoline (17). The olefin **4a** (0.15 g, 1 mmol) was reduced with benzimidazoline (**17**) (0.26 g, 1 mmol) in ethanol (3 ml) for 12 h according to the general procedure. The usual work-up of the reaction mixture gave benzimidazole (**18**) (0.25 g, 97%). Chromatographic purification of the filtrate gave the pure reduced product (**8a**) (0.13 g, 85%).

Reduction of β-Nitrostyrene (6a) with PBI-2-*d*. Nitrostyrene **6a** (0.45 g, 3.0 mmol) was reduced for 1h with *o*-phenylenediamine and benzaldehyde-*d* according to the general procedure. A chromatographic purification of the crude product gave β-deuterated compound (**19**) as a colorless oil (0.42 g, 91%); ^{1}H NMR (CCl_4) δ=3.00 (t, 1H, β-CDH), 4.27 (d, 2H, α-CH_2), and 6.97 (s, 5H, Ar); MS m/z 152 (M^+).

Reduction of β-Nitrostyrene (6a) with PBI-1,3-d_2. Nitrostyrene **6a** (0.45 g, 3.0 mmol) was reduced with *o*-phenylenediamine-d_4 and benzaldehyde for 24 h according to the general procedure, except that acetonitrile was used in place of 1-butanol. A chromatographic purification of the crude product gave α-deuterated compound (**20**) as a colorless oil (0.38 g, 83%); ^{1}H NMR ($CDCl_3$) δ=3.07 (d, 2H, β-CH_2), 4.30 (t, 1H, α-CDH), and 7.00 (s, 5H, Ar); MS m/z 152 (M^+).

On a Solid-State ECD, WO_3/Solid Electrolyte/Metal

Katsumi KUWABARA,* Shoichi ICHIKAWA, and Kohzo SUGIYAMA
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received October 23, 1986)

Electrochromic display (ECD) was investigated using WO_3 as the electrochromic material and metals as the counter electrode. WO_3 was vacuum-evaporated on a glass substrate coated with indium tin oxide. A film of solid electrolyte, $Sn(HPO_4)_2 \cdot H_2O$, was prepared by means of the spray method on the thin film of WO_3. ECDs with metal electrodes were examined from the points of view of the change in optical density, the current-wave forms, and the response speeds in coloring and bleaching processes. ECD cells with noble metals indicated comparatively high optical density changes on coloration at a constant-voltage operation. The cell with Ag showed a high coloration speed compared with the cells containing graphite and other metals.

Much attention has been paid to the electrochromic display (ECD) since Deb reported on the electrochromic properties of WO_3.[1] The ECDs with WO_3 are classified into the following groups:

WO_3/liquid electrolyte[2,3] (I)

WO_3/dielectric material[4,5] (II)

WO_3/solid electrolyte (super ionic conductor)[6-10] (III)

The first group has been investigated extensively. A few devices in this group have come to practical use because of their excellent performance, especially their distinct image and high response speed, but various problems remain to be solved such as the leakage of liquid electrolytes, the dissolution of the WO_3 film, and the evolution of gases. In the second group, since the dielectric material must adsorb some water in order to have ionic conduction, the performance of the ECD is affected by moisture in the atmosphere. The solid electrolyte in the third group originally contains a mobile ion in its own structure, but the ionic conductivity is not always so high as that of the electrolytic solution. The poor response speed has prevented the ECDs from satisfactory development, although the devices are hopeful because of their stable memory, long life-cycle, and maintenance-free operation.

In previous papers,[11,12] the ECDs were investigated using several inorganic ionexchangers as the solid electrolyte, and an ECD cell with $Sn(HPO_4)_2 \cdot H_2O$ (hereinafter to be referred to as SPA) was found to display the best behavior on coloration. The proton conductivity ($\approx 10^{-5}$ S cm^{-1} at room temperature) of the electrolyte[13] is not high enough for the ECD, but is not affected so much by the temperature as by the humidity in the atmosphere. Therefore, SPA has the possibility of providing an ECD with stable performance.

WO_3 films were studied from various points of view, such as the effect of adsorbed-water, the packing density, and the degree of crystallizatio.[14-16] However, counter electrodes for the ECD had scarcely been examined at all in previous papers. Yoshimura et al. reported that the spontaneous coloration of ECD was suppressed by the use of metal as a counter electrode,[10] and Sakamoto et al. reported the electrochromic behavior to be influenced by the material of the counter electrode.[17] In this paper, we wish to report on solid-state ECDs containing metals as the counter electrode. The performances of the ECDs have been evaluated in comparison with those of the ECD containing graphite as the counter electrode.

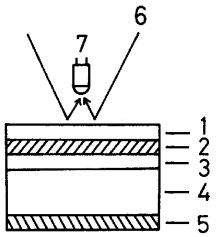

Fig. 1. Schematic diagram of the ECD cell and the experimental set up. 1: glass substrate, 2: ITO electrode, 3: WO_3, 4: $Sn(HPO_4)_2 \cdot H_2O$, 5: counter electrode, 6: tungsten lamp, 7: photo transister.

Experimental

The configuration of the components in the ECD cell is shown in Fig. 1. WO_3 film (450 nm thick) was deposited on an ITO-coated glass substrate by means of vacuum evaporation at a rate of 15 nm s^{-1} and under a vacuum of 2.66×10^{-3} Pa. SPA (Toagosei Chemical Industry Co. Ltd.) was used as the solid electrolyte, and its layer (40—60 μm thick) was formed by spraying the suspension which had beed prepared by mixing SPA fine powder with acetone under ultrasonic vibration.

Metal plates and graphite plate (0.1—0.8 mm thick and 3.29 cm^2) were used as the counter electrode. The metals were Ag, Al, Au, Cu, Fe, Ni, Pt, Pt black, Sn, Ti, Zn, and Zr. The surfaces were polished with tapping film and cleaned with trichloro-ethane before use.

The ITO, the WO_3 film, and the solid-electrolyte layers were sandwiched with the counter electrode in a pile between two bakelite plates (3 mm thick). The bakelite plate facing the glass had a window 10 mm in diameter so as to make it possible to detect the change in color through it.

The change in color was measured in the reflection mode using tungsten lamps and a photo transistor, as is shown in Fig. 2. A d.c. constant current or voltage was supplied to the ECD cell from a d.c. constant-current source (Metronix) and a function generator (Hokuto Denko HB-104). The change in the optical density, $\Delta O.D.$, is defined by the following

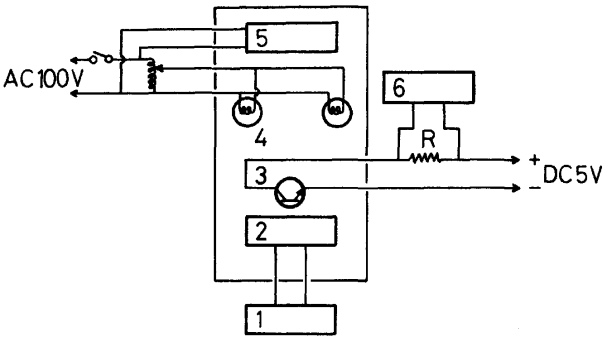

Fig. 2. Schematic diagram for measurement of the optical density changes. 1: d.c. source, 2: ECD cell, 3: photo transistor, 4: tungsten lamp, 5: fan, 6: recorder.

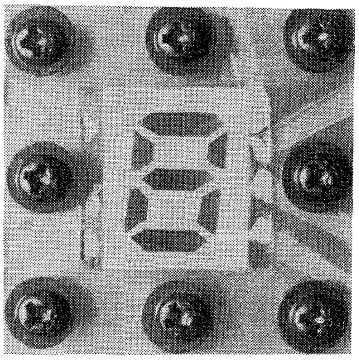

Fig. 3. Demonstration of a seven-segment numeric ECD.

equation:

$$\Delta O.D. = \log CR = \log R_0/R$$

where CR is the contrast ratio and where R_0 and R are the reflection strengths at bleaching and at coloring respectively. In this study, R_0/R was detected in the form of the ratio of the potential drop, V_0/V. V_0 (bleaching) and V (coloring) are the values at a resistor connected in series to the photo transistor. They were recorded by means of a servocoder (Graphtec SR 6341). All the measurements were carried out at room temperature.

Considering the practical ECD cell, a model of the seven-segment numeric ECD was prepared tentatively using WO_3 (EC material), an electrolyte (SPA), graphite (counter electrode), and an acryl plate (package). The appearance is shown in Fig. 3. The white color of SPA can be seen to offer an excellent contrast to the blue color of WO_3.

Results

The optical-density change ($\Delta O.D.$) versus the injected-charge curves at a constant current of 700 μA/cell are shown in Fig. 4. The change in color of the ECD is caused by the double injection of protons and electrons into the WO_3 film (to be described later). Whether or not the distribution of protons in the bulk of the WO_3 film is homogeneous can be considered in principle to influence the $\Delta O.D.$ measured in the reflection mode. In this study, the experimental duration of each run was short, and protons appeared to stay near the surface layer of the WO_3 film on the electrolyte. Therefore, the $\Delta O.D.$ values measured were regarded as not to be influenced by the distribution state of the protons.

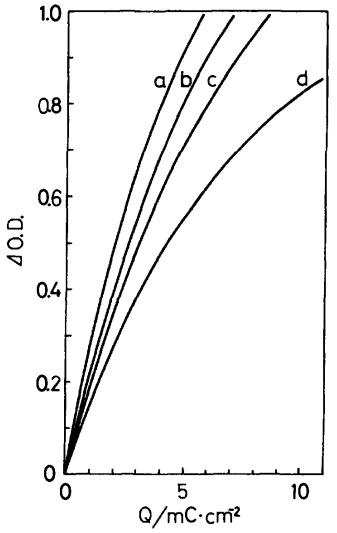

Fig. 4. Optical density changes as a function of injected charge. Counter electrodes a: Au, b: graphite, c: Pt, d: Ag.

Each cell at a certain charge should display a uniform $\Delta O.D.$ value, independent of the material used as the counter electrode. However, as may be seen from Fig. 4, the forms of the curves are different from each other. A high value of the $\Delta O.D.$ at a certain charge means a high current efficiency for coloration, since $\Delta O.D.$ is caused by the concentration change in the color based on an electrochemical reaction. In this experiment, the charge required to achieve $\Delta O.D.$=0.5 was used for the estimation of the current efficiency. The ECDs with Ni, Au, and Cu electrodes colored even in the low-charge region and needed 2.1—2.3 mC cm^{-2} to get $\Delta O.D.$=0.5. The cells with Ag and Pt electrodes indicated efficiencies slightly lower than the efficiency of the cell with graphite as the counter electrode. These data are summarized in Table 1. The three ECDs with Al, Ti, and Zr did not color enough for the $\Delta O.D.$ to be detected.

The current efficiencies shown in Fig. 4 were compared, for reference, with those in the few papers which have described ECDs with a solid-proton conductor. The ECD with antimony (V) oxide as a solid electrolyte and Fe_3O_4 as a counter electrode was reported to require 5 mC cm^{-2} to achieve a $\Delta O.D.$ of 0.5.[18] Similarly, the cell containing *p*-toluenesulfonic acid (TsOH)/urea-glycerol and Pt black was said to need 5 mC cm^{-2}.[9] It can be said from these data that the current efficiencies of ECDs with such counter electrodes as Au and Ag are comparable with, or even higher than, the data previously reported.

In order to examine the coloring-bleaching response to step voltage, the square-wave voltage was applied to

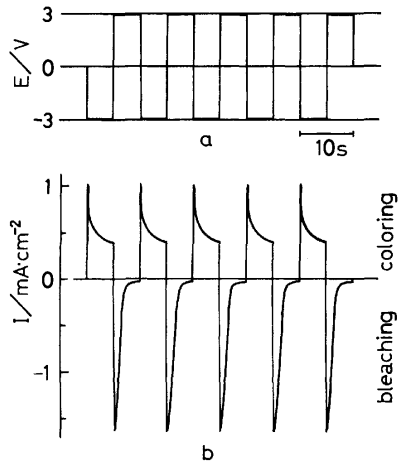

Fig. 5. Current wave form of ECD cell with graphite by applying square-wave voltage (±3 V) to a cell at 0.1 Hz. a: voltage wave form, b: current wave form.

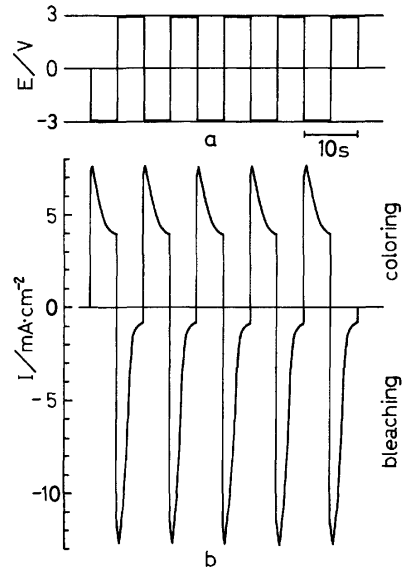

Fig. 6. Current wave form of ECD cell with Ag by applying square-wave voltage (±3 V) to a cell at 0.1 Hz. a: voltage wave form, b: current wave form.

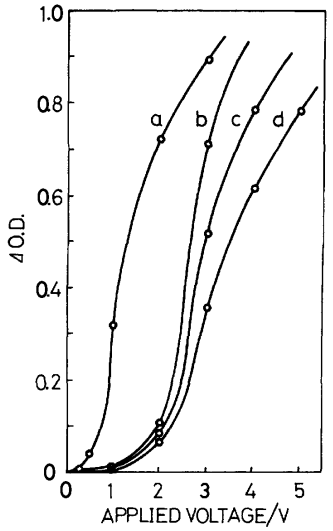

Fig. 7. Optical density changes at various applied voltages. Counter electrodes a: Ag, b: Au, c: graphite, d: Pt.

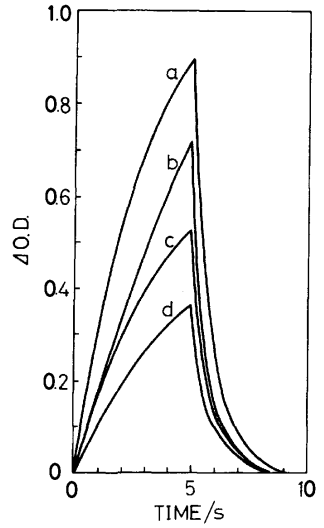

Fig. 8. Response time under an applied voltage of ±3 V. Counter electrodes a: Ag, b: Au, c: graphite, d: Pt.

the ECD and the voltage corresponding to the current was recorded. The current wave form at 0.1 Hz is shown in Fig. 5 on the cell with a graphite electrode, while the current-wave form obtained on the cell with Ag is shown in Fig. 6. In the former case, the current-wave forms differ in their coloring and bleaching processes. The current limit on the coloring process was observed below 1 s. In the latter case, the current was about ten times larger than that in the cell with graphite, and differences in shape in the current-wave forms were observed between the coloring and bleaching processes. The current limit on the coloring process was also observed, but it was slightly more moderate than the current limit shown in Fig. 5.

Figure 7 shows some $\Delta O.D.$ curves obtained at various voltages for a 5-s duration. The cell with Ag colored in the considerably low-voltage region of 1—2 V, while the cell with a graphite electrode did not color so much, even at a voltage higher than 3 V. The ECD with Au exhibited a higher $\Delta O.D.$ value compared with the cell containing graphite. In several papers,[9,19,20] the Pt electrode was used, but in this study the cell set up with Pt did not show so high performance as had been expected.

The minimum voltage at which distinct coloration can be observed is regarded as the threshold voltage for coloration. According to Fig. 7, the threshold voltage can be obtained by a procedure similar to the process of estimating a decomposition voltage on a certain current-voltage curve in an electrolysis. That is, the threshold voltage is found from the point of intersection of two straight lines which are drawn on a $\Delta O.D.$-

Table 1. Characteristic Values of ECDs with Various Electrode Materials. Work Functions of the Materials are Shown for Reference

Material	$Q/\Delta O.D.$ of 0.5	Threshold voltage/V	$\Delta O.D.$ 1 s after start	Work function
	$mC \cdot cm^{-2}$			eV
Ni	2.2	1.7	0.09	4.96
Au	2.1	1.8	0.17	4.83
Graphite	2.6	1.9	0.16	4.83
Cu	2.3	2.0	0.15	4.61
Pt	3.0	2.1	0.09	4.52
Fe	2.7	2.3	0.04	4.40
Sn	4.2	3.5	0.01	4.38
Ag	4.2	0.5	0.28	4.35
Zn	4.4	>5	0.01	4.31
Al	—	—	—	4.25
Zr	—	—	—	4.21
Ti	—	—	—	4.14

voltage curve in a lower $\Delta O.D.$ region ($0 \leqq \Delta O.D. < 0.05$) and in a higher $\Delta O.D.$ region ($0.1 < \Delta O.D. < 0.5$). Most of the cells in this study had the threshold voltage of 1.7—3.5 V. However, the ECD with an Ag electrode had the extremely low value of 0.5 V, as is shown in Table 1.

Figure 8 shows the coloration speed of the ECDs containing four cells with Pt, graphite, Au, and Ag electrodes. Most of the other cells, with various metal electrodes, did not reveal any coloration speed higher than that of the ECD with graphite. The $\Delta O.D.$ values 1 s after the beginning of coloration were 0.28, 0.17, and 0.16 for the Ag, Au, and graphite electrodes respectively. The response speed of the ECD with Ag was proved to be about twice as fast as that of the ECD with graphite. In the same way, the $\Delta O.D.$ values after 5 s were 0.89, 0.72, and 0.53 for Ag, Au, and graphite respectively.

The ECD consisting of Li_2WO_4 and the Au electrode has been reported to take 50 m s to achieve $\Delta O.D.=0.3$ when 3.0 V is applied and the ECD with antimony (V) oxide has been shown to need 500 m s when 1.3 V is applied.[18] In addition, the response speed of the cell of the TsOH/urea-glycerol system was $\Delta O.D.$ of 0.35/s at the applied voltage of 1.5 V.[9] Compared with these values, the coloration speed obtained in this work was not so high.

Discussion

In the ITO/WO_3/SPA/M system (M=metal), the electrochromic reaction on coloration can be written as follows:

$$WO_3 + xH^+ + xe^- \longrightarrow H_xWO_3 \quad (1)$$

where the H^+ ions come to WO_3 from proton-conductive SPA and where, at the same time, the H^+ ions formed at the SPA/M interface move into SPA. The H^+ ions may be formed by the dissociation and/or oxidation of the adsorbed-water at the interface:

$$H_2O \longrightarrow H^+ + OH^- \quad (2)$$

$$H_2O \longrightarrow 2H^+ + 1/2O_2 + 2e^- \quad (3)$$

The $\Delta O.D.$ vs. Q curves obtained at a constant-current operation were not always on a uniform curve, although the deviation was not remarkable; i.e., the charges needed to achieve $\Delta O.D.=0.5$ ranged from 2.1 to 4.4 $mC\,cm^{-2}$, as may be seen in Table 1. Such a difference in Q may be caused by the difference in the voltage applied to the cell to flow the constant current. This was supported by the current behavior obtained at a constant-voltage operation (Figs. 5 and 6).

The voltage applied to the cell during the coloring process will drop first at the SPA/M interface to produce H^+ ions and to make them move into SPA (1st stage), secondly at the SPA layer (2nd stage), and thirdly at the WO_3/SPA interface (3rd stage). In this experiment, the voltage drops at the 2nd and 3rd stages scarcely depend on the material of the counter electrode. Therefore, the 1st stage will dominate the total process. However, the variation in the applied voltage will also have an influence on the behavior of the H^+ ions at the SPA layer and at the WO_3/SPA interface.

Under the application of a d.c. voltage in the coloring process, the density of the H^+ ions in the SPA will vary so as to bring about a concentration gradient which is high at the WO_3/SPA interface and low at the SPA/M interface. When a number of H^+ ions are accumulated at the WO_3/SPA interface under a high voltage, some of them diffuse back to the solid electrolyte and do not always take part in the formation of H_xWO_3.[21] On the other hand, as the voltage increases, the probability of the direct reaction of the H^+ ions with electrons may increase at the WO_3/SPA interface. Such H^+ ions cannot contribute to the formation of H_xWO_3 or in turn, to the coloration of the ECD.

The work functions of the materials[22] used as counter electrodes in this study are summarized for reference in Table 1, together with some numerical values indicating the performances of ECDs. The ECD with electrode material of a large work function seems to have a certain tendency to show a lower threshold

value and a shorter response time on coloration. However, it is not reasonable to analyze the ECD characteristics using only the work function, since there is no distinct difference among the work functions listed in Table 1.

As has been stated above, the current-wave forms (Figs. 5 and 6), threshold voltages, and response times (Table 1) vary with the electrode materials. This suggests that the characteristics of the ECDs in this study are mainly related to the anode reactions. The OH^- ions produced according to Eq. 2 are oxidized to form oxygen gas[5] or metal hydroxide at the counter electrode (anode).

$$2OH^- \longrightarrow H_2O + 1/2O_2 + 2e^- \quad (4)$$

$$M + xOH^- \longrightarrow M(OH)_x + xe^- \quad (5)$$

It may be supposed that materials which bring about the oxidation of OH^- ions at a lower voltage produce H^+ ions with more ease. Furthermore, some materials oxidizing the adsorbed-water at a lower voltage may be supposed to accelerate the production of H^+ ions according to Eq. 3. It is desirable for the oxygen gas produced in Eqs. 3 and 4 to be accommodated by the counter electrode. The surfaces of metals with a strong chemical affinity to oxygen gas, such as Al, will lose their ability as counter electrodes. ECDs using such metals did not show coloration under the present experimental conditions.

The ECD with an Ag electrode showed the lowest threshold voltage and the highest response speed in the coloring process. The reactivity of Ag with the OH^- ion and oxygen gas has to be examined. The OH^- ions produced according to Eq. 2 will react with Ag to form silver (I) hydroxide and silver (I) oxide:[23]

$$2OH^- + 2Ag \longrightarrow 2AgOH + 2e^- \quad (6)$$

$$2AgOH \longrightarrow Ag_2O + H_2O \quad (7)$$

Such redox reactions among Ag, silver (I) oxide, and hydroxide proceed easily. Moreover, Ag can physically take in oxygen gas in the form of lattice oxygen and/or adsorbed oxygen. These reactions will reduce the energy to dissociate the adsorbed-water. According to the equilibrium reactions (2) and (3), the elimination of OH^- ions and oxygen gas leads to the production of H^+ ions. Therefore, the electrochromic reaction in the cell with the Ag electrode may take place at a low-threshold voltage, and the applied voltage may be used effectively to increase the coloration speed.

Besides this explanation, the possibility of the dissolution of Ag into the electrolyte could be considered. If the Ag dissolves to give Ag^+ ions, the Ag^+ ions as well as the H^+ ions will move from the SPA/Ag interface to the electrolyte. In bleaching, some of the Ag^+ ions go back to the SPA/Ag interface with difficulty, since in the coloring process the Ag^+ ions will intercalate in SPA more rigidly than the H^+ ions.[13] However, both the current-wave forms (Fig. 6) and the response feature (Fig. 8) show that the reaction takes place more easily in the bleaching process than in the coloring process. This fact is inconsistent with the assumption mentioned above. Therefore, the possibility of the dissolution of Ag into SPA can be rejected.

Conclusion

All solid-state ECDs, ITO/WO_3/$Sn(HPO_4)_2 \cdot H_2O$ (SPA)/metal or graphite, were examined in the search for good material as counter electrodes. The $\Delta O.D.$-Q curves must be independent of the materials used for the counter electrodes. However, at Q=5 mC cm^{-2} the ECD cells with Au, graphite, Pt, and Ag showed $\Delta O.D.$ values of 0.56—0.93 higher than the cells with other metals. The reason for this phenomenon could not be determined. Asymmetric current-wave forms were, however, observed between the coloring and bleaching processes corresponding to the square-wave voltage (±3 V). The ECD cell with Ag indicated a high $\Delta O.D.$ (0.33), even at 1.0 V, and a high response speed ($\Delta O.D.$=0.28 1 s after the start under 3 V). Such characteristics were discussed with respect to the production of H^+ ions by means of the dissociation and/or oxidation of the adsorbed-water at the SPA/metal interface and the accommodation of OH^- ions and oxygen gas. These anode reactions on coloration will be discussed in a subsequent paper.

The present authors wish to express their sincere thanks to the Research Laboratory, Toagosei Chemical Industry Co., Ltd., for providing an inorganic ion-exchanger and ITO-coated glass.

Synthesis of Sulfoxide-Modified Cellulose Derivatives Designed for the Permselective Membrane of Sulfur Dioxide

Kiyokazu IMAI,* Yasuyuki TEZUKA, Tomoo SHIOMI, and Matsunori TAKADA
Department of Material Science and Technology, Technological University of Nagaoka, Kamitomioka, Nagaoka, Niigata 940-21
(Received September 8, 1986)

The Michael type addition reaction of cellulose with a series of vinyl sulfoxides, namely methyl vinyl sulfoxide, ethyl vinyl sulfoxide, *t*-butyl vinyl sulfoxide, and phenyl vinyl sulfoxide, was performed with NaOH as a catalyst to produce 2-(alkyl- or arylsulfinyl)ethyl cellulose derivatives. The high permselectivity of sulfur dioxide against nitrogen and oxygen was achieved through these sulfoxide modified cellulose membranes.

The increase of the concentration of atmospheric sulfur dioxide(SO_2) caused by anthropogenic sources has been accused of a wide range of environmental dangers, including widely spreading acid rain among industrialized countries. The control techniques for the atmospheric SO_2 concentration are currently carried out in two ways; (1) desulfuration of fuels and (2) desulfuration of combustion gas mixtures. The former system can be applied solely to liquid fuel systems and thus cannot be used for solid fuel systems including widely used coal systems. In the latter system, the technique, which involves alkaline absorption of SO_2 from bulk wasted gas mixtures, requires huge operation facilities, limiting its actual use to big combustion plants. Besides, the disposal of the wasted mass may cause another problem.

The development of the membrane technique which may provide a facile and economic way for a selective accumulation and separation of SO_2, should be of great importance. There have been, however, surprisingly few studies up to now in the search for suitable membrane materials for the selective separation of SO_2.[1-4] We have recently reported that sulfoxide modified poly (vinyl alcohol) can be used as the membrane material for the selective permeation of SO_2.[5] The structure design of this new synthetic membrane was accomplished by taking into account the exceptionally high solubility of SO_2 toward sulfoxides, including dimethyl sulfoxide,[6] since the permeability property of a synthetic membrane is considered to be governed by the solubility and the diffusivity of the gas molecule toward the membrane.

As the continuation and the extension of the previous studies, this paper presents the synthesis of sulfoxide-modified cellulose derivatives and the application to the membrane material for the selective permeation of SO_2. Cellulose, as well as poly (vinyl alcohol), is considered to be another promising candidate for the membrane material for the present purpose due to its good mechanical property and its high gas barrierity. The subsequent modification of cellulose with sulfoxide function is expected to give a membrane material with high permselectivity of SO_2 and good mechanical property.

Experimental

Reagents. A series of vinyl sulfoxides, i.e. methyl vinyl sulfoxide (MVSO), ethyl vinyl sulfoxide (EVSO), *t*-butyl vinyl sulfoxide (BVSO) was prepared by the method described before.[7] Phenyl vinyl sulfoxide (PVSO) was commercially available and was purified by the fractional distillation. Powdery cellulose was supplied from Asahi Chemical Co. (Avicel, PH 101, D.P. 250). Sodium hydroxide was of reagent grade and used without further purification. Water was used after deionization. Ethyl cellulose (from Nakarai Chem., D.S.=2.5, 80—120 cps) was used as received. Other reagents were purified by the conventional procedures.

Synthesis of Sulfoxide-Modified Cellulose Derivatives. A series of sulfoxide modified cellulose derivatives was synthesized through the Michael type addition reaction of cellulose with a series of vinyl sulfoxides. The following example presents the typical reaction procedure. One gram of cellulose powder was slurried and swelled in 20 ml of aqueous NaOH solution at 26—28 °C. A required amount of vinyl sulfoxide was then added and the reaction mixture was stirred for the prescribed period. The reaction solution became gradually less turbid and, in some cases, turned into almost homogeneous. The reaction mixture was then neutralized by acetic acid and poured into an acetone/methanol (7/3 in volume) mixture to isolate the reaction product, which was washed with the above acetone/methanol mixture and finally dried in vacuo at 45 °C for 48 h.

Gas Permeation Measurements. The sample membrane of a series of sulfoxide modified cellulose derivatives was prepared by casting from either 5 wt% water (for MVSO and EVSO adduct) or DMSO (for PVSO adduct) solution on a Teflon-coated plate. MVSO-modified cellulose with low D.S. (0.83 and 0.92), as well as EVSO- and PVSO-modified cellulose samples gave slightly turbid membranes. The casting solvent was evacuated first either in a desiccator containing anhydrous calcium chloride (for water), or in a thermostatic oven at 35 °C (for DMSO) and finally in vacuo at 60 °C for 2 d. An ethyl cellulose membrane was prepared in a similar way from a dichloromethane solution. The gas permeation measurements were carried out by using the volume method apparatus described in the previous report.[5]

Other Measurements. ^{13}C NMR measurements were carried out by a JEOL JNM GX270 apparatus, in which chemical shifts were calibrated either by using cellulose C_1 carbon (103.0 ppm) or DMSO (43.5 ppm) as an internal standard. Sulfur elemental analysis was carried out with a CALRO ERBA Elemental Analyzer MOD 1106. Viscosity measurements were carried out in water at 30 °C with an Ubbelohde

viscometer.

Results and Discussion

1) Synthesis of Sulfoxide-Modified Cellulose Derivatives. The Michael type addition reaction of hydroxyl group to poly (vinyl alcohol), PVA, or cellulose with such vinyl compounds as acrylonitrile, acrylamide, and alkyl vinyl sulfone, has been proved to be a versatile technique to introduce various kinds of functional groups to these polyhydroxy type polymers.[8,9] We have recently adopted this technique to synthesize a series of sulfoxide modified PVA derivatives using a variety of vinyl sulfoxides, i.e. methyl vinyl sulfoxide (MVSO), ethyl vinyl sulfoxide (EVSO) and *t*-butyl vinyl sulfoxide (BVSO).[10]

In the present study, we have carried out the Michael

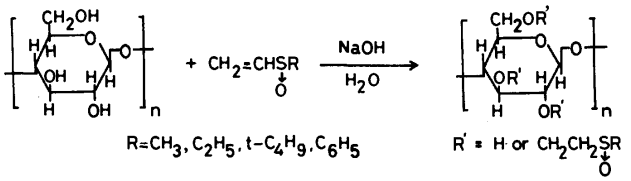
type addition reaction of a series of vinyl sulfoxides against another polyhydroxy polymer, cellulose, in the presence of sodium hydroxide, as a catalyst, to produce various sulfoxide modified cellulose derivatives. As is summarized in Table 1, a series of sulfoxide-modified



cellulose derivatives with various degrees of sulfoxide contents, i.e. the degree of substitution (D.S.) for the sulfinylethyl function, was obtained in the reaction with MVSO, EVSO, and PVSO, while BVSO was found to be very sluggish to react with cellulose under these reaction conditions. The formation of sulfoxide-modified cellulose derivatives through the Michael type addition reaction was confirmed evidently by ^{13}C NMR spectroscopic analysis given in Fig. 1-a—c, where the peaks assigned for the 2-(alkyl- or phenyl-sulfinyl)ethyl group introduced to cellulose appear to

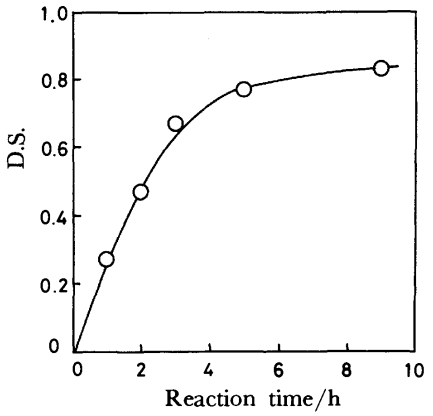


Fig. 2. The degree of substitution of MVSO-modified cellulose at various reaction times. Cellulose 1.0 g(−OH 0.019 mol), MVSO 5.1 g(0.057 mol), NaOH 5.0 g, H_2O 20 ml, 26—28°C.

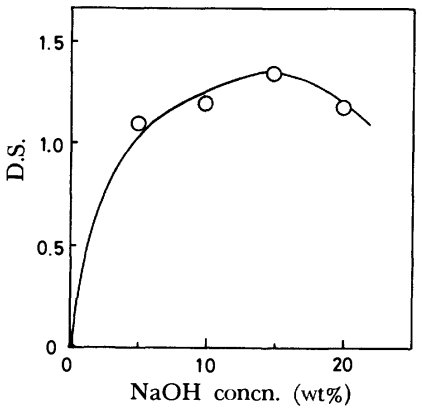

Fig. 3. The degree of substitution of MVSO-modified cellulose at various NaOH concentrations, Cellulose 1.0 g(−OH 0.019 mol), MVSO 15.4 g(0.17 mol), H_2O 20 ml, 9h, 26—28°C.

be present in addition to those for the glucose ring carbon signals.

As is seen in Table 1, the degree of substitution in the cellulose derivatives failed to exceed around 1.4, far less than the total available hydroxyl group in glucose unit 3.0, even when the reaction was performed either with a large excess of vinyl sulfoxide or with a prolonged reaction time (Fig. 2), or with a higher catalyst concentration (Fig. 3). The undesired side reaction, namely the addition reaction of vinyl sulfoxide with water used as the solvent, was observed to give 2-hydroxyethyl sulfoxide in the presence of sodium hydroxide similar to the reaction with poly (vinyl alcohol).[10]

The sulfoxide modified cellulose derivatives with the higher sulfoxide content could be obtained by employing the following reaction technique, where an excess amount of fresh vinyl sulfoxide was repeatedly added to the reaction mixture in an appropriate interval as shown in Table 1 (Runs M-11 and M-12). When such a reaction was repeated three times, sulfoxide-modified cellulose with a D.S. value as high as 2.40 was obtained as listed in Table 1 (Run M-12).

Table 2. Intrinsic Viscosity of MVSO-Modified Cellulose Derivatives with Various Degrees of Substitution[a)]

D.S.	$[\eta]$ (dl g^{-1})
0.83	1.95
1.18	1.81
1.23	1.77
2.01	1.30
2.40	1.25

a) In water at 30°C.

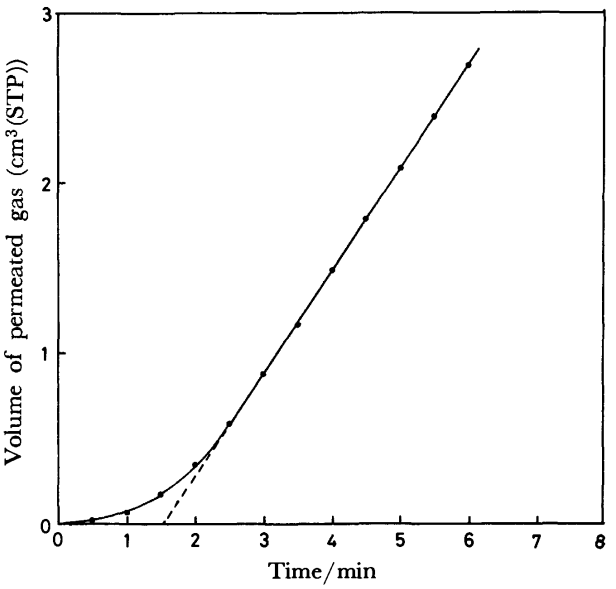

Fig. 4. The permeation measurement of sulfur dioxide through MVSO-modified cellulose membrane (Run 2 in Table 3, 1.0 atm).

The intrinsic viscosity of a series of MVSO-modified cellulose derivatives with various D.S. values was measured as the first-order approximation of the extent of polymer degradation during the sulfoxide-modification reaction. As is summarized in Table 2, MVSO-modified cellulose with the D.S. value of 2.40 was estimated to possess still considerably high molecular weight from its $[\eta]$ value of 1.25, although a slight decrease of $[\eta]$ was actually noticed with the increase in sulfoxide content.

2) Selective Permeation of SO_2 through Sulfoxide-Modified Cellulose Membranes. A series of sulfoxide-modified cellulose derivatives thus obtained was casted to form a membrane and subjected to the gas permeation measurements with such gases as SO_2, N_2, and O_2. The permeation coefficient of each pure gas was obtained through the volume method, where the rate of gas outflow through the sample membrane was measured until a constant flow rate was attained. An example of the permeation experiment for SO_2 by the present system is given in Fig. 4.

Table 3. Gas Permeability of Sulfoxide-Modified Cellulose Derivatives[a)]

Run No.	Modified Cell		Thickness	Temp	P(SO_2)			P(N_2)	P(O_2)	P(SO_2)/P(N_2)
	Type	D.S.	(μm)	°C	1.0atm	1.5atm	2.0atm	2.0atm	2.0atm	2.0atm

7	EC[e)]	2.50	127	20	1010	1640	2140	3.10	14.20	690

a) Unit of permeability, P: $(cm^3\ (STP)\cdot cm)/(cm^2\cdot s\cdot cm\ Hg)\times 10^{10}$. b) MVSO-modified cellulose. c) EVSO-modified cellulose. d) PVSO-modified cellulose. e) Ethyl cellulose. f) Too weak to permeability measurements. g) 1.0 atm.

The results of the gas permeation measurements for a series of sulfoxide-modified cellulose membranes were summarized in Table 3, where the result of ethyl cellulose membrane was also listed for comparison. The permeation coefficient of SO_2 was found to increase markedly with the increase of the sulfoxide function content in cellulose, while the permeation coefficients of N_2 and O_2 remained almost unchanged. This leads to the high permselectivity of SO_2 against N_2 and O_2 with these sulfoxide-modified cellulose membranes.

With the increase in applied SO_2 pressure, the permeation coefficient of SO_2 for the sulfoxide modified cellulose membrane was found to increase far more significantly compared to that for ethyl cellulose. At the same time, the notable swelling of the sulfoxide-modified cellulose membrane during the permeation experiment was observed especially in high applied SO_2 pressure, indicating the absorption of SO_2 in the membrane. This, in turn, weakens the membrane at high applied SO_2 pressure, especially in high sulfoxide content membranes.

The type of the substituent in vinyl sulfoxide was also found to exercise a prominent influence on the permeation behavior of SO_2, while little effect on the permeation coefficients of N_2 and O_2. The phenyl substituent was found to be the most remarkable effect on the permeation coefficient and permselectivity of SO_2, compared to methyl and ethyl counterpart, nevertheless the membrane tended to become too weak for the measurement at SO_2 pressures higher than 1 atm, even when the D.S. value of this cellulose derivative is 0.51.

Conclusion

A series of sulfoxide-modified cellulose derivatives was produced through the reaction of cellulose with various substituted vinyl sulfoxides and the obtained sulfoxide-modified cellulose membranes exhibited the high permselectivity of SO_2 against N_2 and O_2.

Self Regulation in the Cooperative Binding of Small Molecules to Linear Polymers

Takayuki SANO,* Thoru NAKATSUKA, Hirotsugu TSURUTA, and Shoji HARADA
Department of Materials Science, Faculty of Science, Hiroshima University, Hiroshima 730
(Received September 26, 1986)

Synopsis. As for the cooperative binding of small molecules to the linear polymers, including not only synthetic polymers but also biopolymers, an interesting relationship, the so called "self regulation effect" between the isolated binding constant (intrinsic binding constant) and the cooperative binding constant, (binding constant of growth process) can be observed amongst the large amount of data so far reported. The biological significances as well as the possible origin for this "self regulation mechanism" will be discussed.

A number of investigations into the cooperative binding of small molecules to polymers have been undertaken,[1-15] and several theories based on the one dimensional Ising model have been advanced.[6,7,11] For cooperative binding, it has been pointed out that the cooperativity seen in the binding of small dye molecules to counter charged synthetic linear polymers arises from a stacking interaction between bound dyes on polymer.[10,13] However, no systematic investigation of the binding mechanism has been completed. We report here an interesting correlation found between the isolated binding constant and the cooperative interaction parameter obtained for a variety of systems, both synthetic and biological, and propose a "self-regulation" cooperative binding effect in these systems.

Since the theory on the cooperative binding phenomenon was developed, our knowledge of the binding mechanism has been considerably extended. As for the cooperative binding of small molecules to polymers, the following three equations have been independently derived by Scatchard,[1] Schwarz,[7] and McGhee and von Hippel[11] respectively:

$$r/C_f = K_o e^{-2\omega r}(n - r), \tag{1}$$

$$C_f = 1/K_{co} - \{\frac{C_f}{qK_{co}r(n-r)}\}^{1/2}(n - 2r) \tag{2}$$

with

$$K_{co} = q K_o,$$

and

$$r/C_f = K_o(n - r)\{\frac{n - 2r + R}{2(n - r)}\}^2 \tag{3}$$

with

$$R = \{(n - 2r)^2 + 4qr(n - r)\}^{1/2},$$

where r is the ratio of the bound ligand to total polymer concentration, C_f is the concentration of free ligand, K_o is the intrinsic binding constant, ω is the electrostatic force between bound ligands, n is the number of binding sites per residue of polymer, K_{co} is the cooperative binding constant, and q is the cooperative interaction parameter. In these three theories the binding isotherms are described by three parameters, viz., the number of binding sites per residue of polymer, n; the intrinsic binding constant, K_o; and a cooperative interaction parameter, q or ω. The above three equations can be combined as follows through the experimentally measured apparent binding constant, K, determined by the conventional method of using the value of that at the isotherm midpoint;

$$K = \frac{1}{(C_f)_{r=1/2}} = K_o e^{-\omega n} = K_o q = K_{co} \tag{4}$$

The focus of our investigation was to examine the proposed theory and to clarify the origin of the cooperative interaction energy. From the investigations reported so far, it has been found in general that the

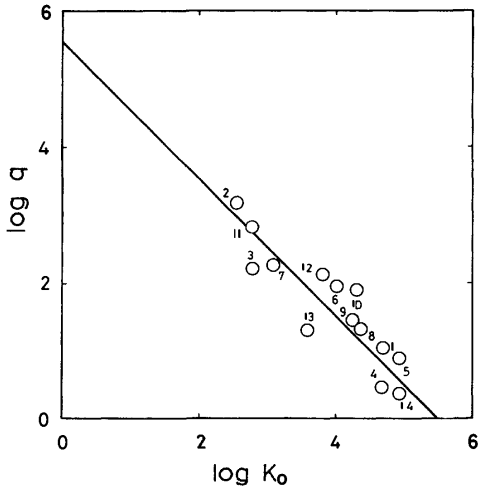

Fig. 1. The logarithmic plots of the cooperative interaction parameter, q against the isolate binding constant, K_o. The numbers on circles correspond to those in Table 1.

binding process of ionic polymers to ionic dye molecules is governed by an electrostatic interaction between bound molecules. The binding parameters obtained by independent workers on various systems at low ionic strength are listed in Table 1. As can be seen from the table there is a systematic trend in the values of q and K_o, i.e., the smaller K_o is, the larger is q. The logarithmic plot of K_o vs. q is shown in Fig. 1 where a general linear correlation was found having a slope equal to -1 regardless of such solution conditions as pH. This new finding between K_o and q has an important meaning with respect to the mechanism of the cooperative binding of small molecules to linear polymers. As described above, the parameter q can be related to K_o by the cooperative binding constant K_{co} or the binding strength K (see, e.g., Eqs. 1—4). Consequently, the obtained linear relationship between K_o and q implies that all the systems listed in Table 1 have essentially the same binding mechanism and also have a single cooperative binding constant, $K_{co}=(2.5\pm 0.5)\times 10^5\ M^{-1}$. In other words, the isolated binding is compensated in strength by the cooperative interaction effect so as to give the same binding strength regardless of the system. We call this effect "self-regulation" in the cooperative binding of small ions to polymers.

It has been reported that the binding mechanisms of the ionic polymer and dye molecules are dependent on the chemical properties of both molecules.[10,13] This is certainly true. However on the basis on the new finding of the linear correlation between K_o and q, it can be pointed out that there must exist a more specific factor in the binding mechanism of small ionic molecules to ionic polymers. At the present time there has still not been enough data reported to clarify what this specific factor is. If, for instance, the electrostatic binding interaction between counter-charged ionic species is the dominant factor in the binding of the systems listed in Table 1, then the state of hydration of the reacting species, especially of the ionic groups of the polymers, may be the most important factor in the "self-regulation" resulting from the cooperative binding interaction.

The "self-regulation" effect has been observed not only for the synthetic polymers but also for biopolymers such as DNA.[13] Therefore it is likely that the effect plays an important role in keeping the in vivo concentration of small ionic molecules at the optimum level. The self-regulation effect proposed here provides motivation for further investigation on the binding of small ligands to polymers, particularly on the role of the state of hydration of the reacting spacies.

^{27}Al High-Resolusion Solid-State NMR Study of Hydration of Ultrafine Powder of Aluminum Nitride

Shigenobu HAYASHI,* Kikuko HAYAMIZU, and Osamu YAMAMOTO
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received July 26, 1986)

Synopsis. ^{27}Al NMR spectra of hydrated aluminum nitride ultafine powder, measured using magic angle sample spinning technique, showed two peaks which can be attributed to Al coordinated by four N atoms and to Al coordinated by six O atoms, and the hydration process was discussed.

Aluminum nitride (AlN) is an attractive material as a substrate of electronic devices, since it has high heat-resisting property and large thermal conductivity.[1,2] Since high density is necessary to obtain the large thermal conductivity, ultrafine powder is promising to obtain a homogeneous and dense AlN substrate by sintering, but the powder easily reacts with atmospheric moisture to form a hydrated surface. The adsorbed oxygen-containing species leave their oxygen atoms after sintering, and the thermal conductivity is largely reduced by the oxygen.[2,3]

In the present work we have studied the hydration process of AlN ultrafine powder by means of ^{27}Al high-resolution solid-state NMR.

Experimental

Two kinds of AlN ultrafine powder were supplied by NEC Corporation; they are called Samples A and B, whose particle diameters are 100—1000 and about 2000 Å, respectively.

^{27}Al NMR spectra were obtained using magic angle sample spinning (MAS) technique by a JEOL FX-200 pulsed spectrometer at a resonance frequency of 52.00 MHz. The spinning speed was about 3.6 kHz. An ordinary one-pulse cycle was used with the flip angle of $\pi/6$ and the recycle time of 1 s. The shift values are referred to $AlCl_3$ aqueous solution. ^{1}H NMR spectra were also measured by a Bruker CXP-100 pulsed spectrometer, operating at a resonance frequency of 90.03 MHz, to obtain the hydrogen content. All the NMR measurements were performed at room temperature.

Results

Figure 1a shows an ^{27}Al MAS NMR spectrum of Sample A. Only one signal is observed at a position of 103 ppm with a width of 1.3 kHz. Other peaks are all attributed to spinning sidebands, which was confirmed by changing the spinning speed. ^{1}H NMR spectrum of this sample consists of two components with different linewidth; one is motionally-narrowed, and the other broadened by dipole-dipole interaction, being attributed to spatially fixed hydrogens. Total hydrogen content was estimated to be 0.71 wt%, while the content of the fixed hydrogens was 0.47 wt%

Figure 1b shows a spectrum of a heavily-hydrated sample of A (called AH). The hydration was carried out by exposing Sample A to liquid water at room temperature for 2 d. A new peak appears at −5 ppm with a width of 2.5 kHz, while the peak at 103 ppm slightly shifts to 109 ppm. Other peaks are attributed

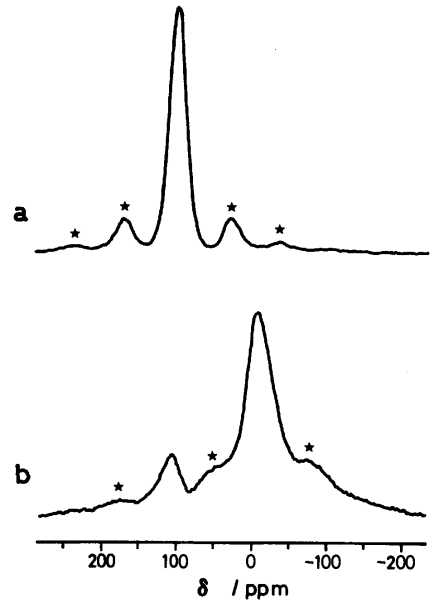

Fig. 1. ^{27}Al MAS NMR spectra of (a) Sample A and (b) Sample AH. The mark ★ denotes spinning sideband.

to spinning sidebands of the above two peaks. The hydrogen content is about 9.0 wt%, and the ^{1}H NMR spectrum shows a very narrow resonance line with a width of 350 Hz and a chemical shift of 5.2 ppm from tetramethylsilane. The shift value agrees with pure H_2O liquid (5.4 ppm),[4] and the line is motionally-narrowed. These facts suggest that most of the hydrogens are contained in the form of physisorbed H_2O left unreacted.

A dehydrated sample of A (Sample AD) was prepared by evacuating Sample A at 250 °C for 1 h. The hydrogen content is reduced to 0.17 wt%, and all hydrogens are spatially fixed. The ^{27}Al MAS NMR spectrum of this sample agrees with that of Sample A.

Sample B has a hydrogen content of 0.028 wt%, much lower than the other samples. The ^{27}Al MAS NMR spectrum agrees with that of Sample A again.

The results of ^{27}Al and ^{1}H NMR are summarized in Table 1.

Discussion

It is well-known that AlN reacts with H_2O in the following way:

$$AlN + 3H_2O \rightarrow Al(OH)_3 + 3NH_3. \quad (1)$$

In the AlN structure an Al atom is coordinated by four N atoms, while an Al atom is coordinated by six O

Table 1. Summary of ^{27}Al and ^{1}H NMR Results

Sample	Treatment	^{27}Al NMR		C_H[c]/wt%	
		Shift[a]/ppm	FWHM[b]/kHz	Total	Fixed
A	as supplied	103	1.3	0.71	0.47
AH	hydrated	−5 109	2.5 2.1	9.0	~0
AD	dehydrated	103	1.3	0.17	0.17
B	as supplied	103	1.3	0.028	0.014

a) Shift from $[Al(H_2O)_6]^{3+}$. b) Full width at half maximum. c) Hydrogen content.

atoms in $Al(OH)_3$. The coordination atom and their number are both changed by the reaction.

In the present work two signals are observed with different chemical shift values; 103 and −5 ppm. Since the hydrogen content is very low in Sample B, the number of Al atoms bonded with H via O is negligible. The signal observed at 103 ppm can therefore be attributed to the Al atom coordinated by four N atoms (abbreviated AlN_4). In the case of Al coordinated by O for aluminates and aluminum oxides, it is established that Al-O tetrahedra (AlO_4) and octahedra (AlO_6) have peaks in the range between 55 and 80 ppm and at about 0 ppm, respectively.[5] Consequently, the −5 ppm line can be assigned to AlO_6 in $Al(OH)_3$.

In a surface region, water reacts with AlN producing NH_3, and leaves surface hydroxyl groups. Some Al atoms may be connected with both N and O atoms. From the viewpoint of the Al coordination the reaction (1) is considered to proceed in the following steps:

$$AlN_4 \xrightarrow{a} AlN_xO_y \xrightarrow{b} AlO_6, \quad (2)$$

where $x+y=4$, 5, or 6. If considerable amounts of AlN_xO_y species were detected, it could be concluded that the reaction (2) proceeds step by step. Experimentally, however, no peaks were observed which can be attributed to AlN_xO_y. Namely, the step b is much faster than the step a.

Heavily hydrated sample, AH, has the two peaks, AlN_4 and AlO_6, indicating that the hydrated sample is a mixture of AlN and $Al(OH)_3$. The slight positive-frequency shift of the AlN_4 peak compared to Sample A is considered to be caused by superposition of the sideband of the AlO_6 peak, and hence it does not mean any structural change.

Samples A and AD have intermediate hydrogen contents between Samples B and AH. If oxygen-containing species such as OH and H_2O are assumed to be distributed homogeneously over all Al atoms, a considerable amount of Al atoms should be bonded to the O atoms. However, the amount of Al atoms bonded to O atoms is less than the detection limit, as shown in Fig. 1a. This fact suggests that oxygen-containing species are distributed over a limited amount of Al atoms.

In summary, the ^{27}Al NMR results demonstrate that the hydration reaction of aluminum nitride takes place quite inhomogeneously. Once an Al atom in AlN reacts with H_2O, the Al atom reacts with H_2O further more easily than the other Al atoms, finally forming $Al(OH)_3$. Consequently, the reaction product is a mixture of $Al(OH)_3$ and unreacted AlN, containing no detectable amounts of intermediate compounds.

The authors acknowledge the supply of materials to NEC Corporation.

Potentiometric Study of Heteropolyanion Formation from Telluric Acid and Molybdate Anion in 1M Na(Cl)

Atsushi YAGASAKI and Yukiyoshi SASAKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 28, 1986)

Synopsis. The equilibria in the H^+-MoO_4^{2-}-$Te(OH)_6$ system in aqueous solutions were studied potentiometrically at 25.0 °C. The data were expained by (6,6,1), (7,6,1), and (8,6,1) with formation constants log $\beta_{6,6,1}$=50.40±0.02, log $\beta_{7,6,1}$= 53.68±0.07 and log $\beta_{8,6,1}$=55.47±0.07.

Molybdotellurate is one of the best known heteropolyanions. It was first described more than 70 years ago.[1] Morphological and optical measurement of $3Na_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 22H_2O$ were made by Donney and Mélon.[2] The crystal structure of $(NH_4)_6[TeMo_6O_{24}] \cdot 7H_2O$ was reported as early as 1948.[3] However, little work has been done on the molybdotellurate system after Evans reported the crystal structure of the double salt $(NH_4)_6[TeMo_6O_{24}] \cdot Te(OH)_6 \cdot 7H_2O$.[4] Nothing has been reported on the equilibrium conditions of molybdotellurate in aqueous solutions to our knowledge. In the present paper we report the result of our potentiometric investigation of molybdotellurate equilibria in a 1M Na(Cl) (1M=1 mol dm^{-3}) ionic medium. This is the first example of an equilibrium analysis of a heteropolyanion which has an octahedral heteroatom unit.

Experimental

$Te(OH)_6$ was prepared by a standard method.[5] NaCl (Matsunaga, JIS Primary Standard) was heated at 200 °C for ca. 8 h before use. $Na_2MoO_4 \cdot 2H_2O$ (Wako, S) was used without further purification. The same apparatus as in our previous reports was employed.[6,7] Throughout the experiment the temperature was kept constant at 25.0±0.1 °C. Thirteen titrations were performed and 236 data points were collected. The data covered the ranges $7.2 \geqq -\log h \geqq 2.0$, $13.2 \leqq B/\mathrm{mM} \leqq 53.3$, $4.5 \leqq C/\mathrm{mM} \leqq 17.2$ and $1.0 \leqq B/C \leqq 8.0$, where h is the concentration of free hydrogen ion. B stands for the total concentration of molybdate, C that of tellurate.

Stable emf values were obtained within 5 min when $-\log h \leqq 3.5$, although we had to wait more than 2 hr before the readings reached stable values in the range $-\log h \geqq 6$.

The equilibria in solution can generally be written as $pH^+ + qMoO_4^{2-} + rTe(OH)_6 \rightleftarrows (H^+)_p(MoO_4^{2-})_q[Te(OH)_6]_r$. The complex on the right hand side will simply be referred as (p,q,r) and its formation constant β_{pqr}. The search for the best set of (p,q,r) and β_{pqr} was performed with the least squares program LETAGROPVRID version ETITR.[8] The function $U=(H_{calcd}-H)^2$ has been minimized, where H_{calcd} and H stand for calculated and actual total hydrogen concentrations over the zero level (H_2O, MoO_4^{2-}, and $Te(OH)_6$). Separate titrations were carried out to obtain the equilibrium constants of H^+-MoO_4^{2-} system in 1M Na(Cl) medium.[9] For H^+-$Te(OH)_6$ equilibria we used the constants obtained by Kaehler and Brito.[10]

Results and Discussion

Figure 1 shows the result of the initial pqr-analysis.

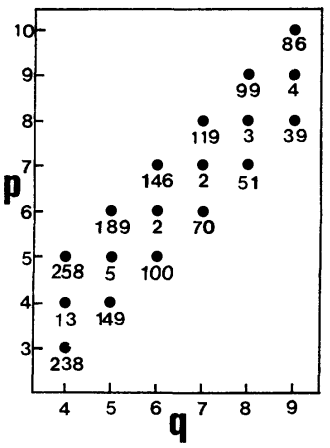

Fig. 1. Result of initial pqr-analysis. Each circle represents a species $(p,q1)$ with obtained U under it in mM^2. 35 points of $-\log h \geq 5$ and $B/C \leq 3$ were employed.

Table 1. Result of the Analysis on High B/C Ratio Points[a]

(p,q,r)	U/mM^2
(5,5,1)	50.1
(6,6,1)	3.4
(7,7,1)	59.7
(8,8,1)	196.0
(9,9,1)	226.8

a) 29 points of $B/C \geqq 6$ and $-\log h \geqq 5$.

The species (6,6,1), (7,7,1), and (8,8,1) gave distinctively low U values.[11] These three species were tested on the data of higher B/C ratios. Figure 1 and Table 1 show that only (6,6,1) can explain both the high and low B/C ratio data. When we tested (6,6,1) on the whole data the residual showed a systematic deviation as h increased. This systematic deviation disappeared after the introduction of (7,6,1) and (8,6,1) to the system. The final model gave U=31.2 mM^2 and $\sigma(H)$=0.37 mM with formation constants log $\beta_{6,6,1}$= 50.40±0.02, log $\beta_{7,6,1}$=53.68±0.07 and log $\beta_{8,6,1}$=55.47± 0.07.[12]

The distribution of molybdate in each species is illustrated in Fig. 2. A notable amount of (6,6,1) is formed even at a high pH of 7. This agrees well with the fact that salts of hexamolybdotellurate crystallize from neutral or slightly basic solutions. Almost all of the molybdate in solution is bound in the molybdotellurate phase in the range $5.0 > -\log h > 2.5$ when the B/C ratio is 6 or lower, which means complex formation between molybdate and tellurate is strong. The composition of the anion (6,6,1) coincides with that of $[TeMo_6O_{24}]^{6-}$, whose structure is shown in Fig. 3.[4] It

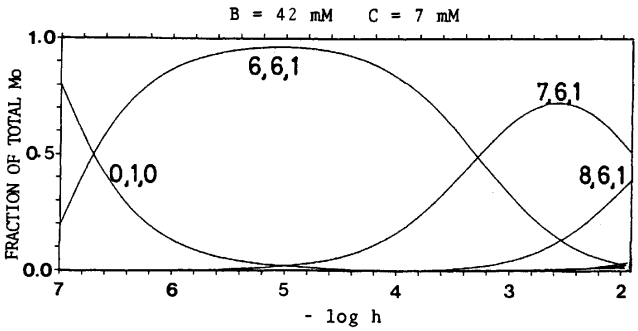

Fig. 2. Distribution diagram of H^+-MoO_4^{2-}-$Te(OH)_6$ system.

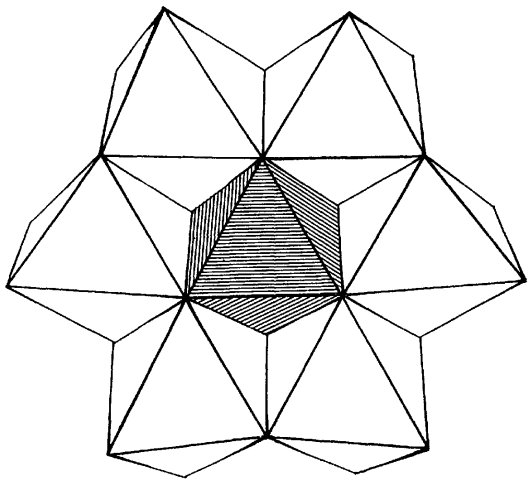

Fig. 3. Structure of $[TeMo_6O_{24}]^{6-}$. Shaded octahedron indicates TeO_6 unit.

is plausible that this structure is also maintained in solution. We presume the protonation of the anion takes place at one of the six oxygen atoms of the central octahedral unit for (7,6,1) case, and two for (8,6,1) case.[13]

The solubility of (6,6,1) seemed to be much lower than those of (7,6,1) and (8,6,1). The sodium salt of $[TeMo_6O_{24}]^{6-}$ sometimes precipitated during titration.[14] The precipitate dissolved when the pH of the solution was lowered to about 3.5.

As we mentioned in the experimental section, the formation of (6,6,1) seemed quite slow. We hope further study of this system will give us some information on the kinetics of polyanion formation.

Double Inclusion of Methylated Cyclodextrin and Sodium Benzenesulfonate by Na-, Ca-, and Cu-Montmorillonites

Tsuyoshi KIJIMA
National Institute for Research in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki 305
(Received September 11, 1986)

Synopsis. The uptake of methylated α- and β-cyclodextrins by Na-, Ca-, and Cu-montmorillonites at 25 °C in the presence of sodium benzenesulfonate has been studied. X-Ray diffraction data revealed that the cyclodextrin molecules that embrace benzenesulfonate anion are intercalated as monolayer in the interlayer space of the clay minerals.

Inclusion phenomena have attracted increasing attention in inorganic chemistry. In the recent papers concerning molecular inclusion, we have reported the complexation of layered montmorillonites and α-zirconium phosphate with several cyclodextrins containing a cylindrical cavity capable of including a variety of substances.[1-4] Further inclusion property of the complexes towards any other guest molecules would be intrigued. For the complex of α-zirconium phosphate with an aminated cyclodextrin, we showed that it is similar to zeolites because the water within the cavity of cyclodextrin molecule is released and readsorbed reversibly.[3] No examination, however, has been made for other complexes hitherto obtained.

The montmorillonite intercalates not only positively charged cyclodextrins but also polar but unchargeable ones such as parent and methylated cyclodextrins.[4] This paper reports that molecules of hexakis(2,6-di-*O*-methyl)-α-(denoteded DM-α- for short) and heptakis(2,6-di-*O*-methyl)-β-(DM-β-)-cyclodextrins (CD) accompanied by sodium benzenesulfonate (NaBS) are intercalated by Na-, Ca-, and Cu-montmorillonites.

Experimental

The Na-, Ca-, and Cu-montbmorillonite samples were the same as those used in the preceding work.[4] DM-α- and DM-β-cyclodextrins and sodium benzenesulfonate were of reagent grade and used without further purification.

Each mineral sample (0.1 g) was immersed in 8 cm^3 of a 1:1 (vol.) mixture of 50 mmol dm^{-3} aqueous cyclodextrin and 1 mol dm^{-3} sodium benzenesulfonate solutions at 25 °C for 5 d. Since methylated cyclodextrin taken up by montmorillonite is easily washed away with water,[4] the reaction mixture was centrifuged and rinsed with the starting cyclodextrin solution and then air-dried at 40 °C to give the complex sample. The similar procedure was applied to the system without sodium benzenesulfonate.[4] X-Ray diffraction measurements were made as similarly as in the previous work.[4]

Results and Discussion

Figure 1 compares the X-Ray diffraction patterns of CD-NaBS-montmorillonite with those of CD-montmorillonite. The results suggest that Na-, Ca-, and Cu-montmorillonites form one complex with DM-α-cyclodextrin and a mixture of two complexes with DM-β-cyclodextrin. The X-Ray diffraction profiles of

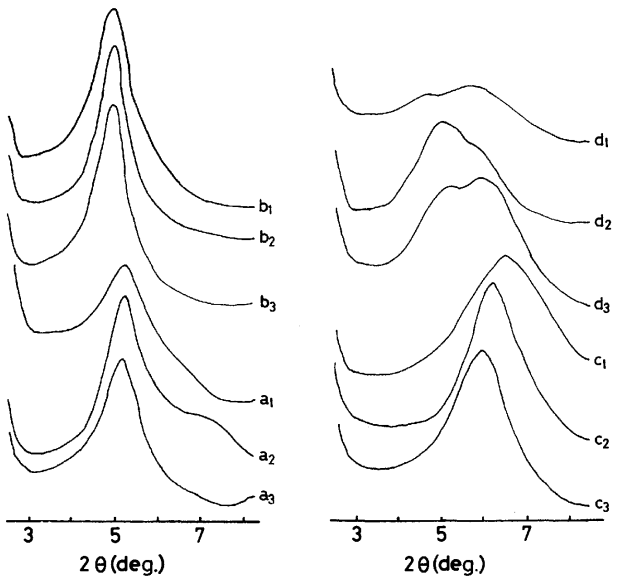

Fig. 1. X-Ray diffraction patterns of (a_i) DM-α-CD-mont, (b_i) DM-α-CD-NaBS-mont, (c_i) DM-β-CD-mont, and (d_i) DM-β-CD-NaBS-mont complexes for Fe*Kα* rays (i=1—3, mont=montmorillonite). Interlayer cations, Na (i=1), Ca (i=2), Cu (i=3).

the clay minerals were not changed by treating with sodium benzenesulfonate solution, indicating that the montmorillonite cannot take up benzenesulfonate anion solely.

The conditions for preparing the complex samples suggest that they contain excess amounts of cyclodextrin and sodium benzenesulfonate. It is, therefore, difficult to determine the equilibrium contents of each compound in the resulting complexes. The complexes were characterized only by their interlayer spacings and change of thickness of intercalated layer (*Δ* value); the obtained values are summarized in Table 1. The *Δ* value was determined by subtracting 9.5 Å for the thickness of the silicate layer[5] from the observed interlayer spacing. The increase of interlayer thickness in the range of 1—5 Å caused by the presence of sodium benzenesulfonate will be attributed to the double inclusion of methylated cyclodextrin and sodium benzenesulfonate by montmorillonite.

The interlayer thickness data in Table 1 also show that the difference of interlayer thickness between CD-NaBS-montmorillonite and CD-montmorillonite complexes with DM-β-cyclodextrin varies from 2.9 to 5.2 Å with the interlayer cation, while the interlayer thickness of complexes with DM-α-cyclodextrin is hardly affected by the variation of interlayer cation. According to the crystal structure analysis of the α-CD-NaBS complex,[6] the benzenesulfonate anion is arranged in the channel which is formed by the stack

Table 1. Characterization of Cyclodextrin-Montmorillonite4) and Cyclodextrin-Sodium Benzenesulfonate-Montmorillonite Complexes with Various Interlayer Cations

Interlayer cation	Cyclodextrin	CD-montmorillonite complex		CD-NaBS-montmorillonite complex[a)]	
		Interlayer spacing/Å	Δ value/Å	Interlayer spacing/Å	Δ value/Å
Na	DM-α-CD	21.4	11.9	22.1	12.6
Ca		21.3	11.8	22.2	12.7
Cu		21.2	11.7	22.4	12.9
Na	DM-β-CD	17.1	7.6	23.3 (19.2)	13.8 (9.7)
Ca		17.9	8.4	22.0 (19.4)	12.5 (9.9)
Cu		18.3	8.8	21.2 (18.6)	11.7 (9.1)

a) Values for the low spacing phases are given in parentheses.

of α-cyclodextrin rings. The benzene ring is located in the cavity, while the sulfonato group is outside the cavity and hydrogen-bonded to the primary hydroxyl groups of the adjacent α-cyclodextrin molecule. The preceding study[4] revealed the following characteristics on the inclusion behavior of methylated cyclodextrins in montmorillonite; (1) the cyclodextrin molecules with cavity axes perpendicular to the silicate layer are intercalated as monolayer with their methylated side chains in fully extended (DM-α-cyclodextrin) and folded (DM-β-cyclodextrin) conformations which give the molecular thickness of 12 and 8 Å, respectively, and (2) the hydrated cations are bound in the intermolecular space within the cyclodextrin layer with hydrophobic methoxyl groups of cyclodextrin molecule. Referring to the structure data in Ref. 5, we assume the length of benzenesulfonate anion to be 9 Å. If we combine the above data and observations with the assumption that the methylated cyclodextrin molecules accompanied by sodium benzenesulfonate are intercalated with the same conformations as in the methylated CD-montmorillonite system, the benzenesulfonate anion would be included completely in the molecular cylinder of fully stretched DM-α-cyclodextrin or partly in the molecular cage of DM-β-cyclodextrin capped by the primary methoxyl groups, as illustrated in Fig. 2. It is also conceivable that the interlayer hydrated cations of DM-α-CD-NaBS-montmorillonite complexes are located in the intermolecular space within the cyclodextrin layer, due to repulsion against the hydrophobic methoxyl groups. As for the high spacing complexes of DM-β-CD, the cations are between the silicate layer and the sulfonato group protruding from the O(2), O(3), side of the cavity, due to the hydrophilic attraction of the sulfonato group. The interlayer thickness of the latter complexes decreases in the order of Na>Ca>Cu. This could be explained by assuming that the interlayer cation with higher polarizing power forms an aqua complex in which all or a part of four coordinating water molecules are located more closely to the sulfonato group, as observed in the case of inclusion of α-cyclodextrin by Na-, Ca-, and Cu-montmorillonites.[4] Furthermore, the interlayer thickness of the low spacing complex of DM-β-CD remains unchanged at 9—10 Å with different interlayer cations. It is likely that the low spacing complex is an intermediate phase whose interlayer space is occupied predominantly by the methylated CD molecules and only partly by those including benzenesulfonate anion.

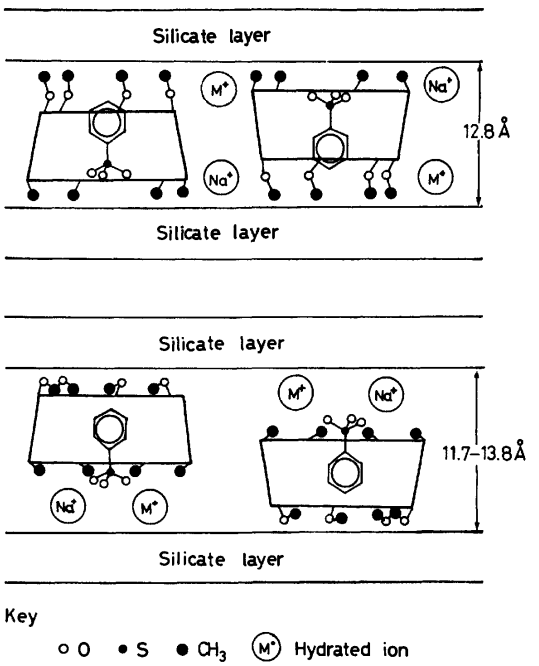

Fig. 2. Models proposed for their probable arrangement of CD molecules, benzenesulfonate anions and interlayer cations in the interlayer space of montmorillonite; (upper) DM-α-CD, (bottom) DM-β-CD (high spacing complex).

We conclude that the methylated cyclodextrin molecules including sodium benzenesulfonate are intercalated as monolayer by Na-, Ca-, and Cu-montmorillonites. The double inclusion method developed in this study may be applied to the micro-encapsulation of various substances such as drugs and dyes for laser.

The author wishes to thank Dr. H. Nakazawa for his encouragement during this work.

(α-Ethoxyvinyl)tributyltin; An Efficient Reagent for the Nucleophilic Acetylation of Organic Halides via Palladium Catalysis

Masanori KOSUGI,* Takashi SUMIYA, Yukimasa OBARA, Motohiro SUZUKI, Hiroshi SANO, and Toshihiko MIGITA*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received September 12, 1986)

Synopsis. (α-Ethoxyvinyl)tributyltin acts as a masked acetylating agent in the palladium catalyzed reaction with various organic halides, such as aryl bromides, vinyl bromides, benzyl chloride, and allyl chloride, giving, after hydrolysis of the resulting reaction mixture, good yields of the corresponding ketone product.

Several reports of ketone syntheses via cross-coupling of organometallics and organic halides have been reported. Palladium catalyzed reactions of organotin compounds with acid chlorides[1] or with organic halides and carbon monoxide[2] are shown to be useful for the preparation of ketone. Recently, palladium catalyzed reaction of α-methoxyvinylzinc compound prepared in situ with organic halides after hydrolytic treatment was reported for the ketone synthesis.[3] Similar reaction of the corresponding tin compound with acid chlorides catalyzed by palladium was reported for the preparation of α-diketones.[4] α-Diketones were also prepared by palladium catalyzed reaction of acid chlorides with acyltin compounds.[5]

In this note, we report the utility of (α-ethoxyvinyl)-tributyltin as a masked acetylating agent in the reactions with organic halides (not only with acid chlorides, but also with aryl and vinyl bromides, benzyl chloride, and allyl chloride). (Eq. 1)

$$n\text{-Bu}_3\text{SnC(OEt)}=\text{CH}_2 + \text{R-X} \xrightarrow{[\text{Pd}]} \xrightarrow{\text{H}^+} \text{R-COCH}_3 \quad (1)$$

As is shown in Table 1, the catalytic efficiency of this reaction, which proceeds smoothly in the presence of only 1 mol% of the catalyst, may be better than that in the reaction of the zinc reagents, which needs 5 mol% of the catalyst.[3] Both of palladium(0) and palladium(II) catalysts gave almost the same results. This implies that palladium(II) complex was reduced by the tin compound under the reaction conditions. The use of nonpolar solvent is recommendable, although the solvent effect was not large. GLC analysis shows that the reaction with bromobenzene proceeds nearly quantitatively. Substituted acetophenones were obtained in good yields from aryl bromides containing a variety of ring functional groups. With β-bromostyrene, the stereochemistry of the substrate was not retained, in contrast to Hegedus's findings for the organozinc compounds.[3]

Experimental

IR spectra were recorded on Jasco A-100 spectrophotometer. ^{1}H NMR spectra were recorded on a Varian EM-360 instrument, using tetramethylsilane as an internal standard. GLC analyses were carried out with Ohkura 802 instrument using columns (1.5 m) packed with 10% Silicone SF-96 and SE-30 on Celite 545.

Materials. (α-Ethoxyvinyl)tributyltin was prepared according to the method described in the literature.[6] Bp.

106/0.4 mmHg (1 mmHg=133.322 Pa). ^{1}H NMR (C_6D_6) δ=0.7—1.8 (m, 30H), 3.60 (q, J=8Hz, 2H), 4.30 (d, J=2Hz, 1H), and 4.83 (d, J=2Hz, 1H). GC-MS m/z 305 (M^+—Bu, 100). Preparation of halides and palladium complexes were already reported.[7]

Reaction Procedures. A mixture of (α-ethoxyvinyl)-tributyltin (5.5 mmol), halide (5.0 mmol), dichlorobis(triphenylphosphine)palladium (0.05 mmol), and toluene (2 cm^3) was heated under argon at 100 °C for 20 h. After hydrolysis of the reaction mixture with 5% hydrochloric acid, the organic layer was extracted with diethyl ether, and dried over sodium sulfate. After evaporation of the solvent, column chromatography of the residue (silica gel; cyclohexane followed by diethyl ether) provided the ketones in the ethereal eluents and the product was isolated by distillation under reduced pressure.

Products. All the products were known and their structures were determined by comparison of their spectroscopic data with the reported values.[3,8,9]

The gift of tributyltin oxide by Hokkoh Kagaku Kogyo Co., Ltd. is gratefully acknowledged. The measurement of GC-MS by Dr. H. Matsuyama of Tokyo Metropolitan University is also acknowledged. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 61225002 from the Ministry of Education, Science and Culture.

The Ring Opening Reaction of Cyclopolysilanes, $(R_2Si)_n$ (n=3—6), with Iodine. A Kinetic Study

Hamao WATANABE,* Hiromi SHIMOYAMA, Tsutomu MURAOKA, Yuichi KOUGO, Motohiko KATO, and Yoichiro NAGAI*

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received August 16, 1986)

Synopsis. Reactions of a series of peralkylcyclopolysilanes with iodine were found to proceed via second-order kinetics. Rate constants show that, in general, the smaller rings react faster than larger rings. Values of the activation parameters, E_a and $\Delta G^{\ddagger}$, decreased with the decreasing ring size and are parallel with those of the oxidation potentials and of the lowest transition energies.

It is well-known that the Si-Si bond in cyclopolysilanes undergoes electrophilic cleavage reaction by halogens to give the corresponding ring-opening adducts, α,ω-dihalopolysilanes. Although several studies on the halogen-cleavage reactions of cyclopolysilanes have appeared so far,[1] there are no reports on their kinetic behaviors. In our continuing work of polysilanes,[1c,2] we now report a kinetic study on the ring-opening reactions of a series of peralkylcyclopolysilanes with iodine (Eq. 1).

$$[R_2Si]_n + I_2 \rightarrow I(R_2Si)_nI \quad (n = 3 - 6) \qquad (1)$$

Rates were determined by spectroscopic method and the reaction was found to obey typical second-order kinetics within 20% completion. Unfortunately, the reactions of the smallest ring, $[(Bu^tCH_2)_2Si]_3$, was so fast that the rate constant could not be betermined by the present method at any convenient temperatures.

Table 1 shows the absolute rate constants at three different temperatures together with the relative rates of the cyclopolysilanes at 20 °C, that of $Me_3SiSiMe_3$ being taken as standard. The relative rates of the cyclopolysilanes (20 °C) were thus found to fall in the order:

$$[(Bu^tCH_2)_2Si]_3 \gg [Bu^tMeSi]_4\,(241) \approx [Pr^i{}_2Si]_4\,(237) > [Bu^s{}_2Si]_4\,(58) > [Bu^n{}_2Si]_5\,(11) \approx [Pr^n{}_2Si]_5\,(8) > [Me_2Si]_6\,(1) \approx Me_6Si_2\,(1)$$

As might be expected from the intrinsic internal strain, the smaller rings generally react faster than

Table 1. The Rate Constants in the Reactions of Cyclopolysilanes with Iodine in Dichloromethane[3]

Compound	$k_2\times10^2$/dm^3 mol^{-1} s^{-1} [a]			$k_x/k_{Me_6Si_2}$ [b] (293 °K)

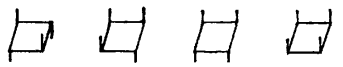
larger rings. This trend shows that the principal factor in determining the reaction rates is ring strain, although the rates for the cyclotetrasilanes vary in a range of 1—4 times as the steric bulk of the substituents varies.

Table 2 lists the activation parameters, electrochemical oxidation potentials, and the longest-wavelength UV absorptions. Values of activation energy decrease with the decreasing ring size and are parallel with those of the oxidation potentials as well as the lowest transition energies. Thus, the promotion of the HOMO level in smaller rings due to the increasing ring strain can be seen in these energy terms.[3-5] The large negative values of $\Delta S^{\ddagger}$ indicate considerable loss of freedom in the transition states, which are common in bimolecular reactions. In short, the rates and activation parameters for the reactions of the cyclopolysilanes are primarily related to the ring size, although other factors such as steric congestion at the reaction site and the geometrical structures of the ring system[6] have to be also taken into account. Further investigation for such ring opening reactions will be described elsewhere.[7]

Experimental

Materials. All the samples used for the rate study were the cyclopolysilanes reported previously.[2d] The sample of $[Bu^tMeSi]_4$ was a mixture comprising four steroisomers (a—d), the distribution of which was determined by a high-resolution NMR spectrum (400 MHz) (see Ref. 2d):



(a) (b) (c) (d)

(a)/(b)/(c)/(d)=13/73/12/2
1: *t*-Butyl group

Measurements of the reaction rates. The CH_2Cl_2-solution of approximately equimolar concentrations of two substrates (a slightly excess in cyclosilanes) ($1—6\times10^{-3}$ mol dm^{-3}) were prepared and kept in a constant temperature bath. Two 2-ml solutions of the substrates were mixed and allowed to react in a spectrometer. The rates were determined by recording concentrations of iodine as a function of time which were monitored by the UV absorption of iodine at λ 555 nm. The rate constant of $[Bu^tMeSi]_4$ sample was determined as a total average of the isomer mixture (see above).

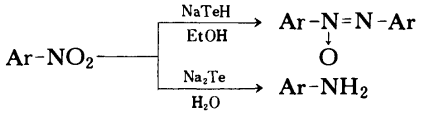
Reduction of Aromatic Nitro Compounds and Thioketones with Sodium Telluride under Aprotic Conditions

Hitomi SUZUKI,* Hajime MANABE, Takashi KAWAGUCHI, and Masahiko INOUYE
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received August 13, 1986)

Synopsis. Sodium telluride, prepared by heating tellurium and sodium hydride in a 1:2 molar ratio in dry *N,N*-dimethylformamide, reduces aromatic nitro compounds to azo compounds and thioketones to hydrocarbons under mild conditions.

Hydrogen telluride is a weak dibasic Brønsted acid and forms two series of salts known as hydrogentelluride $M^{I}TeH$ and normal telluride M^{I}_2Te. Salts of the former type undergo transformation into those of second type in high pH region. Recently, we reported that aromatic nitro compounds behave differently toward these telluride reagents; sodium telluride easily reduces nitrobenzenes to anilines,[1] while sodium hydrogentelluride does not reduce them beyond the stage of azoxy compounds.[2] Both of these types of reductions proceed cleanly in protic media and are complete within a short reaction time under mild conditions. The reduction with sodium hydrogentelluride is sensitive to steric factor as evidenced by the formation of anilines where nitrobenzenes are hindered.[2]



As part of our studies on telluride reduction, we report herein that aromatic nitro compounds undergo another type of reaction with sodium telluride under aprotic conditions, giving not azoxy but azo compounds as the single product. Sodium telluride was also found to effect reductive removal of sulfur atom from aromatic thioketones to yield parent hydrocarbons.

On heating gently with sodium hydride in dry *N,N*-dimethylformamide (DMF) under nitrogen, powdered tellurium dissolved with evolution of hydrogen gas to form a deep red solution of sodium oligotelluride, which on further heating gradually lost color to give sodium telluride as a pale yellow suspension. When a nitroarene (**1**) dissolved in tetrahydrofuran (THF) was added to the suspension and the resulting mixture was heated with stirring at around 70 °C for several hours, smooth reduction took place to give the corresponding azo compound (**3**) in good to moderate yields (Table 1).

$$\underset{\mathbf{1}}{Ar\text{-}NO_2} \xrightarrow[DMF,\ \Delta]{Na_2Te} \underset{\mathbf{2}}{Ar\text{-}\overset{\downarrow}{\underset{O}{N}}\text{=}N\text{-}Ar} \xrightarrow[DMF,\ \Delta]{Na_2Te} \underset{\mathbf{3}}{Ar\text{-}N\text{=}N\text{-}Ar}$$

The reaction proceeded cleanly with nitroarenes **1a—e** and halonitroarenes **1f—g**. The intermediary azoxy compounds (**2**) are too reactive to be isolated under these conditions, although they can be detected in certain cases at an early stage of reduction. A similar reaction of 4-nitrotoluene led to a complex mixture of products arising from abstraction of benzylic hydrogen atom as well as partial reduction of nitro group. Isolation of 1,2-bis(4-nitrophenyl)ethane as one of products revealed the intervention of radical species in the reduction under aprotic conditions. As expected, 3-nitrotoluene **1b** gave azobenzene **3b**. In every case, bis(dimethylcarbamoyl) ditelluride (**4**) was obtained as a common by-product. We attributed the formation of **4** to capture of the initially formed dimethylcarbamoyl radical by telluride anion and subsequent oxidation of the resulting tellurocarbamoyl species. This type of reaction is of interest since it may represent the formal oxidation of DMF to a telluro analog of dimethylcarbamoyl peroxide.

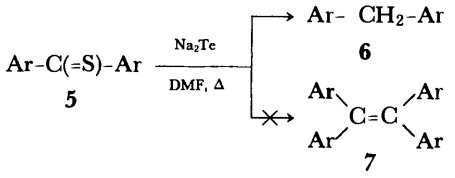
a) Yields refer to the isolated compounds and are not optimized.

Treatment of aromatic thioketones (**5**) with sodium telluride in aqueous media resulted in the generation of original ketones. Under aprotic conditions, however, the same reagent was found to desulfurize thioketones **5** in a reductive way to afford the corresponding hydrocarbons (**6**). The reaction proceeded slowly and the only predominant product was parent hydrocarbon **6**. Dimerization with loss of sulfur leading to tetraarylethylene (**7**), an important process in the reduction of thioketones with diphosphorus tetraiodide,[3] could not be observed.



Experimental

Melting points were determined on a hot stage apparatus and are not corrected. Powdered tellurium (99.9% purity) and sodium hydride (60% dispersion in oil) were commercial products and used as received. Thioketones were prepared from the corresponding ketones by known method.[4] Reactions were performed under nitrogen to protect sodium telluride from oxidation. All products except ditelluride **4** are known and identified by direct comparison with authentic samples obtained by other routes.

Preparation of Sodium Telluride. A mixture of powdered tellurium (0.256 g, 2.0 mmol), sodium hydride (0.10 g, 4.2 mmol; washed thoroughly with hexane prior to use), and DMF (3 ml) was stirred at 140 °C for 1 h under nitrogen. As the tellurium went into solution, hydrogen was evolved and a deep red color developed within 10—15 min. After 1 h, the color faded and the mixture turned to a pale yellow suspension of sodium telluride, which was immediately used for reduction. On contact with air, sodium telluride rapidly decomposes with liberation of elemental tellurium.

Reduction of Aromatic Nitro Compound to Azo Compound. To a stirred suspension of sodium telluride (2.0 mmol) in DMF (3 ml), a solution of nitroarene (**1**; 1.0 mmol) in THF (2 ml) was added by cannula at room temperature under nitrogen. The mixture was gently heated to 70 °C and kept at this temperature for 3—5 h. Progress of the reaction was monitored by TLC on silica. The reaction was quenched by bubbling air into the mixture, to which was then added a saturated sodium chloride solution (20 ml) followed by ether (20 ml). The insoluble material was filtered through a thin layer of Celite and the organic phase was separated from the filtrate, washed with 10% hydrochloric acid to remove any DMF, and evaporated to leave a crude azo compound **3**, which was purified by chromatography on silica gel or recrystallization from appropriate solvent.

Isolation of Bis(dimethylcarbamoyl) Ditelluride (4). The reaction mixture was worked up as described above. Without being washed with 10% hydrochloric acid, the ethereal extract was evaporated to a small volume. Hexane was added to the concentrate and the mixture was left to stand in a refrigerator. Ditelluride **4** separated as fine yellow needles, which begins to darken at 118 °C and decomposes at 121—122 °C with liberation of tellurium. Yields were variable, usually in the range of 5—15%. In solid state this compound could be stored for weeks in the dark, but in a solution it readily decomposed. ^{1}H NMR ($CDCl_3$) δ=3.12 (12H, s, CH_3); IR (KBr disk) 1655,1350, 1245, 1075, 870, and 660 cm^{-1}. Found: C, 18.62; H, 3.04; N, 7.02%. Calcd for $C_6H_{12}N_2O_2Te_2$: C, 18.04; H, 3.03; N, 7.02%.

Reductive Desulfurization of Aromatic Thioketones to Parent Hydrocarbons. Typical Procedure: To a suspension of sodium telluride (2.0 mmol) in DMF (3 ml) was added xanthene-9-thione (0.210 g, 1.0 mmol) in THF (5 ml) and the resulting mixture was heated under gentle reflux. The color changed from green to orange to blue, and finally to black. After 2 d excess sodium telluride was destroyed by exposing to air and water (20 ml) followed by dichloromethane (20 ml) was added. The insoluble material was removed by filtration on a thin layer of Celite, and the organic phase was separated from the filtrate, washed with 10% hydrochloric acid, and evaporated. The residue was chromatographed on silica gel to afford xanthene (0. 161 g, 82%). Mp 96—99 °C (lit,[5] 100 °C).

Under similar conditions, thiobenzophenone and 4-bromothiobenzophenone were reduced to diphenylmethane and 4-bromodiphenylmethane, respectively, in 60—70% isolated yields.

New Birch Type Reduction. Halogen or Halides-Activated Reduction of Disulfides to Thiols with Aluminium in Liquid Ammonia

Ryu SATO,* Ryouichi AKAISHI, Takehiko GOTO, and Minoru SAITO
Department of Resource Chemistry, Faculty of Engineering, Iwate University, Morioka 020
(Received September 11, 1986)

Synopsis. Aromatic and aliphatic disulfides were reduced to the corresponding thiols in high yields by new halogen or halides-activated Birch type reduction with aluminium in liquid ammonia.

In this half century, a great deal of investigations on the Birch type reduction have been reported by many organic and inorganic chemists since the discovery of the reduction with metallic sodium in liquid ammonia by A. J. Birch in 1944.[1] Many improved methods for the Birch reduction have been also developed, for example, use of other metals[2] and amines instead of liquid ammonia,[3] addition of proton sources,[4] and activation of the metals.[5] Recently, Benkeser et al. reported the improved Birch reduction to reveal that a selective reduction of alkynes with metallic calcium in alcohol and amine gave the corresponding alkenes and alkanes in moderate yields.[6] During the course of our investigations on the organic sulfur chemistry in liquid ammonia and amines,[7] we found a new Birch type reduction of disulfides. In this paper, we wish to report this new selective reduction of aromatic and aliphatic disulfides to the corresponding thiols with metallic aluminium, which is activated by halogen or halides in liquid ammonia, as shown in Eq. 1.

$$\underset{\textbf{1a-i}}{R\text{-}S\text{-}S\text{-}R} \xrightarrow[\text{Activator}]{Al/NH_3} \underset{\textbf{2a-i}}{2\ R\text{-}SH} \qquad (1)$$

In initial stage of this investigation, to carry out the reaction at ambient temperature, our efforts were centered on activation of the surface of aluminium, e.g., irradiation of supersonic wave and addition of white sand to the reaction system. Ultimately, the best results were obtained when some halogen or halides were added to the reduction system. Thus, a remarkable acceleration of the reduction was observed by employing iodine and sodium chloride as shown in Table 1 (Runs 2 and 3). In the absence of the halogen or halides, the yield of thiol was only 9% (Run 1). Moreover, we also tested other salts as shown in runs 5 to 9. It should be noted that both halogen (I_2) and halides (NaCl, KCl, KI, and NH_4Cl) exhibited comparable effect (Runs 2 to 7). On the other hand, sulfate and nitrate did not affect this reduction at all (Runs 8 and 9). As shown in Run 4 the sufficient reduction of disulfide to thiol was observed even when a catalytic amount of sodium chloride (0.025 mmol) was used. These results suggest that both the halides and halogen play an important role as activator in this reduction. To our knowledge, there has been no report on the halide or halogen-activated Birch reduction although ammonium sulfate have been used as a proton source.[8] The generality of this method was shown in runs 10 to 17. It is noteworthy that bis(4-chlorophenyl) (**1b**) and bis(2-benzothiazolyl) disulfide (**1i**) could be reduced to give the corresponding thiols in good yields (Runs 10 and 17), since the result implies that only the S-S bond, not C-S, C-Cl, and C=C bond, in the disulfide was reduced selectively.

Table 1. Reduction of Disulfides with Aluminium in Liquid Ammonia

Run[a]	Substrate R-SS-R/R		Catalyst	mmol	React. Time/h	Yield of Thiol	% [b,c]
1	C_6H_5-	**1a**	—	—	8	**2a**	9

3	C_6H_5-	**1a**	NaCl	0.3	2	**2a**	93
4	C_6H_5-	**1a**	NaCl	0.025	4	**2a**	100 (98)
5	C_6H_5-	**1a**	KI	0.3	2	**2a**	62
6	C_6H_5-	**1a**	KCl	0.3	2	**2a**	100
7	C_6H_5-	**1a**	NH_4Cl	0.3	2	**2a**	98
8	C_6H_5-	**1a**	$(NH_4)_2SO_4$	0.15	2	**2a**	9
9	C_6H_5-	**1a**	NH_4NO_3	0.3	2	**2a**	0
10	4-Cl-C_6H_4-	**1b**	NaCl	0.3	15(min)	**2b**	89 (71)
11	4-CH_3-C_6H_4-	**1c**	NaCl	0.3	1	**2c**	94 (94)
12	4-CH_3O-C_6H_4-	**1d**	NaCl	0.3	2	**2d**	93 (92)
13	4-CH_3CO-C_6H_4-	**1e**	NaCl	0.3	1	**2e**	(32)
14		**1f**	NaCl	0.3	12	**2f**	(54)
15	C_6H_5-CH_2-	**1g**	I_2	0.3	4	**2g**	65 (65)
16	CH_3-$(CH_2)_2$-CH_2-	**1h**	I_2	0.3	6	**2h**	45 (45)
17	2-Benzothiazolyl	**1i**	NaCl	0.3	4	**2i**	68 (68)

a) Substrate: 0.5 mmol, Liquid Ammonia: 10 ml, React. Temp: 25°C, Al: 4 mg atom. b) Yield of thiol by iodometry. c) Isolated yields were shown in parenthesis.

Some aliphatic thiols were also obtained upon treating corresponding aliphatic disulfides such as dibenzyl (**1g**) and dibutyl disulfides (**1h**) with aluminium in liquid ammonia at 25 °C (Runs 15 and 16).

In conclusion, aromatic and aliphatic disulfides were reduced by new Birch type reduction, which was activated by halogen (I_2) and halides (NaCl, KCl, KI, and NH_4Cl), with aluminium to afford the corresponding thiols at ambient temperature in good yields. Although, at present stage, the role of the halogen or halides is not necessarily obvious, further applications of this new method to the reduction of other functional groups are expected.

Experimental

Measurements. All melting points were uncorrected. ^1H NMR, IR, and Mass spectra were recorded with HITACHI R-22, HITACHI 295 and HITACHI RMU-6M, respectively. Elemental analyses were determined with YANAGIMOTO MT-3.

Determination of Thiols. The yields of the resulted thiols were determined by the method in the literature.[9]

Materials. Substrates, **1a**, **1b**, **1c**, **1g**, and **1i**, were commercially available and **1d**, **1e**, and **1h** were prepared by the methods in the literature from the corresponding thiols.[10] Bis[4-[1,1-(ethylenedithio)ethyl]phenyl] disulfide (**1f**) was obtained from the corresponding disulfide (**1e**) by the reaction with ethanedithiol in the presence of sodium sulfate and zinc chloride and charaterized as follows. Mp 90 °C; IR (KBr) 2900 and 1480 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10 (s, 6H, CH_3), 3.39 (s, 8H, 0.8Hz, $-CH_2CH_2-$), 7.38 (d, 4H, 8 Hz, arom) and 7.66 (d, 4H, 8 Hz, arom); Found: C,52.47; H,4.79%. Calcd for $C_{20}H_{22}S_6$: C, 52.82; H, 4.88%.

Reduction of Disulfides to the Corresponding Thiols with Aluminium Activated by Halide in Liquid Ammonia. General Procedure. Disulfide (0.5 mmol), aluminium (grain, 4 mg atom) and sodium chloride (0.3 mmol) were taken into a stainless steel autoclave. After evacuation, liquid ammonia (10 ml) was charged into the autoclave and the mixture was allowed to react with stirring at 25 °C for 1 h. Water (20 ml) was added to the residue obtained after evaporation of ammonia. A part of the solution was provided for the iodometric titration to determine the yields of the resulting thiols. After acidification with hydrochloric acid, the aqueous solution was extracted with chloroform (5 ml×3). Evaporation of the combined chloroform after drying on sodium sulfate gave desired thiol (**2**). The products obtained (**2a—e** and **2g—i**) were identified by comparing the ^1H NMR, IR, MS, and elemental analysis with those of the authentic samples which were used for preparation of substrate disulfides.

1-Methyl-1-(4-mercaptophenyl)-1,3-dithiolane (2f): Oil; IR (neat) 2950,2550 and 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.11 (s, 3H, CH_3), 3.23—3.54 (m, 5H, SH and $-CH_2CH_2-$), 7.15 (d, 2H, 9.0 Hz, arom) and 7.58 (d, 2H, 9.0 Hz, arom); MS (70 eV) *m/z* 228 (M^+). Found: C, 53.01; H, 5.46%. Calcd for $C_{10}H_{12}S_3$: C, 52.59; H,5.30%.

Electrogenerated Acid-Assisted Preparation of Ethers from Aldehydes and Ketones

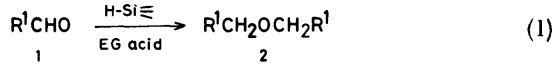
Sigeru TORII,* Sadahito TAKAGISHI, Tsutomu INOKUCHI, and Hiroshi OKUMOTO
Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received July 17, 1986)

Synopsis. Symmetrical and unsymmetrical ethers are prepared from carbonyl compounds and alkoxytrimethylsilanes in the presence of hydrosilane by using an electrogenerated acid catalyst.

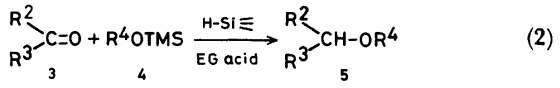
Hydrosilane has been investigated as a good reducing agent for the preparation of ethers from carbonyl compounds in the presence of strong acids such as trifluoroacetic acid,[1] trimethylsilyl triflate,[2] and boron trifluoride etherate.[3] However, these acids have their own problems about their preparation and handling in a practical sense. Recently, trityl perchlorate has also been shown to work as an effective catalyst for the same synthetic purpose.[4]

On the other hand, we have reported that electrogenerated acid (EG acid) played a role of catalyst for the acetalization of ketones[5] and the transesterification of glycerides.[6] Now, we found that when a mixture of carbonyl compounds and alkoxytrimethylsilane was treated with EG acid[7] in situ in the presence of hydrosilane (H-Si ≤) in dichloromethane, the corresponding ethers were obtained as a sole product.

All experiments were carried out using platinum electrodes in a simple undivided cell. A mixture of aldehyde and hydrosilane (1.2 equiv.) in dichloromethane containing lithium perchlorate and tetrabutylammonium perchlorate was electrolyzed to give the symmetrical ether only by passing a small quantity of electricity (Eq. 1). Under the same conditions, the electrolysis of the carbonyl compounds with alkoxysilanes afforded the corresponding unsymmetrical ethers (Eq. 2).



(1)



(2)

As shown in Table 1, we have examined the conversion by using triethylsilane and phenyldimethylsilane as reducing agents, but no significant differences were observed. The present procedure is well-suited for the preparation of alkyl and benzyl ethers. Unsymmetrical ethers could be obtained when allyl-, propargyl-, and 3-phenylpropyl-substituted alkoxysilanes were used as nucleophiles. The results are summarized in Table 2. Phenol trimethylsilyl ether, however, did not work in a similar fashion. Activated carbonyl groups such as α,β-enones and β-keto esters can be led to the corresponding ethers. It is interesting to note that unprotected hydroxy ketones did not give any desired ethers, the siloxy ketone **6**, however, undergoes intramolecular version to give the corresponding tetrahydrofuran ring **7** (Eq. 3). Above results reveal that EG

acid is sufficient to activate carbonyl functions for the formation of ether linkages. Furthermore, EG acid can entry in a new class of acid catalyst, because arbitrarily controlable electricity can reflect the nature of EG acid generated in the medium.

Experimental

General Procedure for the Symmetrical Ether 2. A mixture of aldehyde **1** (1.0 mmol), hydrosilane (1.2 mmol), *n*-Bu_4NClO_4 (0.1 mmol), and $LiClO_4$[8] (0.1 mmol) was dissolved in CH_2Cl_2 (3 ml) in an undivided cell. The resulting solution was electrolyzed under constant current (1.67 mA cm^{-2}) with two platinum foil electrodes (1.5 cm^2) at room temperature. After the completion of the reaction, one drop of triethylamine was added and the solution was concentrated. The residue was chromatographed on SiO_2 to give the symmetrical ether.

General Procedure for the Unsymmetrical Ether 5. A mixture of carbonyl compound **3** (1.0 mmol), alkoxysilane **4** (1.2 mmol), *n*-Bu_4NClO_4 (0.1 mmol), and $LiClO_4$ (0.1 mmol) was dissolved in CH_2Cl_2 (3 ml) in an undivided cell. The mixture was electrolyzed under constant current (1.67 mA cm^{-2}) with platinum electrodes at ambient temperature. After 5 min, hydrosilane (1.2 mmol) was added dropwise and the electrolysis was continued. After the completion of the reaction, the same workup and purification as above afforded the corresponding unsymmetrical ether.

Preparation of the Tetrahydrofuran Derivative 7. A mixture of the siloxy ketone **6** (27 mg, 0.1 mmol), triethylsilane (0.12 mmol), $LiClO_4$ (0.03 mmol) and *n*-Bu_4NClO_4 (0.03 mmol) was dissolved in CH_2Cl_2 (3 ml) in an undivided cell. The solution was electrolyzed under constant current (1.33 mA cm^{-2}) with platinum electrodes at ambient temperature. After 20 min, the same workup and purification as above afforded the compound **7** (13 mg) in 71.0% yield.

Spectral and Physical Data. 2a: Bp 125.0—126.5 °C/2.0 mmHg (1 mmHg=133.322 Pa); IR (neat) 2920, 1602, 1090 (C-O-C) cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.52 (s, 4H, CH_2), 7.28 (s, 10H, C_6H_5).

Synthesis of (1-Halo-1-alkenyl)trimethylsilanes via *gem*-Trimethylsilylation of Vinyl Halides

Nobujiro SHIMIZU,* Fumihiro SHIBATA, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812
(Received July 17, 1986)

Synopsis. Various vinyl halides including enol silyl ethers of α-halo ketones and esters give the corresponding (1-halo-1-alkenyl)trimethylsilanes in fair to good yields on treatment with lithium diisopropylamide at Dry Ice temperature in the presence of chlorotrimethylsilane.

(1-Bromovinyl)trimethylsilane and its homolog are versatile synthetic reagents[1] and obtainable from 1-alkenyl-or 1-alkynyltrimethylsilanes.[2,3] An alternative simple route to (1-halo-1-alkenyl)trimethylsilanes may be provided by *gem*-silylation of vinyl halides which are readily available. Cunico and Han have reported that the treatment of 1-chloro-2-methylpropene with butyllithium below −100 °C, followed by addition of chlorotrimethylsilane (TMS-Cl), gives (1-chloro-2-methyl-1-propenyl)trimethylsilane in 39% yield.[4] The scope of this method, however, would be limited due to the anticipated side reactions including a facile rearrangement of *gem*-haloalkenyllithium species to acetylenic compounds, a metal-halogen exchange reaction, and a coupling reaction between butyllithium and TMS-Cl. For example, we found that under similar metalation conditions to those reported[4] vinyl bromide gave bis(trimethylsilyl)acetylene, while β-bromostyrene afforded β-(trimethylsilyl)-styrene as the major product. This paper deals with the *gem*-trimethylsilylation of various vinyl halides **1a—j** by a modified procedure using lithium diisopropylamide (LDA) in place of butyllithium.

Since LDA is inactive toward TMS-Cl below Dry Ice temperature, the metalation of a vinyl halide can be done in the presence of a trapping agent TMS-Cl. Thus, when a vinyl halide **1** was added to an equimolar mixture of LDA and TMS-Cl in THF/ether (2:1) at −75 °C or below, there was obtained the corresponding (1-halo-1-alkenyl)trimethylsilane **2** in fair to good yields. The results are shown in Table 1.

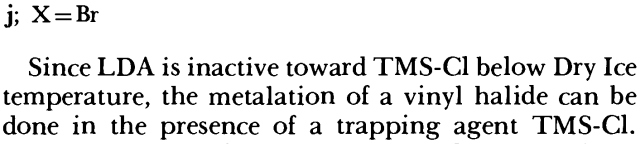
Table 1. *gem*-Trimethylsilylation of Vinyl Halides

Halide	Conditions[a]	Products (Yield/%)[b]
1a	A	**2a** (60) + **3a** (7)[c]
1b	B	**2b** (54)
1c	B	**2c** (55) + **3b** (30)[c]
1d[d]	A	**2d** (23)[d]
1e[d]	B	**2e** (11)[d] + **4a** (58)[d]
1e[d]	B[e]	**2e** (59)[d] + **4a** (5)[c]
1e[d]	B[f]	**4a** (80)[d]
1f[g]	C	**2f** (84)[g]
7a	C[f]	**2f** (67)[h]
1g[i]	C	**2g** (80)[i]
7b	C[f]	**2g** (40)[j]
1h	C	**4b** (74)[k]
1i[d]	C	**2i** (70)[d]
7c	C[f]	**8a** (45)
7b	C[f]	**8b** (45)[l]

a) The silylation was carried out by adding a halide **1** to an equimolar mixture of LDA and TMS-Cl (1—1.2 equiv.) under following conditions: (A) at −100 °C in THF/ether (2:1) for 3 h, (B) at −75 °C in THF/ether (2:1) for 2 h, (C) at −75 °C in THF for 4 h. b) Isolated yield. c) Determined by GLC. d) A mixture of stereoisomers. e) A LDA solution was added to a mixture of **1** and TMS-Cl. f) An excess amount of a LDA/TMS-Cl mixture was used. g) $E/Z<0.05$. h) $E/Z=0.67$. i) $E/Z=0.15$. j) $E/Z=20$. k) Corrected for the recovery of **1**h (49%). l) NMR analysis of a crude product before acidic workup indicated the formation of **2j** ($E/Z=1$) in 58% yield.

The addition of 1,3-dichloropropene **1e** to a LDA/TMS-Cl mixture led to the predominant formation of a doubly silylated product **4a**. Monosilylation at the vinylic site, however, could be effected by inverse addition of a LDA solution to a mixture of **1e** and TMS-Cl. This procedure provides a convenient route to a versatile compound **2e**[5] which otherwise is not readily accessible. **2e** underwent a direct displacement reac-



$CH_3(CH_2)_4CH{=}\overset{SiMe_3}{\overset{|}{C}}(CH_2)_3CH_3$ (**6**) $\xleftarrow{ii}$ **2e** $\xrightarrow{i}$ $Cl{-}\overset{SiMe_3}{\overset{|}{C}}{=}CHCH_2Ph$ (**5**)

i; Ph_2CuLi, ii; *n*-BuMgBr/10%CuI

tion with Ph_2CuLi yielding [1-chloro-3-phenyl-1-propenyl)trimethylsilane (**5**, 73%), whereas it reacted with *n*-BuMgBr in the presence of a catalytic amount of cupper (I) iodide to give (1-butyl-1-heptenyl)trimethylsilane (**6**) in 78% yield via a double rearrangement of the allylic double bond.

gem-Silylation was readily accomplished also for vinyl halides bearing an enol ether function. For example, enol silyl ethers (**1f** and **1g**) of α-halo ketones **7a** and **7b** stereoselectively gave **2f** and **2g** in good yields. The use of 2 equiv amounts of a LDA/TMS-Cl

mixture converted these halo ketones directly to **2f** and **2g**, although the concomitant occurrence of the reduction of the carbonyl group with LDA lowered the yield of **2**, especially so in the case of **7b**.[6] Synthesis of α-trimethylsilyl esters **8a** and **8b** was conveniently accomplished by the treatment of halo esters **7c** and **7d** with excess amounts of a LDA/TMS-Cl mixture followed by acidic workup.

Experimental

NMR spectra were recorded on a Hitachi R-20B spectrometer using carbon tetrachloride as solvent. The following examples are representative.

(1-Bromo-2-methyl-1-propenyl)trimethylsilane (2b). A LDA solution prepared from *n*-BuLi (in hexane, 22 mmol) and diisopropylamine (22 mmol) in THF/ether (2:1, 30 cm^3) was cooled to −75 °C and TMS-Cl (22 mmol) was added. To this mixture was added 1-bromo-2-methyl-1-propene (2.3 g) in THF (5 cm^3) over a period of 20 min and the resulting mixture was stirred for 2h at −75 °C. A crude oil obtained after workup was distilled to give **2b** (1.9 g): Bp 124—125 °C (140 Torr: 1 Torr=133.3 Pa); IR 1615 cm^{-1}; ^1H NMR δ=0.26 (9H, s), 1.89 (3H, s), 1.97 (3H, s). Found: C, 40.62; H, 7.35%. Calcd for $C_7H_{15}BrSi$: C, 40.58; H, 7.30%.

(1,3-Dichloro-1-propenyl)trimethylsilane (2e). An ethereal solution (50 cm^3) of LDA (34 mmol) was added to a mixture of 1,3-dichloropropene (3.8 g) and TMS-Cl (3.8 g) in THF (50 cm^3) over a period of 1 h at −75 °C and the resulting mixture was stirred for 1 h at that temperature. Usual workup gave **2e** (3.4 g) as a mixture of stereoisomers (*E*/*Z*=0.48): Bp 65—68 °C (2 Torr) [lit,[5] Bp 25 °C (0.03 Torr)].

1-Chloro-2-trimethylsiloxy-1-trimethylsilylpropene (2f). To a mixture of LDA (18 mmol) and TMS-Cl (18 mmol) in THF (20 cm^3) was added an enol silyl ether **1f** (*E*/*Z*<0.05, 2.4 g) over a period of 10 min at −75 °C and the mixture was stirred at −75 °C for 4h. A crude oil obtained after workup was distilled to give **2f** (2.98 g, *E*/*Z*<0.05): Bp 106—108 °C (29 Torr); IR 1605 cm^{-1}; ^1H NMR δ=0.20 (18H, s), 1.86 (3H, s).

Methyl Chloro(trimethylsilyl)acetate (8a). To a cold (−75 °C) solution of LDA (44 mmol) and TMS-Cl (44 mmol) in THF (25 cm^3) was added a THF solution of methyl chloroacetate (2.16 g) and the mixture was stirred at −75 °C for 4 h. Solvent was removed on a rotary evaporator and the residue was extracted with petroleum ether. The organic layer was washed first with a cold hydrochloric acid (5 M (1 M=1 mol dm^{-3}), 20 cm^3), then with a saturated sodium hydrogencarbonate solution, and dried. A crude oil obtained after workup was distilled to give **8a** (1.63 g): Bp 78—79 °C (20 Torr); IR 1745, 1720 cm^{-1}; ^1H NMR δ=0.18 (9H, s), 3.70 (3H, s), 3.72 (1H, s). Found: C, 39.55; H, 7.28%. Calcd for $C_6H_{13}ClO_2Si$: C, 39.88; H, 7.25%.

Physical and spectral data for other new compounds listed in Table 1 are as follows.

2C: Bp 126—128 °C (16 Torr); IR 1255, 840 cm^{-1}; ^1H NMR δ=0.04 (9H, s), 7.14 (5H, m), 7.84 (1H, s).

2d: Bp 130—135 °C [as a mixture of stereoisomers in the ratio 1:3.3); IR 1610 cm^{-1}; ^1H NMR (Signals of the less abundant isomer were shown in italics.) δ=*0.16* and 0.24 (together 9H, both s), 1.76 (d, *J*=7 Hz) and *1.82* (d, *J*=7 Hz) (together 3H), *6.02* and 6.41 (together 1H, both q, *J*=7 Hz).

***E*-2f**: ^1H NMR δ=0.15 (9H, s), 0.24 (9H, s), 2.03 (3H, s).

2g: Bp 98—100 °C (2 Torr); IR 1605, 1585 cm^{-1}; ^1H NMR δ=−0.09 g (9H, s), 0.06 (9H, s), 7.30 (5H, m); (Found: C, 49.25; H, 6.90%).

2i: Bp 101—103 °C (23 Torr): IR 1615, 1250, 840 cm^{-1}; ^1H NMR δ=0.13 (s), 0.23 (s), 0.28 (s) (1.7:1:1.2, together 18H), 3.49 (s) and 3.78 (s) (1.9:1, together 3H).

2j: 105—108 °C (7 Torr) (*E*/*Z*=1): IR 1610 cm^{-1}; ^1H NMR δ=0.14 (s), 0.24 (s), 0.29 (s) (1.8:1:1, 18H altogether), 3.50 (s) and 3.72 (s) (1:1, together 3H)

4a: Bp 95—98 °C (2 Torr) (*E*/*Z*=0.56). *E*-isomer: IR 1580 cm^{-1}; ^1H NMR δ=0.14 (9H, s), 0.27 (9H, s), 3.89 (1H, d, *J*=13 Hz), 6.36 (1H, d, *J*=13 Hz). *Z*-isomer: IR 1600 cm^{-1}; ^1H NMR δ=0.12 (9H, s), 0.18 (9H, s), 4.40 (1H, d, *J*=10.5 Hz), 5.93 (1H, d, *J*=10.5 Hz); (Found (as a mixture of stereoisomers): C, 42.45; H, 7.80%).

4b: Bp 145—146 °C (35 Torr); IR 1580 cm^{-1}; ^1H NMR δ=0.12 (9H, s), 0.24 (9H, s), 3.95 (1H, s).

8b: Bp 49—50 °C (3 Torr); IR 1745, 1720 cm^{-1}; ^1H NMR δ=0.20 (9H, s), 3.54 (1H, s), 3.70 (3H, s); (Found: C, 31.71; H, 5.60%).

(1-Chloro-3-phenyl-1-propenyl)trimethylsilane (5). **2e** (0.50 g) was added to a solution of lithium diphenylcuprate(I) (12 mmol) in ether (15 cm^3) and the mixture was stirred for 1 h at 0 °C. Bulb-to-bulb distillation of a crude oil gave **5** 450 mg, as a mixture of stereoisomers in the ratio 1:2.6: IR 1615 cm^{-1}; ^1H NMR (Signals of the less abundant isomer were shown in italics.) δ=*0.18* (s) and 0.29 (s) (together 9H), 3.44 (d, *J*=7.8 Hz) and *3.60* (d, *J*=6.6 Hz) (together 2H), *6.08* (t, *J*=6.6 Hz) and 6.51 (t, *J*=7.8 Hz) (together 1H), 7.15 (5H, m); (Found: C, 64.01; H, 7.58%).

(1-Butyl-1-heptenyl)trimethylsilane (6). A solution of butylmagnesium bromide prepared from 2.74 g of butyl bromide in THF (15 cm^3) was added to a mixture of **2e** (930 mg, *E*/*Z*=1.5) and cupper(I) iodide (0.5 g) in THF (15 cm^3) and HMPA (2 cm^3) and the resulting mixture was stirred for 4 h at 0 °C. A crude oil (1.25 g) obtained after workup was distilled to give **6** (880 mg, as a mixture of stereoisomers in the ratio 1:1.9): Bp 108—109 °C (12 Torr); IR 1615 cm^{-1}; ^1H NMR (Signals of the less abundant isomer were shown in italics.) δ=*0.04* (s) and 0.12 (s) (together 9H), 0.75—1.1 (6H, m), 1.1—1.7 (10H, m), 1.8—2.4 (4H, m), *5.64* (t, *J*=7 Hz) and 5.86 (t, *J*=7 Hz) (together 1H); (Found: C, 74.25; H, 13.28%).

Microscopic and Dielectric Studies of CH_3NH_3I Crystal

Osamu YAMAMURO, Masaharu OGUNI, and Hiroshi SUGA*
Department of Chemistry and Chemical Thermodynamics Laboratory, Faculty of Science,
Osaka University, Toyonaka, Osaka 560
(Received September 6, 1986)

Synopsis. Observation of CH_3NH_3I crystal under a polarizing microscope showed a rectangular domain structure in the δ phase. Dielectric measurement revealed an antiferroelectric behavior of the same phase. These results indicate that the δ phase has orthorhombic or monoclinic structure with C-N axes of $CH_3NH_3^+$ ions inclining along its a or b axis in an antiferroelectric way.

Methylammonium iodide CH_3NH_3I crystal has the tetragonal structure (α') at room temperature with their C-N axes arranged in the antiparallel way along the c axis of the unit cell ($P4/nmm$, $z=2$). The $CH_3NH_3^+$ ion is orientationally disordered[1-4] with locating its three-fold axis on the four-fold crystallographic axis. The crystal undergoes two different types of transition depending on cooling rate, either discontinuously to the stable β' phase at 220 K or continuously to the metastable δ phase at 166 K. The previous calorimetric study[5] revealed that the $CH_3NH_3^+$ ions were ordered at zero Kelvin in both of the low temperature phases and the higher-order α'-δ transition corresponded to the orientational order-disorder process of the $CH_3NH_3^+$ ions possibly without drastic structural change.

It is the purpose of this paper to report a polarizing microscopic observation of a single crystal and a dielectric measurement of a powdered crystal in order to clarify the nature of the α'-δ phase transition and to discuss a possible structure of the δ phase.

Experimental

A polarizing microscope, Olympus model POM with magnification of 4×10, was used with a home-made cold stage which was designed for the observation of single crystal at liquid N_2 temperature with a rapid cooling. The rapid cooling is important in realizing the full formation of the δ phase. Single crystal was grown by a slow recrystallization from the methanol solution at 5 °C in the dark. The obtained crystal was of a square plate whose side length was about 1 mm.

The complex dielectric permittivity was measured from 80 to 270 K at several frequencies ranging from 50 Hz to 100 kHz with a capacitance bridge, General Radio Co. type 1615A. Powdered crystal was pressed to form a disc, 10 mm in diameter and 1.158 mm in thickness. Circular gold leaves of the size of 60.1 mm^2 in area were stuck with N-Apiezon grease on both faces of the disc as the electrodes.

Results and Discussion

Figure 1(A) shows a room-temperature photograph of the single crystal with its face perpendicular to the c axis, the side lines being parallel to the [110] or its equivalent axis. The equivalent tetragonal axes are shown in the figure. This crystal habit was examined in advance by an X-ray diffraction method. The light passes through the crystal along its c axis. No anomaly was observed by the rotation of polarized light. The observation was obscured around the central part of the specimen owing to the coexistence of adhesively grown powdery crystals, but this did not disturb much the optical features of the following observations. Figure 1(B) and 1(C) show the photographs of the crystal in the δ phase obtained by a rapid cooling down to the liquid N_2 temperature. Dark and bright (green and yellow in the original photograph) bands appeared alternately with the boundaries in parallel to the a axis of the tetragonal phase. The directions of the polarization of light for (B) and (C) were just perpendicular to each other. The alternating colors of the domains were just reversed between (B) and (C), indicating the rectangular domain structure of the crystal. It follows that the two equivalent a axes of the tetragonal structure becomes nonequivalent ($a \neq b$) with keeping γ (the $\angle$ab angle) the same 90° in the δ phase. In other words, the crystal structure of the δ phase belongs to the orthorhombic or monoclinic system. In view of the necessary condition for the formation of rectangular domain structure, the directions of its a and b axes must be inclined by 45° from the original a axis of the tetragonal structure as shown in the figure.

The complex dielectric permittivities of the δ and α' phases were measured in the following way. First, the complex dielectric permittivities were measured at eight frequencies (50, 100, 500, 1 k, 5 k, 10 k, 50 k, and 100 kHz) from 270 to 220 K at 5 K intervals in the cooling direction. After that, the sample was cooled rapidly to the liquid N_2 temperature from 260 K. The cooling rate 10 K min^{-1}, was rapid enough to prevent a possible transformation of the α' to β phase around 200 K. The dielectric constant ε' was then measured at the same frequencies from 77.5 K at 5 K intervals and especially in the δ-α' transition region at 1—2 K intervals in the heating direction. There was no considerable dielectric loss observed in the whole temperature and frequency regions, and the real part ε' was independent of the frequency. Figure 2 shows the temperature dependence of ε' measured at 1 kHz. The data between 190 and 220 K were omitted from the plots because they reflect partial transformation into the β' phase. From the high temperature side, ε' increases gradually and reaches a maximum at about 175 K. After that, it decreases steeply with decreasing temperature. This behavior is quite similar to those of the following antiferroelectric compounds; Pb_4SiO_6,[6] $CsH_3(SeO_3)_2$,[7] and $NH_4PF_6 \cdot NH_4F$.[8] The α'-δ phase transition is thus concluded to be accompanied by the antiparallel arrangement of electric dipoles in the δ phase.

The $CH_3NH_3^+$ ions lie in the (100) plane in an antiparallel arrangement along the c axis in the tetragonal α' phase, and the orientations of the ions around the

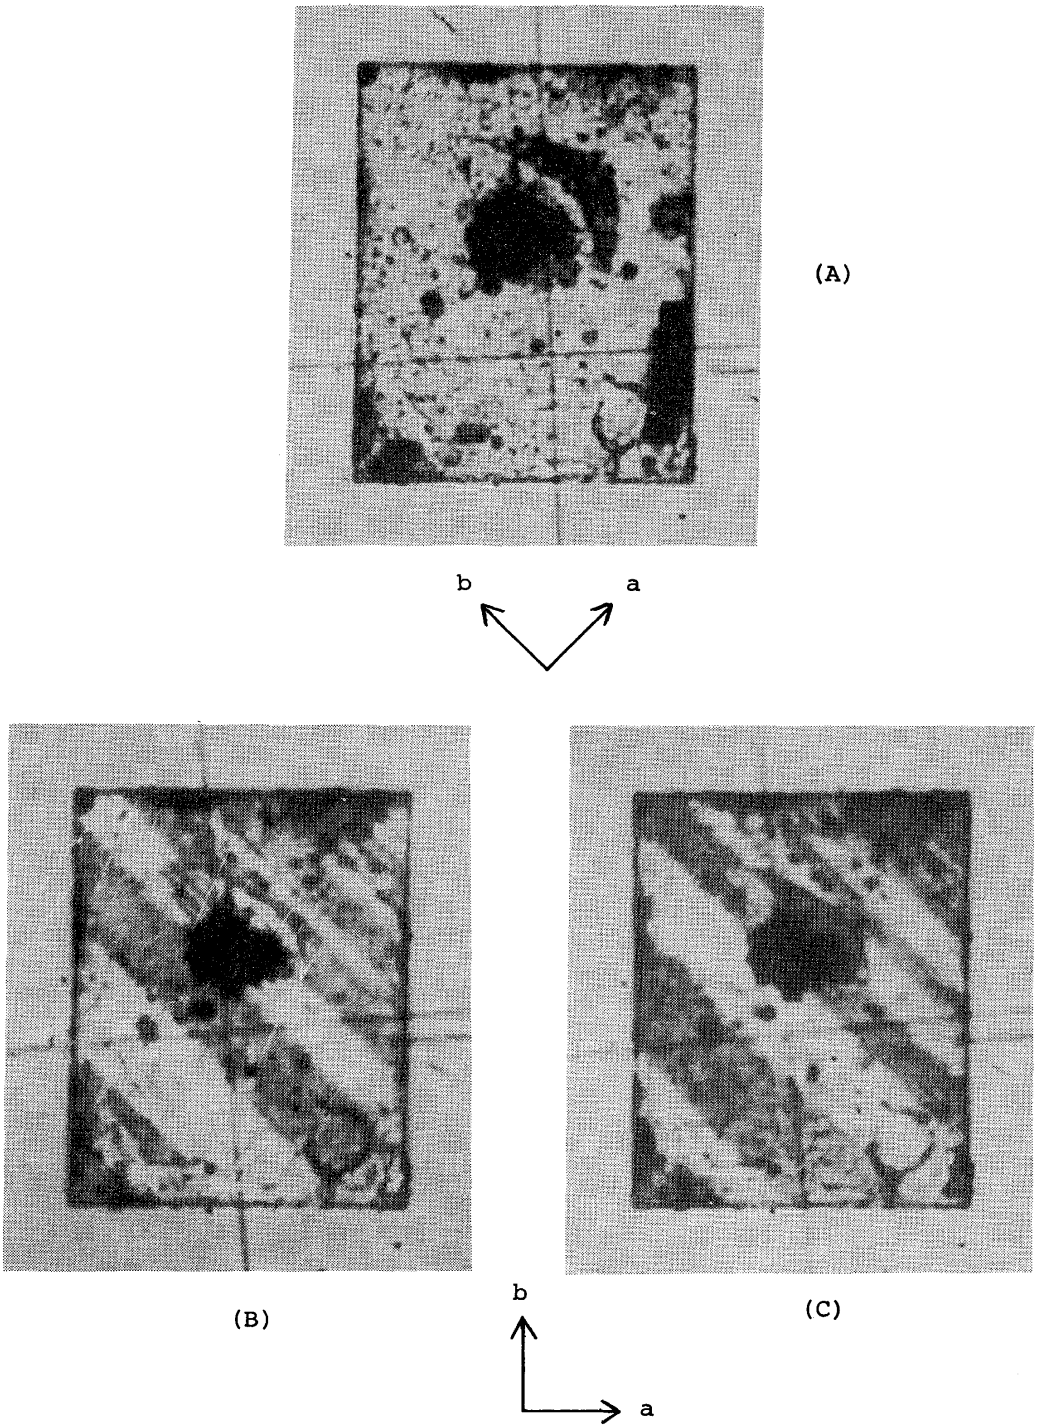

Fig. 1. Microphotographs of the domain structure in CH_3NH_3I single crystal; (A) at room temperature in the α' phase; (B),(C) at the liquid N_2 temperature in the δ phase. (B) and (C) were taken by using the polarized lights whose directions are perpendicular to each other. The crystallographic axes in each phase are shown in the figure.

C-N axes fall into the ordered state through the α'-δ phase transition.[5] The antiferroelectric fluctuation in the phase transition is therefore interpreted to originate from the motion coupled with the orientational ordering; that is, the tilt of the C-N axes from the c axis of the tetragonal structure probably resulting in the strengthening of some hydrogen bonds formed between I^- and $CH_3NH_3^+$ ions. Taking the above microscopic observation into consideration, the tilt would occur either in the (110) or ($1\bar{1}0$) plane in an antiferroelectric way in the δ phase, leading to the loss of the tetragonal symmetry. There are many possible ways of antiferroelectric arrangement of the $CH_3NH_3^+$ ions in space, if we consider larger unit cells than the original one. None of them can be beyond a simple possibility. Direct determination of the low tempera-

(Received August 4, 1986)

Synopsis. The crystal structure of bis(trimethylene)tetrathiafulvalenium triiodide (hexamethylenetetrathiafulvalenium triiodide) has been determined. The space group is $P\bar{1}$, with a=7.973 (2), b=11.849 (3), c=14.412 (4) Å, α=82.86 (2), β=89.13 (3), γ=95.85 (2)°, and Z=3. The crystal has intermolecular S... S contacts 3.36 and 3.37 Å shorter than the van der Waals distance of 3.7 Å.

Recent attention paid to organic charge-transfer complexes has demonstrated the possibility of their application to new electronic materials because of their large electronic anisotropy and/or conductivity. A series of complexes of bis(trimethylene)tetrathiafulvalene (hexamethylenetetrathiafulvalene[2)]; HMTTF) has been one of the candidates for organic metals since the discovery of HMTTF·TCNQ.[2)] The present authors have attempted the electrocrystallization of HMTTF salts with I_3^-, ClO_4^-, and PF_6^-; they have obtained single crystals of HMTTF·I_3 for the first time. Here, the crystal structure and the electrical properties will be reported.

Experimental

Black plates of HMTTF·I_3 were obtained by electrochemical oxidation (at a constant current of 1 μA under nitrogen at 20 °C) from a 80-ml THF solution containing 0.091 mmol of HMTTF and 0.27 mmol of tetrabutylammonium triiodide.[3)] The electrical resistivity of the single crystal was measured along the long axis (a axis) by the four-terminal method. The cell dimensions and diffraction intensities were measured on a Rigaku AFC-4 four-circle diffractometer by using graphite monochromated Mo$K\alpha$ radiation (λ= 0.71069 Å) at room temperature. 3998 independent reflections with 2θ values from 3° up to 55° ($|F_o| \geqq 3\sigma(|F_o|)$) were used for the analysis.

Crystal Data: $C_{12}H_{12}S_4 \cdot I_3$; FW=665.20; triclinic; space group, $P\bar{1}$; Z=3; a=7.973 (2), b=11.849 (3), c=14.412 (4) Å, α=82.86 (2), β=89.13 (3), γ=95.85 (2)°, U=1343.4 (6) Å^3; D_{obsd}=2.5, D_{calcd}=2.48 gcm^{-3}; μ(Mo $K\alpha$)=55.10 (cm^{-1}). The structure was solved by the use of the *MULTAN* 78 program.[4)] The structural parameters were refined by a block-diagonal least-squares method. The hydrogen atoms were placed at the calculated positions.[5)] All the computations were carried out on a FACOM M-380 computer using the *UNICS* III system.[6)] The final refinement after the absorption correction led to the R value of 0.045. The possibility of another space group, $P1$, was excluded because the I-I bond distance of the I_3 anion on the inversion center was unacceptably prolonged (3.40 Å).

Results and Discussion

The final atomic coordinates of the non-hydrogen atoms are given in Table 1.[7)] An *ORTEP*[8)] projection of the crystal structure along the a axis is shown in Fig. 1. The unit cell contains three HMTTF (A, B, B') and three I_3. One HMTTF (A) and one I_3 have their centers of mass on the crystallographic inversion center. Two I_3 anions are aligned almost parallel to the c axis, and the other one is aligned almost parallel to the b axis. These two types of I_3 anions are alternately stacked along the c axis. The anisotropic temperature factors of the I_3 anion on the inversion center are quite large, indicating that the I_3 anion is probably disordered. Figure 2 shows the bond distances in the HMTTF molecules. In the case of tetrathiafulvalene (TTF) salts,[9)] oxidation is accompanied by a lengthening of

the exocyclic double bond (x) and a shortening of the contacts between the two carbon atoms involved in the exocyclic double bond and the sulfur atoms (y). It is impossible to compare the bond distances of HMTTF·I_3 with those of the neutral HMTTF molecule, for the single crystal of the HMTTF has not yet been obtained. The distances of x (1.39 Å) and y (1.73 Å) of HMTTF·I_3, however, agree with the corresponding distances of TTF·I_3 (x, 1.382 (7) Å and y, 1.719 (8) Å). Molecule A is almost planar, within the deviations of 0.05 Å. In Molecule B, both rings I (S1B-C1B-S2-B-C2B-C3B-C4B-C5B-C6B) and II (S3B-C7B-S4B-C8B-C9B-C10B-C11B-C12B) are almost planar, within deviations of 0.08 Å. However, the least-square plane of Molecule B, as a whole, has a deviation of 0.31 Å (C10B); that is, B is slightly folded (8.7°) at the central double bond (C1B—C7B). Figure 3 shows the projection along the c axis. The least-square planes of Molecules A and B have a dihedral angle of 38.0°. The enantiomers B and B′ are parallel and facing to each other, with close S ... S contacts of 3.355 (4) and 3.366

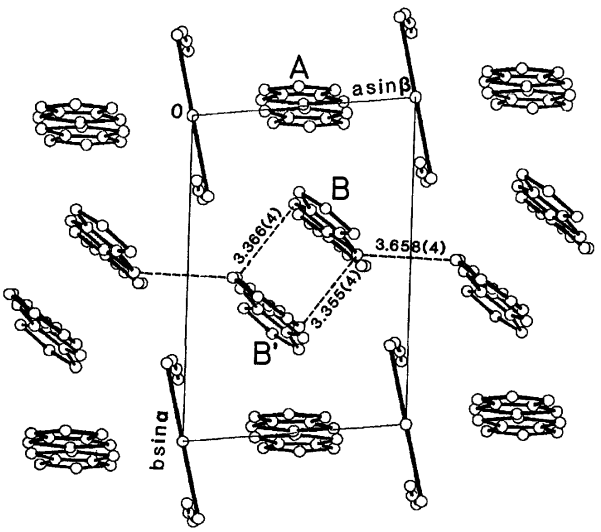

Fig. 3. Crystal structure projected along the c axis. Close intermolecular S···S contacts (Å) are indicated.

(4) Å shorter than the van der Waals distance of 3.7 Å, which may cause the foldings of Molecules B (and B′) described above. A slightly close S ... S contact of 3.658 (4) Å is also found between B and B′ in adjacent cells, but no sufficient overlapping of π-electrons can be expected. No other close S ... S contacts are found around Molecules B and B′ nor around Molecule A.

The temperature dependence of the electrical resistivity along the a axis was also measured. The resistivity increases as the temperature decreases ($\rho=3.7\times10^5$ Ωcm and activation energy $K=0.32$ eV at 300 K);[10] that is, this crystal is semiconductive, which is consistent with the molecular stacking along the a axis.

The ESR Detection of N Atoms in Methane-Air Combustion Flames Doped with Nitrogen Compounds

Masayuki TANIGUCHI, Shoji NODA,† and Hiroshi YOSHIDA*
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received August 20, 1986)

Synopsis. The ESR spectra of nitrogen atoms were detected for the first time in the combustion flames of methane doped with ammonia. The dependence of the N-atom concentration on the flame conditions was examined. The results were then discussed with reference to the models of the reduction of NH_3, leading to the NO formation.

The elucidation of the mechanism of NO formation in combustion flames is currently one of the most important subjects in combustion-chemical studies. NO is now believed to be formed by three different mechanisms: Thermal NO (from a reaction between N_2 and O_2, the Zeldovich mechanism), prompt NO (originating from reactions between labile intermediates, such as CH or C_2 and N_2), and fuel NO (originating from fuel-bound nitrogen).[1] Nitrogen atoms have been suggested to be of essential importance as the reaction intermediates in the prompt and fuel NO formation. However, there has been very little direct observation of N atoms in combustion flames. Although the paramagnetic intermediates in flames, such as the H and O atoms and the OH radicals, have recently been studied extensively by means of the electron-spin-resonance (ESR) method,[2-4] the ESR detection of N atoms in flames has, as far as the present authors know, not yet been reported.

This note aims to report the first successful ESR detection of N atoms in Bunsen-type flames of methane doped with ammonia under atmospheric pressure. It will also compare the observed dependence of the N-atom yield on the flame conditions with the models of the fuel NO formation reported previously.

Experimental

The Bunsen-type flame was obtained by using a burner composed of three concentric quartz tubes, as has been described in detail previously.[5] Premixed combustible gases, mixtures of methane and air with or without ammonia, were flowed through the innermost tube (4 mm in diameter). The secondary air was supplied through the second tube to support the flame. The outermost tube was used for the flowing of the coolant nitrogen gas, so that the flame was isolated from the surroundings. The flame temperature was measured by using a fine (0.1 mm in diameter) Pt/Pt-Rh thermocouple coated with SiO_2.

The paramagnetic entities were detected by means of the flame-in-cavity method[6] using an X-band spectrometer (Varian, Model E-109) equipped with a TE_{011} large-access cavity (Model E-235). The spectrometer was operated with a 100-kHz field modulation. Because the paramagnetic entities were subjected to ESR measurements under the atmospheric pressure, neither non-S-state atoms nor free radicals could be observed because of the collision broadening. Only H and N atoms with a S-state as the ground electronic state were observed. Another limitation of the flame-in-cavity method is that the paramagnetic entities in a flame are observed as a whole, so that their locations in the flame cannot be determined. This means that neither the concentration distribution in the flame nor the absolute concentration at particular positions in the flame can be determined. Therefore, we are mainly concerned with the relative change in the total amount of the paramagnetic entities dependent on the flame conditions. Occasionally, however, the absolute concentrations of H and N atoms in the flames were estimated from the integrated intensity of the ESR spectra.

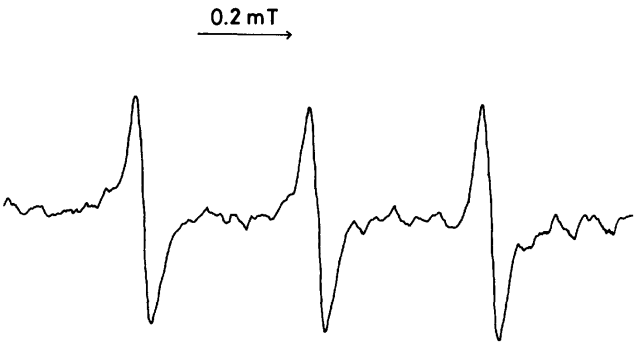

Fig. 1. ESR spectrum of N atoms observed from a Bunsen-type flame of methane-air premixed gas doped with ammonia under atmospheric pressure by the flame-in-cavity method. The flow of premixed gas was 200 cm^3min^{-1} of air, 33 cm^3min^{-1} of methane, and 8 cm^3min^{-1} of ammonia. The flow rate of secondary air was 220 cm^3min^{-1}.

Results and Discussion

The ESR signals observed from the flames of methane-air mixtures doped with ammonia were composed of an intense two-line spectrum with the hyperfine separation of 51.0 mT due to H atoms and a weak three-line spectrum with the hyperfine separation of 0.38 mT at g=2.002. An example of the latter is shown in Fig. 1. This spectrum is attributed to N atoms on the basis of the ESR parameters, which are identical with those of the N atoms studied by the flow-discharge method.[7] The only difference in the spectral features is the much larger linewidth of each hyperfine line in the present study, but this can be attributed to the collision broadening, very probably due to collisions with paramagnetic molecular oxygen[6,8] at high pressures.

When triethylamine was added to the premixed gas instead of ammonia, the ESR spectrum of N atoms was also observed. The premixed gas without nitrogen compounds gave no N-atom spectrum. These observations indicate that the N atoms in the flames come from the added nitrogen compounds and are involved

†Present address: Toyota Central Research and Development Labs., Inc., Nagakute-cho, Aichi 480-11.

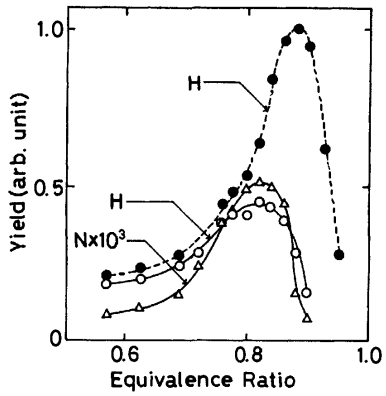

Fig. 2. Dependence of the yield of (circles) H and (triangles) N atoms in Bunsen-type flames of methane-air premixed gas (solid curves) with and (dashed curve) without ammonia on the equivalence ratio of the flame. The equivalence ratio of the flame (calculated by assuming complete mixing of the premixed gas and the secondary air) was changed by changing the flow rate of the secondary air, while the equivalence ratio of the premixed gas was kept constant, 1.71, both in the presence and absence of the added ammonia.

in the fuel-NO mechanism of the NO formation. The yields of N atoms due to the other mechanisms, thermal and prompt NO, are too low to be detected under the present experimental conditions.

The dependence of the ESR intensities of the H- and N-atom spectra on the equivalence ratio (stoichiometric oxygen concentration/actual oxygen concentration) was examined for methane-air flames doped with ammonia by keeping the flow rate of the premixed gas unchanged (33 $cm^3 min^{-1}$ of methane, 200 $cm^3 min^{-1}$ of air, and 8 $cm^3 min^{-1}$ of ammonia) and by changing the flow rate of the secondary air. The composition of the premixed gas corresponds to the equivalence ratio of 1.71, if the combustion of ammonia is expressed as $NH_3+(3/4)O_2 \rightarrow (1/2)N_2+(3/2)H_2O$. The observed dependence is shown in Fig. 2. Both the H and N atoms show their maximum yield at the equivalence ratio of 0.82. The variation in the N-atom yield is found to be parallel with that of the H atom.

For purpose of comparison, the dependence of the H-atom yield for the undoped flame on the equivalence ratio is also shown in Fig. 2. The observed trend of the H-atom yield is essentially the same as has previously been reported and been attributed to the effect of the diffusion of the secondary air (oxygen) into the flame.[5] The composition of the premixed gas was unchanged at the corresponding equivalence ratio of 1.71 here, also. For the undoped flame, the H-atom yield reaches its maximum at the equivalence ratio of 0.88. It should be noted that the H-atom yield is higher in the undoped flame than in the ammonia-doped flame throughout the region of equivalence ratios examined.

The effect of the concentration of added ammonia was also examined at a constant equivalence ratio, 0.88. Qualitatively, the H-atom yield decreases, while the N atom yield increases, with an increase in the concentration of ammonia in the range of the flow rate of ammonia, 0—8 $cm^3 min^{-1}$. The maximum yield of both the H and N atoms appears at a lower equivalence ratio with a higher concentration of added ammonia.

The ESR intensities changed depending on the position of the burner when it was moved along the center axis of the ESR cavity. This is because the H and N atoms are confined in a comparatively narrow region of the flame and because the ESR sensitivity depends on the location of the paramagnetic entities in the cavity (the sensitivity is expressed by the squared sinesoidal function). When the luminous inner cone was at the center of cavity (the position of the highest sensitivity), both the H and N atom signals showed the largest intensity. This indicates that the H and N atoms are located mostly in the inner cone, the height of which is less than 10 mm.

Assuming a uniform distribution of the H atoms in the region within 10 mm from the burner mouth, an assumption based on the concentration profile observed by the probe-sampling-ESR method,[2] the absolute concentration of the H atoms was estimated from the integrated ESR intensity to be 1×10^{15} atoms cm^{-3} (1×10^{-4} mole fraction) for the undoped flame at the concentration maximum shown in Fig. 2. The absolute concentration of N atoms was estimated in the same way to be 5×10^{11} atoms cm^{-3} (5×10^{-8} mole fraction) in the doped flame, also at the concentration maximum in Fig. 2. These estimations were made by calibrating the ESR intensities with reference to the ESR signals of molecular oxygen of known concentrations, and by correcting the temperature effect (the effect of the Boltzman distribution between spin states and of the gas density)[9] on ESR intensities using the highest temperatures actually measured in the luminous cone, 1660 and 1700 K for the doped and undoped flame, respectively.

It has been commonly accepted that the N atoms are generated in the ammonia-doped flame by the successive oxidation of NH_3 with H atoms or OH radicals as $NH_3 \rightarrow NH_2 \rightarrow NH \rightarrow N$. However, the detailed mechanism of the oxidation of ammonia has not been fully elucidated, though it is thought to be dependent on the flame conditions. Miller et al.[10] have studied the reaction mechanism of the ammonia oxidation in one-dimensional flames based on numerical-model calculations. Their conclusion is that NH_i species are oxidized mostly by H atoms or OH radicals, that the increase in the equivalence ratio results in the increase in the mole-fraction ratio of H to O and also in the increase in the N-atom concentration, and that NO is generated not only from N, but also directly from NH_2 by the reaction with the O atom, especially in fuel-lean flames.

The present experimental results may be summarized as: (1) the H and N atoms are observed concomitantly, and (2) the formation of N atoms in the presence of NH_3 accompanies the decrease in the H-atom concentration. Although the present results are still insufficient for the comprehension of the complex reaction mechanism of fuel-NO formation, they seem to be consistent with the view that the N-atom formation by

the fuel-NO mechanism is assisted by the existence of H atoms.[10] The present success in detecting the ESR spectrum of N atoms in combustion flames will encourage the further application of the ESR method to studies of combustion chemistry.

(Received August 13, 1986)

Synopsis. A reaction of 4-chlorobiphenyl with lithium diisopropylamide in a polar solvent gave 3- and 4-(diisopropylamino)biphenyl together with biphenyl, similar to the case of photoinduced reactions of 4-chlorobiphenyl with diisopropylamine. A common electron-transfer mechanism is proposed.

Lithium diisopropylamide(LDA) has been widely used for deprotonation and lithiation as a very strong nucleophile.[1] Recently, Ashby reported that the reaction of an alkyl halide with LDA proceeds through an electron-transfer rather than a lithiation or nucleophilic attack and gives a radical ion pair which collapses via concomitant reactions.[2] If the reaction starts from electron-transfer, the products are expected to be similar to those obtained from the well-known photoinduced electron-transfer reactions of halides with amines.[3-6] In accord with this expectation, comparing the products of reaction between 4-chlorobiphenyl (4-CB, **1**) and LDA with those of the photoinduced reactions of **1** with diisopropylamine (DIA), we found that the products of a thermal reaction in a polar solvent was similar to those of photochemical reactions, and their formation could be accounted for in terms of electron-transfer reactions. However, the features of a thermal reaction in THF at 0 °C were different from those of the photochemical reactions and the product ratios may be explained on the basis of a benzyne intermediate.[7]

We tried thermal reactions under two different reaction conditions; i) 0 °C in tetrahydrofuran(THF) and ii) 0 °C in THF-hexamethylphosphoramide(HMPA) (8:2). The yields of products, 3-and 4-(diisopropylamino)biphenyls (**3** and **4**) and biphenyl (**2**) were calculated by the standard GC analyses. On the other hand, irradiations of **1** in the presence of DIA were carried out in three different solvents, i.e., hexane, THF and acetonitrile. The yields of the products were analyzed in the same way as cases involving thermal reactions. The results are summarized in Table 1.

The major product of photochemical reactions is **2**, in accordance with our previous results.[3] Small amounts of amination products **3** and **4** were also isolated together with **2**. The yields of amination products seem to depend on the solvent polarity, i.e., the relative yield [**3**]/[**4**] is 1.8 in hexane, while 0.04 in acetonitrile. There is ample evidence that photoaddition of aromatics to a primary or secondary amine proceeds through proton-transfer in an exciplex to give a solvent caged radical pair in a nonpolar solvent, while in a polar solvent a solvent separated radical cation-radical anion pair is produced.[8] The solvent depen-

a) Yields were calculated based on GC analyses by using 2% OV-17 on Chromosob W NAW. b) 1,4-dihydrobiphenyl which may be produced by further reduction of biphenyl.[10] c) A mixture of THF-HMPA (8:2). d) A 6W low pressure mercury lamp was used.

dency of the product ratio observed in these photochemical reactions may reflect the different behavior of those different intermediate species. However, since the processes leading to the amination products are minor, discussion regarding the reaction mechanism based on the product ratios should be avoided at this stage. We would like to emphasize here that the major product of photoinduced electron-transfer is the reduction product **2**. The mechanism for formation of **2** may be complicate as shown in the case of 1-triethylamine system.[4-6]

The product ratios of thermal reaction of **1** with LDA carried out at 0 °C in THF-HMPA were similar to those of photochemical reactions, i.e., the major product is **2** and small amounts of the amination products **3** and **4** are also produced. Thus, the mechanism of this thermal reaction seems to be similar to that of photochemical reaction. A radical cation radical anion pair formed through thermal electron-transfer may participate in the reaction sequence. We, thus, propose path A in Scheme 2 as the most plausible mechanism for the major reaction between **1** and LDA in the polar solvent.

In sharp contrast with the thermal reaction in a polar solvent, the reaction in THF gave **3** and **4** as the major products and **2** as the minor one. This result is consistent with the case of thermal reaction between 4-bromobiphenyl and lithium piperidide in ether reported previously,[9] where the formation of the major products, 3- and 4-piperidinobiphenyl (47 and 37%), is explained in terms of the well known benzyne intermediate (Scheme 2, path B).[7,9] It is evident that both processes, i.e., electron-transfer and benzyne routes, participate in the thermal reactions aforementioned; however, the former is predominant in a polar solvent, while the latter is the major process in a nonpolar solvent.

In conclusion, on the basis of product analyses of photochemical reactions of **1** with DIA and of thermal reactions of **1** with LDA, we conclude that the reaction of **1** with LDA in a polar solvent proceeds through the electron-transfer mechanism similar to that in the photochemical reactions of **1** with DIA.

Experimental

IR spectra were determined on a JASCO IRA-1 spectrometer. H-and C-13 NMR were taken by using a JEOL GX-270 spectrometer in a $CDCl_3$ solution. UV-VIS spectra were taken on a Hitachi 320 spectrometer. Quantitative GC analyses were conducted with a Shimadzu GC-8 gas chromatograph using Pyrex column (2.5 mm i.d.×2 m) packed with 2% OV-17 on Chromosorb W NAW (80/100) at 130 to 230 °C. **1** and four products showed the following retention times; **1**, 7.5′; **2**, 4′; **3**, 10′; **4**, 10.5′ and 1,4-dihydrobiphenyl (**5**), 3′. GC-MS analyses were carried out on a Hitachi RMU-6MG mass spectrometer (20 eV). High resolution MS were measured with a Hitachi M-80 instrument.

THF was purified by refluxing over and distillation from $LiAlH_4$ under nitrogen. DIA and hexane were distilled from calcium hydride. Acetonitrile was distilled from P_2O_5 before use. *n*-BuLi in hexane was titrated immediately before use.

Typical Thermal Reaction of 1 with LDA. To a solution of LDA (3.13 mmol) prepared from DIA (316 mg, 3.13 mmol) and 1.20 mol dm^{-3} of *n*-BuLi in hexane (2.61 cm^3) was added a solution of **1** (200 mg, 1.06 mmol) in THF (1 cm^3) at 0 °C under nitrogen. The colorless solution gradually turned to deep red (λ_{max}=508 nm). After being allowed to stand for 3 h at 0 °C, the mixture was quenched with methanol, while the color was discharged, and extracted with ether to give 29% of **3**, 19% of **4**, 16% of **2** and 10% of recovered **1**. 1,3-(diisopropylamino)biphenyl (**3**): Bp 170—180 °C/0.5 mmHg* (Kugelrohr) ^1H NMR ($CDCl_3$) δ=7.60—6.85 (9H, m), 3.84 (2H, septet, J=6.8 Hz) and 1.25 (6H, d, J=6.8 Hz); ^{13}C NMR ($CDCl_3$) δ=148.35 (C-1), 118.06 (C-2), 142.21 (C-3), 118.12 (C-4), 117.22 (C-6), 141.57 (C-1′), 47.66 (methine) and 21.42 (methyl); IR (liquid film) 790 cm^{-1}; MS (20 eV) *m/z* (rel intensity) 253 (M^+ 11), 238 (37), 196 (100), 180 (18), 154 (26), 153 (26), and 152 (26): Found; *m/z* 253.1834, Calcd, for $C_{18}H_{23}N$; M^+ 253.1830. 4-(diisopropylamino)biphenyl (**4**): Bp 170—185 °C/0.5 mmHg (kugelrohr); ^1H NMR ($CDCl_3$) δ=7.69—7.20 (5H, m), 6.93 (2H, d, J=8.79 Hz) and 7.45 (2H, d, J=8.79 Hz) ^{13}C NMR ($CDCl_3$) δ=147.44 (C-1), 118.22 (C-2), 129.59 (C-4), 141.18 (C-1′), 47.54 (methine) and 21.32 (methyl); IR (liquid film) 830, 760 and 700 cm^{-1}; MS (20 eV) *m/z* (rel intensity) 253 ((M^+ 16), 239 (18), 238 (46), 223 (8.2), 210 (23), 196 (100), 180 (16), 154 (23), 153 (17) and 152 (16). Found; *m/z* 253.1815, Calcd. for $C_{18}H_{23}N$; M^+ 253.1830.

Alternative Preparation of 4. A suspension of 4-aminobiphenyl (34 mg), KOH (28 mg) and isopropyl iodide (69 mg) in THF (2 cm^3) was refluxed overnight. Extraction with ether gave a crude oil (35 mg). To a solution of the oil in 1,2-dimethoxyethane (2 cm^3) was added 1.20 mol dm^{-3} *n*-BuLi in hexane (0.2 cm^3) at 0 °C under nitrogen. The mixture was refluxed over 2 d and extracted with ether to give 33 mg of a yellow oil in 65% yield.

Typical Photoreaction of 1 with Diisopropylamine. Irradiation of a solution of **1** (20 mg, 0.106 mmol) and diisopropylamine (0.3 cm^3) in acetonitrile (1 cm^3) with a 6 W low-pressure mercury arc for 5 h gave **3** and **4** in 0.30 and 7.8% yields, respectively, in addition to 43% of 1,4-dihydrobiphenyls (**5**)[10] and 19% of **2** as major products.

The present study was partially supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture(No. 61123005). Thanks

Synopsis. The steam stability of H-ZSM-5-type zeolites containing alkaline earth metals was investigated by means of ^{27}Al MASNMR, the TPD of NH_3, and methanol conversion reactions. It was found that the steam stability of the H-ZSM-5-type zeolites is greatly improved by adding alkaline earth metals.

The production of light olefins, such as ethylene and propylene, from methanol with zeolites has been extensively studied. Several patents and articles have claimed that high selectivities to light olefins are attained at high temperatures over highly siliceous zeolites.[1-3] Recently, we have also found that methanol is converted to light olefins with a high selectivity over H-ZSM-5-type zeolites containing alkaline earth metals, especially calcium.[4,5]

It is well-known that many types of zeolites undergo structural degradation when subjected to water vapor at elevated temperatures. Therefore, if the zeolites are used in a moisture-rich atmosphere such as is encountered in the methanol-to-olefin (or gasoline) conversion, their resistance to steaming must be much improved.

From this standpoint, the steam stability of the H-ZSM-5-type zeolites containing alkaline earth metals has been investigated; the results will be described in this paper.

Experimental

The reagents used were aluminium nitrate (Kokusan, guaranteed reagent), colloidal silica (Cataloid SI-30 from Shokubai Kasei, 30—31 wt% SiO_2, 0.36—0.47 wt% Na_2O, 0.03 wt% Al_2O_3), sodium hydroxide (Nakarai, guaranteed reagent), tetrapropylammonium bromide (Tokyo Kasei, guaranteed reagent), and alkaline earth metal acetates (Nakarai, guaranteed reagent). The H-ZSM-5-type zeolites containing alkaline earth metals (M-H-ZSM-5, M=alkaline earth metals) were synthesized as follows. Certain amounts of aluminium nitrate, colloidal silica, and alkaline earth metal acetate were added to a stirred mixture of tetrapropylammonium bromide and sodium hydroxide in a solution. The resultant hydrogel, with the composition of 0.025 M · 0.1 R · 0.052 Na_2O · 0.005 Al_2O_3 · SiO_2 · 40H_2O (M=alkaline earth metal acetates; R=tetrapropylammonium bromide), was then transferred into a 300-ml stainless steel autoclave and stirred at 150—160 °C under an autogeneous pressure for 15—24 h. After the crystallization of the zeolite, the autoclave was rapidly cooled; the precipitated crystals were then filtered off, washed thoroughly with deionized water, dried at 120 °C, and calcined at 500 °C for 16 h in order to remove the organic base occluded in the zeolite framework. The zeolite thus obtained was protonated in a 0.6-M (1M=1 mol dm^{-3}) hydrochloric acid solution and calcined in air at 500 °C for 6 h.

The steaming was carried out using an atmospheric-pressure flow system at 600 °C in 100% steam for 2.5-g of the charged zeolite (14—28 mesh pieces). The rate of the addition of water was 3 ml h^{-1}.

High-resolution ^{27}Al NMR was measured at 51.9 MHz on a JEOL FX-200 Spectrometer equipped with a probe for magic-angle spinning (MAS). The spectra of the various H-ZSM-5-type zeolites were obtained using 0.33-g samples in Delrin bullets spinning at about 3.5 kHz, using 4.6 μs pulses. The chemical shifts in ppm were measured with respect to $Al(OH)_6^{3+}$ as an external reference.

The temperature-programmed desorption (TPD) spectra of the NH_3 adsorbed on the zeolites were obtained using a conventional TPD apparatus. A thermal-conductivity detector was employed for the detection of desorbed NH_3 molecules. The measurement was performed from 100 to 600 °C at a heating rate of 10 °C min^{-1} in helium as the carrier gas (a flow rate, 20 ml min^{-1}) for 0.30-g of the charged zeolite.

Methanol conversion was carried out by the use of an atmospheric-pressure flow reactor at 600 °C and LHSV=4 h^{-1}. The reaction gas was fed in a composition of 50 mol% methanol and 50 mol% argon. The products thus obtained were analyzed by gas chromatography. The methanol conversions and carbon-based selectivities were calculated from the concentration of argon used as the internal standard.

Results and Discussion

The prepared H-ZSM-5-type zeolites containing

a) Determined by X-ray fluoresence spectrometry.

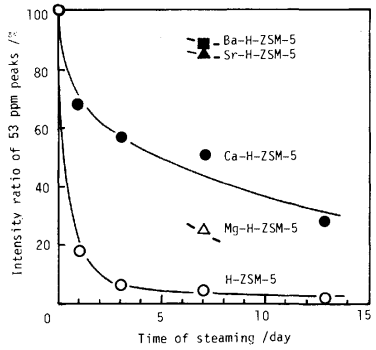

Fig. 1. Relationship between time of steaming and intensity ratio of 53 ppm peaks. Zeolite was subjected to water vapour at 600°C under atmospheric pressure.

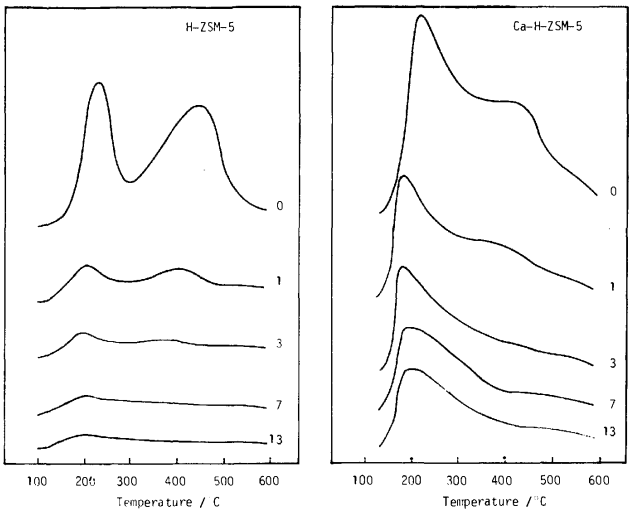

Fig. 2. TPD spectra of NH_3 from steamed zeolites Arabic numbers in Fig. denote a steaming time (day).

alkaline earth metals (M-H-ZSM-5) had a well-defined H-ZSM-5-type structure, as was demonstrated by their X-ray powder diffraction patterns. Some analytical data of the zeolites are given in Table 1. The amounts of alkaline earth metals occluded in the zeolites were more than those of the alkaline earth metals which would be introduced by a conventional ion-exchange method, in which the atomic ratio of alkaline earth metal to aluminium is, at most, 0.5. However, a full explanation of this rare phenomenon will be given in a future study.

As has already been reported, the ^{27}Al MASNMR spectrum of the conventional H-ZSM-5 has one peak, at about 53-ppm, assigned to the framework (tetrahedrally coordinated) aluminiums.[6] The ^{27}Al MASNMR spectra of various M-H-ZSM-5 have the same peak as that of H-ZSM-5. Figure 1 shows the relationship between the time of steaming and the intensity ratio, which means the percentage of a 53-ppm peak intensity of the steamed zeolites relative to that of the corresponding unsteamed zeolites. The rapid decay curve was obtained for H-ZSM-5, whereas the slow decay curves were obtained for M-H-ZSM-5. The intensity ratios of M-H-ZSM-5 decreased in the following order: Ba-H-ZSM-5 > Sr-H-ZSM-5 > Ca-H-ZSM-5 > Mg-H-ZSM-5 > H-ZSM-5, indicating a great stability of Ba- and Sr-H-ZSM-5 for steaming. These results suggest that the release of tetrahedrally coordinated aluminiums from a framework is depressed by the presence of alkaline earth metals to the different degree described above.

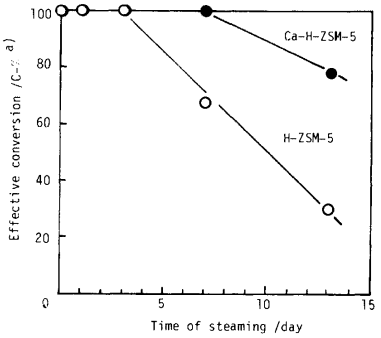

Fig. 3. Effect of steaming on catalytic activity. Reaction conditions: LHSV=4 h^{-1}, T=600°C. a) Effective conversion=100-(Methanol+Dimethyl Ether)-Yield

Some typical TPD spectra of NH_3 for H-ZSM-5 and Ca-H-ZSM-5 before and after the steaming are illustrated in Fig. 2. The TPD spectra from H-ZSM-5 exhibited two fairly sharp peaks at about 220 (l-peak) and 450 °C (h-peak). On the other hand, the two peaks of the TPD spectra from Ca-H-ZSM-5 are broad. The total amount of desorbed NH_3 decreased with an increase in the steaming time for both H-ZSM-5 and Ca-H-ZSM-5, but the amount of desorbed NH_3 of the former was less than that of the latter. As a part of the desorbed NH_3 might originate from physically adsorbed NH_3, the total amount of desorbed NH_3 is not necessarily proportional to the amount of acid sites which would originate from aluminiums in zeolites. Nevertheless, the result of the NH_3 TPD is in accordance with that of ^{27}Al NMR: less desorption for a lower intensity ratio.

Figures 3 and 4 show the results of methanol conversion over various zeolites before and after the steaming. The steaming affected both the catalytic activity and the product distribution. As is shown in Fig. 3, the catalytic activity of H-ZSM-5 decreased markedly with the increase in the steaming time, while that of Ca-H-ZSM-5 decreased slightly. For the steamed zeolites, a remarkable decrease in the selectivities to (C_2H_4+C_3H_6) and (benzen+toluene+xylene) was observed, while those to CH_4 and hydrocarbons with carbons more than six (C_6^+) were increased.

From all of these results, it is concluded that the steam stability of the H-ZSM-5-type zeolites is greatly improved by adding alkaline earth metals. The role of the alkaline earth metals in steam stability is considered to be similar to those of Co or Cu in the previously reported cobalt-ZSM-5 zeolites or cupper-Y-zeolites.[7,8] Although the essential role played by the alkaline earth metals is not very well understood in this work, in any event, the metals seem to prevent the release of aluminium species from the framework during the steaming.

This work is a part of the "C_1 Chemistry Project," a

Photochromism of Viologen Crystals

Hiroyoshi KAMOGAWA* and Tsuyoshi SUZUKI
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received July 8, 1986)

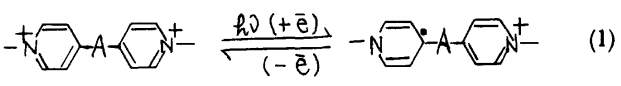
Synopsis. Some viologen crystals bearing a *p*-toluenesulfonate anion as a counter ion were shown to exhibit reversible photoreductions (photochromism) either in air or under vacuum, whereas in a poly(*N*-vinyl-2-pyrrolidone) matrix all investigated viologens indicated reversible photocolor developments. Amphoteric ions such as 1,1′-bis(3-sulfonatopropyl)-4,4′-bipyridinium also developed colors with high stabilities.

It was known that viologens undergo reversible photoreductions in either poly(*N*-vinyl-2-pyrrolidone) (PVP) matrix[1] or in films of the copolymers of *N*-vinyl-2-pyrrolidone (VP) containing viologen units as pendants.[2] Some viologen crystals, on the other hand, have been found to undergo reversible photoreductions accompanied by intense blue or pink color developments.[3]

In this study, various viologen crystals were synthesized and subjected to irradiations of UV light either in air or under vacuum. The resulting color developments were measured to provide preliminary data in order to utilize this phenomenon in the fields of photomemory or control of light quantity.

Results and Discussion

Viologens were synthesized as bromides in acetonitrile as described before.[1] The bromides were converted to *p*-toluenesulfonate (PTS)s either by adding a large excess of *p*-toluenesulfonic acid to precipitate the latters or by passing through an anion-exchange resin (Diaion SA 10) loaded with *p*-toluenesulfonic acid. Amphoteric ions like 1,1′-bis(3-sulfonatopropyl)-4,4′-bipyridinium were synthesized by treating 4,4′-bipyridine with sultones. Analytical data indicated that all viologens were satisfactorily pure. All viologens were soluble in water but amphoteric types provided turbid films when incoporated in a PVP matrix from aqueous solutions. Some viologen crystals afforded (more or less) intense color developments when they were irradiated by near-UV light.[3] Their reflection spectra are shown in Fig. 1 as either absorbance (on a spectrophotometer) or reflectance (on a color sensor). The shapes and positions of the absorption maximum and reflectance minima correspond exactly with those of single radical cations of viologens.[4] The appearance of ESR signals also corresponds to color development, thereby indicating the following generation of radical cation by ilumination:



(1)

Here, A denotes -CH=CH- or none.

In Table 1 can be found the results of an investigation of UV irradiation for viologen crystals synthesized in this experiment. It can be recognized in this table

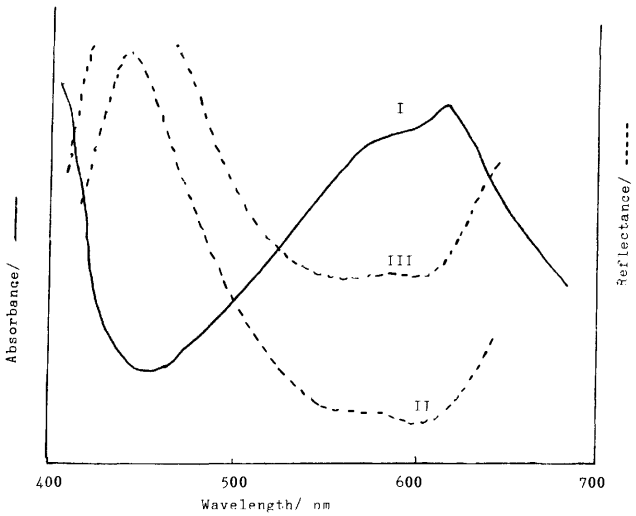


Fig. 1. Reflection curves of the colors developed on viologen crystals with irradiation of near UV light(>350 nm). Curve I: Absorbances for 1,1′-bis-(3-sulfonatopropyl)-4,4′-bipyridinium (**6**). Curves II and III: Reflectances for 1,1′-dibenzyl-4,4′-bipyridinium bis(*p*-toluenesulfonate) (**1a**) under vacuum immediately after 90s irradiation and 10 min after, respectively (color sensor).

that only viologens having PTS as counter anion afford color development in crystals (**1a** and **5a**). In PVP matrix, however, all investigated viologens provided blue (absorption maximum, 610 nm) color developments. Viologen crystals in the form of amphoteric ions also develop colors on UV irradiation (**6**, **7**, and **9**).

Table 2 shows the half recovery times of the color developments in crystals as compared with those in a PVP matrix. It can be seen from this table that the effect of air oxygen is very great for viologens **1a** and **5a**, whereas **6** and **7** are almost insensitive to air oxygen. This fact, together with the very long half recovery times, tells us that amphoteric-type viologens, particularly **6**, afford stable color developments for long times under dry conditions. The developed color disappears quickly upon strong heating. Quantitative data have not yet been taken. The reason why only PTS gives cation radicals discernible even in air is unknown at the present stage. One reason may be that radical anion produced on the part of PTS by a photoelectron transfer from the tosylate anion to viologen dication is relatively stable due to a delocalization of both odd electron and negative charge. The crystal structure, i.e., relative position of an anion against a viologen dication in the crystal lattice, may also make the electron transfer impossible, since the benzenesulfonate (**1b**) does not afford any color development as indicated in Table 1. The effect of air oxygen on both

color development and its recovery is significant for some viologen crystals, e.g., viologens **1a** and **5a** in Table 2. Generally, the oxygen accelerates the back oxidations of viologen radical cations to dications. The color developed in the crystal lattice, however, may be more stable to air oxidation than that on a crystal surface. It appears that the rate and extent of the back reaction depend upon the stability of radical ion pair generated in crystal, as shown in pendant copolymers,[5] when the effect of air oxygen, i.e., environmental conditions, is the same.

Experimental

Infrared (IR), ^1H NMR, and elemental analyses were conducted using a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Perkin-Elmer 240 instrument, respectively. The esr was taken with a JES-FE1XG spectrometer.

1,1′-Dibenzyl-4,4′-Bipyridinium Dibromide(1). This compound was prepared according to a previous report[1] starting with 4,4′-bipyridine (2.00 g, 12.8 mmol) and benzyl bromide (3.91 g, 25.6 mmol) in anhydrous acetonitrile (50 ml) under 6 h refluxing (yield, 93%). Found: C, 57.96; H, 4.33; N, 5.52%. Calcd for $C_{24}H_{22}N_2Br_2$: C, 57.80; H, 4.45; N, 5.62%. IR (KBr) 1630 cm^{-1}; ^1H NMR (D_2O) δ=6.0 (s, 4H, $2CH_2$), 7.7 (s, 10H, ArH), 8.6 (d, 4H, bipyridinium H), 9.3 (d, 4H, bipyridinium H).

All other viologen bromides were prepared in the same manner. Analytical data were all satisfactory.

1,1′-Dibenzyl-4,4′-Bipyridinium Bis(*p*-toluenesulfonate) (1a). To a solution of *p*-toluenesulfonic acid (6.88 g, 40 mmol) in absolute ethanol (50 ml) was added 1,1′-dibenzyl-4,4′-bipyridinium dibromide (**1**; 2.00 g, 4 mmol). To the resulting solution was added anhydrous ether (70 ml) and the mixture was allowed to stand overnight in order to precipitate a crude product, which was recrystallized from methanol-ether to provide white crystalline powder in 56% yield. Found: C, 66.84; H, 5.23; N, 4.12%. Calcd for $C_{38}H_{38}N_2S_2O_6$: C, 67.04; H, 5.33; N, 4.11%. IR (KBr) 1630 cm^{-1}; ^1H NMR (D_2O+DMSO-d_6) δ=2.4 (s, 6H, $2CH_3$), 7.2—7.8 (m, 18H, PTS+ArH), 8.6 (d, 4H, bipyridinium H), 9.3 (d, 4H, bipyridinium H).

1,1′-Dibenzyl-4,4′-bipyridinium bis(benzenesulfonate) (**1b**; yield, 52%), 1,1′-dibenzyl-4,4′-bipyridinium bis(1-naphthalenesulfonate) (**1d**; 79%), and trans-4,4′-vinylenebis[1-benzylpyridinium] bis(*p*-toluenesulfonate) (**8a**; 45%) were prepared in the same manner using benzene- and 1-naphthalenesul-

fonic acids(water as solovent) and *p*-toluenesulfonic acid from respective bromides.

The results of elemental analyses, IR, and NMR were all satisfactory.

1,1'-Diphenethyl-4,4'-bipyridinium Bis(*p*-toluenesulfonate) (5a). A solution of *p*-toluenesulfonic acid (20 g) in water (50 ml) was stirred with an anion-exchange resin (Diaion SA 10A, OH-type, 16 g) overnight. The mixture was then filtered, and the resin was washed thoroughly with distilled water until a neutral to litmus. A solution of 1,1'diphenethyl-4,4'-bipyridinium dibromide (5; 2.00 g) in water (70 ml) was added and the mixture was gently stirred overnight. The ion-exchange resin was filtered off and the filtrate was freeze dried to afford a crude product, which was recrystallized from methanol-ether to give white crystalline powder in 59% yield. Found: C, 67.45; H, 5.79; N, 3.76%. Calcd for $C_{40}H_{40}N_2S_2O_6$: C, 67.70; H, 5.69; N, 3.95%. IR (KBr) 1620 cm^{-1}; ^1H NMR (D_2O) δ=2.3 (s, 6H, $2CH_3$), 3.3 (t, 4H, $2CH_2$), 5.0 (t, 4H, $2CH_2$-$\overset{+}{N}$<), 7.0—7.7 (m, 18H, PTS+ArH), 8.3 (d, 4H, bipyridinium H), 8.7 (d, 4H, bipyridinium H).

1,1'-Dibenzyl-4,4'-bipyridinium bis(methanesulfonate) (**1c**; 53%), 1.1'-bis(*p*- and *m*-methylbenzyl)-4,4'-bipyridinium bis(*p*-toluenesulfonate) (**2a**, **3a**; 76, 71%), and 1,1'-dipropyl-4,4'-bipyridinium bis(*p*-toluenesulfonate) (**4a**; 45%) were prepared in the same manner using methane- and *p*-toluenesulfonic acids from respective bromides. All analytical data were satisfactory.

1,1'-Bis(3-sulfonatopropyl)-4,4'-bipyridinium (6). A solution of 4.4'-bipyridine (2.00 g, 12.8 mmol) and 1,3-propanesultone (7.8 g, 64 mmol) in anhydrous acetonitrile(50 ml) was heated under reflux for 48 h. The resulting mixture was filtered, washed with acetonitrile, and recrystallized from water to give a white crystalline powder in 77% yield. Found: C, 48.22; H, 5.17; N, 6.89%. Calcd for $C_{16}H_{20}N_2S_2O_6$: C, 48.01; H, 5.00; N, 7.00%. IR (KBr) 1640 cm^{-1}; ^1H NMR (D_2O) δ=2.0—3.6 (m, 8H, $2CH_2CH_2$), 5.2 (t, 4H, $2CH_2$-$\overset{+}{N}$<), 8.8 (d, 4H, bipyridinium H), 9.3 (d, 4H, bipyridinium H).

1,1'-Bis(4-sulfonatobutyl)-4,4'-bipyridinium (**7**; DMF, 90—100 °C, yield 78%) and trans-4,4'-vinylenebis[1-(3-sulfonatopropyl)pyridinium] (**9**; 61%) were prepared in similar manners using 1,4-butane- and 1,3-propanesultones, respectively.

Measurements of Photoreductions. Crystals (in air). A Hitachi 200-10 spectrophotometer fitted with a reflection attachment was employed for measurements of reflection spectra in air (20 °C).

Crystals (under vacuum). When measurements in the absence of air oxygen were required, a sample of viologen crystals was sealed in a 5-ml Pyrex glass tube under vacuum (0.1 mmHg) as usual. The sealed tubes were subjected to measurements of reflection spectra on a Hitachi C-120 Color Sensor and spectra ranging from 400 to 700 nm were taken within one second.

In Matrices. Measurements were performed using a Hitachi 200-10 spectrophotometer, as previously described.[1] The irradiation source was Toshiba SHL-100UV (75 W) mercury lamp cut below 350 nm with a glass filter. The irradiation distance was 10 cm.

Fast Cis-Trans Isomerization of Square-Planar Bis(diethyl sulfide)platinum(II) Complexes. Reaction of *cis*-Dichlorobis(diethyl sulfide)platinum(II) with Mesityllithium

Hiromi TOBITA, Hiroki HABAZAKI, and Hiroshi OGINO*
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
(Received September 10, 1986)

Synopsis. Reaction of *cis*-[$PtCl_2(SEt_2)_2$] with a slight excess of mesityllithium in benzene-ether mixture afforded *trans*-[PtCl(Mes)(SEt_2)$_2$] (Mes=2,4,6-trimethylphenyl; SEt_2= diethyl sulfide) as a major product. When mesityllithium reagent containing lithium bromide was used, *trans*-[PtBr(Mes)(SEt_2)$_2$] was obtained. Acceleration of cis-trans isomerization in the presence of mesityllithium was observed.

Arylplatinum(II) complexes having sulfide ligands are useful precursors of various organoplatinum complexes, since the sulfide ligands can be replaced easily by phosphine, pyridine, carbonyl, etc.[1] The reaction of *trans*-[PtX_2L_2] (X=Cl, Br, or I; L=SEt_2 or $SeEt_2$) with phenyl, *o*-tolyl, or mesityllithium has been reported by Sergi et al.[2,3] who found that the trans isomers of [$PtXArL_2$] and/or [$PtAr_2L_2$] were the exclusive products with the exception of the reaction of *trans*-[$PtCl_2(SEt_2)_2$] with phenyllithium. In the latter reaction, the major product was *cis*-[$PtPh_2(SEt_2)_2$] (60%) with 20% of the trans isomer.

The reaction of *cis*-[$PtCl_2(SR_2)_2$] (R=Et, *n*-Pr, or *i*-Pr) with excess phenyl or *p*-tolyllithium has been reported by Steele and Vrieze to give the dimeric [$PtAr_2(SR_2)]_2$ (Ar=Ph or *p*-tolyl).[1] Exceptionally, the reaction of *cis*-[$PtCl_2(SEt_2)_2$] with C_6F_5Li afforded monomeric *cis*-[$Pt(C_6F_5)_2(SEt_2)_2$] in high yield.[1] They also carried out the reaction of *trans*-[$PtCl_2(SEt_2)_2$] with phenyllithium and obtained products which were different from Sergi's, i.e., a dimer [$PtPh_2(SEt_2)]_2$ (55%) and a monomer *cis*-[$PtPh_2(SEt_2)_2$] (20%).

This paper deals with the reaction of *cis*-[$PtCl_2(SEt_2)_2$] with bulky mesityllithium which has not been examined before. When *cis*-[$PtCl_2(SEt_2)_2$] was allowed to react with mesityllithium reagent containing lithium bromide, *trans*-[PtBr(Mes)(SEt_2)$_2$] was obtained. A possible mechanism is proposed for the reaction.

Experimental

Apparatus. ^{1}H NMR spectra were recorded on JEOL FX-90Q and Varian EM-390 spectrometers, and ^{13}C NMR spectra on a JEOL FX-90Q spectrometer. Electronic spectra were measured on a Hitachi 330 spectrophotometer. Mass spectra were obtained on a Hitachi M-52 spectrometer.

Reaction of *cis*-[$PtCl_2(SEt_2)_2$] with Mesityllithium. Reactions were carried out under nitrogen using dried solvents. *cis*-[$PtCl_2(SEt_2)_2$] was prepared according to a literature procedure.[4]

***trans*-[PtBr(Mes)(SEt_2)$_2$] and *trans*-[$PtBr_2(SEt_2)_2$].** A suspension of mesityllithium was prepared by adding 1.5 mol dm^{-3} butyllithium in hexane (10 ml) to an ether solution (40 ml) of bromomesitylene (2.00 g, 10.0 mmol) at room temperature. A 3 ml portion of this suspension (ca. 0.60 mmol) was added to a benzene (20 ml) solution of *cis*-[$PtCl_2(SEt_2)_2$] (200 mg, 0.448 mmol) at 0 °C. After stirring for 15 min, the reaction mixture was allowed to warm to room temperature and stirred for 17 h. The turbid reaction mixture was filtered through a Celite 545 column and the filtrate was evaporated to give a brown crystalline residue. It was then placed on an alumina column (200 mesh) and eluted with benzene. Evaporation of the eluates afforded *trans*-[$PtBr_2(SEt_2)_2$][5] as yellow crystals (12.0 mg, 5%): mp 117—118 °C (lit, mp 129, 124, 118 °C)[5] and *trans*-[PtBr(Mes)(SEt_2)$_2$] as colorless crystals (104 mg, 40%): mp 130—131 °C. Found: C, 35.90; H, 5.57; Br, 14.35%. Calcd for $C_{17}H_{31}BrPtS_2$: C, 35.54; H, 5.44; Br, 13.91%. ^{1}H NMR (90 MHz, C_6D_6) δ=0.95 (12H, t, J_H=7.3 Hz, CH_3 of Et), 2.22 (3H, s, J_{Pt}=5.2 Hz, *p*-CH_3), 2.63 (8H, q, J_H=7.1 Hz, J_{Pt}=42.7 Hz, CH_2 of Et), 2.74 (6H, s, J_{Pt}=8.1 Hz, *o*-CH_3), 6.78 (2H, s, J_{Pt}=8.9 Hz, *m*-H);[6] ^{13}C NMR (22.6 MHz, C_6D_6) δ=13.0 (q, J_{Pt}=42.7 Hz, CH_3 of Et), 20.8 (q, *p*-CH_3), 26.4 (q, J_{Pt}=52.9 Hz, *o*-CH_3), 30.2 (t, J_{Pt}=13.2 Hz, CH_2 of Et), 133.2, 133.4, and 141.3 (aromatic ring carbons);[6] MS *m*/*z* 572 (M^+, based on ^{194}Pt; 6), 482 (1), 403 (10), 392 (1), 374 (42), 362 (7), 346 (21), 281 (9), 120 (96), 105 (83), 90 (100), 75 (73).

***trans*-[PtCl(Mes)(SEt_2)$_2$].** Lithium bromide-free mesityllithium was prepared by removing the supernatant of the reaction mixture by decantation and washing the white, fine crystals of mesityllithium with dry ether several times. This suspension of mesityllithium (0.45 mmol) in ether was added to a solution of *cis*-[$PtCl_2(SEt_2)_2$] (200 mg, 0.448 mmol) in benzene (20 ml) and the mixture was stirred for 2.5 h at room temperature. After removal of the solvent, purification by column chromatography (200 mesh alumina, benzene) followed by recrystallization from hexane gave *trans*-[PtCl(Mes)-(SEt_2)$_2$] as colorless crystals (94 mg, 36%): mp 119 °C. Found: C, 38.81; H, 5.95; S, 12.05; Cl, 7.05%. Calcd for $C_{17}H_{31}ClPtS_2$: C, 38.52; H, 5.89; S, 12.10; Cl, 6.69%. ^{1}H NMR (90 MHz, C_6D_6) δ=0.97 (12H, t, J_H=7.6 Hz, CH_3 of Et), 2.23 (3H, bs, *p*-CH_3), 2.60 (8H, q, J_H=7.9 Hz, J_{Pt}=44.0 Hz, CH_2 of Et), 2.78 (6H, s, J_{Pt}=7.9 Hz, *o*-CH_3), 6.80 (2H, s, J_{Pt}=8.0 Hz, *m*-H);[6] ^{13}C NMR (22.6 MHz, C_6D_6) δ=12.8 (q, J_{Pt}=41.2 Hz, CH_3 of Et), 20.8 (q, *p*-CH_3), 28.8 (q, J_{Pt}=50.9 Hz, *o*-CH_3), 29.1 (t, J_{Pt}=13.4 Hz, CH_2 of Et), 133.1 and 141.6 (aromatic ring carbons);[6] MS *m*/*z* 528 (M^+, based on ^{194}Pt; 6), 438 (1), 403 (2), 374 (41), 346 (24), 318 (8), 282 (6), 120 (81), 105 (77), 90 (100), 75 (97).

***trans*-[Pt(Mes)$_2$(SEt_2)$_2$].** To a solution of *cis*-[$PtCl_2(SEt_2)_2$] (200 mg, 0.448 mmol) in ether (20 ml) was added a suspension of mesityllithium (1.2 mmol) in ether. After stirring for 14 h at room temperature, the solvent was removed in vacuo. The ^{1}H NMR spectrum of the residue in $CDCl_3$ showed both signals of *trans*-[PtBr(Mes)(SEt_2)$_2$] and *trans*-[Pt(Mes)$_2$(SEt_2)$_2$]. The molar ratio of these two products was nearly 1 : 1. Ether and water were added to the residue to remove salt and the ether layer was concentrated. Recrystallization of the residue from methanol yielded *trans*-[Pt(Mes)$_2$(SEt_2)$_2$][3] as colorless crystals (24 mg, 18%): Mp 175—178 °C (decomp) (lit, mp 180 °C (decomp)).[3]

Spectral Measurements. The reactions of *cis*-[$PtCl_2(SEt_2)_2$] with lithium bromide and mesityllithium were followed by monitoring the spectral changes. To a benzene solution of the complex placed in a quartz cell (optical path length=1 cm) was added a solution of slightly excess lithium bromide

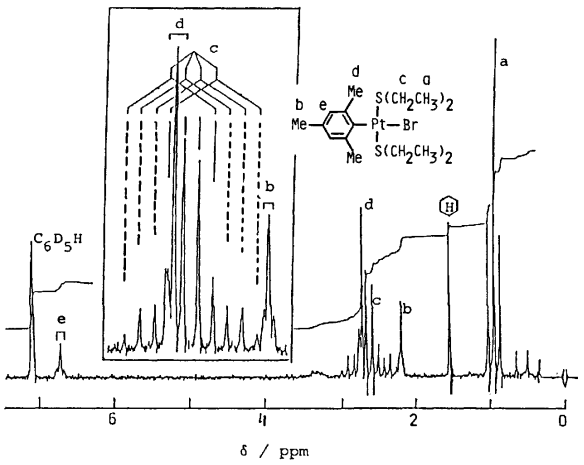

Fig. 1. ^{1}H NMR spectrum of *trans*-[PtBr(Mes)-$(SEt_2)_2$] in C_6D_6 (internal standard, cyclohexane). The inset shows an expanded spectrum in the region of about 2 to 3 ppm.

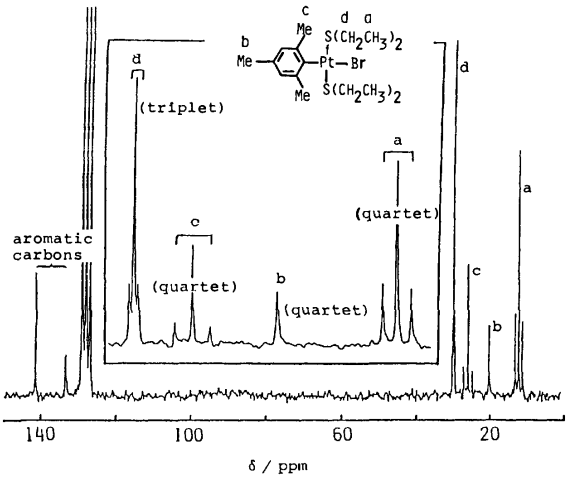

Fig. 2. ^{13}C NMR spectrum of *trans*-[PtBr(Mes)-$(SEt_2)_2$] in C_6D_6. The inset shows an expanded spectrum in the region of the signals of aliphatic carbons. Off resonance patterns are shown in parentheses.

or mesityllithium in ether. Absorption maxima of *cis*-$[PtCl_2(SEt_2)_2]$, *trans*-$[PtBr(Mes)(SEt_2)_2]$, *trans*-$[PtCl_2(SEt_2)_2]$, and *trans*-$[PtBr_2(SEt_2)_2]$ appear at 330, 306 (shoulder), 338, and 357 nm, respectively.

Results and Discussion

Reaction of *cis*-$[PtCl_2(SEt_2)_2]$ with Mesityllithium. When *cis*-$[PtCl_2(SEt_2)_2]$ in benzene was treated with an ether solution of slightly excess mesityllithium prepared from bromomesitylene and butyllithium, two products, *trans*-$[PtBr(Mes)(SEt_2)_2]$ and *trans*-$[PtBr_2(SEt_2)_2]$, were obtained in 40 and 5% yields, respectively, after purification with an alumina column.

$$cis\text{-}[PtCl_2(SEt_2)_2] + MesLi/LiBr \xrightarrow[0\ ^\circ C - r.t.]{\text{ether-benzene}} trans\text{-}[PtBr(Mes)(SEt_2)_2] + trans\text{-}[PtBr_2(SEt_2)_2]$$

The molecular formula of *trans*-$[PtBr(Mes)(SEt_2)_2]$ was determined by elemental analysis and mass spectroscopy. The ^{1}H NMR spectrum of *trans*-$[PtBr(Mes)(SEt_2)_2]$ shows only one set of signals assigned to ethyl groups (Fig. 1) that is consistent with the trans form. The configuration is further confirmed by the ^{13}C NMR spectrum which likewise exhibits a set of ethyl carbon signals (Fig. 2). The known compound *trans*-$[PtBr_2(SEt_2)_2]$ was identified by comparing its melting point (117—118 °C) to the literature value (129, 124, and 118 °C; cf. cis-isomer, mp 93—95 °C)[5] and by measuring mass, ^{1}H NMR, and ^{13}C NMR spectra.

The origin of bromo ligands in *trans*-$[PtBr(Mes)(SEt_2)_2]$ and *trans*-$[PtBr_2(SEt_2)_2]$ is considered to be lithium bromide which was formed as a by-product when mesityllithium was prepared. In fact, when lithium bromide-free mesityllithium was used for the reaction, the major product was *trans*-$[PtCl(Mes)(SEt_2)_2]$ (36%). The reaction of *cis*-$[PtCl_2(SEt_2)_2]$ with ca. 2.5 equivalent of mesityllithium afforded a 1 : 1 mixture of *trans*-$[PtBr(Mes)(SEt_2)_2]$ and *trans*-$[Pt(Mes)_2(SEt_2)_2]$.

Reaction Mechanism. The mechanism of the conversion from *cis*-$[PtCl_2(SEt_2)_2]$ to *trans*-$[PtBr(Mes)(SEt_2)_2]$ should, at least, involve the following three reactions: (a) nucleophilic substitution of halide by mesityl anion, (b) cis-trans isomerization of a square-planar complex, and (c) substitution of chloro ligand by bromo ligand. The ligand substitution reaction of square-planar platinum(II) complexes usually occurs with the retention of geometrical configuration.[7] In other words, the reaction (b) (cis-trans isomerization) is normally much slower than the reactions (a) and (c) (ligand substitutions). However, this empirical rule seems not to apply to the present reaction, since only the isomerized products have been obtained.

The reaction of *cis*-$[PtCl_2(SEt_2)_2]$ in a benzene-ether mixture in the presence of lithium bromide was monitored at 21 °C by periodic measurements of UV-visible spectra, but only a slight change of the spectrum was observed even after two hours. In sharp contrast with this result, when mesityllithium was added to a benzene solution of *cis*-$[PtCl_2(SEt_2)_2]$, this compound disappeared within 30 min and *trans*-$[PtBr(Mes)(SEt_2)_2]$ was formed. These experimental results indicate that mesityllithium accelerates the geometrical isomerization. The formation of *trans*-$[PtBr_2(SEt_2)_2]$ shows that the geometrical isomerization of the platinum(II) complex occurs before the displacement of a coordinated halide ion by a mesityl anion. Low solubility of mesityllithium in ether as well as the bulkiness of mesityl group may significantly contribute to the slow substitution.

From these results, the following mechanism is suggested, where mesityllithium catalyzes the fast cis-trans isomerization followed by the relatively slow substitution by mesityl group (Scheme 1).

$$cis\text{-}[PtCl_2(SEt_2)_2] \xrightarrow{MesLi,\ LiX} trans\text{-}[PtX_2(SEt_2)_2] \quad X = Cl \text{ or } Br$$

$$trans\text{-}[PtX_2(SEt_2)_2] + MesLi \longrightarrow trans\text{-}[PtX(Mes)(SEt_2)_2]$$

Scheme 1.

^{13}C NMR Spectra. The ^{13}C NMR spectrum of *trans*-[PtBr(Mes)(SEt_2)$_2$] shows typical ^{195}Pt couplings on the signals of diethyl sulfide ligands (Fig. 2). A somewhat surprising result is that the methylene carbons show smaller coupling constant ($^2J_{Pt}$=13.2 Hz) than the methyl carbons ($^3J_{Pt}$=42.7 Hz). The spectrum of chloro complex exhibits the same phenomenon ($^2J_{Pt}$=13.4 Hz, $^3J_{Pt}$=41.2 Hz). To our knowledge, there is no report which mentions this phenomenon, but a similar reversal of ^{195}Pt coupling constants can be seen in the ^{13}C NMR spectra of aryl groups in many arylplatinum complexes, where the ^{195}Pt coupling constant on ortho carbon ($^2J_{Pt}$) is smaller than that on meta carbon ($^3J_{Pt}$).[1)]

The present study was supported by Grant-in-Aids for Scientific Research, No.60430011 and 61125007, from the Ministry of Education, Science and Culture.

Conversion of β-Senepoxide to Crotepoxide: Total Synthesis of (+)-Crotepoxide

Seiichiro OGAWA* and Tohei TAKAGAKI
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received July 26, 1986)

Synopsis. Total synthesis of (+)-crotepoxide has been accomplished by chemical conversion of (+)-β-senepoxide which was prepared from (−)-7-*endo*-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid.

Crotepoxide (**1**) was isolated from *Croton macrostachys*[1,2] and *Piper futokadzura*,[3] and has been found to possess significant activity against Lewis lung carcinoma and Walker intramuscular carcinoma. The structure was established by an X-ray crystallographic analysis of the iodohydrin[4] of **1**. Although three total[5-7] and one formal[8] syntheses of the racemic modification of **1** have so far been reported, the optically active natural form (+)-**1** has never been synthesized.

In continuation of our study[9] of highly oxygenated cyclohexane compounds,[10,11] we now describe a total synthesis of (+)-**1** by the chemical conversion of (+)-β-senepoxide[12] [(+)-**6**], the absolute configuration of which has previously been confirmed by a total synthesis.[12,13]

Several attempts to prepare **1** by direct introduction of the *cis*-1,2:3,4-diepoxy functions into *trans*-5,6-diacetoxy-1-benzoyloxymethyl-1,3-cyclohexadiene[14] (**4**) or its *O*-deacetylated derivative[15] using peroxy acid were unsuccessful, and the 4,5-epimer (**5**,[7] epicrotepoxide) of **1** was obtained as a sole diepoxide out of the four possible stereoisomers. Epoxidation of **6**, one of the monoepoxides derived from **4**, also produced **5** exclusively.[14] In this study, epoxidation of **6** to **1** was successfully undertaken through the intermediate bromohydrin **11** prepared from **6**.

Treatment of (±)-**6**[14] with 2 mol equiv *N*-bromoacetamide (NBA) or *N*-bromosuccinimide (NBS) in aqueous dimethyl sulfoxide[16] resulted in the cleavage of the epoxide group to afford the bromohydrin (±)-**7** (49%) and the dihydroxy compound (±)-**8** (21%). The structure of (±)-**7** was confirmed by its conversion to (±)-**6** (63%) with sodium hydrogencarbonate in methanol. A similar treatment of (±)-**6** with NBS in aqueous acetone, ethanol, or dioxane afforded (±)-**7** as the major product. In contrast, when aqueous *N*,*N*-dimethylformamide (DMF) was used as the solvent,[17] (±)-**6** produced two bromo formates [(±)-**9**, 26% and (±)-**10**, 38%], which were obtained by the prefered diaxial opening of the intermediate bromonium ions by an iminium ion. Considering from the product ratio, the formation of the bromonium ion seemed not to be affected by the orientation of the epoxide ring. The structures of (±)-**9** and (±)-**10** were confirmed on the basis of their ^{1}H NMR spectra, which showed the signals due to the ring protons on carbon atoms bearing the bromo atoms as doublets of doublets at δ 4.28 (J=2 and 7.5 Hz) and 4.43 (J=3 and 7.5 Hz), respectively. The former signal did not couple with the epoxide proton, supporting the structure proposed. A treatment of (±)-**9** with methanol at reflux temperature gave the bromohydrin (±)-**11** in good yield. The hydroxy tosylate **12**, prepared by treatment of **1** with *p*-toluenesulfonic acid, was shown to regenerate **1** under the influence of basic alumina.[3] When (±)-**11**, with the same configuration as **12**, was treated in a similar manner, (±)-**11** was recovered unchanged. Finally, it was found that (±)-**11** could be epoxidized only by use of a base strong enough to result in the undesired, partial *O*-deacylation. Thus, (±)-**9** was treated with potassium carbonate in methanol at room temperature for 3 h and the resulting diepoxide (±)-**2** was without isolation acetylated with acetic anhydride in pyridine to give the triacetate (±)-**3** in 60% yield. The ^{1}H NMR spectrum of (±)-**3** was very similar to that of **1**. This is consistent with the proposed structure and excludes a possible migration of the initially formed epoxide group via attack of the vicinal trans hydroxy group. Therefore, the crude (±)-**2** was first selectively benzoylated with benzoyl chloride in pyridine and then acetylated to give rise to a 20% yield[18] of racemic crotepoxide (±)-**1**, which was identified with an authentic sample by comparison of the ^{1}H NMR spectral data.[1]

Likewise, starting from optically active (+)-**6**,[13] (+)-**1** was synthesized. Thus, treatment of (+)-**6** with NBS in aqueous DMF afforded two bromo formates (+)-**9** (22%) and (+)-**10** (30%). The former was converted into (+)-**1** (23%), $[\alpha]_D$ +73° ($CHCl_3$), as described for the preparation of the racemate. The ^{1}H NMR spectrum and the optical rotation were similar with those of an authentic sample.[1]

The absolute structure[4] of (+)-**1** was also supported by the present synthesis and could be correlated to that of (+)-**6**.

Experimental

Melting points were determined in an open capillary tube in a MEL-TEMP melting point apparatus and are uncorrected. ^{1}H NMR spectra were recorded in chloroform-*d* solution[19] with tetramethylsilane as an internal standard. The peak positions are given in δ values. TLC was performed on precoated silica gel 60 F-254 (E. Merck, Darmstadt; 0.2-mm thickness). The silica gel used for column chromatography was Wakogel C-300 (Wako Co., Osaka; 300 mesh). Organic solutions were concentrated below 30 °C under reduced pressure.

(±)-1,2-Di-*O*-acetyl-(1,4/2,3)-3-*C*-benzoyloxymethyl-4-bromo-5-cyclohexene-1,2,3-triol [(±)-7] and (±)-1,2-di-*O*-acetyl-(1,4/2,3)-3-*C*-benzoyloxymethyl-5-cyclohexene-1,2,3,4-tetrol [(±)-8]. A mixture of (±)-β-senepoxide[14] (±)-**6** (200 mg, 0.58 mmol), NBA (160 mg, 1.16 mmol), dimethyl sulfoxide (2 ml), and water (21 µl, 1.17 mmol) was stirred at room temperature for 1 h. TLC (2-butanone-toluene 1 : 5) showed disappearance of (±)-**6** (R_f 0.57) and appearance of two major spots (R_f 0.32 and 0.12). The mixture was diluted with water (5 ml) and extracted with ether (20 ml). The extract was successively washed with aqueous sodium hydrogencarbonate and water, dried, and concentrated. The residue (260 mg) was chromatographed on silica gel (13 g) with 2-butanone-toluene 1 : 4 to give, as the first fraction, (±)-**7** (121 mg, 49%) as needles (from ethanol): Mp 106—107.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.08 (3H, s, OAc), 3.80 (1H, br s, OH), 4.65 (1H, d, J=4.5 Hz, H-6), 4.52 (1H, d) and 4.73 (1H, d) (J=12 Hz, CH_2OBz), 5.57—5.87 (3H, m, H-2, H-3, H-4), 6.01 (1H, ddd, J=1.5, 4.5, and 10.5 Hz, H-5), 7.30—7.67 (3H, m) and 7.98—8.09 (2H, m) (benzoyl).

Found: C, 50.64; H, 4.39%. Calcd for $C_{18}H_{19}BrO_7$: C, 50.60; H, 4.48%.

The second fraction gave (±)-**8** (45 mg, 21%) as a syrup. ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s) and 2.10 (3H, s) (OAc), 3.26 (2H, br s, OH), 5.42—5.60 (1H, br s, H-4), 5.69 (1H, dd, J=1.5 and 10.5 Hz, H-6), 5.94 (1H, dd, J=3.8 and 10.5 Hz, H-5), 7.30—7.66 (3H, m) and 7.99—8.09 (2H, m) (benzoyl).

Found: C, 56.83; H, 5.40%. Calcd for $C_{18}H_{20}O_8 \cdot H_2O$: C, 56.54; H, 5.76%.

The similar results were obtained when NBS was used instead of NBA.

Conversion of (±)-7 to (±)-6. A solution of (±)-**7** (20 mg, 0.05 mmol) in methanol (20 ml) was slowly evaporated in the presence of large excess of sodium hydrogencarbonate at 40 °C. The residue was extracted with chloroform and the product was purified by chromatography to give (±)-**6** (10 mg, 63%), identical with an authentic sample.[14]

(±)-4,5-Di-*O*-acetyl-2,3-anhydro-1-*O*-formyl-(1,2,3,4/5,6)-3-*C*-benzoyloxymethyl-6-bromocyclohexane-1,2,3,4,5-pentol [(±)-9] and (±)-3,4-Di-*O*-acetyl-1,2-anhydro-5-*O*-formyl-(1,2,3,6/4,5)-2-*C*-benzoyloxymethyl-6-bromocyclohexane-1,2,3,4,5-pentol [(±)-10]. A mixture of (±)-**6** (834 mg, 2.41 mmol), NBS (858 mg, 4.82 mmol), DMF (8.2 ml), and water (87 µl, 4.83 mmmol) was stirred at 30 °C for 4 d. TLC (2-butanone-toluene 1 : 5) showed disappearance of (±)-**6** (R_f 0.57) and appearance of two major spots (R_f 0.62 and 0.54). The mixture was processed as described for preparation of (±)-**7** and (±)-**8**. The products (1.35 g) were chromatographed on a silica-gel column (70 g) with 2-butanone-toluene 1 : 2. The first fraction gave (±)-**9** (292 mg, 26%) as prisms (from ether): Mp 113—114 °C. ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s) and 2.17 (3H, s) (OAc), 3.69 (1H, d, J=3 Hz, H-2), 4.58 (1H, dd, J=2 and 7.5 Hz, H-6), 5.15 (1H, dd, J=2 and 4.5 Hz, H-5), 5.52 (1H, d, J=4.5 Hz, H-4), 5.60 (1H, dd, J=3 and 4.5 Hz, H-1), 7.33—7.67 (3H, m) and 8.00—8.11 (2H, m) (benzoyl), 8.19 (1H, s, formyl).

Found: C, 48.68; H, 4.00%. Calcd for $C_{19}H_{19}BrO_9$: C, 48.43; H, 4.06%.

The second fraction gave (±)-**10** (431 mg, 38%) as prisms (from ethanol): Mp 85—87 °C. ^{1}H NMR ($CDCl_3$) δ=1.87 (3H, s) and 2.17 (3H, s) (OAc), 3.77 (1H, d, J=3 Hz, H-1), 4.43 (1H, dd, J=3 and 7.5 Hz, H-6), 4.30 (1H, d) and 4.57 (1H, d) (J=11.5 Hz, CH_2OBz), 5.17 (1H, dd, J=2 and 4.5 Hz, H-4), 5.41 (1H, dd, J=2 and 7.5 Hz, H-5), 5.53 (1H, d, J=4.5 Hz, H-3), 7.33—7.67 (3H, m) and 8.00—8.11 (2H, m) (benzoyl), 8.03 (1H, s, formyl).

Found: C, 48.23; H, 3.98%. Calcd for $C_{19}H_{19}BrO_9$: C, 48.43; H, 4.06%.

Similarly, (+)-β-senepoxide[13] (+)-**6** (795 mg, 2.3 mmol) was treated with NBS in aqueous DMF to give, after chromatography, the (1*S*)-enantiomer (+)-**9** (241 mg, 22%), $[\alpha]_D^{21}$ +2.1° (*c* 2.4, $CHCl_3$), and the (3*S*)-enantiomer (+)-**10** (320 mg, 30%), $[\alpha]_D^{21}$ +40° (*c* 1.8, $CHCl_3$). Both compounds were characterized by comparison of their ^{1}H NMR spectral data with those of racemic modification. Mass spectrum, *m/z* (relative intensity); for (+)-**9**, 425.0203 ($M^+ - HCO_2$, 17.7), for (+)-**10**, 425.0215 ($M^+ - HCO_2$, 90.6).

(±)-4,5-Di-*O*-acetyl-2,3-anhydro-(1,2,3,4/5,6)-3-*C*-benzoyloxymethyl-6-bromocyclohexane-1,2,3,4,5-pentol [(±)-11]. A solution of (±)-**9** (110 mg, 0.23 mmol) in methanol (3 ml) was refluxed for 10 min. TLC (2-butanone-toluene 1 : 5) showed disappearance of (±)-**9** (R_f 0.62) and appearance of one major (R_f 0.28) and one minor spots (R_f 0.34). The mixture was concentrated and the residue was eluted from a silica-gel column (5 g) with 2-butanone-toluene 1 : 6 to give (±)-**11** (82 mg, 80%) as a syrup; ^{1}H NMR ($CDCl_3$) δ=1.95 (3H, s) and 2.14 (3H, s) (OAc), 3.00 (1H, br s, OH), 3.69 (1H, d, J=4.1 Hz, H-2), 4.41 (1H, m, H-1), 4.28 (1H, d) and 4.55 (1H, d) (J=11.5 Hz, CH_2OBz), 5.14 (1H, dd, J=2.2 and 5.7 Hz, H-5), 5.62 (1H, d, J=5.7 Hz, H-4), 7.31—7.68 (3H, m) and 8.00—8.10 (2H, m) (benzoyl).

Found: C, 47.78; H, 4.22%. Calcd for $C_{18}H_{19}BrO_8 \cdot 0.5H_2O$: C, 47.84; H, 4.42%.

(±)-2,3-Di-*O*-acetyl-1,6 : 4,5-dianhydro-(1,2,4,5,6/3)-1-*C*-(acetoxymethyl)cyclohexane-1,2,3,4,5,6-hexol [(±)-3]. A mixture of (±)-**9** (30 mg, 0.06 mmol), anhydrous potassium carbonate (12 mg), and methanol (5 ml) was stirred at room temperature overnight. TLC (chloroform-methanol 8 : 1) showed a formation of one major (R_f 0.19) and one minor components (R_f 0.23). The mixture was neutralized with M hydrochloric acid and concentrated, and the residue was acetylated with acetic anhydride and pyridine in the usual way. The product was purified by chromatography on silica gel and crystallized from ethanol to give, as the main product, (±)-**3** (11 mg, 60%) as needles: Mp 70—70.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.06 (6H, s) and 2.09 (3H, s) (OAc), 3.05 (1H, dd, J=1.5 and 3 Hz, H-4), 3.50 (1H, dd, J=2 and 3 Hz, H-5), 3.50 (1H, d, J=2 Hz, H-6), 3.79 (1H, d) and 4.42 (1H, d) (J=11 Hz, CH_2OAc), 4.87 (1H, dd, J=1.5 and 9 Hz, H-3), 5.58 (1H, d, J=9 Hz, H-2).

Found: C, 52.19; H, 5.16%. Calcd for $C_{13}H_{16}O_8$: C, 52.00; H, 5.37%.

Synthesis of Crotepoxide. Compound (±)-**9** (169 mg, 0.36 mmol) was treated with potassium carbonate (75 mg, 0.54 mmol) in methanol (25 ml) as described for the preparation of (±)-**3**. The resulting trihydroxy compound was selectively benzoylated with benzoyl chloride (84 µl, 0.72 mmol) in pyridine (3 ml) at −15 °C for 10 min, and then for 5 h at room temperature. TLC (chloroform-methanol 8 : 1) showed one major spot (R_f 0.54), together with several minor spots. Acetic anhydride (1 ml) was then added to the mixture, and, after 2 h at room temperature, the mixture was

processed in the usual way. The mixture of products was fractionated by a silica-gel column (10 g) with 2-butanone–toluene 1 : 10 to give, as a major product, (±)-**1** (26 mg, 20% based on **9** used) as needles (from ethanol): Mp 109—111 °C (lit,[4] Mp 110—111, 128—129 °C). Crystals show a double melting point (melted at 109—111 °C, resolidified, and then melted again at ca. 128 °C). The ^{1}H NMR ($CDCl_3$) spectral data were shown to be identical with those of an authentic sample.[4,5] (Found: C, 59.67; H, 4.89%).

Likewise, (+)-crotepoxide (+)-**1** was obtained, in 23% yield, by epoxidation of (+)-**9** followed by selective acylation; needles (from methanol): Mp 145—147 °C, $[\alpha]_D^{25}$ +73° (*c* 0.43, $CHCl_3$). lit,[1] Mp 150—151 °C, $[\alpha]_D^{25}$ +74° (*c* 1.7, $CHCl_3$). The ^{1}H NMR spectrum was superimposable on that of a racemic modification. (Found: C, 59.72; H, 4.88%).

We express our sincere thanks to Mr. Akio Takahashi for his elemental analyses. We also thank Dr. Shigeru Nishiyama (Department of Chemistry, Faculty of Science and Technology, Keio University) for measurement of the mass spectra.

Improvement of Porphyrin Photovoltaic Cells in Panchromaticities and Quantum Yields by Use of Tetrabenzoporphyrin Skeleton

Kazuo YAMASHITA,* Yutaka HARIMA, Hideyuki KUBOTA,† and Hitomi SUZUKI†

(Received August 21, 1986)

Synopsis. Expansion of the porphyrin π electron system by using a tetrabenzoporphyrin (TBP) skeleton leads to better spectral match to the solar spectrum and high quantum yields when the porphyrins are used as sensitizers. Metallotetrabenzoporphyrins such as MgTBP and ZnTBP rank among the most efficient organic photoconducting materials studied so far.

Solar cells that utilize the photoelectric properties of organic materials stand still far from practical use because of conversion efficiencies much lower than those of traditional inorganic solar cells as well as no long-term stability.[1] However, solar cells made from organic compounds have some unique advantages compared with the inorganic devices in respect of low cost, ease of fabrication, flexibleness etc.

Several years ago, we found that the more easily oxidized porphyrins exhibited the higher quantum yields and that peripheral substitution could modulate the oxidation potential of the porphyrin and that long aliphatic chain substituents decreased the quantum yields, presumably by acting as insulators towards electron transport.[2] These results suggest that expansion of the porphyrin π electron system may lead to lower oxidation potentials as well as facilitate energy and electron transfer by increasing π-π interactions between neighbouring molecules and result in the increase of photocurrents and thus the quantum yields.[3]

In the present paper we show evidence that metallotetrabenzoporphyrins such as (tetrabenzoporphyrinato)magnesium (II) (MgTBP) and ZnTBP are indeed oxidized very easily in comparison with other porphyrins studied and act as most efficient sensitizers in simple photovoltaic devices based on Al/porphyrin Schottky barriers and organic *p*-*n* junctions.

Experimental

Porphyrins and metalloporphyrins used were prepared and purified by the methods in references.[4-6] Phthalocyanine (H_2Pc) and (phthalocyaninato)zinc(II) (ZnPc) were purchased from Tokyo Kasei Co. and purified by sublimation before use. Polycarbonate resin Panlite® (Pnl) used as a polymer binder was kindly supplied by Teijin Chemicals Ltd. Dichloromethane and dichloroethane were redistilled after dessication with calcium hydride. An amount of 10 mg of the dye was dispersed in 5 ml of 1 %(W/V) Panlite-dichloroethane solution by using a TomySeiko Handy Sonic UR-20P. A particulate dye film was prepared by casting a suitable amount of the dye-polymer mixture prepared above on an indium-tin oxide(ITO)-coated glass plate. Preparation of an ITO film, fabrication of a M/porphyrin/M′ sandwich-type cell, in which M or M′ denotes an ITO or a metal electrode, and measurements of dark and photoelectric properties of the photovoltaic cells were carried out as described previously.[7,8] Photocurrents were normalized in such a way that the intensity of monochromatic light incident on the interface of the dye film with the illuminated metal was constant at 10 μW cm^{-2} unless otherwise specified.

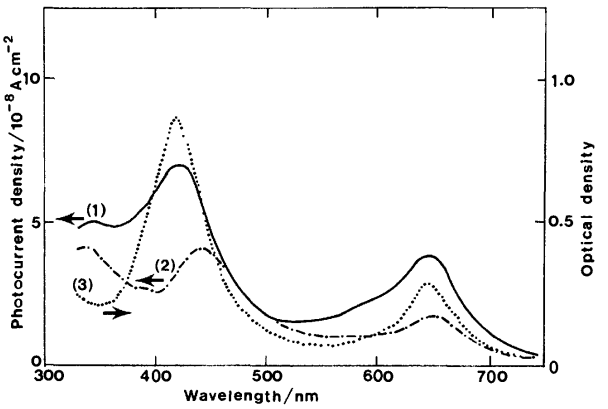

Fig. 1. Action spectra of short-circuit photocurrents for the Schottky barrier cell of Al(8 nm)/CdTBP (60 nm)/Au(9 nm). Curves (1) and (2) are obtained on illumination of the Al and the Au electrodes, respectively. Curve (3) shows the optical absorption spectrum of the CdTBP film used in the sandwich cell.

Results and Discussion

Figure 1 displays short-circuit photocurrent action spectra for the Al/CdTBP/Au Schottky barrier cell with an optical absorption spectrum of the CdTBP film. Currents passing from Al to Au through the cell were taken to be positive. For thin CdTBP films the shapes of the action spectra almost were the same for light incident on both sides. For thick films, however, the action spectra agreed well to the absorption spectrum only when the Al side was illuminated. Similar results were observed with other tetrabenzoporphyrin derivatives and can be explained in terms of an optical filtering effect[9] due to the interposed porphyrin phase on the basis of a band model of *p*-type semiconductors. Namely, only photons absorbed near the Al blocking contact are effective for generation of charge carriers, resulting in the photoresponse, while the Au contact is inert for illumination owing to the ohmic contact.

We further note that the tetrabenzoporphyrins absorb throughout the range of visible light and the light absorbing properties approach those found for chlorophylls in vivo (λ_{max}=680 and 700 nm for Photosystems II and I of green plants, respectively). The maximum fraction of the solar spectrum that can be collected by ZnTBP molecules increases to about 47%,

Table 1. Summary of Photocurrent Quantum Yields of Porphyrin and Metalloporphyrin Films with First Ring Oxidation Potentials

a) Abbreviations used; OMTBP 1,4,8,11,15,18,22,25-octamethyltetrabenzo[*b,g,l,q*]porphyrin; P porphyrin; TBP tetrabenzoporphyrin; TPP 5,10,15,20-tetraphenylporphyrin. b) First ring oxidation potentials at Pt in CH_2Cl_2 with 0.1 mol dm^{-3} tetrabutylammonium perchlorate. c) A Al/Porphyrin/Au; B Al/Porphyrin/Ag; C Al/Porphyrin/0.1 mol dm^{-3} $K_3[Fe(CN)_6]$ and 0.1 mol dm^{-3} $K_4[Fe(CN)_6]$/Pt. d) Quantum yield is defined as the number of the electrons produced per photon incident on the dye film at 10 μW cm^{-2}.

which is about 10 or 15% larger than that for (2,3,7,8,12,13,17,18-octaethylporphyrinato)zinc(II) (ZnOEP) or (5,10,15,20-tetraphenylporphyrinato)zinc-(II) (ZnTPP) molecules.[10] Thus the expansion of the porphyrin π electron system by using the TBP skeleton is very effective to improve the panchromaticity of the porphyrin, resulting in the increase of conversion efficiency as shown below.

The first ring oxidation potentials of 0.23 and 0.40 V vs. SCE found for MgTBP and ZnTBP rank these macrocyclic compounds as the easiest to oxidize among a large variety of Mg and Zn porphyrins (Table 1 and see Felton's review[11]). Judging from the oxidation potentials and the exponential correlation previously found between the oxidation potential of the porphyrin and the photocurrent quantum yield, it is expected that both MgTBP and ZnTBP are effective more than MgP. However, the fact is that MgTBP and ZnTBP show photocurrent quantum yields somewhat smaller than MgP. At this time it is necessary to recall the previous finding that for a given porphyrin ligand the quantum yields parallel the first ring oxidation potentials of the porphyrins, but all porphyrins do not fall on the same curve.[2] This might be attributable to a combination of various factors such as the ease of charge carrier formation relating with the oxidation potential of the porphyrin, the packing of porphyrin molecules in solid films and the extent of π-π overlap between the porphyrin rings, which facilitates energy and electron transfer.[12] The quantum yield of MgTBP may be greater than that of MgP under illumination of polychromatic lights such as solar rays, because the maximum fraction of the solar spectrum that can be collected by the tetrabenzo compound is larger than that by MgP. The photocurrent quantum yields for the sandwich-type Schottky barrier cells made from the metallotetrabenzoporphyrins are in the range from 10^{-2} to 10^{-1}. Comparison of the photocurrent quantum yields found here with those obtained for other porphyrins shows distinctly that tetrabenzo compounds fall within the most efficient organic light converters investigated so far.

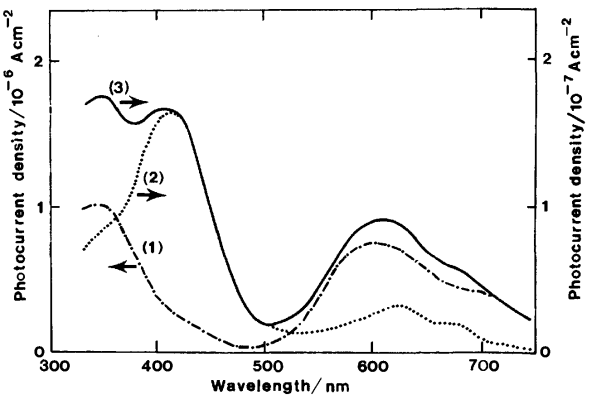

Fig. 2. Action spectra of short-circuit photocurrents for the particulate-type Schottky barrier cells of (1) ITO/H_2Pc-PnI/Al, (2) ITO/TPTBP-PnI/Al and (3) ITO/H_2Pc, TPTBP-PnI/Al. Illumination is made through the Al electrode.

In more recent years photovoltaic cells prepared by dispersing fine particles of pigment in a polymer binder have received much attention as promising devices.[13,14] In particular polar polymers such as poly(vinylidene difluoride) and polyacrylonitrile have been found to give high quantum efficiencies.[15] Up to date, however, there has been no report concerning the particulate-type photovoltaic cells using the porphyrins.

Figure 2 illustrates short-circuit photocurrent action spectra for three kinds of particulate-type Schottky barrier cells. The photocurrents observed with the particulate-type cells are corrected roughly for the reflection and the absorption of light at the Al/dye-PnI interface. Because, it was very hard to measure precisely the intensity of light incident on the dye-polymer film through the Al phase owing to the complex reflection of light, scattering etc. due to the roughness of the Al/dye-polymer interface. The first and the

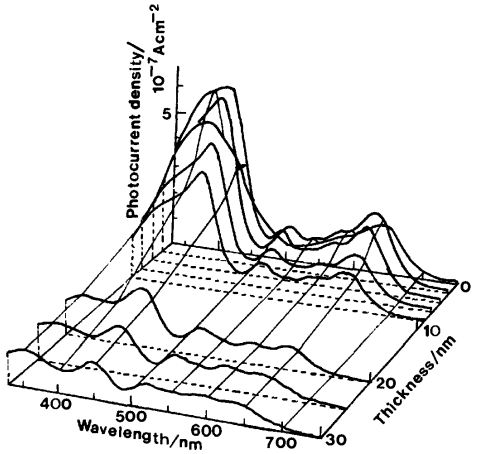

Fig. 3. Dependence of short-circuit photocurrent action spectra for the Au/ZnTBP(40 nm)/T(4-Py)P/Al cells on thickness of the T(4-Py)P film, when illuminated through the Al electrode.

second cells were prepared by dispersing H_2Pc and 5,10,15,20-tetraphenyltetrabenzoporphyrin (TPTBP) in Pnl-dichloroethane solutions, respectively. The third cell was made by dispersing equivalent amounts of H_2Pc and TPTBP in the polymer binder. It is noteworthy that TPTBP is only one sample giving a fairly good photoconducting film with Pnl among porphyrins studied. The shapes of action spectra (1) and (2) resemble those of optical absorption spectra of H_2Pc and TPTBP films. It is clear that combination of TPTBP and H_2Pc brings about the best spectral match to the solar spectrum among them. Unfortunately, however, magnitudes of the photocurrents observed with the third cell are about one tenth as large as those for the ITO/H_2Pc-Pnl/Al cell, though both cells generate photovoltages greater than 1 V.

Figure 3 illustrates short-circuit photocurrent action spectra for the Au/ZnTBP(40 nm thick)/5,10,15,20-tetra(4-pyridyl)porphyrin [T(4-Py)P]/Al *p-n* junction cell with varying thickness of the T(4-Py)P film. The photovoltaic spectral cosensitization effect[16] is clearly observed with the cell having a thin T(4-Py)P film. The optimum thickness of the T(4-Py)P film for the quantum yield seems to be around 2 nm, being somewhat smaller than that (about 7 nm) for the analogue T(3-Py)P in the case of a Au/ZnPc(50 nm thick)/T(3-Py)P/Al cell.[16] Such a thin film of T(4-Py)P may be composed of insular sublimates of the porphyrin. The fraction of the solar spectrum that can be collected by the ZnTBP/T(4-Py)P *p/n* phases becomes 1.3 times as great as that by the ZnTBP phase alone in the Al/ZnTBP Schottky barrier cell. The photocurrent quantum yield and the power conversion efficiency reach about 20 and 2 % respectively for monochromatic incident light (10 μW cm^{-2}) at 430 nm.

Thus the facile, chemical stability (ZnTBP can be heated in air without decomposing), light absorption properties and high quantum yields of the metallotetrabenzoporphyrins suggest that these macrocycles are attractive potential candidates for solar energy conversion devices.

Electrochemical Studies of Poly(mercaptohydroquinone) and Poly(mercapto-*p*-benzoquinone) Films Prepared by Electropolymerization. I. Preparation of pH Microsensor and Its Fundamental Characteristics

Gorou ARAI,* Takashi KOIKE, and Iwao YASUMORI

(Received September 3, 1986)

Synopsis. Carbon fibers were electrochemically modified with poly(mercaptohydroquinones). These modified carbon fiber electrodes showed excellent Nernstian response to pH from ca. 2 to 10 and could respond within 2s in the pH range from 3 to 8. These electrodes could work well one month after kept stored in a weak acidic buffer solution and could be easily restored by electroreduction even after their functions had been lowered by successive pH measurements.

In recent years, there has been considerable interest in chemically modified electrodes because of their novel properties such as selective electrolysis,[1] electrocatalysis,[2] and selective ion sensing.[3] Polymeric quinone-hydroquinone systems have been investigated because of their usefulness as specific regenerable redox reagents.[4] Hence, electrodes modified with several poly(benzoquinone) films have been prepared by either the dip-drying or the adsorption method, and their electrochemical behavior and applications in electrocatalysis have been examined by many workers.[5] Recently, we have prepared a poly(mercapto-*p*-benzoquinone) film (PQ) by electrooxidation of mercaptohydroquinone on a glassy carbon electrode[6] and have reported its basic electrochemical behavior.[7] Electrodes modified with PQ thus prepared or poly(mercaptohydroquinone) film (PH_2Q) obtainable by electroreduction of PQ, are expected to possess several novel properties such as mentioned above. More recently, it has been observed that a fine carbon fiber electrode (CFE) modified with PH_2Q (PH_2Q/CFE) is capable of excellent Nernstian response to pH.[8] But its durability was occasionally observed to get lowered after successive pH measurements. In order to reveal the cause for this poor durability, effects of several pretreatments on CFE have been examined by means of a scanning electron microscope. Moreover, three polymer films, namely poly(mercaptomethylhydroquinones)[9] ($PMeH_2Q$), poly(3-mercapto-2,5-dimethylhydroquinone)(PMe_2H_2Q), and PH_2Q films, were prepared on CFE under the same preparation conditions (with respect to, e.g., supporting electrolyte, pH of electrolytic solution, concentration of mercaptohydroquinones, and oxidation potential) and their behavior as pH sensors were investigated in detail. We report here on preferable pretreatment of CFE for the preparation of PH_2Q's/CFE with good durability and their excellent functions as pH microsensors.

Experimental

Mercaptohydroquinones used were synthesized and purified according to the method of Alcolay.[10] Chemicals used for the synthesis of mercaptohydroquinones were of reagent grade. All the other chemicals were of analytical grade and were used without further purification. Electropolymerization of mercaptohydroquinones was performed under potentiostatic conditions with a three-electrode system consisting of a CFE (Torayca T-300, Toray Industries Co., 7 μm in diameter) working electrode, a Pt wire counter electrode, and a saturated calomel electrode (SCE) in a conventional two-compartment glass cell. Potentiostatic electrolysis and cyclic

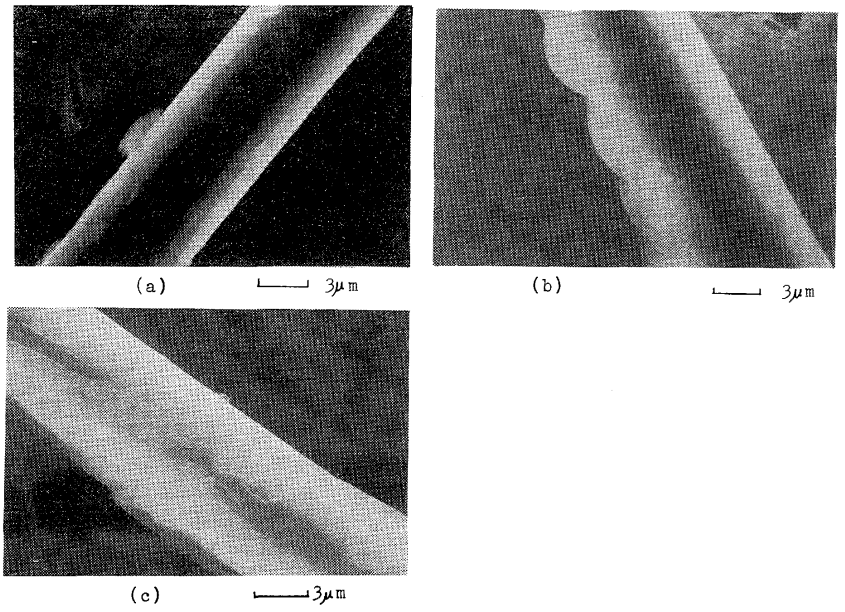

Fig. 1. Scanning electron micrographs of (a) PH_2Q/CFE_0, (b) PH_2Q/CFE_1, and (c) PH_2Q/CFE_2.

voltammetry were performed by using a potentiostat/galvanostat (Model HA-304, Hokuto Denko Co.). PH_2Q/CFE, $PMeH_2Q$/CFE, and PMe_2H_2Q/CFE were attached with Ag paste to an end of a Cu wire which was in a coaxial wire as shown in the previous paper,[8] and their electrode potentials in a buffer solution were measured with an electrometer (Model EM-02, Toho Chemical Research Co.). Scanning electron micrographs were taken on a scanning electron microscope (SEM) (JEOL JSM-35C).

Results and Discussion

Three types of pretreatments were examined on CFE: *Procedure 1* in which a CFE was thoroughly rinsed with deionized water; the CFE thus treated is denoted as CFE_0. *Procedure 2* in which a CFE was thoroughly rinsed with acetone and then washed with deionized water; the CFE thus treated is denoted as CFE_1. *Procedure 3* in which a CFE was rinsed with acetone, then electrochemically cleaned at −1.5 V (vs. SCE), where hydrogen evolution occurs in a Britton-Robinson buffer solution of pH 5.0, for ca. 30 min, and finally washed with deionized water; the CFE thus treated is denoted as CFE_2. CFE_o, CFE_1, and CFE_2 were modified with PQ by potentiostatic electropolymerization using a Britton-Robinson buffer (20 vol% ethanol) solution of pH 6.0 of mercaptohydroquinone (4×10^{-4} mol dm^{-3}) at +0.7 V (vs. SCE) for 30 min under a nitrogen atmosphere at room temperature.

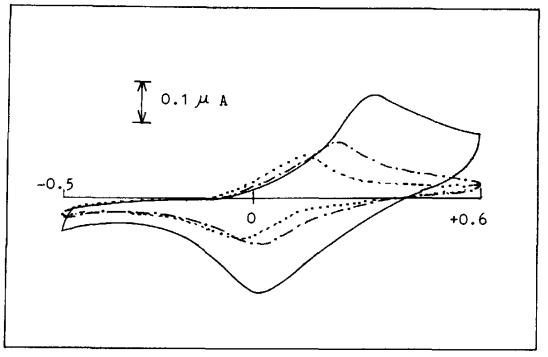

Fig. 2. Cyclic voltammograms of PH_2Q/CFE(——), $PMeH_2Q$/CFE(-·-·-), and PMe_2H_2Q/CFE(·····) in the Britton-Robinson buffer solution of pH 6.0 in an atmosphere of nitrogen at 25°C. Scan rate: 50 mVs^{-1}. Effective lengths of these electrodes dipped into the buffer solution were 3 cm.

Then the PQ's thus prepared were reduced at −0.5 V (vs. SCE) for 30 min in a buffer solution of pH 5.0 to give PH_2Q's. PH_2Q/CFE_0, PH_2Q/CFE_1, and PH_2Q/CFE_2 were stored in a weakly acidic buffer solution and were thoroughly rinsed with deionized water just before SEM measurement. Figure 1 shows scanning electron micrographs of PH_2Q/CFE_0 (a), PH_2Q/CFE_1 (b), and PH_2Q/CFE_2 (c). These micrographs reveal that CFE_2 is uniformly coated over the whole surface with a relatively large amount of PH_2Q, whereas CFE_1 is partially coated with PH_2Q, and that CFE_0 is scarcely coated. Only PH_2Q/CFE_2 displayed good durability. Moreover, PMe_2H_2Q could not be prepared on CFE_1 or CFE_2. These results obtained by SEM indicate that uniform coating of PH_2Q on CFE is required for PH_2Q/CFE to possess good durability as a pH sensor and that the electrochemical cleaning method used here is a preferable pretreatment of the CFE surface. Unless otherwise stated, subsequent examinations were carried out with the CFE_2 prepared as described above. Cyclic voltammograms of CFE's modified with PH_2Q, $PMeH_2Q$, or PMe_2H_2Q are shown in Fig. 2. The anodic and cathodic current integrals of these cyclic voltammograms indicate that the amount of electroactive sites developed on CFE's are in the order: PH_2Q (2.9×10^{-1} mC cm^{-2}) > $PMeH_2Q$ (1.5×10^{-1} mC cm^{-2}) > PMe_2H_2Q (1.1×10^{-1} mC cm^{-2}). The scanning electron micrographs (Fig. 3) of $PMeH_2Q$/CFE and PMe_2H_2Q/CFE surfaces indicate that $PMeH_2Q$ and PMe_2H_2Q, as well as PH_2Q (Fig. 1), are coated uniformly over the whole surfaces of CFE's. Characteristics of their pH responses are summarized in Table 1. Of these three electrodes, only PMe_2H_2Q/CFE could hardly get wetted in an acidic buffer solution having pH lower than 4.5, while in alkaline solution PMe_2H_2Q/CFE was superior to the others in Nernstian response and durability. As seen from Fig. 2, hydroquinone moieties which provide redox sites in PH_2Q, $PMeH_2Q$, and PMe_2H_2Q have an increasing tendency to shift their redox potentials towards negative with increasing number of methyl groups. This tendency is consistent with the fact that redox potentials of hydroquinones are usually shifted more negative with increasing number of electron-releasing substituents such as methyl group.[11] Furthermore, it has been known that acid-base dissociation constants of hydroquinones substituted by electron-releasing groups are smaller than that of unsubstituted hydroquinone

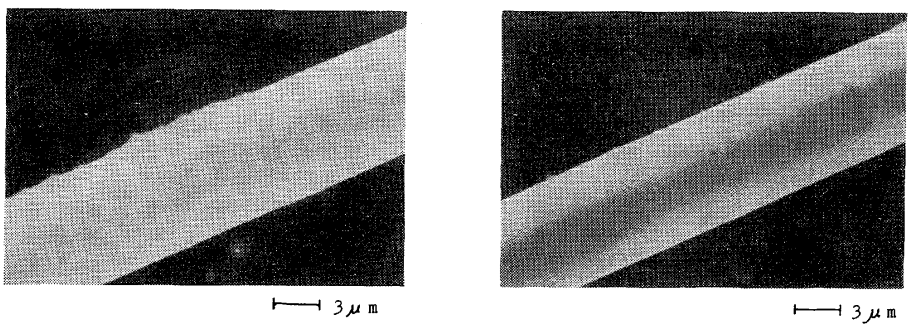

Fig. 3. Scanning electron micrographs of $PMeH_2Q$/CFE (a) and PMe_2H_2Q/CFE (b).

Electrode[b]	Slope	Response range	Response-time pH range (I) within 2s (II) within 10s
	mV/pH	pH	
PH_2Q/CFE	59.0±0.4[c]	1.8—8.5	(I) 3.0—8.0
	30.0±0.8[c]	<10.0	(II) 1.8—3.0, 8.0—9.0
$PMeH_2Q$/CFE	58.9±0.4[c]	2.0—9.0	(I) 3.0—8.0
	30.0±0.8[c]	<10.0	(II) 2.0—3.0, 8.0—9.5
PMe_2H_2Q/CFE	58.9±0.3[c]	4.5—10.0	(I) 4.5—9.0
	30.0±0.7[c]	<11.0	(II) 9.0—10.0

a) Britton-Robinson buffer (2<pH<11) and Clark-Lubs buffer (pH<2) were used as standard pH solutions. b) The effective length immersed into the buffer was ca. 1 mm. c) The standard deviation for slopes obtained with multiple calibrations over 20 times.

in aqueous solution.[12] As can be seen in the response ranges in Table 1, the upper limit of linear response with a slope of ca. 59 mV/pH for each electrode is in the order of PMe_2H_2Q/CFE > $PMeH_2Q$/CFE > PH_2Q/CFE. Consequently, it would be reasonable to judge that the upper limits of linear response (ca. 59 mV/pH) for PH_2Q/CFE, $PMeH_2Q$/CFE, and PMe_2H_2Q/CFE are dependent on the dissociation constants of hydroquinone moieties in PH_2Q, $PMeH_2Q$, and PMe_2H_2Q, respectively. All these electrodes could work well for at least one month when kept stored in a weak acidic buffer solution. But their pH responses gave rise to apparent deviations from the Nernstian behavior after successive measurements in alkaline buffer solution. It is considered that this undesirable behavior results from oxidation of the hydroquinone to quinone moieties in PH_2Q, $PMeH_2Q$, and PMe_2H_2Q by dissolved oxygen gas, because a sufficient deaeration of an alkaline solution by bubbling nitrogen gas could serve to slow down the rate of lowering of their durabilities. Moreover, even after used successively in an alkaline solution, both $PMeH_2Q$/CFE and PMe_2H_2Q/CFE could be practically restored by electroreduction of the resulting quinone moieties to the hydroquinone ones at −0.5 V (vs. SCE) in a weak acidic buffer solution for ca. 30 min in a nitrogen atmosphere. On the other hand, the PH_2Q/CFE whose response function had been lowered could scarcely be restored by the electroreduction. This poor restoration of PH_2Q/CFE may be attributed to the fact that no substituted quinones are more susceptible to aqueous decomposition caused by attack of hydroxide ion than methyl-substituted quinones in alkaline solution.[13] All of PH_2Q/CFE, $PMeH_2Q$/CFE, and PMe_2H_2Q/CFE prepared under the electrolysis conditions of 1×10^{-4} to ca. 1×10^{-3} mol dm^{-3} in concentration, 20 min to ca. one hour in electrolysis time, and +0.5 to +0.7 V (vs. SCE) in electrolysis potential, exhibited similar excellent Nernstian responses to pH as shown in Table 1 and displayed good durabilities. When mercaptohydroquinones were electrooxidized at higher concentrations or for longer period than have been specified above, PH_2Q/CFE, $PMeH_2Q$/CFE, and PMe_2H_2Q/CFE obtained could not respond well to pH. Moreover, when mercaptohydroquinones were oxidized above +0.8 V (vs. SCE) on CFE, the resulting modified CFE's made no response to pH. We have previously reported that mercaptohydroquinone shows an anodic wave which is probably caused by oxidation of a thiol group, at +0.8 V (vs. SCE) on DC polarogram in a Britton-Robinson buffer solution (pH 6.0) using a glassy carbon electrode.[6] Therefore, the no-response behavior observed probably results from oxidation of sulfide linkage in PH_2Q, $PMeH_2Q$, and PMe_2H_2Q.[14] As has been mentioned above, the PH_2Q/CFE, the $PMeH_2Q$/CFE, and the PMe_2H_2Q/CFE are capable of excellent functioning as pH microsensors and will, therefore, be applicable to various microchemical works.

Reactions of α,β-Unsaturated Carboxylates, Malonates and Phenylacetates with Manganese(III) Acetate in the Presence of Chloride Ions

Hiroshi YONEMURA, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received July 26, 1986)

Synopsis. The reaction of alkyl (*E*)-3-phenylpropenoates with manganese(III) acetate in the presence of Cl^- ions gave alkyl (*Z*)-2-chloro-3-phenylpropenoates and alkyl 2,3-dichloro-3-phenylpropanoates. Ethyl (*E*)-2,3-diphenylpropenoate yielded ethyl 2,3-dichloro-2,3-diphenylpropanoate. Alkyl 3,3-diphenylpropenoates gave mainly alkyl 2-chloro-3,3-diphenyl-propenoates. Ethyl 1-cyclohexenecarboxylate gave ethyl 1,2-dichlorocyclohexanecarboxylate. Dimethyl malonate yielded dimethyl dichloromalonate and tetramethyl 1,2-dichloro-1,1,2,2-ethanetetracarboxylate. Substituted malonates resulted in α-chloro derivatives. Methyl phenylacetates gave α-acetoxy derivatives.

Although there have been many investigations into the reaction of manganese(III) acetate,[1] the reaction of this reagent in the presence of the Cl^- ion, which forms a complex, has not been fully examined. In connection with earlier studies of the reactions of aromatic compounds,[2] olefins,[2,3] aryl ketones,[4] and phenyl-substituted propenoic acids,[5] we have now examined the reaction of several kinds of esters with the complex in the hope that this would give chlorinated compounds: we found that α,β-unsaturated esters, malonates, and phenylacetates are reactive towards this complex. We will describe these reactions in this paper.

Results and Discussion

α,β-Unsaturated Esters. The reaction of ethyl (*E*)-3-phenylpropenoate (**1a**) with the manganese(III)-Cl^- complex at a molar ratio of **1a**: Mn(III): Cl^- of 1 : 6 : 12,[6,7] resulted in two products, ethyl 2,3-dichloro-3-phenylpropanoate (**2a**) and ethyl (*Z*)-2-chloro-3-phenylpropenoate (**3a**). The former was the major product. When methyl (*E*)-3-(4-chlorophenyl)propenoate (**1b**) was oxidized with the complex, methyl 2,3-dichloro-3-(4-chlorophenyl)propanoate (**2b**) and methyl (*Z*)-2-chloro-3-(4-chlorophenyl)propenoate (**3b**) were obtained similarly, but in this case **3b** was predominant. Methyl (*E*)-3-(3-nitrophenyl)propenoate (**1c**) and methyl (*E*)-3-(4-methylphenyl)propenoate (**1d**) gave the corresponding 2-chloro derivatives (**3c** and **3d**), while **1d** also yielded **2d** and methyl 3-acetoxy-2-chloro-3-(4-methylphenyl)propanoate (**4d**). When methyl (*E*)-(4-methoxyphenyl)propenoate (**1e**) was oxidized with the complex, methyl (*Z*)-2-chloro-3-(4-methoxyphenyl)propenoate (**3e**), methyl 2-acetoxy-3-chloro-3-(4-methoxyphenyl)propanoate (**4e**) and *p*-anisic acid (**5**) were obtained (Table 1, Entries 1—5).

The reaction of methyl (*E*)-2,3-diphenylpropenoate (**6**) with the manganese(III) acetate-Cl^- complex gave methyl 2,3-dichloro-2,3-diphenylpropanoate (**7**) exclusively (Entry 6).

The reactions of alkyl 3,3-diphenylpropenoates (**8a** and **8b**) gave 2-chloro derivatives (**9a** and **9b**) as the major products, while ethyl 9-fluorenylideneacetate (**8c**) yielded ethyl 9-fluorenylidenechloroacetate (**9c**) and ethyl (9-acetoxy-9-fluorenyl)chloroacetate (**12**) (Entries 7, 8, and 9). The reaction of ethyl 1-cyclohexenecarboxylate (**13**) with the complex yielded only ethyl 1,2-dichloro-1-cyclohexanecarboxylate (**14**) (Entry 10).

Dialkyl Malonates (15a—f). When diethyl methylmalonate (**15a**) was oxidized with the manganese(III) acetate-Cl^- complex, it gave diethyl α-(chloro)-methylmalonate (**16a**) in an excellent yield (Entry 11). Butyl (**15b**) and benzylmalonate (**15c**) yielded monochloro derivatives (**16b** and **16c**) (Entries 12 and 13). Dimethyl chloromalonate (**15d**) gave dimethyl dichloromalonate (**16d**) (Entry 14). Dimethyl malonate (**15e**), on the other hand, yielded two products: dimethyl dichloromalonate (**16d**) and a dimeric compound (**17d**) which was also obtained by the reaction of **15d** with manganese(III) acetate alone (Entries 15 and 16). Dimethyl bromomalonate (**15f**) gave a mixture of various products, from which only tetramethyl 1,2-dibromo-1,1,2,2-ethanetetracarboxylate (**17f**) was isolated and that is in a poor yield (Entry 17). The **15f** yielded tetramethyl ethenetetracarboxylate (**18**) on prolonged heating when the reaction was conducted with manganese(III) acetate alone (Entry 19).

Methyl Phenylacetates (19a and 19b). The reactions of methyl 4-methoxyphenylacetate (**19a**) and methyl 3,4-dimethoxyphenylacetate (**19b**) yielded α-acetoxy derivatives (**20a** and **20b**) in good yields (Entries 20 and 22). When **19a** was oxidized with manganese(III) acetate alone over a prolonged reaction time, methyl 3-(acetoxymethyl)-4-methoxyphenylacetate (**21**) was obtained in a minor quantity, together with **20a** (Entry 21). Unsubstituted ethyl phenylacetate was found to be unreactive towards the manganese(III) acetate-Cl^- complex under the present reaction conditions.

Conclusion. The reaction of methyl (*E*)-3-phenylpropenoate with the manganese(III) acetate-Cl^- was previously briefly reported to give methyl 2,3-dichloro-3-phenylpropanoate and methyl (*E*)-2-chloro-3-phenylpropenoate.[3] However, we found that a substituent on the aromatic ring and an extra phenyl group at the C-2 or C-3 change the product distribution completely. The reaction of methyl (*E*)-3-(4-chlorophenyl)-propenoate (**1b**) gave the 2-chloro derivative (**3b**) as the major product, while methyl (*E*)-3-(4-methoxyphenyl)-propenoate (**1e**) yielded methyl 3-acetoxy-2-chloro-3-(4-methoxyphenyl)propanoate (**4e**). The reaction of **1e** ended in a shorter reaction time compared with the others, whereas **1c**, which has an electron-withdrawing nitro group, was less reactive and 25% of the **1c** was

a) The reaction was carried out at the reflux temperature. b) Substrate: Mn(III): LiCl. c) Isolated yields based on the substrate added. All products were reasonably pure after TLC separation. d) **1c** (25%) was recovered. e) **19a** (39%) was recovered.

recovered even when an excess of the reagent was used. A phenyl group at the C-2 in a propenoate favors the formation of 1,2-dichloro compound **7**, while a phenyl group at the C-3 makes 2-chloro derivatives (**9a** and **9b**) the major products. The reactions of malonic esters and methoxy-substituted phenylacetates with the manganese(III) acetate-Cl^- complex gave α-chloro and α-acetoxy derivatives respectively in excellent yields. These can be useful in organic synthesis.

Experimental

Oxidation of Propenoates (1a—e, 6 and 8a—c), Malonates (15a—f), and Phenylacetates (19a and 19b) with the Manganese(III) Acetate-Chloride Ions. The general procedure for the oxidation of esters was as follows. A mixture of an ester (1 mmol), manganese(III) acetate,[6)] and chloride ions in the molar ratio shown in Table 1 in acetic acid (30 cm^3) was heated under reflux until the color of the solution had changed from brown to transparent. After the removal of the solvent, 2 M (1 M=1 mol dm^{-3}) hydrochloric acid (40 cm^3) was added to the mixture, which was then extracted with benzene or chloroform (3×30 cm^3). The benzene (or chloroform) solution was evaporated in vacuo, and the products were separated on preparative TLC (Kieselgel 60G or Wakogel B-10), with chloroform or benzene as the developing solvent. The yields are summarized in Table 1. The known compounds were identified by comparing them with the spectral data and/or the melting points in the literature. The physical and spectral data for the new compounds are summarized in Table 2.

We wish to thank Professor Hitoshi Takeshita and Associate Professor Akira Mori of the Research Institute of Industrial Science, Kyushu University, and Mr. Hirohisa Yoshida of JEOL, Ltd., for their kind assistance in obtaining the high-resolution mass spectra.

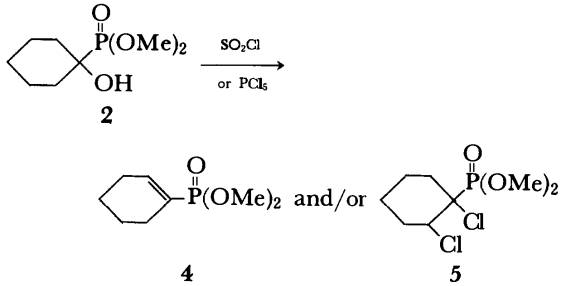
Synopsis. The reactions of dimethyl 1-hydroxycycloalkylphosphonates having a five- to seven-membered ring with sulfuryl chloride and phosphorus pentachloride afforded olefinic and/or dichloro derivatives of phosphonates. The mechanism of the formation of new dichloro derivatives and the reactions of dimethyl 1-methylethylphosphonate with sulfuryl chloride and phosphorus pentachloride were also investigated.

A carbon–phosphorus bond formation is the key step for the preparation of a phosphorus sugar, a sugar analogue having a phosphorus atom in the hemiacetal ring.[2)] Addition of a P–H group of phosphorus compounds to carbonyl group is well-known to give α-hydroxy phosphorus compounds;[3,4)] the reactivity is dependent on the structures of carbonyl compounds, and α-hydroxy phosphorus compounds from aldehydes and ketones give α-halo- and α,β-unsaturated phosphorus compounds, respectively.[5)] Facile formation of α-carbocations from mesylate derivatives of diethyl 1-hydroxyalkylphosphonates are attributable to the potent electron-withdrawing power of the phosphoryl group.[6)] On the other hand, chloro derivatives of phosphonates such as dimethyl 1-hydroxy-2,2,2-trichloroethylphosphonate are biologically active substances (e.g., insecticides).[7)] This note deals with the reaction of cyclic α-hydroxy phosphonates with sulfuryl chloride and phosphorus pentachloride, known as chlorination or dichlorination reagents,[8–11)] as well as that of an acyclic homologue.

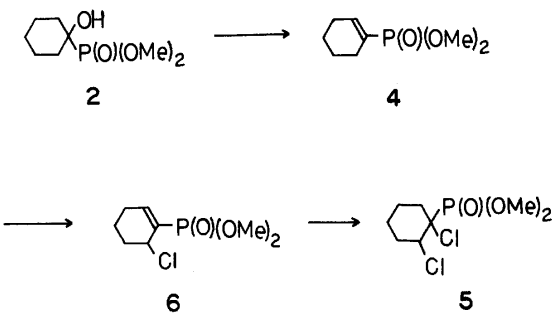
Results and Discussion

Cyclic α-hydroxy phosphonates (**1**—**3**) each having a five to seven-membered ring were prepared by the reaction of cyclic ketones with dimethyl phosphonate in the presence of triethylamine or sodium methoxide.[12)] The reaction of dimethyl 1-hydroxycyclohexylphosphonate (**2**) with sulfuryl chloride in benzene for 8 h at room temperature in the presence of an equivalent amount of pyridine gave dimethyl 1-cyclohexylphosphonate (**4**) in 6% yield and dimethyl 1,2-dichlorocyclohexylphosphonate (**5**) in 58% yield. In the presence of excess amount of pyridine at 50 °C **2** gave 1-cyclohexenylphosphonate **4** in 51% yield, when treated with sulfuryl chloride. Since elimination of chlorine from **5** does not proceed at 50 °C, **4** seems to be formed via **2**, as indicated by the reaction of α-hydroxy phosphonates with thionyl chloride.[5)] In contrast, the reaction of **2** with phosphorus pentachloride gave **4** in quantitative yield.



Reaction of dimethyl 1-hydroxycyclopentylphosphonate (**1**) with sulfuryl chloride or phosphorus pentachloride gave the corresponding 1,2-dichloro derivative (**8**) in 58% yield, or the olefin (**9**) in 49% yield. These results together with those for dimethyl 1-hydroxycycloheptyl- and 1-hydroxy-1-methylethylphosphonates (**3** and **12**) are summarized in Table 1. Dichlorination of cyclohexenones and ethylenic compounds and dehydration of sugar derivatives with sulfuryl chloride are known,[9,13,14)] however, the reaction of phosphonates presented here (Table 1) should be attributable to the activation by a phosphoryl group,[15)] whose powerful electron-withdrawing nature is typically shown by the σ_p (0.52) and σ^+ (0.505) values for the diethylphosphoryl group[6,16)] as well as the high reactivity of Horner-Emmons reaction.[17)]

The reaction of **4** with sulfuryl chloride in the presence of excess or equivalent amount of pyridine afforded monochloride **6** or dichloride **5** in 43 or 60% yield, respectively. Compound **6** was also prepared by treatment of **4** with NCS in 93% yield, while the bromo derivative (**7**) was prepared by the analogous reaction with NBS in quantitative yield. With sulfuryl chloride in the presence of equivalent amount of pyridine **6** afforded dichloride **5** in 79% yield. These findings suggest that the formation of dichloride **5** would proceed via intermediates **4** and **6** as shown in Scheme 1. The amount of pyridine suppressed the production of the dichloride, which may presumably be formed by addition of hydrogen chloride to the olefin.



Scheme 1. Plausible mechanism for the reaction of compound **2** with sulfuryl chloride to form dichloro derivative **5**.

Experimental

Measurements. ^{1}H NMR spectra were measured on Hita-

chi R-24 (60 MHz) or R-20 (60 MHz) spectrometer with tetramethylsilane as an internal standard. IR spectra were recorded with Japan Spectroscopic Co., Ltd. A-3 infrared spectrometer. MS spectra were measured by Hitachi RMU 7M GC-MS spectrometer.

Reaction of Dimethyl 1-Hydroxycyclohexylphosphonate (2) with Sulfuryl Chloride. To a solution of compound **2** (4.87 g, 23.4 mmol) in benzene (6 ml) and pyridine (1.85 g) was added sulfuryl chloride (1.89 ml), then the mixture was stirred for 8 h at 50 °C. The product was extracted with diethyl ether and the organic layer was washed with water and dried over anhydrous magnesium sulfate. Evaporation of the solvent in vacuo followed by chromatography on silica gel and recrystallization from carbon tetrachloride gave 1,2-dichlorocyclohexylphosphonate **5** (3.5 g, 58%), mp 76—77 °C, as well as dimethyl 1-cyclohexenylphosphonate (**4**, 0.27 g, 6%). Spectral data for **4**: ^{1}H NMR ($CDCl_3$) δ=1.4—2.5 (m, 8H, C_6H_8), 3.68 (d, 6H, J_{HP}=11.1 Hz, 2OMe), and 6.75 (dt, 1H, J_{HP}=22.2 Hz, J_{HH}=1.2 Hz, CH=CP); IR (neat) 1637 (C=C), 1238 (P=O), and 1180, 1028 cm^{-1} (P-O-C); MS *m/z*, 190 (M^+). Spectral data for **5**: ^{1}H NMR ($CDCl_3$) δ=1.2—2.3 (m, 8H, C_6H_8), 3.82, 3.88 (2d, 6H, J_{HP}=11.1 Hz, 2OMe), and 4.43 (ddd, 1H, J_{PCCH}=3.9 Hz, $J_{H_{ax}CC(Cl)H_{ax}}$=7.8 Hz, $J_{H_{eq}CC(Cl)H_{ax}}$=3.9 Hz, $CH_{ax}Cl$); IR (KBr) 1250 (P=O), 1186, 1015 (P-O-C), and 740, 691 cm^{-1} (C-Cl); MS *m/z*, 260 (M^+, rel intensity 100%), 262 (M^+ + 2, 65%), and 264 (H^+ 4, 9.7%).

Found: C, 36.37; H, 5.91%. Calcd for $C_8H_{15}Cl_2O_3P$: C, 36.80; H, 5.79%.

Reaction of compound **2** (4.00 g) with sulfuryl chloride (1.8 ml) in pyridine (7 ml) for 18 h at 50 °C afforded product **4** (1.86 g, 51%) after work-up and separation by TLC on silica gel.

Reaction of Compound 2 with Phosphorus Pentachloride. To a solution of compound **2** (3.01 g, 14.5 mmol) in benzene (8 ml) was added phosphorus pentachloride (3.50 g, 14.5 mmol) with stirring, and the mixture was then stand for 10 h at room temperature. The reaction mixture was poured into ice-water (50 ml) and extracted with chloroform (total 50 ml). The extract was washed with sodium hydrogencarbonate and water, and dried over anhydrous magnesium sulfate. Removal of the solvent in vacuo gave product **4** (2.75 g, quantitative).

Reaction of Dimethyl 1-Hydroxycyclopenthylphosphonate (1) or Dimethyl 1-Hydroxycycloheptylphosphonate (3) with Sulfuryl Chloride. Reaction of compound **1** or **3** with sulfuryl chloride in the presence of an equivalent amount of pyridine afforded the corresponding dichloride, dimethyl 1,2-dichlorocyclopentylphosphonate (**8**) or dimethyl 1,2-dichlorocycloheptylphosphonate (**10**) in 58 or 35% yield, respectively (Table 1). Spectral data for **8**: ^{1}H NMR ($CDCl_3$) δ=1.9—3.0 (m, 6H, C_5H_6), 3.98, 4.03 (2d, 6H, J_{HP}=10.2 Hz, 2OMe), and 4.4—4.7 (m, 1H, CHCl); MS *m/z*, 246 (M^+), 248

(M^+ +2), and 250 (M^+ +4). Spectral data for **10**: ^{1}H NMR ($CDCl_3$) δ=1.0—3.5 (m, 10H, C_7H_{10}), 3.37, 3.49 (2d, 6H, J_{HP}=10.1 Hz, 2OMe), and 4.4—4.8 (m, 1H, CHCl); MS *m/z*, 278 (M^+), 280 (M^+ +2), and 282 (M^+ +4).

Reaction of Compound 1 or 3 with Phosphorus Pentachloride. Reaction of compound **1** or **3** with phosphorus pentachloride gave the corresponding olefinic product, dimethyl 1-cyclopentenylphosphonate (**9**) or dimethyl 1-cycloheptenylphosphonate (**11**) in 49 or 37% yield, respectively. Spectral data for **9**: ^{1}H NMR ($CDCl_3$) δ=1.3—3.0 (m, 6H, C_5H_6), 3.82 (d, 6H, J_{HP}=15.8 Hz, 2OMe), and 6.75 (dt, 1H, J_{PCCH}=14.3 Hz, J_{HH}=2.0 Hz, CH=CP). Spectral data for **11**: ^{1}H NMR ($CDCl_3$) δ=1.3—2.2 (m, 10H, C_7H_{10}), 3.68 (d, 6H, J_{HP}=10.8 Hz, 2OMe), and 6.98 (dt, 1H, J_{PCCH}=24.3 Hz, J_{HH}=6.5 Hz).

Reaction of Compound 4 with Sulfuryl Chloride. Reaction of compound **4** (0.48 g, 2.5 mmol) with sulfuryl chloride (0.34 g, 2.5 mmol) in pyridine (0.19 ml, equivalent)-benzene (1 ml) or in pyridine (2 ml, excess) for 8 h at 50 °C afforded product **5** or **6** in 60 or 43% yield, respectively. Spectral data for **6**: ^{1}H NMR ($CDCl_3$) δ=1.2—2.4 (m, 6H, ring protons), 3.70 (d, 6H, J_{HP}=10.4 Hz, 2OMe), 4.0—4.6 (m, 1H, CHCl), and 6.67 (dt, 1H, J_{PCCH}=22.7 Hz, J_{HH}=1.7 Hz, CH=CP); IR (neat) 1230 (P=O), 1190, 1018 (P-O-C), and 735, 600 cm^{-1} (C-Cl); MS *m/z*, 224 (M^+, 100%) and 226 (M^+ +2, 29%).

Reaction of Compound 4 with *N*-Chlorosuccinimide (NCS) or *N*-Bromosuccinimide (NBS). Reaction of compound **4** (2.0 mmol) with NCS or NBS (2.0 mmol) was carried out in carbon tetrachloride (2 ml) for 5 h at 60 °C. Usual work-up of the reaction mixture afforded chloride **6** or bromide **7** in 93% or quantitative yield, respectively. Spectral data for **7**: ^{1}H NMR ($CDCl_3$) δ=1.3—2.7 (m, 6H, ring protons), 3.74 (d, 6H, J_{HP}=10.0 Hz, 2OMe), 4.3—5.1 (m, 1H, CHBr), and 6.83 (dt, 1H, J_{PCCH}=20.0 Hz, J_{HH}=1.3 Hz, CH=CP); IR (neat) 1240 (P=O), 1190, 1040 (P-O-C), and 580 cm^{-1} (C-Br); MS *m/z*, 268 (M^+, 100%) and 270 (M^+ +2, 91%).

Reaction of Compound 6 with Sulfuryl Chloride. Reaction of compound **6** (49 mg, 0.22 mmol) with sulfuryl chloride (30 mg, 0.22 mmol) in pyridine (25 μl, equivalent)-benzene (1 ml) for 8 h at 50 °C afforded product **5** (45 mg, 79%).

Reaction of Dimethyl 1-Hydroxy-1-methylethylphosphonate (12). Reaction of compound **12** (0.84 g, 5.0 mmol) with sulfuryl chloride or with phosphorus pentachloride afforded dimethyl 1,2-dichloro-1-methylethylphosphonate (**13**, 0.18 g, 27%) or dimethyl 1-methylvinylphosphonate (**14**, 0.57 g, 76%), respectively. Spectral data for compound **13**: ^{1}H NMR ($CDCl_3$) δ=1.73 (d, 3H, J_{HP}=15.0 Hz, PCMe), 3.69 (d, 2H, J_{HP}=15.0 Hz, $PCCH_2$), and 3.81 (d, 6H, J_{HP}=10.6 Hz, 2POMe); IR (neat) 1260 (P=O), 1040 (P-O-C), and 760, 602 cm^{-1} (C-Cl); MS *m/z*, 220 (M^+, 100%), 222 (M^+ +2, 54%) and 224 (M^+ 4, 19%). Spectral data for compound **14**; ^{1}H NMR ($CDCl_3$) δ=1.95 (ddd, 3H, J_{HP}=14.0 Hz, J_{HH}=1.7 Hz, J_{HH}=1.3 Hz, PCMe), 3.71 (d, 6H, J_{HP}=10.8 Hz, 2POMe), 5.80 (ddq, 1H, J_{HP}=47.0 Hz, J_{HH}=1.7 Hz, J_{HH}=1.3 Hz, $PC=CH_{(trans)}$), 5.97 (ddq, 1H, J_{HP}=22.7 Hz, J_{HH}=1.7 Hz, J_{HH}=1.3 Hz, $PC=CH_{(cis)}$); IR (neat) 1250 (P=O), 1040 cm^{-1} (P-O-C); MS *m/z*, 150 (M^+).

Deacylation Effect in the Hydrolysis of *p*-Nitrophenyl Esters by Bifunctional Comicelles Containing Imidazolyl and Hydroxyl Groups

Yasuji IHARA,* Mamoru NANGO,† and Joichi KOGA†
Yamaguchi Women's University, 3-2-1 Sakurabatake, Yamaguchi 753
†Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591
(Received June 12, 1986)

Synopsis. The rate constants for hydrolysis of *p*-nitrophenyl acetate, hexanoate, and dodecanoate catalyzed by bifunctional catalysts containing the imidazolyl and hydroxyl groups have been determined in the presence of hexadecyltrimethylammonium bromide micelles at 25 °C. The kinetic analysis suggests a nucleophilic mechanism which involves acylation followed by deacylation at the imidazolyl group. Although no appreciable differences in cooperative catalytic efficiencies are observed between the bifunctional groups in the acylation step, it is found that the deacylation rates are accelerated by the hydroxyl group of the catalyst in the presence of micelles.

In the past several years, many micellar enzyme models have been investigated in order to gain further insight into the nature of enzyme reactions[1-5] and, particularly, bifunctional micellar catalysis has been reported as models of esterolytic enzymes for the hydrolysis of *p*-nitrophenyl esters. The catalytic hydrolysis of *p*-nitrophenyl esters by micelles derived from functional surfactants normally occurs by a nucleophilic mechanism with subsequent decomposition of an acylated micellar intermediate.[3a,4,5] We have previously demonstrated the large rate enhancements in deacylation process during the hydrolysis of *p*-nitrophenyl esters by *N*-acylhistidine or dipeptide catalysts in the presence of hydroxyl functionalized surfactant micelles.[6]

The present study describes the results for deacylation effect of bifunctional comicellar catalysts containing the imidazolyl and hydroxyl groups for the hydrolysis of *p*-nitrophenyl acetate (PNPA), hexanoate (PNPH), and dodecanoate (PNPL) in the presence of hexadecyltrimethylammonium bromide (CTAB) micelles. The catalysts used in this experiment are *N*-decanoyl-L-histidine (**1a**) and *N*-benzyloxycarbonyl-L-phenylalanyl-L-histidine (**2a**), both having an imidazolyl group, and *N*-acyl-L-tyrosine (**1b,c**) and *N*-decanoyl-L-serine (**1d**), both having a hydroxyl group, or *N*-benzyloxycarbonyl-L-tyrosyl-L-histidine (**2b**) and *N*-benzyloxycarbonyl-L-histidyl-L-tyrosine (**2d**), both having imidazolyl and hydroxyl groups.

Experimental

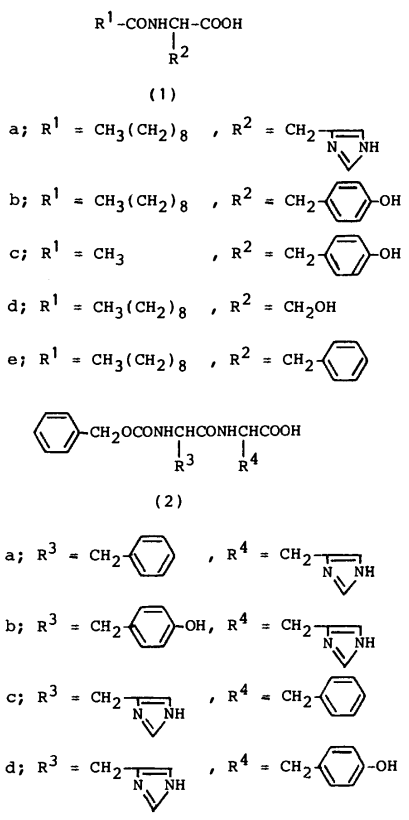
Materials. *N*-Decanoyl-L-tyrosine (**1b**), *N*-decanoyl-L-serine (**1d**), and *N*-decanoyl-L-phenylalanine (**1e**) were prepared and purified by standard methods.[7] *N*-Acetyl-L-tyrosine (**1c**), *N*-benzyloxycarbonyl-L-phenylalanyl-L-histidine (**2a**), *N*-benzyloxycarbonyl-L-tyrosyl-L-histidine (**2b**), *N*-benzyloxycarbonyl-L-histidyl-L-phenylalanine (**2c**), and *N*-benzyloxycarbonyl-L-histidyl-L-tyrosine (**2d**) were commercially available and were used without further purification. Other materials have been described elsewhere.[8-11]

Kinetic Measurements. Reactions were generally monitored on a Hitachi 200 spectrophotometer or a Shimadzu 140 spectrophotometer with a thermostated cell holder at 25 °C. In the general procedure, a solution (25 μl) of substrate in acetonitrile was added to a buffer solution (3.00 cm^3) containing the catalyst and surfactant at the desired concentrations. Pseudo-first-order rate constants were obtained from plots of $\log(A_\infty - A_t)$ versus time (t) by use of the least-squares method. Correlation coefficients were >0.999.

Results and Discussion

The catalytic process can be described by Eq. 1, where C_{Im} designates the imidazole catalyst, AcONp is the substrate, Ac–C_{Im} is the acylated intermediate, and k_a and k_d represent the rate constants for acylation and deacylation processes, respectively.

$$C_{Im} + AcONp \xrightarrow{k_a} Ac - C_{Im} \xrightarrow{k_d} C_{Im} + AcOH \quad (1)$$
$$+$$
$$p\text{-nitrophenol}$$



Kinetic studies are carried out at fixed concentration of the catalyst in the presence of CTAB. The hydrolysis of the substrates was examined under single turnover conditions, [surfactant]>[catalyst]>[ester] at pH 7.30, 0.02 mol dm^{-3} phosphate buffer and 25 °C. The pseudo-first-order rate constant k_ψ was determined by monitoring the release of *p*-nitrophenolate ion spectrophotometrically at 410 nm. The acylation rate constant (k_a) was calculated from the following equation, $k_a = k_\psi - k_{CTAB}$, where k_{CTAB} refers the rate con-

Table 1. Rate Constants for the Hydrolysis of Esters by **2a—d** in the Presence of CTAB[a)]

Ester	Catalytic Systems	$10^3 k_a/s^{-1}$	Rel. k_a	$10^4 k_d/s^{-1}$	Rel. k_d

	2d	2.88	1.13	6.69	1.50

a) At pH 7.30, 0.02 mol dm^{-3} phosphate buffer, and 25 °C, [CTAB]=1.00×10^{-2} mol dm^{-3}, [**2a,b,c,d**]=1.00×10^{-3} mol dm^{-3}, [Ester]=1.0×10^{-4} mol dm^{-3}. From three or more independent experiments, we estimate that the rate constants are reproducible to ±4%.

stant for spontaneous hydrolysis in the presence of CTAB. The deacylation rate constant (k_d) was directly measured spectrophotometrically by following the slow decrease in absorption at 245 nm or at near the isosbestic point[12] for the acylation reactions. In both cases, the kinetics were first order and good rate constants were obtained ($r>0.999$). The deacylation rate constants were calculated from absorbances at 245 nm, near the isosbestic point, and agree with the observed constants within experimental errors. We also carried out some experiments in CTAB under burst conditions, [substrate]≫[catalyst]. The kinetic treatment was that of Bender[13] and has been used by others.[4]

Table 1 summarizes the results for hydrolysis of three esters (PNPA, PNPH, and PNPL) by **2a—d** in the presence of CTAB micelles. The deacylation of the esters by **2b** and **d** which contain both the imidazolyl and hydroxyl functions in the catalysts is 1.4—3.1 times faster than that by **2a** and **c** which contain imidazolyl function alone although the acylation rates are essentially the same. This cooperative effect of the imidazolyl and hydroxyl functions in the catalysts **2b** and **d** for the deacylation process can be visualized in two mechanistic pathways[14] as illustrated in Scheme 1.

In order to obtain more information about the mechanism of deacylation process, the reactions of **2a** and **b** were examined using excess substrate (PNPA) so that there were rapid evolution of *p*-nitrophenol followed by a slow reaction as the acylated intermediates were hydrolyzed to generate the catalyst. The kinetic analysis under burst conditions shows that the deacylation rate enhancement by **2b** is almost similar to that obtained under the single turnover conditions (see Tables 1 and 2). This result suggests that acyl transfer from the imidazolyl to the hydroxyl groups (**ia** or **ib**) is less probable than the general base catalysis by the neighboring phenolic hydroxyl groups (**ii**) as a deacylation mechanism in the present catalytic system (Scheme 1).

The deacylation rate enhancement by **2b** was slightly larger than those by **2d** in all esters used (Table 1). These differences in deacylation process are due to the steric environment of the acylated intermediate in micelles. Thus, these results suggest that the deacylation involves geometrical interactions between the acyl intermediate and the hydroxyl group and that the acyl

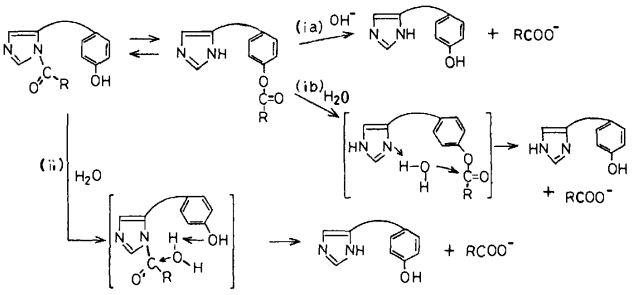
2a	2.38	4.2	1
2b	2.19	11.5	2.74

a) At pH 7.30, 0.02 mol dm^{-3} phosphate buffer, 25 °C, [CTAB]=1.00×10^{-2} mol dm^{-3}, [**2a** or **b**]=1.00—2.50×10^{-5} mol dm^{-3}, [PNPA]=2.50×10^{-3} mol dm^{-3}.



Scheme 1.

intermediate formed from **2b** and PNPA is optimally positioned for reaction by the hydroxyl function of **2b** in micellar phase and results in the largest deacylation rate (3.05).

Tables 3 and 4 summarize the rate constants for acylation and deacylation processes in the hydrolysis of the esters by **1a** and **2a** in four catalytic systems in the presence of micellar CTAB. From Tables 3 and 4, it is apparent that the deacylation is slower than the acylation in all cases. For the acylation process, the catalysis by **1a** was higher than that by **2a** in all esters used. On the other hand, **2a** is more reactive than **1a** in deacylation process. More importantly, PNPA is uniformly most reactive among the esters used in deacylation process. These results indicate that the deacylation process is sensitive to the structures of the catalysts and the esters.

The deacylation rate constants apparently increase in the presence of the catalysts **1b—d** which include the hydroxyl functions, although the acylation rate constants are almost independent of the catalytic systems used. The differences in deacylation rate enhancements suggest that the reaction depends on the catalytic activity of the hydroxyl functions in micelles. This probably reflects the steric environment and acidity of the hydroxyl groups. In our previous papers,[15] we also found the acyl transfer reaction in the hydrolysis of enantiomeric substrates in micelles.

PNPL	**2a**	3.12	1	2.28	1
	2a/1b	2.68	0.86	5.26	2.31
	2a/1c	3.03	0.97	2.54	1.11
	2a/1d	2.65	0.85	3.00	1.32
	2a/1e	2.18	0.70	1.82	0.80

a) At pH 7.30, 0.02 mol dm^{-3} phosphate buffer, and 25°C, [CTAB]$=1.00\times10^{-2}$ mol dm^{-3}, [**2a**]$=1.00\times10^{-3}$ mol dm^{-3}, [**1b**$-$**e**]$=1.00\times10^{-3}$ mol dm^{-3}, [Ester]$=1.0\times10^{-4}$ mol dm^{-3}. From three or more independent experiments, we estimate that the rate constants are reproducible to ±4%.

Although deacylation enhancements in the present catalytic systems are relatively small, it is clear that these micellar systems cause acylation of the imidazolyl group, followed by the deacylation rate acceleration by the hydroxyl group of the catalyst.

Stepwise Oxidation of the Heteroatoms in *O*-Protected Pyridoxine-Like Pyridinophane Containing Thio Groups in the Intramolecular Bridge Chain

Makoto ANDO* and Hiroyoshi KUZUHARA*
RIKEN (The Institute of Physical and Chemical Research), Wako, Saitama 351-01
(Received June 28, 1986)

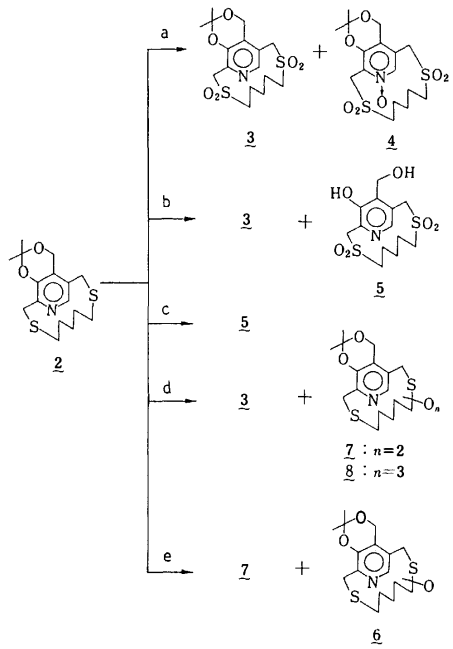
Synopsis. Racemic 14-Hydroxy-15-hydroxymethyl-*O*,*O*′-isopropylidene-2,8-dithia[9](2,5)pyridinophane, a model compound of our chiral pyridoxamine analogs, was oxidized under various conditions in order to examine the reactivities of the sulfur and the nitrogen atoms. Various degree of oxidized compounds, from monoxide to pentaoxide, including the desired *S*,*S*,*S*′,*S*′-tetraoxide, were obtained.

We have prepared several kinds of novel pyridinophanes with sulfur-containing intramolecular bridge chain as chiral analogs of vitamin B_6,[1,2a,3] **1a**, **1b**, and **1c**, corresponding to the *S*-enantiomers of pyridoxal, pyridoxamine, and pyridoxine analogs, respectively. Combination of **1a** or **1b** with appropriate metal ions has been successfully used for simulating the vitamin B_6-dependent enzymatic reactions with a relatively high enantioface differentiation.[1,2]

	R	R′
1a:	CHO	H or Me
1b:	CH_2NH_2	H or Me
1c:	CH_2OH	H

A consideration of the mechanism of such enzyme model reactions suggested that the bulkiness of one of the sulfur atoms in vitamin B_6 analogs might play an essential role in the asymmetric induction.[2c] The sulfonyl group is much bulkier than the corresponding thio group and has a very small tendency to chelate to metal ions. These facts suggest that a conversion of the thio group in **1a** or **1b** to the corresponding sulfonyl group might enhance their potency regarding asymmetric induction. An attempt to prepare such new vitamin B_6 analogs from **1a—c**, however, may be hampered by the fact that the oxidation of the sulfur atoms compete with that of the pyridine nitrogen atom to *N*-oxide. This paper describes the selective oxidation of those sulfides to the corresponding sulfones, employing racemic 14-hydroxy-15-hydroxymethyl-*O*,*O*′-isopropylidene-2,8-dithia[9](2,5)pyridinophane (**2**),[1] an *O*-protected pyridoxine analog, as a model substrate.

The oxidation of **2** with *m*-chloroperbenzoic acid (MCPBA) was studied at room temperature in various organic solvents. The employment of 5.5 mole equivalents of MCPBA to **2** in chloroform for 1 d resulted in a mixture of tetraoxide (**3**) of **2** and pentaoxide (**4**) of **2**. Unreacted MCPBA and **3** were still detectable on TLC, even if the reaction period was prolonged. With 7.5 mole equivalents of MCPBA, however, **4** was obtained in quantitative yield. In the UV spectrum of **4**, a blue shift of the absorption maxima was observed when the solvent was changed from acetonitrile to ethanol, whereas this was not observed in that of **3**. Furthermore, the ε-value of the UV absorption of **4** was somewhat larger than that of **3**. These observations elucidated the structures of **3** and **4** as 14-hydroxy-15-hydroxymethyl-*O*,*O*′-isopropylidene-2,8-dithia[9](2,5)-pyridinophane *S*,*S*,*S*′,*S*′-tetraoxide and *N*,*S*,*S*,*S*′,*S*′-pentaoxide, respectively[4] and showed that the oxidation of sulfur proceeded prior to that of nitrogen. However, decreasing the amount of MCPBA to 4.4—1.1 mole equivalents resulted in many products in all cases, indicating that the oxidation of sulfur proceeds without any selectivity. Although the rate of the oxidation was rather slow in dioxane, **4** was obtained in quantitative yield with 7.5 mole equivalents of MCPBA after 3 d. During these oxidation in chloroform or dioxane, we observed that **3** was once precipitated and dissolved again, giving the final product, **4**. In ethanol, **3** could be isolated in 89% yield after 1 d with **4** also obtained in 11% yield from the filtrate.



a: MCPBA/$CHCl_3$, dioxane, or ethanol, room temp.
b: catalysts[f]/aq dioxane, 60—85 °C, 3 h.
c: no catalysts/acetic acid, 60—85 °C, 3 h.
d: catalysts[f]/aq dioxane, room temp, 1 d.
e: no catalysts/aq dioxane, room temp, 3 d.
f: AcOH (1.5 wt%) + $Na_2WO_4 \cdot 2H_2O$ (0.5 wt%).

Recently, Giam et al. reported that the selective oxidation of alkyl pyridyl sulfides to the corresponding sulfones without *N*-oxide compounds proceeded in aqueous dioxane at 65—85 °C with hydrogen peroxide

and catalytic amounts of acetic acid and sodium tungustate.[5] This procedure was applied to the oxidation of **2** and found to give satisfactory results. The desired **3** (87%) and its *O,O'*-deprotected compound, 14-hydroxy-15-hydroxymethyl-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-tetraoxide (**5**) (5%), were obtained with no *N*-oxide compounds produced. Acidic hydrolysis of **3** gave **5** which precipitated in the form of free base during the reaction. Only **5** was obtained when the oxidation was conducted in acetic acid at 60—85 °C in the absence of sodium tungustate. The hydrogen peroxide oxidation at room temperature gave monoxide (**6**), dioxide (**7**), and trioxide (**8**) of **2** depending on the reaction conditions employed (See experimental). Although **6** and **7** showed the sharp melting points, the NMR signal assignable to the proton attached to the pyridine ring in **6**, **7**, and **8**[6] appeared as 2, 4, and 2 peaks, respectively, suggesting that those compounds were the mixtures of the corresponding *S*-oxides (**6**) (assigned from IR spectrum), *S,S*- and *S,S'*-dioxides (**7**), and *S,S,S'*-trioxides (**8**) of **2**.

In conclusion, the selective oxidation of the sulfides **2** giving the corresponding sulfone derivative **3** was achieved with hydrogen peroxide-acetic acid-sodium tungustate in aqueous dioxane at 60—85 °C or with MCPBA in ethanol at room temperature.

Experimental

General. Melting points are uncorrected. IR and UV-VIS spectra were determined with a Shimadzu IR 27G and a Varian-Cary 2290 spectrometers, respectively. ^{1}H NMR spectra were recorded on a JOEL PS 100 instrument using TMS as an internal standard (100 MHz).[6] Organic extracts were dried over anhydrous magnesium sulfate and evaporated under reduced pressure. TLC was conducted with a precoated silica gel 60F_{254} on aluminium sheet (Merck No. 5554) with chloroform-methanol (50 : 1 or 25 : 1 v/v) as the developing solvent. Column chromatography was performed with a silica gel (Merck No. 7734) column with chloroform-methanol (100 : 1 v/v) as the eluent.

Material. Racemic 14-hydroxy-15-hydroxymethyl-*O,O'*-isopropylidene-2,8-dithia[9](2,5)pyridinophane (**2**) was prepared by the method described in previous papers.[1] Commercially available *m*-chloroperbenzoic acid (MCPBA) (85% purity, Tokyo Kasei) and an aqueous 30% hydrogen peroxide solution (Mitsubishi Gas Chemistry) were used as oxidizing reagents without accurate determination of the contents.

Oxidation of 2 with MCPBA. A typical example is described in the following. A solution of MCPBA (3.43 g, 5.5 mole equivalents to **2**) in chloroform (50 ml) was added to a stirred solution of **2** (1.00 g) in the same solvent (50 ml) cooled in an ice bath over the period of 30 min and the mixture was stirred for 1 d at room temperature. During the addition of MCPBA the precipitate appeared and then gradually dissolved within 5—6 h. After decomposition of the excess MCPBA with an aqueous sodium hydrogensulfite solution, the chloroform solution was washed with a sodium hydrogencarbonate solution and with water, dried, and chromatographed to give **3** (0.25 g, 21%) and **4** (0.91 g, 73%) in this elution order.

Compound **3**: Mp > 280 °C; UV (EtOH) 298 nm (ε 6.2×10^3); (MeCN) 298 nm (ε 6.1×10^3); IR (KBr disk) 1290 and 1100 cm^{-1} (SO_2); ^{1}H NMR ($CDCl_3$) δ=1.65 (6H, s, C-(C$\underline{H}_3$)$_2$), 2.6—3.4 (10H, m), 4.14 (1H, d, J=14 Hz, 2-Py-C$\underline{H}$-S), 4.23 (1H, d, J=14 Hz, 2-Py-C$\underline{H}$-S), 4.28 (1H, d, J=14 Hz, 5-Py-C$\underline{H}$-S), 4.76 (1H, d, J=17 Hz, Py-C$\underline{H}$-O), 4.89 (1H, d, J=13 Hz, 5-Py-C$\underline{H}$-S), 5.31 (1H, d, J=17 Hz, Py-C$\underline{H}$-O), and 8.25 (1H, s, Py-$\underline{H}$). Found: C, 49.31, H, 5.99; N, 3.46; S, 16.50%. Calcd for $C_{16}H_{23}NO_6S_2$: C, 49.34; H, 5.95; N, 3.60; S, 16.47%.

Compound **4**: Mp > 280 °C; UV (EtOH) 279 (ε 7.7×10^3) and 331 nm (ε 3.5×10^3); (MeCN) 282 (ε 7.6×10^3) and 338 nm (ε 2.9×10^3); IR (KBr disk) 1300, 1280 (SO_2 and N→O), and 1120 cm^{-1} (SO_2); ^{1}H NMR ($CDCl_3$) δ=1.72 (6H, s, C-(C$\underline{H}_3$)$_2$), 2.9—3.9 (10H, m), 4.24 (2H, s, 2-Py-C$\underline{H}_2$-S), 4.52 (1H, d, J=13 Hz, 5-Py-C$\underline{H}$-S), 4.80 (1H, d, J=17 Hz, Py-C$\underline{H}$-O), 5.27 (1H, d, J=16 Hz, Py-C$\underline{H}$-O), 5.37 (1H, *d*, J=12 Hz, 5-Py-C$\underline{H}$-S), and 8.25 (1H, s, Py-$\underline{H}$). Found: C, 47.25; H, 5.74; N, 3.31; S, 15.85%. Calcd for $C_{16}H_{23}NO_7S_2$: C, 47.39; H, 5.72; N, 3.45; S, 15.81%.

Oxidation of 2 with Hydrogen Peroxide. a) Reaction at 60—85 °C with Catalysts: Hydrogen peroxide solution (1.5 ml) was added at 60—65 °C over the period of 30 min to a stirred solution of **2** (1.00 g), acetic acid (ca. 15 mg), and sodium tungustate dihydrate (ca. 5 mg) in dioxane (10 ml)-water (10 ml) and the mixture was stirred at 80—85 °C for further 3 h. After the mixture had been cooled, the resulting precipitate of **5** (55 mg, 5%) was filtered off, and the excess hydrogen peroxide was destroyed with an aqueous sodium hydrogensulfite solution. The resulting solution was extracted with chloroform, and the extract was washed with water, dried, and chromatographed to afford **3** (1.04 g, 87%).

Compound **5**: Mp > 280 °C; IR (KBr disk) 3340 (OH), 1290, and 1100 cm^{-1} (SO_2); ^{1}H NMR (DMSO-d_6) δ=2.6—3.4 (10 H, m), 4.40 (1H, d, J=13 Hz, 5-Py-C$\underline{H}$-S), 4.59 (1H, d, J=16 Hz, Py-C$\underline{H}$-O), 4.87 (2H, s, 2-Py-C$\underline{H}_2$-S), 4.89 (1H, s, Py-CH$_2$-O$\underline{H}$), 4.92 (1H, d, J=16 Hz, Py-C$\underline{H}$-O), 5,10 (1H, d, J=13 Hz, 5-Py-C$\underline{H}$-S), 8.43 (1H, s, Py-$\underline{H}$), and 10.09 (1H, s, Py-O$\underline{H}$). Found: C, 44.92; H, 5.48; N, 3.95; S, 18.40%. Calcd for $C_{13}H_{19}NO_6S_2$: C, 44.69; H, 5.48; N, 4.01; S, 18.35%.

b) Reaction in Acetic Acid at 60—85 °C without Catalysts: Hydrogen peroxide solution (1.5 ml) was added to a stirred solution of **2** (1.00 g) in acetic acid (10 ml) at 60—65 °C over the period of 30 min and the mixture was stirred at 80—85 °C for further 3 h. The mixture was cooled and diluted with water and the resulting precipitate of **5** (0.80 g, 75%) was collected.

c) Reaction at Room Temperature with Catalysts: Hydrogen peroxide solution (1.5 ml) was added to a stirred solution of **2** (1.00 g), acetic acid (ca. 15 mg), and sodium tungustate dihydrate (ca. 5 mg) in dioxane (30 ml)-water (10 ml) below room temperature over the period of 30 min, stirred for 1 d at room temperature, and then treated as described in a), giving **3** (0.25 g, 21%), **8** (0.66 g, 58%), and **7** (0.14 g, 13%) in this elution order.

Compound **7**: Mp 201—202 °C dec; IR (KBr disk) 1290, 1090 (SO_2 weak), and 1020 cm^{-1} (SO); ^{1}H NMR ($CDCl_3$) δ=7.91 (0.1H, s, Py-$\underline{H}$), 8.03 (0.2H, s, Py-$\underline{H}$), 8.15 (0.6H, s, Py-$\underline{H}$), and 8.25 (0.1H, Py-$\underline{H}$). Found: C, 53.53; H, 6.46; N, 3.88; S, 17.90%. Calcd for $C_{16}H_{23}NO_4S_2$: C, 53.76; H, 6.49; N, 3.92; S, 17.94%.

Compound **8**: Mp > 280 °C; IR (KBr disk) 1290, 1110 (SO_2), and 1030 cm^{-1} (SO); ^{1}H NMR ($CDCl_3$) δ=8.15 (0.4H, s, Py-$\underline{H}$) and 8.24 (0.6H, s, Py-$\underline{H}$). Found: C, 51.03; H, 6.14; N, 3.78; S, 17.12%. Calcd for $C_{16}H_{23}NO_5S_2$: C, 51.46; H, 6.21; N, 3.75; S, 17.17%.

d) Reaction at Room Temperature without Catalysts: Hydrogen peroxide solution (1.5 ml) was added to a stirred solution of **2** (1.00 g) in dioxane (30 ml)-water (10 ml) below room temperature and the mixture was stirred for 3 d at room temperature. A similar work up gave unreacted **2** (0.25 g, 25%), **6** (0.21 g, 19%), and **7** (0.51 g, 48%) in this elution order.

Compound **6**: Mp 176—177 °C; IR (KBr disk) 1020 cm^{-1} (SO); ^{1}H NMR ($CDCl_3$) δ=7.90 (0.7H, s, Py-$\underline{H}$) and 8.10

(0.3H, s, Py-H). Found: C, 55.97; H, 6.78; N, 3.89; S, 18.78%. Calcd for $C_{16}H_{23}NO_3S_2$: C, 56.27; H, 6.79; N, 4.10; S, 18.78%.

Acidic Hydrolysis of 3. A mixture of **3** (1.00 g), hydrochloric acid (2.5 ml), and water (25 ml) was stirred at 80—85 °C for 2 h and cooled and the resulting precipitate of **5** (0.83 g, 93%) was collected.

The authors wish to express their thanks to the members of the Organic Analysis Center of this Institute for elemental analyses and to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for the measurements of ^1H NMR spectra.

This study was performed through Special Coordination Funds of the Science and Technology Agency of the Japanese Government.

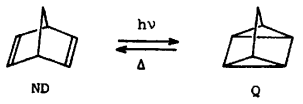
Effect of Aryl Substituents on 2-Aryl-1,4,5,6,7,7-hexachloronorbornadiene-Quadricyclane Reversible Isomerization

Hideo TOMIOKA,* Yukinobu HAMANO, and Yasuji IZAWA
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received July 25, 1986)

Synopsis. 2-Arylhexachloronorbornadiene undergoes photoisomerization to the corresponding quadricyclane, which returns back to the norbornadiene upon heating without catalyst. Effect of aryl substituents on the thermal reversion suggests that both spin delocalization and polar effect equally contribute to the stabilization of the transition state.

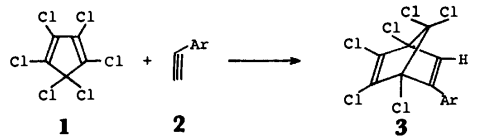
The norbornadiene (ND)-quadricyclane (Q) reversible isomerization is an attractive model system for the chemical conversion of light energy.[1] Energy is stored when norbornadiene is converted photochemically to the higher energy quadricyclane. The energy is



released when quadricyclane is (catalytically) converted back to norbornadiene. Since norbornadiene itself does not undergo efficient valence isomerization upon direct and/or sensitized irradiation, norbornadienes bearing an appropriate chromophore have been synthesized and their photoisomerization has been examined.[2] The properties of quadricyclanes derived from these norbornadienes are also quite important in connection with the design of the system and hence the heat and the rate of the reversion of the quadricyclanes to the starting compounds are measured which provides an important information on the mechanism of the reversion.[3] As a part of such studies we synthesized 2-arylhexachloronorbornadienes and investigated the effect of aryl substituents on the reversible isomerization.

Results and Discussion

The norbornadienes (**3**) were synthesized[4,5] by the Diels-Alder addition between hexachlorocyclopentadiene (**1**) and arylacetylenes (**2**) bearing electron-donating and withdrawing groups in refluxing



1 **2** **3**

Ar=X- C_6H_4 a: X=4-MeO, b: X=4-Me, c: X=H, d: X=4-Br, e: X=3-Br

toluene. These norbornadienes (**3**) were easily purified by vacuum distillation followed by recrystallization from hexane with exception of the methoxy derivative (**3a**). Irradiation of **3** in Pyrex tube with high-pressure Hg lamp gave the corresponding quardricyclanes (**4**) in quantitative yield. Quantum yield of the photocycloaddition with 313 nm light was 0.42 for **3c**.

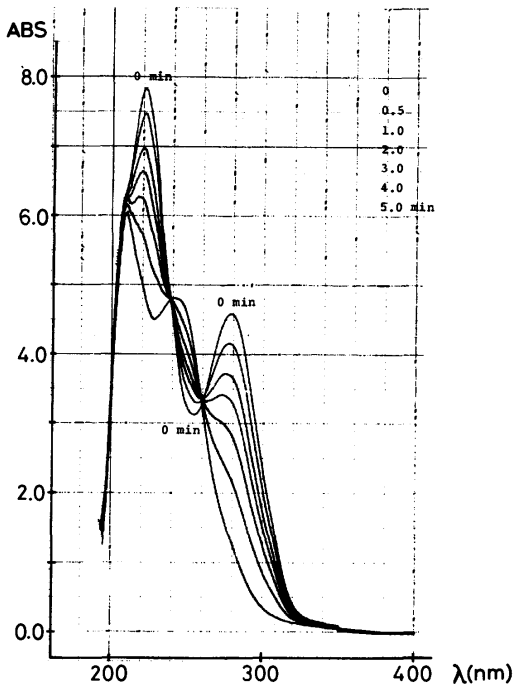


Fig. 1. UV spectra of the photoisomerization of **3c** to **4c**. A carbontetrachloride solution of 1.4×10^{-4} M **3c** was irradiated with 313 nm light.

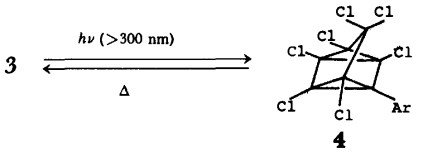

4

Quadricyclanes returned back to the norbornadienes quantitatively upon heating in carbon tetrachloride without catalyst. UV spectra of the photoisomerization of **3c** to **4c** was shown in Fig. 1, which shows the isosbestic point at 238 and 260 nm, indicating the quantitative isomerization of **3c**. UV spectra of the thermal reaction of **4c** to **3c** was superimposable to that of the photoisomerization, again indicating the quantitative isomerization of **4c**. Thus, photoisomerization and thermal back process were completely reversible. The heat of reversion (ΔH) of **4c** to **3c** was 21.6 kcal mol^{-1} (1 cal=4.184 J). The rate constants for the reversion at 60.0 °C were measured by monitoring a ^1H NMR spectra and appear in Table 1 along with Arrhenius parameters.

It has been suggested[3f] that the thermal isomerization of quadricyclanes proceeds via diradical mechanism. While rate constants in Table 1 do not show the wide range distribution that many cationic reactions do, nonetheless there are discernible differences. However, there is no single substituent constant that corre-

Table 1. Rate Constants and Activation Parameters for Thermal Isomerization of **4** to **3**

4	X	k[a)]	E_a[b)]	S[b)]

e	3-Br	73.9	96.2	13.3

a) All rates were measured in CCl_4 at 60 °C. b) These values are each based on 3 runs at temperature between 50 and 60 °C.

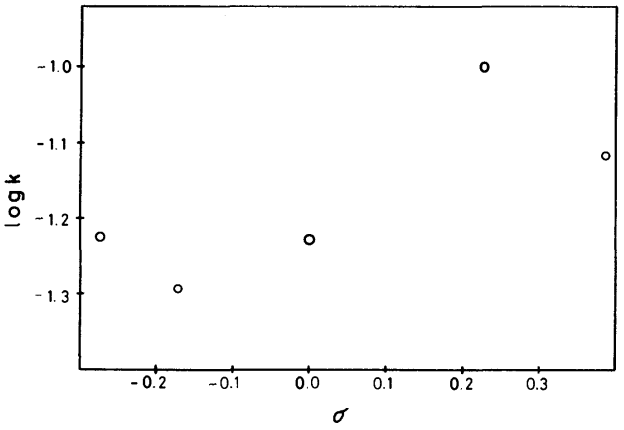

Fig. 2. A plot of relative rate constants for **4**→**3** isomerization at 60.0°C vs. Hammett σ value.

lates all of the data. The effects of substituents on radical stability is not as well understood as in carbocationic reactions. One problem is the separation of true radical-stabilizing effects from polar effects which are known to operate in many radical reactions. Many radical reactions correlate with Hammett σ (σ^+) constants,[6] because of the magnitude of polar effects. No correlation of all the data in Table 1 could be obtained, however, with σ (σ^+) values. On the other hand, various free radical substituent constants ($\sigma\cdot$) have been proposed[7] to separate the polar factors from true free radical stabilizing effects. Attempts to correlate the present data with $\sigma\cdot$ also gave low correlation coefficients.

Recently, a two-parameter Hammett relationship (Eq. 1) has been introduced[7] to evaluate the relative

$$\log k_{rel} = \rho\cdot\sigma\cdot + \rho\sigma \quad (1)$$

importance of radical stabilization vs. polar effects in radical reaction. In this treatment, the data are plotted against two-parameters so as to obtain the best correlation by adjusting the ratio of $\rho\cdot/\rho$ which in turn indicates the relative importance of the radical nature at the transition state. If the value of $\rho\cdot/\rho$ is low, spin delocalization of the intermediates is unimportant and an early transition state, influenced by polar factor, is suggested. If this value is high, the transition state should have radical charactor and polar factors should be relatively unimportant. Using four data available, the best correlation is obtained when the ratio of $\rho\cdot/\rho$

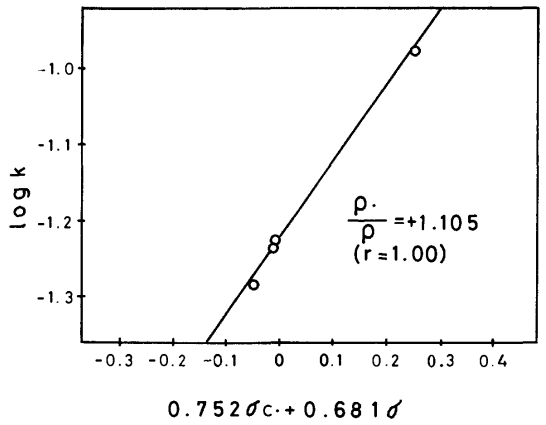

Fig. 3. A plot of relative rate constants for **4**→**3** isomerization vs. two parameters σ and σ_C.

is setted to be 1.105. This indicates that both spin delocalization and polar factors equally contribute to stabilizing the transition state for the thermal isomerization of **4** to **3**.

Thus, the photoisomerization of **3** could be possible with light of wavelength between 300—366 nm, while the heat stored in **4** is as much as that in the parent quadricyclane. Moreover, **4** is fairly stable at room temperature but is easily reverted back to **3** upon heating without catalyst. Finally it should be mentioned that the hexachloro derivatives **3** described in this paper can be prepared much more easily and are much more stable than 2-phenylnorbornadienes, which was synthesized[8] by the Diels-Alder reaction of cyclopentadiene and α-bromostyrene, followed by elimination of HBr by pottasium t-butoxide and decomposed slowly upon standing. Moreover, 2-phenylnorbornadiene-quadricyclane isomerization is not completely reversible.

Experimental

General. All melting and boiling points were uncorrected. UV spectra were recorded on a Hitachi 220-S spectrophotometer. IR spectra were measured on a JASCO IR-G recording spectrometer, and ^{1}H NMR spectra were determined with JEOL JNM-MH-100 NMR spectrometer in CCl_4 with Me_4Si as an internal reference. Mass spectra were recorded on Shimadzu QP-1000 mass spectrometer (70 eV). The heat of isomerization was measured on Rigaku Thermoflex Differential Scanning Calorimeter which was calibrated with KNO_3 standard. Quantum yields were determined using pottasium trioxalatoferrate (III) as an actinometer.

Material. 2-Arylhexachloronorbornadienes were prepared according to the procedure of Fry.[4a] Thus, arylacetylene (0.1 mol) and hexachlorocyclopentadiene (0.1 mol) were dissolved in dry toluene, and the solution refluxed for 3 days. After toluene was removed at the rotary evaporator, the dark brown residue was distilled at reduced pressure to give a viscous oil. A small portion of this oil was triturated with hexane at −10 °C, whereupon it crystallized, with exception of the methoxy derivative (**3a**). The remainder of the adduct was seeded with these crystals, followed by recrystallization from hexane. The data are shown below.

3a: Yield 19%; Bp 123—150 °C/0.4 mmHg (1 mmHg≈ 133.322 Pa); ^{1}H NMR (CCl_4) δ=7.15 (2H, d), 6.80 (2H, d), 6.40 (1H, s), 3.80 (3H, s); MS (70 eV) m/z (rel intensity, %) 401

(M^+, 17.2), 403 (M+2, 33.0), 405 (M+4, 28.9), 407 (M+6, 12.1), 367 (base peak).

3b: Yield 49%; Bp 158—160 °C/0.3 mmHg; Mp 80—81 °C; ^{1}H NMR (CCl_4) δ=7.01 (4H, bs), 6.32 (1H, s), 2.31 (3H, s); MS (70 eV) *m/z* (rel intensity, %) 386 (M^+, 6.3), 388 (M+2, 11.6), 390 (M+4, 9.6), 392 (M+6, 4.1), 317 (base peak).

3c: Yield 25%; Bp 123—124 °C/0.5 mmHg; Mp 94—96 °C; ^{1}H NMR (CCl_4) δ=7.30 (5H, bs), 6.50 (1H, s); MS (70 eV) *m/z* (rel. intensity) 372 (M^+, 7.9), 374 (M+2, 15.2), 376 (M+4, 11.8), 378 (M+6, 5.4), 303 (base peak).

3d: Yield 34%; Bp 60—62 °C/3 mmHg; Mp 76—77 °C; ^{1}H NMR (CCl_4) δ=7.50 (2H, d), 7.15 (2H, d), 6.57 (1H, s); MS (70 eV) *m/z* (rel intensity) 450 (M^+, 5.3), 452 (M+2, 14.5), 454 (M+4, 17.2), 456 (M+6, 11.3), 303 (base peak).

3e: Yield 39%; Bp 150—152 °C/3 mmHg; Mp 93—94 °C, ^{1}H NMR (CCl_4) δ=7.45—7.18 (4H, m), 6.59 (1H, s); MS (70 eV) *m/z* (rel intensity) 450 (M^+, 5.9), 452 (M+2, 15.8), 454 (M+ 4, 17.8), 456 (M+6, 10.4), 303 (base peak).

Photoisomerization of 3 to 4. A solution of **3** (100 mg) in hexane (30 ml) was prepared under an argon atmosphere in Pyrex tubes and was irradiated with a 300-W high-pressure mercury lamp at 10 °C. After irradiation for 5 h, the solvent was evaporated under reduced pressure to leave syrupy oil. Attempts to obtain the quadricyclanes (**4**) in pure forms either by recrystallization or by chromatography were unsuccessful since **4** was always contaminated with **3** due to the thermal back reaction during the work-up even at room temperature. The ^{1}H NMR data of **4** are shown below.

4a: ^{1}H NMR (CCl_4) δ=7.60 (2H, d), 7.18 (2H, d), 3.80 (3H, s), 3.10 (1H, s).

4b: ^{1}H NMR (CCl_4) δ=7.10 (4H, bs), 2.30 (3H, s), 3.08 (1H, s).

4c: ^{1}H NMR (CCl_4) δ=7.27 (5H, bs), 3.02 (1H, s).

4d: ^{1}H NMR (CCl_4) δ=7.53 (2H, d), 7.10 (2H, d), 3.18 (1H, s).

4e: ^{1}H NMR (CCl_4) δ=7.60—7.20 (4H, m), 3.20 (1H, s).

Kinetic Measurement. The rates of thermal back reaction of **4** to **3** were measured in carbon tetrachloride by monitoring ^{1}H NMR spectra. Thus, CCl_4 solution of **3** containing anisole as an internal standard was placed in Pyrex NMR tubes and was irradiated until almost all of **3** were converted to **4**. The tubes were then immersed in a water bath thermostated at a constant temperature (±0.1 °C). The rates were easily measured by monitoring the disappearance of methine proton of **4** at around 2.0 ppm and/or appearance of vinyl proton of **3** at around 6.5 ppm.

The authors gratefully acknowledge a support of this work by the Grant-in-Aid for "Research on Photosynthesis and Photoconversion of Solar Energy" sponsored by the Ministry of Education, Science and Culture. We thank Professor K. Kamiya of this department for measurement of the heat of isomerization.

(Received August 7, 1986)

Synopsis. A solution of equimolar mixture of (±)-phenylsuccinic acid ((±)-PSA) and (−)-proline ((−)-Pro) in ethanol or its suspension in 2-propanol selectively gave a salt composed of 1-molar amount of PSA and 2-molar amount of (−)-Pro. The salt purified gave (+)-PSA with an optical purity of about 100%. A salt composed of equimolar amounts of PSA and (−)-Pro was obtained from the ethanolic mother liquor, and gave (−)-PSA with an optical purity of 98%.

(±)-Phenylsuccinic acid (abbreviated as (±)-PSA) has been used as an intermediate material for phensuximide.[1,2] (±)-PSA has been optically resolved by the diastereomeric procedure using brucine.[3] However, it is not easy to obtain PSA with high optical purity in high yield, since it is difficult to purify the diastereomeric salts separated by repetition of recrystallization. (±)-Proline ((±)-Pro) has been optically resolved through its diastereomeric salts with an optically active dibasic acid, (+)-tartaric acid.[4] This suggests that (−)-Pro would easily form a salt with a dibasic acid such as PSA. Thus, optical resolution of (±)-PSA was attempted by using (−)-Pro as a resolving agent to find out a more practical procedure. In this note, 1-1 and 1-2 salts represent a salt composed of equimolar amounts of PSA and (−)-Pro and one composed of 1-molar amount of PSA and 2-molar amount of (−)-Pro, respectively; salts which contain the PSA rich in the (+)-enantiomer are represented as (+)-1-1 and (+)-1-2 salts, and those rich in (−)-PSA as (−)-1-1 and (−)-1-2 salts.

Experimental

Materials. (±)-PSA was obtained from Aldrich Chemical Co., Inc., (+)-PSA ($[\alpha]_D^{20}$ +168° (*c* 2.00, acetone); lit,[3] $[\alpha]_D^{20}$ +173.3° (*c* 1.8235, acetone)) from Kanto Chemical Co., Ltd., and (−)-Pro ($[\alpha]_D^{20}$ −84.7° (*c* 1.00, water)) from Wako Pure Chemical Ind., Ltd. (−)-PSA was obtained by optical resolution; $[\alpha]_D^{20}$ −170° (*c* 2.00, acetone).

Preparation of Standard Salts. 1-2 Salts: (+)-PSA (0.01 mol, 1.942 g) and 0.02 mol (2.302 g) of (−)-Pro were dissolved in 80 cm^3 of ethanol. After stirring for 1 h at room temperature, the (+)-1-2 salt formed was collected by filtration and recrystallized from ethanol: yield 3.53 g; mp 160 °C; $[\alpha]_D^{20}$ +13.5° (*c* 1.00, methanol); solubility at 30 °C 1.04 g/(100 cm^3 ethanol).

Found: C, 56.49; H, 6.60; N, 6.57%. Calcd for $C_{20}H_{28}N_2O_8$: C, 56,60; H, 6.65; N, 6.60%.

In the case of (−)-1-2 salt, after stirring a similar initial solution for 30 min at 15 °C, the crude (−)-1-2 salt formed was removed by filtration and the filtrate was stirred for 30 min in an ice bath. The (−)-1-2 salt crystallized was collected by filtration and washed thoroughly with diethyl ether: yield 1.70 g; mp 130 °C; $[\alpha]_D^{20}$ −107°(*c* 1.00, methanol); solubility at 30 °C 3.12 g/(100 cm^3 ethanol).

Found: C, 56.78; H, 6.70; N, 6.62%

1-1 Salts: After dissolving 0.02 mol of (+)- or (−)-PSA and 0.01 mol of (−)-Pro in ethanol, the solution was evaporated to dryness under reduced pressure around 50 °C. The residue was stirred in 200 cm^3 of diethyl ether for 1 h. The salt was collected by filtration and washed with diethyl ether.

(+)-1-1 Salt: Yield 2.92 g; mp 141 °C; $[\alpha]_D^{20}$ +51.4° (*c* 1.00, methanol).

Found: C, 58.09; H, 6.14; N, 4.50%. Calcd for $C_{15}H_{19}NO_6$: C, 58.25; H, 6.19; N, 4.53%

(−)-1-1 Salt: Yield 2.90 g; mp 136 °C; $[\alpha]_D^{20}$ −117° (*c* 1.00 methanol).

Found: C, 57.99; H, 6.18; N, 4.56%

Optical Resolution. Procedure I: (−)-Pro (0.02 mol) was dissolved in 80 cm^3 of ethanol. After cooling to 40 °C, 20 cm^3 of an ethanolic solution of 0.02 mol of (±)-PSA was added, and the solution was stirred for 30 min at 40 °C. The (+)-1-2 salt formed was collected by filtration: yield 2.88 g; $[\alpha]_D^{20}$ +3.8° (*c* 1.00, methanol). After evaporating the filtrate to dryness under reduced pressure around 50 °C, the residure was stirred in 200 cm^3 of diethyl ether for 1 h at room temperature. Then, the (−)-1-1 salt formed was collected by filtration: yield 1.98 g; $[\alpha]_D^{20}$ −115° (*c* 1.00, methanol). PSA (1.23 g, $[\alpha]_D^{20}$ +10.5° (*c* 2.00, acetone)) was recovered from the filtrate and resolved similarly to above. (+)-1-2 Salt ($[\alpha]_D^{20}$ +4.0° (*c* 1.00, methanol)) and (−)-1-1 salt ($[\alpha]_D^{20}$ −115° (*c* 1.00, methanol)) were obtained in 0.91 and 0.66 g yields, respectively, and 0.39 g of PSA was recovered.

Procedure II: (±)-PSA (0.02 mol) was dissolved in 100 cm^3 of 2-propanol, and 0.02 mol of (−)-Pro was added. After refluxing for 30 min followed by stirring for 30 min at 25°C, the (+)-1-2 salt formed was collected by filtration and washed with diethyl ether: yield 4.00 g; $[\alpha]_D^{20}$ +4.0° (*c* 1.00, methanol). After evaporating the filtrate to dryness, the residue and 0.780 g of (−)-Pro were dissolved in ethanol, and the solution was again evaporated to dryness under reduced pressure around 50 °C. After stirring the residue in 200 cm^3 of diethyl ether for 1 h at room temperature, (−)-1-1 salt was collected by filtration and washed with diethyl ether: yield 2.37 g; $[\alpha]_D^{20}$ −114° (*c* 1.00, methanol). PSA (0.35 g) was recovered from the filtrate.

The optical purities of the salts obtained by the procedures I and II were calculated on the basis of the specific rotations of the standard salts.

Preparation of (+)- and (−)-Phenylsuccinic Acids: (+)-1-2 Salt with an optical purity of around 80% was added to ethanol (6 cm^3 g^{-1}). After refluxing for 30 min followed by stirring for 30 min at 30 °C, the (+)-1-2 salt purified was collected by filtration. The (+)-1-2 salt purified or the (−)-1-1 salt obtained was added to concentrated hydrochloric acid (5 cm^3 g^{-1}). After stirring for 1 h in an ice bath, PSA was collected by filtration, washed with a small amount of cooled water, and dried. The PSA was dissolved in diethyl ether, and the solution was filtered. The filtrate was evaporated to dryness to obtain (+)- and (−)-PSAs. For example, 3.23 g of (+)-1-2 salt with an optical purity of 98% gave 1.39 g of (+)-PSA with that of 99.1%; the yields of (+)- and (−)-PSAs were calculated on the basis of the half amount of (±)-PSA consumed by reaction (1.942 g). It is confirmed by ^{1}H NMR spectra in acetone-d_6 that the (+)-and (+)-PSAs obtained are free from (−)-Pro.

Measurements. Specific rotations were measured with a

Union Giken high sensitivity PM-101 digital polarimeter. The solubilities of the standard (+)- and (−)-1-2 salts and the ternary phase diagram were obtained in a similar manner as described in our previous paper;[5)] (+)- and (−)-1-2 salts have maximal absorptions at 259 nm and molar absorptivities are 152 $cm^3\ mol^{-1}\ cm^{-1}$, ^1H NMR spectra were recorded on a JEOL JNM-PMX 60 NMR spectrometer.

Results and Discussion

Influence of Temperature on Formation of Salts. A separation of the diastereomeric salts was attempted for an ethanolic solution containing 0.01 mol of (±)-PSA and (−)-Pro at 5—40 °C similarly to the optical resolution described in the experimental section. The total amount of ethanol was 50 cm^3. The ^1H NMR spectrum in deuterium oxide and the specific rotation indicated that (+)-1-2 salt deposited selectively from the solution. (−)-1-1 Salt and unreacted PSA were obtained by evaporating the mother liquor to dryness around 50 °C, and the (−)-1-1 salt had an optical purity of about 100%. These results are given in Table 1. The relationship between the degrees of resolution of (+)-1-2 and (−)-1-1 salts and temperature was examined to resolve (±)-PSA efficiently, as shown in Fig. 1. The degrees of resolution were calculated by

$$\text{degree of resolution}/\% = (\text{yield of salt}/g \times \text{optical purity}/\% \times f)/0.971/g, \quad (1)$$

where f is 0.458 for (+)-1-2 salt and 0.628 for (−)-1-1 salt.

The degree of resolution of (+)-1-2 salt is scarcely influenced by temperature, since the optical purity increases with increase in temperature though the yield decreases. On the other hand, the degree of resolution of (−)-1-1 salt linearly increases with increase in temperature. Therefore, it is found that, of the temperatures employed, the separation of (+)-1-2 salt at 40 °C yields (−)-1-1 salt with an optical purity of 98% in the highest yield from the mother liquor.

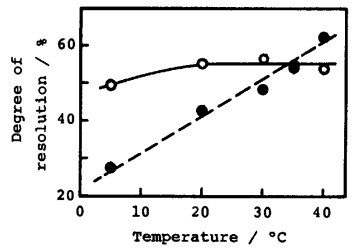

Fig. 1. Relationship between degree of resolution and temperatures. (±)-PSA and (−)-Pro: 0.01 mol. Total amount of ethanol: 50 cm^3.
——○——: (+)-1-2salt, ——●——: (−)-1-1 salt.

A separation of (+)-1-2 salt was attempted at 45 °C with the expectation that (−)-1-1 salt with high optical purity would be obtained in higher yield. However, (+)-1-2 salt did not crystallize under this condition. In the preparation of the standard salts, the salt formation using equimolar amounts of (+)-PSA and (−)-Pro gave (+)-1-2 salt and unreacted (+)-PSA, though (+)-1-1 salt was obtained when (+)-PSA and (−)-Pro were used in the molar ratio of 2 : 1. Moreover, after (+)-1-2 salt was filtered off from a solution of equimolar mixture of (±)-PSA and (−)-Pro, a stirring of the mother liquor in an ice bath or a concentration around 40 °C gave 1-2 salt which was a near racemate. The above results suggest that (+)-1-2 salt tends to form from (±)-PSA and (−)-Pro, and that (−)-1-2 salt forms below 40 °C, whereas (−)-1-1 salt forms above 45 °C.

Optical Resolution by Procedure I. In view of the results in the preceding section, an optical resolution of (±)-PSA was carried out at 40 °C as specified in Table 2. A (+)-1-2 salt with an optical purity of 84% crystallized from the initial solution. A (−)-1-1 salt with an optical purity of 98% and PSA were obtained from the mother liquor. Since the PSA was a near racemate and the yield was about one third of (±)-PSA consumed by reaction, the PSA was again allowed to

a) (±)-PSA: 0.02 mol. b) $[\alpha]_D^{20}$ (*c* 1.00, methanol). c) The optical purities were calculated on the basis of the specific rotations of standard (+)- and (−)-1-1 salts and 1-2 salt. d) The yields were calculated on the basis of 1.942 g. e) $[\alpha]_D^{20}$ (*c* 2.00, acetone). f) The optical purities were calculated on the basis of the specific rotation of (+)-PSA: $[\alpha]_D$ +173.3° (*c* 1.8235, acetone). g) PSA (0.39 g) was recovered; $[\alpha]_D^{20}$ +17.1°. (*c* 2.00, acetone). h) PSA (0.35 g) was recovered; $[\alpha]_D^{20}$ +17.8° (*c* 2.00, acetone). i) The salt was not purified.

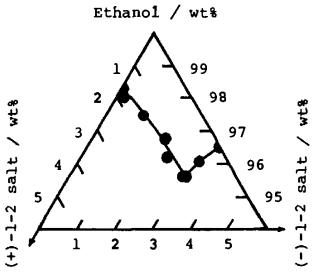

Fig. 2. Ternary phase diagram of solubility of 1-2 salt
Solvent: Ethanol. Temperature: 30°C.

react with an equimolar amount of (−)-Pro. The (±)-1-2 and (−)-1-1 salts obtained in the second run had the same optical purities as the salts obtained in the first run, so that both the salts obtained in the first and second runs were combined. The (−)-1-1 salt was treated with hydrochloric acid without recrystallization, since the salt had an optical purity of about 100%. The salt gave (−)-PSA with an optical purity of 98.1% in 80.3% yield.

For purification of the (+)-1-2 salt, the optimum amount of ethanol was calculated on the basis of the ternary phase diagram of solubility at 30 °C in ethanol shown in Fig. 2;[6)] at the eutectic point, the amount of (+)-1-2 salt is 1.34 wt%, that of (−)-1-2 salt 3.07 wt%, and that of ethanol 95.59 wt%. For 1 g of the (+)-1-2 salt with an optical purity of 80%, the optimum amount of ethanol calculated is 3.99 cm^3. However, 6 cm^3 of ethanol was employed, since 3.99 cm^3 of ethanol was too small to handle. The purification of the crude gave (+)-PSA with an optical purity of 99.1% in 71.7% yield.

Optical Resolution by Procedure II. A suspension of equimolar mixture of (±)-PSA and (−)-Pro in 2-propanol selectively gave (+)-1-2 salt with an optical purity of 84%. The (+)-1-2 salt purified gave (+)-PSA with an optical purity of 98.7% in 83.0% yield. This result is given in Table 2.

It is estimated from the results in ethanol that although equimolar amounts of (+)- and (−)-PSAs in the mother liquor form a racemic compound with each other, the excess of (−)-PSA forms (−)-1-1 salt with an equimolar amount of (−)-Pro. The amounts of (±)-PSA, (−)-PSA, and (−)-Pro in the mother liquor were calculated on the basis of the yield and optical purity of the (+)-1-2 salt obtained: (±)-PSA 0.514 g (0.0026 mol), (−)-PSA 1.540 g (0.0079 mol), and (−)-Pro 0.133 g (0.0011 mol). Therefore, after evaporating the mother liquor to dryness, the residue obtained was allowed to react with 0.780 g (0.0068 mol) of (−)-Pro in ethanol to give (−)-1-1 salt with an optical purity of 96% in 2.37 g yield; the theoretical yield is 2.45 g. (−)-PSA with an optical purity of 96.6% was obtained in 70.5% yield from the (−)-1-1 salt.

The above results indicate that it is possible to resolve (±)-PSA optically by using (−)-Pro as a resolving agent and to obtain (+)- and (−)-PSAs with optical purities of about 100% in 70—83% yield.

Synthesis and Biological Activity of Substance P Analogs Containing Pyrohomoglutamic Acid and Homoglutamine

Tadashi HASHIMOTO,* Naoki SAKURA, Kyoko HIROSE, Yoshiki UCHIDA, Miwako NISHIJIMA, and Tadashi MORO
School of Pharmacy, Hokuriku University, Ho-3, Kanagawa-machi, Kanazawa 920-11
(Received August 26, 1986)

Synopsis. Eight substance P analogs substituted by L- or D-pyrohomoglutamic acid (6-oxo-2-piperidinecarboxylic acid) and L- or D-homoglutamine at the position 5 and 6 were prepared by the solid phase method. The contractile activities of the analogs were compared with that of SP on isolated guinea-pig organs.

Synthetic study[1] on thyrotropin-releasing hormone [TRH: pGlu-His-Pro-NH_2[2]] revealed that TRH analogs containing pyrohomoglutamic acid (pHgu-OH: 6-oxo-2-piperidinecarboxylic acid) at the N-terminus showed relative selectivity for action in the central nervous system. Therefore, the substitution of pHgu residue for pGlu at N-terminus of a bioactive peptide may be able to provide a new knowledge of the structure-activity relationships.

Up to date, L-pHgu moiety has been incorporated into peptide chain using L-pHgu-OH and the usual peptide bond forming reagent. However, the preparation of L-pHgu-OH involves a troublesome work, that is, generally an enzymatic resolution[3] of N-acetyl-DL-homoglutamic acid (DL-Ac-Hgu-OH) to give L-H-Hgu-OH, followed by cyclization procedure. Our investigation[4] developed a simple method for synthesis of pHgu-peptide that Hgn residue at N-terminus in peptide chain could be cyclized to produce pHgu residue. D-Hgn-peptide is readily converted and yields a new amino acid D-pHgu residue. This conversion reaction was applied to the synthetic study on analogs of substance P (SP) related peptides, pGlu-Gln-Phe-Phe-Gly-Leu-Met-NH_2 (**1**) and pGlu-Phe-Phe-Gly-Leu-Met-NH_2 (**2**), which potencies (Table 1) are higher than the contracting activity of SP itself of guinea-pig ileum.[5]

This paper describes syntheses and biological properties of eight analogs (Fig. 1) of the SP related peptides containing L- or D-pHgu and L- or D-Hgn at position 5 and 6. The contracting activities of the synthetic peptides were compared with that of our synthetic SP in order to examine the biological effects of the substitution of L- or D-pHgu for pGlu moiety and of the replacement of Gln residue by L- or D-Hgn on pGlu-peptides.

The SP analogs were synthesized in the same way with the preparation of SP analogs containing L-Hgn[6] and D-Hgn[7] by the solid phase technique[8] on an automated peptide synthesizer. *t*-Butoxycarbonyl (Boc) protection was used for α-amino function except benzyloxycarbonyl(Z) for pGlu-OH, and the amide nitrogen (N^{ca}) of Hgn. N-Terminal Hgn-peptide was kept at 40 °C for 4 h in aq acetic acid (50%) to produce pHgu moiety. The crude product was purified by preparative reverse-phase high-performance liquid chromatography (HPLC) using aq trifluoroacetic acid (0.1%) in acetonitrile as eluent. Highly purified peptides (Table 2, 3) were obtained after gel filtration on Sephadex G-10 column. The yield was sacrificed for the purity. Homogeneity of the peptides was demonstrated by analytical HPLC and thin-layer chromatography (TLC). When single peaks and single spots were observed for a synthetic peptide in all chromatographic systems, the peptide was considered appropriately pure for bioassay. These chromatographic data were reinforced by the amino acid analytical data.

The results of biological properties of the synthetic analogs are shown in Table 4.

The potency of D-pHgu heptapeptide analog **4** was as high as the contractile activity of **1** and higher than that of L-pHgu-peptide **3** on isolated guinea-pig ileum. The both replacements of pGlu and Gln

a) Homoglutamic acid.

Table 4. Relative Potencies of Synthetic Analogs on Guinea-Pig Organs

Analog	Relative activity accepted SP as 1	
	Ileum	Trachea
3	0.65	1.10
4	1.76	0.78
5	2.08	3.64
6	0.07	<0.01
7	0.88	1.74
8	0.10	<0.01
9	1.50	3.01
10	0.17	0.14

residues with L- or D-pHgu and L- or D-Hgn brought the decreases of the contracting activities on the ileum assay. Analogs **7** and **8** had 90 and 10% of the activity of SP, and 50 and 6% of that of **1** respectively. pGlu-peptide analogs **5** possessed the highest activities among the eight analogs **3**—**10** on the both assays, while D-Hgn analog **6** showed the lowest potency. Hexapeptide analog **9** was found to be highly active on the both assays, and had 150 and 300% of the activity of SP on the ileum and trachea assays respectively and 75% of that of **2** on the ileum assay. Similarly to SP analogs containing L-Hgn[6] or D-Hgn,[7] the replacement of Gln moiety with L-Hgn on pGlu-peptide enhanced the biological activity, while D-Hgn analog **6** possessed reduced activity. The data indicate that L-pHgu-peptide analogs exert potent agonistic effects and the substitution of D-pHgu for pGlu, except for analog **4**, brings the drastic decrease of the activity. The results also suggest that the L-configuration of the amino acid residue at the position 6 may be more important than that of the residue at the position 5 for the contractile activities of SP related peptides.

Experimental

Amino acid derivatives were purchased from Peptide Institute, Inc., Osaka, and benzhydrylamine (BHA) resin (available amine of the resin: 0.6 mmol g^{-1} of support) from Beckman Inc. Optical rotations were measured in a Nipponbunkoh DIP-4 Polarimeter. Amino acid analyses on samples previously hydrolyzed with 6 M HCl (1 M=1 mol dm^{-3}) (110 °C, 24 h) were performed on a Hitachi KLA-5 Amino Acid Analyzer. TLC were carried out on silica-gel plates (Merck). The following solvent systems were used: R_f^I, *n*-BuOH : AcOH : H_2O (4 : 1 : 5, upper phase); R_f^{II}, *n*-BuOH: pyridine: AcOH: H_2O (30 : 20 : 6 : 24). Analytical HPLC were effected on the following systems: column, NOVA-PAK C_{18} (3.9×150 mm); flow rate, 1 ml min^{-1}; detection, 210 nm; eluent system, linear gradient for 15 min from 21% to 35% CH_3CN in 20 mM phosphate buffer (pH 3.0).

General Procedure for the Preparation of Analogs. The solid phase synthesis was carried out using a Beckman System 990 C Peptide Synthesizer as described previously.[6] Half gram of BHA-resin hydrochloride for each analog served as the solid support. A 2.5 fold excess of amino acid derivative was used for all coupling. The coupling was affected with DCC/HOBt.† The protected peptide resin was treated with anhydrous liquid HF containing 10% anisole. After evaporation of HF in vacuo, the peptide was extracted with 50% AcOH. The extract of N-terminal Hgn-peptide was kept at 40 °C for 4 h to yield pHgu moiety.

Purification of the Peptides. The crude peptide was subjected to HPLC as reported previously.[6] The apparatus was

†DCC=dicyclohexylcarbodiimide, HOBt=1-hydroxybenzotriazole.

composed of a model 590 pump and a U6K injector (Waters) connecting with a column (20×300 mm) of Chemcosorb ODS (Chemco). The eluates were monitored with a UV detector S-310A model-II (Soma) at 210 nm wavelength. CH_3CN–0.1% TFA solvent system was used as eluent at flow rate 10 ml min^{-1}. Each peptide was emerged at 40—60 min by isocratical elution with 27—34% CH_3CN contents of the solvent system. The desired fraction was passed through a Sephadex G-10 column (16×930 mm) eluted with 2 M AcOH. Homogeneity of the peptides was analyzed by analytical HPLC and TLC.

Bioassay. The agonistic activity of the synthetic analog was measured on ileum and trachea taken from guinea-pig, as described before.[6] The contraction was recorded by means of an isotonic transducer (Nippon Kohden, TD-111T) with load of 1 or 2 g (for trachea and ileum respectively) on a Servocorder (Watanabe Instruments, SR6204). Concentration-response curves were obtained using a cumulative dose-assay, and the time between two consecutive dose-response curves was longer than 10 min.

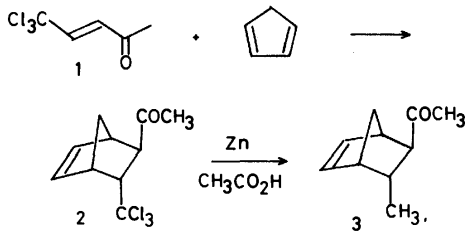
Electrochemical Reduction of *exo*-5-Acetyl-*endo*-6-trichloromethylbicyclo[2.2.1]hept-2-ene

Sadao TSUBOI, Yasuhiro ISHIGURO, and Akira TAKEDA*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received September 5, 1986)

Synopsis. Electrochemical reduction of exo-5-acetyl-endo-6-trichloromethylbicyclo[2.2.1]hept-2-ene (**2**) using a mercury cathode gave chemoselectively either the corresponding monochloromethyl or dichloromethyl derivatives in high yields by selecting supporting electrolyte. The reduction of **2** using a lead cathode gave 2-acetyl-3-methylbicyclo[2.2.1]-hepta-2,5-diene and *cis*-1-(4-vinyl-2-cyclopentenyl)-2-propanone together with by-products.

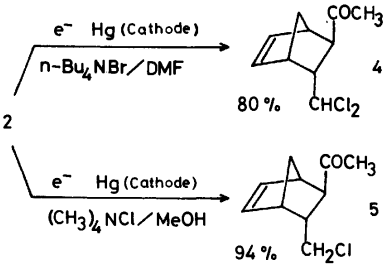
As our continuing studies on the chemistry of 5,5,5-trichloro-3-penten-2-one (**1**),[1] we reported that **1** reacted with cyclopentadiene giving stereospecifically exo-5-acetyl-endo-6-trichloromethylbicyclo[2.2.1]hept-2-ene (**2**) in a high yield.[1d] If conversion of the trichloromethyl group of **2** to a chloromethyl or a methyl group could be accomplished, the stereospecific introduction of these groups into the endo position of norbornene will become possible. This conversion was poorly accomplished by conventional reduction of **2** with zinc in acetic acid affording *exo*-5-acetyl-*endo*-6-methylbicyclo[2.2.1]hept-2-ene (**3**) in 13% yield,[1d] which is a minor component of the mixture obtained from the reaction of 3-penten-2-one with cyclopentadiene.[2] As an electrochemical method may be profitable in conversion of compound **2** to **3**, we investigated the cathodic reduction of **2** under various conditions.



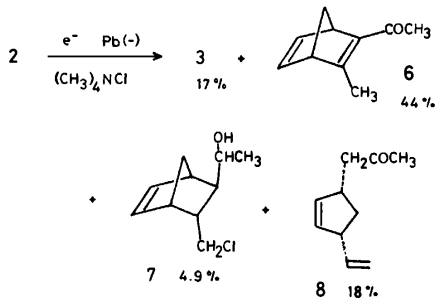
Results and Discussion

Only a few investigations have been made on the electrochemical reduction of trichloromethyl compounds. Nagao, et al.[3] have reported that $\alpha,\alpha,\alpha,\omega$-tetrachloroalkanes can be converted to either α,ω-dichloroalkanes or α,α,ω-trichloroalkanes by selecting cathodic supporting electrolyte. We carried out the reduction of **2** under the similar conditions.

When norbornene **2** was reduced electrolytically at the mercury cathode using tetrabutylammonium bromide as a supporting electrolyte in *N*,*N*-dimethylformamide (DMF), *exo*-5-acetyl-*endo*-6-dichloromethylbicyclo[2.2.1]hept-2-ene (**4**) was obtained in 80% yield. Compound **4** was identical with the major component of the products obtained from the Diels-Alder reaction[1d] of 5,5-dichloro-3-penten-2-one with cyclopentadiene. On the other hand, *exo*-5-acetyl-*endo*-6-chloromethylbicyclo[2.2.1]hept-2-ene (**5**) was formed in 94% yield when tetramethylammonium chloride was used in a 90% methanol solution. It is clear that a supporting electrolyte plays an important role in the present chemoselectivity in the reduction of trichloromethyl group.



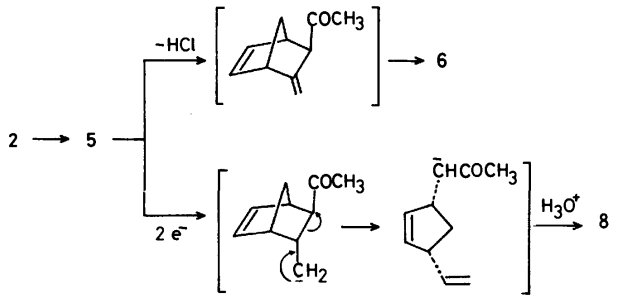
However, the reduction of compound **2** with a lead cathode using tetramethylammonium chloride gave nonchemoselectively 2-acetyl-3-methylbicyclo[2.2.1]-hepta-2,5-diene (**6**) in 44% yield together with **3** (17%), *exo*-5-(1-hydroxyethyl)-*endo*-6-chloromethylbicyclo-[2.2.1]hept-2-ene (**7**) (4.9%) (1 : 1 diastereomeric mixture) and *cis*-1-(4-vinyl-2-cyclopentenyl)-2-propanone (**8**) (18%). The structure of **6** was elucidated by spectral data. Mass spectrum showed a clear peak of molecular ion at m/z 148. The IR bands of **6** at 1665 cm^{-1} are characteristic of the α,β-unsaturated ketone. The structure of **7** was confirmed by the fact that the oxidation with chromium trioxide gave ketone **5**.



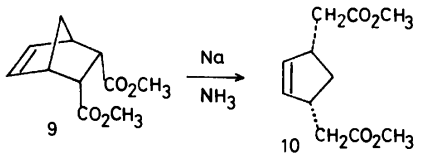
Reduction of **2** with zinc in acetic acid also has afforded cyclopentene **8** as a minor product in addition to **3**, although the structure has not been clarified.[1d] The structure of **8** was determined on the basis of IR, NMR, MS, and elemental analyses. The NMR spectrum of **8** was very similar to that of methyl 4-vinyl-2-cyclopentene-1-acetate with the exception of a singlet (2.15 ppm, $COCH_3$).[4] A signal due to olefin protons of cyclopentene appeared as a singlet at 5.68 ppm along with the disappearence of a signal (ca. 6.2 ppm) due to olefin protons of norbornene. Two multiplets (4.80—5.23 and 5.5—6.1 ppm) due to three olefin protons show the existence of a vinyl group. The unusual high δ value of cis proton of cyclopentene methylene is undoubtedly due to shielding effect of both vinyl and carbonyl groups. In mass spectrum of **8** (MW 150), the

peaks at m/z 107 and 93 show the existence of an acetonyl group. The base peak at m/z 92 must be due to ions of vinylcyclopentadiene.

The following mechanism can be postulated for the formation of **6** and **8**. Compound **6** would be presumably formed from **5** via dehydrochlorination and prototropic shift. Cyclopentene **8** would be produced from **5** via C-C bond cleavage induced by anion. The C-C bond cleavage of norbornene derivatives under



electroreductive conditions is interesting and is similar to a cleavage of diester **9** to produce **10** upon treatment with Na/NH_3.[5,6]



In conclusion, the electrochemical method using mercury cathode could reduce trichloromethyl compound **2** either to dichloromethyl compound **4** or monochloromethyl compound **5** chemoselectively in high yields. In contrast to the conventional method such as the reduction with $Zn-CH_3CO_2H$, the reaction proceeded with no contamination of resinous materials.

Experimental

The melting points and boiling points are uncorrected. Analytical determinations by GLPC were performed on a Hitachi model K-53 gas chromatograph using columns filled with 10% Apiezone Grease L on Chromosorb W (3 mm ϕ×1 m) or 10% polyneopentyl glycol succinate on Chromosorb W (3 mm ϕ×1 m). Preparative GLC was performed on a Yanagimoto model GCG-550 T gas chromatograph. IR spectra were determined on a Hitachi model EPI-S2 spectrometer. ^1H NMR spectra (60 MHz) were obtained with a Hitachi model R-24 apparatus. The mass spectra were measured on a Hitachi model RMS-4 mass spectrometer at 70 ev.

Electrolysis. The electrochemical cell consisted of an anode porcelain cylinder (35 mm in diameter; 150 mm in height) fitted with a calcium chloride tube, and of a cathode glass vessel (80 mm in diameter, ca. 300 ml content) fitted with a gas lead pipe, a thermometer, and a magnetic stirrer. All electrolyses were carried out at room temperature under N_2. Mercury (300 g; surface area, 50 cm^2) or lead (60 mm in diameter; 1.5 mm in thickness; surface area, ca. 58 cm^2) was used as the cathod, while a platinum wire (1.0 mm ϕ×75 mm) was used as an anode.

Material. *exo*-5-Acetyl-*endo*-6-trichloromethylbicyclo-[2.2.1]hept-2-ene (**2**) was prepared from 5,5,5-trichloro-3-penten-2-one (**1**) and cyclopentadiene.[1d]

Reduction of 2 with $Zn-CH_3CO_2H$. This reaction was reported in the previous paper.[1d] The structure of the minor component was newly determined as **8**: 10% yield: IR (neat) 1710 (C=O), 1636 (C=C), 1360, 1160, 910; ^1H NMR ($CDCl_3$) δ=0.8—1.4 (m, 2H, ring CH_2), 2.15 (s, 3H, $COCH_3$), 2.25—2.7 (m, 2H, $C\underline{H}_2COCH_3$), 2.8—3.5 (m, ring methyne), 4.80—5.23 (m, 2H, $CH{=}C\underline{H}_2$), 5.68 (s, 2H, CH=CH), 5.5—6.1 ppm (m, 1H, $C\underline{H}{=}CH_2$); MS (70 ev) m/z (rel intensity) 150 (M^+, 2), 135 (10), 107 (M-$COCH_3$, 38), 93 (56), 92 (100), 91 (86), 79 (58), 77 (60), 66 (58), 43 (72). Found: C, 79.73; H, 9.56%. Calcd for $C_{10}H_{14}O$: C, 79.96; H, 9.39%.

Electrochemical Reduction of 2. (a) Mercury was used as the cathode. A mixture of **2** (2.00 g, 8 mmol), tetrabutylammonium bromide (1.935 g, 6 mmol), and *N,N*-dimethylformamide (100 ml) was charged in a cathode cell. Tetrabutylammonium bromide (0.967 g, 3 mmol) and *N,N*-dimethylformamide (50 ml) was charged in an anode cell. The electrolysis with terminal voltage 27.0 V (current, 40—200 mA) was continued until the starting material **2** was consumed (24 h). The organic materials of the cathode cell were extracted with ether. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated to give 1.43 g (80% yield) of **4** as crystals: 98% pure by GLC analysis (column, polyneopentyl glycol succinate, 150 °C; carrier gas, N_2, 0.5 kg cm^{-2}); mp 68—70 °C (from hexane)(lit,[1d] 66—67.5 °C). IR and ^1H NMR data were identical with those reported previously.[1d] No trace of the isomers was detected by ^1H NMR.

(b) Mercury was used as the cathode. In a cathode cell a mixture of **2** (2.00 g, 8 mmol) tetramethylammonium chloride (2.19 g, 20 mmol), and 90% methanol (100 ml) was charged. In an anode cell a solution of tetramethylammonium chloride (1.10 g, 10 mmol) in 90% methanol (50 ml) was charged. The electrolysis with terminal voltage 27.0 V (44—219 mA) was carried out at room temperature until the starting material **2** was consumed (24 h). The organic materials in the cathode cell were extracted with ether and worked up as described above, giving 1.39 g (94% yield) of **5** as a clean oil: 99% pure by GLC analysis (column, polyneopentyl glycol succinate, 150 °C; carrier gas, N_2, 0.5 kg cm^{-2}); bp 85—87 °C/3 Torr; IR (neat) 1709, 1570 cm^{-1}; MS (70 eV) m/z (rel intensity) 184 (M^+, 7), 149 (M—Cl, 79), 145 (80), 121 (66), 119 (95), 105 (84), 91 (69), 77 (69), 66 (100); ^1H NMR ($CDCl_3$) δ= 1.18—1.74 (m, 2H, C_7-H), 1.87—2.08 (m, 1H, $C\underline{H}COCH_3$), 2.22 (s, 3H, $COCH_3$), 2.5—3.8 (m, 1H, $C\underline{H}CH_2Cl$), 2.85—3.13 (m, 2H, C_1-H, C_4-H), 3.27 (d, 2H, J=6.5 Hz, CH_2Cl), 5.95—6.50 ppm (m, 2H, CH=CH). Found: C, 65.13; H, 7.11%. Calcd for $C_{10}H_{13}ClO$: C, 65.04; H, 7.09%.

(c) Lead was used as the cathode. A mixture of **2** (2.00 g, 8.0 mmol), tetramethylammonium chloride (2.19 g, 20 mmol), and 90% methanol (100 ml) was charged in a cathode cell. A solution of tetramethylammonium chloride (1.10 g, 10 mmol) in 90% methanol was charged in an anode cell. The electrolysis was carried out at terminal voltage 15 V (0.1—0.5 A) at room temperature. Every one hour the reaction mixture was analyzed by GLC. After 10 h, the organic materials in the cathode cell were extracted with ether. The combined extracts were washed with water and dried over $MgSO_4$. Removal of the solvent gave 1.22 g of an oil. GLC (column, Apiezone Grease L, 160 °C; carrier gas N_2, 0.5 kg cm^{-2}) analysis showed five peaks. Peaks, retention times (min), and percentages of peak area are as follows: 1, 1.4, 17%; 2, 1.6, 18%; 3, 2.3, 16%; 4, 3.6, 43%; 5, 7.6, 6%. Each component was separated by preparative GLC and identified. Peak 1: **3**; 17% yield. The retention time, and IR and ^1H NMR data were identical with those of the sample prepared from the reduction of **2** with $Zn-CH_3CO_2H$. Peak 2: **8**; 18% yield. Spectral data were identical with those described above. Peak 3: the structure was unidentified. Peak 4: **6**; 44% yield; IR (neat) 1665 (C=O), 1562 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.82 (s,

3H, CH_3), 2.05 (s, 3H, $COCH_3$), 2.12 (m, 2H, CH_2), 2.94 (br. s, 1H, methyne), 3.40 (m, 1H, methyne), 5.92 (m, 2H, CH=CH); MS (70 eV) *m/z* (rel intensity) 148 (M^+, 29), 133 ($M-CH_3$, 27), 105 ($M-COCH_3$, 100), 103 (47), 79 (73), 77 (69), 70 (82). Found: C, 81.05; H, 8.21%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%. Peak 5: **7**; 4.9% yield; IR (neat) 3380 (OH), 2960, 1330, 900, 715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.29 (d, 3H, J=6 Hz, CH_3), 1.50 (br. s, 1H, ring CH_2), 1.65 (s, 1H, OH), 2.0—4.0 (m, 7H, 5 methyne, CH_2Cl), 6.2 ppm (m, 2H, CH=CH). Found: C, 64.10; H, 8.08%. Calcd for $C_{10}H_{15}ClO$: C, 64.34; H, 8.10%.

Conversion of 7 to 5. To 3 ml of dry pyridine was added CrO_3 (0.31 g, 3.1 mmol) at 15—20 °C with stirring. A solution of **7** (0.199 g, 1.07 mmol) in dry pyridine (3 ml) was added and the mixture was stirred overnight at room temperature, and then poured into cold water. The organic materials were extracted with benzene-ether (1 : 1), washed with water, dried over $MgSO_4$, and concentrated. The residue was chromatographed on SiO_2 (hexane/acetone, 10 : 1), giving 80 mg (40%) of **5**: TLC (SiO_2; hexane/acetone, 3 : 1) R_f 0.54. IR and ^1H NMR spectra were identical with those of the sample prepared above.

We are grateful to Dr. R. D. Miller of International Business Machines Corporation (IBM) for the gift of ^1H NMR spectra of methyl 4-vinyl-2-cyclopentene-1-acetate and for a fruitful suggestion. We also thank Mr. Eiichiro Amano of our laboratory for elemental analyses.

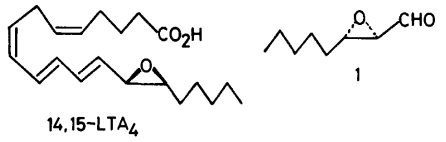
Asymmetric Synthesis of (2*R*,3*S*)-2,3-Epoxyoctanal, a Key Intermediate of 14,15-Leukotriene A_4

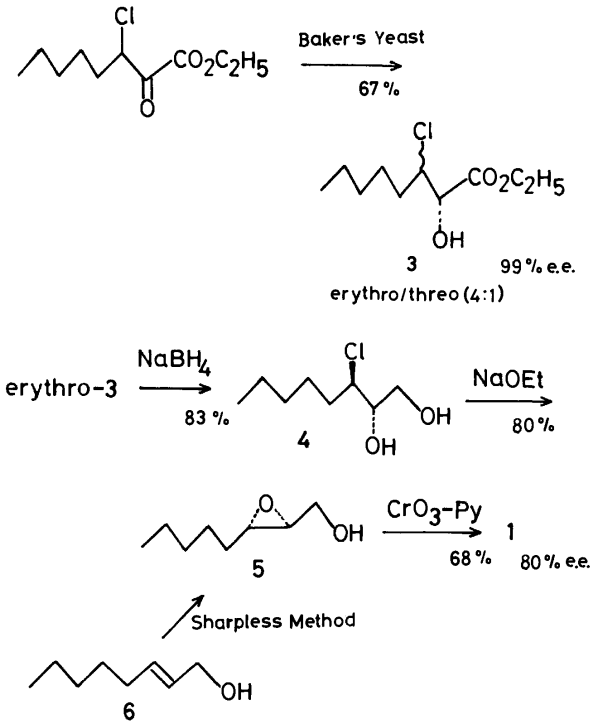
Sadao Tsuboi, Hiroyuki Furutani, and Akira Takeda*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received September 11, 1986)

Synopsis. Asymmetric reduction of ethyl 3-chloro-2-oxooctanoate with baker's yeast gave ethyl 3-chloro-2-hydroxyoctanoate (**3**) [(2*S*,3*R*)/(2*S*,3*S*), 4:1] in 67% yield with >99% e.e. Chlorohydrin (2*S*,3*R*)-**3** was converted to the titled compound in 34% total yield with 80% e.e. via the reduction, dehydrochlorination, and oxidation, successively. (2*R*,3*R*)-2,3-Epoxyoctanal was also prepared from (2*S*,3*S*)-**3** in 33% total yield with 94% e.e.

Samuelsson[1] has reported that (5*Z*,8*Z*,10*E*,12*E*)-icosatetraenoic acid (14,15-LTA_4) is formed by oxidation of arachidonic acid with 15-lipoxygenase and is a key intermediate in further biological transformations. Because of the unavailability of unstable metabolites from natural sources, the synthesis becomes important. Zamboni et al.[2] reported a stereospecific synthesis of 14,15-LTA_4 by using (2*R*,3*S*)-2,3-epoxyoctanal (**1**) as a key intermediate. However, reports on the

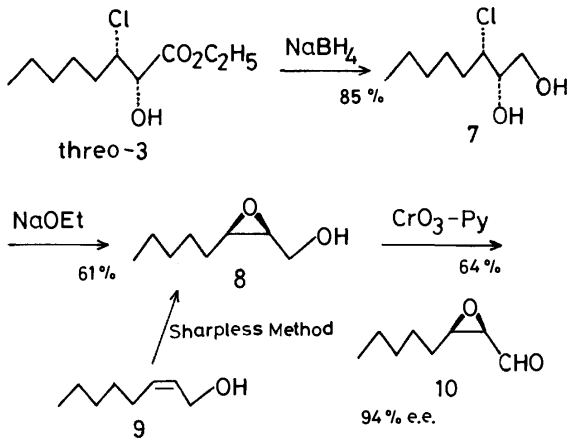


synthesis of **1** are quite few.[3] Here we describe a convenient synthesis of **1** using chiral reduction with fermenting baker's yeast. The reaction sequence is shown in Scheme 1.



Scheme 1.

The starting material, ethyl 3-chloro-2-oxooctanoate (**2**) is readily available by Darzen type condensation which was developed by us.[4] Treatment of **2** with fermenting baker's yeast gave a 4:1 mixture of ethyl *erythro*(2*S*,3*R*)- and *threo*(2*S*,3*S*)-3-chloro-2-hydroxyoctanoate (**3**) in 67% yield. Each isomer was separated by preparative HPLC. Optical purities of both isomers were estimated as >99% e.e. respectively by ^{1}H NMR analysis in the presence of chiral shift reagent (europium tris[3-(heptafluoropropylhydroxymethylene)-(−)-camphorato] (Eu(hfc)$_3$)) and HPLC analysis of its 3,5-dinitrophenylcarbamate. Reduction of *erythro*-**3** with $NaBH_4$ gave diol **4** in 83% yield. Treatment of **4** with two equivalent of NaOEt yielded (2*S*,3*S*)-2,3-epoxyoctanol (**5**) in 80% yield and the subsequent oxidation of **5** with CrO_3–pyridine afforded aldehyde **1** in 68% yield. Enantiomeric excess was estimated as 80% e.e. by comparison of the optical rotation with that of the literature.[3] Decrease of the optical purity would be attributable to the racemization in the course of the reduction and dehydrochlorination. Furthermore we prepared **5** from *trans*-2-octen-1-ol by Sharpless method[2,5] and confirmed the structure of **5** obtained via baker's yeast reduction. Absolute configuration of α-carbon of **3** was determined to be S from that of **1**.



Scheme 2.

Similarly, *threo*-**3**, a minor product by the baker's yeast reduction, was also converted to *cis*-2,3-epoxyoctanol (**8**) via *threo*-diol **7**, as shown in Scheme 2. The spectral data of epoxide **8** was identical with that of the sample prepared by the epoxidation[5] of *cis*-2-octen-1-ol. Oxidation of **8** with CrO_3-pyridine gave (2*R*,3*R*)-2,3-epoxyoctanal (**10**) with 94% e.e. in 64% yield. The coupling constant (5.0 Hz) between two protons of the epoxide ring was a characteristic value for *cis*-epoxide.[6] Compound **10** will be useful for the synthesis of an unnatural form of 14,15-LTA_4.

Our system provides a convenient route to **1**, **8**, and

10 because of availability of the starting material, simplicity of the experiment, and no use of heavy metal.

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carried out by Eiichiro Amano in our laboratory. Infrared (IR) spectra were obtained with a JASCO Model A-102 infrared spectrophotometer. ^{1}H NMR spectra (60 MHz) were recorded with a JEOL JNM-PMX60SI apparatus. ^{1}H NMR (100 MHz) and ^{13}C NMR spectra (25 MHz) were obtained with a JEOL JNM-FX100 apparatus, using $CDCl_3$ as a solvent. Optical rotations were measured on a JASCO DIP-4 spectrometer. Column chromatography was accomplished with 100—200 mesh Wakogel C-200. High-performance liquid chromatography (HPLC) was obtained with Yanagimoto liquid chromatograph L-2000 fitted with Yanapak SA-I (6 mm o.d.×250 mm) and with Sumipax OA-3000 (4 mm o.d.×250 mm) for the determination of enantioselectivity.

Fermentation was carried out in a thermostat-bath at 31—35 °C, using industrial baker's yeast purchased from Oriental yeast Co. LTD. All glasswares were sterilized by boiling water before use.

Ethyl 3-chloro-2-oxooctanoate (**2**) was obtained by the method described in our previous papers.[4]

Ethyl 3-Chloro-2-hydroxyoctanoate (3). To a mixture of KH_2PO_4 (1 g), $NH_4H_2PO_4$ (1 g), $MgSO_4$ (0.25 g), $CaCO_3$ (2.5 g), glucose (75 g), and boiled water (1 l) was added 8 g of baker's yeast at 35°C. After 20 min, 2.00 g (9.07 mmol) of **2** was added and the mixture was stirred for 4 d at 35 °C. The organic materials were extracted 5 times with ethyl acetate (total 1 l), washed with brine, and dried over $MgSO_4$. Removal of the solvent gave 1.39 g of an oil, which was chromatographed on SiO_2 (hexane/ethyl acetate, 20 : 1—1 : 1) to afford 1.33 g (67%) of **3**. HPLC analysis (SA-I, 6 mm o.d.×250 mm; hexane/ethyl acetate (10 : 1), 1.25 ml min^{-1}) showed two peaks at R_t 16.7 and 22.9 min with the 29 : 71 ratio of the integrated peak area. Each component was separated by preparative HPLC. Peak 1: *threo*(2S,3S)-**3**; R_t 16.7 min; $[\alpha]_D^{25}$ −16.0°(*c* 1.45, $CHCl_3$): IR (neat) 3525, 2950, 1745, 1265 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.90 (t, 3H, *J*=6 Hz), 1.40—2.30 (m, 8H), 1.30 (t, 3H, *J*=6.5 Hz), 4.15 (q, 2H, *J*=6.5 Hz), 4.20 (m, 2H). Found: C, 54.01; H, 8.55%. Calcd for $C_{10}H_{19}ClO_3$: C, 53.93; H, 8.60%. Peak 2: *erythro*(2S,3R)-**3**; R_t 22.9 min; $[\alpha]_D^{25}$ +2.3° (*c* 2.20, $CHCl_3$): IR (neat) 3470, 2975, 1740, 1220 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.90 (t, 3H, *J*=6 Hz), 1.5—2.0 (m, 8H), 1.30 (t, 3H), 4.20 (m, 2H), 4.2 (q, 2H, *J*=6.5 Hz). Found: C, 53.99; H, 8.35%. Calcd for $C_{10}H_{19}ClO_3$: C, 53.93; H, 8.60%.

Determination of Enantiomeric Excess of 3. (A) *threo*-**3**: >95% e.e. by ^{1}H NMR (CCl_4) analysis in the presence of 75% (mol/mol) Eu(hfc)$_3$: one singlet at 2.30 ppm ($CO_2CH_2C\underline{H}_3$) when decoupled with the peak of 6.15 ppm ($CO_2C\underline{H}_2CH_3$). *erythro*-**3**: >95% e.e. by ^{1}H NMR (CCl_4) analysis in the presence of 75% (mol/mol) Eu(hfc)$_3$ in a similar manner as described above. On the other hand, ^{1}H NMR (CCl_4) of (±)-*threo*-**3**[7] in the presence of 75% (mol/mol) Eu(hfc)$_3$ showed two singlets at 2.93 and 2.83 ppm ($CO_2CH_2C\underline{H}_3$) when decoupled with the peak of 7.95 ppm ($CO_2C\underline{H}_2CH_3$). (B) To a mixture of **3** (0.46 mmol), dry toluene (1 ml), and 3,5-dinitrophenyl isocyanate (105 mg, 0.5 mmol) was added 0.5 ml of dry pyridine. The mixture was heated at 80 °C for 1 h and cooled. The precipitate was filtered off and washed with ether. Concentration of the filtrate gave crude 3,5-dinitrophenylcarbamate (DNPC) of **3**, which was analyzed by HPLC [column, Sumipax OA-3000 (4φ×250 mm)].

DNPC of *threo*-**3**: >99% e.e.; HPLC [hexane/ethyl acetate/ethanol (20 : 1 : 0.5), 0.8 ml min^{-1}], a single peak at R_t 4.3 min; ^{1}H NMR (CCl_4) δ=0.86 (t, 3H, *J*=6.5 Hz), 1.30—1.90 (m, 8H), 1.35 (t, 3H, *J*=6.5 Hz), 4.32 (m, 3H), 5.38 (d, 1H, *J*=3.2 Hz), 8.63 (s, 3H). ^{1}H NMR (CCl_4) in the presence of 50% Eu(hfc)$_3$ showed no paired peak.

DNPC of *erythro*-**3**: >99% e.e.; HPLC [hexane/ethyl acetate/ethanol (20 : 1 : 0.5), 0.8 ml min^{-1}], a single peak at R_t 6.0 min; ^{1}H NMR (CCl_4) δ=0.86 (t, 3H, *J*=6.5 Hz), 1.30—1.90 (m, 8H), 1.35 (t, 3H, *J*=6.5 Hz), 4.40 (m, 3H), 5.40 (d, 1H, *J*=3.2 Hz), 8.65 (s, 3H).

(2*S*,3*S*)-3-Chloro-1,2-octanediol (4). To a mixture of $NaBH_4$ (98 mg, 1.54 mmol) and ethanol (3 ml) was added dropwise a solution of *erythro*-**3** (0.342 g, 1.54 mmol) in dry ethanol (2 ml) at 0 °C. The mixture was stirred for 7 h at room temperature, and then poured into ice water. The organic materials were extracted with dichloromethane and the combined extracts were washed with brine, dried over $MgSO_4$, and concentrated. The crude product (290 mg) was chromatographed on SiO_2 (hexane/acetone (10 : 1)) to give 193 mg (83%) of **4**: $[\alpha]_D^{25}$ +18.7° (*c* 1.00, $CHCl_3$): IR (neat) 3400 (OH), 1460, 1075, 790 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.85 (t, 3H, *J*=6 Hz, $C\underline{H}_3(CH_2)_4$), 1.1—2.3 (m, 8H, $CH_3(C\underline{H}_2)_4$-), 3.65 (m, 2H, $C\underline{H}ClC\underline{H}OH$), 4.40 (m, 2H, $C\underline{H}_2OH$). Found: C, 53.07; H, 9.78%. Calcd for $C_8H_{17}ClO_2$: C, 53.18; H, 9.49%.

(2*S*,3*S*)-2,3-Epoxyoctanol (5). Method A: from 4. To a solution of sodium ethoxide (95 mg, 1.4 mmol) in absolute ethanol (4 ml) was added dropwise a solution of **4** (228 mg, 1.27 mmol) in absolute ethanol (3 ml) at 0 °C. The mixture was stirred for 30 min at 0 °C and then for 6.5 h at 25 °C. After the mixture was poured into ice water, the organic materials were extracted with dichloromethane. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated in vacuo. The residual oil (201 mg) was chromatographed on SiO_2 (hexane/acetone (10 : 1)) to give 146 mg (80%) of **5**: HPLC analysis [SA-I, 4.0 o.d.×250 mm; hexane/ethyl acetate (5 : 1), 0.8 ml min^{-1}], a single peak at R_t 24.2 min; $[\alpha]_D^{26}$ −27.2° (*c* 0.75, $CHCl_3$). Recrystallization from pentane gave 91.4 mg of **5**: mp 29.5—30 °C; $[\alpha]_D^{25}$ −36.8° (*c* 0.61, $CHCl_3$) [lit,[2] $[\alpha]_D$ −44° (*c* 1.0, $CHCl_3$)]: IR (neat) 3425 (OH), 2950, 1460, 1030, 885 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.90 (t, 3H, *J*=6.5 Hz, $C\underline{H}_3(CH_2)_4$), 1.45 (m, $CH_3(C\underline{H}_2)_4$), 2.82 (m, 2H, C_2-H, C_3-H), 3.10 (s, 1H, OH), 3.60 (br t, 2H, *J*=4 HZ, $C\underline{H}_2OH$); ^{13}C NMR ($CDCl_3$) δ=13.9 (q,), 22.5 (t), 25.6 (t), 31.5 (t), 56.1 (d), 58.7 (d), 61.9 (t).

Method B: by Sharpless Epoxidation.[5] To a stirred mixture of dry dichloromethane (16 ml), titanium tetraisopropoxide (455 mg, 0.48 ml, 1.60 mmol),diethyl (+)-tartrate (329 mg,1.6 mmol) was added dropwise a solution of trans-2-octen-1-ol[8] (204 mg, 1.6 mmol) in dry dichloromethane (4 ml) at −23 °C. *t*-Butyl hydroperoxide (TBHP) (1 ml, 3.62 mmol), which was extracted from commercial TBHP (70% aqueous solution) with dichloromethane and dried over $MgSO_4$ and 4 A molecular sieves, was added and then the mixture was stirred for 9.3 h at −23 °C. Aqueous tartaric acid (10%, 20 ml) was added and the mixture was stirred for 30 min at −23 °C and then for 1 h at room temperature. The organic materials were extracted with ether, and the ethereal extract was stirred with 1 M NaOH (20 ml) (1M=1 mol dm^{-3}) at 0 °C for 30 min and separated, washed with water, and dried over $MgSO_4$. Removal of the solvent gave 296 mg of an oil which was chromatographed on SiO_2 (hexane/acetone (20 : 1)) to give 151 mg (65.4%) of **5**: HPLC analysis [SA-I, 6.0 o.d.×250 mm; hexane/ethyl acetate (2 : 1), 1.1 ml min^{-1}], a single peak at R_t 21.3 min; $[\alpha]_D^{26}$ −38.1° (*c* 1.48, $CHCl_3$). IR and ^{1}H NMR data were identical with those of the sample prepared in Method A.

(2*R*,3*S*)-2,3-Epoxyoctanal (1).[2,3] To dry chromium oxide (997 mg, 9.97 mmol) was added dropwise a solution of dry pyridine (1.1 ml, 13.7 mmol) in dry dichloromethane (11 ml) at room temperature. After the mixture was stirred for 30 min, a solution of **5** (147 mg, 1.02 mmol) in dry dichlorome-

thane (4 ml) was added. The mixture was stirred for 4 h at 25 °C and the organic materials were extracted with ether. The ethereal extract was washed with 5% NaOH (10 ml), dil HCl (10 ml), saturated $NaHCO_3$, and brine successively, and dried over $MgSO_4$. Removal of the solvent gave the crude product, which was purified by column chromatography (SiO_2, hexane/acetone (15:1)) to afford 91 mg (68%) of **1**: $[\alpha]_D^{25}$ +64.6° (*c* 0.87, $CHCl_3$) [lit,[3] $[\alpha]_D^{25}$ +80.4° (*c* 1.39, $CHCl_3$)], 80% e.e.: IR (neat) 1735 (C=O), 1260, 1020, 805 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (t, 3H, *J*= 6.5 Hz, $CH_3(CH_2)_4$), 1.40 (m, 8H, $CH_3(CH_2)_4$), 3.00 (m, 2H, C_2-H, C_3-H), 8.85 (d, 1H, *J*=6.4 Hz, CHO).

(2*S*,3*S*)-3-Chloro-1,2-octanediol (7). To a stirred mixture of $NaBH_4$ (52 mg, 0.81 mmol) and ethanol (3 ml) was added *threo*-**3** (180 mg, 0.81 mmol) at 0 °C. The mixture was stirred for 7 h at room temperature, and poured into ice water. The organic materials were extracted with dichloromethane and the combined extracts were washed with brine, dried over $MgSO_4$, and concentrated. The crude product (176 mg) was chromatographed on SiO_2 (hexane/acetone (10:1)) to give 122 mg (85%) of **7**: $[\alpha]_D^{26}$ −23.2 ° (*c* 2.12, $CHCl_3$); IR (neat) 3400 (OH), 1460, 1040, 875 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (t, 3H, *J*=6 Hz, CH_3), 1.0—2.0 (m, 8H, $(CH_2)_4$), 3.0—4.1 (m, 6H, $CHClCHOHCH_2OH$).

(2*S*,3*R*)-2,3-Epoxyoctanol (8). Method A: from 7. To a solution of sodium ethoxide (54 mg, 0.8 mmol) in absolute ethanol (6 ml) was added dropwise a solution of **7** (116 mg, 0.65 mmol) in absolute ethanol (1 ml) at 0 °C. The mixture was stirred for 9.5 h at 25 °C, and then poured into ice water. The organic materials were extracted with dichloromethane. The combined extracts were washed with water and dried over $MgSO_4$. Removal of the solvent gave an oil (118 mg), which was chromatographed on SiO_2 to give 57 mg (61%) of **8**:[9] $[\alpha]_D^{26}$ −6.12° (*c* 1.42, $CHCl_3$); IR (neat) 3420, 1460, 1030, 880 cm^{-1}; ^1H NMR (CCl_4)δ=0.90 (t, 3H, *J*=6 Hz, CH_3), 1.1—1.8 (m, 8H, $(CH_2)_4$), 2.95 (m, 3H, C_2-H, C_3-H, OH), 3.60 (m, 2H, CH_2OH): ^{13}C NMR ($CDCl_3$) δ=14.0 (q), 22.5 (t), 26.3 (t), 27.9 (t), 31.6 (t), 57.0 (d), 57.2 (d), 60.7 (t).

Method B: by Sharpless Epoxidation.[5] *cis*-2-Octen-1-ol[10] (252 mg, 1.97 mmol) was oxidized at −10 — − 23 °C for 13.5 h by TBHP (1.1 ml, 3.54 mmol) in the presence of titanium tetraisopropoxide (560 mg, 1.97 mmol) and diethyl (+)-tartrate (405 mg, 1.97 mmol), as shown in the preparation of **5**. The crude product was purified by column chromatography (SiO_2, hexane/ethyl acetate (10:1)), giving 206 mg (78%) of **8**: $[\alpha]_D^{26}$ −6.44°(*c* 1.46, $CHCl_3$). IR and ^1H NMR data were identical with those of the sample prepared by method A.

(2*R*,3*R*)-2,3-Epoxyoctanal (10). In the same manner as shown in the preparation of **1**, alcohol **8** (191 mg, 1.33 mmol) was treated with CrO_3 (1.04 g, 10.4 mmol) and pyridine (1.65 g, 20.7 mmol) in dichloromethane (22 ml) at 30 °C for 4.5 h. The same work up as shown in **1** gave 121 mg (64%) of **10**: TLC (hexane/acetone, 3:1), one spot at R_f 0.42. Analytical sample was purified with column chromatography (SiO_2; hexane/acetone, 5:1) to afford 77 mg of pure **10**: $[\alpha]_D^{27}$ +134.6° (*c* 1.47, $CHCl_3$); 94% e.e. by ^1H NMR in the presence of 98% $Eu(hfc)_3$, two paired peaks at 18.0 and 17.6 ppm (intensity ratio of 97:3): IR (neat) 2950, 2840, 1730, 1470, 1050, 835 cm^{-1}; ^1H NMR (CCl_4) δ=0.92 (br. t, 3H, *J*=5 Hz, CH_3), 1.3—1.9 (m, 8H, $(CH_2)_4$), 3.16 (apparent d, 2H, *J*=2.8 Hz, 2 CHO-), 9.35 ppm (d, 1H, *J*=5.8 Hz, CHO); ^1H NMR (CCl_4) in the presence of 13% $Eu(hfc)_3$, δ=1.0 (br. t, 3H, CH_3), 1.2—2.3 (m, 6H, $(CH_2)_3$), 2.56 (m, 2H, C_4-H), 4.35 (m, 1H, C_3-H), 4.76 ppm (t, 1H, *J*=5 Hz, C_2-H).

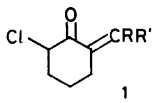
A Michael Addition-Induced Favorskii Rearrangement

Sadao Tsuboi, Hiroyuki Nagae, Hirofumi Yamato, and Akira Takeda*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received August 26, 1986)

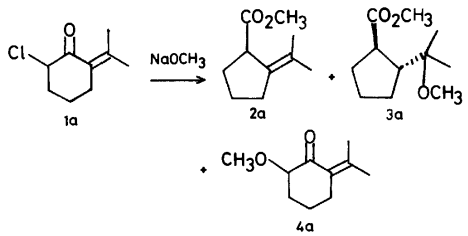
Synopsis. Reaction of 6-chloro-2-vinylidenecyclohexanone with sodium methoxide gave methyl 2-vinylidene-1-cyclopentanecarboxylate and methyl *trans*-2-(1-methoxyalkyl)-1-cyclopentanecarboxylate along with 6-methoxy-2-vinylidenecyclohexanone via a Michael addition-induced Favorskii rearrangement.

The Favorskii rearrangement is the skeletal rearrangement of α-halogenated ketones in the presence of base to give carboxylic acid derivatives.[1] It is useful for organic synthesis, especially for the preparation of highly branched acyclic carboxylic acids.[1] Since the first description of this rearrangement by Favorskii in 1894,[2] various types of the rearrangement have been still reported.[3] In connection with our previous study of Favorskii rearrangement of vinylogs of α-halo ketones,[4] we investigated reactions of 6-chloro-2-vinylidenecyclohexanones (**1**) with sodium methoxide.



1

Treatment of 6-chloro-2-isopropylidenecyclohexanone (**1a**) with five equivalents of sodium methoxide at 25—50 °C gave a mixture of methyl 2-isopropylidenecyclopentanecarboxylate (**2a**), methyl *trans*-2-(1-methoxy-1-methylethyl)cyclopentanecarboxylate (**3a**),[5] and 2-isopropylidene-6-methoxycyclohexanone (**4a**).

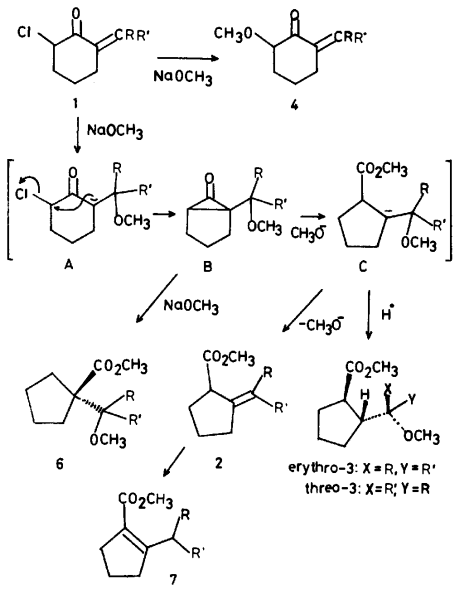


These products were separated by preparative GLC and identified by spectral analysis. To get further support for the structural elucidation, chemical transformations of **2a** were carried out. Hydrogenolysis of **2a** in the presence of palladium-charcoal yielded methyl 2-isopropylcyclopentanecarboxylate (**5**) in 54% yield and oxidation of **2a** with potassium permanganate gave adipic acid which was seemed to be derived from methyl 2-oxocyclopentanecarboxylate.

The formation of **2** and **3** can be explained by Favorskii rearrangement induced by the Michael addition of sodium methoxide to **1**, as shown in Scheme 1. In accordance with the generally accepted mechanism of the Favorskii rearrangement,[1] we suggest three intermediates **A**, **B**, and **C** to account for our results. The elimination of methoxide anion from the intermediate **C** will give vinylidene carboxylate **2** and the protonation of **C** will afford methoxy carboxylate **3**.

Table 1. Reaction of 6-Chloro-2-vinylidenecyclohexanone **1** with $NaOCH_3$

No.	1		Yield/% of Products				
	R	R′	**2**	**3** (erythro/threo)	**4**	**6**	**7**
a	CH_3	CH_3	52	9	4	0	0
b	H	CH_3	0	38 (20/18)	0	24	0
c	H	C_6H_5	0	62 (33/29)	0	0	8



Scheme 1.

We further investigated the reaction of other readily available 6-chloro-2-vinylidenecyclohexanones with sodium methoxide and the results are summarized in Table 1. Treatment of 6-chloro-2-ethylidenecyclohexanone (**1b**) with five equivalents of sodium methoxide at 25—50 °C afforded a mixture of three Favorskii rearrangement product, methyl 1-(1-methoxyethyl)cyclopentanecarboxylate (**6**) (24%) and methyl *trans*-2-(1-methoxyethyl)cyclopentanecarboxylate (**3b**) (erythro/threo, 20:18) (38%). Formation of ester **6** can be explained to be derived from the intermediate **B**, as shown in Scheme 1. Similar treatment of 6-chloro-2-benzylidenecyclohexanone (**1c**) with sodium methoxide gave methyl *trans*-2-(α-methoxybenzyl)methylcyclopentanecarboxylate (**3c**) in 62% yield as a mixture of two stereoisomers (erythro/threo, 33:29) and methyl 2-benzyl-1-cyclopentenecarboxylate (**7c**) in 8% yield. The trans geometry of **3b** and **3c** was determined by comparison of ^{13}C NMR data with those of similar

compounds[6] on the basis of the steric effect.[7] Assignment of erythro and threo between C-2 and C-1′ was made by analyzing the ^{1}H NMR spectra with reference of the literature data.[8] In ^{1}H NMR spectra of *threo*-**3b** and **3c**, signals due to C-2 protons (3.15 and 3.82 ppm) appeared at higher fields than those of erythro-isomers (3.34 and 4.06 ppm, respectively). In the ^{13}C NMR spectrum of *erythro*-**3b**, all signals except those of methyl carbon appeared at higher fields as compared with those of *threo*-**3b**.[9] Similarly, in the spectrum of *erythro*-**3c**, signals due to C-1 (50.6), C-2 (46.5), C=O (176.9), and $\underline{C}HOCH_3$ (86.0) appeared at higher fields than those of *threo*-**3c** (50.8, 47.9, 177.1, and 87.5, respectively).

To our knowledge, the present reaction is a new type of Favorskii rearrangement which includes initiation by the Michael addition of alkoxide and it will be useful for the synthesis of substituted cyclopentane derivatives.

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carried out by Eiichiro Amano in our laboratory. Analytical determinations by GLC were performed on a Hitachi Model K-53 gas chromatograph fitted with 10% Apiezone Grease L on Chromosorb W column (3 mm o.d.×1 m). Preparative isolations by GLC were performed on a Yanagimoto Model GCG-550T gas chromatograph (3 mm o.d.×1 m, Apiezone Grease L on Chromosorb W).

2-Isopropylidenecyclohexanone (**10**) was prepared from 2-ethoxycarbonylcyclohexanone by the method described in the literature:[10] bp 65 °C/3 Torr (1 Torr=133.322 Pa) (lit,[10] 94—98 °C/14 Torr); 32% yield. 2-Ethylidenecyclohexanone (**11**) was prepared by the reaction of 2-formylcyclohexanone with methylmagnesium iodide:[11] bp 59—61 °C/3 Torr; 55% yield. 2-Benzylidenecyclohexanone (**12**) was obtained by the reaction of *N*-(1-cyclohexenyl)morpholine with benzaldehyde:[12] bp 147 °C/4 Torr (lit,[12] 123—126 °C/0.2 Torr); 52% yield.

6-Chloro-2-isopropylidenecyclohexanone (1a) was prepared by the reaction of **10** with 1.2 equiv of *N*-chlorosuccinimide (NCS) in CCl_4 at the reflux temperature for 20 min:[13] 83% yield; IR (neat) 1680, 1610 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.81 (s, 3H), 1.89 (s, 3H), 2.20 (m, 6H), 4.22 (dd, J=4 and 5 Hz, 1H); MS (70 eV) m/z (rel intensity) 172 (48, 1 Cl, M$^+$), 157 (6), 149 (46), 110 (32), 109 (100), 95 (32), 93 (46), 82 (67), 67 (93). Found: C, 62.31; H, 7.42%. Calcd for $C_9H_{13}ClO$: C, 62.61; H, 7.59%.

6-Chloro-2-ethylidenecyclohexanone (1b) was prepared by the reaction of **11** with 1.2 equiv of NCS in CCl_4 at the reflux temperature:[13] 71% yield; bp 65—70 °C/2.5 Torr; IR (neat) 1700, 1625, 1130, 890, 750 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.75 (dt, J=7.5 and 1.0 Hz, 3), 4.27 (dd, J=4.5 and 6.0 Hz, 1), 6.64 (qt, J=7.5 and 2.5 Hz, 1); MS (70 eV) m/z (rel intensity) 158 (40, 1 Cl, M$^+$), 143 (6), 140 (5), 124 (23), 95 (100), 79 (47), 68 (48), 67 (77), 55 (72). Found: C, 60.63; H, 7.00%. Calcd for $C_8H_{11}OCl$: C, 60.58; H, 6.99%.

6-Chloro-2-benzylidenecyclohexanone (1c) was prepared by the reaction of **12** with 1.2 equiv of NCS in CCl_4 at the reflux temperature:[13] 80% yield; mp 60—62 °C (from hexane); IR (neat) 1680, 1598, 1130, 790 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.5—3.0 (m, 6H), 4.50 (apparent dd, J=5 Hz, 1H), 7.26 (br. s, 6H). It was too labile for elemental analysis.

Reaction of 1a with Sodium Methoxide. To a solution of sodium methoxide (1.76 g, 32.6 mmol) in 20 ml of absolute methanol was added 1.12 g (6.50 mmol) of **1a** at room temperature with stirring. The mixture was stirred for 20 min at 50 °C, and then cooled. It was poured into cold water and acidified with 10% HCl. The organic materials were extracted with ether, washed with water, dried over $MgSO_4$ and concentrated. The resulting residue was purified by short column chromatography (SiO_2, hexane/ethyl acetate (10 : 1)) to give 0.725 g of an oil, which was analyzed by GLC (column: 130 °C, carrier gas: N_2, 0.5 kg cm^{-2}). Peaks, retention times (min), and integrated percentages are as follows: 1, 3.0, 78; 2, 4.5, 6; 3, 6.4, 16. Each component was separated by preparative GLC and identified.

Peak 1: **Methyl 2-Isopropyldenecyclopentanecarboxylate (2a);** 52% yield; IR (neat) 1732, 1430, 1160 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.65 (s, 6H), 1.6—2.5 (m, 6H), 3.3 (m, 1H), 3.59 (s, 3H); MS (70 eV) m/z (rel intensity) 168 (36, M$^+$), 109 (100), 108 (53), 93 (40), 67 (73), 55 (33). Found: C, 71.05; H, 9.44%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

Peak 2: **2-Isopropylidene-6-methoxycyclohexanone (4a);** 4% yield; IR (neat) 1695, 1630, 1450, 1130, 1096 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.78 (s, 3H), 1.88 (s, 3H), 1.5—2.6 (m, 6H), 3.32 (s, 3H), 3.56 (m, 1H). Found: C, 71.25; H, 9.41%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

Peak 3: **Methyl trans-2-(1-Methoxy-1-methylethyl)cyclopentanecarboxylate (3a);** 8.9% yield; IR (neat) 1740, 1450, 1200, 1162 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.06 (s, 6H), 1.4—2.8 (m, 8H), 3,10 (s, 3H), 3.59 (s, 3H). Found: C, 65.82; H, 9.96%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Methyl 2-Isopropylcyclopentanecarboxylate (5).[14] A mixture of **2a** (0.79 g, 4.70 mmol), 7 ml of methanol and palladium-carbon (4 mg) was stirred for 12 h under an atmosphere of hydrogen. Preparative TLC (SiO_2, hexane/ethyl acetate (3 : 1)) of the crude product gave 0.431 g (54%) of **5**:[14] IR (neat) 1735, 1435, 1367, 1195, 1155 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.88 (d, J=7 Hz, 6H), 1.74 (m, 8H) 2.30 (m, 1H), 3.60 (s, 3H).

Oxidation of 2a with $KMnO_4$. To a mixture of **2a** (0.447 g, 2.66 mmol), $NaHCO_3$ (0.083 g, 1 mmol), and acetone (3 ml) was added powdered $KMnO_4$ (1.46 g, 9.24 mmol) below 7 °C over 1.5 h. The mixture was stirred for 1 h, and then dilute H_2SO_4 and a small amount of $NaHSO_3$ were added alternately until it becomes clear. The mixture was concentrated, washed with ether and acidified with dilute HCl. The organic materials were extracted with ether three times, washed with brine and dried over $MgSO_4$. Removal of the solvent gave 200 mg (52%) of adipic acid: mp 151—152 °C (from benzene)(lit,[15] 151—152 °C).

Reaction of 1b with Sodium Methoxide. To a stirred solution of sodium methoxide (1.51 g, 28 mmol) in 20 ml of absolute methanol was added dropwise 0.888 g (5.60 mmol) of **1b** at 25 °C. The mixture was stirred for 20 min at 50 °C and then cooled, acidified with 10% HCl. The organic layer was extracted with ether and combined extracts were washed with aqueous $NaHCO_3$, brine and water, and then dried over $MgSO_4$. After concentration, the residual oil was distilled with balb-to-balb tube oven to give 0.850 g of a clean oil, which was analyzed by GLC (column, 120 °C; carrier gas, N_2, 0.5 kg cm^{-2}). Peaks, retention times (min), and integrated percentages are as follows: 1, 1.3, 5.0; 2, 2.4, 19; 3, 3.4, 30; 4, 4.3, 24; 5, 4.8, 22. Each component was separated by preparative GLC. Peaks 1 and 2 were not identified. Peaks 3, 4, and 5 were identified as a stereoisomer of **3b**, respectively: total yield, 62%.

Peak 3: **Methyl 1-(1-Methoxyethyl)cyclopentanecarboxylate (6);** 24% yield; IR (neat) 1735, 1165, 1140, 1104, 1006 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.98 (d, J=6 Hz, 3H), 1.3—2.2 (m, 8H), 3.2 (m, 1H), 3.23 (s, 3H), 3.59 (s, 3H); MS (70 eV) m/z (rel intensity) 186 (1, M$^+$), 172 (2), 154 (5), 139 (13), 128 (76), 95 (46), 67 (34), 59 (100); ^{13}C NMR ($CDCl_3$) δ=17.0 (q, $CH\underline{C}H_3$),

25.2 (t, C-4), 27.0 (t, C-3), 31.0 (t, C-5), 45.9 (d, C-2), 49.3 (d, C-1), 51.5 (q, OCH_3), 56.5 (q, $CO_2\underline{C}H_3$), 80.3 (d, $\underline{C}HOCH_3$), 177.2 (s, C=O). Found: C, 64.25; H, 9.80%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

Peak 4: **Methyl *trans-erythro*-2-(1-Methoxyethyl)cyclopentanecarboxylate (3b)**; 20% yield; IR (neat) 1735, 1195, 1160, 1090 cm^{-1}; ^1H NMR (CCl_4) δ=1.06 (d, J=6 Hz, 3H), 1.5—2.8 (m, 8H), 3.31 (s, 3H), 3.34 (dq, J=4 and 7 Hz, 1H), 3.68 (s, 3H); MS (70 eV) m/z (rel intensity) 186 (1, M^+), 171 (6), 155 (4), 149 (11), 111 (33), 95 (50), 67 (34), 59 (100); ^{13}C NMR ($CDCl_3$) δ=17.0 (q, $CH\underline{C}H_3$), 25.3 (t, C-4), 27.1 (t, C-3), 31.1 (t, C-5), 46.1 (d, C-2), 49.4 (d, C-1), 51.5 (q, OCH_3), 56.6 (q, ester CH_3), 78.0 (d, C-1′), 177.1 (s, C=O). Found: C, 64.43; H, 9.73%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

Peak 5: **Methyl *trans-threo*-2-(1-Methoxyethyl)cyclopentanecarboxylate (3b)**; 18% yield; IR (neat) 1736, 1196, 1158, 1092 cm^{-1}; ^1H NMR (CCl_4) δ=1.10 (d, J=6 Hz, 3H), 1.5—2.7 (m, 8H), 3.15 (m, 1H), 3.27 (s, 3H), 3.65 (s, 3H); MS (70 eV) m/z (rel intensity) 186 (3, M^+), 171 (7), 156 (4), 155 (4), 139 (5), 126 (12), 123 (7), 111 (30), 95 (53), 59 (100); ^{13}C NMR ($CDCl_3$) δ=17.0 (q, $CH\underline{C}H_3$), 25.3 (t, C-4), 29.1 (t, C-3), 31.2 (t, C-5), 47.6 (d, C-2), 50.2 (d, C-1), 51.5 (q, OCH_3), 56.3 (q, ester C=O), 80.4 (d, C-1′), 177.4 (s, C=O). Found: C, 64.68; H, 9.75%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

Reaction of 1c with Sodium Methoxide. To a stirred solution of sodium methoxide (2.35 g, 43.5 mmol) in 30 ml of absolute methanol was added dropwise 1.94 g (8.80 mmol) of **1c** at room temperature. The mixture was stirred for 30 min at 50 °C, cooled, and acidified with 10% HCl. The organic materials were extracted with ether and the combined extracts were washed with aqueous $NaHCO_3$, brine and water, and then dried over $MgSO_4$. After concentration, the residual oil (1.68 g) was analyzed by GLC (column, 180 °C; carrier gas, N_2, 0.5 kg cm^{-2}). Peaks, retention times (min), and integrated percentages are as follows: 1, 7.5, 5; 2, 9.3, 43; 3, 10.5, 37; 4, 27.0, 6; 5, 30.0, 9. Each component was separated by preparative GLC (column, Apiezone Grease L, 185 °C; carrier gas, H_2, 27 ml min^{-1}). Components 1 and 5 were not identified. Components 2 and 3 were identified as a stereoisomer of **3c**, respectively: total yield, 67%.

Peak 2: **Methyl *trans-erythro*-2-Methoxyphenylmethylcyclopentanecarboxylate (3c)**; 33% yield: bp 98 °C/0.15 Torr; IR (neat) 1735, 1605, 1494, 768, 705 cm^{-1}; ^1H NMR (CCl_4) δ=1.3—2.15 (m, 6H), 2.2—2.8 (m, 2H), 3.18 (s, 3H), 3.45 (s, 3H), 4.06 (d, J=5 Hz, 1H), 7.20 (s, 5H); MS (70 eV) m/z (rel intensity) 248 (1, M^+), 233 (2), 184 (2), 157 (14), 121 (100), 115 (15), 105 (24), 91 (51). ^{13}C NMR ($CDCl_3$) δ=25.0 (t, C-3), 28.2 (t, C-4), 31.1 (t, C-5), 46.5 (d, C-2), 50.6 (d, C-1), 51.5 (q, OCH_3), 57.1 (q, $CO_2\underline{C}H_3$), 86.0 (d, $\underline{C}HOCH_3$), 127.4, 127.6, and 128.3 (d, phenyl), 140.9 (s, phenyl), 176.9 (s, C=O). Found: C, 72.39; H, 7.91%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Peak 3: **Methyl *trans-threo*-2-Methoxyphenylmethylcyclopentanecarboxylate (3c)**; 29% yield; bp 98 °C/0.15 Torr; IR (neat) 1735, 1605, 1494, 768, 705 cm^{-1}; ^1H NMR (CCl_4) δ=1.1—2.13 (m, 6H), 2.2—2.9 (m, 2H), 3.10 (s, 3H), 3.52 (s, 3H), 3.82 (d, J=8 Hz, 1H), 7.20 (s, 5H); MS (70 eV) m/z (rel intensity) 248 (1, M^+), 233 (2), 184 (2), 157 (14), 121 (100). ^{13}C NMR ($CDCl_3$) δ=24.7 (t, C-3), 29.1 (t, C-4), 31.1 (t, C-5), 47.9 (d, C-2), 50.8 (d, C-1), 51.4 (q, OCH_3), 56.9 (q, $CO_2\underline{C}H_3$), 87.5 (d, $\underline{C}HOCH_3$), 127.2, 127.6, and 128.1 (d, phenyl), 140.9 (s, phenyl), 177.1 (s, C=O). Found: C, 72.77; H, 8.18%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Peak 4: **Methyl 2-Benzyl-1-cyclopentenecarboxylate (7c)**: 8.0% yield; IR (neat) 1670, 1630, 1600, 1493, 700 cm^{-1}; ^1H NMR (CCl_4) δ=1.5—2.1 (m, 2H), 2.1—2.6 (m, 4H), 3.56 (s, 2H), 3.70 (s, 3H), 7.17 (s, 5H); MS (70 eV) m/z (rel intensity) 216 (86, M^+), 185 (6), 155 (42), 129 (39), 121 (45), 115 (46), 91 (100). Found: C, 77.62; H, 7.51%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

Hydrates of Organic Compounds. XI. Determination of the Melting Point and Hydration Numbers of the Clathrate-Like Hydrate of Tetrabutylammonium Chloride by Differential Scanning Calorimetry

Haruo NAKAYAMA
Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received July 19, 1986)

A thermal analytic method using a differential scanning calorimeter has been applied to binary mixtures of water with tetrabutylammonium chloride. It has been found that this method can give the same results concerning the melting point (15.2 °C) and hydration numbers (around 30) of the clathrate-like hydrate of tetrabutylammonium chloride as those determined phase-diagrammatically. The apparent enthalpy of fusion of water which forms hydrogen-bonded water lattice in the clathrate-like hydrate has been observed to be 5.47 kJ mol^{-1}, which is comparable with 5.20 kJ mol^{-1} determined by the direct calorimetric measurements of enthalpy of solution of the hydrate in water. It has been concluded that the proposed method can be applicable to many similar types of systems, including systems forming a hydrate which decomposes incongruently.

In previous papers the formation of clathrate-like hydrates of tetrabutylammonium salts which have various types of anions (inorganic anions,[1,2] saturated and unsaturated carboxylate anions,[3-6] dicarboxylate anions,[7] and alkanesulfonate anions[8]) has been reported. In these investigations the confirmation of the formation of a hydrate and the determination of melting points and of hydration numbers of the hydrates were made by examining a solid-liquid phase diagram of a binary mixture of a tetrabutylammonium salt with water. The phase diagram was obtained by an ampoule method: the temperature at which the solid phase, formed by cooling a sample solution sealed in an ampoule, completely dissolved was measured; and this temperature was plotted against the concentration of the solution. The ampoule method is one of the most suitable methods since the solid-liquid mixture is thermostated at the desired temperature for sufficient time to establish a solid-liquid phase equilibrium. However, this ampoule method cannot be applied to systems either having extremely high viscosities, as in the case of aqueous solutions containing polymeric ions, or being colored.

In this paper a thermal analytic method using a differential scanning calorimeter has been proposed as an alternative way of confirming the formation of a clathrate-like hydrate as well as of determining a melting point and hydration numbers of the hydrate. The validity of the method has been confirmed by comparing the results concerning the properties of the clathrate-like hydrate of tetrabutylammonium chloride with those obtained in previous investigations.[1,9,10]

Experimental

An aqueous solution of tetrabutylammonium chloride was prepared by neutralization of an aqueous solution of tetrabutylammonium hydroxide with an aqueous solution of hydrochloric acid. The tetrabutylammonium hydroxide solution was prepared by the same procedure as mentioned in a previous paper.[8] The concentration of the tetrabutylammonium chloride was determined by measuring the amount of tetrabutylammonium cation by titration with a sodium tetraphenylborate solution which was standardized by pure tetrabutylammonium iodide.

The differential scanning calorimeter used was the model DSC 10 with SSC 580 thermal controller manufactured by Seiko Instruments and Electronics Ltd. Sample solutions (about 15 mg) at various concentrations were sealed in a 15 μl aluminum pan. The enthalpy changes per unit time (DSC signal) were measured either by cooling or by heating the sample as slowly as possible (usually at the rate of 0.5 °C per minute). An empty 15 μl aluminum pan was used as a reference. The observed enthalpy changes were standardized by the enthalpy of fusion of ice, i.e., 6.0095 kJ mol^{-1}.[11]

Results and Discussion

An example of the DSC curves on cooling the tetrabutylammonium chloride aqueous solutions at various concentrations is illustrated in Fig. 1. The DSC curves on heating the same solutions are shown in Fig. 2. The concentration of the tetrabutylammonium chloride is expressed by the mole fraction X. As is seen in Figs. 1 and 2, except for the concentrated solution of X=0.050, two kinds of peaks are observed in both cooling and heating processes: the first-step solidification (shown by h in Fig. 1) occurs at −3—−15 °C depending upon the concentration of the salt and the second-step solidification (shown by i in Fig. 1) at −18—−20 °C; and the first-step melting (shown by i in Fig. 2) occurs at around 0 °C and the second-step melting (shown by h in Fig. 2) at 5—15 °C depending upon the concentration of the salt. From the facts that (1) supercooled pure water usually freezes at around −20 °C, (2) the area of the peak i in Figs. 1 and 2 decreases with increasing the concentration of the salt, and (3), on the contrary,

the area of peak h in both figures increases with increasing the concentration of the salt, it can be concluded that the peaks indicated by i in both figures are related to an ice phase and, therefore, the peaks indicated by h in both figures are related to a hydrate phase. The disappearance of the peak i in the X=0.050 solution indicates that all the water molecules participate in the formation of the hydrate, i.e., the concentration X=0.050 corresponds to the one which is larger than the congruent composition of the hydrate. It is interesting to note that for the X=0.033 solution small peaks i are observed. This suggests that the congruent composition of the hydrate is close to X=0.033. Firstly, the thermal behavior of the solutions of $X \leqq 0.033$ are discussed in the following sections (1) and (2), and those of the solutions of $X>0.033$ are briefly discussed in section (3).

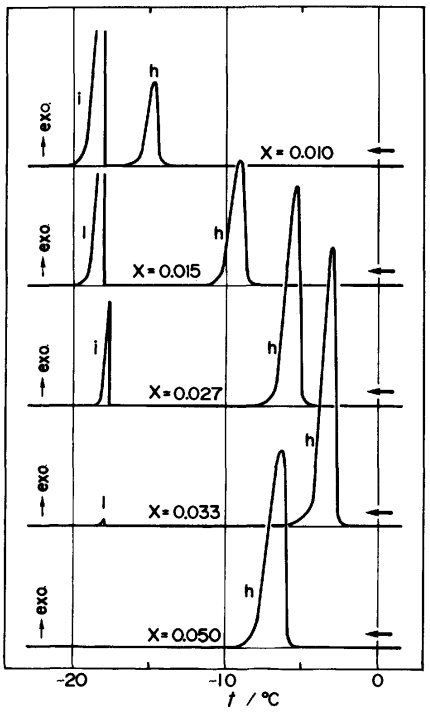

Fig. 1. The DSC curves on cooling for aqueous solutions of tetrabutylammonium chloride at various mole fractions.

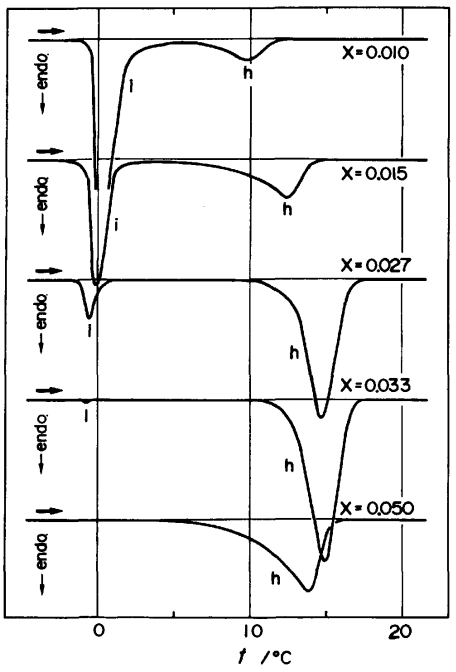

Fig. 2. The DSC curves on heating for the same solutions as shown in Fig. 1.

(1) Determination of the Hydration Numbers of the Clathrate-Like Hydrate of Tetrabutylammonium Chloride. Although two peaks i and h in the cooling processes (Fig. 1) can be completely separated from each other, these two in the heating processes (Fig. 2) cannot always be separated from each other especially in the solutions of $X<0.02$, as is partly seen in Fig. 2. Therefore, in order to know the enthalpy changes due to the melting of ice and of the hydrate separately, the following two enthalpy changes (ΔH_1 and ΔH_2) have been measured by taking advantage of the complete separation of the two peaks (i and h) in the cooling process. These two enthalpy changes are illustrated in Fig. 3 where ΔH_1 is the enthalpy change when heated after the sample solution is completely solidified by cooling below −20 °C (process (a) in Fig. 3). The ΔH_2 is the enthalpy change when heated after the sample solution is partially solidified by cooling the sample down to the temperature at which the hydrate phase is completely solidified but the water which does not participate in the formation of the hydrate remains in a liquid state (process (b) in Fig. 3). The observed values of ΔH_1 and of ΔH_2 are listed in Table 1 together with other data explained below. These values are averages of three to five measurements and the limit of error attached to each value is estimated not only by

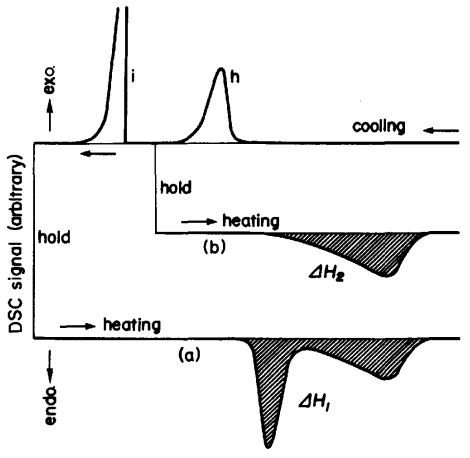

Fig. 3. The measuring processes of the two types of enthalpy changes ΔH_1 and ΔH_2.

the deviations from the mean value but also by the error arising from the procedure of determining the areas of the DSC curves.

The physical meaning of both ΔH_1 and ΔH_2 is not necessarily clear for the following reasons: (1) The composition of the liquid phase co-existing with the hydrate solid which is formed in the first-step cooling (peak h in Fig. 1) is not obvious since this mixture is not in an equilibrium state; and (2) for dilute solutions, especially when X is smaller than 0.005, the observed values of ΔH_2 vary from experiment to experiment, suggesting that the solid phase formed in the first-step cooling has some irregularity. If we neglect all the irregularities concerning the structure and chemical composition of the hydrate solid, ΔH_1 and ΔH_2 can approximately be expressed by the following relations:

$$\Delta H_1 = (n_0 - mn_1)\Delta H_{f,ice} + n_1\Delta H_{f,hyd} + \Delta H_M(n_1), \quad (1)$$

$$\Delta H_2 = n_1'\Delta H_{f,hyd} + \Delta H_M(n_1'), \quad (2)$$

in which n_0 and n_1 are the total number of moles of water and of tetrabutylammonium chloride contained in a sample. $\Delta H_{f,ice}$ and $\Delta H_{f,hyd}$ are the molar enthalpy of fusion of ice and of the hydrate expressed by a formula $(n\text{-}C_4H_9)_4NCl \cdot mH_2O$, in which m is the hydration numbers, and n_1' is the number of moles of the hydrate formed in the first-step cooling. The $\Delta H_M(n_1)$ is the total enthalpy of mixing of $n_0 - mn_1$ moles of water with n_1 moles of the hydrate melt. Similarly $\Delta H_M(n_1')$ is the total enthalpy of mixing of the liquid phase co-existing with the hydrate solid formed in the first-step cooling with n_1' moles of the hydrate melt.

The present results cannot directly be analyzed by these two equations since there is no information about the values of n_1' as well as of the enthalpies of mixing. However, for solutions whose concentration is not extremely low, it can be assumed that n_1' is equal to n_1, at least as a first approximation, since according to the phase-diagrammatic experiment for the same system the eutectic composition of the solution which is in equilibrium with the $(n\text{-}C_4H_9)_4NCl$ hydrate solid+ice mixture is as low as $X=0.002$.[9] This assumption means that the liquid phase which is co-existing with the hydrate solid formed in the first-step cooling is pure water instead of a dilute aqueous solution of $(n\text{-}C_4H_9)_4NCl$. Accordingly it leads to the simple relation that the enthalpy of mixing terms in Eqs. 1 and 2 become identical. Therefore, from Eqs. 1 and 2, the hydration numbers, m, of the hydrate can be expressed by the following relation:

$$m = \frac{1}{n_1}\left\{n_0 - \frac{\Delta H_1 - \Delta H_2}{6.0095 \times 10^3}\right\}, \quad (3)$$

in which both ΔH_1 and ΔH_2 are expressed in J unit and $\Delta H_{f,ice}=6.0095\times10^3$ J is used, which is equal to the molar enthalpy of fusion of ice I at 0 °C.[11]

The calculated values of m, together with the values of n_0 and of n_1 for each sample solution, are listed in Table 1. It is interesting to note that the calculated hydration numbers are around 30, in good agreement with the value 30±1 determined from phase diagrammatic experiments.[9] This suggests that Eq. 3 is appropriate to the determination of the hydration numbers of a clathrate-like hydrate at least as a first approximation. The small value of m obtained for the $X=0.005$ solution indicates that the assumption made to obtain Eq. 3 is not appropriate to such a dilute solution.

It should be noted that the hydration numbers of the hydrate can be determined from the measurements of both ΔH_1 and ΔH_2 for some solutions at any concentrations except for very dilute or very concentrated solutions. Furthermore this method can also be applied to the systems forming a hydrate which decomposes incongruently if the two enthalpy changes, ΔH_1 and ΔH_2, can be measured for the solutions whose concentrations are lower than the composition corresponding to its incongruent melting point.

In Fig. 4, the apparent enthlpy change for one mole of water, $\Delta H_1/n_0$, and the apparent enthalpy change

a) Notations X, n_0, and n_1 are explained in the text.

for one mole of water which forms hydrogen-bonded networks in the hydrate solid, $\Delta H_2/mn_1$, are plotted against X. An exact analysis of both curves is difficult due to the lack of information about the concentration dependence of the enthalpies of dilution and temperature dependence of the enthalpies of fusion and of dilution for both water and the hydrate. However, it is interesting to note that (1) the congruent composition of the hydrate, i.e., the hydration numbers, can also be determined by finding the concentration at which both curves coincide since the relations $\Delta H_1=\Delta H_2$ and $n_0=mn_1$ hold at the congruent composition. It is also notable that the value of $\Delta H_2/mn_1$ (or $\Delta H_1/n_0$) at the congruent composition is equal to 5.47 kJ mol^{-1}, in fair agreement with the value of 5.20 kJ mol^{-1} at 10 °C estimated from direct calorimetric measurements of the enthalpies of solution of the tetrabutylammonium chloride hydrate in water.[10]

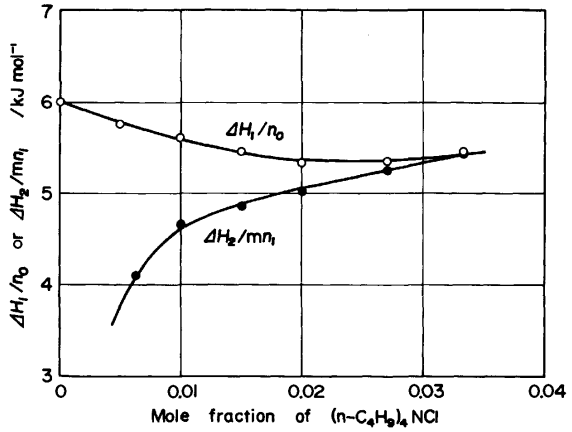

Fig. 4. Concentration dependence of the two apparent enthalpy changes, $\Delta H_1/n_0$ and $\Delta H_2/mn_1$, for tetrabutylammonium chloride–water system. The physical meanings of ΔH_1 and ΔH_2 are shown in Fig. 3, n_0 and n_1 are the total number of moles of water and of the salt contained in a sample solution, and m is the hydration numbers of the hydrate.

(2) Determination of the Melting Point of the Clathrate-Like Hydrate of Tetrabutylammonium Chloride. The melting point of the hydrate can be determined by finding the highest dissolution temperature for solutions at various concentrations. The dissolution temperature is that at which the solid phase completely dissolves when the solidified sample is gradually heated. Although this temperature is measured with the naked eye in an ordinary ampoule method, it can also be determined by the DSC experiments as illustrated in Fig. 5. In the heating process (b) in Fig. 3, the hydrate solid is first heated to a given temperature, t_0 for example, and is held at t_0 for a while. The sample is then further heated to a temperature higher than the presumed melting point. If the dissolution temperature of the sample, t, lies higher than t_0, an additional endothermic enthalpy change can be observed in the reheating process as marked A in Fig. 5. Thus the exact dissolution temperature can be determined by finding the lowest temperature t_0, as t_0'' in Fig. 5, for which no additional enthalpy change (peak A) is observed. It has been found that the dissolution temperature thus determined is practically equal to the temperature at which the heating DSC curves for the hydrate (the (b) process in Fig. 3) show a minimum: i.e., the temperature at which d(DSC signal)/dT=0. The dissolution temperatures so observed are listed in Table 1 for each solution. In Fig. 6, this temperature is compared with that determined by the ampoule method reported earlier.[9] This figure (i.e., a solid-liquid phase diagram) clearly indicates that the dissolution

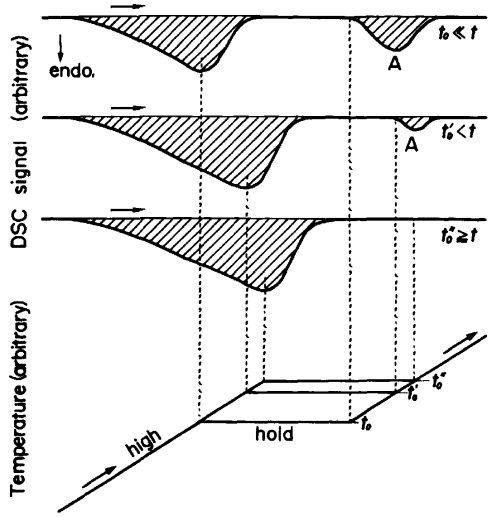

Fig. 5. The measuring process of the dissolution temperature, t, of the hydrate.

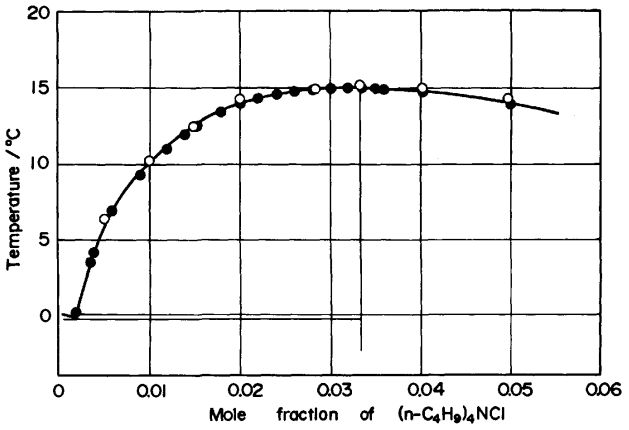

Fig. 6. The solid-liquid phase diagram for tetrabutylammonium chloride–water system determined by the dissolution temperatures. ○: values determined by the present DSC measurements; and ●: values determined by an ampoule method (Ref. 9).

temperature can be exactly determined by the DSC measurements. As is obvious from Table 1 and Fig. 6, a value of X=0.033 gives the maximum dissolution temperature (i.e., the melting point of the hydrate) of 15.2 °C. This indicates not only that this observed melting point is in good agreement with the 15.0 °C, determined phase-diagrammatically[9] but also that X=0.033 corresponds to the hydration numbers of 29, in good agreement with the result obtained in section (1).

In conclusion, through the discussions in the sections (1) and (2), the present thermal analytic method can give the same results concerning the nature of the clathrate-like hydrate of tetrabutylammonium chloride as those obtained phase-diagrammatically. Since the fundamental principle of the present method is not limited to an aqueous solution of the tetrabutylammonium chloride only, this method may be applicable to many similar types of systems, including the systems forming a hydrate which decomposes incongruently, so long as the two enthalpy changes, ΔH_1 and ΔH_2, can be measured.

(3) Thermal Properties of the Solutions at Higher Concentrations Than the Congruent Composition. Finally, the thermal behavior of the solutions above X=0.033 is discussed briefly. The behavior of the DSC signals is exemplified for the solution of X=0.050 in Figs. 1 and 2. The measured enthalpy changes are also listed in Table 1 for two solutions with X=0.040 and 0.050. The two enthalpy changes ΔH_1 and ΔH_2 inevitably become identical since the enthalpy change due to the melting of ice phase is not present for these concentrated solutions (Fig. 1 and 2). If we assume that all the water molecules participate in the formation of the hydrate solid having the hydration numbers around 30 and further that the enthalpy of fusion of these water molecules is equal to 5.47 kJ mol^{-1} estimated in the above discussion, the expected values of ΔH_1 (or ΔH_2) become 3.04 J for the X=0.040 solution and 2.47 J for the X=0.050 solution, respectively. The observed values listed in Table 1, 2.78 J for the X=0.040 solution and 1.69 J for the X=0.050 solution, are apprecially small as compared with those expected values, especially for the X=0.050 solution. At present exact thermal analyses are impossible because of a lack of information concerning the state of the phases existing in such concentrated solutions.

Binding Behavior of Metal Cations and Hydrophobic Ions from a Mixed Solution

Kunio Furusawa,* Miyako Iwamoto, and Hideo Matsumura†
Department of Chemistry, The Univesity of Tsukuba, Sakura-mura, Ibaraki 305
†Electrotechnical Laboratory, Sakura-mura, Ibaraki 305
(Received August 7, 1986)

Critical experimental data are presented on the competitive adsorption of metal cations with different ionic valences to phospholipid vesicles, and on the binding of hydrophobic ions from mixed solutions with multivalent metal cations produced under different conditions by means of the Inductively Coupled Argon Plasma. It is apparent that the preferential effect in binding between the metal cations depends not only on their ionic valences but also on the concentrations of each ion at which the corresponding binding is carried out; i.e., the binding strength of the metal cations on the membrane surface increases in the following order: $K^+ < Mg^{2+} < Ca^{2+} < La^{3+} < Th^{4+}$, and this order comes to be more pronounced in the high-concentration region of each component. Furthermore, it is realized that, in binding from mixed solutions of hydrophobic ions and multivalent metal cations (Ca^{2+} or Th^{4+}), a synergistic interaction between these ions occurs; i.e., the binding of hydrophobic anions is promoted by the presence of metal cations, while the binding of hydrophobic cations is hindered by the metal cations.

From a structural point of view, phospholipids are perhaps the most important of all constituents of living systems, for without them a living cell could not exist. Among the various functions of a biological membrane, its permeability property is one of the most interesting points with relation to its interfacial behavior. Many studies[1] of metal-cation binding to phospholipid vesicles in terms of the permeability have indicated that the metal cations, especially the multivalent cations, are bound to the vesicles with a high affinity and that the presence of even small amounts of the cation exerts a profound effect on the vesicle dispersion.[2,3]

On the other hand, some organic ions, such as detergents, antibiotics, and some other lipidsoluble ions, can be bound to the phospholipid vesicles by hydrophobic interaction with the lipid molecules. It is expected, therefore, that the adsorption of these organic ions into the membrane will bring about not only a change in the membrane-surface potential, but also a change in the dipole potential in the membrane arising from the oriented dipoles of the polar-head groups of phospholipid molecules.[4,5]

Biological membranes sometimes operate in a medium containing simultaneously, several kinds of metal cations with different ionic valences and a few hydrophobic ions. For example, some sea plants grow quickly in sea water in which various ionic materials are included. It is assumed that in their growing stage, the permeability of their ionic materials through the cell membrane plays an important role. In such a case, it is important to know the relation between the permeability of the membrane and the composition of the ionic materials included.

In this work, some critical data on the binding character of these metal cations with different ionic valences on the phospholipid vesicles from their mixed systems have been obtained. Further, the binding behavior of hydrophobic ions from the mixed solution with multivalent metal cations has been examined under various component conditions. We believe that these critical data on the binding will provide a crucial illustration of the functionality of phospholipid bilayers.

Experimental

Materials. Bovine brain-phosphatidylethanolamine (PE) and -phosphatidylserine (PS) were used as the membrane-forming lipids; they were purchased from the Sigma Chemical Co., Ltd. (U.S.A.). Sodium tetraphenylborate (TPB) and tetraphenylphosphonium chloride (TPP), which has been obtained from Dojindo Laboratories, were used as a hydrophobic anion and a hydrophobic cation respectively. The other inorganic reagents (metal chlorides) were of an analytical grade. All the solutions of these materials were prepared by dissolving them in deionized (Barnstead, NANO pure system) and doubly distilled water.

Vesicle Preparation. The PE and PS vesicles were prepared by the usual sonication method in a nitrogen atmosphere at 4 °C, without using any buffer to reduce the spurious effects of the buffer ions included.[6] After the removal of the undispersed materials by centrifugation (26000 G, 1 h), the dispersions were filtered through a membrane filter (0.1 μm pore size).

Measurements of Amounts of Binding. The binding strength of each metal cation from a single-component system on the PE (or PS) vesicles has been measured as follows. Ten-ml portions of the vesicle dispersion (0.3 g dm^{-1}) were poured into 10-ml portions of various salt solutions containing different ionic concentrations, after which the mixture was left standing for one night at 25 °C. Only the vesicle particles were then separated from the medium by ultrafiltration (Millipore PTGC), and the concentrations of the metal cations and hydrophobic ions were measured analytically by means of the Inductively Coupled Argon Plasma (ICP) method (Jarrell-Ash 975), which counts the amounts of boronium for TPB and of phosphonium for TPP respectively. By observing the

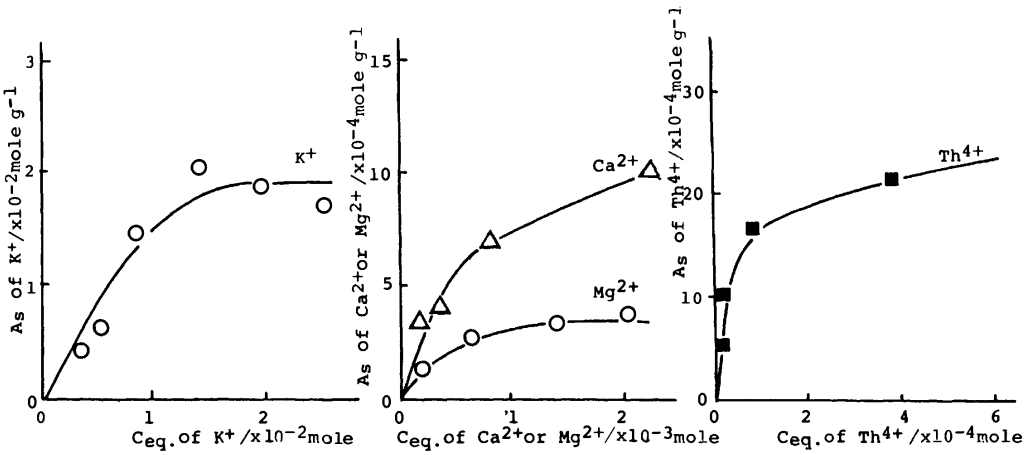

Fig. 1. Binding isotherms of K^+, Ca^{2+}, Mg^{2+}, and Th^{4+} to PE vesicles.

different concentrations in the solutions before and after (C_{eq}) the adsorption process, the amounts of adsorption per unit of vesicle weight (As) were calculated using a calibration curve.

The amounts of binding of each component ion from these mixed solutions of the different ionic species were determined by the same procedure as that used for the singlecomponent system. After a binding period of 24 h, the concentrations of the individual ions remaining in the filtrate as well as in the initial solution were determined simultaneously using the ICP method. By this analysis, the concentrations of many atomic species can be analysed simultaneously from a single liquid solution.

In the simultaneous binding of two ionic species, the effects of the order of addition on their binding are studied as follows. A 5-ml portion of one salt solution is poured into a cylinder with the same volume of the vesicle dispersion, and then the mixture is stored in a thermostat kept at 25 °C for 24 h. After that, a 5-ml portion of another salt solution including the second component ion was added, and the new mixture stored again for 24 h. After the completion of the second binding process, the binding amounts of each component ion were determined in the same analytical way.

Results and Discussion

1) The Binding Behavior of Metal Cations from Single- and Two-Component Systems. Figure 1 presents some typical examples of binding isotherms for metal cations. As may be seen, the affinity of the binding of each cation is much dependent on the ionic valence of the ions, and the affinity increases with an increase in the ionic valence. Especially, the multivalent cations (La^{3+} and Th^{4+}) are bound to the vesicles with very high affinities; even a trace of these ions exerts an important effect on the stability of vesicle dispersion.[2] The present work demonstrated that the binding strength of metal cations to PE and PS vesicles increases in the following order: $K^+ < Mg^{2+} < Ca^{2+} < Mn^{2+} < La^{3+} < Th^{4+}$. Considering their binding order, the competitive (or preferential) binding between the different metal cations has been examined simultaneously in systems including two such species. Figures 2, 3, and 4 show the binding isotherms of K^+ and Ca^{2+}, Ca^{2+} and Mg^{2+}, and Ca^{2+} and Th^{4+}, respectively, as obtained from mixed solutions. It is apparent from Fig. 2 that the preference of Ca^{2+} relative to K^+ can be observed over a wide region except for the lower concentration region of less than 1×10^{-4} mol dm^{-3} $CaCl_2$. It is interesting to notice that the preferential effect of a special ion depends not only on the valence of the ion, but also on the concentration of each ion at which the corresponding binding is carried out. Figure 3 shows the results obtained from the simultaneous binding of Mg^{2+} and Ca^{2+} on the PE vesicles. In the same figure, the isotherms obtained from single-component system are also illustrated by the dotted lines. It follows that

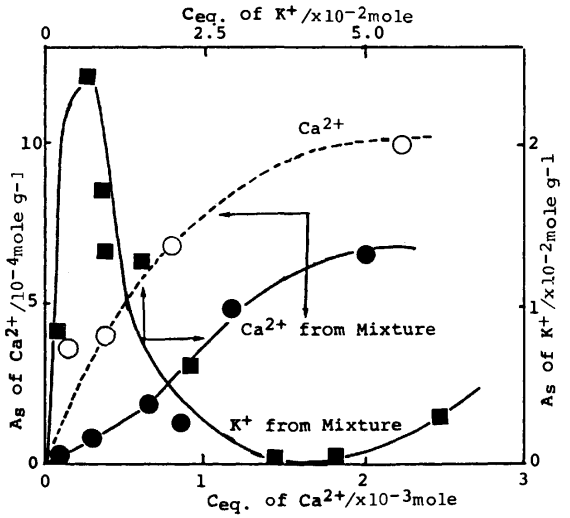

Fig. 2. Binding isotherms of K^+(■) and Ca^{2+}(●) to PE vesicles obtained from their mixed solutions, where the concentration ratio of both the ions is fixed at 30 (K^+) : 1(Ca^{2+}). The dotted line shows the isotherm of Ca^{2+}(○) from the single component system.

the results show a preferential binding of Ca^{2+} in comparison to the binding of Mg^{2+} over the whole concentration region and that the preference of Ca^{2+} depends on the concentration and becomes apparent in concentrations of each ion higher than 1×10^{-3} mol dm^{-3}. As may be seen from Fig. 4, similar results may be found in the simultaneous binding of Ca^{2+} and Th^{4+}, where the concentration of Th^{4+} is fixed at 1×10^{-4} mol dm^{-3}. It is found that the amount of the binding of Th^{4+} is kept constant over the whole concentration region and that only the amount of the adsorption of Ca^{2+} varies with its bulk concentration. All these findings regarding the simultaneous binding between the different metal cations suggest that the binding of metal cations on the membrane surface is influenced by various factors; the ionic species, the ionic valence, the concentration, their ratio in a two-component system and other enviromental factors, and that it is hard to predict the final binding layer from the composition of the equilibrated bulk solution.

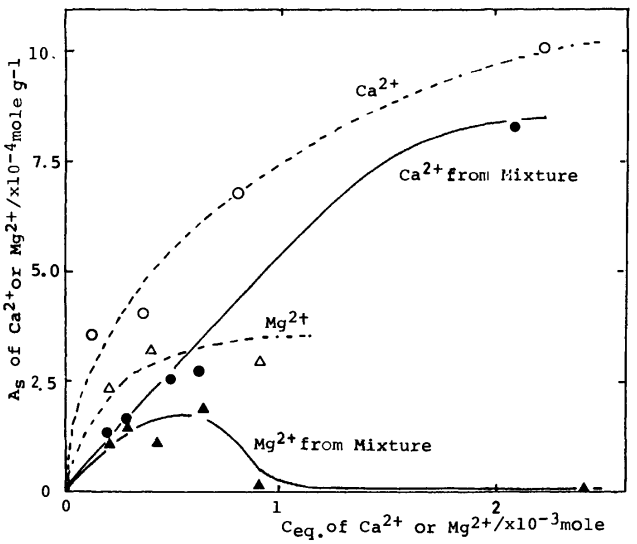

Fig. 3. Binding isotherms of Ca^{2+}(●) and Mg^{2+}(▲) to PE vesicles obtained from their mixed solutions, where the concentration ratio of both the ions is fixed at 1 (Ca^{2+}) : 1(Mg^{2+}). The dotted lines show the isotherms of Ca^{2+}(○) and Mg^{2+}(△) from the single component systems.

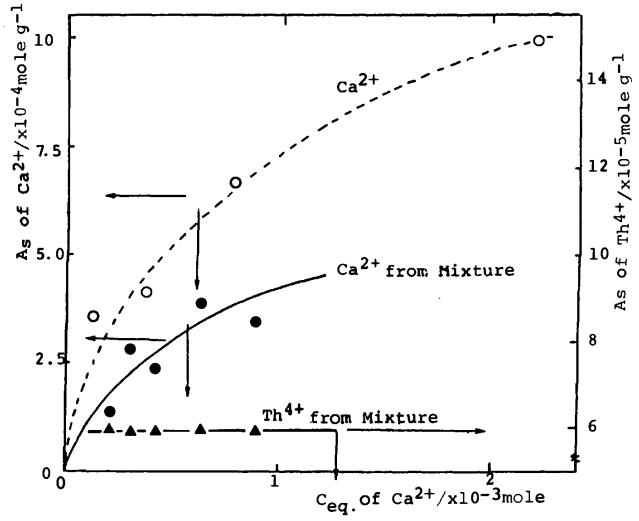

Fig. 4. Binding isotherms of Ca^{2+}(●) and Th^{4+}(▲) to PE vesicles obtained from their mixed solutions, where the concentration of Th^{4+} is kept constant at 1×10^{-4} mol dm^{-3}. The dotted line shows the isotherm of Ca^{2+}(○) obtained from the single component system.

This complexity of the situation in the metal-cation binding from a mixed solution indicates that the binding of their ions will be influenced by the order of the addition of the species. Figure 5 shows some typical results obtained from the two different ways of addition for Ca^{2+} and Th^{4+}, where the concentration of Th^{4+} is fixed at 1×10^{-4} mol dm^{-3}; only the comparison in the binding amounts for Ca^{2+} is indicated for the two mixing methods. As may be seen from the figure, the amounts of bound Ca^{2+} are greatly influenced by the order of addition; the initial addition of Th^{4+} results in decreased amounts of Ca^{2+}. This result indicates that a multivalent cation such as Th^{4+} binds on the membrane surface with an irreversible character and that it is hard to exchange occupied binding-site for other metal cations.

2) Binding Behavior of Hydrophobic Ions from Mixed Solutions with Metal Cations. It has already been reported that there is a great difference between the adsorption behavior of TPB and TPP toward the lipid vesicles from their single-component systems; i.e., the amounts of the binding of TPB are greater than those of TPP, especially at high bulk concentrations.[7] Here, the difference between the binding behavior of the two hydrophobic ions and that of their coexistent systems with the metal cations has been

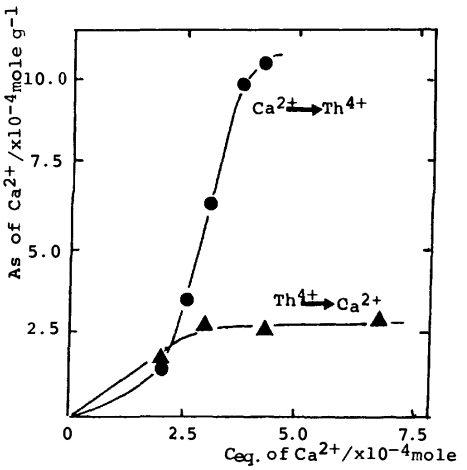

Fig. 5. Binding isotherms of Ca^{2+} to PE vesicles obtained from the two different methods of addition for Ca^{2+}, where the concentration of Th^{4+} is fixed at 1×10^{-4} mol dm^{-3}.

examined using the ICP method. Figures 6 and 7 show the binding isotherms of TPB and Ca^{2+} to the PE and PS vesicles obtained from their mixed solutions with Ca^{2+}. The dotted lines in these figures show the isotherms obtained from the single-component systems of each ion. It is found that the amounts of the binding of TPB are enhanced extensively by the coexistence of Ca^{2+}; a similarly enhanced value is observed in the binding to the PE and PS vesicles. Furthermore, it is apparent that the binding of Ca^{2+} to the PE and PS vesicles is also promoted by the coexistence of TPB. These results indicate that, when the TPB anion and the metal cation are present in the same solution, a synergistic effect by their ions occurs and each ion acts as a cooperator for its binding to the membrane surface.[8]

On the other hand, when the TPP and the metal cations are bound to the vesicles from a mixed solution, very different behavior has been observed. Figures 8 and 9 display the binding isotherms obtained from the mixed solutions of Ca^{2+} plus TPP and of Th^{4+} plus TPP respectively. In Fig. 9, the concentration of Th^{4+} was fixed at 1×10^{-4} mol dm^{-3} and only the binding of TPP is compared. It may be

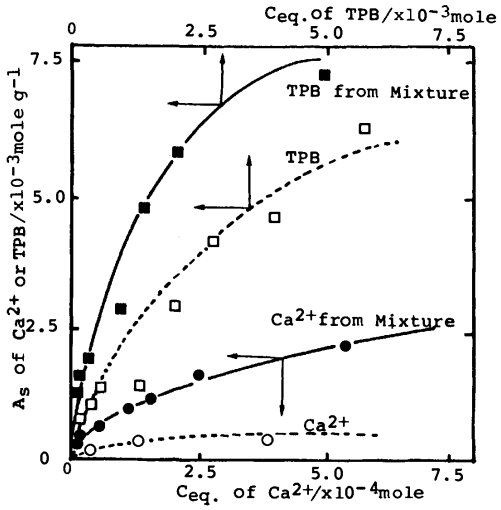

Fig. 6. Binding isotherms of Ca^{2+}(●) and TPB(■) to PE vesicles obtained from their mixed solutions, where the concentration ratio of both the ions is fixed at 1(Ca^{2+}) : 6(TPB). The dotted lines show the isotherms of Ca^{2+}(○) and TPB(□) obtained from the single component systems.

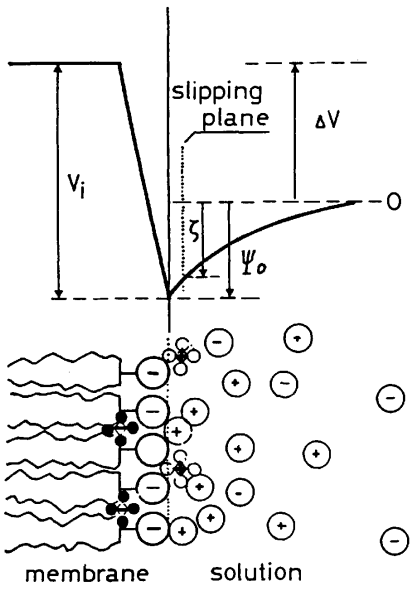

Fig. 10. Schematic picture showing the electrostatic potential through membrane-solution interface and the binding sites on the layer of the lipid membrane (●◇●; TPB, ○⊕○; TPP).

seen from Fig. 8 that the binding of TPP is hindered by Ca^{2+} except in some special concentration regions of TPP. It may be observed by comparison with Fig. 2 that the relations between Ca^{2+} and TPP in their preferential binding resemble those between Ca^{2+} and K^+, suggesting that the binding affinity of TPP results from the same cause as the binding of the metal cation. On the other hand, as may be seen from Fig. 9, the binding of TPP to the vesicles is completely hindered by the coexistence of Th^{4+} because of the strong binding character of Th^{4+} to the membrane surface.

Such a difference in the binding of TPB and TPP to the vesicles from that in mixed solutions with the metal cations may be explained by their different contributions to the electrostatic potential through the membrane-solution interface. Figure 10 shows a schematic picture to elucidate the potential profile near the membrane surface. The membrane potential is described as a combination of potentials arising from the oriented dipoles of polar-head groups of phospholipid molecules and the ionic double-layer potential on their surface.[9] This potential profile can be applied to the PE vesicles under negatively charged conditions.[2] It is usually known that the metal cations bind to the membrane surface and cause the ionic double-layer potential to change. This consideration can be confirmed by measurements of the zeta-potentials of the vesicles (ξ in Fig. 10) and of the surface potentials of the monolayers (ΔV in Fig. 10) in various ionic solutions. On the other hand, the binding of TPB causes a change in both the dipole potential and the double-layer potential as a result of their hydrophobic interaction.[8] According to this concept, if the metal cations and the TPB anions are both present in a solution including PS or PE vesicles, some synergistic interaction in their binding to the vesicles may be expected; some metal cations will initially bind to the negative surface of the vesicles and decrease the negative double-layer potential. This will induce an increase in the binding of some TPB anions by means of their electrostatic forces and again result in a negative surface potential. By repeating the process, a positive cooperative binding between the metal cation and the TPB anion can be observed. On the other hand, when the lipid soluble cations (TPP) are present in a solution with the metal cation, the binding of TPP will be hindered by the positive potential effect induced by the binding of the metal cation to the negative membrane surface. Furthermore, because of the restricted number of binding sites on the outer layer of the lipid membrane which are occupied preferentially by the metal cations, the binding of TPP is extensively hindered by the coexistence of metal cations.

It is clear from the present binding work that the binding sites on the membrane surface for TPP are very different from those for TPB, although they have the same hydrophobic character.

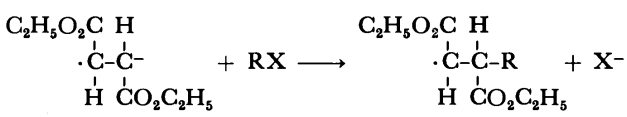
Fast Reactions of Organic Anion Radicals with Organic Halides in Hexamethylphosphoric Triamide Studied by Pulse Radiolysis

Eiji HONDA, Masao TOKUDA, Hiroshi YOSHIDA, and Masaaki OGASAWARA*
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received August 25, 1986)

Fast reactions of diethyl fumarate anion radical (DEF^-) and fluorenone anion radical (Fl^-) with various organic halides (RX) in hexamethylphosphoric triamide have been studied by means of ns pulse radiolysis at room temperature. Reactions of acetophenone anion radical were also studied for comparison. It was found that the reaction rate of Fl^- was subject to the steric and resonance effects of R groups of RX in accord with the classical concept of S_N2 reactions: the rate constant was reduced by 2 orders of magnitude by the steric effect when R was changed from ethyl to bulky isopropyl or *t*-butyl, and it was still large by the resonance effect of R even if R was changed from ethyl to an allyl or a benzyl group. While the reaction rate of DEF^- was not much affected when R was changed to more bulky groups, the rate constant was correlated to the reduction potential of RX. The results were interpreted in terms of a VB correlation diagram approach or rate-equilibrium relationship within a framework of S_N2 reactions.

Most organic anion radicals react efficiently with organic halides, the mechanism being dependent on the kind of anion radical and organic halide. An electron-transfer reaction from radical anions to organic halides accompanied by a dissociation of the electron acceptor into two fragments, organic radical and halide anion, is most commonly observed.[1] Nucleophilic substitution reaction at a saturated carbon atom of the organic halides may also take place. The possibility of an $S_{RN}1$-type substitution reaction,[2] in which the dissociative electron transfer from anion radical to organic halide is followed by addition reaction of the organic radicals to the product neutral molecules, should also be considered.

A few years ago, Satoh et al. studied electrochemical reactions of diethyl fumarate with alkyl halides and confirmed the carbon-carbon bond formation at a saturated carbon atom of the halide.[3] Following nucleophilic substitution reaction of diethyl fumarate anion radical with alkyl halides, RX, was proposed to explain the results.



(1)

Similar nucleophilic substitution reactions were found in electrochemical reactions of the fluorenone anion radical.[4]

We report here the pulse radiolysis kinetics of the reactions of the diethyl fumarate anion radical and the fluorenone anion radical with several organic halides, in special reference to free-energy relationship of the reactions, in hexamethylphosphoric triamide (HMPA) at room temperature. Our aim is to attempt to understand the factors which determine the reactivity of these anion radicals toward organic halides.

Experimental

Pulse Radiolysis Apparatus. The source of the electron pulse was the Hokkaido University 45-MeV linear accelerator. The pulse was reducible in its duration down to as short as 10 ns, but only 100 ns pulse with a dose of 140 Gy/pulse was used in the present study. The cells and optical system have been described elsewhere.[5] The electric signals from a Hamamatsu Photonics R446 photomultiplier were digitized by an Iwatsu TS-8123 Storage-scope and the digitized data were processed by a NEC PC-9801 computer.

Materials. HMPA was dried over calcium hydride for 24 h, refluxed with fresh calcium hydride for 2 h, and distilled at reduced pressure before use. 9-Fluorenone (Nakarai Guaranteed Reagent) was used without purification. Ethyl bromide, iso-propyl bromide, *t*-butyl bromide, allyl bromide and ethyl iodide were distilled over calcium chloride before use. Benzyl bromide was distilled over calcium chloride at a reduced pressure before use. The solutions were degassed in vacuum line and sealed into Suprasil cells of the size $1\times1\times4.5$ cm^3.

Cyclic Voltammetry. Cyclic voltammetry was made with Nichia HP-E_{500} potentiostat at a sweep rate of 0.2 V s^{-1} using a platinum disc electrode (1 mm diameter) or hanging mercury drop electrode (HMDE) in solutions of 0.1 mol dm^{-3} *n*-Bu_4NClO_4 in HMPA. The potential was measured in V vs. Ag/AgI.

Results

Diethyl Fumarate Anion Radical. Figure 1 shows the transient absorption spectra observed in the pulse radiolysis of solutions of 4×10^{-3} mol dm^{-3} diethyl fumarate (DEF) in HMPA. The spectrum with an absorption maximum at 340 nm which was observed immediately after a pulse is assigned to the diethyl fumarate anion radical (DEF^-) formed by electron capture by DEF. For comparison, the absorption spectrum of *dimethyl* fumarate anion radical obtained at 77 K in γ-irradiated 2-methyltetrahydrofuran matrix is also shown.[6] Spectra observed with the samples containing a small amount (1×10^{-2} mol dm^{-3}) of ethyl bromide as the second solute are the same as

those observed without ethyl bromide except for the band in the UV region (<320 nm) which is discernible at 250 μs after the pulse. This UV band may be due to the reaction product of DEF^- with the halide.

The time-profile of the absorption monitored at 340 nm consists of a fast-decaying component and a slow-decaying one, although the contribution of the latter component is only one tenth of the initial absorption. It is assumed that only the fast-decaying component which is separable by subtracting the slow-decaying one from the original curve is due to the DEF^-. In the absence of ethyl bromide the decay curve of DEF^- followed a second-order kinetics, suggesting that the DEF^- disappeared via recombination reactions with solvent cations or radicals produced by ionizing radiation. In the presence of ethyl bromide the decays were analyzed as being mixed first- and second-order processes. Evidently, the first-order process is due to a pseudo- first-order reaction of the DEF^- with ethyl bromide. The rate equation therefore is expressed as:

$$-d[DEF^-]/dt = k_1[DEF^-]^2 + k_2[DEF^-]. \quad (2)$$

Where k_1 is the second-order rate constant of the decay reaction of DEF^- in the absence of RX. This was determined empirically as $(1.1\pm0.3)\times10^9$ $OD^{-1}s^{-1}$ under the same experimental conditions. The k_2 infers the rate constant of the pseudo-first-order process which can be rewritten as $k_2=k[RX]$ with the k being the second-order rate constant between DEF^- and RX. With the k as a parameter the decay curves of the DEF^- were simulated, as exemplified in Fig. 2, by the method described elsewhere.[5] The k thus obtained increases linearly with increase of the RX concentration and the second order rate constants, k, are determined from the slope of the straight lines as summarized in Table 1.

Fluorenone Anion Radical. In the pulse radiolysis of solutions of fluorenone in HMPA, transient absorption spectra with a single peak at 570 nm were observed. The spectra are assigned to the fluorenone

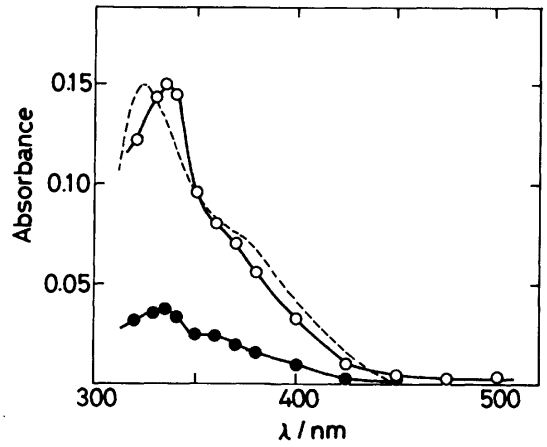


Fig. 1. Transient absorption spectra obtained in the pulse radiolysis of solutions of 4×10^{-3} mol dm^{-3} diethyl fumarate in HMPA: —○— immediately after the pulse, —●— 250 μs after the pulse. The dashed curve indicates the steady state absorption spectrum of dimethyl fumarate anion radical in 2-methyltetrahydrofuran matrix at 77 K.[6]

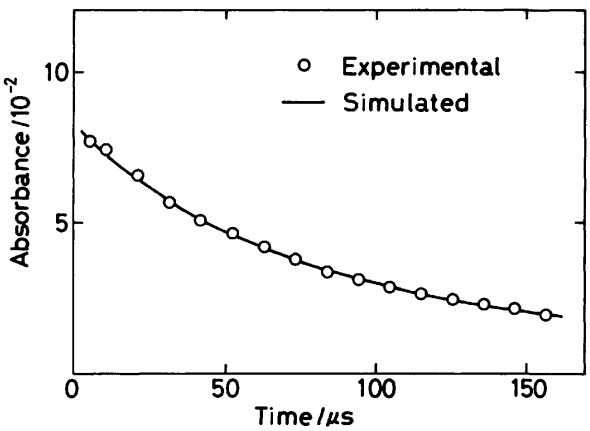

Fig. 2. Decay curve of diethyl fumarate anion radical observed at 340 nm in HMPA solution containing 4×10^{-3} mol dm^{-3} diethyl fumarate and 9×10^{-3} mol dm^{-3} ethyl bromide. The solid line indicates the decay curve simulated on the basis of superimposed first- and second- order kinetics (see the text).

Table 1. Rate Constants of the Reactions between Organic Anion Radicals and Organic Halides

Halogen Compound	Reduction Potential −E/V	DEF^- k/mol^{-1} dm^3 s^{-1}	Fl^- k/mol^{-1} dm^3 s^{-1}	$Acet^-$ [c] k/mol^{-1} dm^3 s^{-1}	Solvent
C_2H_5Br	2.30[a]	$(5.0\pm1.1)\times10^5$	$(3.5\pm0.9)\times10^8$	—	HMPA
$(CH_3)_2CHBr$	2.24[a]	$(8.1\pm1.4)\times10^5$	$(3.1\pm0.9)\times10^6$	$(7.5\pm2.5)\times10^6$	HMPA
ibid.	ibid.	—	$(2.0\pm0.3)\times10^6$	—	CH_3CN
$(CH_3)_3CBr$	2.02[b]	—	$(1.6\pm1.0)\times10^6$	—	HMPA
$CH_2=CHCH_2Br$	1.62[a]	$(1.2\pm0.4)\times10^6$	$(6.3\pm2.8)\times10^8$	—	HMPA
$C_6H_5CH_2Br$	1.47[a]	$(2.6\pm0.9)\times10^6$	$(1.1\pm0.3)\times10^8$	—	HMPA
C_2H_5I	1.84[a]	$(1.6\pm0.4)\times10^6$	—	—	HMPA

anion radical (Fl^-) because of the similarity to those obtained in the pulse radiolysis of ethanol solutions at low temperature and of *N,N*-dimethylformamide solutions at room temperature.[7] In the presence of ethyl bromide essentially the same spectra were observed immediately after the pulse, but a small absorption at ca. 530 nm, probably due to the reaction products of Fl^- with halides, survived for a long time.

The spectra of Fl^- depended markedly on the solvent and the counterion. In acetonitrile solutions the λ_{max} was shifted to ca. 530 nm and a long tail extending on the longer wavelength side was observed. In 2-methyltetrahydrofuran (MTHF) solutions containing sodium tetraphenylborate as *the third solute*, transient spectrum with λ_{max} at 540 nm which was ascribed to ion pair between Fl^- and Na^+ was observed. The shift of λ_{max} in acetonitrile and in MTHF should be due to solvation and coulombic interaction of the counterion, respectively.

The decay kinetics of Fl^- also depended on the solvent. In HMPA, the decay curve monitored at 570 nm arose from a first-order process with a rate constant of $7.3\times10^4\ s^{-1}$. The reaction mechanism of the decay reaction is not known, but the anions may be consumed by reactions with impurities in HMPA. Addition of the second solutes, RX, apparently accelerated the decay rate, indicating efficient reaction of Fl^- with RX. The pseudo-first-order rate constant increased linearly with increase of the RX concentration. Second-order rate constants of Fl^- were determined from the slope of the straight lines for various RX. The reactions of the Fl^- in acetonitrile, which follows a second-order kinetics in the absence of RX, are analyzed by the same method as the case of DEF^-. The results are summarized in Table 1. They showed that the ion pairs, Fl^-Na^+, in MTHF did not react with organic halides in a μs time-domain.

Acetophenone Anion Radical. The absorption spectrum of the acetophenone anion radical in HMPA has a broad band in the visible with double maxima at 460 and 480—490 nm, which disappear following a first-order kinetics. The second-order rate constants k of the reaction between acetophenone anion radical and ethyl bromide are listed in Table 1.

Reduction Potentials of Organic Halides. Reduction potentials (E_{red}) of organic halides in HMPA were determined by cyclic voltammetry. The type of electrode employed in the measurements, Pt or HMDE, did not have much effect, though in general the HMDE electrode gives a little more positive potentials for E_{red}. In Table 1 only the results obtained with the Pt electrode are shown except the one for *t*-butyl bromide.

Figure 3 shows cyclic voltammograms of HMPA solutions containing allyl bromide and n-Bu_4NClO_4. The single peak observed in the cyclic voltammetry

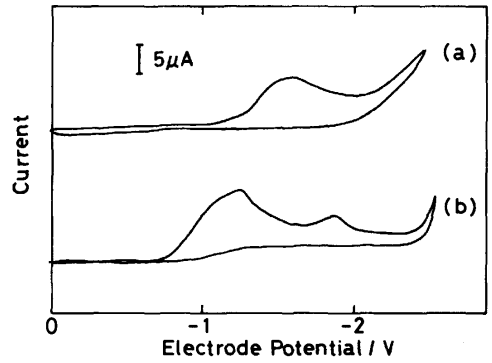

Fig. 3. Cyclic voltammograms of HMPA solutions containing 5×10^{-3} mol dm^{-3} allyl bromide and 0.1 mol dm^{-3} n-Bu_4NClO_4 recorded with Pt electrode (a) and HMDE electrode (b). The electrode potential was measured vs Ag/AgI.

with Pt electrode (Fig. 3(a)) may be ascribed to the following reactions.

$$CH_2{=}CHCH_2Br + e^- \longrightarrow (CH_2{=}CHCH_2Br)^{\cdot-}$$
$$\longrightarrow CH_2{=}CHCH_2\cdot + Br^- \quad (3)$$
$$CH_2{=}CHCH_2\cdot + e^- \longrightarrow CH_2{=}CHCH_2^- \quad (4)$$

The second peak at -1.87 V, which was observed exclusively with HMDE electrode (Fig. 3(b)), can be ascribed to the following reactions.

$$CH_2{=}CHCH_2\cdot + Hg \longrightarrow CH_2{=}CHCH_2Hg\cdot$$
$$\xrightarrow{CH_2=CHCH_2\cdot} (CH_2{=}CHCH_2)_2Hg \quad (5)$$
$$CH_2{=}CHCH_2Hg\cdot + e \longrightarrow CH_2{=}CHCH_2^- + Hg \quad (6)$$

We adopted the value evaluated from the first peak of the cyclic voltammogram shown in Fig. 3(a) as the E_{red} for allyl bromide.

Discussion

The effect of RX on the decay curve of DEF^- clearly indicates that DEF^- reacts with RX very efficiently. In the study of electrochemical reaction of DEF, Satoh et al. concluded that the electron transfer from the electrode to DEF was followed by an S_N2 reaction of the produced DEF^- with RX.[3] Analogously, the most plausible reaction of DEF^- with RX would be an S_N2-type substitution reaction. The resulting radical should be the R-adduct radical of DEF as shown by Eq. 1, although its formation has not yet been confirmed optically. It should be noted that the reaction rate is not much affected when R is changed from ethyl to a bulky isopropyl group. This result is not fully consistent with the classical concept of an S_N2 reaction which is characterized by effective hindrance by the presence of bulky group. Instead, the rate constant is correlated to E_{red} of RX as shown in Fig. 4.

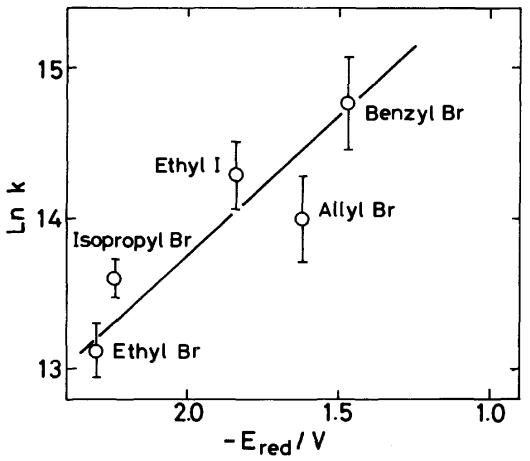

Fig. 4. Second-order rate constant for the reactions at room temperature between diethyl fumarate anion radical and organic halides as a function of the reduction potential of the organic halides.

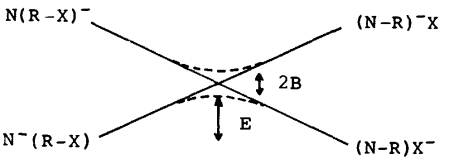
In S_N2 reactions a nucleophilic reagent forms a new bond to the carbon atom under attack, the old bond breaking. In the transition state the incoming group and the leaving group are both "half-bonded" to the carbon atom. Therefore it had been thought that "crowdedness" in the formation of the activated complex was the most important factor in determining the reaction rate.[8] Actually, in the classical bromide-exchange reaction of alkyl bromide in acetone, the reaction rate changes drastically, by a factor of about 100, when alkyl group of the organic halides is replaced from an ethyl to an isopropyl group.[9] However, recently, some of the theoretical and experimental studies suggested that the difference in the shape or size of the reactant molecules played no obvious part in determining the reaction rate. In some cases those effects can be incorporated into parameters such as proton affinity, ionization potential, or reduction potential of the reactants.[10] The reaction of DEF^- with RX observed in the present study is one of the examples of such cases.

In order to interpret the correlation between the k of the S_N2 reaction and the E_{red} of the reactants, the VB correlation diagram approach can be invoked. The S_N2 reaction is a transformation that involves a synchronous electron shift and a bond interchange as expressed below.

$$N^- + R\text{-}X \longrightarrow N\text{-}R + X^- \qquad (7)$$

In the VB correlation diagram model which was invented and developed by Shaik,[11] four anchor states, i.e. the ground state reactants ($N^-(R\text{-}X)$) and products ($(N\text{-}R)X^-$) and the corresponding valence-charge-transfer forms of the reactants ($N(R\text{-}X)^-$) and products ($(N\text{-}R)^-X$), are correlated with each other.



In between these four anchor states a barrier arises owing to avoided crossing of the intersecting curves. The height of the barrier (E) is a fraction (f) of the energy gap separating the anchor states $N(R\text{-}X)^-$ and $N^-(R\text{-}X)$, less the avoided crossing, B, i.e.

$$E = f(I_{N^-} - A_{RX}) - B \qquad (8)$$

I_{N^-} is the vertical ionization potential of the nucleophile, N^-, while A_{RX} is the vertical valence electron affinity of the substrate, RX, that can be related to E_{red}. If constancy of I_{N^-}, f and B for a reaction series is maintained, variation in the activation energy depends only on E_{red}.

Alternatively within a framework of rate-equilibrium relationship originally developed by Marcus,[12] the following elementary steps are assumed.

$$Y^- + RX \rightarrow \underset{\text{I}}{Y^- \; RX} \rightarrow \underset{\text{II}}{YR \; X^-} \rightarrow RY + X^- \qquad (9)$$

Brauman and his co-workers proposed a double minimum potential surface at the first (I) and the second (II) intermediates in Eq. 9.[13] As the reactants approach one another, long-range ion-induced dipole and ion-dipole interactions produce a drop in potential energy. There is then a potential energy increase up to the central transition state between the I and II states which becomes the intrinsic energy barrier of the S_N2 reaction. The difference in the E_{red} of Y and RX may be related to the free energy difference, ΔG, between the I and II states. The ΔG is related, in turn, to the intrinsic energy barrier of the S_N2 reaction by use of the Marcus equation.[10b] Thus, the rate of S_N2 becomes a function of E_{red}. It should be emphasized that the Marcus approach is a very general one and is not limited to electron-transfer reactions, as the parabolic free energy profile arises from summing displacement along many different coodinates.[14]

Another possible reaction mechanism is a dissociative electron-transfer reaction from anion radicals to organic halides. The Marcus quadratic equation for reversible electron-transfer reaction predicts the slope α of the acitivation energy vs. ΔG plot to be >0.5 for positive ΔG. In some systems where the electron-transfer is part of an overall irreversible transformation, such as chemical-bond formation or dissociation into two fragments, the experiments give values for α usually in the ranges 0.2 to 0.5.[15] Actually, α in the present study, which is deduced from the gradient of

the straight line in Fig. 4, is as small as 0.1. This value is not consistent with the prediction or the empirical low of the electron-transfer reaction. Besides, free energy differences of the electron-transfer from DEF^- or FI^- to RX evaluated from the E_{red} of the reactants are very endothermic. The electron-transfer reaction should, even if it occurred, be too slow to be observed by pulse radiolysis in ns or μs time-domains. However, the reaction with benzyl bromide can proceed via an electron-transfer mechanism, since the E_{red} of this halide is only slightly more negative than that of DEF. As it is known that C–C bond formation is accomplished by the reaction of DEF^- with benzyl bromide, so called $S_{RN}1$ mechanism in which the electron transfer occurs prior to C–C bond formation may be applicable.[2]

In the case of the reactions of Fl^-, it is obvious that there is no correlation between the k and the E_{red} of RX. Rather, k is determined by the steric and resonance effect of the R groups as is commonly seen in typical S_N2 reaction. The k is reduced by 2 orders of magnitude by the steric effect when R changes from ethyl to the bulky isopropyl or *t*-butyl groups. However k still remains large because of the resonance effect of R if R changes from ethyl to a bulky allyl or benzyl group. When a benzene ring of the Fl^- is replaced by methyl group, the reaction is accelerated as demonstrated by the rate constant for acetophenone anion radical shown in Table 1. Thus, an S_N2-type substitution reaction between Fl^- and RX is strongly indicated. This conclusion is in accord with the electrochemical study by Lund and Simonet which indicated that Fl^- reacted with RX to form R-adducts.[4] In these substitution reactions,the reaction site of the nucleophilic reagent is supposed to be a negatively charged oxygen atom. The difference between Fl^- and DEF^-, in the hindrance of S_N2 reactions by the presence of a bulky group, may be interpreted as due to the bond length in the transition state between the incoming group and the carbon atom under attacked being shorter as compared with the case of DEF^-, with Fl^- as the nucleophile. The shorter bond length may be caused by the difference in the reaction site, O or C atom, of the substitutions.

The authors would like to express their thanks to Messrs. Hiroaki Tanida and Kohichi Sato for operating the 45-MeV Electron Linear Accelerator of Hokkaido University.

Resonance Raman and ^{129}I Mössbauer Spectroscopic Study of Phenothiazine-Iodine Complexes

Hiroshi SAKAI,* Shu-ichi MURAISHI,† and Yutaka MAEDA
Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04
†Analytical Instrument Division, JEOL, Ltd., Nakagami-cho, Akishima, Tokyo 196
(Received September 5, 1986)

Resonance Raman and ^{129}I Mössbauer spectroscopy have been applied to the phenothiazine-iodine (PT-I_n) complexes, which exhibit relatively low electrical resistivities. It is shown from the resonance Raman spectra that the two iodine species in the PT-I_3 and PT-$I_{2.6}$ complexes are present in essentially the same chemical form, consisting of a distorted I_3^- unit and an I_2 unit strongly coordinated to the I_3^- unit. The ^{129}I Mössbauer spectrum, consistent with the results of the Raman spectra, suggests that the PT-$I_{2.6}$ complex can be approximately formulated as $(PT)_5^{3+}[(I_3)_3(I_2)_2]^{3-}$, in which about three electrons per five PT molecules are transferred to the iodine and the transferred electrons are delocalized on the thirteen iodine atoms. The radical salt is recognized as a partially oxidized mixed-valence compound. The formation of the complex is quite similar to that of the perylene-I_3 complex, which has a low electrical resistivity.

The phenothiazine-iodine (PT-I_n) complex is known to be a typical radical salt, exhibiting a relatively low electrical resistivity.[1] The electrical properties, such as the electrical resistivity, the activation energy, the Seebeck coefficient, and the electromotive force, of the semiconducting complex have been examined in detail as a function of the composition n by Gutmann and Keyzer,[2] Doi et al.,[3] and Matsumoto and Matsunaga.[4] According to their works, anomalous behavior of the electrical properties is observed between n=2.5 and 3: Drastic decreases in the electrical resistivity and in the activation energy, a change in sign of the Seebeck coefficient, and a step-by-step increase in the electromotive force. The vibrational spectrum of the complex at n=3, which exhibits the minimum resistivity of 20 Ωcm at room temperature, indicates that the phenothiazine (PT) exists as a complex radical cation where two PT molecules share a unit positive charge and are equivalent in the time scale of infrared spectroscopy.[1,5] The results of the electrical properties and the vibrational spectrum suggest that the complex with a composition of n=3 is a nonstoichiometric compound, whereas that with the composition of n=2.5 is a stoichiometric one, probably formulated as $(PT)_2^+(I_5)^-$. The latter complex exhibits an electrical resistivity of about 800 Ωcm at room temperature. The crystal structure of the complex has not yet been established because of the difficulty of preparing a good single crystal. Recently, however, Uchida et al.[6,7] have revealed the crystal structures of several phenothiazine complexes with antimony (V) chloride, in which PT forms a segregated stacking column. Generally the structures of iodine complexes with low electrical resistivities consist of stacking columns of partially oxidized donor molecules and reduced iodine acceptor counterions.[8] One might expect the formation of a segregated stacking column of the PT in the present iodine complex because of its low electrical resistivity. However, there is no information on the chemical form and the charge density for the iodine atoms of the complex.

It is important to clarify the chemical form and the electronic structure of iodine in order to understand the electrical properties of the complex. Resonance Raman and ^{129}I Mössbauer spectroscopy are powerful methods for this purpose, and both have been successfully applied to iodine complexes with low electrical resistivities.[9–13] In this paper we wish to report on our resonance Raman and ^{129}I Mössbauer studies of the phenothiazine-iodine complex.

Experimental

Materials. Commercially available phenothiazine was recrystallized from benzene. The PT-I_3 complex was precipitated by mixing PT and I_2, separately dissolved in hot benzene, in a prescribed mole ratio. A complex with a composition of n=2.5 was prepared by the use of a large excess of PT. The iodine contents were determined by elemental analysis and iodometry: Found; C, 24.31; H, 1.55%. Calcd for PT-I_3: C, 24.85; H, 1.56%. Found; C, 26.88, H, 1.72%. Calcd for PT-$I_{2.5}$: C, 27.90; H, 1.76%. By iodometry: Found; I, 65.8%. Calcd for PT-I_3: I, 65.64%. Found; I, 63.9%. Calcd for PT-$I_{2.5}$: I, 61.42%. The elemental analysis and iodometry of the sample prepared by the use of an excess of PT indicated that the composition was approximately PT-$I_{2.6}$. The composition of a precipitate appears to depend on the mole ratio of each component and on the concentration used in the preparation. However, when an excess of PT is used for the preparation, a good crystalline precipitate is obtained with the iodine content of n=2.6. The radioactive ^{129}I-labeled complex used for the measurement of the Mössbauer spectrum was prepared from $Na^{129}I$ in an Na_2SO_3 solution. After the iodide had been oxidized with 3 mol dm^{-3} H_2SO_4 and 10% H_2O_2, the resulting molecular iodine was extracted with benzene. The iodine solution was thoroughly washed with water and passed through a Teflon filter to eliminate any slight amount of water. The hot solution was then added to the hot benzene solution with an excess of PT. The precipitate was identical to that obtained with the natural iodine (PT-$I_{2.6}$). The PT-$^{129}I_3$ complex could not be prepared because of

the uncertainty as to the iodine content in the benzene solution. The sample thickness for the Mössbauer measurement was about 20 mg ^{129}I cm^{-2}.

Measurements. The laser Raman spectra were measured with Ar^+ (514.5 nm) excitation by using a JEOL-JRS-400T triple monochromator. The data were obtained at room temperature with compressed pellets of the powdered complexes (PT-I_3 and PT-$I_{2.6}$) by the front-surface-reflection method, using 60 mW of laser power and a spinning cell. No decomposition was observed with this laser power.

The ^{129}I Mössbauer measurements were carried out in a transmission geometry by cooling the source and the absorber sample (PT-$I_{2.6}$) at 16 K with a closed-cycle helium refrigerator. The Mössbauer source, $^{66}Zn^{129}Te$ ($t_{1/2}$=70 min), was prepared by the neutron irradiation of 140 mg of a $^{66}Zn^{128}Te$ compound at a fluence rate of 2×10^{13} neutrons cm^{-2} s^{-1} for 1 h in the Kyoto University Reactor (KUR). The source activity produced by the $^{128}Te(n,\gamma)^{129}Te$ reaction was initially about 10 mCi. The constant-acceleration Mössbauer drive was calibrated with a six-line spectrum of an Fe foil.

Results and Discussion

Resonance Raman Spectra. In Fig. 1 are presented the resonance Raman spectra of the (a) PT-I_3 and (b) PT-$I_{2.6}$ complexes excited by the Ar^+ 514.5 nm line. Interestingly, the two spectra (107 s, 143 w, 167 m, cm^{-1}) are essentially identical, suggesting that the iodine species exist as an identical chemical form in both complexes. The strong scattering Raman band at 107 cm^{-1} is characteristic of the symmetric stretching vibration of a linear triiodide anion (I_3^-). The isolated and symmetrical I_3^- ions in methanol[14] and $(C_6H_5)_4As^+I_3^-$[9,11] show the strong Raman bands at 112 and 113 cm^{-1} respectively, whereas the corresponding bands are observed at 107—108 cm^{-1} for successive I_3^- chains in (benzamide)$_2H^+I_3^-$[9] and (*N*,*N*′-diphenyl-*p*-phenylenediamine)$(I_3^-)_{0.8}$[13] complexes. In I_3^- units in polyiodides containing I_3^- and I_2, the transition bands are observed in the 105 to 120 cm^{-1} region, depending upon the interaction of the I_3^- and I_2 units.[9,11] The latter distorted I_3^- units give rise to a second, weak Raman band near 145 cm^{-1}; this band has been assigned to the antisymmetric stretching vibration. Therefore, the strong and weak Raman bands at 107 and 143 cm^{-1} observed for the PT-I_n complexes suggest the presence of a distorted I_3^- unit in these complexes.

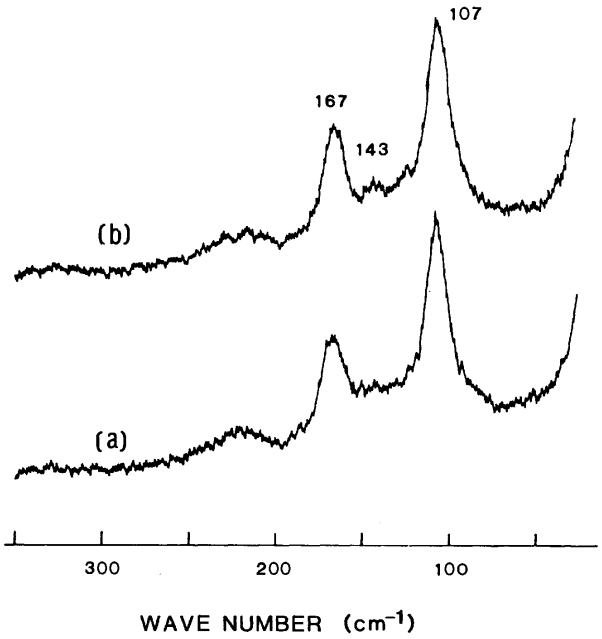

Fig. 1. Resonance Raman spectra excited by the Ar^+ 514.5 nm line of (a) PT-I_3 and (b) PT-$I_{2.6}$ complexes.

On the other hand, the Raman band observed at 167 cm^{-1} can be assigned to a linear pentaiodide anion (I_5^-) or to an I_2 unit coordinated to the I_3^- unit. The resonance Raman spectra of (trimesic acid $H_2O)_{10}H^+I_5^-$ and starch-iodine complexes, in which the iodine atoms exist as linear I_5^- ions, exhibit a strong scattering at 162—163 cm^{-1} and a weaker band at 104—109 cm^{-1}.[9,15] Raman bands for I_2 units in polyiodides are observed at 172—173 cm^{-1} for Cs_2I_8[11] and $(\alpha\text{-CD})_2LiI_5\cdot8H_2O$ (α-CD, α-cyclodextrin).[15] If the I_2 unit strongly coordinates to the I_3^- unit, close to the I_5^- ion, the I-I stretching band shifts to a lower frequency. The band at 167 cm^{-1} observed for the present complexes is just intermediate between those of the I_5^- ion and the I_2 unit coordinated to the I_3^- unit. It may, therefore, be concluded from the resonance Raman spectra that the iodine atoms in the phenothiazine-iodine complexes exist as a polyiodide consisting of a distorted I_3^- unit and an I_2 unit strongly coordinated to the I_3^- unit.

Undoubtedly resonance Raman spectroscopy is a powerful method for the identification of the chemical form of the iodine species in the iodine complexes, but there is a limitation with respect to the quantification of the relative amounts of iodine species, because the relative intensities of the Raman bands are strongly dependent on the excitation wavelength. The ^{129}I Mössbauer spectroscopy can provide complementary information on the relative amounts of iodine species and the presence of an isolated I^- ion. Furthermore, the electronic structure of each iodine atom (Sites 1 to 5) can be directly derived from the Mössbauer spectrum.

Mössbauer Spectra. The ^{129}I Mössbauer spectrum of the PT-$I_{2.6}$ complex at 16 K is shown in Fig. 2. The spectrum consists of roughly three different quadrupole octets (A, B, and C), indicating the presence of three distinct iodine sites in the complex. In the

analysis of the spectrum, a broadening of the line-width is observed. The line-width of the ^{129}I Mössbauer spectra is usually found with our apparatus to be about 1.0 mm s^{-1}.[13] In particular, the quadrupole octets B and C show considerable line-broadening, enhanced in the higher Doppler-velocity region. This broadening is attributable to an overlap of the spectra originating from iodine atoms with slightly different charge densities. The spectrum clearly rules out the presence of the isolated I^- ion and the molecular iodine (I_2). The former ion, inactive and undetectable by Raman spectroscopy, would show a single absorption peak at -0.5 mm s^{-1} in the spectrum. The latter molecular iodine, which has not been observed in the Raman spectra, would indicate a slightly smaller quadrupole splitting ($e^2Qq=-2255\pm 30$ MHz, $\delta=0.94\times0.05$ mm s^{-1})[16] than that of the quadrupole octet A. The obtained Mössbauer parameters, such as the quadrupole coupling constant (e^2Qq), the asymmetry parameter (η), the isomer shift (δ), the line-width (2Γ), and the relative area, are summarized in Table 1.

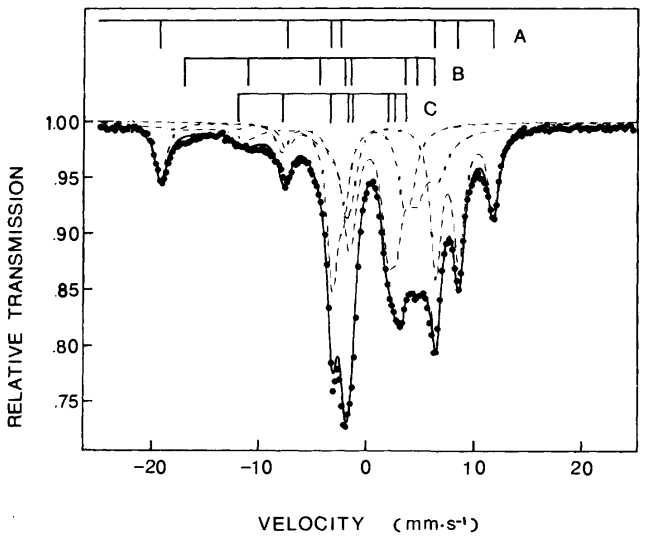

Fig. 2. ^{129}I Mössbauer spectrum at 16 K of the PT-$I_{2.6}$ complex.

The e^2Qq and δ values of the quadrupole octet A, larger than those for the free iodine molecule in inert matrices, indicate that the iodine atom (I_A) corresponding to the octet A has a slightly positive charge density. Such iodine atoms are observed in the central iodine of linear I_3^- ions[12,13] and the intermediate iodines of linear I_5^- ions.[9,15] In addition, when an I_2 unit is strongly coordinated to an I_3^- unit, as is to be expected from the Raman spectra, the iodine atom coordinated to the I_3^- unit has a positive charge density.[11,17] Therefore, it is reasonable to assign the iodine atom I_A to those of Sites 1, 1′, and 4 in the **1** and **2** iodine species. This is the reason for the broadening of the line-width in the sub-spectrum A. Because of the poor resolution of the Mössbauer spectrum of ^{129}I, any distinction among them may be difficult.

The e^2Qq values of the two terminal iodines of the distorted I_3^- ion in CsI_3 are, from the ^{127}I NQR[18] and ^{129}I Mössbauer measurements,[19] found to be about -1440 MHz and -820 MHz. These e^2Qq values are close to those for the quadrupole octets B and C. That is, the iodine atoms, I_B and I_C, corresponding to the B and C octets can be assigned to the iodines of Sites 2 and 3 respectively in the distorted I_3^- species **1**. Since the charge density localized on each iodine of the I_3^- unit is expected to be perturbed by the coordination of the I_2 unit, the e^2Qq and δ values for the iodines of Sites 2′ and 3′ in the **2** species are slightly different from those of Sites 2 and 3 in the **1** species. This difference causes the line-broadening of the quadrupole octets, B and C. The charge density on the iodine of Site 5 may be close to that of Site 2′, because the I_2 unit is strongly coordinated to the I_3^- unit. The spectrum of the iodine Site 5 is included in the broad sub-spectrum B.

The terminal iodine atoms of Sites 2 and 3 in **1** probably interact with the terminal iodines of the other iodine species, **2**. If the interaction is perpendicular to the molecular axis, a large η value must be observed for the iodine atom. The quite large η value observed for the quadrupole octet B suggests that the iodine atoms are, on the average, present in the complex as a polyiodide with the following structure (Fig. 3):

Table 1. Mössbauer Parameters for the Phenothiazine-Iodine (PT-$I_{2.6}$) Complex

		e^2Qq[a] / MHz	η / %	δ[b] / mm s^{-1}	2Γ / mm s^{-1}	Area[c] Ratio	U_p[d]	h_p[e]
PT-$I_{2.6}$	I_A	-2381 ± 25	0	1.34 ± 0.05	1.20 ± 0.10	1.4	1.04	1.25
	I_B	-1414 ± 25	29 ± 10	0.66 ± 0.05	$1.30+\alpha$[f]	1.0	0.62	0.80
	I_C	-918 ± 25	0	0.08 ± 0.05	$1.36+\beta$[f]	1.0	0.40	0.41

a) The e^2Qq values are converted to the ^{127}I nucleus. b) The δ values are relative to the ZnTe source. c) The ratios are normalized with respect to the I_C atom. d) $U_p=-e^2Qq_{obsd}/e^2Qq_{atom}$, $e^2Qq_{atom}=2292.7$ MHz. e) $\delta=1.5\,h_p-0.54$ (mm s^{-1}). f) The values are of the line-widths at zero Doppler velocity. The errors quoted in this work include estimated systematic errors.

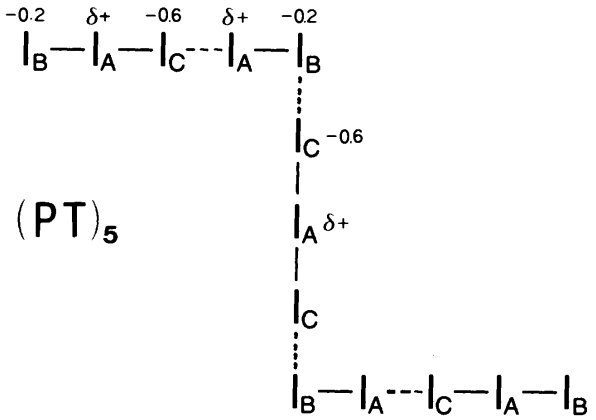

Fig. 3. The speculated structure of the iodine atoms in the PT-$I_{2.6}$ complex.

In Fig. 3 the intermolecular bond (···) between the I_C and I_A atoms implies the strong interaction previously described, whereas the bond (····) between the I_B and I_C atoms indicates a weak intermolecular interaction. The proposed structure with relative populations of 1.25:1.0:1.0 for I_A:I_B:I_C of the iodine species satisfies the relative absorption areas (1.4:1.0:1.0) of the sub-spectra corresponding to I_A, I_B, and I_C. The slight increase in the area of I_A can be explained in terms of the difference in the recoilless fraction. That is, the recoilless fraction of I_A can be expected to be larger than those of I_B and I_C, for the I_A atom is strongly bound to two neighboring atoms. This effect is also found in the other I_3^- ions, where the central atom indicates a stronger absorption intensity than each terminal atom.[12,13]

The charge density localized on each iodine atom is calculated from the values of e^2Qq, η, and δ as follows:[13]

$$U_p = -e^2Qq_{obsd}/e^2Qq_{atom} = -N_z + (N_x+N_y)/2,$$
$$\eta = 3(N_x-N_y)/2U_p,$$
$$\delta = 1.5\,h_p - 0.54 \text{ (mm s}^{-1}\text{, for the ZnTe source)},$$
$$h_p = 6 - (N_x+N_y+N_z),$$

where U_p is the number of unbalanced p-electrons; e^2Qq_{atom}, the atomic iodine quadrupole coupling constant, is equal to 2292.7 MHz for ^{127}I, and h_p is the number of 5p-electrons removed from the $5s^25p^6$ (I^-) configuration. N_x, N_y, and N_z are the populations of 5p-electrons in the x, y, and z directions respectively. When the bonding of iodine is formed by only $5p_\sigma$-electrons, one expects the relationship $U_p=h_p=1\pm i$ to be valid, where i is the ionic character. The U_p and h_p values obtained for each iodine atom are presented in Table 1.

It can be seen that the h_p value is larger than the U_p value for the I_A atom. This phenomenon, also found in the central iodine of linear I_3^- ions,[12,13] can be explained in terms of the contribution of $4d_\sigma$-electrons to the bond formation, in addition to the delocalized three-center four-electron bonding of 5p-electrons.[13] Consequently, the I_A atom has, on the average, a slight positive charge ($\delta+$), less than the $+0.04\,e^-$ obtained from the U_p value. The disagreement of h_p and U_p values for the I_B atom is attributable to the intermolecular interaction in the x or y direction. This result is supported by the large η value of the atom. The charge density localized on the I_B atom is, on the average, estimated from the h_p value to be $-0.2\,e^-$. For the I_C atom, the h_p value is close to the U_p value, suggesting that the bonding of the atom is mainly caused only by $5p_\sigma$-electrons. The charge density on the I_C atom is roughly estimated to be $-0.6\,e^-$ from the h_p and U_p values. The charge densities obtained from the Mössbauer parameters are indicated on the respective iodine atoms in Fig. 3. It should be noted that the charge densities are the averaged values because of the broadening of the line-widths in all sub-spectra.

It is concluded from the results of the resonance Raman and ^{129}I Mössbauer spectra that the present complex with a composition of n=2.6 can be approximately formulated as $(PT)_5^{3+}[(I_3)_3(I_2)_2]^{3-}$. That is, about three electrons per five PT molecules are transferred to a polyiodide, consisting of a distorted I_3^- unit and an I_2 unit strongly coordinated to the I_3^- unit. This complex is apparently not a stoichiometric compound formulated as $(PT)_2^+(I_5)^-$. From the similarity of the resonance Raman spectra, it might be reasonable to speculate that the PT-I_3 complex can be formulated as $(PT)_5^{3+}[(I_3)_3(I_2)_3]^{3-}$ in a manner similar to that used for PT-$I_{2.6}$. The difference in the electrical resistivities of the two complexes is probably the result of a structural factor, such as the stacking of the PT molecules and/or the packing of the polyiodides. These complexes are recognized as partially oxidized mixed-valence compounds. The formation of these complexes is quite similar to that of the perylene-$I_{2.92}$ complex, exhibiting a low electrical resistivity of about 10 Ωcm at 300 K.[11]

The authors wish to express their thanks to Professor Takenobu Higashimura of the Research Reactor Institute, Kyoto University, for his useful discussions and encouragement.

The Role of CO_{ad} in the Oxidation of Methanol at a Platinum Electrode in an Acid Solution

Hiroshi MATSUI* and Takeo HISANO†
Department of Applied Chemistry, Faculty of Engineering, The University of Tokushima, Minami-josanjima-cho, Tokushima 770

(Received September 5, 1986)

The role of the adsorbate CO_{ad} in the oxidation of methanol was studied under a variety of experimental conditions on the basis of the rate-ratio of the path of CO_2 formation via CO_{ad} to the overall oxidation of methanol at a platinum electrode in 0.5 mol dm^{-3} of H_2SO_4. The results: (a) At potentials below 0.55 V and with a short time of oxidation, CO_{ad} inhibited its own formation; (b) at 0.60—0.75 V and with a long time of oxidation, CO_{ad} was a poison to parallel reactions; (c) at above 0.8 V and at $\theta_1 > 0.15$, the formation of CO_2 via CO_{ad} was predominant, and the CO_{ad} never hindered parallel reactions. There was no difference between the role of the CO_{ad} formed from dissolved CO and that of the CO_{ad} formed from methanol, though, in the absence of dissolved CO, the oxidation of methanol was, for some reason, inhibited at small coverages close to the respective limiting values. When the coverage was larger than about 0.85, CO_{ad} remarkably inhibited all the parallel reactions in the methanol oxidation.

This paper will describe the role of the adsorbate CO_{ad} formed from methanol on a platinum electrode during the anodic oxidation of methanol in 0.5 mol dm^{-3} of H_2SO_4.

Chemical analysis[1] has shown that CO_2 is the final product of the oxidation and that, at high concentrations of methanol, formaldehyde and formic acid are also formed as intermediate products which are soluble in solution and which can be further oxidized to CO_2, depending on circumstances. Several parallel paths producing CO_2 have so far been proposed.[1-3] However, only the following two seem to be based more or less upon experimental facts; the others appear to be rather speculative for the time being: (1) The path via a stably chemisorbed substance (SCS), and (2) the path via formaldehyde and formic acid. The formation of SCS and its oxidation to CO_2 were confirmed by Breiter[4] and Petrii et al[2]. The existence of the latter path was experimentally verified[1] only when the oxidation of methanol was prolonged and the concentration of methanol was high. Any adsorbate in this path is considered[5,6] to be so small in surface concentration that can not yet be experimentally identified. Breiter[7] and Petrii et al.[2] determined the rate-ratio of the production of CO_2 by the path via SCS to the overall oxidation of methanol. From these data, they[2,6] concluded that the SCS 'had the effect of a poison on' (Breiter), or 'passivated' (Petrii), the production of CO_2 by covering the surface of the electrode.

Regardless of a number of such papers,[2,6-9] the present work will also attempt to reexamine the same problem, the role of SCS (CO_{ad}), by a rather similar method. Our main reasons are as follows: (a) Contrary to most previous workers, we consider the SCS to be CO_{ad}.[10,11] Petrii[2] regarded it as COH_{ad}, and Breiter[4], as a mixture of COH_{ad} and $COOH_{ad}$. In their estimation of the rate-ratios stated above, the number of electrons participating in the oxidation of SCS to CO_2 was decisively important. For the oxidation of CO_{ad}, that number is, of course, different. (b) Although many workers[2,6,8-9] have supported the idea that a SCS can be a poison, no detailed study has been published on the oxidation conditions under which a particular SCS passivates a particular parallel reaction. (c) As is well-known,[11-13] the presence of trace amounts of impurities such as a chloride anion in a solution reduces the overall rate of methanol oxidation, while the accumulation of reaction products such as formaldehyde in a solution enhances that rate, because these products are more easily oxidized than methanol. These influences are more or less unavoidable in the case of a prolonged electrolysis of methanol, a method which was adopted in most of the previous works in order to bring a process to the stationary state or to collect a gas sample of the products for analysis. (d) It is also known[14] that the degree of coverage with SCS affects the overall rate of methanol oxidation. On the other hand, previous works[2,7] on the contribution of the path via SCS to the overall oxidation seldom dealt with cases of a low coverage.

In short, the experimental conditions of most previous works seem inadequate or insufficient to clarify the role of SCS. A platinum electrode with a large roughness factor is affected only a little by the presence of impurities, but much by the accumulation of the soluble intermediate products. The reverse is true for an electrode with a small roughness factor. Consequently, we used a platinized platinum electrode with a moderate roughness factor of about 17. In order to minimize the harmful influence of impurities, the time of methanol oxidation was limited to within 400 s, during which period the coverage with impurities never exceeded a few per cent. Consequently, it follows that the present work deals

with the process in which the oxidation of methanol changes from a non-stationary state to an approximately stationary state.

We also assumed that, as have the previous workers,[2,7] that the rates for the path via SCS, which were too hard to measure directly, were equal to the rates of the oxidation of CO_{ad} in the supporting electrolyte containing no methanol. Instead of using these rate values directly, however, we first generalized them in the form of a rate equation. Then, the rates for that path at any set of initial coverages and potentials could be calculated by using the equation.

These improved circumstances led to the following conclusions. At potentials below ca. 0.55 V, the CO_{ad} species were formed rapidly and oxidized slowly. They inhibited mainly their own formation. At 0.6—0.75 V, reactions parallel to the reaction via CO_{ad} became predominant; the CO_{ad} hindered mainly these parallel reactions. At potentials and coverages higher than 0.8 V and 0.15 respectively, the oxidation of CO_{ad} was fast, and no hindrance of any reaction by CO_{ad} was any longer seen.

The adsorbate CO_{ad} is formed also from dissolved carbon monoxide,[2,15] which is well-known[15-18] to be a poison to the oxidation of hydrogen. At first sight, therefore, it is strange that CO_{ad} is not always a poison to the oxidation of methanol, which involves the oxidation of the hydrogen atoms of a methanol molecule. Accordingly, the role of CO_{ad} in the methanol oxidation in the presence of dissolved carbon monoxide was also studied. There was no difference between the role of CO_{ad} formed from dissolved CO and that of the CO_{ad} formed from methanol, though, in the absence of dissolved CO, the oxidation of methanol was, for some reason, inhibited at small coverages that were close to the respective limiting values.

Experimental

The procedures for measuring the overall rate of the methanol oxidation and the coverage with CO_{ad} were almost the same as those described in the previous papers.[11,14]

The formation of CO_{ad} from dissolved CO in a test solution of methanol was very fast.[2,15] Consequently, the duration of Step D for the last cleaning of the electrode in the potential sequence (illustrated in Fig. 1 in Ref. 11) was extremely shortened (to 10 ms) in order to suppress the formation of CO_{ad} at that step to approximately nothing. Otherwise, the electrode surface was almost fully covered with CO_{ad}; i.e., the observation of the methanol oxidation at low coverages became impossible. A trace amount of O_2 present in the commercial CO gas was removed with the aid of an alkaline pyrogallol solution.

The coverages with CO_{ad}, θ_1 and θ_2, were expressed, respectively as:

$$\theta_1 = Q^{ox}/Q^{ox}_{max} \quad (1)$$

$$\theta_2 = (Q^{\circ}_H - Q_H)/Q^{\circ}_H \quad (2)$$

where Q^{ox} was the electric quantity required to oxidize an amount of CO_{ad} to CO_2 and where Q^{ox}_{max} was the maximum Q^{ox}. Q^0_H was the quantity required to cover the electrode surface fully with a monolayer of adsorbed hydrogen atoms in the absence of CO_{ad}, and Q_H was that required to do so in the presence of CO_{ad}.

Proper Use of θ_1 and θ_2. On a particular electrode, the Q^{ox}_{max} for the CO_{ad} formed from methanol differs in value from that for the CO_{ad} formed from dissolved carbon monoxide. The former is always smaller; the cause[14] of this lies in the process of the formation of the CO_{ad} from methanol. A considerable number of single sites remain unoccupied, even at the saturated coverage in the methanol system; these sites can be further occupied by hydrogen atoms or the CO_{ad} molecules from dissolved carbon monoxide. When the original substances are the same as each other, θ_1, unlike θ_2, is proportional to the number of moles of CO_{ad}; hence, the use of θ_1 is reasonable in the case of, e.g., determining the amount of CO_{ad}. However, the use of θ_2 is more reasonable when the roles of the two kinds of CO_{ad}, originating from methanol and carbon monoxide, are compared.

Washing-Electrode Method. The rate of the oxidation of CO_{ad} in a supporting electrolyte solution, 0.5 mol dm^{-3} of H_2SO_4, was measured by means of the washing-electrode method.[2] The apparatus and the pretreatment of the electrode were almost the same as those reported previously.[19] A platinized-platinum electrode with a true surface area of 3.8 m^2 was used. After CO_{ad} had been formed from a methanol solution, the electrode was washed several times with an electrolyte solution containing no methanol, while the potential was kept at about 0.1—0.06 V in order to prevent the oxidation of CO_{ad}. It was confirmed that the height and shape of the oxidation wave of the CO_{ad} were scarcely altered by the washing. After the washing, the adsorbate was potentiodynamically oxidized in the electrolyte solution containing no methanol at a scan rate of

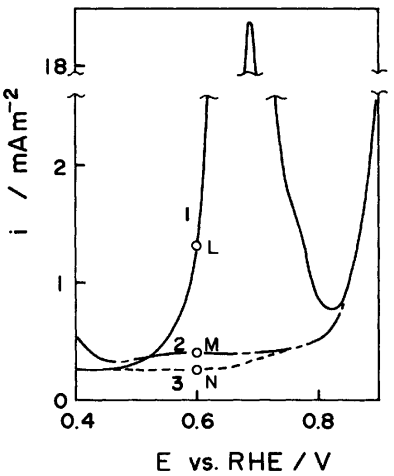

Fig. 1. Potentiodynamic current-potential curve for oxidation of CO_{ad} in 0.5 mol dm^{-3} H_2SO_4, Scan rate= 0.86 mV s^{-1}, CO_{ad} was formed by 10 min-oxidation at 0.6 V in 0.01 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4:
(1) i''_c at $\theta_1^{t=0} \fallingdotseq 1$; (2) i_{d1} at $\theta_1^{t=0}=0$; (3) i_{d1} calculated.

0.8—4 mV s^{-1}. Neither higher rates nor lower ones were adequate, because both resulted in unreliable data. Figure 1 shows an example of these current -potential curves.

The potentials were quoted with respect to the reversible hydrogen electrode in 0.5 mol dm^{-3} of H_2SO_4. All the measurements were made at 0 °C.

Derivation of Equations

Several reaction paths composing the oxidation of methanol will frequently be referred to hereafter. To avoid misunderstandings caused by the descriptions, the reactions and rates will often be expressed by the symbols shows in Table 1.

Rate of Reaction C′ (i'_C). The net rate of Reaction C′ in the supporting electrolyte containing no methanol, i'_C, was determined by subtracting the double-layer-charging current density, i_{dl}, from the directly measured current density, i''_C:

$$i'_C = i''_C - i_{dl}. \tag{3}$$

According to Frumkin,[16]

$$i_{dl} = i^0_{dl}(1-\theta_1) + i^1_{dl}\theta_1, \tag{4}$$

where i^0_{dl} and i^1_{dl} are i_{dl} values at $\theta_1=0$ and $\theta_1=1$ respectively. To determine the i_{dl} values according to Eq. 4, θ_1 values were needed. These values of i_{dl} and θ_1 were determined by the ordinary trial-and-error method of calculation. An example of the calculation will be shown at the end of this section. In the first calculation, the initial value of i_{dl} at a particular potential was assumed to be i^0_{dl}, i.e., the current density indicated by Curve 2 in Fig. 1, while the Q^{ox} value at the potential was determined by the graphical integration of the following equation:

$$Q^{ox} = v^{-1}\int_E^{0.9}(i''_C - i^0_{dl})dE, \tag{5}$$

where v was the scan rate and where 0.9 was the potential at which the adsorbate was completely removed by oxidation. This Q^{ox} value and Eq. 1 gave a first approximate value of θ_1. When this θ_1 value was substituted in Eq. 4, the second approximate value of i_{dl} at the potential E was obtained. The determination of the i_{dl} values in this way at intervals of 0.025 V gave a plot of i_{dl} against E (Curve 3 in Fig. 1). The higher-order calculations were no longer necessary, because they brought about only a negligibly small change in the i_{dl} value. Thus, the variation in i'_C with the potential and the coverage was determined.

Rates of Reaction A and B. When the oxidation of CO_{ad} is slower than the formation, CO_{ad} is accumulated on the electrode surface; i.e., the coverage with CO_{ad} increases. Taking into account the mass balance for CO_{ad}, the rate of methanol consumption can be approximately represented as i_A+i_B, where i_A is the net rate of CO_{ad} formation when no further oxiation of CO_{ad} is assumed and where i_B is the net rate of Reaction B, which is assumed not to contribute at all to the accumulation of CO_{ad} (Table 1). In other words, the CO_{ad} formed by Reaction B is immediately oxidized to CO_2. In the same way, the whole number of moles of CO_{ad} formed at any given moment can be represented as the sum of the number of moles of CO_{ad} contributing to the increase in the coverage (N_A) and that contributing to the formation of CO_2 (N_B).

The formation of CO_{ad} is written as:

$$CH_3OH = CO_{ad} + 4H^+ + 4e \tag{6}$$

therefore, its net rate i_A is:

$$i_A = 4F\mathrm{d}N_A/\mathrm{d}t. \tag{7}$$

The oxidation of CO_{ad} is expressed as:

$$CO_{ad} + H_2O = CO_2 + 2H^+ + 2e \tag{8}$$

By use of the pulse anodic stripping method, N_A at any instant during the formation of CO_{ad} can be determined. Therefore,

$$N_A = Q^{ox}/2F = (Q^{ox}_{max}/2F)\theta_1. \tag{9}$$

Hence, the time dependence of N_A is:

$$\mathrm{d}N_A/\mathrm{d}t = (Q^{ox}_{max}/2F)\mathrm{d}\theta_1/\mathrm{d}t. \tag{10}$$

From Eqs. 7 and 10, we obtain:

$$i_A = 2Q^{ox}_{max}(\mathrm{d}\theta_1/\mathrm{d}t). \tag{11}$$

Thus, i_A can be determined by using the experimental values of Q^{ox}_{max} and $\mathrm{d}\theta_1/\mathrm{d}t$.

Table 1. Symbols of Reactions and Rate

Symbol of Reaction	Rate	Path	Remark
A	i_A	CH_3OH-CO_{ad}	The CO_{ad} is never oxidized
B	i_B	CH_3OH-CO_{ad}-CO_2	The CO_{ad} never accumulates
C′	$i_{C'}$	CO_{ad}-CO_2	The rate in the absence of methanol
C	i_C	CO_{ad}-CO_2	The rate in the presence of methanol
D	i_D	CH_3OH-HCHO-HCOOH-CO_2	The path suggested by Breiter[7]
	i_T		The overall rate of methanol oxidation

From Eqs. 6 and 8, i_B and i_C are deduced as:

$$i_B = 6F\mathrm{d}N_B/\mathrm{d}t, \quad (12)$$

$$i_c = 2F\mathrm{d}N_c/\mathrm{d}t. \quad (13)$$

From Eqs. 12 and 13, we obtain:

$$i_B = 3i_c, \quad (14)$$

where i_C is the rate of oxidation of CO_{ad} 'in the presence of methanol'. The trouble is that neither N_B nor i_C can be directly measured, because the formation and the oxidation of CO_{ad} occur concurrently in the presence of methanol. Out of necessity, therefore, we assumed, following Petrii et al.[2,7] that i_C is equal to i'_C, the net rate of the oxidation of CO_{ad} in the supporting electrolyte containing no methanol.

Reaction C. As may be seen in Fig. 2, the plot of log (i'_C/θ_1) against E under the same experimental conditions as those in Fig. 1 was a straight line with a slope of 0.073 V/decade over the potential range of about 0.50—0.73 V, i'_C/θ_1 corresponding to the rate of the oxidation of one CO_{ad} molecule. The line was expressed as:

$$E = 0.073 \log (i'_C/\theta_1) + 0.794. \quad (15)$$

The potential range over which Eq. 15 held depended both on the coverage at the beginning of the oxidation, $\theta_1^{t=0}$, and on the scan rate of the potential. However, the equation was valid irrespective of the values of $\theta_1^{t=0}$, provided that the momentary coverage, θ_1, during the oxidation was larger than about 0.15 and that the rate was 0.8—4 mV s^{-1}.

The rearrangement of Eq. 15 gave:

$$i'_C = \theta_1 \exp (31.4E - 24.9) \quad (\theta_1 > \text{ca. } 0.15). \quad (16)$$

The coverage range will soon be discussed. This experimental equation was substantially the same as the equation[20] proposed for an electron-transfer process without reactant transport; i.e., the reactants are preadsorbed species alone.

When θ_1 was smaller than about 0.15, the values of log (i'_C/θ_1) deviated in the direction of the decrease from the straight line (Fig. 3). As is shown in Fig. 4, an approximately linear relationship was found between θ_1 and the magnitude of the deviation, D, which was expressed as:

$$D = \log (i'_C/\theta_1) - (31.4E - 24.9)/2.30. \quad (17)$$

Thus, the linear relationship of Fig. 4 was formulated as:

$$D = 6.95\theta_1 - 0.994 \quad (18)$$

The combination of Eq. 17 with Eq. 18 gave Eq. 19:

$$i'_C = \theta_1 \exp (16\theta_1) \exp (31.4E - 27.2) \quad (\theta_1 < 0.15). \quad (19)$$

Equation 16 or 19 can be used for the estimation of i_C $(=i'_C)$ when the values of E and θ_1 are given.

Example of the Determination of i'_C, i_A, and i_B. (a) i'_C at 0.6 V (see Fig. 1): The value of i''_C at 0.6 V is

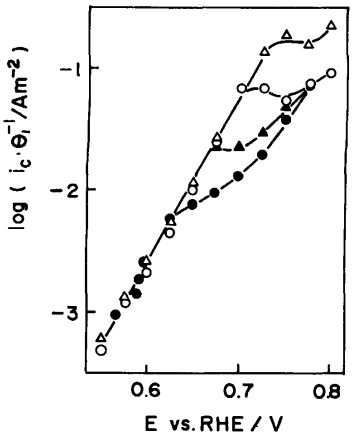

Fig. 3. Relationship between i'_c/θ_1 and potential at different scan rates (mV s^{-1}) and $\theta_1^{t=0}$: △ 2.3, 0.94; ○ 0.86, 1; ▲ 0.86, 0.22; ● galvanostatic oxidation at 0.94 mA m^{-2}, $\theta_1^{t=0}=0.97$.

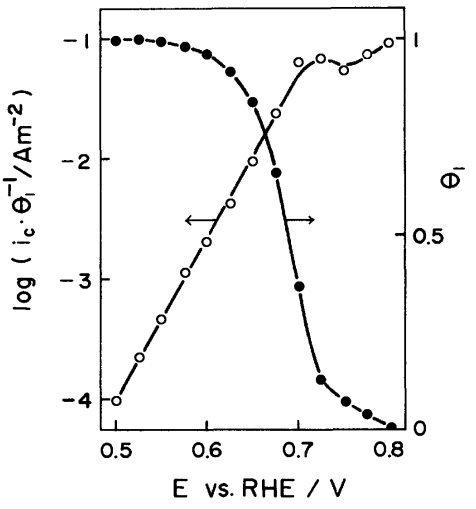

Fig. 2. Relaionship among i'_c/θ_1, potential, and θ_1 (reconstructed curves from Fig. 1.).

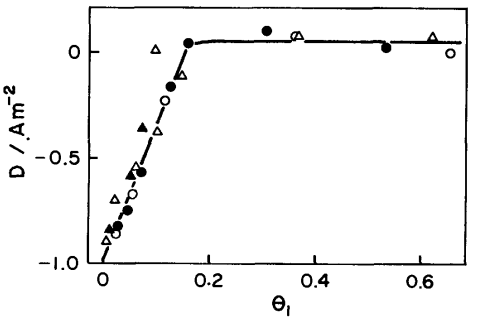

Fig. 4. Relationship between θ_1 and magnitude of deviation, D, from linear line in Fig. 3, $D=\log (i'_c/\theta_1)-13.6E+10.8$, symbols have the same meaning as in Fig. 3.

indicated by Point L, i.e., i''_C=1.35 mA m^{-2}. To determine i'_C, the value of i_{dl} at 0.6 V is necessary (Eq. 3): the i_{dl} can be calculated by the trial-and-error method according to Eq. 4, which requires the values of i^0_{dl}, i^1_{dl}, and θ_1. The i^0_{dl} value at 0.6 V is 0.40 mA m^{-2}, as is indicated by Point M. The θ_1 value at 0.6 V can be obtained if Q^{ox} and Q^{ox}_{max} are given. The graphical determination of the area bounded by Curves 1 and 2 gives the first approximate value of Q^{ox} at 0.6 V, i.e., Q^{ox}=7.65 C. Here, Curve 2, representing i^0_{dl}, is assumed to be the curve of the first approximate values of i_{dl}. The value of Q^{ox}_{max} is measured by an additional experiment at θ_1=1, i.e., Q^{ox}_{max}=7.74 C. Consequently, the substitution of these coverage values into Eq. 1 gives the first approximate value of θ_1 (7.65/7.74=0.988). The value of i^1_{dl} is also found to be 0.23 mA m^{-2} by an additional measurement at θ_1=1 and at 0.4 V. Therefore, by the substitution of the values of θ_1, i^0_{dl}, and i^1_{dl} into Eq. 4 {0.40 (1−0.988)+0.23×0.988=0.23 mA m^{-2}}, the second approximate value of i_{dl} is obtained. The i_{dl} value is represented by Point N on Curve 3. Consequently, the subtraction of the i_{dl} value from the observed i''_C value gives the i'_C value of 1.12 mA m^{-2}. (b) i_A and i_B at 0.55 V, 1 mol dm^{-3} methanol, and 11 s (see Fig. 5): From the curve of θ_1 vs. the time, the $d\theta_1/dt$ value, 0.0076 s^{-1}, at 11 s is obtained. The substitution of this value and Q^{ox}_{max}=2.05 C m^{-2} into Eq. 11 gives the i_A value of 0.031 A m^{-2}. This value is represented by Point F in Fig. 5. At 11 s, the θ_1 value is 0.91, as is indicated by Point G. Consequently, the i'_C value of 0.0020 mA m^{-2} is obtained from Eq. 16, and the i_B value of 0.0059 A m^{-2}, from Eq. 14. The latter is represented by Point H.

Results and Discussion

Effects of Methanol and Its Oxidation Products on i_C. Petrii et al.[2,7] implicitely assumed that the oxidation rate of SCS (COH_{ad}) was not affected by the presence of methanol and its oxidation products, such as hydrogen ions. We consider this assumption to be reasonable, though we differ from them with regard to the kind of SCS. Among the probable products of the oxidation of methanol, the substances not participating in the reaction (Eq. 8) would not affect the rate of the oxidation of CO_{ad} directly. Although some unidentified SCS are formed from formaldehyde and formic acid at low potentials, we found that only very small amount of such SCS was formed at potentials above about 0.5 V in a mixed solution of methanol and formaldehyde or formic acid. The formation of no other influential adsorbate from these two products has ever been reported. According to our test, CO_2 has no effect on the rate so long as the potential is higher than 0.3 V.

Among the products, only the hydrogen ion directly participates in the oxidation of CO_{ad}. However, the effect of the 'increase' in the hydrogen-ion concentration during the oxidation of methanol would be relatively small for the following reasons: (1) The solution originally contains sulfuric acid as the supporting electrolyte at a high concentration of 0.5 mol dm^{-3}. (2) The duration of oxidation is 400 s at the most; hence, the amount of hydrogen ions accumulated on the electrode surface is not very large. (3) The limiting rate of methanol oxidation is relatively small compared with the limiting diffusion rate of methanol; hence, the formation rate for hydrogen ion is relatively small. The amount of hydrogen ions accumulated on a very roughened surface of electrode is larger than that on a smooth surface. However, the roughness factor of the electrode used in the present work is not so large, i.e., 17. Considering this roughness together with the reasons above described, it might safely be said that the effect of hydrogen-ion formation on the rate of CO_{ad} oxidation is relatively small.

Contribution of Reactions A and B to the Overall Oxiation of Methanol. The symbol i_T represents the overall rate of the oxidation of methanol and a quantity directly measured.

As may be seen in Fig. 5, i_B attained a stationary value a short time after the beginning of the oxidation under the conditions described in the figure caption.

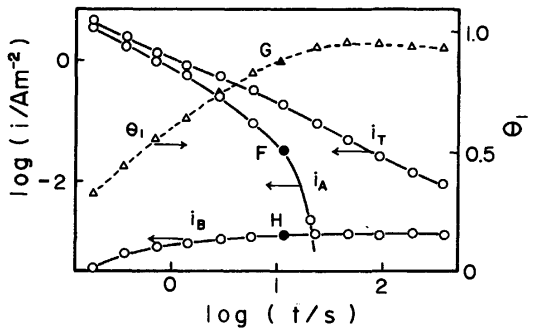

Fig. 5. Variation in i_A, i_R, i_T, and θ_1 with time, 1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0.55 V.

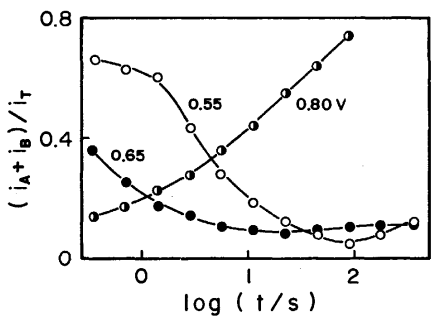

Fig. 6. Variation in $(i_A+i_B)/i_T$ with time, 1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4.

On the contrary, i_A and i_T were decreased towards zero and i_B respectively. The $(i_A+i_B)/i_T$ ratio depended upon the potential, the time of oxidation, and the concentration of methanol, as may be seen in Figs. 6 and 7. The essential points about the ratio were as follows:

(1) When the potential was lower than 0.55 V and the time of oxidation was short, e.g., within 2 s, $(i_A+i_B)/i_T>0.5$ (Fig. 6) and $i_A \gg i_B$ (Fig. 5). That is, the formation of CO_{ad} was predominant over Reaction B. Moreover, i_A and i_T decreased with an increase in θ_1. This indicates that molecules of the CO_{ad} hinder their own formation, and hence i_T decreases. As the oxidation time went by, i_A decreased remarkably (Fig. 5) and $(i_A+i_B)/i_T$ became smaller than 0.5 (Fig. 6). Taking into consideration the fact that the yield of CO_2 at low concentrations of methanol was about 100 per cent,[1,21] together with the low value of the i_B/i_T ratio, we must decidedly support the idea of Breiter et al.[2,6] that a parallel reaction D exists, producing CO_2 without going through SCS. It would also exist at high concentrations and high potentials.

(2) When the potential was about 0.6—0.75 V, $(i_A+i_B)/i_T \ll 0.5$ except for the earliest oxidation stage of a few seconds (Figs. 6 and 7). At these potentials, the electrode surface was a quite thoroughly covered with CO_{ad}. Therefore, reactions other than A and B must take place on the surface free from CO_{ad}. Its rate can be expressed by $(i_T-i_A-i_B)/(1-\theta_1)$, i.e., the current density per unit free surface area. This rate did not decrease with an increase in θ_1, as may be seen in Fig. 8, while, on the contrary, $(i_T-i_A-i_B)$ and i_T did decrease. These findings indicate that at least one of the causes of the decreases in the latter two quantities is the occupation of reaction sites by CO_{ad}. θ_1 is generally large at high concentrations of methanol, as is well known,[22] when the other conditions are maintained constant. Consequently, the inhibition by CO_{ad} of parallel reactions such as Reaction D would become remarkable at high concentrations of methanol.

(3) At potentials higher than about 0.8 V and at high concentrations of methanol, i_B increased as the time of oxidation went by (Fig. 9), and $(i_A+i_B)/i_T$ increased beyond 0.5 (Fig. 6). In this case, CO_{ad} was not longer the inhibitor; rather the adsorbate was an intermediate in Reaction B, which was contributing predominantly to the overall oxidation of methanol. Breiter[7] and Pletcher et al.[23] also observed that CO_{ad} was no longer a poison under similar conditions. At low concentrations, however, i_B/i_T $\{\fallingdotseq(i_A+i_B)/i_T\}$ is small even at higher potentials, as is shown in Fig. 10.

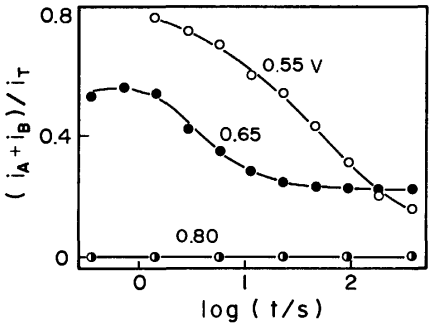

Fig. 7. Variation in $(i_A+i_B)/i_T$ with time, 0.03 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4.

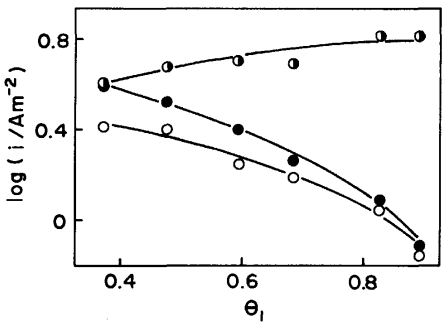

Fig. 8. Variation in i_T[●], $i_T-i_A-i_S$[○], and $(i_T-i_A-i_B)/(1-\theta_1)$[◑] with time, 1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0.65 V.

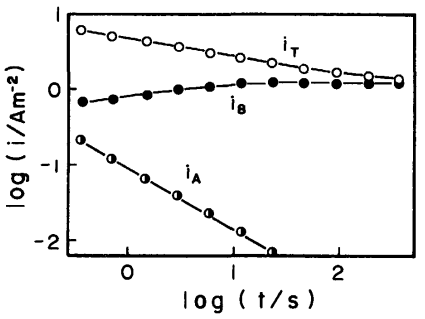

Fig. 9. Variation in i_A, i_B, and i_T with time, 1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, 0.80 V.

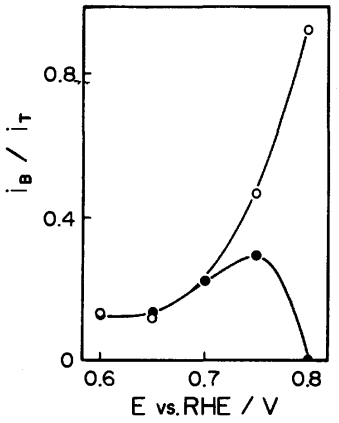

Fig. 10. Variation in i_B/i_T with potential, CH_3OH+0.5 mol dm^{-3} H_2SO_4, concentration of methanol (mol dm^{-3}): ○ 1; ● 0.1, oxidation time=360 s.

In this case, θ_1 was small; therefore, the inhibitory action of CO_{ad} seemed negligibly small. At present it is hard to explain why i_B/i_T decreases towards zero or increases remarkably with an increase in the potential, depending upon the low or high concentrations of methanol respectively.

Oxidation of Methanol in the Presence of Dissolved CO. The adsorbate CO_{ad} is also formed on a Pt electrode from the dissolved CO in a solution. Figure 11 showed potentiodynamic i–E curves taken in the respective solutions of methanol, carbon monoxide, and their mixture. When a solution of methanol was saturated with pure CO, the oxidation of methanol was almost completely inhibited at potentials below about 0.9 V, at which CO began to be oxidized. In this case, the coverage θ_2 with CO_{ad} immediately attained the value of 1 (Fig. 12). The use of a CO gas diluted with N_2 resulted in a slower adsorption of CO, as is indicated by Curve 2 in Fig. 13; that was what made the measurement possible at low coverages in the presence of dissolved CO.

As is indicated by Curve 1 in Fig. 13, the coverage with the CO_{ad} formed from methanol has a limiting value, θ_2^L. It is known[2,22] that this value is less than or equal to about 0.8 at its maximum, depending upon the potential and concentration of methanol. Curve 1 (taken at 0.75 V) in Fig. 14 has about 0.3 as such a limit, while Curve 3 (0.65 V) has about 0.65. As these curves illustrate, a remarkable fall of i_T took place whenever the θ_2 value fell in the narrow range from θ_2^L to (θ_2^L—about 0.1). The fall in a particular case, in which θ_2^L was about 0.8, has been explained[14] by assuming that one CO_{ad} damages a vacant site-aggregate (consisting of two sites) indispensable for the formation of CO_{ad} itself and for the oxidation of methanol to CO_2.

However, the remarkable i_T falls occurring when the θ_2^L values are less than 0.8, e.g., Curves 1 and 3 in Fig. 14, have not yet been explained. Because the falls occur independently of the magnitude of θ_2^L, the CO_{ad} is unlikely to be directly connected. Kita[24] reported an i_T decrease at a small coverage and a high potential in a potentiodynamic oxidation of methanol; he suspected that it was caused by some adsorbate other than CO_{ad}. In any event, further investigations are needed.

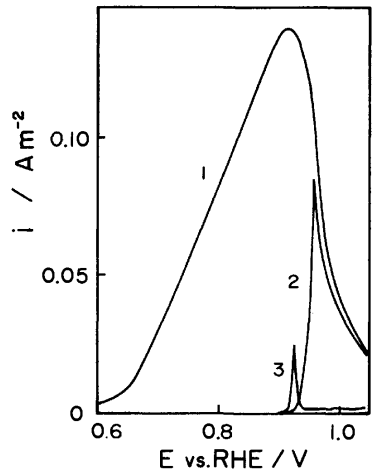

Fig. 11. Potentiodynamic current-potential curve for oxidation of methanol in CH_3OH+0.5 mol dm^{-3} H_2SO_4, concentration of methanol (mol dm^{-3}), staturation gas: (1) 0.3, N_2; (2) 0.3, pure CO; (3) 0, pure CO, scan rate=1 mV/s^{-1}.

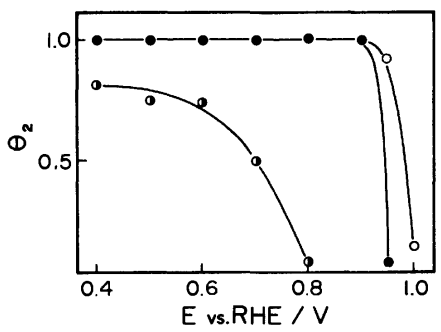

Fig. 12. Variation in θ_2 with potential, methanol was oxidized in CH_3OH+0.5 mol dm^{-3} H_2SO_4, concentration of methanol (mol dm^{-3}), saturation gas: (1) 0.03, N_2; (2) 0, pure CO; (3) 0.03, pure CO, oxidation time=90 s.

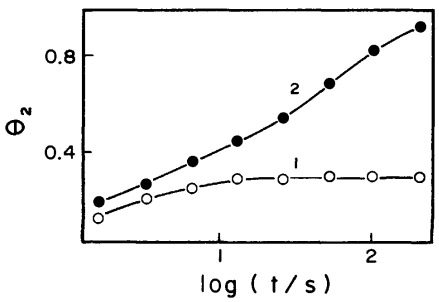

Fig. 13. Variation in θ_2 with time in 0.03 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, saturation gas: (1) N_2; (2) CO+N_2 (vol% of CO=20), 0.75 V.

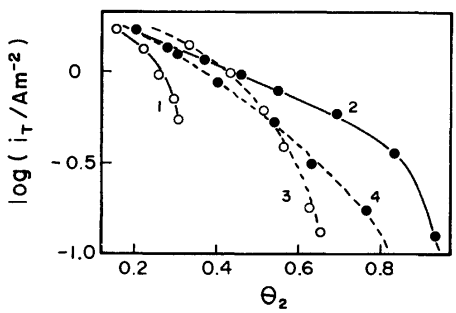

Fig. 14. Variation in i_T with θ_2 in 0.03 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, vol% CO in saturation gas (N_2+CO), potential (V): (1) 0, 0.75; (2) 0, 0.65; (3) 20, 0.75; (4) 20, 0.065.

The presence of dissolved CO always increased the limiting coverages up to 1 (Fig. 13), though Curves 2 and 4 in Fig. 14 do not show the whole results. Also, in these cases remarkable i_T falls took place before and after the coverage attained about 0.8. The cause of these falls is the same as those discussed above.

Gently sloping parts preceding the remarkably-falling parts just considered always appeared on the i_T–θ_2 curves, though this part was very short in the case of Curve 1. When the coverage was smaller than (θ_2^L—about 0.1), (e.g., $\theta_2<0.2$ for the pair of curves 1 and 2, $\theta_2<0.55$ for 3 and 4 in Fig. 14), the values of i_T/θ_2 in the presence and absence of dissolved CO were approximately the same. This supports the idea that the roles of the CO adsorbates formed from methanol and dissolved CO are same in the oxidation of methanol. The gentle falls of i_T are attributed to the effect of the site occupation of the effective electrode surface by CO_{ad}.

In short, there is no great difference between the role of CO_{ad} in the presence and absence of dissolved CO, though, in the absence of dissolved CO, the oxidation of methanol is, for some reason, inhibited at small coverages that are close to the respective limiting values. Because the coverage, θ_2 is readily able to attain a value of 1 in the presence of dissolved CO, the steady-state oxidation of methanol is remarkably inhibited by the CO_{ad}, which, at high coverages, makes unavailable the site-aggregates indispensable for the oxidation of methanol.

(Received May 8, 1986)

Nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica) intercalation complexes were prepared by titrating nickel(II) nitrate solutions in the presence of mica with sodium hydroxide. As the degree of interlayering increased, the $I(002)/I(001)$ intensity ratio increased and the specific surface areas decreased. The composition of fully developed nickel(II) hydroxide interlayer, to be exact, hydroxonickel(II) complex was $[Ni_3(OH)_5(H_2O)]^+$ per formula unit. Nickel(II) hydroxide within the interlayers of the silicate was reduced at about 500 °C in H_2 flow and then 5—10 nm ultra fine nickel particles were distributed over the whole surface of mica. With an increase of reducing temperature, the amount of reduced nickel increased and sintering of nickel particles on the surface of mica proceeded.

Intercalation complexes, particularly graphite intercalations, have been one of the most attractive compounds in the study of low dimensional materials. It is well-known that clay minerals have a layered structure like graphite and that intercalation complexes of clay minerals are formed by introduction of organic and inorganic materials within the interlayers of the silicate. In the past several years, extensive studies have been carried out on the formation and properties of aluminium-hydroxide- and magnesium-hydroxide-montmorillonite intercalation complexes in relation to the formation and alteration of clay minerals.[1] The formation of nickel(II)-hydroxide-montmorillonites have been studied as well.[2,3]

The intercalation complexes containing nickel, a typical transition element, must play an important role, particularly on the development of new catalysts and low dimensional magnetic materials. However, the properties and thermal stability of these intercalation complexes have not been fully clarified, especially under reducing conditions.

In the present work, the formation of nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica) and the thermal stability of the complexes in air and in a H_2 flow were investigated.

Sodium fluoride tetrasilicic mica, $NaMg_{2.5}Si_4O_{10}F_2$, used in this study is an artificial compound, which has swelling properties in water similar to natural montmorillonite and also has a large cation exchange capacity. The layer charge of montmorillonite is -0.33 and that of the silicate is -1.

The thermal stability of sodium fluoride tetrasilicic mica is relatively high compared with that of the natural clay minerals, because the OH ions constituting a part of the crystal lattice in natural clay minerals are substituted by F^- ions in the silicate.[4]

Sodium fluoride tetrasilicic mica has also characteristics of high film forming capability because of its flake-like micro particles. Moreover, the silicate differs from natural montmorillonite in having no acidity at all. Thus it receives much attention as an inert support in the study of catalytic reactions.[5]

Experimental

Materials. A 10 wt% sol of sodium fluoride tetrasilicic mica, (supplied by Topy Ind. Co., under the name of Na-TSM) was used. As the silicate sol contains a little α-cristobalite and magnesium fluoride richiterite ($Na_2Mg_6F_2(Si_4O_{11})_2$) as impurities, the sol was diluted with distilled water and most of the impurities were separated by gravimetric sedimentation. Sodium fluoride tetrasilicic mica was finally dried in air at 100 °C.

A diagramatic sketch of the structure of sodium fluoride tetrasilicic mica is shown in Fig. 1.[6] The silicate is

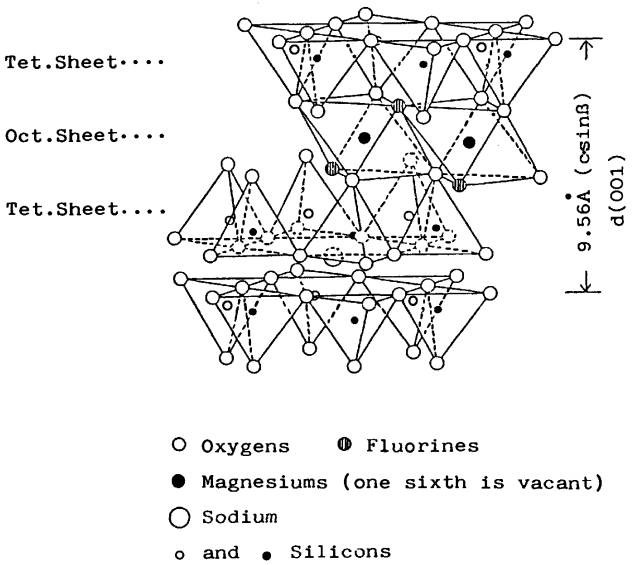

Fig. 1. Diagrammatic sketch of the structure of sodium fluoride tetrasilicic mica ($NaMg_{2.5}Si_4O_{10}F_2$).

composed of units made up of two silicon (Si–O) tetrahedral sheets with a central magnesium (Mg–O,F) octahedral sheet. The unit layers are stacked one above the other. Na^+ ions are located within the interlayers to balance the negative layer charge derived from the vacancies in the octahedral sheets. These Na^+ ions are exchangeable in water and the theoretical cation exchange capacity is 254 meq/100 g·mica.

The crystal structure of sodium fluoride tetrasilicic mica has not been strictly analyzed, only b=9.078 Å and $d(001)=c\cdot\sin\beta$=9.562 Å have been determined.[7] Water molecules can be absorbed within the interlayers. The single water layer hydrated form is stable in air at relative humidities in the range of 40—60% and a double water layer form is stable above that relative humidity.[8] These d-spacings are as follows[7];

$d_1(001)$=12.34 Å (single layer form); $d_2(001)$=15.17 Å (double layer form); $d_3(001)$=18.36 Å (three layer form).

The crystal structure of potassium fluoride tetrasilicic mica ($KMg_{2.5}Si_4O_{10}F_2$), isomorphous substituent of sodium fluoride tetrasilicic mica, was also elucidated[9]; a=5.253 Å, b=9.086 Å, c=10.159 Å, β=99.89.°

Preparation of Nickel(II)-Hydroxide-(Sodium Fluoride Tetrasilicic Mica). Nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica) was prepared by a titration procedure[2] titrating nickel(II) nitrate solution in the presence of the silicate with sodium hydroxide. The preparation procedures are as follows; 10 g samples of the silicate were dispersed in the predetermined amount of 0.1 M (1 M=1 mol dm^{-3}) nickel(II) nitrate solutions. After stirring for 2 d, these suspensions were titrated with a predetermined amount of 0.1 M sodium hydroxide solutions at the rate of 10 ml h^{-1} under vigorous stirring, and stirring was continued for 5 d. Following these treatments, samples were repeatedly washed with distilled water to remove electrolyte and dried at about 100 °C.

Two series of samples were prepared(Table 1); (i) the OH/Ni molar ratio was varied from zero to 1.0 by adding different amounts of 0.1 M sodium hydroxide to 0.1 M nickel(II) nitrate solutions with the sodium fluoride tetrasilicic mica (Ni/mica ratio fixed at 1000 meqNi/100 g·mica). (ii) the Ni/mica ratio was varied from 100 meqNi/100 g·mica to 2000 meqNi/100 g·mica by adding different amounts of 0.1 M nickel (II) nitrate solutions to the silicate (OH/Ni ratio was fixed at 0.5).

Heat Treatment in Air and in H_2 Flow. Since sodium fluoride tetrasilicic mica decomposes at about 800 °C,[10] the thermal stability of the intercalation complexes was studied below 800 °C. The intercalation complexes were heat-treated for 2 h at 100—700 °C in air and at 400—700 °C in H_2 flow (heating rate; 10 °C min^{-1}).

Results and Discussion

Chemical Analyses. Chemical analyses of sodium fluoride tetrasilicic mica and nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica) by atomic absorption analysis are shown in Table 1. The chemical composition of sodium fluoride tetrasilicic mica can be expressed by the formula $Na_{1.00}Mg_{2.63}(Si_{3.98}Al_{0.05}Mg_{0.01}O_{10})O_{0.19}F_{1.81}$,[8] for which the interlayer charge is +1 per formula unit and the interlayer cations are Na^+. Part of interlayer Na^+ cations are displaced by H^+ ions in distilled water when the silicate sol is diluted to eliminate the impurities.

As is shown in Table 1, the amount of nickel taken into the silicate increased with an increase of the OH/Ni ratio or the meqNi/100 g·mica ratio. The highest nickel yields of about 21% were obtained with OH/Ni ratio of 1.0 (No. 8) and meqNi/100 g·mica ratio of 2000 (No. 7). X-Ray diffraction analysis did not detect any free nickel(II) hydroxide in these samples or nickel(II) oxide in the heat-treated ones. Thus, under our experimental conditions, the nickel(II) hydroxide forming reaction took place primarily within the interlayer of the silicate without precipitating free nickel(II) hydroxide.

X-Ray Diffraction. All samples were examined by XRD as thin, oriented films on glass slides. Basal spacings of nickel(II)-hydroxide-(sodium fluoride

Interlayer charge is +1; Interlayer cations are Na^+ and H^+ which replaced the part of Na^+ cations in distilled water.

tetrasilicic mica) are listed in Table 2. These basal spacings are almost constant (ca. 14.7 Å) independent of the amount of the nickel taken into the silicate. Therefore, nickel(II) hydroxide developed onto the horizontal plane within the interlayer of the silicate, forming the brucite like layer. The mechanism of formation of nickel(II) hydroxide interlayers must be the same as in montmorillonite.[2]

X-Ray powder diffraction patterns of nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica) (1000 meq Ni/100 g·mica) are shown in Fig. 2. With an increase of the OH/Ni ratio, the (001) first order reflection decreased in intensity, on the contrary, the (002)—(004) higher order reflections increased in intensities without any changes in basal spacings. With an increase of the meqNi/100 g·mica ratio, the same XRD changes were observed as for samples prepared with an OH/Ni ratio of 0.5. These indicate that the nickel(II) hydroxide forming reaction took place within the interlayer of the silicate, because it is known that the relative intensities of the first and second order reflections are indicative of interlayering and that generally, the $I(002)/I(001)$ intensity ratio increases with an increase of the degree of interlayering.[11]

Thermal Stability of Nickel(II)-Hydroxide-(Sodium Fluoride Tetrasilicic Mica) in Air. Figure 3 shows the DTA and TGA curves for nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica) (No. 2 and No. 8)(the rate of heating was 10 °C min^{-1}). Sample No. 2, which contains a small amount of nickel, showed a single endothermic peak at about 160 °C and a corresponding weight loss. On the other hand, sample No. 8, which contains a large amount of nickel and has a well developed nickel(II) hydroxide interlayer, showed a first endothermic peak at about 120 °C, a second one at about 260 °C, and a third one at about 430 °C with corresponding weight losses. The first endothermic peak corresponds to the loss of absorbed water. The second and the third endothermic peak can be attributed to the dehydration of the nickle(II) hydroxide interlayer, to be exact, hydroxonickel(II) complex $[Ni_m(OH)_{2m-n}\ x(H_2O)]^{n+}$ i.e.; the second one to the loss of coordinated water and the third one to the loss of hydroxo group.

Changes of basal spacings after heat treatment are shown in Fig. 4. With 2 h heat treatment above 200 °C, sample No. 2 collapsed to under 10 Å, while sample No. 8 retained a basal spacing of 14.7 Å up to 300 °C. These results show that nickel(II) hydroxide within the interlayers of the silicate is stable until the loss of hydroxo begins and that samples with fully developed nickel(II) hydroxide interlayer have higher

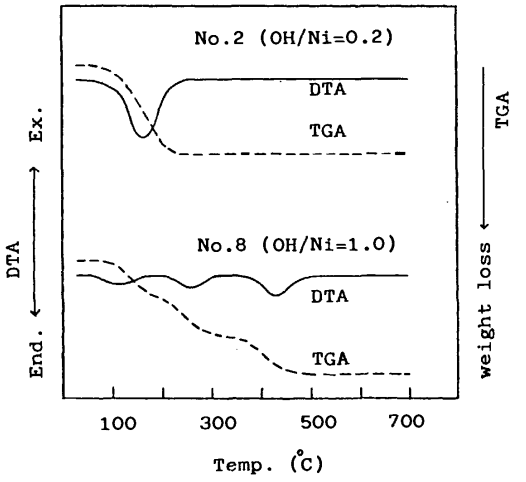

Fig. 3. TGA and DTA curves for nickel(II)-hyroxide-(sodium fluoride tetrasilicic mica) (samles No. 2 and No. 8).

thermal stability. X-Ray diffraction analysis did not detect nickel(II) oxide in these heat-treated samples at 700 °C. Moreover, the (001) mica basal reflection peak of these heat-treated samples broadened with an increase of nickel taken into the interlayer. Therefore, after the nickel(II) hydroxide interlayer has been dehydrated, nickel(II) oxide is present in the interlayers as monomolecules.

The chemical composition of the interlayer material of sample No. 8 was determined by chemical analyses (Table 1) and thermal analyses. From thermal analyses, the amount of coordinated water and hydroxo correspond to the weight loss between 200 and 300 °C, and between 300 and 700 °C respectively. The amounts of dehydration at each temperature are listed in Table 3. Chemical compositions of the interelayer material are calculated to be $Ni_{2.13}(OH)_{3.46}0.61(H_2O)$ per sodium fluoride tetrasilicic mica formula unit. As the ion exchange rate is 68%, this can be rewritten as $[Ni_{3.13}(OH)_{5.09}\text{-}0.90(H_2O)]^{1.17+}_{0.68}$ per formula unit. Therefore, the composition of the fully developed nickel(II) hydroxide interlayer (hydroxonickel(II) complex) must be $[Ni_3(OH)_5(H_2O)]^+$, which balances the negative layer charge of −1, and corresponds to a complete hydroxide interlayer in chlorite. The structure of nickel(II)–hydroxide–(sodium fluoride tetrasilicic mica), shown in Fig. 5, is the same as that of chlorite.[12,13]

Table 3. Chemical Compositions of Nickel(II) Hydroxide Interlayer (Hydroxonickel(II) Complex); $[Ni_m(OH)_{2m-n}xH_2O]^{n+}$ (Sample No. 8)

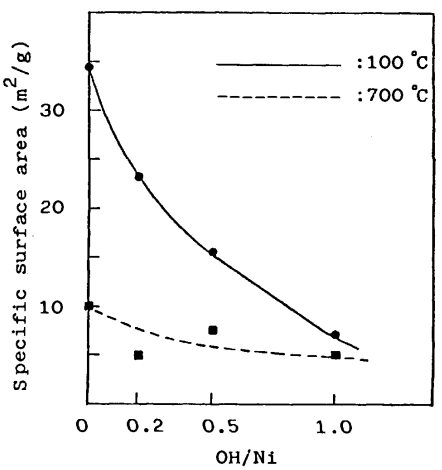

Fig. 6. Specific surface areas of nickel(II)–hydroxide–(sodium fluoride tetrasilicic mica) (1000 meqNi/100 g·mica) heat-treated at 100 °C and 700 °C.

100 °C decreased rapidly. These results correspond to the fact that, according to the development of nickel(II) hydroxide within the interlayers of the silicate, the interlayer space becomes smaller and that finally the internal surfaces are completely covered with nickel(II) hydroxide.

After heat treatment at 700 °C, the specific surface areas were nearly constant, 5—10 $m^2 g^{-1}$, independent of the changes of the OH/Ni ratio, because nickel(II) hydroxide within the interlayers completely dehydrated and collapsed at 700 °C.

The specific surface areas of the sample with an OH/Ni ratio of 1.0 heat-treated at 100 °C is also 5—10 $m^2 g^{-1}$, which is almost equal to that of collapsed sample. This indicates that nickel(II) hydroxide is fully developed within the interlayers of the sample with an OH/Ni ratio of 1.0.

Heat Treatment in H_2 Flow. Nickel(II)-Hydroxide-(sodium fluoride tetrasilicic mica) was heat-treated in H_2 flow at 400, 500, 600, and 700 °C for 2 h. In Fig. 7 are shown the XRD patterns of the H_2 reduced nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica)(sample No. 8). After heat treatment above 500 °C in H_2 flow, sample No. 8 collapsed to a basal spacing of under 10 Å and showed the presence of metallic nickel. With an increase of reducing temperature, the (111) Ni reflection increased in intensity and the (001) mica basal reflection peak became sharper. These results indicate that nickel(II) hydroxide within the interlayer of the silicate decomposed to metallic nickel by H_2 reduction and that reduced nickel atoms migrated from the interlayer of the silicate to its outer surface. This quantity of metallic nickel reduced (shown as relative XRD peak (111) Ni intensity in Fig. 8)increased according to the increase of the OH/Ni ratio, i.e. an increase of nickel(II) hydroxide taken into the silicate interlayer, and an increase of the reducing temperature.

In Fig. 9 are shown the specific surface areas of H_2 reduced nickel(II)-hydroxide-(sodium fluoride tetrasilicic mica). Samples treated above 500 °C in H_2 flow had larger surface areas than those (5—10 $m^2 g^{-1}$) of collapsed samples in air. These increase of specific surface areas are attributed to the reduced nickel

atoms. Specific surface areas decreased with an increase of reducing temperature, which can be explained by the fact that reduction and sintering of nickel particles on the surface of mica simultaneously proceeded with an increace of reducing temperature.

TEM photographs of sample No. 8 heat-treated at 500 °C and at 700 °C in H_2 flow show that ultra-fine metallic nickel particles with almost the same grain diameter are distributed over the whole surface of the mica (Fig. 10). Grain diameter of metallic nickel reduced is about 5—10 nm at 500 °C and 15—25 nm at 700 °C.

A Solvent-Extraction Study of the Hydrolysis of Tracer Concentrations of Bismuth(III) in Chloride Solutions

Hideo SUGANUMA,* Itaru SHIMIZU, and Itsuhachiro HATAYE
Radiochemistry Research Laboratory, Faculty of Science, Shizuoka University,
836, Ooya, Shizuoka 422
(Received July 11, 1986)

The backward solvent extraction with dithizone(H_2dz)–CCl_4 solutions was used to examine the chemical species of bismuth(III) in 1 mol dm^{-3} of a (H,Na)Cl solution. A tracer concentration of bismuth(III) (ca. 10^{-11} mol dm^{-3}) was found to exist mainly in the form of $[BiCl_5]^{2-}$, $[BiCl_5(OH)]^{3-}$, $[BiCl_4(OH)]^{2-}$, and $[BiCl_3(OH)_3]^{3-}$ in the (H,Na)Cl solutions. The constants of the successive hydrolysis, β_1, β_2, and β_3, were calculated by using the distribution data. The resulting $\log\beta_1$, $\log\beta_2$, and $\log\beta_3$ values were 10.9, 17.5, and 30.2 respectively. The chemical composition of the extracted species was most probably $[Bi(Hdz)_3]$.

The hydrolysis of the major concentrations of bismuth(III) in solution has been extensively studied by many investigators. Their works revealed that the chemical species of bismuth(III) exist mainly in polynuclear species in solutions,[1–11] as a result of the hydrolysis of bismuth(III). On the other hand, Bidleman studied the mononuclear species formed in minor concentrations of bismuth(III) (ca. 10^{-5} M; 1 M=1 mol dm^{-3}) in 0.1 M NH_4ClO_4 solutions, based on solvent extraction using dithizone (H_2dz).[12] In his work, the equilibrium constants for the Bi–H_2dz extraction system and the formation constants for the species of $[Bi(OH)]^{2+}$, $[Bi(OH)_3]$, and $[Bi(OH)_4]^-$ have been determined. Furthermore, Hataye et al. studied the mononuclear species formed in more diluted concentrations of bismuth(III) (ca. 10^{-9} M) in 1.0 M (H,Na)ClO_4 and 1.0 M (H,Na)NO_3 solutions, based on the backward solvent extraction with an H_2dz–CCl_4 solution.[13] In their work, they found that chemical species of bismuth exist in the forms of Bi^{3+}, $[Bi(OH)]^{2+}$, $[Bi(OH)_2]^+$, and $[Bi(OH)_3]$ in 1.0 M (H,Na)ClO_4 solutions, and in those of $[Bi(NO_3)_n]^{3-n}$, $[Bi(NO_3)_n(OH)]^{2-n}$, $[Bi(NO_3)_n(OH)_2]^{1-n}$, and $[Bi(NO_3)_n(OH)_3]^{n-}$ in 1.0 M (H,Na)NO_3 solutions, depending on the acidity of the solutions.

In continuation of preceding works on the hydrolysis of tracer concentrations of bismuth(III) in perchlorate and nitrate solutions,[13] we investigated the hydrolysis and chloro complex formation of bismuth(III) in 1.0 M (H,Na)Cl solutions through backward solvent extraction with H_2dz–CCl_4 solutions.

Experimental

Reagents. Water was highly purified with a MILLI-Q reagent-grade water system (MILLIPORE). All the aqueous solutions used were finally purified by extraction with H_2dz–CCl_4 solutions.

Lead (^{210}Pb) containing an equilibrium amount of ^{210}Bi in 3 M HNO_3, imported from the Radiochemical Centre, Amersham, England, was used by diluting it to the appropriate concentration with 3 M HNO_3. A ^{210}Bi tracer solution was prepared by milking with an H_2dz–CCl_4 solution every 4 d from a diluted ^{210}Pb–^{210}Bi solution (pH ≃ca. 1). The ^{210}Bi tracer solution thus prepared was substantially free from any ^{210}Pb and/or ^{210}Po immediately after milking. After the extracted dithizonate (^{210}Bi–H_2dz) has been decomposed with 3 M HNO_3 solution, a portion of the ^{210}Bi tracer solution was transferred into another separatory funnel containing water, and the ^{210}Bi was extracted with an H_2dz–CCl_4 solution of a fixed concentration at $2 \leq pH \leq 3$. The stock solution thus prepared in a lower concentration (less than 10^{-5} M H_2dz) showed practically no change for 3 h after preparation.

Measurements of the Distribution of Bismuth. One ml (1 ml=1 cm^3) of the organic phase containing a given concentration of bismuth was mixed with 10 ml of an aqueous solution (1 M (H,Na)Cl) with a given chemical composition, and the mixture was shaken at room temperature until the partition equilibrium was attained. After the completion of the equilibrium, a 0.5-ml portion of the organic phase was pipetted into a stainless steel planchet, evaporated, and subjected to the measurements of the β-activity (A_{org}) using a G.M. counter with aluminum absorbers against α-particles from ^{210}Po. Because it is difficult to count the activity of the aqueous phase in the same geometrical form as the organic phase in the planchet, it was calculated by using this relation: $A_{aq}=A^{\circ}_{org}-A_{org}$, where A_{aq} is the activity of a 5-ml portion of the aqueous phase and where A°_{org} is the initial activity of a 0.5-ml portion of the organic phase before shaking. Hence, the distribution ratio of bismuth, D, is given by:

$$D = 10 \times A_{org}/(A^{\circ}_{org}-A_{org}).$$

In each case of determining D, the multiple-extraction procedures were repeated under conditions of a definite hydrogen-ion concentration and definite amounts of bismuth in the aqueous phase; the data obtained in the first half were all discarded, and only the reproducible data in the other half were taken.

As for acidic media ($-\log[H^+] \leq 1$), the hydrogen-ion concentration was determined by means of titration with NaOH. In other cases, it was measured with a pH meter (TOA Electronics Ltd, Tokyo), which was adjusted by the use of standard solutions of phthalic acid and oxalate or phosphate at room temperature as soon as possible after shaking.

Results and Discussion

Adsorption of Bismuth onto Vessels Used. To examine the adsorption of bismuth onto glass, the inside surfaces of conical beakers were, in advance, repeatedly and sufficiently equilibrated with respect to the adsorption of bismuth(^{210}Bi) with 30 ml of a 1.0 M (H,Na)Cl solution containing bismuth (ca. 10^{-11} M Bi) at $-\log[H^+]=1.0$. Then, after the conical beaker containing a freshly prepared 1.0 M (H,Na)Cl solution (30 ml, ca. 10^{-11} M Bi), with pH values varying from 0 to 10, has been shaken overnight, the activity of the aqueous phase was measured. The results are shown in Fig. 1. These results indicate that bismuth is leached out from the glass wall in an acidity higher than $-\log[H^+]=1.0$, while on the contrary, it is adsorbed onto it in a lower acidity. Reproducible results of D should, therefore, be obtained in the solvent-extraction study of bismuth only when a distribution equilibrium set up among the aqueous phase, the organic phase, and the glass wall of the vessel used in definite hydrogen-ion and bismuth concentrations.

Dependence of the Distribution Ratio on the Bismuth Concentration. The partition equilibrium of bismuth in a carrier-free state between 1.0 M (H,Na)Cl solutions and the organic phase was reached within 30 min. Accordingly, the partition system involving carrier-free bismuth was shaken for more than 40 min in all the experiments in order to attain a complete equilibrium. On the other hand, in the case of less diluted solutions containing a bismuth carrier, the partition equilibrium of bismuth was not attained within 30 min. Therefore, the shaking time was previously examined in each bismuth concentration. For example, in case of 10^{-7} M Bi, the shaking should be continued for more than 12 h, as is shown in Fig. 2: in addition, it was necessary to take into account the decomposition of the dithizone and dithizonate formed. The higher the carrier concentration, the longer a shaking time was needed. This elongation of the shaking time is thought to be caused by the extreme decrease in the concentration ratio of bismuth to dithizone. However, as far as carrier-free bismuth is concerned, the partition equilibrium of bismuth should be attained within 30 min. Moreover, Fig. 3 shows the variation in the distribution ratios measured as a function of the amounts of the bismuth carrier in minor-to-trace concentrations. No effect of the bismuth concentration was observed for the 1.0 M (H,Na)Cl solutions of $-\log[H^+]=0.83$ and 3.2. These results suggest that there is no difference in the degree of polymerization of bismuth species between aqueous and organic phases. On the other hand, it is impossible for any polymerized species to remain stable in both phases. We may, therefore, safely assume that the monomers are the main species prevailing in the solvent extraction of tracer concentrations of bismuth.

Dependence of Distribution Ratio on the Dithizone Concentration in the Organic Phase. The distribution ratio, D, was plotted as a function of the H_2dz concentration at different hydrogen-ion concentra-

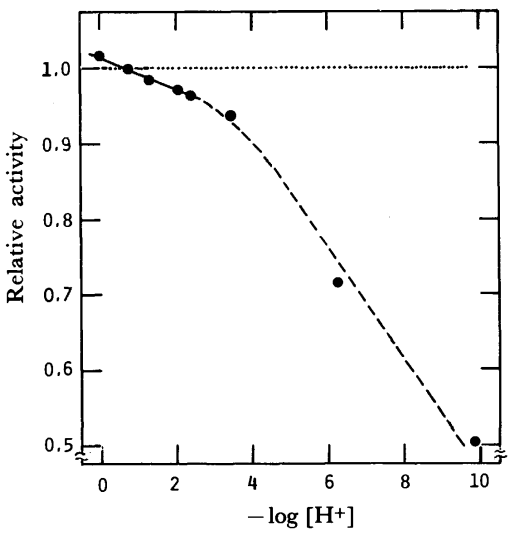

Fig. 1. The adsorption/desorption of bismuth onto/from glass wares (Erlenmeyer flasks). The flasks were in advance equilibrated with 30 ml of ^{210}Bi solution (ca. 10^{-11} M Bi, 1.0 M (H, Na) Cl) at $-\log[H^+]=1.0$.

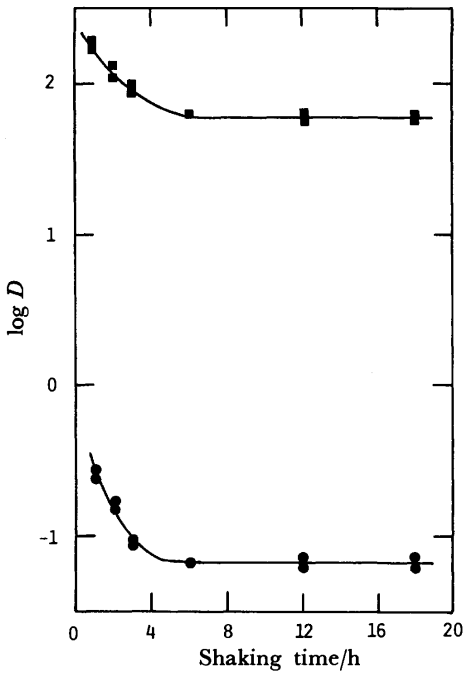

Fig. 2. The effect of shaking time on the distribution ratio in less diluted bismuth concentration (10^{-7} M). ●; $-\log[H^+]=0.83$, $[H_2dz]_{org}=1.9\times10^{-3}$ M. ■; $-\log[H^+]=3.2$, $[H_2dz]_{org}=9.5\times10^{-5}$ M.

tions. Figure 4 shows that the plots of $\log D$ vs. $\log [H_2dz]_{org}$ have the identical slope of +3, independent of the acidity, where H_2dz denotes a neutral dithizone molecule. The narrow range of dithizone concentrations at $-\log [H^+]=0.5$ is attributable to the limited solubility of dithizone in CCl_4, and at the same time the very low values of the distribution ratio might lead to larger experimental errors. In general, the slope of $\log D$ vs. $\log [H_2dz]_{org}$, or $\partial \log D/\partial \log [H_2dz]_{org}$, indicates the difference in the average number of univalent (bidentate) dithizonate ligands (Hdz^-) attached to a bismuth atom between the organic and aqueous phases. It is generally accepted that the coordination number of bismuth(III) is six, so the total number of ligands (as univalent) combined to a bismuth atom can be reasonably assumed not to exceed six; at the same time, the extracted species must be electrically neutral. Since the Hdz^- ion is a bidentate ligand, our results, shown in Fig. 4, lead to the conclusion that bismuth exists in the chemical form of the $[Bi(Hdz)_3]$ in the organic phase. It also means that the concentration of the Bi-Hdz^- complex species is negligibly low in the aqueous phase of 1.0 M (H,Na)Cl solutions.

Dependence of the Distribution Ratio on the Hydrogen-Ion Concentration. The distribution ratio for the extraction system of Bi-H_2dz in chloride solutions, D, is expressed as follows:

$$D = [Bi(Hdz)_3]_{org}/\sum_{x=0}^{6-n}\sum_{n=0}^{6-x}[BiCl_x(OH)_n^{3-x-n}] \quad (1)$$

$$= (K_3[H_2dz]_{org}^3[H^+]^{-3})/(\sum_{x=0}^{6-n}\sum_{n=0}^{6-x}\beta_{x,n}Q_w^n[Cl^-]^x[H^+]^{-n}), \quad (2)$$

where:

$$K_3 = [Bi(Hdz)_3]_{org}/([Bi^{3+}][H_2dz]_{org}^3[H^+]^{-3}), \quad (3)$$

$$\beta_{x,n} = [BiCl_x(OH)_n^{3-x-n}]/([Bi^{3+}][Cl^-]^x[OH^-]^n), \quad (4)$$

$$Q_w = [H^+][OH^-]. \quad (5)$$

D can be rewritten as follows in terms of the hydrolysis of bismuth in the case of $[Cl^-]=1.0$ M:

$$D/[H_2dz]_{org}^3 = K_3/(\sum_{x=0}^{6-n}\sum_{n=0}^{6-x}\beta_{x,n}Q_w^n[H^+]^{3-n}). \quad (6)$$

In the present case, $\sum_{x=0}^{6-n}\sum_{n=0}^{6-x}\beta_{x,n}$ is denoted by $\sum_{n=0}^{6}\beta_n$, because each $\beta_{x,n}$ can not be measured separately, and the $\sum_{x=0}^{6}\beta_{x,0}$ is regarded as unity. Accordingly, Eq. 6 should be rewritten as follows:

$$D/[H_2dz]_{org}^3 = K_3/(\sum_{n=0}^{6}\beta_nQ_w^n[H^+]^{3-n}). \quad (7)$$

In Fig. 5, we plot $\log (D/[H_2dz]_{org}^3)$ as a function of $-\log [H^+]$ in 1.0 M (H,Na)Cl solutions. Since it is difficult to determine the distribution ratio by using only a single solution of a given dithizone concentration in all regions of the hydrogen-ion concentration, $\log (D/[H_2dz]_{org}^3)$ is plotted instead of $\log D$. As is shown in the figure, the slope seems to be nearly +3 at $-\log [H^+]=0$, while it is nearly 0 at $4.5<-\log [H^+]$. Therefore, there exist few chlorohydroxo compounds

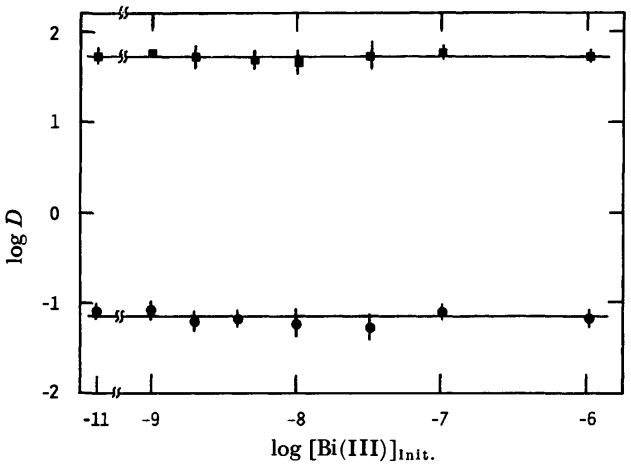

Fig. 3. The dependence of the distribution ratio on the initial concentration of bismuth(III) in 1.0 M (H, Na)Cl solutions.
●; $-\log [H^+]=0.83$, $[H_2dz]_{org}=1.9\times10^{-3}$ M. ■; $-\log [H^+]=3.2$, $[H_2dz]_{org}=9.5\times10^{-5}$ M.

of bismuth in high acidity, while $[BiCl_x(OH)_3]^{x-}$ is predominant in the weakly acidic to neutral solutions. The distribution ratio in Eq. 7 can be expressed in terms of each hydrolysis constant, β_n (n=1, 2, and 3), as follows:

$$D/[H_2dz]^3_{org} = K_3/([H^+]^3 + \beta_1 Q_w[H^+]^2 + \beta_2 Q_w^2[H^+] + \beta_3 Q_w^3), \quad (8)$$

where:

$$\beta_1 = [BiCl_x(OH)^{2-x}]/([Bi^{3+}][Cl^-]^x[OH^-]), \quad (9)$$

$$\beta_2 = [BiCl_x(OH)_2{}^{1-x}]/([Bi^{3+}][Cl^-]^x[OH^-]^2), \quad (10)$$

$$\beta_3 = [BiCl_x(OH)_3{}^{x-}]/([Bi^{3+}][Cl^-]^x[OH^-]^3). \quad (11)$$

Estimation of K_3, $\beta_3 Q_w^3$, $\beta_2 Q_w^2$, and $\beta_1 Q_w$. Figure 5 shows that the slope of $\log(D/[H_2dz]^3_{org})$ vs. $-\log[H^+]$ is nearly 3 at $-\log[H^+]=0$, so Eq. 8 can be simplified to $D/[H_2dz]^3_{org} \simeq K_3$. Consequently, the approximate value of K_3 could be obtained as $(4.27\pm0.24)\times10^4$ from the data in Fig. 5 and the vast number of data on the partition equilibrium at $-\log[H^+]=0$, where the uncertainty is designated by σ. This value is much smaller than the K_3 values in 1.0 M (H,Na)ClO_4 and 1.0 M (H,Na)NO_3, as is shown in Table 1. This fact suggests that the formation of extractable species ([Bi(Hdz)$_3$]) is depressed by forming chloro complexes in trace concentrations of bismuth solutions in the presence of a large amount of chloride ions.

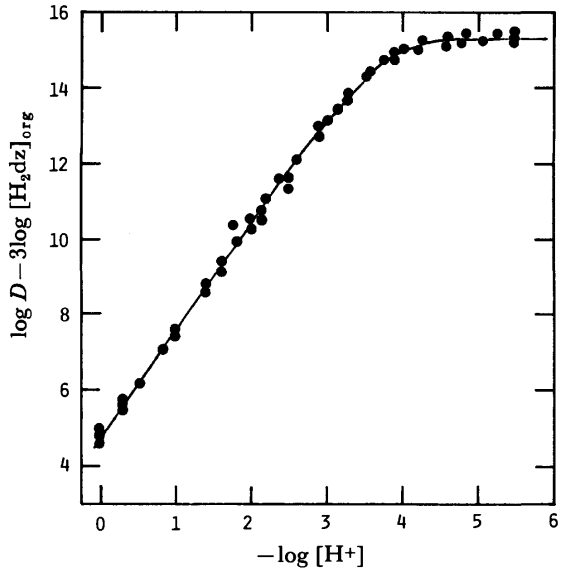

Fig. 5. The dependence of the distribution ratio of bismuth on the hydrogen-ion concentration in 1.0 M (H, Na)Cl solution.

Furthermore, since Fig. 5 shows that the slope of $\log(D/[H_2dz]^3_{org})$ vs. $-\log[H^+]$ ($-\log[H^+]>4.5$) is nearly zero, independent of the acidity, Eq. 8 can be also simplified to $D/[H_2dz]^3_{org} \simeq K_3/(\beta_3 Q_w^3)$. Consequently, the approximate value of $\beta_3 Q_w^3$ was obtained from Fig. 5 ($-\log[H^+]>4.5$) as $(2.04\pm0.13)\times10^{-11}$ for 1.0 M (H,Na)Cl solutions, where the uncertainty is indicated by σ. By using the set of K_3 and $\beta_3 Q_w^3$ values thus obtained, the approximate values of a set of $\beta_1 Q_w$ and $\beta_2 Q_w^2$ were obtained by the least-squares fit from the data in Fig. 5; the results were $\beta_1 Q_w = 1.91\times10^{-3}$ and $\beta_2 Q_w^2 = 2.00\times10^{-10}$ for 1.0 M (H,Na)Cl solutions. Equation 8 is cubic with respect to the hydrogen-ion concentration; therefore, no meaningful error in $\beta_1 Q_w$ and $\beta_2 Q_w^2$ calculations could be obtained. The values obtained for $\log\beta_1$, $\log\beta_2$, and $\log\beta_3$ are 10.9, 17.5, and 30.2 respectively for a 1.0 M (H,Na)Cl solution, when $\log Q_w$ is -13.62.[14] In general, the n-th step-by-step hydrolysis constant gives a lower value than the $(n-1)$ th constant. However, our results for bismuth in this solution exhibit an abnormal sequence, compared with those in 1.0 M (H,Na)ClO_4 and 1.0 M (H,Na)NO_3.[13] For this reason, it is thought that the coordination number of bismuth changes with a variation in the hydrogen-ion concentrations and that, furthermore, the effects of $\Delta H°$ (enthalpy) and/or $\Delta S°$ (entropy) for the formation of the bismuth species in the progressing hydrolysis play an important part. Unfortunately, from the hydrolysis constants alone we can not determine which reason is the dominant factor.

Table 1. Equilibrium Constants on Bismuth Hydrolysis in the Bi-Dithizone Extraction System

Medium	Method[a]	Concentration of Bi [M]	Equilibrium constant[b]					Reference

a) Ex; extraction, P; potentiometry. b) $\beta_n = \dfrac{[Bi(OH)_nX_x^{3-n-x}]}{[Bi^{3+}][OH^-]^n[X^-]^x}$, (X; ClO_4, NO_3, or Cl), and $K_3 = \dfrac{[Bi(Hdz)_3]_{org}[H^+]^3}{[Bi^{3+}][H_2dz]^3_{org}}$.

The percentage abundances of the chemical species of bismuth calculated from each β_n value at different hydrogen-ion concentrations in 1.0 M (H,Na)Cl solutions are presented in Fig. 6(a), along with those for 1.0 M (H,Na)ClO_4 (b) and 1.0 M (H,Na)NO_3 (c) solutions.[13] As can be seen from Fig. 6, the hydrolysis of bismuth in the 1.0 M (H,Na)Cl solution (a) is greatly depressed compared with the other two solutions (b and c); this is caused by the strong complexing ability of the chloride ion. Furthermore, it is found that $[BiCl_x(OH)_2]^{1-x}$ in the 1.0 M (H,Na)Cl solution is a minor species; its maximum abundance is estimated to be only ca. 0.05%.

Number of Chloride Ions Coordinated to a Bismuth Atom. As no effect of the perchlorate-ion concentration on the distribution ratios of bismuth in the extraction with dithizone from a 1.0 M (H,Na)ClO_4 solution was observed,[13] the 1.0 M (H,Na)ClO_4 solution was employed as the diluent in order to examine the effect of the chloride ion by varying its mole fractions in the aqueous phase.

In general, the slope of log D vs. log $\{[Cl^-]/([Cl^-]+[ClO_4^-])\}$ in 1.0 M (H,Na)(Cl,ClO_4) solutions at a given hydrogen-ion concentration indicates the difference in the average number of univalent chloride ions attached to a bismuth atom between the organic and aqueous phases, so we determined the slope by varying the mole fractions of chloride ions in 1.0 M (H,Na)(Cl,ClO_4) solutions at a given hydrogen-ion concentration; a typical example is shown in Fig. 7 (lower line). The slope of -5.07 ± 0.07 (σ) indicates the average number of chloride ions coordinated to a bismuth atom in a 1.0 M (H,Na)Cl solution at $-\log[H^+]=1.21$; that is, it can be presumed that, in that solution, bismuth exists mainly as such a chemical species as $[BiCl_5]^{2-}$. Furthermore, the average numbers of chloride ions coordinated to a bismuth atom in 1.0 M (H,Na)Cl at $-\log[H^+]=0.29$, 0.83, 1.85, 2.54, and 3.12 were all determined to be close to five (4.67—5.07; they are plotted in Fig. 8) in a manner similar to that above mentioned. However, as the plots seemed not to be a straight line, but to form a concave curve upward at $-\log[H^+]=3.8$, as is shown in Fig. 7 (upper line), the number of chloride ions was determined from the slope of the tangential line (dotted line) of an approximate quadratic equation at $\log\{[Cl^-]/([Cl^-]+[ClO_4^-])\}=0$ obtained by the least-squares fit to the experimental data.

On the other hand, this method can not be applied to the solutions of $-\log[H^+]\geq4$, because it is difficult to adjust the hydrogen-ion concentration without using any buffer solutions. Instead, in this case, the value of (log $D-3\log[H_2dz]_{org})_{ClO_4}$[13] minus (log $D-3\log[H_2dz]_{org})_{Cl}$ shown in Fig. 5 was plotted as a function of $-\log[H^+]$ (≥4), as is shown in Fig. 8. Nevertheless, these values are not reasonable because

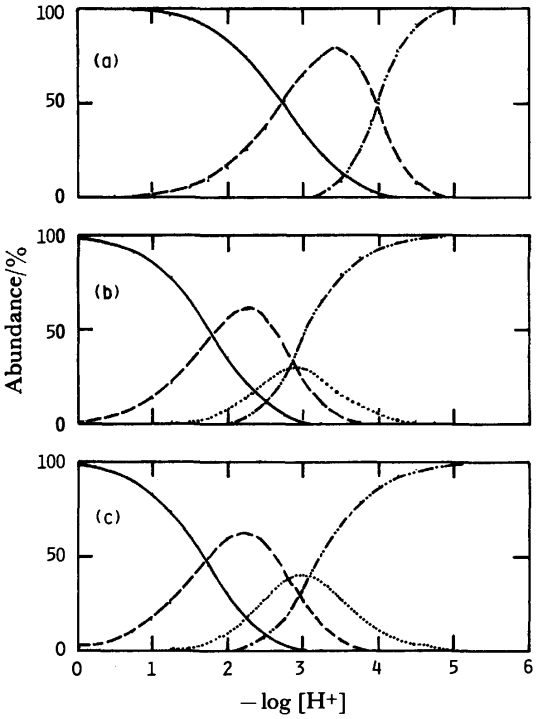

Fig. 6. The abundance of the hydrolyzed chemical species of bismuth(III) in (a) 1.0 M (H, Na)Cl, (b) 1.0 M (H, Na)ClO_4,[13] and (c) 1.0 M (H, Na)NO_3 solutions.[13] (——), (----), (·····), and (—··—) indicate unhydrolyzed, monohydroxide, dihydroxide, and trihydroxide species, respectively.

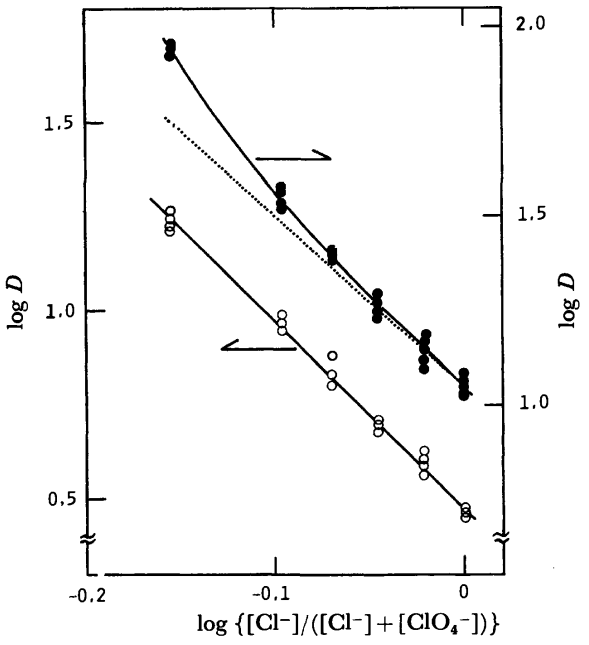

Fig. 7. The dependence of the distribution ratio of bismuth on the chloride ion concentration in 1.0 M (H, Na)(Cl, ClO_4) solutions. ○; $-\log[H^+]=1.21$, $[H_2dz]_{org}=2.6\times10^{-3}$ M, the solid line represents a slope of −5.07. ●; $-\log[H^+]=3.8$, $[H_2dz]_{org}=2.6\times10^{-5}$ M, the dotted line represents a slope of −4.60.

the values were calculated from the inclination of the curve, as is shown in Fig. 9(b), and the total number of ligands (the sum of the chloride and hydroxide ions calculated from the hydrolysis constants) exceeds 6. The reasonable value has to be determined by the method shown in Fig. 9(a) or Fig. 7 (upper line).

The two-dot chain line in Fig. 8 represents a variation in the average number of chloro ligands attached to a bismuth atom, calculated from this relation: (5 minus the average number of hydroxide ligands, as estimated from the hydrolysis constants), by assuming 5 for the coordination number of bismuth (octahedral). In this case, Eqs. 1, 2, 6, and 7 have to be rewritten by using 5 for the coordination number of bismuth, but the original equations remain practically valid to obtain the hydrolysis constants of bismuth. On the other hand, the dash-dotted line was calculated by assuming 6 for the coordination number of bismuth (pentagonal bipyramid), in a way similar to that used for the two-dot chain line. We can assume that the dash-dotted line probably suggests true values at $4 \leq -\log[H^+] < 6$, because the experimental value at $-\log[H^+]=3.8$ is close to the dash-dotted line, while the two-dot chain line is consistent with the experimental results in the region of $-\log[H^+] \leq 1.2$. Moreover, the experimental results in the region of $1.2 < -\log[H^+] < 3.8$ are not consistent with either of the two lines.

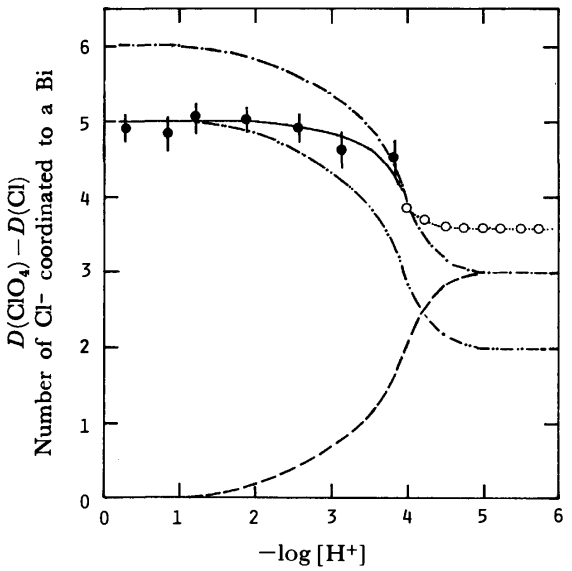

Fig. 8. The number of chloride ions coordinated to a bismuth atom in 1.0 M (H, Na)Cl solutions. ●; experimental values, ○; estimated values from {(log $D-3\log[H_2dz]_{org})_{ClO_4}$[13] − (log $D-3\log[H_2dz]_{org})_{Cl}$}, and (—·—) and (—··—) indicate the values estimated from both formulas; (6 or 5−average number of hydroxide combined to a bismuth atom in 1.0 M (H, Na)Cl), respectively. (----) represents the variation of average number of hydroxide attached to a bismuth atom in 1.0 M (H, Na)Cl.

We are able to make two assumptions on the basis of the above discussion: that the coordination number of bismuth varies from 5 to 6 with a decrease in the hydrogen-ion concentration in 1.0 M (H,Na)Cl, and that the coordination number holds at 6 in all regions of 1.0 M (H,Na)Cl. Unfortunately, we could not determine directly with any experiments on a trace scale of bismuth which assumption should be adopted. Ahrland et al.,[15] Miranov et al.,[16] and Johansson[17] have obtained formation constants for chloro complexes of bismuth (larger concentrations) in 2, 3, and 4 M chloride solutions respectively. Their results revealed the existence of $[BiCl_6]^{3-}$; that is, those results indicated one of the structures of the pentagonal bipyramid by the sp^3d^3 hybridization with a lone pair of electrons. In our results, moreover, the extracted species of bismuth is $[Bi(Hdz)_3]$, as can be seen from Fig. 4. Therefore, it is reasonable to assume 6 for the coordination number of bismuth throughout the pH region of 1.0 M (H,Na)Cl. Accordingly, in our results at $-\log[H^+] < 3.8$, it is necessary to take into account the coordination of water molecules to a

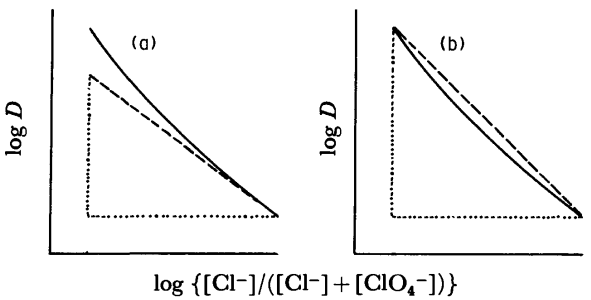

Fig. 9. Estimation of average number of chloride ions attached to a bismuth atom. Tangential broken lines indicate a ture value in (a) and an overestimated value in (b).

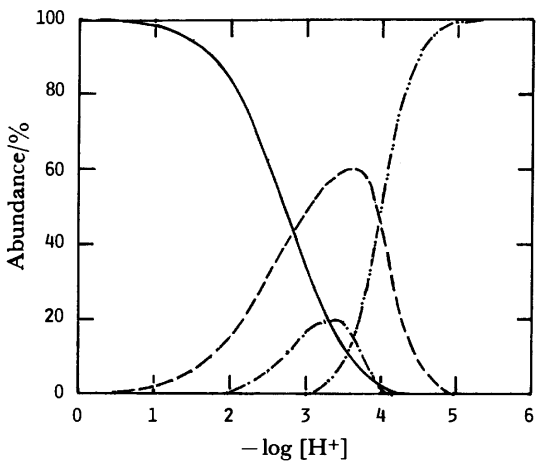

Fig. 10. The abundance of chemical species of Bi(III) in 1.0 M (H, Na)Cl solutions. (——); $[BiCl_5(H_2O)]^{2-}$ (----); $[BiCl_5(OH)]^{3-}$, (—·—); $[BiCl_4(OH)(H_2O)]^{2-}$, (—··—); $[BiCl_3(OH)_3]^{3-}$.

bismuth atom. Hereafter, we will consider the bismuth species in some detail by assuming a pentagonal bipyramid structure.

The average number of chloride ions attached to a bismuth atom in 1.0 M (H,Na)Cl was estimated from a smooth curve combined by the least-squares fit for both the experimental values and the dash-dotted line ($-\log[H^+] \geq 4$) in Fig. 8. In addition, it has been assumed that the only chloride numbers were 3, 4, and 5; that is, 0, 1, 2, and 6 were negligibly low abundances. Consequently, the number of H_2O molecules attached to a bismuth atom was found to be 0 or 1. The average number of hydroxide ions was calculated from the hydrolysis constants, where the second hydrolysis products were neglected because of their very low abundance. Based on the assumptions described above, the following bismuth species can probably be concluded to exist: $[BiCl_5(H_2O)]^{2-}$, $[BiCl_5(OH)]^{3-}$, $[BiCl_4(OH)(H_2O)]^{2-}$, and $[BiCl_3(OH)_3]^{3-}$. In addition, the percentage abundances of the each species were calculated to be as is shown in Fig. 10. The $[BiCl_5(H_2O)]^{2-}$ is present as the main species in a high acidity, while the abundance of $[BiCl_5(OH)]^{3-}$ increases with an increase in $-\log[H^+]$ up to 3.5 and then decreases in the region of further lower acidity. The $[BiCl_4(OH)(H_2O)]^{2-}$ exists in the region of $2 \leq -\log[H^+] \leq 4$. Furthermore, the lower the acidity, the higher the abundance of $[BiCl_3(OH)_3]^{3-}$ in an acidity lower than $-\log[H^+]=3$; its abundance may be nearly 100% at $-\log[H^+]>5$ if our assumption is valid. The abundances of $[BiCl_5(OH)]^{3-}$, $[BiCl_4(OH)(H_2O)]^{2-}$, and $[BiCl_3(OH)_3]^{3-}$ contain some uncertainty at $3.5<-\log[H^+]<4.2$, because the average number of chloride ions attached to a bismuth atom can not be determined exactly.

From the above discussion, it is thought that the abnormal variation in hydrolysis constants is mainly dependent on the effects of $\Delta H°$ and/or $\Delta S°$, which arise from a competition with the chloro ligand; the hydrolysis constants observed are conditional ones.

The authors wish to thank Professor Shunji Utsuno (Shizuoka University) for his valuable discussion.

Sulfur Contents of Volcanic Rocks in Japan

Yoshiko ARIKAWA
Department of Chemistry, Faculty of Home Economics, Japan Women's University, Mejiro-dai, Bunkyo-ku, Tokyo 112
(Received July 26, 1986)

The total sulfur content was determined for 140 samples of Japanese volcanic rock by the mercury(II) thiocyanate photometric method of hydrogen sulfide formed by a wet reduction of the sample by tin(II)–strong phosphoric acid. Though determined values are widely scattered from 5390 down to 10 ppm (or less), the cumulative frequency distribution of the sulfur contents shows lognormality. The geometric and arithmetic means are 26 ppm (mg kg^{-1}) and 116 ppm, respectively. The alkaline rocks have high sulfur contents, the geometric mean of which is 62 ppm. Little significant difference was observed among the rhyolitic rock, the andesite and the trachyte, and the basaltic rock. Japanese and foreign standard rock samples were analyzed for sulfur. Almost all results were in good agreement with those obtained by other authors. In this case foreign standard samples also have higher sulfur contents than those of Japanese samples. The fact that the sulfur contents of Japanese volcanic rocks are lower than the previously accepted values seems to be characteristic of the islands arc of volcanism.

From the geochemical point of view sulfur is one of the most interesting and important volatile components of magma and is released as a volcanic gas into the atmosphere in the form of either sulfur dioxide or hydrogen sulfide. However, certain amounts are considered to be fixed in igneous rocks in such a form as sulfate or sulfide during the course of crystallization of magma.

Ever since the first work involving a determination of the sulfur in igneous rocks by Clark and Washington,[1] many authors have reported sulfur contents in igneous rocks. Especially, from numerous samples Goldschmidt[2] has determined the average value of the sulfur contents in igneous rocks to be 520 ppm. However, his data, together with those of others, were widely scattered over more than one order of magnitude; thus, these determination methods seemed to lack reliability.

It was until the late 1950's when standard rock samples were prepared by geological surveys in several countries that the accuracies of individual determination methods could be compared with each other by using these standard samples. As a consequence, the reliability and accuracy of the determination method were much improved.[3–14] Ricke[7] has attempted a separate determination of the sulfate and sulfide sulfur in various kinds of igneous rocks; he found the total sulfur contents to be 300 ppm. From a series of such investigations he concluded that sulfur was generally inclined to be contained in alkaline rocks. He further pointed out that sulfide sulfur was more abundant in alkaline rocks whereas sulfate sulfur was rich in silicic rocks. Moore and Fabbi[8] reported the sulfur contents in deep ocean-floor erupted basalts to be 800±100 ppm. Recently Ueda and Sakai[9] pointed out that the sulfur contents of Quaternary volcanic rocks from the Japanese Islands Arc were less than 40 ppm, much lower than those of ocean-floor basalts.

The total sulfur contents of standard rock samples were summarized in review papers by Fleisher,[15] Abbey,[16] and Flanagan.[17] All of these determined values were not always in good agreement among individual standard samples and fell, as a whole, in the range from several tens to several hundreds ppm. However, the total sulfur contents of the standard samples prepared by the Geological Survey of Japan showed with no doubt lower values by one order of magnitude than those of the foreign standard samples.

To find a reliable and feasible method of determining the total sulfur in rocks, we investigated and established several different methods by means of: (1) the photometric method,[18] (2) the sulfide ion selective electrode method,[19] and (3) the fluorometric method.[20] Each of these are based on a wet reduction of the sample by tin(II)–strong phosphoric acid. A fourth method, the UV-photometric method[21] is used after the combustion of a sample with vanadium pentaoxide. The determined values by these methods showed excellent agreement.

In this paper we present the total sulfur contents mainly determined by the photometric method[18] for 140 volcanic rocks in Japan.

Experimental

Detailed descriptions of each method for the determination of the total sulfur in volcanic rocks can be found in previous papers;[18–21] thus, only brief analytical description of the photometric method will be presented in this section.

Finely powdered rock samples are accurately weighed (100—300 mg) and heated with tin(II)–strong phosphoric acid at 280 °C for 15 min in a flow of carbon dioxide or nitrogen gas. Both the sulfate and sulfide sulfur contained in rock samples are separated from other components in a form of hydrogen sulfide. The hydrogen sulfide, thus formed, is absorbed in a zinc sulfate solution to be fixed as a zinc sulfide. In order to completely separate micro amounts of zinc sulfide by means of a centrifugal separator, a zinc hydroxide is coprecipitated by adding a sodium hydroxide solution to the absorbing solution. After separating the supernatant solution, an acetic acid, a mercury(II) thiocyanate–methyl alcohol solution and iron(III) nitrate–

perchloric acid solution are added to the precipitation. The mixture is shaken and diluted with redistilled water. Then, carbon tetrachloride is added and shaken vigorously to adsorb the suspending mercury(II) sulfide on the surface of small drops of carbon tetrachloride. After centrifugation, the absorbance of the supernatant solution is measured at the wavelength of 460 nm against the redistilled water as a reference. A standard sample to make a calibration curve is prepared as follows. Barium sulfate is mixed in an agate motor with a finely powdered obsidian in which no sulfur is assured to be detected by this method. The mixture is diluted with the obsidian several times until the sulfur content becomes 300 ppm. The lowest detectable limit of this method is 10 ppm for total sulfur. The coefficient of variation for five repeat analysis is 5% for a sulfur content of 200 ppm. The determination of the sulfur was performed in association with the main components and other elements such as halogen[22] and boron[23] for samples which were widely gathered from many locations in Japan by people listed in the acknowledgements.

Results and Discussion

Sulfur Contents of Volcanic Rocks in Japan. The total sulfur contents of volcanic rocks in Japan are summarized in Table 1. As should be apparent from Table 1, the determined values are widely scattered from the maximum value of 5390 ppm to the lowest detectable limit of 10 ppm. The sulfur contents of the volcanic rocks can be fairly well expressed as a log-normal type distribution when they are plotted on a logarithmic scale (log S ppm) on a cumulative frequency diagram (Fig. 1). Strictly, this curve seems to be composed of two straight lines with different slopes having a bend around log S=2.0. This feature can also be observed in other volatile components of volcanic rocks. For example, the cumulative frequency distribution of boron deviates from lognormality and the curve is composed of three straight lines; this is well understood by classifying rocks into three groups: alkaline rocks, glassy rocks and the other rocks.[23] However, in the case of sulfur the bend in the curve could not be explained by such a classification into two groups, i.e., alkaline rocks and the rest other rocks, because both curves also showed a bend around log S=2.0 (Fig. 1). The mean value of log S was estimated to be 1.41. The geometric mean of the total sulfur content is 26 ppm with a standard deviation of 0.64 ppm, while the arithmetic mean is 116 ppm. This does not seem to reflect a good representative value of a statistical measure. It should be noted here that there are considerable numbers of samples that contain a total sulfur content less than this lowest limit. Threrefore, a more sensitive method is required in order to determine the exact distribution and geometric mean of the sulfur contents. Alkaline rocks have high sulfur contents, as pointed out by Ricke,[7] and Ueda and Sakai.[9] Their geometric mean is 62 ppm and can be clearly distinguished from those of other rocks by an inspection at the significant level 0.01. Moreover, the rocks from the Circum-Japan Sea Province have a geometric mean of the sulfur contents of 41 ppm, also showing a significant difference from the geometric mean of other rocks (at the significant level 0.05). In Fig. 2 are given the frequency distributions of each of the sulfur contents of three types of rocks classified by the silica content, i.e., rhyolitic rock, andesite and trachyte, and basaltic rock.

volatile components as chlorine[22] and boron,[23] the sulfur content of every obsidian, a typical glassy rock, is lower than 10 ppm. This feature is consistent with the experimental result for the sulfur solubility in silicate melts by Katsura and Nagashima,[24] i.e., sulfur has low solubility in silicate melts, especially in silica rich melts. Moreover, sulfur seems to form the heterogeneous phase in silicate rocks even at a fairly low concentration. The sulfur contents of volcanic rocks determined in this study are much lower than those of the igneous rocks reported before. Old data seem to lack reliability concerning the employed determination methods. However, in a recent review by Schneider,[25] the values of the sulfur content of igneous rocks are not so different as the usual values, i.e., about 600 ppm. Samples in his paper are almost entirely from continental, ocean-floor or hot spots; very few are from islands arc. The low sulfur contents of Japanese volcanic rocks may be a characteristic of the islands arc volcanism, as pointed out by Ueda and Sakai.[9] This feature is probably attributed (1) to the extent of an outgassing of sulfur during the course of magmatic emanation and solidification, (2) to the difference of the source magma of the islands arc from those of others, (3) to the isolation of the sulfur containing phase during the fractional crystallization of magma and (4) to the heterogeneous distribution of sulfur in the upper mantle. However, the fact that the sulfur contents of volcanic rocks of the islands arc are low should be discussed more carefully in correlation with the contents of other volatile components.

Comparison of Sulfur Contents of Standard Rock Samples. To confirm the reliability of our determination method, standard rock samples were analyzed by means of three different methods established by the present author;[18-20] the results were compared with those reported by other authors. The sulfur contents of two kinds of andesite were also compared. The results are shown in Table 2. The present three methods (photometric method,[18] sulfide ion selective electrode method,[19] and fluorometric method[20]) are all based on a wet reduction by tin(II)–strong phosphoric acid. These methods together with the UV-photometric method gave good agreeable results for common andesite samples. The results for some standard samples and andesites by the three methods were also in good agreement with each other.

The sulfur content of standard rock sample G-1 (determined by the present author) showed fairly good agreement with those obtained by Frost and Thomas,[10] and Murphy and Sergeant[11] (ranging from 40 to 74 ppm). For the sulfur in W-1, a satisfactory agreement was also obtained between our result and those of Ricke,[7] Frost and Thomas,[10] Murphy and Sergeant,[11] and Ueda and Sakai[12] (showing contents between 120 and 135 ppm). The results of the present author for the standard rock samples of Japan were in good agreement with those by Ueda and Sakai,[12] Terashima,[13] and Terashima et al.[14] (about 20 ppm); this is very close to the geometric mean (26 ppm) of the volcanic rocks in Japan. The sulfur contents of Japanese standard rock samples also show lower values than those of foreign standard rock samples.

The author wishes to express her thanks to emeritus professor Iwaji Iwasaki of Tokyo Institute of Technology for his hearty encouragement throughout this work and professors Takejiro Ozawa of Saitama University and Minoru Yoshida of Tokyo Institute of Technology for their valuable discussions. Thanks are also due to Drs. Ryūji Aoyagi, Shigeo Aramaki, Toshio Ishikawa, Kiyoshi Ishibashi, Jyōyo Ossaka, Takejiro Ozawa, Yoshio Katsui, Takashi Katsura, Masaakira Kamada, the late Isao Kayama and Hisashi

Kuno, Hiroshi Haramura, Hatao Matsumoto, Kenzo Yagi, Masaru Yamaguchi, Kanae Yokoyama and Minoru Yoshida for providing many samples.

Studies of the Hydrous Zirconium(IV) Oxide Ion Exchanger. I. Ion-Exchange Properties and Effect of Heat Treatment

Yasushi INOUE* and Hiromichi YAMAZAKI
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received August 12, 1986)

A satisfactory method was established for synthesizing a hydrous zirconium(IV) oxide ion exchanger; also, its ion-exchange properties and thermal stability were studied. The exchanger was synthesized reproducibly by hydrolyzing a $ZrOCl_2$ solution at pH 9.3 with the addition of NH_3 aq. This material was an amphoteric ion exchanger possessing an isoelectric point close to pH 6.5. The order of affinity for the cations was, transition metal> alkaline earth metal>alkali metal. Transition metal ions form a coordinate bond with OH groups in the exchanger. The OH groups, which were easily condensed by a heat treatment, were not restored even when the samples subjected to thermal treatment were immersed in water: Thirty percent of the initial ion-exchange capacity was lost when the exchanger was heat-treated at a temperature as low as 70 °C, and the exchange sites were completely destroyed between 400 and 550 °C.

Hydrous oxides based on various polyvalent metal ions have been investigated because of their unique selectivity characteristics and the simplicity of preparation. They have, however, a serious disadvantage in that they give inconsistent results to different workers because of the irreproducibility of the synthesis. To promote a further investigation of this group of ion-exchange materials, it is indispensable to reexamine the synthetic conditions for establishing reproducible methods. With this point in mind, the present authors previously established satisfactory methods for synthesizing such hydrous oxides as $TiO_2 \cdot 2.1\,H_2O$, $SnO_2 \cdot 2.2\,H_2O$, and $Nb_2O_5 \cdot 5.3\,H_2O$; they also studied the ion-exchange selectivity, the thermal stability and other important properties of these materials.[1-3]

Hydrous zirconium(IV) oxide is also an important material of this group of inorganic ion exchangers and there is much left to be studied during a series of these investigations. Since the work of Kraus et al., who first reported that hydrous zirconium(IV) oxide was an amphoteric ion exchanger possessing a large anion-exchange capacity, emphasis has been placed on its anion-exchange property. There are, however, a few reports on the cation-exchange properties of hydrous zirconium(IV) oxide. In addition, the effect of a heat treatment on the ion-exchange properties of the material has not yet been investigated, although inorganic ion exchangers are generally expected to be superior to ion-exchange resins regarding thermal stability.

The present paper deals with a study undertaken to establish a reproducible synthetic method for producing hydrous zirconium(IV) oxide, together with its ion-exchange properties and thermal stability. Among various methods for synthesizing hydrous zirconium-(IV) oxides,[4-9] the hydrolysis of a $ZrOCl_2$ solution by alkaline solutions was adopted, because of its applicability to the synthesis of a large amount of the hydrous zirconium(IV) oxide. A recommended procedure was established after examining the effects of such factors as the concentration of the $ZrOCl_2$ solution, the kind of alkaline solutions used, and the pH value during precipitation on the yield as well as the composition and acid-base property of the product. After the reproducibility of the procedure was confirmed, the distribution coefficients of various cations were measured as functions of the pH and temperature in order to study the cation-exchange mechanism. Furthermore, the thermal stability was studied by examining the effect of a heat treatment on the composition and the ion-exchange property of the material.

Experimental

Reagents and Apparatus. All chemicals were of the highest purity grade supplied by Wako Pure Chemical Industries, Ltd. The specific surface area was determined by the BET method (N_2 adsorption at −196 °C) using a Yanagimoto Surface Area Measuring Apparatus, Model GSA-10. All the other equipment was the same as that described previously.[1-3]

Synthesis. The desired amount of $ZrOCl_2 \cdot 8H_2O$ was dissolved in distilled water to make 1 dm^3. The solution was hydrolyzed by adding (drop by drop) either an NH_3 or an NaOH solution of the molar concentration, 2.5-times that of the zirconium solution, up to a desired molar ratio between hydroxide and zirconium ions. After being separated from the mother liquor by a combination of decantation and filtration through Toyo No. 1 filter paper under suction, the precipitate was uniformly dispersed into 5 dm^3 of distilled water and again filtered after being sedimentated. This procedure was repeated until no chloride ions were detected in the filtrate. Then, the precipitate was air-dried at room temperature. The resulting product was then immersed in water in order to break it down into fine particles, which were subsequently again dried at room temperature. At this stage the yield was calculated based on the zirconium recovery. Particles larger than those desired, if any, were ground in a porcelain mortar and seived in order to obtain the required particle size (−100+200 mesh).

The exchanger was converted to the free acidic form (the H form) by the following column method. In the case of the exchangers precipitated at a pH lower than 7, which may adsorb Cl^- ions, 0.05 mol dm^{-3} NaOH was passed through an exchanger column in order to remove Cl^- ions until the pH of the effluent approached that of the influent. Then, the column was washed with distilled water until no Na^+ ions were detected in the effluent and its pH became nearly constant (pH=6.2—6.5). In the case of the exchangers precipitated in the alkaline region, which may adsorb NH_4^+ or Na^+ ions, 0.05 mol dm^{-3} HCl was passed through the column; the column was then washed until no Cl^- ions were detected in the effluent and its pH became nearly constant (pH=6.2—6.5). As shown in Fig. 1, the constant pH value of the effluent corresponds to the isoelectric point of the exchanger. The exchangers, thus prepared, were air-dried at room temperature and allowed to humidify to a constant weight in a desiccator containing a saturated NH_4Cl solution (relative humidity:79% at 25 °C). Table 1 shows the synthetic conditions, yields and compositions of the exchangers.

Ion-Exchange Capacity. The exchanger (0.20 g) in the H form was immersed in 20 cm^3 of various solutions, prepared by the desired combination of 0.1 mol dm^{-3} NaCl, and 0.1 mol dm^{-3} NaOH or 0.1 mol dm^{-3} HCl, for 6 d at room temperature with intermittent shaking. This was followed by a pH measurement and by a determination of the Na^+ and Cl^- ions. The chloride concentration was determined by the Fajans' method after the solution had been neutralized. The sodium ions were converted to an equivalent amount of sodium chloride and were indirectly determined by titrating the chloride ions. The amount of ions taken up by the exchanger was evaluated from the difference between the initial and the final concentrations of the respective ions present in the solution. The dissolved amount of the exchanger was evaluated from the amount of zircoium in the supernatant solution determined spectrophotometrically by the arsenazo III method.[11] The limit of detection was 0.009 wt% of the exchanger used.

Analysis of Chloride Ions in the Exchanger. A half gram of the sample was dissolved by heating with 100 cm^3 of 9 mol dm^{-3} H_2SO_4 in a 500-cm^3 distilling flask, and the HCl evolving therefrom, carried by steam, was absorbed in a slightly alkaline solution and then determined spectrophotometrically using mercury(II) thiocyanate and ammonium iron(III) sulfate as coloring reagents.[10] The limit of detection was 0.009 wt% of the exchanger used.

Analysis of Sodium Ions in the Exchanger. One tenth gram of the sample was dissolved by heating with 10 cm^3 of 6 mol dm^{-3} HCl. After cooling, 6 mol dm^{-3}, NH_3 aq was added, and the precipitate was filtered and washed with 0.05 mol dm^{-3} HCl. A negligible amount of Na^+ ions was lost by occlusion in the precipitate in this procedure (less than 2 wt% of the Na^+ ion to be determined). The filtrate and the washings were collected in a volumetric flask and then diluted to the mark. The concentration of Na^+ ions in this solution was determined by means of atomic absorption spectrophotometry. The limit of detection was 0.007 wt% of the exchanger used.

Analysis of Water in the Exchanger. A quarter gram of the sample was ignited at 800 °C, and the water content was calculated from the weight loss. The validity of the procedure had been confirmed thermogravimetrically.

Density. The apparent density of the exchangers was measured in the usual manner using a 25-cm^3 pycnometer.

Distribution Coefficients. The distribution coefficients, K_d, were determined in the following way. A 0.12-g portion of the exchanger in the H form was immersed in 7 cm^3 of the solution with a suitable pH value, adjusted by using a desired combination of 0.11 mol dm^{-3} NaCl, and 0.11 mol dm^{-3} HCl or 0.11 mol dm^{-3} NaOH, for 2 d at room temperature. A 1-cm^3 portion of the solution containing the metal ion to be examined was added to the slurry to make the concentration of the cation in the test solution 1×10^{-4} mol dm^{-3} and the ionic strength 0.10 mol dm^{-3}. The mixture was then allowed to stand until the concentration of the cation in the supernatant solution became nearly constant (about 6 to 20 d). The pH and the concentration of the cation in the supernatant solution were then measured. The K_d values were calculated by means of the following equation:

Table 1. Synthetic Conditions and Compositions of the Exchangers

a) The rate of addition of alkaline solution: 35 cm^3 min^{-1}, in the other cases 10 cm^3 min^{-1}.

$$K_d = \frac{I-F}{F} \cdot \frac{V}{m} (\mathrm{cm^3\,g^{-1}}),$$

where I and F, respectively, are the initial and final concentrations of the metal ions in the solution, V the volume of the solution in cm^3 and m the weight of the exchanger in grams.

The metal ions were added as their chlorides, except Fe^{3+}, Th^{4+} and UO_2^{2+}, for which the corresponding nitrates were used. The analyses of Cs, Sr, Ba, Mn, Fe, Co, Ce, Eu, and Am were carried out radiometrically using ^{137}Cs, ^{85}Sr, ^{133}Ba, ^{54}Mn, ^{60}Co, ^{144}Ce ^{152}Eu, and ^{241}Am. respectively as tracers. Their radioactive purity was confirmed by means of γ-ray spectrometry. Thorium(IV) and uranium(VI), respectively, were analyzed spectrophotometrically using arsenazo III[11] and 2-(5-Bromo-2-pyridylazo)-5-(diethylamino)phenol[12] as coloring reagents, while the concentrations of the other cations were determined by means of atomic-absorption spectrophotometry.

Heat Treatment. About 5 g of the exchanger in the H form was heated in air to a constant weight at a constant temperature, which was controlled within an accuracy of 1% by using an automatic temperature controller (Chino Workers, Ltd.). After being cooled to room temperature over P_2O_5, the sample was weighed and then immersed in water overnight. The sample was then separated from water and allowed to stand to a constant weight in a desiccator containing a saturated NH_4Cl solution (humidifying operation). The water-recovery of the heat-treated samples was calculated from the difference in water content between samples cooled over P_2O_5 immediately after the heat treatment and subjected to a humidifying operation.

The other experimental procedures were the same as those described previously.[1-3]

Results and Discussion

Synthesis of Hydrous Zirconium(IV) Oxide. It is required for practical purposes that a large amount of pure hydrous zirconium(IV) oxide having reproducible and good ion-exchange properties can be easily prepared; in conformity with this line, we examined the effect of synthetic conditions on the yields and the acid-base properties of the products.

The effect of the pH during precipitation (OH^-/Zr^{4+} molar ratio) and of the kind of alkali used on the uptake curves for Na^+ ions are shown in Fig. 1. This figure indicates that the products are amphoteric ion exchangers possessing larger ion-exchange capacities for anions than for cations and have an isoelectric point close to pH 6.5. The ion-exchange capacity is slightly smaller for the products precipitated from alkaline solutions than for those from acidic or neutral solutions. It is, however, considered that the ion-exchange behavior is not very much affected by the kind of alkali used and the pH during precipitation, since the maximum difference in the ion-exchange capacity is only 0.15 m mol g^{-1}. In contrast, the yield was significantly affected by these factors, as is shown in Table 1. The decrease in the yield is due mainly to the peptization of the precipitate during washing. Only the precipitate formed at around pH 9 by adding NH_3 aq can be washed without sufferings from peptization, and affords an excellent yield exceeding 90%. Efforts were then concentrated on examining the properties of the exchanger precipitated under these conditions.

In order to prepare a large amount of the exchanger in one batch, it is preferred to use a concentration of zirconium during precipitation that is as high as possible. The uptake curves of the exchangers prepared from different concentrations of zirconium (batch (6)—(8)in Table 1) are compared in Fig. 2; this

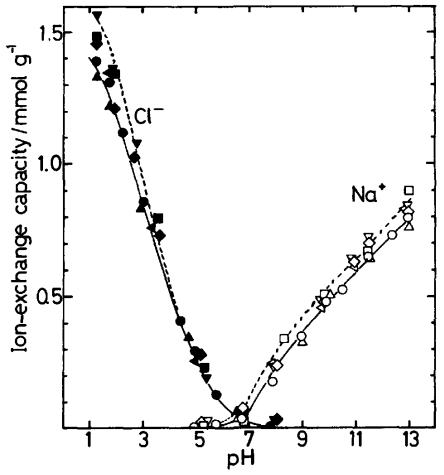

Fig. 1. Uptake curves of various exchangers for Na^+ and Cl^- (Effects of alkali used and pH at precipitation). Exchangers; ◁: No. 1, ◇: No. 2, △: No. 3 (NaOH system). ▽: No. 4, □: No. 5, ○: No. 6(NH_3 system). The numbers are the same as those in Table 1.

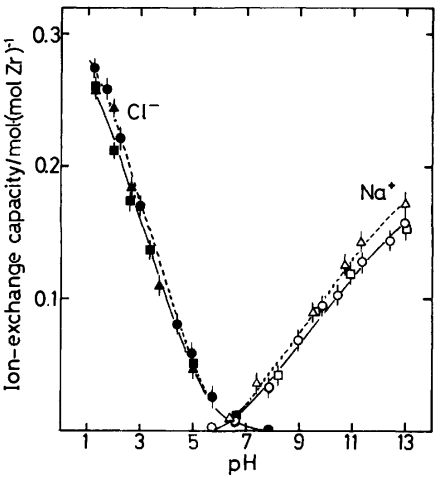

Fig. 2. Uptake curves of various exchangers for Na^+ and Cl^- (Effect of Zr-concentration at precipitation). Exchangers; ○: No. 6, □: No. 7, △: No. 8. The numbers are the same as those in Table 1.

indicates that the concentration did not appreciably affect the ion-exchange property. However, the concentration of zirconium did influence the yield and the physical properties of the product; the exchangers precipitated from the solution with a high concentration of zirconium (1 mol dm^{-3}) had poor physical strength (brittle chalk), while those precipitated from a dilute solution of zirconium had a large, glassy grains. The yield decreased with increasing concentration of zirconium due to the accentuating degree of peptization during washing. Thus, 0.2 mol dm^{-3} of zirconium concentration was selected for preparing the exchanger.

While the water content of the products slightly increased with the volume of NH_3 aq added (less than 5%), the ion-exchange capacity remained unchanged within the limit of the experimental error, as is shown in Table 1 (batch (9)—(11)). Furthermore, the rate of addition of NH_3 aq was not found to affect the composition and ion-exchange properties of the products. Therefore, no exact control of the procedure is necessary; thus, the present method for preparing hydrous zirconium(IV) oxide is considered to be fairly reproducible.

From these results, the synthetic conditions of batch (10) in Table 1 was selected as being the best method for reproducibly synthesizing a hydrous zirconium-(IV) oxide ion exchanger. The contents of both Na^+ and Cl^- ions as impurities were below the limit of detection (0.007 wt%). Thus, the conditioning is effective for converting the exchanger into the H form. The composition of the product was $ZrO_2 \cdot (3.8—4.1)H_2O$, in agreement with that of fully-hydrolyzed zirconium(IV) hydroxide, $Zr_4(OH)_{16}(H_2O)_8$, which was reported by H. Th. Rijnten in the study of the hydrolysis of $ZrOCl_2$ solution.[13] The solubilities of the exchanger in 0.1 mol dm^{-3} NaOH- and HCl solutions were determined to be 0.01 and 0.07 wt%, respectively; this assures the applicability of the exchanger in pH region.

Selectivity for Cations. Figure 3 shows the pH-dependency of the K_d values for the representative elements. As can be seen from this figure, the affinity of the exchanger is much greater for alkaline earth metal ions than for alkali metal ions; this indicates that the electrostatic interaction between counter ions and ion-exchange sites is an important factor in governing the selectivity of the hydrous zirconium(IV) oxide. The higher K_d values for Li^+ than for Cs^+ may suggest that removal of the solvated water molecules from counter ions. However, there is no difference in the affinity between alkaline earth metal ions.

Figure 4 shows the pH-dependency of the K_d values for transition metal ions. The affinity of the exchanger was much greater for the transition metal ions than for the representative elements. The order of selectivity for the transition metals, $Fe^{3+} >> UO_2^{2+} > Th^{4+} >> Am^{3+} > Eu^{3+} > Ce^{3+} > Zn^{2+} > Co^{2+} > Mn^{2+}$, indicates the general trend that the exchanger exhibits a preference for transition metal ions with a larger ionic charge and a smaller crystalline radius. The distribution coefficients for Th^{4+}, which are smaller than would be expected from the ionic charge, are

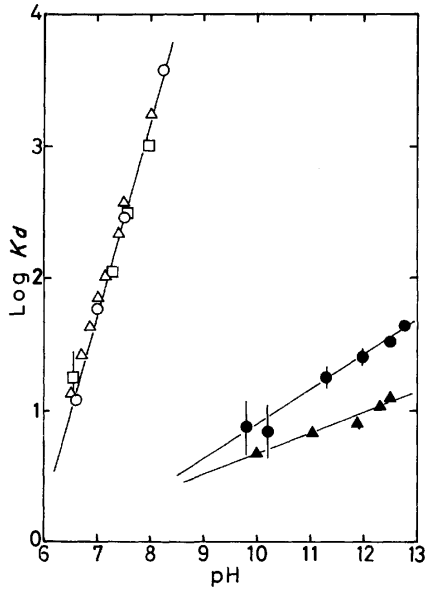

Fig. 3. Log K_d for several representative metal ions. Ionic strength: 0.10 mol dm^{-3} (NaCl-NaOH) at room temperature. Initial concentration of cation: 1×10^{-4} mol dm^{-3}. Cations; ●: Li^+, ▲: Cs^+, □: Mg^{2+}, ○: Sr^{2+}, △: Ba^{2+}.

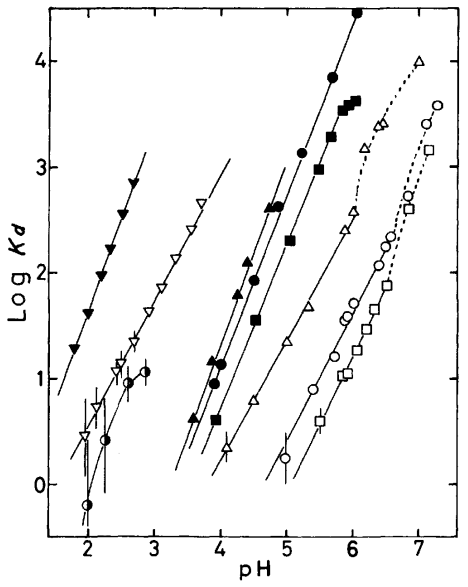

Fig. 4. Log K_d for several transition metal ions. Ionic strength: 0.10 mol dm^{-3} (HCl-NaCl) at room temperature. Initial concentration of cations: 1×10^{-4} mol dm^{-3} (Am^{3+}: Tracer scale). Cations; □: Mn^{2+}, ○: Co^{2+}, △: Zn^{2+}, ▼: Fe^{3+}, ■: Ce^{3+}, ●: Eu^{3+}, ◑: Th^{4+}, ▽: UO_2^{2+}, ▲: Am^{3+}.

attributable to the hydrolysis of ions in the pH region effective for sorption (pH>2). On the other hand, K_d values for UO_2^{2+} ions, which are higher than expected from the ionic charge, may be due to the peculiarity of the structure of UO_2^{2+} ions; the efffective charge on a uranium atom is higher than the formal charge of the ions. With these exceptions, the electrostatic force may be considered as being an important factor in determining the selectivity of the hydrous zirconium(IV) oxide for the transition metals.

In order to obtain further information on the important factors affecting the selectivity for the transition metals, the K_d values at pH 4 were compared with their first hydrolysis constants[14] and the first stability constants of their acetato complexes.[15] The results are shown in Table 2, where the

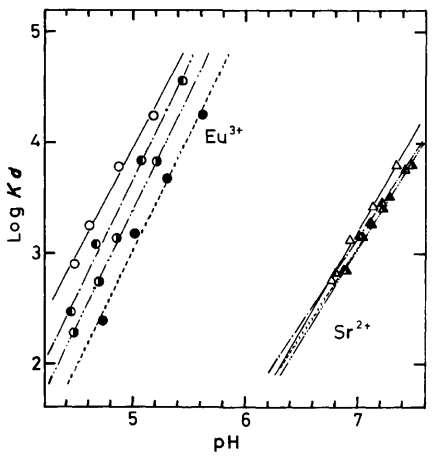

Fig. 5. Temperature dependence of K_d values for Sr^{2+} and Eu^{3+} ions.
Initial concentration of metal ions: 1×10^{-6} mol dm^{-3}. Ionic strength: 0.10 mol dm^{-3} (HCl-NaCl-NaOH). Temperature/°C; ▲●: 14.8, ◭◑: 25.2, ◭◐: 34.5, △○: 44.8.

K_d values which could not be obtained experimentally were estimated from an extrapolation of the log K_d vs. pH plot to pH 4 (Fig. 4). This table indicates that the K_d values is very strongly related to the hydrolysis constants (R=0.99) and the stability constants (R=0.98). Figure 5 shows the temperature-dependence of K_d values for Sr^{2+} and Eu^{3+} ions. The values for Sr^{2+} ions depended little on the temperature, while those for Eu^{3+} ions increase with temperature, indicating an endothermic reaction. From the slope of the linear plot of the logarithm of K_d against $1/T$, the standard enthalpy change of the latter reaction was found from a calculation to be 55±6 kJ mol^{-1}; this is considerably larger than the values (<10 kJ mol^{-1}) associated with the exchange of the dissociated ions in the exchanger and the counter ions in solutions. From these results, we concluded that the formation of a coordination bond between anionic sites in the exchanger and counter cations plays a part in determining the selectivity of the exchanger, along with the remote coulombic interaction. This consideration is in line with the fact that the affinity with the exchanger was greater for transition metals than for representative elements, since the former is stronger than the latter as Lewis acids.

Thermal Stability. Figure 6 shows the effect of a heat treatment of the hydrous zirconium(IV) oxide on the composition and the specific surface area. It should be noted that the water content was normalized to the number of moles of water per 1 mole of ZrO_2. The amount of water contained in the exchanger immediately after the heat treatment at 70 °C was reduced to about 30% of the original value; then, it gradually decreased with temperature, and finally fell to zero at 400 °C. When the exchangers heated at temperatures up to 400 °C were subjected to the humidifying operation, a roughly constant amount of water, viz. 0.85 to 1.4 mole per 1 mole of ZrO_2, was recovered, while the samples heated over 550 °C

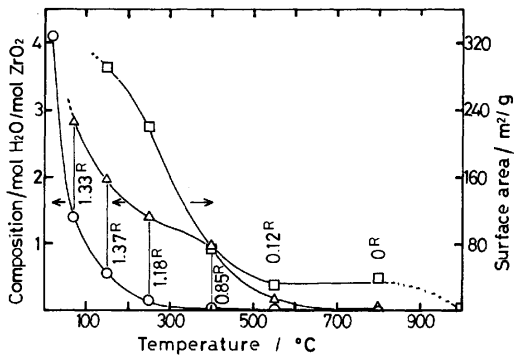

Fig. 6. Change in composition and surface area.
Water content; ○: Immediately after heat treatment, △: Heat-treated, followed by humidifying operation. R: Water recovery. □: Specific surface area of heat-treated sample.

recovered a negligible amount of water. The amount of water recovery as a result of humidifying the exchangers heat-treated even at a temperature as low as 70 °C fell short of the full recovery by 1.4 mole of water per 1 mole of ZrO_2. The surface area decreased sharply with increasing temperature up to 550 °C, where the surface area became nearly constant (40 $m^2 g^{-1}$). As is shown in Table 3, the density of the samples immediately after the heat treatment increased with temperature, approaching to a constant value of 5.53±0.08 g cm^{-3} at 550 °C. This value corresponds to the density of tetragonal ZrO_2, 5.60 g cm^{-3} within the limit of experimental error.

In order to examine the effect of the heat treatment on the acid-base property of the exchanger, the ion-exchange capacities for Na^+ or Cl^- ions were measured as a function of the pH (Fig. 7). The ion-exchange capacities for both ions decreased even at a temperature as low as 70 °C, and were reduced to about 30 % of the original value when the exchanger was heated at 250 °C. The sample heated at 550 °C exhibited a very small exchange capacity for only Cl^- ions. Therefore, the exchange sites of the hydrous zirconium(IV) oxide is susceptible to thermal decomposition.

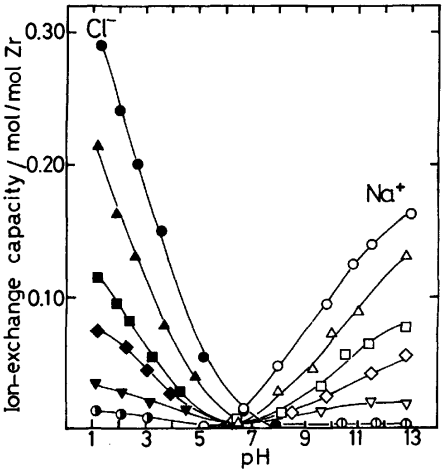

Fig. 7. Uptake curves for Cl^- and Na^+ ions (Effect of thermal treatment).
Temperature of treatment/°C; ○: R. T., △: 70, □: 150, ◇: 250, ▽: 400, ⓓ: 550.

Figure 8 shows DTA curves for the samples subjected to the humidifying operation. The large endothermic peaks appearing in the range lower than 200 °C sharpened and became smaller in area as the temperature of the heat treatment became higher. The position of the peak, observed at 80 °C for the sample without heat treatment, shifted to the lower-temperature side upon increasing the temperature of the heat-treatment (gradually up to 400 °C, and then abruptly). When the exchanger was heat-treated at 550 °C, the peak shifted to 40 °C and developed a very small area. Apparently, this observation is compatible with changes in both the exchange capacity and the degree of water recovery with the heat-treatment temperature, if the peak is considered to correspond mainly to the release of water recoverable by humidifying, that is, a certain kind of zeolitic water. The shoulders observed at the high- and low-

Table 3. Density of the Samples Immediately after the Heat Treatment

Temperature of treatment / °C	Density / g cm^{-3}
150	4.30±0.07
250	5.15±0.06
550	5.53±0.08
700	5.53±0.06

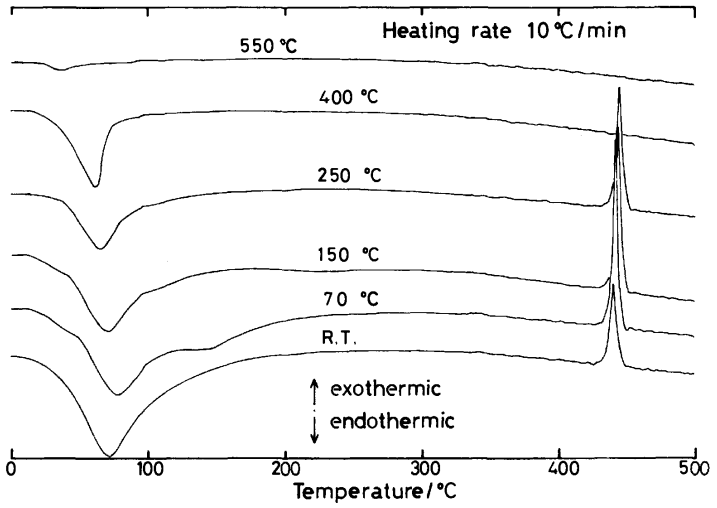

Fig. 8. DTA curves of the samples subjected to the humidification.

temperature sides, respectively, of the peak for the samples heated at temperature below 150 °C are attributable to the bound water liberated by the condensation of the hydroxyl groups and to the adherent water in the exchanger matrix. As the area under the shoulder decreased with increasing temperature of the treatment, both bound and adherent water are considered to be released irreversibly. A large exothermic peak observed at 430 °C for samples heated at a temperature below 400 °C may be assigned to the crystallization of the exchanger as judged from the change in the degree of recovery of water, in the density and in the exchange capacity of the samples. Rijnten obtained a similar thermogram for hydrous zirconium(IV) oxide prepared by a similar method to the present study. In his report, the exothermic peak at 405 °C was attributed to crystallization into monoclinic ZrO_2, which eventually transformed into a mixture of tetragonal and monoclinic ZrO_2 at 800 °C.[13] In the present experiment, however, X-ray studies made on the samples heated at 550 and 800 °C, showed no diffraction peak in spite of prolonged heating for 72 h; a few peaks, indicating the formation of a mixture of tetragonal and monoclinic ZrO_2, appeared only when the sample was heated at 1000 °C for 72 h. With the appearence of such peaks, the surface area of the sample suddenly decreased to about 5 $m^2 g^{-1}$.

From the above observations, the thermal stability of the hydrous zirconium(IV) oxide can be summarized as follows. When the exchanger is heat-treated at a low temperature, a disordered network structure, formed at precipitation, is stabilized by irreversibly releasing adherent water and a portion of structural water. Then, the stabilized matrix can accommodate an approximately constant amount of water which can be recovered by humidification. With the stabilization of the network structure, the water molecules formed by the condensation of a part of the OH groups in the exchanger together with the water molecules bound to these groups are released irreversibly, even at low temperatures, causing a decrease in the ion-exchange capacity. The crystallization occuring at temperatures between 400 to 550 °C brings about densification as well as a decrease in the surface area and in the interstitial space which can accommodate water molecules. Thus, almost all the water is not recovered by the humidifying operation and the ion-exchange capacity completely disappears.

Structure of Aquachloro(4-hydroxy-L-prolinato)copper(II)

Shiroo Itoh, Yasuhiko Yukawa,* Yoshie Inomata, and Toshio Takeuchi
Department of Chemistry, Faculty of Science and Technology, Sophia University,
7-1, Kioi-cho, Chiyoda-ku, Tokyo 102
(Received August 13, 1986)

An X-ray diffraction study of the title complex has been carried out. The crystal is monoclinic, with the space group $P2_1$; $Z=2$, $a=8.712(1)$, $b=6.055(1)$, $c=8.187(1)$ Å, $\beta=109.83(1)°$. Block-diagonal least-squares refinements have led to the final R value of 0.052. The structure consists of a one-dimensional polymer chain bridged by only one carboxylato group of a 4-hydroxy-L-prolinato ligand. The chains are parallel to the b axis; each is connected with the neighboring one by hydrogen bonds between water oxygen atoms and chlorine atoms. Thus a sheet forms parallel to the (0 0 1) plane. One carboxylato oxygen atom of the 4-hydroxy-L-prolinato ligand is coordinated to two copper atoms, and the other is coordinated to one of these two copper atoms. The copper atom is surrounded by three carboxylato oxygen atoms, one water oxygen atom, one nitrogen atom in a pyrrolidine ring, and one chlorine atom. Therefore the copper atom has distorted octahedral coordination.

The amino acids having a pyrrolidine ring, 4-hydroxy-L-proline (Hhpro) and L-proline (Hpro), are a little different from other α-amino acids. Some interesting properties of their metal complexes have been reported: for example, the studies of circular dichroism spectra[1,2] and of stereoisomerism.[3] The properties of their complexes are based on the structures. Therefore studies about syntheses, properties, and structures of some metal complexes with Hhpro and Hpro have been carried out in our group.[4–6]

Two copper(II) complexes with hpro has been reported:[5] one is [Cu(hpro)$_2$] and the other is [CuCl(hpro)(H$_2$O)]. The structure of the latter complex was determined by infrared spectra. In the free ligand, Hhpro, there are some peaks assigned to NH_2^+ stretching and bending vibrations. On the other hand, in the complex there are peaks assigned to NH vibrations without any assigned to NH_2^+. The peak assigned to Cu-Cl stretching vibration is observed at about 280 cm^{-1}. This is a rather low frequency, if we assume that the chlorine atom is a terminal one. For example, ν_{CuX}(terminal)=311 cm^{-1}, ν_{CuX}(bridge)=280, 230 cm^{-1} for $(NH_4)_2[Cu_2Cl_6]$, ν_{CuX}(terminal)=301 cm^{-1}, ν_{CuX}(bridge)=278, 236 cm^{-1} for $K_2[Cu_2Cl_6]$.[7] Therefore the peak should be considered to be based on the bridged chlorine atom and the metal bonding. However, it is difficult to determine the structure from the infrared spectra.

In this work, the confirmation of the structure [CuCl(hpro)(H$_2$O)] by an X-ray diffraction study and the interpretation of the properties based on the structure were carried out.

Experimental

Preparation of the Sample. The samples for the X-ray diffraction study were prepared in the following way, modifying the previous method:[5] equimolar amounts of $CuCl_2 \cdot 2H_2O$ and Hhpro were mixed in aqueous solution, then the aqueous solution was condensed at 60—70 °C for several hours. The sample crystals were obtained from the aqueous solution of the complex by keeping it in a desiccator containing acetone for several days.

Table 1. Crystal Data

$CuCl(C_5H_8NO_3)(H_2O)$	$F.W.=247.14$
Monoclinic	Space group $P2_1$
$a=8.712(1)$ Å	
$b=6.055(1)$ Å	$\beta=109.83(1)°$
$c=8.187(1)$ Å	
$Z=2$	$U=406.3(1)$ Å^3
$D_m=2.015(3)$ g cm^{-3}	$D_x=2.020$ g cm^{-3}
μ(Mo $K\alpha$) = 30.9 cm^{-1}	

X-Ray Measurements and Structure Determination. The crystal data are given in Table 1. The reflection intensities were collected by the θ—2θ scan techniqe ($2\theta<76°$) on a Philips PW1100 automated four-circle diffractometer. The 2253 intensities ($|F_o|>3\sigma(|F_o|)$) were corrected for Lorentz and polarization factors, but not for absorption, because of the low magnitude of μr(=0.46). All calculations were carried out on a HITAC M-200H/M-280H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS.[8] The scattering factors were taken from tables.[9] The structure was solved by a heavy-atom method and refined by a block-diagonal least-squares method. The positions of hydrogen atoms, except for hydroxyl and water hydrogen atoms, were obtained by difference-Fourier syntheses. The weighting scheme was $W=1/[\{\sigma(|F_o|)\}^2+(0.02\times|F_o|)^2]$. The final R value[10] was 0.052.

Results and Discussion

The final atomic parameters are listed in Table 2,[11] the interatomic distances in Table 3, and the bond angles in Table 4. The perspective drawing of the complex and the numbering scheme of the atoms are shown in Fig. 1.

The structure of the complex consists of a one-dimensional polymer chain bridged by only one carboxylato group of hpro. One carboxylato oxygen atom of the hpro is coordinated to two copper atoms to form an oxygen bridge, and the other is coordinated to one of these two copper atoms.

The copper atom is surrounded by six atoms: Three carboxylato oxygen atoms, one water oxygen atom, one nitrogen atom in a pyrrolidine ring, and one chlorine atom. Among them, the O(11)^{I} and Cl are at a longer distance from the metal than the others. The angle O(11)^{I}–Cu–O(12)^{I} is 54.4(1)°. Therefore the octahedron surrounding the copper atom is extremely distorted.

The prediction given by the infrared spectra was confirmed: The nitrogen atom in the pyrrolidine ring

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression:

$B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$.

The B_{ij}'s are in the form:

$\exp\{-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})\}$.

b) The numbering scheme of hydrogen atoms is based on the number of the atom attached to the hydrogen atoms.

is coordinated to the metal. The bond length of Cu–N, 2.024(5) Å, is not very different from that of common amino acid chelate compounds.

The distance of Cu–O(11)^{I}, 2.647(4) Å, is rather longer than the common Cu–O bond. However, this is not so surprising, because similar or more extreme examples have been reported in copper(II) oxalate,[12] bis[(alkylthio)acetato]copper(II)–amine adduct,[13] and mixed amino acid copper complexes.[14,15] The chlorine atom is coordinated to the metal not as a bridging atom, but as a terminal one. In the classification according to bond lengths, the Cu–Cl bond, 2.571(2) Å, however, should belong to Cu–Cl(bridging) rather than of Cu–Cl(terminal). For example, Cu–Cl(bridging): 2.337 Å and 2.769 Å in dichloro(1,2,4-triazole)copper(II),[16] Cu–Cl(terminal): 2.241(6) Å in dichlorobis(tetramethylthiourea)copper-(II).[17]

The bond distances and angles of the binding hpro are not very different from those of the free molecule. In the free molecule the four atoms of a pyrrolidine ring are nearly coplanar, except for the carbon atom carrying a hydroxyl group.[18] On coordination, however, the pyrrolidine ring is bent on the line from N to C(3), and C(4) and C(5) deviate from the plane formed by C(2), N, and C(3) in the direction against the carboxylato group. The deviation is in the opposite direction to that of the Hhpro in [$CdCl_2$-(Hhpro)].[4]

There are two types of chelate rings in this complex. One is the five-membered ring which is formed by Cu, O(11), C(1), C(2), and N, the other is the four-membered ring formed by Cu, O(11)^{I}, C(1)^{I}, and O(12)^{I}. Both chelate rings are fairly flat planes, as shown in Table 5. They neighbor each other between two copper atoms. The dihedral angle of these chelate rings is 172.5°.

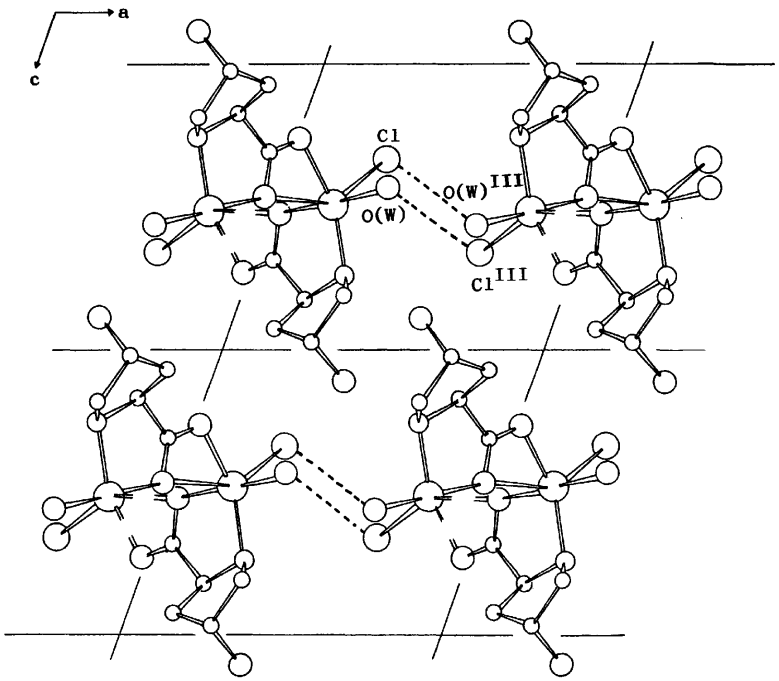

Fig. 2. The projection of the structure along the b axis. (----: Hydrogen bonding).
Key to symmetry operation: III. $1.0-x$, $-0.5+y$, $1.0-z$.

The projection of the structure along the b axis is given in Fig. 2. There are two types of hydrogen bonds between the water oxygen and the chlorine atoms. One is the intra-chain hydrogen bond ($O(W)$-Cl^{II}=3.034(5) Å), shown with broken line, between $O(W)^{I}$ and Cl^{IV}, in Fig. 1. The other is the inter-chain hydrogen bond (Cl-$O(W)^{III}$=3.017(3) Å; see Fig. 2). The rather long bond length of Cu-Cl may be due to the intra- and inter-chain hydrogen bonds. Each chain arranged in parallel with the b axis is linked to the neighboring one, by hydrogen bonds. Thus, a sheet forms parallel to the (001) plane, as shown in Fig. 2. The oxygen atom of the hydroxyl group does not form any hydrogen bonds. On the basis of the structural data, the properties of the complex reported previously[5] are reconsidered.

In the infrared spectra, the peak assigned to Cu-Cl stretching vibration, about 280 cm^{-1}, is a rather low frequency for Cu-Cl(terminal) bonding. In the complex, [CuCl(hpro)(H_2O)], the peaks of carboxylato group stretching vibrations are at 1592 and 1567 cm^{-1} (COO^- antisymmetric) and at 1407 and 1393 cm^{-1} (COO^- symmetric). In the bis-chelate complex, [Cu(hpro)$_2$], the peaks are at 1592 cm^{-1} (COO^- antisymmetric) and 1407 cm^{-1} (COO^- symmetric).[5] The splitting peaks of antisymmetric and symmetric stretching vibrations in the former complex may result from the complicated bridging carboxyl group as mentioned above. The difference between the mean value of COO^- antisymmetric vibrations and that of COO^- symmetric vibrations in [CuCl(hpro)(H_2O)] is smaller than the difference between two peaks of antisymmetric and symmetric vibrations in [Cu(hpro)$_2$] or in free ligand (Hhpro). This fact agrees with the vibrational spectrum patterns of behavior established for the carboxylato ligand:[19,20] in the bidentate (chelate) carboxylato complex, the separation between the COO^- stretching vibrations is smaller than that of the free carboxylate ion or of the unidentate carboxyl complex.

The electronic spectrum of the aqueous solution is different from the powder diffuse reflection one in [CuCl(hpro)(H_2O)]. This indicates that the complex has different coordination types in the aqueous solution and in the crystalline form. In the aqueous solution there is a broad peak at 680 nm, which is characteristic of a six-coordinated Cu^{II} complex. On the other hand, the peak at 769 nm has a shoulder near 900 nm in the powder diffuse reflection:[21] This may result from some extreme distortion of the octahedron surrounding copper(II). This result suggests that the coordination polyhedron changes from its distorted shape into a shape nearer an octahedron, because the polymer chain cleaves and then an octahedron is rebuilt by becoming coordinated to water molecules in the aqueous solution.

The magnetic or thermal properties of this complex are consistent with the structure proposed.

The authors wish to express their thanks to Professor Yoichi Iitaka of The University of Tokyo for X-ray diffractometer measurements. They would also like to thank Dr. F. S. Howell of Sophia University for correcting this manuscript.

A Method of Calculation for d.c. Polarographic Catalytic Wave

Kenji KIKUCHI
Shiga Prefectural Junior College, Hikone, Shiga 522
(Received August 25, 1986)

A new numerical method for theoretical analysis of polarographic catalytic current is proposed and applied to well-studied systems to prove that the method is dependable. In this method, a system of partial differential equations of diffusion is transformed to finite-difference form by using Crank-Nicolson difference scheme, and the latter is solved by using both Gauss-Seidel and successive over relaxation methods. Chemical kinetics terms in the diffusion equations is substituted by ones rewritten by three alternative procedures. The method has been applied to a system of copper(II) and hydrogen peroxide. Resulted rate constant of participating chemical reaction agrees with the rate constant obtained from bulk solution experiments. This and other results show that the method is a useful tool for theoretical analysis of catalytic waves.

Catalytic reaction in polarographic wave has been studied by several methods. The one, which was first used, was a method invented by Bridicka and Wiesner.[1] Although it is simple and appealing, the conception of reaction layer on which the method based is of an approximate nature. Hence numerical values of rate constants of chemical reactions, calculated by this method, are considered unreliable. Kolthoff and Parry found that the rate constant calculated from observed currents was of the order of 10^4 times greater than the one determined from the experiment of bulk solution kinetics in the Fe(III)–hydrogen peroxide system.[2]

Koutecky derived a rigorous solution for a pseudo-first-order reaction at the surface of the expanding sphere electrode.[3] He solved simultaneous differential equations of diffusion, with chemical kinetics terms, using the method of dimensionless parameters. Though it is ingenious, his method can not be applied to reactions of higher orders.

The same kind of simultaneous differential equations are arising in problems of ECE mechanisms. Galvez et al. derived explicit solutions of the simultaneous differential equations without the steady state approximation and obtained current-potential curves of ECE mechanisms.[4–6] However, application of their method is limited to (pseudo-) first-order reactions owing to the common defect of analytic method.

Today numerical method becomes increasingly a popular tool for electrochemists with increasingly easier accessibility to computers. Ruzic et al. solved problems of ECE mechanisms by the method of explicit finite-difference digital simulation, and reported d.c. and a.c. polarographic curves of several ECE mechanisms, calculated by their method.[7–11] However, the method is inherently inflexible with respect to setting boundary conditions, and it is very difficult to apply to more complex systems.

Ultimate aim of this study is to diagnose observed polarograms of catalytic nature by comparing with calculated curves based on several possible mechanisms, and to estimate rate constants. Candidate mechanisms may be of second order or higher. Number of chemical species participated is not necessarily confined to three or four. All methods mentioned above are insufficient to achieve this aim. Another mathematical method is needed in these circumstances.

Winograd used an implicit method of finite-difference to simulate spectro-electrochemical working curves for a diffusion controlled system, and state that the method was much more efficient than explicit method.[12] In this paper the implicit method of Crank–Nicolson is used for calculation of polarograms of a simple system of catalytic current. Before to do this, however, soundness of the method must be established.

Theory

The catalytic current in the Cu^{2+}–H_2O_2 system is well-known through the study of Kolthoff and Woods.[18] This reaction mechanism is given as follows.

$$Cu^{2+} + e^- \rightleftharpoons Cu^+ \quad (1)$$

$$Cu^+ + H_2O_2 \longrightarrow Cu^{2+} + OH^- + OH \quad (2)$$

$$Cu^+ + OH \longrightarrow Cu^{2+} + OH^- \quad (3)$$

To generalize treatment the above reaction scheme is rewritten as

$$O + e^- \rightleftharpoons R, \quad (4)$$

$$R + A \xrightarrow{k} O + B, \quad (5)$$

$$R + B \longrightarrow O, \quad (6)$$

where O represents copper(II) ion, R copper(I) ion, A hydrogen peroxide, and B hydroxyl radical in a scheme of Reactions (1)—(3), and the current is controlled by the rate of Reaction (5). Partial differential equations for concentrations of species in Reactions (4)—(6) are given as follows:

$$\frac{\partial C_O}{\partial t} = D_O\left(\frac{\partial^2 C_O}{\partial r^2}\right) + \left(\frac{2}{r}D_O - u\right)\frac{\partial C_O}{\partial r} + 2kC_AC_R, \quad (7)$$

$$\frac{\partial C_R}{\partial t} = D_R\left(\frac{\partial^2 C_R}{\partial r^2}\right) + \left(\frac{2}{r}D_R - u\right)\frac{\partial C_R}{\partial r} - 2kC_AC_R, \quad (8)$$

and

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r} - kC_R C_A, \quad (9)$$

where C_h is the concentration of a species h, C^*_h its value in bulk solution, D_h the diffusion coefficient of the species h, r the distance from the center of the electrode mercury drop, and

$$u = m/(4\pi\rho r^2). \quad (10)$$

Here m is the flow rate of mercury, and ρ the density of mercury. It is assumed that the center of mercury drop remains fixed.

Initial conditions are

$$C_O = C^*_O, \quad C_A = C^*_A, \quad C_R = 0 \quad (t=0,\ r>0), \quad (11)$$

and boundary conditions are

$$C_O = 0,\ D_O\left(\frac{\partial C_O}{\partial r}\right) = -D_R\left(\frac{\partial C_R}{\partial r}\right),\ \left(\frac{\partial C_A}{\partial r}\right) = 0 \quad (t>0,\ r=a), \quad (12)$$

$$C_O = C^*_O,\ C_R = 0,\ C_A = C^*_A \quad (t>0,\ r=\infty). \quad (13)$$

The current, i, is given by

$$i = FD_O S(\partial C_O/\partial r)_{r=a}, \quad (14)$$

where a is the radius of the mercury drop, S the surface area of mercury drop, and F the Faraday constant. To facilitate calculation one introduces following transformations.

$$y_O = C_O/C^*_A,\ y_R = C_R/C^*_A,\ y_A = C_A/C^*_A,$$
$$x = (r-a)/L,\ d_O = D_O/D_A,\ d_R = D_R/D_A,$$
$$u' = m/(4\pi\rho a^2) \quad (15)$$

In the above L is the representative length. With the aid of Eq. 15, Eq. 7 is transformed as follows.

$$\frac{L^2}{D_A}\frac{\partial y_R}{\partial t} = d_R\frac{\partial^2 y_R}{\partial x^2} + \left\{\frac{2d_R}{x+a/L} + \frac{Lx(x+2a/L)u'}{D_A(x+a/L)^2}\right\}\frac{\partial y_R}{\partial x} - \frac{2L^2C^*_A}{D_A}ky_A y_R \quad (16)$$

Because the reaction proceeds in the neighborhood of the electrode surface, numerical results most desired are those in the proximity of the electrode surface. For this end, numerical integration of the differential equations is carried out more efficiently using a network, of which mesh is finer at near the electrode surface and becomes coarser with increasing the distance from the surface. Hence, one introduces a parameter given by

$$s = 1 - 1/(1+Hx), \quad (17)$$

where H is a constant.

Equation 16 is rewritten with the aid of Eq. 17.

$$\frac{\partial y_R}{\partial T} = d_R H^2(1-s)^4\frac{\partial^2 y_R}{\partial s^2} + \left\{\frac{2D_R}{x+a/L} + \frac{x(x+2a/L)}{(x+a/L)^2}U - 2d_R H(1-s)\right\}H(1-s)^2\frac{\partial C^*_A}{\partial s} - 2ky_R y_A, \quad (18)$$

where

$$T = D_A t/L^2,$$
$$K = L^2 C^*_A k/D_A, \quad (19)$$
$$U = Lu/D_A.$$

Equation 18 is solved by an implicit method of finite difference, Crank-Nicolson's method with some modifications.[14-16] If the domains of s and T are divided into equal intervals Δs and ΔT, respectively, the space and time coordinates are expressed as

$$s_i = i\Delta s,\ T_j = j\Delta T \quad (20)$$

$$x_i = i\Delta s/H(1+i\Delta s) \quad (21)$$

and the concentration $y_R(s,T)$ as

$$y_R(s,T) = y_R(i\Delta s, j\Delta T) = y_{R,i,j} \quad (22)$$

A finite-difference equation is derived from Eq. 18.

$$(E_{R,i}+\Delta TKy_{A,i,j+1})y_{R,i,j+1} = F_{R,i}y_{R,i+1,j+1} + G_{R,i}y_{R,i-1,j+1} + D_{R,i} - \Delta TKy_{A,i,j}y_{R,i,j} \quad (23)$$

Where

$$E_{R,i} = 1 + \frac{\Delta T}{\Delta s^2}d_R H^2(1-s_i)^4 \quad (24)$$

$$F_{R,i} = \frac{\Delta T}{2\Delta s}H(1-s_i)^2\left\{\frac{d_R H(1-s_i)^2}{\Delta s} + \frac{d_R}{x_i+a_{j+1}/L} + \frac{x_i(x_i+2a_{j+1}/L)}{2(x_i+a_{j+1}/L)^2}U_{j+1} - d_R H(1-s_i)\right\} \quad (25)$$

$$G_{R,i} = \frac{\Delta T}{2\Delta s}H(1-s_i)^2\left\{\frac{d_R(1-s_i)^2}{\Delta s} - \frac{d_R}{x_i+a_{j+1}/L} - \frac{x_i(x_i+2a_{j+1}/L)}{2(x_i+a_{j+1}/L)^2}U_{j+1} + d_R H(1-s_i)\right\} \quad (26)$$

$$D_{R,i} = F_{R,i}y_{R,i+1,j} + G_{A,i}y_{R,i-1,j} + \left\{1 - \frac{\Delta T}{\Delta s^2}d_R H^2(1-s_i)^4\right\}y_{R,i,j} \quad (27)$$

In much the same way the equations concerning with species A and O are transformed as follows.

$$E_{O,i}y_{O,i,j+1} = F_{O,i}y_{O,i+1,j+1} + G_{O,i}y_{A,i-1,j+1} + D_{O,i} + \Delta TK(y_{A,i,j+1}y_{R,i,j+1} + y_{A,i,j}y_{R,i,j}) \quad (28)$$

$$(E_{A,i}+\Delta TKy_{R,i,j+1}/2)y_{A,i,j+1} = F_{A,i}y_{A,i+1,j+1} + G_{A,i}y_{A,i-1,j+1} + D_{A,i} - \Delta TKy_{A,i,j}y_{R,i,j}/2 \quad (29)$$

Boundary conditions in finite-difference form are expressed in two alternative ways as shown in the following.

(i) The boundary condition $(D_O(\partial C_O/\partial r)_a=-D_R(\partial C_R/\partial r)_a)$ at the current time $(j+1)$ is expressed with concentrations at the nodes $(0,j+1)$, $(1,j+1)$, and $(2,j+1)$, and Eq. 30 is derived after some modifications.

$$y_{R,0,j+1} = -(4y_{R,1,j+1}-y_{R,2,j+1})/3-d_O(4y_{O,1,j+1} -y_{O,2,j+1}-3y_{O,0,j+1})/3d_R \quad (30)$$

The first derivative $(y'_{R,1j+1})$ of $y_{R,1j+1}$ is given as

$$y'_{R,1,j+1} = (y_{R,2,j+1}+4y_{R,1,j+1}-5y_{R,0,j+1} -2\Delta s y'_{R,0,j+1})/8\Delta s + (y_{R,2,j}+4y_{R,1,j} +5y_{R,0,j}-2\Delta s y'_{R,0,j})/8\Delta S, \quad (31)$$

where $y'_{R,0j+1}$ is calculated by

$$y'_{R,0,j+1} = \frac{4y_{R,1,j+1}-y_{R,2,j+1}-3y_{R,0,j+1}}{2\Delta s} = -\frac{d_O}{2\Delta s d_R}(4y_{O,1,j+1}-y_{O,2,j+1}-3y_{O,0,j+1}), \quad (32)$$

the second derivative $(y''_{R,1j+1})$ is written as

$$y''_{R,1,j+1} = (y_{R,2,j+1}-2y_{R,1,j+1}+y_{R,0,j+1})/2(\Delta s)^2 + (y_{R,2,j}-2y_{R,1,j}+y_{R,0,j})/2(\Delta S)^2. \quad (33)$$

Introduction of Eqs. 31—33 to Eq. 18 gives

$$\begin{aligned}(1+E-F+\Delta TKy_{A,1,j+1})y_{R,1,j+1} &= \\ (E/2-F/4)(y_{R,2,j+1}+y_{R,2,j}) &\\ +\ (E/2-5F/4)(y_{R,0,j+1}+y_{R,0,j}) &\\ +\ (1-E+F-\Delta TKy_{A,1,j})y_{R,1,j} &\\ -\ \Delta sF(y'_{R,0,j+1}+y'_{R,0,j})/2, & \quad (34)\end{aligned}$$

where

$$E = \Delta T d_R H^2(1-s_i)^4/(\Delta s)^2 \quad (35)$$

$$F = \frac{\Delta T}{\Delta s}H(1-s_i)^2\left\{\frac{d_R}{x_i+a_{j+1}/L} +\frac{x_i(x_i+2a_{j+1}/L)}{2(x_i+a_{j+1}/L)^2}U_{j+1}-d_RH(1-s_i)\right\}. \quad (36)$$

The value of $y_{R,1j+1}$ is calculated with Eq. 34.

(ii) The boundary conditions $(D_O(\partial C_O/\partial r)_a=-D_R(\partial C_R/\partial r)_a)$ is expressed with concentrations at nodes $(0,j+1)$, $(1,j+1)$, $(2,j+1)$, and $(3,j+1)$, and Eq. 37 is obtained with some modifications.

$$y_{R,0,j+1} = -(2y_{R,3,j+1}-9y_{R,2,j+1}+18y_{R,1,j+1})/11 -d_O(2y_{O,3,j+1}-9y_{O,2,j+1}+18y_{O,1,j+1} -11y_{O,0,j+1})/11d_R \quad (37)$$

The derivatives at $i=1$ are expressed as following equations.

$$y'_{R,1,j+1} = -(y_{R,3,j+1}-9y_{R,2,j+1}-9y_{R,1,j+1}+17y_{R,0,j+1} +6\Delta s y'_{R,0,j+1})/36\Delta s-(y_{R,3,j}-9y_{R,2,j} -9y_{R,1,j}+17y_{R,0,j}+6\Delta s y'_{R,0,j})/36\Delta S, \quad (38)$$

$$y''_{R,1,j+1} = (-2y_{R,3,j+1}+27y_{R,2,j+1}-54y_{R,1,j+1} +29y_{R,0,j+1}+6\Delta s y'_{R,0,j+1})/36(\Delta s)^2 +(-2y_{R,3,j}+27y_{R,2,j}-54y_{R,1,j} +29y_{R,0,j}+6\Delta s y'_{R,0,j})/36(\Delta S)^2, \quad (39)$$

$y'_{R,0j+1}$ in the above is calculated by

$$y'_{R,0,j+1} = (2y_{R,3,j+1}-9y_{R,2,j+1}+18y_{R,1,j+1} -11y_{R,0,j+1})/6\Delta s = -(d_O/6\Delta s d_R)(2y_{O,3,j+1}-9y_{O,2,j+1} +18y_{O,1,j+1}-11y_{O,0,j+1}). \quad (40)$$

Introduction of Eqs. 38—40 to Eq. 18 results

$$\begin{aligned}(1+3E/2-F/2+\Delta TKy_{A,1,j+1})y_{R,1,j+1} &= \\ (-E-F)(y_{R,3,j+1}+y_{R,3,j})/18 &\\ +\ (-3E/4+F/2)(y_{R,2,j+1}+y_{R,2,j}) &\\ +\ (1-3E/2+F/2-\Delta TKy_{A,1,j})y_{R,1,j} &\\ +\ (29E/36-17F/18)(y_{R,0,j+1}+y_{R,0,j}) &\\ +\ (E/6-F/3)\Delta s(y'_{R,0,j+1}+y'_{R,0,j}). & \quad (41)\end{aligned}$$

The value of $y_{R,1j+1}$ is calculated with Eq. 41.

It is, however, not possible to apply the method described above to the case where chemical kinetics terms are written with concentrations of second order or higher.

Morihara and Chen reported a procedure which makes possible to transform a higher order function to a linear function. Application of their procedure to the parenthesis in the right-hand side of Eq. 23 yields Eq. 42.[13]

$$y_{A,i,j+1}y_{R,i,j+1} + y_{A,i,j}y_{R,i,j} = y_{A,i,j+1}y_{R,i,j} + y_{A,i,j}y_{R,i,j+1} \quad (42)$$

Introduction of Eq. 42 to 28 gives

$$(E_{R,i}+\Delta TK_{A,i,j})y_{R,i,j+1} = F_{R,i}y_{R,i+1,j+1} + G_{R,i}y_{R,i-1,j+1} + D_{R,i} - \Delta TKy_{A,i,j+1}y_{R,i,j}. \quad (43)$$

In much the same way as Eq. 43 is derived from Eq. 23, Eq. 44 is resulted from Eq. 29.

$$(E_{A,i}+\Delta TK_{R,i,j}/2)y_{A,i,j+1} = F_{A,i}y_{A,i+1,j+1} + G_{A,i}y_{A,i-1,j+1} + D_{A,i}-\Delta TKy_{A,i,j+1}y_{R,i,j}/2 \quad (44)$$

Although Morihara-Chen's procedure is useful as shown above, it becomes powerless when it is applied to fractional order of reaction. Following two procedures are proposed to replace it in the case of fractional order of reaction.

The first of them is as follows. In this procedure, the value of concentrations in chemical kinetics terms in the $(n+1)$-th iteration are replaced with the values of concentrations resulted by n-th iteration. The concentrations at each successive repetitions are expressed as

$$(y_{A,i,j+1})_{n+1} = (y_{A,i,j+1})_n + \delta_1 \quad (45)$$

$$(y_{R,i,j+1})_{n+1} = (y_{R,i,j+1})_n + \delta_2, \quad (46)$$

where n is the number of iteration, and δ_1 and δ_2 are differences in successive iterations. If the values of δ_1 and δ_2 approach to zero with increasing n, the product of the left-hand sides of Eqs. 45 and 46 becomes

$$(y_{A,i,j+1})_{n+1}(y_{R,i,j+1})_{n+1} = (y_{A,i,j+1})_n(y_{R,i,j+1})_n. \quad (47)$$

Equation 47 shows that the value of left-hand side of Eq. 47 is known at the beginning of the $(n+1)$-th iteration. Introduction of Eq. 47 to Eqs. 23 and 29, and modification give following relations.

$$E_{R,i}(y_{R,i,j+1})_{n+1} = F_{R,i}(y_{R,i+1,j+1})_{n+1} + G_{R,i}(y_{R,i-1,j+1})_{n+1} + D_{R,i} - \Delta TKy_{A,i,j}y_{R,i,j} - \Delta TK(y_{A,i,j+1})_n(y_{R,i,j+1})_n \quad (48)$$

$$E_{A,i}(y_{A,i,j+1})_{n+1} = F_{A,i}(y_{A,i+1,j+1})_{n+1} + G_{A,i}(y_{A,i-1,j+1})_{n+1} + D_{A,i} - \Delta TKy_{A,i,j}y_{R,i,j}/2 - \Delta TK(y_{A,i,j+1})_n(y_{R,i,j+1})_n/2 \quad (49)$$

The second procedure is as follows. The values at $T+\Delta T$ may be replaced by the values at T if the rate constant of chemical reaction is not so large. Hence Eq. 42 is written as

$$y_{A,i,j+1}y_{R,i,j+1} + y_{A,i,j}y_{R,i,j} = 2y_{A,i,j}y_{R,i,j}. \quad (50)$$

Using the above relation Eqs. 23 and 29 are rewritten as

$$E_{R,i}y_{R,i,j+1} = F_{R,i}y_{R,i+1,j+1} + G_{R,i}y_{R,i-1,j+1} + D_{R,i} - 2\Delta TKy_{A,i,j}y_{R,i,j} \quad (51)$$

$$E_{A,i}y_{A,i,j+1} = F_{A,i}y_{A,i+1,j+1} + G_{A,i}y_{A,i-1,j+1} + D_{A,i} - \Delta TKy_{A,i,j}y_{R,i,j} \quad (52)$$

Three sets of equations (i.e. Eqs. 43 and 44, and Eqs. 48 and 49, and Eqs. 51 and 52) are derived in place of Eqs. 23 and 29. The latter two sets of equations are derived by new procedures of which dependability must be tested.

In order to establish the soundness of present numerical method, the method was applied first to reconfirm well-known relationships between the diffusion current and the concentration of depolarizer, and between the diffusion current and the height of mercury column. In this case the value of reaction rate constant is zero, and the boundary conditions are given as follows.

$$C_0 = C_0^* \quad (t=0,\ r>0) \quad (53)$$

$$C_0 = 0 \quad (t>0,\ r=a) \quad (54)$$

$$C_0 = C_0^* \quad (t>0,\ r=\infty) \quad (55)$$

Then the method was applied to a system of copper(II)–hydrogen peroxide system.

Experimental

All chemicals used were of reagent grade. The concentration of hydrogen peroxide in stock solution was determined by iodometry.[19] Stock solutions of cadmium(II) sulfate and copper(II) sulfate were made by dissolving weighed amounts of anhydrous salts. The solution of copper(I) ion was prepared by dissolving copper(I) chloride dissolved in 1.0 M† hydrochloric acid from which dissolved oxygen was expelled with bubbles of pure nitrogen. The concentration of copper(I) ion was determined from the diffusion current of copper(II) ion after the oxidation of copper(I) ion by pure oxygen.

Measurements of catalytic wave were carried out in the solution of 1.0 M HCl and 0.005% gelatin. An electrolysis cell with a hole of 0.5 mm in diameter at bottom of the cell was used to prevent contamination of mercury ions through oxidation of mercury collected on the bottom of the cell. A Hokuto Denko Model HA-104 Potentio-Galvanostat was used for application of potential with three-electrode arrangement. Catalytic currents were measured at the end of life of mercury drop. Measurements were carried out within 70 min after preparation of test solutions, in order to avoid the influence of their composition variation. The oxygen was expelled from test solutions with bubbling pure nitrogen through the solutions for 50 min. The diffusion coefficient of both reactants and products were determined from respective diffusion current. Measurements of diffusion currents were carried out in the same conditions as measurements of the catalytic wave, except the absence of the hydrogen peroxide.

The numerical computation in the present method was programmed with Gauss-Seidel method and succesive over relaxation method by using FORTRAN, and performed on a FACOM M382 computer in DATA PROCESSING CENTER KYOTO UNIVERSITY.

Results and Discussion

In order to confirm that the present method reproduces the relationship between the diffusion current and the concentration of depolarizer, the method was applied to the diffusion current of copper(II) ion in a solution of 1.0 M HCl and 0.005% gelatin. It was confirmed by computation that the diffusion current was proportional to the concentration of copper(II) ion, and that observed values of diffusion currents agreed with calculated ones. The value of diffusion coefficient used in the computation is taken from the Ref. 2.

Table 1 shows relation between the height of mercury column and the diffusion currents of copper(II) ion. Observed data agree with ones calculated.

The instantaneous current was also calculated with this method. The current-time curve of diffusion current is proportional to $t^{1/6}$ according to Ilkovic

† 1 M=1 mol dm^{-3}.

equation, to $t^{1/5.2}$ according to the equation introduced by Koutecky,[3] and to $t^{1/5.3}$ according to the present numerical method.

The soundness and the accuracy of this method was confirmed by above results that the observed relationships between the diffusion currents and the concentration of depolarizer and between the diffusion currents and the height of mercury column were both reproduced by the present method, and that a current-time curve of instantaneous current calculated with this method agrees with one calculated from Koutecky's equation.[3] Therefore it may be concluded that this method can be used for the aim of present study, theoretical analysis of the catalytic currents.

The chemical kinetic terms in finite-difference equations are expressed in four different forms. The first is expressed in Eqs. 23 and 29 which were derived by straight forward way, the second is shown in Eqs. 43—44 which were derived by using the procedure proposed by Morihara and Chen, and the third and fourth are respectively, expressed in Eqs. 48—49 and Eqs. 51—52 which were derived by the procedures proposed in the present paper. It is found that the numerical computation by using the fourth is more efficient than using others (see Appendex). The differences of four corresponding values obtained with using the four procedures were smaller than one per cent. Differences of converged values obtained with using various values of ΔT and ΔS were within the limits considered generally permissible. These facts show that the procedures proposed in the present study are dependable. Besides, it must be noted that proposed two procedures are applicable to chemical kinetics term with fractional orders. The boundary condition $(D_O(\partial C_O/\partial r)_a=-D_R(\partial C_R/\partial r)_a)$ is written in two forms. These are shown in Eqs. 30—34 and Eqs. 35—41. The former expresses the condition with using the values of functions at three nodes near the electrode surface, whereas the latter with using values at four nodes. It is found that the time consumed for numerical computation using the former is about twice as large as one consumed using the latter. Difference of two corresponding values computed by the two procedures are small and below the level of error considered generally permissible. Therefore it is concluded that the proposed numerical method for catalytic currents is dependable.

The values of diffusion coefficients used for numerical computations were chosen as ones which gave smallest differences between calculated currents and with observed ones. This procedure produced a value of 0.750×10^{-5} cm^2 s^{-1} for the diffusion coefficient of cadmium ion. This value agrees well with the value in the Ref. 2. Therefore the procedure is usable.

The method was applied to the catalytic current in the Cu^{2+}–H_2O_2 system. The diffusion currents of species participated in the catalytic current were measured in a solution of 1.0 M HCl and 0.005% gelatin. Table 2 shows values of diffusion coefficients, which were used for computation and gave best agreements of calculated diffusion currents with observed ones.

Table 1. Diffusion Current of 2.03 mM Cu(II) Ion in 1 M HCl and 0.01% Gelatin

Height of mercury column H / cm	Flow rate of mercury m / 10^{-3} g s^{-1}	Diffusion current i_d / μA	
		observed	calculated[a]
50	0.675	10.26	10.08
60	0.831	11.28	11.05
70	0.998	12.08	12.02
80	1.147	12.86	12.79
88	1.268	13.46	13.42

a) Values of parameters used for computation are as follows. $\Delta T=3.69\times10^{-4}$, $\Delta S=0.01$, and $L=0.01$ cm.

Table 2. Diffusion Current and Diffusion Coefficient

	i_d/C / μA mM^{-1}	T[a] / s	D / 10^{-5} cm^2 s^{-1}	D[c] / 10^{-5} cm^2 s^{-1}
Cu^{2+}	6.40	5.62	0.720	0.72
Cu^{+}	4.68	5.14	1.502	—
H_2O_2	8.95[b]	4.68	1.420	—

a) Dropping time at a potential corresponding to the diffusion current plateau. b) The diffusion current was measured in a solution of 1.0 M $NaNO_3$ and 0.005% gelatin, because it was partly obscured by hydrogen discharge wave in a solution of 1.0 M HCl and 0.005 % gelatin. c) These value are quoted from the Ref. 2.

Table 3. Reaction Rate calculated from Koutecky's Method and Numerical Method in 2.03 mM Cu^{2+}, 1.0 M HCl, and 0.01% Gelatin

$[H_2O_2]$ / mM	i_l/i_d	k / l mol^{-1} s^{-1}	
		Koutecky's method	Present method[a]
2.18	1.396	131.8	55.0
5.45	1.986	106.8	55.0
10.9	2.398	77.3	55.0
21.8	3.121	65.9	55.0
43.6	4.236	60.7	55.0
76.3	5.478	58.0	55.0
109.0	6.274	53.3	55.0
141.7	7.197	53.9	55.0

a) Values of parameters used for computation are as follows. $\Delta T=3.69\times10^{-4}$, $\Delta S=0.01$, and $L=0.01$ cm.

Table 3 shows that the catalytic currents and the reaction rate constants, calculated by Kouteckey's method and the present method. The value of reaction rate constant of Reaction (2) was given as 55.0 ± 0.5 l mol^{-1} s by which gave best agreements between calculated catalytic currents and observed ones. The value calculated with Koutecky's method[17] decreases with increasing concentration of hydrogen peroxide.

Table 4 shows that variation of the catalytic current with increase of the height of mercury column. The present method gives the same value of reaction rate constant as ones in Table 3. But the value calculated with Koutecky's method increases with increase of the height of mercury column.

From the numerical computation for the catalytic wave, it was found that the value of the reaction rate constant is 55.0 l mol^{-1} s as shown in Tables 3 and 4. This value differs from one reported by Kolthoff and Woods.[18] But in their paper, the rate constant of oxidation of copper(I) by hydrogen peroxide in chloride medium, was determined by observing increase of the cathodic wave of copper(II) ion with time. They gave a value of 58 l mol^{-1} s which agrees with the result of the present study.

Figure 1 shows that the relation between the ratio of the catalytic current to the diffusion current of copper(II) ion (i_l/i_d) and the concentration of hydrogen peroxide. It shows that the observed point are on the calculated curve.

The relation between the ratio (i_l/i_d) and the height of mercury column is shown in Fig. 2, where observed points are on the calculated curve.

The value of the rate constant calculated by Koutecky's method decreases with increasing concentration of hydrogen peroxide. This is explained as follows. In the Koutecky's method, it is assumed that the concentration of hydrogen peroxide in the reaction layer is same as to that in the bulk solution. However, that is not the case.

On the contrary the present method gives the only one value for reaction rate constant which is consistent with all experimental data.

Conclusion

A new numerical method is proposed for numerical solution of diffusion equations with chemical kinetics

a) Values of parameters used for computation are as follows. $\Delta T=3.69\times10^{-4}$, $\Delta S=0.01$, and $L=0.01$ cm.

terms, and is established as a useful tool for theoretical analysis of the catalytic current. Diffusion equations with chemical kinetic terms are transformed to finite-difference equations using the implicit method of Crank-Nicolson. New two procedures are proposed for the purpose of rewriting chemical kinetics terms. These are applicable even to chemical kinetics terms with fractional order. The boundary condition $(D_O(\partial C_O/\partial r)_a=-D_R(\partial C_R/\partial r)_a)$ is written in two forms. The one expresses the boundary condition with the values of functions at three nodes near the electrode surface, whereas the other with the values of four nodes. It is found that the time consumed for numerical computation using former is about twice as large as one consumed using latter. The dependability of these procedures is proved through comparison of values of functions obtained with one obtained using other procedures.

Appendix

Differences between calculated values of the catalytic current were within ±0.3%, irrespective of computational procedures used for chemical kinetics terms, when values of ΔT, ΔS, and L were, respectively, 0.369×10^{-14}, 0.01, and 0.01 cm. Times consumed for computations were 5.01, 5.86, 5.12, and 3.56 s with first, second, third, and fourth procedures, respectively. These values show that the fourth procedure is most efficient.

The author wish to express his thanks to Professor Teisuke Murayama of Faculty of Engineering, Shizuoka University for his helpful discussion.

(Received August 30, 1986)

The structural diagnosis and lattice dynamics of three complexes, $\{[R_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$ (R=Me, Bu(*n*-Bu), or Ph), $\{[R_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$ (R=Me, Bu, or Ph), and $\{[R_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ (R=Bu or Ph) have been undertaken by means of ^{57}Fe-, ^{119}Sn-, and ^{197}Au-Mössbauer spectroscopic techniques. The Mössbauer parameters for the complexes indicate that all the tin atoms are coordinated with three alkyl or aryl groups and two cyano groups having a trigonal-bipyramidal structure. The asymmetry of the quadrupole split-peak intensity observed in the ^{119}Sn-Mössbauer spectra for the complexes was attributed to the anisotropic mean square vibrational amplitude with respect to a molecular symmetry axis. The temperature dependence of the recoil-free fraction of the ^{119}Sn-Mössbauer atom shows that the mean-square vibrational amplitude of tin atoms in the complexes falls in the range of values found for a number of one-dimensional organotin polymers. In ^{57}Fe-Mössbauer spectroscopy, the quadrupole splitting for $\{[Bu_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ rapidly decreases with an increase in the temperature, reflecting small separations among the three d_ε levels in energy. The very large ^{197}Au-quadrupole splitting for $\{[R_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$ was explained by assuming strong σ-donating and π-accepting properties of the CN ligand.

Recently, Uson et al. synthesized various kinds of trialkyl- and triaryltin complexes of transition metal cyanides by treating the trialkyl- or triaryltin perchlorates with several cyano compounds of transition metals.[1] If the reaction with anionic dicyano compounds, such as $K[Au(CN)_2]$ and $Bu_4N[Ag(CN)_2]$, is carried out, the reaction products can be expected to have an infinite one-dimensional polymeric structure. On the other hand, the reaction with the square-planar coordinated palladium or platinum cyanides can be expected to give polymer complexes which are assumed to have an infinite two-dimensional structure. In the case of the reaction with $K_3[Fe(CN)_6]$, three-dimensional polymer products will be obtained.

On the basis of the IR spectra of those complexes, Uson et al. proposed that, in every case, the tin atoms are five-coordinated with three alkyl or aryl groups in the equatorial position and two cyano groups in the axial position of a trigonal-bipyramidal and that the tin and the transition metal are bridged by a cyano group.

Mössbauer spectroscopy can provide valuable information about the nature of chemical bonding and the structures of compounds containing "Mössbauer-active atoms," such as tin, iron, and gold, because Mössbauer parameters are very sensitive to the number and nature of ligands coordinated to the Mössbauer atoms.[2-4] Especially, ^{197}Au-Mössbauer spectroscopy is one of the most powerful techniques in the structural diagnosis of the gold compounds. In the present study, ^{57}Fe-, ^{119}Sn-, and ^{197}Au-Mössbauer spectroscopic studies have been undertaken in order to examine the coordination for the iron, tin, and gold atoms and to elucidate the lattice dynamical properties of tin and iron sites in the trialkyl- and triaryltin complexes of transition metal cyanides, such as $\{[R_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$ and $\{[R_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$ (R=Me, Bu, or Ph), and $\{[R_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ (R=Bu or Ph).

Experimental

Materials. All the complexes investigated were prepared by the following method, described in a reference.[1] Organotin perchlorates R_3SnClO_4 (R=Me, Bu, or Ph) were prepared in acetone by treating stoichiometric amounts of the corresponding organotin chloride, R_3SnCl, with $AgClO_4$. The filtrate was used for further reactions without any other treatment. The $\{[R_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$ complexes (R=Me, Bu, or Ph) were obtained by treating a solution of $K[Au(CN)_2]$ (3 mmol) in acetone with an equimolar amount of R_3SnClO_4. The precipitates were filtered off and washed with a mixture of water and acetone. The $\{[R_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$ (R=Me, Bu, or Ph) complexes were prepared by the same procedure using 3 mmol of $K_2[Pt(CN)_4]$ and 6 mmol of R_3SnClO_4. The precipitates were washed with acetone and then hexane. The $\{[R_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ (R=Bu or Ph) complexes were also prepared as has been described above by treating 3 mmol of $K_3[Fe(CN)_6]$ with 9 mmol of R_3SnClO_4. The products were washed with acetone. The purity of the complexes was confirmed by elemental analyses for C, H, and N.

Mössbauer Spectroscopic Measurements. The temperature-dependent Mössbauer-effect measurements for ^{57}Fe and ^{119}Sn were carried out by using a constant-acceleration-type spectrometer over the temperature range of 78 K$\leq T\leq$300 K. Most of the ^{119}Sn-Mössbauer spectroscopic measurements were carried out from 78 to about 200 K, since the recoil-free fraction of the complexes becomes too small to be measured at high temperatures. The temperature of the absorber was controlled within $\pm$0.5 K. ^{197}Au-Mössbauer spectroscopic measurements were carried out with a source and an

absorber, both cooled to 16 K by using a constant-acceleration-type spectrometer in connection with a pure-Ge diode detector. The details of the ^{197}Au-Mössbauer spectroscopy have been described elsewhere.[5]

The spectra observed were fitted with Lorentian-line shapes by using the least-squares fitting procedure. The velocity scale was calibrated by using a metallic iron-foil spectrum. The isomer shifts of the ^{57}Fe and ^{119}Sn spectra are reported with respect to α-Fe and $BaSnO_3$ resonances respectively at room temperature. All the isomer shifts of the ^{197}Au-Mössbauer spectra are referred to metallic gold at 16 K.

Results and Discussion

^{119}Sn-Mössbauer Spectra. Some typical ^{119}Sn-Mössbauer spectra obtained at 78 K are shown in Fig. 1 for $\{[R_3Sn](\mu\text{-CN})[Au(\mu\text{-CN})]\}_x$ (R=Me, Bu, or Ph), while the Mössbauer parameters, such as the isomer shift (*IS*), the quadrupole splitting (*QS*), and the half-width (Γ_{exp}), derived from the observed spectra are summarized in Table 1. The spectra observed consist of one doublet with relatively large *QS* values, as may be seen in Fig. 1.

In ^{119}Sn-Mössbauer spectroscopy, the major variation in the *QS* values observed can be attributed to the difference in the structural change. The range of *QS* values for organotin compounds can be classified into the following four groups:[6] 1) tetrahedral R_nSnX_{4-n} (n=1—3) [0.00—2.31 mm s^{-1}], 2) octahedral *cis*-R_2SnX_4 [1.63—2.34 mm s^{-1}], 3) trigonal-bipyramidal R_3SnX_2 (X axial) [2.76—3.86 mm s^{-1}], and 4) octahedral *trans*-R_2SnX_4 [3.37—4.32 mm s^{-1}]. On the basis of this criterion, the tin atoms in the complexes under discussion can be concluded to have a five-coordinated structure, in which the tin atom is bridged by a CN group. This result is in good agreement with the hypothetical conclusion proposed by Uson et al.[1] for the coordination state of tin atoms in the same compounds.

The *QS* values for Ph_3Sn derivatives are smaller than those of the corresponding Me_3Sn or Bu_3Sn derivatives. The decrease in the *QS* values for the Ph_3Sn derivatives can be explained by the greater partial *QS* value assigned to the phenyl group compared to that of the alkyl group. The same tendency was observed for various kinds of organotin compounds containing the phenyl group.[6]

The temperature dependence of the quadrupole splitting is negligible in every case, since the *QS* for organotin(IV) compounds arises from mainly an inequality in the nature of the tin-ligand bonds, which is temperature-independent. However, the intensity asymmetry of the quadrupole line and its temperature dependence were observed, as is shown in

Fig. 2 for $\{[Bu_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$. This asymmetry is commonly found in one- and two-dimensional polymeric compounds.[7] The temperature dependences of intensity asymmetry observed in other complexes are summarized graphically in Fig. 3, where R is the ratio of the areal intensity, A_+, of the resonance peak at the higher velocity to that, A_-, of the peak at the lower velocity.

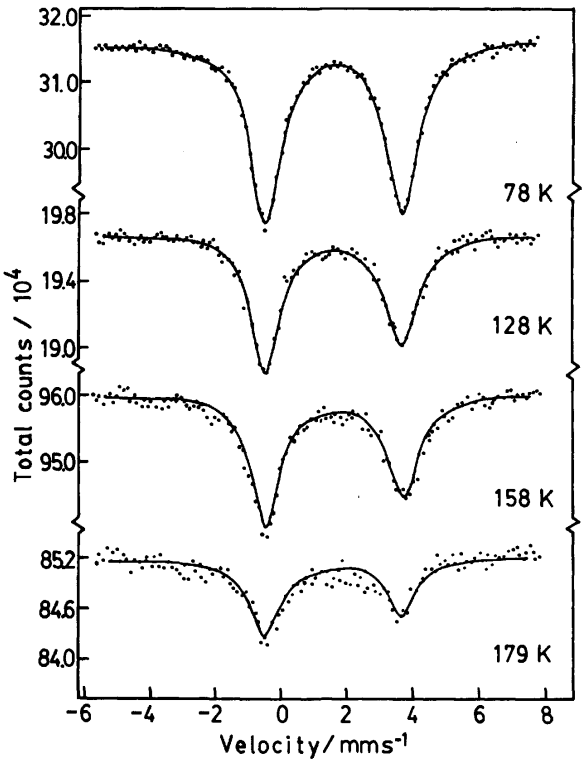

Fig. 2. ^{119}Sn-Mössbauer spectra for $\{[Bu_3Sn]_2[(\mu\text{-}NC)_4\text{-}Pt]\}_x$ at various temperatures.

The intensity asymmetry has been theoretically expressed as a function of the difference in the mean-square vibrational amplitude parallel and perpendicular with respect to the principal axis of the electric-field gradient (EFG) tensor:[8]

$$R' = \frac{I(\pm 1/2 \leftrightarrow \pm 3/2)}{I(\pm 1/2 \leftrightarrow \pm 1/2)} = \frac{\int_0^{\pi} \exp\{-(1/\lambda^2)[\langle z^2\rangle - \langle x^2\rangle]\cos^2\theta\}(1+\cos^2\theta)\sin\theta d\theta}{\int_0^{\pi} \exp\{-(1/\lambda^2)[\langle z^2\rangle - \langle x^2\rangle]\cos^2\theta\}(5/3-\cos^2\theta)\sin\theta d\theta}, \quad (1)$$

where $\langle z^2\rangle$ and $\langle x^2\rangle$ are the mean square vibrational amplitudes parallel and perpendicular respectively to the principal axis of the EFG tensor.

The more intense line can be assigned to the $\pm 1/2 \leftrightarrow \pm 3/2$ transition by assuming that the difference in $[\langle z^2\rangle - \langle x^2\rangle]$ is negative, i.e., that the vibrational motion of the tin atom in the plane of R_3Sn is larger than that along the molecular symmetry axis corresponding to the CN-Sn-NC chain. Thus, the observed intensity asymmetry suggests that the sign of the quadrupole coupling constant, e^2qQ, is negative; that is, the electric-charge distribution around a tin atom can be described as being oblate with respect to the polymer axis. This result is consistent with those for organotin compounds which have tin atoms five-coordinated in a one-dimensional chain structure in a solid.[7,9-11]

The observed intensity asymmetry R shown in Fig.

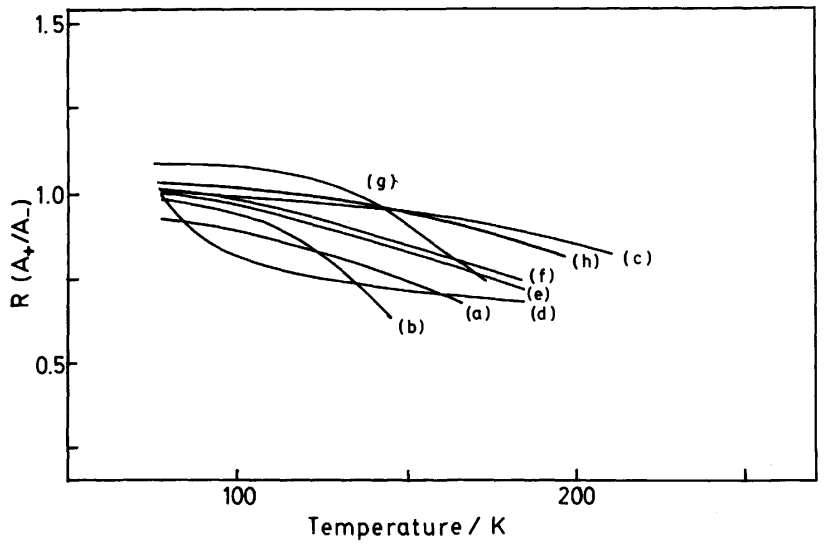

Fig. 3. Temperature dependences of peak intensity ratio for trialkyl- and triaryltin complexes of transition metal cyanides; (a) $\{[Me_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$, (b) $\{[Bu_3Sn](\mu\text{-}CN)[Au(\mu\text{-}CN)]\}_x$, (c) $\{[Ph_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$, (d) $\{[Me_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$, (e) $\{[Bu_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$, (f) $\{[Ph_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$, (g) $\{[Bu_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$, and (h) $\{[Ph_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$.

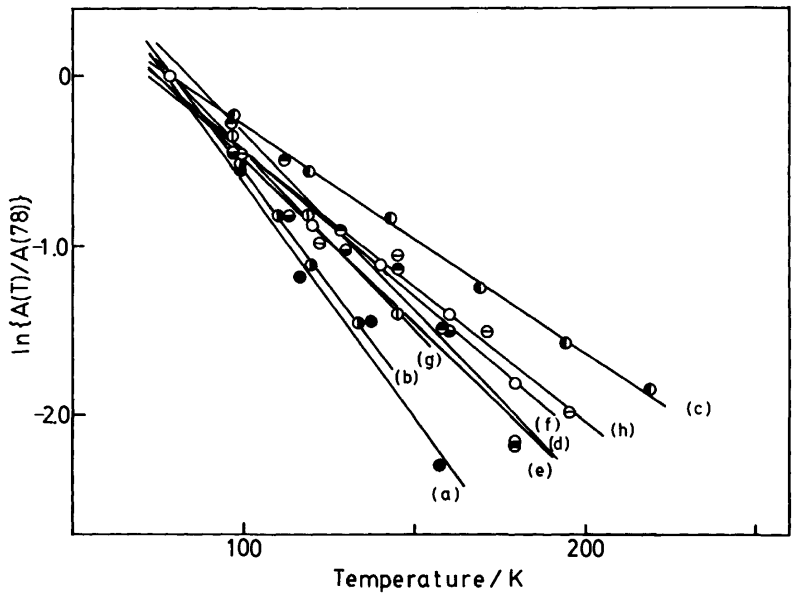

Fig. 4. Temperature dependences of the area under ^{119}Sn-resonance line for (a) $\{[Me_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$, (b) $\{[Bu_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$, (c) $\{[Ph_3Sn](\mu\text{-}NC)[Au(\mu\text{-}CN)]\}_x$, (d) $\{[Me_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$, (e) $\{[Bu_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$, (f) $\{[Ph_3Sn]_2[(\mu\text{-}NC)_4Pt]\}_x$, (g) $\{[Bu_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$, and (h) $\{[Ph_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$.

3 is inversely proportional to the ratio R' in Eq. 1. All the R values decrease with an increase in the temperature. This means that the mean-square vibrational amplitude in the direction perpendicular to the polymer axis depends significantly on the temperature. The temperature dependence of R for Ph_3Sn derivatives is smaller than those for Me_3Sn and Bu_3Sn derivatives. This result can be explained by assuming that the steric effect of the bulky phenyl group restricts the motion of the tin atom.

The recoil-free fraction, f_a, and its temperature dependence provide useful information about the lattice dynamical properties of a solid which are associated with the motion of Mössbauer atoms. The temperature dependences of the area under the resonance line are shown in Fig. 4 for the complexes studied in this work.

According to the Debye approximation at high temperatures, the "relative" values of the recoil-free fraction, f_a, are expressed as:

$$f_a = \exp\left(\frac{-3E_\gamma^2 T}{Mc^2k\theta^2}\right), \tag{2}$$

where E_γ is the energy of the Mössbauer transition, θ is the Debye temperature, M is the effective vibrating mass, and k is the Boltzmann constant. The temperature dependence of the recoil-free fraction, f_a, is given by Eq. 3:

$$\frac{d\ln f_a}{dT} = \frac{-3E_\gamma^2}{Mc^2k\theta^2}. \tag{3}$$

Noting that $k\theta/h=\nu_{max}\propto(\alpha/M)^{1/2}$, the following equation is obtained for the parameter of the intermolecular force constant, α:

$$\alpha \propto \theta^2M = \frac{-3E_\gamma^2}{kc^2}\left[\frac{d\ln f_a}{dT}\right]^{-1}, \tag{4}$$

where ν_{max} is the maximum lattice frequency, which is assumed to be equal to the Debye cut-off frequency, and where h is the Planck constant. The coefficient of the temperature-dependent term, $d\ln f_a/dT$, in Eq. 4 can be replaced for a "thin" absorber by the observed temperature dependence of the areal intensity under the resonance line (normalized to 78 K point).

It was found in our previous study that there was a distribution of the θ^2M values with respect to the state of molecular association in a solid.[12] The values of $\theta^2M/10^6$ deg^2 amu are distributed around unity for a non-polymeric compound, while those of one-dimensional and two-dimensional polymeric compound are distributed around 1.3 and 1.7 respectively. The distribution of the θ^2M values for three-dimensional polymeric compounds may be beyond the value of the two-dimensional polymer. The distribution of the parameters can be used to determine the state of intermolecular association in a solid. Although much overlapping is observed between the non-polymeric compounds and one-dimensional polymeric compounds, and between the one-dimensional and two-dimensional polymers, the discrimination between the nonassociated and one-dimensional polymeric states and between two- and three-dimensional polymeric states can be done by detecting the asymmetric quadrupole split lines, as has been mentioned previously.

The values of θ^2M, as estimated from the data of the

temperature dependence of the area for the complexes, are summarized in Table 1. Although the $\{[R_3Sn]_2[(\mu\text{-}NC)_4Pt]\}$ and $\{[R_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ complexes are considered to be two- or three-dimensional polymer complexes, the values of θ^2M in Table 1 suggest that the state of molecular association for these complexes is close to that of non-polymeric compounds or one-dimensional polymers. The values of θ^2M for Me_3Sn and Bu_3Sn derivatives are smaller than those for Ph_3Sn derivatives in each series. This means that the motion of tin atoms in these complexes depends mainly on the ligands in the first coordination sphere of tin atoms. A large temperature dependence of the mean-square vibrational amplitude perpendicular to the polymer axis strongly affects the values of θ^2M. The relatively large values of θ^2M for Ph_3Sn derivatives presumably reflect the restriction on the motion of tin atoms attributable to the bulky phenyl group, which is packed rigidly in a solid. The same tendency was observed for R_4Sn compounds; e.g., the value of θ^2M for Me_4Sn is 0.77×10^6, while that for Ph_4Sn is 1.28×10^6.[12] Consequently, a comparison of the parameters of the intermolecular force constant, $\alpha \propto \theta^2M$, gives valuable information about the motion of tin atoms associated in a solid.

^{57}Fe-Mössbauer Spectra. The ^{57}Fe-Mössbauer spectra and their temperature dependence for $\{[Bu_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ are shown in Fig. 5, while the Mössbauer parameters derived from the observed spectra are listed in Table 2. The values of *IS* and *QS* and the temperature dependence of *QS* indicate that the iron atom in this complex is at an Fe(III) low-spin state. The temperature dependences of *QS* for $\{[Bu_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ and $\{[Ph_3Sn]_3[(\mu\text{-}NC)_6Fe]\}_x$ are shown in Fig. 6.

A low-spin Fe(III) atom has a nonspheric d shell. The contribution of this configuration to the EFG

a) Relative to Au foil; ± 0.04 mm s^{-1}. b) ± 0.04 mm s^{-1}.

depends on the symmetry of the external field and the temperature. A large temperature dependence of *QS* for the Bu_3Sn derivative indicates that the three d_ε levels are close to each other in energy. The environment around iron(III) atoms is assumed to be almost cubic. On the other hand, the decrease in the *QS* for the Ph_3Sn derivative is slow. This can be explained by assuming that the three d_ε levels are widely separated as a result of the distortion of $Fe(CN)_6$ octahedra caused by the steric hindrance of bulky phenyl groups.

The values of $\theta^2M/10^6$ for ^{57}Fe estimated by using Eq. 4 are 0.97 and 1.63 for Bu_3Sn and Ph_3Sn derivatives respectively. These values are smaller than those expected for three-dimensional polymeric compounds. This result reflects the linkage of a long CN–Sn–NC chain, which probably reduces the motional rigidity of the iron atoms in these complexes. The fact that the value for the Ph_3Sn derivative is larger than that for the Bu_3Sn derivative can be explained by the same interpretation as has been proposed for the case of ^{119}Sn, that is, the motion of the iron atom is restrained by the steric effect of bulky phenyl groups. The similarity between the values of θ^2M of ^{57}Fe and those of ^{119}Sn for $\{[Bu_3Sn]_3[(\mu\text{-NC})_6Fe]\}_x$ and $\{[Ph_3Sn]_3[(\mu\text{-NC})_6Fe]\}_x$ respectively suggests that the motion of iron atoms depends on that of tin atoms in these complexes.

^{197}Au-Mössbauer Spectroscopy. The ^{197}Au-Mössbauer spectra for the $\{[R_3Sn](\mu\text{-NC})[Au(\mu\text{-CN})]\}_x$ complexes (R=Me, Bu, or Ph) consist of one doublet with quite large *QS* values. The Mössbauer parameters derived from the spectra are summarized in Table 3. The values of *IS* and *QS* for these complexes are very close to those of $K[Au(CN)_2]$.[13]

In linear gold(I) compounds, the $5d_{z^2}$, 6s, and $6p_z$ metal orbitals (the z axis being the molecular axis) are suitable for σ-bonding, while the $5d_{xz,yz}$ and $6p_{x,y}$ orbitals are used in π-bonding to the ligands. The $5d_{xy}$ and $5d_{x^2-y^2}$ orbitals are nonbonding. σ-Donation into the $5d_{z^2}$ and $6p_z$ orbitals is expected to contribute negatively to the quadrupole coupling constant, e^2qQ. The absolute value of e^2qQ might be expected to increase the σ-donor strength of the ligands, assuming that the sign of e^2qQ for the two coordinated gold(I) compounds is negative. The negative e^2qQ has been confirmed experimentally for $K[Au(CN)_2]$.[14] π-Bonding and d_π-back-bonding also affect the e^2qQ, but their contribution is estimated to be smaller than that of σ-donor bonding on the basis of theoretical considerations[15,16] and systematic ^{197}Au-Mössbauer studies of many gold(I) compounds.[17–20] Thus, it is reasonable to conclude that the *QS* values mainly depend on the σ-donating ability of the ligands. On the other hand, it has been known that the *IS* value depends on the s electron density at the gold nucleus. The 6s population directly increases the electron density at the nucleus, while the $5d_{z^2}$ and $6p_z$ populations decrease the electron density because of their shielding effect. The shielding effect of 5d electrons is larger than that of 6p electrons. The d_π-back-bonding reduces the d electrons and then increases the electron density at the ^{197}Au nucleus. Increases in the s electron density at the nucleus lead to the increase in the *IS* value because of the positive $\Delta R/R$ in ^{197}Au-Mössbauer spectroscopy. Hence, both the *QS* and *IS* values depend on the σ-donating and π-accepting ability of the ligands. A linear relationship between the observed *IS* and *QS* values has been established for many gold(I) compounds.[18,20,21]

The values of *IS* and *QS* for the gold(I) compounds with a CN group are expected to be larger than those for other gold(I) compounds. This expectation is confirmed by the observed large *IS* and *QS* values for $\{[R_3Sn](\mu\text{-NC})[Au(\mu\text{-CN})]\}_x$ complexes. It can be concluded that the gold atom in these complexes is coordinated linearly with two cyano groups and forms an infinite one-dimensional polymeric structure.

(Received September 12, 1986)

The Raman spectra of the tris(bidentate)cobalt(III) complexes containing the six-membered tn and/or β-ala chelate ring, where tn and β-ala denote 1,3-propanediamine and β-alaninate respectively, were measured in order to investigate the relation between the Raman spectra and the structures of the complexes. The Raman bands can be classified into four vibration modes: A totally symmetric stretching vibration mode in the 440—640 cm^{-1} region, a stretching vibration mode excluding the totally symmetric one in the 380—480 cm^{-1} region, a metal-ligand skeletal bending deformation mode in the 260—400 cm^{-1} region, and a chelate ring deformation mode in the 220—290 cm^{-1} region. The present complexes characteristically exhibited more Raman bands than the complexes with the five-membered chelate rings in the totally symmetric stretching vibration mode. For the $[Co(\beta\text{-ala})_2(tn)]^+$ complex, the three geometrical isomers, *trans(O)*, C_2-*cis(O)*, and C_1-*cis(O)*, which were prepared for the first time, each exhibited characteristic Raman spectral features.

Recently, it has been recognized that the configurational structural characteristics of metal complexes are sensitively reflected on the skeletal vibrations rather than on the intra-ligand vibrations of the Raman spectra. For instance, the Raman spectra of the nitro-ammine series of the cobalt(III) complexes, $[Co(NO_2)_n(NH_3)_{6-n}]$-type,[1] have been studied in order to establish the assignments of the skeletal vibrations. Further, the Raman spectra in the skeletal vibration region have been applied successfully to the differentiation of the geometrical isomers of various sorts of cobalt(III) complexes with unidentate ligands and of mixed complexes with unidentate and bidentate ligands.[2,3] In our previous work, the Raman spectra of the $[Co(gly)_x(ox)_y(en)_z]$-type[4] and $[Co(ida)_n(dien)_{2-n}]$-type complexes,[5] where gly, ox, en, ida, and dien denote glycinate, oxalate, 1,2-ethanediamine, iminodiacetate, and diethylenetriamine respectively, have been measured in order to find general information on the relation between the spectra and the structures of these complexes in the skeletal vibration region.

The present work was undertaken on the tris(bidentate)cobalt(III) complexes containing 1,3-propanediamine (tn) and/or β-alaninate (β-ala) in order to investigate the relation between the Raman spectral characteristics in the 200—700 cm^{-1} region and the structures of the complexes.

Experimental

Complexes. The complexes were prepared and characterized according to the literature procedures except for $[Co(\beta\text{-ala})_2(tn)]Cl$ (vide infra): $[Co(en)_2(tn)]Br_3$,[6] $[Co(en)(tn)_2]Br_3$,[6] $[Co(tn)_3]Cl_3$,[7] $[Co(gly)(tn)_2]Cl_2$,[8] $[Co(\beta\text{-ala})(en)_2]Cl_2$,[9] *trans*(O)-$[Co(\beta\text{-ala})_2(en)]Cl$,[9] *fac(N)*-$[Co(\beta\text{-ala})_3]$,[10] and *mer(N)*-$[Co(\beta\text{-ala})_3]$.[10]

$[Co(\beta\text{-ala})_2(tn)]Cl$. This complex was prepared by a procedure similar to that used for $[Co(gly)_2(en)]Cl$.[11] A solution containing 1.7 cm^3 of 1,3-propanediamine and 3.6 g of β-alanine in 15 cm^3 of water was added to a solution containing 5 g of cobalt(II) chloride hexahydrate in 10 cm^3 of water. The solution was oxidized over a steam bath by gradually adding 10 g of lead dioxide for 1 h. After it had then been cooled to room temperature, the mixture was filtered. The filtrate was poured onto a column of SP-Sephadex C-25 (Na^+ form, 3.5 cm×60 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.05 mol dm^{-3} aqueous solution of NaCl. Three colored bands, violet (A-1), pink (A-2), and red-violet (A-3), were eluted in this order; they were present in a ratio of about A-1:A-2:A-3=1.6:1.4:3.5. Each eluate was concentrated to a small volume by the use of a rotary evaporator below 30 °C, and the deposited NaCl was filtered off. The filtrate was passed through a column of Sephadex G-10 (3 cm×50 cm) by means of elution with water. A small amount of ethanol was added to the eluate after its concentration again. The precipitate which appeared was collected by filtration. Found for A-1: C, 28.76; H, 6.51; N, 14.89%. Calcd for $[Co(\beta\text{-ala})_2(tn)]Cl\cdot 5/4H_2O\cdot 1/7NaCl = CoC_9H_{22}N_4O_4Cl\cdot 5/4H_2O\cdot 1/7NaCl$: C, 28.78; H, 6.58; N, 14.92%. Found for A-2: C, 26.24; H, 6.17; N, 13.57%. Calcd for $[Co(\beta\text{-ala})_2(tn)]Cl\cdot 3/2H_2O\cdot 5/8NaCl$: C, 26.48; H, 6.17; N, 13.72%. Found for A-3: C, 29.18; H, 6.45; N, 15.22%. Calcd for $[Co(\beta\text{-ala})_2(tn)]Cl\cdot 1/2H_2O\cdot 1/4NaCl$: C, 29.35; H, 6.30; N, 15.21%. Absorp. max. $10^{-3}\sigma/cm^{-1}$ (log ε): A-1: 18.1 (2.17), 21.5sh (1.88), 27.3 (2.12); A-2: 19.9 (2.07), 27.6 (1.95); A-3: 19.3 (2.17), 27.4 (1.99). ^{13}C NMR: A-2: δ=27.8, 36.0, 40.3, 40.7, 184.8; A-3: δ=28.0, 36.0, 36.2, 40.0, 40.4, 40.6, 182.1, 185.2. On the basis of the absorption spectra of *trans(O)*-, C_2-*cis(O)*-, and C_1-*cis(O)*-$[Co(gly)_2(en)]^+$,[11] it was found from their absorption spectra that the A-1 eluate contained the trans(O) isomer, and the A-2 and A-3 eluates, cis(O) isomers. Further, from the ^{13}C NMR spectral measurements, it was found that A-2 and A-3 eluates contained C_2-cis(O) and C_1-cis(O) isomers respectively.

Measurements. The Raman spectra were recorded on a JASCO Laser Raman Spectrometer, which was constructed specially with a double monochromator, model CT-25, a He–Ne laser, model NEC GLG-8500, and a data processor, model DP-500, as the main components. The sample solution was excited at 632.8 nm, and the Raman spectra were calibrated with indene. The electronic absorption

spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the ^1H and ^{13}C NMR spectra were recorded in deuterium oxide on a JEOL JNM-FX-100 NMR spectrometer at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as the internal reference.

Results and Discussion

The Raman spectral data in the skeletal vibration region of the tris(bidentate)cobalt(III) complexes containing the six-membered tn and/or β-ala chelate ring are summarized in Table 1, together with those of $[Co(gly)_n(en)_{3-n}]^{(3-n)+}$ and $[Co(NH_3)_6]^{3+}$. There is a significant distinction between the Raman spectral characteristics of the cobalt(III) complexes containing the six-membered chelate ring and those with the five-membered rings; on going from the latter to the former, the number of the Raman bands is increased, and the bands are shifted to lower frequencies (vide infra). For instance, the Raman spectrum of $[Co(en)_3]^{3+}$ exhibits four major low frequency lines, which were assigned to the stretching and bending deformation modes ($A_{1g}+E_g+T_{2g}$ with the effective symmetry of O_h) and to the chelate ring deformation mode on the basis of a comparison with the skeletal vibrations of $[Co(NH_3)_6]^{3+}$,[4,12] whereas the spectrum of $[Co(tn)_3]^{3+}$ exhibits eight Raman bands. The increase in the number of Raman bands reflects the difference between tn and en chelate rings, and it is expected that the Raman bands of $[Co(tn)_3]^{3+}$ can be treated in terms of a molecular symmetry slightly lower than the true one, $D_3(3A_1+5E)$, which is determined by the configuration of the chelate rings. Above all, the 451 cm^{-1} band (strong and polarized) and the 431 cm^{-1} band (shoulder and depolarized) can be assigned to A_1 (totally symmetric stretching mode) and E (stretching vibration mode excluding the totally symmetric one) respectively. An X-ray structure analysis[13] and model consideration of $[Co(tn)_3]^{3+}$ show that the six-membered rings are more flexible than the five-membered ones and that the distortion of the octahedral coordination[13] makes the former more conformationally labile than the latter. In fact, the CD spectrum of Λ-$(+)_{589}$-$[Co(tn)_3]^{3+}$ indicates a conformational equilibrium in solution between the tris skew-boat and tris chair forms.[14] Accordingly, it may be inferred that the Raman spectrum of $[Co(tn)_3]^{3+}$ reflects the conformational complexity of the six-membered chelate ring. Here, we should refer to the Raman spectra of the $[Co(a)(b)(tn)_2]$-type complexes, where a and b denote unidentate ligands, exhibiting also some Raman bands in the region of 400—550 cm^{-1}.[3] The very strong bands at ca. 450 cm^{-1} and the bands in the region of 480—550 cm^{-1} have been assigned to the Co-N(tn) stretching mode, ν(Co-N(tn)), and the deformation vibration of the chelate ring, δ(CNN), respectively, by considering the Raman spectra of the $[Co(a)(b)(en)_2]$-type complexes and the $[M(en)_2]^{2+}$ (M=Cu, Pd, and Pt) complexes based on the normal coordinate analysis. However, in the case of the $[Co(tn)_3]^{3+}$ complex, it seems reasonable to consider that the bands in the region of 450—530 cm^{-1} can be assigned to the totally symmetric stretching vibration mode, because the bands at 451 and 530 cm^{-1} of $[Co(tn)_3]^{3+}$ are shifted to lower frequencies (ca. 15 cm^{-1}) upon a deuteration of the amino protons of the 1,3-propanediamine ligand, as is to be expected for the bands due to the Co-N stretching vibration. On the basis of the above consideration and the Raman spectral characteristics summarized in Table 1, the Raman spectra of the cobalt(III) complexes containing the six-membered chelate ring can be classified into four vibration modes, like those with the five-membered chelate rings:[4] The totally symmetric stretching vibration mode (440—640 cm^{-1}), the stretching vibration mode excluding the totally symmetric one (380—480 cm^{-1}), the metal-ligand skeletal bending deformation mode (260—400 cm^{-1}), and the chelate ring deformation mode (220—290 cm^{-1}) from the higher frequency region.

A comparison of the Raman spectra in the skeletal vibration region of the four $[Co(en)_n(tn)_{3-n}]^{3+}$($n$=0—3) complexes (Fig. 1 and Table 1) clearly demonstrates

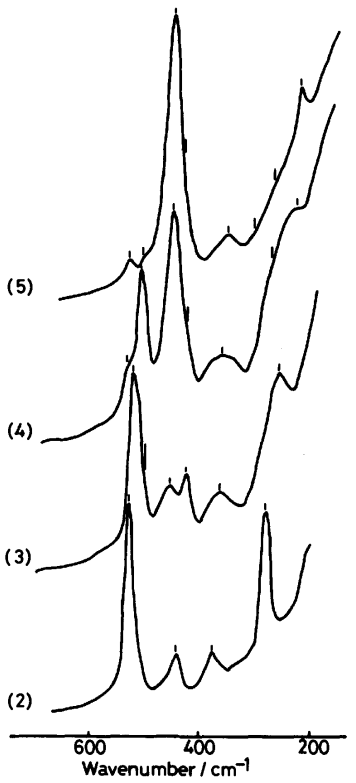

Fig. 1. Raman spectra of $[Co(en)_n(tn)_{3-n}]^{3+}$ (n=0, 1, 2, and 3). Numbers in parentheses correspond to those in Table 1.

a) The following abbreviations are used: s, strong; m, medium; w, weak; vw, very weak; sh, shoulder; p, polarized; dp, depolarized; ν_{ts}, totally symmetric stretching vibration mode; ν, stretching vibration mode excluding the totally symmetric one; δ_{sbd}, metal-ligand bending deformation mode; δ_{crd}, chelate ring deformation mode. The Raman band intensities (s, m, w, vw, and sh) are classified by a comparison of all the Raman bands among all the complexes. The numerical data in the parentheses are the polarization ratios. b) Ref. 4.

that the number of bands increases with the substitution of the en ligand by the tn one and that the Raman bands of the chelate ring deformation mode are shifted to lower frequencies. Furthermore, $[Co(en)_2(tn)]^{3+}$ and $[Co(en)(tn)_2]^{3+}$ exhibit equally the bands due to the Co-N(en) and Co-N(tn) totally symmetric stretching vibration mode; the bands due to ν_{ts}(Co-N(en)) and ν_{ts}(Co-N(tn)) are observed in the region above 500 cm^{-1} and at ca. 450 cm^{-1} respectively. The shift of the Raman bands due to ν_{ts}(Co-N(en)), 525, 517, and 506 cm^{-1} for the $[Co(en)_n(tn)_{3-n}]$-type complexes may be attributed to the increased relaxation of the Co-N(en) bonds by stepwise substitution of the tn ligand for the en one. That is, there is no appreciable vibrational coupling between ν_{ts}(Co-N(tn)) and ν_{ts}(Co-N(en)). In addition, the intensities of the bands, ν_{ts}(Co-N(tn)) and ν_{ts}(Co-N(en)), of the mixed complexes are proportional to the number of the en ligand and the tn one. Here, it is worthy of note that the ν_{ts}(Co-N) Raman shifts of $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, and $[Co(tn)_3]^{3+}$ decrease in the following order; ν_{ts}(Co-N(en))>ν_{ts}(Co-N(NH_3))>ν_{ts}(Co-N(tn)). This decreasing order is in line with that for the $^1T_{1g}\leftarrow{}^1A_{1g}(O_h)$ electronic transition energy of the $[Co(N)_6]$ chromophore; 21.30×10^3 cm^{-1}($[Co(en)_3]^{3+}$)[15]>20.96×10^3 cm^{-1}($[Co(NH_3)_6]^{3+}$)[16]>20.49×10^3 cm^{-1}($[Co(tn)_3]^{3+}$).[7] The spectral behavior caused by the substitution of the en ligand by the tn one is also observed for the $[Co(gly)(en)_2]^{2+}$ and $[Co(gly)(tn)_2]^{2+}$ complexes. That is, $[Co(gly)(tn)_2]^{2+}$ shows more Raman bands than does $[Co(gly)(en)_2]^{2+}$, as is to be expected from the results for the $[Co(en)_n(tn)_{3-n}]$-type complexes (Fig. 2). The Raman band due to the chelate ring deformation mode of $[Co(gly)(tn)_2]^{2+}$ is also shifted to a lower frequency. Furthermore, a comparison of the Raman bands in the totally symmetric stretching vibration region of $[Co(tn)_3]^{3+}$ (Fig. 1) and $[Co(gly)(tn)_2]^{2+}$ suggests that the band at 482 cm^{-1} of $[Co(gly)(tn)_2]^{2+}$ is the characteristic band of the coordinated gly ligand, similar to the spectral relation between $[Co(en)_3]^{3+}$ and $[Co(gly)(en)_2]^{2+}$.[4]

The Raman spectra of $[Co(\beta\text{-ala})(en)_2]^{2+}$ and $[Co(en)_3]^{3+}$ reveal that the replacement of the en ligand in $[Co(en)_3]^{3+}$ by the β-ala one causes no changes in the intrinsic spectral features; the four bands of $[Co(\beta\text{-ala})(en)_2]^{2+}$ can be correlated to those of $[Co(en)_3]^{3+}$ (Fig. 3). This spectral behavior is quite in contrast to that resulting from the replacement of the en ligand by the gly one.[4] The good correlation of the Raman spectral features between $[Co(\beta\text{-ala})(en)_2]^{2+}$ and $[Co(en)_3]^{3+}$ may result from the fact that the skeletal vibration behavior of the former is determined by the two en chelate rings because of the conformational restriction due to the five-membered chelate ring and because of the proximity of the reduced mass of the donor atoms. The Raman spectra of $[Co(\beta\text{-ala})(en)_2]^{2+}$ and *trans(O)*-$[Co(\beta\text{-ala})_2(en)]^+$ show that the Raman spectral features are no longer retained upon a structural change from the former to the latter (Fig. 3), whereas a comparison of the spectra of $[Co(gly)(en)_2]^{2+}$ and *trans(O)*-$[Co(gly)_2(en)]^+$ reveals that the spectral features are well retained

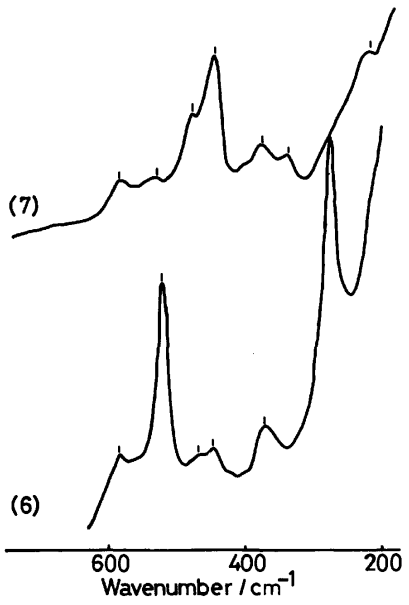

Fig. 2. Raman spectra of $[Co(gly)(tn)_2]^{2+}$ and $[Co(gly)(en)_2]^{2+}$. Numbers in parentheses correspond to those in Table 1.

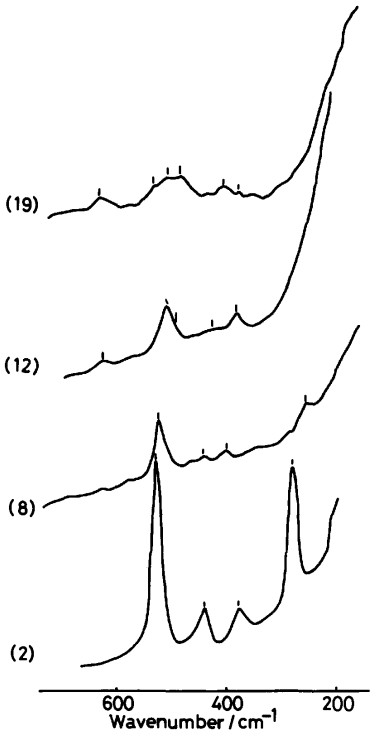

Fig. 3. Raman spectra of *mer(N)*-$[Co(\beta\text{-ala})_3]$, *trans(O)*-$[Co(\beta\text{-ala})_2(en)]^+$, $[Co(\beta\text{-ala})(en)_2]^{2+}$, and $[Co(en)_3]^{3+}$. Numbers in parentheses correspond to those in Table 1.

even after the structural change.[4] This Raman spectral evidence clearly demonstrates that the six-membered β-ala chelate ring is more flexible than the five-membered gly chelate ring, as in the case of the tn and en chelate rings (vide supra).

A conspicuous difference was found in the Raman spectra in the totally symmetric stretching vibration mode of the geometrical isomers, *fac(N)*- and *mer(N)*-[Co(β-ala)$_3$], as is shown in Fig. 4; the mer(N) isomer exhibits a more complicated Raman spectrum than does the fac(N) one. An analogous tendency has been observed for the spectra of *fac(N)*- and *mer(N)*-[Co(gly)$_3$].[4] However, it is interesting that the Raman spectral differences among the geometrical isomers of the cobalt(III) complexes with the six-membered chelate rings are noticed in the totally symmetric stretching vibration mode, whereas those of the complexes with the five-membered chelate rings appear in the stretching vibration mode excluding the totally symmetric one.

As is shown in Fig. 5, the Raman spectral features of the three geometrical isomers, *trans(O)*-, C_2-*cis(O)*-, and C_1-*cis(O)*-[Co(β-ala)$_2$(tn)]$^+$, which have been prepared for the first time in this work are, in a first approximation, similar to each other, as in the case of the geometrical isomers, *trans(O)*-, C_2-*cis(O)*-, and C_1-*cis(O)*-[Co(gly)$_2$(en)]$^+$.[4] On a closer inspection, however, we can find some differences among the Raman spectral features of the three geometrical isomers of [Co(β-ala)$_2$(tn)]$^+$. Firstly, the difference between the trans(O) isomer and the two cis(O) ones can be observed in the skeletal bending deformation region; the trans(O) isomer has no Raman band, but the cis(O) isomers have a few Raman bands.

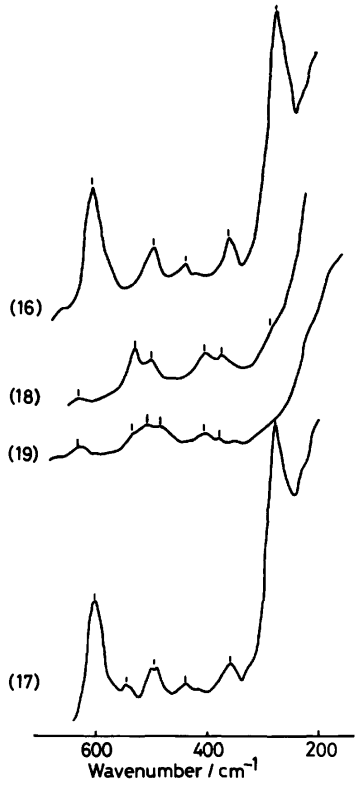

Fig. 4. Ranam spectra of mer(N) and fac(N) isomers of [Co(gly)$_3$] and [Co(β-ala)$_3$]. Numbers in parentheses correspond to those in Table 1.

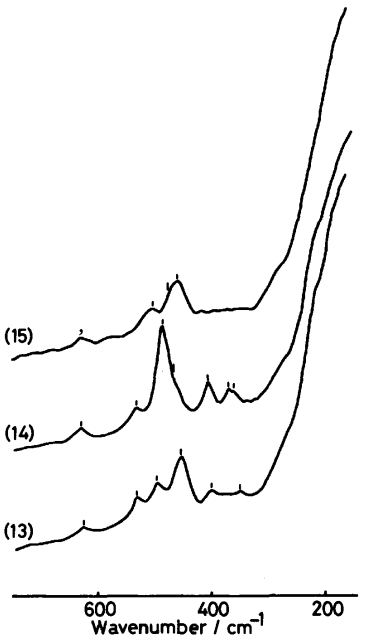

Fig. 5. Raman spectra of three geometrical isomers of [Co(β-ala)$_2$(tn)]$^+$. Numbers in parentheses correspond to those in Table 1.

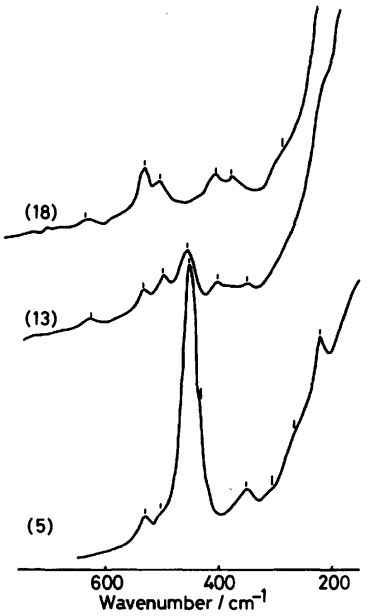

Fig. 6. Raman spectra of *fac(N)*-[Co(β-ala)$_3$], C_1-*cis(O)*-[Co(β-ala)$_2$(tn)]$^+$, and [Co(tn)$_3$]$^{3+}$. Numbers in parentheses correspond to those in Table 1.

Incidentally, the trans(O) isomer exhibits the strong and polarized band (465 cm^{-1}) at a slightly lower frequency than the depolarized one (479 cm^{-1}). Secondly, a difference between the C_2-cis(O) isomer and the C_1-cis(O) one can be observed in the totally symmetric stretching vibration region; the C_2-cis(O) isomer with a higher symmetry exhibits three Raman bands, but the C_1-cis(O) isomer splits into a quartet. This sort of spectral difference has also been observed for the two cis(O) isomers of $[Co(gly)_2(en)]^+$ with five-membered chelate rings[4] in the stretching vibration mode excluding the totally symmetric one (400—520 cm^{-1}). Finally, it should be pointed out that the characteristic feature of the Raman spectrum of C_1-*cis(O)*-$[Co(\beta\text{-ala})_2(tn)]^+$ is considered to be an overlapping with those of *fac(N)*-$[Co(\beta\text{-ala})_3]$ and $[Co(tn)_3]^{3+}$ as is shown in Fig. 6. That is, we can say that the strong and polarized band at 454 cm^{-1} of C_1-*cis(O)*-$[Co(\beta\text{-ala})_2(tn)]^+$ corresponds to the totally symmetric stretching vibration mode, ν_{ts}(Co–N(tn)), and also that the polarized bands in the region above 490 cm^{-1} are principally related to the β-ala ligand. Incidentally, the complexes containing more than one β-ala ligand exhibit their highest frequency polarized bands around 630 cm^{-1}, somewhat higher than those for the complexes containing the gly ligand. It is not certain at present what has brought about this interesting feature, but we can say that it reflects the skeletal vibrational characteristics of the cobalt(III) complexes with six-membered aminocarboxylate chelate rings.

(Received September 12, 1986)

Alkaline phosphatase activity (both dissolved and total) in Lake Kasumigaura was determined periodically together with concentrations of phosphorus compounds therein. Distinct negative correlation was found between the dissolved alkaline phosphatase activity and the orthophosphate concentration during the phosphorus-limited season. The decrease of the concentration of dissolved alkaline phosphatase was observed at the level of 1 ng ml^{-1} of orthophosphate. The present results suggest that both alkaline phosphatase in vivo and dissolved alkaline phosphatase in the lake water play important roles in phosphorus cycles in natural water.

Alkaline phosphatase in natural water was first studied in the context of the phosphorus cycle. In 1938, Steiner first suggested the possibility of the ecological participation of phosphatases in hydrolyzing phosphate esters to orthophosphate for phytoplankton growth in lakes.[1] Since then, several investigations on intercellular alkaline phosphatase have been carried out.[2-4] Alkaline phosphatase activity remaining in filtered water was first reported by Overbeck et al.[5] Not only total (cell-associated plus dissolved) phosphatase activity but also dissolved phosphatase activity per se, have been discussed in relation to their roles in the hydrolysis of phosphatase esters in sea water[6-8] and freshwater.[9-14] The correlation between phosphatase activity and other biological variables such as plankton biomass and chlorophyll *a* were reported as being positive.[15] However, the correlation between phosphatase activity and phosphate concentration has not been clarified. Stevens and Parr concluded that phosphatase activity could not be used as a reliable indicator of algal growth under conditions of phosphorus starvation.[16] Kobori and Taga reported a positive relationship between phosphatase activity and the inorganic phosphorus content of ocean sediment.[17] Berman reported that no correlation was found between them,[10] in spite of the fact that the production of alkaline phosphatase in bacteria is induced by phosphate-deficient media, and suppressed by phosphate-sufficient media.[18]

It has been confirmed in the previous papers[19,20] that dissolved phosphatase activity in sea and lake water is caused by zinc-containing metalloenzyme *alkaline phosphatase*. The seasonal changes in alkaline phosphatases and their sources (algae and bacteria) in Lake Kasumigaura have also been discussed previously.[21] In the present paper, the correlation between phosphatase activity and phosphorus concentration has been studied by using the data obtained through periodic analysis for two years in Lake Kasumigaura. The role of alkaline phosphatase in the phosphorus cycle in the lake is also discussed.

Experimental

Chemicals and Instruments. All the reagents used in the experiments were of analytical reagent grade.

Glassfilter (Whatman GF/C, pore size: 1.0 μm; diameter: 47 mm) was sterilized by heating at 450 °C for 3 h. The membrane filter was purchased from Toyo Kagaku Sangyo Co. (Type TM-4, pore size: 0.20 μm; diameter 47 mm). A Millipore filter holder (Type XX15-046-00) and a Millipore miniature vacuum-press pump Type XX61-000-00) were used for filtration, under mild suction (such that the suction flask pressure was no less than 250 Torr (1 Torr=133.322 Pa)). A thermostatic bath (Hirayama Manufacturing Co., Model TR-900) was used to incubate the sample-substrate mixture.

A Shimadzu UV-210A spectrophotometer with an SFU-6 semi-auto flow cell unit (optical path of the absorption cell: 10 mm) was used to determine phosphatase activity. Concentrations of orthophosphate were determined with a Technicon Autoanalyzer Type II, using the method of Murphy and Riley.[22]

Sampling and Pre-Treatment of Lake Water Samples. Lake water samples were collected with plastic Van Dorn bottles at 10 sampling stations on Lake Kasumigaura (shown in Figs. 2 and 3) once a month from April, 1980 through March, 1982. The sampling depths were: 0.5 m at every station (April, 1980-April, 1981); 1.5 m and 0.5 m at Stations 4 and 9 (April, 1980-April, 1981); and 1.0 m at every station (May, 1981-March, 1982).

[†4] Present address: Sumitomo Metal Mining Co., Ltd., Suehiro-cho, Ome, Tokyo 188.

The samples were cooled in an ice box immediately after being taken. Most of them were then filtered as soon as possible, as shown in Fig. 1. A portion of each sample, to which 2 v/v% of chloroform was added, was kept unfiltered to determine *total phosphatase activity* and *total phosphorus concentration*. A water sample filtered through the 1.0 μm pore size glassfiber membrane filter was used to determine *total dissolved phosphorus concentration* and *orthophosphate concentration*. A sample filtered through the 0.2 μm-membrane filter was used for the determination of *dissolved phosphatase activity*. All the filtered samples were stored at a constant temperature of 0 °C until analyzed.

Determination of Phosphatase Activity and Phosphorus Concentration. Procedures for determination of phosphorus concentration and phosphatase activity are shown in Fig. 1. Total phosphatase activity (TPA) and dissolved phosphatase activity (DPA) were determined by using *p*-nitrophenyl dihydrogen phosphate as a substrate, as described in the previous paper.[21]

Total phosphorus concentration (TP) and total dissolved phosphorus concentration (TDP) were determined with a Technicon Autoanalyzer after peroxodisulfate digestion in an autoclave at 120 °C for 45 min using a culture bottle (50 ml) with a polycarbonate screwcap.[23] Orthophosphate concentration (Pi) was determined with the Autoanalyzer using an unautoclaved filtered sample. The particulate phosphorus concentration (PP) was obtained by subtracting TDP from TP. The dissolved organic phosphorus concentration (DOP) was obtained by subtracting Pi from TDP.

Results and Discussion

Horizontal and Vertical Distribution of Phosphatase Activity and Phosphorus Concentration. Table 1 shows data for phosphatase activity and phosphorus concentrations in Lake Kasumigaura in July, 1980 and January, 1981. TP in Lake Kasumigaura was around 100 μg-P l^{-1} or more, much higher than the eutrophication level of 20 μg-P l^{-1}. No significant change in phosphatase activity and phosphorus concentration vs. vertical position was found, except for the phosphorus concentration at Station 4 in summer, which was higher at a depth of 5 m than at shallower levels. The vertical homogeneity of Lake Kasumigaura is due to the shallowness of the water and the constant agitation of the water by the wind. The increase in phosphorus at the 5.0 m depth at Station 4 in summer may be linked to the release of phosphate into the lake water from the sediments.[24]

Figures 2 and 3 show the horizontal distributions of phosphorus concentration and phosphatase activity,

respectively. Both the concentrations of phosphorus and the phosphatase activity decrease with the horizontal decline of the water stream from the inner part of the two bays, (e.g., Stations 1 and 6), to the center (Station 9) or outlet (Station 12) of the lake. This trend is particularly noticeable in summer. There is known to be a linear relationship between particulate phosphorus concentration (PP) and chlorophyll *a* concentration (which is proportionate to the biomass of photoautotrophs) over the whole area of Lake Kasumigaura.[25] Waters highly mixed with waste-water near urban area (for example, Stations 1 and 6) seem to have a large biomass (which gives high particulate phosphate concentration), and consequently have a high level of phosphatase activity produced by algae and bacteria.[21]

Dissolved phosphatase activity (DPA) was around 10% of total phosphatase activity (TPA), which was about the same ratio as that found in Tokyo Bay[8] and in the Pluss-See.[9]

The correlation factors for phosphatase activity and phosphorus concentration are shown in Table 2. There were positive correlations between the various

phosphorus concentrations (such as TP vs. PP; PP vs. DOP), but there was no apparent correlation between the phosphorus concentrations and phosphatase activity (TPA or DPA). At this point, the value of DPA/PP was seen as being a possible indication of phosphatase activity in lake water normalized by the biomass. As shown in Fig. 4, there was an apparent negative correlation between DPA/PP and Pi (orthophosphate concentration) in May, 1981 (correlation coefficient (r) is −0.72), but no correlation in August, 1981 (r is 0.00).

Seasonal Variations in Phosphatase Activity and Phosphorus Concentration. The seasonal variations in phosphorus concentrations at Stations 2 and 9 are shown in Fig. 5. In most of the stations, phosphorus increased in summer and decreased in winter, as is seen more markedly in the changes at Station 2. Such phenomena are also characteristic of algal blooms in eutrophic lakes.[26] In Fig. 5, the seasonal changes of phosphorus compounds at Station 9 were quite smaller than those at Station 2. These facts may be ascribed to less eutrophication near the lake center at Station 9 compared to the Takahamairi area at Station 2. In 1980, the summer was cooler than usual, so that the phosphorus peak for summer in 1980 shown in Fig. 5 was somewhat distored. The phenomenal increase in orthophosphate concentration (Pi) during mid-summer is probably caused by the chemical and biological release of phosphate from the sediment.[27]

Figure 6 shows the seasonal variations in dissolved phosphatase activity (DPA) and orthophosphate (Pi) at Station 2. DPA has two peaks a year, one of which would appear to be caused by the heavy blooms of blue-green algae (*Microcystis aeruginosa*) in summer, and the other by blooms of diatoms and flagellates in winter or spring.[28] Figure 6 also shows a negative correlation between DPA and Pi.

Seasonal variations in the correlation coefficients (r) of Pi and DPA/PP at the different stations and in the TP/TPA values are shown in Table 3. TP/TPA, whose dimension is $[\text{time}]^{-1}$, may indicate the

turnover time of phosphorus in lake water. In May, TP/TPA was at its minimum value, and r was at its maximum value. These results suggest that microorganisms produce more alkaline phosphatase than usual in vivo, and that they are forced to use phosphorus in lake water more efficiently than usual in order to bloom in the phosphate-deficient season of May.

The Role of Alkaline Phosphatase in the Phosphorus Cycle in Lake Water. Phosphorus is one of the most important nutrient elements. Microorganisms in natural water use phosphorus in the form of orthophosphate. It is recognised that the synthesis of an enzyme in vivo is suppressed by the presence of the

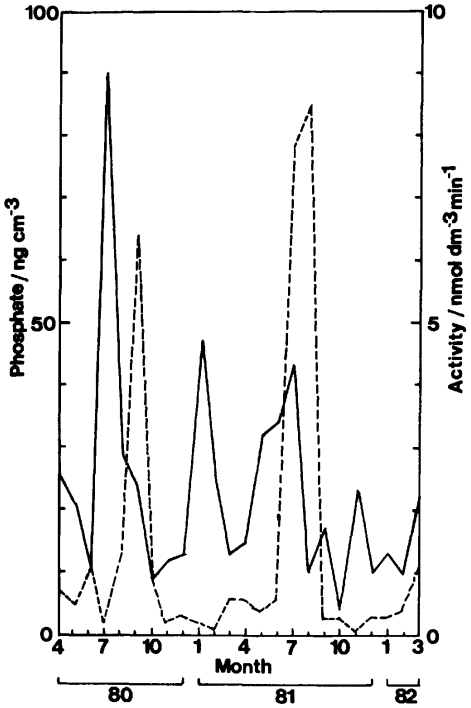

Fig. 6. Seasonal variations in dissolved phosphatase activity and orthophosphate concentration in Lake Kasumigaura (Station 2).
——: Dissolved phosphatase activity; —·—: orthophosphate-P concentration.

final product of its catalysis in the media.[18] It seems that the same phenomenon occurs in ecological systems, such as lake water. In algae's blooming season, the ecological system has a high requirement for nutrients such as inorganic phosphorus and nitrogen. If there is no sufficient orthophosphate in the lake water for the algae to grow, the algae have to produce more alkaline phosphatase in order to get a quick supply of orthophosphate. On the other hand, when the phosphate concentration is high enough to supply the algae's needs, the key element in the bloom of algae is not phosphorus but other nutrient elements such as nitrogen. When the latter conditions prevail, there is no correlation between DPA/PP and Pi. This hypothesis is supported not only by the clear negative correlation between DPA/PP and Pi, but also by the low apparent turnover time of phosphorus (TP/TPA) in phosphorus-deficient season (such as May, 1981).

In the laboratory incubation experiments of bacteria (*Escherichia coli*)[18] and algae,[29] the depression of the enzyme production can be observed under orthophosphate concentration of 7—10 μg-P ml^{-1}. On the other hand, the decrease in the dissolved alkaline phosphatase in the lake water appears at ca. 1 ng-P ml^{-1}, which means more than three order of magnitude in difference between the lake and experimental laboratory systems. When considering that the surface area of Lake Kasumigaura is 171 km^2, it is important to note that such negative feedback is also maintained between orthophosphate and the release of dissolved phosphatase on the scale of a large lake.

Conclusion

A simplified representation of the role of alkaline phosphatase in the phosphorus cycle in lake water is illustrated in Fig. 7. As described above, it is suggested that intercellular phosphatase controls the uptake of phosphorus by algae at times when there is a phosphate deficiency, and that dissolved alkaline phosphatase also plays a part in this process. Conversely, an excess of phosphate suppresses the biosynthesis of alkaline phosphatase in vivo, and is followed by a decrease in dissolved alkaline phosphatase.

Various kinds of microorganisms are present in natural water, and each of them produces its own type of alkaline phosphatase.[21] It is known that different types of algae are frequently in competition within any particular ecological systems; for example, blue-green algae inhibit the blooming of other algae such as diatoms in natural water.[28] In order to elucidate further the role of alkaline phosphatase (in vivo and dissolved forms), it will be necessary to determine alkaline phosphatase activity originating from each source.

The present authors thank Dr. Lawrence J. Sacks, Laboratory of Chemical Evolution, Department of Chemistry, University of Maryland, for his kind help in preparation of the manuscript.

Geochemical Characterization of Geological Standard Rock Samples from Rare Earth Element Distribution Patterns Measured by Inductively Coupled Plasma Atomic Emission Spectrometry

Kazuhiro Toyoda and Hiroki Haraguchi*
Department of Chemistry, Faculty of Science, The University of Tokyo,
7-3-1, Hongo, Bunkyo-ku, Tokyo 113
(Received September 22, 1986)

Rare earth elements (REEs) in twelve standard rock samples have been determined by inductively coupled plasma atomic emission spectrometry after separation of diverse metal ions with cation exchange resin. These rock samples are old six standard rocks (W-1, BCR-1, AGV-1, GSP-1, JB-1, JG-1) and new six standard rocks (JB-2, JB-3, JA-1, JR-1, JR-2, JGb-1) issued from the Geological Survey of Japan. These samples are various types of igneous rocks, which show various shapes of the REE distribution patterns. Geochemical characteristics of these standard rock samples will be discussed from the relationships between rock types and the shapes of the REE pattern.

In recent years, inductively coupled plasma atomic emission spectrometry (ICP-AES) has been extensively used as a convenient and sensitive analytical method for simultaneous multielement determination of geological samples.[1-6] The determination of various elements in the wide range of concentrations can be carried out by ICP-AES without matrix matching of the standard solutions.[1] The analytical sensitivities of REEs have been also improved by ICP-AES.[2-6] Thus, we have tried to perform simultaneous multielement determination of REEs in twelve geological standard rock samples issued from the Geological Survey of Japan.

The determination of rare earth elements have been receiving more attention in geological studies.[7] The behaviors of trace elements such as REEs during the process of genesis and differentiation of magma depend fundamentally on the distribution coefficients between melt and minerals.[8] On the basis of this assumption, for example, mutual genetic relationships of various rock types, such as tholeiitic and alkali rocks, has been studied. Petrogenetic studies of igneous rocks involve the determination of the history of the sources of melts, the conditions of melting, the chemical composition of the sources during melt, melting process and so forth. Since REEs are the most useful elements for such a geochemical study, precise analysis of REEs and trace element modeling using the element distribution coefficients (K_d) in mineral-melt systems have been examined.[7] Then it has been noted that REEs are significantly valuable for placing limits on the applicability of proposed petrogenetic models. Moreover, the REE patterns do not change so significantly through the process of alternation and metamorphism, because REEs belong to the group of chemically resembled elements and are strong to weathering.[9,10] Thus the behaviors of REEs during the melting and differentiation of igneous rock are explained mathematically by the Masuda-Coryell plot REE distribution pattern[11] which is the plot of the REE contents normalized to chondrite abundance.

Genetic classification and characterization of igneous rocks are commonly made by major chemical composition as well as mineral compositions.[13-15] Such classification and characterization, however, are sometimes done by the survey of minor element compositions, for example, first-row transition metal abundance patterns,[16,17] Sr/Ca-Ba/Ca systematics,[18] incompatible element patterns,[19,20] various ratios of two elements[8] and so on. Among the studies of trace elements for geological rock samples, the REE pattern is most popular and useful. Hence, in the present study, the determination of REEs in twelve geological standard rock samples has been performed by ICP-AES; JB-1 (alkali basalt), JB-2 (tholeiitic basalt), JB-3 (high aluminum basalt), BCR-1 (andesine tracky basalt), W-1 (dolelite), JGb-1 (gabbro), AGV-1 (trachy andesite), JA-1 (tholeiitic andesite), JR-1 and JR-2 (rhyolite), JG-1 and GSP-1 (granodiolite). The analytical results have been compared with the literature values,[22,23] which have been mainly determined by isotope dilution mass spectrometry (IDMS) and neutron activation analysis (NAA). Furthermore, the relationship between rock types and the shape of the REE patterns of twelve rock samples will be discussed according to knowledge of REE geochemistry.

Experimental

Instrument. An ICP emission spectrometer used is Jarrell-Ash model 975 Atom Comp MKII with some laboratory modification. The instrumental components and operating parameters for the emission measurements are summarized in Table 1. The analytical lines employed are shown in Table 2. The calibration curves were made by using low (blank) and high standard solutions.

Chemicals and Standard Solution. All the chemicals used were of analytical reagent grade. All the stock solutions (1000 μg ml^{-1}) were prepared from pure metals or oxides, and their concentrations were checked by the EDTA titration method with XO indicator. Working standard solutions for calibration curves were prepared by mixing the

stock solutions into three groups, taking into consideration of minimizing mutual spectral interferences among rare earth elements. The combinations of elements for working standard solutions are summarized in Table 2. Standard IV contains internal standard element (Cd) and interferring elements (Y, Sc, Al, Fe, Zr, Cr), which could not be eliminated by chemical separation mentioned below. The internal standard was used to compensate possible fluctuations in nebulization or droplet transport. In order to minimize the variation of the nebulization efficiency due to the differences of the viscosities of the solutions, the acid content in each standard solution was adjusted to be 3 M (M=mol dm^{-3}) HCl so as to match those in the digested sample solutions.

Sample Digestion and Separation Procedure. Rock samples (0.5 g) were digested by two methods such as HF-HNO_3 acid digestion and Na_2CO_3 alkali fusion.[5] After digestion, the samples were dissolved to 50 ml with 1 M HCl. The solution was loaded onto a 20×1 cm column of 100-200 mesh AG50W-X8 cation exchange resin. The

a) The correction coefficient is expressed as the analyte concentration (ng ml^{-1}) equivalent to the background emission intensity which is provided with 1 μg ml^{-1} of major element.

column was first eluted with 130 ml of 2 M HNO_3 solution. The REEs on the resin were then eluted with 50 ml of 6 M HNO_3, and the eluent was taken in a Teflon beaker. The eluent was then evaporated to dryness on a hot plate. The residue was dissolved again with 5 ml of 3 M HCl, in which 10 μg ml^{-1} of Cd was added as an internal standard. These procedures were carried out for both acid-digested and alkali-fused samples in the same manner. The solutions were then used for the determination of REEs by ICP-AES. Major elements (Al, Fe, Ca, Mg, Na, and K) and interferring elements (Mn, Ti, V, Be, and Th) could be removed from the sample solutions through the above procedures. When removal of Fe was insufficient, Fe was further removed from eluted solution by solvent extraction with MIBK. Total yield of the whole procedure was 96—98%. Cadmium was chosen as the internal standard, because its emission profile in the plasma was similar to most REE profiles and it had no spectral interferences with the selected REE emission lines. It was also noticed that Cd originally contained in the samples were eliminated during the cation exchange separation.

Correction of Spectral Interferences. The influences of background emission intensities due to major elements were investigated by observing the intensity profiles near analytical lines of minor and trace elements. The profiles were obtained by moving the entrance slit horizontally. The profile measurements allowed to distinguish the emission signals caused by major elements (spectral interferences) or impurities. The spectral interference due to other REEs and interfering elements such as Zr, Sc, and Cr were estimated as the correction coefficient expressed as the analyte concentration (ng ml^{-1}) equivalent to the background emission intensity which was provided with 1 μg ml^{-1} of each major element. The correction coefficients of REEs and other diverse elements for spectral interference correction are summarized in Table 3.

Results

The detection limits in solution by ICP-AES are listed in Table 4, where the detection limits are defined as the analyte concentration corresponding to twice the standard deviation of background emission when the standard solution samples are nebulized into the ICP. The detection limits in rock sample are also listed in Table 4, along with the Leedey normarized values of REEs in Chondorite The detection limits in sample are evaluated from the detection limits in solution in case that 0.5 g of rock sample is digested and diluted to 5 ml. As can be seen in Table 4, the detection limits in sample are below the Leedey Chondrite abundance levels of REEs except Pr and Tb in geological samples. This means that the present experimental method is applicable to the determination of REEs in geological samples. After background correction, blank subtraction and spectral interference correction were carried out to obtain the analytical values for the standard rock samples. All the analytical values for REEs in JG-1, JB-1, AGV-1, BCR-1, W-1, and GSP-1 are summarized in Tables 5 and 6. Good agreement between the acid-digested and alkali-fused samples can be seen in terms of both AGV-1 and JB-1, and also the present data in five standard rocks except JG-1 are almost consistent with the literature values determined by NAA and IDMS. From these results it can be noted that the present method is suitable enough for the simultaneous multielement determination of all REEs except Tb and Tm. The analytical values for Tb and Tm were prone to serious interferences with the coexisting other REEs.

Recently it has been pointed out that the proposed values for heavy rare earth elements in JG-1 are not consistent, depending on the analytical methods. The values for heavy REEs in JG-1 obtained by NAA were about twice as much as the proposed values which were determined by IDMS technique.[23,25]

The present authors also pointed out in the previous paper[5] that the values of heavy REEs in JG-1 did not agree with each other, when the different decomposition methods were employed. As can be seen in Table 5, the values obtained by the alkali fusion preparation are about two times larger compared to those obtained by the acid digestion. The present values of REEs by acid digestion are almost identical with the values[23] formerly certified from GSJ, which were mainly determined by IDMS with acid digestion treatment. On the contrary, the REE values for the alkali fusion are consistent with those obtained by NAA.[25] These facts suggest that heavy REEs are enriched in some minerals which can not be completely decomposed by acid digestion. JG-1 is porphric biotite granodiorite, in which zircon is usually found as an accessory mineral. It is well known that zircon ($ZrSiO_4$) is not easily decomposed by acid digestion[26] and enriches heavy REEs.[7] In fact,

Lu	0.9	0.009	0.0387

from the determination of Zr in JG-1 decomposed by two different methods, it was found that Zr contents in JG-1 are 38 μg g^{-1} in acid digestion and 118 μg g^{-1} in alkali fusion, while the recommended value of Zr in JG-1 is 111 μg g^{-1}.[26] The difference of Zr values for JG-1 obtained by two decomposition methods may correspond to mean chemical composition of zircon which can not be dissolved by acid digestion. Then, GSP-1, JR-1, and JR-2, in which zircon is known to exist as an accessory mineral, were also decomposed by alkali-fusion method.

Discussion

The analytical values for 12 standard rock samples are summarized in Tables 5—7. As can be seen from these values, the concentrations of REEs in rock samples are characteristic, depending on the types of rock samples. Thus the geochemical features of standard rock samples will be discussed with emphasis on the REE patterns.

The REE patterns normalized by the Leedey normalizing factors are shown in Figs. 1—6, which were figured from the analytical data in Tables 5—7. Generally the REE patterns provide smooth curves

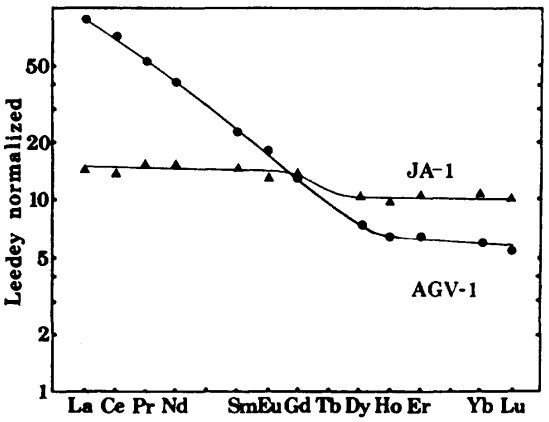

Fig. 3. REE patterns of JA-1 (tholeiitic andesite) and AGV-1 (trachy andesite).

except for Eu. Since Eu exists as the di- and tri-valent ions, it often shows some anomaly. Thus, these REE distribution patterns including Eu anomaly are useful to discuss some geochemical or geological characteristics of rock samples as well as their origin and classification.

Basalt. Masuda analyzed several basalts from Japan and found that basalts can be classified into three groups, based on general petrographic characteristics and REE patterns[27-29]; alkali basalt, tholeiitic basalt, and high aluminum basalt. Alkali basalt shows the REE pattern, in which light REEs are usually enriched, as is seen for JB-1 shown in Fig. 4. On the other hand, tholeiitic basalt contains less light REEs and show the rather flat pattern through all REE elements, which is seen in JB-2. The difference of these two REE patterns may be interpreted as follows. As has been known,[8] tholeiitic basalt magma and alkali olivine basalt magma have different genesis. The difference of the shapes of REE patterns mainly depends on degree of partial melting of upper mantle, when magma is generated from upper mantle. Already, this assumption has been elucidated by high pressure experiment in laboratory.[8,30,31] Most models for the formation of tholeiites assume about 20—30% melting of upper mantle peridotite with various REE contents, which reasonably explains the REE contents in tholeiites.[32] Tholeiites with low REE contents and flat REE distribution in Leedey-normalized curves are assumed to melt from primitive mantle with little or no

a) All values are in $\mu g\ g^{-1}$. b) Acid digestion. c) Alkali fusion.

enrichment of the light REEs relative to the heavy REEs.[33)] On the other hand, the model for the formation of alkali basalt assumes about 0.8—2.9% partial melting and 4.5—5% garnet content in residue.[30)] Garnet, with its very large mineral/melt *D* value for heavy REEs,[31)] must also be present in the residue left after partial melting. BCR-1, which also belongs to alkali rock,[22)] have the REE pattern similar to JB-1, as shown in Fig. 1.

High aluminum basalt is aluminum-rich tholeiitic basalts whose composition of Al_2O_3 is over 17%. Generally high aluminum basalt shows chemical characteristics between alkali basalts and tholeiitic basalts.[34)] This can be seen from the slope of the REE pattern of JB-3 which is between those of JB-1 and JB-2, shown in Figs. 1 and 2.

Andesite and Ryolite. Andesitic magma is generally formed by fractional crystallization of plagioclase, amphibole, pyroxene, or magnetite from the more basic melts.[35,36)] Such crystallization models are common to explain tholeiitic trend. Tholeiitic andesites formed by crystallization have trend to show the flat pattern in Leedey-normalized curves. Its abundance of REEs is slightly increased, but the shapes of the REE patterns do not significantly change during forming andesitic magma from basaltic magma by crystallization differentiation. Then, AGV-1 (trachy andesite, in alkali series) shows the light REE-enriched pattern, while JA-1 (tholeiitic andesite) does rather flat REE pattern. This can be seen in the REE patterns shown Fig. 3.

JR-1 and JR-2 were collected from the same sampling location, and so their REE patterns and major chemical compositions should be similar to each other. This trend can be seen in their REE patterns shown in Fig. 4. In addition, negative Eu anomaly is remarkably observed for both JR-1 and JR-2, which are interpretated in terms of Eu^{2+} depletion in the melting process owing to the crystallization of Ca-feldsper. Since oxygen fugasity is very low in magma chamber, some part of Eu exists as Eu^{2+} which has similar ion radius with Ca^{2+}.[37,38)] The *D* values of REEs (except Eu) for plagioclase/melt are low, and then the concentration of REEs (except Eu) in melt slightly increases through crystallization process of plagioclase. In general, Eu is concentrated in plagioclase rather than other REEs when it precipitates from the magma. Thus the differentiated magma may develop larger negative Eu anomalies from original magma that may have little or no Eu anomaly.

Plutonic Rock. Dolerite (W-1) is hypoabyssal basaltic rock and gabbro (JGb-1) is plutonic basaltic rock. W-1 and JGb-1 generally have the properties between alkali and tholeiitic rocks, and they show small slope in the patterns with light REE-enriched abundance. Positive Eu anomaly is clearly seen in JGb-1, while it is not in W-1. It can be explained that magma of W-1 have been mixed with Eu positive substance such as anorthite.[10,39)]

In JG-1 and GSP-1, light REEs are significantly enriched with negative Eu anomaly. As is well noted,[40)] the origin and genesis of granite is very complicated.[41,42)] The range of granitic melts can be determined by melting a variety of sources (mantle basaltic magma, intermediate and felsic magma, sedimentary rocks etc.). Petrography and experimental petrology of granitic rock indicate a wide range of mineral parageneses due to differences in magma compositions, temperature, pressure, and contents of dissolved volatile species. In addition, granitic magma are very viscous, and so the assumption of complete separation of crystals and magma is not realistic. Then, it is still difficult to

propose an exact model using the REE pattern to help explain the petrogenesis of granitic melts. The REE patterns of JG-1 and GSP-1 cannot be well interpreted only by the present REE data.

Conclusion

The concentration of REEs in standard rock samples have been determined by ICP-AES. The REE patterns obtained from the present analytical data are useful to discuss the geological properties of standard rock samples along with the origins and genesis of these rock samples. From these experimental results and discussion it can be concluded that these standard rock samples can be used as the references in analysis as well as in geological or geochemical characterization of rock samples when their REE patterns can be obtained by proper analytical methods.

The present authors express sincere thanks to Hiroshi Shimizu and Kiyoshi Iwasaki for their valuable discussion. This research has been supported by the Grant-in-Aid for Scientific Research (No. 61030026) from the Ministry of Education, Science and Culture.

(Received October 15, 1986)

A Mössbauer spectrum of a series of potassium vanadate glasses containing 10 mol% Fe_2O_3 shows a paramagnetic quadrupole doublet, of which isomer shift proves to be smaller than 0.4 mm s^{-1} with respect to metallic iron. This indicates that the individual Fe^{3+} ion is present at the substitutional site of the V^{5+} (and probably V^{4+}) ion constituting a VO_4 tetrahedral unit. An increase in the K_2O content of the potassium vanadate glasses results in a continuous decrease in the glass transition temperature (Tg), ranging from 239 to 200 °C, when the K_2O content is changed from 5 to 30 mol%. This suggests a decrease in the coordination number of the V^{5+} (and V^{4+}) ion from 5 to 4 and a formation of nonbridging oxygen atoms in the VO_4 and FeO_4 tetrahedral units. The formation of nonbridging oxygen atoms in the VO_4 and FeO_4 units is also estimated from a continuous decrease in the quadrupole splitting, suggesting a decrease in the electric field gradient at the iron nucleus and an increase in the symmetry around the Fe^{3+} ion. These results lead to the conclusion that the introduction of the alkali oxide (K_2O) into the V_2O_5 results in a structural change of the V^{5+} (and V^{4+}) ions from VO_5 tetragonal pyramid (or trigonal bipyramid) to VO_4 tetrahedral units.

Electric conducting glasses, i.e., superionic conducting glass and semiconducting glass, have attracted much attention because of the scientific interest in the conduction mechanism as well as the high technological applicability. The electric conductivity of the superionic conducting glasses is known to reach the order of 10^{-2} S cm^{-1},[1-14] which is almost equivalent to that of the crystalline superionic conductor (solid state electrolytes) such as α-AgI and β-Al_2O_3. The high electric conductivity of the superionic conducting glasses is assumed to be due to the "ion migration" of monovalent cations such as Ag^+, Li^+, and Na^+. Comparing the magnitude of the electric conductivity of the superionic conducting glasses to that of the ordinary oxide glasses such as borate and phosphate glasses, which is usually smaller than about 10^{-12} or 10^{-13} S cm^{-1},[15] it is easily understood that the former is extraordinary larger than the latter. Also, the electric conductivity of semiconducting glasses is known to be comparable to that of the superionic conducting glasses.[16-18] The essential difference between the two types of the electric conducting glasses lies in the conduction mechanism. Namely, the electric conductivity of the semiconducting glasses, such as V_2O_5-based glasses studied in the present paper, is known to be due to the electron hopping from the metal ion of lower valence state to the metal ion of higher valence state.[19-21] In the case of the V_2O_5-based glasses, the electric conduction is reported to be performed by a step-by-step electron hopping from the V^{4+} ions, which were produced as a result of thermal decomposition of the V_2O_5 during the sample preparation,[22] to the V^{5+} ions of which number is usually larger than that of the V^{4+}.[19-21] A great number of theoretical treatments of the electric conduction have so far been performed on these semiconducting glasses using a "small polaron hopping theory" proposed by Mott.[23-25] Therefore, it should be noted that the electric conductivity of the semiconducting V_2O_5-based glasses has been studied satisfactorily.

In contrast to the variety of studies performed on the physical properties of vanadate glasses, only a few studies have so far been performed on the structure of the semiconducting V_2O_5-based glasses. Structure of crystalline V_2O_5 has been studied by Byström et al.[26] and by Jansen and Sperlich.[27] They reported that each V^{5+} ion is surrounded by five oxygen atoms making a distorted tetragonal pyramid, which can also be viewed as a distorted trigonal bipyramid, sharing edges and corners to form layers. IR study of several vanadate glasses performed by Dimitriev et al.[28] revealed that the introduction of alkali or alkaline earth oxides, which usually play a role of network modifier, into the V_2O_5 matrix results in a destruction of the vanadate layers followed by a formation of tetrahedral VO_4 units. Dimitriev et al.[28] also elucidated that only the VO_4 units are present in the skeleton of metavanadate glasses, where the molar ratio between the alkali or the alkaline earth oxides and the V_2O_5 is equal to 1. They also revealed that the introduction of other kind of oxides, which play a role of network former, such as SiO_2, B_2O_3, GeO_2, and TiO_2 affects no structural change on the skeleton of the glass matrix originally made of only VO_5 units. In the latter case, the individual network-forming atoms, i.e. Si, B, Ge, and Ti were concluded to be substituted for the fivefold-coordinated V^{5+} (or V^{4+}) ions forming VO_5 units. On the other hand, a neutron diffraction study performed by Wright et al.[29] revealed that the coordination number of vanadium is always 5 in the P_2O_5-, BaO-, and PbO-V_2O_5 glasses irrespective of the glass composition, and that the skeleton of the vanadate glasses is composed of interconnected and distorted VO_5 tetragonal pyramid (or trigonal bipyramid), similarly to the VO_5 units in the crystalline

V_2O_5. Besides the VO_4 and VO_5 units described above, the presence of octahedral VO_6 units has also been proposed, based on the composition dependency of specific gravity.[18,30] Iron-Mössbauer spectroscopy has also been utilized for the structural study of vanadate glasses.[31-34] However, the conclusions obtained so far by the Mössbauer spectroscopy are inconsistent with each other. For example, the coordination number of Fe^{3+} ion is reported to be only six in the case of barium vanadate glass[31] and to be both six and four in the cases of barium or calcium borovanadate[32,33] and sodium vanadate[34] glasses. The conclusions concerning the coordination number of the Fe^{3+} ion reported in those papers seem to be very doubtful because all the isomer shifts, which can be a criterion of octahedral and tetrahedral symmetries, actually indicate the presence of only tetrahedral Fe^{3+} species in those vanadate and borovanadate glasses.[31-34] (All the isomer shifts obtained in those glasses are smaller than 0.4 mm s^{-1} with respect to metallic iron.)

In the light of these reasons, the present Mössbauer and DTA (Differential Thermal Analysis) studies were carried out in order to elucidate the local structure and the structural change, brought about by the introduction of K_2O into the V_2O_5 matrix, of a series of potassium vanadate glasses. Small amounts of Fe_2O_3 were incorporated into the vanadate glasses as a Mössbauer probe. DTA method was utilized in order to know the structural change of the vanadate glasses through the glass transition temperature (T_g), because the T_g is known to reflect the change in the coordination number of network forming atoms and the destruction of the network structure followed by a formation of nonbridging oxygen atoms.[14,35-39]

Experimental

A series of potassium vanadate glasses were prepared by fusing the individual mixtures of commercially available K_2CO_3, V_2O_5, and Fe_2O_3, of a guaranteed reagent grade, at 1000 °C for 1 h in an electric muffle furnace. After the fusion in the ambient atmosphere, each melt in a platinum crucible was immediately quenched with ice-cold water in a beaker. The vanadate glasses were tried to prepare in the compositional ranges of $0 \leqq K_2O \leqq 40$ mol%, 50 mol% $\leqq V_2O_5 \leqq$ 90 mol%, and 5 mol% $\leqq Fe_2O_3 \leqq 20$ mol%. All the glass samples prepared in the present study were almost black in color and completely transparent. Mössbauer and DTA measurements were performed only for the vanadate glasses of which composition is expressed by $xK_2O \cdot (90-x)V_2O_5 \cdot 10Fe_2O_3$ in order to investigate the effect of the alkali oxide (K_2O) content on the structure of the vanadate glasses. Mössbauer measurements were performed by a constant acceleration method at room temperature with a proportional counter and a 1024 channel multichannel analyzer. Cobalt-57 (10 mCi) diffused into a palladium foil was used as the Mössbauer source. As the standard material for the isomer shift, a metallic iron foil enriched with iron-57 was used. The iron foil was also used for the velocity-calibration of the spectrometer. Each Mössbauer spectrum was analyzed into a quadrupole doublet with the same peak intensity and the same linewidth. DTA measurements of the vanadate glasses were performed in the temperature range from room temperature to 550 °C with a heating rate of 5 °C min^{-1}. An Al_2O_3 powder was used as the standard material in the DTA measurements.

Results and Discussion

The glass-forming region for the ternary K_2O-V_2O_5-Fe_2O_3 glass system is shown in Fig. 1, where open and closed circles indicate the formations of glass and non-glassy (devitrified) samples, respectively. It is easily understood from Fig. 1 that the introduction of the Fe_2O_3 into the K_2O-V_2O_5 system results in an extended glass-forming region as compared to the binary K_2O-V_2O_5 system. Extended glass-forming region has also been observed in CuO-V_2O_5-TeO_2 glass system,[18] and in BaO-V_2O_5-TeO_2, P_2O_5-V_2O_5-TeO_2, Fe_2O_3-V_2O_5-TeO_2, and ZnO-V_2O_5-TeO_2 glass systems.[40] On the other hand, reduced glass-forming region has been observed when TiO_2 is introduced into the V_2O_5-TeO_2 system.[40] The change in the glass-forming region will be correlated with the chemical and physical properties of the components, such as nature of the chemical bond, ionic radius, melting point, and viscosity. It is understood from Fig. 1 that the formation of the ternary K_2O-V_2O_5-Fe_2O_3 glasses is limited to a relatively small compositional region. A Mössbauer spectrum of the potassium vanadate glasses measured at room temperature is shown in Fig. 2, which indicates the

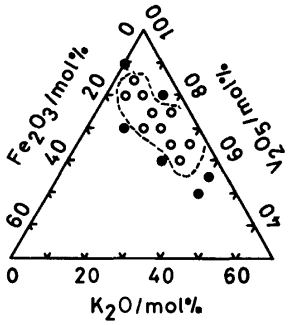

Fig. 1. Glass-forming region for the K_2O-V_2O_5-Fe_2O_3 system.

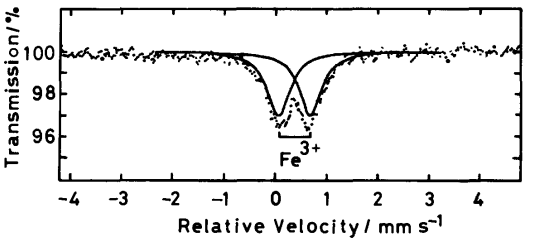

Fig. 2. Mössbauer spectrum of $15K_2O \cdot 75V_2O_5 \cdot 10Fe_2O_3$ glass measured at room temperature.

presence of paramagnetic Fe^{3+} ions of high spin state, since the isomer shift (with respect to metallic iron) of the quadrupole doublet is much larger than 0 mm s^{-1}.[41,42] (In the case of the absorptions due to the Fe^{3+} ions of low spin state, the isomer shift is known to fall to the neighborhood of 0 mm s^{-1}.[41,42]) All the Mössbauer parameters for the vanadate glasses studied in the present paper are summarized in Table 1, from which it is seen that the isomer shifts are located in a small range of 0.35—0.37 mm s^{-1}. As for the coordination number of iron in glasses, earlier works are reviewed by Kurkjian[43] and Coey.[44] Recent works on the structure of glasses are reviewed by Müller-Warmuth and Eckert.[45] Coey suggested that the Fe^{3+} ions are present at the tetrahedral sites in borate and silicate glasses.[44] This is well consistent with the Mössbauer results of a series of borate[14,46-48] and borosilicate[49,50] glasses containing small amounts of Fe_2O_3, performed by the present authors. In those Mössbauer studies,[14,46-50] all the isomer shifts (with respect to metallic iron) proved to lie in a range of 0.22—0.38 mm s^{-1}, and the experimental error for the isomer shift has been estimated to be ±0.01 or 0.02 mm s^{-1}. Judging from the experimental results shown in the reviews on the structure of glasses[43-45] and from the recent Mössbauer results on the structure of glasses performed by the present authors,[14,46-50] the isomer shift of the Fe^{3+} ions is concluded to be smaller than 0.40 mm s^{-1} for the tetrahedral symmetry. On the other hand, octahedrally coordinated Fe^{3+} ions have been observed in several phosphate glasses,[51-53] where all the isomer shifts proved to be larger than 0.42 mm s^{-1}. These experimental results lead to the conclusion that the criterion of the isomer shift for the Fe^{3+} ions with tetrahedral and octahedral symmetries lies at about 0.40 mm s^{-1}. Those symmetries strictly refer to the "distorted" octahedral and "distorted" tetrahedral configurations, since the bond lengths and the bond angles are widely distributed in the amorphous materials such as the glasses. This is well reflected in the magnitude of the linewidth summarized in Table 1, i.e., the linewidth is much larger than that of the ordinary crystalline compounds containing iron.[41,42] Considering all the experimental results described above, the present Mössbauer results, especially the isomer shifts suggest that the Fe^{3+} ions are present at the tetrahedral sites in the alkali vanadate glasses. This conclusion indicates the presence of VO_4 tetrahedral units as well as the FeO_4 units, because all the Mössbauer spectra, e.g. Fig. 2, obtained in the present study indicate the presence of a paramagnetic and homogeneous glass phase. All the Fe^{3+} ions are therefore concluded to be present at the substitutional sites of the V^{5+} (and probably V^{4+}) ions constituting VO_4 tetrahedra, as a constituent of the skeleton of the glass matrix. Similarly to the case of the Fe^{3+} ions incorporated into borate,[14,44,46-48] silicate,[44] and borosilicate[49,50] glasses, it is considered that the Fe^{3+} ions are easily incorporated into the vanadate matrix. The substitution of the iron for the other metal or metalloid ions will easily occur in the high energy and non-equilibrium states where the glass samples are prepared by fusion. It is also concluded that the introduction of the alkali oxide (K_2O in the present study) into the V_2O_5 matrix results in a formation of VO_4 tetrahedral units, instead of the VO_5 tetragonal pyramids (or trigonal bipyramids) which originally constituted the V_2O_5 matrix.[26,27] This conclusion is well consistent with the IR results obtained by Dimitriev et al.[28] They concluded that the introduction of the alkali or alkaline earth oxides into the V_2O_5 matrix results in a formation of VO_4 tetrahedral units. Their conclusion is based on the disappeared vibrational mode, originally observed at 1020 cm^{-1}, of the V=O bond constituting the VO_5 tetragonal pyramid (or trigonal bipyramid).[28] On the other hand, a few Mössbauer studies on the structure of vanadate glasses obtained recently[31-34] suggest that a large number of Fe^{3+} ions are octahedrally present at the interstitial sites, i.e., between the layer structure composed of the VO_5 units. The individual isomer shifts reported in those vanadate glasses are 0.36,[31] 0.35,[34] 0.30,[33] and 0.27—0.29[32] mm s^{-1} with respect to metallic iron. (The isomer shift of 0.36 mm s^{-1} in Ref. 31 was obtained by subtracting 0.26 mm s^{-1} from the isomer shift with respect to sodium nitroprusside.[41,42]) Considering the experimental results obtained in the present study, together with the several Mössbauer results of the structure of several kinds of glasses[14,43-53] and with the reviews on the coordination number of iron in several compounds,[41,42] it should be noted that those isomer shifts[31-34] are actually indicative of the presence of FeO_4 tetrahedral units constituting the skeleton of the glass matrix. Therefore, the conclusion on the structure of the vanadate glasses obtained in those Mössbauer studies,[31-34] i.e. a large number of Fe^{3+} ions are present at the octahedral and interstitial sites (between the layer structure), seems very doubtful.

Table 1. Mössbauer Parameters for K_2O-V_2O_5-Fe_2O_3 Glasses

Composition	δ[a] / mm s^{-1}	Δ[b] / mm s^{-1}	Γ[c] / mm s^{-1}
$5K_2O \cdot 85V_2O_5 \cdot 10Fe_2O_3$	0.37	0.61	0.60
$10K_2O \cdot 80V_2O_5 \cdot 10Fe_2O_3$	0.36	0.63	0.55
$15K_2O \cdot 75V_2O_5 \cdot 10Fe_2O_3$	0.36	0.62	0.53
$20K_2O \cdot 70V_2O_5 \cdot 10Fe_2O_3$	0.37	0.61	0.59
$25K_2O \cdot 65V_2O_5 \cdot 10Fe_2O_3$	0.36	0.59	0.58
$30K_2O \cdot 60V_2O_5 \cdot 10Fe_2O_3$	0.35	0.55	0.67

a) Isomer shift. b) Quadrupole splitting. c) Linewidth.

The composition dependency of the isomer shifts for the Fe^{3+} ions in the vanadate glasses obtained in the present study is shown in Fig. 3. It is seen from Fig. 3 that the isomer shifts are almost constant irrespective of the alkali oxide (K_2O) content, and that the isomer shift shows a slight decrease with the increase in the K_2O content. A drastic decrease in the isomer shifts of the Fe^{3+} ions has already been observed in borate[46-48] and borosilicate[49,50] glasses when the alkali oxide content increases. In those glasses,[46-50] the decrease in the isomer shift of the Fe^{3+} ions, which are present at the substitutional sites of the tetrahedral boron or silicon atoms, was ascribed to the formation of nonbridging oxygen atoms ($-O^-$) in BO_4 and SiO_4 tetrahedral units, because the formation of nonbridging oxygen atoms results in decreased interatomic distances between boron and oxygen or silicon and oxygen atoms. This will cause an increase in the s-electron density at the iron nucleus and the decrease in the isomer shift. The formation of nonbridging oxygen atoms will also affect the degree of the thermal vibration of boron or silicon atoms, and as a result, the increased thermal vibration (second order Doppler effect) will result in the decrease in the isomer shift. In the case of germanate glasses,[37,54] of which network structure is composed of GeO_4 and GeO_6 units, a drastic increase in the isomer shift of Sn^{4+} ions was observed. The increase in the isomer shift of the Sn^{4+} suggests an increased s-electron density at the tin nucleus, brought about by the formation of nonbridging oxygen atoms in GeO_4 tetrahedral units. (In the case of the ^{119}Sn-Mössbauer spectroscopy, an increase in the s-electron density results in the increase in the isomer shift, opposite to the case of the ^{57}Fe-Mössbauer spectroscopy.[41,42]) A slight decrease in the isomer shift shown in Fig. 3 is therefore ascribed to the formation of nonbridging oxygen atoms in the VO_4 tetrahedral units. This conclusion is supported by the remarkable composition dependence of the quadrupole splitting shown in Fig. 4. It is seen from Fig. 4 that the quadrupole splitting shows a distinct decrease when the K_2O content exceeds about 15 mol%. As for the composition dependency of the quadrupole splitting of the Fe^{3+} ions in glasses, distinct decreases in the quadrupole splitting have been observed when the nonbridging oxygen atoms are formed in borate,[46-48] borosilicate,[49,50] and phosphate[52,53] glasses. The decrease in the quadrupole splitting of the Fe^{3+} ions is ascribed to the increased symmetry around the Fe^{3+} ions, because the Fe^{3+} ions of high spin state have a symmetric electron configuration of $3d^5$, and only the electric field gradient brought about by the neighboring atoms or ions primarily affects the quadrupole splitting values. Similar phenomenon has been observed in the germanate glasses containing tin (Sn^{4+}),[37,54] where the nonbridging oxygen atoms are concluded to be formed in GeO_4 tetrahedral units. These considerations lead to the conclusion that the increase in the symmetry around the Fe^{3+} ions constituting the FeO_4 tetrahedral units, observed in the present study, indicates the formation of nonbridging oxygen atoms in the VO_4 tetrahedral units constituting the skeleton of the alkali vanadate glasses, because each Fe^{3+} ion is considered to be present at the substitutional site of the V^{5+} or V^{4+} ion as described above. Therefore, the present Mössbauer results lead to the conclusion that the increase in the K_2O content results in a decrease in the coordination number of vanadium ion from 5 to 4. At the same time, it is also concluded that nonbridging oxygen atoms are formed in some of the VO_4 tetrahedral units. (These Mössbauer results are based on the assumption that the structural change of the V^{5+} or V^{4+} ions, brought about by the introduction of K_2O into the V_2O_5 matrix, is equivalent to that of the Fe^{3+} ions.)

Each DTA curve of the potassium vanadate glasses containing 10 mol% Fe_2O_3 proved to consist of a simple endothermic peak due to glass transition and one or a few exothermic peak(s) due to crystallization. All the glass transition temperatures (T_g) obtained in the present study are shown in Fig. 5, where the T_g values are plotted against the K_2O content of the vanadate glasses. DTA studies on the structure of several glasses have already revealed that

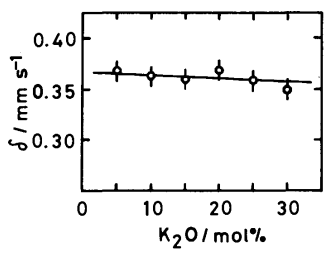

Fig. 3. Composition dependence of the isomer shift (δ) of the Fe^{3+} ions in K_2O–V_2O_5 glasses containing 10 mol% Fe_2O_3.

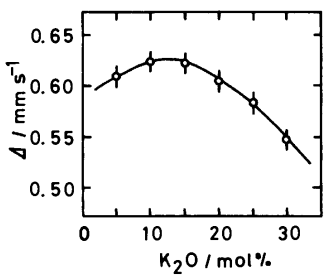

Fig. 4. Composition dependence of the quadrupole splitting ($\triangle$) of the Fe^{3+} ions in K_2O–V_2O_5 glasses containing 10 mol% Fe_2O_3.

T_g shows a close correlation with the change in the coordination number of the network-forming atoms (network former) and with the formation of nonbridging oxygen or fluorine atoms which means a destruction or depolymerization of the network structure.[14,35-38] The T_g, in general, shows a distinct increase when the coordination number of the network former increases. For example, the change in the coordination number of Ge from 4 to 6 is observed as a continuous increase in the T_g in the case of germanate glasses.[35-37] Contrary to this, a formation of nonbridging oxygen is known to cause a decrease in the T_g.[35-37] Considering these results, it is expected that a decrease in the coordination number of the network former, if present, will be observed as a decrease in the T_g. The continuous and distinct decrease in the T_g from 239 to 200 °C observed in the present study, therefore, seems to suggest the gradual decrease in the coordination number of V^{5+} and V^{4+} ions from 5 to 4. This conclusion obtained from the DTA measurements is well consistent with the IR results obtained by Dimitriev et al.[28] All the T_g values obtained in the present study are summarized in Table 2, together with the individual crystallization temperatures (T_c). It is understood from Table 2 that the T_c is higher than the T_g by 20—45 °C. In Table 2, only one crystallization temperature (the lowest one) is given for each glass sample. Considering the Mössbauer results (Figs. 3 and 4) obtained in the present study together with the previous DTA results described above,[35-37] the decrease in the T_g shown in Fig. 5 (and Table 2) is ascribed to the formation of nonbridging oxygen atoms in the VO_4 and FeO_4 tetrahedral units as well as the decrease in the coordination number of the V^{5+} and V^{4+} ions from 5 to 4. The formation of nonbridging oxygen atoms will become pronounced when the alkali oxide content of the vanadate glasses is high.

Table 2. Glass Transition and Crystallization Temperatures of K_2O-V_2O_5-Fe_2O_3 Glasses

Composition	T_g[a]/°C	T_c[b]/°C
$5K_2O \cdot 85V_2O_5 \cdot 10Fe_2O_3$	239	264
$10K_2O \cdot 80V_2O_5 \cdot 10Fe_2O_3$	232	255
$15K_2O \cdot 75V_2O_5 \cdot 10Fe_2O_3$	232	252
$20K_2O \cdot 70V_2O_5 \cdot 10Fe_2O_3$	224	253
$25K_2O \cdot 65V_2O_5 \cdot 10Fe_2O_3$	220	265
$30K_2O \cdot 60V_2O_5 \cdot 10Fe_2O_3$	200	240

a) Glass transition temperature. b) Crystallization temperature.

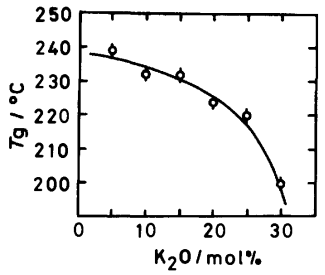

Fig. 5. Composition dependence of the glass transition temperature (T_g) of K_2O-V_2O_5 glasses containing 10 mol% Fe_2O_3.

All the experimental results obtained in the present study suggest that the introduction of alkali oxide into V_2O_5 matrix results in a structural change from VO_5 tetragonal pyramid (or trigonal bipyramid) to VO_4 tetrahedra. In addition to the formation of the VO_4 tetrahedra, a formation of nonbridging oxygen atoms is also concluded in the VO_4 tetrahedral units especially when the alkali oxide content is high. Each Fe^{3+} ion is concluded to be present at the substitutional site of the V^{5+} or V^{4+} ion constituting the VO_4 tetrahedral unit.

The authors are grateful to Dr. Hiroshi Hirashima of Keio University for his useful comments on the structure and physical properties of vanadate glasses. One of the authors (TN) is grateful to the Itoh Science Foundation for the financial support. The present work is partially supported by a Grant-in-Aid for Scientific Research No. 61740350 from the Ministry of Education, Science and Culture.

Racemic Structures of Organic Ammonium Salts of *N*-Acetyl-DL-2-aminobutyric Acid and *N*-Acetyl-DL-norvaline and Optical Resolution by Preferential Crystallization of DL-Ammonium Salts

Tadashi SHIRAIWA,* Hirokazu YOSHIDA, Makoto TSUDA, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received May 19, 1986)

The racemic structures of the ammonium salts (AM salts) and seven organic ammonium salts of *N*-acetyl-DL-2-aminobutyric acid (DL-AcAbu) and *N*-acetyl-DL-norvaline (DL-AcNva) were studied on the basis of thermodynamic analyses to explore the possibility of optical resolution by preferential crystallization. An empirical equation has been derived from thermodynamic data at melting points of ammonium and organic ammonium salts of *N*-acyl-DL-amino acids to predict racemic structures around room temperature. The AM salts of DL-AcAbu and -AcNva exist in conglomerate around room temperature. It is possible to resolve optically these DL-AM salts by preferential crystallization in ethanol at 10 °C, and the successive preferential crystallization followed by purification gave D- and L-2-aminobutyric acids and -norvalines with optical purities close to 100%.

DL-2-Aminobutyric acid[1] (abbreviated as DL-Abu) and DL-norvaline[2] (DL-Nva) have been optically resolved in the form of the *N*-acetyl derivatives by using the optically active α-methylbenzylamine as a resolving agent. However, no optical resolution by preferential crystallization of DL-Abu or -Nva has been reported though this procedure is considered to be useful for industrial operation. This paper describes an attempt to resolve optically the ammonium salts and organic ammonium salts of *N*-acetyl-DL-2-aminobutyric acid (DL-AcAbu) and *N*-acetyl-DL-norvaline (DL-AcNva) by preferential crystallization. The DL-salts employed are the ammonium (AM), *t*-butylammonium (TBA), pentylammonium (PTA), hexylammonium (HA), and 1,1,3,3-tetramethylbutylammonium (TMB) salts of DL-AcAbu and the AM, ethylammonium (EA), butylammonium (BA), and propylammonium (PA) salts of DL-AcNva.

The racemic structures of these DL-salts were examined, since optical resolution by preferential crystallization requires that a racemic modification exists in conglomerate. A racemic modification existing in conglomerate has a positive free energy of formation of racemate,[3-5] shows an infrared spectrum identical with that of the corresponding optically active one,[6] and is more soluble than the optically active one.[6] In this paper, an empirical equation is also derived on the basis of thermodynamic data at melting points of ammonium and organic ammonium salts of *N*-acyl-DL-amino acids[5,7-11] to predict racemic structures around room temperature. Since it was found that the AM salts of DL-AcAbu and -AcNva exist in conglomerate around room temperature, optical resolution by preferential crystallization of these DL-salts were attempted at 10 °C in ethanol.

Experimental

Materials. DL-Abu and -Nva were purchased from Sigma Chemicals, and (−)-α-methylbenzylamine and amines from Wako Pure Chemicals Ind.

***N*-Acetylation.** DL-AcAbu[12] and -AcNva[2] were obtained, respectively, by acetylating DL-Abu and -Nva in the usual way. The DL-AcAbu obtained was recrystallized from ethanol, and the DL-AcNva from water. DL-AcAbu: Mp 134 °C (lit,[12] 128—130 °C); yield 82.0%. DL-AcNva: Mp 117 °C (lit,[2] 118—119 °C); yield 81.7%.

Preparation of Optically Active *N*-Acetylamino Acids. D- and L-AcAbu's[1] and -AcNva's[2] were obtained, respectively, by optical resolution of DL-AcAbu and -AcNva by using (−)-α-methylbenzylamine as a resolving agent. D-AcAbu: Mp 135 °C (lit,[1] 135 °C); $[\alpha]_D^{20}$ +43.3° (*c* 2.00, water) (lit,[1] $[\alpha]_D^{20}$ +43.6° (*c* 2, water)). L-AcAbu: Mp 135 °C (lit,[1] 135 °C); $[\alpha]_D^{20}$ −43.3° (*c* 2.00, water) (lit,[1] $[\alpha]_D^{20}$ −43.5° (*c* 2, water)). D-AcNva: Mp 105 °C (lit,[12] 100 °C); $[\alpha]_D^{20}$ +34.7° (*c* 2.00, water) (lit,[12] $[\alpha]_D^{25}$ +35.0° (*c* 1—2, water)). L-AcNva: Mp 105 °C; $[\alpha]_D^{20}$ −34.3° (*c* 2.00, water).

Preparation of Salts. DL-, D-, or L-AcAbu (0.01 mol) and 0.01 mol of an amine were dissolved in 50 cm³ of acetone. After stirring for 30 min at 5 °C, the salt formed was collected by filtration. The salt obtained was recrystallized from ethanol. The AM salts of DL-, D-, and L-AcNva's were also prepared in a similar manner.

The AM salt of DL-AcAbu: Mp 170 °C; found C, 44.35; H, 8.67; N, 17.43% (calcd for $C_6H_{14}N_2O_3$: C, 44.43; H, 8.70; N, 17.27%); solubility at 10 °C 2.103 g/(100 cm³ ethanol). The D-salt: Mp 188 °C; found C, 44.35; H, 8.66; N, 17.38%; $[\alpha]_D^{20}$ −20.7° (*c* 0.50, ethanol); solubility at 10 °C 1.319 g/(100 cm³ ethanol). The L-salt: Mp 188 °C; $[\alpha]_D^{20}$ +20.7° (*c* 0.50, ethanol).

The AM salt of DL-AcNva: Mp 150 °C; found C, 47.61; H, 9.11; N, 15.99% (calcd for $C_7H_{16}N_2O_3$: C, 47.71; H, 9.15; N, 15.90%); solubility at 10 °C 4.733 g/(100 cm³ ethanol). The D-salt: Mp 181 °C; found C, 47.57; H, 9.11; N, 16.04%; $[\alpha]_D^{20}$ −19.7° (*c* 0.50, ethanol); solubility at 10 °C 2.269 g/(100 cm³ ethanol). The L-salt: Mp 181 °C; $[\alpha]_D^{20}$ +19.7° (*c* 0.50, ethanol).

Optical Resolution by Successive Preferential Crystallization. Ammonium Salt of *N*-Acetyl-DL-norvaline: The AM salt of DL-AcNva (5.208 g) and 0.050 g of the L-salt were dissolved in 100 cm³ of ethanol around 40 °C. The solution was slowly cooled to 10 °C and seeded with 0.010 g of the L-salt. After stirring for 10 min at 10 °C, the salt that

precipitated was collected by filtration, washed with a small amount of diethyl ether, and dried; yield 0.276 g. The DL-salt (0.277 g) was added to the filtrate, and dissolved in ethanol around 40 °C. The solution was cooled to 10 °C and seeded with 0.010 g of the D-salt. After stirring for 11 min at 10 °C, the salt that precipitated was collected by filtration; yield 0.287 g. The filtrate was treated similarly.

Ammonium Salt of *N*-Acetyl-DL-2-aminobutyric Acid: The AM salt of DL-AcAbu (2.103 g) and 0.050 g of the L-salt were dissolved in 50 cm^3 of ethanol and the solution was seeded with 0.020 g of the L-salt at 10 °C. After stirring for 8 min, the salt precipitated was collected by filtration. The DL-salt (0.218 g) was dissolved in the filtrate. After seeding with 0.020 g of the D-salt and stirring for 8 min at 10 °C, the salt precipitated was collected by filtration. The filtrate was treated similarly.

The degree of resolution of the AM salts of D- and L-AcAbu and -AcNva's obtained was calculated by

$$\text{Degree of resolution/\%} = [\text{YOPM/g} \times 100]/[(\text{Operation amount of D- or L-salt/g}) - \text{M}],$$

where YOPM is the yield of optically pure modification[7] and M is 0.526 for the AM salts of AcAbu, and 2.367 g for the AM salts of AcNva.

Purification of Partially Resolved Ammonium Salts. The AM salt of D-AcAbu with an optical purity of 52.7% (3.78 g) was added to 85 cm^3 of ethanol. After stirring around 40 °C for 30 min, the suspension was further stirred for 1 h at 10 °C. The D-salt was collected by filtration, washed with a small amount of diethyl ether, and dried; yield 1.94 g; $[\alpha]_D^{20}$ −20.7° (*c* 0.50, ethanol).

The partially resolved AM salts of D-AcNva were purified by using ethanol similarly to the AM salt of D-AcAbu. The D-salt with an optical purity of 74.1% (6.96 g) was treated with 39 cm^3 of ethanol to give the D-salt with an optical purity of 100% in 5.07 g yield.

Preparation of Optically Active Amino Acids. The AM salts of D- and L-AcAbu's and -AcNva's obtained by preferential crystallization were purified similarly. The salts purified were treated with hydrochloric acid in the usual way to give the respective optically active amino acids.

The AM salt of D-AcNva with an optical purity of 100% (3.50 g) was dissolved in 4 cm^3 of 6 mol dm^{-3} hydrochloric acid around 50 °C, and the solution was stirred around 5 °C for 1 h. The D-AcNva was collected by filtration, washed with a small amount diethyl ether, and dried; yield 3.03 g; $[\alpha]_D^{20}$ +34.9° (*c* 2.00, water). The D-AcNva (2.90 g) was added to 7 cm^3 of 6 mol dm^{-3} hydrochloric acid. After refluxing for 2.5 h, the solution was evaporated to dryness under reduced pressure around 35 °C and the residue was dissolved in 30 cm^3 of methanol. After adding 2.4 cm^3 of concentrated aqueous ammonia, the solution was stirred for 1 h around 5 °C. The D-Nva that precipitated was collected by filtration, washed with small amounts of cold water and methanol, and dried: yield 1.56 g (total yield 71.1%); $[\alpha]_D^{20}$ −24.0° (*c* 2.00, 5 mol dm^{-3} HCl) (for L-Nva[13] $[\alpha]_D^{20}$ +24.1° (5 mol dm^{-3} HCl)).

The purified AM salts of L-AcNva and D- and D-AcAbu's were treated with hydrochloric acid similarly to the AM salt of D-AcNva. L-Nva: total yield 70.5%; $[\alpha]_D^{20}$ +23.9° (*c* 2.00, 5 mol dm^{-3} HCl). D-Abu: total yield 65.3%; $[\alpha]_D^{20}$ −20.7° (*c* 2.00, 5 mol dm^{-3} HCl). L-Abu: total yield 65.1%; $[\alpha]_D^{20}$ +20.9° (*c* 2.00, 5 mol dm^{-3} HCl) (lit,[13] $[\alpha]_D^{20}$ +20.9° (5 mol dm^{-3}HCl)).

Measurements. Specific rotations were measured with a Union Giken high sensitivity PM-101 digital polarimeter using a quartz cell of 0.5 dm path length. Infrared spectra were obtained in the range 4000—400 cm^{-1} with a JASCO A-102 infrared spectrophotometer by the KBr disk method. Enthalpies of fusion and melting points were determined with a Rigaku Denki differential scanning calorimeter DSC-8230.

Results and Discussion

Racemic Structure. Thermodynamic Data: The formation of a racemate in the solid state corresponds to the reaction between the solid enantiomers. The Gibbs energy of formation at *T* K (ΔG_T^F) is calculated

Table 1. Thermodynamic Data for Ammonium and Organic Ammonium Salts of *N*-Acetyl-2-aminobutyric Acid and *N*-Acetylnorvaline

N-Acetylamino acid	Salt	Mp/K		ΔH^f a)/kJ mol^{-1}		ΔG_T^F b)/kJ mol^{-1}

	BA[l]	387	398	35.9	28.9	−0.76	−2.82

a) ΔH^f: Enthalpy of fusion. b) ΔG_T^F: Free energy of formation of racemate. The ΔG_T^F's at the melting point (ΔG_{mp}^F) and at 283 K (ΔG_{283}^F) were calculated from equations in Refs. 3—5. c) AcAbu: *N*-Acetyl-2-aminobutyric acid. d) AcNva: *N*-Acetylnorvaline. e) AM: Ammonium salt. f) TBA: *t*-Butylammonium salt. g) PTA: Pentylammonium salt. h) HA: Hexylammonium salt. i) TMB: 1,1,3,3-Tetramethylbutylammonium salt. j) EA: Ethylammonium salt. k) PA: Propylammonium salt. l) BA: Butylammonium salt.

by the following equation which is derived from the equations reported by Jacques et al.[3] by combination:

$$\Delta G_T^F = (\Delta H_A^f - \Delta H_R^f) - T(\Delta S_A^f - \Delta S_R^f) - RT\ln 2 - \Delta C_p(T_A^f - T_R^f + T\ln T_R^f/T_A^f) + (\alpha/2)(T_{R,A}^f - T)^2, \quad (1)$$

where ΔH^f, ΔS^f, and T^f are the enthalpy of fusion, entropy of fusion, and melting point, respectively, R is the gas constant, and ΔC_p is the difference in heat capacity between the liquid and solid states in the vicinity of melting point; subscripts "A" and "R" represent the optically active and racemic modifications, respectively; $T_{R,A}^f$ represents T_R^f when $T_R^f < T_A^f$ and T_A^f when $T_R^f > T_A^f$; α is calculated from $C_A^s - C_R^s = \alpha T_{R,A}^f$ as a first approximation; C^s is the heat capacity in the solid state.[3] The term containing ΔC_p is negligible for the calculation of ΔG_{mp}^F at the melting point because the contribution is very much smaller than that of the sum of the other terms in the right-hand side of Eq. 1;[3] T is equal to $T_{R,A}^f$ at the melting point and hence the last term is zero. In our calculation, ΔC_p was taken as 105 J mol^{-1} K^{-1} and $C_A^s - C_R^s$ as 31.4 J mol^{-1} K^{-1}.[3-5] The ΔG_T^F's at the melting point (ΔG_{mp}^F) and 283 K (ΔG_{283}^F) are given in Table 1.

As found in Table 1, all salts of DL-AcAbu and -AcNva give negative ΔG_{mp}^F values except the AM salt of DL-AcNva. The eutectic temperatures and compositions calculated on the basis of the ΔH^f and melting points[14] are listed in Table 2, together with the observed melting points of mixtures with eutectic compositions. Only the AM salt of AcNva shows the composition of 0.5. These results indicate that only the AM salt of DL-AcNva exists in conglomerate and that the other DL-salts form racemic compounds in the vicinity of the melting points. The above results are supported by the binary phase diagrams of melting points; the phase diagrams of the AM salts of AcAbu and AcNva are shown in Figs. 1 and 2 as examples.

Table 2. Mole Fractions and Temperatures at Eutectic Points

N-Acetyl-amino acid	Salt	Mole fraction of D-salt[a]	Temperature/K	
			Found	Calcd[a]
AcAbu	AM	0.64	442	441
	TBA	0.94	408	407
	PTA	0.82	377	375
	HA	0.82	378	379
	TMB	0.68	419	418
AcNva	AM	0.50	423	424
	EA	0.76	390	390
	PA	0.73	381	383
	BA	0.72	383	384

a) These values were calculated from the Schröder-Van Laar and Prigogine-Defay equations.

The AM salt of DL-AcNva gives a positive ΔG_{283}^F value, whereas negative ΔG_{283}^F values were obtained for the TBA, PTA, HA, and TMB salts of DL-AcAbu and the EA, BA, and PA salts of DL-AcNva. Therefore, the racemic structures of the latter around room temperature may be identical with those in the vicinity of the melting points, respectively. On the other hand, since the AM salts of DL-AcAbu and DL-AcNva give positive ΔG_{283}^F values, it is inferred that the DL-salts do not form racemic compounds around room temperature.

Racemic Structure Around Room Temperature: The relationship among various thermodynamic data at melting points was examined to predict the racemic structures around room temperature for the 41 kinds of AM and organic ammonium salts of DL-AcAbu, DL-AcNva, and *N*-acyl-DL-amino acids, dealt with in our previous paper.[5,7-11] There is an empirical relationship among their ΔG_{mp}^F, ΔT^f ($=T_R^f - T_A^f$), and $\Delta\Delta H^f$

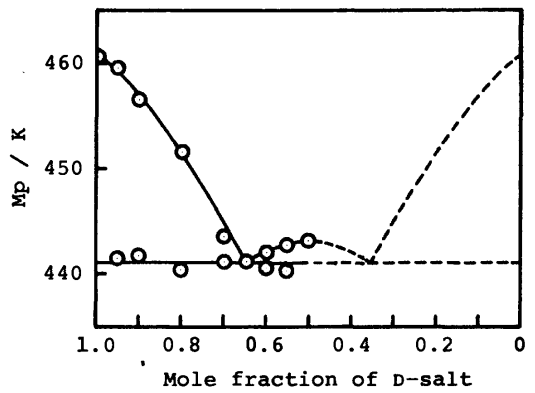

Fig. 1. Binary melting point diagram of ammonium salt of *N*-acetyl-2-aminobutyric acid.

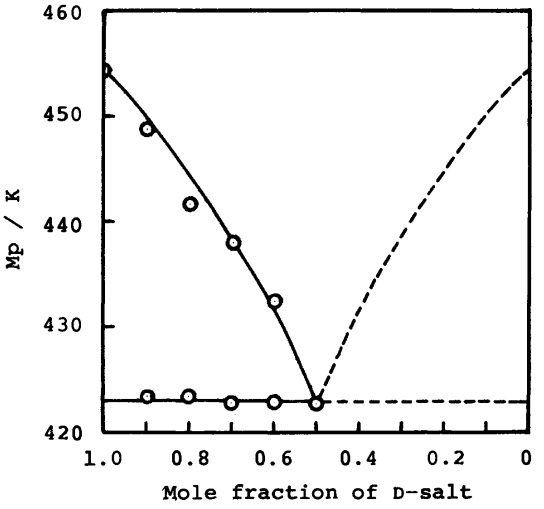

Fig. 2. Binary melting point diagram of ammonium salt of *N*-acetylnorvaline.

$(=H^f_R - \Delta H^f_A)$, which reads

$$\Delta G^F_{mp} = -0.0865\Delta T^f - 0.0223\Delta\Delta H^f - 2.285, \quad (2)$$

where $-0.0865\Delta T^f - 0.0223\Delta\Delta H^f$ $(=\Delta E)$ and 2.285 must be of the same order as ΔG^F_{mp}; the correlation coefficient was 0.958. This empirical equation shows that a DL-salt that exists in conglomerate around room temperature gives ΔE larger than $+1.17$ kJ mol^{-1}, irrespective of whether the DL-salt forms a racemic compound in the vicinity of its melting point, and that a DL-salt forming a racemic compound in the temperature range between room temperature and its melting point gives ΔE smaller than $+1.14$ kJ mol^{-1}. The AM salt of DL-AcAbu gives a ΔE value of $+1.68$, the AM salt of DL-AcNva $+2.87$, and the other DL-salts -2.4—$+1.13$ kJ mol^{-1}. Therefore, the ΔE values may be used to determine if the AM salts of DL-AcAbu and -AcNva exist in conglomerate around room temperature. This is consistent with the conclusion derived from their ΔG^F_{283} values, and is also supported by the infrared spectra and solubilities of these DL- and D-salts; the AM salts of DL-AcAbu and -AcNva show infrared spectra identical with those of the corresponding D-salts, they are more soluble than the D-salts, and the ternary solubility diagram of the AM salt of DL-AcAbu shows what is expected for a conglomerate, as shown in Fig. 3.[15] The above results indicate that the AM salts of DL-AcAbu and -AcNva exist in conglomerate around room temperature though the AM salt of DL-AcAbu forms a racemic compound in the vicinity of the melting point.

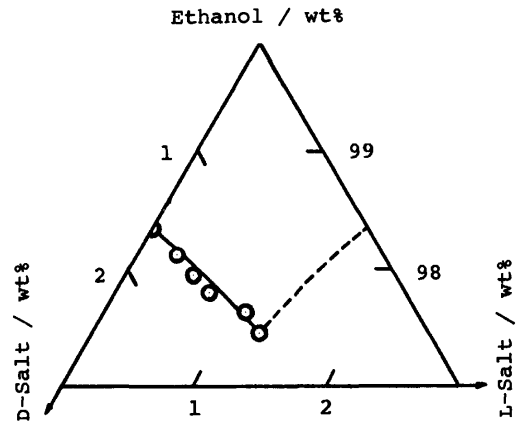

Fig. 3. Ternary solubility diagram of ammonium salt of *N*-acetyl-2-aminobutyric acid.
Solvent: ethanol. Temperature: 10 °C.

The TBA, PTA, HA, and TMB salts of DL-AcAbu and the EA, BA, and PA salts of DL-AcNva probably form racemic compounds around room temperature because their infrared spectra are different from those of the corresponding D-salts and because their ΔG^F_{283} values are negative.

Optical Resolution by Preferential Crystallization. Results of Optical Resolution and Purification of Salts Partially Resolved: Optical resolutions by preferential crystallization of the AM salts of DL-AcAbu and DL-AcNva were attempted at 10 °C in ethanol using a solution of the AM salt of DL-AcAbu with a degree of supersaturation of 200% and a solution of the AM salt of DL-AcNva with 110%, by a procedure similar to that described in our previous paper;[10] the D-salts were used as seed crystals. The results of the optical resolutions are given in Table 3.

The AM salts of D-AcAbu obtained did not have so high optical purities (41—79%) and the degrees of resolution were also low (10—25%); however it was possible to obtain AM salts of D-AcNva with optical purities of 72—95% and degrees of resolution of 40—78%.

The AM salt of D-AcAbu with a low optical purity was easily purified. The AM salt of D-AcAbu with an optical purity of 71.2% (3.00 g) was dissolved in 110 cm^3 of ethanol around 40 °C, and the solution was

Table 3. Optical Resolutions by Preferential Crystallization of Ammonium Salts of *N*-Acetyl-DL-2-aminobutyric Acid[a] and *N*-Acetyl-DL-norvaline[b]

N-Acetyl-amino acid	Resolution time / min	Yield / g	Optical purity / %	YOPM[c] / g	Degree of resolution / %

	15	0.205	94.9	0.184	77.7
	20	0.248	72.5	0.170	71.9

a) Solvent: 50 cm^3 of ethanol. Degree of supersaturation of racemic solution: 200%. Seed crystals: 0.020 g of D-salt. Temperature: 10 °C. b) Solvent: 100 cm^3 of ethanol. Degree of supersaturation of racemic solution: 110%. Seed crystals: 0.010 g of D-salt. Temperature: 10 °C. c) YOPM: Yield of optically pure modification.

allowed to stand for a day around 5 °C to give a D-salt with an optical purity of 100%. However, the yield (1.62 g) was 75.7% of the theoretical (2.14 g) and the recrystallization resulted in a loss of about 24%.

The optimum amount of ethanol was estimated on the basis of the solubility at 10 °C of the DL-salt to obtain the maximum yield of the optically pure salt.[16] The AM salt of D-AcAbu with an optical purity of 52.7% was treated with ethanol. Since 3.78 g of the D-salt was not completely dissolved in 85 cm^3 of ethanol around 40 °C, the suspension was treated by the procedure described in the experimental section; the optimum amount of ethanol calculated was 85.1 cm^3. The purification by this procedure gave the D-salt with an optical purity of 100% in 1.84 g yield; the yield was 92.5% of the theoretical (1.99 g).

The AM salt of D-AcNva partially resolved was also easily purified similarly. The D-salt with an optical purity of 74.1% (6.96 g) was treated with 38 cm^3 of ethanol (the optimum amount 38.0 cm^3) to give the D-salt with an optical purity of 100% in 5.07 g yield; the yield was 98.3% of the theoretical (5.16 g).

Successive Preferential Crystallization: The optical resolution by successive preferential crystallization was carried out to obtain the D- and L-Abu's and -Nva's. The results of such optical resolution are given in Tables 4 and 5.

The AM salts of D- and L-AcAbu obtained had optical purities of 72—81%, and the degrees of resolution were 20—28%. On the other hand, the optical resolution of the AM salt of DL-AcNva was found to give better results; D- and L- salts with optical purities of 90—100% were obtained at degrees of resolution of about 80%. These D- and L-salts purified were treated with hydrochloric acid to give D- and L-Abu's and -Nva's with optical purities of 99—100%.

It was found from the above results that the AM salts of DL-AcAbu and -AcNva exist in conglomerate around room temperature though the AM salt of DL-AcAbu forms a racemic compound in the vicinity of the melting point, and that the optical resolution by preferential crystallization followed by purification gives D- and L-Abu's and -Nva's with optical purities of about 100%.

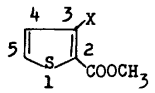
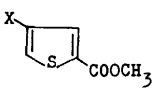
(Received July 4, 1986)

The ^{13}C NMR spectra have been reported on substituted 2-thiophenecarboxylic acid methyl esters. The chemical shift of ring carbons in methyl (4- and 5-substituted 2-thiophenecarboxylate)s was correlated linearly with that of the corresponding carbons in substituted thiophenes. Plots of the ^{13}C-H coupling constants of methyl (substituted 2-thiophenecarboxylate)s against those of substituted thiophenes showed a good linear relation. The ^{13}C NMR data were interpreted by the stable conformation and percent *s* character of C-H bonds obtained by MNDO calculation.

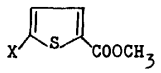
The ^1H NMR spectra of methyl (3-substituted 2-thiophenecarboxylate)s (**1**), methyl (4-substituted 2-thiophenecarboxylate)s (**2**), and methyl (5-substituted 2-thiophenecarboxylate)s (**3**), were reported by one of the present authors,[1] and the effects of the substituents were discussed.[1] The additivity rule for the ^1H chemical shifts of simple substituted thiophenes was applicable to the ring protons in the compounds of series **2** and **3**, but inapplicable to those in the compounds of series **1**. Based on the facts we



1



2



3

examined the ^{13}C NMR spectra of substituted 2-thiophenecarboxylates of these three series. Similar deviation from the additivity rule has also been observed by ^{13}C chemical shift of some 2,3-disubstituted thiophenes by the present authors. The deviation will be due to steric and electronic interaction between the neighboring substituents on thiophene ring. The conformational change may affect on the deviation, because the anisotropy caused by substituents as well as the attractive interaction between substituents considerably perturbs ^{13}C and ^1H chemical shifts. Molecular orbital calculation with geometry optimization has been applied in many investigations as one of the reliable methods for predicting the stable conformer. Among many versions of MO calculation, MNDO[2,3] is known as the most practicable and trustworthy way to estimate the geometry and the energy of conformation of the organic molecule.

We will discuss the relation between observed ^{13}C chemical shift and the stable conformers predicted by MNDO calculation. In addition, this report deals with the correlation between the percent *s* character obtained from $^1J_{C-H}$ and that calculated by MNDO method.

Experimental

The preparation of materials were described previously.[1] ^{13}C NMR spectra were recorded by a JEOL FX-90Q spectrometer. The concentration of sample solutions was adjusted to approximately 0.6 mol dm^{-3}. The chemical shift was measured in an accuracy of ±0.1 ppm with internal TMS reference in a $CDCl_3$ solution at the probe temperature. Data acquisition was done by the following conditions: flip angle of pulse 30°, number of transients 1000, data points 16384, and spectral width 4500 or 5000 Hz. The ^{13}C-H coupling constant in an accuracy of ±0.1 Hz was obtained from proton coupled spectra measured by the normal gated decoupling technique. Data acquisition was done by the following conditions: flip angle of pulse 45°, number of transients 2000, data points 16384, and spectral width 450 Hz.

MNDO Calculation[2,3]

The MNDO (Modified Neglect of Diatomic Overlap) calculation, semiempirical SCF molecular orbital calculation which takes all valence electrons into account, was carried out by MOPAC program[4] on HITACHI M-280H computer at the Computer Center of the University of Tokyo. By the standard MNDO calculation, electronic energy, core-core repulsion energy, ionization potential, heat of formation, density matrix (electron density and bond order), eigenvalue (energy level), and eigenvector of the molecular orbitals can be obtained. The structure of stable conformers of methyl (substituted 2-thiophenecarboxylate)s was estimated by means of XDC data base (Cambridge Crystallographic Data Base) installed at the Computer Center of the University of Tokyo. The structural parameters were used as the input data for the MNDO calculation. The *s* character of the C-H bonds was calculated from the coefficients of the corresponding molecular orbitals.

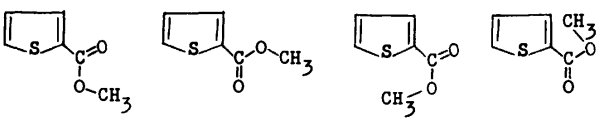
Results and Discussion

The ^{13}C NMR signals of methyl (3-, 4-, and 5-substituted 2-thiophenecarboxylate)s (**1**—**3**) were as-

signed by the procedures described below. The signals of protonated carbons were assigned from the coupling constants of carbon-proton bonds. Since $J_{C_5H_5}$ in thiophene compounds is larger than $J_{C_3H_3}$ or $J_{C_4H_4}$ by ca. 15 Hz,[5-7] C_5 and C_4 in the compounds of series **1** and C_5 and C_3 in the compounds **2** are easily distinguished from each other by ^{13}C-H one bond coupling constants. The ^{13}C-signals of C_3 and C_4 in the compounds of series **3** were assigned by the comparison with those of substituted thiophenes and partly by the analysis of line splitting due to a long-range coupling.[5,6] The signals of quaternary carbons were assigned by their intensity, and also by the ^{13}C-H long-range couplings. The results are given in Tables 1—3.

The plots of the chemical shift of carbons in methyl (4-substituted 2-thiophenecarboxylate)s against that of the corresponding carbons in 3-substituted thiophenes[8] showed good linear correlations (δC_2 r[9] 0.917, p 1.09, s 0.396; δC_3 r 0.993, p 1.06, s 0.464; δC_4 r 1.000, p 0.981, s 0.621; δC_5 r 0.996, p 0.898, s 0.843). The chemical shift of carbons in methyl (5-substituted 2-thiophenecarboxylate)s also correlates linearly with that of the corresponding carbons in 2-substituted thiophenes. These results suggest that the additivity rule for the ^{13}C chemical shift of simple substituted thiophenes is applicable to the chemical shift of the ring carbons in methyl (4- and 5-substituted 2-thiophenecarboxylate)s in which two substituents are attached to non-adjacent ring-carbon atoms. However, the chemical shift of carbons in methyl (3-substituted 2-thiophenecarboxylate)s and that of the corresponding carbons in 3-substituted thiophenes showed poor correlations. Thus, the interaction among substituents seems to result in deviation from the linear correlation. The interaction will be of steric nature, and the perturbation by neighboring substituent in a conformational preference can cause a considerable change in chemical shift.

In order to investigate the relation between chemical shift and stable conformation, we have estimated the stable conformation of these thiophene derivatives and their populations by MNDO calculation. Methyl 2-thiophenecarboxylate can take any one of the planar conformers **a**—**d**. Our calculations showed, however, that this ester is a mixture of **a** (50%) and **b** (50%) conformers and that other two conformers (**c** and **d**) have considerably higher energy than **a** and **b**. The calculations also showed that all other esters do not exist in the **c** and **d** conformers. It agrees with



a (50%) (*s-cis*) **b** (50%) (*s-trans*) **c** (0%) **d** (0%)

the previous reports informing the predominance of (*Z*)-conformations in alkoxycarbonyl groups.[10-12]

In general, conjugated enones take *s-trans* (**b**) conformation preferentially, while the electrostatic interaction between sulfur and carbonyl dipole repels to each other to make the *s-cis* (**a**) conformer

equally populated, because the energy difference between *s-cis* and *s-trans* conformers calculated is small, though the *trans* conformer has a slightly lower energy than the *cis* conformer. This implies that the conformational distribution of these substituted compounds is similar to that of parent methyl 2-thiophenecarboxylate, and, in addition, the four stable conformers exist in a nearly equal population even when the substituent (X) is unsymmetrical with respect to the plane perpendicular to molecular plane

Table 6. The Stable Conformers and Their Abundance (%) of Methyl (5-Substituted 2-Thiophenecarboxylate)s (Series **3**)

(i.e. when the substituent is methyl, formyl, acetyl, and methoxycarbonyl). In methyl (4- and 5-substituted 2-thiophenecarboxylate)s, methoxycarbonyl group was confirmed to be coplanar with thiophene ring. The additivity rule for the ^{13}C chemical shift of substituted thiophenes should be applicable to explain the chemical shift of ring carbons in the compounds of series of **2** and **3**, because the effect of two dissimilar conformations balances in series **2** and **3**.

In the compounds of series **1**, the conformational equilibrium tends to shift to the most stable conformer, and the population sometimes becomes as high as 80%, generally ca. 70%. As a whole, the neighboring substituent effect seems to be governed by the electrostatic interaction between substituent and 2-methoxycarbonyl group, as revealed by calculated dipole moments of conformers (Table 7). As enone is inclined to take the electrostatically stabilized *s-trans* conformation, *s-trans* conformers of **1** predominate over other conformers. In other words, carbonyl group of 2-methoxycarbonyl tends to lie *anti* to the

electronegative group at the 3-position, avoiding close access of two negatively charged atoms. Exceptionally, in methyl 3-formyl-2-thiophenecarboxylate, the *s-cis* conformer which has higher dipole moment is predominant to the *trans* conformer. In the most stable conformer of the formyl derivative, weak intramolecular interaction like hydrogen bonding[13] will occur between formyl proton and carbonyl oxygen of methoxycarbonyl group, because the proton is acidic due to the electron-attracting ability of formyl carbonyl oxygen. The assumption is supported by remarkably large bond population (0.00338) between nonbonded formyl hydrogen and carbonyl oxygen of 2-$COOCH_3$. The bond population between two nonbonded atoms is usually less than 10^{-5}. In respect of this figure, the bond population is exceptionally large and comparable to the value for OH$\cdots\pi$ hydrogen bonded atoms.[14] On the other hand, in acetyl, methoxycarbonyl, and nitro derivatives, methoxycarbonyl group will lose the coplanarity with thiophene ring due to the steric hindrance. Since the alkoxycarbonyl conformation of 3-substituted 2-thiophenecarboxylates is remarkably altered by a neighboring substituent, the magnetic anisotropy and electric field by carbonyl group will affect differently the chemical shift of ring carbons in each compound.[15] The chemical shift of ring carbons of methyl (3-substituted 2-thiophenecarboxylate)s is not correlated linearly with that of substituted thiophenes. However, if various effects by steric and electronic interactions between the neighboring substituents on thiophene ring in the compounds of series **1** are corrected, the ^{13}C chemical shift of compounds of this series will be correlated well with those of substituted thiophenes.

The electron density values derived from MNDO calculation of methyl (substituted 2-thiophenecarboxylate)s are summarized in Table 8. Levy and coworkers have reported that the plot of ^{13}C chemical shift vs. CNDO/2 total charge density for para position of substituted benzene shows fairly good linearity.[16] However, the MNDO electron density on the C_2 of compounds of series **3** which corresponds to *para* position in substituted benzene[17,18] correlates poorly with the ^{13}C chemical shift. For all the compounds studied, plots of the electron density against ^{13}C chemical shift showed poor correlations. As the electron density in MNDO calculation is of the diamagnetic term, the ^{13}C chemical shift in methyl (substituted 2-thiophenecarboxylate)s is considered to be controlled by the paramagnetic contributions as the case of pyridine.[19]

The ^{13}C-H one bond coupling constant of the ring C-H of methyl (substituted 2-thiophenecarboxylate)s is correlated linearly with that of substituted thiophenes [$^1J_{C_4H_4}$ (**1**) r 0.991, p 0.903, s 0.465; $^1J_{C_5H_5}$ (**1**) r 0.975, p 1.04, s 0.442; $^1J_{C_3H_3}$ (**2**) r 0.996, p 0.958, s 0.364; $^1J_{C_5H_5}$ (**2**) r 0.999, p 0.973, s 0.192; $^1J_{C_3H_3}$ (**3**) r 0.990, p 0.854, s 0.301; $^1J_{C_4H_4}$ (**3**) r 0.994, p 0.899, s 0.297]. It is interesting that the relation between the ^{13}C-H one bond coupling constants of methyl (3-substituted 2-thiophenecarboxylate)s and those of 3-substituted thiophenes is linear. Although the substituent effect on the ^{13}C chemical shift of ring carbons is considerably affected by steric and electronic interactions between neighboring substituents, the substituent effect on $^1J_{C_4H_4}$ (**1**) and $^1J_{C_5H_5}$ (**1**) is linear.

The percent s character (ρ_{C-H}) obtained by an empirical correlation expressed by Eq. 1[20] from $^1J_{C-H}$ of methyl (substituted 2-thiophenecarboxylate)s is given in Table 9 together with the results calculated by MNDO method.

$$\rho_{C-H}=0.2\,{}^1J_{C-H} \quad (1)$$

It was shown in Tables 1 and 2 that $^1J_{C_5H_5}$ is larger than

$^1J_{C_3H_3}$ or $^1J_{C_4H_4}$, and the same tendency also appeared in the results by MNDO calculation. Plots of the percent *s* characters for all 28 compounds from $^1J_{C-H}$ and MNDO method showed a good correlation (*r* 0.940, *p* 0.718, *s* 0.386).

The authors wish to thank Mr. Hitoshi Shimazaki for his assistance in MNDO calculation. The calculation was carried out by HITACHI M-280H computers of the University of Tokyo and Institute for Molecular Science.

14) Respective non-bonded OH···C bond populations in the CH···π hydrogen-bonded conformers (two species) of 1-phenyl-2-propanol were reported to be 4.79×10^{-3} and 7.44×10^{-3}. See: K. Abe, M. Hirota, and K. Morokuma, *Bull. Chem. Soc. Jpn.*, **58**, 2713 (1985).
15) For example, the differences between the observed and the calculated ^{13}C chemical shifts of methyl 3-formyl-2-thiophenecarboxylate were 6.8, 5.1, 1.8, and 4.1 ppm, on C_2, C_3, C_4, and C_5, respectively. The differences on C_3 and C_5 are explained by the change of conformation of methoxycarbonyl group, because the differences in electron density (Δe) between the two conformers of methyl 3-formyl-2-thiophenecarboxylate become in the order $C_3(0.013)>C_5(0.007)>C_2(0.002)$, $C_4(0.002)$. The 3-formyl group is fixed to take the (*E*) conformation with respect to the C_3–C_{formyl} bond in methyl 3-formyl-2-thiophenecarboxylate, while 3-thiophenecarbaldehyde exists as a mixture of the two possible conformers. Thus, the reference chemical shift value of 3-thiophenecarbaldehyde corresponds to the equilibrium mixture of the conformers, and the difference in electron density on C_2 of the two conformers (Δe=0.029) may cause large deviation. Accordingly, it is considered that the chemical shift of β-carbon to carbonyl group changes more than 5 ppm by complete change of the carbonyl conformation.

NAD(P)$^+$-NAD(P)H Model. 62. The Mechanism of the Silica Gel-Catalyzed Reduction with an NAD(P)H Model

Shinro YASUI,* Masayuki FUJII,† Kaoru NAKAMURA,† and Atsuyoshi OHNO†

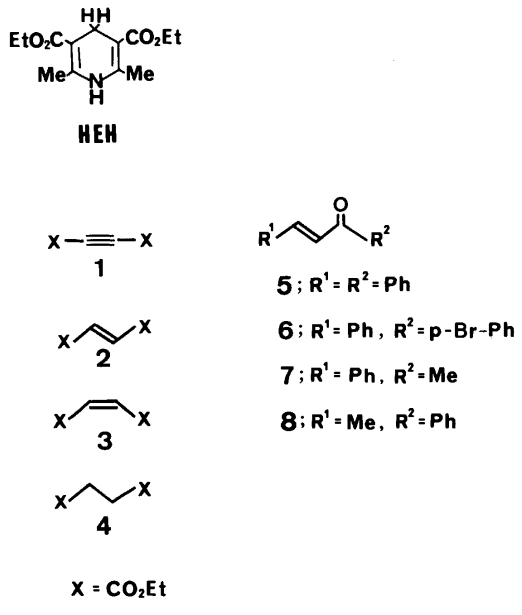
(Received July 23, 1986)

The reduction of diethyl acetylenedicarboxylate, diethyl fumarate, and diethyl maleate as well as several α,β-unsaturated carbonyl compounds by a model of NAD(P)H on silica gel was examined. The order of the reactivity for the reduction was reverse to that of the degree of adsorption of the substrates onto the surface of silica gel. Semiquantitative analysis of the results suggests the possibility that silanol groups on the surface of silica gel act as general acid catalysts in the course of the reduction.

Recently, attentions have been focused on the utility of NAD(P)H models as reducing agents in organic synthesis.[1-5] The advantage of the reduction with an NAD(P)H model relies on its mildness in reducing ability. Thus, the model has a capacity to exert a novel selectivity in the reduction of a particular functional group with the aid of a certain catalyst. We reported previously that an NAD(P)H model selectively gives rise to reductive dehalogenation of an organic halide in the presence of a rhodium complex.[1] Moreover, we found that silica gel is a selective catalyst for the 1,4-reduction of α,β-unsaturated carbonyl compounds by an NAD(P)H model, 3,5-bis(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine (Hantzsch ester: HEH), in benzene.[4]

Silica gel sometimes seems more useful catalyst in organic synthesis than an organometal complex such as a rhodium complex, since one can easily handle it and can remove it from the reaction mixture by filtration after completion of the reaction. Unfortunately, we have little informations in our hands about the mechanism of catalysis by silica gel. In order to apply the silica gel-catalyzed reduction by an NAD(P)H model to other systems more widely, it may be important to reveal the details as to the role of silica gel.

We studied the mechanism of the reduction by using diethyl acetylenedicarboxylate (**1**), diethyl fumarate (**2**), and diethyl maleate (**3**) as model substrates. These substrates are expected to be adsorbed onto the surface of silica gel in a different manner due to their individual configurations. Through the product analyses for the reduction by HEH as well as the measurements of efficiency of substrate adsorption onto the surface of silica gel, we found several interesting facts. We report in this article the possibility that silanol groups on the surface of silica gel contribute to the reduction of the unsaturated carbon-carbon bonds in **1**, **2**, and **3** through general acid catalysis. We also mention briefly the results for the reduction of several α,β-unsaturated carbonyl compounds.



Chart

Results

NAD(P)H Model and Silica Gel. We have found that an NAD(P)H model, Hantzsch ester (HEH), has tolerance against self-decomposition in the presence of silica gel. Furthermore, in polar solvents such as acetonitrile, methanol, and chloroform, the reduction does not take place.[4] Based on these reasons, we employed HEH as an NAD(P)H model and benzene as the solvent in the present studies.

Use of silica gel with a fine mesh (e.g. 200 mesh) afforded scattered results for the yield, probably due to difficulty of complete removal of the materials from the surface of silica gel prior to the product analysis even when the catalyst was washed repeatedly with an appropriate solvent. Moreover, extremely slow rate of sedimentation of silica gel with a fine mesh after the stirring prevented accurate determination of the amount of adsorbed substrate. Then, we utilized silica gel 60 of 35—70 mesh (Nakarai Chem. CO.). The content of water in the silica gel 60 used in this study was measured to be 4.6±0.2 mmol g^{-1} on Kirl-Fisher

moisture content meter. Drying the silica gel over phosphorus pentaoxide in vacuo at 100—120 °C for 7 h removed only ca. 20% of adsorbed water, then causing no appreciable alteration in the yield of the reduction. On the other hand, adsorption of the substrate and HEH as well as the reduction was dramatically suppressed when silica gel contains ca. 12 mmol g^{-1} of water. Water content in the solvent was measured to be negligible relative to that in the silica gel.

Adsorption onto the Surface of Silica Gel. The efficiency of adsorption of diesters **1—3** and HEH as well as diethyl succinate (**4**) onto the surface of silica gel was examined initially. The amount of the substrate as well as HEH in the bulk phase (S_{Bulk}) was determined on vapor phase chromatography (VPC) for **1—4** or high performance liquid chromatography (HPLC) for HEH after stirring an appropriate amount of the substrate (or HEH) and 0.2 g of the silica gel in 1 ml of benzene at 70 °C under nitrogen atmosphere for 30 min.[6] The adsorbed amount of the substrate (or HEH) (S_{Ad}) was given by subtracting S_{Bulk} from the stoichiometric amount of the substrate (or HEH).

In order to analyze the results, we assume a simple equilibrium with respect to the adsorption of substrate (or HEH) onto the surface of silica gel, as is expressed by Eq. 1.

$$S_{Bulk} + Q_{free} \overset{K}{\rightleftharpoons} S_{Ad} \quad (1a)$$

$$Q_{free} = Q_0^{0.2} - S_{Ad} \quad (1b)$$

where S_{Bulk} and S_{Ad} are the amounts (mmol) of the substrate (or HEH) in bulk phase and adsorbed, respectively, and $Q_0^{0.2}$ is the maximum amount (mmol) of substrate being adsorbed onto the surface of 0.2 g of silica gel. Equilibrium constant K in Eq. 1 is given by Eq. 2

$$K = S_{Ad}/(S_{Bulk} \cdot Q_{free}) \quad (2)$$

Note that since these experiments were performed in 1 ml of the solvent, each term with dimension of mmol is equivalent to molarity, and, as a consequent, K has a dimension of M^{-1} (=dm^3/mol). We can readily lead Eq. 2 to Eq. 3.

$$\frac{1}{S_{Ad}} = \frac{1}{K \cdot Q_0^{0.2}} \cdot \frac{1}{S_{Bulk}} + \frac{1}{Q_0^{0.2}} \quad (3)$$

Equation 3 predicts that the plot of $1/S_{Ad}$ vs. $1/S_{Bulk}$ with the amount of the substrate being variable will give a straight line, and each line for different substrates will have a common intercept because the value of $Q_0^{0.2}$ could be reasonably considered to be identical for all substrates. This is indeed the case, and the correlations for diesters **1—4** and HEH are exemplified in Fig. 1. The intercepts for five straight lines are identical within experimental error, affording $Q_0^{0.2}=(7.37\pm0.28)\times10^{-2}$ mmol. Importantly, this value is compatible with the amounts of several types of modifying agents loaded onto the surface of silica gel.[7] Thus, the value elucidated presently designates an "effective" amount of silanol groups on the surface. Dividing the intercept by the slope, we obtain equilibrium constants K for **1—4** and HEH. The values are summarized in Table 1.

Although the plots are scattered a little (correlation coefficient r=0.98—0.998), reinforcement for the validity of this treatment is given by similar examinations for chalcone (**5**), 4′-bromochalcone (**6**), benzylideneacetone (**7**), and crotonophenone (**8**). The relationships between $1/S_{Ad}$ and $1/S_{Bulk}$ for these substrates showed excellent linearity (r>0.9999 except for r=0.9997 for **7**) and from the intercepts of the lines (Fig. 2) the value of $Q_0^{0.2}$ was determined to be $(7.18\pm0.16)\times10^{-2}$ mmol,[8] which is consistent with that obtained from the set shown in Fig. 1. The K values for **5—8** are also summarized in Table 1. The results support our assumption that the ad-

sorbed and free substrates (and HEH) are in equilibrium in the mixtures.

Silica Gel-Catalyzed Reduction by HEH. The reduction of diesters **1—3** were carried out in the presence of the silica gel in 1 ml of benzene at 70 °C under nitrogen atmosphere in the dark for 18 h. After removal of the silica gel by filtration followed by concentration of the filtrate, the residue was analyzed on VPC, GC/MS, and HPLC (see Experimental Section). It was confirmed that the unsaturated carbon-carbon bonds of the substrates are reduced, ester groups remaining intact. The yields of the reduction product(s) and the recovered starting material are listed in Table 2. Although the yields of the reduction product(s) for each run are not so high, the data listed in Table 2 are suggestive of the role of the silica gel when the K values listed in Table 1 are taken into consideration as well (vide infra).

The reduction of α,β-unsaturated carbonyl compounds **5—8** were also carried out under the same conditions mentioned above. Although these substrates were quantitatively reduced into the corresponding saturated carbonyl compounds, their relative reactivities can be roughly compared on the basis of the yield of reduction product after the reaction period of 4 h (Table 3).

We examined the catalytic abilities of heterogeneous acid catalysts, Amberlyst 15 and Nafion 511, toward the reduction of **3** by HEH. Whereas 27 and 33% of 1.0×10^{-1} mmol of **3** was adsorbed on Amberlyst 15 and Nafion 511, respectively, in 1 ml of benzene at 70 °C, no reduction product was found from these systems. This is mainly due to rapid decomposition of HEH under the catalysis of the strong acids.

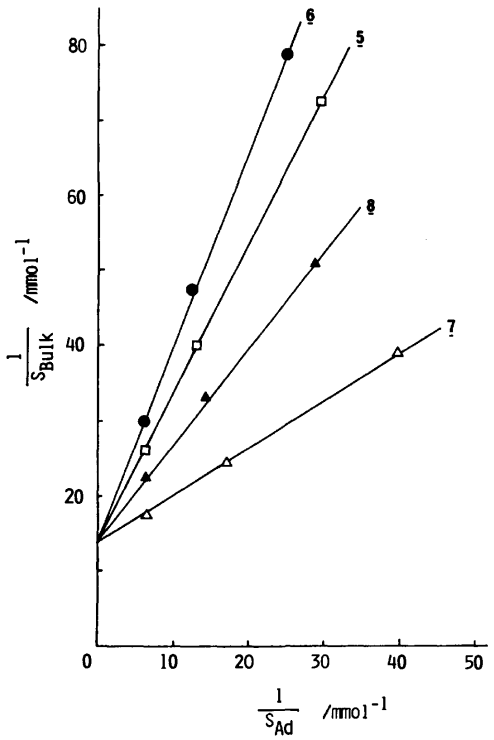

Fig. 2. $1/S_{Ad}$ vs. $1/S_{Bulk}$ plots for α,β-unsaturated carbonyl compounds with 0.2 g of the silica gel in 1 ml of benzene.

a) 1.0×10^{-1} mmol of a substrate, 1.5×10^{-1} mmol of HEH, and 0.2 g of silica gel 60 were used unless otherwise mentioned. The reaction was carried out in 1 ml of benzene at 70 °C in the dark under N_2 atmosphere. b) The yield determined by VPC analysis based on the amount of the substrate used. c) The yield of the recovered starting material. d) The yield of the reduction product, corresponding saturated carbonyl compound. e) Not detected. f) Isolated yield from the reaction of 5.0×10^{-1} mmol of a substrate with 7.5×10^{-1} mmol of HEH in the presence of 1.0 g of silica gel 60 in 5 ml of benzene.

Discussion

The order of K values for diesters is **1**<**2**≪**3**<**4** as shown in Table 1. The examination of CPK models reveals that four oxygen atoms of the two ester groups in **3** and **4** can approach closely, that is, **3**, and **4** are able to have both hydrophilic and hydrophobic faces within one molecule. On the other hand, **1** and **2** cannot assume such a conformation. Therefore, it is reasonably expected that the former substrates are adsorbed onto the surface of silica gel through hydrophilic interaction between the oxygens of the substrate and silanol group(s) on the surface of silica gel. HEH exhibits large K value, to which poor solubility of HEH in benzene may also contribute. The degree of adsorption of α,β-unsaturated carbonyl compounds **5**—**8** seems to depend on the electronegativity of the carbonyl oxygen rather than on the steric factor.

Table 2 shows that the order of reactivity of diesters in the reduction by HEH is **1**>**2**>**3**; the reverse order of the equilibrium constant. The *trans*-alkene **2** is reported to have less negative reduction potential than the *cis*-alkene **3**.[9] Moreover, it is well documented that a carbon-carbon triple bond is more susceptible to a nucleophile than a double bond.[10] Reduction potential and electrophilicity are, of course, predominant factors in determining the reactivity of these reductions. Nevertheless, taking such limited factors alone into consideration, one obtains much less useful informations about the role of the silica gel. Here, it is worthwhile to emphasize that the larger the K value, the lower the reactivity toward the reduction. The reductions of α,β-unsaturated carbonyl compounds **5**—**8** gives similar results. Again, the tendency can be seen that the substrate with a larger K value is less reactive except for **8**. The compound **8** may belong to the category other than that for **5**—**7** because of difference in the structure, i.e., substitution of a methyl group in place of the β-phenyl group.

Now, we can simulate the amounts of the substrate and HEH on the surface of silica gel under the reaction conditions at the incipient stage of the reaction (S_{Ad}). Thus, S_{Ad}'s for two coexisting components are given by resolving Eqs. 4—6, which are derived from Eq. 2, simultaneously.

$$K_A = (S_{Ad})_A/((S_0)_A - (S_{Bulk})_A)Q_{free} \quad (4)$$

$$K_B = (S_{Ad})_B/((S_0)_B - (S_{Bulk})_B)Q_{free} \quad (5)$$

$$Q_{free} = Q_0^{0.2} - (S_{Ad})_A - (S_{Ad})_B, \quad (6)$$

where subscripts A and B denote the parameters referred to components A and B, respectively, and S_0 is the stoichiometric amount of the substrate. Computation without any approximation afforded the S_{Ad} values as listed in Table 4 for each reduction. The validity of this treatment was supported by the excellent agreement between computed and observed S_{Ad} values for the solution containing **5** and **6**, where both values can be directly compared with each other because no reaction takes place in this mixture. The data are also listed in Table 4. Significantly, S_{Ad} values for the substrates to be reduced are not so large; in particular for the reduction of **1** with a small amount of the silica gel, S_{Ad} values for the substrate are nearly two orders less than the total amounts of the products generated. Note that the reduction product(s) is (are) adsorbed onto the surface of silica gel to the extent similar to or larger than that for the starting material as can be seen in Table 1.

Table 4. Calculated S_{Ad} Values[a]

Component ($S_0/\times 10^{-1}$ mmol)[b]		S.G.[c]/g	S_{Ad}(calcd)/$\times 10^{-2}$ mmol

a) Based on $Q_0^{0.2} = 7.18\times 10^{-2}$ mmol and the K values listed in Table 1. See text for details. b) The values in parentheses indicate the stoichiometric amount (S_0) of each component. c) The amount of the silica gel. d) The values in parentheses are observed ones.

One possible explanation for the role of silica gel is that it acts as a carrier of a substrate to its surface on which materials are concentrated to facilitate the reaction.[11] Such an effect would be essential in some heterogeneous catalyst-mediated reactions. In fact, the adsorbents other than silica gel, Celite 545 and cellulose, gave rise to no adsorption of **1**—**3** as well as HEH and then no reduction was observed in these systems. Yet, this effect does not appear to explain entirely the role of the silica gel at least in the present study. A perspective of S_{Ad} values in Table 4 suggests, instead, that the species in bulk phase is responsible for the reaction. There are several examples where an organic reagent adsorbed on heterogeneous catalyst

interacts with another organic reagent in bulk phase to afford a product.[12] Although the possibility cannot be excluded that HEH reduces the substrate only when both reagents are adsorbed in the vicinity of the surface of silica gel at the same time during the time course of dynamic equilibrium between the surface and bulk phase, it is safely speculated that the reaction takes place between HEH on the surface of silica gel and the substrate in bulk phase.[13]

This concept is partly supported by the results from the experiments using acetonitrile as a solvent. In acetonitrile, neither the reduction of **3** by HEH nor adsorption of HEH onto the surface of silica gel was observed, while **3** was adsorbed onto the surface with the equilibrium constant of $4\pm1\ M^{-1}$.[14] This indicates the requirement of adsorption of HEH onto the surface of silica gel for the reaction, adsorption of the substrate being dispensable. Less adsorption in acetonitrile than that in benzene is attributable to higher solubility of the components in acetonitrile and/or stronger adsorption of the solvent molecule onto the surface. Interestingly, no reduction of **3** by HEH occur in the presence of active alumina (acidic and basic) in place of silica gel even though the adsorption of **3** onto the aluminas were 18—26% under the conditions where 1.0×10^{-1} mmol of **3** and 0.2 g of alumina were stirred in 1 ml of benzene at 70 °C for 30 min.

It is not probable that the trace amount of alumina in the silica gel plays an important role in the reactions, because no appreciable alteration in the reactivity of the reduction as well as the equilibrium constant K for the adsorption is recognized in the experiments using highly pure silica gel [special silica gel #923 (100—200 mesh) (Fuji Davison Chem. Co.); the content of alumina is 0.04%] in place of the silica gel 60 used in this study: the yield of the product in the reduction of **5** after the reaction period of 4 h is 55%; the K value for **5** is $8.2\ M^{-1}$; and the value of $Q_0^{0.2}$ for the silica gel #923 is 8.5×10^{-2} mmol. These results are comparable to those obtained by using the silica gel 60.

Consider that in the present system the silica gel not only adsorbs reactants on the surface but also plays certainly a more crucial role for the reduction. Consequently, we propose the possibility that the silica gel facilitates the reduction with HEH through general acid catalysis of silanol group(s) on the surface.[11b] The possibility would persist provided that some quantity of silanol groups on the surface remains free.[15] It was also shown in this study that unnecessarily strong acid catalyst is unfavorable for the reduction due to the sensitivity of an NAD(P)H model toward the acid-catalyzed decomposition. Although the evidence obtained presently is not direct for supporting general acid catalysis by silica gel, the concept might be a useful working hypothesis for the study on the role of silica gel.

Experimental

Apparatus. VPC, HPLC, and GC/MS analyses were performed on a Yanaco G-180 gas chromatograph, a Toyo Soda CCPD high-performance liquid chromatograph equipped with a UV-8000 UV-visible detector, and a Hewlett-Packard 5992B GC/MS spectrometer, respectively. ^{1}H NMR and IR spectra were recorded on a JASCO JNM-FX 100FT NMR spectrometer and a Hitachi 260-10 infrared spectrophotometer, respectively. Water content in the solvent and the silica gel was measured on a Kyoto Electronics MFG Karl-Fisher moisture content meter Model MK-AS. Computer-assisted simulations were run on an NEC PC-9801 personal computer VM2 with a N_{88} BASIC program.

Materials. 3,5-Bis(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine (HEH) was synthesized according to the procedure described in the literature.[16] Diesters **1**—**4** as well as α,β-unsaturated carbonyl compounds **5**, **7**, and **8** were commercially available. 4′-Bromochalcone (**6**) was obtained by condensation of benzaldehyde with 4-bromoacetophenone followed by recrystallization from ethanol (mp 101—104 °C). Spectral data of these compounds were satisfactory. Heterogeneous catalysts, silica gel 60 (35—70 mesh) (Nakarai Chem. Co.), active aluminium oxide (acidic and basic) (Merck & Co. Inc.), Amberlyst 15 (Organo), and Nafion 511 (Toyo Soda),[17] were purchased and, if required, activated with ordinary method prior to the use. Benzene was distilled and deaerated with an inert gas, then the content of water was measured.

Measurement of Adsorption onto the Surface of Silica Gel. In 1 ml of benzene were vigorously stirred an appropriate amount of a substrate and 0.2 g of silica gel 60 (35—70 mesh) at 70 °C under nitrogen atmosphere for 30 min. A 25-μl aliquot from the supernatant was added to 100 μl of benzene containing an internal standard for VPC or HPLC analysis, then the solution was analyzed on VPC (for **1**—**8**; OV-330 column) or HPLC (for HEH; TSKgel ODS-80T$_M$ column, methanol:water=7:3 (v/v) as eluent).

Product Analysis. In the presence of an appropriate amount of silica gel 60, 1.0×10^{-1} mmol of a substrate was allowed to react with 1.5×10^{-1} mmol of HEH at 70 °C in the dark under nitrogen atmosphere with vigorous stirring. After 18 h, the silica gel was filtered off through a glass filter, and washed repeatedly with several portions of 10 ml of benzene. Careful concentration of the filtrate below 40 °C in vacuo to dryness and subsequent addition of 1 ml of methanol to the residue afforded a transparent solution, which was analyzed on VPC, HPLC, and GC/MS. For the isolation of the product, the reaction was performed on the scale five times larger than that mentioned above. Then, the reduction product was isolated on column chromatography (silica gel No. III (200 mesh) (Nakarai Chem. Co.); benzene as eluent), and its ^{1}H NMR and IR spectra were recorded.

Synthesis and Properties of Cyclohepta[*hi*]pyrrolo-[2,1,5-*cd*]indolizines[1)]

Michihiko NOGUCHI,* Ryoichi TAMAI, Noriyuki TANIGAWA, Hiroyuki OKUMURA, and Shoji KAJIGAESHI

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received July 23, 1986)

The oxidation of the methylene moiety of 4,5,6,7-tetrahydrocyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines with NBS gave 5-bromo-6,7-dihydro- (**4**) and 5-bromo-cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines. The dehydrobromination of **4** with DBU afforded cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines in good yields. The characteristic electronic features of these cycloheptapyrroloindolizines are discussed on the basis of the MO calculations and the spectroscopic properties.

Many investigations on cyclazine systems have been reported from synthetic and physicochemical as well as biological viewpoints.[2)] Among them, the cyclazine systems peri-fused by another ring system have attracted our attention regarding the following three points: i) the development of synthetic strategies, ii) the interest for novel chemical and physical properties, and, especially, iii) the investigation on the perturbation of parent nuclei stemmed from the condensation of another ring system.

Recently, we reported that 4*H*-benzo[*hi*]pyrrolo-[2,1,5-*cd*]indolizin-4-ones were synthesized by the regioselective oxidation of 5,6-dihydro-4*H*-benzo[*hi*]-pyrrolo[2,1,5-*cd*]indolizines with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) and that their spectral data implied the exsistence of a peripheral 12 π electronic system in an acidic medium.[3)] As a continuation of our studies, we investigated the synthesis of cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine, a novel ring system,[4)] which was expected to have a highly polarized structure as predicted from MO calculations.

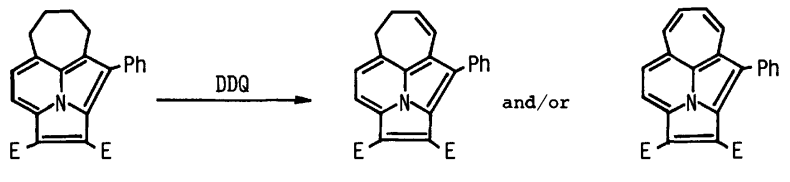
We wish to report here the synthesis of some cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine derivatives by the oxidation of the methylene moiety of 4,5,6,7-tetrahydrocyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines with DDQ or *N*-bromosuccinimide (NBS). The interesting electronic features of the cyclohepta-pyrroloindolizines are also discussed.

Results and Discussion

Synthesis of Cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines. The dehydrogenation of 4,5,6,7-tetrahydro-1,2-bis(methoxycarbonyl)-3-phenylcyclohepta[*hi*]pyrrolo-[2,1,5-*cd*]indolizine (**1a**) with an equimolar DDQ in dry benzene at 5—10 °C gave the 6,7-dihydro derivative **2**[5)] in 31% yield. However, the sequent dehydrogenation of **2** to the expected 1,2-bis(methoxycarbonyl)-3-phenylcyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine (**3a**) with DDQ or palladium-charcoal under various conditions afforded only unsatisfactory results (see experimental section).

In any event, these findings implied an oxidation of the methylene moiety of **1a** with an appropriate oxidizing agent to provide the full conjugated cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine system; therefore, we examined the oxidation of **1a** with NBS.

When a solution of **1a** and NBS (2.2 equimolar) in dry carbon tetrachloride was refluxed under irradiation with a tungsten lamp for 6 h, two kinds of colored products, **4a** and **5a**, were obtained in 56 and 33% yields, respectively. The similar oxidation of the pentadeuteriophenyl derivative (**1a**-d_5) with NBS gave



1a **2** **3a**

E: CO_2Me

2 —(Pd/C or DDQ)→ **3a** (poor yield)

Scheme 1.

corresponding pentadeuteriophenyl-type products, **4a**-d_5 and **5a**-d_5. The heating of **4a** with an equimolar NBS in carbon tetrachloride afforded **5a** in 64% yield. This means that **4a** is an intermediary product leading to **5a**.

The yellow crystalline **4a** was assigned to 5-bromo-6,7-dihydro- and the reddish crystalline **5a** to 5-bromo-3-phenylcyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine from the analytical and spectral data in comparison with those of **2** and **3a**.

Especially, the regiochemistry of the bromo substituent of **4a** or **5a** was confirmed by measurements of nuclear Overhauser effect (NOE) of **5a**-d_5. As shown in Fig. 1, the irradiation at δ 7.38 (8-H) resulted in an 11% enhancement in the signals at δ 6.65 (superimposed signals due to 6- and 7-H). On the other hand, the irradiation at δ 8.10 (9-H) resulted in a 4% decrease in the signals due to 6- and 7-H.

Similarly, the reaction of 4,5,6,7-tetrahydrocyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines **1b—d** with NBS gave the corresponding 5-bromo-6,7-dihydro-**4b—d** and 5-bromo-cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]-indolizines **5b—d** in good total yields (Scheme 2). These results as well as electronic spectral data of **4** and **5** are summarized in Tables 1 and 4, respectively.

A reaction of **4a** with an excess of 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) in toluene under reflux gave **3a** in 64% yield. The 3-arylcyclohepta[*hi*]pyrrolo-[2,1,5-*cd*]indolizines **3a**-d_5-**3d** were also obtained by a similar dehydrobromination of the 5-bromo-6,7-dihydro derivatives **4a**-d_3-**4d**. These results as well as the electronic spectral data of **3** are summarized in Tables 2 and 4, respectively.

Our attention was then focused on the preparation of 1,2-unsubstituted cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]-indolizines. The saponification of **3a** with 5% methanolic potassium hydroxide followed by acidification afforded the diacid. This was decarboxylated in refluxing quinoline in the presence of copper dust to give the expected 3-phenylcyclohepta[*hi*]pyrrolo-[2,1,5-*cd*]indolizine (**6a**) in 84% yield from **3a**. 3-Pentadeuteriophenyl (**6a**-d_5) and 3-(*p*-bromophenyl)-cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine (**6d**) as well as 4,5,6,7-tetrahydro-3-phenylcyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine (**7a**) and its pentadeuteriophenyl derivative **7a**-d_5 were obtained by similar saponification and successive decarboxylation (Scheme 3). However, a similar treatment of **5a** afforded an unseparable mixture of the desired 5-bromo-3-phenylcycloheptapyrrolo-indolizine and **6a**, in which a reductive debromination by copper would occur.

As mentioned above, the full conjugated cyclo-

hepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines **3** and **5** were obtained by the oxidation of the 4,5,6,7-tetrahydro derivative **1** or the dehydrobromination of 5-bromo-6,7-dihydro derivatives **4**. Thus, this oxidation reaction of the methylene moiety turned out to be available for the synthesis of the full conjugated fused [3.2.2]cyclazine systems.

Properties of Cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines. The Hückel molecular orbital calculations for cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine (**B**) were carried out using the reported parameters[6] for pyrrolo[2,1,5-*cd*]indolizine (**A**). These results[7] show that the introduction of the cyclohepta moiety into **A** causes a large change in the electronic features of the parent cyclazine nuclei, as follows: The difference of the π-electron densities at the 8- and 9-positions of **B** becomes remarkably large in comparison with that[6] at the 6- and 7-positions of **A**. The π-electron densities at the 1- and 2-positions of **A** are considerably different from one another, while those of **B** are reversed and averaged. As a whole, in cycloheptapyrroloindolizine **B** the seven-membered ring is slightly positively charged and the negative charge is delocalized over the cyclazine system. Therefore, the contribution of the polarized structure, **C** or **D**, to the ground state of **B** is conceivable (Scheme 4).

The electronic spectra of the 6,7-dihydro derivatives of cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizine, **2** and **4**, shift wholly toward longer wavelengths (10—30 nm) compared with that of the tetrahydro derivative **1a** owing to the extention of π-electron system (Table 4). On the other hand, the electronic spectra of 4,5,6,7-tetrahydro-3-phenyl- (**7a**) and 3-phenylcyclohepta-[*hi*]pyrrolo[2,1,5-*cd*]indolizine (**6a**) in chloroform are shown in Fig. 2. Therein, the spectrum of **6a** exhibits fine structures over the range of 490—620 nm; these would be attributed to the proposed dipolar structure.

The ^{1}H NMR spectra of the cycloheptapyrroloindolizines and their dihydro and tetrahydro derivatives were highly dependent on the concentrations of the measuring probes, i.e., the signals of protons of **6a** were observed at higher field as the concentration of the sample is increased. Thus, considerations on the chemical shifts of ring protons are made using a 0.12 M† solution in deuteriochloroform[8] of the corresponding samples. The chemical shifts and coupling constants of the pentadeuteriophenyl derivatives, **6a**-d_5 and **7a**-d_5, are listed in Table 3.

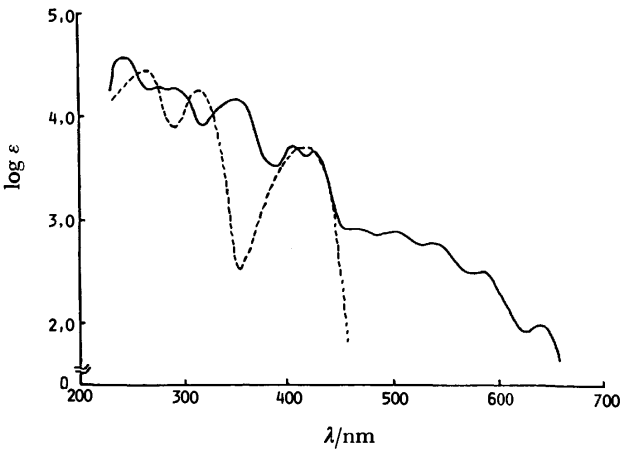

Fig. 2. Electronic spectra of **6a** (——) and **7a** (----) in chloroform.

Scheme 3.

† 1 M=1 mol dm^{-3}.

The seven-membered ring protons of **6a**-d_5 were observed at a higher field than those of 2-phenylcyclohepta[*hi*]imidazolo[2,3,4-*cd*]indolizine,[9] a 2-aza analog of **6**, and comparable to those of acepleiadiene,[10] tropone,[11] or cycloheptatrienylideneamines.[12] On the other hand, taking the deshielding effect due to the newly-formed polyene system into consideration it is noteworthy that the proton at the 8-position of **6a**-d_5 could be observed at a higher field ($\Delta\delta$=0.26) than that of **7a**-d_5. Probably, the negative charge resulted from a dipolar structure (**C** or **D**) partially located at the carbon atom at the 8-position.

The values of the coupling constants between the protons of seven-membered ring of **6a**-d_5 are almost consistent with those of acepleiadiene,[10] tropone,[11] heptafulvenes,[11] or cycloheptatrienylideneamines.[12] This means an apparent bond-alternation of the seven-membered ring of **6**, while the bond-alternation of the seven-membered ring of 2-phenylcyclohepta-[*hi*]imidazolo[2,3,4-*cd*]indolizine[9] can be scarcely seen.

From these results, we suggest that the resonance for **C** is the most predominant polarized structure contributed to the ground state of cyclohepta[*hi*]-pyrrolo[2,1,5-*cd*]indolizine (**B**).

Further investigations on the properties and chemical reactivities of cyclohepta[*hi*]pyrrolo[2,1,5-*cd*]indolizines are now in progress.

Experimental

General. All melting points are uncorrected. The IR spectra were obtained on a JASCO IRA-1 spectrometer. The ^{1}H NMR spectra were recorded on a JEOL FX-200, FX-100, or JMN-MH-100 spectrometer with tetramethylsilane as an internal standard. The mass spectrometer was equipped with a direct inlet and had at an ionization energy of 75 eV. The elemental analyses were performed on a Hitachi 026 CHN analyzer. For thin-layer and preparative column chromatography, silica gel 60F-254 (Merck) and Wakogel C-300 were used, respectively.

The unknown starting materials **1a**-d_5, **1b**, **1c**, and **1d** were prepared from the reaction of the corresponding cyclohepta-[*hi*]pyrroloindolizines and acetylenes in a similar way to a reported method.[13]

1a-d_5: ^{1}H NMR ($CDCl_3$) δ=2.2 (4H, m, 5- and 6-H), 3.26, 3.46 (2H each, 2t, J=7 Hz each, 4- and 7-H), 3.80, 4.06 (3H each, 2s, $-CH_3$), 7.74 (1H, d, J=8 Hz, 8-H), and 8.34 (1H, d, J=8 Hz, 9-H).

1b: Yellow needles (ethanol); mp 144—146 °C.

Found: C, 80.34; H, 5.78; N, 4.46%. Calcd for $C_{22}H_{19}NO_2$: C, 80.22; H, 5.81; N, 4.25%.

1c: Yellow needles (ethanol); mp 152—153 °C.

Found: C, 71.98; H, 5.59; N, 3.34%. Calcd for $C_{25}H_{23}NO_5$: C, 71.93; H, 5.55; N, 3.36%.

1d: Yellow needles (ethanol); mp 161—162 °C.

Found: C, 61.94; H, 4.28; N, 3.22%. Calcd for $C_{24}H_{20}BrNO_4$: C, 61.81; H, 4.32; N, 3.00%.

Oxidation of 1a with DDQ. A solution of **1a** (500 mg, 1.29 mmol) and DDQ (300 mg, 1.32 mmol) in dry benzene (30 mL) was stirred at 5—10 °C for 24 h under a nitrogen atmosphere. After removing of the resultant hydroquinone by filtration, the filtrate was evaporated to dryness. The residue was subjected to chromatography on silica gel to afforded 155 mg (31%) of **2** together with unreacted **1a** (56%) as chloroform eluents.

The oxidation of **1a** with 6.4 equiv of DDQ under similar conditions gave an unseparable mixture of **3a** (11%), **2** (33%), and **1a** (36%).

2: Yellow needles (ethanol); mp 191—192 °C; IR (KBr) cm^{-1}: 1730 and 1710 (CO); ^{1}H NMR ($CDCl_3$) δ=2.8—2.9 (2H, m, 6-H), 3.3—3.4 (2H, m, 7-H), 3.78, 4.00 (3H each, 2s, $-CH_3$), 6.1—6.2 (1H, m, 5-H), 6.89 (1H, br d, J=11 Hz, 4-H), 7.4—7.7 (6H, m, 8-H and phenyl protons), and 8.28 (1H, d, J=8 Hz, 9-H); MS m/z (rel intensity): 385 (M^+, base peak), 354 (M^+-OCH_3, 16), 326 ($M^+-CO_2CH_3$, 10), 308 (M^+—Ph, 6), and 267 ($M^+-2\times CO_2CH_3$, 27).

Found: C, 74.51; H, 5.04; N, 3.65%. Calcd for $C_{24}H_{19}NO_4$: C, 74.79; H, 4.97; N, 3.63%.

Oxidation of 2 with Pd/C or DDQ to 3a. A solution of **2** (33 mg) in dry toluene (10 mL) in the presence of 20 mg of

Table 3. Chemical Shifts and Coupling Constants of **6a**-d_5 and **7a**-d_5

Coupling constants for **6a**-d_5 (Hz): $J_{1,2}$=4.2, $J_{4,5}$=11.2, $J_{5,6}$=8.4, $J_{4,6}=J_{5,7}$=1.2, $J_{6,7}$=11.8, $J_{8,9}$=8.4

Coupling constants for **7a**-d_5 (Hz): $J_{1,2}$=4.2, $J_{8,9}$=8.4

10% Pd/C was refluxed for 72 h. After the Pd/C was filtered off, the filtrate was evaporated to dryness. The residue was subjected to column chromatography on silica gel to afford 5 mg (16%) of **3a** as an eluent of chloroform.

Also, the oxidation of **2** with 1.2 equiv of DDQ under similar conditions gave an unseparable mixture of **3a** (24%) and **2** (46%).

3a: Deep red needles (ethanol); mp 189—190 °C; IR (KBr) cm^{-1}: 1740 and 1720 (CO); ^1H NMR ($CDCl_3$) 3.75, 4.04 (3H each, 2s, $-CH_3$), 6.32 (1H, ddd, J=11, 8, and 1 Hz, 5-H), 6.58 (1H, ddd, J=11, 8, and 1 Hz, 6-H), 6.97 (1H, d, J=11 Hz, 4-H), 7.4—7.7 (7H, m, 4- and 8-H and phenyl protons), and 8.36 (1H, d, J=8 Hz, 9-H); MS m/z (rel intensity): 383 (M^+, base peak), 352 (M^+-OCH_3, 24), and 265 ($M^+-2\times CO_2CH_3$, 48).

Found: C, 75.05; H, 4.45; N, 3.74%. Calcd for $C_{24}H_{17}NO_4$: C, 75.18; H, 4.47; N, 3.65%.

Oxidation of 1 with NBS. Typical Procedure: A solution of **1a** (1.00 g, 2.58 mmol) and NBS (1.00 g, 5.62 mmol) in dry carbon tetrachloride (80 mL) was refluxed under the irradiation of a tungsten lamp for 6 h. The resultant succinimide was filtered off and the filtrate was evaporated in vacuo to give a residue. The residue was subjected to column chromatography (silica gel-chloroform) to afford 543 mg (45%) of **4a** and 387 mg (32%) of **5a**. The similar oxidation of **1a**-d_5 with NBS gave the correspoding pentadeuteriophenyl derivatives **4a**-d_5 and **5a**-d_5, respectively.

4a: Yellow needles (ethanol); mp 232—233 °C; IR (KBr) cm^{-1}: 1730 and 1710 (CO); ^1H NMR ($CDCl_3$) δ=3.4 (4H, m, 6- and 7-H), 3.79, 4.00 (3H each, 2s, $-CH_3$), 7.30 (1H, br s, 4-H), 7.4—7.6 (5H, m, phenyl protons), 7.65 (1H, d, J=8 Hz, 8-H), and 8.29 (1H, d, J=8 Hz, 9-H); MS m/z (rel intensity): 465, 463 (M^+, base peak), 434, 432 (M^+-OCH_3), 384 (M^+-Br, 23), 267 (29), 266 (48), and 265 (53).

Found: C, 62.33; H, 4.02; N, 3.23%. Calcd for $C_{24}H_{18}BrNO_4$: C, 62.08; H, 3.90; N, 3.03%.

4a-d_5: ^1H NMR ($CDCl_3$) δ=3.4 (4H, br s, 6- and 7-H), 3.85, 4.05 (3H each, 2s, $-CH_3$), 7.36 (2H, br s, 4-H), 7.68 (1H, d, J=8 Hz, 8-H), and 8.22 (1H, d, J=8 Hz, 9-H).

5a: Deep red needles (ethanol); mp 195.5—197 °C; IR (KBr) cm^{-1}: 1730 and 1710 (CO); ^1H NMR ($CDCl_3$) δ=3.76, 4.04 (3H each, 2s, $-CH_3$), 6.7 (2H, br s, 6- and 7-H), 7.4—7.7 (6H, m, 8-H and phenyl protons), 7.79 (1H, s, 4-H), and 8.28 (1H, d, J=8 Hz, 9-H); MS m/z (rel intensity): 463, 461 (M^+, base peak), 432, 430 (M^+-OCH_3, 17), 282 (M^+-Br, 14), 265, 264, and 263.

Found: C, 62.62; H, 3.54; N, 3.24%. Calcd for $C_{24}H_{16}BrNO_4$: C, 62.35; H, 3.49; N, 3.03%.

5a-d_5: ^1H NMR ($CDCl_3$) δ=3.88, 4.12 (3H each, 2s, $-CH_3$), 6.65 (2H, br s, 6- and 7-H), 7.38 (1H, d, J=8 Hz, 8-H), 7.83 (1H, br s, 4-H), and 8.10 (1H, d, J=8 Hz, 9-H).

A solution of **4a** (100 mg, 0.22 mmol) and NBS (40 mg, 0.22 mmol) in dry carbon tetrachloride (10 mL) was similarly refluxed for 5 h. After a similar work-up, **5a** was obtained in 64% yield together with the unreacted **4a** (22%).

The reaction of **1b**, **1c**, and **1d** with NBS gave the corresponding 6-bromo-6,7-dihydro-**4** and 6-bromo derivatives **5**, respectively. These results are presented in Table 1.

4b: Yellow needles (ethanol); mp 157—159 °C; IR (KBr) cm^{-1}: 1685 (CO), ^1H NMR ($CDCl_3$) δ=3.4 (4H, m, 6- and 7-H), 4.02 (3H, s, $-CH_3$), 7.43 (1H, br s, 4-H), 7.4—7.8 (6H, m, 8-H and phenyl protons), 8.08 (1H, s, 2-H), and 8.25 (1H, d, J=8 Hz, 6-H); MS m/z (rel intensity): 407, 405 (M^+, base peak), 376, 374 (M^+-OCH_3, 12), 326 (M^+-Br, 48), and 267 ($M^+-Br-CO_2CH_3$, 71).

Found: C, 53.31; H, 3.07; N, 2.70%. Calcd for $C_{24}H_{15}Br_2NO_4$: C, 53.26; H, 2.79; N, 2.59%.

Preparation of 3 by Dehydrobromination of 4 with DBU. Typical Procedure: A solution of **4a** (200 mg, 0.43 mmol) and DBU (300 mg, 2.0 mmol) in dry toluene (30 mL) was heated under reflux for 24 h. The resultant precipitate was filtered off and the filtrate was washed with water (20 mL×3). The toluene layer was dried and evaporated to give a residue. The residue was subjected to column chromatography on silica gel using benzene to afford

159 mg (64%) of **3a**.

Analogously, the dehydrobromination of **4a**-d_5, **4b**, **4c**, and **4d** with DBU gave the corresponding cyclohepta[*hi*]-pyrrolo[2,1,5-*cd*]indolizines **3a**-d_5, **3b**, **3c**, and **3d** in good yields. These results are presented in Table 2.

3a-d_5: Deep brown needles (ethanol); mp 184—186 °C; ^{1}H NMR ($CDCl_3$) δ=3.73, 4.01 (3H each, 2s -CH_3), 6.25 (1H, dd, J=11 and 8 Hz, 5-H), 6.52(1H, dd, J=10 and 8 Hz, 6-H), 6.95 (1H, d, J=10 Hz, 7-H), 7.44(1H, d, J=10 Hz, 4-H), 7.47(1H, d, J=8 Hz, 8-H), and 8.30 (1H, d, J=8 Hz, 9-H).

3b: Red needles (ethanol); mp 170—171.5 °C; IR (KBr) cm^{-1}: 1690 (CO); ^{1}H NMR ($CDCl_3$) δ=4.00 (3H, s, -CH_3), 6.29 (1H, dd, J=11 and 8 Hz, 5-H), 6.44 (1H, dd, J=11 and 8 Hz, 6-H), 6.91 (1H, d, J=11 and 7-H), 7.4—7.6 (5H, m, 4- and 8-H and phenyl protons), 7.85 (2H, m, phenyl protons), 8.13 (1H, s, 2-H), and 8.28 (1H, d, J=8.5 Hz, 9-H); MS m/z (rel intensity): 325 (M^+, base peak), 294 (M^+-OCH_3, 24), and 162.5 ($M^+/2$, 5).

Found: C, 81.44; H, 4.71; N, 4.45%. Calcd for $C_{22}H_{15}NO_2$: C, 81.21; H, 4.65; N, 4.31%.

3c: Deep red needles (benzene); mp 177—178 °C; IR (KBr) cm^{-1}: 1730 and 1710 (CO); ^{1}H NMR ($CDCl_3$) δ=3.82, 3.91, 4.04 (3H each, 3s, -CH_3), 6.27 (1H, dd, J=11 and 8.5 Hz, 5-H), 6.52 (1H, dd, J=11.5 and 8.5 Hz, 6-H), 6.96 (1H, d, J=11.5 Hz, 7-H), 7.02 (2H, br d, J=9 Hz, phenyl protons), 7.41 (1H, d, J=11 Hz, 4-H), 7.54 (1H, d, J=8.5 Hz, 8-H), 7.61 (2H, br d, J=9 Hz, phenyl protons), and 8.33 (1H, d, J=8.5 Hz, 9-H); MS m/z (rel intensity): 413 (M^+, base peak), 398 (M^+-CH_3, 9), 382 (M^+-OCH_3, 11), and 251(15).

Found: C, 72.44; H, 4.68; N, 3.42%. Calcd for $C_{25}H_{19}NO_5$: C, 72.63; H, 4.63; N, 3.39%.

3d: Deep red needles (ethanol); mp 189—190 °C; IR (KBr) cm^{-1}: 1710 and 1690 (CO); ^{1}H NMR ($CDCl_3$) δ=3.81, 4.02 (3H each, 2s, -CH_3), 6.33 (1H, dd, J=11 and 8.5 Hz, 5-H), 6.59 (1H, dd, J=11.5 and 8.5 Hz, 6-H), 7.02 (1H, d, J=11.5 Hz, 7-H), 7.38 (1H, d, J=11 Hz, 4-H), 7.52 (2H, br d, J=9 Hz, phenyl protons), and 8.37 (1H, d, J=8.5 Hz, 9-H); MS m/z (rel intensity): 463, 461 (M^+, base peak), 432, 430 (M^+-OCH_3, 14), 403, 402 ($M^+-CO_2CH_3$, 7), 265, 264, and 263.

Found: C, 62.40; H, 3.51; N, 3.07%. Cacld for $C_{24}H_{16}BrNO_4$: C, 62.35; H, 3.49; N, 3.03%.

Preparation of 1,2-Unsubstituted Cyclohepta[*hi*]pyrolo-[2,1,5-*cd*]indolizines 6 from 3. Typical Procedure: 3a (120 mg, 0.31 mmol) was heated under reflux in 5% methanolic potassium hydroxide (40 mL) for 20 h and the methanol was removed to give a residue. The residue was made acidic with 6 M hydrochloric acid (50 mL). The resultant diacid was filtered, dried and subjected to the next decarboxylation without further purification. A solution of the diacid in quinoline (15 mL) in the presence of copper dust (50 mg) was refluxed for 1 h. The copper dust was filtered off and the filtrate was evaporated to give a residue. The residue was dissolved in dichloromethane and washed with 0.5 M hydrochloric acid (50 mL×3) in order to remove the quinoline completely. The organic layer was evaporated to dryness. The residue was subjected to chromatography on silica gel using hexane–benzene (3:1) to afford 70 mg (84% from **3a**) of the desired **6a**.

6a: Deep red needles (ethanol); mp 79.5—81 °C; IR (KBr) cm^{-1}: 800, 760, and 680; ^{1}H NMR ($CDCl_3$) δ=6.11 (1H, ddd, J=11.2, 8.4, and 1.2 Hz, 5-H), 6.35 (1H, ddd, J=11.8, 8.4, and 1.2 Hz, 6-H), 6.91 (1H, dd, J=11.8 and 1.2 Hz, 7-H), 7.23 (1H, d, J=8.4 Hz, 8-H), 7.4—7.8 (8H, m, 1-, 2-, and 4-H and phenyl protons), and 7.89 (1H, d, J=8.4 Hz, 9-H); MS m/z (rel intensity): 267 (M^+, base peak), 265 (M^+-H_2, 28), 133.5 ($M^+/2$, 10), 132.5 ($M^+-H_2/2$, 17), and 77(7).

Found: C, 89.99; H, 5.04; N, 5.17%. Calcd for $C_{20}H_{13}N$: C, 89.86; H, 4.90; N, 5.24%.

6d: Yield 90% from **3d**; deep brown needles (ethanol); mp 151—153 °C; IR (KBr) cm^{-1}: 1310, 1020, and 800; ^{1}H NMR ($CDCl_3$) δ=6.06 (1H, ddd, J=12, 8, and 1 Hz, 5-H), 6.32 (1H, ddd, J=12, 8, and 1 Hz, 6-H), 6.84 (1H, dd, J=12 and 1 Hz, 7-H), 7.18 (1H, d, J=8 Hz, 8-H), and 7.3—8.0 (9H, m, 1-, 2-, 4-, and 9-H and phenyl protons); MS m/z (rel intensity): 347, 345 (M^+, base peak), 267 (33), 266 (M^+-Br, 31), 265 (M^+-HBr, 88), 173.5, and 172.5 ($M^+/2$, 9).

Found: C, 69.58; H, 3.70; N, 4.24%. Calcd for $C_{20}H_{12}BrN$: C, 69.38; H, 3.49; N, 4.05%.

As referential compounds, **7a** and **7a**-d_5 were obtained similarly from **1a** and **1a**-d_5, respectively.

7a: Yield 78%; orange prisms (ethanol); mp 102—104 °C; IR (KBr) cm^{-1}; 1280, 1020, 790, and 690; ^{1}H NMR ($CDCl_3$) δ=1.7—2.1 (4H, m, 5- and 6-H), 3.1-3.3 (4H, m, 4- and 7-H), and 7.2—8.0 (9H, m, 1-, 2-, 8-, and 9-H and phenyl protons).

Found: C, 88.32; H, 6.36; N, 5.31%. Calcd for $C_{20}H_{17}N$: C, 88.52; H, 6.32; N, 5.16%.

We wish to thank Professors Masashi Tashiro and Hitoshi Takeshita, Institute of Industrial Science, Kyushu University, for the elemental analyses and the measurement of NOE. We are also grateful to Drs.

High-Pressure Kinetics of the (6+4)π Cycloaddition of Tropone with 2,3-Dimethyl-1,3-butadiene, an Acyclic Diene. The Temperature and Solvent Effects

Shigeru SUGIYAMA and Hitoshi TAKESHITA*
Research Institute of Industrial Science, 86, Kyushu University,
Kasuga-koen, Kasuga, Fukuoka 816
(Received July 30, 1986)

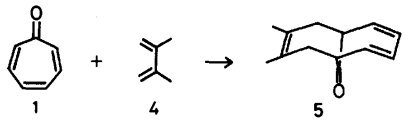
By a high-pressure kinetic analysis in isopropylbenzene, 1,4-dioxane and *N,N*-dimethylformamide, the activation parameters for the (6+4)π cycloaddition reaction of tropone with 2,3-dimethyl-1,3-butadiene were determined. The findings support the concerted nature for the Woodward-Hoffmann rule-allowed thermal addition reaction of tropone. A secondary orbital interaction, which was used to predict the correct stereochemistry of the adducts, exerted no effect on the volume profile.

Previously, we confirmed the concerted nature of the (6+4)π cycloaddition of tropone (**1**) to 1,3-cyclohexadiene (**2**) by a kinetic analysis regarding pressure and temperature effects.[1] The activation enthalpy ($\Delta H^{\neq}$) and activation entropy ($\Delta S^{\neq}$), showing no anomaly, were consistent with those obtained by Tanida and Pfaendler in a reaction of **1** with cyclopentadiene (**3**) under ordinary pressure.[2] Moreover, the activation volume ($\Delta V^{\neq}$) and the volume profile ($\Delta V^{\neq}/\Delta V$, where ΔV represents reaction volume) were also in accord with the concerted cycloadditions.

Herein, we wish to describe the pressure and temperature effects on the cycloaddition of **1** with 2,3-dimethyl-1,3-butadiene (**4**), an acyclic diene, which is conformationally mobile in solutions.[3] The volume profile of the (6+4)π cycloaddition with such a combination has not been investigated; the rate constant showed a little different pressure dependence from our previous combinations.[1,4,5]

Experimental

The purity of **1**[6] was more than 99.0% in respect to a gas-liquid chromatographic analysis. A commercial sample of **4**, from Aldrich Japan Co. Ltd., Tokyo, was purified by distillation over $NaBH_4$ under an N_2 atmosphere. The solvents, isopropylbenzene (cumene), 1,4-dioxane (dioxane) and *N,N*-dimethylformamide (DMF), were purified as stated previously.[1] The adduct (**5**), a pale yellow oil, was purified by repeated silica-gel column chromatography, and showed pertinent figures of elemental analysis. Its IR, NMR, and mass spectra were also consistent with the structure.



Scheme 1.

The same instruments were used for a density measurement and kinetic experiment as those in previous studies.[1,5] The progress of the reaction was monitored by observing an increase of product (**5**) by means of high-pressure liquid chromatography (Nippon Waters' Model 244 Apparatus).

Results and Discussion

Activation Parameters. Although extensive studies have been carried out concerning both theoretical and synthetic aspects of the (6+4)π cycloaddition of **1**, there have been few kinetic studies, even under atmospheric pressure on the subject (e.g., those by Tanida et al.[2] and ours[1]). This could be due to an instability of the popular cycloaddend, **3**, toward spontaneous dimerization. In this respect, **4** is thermally stable and the present combination is appropriate for a kinetic analysis.

Table 1 shows the second order rate constants (k) in three solvents of different polarities at various temperatures (T) under atmospheric pressure. Within the temperature range studied, there is a good linear relationship between ln k and $1/T$ in each solvent (correlation coefficient: $r>0.999$), as predicted by the Arrhenius equation. The $\Delta H^{\neq}$, $\Delta S^{\neq}$ and the activation free energy ($\Delta G^{\neq}$) at 100 °C are listed in Table 2. There

Table 1. Rate Constants for the Reaction of **1** with **4** at Various Temperatures ($10^6 k$/kg mol^{-1} s^{-1})

Solvent	Temperature/°C			
	80	90 (85)[a]	100 (90)[a]	110 (95)[a]
Cumene	2.16±0.05	3.67±0.02	7.47±0.07	13.6 ±0.1
Dioxane	1.58±0.02	2.22±0.04	3.16±0.08	4.28±0.06
DMF	0.99±0.01	1.81±0.02	3.32±0.04	5.41±0.08

a) Rates in dioxane were measured at the temperatures indicated in parentheses.

were very little solvent effects, and the values of $\Delta S^{\neq}$ were similar to those of a typical Diels-Alder reaction[4,5,7,8] and those of other (6+4)π cycloadditions of **1** with **3**[2] and with **2**.[1] Therefore, this reaction could be interpreted as a concerted electrocyclic reaction. The considerably large negative $\Delta S^{\neq}$ indicates that the pressure effect on the reaction is as large as that on a Diels-Alder reaction, because $\Delta S^{\neq}$ is generally known to be related to $\Delta V^{\neq}$.[9]

The rate constants at various pressures are listed in Table 3. The pressure dependence of the rate constants is expressed by

$$(\partial \ln k/\partial P)_T = -\Delta V^{*}/RT. \quad (1)$$

As illustrated in Fig. 1, in each solvent plots of ln k vs. P showed a more pronounced curvature than those obtained in our previous Diels-Alder reactions and the (6+4)π cycloaddition of **1**,[1,4,5] indicating that $\Delta V^{\neq}$ become less negative with increasing pressure. In this respect, there have been very few theoretical studies; however, it has been stated that the differences in the compression between the ground and the transition states may influence the pressure effect on $\Delta V^{\neq}$. In the present case, one reason for this phenomenon might be the conformational mobility of acyclic diene, **4**. Under the atmospheric pressure, **4** may be sufficiently mobile, but its mobility might be restricted with increasing pressure. This means, the ground state may be less rigid reflecting the flexibility of the cycloaddend, **4**, than the transition state, for which, there would be no objection to conceive a rigidity from the cyclic and product-like structure (see below). On the other hand, under high-pressure conditions, the freedom of the ground state is restricted, but the degree of freedom of the transition state is not appreciably altered. Thus, with increasing pressure, the difference in the degree of freedom between the ground state and the transition state ($\Delta S^{\neq}$) might become less negative. Since $\Delta S^{\neq}$ is known to be related to $\Delta V^{\neq}$, the $\Delta V^{\neq}$ would become less negative at higher pressures and the plot of ln k vs. P would show a curvature. This interpretation might be justified by the observation that an almost linear plot was obtained using a conformationally-rigid, cyclic cycloaddends for **1** in the Diels-Alder and the (6+4)π cycloaddition reactions.[1,4,5] To express the present dependence of ln k, we used the following equation because of its established wide usage:

$$\ln k = a + bP + cP^2. \quad (2)$$

Table 4 shows the partial molar volume of each substance (Vi), given by the density measurement, ΔV at 60 °C, $\Delta V^{\neq}$ at 80 °C under atmospheric pressure, and the volume profile ($\Delta V^{\neq}/\Delta V$). As shown, the $\Delta V^{\neq}$ and $\Delta V^{\neq}/\Delta V$ are in the range of those for the typical Diels-Alder reactions.[10] Moreover, the other reliable data from the (6+4)π cycloaddition of **1** with **2**[1] was similar.

With respect to the solvent effect, $\Delta V^{\neq}$ became slightly less negative upon increasing the polarity of the solvent. This behavior resembled our results regarding the concerted cycloaddition of **1** measured in cumene and DMF.[1,5] Also, this solvent effect was

Table 2. Activation Parameters for the Reaction of **1** with **4** at 100 °C.

Solvent	ΔH^{*}/kJ mol^{-1}	ΔS^{*}/J mol^{-1} K^{-1}	ΔG^{*}/kJ mol^{-1}

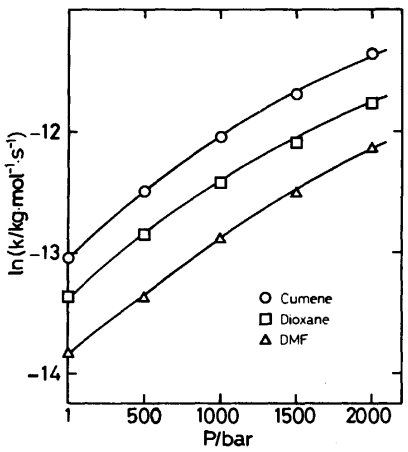

Fig. 1. Pressure dependence of ln k for the reaction of tropone with dimethylbutadiene at 80 °C.

Table 3. Rate Constants for the Reaction of **1** with **4** at Various Pressures at 80 °C ($10^6 k$/kg mol^{-1} s^{-1})

Solvent	Pressure/bar				
	1	500	1000	1500	2000
Cumene	2.16±0.05	3.70±0.04	5.83±0.01	8.29±0.07	11.6 ±0.1
Dioxane	1.58±0.02	2.59±0.06	4.01±0.09	5.57±0.06	7.79±0.05
DMF	0.99±0.01	1.55±0.01	2.57±0.03	3.80±0.01	5.48±0.05

very small and in accord with typical concerted reactions.

Consequently, an effect resulting from the dipolar character of **1** on the volume, pointed out by le Noble and Ojosipe,[11] is insignificant.

Volume Profile. From our previous and the present results, the transition state of the (6+4)π cycloaddition of **1** was found to be very product-like as far as the reaction volume is concerned: that is, $0.87<\Delta V^{\neq}/\Delta V<1.04$.[1] This phenomenon has often been observed in Diels-Alder reactions; in a special case, $\Delta V^{\neq}$ was more negative than ΔV.[12] In view of the secondary orbital interaction by the Woodward-Hoffmann rule for the Diels-Alder reaction,[13] the attractive force between the HOMO of dienes and the LUMO of dienophiles should yield the endo-adducts under kinetically controlled conditions. Accordingly, the transition state could be explained as becoming very product-like, or smaller than the product. On the same grounds, the exemplified exo-orientation for the (6+4)π cycloadducts of **1** has been explained in terms of a repulsive secondary orbital interaction in the endo-transition state.[14]

According to le Noble and Ojosipe,[11] a much larger $\Delta V^{\neq}/\Delta V=1.74$ in the (6+4)π cycloaddition of **1** with **3**, which was invalidated though,[1] was explainable in terms of an attractive, secondary interaction between the HOMO of **1** and the LUMO of **3** in the exo-transition state to make the transition state compressed (Scheme 2: **A**, unfortunately, the illustration contained a false figure).[11] However, an ab initio calculation showed the difference in energy level between the HOMO of **1** and the LUMO of **3** to be ca. 10 eV, and that between the LUMO of **1** and the HOMO of **3** to be ca. 8 eV.[15] Consequently, the former combination is not appropriate; in fact, the (6+4)π cycloaddition of **1** has often been explained[16] on the basis of the latter combination, in which the coefficient of the carbonyl group of **1** in the LUMO is 0 (Scheme 2: **B**).

In such a circumstance, the secondary orbital interaction can not be significant in the exo-(6+4)π cycloaddition of **1**. Moreover, if one considers the contribution of HOMO of **1** and the LUMO of dienes on volume profile, it should at least be discussed on the basis of the correct figure drawn as Scheme 2: **C**.[15] That is, the coefficient of carbon in carbonyl group is 0, and the attractive secondary orbital interaction can not be so strong as mentioned by le Noble. Furthermore, this combination is minor one. Taking these points into accounts, the secondary orbital interaction is concluded to contribute insignificantly to the volume profile of the exo-(6+4)π cycloaddition of **1**. In addition, the comparison on volume profile between (6+4)π cycloaddition of **1** and the Diels-Alder reactions disclosed a remarkable feature; Scheme 3 shows, although (6+4)π cycloaddition and Diels-Alder reaction suffer differently from secondary orbital interaction, very similar volume profiles with illustrations of the HOMO-LUMO combinations for a (6+4)π cycladdition of **1** observed by us[1] and one of the typical Diels-Alder reaction, **3** with methyl acrylate.[17] Therefore, the secondary orbital interaction does not play a significant role on the volume profile, and the often observed $\Delta V^{\neq}/\Delta V>1$ in the Diels-Alder reaction must be explained in terms of another factor, such as a transannular attractive force.[18]

In conclusion, contributions of the dipolar character of **1** and the secondary orbital interaction to the volume profile of the Woodward-Hoffmann rule-allowed thermal (6+4)π electrocyclic reaction of **1** should not be overestimated. Also, the high-pressure cycloadditions of troponoids in organic syntheses are certainly profitable.[19]

(Received August 7, 1986)

Hatching stimuli, designated as glycinoeclepins, for the soybean cyst nematode (*Heterodera glycines*) have been isolated by repeated chromatography of the aqueous extracts of dried roots of kidney bean (*Phaseolus vulgaris*), one of the host plants of the nematode. One of these compounds, glycinoeclepin A, stimulates the hatching and emergence of larvae in vitro in highly diluted aqueous solutions.

The cyst nematodes (genera *Heterodera, Globodera* and others, ca. 40 species)[1] generally have a limited host range. This specificity arises from the fact that the hatching of dormant second stage larvae from eggs and the emergence of the hatched larvae from cysts occur in response to chemical stimuli in the root diffusates secreted by the host plants.[2-5] This fact was first discovered by Baunacke in 1922 for the potato cyst nematode (*G. rostochiensis*).[6] Since then, much time and effort has been expended in attempts to purify and characterize these stimuli,[2-5] in view of their scientific interest and importance in agriculture. However, success has been limited by the extremely small amounts of active substances available.
