Sodium Telluride-Mediated Sulfenylation of α-Halo Carbonyl Compounds with Diphenyl Disulfide

Seetharamaiyer PADMANABHAN, Takuji OGAWA, and Hitomi SUZUKI*
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Mastuyama 790
(Received November 19, 1988)

Synopsis. Under mild aprotic conditions α-halo carbonyl compounds react with diphenyl disulfide in the presence of sodium telluride to give the corresponding α-phenylthio derivatives in good to moderate yields. The reaction appears to proceed involving the sulfur-sulfur bond cleavage of diphenyl disulfide by sodium telluride.

Introduction of a phenylthio unit adjacent to a carbonyl function is an important step for achieving facile structural modifications.[1] Generally the sulfenylated compounds are synthesized by reacting metal enolates with organic disulfides[2,3] or thiosulfonates,[4] by the action of sulfenyl chloride on α-diazo ketones,[5] enamines,[6] 1,3,2-dioxaphospholes,[7] and silyl enol ethers,[8] and also from α-halo carbonyl compounds and thiolate ion,[9] thallium(I) benzenethiolate,[10] or α-thio iminium salts.[11] Other methods include the sulfenylation of active methylene carbon with sulfenamides,[12] thermal decomposition of β-keto sulfonium salts,[13] and controlled oxidation of β-hydroxy sulfides.[14] Sulfenylation accompanied by dealkoxycarbonylation of β-keto esters affords α-thio ketones.[15] Sophisticated approaches using [bis(phenylthio)methyl]lithium[16] and α,β-epoxy sulfoxides[17] were also reported.

As part of our continuing efforts to explore the synthetic utility of sodium telluride, we now wish to report a method for preparing monothio carbonyl compounds from α-halo carbonyl compounds and diphenyl disulfide.

$$\underset{\mathbf{1}}{RCOCH_2X} + Ph_2S_2 \xrightarrow[DMF,\ -40\,^\circ C]{Na_2Te} \underset{\mathbf{2}}{RCOCH_2SPh} \quad (1)$$

When a solution of α-halo carbonyl compounds (**1**) in *N*,*N*-dimethylformamide (DMF) was added to a mixture of sodium telluride and diphenyl disulfide (excess) in DMF at −40 °C, the monosulfenylated compound (**2**) was obtained in fairly good yields (Table 1). Bissulfenylated compounds and dehalogenation products were also isolated in a few cases. Formation of significant amount of dehalogenated compound from bromodibenzoylmethane could be probably due to the desulfenylation of the monosulfenylated compound initially formed by the thiolate ion. Such desulfenation by thiolate ions has been reported earlier.[18]

The monosulfenylated product **2** arises from the reaction between the thiolate, generated in situ from diphenyl disulfide and sodium telluride, and α-halo carbonyl compound **1**. This was concluded by changing the mode of addition: Addition of phenacyl bromide to sodium telluride at −40 °C generated the enolate anion, which was allowed to react with the added diphenyl disulfide. This resulted in the isolation of bissulfenylated product (**2e**) in addition to acetophenone. Simultaneous formation of these two products can be best explained by assuming the rapid proton removal from the initially formed monosulfenylated compound (**2a**) by the enolate anion present in large excess. Isolation of bissulfenylated products from lithium enolates has been observed earlier.[2] Addition of diphenyl disulfide to sodium telluride at −40 °C resulted in the immediate separation of free tellurium and subsequent addition of ethyl iodide led to the isolation of ethyl phenyl sulfide in 45% isolated yield. Thus the overall reaction (1) can be depicted as follows:

$$PhSSPh + Te^{2-} \longrightarrow 2\,PhS^- + Te$$
$$RCOCH_2X + PhS^- \longrightarrow RCOCH_2SPh + X^-$$

From the reaction of phenacyl bromide with dimethyl disulfide, however, bissulfenylated product and acetophenone were the only major products isolated. This result is very much similar to the one obtained by the addition of diphenyl disulfide to the enolate anion. This indicates that the reaction between phenacyl bromide and dimethyl disulfide may proceed through the nucleophilic attack of the enolate anion on the sulfur atom without any involvement of the reductive cleavage of S-S bond by telluride anion. Trost and co-workers[2] observed that simple ketone enolates are not sufficiently reactive toward dimethyl disulfide. Confirmation of the proposed non-cleavage of S-S bond was provided by an attempted reaction between dimethyl disulfide and benzyl chloride. Formation of benzyl methyl sulfide could not be observed under our conditions from the ^{1}H NMR analysis of the reaction mixture.[19]

It has been reported that the bissulfenylated products can be converted to monosulfenylated compounds with sodium ethanethiolate in the presence of excess base.[20] Any doubt regarding the formation of monosulfenylated compounds by such a possible reduction by sodium telluride in the present study was eliminated by a separate experiment. Reaction of bis(phenylthio)acetophenone with excess of sodium telluride under similar reaction conditions resulted only in the recovery of the starting material in 62% isolated yield and no formation of monosulfenylated product was observed from the ^{1}H NMR of the reaction mixture.

Efforts to effect the selenylation under similar conditions using diphenyl diselenide led to the dehalogenated compounds in most of the cases. Only in the case of ω-bromo-ω-phenylsulfonylacetophenone monoselenylated product was obtained in an acceptable yield.

This paper reports a synthesis of α-phenylthio carbonyl compounds without actually handling the evil-

smelling thiol under mild aprotic conditions in fairly good yields and also discloses one more new property of sodium telluride to cleave the S-S bond in aromatic disulfide, but not in aliphatic one. To the best of our knowledge this is the first report employing both α-halo carbonyl compounds and an organic disulfide in a "one pot" way for preparing the α-phenylthio carbonyl compounds.

Experimental

All melting and boiling points were uncorrected. IR spectra were measured as KBr pellets or as neat films between NaCl plates by using a Hitachi 260-10 spectrophotometer

and only prominent peaks between 2000 and 650 cm^{-1} are indicated. ^1H NMR spectra were determined on a Hitachi R-600 spectrometer using chloroform-*d* as solvent and TMS as internal standard. Mass spectra were obtained on a Hitachi M-80B spectrometer using 70 eV.

General Procedure for Sulfenylation: To a suspension of sodium telluride (2.0 mmol; prepared from tellurium and sodium hydride[21]) in DMF was added at −40 °C under nitrogen diphenyl disulfide (4.0 mmol) in DMF (5 ml), followed by the addition of α-halo carbonyl compound (2.0 mmol) in the same solvent (3 ml). The dark reaction mixture was kept with stirring at −40 °C for 2 h and then at room temperature for 1 h. The reaction was quenched with saturated aqueous ammonium chloride solution (10 ml) and the mixture was extracted with benzene. The extract was filtered through a thin bed of Celite, washed with 0.5 M (1 M=1 $mol dm^{-3}$) sulfuric acid and water, and dried over sodium sulfate. The solvent was removed and the crude product was purified by column chromatography on silica gel using hexane as eluent to give the unchanged diphenyl disulfide. Further elution with a mixture of hexane and dichloromethane afforded the sulfenylated compound. Different sulfenylated products prepared and their physical characteristics are given in Table 1.

ω,ω-Bis(phenylthio)acetophenone (2e): To sodium telluride (2.0 mmol) in DMF was added at −40 °C phenacyl bromide (2.0 mmol) in the same solvent (3 ml). The reaction mixture turned black immediately with the separation of free tellurium. After 5 min, diphenyl disulfide (4.0 mmol) in DMF (5 ml) was added. Following the general procedure given above, the bissulfenylated product was isolated in 33% yield. Mp 94—99 °C.

ω,ω-Bis(methylthio)acetophenone (2g) was obtained similarly using dimethyl disulfide instead of diphenyl disulfide. Yield, 30%. Mp 57—62 °C.

ω-Phenylseleno-ω-phenylsulfonylacetophenone: To a mixture of sodium telluride (1.0 mmol) and diphenyl diselenide (2.0 mmol) was added at −40 °C under nitrogen a solution of ω-bromo-ω-phenylsulfonylacetophenone (1.0 mmol) in DMF (2 ml). The reaction mixture was stirred at this temperature for 2 h and then at room temperature for 1 h. After the usual work up the monoselenylated product was isolated in 29% yield in addition to ω-phenylsulfonylacetophenone in 57% yield. The seleno compound was crystallized from ethanol as colorless crystals mp 157—159 °C. MS: *m/z* (rel intensity) 416 (M, 4.4), 275 (21), 167 (23), and 105 (100); IR (KBr): 1690, 1445, 1330, 1315, 1280, 1145, 1085, 745, and 685 cm^{-1}. ^1H NMR ($CDCl_3$): δ=5.71 (s, 1H) and 7.1—8.0 (m, 15H). Found: C, 57.67; H, 3.98%. Calcd for $C_{20}H_{16}O_3SSe$: C, 57.83; H, 3.86%.

Photochemical Decarbonylation of (α-Arylacyl)triphenylgermane

Syun-ichi KIYOOKA,* Tsutomu SHIBUYA, Fuminori SHIOTA, and Ryoji FUJIYAMA
Department of Chemistry, Kochi University, Akebono-cho, Kochi 780
(Received September 12, 1988)

Synopsis. (α-Arylacyl)triphenylgermanes were prepared from the corresponding esters with triphenylgermyllithium at room temperature in good yields. Photochemical decarbonylation of (α-arylacyl)triphenylgermanes took place under UV irradiation to quantitatively give (α-arylalkyl)-triphenylgermanes without by-products.

Organogermaniums are gradually attracting the attention of synthetic organic chemists because of their inherent properties, which are different from organosilicons and organotins.[1] Acylgermanes, among them, are expectantly situated to be relatively unique reagents by considering the acylsilane chemistry.[2] We recently wrote a preliminary report regarding the preparation of acylgermanes from the corresponding esters with triphenylgermyllithium,[3] the process is easier than the other routes.[4]

Upon studying the utility of acylgermanes to organic synthesis, we became aware of the instability of acylgermanes dissolved in solvents toward sunlight. Although the photochemistry of acylsilanes has been well-investigated,[5] little is known concerning that of acylgermanes. The germyl radical via a Norrish type-I cleavage has been observed in the laser photolysis (266 nm) of acylgermanes.[6] When (α-arylacyl)triphenylgermanes were irradiated, decarbonylation was found to take place. We therefore report here the synthesis of (α-arylacyl)triphenylgermanes and the subsequent photochemical decarbonylation to give (α-arylalkyl)-triphenylgermanes.

Results and Discussion

The reaction of *N*,*N*-dimethylpivalamide with triethylgermyllithium, from bis(triethylgermyl)mercury and metallic lithium, in hexane at 20 °C has been reported to give pivaloyltriethylgermane in 30% yield with a by-product of 1,1-bis(triethylgermyl)-2,2-dimethyl-1-propanol (24%).[1c] We examined the reaction of esters with triphenylgermyllithium, which is known to have sufficient nucleophilicity.[7] Triphenylgermyllithium can be produced by the addition of equimolar quantities of butyllithium into a tetrahydrofuran (THF) solution of triphenylgermane.[8] To a flesly produced THF solution of triphenylgermyllithium were added equimolar quantities of esters at ambient temperature. After stirring for 5—10 min, the reaction mixture was quenched with a saturated aqueous ammonium chloride solution to give acylgermanes in satisfactory yields (60—80%). The yield was independent of the bulkyness of R (methyl, ethyl, and *t*-butyl groups).

$$RCOOR' + Ph_3GeLi \rightleftharpoons RCOGePh_3 + LiOR'$$

However, small amounts of triphenylgermane were always recovered without any other by-products. Thus, the reaction is not prone to proceed quantitatively. The incompleteness of the reaction can presumably be attributed to an equilibrium attainted under the basic conditions; but here, by the use of 10% excess of esters, the yield was not improved. Further, the reaction of esters having α-active hydrogen (e.g., (+)-methyl (*S*)-2-phenylpropionate) gave almost racemic acylgermanes under such conditions. The results of a synthesis of (α-arylacyl)triphenylgermanes are presented in Table 1.

The acyl carbon-germanium bond of acyltriphenylgermanes was found to be smoothly fissioned with light with a wavelength >300 nm. Actually, benzoyltriphenylgermane and propionyltriphenylgermane in THF was rapidly degradated in a Pyrex flask upon irradiation by a sunlamp (1 h) or a high-pressure mercury lamp (20 min). Though the reaction is apparently complex (many spots on their thin-layer chroma-

In contrast, α-arylacylgermanes upon irradiation resulted in a different mode of fission. The stability of benzyl radical is well-known in various kinds of photochemistry[9] and the photochemical fission of germanium-carbon bonds with shorter wavelengths has been observed regarding the benzyl radical,[10] as well as that of silicon-carbon bonds via a benzyl radical-silyl radical pair in a primary photochemical process.[11] When a THF solution containing α-arylacylgermanes in a Pyrex flask filled with argon was irradiated at ambient temperature with a 400-W high-pressure mercury lamp for 30 min, the reaction quantitatively gave α-arylalkylgermanes. (α-Arylacyl)triphenylgermanes absorbed light in their n→π* excited states,[12] and might have fissured to give an acyl radical-germyl radical pair; then, decarbonylation might have taken place at the acyl radical, because of the inherent stability of the α-arylalkyl radical. The photoreaction of α-arylacylgermanes in the presence of olefin (e.g., methyl acrylate) did not give any addition products; thus, the recombination between the resulting α-arylalkyl and triphenylgermyl radicals might have been an intramolecular process in a solvent cage.

Experimental

Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. Tetrahydrofuran (THF) was distilled from sodium/bezophenone immediately prior to use. All melting points were uncorrected. IR spectra were determined with a JASCO A-302 infrared spectrophotometer. UV spectra were measured with a JASCO UNIDEC 670 spectrophotometer. ^{1}H NMR spectra were obtained with a Hitachi R-90H spectrometer. Chemical shifts are expressed in ppm downfield from internal tetramethylsilane. Merck silica gel 60 (230—400 mesh) was used for flash column chromatography and Merck aluminium sheets (silica gel 60) was used for thin layer chromatography. Ethyl 2-benzyloxyphenylacetate was prepared by the treatment of ethyl 2-hydroxyphenylacetate with benzyl bromide/sodium hydride in *N,N*-dimethylformamide.

General Procedure for the Reaction of Esters with Triphenylgermyllithium. Preparation of (Phenylacetyl)triphenylgermane (1a): To a solution of triphenylgermane (304.6 mg, 1 mmol) in THF (10 cm^3) was added butyllithium (15% solution in hexane, 0.62 cm^3, 1 mmol) at 0—−5 °C. The solution was stirred at room temperature for 1 h. Methyl phenylacetate (150.2 mg, 1 mmol) was added via syring to the solution. After stirring for 10 min, the reaction mixture was quenched with a saturated aqueous ammonium chloride solution and the organic layer was extracted with diethyl ether. The ethereal layer was dried over magnesium sulfate. After evaporation of the solvent, a crude solid was obtained and then purified by flash column chromatography (9 g of silica gel with 3% ethyl acetate in hexane) to give (phenylacetyl)triphenylgermane **1a** (296 mg) in 70% yield.

General Procedure for the Photochemical Decarbonylation of (α-Arylacyl)triphenylgermanes. Preparation of Benzyltriphenylgermane (2a): The solution of **1a** (84.6 mg, 0.2 mmol) in THF (10 cm^3) was irradiated with a 400-W high-pressure mercury lamp with stirring under argon for 30 min. The solvent was removed with a rotary evaporator to give a solid which was purified by flash column chromatography (6 g of silica gel with hexane) to give benzyltriphenylgermane (75 mg) in 95% yield.

Stereospecific Preparation of Chiral 1,5-Diketone by One-Methylene Incorporated Dimerization Reaction of *d*-Camphor Enolate and Reduction of the 1,5-Diketone

Syun-ichi KIYOOKA,* Tsuneo YAMASHITA, Akihisa YAMAMOTO, and Ryoji FUJIYAMA
Department of Chemistry, Kochi University, Akebono-cho, Kochi 780
(Received September 19, 1988)

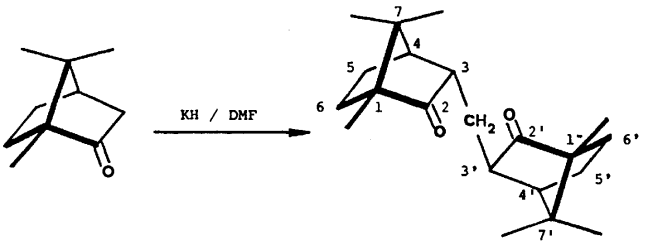
Synopsis. The reaction of *d*-camphor with *N*,*N*-dimethylformamide (DMF) in the presence of potassium hydride stereoselectively gave bis[(1*R*,3*S*,4*R*)-2-oxo-3-bornyl]methane (**1**). This new condensation reaction is proposed to proceed by an attack of the *d*-camphor enolate to DMF and a subsequent reduction. Three chiral diols were obtained from the reduction of **1**.

New-type chiral auxiliaries can be expected to facilitate new developments and some improvements of asymmetric reactions. Such auxiliaries are worth consideration, provided they can be readily prepared from natural compounds by simple procedures. Since *d*-camphor is a cheap chiral pool, a number of effective chiral auxiliaries has been produced by its structural modification and then used for some potential asymmetric reactions.[1)]

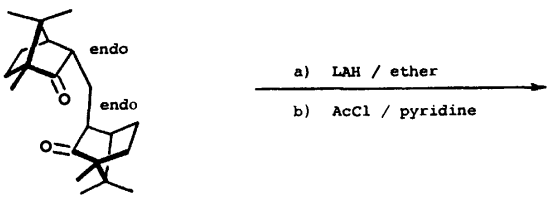
We found a new reaction under way to prepare new chiral auxiliaries from *d*-camphor.[2)] In the reaction of *d*-camphor with equimolar quantities of sodium/benzyl chloride in DMF solvent at ambient temperature, the expected α-benzylated compound was obtained in very low yield. By applying conditions of more elevated temperature (50—80 °C) and/or potassium hydride[3)] in order to increase the yield of the α-alkylated product, an unknown compound (mp 198.5—199.5 °C) (**1**) having a similar IR spectrum to that of starting *d*-camphor was mainly obtained. The reaction without alkyl halide under the same conditions also gave only the compound **1** in high yield.

The structure of **1** was determined to be bis-[(1*R*,3*S*,4*R*)-2-oxo-3-bornyl]methane by analyzing the physical data (as described below). The formura $C_{21}H_{32}O_2$ of **1**, derived from its elemental analysis and MS (M^+ 316), corresponded to that of a compound to be made up of two camphors and one methylene. A characteristic structure suited for **1** could be deduced to have high symmetry from eleven different peaks of carbon resonance, in which each camphor binds with a methylene at the carbonyl α-position (C-3).

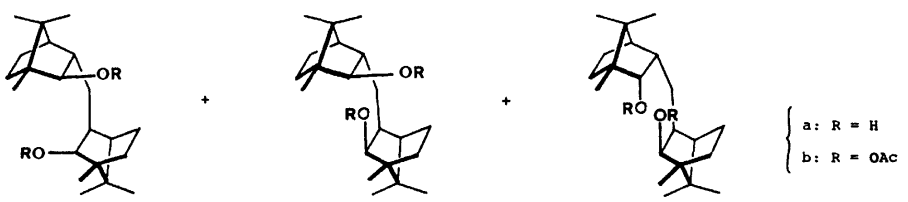
The stereochemistry at C-3, while that at C-3′ is treated in the same manner from the symmetry, was ascertained to be endo on the basis of the following NMR studies. a) The observed γ effect on the ^{13}C chemical shift at C-5 suggests that the methylene bridge situates in endo direction; the ^{13}C chemical shift at C-5 of **1** was observed 6.9 ppm upfield than that at C-5 of *d*-camphor, as observed in *endo*-3-methyl-2-norbornanone system.[4)] b) In addition, in the ^1H NMR spectra such a rigid camphor system permits the application of the Karplus equation[5)] to compound **1** with confidence. If the methylene bridge of **1** is endo at C-3, the dihedral angle between H-3 and H-4 is close to about 40°. From 2D cosy and 2DJ experiments with the 200 MHz NMR, the coupling constant between H-3 and H-4 was determined to be 5.0 Hz which supports to be the endo configuration. Further, the long-range coupling (1.5 Hz) between H-3 and H-5β was observed in **1** by virtue of the "W" configuration[6)] of these protons.



1



1



2a, b (exo, exo) **3a, b** (exo, endo) **4a, b** (endo, endo)

Consequently, in the one-methylene incorporated dimerization reaction of *d*-camphor enolate, thermodynamically more stable endo, endo-isomer turned out to be predominantly produced under the applied conditions, in which steric repulsions are minimized between the methyl groups at C-7 and C-7′ and the bridged methylene reductively incorporated from the formyl group of DMF used as a solvent.[2] This chiral diketone **1** expected to find utility for various asymmetric reactions.

As several chiral diols have been used as chiral modificators of lithium aluminum hydride (LAH),[7] we also tried the reduction of the chiral 1,5-diketone **1** in order to obtain new chiral diols. The reduction of **1** with LAH in diethyl ether easily gave a mixture of diols **2a—4a**.

The stereochemistry of **2a—4a** was determined on the basis of the coupling constants between H-2 and H-3 and/or H-2′ and H-3′ in the diols and diacetates. Compound **2a** with a coupling constant of 4.0 Hz is exo,exo-isomer and compound **3a** with two different coupling constants (4.0 and 9.5 Hz) is exo,endo-isomer, while the compound **4a** with J=9.9 Hz corresponds to endo,endo-isomer. Furthermore, the peak numbers in the ^{13}C NMR spectra of **2a** and **4a** suggested that both are symmetrical structures.

Diols, **2a** (47%) and **3a** (40%), are major and diol **4a** (6%) is minor in the reduction of **1** with LAH (ether, room temperature). The selectivity in the reduction of **1** with diisobutylaluminum hydride (THF, −78 °C) is not so different from that with LAH. On the other hand, the reduction of **1** with lithium tri-*s*-butylhydroborate (THF, −78 °C) gave only diol **2a** in a low yield.

Experimental

Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. Tetrahydrofuran (THF) was distilled from sodium/benzophenone, diethyl ether (ether) was distilled from lithium aluinum hydride (LAH), and *N*,*N*-dimethylformamide (DMF) was distilled from K_2CO_3 immediately prior to use. All the melting points were uncorrected. IR spectra were determined with a JASCO A-302 infrared spectrophotometer. Optical rotations were observed with a Union Giken PM-101 polarimeter. ^{1}H NMR and ^{13}C NMR spectra were determined with Hitachi R-90H and R-250H NMR spectrometers. 2D cosy and 2DJ experiments were performed with a Varian XL-200E NMR spectrometer. Mass spectra were measured on a Hitachi RMU-6L instrument at 70 eV. Merck silica gel 60 (230—400 mesh) was used for flash column chromatography.

Synthesis of Bis[(1*R*,3*S*,4*R*)-2-oxo-3-bornyl]methane (1). Potassium hydride (200 mg, 5 mmol) dispersed in mineral oil (35 wt%) was washed several times with petroleum ether. Onto the hydride was added DMF (10 cm^3) under argon atmospher. The solution was stirred at room temperature until the evolution of gas ceased. To the resulting mixture was added dropwise a solution of (1*R*)-(+)-camphor (609 mg, 4 mmol) in THF (3 cm^3). Then the reaction mixture was stirred at 50 °C for 3 h and quenched with 5% HCl at 0 °C. After extraction with ether, the ethereal solution was washed with brine and dried over $MgSO_4$. Filtration and removal of the solvent gave a residue, which was purified by flash

Synthesis of Diols (2a, 3a, and 4a) by the Reduction of Diketone 1 with LAH. To a suspension of excess LAH (3.0 g, 79 mmol) in ether (300 cm^3) was added dropwise a solution of **1** (13.6 g, 43 mmol) in ether (50 cm^3) at room temperature under argon atmosphere. The solution was refluxed for 1 h and then quenched with ethyl acetate (10 cm^3) at 0 °C. After the addition of water (80 cm^3), the ethereal layer was separated and washed with 10% HCl (20 cm^3), 10% Na_2CO_3 (10 cm^3), and brine (20 cm^3). The organic layer was dried over $MgSO_4$. Evaporation of the solvent gave a mixture of diols; bis[(1*R*,2*R*,3*S*,4*R*)-2-hydroxy-3-bornyl]methane **2a**, [(1*R*,2*R*,-3*S*,4*R*)-2-hydroxy-3-bornyl][(1*R*,2*S*,3*R*,4*R*)-2-hydroxy-3-bornyl]methane **3a**, and bis[(1*R*,2*S*,3*S*,4*R*)-2-hydroxy-3-bornyl]methane **4a**, (12.8 g) in 93% yield. The mixture showed R_f values of 0.5, 0.2, and 0.15, corresponding to **2a**, **3a**, and **4a**, respectively, on its thin-layer chromatography using Merck silica gel 60 on an aluminium sheet with ethyl acetate/hexane (1 : 5). Each diol was isolated by flash column chromatography with ethyl acetate/hexane (1 : 10). Their physical data, along with that of their diacetates, are listed in Table 1.

A 3-Methylene-1,2-dioxetane as a Possible Chemiluminescent Intermediate in Singlet Oxygenation of Allene

Takeshi AKASAKA, Koichiro FUKUOKA, and Wataru ANDO*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received November 1, 1988)

Synopsis. Photosensitized oxygenation of bis(adamantylidene)methane and vinylideneadamantane at −78 °C afforded adamantanone and the former also emitted light when warmed up to room temperature in the presence of a fluorescer. A 3-methylene-1,2-dioxetane as a possible chemiluminescent intermediate is proposed.

The chemistry of 1,2-dioxetanes (**1**) has been extensively studied and utilized for the synthetic and mechanistic exploration of chemienergized electronic excitation in connection with chemiluminescence and bioluminescence systems.[1-3] The thermal stability of 1,2-dioxetanes is affected by a substituent on the dioxetane ring.[4] Work on the synthesis and characterization of dioxetanones[1,2] (**2**) and dioxetanimines[5] (**3**) through the singlet oxygenation of ketenes and ketene imines has recently been reported. Greibrokk[6] and Gollnick et al.[7] reported that the photosensitized oxygenation of allenes yields the corresponding ketones and CO_2, in which singlet oxygen ($^1O_2$) cycloaddition is considered to give the bi(dioxetane) and methylene-1,2-dioxetane (**4**). Recently, Sander and Patyk reported the matrix isolation of a ter(dioxetane) at 10 K in photooxidation of 2,5-dimethyl-2,3,4-hexatriene, in which a methylene-substituted dioxetane intermediate is proposed.[8] As a part of our continuing research for new chemiluminescence systems,[9] we report here our results on the photosensitized oxygenation of bis(adamantylidene)methane[10] (**5a**) and vinylideneadamantane[11] (**5b**) and the chemiluminescence of the product (**4a**) in the presence of a fluorescer.

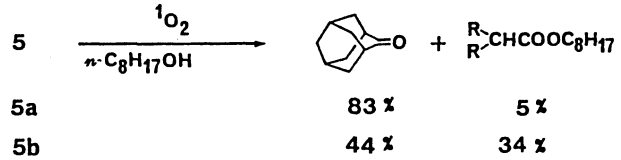
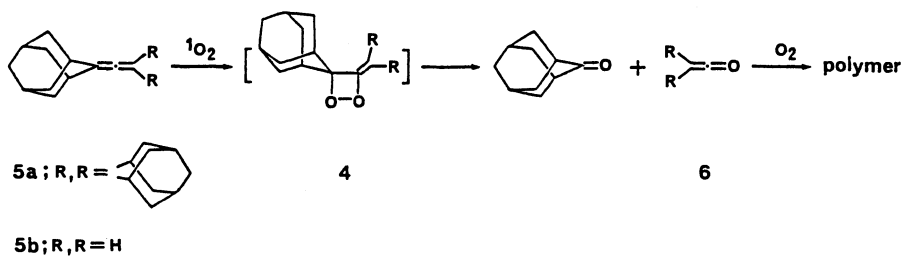
Results and Discussion

Photosensitized oxygenation of **5a** in dichloromethane at 15 °C with Methylene Blue (MB) as sensitizer led to formation of adamantanone in 87% yield as an isolable product accompanied by polymeric products.[12] Very similar results were obtained with allene **5b** (adamantanone; 56% yield). **5** is stable under the reaction conditions in the absence of the sensitizer and light, and 1,4-diazabicyclo[2.2.2]octane, a $^1O_2$ quencher,[13] inhibits the reaction. Moreover addition of triphenylmethane as free radical scavenger[14] and *p*-dimetoxybenzene as an electron-transfer quencher[15] left the photooxygenation unaffected. These results reveal that $^1O_2$ is an actual oxidizing species.

When the reaction of **5a** was carried out at −78 °C with polymer-bound Rose Bengal[16] as sensitizer and then warmed up to room temperature, no direct chemiluminescence could be observed with the naked eye. However, the irradiated solution emitted a strong pale-blue light in the presence of 9,10-diphenylanthracene (DPA) as a fluorescer. The experimental and spectroscopic results suggest that the dioxetane intermediate might be formed during the oxidation. One plausible rationale for these observations is that the oxidation seems to involve [2+2]cycloaddition to yield 3-methylene-1,2-dioxetane **4**. Subsequent decomposition of these dioxetanes may produce adamantanone and the corresponding ketenes **6** as shown in Scheme 1 (with light emission in the presence of a fluorescer in the case of **5a**). To test these possibilities of the formation of ketenes, the following experiments were done. In order to trap the ketene intermediate, the photooxygenations were carried out in the presence of alcohols which were demonstrated ketene acceptors.[17] The formation of the corresponding ester was observed together with that of adamantanone (Scheme 2).[18] Ketene **6a** may react with $^1O_2$ to afford the correspond-



Scheme 2.



Scheme 1.

ing dioxetanone followed by decomposition to give adamantanone and CO_2.[19] This possibility may be ruled out by the following fact that the adamantanone formation was unaffected in the presence of 1-octanol. Since the reaction enthalpy (ΔH)[20] for the conversion **4a** → adamantanone + **6a** was estimated to be ca. 100 kcal mol^{-1}, both singlet (E_S=85 kcal mol^{-1} for acetone, 84 kcal mol^{-1} for adamantanone) and triplet (E_T=78 kcal mol^{-1} for acetone, 87 kcal mol^{-1} for ketene **5b**[25]) excited states of adamantanone and ketene **5a** are energetically accessible from the transition state. The relative intensities of chemiluminescence from the thermolysis of 3-methylene-1,2-dioxetane **4a** were approximately 1, 1, 3, and 22 for no additive, perylene, 9,10-dibromoanthracene and DPA as fluorescers, respectively (see Experimental) (Fig. 1). This result indicates that the role of CIEEL (chemically initiated electron-exchange luminescence) path in the light production from dioxetane **4a** is unimportant,[3,5a] similar to the case of the dioxetanimine[5] and 2-azaspiro[cyclopropane-1,3′-[1,2]dioxetane][9a] and in contrast to that of the dioxetanone.[3] This difference is presumably due to the general property of carbonyl compounds which can undergo one-electron reduction more easily than olefins. Direct ^{13}C NMR observation of **4a** was unsuccessful because of low solubility of **5a** in NMR solvent at low temperature.

It thus appears that singlet oxygen is able to undergo [2+2]cycloaddition with electron-rich allenes[26] to give methylene-substituted dioxetanes which decompose with light emission in the presence of a fluorescer.

Experimental

The light source was two 500-W tungsten-halogen lamps. Irradiations were carried out in Pyrex tubes in a water bath while oxygen passed through them.

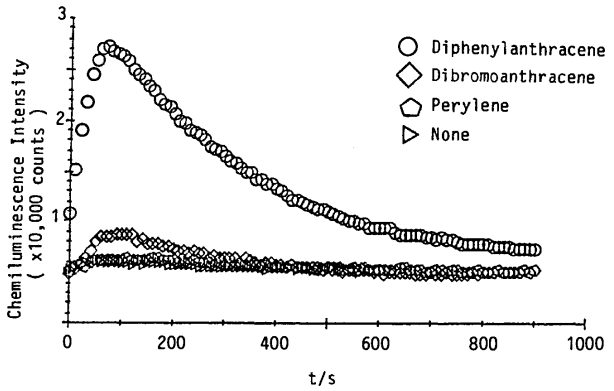


Fig. 1. Chemiluminescence from decomposition of dioxetane **4a**.

Materials. MB (Kanto Chemical) was used as received. Polymer-bound Rose Bengal (Ⓟ-RB) was prepared by the procedure given in the literature,[16] and this was also true of allene **5b**.[11] Oxidation potential (E_{ox} vs. SCE) of **5b** is +1.95 V.

Synthesis of Allene 5a. Triene **7**[27] (4.3 mmol) was treated with potassium peroxomonosulfate (8.8 mmol) by the modified method of Edwards et al.[28] in dichloromethane (70 mL), acetone (17 mL), buffered water (pH 7.5, phosphate buffer, 65 mL) and 18-crown-6 (0.75 mmol), and kept at 10 °C. During the addition of potassium peroxomonosulfate the pH was monitored with a pH-stat and kept at 7.5 by addition of 0.5 M (1 M=1 mol dm^{-3}) NaOH solution. The mixture was stirred at 10 °C. After consumption of **7** monitored by GLC, photolysis of the reaction mixture containing **8** (C=O; 1790 cm^{-1}) with a 400-W high-pressure mercury arc lamp was carried out.[29] (Scheme 3) The mixture was dried over $MgSO_4$ and then removed in vacuo. The residue was chromatographed on silica gel using hexane as an eluent. **5a** was isolated in 60% yield. **5a**: mp 245—247 °C (lit,[10] 224—226 °C); IR (KBr) 1960 cm^{-1} (C=C=C); ^1H NMR ($CDCl_3$) δ=1.67—2.08 (24H, m), 2.26—2.51 (4H, m); ^{13}C NMR ($CDCl_3$) δ=28.4 (d), 36.2 (d), 39.3 (t), 108.5 (s), 184.0 (s); MS (20 eV) m/z 280 (M^+). Anal. ($C_{21}H_{28}$) C,H. E_{ox}=+1.51 V vs. SCE.

Photosensitized Oxygenation of Allene 5. In a typical experiment, **5a** (0.11 mmol) was dissolved in dichloromethane with MB as sensitizer, and this solution was photooxygenated for 7.5 h at 15 °C. After separation by preparative gel permeation chromatography (Japan Analytical Industry Co.), adamantanone was obtained in 87% yield accompanied by polymeric products.

Photosensitized Oxygenation of Allene 5 in the Presence of Alcohol. A typical experiment was as follows: **5a** (0.1 mmol) was dissolved in 4 mL of dichloromethane containing 1 mL of 1-octanol with MB as sensitizer and the resulting solution was photooxygenated. Formation of adamantanone (83%) and 2-adamantanecarboxylic acid octyl ester (5%) was confirmed by comparison of their retention times on GLC (4 mm×1.5 m, 2% OV-1 on Uniport HP) with those of the authentic samples and GC-Mass analysis.

Chemiluminescence Analysis. Chemiluminescence was detected through a quartz window by a photomultiplier (Hamamatsu TV Ind., Model R878) with a chemiluminescence analyzer Model OX-70 (Tohoku Denshi Co.). For quantitative chemiluminescence measurement, a sample solution of **4a** was prepared by photooxygenation of **5a** in dichloromethane using Ⓟ-RB as sensitizer, followed by filtration at −78 °C. To the solution of **4a** thus prepared was added an equal volume of the stock solution of each fluorescer in dichloromethane, and the chemiluminescence was measured at −26 °C.

We thank Drs. Fujio Mizukami and Shu-ichi Niwa, National Chemical Laboratory for Industry, for the chemiluminescent measurements. This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas (No. 62607003) from the Ministry of Education, Science and Culture.

A ^{13}C NMR Relaxation Study of Octyltrimethylammonium Salts in D_2O

Yuhei UZU,* Yasushi SAITO, and Masatoki YOKOI
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received October 3, 1988)

Synopsis. The concentration dependence of the ^{13}C spin-lattice relaxation times (T_1) of the alkyl carbons in octyltrimethylammonium salts was analyzed by means of applying the phase separation model. At higher concentration, the $1/T_1$ value deviates from a linear plot and depends on the magnetic field strength. The molecular motions in monomer and micellar states are discussed, along with the overall motions of the molecule and its internal motion.

Micelles formed by surfactants in aqueous media have been the subject of numerous studies involving various techniques. Especially, in studying micellar solutions on the molecular level, NMR spectroscopy has proved to be one of the most useful experimental techniques. Recently, the internal structure and dynamics of micelles have been examined by a ^{13}C NMR study,[1-3] since the spin-lattice relaxation times (T_1) for individual carbons of the molecules provide quantitative information concerning the rotational mobility of the corresponding C-H vector. Further, a significant observation in ^{13}C T_1 measurements at different magnetic fields is that the relaxation times are dependent on the magnetic field strength at higher surfactant concentrations.[4,5]

In the present work, we systematically examined the ^{13}C-T_1 behavior of octyltrimethylammonium salts in D_2O. For these surfactants, the critical micelle concentrations (cmc) are rather high (ca. 0.3 M; 1 M=1 mol dm^{-3}). Therefore, it is feasible to obtain structural information concerning the motions of the alkyl chain segments in surfactant both in monomer and micellar states.

Experimental

Octyltrimethylammonium bromide (C_8TAB) and octyltrimethylammonium chloride (C_8TAC) were used as the surfactants in this study. The preparative procedures for the surfactants have been described elsewhere.[6] As a check of the purity of the surfactants, cmc determinations were performed by means of a surface tension method; the cmc's agreed closely with those values from the literature.[7]

^{13}C NMR spectra and T_1 values were obtained with complete proton decoupling at 22.5 MHz (2.10 T) on a JEOL-FX90QNMR spectrometer. T_1 measurements were also made at 62.9 MHz (5.87 T) using a Brucker-AC250 NMR spectrometer to examine the magnetic field dependence. The deuterium signal from solvent D_2O was used as a lock signal. T_1 values were obtained by the inversion recovery method, using a 180°-τ-90° pulse sequence. The experimental temperature was controlled by a controller unit. It's reliability was monitored by the alternative insertion of a thermister into the sample position. All T_1 measurements were performed at 36 °C.

Results and Discussion

The representative ^{13}C NMR spectrum in a C_8TAB solution at 36 °C is shown in Fig. 1. With C_8TAB, almost all carbons appear as a resolved resonance. For surfactants containing longer alkyl chains, the differences in chemical shifts of the methylene carbons near the center of the chain are insufficient to obtain a complete resolution of the spectrum, as shown in C-4 and C-5 in the figure: hence, an averaged value of T_1 values of these carbons was given. Similar spectral behavior has been observed for C_8TAC. The assignments for the surfactants studied have been given previously.[2,8]

It is assumed that the ^{13}C spin-lattice relaxation of protonated carbon in large and intermediate sized molecules like an aggregated surfactant system is in general dominated by three kinds of contributions from: (1)the overall motion of micelles, (2)the overall motions of surfactant molecules in a micellar and a bulk phases, and (3)the chain segmentary motion (internal motion) of the hydrocarbon chain in a molecule. Of three, the overall motion of micelle is slow compared with the other two motions and hence it can be neglected.[9]

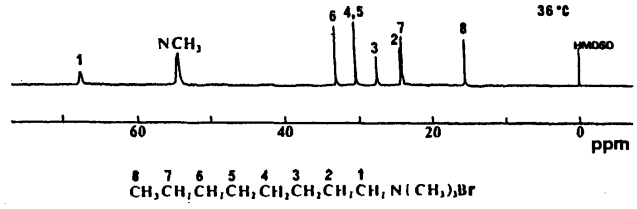

Fig. 1. ^{13}C NMR specturm of C_8TAB in D_2O at 36 °C. Hexamethyldisiloxane (HMDSO) was used as an external reference.

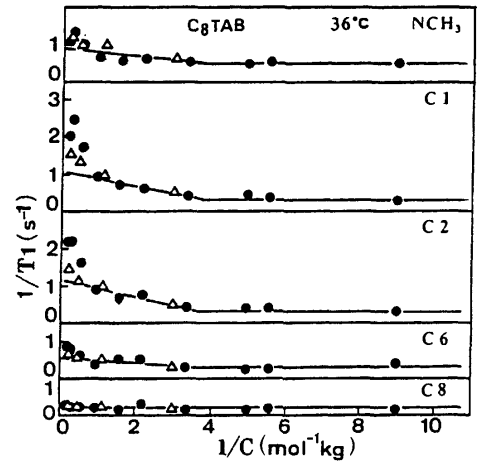

Fig. 2. Plots of $1/T_1$ of carbons for C_8TAB at two different magnetic field strengths against the inverse of surfactant concentration: (△) corresponds to 5.87 T and (●) to 2.10 T. The carbons are numbered as in Fig. 1.

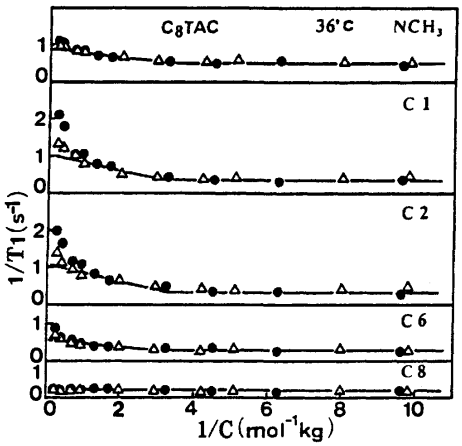

Fig. 3. Plots $1/T_1$ of carbons for C_8TAC at two different magnetic field strengths against the inverse of surfactant concentration: (△) corresponds to 5.87 T and (●) to 2.10 T. The carbons are numbered as in Fig. 2.

The observed relaxation rates, $1/T_1$, for alkyl carbons in the C_8TAB and C_8TAC at two different magnetic field strengths are plotted in Figs. 2 and 3, as functions of the inverse of surfactant concentrations (C). It can be seen that relaxation times are almost constant at low concentrations (high values of $1/C$); however, at high concentrations, there is an increase in the relaxation rate for all carbon atoms, except C-8 of the terminal methyl group. The increase in the $1/T_1$ value indicates an increased restriction on the mobility of the entire chain. Similar ^{13}C-T_1 behavior has been observed for aqueous micellar solutions of sodium hexanoate.[10] The changes in $1/T_1$ are due to the formation of micelles. The obtained cmc values are nearly equal to those by the surface tension method: C_8TAB 0.27 mol kg^{-1}, C_8TAC 0.32 mol kg^{-1}. It can be seen that the cmc of C_8TAB is lower than that of the corresponding chloride. As for T_1 values of individual alkyl carbons in the surfactants, there was no striking difference between C_8TAB and C_8TAC, indicating that both of these micelles are of nearly the same size and shape. Considered together with previously published results,[6] these micelles tend to remain nearly spherical up to high concentrations (above the cmc). In the limited range of concentration above the cmc (ca. 0.3—1.0 mol kg^{-1}), an approximately linear relationship exists between $1/T_1$ and $1/C$. We can also see that there is little difference between both T_1 values at 2.10 T and at 5.87 T in this concentraion range, as well as below cmc. Following the phase separation model, the observed relaxation rate $(1/T_1)_{obsd.}$ is assumed to be a weighted average of the relaxation rates in the micelles and monomers. Then, T_1 in this concentraion range is given by[10,11]

$$\left(\frac{1}{T_1}\right)_{obsd.} = \frac{cmc}{C}\left(\frac{1}{T_1}\right)_{mon.} + \frac{C-cmc}{C}\left(\frac{1}{T_1}\right)_{mic.}.$$

This equation suggests that a plot of the $(1/T_1)_{obsd.}$ against the inverse of the concentration should give two straight lines intersecting at the cmc, as shown in the Figs. 2 and 3. The $1/T_1$ values for all carbons in monomer and micellar states can, therefore, be obtained from the intercepts at cmc and at $1/C=0$, respectively. Thus, the relaxation times obtained for C_8TAB are summarized in Table 1, together with the correlation time (τ_c). In the monomer state, variation of the relaxation along the hydrocarbon chain within a molecule was not large, as compared with those in the micellar state. Precisely, there seems to be a slight increase in the segmentary mobility as one moves away from the polar head. As indicated by the higher T_1 values all along the chain, the overall reorientation motion is faster with a slight degree of segmentary motions along the chain in a molecule, suggesting that the relaxation behavior below cmc is mainly governed by the overall motion of the octyltrimethylammonium ion. From Fig. 2 and Table 1, a marked increase in the $1/T_1$ value above cmc is found along the alkyl chain from C-8 toward C-1 next to the N-methyl head groups. This behavior may be attributed to a severe immobilization at the polar head, because surfactant molecules interact strongly with neighboring molecules, counterions and water molecules at the micellar surface. Accordingly, the overall motion of the molecule becomes more and more restricted, implying that the internal motions become more important for the relaxation behavior. On the other hand, the $1/T_1$ value of N-methyl carbon is rather small, as shown in Table 1. Probably, such N-methyl groups are expected to extend outward from the micellar surface into the solvent. Consequently, they would possess a larger degree of motional freedom than that of the carbons next to the polar group. As for the C-8 carbon, it has a prominent segmentary mobility, irrespective of the surfactant concentration. The micellar interior is likely to have properties that approach those of a liquid-like environment, as already stated by others.[1,12,13] In Figs. 2 and 3 it is remarkable that at the highest concentration range, $1/T_1$ values tend to deviate from the linear plots and the degree of deviation is relatively larger at 2.10 T than that at 5.87 T, suggesting a magnetic field strength dependence for the relaxation behavior. Especially, a marked field dependence is found for the first three methylene car-

Table 1. ^{13}C Spin-Lattice Relaxation Times (T_1) and Correlation Times (τ_c) for the Alkyl Carbons of C_8TAB Solution at 2.10 T

Carbon atom	Micelles		Monomers at cmc	
	T_1/s	τ_c/ps[a]	T_1/s	τ_c/ps[a]
N-CH_3	0.99	16	2.0	7.8

C-8	4.4	3.6	4.4	3.6

a) Calculated from $1/T_1=N\hbar^2\gamma_C^2\gamma_H^2 r_{CH}^{-6}\tau_C$, where γ_C and γ_H: gyromagnetic ratios of ^{13}C and ^{1}H, N: number of directly bonded hydrogen, r_{CH}: C-H distance. $\hbar$: Plank's constant.

bons next to the polar head group. For this field dependence, Wennerström et al.[4] have proposed from ^{13}C T_1 measurements on sodium octanoate that the slow micellar motion contributes to the relaxation, particularly for carbons near the polar head. In addition, the deviation from linearity may suggest that some structural change affecting the relaxation occurs in the micelles. From the results presented above, T_1 is found to be magnetic field independent at low concentrations, so that the relaxation is determined by a correlation time τ_c on the order of 10^{-11} to 10^{-12} s based upon the rotational motion of isotropic reorienting molecule, where extreme narrowing condition is fulfilled. At higher concentrations with field dependence, such a surfactant system is expected to have slow motions on the order of 10^{-8} to 10^{-9} s (or longer), such as the rotation of micelle as a single entity and surfactant lateral diffusion along the micelle surface.[14] Further analysis using a two-step model[4,14] from the multifield relaxation data would be necessary to obtain detailed information on both chain dynamics and orientation.

We express our sincere thanks to Prof. Ryozo Irie, Faculty of Agriculture, Shinshu University, for the NMR measurement at 5.87 T.

(Received July 4, 1988)

Synopsis. Effects of variables such as acid/base reaction temperature, presence of impurities, method of oxide powder preparation, and calcination temperature on the point of zero charge (p.z.c) were investigated for TiO_2-ZrO_2 (79.41—20.59, wt.%) mixed oxides. The visually determined p.z.c. values were also compared with those arrived at by a computational method to obtain an estimate of the error of determination.

Interfacial charge-transfer reactions play a key role in many chemical process industries[1,2] like ceramic, paint, and catalyst industries. The potentiometric investigations of Bolt,[3] and Parks and de Bruyn[4] confirmed that H^+ and OH^- are the potential or charge determining ions for oxides in aqueous medium. They extended the potentiometric titration data to estimate the surface-charge densities as a function of pH and at the same time to detemine the p.z.c. The p.z.c. is determined from the intersecting point of the surface charge density vs. pH curves with the zero surface charge density line. Difficulties arise in determining the exact location of the point of intersection when different ionic concentrations of the supporting inert electrolyte are considered. The p.z.c. values have been found to depend on several factors such as acid/base reaction temperature,[5] impurities,[6] calcination temperature[7] etc.

The present communication intends to show the effects of (i) acid/base reaction temperature, (ii) cationic and anionic impurities, (iii) methods of preparation, and (iv) calcination temperature on the p.z.c. of a TiO_2-ZrO_2 (79.41—20.59, wt.%) double oxide. The visually determined p.z.c. values have also been compared with those arrived at by a computational method to obtain an estimate of the error of determination.

Experimental

Preparation of Double Oxide Powders. Powder samples (Table 1) of TiO_2-ZrO_2 (79.41—20.59, wt%) were prepared in the following way. Sample TZ-1 was prepared by the thermal decomposition of mixed hydroxides which were coprecipitated from a mixture of aqueous $TiCl_4$ (Riedel-de-Haën) and $ZrO(NO_3)_2$ (BDH) solution with aqueous ammonia solution (BDH). Powders having the particle size range of 74—175 μm (obtained by sieving) were used. Sample TZ-2 was prepared from a mixed alkoxide of $Ti(OPr^i)_4$ (Fluka) and $Zr(OPr^n)_4$ (Fluka) by hydrolyzing with doubly distilled deionized water. The average agglomerated particle size was 3.1 μm. This powder sample was impregnated with aqueous H_2SO_4 (Sample TZ-2A, SO_4^{2-} content 0.40 mmol g^{-1}) and NaOH (Sample TZ-2B, Na^+ content 0.04 mmol g^{-1}) solution to observe the effects of impurities on the p.z.c. Sample TZ-3 was prepared from high purity TiO_2 (rutile, National Lead Co.) and $Zr(OPr^n)_4$ (Fluka) by hydrolyzing the latter with water. The average agglomerated particle size of the double oxide was 9.1 μm. Sample TZ-4 was prepared from $Ti(OPr^i)_4$ (Fluka) and pure ZrO_2 (monoclinic, Riedel-de-Haën) by hydrolyzing the former with water. The average agglomerated particle size was 4.0 μm. All the samples were calcined at 500 °C for 3 h in static air unless otherwise mentioned.

Method of Study. A potentiometric titration method described previously by Kita et al.,[8] and Karmakar and Ganguli[9] was used. Briefly, aqueous solutions (200 ml) of 0.004 mol dm^{-3} HNO_3+KNO_3 (10^{-1}, 10^{-2}, and 10^{-3} mol dm^{-3}) were carefully poured into beakers containing accurately weighed 1.000 g of the sample powder, and the suspension equilibrated overnight; potentiometric titration against 0.1 mol dm^{-3} KOH aqueous solution was carried out with the suspension at 40±0.5 °C (some experiments were carried out at 30, 50, and 60±0.5 °C) under a nitrogen stream to avoid CO_2 contamination from air.

The surface-charge density as a function of pH was estimated from the difference between the titration curves obtained without and with the sample. The p.z.c. values were determined from the common point of intersection of the surface-charge density vs. pH curves for 10^{-3}, 10^{-2}, and 10^{-1} mol dm^{-3} KNO_3.

Results and Discussion

The p.z.c.'s of several TiO_2-ZrO_2 (79.41—20.59, wt%) powders were determined following the above described method by varying different parameters and the results have been listed in Table 1. Effects of specific variables are described below in brief.

Effect of Acid/Base Reaction Temperature. The observed p.z.c. values of the Sample TZ-2 indicated decrease with increase in acid/base reaction temperature (in the range of 30 to 60 °C). Such decrease in p.z.c. was apparently caused by the decrease in the relative affinity of the charge-determining ions (i.e. H^+ and OH^-) for the oxide surface with increasing temperature.[5]

The standard thermodynamic functions (ΔH^*=the standard differential heats of transfer of H^+ and OH^- from the bulk solution to the interfacial region, and ΔS^*=the difference in standard ionic entropy of hydration of H^+ and OH^- at p.z.c.) have been calculated (ΔH^*=−92.30 kJ mol^{-1} and ΔS^*=−343.88 J deg^{-1} mol^{-1}) from the slope and intercept of the linear plot of ($1/2$ pK_w−$pH_{p.z.c.}$) vs. $1/T$ (Fig. 1) following the equation proposed by Berube and de Bruyn.[5] Here ΔH^* is negative, ΔS^* is also negative and numerically $T\Delta S^*$ (of the Gibbs-Helmholtz equation) is greater than ΔH^* which make ΔG^* positive. The temperature dependent ΔG^* values, therefore, suggest that the transferring reactions of H^+ and OH^- from the bulk solution to the interfacial region were not a spontaneous process. The negative ΔH^* value also suggests that the deprotonation process of the surface MOH_2^+ and MOH groups was exothermic.

Effect of Impurity. Samples TZ-2A and TZ-2B con-

a) Calcined at 500°C for 3 h unless otherwise stated. b) Calcined at 1000 °C for 3 h.

tained intentionally introduced SO_4^{2-} and Na^+ as typical anionic and cationic impurities respectively. The p.z.c. values of the above samples (Table 1) clearly indicated that on impregnation with (i) SO_4^{2-}, the p.z.c. shifted to the lower pH value, and with (ii), Na^+, the p.z.c. shifted to the higher pH value. Several researchers[6,10] also reported similar trends on single oxides. The SO_4^{2-} apparently greatly increased the amount of surface Brønsted acid sites (any Lewis acid that might form would be transformed to the Brønsted type in an aqueous medium) of the sample TZ-2A, thereby causing a shift of p.z.c. towards the lower pH value. On the other hand, the Na^+ increased the surface basic sites of the Sample TZ-2B due to the neutralization of the acid sites by NaOH, thereby causing a shift of p.z.c. towards higher pH value.

Effect of Methods of Preparation. On comparison of the p.z.c. values among the Samples TZ-1, TZ-2 (40 °C), TZ-3, and TZ-4, it was observed that the p.z.c. depended on the method of preparation and varied in the pH range of 4.45—6.95. The p.z.c. of the anatase containing Samples TZ-1, TZ-2 (40 °C), and TZ-4 remained in a higher pH range than that of the rutile-containing Sample TZ-3. Here the degree of intermixing of the reacting constituents, product homogeneity and the sources of starting materials of samples TZ-3 and TZ-4 were completely different from each other, due to the difference in their methods of preparation (see "Experimental"). Further, the Samples TZ-3 and TZ-4 were obviously less homogeneous than the Samples TZ-1 and TZ-2 (40 °C).

Again, both the Samples TZ-1 and TZ-2 (40 °C) contained the anatase crystal phase, although they were prepared from inorganic salts and metal alkoxides respectively. The excellent chemical homogeneity in mixed oxide systems prepared via mixed alkoxides is well-known.[11] Samples prepared via inorganic salt solutions, though much more homogeneous than those prepared via solid-solid reactions, are less so

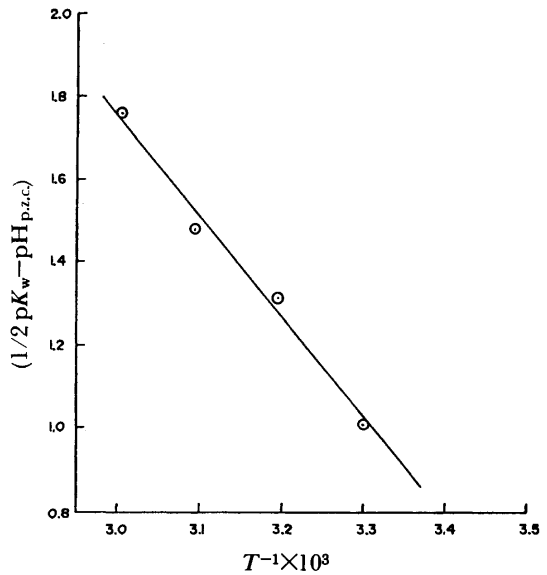

Fig. 1 Plot of $(1/2\,pK_w - pH_{p.z.c.})$ vs. T^{-1} (reciprocal of temperature in Kelvin) for Sample TZ-2.

than alkoxide-derived ones. They are also less pure because of the presence of dissolved ionic impurities etc. Thus, the differences in the origin of starting materials and mode of preparation are amply reflected in the p.z.c. values.

Effect of Calcination Temperature. The p.z.c. values of TZ-1 and TZ-2 (Table 1) indicated that the p.z.c. of TiO_2-ZrO_2 double oxides shifted to higher pH on calcination at 1000 °C. Important factors responsible for changing p.z.c. with calcination temperature are, e.g. change in crystal structure,[7] change in the nature of atomic arrangements (i.e. amorphous to crystalline, or separate components to compound formation), dehydration and dehydroxylation etc. In the present case the formation of $ZrTiO_4$ in addition to anatase-rutile conversion should be considered as a

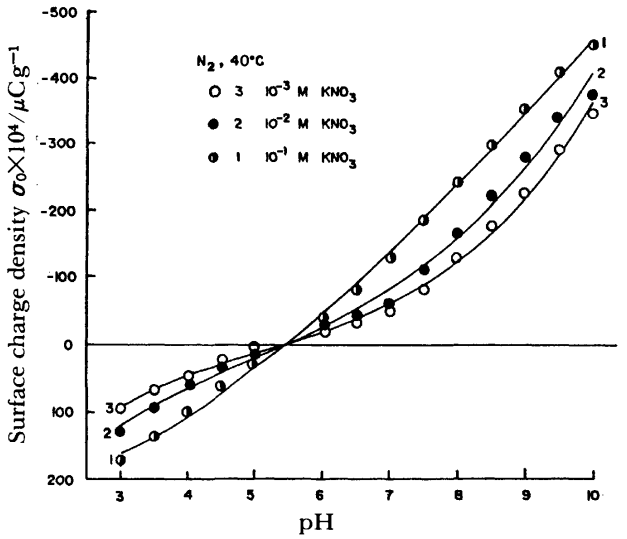

Fig. 2. Experimental and computed surface-charge density as a function of pH for Sample TZ-2 (40 °C). Solid lines are calculated by fitting cubic equations at the minimum standard deviation considering all the three curves; the experimental data points (circles) are shown for comparison.

determining factor.

It is evident from the above discussion that p.z.c. values can be sensitive to various preparative and experimental parameters. However, all such comparisons must ensure a minimum of relative errors in the experimental measurements. To check on this in the present case, where p.z.c. values were determined from the visually estimated cut points of three titration curves at different electrolyte concentrations, cubic equations for the titration curves were set up. The process is described below.

Cubic Equations for Surface-Charge Density vs. pH Curves and Determination of p.z.c. A careful examination of the nature of the experimental surface-charge density vs. pH curve (Fig. 2) showed that this curve having a single inflection point should correspond to cubic (third degree) polynomials.[12,13] For this reason, cubic regression analyses were performed on the experimental points of surface-charge density vs. pH curves and p.z.c. values were determined. The cubic equation (y=surface charge density, x=pH) could be written as:

$$y = A_0 + A_1 x + A_2 x^2 + A_3 x^3 \cdots \quad (1)$$

The values of A_0, A_1, A_2, and A_3, (dependent on both the concentration of supporting electrolyte and the nature of oxide powder considered) were obtained by using a computer program in the following way. Following the theory of p.z.c. two conditions were applied:

(i) At p.z.c., according to the equation[8,14]

$$\sigma_0 = F(\Gamma_{H^+} - \Gamma_{OH^-}),$$

where F is the Faraday constant (C/equiv. wt.), Γ_{H^+} and Γ_{OH^-} are the net adsorption densities of H^+ and OH^- respectively, y=0 and x must have a real and positive value.

(ii) All the three curves (of 10^{-3}, 10^{-2}, and 10^{-1} mol dm^{-3} KNO_3) should pass through the point having coordinates of y=0, x=single fixed value mentioned in (i).

Standard deviations were computed for all the three curves of σ_0 vs. pH in each set of data, considering a large number of points on the line y=0 to be their possible points of intersection. Mean standard deviations were then computed for all such points. The point corresponding to the minimum standard deviation was selected as the point of intersection of the three curves, i.e. the p.z.c. The eleven sets of experimental data on TiO_2-ZrO_2 powders were processed following the above-mentioned procedure and the results have been listed in Table 1. The curves of Sample TZ-2 (40 °C) indicating the difference between the experimental (circles) and the computed (solid lines) points of σ_0 at the corresponding pH values, have been shown in Fig. 2 as an example.

The above diagram indicates the goodness of fit of cubic equations with the experimental points. The differences between the visually determined and the computed p.z.c.'s for the eleven sets of experimental data were found to vary in the range of −0.10 to +0.27 pH unit. These differences arose possibly due to the fact that for visually determined p.z.c., weightage was given to only some experimental points near the p.z.c., whereas for computed p.z.c., uniform importance was given also to the points very much away from the p.z.c. The above differences of p.z.c.'s were, however, not too large in the present case and remained within the errors of measurement.

The authors are thankful to Dr. S. Kumar, Director of the Institute, for his permission to publish this note. Thanks are also due to Dr. R. K. Das, Computer Cell of the Institute for his kind help in the programming.

A Lattice Gas Model for Neopentane

Masato SHINMI and Dale A. HUCKABY*
Department of Chemistry, Texas Christian University, Fort Worth, Texas 76129, U.S.A.
(Received August 16, 1988)

Synopsis. A lattice gas model for neopentane on a bcc lattice was considered. The equation of state and critical point were calculated using a Guggenheim-McGlashan approximation. The liquid phase in the model exhibits the same type of short-range orientational ordering proposed by Nishikawa to exist in liquid neopentane.

Nishikawa recently carried out structure simulation studies for liquid neopentane[1] and reported that the X-ray diffraction intensities from the liquid observed by Narten[2] were reproduced well by a local body centered cubic (bcc) lattice structure model.[1] In this bcc cluster model, the central carbon atoms of the neopentane molecules occupy the sites of a bcc lattice, the molecules are all in the same orientation, and the four carbon-carbon bonds of each molecule point toward the central carbon atoms of neighboring molecules. This local orientational ordering was proposed to occur over a wide range of temperatures.[1] Nishikawa and Murata[3] previously used this bcc cluster model to accurately reproduce the X-ray diffraction intensities from liquid carbon tetrachloride. The X-ray diffraction intensities from liquid 1,1,1-trichloroethane have also been accurately reproduced using the bcc cluster model.[4]

Using a five force center Lennard-Jones potential, Mountain and Brown[5] carried out a molecular dynamics study of neopentane. Their results were consistent with radial distribution functions derived from Narten's diffraction data,[2] and their study indicated that long-range angular correlations in liquid neopentane are weak.[5]

The bcc cluster model[1,3] for short-range orientational ordering has the same local structure as does the long-range orientational ordering proved to exist in a lattice gas of tetrahedral molecules on a bcc lattice.[6,7] We[8] have previously fitted a Guggenheim-McGlashan approximation[9,10] of this lattice gas model to the properties of carbon tetrachloride at the critical point. The lattice gas has properties which are consistent with several aspects of the bcc cluster model[3,11] and provides a fairly good model for carbon tetrachloride.[8]

In the present work we use this bcc lattice gas of tetrahedral molecules as a model for neopentane. A lattice site in the model can be either vacant or occupied by a molecule in either of the two orientations in which the carbon-carbon bonds of the molecule point toward neighboring lattice sites. One such orientation is illustrated in Fig. 1. If two molecules occupy neighboring lattice sites, they repel with a steric bond-bond repulsion $\gamma>0$ if each points a bond toward the other, they attract with an energy $\varepsilon\leq 0$ if exactly one points a bond toward the other, and they attract with an energy $\delta\leq 0$ if neither points a bond toward the other.

An extension of the Peierls argument[12,13] has been used to prove that if $2\varepsilon<\gamma+\delta$, then at sufficiently low temperature and sufficiently high chemical potential an orientationally ordered phase exists in the lattice gas model in which most of the sites are occupied by molecules in a single orientation.[8] Within the Guggenheim-McGlashan approximation, this orientationally ordered structure was found to exist locally in the liquid phase of the lattice gas over a wide range of temperatures.[8]

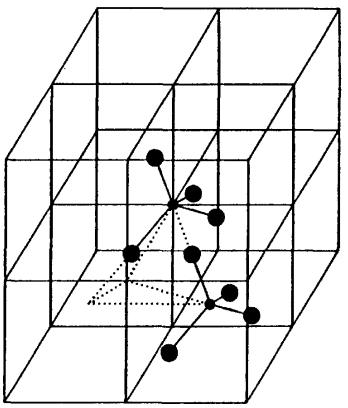

Fig. 1. One of two possible orientations of a neopentane molecule in the bcc lattice gas is shown. A tetrahedron is illustrated which is used in the Guggenheim-McGlashan approximation.

We shall now use a Guggenheim-McGlashan approximation of this bcc lattice gas[8] to model the properties of the liquid and vapor phases of neopentane. The approximation considers the interactions within the various molecular configurations possible on a cluster of sites and then approximates the interactions between various clusters on the lattice.

The following outline of the Guggenheim-McGlashan approximation is described in more detail in Ref. 8. The bcc lattice is composed of tetrahedra, one of which is illustrated in Fig. 1. We consider the set τ consisting of all translates of a single tetrahedron. Each lattice site is covered by a vertex from each of four tetrahedra in τ, and each first neighbor lattice bond is covered by an edge from exactly one tetrahedron in τ.

The set of possible molecular configurations about a tetrahedron in τ is illustrated in Fig. 2 of Ref. 8. For a configuration of type i, the energy ε_i, the number of molecules n_i, and the number of such configurations ω_i are listed in Table II of Ref. 8.

For a lattice of N sites containing M molecules, we let ψ_i be the probability that a given unit tetrahedron in τ has a molecular configuration i. The energy per lattice site is given as

$$E=\sum_i \varepsilon_i\omega_i\psi_i.$$

The entropy per lattice site is given in the

Guggenheim-McGlashan approximation as

$$S=N^{-1}k\ln\Omega_0-k\sum_i\omega_i\psi_i\ln\psi_i.$$

Here there are N tetrahedra in τ, and Ω_0 in a constant which is determined by calculating S at extremely high temperatures.

At equilibrium the Helmholtz free energy, $A=E-TS$, is minimized at constant T, M, and N under the restrictions

$$\sum_i\omega_i\psi_i=1$$

$$\sum_i n_i\omega_i\psi_i=\rho,$$

where $\rho=M/N$ is the number density of occupied sites. The order parameter ρ is sufficient to locate the liquid phase-vapor phase equilibrium and the associated critical point.

The Lagrange multiplier technique then gives expressions for the chemical potential μ, the pressure P, and the density ρ as functions of a parameter r.[8] These equations can be solved to obtain the phase diagram for the model. An iterative technique we developed[8] was used to locate the critical point in the model. For plotting purposes we define the reduced variables $P'=Pv_0/|\varepsilon|$, $T'=kT/|\varepsilon|$, $\gamma'=\gamma/|\varepsilon|$, and $\delta'=\delta/|\varepsilon|$. Here v_0 is the volume per lattice site.

Since steric repulsions are very strong between the methyl groups on neighboring molecules in the bcc cluster model for neopentane,[1] we consider here only the case of infinite bond-bond repulsion, $\gamma'\to\infty$, in the bcc lattice gas model. Using the experimental critical values[14] P_c=31.545 atm, T_c=433.75 K, and $\bar{V}_c$=311 cm^3 mol^{-1} for neopentane, the parameters δ', v_0, and ε in the lattice gas model can be fitted to experiment at the critical point.

The critical compressibility factor $Z_c=P_c'/(\rho_cT_c')$ for the lattice gas is plotted against δ' in Fig. 4 of Ref. 8. Since $Z_c=P_c\bar{V}_c/(RT_c)$, this quantity can be readily fitted to experiment. The best fit occurs at $\delta'=-0.78$.

For the case $\gamma'\to\infty$ and $\delta=0.78\ \varepsilon$, steric bond-bond repulsions are certainly central in producing the orientational ordering, for the two orientations of a pair of neighboring molecules which are attractive have nearly the same energy. The effect of steric repulsion on this ordering can be readily seen within the Guggenheim-McGlashan approximation, for packing considerations (see Fig. 2 of Ref. 8) even in a tetrahedral arrangement of four sites preclude all four sites from being occupied such that an attraction δ occurs in the tetrahedron without the simultaneous occurrence of a steric repulsion γ.

The critical parameters for the lattice gas model with $\gamma'\to\infty$ and $\delta'=-0.78$ were computed to be P_c'=0.08922, T_c'=0.8558, and ρ_c=0.3784. The volume per lattice site, v_0, was then fixed at the critical point using the equation $v_0=\rho_c\bar{V}_c/N_0$, where $\bar{V}_c$ is the experimental critical molar volume and N_0 is Avogadro's number. This gives a value $v_0=1.954\times10^{-22}$ cm^3, and a resulting first neighbor central carbon-central carbon separation of r_{cc}=6.33 Å. This compared quite well with the separations r_{cc}=6.14 Å at −17 °C to r_{cc}=6.90 Å at 150 °C which were used in the bcc cluster model[1] to accurately simulate the experimental X-ray diffraction intensities of the liquid at different temperatures under high pressure.[2]

The energy ε was fitted to experiment using the equation $|\varepsilon|=kT_c/T_c'$, where T_c is the experimental critical temperature. This yields $N_0|\varepsilon|$=4.21 kJ mol^{-1}. In order to compare the fitted value of $|\varepsilon|$ with experiment, we assume the liquid at the normal boiling point is ordered in the bcc local lattice structure. Then $N_0|\varepsilon|\approx\Delta\bar{E}_v/4=(\Delta\bar{H}_v-P\Delta\bar{V}_v)/4$. The experimental values[14] $\Delta\bar{H}_v$=22.64 kJ mol^{-1} and $\Delta\bar{V}_v$=21893.4 cm^3 mol^{-1} at the normal boiling point (T_b=282.628 K and P=1 atm) yields $N_0|\varepsilon|$=5.11 kJ mol^{-1}, which agrees fairly well with the fitted value.

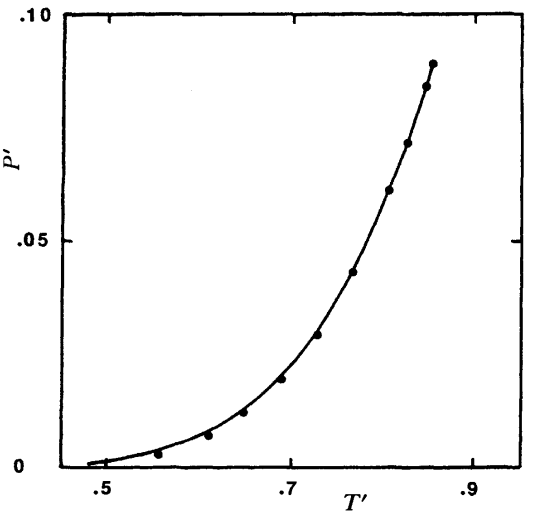

Fig. 2. The liquid-vapor coexistence curve in the (P', T') plane is plotted for the lattice gas case in which $\gamma'\to\infty$ and $\delta'=-0.78$. Several experimental points[14] are illustrated as dots in the figure.

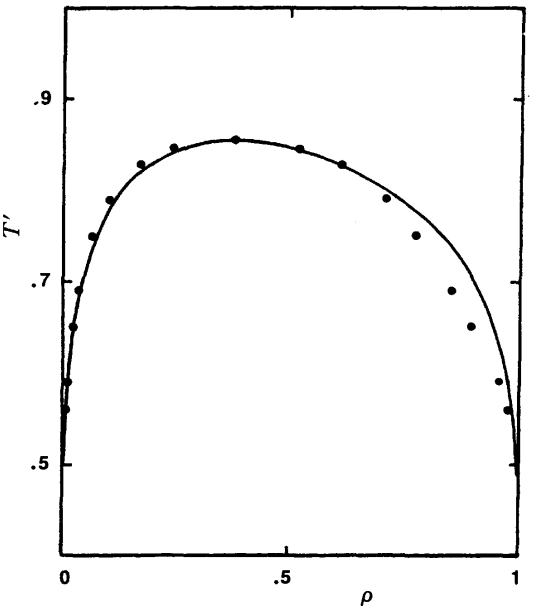

Fig. 3 The liquid-vapor coexistence curve in the (T', ρ) plane is plotted for the lattice gas case in which $\gamma'\to\infty$ and $\delta'=-0.78$. Several experimental points[14] are illustrated as dots in the figure.

The liquid-vapor coexistence curves in the (P', T') plane and in the (T', ρ) plane are plotted in Figs. 2 and 3, respectively, for the lattice gas case in which $\gamma' \to \infty$ and $\delta' = -0.78$. Using the equations $P' = Pv_0/|\varepsilon|$, $T' = kT/|\varepsilon|$, and $\rho = v_0 N_0/V$, several experimental points[14] (P, T) and (T, V) on the liquid-vapor coexistence curve were converted to (P', T') and (T', ρ) values and illustrated in Figs. 2 and 3, respectively.

In conclusion, the lattice gas model studied here is consistent with many aspects of Nishikawa's local bcc lattice structure model and seems to provide a fairly good model for neopentane.

This research was supported by the Robert A. Welch Foundation, grant P-446.

Molecular Complexes of Cyclophanes. XV. Charge-Transfer Complexes of Sterically Hindered[2.2]metapara- and [2.2]paracyclophanes with π-Acceptors

Aboul-fetouh E. MOURAD*, Alaa El-Din A. HASSAN, and Jörg DANNHEIM†

(Received April 18, 1988)

Synopsis. The charge-transfer (CT) complexes of some sterically hindered [2.2]metapara- and [2.2]paracyclophanes as π-donors with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) and tetracyanoethylene (TCNE) as π-acceptors have been investigated by electronic as well as infrared spectroscopy. Electronic, steric, and transannular effects governing the formation and stability of the CT complexes studied are discussed.

The transannular electronic interactions in the [2.2]paracyclophanes were the subject of several spectroscopic investigations in the last decades.[1-9] These studies dealt mainly with the question of how the electronic effects of substituents in one ring are transferred to the second ring of the [2.2]paracyclophane molecule.

This paper dealt with the visible and infrared spectra of intermolecular complexes of di-*t*-butyl[2.2]-metaparacyclophanes (**1—3**), diisopropyl[2.2]paracyclophanes (**4,5**), 4-*t*-butyl[2.2]paracyclophane (**6**) as well as 4-trimethylsilyl[2.2]paracyclophane (**7**) and both acceptors DDQ and TCNE. A new absorption band due to neither donor **1—7** nor acceptor was observed in the visible region for the CT complexes studied. In two cases two new absorption bands were observed (Table 1). These two absorption bands may be explained as due to electron transition from two highest occupied π-molecular orbitals of an electron donor to the lowest vacant π-molecular orbital of an electron acceptor.

It has been reported that the λ_{max} values for the CT complexes were used as a measure of the π-base strengths of the donors used.[2] Comparison of the λ_{max} values for the CT complexes of the donors **1—5** with both DDQ and TCNE demonstrates that the π-base strengths of the donors follow the order: 4>5>1>2>3. Also, [2.2]paracyclophanes (**4** and **5**) are more basic

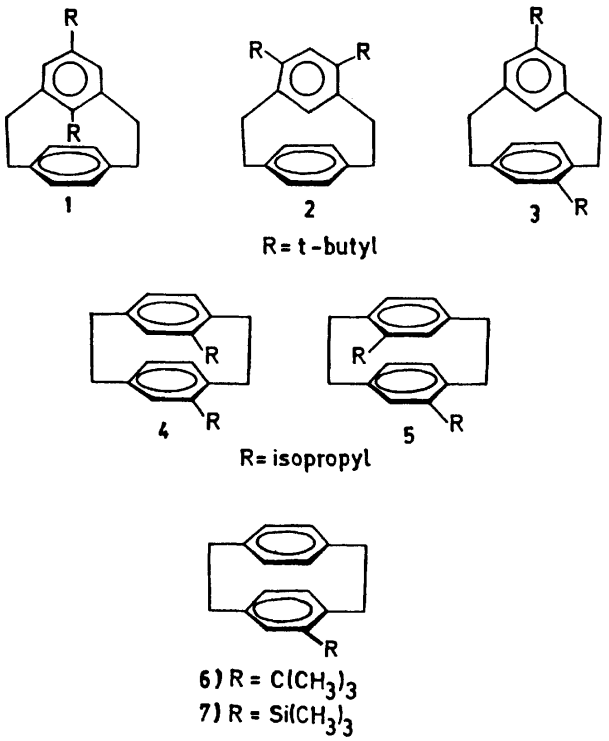

Table 1. CT Spectral Data for Complexes between Donors **1—7** and DDQ, TCNE in Dichloromethane at 20 °C

Donor	Acceptor	λ_{max}	ε	*K*	IP
		nm	$l\,mol^{-1}cm^{-1}$	$l\,mol^{-1}$	eV
1	DDQ	632	109	121.45	8.17

7	TCNE	532	136	67.36	8.31

than [2.2]metaparacyclophanes (**1—3**). In order to explain this trend of basicity two factors must be discussed; electronic and steric. In the metaparacyclophanes (**1—3**) the transannular electronic interactions are absent, since the two aromatic nuclei are perpendicular to each other,[10] and thus the unsubstituted part of compound **1** and **2** may be formally considered as *p*-xylene. The higher values of the λ_{max}'s of the CT complexes of donors **1—3** with TCNE in Table 1 relative to *p*-xylene-TCNE complex (λ_{max}=460 nm[11]) indicated that the substituted ring in **1** and **2** mainly formed complexes with the acceptors. Accordingly, the electronic effects of the *t*-butyl groups are prevailing over steric ones. The presence of two *t*-butyl groups in the *p*-position in **1** and in the *m*-position in **2** is responsible for the greater steric hindrance and consequently lower π-basicity of **2** relative to **1**.[1]

As reported in Table 1, the CT complexes of **4** with DDQ and TCNE absorb at 659 and 580 nm respectively. The CT complexes of its analogue 4,13-di-*t*-butyl[2.2]paracyclophane (**4**, R=*t*-butyl) with the same acceptors absorb at 663 and 595 nm respectively.[12] These results reveal that the *t*-butyl-substituted cyclophane is more basic than the isopropyl-substituted one. In other words, the electron-releasing character is stronger than the steric one. Accordingly if we compare the basicity of di-*t*-butyl-substituted [2.2]metaparacyclophanes (**1—3**) with that of diisopropyl-substituted [2.2]paracyclophanes (**4** and **5**) the former basicity is expected to be larger than that of the latter. Contrary to the expectation the latter was larger than the former as shown in Table 1. This behevior arises undoubtly from transannular electronic interactions within paracyclophanes **4** and **5**.

The existence of steric hindrance in a donor-acceptor system tends to inhibit the interections between the electron-poor π-orbitals of acceptor with the electron-rich π-orbitals of donor, and hence the basic character of donor will be decreased with increasing the steric hindrance, i.e., the absorption of its CT complexes will be shifted to shorter wavelengths. Consequently, on the basis of steric requirements, the CT complexes of **4** with DDQ and TCNE should absorb at shorter wavelengths than those of **5**, since the two isopropyl groups in **4** are pseudo-geminally oriented, and hence more sterically hindered than in the pseudo-ortho case (**5**) On the contrary, the donor **4** exerts higher basic character than **5** as reported in Table 1 for the values of λ_{max}. This may be explained as due to the difference in exiton splitting of the electronic states of the two donor molecules.

The association constants for complex formaation indicate a marked sensitivity to substituent effects and follow the same sequence as the corresponding λ_{max} values. A linear correlation between the association constants and the position of the λ_{max} of the long wavelength CT band has been observed for the two series of complexes.

It is worthwhile to point out that the low *K* values of the CT complexes of 4-trimethylsilyl[2.2]paracyclophane (**7**) with DDQ and TCNE and the absorption at relatively shorter wavelengths than the CT complexes of 4-*t*-butyl[2.2]paracyclophane (**6**) with the same acceptors are in agreement with the low electronegativity of the silicon atom with respect to the carbon one.

It has been reported that for a series of CT complexes the relationship between *K* and ε values is generally linear,[13] and when the electron donor is sterically hindered the ε values will be reduced.[11] The CT complexes in the present work reveal no regular relationship between *K* and ε values. This behavior is believed to be due to the steric hindrance in the donor molecules, which decreases in the following order:

2>1>3 and **4>5>6**.

The empirical relation derived by Aloisi and Pignataro[14] were used to determine the ionization potentials (IP) of the free donors (**1—7**) and their values are given in Table 1; they are another measure of the relative π-basicities of these electron donors. The high IP values in case of the DDQ-complexes is due to the high electron affinity of DDQ with respect to TCNE.[15]

The infrared spectra of some CT complexes as well as their free components are summarized in Table 2. The data reveals that in case of the CT complexes with

DDQ the C=O at 1670 cm^{-1} splits into two bands, whereas that of the C≡N group is weaken. In case of the TCNE-complexes, the two bands characteristic of the C≡N groups show a red shift. Comparison of the infrared spectra of the CT complexes with those of the free components reveals an apparent shift of the bands of the acceptor to lower wavenumbers. However those of the donor are shifted to higher values indicating a decrease in the electron density in the donor part of the CT complex. This behavior is characteristic of π-π^* transitions.[16]

In conclusion, the spectroscopic studies of this type of donor-acceptor interactions revealed the important role played by both electronic effects of the electron-releasing groups and the transannular electronic interactions of the π-electron clouds of the two aromatic rings with one another in [2.2]paracyclophane relative to the eteric factors.

Experimental

Reagents. The electron donors **1—7** were prepared according to the procedure described in Ref 17. Tetracyanoethylene and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (Janssen Chimica) were used without further purification. Dichloromethane (Merck) was dried over phosphorus pentaoxide and distilled as described in Organicum.[18]

Physical Measurements. Association constants (K) and molar extinction coefficients (ε) of the CT complexes studied have been determined by utilizing the Rose-Drago equation:[19,20]

$$K^{-1} = \frac{C_D C_A(\varepsilon - \varepsilon_A)}{d - d_A} - C_D - C_A + \frac{d - d_A}{\varepsilon - \varepsilon_A},$$

where C_D and C_A are the initial concentrations of donor and acceptor respectively, ε_A is the molar absorbance of the acceptor, d_A is the absorbance at the initial concentration of the acceptor, and d corresponds to the total absorbance at any given wavelength for a cell of 1.0 cm path length.

The visible spectra were scanned on a Beckman UV 5230 recording spectrophotometer in stoppered silica cells (1.0 cm). All scans covered the range from 350 to 800 nm. The infrared spectra were recorded on a Perkin-Elmer 157 G spectometer.

Reduction of Halonitrobenzenes with Disodium Ditelluride in *N,N*-Dimethylformamide

Ralph A. ZINGARO* and Chris HERRERA
Department of Chemistry, Texas A & M University, College Station, Texas 77843, U.S.A.
(Received June 6, 1988)

Synopsis. The reaction of disodium ditelluride in *N,N*-dimethylformamide with *o*-halonitrobenzenes results in displacement of the halide, reduction of the nitro group and a ring closure reaction which yields phenazines.

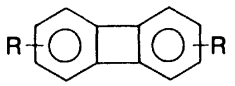
Recently, we reported on the unusual stabilities of bis(benzenetellurenyl) selenides when a carbonyl group is located ortho to the tellurium atom.[1,2] This stability was attributed to a strong Te··· O=C interaction as reflected in a relatively short Te··· O distance (2.658 Å). As an extension of this observation it was decided to synthesize bis(*o*-nitrophenyl) ditelluride and determine its crystal structure. It would be of interest to determine the geometry of the Te-O-C-C-N-O sequence and the Te··· O bond length in order to learn whether the Te··· O interaction represents a more general phenomenon. Because bis(*o*-nitrophenyl) diselenide has been prepared by the reaction between *o*-chloronitrobenzene and sodium diselenide,[3a] the synthesis of the ditelluride by the aromatic nucleophilic displacement reaction of sodium ditelluride on *o*-chloronitrobenzene in *N,N*-dimethylformamide was attempted. However, the only products isolated were phenazine and, in very low yield, bis(dimethylcarbamoyl) ditelluride. The latter compound was first obtained by Suzuki and Inouye[3b] and its crystal structure was determined by us.[4] In this same study, the latter investigators reported that aromatic nitro compounds are reduced to azo compounds by sodium telluride in DMF. These workers investigated the reaction between several substituted nitrobenzenes and sodium ditelluride in DMF. Among these were some *m*- and *p*-chloro derivatives. Both were found to yield the azo compounds without nucleophilic displacement of the halide. It is interesting to note in the work reported herein, that in the reaction between *o*-halonitrobenzenes and sodium ditelluride in DMF there occurs an aromatic nucleophilic displacement of the halide together with deoxygenation of the nitro group and ring closure to the phenazine.

Before proceeding to a presentation and discussion of other experimental observations, we wish to report that nitrobenzene, nitrosobenzene, and azoxybenzene all underwent reaction with Na_2Te_2 in DMF to yield the same product, viz., azobenzene. This confirms the observation of Suzuki et al.[5]

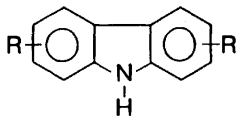
Phenazine was unequivocally identified by its mp, 175 °C, elemental analysis, and ^{13}CNMR spectrum: δ 130.2 ($C_{1,4}$), 129.5 ($C_{2,3}$), and 143.3 (C_{11}). The yields of phenazine were generally of the order of 25—35%. Phenazine was readily identified (GC/MS, comparison with retention time and m./c. of known standard) as the major product formed in the reaction between sodium ditelluride in DMF with *o*-chloro, *o*-bromo, *o*-iodonitrobenzene.

When 4-chloro-3-nitroanisole was used as the substrate the major product was 3,7-dimethoxyphenazine. Similarly, 4-chloro-3-nitro-1-(trifluoromethyl)benzene, as observed from GC/MS data, gave 3,7-bis(trifluoromethyl)phenazine as the major product [(major mass peak at 316)].

Of unusual interest is the evidence for the formation of biphenylenes **1** and carbazoles **2**. The formation of



1
R=-H, -CF_3, -OCH_3



2
R=-H, -CF_3, -OCH_3

biphenylene as one of the products was confirmed in the case of the reaction between *o*-chloronitrobenzene and sodium ditelluride in DMF. The residue remaining after removal of the solids (including phenazine) was subjected to GC/MS. A strong molecular ion at 152 was observed. The experiment was repeated, first using an authentic sample of biphenylene to establish retention time, peak shape, and location, and second with the addition of a small amount of biphenylene to the reaction residue. The retention times and peak shapes and locations were completely superimposable.

Strong molecular ion peaks were observed for the indicated molecular ions **1** and **2** when *o*-bromo-, *o*-iodonitrobenzene, 4-chloro-3-nitroanisole, or 4-chloro-3-nitro-1-(trifluoromethyl)benzene were used as substrates in the reaction with Na_2Te_2. However, the identification of the peaks was not corroborated in these cases by comparison with authentic samples.

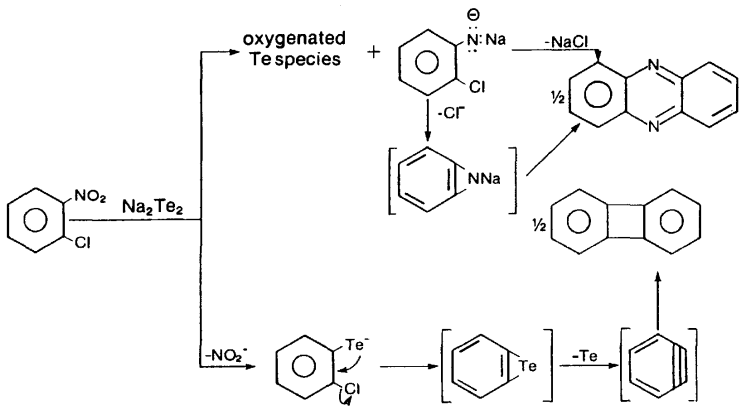
The results of other experiments performed for the purpose of elucidating the nature of the reaction are summarized below.

a. The reaction between 4-chloro-3-nitroaniline and Na_2Te_2 in DMF gave 2,2′-dinitro-4,4′-diaminobiphenyl as the main product. No reduction of the nitro groups was observed.

b. No evidence of formation of phenazine was noted in the reaction between 2-chloroaniline and Na_2Te_2 in DMF.

c. Equimolar quantities of *o*-chloronitrobenzene and 4-chloro-3-nitroanisole were allowed to undergo reaction with Na_2Te_2 in DMF. The major product, as determined from GC/MS studies was methoxyphenazine, but both phenazine and dimethoxyphenazine were also formed. These results are not quantitative because authentic samples of the methoxyphenazines were not used. However, they clearly suggest the occurrence of a bimolecular condensation.

d. Solutions containing Na_2Te_2 and *o*-chloronitro-



Scheme 1.

benzene in DMF were measured, during the course of the reaction, for paramagnetic susceptibility. No evidence of paramagnetism was observed. This, however, does not rule out the possibility for the formation of free radical species since the measurement is not sufficiently sensitive.

e. The grey residue formed from the reaction between Na_2Te_2 and *o*-chloronitrobenzene was separated under oxygen-free conditions and was found to contain 16.5% oxygen (by fast neutron activation analysis). This gives evidence for the deoxygenation of the nitro group, but does not establish the actual chemical form of the oxygen-containing species.

The observed reactions are exceedingly complex. They are difficult to study mechanistically because of the formation and persistence of the tellurium-rich solid phase. While experimental evidence for a detailed mechanism is lacking, product formation does suggest some reasonable possibilities.

The observation of Suzuki and co-workers on the reduction of aromatic nitro compounds to diazo derivatives by Na_2Te in DMF has already been referred to.[5] This group of investigators has also observed the displacement of the nitro group by NaHTe in ethanol.[5,6] In the present study the ditelluride ion is involved in halide displacement and reduction and elimination of the aromatic nitro group ortho to a halogen. The anionic tellurium species presumably function as deoxygenating agents and, as previously indicated,[5,6] are able to displace the nitro groups. An additional example of the displacement of a nitro group by a nucleophile has been reported by Loudon[7] who observed the conversion of 3,4-dinitro-1-chlorobenzene to 3-phenylthio-4-nitro-1-chlorobenzene by treatment with thiophenol.

In the mechanisms proposed in Scheme 1, the formation of diphenylenes is strongly indicative of a benzyne intermediate. One likely possibility, not shown in the scheme, involves the initial nucleophilic displacement of chloride by Te_2^{2-}. Deoxygenation can then be accomplished either by the ring substituted tellurium or by unreacted ditelluride in the reaction medium.

Experimental

Melting points were determined in capillary tubes on a Büchi-SMP 20 melting point apparatus and are uncorrected. Gas chromatographic/mass spectroscopic (GC/MS) measurements were performed on the Hewlett-Packard model 5995C instrument. Nuclear magnetic resonance spectroscopic measurements were performed on the Varian XL-200 instrument. *N,N*-Dimethylformamide (DMF), was stirred with KOH and distilled from BaO (bp 152 °C). Powdered tellurium (99.9% purity) was obtained as a gift from the Selenium-Tellurium, Assn., Inc. Organic reagents were purchased from the Aldrich Chemical Co. and were used as received.

Preparation of Disodium Ditelluride. All reactions were carried out under an atmosphere of nitrogen or argon. Reactions were carried out in the dark or under a red light. The procedure followed was that described by Sandman et al.[8] Powdered tellurium (15.24 g, 0.19 mol) was placed in a three-necked flask (300 ml) containing 100 ml of dried DMF. A thermometer was inserted through one of the necks, another was sealed with a rubber septum, and to the other was attached a reflux condenser. Metallic sodium (2.73 g, 0.119 mol) in 100 ml of DMF was added and the mixture was heated slowly, with continuous magnetic stirring, until it reached a temperature of 110 °C. The reaction can be quite violent at the mp of sodium (ca. 97 °C) and slow, gradual heating is desirable. The mixture was stirred for 1 h at 110 °C and then allowed to cool to 55 °C. The solution is deep purple in color.

Reaction of Aromatic Nitro Compounds with Excess Na_2Te_2. The reactions were carried out using a three-to four-fold excess of Na_2Te_2. A solution of the reagent in 100 ml of DMF was added to the Na_2Te_2 in DMF through the rubber septrum and the mixture was stirred for 23 h at 50 °C. The solution was then filtered under nitrogen and the precipitate was washed with 80 ml of hot DMF. The filtrate was evaporated under reduced pressure. The solid or heavy viscous liquid that remained was then taken up in an appropriate solvent, usually benzene, and allowed to crystallize in the cold. Isolated crystalline solids were recrystallized from appropriate solvents until reproducible mp's were obtained. In those cases where the residual oils were formed, solutions in appropriate solvents, usually benzene, were taken for GC/MS measurements. Details of a specific experiment are given in the next paragraph.

A solution of disodium ditelluride was prepared according to the method previously described from 15.30 g, 0.119 mol of powdered tellurium and 2.78 g, 0.121 mol of sodium in 200 ml of DMF under an atmosphere of nitrogen. The solution was cooled to 60 °C and to it was added with magnetic stirring, through the attached rubber septum, a solution containing 5.15 g, 0.0275 mol of 4-chloro-3-nitroanisole. The temperature jumped to 98 °C upon the addition of the ani-

sole. The mixture was stirred for 20 h at 35 °C. The mixture was filtered, under nitrogen, and the filtrate was evaporated under reduced pressure with heating (external hot water bath) to a viscous dark syrup. This was refluxed with 200 ml dry benzene containing decolorizing charcoal, filtered and again taken to a viscous syrup under reduced pressure. Storage in a refrigerator overnight showed the presence of a crystalline solid. This was recrystallized from ethanol/chloroform in the presence of decolorizing charcoal which was removed by filtration. The final product, green crystals of 3,7-dimethoxyphenazine were obtained in yields of 24, 30, and 37% on three different runs (based on recrystallized material). The recrystallized solid melted at 251—253 °C: A low resolution mass spectral peak corresponding to the molecular ion was observed at 240.17; for $C_{14}H_{12}N_2O_2$. Calcd (Found): C, 69.99 (70.07); H, 5.03 (5.11); N, 11.65% (11.65%); the ^{13}C NMR spectrum showed resonances at δ 55.8 assigned to $-OCH_3$ at δ 160.2 assigned to quaternary ring carbons attached to methoxy groups (C_3 and C_7) and at δ 143.4 and 140.4 (quaternary carbons attached to ring nitrogen atoms). Resonances at δ 129.9 and 125.9 are assigned to ring carbons $C_{2,6}$ and $C_{4,8}$ and at δ 104.9 to ring carbons $C_{1,5}$, but this group of assignments cannot be made unequivocally.

Structural Features and Biological Studies of Dioxomolybdenum(VI) Complexes of Thiosemicarbazones

Neeta KANOONGO, Ranvir SINGH, and Jagdish Prasad TANDON*
Department of Chemistry, University of Rajasthan, Jaipur 302004, India
(Received August 22, 1988)

Synopsis. Synthesis, characterization, and spectral features of six-coordinated dioxomolybdenum(VI) complexes of the type, $[MoO_2(tscz)_2]$ (where Htscz represents the thiosemicarbazone moiety) are reported. These have been characterized by elemental analysis, conductance measurements, molecular weight determinations, and magnetic studies. Based on IR, ^1H NMR, ^{13}C NMR, and electronic spectral studies, an octahedral geometry with *cis*-MoO_2 structure has been proposed. The antibacterial and fungicidal activities of two representative ligands and their dioxomolybdenum complexes have also been evaluated and discussed.

Molybdenum exhibits a large number of stable and accessible oxidation states as well as varying coordination numbers from four to eight.[1] A large number of important chemical reactions catalyzed by molybdenum compounds, e.g. industrial process such as hydrodesulfurization[2] and olefin epoxidation[3] are carried out in presence of molybdenum catalyst. Nature has also incorporated molybdenum into a number of important[4] redox enzymes.

In view of industrial and biological importance of molybdenum complexes,[5,6] it was considered of interest to synthesize some molybdenum(VI) complexes of bidentate Schiff bases and study their structural features as well as biological activity. The ligands used are biologically active thiosemicarbazones and the results of these investigations are being presented in this paper.

Experimental

All the chemicals of analytical grade were used and the solvents were dried by the standard methods. Thiosemicarbazones[7] and $MoO_2(acac)_2$[8] were prepared according to the literature methods and analyzed before use. The ligands derived from 2-furancarbaldehyde, 2-pyridinecarbaldehyde, 2-thiophenecarbaldehyde, 3-indolecarbaldehyde, cinnamaldehyde 2-propanone, 1-phenylethanone and 4-methyl-2-pentanone are abbrevied as $Htscz_1$, $Htscz_2$, $Htscz_3$, $Htscz_4$, $Htscz_5$, $Htscz_6$, $Htscz_7$ and $Htscz_8$, respectively.

Synthesis of $[MoO_2(tscz)_2]$. To a calculated amount (1 mol) of $MoO_2(acac)_2$ in dry MeOH (ca. 40 cm^3) the requisite amount (2 mol) of thiosemicarbazone was added. The resulting mixture was refluxed for 4 h. After the completion of the reaction the solvent was removed and the residue dried in vacuo for 3 h. The analytical data (C, H, N, S, and Mo) of the complexes are within the limit of experimental errors. Molybdenum was determined gravimetrically as bis(8-quinolinalato) dioxomolybdenum(VI). Other methods of analyses and physical measurements are same as reported earlier.[7]

Results and Discussion

The reactions between $MoO_2(acac)_2$ and monobasic bidentate, thiosemicarbazones were carried out in 1 : 2 molar ratio in methanol. The replacement of acetylacetonato group by the ligands resulted in the formation of the products of the type $[MoO_2(acac)_2]$. The resulting derivatives were recrystallized by adding solvent ether to the methanolic solution of the complexes and their purity was further checked by TLC on silica gel G using anhydrous methanol as the solvent. These are soluble in methanol, DMSO, and DMF.

The low values of molar conductance in DMF (10—14 $ohm^{-1}\,cm^2\,mol^{-1}$) show these complexes to be non-electrolytes and the molecular weight determinations by the Rast camphor method correspond to the formula weight indicating their monomeric nature. All the derivatives are diamagnetic as expected for $4d^0$ configuration for Mo(VI) species.

The IR spectra of thiosemicarbazones[7] show a strong band at ca. 3280 cm^{-1} due to ν_{NH} vibrations and which disappears in the metal complexes suggesting its deprotonation on complexation with the metal ion. In the IR spectra of ligands in solution, bands due to ν(C=S) and ν_{NH}, which are observed in the IR spectra in KBr optics do not appear. This may be attributed to the existence of two tautomeric forms, viz, an thioamide form in the solid state and iminothiol form in solution.[9] On complex formation, these bands disappear indicating the coordination of the ligand through the thiolic sulfur. A strong band in the ligands in the region, 1610—1620 cm^{-1} due to the azomethine (>C=N) group shifted to the lower frequency region in the molybdenum complexes.[10]

In the spectra of the complexes, two bands in the regions, 900—920 and 890—900 cm^{-1} can be ascribed to ν_{sym}(O=Mo=O) and ν_{asym}(O=Mo=O) vibrations[11] respectively. The presence of these bands is indicative of *cis*-MoO_2 structure as the *trans*-MoO_2 structure would show only one ν_{asym}(O=Mo=O) band in this region. Further, medium to weak intensity bands in the regions, 450—430 and 370—300 cm^{-1} which do not appear in the ligands, may be attributed to νMo-N and νMo-S, respectively.[12,13]

The electronic spectrum of $Htscz_1$ shows one band of weak intensity at 245 nm and a broad band at 340 nm attributable to π-π^* (double bond) and n-π^* (azomethine) electronic transitions, respectively. In $[MoO_2(tscz_1)_2]$ the first band remains almost unchanged whereas, the second band shows a blue shift due to the donation of nitrogen lone pair of the azomethine group to molybdenum atom. The spectrum of complex also exhibits a strong band at 380—450 nm due to the ligand to metal charge transfer transitions between the lowest empty molybdenum d orbital and the highest occupied ligand molecular orbital as reported earlier.[1]

The proton magnetic resonance spectra of $Htscz_1$

Table 1. ^{1}H NMR Data (δ/ppm) of Ligands and Dioxomolybdenum(VI) Complexes

S. No.	Compound	-NH	Aromatic	Azomethine	$-NH_2$
1	$Htscz_1$[a)]	11.40bs	6.60—7.68m	8.00s	2.40bs
2	$[MoO_2(tscz_1)_2]$[a)]	—	7.35—8.16m	8.20s	2.66bs
3	$Htscz_2$	11.08bs	6.32—6.80m	8.40s	2.55bs
4	$[MoO_2(tscz_2)_2]$	—	7.00—7.72m	8.50s	2.60bs
5	$Htscz_4$	11.78bs	6.00—7.60m	8.32s	2.40bs
6	$[MoO_2(tscz_4)_2]$	—	7.46—8.00m	8.48s	2.80bs

a) ^{13}C NMR data: Ligand; C_1 (179.48), C_2 (150.79), C_3 (134.77), C_4 (114.75), C_5 (146.14), C_6 (199.9).
Complex; C_1 (176.77), C_2 (148.49), C_3 (131.78), C_4 (111.87), C_5 (144.00), C_6 (188.69).

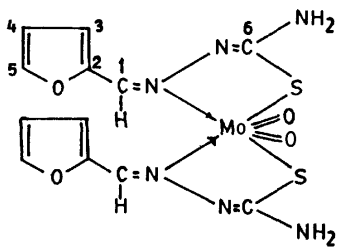
Table 2. Fungicidal Data of Ligands and Their Dioxomolybdenum Complexes

Compound	Average percentage inhibition after 96 h					
	Aspergillus Flaves		Aspergillus niger		Alternaria alternata	
	50 ppm	75 ppm	50 ppm	75 ppm	50 ppm	75 ppm
$Htscz_1$	40	48	32	45	65	70
$[MoO_2(tscz_1)_2]$	52	61	38	50	68	75
$Htscz_3$	44	55	37	47	70	79
$[MoO_2(tscz_3)_2]$	60	67	48	59	77	85

(**1**), $Htscz_2$ (**3**), $Htscz_4$ (**5**), and their corresponding dioxomolybdenum complexes **2**, **4**, and **6** respectively have been recorded in DMSO-d_6 using TMS as the internal standard. The chemical shifts value (δ/ppm) of the different protons have been recorded in Table 1. The broad signals due to NH protons at δ 11.40 (**1**), δ 11.08 (**3**), and δ 11.78 (**5**) in the ligands disappear in the case of molybdenum complexes showing ligation of molybdenum to nitrogen as well as sulfur atoms. The azomethine proton signals (-C(H)=N) appearing at δ 8.00 (**1**), δ 8.40 (**3**), and δ 8.32 (**5**) in the ligands undergo deshielding and appear at δ 8.20 (**2**), δ 8.50 (**4**), and δ 8.48 respectively in the molybdenum complexes indicating the coordination of the azomethine nitrogen to the molybdenum atom. The positions and assignment of other protons are recorded in Table 1.

^{13}C NMR spectra of $Htscz_1$ and its molybdenum complex have also been recorded in Table 1 (foot note). The shifts of the carbons attached to the donor S and N atoms further substantiate the bonding pattern discussed earlier.

Thus on the basis of above evidences the following cis-octahedral structure can be proposed for the molybdenum(VI) complexes with $Htscz_1$ as the ligand:



The antibacterial activity of $Htscz_1$ and $Htscz_3$ and their dioxomolybdenum complexes has been evaluated in vitro against *E. Coli, S. aureus, Eutrobactor aerogenus, Citrobactor, P. Pyocyancus,* and *S. Citrus* at 1000 ppm concentration using the inhibition zone technique.[14] A 5 mm diameter sterilized filter paper disc impregnated with the compound was placed on agar plate seeded with the test organism. The plates were incubated for 24 h at 37 °C. The zone of inhibition of bacterial growth around the disc was observed. The screening data show moderate activity against *E. Coli, S. aureus, Eutrobactor aerogenus,* while all the compounds are highly active against *P. Pyocyancus* and *S. citrus.* The above ligands and complexes were also screened for their fungicidal activity by determining the percentage inhibition of colonial growth in comparison to the growth in control. From the data recorded in Table 2, it is evident that the compounds are capable of inhibiting the fungal growth to a considerable extent both at high and low dilutions.

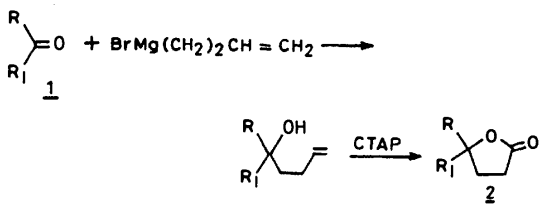
A Simple Iterative Approach to the Synthesis of *cis-cisoid-cis*-Tricyclo[6.3.0.0^{2,6}]undecane Carbon Skeleton

Padma S. VANKAR and Srinivasan CHANDRASEKARAN*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received September 5, 1988)

Synopsis. In an iterative synthesis utilizing only four reagents, cyclopentanone has been converted into *cis-cisoid-cis*-tricyclo[6.3.0.0^{2,6}]undecane carbon skeleton in high yield.

There is much current interest in the synthesis of linearly fused tricyclopentanoids (triquinanes) which is mainly due to their wide occurance in nature with promising biological properties and their likely role as building blocks for the synthesis of the $C_{20}H_{20}$ regular (pentagonal) polycycle, dodecahedrane.[1] As a result, several novel approaches to this ring system have been developed in recent years.[2] In the course of our studies on oxidative transformations with hexadecyltrimethylammonium permanganate (CTAP)[3] we developed a general two step methodology for the synthesis of γ-lactones **2** from ketones **1** (Scheme 1) in very good yield.[4]

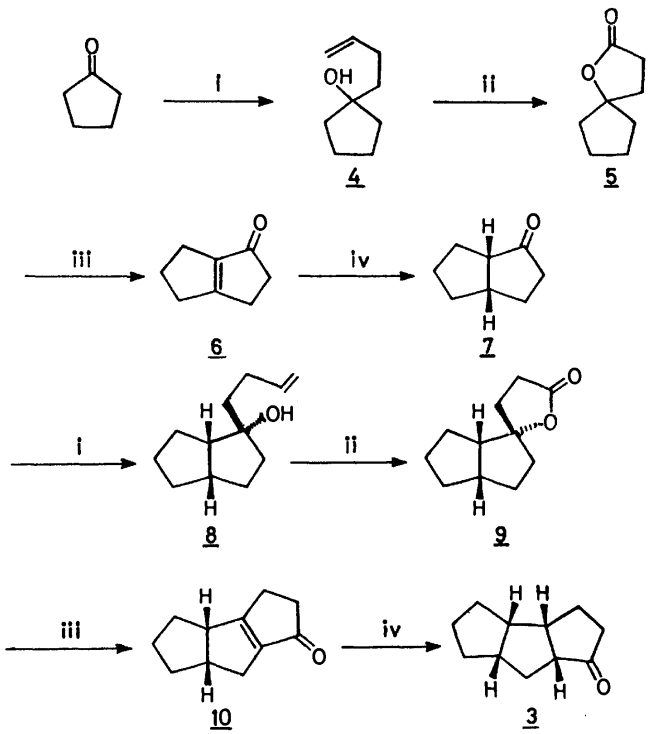


Scheme 1.

Herein, we report an efficient application of this oxidative cyclization strategy in an iterative approach to set up the *cis-cisoid-cis*-tricyclo[6.3.0.0^{2,6}]undecane carbon skeleton. It is anticipated that easy accessibility to **3** and its derivatives would open new possibilities for further synthetic exploitation.

Reaction of cyclopentanone with Grignard reagent derived from 4-bromo-1-butene[5] gave the alcohol **4**[6] (62%) which was then subjected to oxidative cyclization with hexadecyltrimethylammonium permanganate (CTAP) to yield the spirolactone **5**[4] (71%). Treatment of the lactone **5** with phosphorus pentaoxide in methanesulfonic acid[8] for 2 h at 50 °C led to the bicyclic enone **6**[8] (98%). Hydrogenation of **6** in ethyl acetate containing palladium on carbon produced the saturated cis-bicyclic ketone **7**[9] (99%).

To continue the synthesis the bicyclic ketone **7** was subjected to the same sequence of reactions. Thus, reaction with the Grignard reagent produced the adduct **8** (64%). Oxidative cyclization with CTAP afforded the spirolactone **9** (60%). On action of phosphorus pentaoxide in methanesulfonic acid the lactone **9** yielded the tricyclic enone **10** (92%). Catalytic hydrogenation of **10** with palladium on carbon resulted in the cis addition of hydrogen to the less hindered face of the olefin[10] to give the product **3** (95%) (Scheme 2).



Scheme 2. Reagents:
i, $BrMgCH_2CH_2CH{=}CH_2$; ii, CTAP, CH_2Cl_2; iii, P_2O_5-$MeSO_3H$; iv, Pd/C, H_2

Experimental

The NMR spectra were taken on a Varian EM-390 spectrometer and Brucker WP-80 spectrometer. IR spectra were measured using a Perkin Elmer 1320 spectrometer and mass spectra were obtained from a VG micromass 7070F mass spectrometer.

Oxidative Cyclization of 4 with CTAP. To a solution of **4**[6] (1.4 g, 10 mmol) in chloroform (30 ml) was added a solution of CTAP (8.08 g, 20 mmol) in chloroform (25 ml) at room temperature (28 °C) and the mixture was stirred for 6 h. Solvent was evaporated under reduced pressure and ether (200 ml) was added to the residue which was filtered through a pad of Celite. The filter cake was washed thoroughly with ether and the combined filtrate was evaporated. The residue was purfied by flash chromatography on silica gel (elution with 4:1 ether-petroleum ether) to get the spirolactone **5**[4] (0.980 g, 71%) as a colorless oil. IR(CCl_4) 1780 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.5—2.35 (m, 10H) and 2.4—2.7 (m, 2H); MS *m/z* 140 (M^+).

Reaction of 5 with Methanesulfonic Acid-Phosphorous Pentaoxide. A solution of **5** (0.700 g, 5 mmol) in freshly distilled methanesulfonic acid (50 g) containing phsophorus pentaoxide (5 g) was stirred under nitrogen at 50 °C for 2 h. The mixture was cooled in an ice bath and water (150 ml) was carefully added. It was then extracted with ether (3×100

ml). The combined ether extract was washed with 10% potassium carbonate solution and water and then dried over anhydrous magnesium sulfate. After evaporation of solvent the product was purified by flash chromatography on silica gel (elution with 1:10 ether-petroleum ether) to afford **6**[8] (0.600 g, 98%) as a colorless oil. IR(CCl_4) 1645, 1710 cm^{-1}; ^1H NMR($CDCl_3$) δ=1.8—2.0 (m, 2H) and 2.3—2.7 (m, 8H): MS *m/z* 122 (M^+).

Catalytic Hydrogenation of 6. To a solution of **6** (0.610 g, 5 mmol) in ethyl acetate (20 ml) was added 5% palladium on charcoal (0.100 g) and treated with hydrogen at 40 psi for 1 h. The catalyst was filtered and the solvent was evaporated to yield the bicyclic ketone **7**[9] (0.605 g, 99%) as an oil. IR(CCl_4) 1735 cm^{-1}; ^1H NMR($CDCl_3$) δ=1.4—2.0 (m, 9H), 2.2—2.4 (m, 2H), and 2.5—2.7 (m, 1H); MS *m/z* 124 (M^+).

Grignard Reaction of 7 with 4-Bromo-1-butene. Grignard reagent derived from 4-bromo-1-butene[5] (1.35 g, 10 mmol) and magnesium powder (0.288 g, 12 mmol) in dry THF (25 ml) was treated with **7** (1.240 g, 10 mmol) in dry THF (10 ml) at 0 °C for 1 h. The product was purified by flash chromatography on silica gel (elution with 1:2 ether-petroleum ether) to yield the alcohol **8** (1.152 g, 64%) as a coloress oil. IR(CCl_4) 3480, 3080, 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.0 (m, 15H), 2.1—2.3 (m, 2H), 4.8—5.1 (m, 2H), and 5.5—5.9 (m, 1H); MS *m/z* 180 (M^+). Found: *m/z* 180.1510. Calcd for $C_{12}H_{20}O$: M, 180.1515.

Oxidative Cyclization of 8 with CTAP. To a solution of **8** (0.360 g, 2 mmol) in dichloromethane (8 ml) was added CTAP (1.62 g, 4 mmol) in dichloromethane (10 ml) and the mixture was stirred at room temperature for 4 h. The product after purification by flash chromatography on silica gel (elution with 1:2 ether-petroleum ether) yielded the spiro lactone **9** (0.216 g, 60%) as an oil. IR(neat) 1770 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.3—1.8 (m, 14H) and 2.2—2.5 (t, 2H); MS *m/z* 180 (M^+).

Reaction of 9 with Methanesulfonic Acid-Phosphorus Pentaoxide. A solution of **9** (0.360 g, 2 mmol) in freshly distilled methanesulfonic acid (30 g) was added to phsophorus pentaoxide (3 g) and the mixture was heated under nitrogen at 50 °C for 2 h. The product was worked up as described in the synthesis of **6**. The tricyclic enone **10** (0.300 g, 92%) was isolated as an oil after chromatographic purification. IR(neat) 1700, 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.3—1.8 (m, 7H) and 2.1—2.6 (m, 7H); MS *m/z* 162 (M^+). Found: *m/z* 162.1041. Calcd for $C_{11}H_{14}O$: M, 162.1045.

Catalytic Hydrogenation of 10. A solution of **10** (0.162 g, 1 mmol) in ethyl acetate (5 ml) was added to 5% Pd-C and treated with hydrogen at 40 psi for 2 h. The ctalyst was filtered and the solvent was removed to give the tricyclic ketone **3** (0.155 g, 95%) as an oil homogeneous to TLC. IR(neat) 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.0 (m, 13H) and 2.2—2.6 (m, 3H); MS *m/z* 164 (M^+). Found: *m/z* 164.1198. Calcd for $C_{11}H_{16}$: M, 164.1201.

(Received October 6, 1988)

Synopsis. A series of C3 cyclotriveratrylenes and D3 cryptophanes have been resolved by HPLC on Chiralpak-OT (+), allowing the first direct enantiomeric excess assessments for these substances. These results confirm the usefulness of this chiral stationary phase for the resolution of aromatic compounds and extend its scope of application to new classes of highly symmetrical molecules.

Since the first reports on the synthesis of optically active C3 cyclotriveratrylenes (CTV's **1**)[1] in 1978 and D3 cryptophanes (**2**)[2] in 1981, a number of molecules of this kind have been described and have found applications in several fields,[3] including spectroscopy (exciton optical activity),[4-6] liquid crystals,[7] and host-guest chemistry.[8-10] Although a cryptophane was used as a *chiral host shift reagent* for the determination of the enantiomeric composition of a weakly rotating sample of CHFClBr,[11] paradoxically, simple means of establishing the enantiomeric excess (ee) of the resolved CTV's and cryptophanes themselves did not exist so far.

We report herein that the commercially available chiral stationary phase (CSP) Chiralpak-OT(+) is effective for analytical optical resolution of certain C3 CTV's and D3 cryptophanes by HPLC. This CSP can also be used for the structural assignment of D3 (**2**, *dl*) vs. C3h (**3**, *meso*) cryptophane isomers.

Results and Discussion

The use of poly(triphenylmethyl methacrylate), an optically active polymer with a stable helical conformation, was introduced in 1979 by Okamoto et al.[12] This polymer either finely ground or coated on silica gel has since been used for analytical resolution of a wide range of racemates under reversed phase conditions, using a polar eluent such as methanol.[13] Such CSP's and especially Chirapak-OT(+) have proven particularly efficient with regard to two main categories of substances.

Table 1. Optical Resolution of C3 Cyclotriveratrylenes **1a—f**[a]

Compd.	First eluted isomer			k'_2[b]	α	T	estd.
	R_1	R_2	confg.			°C	R_s[c]
1a	H	OCH_3	M(+)	25.5	2.29	15	>3
				26.9	2.35	5	
1b	OC_2H_5	OCH_3	P(−)	13.9	1.41	15	≈1
				14.4	1.48	5	
1c	(*O*-allyl	OCH_3)[d]		16.6	1.37	15	≈1.25
				17.2	1.43	5	
1d	$OC_3H_7^i$	OCH_3	P(+)	14.8	1.43	15	≈1.1
				15.4	1.50	5	
1e	$OCOCH_3$	OCH_3	P(+)	12.5	1.38	15	≈1.15
				12.9	1.43	5	
1f	Br	OCH_3	P(−)	16.3	1.48	15	≈1.3
				16.2	1.50	5	

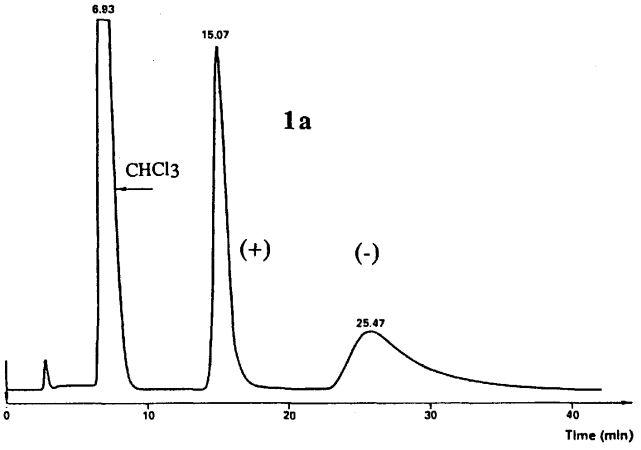
a) Column: Chiralpak-OT(+), 250×4.6 mm i.d.; methanol, 0.5 ml min^{-1}; all solutes were injected in chloroform solution; detection was effected by recording the UV absorption at 230 nm. b) Capacity factor of the slowest eluted enanitiomer; $k'_2=(t_2/t_0)-1$, where t_2 is the retention time of the slowest enantiomer and t_0 that of a nonretained solute. c) The resolution factor R_s is estimated from the depth of valley between the peaks;[14] base line separation corresponds to $R_s>1.3$. d) The enantiomers of this compounds are hitherto unknown.

The first one gathers weakly polar compounds such as oxiranes, halogenated hydrocarbons, some phosphorus insecticides, metal complexes ($M(acac)_3$), as well as more polar compounds such as alcohols and esters. The second category encompasses a variety of molecules (mostly aromatic) that belong to the C2 symmetry point group, such as binaphthol and related atropisomers, spiro (bis) indanones, etc.[13]

In our hands, Chiralpak-OT(+) proved suitable for the resolution of the C3 CTV's **1a—f**. Cyclotriveratrylenes **1b—f**, bearing two different substituents of comparable size on each benzene ring, showed separation factors α ca. 1.4—1.5 (Table 1); **1a** which bears a single substituents on each ring (OCH_3), and hence is "more chiral," was even better separated ($\alpha \approx 2.3$). A slight selectivity increase was obtained by lowering the temperature to 5 °C, as is generally observed. The resolution factor R_s was low (1 to 1.3) for **1b—f**, and good for **1a** (>3). Baseline separations were obtained for **1a** and **1f**, and were almost obtained for the other compounds (see Fig. 1).

Optically active samples of **1a, b, d—f**, which in earlier works[4] had been considered, on the basis of indirect arguments, to have>90% ee, were analyzed by this method. In all cases none or trace amounts of the others enantiomer was detected, thus confirming that the reported maximum rotation data are correct.[4] These experiments also allowed us to establish the order of elution of the two enantiomers in all cases but **1c** (not available in optically active form). For the "disubstituted" series **1b, d—f**, the P isomer, in which R_1 is bulkier than R_2 (see the stereoformula) was eluted first; the "monosubstituted compound **1a** (R_1=H) showed an inverse behavior. Further comments or interpretation of these results would be premature, as the helicity of C3 CTV's is not easy to define and to compare with that of the C2 binaphthyles and analogous compounds discussed by Okamoto.[13]

D3 Cryptophanes **2a—d** were also resolved on this CSP with good selectivities (Table 2). As expected, the achiral C3h isomers **3b—d** each showed a single peak, and this method can therefore be useful to distinguish between *racemic* and *meso* cryptophanes. The elution orders were determined by using the previously described optically active samples of **2a,b,d**.[6] The helicity



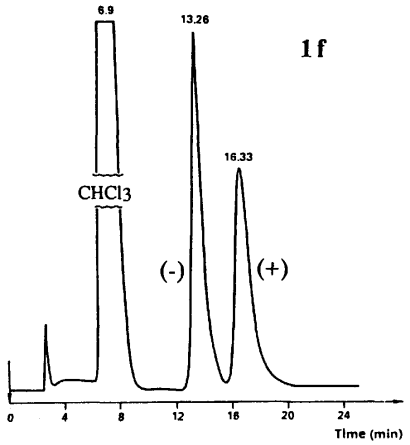


Fig. 1. Chromatographic resolution of (±)-**1a** and (±)-**1f** at 15 °C (conditions indicated in Table 1).

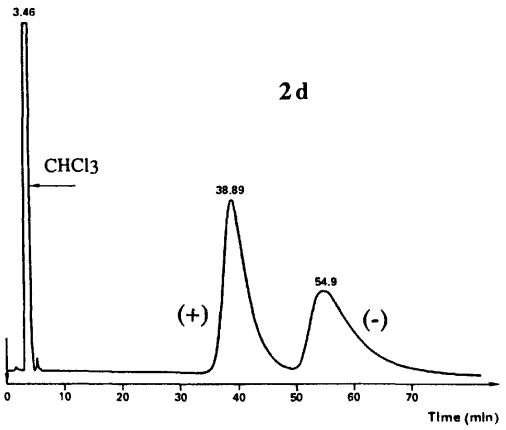

Fig. 2. Chromatographic resolution of(±)-**2d** (conditions indicated in Table 2).

a) Same conditions as indicated in Table 1 except flow rate: 1.0 ml min^{-1}; temperature 15 °C.
b) Enantiomers not available.

of the more retained (−) isomers is that of a right-handed screw, when the molecule is viewed along its C3 axis. Typical chromatograms are shown in Fig. 2.

These results raise interesting questions on the mechanisms of the chiral discrimination between a helical polymer and molecules of high symmetry,[15] and suggest that preparative optical resolution of these substances could be carried out on suitable chiral stationary phases.

Electrochemical Studies of Poly(mercaptohydroquinone) and Poly(mercapto-*p*-benzoquinone) Films Prepared by Electropolymerization. III. Basic Behavior and Properties in Aqueous Solutions

Gorou ARAI,* Shigehiko SHIMAMURA, Yasunobu OHTOMO, and Iwao YASUMORI
Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Kanagawa-ku, Yokohama 221
(Received August 4, 1988)

Electrochemical behavior and properties of poly(mercaptohydroquinone)/poly(mercapto-*p*-benzoquinone) (SQ) films prepared on glassy carbon electrodes (GCE) by anodic polymerization of mercaptohydroquinone were examined in detail by cyclic voltammetry. Almost all hydroquinone and/or *p*-benzoquinone moieties in SQ films of less than ca. 100 monolayers are electroactive in acidic and neutral buffer solutions. The formal redox potential (as estimated from anodic and cathodic peak potentials) vs. solution pH plot, the slope of which is −60 mV/pH, suggests that the overall electrode reaction of SQ films is an H^+/e (1:1) reaction. As to the voltammetric behavior of SQ films, the peak current decreased and the peak potential separaxtion (ΔE_p) increased appreciably in unbuffered solutions as compared with those in buffered solutions. The difference of these voltammetric behaviors in unbuffered and buffered solutions increased with increasing pH. Moreover, the peak current increased and ΔE_p decreased with rising solution temperature. These noticeable behaviors observed on SQ films are discussed in connection with the charge-transport mechanism within SQ films. SQ films on GCE showed good durability over a wide potential range from the hydrogen evolution potential to +1.0 V vs. SCE.

Much attention has recently been drawn to the preparation and properties of thin films of polymeric materials covalently bonded to or coated on glassy carbon electrodes (GCE). Especially electroconductive polymers having hydroquinone/quinone moieties are of particular interest as electrocatalysts because they can act as selective chemical oxidants[1,2] and reductants.[3] However, for all electroactive polymers on GCEs having quinone and/or hydroquinone functionalities so far reported, as far as we know, only a few monolayers are electroactive unless small mediator molecules are present that can penetrate the polymer matrix and carr electrons between redox sites.[4]

In a series of our recent papers,[5-8] we have reported of (i) a preparation method of poly(mercaptohydroquinone/mercapto-*p*-benzoquinone)(SQ) films on GCE and on Pt electrode, (ii) applications of SQ film-coated electrodes to various metal sensors and an electrochromic display, and (iii) the electrocatalytic oxidation of NADH to NAD^+. In the present paper, we will report on basic electrochemical behavior and properties of SQ films on a GCE with particular reference to the following points: (i) the redox response behavior of SQ films of ca. 4 to ca. 100 monolayers in thickness, (ii) the influence of solution pH and solution temperature on the charge-transport process within SQ films, and (iii) the applied potential range in which stable voltammetric response is obtained for SQ films on a GCE.

Experimental

Materials and Preparation of SQ Films. Mercaptohydroquinone was synthesized and purified according to the method described in our previous paper.[5] The chemicals used for the synthesis of mercaptohydroquinone were of reagent grade. The other inorganic reagents and ethanol used for rinsing SQ films were of reagent grade and used without further purification. Deionized water was used for the preparation of solutions, final washing of electrode surface, and rinsing SQ films. The substrate electrode used was a GCE 3 mm in diameter. SQ films on the GCE were prepared by anodic polymerization of mercaptohydroquinone at a constant potential of +0.5 V vs. a saturated calomel electrode (SCE) in a Britton-Robinson buffer solution (pH 5.0) containing 20 vol% ethanol, as previously described.[5] The surface concentration (Γ^x, where the superscript x stands for x nmol cm^{-2}) of the electroactive sites, i.e., the hydroquinone and/or *p*-benzoquinone moieties, in SQ films was controlled by the amount of charges passed during the electrochemical polymerization and estimated by measuring the area of cyclic voltammograms for the oxidation-reduction reaction of SQ films themselves, obtained at a scan rate of 2 mV s^{-1} in the Britton-Robinson buffer solution.

Apparatus and Procedure. The apparatus used for the preparation of SQ films on the GCE was the same as that used in our previous work.[5] Voltammetric measurements were carried out with a standard three-electrode system consisting of an SQ film-coated GCE working electrode, a Pt plate counter electrode, and an SCE reference electrode having an agar salt bridge of saturated KCl. Cyclic voltammetry was performed by using a potentiostat/galvanostat (Model HA-304, Hokuto Denko Co.). Purified nitrogen gas was bubbled for 30 min to remove dissolved oxygen. Unless otherwise noted, all measurements were run under nitrogen atmosphere at room temperature. All potential values cited in this paper are those referred to the SCE.

Results and Discussion

Cyclic Voltammetric Behavior. Figure 1 shows a typical cyclic voltammogram representing the electrochemical response of an SQ film-coated GCE in the Britton-Robinson buffer solution (pH 6.5) at a scan

rate of 50 mV s^{-1}. The SQ film examined has $\Gamma^{10.2}$ corresponding to ca. 17 monolayers based on a close-packed monolayer of ca. 0.6 nmol cm^{-2} for 4-methyl-1,2-benzenediol lying flat on a perfectly flat carbon surface.[2] The voltammetric response remained qualitatively unchanged even after a potential scan cycling of several hours in acidic and neutral buffered aqueous solutions and is similar to that obtained for the ordinary electrode reaction of a solution-phase redox species at an uncoated electrode, that is, the voltammogram has diffusional tails and its shape is unsymmetric as shown in Fig. 1. Cyclic voltammetric behavior at various scan rates in a Britton-Robinson buffer solution of pH 6.0 was examined for SQ film-coated GCEs loaded with three different amounts of Γs, viz., $\Gamma^{2.17}$(=ca. 3.6 monolayers), $\Gamma^{10.2}$, and $\Gamma^{56.0}$(=ca. 93.3 monolayers). The results are summarized in Table 1. For all the three SQ films examined, linear relationships exist between the anodic and cathodic peak currents (i_p^a and i_p^c) and the square root of scan rate ($\sqrt{v}$) on the time scale of 100 mV s^{-1}. At scan rates lower than 50 mV s^{-1}, the anodic and cathodic peak currents are proportional to the Γ values, and the peak separation (ΔE_p) is almost constant irrespective of the film thickness. Thus the amount of the charges consumed in the oxidation-reduction reaction of SQ films are almost proportional to the Γ value. On the other hand, at scan rates higher than 50 mV s^{-1}, the anodic and cathodic peaks were observed to be broader and ΔE_p was increased with increasing scan rate and/or Γ value. These results show that almost all hydroquinone and/or *p*-benzoquinone moieties in SQ films are electroactive even at the scan rate of 50 mV s^{-1} although the charge transport in SQ film was rather slow, and suggest that the electron transfer between the substrate electrode (GCE) and the innermost sublayer of SQ film may be faster than the charge transport within SQ film which may be controlled by electron hopping and/or proton transfer between adjacent electroactive sites, ion migration, polymer motions, or combinations of these actions. From the fact that the SQ film of ca. 100 monolayers may be electroactive on the time scale of 50 mV s^{-1}, SQ film-coated GCEs are superior to other poly(hydroquinone) film-coated electrodes[1-3] in respect of the charge transport within polymer layers.

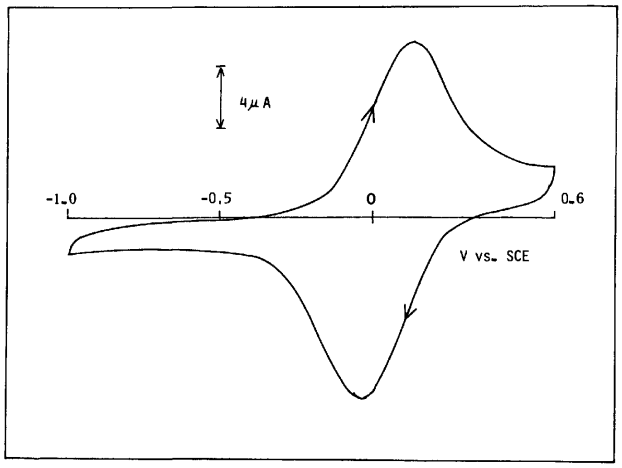

Fig. 1. A typical cyclic voltammogram of SQ film-coated GCE in a Britton-Robinson buffer solution (pH 6.5) at a scan rate of 50 mV s^{-1}. The surface concentration of hydroquinone and/or quinone moieties in SQ film was 10.2 nmol cm^{-2} ($\Gamma^{10.2}$). The arrow indicates the direction of potential scan.

Response in Buffered and/or Unbuffered Solutions. In order to clarify the charge-transport process within SQ film, the pH dependence of cyclic voltammograms of SQ film-coated GCEs was examined over the pH region 2—8 using Britton-Robinson buffer solution. The anodic and cathodic peak potentials (E_p^a and E_p^c) shifted to the negative potential side with increasing pH. E_p^a, E_p^c, and the formal redox potential ($E^{0'}$) which is estimated as the average of E_p^a and E_p^c values, are shown in Fig. 2. Over the pH region 2—8, the slope of the $E^{0'}$ vs. pH plot is about −60 mV/pH. This result suggests that the overall electrode reaction of SQ film is the H^+/e (1:1) reaction in the examined pH region on the time scale examined. On the basis of the fact that SQ film is a hydroquinone/*p*-benzoquinone redox polymer and that the slope of the $E^{0'}$ vs. pH plot is ca. −60 mV/pH in the pH range below 8, and with the assumption that the negative logarithm of the first dissociation constant (pK_1) of the hydroquinone moiety in SQ film is from 9 to 10 based on the pK_1

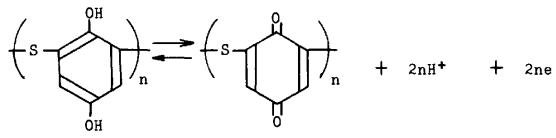
value of hydroquinone (pK_1=9.9), the overall reduction-oxidation reaction of SQ film in aqueous solutions of pH 2 to 8 may be written as



The other pH effects in the buffered solutions on the cyclic voltammograms for SQ film-coated GCEs are summarized in Table 2. The anodic and cathodic peak currents decreased slightly and ΔE_p decreased with increasing pH below 4, while in the pH region higher than 5, both the peak currents increased and ΔE_p decreased with increasing pH. At pH higher than 8, the cyclic voltammograms for SQ films were largely distorted in shape and the integrated current was decreased with increasing pH as shown in Fig. 3, where cyclic voltammograms are illustrated just after 10 cycles since the distortion in shape became more complicated as the potential scan was cycled. Even though the SQ film-coated electrode was transferred to acidic or neutral solution after successive potential sweepings in alkaline solution, the observed distortion remained unchanged. These results show that the distortion in wave shape resulted from some chemical or structural change of SQ film itself because in alkaline aqueous solution *p*-benzoquinone is susceptible to addition of OH^- ion.[9] Turning to the pH dependence of cyclic voltammograms, very similar behavior is seen to an anthraquinone polymer film reported by Degrand[10] with respect to the pH dependence of i_p^a, i_p^c, and i_p^a/i_p^c. To date, a similar pH dependence of redox behavior has also been reported with other types of conductive polymers.[11-13] In order to further detail the pH dependence of the charge transport within SQ films, the cyclic voltammetric

a) All the SQ films examined were prepared on GCEs by a constant-potential electrolysis for 30 min at the same conditions as described in Experimental section.

behavior of SQ film-coated GCEs was examined in unbuffered aqueous solutions since the pH change within SQ films resulting from the oxidation-reduction reaction of SQ films in unbuffered solutions may be more rapid and larger than in buffered solutions. It is, therefore, expected that the charge transport within SQ films will be affected remarkably by this rapid and large pH change. Figure 4 shows cyclic voltammograms for an SQ film-coated GCE having $\Gamma^{13.1}$ (ca. 22.0 monolayers) in unbuffered solutions of various pH values. The wave shapes in the unbuffered solutions differed considerably from those in the buffered solutions. The difference in the wave shapes increased with increasing pH, that is, in the unbuffered solutions the peak current dramatically decreased and ΔE_p remarkably increased with increasing pH, whereas in the buffered solution of pH 5.0 the peak current slightly decreased and ΔE_p slightly increased (see Fig. 2) and at pH 7 two anodic and two cathodic peaks were obscurely observed on the examined time scale. Such voltammetric behavior observed in the unbuffered solutions may be explained as follows: Consider the electro-oxidation process of SQ film (reduced form). The electro-oxidation of one hydroquinone moiety gives one *p*-benzoquinone moiety and two protons over the pH range examined. The numbers of the hydroquinone moieties in the SQ film used were almost equal because the same electrode ($\Gamma^{13.1}$) was used in the examined three cases. The increments of the protons resulting from the electro-oxidation of all the hydroquinone moieties in the SQ film may, therefore, be equal in the three cases. Hence the pH change in the SQ film induced by the electro-oxidation of the film may increase in the order of pH 7>pH 5>pH 3. The pH change in the SQ film results in variation of the redox potential of hydroquinone/*p*-benzoquinone couple in the film. It is clear on the basis of the Nernst equation that the redox potential of hydroquinone/*p*-benzoquinone moieties in SQ films become more negative with increasing pH and more positive with decreasing pH in SQ films. In the case of the oxidation process of SQ films, the decrease in pH within inner layers of SQ films (in the immediate neighborhood of the GCE) may retard the further oxidation of hydroquinone moieties in their outer layers. On the other hand, in the case of the reduction process of SQ films the increase in pH within inner layers may also retard the further reduction of *p*-benzoquinone moieties in outer layers. Judging from their pH dependence described above and their reduction-oxidation behavior in unbuffered solutions, it may safely be said that the propagation of the redox reaction between adjacent hydroquinone/*p*-benzoquinone moieties participates predominantly in the charge-transport process within SQ films on the time scale examined.

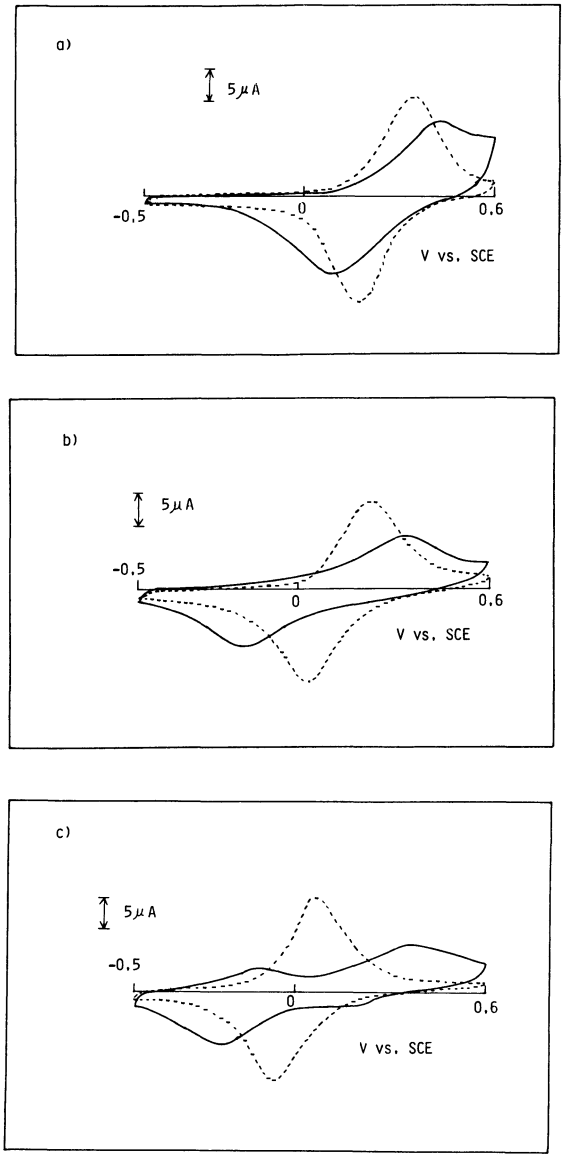

Fig. 4. Comparison between the cyclic voltammograms of SQ film-coated GCE of $\Gamma^{13.1}$ in buffer solutions and those in no buffer solutions. Full lines were obtained in 0.1 mol cm^{-3} KCl solution adjusted to each pH value by addition of an appropriate quantity of dilute HCl or NaOH while broken lines were obtained in Britton-Robinson buffer solutions. Scan rate: 50 mV s^{-1}. a) pH 3.0, b) pH 5.0, c) pH 7.0.

Influence of Temperature. Cyclic voltammetric measurements on the SQ film-coated GCE having $\Gamma^{13.0}$ were carried out over the solution temperatures from 1 to 50 °C. The peak currents increased and ΔE_p decreased with rising temperature, as shown in Fig. 5. The temperature dependence observed is completely reproducible and suggests that the rate of the charge transport through SQ films may be facilitated by rising the temperature. It seems to be a reason for the temperature dependence of the charge transport within SQ films that the rise in temperature makes the segmental polymeric chains in SQ films more mobile

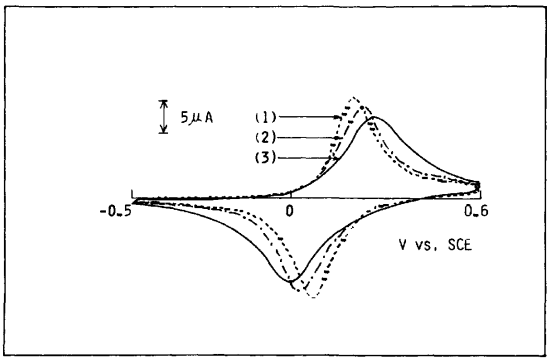

Fig. 5. Temperature-dependence of the cyclic voltammogram of SQ film-coated GCE of $\Gamma^{13.0}$ in the Britton-Robinson buffer solution (pH 5.0). Scan rate: 50 mV s^{-1}. (1) 50 °C, (2)20 °C, (3) 1 °C.

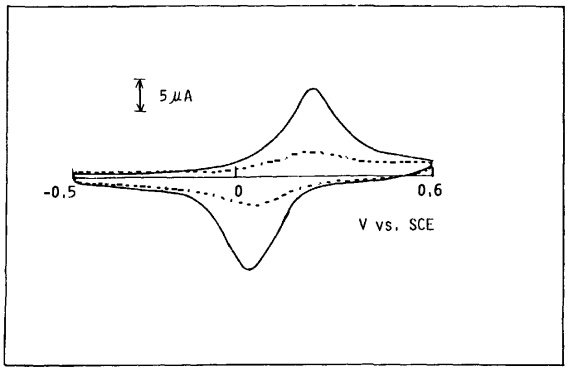

Fig. 7. Change in the cyclic voltammogram of SQ film-coated GCE of $\Gamma^{12.6}$ before and after holding the electrode potential at +1.2 V. Scan rate: 50 mV s^{-1}. ——: 0 min, ---------: 30 min.

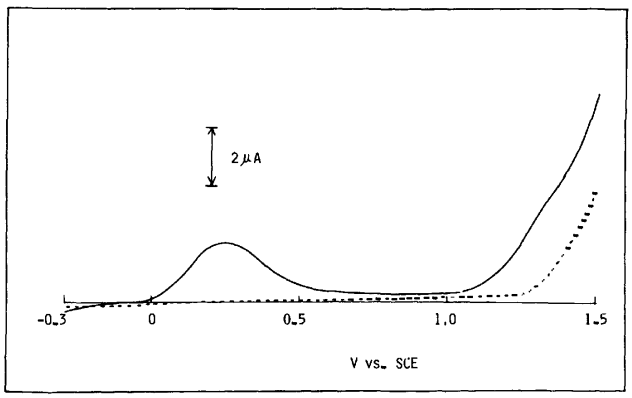

Fig. 6. Current-potential curves of an SQ film-coated GCE and of an uncoated GCE in the Britton-Robinson buffer solution of pH 5.0. Full line was obtained with the SQ film-coated GCE and broken line was obtained with the uncoated GCE. Scan rate: 5 mV s^{-1}.

and that thereby the counter electroactive sites, hydroquinone, and *p*-benzoquinone may be brought more closely together. In addition, the rate of the redox reaction, or the proton migration and electron hopping, between adjacent electroactive sites will also be increased with rising temperature. Thus these two effects are considered to be responsible for the temperature dependence of the charge-transfer rate within SQ films. A similar phenomenon has been reported with a polymerized vinylferrocene.[14]

Stability to Applied Potential. The stability of SQ films on GCE to applied potential was examined over a wide potential range using a weakly acidic Britton-Robinson buffer solution in which SQ films were very stable as described above. Figure 6 shows anodic voltammograms for an SQ film-coated GCE and an uncoated GCE in the Britton-Robinson buffer solution of pH 5.0. The anodic wave in the potential range of +0.2 to +0.4 V observed on the SQ-coated GCE corresponds to the oxidation reaction of hydroquinone moieties to *p*-benzoquinone ones in the SQ film. At more positive potentials than +1.1 V, appreciable increase in anodic current is observed for the SQ-coated GCE, as compared with the uncoated GCE. This increase in anodic current may probably be caused either by some further oxidation of the oxidized SQ film itself or by an unexpected oxidation of some species in the buffer solution. In order to study this increase in anodic current in more ditail, anodic response for the SQ film was examined after the potential of the SQ-coated GCE had been held for 30 min in the Britton-Robinson buffer solution of pH 5.0 at +1.2 V where the increase in anodic current of the SQ film was observed. As shown in Fig. 7, peak currents significantly decreased while peak potentials remained almost unchanged. A similar decrease in peak current was observed in a potential scanning at 50 mV s^{-1} from −0.5 to +1.2 V in the same buffer solution. The cyclic voltammetric wave caused by the reduction-oxidation reaction of the SQ film got smaller as the potential cycling was repeated and almost disappeared after ca. 100 cycles. These results strongly suggest that the increase in anodic current of the SQ film-coated GCE above +1.1 V may result from some further oxidation of the oxidized SQ film itself, followed by an electrochemical inactivation of the film. At present, the mechanism of the further oxidation reaction is obscure. On the other hand, SQ films on GCE were observed to be very stable for the negative shift up to the potential of hydrogen evolution which depends on the solution pH. Judging from the fact that SQ films, even though of ca. 100 layers in thickness, are stable and conductive over a wide potential range in acidic and neutral aqueous solutions, the SQ film-coated GCE may be used as an excellent dehydrogenating and/or hydrogenating agent because the potential of electroactive sites can be controlled exactly to a desired potential with a potentiostat. We will report elsewhere of the electroreduction of quinones and the electrooxidation

of hydroquinones with SQ film-coated GCEs.

Two-Bond Deuterium Isotope Effects on ^{13}C Chemical Shifts of Phenols

Yasuki NAKASHIMA, Akihiro YOSHINO, and Kensuke TAKAHASHI*
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received September 14, 1988)

Two-bond deuterium isotope effects on ^{13}C chemical shifts of 28 substituted phenols are reported and explained in terms of the additivity of substituent parameters which are correlated with the SCS of ^{13}C NMR.

Deuterium isotope effects on ^{13}C chemical shifts are useful parameters for spectral assignments, kinetic studies, and biomechanic studies.[1] The cause of the effect is still unclear, especially regarding further remote effects over one-bond.[2-5] If the magnitudes of the shifts are correlated with any molecular parameters, their applications would be extended in further use. Among such isotope effects, the long-range effects, however, have rarely been reported for aromatic compounds.[6,7] Therefore, more data must be accumulated.

In this study, 28 substituted phenols were selected for the purpose of studying two-bond isotope effects on ^{13}C NMR shifts. One of the reasons for our selection was for an easy preparation of deuterium-labeled compounds. From the sixty nine data points obtained, substituent isotope shifts (hereafter abbreviated as SIS) for seven substituents were quantitatively determined. The SIS's are correlated linearly with the SCS's of the aromatic carbons. Then, the two-bond isotope shifts ($^2\Delta$) can be evaluated from the knowledge of the SCS's. They can also be correlated with the electron densities of the sites under study.

Experimental

Deuterium-labeled compounds were prepared with acid- or base-catalyzed proton-deuteron exchange-reactions of substituted phenols.[8] The starting materials used were commercially available and were used without further purification. Reaction vessels were hand-made Pyrex ampoules. About 0.01 mol of a starting material and a small amount of catalyst (0.1 wt%) dissolved in 1 g of D_2O were sealed into the ampoule, and kept at 80 °C in the thermostatted air oven. After the reaction had reached an extent of about 5—50 D%, the sample was cooled by immersing it in water; the contents were then separated into aqueous and oily (or solid) phases. The latter phase was used for an NMR measurement. Protium-deuterium exchange reactions occurred at 2, 4, and 6-positions and not at 1, 3, and 5-positions of the substituted phenols when they were examined with NMR spectroscopy. The hydroxyl hydrogen of phenol exchanges with that of water and cannot be separately observed on the NMR time scale. Then, the labeled substituent such as OD, ND_2, or NHD did not have any effect on the ^{13}C chemical shifts, as described by Newmark and Hill.[9] Other substituents did not suffer any exchange. Therefore, one- and three-bond isotope effects were observed at the C_2, C_4, and C_6 atoms on the ^{13}C spectra. However, the carbon signals were broadened by the quadrupole effect of deuteron. Thus, accurate values of their isotope effects could not be determined. However, two- and four-bond isotope effects were observed at the C_1, C_3, and C_5 signals. In their spectra two-bond carbon-deuteron couplings are negligibly small and seem to have no effect on their line-widths. An example of the measurement is given in Fig. 1. For the purpose of observing the isotope effect, the extent of the reaction was devised to be nearly 50%. If this is so, the labeled and unlabeled phenols are suitably mixed for their NMR measurements, as shown in Fig. 1. Therefore, the $^2\Delta$ values can be evaluated by using the data obtained from the labeled and unlabeled phenols in a solution contained in the same NMR tube. This might be helpful for decreasing the experimental error of the measurement, which was evaluated to be within 5 ppb. Six C_1 or C_3 signals were observed in Fig. 1. The assignments of the six signals were carried out according to changes in their heights with time. At the starting time of the proton-deuteron exchange reaction only the most downfield signal was observed. When the reaction proceeded with time, five upfield signals appeared in the spectra with gradually increasing heights. Then, the substituent effect of deuteron is an upfield shift. It was also assumed that in polydeuterated compounds deuterons exert their effects additively. If this is so, the six

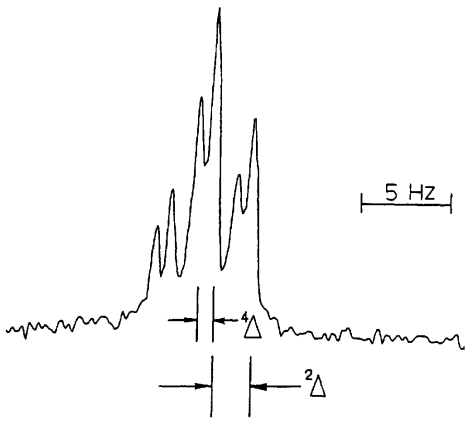

Fig. 1. ^{13}C NMR signals of C_1 or C_3 atoms of the products obtained from the proton-deuteron exchange reaction of 1,3-benzenediol in a 0.14 wt% NaOH-D_2O solution. The signals were averaged for 64 scans. The six signals are assigned as coming from (a) 2,4,6-trideuterated, (b) 2,4- or 2,6-dideuterated, (c) 2,4-, 4,6-, or 2,6-dideuterated, (d) 2- or 6-deuterated, (e) 4-deuterated, and (f) undeuterated 1,3-benzenediols from the right-hand to the left-hand side.

signals can be assigned straightforwardly. The six signals are divided into three groups with a splitting of $^2\Delta$. The three groups can be assigned as those in which the two adjacent sites of the C_1 of the sample have two H's, one H and one D, and two D's. Each of the three groups shows a further small splitting of $^4\Delta$. The six signals were then assigned to be signals coming from (a) 2,4,6-trideuterated, (b) 2,4- or 2,6-dideuterated, (c) 2,4-, 4,6-, or 2,6-dideuterated, (d) 2- or 4-deuterated, (e) 4-deuterated, and (f) undeuterated 1,3-benzenediols from the right-hand (upfield) to the left-hand side (downfield). The value of $^2\Delta$ can be evaluated from the difference of two signals, for example a and c, or c and e. Four-bond isotope effects were accidentally observed in the sample shown in Fig. 1. However, they were generally not determined because of their small magnitudes.

NMR spectra were measured with a Varian XL-200 FT-NMR spectrometer at 50.3 MHz and at about 22 °C. The concentration of the NMR sample solution was neat for the liquid sample and ca. 50 wt%, mostly in dioxane or any other solvent for the solid sample. The ^{13}C NMR spectra were measured by using a gated decoupling technique with no NOE pulse sequence. Data acquisition was carried out under the following conditions: a 45° flip angle of pulse, 24—128 transients, 32000 data points, a delay time of 40 s, and a spectral width of 2600—3500 Hz. Linear regression calculations of the experimental data were carried out on an NEC PC9801VX personal computer in our laboratory using a BASIC program. Details of acid- or base-catalyzed proton-deuteron exchange reactions will be published elsewhere.

Results and Discussion

Sixty-nine two-bond isotope effects of 28 phenols were determined. They are in a range from 32 to 112 ppb (Table 1). All of the observed two-bond isotope effects were toward the high filed. Therefore, the values given in Table 1 should be negative in the conventional manner. However, the signs are neglected in the table. As can be seen in Table 1, the values of $^2\Delta$ of the C_1's are always smaller than those of the C_5's. The values of the C_3's are intermediate between those of the C_1's and C_5's, except for several cases. The $^2\Delta$'s are then correlated with the ^{13}C chemical shifts, which are cited from several articles,[10-13] as shown in Fig. 2. $^2\Delta$ in ppb can be expressed as follows:

$$^2\Delta(\text{ppb}) = -2.06\delta_c(\text{ppm}) + 365. \quad (1)$$

The $^2\Delta$ are roughly related to the ^{13}C chemical shifts. Therefore, their correlation with kinds of substituents might be considered. Then, the contributions of the various substituents to the two-bond isotope shifts were determined by linear regression analyses using

$$^2\Delta = B_0 + n_i a + n_o b + n_m c, \quad (2)$$

where B_0 is the two-bond isotope shift of the unsubstituted benzene (cited as 111 ppb[7]). Three parameters (a, b, and c) are the contributions from ipso, ortho, and meta positioned substituents, respectively. n_i, n_o, or n_m is a weight factor for each substituent parameter. An example of a calculation

using Eq. 2 with three substituent parameters and three weight factors can be illustrated as follows. An example is 1,3-benzenediol (**24**). Its C_1 is affected by a directly bonded substituent and a meta-positioned one. Its C_5 is affected by two meta-positioned substituents. Therefore, its calculated $^2\Delta$ can be expressed as follows:

$$\text{1,3-position: } n_i = 1,\ n_o = 0, \text{ and } n_m = 1;$$
$$^2\Delta = B_0 + a + c;$$
$$\text{5-position : } n_i = 0,\ n_o = 0,\ n_m = 2;$$
$$^2\Delta = B_0 + 2c.$$

The experimentally observed values given in Table 1 are used to evaluate these parameters for each substituent by using linear regression analyses. The parameters obtained for seven kinds of substituents are given in Table 2. These parameters (*a*, *b*, and *c*) are called Substituent Isotope Shift (SIS). The observed two-bond isotope shifts can be calculated with Eq. 2 by using these SIS values with an RMS error of 4.4 ppb and a correlation coefficient of 0.991. So far, a similar analysis has been reported only for one substituent of the CH_3 group by Berger et al.[7] They explained that two-bond isotope shifts for CH_3 can be obtained by two parameters, *a* and *b*, which are consistent with our values given in Table 2. Although the value is rather small, one additional parameter of *c* is included in our analysis.

Correlation between SIS and SCS for ^{13}C NMR. The parameters of SIS decrease in magnitude from *a*, *b*, to *c*. All values of *a* and *b* are large and negative. However, *c* is rather small and either positive or negative. This means that $^2\Delta$ becomes small when any substituent is introduced in the aromatic ring. The magnitudes of *a* are in an order OH>OMe>NO_2>NH_2>*t*-Bu>Me>Cl. This order is parallel to that of the SCS values of the ^{13}C NMR. The SIS values of seven substituents are plotted in Fig. 3, correlated with the SCS values of ^{13}C NMR.[14] As can be seen in Fig. 3, the points are linearly correlated, except for those of the ortho-positions, which are shown by black-filled circles. The correlation coefficient gives a rise from 0.924 to 0.980 when the points of the ortho-positions

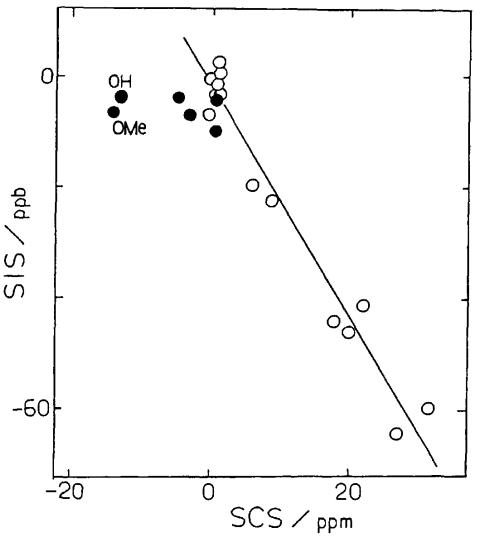

Fig. 3. Correlation between the SIS and SCS values of the ^{13}C NMR determined for substituted phenols. A correlated straight line is expreseed as SIS(ppb)= −2.11 SCS(ppm)−1.30 with r=0.980 and the standard deviation of 5.0 ppb when the black-filled points are excluded.

are excluded. Therefore, both the SIS's and the SCS's are linearly correlated with each other at the ipso and meta positions. This fact means that the factors controlling the SIS's are partly the same as those of the SCS's. Especially the deviation of the black-filled circles are downward from the correlated straight line. The magnitudes of their deviations are in the order OMe>NO_2>*t*-Bu>Cl>Me. Therefore, the deviation seems to be affected by a steric effect of bulky substituents, such as OMe, NO_2, and *t*-Bu groups. The ^{13}C chemical shifts sometime suffer a steric compression effect from bulky substituents.[15,16] The isotope effect, on the contrary, is said not to suffer such a contribution.[7] The deviations of the black-filled circles are thus explained by such steric effects which are effective for SCS but ineffective for SIS. This idea is supported by the fact that the observed deviation of the OMe, NO_2, or *t*-Bu group is given at the negative side of the SCS from a straight line, as can be seen in Fig. 3. Among those black-filled points, however, the

deviation of OMe is much larger than others. Therefore, it must be necessary to consider other effects. In order to clarify this point we made an examination in order to obtain the value of b for OH. The $^2\Delta$ of m-deuterophenol is 108 ppb.[17] From this value b equals to -3.0 ppb (plotted in Fig. 3). The deviation of OH is similar to that of OMe. Therefore, the origin of the deviation must be explained by other effects, such as the lone pair of the oxygen atom.

Presently, the origins of the isotope shifts are considered to be entirely or partly due to the vibration.[18] However, for deuteromethyl-substituted aromatic compounds two explanations have been presented, in which the hyperconjugational part is reversed in sign to the vibrational one.[2,3,7,19] But in cases where the deuterium atom is directly bonded to the aromatic ring, the hyperconjugational effect is not considered.[20] Furthermore, as shown in Figs. 2 and 3, and Eq. 1, the isotope shifts studied here have been correlated to the chemical shifts of the corresponding carbons. A similar discussion was also presented by Arrowsmith and Kresge.[21] These examples suggest the electron densities of the carbon atoms under study can become the origin of the isotope shifts.

Conclusion

Two-bond isotope shifts for the substituted phenols are represented additively by three parameters assigned to each substituent. This additivity can also be applied to polysubstituted benzenes. Further, the SIS values were correlated with the SCS values of the substituents of ^{13}C NMR. This would be a key for considering the origins of the isotope effect.

Continuous Electrochemiluminescence of [Ru(2,2′-bipyridine)$_3$]$^{2+}$ in Solution

Ryuji IGARASHI, Yoshio NOSAKA,* Nobuyuki FUJII, and Hajime MIYAMA
Department of Chemistry, Nagaoka University of Technology,[1] Nagaoka 940-21
(Received September 28, 1988)

Electrochemiluminescence (ECL) of tris(2,2′-bipyridine)ruthenium(2+) ([Ru(bpy)$_3$]$^{2+}$) was observed in a propylene carbonate–dimethylacetamide–water mixed solvent by applying direct current (dc) voltage to a cell which consists of a sheet cathode of metals such as Al and Pt and a wire anode of Pt. The intensity of the dc ECL increased with the water concentration (up to 30 vol%) and the applied voltage. Besides water, oxygen was found to be necessary for observing the dc ECL. A plausible mechanism is the formation of [Ru(bpy)$_3$]$^{2+*}$ from the reaction of [Ru(bpy)$_3$]$^{+}$ and HO_2, those species are both produced at the cathode. This mechanism was supported by a separate experiment in which the chemiluminescence was observed by the reactions with a reducing agent.

The continuous electrochemiluminescence (ECL) of tris(2,2′-bipyridine)ruthenium(2+) ([Ru(bpy)$_3$]$^{2+}$) in acetonitrile solution with a small amount of water was observed recently by the authors.[2] Some unique characteristics of the dc-ECL observation were (i) a quick response to the direct current (dc) application, (ii) the restriction to Al for cathode materials when the applied voltage was 10 V, and (iii) a special arrangement for the electrodes in which the area of the anode was much smaller than that of the cathode. On the application of ac voltage to the same cell, these characteristics did not appear, although the ECL intensity was significantly large. Accordingly the reaction mechanism of the dc ECL should be different from the conventional ac ECL in which a diffusion process is involved. Although the emitting species was considered to be [Ru(bpy)$_3$]$^{2+*}$, its formation mechanism was not clarified in the previous study, where a two-electrode cell was used in connection with its application to ECL devices.[2] In the present study, however, a three-electrode cell was also used to explain the unique characteristics of the dc-ECL. For comparison with the previous study, the cathode potential in the two-electrode cell was measured against the concentration of the supporting electrolyte and by changing the cathode materials. A mechanism of the dc ECL will be proposed based on the influence of oxygen on the emission intensity and the observation of chemical luminescence by using a reducing agent.

Experimental

Materials. Tris(2,2′-bipyridine)ruthenium(2+) complex ([Ru(bpy)$_3$]$Cl_2 \cdot 6H_2O$), obtained from Aldrich Chemical Co., was purified by recrystallizing three times from distilled water followed by drying in vacuum. Propylene carbonate (PC, extra pure reagent) and *N*,*N*-dimethylacetamide (DMA, guaranteed reagent) obtained from Nakarai Chemicals, Ltd. were dried with molecular sieve followed by vacuum distillation. A mixture of PC, DMA, and H_2O was used as a solvent, unless otherwise stated. Tetrabutylammonium perchlorate (TBAP, polarographic grade of Nakarai Chemicals) was used without further purification. Aluminum sheet (0.08 mm in thickness) obtained from Tokai Kinzoku Co., Ltd., was used as received. A copper sheet (0.3-mm thick), a titanium sheet (0.05 mm thick), and a molybdenum sheet (0.1-mm thick) from the Japan Lamp Industrial Co., Ltd., and a Pt sheet (0.023-mm thick), from Itimura Metal Co., Ltd., were rinsed with a 1.2-M HCl solution (1 M=1 mol dm^{-3}) and subsequently with distilled water before use.

Method. The two-electrode cell consists of a metal sheet of 8-mm width and 2-cm effective height and a wire of Pt of 0.5-mm diameter and 1-cm effective length. The sheet was used as a working electrode (WE) while the wire was used as a counter electrode (CE). The three-electrode cell consists of an Al or a Pt sheet WE, a Pt wire CE, and an Ag/Ag$^+$ reference electrode (RE) which are placed in a H-shaped glass vessel having a sintered-glass filter separator. The WE and CE were the electrodes as used in the two-electrode cell, respectively. The ECL intensity was measured for a 0.2-mM [Ru(bpy)$_3$]$^{2+}$ solution under controlled polarization with a potentiostat (Toho Technical Research, Type 2090). The potential was usually supplied by a function generator (Leader, LFG-1300). The ECL light after passing through a grating monochromator (Ritsu, MC-25N) was detected by a photomultiplier (Hamamatsu Photonics, R928). The experimental setup for the two-electrode cell was similar to that in the previous report.[2]

Effective potentials of the metal sheet WE against the Ag/Ag$^+$ RE were measured by using the Pt wire CE, which were the same as for the two-electrode cell. Cyclic voltammograms were measured by using a square Pt WE (0.5 cm×0.5 cm), and a Pt coil CE, and the Ag/Ag$^+$ RE in the H-shaped vessel.

The measurement of chemiluminescence of [Ru(bpy)$_3$]$^{2+}$ was performed by adding 1 M HCl to the mixture of PC, DMA, and H_2O containing 1-mM [Ru(bpy)$_3$]$^{2+}$ and a piece of Mg ribbon.

Results

In our previous study on the dc ECL,[2] acetonitrile was used as a solvent. Since acetonitrile is a volatile and virulent substance, propylene carbonate (PC) was used as a solvent in the present study. In order to observe the dc ECL, a small amount of water had been required in the previous study. Since water is poorly soluble in the PC solution, DMA was added to the mixture to increasing the water solubility. DMA is

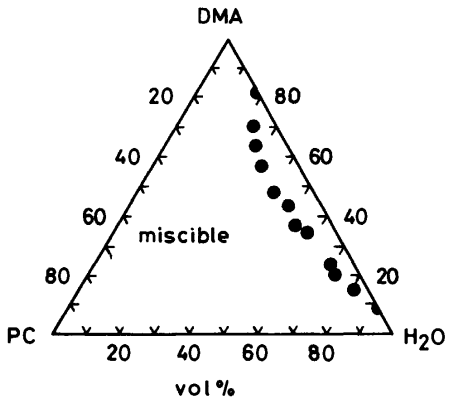

Fig. 1. Limits of miscibility in the ternary system of PC, DMA, and H_2O.

also an aprotic nonvolatile substance used commonly as a solvent. Figure 1 shows the limit of miscibility for the three-component system consisting of PC, DMA, and H_2O. On this basis a DMA concentration of 20 vol% was chosen for this study. The three compositions are completely miscible at this concentration.

The dc-ECL intensity was measured by changing the water concentration. When the water was absent from the solution no emission was observed. The intensity of the emission increased with the water concentration which became saturated at 30 vol%. Therefore, in the following experiments, the contents of the mixed solvent were fixed to be 50 vol% of PC, 30 vol% of H_2O, and 20 vol% of DMA. The dc ECL was observed without delay (less than 0.2 s) and continued for several hours similarly to the case of the acetonitrile-H_2O solution.[2] However, the emission intensity is higher and more stable than that observed in the previous study,[2] although no quantitative comparison was performed.

Redox potentials of $[Ru(bpy)_3]^{2+}$ in the mixture were examined to investigate the mechanism of the dc ECL. The cyclicvoltammetric behavior at the Pt electrode was measured for the PC-DMA-H_2O solution containing 1-mM $[Ru(bpy)_3]^{2+}$ and a supporting electrolyte of 0.1 M TBAP. The potential for each peak obtained from the voltammogram is given in Table 1. These electrode reactions are one-electron reversible processes, because the potential differences between the reduction and oxidation peaks, $E_{pa}-E_{pc}$, were approximately equal to 59 mV.[3] This observation indicates that the mixed solvent does not participate in the electrode reaction over the potential range. For the following discussion, note that $[Ru(bpy)_3]^{2+}$ was reduced to $[Ru(bpy)_3]^{+}$ at −1.52 V vs. Ag/Ag^+ in this solvent.

The emission intensity was measured under the controlled potential using the three-electrode cell. Figure 2 shows the relationship between the dc-ECL intensity

Table 1. Peak Potentials at Cathodic (E_{pc}) and Anodic (E_{pa}) Sweeps of the Cyclic Voltammogram for $Ru(bpy)_3Cl_2$ in PC-DMA-H_2O Mixed Solvent[a]

Oxidation state	I	II	III	IV
E_{pc}	0.96	−1.52	−1.70	−1.91
E_{pa}	1.02	−1.47	−1.64	−1.85

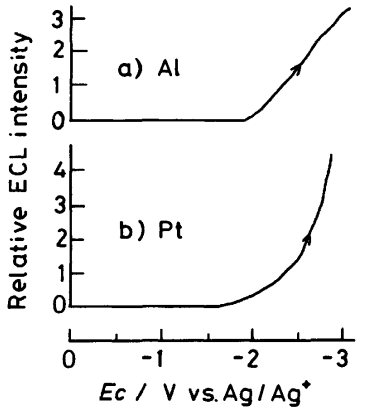

Fig. 2. ECL intensity-potential (E_c) curves at (a) Al and (b) Pt sheet cathodes in PC-DMA-H_2O solution containing 0.2-mM $[Ru(bpy)_3]^{2+}$ and 0.1-M TBAP.

and the electrode potential of the Al and Pt sheet cathodes in the PC-DMA-H_2O solution containing 0.2-mM $[Ru(bpy)_3]^{2+}$ and 0.1-M TBAP. For the Al electrode, emission was observed at −1.9 V vs. Ag/Ag^+ and the intensity increased with the potential. For the Pt sheet cathode, the dc ECL was observed above −1.6 V vs. Ag/Ag^+. This onset potential roughly agrees with the reduction potential for $[Ru(bpy)_3]^{2+}$ mentioned above.

In the experiments using the two-electrode cell with 10-V application, the dc ECL was not observed at the Pt cathode similarly to the case in the previous study. Therefore, the actual potential of the cathode in the two-electrode cell against RE was measured. Table 2 shows the observed potential for various metal sheets to Ag/Ag^+ RE when −10 V was applied against the Pt-wire electrode. The values of the redox potential of the metals and whether the dc-ECL was observed or not are also shown in the table. The dc ECL was observed at the Al and Ti sheet cathodes whose actual potentials were lower than the reduction potential of $[Ru(bpy)_3]^{2+}$. At the Mo, Cu, and Pt sheet cathodes the dc ECL was not observed because the potential was not high enough to reduce the ruthenium complex. The cathode potential appears to correlate with the standard electrode potential.

The actual potential at the Al and Pt sheet cathodes was measured by adding various amount of TBAP as shown in Fig. 3. For both electrodes, the negative

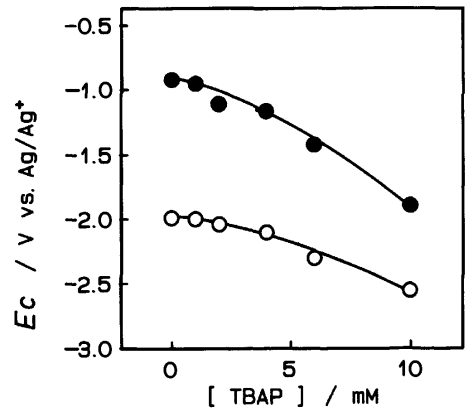

Fig. 3. Observed potentials (E_c) at the Pt (●) and Al (○) cathodes for various concentration of TBAP. At the cathode, −10 V was applied against the Pt wire. PC-DMA-H_2 solution containing 0.2-mM $[Ru(bpy)_3]^{2+}$ was used.

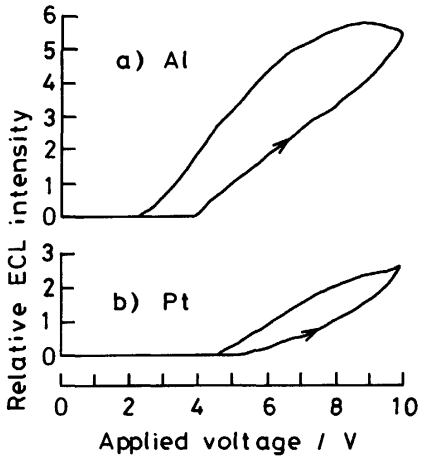

Fig. 4. ECL intensity-applied voltage curves at (a) Al and (b) Pt sheet cathodes in PC-DMA-H_2O solution containing 0.2-mM $[Ru(bpy)_3]^{2+}$ and 0.1-M TBAP.

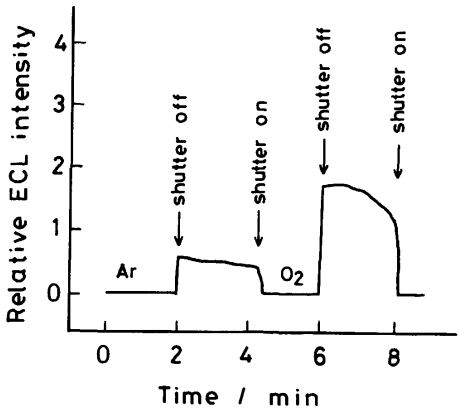

Fig. 5. Effect of oxygen on ECL intensity at Al sheet cathode in PC-DMA-H_2O solution containing 0.2-mM $[Ru(bpy)_3]^{2+}$. Both O_2 and Ar gases were purged alternatively when the shutter for the photomultiplier was on.

potential increased with the TBAP concentration. In the presence of 10-mM TBAP, the cathode potential at the Pt sheet became more negative than −1.52 V which is the reduction potential of $[Ru(bpy)_3]^{2+}$. Consequently, in the presence of TBAP, the dc ECL may be observed for the Pt cathode in the two-electrode cell at a lower applied voltage. Figure 4 shows the dc-ECL intensity in the presence of 0.1-M TBAP as a function of the applied voltage at the Al and Pt sheet cathodes. As mentioned previously, in the absence of a supporting electrolyte, no emission was observed at applied voltages ranging from 0 to 10 V at the Pt cathode. However, when TBAP was added in the solution, emission was observed at the Pt cathode as shown in Fig. 4. The thresholds of the applied voltage for the emission at the Al and Pt cathodes were 3.8 V and 5.5 V, respectively. The threshold voltage for emission at the Al sheet cathode was smaller than that at the Pt sheet cathode. This originates from the fact that the potential of the Al sheet cathode was more negative than the Pt cathode at the same applied voltage as shown in Fig. 3. Thus the influence of the cathode materials on the dc ECL in the two-electrode cell is explained by the cathode potential instead of the participation to the emission mechanism as a chemical reactant.

As mentioned above, H_2O is necessary for the dc-ECL. Besides H_2O, atmospheric oxygen is considered to contribute to the mechanism of the dc ECL. The dc ECL was next measured by alternating the conditions between those in the presence of oxygen by bubbling oxygen gas and in the absence of oxygen by bubbling argon gas through the solution. As shown in Fig. 5, the ECL intensity was weakened without oxygen and recovered on adding oxygen. These results suggest that oxygen participates in the emission mechanism of the dc ECL.

The emission occurs only at the cathode surface, indicating that some reduction process accounts for

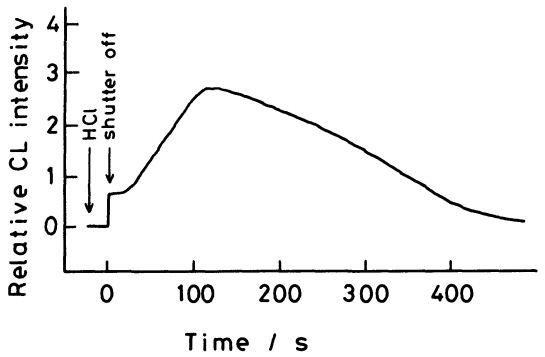

Fig. 6. Emission profile of chemiluminescence (CL) obtained by adding 1-M HCl to the 1-mM $[Ru(bpy)_3]^{2+}$ solution containing a piece of Mg ribbon.

the dc ECL. The chemiluminescence was next measured in order to confirm that the emission is caused by a reduction process. Figure 6 shows the chemiluminescence obtained by adding 1-M HCl to a 1-mM $[Ru(bpy)_3]^{2+}$ solution containing a piece of Mg ribbon. This result suggests that the mechanism of the dc ECL involves a process similar to the chemiluminescence.

Discussion

Although the separation between the anode and the cathode is as large as 8 mm, the dc ECL was observed without delay on the dc application. This phenomenon suggests that the electrochemical reaction proceeds through the short diffusion length at only one electrode. Bard et al. demonstrated that the ECL phenomenon occurred at only one electrode when a sacrificial reagent such as oxalate[4] and peroxodisulfate[5] was employed. In the case of peroxodisulfate, for example, a strong oxidant, $SO_4^{\cdot-}$, was produced by the reduction of $S_2O_8^{2-}$ at the cathode. Then $[Ru(bpy)_3]^{2+*}$ was formed by oxidizing $[Ru(bpy)_3]^{+}$ with $SO_4^{\cdot-}$.[5] In the present study, oxygen and water are essential to the appearance of the dc ECL. Therefore, O_2 and H_2O may be replaced to the peroxodisulfate in the ECL mechanism. For example, Reaction 1 may take place at the cathode.

$$O_2 + e^- \longrightarrow O_2^- \quad (1)$$

At the low pH the super oxide ion becomes the $HO_2^{\cdot}$ radical.

$$O_2^- + H^+ \rightleftharpoons HO_2^{\cdot} \quad pK\ 4.8^{6} \quad (2)$$

The reduction potential of Eq. 1 is −0.32 V vs. NHE.[7] The observation of the $HO_2^{\cdot}$ radical with a UV spectrophotometer failed because of the low estimated concentration and the overlapping of the solvent at the maximum of $HO_2^{\cdot}$ (225 nm).[8] However, the formation of $HO_2^{\cdot}$ by the reduction of water has been reported already.[8] Since the product $HO_2^{\cdot}$ radical is a strong oxidant, it may act in the same role as the $SO_4^{\cdot-}$ radical. Then, $[Ru(bpy)_3]^{2+*}$ was produced via electron transfer from $[Ru(bpy)_3]^{+}$ to $HO_2^{\cdot}$ as expressed by Eq. 3.

$$[Ru(bpy)_3]^{+} + HO_2^{\cdot} + H^+ \longrightarrow [Ru(bpy)_3]^{2+*} + H_2O_2 \quad (3)$$

Here, the redox potencials of $HO_2^{\cdot}+H^+/H_2O_2$ and $[Ru(bpy)_3]^{2+}$ in aqueous solution are +1.495 V[9] and −1.28 V[10,11] vs. NHE, respectively. The difference of the potentials, 1.495−(−1.28), is 2.775 V. This value is larger than the excitation energy for $[Ru(bpy)_3]^{2+}$ of 2.7 eV which corresponds to the absorption maximum of 455 nm. Therefore, $[Ru(bpy)_3]^{2+*}$ is probably produced by the Reaction 3.

At the anode the oxidation of $[Ru(bpy)_3]^{2+}$ and water may occur. One of the products is likely to be oxygen. This oxygen may be used for the reduction at the cathode. Thus the ECL continued for hours.

The contribution of $HO_2^{\cdot}$ in the dc-ECL mechanism was supported by the experiment with a reducing reagent. As shown in Fig. 6 the chemiluminescence was observed when a $[Ru(bpy)_3]^{2+}$ aqueous solution was reduced with the Mg metal in the presence of O_2. In this case the reaction scheme is considered as follows;

$$1/2Mg + [Ru(bpy)_3]^{2+} \longrightarrow 1/2Mg^{2+} + [Ru(bpy)_3]^{+} \quad (4)$$

$$1/2Mg + H^+ + O_2 \longrightarrow 1/2Mg^{2+} + HO_2^{\cdot} \quad (5)$$

Here, the two reactions are highly exothermic as calculated to be ΔG=−105.2 and −372.9 kJ mol^{-1} for Eqs. 4 and 5, respectively. The products of these reactions may produce $[Ru(bpy)_3]^{2+*}$ as shown by Eq. 3, followed by light emission.

The discussion next turns to the third feature of the dc ECL at which the area of the anode is smaller than that of the cathode. In the two-electrode cell, the applied voltage V is represented by

$$V = E_a(i) + (-E_c(i)) + Vr(I) \quad (6)$$

Here, $E_a(i)$ and $E_c(i)$ are the anode and cathode potentials with the current density i, and $Vr(I)$ is the ohmic drop associated with the solution resistance and the current I through the cell. When the area of the cathode is considerably larger than that of the anode, the current density of the cathode is very small and $E_c(i)$ is close to the standard electrode potential of the electrode substance. This explains the fact that the cathode potential correlates with the redox potential of the electrode materials as shown in Table 2. Further-

more, by adding TBAP to the solution, the resistance of the solution decreases and consequently $Vr(I)$ decreases. Thus the cathode potential increases with the TBAP concentration at a constant applied potential as shown in Fig. 3.

In the present study, the current through the cell is limited by the substance transport at a wire CE having a small surface area. Then, at the larger sheet WE the current density is low although the potential is high enough for oxygen and $[Ru(bpy)_3]^{2+}$ to be reduced. This situation may be necessary to produce both $[Ru(bpy)_3]^{+}$ and $HO_2^{\cdot}$ at the cathode. In order to prevent the further reduction of $HO_2^{\cdot}$ and $[Ru(bpy)_3]^{+}$, the species produced must quickly diffuse from the cathode surface to the solution. This may also be achieved by the small current density at the cathode.

Conclusion

The most plausible mechanism of the dc ECL in the two-electrode cell is the formation of $[Ru(bpy)_3]^{2+*}$ by the reaction between $[Ru(bpy)_3]^{+}$ and $HO_2^{\cdot}$ both of which are produced at the cathode. The potential of the sheet cathode in the two-electrode cell is affected by the standard potential of the electrode material and the concentration of the supporting electrolyte. This observation is used to reveal the emission mechanism and to solve the questions in the previous report.

We are grateful to Professor A. J. Bard for very useful discussions on the dc-ECL mechanism and to Dr. Masao Kaneko for valuable discussions. This work was supported by Nippon Seiki Co., Ltd.

Theoretical Investigation of the Interaction Potential of Helium Trimer

Akira ICHIHARA* and Reikichi ITOH
Department of Chemistry, Faculty of Science and Engineering, Waseda University,
3-4-1 Ohkubo Shinjuku-ku, Tokyo 160
(Received September 28, 1988)

Using the help of an ab initio calculation along with a configuration interaction treatment, the interaction potential of a He trimer has been calculated. The basis set superposition error in the He trimer system could be avoided using a reference calculation approximated by a simple formula.

There have been several reports in which the interaction potential between He atoms was calculated by the use of an ab initio MO method. It is known that the He dimer system has a repulsive ground state, with only a van der Waals minimum. We have recently calculated the interaction potential of the He dimer through the configuration interaction (CI) method.[1] For a weakly bonded system the basis set superposition error (BSSE)[2-7] in the He dimer energies could not be neglected and reference calculations had to be performed in order to correct this error. In this paper we will report on the results of CI calculations for the interaction potential of the He trimer. The CI calculations contain all single and double excitations from the SCF ground state (SD CI). A simple formula is proposed for estimating the BSSE for three-body interaction energies. The formulation was performed using a procedure described by Price and Stone.[5]

The Function Counterpoise Method for Three-Body Interactions. In principle the interaction energy (ΔE) of three closed-shell systems (atoms or molecules: A, B, and C) with energies E^A, E^B, and E^C can be written

$$\Delta E^{ABC} = E^{ABC} - E^A - E^B - E^C, \tag{1}$$

where E^{ABC} is the energy of supersystem ABC at some nuclear geometry. However, this expression takes no account of the BSSE. The BSSE arises from the incompleteness of the basis set, and each of the interactuing systems can make partial use of the basis sets centered on the other systems in order to improve its own property. It leads to a nonphysical energy lowering in the supersystem. Boys and Bernardi proposed the function counterpoise (CP) method for correcting the BSSE in two-body interaction energies.[2] This is often denoted as a "full" CP method.[2-7] A generalization of the full CP method to many-body interactions was attempted by Wells and Wilson.[8-10]

In the CP method, the interaction energy for a three-body system can be calculated using the difference between E^{ABC} and an appropriate reference energy, E_{ref};

$$\Delta E^{ABC} = E^{ABC} - E_{ref}. \tag{2}$$

The reference energy, E_{ref}, may be defined as

$$E_{ref} = E^{AG}{}_{BC} + E^{BG}{}_{CA} + E^{CG}{}_{AB}, \tag{3}$$

where $E^{iG}{}_{jk}$ represents the energy for system i with "ghost" orbitals of systems j and k. The term "ghost" represents a nucleus with a nuclear charge of zero and without any electrons. In practice, system i should be calculated with the full basis set of the supersystem. Wells and Wilson called this the "site-site" CP method.[8-10] This method is valid only for both E^{ABC} and E_{ref} calculations which are size consistent.

In the present investigation, however, calculations of the interaction potential were performed using the SD CI treatment; Eq. 3 was not directly used. We therefore propose an approximate formula for calculating the true reference energy. This approach is used to describe the correct reference state by the product $\psi^A\psi^B\psi^C$ of correlated wavefunctions, using ghost orbitals, for three closed shell systems. Then, since each wavefunction (ψ^A, ψ^B, and ψ^C) includes all single and double excitations from the SCF ground state, for size consistency, an elimination of the effect of triple and higher excitations is performed. The formulation is carried out using a procedure proposed by Price and Stone for two-body interactions[5] and the full CP technique.

Development of the Formula. The normalised wavefunction for a closed shell system A, including all single and double excitations, may be written

$$\psi^A = a_0\psi_0^A + a_1\psi_1^A + a_2\psi_2^A, \tag{4}$$

with

$$a_0^2 + a_1^2 + a_2^2 = 1, \tag{5}$$

where ψ_0^A is the normalised SCF function, ψ_i^A is the part of the normalised wavefunctions containing i-fold excitations, and the a_i's the corresponding coefficients.

The wavefunctions for closed shell systems B and C can be written similarly; these three wavefunctions are orthogonal to each other.

Then, the product wavefunction for the three separated systems with ghost orbitals is

$$\begin{aligned}\psi^A\psi^B\psi^C &= (a_0\psi_0^A + a_1\psi_1^A + a_2\psi_2^A)(b_0\psi_0^B + b_1\psi_1^B + b_2\psi_2^B)\\ &\quad (c_0\psi_0^C + c_1\psi_1^C + c_2\psi_2^C)\\ &= a_0b_0c_0\psi_0^A\psi_0^B\psi_0^C + a_1b_0c_0\psi_1^A\psi_0^B\psi_0^C\\ &\quad + \text{--------} + a_2b_2c_2\psi_2^A\psi_2^B\psi_2^C.\end{aligned} \tag{6}$$

In order to obtain our estimated wavefunction for the correct reference calculation, we discard the terms which represent the triple and higher excitations, and obtain

$$\begin{aligned}\psi^{ABC} = Z^{-1}(&a_0b_0c_0\psi_0^A\psi_0^B\psi_0^C + a_1b_0c_0\psi_1^A\psi_0^B\psi_0^C + a_0b_1c_0\psi_0^A\psi_1^B\psi_0^C \\ &+ a_0b_0c_1\psi_0^A\psi_0^B\psi_1^C + a_1b_1c_0\psi_1^A\psi_1^B\psi_0^C + a_1b_0c_1\psi_1^A\psi_0^B\psi_1^C \\ &+ a_0b_1c_1\psi_0^A\psi_1^B\psi_1^C + a_2b_0c_0\psi_2^A\psi_0^B\psi_0^C + a_0b_2c_0\psi_0^A\psi_2^B\psi_0^C \\ &+ a_0b_0c_2\psi_0^A\psi_0^B\psi_2^C),\end{aligned} \tag{7}$$

where z^{-1} is the renormalisation factor.

This product is a CI expansion which includes all single and double excitations from the SCF ground state $\psi_0^A\psi_0^B\psi_0^C$, though the coefficients in Eq. 7 are not variationally optimised. However, as has been noted in the previous calculations for the He-He by Dacre[4] and for the H_2-H_2 by Price and Stone,[5] the product wavefunction with the coefficients of separated systems might be a reasonable approximation to the variational function. We therefore expect that ψ^{ABC} will be a reliable estimation for the variational function.

Normalising Eq. 7, we obtain

$$\begin{aligned}Z^2 = {} & a_0^2b_0^2c_0^2 + a_1^2b_0^2c_0^2 + a_0^2b_1^2c_0^2 + a_0^2b_0^2c_1^2 + a_1^2b_1^2c_0^2 \\ & + a_1^2b_0^2c_1^2 + a_0^2b_1^2c_1^2 + a_2^2b_0^2c_0^2 + a_0^2b_2^2c_0^2 + a_0^2b_0^2c_2^2.\end{aligned} \tag{8}$$

Using the fact that terms like $a_1^2b_1^2c_0^2$ are small (because of Brillouin's theorem), Eq. 8 can be approximated as

$$Z^2 = a_0^2b_0^2 + b_0^2c_0^2 + c_0^2a_0^2 - 2a_0^2b_0^2c_0^2. \tag{9}$$

Rearranging Eqs. 6 and 7, we obtain

$$\psi^A\psi^B\psi^C = Z\psi^{ABC} + (\text{triple and higher excitation terms}), \tag{10}$$

which is used to obtain the energy relationship

$$\begin{aligned}&\langle\psi^A\psi^B\psi^C|H_A + H_B + H_C|\psi^A\psi^B\psi^C\rangle \\ &= Z^2\langle\psi^{ABC}|H_A + H_B + H_C|\psi^{ABC}\rangle \\ &+ a_0^2(b_1^2c_2^2 + b_2^2c_1^2 + b_2^2c_2^2)\langle\psi_0^A|H_A|\psi_0^A\rangle \\ &+ a_1^2(b_1^2c_1^2 + b_0^2c_2^2 + b_2^2c_0^2 + b_1^2c_2^2 \\ &+ b_2^2c_1^2 + b_2^2c_2^2)\langle\psi_1^A|H_A|\psi_1^A\rangle \\ &+ a_2^2(b_0^2c_1^2 + b_1^2c_0^2 + b_1^2c_1^2 + b_0^2c_2^2 + b_2^2c_0^2 \\ &+ b_1^2c_2^2 + b_2^2c_1^2 + b_2^2c_2^2)\langle\psi_2^A|H_A|\psi_2^A\rangle \\ &+ 2a_2a_0(b_0^2c_1^2 + b_1^2c_0^2 + b_1^2c_1^2 + b_0^2c_2^2 + b_2^2c_0^2 \\ &+ b_1^2c_2^2 + b_2^2c_1^2 + b_2^2c_2^2)\langle\psi_2^A|H_A|\psi_0^A\rangle \\ &+ 2a_2a_1(b_0^2c_1^2 + b_1^2c_0^2 + b_1^2c_1^2 + b_0^2c_2^2 + b_2^2c_0^2 \\ &+ b_1^2c_2^2 + b_2^2c_1^2 + b_2^2c_2^2)\langle\psi_2^A|H_A|\psi_1^A\rangle \\ &+ b_0^2(c_1^2a_2^2 + c_2^2a_1^2 + c_2^2a_2^2)\langle\psi_0^B|H_B|\psi_0^B\rangle \\ &+ b_1^2(c_1^2a_1^2 + c_0^2a_2^2 + c_2^2a_0^2 + c_1^2a_2^2 \\ &+ c_2^2a_1^2 + c_2^2a_2^2)\langle\psi_1^B|H_B|\psi_1^B\rangle \\ &+ b_2^2(c_0^2a_1^2 + c_1^2a_0^2 + c_1^2a_1^2 + c_0^2a_2^2 + c_2^2a_0^2 \\ &+ c_1^2a_2^2 + c_2^2a_1^2 + c_2^2a_2^2)\langle\psi_2^B|H_B|\psi_2^B\rangle \\ &+ 2b_2b_0(c_0^2a_1^2 + c_1^2a_0^2 + c_1^2a_1^2 + c_0^2a_2^2 + c_2^2a_0^2 \\ &+ c_1^2a_2^2 + c_2^2a_1^2 + c_2^2a_2^2)\langle\psi_2^B|H_B|\psi_0^B\rangle \\ &+ 2b_2b_1(c_0^2a_1^2 + c_1^2a_0^2 + c_1^2a_1^2 + c_0^2a_2^2 + c_2^2a_0^2 \\ &+ c_1^2a_2^2 + c_2^2a_1^2 + c_2^2a_2^2)\langle\psi_2^B|H_B|\psi_1^B\rangle \\ &+ c_0^2(a_1^2b_2^2 + a_2^2b_1^2 + a_2^2b_2^2)\langle\psi_0^C|H_C|\psi_0^C\rangle \\ &+ c_1^2(a_1^2b_1^2 + a_0^2b_2^2 + a_2^2b_0^2 + a_1^2b_2^2 \\ &+ a_2^2b_1^2 + a_2^2b_2^2)\langle\psi_1^C|H_C|\psi_1^C\rangle \\ &+ c_2^2(a_0^2b_1^2 + a_1^2b_0^2 + a_1^2b_1^2 + a_0^2b_2^2 + a_2^2b_0^2 \\ &+ a_1^2b_2^2 + a_2^2b_1^2 + a_2^2b_2^2)\langle\psi_2^C|H_C|\psi_2^C\rangle \\ &+ 2c_2c_0(a_0^2b_1^2 + a_1^2b_0^2 + a_1^2b_1^2 + a_0^2b_2^2 + a_2^2b_0^2 \\ &+ a_1^2b_2^2 + a_2^2b_1^2 + a_2^2b_2^2)\langle\psi_2^C|H_C|\psi_0^C\rangle \\ &+ 2c_2c_1(a_0^2b_1^2 + a_1^2b_0^2 + a_1^2b_1^2 + a_0^2b_2^2 + a_2^2b_0^2 \\ &+ a_1^2b_2^2 + a_2^2b_1^2 + a_2^2b_2^2)\langle\psi_2^C|H_C|\psi_1^C\rangle\end{aligned} \tag{11}$$

where H_i is the Hamiltonian for system i.

On the other hand, the SCF energy (E_{SCF}) and the total SCF CI energy (E_T) of the individual system A can be written as

$$E_{SCF}^A = \langle\psi_0^A|H_A|\psi_0^A\rangle, \tag{12}$$

$$\begin{aligned}E_T^A = {} & \langle\psi^A|H_A|\psi^A\rangle = a_0^2E_{SCF}^A \\ & + 2a_2a_0\langle\psi_2^A|H_A|\psi_0^A\rangle + a_1^2\langle\psi_1^A|H_A|\psi_1^A\rangle \\ & + 2a_2a_1\langle\psi_2^A|H_A|\psi_1^A\rangle + a_2^2\langle\psi_2^A|H_A|\psi_2^A\rangle,\end{aligned} \tag{13}$$

and similarly for systems B and C.

Then, taking into account the relationships

$$\begin{aligned}&a_0^2b_1^2 + a_1^2b_0^2 + a_0^2b_2^2 + a_2^2b_0^2 \\ &\quad = a_0^2(1 - b_0^2) + b_0^2(1 - a_0^2)\end{aligned} \tag{14}$$

and

$$a_1^2b_1^2 + a_1^2b_2^2 + a_2^2b_1^2 + a_2^2b_2^2 = (1 - a_0^2)(1 - b_0^2), \tag{15}$$

and ignoring terms like $a_1^2b_1^2c_0^2\langle\psi_1^A|H_A|\psi_1^A\rangle$, the reference energy can be approximated as

$$\begin{aligned}E_{ref} = {} & \langle\psi^{ABC}|H_A + H_B + H_C|\psi^{ABC}\rangle \\ = {} & [\{b_0^2c_0^2E_T^A + a_0^2(b_0^2 + c_0^2 - 2b_0^2c_0^2)E_{SCF}^A\} \\ & + \{c_0^2a_0^2E_T^B + b_0^2(c_0^2 + a_0^2 - 2c_0^2a_0^2)E_{SCF}^B\} \\ & + \{a_0^2b_0^2E_T^C + c_0^2(a_0^2 + b_0^2 - 2a_0^2b_0^2)E_{SCF}^C\}] \\ & \times (a_0^2b_0^2 + b_0^2c_0^2 + c_0^2a_0^2 - 2a_0^2b_0^2c_0^2)^{-1}.\end{aligned} \tag{16}$$

The error made in this approximation depends on the values of a_1, b_1, and c_1, as well as a_2, b_2, and c_2. Moreover, changes in these coefficients depend only on the position of the ghost orbitals. As noted by Dacre[4] and by Price and Stone,[5] however, these coefficients vary slightly between different relative positions of the interacting systems. Therefore, we also expect the

error in Eq. 16 to be nearly constant.

On the other hand, if three systems are to be infinitely separated, both the interaction energy and the BSSE must be zero. In this case the reference energy becomes equal to the total energy of super-system (E^{ABC}). Thus, we can estimate the error in Eq. 16 as a constant ε. A final formula is given by adding the constant ε:

$$E_{ref} = [\{b_0^2c_0^2E_T^A + a_0^2(b_0^2 + c_0^2 - 2b_0^2c_0^2)E_{SCF}^A\} + \{c_0^2a_0^2E_T^B + b_0^2(c_0^2 + a_0^2 - 2c_0^2a_0^2)E_{SCF}^B\} + \{a_0^2b_0^2E_T^C + c_0^2(a_0^2 + b_0^2 - 2a_0^2b_0^2)E_{SCF}^C\}] \times (a_0^2b_0^2 + b_0^2c_0^2 + c_0^2a_0^2 - 2a_0^2b_0^2c_0^2)^{-1} + \varepsilon. \quad (17)$$

The reference energy can be calculated using the SCF, total (SD CI) energies, and the corresponding SCF ground state coefficients of separated systems with the ghost orbitals.

For reference, let E_{SCF}^C and E_T^C be zero and c_0 one. We then obtain E_{ref} for two-body interactions:

$$E_{ref} = [b_0^2E_T^A + a_0^2E_T^B + a_0^2(1 - b_0^2)E_{SCF}^A + b_0^2(1 - a_0^2)E_{SCF}^B] \times (a_0^2 + b_0^2 - a_0^2b_0^2)^{-1} + \varepsilon, \quad (18)$$

which is equivalent to the formula proposed by Price and Stone.[5]

Results and Discussion

In all ab initio calculations, a Gaussian-type basis set [4slpld][1] for the He atom was employed. This [4slpld] set could give an improved description for the interaction potential of the He dimer by the use of the SD CI treatment and the CP method of Price and Stone.[1]

The MO calculations were performed by using the Gaussian 82 program provided by J.A. Pople et al. and the graphical unitary group approach (GUGA) program of our group.

Tables 1 and 2 indicate the interaction potentials ($E_{int}^{He_3}$) of the He trimer for two different spatial configurations: (i) an equilateral triangle and (ii) a linear configuration. The BSSE was estimated by $E_{ref}(R) - E_{SD\,CI}^{He_3}(\infty)$. R in Tables 1 and 2 designates the internuclear distance between nearest-neighbour He atoms. For a triangular configuration, Eq. 17 can be simplified to

$$E_{ref} = 3[E_T + 2(1 - a_0^2)E_{SCF}]/(3 - 2a_0^2) + \varepsilon, \quad (19)$$

where E_{SCF}, E_T, and a_0 represent the SCF, total (SD CI) energy, and the SCF ground state coefficient of the He atom with ghost orbitals. For a linear configuration, Eq. 17 can also be simplified to

$$E_{ref} = [b_0^2E_T^A + 2a_0^2E_T^B + 2a_0^2(1 - b_0^2)E_{SCF}^A + 2(a_0^2 + b_0^2 - 2a_0^2b_0^2)E_{SCF}^B]/(2a_0^2 + b_0^2 - 2a_0^2b_0^2) + \varepsilon, \quad (20)$$

where suffix A represents a He atom fixed at the

midpoint of the linear system, and a_0 is the corresponding SCF ground state coefficient. Similarly, suffix B represents the He atom at each side and b_0 the corresponding coefficient.

It can be seen from Tables 1 and 2 that the SCF energy of the He trimer system contributes to the repulsion between He atoms and that the correlation contributes to the attraction. A He dimer interaction potential ($E_{\text{int}}^{\text{He}_2}$) is also indicated in Table 1. In the dimer calculation the same [4slpld] basis set was employed and the BSSE was avoided using the reference calculation of Price and Stone. For the triangular configuration, the interaction energies were found to be about three-times larger than those of dimer calculations. On the other hand, the interaction energies in the linear configuration were almost twice the corresponding dimer energies. This difference is due to the fact that there are only two He-He nearest-neighbor interactions in the linear configuration, as opposed to three in the triangular configuration. It is appearant that the interaction potentials of the He trimer can be mainly described by the sum of two-body interactions.

Then, in order to investigate the accuracy of the interaction potentials, we calculated the three-body components of these potentials. The Three-body component could be calculated using $E_{\text{int}}^{\text{He}_3}(R)-3E_{\text{int}}^{\text{He}_2}(R)$ for the triangular configuration, and $E_{\text{int}}^{\text{He}_3}(R)-2E_{\text{int}}^{\text{He}_2}(R)-E_{\text{int}}^{\text{He}_2}(2R)$ for the linear configuration. The results are indicated in Table 3.

As can be seen from Table 3, the three-body component in the triangular configuration is positive for the whole range of calculated R. A many-body perturbation calculation of Wells and Wilson indicates a three-body component of -0.43 μa.u. (-0.14 K) at R=5.6 Bohr.[9] In their calculation, an even-tempered Gaussian basis set [8s4p2d1f] was employed and the site-site CP method was applied. Our calculated value (2.7 K at R=5.6 Bohr) is significantly larger than the many-body perturbation calculation and of opposite sign. This discrepancy is considered to be mainly due to our small [4slpld] basis set used in the interaction calculation. In fact, this [4slpld] set was optimised just to describe the interaction of the He dimer system. Therefore, the contribution of the three-body component was not included sufficiently in the trimer calculations. Thus, the $E_{\text{SD CI}}^{\text{He}_3}$ was smaller than expected.

On the other hand, the three-body component of the interaction potential for the linear configuration is much less than that for the triangular configuration. For the linear configuration, Wells and Wilson obtained a value of 0.00 μa.u. (0.0 K) at R=5.6 Bohr.[9] Since two He atoms of both sides are far separated, the three-body effect is expected to be quite small. Then, the defect of the basis set may become trivial. From Table 3 we assume that the error in the interaction potential is less than ±0.1 K; the three-body component was estimated to be -0.1—-0.3 K at R=5.6 Bohr. This result is comparable with the calculation of Wells and Wilson.

Finally, we discuss the error made in the reference calculation. It may be pointed out that the error appears in Eq. 17 in two ways. First, we consider that the error made in the approximation is almost constant and substituted it for ε, though the error is not exactly constant. Secondly, Eq. 17 overestimates the BSSE in the trimer system.[6,7] However, a serious error in the reference calculaton is not expected from the interaction calculation of the linear system. Thus, the error in Eq. 17 can be considered to be small.

Conclusion

It has been shown that a reliable interaction potential of the He trimer for the linear configuration can be obtained by the use of the SD CI treatment and a reference calculation approximated by a simple formula. This result indicates that our reference calculation for deriving the interaction potential of the three-body system from the SD CI calculation can be used in general. On the other hand, the interaction potential for the triangular configuration is less reliable compared with the linear configuration. It seems that the difference between these potentials is mainly due to the defect of the basis set employed here.

(Received October 19, 1988)

Transient absorption and resonance CARS spectra of title molecule have been observed in acetonitrile solution to show the presence of cationic pyrenyl group and anionic 9-anthryl group (or 9-anthracenecarbonyloxy group). The 337 nm UV pulse was used for the excitation. The result was combined with the linear dependence of the signals on the intensity of UV pulse to prove that the ionic radicals were produced by the intramolecular electron transfer from the locally excited pyrenyl group to the 9-anthryl group (or 9-anthracenecarbonyloxy group).

As reviewed by De Schryver et al.[1] the intramolecular exciplex formation on electron transfer, which occurs in molecules having two chromophores separated by unconjugated spacer group, have been investigated with such interests as to study the kinetics and mechanisms of intermolecular interactions under the control of separation and mutual orientation of interacting moieties,[2-6] to design and control photochemical reactions,[7,8] or to probe the structure of macromolecules.[9,10] Molecules consisting of identical halves with arylic chromophores such as 1,2-di(9- and 1-anthryl)ethane[11] or 1,3-di(1-pyrenyl)propane[4] and those in which arylic rings and *N,N*-dimethylamino group, functioning as electron acceptor and donor, respectively, are separated by alkyl chains,[2,5] have been studied extensively. The use of alkyl chains as spacer group sometimes poses problem in defining the separation and orientation of the two chromophore groups bacause of low barrier of internal rotation around the carbon–carbon single bonds of alkyl chain, and the investigation of cyclophanes[12,13] or bridged molecules[3] were made to avert this problem by rigidly fixing the chromophores. Vanderauwera et al. carried out an experiment[2] in which alkyl ester groups with various chain length were used to separate dimethylamino group and 9-anthryl group. Aromatic esters are characterized by the C–O single bond where the alkyl group and carbonyl oxygen are in cis conformation and the carbonyl, *O*-alkyl bond, and aryl rings are coplanar. Combining this with the flexibility of alkyl chain, Vanderauwera et al. adjusted the separation between the chromophores by the length of alkyl chain in their investigation of the kinetics of intramolecular exciplex formation and electron transfer in the series of ω-(dimethylamino)alkyl esters of 2-anthracenecarboxylic acid.

Recently, however, the present authors (M. I. and K. T.) have unveiled several unexpected features in the photochemical behavior of 1-pyrenylmethyl 9-anthracenecarboxylate;[4] broad emission band was observed for the solution (10^{-5} M; 1 M=1 mol dm^{-3}) in polar solvent (acetonitrile) when either the pyrenyl (at 313 nm) or the anthracene (at 365 nm) moieties were excited by UV pulse, the intensity of the excitation with respect to that of fluorescence by locally excited species increased monotonically from 200 K to 293 K, and the broad emission of the solution in nonpolar isooctane was asymmetric and double-peaked.

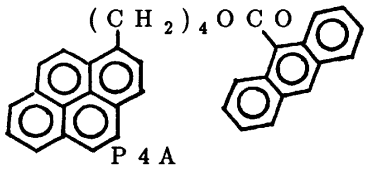
In this paper we describe about the combined use of transient resonant CARS and transient absorption spectroscopy to the characterization of one-photonically produced ionic radical group.

It should be mentioned that the analysis of fluorescence and exciplex emission spectra has been the principal tool for the investigation of the intramolecular exciplex formation and electron transfer, and even in those papers that reported on the transient absorption spectrum of ionic species the possibility that the ionic species can also be produced from the two-photon processes was overlooked, thus the experimental verification of the one-photonical production of ionic species has been lacking.

Transient absorption and the transient resonance Raman spectra have been used for the study of photoinduced species. The resonance Raman effect is particularly useful because we get information of the molecular vibrations in the electronic state. The CARS (coherent anti-Stokes Raman spectroscopy) is a nonlinear Raman spectroscopy having its exclusive advantage for the observation of luminous samples because conventional resonance Raman spectroscopy is not operative in such samples. The vibrational spectrum of the various transient species produced in photoexcited pyrene has been studied by this method.[15,16]

Present study of transient absorption and transient resonance CARS spectra was undertaken to get solid evidence for the occurrence of intramolecular electron

transfer and to investigate the direction and degree of the transfer that takes place between the two chromophores in the UV excited 4-(1-pyrenyl)butyl 9-anthracenecarboxylate (**1**) that is abbreviated as P4A hereafter.



P 4 A

The absorption spectrum of P4A as well as those of other 1-pyrenylalkyl 9-anthracenecarboxylates studied so far exhibits the feature that is the 1 : 1 superposition of the spectra of 1-pyrenylmethanol and 9-anthracenecarboxylic acid, with just slight shifts by a few nm in peak positions, indicating the absence of any specific interaction between the chromophores in the ground state.[14]

Experimental

The preparation of purified sample has been described elsewhere.[14] The purified P4A was dissolved in acetonitrile (spectrograde) to make the sample solution of 10^{-3} M concentration.

The output beam of an N_2 laser (Molectron UV-24) with output power of 9 mJ/pulse and duration time of 10 ns was used both to excite the sample and to pump the dye lasers. No time delay was imposed between the UV and dye laser pulses. The confirmation that the observed signals originated from the transient species of P4A and not from the decomposition products was made by examining the absorption spectrum taken after the experiment. The transient absorption spectrum was obtained by alternately blocking the UV pulse that excited P4A and comparing the intensity of the transmitted dye laser with and without the irradiation by the UV pulse. The two laser beams were adjusted so that the transient absorption was maximal. The intensity I of the transmitted dye laser beam with the UV beam irradiating the cell was divided by the intensity I_0 that is the value recorded without the irradiation at various wavelengths of the dye laser. The derived values of $\log(I_0/I)$ for the deaerated solution are plotted against wavenumber in Fig. 1a for the region where the spectrum of pyrene cation radical is expected. Figure 1c shows the result of the observation in the region where the absorption by anthracene anion radical is expected. Partly owing to the lower sensitivity of the used photomultiplier and the lower intensity of the dye laser output in the longer wavelength region, the observation in the region failed to give distinct absorption peak although the presence of transient absorption was evident from the attenuation of the laser beam on the excitation by UV light.

The procedure for the transient resonance CARS experiment has been described in our previous paper.[15] Briefly, two dye lasers pumped by the N_2 laser were used when ω_1 beam (pump beam) was set resonant with the transient absorption while ω_2 beam (probe beam) was scanned over the range where the difference $\omega_1-\omega_2$ varied from 1000 to 1700 cm^{-1}.

The dependence of both the transient absorption and the resonance CARS signals on the power of excitation UV beam was measured by attenuating the UV beam. The sets of filters with 76% transmission per sheet at 337.1 nm were used.

Results and Discussion

Transient Absorption Spectrum. The transient absorption spectra observed on the photoexcitation of pyrene have been reported by several authors. Post et al. reported the observation of absorption peaks at 19500 cm^{-1} and 21200 cm^{-1} that they assigned to $S_n \leftarrow S_1$ and $S_m \leftarrow S_1$ bands, respectively.[17] The $T_n \leftarrow T_1$ absorption band at 24000 cm^{-1} was reported by the same authors and by Grellmann[18] who also reported on the absorption spectra of anion and cation radicals of pyrene at 20400 cm^{-1} and 22500 cm^{-1}, respectively. Siomos and Christophorou verified that the ion radicals are produced by two-photon ionization and gave the value of 38700 cm^{-1} as the threshold energy of the process.[19] Typical results of our observations of the transient species of pyrene are reproduced in Fig. 1b.

We find from the comparison of Figs. 1a and 1b that the transient absorption spectrum of P4A exhibits close resemblance with that of pyrene in methanol. Considering that the fluorescence lifetime of the S_1 state of pyrene is longer than 100 ns and that the related molecule P1A was found to give the emission with the quantum yield of about 1% and the emission lifetime of less than 1 ns,[14] it is expected under the present experimental condition that the sample contained such transients as the species in which the pyrenyl group was locally excited to the S_1 state, the species where the pyrenyl group was in the lowest triplet state T_1 and the ones that had undergone the intramolecular electron transfer with or without the formation of exciplexes. We thus associate the peaks at 23800 cm^{-1} and 20000 cm^{-1} in Fig. 1a with the pyrenyl-localized $T_n \leftarrow T_1$ and $S_m \leftarrow S_1$ absorption bands, respectively, and the peak at 21500 cm^{-1} is assigned as the overlap of pyrenyl-localized $S_n \leftarrow S_1$ band and the absorption band of cationic pyrenyl group. The presence of cationic pyrenyl group was confirmed by the CARS experiment as described below. The formation of the T_1 species of P4A was verified by the observation of the resonance (ω_1=23750 cm^{-1}) CARS signal at 1365 cm^{-1} that corresponds to the intense Raman band of pyrene in the T_1 state. We note that the $T_n \leftarrow T_1$ absorption of P4A shows up in both the deaerated and air-saturated solutions while the band of pyrene is observed only in the air-saturated solution. The reason for the appearance of the $T_n \leftarrow T_1$ band of pyrene in only air-saturated solutions

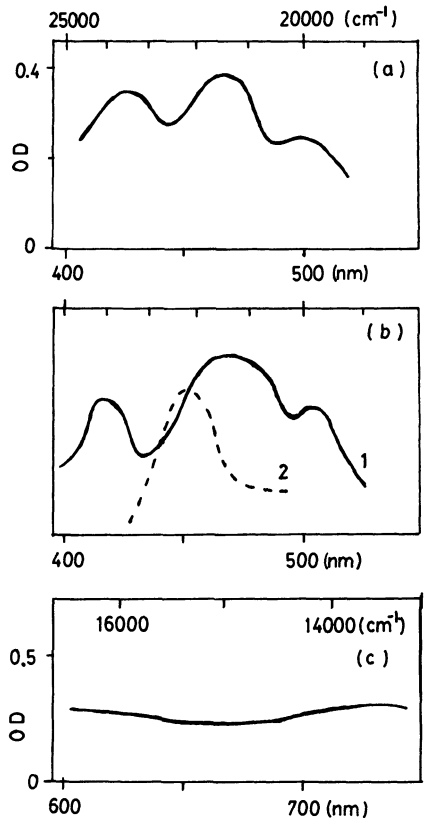


Fig. 1. Transient absorption spectra of the photoproduced transient species of P4A and pyrene. (a): the spectrum from 400 to 550 nm of the deaerated solution of P4A in acetonitrile (10^{-3} M concentration) under the irradiation of UV pulse at 337.1 nm, (b): the spectra from 400 to 550 nm of the UV produced transient species of molecular pyrene and curve 1 is the spectrum observed in air-saturated methanol solution in which the S_1 and T_1 species of pyrene are present and curve 2 is the spectrum of pyrene cation radicals that were produced in the aqueous micellar solution of hexadecyltrimethylammonium bromide, and (c): the spectrum observed from 600 to 740 nm region for the same system as described in (a). The UV pulse at 337.1 nm having the pulse duration time of 10 ns and the repetition rate of 10 pps was used throughout.

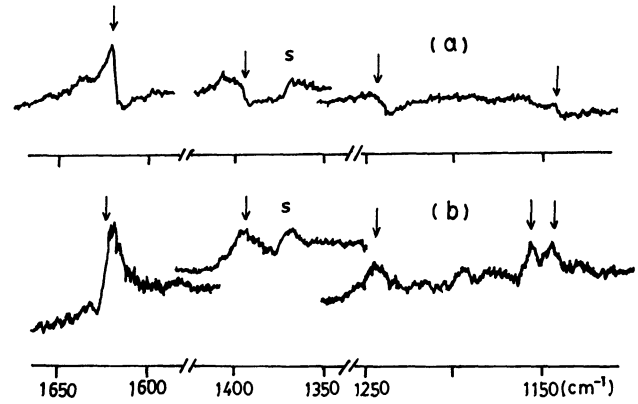

Fig. 2. Transient resonance CARS spectra of P4A in deaerated acetonitrile solution (10^{-3} M concentration) observed when the solution was irradiated by 337.1 nm pulse under the conditions (a): ω_1= 21000 cm^{-1} and (b): 21800 cm^{-1}. Arrow and s denote the Raman bands of the transient species and the solvent molecule, respectively.

is attributed as owing to the dissolved oxygen working as the effective promoter of intersystem crossing. The present observation suggests that the production pathway of the T_1 state from the S_1 state, both localized to the pyrenyl group, of P4A is different from that of pyrene.

Anthracene anion radical has been known to have the peak of the absorption band at 13700 cm^{-1} (730 nm).[20] Actually, the question whether the ionic moiety of the present transient is either the 9-anthryl group, 9-anthracenecarbonyl group, or 9-anthracenecarbonyloxy group remains to be solved and we expect that absorption peak may be shifted outside the present observation for latter two groups. In any event, it is likely that the obvious absorption giving the change of 0.3 in the optical density under the optical pass length of 1 mm in the region.of 730 nm in P4A (see Fig. 1c) originates from one of the above-mentioned species.

Transient Resonance CARS Spectrum. The resonance CARS spectrum of P4A was observed by setting the ω_1 beam resonant with the transient absorption band at 21500 cm^{-1}. Figures 2a and 2b show the results for the settings of ω_1=21800 cm^{-1} and ω_1=21000 cm^{-1}, respectively. From Figs. 2a and 2b one notes that the Raman band at 1622 cm^{-1} shows dispersion dips on mutually opposite side of the peak. The feature shows that one-photon electronic resonance effect is at work on the totally symmetric vibrations and that of the absorption band is the 0–0 band origin located near 21500 cm^{-1}. The wavenumbers of the observed six Raman bands that showed up only when the UV light was incident are listed in the first column of Table 1. The reported values of pyrene in various states are also listed in the following columns. The present result is close to the reported values of the Raman shifts for the cation radical of pyrene that has been produced by UV-irradiation of pyrene in such systems as acetonitrile, methanol, cationic micelle, and pyrene–dicyanobenzene in acetonitrile solutions.[15] It should be noted that the Raman frequencies of the present study were obtained under electronically resonant condition and thus the participation of the pyrenyl group in the ground state can be disregarded.

The behavior of the CARS signals by the change of the intensity of UV light was examined to prove that the signals were associated with the cationic pyrenyl group and not with either the free pyrenyl cation radicals that could have resulted from two-photonic ionization or the photofragmented pyrenyl radicals.

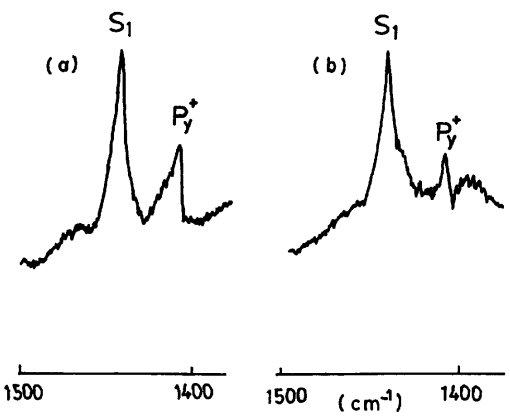

Fig. 3. The effect of UV power on the transient CARS signal of photoproduced species of pyrene under ω_1=21800 cm^{-1}; (a) without attenuation and (b) under attenuation by about 50% of UV power. The methanol solution (10^{-3} M) of pyrene were used for the measurement and the signals from the one-photon excited S_1 species and that from the two-photon ionized pyrene cation radical (marked by S_1 and P_y^+, respectively) are seen to exhibit distinctly different dependence on the intensity of UV pulse.

Figure 3 shows the population change in the pyrene/methanol system as observed on the resonance CARS signals of the pyrene cation radical and the S_1 state species. The frequency of ω_1 was set at 21800 cm^{-1}. The signal at 1445 cm^{-1} originates from the S_1 state of pyrene produced by one-photon excitation and the signal at 1410 cm^{-1} is from the pyrene cation radical that is produced by two-photon ionization. Figure 3 shows that the relative intensity of the two CARS signals changed by the intensity of UV excitation and the change evidently resulted from the difference in the population processes of the two species; the production of S_1 species by one-photon processes vs. the two-photon process to produce the cation radical. Figure 4 shows the decrease of CARS signal of cationic pyrenyl group in P4A at 1396 cm^{-1} (marked by arrow) and that of solvent acetonitrile (marked by s) when the UV power (at 337.1 nm) was attenuated by 0%(a), 58%(b), and 100%(c). Figures 4d—4g are the results of computer simulation. Of three components of CARS susceptibility, the Raman nonresonant background term and the term that is resonant to the Raman band of solvent molecule stay constant of the intensity of UV radiation and their relative magnitude was determined by simulating the feature of Fig. 4c to give the curve shown in Fig. 4f. The term causing the 1396 cm^{-1} band is proportional to the population of photoproducts and its relative magnitude with respect to other terms was determined for the condition that gives the trace in Fig. 4a and the trace shown in Fig. 4d was derived from the simulation. The attenuation of UV power causes the

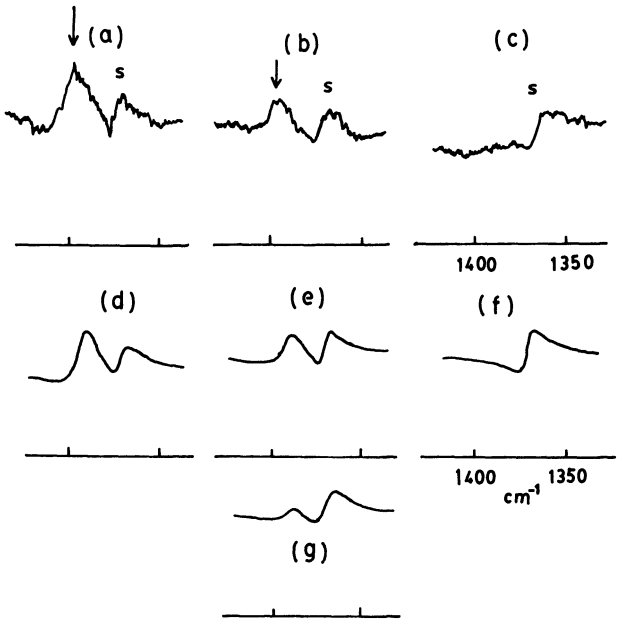

Fig. 4. The UV-power-dependent variation of the observed and simulated features of the CARS spectrum in the region where the resonance CARS signal of photoexcited P4A (marked by arrows) and the CARS signal of solvent acetonitrile are observed. The signals observed under the attenuation of UV power by 0%, 58%, and 100% are shown in (a), (b), and (c), respectively, while the simulation was made by using the traces in (a) and (c) as references giving the reference curves of (d) and (f), respectively, and the theoretical curves of (e) and (g) were obtained for the cases when the population of the transient species changes linearly (e) and quadratically (g), with intensity of UV pulse.

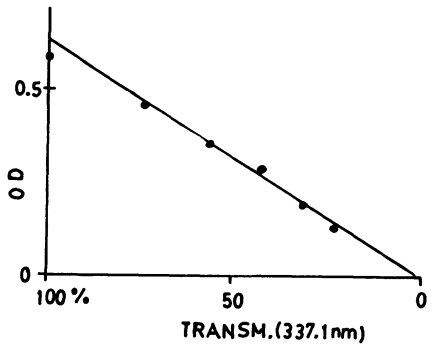

Fig. 5. Plot of the change in the intensity of transient absorption at 21800 cm^{-1} by the intensity of UV irradiation. Linear increase of the absorption with increasing UV power is derived from the plot.

population of the photoproduced species to decrease leading to the change in the spectral profiles. Figures 4e and 4g are the results of the simulations for the linear and quadratic dependencies, respectively, of the population on UV power, and we note that Fig. 4e is the better reproduction of the observed feature of Fig. 4b.

The frequency (21800 cm^{-1}) of the ω_1 beam is inside the absorption band of transient cationic species and the intensity of the ω_1 beam changed by the intensity of UV beam. The intensity of the ω_1 beam at the point through the sample is plotted in Fig. 5 against the UV power used for the photoexcitation where the intensity of ω_1 beam is expressed in the unit of optical density of the sample. The linear production of the cationic pyrenyl radicals with respect to the intensity of UV beam as verified above is in clear contrast with the two-photonic production of the pyrene cation radicals.

The overall feature of the transient absorption spectrum of P4A in the acetonitrile solution resembles that of UV-irradiated pyrene in methanol where the signals from both the cation radical and the S_1 state of pyrene have been observed. The resonance CARS signals of only the cationic pyrenyl group were, however, observed in the present sample, suggesting the different processes of the production of cationic species in the two systems.

The present result points to the conclusion that the cationic species in P4A resulted by the internal conversion and successive intramolecular relaxation from one-photonically excited Franck–Condon state of pyrenyl group. We have also mentioned from the observation of weak yet distinct transient absorption around 730 nm region that either the anthryl group or the anthracenecarbonyloxy group in P4A acquired anionic nature following the photoexcitation of pyrenyl group. Hence the present observation is a direct indication that the pyrenyl group becomes cationic through the intramolecular electron transfer of nearly unit charge from the locally excited 1-pyrenyl group to the 9-anthryl group (or 9-anthracenecarbonyloxy group). Although the attempt to observe the transient CARS signal of negatively charged anthryl group failed owing to small electronic resonance effect and the technical difficulty in obtaining enough power of the dye lasers in the near infrared region, the present picture of intramolecular transfer of an electron from pyrenyl to anthryl group (or anthracenecarbonyloxy group) fits the model that was presented in Ref. 14, that is, through-bond electron transfer takes place before the Coulombic attraction between the two oppositely charged moieties enables the rotation around the C–O bond to let the s-trans conformation of P4A in ground state change into s-cis conformation that is necessary for the formation of stable intramolecular exciplex with two chromophores sitting in face-to-face conformation. The Coulombic attraction is needed to overcome the potential barrier of about 50 kJ mol^{-1} lying expectedly between the two conformations.

In conclusion, the occurrence of intramolecular electron transfer from the locally excited 1-pyrenyl

group to the 9-anthryl group (or 9-anthracenecarbonyloxy group) in the acetonitrile solution of P4A has been confirmed from the observation of transient absorption and resonance CARS spectra. Further work is under way to solve the remaining questions such as if the species under study was identical with the species for which the broad exciplex-like emission band was observed and if the two chromophores are of elongated end-to-end conformation or of sandwitch type. The undertaken experiments on related molecules and of time-resolved spectroscopy are expected to provide further informations on the chemical and physicochemical characteristics of bichromophoric carbohydrates.

Studies of Liquid Water by Computer Simulations. VI. Transport Properties of Carravetta-Clementi Water

Yosuke KATAOKA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received October 24, 1988)

The micro canonical molecular dynamics simulations of liquid water were performed at different temperatures and densities in order to investigate the anomalies of the transport coefficients. The nonempirical Carravetta-Clementi potential was used for the system with 216 molecules in a cubic cell. The order of magnitude of the nonempirically calculated self-diffusion coefficient, shear viscosity, bulk viscosity, and thermal conductivity were in agreement with experimental results. These transport properties were recognized as anomalous as in real liquid water. The temperature-dependence of these quantities was in agreement with the observed values under pressure of 50 MPa. The effects of compression on these transport coefficients were reproduced qualitatively. The obtained bulk viscosity was larger than the shear viscosity at low temperatures in accordance with experiments. The contribution of rotational motion to thermal conductivity seems to be responsible for the anomalous temperature-dependence of thermal conductivity. Several decay constants of the time correlation functions were obtained. The frequency spectra of the correlation functions were discussed. No marked molecule number dependence was observed in the calculated transport coefficients of Matsuoka-Clementi-Yoshimine water.

We have carried out the molecular dynamics (MD) simulation to study the effect of density and temperature on the transport properties of liquid water. This problem was examined in the fourth paper[1] of this series by a simplified 2-dimensional water-like model.[2,3] Although most of the transport properties were reproduced qualitatively, the maximum of thermal conductivity as a function of temperature was not verified.[1]

In the preceding paper[4] we showed that the anomalous thermodynamic properties observed experimentally are nonempirically reproduced on a semi-quantitative level with Carravetta-Clementi (CC) potential.[5] Our study on the liquid-vapor interface of CC water gave reasonable thermodynamic properties.[6] For these reasons we will report in the present paper on MD simulations with CC potential to examine the transport properties of liquid water.

The most interesting characteristics of the transport properties of liquid water are summarized as follows:[7] The initial application of pressure decreases the viscosity and increases the self-diffusion coefficient below about 300 K. The thermal conductivity of liquid water has a maximum as a function of temperature under a constant pressure. Although the density dependence of the self-diffusion coefficient was already studied by MD,[8-14] it seems that the viscosity and the thermal conductivity of liquid water have been studied only at normal conditions (at room temperature and volume, $V=18\ \mathrm{cm^3\ mol^{-1}}$).[13] Therefore, we are going to perform MD simulations at different temperatures and densities. Transport coefficients were calculated by the standard Kubo formula.[15-17]

The dynamical properties of liquid water were studied by Matsuoka-Clementi-Yoshimine (MCY) potential[18] at several state points by Impey et al.[9] They showed that the main features of spectroscopic and transport properties of real water are interpreted by their MD simulations, although some spectra are not reproduced. The collective dynamics in MCY and three body water was studied by Wojcik and Clementi.[13] The calculated shear viscosity is well compared with the experimental value at room temperature and normal density. For this reason, MCY potential is one of the most promising models in the study of transport properties of liquid water. We will further survey the fluid state over a wide range of temperature and density. For such purpose, CC potential is more convenient than MCY model, because the equation of state of CC water has been given by us.[4]

In the fourth paper of this series,[1] we used the constant temperature-pressure MD,[19,20] because this method is more convenient to obtain temperature dependence or pressure dependence of the system. We found, however, that the bulk viscosity obtained by the constant pressure MD is wrong.[1] The value of the shear viscosity calculated by constant temperature-pressure MD seemed to scatter more than that by the micro canonical MD.[1] For this reason the micro canonical MD method is used in this paper.

The molecule number dependence of the transport coefficients was examined with MCY water.[18] The transport coefficients of the systems with 216 and 1000 molecules were compared with the Wojcik and Clementi's result on a 512-molecule system.[13]

The contribution of rotational motion to thermal conductivity is calculated in order to examine the origin of the anomalous temperature dependence. The decaying and oscillatory characters of the time correlation functions related to the transport coefficients are analyzed and compared with those of simple liquids.[21-29]

Molecular Dynamics Calculations

The molecular dynamics method is essentially the same as the previous one.[4] The program MDMPOL coded by Smith and Fincham[30] is used as the basis of the present program. The program calculates the time evolution of the system using a leapfrog algorithm for the center of mass motion and a leapfrog-quaternion algorithm for the angular motion. The electrostatic forces and energy were calculated by the Ewald method. The short range terms were cut off at half of the MD cell width for the 216-molecule system. When the system has 1000 molecules, the cutoff distance is the same as that of the 216-molecule system of the same number density. The cpu time was 0.23 and 1.3 s/step for 216- and 1000-molecule systems respectively by FACOM VP-400E vector processor at Kyoto University Data Processing Center, which includes the calculations of stress tensor components and heat currents.

The time step in this work was 0.5 fs. The root mean square fluctuation of the total energy was less than 0.02% in the case of 40000-step run. The initial data at each state were those of the aged state obtained by the previous calculations.[4] The 18000-, 24000-, or 40000-step runs were repeated several times, from which the molecular dynamics statistical averages were obtained.

The self-diffusion coefficient D was calculated from the mean square displacement $<\Delta r^2>$ and the velocity auto-correlation function given below:[31]

$$D = \lim_{t\to\infty} \frac{<\Delta r^2>}{6t} \tag{1}$$

and

$$D = \frac{1}{3}\int_0^\infty <\boldsymbol{v}(t)\cdot\boldsymbol{v}(0)>\mathrm{d}t. \tag{2}$$

The shear viscosity η_S and the bulk viscosity η_B were calculated by the standard Kubo type formula:[15–17]

$$\eta_s = \frac{1}{\kappa_B TV}\int_0^\infty <J^{xy}(t)J^{xy}(0)>\mathrm{d}t, \tag{3}$$

$$\eta_B = \frac{1}{9\kappa_B TV}\sum_{\substack{\alpha=x\\ \beta=x}}^{z}\int_0^\infty <[J^{\alpha\alpha}(t) - <J^{\alpha\alpha}>]\cdot[J^{\beta\beta}(0) - <J^{\beta\beta}>]>\mathrm{d}t, \tag{4}$$

$$J^{\alpha\beta} = M\sum_{i=1}^{N} v_{i\alpha}v_{i\beta} + \sum_{i=1}^{N} r_{i\alpha}f_{i\beta}, \tag{5}$$

where M is the mass of the molecule, v_i the velocity of the i-th molecule, r_i means the position of the i-th molecule, and f_i is the force that the i-th molecule feels. The suffix α means the α-component of the vector. The Boltzmann constant, temperature, volume, and number of molecules in the basic cell are written as κ_B, T, V, and N, respectively.

The thermal conductivity λ was calculated by the correlation function of the heat current $\boldsymbol{S}(t)$:[15–17]

$$\lambda = \frac{1}{3\kappa_B T^2 V}\int_0^\infty <\boldsymbol{S}(t)\cdot\boldsymbol{S}(0)>\mathrm{d}t \tag{6}$$

and

$$\boldsymbol{S}(t) = \frac{\mathrm{d}}{\mathrm{d}t}\sum_{i=1}^{N} H_i\boldsymbol{r}_i, \tag{7}$$

where H_i is the contribution of the i-th molecule to the total Hamiltonian of the system $\mathscr{H}$:

$$\mathscr{H} = \sum_{i=1}^{N} H_i$$

and

$$H_i = K_{\mathrm{TRANS}}(i) + K_{\mathrm{ROT}}(i) + \frac{1}{2}\sum_{j=1}^{N} U_{ij}, \tag{8}$$

where $K(i)$ is the kinetic energy and U_{ij} is the molecular interaction energy between molecule i and j.

The representative range of the time integration of the correlation function is $0 \leqq t \leqq 1$ ps. The averages of at least 14000 values were taken for the initial time. An example of convergence characteristics is shown in Fig. 1 for shear viscosity. It is seen that the cumulative average is stable although the partial average scatters.

Molecule Number Dependence

As the first step, we are going to see whether 216 molecules are enough for the calculation of transport coefficients. For this purpose, the coefficients of the 216-, 512-, and 1000-molecule system are compared with each other. Wojcik and Clementi[13] gave the results on the 512-molecule system with MCY potential[18] at normal conditions. The systems with 216 and 1000 MCY molecules are compared with their results

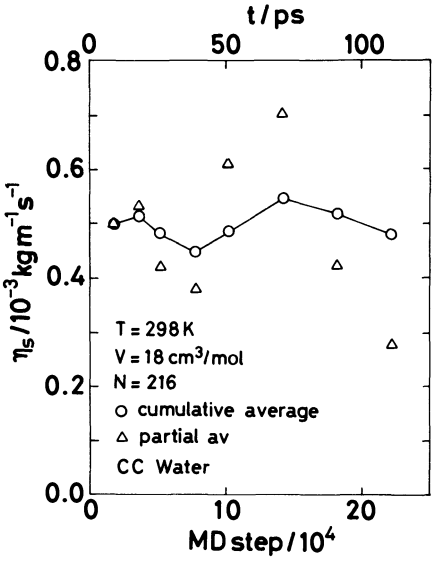

Fig. 1. Convergence characteristics of the shear viscosity.

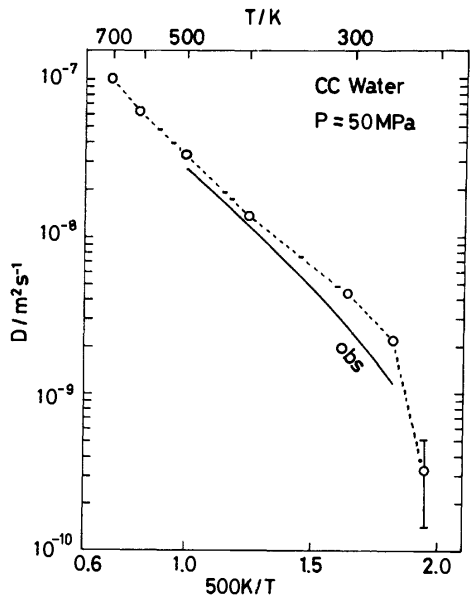

Fig. 3. The self-diffusion coefficient D is plotted against 500 K/T, where pressure P is about 50 MPa. The experimental results at P=50 MPa are shown by the solid line.[35-39]

in Table 1. No marked molecule number dependence is seen in this table. Hence, the basic cell with 216 molecules has been employed hereafter because of simplicity.

Table 1 also includes the coefficients of CC water. They are not so different from those of MCY water. As we have obtained the equation of state (EOS)[4] for CC model, we use CC potential[5] hereafter.

The values of Kirkwood orientational correlation factor G_K are also given, although they are preliminary; it is known that very long MD run is needed to evaluate this quantity.[32-34] These are obtained as follows:

$$G_K = <(\sum_{i=1}^{N} \mu_i)^2>/N, \quad (9)$$

where μ_i is the unit vector along the dipole direction of molecule i. The obtained values of G_K for MCY and CC water were small compared with the experimental values.[32] A similar result on MCY water was given by Neumann.[32]

Temperature and Volume Dependence

In this section, the calculated transport coefficients are compared with the experimental results. We carried out many MD simulations of the 216-molecule system with CC potential[5] in order to examine the temperature and density dependence of the transport coefficients as shown in Fig. 2. Some state points correspond to the states with pressure P of about 50 MPa. The others were selected around the normal density (V=18 cm^3 mol^{-1}).

The calculated self-diffusion coefficient D is plotted against the inverse of temperature T in Fig. 3 by circles where pressure P is about 50 MPa. The experimental results at P=50 MPa are shown by the solid line.[35-39] The calculated D is in agreement with the observed one with respect to the temperature dependence. The

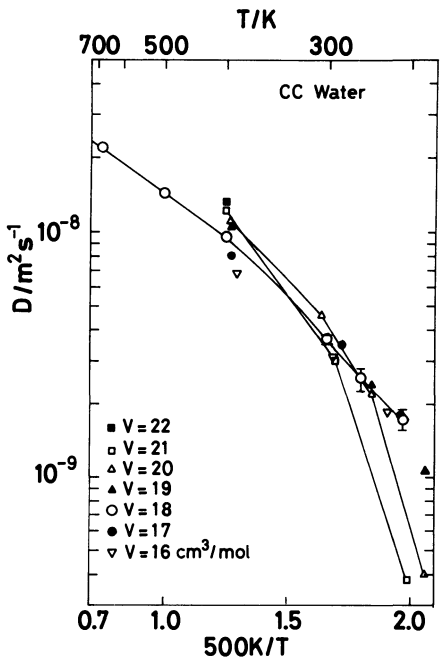

Fig. 4. The self-diffusion coefficient D is plotted against 500 K/T at several volumes.

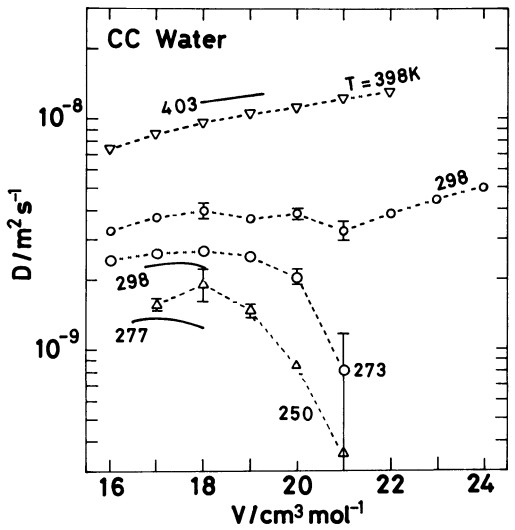

Fig. 5. The self-diffusion coefficient D is plotted against volume V at several temperatures. The experimental results are shown by the solid lines.[35-39]

calculations were repeated at different densities as seen in Fig. 4, where the setting temperatures were 260, 273, 298, 398, 500, and 700 K. As each average temperature was different from set temperature, the self-diffusion coefficients were obtained by interpolation as a function of temperature at each volume. The volume dependence of D obtained is shown in Fig. 5. The anomaly of the self-diffusion coefficient is semi-quantitatively reproduced as shown in Fig. 5. At lower temperatures, D has a maximum around volume V of

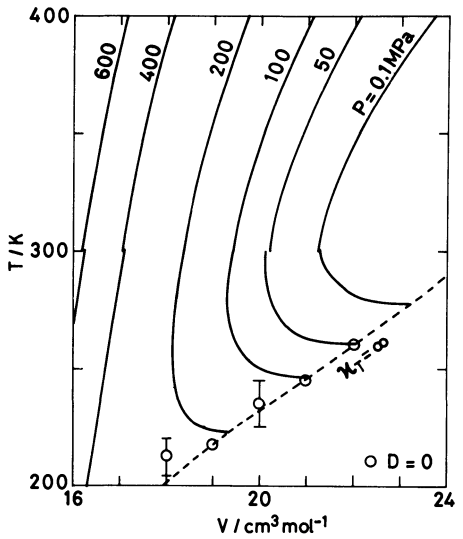

Fig. 6. The equation of state in the T-V plane. Above 300K the G-type EOS is used and below 300K the L-type EOS is shown.[4] The stability limit of the liquid phase is drawn by the dashed line.[4] The temperature where D is equal to zero at each volume is shown by circle.

18 $cm^3 mol^{-1}$ at a given temperature. Because the volume of the low density ice with CC potential is 11% larger than the observed one,[4] the volume with the maximum D at a given temperature varies correspondingly.

In this paper, the nonempirical calculation of the transport coefficients is intended; scaling of volume or adjusting have never been tried. The pressure effect on the self-diffusion coefficient of liquid water has been examined by a simple water-like model[1] and also by TIP4P model.[11]

When temperature is decreased, the self-diffusion coefficient D tends to approach to zero at a finite temperature under constant pressure as seen experimentally.[40] This temperature was discussed with the anomaly of the thermodynamic and transport properties of supercooled liquid water.[40-42] In the previous paper this temperature was assigned to the stability limit of liquid phase.[4]

Now we are going to see the relation between the stability limit of the liquid phase and the temperature of zero diffusion coefficient in this calculation.[43] We can get the temperature of zero D in the condition of fixed density as shown in Fig. 4. We used linear extrapolation for the D vs. T plot. The result is shown in Fig. 6. The circle means the temperature where D is equal to zero and the dotted line is the stability limit of the liquid phase obtained by the L-type equation of state.[4] We see that the zero D points are almost on the stability limit within the error bar. This means that the present calculations on the self-diffusion coefficient are consistent with the static properties obtained before.[4]

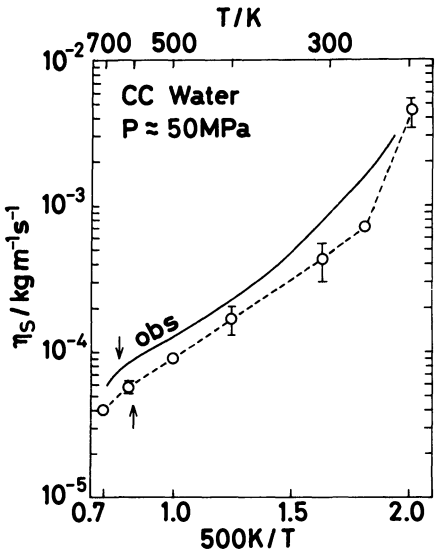

Fig. 7. The shear viscosity η_s is plotted against 500 K/T, where pressure is about 50 MPa. The experimental results at P=50 MPa are shown by the solid line.[44-50] An arrow indicates the critical temperature.

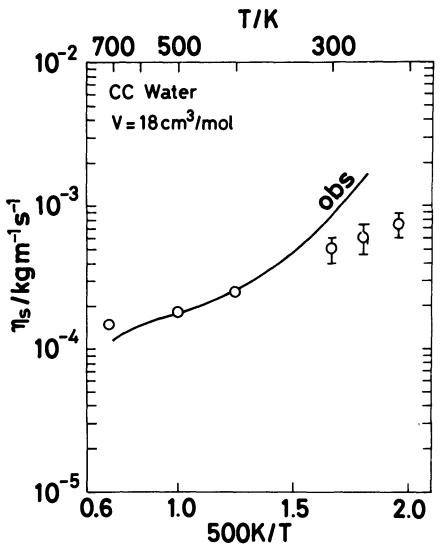

Fig. 8. The shear viscosity η_s is plotted against 500 K/T, where volume is 18 cm^3 mol^{-1}. The experimental results at V=18 cm^3 mol^{-1} are shown by the solid line.[44-50]

The shear viscosity η_s is plotted against the inverse of temperature in Fig. 7, where pressure P is about 50 MPa, and in Fig. 8 with the condition of the normal density (V=18 cm^3 mol^{-1}). The experimental results at P of 50 MPa are shown by solid line.[40-50] As regards the temperature dependence in Fig. 7, the obtained shear viscosity is in agreement with the observed one. Under the condition of normal density (Fig. 8), the calculated shear viscosity is a little smaller than the experimental results below room temperature. This can be understood qualitatively by the facts that the

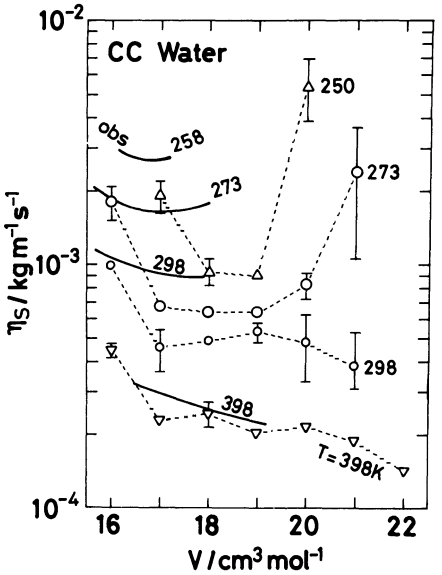

Fig. 9. The shear viscosity η_s is plotted against volume at several temperatures. The experimental reults are shown by the solid lines.[44-50]

shear viscosity of real liquid water at low temperatures has a minimum around P of 2×10^2 MPa as a function of pressure[7] and that the pressure is 2×10^2 MPa at room temperature by the present model.[4]

The volume dependence of η_s at several temperatures is shown in Fig. 9. This was obtained by interpolation as in the case of D. We see that the calculated shear viscosity has a peculiar volume dependence at low temperatures as observed in real water.[40-50] This property is shown much more clearly by the present simulation than in real water because our calculation includes the supercooled and/or minus pressure region. At a given temperature below room temperature, the volume of minimum viscosity is 18.5±0.5 cm^3 mol^{-1}, which is different a little from the observed one (around 17 cm^3 mol^{-1}). This comes from the reason that the length of hydrogen bond of the CC potential is larger than the observed one (see Table IV of Ref. 4).

The bulk viscosity η_B at normal density is plotted against the inverse of temperature in Fig. 10. The order of magnitude of the calculated values around room temperature is in agreement with the observed one.[51-53] As the bulk viscosity η_B is usually discussed by the ratio η_B/η_s, this quantity is plotted as a function of temperature in Fig. 11, where pressure is about 50 MPa for the calculation and the experimental results were obtained under normal pressure. Because of the large fluctuation of the virial term, the bulk viscosity at low temperatures was difficult to calculate in our case. The ratio η_B/η_s was larger than 1 below 500 K in accordance with the observed results.[51-53] The present calculation predicts that this quantity is less than 1 at higher temperatures, around or above the

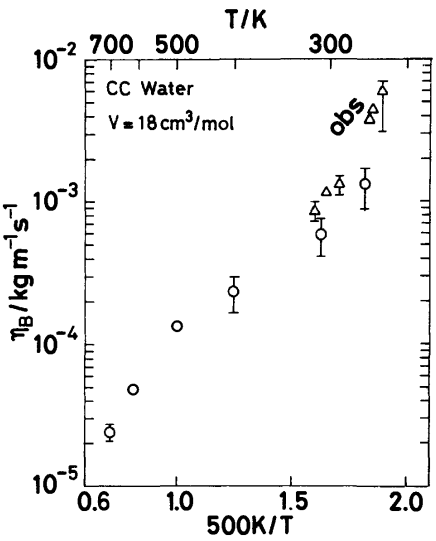

Fig. 10. The bulk viscosity η_B is plotted against 500 K/T, where volume is 18 cm^3 mol^{-1}. The experimental results are shown by the triangles.[51-53]

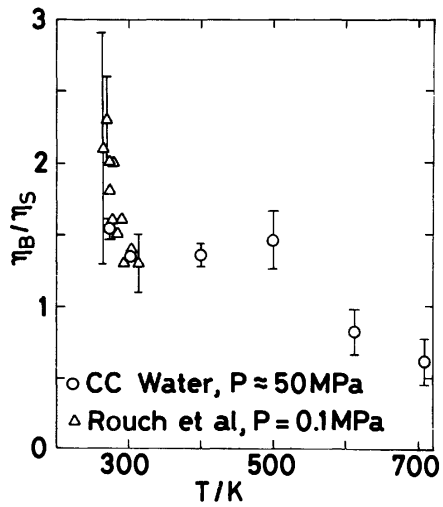

Fig. 11. The ratio η_B/η_s is plotted against temperature, where pressure is about 50 MPa for the calculation. The triangles show the experimental results[51-53] under normal pressure.

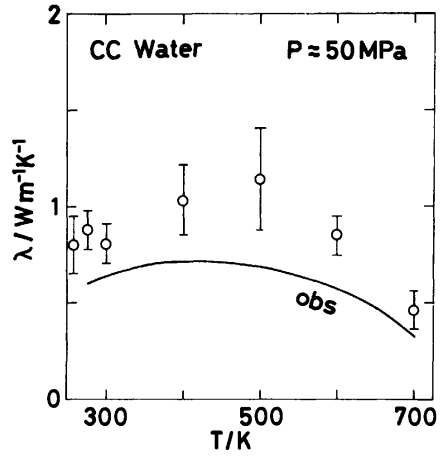

Fig. 12. The thermal conductivity λ is plotted against temperature, where pressure P is about 50 MPa. The experimental results at P=50 MPa are shown by the solid line.[50,54,55]

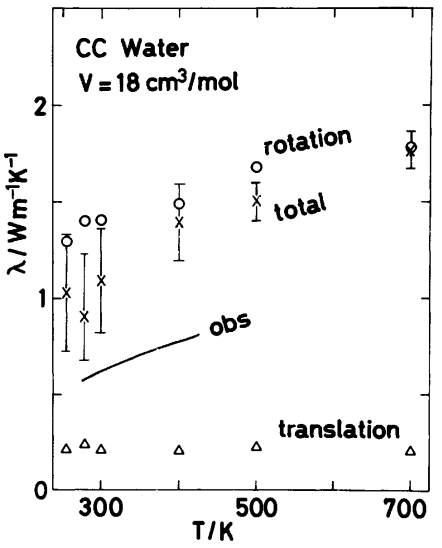

Fig. 13. The thermal conductivity λ is plotted against temperature, where volume is 18 cm^3 mol^{-1}. The cross means the total conductivity. The contribution from rotation and translation are plotted by circle and triangle respectively. The experimental results at V=18 cm^3 mol^{-1} are shown by the solid line.[50]

critical temperature (603 K for CC water).

The calculated thermal conductivity λ is shown as a function of temperature by open circle in Fig. 12, where pressure is about 50 MPa. We see that the present result is in agreement with the observed one at P of 50 MPa shown by the solid curve.[50,54,55] The thermal conductivity decreases as temperature increases above 500 K, because the density decreases abruptly around the critical temperature. So the essential point of anomaly in the thermal conductivity of liquid water is its increasing property with temperature at constant density. For this reason the thermal conductivity is plotted against temperature under the condition of normal density (V=18 cm^3 mol^{-1}) in Fig. 13. The cross indicates the calculated thermal conductivity at normal density, which is to be compared with the observed result shown by the solid curve at the same density.[50] The order of magnitude and the temperature dependence of the present values are in agreement with experiments.

In order to see the origin of this anomaly, partitioning of the thermal conductivity is tried as follows. The heat current $S(t)$ was divided into three parts, which are tentatively called translational, rotational, and molecular Hamiltonian part;

$$S(t) = S_{TRANS}(t) + S_{ROT}(t) + S_{MH}(t), \qquad (10)$$

$$S_{\mathrm{TRANS}}(t) = \sum_{i=1}^{N}\{\frac{\mathrm{d}K_{\mathrm{TRANS}}(i)}{\mathrm{d}t} + \frac{1}{2}\sum_{i=1}^{N}(\frac{\partial U_{ij}}{\partial x_j}\frac{\mathrm{d}x_j}{\mathrm{d}t} + \frac{\partial U_{ij}}{\partial y_j}\frac{\mathrm{d}y_j}{\mathrm{d}t} + \frac{\partial U_{ij}}{\partial z_j}\frac{\mathrm{d}z_j}{\mathrm{d}t})\}r_i, \quad (11)$$

$$S_{\mathrm{ROT}}(t) = \sum_{i=1}^{N}\{\frac{\mathrm{d}K_{\mathrm{ROT}}(i)}{\mathrm{d}t} + \frac{1}{2}\sum_{i=1}^{N}(\frac{\partial U_{ij}}{\partial \omega_{1j}}\frac{\mathrm{d}\omega_{1j}}{\mathrm{d}t} + \frac{\partial U_{ij}}{\partial \omega_{2j}}\frac{\mathrm{d}\omega_{2j}}{\mathrm{d}t} + \frac{\partial U_{ij}}{\partial \omega_{3j}}\frac{\mathrm{d}\omega_{3j}}{\mathrm{d}t})\}r_i, \quad (12)$$

and

$$S_{\mathrm{MH}}(t) = \sum_{i=1}^{N} H_i \frac{\mathrm{d}r_i}{\mathrm{d}t} \quad (13)$$

where ω is the Euler angle. The total heat current was calculated by means of numerical differentiation as Eq. 7. The first and third terms of Eq. 10 were obtained at each MD step by Eqs. 11 and 13,[17] and the second term was indirectly calculated from other terms.

It was found that the contribution from molecular Hamiltonian part is negligible. The contributions from $S_{\mathrm{TRANS}}(t)$ and $S_{\mathrm{ROT}}(t)$ are shown as a function of temperature at normal density in Fig. 13. Although the contribution from the cross term of $S_{\mathrm{TRANS}}(t)$ and $S_{\mathrm{ROT}}(t)$ is not shown, we can estimate it graphically from the rest in Fig. 13. The main part is the contribution from the rotational one shown by circles. This part increases as temperature increases. On the other hand, the contribution from the translation part $S_{\mathrm{TRANS}}(t)$ is almost constant as a function of temperature and the magnitude is much less than that of the rotational one. The strong anisotropic interaction seems to be responsible to the rotational part.

Here we are going to understand the temperature dependence of the thermal conductivity in terms of the time correlation functions. For this purpose, we define the time correlation function as follows:

$$f_\lambda(t) = \langle S(t)\cdot S(0)\rangle. \quad (14)$$

The time correlation functions (translational and rotational parts) are shown in Figs. 14 and 15, respectively. The normal temperature case and the high temperature one are compared at normal density. As temperature increases, the correlation function of the rotational part changes more than that of the translational one at normal density as seen in Figs. 14 and 15.

For quantitative discussion on the temperature dependence, the time integral of the normalized correlation function is shown in Table 2. It is found that the time integral changes only a little with temperature under the condition of normal density (V=18 cm^3 mol^{-1}). However, not only the time integral but also the normalization constant $\langle S(0)^2\rangle$

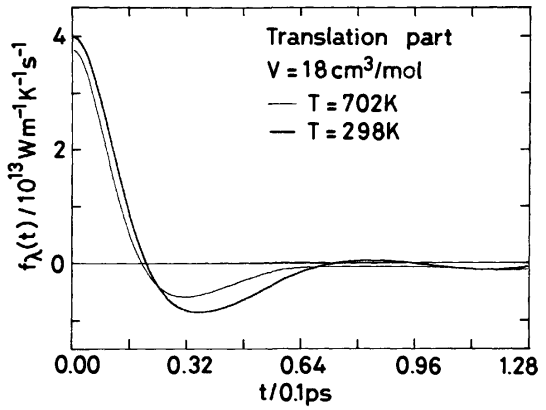

Fig. 14. The time correlation function related to the thermal conductivity, translational part.

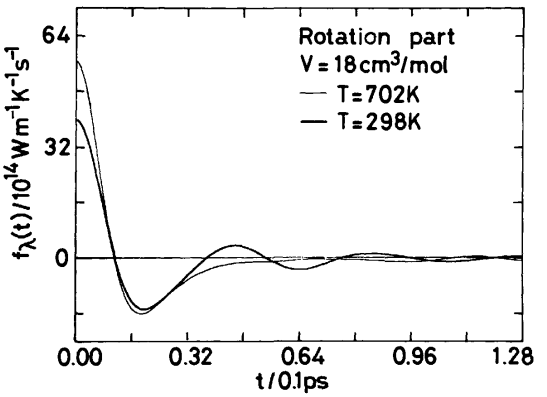

Fig. 15. The time correlation function related to the thermal conductivity, rotational part.

depends on temperature. These are summarized in Table 2 (cf. Eq. 6). From this table, it is seen that the increase of the factor $\langle S(0)^2\rangle/T^2$ of the rotational part as a function of temperature is the main cause for the anomaly in the temperature dependence of the thermal conductivity of liquid water. The excitation of rotational motion is responsible to the increase of this factor.

In this paragraph we will try to compare liquid water with a simple liquid by the correlation function related to thermal conductivity. The heat current autocorrelation function in Lennard-Jones liquid does not have any clear oscillatory character.[27] On the other hand, the translational part of the correlation function of liquid water oscillates clearly as shown in Fig. 14. The Fourier transform has a maximum around 70 ps^{-1} although the figure is not shown. The above difference between simple liquid and liquid water comes from rotational motion and anisotropic interaction. The anisotropic potential energy has high frequency component because of the rotational motion in liquid water. This effect will be discussed in the next section.

Time Correlation Functions

As the CC model[5] is not so different from MCY potential,[18] the kinetic properties of CC water are similar to those of MCY water.[9] Qualitatively these properties are not so different from those of BNS water.[8] The frequency spectrum of the velocity autocorrelation function has peaks at 8 and 30 ps^{-1}. The frequency spectra of angular velocity autocorrelations have peaks at 76, 120, and 100 ps^{-1} for α=1, 2, and 3 components in the Rahman and Stillinger's notation.[8]

The normalized correlation function related to shear viscosity is drawn in Fig. 16 at normal conditions (at room temperature and V of 18 cm^3 mol^{-1}). Its Fourier transform is compared with that at a higher temperature (T=702 K) in Fig. 17. We see two characteristic frequencies 40 and 160 ps^{-1} in Fig. 17 at room temperature. At high temperature (T=702 K), these peaks shift to lower frequencies. The oscillation of the time correlation function related to shear viscosity is not intrinsic in Lennard-Jones liquid.[26] However oscillation is clear in liquid water. Since there is strong anisotropic interaction in liquid water, the rotation-translation coupling can cause such an oscillatory behavior as discussed below in the paragraph on the thermal conductivity.

The bulk viscosity was obtained by the time integration of time correlation functions as shown in Fig. 18. In this case, an exponential decay is clear in short term. It is also possible to analyze the second part as another exponential decay as shown by the dotted line. The Fourier transform is given in Fig. 19, where the abscissa is in logarithmic scale. The zero-frequency is the main component at room temperature and a peak is seen around 6 ps^{-1} at T of 702 K in Fig. 19.

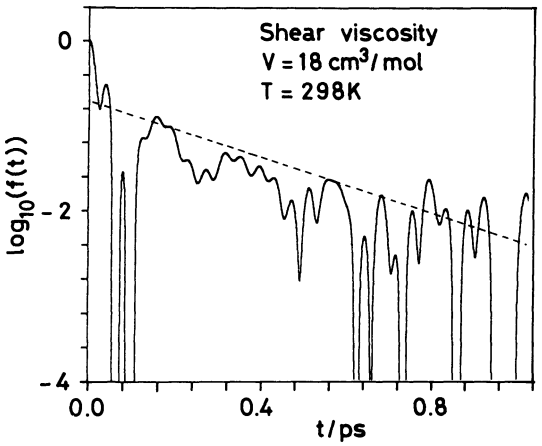

Fig. 16. The normalized time correlation function related to the shear viscosity. A decay character of the envelope is analyzed as shown by the dotted line.

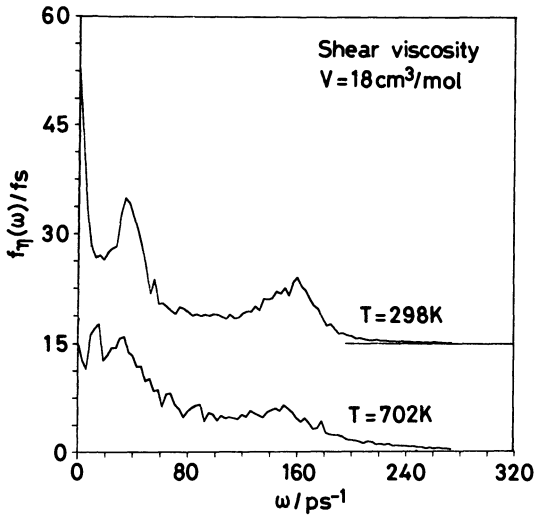

Fig. 17. The Fourier spectrum of the normalized time correlation function related to the shear viscosity.

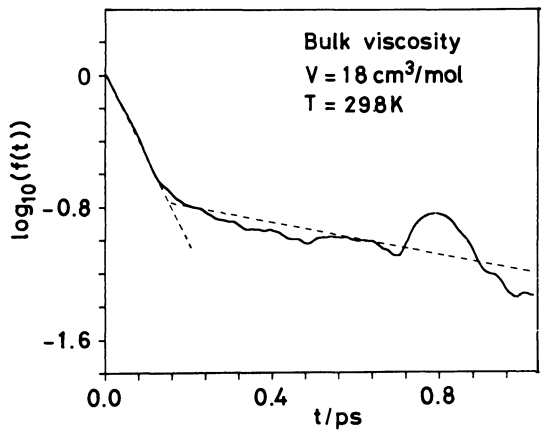

Fig. 18. The normalized time correlation function related to the bulk viscosity.

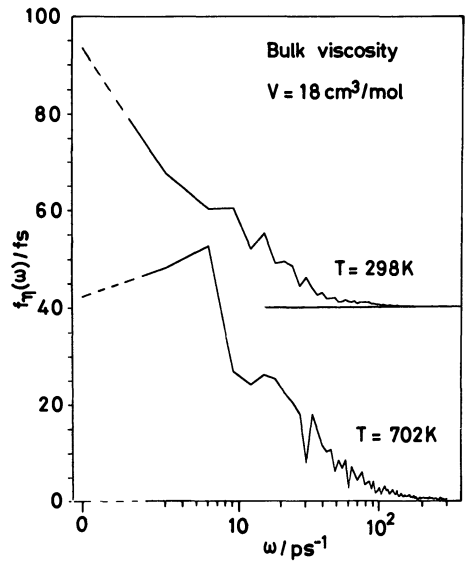

Fig. 19. The Fourier spectrum of the normalized time correlation function related to the bulk viscosity.

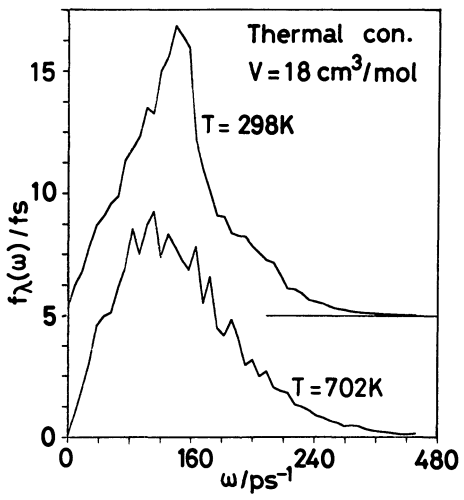

Fig. 20. The Fourier spectrum of the normalized time correlation function related to the thermal conductivity.

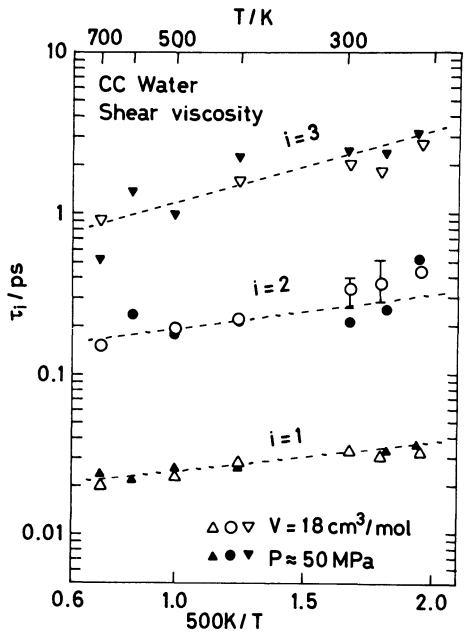

Fig. 21. The decay constant τ_i in Eq. 15, shear viscosity.

The decay character of the time correlation function related to bulk viscosity shown in Fig. 18 is qualitatively similar to that of Lennard-Jones liquid[28] in contrast with the case of shear viscosity.

Because the rotational part is main, the time correlation function related to thermal conductivity is not so different from that given in Fig. 15. The Fourier transform of the total correlation function related to thermal conductivity is plotted in Fig. 20. An oscillatory character is very clear. It is interesting to see that the characteristic frequency at about 140 ps^{-1} in thermal conductivity is close to the frequency seen in shear viscosity. The translational motion coupled with rotational one may have this frequency.

The long tails of the normalized time correlation functions are analyzed by the time averaged correlation functions which are averaged over a period of 0.144 ps, because the time correlation function oscillates with high frequency. The decay character of the time averaged correlation function was obtained by its envelope at long term. The short term was, however, analyzed by the original time correlation function. The following function was assumed (see Fig. 18):

$$f(t) = C_1 \exp(-t/\tau_1)\ t<0.1\ \mathrm{ps}(\eta_S),\ t<0.2\ \mathrm{ps}(\eta_B),$$

$$f(t) = C_2 \exp(-t/\tau_2)\ 0.1\ \mathrm{ps}<t<0.5\ \mathrm{ps}(\eta_S),\ 0.2\ \mathrm{ps}<t(\eta_B),$$

and

$$f(t) = C_3 \exp(-t/\tau_3)\ 0.5\ \mathrm{ps}<t<4\ \mathrm{ps}(\eta_S). \quad (15)$$

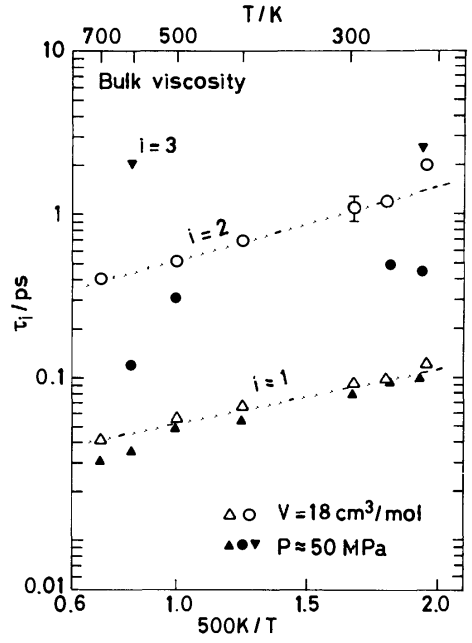

Fig. 22. The decay constant τ_i in Eq. 15, bulk viscosity.

The results on the decay constants τ_i are summarized in Figs. 21 and 22 for shear and bulk viscosity. It was difficult to perform such analysis on the time correlation function related to thermal conductivity, because of too high frequency components. These figures show that there are several decay constants and that the order of magnitude of them are 0.01, 0.1, and 1 ps. Wide distribution of decay constants means that there are so many time constants in the molecular motion in liquid water.

It is shown in this paper that anomalous behavior of the transport coefficients of liquid water can be reproduced nonempirically on a qualitative level. Some microscopic characteristics were revealed by the time correlation function related to the transport coefficients. The dynamical structure of liquid water will be studied in the next step.

The author would like to thank Prof. Nobuhiro Go and Mr. Mitsuhiro Matsumoto for valuable discussions. He also thanks Dr. D. Fincham, Queen Mary College, and Dr. W. Smith, Science and Research Council, Daresbury Laboratory, UK for their program MDMPOL as the basis of the present program. This work has been supported in part by a Grant-in-Aid for Scientific Research (Nos. 62103012, 62124039, and 63430023) from the Ministry of Education, Science and Culture. The author thanks the Computer Center of the Institute for Molecular Science for the use of HITAC M-680H and S-820/80 computers. The computation was also done by FACOM VP-400E and M-780 computers at Kyoto University Data Processing Center.

(Received October 31, 1988)

The electrical conductivity and the ESR spectra of the single crystal of (BEDT-TTF)$_4$Ni(CN)$_4$ complex were measured. This crystal exhibits a metal-insulator transition at 160 K. The ESR signals show the presence of the [Ni^{III}(CN)$_4$]$^-$ anion in addition to the BEDT-TTF cation radical. The spin concentration of Ni(III) ion was estimated to be 0.01 of the total Ni ions from the temperature dependence of the spin susceptibility of these components. The X-ray photoelectron spectra were also taken.

The discovery of superconductivity in β-(BEDT-TTF)$_2$I$_3$ at T_c=1.3 K under ambient pressure[1-3] has promoted the preparation of radical salts of BEDT-TTF (bis(ethylenedithio)tetrathiafulvalene) with the linear triatomic anion such as I_2Br^-[4] and AuI_2^-.[5] After that, the studies of many complexes including the metal salts as the counter anion were made and the stable organic superconductor, (BEDT-TTF)$_2$Cu(NCS)$_2$, exhibiting complete superconductivity around 10 K at ambient pressure was discovered.[6] Such charge transfer complexes between BEDT-TTF and metal salts are interesting on magnetic properties in addition to electrical properties, because the metal ion can have the incompletely occupied electron shell. From this point of view, we investigated the magnetic and electronic properties of (BEDT-TTF)$_2$CuCl$_2$[7] and obtained the result that the Cu atoms in (BEDT-TTF)-CuCl$_2$ are in a mixed-valence state consisting of mono and bivalent cations. In the present paper, we report the complex of (BEDT-TTF)$_4$Ni(CN)$_4$.

Experimental

Black plate-like crystals were grown by the electrochemical crystallization of BEDT-TTF in 1,1,2-trichloroethane by using $K_2Ni(CN)_4$ as a supporting electrolyte. The electrical conductivity of the single crystal was measured by the four probe method using gold paste as a contact. The ESR spectra were taken by a Varian E112 at X-band with a continuous helium flow cryostat and a rectangular microwave cavity. The crystal was rotated around the a axis and was measured over a temparature range of 4—300 K. The X-ray photoelectron spectra were recorded on a VG ESCALAB MkII. Mg $K\alpha$ radiation (1253.6 eV) was used as the X-ray excitation source and the measurements were carried out at 10^{-7} Torr (1 Torr≈133.322 Pa) or below.

Results and Discussion

Figure 1 shows the temperature dependence of electrical conductivity of the single crystal. The room temperature conductivity was about 20 S cm^{-1}. The crystal was metallic between 230 and 300 K and became

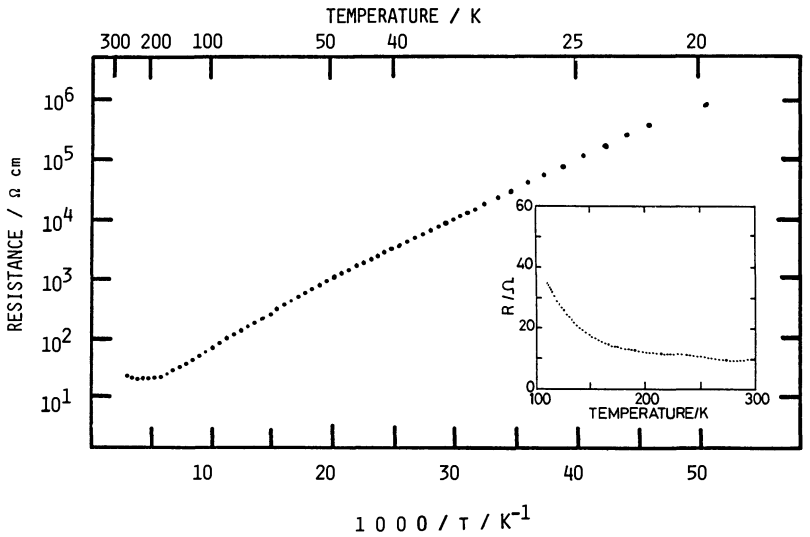

Fig. 1. Temperature dependence of the a axis electrical conductivity of the single crystal of (BEDT-TTF)$_4$Ni(CN)$_4$.

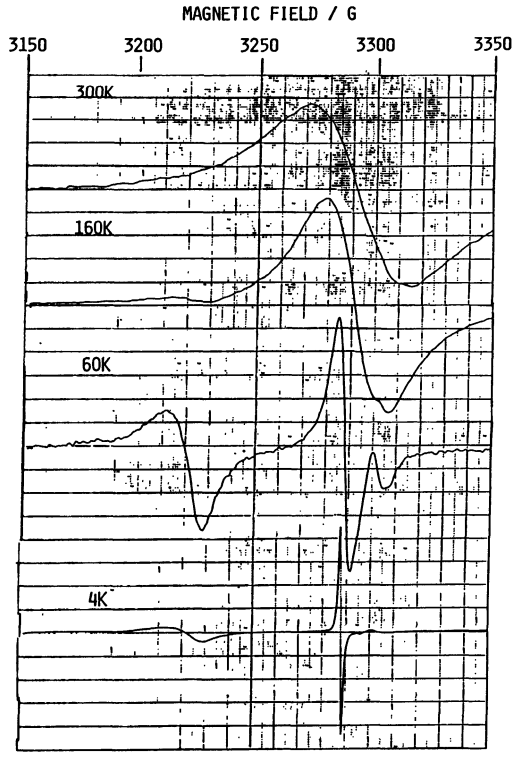

Fig. 2. ESR spectra of (BEDT-TTF)$_4$Ni(CN)$_4$ for the field direction giving the maximum g value around the a axis.

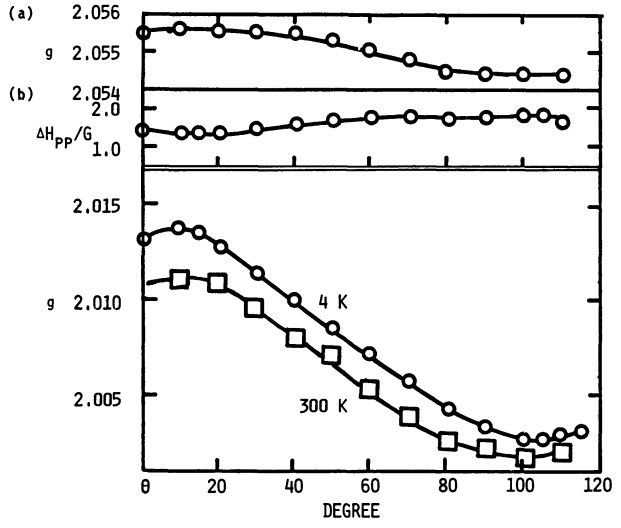

Fig. 3. Angular dependence of the g value around the a axis. The field is perpendicular to the ac plane at 0 degree. (a) Weak band at 4 K (—○—○—). (b) Strong band at 4 K (—○—○—) and 300 K (—□—□—).

semi-conductive with the energy gap of 100 K below 160 K after the temperature dependence of the conductivity was not observed between 160 and 230 K. This kind of resistance behavior may be explained by the phase transition of the crystal between 160 and 230 K.

The ESR spectra of the single crystal of (BEDT-TTF)$_4$Ni(CN)$_4$ are shown in Fig. 2. The angular

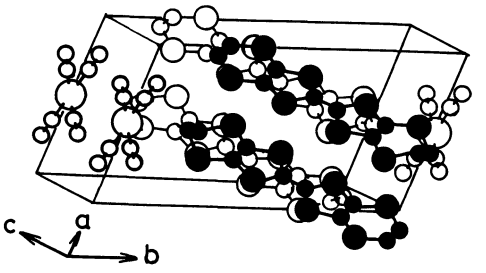

Fig. 4. Crystal structure of (BEDT-TTF)$_4$Ni(CN)$_4$.[8]

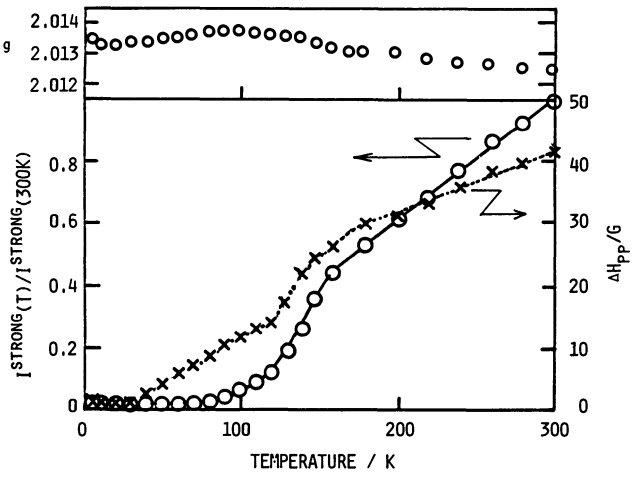

Fig. 5. Temperature dependence of the g value, the linewidth and the absorption intensity of the ESR spectra of the strong band for the field giving the maximum g value.

dependence of the g value and linewidth for the strong and weak bands at 4 and 300 K is shown in Fig. 3. The g value exhibits the maximum for the field applied nearly perpendicular to the ac plane. As is shown in Fig. 4, the molecular plane of BEDT-TTF is almost normal to the ac plane and the Ni(CN)$_4$ anion is located in the ac plane.[8] Accordingly the direction of the maximum g value is in accordance with the direction normal to the Ni(CN)$_4$ anion plane or parallel to the long axis of BEDT-TTF molecule.

The ESR spectrum at 4 K consists of the strong band at g=2.013 (3300 G; 1G=10^{-4} T), the weak band at g=2.056 (3220 G) and the satellite band at g=2.004 (3305 G). The strong band is assigned to the unpaired π-electron of the BEDT-TTF cation radical.[7] The weak band can be assigned to the d electron of [Ni^{III}(CN)$_4$]$^-$ in a square planar arrangement.[9]

Figure 5 shows the temperature dependence of the g value, the linewidth ΔH_{pp} and the absorption intensity of the ESR spectra of the strong band for (BEDT-TTF)$_4$Ni(CN)$_4$. The magnetic susceptibility $\chi^{strong}(T)$ at temperature T is given by the absorption intensity of the ESR signal,

$$\chi^{strong}(T) = C\{I^{strong}(T)/I^{strong}(300\ \mathrm{K})\}. \quad (1)$$

The coefficient C may be estimated with the observed static magnetic susceptibility at room temperature of 9×10^{-4} emu mol^{-1}. This value was corrected by considering the diamagnetic effect of the constitution atoms. The magnetic susceptibility and the linewidth of the strong band decrease almost linearly with decreasing temperature between 300 and 160 K and exponentially below 160 K. The activated behavior below 160 K corresponds to that of the electrical conductivity and means the occurence of the metal-semiconductor transition. If the susceptibility at room temperature may be described by the Pauli paramagnetism of the tight binding model, the calculated susceptibility is given the simple equation,[10]

$$\chi = \frac{N_0\mu_B^2}{\pi t \sin(\rho\pi/2)}, \tag{2}$$

where N_0 is Avogadro's number, μ_B is the Bohr magneton and t is the transfer integral. The degree of the charge transfer (ρ=1/2) per BEDT-TTF molecule and the observed susceptibility of 9×10^{-4} emu mol^{-1} gives t=0.016 eV.

The temperature dependence of the absorption intensity of the weak band can be depicted by the Curie law as shown in Fig. 6. The magnetic susceptibility of $[Ni(III)(CN)_4]^-$ ion is given by the next equation,

$$\chi^{weak}(T) = n_{Ni}\frac{N_0 g_{Ni}^2\mu_B^2}{3kT}s(s+1) \tag{3}$$

$$= C\{I^{weak}(T)/I^{strong}(300\text{ K})\}. \tag{4}$$

Then, the number of spins per $[Ni(CN)_4]^-$ anion is estimated to be n_{Ni}=0.01.

Figure 7 shows the X-ray photoelectron spectra (ESCA) of $(BEDT\text{-}TTF)_4Ni(CN)_4$ complex and $K_2Ni(CN)_4$. The Ni 2p3/2 and Ni 2p1/2 peaks were observed in both components and no difference of the

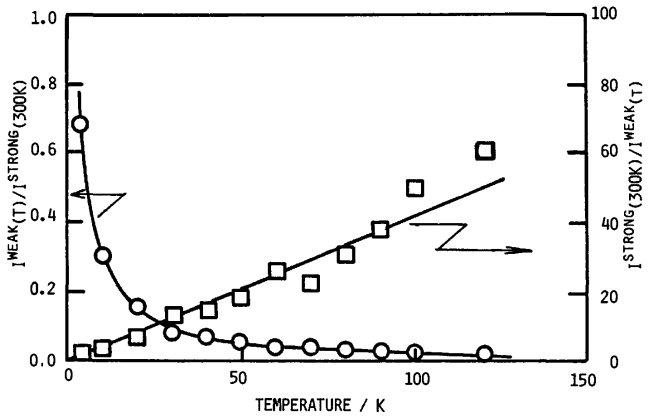

Fig. 6. Temperature dependence of the absorption intensity of the ESR spectra of the weak band.

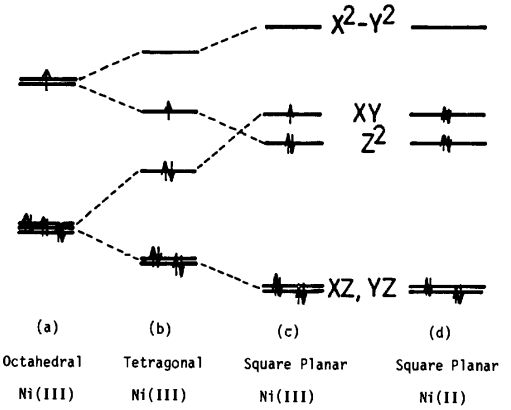

Fig. 8. Energy level diagram for Ni(III) and Ni(II) ions. The z axis is normal to the $Ni(CN)_4$ plane.

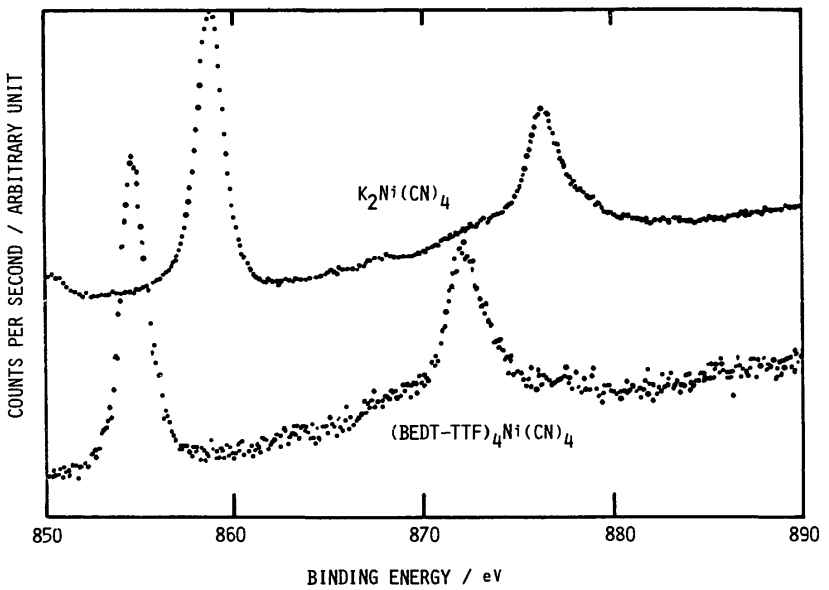

Fig. 7. X-Ray photoelectron spectra (ESCA) of $(BEDT\text{-}TTF)_4Ni(CN)_4$.

line shape and the intensity ratio is found between them. That is, most parts of the Ni atoms in (BEDT-TTF)$_4$Ni(CN)$_4$ complex are in the bivalence state and the low spin d^8 configuration of Ni(II) ion forms the closed shell in the square-planar arrangement as is shown in Fig. 8, while a few Ni(III) complexs prepared by the electrochemical oxidation have the unpaired electron in the d_{xy} orbital. Such mixed valence state of the metal ion in the BEDT-TTF complex was observed for the Cu ion in (BEDT-TTF)$_2$CuCl$_2$.[7] These ESR spectra consist of both signals of BEDT-TTF cation and metal ion. This fact shows the possibility of the coexist of the free carrier in the conducting BEDT-TTF band and the paramagnetic electron in the metal ion.

The above-mentioned results about the magnetic and electrical measurements show that the electrical conductivity of (BEDT-TTF)$_4$Ni(CN)$_4$ complex is metallic at room temperature and the metal-insulator transition occurs at 160 K by the dimerization of the BEDT-TTF molecules.

The authors would like to thank Dr. Tetsuo Asaji of Nagoya university for the measurement of the static magnetic susceptibility.

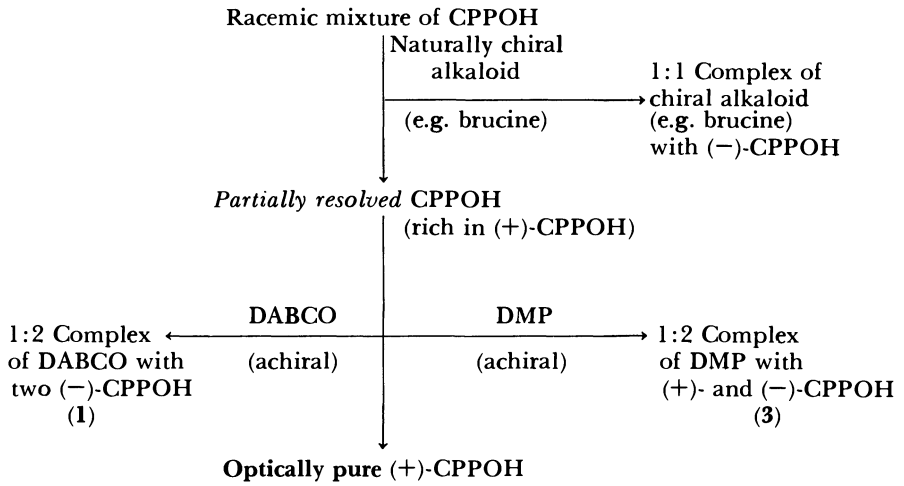
(Received April 22, 1988)

X-Ray crystal structure analysis of the title four complexes showed that crystals consist of CPPOH···achiral diamine···CPPOH units. In the first two crystals a DABCO molecule is bound by two (−)-CPPOH molecules (**1**) or by (+)- and (−)-CPPOH (**2**) to form 1:2 complex by strong intermolecular O-H···N hydrogen bonds [O-H···N=2.707(3) and 2.755(3) (**1**) and 2.704(4) and 2.747(4) Å (**2**)]. The latter two crystals are respectively formed by (+)-CPPOH···DMP···(−)-CPPOH complex (**3**) [O-H···N=2.771(3) Å] and (−)-CPPOH···DMP···(−)-CPPOH complex (**4**) [O-H···N=2.768(5) and 2.730(6) Å].

In a series of studies on the novel optical resolution of tertiary acetylenic alcohols by complexation with naturally chiral alkaloids,[1-3] Toda and Tanaka found that the partially resolved enantiomers, obtained after the separation of the 1:1 complex of optically pure enantiomers with alkaloid, can easily be purified by complexation with simple achiral diamines such as DABCO, *N,N'*-dialkylpiperazine, *N,N,N',N'*-tetramethylethylenediamine, or pyrazine to give the optically pure alcohols.[4] Among the complexation reactions mentioned above, achiral DABCO forms 1:2 complex selectively with two (−)-CPPOH molecules to give **1** crystal, and in result optically pure (+)-CPPOH remains in solution. On the other hand, achiral DMP easily forms 1:2 complex (**3**) with (+)- and (−)-CPPOH molecules. However, under appropriate but severe conditions, DABCO and DMP were found to form the other 1:2 complex crystals of (+)-CPPOH···DABCO···(−)-CPPOH (**2**) and (−)-CPPOH···DMP···(−)-CPPOH (**4**), respectively. In order to obtain a clue to clarify the fact that leads the selective 1:2 complex formation of achiral DABCO with two chiral (−)-CPPOH molecules, the crystal and molecular structures of **1** has been determined by means of X-ray diffraction. As a reference, the structure of **2**, which is not formed under ordinary condition, has also been determined. The crystal and molecular structures of 1:2 complexes of DMP with two CPPOH molecules, (+)-CPPOH··· DMP···(−)-CPPOH (**3**) and (−)-CPPOH···DMP···(−)-CPPOH (**4**, obtained under severe condition), which have been already reported briefly,[5] are compared with those of **1** and **2**.

Experimental

Crystal Data. $C_6H_{12}N_2$,2($C_{15}H_{11}OCl$), *F.W.* 597.6; **1**, monoclinic, space group $P2_1$, a=15.785(2), b=11.511(1), c=8.878(1) Å, β=102.89(1)°, V=1565.6(3) Å^3, D_c=1.262 g cm^{-3} for Z=2. **2**, monoclinic, space group $C2/c$, a=49.319(13), b=9.237(1), c=14.343(1) Å, β=105.96(1)°, V=6281.8(19) Å^3, D_c=1.264 g cm^{-3} for Z=8. $C_6H_{14}N_2$,2($C_{15}H_{11}OCl$), *F.W.* 599.6; **3**, triclinic, space group $P\bar{1}$, a=10.752(4), b=9.057(4),



c=8.350(5) Å, α=100.28(4), β=81.87(3), γ=102.38(2)°, V=777.0(7) Å^3, D_c=1.282 g cm^{-3} for Z=1. **4**, monoclinic, space group $P2_1$, a=17.511(2), b=7.606(1), c=13.311(2) Å^3, β=111.55(1)°, V=1648.9(5) Å^3, D_c=1.208 g cm^{-3} for Z=2.

The crystals used has approximate dimensions of 0.4×0.3×0.2 mm (**1**) and 0.5×0.3×0.2 mm (**2**). X-Ray diffraction data were collected on a Rigaku four-circle diffractometer by the θ-2θ scan technique ($2\theta_{max}$=120°). For **1** and **4**, hkl and $h\bar{k}l$ reflections were measured in order to determine the absolute configuration of (−)-CPPOH molecule. Nickel-filtered Cu $K\alpha$ radiation was used (λ=1.5418 Å). The θ-scan rate was 4° min^{-1} and the scan width $\Delta\theta$=(1.2+0.15 tan θ)°. Backgrounds were counted for 4 s at both ends of a scan. Three standard reflections measured after every 100 reflections to monitor the stability and orientation of the crystal showed no significant decay throughout the experiment. Of the 2461 and 4663 independent reflections measured, 2393 and 3834 reflections were observed for **1** and **2**, respectively ($|F_o|>2\sigma(F_o)$, where σ is the standard deviation obtained by the counting statistics of reflections). Usual Lorentz and polarization corrections were applied but absorption effect was ignored [μ(Cu $K\alpha$)=21.4 cm^{-1} for both **1** and **2**]. X-Ray experiments on **3** and **4** crystals have been already descrived in the previous letter.[5]

Bijvoet pair reflections were used for the determination of absolute configuration of (−)-CPPOH molecule in **1** and **4**. These pair reflections were also included in the Hamilton's R value test,[6] but intensities of each pair reflections were averaged for the ordinary use of the structure determination.

Structure Solution and Refinement

The structure of **1** was solved by the heavy atom method and that of **2** by the direct method (*MULTAN* 78).[7] Both structures were refined anisotropically by the block-diagonal least-squares procedure (*HBLS*

V).[8] The function minimized was $\sum w\Delta F^2$. The hydrogen atoms which could be located on the difference Fourier maps were refined with isotropic temperature factors. The final R indices are 0.045 (R_w=0.038) and 0.063 (R_w=0.092) for **1** and **2**, respectively. The weighting schemes used at the final stage of the refinement were $w=(\sigma^2+a|F_o|+b|F_o|^2)^{-1}$, where a=−0.65941 and 0.12269 and b=0.03381 and 0.00105 for **1** and **2**, respectively.

The structures of **3** and **4** have been determined in a similar manner as mentioned above.[5] R=0.060 (R_w=0.074) (**3**) and R=0.077 (R_w=0.083) (**4**).

The absolute configuration of the (−)-CPPOH molecule has been determined by examining the magnitude of structure factors of Bijvoet pair reflections of the **1** and **4** crystals, and the chirality of the asymmetric C(1) atom of the (−)-CPPOH in both complexes was found as R. Hamilton's R value test for the **1** and **4** is consistent with this result.

Final atomic parameters of **1**, **2**, **3**, and **4** are given in Table 1.†† Atomic scattering factors used were taken from those of International Tables for X-Ray Crystallography, Vol. IV.[10] Computations were done on an ACOS S850 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

†† Tables of anisotropic thermal parameters and those of observed and calculated structure factors of **1**, **2**, **3**, and **4** are kept at the Chemical Society of Japan, Document No. 8871.

Results and Discussion

Crystal Structures. The packings of molecules in **1** and **2** crystals[11] are depicted in Fig. 1, which are compared with those of **3** and **4**. The remarkable feature of the structure is that all these crystals consist of discrete 1:2 host-guest complexes of CPPOH···achiral diamine···CPPOH consolidated by O-H···N hydrogen bonds. Each DABCO molecule is bound to two (−)-CPPOH in **1** and bound to (+)- and (−)-CPPOH molecules in **2** by strong hydrogen bondings [O-H···N=2.707(3) and 2.755(3) Å (**1**) and 2.704(4) and 2.747(4) Å (**2**) (Fig. 2, (a) and (b))]. This 1:2 complex formation seems to be similar to that of achiral DMP with (+)- and (−)-CPPOH (**3**) and two (−)-CPPOH molecules (**4**) (Fig. 2, (c) and (d)). The geometry about the hydrogen bondings in **1** and **2** complexes are compared with those in **3** and **4** in Table 2. In **1** and **2**, the H(1) atom of CPPOH locates at the direction of lone pair electrons of the N atom which occupies the apex of the pyramid made by one N and three C atoms at one end of DABCO. The O(1), H(1), and N atoms of each of the hydrogen bonds lie approximately on a line. In **3** and **4**, the H(1) atom of CPPOH is approximately at the direction of lone pair electrons of one of the N atoms of DMP. The O(1), H(1), and N atoms of each of the hydrogen bonds are not on a line in **3** [O-H(1)···N=161(3)°].

In **1** crystal very close inter-complex atomic contacts are observed. The closest distance, 3.160(5) Å was found between the hydroxyl oxygen atom of one complex, O(1A)(x, y, z) and the acetylenic carbon atom of the adjacent complex, C(3A)($-x$, $-0.5+y$, $1-z$). The second closest contact, 3.290(5) Å was observed between the chlorine atom of the *o*-chlorophenyl group of one complex, Cl (1B)(x, y, z) and the carbon atom of the phenyl group of the other complex, C(14B)($1-x$, $-0.5+y$, $2-z$)]. On the other hand, no close contact shorter than 3.465(5) Å [Cl(1A)(x, y, z)···C(13A)(x, $1-y$, $-0.5+z$)] was observed in **2**. In addition to this, most of the close inter-complex contact distances involved with hydrogen atoms in **1** are shorter than those in **2**. These facts suggest that the stronger inter-complex interaction leads the selective crystallization of (−)-CPPOH···DABCO···(−)-CPPOH (**1**), which makes the optical resolution of (−)-CPPOH enantiomers from the partially resolved CPPOH.

In **3** and **4** crystals, however, no short inter-complex contact distances are found between non-hydrogen atoms. Instead, intercomplex atomic contacts involved with hydrogen atoms in **3** are mostly shorter than those in **4**, and the **3** crystal has the denser structure (D_c=1.282 g cm^{-3}) than **4** (D_c=1.208 g cm^{-3}).

Molecular Structures. Selected bond distances and bond angles in **1**, **2**, **3**, and **4** are listed in Table 3.

1-(*o*-Chlorophenyl)-1-phenyl-2-propyn-1-ol(CPPOH). The C(2)-C(3) acetylenic bonds have distances of 1.187(5) and 1.180(5) Å (**1**) and 1.179(6) and 1.181(6) Å (**2**), which are slightly shorter than the standard C-C triple bond distance, 1.204(2) Å. The C(1)-C(2)-C(3) angles are smaller than 180° [175.5(4) and 178.8(4)° (**1**) and 175.9(4) and 177.6(4)° (**2**)].

Two benzene rings of *o*-Cl-Ph and Ph groups are planar, which make angles of 88.6(1) and 89.1(1)° in **1** and 80.4(1) and 89.1(1)° in **2**. The corresponding angles in **3** and **4** are 82(1)° and 87.7(1) and 85.8(1)°, respectively. Among the bond angles around the C(5) atom, the C(4)–C(5)-Cl(1) angle is approximately equal to the C(4)-C(5)-C(6), which are larger than the C(6)–C(5)–Cl(1) throughout the complexes **1** to **4** (Table 2).

The (−)-1-(*o*-bromophenyl)-1-phenyl-2-propyn-1-ol molecule in its 1:1 complex with brucine and also that with (−)-sparteine[3] have similar structure as (−)-CPPOH in the present complexes of **1** and **2**.

1,4-Diazabicyclo[2.2.2]octane (DABCO). The DABCO molecule completely lost its original $\bar{6}m2$ symmetry by the formation of 1:2 complex with CPPOH. However, in the 1:2 complex with *p*-cresol, it was observed that the molecular symmetry of DABCO decreased down to 2. All the thermal ellipsoids of carbon atoms of DABCO are much larger than those of the other carbon atoms, and they also show remarkable elonga-

tion along the direction perpendicular to the N(1)···N(2) axis of DABCO molecule. This suggests an existence of hindered rotation of the molecule along the N(1)···N(2) axis, similar to that in the 1:2 complex of DABCO with *p*-cresol.[12] The C-N bond distances are equal in each molecule [av. 1.469 Å(**1**) and av. 1.461 Å(**2**)] and also equal to that observed in uncomplexed DABCO by the neutron diffraction study [1.470(7) Å][13] within the range of errors. The C-C distances [av. 1.548 Å (**1**) and av. 1.554 Å (**2**)] are

larger than those in DABCO crystal [1.513(5) Å]. The C-N-C and N-C-C bond angles of **1** and **2** showed no significant difference respectively from the corresponding angles of DABCO in the crystal[108.4(2) and 110.5(4)°].

***N,N'*-Dimethylpiperazine (DMP).** The DMP molecule in **3** takes a chair form, the center of which lies on a crystallographic center of symmetry. In **4**, the DMP molecule is also in a chair form but not centrosymmetric structure.

Part of the cost of the present study was defrayed by the Grant-in-Aid by the Ministry of Education, Science and Culture, for which the authors thanks are due.

Adsorption of 2-(Octylsulfinyl)ethanol at Ethanol-Water Mixture/Air Interface

Hidemi IYOTA* and Kinsi MOTOMURA†
Kagoshima Women's Jr. College, Murasakibaru, Kagoshima 890
†Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received November 11, 1988)

The surface tension of the solution of 2-(Octylsulfinyl)ethanol (OSE) in ethanol-water mixture was measured as a function of molality of OSE at constant composition of ethanol at 298.15 K under atmospheric pressure. The slope of surface tension vs. molality curve decreased with increasing composition. Two break points were observed on the curve: the break point at a low molality was attributed to the phase transition of the adsorbed film of OSE and the one at a high molality to the micelle formation of OSE. The surface excess numbers of moles per unit area of OSE and ethanol and their ratio were evaluated by applying the thermodynamic equations developed previously to the experimental results. It was clarified that the adsorbed film of OSE expels ethanol molecules from the surface region at a small composition of ethanol. The ratio of the excess number of molecules of ethanol per micelle particle to that of OSE was found to be similar to the corresponding ratio of the surface excess number of moles at the critical micelle concentration. This fact led us to the conclusion that the OSE molecules in the micelle behave similarly to those in the adsorbed film even in the mixed solvent.

The adsorption of surface active substances at various oil/water interfaces has been studied thermodynamically and the significant influence of solvent has been revealed in the previous papers.[1,2] Furthermore, the thermodynamic treatment has been extended so as to be applicable to the adsorption of surfactant from mixed solvent.[3] It is now necessary to examine the effect of the composition of mixed solvent on the interfacial behavior of surfactant molecules. Such examinations were rarely conducted by investigators.[4-6] The present purpose is that the surface tension of the solution of 2-(octylsulfinyl)ethanol in ethanol-water mixture is measured as a function of the concentration of OSE and the composition of the mixture and analyzed thermodynamically.

Experimental

2-(Octylsulfinyl)ethanol was synthesized and purified by the method described in the previous paper.[7] Its purity was checked by gas-liquid chromatography; no minimum was observed on the surface tension vs. concentration curve around the critical micelle concentration. Ethanol (Nakarai Chemicals Ltd., specially prepared reagent for spectroscopy) was dried by the refluxion over calcium oxide and then distilled. Water was triply distilled, the second and third steps being carried out from dilute alkaline permanganate solution.

Surface tension was measured by the drop volume technique[8] at 298.15 K under atmospheric pressure. The error inherent in the surface tension measurement was less than 0.02 mN m^{-1} throughout this experiment. Temperature was regulated to a precision of 0.01 K by the use of thermister controller.

The surface tension γ of the solution of 2-(octylsulfinyl)-ethanol (OSE) in ethanol-water mixture was measured as a function of molality of OSE, m, at a given mole fraction of ethanol, X, in the mixed solvent at 298.15 K under atmospheric pressure.

Results

Figures 1a and 1b show the γ vs. m curves at constant X. The γ value decreases steeply with increasing m and remains almost constant at concentrations above the critical micelle concentration (cmc) when X is smaller than about 0.05. Further, another break point is seen at a very small m value on γ vs. m curve, which is designated by the arrow on the curve in Fig. 1b. The m value at the break point and the cmc value increase as X increases. At larger mole fractions of ethanol, however, the slope of the γ vs. m curve

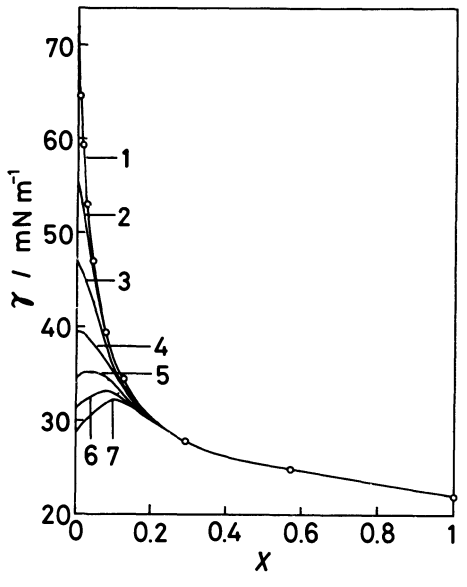

Fig. 2. Surface tension vs. mole fraction of ethanol curves at constant molality of OSE at 298.15 K under atmospheric pressure: (1) m=0 mmol kg^{-1}, (2) 2, (3) 5, (4) 10, (5) 15, (6) 20, (7) 25.

becomes gentle. It should be noticed that the γ value does not vary with m at compositions above X=ca. 0.3.

In order to examine the variation of surface tension with the composition of mixed solvent, the values of γ taken from Fig. 1a at constant m are plotted against X in Fig. 2. The γ value decreases monotonously with increasing X at low concentrations of OSE. At high concentrations of OSE, the γ vs. X curve has a distinct maximum at small X. However, all the curves approach each other above at X=ca. 0.3.

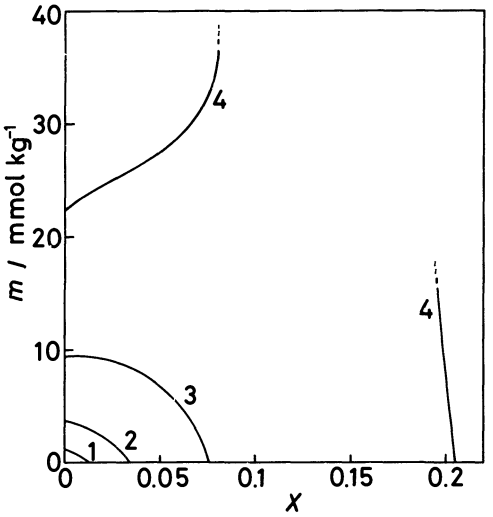

Fig. 3. Molality of OSE vs. mole fraction of ethanol curves at constant surface tension at 298.15 K under atmospheric pressure: (1) γ=60 m N m^{-1}, (2) 50, (3) 40, (4) 30.

In Fig. 3 shown is how the molality m changes with the composition X at constant surface tension. The value of m decreases with an increase in X at large γ, while the m vs. X curve has a maximum at small γ.

Discussion

Since the system under consideration consists of 2-(octylsulfinyl)ethanol, ethanol, water, and air, the information regarding the surface of the system is provided by applying the thermodynamic equations derived in the previous paper[3] to the above experimental results. Employing the molality of OSE m and the mole fraction of ethanol X as the independent variables at constant temperature T and pressure p, the fundamental equation is written in the form

$$d\gamma = -RT[(1-X)X]^{-1}[1+(\partial nf/\partial \ln X)_{T,p,m}]\Gamma_1^H dX - RTm^{-1}\Gamma_2^H dm, \quad (1)$$

where OSE is assumed to behave ideally at any X value and f is the activity coefficient of ethanol in the mixture. The interfacial density of ethanol Γ_1^H and that of OSE Γ_2^H are defined with respect to the dividing planes which satisfy the condition that the interfacial density of air Γ_a^H and the sum of those of ethanol and water $\Gamma_1^H+\Gamma_w^H$ are zero simultaneously. Now, the following equations derived from Eq. 1 enable us to evaluate the thermodynamic quantities $\Gamma_1^H(=-\Gamma_w^H)$, Γ_2^H, and Γ_1^H/Γ_2^H from the experimental

results:

$$-(\partial\gamma/\partial m)_{T,p,X} = RTm^{-1}\Gamma_2^{H}, \quad (2)$$

$$-(\partial\gamma/\partial X)_{T,p,m} = RT[(1-X)X]^{-1}[1+(\partial\ln f/\partial\ln X)_{T,p,m}]\Gamma_1^{H} \quad (3)$$

and

$$-(\partial m/\partial X)_{T,p,\gamma} = m[(1-X)X]^{-1}[1+(\partial\ln f/\partial\ln X)_{T,p,m}]\Gamma_1^{H}/\Gamma_2^{H}. \quad (4)$$

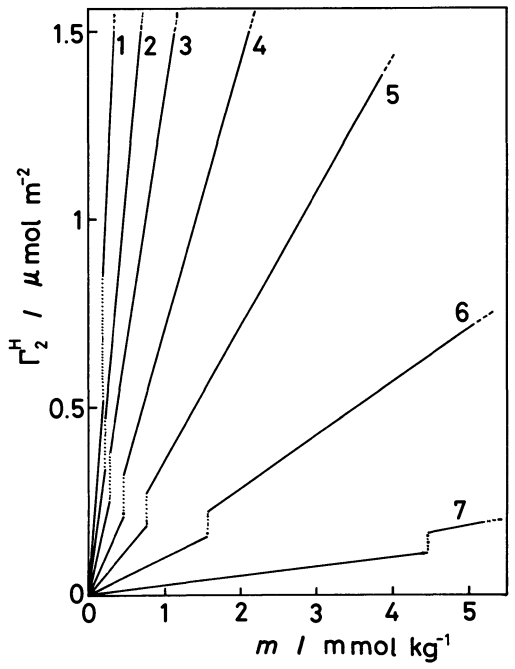

Fig. 4b. Interfacial density of OSE vs. molality of OSE curves at constant mole fraction of ethanol at 298.15 K under atmospheric pressure: (1) X=0, (2) 0.0060, (3) 0.0130, (4) 0.0258, (5) 0.0439, (6) 0.0798, (7) 0.1253.

First, the numerical values of Γ_2^H were estimated by applying Eq. 2 to the curves in Figs. 1a and 1b and plotted against m at constant X in Figs. 4a and 4b. It is seen from Fig. 4a that the Γ_2^H value increases steeply with m and then approaches that of saturation adsorption at the cmc indicated by the closed circle when X is small. With increasing X, the Γ_2^H value decreases and becomes zero at a composition above X=ca. 0.3. Therefore, it can be said that the enhancement of ethanol in the mixed solvent diminishes the adsorption of OSE. Now, let us focus our attention on the variation of Γ_2^H with m in the dilute concentration region depicted in Fig. 4b. The Γ_2^H value changes discontinuously at the concentration where the γ vs. m curve breaks. This discontinuous change in the Γ_2^H vs. m curve is attributed to the phase transition of the adsorbed film between a gaseous and an expanded state which has been observed in the previous papers.[8-10] It is also seen that the concentration at which the phase transition takes place increases with increasing X and eventually vanishes at a

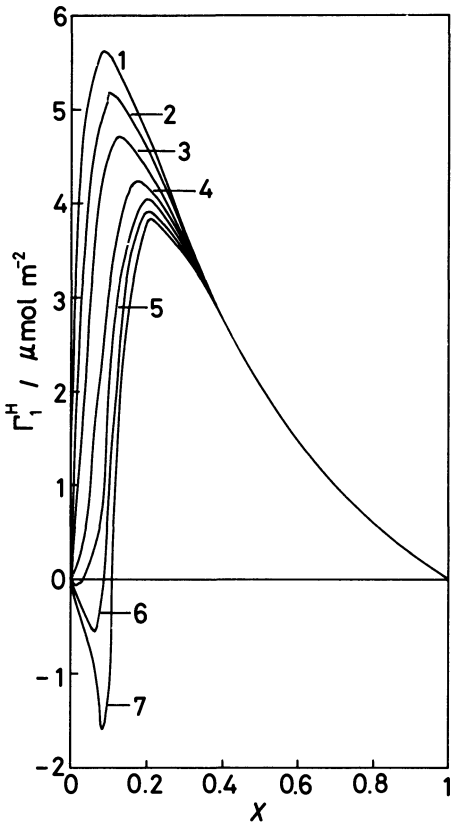

Fig. 5. Interfacial density of ethanol vs. mole fraction of ethanol curves at constant molality of OSE at 298.15 K under atmospheric pressure: (1) m= 0 mmol kg^{-1}, (2) 2, (3) 5, (4) 10, (5) 15, (6) 20, (7) 25.

composition above X=ca. 0.3. This fact is reconciled with the view that the enhancement of ethanol diminishes the adsorption of OSE.

Next, the value of Γ_1^H was evaluated by applying Eq. 3 to the γ vs. X curve drawn in Fig. 2 and using the activity coefficient of ethanol.[11] The Γ_1^H vs. X plot at constant m is shown in Fig. 5. The value of Γ_1^H at m=0 is positive over the whole range of composition and has a maximum. With increasing m, the value decreases considerably and becomes negative at a small X value, though it remains unchanged at a high X value. Taking into account that the maximum value of Γ_1^H is comparable with the value of the saturated adsorption of normal aliphatic alcohol,[12] we may say that ethanol molecules pack closely in the adsorbed film. However, the dependence of Γ_1^H on m suggests that the formation of OSE film expels ethanol molecules from the surface region. On the other hand, we notice that the surface activity of OSE becomes extinct in an ethanol-rich solution. Therefore, it seems to be useful to examine the relation of the adsorption of OSE to that of ethanol. This can be achieved by evaluating the ratio Γ_1^H/Γ_2^H.

The numerical values of Γ_1^H/Γ_2^H were evaluated by making use of Eq. 4 and the m vs. X curves in Fig. 3; they are plotted against X at fixed γ in Fig. 6, where r^H denotes Γ_1^H/Γ_2^H. The values at γ=60, 50, and 40 mN m^{-1} are seen to increase greatly with increasing X. On the other hand, the value at γ=30 mN m^{-1} first decreases and then increases steeply. These findings indicate that the competitive adsorption of OSE and ethanol molecules takes place at the surface.

Now it is useful to examine the adsorption of OSE from its micellar solution in the ethanol-water mixture. The behavior of micelles can be described by the excess thermodynamic quantities with reference to the spherical dividing surface around the micelle chosen so that the sum of the excess number of water molecules per micelle particle N_w^M and that of ethanol molecules N_1^M is equal to zero. The analogue of the Gibbs-Duhem equation for the micelle particle is written as[13]

$$N_w^M d\mu_w + N_1^M d\mu_1 + N_2^M d\mu_2 = 0, \quad (5)$$

where N_2^M is the excess number of OSE molecules per micelle particle and μ_i the chemical potential of component i. Adopting T, p, X, and m as the independent variables and assuming that OSE behaves ideally in the solution, Eq. 5 is rewritten in the following form at constant T and p

$$[(1-X)X]^{-1}[1+(\partial \ln f/\partial \ln X)_{T,p,m}]N_1^M dX + m^{-1}N_2^M dm = 0. \quad (6)$$

Combination of Eqs. 1 and 6 yields the relation representing the variation of surface tension of the micellar solution with X:

$$-d\gamma = RT[(1-X)X]^{-1}[1+(\partial \ln f/\partial \ln X)_{T,p,m}]\Gamma_2^H(r^H - r^M)dX, \quad (7)$$

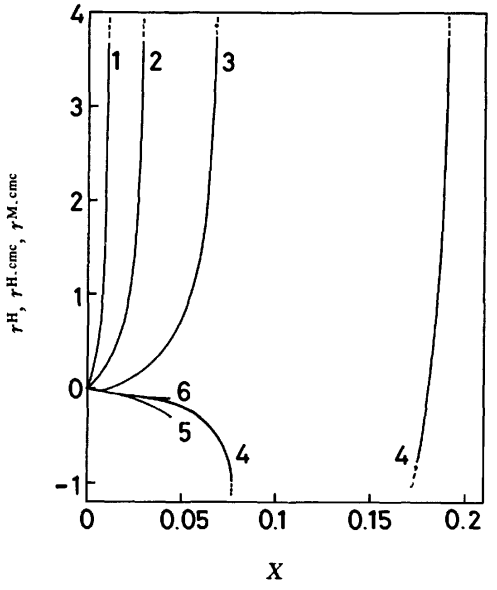

Fig. 6. Ratios r^H, $r^{H,cmc}$, and $r^{M,cmc}$ vs. mole fraction of ethanol curves at constant surface tension at 298.15 K under atmospheric pressure: (1) γ=60 mN m^{-1}, (2) 50, (3) 40, (4) 30, (5) $r^{H,cmc}$ vs. X, (6) $r^{M,cmc}$ vs. X.

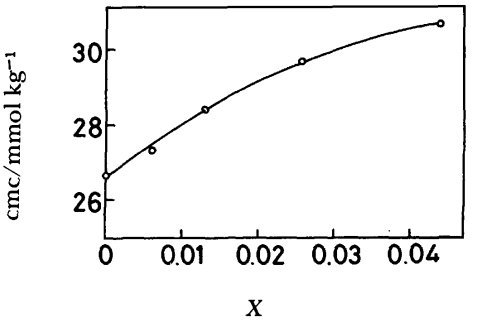

Fig. 7a. Critical micelle concentration vs. mole fraction of ethanol curve at 298.15 K under atmospheric pressure.

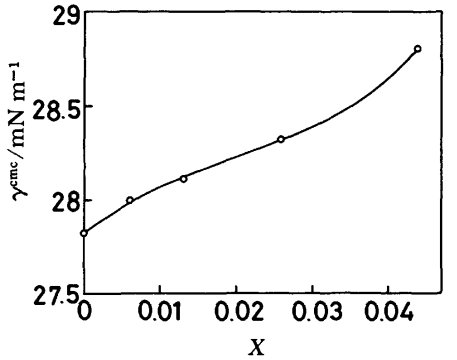

Fig. 7b. Surface tension at critical micelle concentration vs. mole fraction of ethanol at 298.15 K under atmospheric pressure.

where r^{M} expresses N_1^M/N_2^M. Since $\gamma \cong \gamma^{cmc}$ and $m \cong$cmc in the vicinity of the cmc, the following equations are obtained from Eqs. 6 and 7:

$$-(\partial \mathrm{cmc}/\partial X)_{T,p} = (\mathrm{cmc})[(1-X)X]^{-1}[1+(\partial \ln f/\partial \ln X)_{T,p,m}] \times r^{M,cmc} \quad (8)$$

and

$$-(\partial \gamma^{cmc}/\partial X)_{T,p} = RT[(1-X)X]^{-1}[1+(\partial \ln f/\partial \ln X)_{T,p,m}] \times \Gamma_2^{H,cmc}(r^{H,cmc} - r^{M,cmc}), \quad (9)$$

where the superscript cmc indicates that the values of the thermodynamic quantities are those at the cmc. Therefore, we can evaluate the values of $r^{H,cmc}$ and $r^{M,cmc}$ by applying Eqs. 8 and 9 to the experimental results.

The values of cmc and γ^{cmc} obtained from the γ vs. m curves in Fig. 1a are plotted against X at constant T and p in Figs. 7a and 7b. The cmc vs. X curve is qualitatively consistent with those observed by some other work.[4-6,14-17] The numerical values of $r^{H,cmc}$ and $r^{M,cmc}$ estimated are drawn as a function of X at 298.15 K under atmospheric pressure in Fig. 6. Comparing these curves with the r^{H} vs. X curves, the values of $r^{H,cmc}$ and $r^{M,cmc}$ may be said to be not so different from each other. Therefore, we can conclude that the behavior of OSE molecules in the micelle is similar to that in the adsorbed film. Moreover, the negative values of $r^{H,cmc}$ and $r^{M,cmc}$ indicate that ethanol molecules are expelled from the adsorbed film and the micelle particle of OSE.

Further information about the interaction between OSE and ethanol molecules in the adsorbed film and the micelle will be provided by a thermodynamic treatment which regards the present system as an aqueous solution of surfactant mixture.

Host-Guest Complexation of Mono[6-(1-pyridinio)-6-deoxy]-α-cyclodextrin with Several Inorganic Anions

Yoshihisa MATSUI,* Masahiko FUJIE, and Kaori HANAOKA
Faculty of Agriculture, Shimane University, Nishikawatsu, Matsue 690
(Received November 16, 1988)

Mono[6-(1-pyridinio)-6-deoxy]-α-cyclodextrin (**1**) formed 1:1 charge-transfer complexes with such inorganic anions as I^-, SCN^-, and Br^- in an aqueous solution to afford characteristic UV absorption bands. The binding constant (K_a) for a I^- complex with **1** was ca. 45 times as large as that with a nonmacrocyclic analog of **1**, ca. 10 times that with native α-cyclodextrin, and 4.4 times that with a β-cyclodextrin analog. The I^- ion was bound to a dipyridinio analog of **1** more strongly than to **1** by a factor of 10. The K_a values decreased with an increase in the ionic strength of the medium. The complexation was competitively inhibited by ClO_4^-. Hydrophobic, van der Waals, electrostatic, and charge-transfer interactions were supposed to take part in the complexation co-operatively.

Cyclodextrin (CD) forms host-guest complexes with a variety of molecules or ions in aqueous solutions. Several intermolecular interactions have been proposed as being responsible for the complexation:[1—4] Hydrophobic interactions, van der Waals interactions including dipole-dipole interactions and London dispersion forces, hydrogen-bonding, interactions due to the relief of high-energy water from the CD cavity upon guest complexation, and interactions due to the relief of conformational strain in a CD-water complex upon guest inclusion. Recently, the modification or functionalization of CD has attracted much attention to enhancing the binding force and/or the selectivity of a host. For example, a CD derivative in which the OH groups of CD are displaced by the apolar OCH_3 groups forms a host-guest complex with an apolar guest more stable than the native CD does.[5] In this case, the modification enhances hydrophobic and van der Waals interactions between a host and a guest. The replacement of the OH group(s) of CD with positively or negatively charged group(s) results in an increase in the affinity of the host for the oppositely charged guests.[6—9] Electrostatic interactions between the host and guests are responsible for the binding.

In the course of an investigation of charged CD,[8—10] we recently found that a positively charged CD, mono[6-(1-pyridinio)-6-deoxy]-α-CD (**1**), forms stable 1:1 charge-transfer (CT) complexes with such inorganic anions as I^- and SCN^- to give characteristic absorption bands in the UV spectra. It has been known that the 1-alkylpyridinium ions form CT complexes with a few inorganic anions.[11—13] However, the interactions between them are very weak in an aqueous solution.[12] In contrast, the binding constant (K_a) for a complex of I^- with **1** is considerably larger than that for a complex of I^- with either the native α-CD or the 1-alkylpyridinium ion. This finding seems interesting in view of the development of host compounds to which inorganic anions are bound strongly and/or selectively. Only a few host compounds with such ability have hitherto been reported.[14—17] The present article deals with the binding properties of **1** and related compounds in aqueous solutions, together with the effects of environmental factors, such as the ionic strength (I_c) and polarity of the medium, on the complexation of **1** with the I^- and SCN^- ions.

Experimental

Materials. The α- and β-CD's were kindly supplied by the Nihon Shokuhin Kako Co., Ltd., and were dried overnight in vacuo at 110 °C. Reagent-grade pyridine and dimethyl sulfoxide (DMSO) were dried over calcium hydride and distilled in the presence of fresh calcium hydride before use. The hydrogencarbonate salts of **1** and A,D-bis[6-(1-pyridinio)-6-deoxy]-α-CD (**2**) were prepared by refluxing solutions of the corresponding C(6)-*O*-sulfonylated α-CD's in dry pyridine, followed by the column chromatography of the products on a CM-cellulose column with the elution of aqueous ammonium hydrogencarbonate solutions.[10] The hydrogencarbonate salts of mono[6-(1-pyridinio)-6-deoxy]-β-CD (**3**)[9] and methyl 6-(1-pyridinio)-6-deoxy-α-D-glucopyranoside (**4**)[10] were also prepared in a similar manner. Reagent-grade methanol was used after distillation. The inorganic salts, such as KI, KSCN, KBr, KCl, $KClO_4$, K_2SO_4, and NH_4HCO_3, were reagent grade and were used without further purification. The ionic strengths of aqueous solutions were adjusted, if necessary, using K_2SO_4 or KCl. The deuterium oxide (Merck, 99.75%) and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) were available for ^1H NMR use.

Apparatus. The absorption spectra were measured with a Hitachi Model 220 spectrophotometer. The quartz cells (1.0 cm) were maintained at a constant temperature (25 °C) by means of a jacket through which water was circulated from a constant-temperature bath. The ^1H NMR spectra were recorded using a JEOL Model JNM-GX270 FT NMR spectrometer (270 MHz).

Results

Formation of CT Complexes of 1—4 with I^-. Aqueous solutions of 0.4—0.8 mmol dm^{-3} **1**—**3** (pH 8.1—8.5[18]) or 5 mmol dm^{-3} **4** (pH 8.8[18]) exhibited virtually nothing of either UV or visible absorption in the region of wavelengths longer than 280 nm. When KI was added to the solutions, characteristic absorp-

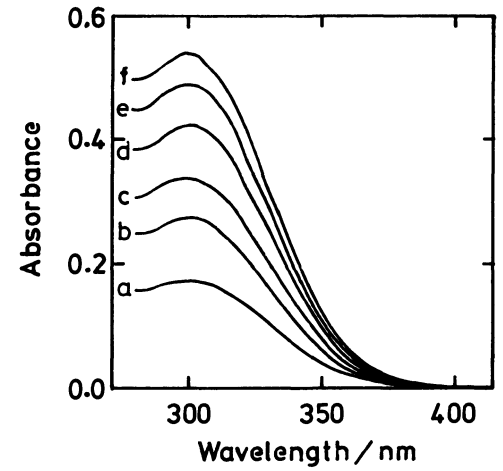

Fig. 2. Absorption spectra of 0.80 mmol dm^{-3} **1** in aqueous solutions containing various amounts of KI at 25 °C. [KI]/mmol dm^{-3}: (a) 2.5, (b) 4.9, (c) 7.1, (d) 11.3, (e) 17.0, and (f) 23.5.

tion bands appeared in the wavelength region from 280 to 350 nm. In a **3**–KI system (Fig. 1), the absorbance gradually increased with a decrease in the wavelength. No absorption maximum was observed in this wavelength region, similarly to the case of a CT complex of the 1-methylpyridinium ion (**5**) with I$^-$.[11] On the other hand, a **1**–KI system (Fig. 2) gave an apparent absorption maximum (λ_{max}) at 300 nm, indicating that a CT complex between **1** and I$^-$ is more stable than one between **3** and I$^-$.[13] The addition of KI to an aqueous solution of the dipyridinium derivative **2** also resulted in the appearance of a CT absorption band (λ_{max}=297 nm) very similar to that for a **1**–KI system. A CT band observed for an aqueous mixture of a nonmacrocyclic analog **4** with KI resembled that for a **3**–KI system.

The binding constants, K_a, for CT complexes of **1**—

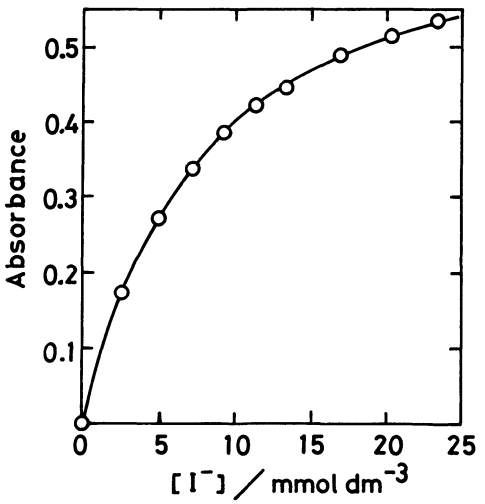

Fig. 3. Changes in absorbance at λ=300 nm of an aqueous **1** solution with increasing [I$^-$] at 25 °C. The solid line was obtained by the curve-fitting analysis upon an assumption of 1:1 complexation between **1** and I$^-$.

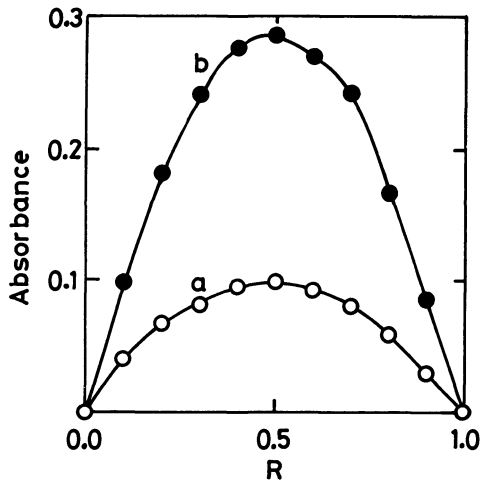

Fig. 4. Plots of absorbance at 300 nm against the ratio R=[host]/([host]+[guest]) for a **1**–KI system (a) at [host]+[guest]=2.0 mmol dm^{-3} and a **2**–KI system (b) at [host]+[guest]=1.0 mmol dm^{-3}.

4 with I$^-$ were determined by the curve-fitting analysis, by means of a microcomputer, of the changes in the absorbance at a given wavelength with the KI concentration, upon an assumption of a 1:1 complexation. The curves thus calculated were well fitted to the observed data (Fig. 3), indicating that the assumption of a 1:1 complexation is valid. The 1:1 stoichiometry was also confirmed by the continuous-variation method for complexes of **1** and **2** with I$^-$. Figure 4 shows the plots of the absorbance at 300 nm against the R=[host]/([host]+[guest]) ratio. The plots for both **1**–I$^-$ and **2**–I$^-$ systems gave maximum absorbances at R=0.5, indicating the 1:1 complexation. No indication of 1:2 complexation was

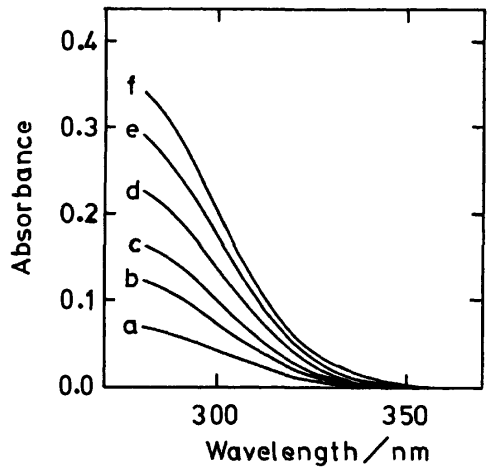

Fig. 5. Absorption spectra of 0.80 mmol dm^{-3} **1** in aqueous solutions containing various amounts of KSCN at 25 °C. [KSCN]/mmol dm^{-3}: (a) 0.6, (b) 1.2, (c) 1.8, (d) 3.0, (e) 4.8, and (f) 7.2.

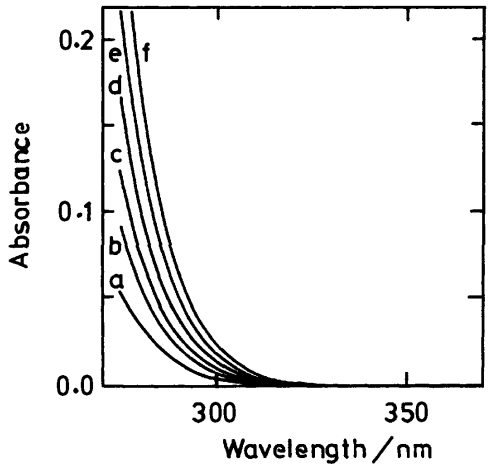

Fig. 6. Absorption spectra of 0.50 mmol dm^{-3} **1** in aqueous solutions containing various amounts of KBr at 25 °C. [KBr]/mmol dm^{-3}: (a) 14, (b) 28, (c) 41, (d) 63, (e) 103, and (f) 173.

recognized, even for a dipyridinio derivative **2**. The K_a values thus determined are shown in Table 1. The K_a value (3.0 mol^{-1} dm^3) for a nonmacrocyclic compound **4** was close to that (2.3 mol^{-1} dm^3) for **5**.[12] Interestingly, the K_a value (136 mol^{-1} dm^3) for **1** was remarkably larger than those for **4** and native α-CD by factors of about 45 and 10 respectively. It is evident that the hydrophobic cavity of **1** contributes to the stabilization of a CT complex of **1** with I$^-$. The K_a value (31 mol^{-1} dm^3) for a β-CD analog **3** was significantly smaller than that for **1**, though it was larger than those for **4** and native β-CD. Since the cavity size of **3** is larger than that of **1**, the van der Waals interactions between **3** and I$^-$ may be weaker than that between **1** and I$^-$. The K_a value (1320 mol^{-1} dm^3) for a dipyridinio derivative **2** was about 10 times as large as that for the monopyridinio derivative **1**. It is also noteworthy that the molar absorption coefficient (ε) for a **2**–I$^-$ CT complex was about twice that for a **1**-I$^-$ complex. The two pyridinio groups in **2** may participate cooperatively in the stabilization of a CT complex with I$^-$.

Formation of CT Complexes of 1 and 2 with Inorganic Anions Other than I$^-$. According to Kosower and Klinedinst,[11] 1-alkylpyridinium ions form CT complexes not only with I$^-$, but also with SCN$^-$ and Br$^-$. Hence, the complexation of **1** and **2** with inorganic anions other than I$^-$ was examined by means of absorption spectrophotometry. The addition of KSCN or KBr to an aqueous solution of **1** resulted in the appearance of UV absorption in the wavelength region from 280 to 350 nm; such absorption is characteristic of a CT complex (Figs. 5 and 6). An aqueous mixture of **2** with KSCN or KBr also gave a similar CT band. The spectral data were analyzed by the curve-fitting method described in the preceding paragraph. The results indicated that **1** and **2** form 1 : 1 complexes with SCN$^-$ and Br$^-$. The K_a values thus determined are summarized in Table 1. The K_a values for the **1**– and **2**–SCN$^-$ systems were, respectively, about 12 and 80 times as large as that for a native α-CD-SCN$^-$ system. The K_a values for the **1**– and **2**–Br$^-$ systems were also larger than that for a native α-CD–Br$^-$ system by factors of ca. 10 and 42 respectively. No CT absorption band was observed for aqueous mixtures of **1** and **2** with such inorganic salts as KCl, $KClO_4$, and K_2SO_4. Kosower and Klinedinst[11] also reported that the ClO_4^- ion forms no CT complex with **5**.

Effect of the Ionic Strength on the Binding Constants for CT Complexes of 1—3 with I$^-$ and SCN$^-$. Kosower and Burbach[12] suggested that the K_a value for a CT complex of **5** with I$^-$ is sensitive to the ionic strength, I_c, of the medium. Hence, the effect of I_c on the K_a values was examined for CT complexes of **1** and **2** with I$^-$ and SCN$^-$. The I_c of the medium was adjusted by K_2SO_4. It is known that the sulfate ion forms no inclusion complex with α- and β-CD.[19–22] The K_a values were spectrophotometrically determined at I_c=1.0; they are summarized in Table 2. An increase in I_c caused a marked decrease in K_a values for the systems examined. Thus, the K_a values for the **1**–I$^-$ and **1**–SCN$^-$ systems at I_c=1.0 were 0.54—0.58 times those determined at I_c<0.024. The effect of I_c on K_a was more remarkable in divalent **2** systems than in monovalent **1** systems. In the **2**-I$^-$ and **2**–SCN$^-$ systems, the K_a values were only 0.25—0.28 times those at I_c<0.007. The addition of K_2SO_4 causes a decrease in the ionic activities of the host and guest ions, thus weakening the complexation between them. Thus, it is evident that electrostatic interactions are also responsible for the complexation of **1** and **2** with I$^-$ and SCN$^-$ and that the contribution of the electrostatic interactions to the complexation is larger in divalent **2**

Table 1. Binding Constants, K_a, for CT Complexes of **1** and the Related Compounds with a Few Inorganic Anions in an Aqueous Solution at 25 °C

Anion	Host	K_a / mol^{-1} dm^3	$\varepsilon \times 10^{-3}$ [a] / mol^{-1} dm^3 cm^{-1}	I_c / mol dm^{-3}

	3	14 ± 1			

a) The ratio of K_a at I_c=1.0 to K_a in Table 1.

systems than in monovalent **1** systems.

Table 2 also includes the K_a values for CT complexes of **1** and **3** with I^- and SCN^- at I_c=1.0, as adjusted by the use of KCl. It is known that Cl^- forms inclusion complexes with α-CD, though the K_a value is very small.[19,23,24] The K_a values at I_c=1.0 (KCl) were always smaller than those at I_c=1.0 (K_2SO_4) by a factor of ca. 0.55. It is reasonable to consider that Cl^- retards the complexation of **1** or **3** with I^- or SCN^- not only electrostatically but also by competitive binding to the host cavity. The competitive binding of an inorganic anion to the host cavity was distinctly demonstrated by an examination of the effect of $KClO_4$ on the complexation of **1** with I^-. The perchlorate ion is known to form a relatively stable inclusion complex with α-CD.[22-26] The addition of $KClO_4$ to an aqueous solution of 0.792 mmol dm^{-3} **1** containing 19.8 mmol dm^{-3} KI caused an apparent decrease in the absorbance in the wavelength region from 280 to 350 nm due to a CT complex (Fig. 7). The I_c value of the medium was maintained at 1.0 by the use of K_2SO_4. Since the I_c of the medium was kept constant, the retarding effect of $KClO_4$ on the complexation of **1** with I^- is attributable to the competitive binding of ClO_4^- to the host cavity. In other words, the inclusion of I^- within the host

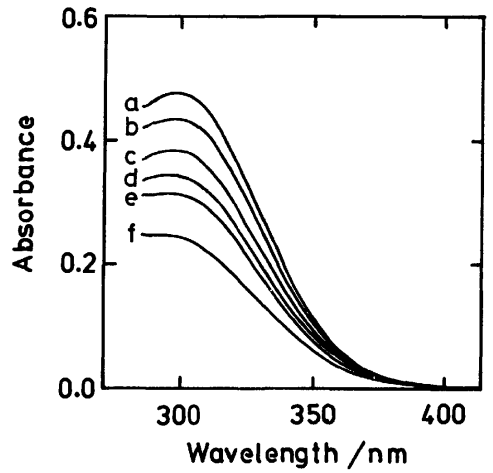

Fig. 7. Absorption spectra of a CT complex of **1** with I^- in aqueous solutions containing various amounts of $KClO_4$ at I_c=1.00 (K_2SO_4) and 25 °C. [**1**]=0.792 mmol dm^{-3}, and [KI]=19.8 mmol dm^{-3}. [$KClO_4$]/ mmol dm^{-3}: (a) 0.0, (b) 2.5, (c) 6.4, (d) 10.4, (e) 13.8, and (f) 27.8.

cavity is essential for the formation of a stable CT complex of **1** with I^-. The K_a value for a **1**-ClO_4^- system was determined to be 110 mol^{-1} dm^3 by the analysis of the inhibitory effect of ClO_4^- on the

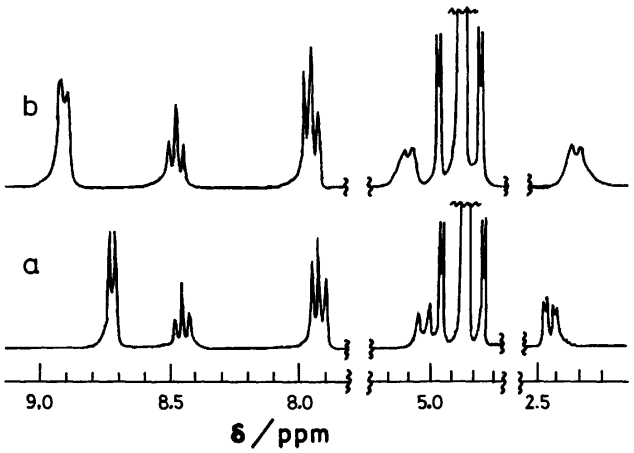

Fig. 8. Partial ^{1}H NMR spectra (270 MHz, D_2O, ref. DSS, 30 °C) of 20 mmol dm^{-3} **1** in the absence (a) and in the presence (b) of 92 mmol dm^{-3} KI.

complexation of **1** with I^-.[27] The K_a value is 3.7 times as large as that for a native α-CD-ClO_4^- system (K_a=30.6 mol^{-1} dm^3).[22]

^{1}H NMR Spectrometry of a CT Complex of 1 with I^-. The complexation of **1** with I^- was also examined by means of ^{1}H NMR spectrometry. Figure 8-a illustrates parts of the ^{1}H NMR spectrum of **1** in the absence of KI. The ortho-, meta-, and para-protons of the pyridinio group of **1** gave a doublet at δ=8.72 (2H, J=5.9 Hz), a triplet at δ=7.92 (2H, J=7.1 Hz), and a triplet at δ=8.45 (1H, J=8.1 Hz) respectively. An apparently doublet signal at δ=5.04 (1H, J=13.2 Hz) was assigned to one of the diastereotopic geminal C(6)-H's involved in the substituted glucopyranose ring [GP(A)], and a doublet-doublet signal at δ=2.43 (1H, J=3.3, 12.1 Hz), to one of geminal C(6)-H's involved in the unsubstituted glucopyranose ring [GP(B)] adjacent to GP(A).[10] The doublets at δ=4.76—4.96 (6H, J=ca. 3.2 Hz) were due to the anomeric C(1)-H's. Figure 8-b shows parts of the ^{1}H NMR spectrum of **1** in the presence of KI. The addition of KI caused a marked lower-field shift of the doublet signal due to the ortho-H's of the pyridinio group from δ=8.72 to 8.93. Furthermore, the doublet signal was significantly broadened by the addition of KI. In contrast to the signal of the ortho-H's, the triplet signals due to the meta- and para-H's of the pyridinio group showed only slight lower-field shifts and virtually no broadening of the signals upon the addition of KI. On the other hand, the apparent doublet signal and the dd-signal, due to the C(6)-H's of GP(A) and GP(B) respectively, showed a significant lower- or higher-field shift and signal broadening, whereas virtually no change was observed for the doublet signals due to the C(1)-H's. These facts indicate that the complexed I^- ion is located in the vicinity of the ortho- and C(6)-H's of **1**. The protons other than those described above gave ^{1}H NMR signals at δ=2.7—4.7; those signals were too complex to be completely assigned at the present stage of investigation. However, we also found that the complexation of **1** with I^- causes some changes in the pattern of the signals in this region.

Table 3. Effects of Organic Solvents on the λ_{max} and K_a Values of a CT Complex of **1** with I^- at 25 °C

Solvent	λ_{max}/nm	K_a/mol^{-1} dm^3
H_2O only	300	136 ±2

80% (v/v) DMSO	321	6.9±0.6

The Effect of Organic Solvents on the Complexation of 1 with I^-. Kosower showed that the CT absorption bands of 1-alkylpyridinium iodides are very sensitive to the polarity of the medium.[13] In the present work, we examined the effect of such organic solvents as methanol and DMSO on the CT absorption band and the K_a value of a **1**-I^- system (Table 3). The absorption maximum of the CT complex shifted to the direction of longer wavelengths. The effect was larger in DMSO than in methanol. These results are in agreement with those observed for 1-alkyl-4-(methoxycarbonyl)pyridinium iodides by Kosower.[13] The K_a value of a CT complex of **1** with I^- increased slightly with an increase in the DMSO concentration from 0 to 10% (v/v). A further increase in the DMSO concentration resulted in a significant decrease in the K_a value. The K_a value also decreased with the addition of methanol. DMSO and methanol are less polar than water. A decrease in the polarity of the medium with an increase in the concentration of the organic solvents is favorable for both electrostatic and CT interactions between **1** and I^-. However, it is unfavorable for hydrophobic interactions between them. Moreover, both DMSO and methanol are included within the α-CD cavity,[27,28] so they competitively inhibit the complexation of **1** with I^-. These unfavorable effects of the organic solvents may surpass the favorable effects in the systems examined, except for the cases of 10 and 20% DMSO.

Discussion

Judging from the results described in the preceding section, it seems that at least four kinds of intermolecular interactions are responsible for the complexation

of **1** with I^-: (1) Hydrophobic interactions, (2) van der Waals interactions, (3) electrostatic interactions, and (4) CT interactions. The host, **1**, forms relatively stable complexes with I^-, SCN^-, and ClO_4^-, which are known to be chaotropic or lipophilic anions.[29] On the other hand, **1** binds very weakly, if at all, to SO_4^{2-} and Cl^-, which are known to be antichaotropic or hydrophilic.[29] This fact indicates that hydrophobic interactions are involved in the complexation. The binding constant (K_a) for a I^- complex with **1** was ca. 45 times that with a nonmacrocyclic analog **4** and ca. 4.4 times that with a β-CD analog **3**. This suggests that the macrocyclic cavity of α-CD is essential for the formation of a stable complex of **1** with I^-. The I^- ion may be in close van der Waals contact with the α-CD cavity. The β-CD cavity in **3** may be too large to be in close contact with I^-. The host **1** is positively charged, and the guest, negatively charged. Thus, electrostatic interactions must also take part in the complexation. In fact, the K_a value for a **1**–I^- system decreases significantly with an increase in the I_c value of the medium. CT interactions may also contribute to the stabilization of the complex. This postulate is supported by the following observations. A mixture of **1** with I^-, SCN^-, or Br^- affords an distinct absorption band characteristic of a CT complex. The I^- and SCN^- ions are bound to **1** more strongly than to the native α-CD by factors of 6—7 at I_c=1.0. On the other hand, the K_a value for a **1**–ClO_4^- system at I_c=1.0 is only 3.7 times that for a native α-CD–ClO_4^- system. The ClO_4^- ion forms no CT complex with **1**. In conclusion, the four kinds of intermolecular interactions described above may take part cooperatively in the complexation of **1** with such inorganic anions as I^-, SCN^-, and Br^-.

Kosower and Burbach[12] suggested that, in a complex of **5** with I^-, the I^- ion is located over the center of the pyridine ring, although it is undeniable that the complexed I^- ion is located near the nitrogen of the pyridinio group. In the present **1**–I^- system, we found that ^1H NMR signals due to the ortho-H's of the pyridinio group and C(6)–H's of GP(A) and GP(B) are significantly influenced by the complexation, whereas only small changes, if any, in the signals are observable for the meta- and para-H's of the pyridinio group and the C(1)–H's of the GP's. This suggests that the complexed I^- ion is located in the vicinity of the nitrogen of the pyridinio group. The nitrogen is positively charged, so that the location of the complexed I^- ion near the nitrogen is advantageous for electrostatic interactions.

We have showed that I^- forms more stable complexes with the C(6)-mono- and C(6)-dipyridinio derivatives, **1** and **2**, than with the native α-CD by factors of ca. 10 and 100 respectively at I_c<0.024. This finding directed our attention to the development of a host compound to which inorganic anions are bound strongly and/or selectively. Very recently, we have found that the I^- is bound to the C(6)-tri- and C(6)-hexapyridinio derivatives of α-CD more strongly than to the native α-CD by factors of ca. 10^3 and 10^5 respectively at I_c<0.01. Thus, the effect of the number of the pyridinio groups on the stability is extremely large. The C(6)-di- and C(6)-tripyridinio derivatives of α-CD involve three and four regioisomers respectively. The effects of the positions of the pyridinio groups on the stability may also be interesting. The experimental results on these subjects will be presented elsewhere in detail.

It is anticipated that electrostatic and CT interactions between **1** and I^- will be strengthened by lowering the polarity of the medium. However, the addition of an organic solvent to the medium caused virtually no such favorable effect on the complexation as had been anticipated; this was because of the competitive binding of the organic molecule to the host cavity. It may be advantageous, for strengthening the electrostatic and CT interactions, to make the microenvironment around the pyridinio group less polar. In fact, we recently found that I^- is bound to the peracetylated derivative of **1** more strongly than to **1** by a factor of ca. 4 at I_c<0.024. Further details will be reported elsewhere.

Light-Induced Generation of Charge Carriers in Porphyrin Solids Doped with Electron-Accepting and Donating Molecules

Yutaka HARIMA,* Kazuyo YAMAMOTO, Kazuhiko TAKEDA, and Kazuo YAMASHITA
Department of Material and Life Sciences, Faculty of Integrated Arts and Sciences, Hiroshima University, Naka-ku, Hiroshima 730
(Received November 24, 1988)

Fluorescence and photocurrent generation efficiencies of thin films of 5,10,15,20-tetraphenylporphyrin (TPP) and its zinc complex (ZnTPP) doped with electron-accepting and -donating molecules were investigated to get an insight into a charge-carrier generation in organic solid films upon irradiation. Photogeneration of charge carriers in I_2-doped ZnTPP solids was found to consist mainly of a direct ionization process via an excited singlet state of ZnTPP while that in TPP solids was consistent with an exciplex formation model. From a practical view point, the doping of acceptor molecules into p-type porphyrin solids was effective to improve photovoltaic efficiencies of Al/porphyrin/Au sandwich-type cells.

The effect of electron acceptors or donors upon the conductivity and photoconductivity of molecular solids is well-known. As early as in 1960, Calvin et al. examined electrical properties of phthalocyanine (Pc) films on addition of *o*-chloranil and found the increase in the dark conductivity and photoconductivity by orders of magnitude.[1,2] Based on the ESR measurement, they ascribed the striking enhancement of the currents to an electron transfer from Pc to the acceptor molecule in the dark, which produces holes in the Pc layer and *o*-chloranil anion radicals. More recently, Loutfy and Menzel have investigated a correlation between fluorescence and charge-carrier photogeneration efficiencies of an X-type Pc film doped with 2,4,7-trinitrofluorenone (TNF).[3] In consequence, they have found that with an increase in TNF concentration the carrier generation efficiency increases while the fluorescence is quenched. Their finding is explained by the singlet exciton diffusion to the surface of the X-Pc at the dopant site, followed by the exciplex formation and its subsequent dissociation into charge carriers. In other words, the former authors have postulated a dominant role of the ground-state complex for the doping effect, which is equivalent to the band model of doped semiconductors,[4] as opposed to the exciplex formation proposed by the latter.

The electronic processes in molecular solids are complicated and their interpretation occasionally requires molecular level considerations.[5-8] However, a close examination of the doping effect on the organic semiconductors could be a clue to understand the electronic processes such as a charge-carrier generation upon irradiation, the process being essential in photosynthesis and in solar energy conversion.

In this report, we describe the effects of doping with electron acceptors and donors on the fluorescence intensity of porphyrin films as well as on the performance of photovoltaic cells based on these porphyrins. The reasons of using porphyrins as host molecules are four-fold: 1) Electronic processes in nondoped porphyrin films have been the subject of recent investigations.[9,10] Especially, the choice of the two porphyrins, i.e. 5,10,15,20-tetraphenylporphyrin (TPP) and its zinc derivative (ZnTPP), is due to the large differences in exciton diffusion length[9,10] and in oxidation potential[11] between these porphyrins. 2) Different from phthalocyanines most investigated, porphyrins are soluble in some organic solvents to allow a preparation of organic thin films by use of a spinner coating method. This enables us to distribute guest molecules into the porphyrin layers uniformly. In most of previous studies[2,3,12] a surface doping in place of our bulk doping is employed. 3) Fluorescence from porphyrin solids is intense and gives us the information on the fate of excited states. 4) Aggregates of porphyrin molecules, organic oxidizing agents (quinones, coenzyme Q, etc.) and reducing agents (carotenoids) occur together in photosynthetic materials, and their interaction may be of importance in the primary quantum conversion process.

Experimental

TPP and its metal complex (ZnTPP) were purchased from Strem Chemicals Inc. ZnTPP was purified according to the literature method to remove a trace of chlorin.[13] Thin films of TPP and ZnTPP are known to exhibit a p-type semiconducting behavior. Iodine (I_2) was of reagent grade from Katayama Chemicals and used without further purification. Tetracyanoquinodimethane (TCNQ) from Tokyo Kasei Co. was recrystallized twice from ethyl acetate. *o*-Chloranil (Chl) and phenothiazine (Pz) from Tokyo Kasei Co. were purified by recrystallization from acetone and toluene, respectively. I_2, TCNQ, and Chl are well-known to be electron acceptors while Pz is an electron donor. Dichloromethane was redistilled after desiccation with calcium hydride. Sandwich-type photovoltaic cells of Al/(porphyrin+dopant)/Au were fabricated by first evaporating aluminum directly onto a precleaned glass substrate at 10^{-4} Pa by use of a Tokuda CFS-8EP vacuum deposition apparatus. The transmittance of the aluminum film was 20—50%. Porphyrin films doped with acceptors and donors were prepared using a Kyowa-Riken K359SW spinner as follows: a given amount of dopant molecules was dissolved into a 8 mM (1 M=1 mol dm^{-3}) TPP or ZnTPP solution of dichloromethane, and then one drop of the solution of

porphyrin plus dopant was put onto the aluminum-coated glass slide spinning at the rate of 4600 rpm. Absorbance of the films prepared in this manner was 0.8—1.0 at the Soret band of the porphyrin films irrespective of the amount of dopant molecules involved. Only uniformly prepared samples were used for further vacuum-deposition of gold on the porphyrin films to make an ohmic contact. Measurements of spectral responses of the short-circuit (s.c.) photocurrents were performed with the aid of a microcomputer, where photocurrents were normalized in such a way that the intensity of monochromatic light incident on the interface between the dye film and Al was at 10 μW cm^{-2}. The light source consisted of a 300 W tungsten halogen lamp and a JASCO CT-10S monochromator. Open-circuit photovoltages (V_{oc}) of photovoltaic cells were measured by a Takeda Riken TR8651 electrometer. Samples for fluorescence measurements were prepared by the spinner coating onto Pyrex glass substrates. Measurements of fluorescence from spun films of porphyrins were made by use of a Hitachi MPF-4 fluorescence spectrophotometer. In most experiments, the angle of the exciting light to the normal of the sample side of the glass slides was adjusted within 65±5° to give a maximum fluorescence intensity, and the luminescence was detected at the right angle to the exciting beam. All measurements were carried out at room temperature.

Results

Figure 1 depicts spectral responses of s.c. photocurrents for a) Al/TPP/Au and b) Al/ZnTPP/Au photovoltaic cells with and without doping of electron accepting I_2 and TCNQ molecules. In all cases, illumination is carried out from the Al/p-type porphyrin interface which provides an effective site for the light-induced generation of charge carriers. Photocurrents (i_p) flow from Au to Al through the external circuit. It is seen that the addition of I_2 or TCNQ enhances the photocurrents greatly over the entire spectral range investigated. In addition, the spectral responses of photocurrents for the doped samples coincide well in shape with the absorption and action spectra of the corresponding pure porphyrin films, suggesting that no spectral sensitization by the dopants takes place. The photocurrent quantum yield (η), defined as the number of electrons produced per photon incident on the dye film, at the Soret band changes from 1.4% for pure TPP to 6.3% for I_2-doped TPP and from 2.9% for pure ZnTPP to 11% for I_2-doped ZnTPP. In addition to this, no appreciable decay of i_p with a lapse of time indicates that the doping is an important technique to improve efficiencies of solar cells based on organic materials.

Figure 2a shows changes of s.c. photocurrents at the Soret band for the Al/TPP/Au photovoltaic cells when I_2, Chl, TCNQ, or Pz are doped into the TPP solids at various mole fractions, where η_0 in ordinate denotes the η value in the absence of dopant. Figure 2b depicts similar plots for the Al/ZnTPP/Au photovoltaic cells with I_2 or TCNQ as a dopant. With I_2 being doped, the photocurrents for the both cells start to increase at the I_2 mole fraction as high as 0.1, whereas the TCNQ doping is effective at its mole fraction as low as 0.01. In the TCNQ case, the photocurrents for TPP as well as ZnTPP level off at a 0.2 mole fraction and decrease with TCNQ mole fractions beyond this value. The photocurrent reduction when TCNQ is doped heavily might be ascribed to a steric effect which prevents an intermolecular interaction between porphyrin molecules. As is seen in Fig. 2a, the doping of Chl into the TPP film was the most effective and enhanced the photocurrent by almost one order of magnitude. On the other hand, the photocurrent is slightly reduced by the addition of electron-donating Pz molecules into the TPP film.

Figure 3 summarizes the results of fluorescence measurements, where F and F_0 correspond to intensities of fluorescence from porphyrin solids with and

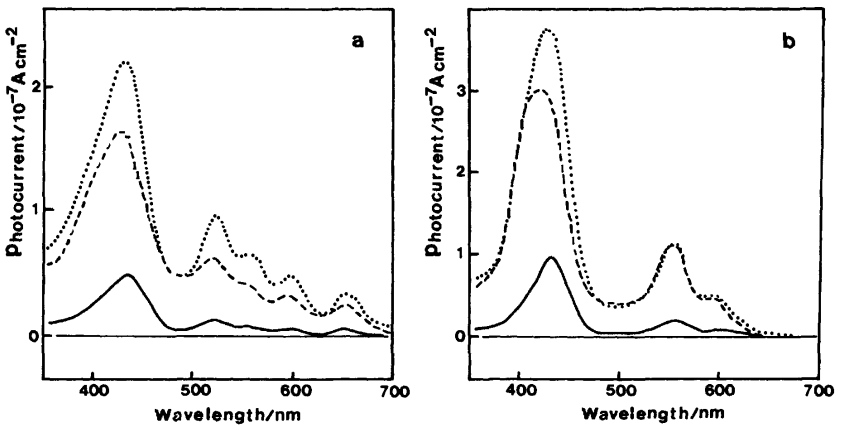

Fig. 1. Spectral responses of s.c. photocurrents for a) Al/TPP/Au and b) Al/ZnTPP/Au photovoltaic cells, where porphyrin solids are nondoped (solid line) and doped with I_2 (dotted line) and TCNQ (broken line).

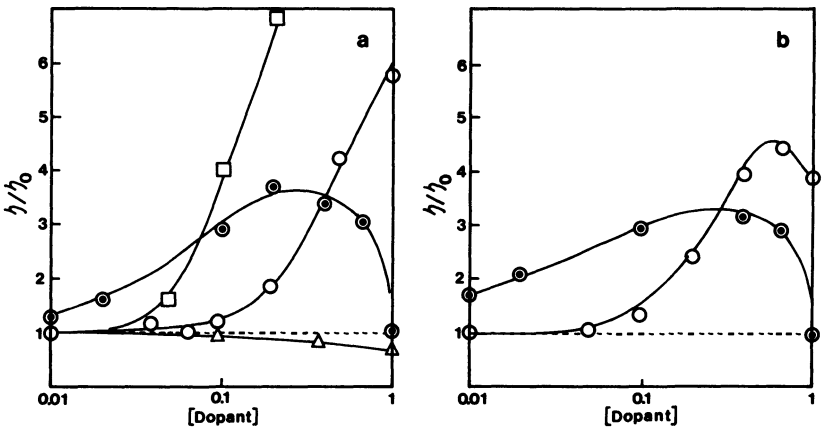

Fig. 2. Effect of doping on photocurrent quantum yield (η) for a) Al/TPP/Au and b) Al/ZnTPP/Au photovoltaic cells, where photocurrents are measured at the respective Soret bands of TPP and ZnTPP solids. Abscissas in Figs. 2 and 3 denote a mole fraction of the respective dopants: (○) I_2; (◉) TCNQ; (□) Chl and (△) Pz.

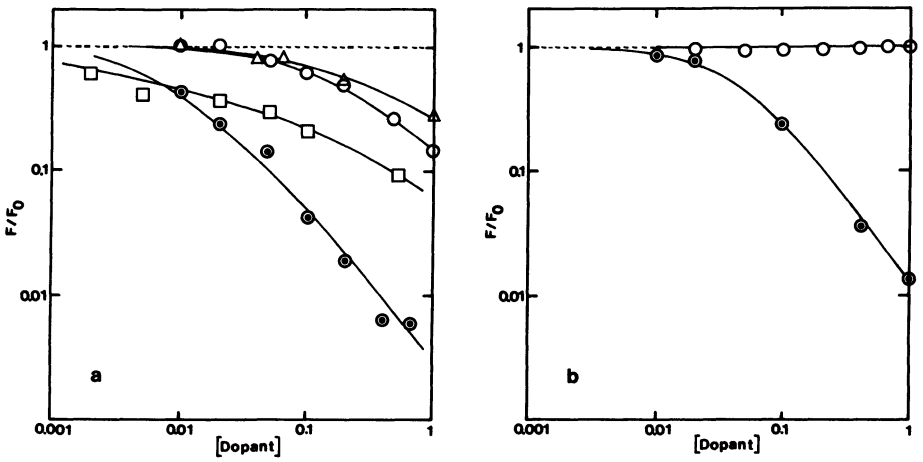

Fig. 3. Effect of doping on fluorescence intensity (F) of TPP and ZnTPP films, where excitation is made at 430 nm in both cases and emission is detected at 655 nm for TPP and 605 nm for ZnTPP. Each symbol has the same meaning as that of Fig. 2.

without doping, respectively. The excitation is made at the respective Soret bands of TPP and ZnTPP films, and the emission is detected at 655 nm for TPP and 605 nm for ZnTPP. It is seen from this figure first that TCNQ is the most effective in quenching ability among dopants used in the present study and second that fluorescence of TPP is quenched by TCNQ or I_2 more strongly than that of ZnTPP is. The second feature of the fluorescence quenching may be associated with the exciton diffusion length being greater for TPP than ZnTPP,[9] if the quenching ability of either of the dopants is similar between the two porphyrins. It should be noticed in Fig. 3 that fluorescence from the ZnTPP films is not quenched at all by I_2 ranging in mole fraction up to unity although the photocurrents are enhanced by the factor of 4 at the highest I_2 mole fraction. In contrast to this, fluorescence of the TPP films is quenched by Pz with an electron donating character although the photocurrents for the Pz-doped porphyrin films are almost constant irrespective of the amount of Pz doped. When the data in Fig. 3 were replotted as a reciprocal of a fluorescence intensity against a dopant mole fraction, all the plots yielded straight lines in the ranges of mole fractions up to 0.2—0.5 depending on the sort of the dopant. This finding indicates that the present bulk-doping technique using the spinner is successful to attain a uniform distribution of dopants in the solid films at low doping levels, at least.

Figure 4 displays the effect of I_2-doping on relative

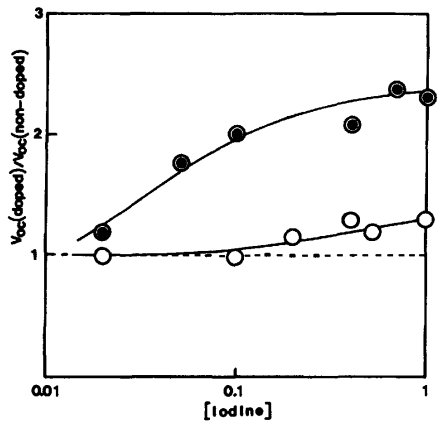

Fig. 4. Effect of I_2-doping on relative photovoltages of (○) Al/TPP/Au and (◉) Al/ZnTPP/Au photovoltaic cells.

open-circuit photovoltages of a) Al/TPP/Au and b) Al/ZnTPP/Au cells, where V_{oc}'s for the doped samples are divided by V_{oc} for the nondoped sample. V_{oc} for TPP stays almost constant irrespective of concentrations of I_2 doped, while that for ZnTPP increases with increasing I_2 concentration.

Discussion

According to the exciplex formation model,[3] deactivation routes for singlet excitons (S_1) consist of the following two competitive reactions:

$$S_1 \longrightarrow S_0 + h\nu(\text{fluorescence}) \quad (1)$$

$$S_1 + Q \longrightarrow (S.Q)^* \quad (2)$$

where Q is the quencher or the electron acceptor in the present case, S_0 the ground state of an organic dye molecule and $(S.Q)^*$ denotes the exciplex. The exciplex is assumed to dissociate into free charge carriers with a probability of $\phi(E)$ or into S_0 and Q as follows:

$$(S.Q)^* \xrightarrow{\phi(E)} e^- + h^+ \quad (3)$$

$$(S.Q)^* \xrightarrow{1-\phi(E)} S_0 + Q \quad (4)$$

Obviouly, this mechanism predicts the increase in charge carrier photogeneration efficiency on addition of Q concomitant with a decrease in fluorescence, in accord with the observations for the I_2-, TCNQ-, and Chl-doped TPP films. The same effects of doping can be expected also by assuming a dissociation of the exciton due to a local electric field caused by the charge-transfer complex between S_0 and Q in the dark. However, neither of these mechanisms explains the increase in photocurrents of the Al/ZnTPP/Au cell on addition of I_2, accompanied by no quenching of fluorescence. Concurrent changes in efficiencies of fluorescence and charge-carrier generation are essential in both models because a charge-carrier generation and a fluorescence quenching follow the reaction of S_1 with Q or with the CT complex comprising S_0 and Q.

One possible way to account for the results with ZnTPP is to assume, in place of the above impurity-dependent route, a direct charge-carrier generation from the S_1 state and/or the excited state of ZnTPP together with the band model description of the ZnTPP solid. In a preceding paper,[10] we have estimated diffusion lengths of excitons as 3±2 nm for ZnTPP and 15±10 nm for TPP on the basis of the analysis of the optical filtering effect observed for the Al/porphyrin/Au photovoltaic cells. In view of the fact that our estimate of the exciton diffusion length involves a contribution from the direct ionization process as well, the short exciton diffusion length found for the ZnTPP solid suggests that the direct charge-carrier generation may prevail in the ZnTPP solid in support of the above assumption. On the other hand, the ZnTPP molecule is known to be more easily oxidized than the TPP molecule.[11] This suggests that the valence band edge of the ZnTPP solid locates above that of TPP. Therefore, the postulated relative positions of energy levels denote that the acceptor doping should be more effective in ZnTPP than in TPP or that the acceptor molecule is likely to produce a ground-state complex, as suggested by Calvin et al.,[2] with the ZnTPP molecule more easily than with TPP. The ground-state complex formation leading to a production of the majority carrier (hole) in the ZnTPP solid in the dark induces a shift of the Fermi level of the molecular solid toward the valence band. The lowering of the Fermi level of the p-type solid leads to the increase of a built-in potential in the ZnTPP bulk close to Al, consistent with the increase in V_{oc} with increasing I_2 concentrations as shown in Fig. 4. Furthermore, the increase in the built-in potential can be responsible for the improvement in the photocurrent quantum yield since the enhanced electrostatic field in the depletion layer reduces a recombination probability of electron-hole pairs produced by the direct ionization process. It is quite evident that this model, in place of the exciplex formation model, does not necessarily require a parallelism between the fluorescence quenching and the improvement in the photocurrent quantum yield.

A spectroscopic attempt to detect the ground-state complex between ZnTPP and I_2 was performed by measuring absorption and fluorescence spectra of pure ZnTPP films and ZnTPP films doped with I_2 at various concentrations. However, no change at all was found in both spectra, suggesting that the equilibrium concentration of the ground-state complex is very low in comparison with that of the dopant added unless it has an absorption and a fluorescence spectra essentially indistinguishable from those of ZnTPP itself. The low concentration is not in conflict with the

observed changes in V_{oc} and i_p on addition of I_2 because even a small amount of the ground-state complex, if its concentration being higher than the hole concentration of the pure ZnTPP film, can be sufficient to alter electrical properties of the ZnTPP solids greatly.

For the TCNQ-doped ZnTPP solids, one can expect a similar carrier generation mechanism with the above one. In this case, however, fluorescence was quenched highly on addition of TCNQ. The result shows clearly an involvement of deactivation routes of S_1 such as expressed by Eqs. 1 and 2 besides, probably, the direct carrier generation path, which is predominant in the illuminated I_2-doped ZnTPP film.

Finally, the fluorescence quenching and no change of i_p observed with the Pz-doped TPP film are understandable by assuming the exciplex model with a small $\phi(E)$ value.

In conclusion, the present study shows that the mechanism of photogeneration of charge carriers depends on the combination of a dopant and an organic solid. Measurements of fluorescence and charge-carrier generation efficiency for the TPP solids doped with Chl, I_2, TCNQ, or Pz were consistent with those expected from the exciplex formation model. On the other hand, the mechanism of charge-carrier generation upon irradiation for the I_2-doped ZnTPP was explained based on the band model for the doped semiconductors together with the assumption of the direct photoionization process, in which the photocurrent increase was ascribed to a reduction in recombination rate of electron-hole pairs in the depletion layer. In the case of TCNQ-doped ZnTPP, both direct and indirect processes appeared to prevail.

The Model Compounds and the Conformational Analysis of Poly(thiomethylene)

Taira MIYASAKA* and Takaichi YOSHIDA
Department of Dental Materials Science, School of Dentistry at Tokyo, The Nippon Dental University, 1-9-20, Fujimi, Chiyoda-ku, Tokyo 102
(Received November 29, 1988)

The conformational energies of model compounds of poly(thiomethylene), $CH_3(SCH_2)_nSCH_3$, (n=1—6) were calculated by the molecular-mechanics method. Based on these conformational energy differences, the configuration-dependent properties of poly(thiomethylene) were estimated under the rotational isomeric-state approximations. The first-order interaction energy of the $C\diagdown S\diagup C\diagdown S$ bond, obtained from the energy differences among the conformers of $CH_3(SCH_2)_3SCH_3$, is coincident with that estimated from the same bond sequence for poly(1,3-dithiocane). Based on this coincidence, the monomeric sequential length of the model compound, which is representative of poly(thiomethylene), was decided. The propriety of the method of coupling the molecular-mechanics with the statistical-mechanics was also demonstrated.

Because of the structural similarity between poly(oxyalkylenes) and poly(thioalkylenes), the anomalous preference of the gauche states to the trans, i.e. the "gauche effect," which had been found in poly(oxyalkylenes),[1] is expected also to be present in poly(thioalkylenes). Based on the success of the estimation of the "gauche effect" and that of the proper approximation for rotational states of poly(oxyalkylenes),[2-4] poly(thiotrimethylene) was studied by the molecular-mechanics method in a previous report.[5] This polymer has the simplest chemical structure among the analogous poly(thioalkylenes), whose configuration-dependent properties had previously been observed experimentally. In that earlier paper,[5] the dipole-moment ratio and its temperature coefficient, observed experimentally, were reproduced with satisfactory success under the isomeric-state approximation of the molecular-mechanics method. It was shown that the "gauche effect" caused by sulfur atoms is significantly different from that of poly(oxyalkylenes); in the case of poly(thiotrimethylene), a longer-range steric interaction plays an important role. It was also shown that the molecular mechanics is effective in the analysis of the anomeric gauche effect of poly(thiotrimethylene).

Poly(thiomethylene) is the simplest member of the poly(thioalkylenes) and possesses the characteristic $C\diagdown S\diagup C\diagdown S$ sequence. Therefore, it can be expected to exhibit the even more characteristic "sulfur gauche effect." Recently, a vibrational analysis of poly(thiomethylene) was done[6] based on the group-coordinate force-field method, which clarified that the dominant conformational state of the skeletal bonds in the crystal, liquid, and gaseous states is gauche, although the energy difference between possible conformers had not yet been estimated accurately.

In this paper, the molecular conformation and the related properties of poly(thiomethylene) are studied by the method of statistical mechanics coupled with the molecular mechanics, since the configuration-dependent properties have not been observed experimentally because of the low solubility of poly(thiomethylene) in any solvents and its high melting point. Several model compounds possessing various chain lengths are investigated in an attempt to estimate the rotational isomeric-state approximations of the polymer. The most suitable chain length for the model compound of poly(thiomethylene) should satisfy the following conditions: it gives all the statistical and geometrical parameters required in the statistical-mechanics calculations for poly(thiomethylene), and it gives a first-order interaction ($C\diagdown S\diagup C\diagdown S$) parameter of the same magnitude as that which has experimentally estimated for poly(1,3-dithiocane). Using the parameters thus obtained, the configuration-dependent properties of poly(thiomethylene) are calculated.

Theoretical

Molecular-Mechanics Method. The molecular-mechanics method, also called the force-field method, has become one of the most popular methods in the field of computer chemistry. In this calculation, a molecule is treated as a system of particles held to one another with classical mechanical interatomic forces. The steric energy of the molecule is obtained as a function of the bond-stretching, bending, torsional, van der Waals, and electrostatic interactions; then, the optimum conformation is searched for.

Although many force fields have been suggested, Allinger's force-field[7] can be used for a wide range of problems in organic chemistry because its parameters for hydrocarbons and some hetero atoms are made carefully. An old type of this type of force field, i.e., MMI,[7] has been successfully used in a series of our studies of the conformational analysis of poly(oxyalkylenes); a newer version, i.e., MM2[8] has also been used in our previous reports on a similar analysis of poly(thiotrimethylene). In the present calculation, we used the new version of MM2,[9] which can run on a microcomputer.

In order to ascertain the optimal length of model compounds used as representative poly(thiomethylenes), the following compounds including one to six $-SCH_2-$ units with terminal methyl and methylthio groups were selected for study; 2,4-dithiapentane [**2T**] $CH_3-SCH_2-SCH_3$, 2,4,6-trithiaheptane [**4T**] $CH_3-(SCH_2)_2-SCH_3$, 2,4,6,8-tetrathianonane [**6T**] $CH_3-(SCH_2)_3-SCH_3$, 2,4,6,8,10-pentathiaundecane [**8T**] $CH_3-(SCH_2)_4-SCH_3$, 2,4,6,8,10,12-hexathiatridecane [**10T**] $CH_3-(SCH_2)_5-SCH_3$, and 2,4,6,8,10,12,14-heptathiapentadecane [**12T**] $CH_3-(SCH_2)_6-SCH_3$. Here ***n*T** in square brackets denotes the number of skeletal bonds whose internal rotations experience the butane interaction between CH_2 groups and S atoms; these abbreviations will be used hereafter instead of the full names of the model compounds. The all-trans conformer, the conformers including one gauche state, and those including two consecutive gauche bonds with the same or opposite signs are calculated by means of the molecular-mechanics.

Results and Discussion

Model Compounds of Poly(thiomethylene). The results of molecular-mechanics calculations on the six above-mentioned kinds of model compounds of poly(thiomethylene) are listed in Table 1, where the energy differences between the conformers including one or two consecutive gauche states and the corresponding all-trans conformer are also shown.

In the case of the simplest model compound, **2T**, the GG conformer has the lowest energy, the TG conformer is next, and the TT has the highest. In the vibrational analysis of this model compound, more than two conformers were found in the liquid or gaseous states.[6] These results can be compared with those for the corresponding model compounds of poly(oxymethylene),[2] i.e. 2,4-dioxapentane, in which the energy differences of the TG, GG, and G$\bar{\text{G}}$ conformers from TT are −10.84, −18.45, and −3.18 kJ mol^{-1} respectively. Comparing these values with the values of **2T** shows that the energy of TG, i.e., −4.01 kJ mol^{-1}, is much higher than that of 2,4-

dioxapentane. The energies of the two consecutive gauche states of 2,4-dioxapentane (E_{GG} and $E_{G\bar{G}}$) are larger than twice the energy difference in the conformer including one gauche state ($2E_{TG}$), while the energy of E_{GG} of **2T** is smaller than $2E_{TG}$. Such a difference may be caused by the difference in the skeletal-bond length: the long C-S bond and the short C-O bond. The energy differences between the conformers of **2T** are mainly caused by the difference in the torsional and electrostatic interactions. These interactions also play an important role in the energy difference among the conformers of 2,4-dioxapentane. However, the energy difference between **2T** and 2,4-dioxapentane may also be caused by the electrostatic interactions: the electrostatic attraction in 2,4-dioxapentane is much larger than that in **2T**. This model compound, **2T**, is too short in length to give all the statistical-weight parameters required in the statistical-mechanics calculations for poly(thiomethylene). The smallest model compound giving the five required statistical-weight parameters is **4T**.

The conformers of **4T** including the two consecutive gauche bonds with the same sign are the lowest in energy, those including one gauche bond are the next lower, and the all-trans conformer is the highest. In the case of the corresponding model compounds of poly(oxymethylene),[2] i.e., 2,4,6-trioxaheptane, the order of the conformers in terms of energetic stability are the same as in **4T**, although the energy of the conformer including one gauche is lower by a factor of about 2.7 than that of the corresponding conformer of **4T**. The energy difference among the conformers is mainly caused by the torsional and electrostatic interactions. Especially the electrostatic interaction plays an important role in the steric-energy difference between **4T** and 2,4,6-trioxaheptane. The vibrational and normal-coordinate analysis of poly(thiomethylene) and its model compounds[10] made it clear that the lone-pair electrons on the sulfur atoms in the trans form are all located in the same direction and that the repulsion force between the lone-pairs becomes large (rabbit-ear effect), resulting in the stability of the gauche state.[10] This stability of the gauche state is consistent with the calculated results for the model compounds in this study.

Based on the calculated results for the various conformers from **2T** to **12T**, it was clarified that the conformation energy is smaller for the compound which includes the gauche bond in the inner position of the skeletal chain. This is always true for the conformers with a gauche state located within the fourth position from the terminal point, except for the sequence of TTTTTTGT and TTTTTGTT of **8T**. On the contrary, the conformers of **10T** and **12T**, which include a gauche bond at a position more inward than the fourth from the terminal point, show larger energies than those of the conformers which include a gauche bond at the fourth position. It seems that, when the length of the chain becomes long, the gauche state of the central position experiences a severe steric interaction because of the large substituent groups being brought close to each other. Therefore, the **10T** and **12T** molecules seem too long to be adopted as suitable model compounds of poly(thiomethylene). For the conformers including two consecutive gauche bonds of the same sign, the energy becomes lower as the two gauche bonds are positioned at the inner part of the chain, except for the cases of the TTTTTTGGTTTT and TTTTTGGTTTTT of **12T**.

Statistical-Mechanics Calculation of Configuration-Dependent Properties. A parameter of the first-order interaction and the four parameters of the second-order interactions are required to make statistical-mechanics calculations of configuration-dependent properties of poly(thiomethylene). The statistical-weight parameter of the first-order interaction for a gauche in the  bond sequence is denoted by σ. The parameters of the second-order interaction in the sequence are denoted by ϕ and ω for the two consecutive gauche bonds with the same and with opposite signs respectively. The second-order interaction parameters of the two other consecutive gauches in the sequence are defined by ϕ' and ω' for the GG($\bar{G}\bar{G}$) and G$\bar{G}$($\bar{G}$G) respectively. These parameters are obtained from the above-mentioned results of the molecular-mechanics calculation of the conformers of each model compound. The first-order interaction energy E_σ is calculated as the averaged value of the conformational-energy differences between the conformers including one gauche state and the all-trans conformer. The second-order interaction energy is obtained as the energy increment upon the introduction of one additional gauche state into the corresponding conformation with one gauche bond; for example, $E_{\phi'}=E_{TTGG}-E_{TTGT}-E_{TTTG}$. These energy values are averaged over all the model compounds. The energies of the first- and second-order interactions thus obtained are plotted for the number of skeletal bonds of model compounds in Fig. 1. The first-order interaction energy E_σ decreases with the increase in the chain length: -4.02 kJ mol^{-1} in **2T** and -6.11 kJ mol^{-1} in **12T**. In contrast, E_ϕ and $E_{\phi'}$ are held at almost the same level; E_ϕ is nearly zero, and $E_{\phi'}$ is between -0.17 and -0.33 kJ mol^{-1}. The second-order interaction energies for the two consecutive oppositely signed gauche sequences, i.e., E_ω and $E_{\omega'}$, vary significantly. The E_ω increases with an increase in the chain length, while the $E_{\omega'}$ tends to decrease slightly with some vibration. The conformations of poly(thiomethylene) are estimated from these energy parameters. The gauche state occurs most frequently because of a large negative value of E_σ. The

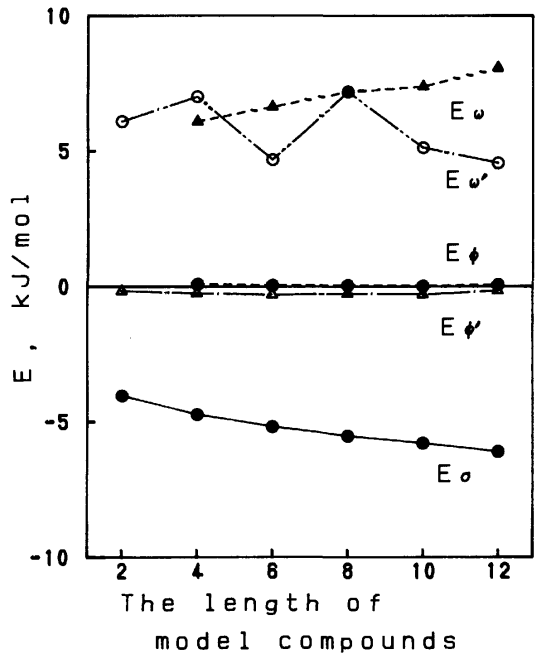

Fig. 1. The variation of statistical-weight parameters plotted against the chain length of model compounds of poly(thiomethylene).

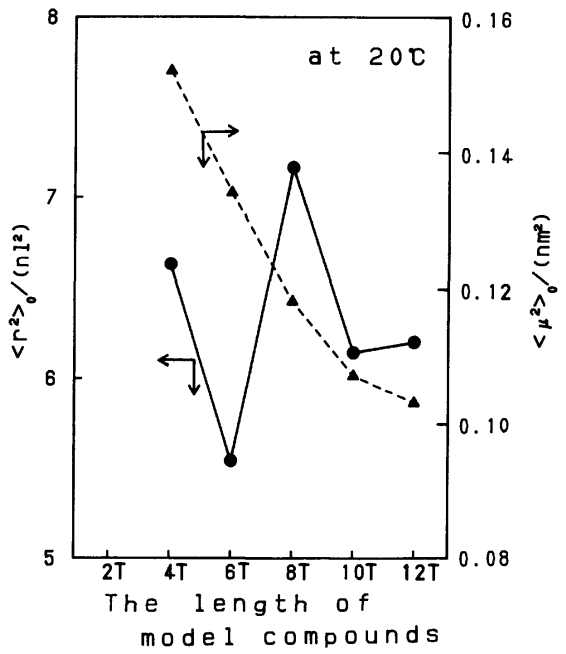

Fig. 2. The dependence of the characteristic ratio and the dipole-moment ratio of poly(thiomethylene) on the chain length of model compounds. Filled circles represent the characteristic ratios and filled triangles represent the dipole-moment ratios.

conformers containing two consecutive gauche states with the same sign in the $^{C}_{S}\!\!\diagup\!\!\diagdown^{C}_{S}\!\!\diagup\!\!\diagdown^{C}$ bond sequence occur more frequently than those in $^{S}_{C}\!\!\diagup\!\!\diagdown^{S}_{C}\!\!\diagup\!\!\diagdown^{S}$ because the value $E_{\phi'}$ is negative and smaller than $E_{\phi}(\simeq 0)$. The $E_{\omega'}$ value is apparently smaller than E_{ω} in **6T**, **10T**, and **12T**; therefore, the conformers containing two consecutive gauche states with the opposite signs in the $^{C}_{S}\!\!\diagup\!\!\diagdown^{C}_{S}\!\!\diagup\!\!\diagdown^{C}$ bond sequence occur more frequently than those in $^{S}_{C}\!\!\diagup\!\!\diagdown^{S}_{C}\!\!\diagup\!\!\diagdown^{S}$. Such an estimation can be compared with the experimental results of poly(thiomethylene) and its model compounds. The crystal structure of this polymer had been investigated,[11] and the molecular form in the solid state has been confirmed to be the [G] form. However, this X-ray study was carried out in the solid state, and so the results could not be directly compared with the present results, for in this study the conformation of poly(thiomethylene) in a liquid (dilute solution) or an isolated molecule has been investigated. A recent study of the vibrational analysis of poly(thiomethylene) and its model compounds[10] pointed out that many forms coexist in a liquid or gaseous state: for example, GG, TT, TG in **2T**. Their results correspond well with those obtained in this study.

The geometrical parameters necessary for the statistical-mechanics calculations were also obtained from the results of the molecular-mechanics calculations on each model compound. All the geometrical parameters for the conformers of each model compound were then averaged, taking the weight of their energy differences and occurrence into account. The Boltzmann-averaged geometric parameters thus obtained were found to be scarcely influenced at all by the chain length of the model compounds; $\angle$CSC=80.6°—81.2°, $\angle$SCS=64.2°—66.4°, $\phi^{T}_{C\text{-}C}$=−0.8°—0.7°, $\phi^{G}_{C\text{-}C}$=109.3°—112.5°, $l_{C\text{-}S}$=1.819 Å, and $m_{C\text{-}S}$=1.20 D, where ϕ^{T}, ϕ^{G}, and m are the torsional angles of the trans and gauche states, and the bond dipole-moment, respectively.

The configuration-dependent properties of poly(thiomethylene) that is, the characteristic ratio, the dipole-moment ratio, and their temperature coefficients were calculated as functions of the chain length of the model compound by using these statistical-mechanics parameters; the results are shown in Figs. 2 and 3. Although the characteristic ratios $\langle r^2\rangle_0/(nl^2)$ ($\langle r^2\rangle_0$: an unperturbed dimension, n: the number of skeletal bonds, l: the length of the bond) show some variation (from 5.5 to 7.2) for **6T** and **8T**, those of **4T**, **10T**, and **12T** are all at almost the same level (6.1—6.3). The dipole-moment ratio $\langle\mu^2\rangle_0/(nm^2)$ decreases from 0.17 to 0.10 with the increase in the chain length, although the decrement rate becomes small. As is shown in Fig. 3, the temperature coefficient of the dipole-moment ratio $d\log_e\langle\mu^2\rangle_0/dT$ is positive and increases with the increase in the chain length. The temperature coefficients of the characteristic ratio $d\log_e\langle r^2\rangle_0/dT$ are all negative and show a rapid decrease from -3.2×10^{-3} K^{-1} at **4T**

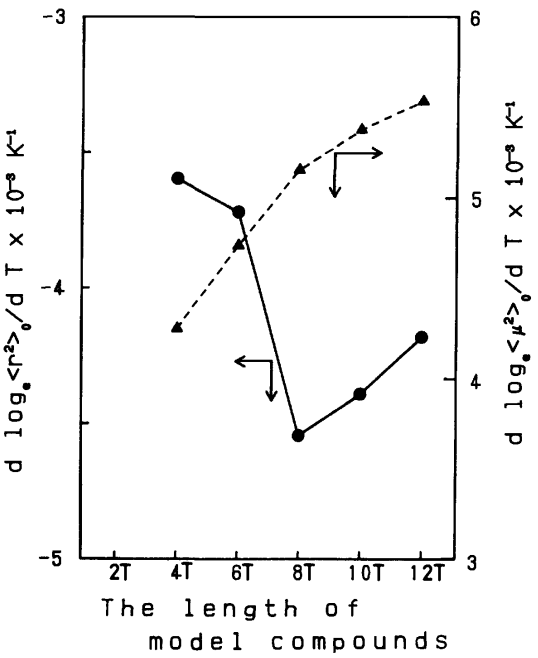

Fig. 3. The dependence of the temperature coefficients of the configuration-dependent properties of poly(thiomethylene) on the chain length of model compounds. Filled circles represent the temperature coefficients of characteristic ratios and filled triangles represent those of dipole-moment ratios.

to $-4.5\times10^{-3}K^{-1}$ at **8T**, after which they slightly increase to -4.2×10^{-3} K^{-1} for **12T**. The reliability of these forecast values depends upon the reliability of the statistical-mechanics parameters obtained from the molecular-mechanics calculations on the model compounds. No experimentally obtained value of the configuration-dependent properties of poly(thiomethylene) has yet been reported. The configurational study of poly(1,3-dithiocane)[12] is the only experimental report available for comparison with the calculated values of poly(thiomethylene). The experimental values of the dipole-moment ratio and its temperature coefficient of poly(1,3-dithiocane) were reproduced by using the value of $E_\sigma=-5.02$ kJ mol^{-1}. This value of the first-order interaction energy is very close to those obtained from the model compounds of poly(thiomethylene); $E_\sigma=-4.73$ kJ mol^{-1} for **4T**, and -5.19 kJ mol^{-1} for **6T**. This fact suggests the reliability of the results obtained by the molecular-mechanics calculations on these model compounds of poly(thiomethylene). Our previous report[5] on poly(thiotrimethylene) showed that the approximate model compound of this polymer contains two or three repeating units with proper terminal groups. According to this conclusion, the appropriate model compounds of poly(thiomethylene) may be either **6T** or **8T**. The present calculation also supports this result, because: (1) the E_σ value of the model compound is of the same magnitude as that of poly(1,3-dithiocane), and (2) the gauche states in the central position of the long model compounds (above the **10T**) experience a severe steric interaction. When the **6T** is adopted as the model compound of poly(thiomethylene), the configuration-dependent properties are calculated as follows; $\langle r^2\rangle_0/(nl^2)=5.54$, $\langle\mu^2\rangle_0/(nm^2)=0.13$, d log$_e$ $\langle r^2\rangle_0$/d $T=-3.72\times10^{-3}$ K^{-1} and d log$_e\langle\mu^2\rangle_0$/d $T=4.73\times10^{-3}$ K^{-1}.

In an earlier report on poly(1,3-dithiocane),[12] the energy of the first-order interaction for the $\overset{C}{\diagdown}\!\!\underset{S}{\diagup}\overset{C}{\diagdown}\!\!\underset{S}{\diagup}$ bond sequence was estimated as $E_\sigma=-1.42$ kJ mol^{-1} on the basis of the calculation of the model compound, but the experimental data of the dipole-moment ratio and its temperature coefficient could not be reproduced well by this energy value. The E_σ was, therefore, modified so as to fit the experimentally obtained configuration-dependent properties; then $E_\sigma=-5.02$ kJ mol^{-1} was obtained, as has been reported above. This energy variation of E_σ, 3.60 kJ mol^{-1}, was named the "extra stabilization energy" and assumed to be the first evidence for a large attractive sulfur gauche effect in poly(sulfides).[12] In the present study, this energy difference between the trans and gauche states was estimated to be 5.19 kJ mol^{-1} for the **6T** molecule by the molecular-mechanics method.

The present authors wish to thank Prof. Dr. Yoshio Imamura of the Science University of Tokyo for his valuable advice and guidance. They also wish to thank a referee for his helpful suggestions and observations and for his critical reading of the manuscript.

Solvent Extraction of Various Metal Picrates with Benzo-18-crown-6 into $CHCl_3$

Yasuyuki TAKEDA* and Minoru NISHIDA
Department of Chemistry, Faculty of Science, Chiba University,
Yayoi-cho, Chiba 260
(Received December 16, 1988)

Overall extraction equilibrium constants (K_{ex}) of various metal picrates (MA_m) with benzo-18-crown-6 (B18C6) and distribution constant ($K_{D,L}$) of B18C6 were determined at 25 °C between water and chloroform. The K_{ex} values were analyzed by constituent equilibria, e.g., $K_{D,L}$, formation constant in water and ion-pair extraction constant ($K_{ex,ip}$) with a picrate anion of the B18C6–metal ion complex. K_{ex} orders for univalent and bivalent metal ions are $Tl^+>K^+>Rb^+>Ag^+>Cs^+>Na^+$ and $Pb^{2+}\gg Sr^{2+}>Ca^{2+}$, respectively. Extraction selectivities of B18C6 for the alkali and alkaline earth metal ions are consistent with the size-fit concept; namely, the more closely a cation fits into a crown ether cavity, the more extractable the complex is. For a given B18C6–M^{m+} system, $K_{ex,ip}$ value is much larger than values of the other constituent equilibria. Thus, the magnitude of K_{ex} value is determined largely by that of $K_{ex,ip}$ value. $K_{ex,ip}$ value of B18C6 for univalent and bivalent metal ions increases in the order $Na^+<Ag^+<Cs^+<K^+<Rb^+<Tl^+$ and $Sr^{2+}<Ca^{2+}<Pb^{2+}$, respectively. Factors governing the magnitude of the $K_{ex,ip}$ value were discussed in detail.

Overall extraction equilibrium constant of a crown ether with a metal picrate consists of several constituent equilibria. In a series of our solvent-extraction studies regarding crown ethers,[1] the overall extraction equilibrium constants of metal picrates with crown ethers and some constituent equilibria have been measured, and the overall extraction equilibrium constants have been analyzed by the constituent equilibria in order to clarify factors governing selectivities and extractabilities of crown ethers for metal ions, and, moreover, obtain information on solute–solvent interactions of the crown ether complexes.

In this study, the overall extraction equilibrium constants of various metal picrates with benzo-18-crown-6 (B18C6) between water and chloroform were determined at 25 °C and analyzed by constituent equilibria. The role of B18C6 in the metal ion-extraction process was discussed.

Experimental

Materials. Benzo-18-crown-6 was prepared according to Pedersen.[2] The product was recrystallized four times from heptane and, prior to use, dried at 40 °C in a vacuum oven. Its purity was checked by melting point, elemental analysis, and NMR. Chloroform, picric acid, NaOH, KOH, $AgNO_3$, $TlNO_3$, $Ca(NO_3)_2$, $Sr(NO_3)_2$, and $Pb(NO_3)_2$ were analytical grade reagents. Rubidium and caesium hydroxides were reagent-grade. Chloroform was washed three times with distilled water. The other reagents were used without further purification.

The experimental procedures were almost the same as those described in previous papers.[3,4] Extractions were conducted at 25±0.2 °C. Concentrations of B18C6, metal salts, and picric acid were 1×10^{-5}—7×10^{-3} M (1 M=1 mol dm^{-3}), 1×10^{-3}—5×10^{-2} M, and (1—5)$\times10^{-3}$ M, respectively. For hydroxide and nitrate systems, the extractions were performed at pH 11.2—12.1 and pH 2.4—3.1, respectively. For the Ba system, turbidity was always found in the interface between chloroform and water under all experimental conditions.

The Distribution Coefficient of B18C6. A 10 ml portion of a chloroform solution of B18C6 and an equal volume of distilled water were placed in a stoppered glass tube (volume 30 ml) and shaken in a thermostated water bath for 2 h at 25±0.2 °C. The concentration range of B18C6 was from 0.1 M to 0.2 M. After centrifugation, the B18C6 concentration of the aqueous phase was spectrophotometrically determined at 273 nm ($\varepsilon=2.49_5\times10^3$ cm^{-1} M^{-1}). The distribution coefficient value of B18C6 is 371±4, which is the average of twenty measurements.

Results

In an equilibrium between a chloroform solution of a crown ether (L) and an aqueous solution of a metal ion (M^{m+}) and a picrate ion (A^-), the equilibrium constants are defined as

$$K_{ex} = [MLA_m]_o[H^+]^m/[M^{m+}][L]_o[HA]_o^m, \quad (1)$$
$$K_{D,L} = [L]_o/[L], \quad (2)$$
$$K_{ex}(HA) = [HA]_o/[H^+][A^-], \quad (3)$$
$$K_{ML} = [ML^{m+}]/[M^{m+}][L], \quad (4)$$
$$K_{ex,ip} = [MLA_m]_o/[ML^{m+}][A^-]^m, \quad (5)$$

where the subscript "o" and the lack of subscript denote the organic and the aqueous phase, respectively. The overall extraction equilibrium constant (K_{ex}) can be written as

$$K_{ex} = K_{ML}K_{ex,ip}K_{D,L}^{-1}K_{ex}(HA)^{-m}. \quad (6)$$

The distribution ratio of the metal is represented by

$$D = [MLA_m]_o/([M^{m+}] + [ML^{m+}]). \quad (7)$$

In the case of $[M^{m+}]\gg[ML^{m+}]$, Eq. 7 is transformed into

$$D = K_{ex}K_{ex}(HA)^m[L]_o[A^-]^m. \quad (8)$$

For the univalent metal ion system, $\log(D/[A^-])$ vs. $\log[L]_o$ plot in Fig. 1 shows a straight line with a slope

of 1 in every case. This indicates that B18C6 forms a 1:1 complex with the univalent metal ion. For the bivalent metal ion system, $\log(D/[A^-]^2)$ vs. $\log[L]_o$ plot in Fig. 2 always shows a line with a slope of 1. This indicates that B18C6 forms a 1:1 complex with the bivalent metal ion.

From the mass balances, $[L]_o$, $[M^{m+}]$, and $[HA]_o$ are given by

$$[L]_o = ([L]_t - [MLA_m]_o)/(\alpha + \beta[M^{m+}]), \quad (9)$$

$$[M^{m+}] = ([M]_t - [MLA_m]_o)/(1 + \beta[L]_o), \quad (10)$$

$$[HA]_o = ([HA]_t - m[MLA_m]_o)/\{1 + ([H^+]^{-1} + K_{HA})K_{ex}(HA)^{-1}\}, \quad (11)$$

where the subscript "t" denotes the total concentration, $\alpha = 1 + K_{D,L}^{-1}$, and $\beta = K_{ML}K_{D,L}^{-1}$. The K_{ex} value was determined by using the $[L]_o$ value of Eq. 9, the $[M^{m+}]$ value of Eq. 10, and the $[HA]_o$ value of Eq. 11. The value of $K_{ex}(HA)$ was spectrophotometrically determined as 87.1±0.4 using the association constant ($K_{HA}=1.9_5$ at 25 °C[5]) of picric acid in water, $K_{HA}=[HA]/[H^+][A^-]$. Equilibrium constants are summarized in Table 1.

Discussion

The contribution of an ether oxygen atom to log $K_{D,L}$ (Π_O) and that of a methylene group to extraction constants of ion pairs (Π_{CH_2}) at 25 °C for the $CHCl_3$/water system are −0.79[8] and 0.47,[17] respectively. The contribution of a benzo group to log $K_{D,L}$ ($\Pi_{C_6H_4}$) can be calculated to be 2.61 from the log $K_{D,L}$ value of B18C6 by using the values of Π_O and Π_{CH_2} ($\Pi_{C_6H_4}$=2.57−{0.47×10+(−0.79×6)}). Values of $\Pi_{C_6H_4}$ are 2.5_9 for benzo-15-crown-5 (B15C5) and 2.4_4 for dibenzo-18-crown-6 (DB18C6).[8] They are nearly equal. The $\Pi_{C_6H_4}$ value is 2.5_4 on the average. From these empirical parameters, the log $K_{D,L}$ value of B18C6 at 25 °C between $CHCl_3$ and H_2O can be estimated to be 2.5_0. This is consistent with the experimental log $K_{D,L}$ value of B18C6 (2.569± 0.005). The same is true for the cases of B15C5 (2.3_5(calcd), 2.4(exptl)[18]) and DB18C6 (4.1_0(calcd), 3.9 (exptl)[13]).

From Table 1, the order of log K_{ex} of B18C6 for the univalent metal ions is $Tl^+ > K^+ > Rb^+ > Ag^+ > Cs^+ > Na^+$. The extraction selectivity of B18C6 for the alkali metal ions is in accord with the size-fit concept; namely, the more closely a cation fits into a crown ether cavity, the more extractable the crown ether-cation complex is (cavity radius of 18-crown-6 (18C6)=1.38 Å (CPK model)[19]). Although log K_{ML} values of Ag^+ and Tl^+ are the largest and the third greatest of all the univalent metal ions, B18C6 shows the third lowest and the highest extractability for Ag^+ and Tl^+, respectively; this is attributed completely to the second smallest and the largest log $K_{ex,ip}$ values of Ag^+ and Tl^+, respectively. log K_{ex} value sequences of B18C6 for the alkali metal ions are consistent with log K_{ML} value sequences except for Na^+ and log $K_{ex,ip}$ value sequences except for K^+. Although log K_{ML} value of Na^+ and log $K_{ex,ip}$ value of K^+ are the second largest of all the alkali metal ions, extractabilities of B18C6 for Na^+ and K^+ are the lowest and the highest, respectively; this is ascribed to the smallest log $K_{ex,ip}$ value of Na^+ and the greatest log K_{ML} value of K^+, respectively.

For the bivalent metal ions, the log K_{ex} value of B18C6 decreases in the order, $Pb^{2+} \gg Sr^{2+} > Ca^{2+}$ (Table 1). The highest extractability of B18C6 for Pb^{2+} of all the metal ions in this study depends on both the greatest log K_{ML} and log $K_{ex,ip}$ value.

For a given B18C6-M^{m+} system, log $K_{ex,ip}$ value is much larger than log K_{ML}, log $K_{D,L}$, and $m$log K_{ex}(HA) value. Thus, the magnitude of log K_{ex} value is determined largely by that of log $K_{ex,ip}$ value. The same is true for the cases of 18C6 and DB18C6 (Table 1). The K_{ex} value of a given metal ion among 18C6, B18C6, and DB18C6 increases with a decrease in the size of the crown ether; the same tendency is observed for the K_{ML} value of a metal ion among the crown ethers except for the case of a Na^+-18C6 complex; but, the reverse is true for the $K_{ex,ip}$ value except for the cases of Sr^{2+}-B18C6 and 18C6 complexes. Since the $K_{D,L}^{-1}$-value sequence is in the order DB18C6<B18C6<18C6, the K_{ex}-value sequence of a metal ion among the crown ethers depends on both the $K_{D,L}^{-1}$- and K_{ML}-value sequence (Eq. 6).

It can be seen from Table 1 that log $K_{ex,ip}$ value of B18C6 varies with a cation of the same charge trapped in the cavity. The same is true for 18C6 and DB18C6. For alkali metal ions, log $K_{ex,ip}$ value of B18C6 increases in the order, $Na^+ < Cs^+ < K^+ < Rb^+$ (Table 1). The same trend is observed for the cases of 18C6 and DB18C6. This shows that, generally, a crown ether–metal ion complex, where the metal ion has a suitable size for the cavity, is more extractable as an ion pair with a picrate ion. From the structure of the crown ether complex with the univalent metal ion held in the cavity, anion- and solvent-contact are possible in respective directions perpendicular to the plane of the ring. It thus appears that strength of interaction between the central univalent metal ion and water molecules is one of the most important factors in determining the magnitude of $K_{ex,ip}$ value of the univalent metal ion. Consequently, the lowest $K_{ex,ip}$ value of Na^+ among all the alkali metal ions listed in Table 1 is probably attributed to the strongest interaction of Na^+ with water molecules. Gibbs free energies of hydration ($\Delta G_h°$/kJ mol^{-1}) of K^+, Rb^+, and Cs^+ are −338, −320, and −297, respectively.[20] The interaction of Cs^+ with water is weaker than those of K^+ and Rb^+. The interaction with water of Cs^+ held in the crown ether cavity is expected to be weaker than those of K^+ and Rb^+. Association constant of Cs^+ with a picrate ion in water is larger than those of K^+ and Rb^+.[21] Association constant with a picrate ion of Cs^+ held in the crown ether cavity is expected to be greater than those of K^+ and Rb^+. However, $K_{ex,ip}$ value of a Cs^+-crown ether complex is smaller than those of the corresponding K^+- and Rb^+-crown ether complex. Judging from the structure of a crown ether-univalent metal ion complex. this may be attributable to negligible effect of water on association of the K^+- and Rb^+-crown ether complex with a picrate ion and/or very weak interactions with water of the K^+- and Rb^+-complex. The above discussion is supported by the following data. When L=18C6, B18C6, and DB18C6, differences in the numbers of water molecules coextracted into nitrobenzene among ML^+ complexes (M=K, Rb, Cs) are small, whereas those among uncomplexed K^+, Rb^+, and Cs^+ are relatively large.[22]

Ionic radii of Rb^+ and Tl^+ are nearly identical (Table 1); $-\Delta G_h^\circ$ value of Tl^+ (343 kJ mol^{-1})[20] is slightly greater than that of Rb^+; $K_{ex,ip}$ values of RbL^+ and TlL^+ complexes (L=B18C6 and DB18C6) are approximately equal. This indicates that strength of interaction with a picrate ion of the RbL^+ complex is nearly equal to that of the corresponding TlL^+ complex. The sizes of Na^+ and Ag^+ are smaller than those of B18C6- and DB18C6-

cavity; $-\Delta G_h^\circ$ of Ag^+ (479.1 kJ mol^{-1})[20] is greater than that of Na^+ (411.3 kJ mol^{-1});[20] but, in each case of B18C6 and DB18C6, $K_{ex,ip}$ value of Ag^+ is larger than that of Na^+. Since specific interaction between Ag^+ and $CHCl_3$ is considered to be impossible, the higher $K_{ex,ip}$ value of Ag^+ may be caused by stronger association with a picrate ion and weaker interaction with water of the Ag^+ complex compared with the case of the corresponding Na^+ complex.

From the structure of a crown ether-bivalent metal ion complex, two picrate anion-contacts are possible in respective directions perpendicular to the plane of the ring. Sizes of Sr^{2+} and Pb^{2+} are almost the same; they are smaller than the B18C6- and DB18C6-cavity; $-\Delta G_h^\circ$ value of Sr^{2+} (1447 kJ mol^{-1})[20] is nearly equal to that of Pb^{2+} (1497 kJ mol^{-1}).[20] However, in each case of B18C6 and DB18C6, $K_{ex,ip}$ value of Pb^{2+} is larger than that of Sr^{2+}. This may be ascribed to stronger interaction with two picrate anions of the Pb^{2+} complex compared with the corresponding Sr^{2+} complex.

$K_{ex,ip}$ value of a univalent metal ion increases with an increase in the size of crown ether (18C8<B18C6< DB18C6) (Table 1). However, it does not always hold for the bivalent metal ions. For a univalent metal ion, the difference in $\log K_{ex,ip}$ values between 18C6 and B18C6 is 0.75—1.15, which is approximately constant; that between B18C6 and DB18C6 is 0.6_3—0.9_9, which is approximately constant; they are roughly equal. This indicates that an increment of $\log K_{ex,ip}$ value per a benzo group is about 0.9 (on the average).

$K_{ex,ip}=K_{MLA}K_{D,MLA}$, where $K_{MLA}=[MLA]/[ML^+][A^-]$ and $K_{D,MLA}=[MLA]_o/[MLA]$. Since $K_{D,MLA}$ is a distribution constant of a neutral complex MLA between water and $CHCl_3$, an increment of $\log K_{D,MLA}$ per a benzo group is estimated to be about 2.5 on the basis of $\Pi_{C_6H_6}$ value (2.5_4). From an increment of $\log K_{ex,ip}$ per a benzo group (ca. 0.9), a decrement of $\log K_{MLA}$ per a benzo group is calculated to be 1.6. This indicates that the larger the size of a crown ether-univalent metal ion complex is, the smaller the $\log K_{MLA}$ value is. It is interesting from a structural point of view that the two-dimensional increase in the size of the crown ether-univalent metal ion complex causes the constant decrease in the $\log K_{MLA}$ value.

Since MLA_2 is a neutral complex, it seems reasonable to assume that the K_{D,MLA_2} value increases with an increase in the size of the crown ether (18C6<B18C6< DB18C6), where $K_{D,MLA_2}=[MLA_2]_o/[MLA_2]$. Consequently, the $K_{ex,ip}$-value sequences of a bivalent metal ion among the crown ethers may be determined chiefly by the K_{MLA_2}-value sequences, where $K_{MLA_2}=[MLA_2]/[ML^{2+}][A^-]^2$.

Preferential Solvation of Ni(II) and Mg(II) Ions in Water-Acetonitrile Mixtures. Enthalpies of Transfer and the Electronic Spectra

Kiyoshi MIYAJI,* Kiyokazu NOZAWA,† and Kenichi MORINAGA
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338
(Received May 10, 1988)

The enthalpies of transfer (ΔH_t°) from water to water-acetonitrile (W-AN) mixtures for Ni^{2+} and Mg^{2+} ions were estimated using the enthalpies of dilution of the concentrated aqueous electrolyte solutions into water and mixtures, and the enthalpies of solution of water in the mixtures. The ΔH_t° values for these ions decreased with an increase in the mole fraction of AN (x_{AN}) in the range of x_{AN}<ca. 0.9, however, they increased rapidly in the range x_{AN}>ca. 0.9. The values of ΔH_t° for the Ni^{2+} ion were more negative than those for the Mg^{2+} ion throughout the x_{AN} regions, especially in the extremely AN-rich region and in pure AN. The average number of coordinated water molecules, N, for the $[Ni(AN)_{6-N}(W)_N]^{2+}$ ion in the mixtures (x_{AN}=0.2, 0.6, and 0.9), as estimated from the electronic absorption spectra, was always greater than that calculated on the basis of the bulk-solvent composition, indicating that the Ni^{2+} ion was preferentially solvated by water. These results, including the conductance data, were discussed in terms of the principle of hard and soft acid and base.

The preferential solvation of an ion in a mixed solvent has been one of the most fundamentally important problems in solution chemistry, and some phenomena have been applied in chemical technology.[1,2] Although various types of ion-solvent interactions have been noted to contribute to the ionic solvation in pure solvents,[3] in mixed solvents the concept of hard and soft acid (cation) and base (solvent) (i.e., the HSAB principle) is considered to be one of the most important factors. We have studied previously the preferential solvation behavior of ions in water-acetonitrile (W-AN) mixtures by means of the conductance[4,5] and the enthalpies of transfer (ΔH_t°). The majority of papers on ionic solvation so far have been concerned with monovalent ion. A difference in limiting ionic conductances was observed between the Ni^{2+} and Mg^{2+} ions in the mixtures, while they have equal conductance values in both water and acetonitrile.[5] Since the Ni^{2+} and Mg^{2+} ions have similar ionic radii, the electrostatic contributions to the overall ion-solvent interaction for the free ions can be regarded as similar. Therefore, the difference in the solvation property of the Ni^{2+} and Mg^{2+} ions should reflect the difference in the covalency of ion-solvent bonding. The nickel ion is expected to have a stronger affinity for acetonitrile than the Mg^{2+} ion, since the former ion is less hard than the latter. The ΔH_t° method was found to be a powerful tool in studying the preferential solvation of ions in the mixtures,[6,7] so the ΔH_t° values for the Ni^{2+} and Mg^{2+} ions from water to water-acetonitrile mixtures were estimated in this study.

It is not easy to measure directly the enthalpies of solution for highly hygroscopic salts of divalent cations. In such cases, the enthalpic measurements of dilution of a concentrated aqueous electrolyte solution into water and a mixed solvent, as proposed by Valera et al., are very attractive.[9] We have applied this method to estimate the enthalpies of transfer for nickel and magnesium perchlorates from water to the mixtures. The electronic absorption spectra have also been measured for nickel perchlorate solutions.

Experimental

Materials. Hexakis(acetonitrile)nickel perchlorate, $[Ni(CH_3CN)_6](ClO_4)_2$, was prepared from the hexaaqua salt and purified by the method described in the literature.[10] Commercially available magnesium perchlorate, $Mg(ClO_4)_2$ ("Anhydron"), was used without further purification. For the measurement of the enthalpies of solution it was dried in vacuo at 250 °C just before its use. The anhydrous salt was weighed in a glove bag filled with dried nitrogen gas. The other reagents and solvents were purified as described previously.[7,11] The alkali and acid solutions were prepared and standardized by the usual method. The concentrations of aqueous perchlorate solutions were determined by the EDTA titration method.

Enthalpic Measurements. The enthalpies of solution and dilution were measured by a heat-exchange type calorimeter.[12] Liquid samples were introduced continuously into the mixtures via a peristatic pump (LKB 2132) after having been passed through a Teflon heat exchanger at 25±0.02 °C. Aliquots of a solution (0.1—0.5±0.001 ml) were added to ca. 40 ml of the solvent in the reaction vessel. The enthalpies of dilution were determined in series by measuring the enthalpy changes accompanying the successive addition of the concentrated solution in the reaction vessel.

The calorimeter was calibrated by the measurements of the enthalpies of neutralization for NaOH and HCl solutions[12] and also the enthalpies of dilution for aqueous KNO_3 solution.

Spectral Measurements. The electronic absorption spectra were measured with a Hitachi 340 spectrophotometer.

Results and Discussion

Principle of Measurements. The enthalpy change, ΔH_R^C(mixt), when a small aliquot of a concentrated

† Present address: The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106.

aqueous electrolyte solution is added to a large amount of a mixed solvent can be regarded as involving the enthalpy of dilution for electrolytes to a definite concentration and the enthalpy of solution of the water contained in the original electrolyte solution with the mixed solvent. The latter enthalpy of solution of water in a mixed solvent, ΔH_W^C(mixt), can be measured directly by the use of the present titration calorimeter. The enthalpy of dilution for an electrolyte, ΔH_D^C(mixt) ($=\Delta H_R^C$(mixt)$-\Delta H_W^C$(mixt)), changes with the electrolyte concentration according to the following equation:

$$\Delta H_D^C(\text{mixt}) = \Delta H_D^\circ(\text{mixt}) + (2/3)A_H C^{1/2} + BC, \quad (1)$$

where A_H is the Debye-Hückel coefficient (1.48 kJ mol$^{-1/2}$ for a 1:1 electrolyte aqueous solution and 5.12$_9$ kJ mol$^{-3/2}$ dm$^{-3/2}$ for a 2:1 electrolyte aqueous solution)[13] and where B is the experimental parameter.

Defining the enthalpy of solution for preparing a concentrated aqueous electrolyte solution as ΔH_S^C(W),[9] the standard enthalpy of solution for electrolytes in an aqueous solution, ΔH_S°(W), and in a mixed solvent, ΔH_S°(mixt), can be expressed as follows:

$$\Delta H_S^\circ(\text{W}) = \Delta H_S^C(\text{W}) + \Delta H_D^\circ(\text{W}) \quad (2)$$

$$\Delta H_S^\circ(\text{mixt}) = \Delta H_S^C(\text{W}) + \Delta H_D^\circ(\text{mixt}). \quad (3)$$

The enthalpy of transfer for an electrolyte from water to a mixed solvent, ΔH_t°, can be then obtained as:

$$\Delta H_t^\circ = \Delta H_D^\circ(\text{mixt}) - \Delta H_D^\circ(\text{W}). \quad (4)$$

Relative Partial Molar Enthalpies for Water in Water-Acetonitrile Mixtures. The enthalpy of solution of water in the mixtures, ΔH_W^C(mixt), was found to vary linearly with the concentration of water added. An extrapolation of the experimental ΔH_W^C (mixt) values to zero concentration of water will give the relative partial molar enthalpies of water ($\bar{L}_W$) in the mixtures. The values thus obtained are shown in Table 1, together with those values estimated by the method of graphical intercepts[14] on the basis of excess enthalpy data.[15] The values estimated in this experiment are derived from directly measurable quantities and are, therefore, more accurate than those in the literature.[15]

Table 1. Relative Partial Molar Enthalpies of Water in Water-Acetonitrile Mixtures, $\bar{L}_W$/kJ mol^{-1}

x_{AN}	$\bar{L}_W$	
	This Exper.	Lit.[a]
0	0	0
0.1	−0.154±0.002	−0.15±0.14
0.2	−0.049±0.003	−0.04±0.07
0.4	0.276±0.006	0.30±0.05
0.6	0.864±0.001	0.79±0.01
0.8	2.51 ±0.05	2.5 ±0.1
0.9	4.41 ±0.06	4.5 ±0.1

a) From Ref. 15.

As may be seen in Table 1, $\bar{L}_W$ decreases with the addition of a small amount of AN, passes through a minimum at the mole fraction of AN(x_{AN}) (ca. 0.1), and then increases with an increase in x_{AN}. Beyond x_{AN} ca. 0.2, the $\bar{L}_W$ values become positive, increase almost linearly until x_{AN} reaches ca. 0.65. With a further increase in x_{AN}, the $\bar{L}_W$ values increase more rapidly. The x_{AN} dependence of $\bar{L}_W$ appears to reflect the change in the solvent structure of these mixtures: a water-rich region, an intermediate region, and an acetonitrile-rich region.[7]

Enthalpies of Transfer for Nickel and Magnesium Perchlorates. The enthalpies of dilution, ΔH_D^C(mixt), change with the electrolyte concentration in the final electrolyte concentration range from 5×10^{-3} to 0.09 mol dm^{-3}. Examples of the plots for obtaining the ΔH_D°(mixt) values are shown in Fig. 1. The ΔH_D°(mixt) values were obtained using the A_H values for water. There were no significant differences between the ΔH_D°(mixt) values calculated using A_H value for water and those calculated using the A_H value for AN. The enthalpies of transfer obtained on the basis of Eq. 4 for nickel and magnesium perchlorates are given in Table 2. As may be seen in Table 2, the change in the initial concentration of an electrolyte aqueous solution does not seem to cause any significant error in the estimation of the ΔH_t° values.

The enthalpy of transfer for $Mg(ClO_4)_2$ from water to AN was obtained from the direct measurements of the enthalpies of solution. The enthalpy of solution in water is found to be −157.$_3$±2 kJ mol^{-1} in good agreement with the literature value of −156.6$_1$ kJ mol^{-1}.[16] The enthalpy of solution in AN was difficult to measure because of its high hygroscopicity, but the most careful repeated measurements (more than ten times) gave the enthalpy of solution of −185.$_5$±5 kJ mol^{-1}. The enthalpy of transfer for $Mg(ClO_4)_2$ from water to AN was taken as −28±5 kJ mol^{-1}. The

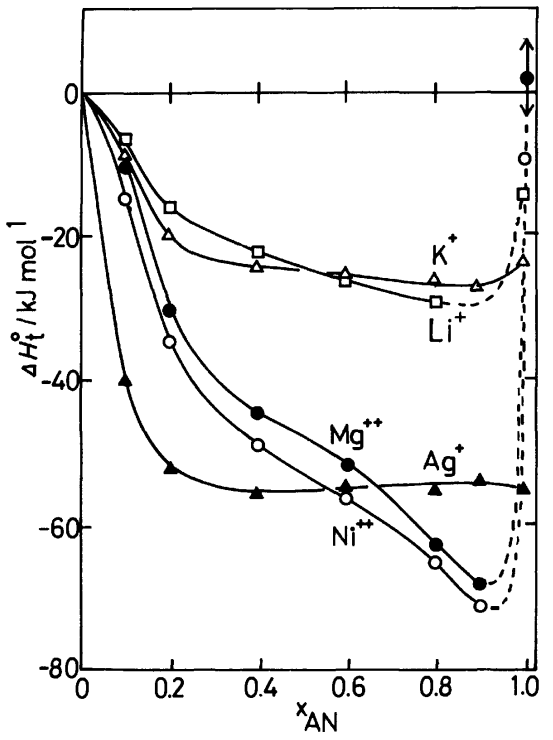

Fig. 2. Plots of the ionic enthalpies of transfer (ΔH_t°) vs. the mole fraction of acetonitrile (x_{AN}). Data for M^+ ions were cited from Ref. 6.

enthalpy of transfer for $Ni(ClO_4)_2$ from water to AN was cited from the literature.[17]

The ionic enthalpies of transfer were calculated by using the reported values of the ClO_4^- ion estimated on the basis of the TATB assumption $\{\Delta H_t^\circ(Ph_4As^+) = \Delta H_t^\circ(Ph_4B^-)\}$.[6] The estimated ΔH_t° values for the Ni^{2+} and Mg^{2+} ions are plotted as a function of x_{AN} in Fig. 2. For convenience of comparison, the x_{AN} dependences of ΔH_t° for the Li^+, K^+, and Ag^+ ions are also shown in Fig. 2.[6] It has been established by several kinds of measurements that the Ag^+ ion is preferentially solvated by AN in this mixed solvent system.[8] The ΔH_t° values for the Ag^+ ion decrease very rapidly in the water-rich region, but change only slightly in the other regions. The ΔH_t° values for the K^+ ion, similar in ionic size to the Ag^+ ion, decrease much less rapidly in the water-rich region, and its x_{AN} dependence profile in the other regions is nearly the reverse of that of the Ag^+ ion. The values of ΔH_t° for the Li^+ ion decrease a little more slowly than that for the K^+ ion in the water-rich region, continue to decrease less slowly in the intermediate region, and increase rapidly in the AN-rich region. Such an x_{AN} dependence profile of the Li^+ ion is characteristic of the most preferentially hydrated monovalent cation.

Previously, the present authors have discussed semiquantitatively the solvation enthalpies for halide ions in the W-rich and intermediate regions based on a modified hydration model, and noted that the exothermic shift of the ΔH_t° values in the intermediate region may be attributed to the reduction in the cavity formation energy.[7] Therefore, the exothermic shift of ΔH_t° values for cations in the range of x_{AN} may also be attributed to the change in the solvent structure of the mixtures, although it is difficult to discuss the solvation enthalpies for cations quantitatively. However, the difference in ΔH_t° values at an x_{AN} value between Ni^{2+} and Mg^{2+} ions may not be influenced by the solvent structure, since these ions have similar ionic radii.

As shown in Fig. 2, when a small amount of water is added to a pure AN solution, the ΔH_t° values for the Ni^{2+} and Mg^{2+} ions decrease markedly. And the ΔH_t° values for both ions are almost twice as negative as those for the Li^+ ion in the range of x_{AN}<ca. 0.9. Therefore, the x_{AN} dependence of the ΔH_t° values suggests that both Ni^{2+} and Mg^{2+} ions are totally preferentially hydrated in water-acetonitrile mixtures. The same conclusion can be drawn from the electronic spectral measurements of a nickel perchlorate solution to be described below. However, the more negative ΔH_t° values for the Ni^{2+} ion than for the Mg^{2+} ion indicate that the Ni^{2+} ion has a stronger affinity for AN than the Mg^{2+} ion over the whole x_{AN} region. The nickel and Mg^{2+} ions have quite different electronic configurations in spite of the similar ionic sizes. The magnesium ion is a hard divalent cation, while the Ni^{2+} ion is situated on the borderline between hard and soft divalent cations.[18] The σ value, which is used as a parameter of the softness for metal ions, is largest for the Ni^{2+} ion among the borderline cations.[19] Furthermore, as has been pointed out by Munatake, Kitagawa, and Myajima, the covalent bonding in the metal ion-CH_3CN bonds is enhanced in this order;

$Mg^{2+}<Ni^{2+}<Ag^{+}$. Therefore, the stronger solvation of the Ni^{2+} ion in AN can be ascribed to its acid property being less hard than the Mg^{2+} ion. In view of the HSAB principle it is very reasonable, that the much more rapid increase in ΔH_t° values is observed for the Mg^{2+} ion in the extremely AN-rich region.

Electronic Absorption Spectra of Nickel Perchlorate Solutions in Water-Acetonitrile Mixtures. The electronic absorption spectra have been measured in order to obtain more information concerning the average number of water molecules in the solvation cosphere of the Ni^{2+} ion in these solvent mixtures. Figure 3 shows the variation in the electronic absorption maxima, λ_{max}, as a function of the $Ni(ClO_4)_2$ concentration at x_{AN}=0.2, 0.6, and 0.9; Fig. 3-a corresponds to those with shorter wavelength λ_{max} values, and Fig. 3-b, to those with longer wavelength λ_{max} values. In aqueous solutions, the absorption maxima λ_{max} are 395 and 656 nm, while in AN solutions they are 365 and 580 nm. It has been confirmed that there is a linear relationship between the number of water molecules coordinated in the $[Ni(NH_3)_{6-N}(H_2O)_N]^{2+}$ ion and the wavenumber ν.[11] Since a similar relationship is expected to hold in the case of the $[Ni(CH_3CN)_{6-N}(H_2O)_N]^{2+}$ ion, the number of water molecules coordinated in the aquaacetonitrile nickel complex ion can be estimated from the absorption spectral data. The values estimated at the electrolyte concentrations of 0.005, 0.05, and 0.32 M (1 M=1 mol dm^{-3}) are 5.0, 5.1, and 5.5 (x_{AN}=0.2); 4.9, 5.3, and 4.4 (x_{AN}=0.6), and 3.2, 3.2, and 2.0 (x_{AN}=0.9), respectively. The number of water molecules in the actual solvation sphere is always greater than that calculated on the basis of the bulk solvent composition, therefore, water is clearly enriched preferentially in the cosphere of the nickel ion. The λ_{max} value in the W-rich region (x_{AN}=0.2) approaches that observed as in an aqueous solution as the electrolyte concentration increases. In contrast with this, in the AN-rich region (x_{AN}=0.9), the λ_{max} value approaches that observed as in the AN solution. In the intermediate region (x_{AN}=0.6), the increase in electrolyte concentration causes the shift of λ_{max} to the longer wavelength side, as in the W-rich region when electrolyte concentration is small. On the contrary, a further increase in the electrolyte concentration beyond a certain limit causes a shift of the λ_{max} value to the shorter wavelength side, as in the AN-rich region. Such dependence of the λ_{max} value on the electrolyte concentration in the mixtures may be attributed to the ion-pair formation of nickel species, since it is difficult to explain the such behavior in terms only of the variation in the equilibrium concentration of the $[Ni(CH_3CN)_{6-N}(H_2O)_N]^{2+}$ species.

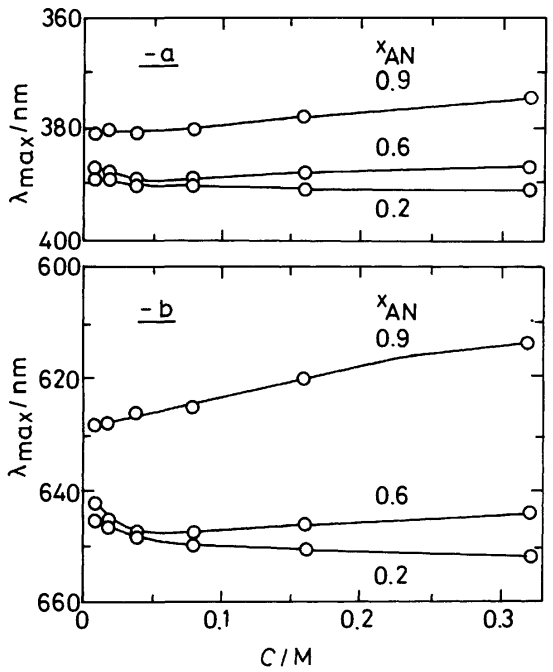

Fig. 3. Dependences of the electronic absorption maxima (λ_{max}) for Ni^{2+} ion on the electrolyte concentration in the mixtures; -a: maximum at shorter wavelength, -b: maximum at longer wavelength.

Relationship between Enthalpies of Transfer and Conductance for Nickel and Magnesium Perchlorates. Finally, the difference in the conductance behavior of nickel and magnesium perchlorates in the mixtures will be discussed in connection with the ΔH_t° values described above. It has been reported that the Ni^{2+} and Mg^{2+} ions were differentiated only in the x_{AN} range from 0 to 0.4, that is, the limiting ionic conductances (λ_0^+) for the Ni^{2+} ion were smaller than those for the Mg^{2+} ion in this range.[5] In this range, the ΔH_t° values for the Ni^{2+} ion are found to be more negative than those for the Mg^{2+} ion. This indicates that the Ni^{2+} ion has a stronger affinity for acetonitrile than does the Mg^{2+} ion. The smaller limiting ionic conductance for the Ni^{2+} ion may be related to the larger ionic species resulting from the displacement of the water molecule by a larger acetonitrile molecule in its solvation cosphere. Spectral measurements show that the Ni^{2+} ion becomes increasingly hydrated with an increase in the concentration in this range. Consequently, the hydration state of the Ni^{2+} ion can be expected to be similar to that of the Mg^{2+} ion at a certain concentration. In fact, nearly equal molar conductances are observed for 10 mmol dm^{-3} solutions of $Ni(ClO_4)_2$ and $Mg(ClO_4)_2$.[5]

The enthalpies of transfer from pure acetonitrile to mixtures (x_{AN}=0.9) clearly indicate that the Mg^{2+} ion is more strongly hydrated than the Ni^{2+} ion. In the extremely AN-rich region ($x_{AN}\geqq 0.95$), the limiting ionic conductances are found to be nearly equal for the Ni^{2+} and Mg^{2+} ions. However, the molar conductance for $Mg(ClO_4)_2$ is much smaller than that for $Ni(ClO_4)_2$ at 10 mmol dm^{-3}. From spectral measurements at x_{AN}=0.9, acetonitrile appears to be increasingly enriched in the cosphere of the Ni^{2+} ion with an increase in

the electrolyte concentration. A similar concentration dependence may not necessarily be expected for the Mg^{2+} ion in view of its stronger affinity for water. The notable decrease in molar conductance for $Mg(ClO_4)_2$ in the extremely AN-rich region may be due to the easier formation of the solvent (water)-separated ion-pair, as is suggested by the ^{35}Cl NMR measurements for the 1.0 mol dm^{-3} AN solution containing a small amount of water.[21]

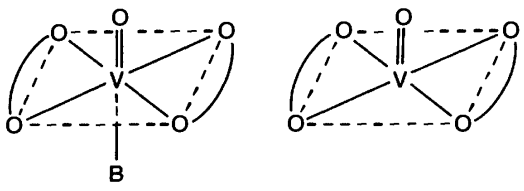
Thermal Stability of Substituted Pyridine Adducts of Bis(acetylacetonato)-oxovanadium(IV) in Solid State

Yasuhiko SHIBUTANI* and Koichiro SHINRA†
Department of Applied Chemistry, Osaka Institute of Technology,
Omiya, Asahi-ku, Osaka 535
(Received August 22, 1988)

The kinetic of the elimination reaction of axial ligand B in [VO(acac)$_2$B] complexes (Hacac=acetylacetone; B=pyridine, its derivatives, and ammonia) was studied in solid state by the Coats-Redfern method. The frequency factor and activation energy were determined, from which the activation free energy (ΔG^*) was calculated. The ΔG^* values varied with the nature of pyridine derivatives in the range of 99—109 kJ mol^{-1}. The insight into ΔG^* values suggests that the kinetic stability of vanadium-substituted pyridine bond is influenced by both the basicity (pK_a) and heat of sublimation ($\Delta H_{(sub)}$) of the axial ligand. Furthermore, the E' values which appear to reflect coordination ability of base B were determined by reflectance spectra of the complexes. The E' value was found to increase linearly with the increase in pK_a and $\Delta H_{(sub)}$ of the axial ligand.

The stability and reactivity of metal complexes have generally been discussed on the basis of kinetic and thermodynamic data of substitution reactions in solution. Since the reactant and product are naturally solvated with medium molecules, the kinetic and thermodynamic data have to be corrected for interaction between reactants and solvent. On the other hand, the thermal reaction in solid state will directly provide information concerning not only the strength of metal–ligand bond,[1] but also the formation of intermediate products.[2] We studied previously the thermal aniline elimination reaction of [Co(Hbhpn)A$_2$]X$_2$[3] and [Ni(acac)$_2$A$_2$][4] complexes, where H$_2$bhpn: *N,N'*-bis(2-hydroxyimino-1-methylpropylidene)-1,3-propanediamine, A: aniline or its derivatives, X: Cl^-, Br^-, or I^- ion, and Hacac: acetylacetone. The results revealed that the kinetic stability of metal-substituted aniline bond for these complexes mainly depends on the pK_a and the heat of sublimation of aniline and its derivatives; a linear correlation between the experimental ΔG^* of the elimination reaction and pK_a values of the aniline derivatives was observed except the complexes with *p*-chloroaniline and *p*-bromoaniline having larger heat of sublimation than other aniline derivatives.

In the present work, thermal analysis has been carried out on the thermal elimination reaction of a series of adduct complexes, mono(substituted pyridine)bis(acetylacetonato)oxovanadium(IV) shown in Fig. 1-[I], (abbreviated as [VO(acac)$_2$B], B=pyridine, its derivatives,[5] and ammonia) to elucidate the influence of heat of sublimation of axial ligand on thermal stability of these complexes. In the thermal analysis of [VO(acac)$_2$B] complexes, it was confirmed that these complexes endothermically dissociate the axial ligand to give green [VO(acac)$_2$] complex shown in Fig. 1-[II]. The activation free energy of the elimination reaction will be briefly discussed in connection with the nature of vanadium-substituted pyridine bond.



[I] [VO(acac)$_2$B] [II] [VO(acac)$_2$]

Fig. 1. [VO(acac)$_2$B][I] and [VO(acac)$_2$][II].

† Present address: Okamachiminami, Toyonaka-shi 560.

Experimental

Materials. The parent complex [VO(acac)$_2$] was prepared as described in the literature.[6] Its pyridine adducts, [VO(acac)$_2$B], were prepared as described in the literature,[7] except those with 4-CN-py and 3-CN-py. Because 4-CN-py and 3-CN-py are slightly soluble in ether, they were first dissolved in a minimum quantity of water and then added to [VO(acac)$_2$] in ether. The mixture was refluxed for about 1 h and solid residue was filtered off as the complex desired. The ammonia adduct, [VO(acac)$_2$(NH$_3$)], was prepared by the method of Claunch et al.[8] These adducts were identified by elemental analyses and IR spectroscopy.

Analytical Data for [VO(acac)$_2$B]. Found: C, 52.37; H, 5.45; N, 4.14; V, 14.38%. Calcd for [VO(acac)$_2$(py)]: C, 52.33; H, 5.57; N, 4.07; V, 14.80%. Found: C, 52.38; H, 5.74; N, 3.90; V, 13.90%. Calcd for [VO(acac)$_2$(4-CH$_3$-py)]; C, 53.68; H, 5.92; N, 3.91; V, 14.22%. Found: C, 54.58; H, 6.14; N, 3.92; V, 13.33%. Measurements. The TG and DSC curves were recorded in a flowing nitrogen atmosphere of 100 cm^3 min^{-1} at a heating rate of 10 °C min^{-1} on a Rigaku Denki 8002 thermal analyzer. α-Al$_2$O$_3$ was used as reference material. The heat of the elimination reaction was determined by measuring the DSC peak area. The instrument was calibrated against the heat of

transition of potassium nitrate and silver nitrate. The kinetic analysis under nonisothermal conditions was carried out on the TG curves recorded at a heating rate of 1 °C min^{-1} for 8—9 mg of sample. The particle size of samples for the measurements was under 100 mesh.

Reflectance spectra of the complexes in the visible region were recorded on a Hitachi Model 340 spectrophotometer equipped with a R-10A integrating sphere, using MgO as the reference substance.

Results and Discussion

Thermal Analysis. The TG and DSC curves for [VO(acac)$_2$B] complexes are shown in Figs. 2-(a) and 2-(b). The DSC data are summarized in Table 1.

As shown in Fig. 2-(a), in the case of [VO(acac)$_2$(py)] complex, the weight-loss (21.3%) on the TG curve in the temperature range of 83—142 °C, can be attributed to the elimination of one mole of pyridine (22.9%). An endothermic phenomenon was observed on the DSC curve corresponding to this weight decrease. For other complexes, the decrease in weight and endothermic phenomenon corresponding to the ligand elimination were similarly observed in the range of 90—170 °C; the weight loss was 25.8% (Calcd 26.0%) for [VO(acac)$_2$(4-CH$_3$-py)], 29.0%(28.8%) for [VO(acac)$_2$(4-C$_2$H$_5$-py)], 26.6%(28.2%) for [VO(acac)$_2$(4-CN-py)], 27.1%(28.2%) for [VO(acac)$_2$(3-CN-py)], 36.5%(37.3%) for [VO(acac)$_2$-(3-Br-py)], and 5.8%(6.0%) for [VO(acac)$_2$(NH$_3$)].

The infrared spectra of the decomposition products were measured at appropriate steps of the reaction process appearing in the TG and DSC curves. As mentioned above, [VO(acac)$_2$(py)] loses one mole of pyridine at about 142 °C. The IR spectrum of [VO-(acac)$_2$(py)] at 142 °C does not give the bands of pyridine ring[9,10] at 1444, 1218, and 711 cm^{-1} at room temperature. However, substantial change in the bands at 1523, 1371, and 934 cm^{-1} due to the coordinated acetylacetonate[10] were not observed, and the spectrum of this decomposition product was found to be the same as that of [VO(acac)$_2$]. Analyses of the infrared spectra of thermal decomposition products suggested that the thermal decomposition of complexes was elimination of pyridine derivatives from [VO(acac)$_2$B] as expressed below:

$$[VO(acac)_2B] \xrightarrow[endo.]{} [VO(acac)_2] + B\uparrow.$$

As seen in Table 1, the enthalpy changes (ΔH) for [VO(acac)$_2$(py)] and [VO(acac)$_2$(4-CH$_3$-py)] were 69.4 and 81.4 kJ mol^{-1}, respectively, which are comparable

to those of the thermal elimination of [VO(dbm)2(py)] (71.5 kJ mol^{-1}) and [VO(dbm)2(4-CH3-py)] (93.5 kJ mol^{-1}), where dbm is dibenzoylmethane.[11]

Kinetic Stability. The thermal stability of complexes has often been discussed in terms of the initiation temperature of decomposition reaction or the DSC maximum peak temperature. Since the temperature observed on the thermoanalytical curves is affected by the experimental conditions and the reaction mechanism, the thermal stability concerning the bond strength of metal-ligand linkage should be discussed by using a kinetic parameter rather than the initiation temperature.

Hence the kinetic analysis was carried out in order to ascertain the kinetic feature of [VO(acac)2B] complexes. The rate plot under nonisothermal conditions was obtained by use of the following Eq. 1 proposed by Coats and Redfern:[12]

$$\left.\begin{array}{l}\text{(when } n=1)\ \log\left\{\dfrac{-\log(1-\alpha)}{2.303T^2}\right\}\\ \text{(when } n\neq 1)\ \log\left\{\dfrac{1-(1-\alpha)^{1-n}}{T^2(1-n)}\right\}\end{array}\right\} = \log\frac{AR}{\phi E_a}\left(1-\frac{2RT}{E_a}\right)-\frac{E_a}{2.303RT}, \quad (1)$$

where E_a is activation energy; A, frequency factor; α, molar fraction of complex decomposed; T, absolute temperature; R, gas constant; ϕ, heating rate; and n, order of reaction. The plot of $\log\{-\log(1-\alpha)/(2.303T^2)\}$ against $1/T$ when $n=1$ gives a straight line, as shown in Fig. 3. The E_a and A values were calculated from the slopes and intercepts of these straight lines, respectively. The activation enthalpy ΔH^* was calculated from $\Delta H^*=E_a-RT$, while the activation entropy ΔS^* was obtained from $\Delta S^*=R[\ln(Ah/kT)-1]$, where k is the Boltzman constant, and h, the Planck constant, assuming the transmission coefficient to be 1. In addition, in order to disclose the contribution of the entropic term to the reaction, the activation free energy ΔG^* was calculated by the relation, $\Delta G^*=\Delta H^*-T\Delta S^*$. The kinetic characteristics are tabulated in Table 2.

Since the thermal reaction of [VO(acac)2B] complexes belongs to the elimination reaction of base B, the kinetic stability of the vanadium-base bond was expected to vary with the basicity of the bases. However, as seen in Table 2, in spite of pK_a values of the bases varying in wide range of 1.90—9.26, the activation free energy ΔG^* change in narrow range of 99—109 kJ mol^{-1}. On the other hand, when pyridine or its derivative forms a complex with a transition metal, the bonding consists of σ and π interactions between metal and substituted pyridine. It has been reported that in the thermal decomposition of [Ag(B)2NO3][13] and [Co(salen)(B)][14] (salen=*N*,*N*′-ethylenebis(salicylideneaminato)dianion), the complex with 4-CN-py has unusually large E_a value in comparison with those of py, 3-CH3-py, and 3-CN-py complexes. The large E_a value observed in 4-CN-py complex has been interpreted by taking into account a significant contribution of metal-base π-back-bonding to the bond stability. In the present complexes, [VO(acac)2(4-CN-py)] was also expected to be more stable than [VO(acac)2(3-CN-py)], [VO(acac)2(3-Br-py)], and [VO(acac)2(py)]. However, no remarkable difference in ΔG^* values among these complexes was observed.

These facts suggest that the thermal stability of

complexes is affected by various interactions, including the metal–base σ-bond, π-bond, and steric interaction.

As mentioned before, our previous studies[3,4] for the thermal reactions of $[Ni(acac)_2A_2]$ and $[Co(Hbhpn)A_2]X_2$ complexes revealed that the thermal stability of these complexes is influenced by the heat of sublimation of base A itself as well as basicity of the base. As for $[VO(acac)_2B]$, it is assumed that the thermal stability may be influenced by the thermal properties such as the heat of fusion and vaporization in the following equation:

$$\Delta G^* = \alpha pK_a + \beta \Delta H_{(sub)}, \quad (2)$$

where α and β are constants determined by the reaction system, and $\Delta H_{(sub)}$ is the heat of sublimation (sum of heat of fusion and vaporization). Dividing both sides of Eq. 2 by pK_a yields Eq. 2′:

$$\Delta G^*/pK_a = \alpha + \beta \Delta H_{(sub)}/pK_a, \quad (2')$$

If the above assumption is adequate, a straight line with slope β will be obtained. As shown in Fig. 4, the plot between $\Delta G^*/pK_a$ and $\Delta H_{(sub)}/pK_a$ indicates that $\Delta G^*/pK_a$ and $\Delta H_{(sub)}/pK_a$ bear a linear correlation. This result suggests that the thermal stability of $[VO(acac)_2B]$ complexes investigated here depends mainly on the basicity and the heat of sublimation of base B.

Reflectance Spectra. The reflectance spectral data for $[VO(acac)_2B]$ are summarized in Table 3. The lowest energy band can be assigned to $^2E \leftarrow {}^2B_2$ transition and the second band to $^2B_1 \leftarrow {}^2B_2$ transition (10 Dq). Selbin et al.[15] reported that a parameter D_{12}, the difference in positions between the first and the second

Table 3. Reflectance Spectral Data of $[VO(acac)_2B]$ Complexes in Solid State

Base	Band 1	Band 2	D_{12}	E'
	cm^{-1}	cm^{-1}	cm^{-1}	kJ mol^{-1}
py	12890	17300	4410	52.7

E', Calculated from D_{12} values.

band maxima, is more sensitive than 10 Dq in the coordination ability of ligands. Then, the D_{12} values for these complexes were determined and converted to energy E'(kJ mol^{-1}) as shown in the 5th column of Table 3.

The tendency in E' value for each complex is similar to that for ΔG^* value as described above. In other words, no dependence of E' on basicity of the bases was observable. Therefore, in this case, Eq. 2″ was assumed:

$$E'/pK_a = \alpha' + \beta' \Delta H_{(sub)}/pK_a, \quad (2'')$$

where α' and β' are constants. As seen in Fig. 4, a linear correlation was observed between E'/pK_a and $\Delta H_{(sub)}/pK_a$. These results support the assumption that the stability in connection with the strength of metal-ligand bond is affected by the electron donating power and the heat of sublimation of base B.

Variations in the values of ΔG^* and E' with different ligand can be attributed to changes in the strength of metal–ligand σ-bond, the magnitude of metal-ligand π-bond, and the steric interaction. The basicity of ligand will relate to the strength of σ-bond. However, it is difficult to evaluate the degree of the character of π-bond and steric interaction. Although the heat of fusion and vaporization of ligand does not necessarily reflect the character of π-bond and steric interaction, both the characters may have correlation to the thermal property through hydrogen bond and van der Waals force. Therefore, the thermal properties such as heat of fusion and vaporization were used for explaining the difference in ΔG^* and E' values. Thus, the thermal stability of $[VO(acac)_2B]$ complexes seems to depend mainly on the pK_a and $\Delta H_{(sub)}$ of base B. A similar observation has been reported for dehydration-anation reaction of $[Cu(en)_2(H_2O)_2]X_2$[16] (en=ethylenediamine, X=Cl^-, Br^- ion) and $CoCl_2 \cdot nH_2O$ (n=1—6)[17] to discuss the influence of intermolecular hydrogen bonds on the activation energy and the enthalpy change of dehydration reaction.

The Spectrophotometric Determination of Phosphate Following the Collection of Ion Pair of Molybdophosphate with Bis[2-(5-chloro-2-pyridylazo)-5-diethylaminophenolato]cobalt(III) on an Organic Solvent-Soluble Membrane Filter

Mitsuhiko TAGA* and Masahiko KAN
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received September 1, 1988)

A rapid and sensitive method of determining phosphate was described. The ion pair of molybdophosphate with bis[2-(5-chloro-2-pyridylazo)-5-diethylaminophenolato]cobalt(III) (Co-5-Cl-PADAP) formed in 0.075 mol dm^{-3} sulfuric acid, 0.225 mmol dm^{-3} ammonium molybdate, and 25 μmol dm^{-3} Co-5-Cl-PADAP was collected on an organic solvent-soluble membrane filter made of cellulose nitrate. The membrane filter with the ion pair was then dissolved into *N,N*-dimethylformamide, and the absorbance of the solution was measured for the determination of phosphate. The calibration curve was linear up to 0.4 μg as phosphorus, with the correlation coefficient of 0.999, and the apparent molar absorption coefficient of phosphate was 2.9×10^5 dm^3 mol^{-1} cm^{-1}. The relative standard deviation was 1.7% for 0.4 μg of phosphorus. Although dodecyl sulfate existing in an amount ten times that of phosphorus caused a positive error, no ions commonly existing in natural waters interfere with the determination of phosphate. The proposed method was applied to the determination of μg dm^{-3} levels of phosphate-phosphorus in natural waters, and satisfactory results were obtained.

Since the determination of traces of phosphate in environmental samples is important for environmental chemistry and geochemistry, the development of a sensitive and rapid method of determining phosphate has been promoted. In addition to conventional heteropoly blue methods, many more sensitive methods have been reported, such as spectrophotometry using Malachite Green[1,2] and differential-pulse anodic voltammetry.[3]

For the determination of traces of phosphate in natural waters, an extraction procedure using a separating funnel is required in most determination methods. For the rapid and sensitive determination of phosphate and silicate, the collection of the ion pair of molybdophosphate or molybdosilicate with a cationic surfactant on an organic solvent-soluble membrane filter has been reported.[4-6] These methods are superior to the extraction method using a separating funnel because there is no use of toxic and combustible solvents and the operation is easy. However, greater sensitivity is required for the determination of traces of phosphate in natural waters.

For the highly sensitive determination of phosphate with membrane-filter collection, the use of Malachite Green as the ion pair reagent has been reported.[7] Although this method had a high sensitivity, the interferences caused by silicon and iron(III) were so serious that pretreatment was required for the determination of phosphate in natural waters.

In their previous studies, the present authors have developed highly sensitive methods of determining phosphate by means of indirect atomic absorption spectrophotometry using the copper(II)-1,10-phenanthroline complex[8] and have also developed flotation-spectrophotometry[9] and indirect atomic absorption spectrophotometry[10] using bis[2-(5-chloro-2-pyridylazo)-5-diethylaminophenolato]cobalt(III) chloride (Co-5-Cl-PADAP), which has previously been used for the extraction-spectrophotometric determination of anionic surfactants.[11,12]

In the present paper, the present authors have developed a highly sensitive and rapid method of determining phosphate. In the acidic solution, phosphate forms molybdophosphate with molybdate. The ion pair of the molybdophosphate anion with the Co-5-Cl-PADAP cation is formed and collected on the organic solvent-soluble membrane filter made of cellulose nitrate. The membrane filter with the ion pair is dissolved into *N,N*-dimethylformamide (DMF). The absorbance of the solution is proportional to the concentration of phosphate. By using this procedure, traces of phosphate in natural waters can easily be determined.

Experimental

Reagents. A standard solution of phosphate was prepared by dissolving potassium dihydrogenphosphate (special grade, Wako Pure Chemical Industries, Ltd.) in water. The Co-5-Cl-PADAP was purchased from Dojindo Laboratories and used as an aqueous solution without any further purification.

Apparatus. A Hitachi Model 124 double-beam spectrophotometer was used for measuring the absorbance. The absorption spectra were constructed with a Hitachi Model U-3200 recording spectrophotometer.

Procedure. A sample is placed in a 20-cm^3 beaker, and 1-cm^3 portions of 0.75 mol dm^{-3} sulfuric acid, 2.25 mmol dm^{-3} ammonium molybdate, and 0.25 mmol dm^{-3} Co-5-Cl-PADAP are added, after which the total volume is made up to 10 cm^3 with water. The solution is filtered through a 3.0-μm-pore sized membrane filter made of cellulose nitrate 25 mm in diameter (Toyo Roshi Kaisha, Ltd.). After washing with two portions of 10 cm^3 of water, the membrane

filter with the ion pair is transferred into a 10-cm³ beaker. By the addition of 5.0 cm³ of DMF, both the ion pair and the membrane filter are dissolved. The absorbance of the solution is measured at the absorption maximum wavelength of 560 nm against water with a 1-cm measuring cell.

Results and Discussion

Absorption Spectra. The absorption spectra of the ion pair of molybdophosphate with Co-5-Cl-PADAP and a reagent blank are shown in Fig. 1. The maximum absorbance is observed at the wavelength of 560 nm.

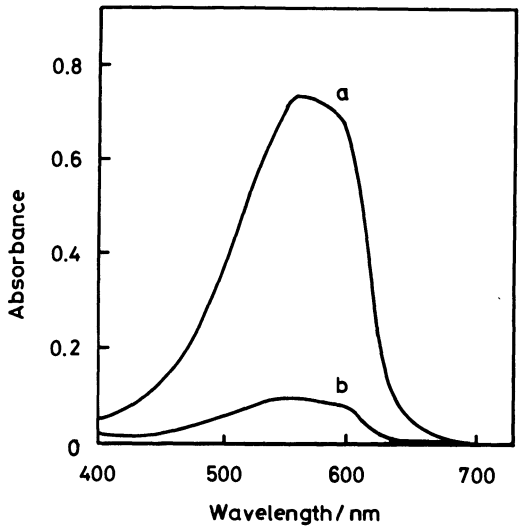

Fig. 1. Absorption spectra of ion pair of Co-5-Cl-PADAP with molybdophosphate and reagent blank. a: 0.4 μg phosphorus against reagent blank, b: reagent blank against water. [H_2SO_4]: 0.075 mol dm^{-3}, [$(NH_4)_6Mo_7O_{24}$]: 0.225 mmol dm^{-3}, [Co-5-Cl-PADAP]: 25 μmol dm^{-3}.

Selection of Acid. For adjusting the concentration of acid, sulfuric acid and hydrochloric acid can be used because of the small absorbance of the blank. The use of nitric acid or perchloric acid leads to a large absorbance of the blank due to the formation of the ion pair of nitrate or perchlorate with Co-5-Cl-PADAP. In the proposed method, sulfuric acid is used because the preservation and pretreatment needed for the determination of total phosphorus in natural waters often require the use of sulfuric acid.[13,14]

Effect of Concentration of Sulfuric Acid. Figure 2 shows the effect of the concentration of sulfuric acid on the absorbance of the ion pair and the reagent blank. The absorbance of the reagent blank was small above the concentrations of 0.05 mol dm^{-3}. The maximum absorbance of the ion pair was obtained in the concentration range from 0.05 to 0.1 mol dm^{-3}. The reason for the large absorbance of the reagent blank in the concentrations below 0.05 mol dm^{-3} was the formation and collection of the ion pair of Co-5-Cl-PADAP with molybdate. No molybdophosphate was formed in the concentration range above 0.2 mol dm^{-3}. The concentration of 0.075 mol dm^{-3} was chosen as the concentration of sulfuric acid.

Effect of Concentration of Ammonium Molybdate. The effect of the concentration of ammonium molybdate is shown in Fig. 3. The maximum and constant absorbance of the ion pair was obtained in the concentration range above 0.15 mmol dm^{-3}. As the concentration of ammonium molybdate, 0.225 mmol dm^{-3} was chosen.

Effect of Concentration of Co-5-Cl-PADAP. Figure 4 shows the effect of the concentration of Co-5-Cl-PADAP on the absorbance. The maximum and constant absorbance of the ion pair was obtained

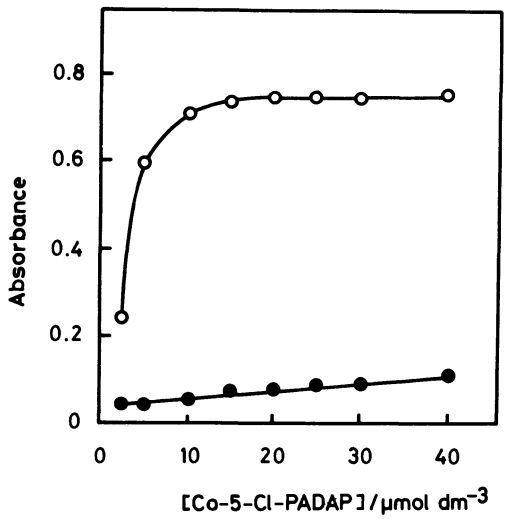

Fig. 4. Effect of concentration of Co-5-Cl-PADAP on absorbance. [H_2SO_4]: 0.075 mol dm^{-3}, [$(NH_4)_6Mo_7O_{24}$]: 0.225 mmol dm^{-3}. ○: 0.4 μg phosphorus against reagent blank, ●: reagent blank against water.

above the concentrations of 15 μmol dm^{-3}, while the absorbance of the reagent blank increased with the increase in the concentration of Co-5-Cl-PADAP. This increase in the absorbance of the reagent blank was explained by the formation and collection of the ion pair of molybdate with Co-5-Cl-PADAP. A concentration of 25 μmol dm^{-3} was chosen as the concentration of Co-5-Cl-PADAP.

Selection of Membrane Filter. The membrane filter collecting the ion pair of Co-5-Cl-PADAP with molybdophosphate must be dissolved into such organic solvents as DMF. Membrane filters made of cellulose nitrate, cellulose acetate, and a mixture of cellulose acetate and cellulose nitrate can be dissolved in DMF; a cellulose nitrate filter was used.

Effect of Pore Size of Membrane Filter. The effect of the pore size of the membrane filter on the absorbance was also studied. The constant absorbance of the ion pair was obtained in the pore-size range from 1.0 μm to 5.0 μm. The absorbance of the blank was also constant in this region. With the decrease in the pore size to less than 1.0 μm, the absorbance of the blank increased and the absorbance of the ion pair decreased. These results are similar to those reported in the collection of the ion pair of Malachite Green with molybdophosphate on a membrane filter.[7)]

As the pore size of the membrane filter, 3.0 μm was used because of the constant absorbance of the ion pair and the facility of the filtration.

Other Conditions. The effect of the standing time on the absorbance was examined for the reaction after the addition of Co-5-Cl-PADAP. From 30 s to 5 min, the constant absorbance was obtained for both the ion pair and the reagent blank.

Two portions of 10 cm^3 of water were sufficient for washing the membrane filter with the ion pair.

As the solvent dissolving the membrane filter with the ion pair, DMF was used. Dimethyl sulfoxide and Methyl Cellosolve could also be used. Although 5.0 cm^3 of DMF was used for dissolving the membrane filter with the ion pair, 2.0 cm^3 was sufficient for a complete dissolution.

Calibration Curve, Sensitivity, and Precision. The calibration curve of phosphate was linear up to 0.4 μg of phosphorus, with a correlation coefficient of 0.999. The apparent molar absorption coefficient of phosphate was 2.9×10^5 dm^3 mol^{-1} cm^{-1}. The relative standard deviation was 1.7% for 0.4 μg of phosphorus.

Effect of Diverse Ions. The effect of diverse ions on the determination of phosphate is shown in Table 1. Arsenic(V) showed a serious positive error when it coexisted in the same amount as phosphorus. This is due to the formation and collection of the ion pair of molybdoarsenate with Co-5-Cl-PADAP. For the elimination of the error caused by arsenic(V), the reduction of arsenic(V) to arsenic(III) with thiosulfate[15)] can be used. In the proposed method, arsenic(III) and thiosulfate showed no interference with the determination of phosphate.

Dodecyl sulfate, an anionic surfactant, exhibited a positive error of 5% when coexisting in an amount ten times that of phosphorus.

Although silicon showed a little positive error when coexisting in a 1000-fold amount, no serious problem arise in the determination of phosphate in natural waters.

Table 2. Determination of Phosphate-Phosphorus in Natural Waters[a]

Sample	Phosphorus content[b]/μg l^{-1}	
	Proposed method	Other method[c]
River water	3.6±0.3	4±1
Ground water	19.4±0.3	18±1

a) Sample taken; 5.0 cm^3. b) Mean±standard deviation (n=3). c) Flotation-spectrophotometry using Co-5-Cl-PADAP previously proposed by the present authors.[9]

Table 3. Spike and Recovery Test for Phosphate-Phosphorus in River Water[a]

Phosphorus/μg		Recovery/%
Added	Found	
0.000	0.035	—
0.050	0.089	108
0.100	0.130	95
0.150	0.193	105

a) Sample taken; 5.0 cm^3.

Iron(III) showed no interference with the proposed method. In the method using Malachite Green proposed by Matsubara et al.,[7] the presence of iron(III) in an amount equal to that of phosphorus caused an increase in the absorbance. Therefore, the pretreatment of samples with cation-exchange resin was required to remove iron(III). The proposed method is superior in the points of little interference caused by silicon and no interference by iron(III).

No ions commonly existing in natural waters, such as sodium, potassium, magnesium, calcium, chloride, and sulfate, interfere with the determination of phosphate. Organic substances, such as tartrate, citrate, ascorbate, and ethylenediaminetetraacetate, also showed no interference.

Determination of Phosphate in Natural Waters. The proposed method was applied to the determination of phosphate-phosphorus in natural waters. The samples were filtered with a 0.45 μm pore sized membrane filter and analyzed immediately or stored in a freezer until determination.[13] The results are shown in Table 2, in comparison with those of flotation-spectrophotometry using Co-5-Cl-PADAP previously proposed by present authors.[9] A satisfactory agreement was obtained between the two methods.

The spike and recovery test was examined for phosphate-phosphorus in another river water sample. The result, shown in Table 3, was satisfactory.

Enrichment of the Ion Pair on the Membrane Filter. Although the proposed method has a high sensitivity for the determination of traces of phosphate in natural waters, the enrichment of the ion pair on a membrane filter leads to an even more sensitive determination method.

To a 100-cm^3 portion of a sample, 1-cm^3 portions each of 7.5 mol dm^{-3} sulfuric acid, 22.5 mmol dm^{-3} ammonium molybdate, and 2.5 mmol dm^{-3} Co-5-Cl-PADAP were added. After filtration, the membrane filter with the ion pair was washed with three 30 cm^3 portions of water.

The calibration curve of phosphate was also linear up to 0.4 μg of phosphorus, with a correlation coefficient of 0.998. The molar absorption coefficient had the same value as that obtained by using 7 cm^3 of the sample. The absorbance of the reagent blank was 0.25, while that of 1 μg dm^{-3} of phosphrus was 0.19 against the reagent blank. The determination of 0.1 μg dm^{-3} levels of phosphorus can be made by using 100 cm^3 of the sample.

Complexation of Lanthanoid(III) with Substituted Benzoic or Phenylacetic Acids and Extraction of These Acids

Yuko HASEGAWA,* Yoko MORITA, Masako HASE, and Mayumi NAGATA
Department of Chemistry, Science University of Tokyo,
Kagurazaka, Shinjuku-ku, Tokyo 162
(Received September 8, 1988)

The stability constants of lathanoid(III) complexes with several benzoic and phenylacetic acids substituted with -OH, $-OCH_3$, or $-NH_2$ groups as well as the dissociation constants of these acids have been determined potentiometrically in 0.1 mol dm^{-3} sodium perchlorate solution at 25 °C. The distribution constants of these acids between the perchlorate media and chloroform and the dimerization constants in chloroform were also determined. The distribution constants of ortho-substituted benzoic acids seem to be larger than those of α-substituted phenylacetic acids with the same substituent. There is a trend that the higher the pK_a, the larger the dimerization constant. The order of pK_a is : *o*-aminobenzoic>*o*-methoxybenzoic>β-hydroxy-β-phenylpropanoic>α-hydroxyphenylacetic(mandelic)>α-methoxyphenylacetic>*o*-hydroxybenzoic acid and the sequence of the stability constants of their complexes for a given lanthanoid is also in a same order except for the mandelate. Mandelic acid forms more stable complexes with the heavier lanthanoid(III) while others are similar to each other regardless of the lanthanoid.

Most α-hydroxy carboxylic acids have been used as eluents in the mutual separation of lanthanoid(III) by ion-exchange method, because these form more stable complexes with the heavier lanthanoid(III). It has also been reported that most carboxylic acids, such as benzoic acid[1] and benzilic acid (α-hydroxydiphenylacetic acid[2]), form adducts with tris(β-diketonato)-lanthanoid(III) in organic solvents.

However, it is not always clear what properties of the acids are effective to form stable complexes with lanthanoid(III) in organic and in aqueous solutions. In order to get some information about this point, the effect of the characteristics of acids such as the acid strength, the structure, and the nature of the functional group on the liquid–liquid distribution and the dimerization constants has been examined, using several benzoic and phenylacetic acids substituted with -OH, $-OCH_3$, or $-NH_2$ group at the 2-position of the parent acids. Furthermore, the stability constants of these complexes with lanthanoid(III) have been determined potentiometrically.

Experimental

Reagents. All reagents used were of analytical grade. Mandelic acid (α-hydroxyphenylacetic acid) and tropic acid (β-hydroxy-β-phenylpropanoic acid) were obtained from Nacalai Tesque, Inc., salicylic acid (*o*-hydroxybenzoic acid) and anthranilic acid (*o*-aminobenzoic acid) from Kanto Chemicals, *o*-anisic acid (*o*-methoxybenzoic acid) from Tokyo Kasei Co., and α-methoxyphenylacetic acid from Aldrich Chemical Co. Lanthanoid oxides(III) were obtained from the following companies: Aldrich Chemicals (lanthanum), Mitsuwa Chemicals (neodymium, europium, thulium), Shin-Etsu Chemical Co. (praseodymium, samarium, and lutetium), and American Potash & Chemical Corporation (others). The purity of each oxide was 99.99%. Sodium perchlorate was prepared from sodium carbonate and perchloric acid; it was recrystallized twice from water. Chloroform was washed three times with deionized water. The other reagents were employed without further purification.

Procedures. All the procedures were carried out in a thermostated room at 25 °C. The total anion concentration was adjusted to 0.1 M (1 M=1 mol dm^{-3}) with sodium perchlorate. The solution containing 0.010 M $HClO_4$+0.09 M $NaClO_4$ solution was employed as the standard of $-\log[H^+]=2.00$ (hereafter $-\log[H^+]$ is abbreviated as pC_H).

i) Dissociation, Distribution, and Dimerization Constants of the Carboxylic Acids.

Dissociation Constants of Carboxylic Acids. A certain volume (about 50 cm^3) of a buffered carboxylic acid solution ($[A^-]/[HA]=1$), in other words, the acid solution in which a half of the acid was neutralized with sodium hydroxide, was titrated with perchloric acid potentiometrically. The total acid concentration was about 0.02 M. The other dissociation constant of anthranilic acid owing to the amino group associated with proton, K_a' ($=[H^+][HA]/[H_2A^+]$), was similarly determined by titrating the acid solution, in which perchloric acid equivalent to a half concentration of the total anthranilic acid had been added, with sodium hydroxide solution. The titrations were repeated several times. In all cases, the repetitive runs agreed satisfactorily.

Distribution and Dimerization Constants of the Acids. A portion of chloroform solution containing one of the acids at various concentrations and an equal volume of 0.1 M sodium perchlorate solution adjusted to a certain pC_H were placed in a stoppered glass tube and the two phases were agitated vigorously. After then, the mixtures were centrifuged. The pC_H in the aqueous solution was measured. The acid concentrations in the aqueous phases were determined by measuring the absorbance at a certain wavelength, near the wavelength giving the maximum absorbance, e.g., for salicylic acid, at 301.7 nm where the molar absorptivity was 3.53×10^3, and for mandelic acid at 260 nm (the absorptivity was 1.64×10^2). The concentration in the organic phases was also determined by measuring the absorbance directly except for anthranilic acid. The molar absorptivity was 4.10×10^3 at 309 nm for salicylic acid, and 1.85×10^2 for mandelic acid at 260 nm. The concentration of anthranilic acid in chloroform was determined from the absorbance after back-extraction into sodium hydroxide

solution. The molar absorptivity of anthranilic acid at the wavelength was constant at $pC_H>7$. However, at lower pC_H, the absorptivity decreased.

The distribution ratio is defined as,

$$D = [HA]_{org,total}/[HA]_{aq,total}$$

hereafter, the organic phase is denoted by the subscript "o" and the aqueous phase has no subscript. The distribution ratio of the monocarboxylic acid can generally be represented as follows:

$$D = \frac{[HA]_o + 2[(HA)_2]_o}{[HA] + [A^-]} = \frac{K_d(1 + 2K_dK_{dim}[HA])}{1 + K_a/[H^+]} \quad (1)$$

where K_d is the distribution constant of the acid ($K_d=[HA]_o/[HA]$) and K_{dim} is the dimerization constant ($K_{dim}=[(HA)_2]_o/[HA]_o^2$).

The distribution ratio was also measured at various pC_H for each acid at 1.0×10^{-3} M.

ii) Stability Constants of the Complexes. The metal(III) solutions were prepared by dissolving the respective weighed oxide in perchloric acid. The lanthanoid(III) concentration was determined by titration with EDTA using Xylenol Orange as the indicator at about $pC_H=5$. The pC_H in the metal(III) solution was adjusted, just prior to use to a similar pC_H in the buffered ligand acid solution in order to avoid the change in the pC_H due to the acid-base neutralization. The stability constants of the lanthanoid(III) complexes were determined by titrating the metal(III) solutions with the half-neutralized carboxylate solution potentiometrically. The potentiometric titration data were analyzed using the following equation based on the Bjerrum formation function.

$$\frac{\bar{n}}{1-\bar{n}} \cdot \frac{1}{[A^-]} = \beta_1 + \beta_2 \frac{2-\bar{n}}{1-\bar{n}} [A^-] \quad (2)$$

where $\bar{n}$ is the average number of ligands combined with the metal ion. More detailed data treatment is reported elsewhere.[3]

Results and Discussion

i) Dissociation, Distribution, and Dimerization Constants of the Carboxylic Acids. The pK_a values obtained by potentiometric titration are listed in Table 1. Since the pK_a of the parent acids, i.e., benzoic and phenylacetic acids, is almost 4,[6,7b] the introduction of these functional groups decreases the values of pK_a except for $-NH_2$. The values of the dissociation constant obtained in the present work agree with the several results reported earlier.[7] The pK_a of salicylic acid reported in the literature scatters. However, a value which agrees with the present result, (2.70±0.02 in 0.10 M ionic medium), has also been reported.[8]

Figure 1-a shows the log–log plots of the distribution ratio of salicylic and anthranilic acids against the undissociated acid concentration in the aqueous phase. Since the distribution ratio depends on the pC_H as given in Eq. 1, the pC_H at equilibrium was measured and $\log D(1+K_a/[H^+])$ for salicylic acid and $\log D(1+K_a/[H^+]+[H^+]/K_a')$ for anthranilic acid instead of $\log D$ are plotted against log[HA]. The undissociated acid concentration was calculated from the total acid concentration in the aqueous phases (A_T) and the K_a, according to $[HA]=A_T/(1+K_a/[H^+])$ while that of anthranilic acid was calculated according to $[HA]=A_T/(1+K_a/[H^+]+[H^+]/K_a')$. The data were analyzed by a curve-fitting method using a normalized curve, $Y=\log(1+v)$ where $v=2K_d\times K_{dim}[HA]$ (see Eq. 1). Consequently, K_d and K_{dim} were obtained. Since the distribution ratio could not be determined over a wide range of [HA] for the other acids (due to the restriction of solubilities), the relation in Eq. 1 was plotted in antilog units (an example is shown in Fig. 1-b) and from the intercept and the slope of the straight lines obtained, the constants were determined. All the constants obtained are listed in Table 1. The solid curves in Fig. 1 were calculated using the constants obtained. The curves fit well to the data.

Table 1. Equilibrium Constants of Acids
Aqueous Solution : 0.1 M $NaClO_4$
Organic Solvent : $CHCl_3$

Acid	pK_a	$\log K_d$	$\log K_{dim}$
Salicylic (*o*-Hydroxybenzoic)	2.72	0.48	1.64
Anisic (*o*-Methoxybenzoic)	3.92	1.58	—
Anthranilic (*o*-Aminobenzoic)	4.68 (2.15)[a]	−0.20	2.15
Mandelic (α-Hydroxyphenylacetic)	3.18	−1.47[4]	1.50[4]
α-Methoxyphenylacetic	2.97	0.40	1.10
Tropic (β-Hydroxy-β-phenylpropanoic)	3.90	−1.09	1.54
Benzoic	4.01[6]	0.44[5]	2.22[5]

a) In the parentheses $K_a'=[HA][H^+]/[H_2A^+]$.

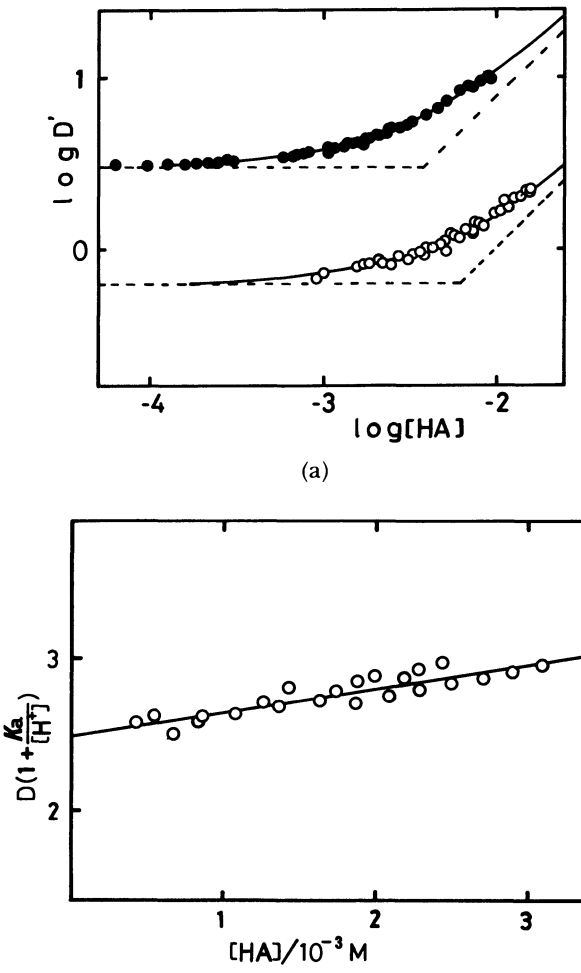

Fig. 1. Typical examples of extraction curves as a function of undissociated acid concentration in aqueous phases. a) Log-log plot of distribution ratio of salicylic and anthranilic acids as a function of [HA]. The $-\log[H^+]$ is around 2.0 for salicylic acid (●) and 3.4 for anthranilic acid (○). $\log D' = \log D(1+K_a/[H^+])$ for salicylic acid and $\log D' = \log D(1+K_a/[H^+]+[H^+]/K_a')$. The dotted lines are $Y = \log K_d$ and $Y = \log[HA] + \log 2K_d^2K_{dim}$. b) Distribution ratio of α-methoxyphenylacetic acid against [HA]. The solid line is $Y = 2.49 + 1.57\times10^2[HA]$. The correlation coefficient is 0.89₄. The $-\log[H^+]$ is around 2.0.

In order to ascertain the validity of Eq. 1 and of applying pK_a, which was determined in 0.1 M sodium perchlorate media without saturation with chloroform, to the analysis of the solvent extraction data, the distribution ratio was measured at various pC_H at a constant acid concentration. Figure 2 shows the plots of the distribution ratio of salicylic, anthranilic, and mandelic acids against pC_H using a total acid concentration of 10^{-3} M. The solid curves are calculated from Eq. 1 using all the constants in Table 1. The curves fit well to the data. The data obtained by similar experiments with other acids fitted well to

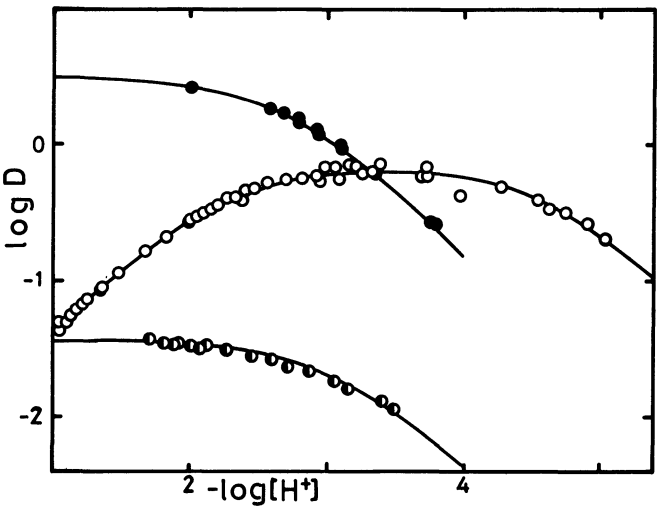

Fig. 2. Distribution ratio of salicylic, anthranilic, or mandelic acid as a function of $-\log[H^+]$. Total acid concentration: 1.0×10^{-3} M. Aqueous phase: 0.1 M $NaClO_4$, organic phase: $CHCl_3$. Salicylic (●), anthranilic (○), and mandelic (◐) acids.

the values calculated from the constants obtained. The fact that all the constants, including pK_a, explain the data well would suggest that the constants obtained in an aqueous solution without saturation with organic solvents can be applied to solvent extraction data.

As seen from Table 1, it is not easy to find definite correlation among pK_a, K_d, and/or K_{dim}. The distribution constants of the substituted benzoic acids seem to be larger than those of the phenylacetic acids substituted with the same functional group. There is a trend that the higher the pK_a, the larger K_{dim}, at least in the family of phenylacetic acid. The trend would be explained as: the acid anion capable of attracting hydrogen ion strongly, i.e., the oxygen atom in carboxyl group to be the stronger Lewis base, may also attract a hydrogen atom in other acid molecules to form a hydrogen bond. This result suggests that a carboxylic acid having higher pK_a may form more stable adducts with lanthanoid(III) chelates such as tris(β-diketonato)lanthanoid(III) in organic phases. The high pK_a and small K_{dim} of *o*-anisic acid may be caused by the methoxyl group at the ortho position. This could form an inner complex with the hydrogen atom in the carboxyl group. Consequently, the dissociation is depressed and the distribution constant is large, due to less hydration. Furthermore it would not easily associate with other *o*-anisic acid, i.e., low K_{dim}. We can not explain the low pK_a, and high distribution and dimerization constants of salicylic acid, most presumably, owing to inner complexation in salicylate ion.

ii) Complexation of Lanthanoid(III) with These Acids. Table 2 gives typical examples of the potentiometric titration data. Using these data, $\bar{n}/((1-\bar{n})[A^-])$ and $(2-\bar{n})[A^-]/(1-\bar{n})$ were calculated (see Eq. 2),

Table 2. Potentiometric Titration Data in 0.10 M ($NaClO_4$) at 25 °C

a) Free carboxylate ion concentration at equilibrium.

and the former was plotted against the latter. Straight lines having positive slopes were obtained. The first and second stability constants were determined from the intercept and the slope, respectively. The constants so obtained are listed in Table 3 together with the error limits based on the agreement in repetitive titrations. In these experiments, owing primarily to two reasons, high $\bar{n}$ could not be obtained, that is, i) lanthanoid(III) does not form stable complexes with these ligands except for mandelate ions, and ii) since the solubility of the acids employed in water is not high, the free carboxylate anion concentration at equilibrium was not over 2×10^{-3} M. Consequently, the second stability constants have rather big errors.

It would appear from the values in Table 3 that the order of the stability constants for a given lanthanoid(III) is in the following sequence: mandelates≫anthranilates>*o*-anisates≃tropates≃α-methoxyphenylacetates≃benzoates>salicylates. This sequence may be due to the differene of pK_a of the ligand acids. Actually, it has been reported[6] that the correlation

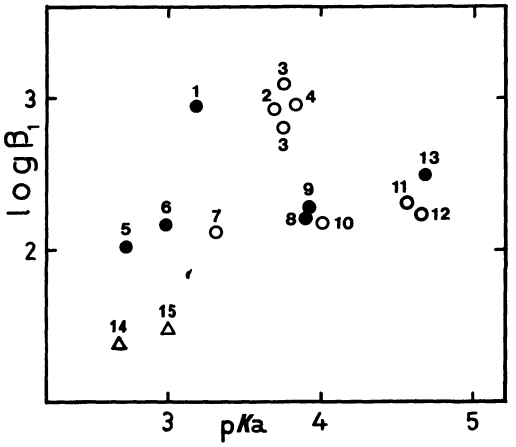

Fig. 3. Correlation between the first stability constants (log β_1) of Eu^{III} complexes and the dissociation constants of the ligand acids (pK_a). 1. Mandelate, 2. hydroxyacetate, 3. α-hydroxymethylpropanoate, 4. α-hydroxypropanoate, 5. salicylate, 6. α-methoxyphenylacetate, 7. methoxyacetate, 8. β-hydroxy-β-phenylpropanoate, 9. *o*-methoxybenzoate, 10. benzoate, 11. acetate, 12. propanoate, 13. anthranilate, 14. chloroacetate, 15. iodoacetate, solid circles: present work, open circles: taken from Refs. 6 and 7, triangles: taken from Ref. 9.

between log β_1 and pK_a is linear, when the interaction between lanthanoid ion and a ligand is ionic and there is no variation in the steric effects. Figure 3 shows the correlation between the first stability constants of europium(III) complexes (log β_1) and pK_a of the ligand acid together with that reported for several monocarboxylates in the literature. The constants are classified into two different groups. The α-hydroxy carboxylic acids which may form five-membered chelates belong to the upper group, and other carboxylic acids belong to the lower group. Although α-methoxyphenylacetic acid may form a five-membered ring, it does not belong to the upper group. Similarly, methoxyacetic acid[10] also does not belong to the upper group. In the lower group, the order of the stability constants in magnitude seems to be correlated with the difference of pK_a. Furthermore, as seen in Table 1, only mandelic acid forms more stable complexes with the heavier lanthanoid(III), and the stability constants (log β_1) of the series of lanthanoid(III) complexes with other carboxylic acids employed in the present work are similar to each other.

In a word, the presence of the OH group at the α-position of carboxylates seems to be very effective to form a more stable complex with the heavier lanthanoid(III). However, β-position of carboxylates, *o*-position of benzoic acid or other functional group such as methoxyl group are not effective. Further accumulation of data would be necessary in order to know the reason why α-hydroxy carboxylic acids form more stable complexes with the heavier lanthanoid.

a) δ denotes error limits based on the agreement in repetitive titrations.

The larger stability constants and the monotonical increase of $\log \beta_1$ against the atomic number could be caused by the match of the bond angle of the hydroxyl group and the carboxyl group to the smaller sized lanthanoid(III). In α-methoxy carboxylates, the one carbon and the three hydrogen atoms in the methoxyl group could interfere with taking up an appropriate bond angle to accept lanthanoid(III).

As seen from Fig. 3, the stability constant of the salicylate seems to be a little larger than estimated from the correlation between pK_a and $\log \beta_1$ of monocarboxylates. This may be due to the formation of stable chelates between the salicylic acid and lanthanoid(III),[11] or due to a proper character of salicylate ion.

The above results may suggest that: 1) there is a trend that the acid of higher pK_a has a larger dimerization constant. When the ligand acids are not

α-hydroxy carboxylic acids, log β_1 increases in proportion to pK_a. Accordingly, pK_a will be one of the important parameters for the complexation in the organic phases as well as in the aqueous solutions. 2) The behavior of salicylic acid in aqueous and/or in organic solvents including complexation with lanthanoid(III) is different from that of other carboxylic acids. 3) Only carboxylic acids having a hydroxyl group at the α-position are effective to form the more stable complexes with the heavier lanthanoid(III). Other functional groups, and hydroxyl group at the β-position or the *o*-position are not effective.

Dispersion Behavior of Solutes in an Ideal Laminar Flow with Small-Bore Glass Tubes†

Takashi KORENAGA,* Fenghua SHEN, Hirofumi YOSHIDA, and Teruo TAKAHASHI
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700
(Received September 14, 1988)

The dispersion behavior of solute molecules injected as a sample plug into an ideal laminar capillary flow was experimentally analyzed by means of microscopic and microphotometric methods. The flow pattern in small-bore glass tubes was directly observed by the microscopic method using a camera. The peak responses obtained for the colored solutes by means of the microphotometric method consist of double-humped peak features which resulted from both laminar flow convection and the molecular diffusion of solute molecules at the parabolic interface between the sample plug and the carrier fluid. The influences of the diffusion coefficient of the solute, the flow rate, the tube length, the tube diameter, etc. were mainly investigated in order to guide the design and optimization of the flow systems of capillary liquid chromatography (CLC), capillary electrophoresis (CEP), flow-injection analysis (FIA), etc. The experimental results obtained here are in good agreement with the theoretical results obtained by the numerical solution for the diffusion-convection equation.

Many open-tubular glass capillary columns have been utilized in the fields of analytical separation chemistry, such as in gas or liquid chromatography, since 1956.[1] Their main advantage is in the use of long glass capillary columns in order to obtain a high resolution, but it is difficult to operate and provide instrumentation for the apparatus. Therefore, an understanding of the dispersion behavior of the solute molecules in the sample plug flowing with the carrier stream through a small-bore glass tube or the characterization of the response peak feature is important in designing flow systems with or for capillary liquid chromatography (CLC), capillary electrophoresis (CEP), flow-injection analysis (FIA), electrokinetic chromatography (EKC), field-flow fractionation (FFF), membrane-separation analysis (MSA), etc. In CLC, for example, the band broadening is just an important parameter to obtain a higher sensitivity and resolution, and it is mainly controlled by the eddy diffusion from unions, joints, and connectors,[2] the molecular diffusion in both mobile and stationary phases, and the interactions between stationary and mobile phases.[3]

For the dispersion phenomena in straight open tubes, several theoretical approaches have been studied in order to overcome the above-mentioned problems,[4-8] but few experimental studies have been carried out. Recently, though, Atwood and Golay[9] theoretically and experimentally reported the dispersion behavior of peak features using short, straight tubes in LC systems. In their experiments, however, a usual chromatographic apparatus was used, and it was difficult to obtain an ideal laminar flow because of the turbulence resulting from the sample injection, unions, joints, connectors, or the detector flow cell. Since the theoretical analyses were based on the assumption that the capillary flow was completely laminar, a model apparatus which achieves an ideal laminar flow should be used for the experimental research.

The present authors[10] previously analyzed the transport phenomena and dispersion behavior of a small quantity of a sample solution injected as a plug into a carrier fluid flowing through open-tubular small-bore tubes and built a simple simulation without considering the molecular diffusivities of the solutes in the sample-solution plug.

The present paper will mainly describe some experimental results on sample-dispersion behavior obtained for open tubular and small-bore glass capillary tubes with a circular cross-section using some diffusive solutes or a nondiffusive one in the injected sample plug. Using an ideally-composed model experimental apparatus with the microcomputer developed here, we investigated the fundamental dispersion behavior and transport phenomena of the solute dissoved in the sample solution plug in order to compare them quantitatively with the theoretical results obtained by the numerical solution for Taylor's diffusion-convection equation.[4]

Experimental

Apparatus. A schematic description of the experimental apparatus used for taking photographs continuously is given in Fig. 1. It is simply constructed of a Furue (Tokyo, Japan) model JP-V-W microfeeder-type syringe pump, an Olympus (Tokyo, Japan) model BH-2 microscope (equipped with an Olympus model OM-2N camera with a motor-drive unit and a shutter control unit), and various kinds (various diameters and lengths) of small-bore (capillary: less than 1 mm i.d.) glass tubes.

In order to investigate the dispersion behavior, the residence-time distribution of solutes injected as a plug were measured by means of a hand-made microphotometric detection system, as is shown in Fig. 2. The detector is mainly constructed of a Sugiura (Tokyo, Japan) model SL-

† This paper was partly presented at the 7th International Symposium on Capillary Chromatography, held in May, 1986, at Gifu, Japan.

FI-150T cold light source using a halogen lamp and an optical fiber, a Hamamatsu Photonics model S-1033-01 photodiode, an Analog Devices model 757N logarithmic amplifier, and a data-recording and -processing system using a Sharp model MZ-80C microcomputer.

Reagents. Colored aqueous sample solutions of potassium permanganate, Methylene Blue dye (MB; Colour Index 52015), and commercially available blue ink containing submicron pigment particles were used in the present experiments. The potassium permanganate solution was prepared by dissolving analytical-reagent-grade potassium permanganate in distilled water. The dye solution was directly prepared by dissolving analytical-reagent-grade MB dye (Wako Pure Chemicals, Japan) in distilled water. The ink solution was prepared from a commercial submicron pigment ink (Sakura Color Products, Japan) by removing relatively large particles using a centrifugal separation technique. The molecular diffusion coefficient of potassium permanganate in water at a concentration of 2.5×10^{-3} mol l^{-1} is 1.2×10^{-3} $mm^2 s^{-1}$,[4] and that of MB in water is 3.0×10^{-4} $mm^2 s^{-1}$.[10] The ink consists of colored submicron pigment particles, and its molecular diffusion coefficient is assumed to be about 10^{-5} $mm^2 s^{-1}$, so that the dispersion in water occurs mainly by means of the laminar-flow convection. Distilled water and glycerol/water (1+1) mixture were used as the carrier fluids in this work.

Procedure. A small portion of the sample solution, dissolved in the respective carrier fluid, was injected precisely by the use of a micro syringe into a stopped-flow carrier fluid, and the syringe pump was then immediately started. By this open-column sample-injection method, the dead volumes, abrupt changes in the internal diameter, and disturbances of the flow can be reduced to a minimum. The injected sample volume was less than 10 μl, and the injected sample length was less than 12 mm in the 1.0 mm-i.d. glass capillary column.

In the photographic experiments, a motor-drive camera was started as soon as the sample zone entered in the view of the microscope. Many photographs were taken at every 0.25 s. In the case of microphotometric detection, the BASIC program for data recording was started when the pump started. The signals obtained from the photodiode were transmitted to the microcomputer after the conversion of the analog signals to digital ones. The data stored on floppy

disk were then treated and printed out to a dotted printer or a X-Y plotter to observe the response-peak features.

Results

Theory on Laminar-Flow Model of Sample Plug in Small-Bore Tube. In small-bore capillary tubes, the flow pattern of the nondiffusive sample plug can theoretically be described as a laminar-flow profile. The diameters of the capillary tubes used in this research are below 1 mm, and the average flow rates are below 110 mm s^{-1}, so the Reynolds number is smaller than 110, much smaller than the critical Reynolds number of the laminar flow (2000—2300) in a round pipe.

The velocity profile of the laminar flow may be described as follows:

$$u_r = 2u(1 - r^2/R^2) \quad (1)$$

where u_r denotes the flow rate at the tube radius r of the capillary and where u and R denote the average flow rate and the tube radius respectively. Equation 1 shows that the laminar-flow velocity profile has a parabolic dispersion of the injected sample plug and that the velocity profile possesses a large possibility of the molecular diffusion of the solute molecules caused by the concentration gradient. Equation 1 shows that the smaller the tube radius, the steeper the parabolic profile (velocity gradient) in capillary columns.

Assuming that the solute molecule used in a sample solution is nondiffusive, the following equation is obtained:

$$d_s = 2ut \quad (2)$$

where d_s and t denote the traveling distance of the sample zone head (front) and time respectively.

The apparent sample arrival time at the detection point $t_{a'}$, that is, the time required for the sample-zone front to reach the detector, can be calculated for the nondiffusive solute molecules by means of Eq. 3:

$$t_{a'} = d_s/(2u) \quad (3)$$

where the d_s nearly equals the tube length of the capillary column (L), since short joint tubes are necessary in column connections.

For diffusive solute molecules, the baseline-to-baseline time Δt_b, which is the band-width in time, was investigated as a means of measuring the dispersion behavior in the response-peak profile. Vanderslice et al.[8] solved Taylor's convection-diffusion equation by the finite differential method and obtained Eq. 4 for the calculation of Δt_b:

$$\Delta\tau_b = 1.93X^{0.64} \quad (4)$$

where $\Delta\tau_b$ and X denote the dimensionless baseline-to-baseline time and the dimensionless traveling distance respectively, as defined by Eqs. 5 and 6:

$$\Delta\tau_b = D\Delta t_b/R^2 \quad (5)$$
$$X = DL/(2R^2u) \quad (6)$$

where D denotes the molecular diffusion coefficient of the solute in the injected sample plug.

Evaluation of the Apparatus by Eye Measurement of Sample-Dispersion Behavior. The traveling distances (d_{MB}) of the colored-sample-zone front as a function

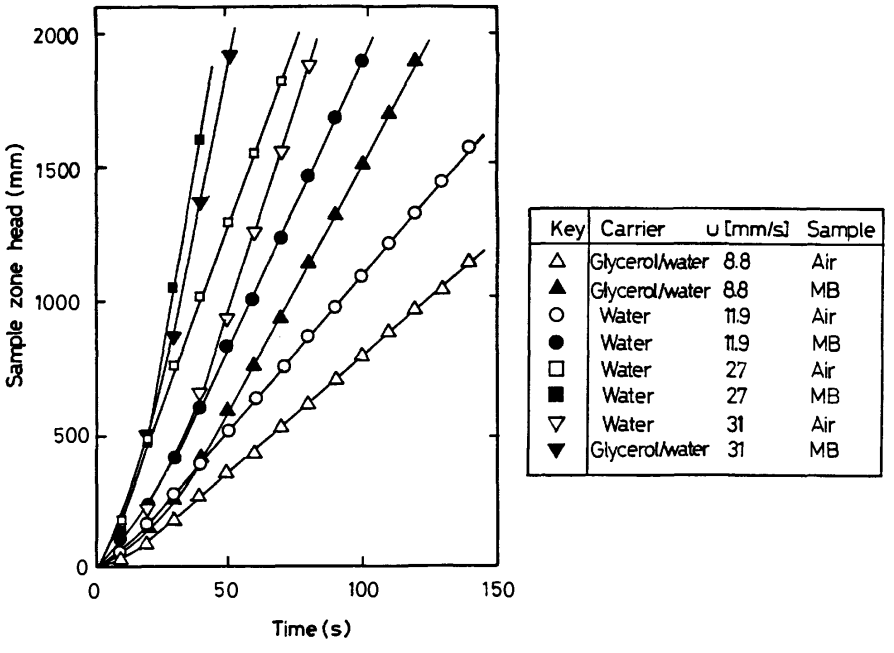

Fig. 3. Relationship between traveling distance of sample zone head and time.

of the time were measured with the eye for the solute molecules of MB dye (Fig. 3). The traveling distances of the air-segment front (d_{air}), which was injected instead of the colored-sample-solution plugs containing solute molecules, were also represented as typical examples for the comparison of the dispersion behavior. When the air segment is injected, the flow rate of the air segment just equals the average flow rate (u) of the carrier fluid according to Eq. 2. In the case of the plots for the air segment, the slopes of the curves equal u except for each transition period. The laminar capillary-flow model of the MB solute in the injected sample plug is shown in Fig. 4(a). The traveling distances of the front interface of the MB solute were smaller than that calculated by Eq. 2. This might be because the MB molecule diffuses to the radial direction at the interface of the sample plug. The component substance (i.e., the MB solute) at the front interface of the sample plug naturally diffuses to the low-velocity-gradient region in the laminar capillary flow near the tube wall. Of course, the MB molecule at the back interface of the sample plug zone conversely diffuses to the high-velocity-gradient region in the center of the tube. Thus, the sample-dispersion length between the sample-zone front in the tube center and at the back in the tube wall decreases, so that the peak broadening on response-peak profiles can be minimized, as is shown in Fig. 4(b). This phenomenon can easily be understood by comparing the results obtained by using the same MB dye as a solute molecule in water and a glutinous glycerol/water (1+1) (G/W) solution as a carrier fluid, and those obtained by using the MB dye and nondiffusive submicron ink in a water carrier. When the G/W carrier was used, the measured d_{MB} value was about twice as large as the d_{air} one, because the apparent molecular diffusivity of the MB dye molecule in the G/W solution is negligibly small, probably less than 10^{-5} mm^2 s^{-1}. The relationship between the measured d_{MB} and d_{air} values is studied in this work. The ordinate represents the slopes of the d_{MB} values in Fig. 3; the abscissa represents those of the d_{air} values. The results obtained by using glass tubes with an inner diameter between 0.5 mm and 1 mm i.d. show that a narrower glass column has a larger velocity gradient and that the profile of the colored sample plug loses its sharpness as a result of the molecular diffusivities of the solute molecules into a water carrier larger than 10^{-4} mm^2 s^{-1}. The model apparatus is, therefore, useful for fundamental and experimental studies of the dispersion behavior of an injected sample plug containing solute molecules as tracers in a flowing carrier stream in small-bore glass tubes.

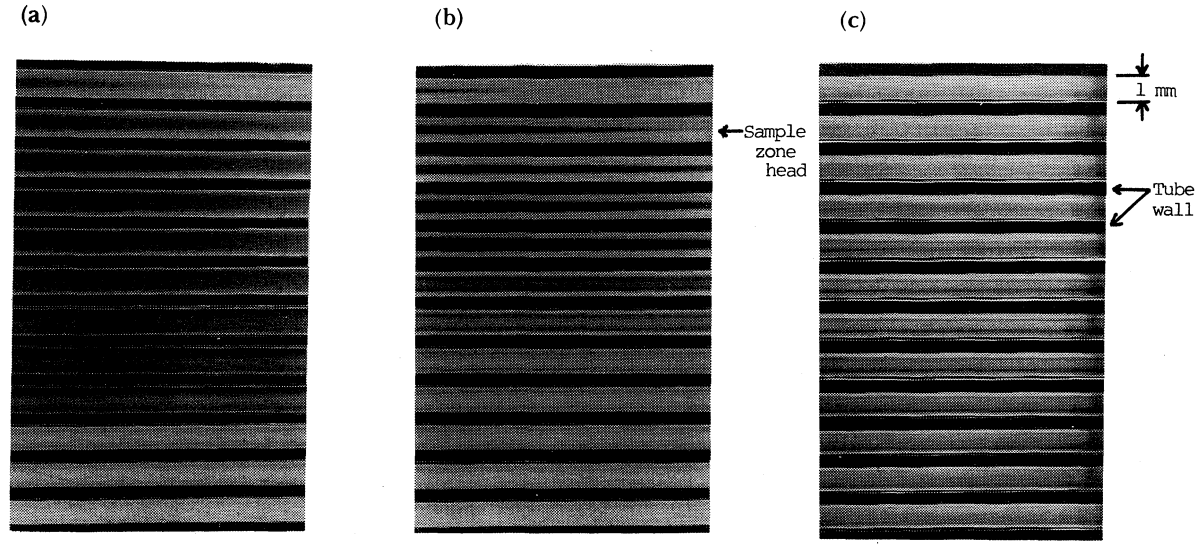

Fig. 5. Photographs continuously obtained with a microscope for the mobile sample plug zones. Ten-μl of 1 mM MB dye or submicron particle ink solutions were injected by the open-column method into a water carrier. A glass tubing (1 mm i.d. and 200 mm detection distance) was used as a capillary column. (a) MB dye; flow velocity: 11.9 mm s^{-1}, (b) MB dye; flow velocity: 110 mm s^{-1}, and (c) submicron ink; flow velocity: 21 mm s^{-1}.

Flow Pattern Analysis by Means of a Photographic Method with a Microscope. A typical flow pattern, obtained by the present photographic method with a microscope, is shown in Fig. 5, where the mobile colored sample zone travels through the capillary tube. According to the procedure, a motor-drive camera starts and many photographs are continuously taken, using a 100-feet roll film, as soon as the injected sample zone front enters the view of the microscope. The photographs show that the injected-sample zone flows with the laminar-flowing carrier fluid and rapidly broadens along with the flow-velocity profile in the axial direction. The flowing sample zone contains a sharply-pointed, needle-like top and has two parabolic interfaces (front and back) lying between the sample plug and the carrier fluid. According to the parabolic-velocity distribution in the laminar flow, represented by Eq. 1, the flow pattern of the sample zone becomes sharper with the increase in the flow rate of the carrier fluid, as is shown in Figs. 5(a) and 5(b). This result is due to the difference in the diffusion time.

Many photographs were taken for the MB-dye samples under various operating conditions by changing the flow rate and the tube length. All the photographs show the same results as those presented above; that is, the sample zone became sharper and spread wider in the axial direction with an increase in the flow rate and/or the tube length. The mixing of the sample component (i.e., the solute) with the carrier component depends on the convection (i.e., the laminar flow profile), and their molecular diffusivities occurred at the porabolic interfaces (front and back). By comparing Figs. 5(a) and (b), it is also found that the interfaces become more distinct because of the smaller extension of the molecular diffusion when the flow rate becomes faster, viz., when the mean residence time ($t_m=L/u$) decreases. Furthermore, when the nondiffusive ink sample was injected, the front and back interfaces were much more distinct than the diffusive ones because the molecular diffusion of the component substances was one of the most important parameters in controlling peak dispersion (cf. the photographs in Fig. 5(c)).

Peak-Dispersion Observation by Means of a Micro-Photometric-Detection System. In stead of the qualitative photographic method, the hand-made micro-photometric-detection system developed here was used to evaluate quantitatively the axial dispersion, that is, the sample-zone broadening as the response-peak profile. In order to optimize the operating conditions in several analytical instrumentation methodologies using small-bore tubes as reactors, the physical properties of the injected-sample plug and the carrier solutions are the most important parameters for the design of the flowing systems. The effects of the molecular diffusivities of the solutes were first studied; the peak features are shown in Fig. 6. For a large molecular diffusivity (i.e., the potassium permanganate solute), the second peak is more apparent than the first one, the width of the peak feature being much narrower and the dispersion in the axial direction being reduced because of the molecular diffusion of the solute in the radial direction in the water carrier. When the ink sample, which contains colored submicron particles and has much less molecular diffusivity than the potassium permanganate and MB-dye samples, is injected as the sample plug, the double-peak features cannot be obtained as expected for a molecule having a molecular-diffusion coefficient of less than 10^{-5} mm^2 s^{-1} by means of the computer simulation.[10]

The response-peak features under various operating conditions are very interesting, as is shown in Fig. 7. Nine figures are summarized at different flow rates and different tube lengths in the present apparatus with a horizontally placed capillary tube (Fig. 2). Almost all of these response peaks show the clear double-humped peak features expected from computer simulation using the numerical-analysis method.[8] This means that the experimental apparatus used in this study is quite satisfactory for studying the dispersion behavior of the solutes in a laminar capillary flow, since many theoretical analyses were carried out on the basis of the assumption that the flow was really laminar.[4-8] From these figures, the sharper part (the first peak) is seem to

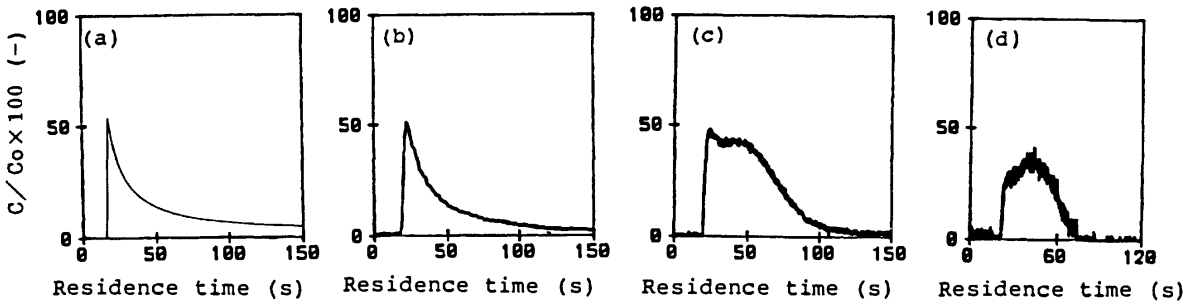

Fig. 6. Difference of peak features for different molecular diffusion coefficient samples. (a) Simulation results for nondiffusive solute, (b) submicron particle ink, (c) MB dye, and (d) potassium permanganate. Each 10 μl of the sample solutions was injected into distilled water flowing in a 1 mm i.d. and 400 mm length glass tubing as a capillary column.

result from convection by the parabolic-velocity profiles, while the other part (the second peak) is caused by the molecular diffusion of the solute injected as the plug of the sample solution.

It may be found in Fig. 7 that the second diffusion peak becomes more apparent when the flow rate is relatively slow and that the peak height becomes lower and the peak width increases with a longer traveling distance (i.e., tube length). When the column reactor becomes longer in various analytical instruments, the sample zone is dispersed along with a longer laminar-flow velocity profile in the axial direction; the large concentration distribution of the solute in the sample solution causes the lower peak-height response. It can also be found that the response-peak feature becomes nearly a Gaussian distribution for a long retention time (e.g., for a long traveling distance and/or a slow flow rate).

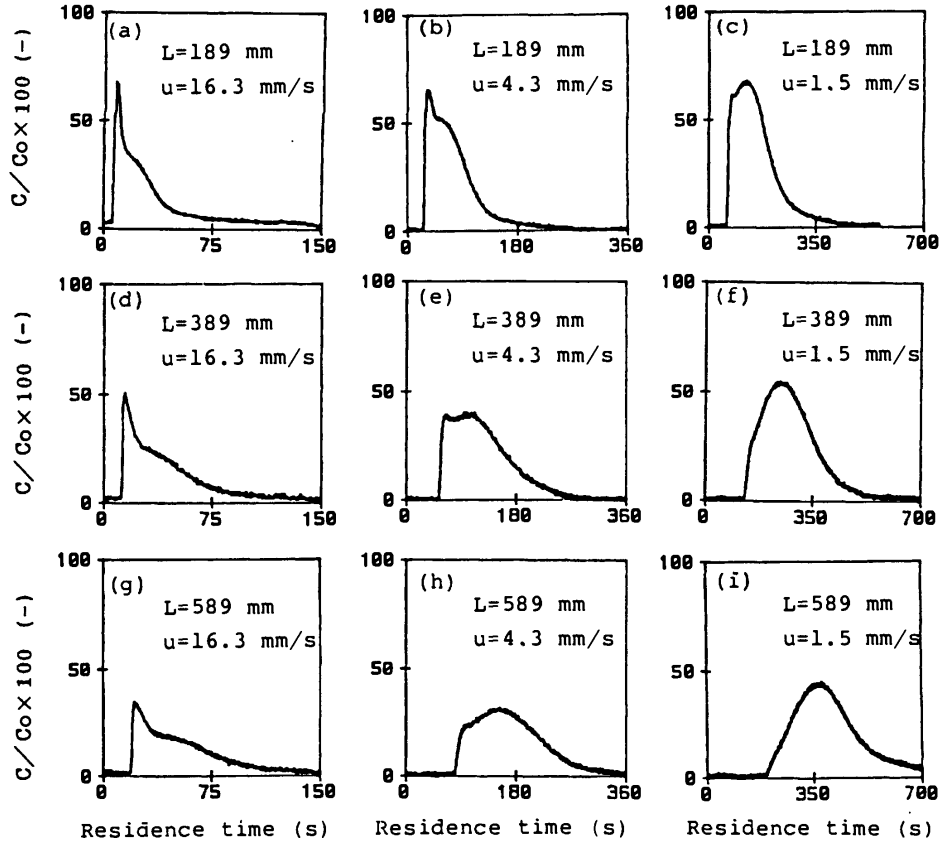

Fig. 7. Peak features obtained for MB dye sample solutions by the microphotometric detection system. Capillary column: 1 mm i.d. glass tubing. Carrier fluid: distilled water. u denotes the average velocity, c and c_0 denote the respective and original concentrations of the MB dye sample respectively.

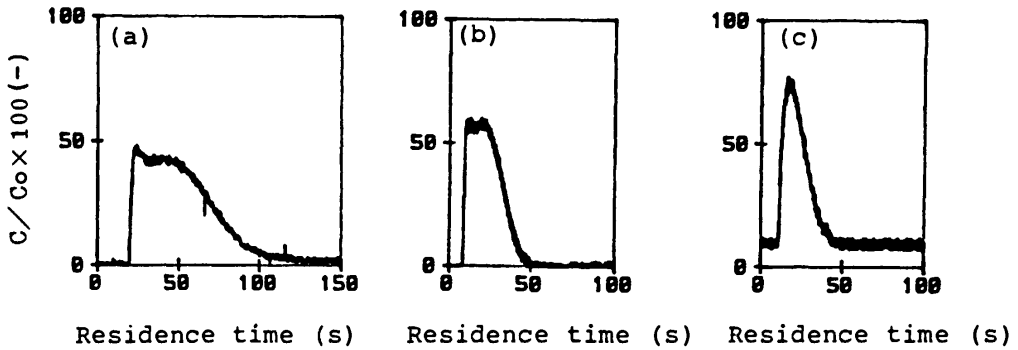

Fig. 8. Peak features obtained by changing capillary conditions. MB dye sample and a 400 mm length glass tubing were used. (a) 1 mm i.d. straight capillary column, (b) 0.6 mm i.d. straight capillary column, and (c) 0.6 mm i.d. coiled capillary column (one loop, 100 mm in loop diameter) were used.

Figs. 8(a) and (b) directly illustrate the qualitative results for the column-radius effect on the peak features. It is found that the narrower capillary tube is effective in obtaining a higher and narrower peak. When the inner diameter of the capillary column decreases, the velocity profile becomes more adrupt between the wall and the center of the capillary tube, according to Eq. 1. Thus, the sample broadening in the axial direction is strongly reduced by the molecular diffusion in the radial direction.

Peak broadening, caused by the sample dispersion in the capillary columns, may generally be far more reduced in the coiled capillary tubes than in straight tubes in consequence of the coiling effect induced by the secondary flow phenomenon,[12] for the secondary flow effectively enhances mixing and mass transfer in the radial direction. Coiled capillary tubes are, therefore, examined in this work. As is also shown in Figs. 8(b) and 8(c), on the basis of Tijssen's theoretical work on FIA[12] it has been concluded that peak broadening can be far more reduced by coiling tubes than in straight tubes in consequence of the coiling effect induced by the secondary flow phenomenon. Because the secondary flow enhances mixing and mass transfer in the radial direction, reduces the dispersion in the axial direction, its peak feature consequently becomes nearly a Gaussian distribution, as is suggested by Fig. 8(c). It is, therefore, recommended that the column of CLC also be coiled into a helical configuration in order to reduce the peak broadening and to obtain a high sensitivity and resolution.

Traveling Distance and Sample Arrival Time. As has been noted in the former section, the traveling distance of the sample-zone head (d_{head}) is smaller than that calculated because of molecular diffusion. A similar phenomenon of the shortening effect can also be seen by comparing the sample traveling time measured (t_a) with the one calculated (Fig. 9). Figure 9 shows the relationship between the measured t_a value and the tube length. Each broken line is a theoretical line based on Eq. 3. All the t_a values measured seem to be larger than the theoretical values since the sample-zone head has lost its sharpness by molecular diffusion at the front of the interfaces, as is suggested in Fig. 4(b). Hence, it requires a longer arrival time for the sample-plug-zone head to reach the detector view.

Effect of Flow Rate. The variations in the peak height as a function of the flow rate are shown in Fig. 10 for different lengths of tubes. As the peak consists of double-humped peak features, the peak-height data presented here are the heights of the higher among the first- and second-peak features. The flow rate at which the peak height reaches a minimum just corresponds to the double-humped peaks with the same two peak heights, that is, a critical flow rate (CFR). At just this point, both diffusion and convection are found significant. Below this critical point on the flow rate, the second peak is higher than the first one because of sufficient molecular diffusions; thereafter, its height decreases with the increases in the flow rate, as has been discussed before. Over the point of CFR, however, the first convection peak is higher than the secondary one, because it is mainly controlled by convection. The first peak, unlike the secondary peak, represents the concentration distribution of the component substance (i.e., the solute) in the sample-plug head. The first peak height seldom varies with the flow rate, as is shown in Fig. 10, when the flow rate becomes faster. These results, therefore, show that the CFR point can be used as a judging point for the flow rate on the dispersion behavior of the response-peak features by molecular diffusion. Below the point of CFR, the peak features are controlled predominantly by the diffusion in order to make higher the peak

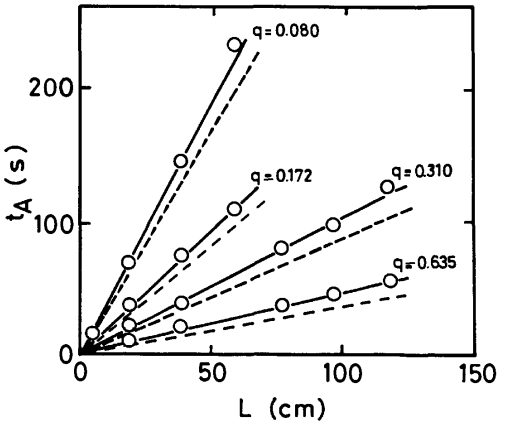

Fig. 9. Relationship between traveling time of sample zone head and the length. Each 10 µl of MB dye sample solution was injected into distilled water flowing in a 1 mm i.d. glass capillary column. q denotes the volume flow rate, and dotted lines show the calculated values against each q values.

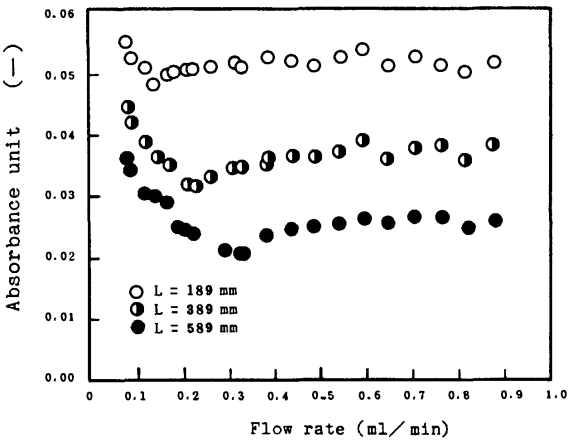

Fig. 10. Peak height value in absorbance unit vs. volume flow rate for three different tube lengths. Each 10 µl of MB dye sample solution was injected in distilled water flowing in a 1 mm glass tubing as a capillary column.

height with the Gaussian distribution and to minimize the dispersion of the flowing-sample plug, as is shown in Fig. 10, although such slower flow-rate regions have seldom been studied.

Discussion

The dispersion of the injected-sample plug in capillary-column reactors was experimentally investigated by means of direct observation, microscopic photographs, and photometric-detection methods newly developed. The baseline-to-baseline times are measured in those response peaks obtained by the microphotometric detection system. According to Eq. 4,[10] the dimensionless baseline-to-baseline time values are then compared with the dimensionless traveling-distance values (Fig. 11). It is concluded that they have a good agreement with the various experimental results obtained with the present model apparatus. This means that an ideal laminar capillary flow can be attained by the use of the model experimental apparatus described above. A great advantage of the present work is, therefore, that an ideal laminar flow can be attained by the model experimental apparatus. It is essential to use such a model apparatus for fundamental and/or experimental approaches since several theoretical analyses of this problem have been carried out on the assumption of a complete laminar capillary flow. In usual LC systems, however, disagreements between experimental and theoretical results are often found, as was pointed out first by Atwood and Golay.[9] They attributed the disturbance to the laminar flow resulting from the unions. Since the parts and components used in the LC, CGC, and CLC systems, such as a high-pressure double-reciprocating micropump, a loop-injection valve, or a detector with flow-throu h cells, cannot suppress the dead volume, abrupt changes in the internal diameter of the flowing stream, the turbulence of the flow, or the occurrence of large time constants in detectors and recorders, etc., it is not desirable to use these components for the model experiments under just a laminar flow. Before starting the work, we elaborated the apparatus in order to obtain as ideal a lamilar flow as is possible. In the present experiment, a syringe pump was used to obtain a steady and smooth pumping. In order to reduce the disturbance of the laminar flow, a stopped-flow injection technique for sample injection and a hand-made microphotometric detection system were adopted. The light source and the light accepter as the detector were mounted on the small-bore glass tube wall without any disturbance to the flowing stream. As has been described above, the results presented here show a primary success in the development of an ideally-composed model experimental apparatus for undertaking sample-dispersion-behavior analysis in capillary tubes. Although the results presented in this paper support only fundamental and qualitative conclusions, they are very important to attempts to improve, design, and optimize the FIA, CLC, and other LC families.

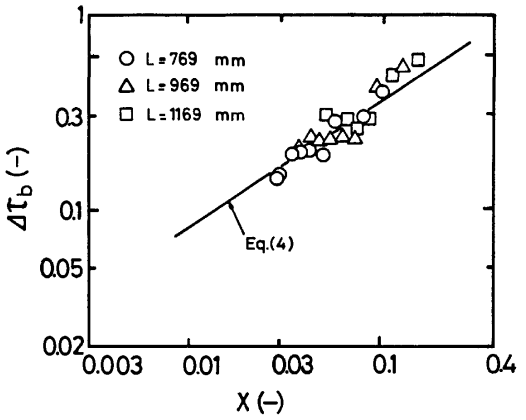

Fig. 11. Comparison of experimental results and numerical-analysis equation between dimensionless baseline-to-baseline time ($\Delta\tau_b$) and dimensionless traveling distance (X).[8]

Since the disturbance to the laminar flow by the apparatus itself has been eliminated in this work, the influences on sample dispersion by a variety of parameters, such as tube length, diameter, flow rate, and molecular-diffusion coefficient, can be clearly found, as has been discussed above. For example, Fig. 10 shows the influence of the flow rates on the peak height. For three tube lengths, below a flow rate of about 0.1 ml min^{-1}, the peak height depends closely on the flow rate, while above that flow rate the peak height tends to be constant. Therefore, if one wants to obtain a high sensitivity by adjusting the flow rate, the operation should be conducted at flow rates below 0.1 ml min^{-1}.

This research was funded in part by the Grants-in-Aid for Scientific Reasearch from the Japanese Ministry of Education, Science and Culture, and also by the Shorai Foundation for Science and Technology.

The Determination of a Small Amount of a Biological Constituent by the Use of Chemiluminescence. XV. A Zeolite Column-Chemiluminescence Detection System for the Separation and the Determination of a Protein Mixture

Tadashi HARA,* Kazuhiko TSUKAGOSHI, and Yuichiro KURITA

(Received September 27, 1988)

To make use of zeolite as the packing material for the separation of proteins by means of adsorption chromatography, the adsorption behavior of protein onto the Na-X type of zeolite (Molecular Sieve 13X) in an aqueous solution or onto a column (3 mm i.d.×50 mm) packed with the same zeolite as above was examined using a ultraviolet absorption detector and model proteins, such as human-serum albumin and human-serum γ-globulin. The following results were obtained: 1) Human-serum γ-globulin was much more adsorbed onto the zeolite than was human-serum albumin and 2) in general, more protein was adsorbed in an acidic solution than in an alkaline solution. Moreover, a chemiluminescence detector using a 1,10-phenanthroline-hydrogen peroxide-copper(II) system, which has been developed by the present authors, was modified to improve its sensitivity for the determination of protein. Both the carrier solution and the eluting solution which were used in combination with a zeolite column with a chemiluminescence detector were optimized so as to give a smooth baseline on a recorder. A microbore zeolite column (1 mm i.d.×250 mm)-chemiluminescence detection system suitable for the separation and the determination of a small amount of a protein mixture was established on the basis of these experimental results. Since human-serum albumin passed through a microbore zeolite column, while human-serum γ-globulin was retained on the column, when a model sample containing human-serum albumin and human-serum γ-globulin was injected into the column, human-serum albumin was first determined, followed by the determination of human-serum γ-globulin after its desorption. Both human-serum albumin and human-serum γ-globulin in the concentration range of 2×10^{-5}—5×10^{-3} g dm^{-3} could be determined economically and conveniently, with a detection limit of about 1 ng (injected sample volume: 50 mm^3; S/N=2). The present method was, therefore, applicable to the separation and the determination of albumin and globulin in a serum sample.

It has been desired to develop a new method for the determination of a trace amount of a protein, such as a tumor marker in serum. The present authors have already reported a flow-injection analysis (FIA) method for the determination of a small amount of a protein, in which method a chemiluminescence (CL) detector using the CL reaction of a 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol)-hydrogen peroxide (H_2O_2)-copper(II) (Cu(II)) system or a 1,10-phenanthroline (phen)-H_2O_2-Cu(II) system is used.[1,2] The determination of a protein was based on the measurement of the decreasing catalytic activity of Cu(II) for the CL reaction in the presence of the protein. These methods were about 10^2—10^6 times as sensitive as the conventional methods,[3-7] such as colorimetry and fluorometry.

Immunoaffinity chromatography and metal-chelate-affinity chromatography, in which conventional affinity columns were combined with the CL detector for the separation of protein, have also previously been established by the present authors for the analysis of a model sample containing albumin and globulin.[8,9] These affinity columns were confirmed to have some excellent characteristics for the separation of proteins, but they were, in general, expensive, difficult to operate, and time-consuming, and they required a complicated operation for their pretreatment and regeneration. Furthermore, some serious problems, such as an abnormally large blank value and a lowering of the sensitivity for the detection of protein, appeared since protein was eluted from the column with an acidic solution, and so the resulting acidic eluate was subjected to the measurement of the CL intensity in an alkaline solution.

In addition to the packing materials used in the above affinity columns, there are several commercially available ones. However, these packing materials are ordinarily difficult to handle and expensive because most of them necessitate a specific regand or functional group. On the other hand, some metal-oxide beads, such as silica and alumina, have been used as the packing material for the separation column of a protein[10,11] because of their ease of handling and their inexpensiveness. Since zeolite is a crystalline aluminosilicate and is stable enough in an alkaline solution, unlike silica, it seems a possible packing material which is inexpensive, easy to handle, and durable enough for use in an alkaline solution. And zeolite shows a cation-exchange phenomenon and has a specific and definite diameter of its cavity. Moreover, zeolite has often been utilized as a packing material for gas chromatography, but only rarely for liquid chromatography,[12] and its adsorption behavior against protein has not yet been examined. The present authors were, therefore, interested in the application of zeolite to protein-separation.

On the basis of the results obtained in the preliminary experiment, the present paper with deal with zeolite as a packing material for the separation of proteins by adsorption chromatography. First, the adsorption behavior of protein onto the Na-X type of zeolite will be examined using a ultraviolet absorption (UV) detector. Moreover, a CL detector using a phen-H_2O_2-Cu(II) system will be modified to improve the sensitivity for the determination of protein. Then, both the carrier solution and the eluting solution used in the combination of a zeolite column with a CL detector will be optimised. A microbore zeolite column-CL detection system suitable for the separation and the determination of a small amount of a protein mixture will be established on the basis of these experimental results.

Experimental

All of the reagents used were of a commercially available special grade. Deionized water was distilled for use. A sodium dihydrogenphosphate (NaH_2PO_4)-disodium hydrogenphosphate (Na_2HPO_4) buffer solution (pH 5.8—8.3) and a sodium hydroxide (NaOH)-sodium chloride (NaCl) buffer solution (pH 12.0—13.0) were mainly used. HSA (Chemical Dynamics Co.) and HγG (SIGMA), which comprise most of the serum protein and the determination of which is regarded as significant in a clinical laboratory, were used as the model proteins. Control serum (Q-PAK-Chemistry Control Serum I, Human) from Hyland Diagnostics was also used. A Molecular Sieve 13X (Nishio Kogyo, Ltd.) (chemical formula; $Na_{86}[(AlO_2)_{86}(SiO_2)_{106}]\cdot 276H_2O$; particle size 100—120 mesh; and cavity diameter 10 Å) was used as the Na-X type of zeolite. Cation-exchanged zeolites, such as Mg-, Ca-, and Zn-X types of zeolites, were prepared from the Molecular Sieve 13X in accordance with the procedure described in the literature.[13-15]

The zeolite was packed in an ordinary (3 mm i.d. ×50 mm) or a microbore column (1 mm i.d. ×250 mm) which has been manufactured by the present authors using a Teflon tube (2 mm o.d. ×1 mm i.d.) and a Teflon line-filter (Nishio Kogyo, Ltd.) (Fig. 1).

The adsorption behavior of protein onto the zeolite in an aqueous solution was examined by means of the depletion method (indirect-determination method)[16,17] (Scheme 1) using a UV detector (measured at 280 nm). The adsorption behavior of protein onto a zeolite column (3 mm i.d. ×50 mm) was also examined by means of the determination of the protein in an eluate by means of a UV detector (measured at 280 nm) connected to a column.

A schematic flow diagram of a zeolite column-CL detection system is shown in Fig. 2. A CL detector using a phen-H_2O_2-Cu(II) system was used, in which the concentrations of phen, H_2O_2, and Cu(II) in the individual solutions were the same as in a previous paper.[2] A carrier solution (d) and an eluting solution (e) were fed is at the flow rate of 1.0 ml min^{-1} by means of a pump (Pharmacia Fine Chemicals, High-precision Pump, P-500) (j). A 50-mm^3 portion of the sample solution was injected into the carrier solution line through a sampling loop (m) and a six-way cock (l), and then passed through a zeolite column (o).

Globulin was adsorbed selectively onto the zeolite column, but albumin was not adsorbed. Then the eluting solution was fed into the column by operating a four-way cock (k) to elute the globulin. The protein in the eluate was detected by the CL detector.

The CL intensity of the solution containing no protein was recorded as a baseline on a recorder, while the CL intensity of the solution containing protein was recorded as a negative peak because the catalytic activity of Cu(II) decreased due to the formation of a complex compound between Cu(II) and the protein. The amount of protein was

estimated from the peak area.

Results and Discussion

Preliminary Experiment. To make use of zeolite as a packing material for each mode of chromatography, such as chromatofocusing, metal-chelate-affinity, molecular exclusion, and adsorption chromatographies, preliminary experiments were carried out.

The pH buffering action, which is indispensable for a material used as packing in chromatofocusing,[18,19] was examined by titrating a sodium hydroxide solution containing a definite amount of zeolite with a standard hydrochloric acid solution. The following Na-X-type zeolites were used: A) Commercially available zeolite (untreated zeolite); B) zeolite treated with an alkaline solution (1.32×10^{-1} mol dm^{-3} NaOH-5.00×10^{-2} mol dm^{-3} NaCl; pH 13.0); C) zeolite treated with a neutral solution (3.90×10^{-2} mol dm^{-3} NaH_2PO_4-6.10×10^{-2} mol dm^{-3} Na_2HPO_4; pH 7.0); D) zeolite treated with an acidic solution (7.35×10^{-2} mol dm^{-3} NaH_2PO_4-2.65×10^{-2} mol dm^{-3} Na_2HPO_4; pH 6.4), and E) a proton-type zeolite prepared from the Na-X type of zeolite.[20] As can be seen from Fig. 3, zeolite B, with less proton, showed a buffer capacity in an acidic region, whereas zeolite A≃C, D, and E showed a buffer capacity in an alkaline region, in that order.

In the mode of metal-chelate-affinity chromatography, different affinities of proteins against cation-exchanged zeolite are utilized for the separation of proteins. The amounts of cation on each Mg-, Ca-, and Zn-X-type zeolite, as estimated by chelatometric titration, were 1.0, 1.3, and 1.2 mequiv g^{-1} respectively. Each cation on the cation-exchanged zeolite was held in the cavity of the zeolite crystal; no cation was found in a solution, even after standing for 3 h in a phosphate buffer solution (pH 7.0). Then, the amount of protein adsorbed onto the cation-exchanged zeolite was determined by means of a depletion method after 3 hours' shaking with the phosphate buffer solution (pH 7.0) (Table 1). As is shown in Table 1, the amounts of HSA adsorbed onto the four types of zeolites were almost definite, whereas the amount of HγG adsorbed onto the Zn-X type zeolite was about 6% larger than the amounts of HγG adsorbed onto the other types of zeolites.

Since zeolite, having a definite diameter of its cavity, is quite different from the packing material, which has a pore-size distribution for molecular exclusion chromatography, the molecular-sieve effect on peptide and protein of a column packed with the Na-X type of zeolite was examined. The retention times obtained in

Table 1. Amount of Protein Adsorbed onto Each Cation-Exchanged Zeolite

Zeolite	Relative peak area	
	HSA	HγG
None	1.00	1.00
Molecular sieve 13X (Na-X type)	0.95	0.14
Mg-X type	0.96	0.17
Ca-X type	0.96	0.16
Zn-X type	0.95	0.10

a) Conditions: Zeolite, 1.5 g; soln volume, 3.0 ml; protein concn, 1.0×10^{-1} g dm^{-3}; shaking time, 3 h, and pH 7.0 (Na_2HPO_4-NaH_2PO_2).

Table 2. Retention Times for Polypeptides and Proteins

Sample	Retention time/s
Glycylglycine	321
Glycylglycylglycine	276
Glycylglycylglycylglycine	252
HSA	245
HγG	244

Conditions: Column, 3 mm i.d.×50 mm; polypeptide concn, 1.0×10^{-3} mol dm^{-3}; protein concn, 1.0×10^{-1} g dm^{-3}; injection volume, 50 mm^3; flow rate, 0.1 ml min^{-1}, and measurement wavelength, 220 nm.

the zeolite column for several kinds of polypeptides, HSA, and HγG are shown (Table 2). Here, a phosphate buffer solution containing 1.0 mol dm^{-3} of NaCl was used as the carrier solution because several kinds of polypeptides, HSA, and HγG were not adsorbed onto the zeolite column in a 1.0 mol dm^{-3} NaCl solution. No difference was observed between the retention times of HSA and HγG, but some differences were observed between the retention times of protein and polypeptides or among the retention times of polypeptides. These differences seemed to be based on the molecular-sieve effect, since the retention time decreased with an increase in the molecular weight of the polypeptides and proteins.

To investigate if zeolite could be used as a packing material for adsorption chromatography, much like silica beads,[10] the effect of the pH on the amount of protein adsorbed onto the Na-X type of zeolite in an aqueous solution was examined by means of a depletion method. The experiment was carried out in a solution of pH 5.8—8.3, in which the crystal structure of zeolite was stable and the protein was not denatured. The following results were obtained: 1) much more HγG was adsorbed onto the zeolite than HSA, and 2) more protein was adsorbed in an acidic solution than in an alkaline solution.

On the basis of the results thus obtained, a column packed with the Na-X type of zeolite was used in the present paper for the separation of proteins by means

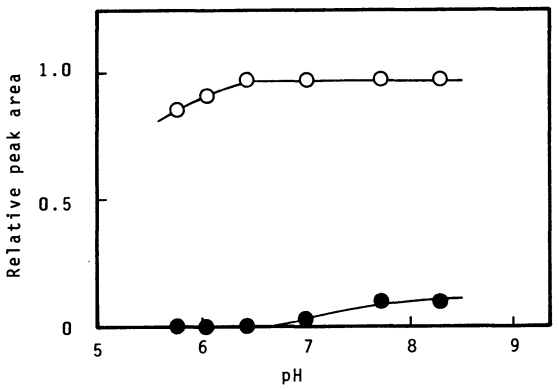

Fig. 4. Adsorption of protein onto column packed with zeolite. ○: HSA and ●: HγG. Conditions: Column size 3 mm i.d.×50 mm, protein concn 1.0×10^{-1} g dm^{-3}, injection volume 50 mm^3, and flow rate 0.1 ml min^{-1}.

of adsorption chromatography. The application of a zeolite column to the other chromatography will be described later.

Adsorption Behavior of Protein onto Zeolite. The adsorption behavior of protein onto the Na-X type of zeolite was further examined.

The adsorption equilibrium of protein on the zeolite in an aqueous solution was attained in about 1 h; thereafter, the amount of adsorbed protein did not change, even an standing for 5 h. In the present study, the amount of protein adsorbed at equilibrium was determined after 3 hours' standing.

It was found that the adsorption behavior of protein onto the zeolite in an aqueous solution was shown by Langmuir's adsorption isotherm.[16,17] The amount of HSA or HγG adsorbed onto the zeolite was constant above protein concentrations of about 4 g dm^{-3} or 6 g dm^{-3} respectively.

The effect of the pH on the amount of protein adsorbed onto the zeolite column was also shown (Fig. 4). Here, a series of experiments were carried out at an individual, definite pH value as follows: A 50-mm^3 protein solution was placed in the column, and then the corresponding buffer solution was fed, followed by the measurement of the protein eluted from the column by means of a UV detector connected to the column. The relative peak area in Fig. 4 was referred to as the ratio of the peak area of the protein passing through the column to the peak area of the protein obtained without passing through the column. The results obtained using the zeolite column showed a trend similar to that obtained in a preliminary experiment using the zeolite in an aqueous solution.

The adsorption of protein onto a silica bead is known to be attributable to the negative charge due to a hydroxyl group on its surface in an aqueous solution. Since the adsorption of protein onto the zeolite was thought to be similar, Results 1) and 2)

described in the preliminary experiment were explained as follows: 1) was explained by considering that globulin, having a much more positive charge than albumin, showed a larger affinity than albumin against the negative charge due to a hydroxyl group on the zeolite surface, while 2) was explained by considering that protein, as an amphoteric electrolyte, had a much more positive charge in an acidic solution than in an alkaline solution.

As is shown in Fig. 4, HγG was completely adsorbed onto the zeolite column from the phosphate buffer solution (pH 6.4), while HSA was not adsorbed from the same buffer solution. The effect of the coexisting substance on the adsorption of HγG onto the zeolite column was examined by the use of the phosphate buffer solution (about pH 6.4) containing: 1) NaCl as a moderator of the ionic strength, 2) urea as a denaturing agent, 3) glycine as a competitive inhibitor, and 4) ethylene glycol or 1,4-dioxane as a representative of a polar-to-nonpolar solvent (Table 3). The amount of HγG adsorbed onto the zeolite column tended to decrease with the use of all these solutions except the glycine solution. Neither HSA nor HγG was adsorbed onto the column at all by the use of a phosphate buffer solution (pH 6.4) containing 1.0 mol dm^{-3} of NaCl.

On the basis of these results, albumin and globulin in a control serum were separated and determined using a zeolite column-UV detection system. A control serum sample diluted 100 times (50 mm^3) was placed in the zeolite column, after which a phosphate buffer solution (pH 6.4) was fed in. Here, globulin was adsorbed onto the column, while albumin passed through the column. The globulin on the column was eluted by a phosphate buffer solution (pH 6.4) containing 1.0 mol dm^{-3} of NaCl. As can be seen from Fig. 5, the practical peak for globulin is given by II′, which corresponds to the difference between the true peak II for globulin and the negative peak II″ for the interference fringe appearing in the mixing area of two kinds of solutions. The recovery of 50 mm^3 of the 1.0×10^{-1} g dm^{-3} HγG solution was 80% by the present method.

Table 3. Effects of the Coexisting Substance on Adsorption of Protein onto Zeolite Column

Solution	Relative peak area	
	HSA	HγG
Phosphate buffer soln (pH 6.4)	0.97	0.00
Phosphate buffer soln (pH 8.3)	0.97	0.10
Phosphate buffer soln -1.0 mol dm^{-3} sodium chloride (pH 6.4)	0.96	0.97
Phosphate buffer soln -1.0 mol dm^{-3} Urea (pH 6.4)	0.97	0.07
Phosphate buffer soln -1.0 mol dm^{-3} glycine (pH 6.4)	0.96	0.00
Phosphate buffer soln (pH 6.4) -ethylene glycol (9:1)	0.97	0.15
Phosphate buffer soln (pH 6.4) -1,4-dioxane (9:1)	0.97	0.10

Conditions: Column, 3 mm i.d.×50 mm; protein concn, 1.0×10^{-1} g dm^{-3}; injection volume, 50 mm^3, and flow rate, 0.1 ml min^{-1}.

Improvement of the Sensitivity of a CL Detector and Optimization of a Carrier Solution and an Eluting Solution. In the previous papers,[1,2] the reaction between Cu(II) and protein in the CL detector was done at pH 10.2 using a borate buffer solution. On the other hand, the biuret reaction for the determination of protein based on the formation of a complex compound between Cu(II) and protein is generally carried out in a solution above pH 12. This suggests that the effect of the pH on the reaction between Cu(II) and protein should be reinvestigated in order to improve the sensitivity of a CL detector.

Then, the pH (pH ①) of the solution being passed through a reaction tube (r in Fig. 2), the pH (pH ②) of the solution being passed through a flow cell (t in Fig. 2), the CL intensity of a base-line (CL_{BL}), and the percentage of the decrease in the rate of CL intensity (CL_{DR}) ($|$(the lowering of the CL intensity in the presence of protein)/(CL_{BL})$|\times100$) were measured using various pH values of phen, the Cu(II) catalyst, and the carrier solutions. Based on the results obtained, the relationship between pH ① and CL_{DR}, as well as that between pH ② and CL_{BL}, were established (cf. Figs. 6 and 7). From Figs. 6 and 7, the optimum values may be supposed to be about pH 13 for pH ① and about pH 10.5 for pH ②.

In order to separate and determine a small amount

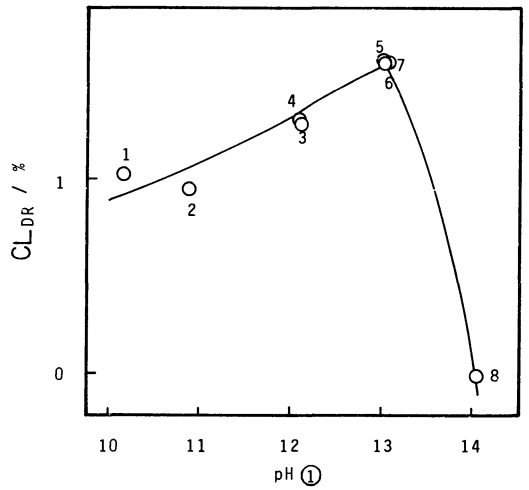

Fig. 6. Relationship between pH ① and CL_{DR}.

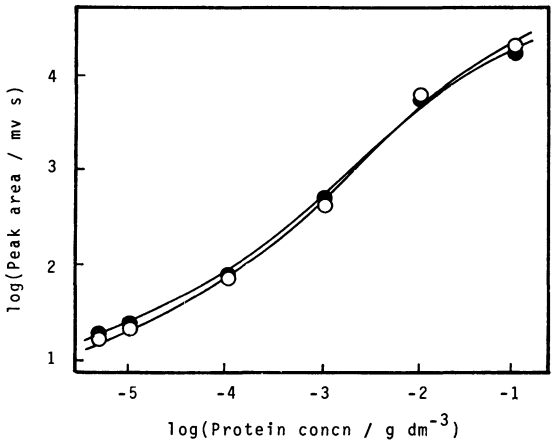

Fig. 8. Calibration curves of proteins using a FIA method. O: HSA and ●: HγG.

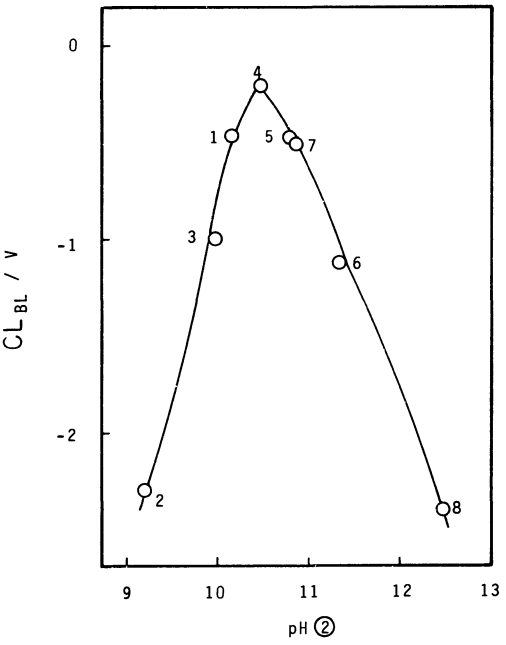

Fig. 7. Relationship between pH ② and CL_{BL}.

of a protein mixture using a zeolite column-CL detection system, the following conditions are required: 1) pH ① and pH ② were satisfied with the optimum pH values, as above, and 2) the change in CL_{BL} with the change in from a carrier solution to an eluting solution was negligible. The buffer capacities of the Cu(II) catalyst, carrier, and eluting solutions, which significantly influenced the pH ①, pH ②, and the change in CL_{BL}, were changed, and then the change in CL_{BL} was measured. Here, the phosphate buffer solutions (pH 6.4—6.5) were used as carrier solutions because these buffer solutions gave the most favorable results for the separation of HSA and HγG on the zeolite column. The NaOH-NaCl buffer solutions (pH 12.0—13.0) were also used as eluting solutions, because all the proteins adsorbed onto the zeolite column were expected to be eluted. As a result, the conditions using a Cu(II) catalyst solution (3.96×10^{-1} mol dm^{-3} NaOH-1.50×10^{-1} mol dm^{-3} NaCl; pH 13.2), a carrier solution (7.35×10^{-3} mol dm^{-3} NaH_2PO_4-2.65×10^{-3} mol dm^{-3} Na_2HPO_4; pH 6.5), and an eluting solution (1.32×10^{-2} mol dm^{-3} NaOH-5.00×10^{-3} mol dm^{-3} NaCl; pH 12.0) were recommended for the following experiments, because the change in CL_{BL} with the change from a carrier solution to an eluting solution was negligibly small and because the pH ① and pH ② were near to the optimum values of about 13 and about 10.5 under these conditions.

The calibration curves for HSA and HγG under the above conditions were obtained by means of an FIA method without using a zeolite column (Fig. 8). Both proteins could be determined in the concentration range of 5×10^{-6}—1×10^{-1} g dm^{-3}, with the detection limit of 250 pg (injected sample volume 50 mm^3, S/N=2). The present FIA method was about 4 times as sensitive as the previous method,[2] in which up to 250 pg of protein could be detected only by the use of the amplifying effect of an amino acid. Though several FIA methods for the determination of protein have recently been reported,[21-24] the present FIA method is much superior to these FIA mehods in termes of the detection limit and the concentration range.

Development of a Zeolite Column-CL Detection System. A zeolite column-CL detection system was investigated in an attempt to develop a method for the separation and determination of a small amount of a protein mixture. To minimize the dilution of a sample solution in a columm, a microbore column was used in the present study. An ordinary zeolite column (3 mm i.d.×50 mm) or a microbore zeolite column (1 mm i.d.×250 mm), both packed with the Na-X type of zeolite, was combined with the CL

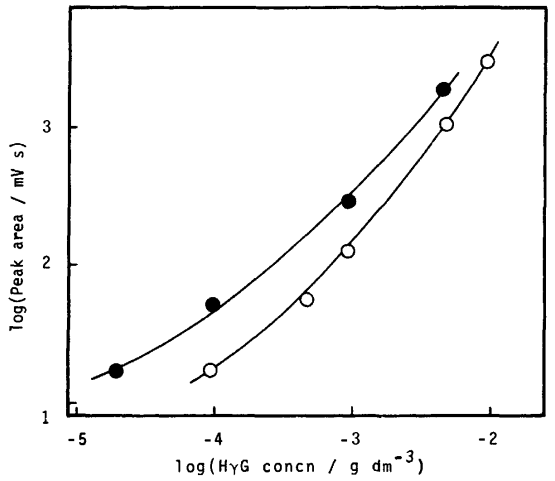

Fig. 9. Comparison of HγG calibration curves obtained on a microbore and an ordinary columns. ○: Ordinary column (3 mm i.d.×50 mm) and ●: microbore column (1 mm i.d.×250 mm).

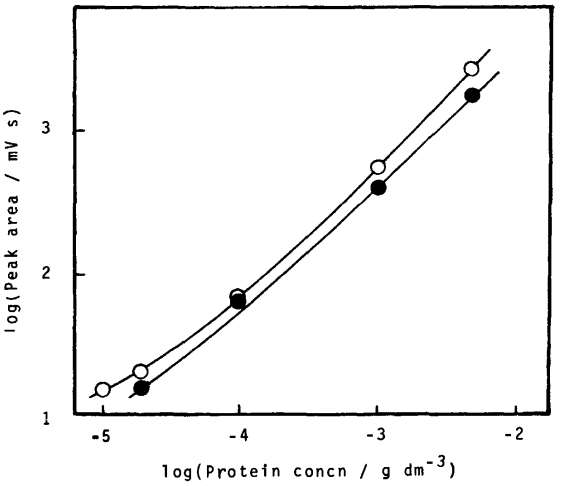

Fig. 10. Calibration curves of proteins using a microbore zeolite column-CL detection system. ○: HSA and ●: HγG.

detector; they were then used under the conditions specified above. 50-mm^3 HγG sample solutions in various concentrations were injected and adsorbed on the column, followed by elution and the measurement of the HγG. The calibration curves of HγG eluted from an ordinary zeolite column and a microbore zeolite column are shown in Fig. 9. As can be seen from Fig. 9, HγG could be determined by the use of a microbore column less well than by the use of an ordinary column.

It was first confirmed that 5.0×10^{-3} g dm^{-3} HSA was not adsorbed onto the microbore zeolite column, while the same concentration of HγG was completely adsorbed by the carrier solution. The model sample containing HSA and HγG was separated on the microbore zeolite column, and then the HSA passing through the column was first determined, followed by the determination of the HγG after its desorption. According to the present method using the microbore zeolite column, both HSA and HγG in the concentration range of 2×10^{-5}—5×10^{-3} g dm^{-3} could be determined with a detection limit of about 1 ng (injected sample volume, 50 mm^3; S/N=2) (Fig. 10). Here, the recovery of 1.0×10^{-3} g dm^{-3} of HγG was 84%, the coefficients of the variation of HSA and HγG were 5.4% and 8.3% (1.0×10^{-3} g dm^{-3} protein; n=5), and the time necessary for an analysis was about 16 min, including adsorption, elution, and regeneration. The present method may, therefore, be characterized as follows: 1) High sensitivity and a wide dynamic range for the determination of protein; 2) a consecutive operation for the separation and the determination of protein by means of high-performance liquid chromatography, and 3) the advantage of a zeolite column, that is, its inexpensiveness, ease of operation, and convenience for pretreatment and regeneration.

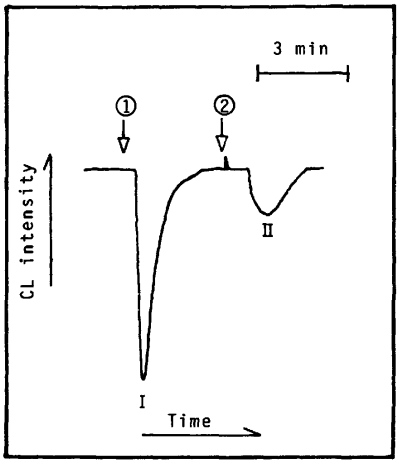

Fig. 11. Chromatogram of control serum using a microbore zeolite column-CL detection system. ①: Sample was injected, ②: eluent was fed, I: peak for albumin, and II: peak for globulin.

The immunoaffinity chromatography and metal-chelate-affinity chromatography using the CL detector previously developed by the present authors could determine up to 15 ng of HSA or 5 ng of bovine serum γ-globulin.[8,9] However, the present method could determine up to 1 ng of HγG. The high sensitivity of the present method may be supposed to be due to: 1) Improvement in the sensitivity in the CL detector, 2) utilization of a microbore column, and 3) the combination of the zeolite column with the CL detector using an alkaline-eluting method. The separation and the determination of several kinds of proteins using a pH-gradient method or a step-by-step eluting method are now in progress.

Finally, the present method was applied to a control serum sample. A control serum sample was diluted 10^4 times, and then an aliquot (50 mm^3) of it was analyzed

by the present method (Fig. 11). As is shown in Fig. 11, there were two peaks, I and II; Peak I corresponded to albumin, and Peak II, to globulin.

The authors wish to thank Mr. Masakatsu Imaki (Horiba, Ltd.) for providing the apparatus necessary for the present study.

The present study was supported by a Grant-in-Aid for General Scientific Research from the Ministry of Education, Science and Culture.

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. XVI. Mechanism of Sulfur Inversion in Platinum(II)-Thioether Complexes Revisited[1)]

Shinji TOYOTA, Yasuhisa YAMADA, Masami KANEYOSHI, and Michinori ŌKI*,†

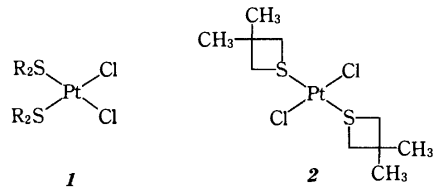
(Received October 24, 1988)

The mechanism of sulfur inversion in some platinum(II)-thioether complexes was reinvestigated with the use of the dynamic NMR technique. Activation parameters for the sulfur inversion in [(isopropylthio)acetato-*O*,*S*]bis(triphenylphosphine)platinum(II) perchlorate in $CDCl_3$ were obtained by taking advantage of the line shape changes in its ^1H NMR spectra at various temperatures as follows: ΔH^* 18.0±0.4 kcal mol^{-1}, ΔS^* 4.0±1.4 cal mol^{-1} K^{-1}. The kinetic parameters varied little, though the rates of inversion were determined in other solvents. The entropy of activation and the solvent effects together with the presence of coupling between the phosphine-^{31}P and the methine-^1H throughout the temperature range of investigation evidence the sulfur inversion without breaking the Pt–S bond. The sulfur inversion in dichlorobis(dialkyl sulfide)platinum(II) in nonpolar solvents was also concluded to take place without bond breakage.

While it is well known that the sulfur inversion in organic sulfonium ions is slow to make it possible to isolate enantiomers at room temperature,[2)] if they are properly substituted, that in coordination compounds is much faster to make it amenable to dynamic NMR study and consequently isolation of isomers due to the sulfur inversion impossible at room temperature. The typical examples among the coordination compounds are *cis*-dichlorobis(dialkyl sulfide)platinum(II) (**1**) and *trans*-dichlorobis(3,3-dimethylthietane)platinum(II) (**2**).



1 *2*

Dynamic NMR spectral study on the inversion of the thioether ligands in compound **1** was carried out and it was concluded that the inversion did not involve the scission of the Pt–S bond by observing the coupling between ^{195}Pt and ^1H nuclei even at temperatures where coalescence of diastereotopic proton signals took place.[3,4)] However, close examination of the published figure discloses that the peaks attributed to the coupling are rather broad. In addition, it might be possible to argue that, since the compounds in question possess a pair of dialkyl sulfide ligands, one of the sulfur-ligands may be bonded to the platinum during the process of sulfur-detachment, thus the coupling being observed always.

We have shown in our previous works that, if the process involves bond-breakage in compounds of which ground state is ionic, the entropy of activation must be large positive, whereas it is large negative, if the compound in question is of covalence in its ground state.[5)] Using this generalization, we have shown that sulfur compounds are no exceptions. The entropy of activation for sulfur inversion in a thioether-borane and another complex was shown to be large negative, because the mechanism involves bond-dissociation,[1)] suggesting that the thioether complex possesses ionic nature at its ground state. By contrast, sulfonium salts, in which bond-dissociation was not likely, showed nearly zero entropy of activation by both classical[6)] and dynamic NMR method.[7)]

Actually, the dynamic NMR study of compounds **1** and **2** has been carried out. However, the method used for compound **1** was the line-width method which is known to tend to give erroneous entropy of activation.[8)] The total line shape analysis was carried out for compound **2**.[9)] However, due to the simplicity of the line shapes of the diastereotopic gem-dimethyl group,[10)] the reliability of the entropy of activation can be questioned.

Based on these experiences, we felt it would be appropriate to apply the total line shape analysis with the use of probes which would give complex signals[10)] for diagnosis of the mechanism of sulfur inversion in platinum-thioether complexes. This paper is to report the results of such investigation.

Results and Discussion

Platinum(II) Complexes with One Thioether Ligand. Clearly, a compound which has only one thioether ligand is desirable to avoid the complexity. A recent publication described the preparation of compound **3**, of which thioether ligand showed the dynamics in its NMR spectra, though the free energies of activation only have been reported.[11)]

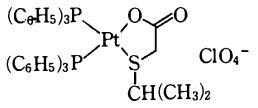
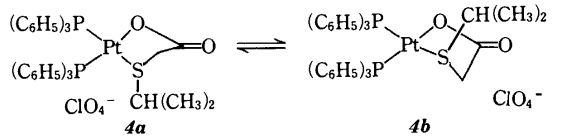
3



4

We decided to use this type of compounds for our investigation and prepared compound **4** by treating *cis*-dichlorobis(triphenylphosphine)platinum(II) with potassium (isopropylthio)acetate followed by silver perchlorate. We have selected this compound because the isopropyl probe for the exchange of their magnetic sites on inversion should not show coupling with platinum to make it much easier to carry out the line shape simulation and the isopropyl-methyls give complex enough signals to assure the reliability of the data thus obtained.

Although similarly prepared chloro[(isopropylthio)-acetato-*O,S*](triphenylphosphine)platinum(II) did show the change in the line shapes on heating at above 100 °C, decomposition set in at the same time. Compound **4** by contrast showed the desired line shape change without decomposition, thanks to the trans influence.[12] The process may be written as in the following scheme.



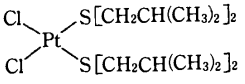
4a 4b

Kinetic parameters obtained by simulation of the line shapes are shown in Table 1. The feature of the kinetic parameters is the near zero entropy of activation. From our experience in the past, the results support the idea that the sulfur inversion in the platinum complex takes place without bond dissociation, namely the simple inversion of sulfur. Further support for the mechanisms proposed is obtained from the following observations.

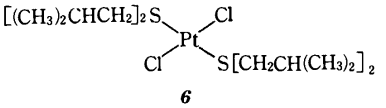
One is the coupling between the isopropyl-methine proton and one of the phosphorus atoms in the ligands. This coupling was observed at room temperature and was persistent at 90 °C where the coalescence of the signals due to the isopropyl-methyl group took place.

The other piece of evidence is the solvent effects. The activation parameters obtained with **4** in various solvents are listed in Table 1. The data clearly show that the activation parameters are not dependent on the solvent used and entropy of activation is always close to zero. If the mechanism of the sulfur-inversion involved the S-Pt bond scission, the inversion would have been fast in the solvents of which affinity toward platinum was high.

Platinum(II) Complexes with Two Thioether Ligands. Coming back to the problem of the platinum complexes that contain two molecules of sulfur ligands, we were interested in knowing whether these compounds as well demonstrate the near zero entropy of activation for sulfur inversion. We selected *cis*- and *trans*-dichlorobis(diisobutyl sulfide)platinum(II) (**5** and **6** respectively) for our investigation. These compounds were prepared by the known method from potassium tetrachloroplatinate(II) and diisobutyl sulfide. Their cis- and trans-isomers were assigned by the behavior in chromatography as well as the coupling constants between the platinum and the α-proton of the isobutyl group: the cis compound gives a larger coupling constant than the trans.[13]



5



6

The kinetic parameters obtained by total line shape analysis of these compounds are shown in Table 2, in which rate constants rather than free energies of activation are shown to demonstrate small differences in the rates. The results clearly show that the inversion of the thioether ligands in the trans isomer is more facile than in the cis, again due to the trans influence. The entropy of activation is not very far from zero.

The results can be interpreted on the basis of sulfur inversion without bond dissociation and that the complexity in the sulfur-inversion due to the presence of two thioether ligands can be ruled out. The existence of coupling between ^{195}Pt and ^{1}H at the α-position of the thioether ligand at temperatures higher than the coalescence point of the isopropyl-methyl

Table 1. Kinetic Parameters for Sulfur Inversion in Compound **4** in Various Solvents[a]

Solvent	$\Delta H^{\ddagger}$/kcal mol^{-1}	$\Delta S^{\ddagger}$/kcal mol^{-1} K^{-1}	$\Delta G^{\ddagger}_{298}$/kcal mol^{-1}

proton signals was confirmed.

Factors Affecting Sulfur-Inversion. Interesting is the fact that the solvent effect on the rates of sulfur-inversion in **5** is significant. The rates of inversion is larger in more polar solvents than in the less polar. We postulate that in these compounds solvent-assisted inversion of sulfur is involved to some extent. The difference between **4** and **5** may be attributed to the trans influence: if the Pt-S bond is weakened, the solvent assistance becomes more important.

The results provide a hint in considering the cause of the fast or slow inversion of sulfur. It was suggested in the literature[4] that the stabilization of the transition state for inversion due to the pπ-dπ interaction would be the cause for more facile inversion in the platinum complexes than in the sulfonium ions. It may be argued that the sulfur inversion in the platinum complexes is easier than in organic sulfonium compounds because the pyramidality[14] of the sulfur which is connected to the platinum and two alkyl ligands is smaller in the ground state than the sulfonium ions because of the pπ-dπ interaction. However, if it were the case, the thioethers that are bonded by a short bond should invert more rapidly than that connected by a long bond. Thus we agree with the old postulate as the explanation of the easier sulfur inversion in the platinum complexes.

The relatively slow inversion of the thioether ligand in compound **4**, despite the fact that the strong trans effect of the phosphine ligand[4] should reduce the barrier, deserves mention here. We believe this is due to the ring puckering of the ligand. The facts that the chemical shift difference between the two protons of the α-methylene group in the acetate ligand is as large as ca. 1 ppm and that only one of these protons shows couplings with ^{195}Pt and ^{31}P support that the five-membered ring made by the ligand and the platinum is fairly puckered. Probably the planar transition state for inversion in this compound is accordingly of high energy.

Experimental

***cis*-[(Isopropylthio)acetato-*O,S*]bis(triphenylphosphine)-platinum(II) Perchlorate (4).** (Isopropylthio)acetic acid[16] (34 mg or 0.25 mmol) was added to 19 mg (0.34 mmol) of potassium hydroxide in 20 mL of ethanol. To this solution was added 0.20 g (0.25 mmol) of *cis*-dichlorobis(triphenylphosphine)platinum(II)[17] in 10 mL of dichloromethane and the whole was stirred for 2.5 h at room temperature. The precipitate was removed by filtration and 60 mg (0.29 mmol) of silver perchlorate was added to the filtrate. The resulting silver chloride was immediately removed by filtration and the filtrate was stirred for 20 h. The solvent was evaporated and the residue was extracted with dichloromethane and the extract was washed with water. After evaporation of the solvent, the residue was recrystallized from ethanol to afford 0.12 g (49%) of the desired compound which contained 1/2 molecule of ethanol, mp 155—160 °C (decomp). Found: C, 51.72; H, 4.34%. Calcd for $C_{41}H_{39}ClO_6P_2PtS\cdot0.5C_2H_6O$: C, 51.45; H, 4.41%. ^{1}H NMR ($CDCl_3$, −20 °C) δ=0.98 (3H, d, J=6.8 Hz), 1.55 (3H, d, J=6.8 Hz), 2.74(1H, double septet, J=6.8 and 1.6 Hz), 3.36 (1H, dd, J=17.1 and 3.2 Hz), 4.26 (1H, d, J=17.1 Hz), 7.3—7.7 (30H, m).

***cis*- and *trans*-Dichlorobis(diisobutyl sulfide)platinum(II) (5 and 6).** To a solution of 0.88 g (2.1 mmol) of potassium tetrachloroplatinate(II) in 40 mL of water was added 0.31 g (2.1 mmol) of diisobutyl sulfide[18] in 6 ml of ethanol. The mixture was stirred for ca. 90 h at room temperature and an oily product was separated by decantation. The product was submitted to chromatography on silica gel with a 1:1 hexane-dichloromethane eluent. The trans form was eluted first and then came the cis form. The separated products were recrystallized from ethanol.

Cis-form, yellowish green crystals, mp 130 °C, was obtained in 21% yield. Found: C, 34.13; H, 6.57; Cl, 12.82; S, 11.79%. Calcd for $C_{16}H_{36}Cl_2PtS_2$: C, 34.41; H, 6.50; Cl, 12.69; S, 11.48%. ^{1}H NMR ($CDCl_3$, −20 °C) δ=1.00 (3H, d, J=6.6 Hz), 1.05 (3H, d, J=6.6 Hz), 2.20 (1H, app septet J=ca. 6.5 Hz), 2.43 (1H, dd, J=11.9 and 8.5 Hz), 3.19 (1H, dd, J=11.9 and 5.7 Hz).

Trans-form, yellow crystals, mp 106 °C, was obtained in 16% yield. Found: C, 34.12; H, 6.55; Cl, 12.85; S, 11.46%. Calcd for $C_{16}H_{36}Cl_2PtS_2$: C, 34.41; H, 6.50; Cl, 12.69; S, 11.48%. ^{1}H NMR (toluene-d_8, −18 °C) δ=0.94 (6H, d, J=6.4 Hz), 1.82 (1H, br s), 2.27 (1H, app septet, J=ca. 6.3 Hz), 3.08 (1H, br s).

Dynamic NMR Spectroscopy. The spectra were obtained with a JEOL GX270 spectrometer. The temperature was calibrated with a thermocouple. The sample was dissolved in appropriate solvents to make up a ca. 50 mmol L^{-1} solution. The simulation of the line shapes was performed with the use of DNMR3 program[19] by assuming the site exchange process of $A_3B_3X\rightleftarrows B_3A_3X$ which was approximated as $ABX\rightleftarrows BAX$.

Table 4. Rate Constants of Sulfur Inversion in Compounds **4**, **5**, and **6** in Various Solvents

Compound	Solvent	k/s^{-1} (temperature/°C)
4	$CDCl_3$	7.4 (33.9), 10.5 (37.9), 16.0 (41.9), 34.0 (49.9), 54 (55.4), 82 (60.4)

a) Toluene-d_8.

The coupling constants and the chemical shift differences at various temperatures were estimated by the tendency observed from the several points in the slow exchange limit. The coupling constants were constant throughout the temperature range to let us assume they were the same at temperatures where the line shapes changed. The chemical shift differences drifted when the temperature was changed and were correlated linearly with temperature. The relationships are given in Table 3. These lines were extrapolated to the temperature where the line shape change was observed. T_2 was estimated from the line width due to the protons which were not involved in the exchange and varied from 0.08 to 0.17 s for compound **4** and 0.14—0.24 s for compounds **5** and **6** according to the conditions of the measurement. The T_2 was adjusted, when necessary, to make the fit of the calculated line shapes better than the fixed value. The rate constants of site exchange thus obtained are compiled in Table 4.

The Co K-edge XANES (X-ray Absorption Near-Edge Structure) of $[Co(edta)]^-$ ($edta^{4-}$=ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetate) complex in crystal varies with the kind of counter cations and it also varies with the kind of solvents when it is dissolved. The amplitude of the oscillation in its EXAFS (Extended X-ray Absorption Fine Structure), or the peak height in its Fourier transform, also varies as much as threefold depending on the kind of counter cations or solvents. The most plausible cause for the variations is the difference in the thermal disorder of the bonds which is enhanced by the formation of hydrogen bonding between carboxylato groups in the complex and the water molecules in crystal or the solvent molecules in solution.

The structures of metal–edta complexes are not necessarily the same. They are known to take various coordination structures.[1] The structures can also vary with the environments, i.e. in crystals[2] or in solutions.[3,4] The EXAFS and XANES techniques appear to be suitable for the structural studies of such complexes since these spectroscopic techniques extract the information regarding the local structure around the central metal irrespective of the environments. The complex treated in this work is $[Co(edta)]^-$ which is considered to be so stable that no structural change in its inner sphere would occur against the variation of the environments. In spite of the expected rigidity of the complex, it was found that its EXAFS and XANES spectra are highly sensitive to the environments. This paper reports the X-ray absorption spectra of the complex in various environments and the possible effects of hydrogen bonding on the Debye–Waller factors or the EXAFS oscillation amplitudes.

Experimental

Samples. Li[Co(III)(edta)]·$3H_2O$ and Na[Co(III)(edta)]·$4H_2O$ were prepared according to the literatures.[5,6] Rb[Co(III)(edta)]·$2H_2O$ was synthesized in the following way; Rb_2CO_3 was added to a warm slurry solution containing RbCl, $(CH_3COO)_2Co·4H_2O$, and H_4edta until the pH of the solution became 4. The $[Co(II)(edta)]^{2-}$ ion was oxidized by adding 3% H_2O_2 aqueous solution. After filtration, this solution was concentrated and cooled, and ethanol was added to crystallize Rb[Co(edta)]·$2H_2O$. NH_4[Co(III)(edta)]·$2H_2O$ was synthesized using a similar method from $Co(NO_3)_2·6H_2O$, H_4edta, and NH_4OH. All the solid samples were recrystallized twice or more from water and ethanol. Elemental analysis: Found for Li[Co(edta)]·$3H_2O$: C, 29.32; H, 4.55; N, 6.85%. Na[Co(edta)]·$4H_2O$: C, 26.56; H, 4.26; N, 6.19%. Rb[Co(edta)]·$2H_2O$: C, 24.21; H, 3.49; N, 5.65%. NH_4[Co(edta)]·$2H_2O$: C, 29.63; H, 5.06; N, 10.41%.

Aqueous solutions of 0.1 mol·dm^{-3} $[Co(edta)]^-$ were prepared from the above Na salt. HNO_3 or NaOH were used to adjust their pH to 3.0, 5.0, 7.0, and 9.0. The solutions of pH 7.0 and 9.0 turned to be pH 6.9 and 8.1, respectively, after the X-ray absorption measurements. DMF (*N*,*N*-dimethylformamide) solution was prepared from K[Co(edta)]·$2H_2O$ which was synthesized by the conventional method.[6] Excess of 18-crown-6 ether was added to raise the solubility of the complex. KBr disks of solid samples were prepared for the measurements of infrared absorption spectra.

Measurements and Calculations. Co K-edge X-ray absorption spectra were obtained at BL-7C of the Photon Factory in the National Laboratory for High Energy Physics using a Si(111) double crystal monochromator. Powder samples of ca. 0.5 mm thick were held between two sheets of adhesive tape. Solution samples were placed in polyethylene pouches. Fourier transform calculations of EXAFS were performed by using the phase shift and scattering amplitude parameters tabulated by Teo and Lee.[7] Transformations were performed over the k range of 2.9—16.75 Å^{-1}. In order to reduce ripple peaks in Fourier transforms, Hamming window function was used.

Results and Discussion

Figure 1 shows XANES spectra and Fourier transforms of EXAFS for aqueous solutions. Both spectra show no dependence on pH. Their Raman scattering and UV-Visible absorption spectra were also measured and showed no dependence on pH. According to Higginson et al.,[4] the form of Co(III)–EDTA is either [Co(Hedta)(H_2O)], [Co(edta)(H_2O)]$^-$, $[Co(edta)]^-$, or $[Co(edta)(OH)]^{2-}$ depending on pH of the solution. In the pH range of 3.0 to 8.1, most of the complex has been known to form $[Co(edta)]^-$. The present results indicate that the structure of $[Co(edta)]^-$ in aqueous solutions is very stable over this pH range.

Figure 2 shows Co K-edge XANES spectra for (a) aqueous solution, (b) Na[Co(edta)]·$4H_2O$, (c) NH_4[Co(edta)]·$2H_2O$, (d) Rb[Co(edta)]·$2H_2O$, (e) Li[Co(edta)]·$3H_2O$, and (f) DMF solution. They can be classified into three groups; (A) aqueous solution and Na salt, (B) NH_4 and Rb salts, and (C) Li salt and DMF solution. The spectra for group A have the lowest threshold energies and the lowest peak heights at around 7740 eV. In contrast, group C has the highest

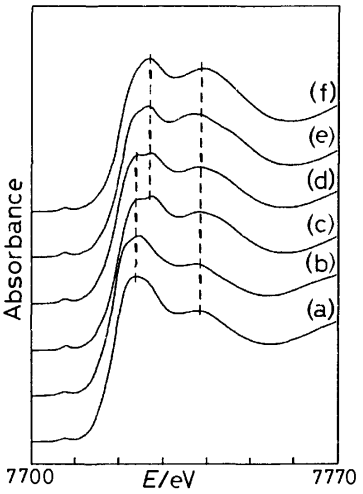

Fig. 2. Co K-edge XANES spectra for (a) aqueous solution, (b) $Na[Co(edta)]\cdot 4H_2O$, (c) $NH_4[Co(edta)]\cdot 2H_2O$, (d) $Rb[Co(edta)]\cdot 2H_2O$, (e) $Li[Co(edta)]\cdot 3H_2O$, and (f) DMF solution.

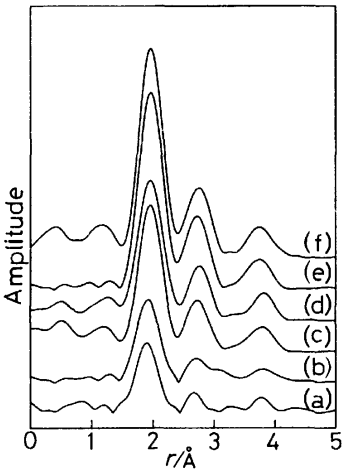

Fig. 3. Fourier transforms of Co K-edge EXAFS for (a) aqueous solution, (b) $Na[Co(edta)]\cdot 4H_2O$, (c) $NH_4[Co(edta)]\cdot 2H_2O$, (d) $Rb[Co(edta)]\cdot 2H_2O$, (e) $Li[Co(edta)]\cdot 3H_2O$, and (f) DMF solution.

threshold energies and the highest peak heights at 7740 eV. Group B is intermediate between A and C. The highest peaks, so called white line, in A or C are composed of a single peak possibly accompanying a shoulder, while those of B are composed of double peaks and the position of its higher energy component agrees with the position of the peak in C.

There are two possibilities which may contribute to the differences in the XANES spectra of three groups. One is the photoelectron scattering by the counter cations or solvent molecules. The other is the indirect effects of the cations or the solvents on the electronic and/or structural conditions of the complex anion, $[Co(edta)]^-$. There is a reason to reject the former possibility, i.e. although the N in NH_3 and Rb are quite different photoelectron scatterers in respect to the amplitude and phase shift (the distances of Co-N and Co-Rb are similar 5.68 and 5.81 Å, respectively[5]), the XANES spectra of the samples having these atoms as counter cations are almost the same. In addition to this, there seems to be no systematic correlation between the XANES spectrum and the kind of counter cation. Therefore, it is almost impossible to consider that the variety of XANES spectra is caused by the direct photoelectron scattering by the counter cation.

Fourier transforms of EXAFS for $[Co(edta)]^-$ in various environments are shown in Fig. 3. One easily finds three peaks in each of the Fourier transforms. By referring to the crystallographic data for NH_4 salt,[5] these peaks are assigned to the bond distances between Co and the scatterers as follows; the most intense peaks at around 1.9 Å correspond to four oxygens (O_1 in Fig. 4) and two nitrogens, the second peaks at around 2.7 Å to ten carbons, and the third peaks at around 3.8 Å to

Table 1. Peak Positions and Their Heights in Fourier Transforms of Co K-edge EXAFS for $[Co(edta)]^-$ Complexes

Sample	Peak position/Å			Peak height[a]		
	1st	2nd	3rd	1st	2nd	3rd
(a) Average of aqueous solution	1.92	2.69	—	0.5	0.4	—
(b) $Na[Co(edta)]\cdot 4H_2O$	1.92	2.75	3.80	0.5	0.5	0.5
(c) $NH_4[Co(edta)]\cdot 2H_2O$	1.96	2.76	3.79	1.0	1.0	1.0
(d) $Rb[Co(edta)]\cdot 2H_2O$	1.95	2.76	3.83	1.0	1.1	1.1
(e) $Li[Co(edta)]\cdot 3H_2O$	1.97	2.75	3.77	1.4	1.4	1.1
(f) DMF solution	1.97	2.78	3.75	1.5	1.3	1.2
$NH_4[Co(edta)]\cdot 2H_2O$	1.91[b]	2.73[b]	3.85[b]	—	—	—
$[Co(sarmp)(NH_3)_3][Co(edta)]\cdot H_2O$	1.92[c]	2.74[c]	3.89[c]	—	—	—

a) Relative intensity. b) and c) The average of the distances of corresponding bonds for $[Co(edta)]^-$ from crystallographic data of Refs. 5 and 9, respectively. $sarmp^{2-}$=sarcosinate-*N*-propionate.

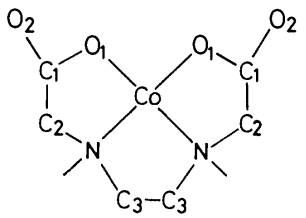

Fig. 4. Numbering on some atoms in $[Co(edta)]^-$ complex.

four oxygens (O_2) not coordinating to Co. In spite of its long distance, the third peaks due to O_2 appear with an unusual intensity, particularly for the samples of groups B and C. Binsted et al.[8] studied EXAFS of cobalt carbonyls such as $[Co(CO)_4]^-$ and found that the linear configuration of Co-C-O atoms enhances the peak corresponding to Co-O bond because of the multiple scattering effect. In the present case, it is plausible that the intensity of the third peak results from the same multiple scattering effect because the angles of $Co\text{-}C_1\text{-}O_2$ are known to be about 160° and those of $Co\text{-}O_2\text{-}C_1$ about 14° from the crystallographic data for NH_4 salt.[5]

Table 1 lists the peak positions in each Fourier transform and the mean distances of corresponding bonds taken from the crystallographic data.[5,9] The third peaks are not clear for some samples of aqueous solutions.

There are large differences in the amplitude of EXAFS oscillation. The ratio of the heights of the first peaks in Fourier transforms is roughly 1:2:3 between groups A, B, and C, respectively. Since the coordination numbers of Co in all the samples are known to be constantly six,[10] the large differences in peak heights must be resulted from the differences in the root-mean-square displacement of Debye-Waller factor. The Debye-Waller factor of a peak originates from two contributions, static bond length distribution and dynamic or thermal disorder. In order to examine the contribution of static distribution, some simulation calculations were performed. The simulated EXAFS spectra were obtained by using a constant value of Debye-Waller factor to each kind of bonds and distributed bond lengths limited within reasonable ranges. However, the spectra could not give such large differences in peak heights in Fourier transforms as shown in experimental spectra. Therefore there must be some large differences in thermal disorder among the samples of group A, B, and C.

One of the origins for the large differences in thermal disorder may be the presence of hydrogen bonding which donates electrons from carboxylato group to water molecule. A water molecule can approach to O_2 and even to O_1 to form hydrogen bonding. This effect appears in other experimental phenomena, e.g. UV absorption spectra[11] and ^{13}C NMR spectra.[12] The presence of such hydrogen bonding has also been known in the $[Co(edta)]^-$ crystals[9] and in an analogous complex, $[Co(III)(trdta)]^-$ ($trdta^{4-}$=trimethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetate) crystal.[13] $NH_4[Co(edta)]\cdot 2H_2O$ crystal must have such hydrogen bonding, since some distances between O in water molecule and O_2 or O_1 are less than 3.0 Å. More hydrogen bonding may exist in Na salt than in NH_4 salt, because the volume of an unit cell of Na salt is larger only about 10% than that of NH_4 salt and the number of waters of crystallization are twice as much. The fact that the spectrum for DMF solution sample is most intense should be due to the absence of the hydrogen bonding.

It is quite interesting to note that the weaker the peak in the Fourier transform, the shorter the bond length read from the first peak position. This may be due to the fact that the Debye-Waller factors for Co-O bonds of longer lengths increase more than the shorter ones upon the hydrogen bonding formation. (cf. the bond lengths are 1.870, 1.896, 1.913, 1.922 Å for Co-O and 1.921 and 1.925 Å for Co-N in NH_4 salt.[5])

The authors thank Drs. Tadashi Matsushita and Masaharu Nomura of the National Laboratory for High Energy Physics (KEK) for their help with X-ray absorption measurements.

Preparation and Characterization of Cobalt(III) Complexes Containing (2-Aminoethyl)dimethylarsine (edma). Resolution and Racemization of *fac*-[Co(edma)$_3$]$^{3+}$

Kazuhiro NEMOTO, Masakazu KITA, Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University,
Chikusa-ku, Nagoya 464-01
(Received December 1, 1988)

(2-Aminoethyl)dimethylarsine (edma) and its cobalt(III) complexes, *trans*(*X*,*X*),*cis*(*As*,*As*)-[CoX$_2$(edma)$_2$]$^+$ (X=Cl, Br, and I), *trans*(*As*,*As*)- and *trans*(*As*,*N*)-[Co(acac)(edma)$_2$]$^{2+}$ (acac=acetylacetonate ion), *trans*(*As*,*N*)-[Co(CO$_3$)(edma)$_2$]$^+$, [Co(acac)$_2$(edma)]$^+$, and *fac*-[Co(edma)$_3$]$^{3+}$ were prepared and characterized. From a comparison of the first d-d absorption bands of analogous diamine and (2-aminoethyl)dimethylphosphine (edmp) complexes, the spectrochemical series of Group 5B elements was found to be P>As>N. The *fac*-[Co(edma)$_3$]$^{3+}$ complex was resolved and the absolute configuration of the $(+)_{490}^{CD}$-isomer was assigned to *Λ* on the basis of the CD spectrum. Racemization of *fac*-[Co(edma)$_3$]$^{3+}$ was studied in aqueous solutions in the pH and temperature ranges of 7.88—9.32 and 35.0—50.0 °C, respectively. The racemization obeyed a rate law of the form, $R=k$[OH$^-$][complex]. The activation enthalpy and entropy values were found to be $\Delta H^*=132\pm4$ kJ mol^{-1} and $\Delta S^*=171\pm11$ J K^{-1} mol^{-1}, respectively.

In previous papers, we reported the preparation of a number of cobalt(III) complexes containing (2-aminoethyl)dimethylphosphine (edmp)[1,2] and its derivatives.[3-5] To our knowledge, however, no cobalt(III) complex with the arsine analog is known. An (aminoalkyl)arsine is an intermediate ligand between a diamine and a diarsine and its complexes will be useful in studying properties of cobalt(III)–arsine complexes, for which several studies have been reported.[6,7] This paper deals with the preparation and characterization of (2-aminoethyl)dimethylarsine (edma) and its several cobalt(III) complexes, including the resolution and absolute configuration of *fac*-[Co(edma)$_3$]$^{3+}$, and its racemization occured in aqueous solution catalyzed by OH$^-$.

Experimental

The arsine ligand was handled under an atmosphere of nitrogen until it formed air-stable cobalt(III) complexes. Tetrahydrofuran was dried with sodium and deoxygenated by distillation in a stream of nitrogen. Other solvents used for the preparation of complexes were deoxygenated by bubbling nitrogen for 20 min immediately before use. Absorption, circular dichroism, and ^{1}H NMR spectra were recorded on JASCO 610B and Hitachi U-3400 spectrophotometers, a JASCO J-40CS spectropolarimeter, and a Hitachi R-90HS spectrometer, respectively.

(2-Aminoethyl)dimethylarsine (edma). A tetrahydrofuran solution of sodium dimethylarsine was prepared by a modified method of Phillips and Vis.[8] To a mixture of tetrahydrofuran (60 cm^3) and metallic sodium (15.4 g, 0.67 mol) in a 300 cm^3 three-necked round bottom flask was added dropwise a tetrahydrofuran solution (80 cm^3) of iododimethylarsine[9] (46.4 g, 0.20 mol) over a period of 90 min with stirring at 0 °C. After a while the mixture was refluxed for 30 min and then cooled to room temperature. The resulting greenish brown solution was filtered to remove precipitated sodium iodide and unreacted sodium. To the filtrate was added aziridine[10] (10.8 g, 0.25 mol), and the solution was stirred at 35 °C for 60 h, the color of the solution becoming pale gradually. Water (40 cm^3) was added dropwise to the solution, and tetrahydrofuran was removed under reduced pressure. The residue was shaken with diethyl ether to extract edma. The extract was evaporated under reduced pressure to give oily, pale yellow edma. Yield: 15.3 g (51% based on AsI(CH$_3$)$_2$). The ligand could not be purifed by distillation because of its decomposition under usual distilling conditions, but done via the nickel(II) complex. The yellow nickel(II) complex (presumably [Ni(edma)$_2$](ClO$_4$)$_2$) was precipitated immediately by the addition of crude edma (15.3 g) to a methanol solution (100 cm^3) of Ni(ClO$_4$)$_2$·6H$_2$O (18.7 g), filtered, washed with methanol and diethyl ether, and air dried. Yield: 14.1 g. The complex is stable in air but tends to be explosive by mechanical or thermal shock. Thus the elemental analysis was not carried out. The free ligand can be obtained from the complex by treating with KCN in water and by extracting with diethyl ether. ^{1}H NMR edma (=(CH$_3$)$_2$AsCH$_2$CH$_2$NH$_2$)(CDCl$_3$, TMS): δ=0.88 (s, 6H, As(CH$_3$)$_2$), 1.53 (t, 2H, AsCH$_2$), 1.83 (s, 2H, NH$_2$), 2.76 (t, 2H, NCH$_2$). The nickel(II) complex (CD$_3$NO$_2$, TMS): δ=1.67 (s, 6H, As(CH$_3$)$_2$), 2.18 (t, 2H, AsCH$_2$), 2.97 (m, 2H, NCH$_2$), 3.56 (br, 2H, NH$_2$).

***trans*(*Cl*,*Cl*)-[CoCl$_2$(edma)$_2$]ClO$_4$.** To an ethanol solution (50 cm^3) of CoCl$_2$·6H$_2$O (5.0 g, 21.0 mmol) was added crude edma (5.0 g, 33.5 mmol) in ethanol (50 cm^3). A pale blue precipitate was observed. Into this mixture air was bubbled for 1 h, then water (1 cm^3) and concd HCl (1 cm^3) were added, and ethanol was removed under reduced pressure. To the resulting green solution was added NaClO$_4$·H$_2$O (10 g) in water (5 cm^3), and the complex was extracted with dichloromethane. The extract was evaporated to dryness, giving green needle crystals, which were filtered and recrystallized from hot methanol. Yield: 2.20 g. Found: C, 17.83; H, 4.62; N, 5.04%. Calcd for C$_8$H$_{24}$N$_2$As$_2$Cl$_3$O$_4$Co: C, 18.21; H, 4.59; N, 5.31%. ^{1}H NMR (CD$_2$Cl$_2$, TMS): δ=1.54 (s, 12H, As(CH$_3$)$_2$), 2.45 (t, 4H, AsCH$_2$), 3.24 (br, 4H, NCH$_2$), 4.80 (br, 4H, NH$_2$).

***trans*(*Br*,*Br*)-[CoBr$_2$(edma)$_2$]ClO$_4$.** A hot methanol solution (10 cm^3) of *trans*(*Cl*, *Cl*)-[CoCl$_2$(edma)$_2$]ClO$_4$ (1.46 g, 2.77 mmol) was mixed with a hot aqueous solution (10 cm^3) of Na$_2$CO$_3$ (0.32 g, 3.0 mmol), and the mixture was warmed at 60 °C for 15 min to give a red solution. Methanol was

removed under reduced pressure, and the solution was passed through a column of QAE-Sephadex (ClO_4^--form) to remove chloride ions. The eluate was concentrated to ca. 2 cm^3 under reduced pressure. On addition of concd HBr (2 cm^3) the concentrate yielded green crystals, which were filtered, washed with methanol and diethyl ether. Recrystallization was carried out from hot methanol. Yield: 1.64 g. Found: C, 15.86; H, 3.40; N, 4.71%. Calcd for $C_8H_{24}N_2As_2Br_2ClO_4Co$: C, 15.59; H, 3.92; N, 4.71%. ^1H NMR (CD_2Cl_2, TMS): δ=1.70 (s, 12H, $As(CH_3)_2$), 2.50 (t, 4H, $AsCH_2$), 3.36 (m, 4H, NCH_2), 5.05 (br, 4H, NH_2).

***trans*(*I*,*I*)-[CoI_2(edma)$_2$]ClO_4.** This complex was obtained as brown crystals by a method similar to that for the above dibromo complex using KI and 60% $HClO_4$ instead of concd HBr. Yield: 76%. Found: C, 14.03; H, 3.40; N, 4.18%. Calcd for $C_8H_{24}N_2As_2ClI_2O_4Co$: C, 13.53; H, 3.41; N, 3.94%. ^1H NMR (CD_2Cl_2, TMS): δ=1.96 (s, 12H, $As(CH_3)_2$), 2.54 (t, 4H, $AsCH_2$), 3.42 (m, 4H, NCH_2), 4.98 (br, 4H, NH_2).

***trans*(*As*,*N*)-[Co(CO_3)(edma)$_2$]$B(C_6H_5)_4$.** A red solution prepared from *trans*(*Cl*,*Cl*)-[$CoCl_2$(edma)$_2$]ClO_4 (1.46 g, 1.77 mmol) and Na_2CO_3 (0.32 g, 3.0 mmol) by the method for *trans*(*Br*, *Br*)-[$CoBr_2$(edma)$_2$]$^+$ was diluted with water (1 dm^3), and the solution was applied on a column (ϕ 3.0×50 cm) of SP-Sephadex C-25. By elution with 0.05 mol dm^{-3} Na_2SO_4 only one red band developed. The eluate was concentrated to a small volume under reduced pressure, and filtered. On addition of $NaB(C_6H_5)_4$ in water the concentrate yielded a red precipitate, which was filtered, washed with water and methanol, and air dried. The complex with other anions such as Cl^- or ClO_4^- was very soluble and could not be isolated. Found: C, 53.80; H, 6.19; N, 3.86%. Calcd for $C_{33}H_{44}N_2As_2BO_3Co$: C, 53.83; H, 6.02; N, 3.80%. ^1H NMR (DMSO-d_6, TMS): δ=1.34, 1.44, 1.55, 1.66 (s, $As(CH_3)_2$).

***trans*(*As*,*As*)- and *trans*(*As*,*N*)-[Co(acac)(edma)$_2$]$(ClO_4)_2$ (acac=acetylacetonate ion).** A mixture of *trans*(*Cl*, *Cl*)-[$CoCl_2$(edma)$_2$]ClO_4 (300 mg, 0.57 mmol) and Li(acac) (61 mg, 0.57 mmol) in a mixture of water and methanol (2:1, 20 cm^3) was warmed at 60 °C for 3 h. The resulting red solution was diluted with water (500 cm^3) and applied on a column (ϕ 2.0×150 cm) of SP-sephadex C-25. The adsorbed product was eluted with 0.1 mol dm^{-3} Na_2SO_4, giving a faster-moving violet band ([Co(acac)$_2$(edma)]$^+$) and then two red bands. The separation between the latter two bands was small. The eluate containing each red band was collected, diluted 10 times with water, applied again on a small column of SP-Sephadex C-25, and the adsorbed complex was eluted with 1 mol dm^{-3} $NaClO_4$. The eluate containing the first red band was evaporated to a small volume under reduced pressure, and the complex was extracted with dichloromethane. The extract was concentrated to a small volume under reduced pressure. Dark red crystals of *trans*(*As*, *As*)-[Co(acac)(edma)$_2$]$(ClO_4)_2$ were precipitated by slow addition of diethyl ether to the concentrate, filtered, washed with diethyl ether, and air dried. Yield: 29 mg (8%). Found: C, 23.47; H, 4.71; N, 4.12%. Calcd for $C_{13}H_{31}N_2As_2Cl_2O_{10}Co$: C, 23.84; H, 4.77; N, 4.28%. ^1H NMR (CD_3OD, TMS): δ=1.66, 1.91, 2.02 (s, $As(CH_3)_2$ and CCH_3), 5.61 (s, CH), 2.1—2.7 (m, CH_2).

The eluate containing the second red band was concentrated under reduced pressure, yielding red crystals of *trans*-(*As*,*N*)-[Co(acac)(edma)$_2$]$(ClO_4)_2$, which were filtered, washed with a small amount of cold water, and recrystallized from methanol and diethyl ether. Yield: 42 mg (11%). Found: C, 23.85; H, 4.70; N, 4.66%. Calcd for $C_{13}H_{31}N_2As_2Cl_2O_{10}Co$: C, 23.84; H, 4.77; N, 4.28%. ^1H NMR (CD_3OD, TMS): δ=1.58, 1.61, 1.70, 1.88, 1.92, 2.28 (s, $As(CH_3)_2$ and CCH_3), 5.70 (s, CH).

[Co(acac)$_2$(edma)]ClO_4. The free ligand was extracted with diethyl ether from a mixture of [Ni(edma)$_2$]$(ClO_4)_2$ (780 mg, 1.4 mmol) and KCN (560 mg, 8.4 mmol) in water (3 cm^3), and ether was removed under reduced pressure. To this were added a methanol solution (60 cm^3) of [Co(acac)$_3$] (1.0 g, 2.8 mmol) and active charcoal (ca. 0.3 g). The mixture was stirred at room temperature for 13 h, and active charcoal was filtered off. The filtrate was diluted 10 times with water and applied on a column (ϕ 3.0×20 cm) of SP-Sephadex C-25. The column was washed with water to remove unreacted [Co(acac)$_3$], and then the violet adsorbed product was eluted with 0.05 mol dm^{-3} NaCl, a trace of a pink product remaining on the column. The eluate was evaporated under reduced pressure to ca. 5 cm^3. On addition of a few drops of a saturated aqueous solution of $NaClO_4$ the concentrate yielded violet crystals, which were filtered, washed with a small amount of cold water, and recrystallized from methanol and diethyl ether. Yield: 0.91 g (67%). Found: C, 33.36; H, 2.66; N, 5.15%. Calcd for $C_{14}H_{26}NAsClO_8Co$: C, 33.25; H, 2.77; N, 5.18%. ^1H NMR (D_2O, TSP): δ=1.46, 1.71, 1.99, 2.02, 2.06, 2.33 (s, $As(CH_3)_2$ and CCH_3), 5.69, 5.77 (s, CH).

The complex was also yielded as a by-product in the preparation of [Co(acac)(edma)$_2$]$^{2+}$ from *trans*(*Cl*,*Cl*)-[$CoCl_2$-(edma)$_2$]$^+$ and Li(acac) (1:1) (vide ante).

***fac*-[Co(edma)$_3$]$Br_3\cdot 3H_2O$.** To edma, which was obtained from [Ni(edma)$_2$]$(ClO_4)_2$ (560 mg, 1 mmol) and KCN (400 mg, 6 mmol) by the above method, were added $Na_3[Co(CO_3)_3]\cdot 3H_2O$[11] (210 mg, 0.58 mmol) and water (3 cm^3), and the mixture was stirred at 40 °C for 30 min. To the resulting orange solution was added excess $NaClO_4$ (ca. 1 g) dissolved in a minimum amount of water. After 2 h a yellow precipitate ([Co(edma)$_3$]$(ClO_4)_3$) was filtered, and dissolved in water. The solution was applied on a column (ϕ 3.0×90 cm) of SP-Sephadex C-25, and the adsorbed product was eluted with 0.5 mol dm^{-3} KBr, giving a single yellow band. Yellow-brown crystals which were precipitated by concentrating the eluate under reduced pressure were filtered, washed with ethanol, and recrystallized from water. Yield: 230 mg (43%). Found: C, 18.10; H, 5.83; N, 5.20%. Calcd for $C_{12}H_{42}N_3As_3Br_3O_3Co$: C, 18.02; H, 5.29; N, 5.25%. ^1H NMR (D_2O, TSP): δ=1.87, 1.97(s, $As(CH_3)_2$).

Resolution of *fac*-[Co(edma)$_3$]$^{3+}$. Complete resolution of *fac*-[Co(edma)$_3$]$^{3+}$ was achieved by a column-chromatographic method similar to that for [Co(en)$_3$]$^{3+}$ (en=NH_2-$CH_2CH_2NH_2$).[12] An aqueous solution of *fac*-[Co(edma)$_3$]-$Br_3\cdot 3H_2O$ (ca. 100 mg) was applied on a column (ϕ 3.0×90 cm) of SP-Sephadex C-25, and the adsorbed complex was eluted with 0.1 mol dm^{-3} $Na_2[Sb_2\{(+)\text{-tartrate}\}_2]$. Two yellow bands were eluted in good separation. Each eluate was diluted 10 times with water and applied on a small column of SP-Sephadex C-25. The column was washed thoroughly with water, and the adsorbed complex was eluted with 1 mol dm^{-3} KBr. Yellow-brown crystals of optically active *fac*-[Co(edma)$_3$]$Br_3\cdot 3H_2O$ were obtained from the eluate by the same procedure as that for the racemate. The $(+)_{490}^{CD}$-*A* isomer was obtained from the faster-moving band. Found: C, 17.94; H, 4.88; N, 5.30%. Calcd for $C_{12}H_{42}N_3As_3$-Br_3O_3Co=[Co(edma)$_3$]$Br_3\cdot 3H_2O$: C, 18.02; H, 5.29; N, 5.25%.

Kinetic Measurements. Optically active *fac*-$[Co(edma)_3]^{3+}$ (ca. 1.10 mmol dm^{-3}) was racemized in sodium 5,5-diethylbarbiturate ($NaC_8H_{11}N_2O_3$)-HCl buffer solution (pH: 7.88—9.32) with ionic strength of 1.0 (LiCl) in the temperature range of 35.0—50.0 °C. Portions of the solution were withdrawn at intervals, and the decreases in CD strength were recorded in the region of 390—540 nm. In each kinetic run, the plot of ln ($\Delta\varepsilon_t$(492 nm)) vs. time gave a straight line for at least three half-lives, where $\Delta\varepsilon_t$(492 nm) denotes the CD strength at time t and at 492 nm. No change in absorption spectrum was observed during the racemization.

Attempts to examine the racemization of *fac*-$[Co(edmp)_3]^{3+}$ [1] were unsuccessful. The complex was stable to racemization in neutral or acidic solution and decomposed in basic solution to give a blue-white precipitate.

Results and Discussion

Preparation and Characterization of the Complexes. The edma ligand was prepared by a method similar to that for the phosphorus analog, (2-aminoethyl)-dimethylphosphine (edmp)[1] from sodium dimethylarsenide and aziridine in a yield of ca. 50%. 2-Chloroethylamine hydrochloride can be used instead of aziridine but the yield was a little poorer. The ligand could not be purified by vacuum distillation because it decomposed at ca. 40 °C. The purification was carried out via $[Ni(edma)_2](ClO_4)_2$ which easily liberated edma by the addition of excess KCN in water. The yellow $[Ni(edma)_2](ClO_4)_2$ complex in CD_3NO_2 shows sharp signals in the ^1H NMR spectrum and is assumed to be a diamagnetic planar complex. The complex tends to be explosive by mechanical or thermal shock, while the perchlorates of Co(III)-edma complexes prepared in this study are rather stable and burn by heating without exploding.

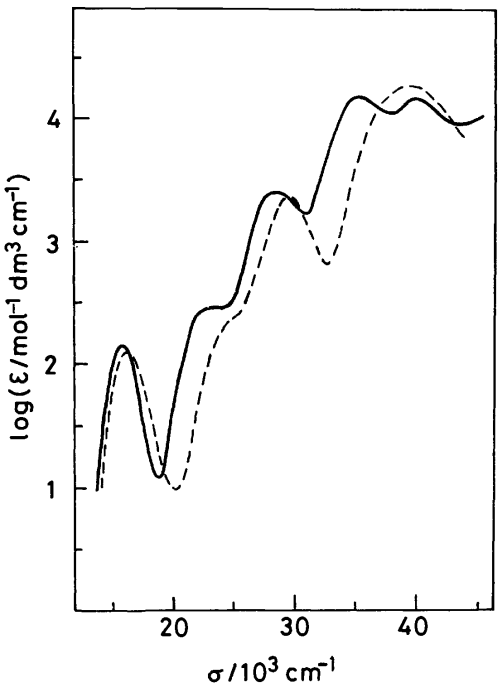

Fig. 1. Absorption spectra of *trans(Cl,Cl),cis(As,As)*-$[CoCl_2(edma)_2]^+$ (——) and *trans(Cl,Cl),cis(P,P)*-$[CoCl_2(edmp)_2]^+$ (----) in methanol.

Only one isomer of $[CoCl_2(edma)_2]^+$ was formed by oxidizing a mixture of $CoCl_2 \cdot 6H_2O$ and edma in ethanol with air, although five geometrical isomers are possible for this type of complex. The reaction of $[Co(CO_3)(edma)_2]^+$ with hydrochloric acid yielded the same isomer. The complex is green in color and shows a medium intensity band at 15800 cm^{-1} in the absorption spectrum. The band is characteristic of a *trans(Cl,Cl)* configuration, and can be assigned to the split component (Ia) of the first d-d band ($^1T_{1g} \leftarrow {}^1A_{1g}$ (O_h)) (Fig. 1). The broad band around 22500 cm^{-1} can be assigned to the other split component (Ib) overlapping with the second d-d band ($^1T_{2g} \leftarrow {}^1A_{1g}(O_h)$). This spectral pattern is very similar to that of *trans(Cl, Cl), cis(P, P)*-$[CoCl_2(edmp)_2]^+$ [3] shown in Fig. 1. Thus the complex can be assingned to the *trans(Cl, Cl), cis(As, As)* isomer, although no clear evidence for the *cis(As, As)* configuration could be obtained from the absorption and ^1H NMR spectra. Table 1 lists the data of absorption spectra.

Figure 2 shows absorption spectra of $[CoX_2(edma)_2]^+$ (X=Br, I), which were prepared from $[Co(CO_3)(edma)_2]^+$ and HX, together with the spectrum of dichloro complex. The lowest energy bands around 15000 cm^{-1} of the dibromo and diiodo complexes are similar in pattern to that of the dichloro complex, and their energies decrease in the order Cl>Br>I in accordance with the spectrochemical series. Thus these dihalogeno complexes can be assigned to the same *trans(X, X), cis(As, As)* isomer.

No *cis(X, X)* isomer was obtained by the reaction of

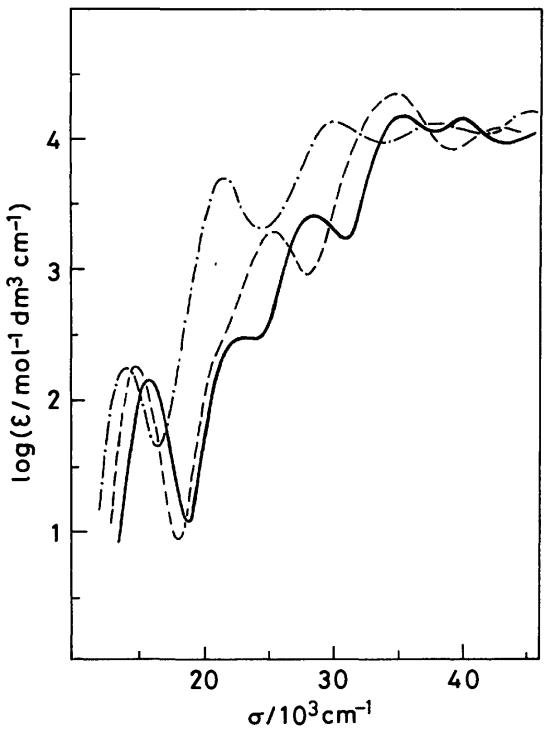

Fig. 2. Absorption spectra of *trans*(*X*,*X*),*cis*(*As*,*As*)-$[CoX_2(edma)_2]^+$ in methanol, X=Cl (——), X=Br (----), and X=I (-·-·-).

$[Co(CO_3)(edma)_2]^+$ with HX under cooling (0 °C). The *cis*(*X*,*X*) isomers of edmp and related (aminoalkyl) phosphine complexes are not known either, while *cis*(*X*,*X*)-$[CoX_2\{(CH_3)_2E(CH_2)_nE(CH_3)_2\}_2]^+$ (n=2, 3. X=Cl, Br. E=P,[13] As[6]) can be prepared from the carbonato complexes by similar procedures. A red aqueous solution of $[Co(CO_3)(edma)_2]^+$ changed to violet and then green fairly rapidly on addition of HX at 0 °C, and gave a green precipitate of the trans dihalogeno complex. The rapid color change from violet to green indicates rapid cis to trans isomerization of the dihalogeno complex.

The $[Co(CO_3)(edma)_2]^+$ complex yielded only one of three possible geometrical isomers, *trans*(*As*, *As*) (C_2 symmetry), *trans*(*As*, *N*) (C_1 symmetry) and *trans*(*N*, *N*) (C_2 symmetry), by the reaction of $[CoCl_2(edma)_2]^+$ with Na_2CO_3. The complex exhibits four kinds of methyl signal in the ^1H NMR spectrum and is clearly assigned to the *trans*(*As*, *N*) isomer from symmetry argument. For the corresponding acac complex, two isomers were obtained by a similar reaction with Li(acac). The isomers are red and dark red in color. The red isomer shows six kinds of methyl signal in the ^1H NMR spectrum and is assigned unequivocally to the *trans*(*As*, *N*) isomer. On the other hand, the dark red isomer gives three kinds of methyl signal, but the structure can not be assigned from the spectrum, since both *trans*(*As*, *As*) and *trans*(*N*, *N*) isomers have a C_2 axis. An analogous phosphine complex, [Co(acac)-$\{(C_6H_5)_2PCH_2CH_2NH_2\}_2]^{2+}$ also yields two isomers.[4]

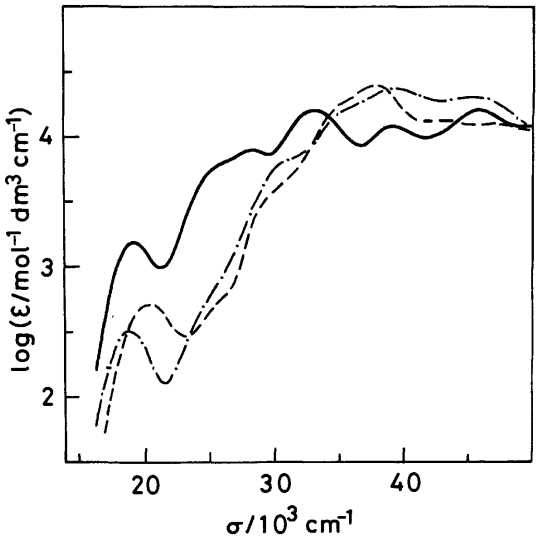

Fig. 3. Absorption spectra of $[Co(acac)_2(edma)]^+$ (-·-·-), *trans*(*As*,*As*)-$[Co(acac)(edma)_2]^{2+}$ (——), and *trans*(*As*,*N*)-$[Co(acac)(edma)_2]^{2+}$ (----) in water.

They were assigned to the *trans*(*P*, *P*) and *trans*(*P*, *N*) isomers on the basis of the coupling constant values between proton or carbon and phosphorus in ^1H and ^{13}C NMR spectra. The isomers of the phosphine complex exhibit absorption spectra quite different from each other; the *trans*(*P*, *P*) isomer shows the first d-d band of strong intensity and a remarkable red shift of charge transfer bands as compared with the corresponding bands of the *trans*(*P*, *N*) isomer. A similar spectral difference is seen between the two isomers of $[Co(acac)(edma)_2]^{2+}$ (Fig. 3). Thus the dark red isomer can be assigned to the *trans*(*As*, *As*) one.

Molecular models indicate that the steric crowding caused by the bulky dimethylarsino group in the three isomers of $[Co(acac)(edma)_2]^{2+}$ increases in the order *trans*(*As*, *As*)<*trans*(*As*, *N*)<*trans*(*N*, *N*). The reason for the *trans*(*N*, *N*) isomer being not formed will be attributable to the most crowded structure. For other two isomers, the more crowded *trans*(*As*,*N*) isomer was formed in a larger amount than the less crowded *trans*(*As*, *As*) isomer. The formation ratio of the dark red *trans*(*As*, *As*) isomer to the red *trans*(*As*, *N*) one was found to be 1:2 by column chromatography of the reaction products. The smaller abundance (less stability) of the less crowded *trans*(*As*, *As*) isomer may be attributable to the trans effect of the arsine donor group. For $[Co(acac)\{(C_6H_5)_2PCH_2CH_2NH_2\}_2]^{2+}$, the formation ratio of the *trans*(*P*, *P*) isomer to the *trans*(*P*, *N*) one is reported to be 1:4.[4] The same reason may be given for the selective formation of more crowded *trans*(*Cl*,*Cl*), *cis*(*As*,*As*)-$[CoCl_2(edma)_2]^+$ than its *trans*-(*Cl*,*Cl*), *trans*(*As*,*As*) isomer.

The violet $[Co(acac)_2(edma)]^+$ complex was obtained by the reaction of $[Co(acac)_3]$ with edma in the presence of active charcoal or as a by-product in the synthesis of $[Co(acac)(edma)_2]^{2+}$. The absorption

spectrum is compared with those of $[Co(acac)(edma)_2]^{2+}$ in Fig. 3.

The reaction of $Na_3[Co(CO_3)_3]$ with edma yielded only one isomer of $[Co(edma)_3]^{3+}$. The isomer showed two kinds of sharp methyl signal in the ^1H NMR spectrum and was assigned to the *fac*-isomer. The phosphorus analog, $[Co(edmp)_3]^{3+}$ also forms only the *fac*-isomer. The selective formation of the *fac*-isomer in these complexes may also be attributable to the trans effect of the arsine or phosphine donor group. The complex was easily resolved on an SP-Sephadex column by elution with an aqueous solution of $Na_2[Sb_2\{(+)\text{-tartrate}\}_2]$. The optically active complex is stable in acidic water but racemizes in basic water (vide infra).

Figure 4 compares the absorption spectrum of *fac*-$[Co(edma)_3]^{3+}$ with those of *fac*-$[Co(edmp)_3]^{3+}$ and

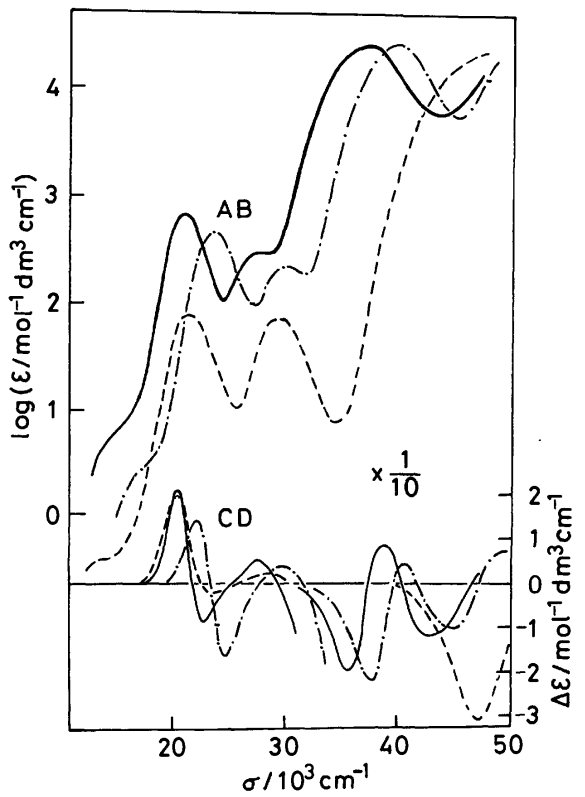

Fig. 4. Absorption and CD spectra of *Λ*-*fac*-$[Co(edma)_3]^{3+}$ (——), *Λ*-*fac*-$[Co(edmp)_3]^{3+}$ (-·-·-), and *Λ*-$[Co(en)_3]^{3+}$ (----) in water.

$[Co(en)_3]^{3+}$, and the data are listed in Table 2. The first absorption band of *fac*-$[Co(edma)_3]^{3+}$ is observed at 21300 cm^{-1}. The energy is almost the same as that of $[Co(en)_3]^{3+}$ (21400 cm^{-1})[14] and much lower than that of *fac*-$[Co(edmp)_3]^{3+}$ (23700 cm^{-1}).[1] The tris-type complex of $(CH_3)_2NCH_2CH_2NH_2$ (Me_2-en) corresponding to edma and edmp is not known. Attempts to prepare $[Co(Me_2\text{-en})_3]^{3+}$ were unsuccessful and bis-diamine complexes such as $[Co(H_2O)_2(Me_2\text{-en})_2]^{3+}$ were yielded even in the presence of a large excess of Me_2-en. However, it is known that cobalt(III) complexes containing Me_2-en exhibit the first d-d band at fairly lower energy than that of the corresponding en complex.[15] For example, the bands of $[Co(acac)_2(Me_2\text{-en})]^+$ and $[Co(acac)_2(en)]^+$ are at 17800 and 18450 cm^{-1}, respectively.[16] Thus it is concluded that the spectrochemical series for the three ligands with donors of the grounp 5B elements is edmp(P)>edma(As)>Me_2-en(N). Besides the first d-d band, *fac*-$[Co(edma)_3]^{3+}$ shows a weak, broad triplet d-d band around 14600 cm^{-1}, the second d-d band at 28000 cm^{-1} and the As to Co(III) charge-transfer band at 37700 cm^{-1}. All these bands are shifted to lower energy by ca. 2000 cm^{-1} than the corresponding bands of *fac*-$[Co(edmp)_3]^{3+}$, but both spectral patterns are very similar. The energy difference between the first and second d-d bands of *fac*-$[Co(edma)_3]^{3+}$ is 6700 cm^{-1}. The value is similar to that of *fac*-$[Co(edmp)_3]^{3+}$ (6500 cm^{-1}) but much smaller than that of $[Co(en)_3]^{3+}$(8100 cm^{-1}). Thus the interelectronic repulsion of the cobalt(III) ion is largely reduced in the edma and edmp complexes. Such large reduction has been reported for other phosphine[1] and arsine complexes[6] of cobalt(III).

Figure 4 shows the CD spectrum of $(+)^{CD}_{490}$-*fac*-$[Co(edma)_3]^{3+}$ togehter with those of *Λ*-*fac*-$[Co(edmp)_3]^{3+}$ [1] and *Λ*-$[Co(en)_3]^{3+}$.[14,17] The $(+)^{CD}_{490}$-$[Co(edma)_3]^{3+}$ isomer gives a similar CD pattern in the first d-d band region to those of other two complexes and can be assigned to the same *Λ* isomer. These isomers are all eluted faster than their antipodes on SP-Sephadex column chromatography by elution with $Na_2[Sb_2\{(+)\text{-tartrate}\}_2]$. In previous papers,[1,18] we reported that the small negative CD component in the first d-d band region of *Λ*-$[Co(en)_3]^{3+}$ is enhanced by replacing en by edmp or $(CH_3)_2PCH_2CH_2P(CH_3)_2$. The strength of the negative CD component of the edma complex is intermedi-

a) From Ref. 1. b) From Ref. 14.

ate between those of the edmp and en complexes. In the ultraviolet region, both edma and edmp complexes exhibit a negative and a positive CD band from the lower to higher energy side corresponding to each charge-transfer band between the arsine (37700 cm^{-1}), the phosphine (39900 cm^{-1}) or the amine donor group (ca. 50000 cm^{-1}) and the cobalt(III) ion. These CD patterns are also known to be characteristic of *Λ*-[Co(diamine)$_3$]-type complex.[14,19]

Racemization of *fac*-[Co(edma)$_3$]$^{3+}$. Racemization of *fac*-[Co(edma)$_3$]$^{3+}$ was studied in aqueous solutions in the pH and temperature ranges of 7.88—9.32 and 35.0—50.0 °C, respectively. Figure 5 shows a representative CD spectral change of *Λ*-[Co(edma)$_3$]$^{3+}$ in a sodium 5,5-diethylbarbiturate ($NaC_8H_{11}N_2O_3$)-HCl buffer solution (pH: 8.36) at 40 °C in a period of 4225 min. In each kinetic run the plot of $\ln(\Delta\varepsilon_t(492\ nm))$ vs. time at a constant pH gave a straight line for at least three half-lives. Thus the rate of racemization at a constant pH can be expressed as $-d[complex]/dt = k_{obsd}$ [complex], where k_{obsd} is the pseudo-first-order rate constant for racemization at a constant pH. The $k_{obsd}/[OH^-]$ ($=k$) values are constant at a given temperature, indicating that the reaction is first order in $[OH^-]$. The values of k_{obsd} and k are listed in Table 3, where the variation of ionic product of water $k_W=[H^+][OH^-]$ with a change in temperature[20] was taken into consideration. From the temperature dependence of k values, the activation enthalpy and entropy were obtained as 132±4 kJ mol^{-1} and 171±11 J K^{-1} mol^{-1}, respectively. No detectable change in absorption spectrum was observed during the racemization.

The mechanism for racemization of *fac*-[Co(edma)$_3$]$^{3+}$ is not clear at present. The fact that the racemization is catalyzed by OH^- indicates that the first step of the racemization is deprotonation of the amine hydrogen(s). For the present complex a dissociative mechanism involving the rupture of the Co-As bond will be ruled out, since the absorption spectrum of the complex remained unchanged during the racemization; if the arsine part of edma were released from the cobalt(III) ion the ligand would be oxidized by atmospheric oxygen to cause the decomposition of the complex.

The values of activation parameters for racemization

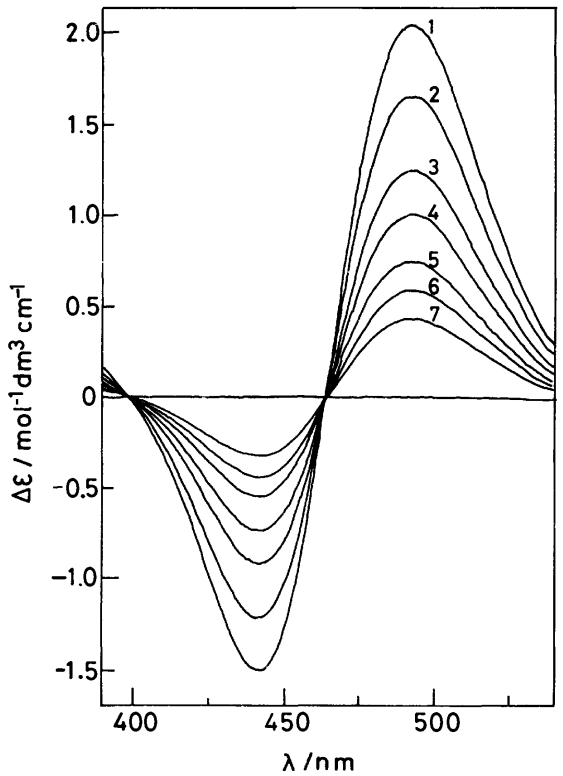

Fig. 5. Change in CD spectrum of *Λ*-*fac*-[Co(edma)$_3$]$^{3+}$ in water at pH 8.36 and 40.0 °C. Spectra 1—7 were measured after 0, 585, 1360, 1960, 2755, 3385, 4225 min, respectively.

Table 3. Racemization Rates of *fac*-[Co(edma)$_3$]$^{3+}$

of *fac*-$[Co(edma)_3]^{3+}$ are similar to those ($\Delta H^{\ddagger}=132\pm6$ kJ mol^{-1}, $\Delta S^{\ddagger}=204\pm18$ J K^{-1} mol^{-1}) reported for racemization of $[Co(stn)]^{3+}$ (stn=$CH_3C(CH_2NHCH_2CH_2CH_2NH_2)_3$), which is also catalyzed by OH^-.[21] For this racemization, a twist intramolecular mechanism via a trigonal twist about the threefold axis of the deprotonated intermediate was proposed. A similar twist mechanism may be assumed for the racemization of *fac*-$[Co(edma)_3]^{3+}$, although it is unknown whether the rupture of the Co-N bond is involved or not.

The *fac*-$[Co(edmp)_3]^{3+}$ complex was stable to racemization in acidic water, but decomposed in basic water to give a blue-white precipitate which was supposed to be cobalt(III) species. The decomposition rate observed by a decrease in intensity of the first d-d band was nearly the same as the diminishing rate of the CD strength. The decomposition of the complex is supposed to take place in preference to the racemization. On the other hand, it is known that $[Co(en)_3]^{3+}$ in water does not racemize and does in the presence of excess en[22] or active charcoal.[23] Such different properties in racemization of three typical complexes, $[Co(en)_3]^{3+}$, *fac*-$[Co(edmp)_3]^{3+}$, and *fac*-$[Co(edma)_3]^{3+}$ will provide useful information in elucidating bonding character between cobalt(III) and 5B group donor atoms.

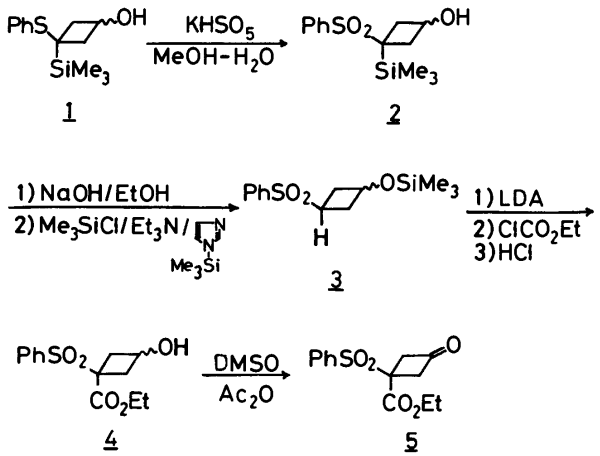
A New Method for the Preparation of α-Methylene-γ-butyrolactones Using 3-Ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone

Tooru FUJIWARA, Koichi MORITA, and Takeshi TAKEDA*
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received July 6, 1988)

The reaction of 3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone with Grignard reagent or aryllithium gave 1-(alkyl or aryl)-3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanol which was treated with potassium hydride, reduced with $LiBH_4$ in the presence of $ZnCl_2$, and treated with *p*-TsOH or aluminum triisopropoxide successively to give α-methylene-γ-butyrolactone in good yield.

In recent years, much attention has been paid on the synthesis of the compounds possessing α-methylene-γ-butyrolactone moiety because of their wide range of biological activity and various methods have been developed for the construction of such a structural unit.[1]

Previously, we showed that β-methylene ketones were obtained by the base-promoted ring-opening reaction of 1,3-dialkyl-3-(phenylsulfonyl)cyclobutanols.[2] Based on the results of above study, we investigated a new synthetic route to α-methylene-γ-butyrolactone (**9**) using 3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone (**5**) as a starting material as shown in the following scheme. The cyclobutanone (**5**) was synthesized from 3-(phenylthio)-3-(trimethylsilyl)cyclobutanol (**1**) which was easily prepared by the reaction of epichlorhydrin with α,α-bis(trimethylsilyl)phenylthiomethyllithium.[3] The cyclobutane (**1**) was oxidized with potassium peroxymonosulfate (oxone) to give the corresponding sulfone (**2**). Hydrolysis of the trimethylsilyl group and trimethylsilylation of the hydroxy group gave **3**. The trimethylsilyl ether (**3**) was treated with lithium diisopropylamide and ethyl chloroformate successively to give the hydroxy ester (**4**) which was then oxidized with dimethyl sulfoxide-acetic anhydride[4] to afford the cyclobutanone (**5**).



Scheme 1.

3-Ethoxycarbonyl-1-phenyl-3-(phenylsulfonyl)cyclobutanol (**6c**) was obtained in good yield by the reaction of the cyclobutanone (**5**) with phenylmagnesium bromide in THF at 0 °C. Then **6c** was treated with 4 equimolar amounts of KH in THF in the presence of HMPA to give γ-oxo-α-methylene ester (**7c**) along with a trace amount of the isomeric α,β-unsaturated ester. The selective reduction of **7c** was performed with $LiBH_4$ in ether at 0 °C in the presence of a catalytic amount of $ZnCl_2$ and a mixture of γ-hydroxy-α-methylene ester (**8c**) and α-methylene-γ-phenyl-γ-butyrolactone (**9c**) was obtained. The treatment of the mixture with *p*-TsOH in toluene at room temperature gave **9c** in good yield.

In a similar manner, several α-methylene-γ-butyrolactones (**9**) were synthesized using Grignard and aryllithium reagents and the results were summarized in Table 1. Since the treatment of **8d** and **8e** with *p*-TsOH gave complex mixtures, the lactonization of these compounds was carried out with an equimolar amount of aluminum triisopropoxide in refluxing THF.

The most coventional methods for the preparation of γ-substituted α-methylene-γ-butyrolactone (**9**) consist of the reaction of aldehyde with various carbanions which have an ester function or its equivalent. It is noted that the γ-substituent of **9** is introduced using carbanion species, which is the distinctive feature of the present method.

Experimental

Preparation of 3-(Phenylsulfonyl)-3-(trimethylsilyl)cyclobutanol (2). To a MeOH (4 ml) solution of 3-(phenylthio)-3-(trimethylsilyl)cyclobutanol (**1**)[3] (252 mg, 1 mmol) was added an aqueous solution (4 ml) of 49.5% $KHSO_5$ (922 mg, 3 mmol) under cooling with ice. After stirring for 1.5 h at room temperature, the reaction mixture was diluted with water. The organic material was extracted with CH_2Cl_2. The extract was dried over Na_2SO_4 and condensed under reduced pressure. The residue was chromatographed on silica gel (AcOEt–hexane) and 3-(phenylsulfonyl)-3-(trimethylsilyl)cyclobutanol (**2**) (265 mg) was isolated in 93% yield.

2: mp 113—115 °C (hexane–benzene); IR (KBr) 3500, 2990, 2940, 1453, 1300, 1256, 1141, 1120, 1090, 850, and 748 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.02 and 0.19 (2s, 9H), 1.98—3.11 (m, 5H), 3.34—4.25 (m, 1H), and 7.21—8.02 (m, 5H). Found: C, 54.99; H, 7.14; S, 11.24%. Calcd for $C_{13}H_{20}O_3SSi$: C, 54.89; H, 7.09; S, 11.27%.

Preparation of 1-(Phenylsulfonyl)-3-(trimethylsiloxy)cyclobutane (3). To a EtOH (200 ml) solution of the cyclobutanol (**2**) (14.22 g, 50 mmol) was added pellet NaOH (1.0 g, 25 mmol). After stirring for 1 h at room temperature, the reaction mixture was diluted with water and neutralized with 1 M hydrochloric acid (1 M=1 mol dm^{-3}). The organic material was extracted with AcOEt and the extract was dried over Na_2SO_4. The extract was condensed under reduced pressure to give crude 3-(phenylsulfonyl)cyclobutanol. A THF (80 ml) solution of the crude cyclobutanol was slowly added to a mixture of triethylamine (7.7 ml, 55 mmol), chlorotrimethylsilane (7.0 ml, 55 mmol), and *N*-(trimethylsilyl)imidazole (0.29 ml, 2 mmol) in THF (50 ml) under cooling with ice. The reaction mixture was stirred overnight at room temperature. The reaction was quenched by addition of saturated aqueous solution of $NaHCO_3$ and the organic material was extracted with AcOEt. The extract was dried (Na_2SO_4) and condensed in vacuo. The residue was purified by column chromatography on silica gel (AcOEt–hexane) to give 1-(phenylsulfonyl)-3-(trimethylsiloxy)cyclobutane (**3**) (12.84 g) in 90% yield.

3: oil; IR (neat) 3080, 2970, 1453, 1312, 1256, 1155, 1132, 1094, 993, 907, 850, 736, and 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.08 (s, 9H), 2.00—4.81 (m, 6H), and 7.33—7.98 (m, 5H). Found: C, 54.72; H, 7.10; S, 11.23%. Calcd for $C_{13}H_{20}O_3SSi$: C, 54.89; H, 7.09; S, 11.27%.

Preparation of 3-Ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanol (4). To a THF (45 ml) solution of lithium diisopropylamide prepared from diisopropylamine (4.912 g, 48.5 mmol) and butyllithium (46.3 mmol) was slowly added a THF (60 ml) solution of the (trimethylsiloxy)cyclobutane (**3**) (12.55 g, 44.1 mmol) under cooling with ice. After stirring for 40 min, the reaction mixture was cooled to −78 °C. A THF solution (20 ml) of ethyl chloroformate (4.6 ml, 48.6 mmol) was added to the reaction mixture and stirred for 2 h at the same temperature. Then 2 M hydrochloric acid (50 ml) was added under cooling with ice and the mixture was stirred for 15 min. The organic material was extracted with AcOEt and the extract was dried over Na_2SO_4. After evaporation of the solvent, the residue was chromatographed on silica gel (AcOEt–hexane) to give 3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanol (**4**) (10.96 g) in 87% yield.

4: viscous oil; IR (neat) 3510, 3060, 2960, 1727, 1450, 1308, 1290, 1151, 1085, 860, 730, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.11 (t, J=7 Hz, 3H), 2.33—3.40 (m, 4H), 3.40—3.82 (m, 1H), 4.03 (q, J=7 Hz, 2H), 4.25 —4.85 (m, 1H), and 7.30—8.07 (m, 5H). MS (FAB) m/z 285 (M^++H).

Preparation of 3-Ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone (5). To a dimethyl sulfoxide (31 ml) solution of the cyclobutanol (**4**) (2.92 g, 10.3 mmol) was added acetic anhydride (20.5 ml) and the mixture was stirred for 17 h at room temperature. Then it was diluted with a phosphate buffer solution (pH 7) under cooling with ice to form brownish precipitate. The precipitate was collected and dried in vacuo. The crude material was recrystallized from hexane–benzene to give pure 3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone (**5**) (1.91 g) in 68% yield.

5: mp 134—135 °C (hexane–benzene); IR (KBr) 3080, 2990, 2950, 1801, 1730, 1452, 1380, 1314, 1288, 1152, 1089, 765, 734, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (t, J=7 Hz, 3H), 3.10—4.25 (m, 4H), 4.16 (q, J=7 Hz, 2H), and 7.27—8.00 (m, 5H). Found: C, 55.34; H, 4.98; S, 11.35%. Calcd for $C_{13}H_{14}O_5S$: C, 55.31; H, 5.00; S, 11.35%.

Reaction of 3-Ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone (5) with Phenylmagnesium Bromide. To a THF (0.5 ml) solution of phenylmagnesium bromide (0.55 mmol) was slowly added a THF (2 ml) solution of 3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanone (**5**) (141 mg, 0.5 mmol) under cooling with ice. After stirring for 10 min at the same temperature, the reaction was quenched by addition of saturated aqueous solution of NH_4Cl and the organic material was extracted with AcOEt. The extract was dried over Na_2SO_4 and condensed under reduced pressure. The residual crude crystal was purified by recrystallization from hexane–benzene and 3-ethoxycarbonyl-1-phenyl-3-(phenylsulfonyl)cyclobutanol (**6c**) (146 mg) was obtained in 81% yield.

6c: mp 141—142 °C (hexane–benzene); IR (KBr) 3480, 3050, 3020, 2980, 1714, 1445, 1368, 1301, 1140, 1086, 1021, 916, 870, 853, 702, and 669 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 and 1.10 (2t, J=7 and 6 Hz, 3H), 2.56—3.60 (m, 5H), 3.91 and 4.06 (2q, J=7 and 6 Hz, 2H), and 6.93—7.90 (m, 10H). Found: C, 63.31; H, 5.55; S, 8.88%. Calcd for $C_{19}H_{20}O_5S$: C, 63.31; H, 5.59; S, 8.90%.

By a similar manner, the cyclobutanol (**6a**) was obtained. The cyclobutanols (**6b**, **6d**, and **6e**) were prepared by the reaction of **5** with butyllithium, 5-methyl-2-furyllithium,

and 2-thienyllithium in the presence of an equimolar amount of $MgBr_2$, respectively. These compounds were isolated by TLC (AcOEt-hexane).

All the cyclobutanols (**6**) were obtained as a mixture of diastereomers and the ratio of isomers of these compounds was not determined.

3-Ethoxycarbonyl-1-methyl-3-(phenylsulfonyl)cyclobutanol (6a): viscous oil; IR (neat) 3500, 3060, 2970, 1724, 1447, 1308, 1290, 1174, 1140, 1085, 955, 725, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (t, J=7 Hz, 3H), 1.29 (s, 3H), 2.42—3.28 (m, 4H) 3.28—3.80 (br s, 1H), 4.06 (q, J=7 Hz, 2H), and 7.28—7.95 (m, 5H). MS (FAB) m/z 299 (M^++H). **1-Butyl-3-ethoxycarbonyl-3-(phenylsulfonyl)cyclobutanol (6b):** viscous oil; IR (neat) 3500, 3060, 2950, 2870, 1723, 1446, 1307, 1141, 1085, 1024, 932, 850, 724, and 692 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.09 (t, J=7 Hz, 3H), 0.62—1.93 (m, 9H), 2.23—3.20 (m, 4H), 3.33—3.73 (br s, 1H), 4.03 (q, J=7 Hz, 2H), and 7.27—7.93 (m, 5H). MS (FD) m/z 341 (M^++H). **3-Ethoxycarbonyl-1-(5-methyl-2-furyl)-3-(phenylsulfonyl)cyclobutanol (6d):** mp 95—96 °C (hexane-benzene); IR (KBr) 3500, 3080, 3070, 2980, 2960, 1710, 1447, 1310, 1145, 1086, 1024, 955, 858, 802, 766, 727, and 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (t, J=7 Hz, 3H), 2.21 (s, 3H), 3.20 (s, 4H), 3.44 (br s, 1H), 3.96 (q, J=7 Hz, 2H), 5.73—5.90 (m, 1H), 6.08 (d, J=3 Hz, 1H), and 7.30—7.98 (m, 5H). Found: C, 59.34; H, 5.52; S, 8.77%. Calcd for $C_{18}H_{20}O_6S$: C, 59.33; H, 5.53; S, 8.80%. **3-Ethoxycarbonyl-3-(phenylsulfonyl)-1-(2-thienyl)-cyclobutanol (6e):** mp 110—111 °C (hexane-benzene): IR (KBr) 3490, 3070, 2990, 1720, 1290, 1156, 1141, 1086, 729, and 703 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (t, J=7 Hz, 3H), 3.27 (br s, 4H), 3.91 (q, J=7 Hz, 2H), 3.67—4.23 (m, 1H), 6.68—6.93 (m, 2H), 7.02—7.23 (m, 1H), and 7.37—7.92 (m, 5H). Found: C, 55.82; H, 4.95; S, 17.30%. Calcd for $C_{17}H_{18}O_5S_2$: C, 55.72; H. 4.95; S, 17.50%.

Preparation of Ethyl 2-Methylene-4-oxo-4-phenylbutyrate (7c). To a suspension of KH (144 mg, 3.6 mmol) in THF (4 ml)-HMPA (3 ml) was added a THF (6 ml) solution of 3-ethoxycarbonyl-1-phenyl-3-(phenylsulfonyl)cyclobutanol (**6c**) (325 mg, 0.9 mmol) at −23 °C. After being stirred for 50 min at the same temperature, the reaction was quenched by addition of a phosphate buffer solution (pH 7). The organic material was extracted with ether and the extract was dried (Na_2SO_4). After removal of the solvent, the residue was chromatographed on silica gel (AcOEt-hexane) and **7c** (168 mg) was isolated in 85% yield. **7c:** viscous oil; IR (neat) 3060, 2980, 1708, 1686, 1632, 1321, 1303, 1199, 1146, 1026, 952, 758, and 690 cm^{-1}; ^1H NMR (CCl_4) δ=1.23 (t, J=7 Hz, 3H), 3.82 (s, 2H), 4.06 (q, J=7 Hz, 2H), 5.49 (br s, 1H), 6.17 (br s, 1H), 7.13—7.53 (m, 3H), and 7.58—7.97 (m, 2H). Found: C, 71.22; H, 6.47%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

In the same procedure, α-methylene-γ-oxo esters (**7a**, **7b**, **7d**, and **7e**) were synthesized. **Ethyl 2-methylene-4-oxovalerate (7a):** viscous oil; IR (neat) 2980, 2950, 2920, 1715, 1635, 1335, 1308, 1205, 1148, 1028, and 950 cm^{-1}; ^1H NMR (CCl_4) δ=1.26 (t, J=7 Hz, 3H), 2.09 (s, 3H), 3.25 (br s, 2H), 4.13 (q, J=7 Hz, 2H), 5.51 (br s, 1H), and 6.18 (br s, 1H). MS m/z 156 (M^+). **Ethyl 2-methylene-4-oxooctanoate (7b):** viscous oil; IR (neat) 2960, 2940, 2880, 1740, 1720, 1633, 1333, 1305, 1190, 1151, 1030, and 954 cm^{-1}; ^1H NMR (CCl_4) δ=1.27 (t, J=7 Hz, 3H), 0.65—1.80 (m, 7H), 2.37 (br t, J=6 Hz, 2H), 3.21 (br s, 2H), 4.08 (q, J=7 Hz, 2H), 5.45 (br s, 1H), and 6.11 (br s, 1H). Found: C, 66.25; H, 9.22%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. **Ethyl 2-Methylene-4-(5-methyl-2-furyl)-4-oxobutyrate (7d):** viscous oil; IR (neat) 3110, 2980, 1720, 1707, 1671, 1637, 1515, 1317, 1202, 1147, 1062, 1030, 956, and 804 cm^{-1}; ^1H NMR (CCl_4) δ=1.21 (t, J=7 Hz, 3H), 2.33 (s, 3H), 3.64 (s, 2H), 4.09 (q, J=7 Hz, 2H), 5.54 (br s, 1H), 6.03 (br d, J=3 Hz, 1H), 6.18 (br s, 1H), and 6.93 (d, J=3 Hz, 1H). MS (FAB) m/z 223 (M^++H). **Ethyl 2-methylene-4-oxo-4-(2-thienyl)butyrate (7e):** viscous oil; IR (neat) 3090, 2970, 1720, 1706, 1658, 1519, 1411, 1313, 1200, 1147, 1024, 951, 855, 818, and 728 cm^{-1}; ^1H NMR (CCl_4) δ=1.20 (t, J=7 Hz, 3H), 3.80 (s, 2H), 4.08 (q, J=7 Hz, 2H), 5.59 (br s, 1H), 6.21 (br s, 1H), 6.97 (dd, J=5 and 4 Hz, 1H), 7.50 (dd, J=5 and 1 Hz, 1H), and 7.62 (dd, J=4 and 1 Hz, 1H). MS (FAB) m/z 225 (M^++H).

Preparation of 4,5-Dihydro-3-methylene-5-phenyl-2(3*H*)-furanone (9c). The ethereal solution (1.8 ml) of $LiBH_4$ (1.1 mmol) was added to a suspension of $ZnCl_2$ (41 mg, 0.3 mmol) in ether (2 ml) under cooling with ice. An ether (2 ml) solution of **7c** (218 mg, 1 mmol) was slowly added to a resulting white suspension and the reaction mixture was stirred for 15 min under cooling with ice. The reaction was quenched by addition of 2 M hydrochloric acid and the organic material was extracted with ether. The extract was washed with water and dried over Na_2SO_4. After evaporation of the solvent, the residue was dissolved in toluene (4 ml) and p-toluenesulfonic acid (75 mg, 0.44 mmol) was added at room temperature. After being stirred for 2 h, the reaction mixture was diluted with ether (10 ml) and the organic layer was washed with water and brine, dried (Na_2SO_4), and condensed under reduced pressure. The residue was chromatographed on silica gel (AcOEt-hexane) and **9c** (138 mg) was obtained in 83% yield.

9c: mp 50—51 °C (lit,[18] 48—49.5 °C); IR (neat) 3020, 2960, 1760, 1704, 1664, 1320, 1276, 1130, 1026, 816, 758, and 701 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.76 (ddt, J=17, 7, and 2.5 Hz, 1H), 3.39 (ddt, J=17, 8, and 2.5 Hz, 1H), 5.46 (dd, J=7 and 8 Hz, 1H), 5.63 (t, J=2.5 Hz, 1H), 6.25 (t, J=2.5 Hz, 1H), and 7.32 (s, 5H).

In a similar manner, α-methylene-γ-butyrolactones (**9a** and **9b**) were synthesized. **9d** and **9e** were prepared by the treatment of the crude reduction product (**8**) with an equimolar amount of aluminum triisopropoxide in refluxing THF (10 ml per 1 mmol of **8**) for 2 h.

4,5-Dihydro-3-methylene-5-methyl-2(3*H*)-furanone (9a): oil; IR (neat) 2980, 2930, 1760, 1665, 1440, 1400, 1340. 1280, 1261, 1116, 1042, 957, and 818 cm^{-1}; ^1H NMR (CCl_4) δ=1.42 (d, J=6 Hz, 3H), 2.47 (ddt, J=17, 6, and 3 Hz, 1H), 3.10 (ddt, J=17, 7, and 3 Hz, 1H), 4.58 (d quint, J=7 and 6 Hz, 1H), 5.55 (t, J=3 Hz, 1H), and 6.04 (t, J=3 Hz, 1H). Found: C, 63.98; H, 7.37%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%. **5-Butyl-4,5-dihydro-3-methylene-2(3*H*)-furanone (9b):** oil; IR (neat) 2960, 2930, 2870, 1760, 1665, 1399, 1350, 1280, 1118, 1007, 933, and 818 cm^{-1}; ^1H NMR (CCl_4) δ=0.60—1.92 (m, 9H), 2.47 (ddt, J=17, 6, and 2.5 Hz, 1H), 3.04 (ddt, J=17, 7, and 2.5 Hz, 1H), 4.01—4.63 (m, 1H), 5.48 (t, J=2.5 Hz, 1H), and 6.00 (t, J=2.5 Hz, 1H). (Received July 18, 1988)

Racemic 2′-methoxy-1,1′-binaphthyl-2-carboxylic acid was separated on a multi-gram scale into its antipodes via silica-gel column chromatography followed by alkaline hydrolysis of the diastereomeric esters prepared from (*R*)-1-phenylethanol or (−)-menthol. The molecular structure of (−)-menthyl (a*S*)-2′-methoxy-1,1′-binaphthyl-2-carboxylate was determined by single-crystal X-ray analysis. The (a*S*)-acid was converted to crystalline acid chloride, which was conveniently utilized as efficient chiral derivatizing agent for differentiation of enantiomeric alcohols and amines by high-performance liquid chromatography on silica gel. The elution behavior of a pair of diastereomeric esters or amides was explained by the steric interactions between the solutes and the silica-gel stationary phase on the basis of the X-ray analysis.

During the last two decades, a number of chiral derivatizing agents have been developed for discrimination of enantiomers.[1,2] Almost all of these possess C-centrochirality to exert stereo-differentiating ability, among which, Mosher's α-methoxy-α-trifluoromethylphenylacetic acid (MTPA) has been most widely used.[3]

It has been well-recognized recently that axially dissymmetric biaryls are efficient chiral auxiliaries in a variety of asymmetric reactions,[4] and then, these biaryls should also be good candidates for chiral derivatizing agents. Only a few reports, however, have appeared dealing with atropisomeric biaryls as such.[5,6] This seems mainly because of the difficulties accompanying the preparation of prerequisite chiral biaryl components. For example, the synthesis of optically active 2′-methyl-1,1′-binaphthyl-2-carbonyl cyanide (**1′**), the first chiral derivatizing agent with axially chiral binaphthyl unit reported in 1982 by Goto et al., required lengthy and subtle manipulations via 1,1′-binaphthyl-2,2′-dicarboxylic acid.[5]

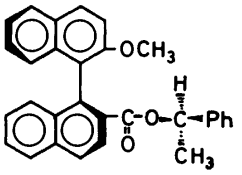
We previously reported a practical method for the synthesis of 1,1′-binaphthyl-2-carboxylic acids.[7] As part of a program in our laboratory directed toward the use of these acids for elaboration of efficient chiral recognizing elements,[8] we wish to report herein a multi-gram scale optical resolution of 2′-methoxy-1,1′-binaphthyl-2-carboxylic acid (**2**) and its application to chiral derivatizing agent for differentiation of enantiomeric alcohols and amines by high-performance liquid chromatography (HPLC).

Results and Discussion

Optical Resolution of 2. Wilson and Cram reported the preparation of optically pure (a*S*)-**2**[9] by repeated crystallization of quinidine salt of rather pure (a*S*)-**2** (81%ee) which had been obtained by a chiral version of the oxazoline-assisted nucleophilic displacement on alkoxyarenes (the Meyers reaction).[10] We repeated the resolution procedure starting from racemic **2**, but realized that it was very sensitive to the experimental conditions, thus making difficult to obtain reproducible results. Furthermore, preferential precipitation of the racemate caused frequent decrease of the optical rotations of partially active samples of **2** during manipulations.[10]

We noticed, however, that many of the pairs of diastereomeric esters prepared from (±)-**2** and chiral alcohols gave two distinct spots on silica-gel TLC. This implies the possibility of optical resolution of **2** via chromatographic separation of the diastereomeric esters followed by hydrolytic removal of the chiral alcohol residue. Our expectation was realized by the fact that a multi-gram sample of diastereomeric esters prepared from (±)-**2** and (*R*)-1-phenylethanol was readily separated into (*R*)-1-phenylethyl (a*S*)-2′-methoxy-1,1′-binaphthyl-2-carboxylate ((a*S*,*R*)-**3a**) and the (a*R*,*R*)-counterpart by a silica-gel column chromatography. Upon alkaline hydrolysis, each of the diastereomers afforded the corresponding optically pure **2** as judged by HPLC on Pirkle column as *N*-butylamide. Practically, inexpensive (−)-menthol was ad-



(aS,R)-3a

vantageously replaced for enantiomeric 1-phenylethanol; although hydrolysis of the diastereomeric esters (**3b**) required longer heating at reflux in aqueous ethanol in the presence of potassium hydroxide, no trace of racemization was observed.

Utilization of Axially Chiral 2 as Chiral Derivatizing Agent. Treatment of (aS)-**2** with thionyl chloride and recrystallization from hexane gave the acid chloride (aS)-**2′** as pale yellow prisms. Several partially active alcohols or amines of known enantiomeric composition were acylated with a small excess of (aS)-**2′** in benzene-pyridine (or triethylamine) in the presence of a catalytic amount of 4-dimethylaminopyridine (DMAP) to give the corresponding diastereomeric pairs of esters or amides. These pairs were subjected to HPLC analysis, and Tables 1 and 2 list the results of separation of alcohols and amines, respectively. Although reversed-phase HPLC on a ODS column eluting with aqueous ethanol or acetonitrile gave not so good separation, normal-phase HPLC on a spherical silica-gel column

a) Operating conditions: column, silica gel; eluent, 1% *i*-PrOH/hexane, 2 ml min^{-1}.

cleanly differentiated two diastereomeric esters with base-line separation (Table 1). It should be noted that among a given diastereomeric pair of esters or amides of α-chiral alcohols or amines, the (a*S*,*R*)-isomer eluted faster than the (a*S*,*S*)-counterpart (vide infra).

Kinetic resolution is a potential problem in using a chiral derivatizing agent, but it was shown that acylation of racemic 1-phenylethanol or 1-phenylethylamine by (a*S*)-**2′** under standard conditions gave essentially 1:1 mixture of (a*S*,*R*)- and (a*S*,*S*)-isomer within the limits of ^{1}H NMR detection at 60 MHz.[11] Furthermore, it was also shown that the diastereomeric composition of a mixture of diastereomeric esters prepared from a sample of partially active 1-phenylethanol was identical to the enantiomeric composition of the starting alcohol as determined by HPLC analysis (see Experimental). These facts indicate that axially chiral **2** is useful as a chiral derivatizing agent for HPLC determination of absolute configuration and enantiomeric purity of α-chiral alcohols and amines.

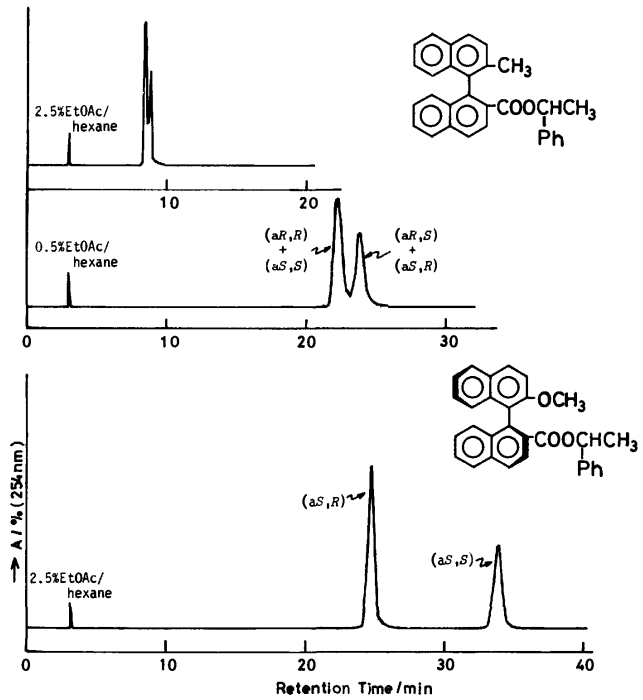

Fig. 1. HPLC resolution of diastereomeric 1-phenylethanol esters of **1** and **2**.

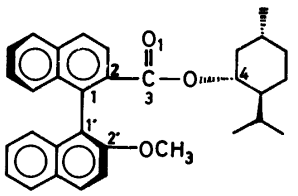
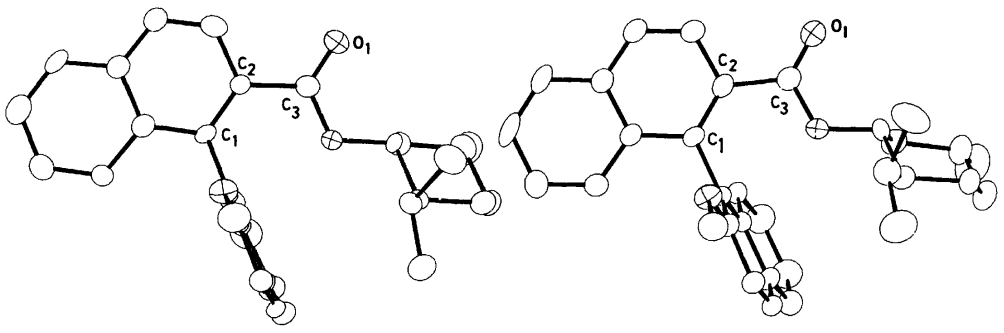
Effects of the Presence of 2′-Methoxyl Group. Figure 1 shows HPLC chromatograms of diastereomeric 1-phenylethanol esters of **1** and **2**. It should be noted that replacement of 2′-methoxyl for 2′-methyl functionality significantly increases both of the retention volumes and the separation factor α.

X-Ray Structure of (−)-Menthyl Ester of (a*S*)-2. Wilson and Cram assigned the absolute configuration of (−)-**2** to a*S* by correlating it to (a*S*)-(−)-1,1′-bi-2-naphthol.[10] Their assignment is now unambiguously confirmed here on the basis of the fact that the configuration of the (−)-menthyl carbon, C_4 in **3b** is *R*: Recrystallization of (−)-menthyl ester of (a*S*)-**2** ((a*S*,*R*)-**3b**) from hexane gave cubic crystals proper for X-ray diffraction. The ORTEP drawings in Fig. 2 show the complete connectivity established by the crystal structure analysis. It was shown that there are two independent molecules in the unit cell (**3b-1** and **3b-2**).



(a*S*,*R*)-**3b**

These two molecules have no significant differences in the bond lengths and angles, but take slightly different conformations around the single bond linking the two naphthalene rings as shown in the ORTEP drawings; the dihedral angle (θ, C_2-C_1-$C_{1'}$-$C_{2'}$) is 89.0° in **3b-1** (see Fig. 3), while that is 97.8° in **3b-2**. At the same time, the torsion angles of the carbonyl groups are also slightly different; the dihedral angles (φ, C_1-C_2-C_3-O_1) are 1.1° and 10.5° for **3b-1** and **3b-2**, respectively.



3b-1 **3b-2**

Fig. 2. ORTEP drawings of (a*S*,*R*)-**3b**.

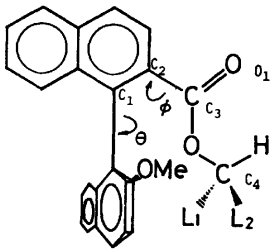


Fig. 3. Schematic view of crystal structure of alcohol (CL_1L_2H–OH) ester of (a*S*)-**2**.

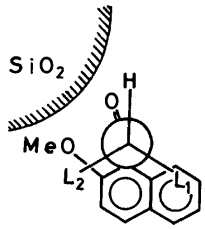

Fig. 4. Schematic view of the interaction of alcohol (CL_1L_2H–OH) ester of (a*S*)-**2** with silica-gel stationary phase.

Thus, the molecule **3b-1** has an almost orthogonal conformation concerning the naphthalene rings with almost coplanar carboxyl group with one of the naphthalene rings, while the molecule **3b-2** has a slightly deviated conformation from that of **3b-1**. These deviations seem to be due to subtle differences in the packing effect into the crystalline state.

Mechanistic Aspects of the Differentiation of Enantiomeric Alcohols and Amines by Axially Chiral 2. The most characteristic features of (a*S*,*R*)-**3b** based on the X-ray analysis are approximated as follows; 1) the dihedral angle confined by the two naphthalene rings is almost orthogonal, 2) CO–O–C_4–H atoms are nearly on the same plane that contains the naphthalene ring connecting the carboxyl function at the C_2-position, and 3), thus the plane roughly bisects the two other ligands (L_1 and L_2) attached at the C_4-carbon. These stereochemical features can be simplified as schematically shown in Fig. 3.

It is said that adsorptions of the solutes to the stationary phase mainly control the chromatographic behavior of the solutes on a normal-phase silica-gel HPLC. In this context, interactions of the diastereomeric esters or amides of **2** with the silica-gel surface by virtue of the carbonyl oxygen and/or methoxyl oxygen may play critical role.

On the assumption that prevailing conformations of these diastereomers in HPLC conditions are deducible from those of the X-ray structure of the (a*S*,*R*)-**3b**,[12] Fig. 4 shows a schematic model for the interaction of the solute with silica-gel surface based on the structure depicted in Fig. 3. It may be said that, among a given diastereomeric pair, the (a*S*,*S*)-isomer should be adsorbed more strongly than the (a*S*,*R*)-counterpart, because in the former the ligand L_2, which is arrayed toward the adsorbent, is smaller than L_1, while in the latter, the relationship of the steric bulk of the two ligands is reversed.

As mentioned above, the idea of utilizing axially chiral biaryl derivatives as chiral derivatizing agent for enantiomeric compounds was first reported by Goto et al.[5] Their 2'-methyl-1,1'-binaphthyl-2-carbonyl moiety was highly efficient for HPLC differenciation of several alcohols which contained oxycarbonyl function. At our hand, however, the moiety did not show so much discrimination, as compared with **2**, for simple alcohols such as 1-phenylethanol (Fig. 1). This is another support for the above reasoning that HPLC behavior of the diastereomeric esters and amides of **2** is largely determined by the coordination to silica-gel surface by the carbonyl oxygen as well as the methoxyl oxygen.

In conclusion, we have shown here that axially chiral **2**, which is readily obtainable in a multi-gram scale,[13] serves as an efficient chiral derivatizing agent for differentiation of enantiomeric alcohols and amines by HPLC.

Experimental

Instruments. HPLC measurements were carried out on a JASCO TRIROTAR-III and/or a Shimadzu LC-5A, with UV detection at 254 nm. Stainless-steel columns (0.46 cm i.d. ×25 cm) were packed with Hitachi Gel 3056 for the silica-gel column and JASCO FINPAK C_{18} for the ODS column, respectively, using conventional slurry techniques. IR and UV spectra were measured on a Shimadzu IR-430 grating spectrophotometer and a Shimadzu UV 160 spectrophotometer, respectively. ^{1}H NMR spectra were recorded on a JEOL JNM-FX60 instrument in benzene-d_6 using tetramethylsilane as an internal standard. Optical rotations were recorded on a Union PM-101 automatic digital polarimeter in a 1-cm cell at 23—25 °C. Melting points were measured on a Yamato MP-21 and uncorrected.

Materials. Racemic binaphthylcarboxylic acids **1** and **2** were prepared as described in previous paper.[7] Samples of partially active alcohols and amines (20—70%ee) were prepared by adding commercial enantiomers to the corresponding racemates unless otherwise noted. (*S*)-(+)-2-Octanamine was the sample obtained in this laboratory.[14] Solvents were purified as usual. Wako Gel C-200 was dried by heating at 120 °C for several hours before use for silica-gel column chromatography. Analytical, and preparative TLC were performed using Merck Kieselgel 60 F_{254}, and Merck Kieselgel 60 G, respectively. Water-sensitive reactions were routinely carried out in a nitrogen atmosphere.

Optical Resolution of 2 via (*R*)-1-Phenylethanol Ester. Racemic **2** (5.0 g, 15.2 mmol) was boiled in 30 ml of freshly distilled thionyl chloride for 5 h. After volatiles were evaporated in vacuo, residual thionyl chloride was removed by addition and evaporation of small portions of benzene (×3) to give (±)-**2'** as a brown solid. The acid chloride was dissolved in 70 ml of benzene. This was added dropwise to a

solution of (*R*)-1-phenylethanol (2.3 g, 18.9 mmol) and 4-dimethylaminopyridine (1 g) in benzene (80 ml) and pyridine (5 ml). The mixture was stirred overnight at ambient temperature, and then heated at ca. 70 °C for 3 h. The cool mixture was diluted with benzene, washed (2 M[††] HCl, 1 M Na_2CO_3, and water), and dried over $MgSO_4$ in the presence of activated charcoal. After filtration and evaporation of volatiles in vacuo, the organic residue was subjected to chromatography using a 7 cm i.d. ×30 cm silica-gel column with benzene as the eluent. Fractions containing two components were combined together and chromatographed again, finally affording the following diastereomerically pure samples beside 0.65 g of a mixture of **3a**:

(a*S*,*R*)-**3a**: 2.75 g (42% based on (±)-**2**); IR (KBr) 3060, 1705, 1272, and 765 cm^{-1}; UV (MeOH) 232.4 (λ_{max}) (ε 10.3×10^4) and ε 1.05×10^4 at 254 nm; ^1H NMR δ=0.68 (3H, d, J=6.45 Hz, C-CH_3), 3.15 (3H, s, O-CH_3), 5.79 (1H, q, J=6.45 Hz, -CH-), and 6.7—8.5 (17H, m, Ar-H). The sense of axial chirality was confirmed by the optical rotaion of **2** obtained by hydrolysis (vide infra).

(a*R*,*R*)-**3a**: 2.40 g (36%); IR (KBr) 3060, 1710, 1272, and 763 cm^{-1}; UV (MeOH) 232.4 (λ_{max}) (ε 9.35×10^4) and ε 1.02×10^4 at 254 nm; ^1H NMR δ=0.86 (3H, d, J=6.45 Hz, C-CH_3), 3.20 (3H, s, O-CH_3), 5.85 (1H, q, J=6.45 Hz, -CH-), and 6.4—8.5 (17H, m, Ar-H).

A sample of (a*S*,*R*)-**3a** (2.0 g, 4.62 mmol) was boiled in a solution of KOH (10 g) in ethanol (100 ml) and water (5 ml) for 3 h. Solvents were evaporated in vacuo, and the residue was dissolved in water. After extracted with ether, the aqueous layer was made acidic with concd HCl, and extracted with ether. Combined ether extracts were treated as usual to give (a*S*)-**2**, 1.50 g (99% yield); IR (KBr) 1690 cm^{-1}; $[\alpha]_D$ −25.5° (*c* 2.60, THF) (lit,[10] $[\alpha]_D$ −25.98° (*c* 1.22, THF)). A sample of (a*S*)-**2** (ca. 20 mg) was treated with excess butylamine in the presence of dicyclohexylcarbodiimide to give the *N*-butylamide,[8] which was confirmed to be more than 99.5%ee by HPLC on a Pirkle column.

Similar treatment of 2.30 g of (a*R*,*R*)-**3b** gave 1.71 g of (a*R*)-**2** which was confirmed enantiomerically pure by HPLC as above; $[\alpha]_D$ +25.4° (*c* 2.66, THF).

Synthesis and Separation of (−)-Menthyl Ester Diastereomers of (±)-2. (−)-Menthol (12.8 g, 82.1 mmol) was treated with (±)-**2′** (prepared from 9.15 g (27.8 mmol) of **2**) in the presence of DMAP (1 g) in benzene (100 ml) and pyridine (5 ml) as above. After as much menthol as possible was removed by sublimation under vacuum, remaining organic material was chromatographed twice on silica-gel column eluting with toluene to give 3.79 g of diastereomerically pure (a*S*,*R*)-**3b** (29% yield based on (±)-**2**)), 4.10 g of (a*R*,*R*)-**3b** (32%), and 2.64 g of a mixture of the diastereomers.

(a*S*,*R*)-**3b**: mp 145—146 °C (hexane); ^1H NMR δ=3.28 (3H, s, OCH_3); $[\alpha]_D$ −142° (*c* 2.11, $CHCl_3$).

(a*R*,*R*)-**3b**: mp 126—129 °C (hexane); ^1H NMR δ=3.24 (3H, s, OCH_3); $[\alpha]_D$ −55.4 °C (*c* 2.75, $CHCl_3$).

Both diastereomers of **3b** were heated at reflux with KOH in aqueous ethanol for 8—10 h to give optically pure acids as judged by HPLC as above.

Preparation of (a*S*)-2′. In a typical run, (a*S*)-**2** (1.09 g, 3.32 mmol) was treated with thionyl chloride as above, dissolved in hot hexane, filtered hot from activated charcoal, and allowed to stand to give (a*S*)-**2′** as prisms, 0.98 g (85% yield), mp 139—142 °C, IR (KBr) 1770 cm^{-1}.

Preparation of Diastereomeric Esters and Amides of (a*S*)-2. General procedure for the preparation of HPLC samples of diastereomers is as follows: To a stirred mixture of partially active alcohol or amine (0.3—0.4 mmol) and DMAP (0.1 g) in benzene (5 ml) and pyridine (1 ml) was added dropwise a solution of 1.2—1.5 equiv of (a*S*)-**2′** in benzene (10 ml). The mixture was stirred overnight, and then heated at 60—70 °C (amines) or at gentle reflux (alcohols) for 2—3 h. To the cool mixture was added 0.1 ml of 3-(dimethylamino)propylamine. It was diluted with ether, washed successively with 2 M HCl, 1 M Na_2CO_3, and water, and dried over $MgSO_4$. After volatiles were evaporated in vacuo, the mixture of diastereomeric esters or amides were recovered by TLC, care being taken not to cause fractionation of either of the diastereomers.

In case of (−)-borneol (*endo*-(1*S*)-1,7,7-trimethylbicyclo-[2.2.1]heptan-2-ol), (−)-menthol ((1*R*, 2*S*, 5*R*)-2-isopropyl-5-methylcyclohexanol), (+)-bornylamine (*endo*-(1*R*)-1,7,7-trimethylbicyclo[2.2.1]heptan-2-amine), and (+)-isobornylamine (*exo*-(1*R*)-1,7,7-trimethylbicyclo[2.2.1]heptan-2-amine), excess of optically pure enantiomers was allowed to react with partially active (−)-**2′** of known enantiomeric composition (ca. 50%ee). For the sake of simplicity, diastereomers of these alcohols and amines were also presented in Tables 1 and 2 as if they were those prepared from (a*S*)-**2′** and partially active enantiomers.

^1H NMR Study of the Diastereomeric Ester or Amide Mixture of (±)-1-Phenylethanol or (±)-1-Phenylethylamine. (±)-1-Phenylethanol (50 mg, 0.41 mmol) was acylated with (a*S*)-**2′** (0.21 g, 0.61 mmol) as above. The diastereomeric ester mixture **3a**, which was obtained in 81% yield (0.144 g) after preparative TLC, was subjected to ^1H NMR measurement. The methoxyl protons of (a*S*,*R*)-**3a** which appeared at δ 3.15 shifted to δ 4.84 on addition of 1 equiv amount of lanthanoide shift reagent Eu(fod)$_3$ to the diastereomeric **3a**, while those of (a*S*,*S*)-**3a** which appeared at δ 3.19 shifted to δ 4.42. The ratio of peak areas of those lanthanoide-shifted methoxyl signals was 50.3:49.7, which should be regarded to indicate that the diastereomeric composition was practically 1:1 whithin the error limits of the integration of NMR peak areas at 60 MHz (vide infra).

Similar treatment of (±)-1-phenylethylamine with (a*S*)-**2′** gave the amide mixture in 93% yield. Addition of 1 equiv amount of Eu(fod)$_3$ caused shift of the methoxyl protons of (a*S*,*R*)-amide from δ 3.04 to δ 5.47, while those of (a*S*,*S*)-isomer from δ 3.12 to δ 5.19, with base-line separation of the two peaks. The ratio of areas of those two peaks measured to be 49.8:50.2.

HPLC Estimation of the Diastereomeric Composition of Partially Active 1-Phenylethanol Esters of (a*S*)-2. A sample of partially active 1-phenylethanol enriched in (*R*)-isomer was prepared to be 50%ee by addition of the racemate to the (*R*)-enantiomer. Aliquot of the sample was converted to the 3,5-dinitrophenylcarbamates. HPLC analysis of the carbamates on a chiral column developed in our laboratory[15] demonstrated that the mixture should be 49.9%ee.

The remainder of the partially active alcohol was converted to the diastereomeric esters by treatment with (a*S*)-**2′**. HPLC analysis of the mixture on silica-gel column showed the peaks of (a*S*,*R*)- and (a*S*,*S*)-**3a** in the ratio of

[††] 1 M=1 mol dm^{-3}.

3.07:1 in the order of increasing retention time. The peak ratio was corrected for molar response indicating that the diastereomeric composition of the sample should be 49.7% de (diastereomeric excess), on the basis that the ratio of the peak areas of the aforementioned diastereomeric (a*S*,*R*)- and (a*S*,*S*)-**3a** from racemic 1-phenylethanol was 1.03:1 (see footnote a in Table 1 for the HPLC operating conditions).

Crystal Structure Determination of (a*S*,*R*)-3b. A prism-like crystal of (a*S*,*R*)-**3b** with the dimensions of 0.2×0.2×0.3 mm was used for the data collection on a Rigaku-Denki automated four-circle diffractometer (Rigaku AFC-5R), equipped with a rotating anode (40 kV, 200 mA) using Mo $K\alpha$ radiation (λ=0.71029 Å). Crystal data are as follows: M.F.=$C_{32}H_{34}O_3$, M.W.=466.59, orthorhombic space group $P2_12_12_1$, a=16.852(3), b=22.307(4), c=14.047(2) Å, V=5280.5(9) Å^3, Z=8, D_{calcd}=1.17 g cm^{-3}, μ(Mo $K\alpha$)=0.688 cm^{-1}. A total of 6027 reflections within 2θ=52° were measured using 2θ-θ scan mode and 3567 reflections with $|F_o|>3\sigma|F_o|$ were used for the structure determination. The structure was solved by the direct method and refined by the block-diagonal least-squares method to give an R factor of 0.09 including all hydrogen atoms which were calculated and verified by the difference Fourier synthesis.

Tables of atomic coordinates, temperature factors, bond lengths, bond angles, and the F_o—F_c list are kept at the Chemical Society of Japan (Document No. 8867).

We are grateful to the Asahi Glass Foundation for Industrial Technology and a Grant-in-Aid for Scientific Research (No. 62101001) from the Ministry of Education, Science and Culture for financial support of this work. We also thank Mr. Takatsugu Suzuki for experimental help and Professor Shozo Yamaguchi and Ms. Fujiko Yasuhara of our university for helpful discussions.

Novel Synthesis of Carbamate Ester from Carbon Dioxide, Amines, and Alkyl Halides

Yasuhiko YOSHIDA,* Shigeru ISHII, Masayo WATANABE, and Tadataka YAMASHITA
Department of Applied Chemistry, Faculty of Engineering, Toyo University,
Kujirai, Kawagoe, Saitama 350
(Received September 6, 1988)

A novel synthesis of carbamate ester using carbon dioxide as a direct material is reported in this article. The direct reaction of carbon dioxide, aliphatic amines, and alkyl halides was found to give the corresponding alkyl carbamate esters in good yields. Reactions using secondary alkyl bromides gave carbamate esters in higher yields than those using primary or tertiary alkyl bromides. The carbamate ester yields increased with the addition of *N*,*N*-dimethylformamide to the reaction system of carbon dioxide, amines and, alkyl halides. This reaction is considered to proceed by an S_N2 displacement reaction of the alkyl halide by the carbamate anion formed from the reaction of carbon dioxide and the amine.

The chemical utilization of carbon dioxide as a raw material in the synthetic chemical industry has so far been limited, because the reactivity of carbon dioxide is considered to be one of the lowest of all carbon compounds. However, carbon dioxide is well-known, to easily react with nucleophilic reagents, such as Grignard reagent or organometallic compounds.[1] Similarly, amine attacks carbon dioxide to form carbamic acid:

$$R_2NH + CO_2 \rightarrow R_2NCOOH \quad (1)$$

Carbamic acid, itself, however, has not been isolated and has been known only as a reaction intermediate in the hydrolysis reaction of carbamate ester or in the hydration reaction of isocyanate.[2] Thus, carbamic acid is very unstable by easy decomposition to carbon dioxide and amine; its esters, however, are stable compounds.

Carbamate esters[3] have so far been prepared by the reactions of amines with alkyl chloroformate, and alcohols with carbamoyl chloride or isocyanate, which were made from phosgene as a starting material. The starting materials for the preparation of carbamate esters, such as phosgene, isocyanate, carbamoyl chloride, and chloroformate, are highly toxic and inconvenient to use for the syntheses of carbamate esters.

The syntheses of carbamate esters by reactions using carbon dioxide as a direct starting component have been reported in recent years.[4-11] Also, we have previously reported that carbon dioxide and aliphatic amine reacted with epoxide to give 2-hydroxyalkyl carbamate in high yields,[12,13] with vinyl ether to give 1-alkoxyalkyl carbamate selectively,[14] and with ortho ester to give the corresponding alkyl carbamate in high yields.[15] In the course of further studies we found that the reaction of carbon dioxide and amines with alkyl halides formed the corresponding carbamate esters (Eq. 2).[16]

$$R_2NH + CO_2 + R'X \rightarrow R_2NCOOR' + [R_2NH_2]^+X^- + [R_2R'NH]^+X^- \quad (2)$$

The structures and reactivities of alkyl halides and amines are considered to be of importance for reactions with carbon dioxide, since the amine reacts directly with the alkyl halide to form an ammonium halide salt. In this paper, we describe the details of reactions of carbon dioxide with amines and alkyl halides to yield carbamate esters.

Results and Discussion

Carbon dioxide reacted with secondary aliphatic amines and alkyl halides to give the corresponding alkyl carbamates with two kinds of ammonium halide salts, depending on the reactivities and structures of the amine and alkyl halide and the reaction conditions (Eqs. 2—4):

$$R_2NH + CO_2 + R'\text{-}X \rightarrow R_2NCOOR' + [R_2NH_2]^+X^- \quad (3)$$
$$R_2NH + R'\text{-}X \rightarrow [R_2R'NH]^+X^- \quad (4)$$

One of the ammonium halide salts is a secondary ammonium salt which is formed by a reaction of the amine and hydrogen halide released as by-products of carbamate ester formation. The other is a tertiary ammonium salt which is obtained by a direct reaction of the amine and alkyl halide.

Reactions of carbon dioxide, diethylamine (Et_2NH) and various isomeric butyl halides were investigated in detail concerning the reaction conditions for the synthesis of the carbamate ester. Table 1 shows the carbamate ester yield and the total recovered amount of ammonium salt under various reaction conditions. Butyl chloride hardly gave the carbamate ester at 60 °C, but carbamate ester was obtained in 18% yield at 100 °C and increased slightly at higher temperature (Runs 1—3).

The yield of carbamate ester was nearly constant for longer reaction times, but the formation of tertiary ammonium salt, which was obtained by the direct reaction of diethylamine and butyl chloride, increased (Runs 2 and 4). In the case of butyl bromide, the carbamate ester was obtained in 8% yield at 40 °C, though the amount of secondary ammonium salt,

which corresponded to the amount of ammonium salt obtained as the by-product of the carbamate ester synthesis, was also obtained (Run 6). The carbamate ester yield was 20—22% from 60 to 100 °C (Runs 7—10). Also, the amount of tertiary ammonium salt, obtained by a direct reaction of the amine and alkyl halide, increased with increasing the reaction temperature (Runs 6—11). Under reaction conditions greater than 80 °C, about 50% of the butyl bromide directly reacted with the amine to give the tertiary ammonium salt (Eq. 4). At 70 °C for 2 days, carbamate ester was obtained in 31% yield; then, the ester yield was almost constant (Runs 12 and 13). Butyl iodide gave the carbamate ester in 20% yield at 40 °C; however, a direct reaction of amine and alkyl halide was preferred to a carbamate ester synthesis at higher temperatures (Runs 14—20).

In conclusion, various butyl halides such as the chloride, bromide, and iodide reacted with carbon dioxide and diethylamine to yield butyl diethylcarbamate in 25, 31, and 20%, respectively, under each best reaction condition (Runs 4, 12, and 15). Since the reactivity of butyl chloride to nucleophilic reagents is low, a higher reaction temperature was required for the carbamate ester synthesis. In the case of butyl iodide, the reaction was accompanied by the formation of a considerable amount of tertiary ammonium iodide salt, which was obtained from a direct reaction of

diethylamine and butyl iodide. The reaction of butyl bromide, carbon dioxide and diethylamine gave the carbamate ester in the highest yield of all butyl halides.

The steric effect of the alkyl group in the reaction of carbon dioxide, diethylamine, and various isomeric butyl bromides was studied (Table 2). The carbamate ester yields obtained using a secondary alkyl bromide were compared with those using primary and tertiary alkyl bromides. In the case of using *s*-butyl bromide, the formation of the carbamate ester was preferred to the formation of ammonium salt (the direct reaction of amine and alkyl bromide), and occurred in higher yields (Run 6). Since the reactivities of primary alkyl bromides, such as butyl and isobutyl bromides, with an amine are higher than that of *s*-butyl bromide, the direct reaction with the amine was preferred to the carbamate ester synthesis (Table 2: Runs 5 and 12, and Table 3: Run 10). Owing to the steric hindrance of the tertiary alkyl group, the reactivity of the *t*-butyl bromide to the nucleophilic reagents was low (Runs 7—11).

The effect of the molar ratio of diethylamine to butyl bromide, [Et_2NH]/[*n*-BuBr], on carbamate ester yield, was examined in detail, as shown in Fig. 1. The carbamate ester yield increased with an increase in the molar ratio, [Et_2NH]/[*n*-BuBr]. The ester yield was approximately constant when the value of [Et_2NH]/[*n*-BuBr] was over 2.

The results of the reaction of carbon dioxide, various amines, and various alkyl halides are summarized in Table 3. While aliphatic amines gave the corresponding carbamate esters (Runs 1, 2, and 4—12), no aromatic amines gave the carbamate esters at all (Runs 13—15). Also, the aliphatic substituent groups of the amine exerted an influence on the synthesis of the carbamate ester by the reaction of carbon dioxide, amine, and alkyl halide (Runs 1, 2 and 3: 4 and 5: 8 and 9).

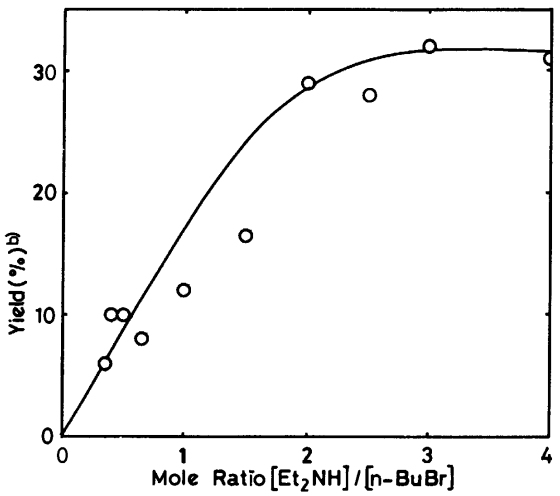

Fig. 1. Effect of [Et_2NH]/[*n*-BuBr] mole ratio on the reaction of Et_2NH, *n*-BuBr, and CO_2.[a]
a) Time: 24 h, temp: 70°C. b) Yield of Et_2NCOO-*n*-Bu based on *n*-BuBr.

As the carbon number in the alkyl bromides increased, the yield of the carbamate ester increased. The reaction of carbon dioxide and diethylamine with ethyl, propyl, or butyl bromide, gave the corresponding carbamate ester in 22, 32, or 42%,[16] respectively (Runs 1 and 4). The carbamate ester yields by a reaction using secondary alkyl bromides are higher than those

using primary alkyl bromides (Runs 4 and 8: 5 and 9). Cyclohexyl bromide gave the corresponding carbamate ester in 3% yield, because of the steric effect of the cyclohexane ring (Run 11). Methylene dibromide reacted with carbon dioxide and propylamine to give methylene bis(propylcarbamate) (Run 12). This product can not be obtained by other synthetic methods, since it is the ester of methanediol and propylcarbamic acid, which are both unstable and not isolable.

It was considered that the polarity of the reaction system influenced the reaction rate, since the synthetic reaction of carbamate ester from aliphatic amines, alkyl halides, and carbon dioxide is a nucleophilic substitution. The addition of DMF (*N,N*-dimethylformamide) into the reaction mixture resulted in an increase in the carbamate ester yield at the lower temperatures. By the addition of 5 mol% DMF for diethylamine, the carbamate ester yield increased from 8 to 11% at 40 °C, and from 22 to 32% at 80 °C. However, the addition of DMF did not exert any influence on the carbamate ester yield at 120 °C. The carbamate ester yields gradually decreased with an increase in the DMF concentration at any temperature, because the addition of DMF resulted in a dilution of the reaction system. No additive effects of other solvents such as dimethyl sulfoxide, acetonitrile, alcohols, tertiary amine, and ether were observed in the synthetic reaction of carbamate ester at any reaction temperature using any additive amount.

The reaction is considered to proceed as follows. Carbon dioxide reversibly reacts with the aliphatic amine to form carbamic acid (Eq. 1). Carbamic acid dissociates to a carbamate anion and a proton (Eq. 5). Then, the carbamate anion attacks the alkyl halide to produce the carbamate ester (Eq. 6). This reaction is considered to be an S_N2 displacement reaction, because the yield of the carbamate ester obtained using cyclohexyl bromide is considerably lower than that using acyclic alkyl bromides.[17] Also, any reactions of carbon dioxide, amines, and alkyl halides give the corresponding carbamate esters without the formation of other isomeric alkyl carbamate esters:

$$R_2NCOOH \rightarrow R_2NCOO^- + H^+ \quad (5)$$

$$R_2NCOO^- + R'\text{-}X \rightarrow R_2NCOOR' + X^- \quad (6)$$

In conclusion, the reaction of amine, carbon dioxide, and alkyl halide to form the carbamate ester accompanied the direct reaction of amine and alkyl halide to yield ammonium salt. In this reaction the secondary alkyl bromides gave the corresponding carbamate ester in high yields. This reaction mechanism is an S_N2 displacement reaction in which the carbamate anion, formed from carbon dioxide and amine, attacks alkyl halide.

Experimental

Materials. Various commercially available amines and alkyl halides were purified by refluxing and distilling over calcium hydride and stored under a nitrogen atmosphere. Commercial available high-purity carbon dioxide gas was introduced directly into an autoclave from a gas cylinder without further purification.

Measurements. IR spectra were recorded on a Hitachi 260-50 apparatus, and NMR spectra were recorded on a Hitachi R-24 spectrometer operating at 60 MHz and JEOL FX90Q at 90 MHz, using hexamethyldisiloxane (HMDS) as the internal standard. GC-MS spectra were measured by a Shimadzu QP-1000 spectrometer, and gas-liquid chromatogram (GLC) were recorded on a Shimadzu GC-4C apparatus with a thermal conductivity detector.

Preparations of Carbamate Ester. A typical example for the synthesis of 1-methylpropyl diethylcarbamate (*s*-butyl diethylcarbamate) is as follows.

A 100 cm^3 stainless-steel autoclave was swept free of air by displacement with nitrogen. Into the autoclave was added a mixture of diethylamine (18.3 g, 0.25 mol) and *s*-butyl bromide (13.7 g, 0.10 mol). Carbon dioxide gas was then introduced directly from the gas cylinder until the pressure reached 40 atm (4.1×10^6 Pa). After the autoclave was allowed to stand in an oil bath controlled at 70 °C for 48 h, the excess carbon dioxide gas was released and the contents of the reaction mixture were filtered to remove any ammonium bromide salts. The filtrate was subjected to fractional distillation under reduced pressure to isolate the product, *s*-butyl diethylcarbamate, bp 67.0—67.3 °C/6 mmHg† (7.5 g, 43%).

Preparations of other carbamate esters were carried out using a similar procedure.

Identification of the Products. Butyl Diethylcarbamate: bp 111.2—111.4 °C/30 mmHg (lit,[18] 60 °C/0.05 mmHg); IR (neat) 1705 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.8—1.8 (13H, m, ($CH_3CH_2)_2N$ and $CH_3CH_2CH_2CH_2$-O), 3.30 (4H,q,($CH_3CH_2)_2N$), and 4.06 (2H, t, $CH_3CH_2CH_2CH_2$-O); MS(70 eV) *m/z* 173(M^+); Calcd for $C_9H_{19}NO_2$: M, 173.

2-Methylpropyl Diethylcarbamate (Isobutyl Diethylcarbamate): bp 73.0—73.8 °C/5.0 mmHg; IR (neat) 1700 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.6—1.3 (12H, m, ($CH_3CH_2)_2N$ and $(CH_3)_2CHCH_2$-O), 1.8 (1H, m, $(CH_3)_2CHCH_2$-O), 3.17 (4H, q, ($CH_3CH_2)_2N$), and 3.70 (2H, d, $(CH_3)_2CHCH_2$-O); Found: C, 62.21; H, 11.00; N, 8.13%; M^+, 173. Calcd for $C_9H_{19}NO_2$: C, 62.39; H, 11.05; N, 8.09%; M, 173.

1-Methylpropyl Diethylcarbamate (*s*-Butyl Diethylcarbamate): bp 67.0—67.3 °C/6.0 mmHg; IR (neat) 1695 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.6—1.9 (14H, m, ($CH_3CH_2)_2N$ and $CH_3CH_2CH(CH_3)$-O), 3.17 (4H, q, ($CH_3CH_2)_2N$), and 4.63 (1H, m, $CH_3CH_2CH(CH_3)$-O); Found: C, 62.41; H, 11.07; N, 8.09%; M^+, 173. Calcd for $C_9H_{19}NO_2$: C, 62.39; H, 11.05; N, 8.09%; M, 173.

1,1-Dimethylethyl Diethylcarbamate (*t*-Butyl Diethylcarbamate): bp 28.4 °C/3.0 mmHg; IR (neat) 1690 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.74 (6H, t, ($CH_3CH_2)_2N$), 1.07 (9H, s, $(CH_3)_3C$-O), and 2.87 (4H, q, ($CH_3CH_2)_2N$); Found: C, 62.32; H, 11.05; N, 8.08%; M^+, 173. Calcd for $C_9H_{19}NO_2$: C, 62.39; H, 11.05; N, 8.09%; M, 173.

† 1 mmHg≈133.322 Pa.

Ethyl Diethylcarbamate: bp 60.8—61.2 °C/13 mmHg (lit,[19] bp 62—63 °C/14 mmHg); IR (neat) 1700 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=1.1 (9H, m, (CH_3CH_2)$_2$N and CH_3CH_2-O), 3.24 (4H, q, (CH_3CH_2)$_2$N), and 4.12 (2H, t, CH_3CH_2-O).

***N*-Ethoxycarbonylpiperidine:** bp 57.7—58.0 °C/1.5 mmHg (lit,[20] bp 55—56 °C/0.9 mmHg); IR (neat) 1705 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.97 (3H, t, CH_3CH_2-O), 1.3 (6H, m, -(CH_2)$_3$-), 3.20 (4H, m, -CH_2NCH_2-), and 3.75 (2H, q, CH_3CH_2-O).

Propyl Diethylcarbamate: bp 58.6—59.0 °C/4.9 mmHg; IR (neat) 1700 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.7—1.4 (9H, m, (CH_3CH_2)$_2$N and $CH_3CH_2CH_2$-O), 1.6 (2H, m, $CH_3CH_2CH_2$-O), 3.27 (4H, q, (CH_3CH_2)$_2$N), and 3.98 (2H, t, $CH_3CH_2CH_2$-O); Found: C, 60.16; H, 10.81; N, 8.57%; M$^+$, 159. Calcd for $C_8H_{17}NO_2$: C, 60.34; H, 10.76; N, 8.79%; M, 159.

***N*-(Propyloxycarbonyl)piperidine:** bp 86.0—86.5 °C/4.4 mmHg; IR (neat) 1695 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.87 (3H, t, $CH_3CH_2CH_2$-O), 1.1—1.9 (8H, m, CH_3CH_2-CH_2-O and -(CH_2)$_3$-), 3.27 (4H, m, -CH_2NCH_2-), and 3.94 (2H, t, $CH_3CH_2CH_2$-O); Found: C, 63.13; H, 10.11; N, 8.09%; M$^+$, 171. Calcd for $C_9H_{17}NO_2$: C, 63.12; H, 10.00; N, 8.17%; M, 171.

Butyl Bis(1-methylethyl)carbamate: bp 55.9—56.9 °C/2.0 mmHg; IR (neat) 1695 cm^{-1} (ester C=O); ^1H NMR ($CDCl_3$) δ=0.6—1.8 (13H, m, ((CH_3)$_2$CH)$_2$N and CH_3CH_2-CH_2CH_2-O), 3.8 (2H, m, ((CH_3)$_2$CH)$_2$N), and 4.00 (2H, t, $CH_3CH_2CH_2CH_2$-O); Found: C, 65.63; H, 11.55; N, 6.96%; M$^+$, 201. Calcd for $C_{11}H_{23}NO_2$: C, 65.63; H, 11.51; N, 6.95%; M, 201.

Benzyl Diethylcarbamate: bp 93.0—94.0 °C/2.0 mmHg; IR (neat) 1700 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.9 (6H, t, (CH_3CH_2)$_2$N), 3.07 (4H, q, (CH_3CH_2)$_2$N), 5.00 (2H, s, $C_6H_5CH_2$-O), and 7.13 (5H, s, $C_6H_5CH_2$-O); Found: C, 69.66; H, 8.35; N, 6.71%; M$^+$, 207. Calcd for $C_{12}H_{17}NO_2$: C, 69.54; H, 8.26; N, 6.76%; M, 207.

1-Methylethyl Diethylcarbamate: bp 44.8—45.4 °C/3.6 mmHg; IR (neat) 1700 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.6-1.5 (12H, m, (CH_3CH_2)$_2$N and (CH_3)$_2$CH-O), 3.13 (4H, q, (CH_3CH_2)$_2$N), and 4.73 (1H, m, (CH_3)$_2$CH-O); Found: C, 60.06; H, 10.75; N, 8.39%; M$^+$, 159. Calcd for $C_8H_{17}NO_2$: C, 60.34; H, 10.76; N, 8.79%; M, 159.

***N*-(1-Methylethoxycarbonyl)piperidine:** bp 61.2—61.4 °C/1.4 mmHg; IR (neat) 1695 cm^{-1} (ester C=O); ^1H NMR ($CDCl_3$) δ=0.8—1.8 (12H, m, (CH_3)$_2$CH-O and -(CH_2)$_3$-), 3.27 (4H, m, -CH_2NCH_2-), and 4.76 (1H, m, (CH_3)$_2$CH-O); Found: C, 63.14; H, 9.98; N, 8.15%; M$^+$, 171. Calcd for $C_9H_{17}NO_2$: C, 63.12; H, 10.00; N, 8.17%; M, 171.

Cyclohexyl Diethylcarbamate: bp 83.1—83.7 °C/1.0 mmHg; IR (neat) 1710 cm^{-1} (ester C=O); ^1H NMR($CDCl_3$) δ=0.6—2.0 (16H, m, (CH_3CH_2)$_2$N and -(CH_2)$_5$-), 3.14 (4H, q, (CH_3CH_2)$_2$N), and 4.50 (1H, m, CH-O); Found: C, 66.23; H, 10.80; N, 7.03%; M$^+$, 199. Calcd for $C_{11}H_{21}NO_2$: C, 66.29; H, 10.62; N, 7.03%; M, 199.

Methylene Bis(propylcarbamate): mp 80.0—81.0 °C; IR (KBr pellet) 1695 cm^{-1} (ester C=O); ^1H NMR ($CDCl_3$) δ=0.85 (6H, m, ($CH_3CH_2CH_2NHCOO$)$_2$), 1.50 (4H, m, (CH_3CH_2-CH_2NHCOO)$_2$), 3.10 (4H, m, ($CH_3CH_2CH_2NHCOO$)$_2$), 5.40 (2H, s, ($CH_3CH_2CH_2NHCOO$)$_2$), and 5.6 (2H, s, O-CH_2-O); Found: C, 49.75; H, 8.52; N, 12.71%. Cacld for $C_9H_{18}N_2O_4$: C, 49.53; H, 8.31; N, 12.84%.

Novel Electron Acceptors Bearing a Heteroquinonoid System. I. Synthesis and Conductive Complexes of 5,5′-Bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene and Related Compounds

Koji YUI, Yoshio ASO, Tetsuo OTSUBO, and Fumio OGURA*
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Saijo, Higashi-Hiroshima 724
(Received September 12, 1988)

Novel electron acceptors bearing a heteroquinonoid system, 5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene, its 3,3′-dichloro, 3,3′-dibromo, and 3,3′,4,4′-tetrabromo derivatives, and 5,5″-bis(dicyanomethylene)-5,5″-dihydro-$\Delta^{2,2':5',2''}$-terthiophene were synthesized by the action of tetracyanoethylene oxide or by Pd(0)-catalyzed substitution reactions with sodium dicyanomethanide on the corresponding α,α'-dihalogeno-heteroaromatics. They showed very small on-site Coulomb repulsion as expected, and afforded several highly conductive molecular complexes with electron donors such as hexamethylenetetratellurafulvalene.

A very large amount of recent work in terms of structural organic chemistry and of material science has been directed toward the design and synthesis of new electron acceptor molecules which can be a potential component of organic electrical conductors. In particular, an excellent acceptor, 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ), giving many conductive charge-transfer complexes, has been widely modified to improve its physical properties up to date.[1] In this current, extension of quinonoid conjugation of TCNQ has been examined to develop new acceptors with smaller on-site Coulomb repulsion in dianion state.[2] Though 13,13,14,14-tetracyanodiphenoquinodimethane (TCNDQ) had attracted considerable interest as one of such candidates, it turned out to be a nonpersistent molecule in neutral state owing to steric repulsion between the biphenylic ortho hydrogens.[3] This was followed by stable isolation of an ethano-bridged derivative of TCNDQ (**1**).[2a] On the other hand, 2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (**2**) has been known as a heteroquinonoid isologue of TCNQ, which was casually synthesized by Gronowitz and Uppström.[4] Though the introduced sulfur atom is expected to act advantageously on the formation of its molecular complexes, **2** has stirred little attention because of its inferior electron-accepting ability and insulating molecular complex formation.[5] Much more extension of quinonoid conjugation in **2** might improve its ability as a component of conductive complex regarding effective diminution of on-site

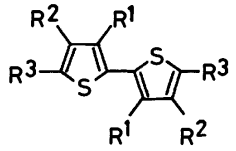
Coulomb repulsion and enlargement of band width. The most expected compounds are 5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (**3a**) and 5,5″-bis(dicyanomethylene)-5,5″-dihydro-$\Delta^{2,2':5',2''}$-terthiophene (**4**). Supposedly, the trans geometry is more preferable for **3a**, because the biphenylic hydrogen repulsion must be advantageously avoided. On the other hand, **4** is a moreover extended homologue of **2**, in which some advanced character involving much smaller on-site Coulomb repulsion and large polarizability is expected.[6] Now we would like to report the syntheses and properties of **3a**, its derivatives with halogeno-substituents (**3b—d**), and **4**. As expected, these acceptors showed very small on-site Coulomb repulsion in their dianion state, and afforded semi- to highly conductive molecular complexes with various electron donors.

Results and Discussion

Synthesis. Gronowitz and Uppström reported that 2,5-dibromothiophene reacted with tetracyanoethylene oxide (TCNEO) in refluxing 1,2-dibromoethane to afford **2** and carbonyldicyanide.[4] At the same time, 2,3,5-tri- and 2,3,4,5-tetrabromothiophenes were formed as minor by-products because the reaction stoichiometrically generated bromine. We have found a similar reaction to be applicable toward bi- and terthiophene systems. 5,5′-Dibromo-2,2′-bithiophene (**5a**)[7] was treated with 0.75 equivalent of TCNEO in



5a : $R^1 = R^2 = H$, $R^3 = Br$
5b : $R^1 = R^3 = Cl$, $R^2 = H$
5c : $R^1 = Br$, $R^2 = R^3 = H$
5d : $R^1 = R^3 = Br$, $R^2 = H$
5e : $R^1 = R^2 = R^3 = Br$

refluxing 1,2-dibromoethane for 8 h to afford **3a** in 42% yield on TCNEO. 3,3′,5,5′-Tetrachloro-2,2′-bithiophene (**5b**) was prepared from one-step treatment of thiophene with sulfuryl chloride and iron powder according to the procedure of Sone et al.[8] In a similar reaction of **5b** and TCNEO, the resulting 3,3′-dichloro-5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (**3b**) was contaminated by further chlorinated one which was caused by chlorine stoichiometrically generated in the reaction, and was difficult to sufficiently purify. This reaction needed to be carried out in the presence of excessive copper(I) chloride as a reducing agent in refluxing 1,3-dibromopropane to obtain pure **3b** in a reasonable yield of 30%. 3,3′,5,5′-Tetrabromo-2,2′-bithiophene (**5d**) was prepared by bromination of 3,3′-dibromo-2,2′-bithiophene (**5c**)[9] (81% yield) or **5a** (90% yield) with NBS in refluxing chloroform–acetic acid (1:1 v/v). When **5d** was treated with an excess of TCNEO in refluxing 1,3-dibromopropane, 3,3′-dibromo-5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (**3c**) was obtained in 27% yield. Treatment of **5a** with an excess of bromine in refluxing carbon disulfide afforded 3,3′,4,4′,5,5′-hexabromo-2,2′-bithiophene (**5e**) in 95% yield. A similar treatment of **5e** with TCNEO gave 3,3′,4,4′-tetrabromo-5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (**3d**) in only 1.5% yield, whereas addition of an excess of copper(I) bromide fairly improved the yield up to 12%.

In the presence of palladium(0) catalyst, a cross coupling reaction[10] between 2,5-dibromothiophene and tributyl(2-thienyl)tin (**7**), which was prepared in 89% yield from 2-thienyllithium and chlorotributyltin, afforded 2,2′:5′,2″-terthiophene (**6a**) in 59% yield as shown in Scheme 1. This procedure is a practical alternative to the reported methods to obtain **6a**.[11,12] The NBS treatment of **6a** in chloroform–acetic acid (1:1 v/v) afforded 5,5″-dibromo-2,2′:5′,2″-terthiophene (**6b**) in 94% yield. The subsequent reaction of **6b** with 0.75 equiv of TCNEO in 1,2-dibromoethane at reflux gave 5,5″-bis(dicyanomethylene)-5,5″-dihydro-$\Delta^{2,2':5',2''}$-terthiophene (**4**) in 11% yield on TCNEO.

Sodium dicyanomethanide prepared in situ from malononitrile and sodium hydride was allowed to react with **5a** and **6b** in refluxing 1,2-dimethoxyethane containing a catalytic amount of tetrakis(triphenylphosphine)palladium(0),[13] followed by oxidation with bromine water, to successfully synthesize **3a** and **4** in 68% and 73% yield, respectively. Scheme 2 illustrates the conversion of **5a** into **3a**.

Nickel(0)-catalyzed coupling reaction[14] of 5-bromo-2,2′-bithiophene (**5f**)[15] gave 2,2′:5′,2″:5″,2‴-quaterthiophene (**8a**) in 87% yield, and its subsequent reaction with NBS afforded 5,5‴-dibromo derivative (**8b**) in 87% yield as shown in Scheme 3. Both TCNEO and malononitrile treatments, however, failed in synthesizing 5,5‴-bis(dicyanomethylene)-5,5‴-dihydro-

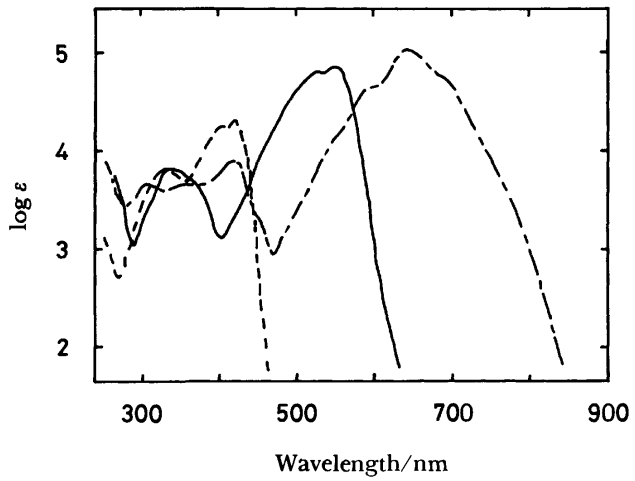

Fig. 1. Electronic spectra of **2** (-------), **3a** (——), and **4** (— — —) in dichloromethane.

$\Delta^{2,2':5',2'':5'',2'''}$-quaterthiophene (**9**).

Structure. The electronic spectra of **2**, **3a**, and **4** are shown in Fig. 1. These spectra strikingly resemble each other in shape, and their absorption maxima in the visible region are bathochromically shifted largely with extending their conjugation systems (**2**: $\lambda_{max}(\varepsilon)$ 330(6400), 400(18000), 421(20300); **3a**: 343(7000), 525 (65700), 550(73100); **4**: 304(4710), 358(4530), 415(7640), 643(106000) nm), suggesting nearly planar quinonoid structures in these molecules. Although TCNDQ is too unstable to isolate as mentioned before,[3] **3a—d** and **4** are extremely stable compounds whose decomposition points are not observed below 300 °C. These facts are attributable to trans geometry of these molecules, being capable of avoiding steric repulsion between hydrogen or halogen atoms at 3,3'-position.

Table 1 shows electrical conductivities of these acceptors (**3a—d** and **4**) on a compressed pellet together with those of **2** and TCNQ. It is very interesting that **3a—d** and **4** are all highly conductive for a pellet sample of a neutral organic compound in contrast to much lower conductivities of **2** and TCNQ, and reminicent of the most conductive, neutral organic compound, tetrakis(methyltelluro)tetrathiafulvalene.[16] This is realized as an increase of the intermolecular interactions due to extension of their heteroquinonoid conjugation.

Table 1. Conductivities of Acceptors

Acceptor	Conductivity[a]/S cm^{-1}
2	$<10^{-11}$
3a	1.2×10^{-6}
3b	4.9×10^{-7}
3c	2.7×10^{-6}
3d	6.9×10^{-5}
4	1.7×10^{-6}
TCNQ	8.1×10^{-10}

a) Measured on compressed pellets with a two-probe method at RT.

Table 2. Half-Wave Reduction Potentials[a]

Acceptor	$E^1_{1/2}$	$E^2_{1/2}$	ΔE/V
2	0.07	−0.54	0.61
3a	−0.03	−0.26	0.23
3b	0.18	−0.06	0.24
3c	0.20	0.03	0.17
3d	0.28	0.13	0.15
4	−0.03	−0.03	0
TCNQ	0.25	−0.47	0.72

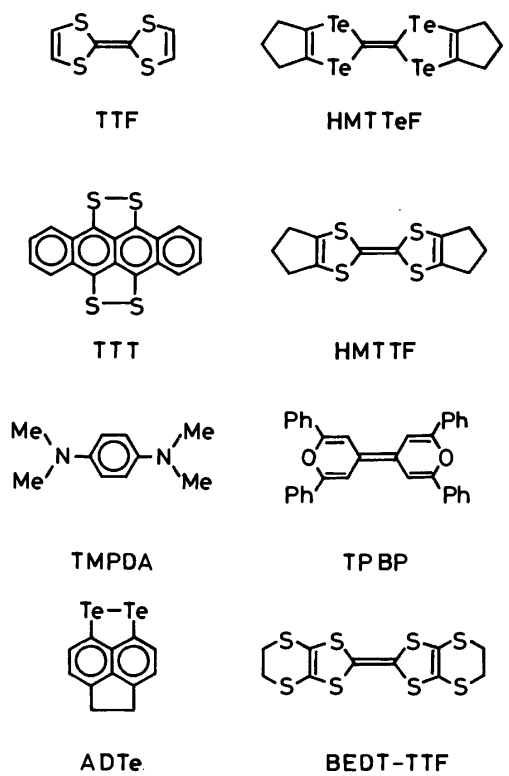
a) Cyclic voltammetry was carried out at RT in dichloromethane containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate using Ag/AgCl as a reference electrode and platinum as a working electrode at a scan rate of 100 mV s^{-1}.

Redox Property. The redox behavior of acceptors **3a—d** and **4** was determined by cyclic voltammetry in dichloromethane. Table 2 summarizes their half-wave reduction potentials together with those of **2** and TCNQ. All **3a—d** show two pairs of reversible redox waves. The first half-wave potential ($E^1_{1/2}$) of **3a** is lower than that of **2**, indicating a smaller electron affinity of **3a**. However, since its second one ($E^2_{1/2}$) is higher, the difference (ΔE) between $E^1_{1/2}$ and $E^2_{1/2}$ becomes smaller. This unambiguously demonstrates much more diminution of on-site Coulomb repulsion in the dianion state of **3a**. Acceptor **4** shows almost the same $E^1_{1/2}$ value as **3a** does. It is remarkable that its

second wave coalesces into its first one as if its on-site Coulomb repulsion were minimized.

The electron-withdrawing halogen substituents of **3b** and **3c** can actually increase the weak electron-accepting ability of parent **3a**, resulting in the $E^1_{1/2}$ values comparable to that of TCNQ. The additional 5,5′-dibromo substituents of **3d**, however, do not so much raise its $E^1_{1/2}$ as its 3,3′-dibromo substituents. Compounds **3b—d** also show very small ΔE values. Both large electron affinity and quite small on-site Coulomb repulsion thus allow **3b—d** to behave as superior electron acceptors.

Molecular Complex. These acceptors did form molecular complexes with electron donors such as tetrathiafulvalene (TTF), tetrathiotetracene (TTT), hexamethylenetetrathiafulvalene (HMTTF), tetramethylphenylenediamine (TMPDA), tetraphenylbipyranylidene (TPBP), hexamethylenetetratellurafulvalene (HMTTeF), 5,6-dihydroacenaphtho[5,6-*cd*]-1,2-ditellurole (ADTe), and bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF). Table 3 summarizes physical properties of the isolated complexes.



Acceptor **2** gave no crystalline complexes with typical donors such as TTT, TMPDA, HMTTF, ADTe, and BEDT-TTF because of its weak accepting ability. It, however, formed nearly insulating 1:1 complexes with TTF and HMTTeF. The TTF and HMTTeF complexes carry no charge transfer, as indicated by no shift in wavenumber of the nitrile stretching vibration absorption (ν_{CN}) in the IR spectra on complexation.[17] On the other hand, **2** formed a highly conductive 1:1 complex with a stronger donor TPBP. A considerable lower wavenumber shift of ν_{CN} (2184 cm^{-1}) of the complex than that (2222 cm^{-1}) of neutral **2** clearly indicates the existence of certain charge transfer, which might be related to its high conductivity.

Acceptor **3a** gave 1:1 complexes with TTF and TTT. These complexes are little ionic on the basis of ν_{CN} nearly comparable to that (2220 cm^{-1}) of **3a** but semiconductive. Acceptor **4** complexed TTF, TTT, TPBP, and HMTTeF. The stoichiometry of these complexes except TTT complex is rich in acceptor. Their ν_{CN} values, referring to that (2213 cm^{-1}) of **4**, indicate no charge transfer in the TTF and HMTTeF complexes and some charge transfer in the TTT and TPBP complexes. Their conductivities are, however, close to metallic, regardless of degree of the charge transfers. Comparison of three TTF complexes of **2**, **3a**, and **4**, though they are all nonionic, demonstrates a marked increase in conductivity in order of the extensive acceptor. These results strongly support that the diminished on-site Coulomb repulsion of the extensive conjugated acceptor makes a significant contribution to the formation of conductive molecular complexes.

Acceptors **3b—d**, further endowed by stronger electron-accepting abilities, could form complexes with all the given donors. However, complexation of **3b** with ADTe and of **3d** with BEDT-TTF failed. Most of complexes obtained were very highly conductive. In particular, marvelously high conductivity of 170 S cm^{-1} was observed for **3b**·HMTTeF in a compressed pellet state.

Conclusion

The accepting ability of 2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (**2**) was successfully improved by

Table 3. Molecular Complexes of **2**, **3a—d**, and **4**

a) Obtained from chlorobenzene unless otherwise described. b) Calculated as stoichiometry indicated for the complex. c) Measured with a KBr disk method unless otherwise mentioned. d) Decomposition point. e) Measured on compressed pellets at RT with a four-probe method unless otherwise described. f) Obtained from acetonitrile. g) Measured on compressed pellets with a two-probe method at RT. h) Obtained from benzonitrile. i) Measured with a Nujol mull method.

introduction of both extensive heteroquinonoid conjugation and electron-withdrawing substituents. For compounds **3a** and **4** the extensive conjugation was very effective for diminution of on-site Coulomb repulsion, which is a requisite for designing conductive molecular complexes. In addition, it was proved that compounds **3b—d** possessing both small on-site Coulomb repulsion and large electron affinity are reliable electron acceptors for forming a variety of very high conductive molecular complexes.

Experimental

General. Melting points are uncorrected. All solvents are of reagent grade. Elemental analyses were measured by Mr. Hideaki Iwatani, Microanalytical Laboratory in Department of Applied Chemistry, Faculty of Engineering, Hiroshima University. Electron donors used to prepare the molecular complexes, TTF,[18] TTT,[19] HMTTF,[20] TPBP,[21] BEDT-TTF,[22] and ADTe[23] were obtained according to the published procedures except commercially available TMPDA and HMTTeF. NMR spectra were recorded on a JEOL PMX-60 spectrometer (60 MHz) using tetramethylsilane as an internal standard. IR spectra were taken on a Hitachi 260-30 or Perkin-Elmer 1600 FTIR spectrophotometer with a nujol mull or a KBr disk method. MS spectra were measured on a Shimadzu GC-MS QP-1000A Mass spectrometer at 70 eV using a direct insertion technique. Electronic absorption spectra were recorded on a Shimadzu UV-160 spectrophotometer. Cyclic voltammetry was carried out on a Hokuto Denko HA-301 potentiostat and a Hokuto Denko HB-104 function generator.

5,5′-Bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (3a). A) Using TCNEO. A mixture of **5a** (324 mg, 1.00 mmol) and TCNEO (216 mg, 1.50 mmol) in dry 1,2-dibromoethane (15 cm^3) was heated under reflux for 8 h, and the solution was diluted with carbon tetrachloride (60 cm^3) at 0 °C. The resulting precipitate was collected by filtration and purified by column chromatography on silica-gel with dichloromethane, followed by recrystallization from acetonitrile, giving **3a** as deep violet fine needles (92 mg, 42% yield on TCNEO): mp>300 °C; IR (KBr) 2220 (CN), 1525, 1500 (C=C) cm^{-1}; MS *m/z* 292 (M^+, 100%); Anal. ($C_{14}H_4N_4S_2$) C, H, N.

B) Using Sodium Dicyanomethanide. Malononitrile (156 mg, 2.40 mmol) was added to an ice-cooled suspension of sodium hydride (192 mg, 60% oily, 4.80 mmol) in 1,2-dimethoxyethane (8 cm^3) under nitrogen atmosphere, and the mixture was stirred at RT for 20 min. To this solution were added **5a** (324 mg, 1.00 mmol) and tetrakis(triphenylphosphine)palladium(0) (156 mg, 0.100 mmol), and the mixture was heated under reflux for 4 h. The reaction mixture was treated with saturated bromine water (30 cm^3) at 0 °C and diluted with cold water (50 cm^3). The resulting precipitate was collected by filtration on Hyflo Super-Cel, Soxhlet-extracted with dichloromethane, concentrated in vacuo, and recrystallized from chlorobenzene to give **3a** (199 mg, 68%).

3,3′-Dichloro-5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (3b). A mixture of **5b** (2.43 g, 8.00 mmol), TCNEO (11.5 g, 80.0 mmol), and copper(I) chloride (5.54 g, 56.0 mmol) in dry 1,3-dibromopropane (130 cm^3) was heated under reflux for 6 h. The solution was twice column-chromatographed on silica gel with dichloromethane, followed by recrystallization from acetonitrile to give **3b** as deep violet fine crystals (880 mg, 30%): mp>300 °C; IR (KBr) 2217 (CN), 1503 (C=C) cm^{-1}; MS *m/z* 360 (M^+, 100%); Anal. ($C_{14}Cl_2H_2N_4S_2$) C, H, N.

3,3′,5,5′-Tetrabromo-2,2′-bithiophene (5d). A) From 3,3′-Dibromo-2,2′-bithiophene (5c). A mixture of **5c** (1.30 g, 4.00 mmol) and NBS (1.50 g, 8.43 mmol) in chloroform–acetic acid (8 cm^3, 1:1 v/v) was heated under reflux for 5 h. The resulting solution was poured into water and extracted with chloroform. The organic layer was washed with 5% sodium hydrogencarbonate aqueous solution and water, and dried on anhydrous magnesium sulfate. After concentration in vacuo, the residual solid was recrystallized from chloroform–hexane to give **5d** as colorless prisms (1.57 g, 81%): mp 138.5—140.5 °C (lit,[24] 139—140 °C); ^1H NMR ($CDCl_3$) δ= 6.97 (s).

B) From 5a. NBS (392 mg, 2.20 mmol) was added to a solution of **5a** (324 mg, 1.00 mmol) in chloroform–acetic acid (9 cm^3, 1:1 v/v), and the mixture was heated under gentle reflux for 3 d. The solution was poured into water, and extracted with chloroform. The organic layer was worked up in the same way as described in Method A to give **5d** (436 mg, 90%).

3,3′-Dibromo-5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (3c). A mixture of **5d** (120 mg, 0.25 mmol) and TCNEO (288 mg, 2.00 mmol) in dry 1,3-dibromopropane (3 cm^3) was heated under reflux for 2 h. The mixture was twice column-chromatographed on silica gel with dichloromethane, followed by recrystallization from acetonitrile to give **3c** as deep violet fine needles (31 mg, 27%): mp>300 °C; IR (KBr) 2224 (CN), 1510, 1495 (C=C) cm^{-1}; MS *m/z* 450 (M^+, 100%); Anal. ($C_{14}Br_2H_2N_4S_2$) C, H, N.

3,3′,4,4′,5,5′-Hexabromo-2,2′-bithiophene (5e). A mixture of **5a** (648 mg, 2.00 mmol), carbon disulfide (25 cm^3), and bromine (3.3 cm^3, 64 mmol) was heated under gentle reflux for 26 h. To this mixture was carefully added a saturated sodium hydrogensulfite aqueous solution (50 cm^3), and the mixture was vigorously stirred for several min. The resulting precipitate was collected by filtration, washed with water and methanol, and dried in vacuo. The organic layer of the filtrate was washed with 5% sodium hydrogencarbonate aqueous solution and water, and dried on anhydrous magnesium sulfate. After concentration in vacuo, the residual solid was combined with the above collected precipitate and recrystallized from chlorobenzene to give **5e** as colorless needles (1.21 g, 95%): mp 262—264 °C (lit,[25] 257—258 °C).

3,3′,4,4′-Tetrabromo-5,5′-bis(dicyanomethylene)-5,5′-dihydro-$\Delta^{2,2'}$-bithiophene (3d). A mixture of **5e** (128 mg, 0.200 mmol), TCNEO (576 mg, 4.00 mmol), and copper(I) bromide (201 mg, 1.40 mmol) in dry 1,3-dibromopropane (5 cm^3) was heated under reflux for 6 h. The solution was column-chromatographed on silica gel with chloroform, followed by recrystallization from chloroform to give **3d** as deep violet fine needles (15 mg, 12%): mp>300 °C; IR (KBr) 2217 (CN), 1500 (C=C) cm^{-1}; MS *m/z* 608 (M^+, 100%); Anal. ($C_{14}Br_4N_4S_2$) C, H, N.

Tributyl(2-thienyl)tin (7). Butyllithium (94 cm^3, 0.15 mol, 1.6 mol dm^{-3} hexane solution) was added to a solution

of thiophene (12.6 g, 0.150 mol) in THF (120 cm³) at 0 °C under nitrogen atmosphere, and the mixture was stirred at 50 °C for 30 min. To this solution was added chlorotributyltin (51.3 g, 0.150 mol, 95% purity) at 0 °C. The resulting suspension was stirred overnight at RT, concentrated, and filtered. The filtrate was distilled in vacuo to give **7** as colorless liquid (50.1 g, 89%): bp 118—125 °C/0.22 mmHg (lit,[26] 150 °C/1 mmHg; 1 mmHg≈133.322 Pa); ^{1}H NMR (CCl_4) δ=0.5—2.3 (m, 27H), 6.9—7.3 (m, 2H), 7.3—7.6 (m, 1H).

2,2′:5′,2″-Terthiophene (6a). A solution of **7** (48.5 g, 130 mmol), 2,5-dibromothiophene (14.5 g, 60.0 mmol), and tetrakis(triphenylphosphine)palladium(0) (3.47 g, 3.00 mmol) in toluene (200 cm³) was heated at reflux for 18 h under nitrogen atmosphere. The reaction mixture was concentrated in vacuo and chromatographed on silica gel with hexane, followed by recrystallization from hexane to give **6a** as pale yellow plates (8.77 g, 59%): mp 89—91 °C (lit,[27] 94—95 °C); ^{1}H NMR ($CDCl_3$) δ=6.9—7.2 (m); Anal. ($C_{12}H_8S_3$) C, H.

5,5″-Dibromo-2,2′:5′,2″-terthiophene (6b). NBS (11.9 g, 66.7 mmol) was portionwise added to a solution of **6a** (8.28 g, 33.3 mmol) in chloroform-acetic acid (1:1 v/v) at RT. The resulting suspension was suirred for an additional hour and then at 50—60 °C for 30 min. Precipitated solid was collected by filtration. The filtrate was successively washed with water, 5% sodium hydrogencarbonate aqueous solution, and again water, and dried on anhydrous magnesium sulfate. After concentration in vacuo, the residual solid was combined with the above precipitate and recrystallized from hexane-chloroform to give **6b** as yellow needles (12.7 g, 94%): mp 158—158.5 °C (lit,[28] 160—161 °C); ^{1}H NMR (CS_2) δ=6.86 (s, 2H), 6.84 (d, J=3.7 Hz, 2H), 6.78 (d, J=3.7 Hz, 2H).

5,5″-Bis(dicyanomethylene)-5,5″-dihydro-$\Delta^{2,2':5',2''}$-terthiophene (4). A) Using TCNEO. A mixture of **6b** (406 mg, 1.00 mmol) and TCNEO (216 mg, 1.50 mmol) in dry 1,2-dibromoethane (16 cm³) was heated under reflux for 2 h. The solution was twice column-chromatographed on silica gel with dichloromethane to give **4** (32 mg, 11% yield on TCNEO): deep green powder from chlorobenzene, mp> 300 °C; IR (KBr) 2213 (CN), 1480 (C=C) cm^{-1}; Found: m/z 374.0294. Calcd for $C_{18}H_6N_4S_3$: M, 373.9755.

B) Using Sodium Dicyanomethanide. Under a nitrogen stream, malononitrile (312 mg, 4.80 mmol) was added to an ice-cooled suspension of sodium hydride (384 mg, 9.60 mmol, 60% oily) in 1,2-dimethoxyethane (24 cm³), and the mixture was stirred at RT for 20 min. To this suspension were added **6b** (812 mg, 2.00 mmol) and tetrakis(triphenylphosphine)palladium(0) (312 mg, 0.200 mmol). The mixture was heated under reflux for 4 h, and treated with saturated bromine water (40 cm³). After dilution with cold water (20 cm³), the resulting precipitate was collected by filtration on Hyflo Super-Cel, and Soxhlet-extracted with dichloromethane, followed by recrystallization from chlorobenzene to give **4** (546 mg, 73%).

2,2′:5′,2″:5″,2‴-Quaterthiophene (8a). A mixture of zinc powder (785 mg, 12.0 mmol), bis(triphenylphosphine)nickel(II) chloride (393 mg, 0.600 mmol), and tetrabutylammonium iodide (2.22 g, 6.00 mmol) in THF (15 cm³) was stirred at RT under nitrogen atmosphere for 30 min. To the resulting reddish brown solution was added a solution of **5f** in THF (5 cm³), and the solution was stirred at 50 °C for 2 h. After addition of water, precipitated solid was collected by filtration, and column-chromatographed on silica gel with carbon disulfide, followed by recrystallization from chloroform to give **8a** as yellow leaflets (867 mg, 87%): mp 216.5—218 °C (lit,[12] 211—212 °C).

5,5‴-Dibromo-2,2′:5′,2″:5″,2‴-quaterthiophene (8b). NBS (911 mg, 5.12 mmol) was added to a solution of **8a** in carbon disulfide-chloroform-acetic acid (270 cm³, 2:5:2 v/v), and the mixture was heated under gentle reflux for an hour. After cooling to 0 °C, the resulting precipitate was collected by filtration, washed with methanol, and dried. The filtrate was successively washed with water, 5% sodium hydroxide aqueous solution, and water, and dried over anhydrous magnesium sulfate. After concentration in vacuo, the residual solid was combined with the above precipitate, and recrystallized from chlorobenzene to give **8b** as orange leaflets (1.09 g, 87%): mp 260—263 °C (lit,[24] 248 °C).

Preparation of Molecular Complexes. All molecular complexes described in this report were prepared by mixing the two hot saturated solutions of donor and acceptor in chlorobenzene, acetonitrile, or benzonitrile. The resulting complexes precipitated out immediately or on cooling appropriately, which were collected by filtration and dried in vacuo.

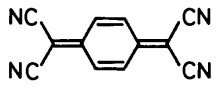
(Received November 19, 1988)

Novel heteroquinonoid compounds as potential electron acceptors, 2,5-bis(dicyanomethylene)-2,5-dihydrothieno[3,2-*b*]thiophene (**4a**), 3,6-dibromo derivative, 2,6-bis(dicyanomethylene)-2,6-dihydrodithieno[3,2-*b*:2′,3′-*d*]thiophene, 3,5-dibromo derivative, and 4,4-dioxide were synthesized by the action of tetracyanoethylene oxide or by a Pd(0)-catalyzed substitution reaction with sodium dicyanomethanide on the corresponding α,α′-dihalo-substituted fused thiophenes. They show effectively diminished on-site Coulomb repulsion owing to the extensive conjugation, and most of their molecular complexes with various electron donors exhibit very high electrical conductivities up to metallic region. In addition, X-ray crystallographic analysis of the complex of **4a** with bis(ethylenedithio)tetrathiafulvalene has elucidated that sulfur atoms embedded in **4a** molecule are capable of inducing a significant intermolecular interaction, forming a sheet-like network structure.

Intermolecular interactions of heteroatoms often play an important role on molecular assemblies. In particular, interstack contacts of chalcogen atoms in the cation radical salts of two organic electron donors, tetramethyltetraselenafulvalene and bis(ethylenedithio)-tetrathiafulvalene (BEDT-TTF), served to suppress typical Peierls-type insulating transitions, leading to the discovery of first organic superconductors.[1] On the other hand, similar multi-dimensionality based on chalcogen atoms has been designed for electron acceptors. Yamashita's and Kobayashi's groups have independently examined the condensation effect of heterocyclic rings on an excellent electron acceptor, 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ).[2] Our previous work has developed novel electron acceptors (**1**, its derivatives, and **2**) as extensively conjugated



TCNQ

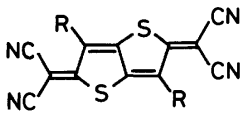
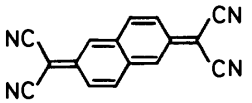
3

homologues of 2,5-bis(dicyanomethylene)-2,5-dihydrothiophene (**3**).[3] These acceptors have advantages of inducing not only increasing intermolecular interactions due to the sulfur atoms embedded in the quinonoid system but also very small on-site Coulomb repulsion due to the extensive conjugation, accordingly forming highly conductive molecular complexes.

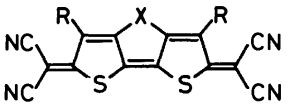
Our present aim is to study condensed homologues of **3** as another potential acceptors. 2,5-Bis(dicyanomethylene)-2,5-dihydrothieno[3,2-*b*]thiophene (**4a**) is



4a : R = H
4b : R = Br



TNAP

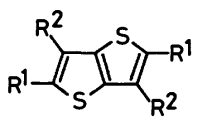


5a : X = S, R = H
5b : X = S, R = Br
5c : X = $-S(O_2)-$, R = H
5d : X = $-S(O)-$, R = H

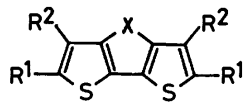
the first molecule of the series and isoelectronic with 11,11,12,12-tetracyano-2,6-naphthoquinodimethane (TNAP), which has better accepting properties, that is, smaller on-site Coulomb repulsion, larger electron affinity, and higher polarizability than TCNQ.[4] A benzenoid compound corresponding to 2,6-bis(dicyanomethylene)-2,6-dihydrodithieno[3,2-*b*:2′,3′-*d*]thiophene (**5a**) is hitherto unknown. Now we wish to report the syntheses of **4a** and **5a** and their conductive molecular complexes as well as those of **4b** and **5b—c**.[5] In addition, the crystal structure of **4a**·BEDT-TTF complex is described, in which the sulfur atoms embedded in the quinonoid conjugation system are capable of inducing a significant intermolecular interaction.[6]

Results and Discussion

Synthesis. *Gronowitz reaction* which refers to a conversion of 2,5-dihalogenothiophene into **3** by a pyrolytic reaction with tetracyanoethylene oxide (TCNEO)[7] was successfully applicable toward bi- and terthiophene systems to synthesize the corresponding heteroquinonoid compounds **1** and **2**.[5] We found that a similar procedure was equally well-applicable toward fused thieno- and dithienothiophene systems. 2,5-Dibromothieno[3,2-*b*]thiophene (**6a**) was treated with an excess of TCNEO at 167 °C of refluxing 1,3-dibromopropane for 2 h to afford **4a** in 36% yield. When accomplished at 131 °C of refluxing 1,2-dibromoethane as done in the synthesis of **1**, **2**, and **3**, the reaction proceeded very slowly and resulted in a lower yield (23%) of **4a**. On the other hand, Gronowitz reaction of 2,6-dibromodithieno[3,2-*b*:2′,3′-*d*]thiophene (**7a**) in refluxing 1,2-dibromoethane for 1.5 h simply produced a 39% yield of **5a**.



6a : $R^1 = Br$, $R^2 = H$
6b : $R^1 = R^2 = Br$
6c : $R^1 = R^2 = H$



7a : $X = S$, $R^1 = Br$, $R^2 = H$
7b : $X = S$, $R^1 = R^2 = Br$
7c : $X = -S^{O_2}-$, $R^1 = Br$, $R^2 = H$
7d : $X = -S^{O}-$, $R^1 = Br$, $R^2 = H$

2,3,5,6-Tetrabromothieno[3,2-*b*]thiophene (**6b**) and 2,3,6,7-tetrabromodithieno[3,2-*b*:2′,3′-*d*]thiophene (**7b**) were prepared in 87% and 94% yields by the treatment of thieno[3,2-*b*]thiophene (**6c**) and **7a**, respectively with a large excess of bromine in refluxing carbon disulfide. These tetrabromides **6b** and **7b** were allowed to react with TCNEO in refluxing 1,3-dibromopropane containing an excess of copper(I) bromide to afford 3,6-dibromo-2,5-bis(dicyanomethylene)-2,5-dihydrothieno[3,2-*b*]thiophene (**4b**) in 40% yield and 3,5-dibromo-2,6-bis(dicyanomethylene)-2,6-dihydrodithieno-[3,2-*b*:2′,3′-*d*]thiophene (**5b**) in 27% yield, respectively.

Oxidation of **7a** with 2 equiv of *m*-chloroperbenzoic acid (MCPBA) in refluxing dichloromethane gave 2,6-dibromodithieno[3,2-*b*:2′,3′-*d*]thiophene 4,4-dioxide (**7c**) in 46% yield. The subsequent Gronowitz reaction of this sulfone **7c** in refluxing 1,3-dibromopropane afforded 2,6-bis(dicyanomethylene)-2,6-dihydrodithieno-[3,2-*b*:2′,3′-*d*]thiophene 4,4-dioxide (**5c**) in 34% yield. When **7a** was oxidized with 1.2 equivalent of MCPBA at 0 °C, 2,6-dibromodithieno[3,2-*b*:2′,3′-*d*]thiophene 4-oxide (**7d**) was obtained as a major product in 46% yield together with **7c** (25%). In contrast to the above sulfone, TCNEO treatment of sulfoxide **7d** did not afford the corresponding heteroquinonoid acceptor **5d** but **5a** in 26% yield. The mechanism of this deoxygenation remains unclarified yet.

An alternative reaction used to synthesize **1** and **2** is nucleophilic substitution reaction of the precursory dibromides by sodium dicyanomethanide in refluxing 1,2-dimethoxyethane containing a catalytic amount of tetrakis(triphenylphosphine)palladium(0), followed by oxidation with bromine water. Scheme 1 shows a similar sequence of preparing **5a** in overall yield of 78%, whereas this procedure failed to synthesize **4a**, **5c**, and **5d**.

Redox Property. The redox behavior of acceptors **4a**, **b** and **5a—c** was determined by cyclic voltammetry in dichloromethane. Table 1 summarizes their half-wave reduction potentials together with those of **3** and TCNQ. All of these acceptors show two pairs of reversible redox waves. The first half-wave potentials ($E^1_{1/2}$) of **4a** and **5a** are comparable to that of **3**, indicating that the extension of heteroquinonoid skelton *in a condensed manner* is not capable of improving the electron accepting ability of **3**. As shown in Fig. 1, the longest wavelength maxima in the electronic absorption spectra of **3**, **4a**, and **5a** are bathochromically shifted largely with extending the conjugation system (**3**: $\lambda_{max}(\varepsilon)$ 330 (6400), 400 (18000), and 421 (20300); **4a**: 444 (66400) and 470 (71000); **5a**: 263

Table 1. Half-Wave Reduction Potentials[a]

Acceptor	$E^1_{1/2}$	$E^2_{1/2}$	ΔE/V
4a	0.06	−0.36	0.42
4b	0.25	−0.13	0.38

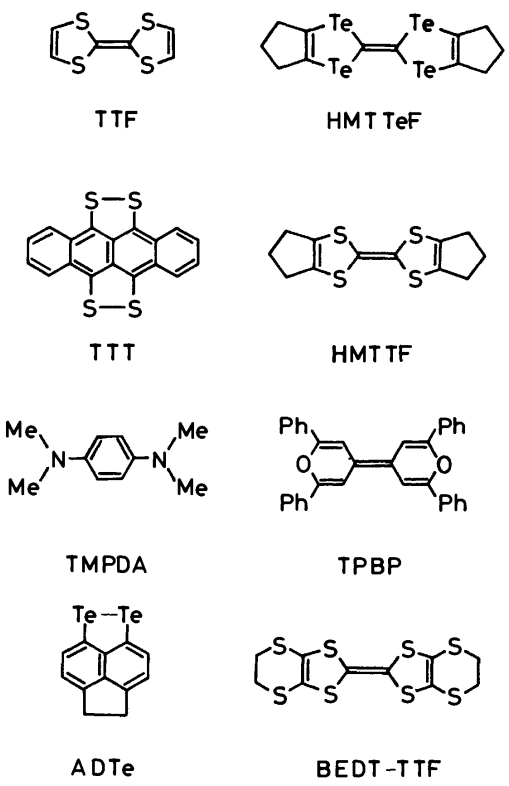
5c	5.5×10^{-8}
3	$<10^{-11}$
TCNQ	8.1×10^{-10}

a) Measured on compressed pellets with a two-probe method at RT.

almost insulating behavior of **3**, being probably due to an increasing intermolecular contacts of the present extensive systems.

Charge-Transfer Salts. These acceptors did form a variety of molecular complexes with known electron donors such as tetrathiafulvalene (TTF), 5,6:11,12-bis(dithio)naphthacene (so-called tetrathiotetracene, TTT), bis(trimethylene)tetrathiafulvalene (HMTTF), *N,N,N′,N′*-tetramethylphenylenediamine (TMPDA), tetraphenylbipyranylidene (TPBP), bis(trimethylene)-tetratellurafulvalene (HMTTeF), 5,6-dihydroacenaphtho[5,6-*cd*]-1,2-ditellurole (ADTe), and BEDT-TTF. They are mostly of 1:1 stoichiometry, but some are of 2:1 rich in either donor or acceptor and include a solvent used for complexation. Table 3 summarizes the physical properties of these isolated complexes.



Acceptors **1**, **2**, and **3** formed CT complexes only with strong electron donors such as TTF, TTT, HMTTeF, and TPBP, and the conductivities of the resulting complexes increased with the extensive conjugation of the acceptor.[5,8] On the other hand, **4a**, having the almost same accepting ability as **1**—**3**, formed complexes with all the other donors except ADTe. In this regard, **3a** of a condensed conjugated type is superior to acceptors **1** and **2** of a linear conjugated type. Moreover, most of the complexes showed very high electrical conductivities as measured on a compressed pellet at room temperature. In particular, the HMTTeF complex recorded the highest value of 140 S cm^{-1}. The BEDT-TTF and TTT complexes, however, exhibited exceptionally low

(9270), 315 (3000), 511 (60300), and 549 (59800) nm). These facts imply that such an extension does not lower the π-LUMO level of the heteroquinonoid acceptors but raises π-HOMO level, so that the energy gap between their HOMO and LUMO decreases in the order of the extensive acceptors. The differences (ΔE) between $E^1_{1/2}$ and $E^2_{1/2}$ values decrease as the quinonoid conjugation extend. This demonstrates that such an extension certainly cotributes to diminution of on-site Coulomb repulsion in dianion state. This effect, however, is not so conspicuous as that of the extension *in a linear manner* seen in molecule **1**, in which ΔE value is down to 0.23 V.[5]

Two bromo substituents on **4b** and **5b** fairly enhance the electron-accepting power. The dibromide **4b**, as a result, is as strong an acceptor as TCNQ. The ΔE values of **4b** and **5b** are also diminished.

The accepting ability of **5a** is markedly strengthened by the conversion into the dioxide **5c** whose $E^1_{1/2}$ value is higher than that of TCNQ. The ΔE value of **5c**, however, becomes a little larger than that of **5a**, indicating that the sulfonation is not available for diminution of on-site Coulomb repulsion.

Table 2 shows electrical conductivities on pellet samples of neutral organic compounds. All new acceptors are relatively conductive in contrast to

a) Obtained from chlorobenzene, which is abbreviated as CB when contained in the complex, unless otherwise described. b) Calculated as stoichiometry indicated for the complex. c) Measured with a KBr disk method unless otherwise mentioned. d) Decomposition point. e) Measured on compressed pellets at RT with a four-probe method unless otherwise described. f) Obtained from acetonitrile. g) Measured on compressed pellets with a two-probe method at RT. h) Obtained from benzonitrile. i) Measured with a Nujol mull method. j) Composition was not estimated by an elemental analysis of C, H, and N.

conductivities. The case of the BEDT-TTF complex is probably because of lack of charge transfer due to the weak electron-donating ability of BEDT-TTF, as indicated by no shift of the CN frequency of the complex relative to neutral **4a** (2223 cm^{-1}).[9] The case of the TTT complex may be ascribed to the formation of a Mot insulator due to the poor fit of a strong donor TTT to **4a**. Acceptor **4b** complexed all the given donors except TPBP. The resulting complexes, except the BEDT-TTF complex, had also very high conductivities including a marverously high value 170 S cm^{-1} of the HMTTeF complex for a pellet sample. It may be furthermore noted as a result of the elevated electron affinity of **4b** that the TTT, TMPDA,and BEDT-TTF complexes are considerably more conductive than the corresponding ones of **4a**. A similar but somewhat different situation is the case for more fused heteroquinonoid system **5**. Acceptor **5a** thus formed complexes with only four strong donors, TTF, TTT, TPBP, and HMTTeF, and its dibromo derivative **5b** with all the given donors. The latter complexes are generally more conductive than the former ones. On the other hand, sulfone acceptor **5c**, though the strongest of the present acceptors, complexed only just the same strong donors as did **5a**. In addition, the conductivities of **5c** complexes are not so high as those of the corresponding **5b** complexes. The sterical bulkiness of the sulfone moiety is realized to interfere crystallization with a conductive molecular arrangement on complexation.

Acceptors **4a**, **5a**, and **5c** were reduced with sodium iodide, potassium iodide, and tetrabutylammonium iodide to form the corresponding anion radical salts. The physical properties of these salts are also summarized in Table 3. Some of these salts are found to have mixed valences in the acceptor because of nonstoichiometric composition, and accordingly they show higher conductivities than the other salts with 1:1 composition.

a) $B_{eq}=(4/3)\sum_{ij}\beta_{ij}(a_i\cdot a_j)$.

Molecular and Crystal Structure of 4a·BEDT-TTF Complex. An X-ray crystallographic analysis was undertaken to elucidate the function of the embedded sulfur atoms in the crystal structures of the present complexes. Most of the complexes, however, appeared as fine crystals or powders. Only the molecular complex of **4a** with BEDT-TTF gave a good single crystal being suitable for the analysis. The crystal is triclinic with space group $P\bar{1}$, the unit cell contains one donor and one acceptor, and each component is present on the crystallographic inversion center. Table 4 summarizes the final atomic parameters.

Figure 2 illustrates the molecular geometries of both components. Acceptor **4a** takes a planar conformation; the largest deviation from the least squares plane is 0.057 Å for the sulfur atoms. On the other hand, the

structure of the BEDT-TTF molecule closely resembles those found in various cation radical salts of BEDT-TTF;[10] the TTF moiety keeps a planar conformation within 0.03 Å deviation and the terminal ethylene groups appreciably deviate from the optimal plane. The bond lengths of the TTF skelton can be used to estimate roughly the degree of charge transfer, ρ.[11] Table 5 shows a comparison of the present complex with neutral BEDT-TTF molecule[12] as a standard of $\rho=0$ and a cation radical salt α-(BEDT-TTF)$_2$PF$_6$[11] with $\rho=0.5$. The central C=C bond length (a) of the complex is between those of the neutral species and the salt, but the other C=C bond length (d) and C-S bond length (b and c) are quite identical to the corresponding ones of the neutral species. This indicates the degree of charge transfer in the present complex to be almost nil, as already judged from the examination of the nitrile stretching frequency.

Figure 3 shows the crystal structure viewed along the c axis (the transverse projection of the molecules) and along the orthogonal axis (the longitudinal projection of the molecules). The segregate stacking columns of both components are observed along the a axis, which is nearly perpendicular to the molecular planes, but the interplanar distances are as long as the unit length

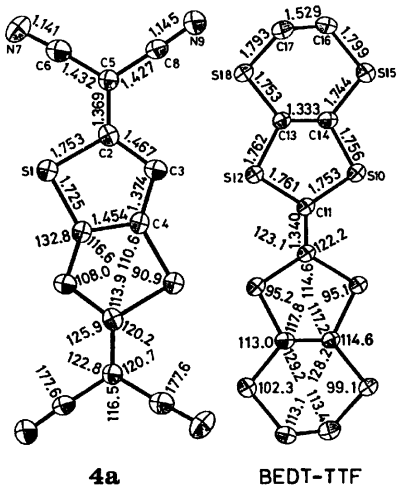

Fig. 2. Bond lengths and bond angles of **4a** and BEDT-TTF in this complex. Estimated standard deviations are 0.005—0.011 Å and 0.3—0.6° for lengths and angles, respectively.

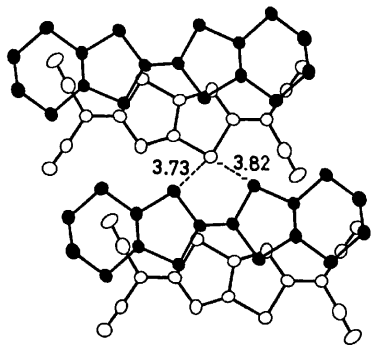

Fig. 4. The mode of the molecular overlap. The view direction is perpendicular to the molecular plane.

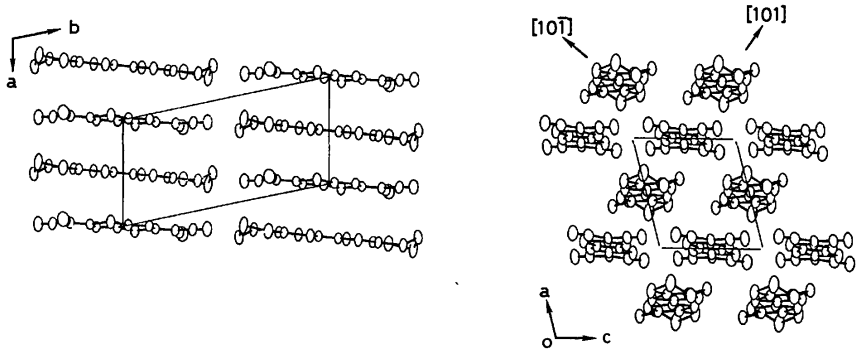

Fig. 3. Crystal structures viewed (a) along c axis and (b) approximately along the long axis of the molecule.

Table 5. A Comparison of the Mean Bond Lengths (Å) of BEDT-TTF

Compound	ρ	a	b	c	d

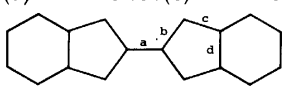
Present complex	ca. 0	1.340(9)	1.757(6)	1.759(5)	1.333(8)



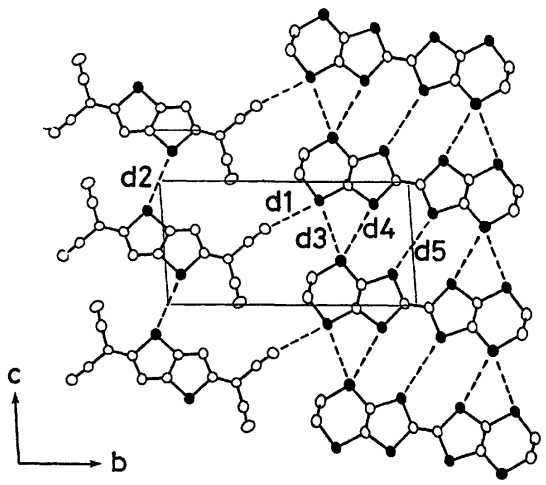


Fig. 5. Sheet-like net works in the $(2\bar{1}0)$ plane. Some of short contacts: d1=3.33, d2=3.48, d3=3.64, d4=3.59, and d5=3.98 Å.

(7.205 Å) of the a axis. On the other hand, an alternate stacking arrangement is observed with a little face-to-face overlap along [101] or [10$\bar{1}$] direction, as illustrated in Fig. 4.

The intermolecular S···S contact distances (3.73 and 3.82 Å) between the alternately stacked components are slightly longer than the sum of van der Waals radius (3.70 Å). On the other hand, several short intermolecular contacts exist in $(2\bar{1}0)$ plane, as shown in Fig. 5. The two components are separately arranged side by side along the transverse direction and alternately along the longitudinal direction, constituting a sheet-like network. In accordance with the structural features of various BEDT-TTF salts[10,11] and neutral BEDT-TTF,[12] the sulfur atoms of the ethylenedithio moiety in BEDT-TTF component play an important role on this side-by-side arrangement, that is, they strongly interact with the same kind of atom (3.64 Å) and the sulfur atoms (3.59 Å) of the 1,3-dithiole ring of the neighboring BEDT-TTF. In addition, they interact with the nitrogen atom of the acceptor with van der Waals contact (3.33 Å). On the other hand, there is no van der Waals contact between the sulfur atoms of the 1,3-dithiole rings (3.98 Å). Figure 5 also demonstrates that there exists a strong S···S interaction between the acceptors (3.48 Å). This indicates that the sulfur atoms embedded in the quinonoid conjugation system are capable of inducing multi-dimensionality in molecular complexes.

Conclusion

Novel compounds **4a**, **b** and **5a—c** of a fused conjugated type have been found to be superior electron acceptors with very small on-site Coulomb repulsion. They formed a variety of molecular complexes with π-electron donors, most of which exhibited high conductivities up to metallic bound. In particular, the HMTTeF complexes of **4a** and **4b** recorded 140 and 170 S cm^{-1}, respectively, marverously high for a pellet measurement at room temperature. The X-ray crystallographic analysis of **4a**·BEDT-TTF complex has elucidated that sulfur atoms embedded in the quinonoid conjugation contribute to intermolecular interactions in the crystal structure. Thus the present fused heteroquinonoid compounds are promising electron acceptors to design multi-dimensional organic metals directed towards a superconductor.

Experimental

General. Melting points are uncorrected. All solvents are of reagent grade. Electron donors used to prepare the molecular complexes, TTF,[13] TTT,[14] HMTTF,[15] TPBP,[16] BEDT-TTF,[17] and ADTe[18] were obtained according to the published procedures except commercially available TMPDA and HMTTeF. NMR spectra were recorded on a JEOL PMX-60 spectrometer (60 MHz) using tetramethylsilane as an internal standard. IR spectra were taken on a Hitachi 260-30 or a Perkin-Elmer 1600 FTIR spectrophotometer with a Nujol mull or a KBr disk method. MS spectra were measured on a Shimadzu GC-MS QP-1000A Mass spectrometer at 70 eV using a direct insertion technique. Electronic absorption spectra were recorded on a Shimadzu UV-160 spectrophotometer. Cyclic voltammetry was carried out on a Hokuto Denko HA-301 potentiostat and a Hokuto Denko HB-104 function generator.

2,5-Bis(dicyanomethylene)-2,5-dihydrothieno[3,2-*b*]thiophene (4a). A mixture of **6a**[19] (838 mg, 2.81 mmol), TCNEO (1.61 g, 11.2 mmol), and dry 1,3-dibromopropane (21 cm^3) was heated under reflux for 2 h. The resulting solution was twice column-chromatographed on silica gel with dichloromethane, followed by recrystallization from acetonitrile to give **4a** (268 mg, 36%) as reddish brown needles: mp>300 °C; IR (KBr) 2223 (CN) and 1508 (C=C) cm^{-1}; MS *m/z* 266 (M^+, 100%); Anal. ($C_{12}H_2N_4S_2$) C, H, N.

2,3,5,6-Tetrabromothieno[3,2-*b*]thiophene (6b). A solution of bromine (2.4 cm^3, 49 mmol) in carbon disulfide (3 cm^3) was dropwise added to a solution of **6c** (200 mg, 1.43 mmol) in carbon disulfide (5 cm^3), and the mixture was heated under gentle reflux for 23 h. To the resulting suspension was carefully added a saturated sodium hydrogensulfite aqueous solution. The precipitated solid was collected by filtration, washed with water and ethanol, and dried in vacuo. The organic layer of the filtrate was washed with brine, 5% sodium hydrogencarbonate aqueous solution, and again brine, and dried over anhydrous magnesium sulfate. After concentration in vacuo, the residual solid was combined with the above precipitate, and recrystallized from benzene to give **6b** (567 mg, 87%) as colorless needles: mp 237—238.5 °C (in a sealed tube); Anal. ($C_6Br_4S_2$) C.

3,6-Dibromo-2,5-bis(dicyanomethylene)-2,5-dihydrothieno-[3,2-*b*]thiophene (4b). A mixture of **6b** (1.60 g, 3.50 mmol), TCNEO (5.04 g, 35.0 mmol), copper(I) bromide (3.51 g, 24.5 mmol), and dry 1,3-dibromopropane (70 cm^3) was heated under reflux for 4 h. The mixture was column-chromatographed on silica gel with dichloromethane, followed by recrystallization from chlorobenzene to give **4b** (627 mg, 40%) as purple micro prisms: mp>300 °C; IR (KBr) 2224 (CN) and 1508 (C=C) cm^{-1}; MS *m/z* 422 (M^+−2, 53%), 424 (M^+, 100%),

and 426 (M^++2, 56%); Anal. ($C_{12}Br_2N_4S_2$) C, N.

2,6-Bis(dicyanomethylene)-2,6-dihydrodithieno[3,2-*b*:2′,3′-*d*]thiophene (5a). A) Using TCNEO. A mixture of **7a** (354 mg, 1.00 mmol),[20] TCNEO (576 mg, 4.00 mmol), and dry 1,2-dibromoethane (16 cm³) was heated under reflux for 1.5 h. The mixture was column-chromatographed on silica gel with dichloromethane, followed by recrystallization from acetonitrile to give **5a** (125 mg, 39%) as deep violet fine crystals: mp>300 °C; IR (KBr) 2219 (CN) and 1496 (C=C) cm^{-1}; MS *m/z* 322 (M^+, 100%); Anal. ($C_{14}H_2N_4S_3$) C, H, N.

B) Using Sodium Dicyanomethanide. Malononitrile (79 mg, 1.2 mmol) was added to an ice-cooled suspension of sodium hydride (96 mg, 2.4 mmol, 60% oily) in absolute 1,2-dimethoxyethane (4 cm³) under nitrogen stream, and the mixture was stirred at RT for 20 min. To this solution was added **7a** (142 mg, 0.40 mmol) and tetrakis(triphenylphosphine)palladium(0) (46 mg, 0.04 mmol), and the mixture was heated under reflux for 2 h. The resulting solution was treated with saturated bromine water (15 cm³) at 0 °C, and filtered on Hyflo Super-cel. The collected solid was extracted with boiling chlorobenzene, and recrystallized from chlorobenzene to give **5a** (101 mg, 78%).

2,3,6,7-Tetrabromodithieno[3,2-*b*:2′,3′-*d*]thiophene (7b). Bromine (2.1 cm³, 41.2 mmol) was added to a solution of **7a** (1.91 g, 5.39 mmol) in carbon disulfide (40 cm³), and the solution was heated at gentle reflux for 24 h. The solution was carefully treated with 10% sodium hydrogensulfite aqueous solution, and diluted with hexane. The resulting precipitate was collected by filtration, washed thoroughly with water and methanol, dried in vacuo, and recrystallized from chlorobenzene to give **7b** (2.59 g, 94%) as off-white leaflets: mp>300 °C; Anal. ($C_8Br_4S_3$) C.

3,5-Dibromo-2,6-bis(dicyanomethylene)-2,6-dihydrodithieno-[3,2-*b*:2′,3′-*d*]thiophene (5b). A mixture of **7b** (2.10 g, 4.10 mmol), TCNEO (5.91 g, 41.0 mmol), copper(I) bromide (4.12 g, 28.7 mmol), and dry 1,3-dibromopropane (120 cm³) was heated under reflux for 1.2 h. The reaction mixture was column-chromatographed on silica gel with dichloromethane, and recrystallized from chlorobenzene to give **5b** (530 mg, 27%) as deep green prisms: mp>300 °C; IR (KBr) 2221 (CN) and 1490 (C=C) cm^{-1}; MS *m/z* 478 (M^+−2, 50%), 480 (M^+, 100%), and 482 (M^++2, 62%); Anal. ($C_{14}Br_2N_4S_3$) C, N.

2,6-Dibromodithieno[3,2-*b*:2′,3′-*d*]thiophene 4,4-Dioxide (7c). MCPBA (216 mg, 1.00 mmol, 80% purity) was added to a solution of **7a** (177 mg, 0.500 mmol) in dichloromethane (15 cm³), and the mixture was heated under gentle reflux for 2 d. The reaction mixture was poured into a concentrated sodium hydrogensulfite aqueous solution, and extracted with dichloromethane. The organic layer was washed with 5% sodium hydrogencarbonate aqueous solution and water, and dried over anhydrous magnesium sulfate. After concentration in vacuo, the residue was purified by column chromatography on silica gel with dichloromethane to give **7c** (90 mg, 47%): yellow prisms from chloroform; mp 248 °C (decomp); IR (KBr) 1348, 1303, 1282, 1154, 1132 (SO_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.21 (s); Anal. ($C_8H_2Br_2O_2S_3$) C, H.

2,6-Bis(dicyanomethylene)-2,6-dihydrodithieno[3,2-*b*:2′,3′-*d*]thiophene 4,4-Dioxide (5c). A mixture of **7c** (1.47 g, 3.81 mmol), TCNEO (5.49 g, 38.1 mmol), and dry 1,3-dibromopropane (50 cm³) was heated under reflux for 5 h. The reaction mixture was twice column-chromatographed on silica gel with dichloromethane–acetone (96:4 v/v), and recrystallized from acetonitrile to give **5c** (462 mg, 34%) as deep violet prisms: mp>300 °C; IR (KBr) 2222 (CN) and 1510 (C=C), 1343, 1323, 1172 (SO_2) cm^{-1}; MS *m/z* 354 (M^+, 100%); Anal. ($C_{14}H_2N_4O_2S_3$) C, H, N.

2,6-Dibromodithieno[3,2-*b*:2′,3′-*d*]thiophene 4-Oxide (7d). MCPBA (517 mg, 2.40 mmol, 80% purity) was added to a solution of **7a** (708 mg, 2.00 mmol) in chloroform (26 cm³) at 0 °C. The mixture was stirred at 0 °C for 9 h and at RT for 4 h, poured into 10% sodium hydrogensulfite aqueous solution, and extracted with chloroform. The organic layer was washed with 5% sodium hydrogencarbonate aqueous solution and water, and dried over anhydrous magnesium sulfate. After concentration in vacuo, the residue was column-chromatographed on silica gel with chloroform to give **7c** (190 mg, 25%) and **7d** (340 mg, 46%): yellow crystals from hexane–chloroform; mp 172.5—174 °C; IR (KBr) 1052 (SO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.34 (s); Anal. ($C_8H_2Br_2OS_3$) C, H.

Reaction of 7d with TCNEO. A mixture of **7d** (143 mg, 0.386 mmol), TCNEO (556 mg, 3.86 mmol), and dry 1,3-dibromopropane (7 cm³) was heated under reflux for 2 h. The reaction mixture was worked up according to the procedure of Method A described in the synthesis of **5a**, and the yield was 26%.

Preparation of Molecular Complexes and Anion Radical Salts. All molecular complexes described in this report were each prepared by mixing saturated solutions of donor and acceptor in hot chlorobenzene, acetonitrile, or benzonitrile. All anion radical salts were obtained by the reaction of the acceptors with the corresponding metal iodide or tetrabutylammonium iodide in hot acetonitrile or benzonitrile. The complexes or salts precipitated out immediately or on cooling appropriately, and were collected by filtration and dried in vacuo.

Crystal Structure Analysis of 3a·BEDT-TTF. The intensities of X-ray diffractions were collected with a Rigaku automated diffractometer using Cu $K\alpha$ radiation monochromatized with a graphite plate. We obtained 1969 independent diffractions within 2θ=126° which had intensities larger than the statistical counting error, and used all of them for analysis. The dimension of the measured crystal was 0.50×0.40×0.01 mm³. The crystal belonged to the triclinic system with the space group, $P\bar{1}$, crystal data being a=7.205(1), b=13.654(1), c=6.898(2) Å, α=91.76(1), β=103.85-(2), γ=101.32(1)°, Z=1, and V=643.9(2) Å³, D_{obs}=1.626, and D_{calcd}=1.679 g cm^{-3}. The structure was solved by the direct method combined with the Monte-Carlo method[21] for the selection of the initial set of phase. It was refined by the full-matrix least squares method after applying the absorption corrections.[22] Atomic scattering factors were taken from International Tables for X-ray Crystallography.[23] Anisotropic temperature factors were used for the refinement, and hydrogen atoms were not included in the refinement. The final R value was 0.073. Computations were carried out partly at the Information Processing Center of Hiroshima University and mainly at the Computation Center of Nagoya University using the library program of CRYSTAN system. Tables of structure factors and anisotropic thermal parameters are deposited as Document No. 8869 at the Office of the Editor of Bull. Chem. Soc. Jpn.

This work was partially supported by Grants-in-Aid for Scientific research Nos. 62550635 and 63604576 from the Ministry of Education, Science and Culture. The authors wish to thank Mr. Hideaki Iwatani, Hiroshima University, for elemental analysis.

Topochemical Photopolymerization and Photo-Copolymerization of the Crystals of Unsymmetrically Substituted Diolefin Compounds Having Pyrimidine Ring

Masaki HASEGAWA,* Yasuhiro ENDO, Masato AOYAMA, and Kazuhiko SAIGO
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 27, 1988)

Several new diolefin compounds, methyl and ethyl 4-[2-(4-pyrimidyl)ethenyl]cinnamates (**1a** and **1b**), and methyl, ethyl, and propyl α-cyano-4-[2-(4-pyrimidyl)ethenyl]cinnamates (**1c**, **1d**, and **1e**) were synthesized, and their photoreactivity in the crystalline state was investigated. The crystals of **1c**, **1d**, and **1e** gave amorphous oligomers having cyclobutane skeletons (average degree of polymerization was approximately 10) through the [2+2] photocycloaddition. The dimers (**2c**, **2d**, and **2e**) were formed in high yields by the exclusive photoexcitation of the monomers. The dimers were isolated by column chromatography. The cyclobutane structure of **2c** and **2d** was β-type homo adduct whereas that of **2e** was β-type hetero adduct. As only one type of adduct was detected for each crystal, photodimerization was interpreted as being of a crystal lattice controlled process. The conversions of these reactions were not as high as that of the reaction in α-type of 2,5-distyrylpyrazine (DSP). The lower conversion was interpreted as being due to alternative reacting sites which inevitably result from the β-type molecular packing and to the drastic displacement of molecules which causes the distortion of crystal lattice. The mixed crystals (**1f**) of **1d** and **1e** (molar ratio 1.3/1), of which the X-ray diffraction pattern is similar to that of **1e**, photopolymerized to give amorphous cooligomers (average degree of polymerization was approximately 5). The reaction went through an intermediate similar to dimer **2e**.

In previous studies we have demonstrated that the topochemical reactivity of various types of diolefin compounds and the configuration of their photoproducts were accurately predictable from the molecular arrangements of these crystals.[1]

Although the correlation between chemical and crystal structures of organic compounds is very sophisticated, it is obvious that the interaction between electron-donating and -accepting groups in the molecule contributes greatly to determining their crystal structure. From recent results of studies on the photochemical behavior of several unsymmetrically substituted diolefinic crystals, we have revealed that pyridyl, cyano and carbonyl groups were the electron-accepting groups which are potent in affording the photoreactive α-type crystal packing.[2] In a preceeding report, we have reported that the unsymmetrically substituted diolefin monomer crystals which have a pyrazine ring produce extremely high molecular weight of crystalline linear polymers.[3]

As the pyrimidine ring is also expected to induce much stronger donor–acceptor interactions with benzene rings, in our present work, we synthesized several new diolefin compounds having pyrimidine rings, as is represented in Scheme 1, and investigated the photochemical behaviors of these crystals. Furthermore, we attempted to prepare several mixed crystals, and investigated these crystals from the point of view of topochemical photo-copolymerization.

Results and Discussion

The photoreactivity of **1a,b** (alkyl 4-[2-(4-pyrimidyl)ethenyl]cinnamates) and **1c—e** (alkyl α-cyano-4-[2-(4-pyrimidyl)ethenyl]cinnamates) in crystalline state was checked by methods 1 and 2 (see Experimental section).

From the results, it was found that three monomer crystals, **1c—e**, were highly photoreactive and gave the products through [2+2] cycloaddition. On the other hand, the crystal of **1a** was photostable and that of **1b** gave intractable cross-linked photoproducts.

Following the photoreaction of **1c—e**, IR spectra of the products showed the decrease in the absorptions due to olefin bonds and the shift to higher wavenumbers of the absorptions of the carbonyl and cyano groups. ^{1}H NMR spectra of the photoproducts also showed the disappearance of olefin protons in the monomer and the appearance of cyclobutane protons. These spectral evidences indicate that the photoreaction is a [2+2] photocyclopolymerization.

The photoproducts after 24 h irradiation were amorphous white-brown powders. From gel permeation chromatogram (GPC) (eluent: *N,N*-demethylformamide), the photoproducts were found to consist of the dimer (**2**) and the oligomers (**3**) of which the average degree of polymerization was about 10.

In order to clarify the structure of the products, isolation of dimers was attempted.

For the purpose of depressing the photoexcitation of the terminal olefins in the oligomers which reduces the polymerization, the crystalline **1c—e** were irradiated through an optical filter which cuts off the shorter

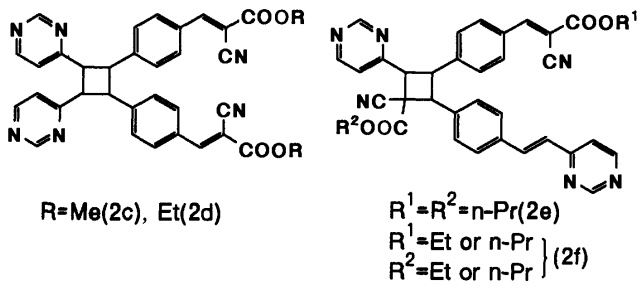
wavelengths.

The irradiation using L38 filter (cut off <350 nm) for **1c** and **1e**, and using L40 filter (cut off <380 nm) for **1d**, respectively, resulted in the accumulation of a great amount (≈90%) of the dimers.

The photoproducts from **1c** and **1d** consisted mostly (≈90%) of the dimer retaining crystallinity whereas the products from **1e** were amorphous. The dimers (**2c—e**) were isolated from the photoproducts and purified by flash column chromatography.

^{1}H NMR and mass analyses revealed that **2c** and **2d** had head-to-head homo adduct type cyclobutane structures, in which two 2-(4-pyrimidyl)ethenyl groups are neighboring, and that **2e** had head-to-head hetero adduct type, in which 2-(4-pyrimidyl)ethenyl and α-cyanocinnamate groups are neighboring to each other, as shown in Scheme 2.

Since only a single structure of the dimers was detected, it was concluded that the photoreaction of **1c—e** crystals proceeded, at least at the photocyclodimerization stage, under the strict control of the monomer crystal lattice.



Scheme 2.

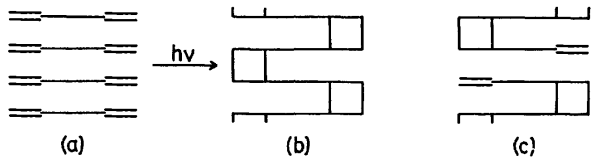


Fig. 1. Schematic illustration of the photopolymerization of (a) β-type crystals of diolefin compounds into (b) zigzag polymers and (c) termination resulting from alternative reactivity of the monomer.

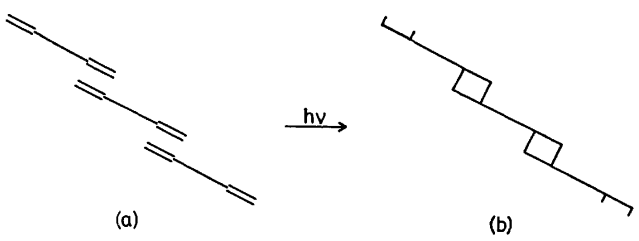

Fig. 2. Schematic illustration of photopolymerization of (a) α-type crystal of diolefin compounds into (b) a linear polymer.

The remarkable change of the dimer skeleton from **1d** to **1e** should doubtlessly correspond to the change of relative orientation of reacting olefins. IR, DSC (differential scanning calorimetry), and PAS (photoacoustic spectra) analyses of the **1d** and **1e** crystals, however, revealed no evident difference between these two crystal structures.

The structures of **2c—e** suggest that the crystals of **1c—e** consist of β-type packing monomers (Fig. 1a), and that the final oligomers are of a zigzag type (Fig. 1b).

In the case of α-type crystals two reacting olefin groups are related with a center of symmetry as is illustrated in the crystals of α-DSP. Therefore, one olefin can react only with one olefin of the neighboring molecule, and the center of gravity of the reacting monomer scarcely moves. These topochemical conditions make possible the α-type crystals to produce linear crystalline polymers of high molecular weight (Fig. 2). On the other hand, such a high crystalline polymer with a high conversion (almost quantitative) has not resulted from the photoreaction of β-type diolefin crystals, not only in the present results but in some of our previous works.[3,4]

The low degree of polymerization with an incomplete conversion (≈85%) and the lack of crystallinity of the photoproducts from β-type crystals can be explained by the following two reasons.

The first reason is that if we assume all olefins are in the same topochemical environment there are four possible reactive sites of the [2+2] photodimerization for each photoexcited molecule in a typical β-type packing crystal. This may cause the termination of further chain growth of the polymer by some probabilities as schemed in Fig. 1c. The second is that with the formation of cyclobutane a large displacement of the reacting molecules may occur to result in serious distortion of crystal lattice. Such a large displacement may make the reacting crystal to be amorphous at latter stages of the photoreaction. In contrast to β-type crystals, the extremely clean-cut photoreaction of the α-type crystals has been interpreted in terms of "seesaw" mechanism,[5] in which the reacting monomer rotates around its center of gravity, that scarcely moves.

In view of the molecular arrangements, the β-type packing is not explicable by electrostatic interactions which seem to be effective in α-type packing. The π-π orbital interaction of facing pyrimidine and benzene rings and/or N–N interaction may contribute to the formation of β-type packings.

It is of great interest to extend the study of a topochemical [2+2] photopolymerization into that of the photocopolymerization. Although there have been a few preliminary reports on the formation of mixed diolefin crystals,[6,7] none of them described [2+2] topochemical copolymerization. In our present work

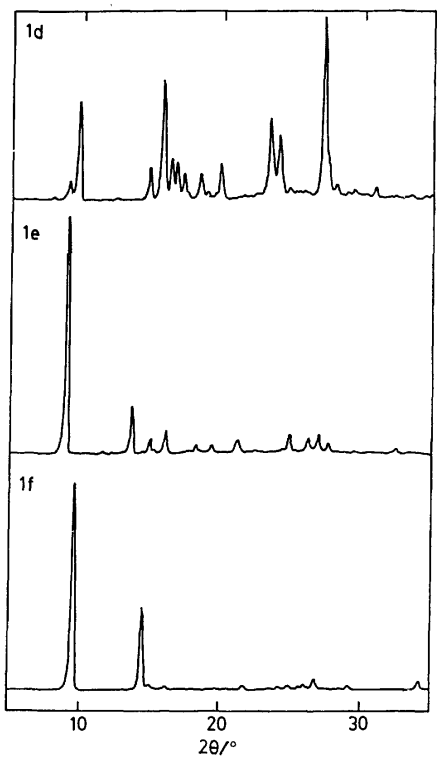

Fig. 3. X-Ray diffraction patterns of the crystals of **1d** (upper), **1e** (middle), and **1f** (lower).

after several attempts a well-defined mixed crystal consisting of two derivatives **1d** and **1e** was successfuly prepared, as was expected from their similar chemical structures. However, no other mixed crystals were obtained from any other combination of the monomers.

A mixed crystal of **1d** and **1e** (molar ratio 1.3:1, **1f**) was obtained by recrystallization from a 1-propanol solution containing an equimolar amount of the two monomers. **1f** had a melting point (160.0—165.0 °C) which is intermediate between those of **1d** (mp 184.0—185.0 °C) and **1e** (mp 149.5—151.0 °C), and showed almost the same X-ray diffraction pattern as that of **1e**, suggesting nearly the same crystal structure (Fig. 3).

The photoirradiation of **1f** for 24 h with a 100 W high-pressure mercury lamp gave amorphous co-oligomers, which had an average polymerization degree of about 5. Structure of the dimer isolated (**2f**) was proved to be head-to-head hetero adduct by mass analysis (Scheme 2), which is the same as that of **2e**, as was expected from the X-ray diffraction pattern of **1f**.

These results indicate that **1d** is included in the crystal lattice of **1e** as isomorphous and that the mixed crystal behaved analogously to **1e**, to afford the head-to-head hetero zigzag type co-oligomers on photoirradiation.

In spite of the electrostatic interaction between electron donating groups of the molecule (benzene ring) and one of the accepting groups (pyrimidine ring, carbonyl, and cyano groups in present crystals), the π-π orbital interaction of facing benzene and pyrimidine rings and/or N-N interaction is considered to contribute to the formation of the β-type stacking.

Experimental

Measurements. Infrared spectra were recorded on a JASCO IR-810 spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL PMX-60SI spectrophotometer or a JEOL GX-400 spectrometer. X-Ray diffraction pattern was recorded on a Rigaku Rotaflex RU-200 spectrometer (λ=1.54184 Å). Melting points were determined by a Laboratory Devices MEL-TEMP and are uncorrected. Gel permeation chromatography (GPC) of the photoproducts was performed at 40 °C on a Shodex (GPC AD 800/P+AD 805/S+AD 803/S+AD 802/S) column (DMF solution).

Preparation of Monomers. 4-[2-(4-Pyrimidyl)ethenyl]-benzaldehyde. Terephthalaldehyde (9.2 g, 69 mmol) was dissolved in a mixed solvent of acetic anhydride (24 ml) and acetic acid (16 ml) at 70 °C. 4-Methylpyrimidine (5.0 g) was added to the solution and refluxed for 4 h. After cooling to room temperature, 50 ml of benzene was added and extracted with 100 ml of 1 mol l^{-1} hydrochloric acid three times, followed by neutralization by 2 mol l^{-1} sodium hydroxide. The precipitates were collected by filtration and dried under reduced pressure. The solid mass was purified by flash column chromatography (Wako gel C-300, eluent: dichloromethane:methanol=99.5:0.5 (v/v)), followed by recrystallization from benzene-hexane. 3.6 g of 4-[2-(4-Pyrimidyl)-ethenyl]benzaldehyde was obtained. Yield 33%; mp 162.0—163.5 (benzene-hexane); IR (KBr) 2850, 1700, 1600, 1390, 1310, 1210, 970, 800 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=10.04 (1H, s, formyl), 9.21 (1H, d, J=1.5 Hz, pyrimidyl), 8.74 (1H, d, J=5.2 Hz, pyrimidyl), 7.96 (1H, d, J=15.6 Hz, olefin), 7.93 (2H, d, J=8.2 Hz, phenylene), 7.76 (2H, d, J=8.2 Hz, phenylene), 7.35 (1H, dd, J=1.5 and 5.2 Hz, pyrimidyl), 7.19 (1H, d, J=15.6 Hz); UV (99.5% CH_2Cl_2): 325 (ε=35000). Found: C, 74.12; H, 4.79; N, 13.31%. Calcd for $C_{13}H_{10}N_2O$: C, 74.27; H, 4.79; N, 13.32%.

4-[2-(4-Pyrimidyl)ethenyl]cinnamic Acid. To a solution of 4-[2-(4-pyrimidyl)ethenyl]benzaldehyde (1.00 g, 4.8 mmol) in 25 ml of pyridine were added malonic acid (1.98 g, 19.0 mmol) and piperidine (0.1 ml), and the solution was stirred for 13 h at 90 °C. After cooling to room temperature, 50 ml of 2 mol l^{-1} hydrochloric acid was added. The precipitates were collected and dried under reduced pressure, and recrystallized from *N,N*-dimethylformamide. 4-[2-(4-Pyrimidyl)ethenyl]cinnamic acid (0.63 g) was obtained as the complex with DMF. The final crystals, containing about 10% molar ratio of DMF, were supplied to the following esterification procedure.

Alkyl 4-[2-(4-Pyrimidyl)ethenyl]cinnamates (1a and 1b). To a suspension of the complex of 4-[2-(4-pyrimidyl)-ethenyl]cinnamic acid with DMF (0.180 g) in methanol (40 ml) was added concentrated sulfuric acid (1.0 ml), and the mixture was refluxed for 3 h to give a homogeneous solution. After cooling to room temperature, the solution was filtered to remove unreacted acid, and the filtrate was neutralized by 1 mol l^{-1} aqueous sodium hydroxide and extracted with dichloromethane. After evaporation of the

solvent, the residue was recrystallized from methanol. 0.091 g of **1a** was obtained. Mp 159.0—160.5 °C (methanol); IR (KBr) 1710, 1580, 1310, 990 cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.19 (1H, d, J=1.5 Hz, pyrimidyl), 8.70 (1H, d, J=5.5 Hz, pyrimidyl), 7.89 (1H, d, J=15.9 Hz, olefin), 7.70 (1H, d, J=16.2 Hz, olefin), 7.62 (2H, d, J=8.2 Hz, phenylene), 7.56 (2H, d, J=8.2 Hz, phenylene), 7.32 (1H, dd, J=1.5 and 5.5 Hz, pyrimidyl), 7.10 (1H, d, J=15.9 Hz, olefin), 6.48 (1H, d, J=16.2 Hz, olefin), 3.82 (3H, s, methyl); UV (99.5% CH_2Cl_2) 343 (ε=46700). Found: C, 71.88; H, 5.24; N, 10.52%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.15; H, 5.31; N, 10.52%.

In a similar manner, 0.150 g of the same complex was esterified with ethanol to give 0.064 g of **1b**. Mp 106.0—108.0 °C (ethanol); IR (KBr) 1720, 1640 ,1210, 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.18 (1H, d, J=1.2 Hz, pyrimidyl), 8.70 (1H, d, J=5.2 Hz, pyrimidyl), 7.89 (1H, d, J=16.2 Hz, olefin), 7.68 (1H, d, J=15.9 Hz, olefin), 7.62 (2H, d, J=8.5 Hz, phenylene), 7.56 (2H, d, J=8.5 Hz, phenylene), 7.32 (1H, dd, J=1.2 and 5.2 Hz, pyrimidyl), 7.10 (1H, d, J=16.2 Hz, olefin), 6.48 (1H, d, J=15.9 Hz, olefin), 4.28 (2H, q, J=7.0 Hz, methylene), 1.35 (3H, t, J=7.0 Hz, methyl); UV (99.5% CH_2Cl_2) 343 (ε=34400). Found: C, 72.54; H, 5.77; N, 10.04%. Calcd for $C_{17}H_{16}N_2O_2$: C, 72.83; H, 5.76; N, 9.99%.

Alkyl α-Cyano-4-[2-(4-pyrimidyl)ethenyl]cinnamates) (1c, 1d, and 1e). To a solution of 4-[2-(4-pyrimidyl)ethenyl]-benzaldehyde (1.99 g, 9.4 mmol) in 200 ml of methanol were addedmethyl cyanoacetate (1.21 g, 12.2 mmol) and piperidine (0.1 ml), and the mixture was refluxed for 7 h. The yellow precipitates appeared during the reaction. After cooling, the precipitates were collected by filtration, and recrystallized from methanol to give 1.23 g of **1c**. Yield 72%; mp 223.0—225.0 °C; IR (KBr) 2210, 1740, 1600, 1290, 990 cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.21 (1H, d, J=1.5 Hz, pyrimidyl), 8.74 (1H, d, J=5.5 Hz, pyrimidyl), 8.26 (1H, s, olefin), 8.05 (2H, d, J=15.9 Hz, phenylene), 7.93 (1H, d, J=15.9 Hz, olefin), 7.72 (2H, d, J=8.6 Hz, phenylene), 7.36 (1H, dd, J=1.5 and 5.5 Hz, pyrimidyl), 7.19 (1H, d, J=15.9 Hz, olefin), 3.95 (3H, s, methyl); UV (99.5% CH_2Cl_2) 360 (ε=65900). Found: C, 70.24; H, 4.46; N, 14.33%. Calcd for $C_{17}H_{13}N_3O_2$: C, 70.10; H, 4.47; N, 14.43%.

Similar condensations of 4-[2-(4-pyrimidyl)ethenyl]benzaldehyde with ethyl and propyl cyanoacetate gave **1d** and **1e** in 83% and 71% yield, respectively.

1d. Mp 184.0—185.0 °C (ethanol); IR (KBr) 2220, 1710, 1590, 1270, 970 cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.21 (1H, d, J=1.2 Hz, pyrimidyl), 8.74 (1H, d, J=5.2 Hz), 8.24 (1H, s, olefin), 8.05 (2H, d, J=8.5 Hz, phenylene), 7.93 (1H, d, J=16.0 Hz, olefin), 7.72 (2H, d, J=8.5 Hz, phenylene), 7.36 (1H, dd, J=1.2 and 5.2 Hz, pyrimidyl), 7.19 (1H, d, J=16.0 Hz, olefin), 4.40 (2H, q, J=7.3 Hz, methylene), 1.41 (3H, t, J=7.3 Hz, methyl); UV (99.5% CH_2Cl_2) 359 (ε=43200). Found: C, 70.55; H, 4.84; N, 13.75%. Calcd for $C_{18}H_{15}N_3O_2$: C, 70.82; H, 4.92; N, 13.77%.

1e. Mp 149.5—151.0 °C (1-propanol); IR (KBr) 2230, 1730, 1600, 1280, 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.21 (1H, d, J=1.2 Hz, pyrimidyl), 8.74 (1H, d, J=5.2 Hz, pyrimidyl), 8.24 (1H, s, olefin), 8.05 (2H, d, J=8.6 Hz, phenylene), 7.93 (1H, d, J=16.2 Hz, olefin), 7.72 (2H, d, J=8.6 Hz, phenylene), 7.35 (1H, dd, J=1.2 and 5.2 Hz, pyrimidyl), 7.19 (1H, d, J=16.2 Hz, olefin), 4.30 (2H, t, J=6.7 Hz, methylene), 1.81 (2H, m, methylene), 1.00 (3H, t, J=1.2 Hz, methyl); UV (99.5% CH_2Cl_2) 360 (ε=69800). Found: C, 71.41; H, 5.47; N, 12.89%. Calcd for $C_{19}H_{17}N_3O_2$: C, 71.47; H, 5.33; N, 13.17%.

Mixed Crystal (1f). Recrystallization of an equimolar mixture of **1d** (300 mg, 0.98 mmol) and **1e** (313 mg, 0.98 mmol) from 180 ml of propanol gave 350 mg of 1.3:1 mixed crystal (**1f**). The ratio was determined by 400 MHz ^1H NMR. Mp 160.0—165.0 °C (1-propanol).

Isolation of Dimers. The crystals of **1c—f** were photoirradiated by method 3. The dimers **2c, d** (1,2-bis[4-[2-cyano-2-(alkoxycarbonyl)ethenyl]phenyl]-3,4-di(4-pyrimidyl)cyclobutane) and **2e,f** (alkyl 1-cyano-3-[4-[2-cyano-2-(alkoxycarbonyl)-ethenyl]phenyl]-2-[4-[2-(4-pyrimidyl)ethenyl]phenyl]-4-(4-pyrimidyl)-1-cyclobutanecarboxylate) were isolated from the products by flash column chromatography (eluent: dichloromethane with 1—5% methanol). IR, ^1H NMR, and mass spectra analyses of **2c—f** were performed without further purification.

2c. IR (KBr) 2220, 1740, 1600, 1580, 1470, 1440, 1390, 1270, 1215, 1190, 1090, 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.01 (2H, d, J=1.2 Hz, pyrimidyl), 8.52 (2H, d, J=5.2 Hz, pyrimidyl), 8.14 (2H, s, olefin), 7.83 (4H, d, J=8.4 Hz, phenylene), 7.26 (4H, d, J=8.4 Hz, phenylene), 7.14 (2H, dd, J=5.2 and 1.2 Hz, pyrimidyl), 4.99 (2H, m, cyclobutane), 4.63 (2H, m, cyclobutane), 3.90 (6H, s, methyl); MS m/z 582 (M^+), 398, 290 ($M^+/2-1$), 276, 258, 230.

Photoreaction. Photoreaction was carried out as follows. Method 1) KBr pellets containing a small amount of monomer crystals were irradiated with a 500 W super high-pressure mercury lamp under nitrogen atomosphere. Method 2) Finely powdered crystals of **1c—f** (200—500 mg) were dispersed in 300 ml of water containing a few drops of surfactant (NIKKOL TL-10FF), and irradiated with a 100 W high-pressure mercury lamp (Eikosha EHBWF-100) through a uranium glass filter with rigorous stirring under nitrogen atomosphere. Method 3) Finely powdered crystals of **1c—f** (100—200 mg) were dispersed in 90 ml of water containing a few drops of surfactant (NIKKOL TL-10FF) and irradiated with a 500 W super high-pressure mercury lamp (Ushio USH-500D) through a L38 filter (cut off <350 nm) for **1c**, **1e**, and **1f**, or a L40 filter (cut off <380 nm) for **1d** with stirring under nitrogen atomosphere.

We gratefully thank Prof. Tsuguo Sawada and Dr. Norio Teramae, Faculty of Engineering, the University of Tokyo, for the measurement of photoacoustic spectra.

Reduction of N_3^- by $[Mo_2Fe_6S_8(SPh)_9]^{3-}$ Modified Glassy Carbon Electrode—Model Study of Nitrogenase

Koji TANAKA,* Susumu KUWABATA, Satoshi DENNO, and Toshio TANAKA

(Received October 6, 1988)

The reduction of N_3^- by a $(Bu_4N)_3[Mo_2Fe_6S_8(SPh)_9]$ modified glassy carbon electrode has been conducted in a pH region 5 to 12 in water. In neutral and acidic conditions, N_3^- undergoes two-and six-electron reductions to afford not only N_2 and NH_3 but also N_2H_4, and the total amounts of N_2 and N_2H_4 produced were essentially consistent with that of NH_3. On the other hand, no N_2H_4 formation was observed in the pH region higher than 10, where an equal amount of N_2 and NH_3 was formed. The rate of N_2H_4 formation was linearly proportional to a concentration of N_3H, which exists as an equilibrium mixture with N_3^- in the aqueous phase, while that of N_2 evolution was controlled by the concentration of free N_3^- in H_2O. These observations indicate that N_2H_4 and N_2 result from the coordination of N_3H and N_3^- to the molybdenum-iron sulfur cluster, respectively.

Nitrogenase is composed of iron proteins and molybdenum-iron proteins and reduces not only N_2 but also various unsaturated small molecules such as C_2H_2, N_3^-, RCN, RNC, and N_2O.[1] Among those nitrogenase substrates, N_3^- is the only anionic substrate which is reduced with inequivalent numbers of electrons and protons. In the initial study on the reduction of N_3^- by crude nitrogenase in the presence of MgATP, N_3^- was reduced with two electrons to give an equal amount of N_2 and NH_3.[2] Later, Hardy et al. have reported that the reduction of N_3^- afforded one N_2 molecule and two NH_3 molecules at low concentration of N_3^-, and the excess NH_3 has been attributed to result from the further reduction of the N_2 formed.[3] Furthermore, the formation of N_2H_4 in addition to N_2 and NH_3 was observed in the reduction of N_3^- by purified nitrogenase.[4] It has been argued whether N_3^- or N_3H is the actual substrate of nitrogenase[2-5] since both species exist as an equilibrium mixture around pH 7. Furthermore, N_3^- has been shown to disturb the electron flow in enzymatic reaction by inhibiting the rate of MgATP hydrolysis by nitrogenase.[3,6] Despite these difficulties, N_3H has been suggested to be a potent substrate for the formation of N_2H_4 based on the reduction of N_3^- conducted in a restricted pH range 6.5—7.3.[7]

It has been demonstrated that various nitrogenase substrates such as C_2H_2,[8] CH_3CN,[9] CH_3NC,[9] and N_2O[10] are reduced by the reduced species of $[Fe_4S_4(SPh)_4]^{2-}$ and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$. One of the principal advantage of those model studies is that the reduction of nitrogenase substrates can be conducted in wide pH range, where proteins are readily denatured. The reduction of N_3^- by a model study, therefore, may give a clue to elucidate whether N_3^- or N_3H is the actual substrate of nitrogenase. The construction of a system which can not only rapidly but also continuously transport electrons to a catalyst having ability of multi-electron reduction of N_3^- is required in order to simulate the enzymatic reaction since N_3^- undergoes two-, six-, and eight-electron reductions by nitrogenase.[3,4] This paper describes the reduction of N_3^- on a $(Bu_4N)_3[Mo_2Fe_6S_8(SPh)_9]$ modified glassy carbon electrode in H_2O.

Experimental

Commercially available guaranteed reagent grade of NaN_3, H_3PO_4, and NaOH were used without further purification. Water insoluble and soluble MoFeS clusters, $(Bu_4N)_3[Mo_2Fe_6S_8(SPh)_9]$[11] ($(Bu_4N)_3$[Mo-Fe]) and $(Et_4N)_3[Mo_2Fe_6S_8(SCH_2CH_2OH)_9]$,[12] and $(Et_4N)N_3$[13] were prepared according to the literature. Solvents used for electrochemical measurements were purified by distillation over appropriate desiccants; DMF from CaH_2 under reduced pressure and CH_3CN from P_2O_5, and stored under N_2 atmosphere. Immediately before the electrochemical reduction of N_3^-, those solvents were bubbled with He at least for 1 h to remove nitrogen dissolved in the solvents. A $(Bu_4N)_3$[Mo-Fe] modified glassy carbon electrode was prepared by dropping a CH_3CN solution of $(Bu_4N)_3$[Mo-Fe] (1.0 mmol dm^{-3}) on a glassy carbon plates with areas 3.0 and 1.0 cm^2 (Tokai Carbon Co., Ltd., SC-2), and dried under N_2 atmosphere. The details of the cluster modified glassy carbon electrode was described in previous papers.[10,14]

Physical Measurements. Electronic absorption spectra were measured with a Union SM-401 spectrophotometer. Spectroelectrochemical experiments were carried out by the use of an optically transparent thin layer electrode.[15] Cyclic voltammetry was carried out by using a potentiostat (Hokuto Denko HA-301), a function generator (Hokuto Denko HB-107A), and an X-Y recorder (Yokogawa Electric Inc., 3077).

Reduction of N_3^- by the [Mo-Fe]/GC Electrode. The reduction of N_3^- by the [Mo-Fe]/GC electrode in water were carried out under the controlled potential electrolysis conditions using an electrolysis cell consisting of three components; a working, a counter, and an SCE reference electrode compartments.[8] A cation exchange membrane (Nafion film) was used as a separator between the working electrode and the counter electrode compartments. After passing He through the electrolysis cell for 1 h to remove air, an aqueous buffer solution (H_3PO_4–NaOH) of NaN_3 was introduced into the working electrode compartment by syringe techniques. Then, the electrolysis cell was placed in a thermostat at 30 °C and the reduction of N_3^- was started by

applying a fixed potential to the [Mo-Fe]/GC electrode with a potentiostat. The charge consumed in the course of reduction was measured with a Hokuto Denko HF-201 coulometer. Analyses of H_2 and N_2 evolved in the reduction were conducted on a Shimadzu GC-3BT gas chromatograph with a 2.0 m column filled with Molecular Sieves 13X and on a Shimadzu GC-7A gas chromatograph with Porapack Q, respectively. Ammonia and N_2H_4 formed in solutions were determined by Shimadzu GC-6A gas chromatograph with Chromosorb 103 and by colorimetric titration,[16] respectively.

Results and Discussion

Interaction of $[Mo\text{-}Fe]^{3-}$ with N_3^-. The electronic absorption spectrum of $(n\text{-}Bu_4N)_3[Mo\text{-}Fe]$ in DMF shows two absorption bands at 360 and 460 nm (a broken line in Fig. 1), which did not change at all by addition of $(Et_4N)N_3$ to the solution. The electrochemical reduction of $[Mo\text{-}Fe]^{3-}$ to $[Mo\text{-}Fe]^{4-}$ at -1.10 V vs. SCE[17] in DMF resulted in a decrease of the absorptivity at the 460 nm band (a dotted broken line in Fig. 1), while the electrochemical reduction of the cluster conducted in the presence of $(Et_4N)N_3$ under otherwise the same conditions leads to an appearance a new band at 306 nm (a solid line of Fig. 1). The 306 nm band can be assigned to PhS^-[14,18] dissociated from $[Mo\text{-}Fe]^{4-}$, and the intensity of this band corresponds to one molecule of PhS^- per one molecule of the cluster. On the other hand, this band gradually disappeared by reoxidation of $[Mo\text{-}Fe]^{4-}$ at -0.60 V vs. SCE, and the final spectrum became almost same as that of original $[Mo\text{-}Fe]^{3-}$ in DMF. These results indicate that the oxidized cluster $[Mo\text{-}Fe]^{3-}$ has no interaction with N_3^-, while a PhS^- ligand of $[Mo\text{-}Fe]^{4-}$ is substituted by N_3^- to afford the 1:1 adduct. Such a substitution reaction may take place on the Fe atom of $[Mo\text{-}Fe]^{4-}$ rather than the Mo atom, since a terminal RS^- is subject to a substitution reaction, while the bridging RS^- ligands of the cluster are inert for substitutions.[19]

Cyclic Voltammograms of the [Mo-Fe]/GC Electrode. The cyclic voltammogram of the [Mo-Fe]/GC electrode in H_2O (pH 8) shows a cathodic wave around -1.25 V vs. SCE, followed by an irreversible cathodic current due to H_2 evolution catalyzed by the reduced species of the cluster, and an anodic wave around at -0.75 V in the reverse scan (a dotted line in Fig. 2). Although the charge consumed in the cathodic process cannot be determined exactly due to the following irreversible cathodic current, that of the anodic one is just two electrons per a cluster modified on the glassy carbon plate. Thus, all the clusters modified on a glassy carbon plate undergo simultaneous two-electron reduction in water. The $[Mo\text{-}Fe]^{3-/5-}$ redox cycle stably works on the glassy carbon plate since the cyclic voltammogram was essentially unchanged by successive potential scan at least for 2 h.[14] The cathodic current density at more negative potentials than -1.1 V fairly increases by addition of NaN_3 (0.2 mol dm^{-3}) to the aqueous buffer solution at the same pH value (a solid line of Fig. 2). The threshold potential of the cathodic current in the presence of NaN_3 is essentially consistent with the reduction wave from $[Mo\text{-}Fe]^{3-}$ to $[Mo\text{-}Fe]^{5-}$ in the absence of NaN_3, suggesting that the reduced forms of the cluster can effectively reduce N_3^- in water. The current density at more negative potentials than -1.1 V increases with decreasing the pH value (dotted broken and broken lines in Fig. 2).

Reduction of N_3^- by the [Mo-Fe]/GC Electrode. As expected from the cyclic voltammograms of the

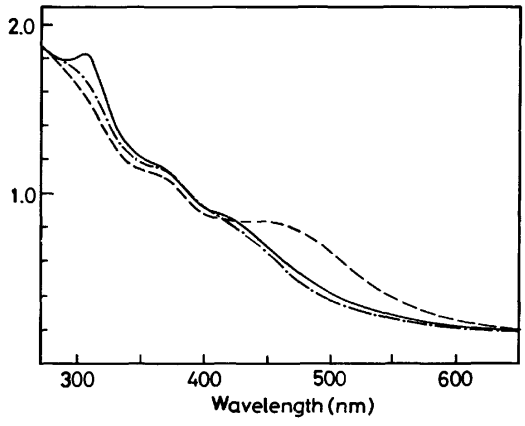

Fig. 1. Electronic absorption spectra of $(Bu_4N)_3[Mo_2Fe_6S_8(SPh)_9]$ (4.0×10^{-4} mol dm^{-3}) (-----) and the reduced species produced at -1.10 V vs. SCE in the absence (—·—) and the presence (-----) of $(Bu_4N)N_3$ (5.0×10^{-2} mol dm^{-3}) in DMF.

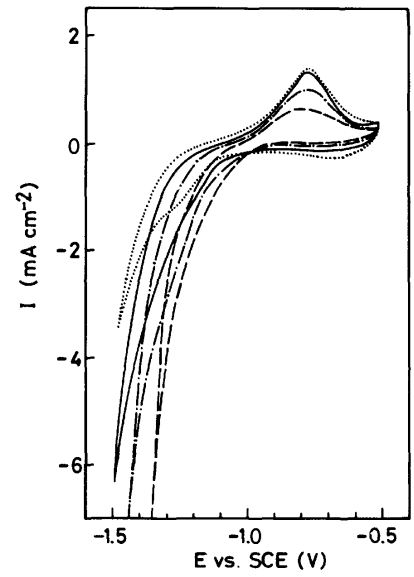

Fig. 2. Cyclic voltammograms of the [Mo-Fe]/GC electrode in H_2O (pH 8.0) in the absence (·····) and the presence of NaN_3 (0.2 mol dm^{-3}) in H_2O at pH 8.0 (——), 7.0 (—·—), and 6.0 (----) : dE/dt= 100 mV s^{-1}.

[Mo-Fe]/GC in the presence of NaN_3 at various pH, the reduction of N_3^- by the [Mo-Fe]/GC electrode at pH 6.0 is much faster than that at pH 12.0 under the controlled potential electrolysis at −1.25 V vs. SCE (Fig. 3). In addition, the reduction products are also altered by the change of pH; N_3^- is reduced to not only N_2 and NH_3 but also N_2H_4 at pH 6.0 (Fig. 3b), while only N_2 and NH_3 are formed in the same reduction at pH 12.0 (Fig. 3a). Thus, in acidic solutions both two- and six-electron reductions of N_3^- (Eqs. 1, 2) take place, and two-electron reduction of N_3^- (Eq. 1) occurs predominantly in

$$N_3^- + 3H^+ + 2e^- \longrightarrow N_2 + NH_3 \quad (1)$$

$$N_3^- + 7H^+ + 6e^- \longrightarrow N_2H_4 + NH_3 \quad (2)$$

alkaline solutions. In order to elucidate such a pH dependency of the N_3^- reduction, reduction of N_3^- was conducted under various reaction conditions, and the results are summarized in Table 1.

The formation of N_2H_4 (Eq. 2) was observed in the pH less than 10 (Entries 1—7 in Table 1). The sum of the amounts of N_2 and N_2H_4 formed in that pH region is essentially consistent with the amount of NH_3, suggesting that N_2H_4 is not the precursor of NH_3. In fact, N_2H_4 was not reduced by the [Mo-Fe]/GC electrode in H_2O under the present experimental conditions. Thus, the [Mo-Fe]/GC electrode can catalyze two- (Eq. 1) and six-electron (Eq. 2) reductions of N_3^- but has no ability to catalyze the eight-electron reduction of N_3^- (Eq. 3). The amounts of not only the

$$N_3^- + 9H^+ + 8e^- \longrightarrow 3NH_3 \quad (3)$$

reduction products of N_3^- but also H_2 increase with decreasing the pH value of the aqueous phase. It should, however, be noticed that the amount of H_2 evolved are controlled by the potential of the [Mo-Fe]/GC electrode under a constant pH, while the amounts of N_2, NH_3, and N_2H_4 are not largely dependent on the electrode potential (Entries 2—4 in Table 1). The result indicates that H_2 evolution is controlled principally by the electron transfer from the GC plate to the cluster, and that the rate of the N_3^- reduction is governed mainly by the chemical reaction. Thus, the cluster modified on the glassy carbon plate effectively functions as a catal st for the reduction of N_3^-. Holm et al. have reported that the reduced species of the present molybdenum-iron sulfur cluster has an

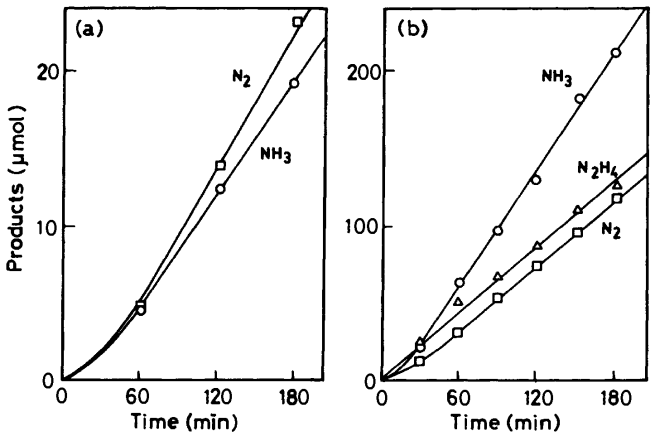

Fig. 3. Reduction of NaN_3 catalyzed by the [Mo-Fe]/GC under the controlled potential electrolysis at −1.25 V vs. SCE in H_2O at pH 12.0 (a) and 6.0 (b). The concentrations of NaN_3 are 0.5 mol dm^{-3} (a) and 0.05 mol dm^{-3} (b).

a) μmol.

ability to reduce protons and metal-hydride species has been proposed as the precursor for the H_2 evolution.[20] The difference of the rate determining steps in the reductions of protons and N_3^- by the [Mo-Fe]/GC electrode suggests that the reaction mechanisms of those two reactions are different from each other. The reduction of N_3^- may, therefore, be initiated by the coordination of N_3^- to the molybdenum-iron sulfur cluster modified on the GC plate since N_3^- is not reduced at all by a glassy carbon electrode at −1.25 V vs. SCE in H_2O.

As described above, the rates of N_2 and N_2H_4 formation[21] increased with decreasing pH values. The former, however, reaches a constant value below around 7 (a broken line in Fig. 4), and the latter also show the saturation behavior around 5 (a solid line in Fig. 4). Such a distinct difference in the formation rates between N_2H_4 and N_2 toward the pH change suggests that the reductions of Eqs. 1 and 2 take place independently. It is well-known that N_3^- exists as an equilibrium mixture with N_3H in H_2O, and the pK_a of N_3H is 4.6 at 30 °C (Eq. 4).[22] The presence of the turning point in the plot of $\log V(N_2H_4)$ vs. pH ($V(N_2H_4)$: the rate of N_2H_4 formation) around pH 5 may, therefore, be associated with the pK_a. The concentrations of N_3H and N_3^- are expressed by Eqs. 5 and 6, where $[N_3^-]_0$ is the initial concentration of NaN_3. Equations 5 and 6 also can be converted into Eqs. 7 and 8 in terms of pK_a and pH in place of

$$N_3H \rightleftharpoons N_3^- + H^+ \quad (4)$$

$$[N_3H] = [N_3^-]_0[H^+]/(K_a + [H^+]) \quad (5)$$

$$[N_3^-] = K_a[N_3^-]_0/(K_a + [H]^+) \quad (6)$$

$$[N_3H] = [N_3^-]_0/(10^{(pH-pK_a)} + 1) \quad (7)$$

$$[N_3^-] = 10^{(pH-pK_a)}[N_3^-]_0/(10^{(pH-pK_a)} + 1) \quad (8)$$

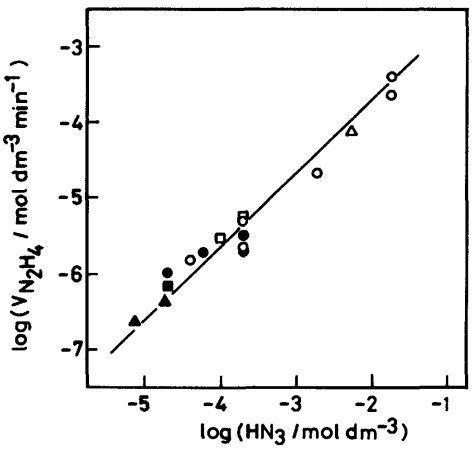

Fig. 5. Relationship between the rate of N_2H_2 formation and the N_3H concentration in the reduction of NaN_3 by the [Mo-Fe]/GC electrode at pH 6.0 (○), 6.5 (△), 7.0 (□), 8.0 (■), and 10.0 (▲).

K_a and $[H^+]$, respectively. Although any linear relationship was not observed between $\log V(N_2H_4)$ and $\log[N_3^-]$ calculated from Eq. 8, a plot of $\log V(N_2H_4)$ vs. $\log[N_3H]$ obtained from Eq. 7 gives a straight line, as shown in Fig. 5. A linear dependence of $V(N_2H_4)$ upon the N_3H concentration in the aqueous phase suggests that N_3H is the actual substrate for the formation of N_2H_4. This conclusion may be supported by the fact that N_2H_4 is not produced above pH 10, where N_3H essentially does not exist as an equilibrium mixture of N_3^-. Equation 9 rather than Eq. 2 may,

$$N_3H + 6H^+ + 6e^- \longrightarrow N_2H_4 + NH_3 \quad (9)$$

therefore, be appropriate for the formation of N_2H_4 in the present study.

The saturation behavior of $\log V(N_2)$ around 7 (Fig. 4) also may be explained by a protonation equilibrium of the reaction intermediate. The reduction of N_3H formed in the aqueous phase may be initiated by the coordination of N_3H to the cluster on the [Mo-Fe]/GC, followed by the electron transfer to the N_3H from the cluster. It should be noticed that N_3^- also can coordinate to the reduced cluster but the rate of the electron transfer to the N_3^- from the cluster may be fairly slower than that to the N_3H ligated on the cluster since N_3^- is apparently much more basic than N_3H. Accordingly, smooth electron transfer from the cluster to the N_3^- coordinated may take place when the N_3^- undergoes a reversible protonation, as expressed by Eq. 10,

$$[[Mo\text{-}Fe]\text{-}N_3^-]_{sur} + H^+ \rightleftharpoons [[Mo\text{-}Fe]\text{-}HN_3]_{sur} \quad (10)$$

where $[[Mo\text{-}Fe]\text{-}N_3^-]_{sur}$ and $[[Mo\text{-}Fe]\text{-}HN_3]_{sur}$ are the cluster-N_3^- adduct and its protonated species, respectively, on the [Mo-Fe]/GC. The protonated cluster-N_3^- adduct ($[[Mo\text{-}Fe]\text{-}HN_3]_{sur}$) formed by the protonation (Eq. 10) is not necessarily the same species as the reaction intermediate involved in the reduction of N_3H affording N_2H_4 and NH_3 (Eq. 9) (vide infra). The proton dissociation constant pK_a' of $[[Mo\text{-}Fe]\text{-}HN_3]_{sur}$ (Eq. 10) may be fairly different from the pK_a of free HN_3 (Eq. 4; pK_a=4.6). As similar to Eq. 5, the surface concentration of $[[Mo\text{-}Fe]\text{-}HN_3]_{sur}$ of Eq. 10 can be expressed by Eq. 11,

$$[[Mo\text{-}Fe]\text{-}HN_3]_{sur} = [[Mo\text{-}Fe]\text{-}N_3^-]_0[H^+]/(K_a' + [H^+]) \quad (11)$$

where $[[Mo\text{-}Fe]\text{-}N_3^-]_0$ is the total surface concentration of the cluster-N_3^- adduct ($[[Mo\text{-}Fe]\text{-}N_3^-]_{sur}$) and its protonated species ($[[Mo\text{-}Fe]\text{-}HN_3]_{sur}$). As discussed in a previous section, the formation of H_2, N_2, and N_2H_4 takes place independently on the [Mo-Fe]/GC. To avoid an extreme difficulty in the determination of each surface concentrations of the active species in those reductions, the surface concentration of [[Mo-

Fe]-N_3^-]$_0$ is assumed to be proportional to the bulk concentration of N_3^- calculated from Eq. 8. The surface concentration of the cluster-N_3^- adduct ([[Mo-Fe]-N_3^-]$_{sur}$ and its protonated species ([[Mo-Fe]-HN_3]$_{sur}$), therefore, can be expressed in terms of [N_3^-], K_a', and [H+] (Eqs. 12, 13). On the basis of the fact

$$[[Mo\text{-}Fe]\text{-}N_3^-]_{sur} \propto K_a'[N_3^-]/(K_a' + [H']) \quad (12)$$

$$[[Mo\text{-}Fe]\text{-}HN_3]_{sur} \propto [N_3^-][H^+]/(K_a' + [H^+]) \quad (13)$$

that $V(N_2)$ is saturated around pH 7, a simulation fitting was conducted in the plots of log $V(N_2)$ vs. log[[Mo-Fe]-N_3^-]$_{sur}$ and log[[Mo-Fe]-HN_3]$_{sur}$ by changing K_a' value around 10^{-7}. The best result was obtained at K_a' is $10^{-6.8}$ in the plot of log $V(N_2)$ vs. log[[Mo-Fe]-HN_3]$_{sur}$, where the rate of N_2 formation in the reduction of N_3^- under various conditions shows a linear dependence on the calculated value $[N_3^-][H^+]/(K_a'+[H^+])$, as shown in Fig. 6, suggesting that [[Mo-Fe]-HN_3]$_{sur}$ selectively affords N_2 and NH_3 (Eq. 1). The large pK_a' value (6.8) of [[Mo-Fe]-HN_3]$_{sur}$ compared with the pK_a value (4.6) of N_3H in water can be explained by an increase in the electron density of N_3^- moiety upon the coordination to the cluster. Such an enhancement of the basicity of N_3^- may be caused by electron transfer through the terminal nitrogen atom bonded to the cluster, since N_3^- usually coordinates to metal complexes with a terminal nitrogen.[23] The initial protonation of N_3^- ligated on the cluster may, therefore, take place on the nitrogen atom bonded to the cluster to produce [Mo-Fe]-HN-N=N (**1**) rather than [Mo-Fe]-N=N=NH (**2**). The structure of **1** seems to explain reasonably the dissociation of the terminal N_2 moiety upon further protonation coupled with electron transfer from the cluster to HN-N=N moiety. In accordance with this, protonation of M-N_3^- complexes (M=Ru,[24] Co,[25]

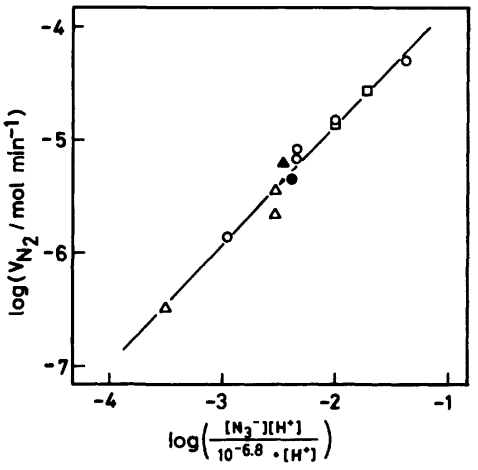

Fig. 6. Relationship between the rate of N_2 formation and log ($[N_3^-][H^+]/(10^{-6.8}+[H^+])$) in the reduction of NaN_3 by the [Mo-Fe]/GC electrode at pH 6.0 (○), 6.5 (△), 7.0 (□), and 10.0 (▲).

$$\bar{N}=\overset{+}{N}=\bar{N} + H^+ \rightleftharpoons \bar{N}=\overset{+}{N}=NH$$

Scheme 1.

Ir[26]) also occurs at the nitrogen atom bonded to the metal, followed by the dissociation of terminal N_2.

The protonation of N_3^- in a solution has been shown to occur at one of a terminal nitrogen atom of N_3^-[27] (Scheme 1). The linear dependence of the rate of N_2H_4 formation upon the concentration of N_3H in the aqueous phase (Eq. 4) indicates the appropriateness of Eq. 9. In contrast to the protonation of [Mo-Fe]-$\bar{N}=\overset{+}{N}=\bar{N}$ affording [Mo- Fe]-HN-$\bar{N}=\overset{+}{N}=\bar{N}$ (**1**), N_3H may bind to the cluster with the nonprotonated terminal nitrogen atom affording [Mo-Fe]-$\bar{N}=\overset{+}{N}=NH$ (**2**) rather than **1**. The intramolecular electron transfer from the cluster to the N_3H moiety of **2** may cause also the increase of the basicity of the nitrogen atom bonded to the cluster, resulting in further protonation to form [Mo-Fe]-NH-N=NH (**3**). The following electron transfer coupled with protonation of **3** may lead the dissociation of N_2H_4. It should be noticed that such the six-electron reduction of N_3^- (Eq. 2) hardly took place under the controlled potential electrolysis of an aqueous solution (pH 7.0, 12 cm^3) containing $(Et_4N)_3[Mo_2Fe_6S_8(SCH_2CH_2OH)_9]$ (0.37 mmol dm^{-3}) and NaN_3 (0.37 mol dm^{-3}) at −1.25 V vs. SCE, where the two-electron reduction of N_3^- (Eq. 1) predominantly occurred with concomitant H_2 evolution. The mole ratios of N_2 and H_2 to NH_2NH_2 formed in this homogeneous system were 25 and 194, respectively, and the turnover number for the formation of N_2H_4 was as low as 0.385/h based on the amount of the cluster. On the other hand, the [Mo-Fe]/GC catalyzes the six-electron reduction of N_3^- affording N_2H_4 with the turnover number 235/h under the same electrolysis potential at pH 7 (Entry 6 in Table 1). Despite that both $[Mo_2Fe_6S_8(SPh)_9]^{3-}$ and $[Mo_2Fe_6S_8(SCH_2CH_2OH)_9]^{3-}$ similarly undergo two successive one-electron reduction at more positive potentials than −1.25 V in solutions, the outstanding ability of the former modified glassy carbon electrode for the six-electron reduction of N_3^- may be explained by the view that the cluster of the [Mo-Fe]/GC exists as the reduced form even after two-electron reduction of N_3^- due to fast and continuous electron transport to $[Mo_2Fe_6S_8(SPh)_9]^{3-}$ from the glassy carbon plate. This assumption is supported by the fact that the cyclic voltammogram of the [Mo-Fe]/GC clearly exhibits the anodic wave of the cluster even in the presence of N_3^- (Fig. 2). Thus, the system which is provided with rapid and continuous electron transport to a redox catalyst may be one of the essential factor to catalyze a multi-electron reduction involving unstable reaction intermediates.

The reduction of N_3^- by nitrogenase affords also N_2, NH_3, and N_2H_4 around pH 7, and the amount of NH_3 has been shown to be larger than the total amount of

N_2 and N_2H_4. This has been ascribed to further six-electron reduction of N_2 formed in the two-electron reduction of N_3^-. The [Mo-Fe]/GC electrode has no ability of catalyzing the eight-electron reduction of N_3^- though the [Mo-Fe]/GC reasonably explains the difference in the two- and six-electron reduction of N_3^- in a wide pH range.

(Received October 17, 1988)

Thermal cycloaddition reactions of 2,3-bis(methoxycarbonyl)-7-oxabicycloheptadiene with cyclohepta[*b*]-pyrrol-2(1*H*)-ones gave the [4+2]adducts and products derived from the [8+2]adducts. Among [4+2]adducts, a new adduct was isolated. Cyclohepta[*b*]pyrrol-2(1*H*)-ones, having a substituent at the C-3 position exclusively, gave [4+2]adducts. The photolysis of 2-azatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one afforded substituted 9-methylenebarbaralane, 5-methylenetricyclo[4.3.0.0^{2,9}]nonadiene, and 1-methylenedihydroindene derivatives.

Currently, we have been interested in the thermal cycloaddition-cycloreversion process of 2,3-bis(methoxycarbonyl)-7-oxabicyclo[2.2.1]heptadiene, an acetylene equivalent, with tropones,[2] cyclohepta[*b*]furan-2(2*H*)-ones,[3] and anthracenes.[4] Since this procedure is useful to construct various cage compounds, we have now investigated the reaction with cyclohepta-[*b*]pyrrol-2(1*H*)-ones (**1**) to obtain 2-azatricyclo-[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-ones. Although Abe and Takehiro recently showed that the thermal cycloaddition between **1** and dimethyl butynedioate (DMBD) gave the products via a [8+2]cycloaddition,[5] we have now found that the reactions of **1** and 2,3-bis(methoxycarbonyl)-7-oxabicyclo[2.2.1]heptadiene (**2**) under 3000 bar afforded [4+2] and [8+2]adducts. In addition, the photorearrangement of 2-azatricyclo-[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one furnished similar products as in the oxa analogues, 2-oxatricyclo-[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-ones.

Results and Discussion

Cycloaddition Reaction of 1 and 2. When a chlorobenzene solution of 1-acetylcyclohepta[*b*]pyrrol-2(1*H*)-one (**1a**) and **2** was heated at 120 °C under 3000 bar, four products (**3a**, and **4**—**6**) were formed and isolated via silica-gel chromatography in 12, 4, 8, and 6% yields, respectively (Scheme 1). Products **3a** and **4** were 1:1-cycloadducts, respectively; the ^{1}H NMR spectrum of product **3a** revealed five methine protons with coupling constants ($J_{1,2}$=$J_{2,3}$=$J_{6,7}$=0—1.1 Hz), which are very similar to those of endo [4+2]adducts formed by the addition of cyclohepta[*b*]furan-2(2*H*)-ones and **2**.[3] On the other hand, the structure of **4** was deduced to be another endo [4+2]adduct; the ^{1}H NMR spectrum showed the presence of four olefinic and six methine protons with coupling constants ($J_{1,2}$=$J_{2,3}$=

Table 1. Product Distribution of **1** and **2**

	Conditions[a]	Products (Yield/%)
1a	3000, 120, 20, CB,[b]	**3a** (12), **4** (4), **5** (8), **6** (6),
	1, 130, 20, CB	**5** (16), **7** (13)
1b	3000, 120, 20, anhydrous dioxane	**3b** (26), **8** (6.5)
	3000, 115, 20, dioxane	**3b'** (45)
1c	3000, 120, 20, anhydrous dioxane	**3c** (20), **3c'** (24)
1d	3000, 120, 20, anhydrous dioxane	No reaction[c]

a) Pressure/bar, temperature/°C, time/h, and solvent. b) Chlorobenzene. c) The reaction of **1d** and DMBD in refluxing acetonitrile gave five products derived from a [8+2]adduct.[5]

† On leave from Yanbian University, Yanji, Jilin, People's Republic of China.

$J_{6,7}=J_{7,8}=0$—1.1 Hz). Additionally, H-14 appeared at δ 7.69 (dd, J=9.5, 1.8 Hz). This signal at the low-field could be explained in terms an α-position to the *N*-acetyl group. These observations were consistent to the structure of **4**. The connectivities of the hydrogens of **3** and **4** were further confirmed by the ^{1}H COSY spectra. Product **5** was the naphthalene derivative, being identical with an authentic sample.[6] Product **6** was assigned as 1-acetyl-3,4-bis(methoxycarbonyl)pyrrolo[4,3,2-*cd*]azulen-2(1*H*)-one by comparing the spectral data with related compounds.[5] The product distributions of **1** and **2** are summarized in Table 1.

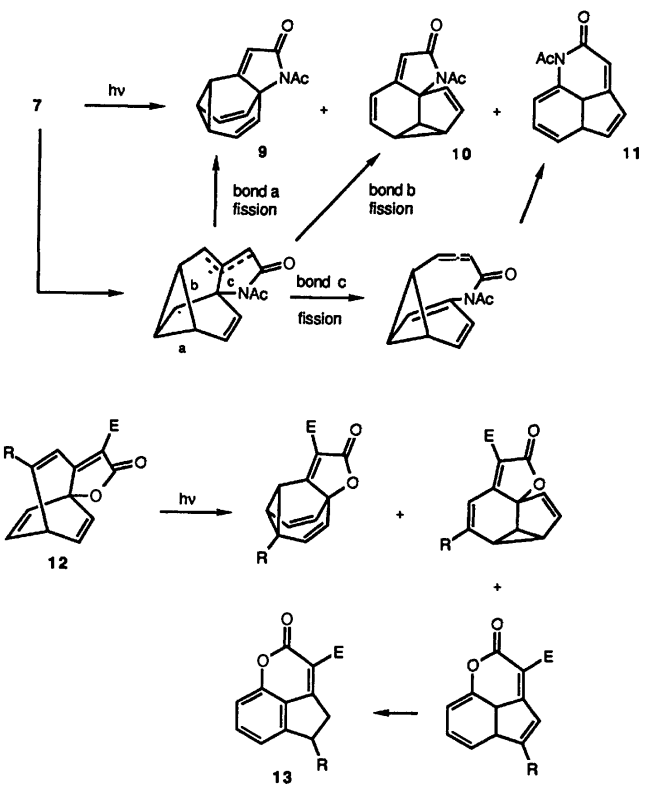
When the reaction between **1a** and **2** was performed at 130 °C in a sealed tube, a new product **7** was obtained in 13% yield together with **5** (16%). Since this new product **7** was also formed together with 3,4-bis(methoxycarbonyl)furan from **3a** by heating at 135 °C and its NMR spectrum indicated to have a symmetry element in a molecule, **7** was assigned to be 2-acetyl-2-azatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one.

The reaction of 1-acetyl-3-ethoxycarbonylcyclohepta-[*b*]pyrrol-2(1*H*)-one (**1b**) and **2** in anhydrous dioxane gave a 1:1-adduct (**3b**) and another 1:1-adduct (**8**) together with a deacetylated derivative (**1b'**)[7] of **1b**. Also, in a moistened medium a deacetylated 1:1-adduct (**3b'**) was isolated instead of **3b**. The structure of **3b** was elucidated to be an endo [4+2]adduct by a direct comparison with the spectral data of **3a**; in the ^{1}H NMR spectrum, **3b** showed signals at δ 6.95—7.15, which were ascribable to H-13 and H-14, being lower than the corresponding signals of **3a**. This low-field shift indicated an intact ethoxycarbonyl group at C-11. The exo [4+2]adduct structure for **8** was deduced from the coupling constant (5.9 Hz) between H-1 and H-2 in the ^{1}H NMR spectrum.

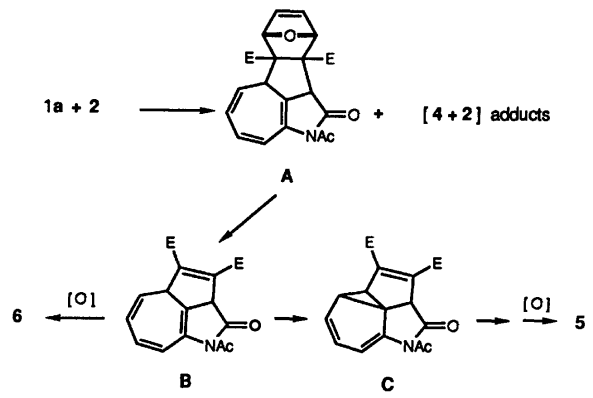
The reaction between 1-acetyl-3-cyanocyclohepta-[*b*]pyrrol-2(1*H*)-one (**1c**) and **2** in anhydrous dioxane under 3000 bar afforded two products (**3c** and **3c'**) and a deacetyl derivative (**1c'**)[8] of **1c**. The latter adduct **3c'** was a deacetylated derivative of **3c**.

Photorearrangement of 7. The irradiation of **7** with a high-pressure mercury lamp (1 kW) gave three products (**9**—**11**). The structures of these products were similar to those obtained from the photolysis of 2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one derivatives (**12**).[9] Interestingly, a dihydroindenone (**11**) was isolated as a proto-photoisomer from **7** in this case; a similar photolysis of **12** gave an aromatized indan derivative (**13**).

Reaction Modes of 1 and 2. There was observed nearly equal amounts of two types of products in the cycloaddition reaction between **1** and **2**, as shown in Table 1. The product distributions were not similar to those of the reactions of **1** and DMBD in a refluxing acetonitrile.[5] For example, the reaction of cyclohepta-[*b*]pyrrol-2(1*H*)-one (**1d**) and DMBD gave two ene



Scheme 2.



Scheme 3.

products in 51% and the deacetyl derivative of **5** in 35% together with a deacetyl derivative of **6** in 5% yields. The reaction of **1d** and **2** did not proceed even at 120 °C under 3000 bar, and the product distributions in the reactions of **1d** with DMBD and **1a** and **2** were completely different. Therefore, products **5** and **6** were formed via a 1:1-adduct (**A**) of **1a** and **2** and not formed from **1a** and DMBD, although DMBD could be available by a cycloreversion of **2** under the reaction conditions. An elimination of furan from **A** and a subsequent autooxidation, via **B**, should yield **6**. A valence bond isomerization of the cycloheptatriene function in **B** followed by a dehydrogenation should afford **5**. Thus, the [8+2]addition occurred exclusively

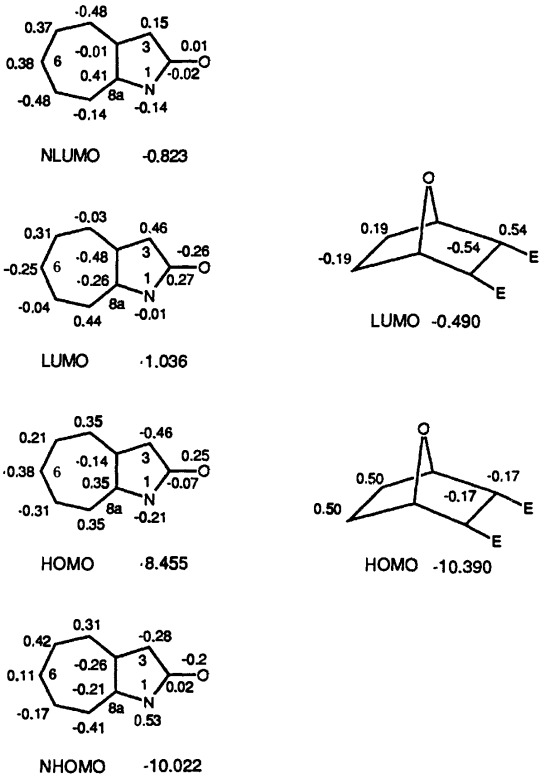


Fig. 1. Coefficients and energy levels of selected molecular orbitals of **1a** and **2**.

at positions of C-3 and C-4 in **1**. So far, no product reacted at C-3 and C-8a of **1** has been isolated, although the coefficient of C-4 in HOMO of **1a** was identical with that of C-8a from the MNDO calculation. An acetyl group might prevent an approach to the C-8a position of **2**. The reaction site of **2** in the [8+2]addition could be reasonably explained by the interaction of HOMO(**1a**) and LUMO(**2**), which favored a reaction to occur at the double bond with methoxycarbonyl groups.

Among [4+2]adducts identified, a new type of an adduct, **4**, should be worthy of note. This type of the product has never been isolated from reactions between cyclohepta[*b*]furan-2(2*H*)-ones and **2**.[3] Therefore, the formation of **4** might be explained in terms of the steric effect of an acetyl group on the nitrogen atom, which prevents an approach of **2** to the C-8a position of **1a**. The interactions of both LUMO(**1a**)-HOMO(**2**) and the NLUMO(**1a**)-HOMO(**2**) favored a [4+2]addition at a double bond having no substituents of **2**.[10]

Experimental

Elemental analyses were performed by Miss S. Hirashima, of Institute of Advanced Material Study, Kyushu University. NMR spectra were measured by a JEOL GSX 270 H Model spectrometer in a $CDCl_3$ solution (unless otherwise specified); chemical shifts are expressed in δ unit. Apparent coupling constants were obtained from the first-order analyses. Mass spectra were measured with a JEOL OlSG-2 spectrometer. IR spectra were taken as KBr disks or as a liquid film inserted between NaCl plates using a Jasco IR-A 102 spectrometer. UV spectra were measured by a Hitachi U-3200 spectrophotometer.

Cycloaddition of 1a and 2. a) A chlorobenzene solution (3 cm^3) of **1a** (191 mg) and **2** (293 mg) was heated at 120 °C for 20 h under 3000 bar. The solvent was removed under reduced pressure and the residue was chromatographed on a silica-gel column to give 45 mg (12%) of **3a**, 15 mg (4%) of **4**, 26.6 mg (8%) of **5**, 20 mg (6%) of **6**, and recovered **1a** (12.4 mg) and **2** (20 mg).

3a: colorless crystals, mp 202—203 °C; ^{1}H NMR δ=2.26 (1H, dd, J=8.1, 1.1 Hz), 2.56 (1H, d, J=8.1 Hz), 2.67 (3H, s), 3.43 (1H, dd, J=8.4, 8.1 Hz), 3.77 (3H, s), 3.81 (3H, s), 4.93 (1H, d, J=1.1 Hz), 5.69 (1H, d, J=1.1 Hz), 5.72 (1H, s), 6.21 (1H, d, J=10.3 Hz), 6.25 (1H, t, J=8.1 Hz), 6.30 (1H, dt, J=8.1, 1.1 Hz), and 6.72 (1H, dd, J=10.3, 8.4 Hz); ^{13}C NMR δ=26.6, 38.8, 46.2, 51.4, 52.4 (2C), 71.8, 83.7, 85.8, 117.3, 122.3, 128.8, 129.5, 144.5, 144.7, 146.4, 160.3, 162.7, 162.9, 170.8, and 171.6; IR 3010, 2890, 1740, 1705, 1640, and 1610 cm^{-1}; UV (MeOH) 245.6 (ε 9600) and 282.8 nm (7300).

b) A chlorobenzene solution (1 cm^3) of **1a** (130 mg) and **2** (350 mg) was heated at 130 °C for 20 h in a sealed tube under a nitrogen atmosphere. After removing the solvent, the residue was chromatographed on a silica-gel column to give 35.8 mg (16%) of **5**, 18 mg (13%) of **7**, and recovered **1a** (52.2 mg) and **2** (106 mg).

7: colorless crystals, mp 136—138 °C; ^{1}H NMR δ=2.63 (3H, s), 3.90 (1H, dtm, J=8.1, 7.7 Hz), 5.73 (1H, s), 5.90 (1H, d, J=10.3 Hz), 6.28 (2H, dd, J=7.7, 1.5 Hz), 6.54 (2H, t, J=7.7 Hz), and 6.57 (1H, dd, J=10.3, 8.1 Hz); ^{13}C NMR δ=25.2, 39.5, 70.5, 118.0, 119.6, 131.5 (2C), 133.1 (2C), 140.2, 153.2, 169.7, and 170.3; IR 2905, 1730, 1620, and 1380 cm^{-1}; UV (MeOH) 260.6 nm (ε 9300).

Found: C, 73.28; H, 5.22; N, 6.58%. Calcd for $C_{13}H_{11}NO_2$: C, 73.23; H, 5.20; N, 6.57%.

Cycloaddition of 1b and 2. a) An anhydrous dioxane solution (2.5 cm^3) of **1b** (54 mg) and **2** (100 mg) was heated at 120 °C under 3000 bar for 20 h. Silica-gel chromatography of the residue gave 16 mg (26%) of **3b**, 4 mg (6.5%) of **8**, and recovered **2** (50 mg) and **1b'** (16 mg).

3b: colorless crystals, mp 125—126 °C; ^1H NMR δ=1.38 (3H, t, J=7.3 Hz), 2.27 (1H, d, J=7.7 Hz), 2.59 (1H, dd, J=7.7, 1.1 Hz), 2.71 (3H, s), 3.53 (1H, m), 3.78 (3H, s), 3.81 (3H, s), 4.37 (2H, q, J=7.3 Hz), 4.94 (1H, d, J=1.1 Hz), 5.64 (1H, d, J=1.1 Hz), 6.3 (2H, m), and 6.95—7.15 (2H, m); ^{13}C NMR δ=14.2, 27.0, 39.5, 46.4, 51.7, 52.5 (2C), 61.6, 70.6, 83.8, 85.7, 117.3, 121.2, 128.8, 130.4, 144.5, 146.8, 149.7, 161.8, 162.4, 162.7, 162.8, 166.8, and 171.8; IR 3000, 1740, 1640, 1610, and 1580 cm^{-1}; UV (MeOH) 248.2 (ε 11100) and 296.4 nm (11700).

Found: C, 61.48; H, 4.96; N, 3.05%. Calcd for $C_{24}H_{23}NO_9$: C, 61.40; H, 4.94; N, 2.98%.

8: colorless crystals, mp 172—173 °C; ^1H NMR δ=1.39 (3H, t, J=7.3 Hz), 2.65 (1H, dd, J=8.8, 5.9 Hz), 2.69 (3H, s), 3.7 (1H, m), 3.73 (1H, d, J=8.8 Hz), 3.75 (3H, s), 3.81 (3H, s), 4.37 (2H, q, J=7.3 Hz), 4.61 (1H, s), 4.89 (1H, d, J=1.1 Hz), 6.18 (1H, d, J=8.4 Hz), 6.42 (1H, dd, J=8.4, 7.3 Hz), 6.69 (1H, dd, J=10.6, 8.4 Hz), and 7.31 (1H, d, J=10.6 Hz); ^{13}C NMR δ=14.3, 26.2, 38.1, 42.8, 48.5, 52.4, 52.5, 61.5, 70.4, 79.9, 83.8, 118.6, 125.9 (2C), 133.2, 134.4, 143.9, 145.6, 161.5, 161.7, 161.8, 162.6, 166.4, and 170.4; IR 3000, 2950, and 1720 cm^{-1}; UV (MeOH) 243.8 (ε 10000) and 299.4 nm (10300).

Found: C, 61.19; H, 4.94; N, 2.99%. Calcd for $C_{24}H_{23}NO_9$: C, 61.40; H, 4.94; N, 2.98%.

1b': mp 185—188 °C (lit,[7] mp 189—190 °C).

b) A dioxane solution (2 cm^3) of **1b** (80 mg) and **2** (240 mg) was heated at 115 °C for 20 h under 3000 bar. Silica-gel chromatography of the mixture gave 35 mg (45%) of **3b'**, 26 mg of **1b'**, and recovered **2** (125 mg).

3b': colorless crystals, mp 197—198 °C; ^1H NMR δ=1.34 (3H, t, J=7.0 Hz), 2.27 (1H, d, J=8.1 Hz), 2.50 (1H, d, J=8.1 Hz), 3.52 (1H, dd, J=8.4, 7.7 Hz), 3.72 (3H, s), 3.81 (3H, s), 4.33 (2H, q, J=7.0 Hz), 4.95 (1H, s), 5.45 (1H, s), 6.00 (1H, d, J=8.8 Hz), 6.29 (1H, dd, J=8.8, 7.7 Hz), 6.78 (1H, dd, J=10.6, 8.4 Hz), 7.06 (1H, d, J=10.6 Hz), and 8.63 (1H, br s); ^{13}C NMR δ=14.2, 39.5, 43.5, 49.8, 52.4, 52.5, 61.1, 65.8, 84.3, 85.5, 118.4, 121.9, 130.6, 132.0, 145.0, 145.4 (2C), 162.1, 162.3, 162.5, 162.6, and 169.9; IR 3400, 3200, 3100, 1740, 1640, and 1570 cm^{-1}; UV (MeOH) 248.6 (ε 10150) and 285.8 nm (11400).

Found: C, 61.46; H, 4.78; N, 3.26%. Calcd for $C_{22}H_{21}NO_8$: C, 61.82; H, 4.95; N, 3.28%.

Cycloaddition of 1c and 2. An anhydrous dioxane solution (1 cm^3) of **1c** (50 mg) and **2** (120 mg) was heated at 120 °C under 3000 bar for 20 h. Silica-gel chromatography of the mixture gave 4 mg (20%) of **3c**, 4.5 mg (24%) of **3c'**, and **1c'** (30 mg).

3c: colorless crystals, mp 198 °C (decomp); ^1H NMR δ=2.28 (1H, d, J=8.1 Hz), 2.59 (1H, dd, J=8.1, 1.1 Hz), 2.70 (3H, s), 3.6 (1H, m), 3.79 (3H, s), 3.81, (3H, s), 4.95 (1H, d, J=1.4 Hz), 5.64 (1H, s), 6.32 (2H, m), 6.53 (1H, d, J=10.3 Hz), and 7.14 (1H, dd, J=10.3, 8.8 Hz); ^{13}C NMR δ=26.7, 39.9, 46.6 (2C), 51.9, 52.6, 72.2, 83.7, 85.8, 102.6, 110.6, 120.7, 127.9, 130.8, 144.3, 146.7, 152.2, 162.4, 162.6, 165.4, 166.9, and 171.3; IR 2975, 2240, 1720, and 1620 cm^{-1}; UV (MeOH) 243.8 (ε 5700) and 300.8 nm (6300).

Found: m/z 380.1015 ($M^+ - CH_3CO$). Calcd for $C_{20}H_{15}N_2O_6$: 380.1008.

3c': colorless crystals, mp 201—203 °C; ^1H NMR δ=2.27 (1H, d, J=8.1 Hz), 2.55 (1H, d, J=8.1 Hz), 3.60 (1H, t, J=8.8 Hz), 3.79 (3H, s), 3.83 (3H, s), 4.95 (1H, d, J=1.5 Hz), 5.26 (1H, s), 5.99 (1H, d, J=8.8 Hz), 6.33 (1H, t, J=8.8 Hz), 6.55 (1H, d, J=10.6 Hz), 6.93 (1H, dd, J=10.6, 8.8 Hz), and 7.76 (1H, br s); ^{13}C NMR (DMSO-d_6) δ=42.8, 49.2, 52.2, 52.3, 67.0, 78.9, 82.8, 84.8, 101.5, 112.4, 119.8, 129.4, 132.5, 143.1, 146.6, 149.3, 161.9, 162.6, 166.4, and 166.6; IR 3400, 2975, 2240, 1710, 1640, and 1620 cm^{-1}; UV (MeOH) 285.4 (ε 13000) and 423.4 nm (1300).

Found: C, 62.14; H, 4.05; N, 7.03%. Calcd for $C_{20}H_{16}N_2O_6 \cdot 1/3H_2O$: C, 62.18; H, 4.31; N, 7.25%.

1c': mp>280 °C (lit,[8] mp 305 °C (decomp)).

Cycloaddition of 1d and 2. A chlorobenzene solution (1 cm^3) of **1d** (72 mg) and **2** (138 mg) was heated at 120 °C under 3000 bar for 20 h. Silica-gel chromatography of the mixture gave only **1d**.

Cycloreversion of 3a. A xylene solution (1 cm^3) of **3a** (55 mg) was heated at 140 °C for 20 h in a sealed tube. The mixture was chromatographed on a silica-gel column to give 12 mg (56%) of **7**, 11 mg (60%) of 3,4-bis(methoxycarbonyl)-furan, and recovered **3a** (15 mg).

Photolysis of 7. A $CHCl_3$ solution (1 cm^3) of **7** (30 mg) was irradiated by a high-pressure mercury lamp (1 kW) for 3 h. The mixture was chromatographed on a silica-gel column to give 4.7 mg (19%) of **9**, 4.5 mg (18%) of **10**, and 3.8 mg (15%) of **11**.

9: colorless crystals, mp 130 °C; ^1H NMR δ=2.58 (3H, s), 2.77 (2H, m), 3.13 (1H, t, J=7.0 Hz), 5.65—5.75 (2H, m), 5.71 (1H, s), and 6.37 (2H, d, J=8.8 Hz); ^{13}C NMR δ=21.6, 25.3, 30.3 (2C), 67.2, 112.8, 119.2 (2C), 129.3 (2C), 162.9, 169.7, and 169.9; IR 3000, 1720, and 1650 cm^{-1}; UV (MeOH) 222.2 (ε 15900) and 268.4 nm (3850).

Found: C, 72.88; H, 5.10; N, 6.43%. Calcd for $C_{13}H_{11}NO_2$: C, 73.23; H, 5.20; N, 6.57%.

10: colorless crystals, mp 129—131 °C; ^1H NMR δ=2.10 (1H, td, J=7.7, 4.8 Hz), 2.55 (3H, s), 2.76 (1H, dd, J=7.7, 6.2 Hz), 2.95 (1H, ddd, J=7.7, 6.2, 2.2 Hz), 5.18 (1H, d, J=5.1 Hz), 5.69 (1H, s), 5.96 (1H, dd, J=5.1, 2.2 Hz), 6.12 (1H, dd, J=9.9, 4.8 Hz), and 6.59 (1H, d, J=9.9 Hz); ^{13}C NMR δ=25.5, 26.6, 37.0, 42.0, 74.2, 114.7, 122.4, 131.9, 133.4, 134.0, 161.4, 169.7, and 170.2; IR 3000, 1720, and 1625 cm^{-1}; UV (MeOH) 238.0 (ε 9800) and 302.6 nm (5900).

Found: C, 73.28; H, 4.94; N, 6.58%. Calcd for $C_{13}H_{11}NO_2$: C, 73.23; H, 5.20; N, 6.57%.

11: colorless crystals, mp 123 °C; ^1H NMR δ=2.64 (3H, s), 3.56 (1H, dm, J=12.1 Hz), 4.0—4.2 (1H, m), 5.51 (1H, dd, J=9.5, 4.0 Hz), 5.71 (1H, dd, J=2.9, 2.6 Hz), 5.79 (1H, dd, J=6.2, 1.8 Hz), 5.88 (1H, ddd, J=9.5, 6.2, 2.6 Hz), 6.61 (1H, dd, J=5.5, 2.6 Hz), and 6.77 (1H, dd, J=5.5, 2.9 Hz); ^{13}C NMR δ=28.0, 40.3, 46.2, 110.2, 114.8, 121.9, 122.5, 129.8, 132.7, 152.1, 166.1, 167.8, and 172.3; IR 3010 and 1695 cm^{-1}; UV (MeOH) 265.8 nm (ε 19100).

Found: C, 73.05; H, 5.07; N, 6.49%. Calcd for $C_{13}H_{11}NO_2$: C, 73.23; H, 5.20; N, 6.57%.

(Received October 25, 1988)

Several oxetane derivatives having functional groups, such as ester, ketone, ether, acetal, and azo, at the end of 2-oxapolymethylene spacers which were linked to the C-3 carbon of an oxetane ring were readily prepared by a substitution reaction of the corresponding bromide of the oxetane. These oxetanes were polymerized by cationic ring-opening polymerization to give their polymers with molecular weights ranging from 16000 to 1000, depending on the structure of the functional group of the monomer used. When using bisoxetanes as a cross-linking agent in the above polymerization, insoluble resins containing soft, somewhat polar polyether networks as a polymer support were obtained. Some chemical reactions of the pendant functional groups were also examined for the oxetane derivatives and their polymers.

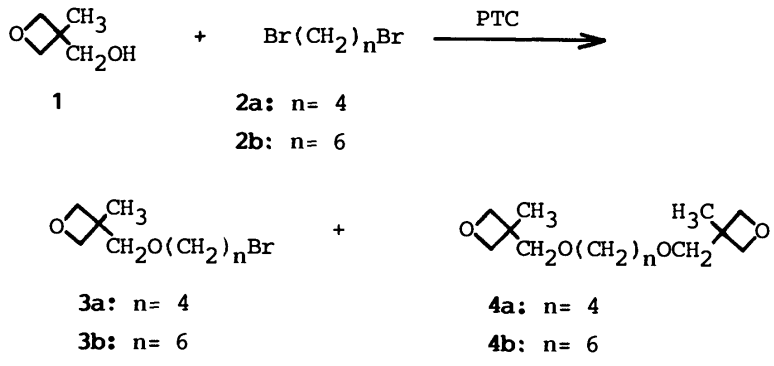
Since the mid-1960s, synthesis of functional polymers has been increasingly recognized to be one of the most interesting subjects in polymer chemistry. So far, a variety of monomers and their polymers have been prepared in order to design polymers which realize respective functionalities desired in using those polymers under applied conditions.[1-3] However, there have been few studies on the use of polyethers as materials for producing the functional polymers, particularly as polymer supports. In the course of our investigations of cationic ring-opening polymerization of oxetanes, we hoped to utilize oxetane derivatives for preparing various functional polymers which possess functional groups in the pendant groups of a soft, somewhat polar, polyether network. Accordingly, we have prepared oxetanes **3a** and **3b**, which have a bromine atom at the end of 2-oxapolymethylene spacers, as well as bisoxetanes **4a** and **4b**, which were used successfully as a cross-linking agent capable of forming polyether networks by cationic ring-opening copolymerizations with **3a** and **3b**.[4]

In the ordinary way of obtaining oxetanes with functional substituents, chlorine atoms of 3,3-bis(chloromethyl)oxetane were replaced with acetoxyl, alkoxyl, cyano, and azido groups.[5-8] Substitution reactions on the chloromethyl groups of poly[3,3-bis(chloromethyl)oxetane] were also examined to form ester, ether, thioether, and cyano groups at the side chain end of the uncross-linked polyoxetane.[9] In this article, we report the preparation and chemical reactions of oxetane derivatives and their polymers which will be used conveniently for designing various functional polyethers.

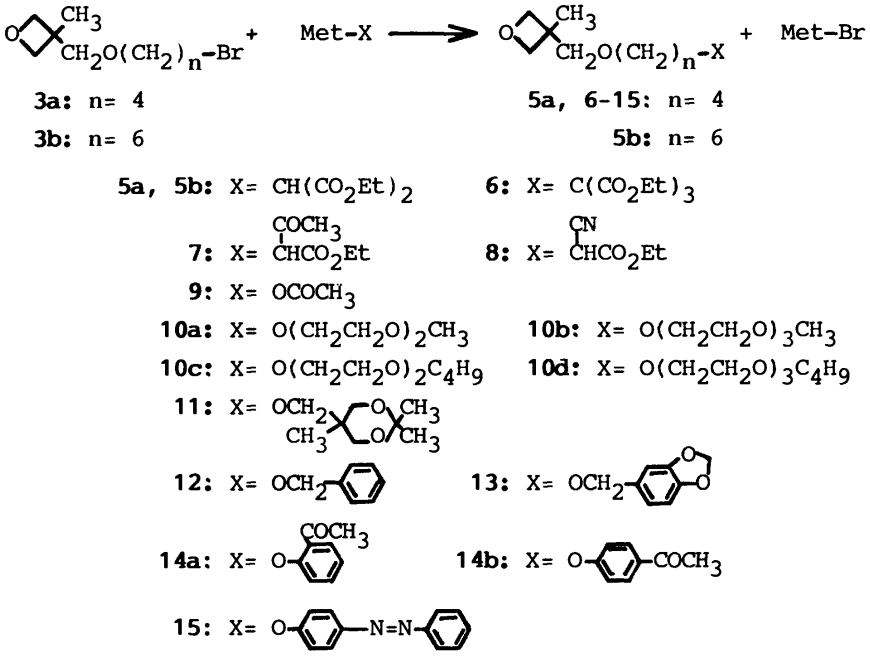
Results and Discussion

Oxetane Derivatives. Bromine atoms in oxetanes **3a** and **3b**, which were readily obtained by a reaction between **1** and **2** in the presence of tetrabutylammonium bromide (TBAB) as a phase-transfer catalyst (PTC), were replaced with several nucleophiles to give the corresponding functional groups at the C-3 position of an oxetane ring in fairly good yields. Results of the substitution reactions are summarized in Scheme 2 and Table 1.

The ^{1}H NMR spectrum of **5b** is exemplified in Fig.



Scheme 1.



Scheme 2.

Table 1. Preparation of Oxetane Derivatives by Substitution Reaction of **3a** with Nucleophilic Reagents

Nucleophilic reagent	Conditions	Product	
	Base or PTC/solvent/temp	No.	Yield/%
$CH_2(CO_2Et)_2$	NaOEt/EtOH/reflux	**5a**	88
$CH_2(CO_2Et)_2$	NaOEt/EtOH/reflux[a)]	**5b**	75
$NaC(CO_2Et)_3$	TBAB/PhMe/reflux	**6**	74
$AcCH_2CO_2Et$	NaOEt/EtOH/reflux	**7**	54
$NCCH_2CO_2Et$	NaOEt/EtOH/reflux	**8**	52
KOAc	TBAB/PhH/reflux	**9**	84
$HO(CH_2CH_2O)_2Me$	TBAB/hexane-50%NaOH/rt[b)]	**10a**	69
$HO(CH_2CH_2O)_3Me$	TBAB/hexane-50%NaOH/rt	**10b**	68
$HO(CH_2CH_2O)_2Bu$	TBAB/hexane-50%NaOH/rt	**10c**	59
$HO(CH_2CH_2O)_3Bu$	TBAB/hexane-50%NaOH/rt	**10d**	67
HTMDO[c)]	TBAB/hexane-50%NaOH/reflux	**11**	58
$HOCH_2Ph$	TBAB/hexane-50%NaOH/rt	**12**	73
MDOBA[d)]	TBAB/hexane-50%NaOH/rt	**13**	72
(*o*)-HOArAc	TBAB/PhH-50%NaOH/reflux	**14a**	81
(*p*)-HOArAc	TBAB/PhH-50%NaOH/reflux	**14b**	88
(*p*)-HOArN=NPh	TBAB/PhMe-50%NaOH/70°C	**15**	41

a) **3b** was used in place of **3a**. b) Room temperature. c) HTMDO refers to 5-hydroxymethyl-2,2,5-trimethyl-1,3-dioxane. d) MDOBA refers to 3,4-methylenedioxybenzyl alcohol.

1(A) to demonstrate the characteristic signals of these oxetane derivatives. Generally, methylene protons (H_a) of an oxetane ring show an AB quartet around δ 4.5—5.3, and methylene protons (H_b) adjacent to the oxetane ring and methyl protons (H_g) on the oxetane ring exhibit their singlets at about δ 3.5 and 1.3, respectively. Furthermore, in the IR spectra of oxetane derivatives, cyclic and acyclic ethers possess absorption bands due to a C-O-C stretching vibration, respectively, at 980 and 830, and 1100 cm^{-1}, as described in our previous report.[4)]

In *C*-alkylation reactions of malonic and acetoacetic esters with the bromide of **3a** or **3b**, their oxetane rings were not susceptible to the attack of carbanions, derived from the esters with sodium ethoxide as a base, while it is known that an oxirane ring is attacked by such carbanions to give a γ-lactone ring.[10,11)] *C*-Alkylation products of triethyl methane-1,1,1-tricarboxylate have been obtained by Newkome and coworkers by a reaction between alkyl bromide and triethyl sodiomethane-1,1,1-tricarboxylate in a benzene/*N*,*N*-dimethylformamide (DMF) mixture (1 : 1).[12)]

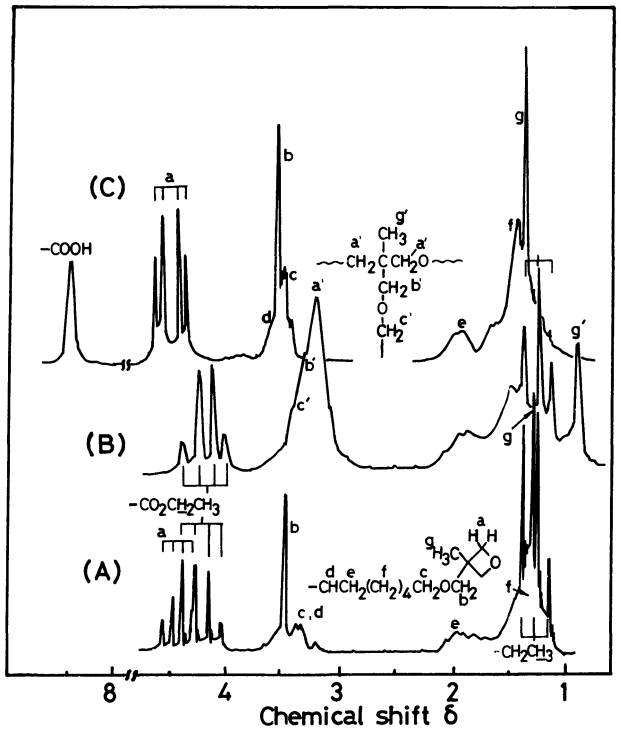


Fig. 1. ^{1}H NMR spectra of (A) **5b**, (B) poly (**5a**), and (C) **16b** (hydrolysis product from **5b**).

However, we have found that the *C*-alkylation product **6** was more readily prepared in an isolated yield of 74% by a phase-transfer catalytic equimolar reaction between the sodium salt of the triester and the bromide **3a** using TBAB as a PTC in toluene at 100 °C.

In connection with the further conversion of diesters **5** and **7** into other oxetane derivatives, some of their chemical reactions were examined. 1,1-Dicarboxylic esters in **5** were converted into the corresponding dicarboxylic acid of **16**, but not to a monocarboxylic acid, on hydrolysis of **5** with an aqueous sodium hydroxide (NaOH) solution in methanol at reflux temperature. As shown obviously from the ^{1}H NMR spectrum of **16b** in Fig. 1(C), a signal due to a carboxyl proton at δ 8.58 and an AB quartet due to methylene protons of the oxetane ring at δ 4.3—4.7 appear in an integral intensity ratio of 2:4, indicating that a decarboxylation reaction of **5** is difficult to achieve under the hydrolysis conditions applied. However, heating keto ester **7** in 1.0 mol dm^{-3} NaOH at 90 °C gave the corresponding ketone **17** via a decarboxylation of the sodium carboxylate formed from **7**. The ^{1}H NMR spectrum of **17** showed a distinct singlet due to an acetyl group and an AB quartet due to methylene protons of the oxetane ring, respectively, at δ 2.12 and 4.4—4.7, but did not show any signals due to the ester group or to a carboxyl proton.

As reported by Shih and Tirrell, polyoxiranes carrying ω-hydroxyalkyl pendant chains were prepared by methanolysis of the corresponding ω-acetoxyl and -benzoyloxyl groups of the pendants. The benzoate was derived from the chloride of a 3-chloropropyl pendant group by a phase-transfer catalytic reaction using tetrabutylammonium benzoate as a PTC in DMF.[13] These resulting polyoxiranes are considered to be new hydrophilic polyether elastomers. Concerning this preparation method for elastic polyhydroxyl polyethers, we have also found a facile method for preparing the elastic polyoxetane networks carrying a terminal hydroxyl group in the side chain; a bromine atom of **3a** was converted into a hydroxyl group of **18** by a phase-transfer catalytic reaction using potassium acetate in refluxing benzene in the presence of TBAB and by subsequent hydrolysis of the resultant acetate **9** with a 2.5 mol dm^{-3} aqueous NaOH solution in methanol under reflux. Alcohol **18** was soluble in water, although both the bromide **3a** and the acetate **9** were insoluble in water. The hydroxyl group of **18** can be further changed to esters of other carboxylic acids by reactions of **18** with acid chlorides in the presence of pyridine; thus, the cinnamate **19** was obtained in a 77% yield when using cinnamoyl chloride as an acid chloride. Additionally, acetates with aromatic residues **20a** and **20b** were readily obtained by reduction of the corresponding acetophenone derivatives **14a** and **14b**

with $NaBH_4$ in ethanol, followed by *O*-acylation of the resultant secondary alcohols with acetyl chloride. In the preparation of such esters as **19**, **20a**, and **20b** via the *O*-acylation of the pendant alcohol moiety with acyl chlorides, pyridine should be employed as a base in order to avoid a ring-opening reaction of the oxetane ring by the used acyl chloride. When pyridine was not added to the above reaction mixture, the required ester was not obtained, since none of the IR bands (980 and 830 cm^{-1}) and of ^1H NMR signals (δ 4.3—4.7) assignable to the oxetane ring were indicated in the spectra of the product.

Phase-transfer catalysis of **3a** with hydroxyl compounds having such functional groups as cyclic acetal, ketone, and azo also afforded desirable products in the presence of TBAB in 50% NaOH and either of hexane or benzene. In the preparation of these products, use of an equimolar amount of the hydroxyl compound to **3a** was enough to realize fairly good yields of products. By the Williamson synthesis, sodium salts of alkoxides and phenoxides have been prepared using sodium metal, sodium hydride, or potassium carbonate as a base in dry alcoholic (which give their alkoxide anions with the base too) or aprotic polar solvents such as DMF, in order to obtain ether products by a reaction of the sodium salts with halides. The present method using a small amount of TBAB in 50% NaOH as a base and commercially available hexane or benzene as the solvent is more facile and less expensive. In particular it can be applied conveniently when the sodium salts are insoluble or hardly soluble in the reaction medium used in the Williamson synthesis. An example is described for the synthesis of **3a** and **4a** by a phase-transfer catalytic reaction between **1** and **2a**.[4]

Preparation of Polyoxetanes. Those oxetanes carrying a functional group at the C-3 position of an oxetane ring can be used as a monomer of the cationic ring-opening polymerization in dichloromethane (DCM) at 0 °C with a boron trifluoride (BF_3)–THF (tetrahydrofuran) complex as an initiator. A 20-h polymerization of those oxetanes gave viscous liquid polymers, which were soluble in such common organic solvents as DCM, chloroform, benzene, acetone, ether, DMF, and THF. Uncross-linked polymers with the comb-like oligo(oxyethylene) side chains were soluble in methanol but not in water, although all the corresponding monomers were appreciably soluble in water because of the hydrophilicity of their oligo(oxyethylene) groups. When the bisoxetane **4a** was used as a comonomer in the above polymerizations of the oxetane derivatives, elastic gel polymers insoluble in the ordinary solvents were produced.

Table 2. Cationic Ring-Opening Polymerization of Oxetane Derivatives in CH_2Cl_2 at 0 °C for 20 h[a]

Monomer (Mole ratio)	Polymer[b]			
	Name	Yield/%	$10^{-3}\overline{M}_n$	Wavenumber[c]/cm^{-1}
5a	Poly (**5a**)	92	12.0	1750, 1250, 1030 (ester); 1100 (acyclic ether)
5a+**4a** (85/15)	**R-1**	89	Gel	
5b+**4a** (70/30)	**R-2**	89	Gel	
6	Poly (**6**)	91	5.9	1760, 1740, 1260, 1040 (ester) 1100 (acyclic ether)
7	Poly (**7**)	85	1.1	1740, 1250, 1070 (ester); 1720 (C=O); 1620 (C=C); 1100
8	—	0	—	—
9	Poly (**9**)	52[d]	16.4	1740, 1250, 1040 (ester); 1100

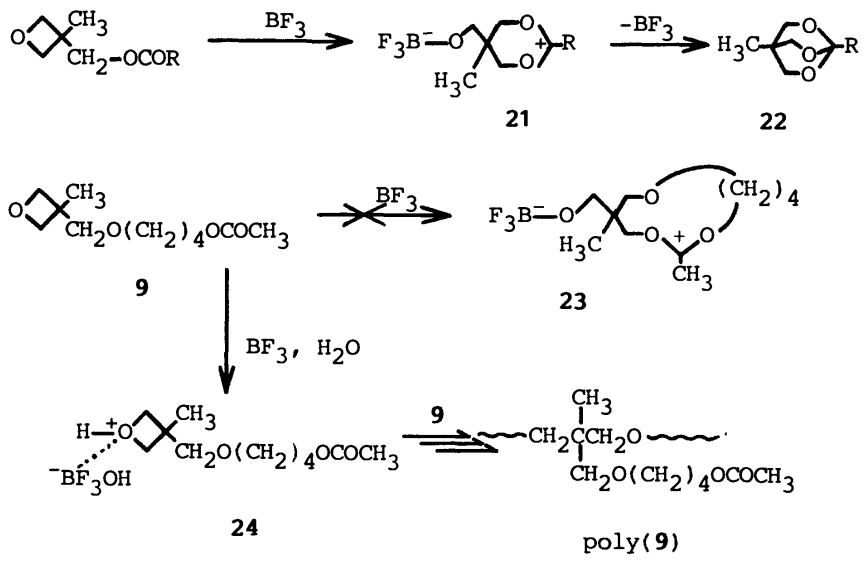
15	Poly (**15**)	33[g]	3.7	1255; 1110; 840 (para); 690 (phenyl)

a) Initiator, BF_3·THF (0.5 mol% to monomer); initial monomer concentration, 1.0—3.5 mol dm^{-3}. b) For a methanol-insoluble fraction. c) IR bands characteristic of functional groups are presented. d) For the rest, 39% yield of polymer with $\overline{M}_n$ of 2000 was obtained as a methanol-soluble fraction. e) Not determined. f) 37% of lower-molecular-weight polymer was obtained as a methanol-soluble fraction. g) In a methanol-soluble fraction, a considerable amount of unreacted monomer was present.

Existence of an ester group at the end of a 2-oxapolymethylene spacer did not prevent the oxetane monomer from expanding into its polymer with a considerably high molecular weight. It has been found by Corey and Raju that some esters of **1** are converted into the 2,6,7-trioxabicyclo[2.2.2]octane structure, but not the polyoxetane structure, via the zwitterion intermediate **21** which was derived from the (3-methyl-3-oxetanyl)methyl ester of a carboxylic acid in the presence of a 25 mol% of BF_3 etherate.[14] We also confirmed that (3-methyl-3-oxetanyl)methyl acetate could not give its polymer in the presence of a 0.5 mol% of BF_3·THF. However, **9** can be converted into its polymer, poly(**9**), but not an 11-membered heterocyclic intermediate **23**, via formation of a cyclic oxonium ion **24**, which is highly susceptible to a nucleophilic attack of **9**, by BF_3 besides a trace of moisture present in a reaction mixture.[15] Difficulty in forming the intermediate **23** may be ascribed to requiring a higher ring-strain energy for the formation of **23** than that of a stable six-membered ring in **21**, following the theory of ring-strain energies of cycloalkanes.[16]

Ester groups of poly(**9**), poly(**19**), and their **4a**-cross-linked analogues were hydrolyzed with 1.0 mol dm^{-3} NaOH in methanol at reflux temperature within reaction periods of 1 to 5 h, depending on the structure of the polymer used. The resultant uncross-linked polyols were soluble in methanol, but not in water. A **4a**-cross-linked polymer of **11** was also used to obtain a polyoxetane resin carrying a 1,3-glycol moiety at the spacer end; a cyclic acetal of **11** was refluxed in acetone containing 3.0 mol dm^{-3} aqueous HCl to give the 1,3-glycol moiety. The presence of this 1,3-glycol in the product is confirmed by its IR spectrum indicating absorption bands of the primary alcohol at 3400 and 1040 cm^{-1} as well as disappearance of bands due to the cyclic acetal at 1085 and 830 cm^{-1} (Fig. 2C). On the other hand, these acetal ring bands appear in the IR spectra of the copolymer **R-7** and monomer **11**, although IR bands due to the acetal and oxetane rings in **11** overlap each other at 830 cm^{-1} (Figs. 2A and 2B).



Scheme 7.

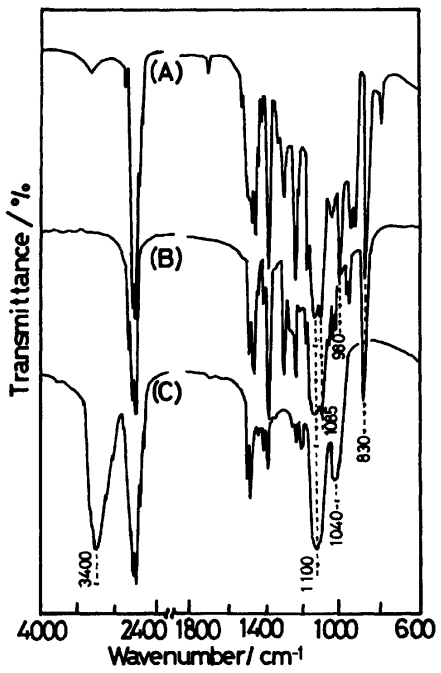


Fig. 2. IR spectra of (A) monomer **11**, (B) **4a**-cross-linked polymer of **11**, and (C) product polymer obtained by hydrolysis of the pendant cyclic acetal.

Polyoxetanes with terminal aliphatic and aromatic ketones in the side chain were prepared by cationic ring-opening polymerizations of **7**, **17**, **14a**, and **14b**, although they had low molecular weights of about 1000. In each of these polymerizations, the polymerization solution changed from colorless to orange or wine red during polymerization. This color disappeared on adding methanol to the solution after a reaction time of 20 h. Residual monomer was not detected by gas chromatography (GC) analysis of the polymerization mixture. These facts suggest that some other undesired side reaction than a termination reaction produced such low-molecular-weight polymers. On the other hand, **20a** and **20b** having an acetoxyl group in their side chains were polymerized under the same polymerization conditions as those applied for the polymerization of **14a** and **14b**, and gave colorless gel polymers, which were insoluble in the usual solvents, in spite of using no cross-linking agents such as **4a** and **4b** in this polymerization. The insolubility of those polymers may be interpreted as due to a high molecular weight, highly crystallized structure, or a cross-linked structure formed by an unexpected side reaction. The acetyl group of poly(**14a**) and poly(**14b**), which showed a strong IR band at 1680 cm^{-1}, were completely reduced with $NaBH_4$ to the corresponding secondary alcohol, a broad band of which appeared around 3400 cm^{-1}. IR spectra of the $NaBH_4$-reduced polymers were identified, respectively, with IR spectra of the polymers obtained by hydrolysis of poly(**20a**) and poly(**20b**) with 2.0 mol dm^{-3} NaOH in methanol. Presumably, the acetyl carbonyl group seems to be involved in the occurrence of a side reaction during the polymerization. A mechanism for this side reaction has not yet been clarified. The investigation of cationic ring-opening polymerization of **14a**, **14b**, **20a**, and **20b** is in progress in our laboratory. Oxetane **8** with a pendant cyano group did not give the corresponding polymer, presumably due to the existence of the cyano group which is considered to be a Lewis base capable of coordinating with a BF_3 initiator, resulting in lack of a reaction step initiated by BF_3.

Concerning the hydrolysis of the malonic ester group of **5**, a hydrolysis of the corresponding diester of a cross-linked polymer was also examined by warming

it in 1.0 mol dm^{-3} aqueous NaOH and methanol. One gram of the resultant polymer, which showed no IR bands due to the ester group, was neutralized with 7.3 mmol of NaOH, indicating that the hydrolyzed polymer had a pendant dibasic acid group. The calculated amount of the carboxyl group is 6.5 mmol per 1.0 g of the dry polymer containing a 15 mol% of **4a** as a cross-linking agent. If the polymer has a monobasic acid pendant group by decarboxylation of the dibasic acid formed intermediately upon the hydrolysis, the amount of carboxyl group is calculated to be 3.7 mmol per 1.0 g of the resultant polymer. Therefore, it is also confirmed that the decarboxylation reaction does not take place under reaction conditions applied for the hydrolysis of the malonic ester at the spacer end of the polyoxetane resin. Oxetane **16b** with a pendant carboxyl group polymerized on leaving **16b** in a test tube at room temperature for at least 3 months, as confirmed by the IR spectrum lacking absorption bands due to an oxetane ring.

The preceding information about the chemical reactions of the oxetane derivatives and their polymers will be of assistance in guiding work on the design of functional polymers that are composed of a soft, somewhat polar polyether network with qualities different from those of a hard, less polar polystyrene support widely used in functional polymer synthesis.

Experimental

Materials. Oxetanes **3a** and **3b**, and bisoxetanes **4a** and **4b** were obtained according to the method described by us previously.[4]

Diethyl 7-(3-Methyl-3-oxetanyl)-6-oxaheptane-1,1-dicarboxylate (5a) and Diethyl 9-(3-Methyl-3-oxetanyl)-8-oxanonane-1,1-dicarboxylate (5b): Diethyl sodiomalonate was formed from diethyl malonate (26 mmol) and sodium metal (21 mmol) in dry ethanol (200 ml) and, subsequently, allowed to react with **3a** or **3b** (17 mmol) under reflux for 2 h. After removing ethanol from the reaction mixture by evaporation, the residue was neutralized with acetic acid and shaken both with ether and water. The organic layer was separated from the aqueous layer, dried over Na_2SO_4, and distilled to give **5a** (88%) or **5b** (75%).

5a: bp 140—142 °C (79 Pa); IR (neat) 1750, 1735, 1240, 1155, and 1025 (ester), 1115 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.25 (6H, t, J=7.0 Hz, CH_2CH_3), 1.28 (3H, s, CH_3 on the oxetane ring), 1.6—2.2 [6H, m, $CH_2OCH_2(CH_2)_3CH$], 3.28—3.70 [total 5H: s (δ=3.46), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_3CH$], 4.18 (4H, q, J=7.0 Hz, CH_2CH_3), and 4.31 and 4.47 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring).

Found: C, 60.65; H, 9.03%. Calcd for $C_{16}H_{28}O_6$: C, 60.73; H, 8.94%.

5b: bp 173—175 °C (53 Pa); IR (neat) 1755, 1735, 1240, and 1025 (ester), 1115 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.00—2.13 [total 19H: t (δ=1.26), J=7.0 Hz, CH_2CH_3; s (δ=1.31), CH_3 on the oxetane ring; m, $CH_2OCH_2(CH_2)_5CH$], 3.25—3.65 [total 5H: s (δ=3.48), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_5CH$], 4.23 (4H, q, J=7.0 Hz, CH_2CH_3), and 4.35 and 4.49 (each 2H, AB quartet, J=5.0 Hz, CH_2 of the oxetane ring).

Found: C, 62.48; H, 9.57%. Calcd for $C_{18}H_{32}O_6$: C, 62.75; H, 9.38%.

9-(3-Methyl-3-oxetanyl)-8-oxanonane-1,1-dicarboxylic Acid (16b): **5b** was allowed to react with 1.0 mol dm^{-3} NaOH (twofold equivalence to the ester) in 50% aqueous methanol at reflux temperature for 5 h. After the reaction mixture has been concentrated by means of an evaporator, the residue was acidified to pH 5 with aqueous HCl, saturated with Na_2SO_4, and extracted three times with ether. The combined extracts were evaporated to obtain an oily hydrolysis product **16b** in a 72% yield: IR (neat) 3400 and 1720 (COOH), 1110 (acyclic ether), and 980 and 830 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10—1.74 [total 11H: s (δ=1.31), CH_3; m, $CH_2OCH_2(CH_2)_4CH_2CH$], 1.74—2.10 [2H, m, $CH_2CH(COOH)_2$], 3.20—3.60 [total 5H: s (δ=3.46), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_4CH_2CH$], 4.41 and 4.59 (each 2H, AB quartet, J=5.9 Hz, CH_2 of the oxetane ring), and 8.58 (2H, bs, COOH).

Triethyl 7-(3-Methyl-3-oxetanyl)-6-oxaheptane-1,1,1-tricarboxylate (6): Prepared in a 74% yield by a phase-transfer catalytic reaction between triethyl sodiomethane-1,1,1-tricarboxylate[17] (21 mmol) and **3a** (21 mmol) in the presence of TBAB (1.1 mmol) in toluene (50 ml) at 100 °C for 7 h: bp 156 °C (10 Pa); IR (neat) 1760, 1749, 1260, and 1040 (ester), 1110 (acyclic ether), and 980 and 830 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.29 (9H, t, J=6.6 Hz, CH_2CH_3), 1.31 (3H, s, CH_3 on the oxetane ring), 1.46—1.95 [4H, m, $CH_2OCH_2(CH_2)_2CH_2C$], 1.95—2.39 [2H, m, $CH_2OCH_2(CH_2)_2CH_2C$], 3.37—3.70 [total 4H: m, $CH_2OCH_2(CH_2)_2CH_2C$; s (δ=3.50), CH_2 adjacent to the oxetane ring], 4.29 (6H, q, J=6.6 Hz, CH_2CH_3), and 4.35 and 4.53 (each 2H, AB quartet, J=5.8 Hz, CH_2 of the oxetane ring).

Found: C, 58.57; H, 8.34%. Calcd for $C_{19}H_{32}O_8$: C, 58.74; H, 8.32%.

Ethyl 8-(3-Methyl-3-oxetanyl)-2-acetyl-7-oxaoctanoate (7) and 9-(3-Methyl-3-oxetanyl)-8-oxa-2-nonanone (17): **7** was prepared from ethyl acetoacetate (50 mmol), bromide **3a** (42 mmol), and sodium metal (50 mmol) in dry ethanol. Working up the reaction mxture and distilling the resultant organic layer gave **7** with a purity of 98% by GC analysis: bp 116—124 °C (57 Pa); IR (neat) 1740, 1240—1150, and 1060—1020 (ester), 1710 (C=O), 1620 (C=C of an enol form), 1120 (acyclic ether), and 980 and 830 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.0—2.0 [total 12H: t (δ=1.27), J=7.0 Hz, CH_2CH_3; s (δ=1.30), CH_3 on the oxetane ring; m, $CH_2OCH_2(CH_2)_3CH$], 2.21 (3H, s, $COCH_3$), 3.28—3.70 [total 5H: s (δ=3.47), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_3CH$], 4.21 (2H, q, J=7.0 Hz, CH_2CH_3), and 4.31 and 4.39 (each 2H, AB quartet, J=5.0 Hz, CH_2 of the oxetane ring).

Oxo ester **7** (42 mmol) was stirred in 1.0 mol dm^{-3} NaOH (84 mmol) at 50 °C for 3 h until an oily layer of **7** disappeared completely. The alkaline solution was heated at 90 °C for 4 h. The resulting organic layer was extracted with ether, separated from the aqueous layer, dried over Na_2SO_4, and distilled to give pure **17** in a 53% yield based on **3a**: bp 110—115 °C (107 Pa); IR (neat) 1710 (C=O), 1120 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$)

δ=1.21—1.96 [total 9H: s (δ=1.29), CH_3 on the oxetane ring; m, $CH_2OCH_2(CH_2)_3CH_2$], 2.12 (3H, s, $COCH_3$), 2.24—2.63 (2H, m, CH_2Ac), 3.31—3.64 [total 4H: s (δ=3.46), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_3CH_2$], and 4.32 and 4.47 (each 2H, AB quartet, J=5.6 Hz, CH_2 of the oxetane ring).

6-(3-Methyl-3-oxetanyl)-5-oxahexyl Acetate (9) and 3-(6-Hydroxy-2-oxahexyl)-3-methyloxetane (18): **3a** (84.3 mmol) was heated with powdered potassium acetate (0.28 mol) in benzene (50 ml) in the presence of TBAB (4.3 mmol) under reflux for 6 h with efficiently stirring. The organic layer was washed with water and dried over Na_2SO_4. After removing the solvent from the reaction mixture, fractional distillation of the residue gave slightly impure **9** in about 84% yield: bp 107 °C (116 Pa); IR (neat) 1745, 1245, and 1040 (ester), 1110 (acyclic ether), and 980 and 830 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.33 (3H, s, CH_3), 1.48—1.90 [4H, m, $OCH_2(CH_2)_2CH_2OAc$], 2.05 (3H, s, $COCH_3$), 3.35—3.78 [total 6H: m, $CH_2OCH_2(CH_2)_2CH_2OAc$; s (δ=3.49), CH_2 adjacent to the oxetane ring], 4.13 (2H, t, J=5.6 Hz, CH_2OAc), and 4.37 and 4.53 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring).

The acetate **9** was refluxed with 2.5 mol dm^{-3} NaOH in methanol for 2 h. The methanol was evaporated and the residue shaken with hexane. The alkaline aqueous layer was separated from the organic layer, saturated with sodium chloride, and shaken with ether to extract an alcoholic product. The ethereal layer was concentrated and distilled to give **18** in a 73% yield based on **3a**: bp 98—99 °C (93 Pa); IR (neat) 3400 and 1065 (alcohol), 1120 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.31 (3H, s, CH_3), 1.43—1.90 [4H, m, $OCH_2(CH_2)_2CH_2OH$], 3.12—3.86 [total 7H: m, $CH_2OCH_2(CH_2)_2CH_2OH$; s (δ=3.50), CH_2 adjacent to the oxetane ring], and 4.35 and 4.51 (each 2H, AB quartet, CH_2 of the oxetane ring).

Found: C, 61.89; H, 10.64%. Calcd for $C_9H_{18}O_2$: C, 62.02; H, 10.43%.

6-(3-Methyl-3-oxetanyl)-5-oxahexyl Cinnamate (19): The alcohol **18** (32 mmol) was esterified with cinnamoyl chloride (33 mmol) and pyridine (3 ml) in DCM (30 ml) at −10 to 0 °C for 5 h. The desired product **19** was isolated in a 77% yield by distillation: bp 172—174 °C (12 Pa); IR (neat) 1580, 1500, 1450, and 770 (phenyl), 1715, 1315, and 1175 (ester), 1640 (C=C), 1120 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.34 (3H, s, CH_3), 1.57—2.07 [4H, m, $CH_2OCH_2(CH_2)_2$], 3.36—3.73 [total 4H: s (δ=3.50), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_2$], 4.41—4.69 [total 6H: m, CH_2OCO; AB quartet (δ=4.39 and 4.55), J=6.9 Hz, CH_2 of the oxetane ring], 6.49 (1H, d, J=16.0 Hz, CH=CHPh), and 7.34—7.69 [total 6H: m, ArH; d (δ=7.27), J=16.0 Hz, CH=CHPh].

3-(2,7,10,13-Tetraoxatetradecyl)- (10a), 3-(2,7,10,13,16-Pentaoxaheptadecyl)- (10b), 3-(2,7,10,13-Tetraoxaheptadecyl)- (10c), and 3-(2,7,10,13,16-Pentaoxaicosyl)-3-methyloxetanes (10d): Each of these compounds was prepared by the phase-transfer catalytic reaction of **3a** (41 mmol) with an appropriate di- or triethylene glycol monoalkyl ether (21 mmol) in hexane (20 ml) and 50% NaOH (28 g) for 5 h under reflux in the presence of TBAB (1.1 mmol). The reaction mixture was diluted with water (70 ml), saturated with Na_2SO_4, and extracted continuously with ether for 30 h. The ether extract was distilled to give **10a** (69%), **10b** (59%), **10c** (68%), or **10d** (67%). These compounds had characteristic IR bands at 1110 (acyclic ether) and 980 and 835 cm^{-1} (cyclic ether).

10a: bp 116—119 °C (20 Pa); ^1H NMR ($CDCl_3$) δ=1.30 (3H, s, CH_3 on oxetane ring), 1.50—1.85 [4H, m, $CH_2OCH_2(CH_2)_2CH_2$], 3.31—3.89 [total 17H: s (δ=3.38), OCH_3; s (δ=3.48), CH_2 adjacent to the oxetane ring; s (δ=3.62), $(CH_2CH_2O)_2$; m, $CH_2OCH_2(CH_2)_2CH_2$], and 4.32 and 4.50 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring).

10b: bp 144—145 °C (49 Pa); ^1H NMR ($CDCl_3$) δ=1.30 (3H, s, CH_3 on the oxetane ring), 1.40—1.84 [4H, m, $CH_2OCH_2(CH_2)_2CH_2O$], 3.30—3.80 [total 21H: s, (δ=3.37), OCH_3; s (δ=3.47), CH_2 adjacent to the oxetane ring; s (δ=3.60), $OCH_2CH_2OCH_2CH_2OCH_2CH_2O$; s ($\delta$=3.66), $OCH_2CH_2OCH_2CH_2OCH_2CH_2O$; m, $CH_2OCH_2(CH_2)_2CH_2O$], and 4.32 and 4.48 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring).

Found: C, 60.02; H, 10.27%. Calcd for $C_{16}H_{32}O_6$: C, 59.96; H, 10.09%.

10c: bp 120—132 °C (45 Pa); ^1H NMR ($CDCl_3$) δ=0.71—1.06 (3H, m, CH_3 of butyl), 1.22—1.81 [total 11H: s (δ=1.24), CH_3 on the oxetane ring; m, $CH_2OCH_2(CH_2)_2CH_2O$ and $OCH_2(CH_2)_2CH_3$], 3.29—3.78 [total 16H: s (δ=3.46), CH_2 adjacent to the oxetane ring; s (δ=3.60), $O(CH_2CH_2O)_2$; m, $CH_2OCH_2(CH_2)_2CH_2O$ and $OCH_2(CH_2)_2CH_3$], and 4.31 and 4.49 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring).

10d: bp 142—157 °C (51 Pa); ^1H NMR ($CDCl_3$) δ=0.76—1.12 (3H, m, CH_3 of butyl), 1.24—1.94 [total 11H: s (δ=1.31), CH_3 on the oxetane ring; m, $CH_2OCH_2(CH_2)_2CH_2O$ and $OCH_2(CH_2)_2CH_3$], 3.32—3.48 [total 20H: s (δ=1.47), CH_2 adjacent to the oxetane ring; s (δ=1.61), $OCH_2CH_2OCH_2CH_2OCH_2CH_2O$; s ($\delta$=1.66), $OCH_2CH_2OCH_2CH_2OCH_2CH_2O$; m, $OCH_2(CH_2)_2CH_2O$ and $OCH_2(CH_2)_2CH_3$], and 4.33 and 4.49 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring).

3-[8-(2,2,5-Trimethyl-1,3-dioxan-5-yl)-2,7-dioxaoctyl]-3-methyloxetane (11): **11** was prepared by a phase-transfer catalytic reaction using **3a** (21 mmol) and 5-hydroxymethyl-2,2,5-trimethyl-1,3-dioxane (21 mmol) in hexane (30 ml) and 50% NaOH (28 g) in the presence of TBAB (1.1 mmol) at reflux temperature for 12 h. The ordinary work-up gave pure **11** in a 58% yield: bp 126.0—126.5 °C (69 Pa); IR (neat) 1110 (acyclic ether), 980 and 830 (cyclic ether), and 1085 and 830 cm^{-1} (cyclic acetal); ^1H NMR ($CDCl_3$) δ=0.87 (3H, s, nongeminal CH_3 on the acetal ring), 1.31 (3H, s, CH_3 on the oxetane ring), 1.39 and 1.42 (each 3H, each s, geminal CH_3), 1.50—1.74 [4H, m, $CH_2OCH_2(CH_2)_2CH_2OCH_2$], 3.32—3.80 [total 12H: s (δ=3.39), CH_2 adjacent to the acetal ring; s (δ=3.47), CH_2 adjacent to the oxetane ring; m (δ=3.32—3.52), $CH_2OCH_2(CH_2)_2CH_2OCH_2$; AB quartet ($\delta$=3.53 and 3.70), J=11.0 Hz, CH_2 of the acetal ring], and 4.43 and 4.50 (each 2H, AB quartet, J=5.6 Hz, CH_2 of the oxetane ring).

3-[8-Phenyl-2,7-dioxaoctyl]-3-methyloxetane (12): A phase-transfer catalytic reaction of **3a** (42 mmol) with benzyl alcohol (38 mmol) gave **12** in a 72% yield in the presence of TBAB (1.9 mmol) in hexane (40 ml) and 50% NaOH (50 g): bp 144.0—144.5 °C (67 Pa); IR (neat) 1605, 1590, 1500, 740, and 700 (monosubstituted benzene), 1110 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.28 (3H, s, CH_3), 1.47—1.97 [4H, m, $OCH_2CH_2(CH_2)_2CH_2O$], 3.29—3.71 [total 6H: m, $OCH_2(CH_2)_2CH_2O$; s (δ=3.43), CH_2 adjacent to the oxetane ring], 4.23—4.65 [total 6H: s

(δ=4.49), CH_2Ph; AB quartet (δ=4.31 and 4.49), J=5.5 Hz, CH_2 of the oxetane ring], and 7.3—7.5 (5H, m, ArH).

Found: C, 72.73; H, 9.39%. Calcd for $C_{16}H_{24}O_3$: C, 72.68; H, 9.17%.

3-[8-(3,4-Methylenedioxyphenyl)-2,7-dioxaoctyl]-3-methyloxetane (13): In the same way as above, **13** was prepared from **3a** and piperonyl alcohol in a 72% yield: bp 152—160 °C (7.3 Pa); IR (neat) 1110 (acyclic ether), 980 and 830 (cyclic ether), 1040 and 930 (cyclic acetal), and 1610, 1505, 1495, and 810 cm^{-1} (1,2,4-trisubstituted benzene); ^1H NMR ($CDCl_3$) δ=1.29 (3H, s, CH_3), 1.56—1.76 [4H, m, CH_2OCH_2-(CH_2)$_2CH_2$], 3.36—3.56 [total 6H: s (δ=3.47), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_2CH_2OCH_2Ar$], 4.39 (2H, s, CH_2Ar), 4.33 and 4.49 (each 2H, AB quartet, J=5.8 Hz, CH_2 of the oxetane ring), 5.93 (2H, s, CH_2 of acetal), and 6.72—6.87 (3H, m, ArH).

Found: C, 66.10; H, 8.08%. Calcd for $C_{17}H_{24}O_5$: C, 66.20; H, 7.86%.

3-[7-(2- and 4-Acetylphenyl)-2,7-dioxaheptyl]-3-methyloxetanes (14a and 14b): These products were prepared by the phase-transfer catalytic reaction of *o*- or *p*-hydroxyacetophenone (37 mmol) with **3a** (37 mmol) in benzene (50 ml) and 50% NaOH (49 g) at 80 °C for 6—8 h in the presence of TBAB (1.8 mmol). The ordinary work-up of the reaction mixture gave **14a** (81%) or **14b** (88%).

14a: bp 172 °C (19 Pa); IR (neat) 1600, 1580, 1490, and 760 (1,2-disubstituted benzene), 1675 (acetyl C=O), 1240 (aromatic ether), 1115 (acyclic ether), and 980 and 830 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.29 (3H, s, CH_3 on the oxetane ring), 1.52—2.20 [4H, m, $CH_2OCH_2(CH_2)_2CH_2O$], 2.62 (3H, s, $COCH_3$), 3.37—3.70 [total 4H: s (δ=3.47), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_2CH_2OAr$], 4.08 (2H, bt, CH_2OAr), 4.32 and 4.50 (each 2H, AB quartet, CH_2 of the oxetane ring), and 6.8—7.9 (4H, m, ArH).

Found: C, 69.66; H, 8.29%. Calcd for $C_{17}H_{24}O_4$: C, 69.82; H, 8.29%.

14b: bp 154—156 °C (8Pa); IR (neat) 1600, 1575, 1515, and 835 (1,4-disubstituted benzene), 1680 (acetyl C=O), 1255 (aromatic ether), 1115 (acyclic ether), and 980 and 830 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.12 (3H, s, CH_3 on the oxetane ring), 1.40—1.97 [4H, m, $CH_2OCH_2(CH_2)_2CH_2O$], 2.34 (3H, s, $COCH_3$), 3.25—3.52 [total 4H: s (δ=3.30), CH_2 adjacent to the oxetane ring; m, $CH_2OCH_2(CH_2)_2CH_2OAr$], 3.88 (2H, bt, CH_2OAr), 4.15 and 4.33 (each 2H, AB quartet, CH_2 of the oxetane ring), and 6.6—7.9 (4H, AB quartet-like, ArH).

Found: C, 69.65; H, 8.46%. Calcd for $C_{17}H_{24}O_4$: C, 69.82; H, 8.29%.

3-[7-[2- and 4-(1-Acetoxyethyl)phenyl]-2,7-dioxaheptyl]-3-methyloxetanes (20a and 20b): **14a** or **14b** (17 mmol) was stirred with $NaBH_4$ (17 mmol) in ethanol (80 ml) at 60 °C for 2 h. The ethanol was evaporated, and the residue shaken with both water and ether. The organic layer was separated from the aqueous layer and dried over Na_2SO_4. The crude product, which was obtained by removing the solvent from the organic layer, was allowed to react with acetyl chloride (17 mmol) in DCM (50 ml) containing pyridine (3 ml) at 20—25 °C for 9 h. The reaction mixture was poured into ice and extracted with DCM. The organic layer was washed with water and dried over Na_2SO_4. Removal of the solvent followed by distillation of the residue gave **20a** (90%) or **20b** (83%).

20a: bp 151 °C (23 Pa); IR (neat) 1740, 1250, and 1060 (ester), 1605, 1590, 1500, 1475, 755 (1,2-disubstituted benzene), 1240 (aromatic ether), 1120 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.21 (3H, s, CH_3 on the oxetane ring), 1.50 [3H, s, J=6.6 Hz, CH_3CH-(OAc)Ar], 1.64—2.05 [4H, m, $CH_2OCH_2(CH_2)_2CH_2O$], 2.07 (3H, s, $OCOCH_3$), 3.34—3.70 [total 4H: s (δ=3.49), CH_2 adjacent to the oxetane ring; t-like, $CH_2OCH_2(CH_2)_2CH_2$-OAr], 3.87—4.19 (3H, t-like, CH_2OAr), 4.33 and 4.51 (each 2H, AB quartet, J=6.0 Hz, CH_2 of the oxetane ring), 6.30 (1H, q, J=6.6 Hz, CHAr), and 6.2—7.5 (4H, m, ArH).

20b: bp 174—175 °C (41 Pa); IR (neat) 1744, 1245, and 1060 (ester), 1620, 1590, 1520, and 835 (1,4-disubstituted benzene), 1240 (aromatic ether), 1120 (acyclic ether), and 980 and 835 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.29 (3H, s, CH_3 on the oxetane ring), 1.39 [3H, d, J=7.0 Hz, CH_3CH-(OAc)Ar], 1.63—1.93 [4H, m, $CH_2OCH_2(CH_2)_2CH_2O$], 2.04 (3H, s, $OCOCH_3$), 3.41—3.69 [total 4H: s (δ=3.51), CH_2 adjacent to the oxetane ring; t-like, $CH_2OCH_2(CH_2)_2CH_2$-OAr], 3.88—4.18 (2H, t-like, CH_2OAr), 4.35 and 4.53 (each 2H, AB quartet, J=5.0 Hz, CH_2 of the oxetane ring), 5.87 (1H, q, J=7.0 Hz, CHAr), and 6.8—7.5 (4H, AB quartet-like, ArH).

4-[[6-(3-Methyl-3-oxetanyl)-5-oxahexyl]oxy]azobenzene (15): **15** was prepared by a phase-transfer catalytic reaction using **3a** (21 mmol) and 4-hydroxyazobenzene (21 mmol) in toluene (30 ml) and 50% NaOH (30 g) in the presence of TBAB (1.1 mmol) at reflux temperature. After working up the reaction mixture in the ordinary way, recrystallization of the crude product from ethanol-DCM gave a yellow-colored **15** in a 41% yield: mp 57—59 °C; IR (KBr) 1615, 1580, 1475, 840, and 685 (mono- and disubstituted benzenes), 1260 (aromatic ether), 1110 (acyclic ether), and 980 and 840 cm^{-1} (cyclic ether); ^1H NMR ($CDCl_3$) δ=1.31 (3H, s, CH_3), 1.36—2.00 [4H, m, $CH_2OCH_2(CH_2)_2CH_2$], 3.40—3.60 [total 4H: s (δ=3.48), CH_2 adjacent to the oxetane ring; t-like, CH_2OCH_2-$(CH_2)_2CH_2OAr$], 3.92—4.14 (2H, t-like, CH_2OAr), 4.35 and 4.52 (each 2H, AB quartet, J=5.9 Hz, CH_2 of the oxetane ring), and 6.8—8.0 (9H, m, ArH).

Preparation of Polymers: Polymers of oxetane derivatives were prepared by their cationic ring-opening polymerization in DCM with BF_3·THF as an initiator, according to the method we previously reported.[4]

Polymer Reactions. Hydrolysis of Malonic Ester Groups of Cross-Linked Resins: The ester groups were hydrolyzed by warming the resins with an excess amount of 1.0 mol dm^{-3} NaOH in methanol under reflux. The reaction mixture was concentrated by means of an evaporator and acidified to pH 5 with aqueous HCl. The resinous product was filtered and washed with water and then with methanol. After drying the resin, its weight was measured (yield, 94%). After immersing the resin in 0.05 mol dm^{-3} NaOH for 24 h, an aliquot of the alkaline supernatant was withdrawn to determine acid equivalent of the carboxyl group of the resin by back titration with 0.05 mol dm^{-3} HCl; 1 g of the dry resin was neutralized with 7.28 mmol of NaOH.

Hydrolysis of Polymers Carrying Acetate and Cinnamate Groups in the Side Chain: These polymers were stirred with an excess amount of 2.5 mol dm^{-3} NaOH in methanol under reflux for 1—5 h. After removing the methanol by evaporation, the residue was extracted with ether or benzene in the case of the hydrolysis of uncross-linked polymers.

When using cross-linked polymers, the resultant polymers were filtered and washed successively with water and methanol. Hydrolyzed polymers were obtained in 85—95% yields. IR spectra of these product polymers indicated a strong band due to the hydroxyl group around 3400 cm^{-1}, but did not show bands due to ester and carboxylate groups.

Hydrolysis of a Cyclic Acetal of Resin R-7: A **4a**-cross-linked polymer, **R-7**, was stirred in acetone containing 10% of its volume of 3.0 mol dm^{-3} aqueous HCl for 8 h under reflux. The acetone was removed by evaporation. A polymerized product was collected by filtration and washed successively with water and methanol. After being dried at 70 °C for 7 h in vacuo, the polymer was weighed (yield, 95%).

Measurement. GC analysis of the products was performed in a Shimadzu GC-8A apparatus: glass column (3.2ϕ×1 m) packed with Silicone High Vacuum Grease (30%)/Celite (80—100 mesh); carrier gas, He (66 cm^3 min^{-1}); temp, 200 °C. The IR spectra were recorded on a JASCO A-202 spectrometer and ^1H NMR on a 60 (Hitach R-24B) or 100 MHz instrument (JEOL FX-100S) using $CDCl_3$ as a solvent and TMS as an internal standard at 25 °C. Molecular weight measurements were made by VPO in a Corona molecular weight apparatus (model 117).

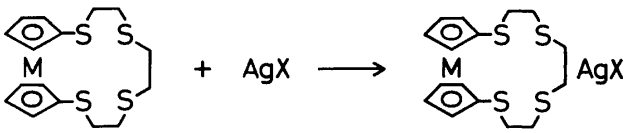
(Received November 1, 1988)

Tetrathia[10](1,1′)ferrocenophane reacts with silver(I) perchlorate and/or trifluoromethamesulfonate to form dimeric 1:1 complexes (**2c** and **2d**) in 73 and 60% yields, respectively. The corresponding complexes (**2a** and **2b**) of tetrathia[10](1,1′)ruthenocenophane were also obtained in 45 and 33% yields, respectively. The crystal structure of complex **2c** was determined by the X-ray method. The crystal data: monoclinic, space group $P2_1/a$, a=19.227(3), b=10.619(3), c=9.739(2) Å, β=91.71(2)°, U=1987.8 Å^3, D_c=2.02 g cm^{-3}, Z=4, μ(Mo $K\alpha$)=23 cm^{-1}, R=0.075. In complex **2c** the inner coordination sphere of the silver is completed by a sulfur atom of another ligand bonded axially to produce a five-coordinate silver ion with an overall slightly distorted square-pyramidal geometry. The temperature dependence of the ^{1}H NMR spectra of **2** was also examined. The rate between the silver free ligand **1a** and complex **2b** at room temperature was very first by the ^{1}H NMR scale.

Transition metal complexes with thioether ligands are of much current interest from the viewpoint of coordination chemistry and biological aspects. Such complexes have been extensively reviewed recently.[1] Of particular interest in coordination chemistry are the metal complexes of macrocyclic polythiaethers. For example, the polythiacrown ether ligands, such as 1,4,7-trithiacyclononane and 1,4,7,10,13,16-hexathiacyclooctadecane, often impose novel electronic properties on transition metal ions.[2,3] It is well-known that the complexes of silver(I) exhibit a preference for linear two coordination and occasionally, tetrahedral four coordination. Higher numbers of coordination can be forced by polydentate macrocyclic ligands, though such complexes generally show irregular geometries and ambiguous coordination numbers due to a poor fit between the metal ion and ligand.[4-13] For example, six and four coordination of Ag(I) are typical examples. However, to the best of the author's knowlege, no mention has been made in the literature about the fivehold coordination of thiaethers on Ag(I) ion. We have previously reported on the preparation of polythia[n]ruthenocenophanes,[14] -ferrocenophanes,[15] and 1,n-dioxathia[n]ruthenocenophanes,[16] which exhibited considerably enhanced Ag(I) cation binding compared with the corresponding ring membered crown ethers. We report here the preparation and the first novel structure of tetrathiaferrocenocrown ether complex of silver(I).

Silver(I) perchlorate or silver(I) trifluoromethanesulfonate (0.1 mmol) in acetonitrile (5 ml) was slowly added to a gently refluxing acetonitrile solution (10 ml) containing tetrathia[10]metallocenophane (**1**, 0.1 mmol). The resulting crystals were collected by filtration and washed with a small amount of acetonitrile to give 1:1 complexes (**2**) in 33—73% yields.

X-Ray Analyses. Recrystallization of **2c** from hot acetonitrile afforded brown crystals suitable for X-ray diffaction studies. The conformation of the complex (**2c**) is illustrated in Fig. 1, which also shows the atom



1a: M=Ru
1b: M=Fe

2a: M=Ru, X=ClO_4
2b: M=Ru, X=CF_3SO_3
2c: M=Fe, X=ClO_4
2d: M=Fe, X=CF_3SO_3

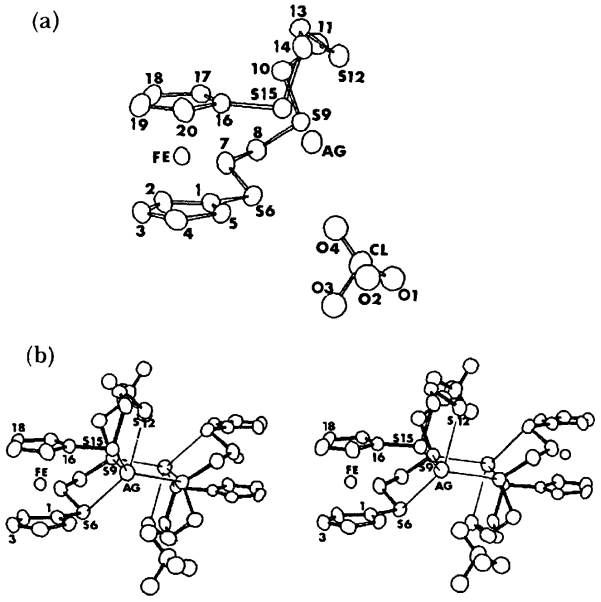


Fig. 1. ORTEP drowing of **2c**. (a) Molecular conformation and atomic labelling. (b) Stereoscopic drowing of the molecule.

labels used. The positional parameters for nonhydrogen atoms are listed in Table 1. Also, the bond lengths, bond angles and torsion angles are listed in Table 2.

As shown in Fig 1, **1b** forms a 1:1 complex with silver perchlorate which is dimeric in relation to the center of symmetry; two silver atoms are sandwiched between the two ferrocenophanes to yield a five-coordinated complex, in which each silver atom is coordinated with four sulfur atoms (S(6), S(9), S(12), and S(15)) of the organic ligand moiety and one sulfur atom (hereafter denoted as S(9')) of another ligand. The deviations of the four sulfur atoms from their mean plane are between +0.14 and −0.11 Å, and such that the configuration of these four atoms is a very flattened tetrahedron. The Ag atom is 0.87 Å out of the plane. The inner coordination sphere of the silver atom is completed by the S(9') atom bonded at the apex to produce a five-coordinate silver atom with overall square-pyramidal geometry. However, the line Ag···S(9') is displaced from the normal square-pyramidal geometry, the angle S(9')-Ag-X ranging from 77.3(4) to 133.4(4)°. The perchlorate ion does not appear to be coordinated to the silver ion, and the shortest interatomic distance between the Ag and O atoms is 3.035(18) Å. Silver-sulfur distances range from 2.629(4) to 2.883(4) Å. Although bond lengths of Ag-S(6)(2.668(4) Å), Ag-S(15)(2.629(4) Å) and Ag-S(9')(2.474(4) Å) are in same range as those observed in bis(1,4,7-trithiacyclononane)silver(I) trifluoromethanesulfonate (which contains a six-coordinate silver atom)[17] and in 1,3,5-trithiane silver(I) perchlorate (which contains both four- and five-coordinate silver),[18] the bond lengths of Ag-S(9)(2.883(4) Å) and Ag-S(12)(2.805(4) Å) are comparable with that in μ-(1,3,5-trithiane-S^1,S^3)-bis[bis(1,3,5-trithiane)silver(I)] bis-[hexafluoroarsenate(V)]-sulfur dioxide (in which contains five-coordinate silver).[6] The Cp rings take an eclipsed conformation, in which the dihedral angle between them is 3.9(6)° and the torsion angle C(1)-Cp1-Cp2-C(16) (Cp1 and Cp2 being the centroids of the Cp rings) is 57.7(15)°. These results agree well with those in the platinum complex of 1,4,7,10-tetrathia[10](1,1')ruthenocenophane.[19] The distances between the iron atom and the carbon atoms of the Cp rings range from 2.002(12) to 2.056(14) Å. The perpendicular distances from the iron atom to the least square planes of the two Cp rings, 1.631 and 1.636 Å, respectively, are both slightly shorter than those found in the NaSCN complex[20] of pentaoxa[12](1,1')ferrocenophane but agree well with those of some bridged ferrocenophanes. The intramolecular atomic distances between the Fe and Ag(I) atoms is 4.101(2) Å. This value is much longer than the sum of the covalent radii of the Fe and Ag(I) atoms[21] and indicates no direct metal–metal interaction between the coordinated Ag(I) atom and the iron atom of the ferrocene nucleus in the complex **2c**.

^{1}H NMR Spectra. The 400 MHz ^{1}H NMR spectra of **1b** in acetonitrile-d_3 showed a pair of triplets corresponding to the α- and β-ring protons of the ferrocene nucleus at δ 4.29 (t, J=1.8 Hz, 4H) and 4.27 (t, J=1.8 Hz, 4H), in addition to a singlet at δ 3.05 (s, 4H, -SCH_2CH_2S-) and two triplets at δ 3.15 (t, J=7.0 Hz, 4H, -SCH_2-) and 2.85 (t, J=7.0 Hz, 4H, -SCH_2-). The ^{1}H NMR spectra of **2c** in acetonitrile-d_3 showed a pair of triplets due to the α- and β-protons of Cp-rings at δ 4.43 (t, J=1.8 Hz, 4H) and 4.36 (t, J=1.8 Hz, 4H) together with two broad singlets at δ 3.12 (8H) and 3.06 (4H) due to the methylene protons, although these peaks shifted downfield to about 0.12—0.29 ppm. This result suggests that the counter ion (ClO_4^-) of the complex **2c** is completely separated from the silver(I) ion and the Fe atom of the ferrocene nuclues, and that the anions are surrounded by the acetonitrile-d_3 in solution. Furthermore, the change in the methylene protons' absorption pattern upon complexing (compared with the corresponding silver free ligand) can be explained by the coordination of the sulfur atoms to the silver atom described below. That is, the methylene protons at 7-, 8-, 13-, and 14-, and 10- and 11-positions become equivalent to each other upon complexing. The ^{1}H NMR spectra of **2a** in acetonitrile-d_3 showed also a pair of triplets corresponding to the α- and β-ring protons of the

ruthenocene nucleus at δ 4.84 (J=1.7 Hz, 4H) and 4.76 (t, J=1.7 Hz, 4H), in addition to a broad singlet at δ 3.03 (bs, 4H) and a multiplet at δ 3.05—3.14 (m, 8H). The peak due to the methylene protons at the 7-, 8-, 13-, and 14-positions of the ruthenocenophane complex **2a** is broadened and appears as a multiplet, although the chemical shift value is very similar to that of the ferrocenophane complex **2c**. Furthermore, the methylene protons at the 10- and 11-positions of **2a** and **2c** also showed nearly the same chemical shift values. These results suggest that **2a** in solution forms a 1:1 complex similar to that of **2c**, but the methylene protons at 7- and 8- (and/or 13- and 14-) positions become nonequivalent environments due to the long distance between the two Cp-rings of the ruthenocene nucleus in **2a** compared with that of the ferrocene nucleus in **2c**. A similar relationship is observed between **2b** and **2d**.

In order to investigate the stability of the silver complex, the VT NMR technique was used. According to the rise in temperature the spectral pattern and chemical shift of **2b** in DMSO-d_6 changed. At 65 °C a sharp singlet due to the methylene protons at the 7-, 8-, 13-, and 14-positions became a broad singlet and then the broad singlet separated completely to two multiplet peaks at 90 °C. Furthermore the methylene protons at the 7-, 8-, 13-, and 14-positions became a pair of A_2B_2 triplets at δ 3.11 (J=6.6 Hz) and 2.94 (J=6.6 Hz), and the peaks of the Cp ring protons shifted up-field and showed a pair of AA'BB' triplets at δ 4.82 and 4.68 at 170 °C. The spectrum of **2b** at 170 °C is very similar to that found in the silver-free ligand **1a** at room temperature. These results suggest that the dissociation of **2b** to (**1a**+$AgCF_3SO_3$) began at 65 °C and finished completely at about 170 °C. In order to calculate the formation energy of **2b** from **1a**

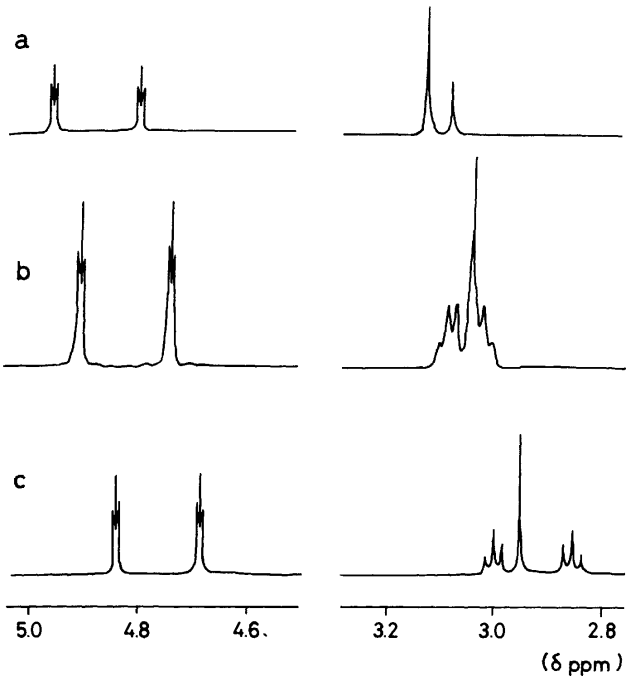

Fig. 2. ^{1}H NMR spectra (in DMSO-d_6) of (a) **2b**, (b) an equimolar mixture of **1a**+**2b**, and (c) **1a**.

and $AgCF_3SO_3$, a VT NMR measurement of the 1:1 mixture of **1a** and **2b** was carried out. First, the 1:1 mixture of the complex **2b** and silver free ligand **1a** in DMSO-d_6 was measured at room temperature. The spectrum showed a pair of AA'BB' triplets corresponding to the α- and β-ring protons at δ 4.91 (J=1.8 Hz) and 4.74 (J=1.8 Hz), a singlet due to the methylene protons at the 10- and 11-positions, together with a broad pair of triplets due to the methylene protons at the 7-, 8-, 13-, and 14-positions. However the spectrum did not show any peaks due to the methylene protons at the 7-, 8-, 13-, and 14-positions of **1a** and **2a** at room temperature. These results showed that there is a relatively fast equilibrium by ^{1}H NMR scale between the following equations. Then, low-temperature measurements of the mixture in various solvents were attempted. Unfortunately, though, they failed because of the low solubility of the samples at low temperatures.

Experimental

The melting points are uncorrected. The IR spectra were measured on a JASCO IRA-2 Diffraction Grating Infrared Spectrometer. The ^{1}H NMR spectra were obtained on a JEOL GX400 spectrometer with TMS as the internal standard. Elemental analyses of **2b** and **2d** were not carried out because of the explosive property of these complexes at high temperature.

Materials. 1,4,7,10-Tetrathia[10]ruthenocenophane[19] and 1,4,7,10-tetrathia[10]ferrocenophane[23] were prepared according to a method discussed in the previous papers. Silver(I) perchlorate and trifluoromethanesulfonate (triflate) were commercially available. The solvents used were reagents grade and/or purified by distillation.

(1,4,7,10-Tetrathia[10]ruthenocenophane)silver(I) Perchlorate (2a). To a solution of **1a** (11.0 mg, 2.5×10^{-2} mmol) in acetonitrile (2 cm^3) was added a solution of silver(I) perchlorate (5.2 mg, 2.5×10^{-2} mmol) in acetonitrile (1 cm^3). After the solution was refluxed for 3 min, it was diluted with diethyl ether (1 cm^3). The solution was kept overnight in a refrigerator. The resulting crystals were collected by filtration and washed with small amounts of acetonitrile to give **2a** in 45% yield as white needles. Mp 170 °C (decomp). ^{1}H NMR (in CD_3CN) δ=4.84 (t, J=1.7 Hz, 4H), 4.76 (t, J=1.7 Hz, 4H), 3.14—3.05 (m, 8H), and 3.04—3.01 (m, 4H). IR (KBr) 3090, 2910, 1410, 1090, 1050, 820, 618, and 490 cm^{-1}.

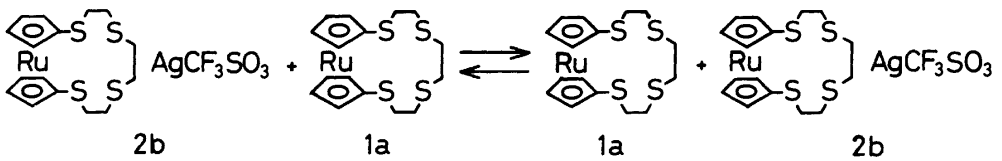
(1,4,7,10-Tetrathia[10]ruthenocenophane)silver(I) Triflate (2b). Complex **2b** was prepared using the same method as described above. Yield 33%. Mp 190 °C (decomp). Found: C, 29.59; H, 2.90%. Calcd for $C_{17}H_{20}AgF_3O_3RuS_5$: C, 29.23; H, 2.89%. ^{1}H NMR (in CD_3CN) δ=4.84 (t, J=1.7 Hz, 4H), 4.76 (t, J=1.7 Hz, 4H), 3.14—3.05 (m, 8H), and 3.03 (s, 4H). IR (KBr) 3100, 2910, 1410, 1280, 1110, 810, 625, and 570 cm^{-1}.

(1,4,7,10-Tetrathia[10]ferrocenophane)silver(I) Perchlorate and Triflate (2c and 2d). Complexes **2c** and **2d** were prepared using a method described in a previous paper.[15]

2c was identified by a comparison with melting point and the spectral data of an authentic sample.

2d. Yield 60%. Mp 195 °C (decomp). Found: C, 31.16; H, 3.06%. Calcd for $C_{17}H_{20}AgF_3FeO_3S_5$; C, 31.25; H, 3.06%. ^{1}H NMR (in CD_3CN) δ=4.43 (t, J=1.8 Hz, 4H), 4.36 (t, J=1.8 Hz, 4H), 3.12 (s, 8H), and 3.06 (s, 4H). IR (KBr) 3090, 2910, 1410, 1275, 1250, 1023, 622, and 510 cm^{-1}.

X-Ray Crystallography of 2c. Lattice constants were determined by a least-squares fit of angular settings of 2θ reflections within the range $15<2\theta<25°$. Intensity data were obtained on a Rigaku AFC-5R apparatus equipped with graphite monochromated Mo $K\alpha$ radiation and using the ω-2θ scan technique ($2\theta\leq50°$). During data collection three standards (measured g before every 200 reflections) showed no significant variation. Of 3510 independent reflections measured, only 3122 were considered as being observed on the basis of the criterion $F_o>2\sigma(F_o)$. All intensities were corrected for Lorentz and polarization effects, but not for absorption. Crystal data: $C_{16}H_{20}S_4FeAgClO_4$, Mw=603.8, crystal size 0.5×0.5×0.15 mm, monoclinic, space group $P2_1/a$, a=19.227(3), b=10.619(3), c=9.739(2) Å, β=91.71(2)°, U=1987.8 Å^3, Z=4, D_c=2.02 g cm^{-3}, μ(Mo $K\alpha$)=23 cm^{-1}, T=



297 K. The structure was solved by heavy-atom methods, and refined by block-diagonal least-squares methods. The positions of the hydrogen atoms were estimated from standard geometry. The final refinements with anisotropic temperature factors for the nonhydrogen atoms and isotropic temperature factors for the hydrogen atoms lowered the R value to 0.075 (R_w=0.086, $w=1/\sigma^2(F_o)$). The goodness of fit was 5.6. The excursions in the final difference Fourier synthesis were within ± 0.7 e Å^{-3}.

The complete F_o-F_c data are deposited as Document No. 8868 at the office of the editor of Bull. Chem. Soc. Jpn.

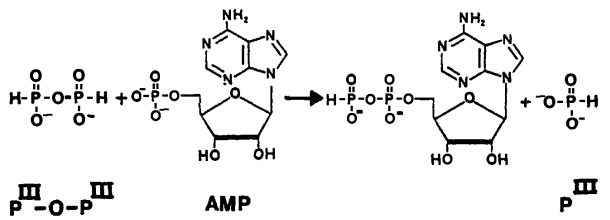
(Received November 9, 1988)

Phosphonylation of adenosine 5′-diphosphate (ADP) with inorganic diphosphonate was investigated by use of ^{31}P NMR spectroscopy and the coupled system of high-performance liquid chromatography and flow injection analysis. ADP was phosphonylated by inorganic diphosphonate to form an H-phosphonate analogue of adenosine 5′-triphosphate (ATP) in aqueous solutions. The yield of the H-phosphonate analogue of ATP varied strongly depending on reaction conditions: pH and initial concentration of inorganic diphosphonate. The maximum yield of the H-phosphonate analogue of ATP was 56% under the following conditions: initial concentration of inorganic diphosphonate and ADP were 1.8 and 0.1 mol dm^{-3}, respectively; 50 °C; pH 5; 90 min. In basic solutions, 2′ or 3′-hydroxyl group on ADP was predominantly phosphonylated.

More recently much interest has been focused on an H-phosphonate approach for the development of new and efficient methods of synthesizing DNA and RNA,[2-4] nucleoside-phospolipid conjugates,[5a] and internucleotide phosphate analogues[5b] which are widely used as metabolic regulators.[6] The increasing significance of H-phosphonate approach has also stimulated further research in organic synthesis. The application of H-phosphonate approach, however, has been limited to the syntheses of monophosphate analogues, such as nucleoside 3′-H-phosphonate.

One of our current projects is the synthesis of H-phosphonates involving a P-O–P linkage as analogues of nucleoside polyphosphates, the analogues which become new important probes for the mechanistic studies on enzymatic reactions. We have recently reported that the phosphonylation of nucleoside 5′-monophosphate such as adenosine 5′-monophosphate (AMP) using a new phosphonylating agent, inorganic diphosphonate (P^{III}-O-P^{III}), gave an H-phosphonate analogue of nucleoside 5′-diphosphate such as adenosine 5′-diphosphate (ADP) in aqueous solutions according to Eq. 1.[1,7,8]



(1)

This method using P^{III}–O-P^{III} is extended in the present paper to phosphonylation of ADP to obtain an H-phosphonate analogue of adenosine 5′-triphosphate (ATP).

Experimental

Chemicals. Unless otherwise stated, guaranteed reagents from Wako (Osaka, Japan) were used without further purification. Disodium adenosine 5′-diphosphate dihydrate was purchased from Oriental Yeast (Tokyo, Japan).

Disodium inorganic diphosphonate, $Na_2P_2H_2O_5$, was prepared according to the previous paper.[1] The purity of disodium diphosphonate thus obtained was checked by HPLC[9-11] to be 98% (as P).

Phosphonylation of ADP with Diphosphonate. Initial concentration of diphosphonate varied from 0.5 to 1.8 mol dm^{-3}, keeping the initial concentration of ADP at 0.1 mol dm^{-3} constant. The pH of aqueous reaction mixture was ca. 5. If necessary, the reaction mixture was adjusted to the prescribed pH value (10, 8, 7, 6, or 4) with a sodium hydroxide or hydrochloric acid solution. The reaction mixtures with and without pH adjustment were allowed to react at 50, 60, and 70 °C. The pH change during the reactions was not controlled strictly.

HPLC Measurement. Two HPLC systems were used in the present study: 1) an HPLC system with UV-detector for determination of ADP and products; 2) an HPLC system coupled with a flow injection analysis (FIA) designed for the sensitive detection of phosphate and phosphonate groups.[1,9-13]

A TRI ROTAR VI system (Jasco, Tokyo, Japan) was used as an HPLC system with UV-detector. An aliquot (0.1 ml) of reaction mixture was injected onto a separation column (250×4.6 mm I.D.). Two kinds of anion-exchange columns were used: 1) an MCI column (MCI Gel CDR-10, 7 μm, Mitsubishi Chemical Industry, Tokyo, Japan) in Fig. 1; 2) a TSK column (TSKgel SAX, 10 μm, TOSOH, Tokyo, Japan) in Figs. 2 and 3. Flow rate was 1.0 ml min^{-1} and column temperature was kept at 40 °C. Separated ADP and products were detected at 260 nm by use of UV spectrophotometer (UVIDEC-340, Jasco, Tokyo, Japan). Eluent for the MCI column was composed of 0.4 mol dm^{-3} ammonium sulfate, 0.2 mol dm^{-3} potassium dihydrogenphosphate, 0.2 mol dm^{-3} dipotassium hydrogenphosphate, and 4% (V/V) acetonitrile

(pH 6.6). Eluent for the TSK column was composed of 0.3 mol dm^{-3} potassium chloride and 0.1% (W/V) tetrasodium ethylenediaminetetraacetate (pH 10).

To detect ADP, diphosphonate, phosphonate, and products simultaneously, an FIU-300 FIA system (Jasco, Tokyo, Japan) was coupled with the TRI-ROTAR VI HPLC system. The separation was performed on the TSK column. Flow rate, column temperature, and eluent were the same as described above. Phosphate and phosphonate groups on separated reactants and products were monitored by the on-line coupled FIA system.[1,9-13] A molybdenum(V)-molybdenum(VI) reagent[12] was used as a chromogenic agent. To oxidize phosphonate to detectable phosphate, sodium hydrogensulfite was introduced into the FIA system.[9-11]

^{31}P NMR Measurement. Pulse FT ^{31}P NMR spectra were recorded at room temperature by use of Varian XL-VXR300 (121 MHz) and Varian XL-200 (81.0 MHz). Orthophosphoric acid (85%) was used as an external standard.

Results and Discussion

Characterization of Phosphonylated Products by HPLC. A chromatographic peak (A) in Fig. 1 for a phosphonylated product appeared after 5 min incubation of ADP (0.1 mol dm^{-3}) with P^{III}-O-P^{III} (1.8 mol dm^{-3}) at 70 °C and pH 5 in an aqueous solution. Area of the peak (A) increased gradually to a maximum value, 55%, after 15 min incubation and then decreased slowly. The retention time for (A) was 16.4 min measured by the HPLC system with UV-detector using the MCI column. No peaks for other phosphonylated products were observed by the HPLC measurements. A small peak for adenosine 5′-monophosphate (AMP) which would be formed by hydrolysis of ADP was also recorded.

The peak (A) for the phosphonylated product involves both phosphate and phosphonate groups as shown in Fig. 2b, because the solid line represents the sum of the absorbances (830 nm) due to phosphate and phosphonate groups and the dotted line represents the absorbance (830 nm) due to phosphate group measured by the HPLC system coupled with the FIA using the TSK column. The peak (A) (Fig. 2a) measured by use of the HPLC system with UV-detector using the TSK column was also observed at the same retention time as that of the peak (A) in Fig. 2b. The retention time (35.4 min) for (A) measured by use of the TSK column (Fig. 2) was longer than that for (A) measured by use of the MCI column (Fig. 1).

Three chromatographic peaks (Fig. 3) for two main

Eluent: 0.4 mol dm^{-3} $(NH_4)_2SO_4$, 0.2 mol dm^{-3} KH_2PO_4, 0.2 mol dm^{-3} K_2HPO_4, and 4% CH_3CN (pH 6.6). Wavelength: 260 nm.

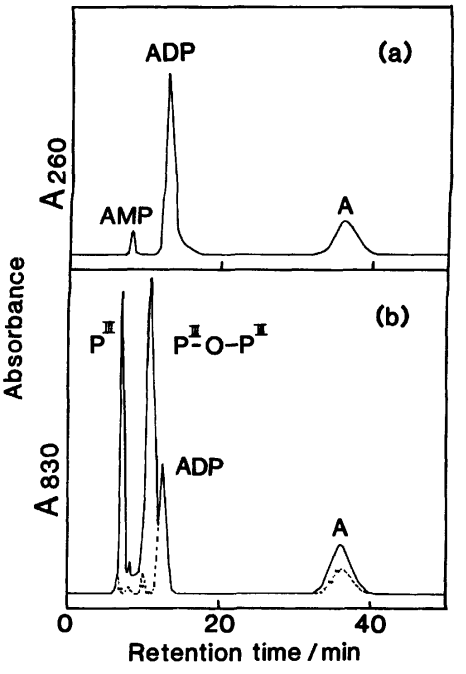


Fig. 2. HPLC profiles for ADP (0.1 mol dm^{-3}) phosphonylated by inorganic diphosphonate (1.0 mol dm^{-3}) at pH 5 and 70 °C for 50 min. Column: the TSK anion-exchange column. Eluent: 0.3 mol dm^{-3} KCl and 0.1% EDTA 4Na (pH 10). Wavelength: 260 nm(a) and 830 nm(b). The solid line in (b) indicates the sum of the absorbances due to both phosphate and phosphonate groups and the dotted line indicates the absorbance due to only a phosphate group.

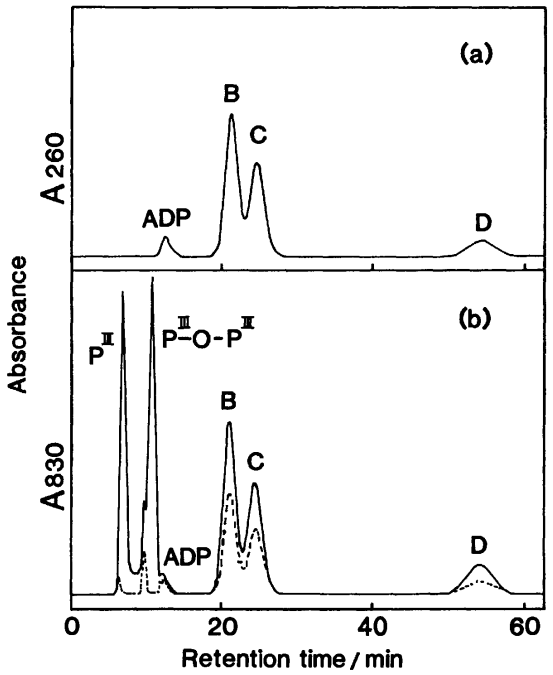

Fig. 3. HPLC profiles for ADP (0.1 mol dm^{-3}) phosphonylated by inorganic diphosphonate (1.0 mol dm^{-3}) at pH 10 and room temperature for 30 min. Other conditions are the same as in Fig. 2.

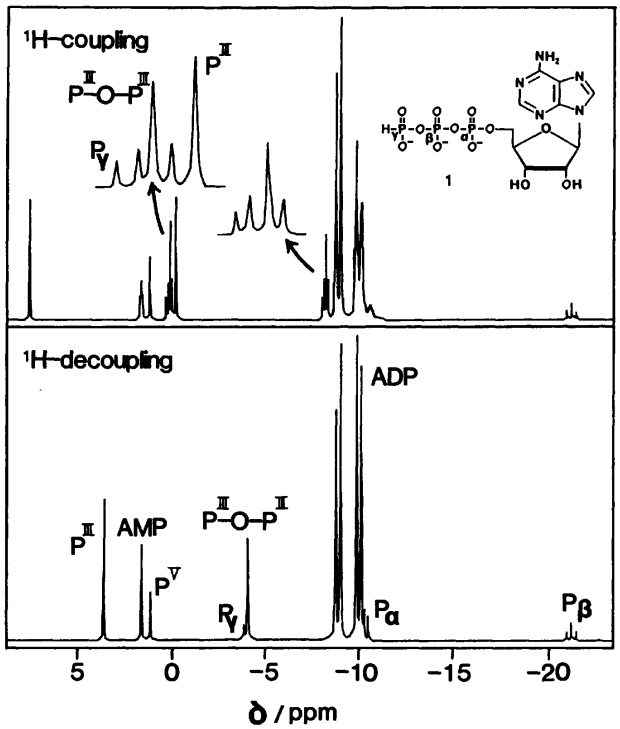

Fig. 4. ^{31}P NMR spectra for ADP (0.5 mol dm^{-3}) phosphonylated by inorganic diphosphonate (0.1 mol dm^{-3}) at pH 5 and 70 °C for 90 min.

products (B and C) and a by-product (D) were observed for the reaction mixture incubated at pH 10 by use of the same HPLC systems in Fig. 2. Although these peaks also involve phosphate and phosphonate groups as shown in Fig. 3b, retention times of these peaks are different from that of peak (A). This shows that in an alkaline solution different products are formed.

Structure of Phosphonylated Products by ^{31}P NMR. To establish the structure of phosphonylated products, ^{31}P NMR spectra were recorded. Figure 4 shows ^{31}P NMR spectra for the reaction mixture of ADP (0.5 mol dm^{-3}) and P^{III}-O-P^{III} (0.1 mol dm^{-3}) incubated at pH 5 and 70 °C for 90 min.

A proton-decoupled spectrum (Fig. 4) represents two unknown doublets (−4.1 and −10.4 ppm) and an unknown triplet (−21.2 ppm) in addition to the signals assigned to phosphonate (P^{III}; 3.5 ppm), AMP (1.5 ppm), orthophosphate (P^{V}; 1.0 ppm), P^{III}-O-P^{III} (−4.2 ppm), and ADP (two doublets at −9.0 and −10.0 ppm) on the basis of the chemical shifts for the authentic samples. These unknown peaks are the signals for the phosphonylated product observed by the HPLC measurement in Figs. 1 and 2. AMP and P^{V} would be formed by hydrolysis of ADP in the course of reaction.

The triplet at −21.2 ppm is the most important signal to characterize the chemical structure of the phosphonylated product, because the triplet at around −20 ppm is caused by the middle-group phosphorus on triphosphate species such as ATP[14,15] and inorganic triphosphate.[16,17] In addition, coupling constant (19.0 Hz) of the triplet is approximately equal to that (19.3 Hz) of ATP.[15] We concluded that, as shown in Fig. 4, product **1** similar in structure to ATP (H-phosphonate analogue of ATP) was fromed by phosphonylation of ADP with P^{III}-O-P^{III} at pH 5. The triplet is assigned to middle phosphorus atom (P_β of **1**). Other unknown doublets at −4.1 and −10.4 ppm would be signals for P_γ and P_α atom of **1**. A signal of the doublet at −4.1 ppm overlapped with that of P^{III}-O-P^{III}.

The doublet at −10.4 ppm is further split into a double-triplet in a proton-coupled spectrum (Fig. 4). The double-triplet is assigned to P_α atom of **1**, because the double-triplet shows a splitting of 4.5 Hz, the value of which is similar to the three-bond coupling constant ($^3J_{PH}$) for P_α atom on ATP split by the 5′-hydrogens of the ribose moiety.[16]

Further splitting of the doublet at −4.1 ppm into a double-doublet is shown in a proton-coupled spectrum. The double-doublet is assigned to P_γ atom of **1** for phosphonyl group transferred from P^{III}-O-P^{III} to ADP, because the double-doublet shows the splitting of 669.1 Hz for the hydrogen atom attached directly to a phosphorus atom.[1,18]

The ^{31}P NMR spectra (Fig. 5) for the reaction mixture adjusted to pH 10 differ from those observed at pH 5. A proton-decoupled spectrum shows four singlets and three doublets. The singlets at 6.3 and

−1.8 ppm are assigned to P^{III} and P^{III}–O–P^{III}, respectively. Two unknown singlets (E and F) and three unknown doublets are the signals for the main phosphonylated products observed in Fig. 3.

In a proton-coupled spectrum, both singlets (E and F) are split into double-doublets. These double-doublets are assigned to the signals for compounds **2** and **3** (Fig. 5) producing the phosphonylation of 2′- or 3′-hydroxyl group, because each double-doublet shows one-bond coupling constant ($^1J_{PH}$=650 Hz) and three-bond coupling constant ($^3J_{PH}$=10 Hz).[1] Doublet at −7.1 ppm is then assigned to P_α of these compounds and two doublets at −2.4 ppm are assigned to P_β of these compounds. ^{31}P NMR spectrum of a by-product could not be observed, owing to a low yield.

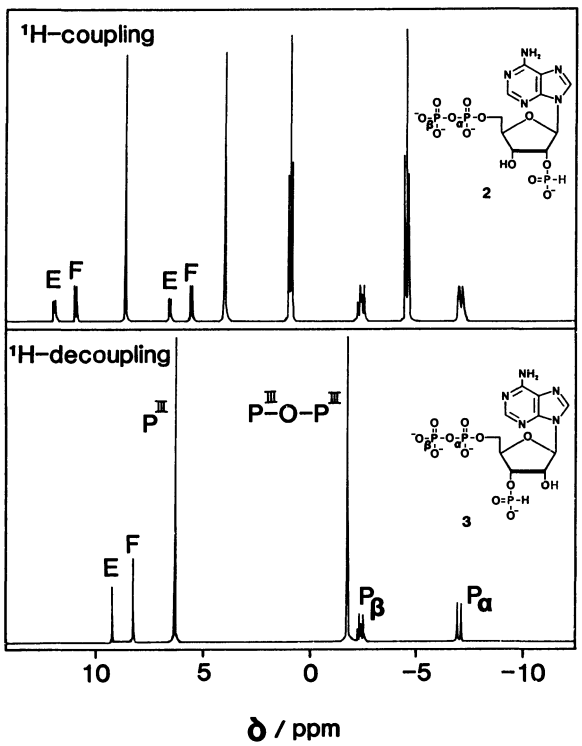

Fig. 5. ^{31}P NMR spectra for ADP (0.1 mol dm^{-3}) phosphonylated by inorganic diphosphonate (0.5 mol dm^{-3}) at pH 10 and room temperature for 20 min.

Effect of pH on the Phosphonylation of ADP. The product **1** was predominantly formed at pH 5 as shown in Figs. 1 and 6. The amount of the product **1** increased gradually with time at pH 5 as shown in Fig. 6. The yield of **1** reached a maximum (about 40%) at 120 min, and then slowly decreased.

In the reaction at pH 10, very little amount of **1** was formed, so that the datum for **1** was omitted in Fig. 7. The amount of both products **2** and **3** showed a gradual increase with time, reaching a maximum (about 74%) after 60 min. The maximum amount remained constant at least after 100 min incubation. The unknown by-product was formed in the amount of ca. 20% after 240 min.

Table 1 which lists the yields of products **1**, **2**, and **3** in the pH 4 to 10 region shows that the yield of product **1** at pH 6 is higher than those at any other pH's. To get product **1** selectively without impurities of **2** and **3**, however, ADP should react in more acidic solu-

10	0	74	60

a) Reaction conditions: initial concentrations of ADP and P^{III}–O–P^{III} were 0.1 mol dm^{-3} and 1.0 mol dm^{-3}; 60 °C.

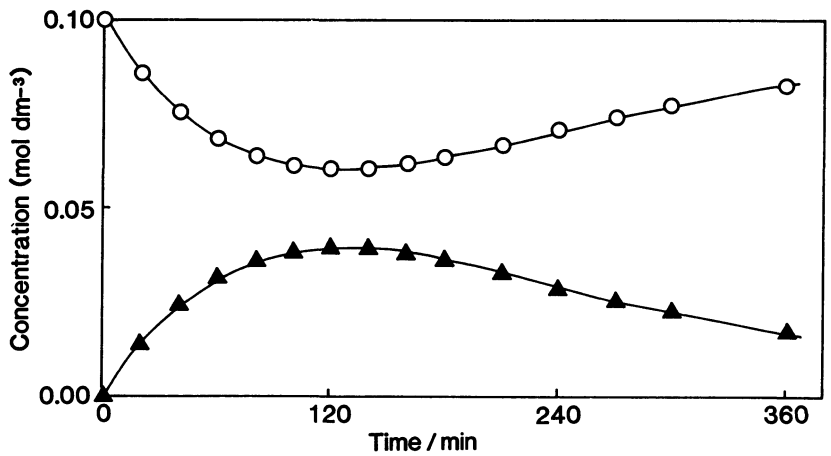

Fig. 6. Time dependence of the reaction components of phosphonylation for ADP (0.1 mol dm^{-3}) with inorganic diphosphonate (1.0 mol dm^{-3}) at pH 5 and 60 °C. Plots of the observed molar concentrations of ADP (○) and product **1** (▲) vs. time.

tions, because small amount of **2** and **3** was formed at pH 6.

Products **2** and **3** were formed in alkaline solutions more favorably than in acidic solutions. For example, the yield of **2** and **3** at pH 6 was only 7%, while the yield reached a maximum value of 74% at pH 10. The results show that the hydroxyl group at 2′- or 3′-position becomes reactive by dissociation of a proton in a basic solution, because such hydroxyl groups have very large protonation constant more than 12 in log scale.[19] Phosphonylation of hydroxyl groups will be described in more detail in a subsequent paper of this series.

It is interesting that the yields of these products strongly depend on pH of reaction solution. The pH dependence can be explained as follows: the degradation of products is in competition with the formation of products. In acidic and neutral solutions, diphosphate group on ADP reacts with P^{III}-O-P^{III} to form product **1**, which is relatively stable as shown in Fig. 6. The hydroxyl groups at 2′- and 3′-positions are protonated in acidic and neutral solutions, so that the hydroxyl groups do not react with P^{III}-O-P^{III}. On the other hand, in basic solution product **1** is very unstable and undergoes rapid hydrolysis to ADP and phosphonate in spite of the formation of **1** from ADP and P^{III}-O-P^{III}. A hydroxyl group is deprotonated in a basic solution, consequently, a deprotonated hydroxyl group reacts with P^{III}-O-P^{III} to form products **2** and **3**, which are very stable even in a basic solution as shown in Fig. 7. To provide further support for the proposed reaction pathway, we carried out an additional ^{31}P NMR experiment by addition of sodium hydroxide solution to the reaction mixture shown in Fig. 4. As a result, the NMR signals for **1** disappeared rapidly and the signals for **2** and **3** appeared.

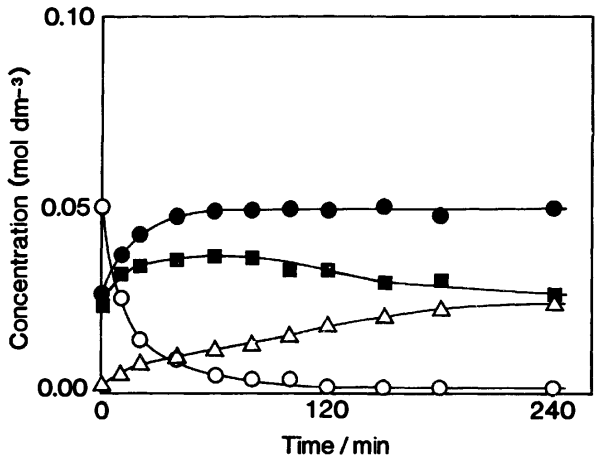

Fig. 7. Time dependence of the reaction components of phosphonylation for ADP (0.1 mol dm^{-3}) with inorganic diphosphonate (1.0 mol dm^{-3}) at pH 10 and 50 °C. Plots of the observed molar concentrations of ADP (○) and product **2** and **3** (●, ■), and unknown product (△) vs. time.

Effects of Initial Concentrations of Diphosphonate and Temperature on Yield of Product 1. As shown in Fig. 8, phosphonylation of ADP gave H-phosphonate analogue of ATP (**1**) at pH 5 selectively, while 2′- or 3′-hydroxyl group was phosphonylated at pH 10. The yields of **1** were measured at pH 5 varying initial concentration of P^{III}-O-P^{III} and temperature to find the optimal conditions for phosphonylation of ADP.

Yield of **1** (Table 2) increased with increasing initial concentration of P^{III}-O-P^{III}: from 28% (0.5 mol dm^{-3}) to 54—56% (1.8 mol dm^{-3}). Yield was found to be maximum at initial concentration of 1.8 mol dm^{-3} in the temperature range studied here. The solution of P^{III}-O-P^{III} is saturated at 1.8 mol dm^{-3}. No improvements of the yields were observed with an increase in temperature, in spite of an decrease in time required to

		50	120	51
		60	60	50
		70	30	48
1.8	0.1	40	210	55
		50	90	56
		60	30	54
		70	15	55

reach a maximum amount. The optimal conditions for phosphonylation of ADP with P^{III}-O-P^{III} were found to be initial concentration of P^{III}-O-P^{III} 1.8 mol dm^{-3}, pH 5, and 50 °C.

The overall tendencies of the results are similar to those obtained in the phosphonylation of AMP,[1] except that the yield of **1** is smaller than that of H-phosphonate analogue of ADP (ca. 70%).[1] The difference in yield between ATP analogue and ADP ananlogue is attributalbe to the different negative charges on nucleophiles, ADP and AMP, because more negatively charged ADP is repulsed and slowed down to higher degree in attacking dianionic P^{III}-O-P^{III}.

We appreciate Professor Tsujiaki Hata and Dr. Mitsuo Sekine at Tokyo Institute of Technology for their helpful discussions on the synthesis of H-phosphonates and sending us many valuable reprints. We are indebted to Professor Jacek Stawinski at University of Stockholm, Dr. Brian Froehler at Genentech, Inc., and Associate Professor Hiroshi Takaku at Chiba Institute of Technology, for sending us many valuable reprints. The authors wish to express their thanks to Dr. Makiko Sugiura of Kobe Women's College of Pharmacy for her help in measuring ^{31}P NMR spectra.

A Spectroscopic Characterization of Metal Ion-Complexed NADH Models and Their Kinetic Behavior in Nitrosobenzene Reduction

Seizo TAMAGAKI, Yoshitaka SIMOJO, Takasi MIMURA, and Waichiro TAGAKI*
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3-3-138, Sumiyoshi-ku, Osaka 558
(Received November 14, 1988)

The structures of metal ion complexes of a series of NADH models were spectrophotometrically investigated. The electronic spectra were sensitive to variation of both the 1,4-dihydropyridines and the metals; particularly, 1-benzyl-3,5-bis(1-pyrrolidylcarbonyl)-1,4-dihydropyridine (BPDH) was recognized to produce two types of complexes with zinc and lead perchlorates, whereas 1-benzyl-1,4-dihydronicotinamides (BNAH) complexed metal ion only at the amide oxygen. In order to elucidate these structures, the effect of changing perchlorate ion concentrations was examined. In addition, reduction of nitrosobenzene in the presence of bivalent metal cations was kinetically investigated.

The coordination between zinc and NADH plays an important role in alcohol dehydrogenase enzymes.[1] Thus, the role of metal ion is fundamental to our better understanding of NADH coenzymes. Then, there do exist a number of reports on NADH models. Ohno and other workers have demonstrated that metal ion coordination to NADH models such as BNAH and its optical active analogs exhibits a significant influence on rate acceleration[2a] and stereodifferentiation[2b] in carbonyl reductions. However, the systematic spectroscopic study on metal ion complexation has received less attention thus far.[3] This study provides a spectroscopic analysis of zinc and lead complexes with NADH models, the results of which are discussed in this paper and also presents experimental data on the reduction of nitrosobenzenes by these complexes, since interest in a fundamental understanding of the relationship between the structure and the reactivity of NADH models continues to be an area of considerable experimental effort.

1,4-Dihydronicotinamides themselves have a disadvantage for their applications as coenzyme models owing to their relative instability toward electrophilic reagents. In order to overcome this drawback, we have recently synthesized symmetrically substituted 1,4-dihydropyridines and have used them for studies under acidic conditions. In this study we have employed such NADH models as a proper choice.

Experimental

Materials. 1-Benzyl-3,5-bis(pyrrolidylcarbonyl)-1,4-dihydropyridine (BPDH, **1**) and its 1-(substituted benzyl) derivatives was prepared according to the method described in the previous paper.[4] Special grade metal perchlorates as the hydrates from Kishida Chemicals Co. were used without further purification. Tetrabutylammonium perchlorate of special grade was purchased from Tokyo Kasei Kogyo Co. and dried in vacuo at 50 °C for one day. *p*-Substituted nitrosobenzenes were prepared according to the literature method.[5] Acetonitrile was distilled from P_4O_{10}.

Kinetic Procedure. The kinetic data were determined at 25 °C in acetonitrile under anaerobic conditions, as described in our previous paper.[6] UV-visible spectra and absorbance-time measurements were recorded on a Hitachi model-220 spectrophotometer equipped with constant temperature cell holders. The progress of the reaction was monitored by the disappearance of the absorbance at, for example, 355 nm due to **1**. Generally, the initial concentrations of **1** and nitrosobenzene were 0.1 mM and 1.0 mM, respectively, throughout this work (M=mol dm^{-3}).

Results and Discussion

Spectral Changes of Dihydropyridine-Zinc(II) Complexes. The spectral changes in acetonitrile as solvent were monitored by UV-visible spectrometry in an appropriate region 300—400 nm. In Table 1 are summarized the spectroscopic data for a series of substituted 1-benzyl-1,4-dihydronicotinamides in the presence and absence of a 100-fold molar excess of zinc perchlorate. All these compounds have a strong absorption band somewhere ranging from 300 nm to 400 nm, depending on the metal ion and the substituents. It has been proposed that these absorption could be

ascribed to the n-π^* transition.[7]

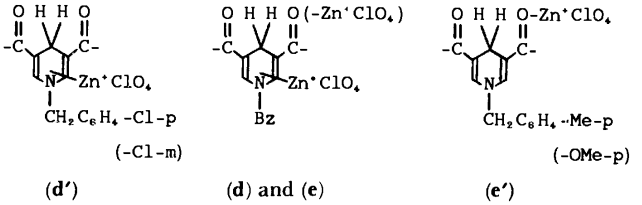
There are a few limiting resonance structures (**A**, **B**, and **C**) for 1,4-dihydronicotinamide in which the lone pair of electrons on N-1 is delocalized into the ring and conjugates further with the π-system of the carbonyl group. The delocalization will be maximized when the carbonyl group lies in the plane of the ring. Therefore, the twist of the bulky amide group out of the dihydropyridine ring destabilizes the LUMO more than destabilizes the HOMO, resulting in a blue shift of the electronic absorption band (Fig. 1). Indeed, the λ_{max} values shift toward a shorter wavelength in going from R,R'=H,H (345 nm) to R,R'=H,Et (340 nm) and to R,R'=Et,Et (330 nm). Obviously, the steric repulsions diminish π-conjugation. Nevertheless, despite its bulkiness, R,R'=$(CH_2)_4$ substitution affords an electronic absorption band at an exceptionally rather longer wavelength.

Upon complexation with zinc ion, the dihydronicotinamides undergo spectral shifts toward long wavelengths without exception. The extent of the spectral shift for a less bulky amide is twice as large as that for a more bulky amide. This is because the relative extent of delocalization in nonplanar dihydropyridine molecules is originally small. Thus, two isopropyl groups in an amide may extremely destabilize the metal complex and actually the λ_{max} could not be defined.

A similar situation is continued in 3,5-disubstituted 1,4-dihydropyridines; bulky carbamoyl groups may destabilize the dihydropyridines and causes a blue shift irrespective of with and without the metal ion. In Table 1 are collected observed λ_{max} values in the presence or absence of a 100-fold excess of zinc perchlorate. The most remarkable feature is the unusual behavior of the dihydropyridine having R,R'=$(CH_2)_4$, which shows a greater red shift and exceptional stability inspite of the bulkiness of the carbamoyl substituent. The exact reason for this behavior is not understood at present. This anomaly, however, may be understood if we accept the view that the hydrogens α to the nitrogen in a rigidly planar pyrrolidine ring fit well between the ring methylenes of the dihydropyridine without significant steric interference, making possible a nearly planar molecule with almost maximum conjugation.[7] Owing to this stability, only the dihydropyridines bearing 1-pyrrolidinylcarbonyl groups were used for further investigations.

The absorption peak of BPDH in acetonitrile was only at 355 nm (ε: 6070) in the absence of zinc perchlorate. An addition of a large excess of zinc perchlorate to that solution resulted in the displacement of the absorption maximum to 320 nm accompanied by a poor shoulder at a slightly longer wavelength than the original, i.e., at around 365 nm, which lies within the envelope of bands with λ_{max} 355 nm and 320 nm. In a previous paper,[6] the blue shift toward 320 nm (343 nm for $Mg(ClO_4)_2$) was attributed to complexation of the metal ion on the dihydropyridine nitrogen.[8] In contrast, the bathochromic shift toward 365 nm would be that generally expected for the complexation with the amide oxygen. The existence of the corresponding complex is not strictly recognized by the spectrum of the 1-benzyl or 1-(*p*-chlorobenzyl) derivative (Figs. 4 and 2a). However, the band of the 1-(*p*-methyl- or *p*-methoxybenzyl)-1,4-dihydropyridine derivative (**e'**) explicitly distinguishes itself as an independent band with a slightly smaller extinction coefficient in the presence of a 100-fold excess of zinc perchlorate relative to BDPH (Fig. 2b). The absorption belonging to the same category was also found with less Lewis acidic zinc nitrate (361, 5680) as well as perchlorates of manganese (λ_{max} 355 nm, ε 5590 M^{-1} cm^{-1}), cobalt (359, 5870), nickel (356, 5640), where no largely blue-shifted bands could be seen (Fig. 3).

With the 1-benzyl or 1-(*p*-chlorobenzyl) derivative, the stronger absorption at 320 nm than at around 365 nm suggests that the complexation with the dihydropyridine nitrogen (**d'**) is dominant, while with the 1-(*p*-methylbenzyl) derivative, the amide oxygen is a major coordination site (**e'**).



These observations can be well-explained as follows: an electron-accepting group increases the contribution

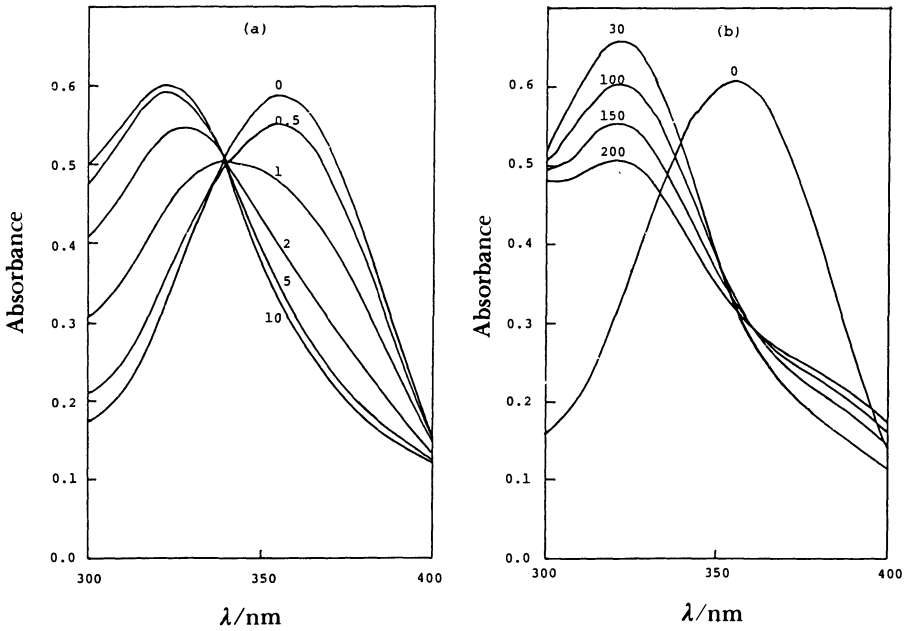


Fig. 2. Spectral changes of 1-(substituted benzyl)dihydropyridines (BPDH) in the presence of various amounts of zinc perchlorate in CH_3CN. [dihydropyridine]=0.1 mM. The numbers indicate the ratio [$Zn(ClO_4)_2$]/[dihydropyridine]. a) *p*-Cl, b) *p*-Me.

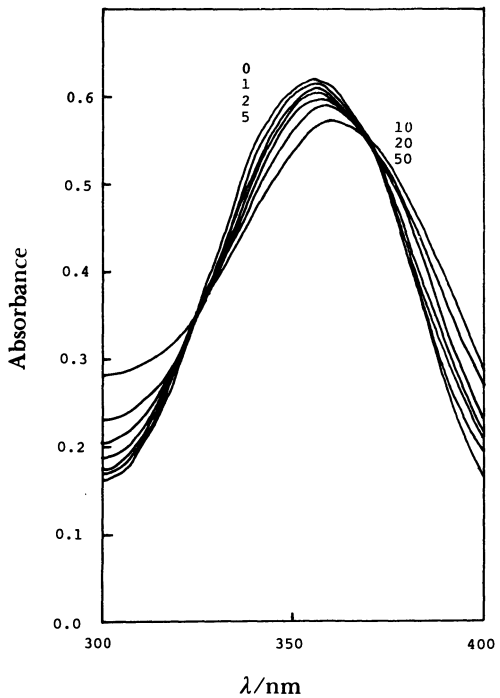

Fig. 3. Spectral changes of BPDH in the presence of $Zn(NO_3)_2$. The numbers indicate the ratio [$Zn(NO_3)_2$]/[BPDH].

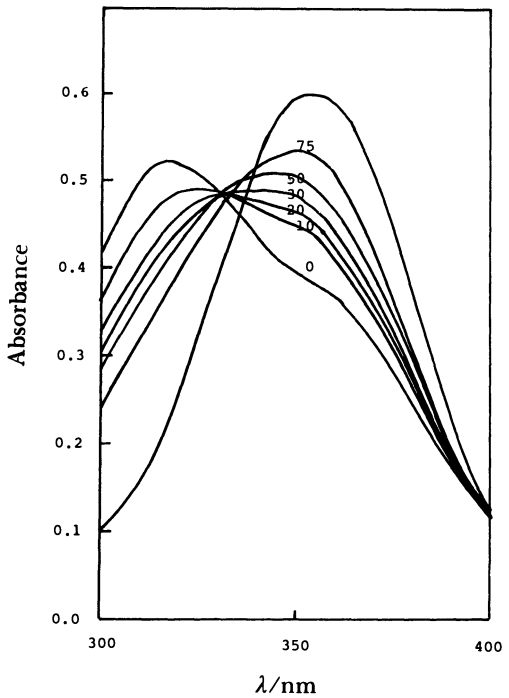

Fig. 4. Spectral changes of the BPDH-zinc ion complexes induced by addition of TBAP. [BPDH]= 0.1 mM; [$Zn(ClO_4)$]=3 mM. The numbers indicate the ratio [TBAP]/[$Zn(ClO_4)_2$].

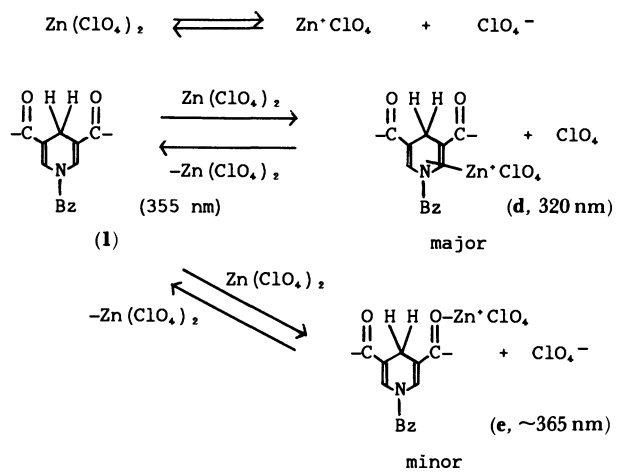
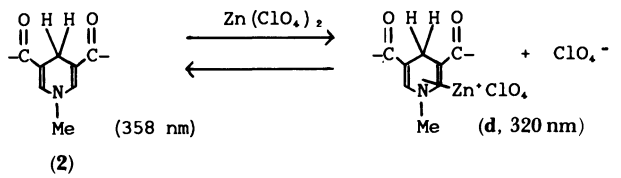
of the resonance form **A** (shown in Fig. 1) and then the geometry around the ring nitrogen becomes more pyramidal to be suitable for accomodation of a metal cation, whereas an electron-donating group increases the contribution of the resonance form **C**, which makes the carbonyl oxygen more Lewis basic than the ring nitrogen.

Figure 4 illustrates the spectral changes as a function of the concentration of tetrabutylammonium perchlorate (TBAP); as the 320 nm band diminishes, the original 355 nm band develops. These observations can only be consistent with the conclusion that the absorption at 320 and 365 nm should be ascribed to cationic complexes of zinc monoperchlorate with the dihydropyridine nitrogen and the amide oxygen, respectively, and these positively charged complexes would be readily decomposed by addition of perchlorate anion. In the meantime, these complexes are completely hydrolyzed by water in excess to regenerate the original BPDH. Thus, the following are the overall equilibria established for the complexation between zinc and BPDH in solution:

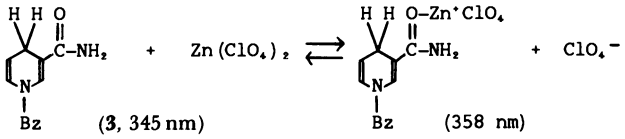


Scheme 1.

Meanwhile, the 1-methyl derivative (MPDH, **2**) behaves in spectroscopically a similar manner to the 1-benzyl derivative. In a series of the spectral changes an excellent isosbestic point can be seen at 342 nm on the original MPDH curve and no complex characterized by a red shift is produced in detectable concentration. Thus, metal coordination onto the dihydropyridine moiety rather than onto the amide carbonyl is dominating, since the ability of the 1-methyldihydropyridine moiety for coordination is superior to that of the 1-benzyldihydropyridine moiety owing to the less sterically hindering nature of the methyl vs. benzyl group rather than the electronic origin.



On the other hand, an absorption maximum of a typical NADH model, 1-benzyl-1,4-dihydronicotinamide (BNAH, **3**, λ_{max} 345 nm), was previously reported to shift toward a longer wavelength on complexation;[6] for example, 357 and 358 nm with magnesium and zinc perchlorates, respectively. It should be emphasized, however, that no spectral change was observed even by addition of a large excess (100-fold relative to BNAH) of TBAP probably because of the strong ability of the metal complexation of BNAH relative to the association of Zn^+ClO_4 with ClO_4^-.[6] Incidentally, the complexing ability (K_m) of BNAH has been estimated to be one order of magnitude greater than that of BPDH.[3,6]



Spectral Changes of Dihydropyridine-Lead(II) Complexes. Inspection of the spectra in Fig. 5a and 5b is quite instructive. Upon addition of lead perchlorate to a BPDH solution, two positively charged complexes may be inferred to be produced; a definite absorption band appears at 325 nm in the range of lead perchlorate concentrations 0—1 mM, which corresponds to a 1:1 complex of the dihydropyridine nitrogen and Pb^+ClO_4 (**g**). Further addition of the metal perchlorate gives, at the sacriface of the 325 nm band, another band at around 385 nm due probably to the complex between the dihydropyridine nitrogen and lead perchlorate (**h**). In order to verify this assignment, the effect of addition of TBAP on spectral changes was examined. The results are displayed in Fig. 6; as the band at 325 nm diminished, the corresponding broad band newly developed at around 385 nm and there was observed a single definite isosbestic point between these bands over the wide range of changing perchlorate concentrations. It is of particular interest to point out that the isosbestic point is not on the original BPDH curve, indicating that, in contrast to zinc complexes, the positively charged lead complexes do not furnish the free BPDH, even if large excesses of perchlorate anions are added to the solution. Instead, the proportion of the uncharged complex **h** is increased with increasing concentrations of TABP; namely, in the presence of excess TABP only the complex **h** can exist in a relatively stable form. This result allows the conclusion that bonding of BPDH to Pb^{2+} may be much stronger than that to Zn^{2+} because of the smaller hydration enthalpy and/or the larger ionic radii of Pb^{2+} than Zn^{2+} to be capable of accomodating two bulky perchlorate anions. Therefore, we may say that the ring nitrogen can be complexed not by lead perchlorate but by a lead monoperchlorate cation probably for its steric requirements.

In contrast to the characteristic feature of zinc com-

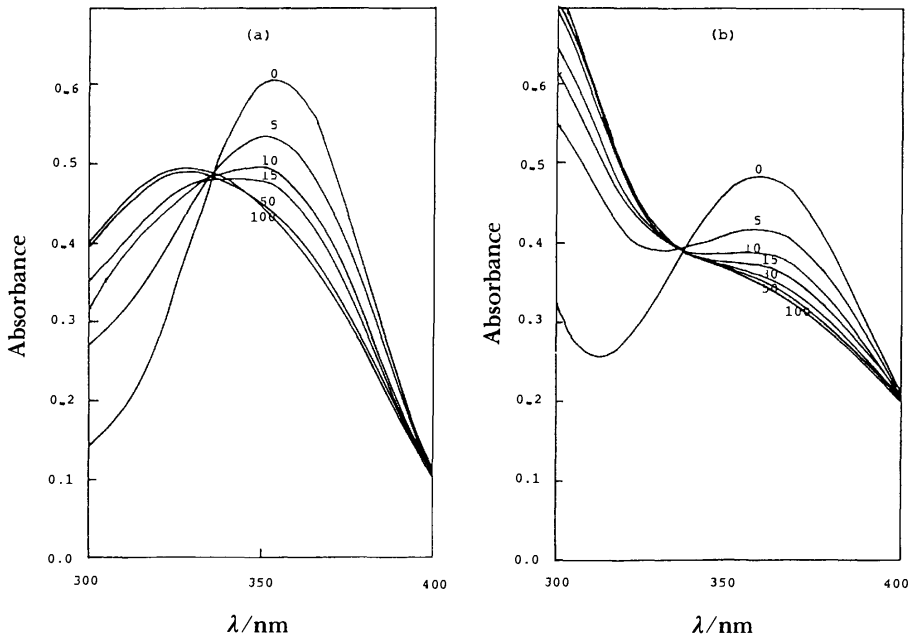


Fig. 5. Spectral changes of BPDH in the presence of various amounts of lead perchlorate: (a) 0—1.0 mM; (b) 3.0—20.0 mM. The numbers indicate the ratio $[Pb(ClO_4)_2]/[BPDH]$.

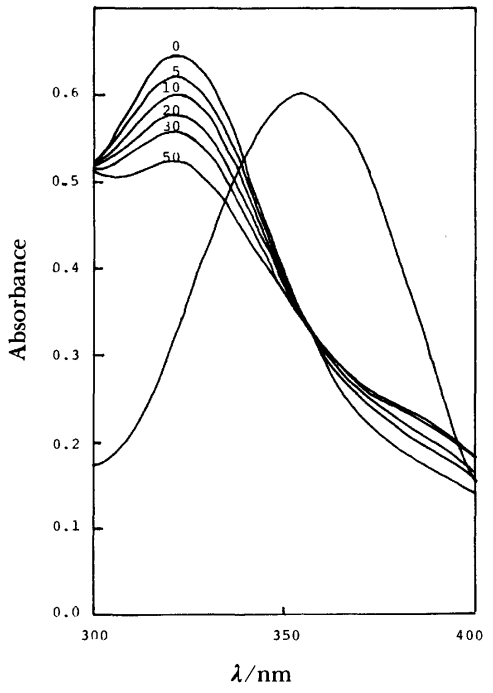

Fig. 6. Spectral changes of BPDH induced by addition of various amounts of TBAP in the presence of lead perchlorate. [BPDH]=0.1 mM; $[Pb(ClO_4)_2]$=3.0 mM. The numbers indicate the ratio $[TBAP]/[Pb(ClO_4)_2]$.

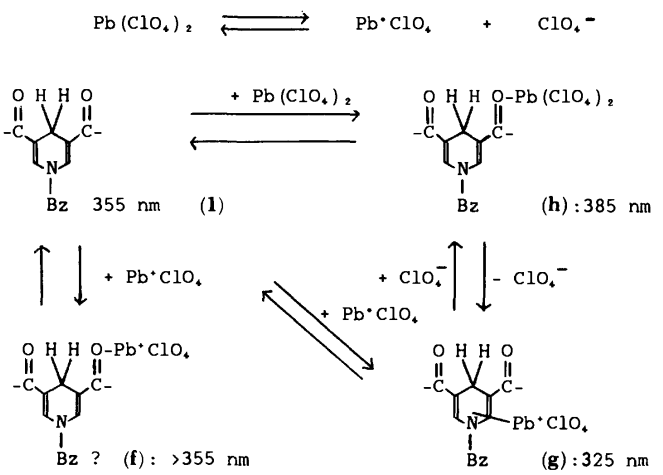
plexation, definite evidence for the presence of a complex **f** bearing a red-shifted band was not obtained. Even in any case examined here, the presence of a complex between the metal ion and the dihydropyridine with a stoichiometry of 1:2 or more was not evidenced under the present conditions, although such a higher metal complex of a dihydropyridine has been precedented with 3,5-diethoxy-2,6-dimethyl-1,4-dihydropyridine as was reported by Pandit.[9] From the above results, the complexation events can be summarized as in Scheme 2:



Scheme 2.

We shall discuss in the next section that the kinetic and spectroscopic features are closely interrelated.

Effect of Metal Cations on the Rate of Reduction. In the previous paper, we reported that bivalent metal ions catalyze the nitrosobenzene reduction with BPDH according to a Michaelis-Menthen type saturation kinetics and a linear relationship was found between

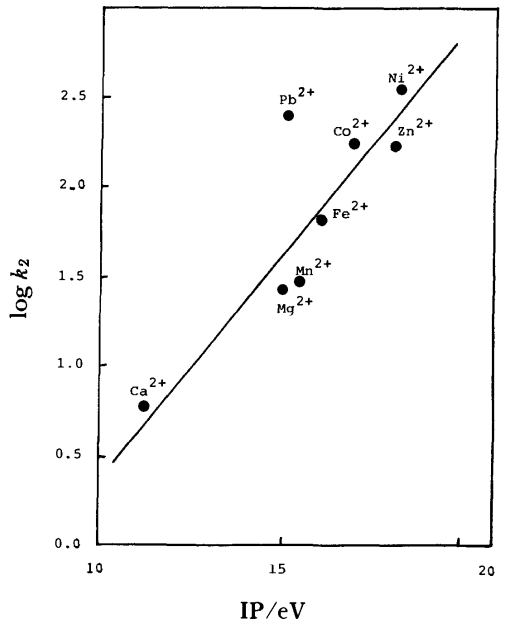


Fig. 7. Plot of log k_2 vs. ionization potential of the metal ion for the reduction of nitrosobenzene with BPDH in the presence of bivalent metal ions in CH_3CN under nitrogen at 25 °C. [metal perchlorates]=3.0 mM; [nitrosobenzene]=1.0 mM.

log k_2 and the ionization potentials of metal ions with a positive slope.[6]

We have found here that the rate with lead perchlorate as catalyst is somewhat higher than the rate with zinc perchlorate and lead ion is one order of magnitude active than metal ions such as Mn^{2+} and Mg^{2+} having a similar ionization potential (Fig. 7). As for zinc and lead perchlorates, the effect of the substituents (X) in nitrosobenzenes was studied, the metal ion concentration being kept constant at 30×10^{-4} M. When σ parameters are used, the Hammett plots exhibit straight lines (ρ: 0.81 and 0.75 for zinc and lead salts, respectively). The similarlity in magnitude of the Hammett ρ values is indicative of both reductions as occurring by way of the same mechanism (Fig. 8).

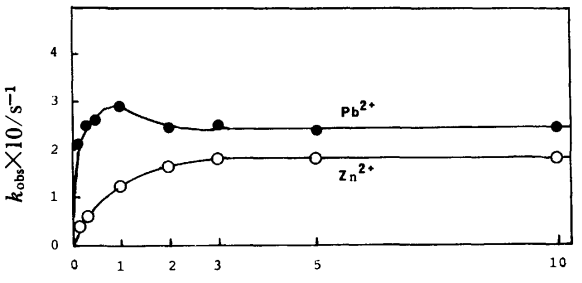

Fig. 9. Reduction of nitrosobenzene in the presence of changing amounts of bivalent metal perchlorates in CH_3CN at 25 °C under nitrogen. [BPDH]= 0.1 mM; [nitrosobenzene]=1.0 mM.

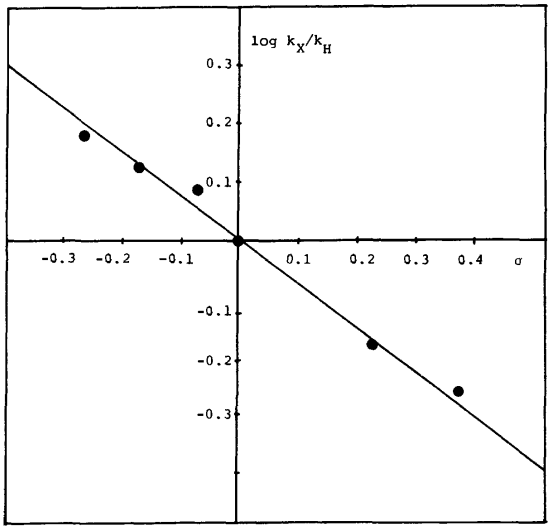

Fig. 10. Hammett plot for metal ion-catalyzed reduction of nitrosobenzene with 1-(substituted benzyl) BPDH in CH_3CN under nitrogen. [metal perchlorates]=5.0 mM. The reaction conditions are the same as described in Fig. 9, unless noted otherwise.

In Fig. 9 are depicted the plots of k_{obs} versus the concentrations of $Pb(ClO_4)_2$ and $Zn(ClO_4)_2$ for comparison. The clear saturation curve for zinc perchlorate might be explained by either or both of the following assumptions; the 320 and 360 nm zinc complexes (**d** and **e** types) are kinetically almost equivalent, or these complexes exist in the same ratio throughout changing concentrations of zinc perchlorate. In order to test the former assumption, an experiment was done, in which the reduction of nitrosobenzene with 1-(substituted benzyl)dihydropyridines was studied. The plotting of the logarithm of the observed rate constant against the Hammett σ constant affords a linear correlation within the experimental error (Fig. 10), which would presents a piece of evidence that, despite the overall differences in structure between complexes **d** and **e**, their kinetic behavior is inherently identical. Thus, we may safely say that zinc ion in any complex is displaced to the same position most suitable for the

Table 2. K_m and k_2 Values for Metal Ion-Catalyzed Nitrosobenzene Reduction

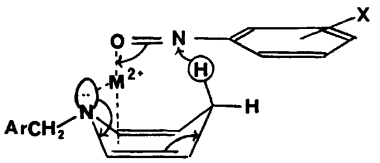
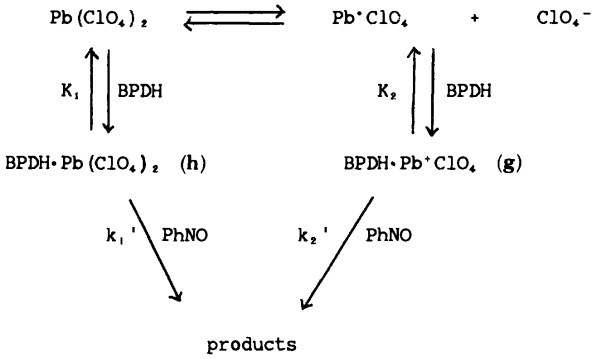
Zn^{2+} [a]	17.96	0.74	1870	1.80
Zn^{2+} [b]			1350	0.75
Pb^{2+} [a]	15.03	1.24	18400	2.44

a) Counter anion: ClO_4^-. b) Counter anion: NO_3^-.

transition state of reduction, as illustrated below:[5]



Unlike zinc perchlorate giving a usual saturation plot, lead perchlorate exhibits a significant feature in the rate-concentration plot; the maximum rate is observed at around 1 mM, suggesting that at least two kinetically important species are present in solution; namely, at its lower concentrations (<1 mM) added $Pb(ClO_4)_2$ would almost completely dissociate into Pb^+ClO_4 and ClO_4^- and the BPDH·Pb^+ClO_4 complex (**g**) thus formed could be the major species active for reduction, while at concentrations above 1 mM the BPDH·$Pb(ClO_4)_2$ complex (**h**) might also participate in the reaction. It is natural to conclude that the reaction with the former complex is faster than is the reaction with the latter and then the maximum rate has been observed. The contribution of the not identified complex **f** toward the overall rate, if any, is negligible, because of its only minor existence. Thus, the overall reaction proceeds by two competitive pathways involving totally different transition state, as illustrated below;



Scheme 3.

In Table 2 are compared the K_m and k_2 values calculated by assuming a Michaelis-Menthen equation, in which K_m is an association constant between BPDH and metal ion and k_2 is a second-order rate constant for the reaction of BPDH·metal complex and the substrate ArNO.[6] In the case of lead perchlorate, the data

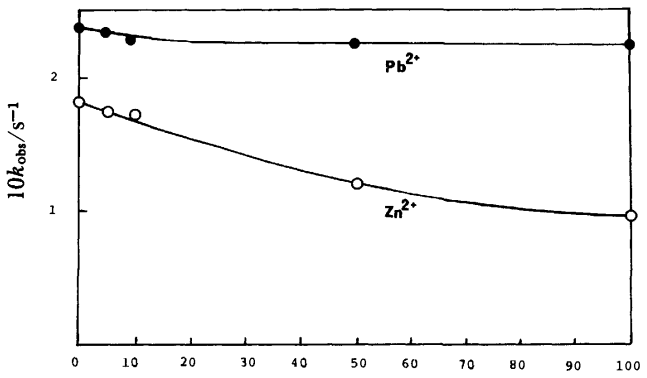


Fig. 11. Effect of addition of altering amounts of TBAP on rate of metal ion-catalyzed reduction of nitrosobenzene with BPDH in CH_3CN under nitrogen. [metal perchlorates]=3.0 mM.

points at lower metal ion concentrations (<1 mM) were only used for the calculation of K_m and k_2 values. The table shows that the apparent association

$$DH + M^{2+} \overset{K_m}{\rightleftharpoons} [DH\cdot M^{2+}] \xrightarrow{k_2[ArNO]} D^+ + PhNHO^- + M^{2+}$$

constant (K_m) for zinc complexes is tenfold smaller than that for lead complexes. This implies that the zinc complexes are relatively quite unstable as compared with the corresponding lead complexes. In order to verify this statement further, the effect of TBAP on the rate was also examined and the results thus obtained are depicted in Fig. 11; as for zinc perchlorate, the rate decreases steadly with increasing concentrations of added TBAP, indicating again all of the zinc complexes being unstable toward addition of perchlorate anions. On the other hand, as for the lead complexes, only a little rate depression resulted. This is in line with the conclusion which would be expected from the spectroscopic analysis and suggests that the uncharged BPDH·$Pb(ClO_4)_2$ (**h**) complex is slightly less reactive than the cationic BPDH·Pb^+ClO_4 complex (**g**).

Synthesis of 2-Alkyl-Substituted 1,3-Diketones via the 1,4-Addition of the Grignard Reagents to α,β-Unsaturated Imidates

Seiichi Inoue, Osamu Suzuki, and Kikumasa Sato*
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku Yokohama 240
(Received November 17, 1988)

4-Propyl-3,5-nonanedione was selectively formed by the reaction of methyl *N*-phenylacrylimidate with ethylmagnesium bromide in 80% yield. Similar diketones were obtained from methyl *N*-phenylcrotonimidate and *N*-phenylcinnamimidate with the Grignard reagents. The coupling of *N*-magnesio α-methoxy enamine and ketenimine, both of which are formed through the initial 1,4-addition of the Grignard reagent to α,β-unsaturated imidate, is the most plausible pathway for the formation of the diketones.

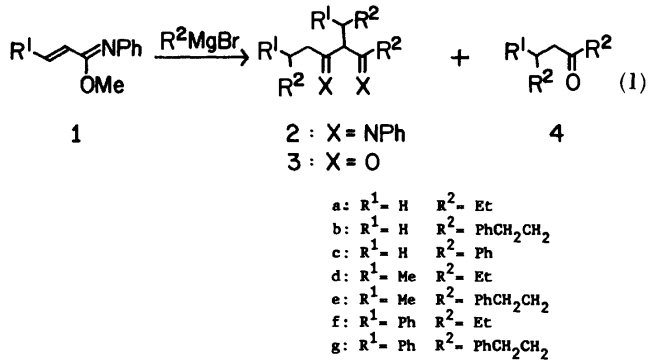
There is presently an interest in imidates (imino ethers) and related compounds from both synthetic and mechanistic points of view.[1] When imidates were treated with acyl halides, imidates gave amides. This reaction has been very important for amide side chain syntheses of β-lactam antibiotics.[2] On the other hand, Meyers et al. reported that the reaction of 2-alkenyldihydro-1,3-oxazines, cyclic version of α,β-unsaturated imidates, with organolithium or the Grignard reagents gave aldehydes or ketones via ketenimines as the key intermediates.[3] It has been reported by Adams and Reifschneider[4] that methyl *N*-phenylsulfonyl-3,3-diphenylpropionimidate is formed by the reaction of methyl *N*-phenylsulfonylcinnamimidate with phenylmagnesium bromide. In this case, however, elimination of methoxymagnesium bromide from the initial 1,4-addition product has not been observed. In this instance we became interested in whether acyclic α,β-unsaturated imidates may afford nucleophilic species upon reaction with organometallic compounds or afford electrophilic species such as ketenimines through further elimination of metal alkoxide. Now we found that the acrylimidates selectively undergo initial 1,4-addition of the Grignard reagents to finally produce 2-alkyl-1,3-diimines as a result of selective coupling between the two intermediates, magnesio enamines and ketenimines.[5] In this paper we wish to report the results in detail and discuss the pathway of the reaction.

Results and Discussion

A series of α,β-unsaturated imidates (**1**) was prepared by the reaction of the corresponding amides and trimethyloxonium tetrafluoroborate according to the literature.[6]

Treatment of methyl *N*-phenylacrylimidate (**1a**) with one equiv. of ethylmagnesium bromide in ether at 0 °C, followed by work-up with dilute hydrochloric acid, afforded 4-propylnonane-3,5-dione (**3a**) as a colorless liquid in 10% yield.

It was then found out that the yield of dione **3a** increased with increase of the amount of ethylmagnesium bromide and the maximum yield (80% yield) was obtained with 6 equiv. of the Grignard reagent (Fig. 1). Ethyl *N*-phenylacrylimidate gave the same diketone (**3a**). Similar treatment of **1a** with 6 equiv. of 2-phenylethylmagnesium and phenylmagnesium bromide also afforded 1,3-diketones **3b** and **3c**, respectively (Table 1, Eq. 1). It was thought that these diketones came out from two moles of **1a** and three moles of the Grignard reagents.



Reaction of crotonimidate (**1b**) and cinnamimidate (**1c**) with the alkyl Grignard reagents afforded 1,3-diimines **2** as stable liquids along with minor amounts of monoketones **4**. The diimines (**2**) could be hydrolyzed with 1 M HCl (1 M=1 mol dm^{-3}) at room tem-

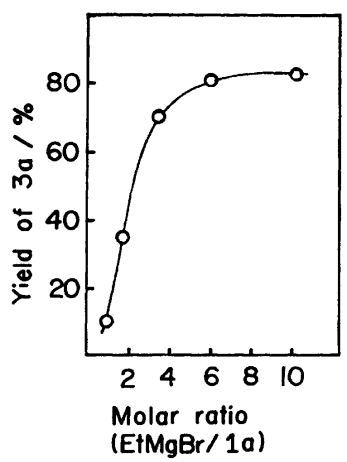


Fig. 1. Effect of the amount of the Grignard reagent.

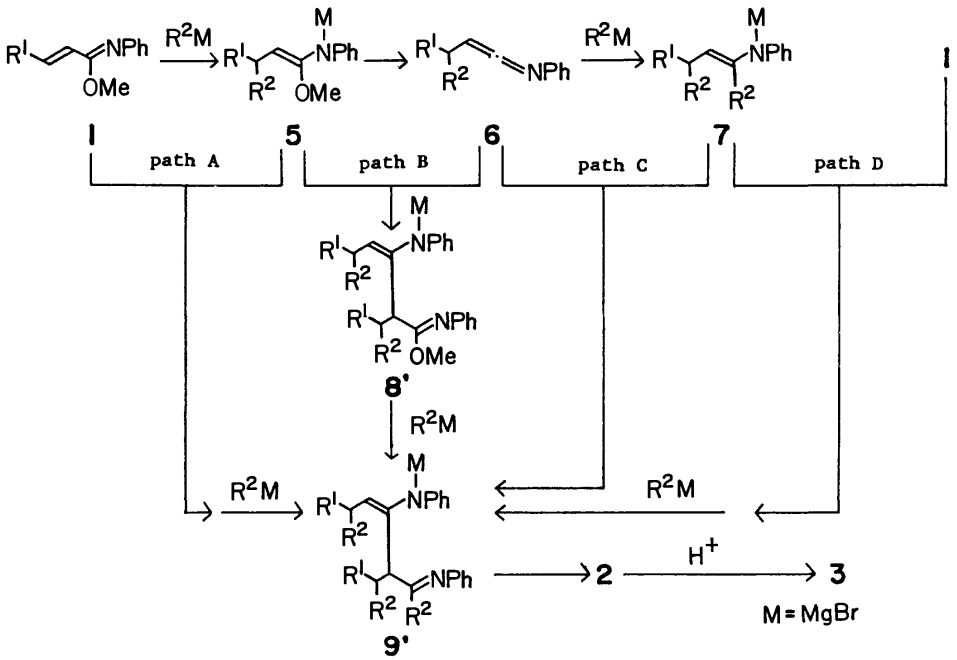
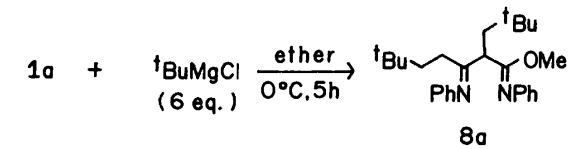


Scheme 1.

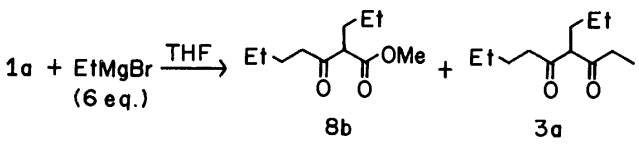
perature for 1—4 days to give 1,3-diketones **3** (Table 1). These results clearly suggest that the reaction of **1a** with the Grignard reagents leads to diimines **2** which are susceptible to hydrolysis during the work-up.

In contract with acryl or β-monosubstituted acrylimidates, α-substituted and β,β-disubstituted imidates, e.g., methacrylimidate, (*E*)-2-methyl-2-butenimidate, and 3-methyl-2-butenimidate gave only monoketones (**4**) upon reaction with alkyl and aryl Grignard reagents.

Several interpretations can be afforded as to the mechanism of formation of diketone **3** (Scheme 1). At first, we tried to detect a presumable key intermediate **6**. But ketenimine **6** was not isolated even by the use of limited quantities of the Grignard reagent or by carring out the reaction at low temperature. When 6 equiv. of *t*-butylmagnesium chloride was used to intercept the reaction at an intermediary stage by preventing further reactions by steric hindrance, β-imino imidate **8a** was obtained in 60% yield (Eq. 2). Moreover, treatment of **1a** with 6 equiv. of ethylmagnesium bromide in tetrahydrofuran (THF), followed by work-up with dilute hydrochloric acid gave 2-valerylpentanoate (**8b**) in 36% yield along with diketone **3a** (29% yield) (Eq. 3). The above results of the formation of β-imino or β-keto esters strongly suggest the presence of **8'** as intermediates in the reaction.

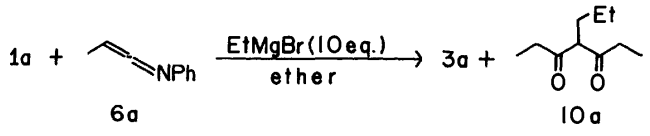


(2)



(3)

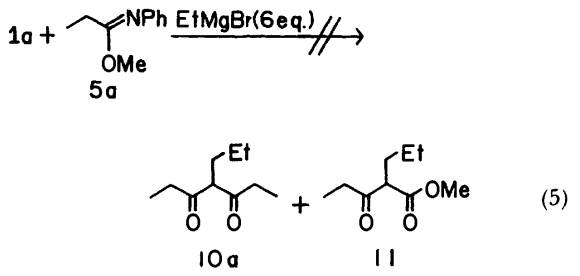
When a mixture of **1a** and 1-phenylimino-1-propene (**6a**), prepared by the reaction of *N*-phenylpropionimidoyl chloride with triethylamine,[7] was treated with 10 equiv. of ethylmagnesium bromide, 4-propyl-3,5-heptanedione (**10a**) was formed in 15% yield as well as **3a** in 43% yield (Eq. 4).



(4)

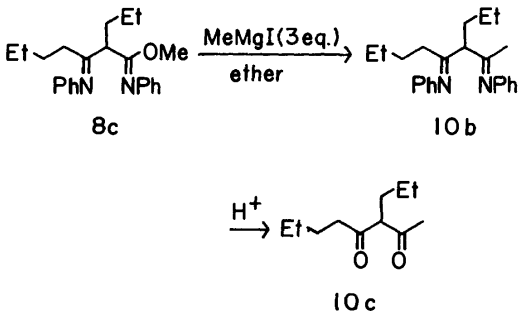
The formation of diketone **10a** suggests that the coupling reaction of *N*-magnesio α-methoxy enamine (**5**) with ketenimine (**6**) is probable (path B). Furthermore, the addition of **1c** to an ethereal solution of the *N*-magnesio enamine, which was in situ prepared from *N*-(1-methylhexylidene)aniline and ethylmagnesium bromide, at 0 °C resulted only in recovering the starting imidate (**1c**) and the imine. These results are not favorable to paths C and D.

In order to test whether the coupling of unsaturated imidate **1** and *N*-magnesio α-methoxy enamine **5** (path A) was possible, the reaction of **1a** with ethylmagnesium bromide was carried out in the presence of methyl *N*-phenylpropionimidate (**5a**). If the coupling reaction between **1** and **5** is possible, *N*-magnesio α-methoxy enamine (**5**) should also react with **5a** to give diketone **10a** and methyl 2-propyl-3-oxopentanoate (**11**) as well as diketone **3a**. The reaction of an equimolar mixture of **1a** and **5a** with 6 molar equiv. of ethylmagnesium bromide in ether at 0 °C for 3 h turned out to give **3a** in 77% yield as a sole product and **5a** was recovered quantitatively (Eq. 5).



(5)

Although the methoxyl group in **5a** was not replaced by the ethyl group upon reaction with ethylmagnesium bromide as shown above, this fact does not deny the path from **8′** to **9′**. A facile replacement of the methoxy group with the Grignard reagent in imidates of the type of **8′** was demonstrated as follows. β-Imino imidate **8c**, the precursor of **8b**, was prepared by the reaction of **1a** and 6 equiv. of ethylmagnesium bromide in THF at 0 °C (vide supra) followed by work-up with aqueous ammonium chloride. When this β-imino imidate **8c** was treated with methylmagnesium iodide in ether at 0 °C, diimine **10b** was formed immediately and, after work-up with dilute hydrochloric acid, diketone **10c** was isolated in 31% yield (Eq. 6). This facilitated alkylation of imidates at the imino nitrogen can be explained by the chelating effect of the imino nitrogen at the β-position toward alkylmagnesium species.



(6)

Finally, the possibility of the initial 1,2-addition, instead of the 1,4-addition discussed so far, of the Grignard reagent to imidate **1** can be deniable by the fact that the reaction of magnesio enamine **7** and **1** did not occur.

By the fact mentioned above, the most plausible pathway seems to involve the initial conjugate addition of the Grignard reagent to imidates affording very reactive *N*-magnesio α-methoxy enamine **5**, which leads to unstable, electrophilic ketenimine **6** upon β-elimination of metal methoxide. The ketenimine (**6**) is selectively alkylated by the strongly nucleophilic species **5** to yield **8′** which are then alkylated at the imidate carbon by the Grignard reagent to give diimine precursor (**9′**). When α-methylated and β,β-dimethylated unsaturated imidates were used, ketenimines **6** could not react with **5** by the steric hindrance, then **6** are attacked by the Grignard reagent to give **7**.

When organolithium reagent was used instead of the Grignard reagents, ketenimine (**6**) was exclusively trapped by the organolithium reagent instead of **5** to give monoketone (**4**).

The most unusual feature of the reaction of α,β-unsaturated imidates with the Grignard reagents is the facile formation of 2-branched 1,3-diketones by the selective coupling of **5** and **6**.

Experimental

General. Boiling points and melting points are uncorrected. IR spectra were measured on a Hitachi 260-10 spectrometer. ^{1}H NMR spectra were obtained with a JEOL JNM-C-60M or a JEOL FT-90-Q with tetramethylsilane as an internal standard. Column chromatography was normally effected with Wakogel C-200 (Wako Pure Chemical Industries). GLC analyses were performed on a Shimadzu GC-7A chromatograph using a column packed with Silicone OV-17 (3 mm×3 m). Trimethyloxonium tetrafluoroborate[9] and α,β-unsaturated imidate[6] were prepared according to the literature. The structure of the known compounds were

established on the basis of their spectroscopic properties and from descriptions in the literature.

Reaction of Methyl *N*-Phenylacrylimidate (1a) with Grignard Reagents. To a stirred ether solution of the Grignard reagent (18.6 mmol), **1a** (0.50 g, 3.1 mmol) was added at 0 °C and stirred for 5—8 h at 0 °C. Then the solution was poured into 1 M HCl at 0 °C and stirred for 1 h. The resulting mixture was extracted with ether and the organic layer was washed with $NaHCO_3$ aq. then brine and dried over $MgSO_4$. After filtration, the solvent was removed and the residue was purified by column chromatography (silica gel-hexane/chloroform) to give diketone.

4-Propyl-3,5-nonanedione (3a): bp 129—130 °C/11 mmHg (1 mmHg=133.322 Pa.); IR (neat) 2970, 1730, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (6H, m), 1.04 (3H, t, J=7 Hz), 1.27 (4H, m), 1.53 (2H, m), 1.82 (2H, m), 2.46 (2H, t, J=7 Hz), 2.49 (2H, q, J=7 Hz), and 3.67 (1H, t, J=7 Hz); MS m/z 198 (M^+).

Found: C, 72.70; H, 11.43%. Calcd for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

1,9-Diphenyl-4-(3-phenylpropyl)-3,5-nonanedione (3b): IR (neat) 3060, 2860, 1725, 1695, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=1.50 (8H, m), 2.60 (10H, m), 3.42 (1H, t, J=7 Hz), and 7.12 (15H, s).

Found: C, 84.51; H, 8.13%. Calcd for $C_{30}H_{34}O_2$: C, 84.46; H, 8.03%.

1,5-Diphenyl-2-benzyl-1,3-pentanedione (3c): mp 66—67 °C (MeOH); IR (KBr) 1710, 1680, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.79 (4H, bs), 3.30 (2H, d, J=7 Hz), 4.79 (1H, t, J=7 Hz), 7.23 (10H, s), and 7.70 (5H, m); MS m/z 342 (M^+).

Found: C, 83.96; H, 6.46%. Calcd for $C_{24}H_{22}O_2$: C, 84.18; H, 6.48%.

Reaction of Methyl *N*-Phenylcrotonimidate (1b), Methyl *N*-Phenylcinnamimidate (1c) with Alkyl Grignard Reagents. To a stirred ether solution of Grignard reagent (18.6 mmol), imidate (3.1 mmol) was added at 0 °C. After further stirring at 0 °C or r.t., the resulting mixture was poured into aqueous ammonium chloride then extracted with ether and dried over $MgSO_4$. After filtration, the solvent was removed and distilled with Glass Tube Oven to give monoketone. The resulting residue was purified by column chromatography (silica gel-hexane/chloroform) to give diimine. To a solution of diimine (1 mmol) in ether (10 ml), 1 M HCl (40 ml) was added and stirred for 1—4 days. The resulting mixture was extracted with ether and washed with brine, dried over $MgSO_4$. After filtration, the solvent was removed and the residue was purified by column chromatograpy (silica gel-hexane/chloroform) to give diketone. The following compounds were prepared.

5-Methyl-3-heptanone (4d): bp 152—154 °C (lit,[10] 153—155 °C).

***N,N'*-Diphenyl-7-methyl-4-(1-methylpropyl)-3,5-nonanediimine (2d):** IR (neat) 2960, 1640, 1595, 755, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (15H, m), 2.20 (10H, m), 3.73 (1H, d, J=7 Hz), and 6.87 (10H, m).

Found: C, 82.71; H, 9.64; N, 7.60%. Calcd for $C_{26}H_{36}N_2$: C, 82.93; H, 9.64; N, 7.44%.

7-Methyl-4-(1-methylpropyl)-3,5-nonanedione (3d): bp 133—134 °C/17 mmHg; IR (neat) 2960, 1720, and 1695 cm^{-1}; ^1H NMR (CCl_4) δ=0.89 (19H, m), 2.10 (8H, m), and 3.34 (1H, d, J=7 Hz); MS m/z 226 (M^+).

Found: C, 74.50; H, 11.57%. Calcd for $C_{14}H_{26}O_2$: C, 74.29; H, 11.58%.

5-Methyl-1,7-diphenyl-3-heptanone (4e): bp 174—175 °C/0.30 mmHg; IR (neat) 3030, 2930, 1715, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=1.10 (3H, d, J=7 Hz), 2.10 (10H, m), 3.37 (1H, m), and 7.12 (10H, s).

Found: C, 85.65; H, 8.61%. Calcd for $C_{20}H_{24}O$: C, 85.67; H, 8.63%.

***N,N'*-Diphenyl-7-methyl-4-(1-methyl-3-phenylpropyl)-1,9-diphenyl-3,5-nonanediimine (2e):** IR (neat) 3030, 2930, 1640, 1595, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=0.97 (6H, m), 2.10 (16H, m), 3.50 (1H, d, J=7 Hz), and 6.89 (25H, m).

Found: C, 87.66; H, 8.25; N, 4.33%. Calcd for $C_{44}H_{48}N_2$: C, 87.37; H, 8.00; N, 4.63%.

7-Methyl-4-(1-methyl-3-phenylpropyl)-1,9-diphenyl-3,5-nonanedione (3e): IR (neat) 3030, 2930, 1690, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=0.80 (3H, d, J=7 Hz), 0.83 (3H, d, J=7 Hz), 2.00 (16H, m), 3.32 (1H, d, J=7 Hz), and 7.05 (15H, s).

Found: C, 84.75; H, 8.35%. Calcd for $C_{32}H_{38}O_2$: C, 84.45; H, 8.42%.

5-Phenyl-3-heptanone (4f): bp 120—125 °C/2.5 mmHg (lit,[11] 255 °C).

***N,N'*-Diphenyl-4-(1-phenylpropyl)-7-phenyl-3,5-nonanediimine (2f):** IR (neat) 3030, 2930, 1640, 1595, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=1.54 (19H, m), 3.48 (1H, d, J=7 Hz), and 6.90 (20H, m).

Found: C, 86.62; H, 8.00; N, 5.20%. Calcd for $C_{36}H_{40}N_2$: C, 86.35; H, 8.05; N, 5.59%.

4-(1-Phenylpropyl)-7-phenyl-3,5-nonanedione (3f): IR (neat) 3040, 2970, 1720, 1700, 760, and 705 cm^{-1}; ^1H NMR (CCl_4) δ=0.68 (9H, m), 1.67 (8H, m), 3.17 (2H, m), 3.93 (1H, d, J=7 Hz), and 7.15 (10H, s); MS m/z 350 (M^+).

Found: C, 82.51; H, 8.74%. Calcd for $C_{24}H_{30}O_2$: C, 82.24; H, 8.63%.

1,5,7-Triphenyl-3-heptanone (4g): bp 194—196 °C/0.19 mmHg; IR (neat) 3030, 2915, 1715, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=2.10 (11H, m), 7.12 (15H, s).

Found: C, 87.97; H, 7.37%. Calcd for $C_{25}H_{26}O$: C, 87.68; H, 7.65%.

***N,N'*-Diphenyl-1,7,9-triphenyl-4-(1,3-diphenylpropyl)-3,5-nonanediimine (2g):** IR (neat) 3030, 2930, 1640, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=2.08 (16H, m), 3.50 (1H, d, J=7 Hz), and 6.89 (35H, m).

Found: C, 89.26; H, 6.91; N, 3.54%. Calcd for $C_{54}H_{52}N_2$: C, 88.97; H, 7.19; N, 3.84%.

1,7,9-Triphenyl-4-(1,3-diphenylpropyl)-3,5-nonanedione (3g): IR (neat) 3040, 2970, 1720, 1700, 760, and 705 cm^{-1}; ^1H NMR (CCl_4) δ=1.60 (6H, m), 1.76 (10H, m), 3.95 (1H, d, J=7 Hz), and 7.15 (25H, s).

Found: C, 87.41; H, 7.35%. Calcd for $C_{42}H_{42}O_2$: C, 87.16; H, 7.31%.

Reaction of 1a with *t*-Butylmagnesium Chloride. To a stirred ether solution of *t*-butylmagnesium chloride (31 mmol), ether solution of **1a** (0.50 g, 3.1 mmol) was added at 0 °C and stirred at r.t. for 5 h. After usual work-up, the residue was purified by column chromatography (alumina-dichloromethane) to give methyl *N*-phenyl-2-(2,2-dimethylpropyl)-6,6-dimethyl-3-phenyliminoheptanimidate (**8a**) (0.38 g, 60%); bp 165—170 °C/0.80 mmHg; IR (neat) 3030, 2960, 1660, 1245, 750, and 700 cm^{-1}; ^1H NMR (CCl_4) δ=0.77 (18H, m), 1.90 (6H, m), 3.67 (1H, t, J=7 Hz), 3.80 (3H, s), and 6.95 (10H, m); MS m/z 406 (M^+). Found: C, 79.74; H, 9.71; N,

6.58%. Calcd for $C_{27}H_{38}N_2O$: C, 79.76; H, 9.42; N, 6.89%.

Reaction of 1a with Ethylmagnesium Bromide in THF. According to the general procedure, 0.50 g (3.1 mmol) of **1a** and ethylmagnesium bromide (31 mmol) were treated in THF. After usual work-up, the residue was purified by column chromatography (silica gel-hexane/ethyl acetate) to give **3a** (111 mg, 36%), methyl 2-valerylpentanoate (**8b**) (89 mg, 29%); bp 130—135 °C/20 mmHg; IR (neat) 2960, 1740, and 1235 cm^{-1}; ^1H NMR (CCl_4) δ=0.95 (6H, m), 1.83 (10H, m), 3.29 (1H, t, J=7 Hz), and 3.67 (3H, s); MS m/z 200 (M^+).

Reaction of 1a and *N*-(1-Propenylidene)aniline (6a) with Ethylmagnesium Bromide. According to the general procedure, **1a** 0.50 g (3.1 mmol) and **6a** 0.40 g (3.1 mmol) were treated with 31 mmol of ethylmagnesium bromide in ether at 0 °C. After usual work-up, the residue was purified by column chromatography (silica gel-hexane/chloroform) to give **3a** (132 mg, 43%), 4-propyl-3,5-heptanedione (**10a**) (40 mg, 15%); IR (neat) 2950, 1720, 1695, and 1460 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (3H, t, J=7 Hz), 0.99 (6H, t, J=7 Hz), 1.45 (4H, m), 2.38 (4H, q, J=7 Hz), and 3.49 (1H, t, J=7 Hz); MS m/z 170 (M^+).

Reaction of Methyl *N*-Phenyl-3-(phenylimino)-2-propylheptanimidate (8c) with Methylmagnesium Iodide. 1a (0.50 g, 3.1 mmol) and 10 equiv. of ethylmagnesium bromide were treated in THF at 0 °C, then poured into aqueous ammonium chloride, and extracted with ether, the organic layer was dried ($MgSO_4$) and concentrated. The crude mixture was dissolved in ether (5 ml), added to methylmagnesium iodide in ether at 0 °C and stirred for 5 min then poured into 1 N HCl, stirred for 1 h. After usual work-up and distillation (125—130 °C/10 mmHg) to give a mixture of **3a** and 3-propyl-2,4-octanedione (**10c**); MS m/z 184 (M^+), which was separated by GLC.

Kinetic Study for Reactions of Nitrate Radical (NO_3·) with Alcohols in Solutions

Osamu Ito,* Seiji Akiho, and Masashi Iino
Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received November 18, 1988)

The rate constants for the reaction of nitrate radical (NO_3·) with alcohols have been determined by flash photolysis method in aqueous and nonaqueous solutions. The reactivity of NO_3· in acetonitrile was higher than that in aqueous solution, suggesting that hydrogen bonds between solvent and NO_3· or alcohols decrease the reaction rate. From the deuterium-isotope effect, the main reaction path was confirmed to be hydrogen atom abstraction from the carbon atom bonded with the OH group. For 2-methyl-2-propanol, the hydrogen atom abstraction from the OH group was presumed. These reaction paths were confirmed, since the reaction rate constants decreased with an increase in the corresponding bond-dissociation energies. From strong dependency of the rate constants upon the ionization energies of alcohols, the polar transition states of the reactions were suggested.

By photolysis of $(NH_4)_2[Ce(NO_3)_6]$ in the presence of alcohols, the intermediate radicals produced by the loss of the hydrogen atom from alcohols were observed by the low temperature ESR measurements and spin trapping technique.[1-3] As the initial step, it has been presumed that the electron transfer from alcohols to cerium(IV) ion occurs producing the radical cations of alcohols (Reaction 1), which undergo deprotonation forming the neutral radicals of alcohols (Reaction 2).[1-3]

$$R'R''CHOH + Ce^{4+} \xrightarrow{h\nu} R'R''CHOH^{+\cdot} + Ce^{3+} \quad (1)$$

$$R'R''CHOH^{+\cdot} \longrightarrow R'R''C{\cdot}OH + H^{+} \quad (2)$$

On the other hand, it was also reported by flash photolysis method that the nitrate radical (NO_3·) was efficiently produced from $(NH_4)_2[Ce(NO_3)_6]$ in aqueous solution[4,5] and in nonaqueous solution.[6,7] For a few alcohols, the rate constants for the reaction with NO_3· in aqueous solution were determined by using the flash photolysis[8] and pulse radiolysis method.[9] The high reactivities of NO_3· with alcohols suggest that different reactions from Reactions 1 and 2 are responsible to the photooxidation of alcohols by $(NH_4)_2[Ce(NO_3)_6]$.

Since NO_3· also plays an important role in air pollution, many kinetic studies in gas phase have been reported.[10,11] By comparing the rate constants in gas phase with the corresponding ones in solutions, considerable differences attributable to the medium effect were found for the reactions with aldehydes in our previous paper.[12] In this study, we report the rate constants for the reactions of NO_3· with various alcohols in acetonitrile and in aqueous solution by using flash photolysis technique. In order to reveal the reaction paths, the deuterium-isotope effects on the reaction rates were investigated. The correlation of the observed rate constants with bond-dissociation energies also afforded information about the reaction mechanisms. The polar nature of the transition state for the reaction was also revealed.

Experimental

$K_2[Ce(NO_3)_6]$, which was used as a radical source, was prepared from the ammonium salt by the action of KOH. Alcohols were purified by distillation before use. Commercially available deuterium derivatives (Merck Co. INC.) were used as received; deuterium degrees for both CH_3OD and CD_3OD are >99%. Distilled acetonitrile (over P_2O_5 under N_2) and distilled water were used as solvents.

The xenon flash photolysis apparatus was of a standard design with two xenon flash-lamps (Xenon Corp. N-815C);[13,14] the half-duration was ca. 10 μs and input energy was ca. 100 J. By using the light filters, $K_2[Ce(NO_3)_6]$ was flash-photodecomposed with the light between 310 and 450 nm. The temperature of the reaction was controlled by dipping the flash cell (1 dm of optical lenght and 0.1 dm of diameter) in a cooled methanol bath or water bath. For the measurements of Arrhenius parameters, temperature was varied from −40 to 20 °C. Within this temperature range, spontaneous reaction between the radical source and alcohols was not observed in the dark. Above 50 °C, bleaching of yellow color of the radical source was observed on the addition of benzene-methanol (benzyl alcohol) as reported in the literature.[15]

Results and Discussion

Figure 1 shows a transient absorption spectrum appeared by the flash photolysis of $K_2[Ce(NO_3)_6]$ in acetonitrile. The absorption bands with vibronic structure (peak at 635 nm) are attributed to the absorption bands of NO_3· in acetonitrile, indicating that photodissociation Reaction 3 occurs efficiently even in acetonitrile.[6-9]

$$K_2[Ce^{IV}(NO_3)_6] \underset{k_b}{\overset{h\nu}{\rightleftharpoons}} NO_3{\cdot} + K_2[Ce^{III}(NO_3)_5] \quad (3)$$

Insert of Fig. 1 shows the first-order plots for the decay of NO_3· in the presence of alcohols. In the absence of alcohol, the decay of NO_3· was attributed to the back process of Reaction 3. The half-life of NO_3· in the absence of alcohols was ca. 1000 μs which is long enough to follow decay kinetics of NO_3· by our flash photolysis apparatus with half-duration of flash lamp

of 10 μs even in the presence of excess of alcohols. In the presence of alcohol, a sufficiently linear line was obtained for each concentration. The slope yields pseudeo first-order rate constant ($k_{first\text{-}order}$). The decay rate increases with the concentration of additive. Since the concentration of NO_3· produced by each flash exposure was evaluated less than ca. 1×10^{-6} mol dm^{-3} by assuming the extinction coefficient to be ca. 1000 dm^3 mol^{-1} cm^{-1} at 635 nm in acetonitrile,[3,4,16] the addition of alcohols higher than ca. 1×10^{-5} mol dm^{-3} is enough to establish pseudo first-order kinetics.

Figure 2 shows the pseudo first-order plots for various alcohols. The linear lines are obtained; from the slopes the second-order rate constants, which are referred to as k_{obs}, are evaluated. The k_{obs} values at 20 °C obtained in acetonitrile and 6 M HNO_3 (1 M=1 mol dm^{-3}) aqueous solution are summarized in Tables 1 and 2, respectively. In Table 2, the reported rate constants in aqueous solutions are also listed. Agreement between the rate constants in this study and those of pulse radiolysis method by Neta and Huie[9] is better than that with flash photolysis method by Dogliotti and Hayon.[8] With the change of acidity of aqueous solution from 6 M HNO_3 to 2 M HNO_3, appreciable change was not observed. The k_{obs} values in acetonitrile are ca. 10 times larger than the rate constants for hydrogen atom abstraction of $(CH_3)_3CO$·

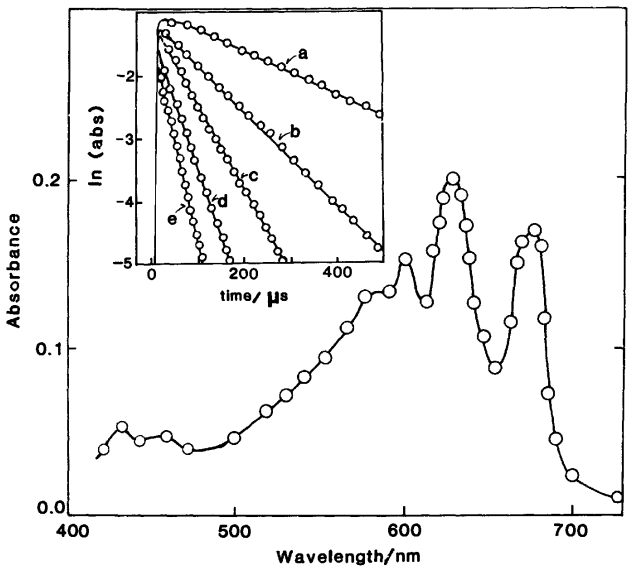

Fig. 1. Transient absorption spectrum observed by flash photolysis of $K_2[Ce(NO_3)_6]$ (10^{-3} mol dm^{-3}). Absorbance at 10 μs after each flash exposure is plotted. Insert: First-order plots for decay of absorbance at 635 nm in acetonitrile (at 20 °C) in the presence of 2-propanol; (a) 0, (b) 0.6, (c) 1.3, (d) 1.9, and (e) 2.5 mmol dm^{-3}.

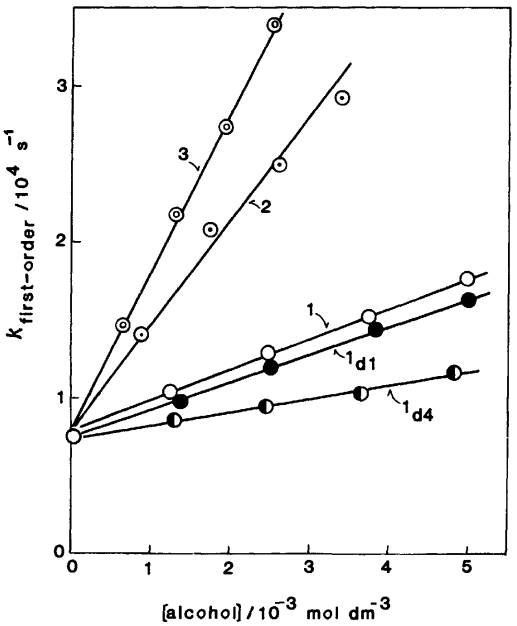

Fig. 2. Pseudo first-order plots for some alcohols in acetonitrile at 20 °C; numbers in figure are referred to as Tables.

Table 1. Rate Constants (at 20 °C) and Arrhenius Parameters for Reactions of NO_3· with Various Alcohols in Acetonitrile;[a] Bond Dissociation Energy (BDE)[b] and Ionization Energy (IE)[c]

	Alcohol	10^{-6} k_{obs}	10^{-6} k_H	log A_H	E_a	BDE	IE
		mol^{-1} dm^3 s^{-1}	mol^{-1} dm^3 s^{-1}		kJ mol^{-1}	kJ mol^{-1}	eV

7	$CH_2{=}CHCH_2OH$	210	210
		230 (2M HNO_3)	230

a) E_a=19±2 kJ mol^{-1}; log A_H=8.4±0.2. b) E_a=11±2 kJ mol^{-1}; log A_H=8.6±0.2. c) Pulse radiolysis data (Ref. 9). d) Flash photolysis data (Ref. 8).

from alcohols in organic solvent determined with laser flash photolysis.[17]

In Fig. 2, it is noticeable that the slope of CH_3OD is practically equal to that of CH_3OH (rate constant is referred to as k^H), whereas that of CD_3OD (k^D) is considerably small. This difference (k^H/k^D=3.4) is clearly larger than estimation errors (±5%) which were contained in our method. Although this deuterium-isotope effect is larger than that expected from the primary deuterium-isotope effect (k^H/k^D=1.63), further large ratios were reported for the hydrogen-atom abstraction reaction by various radicals.[18] Especially, the reported ratio (3.2)[17] for the reaction of $(CH_3)_3CO^{\cdot}$ with 2-propanol is in good agreement with our value. These observations clearly indicate that the reaction path of $NO_3^{\cdot}$ with alcohols with hydrogen atoms at the carbon atom with the OH group is direct hydrogen (deuterium) atom abstraction as shown in Reaction 4.

$$R'R''CHOH + NO_3^{\cdot} \longrightarrow R'R''C^{\cdot}OH + HNO_3 \quad (4)$$

Since the oxygen-centered radicals are known to be highly reactive to hydrogen atom abstraction,[19,20] the observed large rate constants of $NO_3^{\cdot}$ suggest that $NO_3^{\cdot}$ can be shown in canonical structures **I** and **II**, in which an unpaired electron localizes on one oxygen atom.

$$\underset{\mathbf{I}}{{}^{\cdot}O\text{-}N^{+}(O^{-})=O} \longleftrightarrow \underset{\mathbf{II}}{{}^{\cdot}O\text{-}N^{+}(=O)\text{-}O^{-}}$$

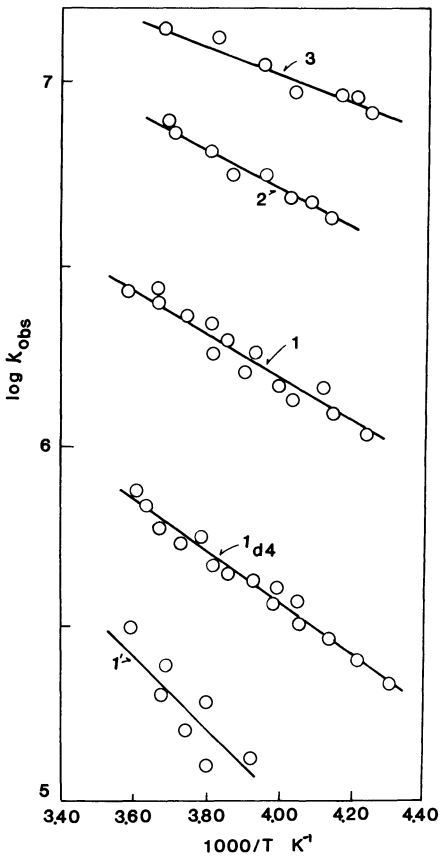

Fig. 3. Arrhenius plots for some alcohols. Numbers are referred to as Tables; **1'** is for methanol in aqueous solution.

In Tables 1 and 2, the rate constants per an active hydrogen (k_H and k_D) are also added by assuming that hydrogen atoms at the α-carbon are predominantly abstracted by $NO_3^{\cdot}$. In the case of 2-methyl-2-propanol (*t*-butyl alcohol), two possible reaction paths (i.e., hydrogen atom abstraction from O–H and from C–H) must be taken into consideration. For 2-propen-1-ol (allyl alcohol), addition reaction mode must be considered besides the hydrogen atom abstraction from allyl position. In each Table, the k_H values increase in the order of $CH_3OH < CH_3CH_2OH < (CH_3)_2CHOH <$ benzenemethanol (benzyl alcohol); this order is in good agreement with the reported tendency for other oxygen-centered radicals such as $(CH_3)_3CO^{\cdot}$ and $OH^{\cdot}$.[17-20]

Figure 3 shows the Arrhenius plots for the rate con-

stants for some alcohols between −40 and 20 °C. Fairly good linear lines are obtained for various alcohols. In the case of methanol in acetonitrile, the rate constant at 20 °C is about three times larger than that at −40 °C. In Table 1, the activation energies (E_a) and frequency factors per an active hydrogen atom ($\log A_H$) obtained in acetonitrile are summarized. By the variation of ±1 kJ mol^{-1} in E_a, the A value varies ±30%; thus, they are shown in the form of $\log A$. The E_a values for aliphatic alcohols seem to be smaller than the reported values for the carbon-centered radicals.[19] In the reported activation energies, we can find a tendency that the activation energies for the hydrogen-atom abstraction reactions by the oxygen-centered radicals are smaller than those by other radicals.[19] For example, the reported E_a value of 22.2 kJ mol^{-1} for $(CH_3)_3CO$·-methanol is comparable with our value for NO_3· by taking smaller rate constant for $(CH_3)_3CO$· (1.3×10^5 mol^{-1} dm^3 s^{-1}) into consideration.[21]

In Table 1, the E_a values decrease with an increase in the k_H values, showing linear free energy relationship.[19] With the increase in the k_H values, the $\log A_H$ values seem to increase. The reactivity at ambient temperature is determined by the combination of both E_a and A.

In Fig. 4, the rate constants in acetonitrile are plotted against the rate constants in aqueous solution. In the range of k_H smaller than 10^8 mol^{-1} dm^3 s^{-1}, the rate constants in acetonitrile are larger than the corresponding rate constants in aqueous solution by a factor of ca. 10. This difference may be attributed to the interaction between the attacking radical and acidic aqueous solvent via hydrogen bond. From the canonical structures of NO_3· (**I** and **II**), the electron-deficient oxygen radical center may interact with oxygen atom of H_2O. Such interaction may interfere the approach of alcohols to NO_3·. In addition, the hydrogen bonds between alcohols and H_2O also tend to decrease the reaction rates.

For benzyl alcohol, the rate constants in both solvents approach to the same value. Interchange of the reaction modes from hydrogen atom abstraction was not expected, since the rate constant of benzyl alcohol is similar to that of toluene, in which benzylic hydrogen atom is abstracted.[7,22] Taking the high ionization energy of benzyl alcohol into consideration,[23] electron-transfer reaction is not probable. Addition of NO_3· to the benzene ring is not probable, because the reactivity for addition to the phenyl ring is low.[12] Thus, the approach of the rate constants in the both solvents suggests the reactivity-selectivity principle;[24] for fast reactions, selectivity is reduced. Indeed, the rate constants are only ca. 1/10 of the diffusion controlled limits in the both solvents.[25] In the case of allyl alcohol, although the addition reaction of NO_3· to the double bond must be taken into consideration, the similar behavior was found.

In Fig. 5, the rate constants ($\log k_{obs}$ and $\log k_H$) in acetonitrile are plotted against the bond-dissociation energies between C-H at the α-position; for *t*-butyl alcohol, the plot for O-H is also shown. A general tendency was found, showing that the reactivities of alcohols increase with a decrease in the bond-dissociation energies.[26] Since the reactivities of alcohols are correlated linearly with the bond-dissociation energy at C_α-H, the reaction mode was confirmed to be Reaction 4. For *t*-butyl alcohol, the rate constant plotted against the bond-dissociation energy for O-H is found near the extrapolated line for $\log k_{obs}$ and for $\log k_H$. The reported ESR spectra support the hydrogen-atom

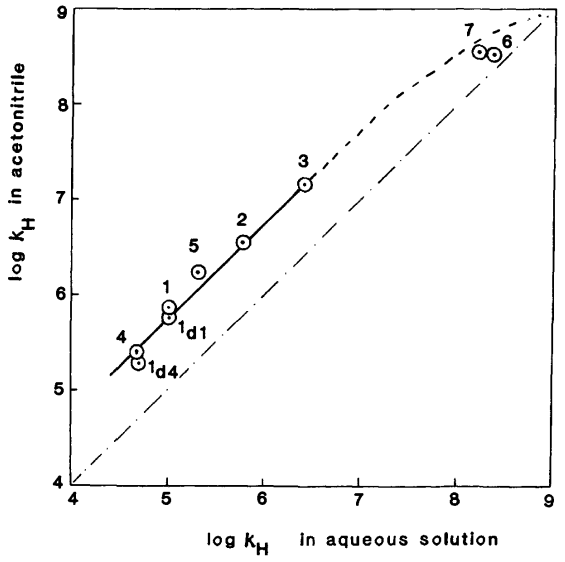

Fig. 4. Correlation between $\log k_H$ in acetonitrile and $\log k_H$ in 6 M HNO_3 at 20 °C.

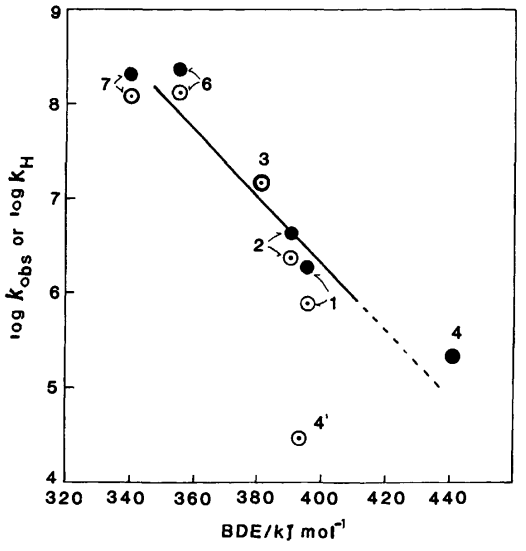

Fig. 5. $\log k_{obs}$ (●) or $\log k_H$ (⊙) at 20 °C in acetonitrile vs. bond-dissociation energy (BDE); **4** is for BDE(O-H) and **4'** for BDE(C-H).

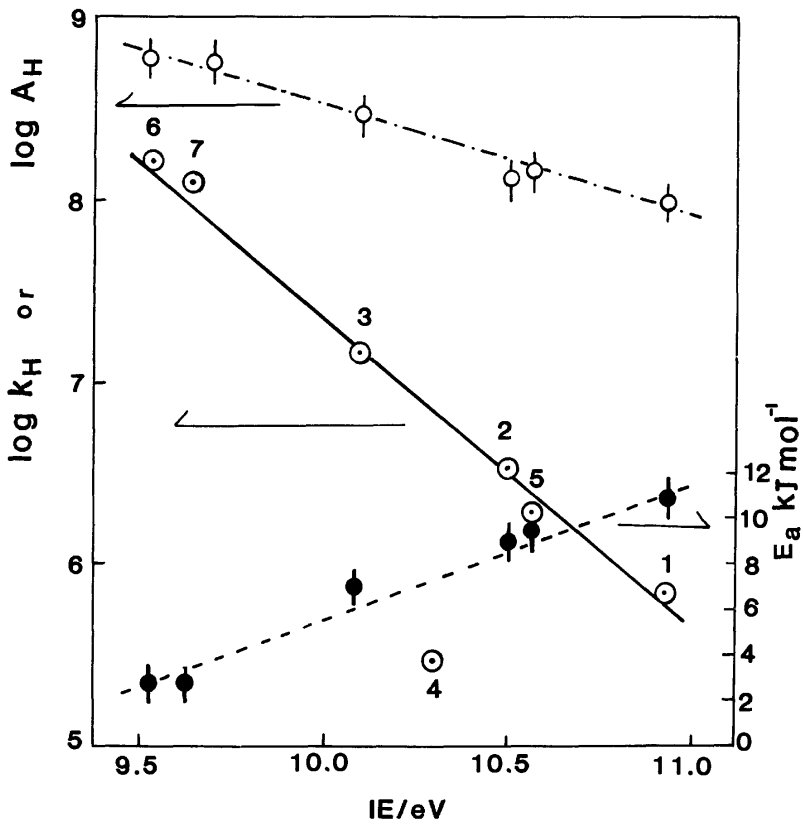

Fig. 6. $\log k_H$ (⊙), $\log A_H$ (○), and E_a (●) at 20 °C in acetonitrile vs. ionization energy (IE).

abstraction reaction from the OH group [Reaction 5].[1-3]

$$R_3COH + NO_3^{\cdot} \longrightarrow R_3CO^{\cdot} + HNO_3 \qquad (5)$$

In the case of allyl alcohol, since the rate constant is found near the line, the hydrogen-atom abstraction reaction from allylic position was suggested.

Figure 6 shows the plot of $\log k_H$, $\log A_H$, and E_a, against the ionization energies of alcohols.[23] Fairly good linear relationship is found for $\log k_H$ of alcohols except *t*-butyl alcohol. There seems to be a general tendency that the reactivity increases with a decrease in the ionization energy. This suggests a high electrophilicity of $NO_3^{\cdot}$, which is in good agreement with the reported high electron affinity (3.5 eV).[27] Furthermore, it is indicated that there are contributions of the polar resonance structures to the transition state; charge transfer from alcohols to $NO_3^{\cdot}$ occurs in the transition state as shown by **III** and **IV**.[18] By the contribution of these polar resonance structures, it is expected that the activation energy is decreased; indeed, a decrease in E_a with a decrease in the ionization energy was seen in Fig. 6.

$$[R'R''\overset{\cdot}{C}\cdot H\cdot O\text{-}NO_2] \longleftrightarrow [R'R''\overset{+}{C}H{:}O^{-}\text{-}NO_2]$$
$$\quad\;\; | \qquad\qquad\qquad\quad |$$
$$\quad OH \qquad\qquad\qquad OH$$
$$\quad \textbf{III} \qquad\qquad\qquad \textbf{IV}$$

The $\log A_H$ values are also influenced by the ionization energies of alcohols, suggesting that polar effect also presents in the orientation factor.[12]

The slightly lower reactivity of 1,2-ethanediol than that of ethanol is attributed to its higher ionization energy. Downward deviation of k_H of *t*-butyl alcohol suggests a different reaction mode having less polar transition state. The hydrogen atom of the OH group in *t*-butyl alcohol is more electron-deficient than that of C-H; thus, Reaction 5 proceeds via less polar transition state.

Although the point for allyl alcohol in Fig. 6 is on a line for the hydrogen-atom abstraction [Reaction 4], one can not exclude a possibility of addition reaction path, because the rate constant for vinyl acetate (2.5×10^8 mol^{-1} dm^3 s^{-1} at 5 °C in acetonitrile),[28] which is a nonconjugate vinyl monomer similar to allyl alcohol, is close to that of allyl alcohol.

We are thankful to the Grant-in-Aid (No. 63550676) for Scientific Research from the Ministry of Education, Science and Culture.

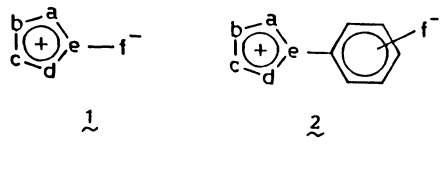
Syntheses and Properties of Quinonoid Mesoionic Compounds

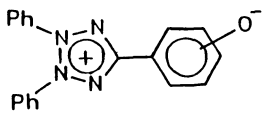
Shuki ARAKI,* Naomitsu AOYAMA, and Yasuo BUTSUGAN
Department of Applied Chemistry, Nagoya Institute of Technology,
Gokiso-cho, Showa-ku, Nagoya 466
(Received November 21, 1988)

Quinonoid mesoionic compounds having a 2,3-diphenyltetrazolium ring were synthesized and characterized spectroscopically. Compounds possessing an inserted benzene ring were found that a dipolar (5-tetrazolylio)-phenolate structure contributes importantly to the ground state of the mesoions. On the contrary, a mesoion having an inserted anthracene ring is a less polar compound, anthraquinone methide structures being dominant in its ground state electronic structure.

Mesoionic compounds of the general formula **1**, where a—f are suitably substituted carbons or heteroatoms, are an interesting family of heterocycles because of their unique structure, reaction behavior, and pharmaceutical activity; and numerous works have been focused on the chemistry of these novel electronic systems.[1] Quinonoid mesoionic compounds **2**, derived from **1** by insertion of a benzene ring into the exocyclic e–f bond of **1**, are one of unique modifications of mesoions, and their properties are intriguting in connection with those of the original mesoions **1**. Recently, we reported[2] the preparation of (2,3-diphenyl-5-tetrazolylio)phenolates (**3a**—c) as the first representatives of such quinonoid mesoions. Now, we describe here the synthesis and physicochemical properties of the further examples of the related quinonoid mesoions possessing a tetrazolium ring, together with a full account of the study on **3a**—c.

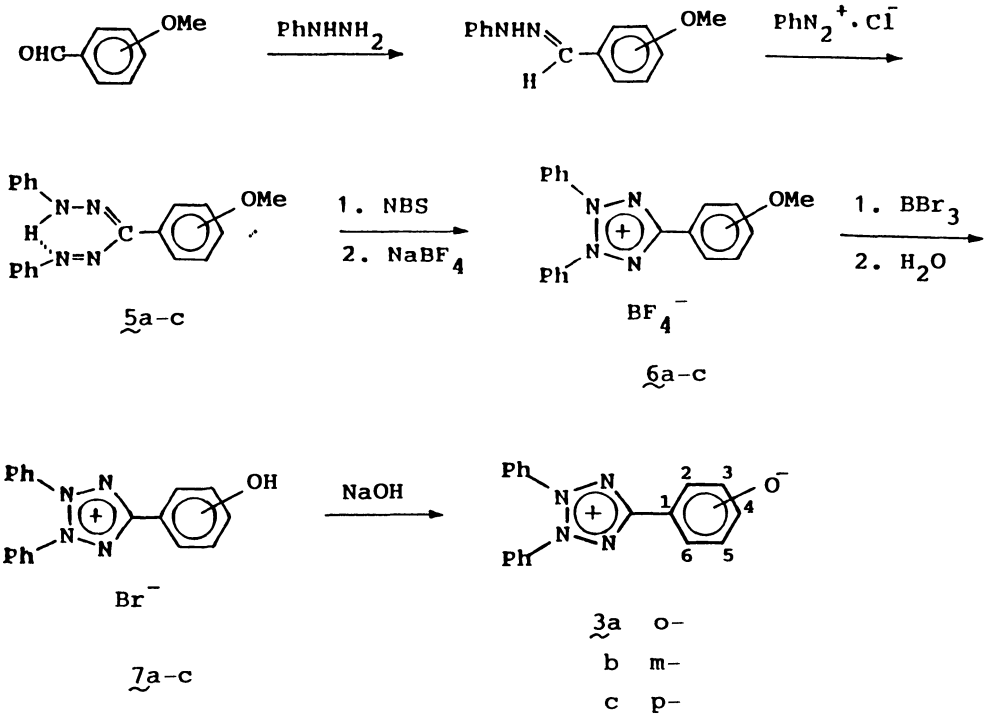


1 **2**

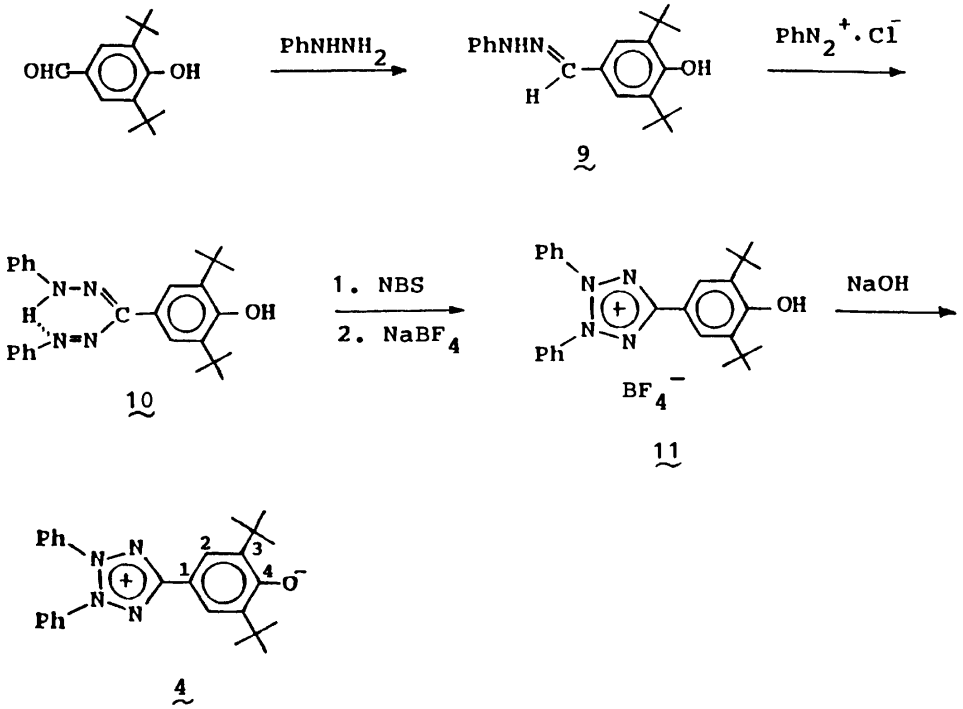


3

Synthesis. The synthetic pathway of the tetrazoliums **3a**—c is illustrated in Scheme 1. Phenylhydrazones of anisaldehydes (*o*, *m*, and *p*) were reacted with benzenediazonium chloride to give formazanes **5a**—c. Oxidation of **5a**—c with chromium(VI) oxide[3] or *N*-bromosccinimide[4] (NBS) afforded tetrazolium salts **6a**—c. The salts **6a**—c were isolated as tetra-



Scheme 1.



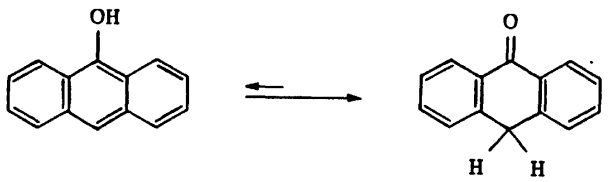
Scheme 2.

fluoroborates after an anion exchange with sodium tetrafluoroborate. Demethylation with boron tribromide furnished phenols **7a—c** in good yields. Deprotonation with a base followed by column chromatography on Sephadex 20 afforded quinonoid mesoions **3a—c** as hydrated crystals.

2,6-Di-*t*-butyl derivative **4** was synthesized by a similar synthetic scheme (Scheme 2) starting with 3,5-di-*t*-butyl-4-hydroxybenzaldehyde. In this synthesis, the protection of the hydroxyl group was unnessesary. The phenolate **4** was isolated as stable pale blue crystals.

Quinonoid mesoion **16** having three phenolate rings was synthesized according to Scheme 3. The dianion **16** is hygroscopic orange-red crystals. Upon the treatment of **16** with bromine, hexabrominated salt **17** was obtained. Deprotonation of **17** gave the conjugate anion **18** as brownish red crystals.

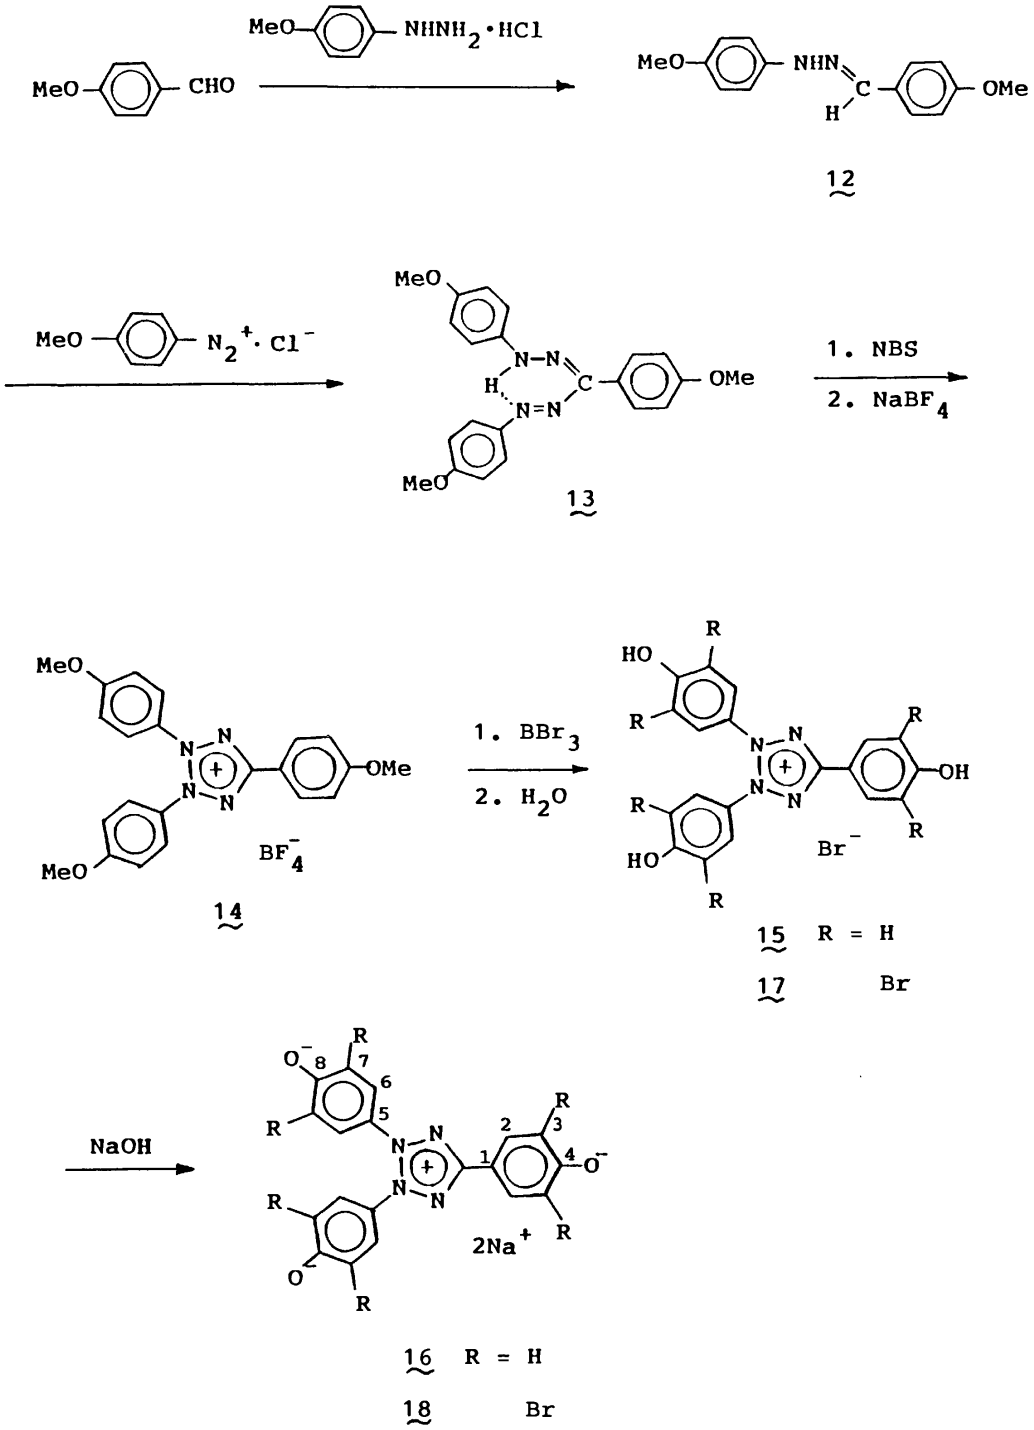
Quinonoid mesoionic compound **23** having an inserted anthracene ring instead of a benzene ring is of particular interest from the viewpoint of the comparison of the effects of the inserted aromatic ring (benzene vs. anthracene ring) upon the electronic structure of the quinonoid mesoions. The compound **23** was synthesized as shown in Scheme 4 and isolated as greenish brown crystals. It is worth noting here that compound **22** was isolated as the anthrol form rather than the anthrone form, despite the equilibrium between 9-anthrol and anthrone which lies to anthrone.[5] All the quinonoid mesoions **3a—c**, **4**, **16**, **18**, and **23** gave back to the corresponding conjugate acids



reversively by an acid treatment.

Properties of Quinonoid Mesoions 3a—c. The conjugate acids **7a—c** are stable pale yellow crystals. Their pK_a values measured by a UV method are 7.75 (for **7a**), 8.65 (**7b**), and 8.08 (**7c**), which are smaller by 1.3—2.2 than of phenol itself (pK_a=9.96) owing to the substitution of the strongly electron-withdrawing tetrazolium ring. Treatment of the salts **7a—c** with a base such as aqueous sodium hydroxide and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in dimethyl sulfoxide (DMSO) gave quinonoid mesoions **3a—c**.

Electronic Spectra: The quinonoid mesoions **3a—c** are brown (**3a**) to purple crystals (**3b**, **c**) and soluble in polar solvents such as water, methanol, and DMSO but practically insoluble in nonpolar solvents such as benzene, carbon tetrachloride, and hexane. The mesoions **3a—c** showed lowest excitation absorptions at 496—513 nm in the electronic spectra (see Experimental). These bands showed a distinctive negative solvatochromism: by decreasing a solvent polarity, large bathochromic shifts were observed. For example, by changing the solvent from water to less polar chloroform, the absorption maximum of **3c** was shifted by $\Delta\lambda$=152 nm. As shown in Fig. 1, linear



Scheme 3.

relation was observed between the wavenumber ($\tilde{\nu}$) of the longest-wavelength absorption and solvent polarity (E_T parameter[6]). The observed large solvent effect indicates that **3a—c** are polar compounds, mesoionic dipolar character contributing importantly to their ground state structures.[7]

^{1}H and ^{13}C NMR Spectra: The ^{1}H NMR parameters of the compounds **3a—c** are listed in Table 1 together with those of the corresponding conjugate acids **7a—c**. By deprotonation, the chemical shifts of the phenol ring protons of **7a—c** were shifted to higher field. For example, the AA'BB' pattern of the *p*-isomer **7c** at δ 7.08 and 8.15 (J=9 Hz) was shifted to 6.29 and 7.74 (J=9 Hz). On the other hand, the chemical shifts of the phenyl protons of **3a—c** and **7a—c** are almost coincident. This means the negative charge of the

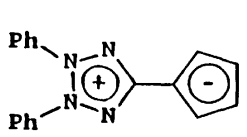
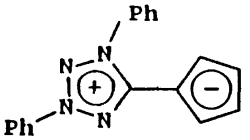
mesoions 3a—c is locarized in the phenolate ring. By comparison of the ^{13}C chemical shifts (Table 2) of 3a—c and 7a—c, it is evident that the oxygen-bearing carbons were shifted to lower field (by 11.8—14.2 ppm) by deprotonation. This corresponds well to the chemical shift difference (12.7 ppm) between the corresponding carbons of phenol (δ 155.6) and phenolate anion (δ 168.3). In contrast, the tetrazolium ring carbon and phenyl carbons were very little affected on going from 7a—c to 3a—c. These magnetic properties indicate that the mesoions 3a—c can be regarded as phenolate anions substituted by a 2,3-diphenyltetrazolium ring.

Mass Spectra: The electron-impact mass spectra of the three quinonoid mesoions 3a—c were essentially identical; no molecular ion peaks were observed but a characteristic fragment ion appeared at m/z 286. This peaks is considered due to mesoionic fulvalene **24** arising from the elimination of carbon monoxide from the quinonoid mesoions 3a—c. The fulvalene **24** is an isomer of the 1,3-diphenyl derivative **25** which was recently prepared and fully characterized.[8] Attempts to synthesize **24** by flash vacuum thermolysis of 3a—c are now in progress.

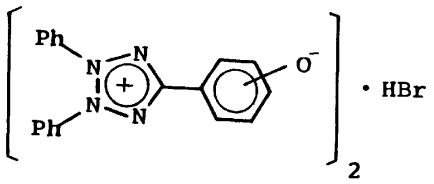


24



25

Adducts with Hydrobromic Acid: When an excess of DBU was added into a suspension of phenol **7c** in dichloromethane, the mixture turned to reddish purple and **7c** went into solution. After a few minutes, orange crystals of **8c** were precipitated. They were filtered and purified by recrystallization. Elemental analysis of the compound **8c** revealed that **8c** is the 2:1 adduct of mesoion 3c and hydrobromic acid. Similar adducts **8a, b** were obtained in the same manner. The electronic spectra of **8a—c** were the sum of the absorptions of both mesoions 3a—c and phenols 7a—c. Moreover, the ^1H and ^{13}C NMR chemical shifts (Table 3) of **8a—c** are average of those of 3a—c and 7a—c, indicating that **8a—c** exist as the rapid equiliblium between 3a—c and 7a—c in the solution.



8a o-

Properties of Quinonoid Mesoions 4 and 16. The quinonoid mesoion **4** having two *t*-butyl groups at the ortho positions of the oxygen atom revealed similar spectroscopic properties to the parent compound **3c**. The lowest excitation band in the electronic spectrum showed large bathochromic shift on going from polar to less polar solvent (Fig. 1). The phenol ring protons of **11** at 8.00 ppm shifted to 7.64 by deprotonation, indicating high electron density of the phenolate ring of **4**. The phenolate ring carbons of **4** resonate at higher field than those of the phenol **11** (Table 4),

Table 3. ^{13}C NMR Data of **8a—c**[a]

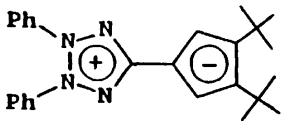
except for the oxygen-bearing carbon whose chemical shift is δ 175.4, 15.8 ppm downfield than that of **11**. In contrast to **3a—c**, the mass spectrum of **4** exhibits the intense molecular ion peak at *m/z* 426 and the daughter ion corresponding to M^+-CO was not observed at all. This is because fulvalene **26**, which is expected to be formed by the loss of carbon monoxide from **4**, is energetically unfavorable owing to the presence of the two adjacent *t*-butyl groups.



26

The triphenolate **16** prepared by the base treatment of the triphenol **15** was isolated as a disodium salt. It showed similar solvatochromism and magnetic properties to the quinonoid mesoions **3a—c** and **4**, as shown in Fig. 1. The three negative charges are located in the three phenolate rings, and this compound is rationalized as a tetrazolium cation having three phenolate rings in the 2, 3, and 5 positions. Attempts to oxidize **16** to its anion radical or other oxidized species with various oxidants (potassium hexacyanoferrate(III), silver(I) oxide, lead tetracetate, etc.) were unsuccessful. Only with bromine, hexabrominated compound **17** was isolated. The conjugate anion **18** of the acid **17** is an another example of quinonoid mesoions.

Properties of Anthracene-Inserted Mesoion 23. The compound **23** having an inserted anthracene ring shows marked differences in its electronic structure from those of the benzene-ring-inserted mesoions **3a—c, 4, 16**, and **18**. The longest wavelength absorption of **23** in its visible spectrum exhibits very smaller solvent effect than **3c, 4**, and **16** do as shown in Fig. 1. The carbonyl carbon of **23** resonates at δ 185.9, more than 17 ppm downfield than that of phenolate anion (δ 168.3). The chemical shift of the tetrazolium ring carbon is δ 175.7 and this value is also shifted downfield by 7.5—13.4 ppm compared with those of **3a—c, 4, 16**, and **18**. These spectroscopic properties clearly indicate that the compound **23** has a different type of electronic structures from the mesoions with an inserted benzene ring; the dipolar 10-(5-tetrazolylio)-anthrolate structure **27** is not important but the mesoionic betain **28** and/or bis(phenylazo)methylene structure **29** make(s) a significant contribution to the ground state of the compound **23**. This large difference in the ground state electronic structure between the benzene-inserted mesoions **3a—c, 4, 16**, and **18** and the anthracene-inserted mesoion **23** can be explained in terms of little stabilization of **27** compared to **28** or **29**, whereas **30** has a larger aromatic resonance energy compared to **31** or **32**.

Experimental

General. Melting points were determined with a hot-stage apparatus and uncorrected. IR spectra were taken for KBr discs with a JASCO A-102 instrument. Electronic spectra were measured on a Hitachi 124 spectrophotometer. Mass spectra were recorded with a Hitachi M-52 instrument at 20 eV using a direct inlet system. ^1H NMR spectra were run with Hitachi R-24A (60 MHz) and Varian XL-200 (200 MHz) spectrometers. ^{13}C NMR spectra were recorded with a Varian XL-200 (50.3 MHz) spectrometer. Elemental

analysis were performed at Elemental Analysis Center in Kyoto University.

1,5-Diphenyl-3-(*o*-methoxyphenyl)formazane (5a). *o*-Anisaldehyde phenylhydrazone (9.09 g, 40.2 mmol) in pyridine (60 cm³) was slowly added below 5 °C to a solution of benzenediazonium chloride prepared from aniline (3.7 cm³, 40.8 mmol) and sodium nitrite (2.82 g, 40.9 mmol) in a mixture of acetic acid (5 cm³) and concd hydrochloric acid (15 cm³). After stirring for 2 h, the mixture was poured into water (300 cm³). The precipitate was filtered, washed with warm water and a small amount of ethanol and then dried giving formazane **5a** (10.2 g, 77%), a reddish orange powder. The corresponding *m*- (**5b**) and *p*-isomers (**5c**) were synthesized in the same manner in 55 and 89% yields, respectively.

5a: Mp 147—149 °C; IR: 3250, 3050, 2850, 1602, 1564, 1508, 1490, 1460, 1438, 1410, 1290, 1168, 1136, 1090, 1070, 1044, 1020, 760, 750, 690 cm⁻¹; MS: *m/z* 330 (M^+).

1,5-Diphenyl-3-(*m*-methoxyphenyl)formazane (5b): Mp 126 °C; IR: 3050, 2950, 2850, 1598, 1580, 1514, 1488, 1452, 1432, 1356, 1318, 1242, 1220, 1078, 1060, 1038, 920, 884, 860, 770, 750, 690, 684 cm⁻¹; MS: *m/z* 330 (M^+).

1,5-Diphenyl-3-(*p*-methoxyphenyl)formazane (5c): Mp 155 °C (lit,[8] mp 156—158 °C); IR: 3050, 2950, 2850, 1610, 1600, 1520, 1500, 1456, 1360, 1318, 1300, 1252, 1230, 1180, 1080, 1048, 1030, 1010, 844, 822, 776, 760, 740, 690, 660 cm⁻¹; MS: *m/z* 330 (M^+).

2,3-Diphenyl-5-(*o*-methoxyphenyl)tetrazolium Tetrafluoroborate (6a). A mixture of formazane **5a** (2.20 g, 6.7 mmol) and chromium(VI) oxide (2.16 g, 21.6 mmol) in acetic acid (50 cm³) and 5—6 drops of water was refluxed for 15 min. When the mixture turned to green, it was cooled and poured into water (200 cm³). The yellow precipitate deposited was collected by filtration. The precipitate was dissolved in dichloromethane and shaked with aqueous sodium tetrafluoroborate. The dichloromethane layer was separated and dried over anhydrous sodium sulfate. After evaporation, the residue was recrystallized from dichloromethane–ether giving **6a** (723 mg, 26%), a pale yellow powder. Oxidation with NBS (vide infra) gave a much better yield (79%).

6a: Mp 200 °C; IR: 3090, 2950, 2850, 1610, 1586, 1520, 1490, 1440, 1280, 1260, 1164, 1140—1000, 776, 760, 690 cm⁻¹; ¹H NMR (DMSO-d_6): δ=4.00 (s, 3H, OMe), 7.20—8.20 (m, 14H, Ph); Found: C, 57.70; H, 4.08; N, 13.18%. Calcd for $C_{20}H_{17}BF_4N_4O$: C, 57.72; H, 4.12; N, 13.46%.

2,3-Diphenyl-5-(*m*-methoxyphenyl)tetrazolium Tetrafluoroborate (6b). Into a solution of formazane **5b** (1.70 g, 5.2 mmol) in ethyl acetate (16 cm³) was added a solution of NBS (1.86 g, 10.5 mmol) in ethyl acetate (12 cm³) at 50 °C and the mixture was stirred at 50 °C for 2 h. After evaporation, the residue was dissolved in dichloromethane and shaked with aqueous sodium tetrafluoroborate. The dichloromethane layer was separated and dried (Na_2SO_4). After evaporation, the residue was recrystallized from dichloromethane–ether giving **6b** (0.77 g, 36%), pale yellow needles. The *p*-isomer **6c** was similarly prepared as pale yellow crystals.

6b: Mp 201 °C; IR: 3090, 2970, 2850, 1620, 1588, 1534, 1490, 1440, 1286, 1250, 1230, 1170, 1126, 1110—1000, 880, 856, 800, 776, 770, 750, 690 cm⁻¹; ¹H NMR (DMSO-d_6): δ=3.90 (s, 3H, OMe), 7.30—7.95 (m, 14H, Ph); Found: C, 57.95; H, 3.99; N, 13.41%. Calcd for $C_{20}H_{17}BF_4N_4O$: C, 57.72; H, 4.12; N, 13.46%.

6c: Mp 230 °C; IR: 3100, 2980, 2850, 1612, 1490, 1468, 1440, 1310, 1280, 1266, 1180, 1162, 1130—1030, 1000, 930, 856, 770, 750, 688 cm⁻¹; ¹H NMR (DMSO-d_6): δ=3.90 (s, 3H, OMe), 7.25 (d, J=9.0 Hz, 2H, Ar), 7.65—7.75 (m, 10H, Ph), 8.20 (d, J=9.0 Hz, 2H, Ar); Found: C, 57.96; H, 4.03; N, 13.38%. Calcd for $C_{20}H_{17}BF_4N_4O$: C, 57.72; H, 4.12; N, 13.46%.

2,3-Diphenyl-5-(*o*-hydroxyphenyl)tetrazolium Bromide (7a). To a solution of tetrazolium salt **6a** (1.49 g, 3.58 mmol) in dichloromethane (10 cm³) was added boron tribromide (0.60 cm³, 6.3 mmol) at −78 °C under argon. The reddish brown mixture was gradually warmed to room temperature and poured into water. The precipitate was filtered, dried, and recrystallized from ethanol giving pale yellow needles of **7a** as the 1:1 complex with ethanol (1.19 g, 84%). Phenols **7b** and **7c** were similarly synthesized and obtained as pale yellow crystals.

7a: Mp 259 °C (decomp); IR: 3600—3300, 3050, 1616, 1600, 1522, 1484, 1456, 1410, 1370, 1294, 1260, 1162, 1110, 1070, 1068, 1022, 1000, 938, 880, 840, 778, 760, 690 cm⁻¹; UV (MeCN): λ_{max} (log ε) 216 nm (4.42), 248 (4.28), 300 (4.01); Found: C, 57.24; H, 4.70; N, 12.82%. Calcd for $C_{19}H_{15}BrN_4O \cdot C_2H_5OH$: C, 57.15; H, 4.80; N, 12.70%.

7b: Mp 258 °C (decomp); IR: 3550—3350, 3150, 1620, 1590, 1530, 1486, 1440, 1346, 1290, 1216, 1160, 1126, 1076, 1042, 1000, 920, 888, 870, 794, 766, 740, 682 cm⁻¹; UV (MeCN): λ_{max} (log ε) 218 nm (4.56), 252 (4.37), 297 (3.96); Found: C, 57.71; H, 3.71; N, 14.19%. Calcd for $C_{19}H_{15}BrN_4O$: C, 57.74; H, 3.82; N, 14.17%.

7c: Mp 280 °C (decomp); IR: 3550—3350, 3100—2950, 1610, 1588, 1486, 1460, 1448, 1278, 1224, 1170, 1160, 1000, 856, 770, 750, 690, 680 cm⁻¹; UV (MeCN): λ_{max} (log ε) 213 nm (4.21), 271 (4.40); Found: C, 57.79; H, 3.63; N, 14.01%. Calcd for $C_{19}H_{15}BrN_4O$: C, 57.74; H, 3.82; N, 14.17%.

2-(2,3-Diphenyl-5-tetrazolylio)phenolate (3a). Phenol **7a** (246 mg, 0.62 mmol) was dissolved in an aqueous sodium hydroxide solution (1 M, 1.5 cm³; 1 M=1 mol dm⁻³) at room temperature. Water was removed under reduced pressure and the residue was purified by column chromatography on Sephadex LH-20 using dichloromethane as an eluent. Mesoion **3a** was obtained as a brown powder (186 mg, 95%). By the same method, **3b** and **3c** were isolated in 84 and 68% yields, respectively, purple crystals.

3a: Mp 140 °C (decomp); IR: 3060, 1602, 1504, 1478, 1434, 1318, 1240, 1152, 1000, 846, 760, 686 cm⁻¹; UV (MeCN): λ_{max} (log ε) 220 nm (4.18), 258 (sh, 4.00), 381 (4.03), 496 (2.59); solvent dependence of the longest wavelength band: 398 nm (sh) (H_2O), 412 (MeOH), 425 (EtOH), 460 (*i*-PrOH), 491 (DMSO), 499 (Me_2C=O), 496 (CH_2Cl_2), 525 ($CHCl_3$); MS: *m/z* (rel intensity) 286 (M−CO, 15), 238 (23), 211 (50), 169 (14), 167 (14), 119 (14), 91 (100); Found: C, 70.44; H, 4.37; N, 17.18%. Calcd for $C_{19}H_{14}N_4O \cdot 0.5H_2O$: C, 70.57; H, 4.68; N, 17.33%.

3b: Mp 141 °C (decomp); IR: 3060, 1588, 1570, 1504, 1486, 1460, 1316, 1282, 1160, 1000, 982, 892, 764, 746, 688 cm⁻¹; UV (MeCN): λ_{max} (log ε) 250 nm (4.42), 320 (sh, 3.64), 535 (2.61); solvent dependence of the longest wavelength band: 396 nm (sh) (H_2O), 428 (MeOH), 443 (EtOH), 484 (*i*-PrOH), 536 (DMSO), 477 (Me_2C=O), 537 (CH_2Cl_2), 538 ($CHCl_3$); MS: *m/z* (rel intensity) 286 (M−CO, 19), 211 (92), 91 (100); Found: C, 68.12; H, 4.57; N, 16.17%. Calcd for $C_{19}H_{14}N_4O \cdot H_2O$: C, 68.66; H, 4.85; N, 16.86%.

3c: Mp 154 °C (decomp); IR: 3060, 1590, 1442, 1336, 1162, 1000, 980, 844, 762, 690 cm^{-1}; UV (MeCN): λ_{max} (log ε) 213 nm (4.06), 228 (3.97), 300 (sh, 4.05), 347 (4.54), 513 (2.68); solvent dependence of the longest wavelength band: 390 nm (H_2O), 419 (MeOH), 437 (EtOH), 467 (*i*-PrOH), 512 (DMSO), 530 (Me_2C=O), 542 (CH_2Cl_2), 542 ($CHCl_3$); MS: *m/z* (rel intensity) 286 (M−CO, 47), 211 (60), 169 (17), 167 (17), 91 (100); Found: C, 65.14; H, 4.91; N, 16.14%. Calcd for $C_{19}H_{14}N_4O \cdot 2H_2O$: C, 65.13; H, 5.13; N, 15.99%.

Adducts 8a—c of Mesoions 3a—c and Hydrobromic Acid. The following preparation of **8c** represents the general procedure. Phenol **7c** (143 mg, 0.36 mmol) was suspended in dichloromethane (15 cm^3) and DBU (0.1 cm^3, 0.67 mmol) was added at room temperature. Phenol **7c** went into solution and the mixture turned to reddish purple. After a few minutes, orange crystals deposited which were filtered off and dried giving **8c** (113 mg, 89%).

8c: Mp 179 °C (decomp); IR: 1610, 1486, 1460, 1174, 1000, 842, 770, 750, 692, 682 cm^{-1}; ^1H NMR (DMSO-d_6): δ=6.72 (d, 2H, *J*=9 Hz, H-3), 7.57—7.80 (m, 10H, Ph), 7.91 (d, 2H, *J*=9 Hz, H-2); Found: C, 63.55; H, 4.27; N, 16.26; Br, 11.29%. Calcd for $C_{38}H_{29}BrN_8O_2$: C, 64.37; H, 4.09; N, 15.80; Br, 11.28%.

Adducts **8a** and **8b** were similarly synthesized in almost quantitative yields.

8a: Mp 143 °C (decomp); IR: 1642, 1608, 1584, 1440, 1370, 1322, 1296, 1160, 1104, 1000, 836, 768, 752, 686 cm^{-1}. ^1H NMR (DMSO-d_6): δ=6.38—6.50 (m, 1H, Ar), 6.69—6.74 (m, 1H, Ar), 7.14—7.24 (m, 1H, Ar), 7.66—8.00 (m, 11H, Ar and Ph).

8b: Mp 180 °C (decomp); IR: 1500, 1490, 1422, 1260, 1160, 1074, 1016, 1000, 992, 894, 880, 870, 790, 762, 740, 680 cm^{-1}; ^1H NMR (DMSO-d_6): δ=6.93—7.02 (m, 1H, Ar), 7.36—7.40 (m, 2H, Ar), 7.52 (s, 1H, Ar), 7.70—7.97 (m, 10H, Ph).

1,5-Diphenyl-3-(3,5-di-*t*-butyl-4-hydroxyphenyl)formazane (10). This compound was synthesized in 94% yield as a dark purple powder by a similar synthetic method to **5a—c** from 3,5-di-*t*-butyl-4-hydroxybenzaldehyde phenylhydrazone (**9**). Mp 122 °C; IR: 3650—3370, 2960, 2910, 2870, 1600, 1510, 1500, 1438, 1360, 1314, 1254, 1236, 1150, 1118, 1080, 1068, 996, 920, 898, 884, 796, 770, 744, 698 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.44 (s, 18H, *t*-Bu), 5.25 (s, 1H, OH), 7.02—7.71 (m, 10H, Ph), 7.90 (s, 2H, Ar), 8.58 (s, 1H, NH).

2,3-Diphenyl-5-(3,5-di-*t*-butyl-4-hydroxyphenyl)tetrazolium Tetrafluoroborate (11). Formazane **10** was oxidized with NBS as described above and tetrafluoroborate **11** was obtained in 28% yield, colorless crystals, after an anion exchange with sodium tetrafluoroborate. Mp 246 °C (decomp). IR: 3630—3330, 3080, 2960, 1604, 1516, 1488, 1410, 1120—1030, 762, 690 cm^{-1}; ^1H NMR (DMSO-d_6): δ=1.46 (s, 18H, *t*-Bu), 5.73 (s, 1H, OH), 7.65—7.84 (m, 6H, Ph), 7.89—7.96 (m, 4H, Ph), 8.00 (s, 2H, Ar); UV (MeCN): λ_{max} (log ε) 217 nm (4.56), 272 (4.46); Found: C, 62.34; H, 6.11; N, 10.89%. Calcd for $C_{27}H_{31}BF_4N_4O \cdot 0.25H_2O$: C, 62.50; H, 6.12; N, 10.80%.

2,6-Di-*t*-butyl-4-(2,3-diphenyl-5-tetrazolylio)phenolate (4). Into a solution of **11** (630 mg, 1.23 mmol) in methanol (5 cm^3) was added aqueous sodium hydroxide (1 M, 2 cm^3). The mixture turned to purple and a precipitate deposited. Water was evaporated under reduced pressure and the residue was chromatographed on Sephadex LH-20 (dichloromethane–acetone) giving **4** quantitatively, pale blue crystals. Mp 209 °C; IR: 3060, 2950, 2910, 1586, 1478, 1440, 1350, 1334, 992, 900, 808, 760, 684 cm^{-1}; ^1H NMR (DMSO-d_6): δ=1.38 (s, 18H, *t*-Bu), 7.64 (s, 2H, Ar), 7.64—7.78 (m, 6H, Ph), 7.82—7.88 (m, 4H, Ph); UV (MeCN): λ_{max} (log ε) 249 nm (sh, 3.97), 282 (4.08), 373 (4.48), 605 (2.50); solvent dependence of the longest wavelength band: 510 nm (MeOH), 543 (EtOH), 583 (*i*-PrOH), 591 (DMSO), 631 (Me_2C=O), 690 (CH_2Cl_2); MS: *m/z* (rel intensity) 426 (M^+, 100), 411 (77), 384 (73), 342 (47), 322 (67), 105 (40), 77 (40). Found: C, 75.04; H, 7.11; N, 12.83%. Calcd for $C_{27}H_{30}N_4O \cdot 0.25H_2O$: C, 75.24; H, 7.12; N, 12.99%.

1,3,5-Tris(*p*-methoxyphenyl)formazane (13). This compound was prepared in 81% yield from *p*-anisaldehyde *p*-methoxyphenylhydrazone[9] (**12**) (7.05 g, 27.5 mmol) and *p*-methoxybenzenediazonium chloride (35.1 mmol) in a similar manner as **5a—c**. Mp 136—138 °C (lit,[9] mp 140 °C); IR: 3020, 2950, 2850, 1600, 1580, 1510, 1460, 1440, 1422, 1306, 1256, 1230, 1182, 1166, 1142, 1102, 1022, 836, 824, 796, 740, 702 cm^{-1}; ^1H NMR (DMSO-d_6): δ=3.75 (s, 9H, OMe), 6.80 (d, 4H, *J*=9 Hz, Ar), 6.84 (d, 2H, *J*=9 Hz, Ar), 7.55 (d, 4H, *J*=9 Hz, Ar), 7.68 (d, 2H, *J*=9 Hz, Ar), 14.35 (s, 1H, NH); MS: 390 (M^+).

2,3,5-Tris(*p*-methoxyphenyl)tetrazolium Tetrafluoroborate (14). This salt was obtained by the oxidation of **13** (1.98 g, 5.07 mmol) with NBS (3.60 g, 20.2 mmol) in 65% yield. Mp 176 °C; IR: 3100, 2970, 2850, 1616, 1600, 1588, 1510, 1460, 1438, 1310, 1260, 1178, 1160, 1130—1020, 990, 840, 750, 660 cm^{-1}; ^1H NMR (DMSO-d_6): δ=3.82 (s, 6H, 2 OMe), 3.86 (s, 3H, OMe), 7.16 (d, 4H, *J*=9 Hz, H-7), 7.23 (d, 2H, *J*=9 Hz, H-3), 7.72 (d, 4H, *J*=9 Hz, H-6), 8.20 (d, 2H, *J*=9 Hz, H-2); ^{13}C NMR (DMSO-d_6): δ=55.7 (OMe), 56.1 (2 OMe), 115.2 (C-1), 115.4 (C-7), 115.6 (C-3), 125.4 (C-5), 128.1 (C-6), 129.1 (C-2), 162.8 (C-8), 163.1 (C-4), 163.7 (C^+); Found: C, 55.71; H, 4.33; N, 11.79%. Calcd for $C_{22}H_{21}BF_4N_4O_3$: C, 55.49; H, 4.44; N, 11.76%.

2,3,5-Tris(*p*-hydroxyphenyl)tetrazolium Bromide (15). The compound **14** (1.28 g, 2.69 mmol) was demethylated by the action of boron tribromide (0.85 cm^3, 8.95 mmol) in the same manner as **7a—c** giving yellow needles of **15** in 94% yield. Mp 279 °C (decomp); IR: 3450—3050, 1616, 1594, 1512, 1462, 1452, 1350, 1290, 1260, 1220, 1172, 1160, 1104, 1028, 1000, 840, 748, 710, 684 cm^{-1}; ^1H NMR (DMSO-d_6); δ=6.98 (d, 4H, *J*=9 Hz, H-7), 7.07 (d, 2H, *J*=9 Hz, H-3), 7.62 (d, 4H, *J*=9 Hz, H-6), 8.10 (d, 2H, *J*=9 Hz, H-2), 10.58 (s, 1H, OH); ^{13}C NMR (DMSO-d_6): δ=113.9 (C-1), 116.4 (C-7), 116.9 (C-3), 124.1 (C-5), 128.2 (C-6), 129.2 (C-2), 161.7 (C-8), 161.9 (C-4), 163.8 (C^+); UV (MeCN): λ_{max} (log ε) 217 nm (4.52), 262 (4.45), 272 (sh, 4.42), 308 (sh, 4.07), 352 (sh, 3.80); Found: C, 53.16; H, 3.43; N, 12.88%. Calcd for $C_{19}H_{15}BrN_4O_3$: C, 53.42; H, 3.54; N, 13.11%.

Disodium 4,4′,4″-(Tetrazole-2,3,5-triylio)tris[phenolate] (16). Bromide **15** (160 mg, 0.38 mmol) was dissolved in a sodium hydroxide solution (1 M, 2 cm^3) at room temperature. Water was pumped off and the residue was recrystallized twice from methanol–ether giving reddish orange crystals of **16** quantitatively. Mp 190 °C (decomp); IR: 1580, 1496, 1446, 1332, 1320, 1164, 1140, 842 cm^{-1}; ^1H NMR (DMSO-d_6): δ=6.36 (d, 4H, *J*=9 Hz, H-7), 6.69 (d, 2H, *J*=9 Hz, H-3), 7.23 (d, 4H, *J*=9 Hz, H-6), 7.82 (d, 2H, *J*=9 Hz, H-2); ^{13}C NMR (D_2O): δ=111.7 (C-1), 121.7 (C-5), 121.9 (C-7), 122.7 (C-3), 129.2 (C-6), 131.9 (C-2), 173.3 (C-4), 174.3 (C-8), 167.2

(C^+); UV (MeOH): λ_{max} (log ε) 260 nm (4.29), 274 (sh, 4.24), 320 (sh, 3.93), 425 (3.79); solvent dependence of the longest wavelength band: 372, 413 nm (sh) (H_2O), 425 (MeOH), 448 (EtOH), 480 (*i*-PrOH), 506 (DMSO); Found: C, 48.51; H, 4.62; N, 11.49%. Calcd for $C_{19}H_{12}N_4Na_2O_3 \cdot 4.5H_2O$: C, 48.41; H, 4.49; N, 11.89%.

2,3,5-Tris(3,5-dibromo-4-hydroxyphenyl)tetrazolium Bromide (17). 2,3,5-Tris(*p*-hydroxyphenyl)tetrazolium bromide (**15**) (222 mg, 0.52 mmol) was dissolved in aqueous sodium hydroxide (1 M, 20 cm^3) and bromine (0.16 cm^3, 3.2 mmol) was added at room temperature. The reaction mixture was stirred at room temperature for 3 h. The mixture was acidified with hydrochloric acid (2 M) and the resulting solid was filtered. Recrystallization from methanol–ether gave a yellow powder of **17** (403 mg, 86%). Mp ca. 200 °C; IR: 3630—3310, 3090, 1600, 1560, 1470, 1436, 1312, 1240, 1170—1000, 880, 750, 736 cm^{-1}; ^1H NMR (DMSO-d_6): δ=4.80 (s, 3H, OH), 8.12 (s, 4H, H-6), 8.33 (s, 2H, H-2); ^{13}C NMR (DMSO-d_6): δ=111.7 (C-7), 113.0 (C-3), 116.3 (C-1), 124.0 (C-5), 130.3 (C-6), 131.3 (C-2), 155.6 (C-4), 156.6 (C-8), 161.8 (C^+); UV (MeCN): λ_{max} (log ε) 218 nm (4.46), 266 (4.08), 315 (3.78), 520 (3.62); Found: C, 25.38; H, 0.97; N, 5.85%. 1,5-Diphenyl-3-(10-methoxy-9-anthryl)formazane (20). From 10-methoxy-9-anthraldehyde phenylhydrazone (**19**) (1.05 g, 3.20 mmol) and benzenediazonium chloride (3.2 mmol), **20** was obtained as an orange powder (1.32 g, 96%). Mp 174—175 °C (decomp); IR: 1600, 1562, 1558, 1500, 1438, 1360, 1286, 1260, 1216, 1200, 1160, 1092, 982, 962, 780, 750, 726, 700, 680 cm^{-1}; ^1H NMR ($CDCl_3$): δ=4.24 (s, 3H, OMe), 7.12—7.56 (m, 12H, Ar), 7.63—7.76 (m, 4H, Ar), 8.40—8.48 (m, 2H, Ar).

2,3-Diphenyl-5-(10-methoxy-9-anthryl)tetrazolium Tetrafluoroborate (21). Formazane **20** (680 mg, 1.58 mmol) was oxidized with NBS (1.12 g, 6.29 mmol) as the same manner to **5a**—c. The crude product was purified by column chromatography on silica gel with dichloromethane–acetone (1:1) as the eluent. Pure **21** was obtained as pale yellow crystals. Mp 150—153 °C; IR: 1664, 1600, 1488, 1458, 1324, 1266, 1122, 1100—1020, 760, 720, 704, 682 cm^{-1}; ^1H NMR (DMSO-d_6): δ=4.06 (s, 3H, OMe), 7.24—7.94 (m, 14H, Ar), 8.06—8.44 (m, 4H, Ar); ^{13}C NMR (DMSO-d_6): δ=64.2 (OMe), 111.7 (=C–), 122.8 (=C–), 123.8 (=CH–), 125.2 (=CH–), 126.4 (=CH–), 126.4 (ortho), 128.9 (=CH–), 130.6 (meta), 132.0 (=C–), 133.3 (ipso), 134.3 (para), 158.2 (C–O), 163.9 (C^+).

2,3-Diphenyl-5-(10-hydroxy-9-anthryl)tetrazolium Bromide (22). The compound **21** (335 mg, 0.65 mmol) was demethylated with boron tribomide (0.20 cm^3, 2.1 mmol) as the cases of **6a**—c yielding **22** (239 mg, 74%), orange powder. Mp 215 °C (decomp); IR: 3600—3350, 1558, 1500, 1486, 1422, 1348, 1312, 1176, 1162, 1140, 998, 924, 770, 686 cm^{-1}; ^1H NMR (DMSO-d_6): δ=7.61—7.95 (m, 10H, Ar), 8.03—8.09 (m, 4H, Ar), 8.49 (d, 2H, J=9 Hz, Ar), 8.70 (d, 2H, J=9 Hz, Ar), 11.56 (s, 1H, OH); ^{13}C NMR (DMSO-d_6): δ=103.8 (=C–), 119.4 (=C–), 123.3 (=CH–), 124.5 (=CH–), 124.6 (=CH–), 126.4 (ortho), 128.7 (=CH–), 130.4 (meta), 132.0 (=C–), 133.3 (ipso), 134.1 (para), 154.5 (C–O), 163.2 (C^+); UV (MeCN): λ_{max} (log ε) 214 nm (4.40), 259 (4.69), 275 (sh, 4.18), 386 (sh, 3.60), 400 (3.63): Found: C, 64.14; H, 3.95; N, 10.97%. Calcd for $C_{27}H_{19}BrN_4O \cdot 0.5H_2O$: C, 64.29; H, 4.00; N, 11.11%.

Synthesis of 23 by the Deprotonation of 22. Into a solution of **22** (60 mg, 0.12 mmol) in methanol (10 cm^3) was added an aqueous solution of NaOH (1 M, 0.5 cm^3) at room temperature. The solvent was removed under reduced pressure and the residue was chromatographed on Sephadex LH-20. Recrystallization from acetonitrile–ether gave pure **23** as greenish brown crystals in a quantitative yield. Mp 125 °C (decomp); IR: 3060, 1602, 1558, 1480, 1440, 1424, 1334, 1260, 1180, 1120, 1030, 1016, 996, 772, 768, 732, 690, 674 cm^{-1}; ^1H NMR (DMSO-d_6): δ=7.01—7.13 (m, 2H, Ar), 7.37—7.49 (m, 2H, Ar), 7.53—7.85 (m, 6H, Ph), 7.93—8.01 (m, 4H, Ph), 8.44—8.60 (m, 4H, Ar); ^{13}C NMR (DMSO-d_6): δ=118.4 (=C–), 118.4 (=CH–), 122.0 (=C–), 123.9 (=CH–), 126.5 (ortho), 126.7 (=CH–), 128.6 (=CH–), 130.4 (meta), 133.4 (para), 133.5 (ipso), 135.6 (=C–), 175.7 (C^+), 185.9 (C=O); UV (MeCN): λ_{max} (log ε) 257 nm (4.67), 275 (4.82), 343 (sh, 4.27), 366 (4.37), 425 (sh, 3.75), 450 (3.98), 478 (4.19), 509 (4.19); solvent dependence of the longest wavelength band; 486 nm (sh) (MeOH), 495 (EtOH), 504 (*i*-PrOH), 513 (DMSO), 510 (Me_2C=O), 508 (CH_2Cl_2), 509 ($CHCl_3$), 513 (DMF); MS: *m/z* (rel intensity) 414 (M^+, 45), 413 (100), 325 (41), 324 (59), 308 (34), 237 (32), 232 (54), 93 (59), 92 (43), 77 (64); Found: C, 72.33; H, 5.30%. Calcd for $C_{27}H_{18}N_4O \cdot 2H_2O$: C, 71.99; H, 4.92%.

Aryliminodimagnesium Reagents. XVI.[1] Formation of *o*-Hydroxyazoarenes by Condensation with *o*-Hydroxynitroarenes. Favorable Role of *o*-Hydroxyl Group in the Reaction

Masao Ōkubo,* Takanori Nakashima, and Haruko Shiku
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received November 24, 1988)

Hydroxy(HO)-azoxy- and -azoarenes were formed by condensation of $ArN(MgBr)_2$ with *o*-, *m*-, and *p*-HO-nitrobenzenes; nuclear substitution took place as a minor or a major pathway. *o*-HO-azobenzene was obtained in sufficiently high yield. Relative yields of the products varied according to the position of HO group and reaction conditions. The yield variation was explained by the effects of relative efficiency of single electron transfer, σ-complexation, and cooperation of reagent molecules.

o-Hydroxyazoarenes are useful chelating reagents,[2] and have usually been prepared by diazotization of appropriate phenols and naphthols.[3] This paper concerns exploration of an alternative procedure for preparing hydroxyazoarenes by condensation of N-Mg reagent, aryliminodimagnesium ($ArN(MgBr)_2$ derived from aniline, IDMg), with some hydroxy(HO)-substituted nitroarenes (Scheme 1).

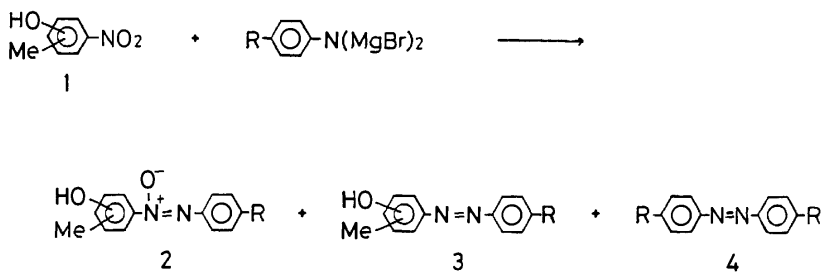
Grignard-type reagent has seldom been applied to HO-substituted substrate, although an example of conversion of 2-HO-5-Me-nitrobenzene (**1a**) into *o*-HO-azoxy- and -azobenzenes by use of *p*-MeC_6H_4-IDMg was reported.[4] A large molar excess of IDMg was used, because at least one mol of the reagent is consumed by exchange with HO-proton. Nevertheless, according to the general pathway,[5] *o*-HO-azoxy product (**2a**) is formed and deoxygenated by molar excess of reagent to give *o*-HO-azo product (**3a**). The alternative procedure using HO-substituted IDMg was impossible.[4]

In order to establish the grounds for synthetic application of IDMg reaction, the effect of HO group on the product distribution was examined using isomeric HO-nitrobenzenes and some related substrates. Condensation and nuclear substitution took place, and the product yields depended greatly on the position of HO group, electron-accepting and -donating abilities (EAA and EDA) of reactants (due to involvement of single electron transfer (SET)), and reaction conditions. Reasons for the variations in types and relative yields of products will be discussed.

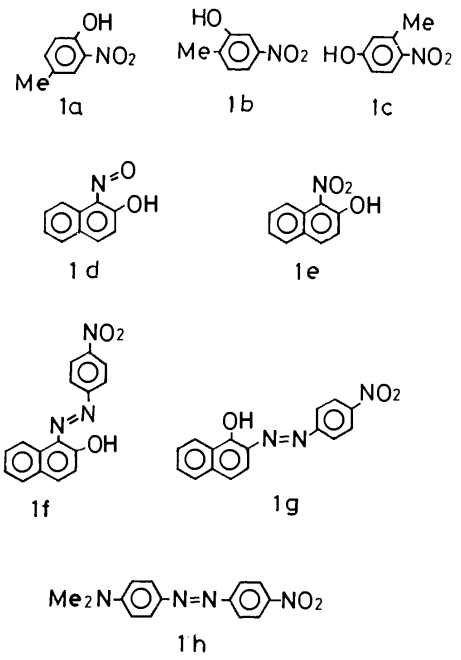
Results and Discussion

The distribution of major and minor products in IDMg reaction of **1a** was compared with that of the products from two positional isomers, 3-HO-4-Me- and 4-HO-2-Me-nitrobenzenes (**1b** and **1c**). The position of HO group of **1a**, **1b**, and **1c** to nitro groups is ortho, meta, and para, respectively. By typical treatments of **1a** with a small (1.9 or 2.0) and a large (8.0) molar excess of *p*-RC_6H_4-IDMg (R=Me, MeO, Cl) at 55 °C for 3 h, the HO-azoxy and HO-azo products (**2** and **3**), symmetrical azoarene (**4** formed via oxidative coupling of IDMg[5]), and nuclear substitution products (**5—10**) were obtained. The yields of products including those obtained from some related substrates (**1d—1h**) are given in Table 1 (Runs 1—18).

The results of Runs 1—6 using *p*-Me reagent and **1a—1c** were complicated, but reveal three noticeable features unexpected from the reported product distributions in IDMg reactions with ordinary nitroarenes.[5-9] First, nuclear substitution products were formed from **1a** and **1b** and not from **1c** (Run 1, 3, and 5). Second, independent of molar amount of reagent used, combined yield of **2** and **3** from **1a** (Runs 1 and 2) was



Scheme 1.



higher than that from **1b** and **1c** (Runs 3—6). Third, also independent of molar amount of IDMg, yield of **3a** was higher than that of **2a** (Runs 1 and 2). Reasons for the unexpected features, however, were explained on the basis of governing factors generally reported for reactions with C-Mg (Grignard) and N-Mg reagents; the relative SET efficiency as a major factor,[6] and σ-complexation[6] and cooperation of reagent molecules[7,8] as minor factors. Discussion will be described in the following sections.

Product Distribution and SET Efficiency. The "first feature" concerns relative SET efficiency estimated by the combination of EAA and EDA.[6] If the redox potentials of substrates cited in Table 1 are compared with the relative yields of **2** plus **3** with reference to those of substitution products (depending on molar amount of IDMg, vide infra), formation of **2** and **3** is favored with strong EAA's (small negative potentials of **1a**, **1b**, **1d**, and 1-nitro-2-naphthol (**1e**)) and not with weak EAA (large negative potential of **1c**). Strong EAA is explained by participation of *o*-quinonoid structure of **1a**, **1d**, and **1e** (Fig. 1). The similar substitution on aromatic ring having low π-electron density is observed in IDMg reactions of quinones without electron-repelling MeO group.[6,9] In contrast to **1c** having *p*-HO group, fairly strong EAA of **1b** due to the lack of electron-repelling resonance of *m*-HO group causes intramolecular successive substitution leading to novel phenazine-type products (**7** and **8**, see Experimental).

The product distribution in the reaction with **1a** is also affected by relative EDA of IDMg (MeO>Me>Cl,[6]

Table 1. Product Distribution in the Reaction of Hydroxynitroarenes with *p*-RC_6H_4-IDMg

Run No.	Substrate (Redn. Pot) (/V)	IDMg R	IDMg molar equiv.	Yield/%[a] 2	3	4	5	6	7	8	9	10	Recovery/%

18	**1h** (−1.081)	Me	2.0	55	18	9	—	—	—	—	—	—	0

a) Yield based on the amount of substrate used. b) IDMg was added in reverse manner for 100 min and the mixture was heated at 55 °C for 3 h. c) IDMg was added in normal manner and the mixture was heated at 55 °C for 1 h. d) Nuclear substitution and replacement product was obtained as a mixture of tautomer (see Experimental). Product formed via replacement of hydroxynaphthylazo group (see text).

Runs 7—10). In comparison with the results of Runs 1 and 2, strong EDA of *p*-MeO reagent causes rapid deoxygenation leading to higher yield of **3** than **2** but to low overall yield due to self-decomposition of substrate via vigorous SET.[6] Weak EDA of *p*-Cl reagent leads sluggishly to fairly high combined yield of **2** and **3** (the yield of **2** was higher than that of **3**) and leaves a part of **1a** unreacted.

The effects of addition manner and molar ratio are remarkable. By comparison of the results of Runs 3 and 11, "normal addition" of *p*-Me reagent to solution of **1b** favors condensation slightly over substitution compared with "reverse addition." Further comparison of the results of Runs 1 and 2 (using **1a**) reveals that "normal addition" of substrate to large molar excess of IDMg favors condensation. The advantage of these conditions for the condensation with nitro group, due to "cooperation of reagent molecules essential for the pathway," was previously shown by the reaction of *p*-MeC_6H_4-IDMg with *o*-MeO- and *o*-halo-nitrobenzenes[7] and by that of IDMg having long-chain *p*-alkoxyl substituent.[8] An equimolar amount of *p*-Me reagent added even in "normal manner" to **1b** leads to almost complete recovery (Run 12); this indicates that HO-proton of substrate is precedently exchanged with reagent (vide infra) and the derived

ortho-Quinonoid Structure

Fig. 1. Quinonoid structure of *o*-hydroxynitrobenzene.

-OMgBr and -NHMgBr species form a stable complex which is incapable of SET.

Special Role of *o*-Hydroxyl Group. The "second feature" concerns good overall yeilds of four products from **1a** (**2**—**5**, over 80% yield, Runs 1 and 2) and a small amount of unidentified materials compared to the results of Runs 3—6. Though the clean reaction involving effective condensation of **1a** compared to **1b** and **1c** is appropriate for synthetic use of *o*-hydroxy-substituted nitroarenes, the cleanliness seems to contradict with **1a**'s strong EAA causing usually remarkable substitution or decomposition with much rapid SET.[6] The contradiction arises from special role of *o*-HO group, which is converted into "OMgBr acting as a center of IDMg aggregate in the proximity of nitro group" to facilitate the cooperation of IDMg molecules for condensation.[7,8] The aggregation of Grignard molecules in the presence of alkoxymagnesium species was reported.[10] The conversion of *o*-OH into OMgBr prior to SET is established by Run 12 (vide supra), and by the recovery (over 85%) of **1a** from an equimolar mixture with EtMgBr (having stronger EDA than IDMg[6]), which was added at −70 °C in 1 h. The mixture was gradually warmed up to room temperature, stirred at 55 °C for 1 h, and quenched with aqueous NH_4Cl.

It is likely that in the case of **1b** or **1c**, IDMg molecules are gathered by *m*- or *p*-OMgBr group apart from nitro group; condensation is thus retarded and strong EAA of **1b** will cause substitution. The *p*-HO and weak EAA of **1c** are unfavorable for both the pathways, and consequently result in self-decomposition even with mild SET. The steric repulsion caused by *o*-Me group of **1c** may be negligible (see poor combined product yield and recovery in Runs 5 and 6),[7] because the comparable result was obtained by the reverse addition of 8.0 mol of *p*-Me reagent to noncrowded 4-HO-nitrobenzene though the yields of **2**, **3**, and **4** were slightly improved by the normal addition.

Azoxyarene Precursor. Concerning the "third feature," the higher yield of **3a** than **2a** in spite of consumption of one of the two mol of IDMg used in Run 1 is noted. This fact seems to contradict to the usual tendency of yield variation,[5] i.e., the use of small molar excess of IDMg in the reaction with ordinary nitroarenes leads to a lower yield of **3** than **2**.[5] In order to examine the reason for the contradiction, two attempts were carried out: the one to test facile deoxygenation of **2a**, and the other to test facile condensation of *o*-HO-nitrosoarene[5] expected as an intermediate from deoxygenation of **1a**.

Both the two attempts were unsuccessful. First, treatment of pure **2a** (reduction peak potential: −1.438 V) at 55 °C with 5.0 mol of *p*-MeO reagent for 3 h,[5] caused sluggish deoxygenation leading to **3a** in 15% yield and 75% recovery of **2a**. Another attempt was

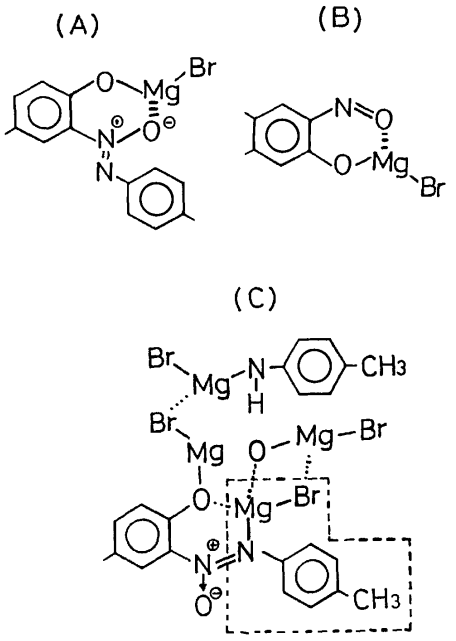

Fig. 2. Depiction of chelates formed in the IDMg reaction. (A): Formed from isolated **2a**. (B): Formed from **1d**. (C): Precursor of **2a** formed from **1a**. A fragment of IDMg is enclosed by broken line.

the treatment of 1-nitroso-2-naphthol (**1d**, reduction peak potential: 0.898 V) with 3.0 mol of *p*-Me reagent at 55 °C (Run 13, **1d** was used instead of nitrosophenol which is difficult to handle because of its high volatility). Yield of the expected 1-arylazo-2-naphthol was 5%, and a nuclear substitution product (cf. Run 14) was obtained in 59% yield. Poor results of the attempts (irrespective of the potential) using isolated **2a** and nitrosonaphthol are ascribed to the formation of Mg chelates (Fig. 2A, 2B): The azoxy and nitroso oxygen atoms incorporated in the chelates may be weakly reactive or almost inert toward IDMg.

As shown by the alternative chelate depicted in Fig. 2C, the "precursor of **2a** formed in the reaction mixture" must involve the ArN moiety of IDMg (enclosed by broken line). As discussed in the preceding section, the precursor 2C must be flanked further by an aggregate of N-Mg species around the OMgBr group. The azoxy oxygen of 2C, not incorporated in the chelate, will be easily attacked by IDMg aggregate and removed.

Reactions of Related Nitroarenes. The results obtained by use of some related nitroarenes (Runs 14—18) were explained similarly as the above discussion. The low overall yield from **1e** by use of both small and large molar excesses of *p*-Me reagent (Runs 14 and 15) is due to decomposition via SET caused by strong EAA. The nitro group of **1e** is sterically hindered by peri-hydrogen, and, at the expense of condensation products (**2e** and **3e**), gives tautomeric compound via substitution-replacement (**9**, the same as that obtained in Run 13, see Experimental). Two noncrowded hydroxy-substituted azonitroarenes (1-(4-NO_2-phenyl-azo)-2-naphthol and its 2,1-isomer (**1f** and **1g**)) condensed effectively with *p*-Me reagent (3.0 mol, Runs 16 and 17) giving azoxy-azo (**2f** and **2g**, 34—36%) and bis-azo (**3f** and **3g**, 41—44%) products. The slightly higher yield of **3** than **2** is ascribed to azo-OMgBr chelation (Fig. 3). The chelation will enhance the positive charge on azoxy nitrogen to facilitate the removal of oxygen,[5] and will also be responsible for the novel replacement of hydroxynaphthylazo groups leading to 4-Me-4′-NO_2-diphenylamine (**10**, 11—17%).

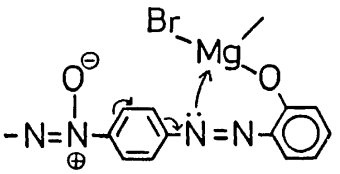

Fig. 3. Illustration of chelation effect on the deoxygenation and replacement in the reaction of **1f** and **1g**.

By comparison, 4-Me_2N-4′-nitroazobenzene (**1h** having no HO group) was treated with 2.0 mol of *p*-Me reagent (Run 18). In spite of strong EAA of **1h**, comparable to **1a** in isolated state, a moderate reaction took place leading to a good combined yield of azoxy-azo (**2h**, 55%) and bis-azo (**3h**, 18%) products. Lack of HO group may be at least partly responsible for the higher yield of **2h** than **3h**. The reaction must be moderated by stabilization of IDMg due to coordination of dimethylamino nitrogen to Mg atom, because the oxidation peak potential of *p*-Me reagent in the presence of equimolar amount of *N,N*-dimethylaniline is larger by ca. 200 mV than the potential in the absence.[5] A similar example of IDMg stabilization by interaction with a remote substituent of nitroarene was reported.[11]

Conclusion

The complicated results of IDMg reactions with HO-substituted nitroarenes were explained on the basis of governing factors and effects of various types of coordination[5-11] originating from strong affinity of Mg with O, Br, and N atoms of substrates. The moderate reactivity of IDMg[6] is responsible for observation of the coordination factors. Though the precise mechanism of condensation still remains to be studied, the grounds for synthetic use of *o*-HO-nitroarenes seem to be established.

Experimental

Procedures and Products. The nitrophenols and nitro- and nitrosonaphthols were commercially available. The isomeric (nitrophenylazo)naphthols were prepared from 1- and 2-naphthols by diazotization using 4-nitroaniline. The preparation of IDMg was previously described,[4] and most of its reactions were carried out under typical conditions at 55 °C for 3 h.

After quenching the reaction mixture with saturated

a) Melting point was undetermined, because the product was not purified. b) One of the tautomers: the signal at δ 12.84 is assigned to HO-proton.

aqueous NH_4Cl, the products were separated by column and thin-layer chromatography on silica gel (Wako Gel C-200 and C-300). The elemental analyses of products gave satisfactory results. The melting points (uncorrected) and ^1H NMR data of **2a—2h**, **3f** and **3g**, **5**[R], and **6—10** are given in Table 2. The data for **3a—3e** and **4** are known.

The phenazine-type products (**7** and **8**) formed from **1b** (Runs 3 and 4) arise from substitution at 2-position (cf. **6**) followed by intramolecular attack of a nitrogen radical (derived from nitro group) at the *o*-position of anilino moiety, the precise mechanism being ambiguous. The two tautomeric products (**9**) formed from nitroso- and nitronaphthols (Runs 13—15) arise from substitution at 4-position followed by replacement of nitroso or nitro group; the physical data for the stable one having HO group is given in Table 2. The structure of **9** was confirmed by hydrolysis with aqueous hydrochloric acid to convert into 2-HO-1,4-naphthoquinone and 4-Me-aniline.

Reduction (redox) potentials of substrates were measured by the reported method[9] using bis(biphenyl)chromium(I) tetraphenylborate (BCTB) as an internal reference.

The gift of BCTB samples by Professor Gerhard Gritzner, University of Linz, is gratefully acknowledged. The authors thank Mr. Kōji Matsuo for measuring redox potentials of substrates and the recovery experiment using **1a** and EtMgBr. They are grateful to the Advanced Instrumentation Center for Chemical Analyses, Ehime University, for elemental analyses. A part of this work was financially supported by Grants-in-Aid for Scientific Research (Nos. 60470024 and 63540405) from the Ministry of Education, Science and Culture.

(Received November 26, 1988)

In spite of large steric repulsion between aromatic quinone moiety and dicyanomethylene moiety the title compounds (BDCNBA) were synthesized by $TiCl_4$-catalyzed reactions of the corresponding aromatic quinones and malononitrile. BDCNBA showed electronic spectra indicating the intramolecular charge-transfer interaction and redox properties similar to 11,11,12,12-tetracyano-9,10-anthraquinodimethane (TCNAQ) derivatives. BDCNBA showed a low electrical conductivity ($\approx 10^{-7}\ \Omega^{-1}\ cm^{-1}$). Strongly deformed structure of BDCNBA was established by X-ray crystallographic analysis.

Recently much attentions have been centered to organic metals.[1] Organic metals are generally composed of donors and acceptors, but acceptors investigated so far have been limited mostly to tetracyanoquinodimethane (TCNQ) analogues, while a variety of donors have been examined. 11,11,12,12-Tetracyano-9,10-anthraquinodimethane (TCNAQ) deviates deform from flat molecular plane of the corresponding anthraquinone, having butterfly form, because of steric repulsion between peri-hydrogen of aromatic moiety and dicyanomethylene group.[2] Nevertheless they make complex with aromatic donors in many cases.[3] It is important to elucidate the relationship between steric factor in organic metals and complex formation between donors and acceptors or electrical conductivity for designing excellent organic metals. We synthesized polyaromatic TCNQ compounds to investigate the effect of aromaticity and steric repulsion between dicyanomethylene moiety and aromatic moiety by introducing a benzene ring to TCNAQ framework. Now we wish to report here syntheses and properties of 7,12-bis(dicyanomethylene)-7,12-dihydrobenz[*a*]anthracene derivatives.

Results and Discussion

Synthesis of BDCNBA. 7,12-Bis(dicyanomethylene)-7,12-dihydrobenz[*a*]anthracenes (BDCNBA) **3** were synthesized from the corresponding benz[*a*]anthracene-7,12-diones **1** according to the Aumüller[4] and Ong[5] method. The results are summarized in Table 1. In spite of large steric repulsion between dicyanomethylene groups and aromatic moieties, especially naphthalene moiety, BDCNBA **3a—g** were produced in high yields compared to the case of TCNAQ,[3-6] while 7-(dicyanomethylene)benz[*a*]anthracen-12(7*H*)-ones (DCNBA) **2a—g** were not obtained. 5,12-Bis-(dicyanomethylene)-5,12-dihydronaphthacene **6** which is less crowded than **3c** was also obtained in similar yield. In Runs 8—12, BDCNBA **3h—l** were obtained in low yields, whereas DCNBA **2h—l** were obtained majorly. The respective structures of compounds **2**, **3** were assigned by the spectroscopic data as well as X-ray analyses of **2j** and **3c**. A proton at C-1 of **2** showed characteristic shift in the ^{1}H NMR spectrum ($\delta \approx 9$—10) similar to that in the corresponding quinone **1** due to the additional deshielding of carbonyl group, while no similar downfield shift of C-1 proton in the ^{1}H NMR spectrum of the corresponding BDCNBA **3** was observed (see Experimental section). This indicates that the position of dicyanomethylene group in **2** probably is at less crowded C-7 site. The structure was unambiguously determined by X-ray analysis of **2j**. It is known that only 1,3-dimethyl-10-(dicyanomethylene)anthrone was formed exclusively when 1,3-dimethylanthraquinone was subjected to the same reaction,[5] while 1,5-dichloro-9,10-bis(dicyanomethylene)-9,10-dihydroanthracene was obtained in a low yield (19%) when the corresponding anthraquinone was used.[4] In our case it is amazing that BDCNBA **3** was produced in a high yield in spite of supposedly larger steric repulsion between aromatic moieties and dicyanomethylene groups compared to other cases.

UV-Visible Absorption Spectrum. The UV-visible absorption spectrum of BDCNBA **3c** in dichloromethane shows bands at 231 (log ε=4.29), 285 (4.19), 337 (4.46), and 431 (3.46) nm. Thus, the lowest energy electronic transition (λ_{max}=431 nm) is red-shifted by ca. 80, 30, 30 nm, compared to those of TCNAQ,[7] 9,9,10,10-tetracyano-1,4-naphthoquinodimethane (TCNNQ),[7] tetracyanoquinodimethane (TCNQ), respectively (Table 2). In addition, the longest wavelength band (λ_{max}) of TCNAQ is blue-shifted by ca. 70 nm compared with that of anthraquinone, while that of **3c** is red-shifted by ca. 100 nm compared with that of **1c** (Table 2). It is well-known that the central ring in TCNAQ is bent into a boat form and the two benzene rings are noncoplanar to avoid the severe steric interactions between the cyano groups and the peri-hydrogens.[2] Since the structure of **3c** deforms more severely than that of TCNAQ as discussed later, the observed large red shift (λ_{max}) in the longest wavelength band is unusual. These data suggest that the large red shift of the longest wavelength bands is not ascribed to the larger delocalization of the π system, but to the intramolecular charge-transfer (CT) interaction[8] between dicyanomethylene groups and aromatic moieties. The peak values (λ_{max}^{CT}) in the longest wavelength region were more blue-shifted for **3a—g** and **3h—l**, as electron-withdrawing substituent groups were introduced into the naphthalene moiety (Table 3). As the polarity of solvent increased,[9] blue shifts of the λ_{max}^{CT} were observed in the UV spectra of **3c** and **3j** (Table 4). Since the corresponding CT band

3c	231 (4.29), 285 (4.19), 337 (4.46), 431 (3.46)

a) From Ref. 7.

was also observed in **6**, these effects are not due to the deformation derived from larger steric interaction compared to TCNAQ, but due to the easier electron-releasing character from naphthalene moiety to dicyanomethylene group caused by replacement of benzene ring to naphthalene one. Indeed, similar substituent (Table 3) and solvent effects (Table 4) in **2h—l** were observed. That is, the values of λ_{max}^{CT} were blue-shifted as electron-withdrawing substituent groups were introduced in the naphthalene moiety. The similar inclination was observed as the polarity of solvent increased. Thus, these longest bands are due to the intramolecular CT interaction.

Electrochemical Studies. Table 5 shows the results of cyclic voltammogram of TCNQ derivatives in acetonitrile, taken at room temperature using with tetraethylammonium perchlorate as the supporting electrolyte. For BDCNBA only one reversible redox wave, which corresponds to two electron reduction observed in the case of TCNAQ,[2-4,7] was observed in the range from 0 to −2.0 V and the value of $E_{1/2}^{red}$ is much lower than that in TCNQ, but is a little lower than that in TCNAQ. These facts suggest that extension of aromatic system contributes only slightly to the reduction potential, but decrease of the aromaticity due to big steric repulsion between dicyanomethylene groups and aromatic moieties has a greater effect. From the value of $E_{1/2}^{red}(1)-E_{1/2}^{red}(2)$ (+0.016) obtained by Myers and Shain's method,[10] we can estimate the value of semiquinone formation constant K_{sem} as the following;

$$\log K_{sem} = \log([BDCNBA^{-}]^2/[BDCNBA][BDCNBA^{2-}]) = (E_{1/2}^{red}(1) - E_{1/2}^{red}(2))/0.058$$

The small log K_{sem} (+0.28) value of **3c** relative to that of TCNQ, but nearly equal to that of TCNAQ indicates that anion radical $\mathbf{3c}^{-}$ is unstable. It has been concluded from the ESR and the ENDOR studies of TCNQ derivatives that the negative charges in the dianions tend to localize on the two dicyanomethylene groups.[11] This inclination is enhanced in $TCNAQ^{2-}$ because of the steric repulsion between peri-hydrogen and dicyanomethylene group.[6,7] Since C7—C13 and C12—C16 bonds (see Fig. 2) turn to be single in the dianion of **3c**, steric repulsion between dicyanomethylene groups and aromatic moieties including peri-hydrogen atoms in $\mathbf{3c}^{2-}$ would be readily released by twisting the two negatively charged dicyanomethylene groups out of the aromatic plane rather than by bending the central benzene ring (consisting of C6a, C7, C7a, C11a, C12, C12a) in the benz[*a*]anthracene moiety. Thus, disproportionation between dianion $\mathbf{3c}^{2-}$ and **3c** easily would occur because of the steric interaction.[12]

Electrical Conductivity. Mukai et al. reported that TCNAQ forms CT complex with many aromatic donors and steric factor is important to form complexation.[3,6] On the contrary, 2,3,5,6-tetramethyl-7,7,8,8-tetracyanoquinodimethane (TMTCNQ), which has strong deformation of the TCNQ skeleton into a boat-conformation,[13] formed no complex with tetrathiafulvalene (TTF), tetramethyltetrathiafulvalene (TMTTF), tetramethyltetraselenafulvalene (TMTSF).[14] In our case, no complex was formed between **3c** and a variety of electron donors, like as naphthalene, pyrene, anthracene, TMTTF, although they showed charge-transfer bands in dichloromethane solution similar to the cases observed between TCNAQ and aromatic donors (Table 6 and Experimental section), indicating that the larger steric hindrance between donor and

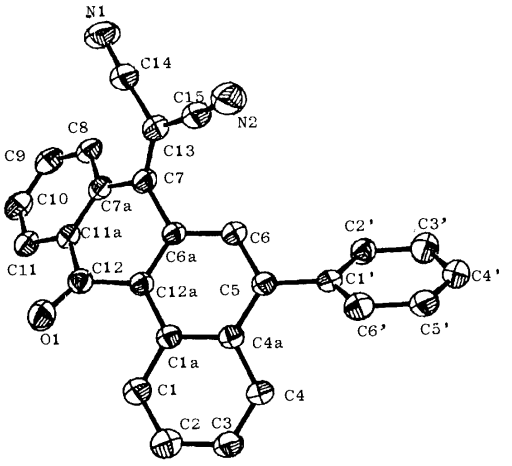

Fig. 1. ORTEP view of **2j**.

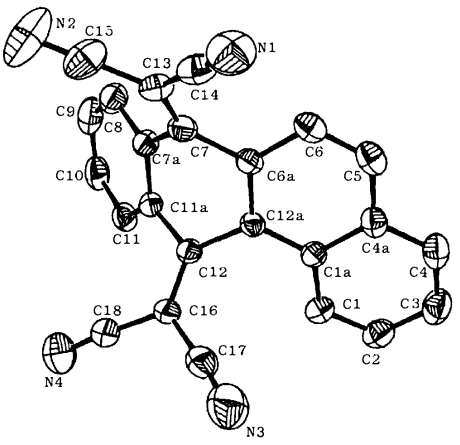

Fig. 2. ORTEP view of **3c**.

acceptor interrupts the complex formation.

It is well-known that partial charge transfer from donor to acceptor is important for high quality of organic metals.[1] Thus, **3c** itself has possibility of showing high electrical conductivity, since **3c** has intramolecular CT character. Against our expectation, **3c** showed low electrical conductivity (1×10^{-7} Ω^{-1} cm^{-1}) at room temperature. These results suggest that large steric deformation reduces intermolecular interaction and results in low electrical conductivity.

X-Ray Structures of DCNBA 2j and BDCNBA 3c. The structures of DCNBA and BDCNBA frameworks were definitely confirmed by X-ray diffraction analyses of **2j** and **3c** (Figs. 1 and 2). The atomic positional and equivalent isotropic thermal parameters are listed in Table 7. Bond distances and angles of **2j** and **3c** are listed in Tables 8 and 9, respectively.

Table 6. Charge-Transfer Absorption Maxima of BDCNBA **3c** and Aromatic Donors[a] (λ_{max}/nm in CH_2Cl_2)

Naphthalene	Pyrene	Anthracene	TMTTF
485	502	518	632

a) BDCNBA: 2.5×10^{-3} mol dm^{-3}, donors: 5.0×10^{-2} mol dm^{-3}.

Bond lengths and angles of TCNQ unit (consisting of C6a, C7, C7a, C11a, C12, C12a) in **3c** are almost the same as those in TCNAQ. However, deformation of the structure of **3c** is larger than that of TCNAQ. The dihedral angle between planes A (consisting of C8, C9, C10, C11, C11a, C7a) and B (consisting of C1, C2, C3, C4, C4a, C5, C6, C6a, C12a, C1a) is 49.5° for **3c**, while that of TCNAQ is 35.4° (see Fig. 2 and Table 10). The dihedral angle between planes A and B in **2j** is 33.3°, and that in 10-dicyanomethyleneanthrone is 28°.[15] These facts indicate that introduction of naphthalene unit into TCNAQ causes the larger deformation of the structure because of the steric repulsion between naphthalene moiety and dicyanomethylene group. Comparison of bond distances of naphthalene moiety for benz[*a*]anthracene-7,12-dione vs. **3c** or **2j** reveals us degree of the deformation for naphthalene moiety, for example, 142.0 pm for **3c**, 144.4 pm for **2j** vs. 147.2 pm for 8-methylbenz[*a*]anthracene-7,12-dione (MBAD) (C1a-C12a); 134.8 pm for **3c**, 138.5 pm for **2j** vs. 139.3 pm for MBAD (C5-C6).[16] Thus, bond lengths of naphthalene moiety in **3c** and **2j** (C1-C1a, C1a-C12a, C6a-C12a, C6–C6a, C5-C6, C4a-C5, C4-C4a) are different from those in MBAD due to effect of the butterfly form. On the other hand, bond lengths of

C1-C2, C2-C3, and C3-C4 in **3c** and **2j** are similar to those in MBAD due to the less effect of the butterfly form. The larger values of dihedral angle between planes A and C (consisting of C6a, C7a, C11a, C12a) (25.2°) or planes B and C (24.4°) compared to that of TCNNQ (15.3°),[17] TCNAQ (16.6°, 18.9°),[2] tetracyanobianthraquinodimethane (TBAQ) (23.6°, 26.1°),[18] and **2j** (15.1°, 18.3°) show that planes A and B in **3c** are more folded out of the central ring plane C than those in TCNQ derivatives. Planes D (consisting of C6a, C7, C7a, C13) and F (consisting of C16, C12, C11a, C12a) are tilted more sharply from the central ring plane C by 34.4°, 41.0°, respectively than those of TCNNQ (16.7°, 21.6°), TCNAQ (30.1°, 30.7°), TBAQ (29.8°, 35.4°), and **2j** (33.1°). Dihedral angle between planes D and E (consisting of C7, C13, C14, C15, N1, N2) (3.6°) or planes F and G (consisting of C12, C16, C17, C18, N3, N4) (3.9°) is small, thus, planes D and E (or planes F and G) are almost coplanar. Yamaguchi et al.[18] reported that TBAQ, which is the most strongly deformed of all TCNQ derivatives, was synthesized from bianthron and malononitrile, while tetracyanodiphenoquinodimethane could not be synthesized. Comparison of the corresponding dihedral angles of TBAQ and BDCNBA **3c** reveals that BDCNBA is more strongly deformed than TBAQ.

In conclusion, BDCNBA and TCNAQ are very similar except that BDCNBA shows intramolecular CT character. BDCNBA has the most strongly deformed structure of all TCNQ derivatives due to the steric interaction between benzene rings and dicyanomethylene groups.

Experimental

General Procedures. All melting points were determined with a Yanagimoto micro melting point apparatus and uncorrected. Mass spectra were taken on a JEOL JMS-DX 300 mass spectrometer. The electronic spectra were obtained by Shimadzu UV-200 spectrometer. ^{1}H NMR spectra were taken by using a JEOL-JNM-PS-100 spectrometer or a JEOL JNM-GX-400 spectrometer and chemical shifts were recorded in parts per million (ppm) on the δ scale from tetramethylsilane as an internal standard. IR spectra were obtained by using a JASCO IRA-1 spectrometer on KBr

pellets. Elemental analyses were performed at the Micro Analytical Center of Kyoto University. Cyclic voltammetry was performed with a PAR Model 174. The working electrode was platinum wire. A Ag/Ag^+ (0.1 M; 1 M=1 mol dm^{-3}) electrode was used as a reference and 0.1 M tetraethylammonium perchlorate as supporting electrolyte. The reduction potential was measured in a nitrogen-purged acetonitrile solution and the value measured was corrected to that relative to SCE (+0.24 V). The impedance measurements (pellet) were made in the frequency range 10 Hz—1 MHz using a gain-phase meter YHP 4276A LCZ METER at room temperature. All the solvents were used after distillation.

Starting Material. Quinone **1c** was purchased from Aldrich, Inc. and used without further purification. Quinones **1a—b, d—g** were prepared from naphthoquinone and the corresponding styrenes.[19] Quinone **4** was prepared according to the reported method.[20] Quinones **1h—l** were prepared by photochemical reactions of 2,3-dichloro-1,4-naphthoquinone with corresponding 1,1-diphenylethylenes.[21] Anthraquinone was purchased from Nacalai tesque Co. and used after recrystallization. TCNQ was prepared according to the reported method.[22]

Preparation of 2 and 3 (or 6). **2** and **3** (or **6**) were prepared according to Ong and Aumüller method. To a well-stirred mixture of 1 mmol of quinone **1** (or **4**) and 10 mmol of malononitrile in 20 ml of dichloromethane at an ice-bath temperature were added dropwise 10 ml of 1 mol dm^{-3} $TiCl_4$ solution and 20 mmol of pyridine. After end of addition, ice bath was removed to continue reaction at room temperature for overnight. The reaction mixture was treated with 50 ml of 10% aqueous HCl solution with vigorous stirring. Organic layer was separated and washed with brine and

dried. Purification of the products was accomplished by column chromatography developing hexane-benzene (2:1) and subsequently benzene. First bands contains **1** (or **6**), second one contains **2**, and third one contains **3**. The products were assigned from the following spectroscopic data.

7-Dicyanomethylene-2-fluoro-5-(4-fluorophenyl)benz[*a*]anthracen-12(7*H*)-one (2h): Red crystals from hexane-chloroform; mp>300 °C. MS; *m/z* 418 (M^+). Found: C, 77.57; H, 2.74; F, 8.91; N, 6.47%. Calcd for $C_{27}H_{12}F_2N_2O$: C, 77.51; H, 2.89; F, 9.08; N, 6.70%. IR (KBr); 2230 (C≡N), 1660 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.2—8.5 (11H, m), 9.56 (1H, dd, *J*=11, 3 Hz). UV (CH_2Cl_2) λ_{max}: 234 (log ε=4.36), 257 (4.25), 315 (4.48), 377 (3.92), 422 (3.41) nm.

2-Chloro-5-(4-chlorophenyl)-7-(dicyanomethylene)benz[*a*]anthracen-12(7*H*)-one (2i): Orange crystals from hexane-chloroform; mp>300 °C. MS; *m/z* 450, 452, 454 (M^+). Found: C, 71.89; H, 2.61; Cl, 15.62; N, 6.17%. Calcd for $C_{27}H_{12}Cl_2N_2O$: C, 71.86; H, 2.68; Cl, 15.71; N, 6.21%. IR (KBr); 2210 (C≡N), 1650 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.4—8.7 (11H, m), 9.88 (1H, d, *J*=3 Hz). UV (CH_2Cl_2) λ_{max}: 236 (4.56), 259 (4.38), 316 (4.56), 379 (4.01), 425 (3.50) nm.

7-Dicyanomethylene-5-phenylbenz[*a*]anthracen-12(7*H*)-one (2j): Orange crystals from hexane-chloroform; mp> 300 °C. MS; *m/z* 382 (M^+). Found: C, 85.08; H, 3.50; N, 7.31%. Calcd for $C_{27}H_{14}N_2O$: C, 84.80; H, 3.69; N, 7.33%. IR (KBr); 2200 (C≡N), 1650 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.4—8.7 (13H, m), 9.77 (1H, d, *J*=10 Hz). UV (CH_2Cl_2) λ_{max}: 234 (4.46), 257 (4.27), 317 (4.61), 380 (3.98), 427 (3.49) nm.

7-Dicyanomethylene-2-methyl-5-(4-methylphenyl)benz[*a*]anthracen-12(7*H*)-one (2k): Orange needles from hexane-chloroform; mp>300 °C. MS; *m/z* 410 (M^+). Found: C, 84.85; H, 4.26; N, 7.00%. Calcd for $C_{29}H_{18}N_2O$: C, 84.86; H, 4.42; N, 6.82%. IR (KBr); 2230 (C≡N), 1650 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.50 (3H, s), 2.68 (3H, s), 7.3—8.6 (11H, m), 9.58 (1H, s). UV (CH_2Cl_2) λ_{max}: 235 (4.51), 265 (4.33), 325 (4.58), 383 (3.96), 450 (3.46) nm.

7-Dicyanomethylene-2-methoxy-5-(4-methoxyphenyl)-benz[*a*]anthracen-12(7*H*)-one (2l): Red crystals from hexane-chloroform; mp>300 °C. MS; *m/z* 442 (M^+). Found: C, 78.79; H, 4.18; N, 6.14%. Calcd for $C_{29}H_{18}N_2O_3$: C, 78.72; H, 4.10; N, 6.33%. IR (KBr); 2220 (C≡N), 1640 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.94 (3H, s), 4.12 (3H, s), 7.1—8.5 (11H, m), 9.32 (1H, d, *J*=3 Hz). UV (CH_2Cl_2) λ_{max}: 235 (4.63), 265 (4.45), 332 (4.58), 395 (3.97), 477 (3.61) nm.

7,12-Bis(dicyanomethylene)-2-fluoro-7,12-dihydrobenz[*a*]anthracene (3a): Orange cubics from acetonitrile; mp> 300 °C. MS; *m/z* 372 (M^+). Found: C, 77.51; H, 2.17; F, 5.16; N, 15.15%. Calcd for $C_{24}H_9FN_4$: C, 77.42; H, 2.44; F, 5.10; N, 15.05%. IR (KBr); 2240 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.54 (1H, m), 7.7—7.8 (3H, m), 8.04 (1H, m), 8.1—8.3 (4H, m). UV (CH_2Cl_2) λ_{max}: 232 (4.30), 285 (4.23), 334 (4.40), 424 (3.42) nm.

2-Chloro-7,12-bis(dicyanomethylene)-7,12-dihydrobenz[*a*]anthracene (3b): Orange cubics from acetonitrile; mp> 300 °C. High-resolution mass spectrum. Found: *m/z* 388.0521. Calcd for $C_{24}H_9N_4{}^{35}Cl$: M, 388.0515. Found: *m/z* 390.0483. Calcd for $C_{24}H_9N_4{}^{37}Cl$: M, 390.0486. IR (KBr); 2240 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.6—7.8 (3H, m), 7.97 (1H, d, *J*=8.9 Hz), 8.07 (1H, s), 8.17 (1H, d, *J*=8.5 Hz), 8.2—8.3 (3H, m). UV (CH_2Cl_2) λ_{max}: 232 (4.66), 286 (4.37), 336 (4.54), 426 (3.52) nm.

7,12-Bis(dicyanomethylene)-7,12-dihydrobenz[*a*]anthracene (3c): Orange plates from acetonitrile; mp>300 °C. MS; *m/z* 354 (M^+). Found: C, 81.29; H, 2.61; N, 15.76%. Calcd for $C_{24}H_{10}N_4$: C, 81.35; H, 2.84; N, 15.81%. IR (KBr); 2240 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.7—7.9 (4H, m), 8.02 (1H, d, *J*=8.2 Hz), 8.11 (1H, d, *J*=8.1 Hz), 8.1—8.3 (4H, m). UV (CH_2Cl_2) λ_{max}: 231 (4.29), 285 (4.19), 337 (4.46), 431 (3.46) nm.

7,12-Bis(dicyanomethylene)-2-methyl-7,12-dihydrobenz[*a*]anthracene (3d): Red cubics from acetonitrile; mp>300 °C. MS; *m/z* 368 (M^+). Found: C, 81.32; H, 3.04; N, 15.51%. Calcd for $C_{24}H_{12}N_4$: C, 81.51; H, 3.28; N, 15.21%. IR (KBr); 2230 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.67 (3H, s), 7.57 (1H, d, *J*=8.2 Hz), 7.6—7.8 (2H, m), 7.83 (1H, s), 7.90 (1H, d, *J*=8.3 Hz), 8.12 (1H, d, *J*=8.2 Hz), 8.19 (1H, d, *J*=8.5 Hz), 8.2—8.3 (2H, m). UV (CH_2Cl_2) λ_{max}: 232 (4.42), 286 (4.28), 345 (4.48), 444 (3.43) nm.

7,12-Bis(dicyanomethylene)-2-methoxy-7,12-dihydrobenz[*a*]anthracene (3e): Red crystals from acetonitrile; mp>300 °C. High-resolution mass spectrum. Found: *m/z* 384.1008. Calcd for $C_{25}H_{12}N_4O$: M, 384.1010. IR (KBr); 2230 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.08 (3H, s), 7.23 (1H, d, *J*=2.1 Hz), 7.39 (1H, dd, *J*=8.8, 2.1 Hz), 7.7—7.8 (2H, m), 7.90 (1H, d, *J*=9.2 Hz), 8.0—8.2 (2H, m), 8.2—8.3 (2H, m). UV (CH_2Cl_2) λ_{max}: 234 (4.56), 289 (4.39), 349 (4.39), 474 (3.41) nm.

7,12-Bis(dicyanomethylene)-3-methoxy-7,12-dihydrobenz-[*a*]anthracene (3f): Orange needles from acetonitrile; mp> 300 °C. MS; *m/z* 384 (M^+). Found: C, 78.27; H, 2.94; N, 14.42%. Calcd for $C_{25}H_{12}N_4O$: C, 78.12; H, 3.15; N, 14.58%. IR (KBr); 2230 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.99 (3H, s), 7.25 (1H, m), 7.44 (1H, dd, *J*=9.4, 2.4 Hz), 7.7—7.8 (2H, m), 7.98 (1H, d, *J*=9.4 Hz), 8.02 (1H, d, *J*=8.5 Hz), 8.1—8.3 (3H, m). UV (CH_2Cl_2) λ_{max}: 234 (4.54), 294 (4.28), 349 (4.56), 462 (3.76) nm.

7,12-Bis(dicyanomethylene)-4-methoxy-7,12-dihydrobenz-[*a*]anthracene (3g): Orange needles from acetonitrile; mp> 300 °C. MS; *m/z* 384 (M^+). Found: C, 78.40; H, 2.92; N, 14.51%. Calcd for $C_{25}H_{12}N_4O$: C, 78.12; H, 3.15; N, 14.58%. IR (KBr); 2230 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.06 (3H, s), 7.04 (1H, d, *J*=7.6 Hz), 7.63 (1H, d, *J*=8.8 Hz), 7.7—7.8 (3H, m), 8.2—8.3 (3H, m), 8.66 (1H, d, *J*=9.2 Hz). UV (CH_2Cl_2) λ_{max}: 233 (4.40), 286 (4.34), 346 (4.46), 480 (3.31) nm.

7,12-Bis(dicyanomethylene)-2-fluoro-5-(4-fluorophenyl)-7,12-dihydrobenz[*a*]anthracene (3h): Orange crystals from hexane-chloroform; mp>300 °C. High-resolution mass spectrum. Found: *m/z* 466.1029. Cacld for $C_{30}H_{12}F_2N_4$: M, 466.1029. IR (KBr); 2240 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.3—8.6 (12H, m). UV (CH_2Cl_2) λ_{max}: 234 (4.51), 287 (4.35), 343 (4.49), 449 (3.64) nm.

2-Chloro-5-(4-chlorophenyl)-7,12-bis(dicyanomethylene)-7,12-dihydrobenz[*a*]anthracene (3i): Orange crystals from hexane-chloroform; mp>300 °C. MS; *m/z* 498, 500, 502 (M^+). Found: C, 71.96; H, 2.30; Cl, 14.43; N, 11.14%. Calcd for $C_{30}H_{12}Cl_2N_4$: C, 72.16; H, 2.42; Cl, 14.20; N, 11.22%. IR (KBr); 2250 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.4—8.7 (12H, m). UV (CH_2Cl_2) λ_{max}: 234 (4.59), 288 (4.33), 343 (4.48), 458 (3.59) nm.

7,12-Bis(dicyanomethylene)-5-phenyl-7,12-dihydrobenz[*a*]anthracene (3j): Red crystals from hexane-chloroform; mp>300 °C. MS; *m/z* 430 (M^+). Found: C, 83.67; H, 3.15; N,

12.79%. Calcd for $C_{30}H_{14}N_4$: C, 83.71; H, 3.28; N, 13.02%. IR (KBr); 2240 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.6—8.7 (14H, m). UV (CH_2Cl_2) λ_{max}: 233 (4.56), 288 (4.40), 345 (4.61), 458 (3.70) nm.

7,12-Bis(dicyanomethylene)-2-methyl-5-(4-methylphenyl)-7,12-dihydrobenz[*a*]anthracene (3k): Orange crystals from hexane–chloroform; mp>300 °C. MS; *m/z* 458 (M^+). Found: C, 84.02; H, 3.83; N, 11.96%. Calcd for $C_{32}H_{18}N_4$: C, 83.82; H, 3.96; N, 12.22%. IR (KBr); 2230 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.50 (3H, s), 2.71 (3H, s), 7.2—8.8 (12H, m). UV (CH_2Cl_2) λ_{max}: 236 (4.60), 290 (4.47), 354 (4.59), 478 (3.70) nm.

7,12-Bis(dicyanomethylene)-2-methoxy-5-(4-methoxyphenyl)-7,12-dihydrobenz[*a*]anthracene (3l): Purple crystals from hexane–chloroform; mp>300 °C. MS; *m/z* 490 (M^+). Found: C, 78.09; H, 3.43; N, 11.42%. Calcd for $C_{32}H_{18}N_4O_2$: C, 78.36; H, 3.70; N, 11.42%. IR (KBr); 2220 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.92 (3H, s), 4.11 (3H, s), 7.0—8.5 (12H, m). UV (CH_2Cl_2) λ_{max}: 238 (4.61), 287 (4.45), 358 (4.45), 502 (3.68) nm.

5,12-Bis(dicyanomethylene)-5,12-dihydronaphthacene (6): Yellow needles from hexane–chloroform; mp>300 °C. MS; *m/z* 354 (M^+). Found: C, 81.10; H, 2.66; N, 15.64%. Calcd for $C_{25}H_{12}N_4$: C, 81.35; H, 2.84; N, 15.81%. IR (KBr); 2240 (C≡N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.76 (4H, m), 8.05 (2H, m), 8.27 (2H, m), 8.72 (2H, s). UV (CH_2Cl_2) λ_{max}: 233 (4.39), 260 (4.51), 306 (4.51), 424 (3.96) nm.

Molecular Complexes of 3c. Naphthalene, pyrene, anthracene was purchased from Nacalai tesque Co. and used after recrystallization. TMTTF was prepared according to the reported method.[23] **3c** and an excess amounts of a donor were dissolved in dichloromethane, and ethanol was added to precipitate a complex and prevent the precipitate of excess donor. The mixture was concentrated by distillation, and then cooled, but complex did not precipitate. However, a dichloromethane solution containing **3c** (0.0025 mol dm^{-3}) and donors (0.05 mol dm^{-3}) showed a CT band, which was obtained by substracting the "background" absorption of samples (absorption of **3c** and donors). Intensity of these CT bands increased as donors were added into the mixture.

X-Ray Structure Analyses. The X-ray structure analyses were made with a Rigaku Denki AFC-4 automatic four-circle diffractometer [Ni-filtered Cu $K\alpha$ radiation (154.184 pm), ω–2θ scan technique, $2\theta \leqq 120°$, scan speed 4° min^{-1} (θ), scan range (1.5+0.15 tan θ)°]. Three standard reflections measured every 100 reflections showed no significant X-ray damage or crystal decay. Unique 3031 (for **2j**) and 2792 (for **3c**) reflections were used for structure determination. The structure was solved by direct methods with MULTAN 78[24] (with atomic scattering factors from International Tables for X-ray Crystallography)[25] and refined by block-diagonal least squares[26] with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogen atoms. **2j**: R=0.0754 and R_2=0.0681, where ω=1.0 for Fobs≠0, ω=0.8 for Fobs=0.0, **3c**: R=0.0589 and R_2=0.0656 where ω=1.0 for Fobs≠0, ω=0.8 for Fobs=0.0. Crystal data are as follows; **2j**: a=1150.0 (1), b=1163.0 (1), c=815.4 (1) pm, α=106.31 (1), β=89.33 (1), γ=116.29 (1)°, space group=P-1 (triclinic) (Z=2). V=9.303×10^8 (1) pm^3, D_c/g cm^{-3}=1.366 (1). **3c**: a=891.4 (1), b=1489.0 (1), c=733.8 (1) pm, α=90.67 (1), β=110.36 (1), γ=104.00 (1)°, space group=P-1 (triclinic) (Z=2). V=8.812×10^8 (1) pm^3, D_c/g cm^{-3}=1.336 (1).

We are grateful to Professor Yukiteru Katsube and his co-worker at Institute for Protein Research, Osaka University, for the measurement of X-ray analyses.

Facile Synthesis of AM-Toxin II

Kazuo UEDA, Michinori WAKI,* Yoshio TERUYA,† and Nobuo IZUMIYA†
Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
†Laboratory of Chemistry, Kurume Institute of Technology, Kurume, Fukuoka 830
(Received December 2, 1988)

In a search for a more effective synthetic route for AM-toxins (cyclic tetradepsipeptides), the syntheses of [L-Phe³]AM-toxin II as a preliminary peptide and AM-toxin II as a target were attempted. The cyclization of H-L-Ser(Bzl)-L-Ala-L-Hmb-L-Phe-ONSu (Hmb, 2-hydroxy-3-methylbutanoic acid) in pyridine gave a cyclic monomer in high yield (59%). The removal of *O*-Bzl in the cyclopeptide and a subsequent dehydration of Ser with carbodiimide-CuCl afforded [L-Phe³]AM-toxin II in 24% yield. AM-Toxin II was synthesized in similar yield as in the case of the analog. The characteristic features of synthetic AM-toxin II were identical to those of the natural one.

AM-Toxins are host-specific phytotoxins and cause a spot disease on apple leaves. The structures of three congeners (I, II, and III) of AM-toxins were determined to be cyclotetradepsipeptides, the structure of the II being shown in Fig. 1. AM-Toxin I and III contain L-Amp and L-Ahp, respectively, instead of L-App residue at position 3.[1] We have already synthesized three congeners in order to confirm their structures, and also various analogs to clarify the structure-activity relationship. However, the synthetic yield has still been unsatisfactory from the standpoints of two crucial steps involving preferential monomeric cyclization from linear tetrapeptides and effective ΔAla formation in cyclotetrapeptide. Therefore, it has been our continuing interest to search for more facile synthetic routes for AM-toxins.

We previously found that the cyclization of a linear tetrapepetide containing an L-Ser residue at N-terminus gave a considerable amount of cyclic polymers in addition to the desired cyclic monomer (see, Table 1),[2,3] while a linear peptide with a D-Ser residue gave a cyclic monomer exclusively.[2] However, the subsequent conversion of the D-Ser residue in cyclotetrapeptide into ΔAla with Tos-Cl, followed by Et_2NH (Photaki method), was impossible because of a steric hindrance of the D-Ser (see, Table 2).[2] On the contrary, the L-Ser in cyclopeptide was converted into ΔAla, even though yields were poor (15% and 2% in Table 2).[3,4]

In the present study, we first attempted an easier

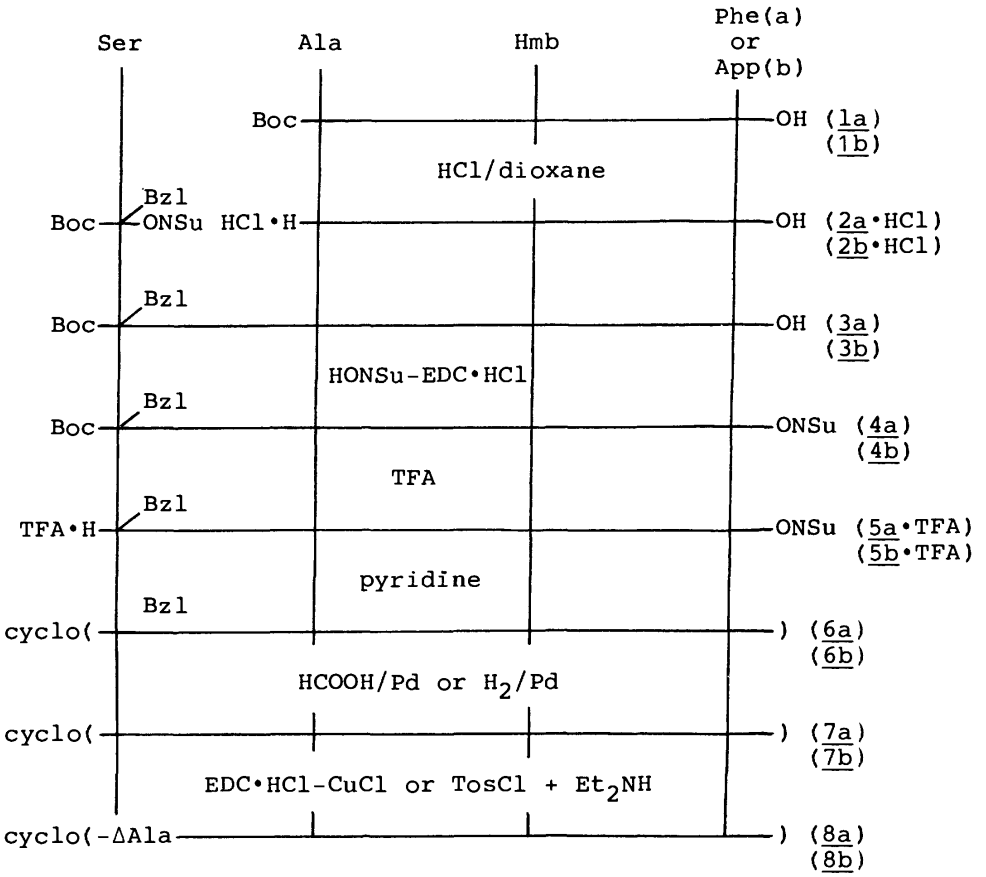

Fig. 2. Synthesis of [L-Phe^3]AM-toxin II (**8a**) and AM-toxin II (**8b**).

synthesis of cyclopeptide with the L-Ser residue from a linear peptide precursor. In a peptide synthesis, there is a tendency that a peptide with an L-Ser(Bzl) residue is obtained as a better crystalline product than a peptide with L-Ser. We therefore chose H-Ser(Bzl)-Ala-Hmb-Phe-ONSu (**5a**) as a preliminary precursor, the synthetic route of **5a** being shown in Fig. 2. Then, the cyclization of **5a** was carried out in pyridine at a concentration of 3 mM (1 M=1 mol dm^{-3}) at 20 °C for 2 d. Unexpectedly, the TLC of the reaction mixture showed the presence of a major cyclic monomer (**6a**) and a trace cyclic polymer. Indeed, an isolated solid was almost **6a**; and pure **6a** was obtained in good yield (59%) after simple recrystallization. The results indicate that the cyclization-mode of a linear tetrapeptide precursor is influenced by not only the configuration, but also the side-chain nature of the N-terminal amino acid residue in the precursor. For the synthesis of AM-toxin II, the cyclization of **5b** with L-App was carried out similarly in pyridine, and pure

6b was obtained in 57% yield.

The removal of the *O*-Bzl group in **6a** and **6b** was achieved by catalytic transfer hydrogenation[5] using Pd black and formic acid in almost quantitative yield after 2 h to produce the desired **7a** and **7b**. The **6a** was subjected to conventional hydrogenation in a solvent of DMF with Pd black; **7a** was obtained after 7d in 76% yield.

Secondly we attempted an easier formation of the ΔAla residue from L-Ser in **7a**. Recently, Miller reported an efficient one-pot dehydration of the Ser derivative to form the ΔAla derivative using carbodiimide and CuCl.[6] Thus, we examined the applicability of the Miller method for the synthesis of [L-Phe[3]]AM-toxin II (**8a**) from cyclotetrapeptide (**7a**) containing the L-Ser residue. The **7a** was treated with hydrochloride of water-soluble carbodiimide (EDC·HCl) in the presence of CuCl. In this case, more reagents and a longer time than reported in the literature[6] were needed for the completion of the reaction; however, we could obtained pure **8a** in 24% yield. When the Photaki method[7] was applied to **7a**, the yield of pure **8a** was 6.5%. We applied the procedure of the Miller method for **7b**, and could isolate pure AM-toxin II (**8b**) in 20% yield. The physicochemical properties of **8b** were identical to those reported for natural AM-toxin II, and the minimum toxic activity of the **8b** and natural II was the same for the induction of necrosis on apple leaves.

For the syntheses of natural AM-toxins and their analogs, a route using the D-Dpr residue[8] has been giving the best yield; the yields for the cyclization of the linear peptide and dehydration in cyclotetrapeptide are approximately 57%[9] (Table 1) and 26%[9] (Table 2), respectively. Yields in the present study are comparable with those in the D-Dpr route; it should be further noted that the preparation of an amino acid, L-Ser(Bzl), is easier than that of D-Dpr(Z). Thus, we believe that the present study gives a facile method for synthesizing AM-toxin II and other related cyclotetrapeptides.

Experimental

Optical rotations were measured with a JASCO polarimeter Model DIP-140. Mass spectra were taken on a Jeol mass spectrometer Model JMS-01SG operating at 75 eV. IR spectra were recorded with KBr disks on a JASCO IRA-2 spectrophotometer. UV spectra were taken on a Hitachi 124 spectrophotometer. TLC was performed on silica gel 60 F_{254} pre-coated plates (Merck) with the following solvent systems: R_f^1, $CHCl_3$–MeOH (5:1); R_f^2, $CHCl_3$–MeOH–AcOH (95:5:1); R_f^3, *n*-BuOH–AcOH–H_2O (4:1:1); R_f^4, *n*-BuOH–AcOH–pyridine–H_2O (15:3:10:12); R_f^5, EtOAc–$CHCl_3$ (1:1).

Boc-Ala-Hmb-Phe-OH (1a). Boc-Ala-Hmb-Phe-OBzl (5.27 g, 10 mmol)[2] dissolved in THF (20 ml) was hydrogenated in the presence of Pd black at 20 °C for 5 h. After removal of the catalyst, the filtrate was evaporated in vacuo and the residual oil was solidified by the addition of hexane. The resulting solid was recrystallized from EtOAc-ether-hexane: yield, 3.99 g (91%); mp 145 °C; $[\alpha]_D^{25}$ −6.9° (*c* 1, $CHCl_3$); R_f^1 0.49, R_f^2 0.33.

Found: C, 60.58; H, 7.37; N, 6.40%. Calcd for $C_{22}H_{32}O_7N_2$: C, 60.53; H, 7.39; N, 6.42%.

Boc-Ala-Hmb-App-OH (1b). Boc-Ala-Hmb-ONSu (2.07 g, 5.4 mmol)[10] was added to a suspension of H-L-App-OH (1.14 g, 5.9 mmol)[11] and Et_3N (0.83 ml, 5.9 mmol) in DMF (40 ml) at 0 °C. The mixture was stirred at 4 °C for 24 h, and the filtrate was evaporated. The residue was dissolved in EtOAc (80 ml) and washed with 10% citric acid and water, and dried over $MgSO_4$. After evaporation, the residual oil was solidified by the addition of petroleum ether, and the resulting solid was recrystallized from EtOAc–ether–petroleum ether: yield, 2.10 g (84%); mp 113 °C; $[\alpha]_D^{20}$ −10.2° (*c* 1, $CHCl_3$); R_f^1 0.56.

Found: C, 61.84; H, 7.81; N, 6.00%. Calcd for $C_{24}H_{36}O_7N_2$: C, 62.05; H, 7.81; N, 6.03%.

H-Ala-Hmb-Phe-OH·HCl (2a·HCl). Compound **1a** (3.49 g, 8 mmol) was dissolved in dioxane (13 ml) and treated with 6 M HCl in dioxane (13.3 ml, 80 mmol) at 20 °C for 3 h. The solvent was evaporated, and the residual solid was triturated with ether and collected: yield, 2.96 g (99%); mp 206—208 °C; $[\alpha]_D^{25}$ −18.5° (*c* 1, DMF); R_f^3 0.33.

H-Ala-Hmb-App-OH·HCl (2b·HCl). This compound was prepared from **1b** (1.86 g, 4 mmol) as described for **2a**·HCl: yield, 1.60 g (100%); mp 198—199 °C; $[\alpha]_D^{25}$ −17.3° (*c* 1, DMF); R_f^3 0.38.

Boc-Ser(Bzl)-Ala-Hmb-Phe-OH (3a). Boc-L-Ser(Bzl)-ONSu (2.88 g, 7.4 mmol)[12] was added to a solution of **2a**·HCl (2.61 g, 7 mmol) and Et_3N (1.96 ml, 14 mmol) in DMF (30 ml) at 0 °C. The mixture was stirred at 0 °C for 1 h and at 20 °C overnight. The mixture was treated as described for **1a**: yield, 4.20 g (98%); mp 103 °C; $[\alpha]_D^{25}$ −4.3° (*c* 1, $CHCl_3$); R_f^1 0.43.

Found: C, 62.40; H, 6.99; N, 6.79%. Calcd for $C_{32}H_{43}O_9N_3$: C, 62.62; H, 7.06; N, 6.85%.

Boc-Ser(Bzl)-Ala-Hmb-App-OH (3b). This compound was prepared from Boc-L-Ser(Bzl)-ONSu (1.57 g, 4 mmol) and **2b**·HCl (1.73 g, 4.3 mmol) as described for **3a**: yield, 2.07 g (81%); mp 114 °C; $[\alpha]_D^{20}$ −0.4° (*c* 1, $CHCl_3$); R_f^1 0.48.

Found: C, 62.79; H, 7.37; N, 6.64%. Calcd for $C_{34}H_{47}O_9N_3 \cdot 1/2H_2O$: C, 62.75; H, 7.44; N, 6.46%.

Boc-Ser(Bzl)-Ala-Hmb-Phe-ONSu (4a). To a stirred solution of **3a** (3.68 g, 6 mmol) and HONSu (1.04 g, 9 mmol) in DMF was added EDC·HCl (1.50 g, 7.8 mmol) at 0 °C. The mixture was stirred at 4 °C for 24 h. After evaporation, the residue was solidified by the addition of cold water and dried in vacuo over P_2O_5: yield, 4.30 g (100%); R_f^1 0.83, R_f^2 0.37. This was used to the next step without further purification.

Boc-Ser(Bzl)-Ala-Hmb-App-ONSu (4b). This compound was prepared from **3b** (1.60 g, 2.5 mmol) as described for **4a**: yield, 1.85 g (100%); R_f^1 0.73.

Cyclo(-Ala-Hmb-Phe-Ser(Bzl)-) (6a). A solution of **4a** (711 mg, 1 mmol) in TFA (4 ml) was allowed to stand at 0 °C for 30 min. After evaporation, the residual oil was solidified by the addition of ether to afford H-Ser(Bzl)-Ala-Hmb-Phe-ONSu·TFA (**5a**·TFA). This was dissolved in DMF (13 ml) and the solution was added dropwise into dry pyridine (320 ml) with stirring at 20 °C. The stirring was

continued at 20 °C for 2 d and the mixture was evaporated. The resulting solid was collected with the aid of cold water, washed with 10% citric acid and dried over P_2O_5. This was recrystallized from DMF-EtOAc: yield, 292 mg (59% from **4a**); mp 288—289 °C (decomp); $[\alpha]_D^{25}$ −140° (*c* 0.5, DMF); MS, *m/z* 495 (M^+); R_f^1 0.79, R_f^2 0.24.

Found: C, 64.43; H, 6.73; N, 8.49%. Calcd for $C_{27}H_{33}O_6N_3 \cdot 1/2H_2O$: C, 64.27; H, 6.79; N, 8.33%.

Cyclo(-Ala-Hmb-App-Ser(Bzl)-) (6b). This compound was prepared from **4b** (739 mg, 1 mmol) as described for **6a**: yield, 299 mg (57% from **4b**); mp 233—234 °C (decomp); $[\alpha]_D^{20}$ −187° (*c* 0.5, DMF); MS, *m/z* 523 (M^+); R_f^1 0.80, R_f^2 0.32.

Found: C, 65.49; H, 7.15; N, 7.97%. Calcd for $C_{29}H_{37}O_6N_3 \cdot 1/2H_2O$: C, 65.39; H, 7.19; N, 7.89%.

Cyclo(-Ala-Hmb-Phe-Ser-) (7a). This compound was prepared by catalytic transfer hydrogenation as follows. To a stirred solution of **6a** (130 mg, 0.26 mmol) in DMF (10 ml) were added Pd black and HCOOH (0.5 ml) at 20 °C. The stirring was continued at 20 °C for 2 h. The filtrate was evaporated and the residual solid was recrystallized from DMF-EtOAc: yield, 103 mg (97%); mp 219 °C; $[\alpha]_D^{25}$ −221° (*c* 0.5, DMF); MS, *m/z* 405 (M^+); R_f^1 0.31, R_f^2 0.10.

Found: C, 57.04; H, 6.58; N, 10.19%. Calcd for $C_{20}H_{27}O_6N_3 \cdot 4/5H_2O$: C, 57.21; H, 6.87; N, 10.01%.

The same compound was obtained by conventional hydrogenation. Compound **6a** (53 mg, 0.11 mmol) in DMF (4 ml) was hydrogenated in the presence of Pd black at 20 °C for 7 d. The filtrate was treated as above: yield, 34 mg (76%); mp 218 °C; $[\alpha]_D^{25}$ −220° (*c* 0.5, DMF); R_f^1 0.31, R_f^2 0.10.

Cyclo(-Ala-Hmb-App-Ser-) (7b). This compound was prepared from **6b** (236 mg, 0.45 mmol) by catalytic transfer hydrogenation as described for **7a**: yield, 182 mg (93%); mp 199—200 °C; $[\alpha]_D^{20}$ −248° (*c* 0.5, DMF); MS, *m/z* 433 (M^+); R_f^1 0.44.

Found: C, 58.99; H, 7.13; N, 9.48%. Calcd for $C_{22}H_{31}O_6N_3 \cdot 4/5H_2O$: C, 58.99; H, 7.34; N, 9.38%.

Cyclo(-Ala-Hmb-Phe-ΔAla-) ([L-Phe³]AM-toxin II, 8a). This compound was prepared by Miller method as follows. To a suspension of **7a** (41 mg, 0.1 mmol) in CH_2Cl_2 (10 ml) were added CuCl (5 mg, 0.05 mmol) and EDC·HCl (38 mg, 0.2 mmol). The mixture was refluxed with stirring in the dark. After 2 d, the same amounts of CuCl and EDC·HCl were added, the stirring being continued for further 4 d. Then, the solution was evaporated, and the residue was dissolved in $CHCl_3$ (3 ml). The solution was applied to a silica-gel column (0.9×9 cm, Wako silica gel C-200, 100—200 mesh) and eluted with a solvent of $CHCl_3$–acetone (4:1). The fractions (9—42 ml) were evaporated and the residual solid was recrystallized from EtOAc–petroleum ether: yield, 9.3 mg (24%); mp 230—232 °C; MS, *m/z* 387 (M^+); IR (KBr) 1740, 1655, 1630, 1520, 1040 cm^{-1}; R_f^2 0.24, R_f^3 0.81, R_f^4 0.86, R_f^5 0.24. Reported value,[2] mp 231—232 °C.

Found: C, 61.12; H, 6.65; N, 10.65%. Calcd for $C_{20}H_{25}O_5N_3 \cdot 1/3H_2O$: C, 61.05; H, 6.58; N, 10.68%.

Same **8a** was prepared by the Photaki method as follows. To a chilled solution of **7a** (80 mg, 0.2 mmol) in pyridine (2 ml) was added Tos-Cl (76 mg, 0.4 mmol) at 0 °C. After 24 h, the solution was evaporated and the solid was collected by the aid of cold water. The solid was washed with a mixture of ether–petroleum ether to remove excess Tos-Cl: yield of cyclo(-Ala-Hmb-Phe-Ser(Tos)-), 105 mg (94%); R_f^5 0.64. This tosylated cyclopeptide (105 mg, 0.19 mmol) in DMF (1 ml) was treated with 1 M Et_2NH in dioxane (0.38 ml, 0.38 mmol) at 20 °C. After 6 h the solution was evaporated and the solid was collected with cold water. The solid was suspended in EtOAc (4 ml), and the filtrate was subjected to purification by preparative TLC on silica gel 60 F_{254} precoated plate (layer thickness: 2 mm, Merck) using a solvent EtOAc–$CHCl_3$ (1:1). A portion of R_f^5 0.16 on the plate was extracted with EtOAc, evaporated and the solid was recrystallized from EtOAc–ether–petroleum ether: yield, 4.7 mg (6.5% from **7a**); mp 228—230 °C; R_f^2 0.24, R_f^4 0.86.

Cyclo(-Ala-Hmb-App-ΔAla-) (AM-toxin II, 8b). This compound was prepared from **7b** (43 mg, 0.1 mmol) by the procedure of Miller as described for **8a**: yield, 8.2 mg (20%); mp 212—213 °C; MS, *m/z* 415 (M^+); IR (KBr) 1656, 1630, 1519, 1040 cm^{-1}; UV λ_{max} (MeOH) 202 nm (ε 5500), 208 (11300), 224 (6000), 267 (800); R_f^2 0.30, R_f^3 0.83, R_f^4 0.87, R_f^5 0.30. Reported values; mp 213—214 °C,[13] 212—213 °C.[2]

Bioassays. Bioassays on apple leaves (susceptible cultivar, Indo) was carried out as described in the literature.[13] Compound **8b** and natural AM-toxin II possessed the same minimum toxic activity for the induction of necrosis at 0.02 μg ml^{-1}, where [L-Phe³]AM-toxin II (**8a**) showed the activity at 20 μg ml^{-1} level.

Synthesis of a Functionalized Carbocyclic Skeleton of Ptaquilosin, the Aglycone of a Bracken Carcinogen Ptaquiloside Based on an Intramolecular Diels-Alder Reaction

Hideo KIGOSHI, Akihiko SAWADA, Haruki NIWA, and Kiyoyuki YAMADA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received December 10, 1988)

A tricyclic compound **13** possessing the carbocyclic skeleton of ptaquilosin (**2**), the aglycone of a bracken carcinogen ptaquiloside (**1**) has been synthesized by the intramolecular Diels-Alder reaction of trienes **12a** and **12b**.

Since the carcinogenicity of bracken fern (*Pteridium aquilinum*: "warabi" in Japanese) was found in 1960,[1] studies in search for the carcinogen(s) have been carried out intensively: we isolated ptaquiloside (**1**) as a carcinogenic principle from bracken in 1983, determined the structure,[2] and proved its potent carcinogenicity.[3] Ptaquilosin (**2**),[4] the aglycone of **1** is a norsesquiterpene of the illudane-type. Illudin-S (**3**)[5] and -M (**4**)[5] are the representative members of the illudane-type sesquiterpenes and the total synthesis of **3** and **4** was reported.[6] Some synthetic studies on this class of sesquiterpenes have been reported.[7]

In connection with the synthesis of ptaquilosin (**2**), we have synthesized the functionalized carbocyclic skeleton of **2** based on the intramolecular Diels-Alder reaction. The Diels-Alder reaction of allylidenecyclopropane with various dienophiles to form spiro[2.5]-oct-4-enes was reported by Krief and Zutterman.[8] We attempted to utilize the Diels-Alder reaction of this type intramolecularly for a triene **11a** and for a stereoisomeric mixture of **12a** and **12b** toward the construction of the tricyclic carbon skeleton of **2**.

The triene **11a** was prepared as follows. Diethyl cyanomethylphosphonate[9] was alkylated with the iodide **5**[10] to afford the phosphonate **6** (91%), the reaction of which with the aldehyde **7**[11] provided the diene **8**[12,13] (54%, $Z:E=8:1$).[14] After removal of the tetrahydropyranyl protecting group in **8**, the resulting alcohol **9**[12,13] was oxidized to give the aldehyde **10**[12,13] (68% overall), which on reaction with diethyl (1-cyanoethyl)phosponate[9] furnished two stereoisomeric trienes **11a**[12,13] (42%) and **11b**[12,13] (29%). When **11a** was heated, the intramolecular Diels-Alder reaction did not occur, but a mixture of dimeric products resulted. Although the intramolecular Diels-Alder reaction of **11a** in the presence of $AlCl_3$ was examined, again a mixture of the dimers was obtained. The fail-

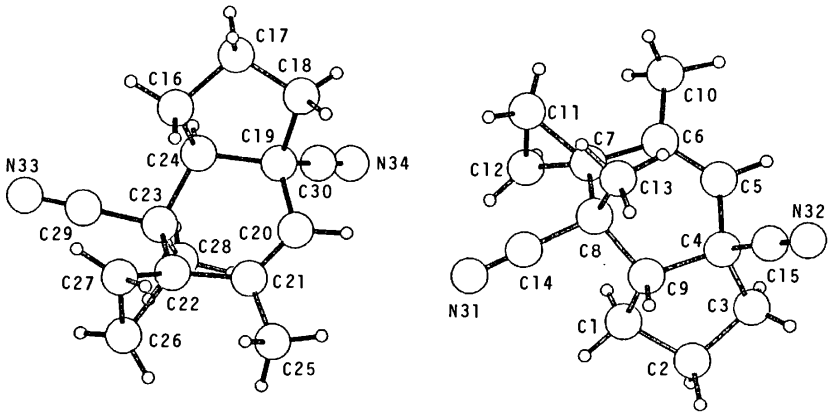

Fig. 1. Perspective drawing of the compound **14a**.

ure of the intramolecular Diels-Alder reaction of **11a** is presumably due to the steric hindrance in the transition state caused by the vinyl methyl group in the dienophilic part. Thus, the intramolecular Diels-Alder reaction of the trienes **12a** and **12b** was examined, the preparation of which follows: the reaction of **10** with diethyl cyanomethylphosphonate[9] afforded an inseparable 1:1 mixture of **12a**[12,13] and **12b**[12,13] (66%). On heating the trienes **12a** and **12b** in toluene (190—210 °C, 20 h) the tricyclic compound **13** was obtained as a single isomer (15%) together with a mixture of dimeric products (83%). The stereochemistry of **13** except for C-9 was established after conversion to the methylated derivative **14a**. The carbanion generated from **13** was methylated with methyl iodide to give two diastereomers, **14a** (mp 84—86 °C, 36%) and **14b** (mp 113—114 °C, 47%), and **14a** was subjected to X-ray crystallographic analysis. A perspective drawing of the final X-ray model of **14a** is shown in Fig. 1.[15] The result of the X-ray crystallographic analysis of **14a** reveals that the tricyclic compound **13** possesses the spirocyclopropane-containing *cis*-hexahydroindene skeleton desired for the synthesis of ptaquilosin (**2**). In summary, a functionalized tricyclic compound **13** potentially useful for the synthesis of ptaquilosin (**2**) has been synthesized, although in low yield, based on the intramolecular Diels-Alder reaction.

Experimental

Melting points are uncorrected. IR spectra were obtained in $CHCl_3$ with a JASCO IR-810 or a JASCO IR-S spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a JEOL FX-90QE spectrometer in $CDCl_3$, unless otherwise stated: chemical shifts (δ) are reported in ppm downfield from internal Me_4Si, and coupling constants are given in herz. The low-resolution mass spectra were recorded on a Hitachi RMU-6C spectrometer. The high-resolution mass spectra (HRMS) were measured on a JEOL JMS-DX300 or a JEOL JMS-LG2000 instrument. Fuji-Davison silica gel BW-820 MH was used for column chromatography. Merck precoated silica gel 60 F_{254} plates, 0.25 mm thickness, were used for thin-layer chromatography. Toluene was distilled from Na under nitrogen. Dichloromethane was distilled from CaH_2 under nitrogen. 1,2-Dimethoxyethane (DME) and tetrahydrofuran (THF) were distilled from Na-benzophenone ketyl under nitrogen. Hexamethylphosphoric triamide (HMPT) and dimethyl sulfoxide (DMSO) were distilled from CaH_2 under reduced pressure. Organic solutions were washed with saturated NaCl solution, dried over anhydrous Na_2SO_4, and concentrated under reduced pressure by a rotary evaporator.

Phosphonate 6. To a solution of diethyl cyanomethylphosphonate[9] (378 mg, 2.14 mmol) in DME (4 ml) was added KH (35% dispersion in mineral oil, 0.24 g, 2.10 mmol) under nitrogen. The suspension was stirred at room temperature for 1.5 h and then a solution of **5**[10] (582 mg, 2.05 mmol) in DME (2 ml) was added. The reaction mixture was stirred at room temperature for 2 h, diluted with the 0.25 M phosphate buffer solution (pH 7.0, 15 ml) (1 M=1 mol dm^{-3}), and extracted with EtOAc (3×20 ml). The combined extracts were washed with saturated NaCl solution, dried, and concentrated. The crude product was purified by chromatography on silica gel (15 g, EtOAc) to give **6** (644 mg, 91%) as a colorless oil: IR 2250, 1265, and 1025 cm^{-1}; ^1H NMR (90 MHz) δ=1.20—2.10 (12H, m), 1.39 (6H, t, J=7.0 Hz), 2.92 (1H, m), 3.20—4.00 (4H, m), 4.24 (4H, m), and 4.59 (1H, m); MS m/z (rel intensity) 333 (M^+; 2), 304 (2), 278 (3), 250 (40), 249 (40), 233 (60), 232 (60), 219 (30), 204 (50), 176 (75), and 165 (100). HRMS Found: m/z 333.1692. Calcd for $C_{15}H_{28}NO_5P$: M, 333.1705.

Diene 8. To a solution of **6** (2.17 g, 6.52 mmol) in DME (22 ml) was added KH (35% dispersion in mineral oil, 0.76 g, 6.65 mmol) under nitrogen. The mixture was stirred at room temperature for 1.5 h and then a solution of **7**[11] (0.99 g, 10.3 mmol) in DME (4 ml) was added. After being stirred at room temperature for 1 h, the reaction mixture was poured into the 0.25 M phosphate buffer solution (pH 7.0, 50 ml) containing hydroquinone (40 mg). The mixture was extracted with EtOAc (3×50 ml) and the combined extracts were washed with saturated NaCl solution, dried, and concentrated. The residue was separated by chromatography on silica gel (30 g, hexane/EtOAc=10:1) to afford an 8:1 mixture of (*Z*)-**8**[12] and (*E*)-**8**[12] (974 mg, 54%) as a colorless oil: IR 3010, 2210, 1735, and 1605 cm^{-1}; MS m/z (rel intensity) 275 (M^+; 2), 191 (20), 118 (20), and 85 (100). HRMS Found: m/z 275.1886. Calcd for $C_{17}H_{25}NO_2$: M, 275.1885.

^{1}H NMR (90 MHz) of (*Z*)-**8**:[16] δ=1.22 (4H, m), 1.35—1.90 (10H, m), 2.25 (3H, m), 2.10—2.50 (2H, m), 3.20—4.00 (4H, m), 4.56 (1H, m), and 6.71 (1H, br s). The *Z*/*E* ratio of **8** was determined by ^{1}H NMR spectral analysis.

Alcohol 9. A solution of **8**[13] (974 mg, 3.54 mmol) and hydroquinone (9 mg) in AcOH (30 ml)–H_2O (10 ml) was stirred at 45 °C for 1 h under nitrogen and then concentrated. The residue was dissolved in toluene (10 ml) and the solution was concentrated under reduced pressure. The residue was purified by chromatography on silica gel (20 g, hexane/EtOAc=2:1) to provide **9**[12,13] (513 mg, 76%) as a colorless oil: IR 3620, 3450 (broad), 3010, 2210, 1735, and 1605 cm^{-1}; MS *m*/*z* (rel intensity) 191 (M^+; 15), 176 (4), and 118 (100). HRMS Found: *m*/*z* 191.1289. Calcd for $C_{12}H_{17}NO$: M, 191.1310. ^{1}H NMR (90 MHz) of (*Z*)-**9**:[16] δ=1.23 (4H, m), 1.45—1.85 (5H, m), 2.25 (3H, m), 2.10—2.50 (2H, m), 3.67 (2H, br t, *J*=6.5 Hz), and 6.71 (1H, br s).

Aldehyde 10. To a solution of oxalyl dichloride (0.31 ml, 3.56 mmol) in CH_2Cl_2 (7 ml) was added a solution of DMSO (0.50 ml, 7.18 mmol) in CH_2Cl_2 (1.5 ml) at −65 °C under nitrogen. The mixture was stirred at −65 °C for 2 min, and then a solution of **9**[13] (0.34 g, 1.78 mmol) and hydroquinone (4 mg) in CH_2Cl_2 (4 ml) was added. The mixture was stirred at −60 °C for 15 min and Et_3N (2.5 ml, 18.0 mmol) was added. After stirring at −50 °C for 5 min, the reaction mixture was allowed to warm to room temperature and was kept for 1 h. Water (20 ml) was added to the mixture and the resulting mixture was extracted with CH_2Cl_2 (3×20 ml). The combined extracts were washed with saturated NaCl solution, dried, and concentrated. The residue was separated by chromatography on silica gel 10 g, hexane/EtOAc=6:1) to give **10**[12-13] (0.30 g, 89%) as a colorless oil: IR 3020, 2210, 1725, and 1625 cm^{-1}; MS *m*/*z* (rel intensity) 189 (M^+; 5), 174 (1), 160 (5), and 118 (100). HRMS Found: *m*/*z* 189.1147. Calcd for $C_{12}H_{15}NO$: M, 189.1154. ^{1}H NMR (90 MHz) of (*Z*)-**10**:[16] δ=1.25 (4H, m), 1.50—2.10 (2H, m), 2.27 (3H, m), 2.15—2.65 (4H, m), 6.71 (1H, br s), and 9.79 (1H, t, *J*=1.5 Hz).

Trienes 11a and 11b. To a solution of diethyl (1-cyanoethyl)phosphonate[9] (151 mg, 0.791 mmol) in DME (3 ml) was added KH (35% dispersion in mineral oil, 86 mg, 0.753 mmol) under nitrogen. The suspension was stirred at room temperature for 1.5 h and then a solution of **10**[13] (113 mg, 0.592 mmol) and hydroquinone (2 mg) in DME (1 ml) was added. The mixture was stirred at room temperature for 2.5 h and then to this mixture was further added the carbanion solution, prepared from diethyl (1-cyanoethyl)phosphonate (54 mg, 0.28 mmol) and KH (35% dispersion in mineral oil, 33 mg, 0.29 mmol) in DME (0.5 ml) as described above. After stirring at room temperature for further 30 min, the mixture was diluted with H_2O (5 ml) and extracted with EtOAc (4×5 ml). The combined extracts were washed with saturated NaCl solution and dried. Hydroquinone (23 mg) was added to the EtOAc solution, which was concentrated. The oily residue was purified by chromatography on silica gel (10 g, hexane/ether=8:1) to provide **11a**[12,13] (colorless oil, 56.9 mg, 42%) and **11b**[12,13] (colorless oil, 37.5 mg, 29%), respectively.

11a: IR 3020, 2220, 1735, 1645, and 1605 cm^{-1}; MS *m*/*z* (rel intensity) 226 (M^+; 10), 211 (8), and 118 (100). HRMS Found: *m*/*z* 226.1477. Calcd for $C_{15}H_{18}N_2$: M, 226.1470. ^{1}H NMR (90 MHz) of (3*Z*)-**11a**:[16] δ=1.26 (4H, m), 1.50—2.00 (2H, m), 1.94 (3H, d, *J*=1.5 Hz), 2.20—2.55 (4H, m), 2.27 (3H, m), 6.13 (1H, tq, *J*=7.5, 1.5 Hz), and 6.54 (1H, br s).

11b: IR 3020, 2220, 1735, 1640, and 1605 cm^{-1}; MS *m*/*z* (rel intensity) 226 (M^+; 10), 211 (15), and 118 (100). HRMS Found: *m*/*z* 226.1490. Calcd for $C_{15}H_{18}N_2$: M, 226.1470. ^{1}H NMR (90 MHz) of (3*Z*)-**11b**:[16] δ=1.25 (4H, m), 1.40—2.00 (2H, m), 1.88 (3H, d, *J*=1.5 Hz), 2.00—2.55 (4H, m), 2.27 (3H, m), 6.34 (1H, tq, *J*=7.5, 1.5 Hz), and 6.72 (1H, br s).

Trienes 12a and 12b. To a solution of diethyl cyanomethylphosphonate[9] (434 mg, 2.45 mmol) in DME (5 ml) was added KH (35% dispersion in mineral oil, 0.27 g, 2.36 mmol) under nitrogen. The suspension was stirred at room temperature for 50 min, and then a solution of **10**[13] (300 mg, 1.59 mmol) and hydroquinone (3 mg) in DME (4 ml) was added. The mixture was stirred at room temperature for 1 h, diluted with H_2O (20 ml), and extracted with EtOAc (4×10 ml). The combined extracts were washed with saturated NaCl solution, dried, and concentrated. The oily residue was separated by chromatography on silica gel (10 g, hexane/EtOAc=6:1) to afford an inseparable 1:1 mixture[14] of **12a**[12,13] and **12b**[12,13] (268 mg, 66%) as a colorless oil: IR 3030, 3020, 2230, 2210, 1735, 1635, and 1605 cm^{-1}; MS *m*/*z* (rel intensity) 212 (M^+; 5), 197 (3), and 118 (100). HRMS Found: *m*/*z* 212.1300. Calcd for $C_{14}H_{16}N_2$: M, 212.1313. ^{1}H NMR (90 MHz) of (3*Z*)-**12a**[16] and (3*Z*)-**12b**:[16] δ=1.26 (4H, m), 1.50—2.00 (2H, m), 2.00—2.65 (4H, m), 2.27 (3H, m), 5.37 (1H, m), and 6.35—6.90 (2H, m).

Tricyclic Compound 13. A solution of the 1:1 mixture of **12a**[13] and **12b**[13] (23 mg, 0.11 mmol) and hydroquinone (1 mg) in toluene (1 ml) in a Pyrex sealed tube under nitrogen was heated at 190—210 °C for 20 h. The solution was concentrated and the residue was separated by chromatography on silica gel (2 g, hexane/EtOAc=6:1) to give **13** (3.4 mg, 15%) and a mixture of dimeric products (19 mg, 83%).

13: colorless oil; IR 3020, 2230, 1655, and 1450 cm^{-1}; ^{1}H NMR (90 MHz) δ=0.75—1.25 (4H, m), 1.50 (3H, d, *J*=1.5 Hz), 1.70—2.40 (6H, m), 2.76 (1H, m), 3.34 (1H, d, *J*=4.0 Hz), and 5.33 (1H, br s); ^{13}C NMR (22.5 MHz, C_6D_6) δ=8.2 (t), 10.6 (t), 18.1 (s), 18.2 (q), 22.8 (t), 26.4 (t), 35.8 (d), 38.9 (t), 41.8 (s), 45.7 (d), 118.5 (s), 121.8 (d), 122.6 (s), and 137.7 (s); MS *m*/*z* (rel intensity) 212 (M^+; 65), 197 (30), 185 (35), 170 (100), and 155 (75). HRMS Found: *m*/*z* 212.1283. Calcd for $C_{14}H_{16}N_2$: M, 212.1313. The mixture of dimeric products: colorless oil; IR 3020, 2220, and 1635 cm^{-1}; ^{1}H NMR (90 MHz) δ=−0.10—1.00 (8H, m), 1.30—1.90 (6H, m), 1.50 (6H, br s), 2.10—2.65 (6H, m), 5.25—5.50 (3H, m), and 6.25—6.90 (3H, m); MS *m*/*z* (rel intensity) 424 (M^+; 35), 409 (30), 358 (20), 344 (30), and 330 (100).

Methylation of 13. To a stirred solution of diisopropylamine (0.35 ml, 2.50 mmol) in THF (8.35 ml) at 0 °C was added dropwise a 1.64 M solution of *n*-BuLi in hexane (1.3 ml, 2.1 mmol) under nitrogen, and the solution was stirred for 10 min. The 0.2 M solution of LDA described above (1.0 ml, 0.2 mmol) was added to a solution of **13** (11 mg, 0.052 mmol) in THF (0.06 ml) at 0 °C and the mixture was stirred at 0 °C for 40 min under nitrogen. To this mixture was added a solution of MeI (13 μl, 0.21 mmol) and HMPT (18 μl, 0.10 mmol) in THF (0.17 ml). The mixture was stirred at 0 °C for 1 h, diluted with 1 M HCl (2 ml), and extracted with ether (3×5 ml). The combined extracts were washed with saturated $NaHCO_3$ solution and saturated NaCl solution successively, dried, and concentrated. The

residue was separated by chromatography on silica gel (2 g, hexane/EtOAc=10:1 to 4:1) to afford **14a** (4.2 mg, 36%) and **14b** (5.5 mg, 47%).

14a: mp 84—86 °C (hexane); IR 3020, 2230, 1650, and 1450 cm^{-1}; ^1H NMR (90 MHz) δ=0.55—1.20 (4H, m), 1.20—2.50 (6H, m), 1.50 (3H, d, J=1.5 Hz), 1.65 (3H, s), 2.73 (1H, br t, J=8.5 Hz), and 5.33 (1H, br s); MS m/z (rel intensity) 226 (M^+; 80), 211 (70), 199 (35), 197 (35), and 184 (100). HRMS Found: m/z 226.1488 . Calcd for $C_{15}H_{18}N_2$: M, 226.1470.

14b: mp 113—114 °C (hexane-benzene); IR 3020, 2230, 1650, and 1450 cm^{-1}; ^1H NMR (90 MHz) δ=0.75—1.10 (4H, m), 1.21 (3H, s), 1.54 (3H, d, J=1.5 Hz), 1.60—2.50 (6H, m), 2.77 (1H, br t, J=8.5 Hz), and 5.45 (1H, br s); MS m/z (rel intensity) 226 (M^+; 90), 211 (85), 199 (80), and 184 (100). HRMS Found: m/z 226.1481. Calcd for $C_{15}H_{18}N_2$: M, 226.1470.

X-Ray Crystallographic Analysis of 14a. Crystals of **14a** were obtained by slow crystallization from hexane. D_m was measured by floatation. Crystal data of **14a** were as follows: $C_{15}H_{18}N_2$, M=226.32; monoclinic, space group $P2_1/n$, a=16.770(2) Å, b=11.076(1) Å, c=15.745(1) Å, β=117.91(1)°, V=2584.6(4) $Å^3$; D_c=1.163 g cm^{-3}, D_m=1.163 g cm^{-3}; Z=8; μ=4.565 cm^{-1}; crystal size 0.30×0.25×0.20 mm. Total 4764 reflections with $2\theta \leqq 126°$ were collected on a RIGAKU ARC-5R automated four-circle diffractometer using graphite monochromated Cu $K\alpha$ radiation (1.54178 Å). Structure was solved by Monte-Carlo direct method[17] with the aid of MULTAN 78 program system[18] using 4097 unique reflections with $|F_o| \geqq \sigma(|F_o|)$ and refined by full-matrix least-square program. Non-H atoms were assigned with anisotropic thermal parameters. All H atoms were located in a difference Fourier map and refined with the equivalent isotropic thermal parameters to those for the bonded atoms. The final unweighted R factor was 0.09 after minimizing $\sum\omega(|F_o|^2-|F_c|^2)^2$ with $\omega=1/\sigma^2(F_o^2)$; R_w=0.13, S=3.8. Atomic scattering factors were from Ref. 19. PLUTO 78 program[20] was employed in drawing the computer-generated molecular structure. All crystallographic calculations were performed on a FACOM M-382 computer, operated by Computation Center of Nagoya University, using the library program of CRYSTAN system.

Immobilized β-Cyclodextrins. Preparation with Various Crosslinking Reagents and the Guest Binding Properties

Izuru SUGIURA, Makoto KOMIYAMA,† Naoki TOSHIMA,* and Hidefumi HIRAI††
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 2, 1988)

β-Cyclodextrin (β-CyD) was immobilized by crosslinking with 1,2-ethanediol diglycidyl ether, 1,4-buthanediol diglycidyl ether, 1,6-hexanediol diglycidyl ether, 1,3-butadiene diepoxide, 1,7-octadiene diepoxide, and epichlorohydrin. The molar ratio of the crosslinking residue to β-CyD (degree of crosslinking) for each macromolecular product was determined by the corresponding elemental analysis. The equilibrium constant K of complex formation of each crosslinking macromolecule for cresols, phenol, nitrophenols, and 2-naphthol was determined, respectively, by the use of electronic absorption spectroscopy in pH 4 and 10 (or 11) buffer solutions. The concept of a hydrophobic enhancement coefficient R was introduced in order to compare the effect of a hydrophobic crosslinking residue upon the complex formation of the immobilized CyD.

Cyclodextrin (CyD), a cyclic oligomer of the 6—8 glucose units, forms an inclusion complex with various kinds of guest compounds.[1] The complex formation, however, proceeds selectively, since it includes guest compounds in various ways of binding. From the viewpoint of selective complexation, CyD has been studied as an enzyme model, a selective catalyst for organic synthesis, a device for separation of mixtures, and so on.

Recently, the selective "host-guest" complex formation of β-CyD has been studied by many investigators with an interest in its utilization for the stationary phase of HPLC.[2a-d] Since CyDs are composed of natural D-glucose units and, therefore, are optically active, they are expected to be utilized as the stationary phase for the optical resolution of racemic compounds.[2b] Few investigations, however, have been made concerning the effect of the supporting groups of the stationary phase on the property of CyDs to include a guest compound. Furthermore, some kinds of these stationary phases which were investigated contain nitrogen atoms (amines and/or amides) to combine the CyD residue to the supporting gel. This existence of =NH groups is considered to result in complicated interactions between the guest molecules and the CyD residues. For instance, a hydrogen bonding of an =NH group should be very sensitive to pH and the structure of a guest molecule. It could therefore be difficult to analyze the mechanism of complex formation[2c] and, in consequence, to design an efficient stationary phase.

β-CyD forms inclusion complexes selectively with many kinds of aromatic compounds. They have been studied mainly as models of hydrolysis enzymes.[1,3,4] On the other hand, many investigators have already reported that β-CyD is very effective as a selective catalyst for bond formation.[5-7] Previously, we reported the selective synthesis of 4-hydroxybenzoic acid from phenol and carbon tetrachloride in β-CyD.[7] Moreover, we have succeeded in the immobilization of β-CyD by crosslinking with epichlorohydrin and its utilization as an immobilized catalyst for the selective synthesis of 4-hydroxybenzoic acid without any decrease in the catalytic activity.[8] An immobilized catalyst is expected to have the advantage to simplify the system by easy removal from a reaction system and repeated usage, in spite of the usual observation that the activity of the immobilized catalyst tends to decrease by immobilization.[9]

On the basis of these studies, we have prepared the immobilized β-CyD with various kinds of crosslinking reagents and have investigated the property of the inclusion phenomena.[10]

Here, we report the syntheses of various immobilized β-CyD macromolecules without nitrogen atoms, and their characteristic features to form inclusion complexes with phenol, nitrophenols, cresols, and 2-naphthol under various pH conditions. The effects of crosslinking residues on the formation of inclusion complexes are discussed from the viewpoint of hydrophobic interaction. A hydrophobic enhancement coefficient R is introduced, which indicates the contribution of the crosslinking residue to the hydrophobicity of the binding site in the immobilized CyD. The correlation between a crosslinking residue and a guest molecule is discussed by use of R.

Experimental

Materials. β-CyD from Nakarai Chemical Co. was purified by recrystallization from water. The crosslinking reagents, 1,2-ethanediol diglycidyl ether, 1,4-buthanediol diglycidyl ether, 1,6-hexanediol diglycidyl ether, 1,3-butadiene diepoxide, 1,7-octadiene diepoxide, and epichlorohydrin (Tokyo Kasei Kogyo Co.) were used without further purification. (See Fig. 1 for the structures.) Cresols, phenol, nitrophenols, 2-naphthol, and all other chemicals were

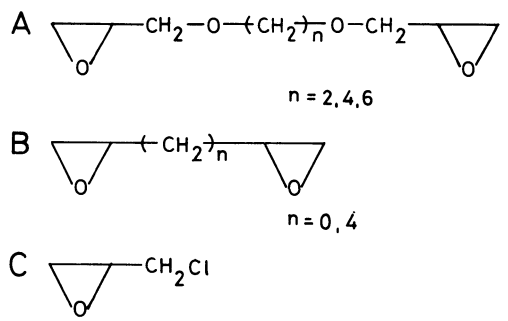

Fig. 1. Crosslinking reagents used for preparation of immobilized β-CyD.

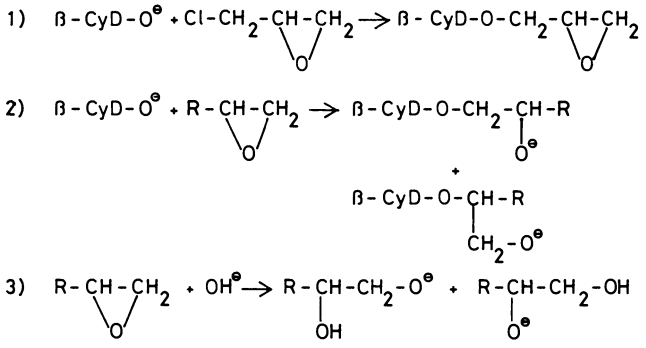
purified by the usual methods, respectively.

Preparation of Immobilized β-CyD. Immobilized β-CyDs were prepared according to the modified method we reported previously.[10] Fifty grams (44 mmol) of β-CyD were completely dissolved in 80 ml of a 50 wt% aqueous sodium hydroxide solution, to which 440 mmol of a crosslinking reagent was added dropwise. The mixtures were kept at 50 °C which being vigorously stirred with a mechanical stirrer. As the crosslinking reaction proceeded, the viscosity of the solution increased. After several hours the solid gel appeared. Then, 150 ml of acetone was added. The resulting solids were repeatedly washed with acetone and water, and were dried in vacuo at 60 °C for 24 h.

Evaluation of the Equilibrium Constants for Complex Formation of the Immobilized β-CyDs with Guest Molecules. The equilibrium constants (K) of complex formation of the immobilized β-CyD were measured for cresols, phenol, nitrophenols, and 2-naphthol. Each K value was measured at pH 4 for all guest molecules, at pH 10 for nitrophenols and 2-naphthol, and at pH 11 for phenol and cresols. The experiments were performed by incubating 200 mg of the immobilized macromolecules and the guest compounds in 10 cm^3 of buffer solutions under pH 4, 10, or 11 at 25 °C. The charged concentrations of the guest compounds ($[G]_0$) and the ionic strength were 1.0×10^{-3} and 1.0 mol dm^{-3}, respectively. After 40 h the concentrations of the solutes in the liquid phase ($[G]_{free}$) were determined by electronic absorption spectroscopy. Completions of the equilibria were confirmed by the consistency of the concentration measured after a 60 h incubation with that after 40 h. During the long-term incubation, especially in a pH 4 buffer solution, a very slow fragmentation of one part of the immobilized macromolecule was observed, probably due to the hydrolysis of the macromolecule, resulting in a dispersion of microparticles. In order to compensate the scattering by dispersion, a blank test was performed by incubation of the immobilized macromolecules in a pH 4 buffer solution for 40 h without guest compounds. The scattering absorption caused by the microparticles was measured and subtracted from the corresponding absorption in the presence of the guest compounds.

The equilibrium constants (K) for the complex formation were calculated by

$$K = \frac{[\text{Complex}]}{[\beta\text{-CyD}]_{free}\,[G]_{free}}$$



Scheme 1.

$$= \frac{[G]_0 - [G]_{free}}{([\beta\text{-CyD}]_0 - [G]_0 + [G]_{free})[G]_{free}}, \quad (1)$$

where $[G]_0$, $[G]_{free}$, and $[\beta\text{-CyD}]_0$ refer to the concentrations of the guest molecule in an initial solution, the guest molecule in the filtrate after the complex formation, and the CyD residue in the macromolecule matrix, respectively.

Equation 1 was defined on the basis of 1:1 complex formation between CyD and a guest molecule.[1] The numerator of Eq. 1 ($[G]_0-[G]_{free}$) indicates the concentration of the complex.

Evaluation of the Equilibrium Constant for Complex Formation of Free β-CyD with Guest Molecules. The equilibrium constants of the complex formation of free β-CyD with the guest molecules were evaluated according to the method reported by VanEtten et al. by using electronic absorption spectroscopy.[3b]

Results

Preparation and Characterization of Immobilized β-CyDs. Immobilization of β-CyD was carried out by a substitution or ring-opening reaction between the hydroxyl groups of β-CyD and the chlorine atoms of epichlorohydrin or the epoxide rings of the crosslinking reagents in an alkaline solution at 50 °C according to the reaction shown in Scheme 1. As shown in Scheme 1, the first step of the crosslinking reaction is a nucleophilic attack by the $-O^-$ group of β-CyD to the crosslinking reagent.[11] The spontaneous ring-opening reaction by free hydroxide OH^- proceeds at the same time (the 3rd reaction in Scheme 1), followed by the propagation reaction by the nucleophilic $-O^-$ group newly produced.

The immobilized β-CyD was obtained as a white to pale-yellow solid in sponge or beads of 1—3 mm in diameter. They are insoluble in water, methanol, ethanol, acetone, and chloroform.

The IR spectra of free β-CyD, epichlorohydrin-immobilized CyD, and 1,6-hexanediol diglycidyl ether-immobilized CyD were measured by a KBr pellet method, giving the following results: 1) The IR spectra of the immobilized CyDs maintain the specific absorptions due to free CyD. 2) The new absorption

derived from a $-(CH_2)_n-$ residue (2860—2875 cm^{-1}) appears for the immobilized CyDs. 3) The specific absorption derived from an epoxy ring (ca. 1250 cm^{-1}) is not observed for the immobilized CyDs. 4) The specific absorption derived from a $-CH_2Cl$ group (735—720 cm^{-1}) does not appear for the epichlorohydrin-immobilized CyD. 5) The absorption derived from a C-O-C stretching vibration (1070—1150 cm^{-1}) for free CyD is sharp, while that for the immobilized CyD is broad because of the crosslinkage. A new absorption derived from the C-O-C stretching vibration of the crosslinking residue (1110 cm^{-1}) appears for the 1,6-hexanediol diglycidyl ether-immobilized CyD.

The immobilized macromolecules prepared are listed in Table 1 with the results of an elemental analysis, the degree of crosslinking, and reaction conditions. The degree of crosslinking m, a molar ratio of a crosslinking residue to a β-CyD residue, is determined by calculation according to Eq. 2, by using the results of the elemental analysis of carbon in the case of the immobilized macromolecule crosslinked by diol diglydidyl ethers:

$$C(\%) = \frac{12.011[42 + (6 + n)m] \times 100}{(\text{MW of a crosslinking reagent})m + (\text{MW of } \beta\text{-CyD})}, \quad (2)$$

where m and n are the degree of crosslinking and the number of the methylene moiety of the crosslinking reagent shown in Fig. 1, respectively. The numerator of Eq. 2 intends the summation in atomic weight of the whole carbon atoms of the immobilized β-CyD per β-CyD residue. The degree of crosslinking m for the epichlorohydrin-immobilized β-CyD is calculated by a similar method.

The crosslinking reagents are not so much soluble in an aqueous solution that the reaction time required for the crosslinkage increases with the number of the hydrophobic methylene units in a reagent molecule.

The degree of crosslinking in the present system was determined to be 3—6, as shown in Table 1. Even by using the same crosslinking reagent and under the similar reaction conditions, the resulting immobilized macromolecules exhibited different values in the degree of crosslinking, depending on the lot (cf. I-3a, -3b, and -3c).

Evaluation of the Equilibrium Constants for Complex Formation of the Immobilized β-CyDs with Guest Molecules. The equilibrium of the complex formation between a β-CyD residue of the immobilized macromolecule and a guest molecule is completed by incubating the aqueous mixtures for 40 h. Since the equilibrium constant K refers the ratio of the concentration of the inclusion complex to the mathe-

matical product of the concentration of a free β-CyD residue and that of a free guest molecule, the practical K value can be evaluated by Eq 1. The equilibrium constants for the 1 : 1 complex formation of the β-CyD residues in the immobilized macromolecules with *o*-, *m*-, and *p*-cresols, and phenol (Table 2), with *o*-, *m*-, and *p*-nitrophenols (Table 3), and with 2-naphthol (Table 4) were obtained at 25 °C and are shown in tables, respectively. The 1 : 1 complex formation is confirmed by the independence of the K value from the charged amount of the immobilized CyDs in the range of 30—200 mg. The reproducibility of K was checked by using the immobilized beads of I-3a at various diameters. The equilibrium constants for *m*-nitrophenol at pH 4, for example, were 264, 268, and 254 $mol^{-1}\,dm^3$ for the small (1—3 mm in size, 2 mm in an average diameter), medium (2—7 mm in size, 4 mm in an average diameter), and large (4—7 mm in size, 6 mm in an average diameter) macromolecular beads, respectively. The result of these series of K values indicates that the reproducibility for the K measurement is fairly excellent and, in addition, the macromolecules employed here swell sufficiently for the measurement of the equilibrium constants in a limited time.

As shown in Tables 2—4, the equilibrium constant K depends on the crosslinking reagents. This suggests that the interaction between the crosslinking residue and the guest molecule exists in the complex formation of the immobilized β-CyD with the guest molecule. The effect of the degree of crosslinking on the complex formation constant K was examined by

using the immobilized β-CyDs which are crosslinked by 1,6-hexanediol diglycidyl ether and cresols as a guest molecule. The results are summarized in Table 5.

Discussion

Preparation of Immobilized β-CyDs. Immobilization of β-CyD was successfully performed by using various crosslinking reagents. These macromolecules involve no nitrogen atoms (amines and/or amides) in the linkage. The results of the IR spectra of the immobilized CyDs are in good agreement with the immobilizing reactions shown in Scheme 1. The specific absorptions of the CyD residue in the IR spectra indicate that the structure of CyD is maintained in the immobilized CyD macromolecule. The absence of the absorption bands due to an epoxy ring and a chloromethyl group indicates that the immobilizing reaction proceeds the nucleophilic attack by the hydroxyl group of β-CyD to the epoxy ring and the chloromethyl group. The insolubility of the immobilized CyD in water suggests that the macromolecule has a tangly network composed of crosslinking residues and CyD residues. Since the CyD residues have many hydroxyl groups, in fact the strong IR absorptions due to the hydroxyl groups are observed, the crosslinked macromolecules are able to swell in water.

The number of the crosslinking residues which can bind to one CyD residue (m) is 3—6, as shown in Table 1. Harada et al. reported that the substitution of the secondary hydroxyl groups by the crosslinking residues was observed in the ^{13}C NMR spectrum of the epichlorohydrin-immobilized CyD.[11] In general, however, the reactivity of the primary hydroxyl group of CyD is thought to be much higher than that of the secondary hydroxyl group of CyD.[12] In the immobilizing reactions examined here, some parts of the crosslinking residue probably bind to the secondary hydroxyl group of CyD (as the case reported before[11]), besides the primary one, because of the present severe reaction conditions with extraordinarily high concentration of sodium hydroxide. The immobilized β-CyDs I-3a, 3b, and 3c shown in Table 1 were prepared by the same crosslinking reagent (1,6-hexanediol diglycidyl ether). The charged molar ratio of the crosslinking reagent to β-CyD is the same for I-3a and I-3c, and other reaction conditions are similar to each other. The resulting immobilized β-CyDs, however, exhibit different values of the degree of crosslinking. This is probably due to the heterogeneity of the reaction system. For instance the addition rate of the crosslinking reagents and the stirring rate of the mixtures may be effective for the constitution of the macromolecules in the heterogeneous system. In case of the macromolecule I-3b, the charged molar ratio of the crosslinking reagent was 7.5 times to CyD, and less than those for I-3a and I-3c. The degree of crosslinking, however, exhibits 5.0 which is higher than that of I-3a. This reverse phenomena would be explained by the longer reaction time for I-3b. The difference in their inclusion properties will be discussed later.

Complex Formation of the Immobilized β-CyD. From the data in Tables 2, 3, and 4, one can conclude the general tendency for the complex formation. 1) The different crosslinking residues result in a different equilibrium constant K. This indicates that the crosslinking residues affect the complex formation. 2) The long crosslinking residue which has long hydrophobic moieties (A n=6) results in a large equilibrium constant, especially at pH 4. This indicates that the hydrophobic residue plays an important role in complex formation. 3) The equilibrium constant K at pH 4 is generally larger than that at pH 10 or 11. In a pH 4 buffer solution, the guest molecules are electrically neutral, while in pH 10 or 11 they are anionic, since the pK_a values of nitrophenols, cresols, and phenol are 8.0—9.3, 10.0—10.3, and 9.8, respectively. The hydroxyl group of CyD cannot dissociate into ionic species under these conditions since the pK_a of CyD is more than 12.[1] Therefore, the present result of the larger K value at pH 4 than at pH 10 or 11 indicates that the immobilized CyDs include the neutral guest molecule strongly in its hydrophobic cavity and do the anionic molecule weakly. In other words, the hydrophobic interaction is very important for inclusion complex formation.

In order to clarify the importance of the hydrophobic interaction between the crosslinking residues and guest molecules, the relation between the degree of crosslinking and the equilibrium constant K was investigated. Three types of immobilized CyDs exhibiting different degrees of crosslinking were synthesized by using 1,6-hexanediol diglycidyl ether as a crosslinking reagent. The equilibrium constants were measured for these three kinds of immobilized CyDs against cresols as guest molecules, since cresol is considered to be a proper guest molecule in order to examine the hydrophobic interaction between the guest molecule and the new binding site composed of the CyD cavity and the crosslinking residue.

In general, the hydrophobic modifying residue of CyD can affect the inclusion complex formation of the modified CyD with a guest molecule in various ways. From a micro point of view, two kinds of effects can be reasonably considered: 1) The hydrophobic modifying residue is competitively included in the cavity of CyD[13,14] so as to inhibit the inclusion of a guest molecule, resulting in the decrease of the equilibrium constant K. 2) The hydrophobic modifying residue forms a cap and/or a floor of the CyD cavity[15] so as to promote the inclusion complex formation by the

cavity, resulting in the increase of K. From a macro point of view, the other two kinds of effects are also considered: 3) The modifying residue can reduce the flexibility of the CyD residue and the movement of the guest molecule near the CyD cavity by the steric hindrance so as to hinder the inclusion complex formation,[1] resulting in the decrease of K. 4) The hydrophobic environment composed of the modifying residue can interact with a hydrophobic guest molecule so as to increase the local concentration of the guest molecule or the frequency factor of the complex formation,[16] resulting in the increase of K.

As shown in Table 5, the K value of I-3c (m=5.8) at pH 4 is much larger than those of I-3a and I-3b (m=4.5 and 5.0, respectively). From the general considerations described above, this result can be explained by the larger contribution of 2) and/or 4) than 1) and/or 3). In other words, the hydrophobic crosslinking residues in the macromolecules do enhance the complex formation with the hydrophobic guest molecules in the micro and/or macro ways.

In a preliminary communication,[10a] we reported that the K values of the 1,2-ethanediol diglycidyl ether-immobilized CyDs with the different degree of crosslinking (m=3.1 and 5.9) for p-nitrophenol are not so different from each other (K=130 and 119 mol^{-1} dm^3, respectively). This is considered to be a rather special case, since p-nitrophenol is known to interact with the CyD cavity[1] in a special way, for instance, the dipole–dipole interaction[1,17] and the crosslinking residue of 1,2-ethanediol diglycidyl ether is rather hydrophilic.

Evaluation of the Hydrophobic Coefficients of the Immobilized β-CyD. As described above, the CyD residue and the crosslinking residue in the immobilized CyD coopetate to form an inclusion complex. The crosslinking residue can affect the complex formation not only by the so-called "general polymer effect" but also by altering the quality of the binding site. To distinguish these two factors, further analysis of the equilibrium constant K was attempted by comparing the complex formation property of free CyD with that of the immobilized CyD.

A direct comparison of the K values of free and immobilized CyD for the same guest molecule under the same pH condition reflects not only the effect of the crosslinking residue to alter the complex formation ability of the CyD residue but also the other contribution of the crosslinking or "general polymer effect," for example, the effect on the diffusion of the guest molecule to access to the binding site of the CyD residue, the swelling property of the immobilized CyD, the degree of freedom of the CyD residue, and so on. These varieties of "general polymer effects" by the crosslinking residue conceal the pure property of the binding site in the immobilized CyD. To compensate this disturbance, a concept of the hydrophobic enhancement coefficient R is introduced.

The hydrophobicities of the free CyD and the immobilized CyDs can be estimated by the ratio of the corresponding K value at pH 4 to that at pH 10 (or 11), since the guest molecule is neutral or hydrophobic at pH 4 and anionic or hydrophilic at pH 10 (or 11). The influence of the crosslinking residue to the complex formation property of the CyD residue can be evaluated by the increase of the hydrophobicity by crosslinking.

On the basis of the above consideration, the hydrophobic enhancement coefficient R is defined by

$$R = \frac{K_{imm}(\text{pH 4})}{K_{imm}(\text{pH 10 of 11})} \Big/ \frac{K_{free}(\text{pH 4})}{K_{free}(\text{pH 10 or 11})}, \quad (3)$$

where K_{imm} and K_{free} are the equilibrium constants of complex formation of the immobilized β-CyDs and the free β-CyD, respectively. The ratio K_{imm}(pH 4)/K_{imm}(pH 10 or 11) indicates the ability of the immobilized CyD to discriminate a neutral guest molecule from an anionic one, reflecting the property of the hydrophobic field composed of the crosslinking residues and the CyD residue. (This hydrophobic field binds the hydrophobic part of guest molecule and repulses the anionic part of guest molecule.) In the similar way, the ratio K_{free}(pH 4)/K_{free}(pH 10 or 11) indicates the ability of free CyD to discriminate a neutral from an anionic. (This original property will be altered by the crosslinking.) In short, the ratios K_{imm}(pH 4)/K_{imm}(pH 10 or 11) and K_{free}(pH 4)/K_{free}(pH 10 or 11) reflect the hydrophobicity of the immobilized and free CyD, respectively. Thus, the ratio of these two ratios is the hydrophobic enhancement coefficient by crosslinking (R), which indicates how the crosslinking affects on

the property of the CyD binding site.

Table 6 lists the enhancement coefficients R which are calculated by using the K values listed in Table 3 according to the Eq. 3. It is surprising that the actual R values change to a great extent depending on the kind of the guest molecule but do not change with the kind of the crosslinking residues. In fact, they are 3.0—7.5 for *o*-cresol, 0.4—0.6 for *m*-cresol (except I-3a), 1.4—2.0 for *p*-cresol, and 1.3—2.4 for phenol. The coefficients Rs for *o*-cresol are largest among these, which means that the immobilization enhances the hydrophobicity of the CyD binding site so that the ability of CyD to discriminate *o*-cresol from *o*-cresolate is strengthened by the immobilization. For *p*-cresol and phenol, the Rs are larger than 1 but smaller than those for *o*-cresol, which means that the above ability is strengthened a little. For *m*-cresol, in contrast with other three guests, the Rs are smaller than 1 (except for I-3a), meaning that the ability of CyD to discriminate *m*-cresol from *m*-cresolate is weakened by the crosslinking. This large dependence of the R values on the guest molecule and the slight dependence of the crosslinking residue suggest that the quality of the effect of the crosslinking residue on the binding site alters with the structure of a guest molecule. In other words, the interaction between the crosslinking residue and the guest molecule may vary with the steric structure of the included guest molecule.

This might be explained in, for example, the following way: the crosslinking residue can form a cap and/or a floor of the CyD residue in the immobilized CyD.[11,15] The main interaction between the immobilized CyDs and cresols is a hydrophobic interaction. The most hydrophobic part of a cresol molecule is the methyl group and, then, the benzene ring.[18] Under the condition of pH 4, the CyD cavity includes these hydrophobic parts of a guest molecule, and the hydroxyl groups of the host and the guest molecules may interact with each other through hydrogen bonding. At pH 11 the hydrophobic interaction works in a similar way as that described above, even though the difference between the strengths of the interactions at pH 4 and at pH 11 is unknown. However, repulsion may arise between the anionic oxygen of cresolate and the hydrophobic field composed of the CyD residue and the crosslinking residue. The former hydrophobic interaction can promote a deep inclusion of cresolates into the CyD cavity at the position of the methyl group and the benzene ring. The latter repulsion, however, can make the anionic oxygen of the cresolates far from the CyD cavity or the hydrophobic crosslinking residue.

If these two effects, a hydrophobic interaction and a repulsion, cooperatively work to make the actual R value different from each other, depending on the isomers of cresolate, the structures of the inclusion complexes of the isomers are possibly illustrated as shown in Fig. 2. In the case of *o*-cresolate ($R \gg 1$), the methyl group of *o*-cresolate inhibits a deep inclusion of the benzene ring because of a steric hindrance, so that the anioic oxygen may be compelled to locate near the hydrophobic crosslinking residue which forms a cap or a floor for the CyD cavity. This situation can induce a strong repulsion between the anionic oxygen and the crosslinking residue, which results in the large R values for *o*-cresol. For *p*-cresolate, and phenolate ($R>1$), the inclusion may be deeper than that of *o*-cresolate so that the repulsion may exist but being weaker than that for *o*-cresolate. This results in the larger R values for *p*-cresol and phenol than 1, but smaller than those for *o*-cresol. On the contrary, the inclusion of *m*-cresolate ($R<1$) may be achieved by the structure shown in Fig. 2(b), where the methyl group of *m*-cresolate is deeply included in the CyD cavity. However, the anionic oxygen may be able to avoid the hydrophobic crosslinking residue. In this structure, the interaction between the benzene ring of the guest molecule and the hydrophobic crosslinking residue of the immobilized CyD may become favorable, resulting in the strengthening of the inclusion of the guest molecule by capping the CyD cavity with the crosslinking residue. These interactions, as a whole, result in the small R values for *m*-cresol. In the case of macromolecule I-3a (crosslinked by 1,6-hexanediol diglycidyl ether), the R for *m*-cresol is 2.2, which is exceptionally large. This peculiarity is probably derived from a strong hydrophobic field composed of a long hydrophobic residue of this macromolecule, resulting in the strong repulsion between the anionic oxygen of *m*-cresolate and the binding site of the immobilized CyD. The hydrophobic field may be so large that even for *m*-cresol R is larger than 1.

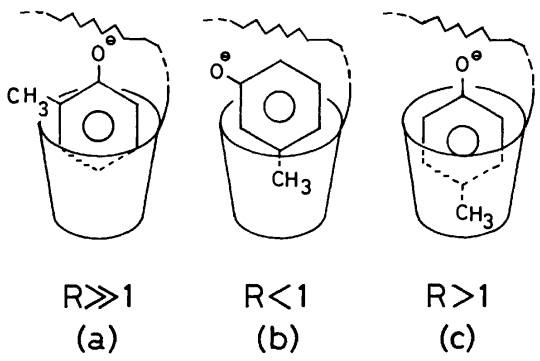

Fig. 2. Proposed structures of the complexes of the immobilized β-CyD, with *o*-, *m*-, and *p*-cresol.

The hydrophobic enhancement coefficients Rs for nitrophenols and 2-naphthol are listed in Table 7, respectively. Here again, the R value changes with the guest molecule and not so much with the crosslinking reagent. In the case of nitrophenols, the R values for the ortho-isomer is quite large in the order of the

Table 7. The Hydrophobic Enhancement Coefficient (R) for Nitrophenols and 2-Naphthol

Immobilized β-CyD[a]	Crosslinking reagent[b]	R[c]			
		Nitrophenol			2-Naphthol
		ortho	meta	para	
I-1	A (n=2)	90	3.7	0.9	0.8
I-2	A (n=4)	61	2.4	0.6	2.1
I-3a	A (n=6)	225	11.0	4.0	1.1
III	C	16	1.4	0.2	0.5

a) See Table 1 for abbreviation. b) See Fig. 1 for the chemical structures. c) The coefficient R is calculated by the Eq. 3 in the text.

magnitude of R, ortho≫meta>1>para, except for the case of the macromolecule I-3a (crosslinked by 1,6-hexanediol diglycidyl ether) for *p*-nitrophenol. It is known that a nitro group is deeply included in a CyD cavity and, in consequence, plays an important part for the inclusion complex formation.[1,17] According to the results of two-dimensional NMR studies using a nuclear Overhauser effect (NOESY), the nitro groups of *m*- and *p*-nitrophenol are suggested to be included in the CyD cavity from the secondary hydroxyl side (the wide side) of the CyD cavity; in contrast with these two guests, the nitro group of *o*-nitrophenol will be included in the cavity from the primary hydroxyl side (the narrow side) of the CyD cavity.[19] This suggests that in the immobilized CyD *o*-nitrophenol may locate near the narrow side of a CyD residue which is connected by the crosslinking residues to form a crowded and strong hydrophobic field; in consequence there may be a strong repulsion resulting in the very large R values.

For *m*- and *p*-nitrophenol, the order of the R values is reverse to that for *m*- and *p*-cresol. Though the reason is unknown there may be a special participation of the nitro group, since the interaction of the nitro group with CyD cavity can not be explained only by hydrophobic interaction and hydrogen bonding.[17]

For 2-naphthol the R is rather near unity. This might be due to the fact that the main interaction between the binding site and 2-naphthol is a hydrophobic interaction.

Conclusion

1. Many kinds of immobilized β-CyDs can be successfully synthesized as solid products by crosslinking β-CyD with six kinds of crosslinking reagents. The immobilized β-CyD prepared in the present investigations involves no nitrogen atoms (amines and/or amides) in the linkage. The degree of crosslinking was 3.6—5.8 on the basis of the elemental analysis.

2. The equilibrium constants Ks of the immobilized β-CyDs were determined for cresols, phenol, nitrophenols, and 2-naphthol. The independence of K from the amount of immobilized CyD indicates 1:1 complex formation between the CyD residue and the guest molecule.

3. The K values measured at pH 4 (a neutral guest) are generally larger than those measured at pH 10 or 11 (an anionic guest). The K values reflect the property of the crosslinking residue, indicating the participation of the crosslinking residue to the inclusion complex formation. Macromolecules containing the long crosslinking residues (I-3a, 3b, and 3c) exhibit large K values, which indicate the existence of a hydrophobic interaction between the crosslinking residue and the guest molecule. A high degree of crosslinking results in the large K values, indicating that the crosslinking residue promotes complex formation but does not inhibit it.

4. A hydrophobic enhancement coefficient R has been introduced. The R values indicate how the crosslinking residue effects on the property of the binding site for complex formation. The R values calculated from the K constants are independent of the crosslinking reagents, but dependent on the structure of the guest molecule, suggesting the expected potential for high guest selectivity of the immobilized CyD.

The authors would like to thank Mr. Katagiri for his technical assistance. The author (I. S.) would like to express his grateful thanks for the Fellowship of the Japan Society for the Promotion of Science for Japanese Junior Scientists.

Oxidation of Methoxy- and/or Methyl-Substituted Benzenes and Naphthalenes to Quinones and Phenols by H_2O_2 in HCOOH

Hideo ORITA,* Masao SHIMIZU, Takashi HAYAKAWA, and Katsuomi TAKEHIRA
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received November 25, 1988)

The oxidation of a number of arenes (methoxybenzenes, methylbenzenes, and naphthalenes) to quinones and phenols by H_2O_2 in HCOOH has been examined. Methoxybenzenes were much more easily oxidized to *p*-benzoquinones than methylbenzenes (e.g., 1,3,5-trimethoxybenzene was oxidized to 2,6-dimethoxy-*p*-benzoquinone in a 75% yield and 1,2,4-trimethylbenzene to 2,3,5-trimethyl-*p*-benzoquinone in a 16% yield). Electron-withdrawing substituents, such as nitro, cyano, and chloro groups, lowered the conversion of reactants and changed the product selectivity from quinones to phenols. Methoxybenzonitriles were oxidized to corresponding phenols in a moderate yield (e.g., 2,6-dimethoxybenzonitrile to 3-hydroxy-2,6-dimethoxybenzonitrile in a 39% yield and a 64% selectivity).

Hydrogen peroxide is an economical and clean oxidant whose waste product is only water, and can oxidize a variety of organic substrates including arenes in the presence of catalysts. However, there are few applications to organic synthesis, excepting some examples such as the manufacturing of catechol and hydroquinone from phenol.

Some of quinones are naturally occurring materials with biological activities,[1] and are the key intermediates of medicines. For example, trimethyl-*p*-benzoquinone is key compound in synthesis of vitamin E, and 2,3-dimethoxy-5-methyl-*p*-benzoquinone is useful for production of coenzyme Q, and 2-methyl-1,4-naphthoquinone is the simplest synthesized vitamin K (vitamin K_3) and used for producing vitamin K_1.[2] On the other hand, there are few papers on the direct oxidation of arenes to quinones by H_2O_2.[3-5] Ito et al.[3] reported that $RuCl_3$ catalyzed the oxidation of trimethylphenol in acidic medium to trimethyl-*p*-benzoquinone in a high yield. In this case, the high cost of $RuCl_3$ requires its recovery for practical use, which is difficult in homogeneous system. Matsumoto et al.[4] showed that trimethoxybenzenes were oxidized to dimethoxy-*p*-benzoquinones by H_2O_2 in the presence of hexacyanoferrate(II or III) ion, which is harmful. A palladium catalyst supported on sulfonated polystyrene type resins was used for the oxidation of methylbenzenes and naphthalenes.[5] Naphthalenes were oxidized to naphthoquinones in fairly good yields, but methylbenzenes gave *p*-benzoquinones in poor yields of 3—8%.

In the present work, we have investigated the oxidation of arenes (methoxybenzenes, methylbenzenes, and naphthalenes) by H_2O_2 in HCOOH. The reaction rates and selectivity were very dependent on the substituents on aromatic ring. Electron-withdrawing substituents slowed down the reaction and changed the product selectivity from quinones to phenols.

Experimental

Reagents and Apparatus. 3,5-Dimethoxytoluene was prepared by the published procedure.[6] All other reagents were commercial products of the highest purity obtainable. Infrared (IR) spectra were measured by a JASCO FT/IR-7000 spectrometer. Mass spectra were recorded at 70 eV on a Shimadzu GCMS-QP 1000 mass spectrometer. A Hitachi R-40 (90 MHz) spectrometer was used to obtain ^1H nuclear magnetic resonance (NMR) spectra.

General Procedure for Oxidation of Arenes by H_2O_2. Aqueous hydrogen peroxide (31%, 2 ml, ca. 20 mmol) was added to a solution of an arene (4 mmol) in formic acid (10 ml). The reaction mixture was stirred for 1—24 h (usually 2 h) at a desired temperature (30—50 °C) under nitrogen atmosphere. The solution was poured into water and the products were extracted with CH_2Cl_2. The organic layer was washed with water, and dried with $MgSO_4$. Generally, the products were analyzed by gas chromatography using a Thermon 3000 column (10% on Celite 545, 1 m, thermal conductivity detector) and *o*-dichlorobenzene as an internal standard. Some quinones (e.g., 2,5- and 2,6-dimethoxy-*p*-benzoquinone) are not well soluble in either H_2O or CH_2Cl_2. In these cases, the extracted organic solution was evaporated and the residue was rinsed with methanol or hexane to separate crystals of a quinone. The organic solution was analyzed by gas chromatography to determine the conversion of a reactant. The identification of products was carried out by means of ^1H NMR and/or FT-IR after separation by column (Merck, silica gel 60) and/or thin-layer (Whatman, silica gel 150A, PLK5F) chromatography. The products were also identified by GC-MS.

Results and Discussion

Oxidation of Methoxybenzenes. Various methoxybenzenes (methoxytoluenes, dimethoxybenzenes, dimethoxytoluenes, trimethoxybenzenes, and trimethoxytoluenes) were oxidized by H_2O_2 in HCOOH, and the results are tabulated in Table 1. Generally, *p*-benzoquinones were obtained as main products in relatively good yields, but some phenols were produced occasionally in small yields (Runs 3 and 8). When the para-position for methoxyl group is not substituted, a *p*-benzoquinone which has one less methoxyl group than the starting methoxybenzene is obtained as a main product. 3,4,5-Trimethoxyphenol was oxidized to 2,6-dimethoxy-*p*-benzoquinone under the same re-

action conditions (Run 16). Therefore, the oxidation yielding quinones probably proceeds through the corresponding phenols which are produced by the hydroxylation of benzene ring at the para-position for methoxyl group, as proposed previously.[4] If the para-position for methoxyl group is substituted (Runs 1 and 4), a corresponding *p*-benzoquinone without loss of methoxyl group is obtained. It is considered that these quinones are produced through the hydroxylation of benzene ring at the ortho-position for methoxyl group followed by the further oxidation of phenols. Under the present reaction conditions, 1,2,3-substituted benzenes gave a poor yield of quinones (Runs 6, 8, and 11). These poor yields of quinones can be explained as follows: two hydroxyl groups can be introduced very easily at the para-positions for the two methoxyl groups before the oxidation to a quinone occurs, because these positions are not crowded sterically, and the further oxidation of these hydroxylated compounds proceeds rapidly. In Run 8, 2-hydroxy-5-methoxy-3-

Table 1. (Continued)

No.	Temp °C	Time h	H_2O_2 aq. wt%	H_2O_2 aq. ml	Reactant	Conv. %	Product	Yield %	Sel. %

12	40	2	31	2		100		45	45

methyl-*p*-benzoquinone was obtained in a moderate yield, which is considered to form through the oxidation of 2,3-dihydroxy-5,6-dimethoxytoluene as the intermediate. On the other hand, 1,2,4-, 1,3,4-, or 1,3,5-substituted benzenes gave a good yield of corresponding *p*-benzoquinones (Runs 5, 7, 9, 10, and 12). In these cases, it is considered that only one hydroxyl group can be introduced into benzene ring, because the para-positions for methoxyl groups are crowded, and that the oxidation yielding quinones proceeds smoothly. When the reaction was carried out in methanol or acetonitrile, no quinone was obtained. The oxidation of 3,4,5-trimethoxytoluene in acetic acid gave only a 4% yield of 2,3-dimethoxy-5-methyl-*p*-benzoquinone at a 40% conversion (cf. Run 13). The active species of this reaction system is not clear at the present stage, but the most probable candidate is performic acid which is produced in situ from the reaction with H_2O_2.

Oxidation of Methylbenzenes and Naphthalenes. Oxidation of methylbenzenes and naphthalenes by H_2O_2 in HCOOH was also examined, and the results are shown in Table 2. Methylbenzenes were oxidized to

corresponding quinones, but the yields were rather poor, and higher temperature and concentration of H_2O_2 were required. Many unidentified by-products which probably formed through the oxidation of methyl groups were observed with GC-MS. The yield of quinones was not dependent on the number of methyl groups in benzenes, but increased with the number of methyl groups in naphthalenes (the solubility of naphthalenes in HCOOH is small, and so the mixed solvent of formic and acetic acid was used).

Oxidation of Benzenes Substituted with Electron-Withdrawing Groups. The effect of electron-withdrawing groups such as cyano, nitro, and chloro groups on the reaction was investigated, and Table 3 lists the results of oxidation of methoxybenzonitriles. In these cases, phenols were obtained as main products, but quinones were not. When one cyano group is introduced into benzene ring, the conversion of reactants decreased up to about 60% (e.g., compare Runs 5, 9, and 12 in Table 1 with Run 1 in Table 3). Some dimethoxybenzonitriles did not give phenols in a yield more than 1% and the conversion of benzonitriles was negligible (Runs 4 and 5). The hydroxyl group is introduced only at the positions where resonance effect of both two methoxyl groups is working (i.e., the ortho- and ortho-, or para- and ortho-position for either methoxyl group). Therefore, it is considered that cyano group reduces the reactivity of methoxybenzenes by decreasing electron density of benzene ring (one cyano group effectively cancels the reactivity en-

hancement originated from resonance effect of one methoxyl group), and it inhibits the further oxidation of phenols to quinones.

Nitro group also retarded the oxidation greatly and only a trace of phenols was obtained. In the case for chloro group, which is a weak electron-withdrawing substituent and shows ortho-para-orientation in electrophilic aromatic substitutions, chloroanisoles were oxidized to phenols. For example, *m*-chloroanisole was oxidized to three isomers of phenols in a 19% yield at a 35% conversion (hydroxyl group is introduced at two ortho- and one para-positions for methoxyl group at approximate ratio of 1:1:1). Accordingly, the electron-withdrawing substituents decrease the reactivity of benzene ring with H_2O_2 in HCOOH and inhibits the further oxidation of phenols to quinones.

The Determination of the Selectivity Coefficient of Na^+ versus Li^+ on Prussian Blue Thin Film in Propylene Carbonate by Means of a Quartz Crystal Microbalance

Katsunori AOKI, Takeshi MIYAMOTO, and Yasuhiko OHSAWA*
Materials Research Laboratory, Central Engineering Laboratories, Nissan Motor Co., Ltd.,
1, Natsushima-cho, Yokosuka, Kanagawa 237
(Received November 12, 1988)

Synopsis. The cation selectivity on a Prussian Blue (PB) modified electrode in propylene carbonate was examined by means of a quartz crystal microbalance. It was found that the selectivity coefficient of Na^+ versus Li^+ on the PB film was about 15.

Since Neff established the redox and electrochromic (EC) behavior of a Prussian Blue (PB) electrode[1] and Itaya et al. reported an electroplating method of PB,[2] many works on Prussian Blue (PB) modified electrodes have appeared.[3] Much attention has been paid to the Prussian Blue thin films not only because of their potential use as electrochromic devices,[4,5] batteries,[6] and catalysts,[7] but also because of their use as model compounds for such basic research as electron-hopping kinetics study.[8] It has been shown that Prussian Blue electrodes could be electrochemically reduced to Prussian White reversibly by means of a mechanism which involves the injection of both cations and electrons. The cations with Stokes radii of smaller sizes could penetrate the PB lattice more easily. In fact, it has been reported that, in aqueous media, K^+, Rb^+, and Cs^+ can smoothly penetrate the lattice, while repeated redox cycles are blocked in the presence of Li^+ or Na^+.[2] In an organic solvent of propylene carbonate, however, the redox reaction of PB in the presence of Li^+ or Na^+ is very stable.[4,9] Although the mechanism of ion transport has not yet been completely elucidated in detail, one of the applications of the PB modified electrode would be ion-separation making use of the different selectivities of the cations. It has been reported, that is, that the electrochemical redox cycles of the PB electrode could make it possible to separate alkali metal ions.[10]

The quartz crystal microbalance (QCM) in solution[11-13] offers a direct way of measuring the mass change of the PB film during electrochemical reduction and oxidation,[14] which would lead to quantitative estimations of the cation selectivities.

This paper will describe a new method for the determination of the selectivity coefficient of a cation versus another one on the PB film by using QCM.

Experimental

Indium tin oxide (ITO) was sputtered (ca. 20 Ω/□) on one side of a 6-MHz AT-cut quartz crystal (Inficon) with gold film electrodes on both sides. ITO was sputtered in order to prevent a chemical deposition of PB on the gold substrates.[2] The oscillating surface area was about 0.33 cm^2. Films of PB on ITO-coated crystals were electrochemically deposited under galvanostatic conditions of 5 $\mu A\ cm^{-2}$ in a freshly prepared solution of an equivolume mixture of 10 mM† $FeCl_3$ and 10 mM $K_3[Fe(CN)_6]$ aqueous solutions. The charge passed through for electroplating was 9 $mC\ cm^{-2}$. After the deposition of the PB, the film was thoroughly rinsed with distilled water and then mounted in a Teflon-made electochemical cell using O-rings. The frequency of the oscillating circuit, made up by following the method in the literature,[15] was monitored with a frequency counter. Cyclic voltammetry was conducted under a nitrogen atmosphere. Unless otherwise noted, a scan rate of 10 $mV\ s^{-1}$ was used. Simultaneously the charge passed through was recorded with a coulometer. A Pt wire and an Ag/AgCl electrode were used as the counter and the reference electrodes respectively. A propylene carbonate (PC) solution of 1 M $LiClO_4$, $NaClO_4$, or a mixture of them with 1.5 wt% H_2O[4] was used as the electrolyte solution. The mass change of the PB film upon reduction was calculated from the frequency change according to Sauerbrey's equation. The equation held within a 5% error, which was confirmed by the galvanostatic electrodeposition of Ag on Au quartz crystal electrodes.

† 1 M=1 mol dm^{-3}.

Results and Discussion

Figure 1 shows typical cyclic voltammetric (A) and frequency-potential(B) curves of the PB thin film in the $NaClO_4$/PC system, the latter illustrating that the observed mass change is reversible. It is clear that, when PB is reduced to Prussian White (PW), the weight of the film increases, while the succeeding oxidation of PW to PB is accompanied by a mass loss. The ratio of the mass change to the charge passed through (molar mass) was 21.9 $g\ mol^{-1}$, indicating that the sodium ion penetrates into the PB film upon reduction and exits from it upon oxidation.

In contrast with the $NaClO_4$/PC system, the molar

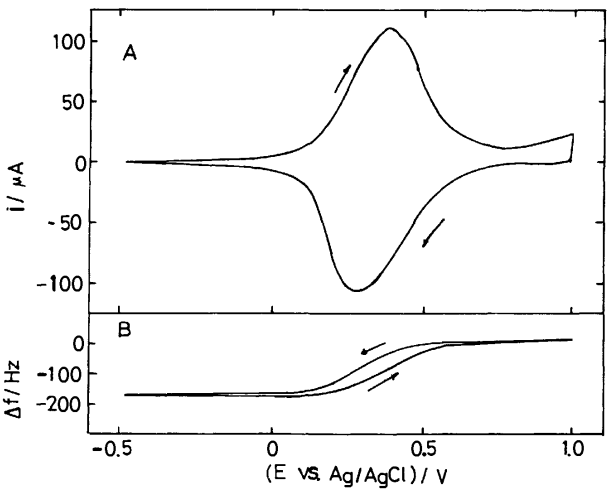

Fig. 1. Cyclic voltammetric (A) and potential-frequency curves (B) for a Prussian Blue modified quartz crystal electrode in 1M $NaClO_4$ of propylene carbonate. v=10 $mV\ s^{-1}$.

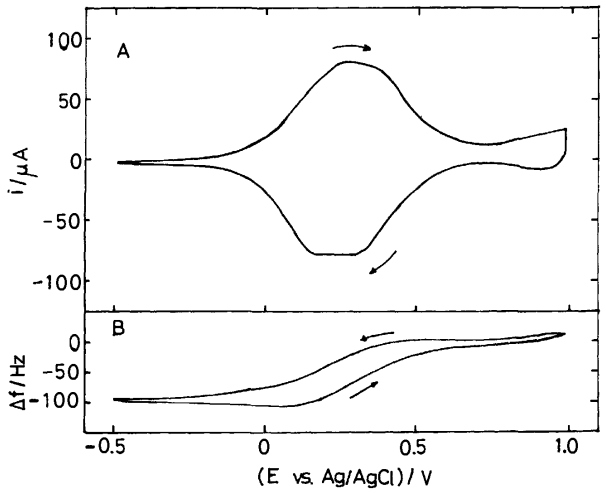

Fig. 2. Cyclic voltammetric (A) and potential-frequency curves (B) for a Prussian Blue modified quartz crystal electrode in 1M $LiClO_4$ of propylene carbonate. v=10 mV s^{-1}.

mass for PB in $LiClO_4$/PC of 10.9 g mol^{-1}, somewhat larger than that expected for Li^+ (6.9 g mol^{-1}), suggests that some water molecules are also incorporated into the PB film with Li^+ upon reduction. Typical cyclic voltammetric (A) and frequency-potential(B) curves in this system are shown in Fig. 2.

Figure 3 shows the relationship between the molar fraction of Na^+ and the molar mass in Na^+/Li^+ mixed electrolyte solutions. The molar mass was calculated for the reduction process of PB. The experimental curve indicates that Na^+ is more favorably intercalated into the PB lattice than is Li^+; this is consistent with the qualitative result in Ref. 9.

Since the molar mass was not much influenced by the scan rate, which ranged from 2 to 100 mV s^{-1}, it may be safe to conclude that distribution equilibrium of ions between the PB thin film and the electrolyte solution is established. The selectivity coefficient of Na^+ against Li^+ on the PB film (α) can be defined as:

$$\alpha = \frac{Y(1-X)}{X(1-Y)} \tag{1}$$

where X is the molar fraction of Na^+ in the solution and Y, the molar fraction of Na^+ in the PB film. The molar mass (Mm) in a Na^+/Li^+ mixed solution is the average of the Mm's for Na^+(ca. 22) and Li^+(ca. 11) obtained as above:

$$Mm = 22Y + 11(1-Y) \tag{2}$$

From Eqs. 1 and 2, we obtain:

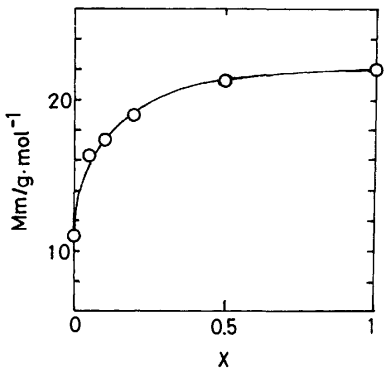

Fig. 3. Relationship between molar fraction of Na^+ in solution (X) and the molar mass (Mm) in Na^+/Li^+ mixed propylene carbonate solutions.

$$Mm = \frac{22X\alpha + 11(1-X)}{X\alpha + (1-X)} \tag{3}$$

which gives a good fit with the experimental curve provided that α is about 15. Consequently, when both ions are incorporated into the PB film, the concentration of Na^+ in the film is almost equal to that of Li^+, even in a solution with a Na^+ molar fraction lower than 0.1.

In conclusion, the quartz crystal microbalance can offer a direct and in situ measurement of ion selectivity on the PB thin film; this method may also be useful for other ion exchangers.

(Received November 30, 1988)

Synopsis. Luminous oxidation with acidic permanganate was found to be usable for chemiluminescent determination of catecholamines and other polyhydroxybenzenes at picomol levels. The sensitivity is high enough to determine catecholamines in urine. The present CL method is expected to be applicable to the post-column detection of these compounds in high-performance liquid chromatography.

Analytical methods using solution chemiluminescence (CL) as detection means are unique in being capable of low detection limits with simple instrumentation and have been applied to a variety of analytes of clinical and environmental significance.[1-3] The combination with flow injection method[4] and high-performance liquid chromatography[5] have made CL techniques more attractive. However, limited CL reaction system has caused the slow recognition of CL analysis, despite of other advantages including wide linear dynamic range, simplicity, rapidity, low cost per analysis, etc. In order to overcome this shortcoming, for the past several years our effort has been directed toward searching for new CL systems usable for analysis.[6-8] As a part of the investigations, we have reported on the screening of CL systems for determination of some biologically important organic compounds and made it clear that acidic permanganate oxidation may draw intense CL from many of the organic compounds tested, especially catecholamines and other polyhydroxyphenols.[8] Acidic permanganate is a strong oxidizing agent and has been used for CL determination of some drugs.[9]

In this paper, we describe the details of acidic permanganate CL system for the determination of catecholamines and other polyhydroxybenzenes by means of flow injection technique. This has been undertaken for aiming at the post-column detection of these compounds in high performance liquid chromatography.

Experimental

Apparatus. Prior to flow experiments, batch experiments were performed as described previously[10] in order to know luminescent characteristics through the measurements of time course of CL.

A schematic diagram of the flow system is illustrated in Fig. 1. An acidic permanganate solution is delivered through a flow line R_1 and water as a carrier solution through R_2 by a peristaltic pump P, respectively. Catecholamines and other organic compounds are injected by means of a 70-μl rotary value injector S. In order to block stray light, black Teflon tubing (1-mm i.d.) is used for the flow line except pump tubes and a detection flow cell D. For D a spiral flow cell (ca. 450-μl inner volume) made of flexible, transparent Teflon tubing (0.8-mm i.d.) is assembled as before.[11] The distance between S and D is about 4 cm, the minimum distance achieved. The light emitted is detected directly by a photomultiplier tube (Hamamatsu Photonics R376) with no wavelength discrimination. The signal from the photomultiplier tube is fed to picoammeter (Advantest TR-8651) and then recorded on a strip chart recorder. Peak height of the signal recorded is measured as CL signal.

Reagent. Chemicals of reagent grade were used as received. The water used was prepared by deionization of distilled water from a stainless steel apparatus. Each reagent solution was prepared daily from 10^{-1} M (permanganate) or 10^{-2} M (catecholamines and other organic compounds) stock solution (1 M=1 mol dm^{-3}). The permanganate stock solution was standardized with oxalate and stored in a dark room. Each catecholamine stock solution was prepared by dissolving its hydrochloride into and diluted with 10^{-2} M hydrochloric acid.

Results and Discussion

Batch Experiments. CL reaction often proceeds in different ways depending on the mixing order of reagent solution. This may cause considerable retardation of CL reaction and sometimes complete disappear-

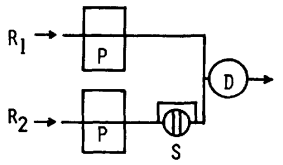

Fig. 1. Schematic diagram of the flow system (for key, see text). Recommended conditions: R_1= 1×10^{-3} M $KMnO_4$/1 M H_2SO_4, 3.2 ml min^{-1}; R_2= water, 4.5 ml min^{-1}.

Table 1. Effect of the Mixing Order of Reagent on the CL Signal for Catecholamines

Mixing order[a]			Relative CL signal[b]		
1 +	2 +	3	Dopamine	Noradrenaline	Adrenaline
$KMnO_4$[c]	H_2SO_4[c]	CA[d]	200	100	400
$KMnO_4$	CA	H_2SO_4	40	130	400
CA	H_2SO_4	$KMnO_4$	220	30	320

a) 0.1 ml of each solution was mixed in that order. b) Normalized with respect to the CL signal (=100) for noradrenaline. c) 10^{-3} M. d) 10^{-4} M catecholamines.

ance of CL. And also how fast CL reaction occurs is a dominant factor which decides sensitivity in flow CL analysis because transient light emission is monitored. Accordingly, the exploration of the dependency of mixing order is of significant importance for the design of flow system. Thus, time courses of CL were measured on varying mixing orders of the reagent (permanganate, sulfuric acid, catecholamine) by the batch method. The results are shown in Table 1, indicating that the best mixing is in the order, permanganate, sulfuric acid, and catecholamines. Such a mixing order allows us to mix permanganate with sulfuric acid in advance. Consequently, this appears to permit the design of flow system consisting of a single flow line, namely, a sample injection into the stream of acidic permanganate solution. Unfortunately, a single line-flow system may not be assembled owing to a poor matching of the flow system with the speed of CL reaction. That is to say, as can be seen from the time course of CL in Fig. 2, the present CL reaction proceeds very fast and the light emission comes flashingly, resulting in an occurrence of most of light emission before the flow cell. Hence a dual line-flow system was assembled as shown in Fig. 1; the carrier stream of water into which a sample is injected enables the sample to join the stream of acidic permanganate solution just before the flow cell so that the light emission occurs mostly inside the flow cell.

Optimization. In order to determine optimum operating conditions, the CL signal for noradrenaline was taken with respect to reaction variables, i.e., the concentrations of permanganate and sulfuric acid and the flow rates of both streams. As expected, the CL signal was strongly dependent on both reagent concentrations because the oxidizing power of permanganate increases with an increase in the sulfuric acid concentration. The permanganate concentration above the concentration (1×10^{-3} M) providing the highest signal caused a decrease in the signal which was mainly due to the intense color of the permanganate solution, showing absorption maxima at 527 and 546 nm. The higher the sulfuric acid concentration, the higher the CL signal, but the higher the noise level. The highest signal-to-noise ratio was obtained at 1 M sulfuric acid. Other acids such as hydrochloric acid, phosphoric acids ($H_{n+2}P_nO_{3n+1}$, n=1, 2, 4), and monocarboxylic acids (C_1—C_4) were also examined, but none of them surpassed sulfuric acid with regard to the signal-to-noise ratio. The flow rate of the acidic permanganate solution provided a maximum signal at ca. 3 ml min^{-1}, but the increasing flow rate of carrier solution (water) gave an gradually increasing signal under any flow rates of the permanganate solution. For subsequent experiments, the optimum operating conditions were chosen as specified in Fig. 1.

Table 2. CL Signal for Catecholamines and Other Polyhydroxybenzenes

Compound (10^{-5} M)	Relative CL signal[a]
Dopamine	1.3
Noradrenaline	1.0
Adrenaline	1.0
L-Dopa	1.3
3,4-Dihydroxybenzylamine	1.5
Normethanephrine	1.0
Hydroquinone	2.1
Resorcinol	0.5
Catechol	2.1
4-Methylcatechol	1.5
4-*t*-Butylcatechol	5.6
Phloroglucinol	0.8
Pyrogallol	2.9
Gallic acid	0.4
Ethyl gallate	0.4
Tannic acid	0.6

a) Normalized with respect to the CL signal (=1.0) for noradrenaline.

Characteristics of the System. Under the optimum conditions, the background signal is 9×10^{-12} A, comparing with a noise current of 3×10^{-12} A. This high background, and consequently high noise are conceivably based on the luminous oxidation of organic impurities in the water used or from the flow line due to the use of highly acidic and concentrated permanganate solution. In a previous work,[12] the mild conditions (2×10^{-6} M permanganate at pH 2.5) gave much lower background and noise current (10^{-13} A levels), despite the presence of a fluorescent organic compound as sensitizer in the system. Calibration graphs for dopamine, noradrenaline, and adrenaline exhibited straight lines over the concentration ranges of 10^{-7} to 10^{-4} M with a slope of unity and signal ratio of 1.3:1.0:1.0, respectively. The limit of determination (S/N=3) is 7 pmol (70-μl injection of 10^{-7} M solution) for each catecholamine. This sensitivity is high enough to detect catecholamines in urine at 10^{-6} M levels. The relative standard deviation (n=10) for adrenaline (70 pmol) is 2.3%. The good reproducibility is based on an effective mixing caused by the fast flow of solution in the flow cell. The sampling rate can be as high as 500 h^{-1}.

It is known that some polyhydroxybenzenes give rise to light emission by permanganate oxidation under basic conditions.[13] Thus thirteen polyhydroxybenzenes were subjected to test in the present CL system, and CL signals obtained are summarized in Table 2 along with those for catechloamines. It can be roughly said from Table 2 that the unsubstituted phenols with a hydroxyl group at the ortho- or para-position provides higher signals and that the substituted phenols with an electron-donating group provides higher

Table 3. Effect of the Mobile Phase Used for Chromatographic Separation of Catecholamines on the CL Signal for Noradrenaline[a]

Mobile phase[b]	CL signal[c]	S/N[d]
0.2 M sodium formate	460	15
0.05 M citric acid (300 ml)+0.05 M disodium hydrogenphosphate (160 ml)+sodium dodecyl sulfate (15 mg)	140	5
Citric acid (10.5 g)+acetic acid (2.1 ml)+sodium hydroxide (4.8 g)+sodium acetate (8.2 g)	140	4
45% methanol/0.05 M sodium dihydrogenphosphate	120	5
Methanol+0.08 M acetic acid (1:1)	110	3
Water+methanol (28:72)	110	3
0.075 M citric acid	100	1
Ethyl acetate+cyclohexane (3:7)	70	4
0.12 M succinic acid+0.35 M boric acid +0.002 M EDTA (1:1:1)	60	15
0.2 M sodium acetate	50	25
0.15 M sodium dihydrogenphosphate	50	25
0.5 M sodium dihydrogencitrate	50	6
0.17 M acetic acid	40	5
6% acetonitrile/0.03 M sodium dihydrogenphosphate	10	5
0.1 M tris/HCl buffer (pH 8.5)+acetonitrile (87:13)	6	6
Water	50	17

a) 10^{-6} M. b) Flown to R_2 in place of water. c) 10^{-12} A. d) Signal-to-noise ratio.

signals, but those with an electron-withdrawing group lower signals. These trends were not observed in the above basic permanganate system. At any rate, the polyhydroxybenzenes are detected with sensitivity not so much different as those for catecholamines. This implies that these compounds can also be determined by means of the acidic permanganate CL system.

Applicability to Post-Column Detection. It is expected that the present CL system may be applied to the determination of catecholamines and other polyhydroxybenzenes in biological and clinical samples, drugs, foods, beverages, etc. after chromatographic separation. In that case, it should be noted that the constituents of mobile phase might inhibit the CL reaction. Accordingly, various kinds of mobile phases used for the elution of catecholamines were flown to R_2 in place of water, in order to know to what extent the CL signal for noradrenaline was affected. The results are shown in Table 3; the comparison of signal-to-noise ratio indicates that sodium formate, succinic acid/boric acid/EDTA, sodium acetate, and sodium phosphate may be utilized as eluent. The use of mobile phase containing alcohols seems to be undesirable because alcohols increase not only signal itself but also background noise, resulting in a deterioration of the signal-to-noise ratio. This was confirmed by the dependency of organic solvent on the signal for adrenaline. The presence of 20% methanol and ethanol in the carrier water gave about 2 and 18 times higher signal than in the absence of alcohol, but 10 and 100 times increased noise reduced both signal-to-noise ratios to one-sixth, respectively. Acetonitrile and acetone may not also be recommended as the constituent of mobile phase since they reduce signal itself to ca. 1/24 and signal-to-noise ratio to ca. 1/4, respectively.

(Received June 27, 1988)

Synopsis. Formerly-proposed structures, cyclopent[*de*]-isoquinolin-3(4*H*)-ones, for ring contracted by-products obtained from 1-substituted cyclohepta[*b*]pyrrol-2(1*H*)-ones and acetylenes, were revised to benz[*cd*]indol-2(1*H*)-ones on the basis of spectroscopic analysis.

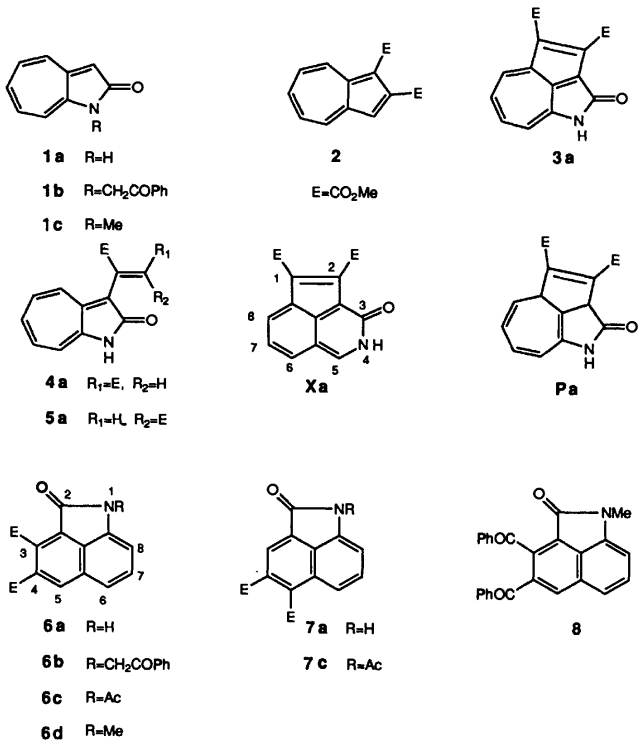
In our recent study of the cycloaddition of 1-substituted cyclohepta[*b*]pyrrol-2(1*H*)-ones (**1**) to electron-deficient acetylenes, dimethyl butynedioate (DMBD) and dibenzoylacetylene (DBA),[1,2] we have isolated, other than the predicted azulenes and Michael-type adducts, a series of ring-contracted compounds. We have given them isoquinoline structures (**X**) mainly from an appearance of singlet signals around δ=8.8, which, we thought, might be ascribable to H-5 of **X**. However, after reconsideration, we came to a view that benz[*cd*]indol-2(1*H*)-one structures were more plausible than the previously-proposed **X** in the ^{1}H NMR and UV spectral points of view. In this paper, we wish to correct the structures.

Results and Discussion

In the previous paper, we described the characterization of a series of compounds: the reaction of cyclohepta[*b*]pyrrol-2(1*H*)-one (**1a**) and DMBD after refluxing in acetonitrile for 45 h gave five products (**2**, **Xa**, and **3a**—**5a**) in good combined yields. However, a doubt has arisen concerning the isoquinoline structure of **Xa**.[1,2] Namely, the structure **Xa** possesses a quinodimethane structure, and the formation of **Xa** from the protoadduct (**Pa**) involves an autooxidative dehydrogenation step. The occurrence of such a process to lead non-aromatic compounds seems unlikely. Moreover, in the ^{1}H NMR spectrum[3] of **X**, the singlet signals, which were ascribed to H-5 signals, showed only a slight variation on changing the substituent on the nitrogen atom. In this paper, we revise the structures of **X** to **6**, benz[*cd*]-indol-2(1*H*)-one derivatives, from the following evidence.

To provide more information on the structures of **X** and **6**, we extended the reaction of DMBD to 1-phenacylcyclohepta[*b*]pyrrol-2(1*H*)-one (**1b**). From **1b**, only two products (**2** and **6b**) were isolated in 12 and 14% yields, respectively. The latter, **6b**, was identical with the sample prepared by the condensation of phenacyl bromide with **6a**. In the same time, **6a** was converted to an acetyl derivative (**6c**).[2,4] The **6c** was identical with one of the cycloadducts by the reaction of *N*-acetylcyclohepta[*b*]pyrrol-2(1*H*)-one with 2,3-bis(methoxycarbonyl)-7-oxabicycloheptadiene under high-pressure conditions (3000 bar).[5]

Since the UV spectra of **6a** and **6c** were almost superimposable on those of corresponding dimethyl naphthostyril-4,5-dicarboxylates (**7a** and **7c**),[6] the same structural units in both compounds are strongly



Scheme 1.

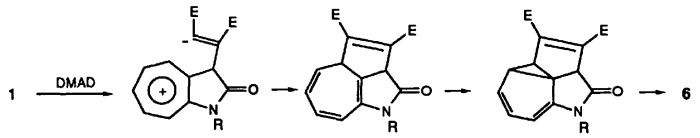
C-8	108.6	107.8	116.7	106.9	



Scheme 2.

suggested (Table 1). This UV similarity is reasonable; since in both **6a, c** and **7a, c**, one of the methoxycarbonyl groups at C-4 or C-6, which is in an extended ortho- or para-position of the nitrogen-carrying carbon. This must largely influence the UV maxima, while the rest of methoxycarbonyl groups at C-5 in **6a, c** and **7a, c** are in the extended meta-position, having less affective on the UV maxima. Therefore, **6** are naphthostyril derivatives. For the vicinal bis(methoxycarbonyl) naphthostyrils having three consecutive hydrogens and one isolated hydrogen, only four structures are feasible.

The ^{1}H NMR spectra provide diagnostic information to select the correct structure, **6**. Thus, the ^{1}H NMR spectra of **6a** to **6b** and the corresponding derivative (**8**) derived from DBA and 1-methylcyclohepta-[*b*]pyrrol-2(1*H*)-one (**1d**) revealed characteristic features; i.e., they showed a singlet at δ=8.3—8.9 and aromatic proton signals at δ=6.9—8.3 (Table 2). Among them, a doublet signal, part of the three consecutive proton system, appeared at relatively high field. It was close to a substituent on the nitrogen atom, since the chemical shifts at ca. δ=6.9 or lower field were largely dependent on the *N*-substituents. The chemical shift difference, $\Delta\delta$, caused by acetylation of **6a** to **6c** was 7.11−8.32=−1.21 in chloroform-*d*. Therefore, it must be ascribable to H-8.

As has already been noticed, the singlet signals were slightly sensitive to the *N*-substituents and moved to a larger extent on changing the carbonyl substituents. Therefore, the singlet signals were close to one of the methoxycarbonyl groups, and could be assigned to H-5. Accordingly, only two possibilities remain for **6**; one is the 4,5-bis(methoxycarbonyl) structure and the other the 3,4-bis(methoxycarbonyl) structure. However, the former is already known to be **7**, and the latter remaining must be **6**.

The mechanism of formation of **6** is straightforward: a valence-bond isomerization of the initial [8+2]cycloadducts to norcaradiene derivatives and a subsequent dehydrogenative aromatization. It is difficult to explain the formation of any other naphthostyril derivatives from protoproducts of **1** and DMBD.

In conclusion, cyclopent[*de*]isoquinolin-3(4*H*)-one structures, **X**, were revised to benz[*cd*]indol-2(1*H*)-one (naphthostyril) structures, **6**, from the UV- and NMR-spectral analyses as well as the mechanistic considerations.

Experimental

Preparation of 1b. To an EtOH solution (50 cm^3) of **1a** (1.08 g) was added concd NaOH (4 cm^3) and the mixture was kept at room temperature for 4 h. A yellow sodium salt of **1a** (1.20 g, 97%; mp 300 °C) was collected by filtration. An anhydrous benzene suspension (50 cm^3) of sodium salt (836 mg) and phenacyl bromide (995 mg) was refluxed for 12 h. The mixture was poured into water and extracted with benzene. The benzene solution was washed with dil NaOH solution, dried over Na_2SO_4, and evaporated. The residue was chromatographed on a silica-gel column to give 560 mg (43%) of **1b**: yellow needles; mp 172—173 °C; ^{1}H NMR[3] δ=5.50 (2H, s), 6.17 (1H, s), 6.66 (1H, d, J=9.2 Hz), 6.86 (1H, t, J=9.2 Hz), 7.02 (1H, t, J=9.2 Hz), 7.05 (1H, t, J=9.2 Hz), 7.51 (1H, d, J=9.2 Hz), 7.52 (2H, t, J=7.3 Hz), 7.64 (1H, t, J=7.3 Hz), and 8.08 (2H, d, J=7.3 Hz); IR ν: 1698, 1680, 802, 760, 754, and 692 cm^{-1}.

Found: C, 77.47; H, 5.01; N, 5.26%. Calcd for $C_{17}H_{13}NO_2$: C, 77.55; H, 4.98; N, 5.32%.

Reaction of 1b with DMBD. An anhydrous MeCN solution (30 cm^3) of **1b** (500 mg) and DMBD (540 mg) was refluxed for 2 d. The solvent was evaporated and the residue chromatographed on a silica-gel column to give 56 mg (12%) of **2**,[2] 110 mg (14%) of **6b**, and 149 mg (30%) of unreacted **1b**. **6b**: yellow needles; mp 151—153 °C; ^{1}H NMR δ=4.00 (3H, s), 4.10 (3H, s), 5.33 (2H, s), 6.89 (1H, d, J=6.7 Hz), 7.45—7.7 (5H, m), 8.07 (2H, d, J=7.9 Hz), and 8.81 (1H, s); ^{13}C NMR δ=46.5, 52.9, 53.1, 107.8, 121.0, 123.5, 126.4, 127.9, 128.1 (2C), 128.3, 128.9 (2C), 130.3, 130.9, 134.0, 134.4 (2C), 139.1, 165.4, 165.5, 166.8, and 192.2; IR ν: 1730, 1710, 1690, 1636, 790, 757, and 685 cm^{-1}.

Found: C, 68.55; H, 4.32; N, 3.32%. Calcd for $C_{23}H_{17}NO_6$: C, 68.48; H, 4.25; N, 3.47%.

Reaction of 6a and Phenacyl Bromide. An anhydrous benzene (30 cm^3) of **6a** (18 mg), diazabicycloundecene (30 mg),

and phenacyl bromide (40 mg) was refluxed for 7 h. After removing the solvent, the residue was chromatographed on a silica-gel column to give 9 mg (35%) of **6b** and 11 mg (61%) of unreacted **6a**.

Synthetic Photochemistry. L.[1] Isolation and the X-Ray Structure Determination of Photocyclodimers Formed by UV-Light Irradiation of Alkyl 2,4-Dioxopentanoates

Akira MORI,* Nobuaki NISHIYAMA,† Yukiko KOHGUCHI, Hisayo SHINKA, and Hitoshi TAKESHITA*

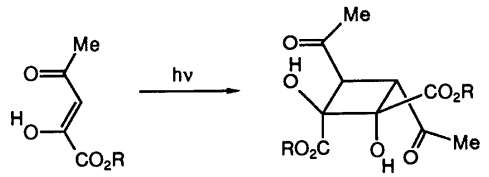
(Received October 19, 1988)

Synopsis. Upon UV-light irradiation with a high-pressure mercury lamp, methyl 2,4-dioxopentanoate in a mixture of benzene and cyclohexane afforded a crystalline head-to-head-[2+2]cyclodimer. Its structure was elucidated by a single-crystal X-ray analysis, as well as ^{1}H and ^{13}C NMR spectroscopy. Ethyl 2,4-dioxopentanoate also gave a cyclodimer.

The de Mayo reaction[2] has been regarded as one of the most synthetically useful photocycloaddition reactions. Among the previously-studied β-diketone photocycloaddends, alkyl 2,4-dioxoalkanoates,[3] being fully enolized in various solvents, have a characteristic reactivity to form regiospecific [2+2]cycloadducts with conjugated olefins, and to give useful intermediates for natural product syntheses.[4] Herein, we wish to report the isolation and structure determination of head-to-head-[2+2]dimers.

When methyl 2,4-dioxopentanoate (**1a**) was irradiated by means of a 400-W high-pressure mercury lamp through a Pyrex glass filter in a mixture of benzene and cyclohexane, a colorless crystalline product (**2a**) was formed and isolated by filtration. Its mass spectrum indicated its molecular composition to be dimeric, and the ^{1}H and ^{13}C NMR strongly suggested the presence of a symmetry element in the molecule. Presumably, **2a** is, therefore, a [2+2]cyclodimer. From the mechanism of photoaddition, the cis relationship for the acet l and hydroxy groups was expected,[5,6] though the syn- or anti-stereochemistry could not be determined. Unfortunately, spectroscopic differentiation at this point failed; i.e., an ^{1}H NMR satellite band due to the ^{13}C-H coupling could not be detected, or an attempt to measure lanthanoid-induced chemical shift change caused a decompostion of **2a**.



1a R=Me
b R=Et

2a R=Me
b R=Et

Scheme 1.

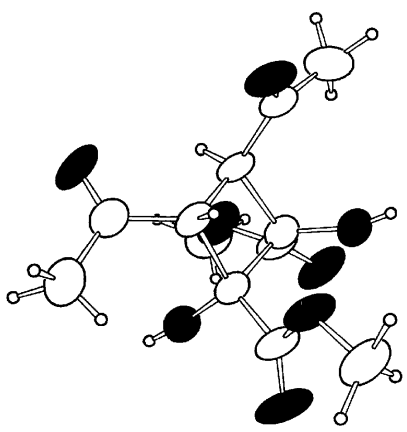


Fig. 1. The ORTEP drawing of **2a**. Dark atoms denote the oxygen atoms.

Therefore, an X-ray structure analysis with a single crystal of **2a** was carried out (see Experimental): The molecular structure obtained by the analysis was displayed as a computer-generated drawing (Fig. 1).

Similar irradiation of ethyl 2,4-dioxopentanoate (**1b**) gave a homologous cyclodimer (**2b**) in 10% yield. From the ^{1}H NMR spectral similarity it is certain that **2b** and **2a** have the same stereochemistry.

Previously, no dimer of free enolized β-diketones have been detected, although a cyclodimer of dehydroacetic acid reacted at the β-acyloxy enone moiety.[7] This is particularly interesting since none of the proto-photoadducts from ordinary 2,4-diketoalkanes with olefins has been known. On the other hand, from the 2,4-dioxoalkanoates, several proto-cycloadducts have been characterized; i.e., a) the [2+4]- and [2+6]photocycloadducts, from conjugated olefins, were normally stable and not dealdolyzed under mild conditions[6,8] and b) as a [2+2]cycloadduct, the protoadduct from *p*-isopropenyltoluene with **1a** was obtained in a trace amount after silica-gel column chromatography.[9] The present case, the isolation of stable compounds having two aldol groups as parts of a strained cyclobutane ring, seems to be quite extraordinary.

Experimental

Photodimerization of 1a. A mixed solution of benzene (6.5 cm^3) and cyclohexane (4.5 cm^3) of **1a** (884 mg) was irradiated through a Pyrex-glass filter with a 400-W high-pressure mercury lamp cooled with an ice-water for 12 h. Crystalline solid separated out was collected by filtration, and recrystallized from benzene to give **2a** [colorless needles, mp 135—136 °C, 153.4 mg; 17%. Found: C, 50.05; H, 5.71%. Calcd for $C_{12}H_{16}O_8$: C, 50.00; H, 5.50%. ^{1}H NMR δ[10]=2.20 (6H, s), 3.89 (6H, s), 4.24 (2H, s), and 4.58 (2H, s). ^{13}C NMR δ=29.3 (2C), 48.6 (2C), 53.4 (2C), 79.3 (2C), 169.9 (2C), and 205.3 (2C). *m/z*, 288 (M^+, 0.7), 271 (4), 201 (8), 169 (12), 159 (14), 145 (23), 143 (9), 141 (23), 99 (33), 84 (37), and 43 (100)].

Photodimerization of 1b. Similarly, irradiation of **1b** (349 mg) gave **2b** [colorless crystals, mp 114—115 °C, 35 mg; 10%. Found: C, 52.78; H, 6.55%. Calcd for $C_{14}H_{20}O_8$: C,

53.16; H, 6.33%. ^{1}H NMR δ=1.34 (6H, t, J=7 Hz), 2.28 (6H, s), 4.22 (2H, s), 4.32 (4H, q, J=7 Hz), and 4.45 (2H, br s). ^{13}C NMR (acetone-d_6) δ=14.3 (2C), 49.4 (2C), 62.5 (2C), 81.3 (2C), 169.8 (2C), and 203.7 (2C)].

X-Ray Analysis of 2a. Crystal and intensity data were collected on an Enraf-Nonius CAD 4 Diffractometer using Graphite monochromated Mo $K\alpha$ radiation. Crystal data: $C_{12}H_{16}O_8$, M.W., 288.25; monoclinic, Space group, $C_{2/c}$; a=15.6873(9), b=6.4078(4), c=14.6453(8) 10^{-8} cm, β=116.23(5)°. D_c=1.450 g cm^{-3} for Z=4. The intensities of 3195 reflections were measured and 603 independent reflections within a 2θ angle range of 2° through 54° were used for analysis. The structure was solved by MULTAN 78 and the positional and thermal parameters were refined by a full-matrix least-square method; anisotropic thermal parameters for all non-H atoms and fixed isotropic thermal parameters for H atoms (4.0×10^{-16} cm^2). The final R values were found to be 8.1%.[11]

The authors with to thank Dr. Hiroaki Mametsuka for his elaboration on a preliminary survey of this work.

A Convenient Synthesis of Diketones via Alkylation of Alkyl Methyl Ketone Dimethylhydrazones

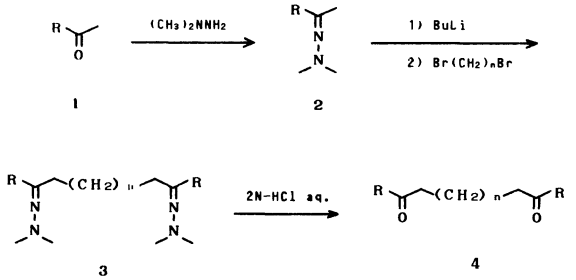
Masakazu YAMASHITA,* Kaoru MATSUMIYA, Hiroko MORIMOTO, and Rikisaku SUEMITSU
Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto 602
(Received July 18, 1988)

Synopsis. Symmetrical diketones were prepared by the reaction of the lithium salts of alkyl methyl ketone dimethylhydrazones with dibromoalkanes.

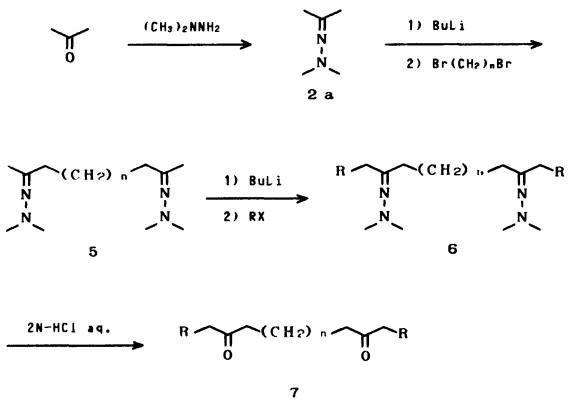
We previously reported a facile synthesis of unsymmetrical ketones by successive alkylation of acetone dimethylhydrazone,[1] and the application of this reaction to the synthesis of jasmones and the sex pheromone of the peach fruit moth.[1,2]

In this paper we wish to report a simple and convenient synthesis of the symmetrical diketones by alkylation of alkyl methyl ketone dimethylhydrazones[3] with dibromoalkanes. By the use of this method, 2,15-hexadecanedione, a precursor of muscone,[4] was also prepared in good yield.

The symmetrical diketones (**4**) were synthesized from a variety of alkyl methyl ketones (**1**) according to Scheme 1. For example, 2-octanone dimethylhydrazone (**2c**), readily available from 2-octanone and *N,N*-dimethylhydrazine using trifluoroacetic acid as a catalyst, was allowed to react with 1 equiv of butyllithium in THF at −5 °C under argon, followed by half equiv of 1,4-dibromobutane to give 7,14-icosanedione (**4f**) in 83% yield after hydrolysis. The results are listed in Table 1. 2,15-Hexadecanedione (**4b**) is a precursor of muscone,[4] which is one of the famous perfume materials.



Scheme 1.



Scheme 2.

Furthermore, diketones (**7**) were also prepared by an alternative route starting from acetone dimethylhydrazone (**2a**), as shown in Scheme 2. For example, to the THF solution of the hydrazone (**2a**), 1 equiv of butyllithium and a half equiv of 1,6-dibromohexane was added successively. Then, dihydrazone was dilithiated by butyllithium, and 1-bromobutane was added to form dibutylated hydrazone, which was hydrolyzed using hydrochloric acid to afford 6,15-icosanedione (**7b**) in 84% yield. The other results are presented in Table 2.

By the methods described above, a variety of symmetrical diketones were prepared in satisfactory yields. No isomeric ketones were detected by TLC.

Table 1. Synthesis of Symmetrical Diketones (**4**) from Alkyl Methyl Ketone Dimethylhydrazones (**2**)

Run	Hydrazone	$Br(CH_2)_nBr$	Product	Yield/%[a]
1	**2a**	$n=3$	 **4a**	54
2		$n=10$	 **4b**	66

9	**2f**	$n=8$	 **4i**	76
10	**2g**	$n=4$	 **4j**	68

a) Isolated yields.

In conclusion, this synthetic method for symmetrical diketones has been found to be a prominent procedure in terms of good product yield, high regioselectivity of the alkylations, facile operations, and mild reaction conditions.

Experimental

The NMR spectra were measured on a Hitachi R-600 FT-NMR Spectrometer at 60 MHz using tetramethylsilane (δ=0.00) as an internal standard; chemical shifts are given in ppm. The IR spectra were recorded on a Hitachi 260-10 Infrared Spectrophotometer. The mass spectra (MS) were recorded on a Hitachi RM-50 GC-MS spectrometer. The GLC analysis was carried out on a Shimadzu GC-14A gas chromatograph, and the column chromatography was performed on Merck silica gel (230—400 mesh). Melting points were taken on a Yanagimoto micro melting point apparatus. No correction was made for melting and boiling points, and all the yields were isolated ones.

Run	$Br(CH_2)_nB$	RX	Product	Yield/%[a]
1	$n=3$	CH_3I	 **7a**	77
2	$n=6$		 **7b**	84
3	$n=6$		 **7c**	24

a) Isolated yields.

Preparation of Ketone Dimethylhydrazone (2). A typical procedure is as follows: a mixture of 2-octanone (50 mmol, 7.8 ml), *N,N*-dimethylhydrazine (75 mmol, 4.0 ml), trifluoroacetic acid (0.05 ml) and benzene (20 ml) was placed in a flask equipped with a trap used to remove water and refluxed for 2 h. After cooling to room temperature, the reaction mixture was added to brine and extracted with ethyl acetate. The organic layer was dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and residual liquid was distilled to give 2-octanone dimethylhydrazone (**2c**) (7.47 g, 88% yield), bp 87 °C/20 Torr (1 Torr≈ 133.322 Pa).

^{1}H NMR, IR, and mass spectral data and boiling points of new hydrazones (**2**) are shown in Table 3.

General Procedure for the Preparation of Symmetrical Diketones (4). Butyllithium (4.4 mmol) was added via a syringe at −5 °C with stirring under argon to a solution of methyl ketone dimethylhydrazone (**2**) (4 mmol) in THF (15

a) Uncorrected melting point.

ml). After 1 h dibromoalkane (2 mmol) was added at −5 °C; the reaction mixture was stirred for 15 h at room temperature before the addition of 2 mol dm^{-3} hydrochloric acid (15 ml). After standing for 15 h, the solution was diluted with water and extracted with ethyl acetate. The organic layer was washed with brine, dried over anhydrous magnesium sulfate, filtered and concentrated. The residure was purified by column chromatography over silica gel (hexane:ethyl acetate=8:2).

^{1}H NMR, IR, and mass spectral data and melting points of new diketones (**4**) are given in Table 4.

Preparation of Symmetrical Diketones (7) by Successive Alkylation Procedure. According to a method similar to that described above, using dibromoalkane and alkyl halide, the successive alkylations of acetone dimethylhydrazone (**2a**) and the hydrolysis were carried out. After the usual work up, column chromatography (hexane:ethyl acetate=9:1) gave the desired diketone.

^{1}H NMR, IR, and mass spectra data and melting points of new diketones (**7**) are given in Table 4.

Solubilization of β-Carotene in Water by Water-Soluble Linear Macromolecules

Isamu INAMURA,* Masayuki ISSHIKI, and Takeo ARAKI
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690
(Received September 21, 1988)

Synopsis. β-Carotene was solubilized in water by the water-soluble linear macromolecules of poly(*N*-vinylpyrrolidone) (PVP), polyethylene glycol (PEG), poly(vinyl alcohol) (PVA), and dextran. Absorption of β-carotene in aqueous macromolecular solutions were red-shifted. The rate of photobleaching of β-carotene in water depended on the polymer species.

It is well-known that carotenoids are soluble in oragnic solvents but insoluble in water. Therefore, these have been studied in vivo and in organic solvents by many investigators,[1,2] but not in water. However, Shibata et al.[3] recently solubilized β-carotene in water by forming complexes with egg albumin. As shown in this report, we have succeeded in solubilizing β-carotene in water by means of water-soluble linear polymers of PVP, PEG, PVA and dextran.

Experimental

Materials. β-Carotene manufactured by Kanto Chemical Co., Inc. was used without further purification. PVP: molecular weight (mol wt), 40000 and PEG: mol wt, 20000 were purchased from Kishida Chemical Co., Ltd. PVA; PVA-117: mol wt, 77000, degree of saponification, 98.5 mol%, was kindly donated by Kuraray Co., Ltd. Dextran: mol wt, 75000 was purchased from Wako Pure Chemical Industries, Ltd. PVP, PEG, PVA, and dextran were purified by reprecipitation of them in solvent-nonsolvent, namely in water-acetone, benzene-petroleum ether, water-methanol, and water-ethanol, respectively. Bovine serum albumin (BSA) manufactured by Armour Pharmaceutical Company was used without further purification.

Method for Solubilization of β-Carotene. β-Carotene was solubilized in water as follows. An organic solvent containing β-carotene was added to a polymer/org. solv. or water solution. (The compositions of raw materials are shown in Table 1 for all the samples). The solution was evaporated to a dry β-carotene/polymer film under a reduced pressure at room temperature. A small amount of water was added onto the film, and stirred gently at room temperature until a homogeneous paste was formed. The paste was diluted with water to a given concentration of β-carotene. In the same way, β-carotene was solubilized in water by BSA or Triton X-100.

Analytical Methods. Absorption spectra at room temperature were measured with a double beam spectrophotometer, UVIDEC-510 (Japan Spectroscopic Co., Ltd.). Photobleaching experiments of β-carotene in different states were done under while light (2.7×10^2 J m^{-2} s^{-1}) from a projector lamp.

Results and Discussion

Figure 1 shows the absorption spectra of β-carotene in different states. β-Carotene in acetone had three ab-

a) β-Carotene. b) Mole ratio polymer/β-catotene. c) The number in parenthesis indicates an absorption maximum of a shoulder. d) Concentrations of β-carotene are 2×10^{-5} mol dm^{-3}.

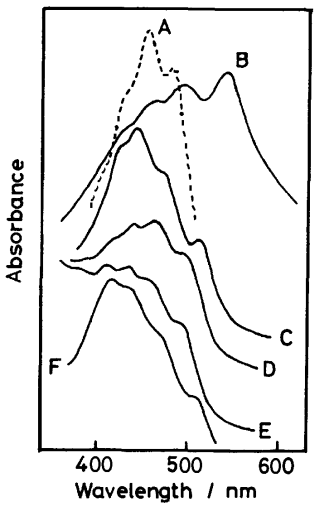

Fig. 1. Absorption spectra of β-carotene in different states. Concentrations of β-carotene are 2×10^{-5} mol dm^{-3}. The sample numbers indicated in Table 1 are shown in parentheses. (A) β-carotene in acetone, (B) β-carotene in aqueous PEG solution (No. 2), (C) β-carotene in aqueous PVP solution (No. 14), (D) β-carotene in aqueous PVA solution (No. 18), (E) β-carotene in aqueous dextran solution (No. 20), (F) β-carotene in aqueous BSA solution (No. 21).

sorption bands at 430, 450, and 481 nm. On the other hand, β-carotene in aqueous solutions of the water-soluble linear polymers and BSA had a red-shifted absorption band at the wavelength longer than 495 nm, in addition to the other three bands of shorter wavelength.

Also in Table 1, there was observed a red-shifted absorption band at the wavelength longer than 495 nm, in addition to the three or four bands of shorter wavelength, for all the β-carotene in aqueous macromolecular solutions. The red-shifted absorption appeared in the 495—543 nm range with different samples. The mole ratio polymer/β-carotene of raw material did not affect the wavelength of red-shifted absorption. It is noted, however, that the absorption bands of longer wavelength than 535 nm were observed only for the solutions with the mole ratio polymer/β-carotene of 1:1. Further, it was ascertained that the absorption spectra of β-carotene in aqueous PVP and PEG solutions were almost identical with those of the β-carotene/PVP and PEG films described in the Experimental section, respectively (data not shown).

Figure 2 shows the time-dependent spectral change of β-carotene in aqueous PVP solution caused by irradiation of white light. The intensity of red-shifted peak at 510 nm decreased at the same rate as the other bands of shorter wavelength. Such a spectral change was observed for all the β-carotene in aqueous macromolecular solutions shown in Fig. 3, suggesting that the red-shifted bands have the same origin as the other bands of shorter wavelength.

Figure 3 shows the results of photobleaching of β-carotene in different states by irradiation of while light. The rate of photobleaching of β-carotene in

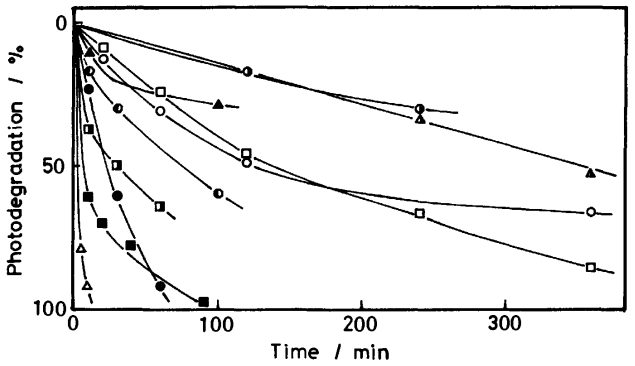

Fig. 3. Photobleaching of β-carotene in different states by irradiation of white light. The wavelengths monitoring the photobleaching were those of absorption peaks in the 440—465 nm range. The initial concentrations of β-carotene were 2×10^{-5} mol dm^{-3}. ▲, β-carotene in acetone; ◑, β-carotene in hexane; ▲, β-carotene in benzene; ◧, β-carotene in aqueous acetone (80%) solution; ◐, β-carotene in aqueous Triton X-100 solution (No. 23); ○, β-carotene in aqueous PVP solution (No. 14); □, β-carotene in aqueous PEG solution (No. 8); ■, β-carotene in aqueous PVA solution (No. 17); △, β-carotene in aqueous dextran solution (No. 19); ●, β-carotene in aqueous BSA solution (No. 22).

aqueous macromolecular solutions depended on the polymer species; the order of the rate of photobleaching was dextran>PVA>BSA>PEG>PVP. β-Carotene in aqueous dextran solution was photobleached almost completely after 10 min irradiation, while β-carotene in aqueous PVP solution remained unphotobleached by 35% after 360 min irradiation.

It should be also noted in Fig. 3 that β-carotene in acetone, hexane and benzene was more stable against light irradiation than that in aqueous macromolecular solutions. This result is unexpected because chlorophyll in the macromolecular complexes in water was more stable against light irradiation than chlorophyll in organic solvents.[4] Since β-carotene in aqueous acetone (80%) solution, having three absorption bands at 432, 457, and 483 nm, was photobleached at a higher rate than that in acetone as shown in Fig. 3, it is considered that the medium of water or organic solvents

was an important factor in the stabilization of β-carotene under light irradiation, in addition to the presence of polymer.

Recently, Wloch et al.[5-7] investigated a long-wavelength absorbing form (LWAF) of β-carotene and believed that it represents a fine-crystalline form of the pigment where head-to-tail aggregation occurs. According to them, it can be inferred that the linear macromolecules formed complexes with the fine-crystalline form of β-carotene, resulting in solubilization of the pigment in water. The polymers probably bound it within random coil of the chain. The difference in position of the red-shifted absorption bands may reflect the variation in size of the crystals of β-carotene.

Formation of Solvent-Separated Ion Pairs in Calixarene Ester-Alkali Picrate Complexes

Takashi ARIMURA, Michio KUBOTA, Tsutomu MATSUDA, Osamu MANABE,† and Seiji SHINKAI*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received December 5, 1988)

Synopsis. Association constants (K_a) of calix[n]arene esters ($\mathbf{1}_n$: n=4, 6, 8) for alkali picrates have been determined in tetrahydrofuran and compared with the $\mathbf{1}_n$-induced bathochromic shifts of the absorption maxima of alkali picrates. It has been established that (1) $\mathbf{1}_n$'s mostly form the 1:1 complexes with alkali metal cations, (2) the K_a values for $\mathbf{1}_n$ are generally smaller than those for crown ethers, and (3) the certain M^+-$\mathbf{1}_n$ complexes are considerably solvent-separated because of the "encapsulation effect" of the calixarene cavity. This is the first example for the systematic investigation on the relation between K_a and the geometry of the calixarene ester complexes.

Calixarenes are cyclic oligomers made up of phenol units. It has been found that the ester derivatives ($\mathbf{1}_n$'s) show the ionophoric nature and capable of binding alkali metal, alkaline earth metal, and diazonium ions are crown ethers do.[1-6] In particular, the tetramer ($\mathbf{1}_4$) exhibits the markedly high Na^+ selectivity.[1-5,7] Arduini et al.[2] proposed on the basis of the ^1H NMR measurements that Na^+ is "encapsulated" in the cavity constructed with the ionophoric -OCH_2COO- groups (Fig. 1). Here, two questions occur to us which are both related to the essential behaviors of $\mathbf{1}_n$ as ionophores: that is, if $\mathbf{1}_n$ really forms the encapsulated complexes as illustrated in Fig. 1, then (i) do they form only the 1:1 metal/$\mathbf{1}_n$ complexes but not the 1:2 metal/$\mathbf{1}_n$ sandwich complexes as seen for certain crown ethers? and (ii) do they show the characteristics of solvent-separated ion pairs? Recently, Inoue et al.[8] suggested an interesting idea that the bathochromic shift of the absorption band of the picrate anion, extracted into the organic phase with a macrocyclic ligand from aqueous metal picrate solutions, serves as a convenient measure for evaluating the ion pair tightness in solution. We thus studied the spectroscopic behaviors of alkali picrates (M^+Pic^-) in tetrahydrofuran (THF) in the absence and the presence of $\mathbf{1}_n$ and estimated the stoichiometry and the nature of the ion pairs.

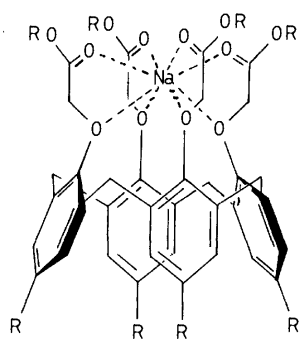

Fig. 1. Encapsulation of Na^+ by $\mathbf{1}_4$.

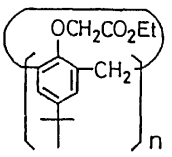

$\mathbf{1}_n$

Experimental

Preparations of $\mathbf{1}_4$ (25,26,27,28-tetrakis(ethoxycarbonylmethoxy)-*p*-*t*-butylcalix[4]arene), $\mathbf{1}_6$ (37,38,39,40,41,42-hexakis(ethoxycarbonylmethoxy)-*p*-*t*-butylcalix[6]arene), and $\mathbf{1}_8$ (49,50,51,52,53,54,55,56-octakis(ethoxycarbonylmethoxy)-*p*-*t*-butylcalix[8]arene) were described elsewhere.[1-6] All the spectroscopic measurements were carried out at 30 °C in THF.

Results and Discussion

The λ_{max} of M^+Pic^- shifted to longer wavelengths with a few isosbestic points with increasing $\mathbf{1}_n$ concentrations. The spectral change is similar to that in the presence of crown ethers.[9] From a plot of the absorbance for the new λ_{max} vs. $\mathbf{1}_4$ concentration we could determine the stoichiometry (by the molar ratio method) and the K_a (by the Benesi-Hildebrand plot). When the spectral change was relatively small, we employed the continuous variation method (absorbance for the new λ_{max} vs. $[M^+Pic^-]/([M^+Pic^-]+[\mathbf{1}_n])$ to determine the stoichiometry. However, the spectral changes observed for Li^+-$\mathbf{1}_n$(n=4, 6, 8), K^+-$\mathbf{1}_4$ and Cs^+-$\mathbf{1}_4$ were still too small to determine the stoichiometry. The results are summarized in Tables 1—3.

It is seen from Table 1 that $\mathbf{1}_n$'s mostly form the 1:1 complexes with alkali metal cations. This implies that metal cations are bound deeply in the cavity, the complexes being classified as a "nest-in-type". In crown ether chemistry, "perch-on-type" complexes, which frequently lead to the formation of 1:2 metal/crown sandwich complexes, result when the size of metal cations is greater than the cavity size. The metal selectivity in Table 3 suggests that the cavity

Table 1. Stoichiometry of $\mathbf{1}_n$-Alkali Picrate (M^+Pic^-) Complexes

$\mathbf{1}_n$	M^+Pic^-

n=4	a)	1:1	a)	a)
n=6	a)	1:1	1:1	1:1
n=8	a)	1:1	1:1	1:1

a) The spectral change was too small to determine the stoichiometry.

Table 2. Bathochromic Shifts ($\Delta\lambda$, nm) of λ_{max}[a)]

Ionophore	M^+Pic^-			
	M^+=Li^+	Na^+	K^+	Cs^+
$\mathbf{l}_4$	1	31	2	0
$\mathbf{l}_6$	1	6	25	20
$\mathbf{l}_8$	1	1	11	6
18-Crown-6	1	29	13	5
Cryptand 222	—	31	29	25

a) The λ_{max} values of M^+Pic^- in the absence of $\mathbf{l}_n$ are 343 nm for Li^+, 351 nm for Na^+, 357 nm for K^+, and 362 nm for Cs^+.

Table 3. Association Constants (K_a)

Ionophore	log K_a for M^+Pic^-[b)]			
	M^+=Li^+	Na^+	K^+	Cs^+
$\mathbf{l}_4$	3.00	3.95	3.08	1.60
$\mathbf{l}_6$	2.78	3.15	4.13	4.52
$\mathbf{l}_8$	2.08	2.61	3.11	3.08
18-Crown-6[a)]	3.72	4.29	5.33	4.91
Cryptand 222	—	6.69	8.38	6.61

a) The measurements were carried out mainly at [18-crown-6]/[M^+Pic^-]<2.0 so that the K_a values reflect those for the 1:1 complexes. b) K_a=[$M^+Pic^-\cdot\mathbf{l}_n$]/[$M^+Pic^-$][$\mathbf{l}_n$].

sizes of $\mathbf{l}_4$ and $\mathbf{l}_6$ are comparable with those of 15-crown-5 and 18-crown-6, respectively. Hence, the formation of the sandwich complex with $\mathbf{l}_n$ is expected, if it exists, for Cs^+-$\mathbf{l}_4$. Although the stoichiometry for this complex could not be determined even by the continuous variation method, the Benesi-Hildebrand plot (at [$\mathbf{l}_4$]/[Cs^+Pic^-]=10—100) used assuming the formation of the 1:1 complex gave a good linear relationship (r>0.98). Probably, this complex also consists of 1:1 $Cs^+/\mathbf{l}_4$. It is known that calix[8]arene derivatives having a large cavity are capable of including two guest molecules.[10,11] In the present system, however, we could not find any evidence for the formation of 2:1 $M^+/\mathbf{l}_8$ complexes.

The λ_{max} for M^+Pic^- in the absence of $\mathbf{l}_n$ shifted to longer wavelengths in the order of Li^+<Na^+<K^+<Cs^+. This order reflects the looseness of the ion pairs. The bathochromic shifts of λ_{max} induced by the addition of $\mathbf{l}_n$ are recorded in Table 2. The largest shift (31 nm) was attained for Na^+-$\mathbf{l}_4$. This shift is comparable with that induced by cryptand 222 and even greater than that induced by 18-crown-6, supporting the formation of the solvent-separated ion pair.[9,12] The significant bathochromic shifts were also observed for K^+, Cs^+-$\mathbf{l}_6$ (20—25 nm). In contrast, the shifts induced by $\mathbf{l}_8$ were generally small. Presumably, even though M^+ is entrapped in the cavity of $\mathbf{l}_8$, the M^+-Pic^- interaction can still exist because of the flexible, large cavity.

Comparison of Table 2 with Table 3 reveals that these two recognition patterns are surprisingly similar: that is, the greater the K_a, the larger bathochromic shift occurs. This means that the stable $\mathbf{l}_n$ complex encapsulates M^+ deeply in the cavity resulting in the solvent-separated ion pair. The largest K_a was attained for Cs^+-$\mathbf{l}_6$ but not for Na^+-$\mathbf{l}_4$. This implies that

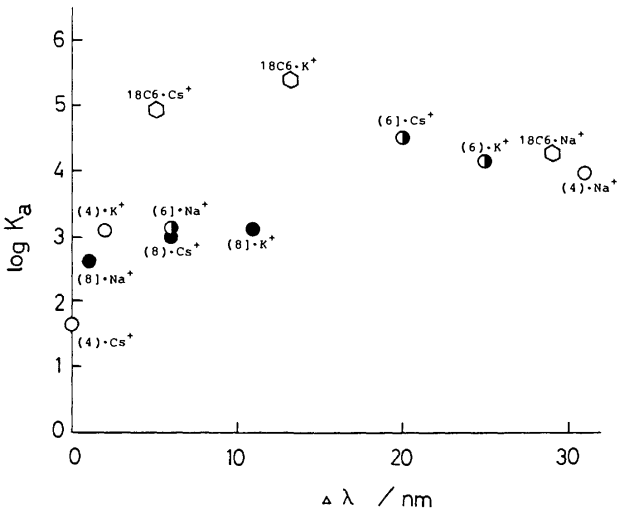

Fig. 2. log K_a vs. $\Delta\lambda$ map. In the figure $\mathbf{l}_n$'s are abbreviated with [n].

Na^+Pic^- bound to $\mathbf{l}_4$ is considerably solvent-separated but the complex is not so stable as that of Cs^+-$\mathbf{l}_6$. The discrepancy is probably related to the rigid nature of the calix[4]arene skeleton which is the origin of the sharp Na^+ selectivity: that is, the cavity of $\mathbf{l}_4$ is so small and so rigid that the Na^+-Pic^- interaction is efficiently shut down by the encapsulation of Na^+. On the contrary, $\mathbf{l}_6$ having the moderately rigid skeleton rather gives the stable complexes although the metal selectivity becomes inferior to that of $\mathbf{l}_4$.

Based on these foregoing findings, we illustrated a log K_a vs. $\Delta\lambda$ map (Fig. 2). The map explicitly clarifies several novel facets of the M^+-$\mathbf{l}_n$ complexes. Firstly, 18-crown-6 forms the considerably stable K^+ and Cs^+ complexes but they are less solvent-separated. In contrast, the K_a for Na^+ is smaller than these but the ion pair is much more solvent-separated. Secondly, the K_a values for $\mathbf{l}_n$ are generally smaller than those for 18-crown-6. Nevertheless, certain complexes (e.g., Na^+-$\mathbf{l}_4$, K^+-$\mathbf{l}_6$, and Cs^+-$\mathbf{l}_6$) result in the solvent-separated ion pairs in which the bathochromic shifts greater than 20 nm are observed. This indicates that the solvent-separatedness of these complexes is comparable with that of the cryptand complexes. The unusual power of $\mathbf{l}_n$ is ascribed to the "encapsulation effect", which appears most clearly in $\mathbf{l}_n$ having the small, rigid skeleton. Thirdly, the $\mathbf{l}_8$ complexes give the log K_a=2.8±0.3 for Na^+, K^+, and Cs^+. The nonselective nature suggests that the ion complexation with $\mathbf{l}_8$ occurs according to an "induced-fit" manner. Lastly, the Cs^+-$\mathbf{l}_4$ complex, a combination of the large alkali metal cation and the small calixarene cavity, did not cause any bathochromic shift but slightly increased the absorbance. The K_a estimated from this absorbance increase was only 40 $dm^3\,mol^{-1}$. The data visualize the Cs^+-$\mathbf{l}_4$ complex geometry: $\mathbf{l}_4$ weakly interacts with Cs^+ but cannot encapsulate Cs^+ enough to interfere with the Cs^+-Pic^- interaction.

In conclusion, the present study systematically demonstrated that (i) calixarene esters $\mathbf{l}_n$'s mostly form the 1:1 complexes with alkali metal cations and (ii)

they have a tendency to produce the solvent-separated ion pairs. Thus, small Na^+ ion is easily encapsulated leading to the solvent-separated ion pairs, whereas large Cs^+ ion is exposed to solvent media leading to the contact ion pairs. Further investigation on the reactivities and the geometries of these solvent-separated ion pairs is currently continued in our laboratories.

12) In order to obtain a further insight into the $\mathbf{l}_n \cdot M^+Pic^-$ ion pairs we measured the ^{23}Na NMR in THF/THF-d_8 mixed solvent at 30 °C. We unexpectedly found that the peak for Na^+ (added as M^+Pic^- (6.8×10^{-3} mol dm^{-3})) is invariably broadened in the presence of $\mathbf{l}_n$: for example, the T_2 values, which can be directly calculated from the peak width ($T_2=(\pi\delta_{\nu 1/2})^{-1}$ where $\delta_{\nu 1/2}$ denotes the half height line width in Hz) are 7.08×10^{-4} s in the absence of $\mathbf{l}_n$, 1.62×10^{-5} s in $\mathbf{l}_4$ (140 mmol dm^{-3}), 2.11×10^{-5} s in $\mathbf{l}_6$ (470 mmol dm^{-3}), and 3.18×10^{-5} s in $\mathbf{l}_8$ (340 mmol dm^{-3}). Such a broadening effect was not found for Na^+ bound to cyclic polyethers: $T_2=8.85\times10^{-4}$ s in 18-crown-6 (340 mmol dm^{-3}) and 1.47×10^{-3} s in cryptand 222 (670 mmol dm^{-3}). The similar observation was reported by Jin and Ichikawa: paper presented at the 57th Annual Meeting of the Chemical Society of Japan, Sendai, 1988, September.

Synthesis and Molecular Structure of Hexacarbonyl(tropone)diiron

Noboru MORITA, Chizuko KABUTO,† and Toyonobu ASAO*
Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980
†Instrumental Analysis for Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
(Received December 5, 1988)

Synopsis. Molecular structure of hexacarbonyl(tropone)-diiron has been investigated by X-ray diffraction studies.

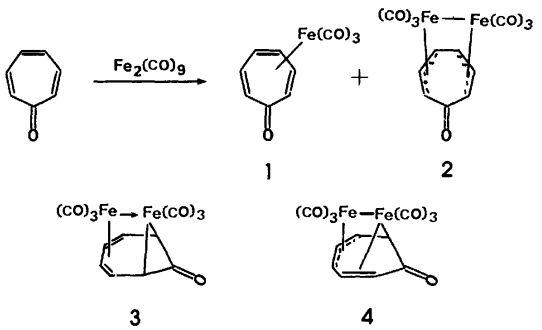
Previously, tricarbonyl(tropone)iron has been obtained by the reaction of acetylene with $Fe_2(CO)_9$,[1] or of tropone with $Fe(CO)_5$,[2] $Fe_2(CO)_9$,[3,4] or $Fe_3(CO)_{12}$,[5] and the complexes of tropone derivatives have also been obtained by the reaction of substituted tropones with $Fe_2(CO)_9$.[4]

Dodge reported in 1964[6] the X-ray analysis of the complex to clarify the structure of tricarbonyl[(2,3,4,5-η)-2,4,6-cycloheptatrienone]iron. Furthermore, many interesting chemical properties have been explored for the complexes.[7] Recently we have succeeded in optical resolution of the complex,[8] although partial resolution has been reported,[9] and kinetic data of 1,3-haptotropic rearrangement,[8] absolute configuration[10] of the complex and the related complexes have been reported.

In the course of our studies on synthesis and properties of tricarbonyl iron complex of tropone and its derivatives, we have isolated new hexacarbonyl diiron complexes along with tricarbonyl iron complexes. We have tentatively proposed a structure of hexacarbonyl-[μ-[(2,3,4-η:5,6,7-η)-2,4,6-cycloheptatrienone]]diiron for the new complex of tropone based on the spectroscopic data.[11]

Recently, we have investigated a molecular structure of the new complex by X-ray diffraction and we have found our proposed structure is correct, the results of which will be reported herein.

In the synthetic study of tricarbonyl(tropone)iron **1** by the reaction of tropone with excess of $Fe_2(CO)_9$ in refluxing ether, we isolated a new complex **2** as dark reddish crystals in 14% yield besides known complex **1** in 56% yeild.[11] Some substituted tropones also afforded mixtures of type **1** and type **2** complexes.[12] The complex **2** was also obtained from **1** by the reaction with $Fe_2(CO)_9$ in 25—30% yeild, and it was also found that **2** gradually decomposed by heating in benzene to give **1** and tropone itself.



Mass spectrum of the new complex **2** by FD method showed a molecular ion peak at m/z 386 corresponding to $C_7H_6OFe_2(CO)_6$, coincided with the results of elemental analysis, and the abundant fragment ions by electron impact mode were observed at m/z 274 (1), 246 (1), 218 (5), 106 (58), and 78 (100). The infrared spectrum of **2** in KBr disk showed absorptions at 2060, 2025, 2010, 1995, 1980, 1960, 1955, and 1599 cm^{-1}, the ultraviolet absorption spectrum in ethanol showed maxima at 224 nm (log ε 4.26), 341 (3.94), and 432 (3.49), and ^1H NMR in $CDCl_3$ at 90 MHz showed signals at δ=3.33 (d, J=7.15 Hz, H-2,7), 4.40—4.67 (m, H-3,6), and 4.67—4.99 (m, H-4,5), ^{13}C NMR in $CDCl_3$ at 22.5 MHz showed signals at δ=209.50 (s, C-1), 191.96 (s, Fe-CO), 74.10 (d, J=161.6 Hz, C-3,6), 63.69 (d, J=156.2 Hz, C-2,7), and 62.49 (d, J=161.9 Hz, C-4,5).

From these sepctroscopic data we assigned a structure of hexacarbonyl[μ-[(2,3,4-η:5,6,7-η)-2,4,6-cycloheptatrienone]]diiron for the complex **2**, similar to hexacarbonyl(cycloheptatriene)diiron.[13] However, we could not exclude other structures such as **3** and **4**. Therefore, we carried out an X-ray crystallographic analysis of **2**. The molecular structure and atom labeling scheme for the complex **2** are presented in Fig. 1.

The crystallographic result shows that the structure **2** is indeed correct for this complex. Two independent

a) The values are averaged over the equivalent bonds for mirror symmetry of the structure between two independent molecules. The e.s.d.'s are 0.003, 0.017, 0.023 Å for Fe-Fe, Fe-C, C-C bonds and 0.5, 0.8, 1.6° for Fe-Fe-C, C-Fe-C, C-C-C angles.

complexes of **2** exist in the crystalline state; however there is no essential difference in the structure of tropone ligand as well as in the way of coordination. As shown in perspective views of complex **2** (Fig. 1), the structure has an approximate mirror plane within the experimental errors. Table 1 lists the average values over the geometrically equivalent bond distances and angles for the two molecules. Tropone ligand is bent in a similar way to the case of cycloheptatriene complex, though the planarity is more retained. Somewhat longer distance of Fe_1-Fe_2 (2.894 Å) in **2** compared to that in the latter (2.866 Å) may be due to the difference of the planarity.

Experimental

Reaction of Tropone and $Fe_2(CO)_9$. A slurry of tropone (0.9 g, 8.5 mmol) and $Fe_2(CO)_9$ (8 g, 22 mmol) in 60 ml of anhydrous ether was heated at reflux under argon atmosphere for ca. 7 h. The reaction mixture was chromatographed on silica gel. The first eluent with a mixture of ether and benzene (1:9) gave green-colored $Fe_3(CO)_{12}$. From the next orange colored band eluted with a mixture of benzene and CH_2Cl_2 (1:9), complex **1** (1.18 g, 56%) was obtained as orange solid. From the successive reddish colored band eluted with ethyl acetate, complex **2** (466 mg, 14%) was obtained as dark reddish crystals. Recrystallization of **2** from benzene afforded an analytical sample, mp 118—120 °C as dark reddish prisms. Found: C, 39.92; H, 1.44%. Calcd for $C_7H_6OFe_2(CO)_6$; C, 40.45; H, 1.57%.

Reaction of 1 and $Fe_2(CO)_9$. A slurry of **1** (500 mg, 2.0 mmol) and $Fe_2(CO)_9$ (1.25 g, 3.4 mmol) in 60 ml of anhydrous ether was heated at reflux for 2 h. The reaction mixture was separated by chromatography on silica gel to afford **1** (186 mg, 37%) and **2** (247 mg, 29%).

Crystal Measurements, Data Collection, and X-Ray Structure Refinement for 2. A redish crystal with the sizes of 0.2×0.2×0.23 mm was used for data collection on a Rigaku automated four-circle diffractometer with a rotating anode (40 kV, 150 mA) using graphite monochromated Cu $K\alpha$ radiation (1.5418 Å). Crystal data are as follows: M.F.=$C_7H_6OFe_2(CO)_6$, M.W.=385.88, triclinic, space group $P\bar{1}$, a=14.660(3), b=12.919(3), c=9.086(3) Å, α=92.50(2), β=115.20(2), γ=112.00(2)°, V=1400.7(9) Å^3, Z=4, $D_{calcd.}$=1.83 g cm^{-3}. A total of 4250 reflections within 2θ=128° were collected by the θ-2θ scan mode. The structure determination was rather difficult, but finally succeeded by the direct method in consideration of pseudo-symmetrical location for eigth Fe atoms in the unit cell. The structure, thus obtained, were refined by the block diagonal least-squares method to prove the correct space group of $P\bar{1}$. After the Fe, C, and O atoms were refined anisotropically and the calculated H atoms were included, the final R value was 0.082 (R_w=0.093) for 3074 reflections with $F_o > 3\sigma(F_o)$.

Tables of positional and anisotropic thermal parameters of heavy atoms, and observed and calculated structural factors are kept at the Chemical Society of Japan, Document No. 8872. The details of crystallographic data should be requested to the author.

The authors are grateful to Dr. Hideo Sotokawa, Research Institute of Non-aqueous Solutions, Tohoku University for the technical asistant in X-ray diffraction analysis.

Reactions of Metal Benzoylacetonates and Acetylacetonates with Formaldehyde

Tsutomu TAKEICHI,* Hiroaki OKUMURA, Yoshihiro SAKURADA, and Yuzi TAKAYAMA
School of Materials Science, Toyohashi University of Technology, Toyohashi 440
(Received December 13, 1988)

Synopsis. The reaction of cobalt benzoylacetonate with formaldehyde in water or methanol gave benzoic acid along with 4-hydroxy-3,3-bis(hydroxymethyl)-2-butanone or 4-methoxy-3,3-bis(hydroxymethyl)-2-butanone, respectively. The result suggests the formation of acetic acid in the reaction of metal acetylacetonate.

"Formose Reaction",[1] by which a complex mixture of sugars and sugar alcohols is formed by the base-catalyzed condensation of formaldehyde, has been attracting much attention in connection with the prebiotic synthesis of carbohydrates,[2] the possibility of the production of edible sugars from a simple materials, and the establishment of a metabolic cycle system of carbon resources in sustained space flight.[3] In general, however, the reaction results in complex products mixture, which hinders the utility of the attractive reaction. Selective formation of specific product is actively explored by using inorganic[4] or organic bases[5] as catalyst, or by photo- and γ-irradiation.[6]

During our attempt for a selective formose reaction using metal complexes, it was found out that a variety of metal acetylacetonates afforded 4-hydroxy-3,3-bis(hydroxymethyl)-2-butanone, **1**, and 4-methoxy-3,3-bis(hydroxymethyl)-2-butanone, **2**, selectively in water and methanol, respectively.[7] It was considered that **1** and **2** were formed from C-C bond cleavage of the ligand and the condensation with formaldehyde and the solvent.[7] But the fate of the other half of the ligand remained unknown. To clarify the feature of this reaction, the reaction of cobalt benzoylacetonate, instead of metal acetylacetonates, with formaldehyde was examined.

Experimental

Measurement. The gas chromatography (GC) was carried out with an OKURA Model 103 or a SHIMADZU Model GC-7AG equipped with a glass capillary column (i.d. 0.28 mm, 10 m) containing OV-1 or SE-30, the temperature of which was programmed from 100 °C to 260 °C at 6 °C min^{-1}. IR analyses were observed by JASCO Infrared Spectrophotometer Model A-3 or by JEOL JIR-40X FT-IR Spectrophotometer. ^1H NMR spectra were taken by JEOL JNM-GX 270 FT-NMR Spectrometer. Consumption of formaldehyde was determined by the method of Bricker[8] at 579 nm with HIRATA model 6B.

Formaldehyde Solution. Paraformaldehyde (1.20 g, 0.400 mol) was added into 200 ml of distilled water or anhydrous methanol and dissolved by heating to reflux for 6 h under N_2 atmosphere.

Reaction of Cobalt Benzoylacetonate with Formaldehyde. Into 30 ml of above prepared solution containing 1.80 g (60 mmol) of formaldehyde was added 1.0 mmol (0.3813 g) of cobalt benzoylacetonate,[9] and the mixture was stirred at 60 °C for 20 h under N_2 atmosphere. A 2 ml of aliquot was taken out to measure the formaldehyde consumption.

GC Analysis of the Products. After the removal of solvent and the unreacted formaldehyde, the products were trimethylsilylated[10] and analyzed by GC. Quantitative analysis of the silylated products was performed using tetradecane as an internal standard.

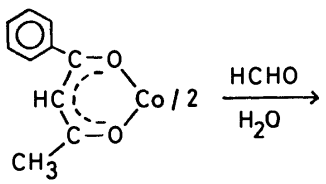
Isolation of the Products. The reaction mixture was treated with cation-exchange resin (Amberlite IR 118), followed by the removal of water and the unreacted formaldehyde, and then purified by column chromatography on silica gel (acetone/chloroform).

From the reaction of cobalt benzoylacetonate (3.813 g, 10 mmol) with formaldehyde (18.0 g, 600 mmol) in 300 ml of water, 0.50 g (4.1 mmol) of benzoic acid was obtained as white or pale-yellow crystal.

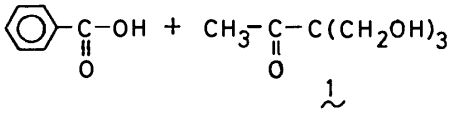
Results and Discussion

Reaction of Cobalt Benzoylacetonate with Formaldehyde in Water. Cobalt benzoylacetonate was reacted with formaldehyde in water at 60 °C for 20 h under N_2 atmosphere. The GC pattern of the trimethylsilylated products, as shown in Fig. 1a, was simple and a major peak, **A** in Fig. 1a, appeared, which was not observed in the case of metal acetylacetonates as shown in Fig. 1b.[7] It is to be noticed that a peak **B**, corresponding to **1**, was observed in the GC.

The reaction mixture treated with cation-exchange resin and purified by column chromatography to give the major product, corresponding to **A**, as a colorless or yellow crystal, which was identified to be benzoic acid by ^1H NMR, IR, and GC. The formation of **1** was also confirmed. Accordingly, equation shown below will be given for this reaction.



(1)



1

Quantitative analysis of the silylated products by GC using tetradecane as an internal standard gave 53 mg (0.43 mmol) of benzoic acid and 7 mg (0.05 mmol) of **1** from 1.0 mmol of cobalt benzoylacetonate. The conversion of formaldehyde was 8.0%, which means that 4.8 mmol of formaldehyde was consumed.

In the case of benzoylacetone complex, two mode of cleavage of ligand is possible as shown in Scheme 1. Route X leads to the formation of benzoic acid and **1**, and route Y to acetic acid and another polyol. Route X was confirmed here. The possible formation of other

products by route Y can not be neglected, but selective formation of benzoic acid and **1**, as shown in Fig. 1a, suggest that Route X is favored in this reaction.

Reaction of Cobalt Benzoylacetonate with Formaldehyde in Methanol. The same procedure was followed using methanol as solvent. The gas chromatogram of the trimethylsilylated products, as shown in Fig. 2a, suggests the formation of benzoic acid in the peak **A**. A peak **C**, corresponding to **2**, also appeared on the gas chromatogram. Benzoic acid was confirmed by isolating it following the above mentioned procedure, giving equation 2, shown below, for this reaction.

The quantitative analysis of the product by GC using tetradecane gave 33 mg (0.27 mmol) of benzoic acid and 2 mg (0.01 mmol) of **2** from 1.0 mmol of cobalt benzoylacetonate. The conversion of form-

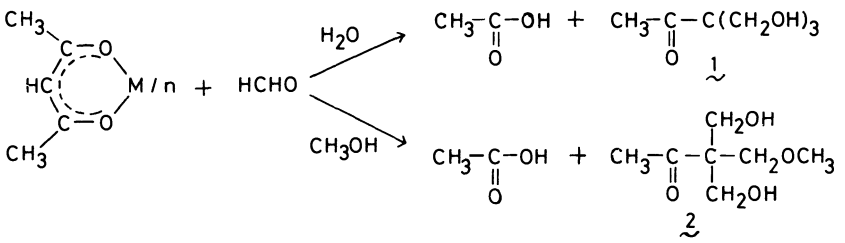
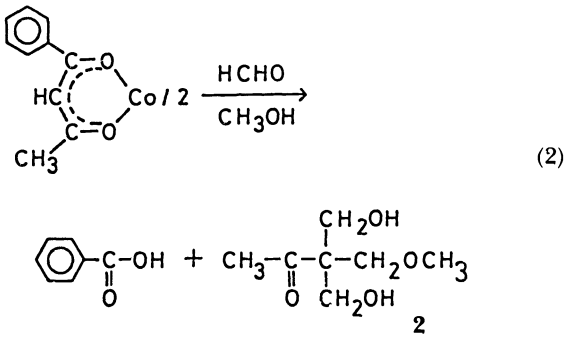


Scheme 2.



(2)

aldehyde was 1.9%, which correspond to 1.1 mmol of formaldehyde consumption.

Reaction of Metal Acetylacetonates. As menthioned before, the reaction of metal acetylacetonate with formaldehyde in water and methanol gave **1** and **2**, respectively, but the fate of the other half of the acetylacetone ligand was unknown. From the similarity of the reactions of acetylacetone and benzoylacetone complexes, the formation of benzoic acid in the reaction of metal benzoylacetone with formaldehyde, in turn, suggests the structure of the other half of the acetylacetone in the reaction of metal acetylacetonates, as acetic acid, which could not be isolated due to the volatility.

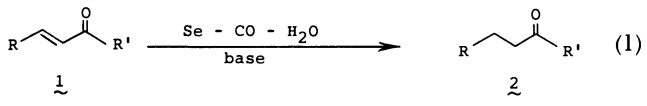
Selective Reduction of α,β-Unsaturated Carbonyl Compounds with Carbon Monoxide and Water Assisted by Selenium

Yutaka NISHIYAMA,* Yasuhiko MAKINO, Sawako HAMANAKA, Akiya OGAWA,† and Noboru SONODA†,*
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564
†Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received December 22, 1988)

Synopsis. Carbon–carbon double bond of α,β-unsaturated carbonyl compounds can be reduced selectively with hydrogen selenide, generated in situ by the reaction of elemental selenium with carbon monoxide and water in the presence of strongly basic tertiary amine.

Recently we have developed a new reduction system, in which hydrogen selenide or its amine salt, formed in situ by the reaction of selenium with carbon monoxide and water, acts as an active reducing species.[1] The advantage of the utilization of this reduction system is to use strongly toxic hydrogen selenide[2] safely for reduction of organic compounds.[3] Now we have found that the Se–CO–H_2O reaction system is successfully usable for the selective reduction of the olefinic linkage of various α,β-unsaturated carbonyl compounds (Eq. 1).



(1)

When benzylideneacetone (**1a**) was treated with carbon monoxide, water, and an equivalent amount of selenium in the presence of 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU)[4] at 50 °C, reduction of the carbon–carbon double bond took place selectively to give 4-phenyl-2-butanone (**2a**) in 82% yield. It was confirmed that similar reduction was widely applicable for the reduction of various α,β-unsaturated carbonyl compounds, and the results are summarized in Table 1. Enones having furyl or thienyl group undergo selective reduction without affecting the furyl or thienyl group (Runs 3 and 4). Reduction of α,β-unsaturated carboxylic acid (Run 5), ester (Run 6), and nitrile (Run 7) also proceeds at somewhat higher temperatures (80—100 °C). In the case of α,β-unsaturated aldehydes such as cinnamaldehyde, the similar reduction did not take place under the conditions employed.[5] Interestingly, enone (**1i**), which has no aromatic ring at the β position, underwent reduction of only conjugated C–C double (Run 9).[6] β-Ionone was reduced to 4-(2,6,6-trimethyl-

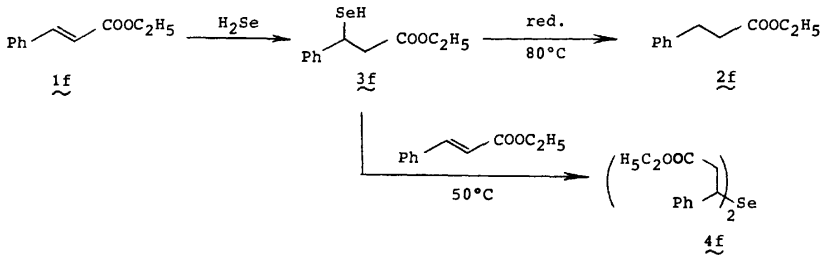
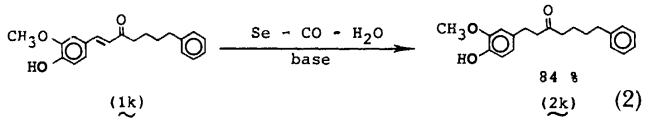


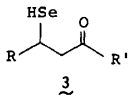
Scheme 1.

1-cyclohexenyl)-2-butanone (**2j**) in good yield (Run 10). This method is effective for the conversion of yakuchinone B (**1k**) to yakuchinone A (**2k**), both of which are linear diarly heptanoids with high pungency (Eq. 2).



(2)

Although the mechanism of the reduction is not fully clarified, the reaction proceeds most probably through the Michael adduct **3** formed in situ by the



addition of hydrogen selenide to α,β-unsaturated carbonyl compound **1**. The formation of **3** is supported by the following observation: when the reaction of ethyl cinnamate (**1f**) with carbon monoxide, water, and selenium was carried out under controlled conditions (see Experimental section), the selenide **4f** was mainly formed probably through the Michael adduct **3f** (Scheme 1).

A number of methods have been reported for selective reduction of α,β-unsaturated carbonyl compounds: for example, catalytic hydrogenation using metal catalysts,[7] reduction with metal hydrides,[8] and reduction with metal or metal alloy.[9] However, high functional selectivity demonstrated in the text makes the present method more attractive.

Experimental

Instruments. The Instruments Used Were as Follows: ^{1}H NMR JEOL JNM-PS-100 and JEOL JNM-GXS-400; ^{13}C NMR Hitachi R-90H; IR, JASCO A-202; MS, Hitachi RMU-6A and JEOL JMS-QH100; melting points, Yanagimoto micro melting point apparatus.

Materials. Metallic selenium (99%) of Wako Chem. Co. and carbon monoxide (99.9%) of Seitetsu Chem. Co. were used. α,β-Unsaturated ketones (**1b**,[10] **1c**,[11] and **1k**[12]) were prepared according to the literatures. Preparation of **1d** was described below. Tetrahydrofuran (THF), amines, and other α,β-unsaturated carbonyl compounds were all purchased from commercial sources and purified by distillation or recrystallization.

4-(2-Thienyl)-3-buten-2-one (1d). To a mixture of 2-thiophenecarbaldehyde (22.4 g, 200 mmol), acetone (26.3 g, 453 mmol), and water (150 mL) was added 33% sodium hydroxide solution (3.8 mL) at 0 °C, and the mixture was stirred for 4 h at room temperature. The reaction mixture was neutralized with dilute sulfuric acid (10%). The organic layer was separated and dried over $MgSO_4$. The solvent was evaporated and the resulting liquid was distilled to give 24.1 g (79%) of 4-(2-thienyl)-3-buten-2-one (**1d**): bp 103—104 °C/6 mmHg (1 mmHg≈133.322 Pa). IR (NaCl) 1660, 1610, 960, 700 cm^{-1}; ^{1}H NMR δ=2.24 (s, 3H), 6.40 (d, J=16 Hz,1H), 6.84—7.40 (c, 3H), 7.53 (d, J=16 Hz,1H); MS (m/z) 152 (M^+).

Typical Procedure for Reduction of α,β-Unsaturated Carbonyl Compounds. A stirred mixture of benzylideneacetone (1.46 g, 10 mmol), selenium (0.79 g, 10 mmol), water (1.8 mL, 100 mmol), DBU (3.0 mL, 20 mmol), and THF (5 mL) sealed in a 50 mL stainless steel autoclave was heated under the pressure of carbon monoxide (30 atm; initial pressure at 25 °C) at 50 °C for 24 h. After the reaction was complete, carbon monoxide was purged in a well-ventilated hood, and air was blown into the solution for 10 min in order to oxidize the remaining hydrogen selenide to elemental selenium. Selenium deposited was filtered off and the filtrate was acidified with aqueous hydrochloric acid (2 M; 1 M=1 mol dm^{-3}) to pH 1—2, followed by extracted with diethyl ether (4×50 mL) and benzene (50 mL). The combined extracts were dried over $MgSO_4$. After the filtration, the solvent was evaporated in vacuo to leave yellow oil of crude material, which was chromatographed on silica gel (benzene/Et_2O=1:1) to give 1.22 g (82%) of 4-phenyl-2-butanone (**2a**): IR (neat) 1700, 740, 700 cm^{-1}; ^{1}H NMR δ=1.96, (s, 3H), 2.62 (t, J=7 Hz, 2H), 2.68 (t, J=7 Hz, 2H), 6.96—7.10 (m, 5H); MS (m/z) 148 (M^+).

Reduction of other α,β-unsaturated carbonyl compounds (**1b—1k**) and the following isolation were performed with the similar procedure described above, and the spectral data of the reduced products (**2b—2k**) were shown below. All products were identified by comparison of their ^{1}H NMR, IR, and mass spectra with those of samples commercially available or synthesized independently.

1,3-Diphenyl-1-propanone (2b). IR (neat) 1675, 740, 690 cm^{-1}; ^{1}H NMR (CCl_4) δ=2.76—3.17 (c, 4H), 6.90—7.40 (c, 8H), 7.78 (dd, J=8 and 2 Hz, 2H); MS (m/z) 210 (M^+); mp 71.5—73 °C (lit,[7a] 72—73 °C).

4-(2-Furyl)-2-butanone (2c). IR (neat) 1715, 730 cm^{-1}; ^{1}H NMR (CCl_4) δ=2.03 (s, 3H), 2.72 (t, J=8 Hz, 2H), 2.79 (t, J=8 Hz, 2H), 5.85—5.98 (m, 1H), 6.10—6.24 (m, 1H), 7.15—7.29 (m, 1H); MS (m/z) 138 (M^+).

4-(2-Thienyl)-2-butanone (2d). IR (neat) 1710, 695 cm^{-1}; ^{1}H NMR (CCl_4) δ=2.10 (s, 3H), 2.62 (t, J=8 Hz, 2H), 2.94 (t, J=8 Hz, 2H), 6.60—7.00 (c, 3H); MS (m/z) 154 (M^+).

3-Phenylpropionic Acid (2e). IR (KBr) 3500—2800, 1710, 735, 695 cm^{-1}; ^{1}H NMR (CCl_4) δ=2.50 (t, J=7 Hz, 2H), 2.82 (t, J=7 Hz, 2H), 7.02—7.24 (m, 5H), 11.68 (s, broad, 1H); MS (m/z) 150 (M^+); mp 47—48.5 °C (lit,[13] 47—49 °C).

Ethyl 3-Phenylpropionate (2f). IR (neat) 1720, 1180, 740, 695 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.12 (t, J=8 Hz, 3H), 2.45 (t, J=8 Hz, 2H), 2.82 (t, J=8 Hz, 2H), 3.99 (q, J=8Hz, 2H), 7.00—7.35 (m, 5H); MS (m/z) 178 (M^+).

3-Phenylpropiononitrile (2g). IR (neat) 2240, 745, 695 cm^{-1}; ^1H NMR (CCl_2) δ=2.30 (t, J=8 Hz, 2H), 2.68 (t, J=8 Hz, 2H), 6.94—7.26 (m, 5H); MS (m/z) 131 (M^+).

Diethyl Succinate (2h). IR (neat) 1720, 1150 cm^{-1}; ^1H NMR (CCl_4) δ=1.34 (t, J=12 Hz, 6H), 2.54 (s, 4H), 4.18 (q, J=12 Hz, 4H); MS (m/z) 174 (M^+).

Dihydrocarvone (2i). IR (neat) 1710, 1650 cm^{-1}; ^1H NMR (CCl_4) δ=1.00—1.20 (m, 3H), 1.35—2.10 (c, 8H), 2.15—2.85 (m, 3H), 4.80—4.95 (m, 2H); MS (m/z) 152 (M^+).

4-(2,6,6-Trimethyl-1-cyclohexenyl)-2-butanone (2j). IR (neat) 1720, 1365, 1165 cm^{-1}; ^1H NMR (CCl_4) δ=1.00 (s, 6H), 1.40—2.15 (c, 8H), 1.57 (s, 3H), 2.15 (s, 3H), 2.25—2.55 (m, 2H); MS (m/z) 194 (M^+).

1-(3-Hydroxy-4-methoxyphenyl)-7-phenyl-3-heptanone (Yakuchinone A) (2k). IR (neat) 3560, 1710, 1275 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.51—1.62 (m, 4H), 2.38 (t, J=8 Hz, 2H), 2.58 (t, J=8 Hz, 2H), 2.60—2.90 (m, 4H), 3.82 (s, 3H), 5.50 (s, broad, 1H), 6.61 (dd, J=2,8 Hz, 1H), 6.73 (d, J=2 Hz, 1H), 6.78 (d, J=8 Hz, 1H), 7.00—7.40 (m, 5H); MS (m/z) 312 (M^+).

Isolation of Monoselenide (4f). A stirred mixture of ethyl cinnamate (**1f**) (1.76 g, 10 mmol), selenium (10 mmol), water (10 mmol), *N*-methylpyrrolidine[14] (20 mmol), and THF (5 mL) was heated under CO (30 atm) at 50 °C for 24 h. By a similar workup and purification as described above, the selenide (**4f**) was obtained in 84% yield as a mixture of its diastereoisomers whose IR, ^1H NMR, ^{13}C NMR, and mass spectrum are listed. Owing to thermal instability of the selenide, confirmation of their structures by elemental analyses was unsuccessful. IR (neat) 1730 (C=O), 1250, 1180 cm^{-1}; ^1H NMR (CCl_4) δ=1.10 (t, J=7.1 Hz, 3.6H), 1.15 (t, J=7.1 Hz, 2.4H), 2.76—2.98 (m, 2H), 3.94—4.07 (m, 4H), 4.18 (dd, J=7.3 and 8.4 Hz, 1.2H), 4.43 (dd, J=7.8 and 8.1 Hz, 0.8H), 7.11—7.29 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=13.9 ($\underline{C}H_3CH_2$–), 39.3 and 39.5 ($\underline{C}$–C=O), 41.5 and 41.8 ($\underline{C}$–Se), 60.2 (O–$\underline{C}$). 126.8, 127.0, 127.3, 127.6, 128.2, 141.6 (Ph), 170.1 and 170.2 ($\underline{C}$=O); MS (m/z) 434 (M^+,^{80}Se).

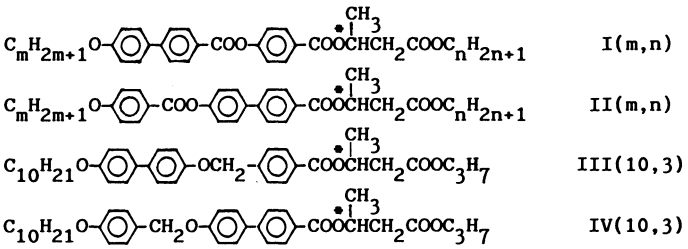
Novel Ferroelectric Liquid Crystals Derived from *n*-Alkyl Esters of (*R*)-3-Hydroxybutanoic Acid (II), the Correlation between Their Ferroelectric Properties and Their Molecular Structure

Jun NAKAUCHI,* Yoshitaka KAGEYAMA, Seiji HAYASHI, and Keiichi SAKASHITA
Tokyo Research Laboratories, Mitsubishi Rayon Co., Ltd., Noborito, Tama-ku, Kawasaki, Kanagawa 214
(Received September 16, 1988)

The temperature dependence of the spontaneous polarization (*Ps*) and the optical tilt angle (θ) of the following series of novel ferroelectric liquid crystals, derived from normal alkyl esters of (*R*)-3-hydroxybutanoic acid, have been investigated.



The magnitude of *Ps* and θ depends on the kind of linkage groups and their position in the core moiety as well as on the lengths of both terminal chains. The *Ps*'s for **I**(*m*,*n*) and **II**(*m*,*n*) show a maximum at (*m*,*n*)=(10, 3), whereas their θ's increase with the *m* and do not change very much with *n*. In comparison with four analogues (**I**(**10**,**3**), **II**(**10**,**3**), **III**(**10**,**3**), and **IV**(**10**,**3**)), which have the same terminal chains, but which show a different phase sequence, the magnitudes of *Ps* and θ are in the orders of: **III**(**10**,**3**)>**IV**(**10**,**3**)>**I**(**10**,**3**)~**II**(**10**,**3**) and **III**(**10**,**3**)>**I**(**10**,**3**)>**II**(**10**,**3**)>**IV**(**10**,**3**) respectively. Among all the compounds, the **III**(**10**,**3**) shows the maximum *Ps* as high as 1100 μC m^{-2} in the chiral smectic C phase and as high as 1750 μC m^{-2} in the chiral smectic I phase.

Ferroelectric liquid crystals are of great interest because of their application in a new type of high-speed switching device.[1] In the practical use of the liquid crystals, several smectogens have been blended in order to obtain a composition with properties suitable for the divice. For this purpose, it is necessary to know the material constants, such as the transition temperatures, the porality, the magnitude of spontaneous polarization (*Ps*), the optical tilt angle (θ), and the refractive index, and to understand the correlation between these physical properties and the molecular structure. Especially, it is important, not only from the practical point of view but also from the fundamental point of view, to elucidate the relationship between the two material constants (*Ps*,θ) and the molecular structure.

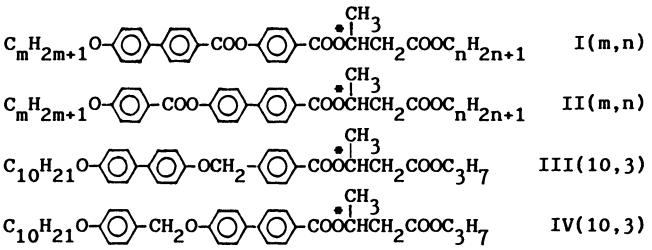
Ph. Martinot-Lagarde et al. showed simple formulae for the temperature dependence of *Ps* and θ for the compounds with a smectic A(SmA)-chiral smectic C(Sm*C) transition:[2]

$$Ps(T)=Ps^{\circ}(T_c-T)^a \quad (1)$$

$$\theta(T)=\theta^{\circ}(T_c-T)^b \quad (2)$$

where *Ps*(*T*) is the spontaneous polarization at temperature *T* °C, T_c is the SmA-Sm*C transition temperature, *T* is the actual temperature, $\theta(T)$ is the tilt angle at temperature *T* °C, and *Ps*°, θ°, *a*, and *b* are constants. These equations have been used in many papers; however, recent studies have shown that some materials do not exhibit the usual tendency in the temperature dependency of θ and *Ps* and that, therefore, the equations cannot be accepted as embodying general principles.[3-6] Furthermore, it has been recognized that the temperature dependency of θ in the SmC phase depends on the kind of phases adjacent to the Sm C phase.[7,8] In order to obtain a better understanding of the correlation between these material constants and the molecular structure, it is necessary to measure the material constants for various compounds and to accumulate data relating to the structural factors concerned with the ferroelectric properties.

We have synthesized the following series of novel ferroelectric liquid crytals, derived from *n*-alkyl esters of (*R*)-3-hydroxybutanoic acid, and investigated their physical properties:



One of these compounds **I**(**8**,**2**) has already been synthesized, and the temperature dependence of its *Ps* has been reported by Taniguchi et al.[9] However, no systematic investigation of the ferroelectric properties

of the homologous series has yet been done.

In a previous paper,[10] we reported a synthetic method and the mesomorphic properties of these homologous series. In this paper, we wish to report the temperature dependency of θ and *Ps* for these compounds and discuss the correlation between their ferroelectric properties and the molecular structures.

Experimental

Measurement of Physical Properties. Miscibility tests for the unidentified smectic phase below the Sm*C phase were carried out by mixing the compounds with standard materials whose phase sequences has been assigned and by observing the microscopic textures by means of a Nikon polarizing microscope equipped with a Mettler FP52 heating stage. The spontaneous polarization (*Ps*) was determined by a triangular-wave method reported by Miyasato et al.[11] The frequency, the maximum amplitude, and the cell thickness were 10 Hz, ±150 V, and 50 μm, respectively. The optical tilt angle (θ°) and the polarity(the direction of *Ps*) were determined by applying a d.c. field to a specimen placed between crossed polarizers and by observing the direction of extinction by rotating the stage. The helical twist sense was determined by observing the variation in pitch in the Sm*C phase upon mixing with the reference compound.

Results and Discussion

The mesomorphic transition temperatures and the phase sequences of the compounds used in the experiments are summarized in Table 1. In order to assign the unidentified smectic phases below the Sm*C, we carried out miscibility tests for the analogues, **I(10,3)**, **II(10,3)**, and **III(10,3)**, by mixing them with the following standard materials:

Terephthalidene-bis-4-n-decylaniline (TBDA)

Iso→SmA→SmC→SmI→SmF→SmG

4-n-Hexyloxyphenyl 4'-n-octyloxybiphenyl-4-carboxylate (HPOBC)

Iso→Ne→SmA→SmC→SmB

The miscibility diagrams of the binary mixtures, **I(10,3)**-TBDA, **II(10,3)**-HPOBC, and **III(10,3)**-TBDA, are shown in Figs. 1, 2, and 3 respectively. As can be seen in the figures, the Sm3 phases of **II(10,3)** and **III(10,3)** are smectic B(SmB) and chiral smectic I(Sm*I), respectively. The Sm3 phase of **I(10,3)**, which was speculated in the previous paper to be the Sm*I phase from the microscopic texture, is really chiral smectic G(Sm*G) or chiral smectic J(Sm*J). These two phases cannot be distinguished by only miscibility tests.

All the compounds used in the experiments show a

Table 1. Phase Sequences and Transition Temperatures for the **I**(*m*,*n*) and **II**(*m*,*n*) Homologous Series, and the **III**(10,3) and **IV**(10,3) Analogues

a) Mp; melting point, Sm3, Sm4; unidentified smectic phase, Sm*C chiral smectic C, SmA; smectic A, Iso; isotropic liquid. b) ( ); monotropic transition. c) This transition was designated as Sm2-Sm*C in a previous paper.[10]

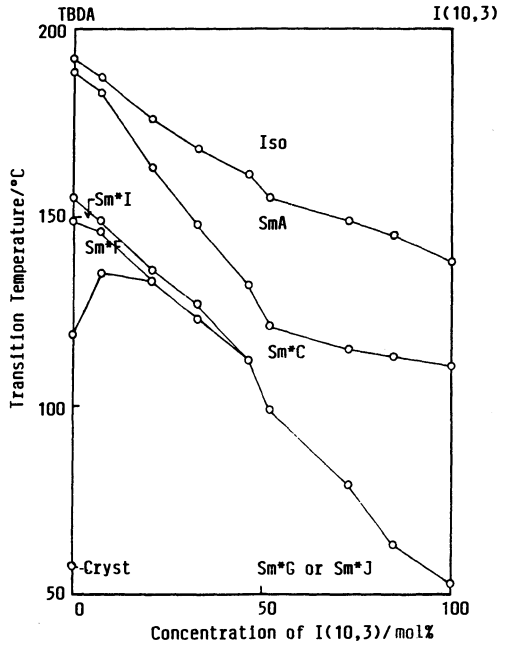

Fig. 1. Phase diagram for the binary mixtures of **I(10,3)** with TBDA.

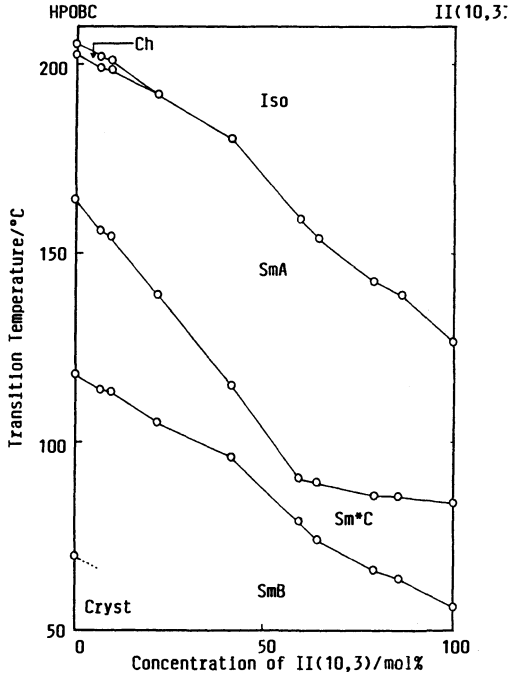

Fig. 2. Phase diagram for the binary mixtures of **II(10,3)** with HPOBC.

negative polarity and have a left-hand helix in the Sm*C phase. This tendency is consistent with the empirical rule about the relation between the absolute spatial configuration of a chiral group and the polarity and helical twist sense reported by Goodby et al.[12,13]

Figures 4(a,b) and 5(a,b) show the tempereature dependence of θ and *Ps* for the **I(*m*,3)** and **I(10,*n*)**

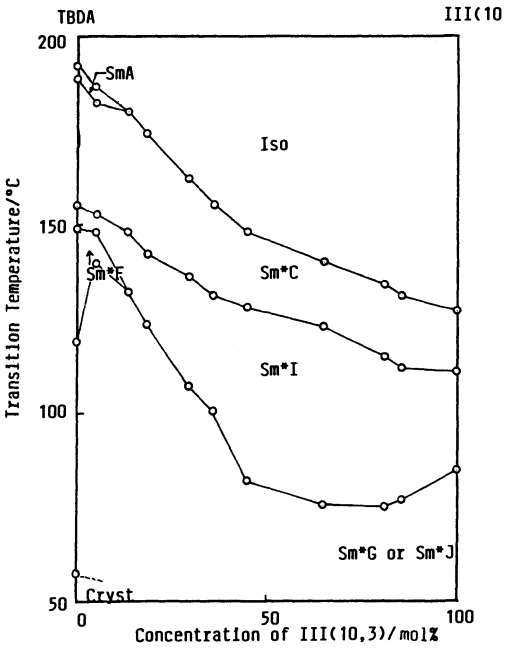

Fig. 3. Phase diagram for the binary mixtures of **III(10,3)** with TBDA.

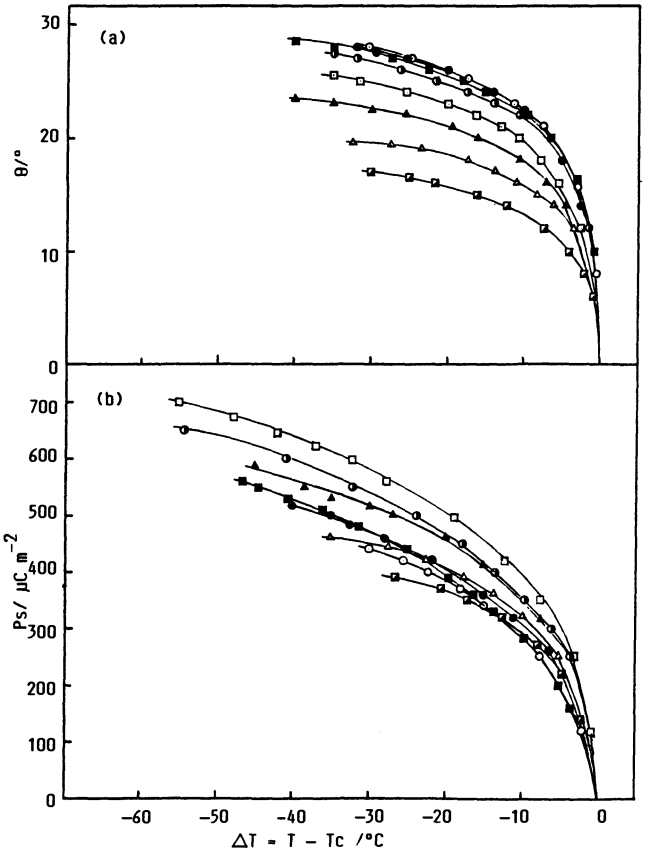

Fig. 4. Temperature dependence of the optical tilt angle (θ°) (a) and the spontaneous polarization (*Ps*) (b) for the homologous series **I(*m*,3)**: *m*=7 (—◪—); *m*=8 (—△—); *m*=9 (—▲—); *m*=10 (—□—); *m*=11 (—◑—); *m*=12 (—□—); *m*=14 (—●—); *m*=16 (—○—).

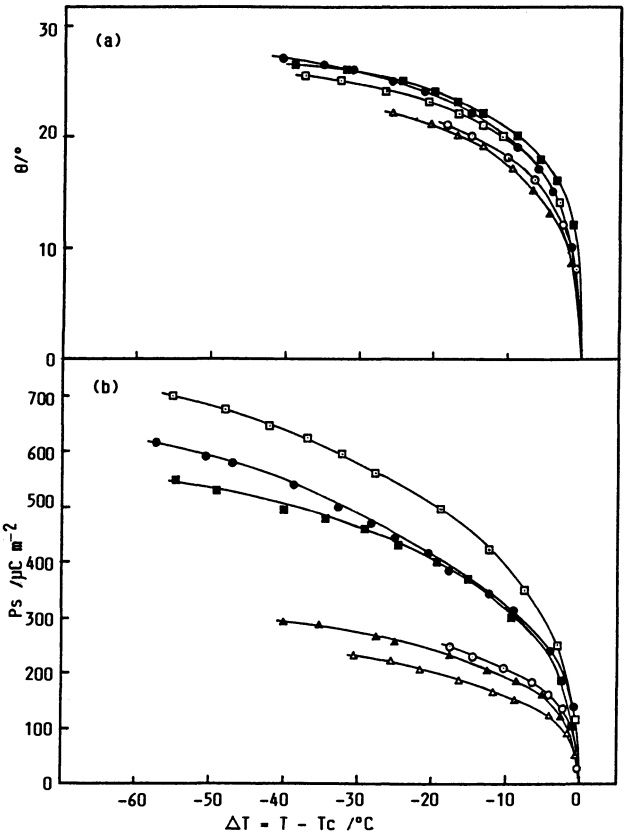

Fig. 5. Temperature dependence of the optical tilt angle (θ°) (a) and the spontaneous polarization (Ps) (b) for the homologous series **I(10,*n*)** n=1 (—○—); n=2 (—●—); n=3 (—□—); n=4 (—■—); n=5 (—▲—); n=8 (—△—).

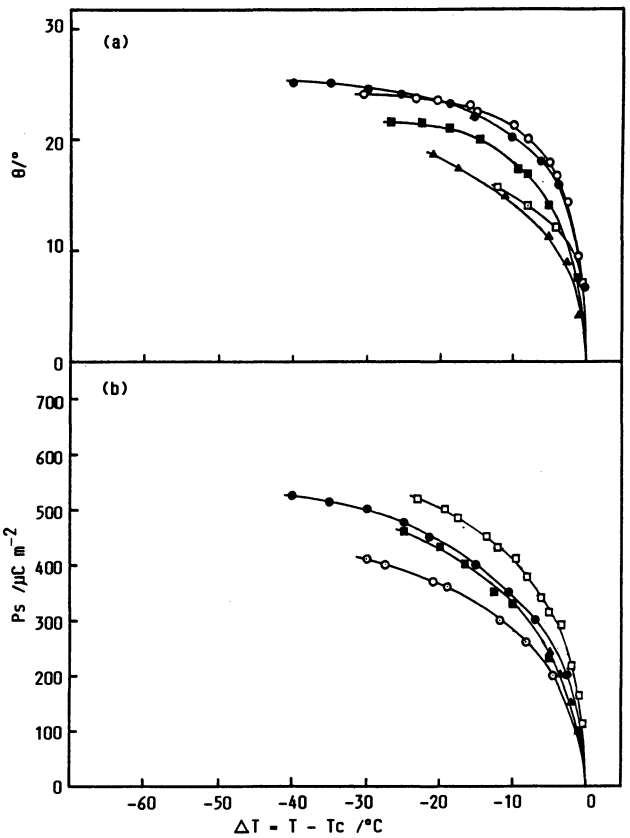

Fig. 6. Temperature dependence of the optical tilt angle (θ°) (a) and the spontaneous polarization (Ps) (b) for the homologous series **II(*m*,3)**: m=9 (—▲—); m=10 (—□—); m=12 (—■—); m=14 (—●—); m=16 (—○—).

homologous series, respectively. As is evident from the figures, the θ for **I(*m*,3)** increases with the number of carbon atoms (m) in the terminal alkoxyl chain and approaches a constant value (ca. 28°), whereas the Ps for **I(*m*,3)** increases with m up to m=10 and then decreases with m. The maximum Ps value (700 μC m^{-2}) was observed in the **I(10,3)** at ΔT=−55°C. On the other hand, the θ for **I(10,*n*)** slightly increases with n up to n=4 and then gradually decreases with n, whereas the Ps for **I(10,*n*)** abruptly increase with n up to n=3 and then rapidly decrease with n. Figures 6(a,b) and 7(a,b) show the temperature dependence of the θ and Ps values for the **II(*m*,3)** and **II(10,*n*)** homologous series, respectively. These series have the same linkage group (-COO-) as the **I(*m*,3)** and **I(10,*n*)** except for its position in the core moiety. We could not measure the θ and Ps values for all the homologues because the majority of their Sm*C phases were unstable monotropic phases and because recrystallization often occurred during the measurements. The θ for **II(*m*,3)** also increases with m and approaches a constant value (ca. 25 °C), whereas the Ps for **II(*m*,3)** increases with m up to m=3 and then decreases with m. The maximum Ps (520 μC m^{-2} was observed in the **II(14,3)** at ΔT=−40 °C. In the case of **II(10,*n*)** (Fig. 7(a,b)), the effect of the chain length (n) on the temperature dependency of θ and Ps cannot be clarified because the θ and Ps have been measured in only a few of the **II(10,*n*)**.

In order to elucidate the effect of the length of the terminal chains (m,n) on the θ and Ps for **I(*m*,*n*)** and **II(*m*,*n*)**, the values of θ and Ps at ΔT=−10 °C were plotted against the carbon number (m and n) in the terminal chains (Figs. 8A(a,b) and 8B(a,b)). As can be seen in the figures, in the case of **I(*m*,*n*)**, the dependencies of the lengths of the two terminal chains (m,n) on the θ and Ps are significantly different from one another. The θ for **I(*m*,3)** increases with m, whereas that for **I(10,*n*)** does not change very much with n. On the other hand, the Ps values for **I(*m*,3)** and **I(10,*n*)** show maxima at m=10 and n=3, respectively. Moreover, the effect of n on the magnitude of Ps is stronger than that of m on the magnitude of Ps. A similar tendency can be seen in the **II(*m*,*n*)** except for the dependency of n on the θ for **II(10,*n*)** whose θ is much smaller than that of **I(10,*n*)**; that is, the effect of m on the θ and Ps for **II(*m*,3)** is almost the same as that for **I(*m*,3)**. The effect of n on the Ps for **I(10,*n*)**, although there are only two data plotted on the figure.

These results indicate that the structural factors

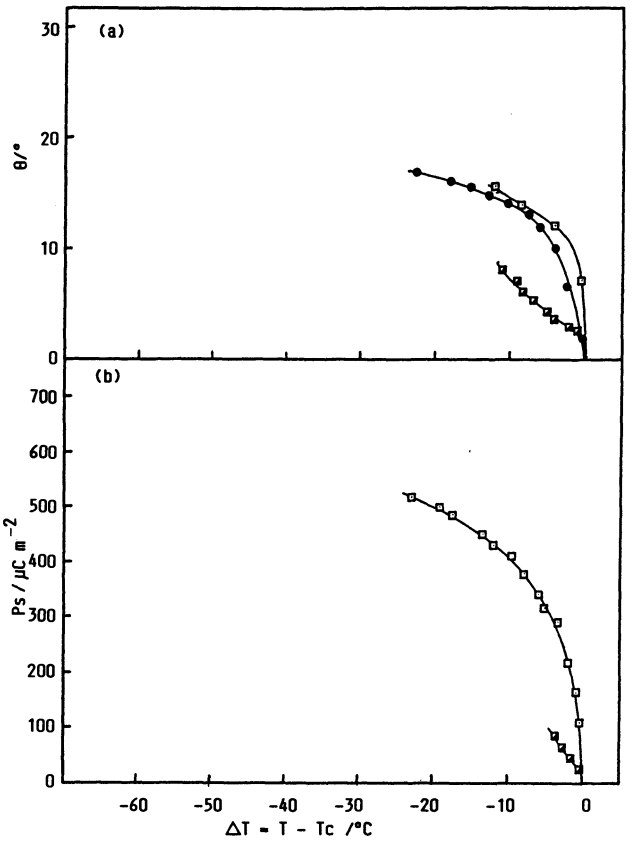

Fig. 7. Temperature dependence of the optical tilt angle (θ°) (a) and the spontaneous polarization (*Ps*) (b) for the homologous series **II**(**10**,*n*): n=2 (—●—); n=3 (—□—); n=7 (—◪—).

concerned with the temperature dependency of the terminal chains on the *Ps* are quite different from those concerned with the temperature dependency of the terminal chains on the θ and that the constants, *a* and *b*, in Eqs. 1 and 2 are generally not equal. Additionally, judging from these data, the magnitude of *Ps* seems to be independent of the position of the linkage group -COO- in the core.

For the purpose of investigating more closely the effect of the core structure on the *Ps* and θ, the temperature dependence of *Ps* and θ for four analogues, **I**(**10**,**3**), **II**(**10**,**3**), **III**(**10**,**3**), and **IV**(**10**,**3**), were examined (Fig. 9). It is noteworthy that these analogues have different phase sequences. As is evident from the figures, the magnitudes of *Ps* and θ depend strongly on the core structures, that is, the kind and position of the linkage group in the core, and are in the orders of **III**(**10**,**3**)>**IV**(**10**,**3**)>**I**(**10**,**3**)~**II**(**10**,**3**) and **III**(**10**,**3**)>**I**(**10**,**3**)>**II**(**10**,**3**)>**IV**(**10**,**3**), respectively. Among all the compounds used in the experiments, the **III**(**10**,**3**) with a -OCH_2- linkage shows the largest values of *Ps* and θ. Especially, the magnitude of *Ps* is as high as 1100 $\mu C m^{-2}$ in the Sm*C phase and 1750 $\mu C m^{-2}$ in the Sm*I phase.

Generally, the magnitude of *Ps* is considered to depend on the perpendicular component of the dipole moment of the polar group adjacent to the chiral part. These four analogues have the same group adjacent to the same chiral group; therefore, the origin of the *Ps* is considered to be same. Even if we take into consideration the difference in other factors (θ and T_c) con-

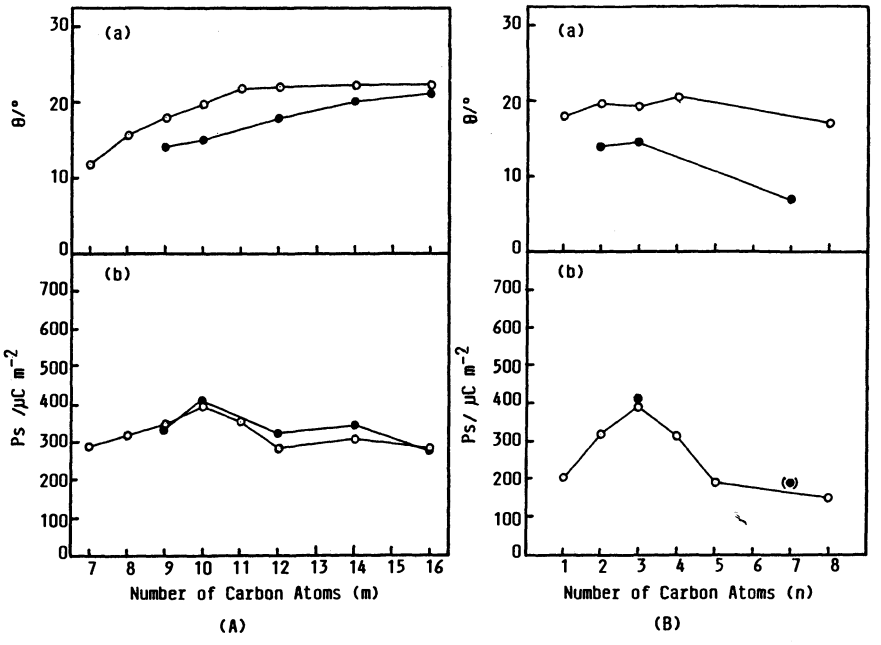

Fig. 8. Plots of the θ (a) and *Ps* (b) measured at ΔT=−10 °C against the number of carbon atoms (*m*) in the alkoxyl chain (n=3) (A) and the number of the carbon atoms (*n*) in the alkyl ester chain (m=10) (**B**): **I**(*m*,*n*) homologues (—○—); **II**(*m*,*n*) homologues (—●—). *( ): extrapolated value.

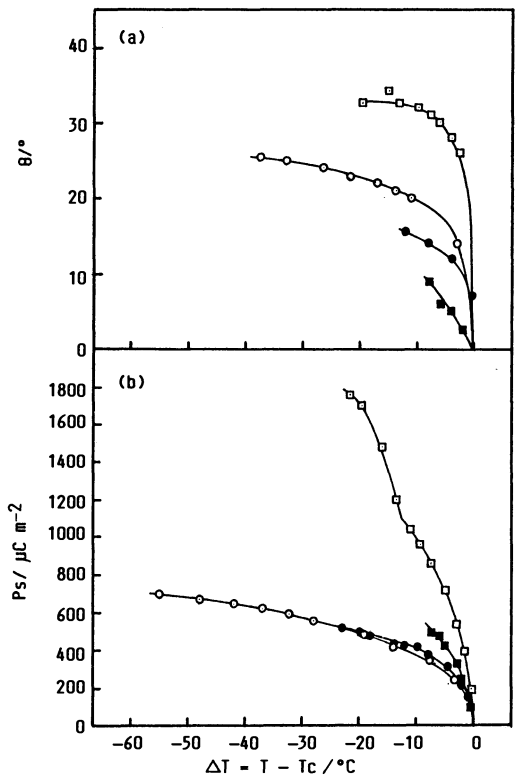

Fig. 9. Temperature dependence of the θ (a) and the *Ps* (b) for four analogues: **I(10,3)** (—○—); **II(10,3)** (—●—); **III(10,3)** (—□—); **IV(10,3)**.

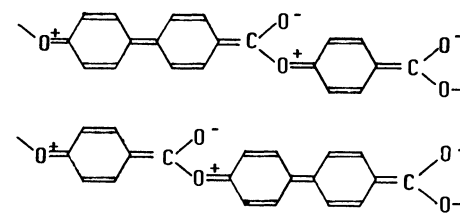
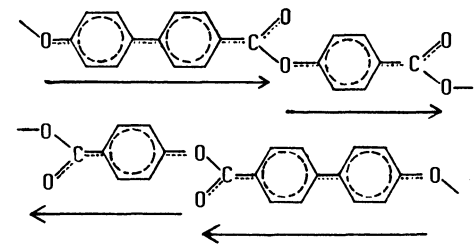
nected to the magnitude of *Ps*, we cannot explain the reason for the difference in the magnitude of *Ps* among these analogues.

Taniguchi et al. investigated the effect of linkage groups (-COO- and -CH_2O-) in the core on the *Ps* for four couples, each of which was a pair of analogues with the same chiral group, and showed that the compounds with the -COO- linkage had larger *Ps* values than those with the -CH_2O- linkage, except for one couple.[14] They speculated that the -COO- linkage enhanced the *Ps* more than the -CH_2O- linkage because of its larger dipole moment, although they did not measure the effect of θ on the *Ps*. Taking the effect of θ on the magnitude of *Ps* into consideration, among the four analogues investigated in this study, the **III(10,3)** and **IV(10,3)** with the -CH_2O- linkage show much larger *Ps* value than of the **I(10,3)** and **II(10,3)**; therefore, in this case, the -CH_2O- linkage seems to enhance the *Ps* more than the -COO- linkage. Similar results were also obtained in the mesogenic compounds with -CH_2O- linkage in the same core as that of **III(10,3)**.[15]

There is another difference in the natures of the -CH_2O- and -COO- bonds. Compared with the -CH_2O- bond, the -COO- bond is conjugated to the phenyl or biphenyl moiety in the core, leading to the production of induced dipole moments parallel to the molecular axis, as is shown in the following picture:



As has been pointed out by Goodby,[16] these induced dipoles cannot contribute to the *Ps*, but they do promote the following anti-parallel paking among the core moiety:



The formation of an anti-parallel pair could enhance the thermal stability of the Sm*C phase and also affect the temperature dependencies of *Ps* and θ in the Sm*C phase because of the intermolecular force attributed to the induced dipoles could suppress the interaction between the out-board dipoles and disturb the arrangement of the dipoles, thus contributing to the magnitude of *Ps*. Such difference in the intermolecular interactions may also affect the formation of higher-order smectic phases; that is, the packing state of the molecules in the Sm*C phase may some relation to the kinds of smectic phase below the Sm*C phase.

More detailed studies of the higher-order structures in smectic mesophase, including the effect of induced dipoles in the core, will be necessary to elucidate the correlation between the ferroelectric properties and the molecular structure.

The authors would like to thank Dr. Hiroshi Sato for his hearty encouragement throughout this work and also Dr. Toshio Yoshihara for his useful suggestions. The authors also wish to thank to Mr. Yoshihiro Sako for his assistance with the experiments.

Basicity of Water in Hydrogen-Bonded Networks of Methanol-1,2-Dichloroethane Mixtures Using the [(1*R*,4*S*,8*R*,11*S*)-1,4,8,11-Tetramethyl-1,4,8,11-tetraazacyclotetradecane]nickel(II) Cation as a Probe of Electron-Pair Acceptance

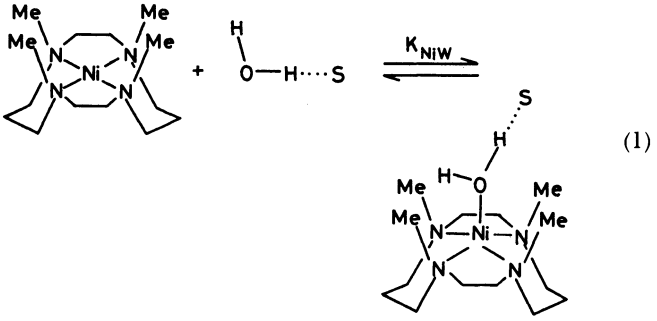
(Received September 22, 1988)

The basicity of water in methanol (MeOH) and MeOH-1,2-dichloroethane (DCE) mixtures was examined by using spectral data of the title square planar chelate cation ([Ni(tmc)]$^{2+}$). Although MeOH molecules are hardly coordinated to the chelate, the water molecules hydrogen-bonded with MeOH are easily coordinated to the cation, depending on the degree of hydrogen-bonded networks of MeOH. A fitting method showed that in the MeOH-rich mixtures the dimerization of water occured and only the terminal monomeric water molecule in the MeOH oligomer could be coordinated. The equilibrium constant K_{NiWl}=[Ni(tmc)(H$_2$O)$^{2+}$]/[Ni(tmc)$^{2+}$][H$_2$O] was 3.2 in the 0.1 MeOH mole fraction mixture, 3.0 in 0.3, 3.2 in 0.5, 6.2 in 0.7, 9.5 in 0.9, 10.0 in 1.0. Linear relationships of ^{1}H chemical shift of the OH group for MeOH in various solvents with the K_{NiWl} values and Gutmann's donor number (DN) were found and DN values were estimated for the DCE-MeOH mixtures. The enhancement of basicity of the water molecules was discussed from the viewpoints of the charge transfer effect through hydrogen bonding and the development of hydrogen-bonded networks.

In our previous papers,[1,2] effects of intermolecular interactions between water and dipolar aprotic solvent molecules on the basicity of water have been studied by using spectral data of [(1*R*,4*S*,8*R*,11*S*)-1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane]nickel(II) ([Ni(tmc)]$^{2+}$) with an 1*R*,4*S*,8*R*,11*S*- set of nitrogen configurations as a probe of electron pair acceptance. Although it is known that the red, square planar chelate cation forms a green, five-coordinate square pyramidal complex by axial ligation with a donor solvent or ion,[3-5] we found that oxygen donor coordinating molecules such as H$_2$O, MeOH, acetone (AC), and 1,2-propanedyl carbonate (PDC) of which DNs are less than 20, were not coordinated to the nickel cation in nitrobenzene (NB) as a diluent.[1,6] However, the water molecules in pure water and in hydrogen bonding acceptor solvents such as AC, PDC, and *N*,*N*-dimethylacetamide (DMA) can be coordinated and furthermore the dimerization of water in nitromethane (NM), PDC, and AC leads to coordination of water, of which the equilibrium constant increases with increasing the basicity of the bulk solvent molecules, i.e. in the order NM<PDC<AC. The basicity of water was related with the formation constant (K_{NiW}) of the aqua chelate cation in Reaction 1



(1)

where S is hydrogen-bonding acceptors or basic solvents.

The above phenomena are explained by the increase in the charge density on the oxygen atom of water due to hydrogen bonding with such basic molecules. Thus, the donor number 18 of water proposed by Gutmann[7,8] is ascribed to the isolated water molecules of the lowest basicity, for example, dissolved in much lower basic DCE and NB. Mayer and Gutmann[9] also introduced the term "bulk donicity" to characterize the basic properties of water. The basicity of water greatly depends on the strength of hydrogen bonding and little is known concerning the nature of water basicity, especially, in protic solvents. The water molecule in aqueous mixtures is the solute or the solvent that takes our major interest.

The purpose of this work is to study the effect of network structure of MeOH on the basicity of water in DCE-MeOH mixtures. The two- or three-dimensional cross-linked polymer for the amphiprotic solvent, unlike aprotic solvents, make it more difficult to understand the water-solvent interactions. However, mixtures of MeOH with inert DCE give information concerning the network structure which is relatively easily obtained using IR and NMR data. Hydrogen-bonded networks of MeOH are promoted with increasing the MeOH fraction and the K_{NiW} value for the water molecules present in the DCE-MeOH mixtures is expected to increase with growing hydrogen bonds among MeOH molecules.

Experimental

The metal chelate electrolyte (*R*,*S*,*R*,*S*)-[Ni(tmc)](ClO$_4$)$_2$ was prepared as described previously.[1-3] DCE, MeOH, pyridine (Py), hexamethylphosphoric triamide (HMPA),

N,N-dimethylformamide (DMF), DMA, dimethyl sulfoxide (DMSO), AC, and PDC (Reagent grade, Wako Pure Chemical Industries Ltd.) were purified by fractional distillation through a 1.2-m column without washing. NB (Reagent grade, Wako Pure Chemical Industries Ltd.) was purified by fractional distillation under reduced pressure after washing with 1.5 mol dm^{-3} H_2SO_4 and 1 mol dm^{-3} $NaHCO_3$. Tetrahydrofuran (THF) (Wako Pure Chemical Industries Ltd.) and benzonitrile (BN) (Aldrich Chemical Company) were used without further purifications. All solvents were used after standing over molecular sieves (Type 4A) for one week.

The apparatus and the procedures used for measurements of the water content, the high-resolution proton chemical shift, and infrared spectra have been described earlier.[1,2]

Results and Discussion

Typical visible spectra of the chelate cation in a mixture of the 0.7 MeOH mole fraction with DCE containing water are shown in Fig. 1. The absorption peak at 520 nm is referred to the four-coordinate planar complex, and the peaks at 396 nm and ca. 660 nm are referred to the five-coordinate square pyramidal complex. When the water content is 8.30×10^{-3} mol dm^{-3}, the chelate is almost four-coordinate. The absorbance at 520 nm decreases with increasing the water concentration. This shows that the bulk solvent molecules can not be coordinated to the chelate, but the water molecules in this solution can be coordinated. The dependence of the absorbance on the water concentration in various DCE-MeOH mixtures is shown in Fig. 2 together with the results for Py. Although highly basic Py (DN=33.1[7]) molecules can not be coordinated due to steric hindrance,[6] it is seen that the water in Py can become much easily coordinated.

Ionic association of the nickel complex with the perchlorate ion may occur in mixtures containing DCE with a low dielectric constant. In our previous study,[6] ionic association effects on coordination were hardly observed even in AC solution with a first association constant of 12200. Since the basicity of the perchlorate ion is very weak, it is reasonably assumed that there is no ionic association effect on the water coordination.

cules to the cation depends on the degree of complex formation of water with solvent molecules or self-association,[1,2] it is necessary to consider the structure of water complexes and MeOH net works.

Figure 3 shows IR spectra for MeOH in DCE-MeOH mixtures. A sharp band at 3613 cm^{-1} and a broad band at 3472 cm^{-1} exist below the 0.1 MeOH mole fraction (spectra 1, 2, and 3). The sharp high-frequency band and the broad low frequency band are assigned to the free O-H oscillator of MeOH molecules and to the bonded O-H oscillator in MeOH dimers, respectively, comparing with IR spectra of MeOH in dichloromethane (DCM) by Symons and Thomas.[10] Dependence of the IR spectrum on the MeOH fraction below the 0.1 mole fraction is predominantly elucidated by dimerization equilibrium for MeOH. As the MeOH fraction increases, the broad band is shifted to lower frequency region (toward 3300 cm^{-1} of polymer) and the band of the freee O-H group relatively decreases, and moreover, the free O-H group almost disappeared at the 0.7 MeOH mole fraction.

Chemical shifts of the O-H proton resonance of MeOH are shown as a function of the MeOH mole fraction in Fig. 4. There is a linear relationship between them below the 0.2 MeOH mole fraction. This can be explained by dimerization of MeOH, as supported by the IR results in Fig. 3. The dimer model yields a simple expression for the chemical shift ν which is referenced to TMS as inner standard at low MeOH concentrations

$$\nu=(1-2x)\nu_m+2x\nu_d \quad (1)$$

$$x=(4+1/K_{M2}C)-[(4+1/K_{M2}C)^2-16]^{1/2}/8 \quad (2)$$

where ν_m is the chemical shift of the monomer protons, ν_d is the hypothetical mean chemical shift of the dimer protons, K_{M2} is the dimer formation constant in molar unit and C is a molar concentration of MeOH. A ν_m value of 75.2 Hz at the 0.03 MeOH mole fraction where the MeOH monomers are predominant was used for evaluating the K_{M2} value. A K_{M2} value of 0.29 and a ν_d value of 175 Hz were obtained. At the 0.1 MeOH mole fraction (1.4 mol dm^{-3}), for example, the K_{M2} value indicates that 34% of MeOH is dimerized.

However, the IR and NMR results could not give information as to whether the electron pairs of the oxygen atom of water remains free or not, and whether the water molecules dimerizes or not.

Estimation of K_{NiW} Values. The K_{NiW} value was estimated at each concentration of water for the data given in Fig. 2 using the equation

$$K_{NiW}=(\varepsilon_0-\varepsilon)/(\varepsilon-\varepsilon_s)[W] \quad (3)$$

where ε is the apparent molar absorptivity at 520 nm, ε_0 is the molar absorptivity at the zero water concentration, ε_s is the molar absorptivity of the water coordinate-chelate cation and [W] is the analytical concentration of water. A constant value of ε_s=10 $dm^3 mol^{-1} cm^{-1}$ obtained in the oxygen-atom donor solvent, *N,N*-diethylformamide[6] was used. The K_{NiW} values are plotted as a function of the water concentration in Fig. 5.

The K_{NiW} values in the 0.1 and 0.3 MeOH mole fraction mixtures do not depend on the water concentration, but those in mixtures above the 0.5 MeOH mole fraction decrease with increasing the water concentration, showing a decrease in activity of water molecules. Since the isolated monomeric water which is not hydrogen-bonded to bulk solvents is hardly coordinated to the nickel,[1,2] the results in Fig. 5 show that the water molecules in the mixed solvents are hydrogen bonded to MeOH and suggest that the heterodimer with MeOH is dominant in the MeOH poor region and additional species of water leading to a decrease in activity of water appear in the MeOH rich region.

As shown in Fig. 3, in the MeOH rich region the free OH group for MeOH was hardly found, the oligomerization being enhanced. This may make it

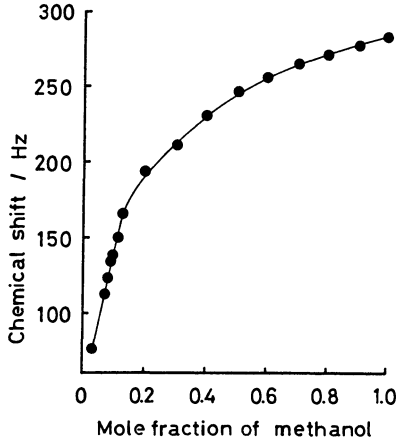

Fig. 4. Dependence of ^1H NMR chemical shift for hydroxyl group of MeOH referenced to TMS on the mole fraction of MeOH in DCE-MeOH mixtures.

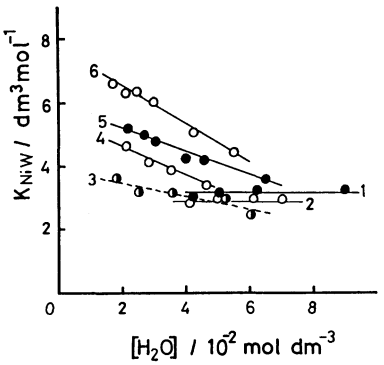

Fig. 5. Dependence of K_{NiW} on the water concentration in DCE-MeOH mixtures at 25 °C. Mole fraction of MeOH: 1, 0.1; 2, 0.3; 3, 0.5; 4, 0.7; 5, 0.9; 6, 1.0. K_{NiW} values were estimated by Eq. 3 at each concentration of water.

difficult for MeOH to act as a proton donor to water, and so it is assumed that the possibility of dimerization of water is present.

When the dimerization of water occurs, the apparent coordination constant of water $K_{NiW(app)}$ can be written by

$$K_{NiW(app)} = (K_{NiW1} + K_{NiW2}K_{W2}[H_2O])/(1 + K_{W2}[H_2O]) \quad (4)$$

where K_{NiW1} and K_{NiW2} are the coordination constants for the monomeric water (heterodimer) and dimeric water, respectively, K_{W2} is the dimerization constant of water, and $[H_2O]$ is the concentration of the monomeric water. Therefore, the apparent molar absorptivity ε is expressed by

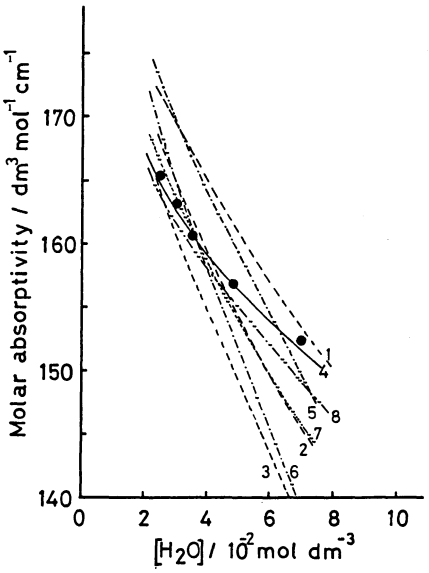

Fig. 6. Variation of molar absorptivities (●) at 520 nm and lines calculated using Eq. 4 (ε_0=183.7 and ε_s=10) with various K_{NiW1} with the water concentration in pure MeOH at 25 °C. 1, K_{NiW1}=3.0, K_{NiW2}=0, K_{W2}=0; 2, 4.0, 0, 0; 3, 5.0, 0, 0; 4, 10.3, 0, 50; 5, 0.0, 10, 50; 6, 0.0, 14, 50; 7, 6.0, 6, 50; 8, 10.3, 0, 40.

$$\varepsilon = (\varepsilon_0 + \varepsilon_s K_{NiW(app)}[H_2O'])/(1 + K_{NiW(app)}[H_2O']) \quad (5)$$

where $[H_2O']$ is the sum of concentrations of the monomeric and dimeric water.

It is assumed that all the water species are hydrogen-bonded to the MeOH oligomers, and that these are terminal water molecules with the free electron pairs except water molecules which are the proton acceptor in the dimer. Typical results for the fitness in the pure MeOH are shown in Fig. 6. It should be noted that the best fitness was obtained when only the monomeric water was regarded as a coordinated species with a K_{W2} value of 50 dm³ mol⁻¹ and a K_{NiW1} value of 10.3 dm³ mol⁻¹ and the dimeric water is hardly coordinated. In this connection protic MeOH in the hydrogen-bonded networks is remarkably contrastive with aprotic solvents such as AC and PDC in which the dimeric water is coordinated. Since the dimeric water is more basic and more acidic than the monomeric water,[1,2,11-16] it seems that the strengthened basicity and acidity of the dimer allow itself to be a member of the oligomers of MeOH which mask the electron pair effective for coordination. This is compatible with the suggestion from Symons[17] that the linear dimer of MeOH in DCM-MeOH mixtures should be more basic and more acidic than the monomer, and this would lead to a less of dimers and a gain of oligomers.

In the same way, the best fitting values for K_{W2} and K_{NiW1} were obtained in the 0.5—0.9 MeOH fractions and the results are given in Table 1. Both the values of K_{NiW1} and K_{W2} increase with increasing the MeOH fraction, that is, the hydrogen-bond energy of networks for MeOH.

In Py,[18] water forms the 1:1 and 1:2 water-Py species below 0.1 mol dm⁻³ of water. The K_{NiW1} values were estimated at each concentration of water using Eq. 3, and the average value 21±2 was obtained.

Figure 7 shows a correlation of logarithm of K_{NiW} with ^1H chemical shift (ν_{OH}) of the hydroxyl group for

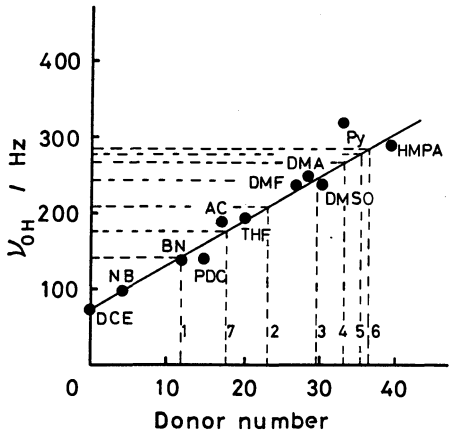

Fig. 8. Relationship between the ^{1}H NMR chemical shift (Hz) in MeOH complexes and donor number of the donor component. The apparent chemical shift of MeOH in various mixtures with DCE: 1, 0.1 mole fraction of MeOH; 2, 0.3; 3, 0.5; 4, 0.7; 5, 0.9; 6, 1.0. The hypothetical mean chemical shift of the MeOH dimer protons: 7.

MeOH in DCE-MeOH mixtures, DMA, and Py. The ν_{OH} for DCE-MeOH mixtures are mean values for protons under various circumstances in MeOH oligomers, but there is a good linear relationship between ln K_{NiWI} and ν_{OH}, indicating that the ν_{OH} mean values reflect the basicity of the oxygen atom for terminal water molecules attached to MeOH oligomers. Thus, it can be said that the basicity of the terminal waters increases with increasing the hydrogen bond energy for the oligomer. This property of basicity of protic solvents is agreement with that expected by the theoretical calculations.[11-16]

^{1}H NMR chemical shifts of the O-H group for MeOH in various organic solvents were plotted as a function of their donor number (DN) (Fig. 8). The ν_{OH} values for DCE, NB, BN, and PDC were obtained by extrapolating observed ν_{OH} values at the zero concentration of MeOH. There was found a good linear relationship expressed with Eq. 5

$$DN = 0.167\ \nu_{OH} - 11.7 \quad (5)$$

where ν_{OH} is the ^{1}H NMR chemical shift in Hz of the O-H group of MeOH.

Since the ν_{OH} value for the 0.1 MeOH mole fraction mixture is a mean value for the monomer and dimer of MeOH, the corresponding DN value only indicates a mean DN value for DCE and the monomeric MeOH. In spite of the equal number of the hydrogen-bonding proton and the free proton for dimeric MeOH, its hypothetical mean ν_{OH} value 175 gives a DN value of 18 which is very close to 19[7] for MeOH. Therefore, it is reasonably assumed that ν_{OH} values in the higher MeOH mole fraction mixtures in which the number of the free proton is much less, give meaningful DN values.

The chemical shift and K_{NiWI} in the 0.5 MeOH mole fraction mixture are nearly the same as those in DMA (DN=27.8[7]). This means that the charge transfer among MeOH molecules in the mixture is the same as that from the DMA molecule to the MeOH molecule, and moreover, the charge-transfer effect of MeOH on the water basicity is closely similar to that from DMA to the water molecules. Therefore, a DN value of 29 is reasonable for the 0.5 MeOH mole fraction mixture. In the same way, DN values 23, 33, 35, and 36 were evaluated for the MeOH mole fractions 0.3, 0.7, 0.9, and 1.0, respectively. The K_{NiWI} value for the heterodimer of water and MeOH which is between those for the water dimer (DN=26[2]) in PDC and that (DN=27[2]) in AC, gives a DN value of 26.5 for the heterodimer. The DN value for the pure MeOH is higher than DNs estimated by using other methods (DN=24—33.5).[19-22] In view of the linear relationships of ln K_{NiW}-ν_{OH} and ν_{OH}-DN plots (Figs. 7 and 8), DN of Py should be 42 in place of 33.1 with respect to charge transfer for hydrogen bonding.

The Preparation of Stable Colloidal Poly(vinyl alcohol) Composites of Cu_2O and Cu

Hiroshi YOKOI,* Akihide KADOWAKI, and Shuji IKOMA
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
(Received September 30, 1988)

Stable colloidal particles of reddish brown Cu_2O-PVA and grayish black Cu-PVA composites have been prepared by the reduction of green Cu^{2+}-PVA complexes in aqueous solutions with hydrazine, at the [hydrazine]/[Cu^{2+}] ratios of 1—3 and 15 or more respectively, where PVA represents poly(vinyl alcohol). The average diameters of the Cu_2O and Cu particles in these composites have been estimated to be about 200 and 300 Å respectively from the half widths of the X-ray diffraction peaks for the corresponding powder samples.

There have been several papers on the preparation of copper sols by the chemical reduction of copper(II) salts in aqueous solutions in the presence and absence of polymer-protecting agents.[1-4] These colloidal dispersions have found interesting applications. Cu^{2+} ions and poly(vinyl alcohol) (PVA) react at pH$\gtrsim$6 to form green Cu^{2+}-PVA complexes, which have been identified as polynuclear $Cu(OH)_2$ complexes hydrophobically included by PVA.[5,6] In this work, the chemical reduction of these green Cu^{2+}-PVA complexes has been investigated in an effort to obtain some useful materials. The resulting reduction products have been characterized in some detail, with special interest taken in the role of PVA in them.

Experimental

Materials. Hydrolyzed (100%) PVAs with the average molecular weight of 14000 were purchased from the Aldrich Chemical Co. The concentration of PVA in this work was expressed as [PVA polymer residue], in terms of monomeric residues. All the other reagents were of a reagent grade or higher and were used without further purification. Aqueous solutions of green Cu^{2+}-PVA complexes containing 0.20 M PVA and 10 or 20 mM Cu^{2+} ions were prepared by dissolving the required amounts of $CuSO_4 \cdot 5H_2O$ and PVA in aqueous solutions and by then adjusting the pH to 8.0 with NaOH without any buffer (1 M=1 mol dm^{-3}). Chemical reductions of the complexes in aqueous solutions with sodium tetrahydroborate, hydrazine, hydroxylamine, hydroquinone, and ascorbic acid gave variously colored hydrosols. These sols, except those prepared by hydrazine reduction, were not stable in air, resulting in color changes and precipitations within a day. Hydrazine was found to reduce the Cu^{2+}-PVA complexes to differently colored hydrosols according to the value of R_r=[hydrazine]/[Cu^{2+}]. The colors of these hydrosols were reddish brown, bright yellow, and grayish black at the R_r values of 1—3, 4—15, and >15 respectively. Powder samples were obtained from these hydrosols and their original Cu^{2+}-PVA solutions by pouring them into acetone and by washing the resulting precipitates with acetone several times, as in the recovery of PVA powder from its aqueous solutions. Surprisingly, it has been found that these powder samples include microcrystals of Na_2SO_4 as will be seen in the X-ray diffraction measurements; details will be reported elsewhere.[7] Quantitative analyses of the SO_4^{2-} in these samples by means of an ion chromatograph Model HCL-601 (Tosoh Co., Ltd.) showed that 6.5, 6.2, and 6.2% of SO_4^{2-} are included in the powder samples obtained from the Cu^{2+}-PVA solution at R_p=[PVA Polymer residue]/[Cu^{2+}]=20, the reddish brown hydrosol at R_r=1, and the grayish black hydrosol at R_r=20 respectively. These SO_4^{2-} contents remarkably decreased upon dialysis with cellophane membranes. Elemental analyses for the last two powder samples gave similar results near to C 40.5, H 7.8, and Cu 5.5% (determined by atomic-absorption spectroscopy); these results were not yet useful for the identification of these complicated samples. Strictly speaking, the first sample, whose elemental analysis has already been reported,[6] was analogous. After all, elemental analyses of this kind of complicated polymer are a subject for further investigation.

Measurements. X-Ray diffraction measurements of powder samples were carried out by a Geigerflex recording X-ray diffractometer Model D-3F (Rigaku Denki Co., Ltd.). The visible absorption spectra of hydrosols were measured by means of a Hitachi U-2000 spectrophotometer using a 5-mm quartz cell. Far-infrared spectra of powder samples were recorded with a grating infrared spectrophotometer, Model IR-F (Japan Spectroscopic Co., Ltd.). Magnetic-susceptibility measurements of powder samples were carried out at room temperature by the usual Gouy method, where the contents of the copper or copper-ion species required for the calculation of the effective magnetic moments (μ_{eff}) were determined by means of an atomic absorption and flame-emission spectrophotometer Model AA-782 (Nippon Jarrel-Ash Co., Ltd.).

Results and Discussion

Reduction products of copper(II) salts in aqueous solutions are generally unstable in air, even in the presence of poly(*N*-vinyl-2-pyrrolidone) as a protective polymer.[3,4] Interestingly, however, the reduction of the green Cu^{2+}-PVA complexes in aqueous solutions by hydrazine gave stable hydrosols in air. Powder samples prepared as precipitates by pouring these hydrosols into acetone were also stable in air. All the copper or copper-ion species in the hydrosols were included in the powder samples, since such species could not be detected in the filtrates. This fact, together with the extremely high stability of the reduction products in air, indicates that copper or copper-ion species are bound to PVA and, furthermore, that

particles of these species may be protectively coated with PVA. This also seems to be responsible for the stable formation of hydrosols. At present, however, the reason why only hydrazine produces this kind of hydrosol is still obscure.

Figure 1 shows the X-ray diffraction patterns of two powder samples. In both patterns, peaks with the following 2θ values are due to Na_2SO_4: 33.8 (33.9), 31.6 (32.1), 29.7 (29.0), 23.4 (23.1), and 19.2 (19.0), where the numbers in parentheses are the values cited from the literature.[8] In addition, the following peaks assignable to Cu_2O and Cu are observed in the A and B patterns respectively:[9,10] 73.6 (73.5), 61.4 (61.3), 52.2 (52.4), 42.2 (42.3), 36.4 (36.4), and 29.7 (29.6) for the A pattern, and 73.8 (73.9), 50.2 (50.3), and 43.0 (43.3) for the B pattern. Accordingly, these results show the formation of Cu_2O and Cu microcrystals in the reddish brown and grayish black powder samples respectively. X-Ray diffraction patterns for the other powder samples obtained from hydrosols at R_r=4—15 were made up by the superposition of the A and B patterns at varying intensity ratios.

The existence of Cu_2O microcrystals in the reddish brown sample was also supported by the observation of a far-infrared absorption at 615 cm^{-1} assignable to ν_{Cu-O} in Cu_2O crystals.[11] Figure 2 shows the visible absorption spectra of hydrosols corresponding to the two powder samples in Fig. 1. The absorption maxima at 510 and 590 nm for the reddish brown and grayish black hydrosols are characteristic of Cu_2O and Cu polycrystals respectively.[12]

All the results of the magnetic-susceptibility measurements for the powder samples obtained from hydrosols at various R_r values are summarized in Fig. 3, which shows a plot of the μ_{eff} values of the samples against their R_r values. The μ_{eff} value of the Cu^{2+}-PVA complexes corresponding to R_r=0 is 1.49±0.01 B.M.[6] The errors of the other μ_{eff} values are ±0.05 or so. The fact that μ_{eff}=0 B.M. for the reddish brown samples at R_r=1—3, as is shown in Fig. 3, indicates that the addition of hydrazine at these R_r values completely reduces all the Cu^{2+} ions in the Cu^{2+}-PVA complexes to diamagnetic Cu^+ ions. The μ_{eff} value tends to increase with an increase in R_r in the range of R_r>3 and then finally to level off at R_r>15. The implication of this final μ_{eff} value of about 0.8 B.M. is now being considered.

It is important to obtain information on the sizes of Cu_2O and Cu particles in the hydrosols or powder samples. We can approximately estimate these sizes from the half widths of the X-ray diffraction peaks, using the Debye equation of $B=0.9\lambda/(t\cos\theta)$,[13] where B, t, and θ are the half width of a X-ray diffraction peak, the average diameter of crystalline particles, and the diffraction angle respectively, and where λ=

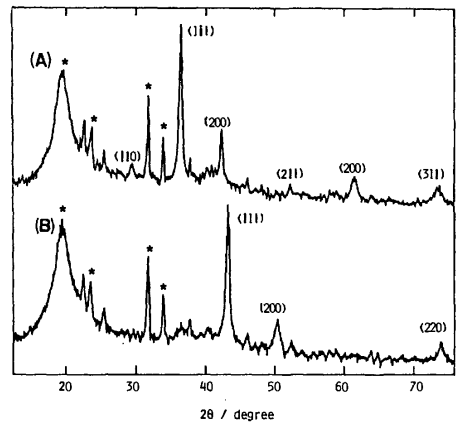

Fig. 1. X-Ray diffraction diagrams: (A) the reddish brown powder sample obtained from the hydrosol which was prepared by the reduction of Cu^{2+}-PVA complexes with hydrazine at R_r=[hydrazine]/[Cu^{2+}]=1; (B) the grayish black powder sample similarly obtained except at R_r=20 (the Cu^{2+}-PVA complexes were prepared at R_p=[PVA polymer residue]/[Cu^{2+}]=20). Peaks with asterisks are due to Na_2SO_4, and some peaks are marked with the Miller indices of Cu_2O crystals in (A) and Cu crystals in (B).

1.54178 Å for Cu $K\alpha$ radiation. In this work, a strong X-ray diffraction peak for the (111) plane in every particle species was used for the purpose mentioned above. The results, summarized in Fig. 4, indicate that the average diameter of Cu particles in the grayish black samples of $R_r>15$ are almost constantly about 300 Å, while that of Cu_2O particles in the reddish brown sample of $R_r=1$ is about 200 Å. Further, there is a tendency for the diameter to decrease with the increase in R_r. We have a plan on hand for reinvestigating these particle sizes in the cast films of the present colloidal solutions by the use of a transmission electron microscope. It has been reported that the particle size of $Cu(OH)_2$ in the Cu^{2+}-PVA complexes may be extremely small, as small as less than 20 Å.[6] From this result and Fig. 4, it is concluded that there is a gathering process of small particles and, therefore, a growing process of particle size during the reductions of $Cu(OH)_2$ to Cu_2O and of Cu_2O to Cu by hydrazine in the presence of PVA, suggesting a reorganization in the interaction of such particles with PVA at every stage of reduction.

(Received October 7, 1988)

The infrared multiple-photon decomposition (IRMPD) of saturated open-chain ethers has been systematically investigated with the intention of establishing their decomposition patterns. The main products in the IRMPD of ethers (**1a—f**, **2**) are H_2CO, CO, H_2, and lower hydrocarbons. Acetaldehyde is additionally formed in the IRMPD of **1b** and **1d**, while acetone is formed in the IRMPD of **1d**. The observed results are explained on the basis of the decomposition of the highly vibrationally excited ethers produced in the IRMP excitation. The initial process is the homolytic cleavage of a C-O bond to yield the corresponding alkyl and alkoxyl radicals. The alkyl radicals are trapped by Br_2. Sequential splitting and addition reactions of the radicals yield primary products with a high internal energy. The primary products also decompose sequentially into stable products, in part. The sequential processes compete with collisional deactivation. Therefore, the branching ratio depends on the internal energy of the radicals and the primary products.

The infrared multiple-photon decomposition (IRMPD) of organic compounds induced by a TEA CO_2 laser irradiation has been extensively investigated, especially with relation to laser isotope separation.[3] The laser isotope separation of oxygen has received relatively little attention compared with the separation of hydrogen and carbon isotopes using Freon compounds.[4] Ethers absorb at 900—1150 cm^{-1} because of the C-O stretching vibration, and the absorption usually falls in the tunable range of a TEA CO_2 laser. Moreover, ethers have relatively high vapor pressures and a large isotopic shift of oxygen in the C-O stretching vibration among various oxygen-containing organic compounds. Therefore, ether is very suitable as the starting material in the oxygen-isotope separation by means of a TEA CO_2 laser. In fact, the ^{18}O separation in the IRMPD of dimethyl ether has been studied by Vizhin et al.[5] and Kutschke et al.[6] We have recently studied the ^{18}O separation in the IRMPD of perfluorodimethyl ether.[1] The separation selectivity was found to be 2.5 in the irradiation of 3.5 Torr (1 Torr=133.322 Pa) of perfluorodimethyl ether with the CO_2 laser radiation at 940.55 cm^{-1}, 15 J cm^{-2}, and room temperature, where the conversion was 1.4%. No other work on oxygen-isotope separation in the IRMPD of ethers has been reported, although a number of studies have been published with respect to the kinetics and dynamics in the IRMPD of ethyl vinyl ether,[7] allyl methyl ether,[8] dialkoxyalkanes,[9] 2,5-dihydrofuran,[7d] tetrahydrofuran,[10] methylated tetrahydrofuran,[11] oxetanes,[12] and tetramethyldioxetane.[13]

In order to find a suitable compound for the laser isotope separation of oxygen, it is important to study the mechanism and final products in the IRMPD of oxygen-containing compounds. In the present work we wish to report on the decomposition mechanism on the IRMPD of saturated open-chain ethers; dimethyl (**1a**), diethyl (**1b**), dipropyl (**1c**), diisopropyl (**1d**), dibutyl (**1e**), and *t*-butyl methyl (**1f**) ethers, and 1,2-dimethoxyethane (**2**). We have analyzed the stable decomposition products. Several radical intermediates are trapped by Br_2. On the basis of the results, suitable ethers for oxygen-isotope separation using a TEA CO_2 laser are suggested.

Experimental

Material. The saturated open-chain ethers (**1a—f**, **2**) were purchased from Tokyo Kasei Kogyo or Nakarai Chemicals. Each ether was distilled and degassed by several freeze (−196 °C)-pump-thaw cycles. Gas-chromatographic analyses of the ethers showed their purities to be over 99.5% and revealed no trace of possible decomposition products. All the other reagents and chemicals were commercially available and were used after distillation and degassing.

Apparatus and Procedure. A schematic diagram of the experimental set-up is shown in Fig. 1. A conventional glass vacuum system with an oil diffusion pump was used for the gas handling. The pressures were measured with a MKS Baratron-type 222B (0—10 Torr) gauge. The irradiation cell was a cross-type Pyrex tube equipped with four KBr windows (5 mm thick). The dimensions were 2 cm in diameter, 10 cm in the direction of the laser irradiation, and 5 cm in the direction of the infrared spectroscopic measurements. The IR absorption spectra were measured before and after irradiation by using a Japan Spectroscopic A-102 spectrophotometer.

A Lumonics 103-2 TEA (transversely excited atmospheric) CO_2 laser was operated using a mixture of CO_2 and He as flowing gases at a repetition rate of 0.7 Hz. The pulse width was about 80 ns FWHM without tailing. The laser lines were checked with an Optical Engineering CO_2 spectrum analyzer. The laser beam was passed through an aperture 1.0 cm in diameter and then tightly focused into the center of the cell using a BaF_2 lens with a focal length of 7.5 cm. The incident laser energy was attenuated by inserting one or more polyethylene films perpendicular to the beam path, and it was calibrated with a Scientech 364 disk calo-

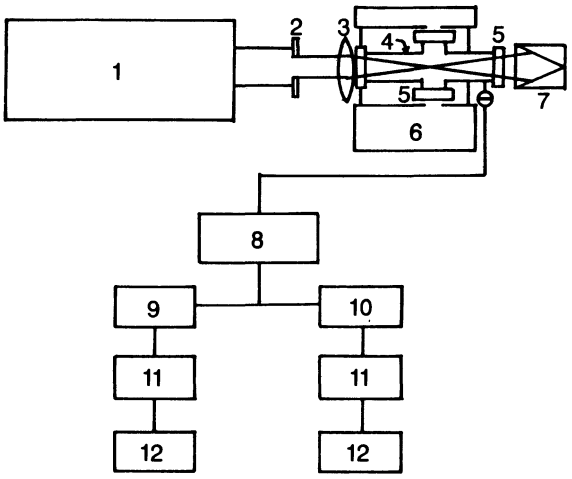

Fig. 1. Schematic diagram of the experimental set-up. 1: TEA CO_2 laser, 2: aperture, 3: BaF_2 lens, 4: reaction cell, 5: KBr window, 6: IR spectrometer, 7: power meter, 8: Toepler pump, 9: condensable gas at −196 °C, 10: non-condensable gas at −196 °C, 11: gas chromatograph, 12: mass spectrometer.

rimeter. The laser fluence at the focus corresponds to the incident pulse energy divided by the focus area (7.1×10^{-4} cm^2), which can be calculated from the aperture diameter, the focal length, and the beam divergence of 2 mrad.

Analysis. After the IR spectral measurements, sample mixtures were separated into two components, condensable gases and non-condensable gases, at −196 °C (H_2, CO, and CH_4) by using a Toepler pump. Both components were analyzed with gas chromatography (Shimadzu GC-7A, Hitachi 163, or Gasukuro Kogyo 373 gas chromatographs) using a flame-ionization or thermal-conductivity detector. Each gas chromatograph was connected to a sample injector and a integration recorder (Shimadzu Chromatopac C-R1B, Hewlett-Packard Integrator 3380, or SIC Chromatocorder 11). The lower hydrocarbons were analyzed on a Porapak Q 50/80 mesh column. The conditions were as follows: column length and diameter (L×ϕ), 6 m×3 mm; column temperature (CT), 150 °C; injection temperature (IT), 170 °C; detector (D), flame-ionization detector at 150 °C; carrier gas (CG), N_2; flow rate (FR), 50 $cm^3\,min^{-1}$. The lower hydrocarbons were also analyzed on a Sebaconitrile 10%-Uniport C 60/80 mesh column (L×ϕ, 10 m×3 mm; CT, 30 °C; IT, 50 °C; D, flame-ionization detector at 50 °C; CG, N_2; FR, 20 cm^3 min^{-1}). The ethers and bromine-containing compounds were analyzed on a PEG-20 M column (L×ϕ, 7 m×3 mm; CT, 90 °C; IT, 100 °C; D, flame-ionization detector at 100 °C; CG, N_2; FR, 30 cm^3 min^{-1}). The aldehydes were analyzed on a TSR-1 10%-Flusin T 30/60 mesh column (L×ϕ, 2 m×3 mm; CT, 100 °C; IT, 120 °C, D; thermal-conductivity detector at 100 °C; CG, He; FR, 27 cm^3 min^{-1}). The non-condensable gases (H_2, CO, CH_4) were analyzed on an Unibeads C 80/10 mesh column (L×ϕ, 3 m×3 mm; CT, 40—100 °C; IT, 100 °C; D, thermal-conductivity detector at 100 °C; CG, He; FR, 50 cm^3 min^{-1}).

A typical chromatogram of each irradiated ether showed that the peaks were fully resolved and reproducible. Standard mixtures were prepared to calibrate the gas chromatograms. The identification of the products by gas-chromatograph was based on a comparison of the product-retention times with those of the standards. The quantitative amounts of products and reactants were calibarted using gas-chromatographic sensitivity factors which had been determined by measuring the peak areas of pure standards on a integration recorder.

A mass spectrometer (Japan Electron Optics JMS-01SG) and GC-MS system (a NEVA TE-150 mass spectrometer combined with a Shimadzu GC-7A gas chromatograph) were also used to identify products, especially bromine-containing products, in the IRMPD of ether-Br_2 mixtures.

Results

The irradiation of ethers at 3.0 Torr with TEA CO_2 laser pulses caused the IRMPD to yield various products, as is shown in Tables 1—4. The laser line was tuned to the frequency coinciding with the strong absorption of the ether. The numbers of laser pulses were 100—500, and the conversions were 10—20%. The absorption coefficient (ε) of ether at the laser line changes from ether to ether in the range of 1.0×10^{-3}—7.5×10^{-2} $Torr^{-1}cm^{-1}$, while the decomposition yield ($Y_d=(1-P/P_0)/$(number of laser pulses)) varies slightly in the range of 3.7×10^{-4}—8.0×10^{-4} $pulse^{-1}$ (Table 1), where P_0 (=3.0 Torr) and P are the ether pressures before and after irradiation respectively.

The main decomposition products were H_2, CO,

a) Relative yield of product to total yield of hydrocarbon products.

H_2CO, and lower hydrocarbons. Additionally, acetaldehyde (CH_3CHO) and acetone (CH_3COCH_3) were formed in the IRMPD of **1b** and **1d** and of **1d**. The yields (Y=(pressure of product)/(P_0×(number of laser pulses)) of H_2, oxygen-containing compounds, and hydrocarbons are shown in Tables 2 and 3. Neither alcohol nor aldehyde containing more than three carbon atoms was detected. The material balance based on the oxygen atoms were very good—60—85%, as is shown in Table 2. The material balance is defined as {∑(pressures of oxygen-containing products)/(consumed ether) (number of oxygen atoms in ether)}×100%. Thus, the oxygen atoms in the decomposed ether were found mostly in CO, H_2CO, or CH_3CHO.

On the other hand, the distributions of the hydrocarbons were dependent on the ethers. The yield of a hydrocarbon relative to the total yield of hydrocarbons is presented for each ether in Table 4. The main hydrocarbons reflected the structures of the alkyl groups of the ethers: ethane (C_2H_6) and ethylene (C_2H_4) for **1a**, **1b**, and **2**; propylene (C_3H_6) for **1c** and **1d**; C_2H_4 for **1e**; isobutene for **1f**.

The value of Y_d increased with the increase in the laser fluence at the focus (F); Y_d was proportional to $F^{1.3-1.7}$. In addition, the product distributions also changed with F. The relationships between Y_d and F and the product distribution vs. F in the IRMPD of **1a**

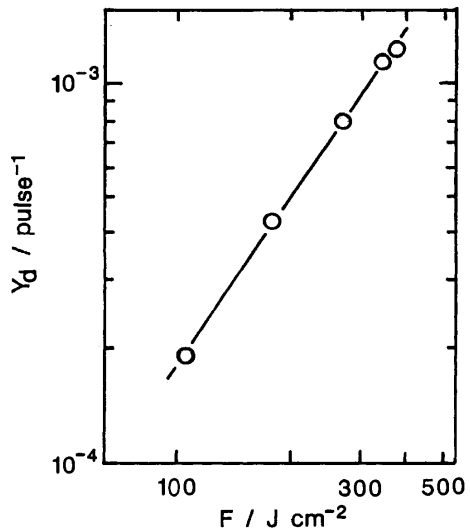

Fig. 2. Log-log plot of the decomposition yield (Y_d) vs. laser fluence at the focus (F) in the IRMPD of **1a** of 3.0 Torr.

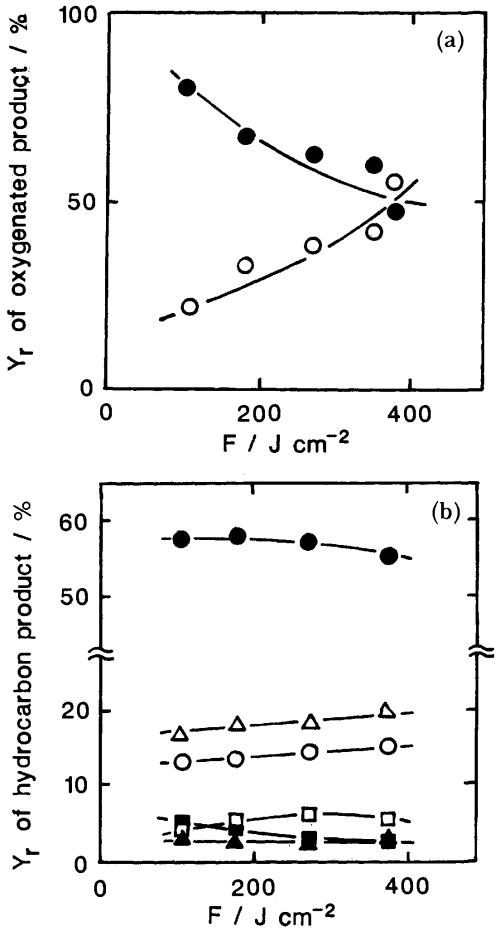

Fig. 3. Effects of F on the distribution (a) of oxygen-containing products: CO (○) and H_2CO (●) and (b) of hydrocarbon products: CH_4 (○), C_2H_6 (●), C_2H_4 (△), C_2H_2 (▲), C_3H_8 (□), and n-C_4H_{10} (■) in the IRMPD of **1a** at 3.0 Torr. The ordinate, Y_r, indicates relative yields of an oxygen-containing product and of a hydrocarbon product to the total yields of oxygen-containing products and of hydrocarbon products respectively.

Table 5. Relative Yields of Bromine-Containing Products in the IRMPD of Ether-Br_2 Mixtures

Ether	Relative yields of bromine-containing product[a](%)					
	CH_3Br	CH_2Br_2	C_2H_5Br	$C_2H_4Br_2$	C_3H_7Br	t-C_4H_9Br
1a	95	5	0	0	0	0
1b	46	1	54	2	0	0
1c	23	2	10	1	64	0
1f	12	0	0	0	0	88

a) Relative yield of product to total yield of bromine-containing products.

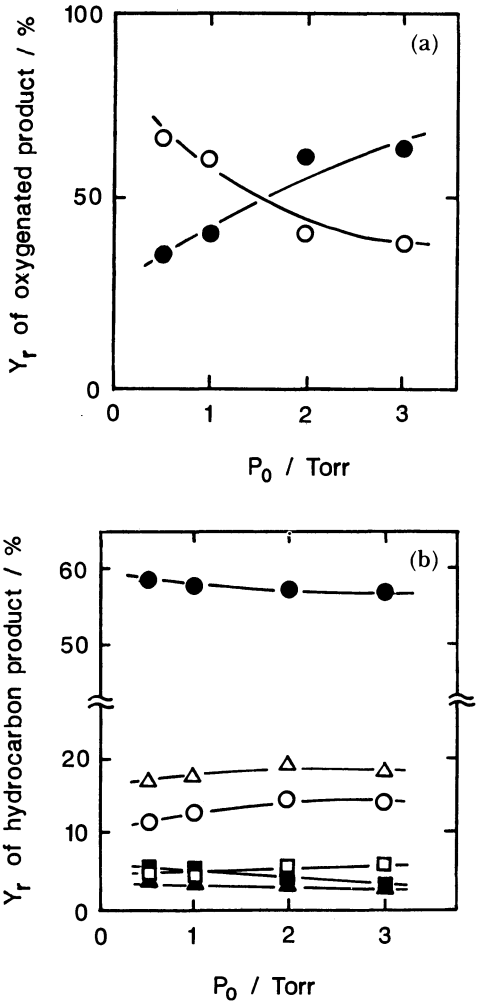

Fig. 4. Effects of P_0 on the distribution (a) of oxygen-containing products: CO (○) and H_2CO (●) and (b) of hydrocarbon products: CH_4 (○), C_2H_6 (●), C_2H_4 (△), C_2H_2 (▲), C_3H_8 (□), and n-C_4H_{10} (■) at F=271 J cm^{-2} in the IRMPD of **1a**.

are shown in Figs. 2 and 3 respectively. With the increase in F, H_2CO decreased, while CO increased in its relative yield, as is shown in Fig. 3a. On the other hand, the distribution of hydrocarbon products was hardly affected by F, as is shown in Fig. 3b.

The pressure dependence on the product distribution was examined in the range of 0.5—3.0 Torr at the same F in the IRMPD of **1a**. With the increase in the P_0 of **1a**, the relative yield of H_2CO increased, while that of CO decreased, as is shown in Fig. 4a. On the other hand, the distribution of hydrocarbon products did not significantly change with the P_0, as is shown in Fig. 4b.

When 3.0 Torr of ether was irradiated in the presence of 3.0 Torr of Br_2, bromine-containing compounds were formed with the decreases in the decomposition products (Table 5). Methyl bromide (CH_3Br) was the main product in the IRMPD of the **1a**-Br_2 mixture. A small amount of dibromomethane (CH_2Br_2) was also formed. Both CH_3Br and ethyl bromide (C_2H_5Br) in the ratio of 46 : 54 were formed in the IRMPD of the **1b**-Br_2 mixture, while t-butyl bromide (t-C_4H_9Br) and CH_3Br in the ratio of 88 : 12 were formed in the IRMPD of the **1f**-Br_2 mixture.

Discussion

Infrared multiple-photon excitation is different from UV excitation into an electronically excited state or thermal excitation, although there are similarities among the products formed in the IRMPD, vacuum-UV photolysis,[14] and thermolysis.[14a,15] The irradiation of ether using a TEA CO_2 laser yields highly vibrationally excited ether, E*, through IRMP excitation, with the asterisk denoting vibrational excitation.[3,4,16,17] The distribution of vibrational energy is usually approximated by the Boltzmann law.[16] Thus, the IRMPD can be well-explained by the statistical unimolecular decomposition according to the RRKM theory.[17,18] At high fluences, however, most of the molecules absorb more energy than is required for the dissociation of a bond.

Generally the weakest bond is broken in highly vibrationally excited molecules.[17] The cleavage of a C-O bond is obviously the lowest dissociation channel; the dissociation energy (E_{diss}) has been reported to be 81 kcal mol^{-1} in **1a**. A decomposition mechanism involving the initial cleavage of the C-O bond has been proposed in the IRMPD of **1a**.[5,6] Vacuum-UV photolysis and conventional thermolysis of ether in a vapor phase have also been explained on the basis of the initial cleavage of a C-O bond. The product distributions in the IRMPD of ethers are similar to those in UV-photolysis and thermolysis. Therefore, it is strongly suggested that the initial process in E* is the homolytic cleavage of the C-O bond, yielding

alkyl (R·) and alkoxyl radicals (R'O·) according to Eq. 1 (all the products are postulated to arise from the radicals):

$$\text{R-O-R}' \xrightarrow{nh\nu} \text{R}\cdot + \cdot\text{OR}' \quad (1)$$

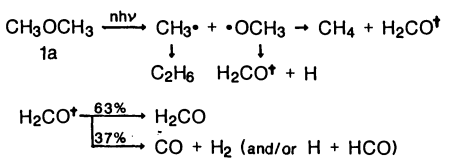
1a—f, 2 (R, R'=alkyl)

The energy absorbed by ethers (E_{abs}) must be as large as the E_{diss} of the C-O bond in ethers. Since the E_{abs} of decomposing ether is generally much larger than the E_{diss} at high fluences, R· and R'O· are formed with a high internal energy and decompose into the primary products either sequentially or via secondary IRMPD. The primary products are also formed with a high internal energy and, therefore, decompose into stable products or are stabilized via collisional deactivation. It has previously been pointed out that the sequential decomposition or secondary IRMPD of radical intermediates and primary products with a high internal energy occurs favorably in the IRMPD of organic compounds, even if their $1\leftarrow0$ absorptions are not resonant with the laser radiation.[10,19]

In the IRMPD of ethers, radicals are formed spatially at a higher concentration by using a tightly focused laser beam. The relationship of $Y_d \propto F^{1.3-1.7}$ (shown in Fig. 2) means that the decomposition yield in the IRMPD of **1** and **2** approximately follows the 1.5-power rule; the fluence is much higher than the threshold one, and all the molecules in the region around a focal point decompose completely and yield radicals at high concentrations. Therefore, radical-radical reactions occur, while reactions between radicals and starting ethers are not involved. In fact, all the products in the IRMPD of ethers were either decomposition fragments or radical-radical reaction products. There were no detectable products originating from the reactions between radicals and ethers.

1a. From the distribution of decomposition fragments, the reaction processes of the radicals are considered to be as follows. The cleavage of the C-O bond in **1a*** gives primarily a methyl radical (CH_3·) and a methoxyl radical (CH_3O·). The radicals then react each other via coupling and disproportionation (Scheme 1).

Since methanol was not detected, disproportionation between two CH_3O· or H-abstraction from **1a** by CH_3O· did not occur. Thus, CH_3O· reacts with CH_3· via H-abstraction to yield H_2CO and CH_4 or decomposes into H_2CO and H. The activation energy (E_a) for the latter process has been reported to be 30 kcal mol^{-1}.[20] When the E_{diss} of decomposing **1a*** is higher than the summation of E_{diss} for the C-O bond plus E_a for the decomposition of CH_3O· into H $+H_2CO$ (i.e., $E_{abs}>E_{diss}+E_a=111$ kcal mol^{-1}), the internal energy of CH_3O· is so high that CH_3O· decomposes sequentially. Alternatively, there is a possibility that the secondary IRMPD of CH_3O· occurs within a laser pulse, if CH_3O· is formed in highly excited vibrational states and absorbs further laser radiation. The primary product H_2CO is probably formed with a high internal energy. Therefore, $H_2CO^\dagger$ may, at least in part, decompose sequentially or via the secondary IRMPD into $CO+H_2$. (The dagger denotes a high internal energy.) This decomposition is strongly suggested because the heat of reaction is only 1.3 kcal mol^{-1}.[21] Alternatively the decomposition of $H_2CO^\dagger$ into HCO+H may occur to yield CO as the final product. It is not clear whether the molecular pathway or the radical pathway is involved in the sequential decomposition of $H_2CO^\dagger$. However, CO is the final product in both pathways.



Scheme 1.

The sequential decomposition of $H_2CO^\dagger$ competes with the collisional deactivation process to give H_2CO in the ground state. The ratio of the sequential decomposition of $H_2CO^\dagger$ to the deactivation process depends on the internal energy and can be estimated from the ratio of CO to H_2CO. At higher F values, a faster IRMP excitation leads to higher internal energies of **1a*** and $H_2CO^\dagger$ and accelerates the sequential decomposition. At lower P_0 values, the collisional deactivation decreases, while the sequential decomposition increases. In fact, we observed that the ratio increased from 20 to 50% with the increase in F from 105 to 375 J cm^{-2} (Fig. 3a) and that the ratio increased from 37 to 65% with the decrease in P_0 from 3 to 0.5 Torr (Fig. 4a).

Since CH_3· is also produced with a high internal energy, such primary products as CH_4 and C_2H_6 are probably formed with high internal energies. However, the primary hydrocarbon products are mostly stabilized by the collisional deactivation processes because of the higher E_a values for the cleavage of C-H and C-C bonds, 102 and 85 kcal mol^{-1} respectively[22] in CH_4 and C_2H_6 compared with those in $H_2CO^\dagger$.[21] This is consistent with the absence of any effect of F and P_0 on the distribution of hydrocarbon products in the range of 105—375 J cm^{-2} of F (Fig. 3b) and in the range of 0.5—3 Torr (Fig. 4b). The formation of C_2H_4, C_2H_2, C_3H_8, and other hydrocarbons is explained by the following sequence of reactions (Eqs. 2—12), which are all involved in high-temperature chemistry:[23]

$$\text{CH}_3\cdot + \text{CH}_3\cdot \rightarrow \text{C}_2\text{H}_6 \quad (2)$$

$$\text{CH}_3\cdot + \text{C}_2\text{H}_6 \rightarrow \text{CH}_4 + \text{C}_2\text{H}_5\cdot \quad (3)$$

$$\text{C}_2\text{H}_5\cdot \rightarrow \text{C}_2\text{H}_4 + \text{H} \quad (4)$$

$$\text{H} + \text{C}_2\text{H}_6 \rightarrow \text{H}_2 + \text{C}_2\text{H}_5\cdot \quad (5)$$

$$\text{CH}_3\cdot + \text{C}_2\text{H}_5\cdot \rightarrow \text{C}_3\text{H}_8 \quad (6)$$

$$CH_3\cdot + C_2H_5\cdot \rightarrow CH_4 + C_2H_4 \quad (7)$$

$$H + C_2H_4 \rightarrow H_2 + C_2H_3 \quad (8)$$

$$CH_3\cdot + C_2H_4 \rightarrow CH_4 + C_2H_3 \quad (9)$$

$$C_2H_3 \rightarrow H + C_2H_2 \quad (10)$$

$$H + C_2H_5\cdot \rightarrow 2CH_3\cdot \quad (11)$$

$$H + C_2H_3 \rightarrow C_2H_4 \quad (12)$$

According to Scheme 1, the total yield of oxygen-containing products is expected to be equal to the total yield of C_n hydrocarbon products multiplied by n. The actual ratio of the two yields was, however, 1 : 0.74; several oxygen-containing products have not been detected. The value of $[CO]/([CO]+[H_2CO])=0.37$ means that H_2CO^+ decomposes into $CO+H_2$ in a 37% yield and is stabilized into H_2CO in a 63% yield. The ratio of $[H_2]/[CO]=2.0$ suggests that H_2 is formed not only via the decomposition of H_2CO^+ but also via other reactions of the alkyl radicals.

Similar mechanisms involving the sequential decomposition of primary products into final products have been proposed in the IRMPD of organic molecules.[10,19] The sequential decomposition process competes with the collisional deactivation process and, therefore, occurs more easily with smaller E_a and larger E_{abs} values. The sequential (and/or secondary) process distinguishes the IRMPD from thermolysis and shock-wave decomposition, although the sequential decomposition process sometimes occurs in thermolysis at extremely high temperatures.[24]

1b. A similar mechanism is proposed for the IRMPD of **1b** (Scheme 2). The initial cleavage of the C-O bond yields $C_2H_5\cdot$ and $C_2H_5O\cdot$. The disproportionation of $C_2H_5\cdot$ gives C_2H_4 and C_2H_6. The β-fission of $C_2H_5O\cdot$ yields H_2CO^+ and $CH_3\cdot$, while $C_2H_5O\cdot$ decomposes partly into CH_3CHO^+ by the splitting of H. The energy requirement for the cleavage of the C-C bond is considerably less in the decomposition of $C_2H_5O\cdot$.[25] Therefore, the cleavage of the C-C bond must occur favorably; the yield of H_2CO^+ is then higher than that of CH_3CHO^+.

The sequential decomposition of CH_3CHO^+ with a high internal energy yields CH_4+CO (and/or $CH_3\cdot$ +HCO) in a manner similar to that found with H_2CO^+ (Scheme 1). Even if $CH_3\cdot$ and HCO are formed, CH_4, C_2H_6, and CO are mainly formed. Therefore, CH_4 and CO are the final products in the sequential decomposition of CH_3CHO^+.

On the basis of the value of [CO]/[oxygen-containing products]=0.25 and the value of $[CH_3CHO]/([H_2CO]+[CH_3CHO])=0.12$, the branching ratios in the decomposition of $C_2H_5O\cdot$ and in the decomposition of H_2CO^+ and CH_3CHO^+ can be roughly estimated. When x, y, and z denote the ratios of the decomposition of $C_2H_5O\cdot$ into H_2CO^+ plus $CH_3\cdot$, and those of the deactivations of H_2CO^+ into H_2CO and of CH_3CHO^+ into CH_3CHO, respectively, Eqs. 13 and 14 are derived (see Scheme 2):

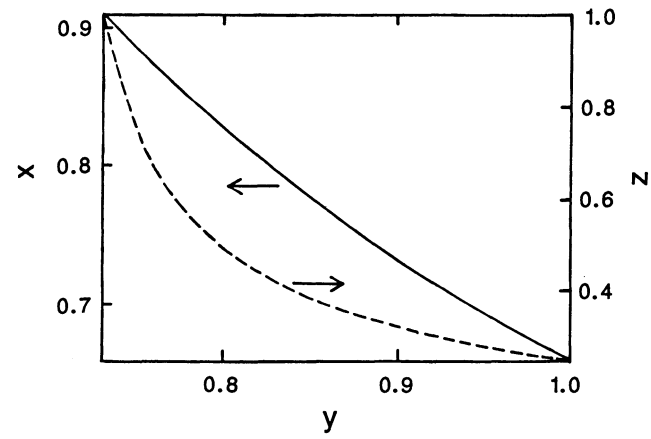


Fig. 5. Relationships of x, y, and z. Values of x and z are calculated as a function of y. For x, y, and z, see the text.

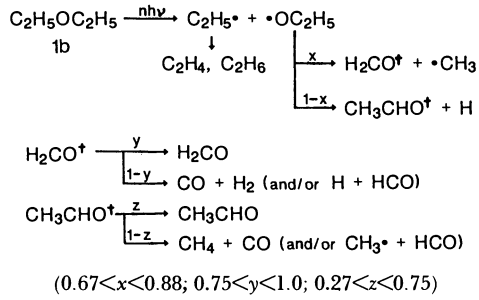
$$x = 1/(1 + 0.136y/z) \quad (13)$$

$$z = 1/(11.1 - 7.33/y) \quad (14)$$

The values of x and z are calculated as a function of y, as is shown in Fig. 5.

A higher branching ratio of the decomposition of $C_2H_5O\cdot$ into H_2CO^+ and $CH_3\cdot$ than that into CH_3CHO^+ and H can easily be expected from the energy difference between the cleavages of the β C-C and β C-H bonds in $C_2H_5O\cdot$. When the branching ratios of the sequential decomposition to collisional deactivation are equivalent in H_2CO^+ and CH_3CHO^+, one can obtain $y=z=0.75$ and $x=0.88$. However, the sequential decomposition is considered to be much more favored in CH_3CHO^+ than in H_2CO^+. It is expected that a small fragment H does not remove the excess energy, while the excess energy remains mainly in a large fragment. Therefore, CH_3CHO^+ has a higher internal energy and decomposes sequentially in a higher yield than does H_2CO^+. This means that $y>0.75$ and $z<0.75$ and that, therefore, $x<0.88$. If y is close to unity, one can obtain $x=0.67$ and $z=0.27$. The ranges of x, y, and z are determined to be as shown in Scheme 2.

The formation of hydrocarbon products is also explained by these reactions (Eqs. 2—12) and similar reactions involving $C_2H_5\cdot$. Since a considerable

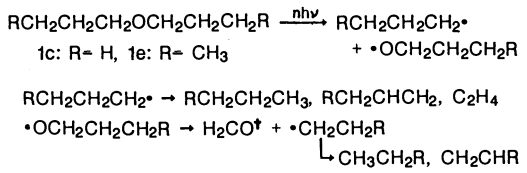


$(0.67<x<0.88;\ 0.75<y<1.0;\ 0.27<z<0.75)$

Scheme 2.

amount of propane (C_3H_8) is formed, the coupling reaction between C_2H_5· and CH_3· (Eq. 6) is particularly important.

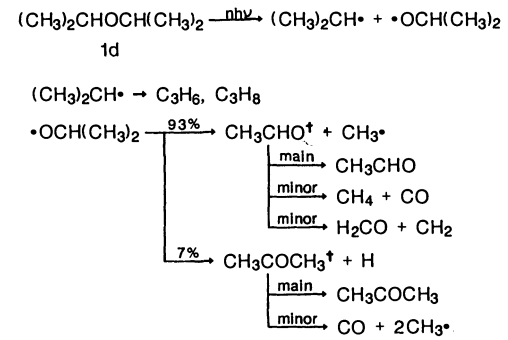
1c and 1e. The cleavage of the C-O bond produces propyl (n-C_3H_7·) and propoxyl radicals (n-C_3H_7O·) in the IRMPD of **1c**, and butyl (n-C_4H_9·) and butoxyl radicals (n-C_4H_9O·) in the IRMPD of **1e** (Scheme 3).



Scheme 3.

n-C_3H_7· disproportionates into C_3H_8 and C_3H_6, while n-C_4H_9· decomposes into C_2H_4 and C_2H_5· via β-fission. Since CO and H_2CO were the only detectable products containing an oxygen atom, it can be said that the cleavage of the β C-C bond in n-C_3H_7O· and n-C_4H_9O· occurs predominantly to form $H_2CO^{\dagger}$+C_2H_5· and $H_2CO^{\dagger}$+n-C_3H_7· respectively. It is well-established that the elimination of an alkyl redical from alkoxyl radicals occurs much faster than that of a hydrogen atom in thermolyses and UV photolyses.[25,26]

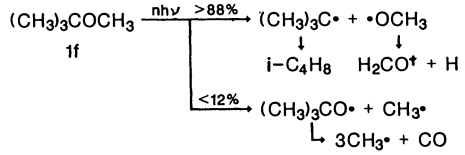
1d. The isopropoxyl radical (i-C_3H_7O·) formed in the IRMPD of **1d** decomposes mostly into $CH_3CHO^{\dagger}$+CH_3· and slightly into $CH_3COCH_3^{\dagger}$+H (Scheme 4). The estimation of the branching ratio



Scheme 4.

between the two processes from the value of $[CH_3COCH_3]/([CH_3COCH_3]+[CH_3CHO])$ shows that the latter process produces only in a 7% yield. It is assumed in the estimation that the branching ratios of stabilization and decomposition for $CH_3CHO^{\dagger}$ and $CH_3COCH_3^{\dagger}$ are similar to each other. The selective decomposition of i-C_3H_7O· into CH_3CHO+CH_3· is due to the smaller value of E_a=11.8 kcal mol^{-1}.[27] Additionally, H_2CO is formed in an 8% yield relative to the total yield of the oxygen-containing products. Therefore, $CH_3CHO^{\dagger}$ is mainly deactivated into CH_3CHO and slightly decomposes into CH_4+CO and H_2CO+CH_2. Similarly, $CH_3COCH_3^{\dagger}$ is mostly stabilized to CH_3COCH_3 and partly decomposes into 2CH_3·+CO, probably via the secondary IRMPD.

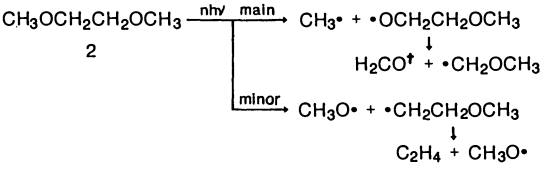
1f. In contrast to **1a—d**, **1f** does not have a symmetric structure; rather it has two different alkyl groups separated by an oxygen atom. Therefore, it is interesting to see which C-O bond cleaves initially in the IRMPD of **1f**. The oxygen-containing products are CO and H_2CO, while isobutene (i-C_4H_8) is formed in a 75% yield relative to the total yield of hydrocarbon products. Thus, the cleavage of the C-O bond of a t-butyl group occurs selectively to form the t-butyl radical ($(CH_3)_3C$·) and CH_3O· (Scheme 5). The



Scheme 5.

minor cleavage of the other C-O bond gives the t-butoxyl radical (t-C_4H_9O·) and CH_3·. Since neither CH_3CHO nor CH_3COCH_3 was detected, t-C_4H_9O· may be scarcely formed at all, or it may decompose into small fragments. If i-C_4H_8 is formed in the main channel and C_2 hydrocarbons are formed from the CH_3· produced in the minor channel, the selectivity for the main cleavage can be estimated to be 88% from $[i\text{-}C_4H_8]/([i\text{-}C_4H_8]+0.5\times[C_2\text{ hydrocarbons}])=0.88$. This value probably corresponds to the lower limit, because CH_3· may be produced from t-C_4H_9O·. The selectivity is due to the considerably smaller value of E_{diss} for a t-C_4H_9-O bond (ca. 60 kcal mol^{-1})[28] than that for a CH_3-O bond (81 kcal mol^{-1}).[17]

2. On the other hand, the cleavages of two different C-O bonds are involved in the IRMPD of **2**. One process gives $CH_3OCH_2CH_2$·+CH_3O·, while the other gives $CH_3OCH_2CH_2$·+CH_3·, as is shown in Scheme 6. Both $CH_3OCH_2CH_2$· and $CH_3OCH_2CH_2O$· de-



Scheme 6.

compose mainly via β-fission. Since C_2H_6 is formed in a higher yield than is C_2H_4 (1.7 : 1), the C-O cleavage to form CH_3· occurs more preferentially than that to form CH_3O·. However, the selectivity of the cleavage is small because of the similar values of E_{diss} for the two C-O cleavages.

On the basis of the distributions of the products in the IRMPD of open-chain ethers, the decomposition

mechanisms discussed above may be summarized as follows. The homolytic cleavage of the C-O bond in E* occurs primarily to form alkyl and alkoxyl radicals. Since radicals are formed with high internal energies, they further decompose and rearrange sequentially or via the secondary IRMPD. The primary products are mainly formed through β-fission. Since the primary products are also considered to be formed with high internal energies, further decomposition into the stable products occurs, at least in part. The stable products are mostly decomposition fragments, plus a few radical-radical reaction products. No product from any reactions between redicals and ethers was detected. These results are attributable to either the properties of E* in the high vibrational states or to the geometrical specificities of the reaction field in the focused laser beam.

It has been demonstrated that Br_2 is an efficient scavenger of radicals, but it does not initiate chain reactions.[29] The formation of CH_3Br has already been reported in the IRMPD of a mixture of **1a** and Br_2 by Vizhin et al.[5] We have also studied the IRMPD of mixtures of several ethers and Br_2 in order to elucidate the radical intermediates (Table 5). The predominant formation of CH_3Br in the IRMPD of mixture of **1a** and Br_2 clearly shows the intermediary of $CH_3\cdot$ (Scheme 1). The formation of a small amount of CH_2Br_2 suggests that CH_2 is trapped by Br_2. Comparable amounts of CH_3Br and C_2H_5Br were formed in the IRMPD of a mixture of **1b** and Br_2. This suggests a comparable formation of $CH_3\cdot$ and $C_2H_5\cdot$. Therefore, $C_2H_5O\cdot$ splits mainly into $H_2CO+CH_3\cdot$ (Scheme 2). The ratio of $[t\text{-}C_4H_9Br]:[CH_3Br]=88:12$ was obtained in the IRMPD of a mixture of **1f** and Br_2. This shows that the cleavage of a $t\text{-}C_4H_9\text{-}O$ bond occurs selectively in an 88% yield to produce $t\text{-}C_4H_9\cdot+\cdot OCH_3$. The value of the selectivity is equal to the value estimated from the product ratio of $[i\text{-}C_4H_8]/([i\text{-}C_4H_8]+0.5\times[C_2 \text{ hydrocarbons}])=0.88$ (Scheme 5). On the other hand, no bromine-containing compounds of alkoxyl radicals were observed because of the instability of an O-Br bond, even at room temperature.[30]

We have discussed the mechanism of the IRMPD of ethers on the basis of the distribution of the products. However, it has been pointed out that the distribution of the products is generally changed by variations in the irradiation parameters in the IRMPD of organic compounds.[3,4] The sequential processes and the secondary IRMPD of the intermediates compete with collisional deactivation. The branching ratio depends on the internal energies of the radicals and the primary products. Therefore, the branching ratios obtained in the present study are limited to the irradiation conditions of the present experiment. Other competitive processes might produce lower yields under different conditions. However, the main decomposition products are always the same, as is shown in Schemes 1—6, because the initial process is always the cleavage of a C-O bond.

There is a notable finding with respect to the values of ε and Y_d in Tables 1 and 2. **1a** and **1f** have larger ε and Y_d values compared with the other ethers. This result suggests that the $1\leftarrow0$ absorption is very important in IRMP excitation. On the other hand, **1c** has a relatively smaller ε value but a larger Y_d value. The dissociation energy of the bond cleavage and the activation energy of a sequential reaction process probably change with **1a—f** and **2**. Therefore, the decomposition efficiency is dependent not only on the $1\leftarrow0$ absorption, but also on the dissociation and the activation energies for the reaction processes.

Ethers have several advantages as starting materials for the oxygen-isotope separation by use of a TEA CO_2 laser. Firstly, the initial step is the cleavage of a C-O bond. Secondly, the resulting alkoxyl radicals sequentially split into H_2CO or CH_3CHO, which further decompose partly into CO as a stable oxygen-containing product. Since no reactions of alkoxyl radicals with ethers are involved, the isotope selectivity in the cleavage of a C-O bond is predicted to be retained even in the final product, CO. Although the sequential decomposition processes of alkoxyl radicals complicate hydrocarbon products, CO is always the main product among the oxygen-containing products.

When ^{18}O-ether decomposes into alkyl and alkoxyl racicals through selective IRMP excitation, the ^{18}O-alkoxyl radical decomposes sequentially into CO and also reacts partly with ^{16}O-ether in the reaction volume. The bimolecular reactions, together with the vibrational energy transfer between ^{18}O- and ^{16}O-ethers during IRMP excitation, decreases the isotope selectivity. Practically, a lower pressure and a lower F value are used to obtain higher selectivities. The addition of a radical scavenger sometimes effectively prevents isotope-scrambling processes.

The material balance based on oxygen atoms is high enough for it to be concluded that the oxygen atoms in decomposed ethers are found mostly in CO, H_2CO, or CH_3CHO. However, approximately 10—30% of the oxygen-containing products have not been detected. This is probably because of the adsorption of H_2CO and CH_3CHO on the cell wall. It may, alternatively, be suggested that low-volatile oxygen-containing products, including a large number of carbon and oxygen atoms, are formed on the cell wall through the complicated reactions between the radicals and the starting ether.

From the observed results, the criteria for a suitable ether for oxygen-isotope separation by means of IRMPD are considered to be as follows. A higher selectivity of oxygen-isotopes in the cleavage of a C-O bond is, of course, the most important factor. Moreover, it is necessary for a good candidate (1) that the ether have a large Y_d, (2) that a highly selective

decomposition process occur, and (3) that simple products be formed. On the basis of these factors, **1a** and **1f** may be said to be the most suitable ethers among the saturated open-chain ethers. In fact, the ^{18}O enrichment induced by a TEA CO_2 laser has been demonstrated in **1a**[5,6] and $(CF_3)_2O$.[1]

The ^{18}O enrichment by the IRMPD of **1a** and **1f** is now under investigation. We are also studying the IRMPD of cyclic ethers for the ^{18}O enrichment.

Thanks are due to Mr. Masahiro Toyoda, undergraduate student of Science University of Tokyo in 1982—1983, for his collaboration in the course of this experiment.

Gas Sensitivities of Polypyrrole Films to Electron Acceptor Gases

Tetsuro HANAWA and Hiroshi YONEYAMA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565
(Received November 29, 1988)

Electropolymerized polypyrrole films exhibited noticeable gas sensitivities to electron acceptor gases such as PCl_3, SO_2, and NO_2 at room temperature only when they were reduced electrochemically, and the resistance decrease was larger with the gas of larger electron affinity. It was also found that the resistance decrease obeyed the Elovich equation in an early stage of the gas exposure.

Conducting polymers such as polypyrrole and polyaniline have a characteristic feature that anion-doping reactions occur reversibly, and this property has been utilized in several applications such as rechargeable batteries,[1-3] electrochromic displays[4-6] and electronic devices.[7,8] The use of conducting polymers as gas-sensing elements has also been reported in the case of polypyrrole for ammonia,[9] nitrogen dioxide,[10] and alcohols.[11] We previously investigated[12] the NO_2 sensing mechanism of polypyrrole films and found that the NO_2 sensitivity was mainly indebted to chemical doping of NO_2 to give NO_2^-, as in the case of polyacetylene with iodine and bromine etc.[13,14] and of polypyrrole with iodine vapor.[15,16] The present study was intended to investigate comparatively the gas sensitivity of polypyrrole to several electron acceptor gases such as O_2, PCl_3, SO_2, NO_2, and I_2.

Experimental

Film Preparation. Electropolymerization of pyrrole was performed in acetonitrile containing 1 vol% twice distilled water, 0.1 mol dm^{-3} $LiClO_4$ and 0.1 mol dm^{-3} pyrrole under N_2 atmosphere. Distilled pyrrole, reagent grade $LiClO_4$, and acetonitrile were used for the preparation of the electrolyte solution, and prior to electrolysis N_2 was bubbled into the solution for more than 20 min to purge dissolved oxygen. An electrode used for gas sensitivity measurements is illustrated in Fig. 1. Two pieces of Pt wires (d=0.5 mm) were connected to a Pyrex male ground glass joint with 0.3 mm distance which was provided by inserting a thin adhesive tape between the Pt electrodes. The separation of the Pt electrode was fixed with epoxy resin in such a manner as to leave 3 mm bare portion of the Pt wires in their ends which served as electrodes. The polypyrrole deposition was made with the electrolysis at 1 mA for 20 min. By the electrolysis, polypyrrole was deposited in such a manner as to connect the two Pt wire electrodes with each other.

The preparation of polypyrrole films for elemental analyses and for EPMA was made using a rectangular ITO glass electrode (4.0×1.5 cm^2) and a circular ITO glass electrode with 10 mm diameter, respectively. The electrolysis was carried out at 0.5 mA cm^{-2} for 30 min for both cases.

Polypyrrole films used for an multireflectance FT-IR measurement were prepared on a Pt-sputtered rectangular ITO glass electrode (4.0×1.5 cm^2) which provided a flat reflective surface, and those for optical absorption spectrometry were prepared on a rectangular ITO glass electrode

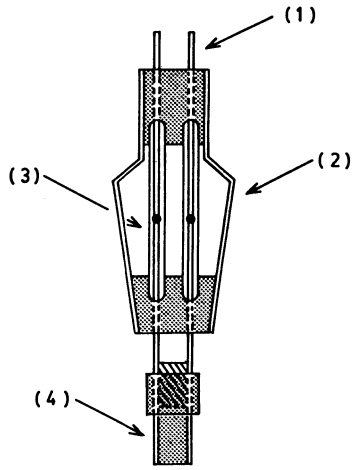

Fig. 1. Schematic illustrations of electrode used for the polypyrrole electrodeposition, designed for the gas sensitivity measurement. Dotted part and slash-lined part denote epoxy resin and adhesive tape, respectively.
(1) Cu lead wire, (2) ground pyrex glass male joint, (3) glass tube, (4) Pt wire (d=0.5 mm).

(2.5×1.5 cm^2) covered with a very thin Pt layer which assisted in homogeneous reduction of the deposited polypyrrole film. The covered Pt was thin enough to allow light penetration in the absorption measurements. In both cases, the current density of 0.2 mA cm^{-2} was used and the quantities of electricity chosen for the former and the latter were 200 mC cm^{-2} and 100 mC cm^{-2}, respectively.

After thoroughly rinsed with acetonitrile, the electropolymerized polypyrrole films were transferred into a N_2-saturated dry box, and subjected to electrochemical reduction in distilled acetonitrile containing 0.1 mol dm^{-3} $LiClO_4$ at −400 mV (vs. Ag/AgCl) for longer than 15 min. Immediately after the reduction, the polypyrrole films were rinsed with distilled acetonitrile and then transferred into a vacuum vessel having a ground female joint which allowed the connection to a vacuum line. These procedures were conducted in the dry box. The polypyrrole samples were vacuum dried at ca. 10^{-4} Torr (1 Torr=133.322 Pa) for more than 1 h.

Measurements of Gas Sensitivities. The electrode shown in Fig. 1 was connected to a branch of a three way tubing. The branch contained a stopcock and a fitted female joint for connecting the electrode. Another branch of the tubing contained a stopcock through which a gas reservoir was connected. The gas reservoir contained an injection port like

that of a gas chromatograph for the injection of test gases. The third branch of the tubing was connected to a vacuum line. Before measurements, the electrode housing and the gas reservoir were evacuated, stopcocks of them were then closed, and the test gas was introduced into the gas reservoir using a gas syringe so as to give 300 Pa in the whole cell. In the measurements of gas sensitivity to iodine vapor, however, solid iodine was first placed in the gas reservoir which was cooled by liquid N_2, and then the electrode housing and the gas reservoir were evacuated. The iodine vapor of ca. 27 Pa in the whole cell was prepared by warming the gas reservoir to room temperature. By opening the stopcock of the electrode housing part, the electrode was exposed to the test gas. Gas sensing behaviors of the polypyrrole films were obtained by measuring current transients under application of 100 mV. In this paper, the gas sensing behaviors will be shown by resistance-time relations. Oxygen, PCl_3, SO_2, NO_2, and iodine vapor which have electron affinities of 0.45 eV, 0.8 eV, 1.1 eV, between 2.1 and 2.5 eV and between 2.5 and 2.6 eV, respectively[17] were used as sample gases.

Spectral Measurements. Polypyrrole films were vacuum dried in the vessel connected to the vacuum line as in the case of the gas sensitivity measurements, and then exposed to sample gases for more than 1 h. After the vacuum evacuation of the gas-exposed films for more than 1 h, spectral measurements were carried out.

Electron probe X-ray microanalysis (EPMA) was performed using an energy dispersive X-ray analyzer EMAX-1800E (Horiba) connected to a scanning electron microscope S-450 (Hitachi). A FT-IR spectrometer FT/IR-3 (JASCO) and an UV-visible spectrometer MPS-5000 (Shimadzu) were used for multireflectance FT-IR measurements and the optical absorption measurements, respectively. The latter two measurements were performed in air.

Results and Discussion

Gas Sensitivities of Reduced Polypyrrole Films to Electron Acceptor Gases. The resistance of the polypyrrole films prepared in the electrode assembly shown in Fig. 1 was ca. 10 Ω and it increased to several kiloohms by electrochemical reduction. When the reduced polypyrrole films were exposed to either one of PCl_3, SO_2, or NO_2 in 300 Pa, or ca. 27 Pa I_2 vapors at room temperature, the resistance of the films was decreased as shown in Fig. 2, and the decreased resistance was not recovered by the subsequent vacuum evacuation. The O_2 sensitivity was also examined, but the exposure of the reduced polypyrrole film to 300 Pa O_2 did not result in any remarkable resistance change. This observation might be related to the finding reported by Scott et al. that the O_2 exposure of reduced polypyrrole films resulted in the conductivity of 10^{-2} $S\,cm^{-1}$ at most,[18] the conductivity being the same order as that of reduced polypyrrole films used in this study.

It is shown in Fig. 2 that the initial resistance of reduced polypyrrole films were different. The scatter seems to have resulted from rather ill-reproducible connections of two Pt wire electrodes with the deposited polypyrrole, but it is believed that the difference

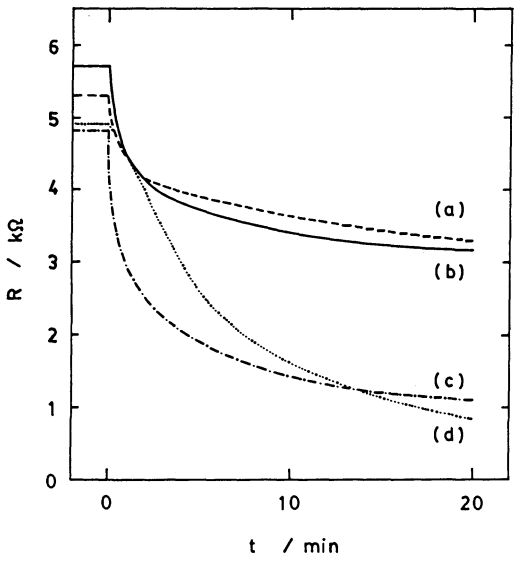

Fig. 2. Resistance changes of electrochemically reduced polypyrrole films caused by the exposure to electron acceptor gases:
(a) 300 Pa PCl_3, (b) 300 Pa SO_2, (c) 300 Pa NO_2, (d) ca. 27 Pa iodine vapor at room temperature.

in the initial resistances did not bring about any serious problem in qualitative analysis of the gas sensitivities of polypyrrole films which will be described below. It is seen in Fig. 2 that the gas sensitivities to iodine and NO_2 are larger than those to SO_2 and PCl_3. This was true even for the gas exposure for long term such as for more than 10 h. The resistance decrease rapidly occurred within initial ca. 2 hours of the gas exposure, followed by a gentle decrease. The resistance attained at the 10 h-gas exposure was 10^2 Ω for the iodine vapor, 1.8×10^2 Ω for NO_2, 1.8×10^3 Ω for SO_2 and 2.0×10^3 Ω for PCl_3. Considering that the electron affinity of NO_2 and I_2 is very near to each other and is more than 1 eV greater than those of PCl_3 and SO_2, the electron affinity seems to play an important role in determining the gas sensitivity of polypyrrole films.

Gas-Sensing Mechanisms. To analyze the resistance changes as shown in Fig. 2, FT-IR and optical absorption spectra of reduced polypyrrole films were measured before and after the gas exposure. Spectra of the reduced film, that of a film first reduced and then exposed to the sample gases, and that of an as-grown film are shown in Fig. 3. The reduced film gave a spectrum (a), while the as-grown film (b). Spectra (c), (d), and (e) concern polypyrrole films that were first reduced and then exposed to NO_2, SO_2, and PCl_3, respectively. It is shown for all cases that by the gas exposure the absorption around 1 eV was enhanced, while that around 3 eV was decreased. It is well-established that absorption having its maximum around 1 eV is related to bipolaron-related transition which is dominant in anion-doped polypyrrole, and that around 3 eV is related to π-π^* transition which is

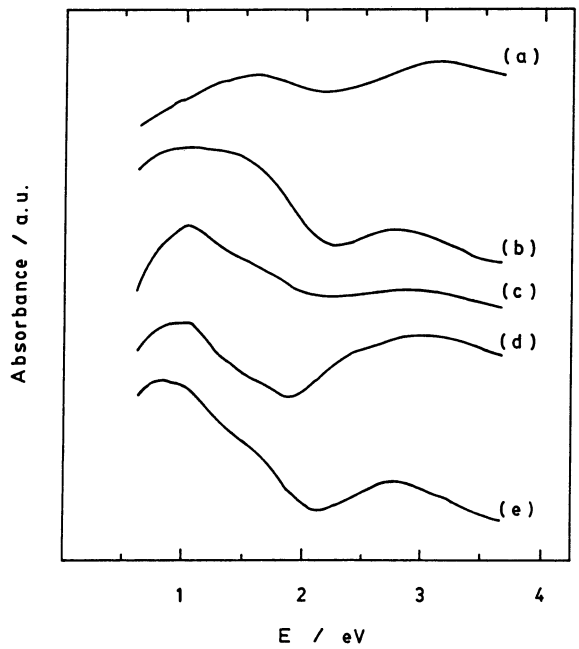

Fig. 3. Optical absorption spectra of polypyrrole films:
(a) reduced, (b) as-grown, (c) reduced and then exposed to NO_2, (d) reduced and then exposed to SO_2, (e) reduced and then exposed to PCl_3.

Table 1. Elemental Analyses of Various Polypyrrole Films[a)]

Sample	Molar ratio to carbon (C=4)				
	C	H	N	Cl	I
As-grown	4	3.03	0.96	0.33	—
Reduced	4	2.83	0.97	0.11	—
Reduced and then exposed to iodine vapor	4	3.20	1.00	0.11[b)]	0.36[c)]
Reduced and then exposed to NO_2	4	3.03	1.11	0.08	—
Reduced and then exposed to PCl_3	4	3.78	0.95	0.33	—

a) The exposure to each gas was carried out for 12 h at room temperature. The gas pressure was 300 Pa for NO_2 and PCl_3, and ca. 27 Pa for iodine vapor. b) Based on the results obtained for the reduced film. c) Estimated by subtracting the chlorine content from the total halogen content (see text).

dominant in reduced polypyrrole.[18,19)] Then it is concluded that the resistance change of polypyrrole films caused by the exposures to SO_2 and PCl_3 results from the doping reactions, as already reported for iodine[15,16)] and NO_2[12)] exposures.

Figure 4 shows FT-IR spectra for reduced films before and after SO_2-exposure. It is recognized that new absorption peaks appeared at 493, 634, 930, 940, 976, and 987 cm^{-1} with the SO_2-exposure. If polypyrrole reacts with SO_2 to give sulfur compounds like sulfone, sulfate and sulfonate, absorption should appear between 1100—1400 cm^{-1},[21)] being in contradiction to the obtained results. It is known that SO_2 gives absorption peaks at 1147, 517, and 1351 cm^{-1},[21)] SO_2^- at 984.8, 495.6, and 1042 cm^{-1},[21)] SO_3 at 484, 1391, and 536 cm^{-1},[21)] SO_2^{2-} at 967, 620, 933, and 469 cm^{-1},[21)] and SO_4^{2-} at 981 and 1104 cm^{-1}.[21)] Judging from these published data, new peaks which appeared in the spectrum (b) are attributable to doped SO_2^- and SO_3^{2-}. Multireflectance FT-IR spectrum of reduced and then PCl_3-exposed polypyrrole film was also measured. The spectrum showed the absorption around 500 cm^{-1} which is related to P-Cl stretching. However, due to lacking of published absorption data of compounds containing P and Cl, the identification of the doped anion species has not yet been done.

Table 1 shows results obtained by elemental analyses of as-grown films, reduced films, and films reduced and then exposed to one of the sample gases used. The data are given as the relative molar ratio of each elements to carbon which is fixed to 4, the number being equal to that of carbon atoms of a pyrrole ring. It was found that the reduced polypyrrole films contained 0.11 moles of ClO_4^- per unit mole of pyrrole probably due to difficulty of complete undoping in a thick film used for elemental analysis. Since the elemental analysis of halogens gives information not on each kind of halogen but on the sum of all kinds of halogens included in the polypyrrole film, the amount of iodine of iodine-exposed polypyrrole films was deduced by subtracting the amount of chlorine content of the reduced polypyrrole films from the total halogen content determined. The sulfur content could not be determined, because the analysis is unsuccessful in the presence of both chalcogen and halogen.

By counting the difference in nitrogen content between the reduced film and the reduced and then NO_2-exposed one, the amount of nitrogen species doped by the NO_2-exposure is deduced to be 0.14 atoms per pyrrole ring. The doped nitrogen species must be NO_2^-.[12)] In the case of iodine-exposed film, the amount of doped anionic species would be 0.12 per pyrrole ring, because it is highly probable that the doped iodine species is I_3^-.[20)] When the reduced polypyrrole film was exposed to PCl_3, chlorine was increased by 0.22 atoms per pyrrole ring. Though the doped anionic species produced by the PCl_3-exposure has not yet been known, the number of doped anions would be 0.07 per pyrrole ring if a single ionization to give PCl_3^- is assumed to take place on the doping. The finding that the doped ionic species was smaller in the PCl_3-doped film than in the iodine-doped films and NO_2-doped one correlates well with the resistance decrease caused by the gas exposure (Fig. 2). It is then concluded that the degree of anion doping caused by the gas exposure is primarily controlled

by the electron affinity of the exposed gas.

Chemisorption Kinetics of Exposed Gases. It was found that the resistance changing behavior as shown in Fig. 2 follows to the Elovich equation (Eq. 1), which is applicable to slow kinetics of chemisorption under a constant gas pressure,[22]

$$\frac{dv}{dt} = a \exp(-bv) \quad (1)$$

where v is the amount of an adsorbed species, a and b represent the rate of adsorption at $v=0$ and the relative rate of disappearance of active sites for chemisorption, respectively. Integration of Eq. 1 gives Eq. 2.

$$v = \frac{1}{b} \ln\left(t + \frac{1}{ab}\right) + \frac{1}{b} \ln(ab) \quad (2)$$

It is thought that the conductivity of gas-exposed polypyrrole film is proportional not to the amount of adsorbed gas but to the amount of ionized dopants. Then the v of the Elovich equation should be read to be the amount of ionized dopant. Since it is believed that the anion doping in polypyrrole occurs like adsorption on polymer fibrils, the establishment of the Elovich equation in the doping process is not strange provided that the ionization is rate-determining in the gas sensing. It is of significance to remark here that the resistance change was observed only when components of the exposed gases were detected in the polypyrrole films.

If it is assumed that the film conductance is proportional to the amount of doped anionic species,[23] then Eq. 3 holds,

$$\frac{1}{R} = Kv \quad (3)$$

where R is the resistance of polypyrrole films and K is a proportional constant. It seems important to remark here that Eq. 3 is not always valid; electrostatic interaction between dopants and positive charges induced in polypyrrole may sometimes greatly influence the conductivity.[24] However, the assumption of Eq. 3 seems to be valid as long as the results obtained at least for NO_2, SO_2, and PCl_3-exposure, as will be shown below. By combining Eq. 3 with Eq. 2, Eq. 4 is derived,

$$\frac{1}{R} = \frac{K}{b} \ln(t + t_0) - \frac{K}{b} \ln(t_0) \quad (4)$$

where t_0 is an adjustable variable to establish a linear relation between $1/R$ and logarithms of the gas exposure time and satisfies $t_0 = 1/ab$. The application of this equation to the time course of the resistance change shown in Fig. 2 gives Fig. 5 for NO_2, SO_2, and PCl_3 in an initial stage of the gas exposure, if t_0 values as given in Table 2 are used. In the case of the iodine vapor, however, the choice of any t_0 values failed to give a linear relation. In Table 2, K/b and Ka values which were determined from $t_0 = 1/ab$ and the slope of the linear relations are also given. The Ka gives a measure of the easiness of the ionization in an initial stage of gas exposure, because the a concerns the rate of adsorption at $v=0$, and K is the proportional constant in Eq. 3 which is believed to be eventually the same among the kind of gases used as long as this equation is valid. Then the results in Table 2 clearly shows that the gas having larger electron affinity has a

Direct Determination of Hyperfine Coupling Constants from Complex and Poorly Resolved ESR Spectra with Numerical Decoupling Analysis

Koichi Nozaki, Akira Naito, Hiroyuki Hatano, and Satoshi Okazaki*
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received November 4, 1988)

Numerical decoupling analysis (NDA) has been developed as a useful analytical method for determining accurate hyperfine coupling constants (hfccs) involved in isotropic ESR spectra with constant linewidths. NDA was found to have a number of advantages over other methods developed for the extraction of hfccs from ESR spectra. For example, the nuclear spin (e.g., $I=1/2$ or 1) can easily be distinguished and hfccs as small as a linewidth can be determined. Furthermore, false hfccs which often appear and lead to confusion in obtaining the true values in other methods are largely eliminated. Owing to these advantages NDA has enabled us to interpret not only complex but also poorly resolved ESR spectra. The practical use of NDA could be demonstrated by analyzing the ESR spectra of *t*-butyl 4-nitrophenyl nitroxide and *t*-butyl 2-chlorophenyl nitroxide radicals.

While a computer simulation method has usually been used as a suitable means of interpreting complicated ESR spectra, it is tedious to determine the ESR parameters with increasing numbers. Furthermore, when an ESR spectrum is poorly resolved it is rather difficult to accurately determine the parameters. Thus, in any case, some degree of experience is required to analyze such an ESR spectrum.

In order to help with the computer simulation analysis of ESR spectra various useful techniques have been reported. For an automatic improvement in the initially estimated set of parameters, a large number of curve-fitting methods are available.[1-4] Most of them employ nonlinear least-squares techniques which generally require a finely tuned data set as the initial parameters. Without such parameters they may not converge or be trapped in an undesirable local minimum of the error function. However, new methods using Simplex[5] or Monte Carlo[6] techniques have proven to be very reliable, especially in systems involving many parameters since they enable one to search for the minimum globally.

On the other hand, if accurate parameters can be independently determined from the hyperfine structure (hfs) of an observed ESR spectrum, one could readily interpret the ESR spectrum without relying on any experience or prejudices, which sometimes cause incorrect interpretations. For this purpose, an autocorrelation method[7-10] as well as Cepstral[11] and Fourier analyses[12,13] have been applied. More recently, Dračka obtained proton and nitrogen hfccs from a complex ESR spectrum by using a 'contraction' method.[14] Motten introduced a simple method using a concept similar to those of Dračka and Newton[15] in order to extract proton hfccs.[16] Lüders determined the hfcc as small as a linewidth by means of a symmetry development transformation.[17] It is, however, still difficult to obtain parameters from poorly resolved and complex ESR spectra, since most of these methods suffer from the appearance of false hfcc peaks, such as ghosts[11,17] or odd harmonics,[15,16] and some methods can only be applied to well-resolved ESR spectra.[14]

Numerical decoupling analysis (NDA), as described in this paper, has been developed as a convenient method to determine hfccs from poorly resolved and complex ESR spectra. The basic principle of NDA involves a search for hfccs by trial and error using a micro-computer. The procedure contains two steps. The first step is a trial to remove the splittings of a given value using the least-squares method. We call this procedure 'numerical decoupling'. The second step involves an evaluation of the results of the numerical decoupling using a specific index function, ascertaining whether the value is one of the hfccs.

NDA possesses some advantages over the other methods. For example, NDA enables one to determine hfccs as small as a linewidth and to distinguish the nuclear spin. Moreover, false hfccs, which sometimes disturb the determination of the hfccs, were largely discriminated.

This paper describes the theory of NDA and its practical applications to several systems.

Theory

Numerical Decoupling Analysis for Nuclei with $I=1/2$. When one nucleus with nuclear spin, I, of 1/2 and a hfcc of **a** contributes to an isotropic ESR spectrum with a constant linewidth, $R(\omega)$, it can be represented by the following form:

$$R(\omega)=F(\omega+\mathbf{a}/2)+F(\omega-\mathbf{a}/2), \quad (1)$$

where $F(\omega)$ is the ESR spectrum without the contribution of this nucleus. We call it a *sub-spectrum*. Furthermore, at least some of the x values at which $R(\omega)$ can be written in the same form as Eq. 1 must be the hfccs involved in $R(\omega)$:

$$R(\omega)=S(\omega+x/2)+S(\omega-x/2). \quad (2)$$

Here $S(\omega)$ is a certain function.

First, these x values are obtained through the following procedures. An error function, $d(x)$ is defined by

$$d(x)\equiv\int_{-\infty}^{\infty}[R(\omega)-S(\omega+x/2)-S(\omega-x/2)]^2\,d\omega, \quad (3)$$

where $R(\omega)$ is an observed ESR spectrum. Actually, $R(\omega)$ is represented by a series of data sampled under a magnetic field that is increasing with a constant increment. Thus, Eq. 3 can be rewritten as Eq. 4 for numerical calculation:

$$d(x)\equiv\sum_{i=1+x/2}^{N-x/2}[R(i)-S(i+x/2)-S(i-x/2)]^2, \quad (4)$$

where N is the number of data points of $R(\omega)$ and $x/2$ must be an integer having a value between 0 and N.

According to the basic theory of the least-squares method, the following simultaneous equations are obtained under the conditions $\partial d(x)/\partial S(i)=0$ ($i=x+1,x+2,\cdots,N-x$):

$$\begin{aligned}
&S(1)+2S(1+x)+S(1+2x)=R(1+x/2)+R(1+3x/2)\\
&S(2)+2S(2+x)+S(2+2x)=R(2+x/2)+R(2+3x/2)\\
&\qquad\vdots\qquad\qquad\qquad\vdots\\
&S(N-2x)+2S(N-x)+S(N)=R(N-3x/2)+R(N-x/2).
\end{aligned} \quad (5)$$

In addition, Eq. 6 is obtained as the result of the reasonable assumption that the intensities at the far ends of the tails of an observed ESR spectrum are regarded as zero:

$$\begin{aligned}
&S(1)=S(2)=\cdots S(x)=0.0,\\
&S(N-x+1)=\cdots=S(N)=0.0.
\end{aligned} \quad (6)$$

Thus, $S(i)$, ($i=1,2,\cdots N$) and $d(x)$ can be calculated from Eqs. 5 and 4, respectively. Since the error function $d(x)$ is equal to 0 when Eq. 2 holds, one can readily determine the x value at which $d(x)$ becomes 0 in a plot of $d(x)$ against x.

Second, we considered the relationship between these x values and the hfccs. When $R(\omega)$ is represented by Eq. 1, namely, the hfcc of **a** is involved in $R(\omega)$, $d(\mathbf{a})$ is obviously equal to 0 and $S(\omega)$ is identical to the *sub-spectrum* $F(\omega)$. However, in this case, $d(\mathbf{a}/3)$, $d(\mathbf{a}/5)$, $d(\mathbf{a}/7)\cdots$ are also found to values of 0. The x values at which $d(x)=0$ can be represented by

$$x_n=\mathbf{a}/(2n+1) \qquad (n=0,1,2,3\cdots), \quad (7)$$

and $S_n(\omega)$ corresponding to the x_n values can be expressed by

$$S_n(\omega)=\sum_{i=-n}^{n}(-1)^{i+n}F(\omega-ix_n). \quad (8)$$

These x values (except for $n=0$) are not hfccs but are recognized as false hfccs. Therefore, the x values leading to $d(x)=0$ consist not only of the true hfccs but also of many false hfccs. If a number of hfccs are involved in an ESR spectrum, it is impossible to select the true values from the infinite number of these x values.

Finally, we discriminated the true hfccs from the false ones. An index function defined by Eq. 9 was found to be the best for this purpose:

$$I_2(x)\equiv\left[\frac{\int_{-\infty}^{\infty}|R(\omega)-R(\omega-\delta)|\,d\omega}{\sum_{j=1}^{2}\int_{-\infty}^{\infty}|R(\omega)-S(\omega-x/2)-S(\omega+x/2+(-1)^j\delta)|\,d\omega}\right]^2, \quad (9)$$

where δ is a very small value. It is replaced by 1 or 2 in actual calculations, which is sufficiently small when compared to N. The subscript in $I_2(x)$ indicates the multiplicity of the nuclear spin of $I=1/2$, namely, $2I+1=2$. The numerator of $I_2(x)$ is used for normalization. Squaring the bracket in this equation is performed for an enhancement of the resolution. Since the denominator of $I_2(x)$ is one of the error functions, such as $d(x)$, it also approaches 0, namely, $I_2(x)$ gives a maximum value when x is equal to **a**. From Eqs. 1, 7, 8, and 9, $I_2(\mathbf{a})$ can be represented by

$$I_2(\mathbf{a})=\left[\frac{\int_{-\infty}^{\infty}|F'(\omega+\mathbf{a}/2)+F'(\omega-\mathbf{a}/2)|\,d\omega}{2\int_{-\infty}^{\infty}|F'(\omega+\mathbf{a}/2)|\,d\omega}\right]^2, \quad (10)$$

where $F'(\omega)$ represents $[F(\omega)-F(\omega+\delta)]/\delta$ or $[F(\omega)-F(\omega-\delta)]/\delta$, which is a form of the derivative of $F(\omega)$. If each line in $F'(\omega+\mathbf{a}/2)+F'(\omega-\mathbf{a}/2)$, that is, in the spectrum obtained from the differentiation of $R(\omega)$, is well resolved and there is no overlap between $F'(\omega+\mathbf{a}/2)$ and $F'(\omega-\mathbf{a}/2)$, the numerator of Eq. 10 can be approximately represented by Eq. 11. Hence, $I_2(\mathbf{a})$ is nearly equal to unity.

$$\begin{aligned}
\int_{-\infty}^{\infty}|F'(\omega+\mathbf{a}/2)+F'(\omega-\mathbf{a}/2)|\,d\omega &\approx\int_{-\infty}^{\infty}|F'(\omega+\mathbf{a}/2)|\,d\omega\\
&+\int_{-\infty}^{\infty}|F'(\omega-\mathbf{a}/2)|\,d\omega=2\int_{-\infty}^{\infty}|F'(\omega)|\,d\omega.
\end{aligned} \quad (11)$$

Since the lines in most of the observed ESR spectra are more or less overlapped, $I_2(\mathbf{a})$ is usually smaller than unity. However, it should be pointed out that the line shape in the ESR spectrum, $R(\omega)$, was not specified in this analysis. If one analyzes the differentiated ESR spectrum, i.e., the 2nd or 3rd derivatives, $I_2(\mathbf{a})$ increases and shows a value closer to unity because the separation of each line becomes better. This distinctive feature is very useful, especially in the analysis of poorly resolved ESR spectra.

If the large second-order effects contribute in the ESR spectra the intensity of $I_2(\mathbf{a})$ will decrease since the basic assumption of NDA, represented by Eq. 1, is not fulfilled.

To discuss the relative intensities of the false and true peaks, the ratio $I_2(\mathbf{a}/3)/I_2(\mathbf{a})$ represented by Eq. 12 is derived from Eqs. 1,7,8, and 9:

$$\frac{I_2(a/3)}{I_2(a)}=\left[\frac{\int_{-\infty}^{\infty}|F'(\omega+a/2)|d\omega}{\int_{-\infty}^{\infty}|F'(\omega+a/2)-F'(\omega+a/6)+F'(\omega-a/6)|d\omega}\right]^2,$$

$$=\left[\frac{\int_{-\infty}^{\infty}|F'(\omega)|d\omega}{\int_{-\infty}^{\infty}|F'(\omega+a/3)-F'(\omega)+F'(\omega-a/3)|d\omega}\right]^2 \quad (12)$$

The results described in the Appendix indicate that this ratio changes between 1/9 to 1, depending on the degree of overlap of the following three functions: $F'(\omega+a/3)$, $F'(\omega)$, and $F'(\omega-a/3)$. When the overlap is small, in other words, the ESR spectrum is well resolved, the intensity of $I_2(a/3)$ is only one-ninth that of $I_2(a)$. $I_2(a/3)$ increases with decreasing the resolution of the spectrum, but is still less than $I_2(a)$, even in the worst case. Therefore, $I_2(a/3)$ is always less than $I_2(a)$. In a similar way, other false hfccs appearing at a/5, a/7,··· are found to be much less than $I_2(a)$.

The reason why these false hfccs can be distinguished by the index function $I_2(x)$ is explained as follows: Though $S_1(\omega)$ represented by Eq. 8 is quite different from the real *sub-spectrum* $F(\omega)$, $S_1(\omega+a/6)+S_1(\omega-a/6)$ becomes identical to $R(\omega)$ due to a partial canceling between $S_1(\omega+a/6)$ and $S_1(\omega-a/6)$ (Fig. 1b). This suggests that these false hfccs can not be distinguished from real values by simply using the error function $d(x)$. However, the index function $I_2(a)$ contains a small distortion of δ which interferes with the canceling, as illustrated in Fig. 2b. Therefore, false values can readily be eliminated by this index function.

Thus, the hfccs contributing to $R(\omega)$ can be readily determined by inspecting the peaks near to unity in a plot of $I_2(x)$ against x.

Numerical Decoupling Analysis for Nuclei with I=1. In the case of a nucleus of I=1, Eqs. 1 and 5 can be substituted by Eqs. 13 and 14, respectively:

$$R(\omega)=F(\omega+a)+F(\omega)+F(\omega-a), \quad (13)$$

$$\begin{aligned}&S(1)+2S(1+x)+3S(1+2x)+2S(1+3x)+S(1+4x)\\&\quad=R(1+x)+R(1+2x)+R(1+3x)\\&S(2)+2S(2+x)+3S(2+2x)+2S(2+3x)+S(2+4x)\\&\quad=R(2+x)+R(2+2x)+R(2+3x)\\&\qquad\vdots\\&S(N-4x)+2S(N-3x)+3S(N-2x)+2S(N-x)+S(N)\\&\quad=R(N-3x)+R(N-2x)+R(N-x).\end{aligned} \quad (14)$$

Some false hfccs appear at

$$x_n=a/(3n+1)\ (n=1,2,\cdots), \quad (15)$$

or

$$x_m=a/(3m+2)\ (m=0,1,2,\cdots). \quad (16)$$

S_n and S_m corresponding to x_n and x_m, respectively, can be represented by

$$S_n=\sum_{i=-3n}^{3n} c(|i|)\cdot F(\omega-ix_n), \quad (17)$$

and

$$S_m=\sum_{i=-3m-1}^{3m+1} c(|i|+2)\cdot F(\omega-ix_m), \quad (18)$$

where

$$\begin{aligned}c(k)&=1 \quad k=3p\\&=0 \quad k=3p+1\\&=-1 \quad k=3p+2,\ p=0,1,2,\cdots.\end{aligned} \quad (19)$$

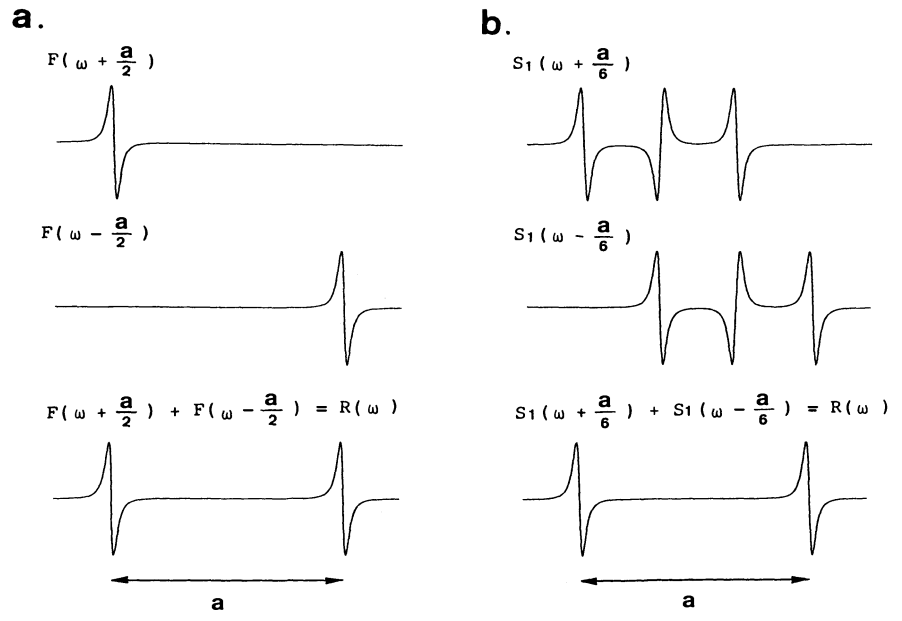

Fig. 1. The illustration of the relationship between the *sub-spectra* and the original ESR spectra (a) at the real hfcc of a and (b) at a/3, one of the false hfccs.

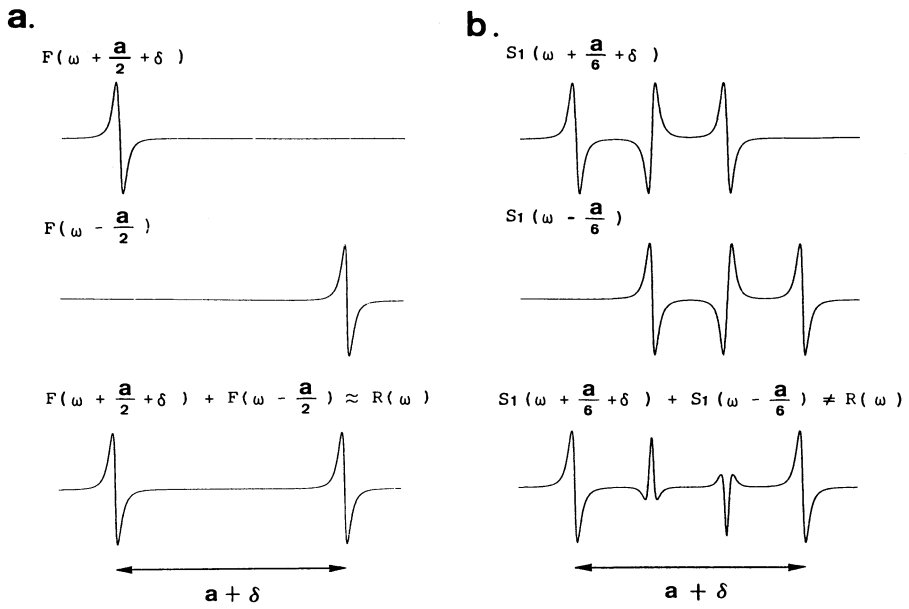

Fig. 2. An illustration showing why false hfccs can be distinguished from the real hfcc by introducing the small distortion δ. (a) The synthesized spectrum from $F(\omega)$ is almost same as the original, $R(\omega)$. (b) The synthesized spectrum from $S_1(\omega)$ is quite different from $R(\omega)$.

The index function for $I=1$ is defined by Eq. 20:

$$I_3(x)=\left[\frac{2\int_{-\infty}^{\infty}|R(\omega)-R(\omega-\delta)|d\omega}{3\sum_{j=1}^{2}\int_{-\infty}^{\infty}|R(\omega)-S(\omega+x)-S(\omega+(-1)^j\delta)-S(\omega-x)|d\omega}\right]^2 \quad (20)$$

In a similar manner as with $I=1/2$, one can show that a plot of $I_3(x)$ against x also gives a maximum value close to unity at $x=\mathbf{a}$.

The ratio $I_3(\mathbf{a}/2)/I_3(\mathbf{a})$ can be represented by

$$\frac{I_3(\mathbf{a}/2)}{I_3(\mathbf{a})}=\left[\frac{\int_{-\infty}^{\infty}|F'(\omega)|d\omega}{\int_{-\infty}^{\infty}|F'(\omega+\mathbf{a}/2)-F'(\omega)+F'(\omega-\mathbf{a}/2)|d\omega}\right]^2 \quad (21)$$

From the results described in the Appendix, the ratio is also found to change between 1/9 to 1, depending on the degree of overlap of the following three functions: $F'(\omega+\mathbf{a}/2)$, $F'(\omega)$, and $F'(\omega-\mathbf{a}/2)$. Therefore, the hfccs of nuclei with $I=1$ can be obtained from a plot of $I_3(x)$ against x in the same way as with $I=1/2$.

Experimental

The preparation of *t*-butyl 4-nitrophenyl nitroxide radical was as follows: 4-nitrophenyl radical produced by the reduction of 4-nitrobenzenediazonium salt with iodide in acetonitrile was trapped by 2-methyl-2-nitrosopropane. After evaporation of the solvent, the nitoxide radical obtained as a spin adduct was separated and purified on a silica-gel column using benzene as an eluent. *t*-Butyl 2-chlorophenyl nitroxide radical was prepared from 2-chlorobenzenediazonium salt in a similar way.

Before ESR measurements benzene solutions of nitroxide radicals in sample tubes were carefully deoxygenated by nitrogen gas bubbling and by several freeze-pump-thaw cycles.

ESR spectra were measured using a JEOL PE-3E, X band ESR spectrometer. ESR spectra were digitized using a 16bit A/D converter (Nippon Protec, Co., Ltd.) of which the acquisition time was 78 ms.

Numerical analyses and calculations of ESR spectra were performed on a PC9801 VX2 micro-computer equipped with a 80286 CPU, and a 80287 co-processor, at a CPU clock cycle of 10 MHz (NEC). Data of a calculated ESR spectrum comprised 1500 points and those of an observed ESR spectrum comprised 1500—2500 points after appropriate treatments, such as digital filtering, centering, and corrections of the offset of the amplifier. These programs for the spectrum treatment, NDA and the calculation of ESR spectra were written in FORTRAN 77. The required computing time for the $I_2(x)$ plot was about 5 minutes and that of the $I_3(x)$ plot was about 10 minutes.

Results and Discussion

Discrimination of the Nuclear Spin of I=1/2 and 1. The plots of $I_2(x)$ in Fig. 3b and $I_3(x)$ in Fig. 3c were obtained for the calculated ESR spectrum (Fig. 3a) from the parameters of $I=1/2$, hfcc=0.06 and a linewidth=0.01 mT. A Lorentzian line shape function was used to obtain all of the calculated spectra in this work. In the $I_2(x)$ plot (Fig. 3b), one well-defined peak of unity height appeared at 0.06 mT. Several additional peaks also appeared at 0.02, 0.012 mT, etc., which were assigned to be false peaks. The ratio

$I_2(\mathbf{a}/3)/I_2(\mathbf{a})$ was calculated to be 0.17, slightly larger than the lowest value predicted by Eq. 12, i.e., 1/9=0.11, since the two lines in the ESR spectrum in Fig. 3a slightly overlapped. However, $I_2(\mathbf{a}/3)$ is still considerably less than $I_2(\mathbf{a})$.

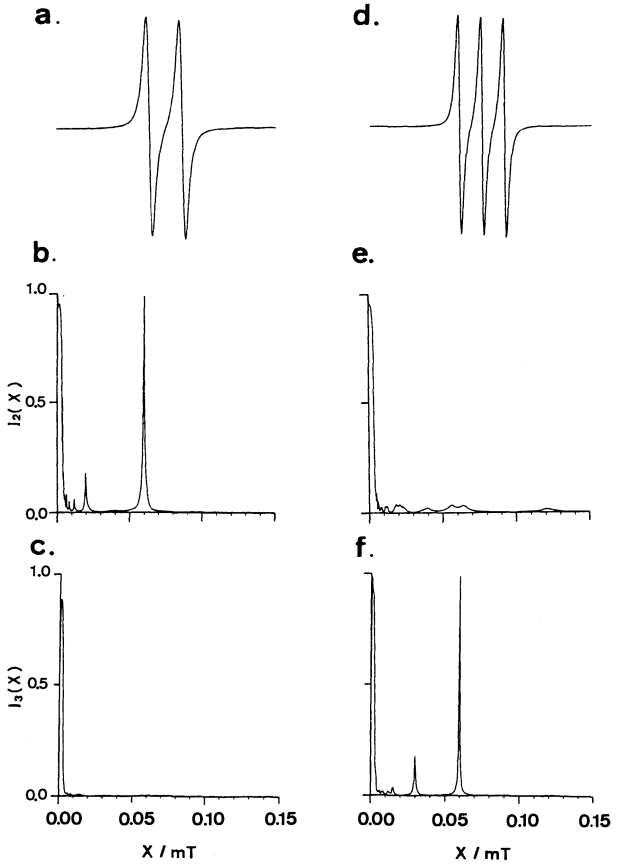

Fig. 3. (a) Simple ESR spectrum calculated using I=1/2, hfcc=0.06 and linewidth=0.01 mT. (b) The $I_2(x)$ plot and (c) $I_3(x)$ plot for the spectrum (a) calculated with δ=1. (d) Simple ESR spectrum; I=1, hfcc=0.06, linewidth=0.01 mT. (e) The $I_2(x)$ plot and (f) $I_3(x)$ plot for the spectrum (d) with δ=1.

A peak with nearly unity height appeared at 0 mT because it was regarded as a hfcc in NDA. This peak is also attributed to the overlap of an infinite number of false peaks. The singularity very near to 0 mT can not be considered as hfcc since it appears at an x value much less than the linewidth (0.01 mT). On the other hand, it is of particular interest to note that the $I_3(x)$ plot (Fig. 3c) did not show any peaks, except that at 0 mT.

Figures 3e and 3f show $I_2(x)$ and $I_3(x)$ plots for the calculated ESR spectrum (Fig. 3d) with I=1, hfcc= 0.06 and linewidth=0.02 mT. In the $I_3(x)$ plot, one well-defined peak of unity height appeared at 0.06 mT and several false peaks at 0.03 and 0.015 mT, etc. The ratio $I_3(\mathbf{a}/2)/I_3(\mathbf{a})$ was also evaluated to be 0.17. No peak appeared, except at 0 mT in the $I_2(x)$ plot in this case also.

As indicated by these results, both the nuclear spin and each hfcc involved in an ESR spectrum are readily determined by NDA without interference by any false peaks.

Determination of Small hfcc. The ESR spectra shown in Figs. 4a and 4b were calculated from the hfcc value of 0.06 (5H) and linewidths of 0.02 and 0.05 mT, respectively. When the hfcc was larger than the linewidth, it was readily determined from the position of the peak appearing in the $I_2(x)$ plots (Figs. 4a′ and 4b′). When the linewidth became 0.06 mT, which is the same as the hfcc, the hfs almost disappeared (Fig. 4c) and, hence, it was difficult to determine the hfcc from the ESR spectrum. Even in such a case, one broad peak appeared in the $I_2(x)$ plot (Fig. 4c′), while its peak position shifted slightly to a smaller hfcc value. The accuracy in determining the hfccs by NDA will be discussed later.

Since the line shape is not specified in this analysis, a 2nd-derivative spectrum can also be analyzed. One

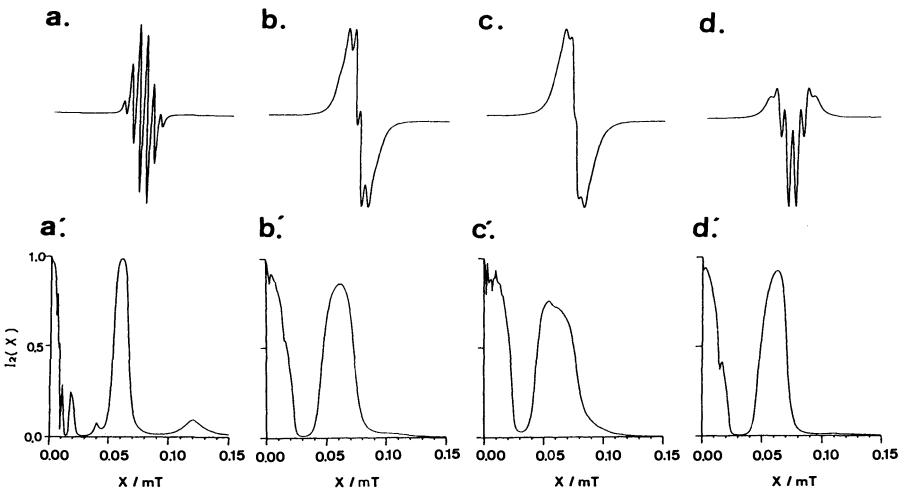

Fig. 4. ESR spectra calculated with hfcc=0.06 mT (5H) and various linewidths of (a) 0.02 (b) 0.05 (c) 0.06 and (d) 0.06 mT (2nd-derivative). (a′), (b′), (c′), and (d′) are respective $I_2(x)$ plots which were obtained with δ=1.

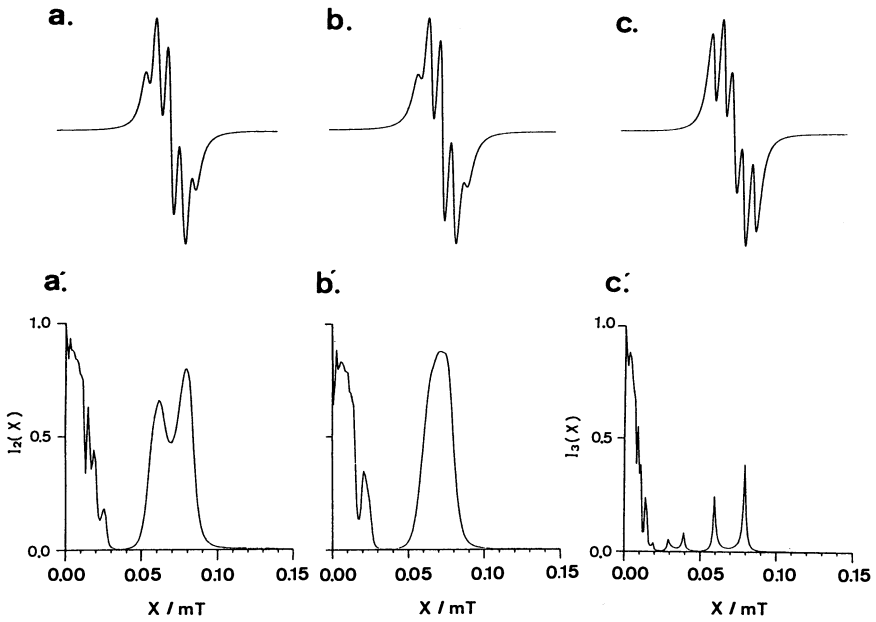

Fig. 5. (a) Calculated ESR spectrum; hfccs=0.06 (2H), 0.08 (2H), linewidth=0.04 mT. (b) hfcc=0.07 (4H), linewidth=0.045 mT. (c) hfccs=0.06 (1N), 0.08 (1N), linewidth=0.04 mT. (a′) and (b′) are the $I_2(x)$ plots for (a) and (b) with δ=1. (c′) was the $I_3(x)$ plot for (c) with δ=1.

sharp peak appeared at 0.06 mT in the $I_2(x)$ plot (Fig. 4d′) for the 2nd-derivative spectrum (Fig. 4d) obtained by differentiating the ESR spectrum in Fig. 4c. Thus, the application of NDA to a higher derivative spectrum permits one to determine accurate hfccs involved in poorly resolved ESR spectra.

The lower limit of the hfcc values for I=1 was also found to be almost the same as for I=1/2 when the first-derivative ESR spectra were analyzed with NDA.

Resolution for Small Difference between hfccs. Next, the resolution for small differences between hfccs was demonstrated. Figure 5a shows the ESR spectrum calculated with a hfcc of 0.06 (2H) and 0.08 (2H), and a linewidth of 0.04 mT. Though the linewidth was twice as large as the difference between the two hfccs, they were completely separated in the $I_2(x)$ plot (Fig. 5a′). On the other hand, this ESR spectrum closely resembled that calculated with hfcc of 0.07 mT (4H) (Fig. 5b). Thus, the hfcc of 0.07 mT would be accidentally obtained if the ESR spectrum in Fig. 5a is analyzed with ordinary methods. It is, however, very interesting to note that the $I_2(x)$ plots shown in Figs. 5a′ and 5b′ obtained for the ESR spectra in Figs. 5a and 5b, respectively, were quite different.

Figure 5c shows an $I_3(x)$ plot for the ESR spectrum calculated from hfccs of 0.06 (1N) and 0.08 (1N), and a linewidth of 0.04 mT. Though two peaks at 0.06 and 0.08 mT were fairly small, they were well resolved.

Effect of Equivalent Nuclei and Delta. Figures 6a and 6d show the ESR spectra calculated from the hfccs of 0.07 (1H) and 0.02 (10H), and linewidth of 0.005 and 0.015 mT, respectively. Figure. 6b shows the $I_2(x)$ plot obtained for the spectrum in Fig. 6a when

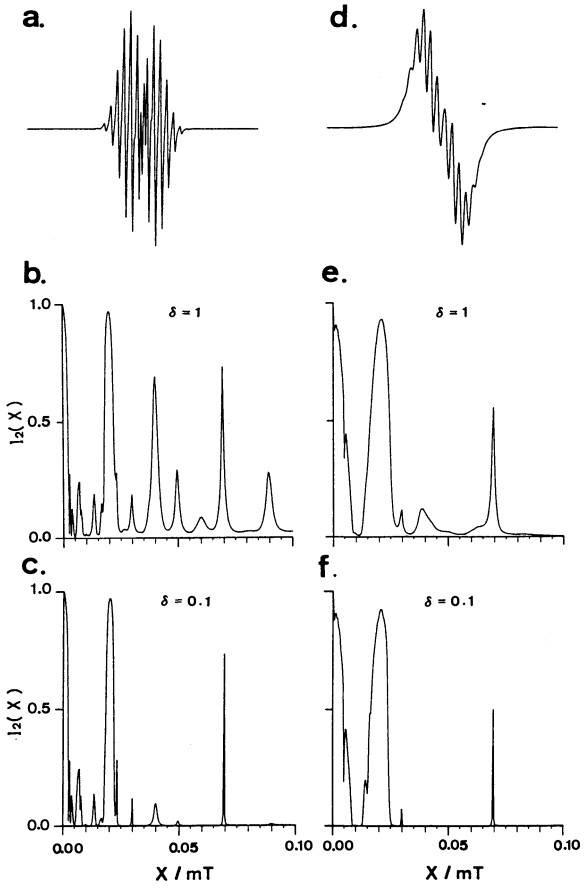

Fig. 6. (a) Calculated ESR spectrum; hfccs=0.02 (10H), 0.07 (1H), linewidth=0.005 mT. (b) The $I_2(x)$ plot for (a) with δ=1 and (c) with δ=0.1. (d) Calculated ESR spectrum with the same parameters as (a) except for a linewidth of 0.015 mT. (e) The $I_2(x)$ plot for (d) with δ=1, and (f) with δ=0.1.

δ=1, which was equal to 0.00035 mT in this calculation. Several peaks appeared in the $I_2(x)$ plot in addition to the hfcc peaks (at 0.02, 0.07 mT) and their false peaks (at 0.014, 0.007 mT). The peaks, which appeared at 0.05 and 0.09 mT, corresponded to 0.07—0.02 and 0.07+0.02 mT, respectively. Those at 0.04 and 0.06 mT seemed to be overtone peaks corresponding to 2×0.02 and 3×0.02 mT, respectively. We call these peaks *sub-peaks*, which differ from false peaks. They sometimes appear when many equivalent nuclei contribute to the hfs. On the other hand, when the linewidth was 0.015 mT, these *sub-peaks* were very small (Fig. 6e), while the hfcc peaks at 0.02 and 0.07 mT were substantially unchanged.

These results indicate that the intensities of the *sub-peaks* are closely related to the ratio of δ to the linewidth. The intensities of the *sub-peaks* increased when the value of δ was not small compared with the linewidth. To suppress the *sub-peaks*, the δ value should be chosen to be less than about 1/40 of the linewidth. Consequently, if the δ value is equal to the sampling interval of the data, each line in an observed ESR spectrum must be composed of more than 100 data points. However, when an observed ESR spectrum includes many lines this condition may be difficult to achieve on a micro-computer with limited memory space and, hence, *sub-peaks* will prohibit obtaining the exact parameters.

In order to calculate Eq. 9 for a δ value less than 1 the following approximations are used:

$$R(\omega-\delta)\approx R(\omega)-[R(\omega)-R(\omega-1)]\delta, \quad (22)$$

and

$$S(\omega\pm\delta)\approx S(\omega)-[S(\omega)-S(\omega\pm1)]\delta. \quad (23)$$

Substitution of Eqs. 22, 23 into Eq. 9 yields Eq. 24.

$$I_2(x)=\left[\frac{\delta\int_{-\infty}^{\infty}|R(\omega)-R(\omega-1)|\,d\omega}{\sum_{j=1}^{2}\int_{-\infty}^{\infty}|R(\omega)-S(\omega-x/2)-S(\omega+x/2)(1-\delta)-S(\omega+x/2+(-1)^j)\delta|\,d\omega}\right]^2. \quad (24)$$

Figures 6c and 6f show $I_2(x)$ plots calculated from Eq. 24 when δ=0.1. The heights of the *sub-peaks* decreased dramatically and the two hfccs of 0.02 and 0.07 mT were readily determined without any ambiguity. It was also realized that the linewidths of the peaks in the $I_2(x)$ plot obtained from the δ value of 0.1 were narrower than those for δ=1. The linewidths of the peaks in $I_2(x)$ and $I_3(x)$ plots seem to depend on the following factors: the linewidth of an ESR spectrum, the number of nuclei, the nuclear spin, and the δ value. The detailed relationship between them is not presently understood.

Effect of Noise. The value of the numerator in Eq. 10, which is equal to $\delta\int_{-\infty}^{\infty}|R(\omega)-R(\omega-\delta)|d\omega$, increases as the noise in $R(\omega)$ increases. In particular, it is greatly affected by the noise of which frequencies higher than those of the signals in $R(\omega)$. Although the value of the denominator in Eq. 10 also becomes large with increasing noise, it may be larger than that of the numerator since the signal-to-noise ratio in the *sub-spectrum* is always worse than that of the original

Table 1. Hfcc Detected by NDA at Various Linewidths

ESR spectrum. Therefore, the value of I_2(a) decreases with increasing noise in the original ESR spectrum. In order to avoid this problem it is advisable that a noisy ESR spectrum is treated with a smoothing filter before being examined by NDA.

Accuracy of hfcc Determined by NDA. Hfcc values determined by NDA from the calculated ESR spectra with hfcc=1.00 mT and various linewidths are given in Table 1. The 1st-derivative Lorentzian function was used in the calculation of all the ESR spectra. Table 1 also contains the values determined from the positions of minima of the error function, $d(x)$ (Eq. 4). In the cases of ESR spectra with a nucleus of I=1/2, the hfcc at 1.00 mT could be determined even at a linewidth of 5.0 mT, whereas a hfcc as small as the linewidth may be the smallest which can be determined by NDA in an actual ESR spectrum containing some noise and distortions. As described in the previous section, hfcc smaller than the linewidth can be determined with the aid of numerical differentiation. However, it must be considered that the calculation of a higher derivative of an observed ESR spectrum usually increases the noise, which leads to a decrease in the intensities of the hfcc peaks in the $I(x)$ plot.

It should be pointed out that when linewidths are large, the hfccs values obtained from the $I_2(x)$ plots with δ=1 become less accurate with increasing number of equivalent nuclei, or probably with increasing number of lines in the hfs. However, hfcc values could be accurately determined either from an $I_2(x)$ plot with δ=0.1 or from $d(x)$. Therefore, exact hfccs should be determined either from the index function $I(x)$ calculated with a smaller δ value or from minima of the error function $d(x)$, especially in interpreting poorly resolved ESR spectra.

When the ESR spectra involving the nuclear spin of 1 was examined less accurate values could be obtained, even from $d(x)$ or $I_3(x)$ with δ=0.1 at the larger linewidth (2 and 3 mT). This is because both tails of the ESR spectrum did not decrease to zero and, therefore, the assumption leading to Eq. 6 was not fulfilled.

Analysis of the ESR Spectrum of *t*-Butyl 4-Nitrophenyl Nitroxide Radical. Figure 7a shows the expanded ESR spectrum of the M_I=+1 components due to the nitrogen nucleus of the nitroxide group in *t*-butyl 4-nitrophenyl nitroxide radical (the entire ESR spectrum was depicted in Fig. 7). In the plots of $I_2(x)$ in Fig. 7b and $I_3(x)$ in Fig. 7c one can readily distinguish the hfcc peaks from the false peaks. Values of 0.090 and 0.223 mT as the proton hfcc and 0.0555 mT as the nitrogen hfcc were obtained, though their intensities were less than unity. The peak at 0.074 mT in Fig. 7b is a false peak for 0.223 mT and those at 0.018 and 0.030 mT are false peaks for 0.090 mT.

The simulated spectrum in Fig. 7d using hfccs of 0.090 (2H, *m*), 0.223 (2H, *o*) and 0.0555 mT(1N, NO_2) is in excellent agreement with that of Fig. 7a.

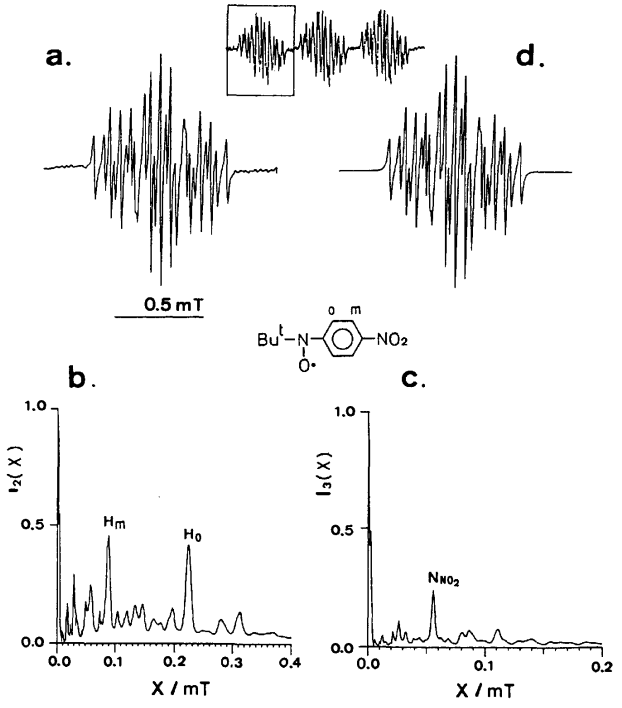

Fig. 7. (a) Expanded ESR spectrum of the M_I=+1 components of *t*-butyl 4-nitrophenyl nitroxide radical (inserted the entire ESR spectrum) measured in a benzene solution. (b) The $I_2(x)$ plot and (c) $I_3(x)$ plot for the spectrum (a) obtained with δ=1. (d) The simulated ESR spectrum using the parameters determined by NDA, i.e., 0.090 (2H, *m*), 0.223 (2H, *o*) and 0.0555 mT (1N, NO_2).

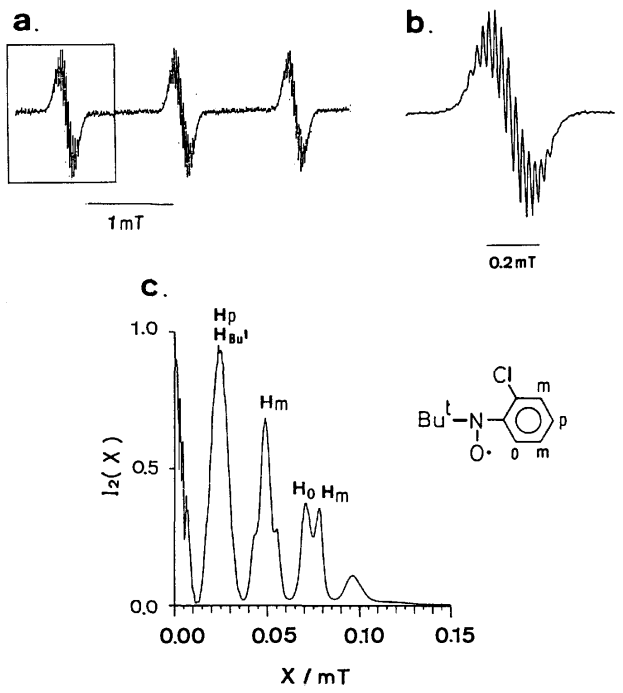

Fig. 8. (a) ESR spectrum of *t*-butyl 2-chlorophenyl nitroxide radical measured in a benzene solution. (b) Expanded spectrum of the M_I=+1 components in (a). (c) The $I_2(x)$ plot for (b) obtained with δ=1.

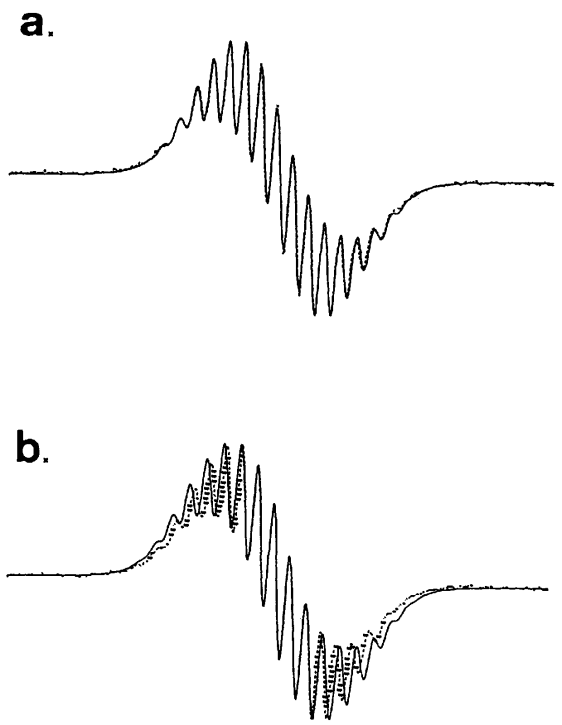

Fig. 9. (a) The simulated spectrum (solid line) using the parameters determined by NDA and (b) using those from NMR data. Experimental ESR spectra were superimposed in both figures with a dotted line (see text).

As indicated here, the nuclear spins and the hfcc values could be obtained from $I_2(x)$ and $I_3(x)$ plots without difficulty, although they were not easily obtained directly from the ESR spectrum (Fig. 7a). Furthermore, since accurate hfccs were determined with the aid of NDA, a computer simulation could be performed only by adjusting the linewidth, and the time for analysis of the ESR spectrum was greatly shortened.

Analysis of the Low-Resolved and Complex ESR Spectrum of *t*-Butyl 2-Chlorophenyl Nitroxide Radical. Figure 8b shows an expanded ESR spectrum of the M_I=+1 components in the ESR spectrum (Fig. 8a) of *t*-butyl 2-chlorophenyl nitroxide radical in benzene. It is obvious that the interpretation of the ESR spectrum is very difficult by ordinary analytical methods since no characteristic pattern appeared in the hfs. It should be noted that four peaks clearly appeared in the $I_2(x)$ plot (Fig. 8c) and, hence, the four hfccs could be precisely determined from these positions. The peak at 0.096 mT, which is nearly equal to 0.024+ 0.0705 mT, seems to be a *sub-peak*. Many peaks appearing in the region from 0 to 0.015 mT could be attributed to the overlap of false peaks for each hfcc. These peaks were excluded because they appear at x values that are much smaller than the linewidth, which is about 0.02 mT in this case.

The ESR spectrum represented by the solid line in Fig. 9a was simulated using hfccs of 0.0240 (10H), 0.0490 (1H), 0.0705 (1H) and 0.0785 (1H), and a linewidth of 0.018 mT. It is in good agreement with the experimental spectrum (superimposed using a dotted line). The hfccs determined by NDA are slightly inconsistent with those obtained from an NMR study of synthesized radicals,[18] which are 0.024 (9H, *t*-butyl), 0.078 (1H, *o*), 0.082 (1H, *m*), 0.049 (1H, *m*), and 0.028 mT (1H, *p*). The small differences between their values and ours can probably be attributed to the large difference in the concentration of radicals (> 1 mol dm^{-3} for NMR and 0.1—1mmol dm^{-3} for ESR observation). These NMR data were obviously inadequate for the analysis of the present ESR spectrum since the simulated spectrum using the NMR data was not in good agreement with the experimental one (Fig. 9b).

These results demonstrate the excellent potentialities of NDA, namely, high resolution for hfcc and an effective elimination of false hfccs.

Conclusion

The general characteristics of NDA can be summarized as follows:

1. One peak in the $I_2(x)$ or $I_3(x)$ plot essentially corresponds to one hfcc.
2. The peak height at the hfcc is nearly equal to unity, but decreases in a poorly resolved ESR spectrum.
3. The height of each hfcc peak does not depend on the number of equivalent nuclei.
4. The nuclear spin can readily be discriminated. For example, nuclei with I=1/2 give peaks in an $I_2(x)$ plot. However, other nuclei, such as nitrogen with I=1, give no peaks.
5. A hfcc as small as a linewidth can be detected.
6. The difference between hfccs as small as about half of the linewidth can be resolved.
7. The line shape in an ESR spectrum is not specified.
8. The δ value used for the calculation of $I(x)$ should be as small as possible, approximately less than 1/30—1/40 of the linewidth. Otherwise, the peak heights of *sub-peaks* usually increase.
9. A noisy ESR spectrum should be treated with a smoothing filter before being examined by NDA.

Among these characteristics, 1, 4, 5, 6, and 7 were better than those of the other numerical methods. In particular, NDA was found to be a valuable tool in analyses of poorly resolved and complex ESR spectra. Since most of these ESR spectra give fewer characteristic patterns in the hfs's, it is very difficult to obtain hfccs from the spectra with ordinary methods. As is demonstrated in Fig. 7, NDA enables one to determine the hfccs exactly, even from spectra showing poorly resolved and monotonous hfs's.

NDA is applicable to the analysis of isotropic ESR spectra with constant linewidths, in which the spectra the basic assumptions represented by Eqs. 1 and 13 are

fulfilled. The deviation from the isotropic spectrum arising, for example, from alternating linewidths, restricted motions, anisotropic interactions, or large second-order effects leads to a decrease of the peak heights in an $I(x)$ plot.

NDA is not a suitable method for analyzing ESR spectra of mixtures of paramagnetic species or those of anisotropic polycrystalline powders.

The well-developed method of electron nuclear double resonance (ENDOR) is better than NDA for the determination of hfccs. However, the ENDOR spectra can be obtained only in limited temperature ranges and, moreover, it costs much more than a micro-computer.

Appendix

Let the areas surrounded by the functions $y=f(\omega+c)$, $y=f(\omega)$ and $y=f(\omega-c)$, and by $y=0$ be $S1$, $S2$, and $S3$, respectively:

$$S1=\int_{-\infty}^{\infty}|f(\omega+c)|\,d\omega, \tag{A-1}$$

$$S2=\int_{-\infty}^{\infty}|f(\omega)|d\omega, \tag{A-2}$$

$$S3=\int_{-\infty}^{\infty}|f(\omega-c)|d\omega. \tag{A-3}$$

Moreover, let the shared area among $S1$, $S2$, and $S3$ be $S123$, and those between $S1$, and $S2$, be $S12$ and between $S2$ and $S3$ be $S23$. Let the unshared areas in $S1$, $S2$, and $S3$ be $S1r$, $S2r$ and $S3r$, respectively.

Using these notations, $S1$, $S2$, and $S3$ can be represented by Eqs. A-4, A-5, and A-6, respectively:

$$S1=S123+S12+S1r, \tag{A-4}$$

$$S2=S123+S12+S23+S2r, \tag{A-5}$$

$$S3=S123+S23+S3r. \tag{A-6}$$

From the relation of $S1=S2=S3$ and Eqs. A-4, A-5, and A-6, one obtains:

$$S1r = S23 + S2r, \tag{A-7}$$

$$S3r = S12 + S2r. \tag{A-8}$$

The denominator of Eq. 12 can be represented by Eq. A-9 by replacing $F'(\omega)$ with $f(\omega)$ and $\mathbf{a}/3$ with c as follows:

$$\begin{aligned}\int_{-\infty}^{\infty}&|F'(\omega+\mathbf{a}/3)-F'(\omega)+F'(\omega-\mathbf{a}/3)|d\omega\\ &=\int_{-\infty}^{\infty}|f(\omega+\mathbf{a}/3)-f(\omega)+f(\omega-\mathbf{a}/3)|d\omega,\\ &=S123+S1r+S2r+S3r.\end{aligned} \tag{A-9}$$

That of Eq. 21 can also be represented by Eq. A-10:

$$\begin{aligned}\int_{-\infty}^{\infty}&|F'(\omega+\mathbf{a}/2)-F'(\omega)+F'(\omega-\mathbf{a}/2)|d\omega\\ &=\int_{-\infty}^{\infty}|f(\omega+\mathbf{a}/2)-f(\omega)+f(\omega-\mathbf{a}/2)|d\omega,\\ &=S123+S1r+S2r+S3r.\end{aligned} \tag{A-10}$$

Substitution of Eqs. A-7 and A-8, and then A-5 into Eq. A-9 yields:

$$\begin{aligned}S123+S1r+S2r+S3r&=S123\\ &+3S2r+S12+S23=S2+2S2r.\end{aligned} \tag{A-11}$$

Since both numerators of Eqs. 12 and 21 are equal to S2, the value of Eqs. 12 and 21 can be represented by

$$\frac{I_2(\mathbf{a}/3)}{I_2(\mathbf{a})}=\frac{I_3(\mathbf{a}/2)}{I_3(\mathbf{a})}=\left[\frac{S2}{S2+2S2r}\right]^2. \tag{A-12}$$

If there is no overlap between $S1$, $S2$ and $S3$, $S2r$ equals $S2$ and the value of Eq. A-12 is 1/9. With increasing the overlap between them, $S2r$ decreases and the value of Eq. A-12 approaches 1:

$$\frac{1}{9}<\left[\frac{S2}{S2+2S2r}\right]^2<1. \tag{A-13}$$

Gel Filtration Chromatographic Study on the Micelle Formation of Triton X-100

Noriaki FUNASAKI,* Sakae HADA, and Saburo NEYA
Kyoto Pharmaceutical University, Yamashina-ku, Kyoto 607
(Received November 17, 1988)

The aggregation properties of Triton X-100 are investigated by frontal gel (Sephadex G-200) filtration chromatography (GFC) at 25 °C and considered in the framework of the monomer-m-mer equilibrium on the basis of both asymptotic and plate theories. The analysis of GFC data by asymptotic theory yields an equilibrium constant of $K=1.3\times10^{68}$ (mmol dm^{-3})$^{-138}$ and a micellar elution volume of $V_m=15.30$ cm^3. By using this V_m value, we calculate a micellar hydrodynamic radius of 4.6 nm and the monomer concentration C_1 for Triton X-100. Values of cmc=0.30 mmol dm^{-3} (UV at 245 nm) and 0.31 mmol dm^{-3} (UV at 265 nm and GFC) are determined and are very close to the cmc value theoretically calculated by using Phillips' definition of the cmc. The C_1 value above the cmc is larger than these cmc values by about 0.06 mmol dm^{-3}. The derivative elution pattern at the trailing boundary exhibits two maxima and a minimum (V_{min}), and indicates the formation of small micelles near the cmc. The concentration at V_{min} on the elution curve, C_{min}, is close to the cmc, as we have already predicted by both asymptotic and plate theories. The present work demonstrates the utility of these theories for analyzing the GFC pattern of self-associating systems and will serve to understand the actions of Triton X-100 on membrane bound proteins and on lipid bilayers.

Triton X-100 is a commercial, polydisperse preparation of polyethylene glycol mono[p-(1,1,3,3-tetramethylbutyl)phenyl] ethers, containing an average of 9.6 oxyethylene units per molecule. This surfactant is very frequently used in the isolation and study of membrane bound proteins and water insoluble lipids. Furthermore, this interaction of membrane proteins with Triton X-100 monomers and micelles can provide information on the mechanism whereby they are attached within membranes.[1,2] Micelle formation of Triton X-100 in aqueous solution has been studied by light scattering,[3-5] viscosity,[5,6] ultracentrifugation,[5-8] fluorescence,[8] gel filtration chromatography (GFC),[5,9] and small-angle X-ray scattering measurements.[5]

For the quantitative investigation of self-associating systems by GFC, the large sample size (frontal) method is superior to the small sample size (zonal) method.[10-14] Recently, we developed a plate theory based on mass action model for micelle formation,[13,14] but this theory has rarely been used for analysis of GFC data on surfactants. Furthermore, asymptotic theory provides analytical solutions for GFC patterns, but most of them have not yet been used for surfactants.[10-14]

In this work, we report the frontal GFC elution curve and its derivative for Triton X-100 as a function of concentration at 25 °C. These data are analyzed with the above-mentioned theories. The aggregation properties obtained of Triton X-100 are compared with those by other workers.

Theoretical Basis

For the sake of simplicity, we regarded the micelle formation of a nonionic surfactant as the following equilibrium:

$$\underset{C_1}{m \text{ monomers}} \overset{K}{\rightleftharpoons} \underset{C_m}{\text{micelle}}, \qquad (1)$$

where C_1 and C_m denote the molarities of monomer and m-mer of the surfactant on a monomer basis. The equilibrium constant K of this reaction may be written as

$$K=C_m/C_1^m. \qquad (2)$$

The total molarity C_0 of surfactant can be written as

$$C_0=C_1+C_m=C_1+KC_1^m. \qquad (3)$$

When a large volume of a sample with the concentration C_0 is charged in a column, a plateau region with the same concentration appears on the elution curve, e.g., as shown in Fig. 1a. Approximately, we may assume that the equivalent sharp boundary for the solute zone leading or trailing boundary is the first moment (centroid) of the elution profile and satisfies the relationships:[10]

$$V_c=\int_0^{C_0} V\mathrm{d}C/C_0 \qquad \text{(leading boundary)} \qquad (4)$$

and

$$V_c'=\int_0^{C_0} V\mathrm{d}C/C_0+S \qquad \text{(trailing boundary)}, \qquad (5)$$

where S is the charged volume of the sample. For these determinations the volume coordinate V is assigned a zero value when the leading boundary of the charged sample enters the column bed. According to this approximation (called asymptotic theory), the elution curve for a nonassociable solute is expected as a rectangle of C_0 in height and of S in width.

Above the cmc (for the case of $m\geqq3$)[10,13] the second "plateau region" generally appears at the trailing boundary. This region is clearly shown in its derivative, e.g., as shown in Fig. 1b. According to the asymptotic theory we can expect the derivative pattern shown by the dot-dash line and the following equations:[10,13,14]

$$m=(3V_{min}-V_1-2V_m)/(3V_{min}-2V_1,-V_m), \qquad (6)$$

$$K=(m-2)[2(m^2-1)]^{m-1}/[m(2m-1)]^m/(C_{min})^{m-1}, \qquad (7)$$

$$V_c=C_1V_1/C_0+C_mV_m/C_0, \quad (8)$$

and

$$V_c=(V_1-V_m)^{(m-1)/m}C_0^{(1-m)/m}(V_1-V_C)^{1/m}/K^{1/m}+V_m. \quad (9)$$

Here V_1 and V_m denote the centroid elution volumes of the monomer and the micelle and C_{min} may be taken as the concentration corresponding to the minimum V_{min} on the derivative curve (Fig. 1). Both V_{min} and C_{min} are expected to be independent of C_0 from Eqs. 6 and 7.

According to plate theory, a gel column may be assumed to be composed of n plates and each plate consists of the mobile and stationary phases. The total volume of the mobile phase equals to the void volume of the column. The partition ratio, P, of a solute between these phases may be written as

$$P=(V_e-V_0)/V_0, \quad (10)$$

where V_e is the elution volume of the solute and V_0 the void volume. Assuming appropriate values for V_0, n, V_1, V_m, K, m, and C_0, we can simulate the theoretical elution curve and its first-derivative curve. The plate theory predicts more realistic elution and derivative patterns than the asymptotic theory. The computer simulation procedure of the plate theory has been reported in detail elsewhere.[14]

In the both theories, micelle formation and partition equilibrium of surfactant are assumed to be instantaneously established.[14]

Experimental

Materials. Triton X-100 was purchased from Tokyo Kasei Organic Chemicals. Sephadex G-200 was obtained from Pharmacia Fine Chemicals and used as suggested by the manufacturer.[15] Four proteins whose hydrodynamic radii R_h (nm) are known[15,16] were used as standards for the determination of R_h of the Triton X-100 micelle. From Sigma are whale myoglobin type II (R_h=1.9), bovine serum albumin (R_h=3.5), yeast alcohol dehydrogenase (R_h=4.6), and thyroglobulin (R_h=8.5). The ion-exchanged water was twice distilled and degassed before use.

Methods. A gel column of an inner diameter of 1 cm and a total gel volume of V_t=26.94 cm^3 was jacketed to maintain a constant temperature at 25±0.2 °C. A sample or eluent was flown into the column at a constant flow rate of about 8 cm^3 h^{-1} by using a mini-pump. The concentration of Triton X-100 in eluate was continuously monitored with a Shimadzu SPD-2A spectrophotometric detector and recorded with a Shimadzu Chromatopac C-R1B data processor. A wavelength of 265 nm or 245 nm was used for absorbance measurements. The absorbance was converted to concentration by using the absorbances of several Triton X-100 solutions at known concentrations.

Computer simulation was carried out with an NEC PC-9801 VX personal computer.

Results and Discussion

Frontal GFC Patterns of Triton X-100. The elution curve, like Fig. 1a, was determined at 10 concentrations (C_0=0.203—10.048 mmol dm^{-3}). From the leading and trailing boundaries, we can determine the centroid volumes, V_c and V_c'. Since these values were in a agreement with each other within experimental errors, we used the average of them hereafter. As Fig. 2 shows, V_c rapidly decreased with an increase of C_0 above the cmc (Table 1). These V_c values were plotted against $1/C_0$ in Fig. 3. From the intersection of two straight lines drawn above and below the cmc, we determined a cmc value of 0.31 mmol dm^{-3}. This value is very close to the cmc values obtained from the absorbance-C_0 plots at 265 nm and 245 nm, as well as

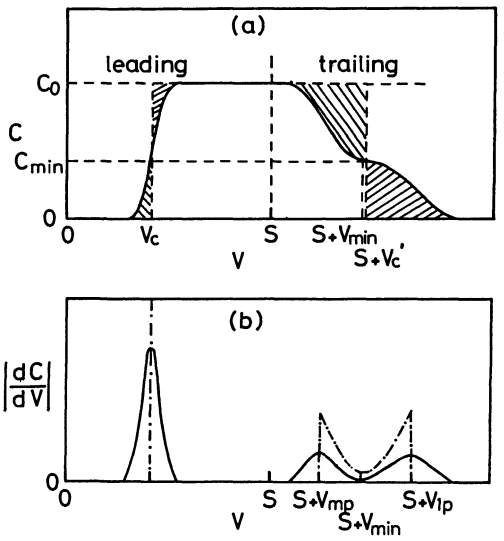

Fig. 1. Schematic elution curve (a) and its derivative (b) for a micellar system and definitions of characteristic parameters. The shaded areas around V_c and V_c' are related to Eqs. 4 and 5. The dot-dash line shows the derivative curve predicted by asymptotic theory and the solid lines show the observed results and those predicted by plate theory.

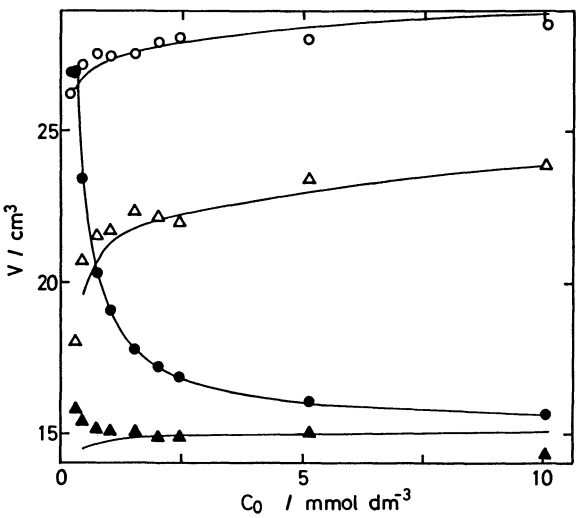

Fig. 2. Characteristic elution volume parameters as a function of total concentration for Triton X-100: ○; V_{1p}, △; V_{min}, ●; V_c, ▲; V_{mp}. The solid lines show the computer-simulated values.

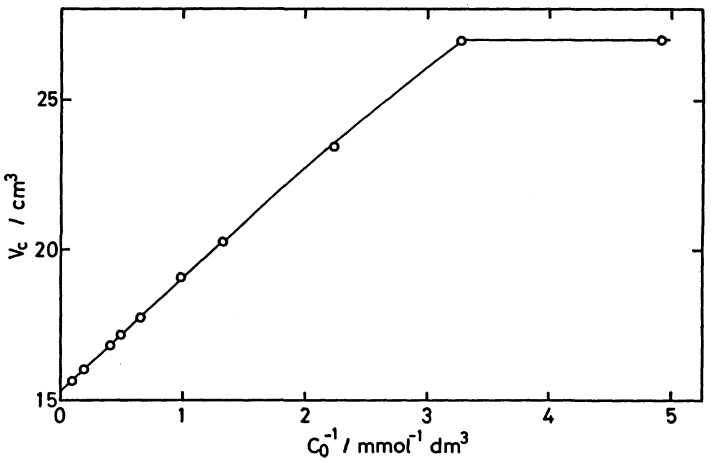

Fig. 3. Centroid volumes as a function of reciprocal concentration for Triton X-100. The solid line shows the computer-simulated values.

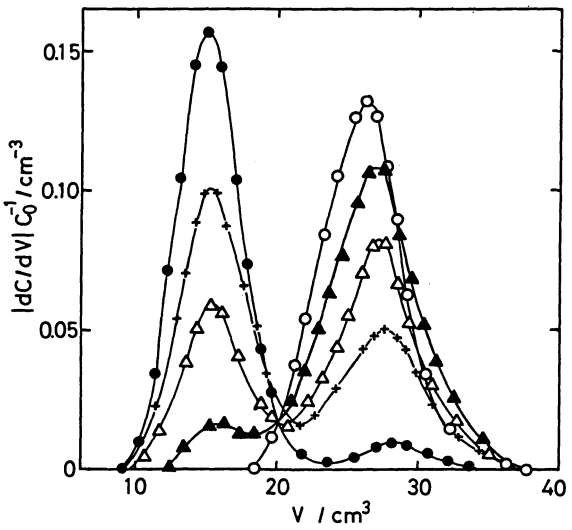

Fig. 4. Reduced derivative elution curves for Triton X-100 at five concentrations (mmol dm^{-3}): ○; 0.203, ▲; 0.305, △; 0.448, +; 0.753, ●; 5.123.

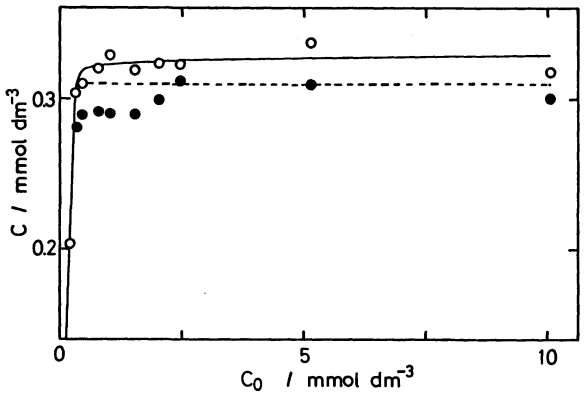

Fig. 5. Values of monomer concentration C_1 (○) and C_{min} (●) as a function of total concentration for Triton X-100. The solid line was calculated from Eq. 3 and the dashed line was computer-simulated for C_{min}.

to the literature value.[17]

Figure 4 shows the reduced derivative profiles for the trailing boundary at five concentrations, where the volume coordinate V is assigned a zero value when eluent enters the column bed. At C_0=0.305 mmol dm^{-3} a small peak of the micelle appears together with a large peak of the monomer. From the elution and derivative profiles we can determine values of V_{1p}, V_{mp}, V_{min}, and C_{min}. In Fig. 2 are shown V_{1p}, V_{mp}, and V_{min} as a function of C_0. Values of C_{min} are shown in Fig. 5.

Triton X-100 is not a pure substance, but a lot of data have been analyzed with the assumption that it was a pure surfactant.[3-8] A number of m values near 25 °C have been reported; m=139 (room temperature)[3] and 135 (25 °C)[4] by light scattering, m=134 (20 °C),[6] 100 (25 °C),[7] and 125 (25 °C, 10 mmol dm^{-3} phosphate buffer)[8] by ultracentrifugation, m=121 (25 °C, 10 mmol dm^{-3} phosphate buffer) by fluorescence titration,[8] and m=147 (20 °C) and 231 (30 °C) by small-angle X-ray scattering.[5] For the purpose of analysis of our GFC data, we used a value of m=139. When m is a large value like this, analyzed results little change with variation in m.

Figure 6 shows the plot according to Eq. 9 by employing m=139 and V_1=27.00 cm^3. This V_1 value was taken from V_e at C_0=0.203 mmol dm^{-3}, the lowest concentration used herein. From this plot we can estimate values of K=1.3×10^{68} (mmol dm^{-3})$^{-138}$ and V_m=15.30 cm^3. By using the linear relationship between $\{(-\log[(V_e-V_0)/(V_t-V_0)]\}^{1/2}$ and R_h for the proteins described in the Experimental section, we estimated a value of R_h=4.6 nm for the Triton X-100 micelle from this V_m value. This R_h value is consistent with the literature values shown in Table 1.[5,6,9]

From Eq. 8 we can estimate the monomer concentration C_1 by using the above values of V_1 and V_m. The C_1 values thus obtained are shown in Fig. 5.

Table 1. Values of Cmc and R_h for Triton X-100 Micelles at 25 °C

Method	Cmc / mmol dm^{-3}	R_h(temp) / nm	Reference

a) Calculated from Eq. 11. b) Dynamic light scattering. c) Sedimentation velocity.

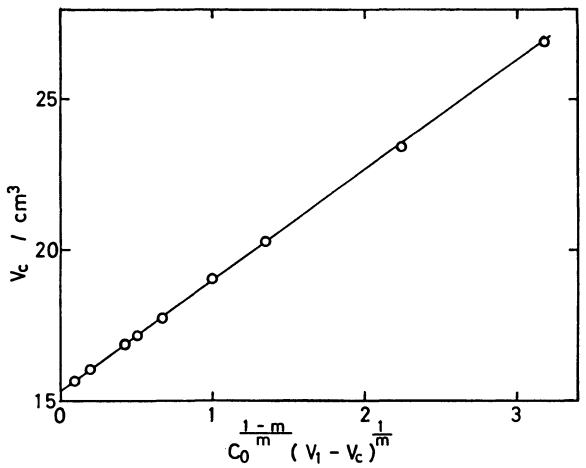

Fig. 6. Centroid volumes plotted according to Eq. 9. The straight line was fitted to the seven high-concentration data by the least-squares method.

The monomer concentration above the cmc is usually assumed to be equal to cmc. As Fig. 5 shows, C_1 is slightly larger than cmc. This is an important result when one considers various actions of Triton X-100.

Comparison between Theory and Experiment. By using the estimated values of V_1, V_m, and m, we can calculate a value of V_{min}=23.13 cm^3 from Eq. 6, regardless of C_0. This value is close to the observed values of V_{min} shown in Fig. 2, but Eq. 6 cannot explain the observed increase of V_{min} with increasing C_0. By using the estimated values of K and m, we can calculate a value C_{min}=0.309 mmol dm^{-3} from Eq. 7, regardless of C_0. This value is similar to the observed C_{min} values shown in Fig. 5, and practically the same to the cmc values shown in Table 1. Recently, by using Phillips' definition of the cmc,[18] we could derive the equation:[14]

$$\text{cmc}=[Km(2m-1)/(m-2)]^{1/(1-m)}. \quad (11)$$

When m is large enough, we can obtain from Eqs. 7 and 11

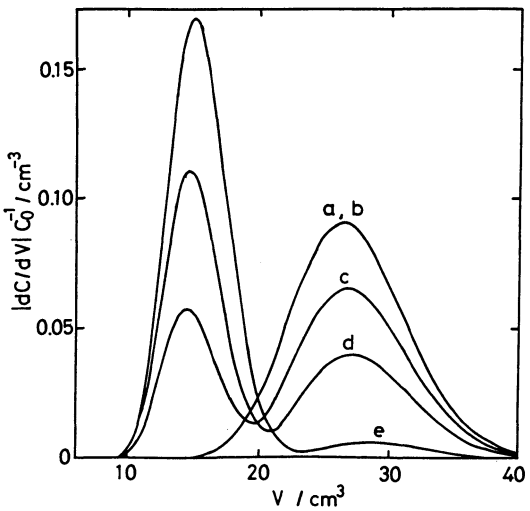

Fig. 7. Computer-simulated derivative patterns at five concentrations (mmol dm^{-3}): a; 0.203, b; 0.305, c; 0.448, d; 0.753, e; 5.123.

$$C_{min}=\text{cmc}=(2Km)^{1/(1-m)}. \quad (12)$$

Substitution of the estimated values of m and K yields a value of C_{min}=cmc=0.309 mmol dm^{-3}. This result explains the experimental observation that C_{min} is close to cmc.

Based on the plate theory, we can computer-simulate the elution curve and its derivative by assuming appropriate values for V_0, n, V_1, V_m, K, m, and C_0. For V_1, V_m, K, and m we used the values estimated above, and regarded V_0 and n as fitting parameters; we used V_0 =5.0 cm^3 and n=30.

The solid lines for V_c shown in Figs. 2 and 3 were computed by the plate theory and are very close to the observed values, as expected; for many m values we have theoretically shown that the plate theory and Eq. 8 predict the same value for V_c.[13,14] Figure 7 shows the derivative elution profiles at the five concentrations, corresponding to Fig. 4. These figures show similar results, except the results at C_0=0.305 mmol dm^{-3}. At this concentration the micellar peak experimentally observed do not appear on the theoretical curve. This discrepancy will be considered below. As Fig. 2 shows, the plate theory explains the increase of V_{1p} and V_{min} with increasing C_0, whereas it predicts a minor increase of V_{mp} with increasing C_0. As Fig. 5 shows, the comupted C_{min} values (dashed line) decreased only slightly with increasing C_0 and are very close to the cmc values shown in Table 1.

Aggregation Properties of Triton X-100. Triton X-100 is an important surfactant for the investigation of biological membranes.[1,2] To consider the action of Triton X-100 on biological membranes, we need to estimate the concentrations of the monomer and the micelle. In most cases the monomer concentration C_1 is taken as the cmc. From the analysis of our GFC data, we determined C_1 as a function of C_0. As Fig. 5 shows, C_1 is larger than the cmc by about 0.06 mmol

dm^{-3}. From Eq. 12 we can estimate the K value by using the cmc and m values and subsequently we can estimate the C_1 value from Eq. 3 by using these m and K values. The estimated C_1 value may be used, when no observed C_1 value is available. Another reason why we chose this surfactant is that its concentration can be very accurately determined by ultraviolet spectroscopy (UV). Most surfactants do not absorb ultraviolet or visible light. Therefore the refractive index (RI) measurement is usually used for monitoring their concentrations.[12] Generally speaking, UV is a more accurate method than the RI method, since the UV absorbance is less temperature-dependent than RI. An accurate concentration determination is essential for obtaining the derivative elution curve.

According to Makino et al.[17] typical samples of Triton X-100 consist of 93% polyethylene glycol mono(octylphenyl) ether and 7% of polyethylene glycol bis(octylphenyl) ether. Most of it is *p*-substituted, but about 10% of the monooctyl ether and the second alkyl group of the dioctyl ether are *o*-substituted. The presence of these impurities must be taken into consideration.

Zonal GFC,[5,9] viscosity,[5,6] and ultracentrifugation[5,8] measurements have all suggested that the size of Triton X-100 micelles little changes with variation of C_0 around 25 °C (it should be noted that these measurements were not carried out at low concentrations). This result is consistent with the data of Tanford et al.[19] They showed that micelles of dodecyl ethers possessing eight or more oxyethylene units do not grow with increasing C_0 at 25 °C.

Assuming only the micelle with an aggregation number of 139, we have applied the asymptotic and plate theories to our frontal GFC data. Taking into consideration inaccuracies of both these data and theories, agreement between theory and experiment in Figs. 2—5 and 7 is generally good except at low concentrations near the cmc. As Fig. 4 shows, a micellar peak appears at C_0= 0.305 mmol dm^{-3}. At the same concentration, however, no micellar peak is observed on the computer-simulated curve (Fig. 7). Furthermore, as Fig. 2 shows, the observed V_{mp} values at low concentrations are larger than those predicted by the plate theory. These results indicate the presence of small micelles at low concentrations and are consistent with light scattering data at low concentrations.[3] The formation of the small micelles may result in negative deviations of the observed V_1 and C_{min} values from the theoretical values at low concentrations (Fig. 5). These small micelles will contain the dioctyl ether preferentially, since the dioctyl ether is expected to be more surface-active than the monooctyl ether.

In this work, the micelle formation of Triton X-100 was analyzed in terms of the monomer-m-mer equilibrium, but we showed that smaller micelles are formed near the cmc. When attempting to take into consideration the concentration dependence of m, we encounter the difficulty that Triton X-100 contains the above-mentioned impurities. Therefore we must consider the concentration dependences of m and the micellar composition for this surfactant. Prior to overcoming this difficulty, we must understand the concentration dependence of m. This may be possible for pure surfactants.[20] Furthermore, from the theoretical view-point, the concentration of the micelle should be expressed as the "true"molarity, viz., C_m/m, and then the equilibrium constant should be denoted as K/m.

Conclusion

The monomer concentration C_1 for Triton X-100 was determined as a function of total concentration from the concentration dependence of the centroid volume by using the asymptotic theory. This C_1 value was close to that expected from the monomer-m-mer equilibrium with values of m=139 and K= 1.3×10^{68} (mmol dm^{-3})$^{-138}$. Observed values of cmc= 0.30 mmol dm^3 (UV) and 0.31 mmol dm^{-3} (UV and GFC) were smaller than the C_1 value by about 0.06 mmol dm^{-3}. The above-mentioned K value was determined from the concentration dependence of the centroid volume. The hydrodynamic radius of the Triton X-100 micelle was determined to be 4.6 nm from the elution volume V_m of the micelle. The derivative elution pattern showed the formation of small micelles near the cmc. The plate theory and asymptotic theory were useful for analyzing the elution curve and its derivative for Triton X-100. These results will serve to understand the mechanism of actions of Triton X-100 on biological membranes.

Thanks are due to Professor J. Paiement, Laval University, Canada, for helpful discussion and to Ms. A. Ohtani and Mr. M. Tanigawa for technical assistance.

Catalysis by Heteropoly Compounds. XIII.† An Infrared Study of Ethanol and Diethyl Ether in the Pseudoliquid Phase of 12-Tungstophosphoric Acid

Kwan Young LEE, Noritaka MIZUNO, Toshio OKUHARA, and Makoto MISONO*
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 24, 1988)

Ethanol, diethyl ether, and water absorbed in, and their thermal desorption from, the pseudoliquid phase of 12-tungstophosphoric acid have been studied by means of infrared spectroscopy. For all three molecules, the state of the absorption of 6 molecules per anion, $H_3PW_{12}O_{40}\cdot 6R_2O$ (R; C_2H_5 or H), was quite stable and the secondary structures were similar. The intensities of the C-H vibrations indicated that the methyl group of the ethanol molecules interacted with the anions and that its interaction became stronger as the amount of absorbed molecules decreased. In the thermal desorption of absorbed ethanol or diethyl ether, a protonated monomer and dimer as well as an ethoxy group were detected by means of infrared spectroscopy. These species are reaction intermediates of the dehydration of ethanol which were assumed previously (*J. Am. Chem. Soc.*, **109**, 5535 (1987)). It was also found that, upon the dehydration of $H_3PW_{12}O_{40}\cdot 6H_2O$, the proton which had been hydrogen-bonded to the oxygen atom of the water molecule ($(H_2O)_2H^+$) migrated onto the bridging oxygen of the heteropoly anion ($PW_{12}O_{40}^{3-}$).

Heteropoly acids such as $H_3PW_{12}O_{40}$ and their salts have been used as both heterogeneous solid catalysts[1-3] and homogeneous solution catalysts.[4] It has been reported that polar molecules are readily absorbed into the bulk of certain heteropoly acids[5] and that some catalytic reactions take place in the "pseudoliquid phase".[1,6] Since the whole protons in the bulk $H_3PW_{12}O_{40}$ can take part in the reactions, it shows a very high catalytic activity for the dehydration of alcohol or ether at low temperatures.[7,8] We recently demonstrated that the unusual pressure dependencies of the rate and selectivity of the dehydration of ethanol over $H_3PW_{12}O_{40}$ were closely correlated with the amount and the chemical state of the ethanol present in the bulk.[9] Thus, it is very important, for an understanding of the heterogeneous catalysis of heteropoly compounds, to elucidate at the molecular level the activated state of the molecules absorbed in the pseudoliquid phase.

In the case of heteropoly compounds, it is possible to investigate the reacting molecules and the polyanions simultaneously by means of spectroscopy. The primary structure of the heteropoly anion can be monitored by means of IR, as has been described by Rocchiccioli-Deltcheff et al.[10] and other groups.[11] The thermal desorption and transformation processes of acetone and ethanol in $H_3PW_{12}O_{40}$ have been studied with IR by Misono et al.[5] and Moffat et al.[12] Solid-state NMR is also useful for the study of heteropoly acid.[13] The present authors have previously investigated, by the use of solid-state NMR (^{31}P, ^{13}C, ^{1}H), the activated states of ethanol in the pseudoliquid phase of $H_3PW_{12}O_{40}$[14] and demonstrated the presence of protonated ethanols and the ethoxy group. Farneth et al. have observed a methoxy intermediate formed on the polyanion of $K_{3-x}H_xPW_{12}O_{40}$ by ^{13}C CP-MAS NMR.[13b]

In the present study, we have investigated the structure and the thermal transformation of activated ethanol and ether, mainly on the basis of the IR spectral changes brought about by heating. The local position of the protons of $H_3PW_{12}O_{40}$ during the dehydration process of $H_3PW_{12}O_{40}\cdot 6H_2O$ was also examined. These processes were then further discussed in relation to the catalytic dehydration.

Experimental

Materials. The $H_3PW_{12}O_{40}$ was purchased from the Nippon Inorganic Color and Chemical Co., Ltd., and was used after purification by ether extraction and recrystallization from water. The stoichiometric cesium salt ($Cs_3PW_{12}O_{40}$) was prepared using a Cs_2CO_3 aqueous solution as has been described previously.[15]

The C_2H_5OH (Amakasu Chemical Ind.; 99.5%), $(C_2H_5)_2O$ (Showa Ether Co. Inc., Research Grade), C_2H_5OD (Aldrich; 99.5%D), and D_2O (Aldrich; 99.8%D) were degassed by several freeze-pump-thaw cycles. The Al_2O_3 (Reference Catalyst of Catalysis Society of Japan, ALO-4, 170 m^2g^{-1}) and SiO_2 (Cabosil, 200 m^2g^{-1}) were pretreated in a vacuum at 400 °C for 2 h.

The deuterated 12-tungstophosphoric acid ($D_3PW_{12}O_{40}$) was obtained by exchange with D_2O as follows. After $H_3PW_{12}O_{40}\cdot nH_2O$ had been evacuated at room temperature (n=6), it was exposed to D_2O (15 Torr; 1 Torr ≈ 133.322 Pa) and reevacuated. This procedure was repeated several times. After the complete change of ν(O-H) to ν(O-D) had been confirmed by IR, the sample was treated at 130 °C in a vacuum for 1 h to obtain $D_3PW_{12}O_{40}$.

Absorption and Desorption Measurements. The absorption amounts of water, ethanol, and diethyl ether into $H_3PW_{12}O_{40}$ were measured by the use of a thermal gravimeter (Shimadzu TG-30) connected directly to a vacuum system. After the evacuation of the $H_3PW_{12}O_{40}$ (ca. 40 mg) for 1 h at 130 °C, ethanol (20 Torr) or diethyl ether (50 Torr)

† Part XII: T. Okuhara, S. Tatematsu, K. Y. Lee, and M. Misono, *Bull. Chem. Soc. Jpn.*, **62**, 717 (1989).

was introduced at room temperature. The thermal desorption, in which temperature was raised step-by-step, was carried out in the same system.

The content of the crystallization water was measured by the TG. After evacuation at room temperature, the amount of water which remained was 6 molecules per anion; by further evacuation at 100 °C and 200 °C, it became 1 and 0.5 molecules per anion respectively.

Thermal Desorption. The thermal desorption of ethanol and diethyl ether absorbed in $H_3PW_{12}O_{40}$ was carried out in a closed circulation system connected to a gas chromatograph. After about 0.5 g of the catalyst was evacuated at 130 °C for 1 h, the gas was added at 25 °C. Then, the temperature of the catalyst was raised step-by-step. Gases desorbed at each temperature were collected in a trap kept at the temperature of liquid nitrogen and analyzed with a gas chromatograph (Shimadzu GC 8A, TCD, Porapak Q and/or Yanaco G 2800, FID, VZ-10).

IR Measurements. The heteropoly compounds (2—7 mg) were dispersed on a thin silicon plate and were pretreated by the same method as in the thermal desorption. Their IR spectra were recorded in an in situ IR cell,[16] connected to a closed circulation system, by means of an FT-IR spectrometer (JEOL, JIR-10, MCT detector, 4 cm^{-1} resolution).

NMR Measurements. The samples for the NMR measurements were prepared using the closed circulation system or a quartz spring balance connected to the vacuum system. The amount of ethanol absorbed into $H_3PW_{12}O_{40}$ (ca. 0.5—1 g) was determined by measuring the pressure decrease or the change in weight.

High-resolution solid-state MAS NMR spectra were obtained on a Fourier Transform pulsed NMR spectrometer (JEOL JNM-GX270) equipped with a CP-MAS unit (JEOL NM-GSH27MU). The instrumental conditions were the same as those previously described.[14]

Results

IR Spectra of $H_3PW_{12}O_{40}\cdot nH_2O$ ($n\leq 6$). The infrared spectra of $H_3PW_{12}O_{40}\cdot nH_2O$ and $D_3PW_{12}O_{40}\cdot nD_2O$, evacuated at various temperatures, are shown in Figs. 1 and 2 respectively. The spectrum of $H_3PW_{12}O_{40}\cdot 6H_2O$ after evacuation at room temperature was quite similar to that in the literature (Fig. 1a).[10] The bands were assigned as follows, with reference to the structure in Fig. 3a. The band at 1080 cm^{-1} is attributed to the asymmetric stretching vibration of the central PO_4 tetrahedron (ν_{as}(P-O)), and the band at 976 cm^{-1}, to a stretching vibration of W=Ot, where Ot is the terminal oxygen. The other two bands, 887 and 795 cm^{-1}, are assigned to the stretching of the W-Oc-W bridges between corner-shared WO_6 octahedra (ν_{as}(W-Oc-W)), and to the stretching of the W-Oe-W bridges between edge-shared WO_6 octahedra (ν_{as}(W-Oe-W)), respectively.

As is shown in Fig. 1, the IR spectrum changed remarkably upon evacuation above 100 °C (Fig. 1b—d). The intensity of the ν(W=Ot) band at 976 cm^{-1} decreased, and a new band at 1007 cm^{-1} appeared. After the evacuation at 300 °C, the band at 1007 cm^{-1} remained, while the band at 976 cm^{-1} disappeared. In the ν_{as}(W-Oe-W) region, the band at 795 cm^{-1} split into two bands (798 and 768 cm^{-1}) after the 100 °C-evacuation. It was confirmed that the addition of

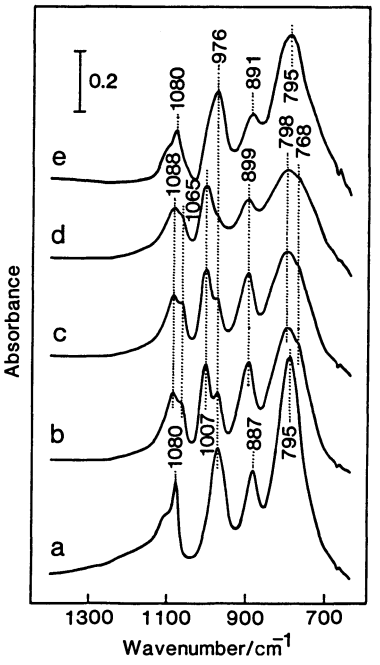

Fig. 1. Infrared spectra of $H_3PW_{12}O_{40}\cdot nH_2O$ during dehydration process; evacuated at (a) room temperature (n=6), (b) 100 °C, (c) 200 °C, (d) 300 °C, and (e) after (d), the sample was exposed to H_2O (15 Torr) and was evacuated at room temperature.

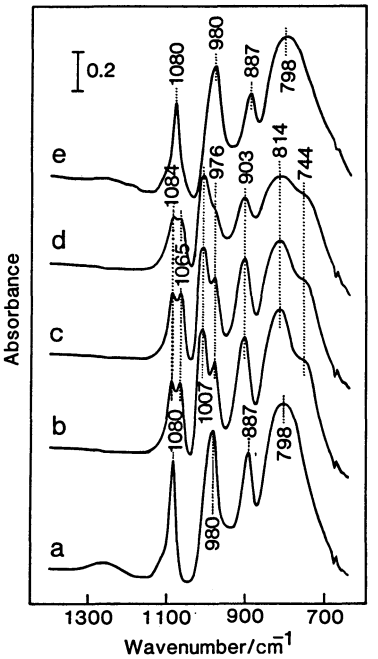

Fig. 2. Infrared spectra of $D_3PW_{12}O_{40}\cdot nD_2O$ during dehydration process; evacuated at (a) room temperature (n=6), (b) 100 °C, (c) 200 °C, (d) 300 °C, and (e) after (d), the sample was exposed to D_2O (15 Torr) and was evacuated at room temperature.

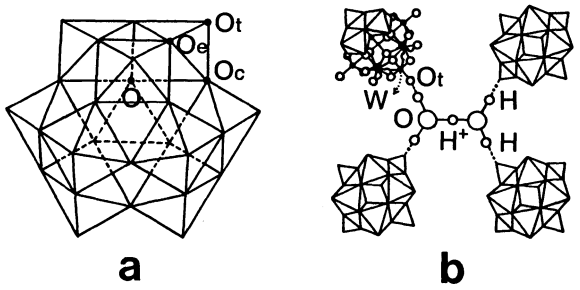

Fig. 3. Structure of (a) the primary structure of heteropoly anion ($PW_{12}O_{40}^{3-}$) and (b) the secondary structure of $H_3PW_{12}O_{40}\cdot 6H_2O$.

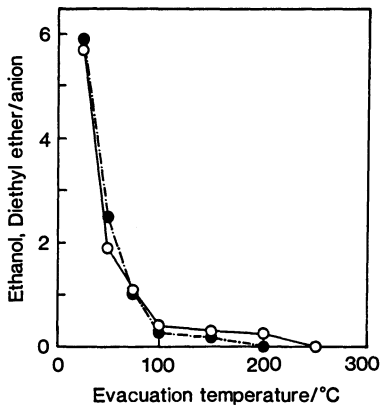

Fig. 4. The amount of ethanol (●) and diethyl ether (○) remained in the bulk of $H_3PW_{12}O_{40}$ during step-by-step thermal desorption.

water (15 Torr) to the 300 °C-evacuated sample and subsequent evacuation at room temperature completely recovered the original spectrum (Fig. 1e).

The infrared spectrum (Fig. 2a) of $D_3PW_{12}O_{40}\cdot 6D_2O$ was similar to that of $H_3PW_{12}O_{40}\cdot 6H_2O$ (Fig. 1a). During heating, the ν(W=Ot) band showed the same changes as that of $H_3PW_{12}O_{40}$. However, it was noted that the ν_{as}(W-Oe-W) band at 798 cm^{-1} split into two bands (814 and 744 cm^{-1}) which were distinctly different from the two bands observed for $H_3PW_{12}O_{40}$ (798 and 768 cm^{-1}). Also, in this case, the original IR spectrum (Fig. 2a) was recovered by the treatment with D_2O (Fig. 2e).

Amounts of Diethyl Ether and Ethanol Absorbed. Figure 4 shows the amounts of diethyl ether and ethanol which remained after the step-by-step thermal desorption. When diethyl ether vapor (150 Torr) was introduced at room temperature, the amount of diethyl ether absorbed became 6 molecules per anion after 30 min. This amount remained unchanged upon the evacuation at room temperature,[17] suggesting that the state of 6 molecules of diethyl ether per polyanion is stable, as in the case of water. The amounts of diethyl ether held were about 2 and 0 molecules per anion after 50 °C and 250 °C-evacuation respectively, as is shown in Fig. 4.

In the case of ethanol,[17] the absorption amount

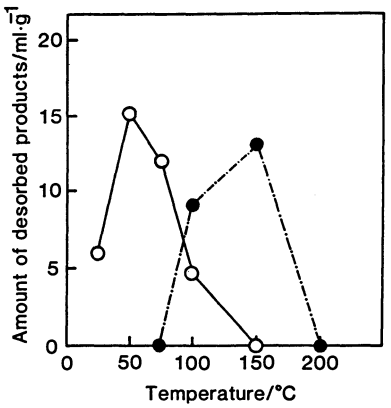

Fig. 5. Variation of products for thermal desorption of diethyl ether from $H_3PW_{12}O_{40}$. ○: $(C_2H_5)_2O$, ●: C_2H_4.

reached about 14 molecules per anion at 20 Torr. It decreased to 6, 2.5, and about 0 molecules per anion after evacuation at room temperature, 50 °C, and 200 °C respectively. At 45 °C, 9 and 6 molecules of ethanol per anion were absorbed when the pressures of ethanol were 40 and 5 Torr respectively. This value decreased to 3 molecules per anion upon the evacuation at 45 °C. In this way, the stable states of 3, 6, and 9 molecules of ethanol per anion could be obtained by controlling the pressure at 45 °C.

Figure 5 shows the products of the thermal desorption of diethyl ether from $H_3PW_{12}O_{40}$. Below 75 °C, only diethyl ether was desorbed. Ethylene was evolved in the range of 75—150 °C. Ethylene showed a maximum at 150 °C, but above 200 °C it was not detected. At 150—300 °C, small amounts of ethane, propane, and butane were detected in the gases desorbed. The total amount of these saturated hydrocarbons was about one-tenth that of the ethylene formed. The carbon balance in the absorption-desorption (up to 300 °C) was confirmed to be close to 100%.

As has been reported previously,[7b] ethanol was desorbed below 100 °C in the case of the thermal desorption of ethanol. The amount of ethylene desorbed reached a maximum at about 100 °C. Above 150 °C, ethane, propane, and methane were produced instead of ethylene.

IR Spectra of $H_3PW_{12}O_{40}\cdot n(C_2H_5)_2O$ ($n\leq 6$) during Thermal Desorption. The changes in the IR spectra of diethyl ether present in $H_3PW_{12}O_{40}$ during step-by-step heating in a vacuum are shown in Fig. 6. After the evacuation at room temperature (6 molecules of diethyl ether per anion), four bands appeared, at 2985, 2939, 2900, and 2873 cm^{-1}, which corresponded to the ν(C-H) bands (Fig. 6a). The bands at 2985 and 2939 cm^{-1} are attributed to the degenerate stretching vibrations of CH_3, while the bands at 2900 and 2873 cm^{-1} are assigned to the symmetric stretching vibrations of CH_3 and CH_2 respectively.[18] After heating up to 75

°C, these bands became weaker, without any shifts in their positions. The evacuation at 100 °C broadened these bands and produced new, weak bands at 2954, 2924, 2897, and 2870 cm^{-1}. After 150 °C-evacuation, only the latter four bands remained. These bands completely disappeared after evacuation at 300 °C, however.

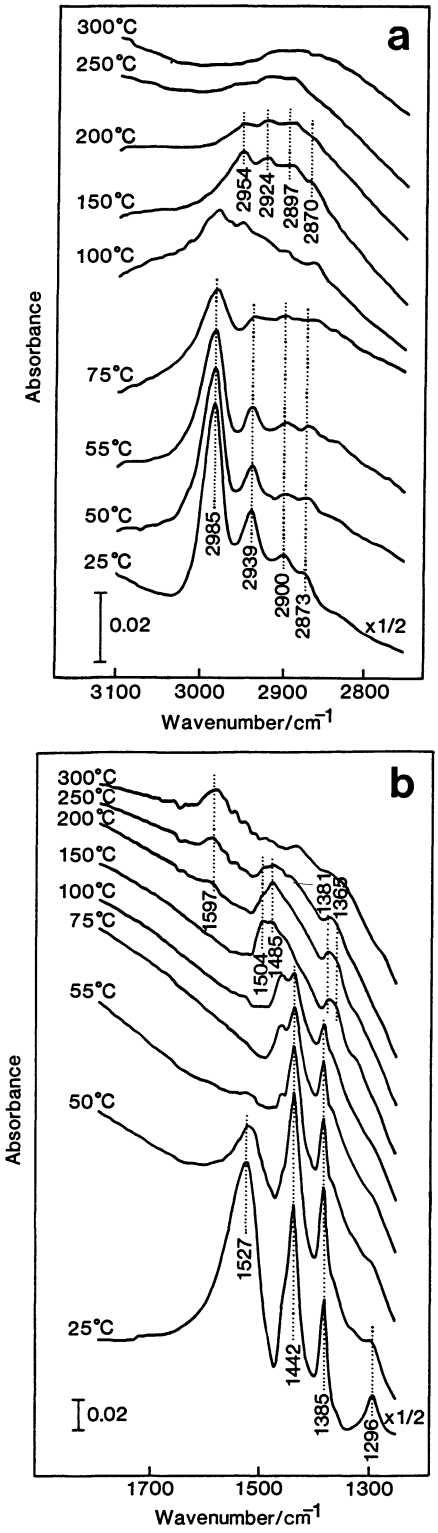

Fig. 6. Changes of IR spectra of diethyl ether absorbed in $H_3PW_{12}O_{40}$ during stepwise heating in vacuum; (a) in the ν(C-H) region; 3100—2750 cm^{-1}, (b) in the deformation region; 1800—1250 cm^{-1}.

The bands in the deformation region (1800—1250 cm^{-1}) are shown in Fig. 6b. The band at 1442 cm^{-1} is a characteristic band of the CH_3 degenerate deformation, and the shoulder at 1468 cm^{-1} is assignable to the CH_2 deformation band.[18] The 1385 cm^{-1} band is due to both the CH_3 symmetric deformation and the CH_2 wagging vibration.[18] It was notable that the band at 1527 cm^{-1} was present for $H_3PW_{12}O_{40} \cdot 6(C_2H_5)_2O$. This band was absent in the spectra of the gaseous and liquid diethyl ether[18] and for diethyl ether adsorbed on Al_2O_3 and SiO_2. In addition, when diethyl ether was introduced over $D_3PW_{12}O_{40}$, the 1527 cm^{-1} band was not observed. It probably shifted to about 1100 cm^{-1} (isotope shift), but this band was not obvious because of the presence of the strong IR bands of the heteropoly anion. As is shown in Fig. 6b, the intensity of the band at 1527 cm^{-1} decreased upon heating at 55 °C in a vacuum, in preference to the 1385 and 1442 cm^{-1} bands.

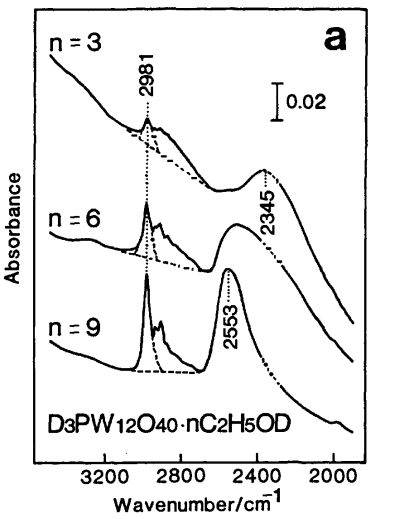
Upon heating at 150 °C, new bands at 1504, 1485, 1381, and 1365 cm^{-1} appeared, instead of the bands at 1442 and 1385 cm^{-1}. After the 200 °C-evacuation, a broad band at 1597 cm^{-1} appeared, and this band became intense at higher temperatures.

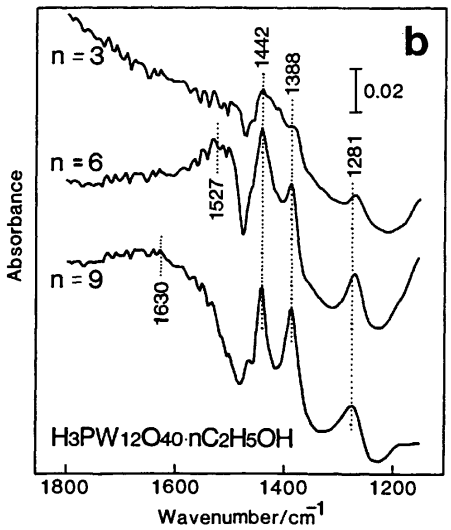
IR Spectra of $H_3PW_{12}O_{40} \cdot nC_2H_5OH$ (n=3, 6, 9). Figure 7a—d shows the IR spectra of ethanol absorbed in $H_3PW_{12}O_{40}$ or $D_3PW_{12}O_{40}$. In the case of the C_2H_5OD-$D_3PW_{12}O_{40}$ system, the O-D stretching band shifted from 2553 to 2345 cm^{-1} as the amount of C_2H_5OD decreased from 9 to 3 molecules per anion. In the ν(C-H) region (Fig. 7a), the $\nu_{deg}(CH_3)$ bands at 2981 and 2935 cm^{-1}, the $\nu_s(CH_3)$ band at 2904 cm^{-1}, and the $\nu_s(CH_2)$ band at 2870 cm^{-1} appeared. These bands were quite similar to those of absorbed diethyl ether. The integrated intensities of the 2981 cm^{-1} band ($\nu_{deg}(CH_3)$) decreased from 1.00 to 0.53 and 0.30 as the amounts of C_2H_5OD absorbed decreased from 9 to 6 and 3 molecules per anion respectively.

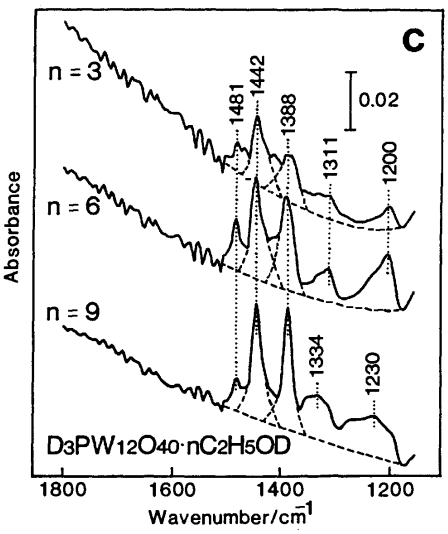
The IR spectra of $H_3PW_{12}O_{40} \cdot nC_2H_5OH$ in the deformation region (1800—1150 cm^{-1}) are shown in Fig. 7b. There was a broad band around 1630 cm^{-1} for the state of 9 molecules per anion. This band shifted to 1527 cm^{-1} for 6 molecule per anion; this position was in good agreement with that for 6 molecules of diethyl ether per anion. This band disappeared at 3 molecules per anion, however. Those bands at 1700—1500 cm^{-1} (Fig. 7b) shifted to about 1200 cm^{-1} upon the substitution of D for H in the OH group of C_2H_5OH, as is shown in Fig. 7c ($D_3PW_{12}O_{40} \cdot nC_2H_5OD$). For the states of 9, 6, and 3 molecules of C_2H_5OD per anion, the relative integrated intensities of the bands at 1442 cm^{-1} were 1.00, 1.17, and 0.77, while those at 1388 cm^{-1} were 1.00, 1.23, and 0.70.

Figure 7d shows the IR bands of the heteropoly anion of $D_3PW_{12}O_{40}$ absorbing different amounts of

C_2H_5OD. There was little difference in the IR spectra of the anion between 6 and 9 molecules of C_2H_5OD per anion. For 3 molecules per anion, the ν(W-Oe-W) band tended to split into 814 and 764 cm^{-1} and the ν(W=Ot) band, into 991 and 980 cm^{-1}.







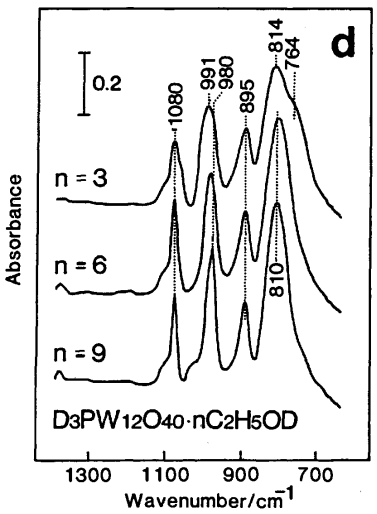


Fig. 7. IR spectra of ethanol absorbed in $H_3PW_{12}O_{40}$ or $D_3PW_{12}O_{40}$; (a) $D_3PW_{12}O_{40}\cdot n C_2H_5OD$, in the region of ν(C-H) and ν(O-D) (3500—1900 cm^{-1}), (b) $H_3PW_{12}O_{40}\cdot n C_2H_5OH$, in the region of δ(C-H), ν(O-H), and δ(O-H) (1800—1150 cm^{-1}), (c) $D_3PW_{12}O_{40}\cdot n C_2H_5OD$, in the region of δ(C-H), ν(O-D), and δ(O-D) (1800—1150 cm^{-1}), (d) $D_3PW_{12}O_{40}\cdot n C_2H_5OD$, in the region of characteristic bands of heteropoly anion (1400—633 cm^{-1}).

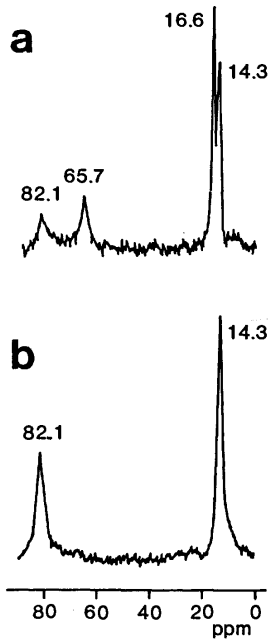

Fig. 8. The change of ^{13}C CP-MAS NMR spectra of $H_3PW_{12}O_{40}\cdot n C_2H_5OH$ by heating; (a) after evacuation at 45 °C (n=2.2), (b) after heating at 150 °C.

It was noted that there were little differences between the spectral changes of $H_3PW_{12}O_{40}\cdot n C_2H_5OH$ and $H_3PW_{12}O_{40}\cdot n(C_2H_5)_2O$ during thermal desorption.

^{13}C CP-MAS NMR of Ethanol Absorbed into $H_3PW_{12}O_{40}$. The ^{13}C CP-MAS NMR spectra of $H_3PW_{12}O_{40}\cdot 2.2C_2H_5OH$ are shown in Fig. 8a. As has been described previously,[14] the peaks at δ 16.6 (CH_3) and

65.7 (CH_2) were assigned to the protonated ethanol monomer ($C_2H_5OH_2^+$), and the signal at δ 14.3 and 82.1, to the ethoxy group on the heteropoly anion (C_2H_5O). In addition, a protonated dimer (($C_2H_5OH)_2H^+$) has been detected with ^{13}C peaks at δ 17.2 and 61.9 for $H_3PW_{12}O_{40}\cdot 6C_2H_5OH$.[14] After heating at 150 °C, the peaks at δ 16.6 and 65.7 disappeared, leaving only the peaks at δ 14.3 and 82.1.

Discussion

Location of H^+ in the Heteropoly Anion. The primary structure (Keggin structure)[19] and the secondary structure[20] of $H_3PW_{12}O_{40}\cdot 6H_2O$ are illustrated in Fig. 3. $H_3PW_{12}O_{40}\cdot 6H_2O$ has a stable structure, which has been established by X-ray and neutron diffraction.[20] The polyanions are packed in a bcc structure, in which the protonated water dimer, $(H_2O)_2H^+$, is connected to four anions by hydrogen bonding at the terminal oxygen atoms (Ot) of the anions, as is shown in Fig. 3b. Therefore, the band at 976 cm^{-1} (Fig. 1a) can firmly be assigned to the stretching vibration of the W=Ot bond, the Ot atom of which is bonded to the protonated water molecules, as is shown in Fig. 3b, and the 887 and 795 cm^{-1} bands, to the asymmetric stretching vibrations of W-Oc-W and W-Oe-W, which are not connected to either water or proton.

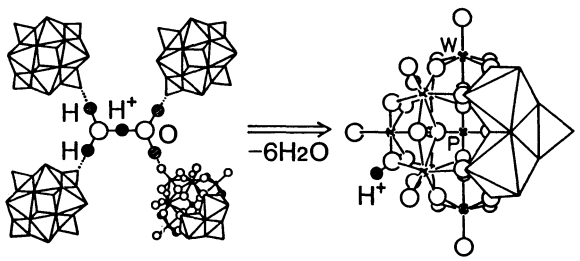
As the sample was dehydrated, the 976 cm^{-1} band decreased and the band at 1007 cm^{-1} grew correspondingly (Fig. 1a—d), as in the case of $H_3PMo_{12}O_{40}$.[16] The 1007 cm^{-1} band observed for dehydrated $H_3PW_{12}O_{40}$ may reasonably be assigned to W=Ot, which is not coordinated with either a free proton, water, or $(H_2O)_2H^+$. The shift of the W=Ot band to a wavenumber higher by 31 cm^{-1} is consistent with the disappearance of hydrogen bonding.[21]

The substitution of D for H caused no change in the wavenumber of the W=Ot band (compare $H_3PW_{12}O_{40}\cdot 6H_2O$ (Fig. 1a) and $D_3PW_{12}O_{40}\cdot 6D_2O$ (Fig. 2a)). The absence of the isotope shift for the W=Ot band indicates that the hydrogen bonding between the terminal oxygen and the hydrogen of the water molecules is weak. It is known that the O-H bond becomes longer as the hydrogen bonding becomes stronger.[22] The O-H bond distance of the water molecule in $H_3PW_{12}O_{40}\cdot 6H_2O$ is 0.951 Å,[20] which is close to the O-H bond length (0.958 Å) of the water molecule in the gas phase. Therefore, the hydrogen bonding between W=Ot and $(H_2O)_2H^+$ is considered to be weak.

As for the dehydration process (Figs. 1b—d and 2b—d), a significant difference was noted in the W-Oe-W band (795 cm^{-1}) between $H_3PW_{12}O_{40}$ and $D_3PW_{12}O_{40}$; the W-Oe-W band split into 798 and 768 cm^{-1} for $H_3PW_{12}O_{40}$, but it split into 814 and 744 cm^{-1} for $D_3PW_{12}O_{40}$. In contrast, there was no difference detected for the W=Ot band. This fact shows that, after dehydration, the proton interacts with the bridging oxygen (Oe), but not with the terminal oxygen (Ot). The above-mentioned shift of W=Ot to a higher wavenumber after dehydration is consistent with this idea. This is also in agreement with the fact that the bridging oxygen is more basic than the terminal oxygen.[23-25] For example, Knoth et al. have reported that the methyl cation in $CH_3OPMo_{12}O_{39}^{2-}$ is located on the bridging oxygen atom,[24] and Tonomura et al. observed a shift of the W-Oe-W band which was presumably due to the interaction with tetrahydrofuran through a proton located on the bridging oxygen atom.[25]

Since there are twelve Oe's and three protons per $PW_{12}O_{40}^{3-}$, the band at 814 cm^{-1}, which was stronger (Fig. 2b—d), may be assigned to nine W-Oe-W (non-protonated) bonds, and the 744 cm^{-1} band, to three W-OeD$^+$-W (protonated) bonds. The shift to a lower wavenumber for the latter is consistent with the presence of hydrogen-bonding.[21]

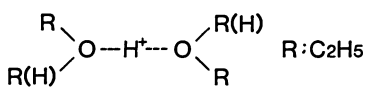
On the basis of these results, the following dehydration scheme for $H_3PW_{12}O_{40}\cdot 6H_2O$ is proposed. This process is reversible upon dehydration-hydration.



Dehydration scheme

States of Molecules in $H_3PW_{12}O_{40}\cdot nC_2H_5OH$ and $H_3PW_{12}O_{40}\cdot n(C_2H_5)_2O$ (n=3, 6, and 9). The amounts of molecules absorbed in $H_3PW_{12}O_{40}$ showed discrete values—for example, 3, 6, and 9 molecules per anion for ethanol and 6 molecules per anion for diethyl ether.[17]

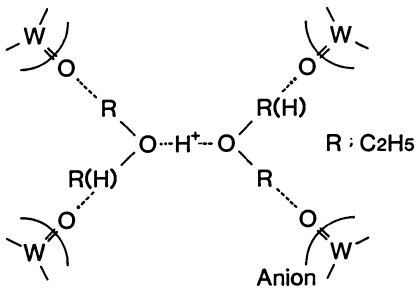
First, we will discuss the absorption state of 6 molecules per anion for ethanol, diethyl ether, and water. The states of $H_3PW_{12}O_{40}\cdot 6C_2H_5OH$ and $H_3PW_{12}O_{40}\cdot 6(C_2H_5)_2O$ (Fig. 7b and 6b) exhibited a characteristic band at 1527 cm^{-1}. Klages et al. observed the same band for the 2:1 complex of diethyl ether and $HSbCl_6$.[26] It is probably assignable to a ν(O-H) mode of $[(C_2H_5)_2O\cdots H\cdots O(C_2H_5)_2]^+SbCl_6^-$ by analogy with a protonated water dimer.[27] This band was absent for the 1:1 complex ($[(C_2H_5)_2OH]^+SbCl_6^-$). Therefore, the band at 1527 cm^{-1} is considered to be a characteristic band of the protonated dimer species, **1**.



1

The presence of the protonated dimer species, $(C_2H_5OH)_2H^+$, has previously been indicated by the solid-state MAS NMR study of the present authors.[14] Note that six ether or ethanol molecules per anion correspond to two molecules per proton. The fact that this band was not observed for ethanol adsorbed on $Cs_3PW_{12}O_{40}$ as for diethyl ether adsorbed on Al_2O_3 or SiO_2 is reasonable, since these oxides do not have Bronsted-acid sites. The absence (because of a shift to a lower wavenumber) of the 1527 cm^{-1} band for $D_3PW_{12}O_{40}\cdot 6C_2H_5OD$ and $D_3PW_{12}O_{40}\cdot 6(C_2H_5)_2O$ is also consistent with the above assignment.

The positions of the ν(C-H) bands (2985, 2939, 2900, and 2873 cm^{-1}) observed for $H_3PW_{12}O_{40}\cdot 6(C_2H_5)_2O$ were very similar to those of $(C_2H_5)_2O$ in CCl_4 (2980, 2935, 2897, and 2868 cm^{-1})[18] and in the $(C_2H_5)_2O$-$AlCl_3$ complex (2983, 2940, and 2877 cm^{-1}).[28] However, the relative intensities of these bands were quite different. The $\nu_s(CH_2)$ band (2868 cm^{-1}) is more intense than the $\nu_{deg}(CH_3)$ band (2980 cm^{-1}) for $(C_2H_5)_2O$ in CCl_4, while the $\nu_{deg}(CH_3)$ band is stronger for $(C_2H_5)_2O$-$AlCl_3$. The suggested reason why $\nu_s(CH_2)$ in $(C_2H_5)_2O$-$AlCl_3$ is weak is a stronger electron-withdrawing effect of $AlCl_3$, which destabilizes the dipolar contribution to the C-H bond of the CH_2 group.[29] In the case of $H_3PW_{12}O_{40}\cdot 6(C_2H_5)_2O$, the relative intensity was similar to $(C_2H_5)_2O$-$AlCl_3$ (Fig. 6a). This supports the formation of $[(C_2H_5)_2O]_2H^+$. From these results, we can propose the following model.



Dimer model

Since the XRD pattern, which mainly reflects the secondary structure of the polyanion packing, was very similar for $H_3PW_{12}O_{40}\cdot 6C_2H_5OH$ and $H_3PW_{12}O_{40}\cdot 6H_2O$,[14] the structure of $H_3PW_{12}O_{40}\cdot 6C_2H_5OH$ indicated above may be reasonable.

The δ(C-H), ν(O-D), and δ(O-D) region of $D_3PW_{12}O_{40}\cdot nC_2H_5OD$ can be examined in more detail because there is no overlapping of the bands in this region. The intensities of the ν(C-H) band and the δ(C-H) bands were not proportional to the concentrations of ethanol (Fig. 7a, c). Moreover, the intensities of the bands at 1442 cm^{-1} ($\delta_{deg}(CH_3)$) and 1388 cm^{-1} ($\delta_s(CH_3)$ $+w(CH_2)$) relative to the 2981 cm^{-1} band ($\delta_{deg}(CH_3)$) changed significantly with the n, as is shown in Fig. 9. Higuchi et al. have reported that the

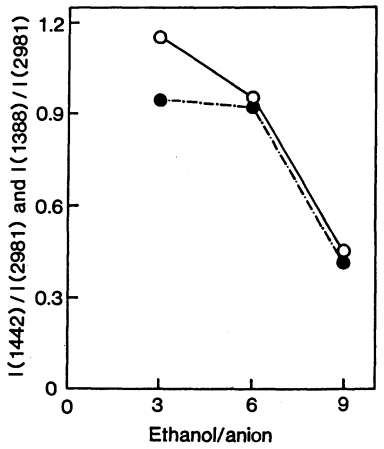


Fig. 9. Changes of the peak intensity of the 1442 (○) and 1388 (●) cm^{-1} relative to the 2981 cm^{-1} band as a funtion of the amount of C_2H_5OD absorbed into $D_3PW_{12}O_{40}$. I(1388), I(1442), and I(2981) are the integrated peak intensities of the bands at 1388, 1442, and 2981 cm^{-1}, respectively.

intensities of ν(C-H) and δ(C-H) of the methyl group of CH_3I varied greatly depending on the polarities of the solvents.[30] The changes in Fig. 9, together with the nonproportionality (Fig. 7a, c), suggest that the CH_3 group interacts with heteropoly anions and that the interaction becomes stronger as the amount of the absorption of ethanol decreases.

Transformations of Molecules during Thermal Desorption. When $H_3PW_{12}O_{40}\cdot 6(C_2H_5)_2O$ was heated at 55—75 °C in a vacuum, the characteristic band of $[(C_2H_5)_2O]_2H^+$ (at 1527 cm^{-1}) disappeared, while the frequencies of the δ(C-H) bands did not change (Fig. 6b). The species formed is probably a monomer of protonated diethyl ether, since the IR spectrum was very similar to that of $[(C_2H_5)_2OH]^+SbCl_6^-$.[26] Therefore, it is concluded that $[(C_2H_5)_2O]_2H^+$ (dimer) was transformed to $(C_2H_5)_2OH^+$ (monomer) upon the heat treatment at 55 °C.

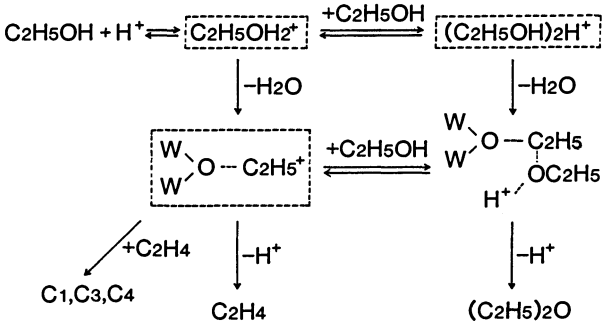
As is shown in Fig. 6b, the evacuation at 100—150 °C brought about significant changes in the δ(C-H) bands, indicating that the monomer of protonated ether was transformed to another species. Correspondingly, the $\nu_{deg}(CH_3)$ band distinctly shifted from 2985 cm^{-1} (75 °C) to 2954 cm^{-1} (Fig. 6a). These spectral changes are due to the formation of ethoxide formed on the polyanion (C_2H_5O), which was previously detected by NMR.[14] The large shift of the $\nu_{deg}(CH_3)$ band from 2980 cm^{-1} to a lower frequency is often observed upon the formation of alkoxide—for example, the shifts of C_2H_5O-Mg to 2950 cm^{-1},[31] of C_2H_5O-Al to 2959 cm^{-1},[32] and of C_2H_5O-Ca to 2945 cm^{-1}.[31]

This assignment is confirmed by ^{13}C NMR. As is shown in Fig. 8, only one species (14.3 and 82.1 ppm) remained after $H_3PW_{12}O_{40}\cdot nC_2H_5OH$ was heated at 150 °C, and the ^{13}C chemical shifts are close to those of

$-OCH_2CH_3$ in $(CO)_5WC(OCH_2CH_3)CH_3$: δ 80.4 for α-carbon (CH_2) and δ 14.6 for β-carbon (CH_3).[33] Moffat et al. have claimed, on the basis of the IR data, the formation of an isopropyl group during the thermal desorption of ethanol from $H_3PW_{12}O_{40}$.[12] The bands at 2954, 2924, and 2897 cm^{-1} (Fig. 6a) are also consistent with the isopropyl group (2950, 2936 cm^{-1})[34] and with tertiary CH (2890 cm^{-1}).[35] However, the species responsible for the spectrum b in Fig. 8 may not be an isopropyl group, for the following reasons. First, it is not probable that isopropyl group, which is a polymerization-decomposition product of ethanol, was formed as a single species. Secondly, the ^{13}C chemical shifts of CH_3 of ethanol and diethyl ether (δ 17.6 and 16.4, respectively) are much closer to that in Fig. 8b than are those of isopropyl alcohol and diisopropyl ether (δ 25.1 and 24.3, respectively).[36] It must be considered that the CH_3 group usually shows much smaller shifts than the CH_2 group.[36] Therefore, the species formed by heating at 150 °C is assignable to ethoxide on the heteropoly anion.

It should be noted that this species showed the peak of α-carbon (δ 82.1) downfield from tungsten ethoxide, $W(OC_2H_5)_6$ (δ 69.8).[37] Olah et al. reported that the isopropyl cation in a superacid solution showed a peak at δ 320.6,[38] while the peak of $W(O\text{-}i\text{-}Pr)_6$ appeared at δ 76.1.[37] This suggests that the ethyl cation should have a peak greatly downfield from the ethoxide, although it has not been detected by NMR. Thus, the species at δ 82.1 is considered to be the ethoxy group, the ethyl group of which has a more cationic character than does ordinary ethoxide.

On the basis of these results, we propose the following scheme for the thermal desorption of ethanol absorbed in $H_3PW_{12}O_{40}$.



Reaction scheme

The authors wish to thank Drs. Shin-ichi Nakata and Sachio Asaoka (Chiyoda Chemical Engineering & Construction Co., Ltd.) for the solid-state NMR measurements and for their helpful discussions. The present work was supported in part by a Grant-in-Aid for Scientific Research (No. 6247007) from the Ministry of Education, Science and Culture and the Asahi Glass Foundation.

Novel Effects of K-Addition to Ru/SiO_2 on Conversion of Cyclohexane

Zheng-Zhong LIN,† Toshiyuki ENOMOTO,†† Toshio OKUHARA,* and Makoto MISONO

(Received December 5, 1988)

The effects of the addition of alkalis to a Ru/SiO_2 catalyst upon the conversion (hydrogenolysis and dehydrogenation) of cyclohexane, hydrogenolysis of butane, and hydrogenations of benzene and CO were studied. The addition of K or Cs slightly enhanced the catalytic activity for the hydrogenolysis of cyclohexane, whereas dehydrogenation to benzene was markedly suppressed. This result is contrary to the effect of the addition of Cu or Au to group-VIII metals, as reported in the literature. Changes in the activities became less significant as the atomic number of the added alkali decreased. From a systematic examination by varying the alkali content, it was revealed that dehydrogenation and CO hydrogenation were very sensitively suppressed by an electronic effect imposed by the alkalis, whereas changes in the activities of hydrogenolysis and benzene hydrogenation were not great.

Practically important heterogeneous catalysts are often modified by alkali metals.[1,2] K_2O in doubly promoted Fe catalysts for ammonia synthesis and Cs in a Ag catalyst for the epoxidation of ethylene are typical examples.[2] There have been many fundamental studies on the enhancement of the activities and selectivities by the addition of alkali. Regarding activity, K to Ru in ammonia synthesis,[3] Na or K to Ni/SiO_2-Al_2O_3 in methanation reaction,[4] and Li to Pd/SiO_2 in methanol synthesis[5,6] were effective.

The selectivity is also improved by the addition of alkali. In a Fischer-Tropsch synthesis, the modification of Ru by alkali greatly increased the olefin/paraffin ratios in the product hydrocarbons.[7,8] K to Rh/TiO_2[9] or Mo/SiO_2 increased C_2-oxygenated products[10] or higher alcohols[11] from the $CO+H_2$ reaction.

Alloying also brings about changes in both the activity and selectivity. Sinfelt et al.[12] reported that the addition of Cu to Ni markedly suppressed the hydrogenolysis of ethane, but did not change the rate of dehydrogenation of cyclohexane. Also, it has been shown by Ponec et al.[13] that the hydrogenolysis reaction was sensitively affected by the Pt content of the $Pt-Au/SiO_2$ catalyst. SMSI (Strong Metal-Support Interaction) caused a change in the activities of hydrogenolysis and dehydrogenation. Resasco and Haller[14] found that hydrogenolysis was suppressed by a high-temperature reduction, while dehydrogenation was only slightly influenced.

IR[7,15] and XPS[16] studies have shown that K (probably as K_2O) on Ru/Al_2O_3 or Ru/SiO_2 acts as a base capable of electron-donating to Ru. On the other hand, Li exhibited a different effect from K;[17] the addition of Li to Ru/SiO_2 effectively suppressed methane formation in CO hydrogenation without any great decrease in activity, while K significantly decreased the activity while not suppressing methane formation. It was concluded that a Li compound on Ru particles brought about a geometrical effect similar to an ensemble effect, rather than an electronic effect.

Contrary to CO hydrogenation, so far there are very few reports about the effect of alkali on the conversion of hydrocarbons, such as hydrogenolysis and dehydrogenation. We have preliminarily reported that K to Ru/SiO_2 appreciably enhances the activity for the hydrogenolysis of cyclohexane, but completely suppresses dehydrogenation.[18] Since it has been reported that the addition of Au to Pt,[19] Ru to Pt,[20] and Cu to Ru[21] preferentially enhances the dehydrogenation of cyclohexane, the effect of K observed here is novel. In order to elucidate this novel effect, we systematically examined the effects of various alkalis added to a Ru/SiO_2 catalyst on several reactions such as the conversion of cyclohexane, the hydrogenolysis of butane, and hydrogenations of benzene and CO.

Experimental

Materials. Silica (Aerosil 200, 160 $m^2 \cdot g^{-1}$) was used as a support after being calcined at 773 K in air for 20 h. The Ru/SiO_2 catalyst, which contained 2.5 wt% of Ru, was prepared by incipient-wetness impregnation with an aqueous solution of $RuCl_3$. It was then dried at 373 K for 10 h and reduced at 723 K in flowing H_2 for 2 h. Alkali-promoted Ru/SiO_2 catalysts were prepared in two different ways, as described previously.[17] The first catalysts were obtained as follows. SiO_2 was impregnated with an aqueous solution of an alkali carbonate. It was then calcined at 773 K for 10 h in air, and was again impregnated with an aqueous solution of $RuCl_3$. The product was dried at 373 K and reduced at 723 K in flowing H_2 for 2 h. The loading amount of Ru was fixed to 2.5 wt%, and the alkali content (defined as M/(M+Ru) in atom basis, M=alkali) was changed from 0.20 to 0.82. Hereafter, these catalysts will be designated as, e.g., Ru-Li(0.20)/SiO_2, where the figure in the parenthesis is the alkali content. The second catalysts were obtained by impregnating the reduced Ru/SiO_2 with an aqueous solution of alkali carbonate. These were dried at 373 K and reduced at 723 K in flowing H_2. These will be

† Present address: Nippon Oil Company, Ltd., 8 Chidoricho, Naka-ku, Yokohama, Kanagawa 231.

designated as, e.g., K(0.2)-Ru/SiO_2. As references, 1 wt% K/SiO_2 and 0.18 wt% Li/SiO_2 were prepared from K_2CO_3 and Li_2CO_3, respectively.

Butane and CO in a glass cylinder were obtained from Takachiho Chem. Co., Ltd. The butane was purified by a freeze-thaw cycle prior to the reaction. The cyclohexane and benzene were purchased from Nakarai Chemicals, Co. and used without any treatment.

Apparatus and Procedure. The adsorption of H_2 was volumetrically measured after the catalysts were reduced with H_2 at 723 K for 2 h, as in the previous work.[22] A chemisorption measurement was carried out at room temperature in a static system (60 cm^3). The total uptakes of hydrogen were measured after the H_2 pressure became constant (in about 1.5 h). The equilibrium H_2 pressure was adjusted to about 60 Torr (1 Torr=133.3 Pa). Hydrogenations of benzene and the conversion of cyclohexane (hydrogenolysis and dehydrogenation) were carried out in a conventional flow reactor under 1 atm. In the case of benzene hydrogenation, a mixture of benzene and hydrogen (1:6 in molar ratio) was supplied at 358 K just after the catalysts were reduced at 723 K for 2 h in flowing H_2. The benzene and cyclohexane produced were analyzed by using a Methoxy PEG column (4 m, 4 mm of inside diameter, 473 K).

In the case of the conversion of cyclohexane, a mixture of cyclohexane and hydrogen (1:5) was introduced to the catalysts at 573 K. Benzene was analyzed by a Methoxy PEG column; the C_1—C_6 hydrocarbons produced were analyzed by an FID gas chromatograph (Yanagimoto GC 2800) using a Porapak R column (1.5 m, 2 mm of inside diameter), the temperature of which was increased from 323 to 473 K at a rate of 2 K s^{-1}.

The hydrogenolysis of butane was carried out in a closed circulation system (volume; 250 cm^3). Prior to the reaction, the catalysts were reduced at 723 K in H_2 (300 Torr) for 2 h. A mixture of butane (50 Torr) and H_2 (100 Torr) was introduced to the catalysts at 373 K. The product hydrocarbons were analyzed by a gas chromatograph with a VZ-10 column. Hydrogenation of CO was performed in a flow reactor under 1 atm pressure at 533 K, as described previously.[17]

Results

Adsorption of H_2. Data regarding H_2 adsorption are given in Table 1. No H_2 was adsorbed on SiO_2, K/SiO_2, and Li/SiO_2. Here, the dispersion of Ru is expressed by H/Ru (the amount of hydrogen atom adsorbed divided by the amount of Ru atom in the catalyst), assuming that one H atom is adsorbed on one exposed Ru atom. It was observed that the dispersion decreased as the content of alkali increased for the Ru-M/SiO_2 systems (M=alkali).[17] For example, the dispersion of Ru on Ru-Li(0.82)/SiO_2 was one-third that of Ru/SiO_2. K-addition caused greater decreases in the dispersion than Li-addition.

Hydrogenolysis of Butane. The hydrogenolysis of butane was carried out over Ru/SiO_2 and Ru-Li/SiO_2. The product composition was independent of the conversion levels (<80%) over these catalysts, showing that the distributions of the carbon number of the products are of the primary products. The influence of the Li content on the activity and selectivity are given in Table 2. The catalytic activity per unit weight of Ru was almost independent of the Li content, although H/Ru decreased as the Li content increased (Table 1). For all the catalysts given in Table 2, the main product was ethane, which constituted about 50 mol% of the products; the mole fraction of methane slightly increased as the Li content increased.

Hydrogenation of Benzene. The product was only cyclohexane at 358 K for all catalysts. The conversion of benzene gradually decreased with the reaction time and reached stationary values after 1.5 h, which were about one half of the initial conversions. The catalytic activities were calculated from the stationary conversions. The conversions were adjusted to be less than 40% by controlling the flow rate and the catalyst weight. Table 3 shows the effects of Li, Na, and K on the activity. The reaction rate decreased as the contents of alkali increased. The effect of K was

not significant when the K content was less than 0.60. However, the activity decreased to 1/20 at a K content of 0.82. This decrease caused by Li was not significant, even at a Li content of 0.82.

Conversions of Cyclohexane. At 573 K, Ru/SiO_2 produced both benzene (dehydrogenation) and C_1—C_6 hydrocarbons (hydrogenolysis) in this reaction. The main product of the hydrogenolysis was methane (about 90%). The conversions of both reactions gradually decreased with the reaction time without marked changes in selectivity. Then, the conversions reached stationary values (about half that of the initial conversion) after about 1.5 h. Similar changes in the conversions were obtained for alkali-added catalysts.

Table 4 shows the activities and selectivities obtained at the stationary states. For all catalysts, the selectivity was measured at a conversion level of less than 30%. As shown in Table 4, the activities for hydrogenolysis were almost independent of the Li content, which is the same trend as was observed for the hydrogenolysis of butane (Table 2). On the other hand, dehydrogenation to benzene decreased significantly as the Li content increased. Contrary to this, the presence of K or Cs enhanced the hydrogenolysis. It is remarkable that the formation of benzene was completely suppressed by K or Cs.

In Fig. 1, the effects of K on the conversions of cyclohexane are given; the results of K-Ru/SiO_2 as well as Ru-K/SiO_2 are plotted. It is clear that hydrogenolysis was accelerated by the addition of K at a content level varying from 0.2 to 0.5. This trend was the same in the two different preparation methods.

The effects of the kinds of alkali are illustrated in Fig. 2, where the content of alkali was 0.2. The addition of Cs accelerated the hydrogenolysis, while Li and Na showed little effect. In contrast, the activity for benzene formation decreased monotonically as the atomic number of alkali increased.

Figure 3 shows the effects of the K content on TOF (turnover frequency), where TOF was defined as the number of molecules reacted per exposed Ru atom per second. The TOF of CO hydrogenation, obtained previously,[17] is also plotted in this figure. From Fig. 3, the reactions may be classified into two groups. The first group includes the hydrogenation of benzene and the hydrogenolysis of cyclohexane. In this group the changes of TOF were not significant, that is, within one order of magnitude. The dehydrogenation of

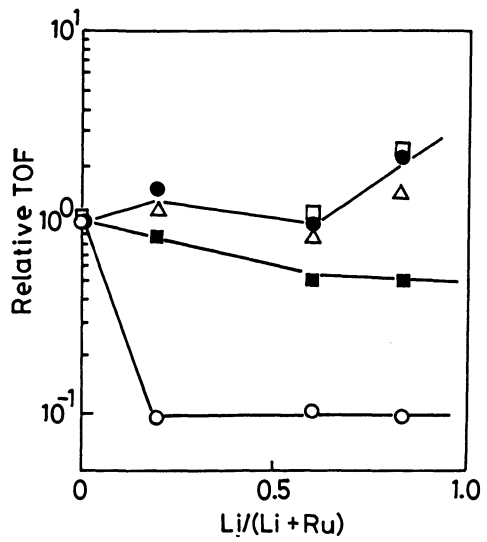

Fig. 4. Changes of TOF of various reactions as a function of Li content in Ru-Li/SiO_2.
O: $CO+H_2$, ●: hydrogenolysis of cyclohexane, ■: dehydrogenation of cyclohexane, △: hydrogenation of benzene, □: hydrogenolysis of butane.

cyclohexane and the CO hydrogenation belong to the second group. The rates of these reactions were markedly suppressed by the addition of K.

In Fig. 4, the effects of Li are summarized. Similarly to the case of K, the TOF's of CO hydrogenation and dehydrogenation of cyclohexane decreased and those of hydrogenolysis of cyclohexane and butane increased as the alkali content increased. However, these changes in both reaction groups were distinctly smaller than in the case of K.

Discussion

The dehydrogenation of cyclohexane is an important reaction involved in the reforming process. Recent studies have shown that the addition of Au to Pt[19] or Cu to Ru(0001)[23] results in enhanced catalytic activities for the formation of benzene from cyclohexane. Miura et al.[20] also observed an enhancement in dehydrogenation and a suppression of hydrogenolysis upon Pt-addition to Ru/SiO_2. However, there has been no report on the effect of alkali-addition for this reaction.

Notable points concerning the present results are (1) the addition of K or Cs enhanced the activity for the hydrogenolysis of cyclohexane, while dehydrogenation to benzene was completely suppressed and (2) the activity changes caused by the alkali depended markedly on both the kinds of alkali and the kinds of reaction. The first result is in contrast with those of the bimetallic catalysts described above.

Effect of K on Conversion of Cyclohexane. Goodman et al.[23] reported that the dehydrogenation of cyclohexane over Ru was enhanced by surface overlayers of carbon or Cu. Over fresh Ru(0001) surface, only hydrogenolysis took place, and benzene (dehydrogenation) began to be formed after an induction period. During this period, a surface layer of carbon was gradually formed, and the dehydrogenation rates increased, indicating that the carbonaceous layer is necessary for benzene formation. On the other hand, the hydrogenolysis rates decreased as the amount of carbon increased. Therefore, the carbonaceous layer effectively suppresses the C-C bond scission of cyclohexane. Goodman et al.[23] also showed that Cu on Ru(0001) played a role similar to that of the carbonaceous layer. Over Cu/Ru(0001), of which Ru(0001) was precovered with submonolayer quantities of Cu, benzene was formed from the beginning of the reaction and the hydrogenolysis reaction did not take place.

If, as described above, the carbonaceous layer is necessary for benzene formation and acts as a poison for the hydrogenolysis reaction, it may be concluded that K suppresses the formation of the carbonaceous layer.

Acceleration of C-C Bond Scission. As shown in Table 1, the addition of K or Cs gave rise to a decrease in dispersion. Therefore, an increase in the activity for the hydrogenolysis (in the unit of per weight of Ru) is not due to an increase in the number of active sites. A certain step of the hydrogenolysis reaction must have been accelerated by the addition of K or Cs. It is accepted for the hydrogenolysis reaction that a hydrogen-deficient species is formed in the initial step by a scission of the C-H bond; subsequently, the C-C bond is broken, and finally the hydrocarbon fragments, thus formed, are hydrogenated.[24-27] Over metallic catalysts, the scission of the C-H bond and

the hydrogenation of hydrocarbon fragments are considered to be rapid. Therefore, the rate-determining step is presumably the C-C bond breaking.[27,28] Since K really increased the rates of hydrogenolysis, K must have accelerated the C-C bond breaking step. Probably the carbonaceous layer was not formed on Ru/SiO_2 promoted by K due to the rapid C-C bond breaking.

Effect of Kinds of Alkali. As shown in Fig. 2, the suppression of dehydrogenation and the enhancement of hydrogenolysis became more significant as the atomic number of alkali increased. If one considers the fact that the ability of electron donation of the alkali cation M^+ and/or M_2O, increases as the atomic number increases,[1,2] the results in Fig. 2 may be considered to be mainly brought about by the electronic effects of the alkali. As a matter of fact, the IR band positions of the CO adsorbed on Ru/SiO_2 were not affected by the addition of Li, but these shifted considerably to lower frequencies upon the addition of K.[17] In addition, electron transfer from K to Ru in XPS measurements of Ru/SiO_2[16] and by the IR band positions of the CO or NO adsorbed on Ru/Al_2O_3.[7,15]

A comparison of Figs. 3 and 4 makes clear the influence of the electronic effect on the various kinds of reactions. Although the TOF of the CO hydrogenation decreased by the addition of both Li and K, the decrease was remarkable for K, showing that CO hydrogenation was strongly influenced by an electronic effect.[7] Since H_2 adsorption data indicated that Li and K covered the Ru particles to a similar extent,[17] these alkalis probably bring about similar ensemble effects. Actually, the addition of Cu to Ru also resulted in a great decrease in the rate of CO hydrogenation by the ensemble effect.[29] Thus, the greater effect of K may be due to its stronger electronic effect.

Interactions between the Tris(1,10-phenanthroline)iron(II) Cation and Anionic Surfactants: Diffusion and Conductance Studies

Toshihiro TOMINAGA,* Toru MARUYAMA, Takayuki KOSHIBA, and Yuroku YAMAMOTO†
Department of Applied Chemistry, Okayama University of Science, 1-1 Ridai-cho, Okayama 700
†Environmental and Safety Engineering Department, Fukui Institute of Technology, 3-6-1 Gakuen, Fukui 910
(Received December 7, 1988)

Tracer diffusion coefficients for the $[Fe(phen)_3]^{2+}$ cation (phen=1,10-phenanthroline) have been measured in aqueous solutions of sodium 1-hexane-, 1-octane-, 1-decane-, and 1-dodecanesulfonate (NaDSO) in concentration ranges below the critical micelle concentrations of the surfactants and at 298.2 K. The diffusion coefficient decreases with an increase in the concentration of the surfactants. At a fixed concentration, the diffusion coefficient decreases with an increase in the carbon number of the surfactants. The results are compared with our previous results in sodium dodecyl sulfate (NaDS) solutions. The conductivities of the NaDSO and NaDS solutions were also measured at 298.2 K in the presence and absence of $[Fe(phen)_3]SO_4$. In the presence of $[Fe(phen)_3]SO_4$, the molar conductivities of the surfactants first decrease, then increase, and finally decrease again with an increase in the concentration of the surfactants.

Metal chelate ions of 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy) are known to be hydrophobic.[1,2] When counter ions are hydrophobic, such ions are extracted into water-immiscible organic solvents. Particularly, the red-colored chelate ions of iron(II) have been used extensively in analytical chemistry.[3] In recent years, there has been considerable interest in the reactions of these ions in aqueous surfactant media, i.e., racemization and dissociation reactions,[4] photochemical reactions,[5-8] and electron-transfer or electrochemical reactions.[9]

The elucidation of the solute-solute interactions between these metal chelate ions and other hydrophobic ions is important for an understanding of the reactions of these ions. Our previous study of the tracer diffusion of $[Fe(phen)_3]^{2+}$ in aqueous solutions showed that the hydrophobic interaction between $[Fe(phen)_3]^{2+}$ and $[Ni(phen)_3]^{2+}$ reduced the translational diffusivity of $[Fe(phen)_3]^{2+}$.[10] Furthermore, we found that the tracer diffusion coefficient of $[Fe(phen)_3]^{2+}$ in water decreases greatly in the presence of sodium dodecyl sulfate (NaDS), even when the concentration of the latter is below its critical micelle concentration (cmc).[11]

We wish to report here the tracer diffusion coefficients for $[Fe(phen)_3]^{2+}$ in aqueous solutions of sodium 1-hexane-, 1-octane-, 1-decane-, and 1-dodecanesulfonate (NaHSO, NaOSO, NaDeSO, and NaDSO respectively), and the results will be compared with those in NaDS solutions. We also wish to report the conductivities of the $[Fe(phen)_3]SO_4$-NaDSO and $[Fe(phen)_3]SO_4$-NaDS systems.

Experimental

Materials. Reagent-grade Mohr's salt $[FeSO_4(NH_4)_2SO_4 \cdot 6H_2O]$, 1,10-phenanthroline monohydrate, $NiSO_4 \cdot 6H_2O$, $NaClO_4 \cdot H_2O$ (Wako Pure Chemicals), NaHSO, NaOSO, NaDeSO, (Tokyo Chemical Industry), and NaDS (BDH)[12,13] were used as received. The NaDSO (Tokyo Chemical Industry; ion-pair-chromatography grade) was recrystallized from an ethanol-methanol (5:1) mixture. The water was distilled twice. A stock solution of $[Ni(phen)_3]SO_4$ was prepared by mixing $NiSO_4 \cdot 6H_2O$ and phen$\cdot H_2O$ in water. A stock solution of $[Fe(phen)_3]SO_4$ was prepared by mixing $[Fe(phen)_3](ClO_4)_2$ with the sulfate form of an anion exchanger in water, after $[Fe(phen)_3](ClO_4)_2$ had been prepared from Mohr's salt, phen$\cdot H_2O$, and $NaClO_4 \cdot H_2O$.[10]

Measurements. The diffusion measurements were made by the Taylor dispersion method.[14] In this method, a small amount of a solution is injected into a solvent flowing through a capillary tube. The solute is dispersed along the tube as a result of a combination of convection and molecular diffusion. By detecting the concentration profile at the end of the stream, we can calculate the diffusion coefficient. The solvent contained a specified amount of a surfactant plus 0.1 mM (1 M=1 mol dm^{-3}) $[Ni(phen)_3]SO_4$, while the solution contained the same amount of the surfactant plus 0.1 mM $[Fe(phen)_3]SO_4$. The concentration profile of $[Fe(phen)_3]^{2+}$ was detected by the absorption at 510 nm using a spectrophotometric detector for HPLC (either Japan Spectroscopic Co., Model UVIDEC-100-IV or Waters, Model 490). The other details have been described elsewhere.[10,11,15]

The conductivities of the solutions were measured at 5 kHz by means of a linear-bridge conductometer[16] (Huso, Model 360B) in an oil thermostat controlled to ± 0.005 K. Two conductivity cells were used: either a 500-cm^3 Kraus-type cell[17] with a cell constant of 0.3575 cm^{-1} or a 10-cm^3 cell with a cell constant of 2.464 cm^{-1}. Most of the measurements were made with the 500-cm^3 cell. A solvent was introduced into the cell, nitrogen gas was bubbled through when the solvent was pure water, and the cell with a solvent was weighed. A weighed amount of a solid solute was added after each resistance measurement under a nitrogen atmosphere. Some of the measurements on the concentrated solutions were, however, made by using the 10-cm^3 cell, where solutions were prepared by weight separately and transferred into the cell. The densities of some of the solutions were measured by means of a single-neck pyc-

nometer to calculate the molar concentrations.

Results

Table 1 shows the diffusion coefficients of the $[Fe(phen)_3]^{2+}$ ion in sodium 1-alkanesulfonate solutions. Each value is the average of more than five measurements. The diffusion coefficients we measured are the interdiffusion coefficients between $[Fe(phen)_3]^{2+}$ and $[Ni(phen)_3]^{2+}$. If we assume that the diffusion coefficients of $[Fe(phen)_3]^{2+}$ and $[Ni(phen)_3]^{2+}$ are essentially the same, the results may be taken as the intradiffusion coefficients[18] of $[M(phen)_3]^{2+}$, M being Fe or Ni. Because the concentration of the $[M(phen)_3]^{2+}$ ions (0.1 mM) is low compared to those of the surfactants, the results obtained can be considered as the tracer diffusion coefficients.

In Fig. 1, the diffusion coefficient is plotted as a function of the surfactant concentration. Our previous results in NaDS solutions[11] are included in the figure. As the surfactant chain length increases, the diffusion coefficient decreases, reflecting the interactions between $[Fe(phen)_3]^{2+}$ and the surfactant anions. Note that the concentrations of the surfactants are no greater than their cmc values except for the two solutions of NaDS (10 and 20 mM).[19,20] Figure 2 shows the Stokes radius, which was calculated from

$$r_S = \frac{kT}{6\pi\eta D}, \quad (1)$$

where k is Boltzmann's constant, T is the absolute temperature, and η is the viscosity of the solvent, for which we used the value for pure water.[21] Many workers have studied the NaDS diffusion coefficient using different techniques; the Stokes radius for the micelles at cmc is 2.2—2.5 nm.[22] Although we do not have data for NaDeSO, the Stokes radius for sodium decyl sulfate (NaDeS) micelles at the cmc has been reported to be 1.98 nm in 0.1 M NaCl.[23] Thus, even in the premicellar concentration range, in NaDS and NaDSO solutions, the Stokes radius of $[Fe(phen)_3]^{2+}$ is larger than that of the NaDS micelles; in 30 and 40 mM NaDeSO solutions, the Stokes radius of $[Fe(phen)_3]^{2+}$ is close to that of the NaDeS micelles.

In order to obtain more information, we measured the conductance of solutions. The molar conductivities of NaDSO and NaDS in water and $[Fe(phen)_3]SO_4$ solutions were calculated from

where κ is the conductivity of the solution, κ_0 is the conductivity of the solvent (i.e., either water or a $[Fe(phen)_3]SO_4$ solution without surfactant), and C is the molarity of the surfactant. The molar conductivities of NaDSO and NaDS are listed in Tables 2 and 3 respectively; they are plotted as a function of the surfactant concentration in Fig. 3.

In the presence of $[Fe(phen)_3]SO_4$, the molar conductivity of NaDSO decreases, passes through a minimum, and increases again with an increase in the concentration of NaDSO. This tendency becomes more marked with an increase in the concentration of $[Fe(phen)_3]SO_4$. Measurement in higher concentrations of NaDSO was not possible because the Krafft temperature of NaDSO is high (306 K).[20] In the case of NaDS, when we add the surfactant to a solution of $[Fe(phen)_3]SO_4$, a precipitate of $\{[Fe(phen)_3](DS)_2\}_n$

a) These measurements were made using a 10-cm^3 cell. See text for more details.

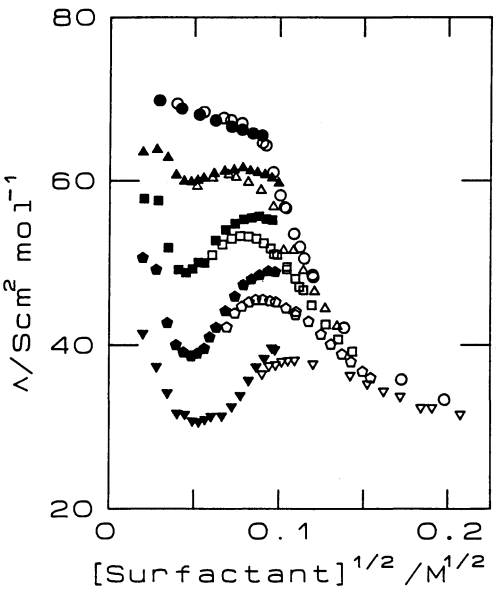

Fig. 3. Molar conductivities of NaDSO (closed symbols) and NaDS (open symbols) in water and aqueous $[Fe(phen)_3]SO_4$. Concentrations of $[Fe(phen)_3]SO_4$ are 0 mM (● and ○), 0.2 mM (▲ and △), 0.5 mM (■ and □), 1 mM (⬟ and ⬠), and 2 mM (▼ and ▽).

appears; this precipitate is then resolubilized by the further addition of NaDS.[24,25] For example, in the case of 0.2 mM $[Fe(phen)_3]SO_4$, we found that a precipitate appears when the NaDS concentration is 0.13 mM and that it is resolubilized when the NaDS concentration reaches 2.1 mM. The results shown in Fig. 3 are in NaDS concentration ranges higher than the resolubilization points. In this case, we made measurements also in the NaDS concentrations above the cmc. With an increase in the concentration of NaDS, the molar conductivity increases, passes through a maximum, decreases, and finally approaches that in pure water.

Discussion

When $[Fe(phen)_3]SO_4$ and a surfactant NaA are mixed, the reaction which takes place may be written as:

$$x[Fe(phen)_3]^{2+} + yA^- + zNa^+ \leftrightarrows Na_z[Fe(phen)_3]_xA_y^{(y-2x-z)-}. \quad (3)$$

As we noted earlier, in 3—8 mM NaDS and 3—7 mM NaDSO the Stokes radius of $[Fe(phen)_3]^{2+}$ is larger than that of the NaDS micelles. However, the conductance results do not show the existence of normal micelles in these concentration ranges. As may be seen in Fig. 3, even in 0.2 mM $[Fe(phen)_3]SO_4$ the molar conductivities of NaDS and NaDSO are much higher than that of NaDS above the cmc. (Note that the concentration of $[M(phen)_3]^{2+}$ was 0.1 mM in the diffusion measurements.) A similar conclusion has been reached on the basis of surface-tension and light-scattering measurements.[24]

The Stokes radius may reflect electrostatic interactions as well as the size of the premicellar aggregates. The electrostatic interaction is reduced when a salt is added. Even when Na_2SO_4 was added to 3 mM NaDS, the Stokes radius of $[Fe(phen)_3]^{2+}$ was still larger than that of the NaDS micelles.[11] In a 3 mM surfactant solution, the molar ratio of the surfactant to $[Fe(phen)_3]^{2+}$ is 30. If the size of an aggregate is larger than that of an NaDS micelle which contains 60 monomers, the value of x in Eq. 3 has to be larger than 2. From a luminescence-quenching study, it has been reported that $[Ru(bpy)_3]^{2+}$ forms premicellar "clusters" with NaDS which contain several $[Ru(bpy)_3]^{2+}$.[5]

The fact that there is precipitate-formation between $[Fe(phen)_3]^{2+}$ and DS^-, but not between $[Fe(phen)_3]^{2+}$ and DSO^-, together with the fact that there is a lower diffusion coefficient for $[Fe(phen)_3]^{2+}$ in NaDS than in NaDSO (Fig. 1), suggests a stronger interaction between $[Fe(phen)_3]^{2+}$ and DS^- than between $[Fe(phen)_3]^{2+}$ and DSO^-. Just above those concentrations, where the precipitate $\{[Fe(phen)_3](DS)_2\}_n$ is resolubilized, the molar conductivities of NaDS are only slightly lower than those of NaDSO, as if the system has lost the memory that it has had a precipitate. This is in contrast to the definitely smaller diffusion coefficient of $[Fe(phen)_3]^{2+}$ in NaDS than in NaDSO (Fig. 1). In the case of diffusion, we are looking at the movement of $[Fe(phen)_3]^{2+}$ ions. Because the concentration of $[Fe(phen)_3]^{2+}$ is small almost all $[Fe(phen)_3]^{2+}$ ions are considered to be in premicellar aggregates, and the diffusion coefficient of $[Fe(phen)_3]^{2+}$ is essentially that of the aggregates; thus, it is sensitive to the aggregate size.

In the case of conductivity, the situation is more complicated. Below the cmc of a surfactant NaA, the molar conductivity of the surfactant can be expressed by

$$\begin{aligned}\Lambda(\mathrm{NaA}) = \{&[C_t(\mathrm{NaA}) - \Delta C(\mathrm{Na^+})]\lambda(\mathrm{Na^+}) \\ &+ [C_t(\mathrm{NaA}) - \Delta C(\mathrm{A^-})]\lambda(\mathrm{A^-}) \\ &- 2[\Delta C([\mathrm{Fe(phen)_3}]^{2+})]\lambda([\mathrm{Fe(phen)_3}]^{2+}) \\ &+ (y-2x-z)[\Delta C(\mathrm{A^-})/y]\lambda(\mathrm{aggregate})\}/[C_t(\mathrm{NaA})], \end{aligned} \quad (4)$$

where "aggregate" refers to the right-hand side of Eq. 3, $C_t(X)$ means the total molar concentration of X in the solution, $\Delta C(X)$ means the molar concentration of X in the aggregates, and $\Lambda(X)$ or $\lambda(X)$ means the molar conductivity of X, expressed as the (X/valency) molar unit, i.e., the equivalent conductivity. In other words, the molar conductivity of NaA, as calculated from Eq. 2, has contributions from: 1) the free ions of Na^+ and A^-, 2) the $[Fe(phen)_3]^{2+}$ ions which were used to form the aggregate (negative contribution), and 3) the aggregates themselves. In Fig. 3, the initial part of the decrease in Λ of NaDSO may be attributed to

aggregate formation, which reduces the concentrations of the free Na^+, DSO^-, and $[Fe(phen)_3]^{2+}$ ions. After passing through the minima, A increases because the concentration of $[Fe(phen)_3]^{2+}$ is fixed and the aggregate formation is saturated. This is the concentration region where the precipitate $\{[Fe(phen)_3](DS)_2\}_n$ is resolubilized, and the system has sufficient free ions of Na^+ and DS^-. This is why the conductance results do not differ drastically between NaDS and NaDSO. After passing through the maxima, the conductivities decrease because normal micelles are formed.

Although DSO^- and DS^- differ from each other by only one oxygen atom, there is a large difference between their behavior when the solid state or a highly condensed state is involved, i.e., 1) DS^- forms a precipitate with $[Fe(phen)_3]^{2+}$ but DSO^- does not, 2) NaDSO is stable in a solid state rather than micelles at 298 K (the Krafft temperature is high) but NaDS forms micelles at the same temperature. Also, there are differences between their premicellar aggregates, as seen in the differences in their diffusion coefficients (Fig. 1).

Comparison with Other Studies. It is of interest to compare the above results with those in the previous work of others. Tachiyashiki and Yamatera have found that the reaction rates for the racemization and dissociation of $[M(phen)_3]^{2+}$ (M=Fe or Ni) increase significantly when anionic surfactants are added.[4] They start increasing below the cmc's of the surfactants: 20, 1—2, and 0.3—0.4 mM for NaDeSO, NaDSO, and NaDS respectively. It is worth noting that, at these concentrations, the diffusion coefficient is significantly lowered, i.e., to ca. 2×10^{-10} m^2 s^{-1} or lower (Fig. 1). Tachiyashiki and Yamatera could explain their results by assuming the formation of $1:m$ premicellar aggregates between the metal chelate cations and surfactant anions, i.e., 1 : 8 aggregates for NaDeSO, and 1 : 3 or 1 : 4 plus 1 : 8 aggregates for NaDSO and NaDS. They could also explain the result for $[Fe(bpy)_3]^{2+}$ in NaDS in terms of 1 : 3 or 1 : 4 plus 1 : 8 aggregates.

Baxendale and Rodgers found that the luminescence quenching rate of $[Ru(bpy)_3]^{2+}$ is increased by 9-methylanthracene (MeA) in a NaDS solution, even when the concentration of NaDS is below the cmc.[5] They interpreted this result as being due to the formation of premicellar clusters which incorporate the emitter and quencher molecules. The quenching rate constant is larger in 6 mM NaDS than in 3 mM NaDS (both below the cmc). This led them to state, "The higher value of k_1 (the rate constant) for 6 mM NaDS probably reflects the smaller cluster size which could put quencher and emitter in closer proximity." This is in conformity with the smaller Stokes radius of $[Fe(phen)_3]^{2+}$ in 6 mM than in 3 mM NaDS (Fig. 2). They also found that the quenching rate constant is larger in micellar systems than in premicellar solutions; they stated that this "may arise from a higher mobility of the species on the micelle surface." However, from the data presented in Fig. 2, an alternative interpretation would be that the smaller size of the micelles puts emitter and quencher in closer proximity, thereby increasing the quenching rate. The quenching of $[Ru(bpy)_3]^{2+}$ fluorescence by the 1,1′-dimethyl-4,4′-bipyridinium cation (MV^{2+}) has also been reported to be enhanced in NaDS solutions below the cmc.[6-8]

Bruhn and Holzwarth have found that the rates of electron-transfer reaction between the $[Os(bpy)_3]^{3+}/[Mo(CN)_8]^{4-}$, $[Os(bpy)_3]^{3+}/[Fe(CN)_6]^{4-}$, and $[Ir(CN)_6]^{2-}/[Os(bpy)_3]^{2+}$ ions decrease when NaDS is added; they start decreasing when the NaDS concentration is still below the cmc.[9a] This may be interpreted as a result of the interaction between the $[Os(bpy)_3]^{n+}$ (n=2 or 3) and DS^- ions, which prevents $[Os(bpy)_3]^{n+}$ ions from coming in contact with the hydrophilic anions.

Thus, although there are some exceptions,[9c,25] there are many observations of different kinds which support the formation of premicellar aggregates when $[M(phen)_3]^{2+}$ or $[M(bpy)_3]^{2+}$ cations and anionic surfactants are mixed together. The detailed picture of the aggregates, however, still differs from one observation to another; especially, our finding of a large premicellar aggregate size is unique.

Relationships between Mesophase Behavior and Crystal Structures of Chiral Smectogenic 4-[(*S*)-2-Methylbutyl]phenyl 4′-Alkoxybiphenyl-4-carboxylates

Kayako Hori,* Miho Takamatsu, and Yuji Ohashi
Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received December 8, 1988)

Interlayer distances of Sm*C and Sm A phases of the title series were measured as functions of temperature by X-ray diffraction. With increase in temperature, molecular tilt angles in Sm*C decrease from 22—25 to 0°. Crystal structures of the heptyl (**1**) and octyl (**2**) homologues have been determined by X-ray analysis. (**1**): 4-[(*S*)-2-Methylbutyl]phenyl 4′-heptyloxybiphenyl-4-carboxylate, monoclinic, $P2_1$, a=26.929(4), b=5.4249(5), c=9.2607(9) Å, β=96.78(1)°, Z=2. (**2**): 4-[(*S*)-2-Methylbutyl]phenyl 4′-octyloxybiphenyl-4-carboxylate, orthorhombic, $P2_12_12_1$, a=9.249(1), b=56.259(9), c=5.412(1) Å, Z=4. Final R were 0.076 and 0.121, respectively. Both crystals have distinct layer structures similar to those of Sm*C. In the former crystal, the molecules tilt to one direction uniformly throughout layers, while in the latter, they take two opposite directions alternately from layer to layer. However, structures within a layer are very similar to each other. Each molecule has a coplanar biphenyl moiety and a twisted paraffin chain. Mesophase behavior was interpreted very well by the molecular interaction revealed in the crystal structures.

In the preceding paper,[1] we reported crystal structures of 4-pentyloxyphenyl and 4-heptyloxyphenyl 4′-[(*S*)-2-methylbutyl]biphenyl-4-carboxylates (series I crystals, abbreviated as I-5 and I-7, respectively) and discussed a relationship between the crystal structures and Sm*C phase characteristics. In order to make the relationship clearer, we extended the study to 4-[(*S*)-2-methylbutyl]phenyl 4′-alkoxybiphenyl-4-carboxylate series, $C_nH_{2n+1}O$-C_6H_4-C_6H_4-COO-C_6H_4-$CH_2CH(CH_3)C_2H_5$ (Series II, abbreviated as II-n), which is one of the isomeric series of the series I. While the series I has a Sm*C phase between crystalline and cholesteric phases, the series II has a Sm*C which transforms to a Sm A phase.[2] It has been pointed out that temperature dependence of the molecular tilt angles and behavior of transition to a higher temperature phase are different between the two kinds of Sm C, one which transforms to a nematic and the other to a Sm A.[3] This suggests different intermolecular interactions between the two Sm C. Therefore, it is considered to be very useful to find a relationship between crystal structures and mesophase behavior of the series II, and compare the relationship with that of the series I, in order to elucidate the intermolecular interaction.

This paper describes the mesophase behavior of the series II (n=6, 7, 8, 10, and 12) and the crystal structures of II-7 and II-8. Finally, relationships between the mesophase behavior and the crystal structures are discussed.

Experimental

Compounds. All the members were synthesized in a similar way to that described previously[4] from commercially available 4-alkoxy-4′-cyanobiphenyl (BDH Chemicals Ltd.) and 4-[(*S*)-2-methylbutyl]phenol supplied by BDH Chemicals Ltd., and purified by repeated crystallization from ethanol. All the crystalline samples thus obtained showed sharp melting (cryst-mesophase) peaks in the DSC measurements.

Studies of Mesophase Characteristics. Transition temperatures were measured using a Mettler TA 3000 DSC and an Olympus POM polarizing microscope equipped with a Mettler FP82. Interlayer distances were measured on a Rigaku 2001 diffractometer with Cu $K\alpha$ (λ=1.5418 Å) and Cr $K\alpha$ (λ=2.2902 Å). Helical pitches were measured as described previously.[4]

Crystal Structure Analysis. Transparent long parallelepiped crystals were grown from a methanol-chloroform solution. Crystals of approximate dimensions, 0.2×0.2×0.05 mm of II-7 and II-8 were used. The unit cell dimensions and space groups were determined from oscillation and Weissenberg photographs. Accurate cell parameters were determined by a least-squares fit for 15 reflections within the ranges 33°<2θ<58° (II-7) and 37°<2θ<50° (II-8), measured on a Rigaku AFC-4 diffractometer with Cu $K\alpha$ radiation (λ=1.54184 Å) monochromated by graphite.

Crystal Data. II-7, M_r=458.61, $C_{31}H_{38}O_3$, monoclinic, $P2_1$, a=26.929(4), b=5.4249(5), c=9.2607(9) Å, β=96.78(1)°, V=1343.4(3) Å^3, Z=2, d_x=1.134 g cm^{-3}, μ=4.84 cm^{-1}, $F(000)$=496; II-8, M_r=472.64, $C_{32}H_{40}O_3$, orthorhombic, $P2_12_12_1$, a=9.249(1), b=56.259(9), c=5.412(1) Å, V=2816(1) Å^3, Z=4, d_x=1.123 g cm^{-3}, μ=4.73 cm^{-1}, $F(000)$=1024. Reflection data were collected on a 2θ-ω scan mode, up to 2θ=125°, with scan widths of $\Delta\omega$=(1.0+0.15 tan θ) for II-7 and $\Delta\omega$=(0.7+0.15 tan θ) for II-8. Backgrounds were counted for 5 s at both ends of a scan. Three standard reflections were recorded after every 50 reflections. No significant intensity variations were observed. For II-7, a total of 2412 reflections were collected at the rate of 4° (2θ) min^{-1}, of which 1874 were treated as significant ($|F_o|>3\sigma(|F_o|)$). For II-8, 2691 reflections were collected at the rate of 4° (2θ) min^{-1}, of which 1540 were treated as significant. The data were corrected for Lorentz and polarization factors but not for absorption.

The structures were determined by applying the program MULTAN78[5] and refined by constrained block-matrix least-squares using SHELX76.[6] The quantity minimized

a) $B_{eq}=(4/3)\sum_{ij}\beta_{ij}(a_i\cdot a_j)$. b) Isotropic temperature factor. c) Occupation factors are fixed as 0.7 and 0.3 for C(25) and C(25′), respectively.

was $\sum w(|F_o|-|F_c|)^2$, where $w=(\sigma(F_o)^2+0.004|F_o|^2)^{-1}$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[7] All the non-hydrogen atoms except for the disordered C(25′) atom of II-7 were refined anisotropically. Hydrogen atoms found in the difference Fourier maps and derived geometrically were refined isotropically. Max. Δ/σ and max. $\Delta\rho$ in the final difference map were 0.21 and 0.15 e Å^{-3} for II-7, and 0.45 and 0.27 e Å^{-3} for II-8. Final R (and R_w) were 0.076 (0.090) and 0.121 (0.141) for II-7 and II-8, respectively. Considerably large R value for II-8 is due to somewhat poor crystallinity. In spite of the repeated attempts of crystallization, the best crystal still showed broad rocking-curve along the ω direction. Data collected by ω-scan mode did not improve the ratio, $|F_o|/\sigma(|F_o|)$ and hence the final R-value, probably because of the wide-based peaks. The final coordinates of non-hydrogen atoms are given in Tables 1 (II-7) and 2 (II-8).[8] Computations were carried out on a HITAC M-280H computer at the Computer Center of the University of Tokyo.

a) $B_{eq}=(4/3)\sum_{ij}\beta_{ij}(a_i\cdot a_j)$.

Results

Phase Sequences. In order to discuss a relationship between a crystal structure and mesophase behavior, it is necessary to know to which mesophase the crystal transforms. While the series I has a relatively simple phase sequence, cryst.-Sm*C-chol.-isotropic, the series II was reported to have more complicated ones depending on the paraffin chain lengths and thermal history.[2] For example, it was reported that II-8 exhibits a phase sequence, cryst.-Sm*I-Sm*C SmA-chol.-iso., while the II-7 crystal transforms directly to Sm*C. Besides, as supercooled phases, Sm*K and Sm*J for II-8 and Sm*K, Sm*J, and Sm*I for II-7 were reported. In the present DSC measurements, mesophase-mesophase or mesophase-isotropic transition temperatures were in good agreement with those reported for all the members, while cryst.-mesophase transition behavior for some members were slightly different from the reported one. For II-8, a solid sample obtained from a melt showed a complex curve corresponding to the reported supercooled

phase sequence, while the crystals obtained from a solution showed a simple and sharp melting curve similar to that of II-7, as shown in Fig. 1. This indicates that the crystal structures determined in this work transform directly to Sm*C. The enthalpy changes are 24.5 kJ mol^{-1} (II-7) and 25.5 kJ mol^{-1} (II-8).

Interlayer Distances and Helical Pitches in the Mesophase. Figure 2 shows the temperature dependence of the interlayer distances, d, in Sm*C and Sm A phases. The bending points are Sm*C-Sm A phase transition points. With increase in temperature, the d-values increase rapidly near the Sm*C-Sm A transition point in the Sm*C phase, while they decrease slightly in Sm A. Similar rapid dependence was observed for Sm C of 4'-octyloxybiphenyl-4-carboxylic acid[9] and attributed to the change of the molecular tilt angle in the Sm C phase. Figure 3 shows the relationship of the d-values at the transition points with the chain lengths, n. Good linearlity is obtained except for the member n=6 at the solid-Sm*C transition point. This exception is due to the extremely narrow temperature range for this member. Applying the equation, $d=d_r+n\times d_m$, to each line, the contribution to the layer thickness per methylene group, d_m, is obtained to be 0.90 (at the solid or other Sm-Sm*C), 0.77 (at Sm*C-Sm A) and 0.75 Å (at Sm A-chol. or isotropic transition point), showing that the contribution of the paraffin chain to the interlayer distances decreases slightly with increase in temperature throughout the two phases. On the other hand, the d_r value, i.e., that of the rest moiety of the molecule involving the core part and the bulky 2-methylbutyl group, is estimated to be 20.2 (at the solid or other Sm-Sm*C), 24.1 (at Sm*C-Sm A), and 23.9 Å (at Sm A-chol. or isotropic transition point). The latter two values are almost the same and attributed to the value for a molecule oriented vertically, on average, to the layer plane.

The tilt angle is estimated for each member, assuming that the layer thickness change is only due to the change of the average tilt angle of a whole molecule, since the change of the interlayer distances due to the

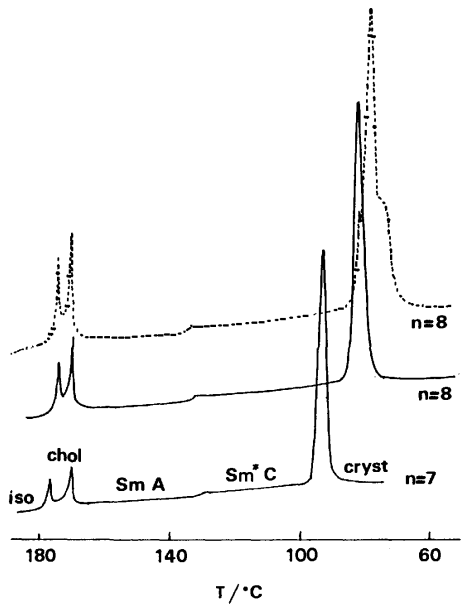

Fig. 1. DSC curves of 4-[(*S*)-2-methylbutyl]phenyl 4'-heptyloxybiphenyl-4-carboxylate (II-7) and 4-[(*S*)-2-methylbutyl]phenyl 4'-octyloxybiphenyl-4-carboxylate (II-8). A broken line denotes a curve for the solid of II-8 obtained from a melt. For II-7, DSC curves were almost independent of thermal history.

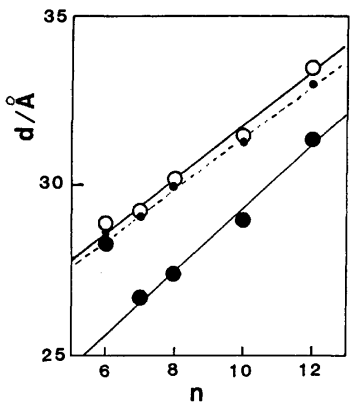

Fig. 3. Dependence of interlayer distances on the chain lengths. Open, filled (large), and filled (small) circles denote the d-values at solid (or Sm)-Sm*C, Sm*C-Sm A, and Sm A-chol. (or iso.), respectively.

paraffin chain is small, as mentioned above. The results are shown in Fig. 4. For the members with sufficiently wide temperature range of Sm*C, tilt angles are estimated to vary from 22—25 to 0° (assumed) with increase in temperature, approximately in accordance with a relation, $\theta \propto (T_c - T)^{\alpha}$, where T_c is Sm*C-Sm A transition temperature and α is estimated from the slope of relatively linear portions of the log-log plots ($T_c - T < 10$ K) to be 0.5±0.1. Similar temperature dependence of θ was generally observed for other Sm C or Sm*C adjacent to Sm A.[10]

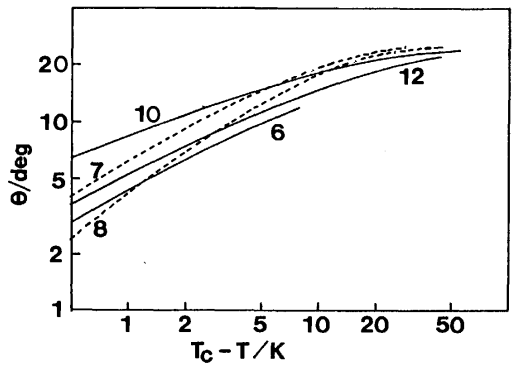

Fig. 4. Temperature dependence of tilt angles. T_c is Sm*C-Sm A transition temperature.

Selective reflection wavelengths were also measured to estimate helical pitches from the relation, $\lambda = \bar{n}p$, where λ is the wavelength, $\bar{n}$ is the average refractive index and p is the pitch. They are located in the IR region, while those of the series I were in the wavelengths of visible light.[11] Furthermore, they are less dependent on the chain lengths, especially in the lower temperature range (<100 °C), as shown in Fig. 5, than in the case of the series I with a remarkable

dependence on the chain length.[4] A pitch increases with increase in temperature near the Sm*C-Sm A transition point and the increase is more rapid for a longer member.

Molecular Conformations in the Crystals. The ORTEP drawings[12] of the molecular conformations with numbering schemes are shown in Fig. 6. All the bond lengths and angles are compatible with those found in other mesogens,[1] as shown in Table 3. All the phenyl rings are planar within the experimental error. Table 4 shows torsion angles. The conformations of II-7 and II-8 are very similar to each other:

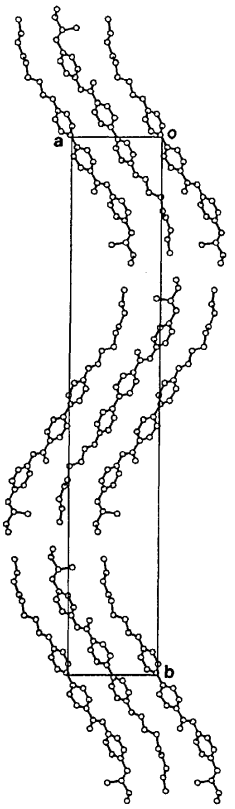

Fig. 8. Crystal structure of II-8 viewed along the c axis.

approximately coplanar biphenyl moieties and paraffin chains with the twisted C(32)-C(33)-C(34)-C(35) moieties. The twisted chains result in straight rod-

shaped molecules as a whole. For II-7, the C(25) atom is slightly disordered.

Crystal Packing. Figures 7 and 8 show the crystal structures of II-7 and II-8, respectively. Both crystals have distinct layer structures, whose layer planes are parallel to (100) plane (II-7) and (010) plane (II-8). Such layer structures were also observed in other smectogens. Structures within a layer are also strikingly similar, composed of the rod-shaped molecules described above. Intermolecular relation except the "extra" C(38) is almost the same in spite of the difference in the chain length. The whole molecule including a normal paraffin chain relates to the lateral packing in the layer, in contrast to the case of the series I, in which paraffin chains have contacts with each other between layers.[1] These facts suggest that interaction between core parts is more dominant in the crystal packing of the series II than that of the series I. This results in a large extent of molecular overlapping within a layer, leading to distinct layer structures with a small tilt angle (30°).

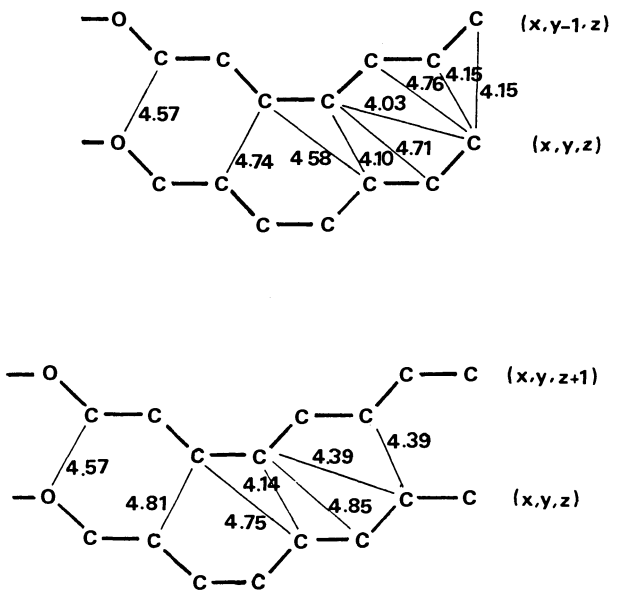

Fig. 9. Interchain distances (Å) of II-7 (upper) and II-8 (lower). Symmetry codes are shown in parentheses.

Figure 9 shows interchain distances. The chains make contacts each other only within a layer. Most of the distances are remarkably longer than those of interlayer chain contacts in the series I. This also suggests that interaction between cores is dominant in the series II.

The phenyl rings of adjacent molecules have nonparallel contacts as found in the I crystals. The angles between the mean planes are 67° (II-7) and 66° (II-8).

The II-7 crystal has a uniform direction of molecular tilt throughout layers, while in the II-8 crystal molecules have two opposite tilt direction alternately from layer to layer. This difference is regarded as induced by a small interlayer interaction in these crystals, since the two crystals of the series I with close contacts of paraffin chains between layers showed similar modes of layer stacking to each other. Both arrangements are known as polytypes for normal long-chain compounds and energy difference is reported to be very small; an alternate arrangement was evaluated to be more stable than a uniform one by 0.73 kJ mol^{-1} for octadecanoic acid.[14] In the present case, less penetration of chains into an adjacent layer in II-8 means less interlayer interaction than in II-7, corresponding to the lower melting point as described above.

Discussion

A relationship between the mesophase structures and the crystal structures are shown schematically in Fig. 10. The tilt angle in the crystals (30°) is closely related to that (22—25°) at the lowest temperature in Sm*C. This suggests that molecular rearrangements at the cryst.-Sm*C transition point are not large in spite of the large enthalpy of transition, as in the case of the series I. Nonparallel contacts of the phenyl rings would enable the molecules to begin to rotate at the melting points, leading to the direct transition to Sm*C. The transition is supposed to be caused by loosening of the core-core interaction, because the contacts of normal alkyl chains within a layer are

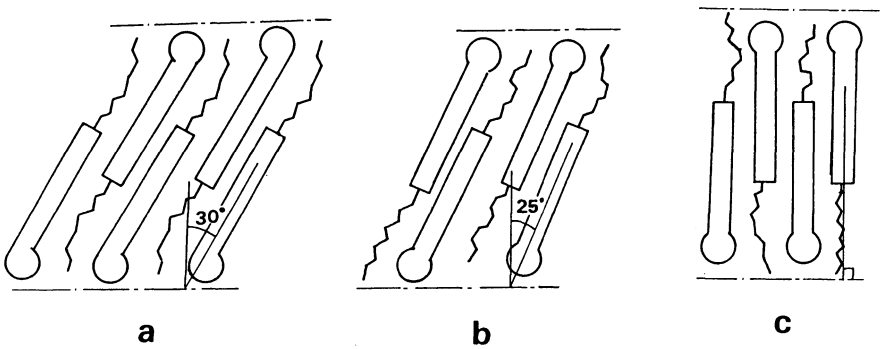

Fig. 10. Schematic diagrams of the structures of the crystal (a), Sm*C (b), and Sm A (c).

loose enough in the crystalline states. On the other hand, molecular overlapping in the layer is much larger than that in the series I. Besides, the interlayer aggregation of the paraffin chains observed in the series I, which was proposed to keep the tilt angles constant, is not found in the series II. Therefore, the molecules gradually change the tilt angles to zero with keeping layer structures; i.e. Sm*C transforms to Sm A. Paraffin chains have a twisted form even in the crystalline states. This corresponds to the small change of their contribution to the layer thickness throughout the Sm*C and Sm A phases, while in the series I, the large change of the paraffin chain organization in the Sm*C was interpreted as the melting process of the chains which are regularly organized in the crystalline states.

Interlayer interaction in the series II is found to be much less than in the series I. This fact seems to be related to the fact that helical pitches in the series II are larger than those in the series I and they are less dependent on the chain lengths. However, further investigation for more variety of compounds would be required to confirm the relationship between the helical pitch and the interlayer interaction.

It is concluded that the mesophase behavior of Sm*C between crystalline and Sm A phases is well interpreted by the intermolecular interaction revealed in the crystal sturctures, as in the case of Sm*C between crystalline and cholesteric phases.

The authors express their thanks to Professor Naoyuki Koide of Science University of Tokyo for DSC measurements and BDH Chemicals Ltd. for supplying the chiral phenol. Metal Colloids Produced by Means of Gas Evaporation Technique. V. Colloidal Dispersion of Au Fine Particles to Hexane, Poor Dispersion Medium for Metal Sol

Naoki SATOH† and Keisaku KIMURA*

(Received December 14, 1988)

Metal fine particles are not dispersed at all in pure solvents with a low dielectric constant, such as hexane. The gas flow-cold trap method combined with surfactants was found to be effective in stabilizing ultrafine metal particles in solvents with a low dielectric constant. Ultrafine gold particles can be stably dispersed in hexane in a colloidal state by this method. It was found that the stabilizability of the colloid depends on the ionic types of the surfactant. Thus, a cationic surfactant such as dimethyldioctadecylammonium chloride (DOAC) shows good dispersibility, whereas an anionic surfactant such as 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (AOT) dose not. The optical spectra of colloid solutions suggest a difference in the local colloidal state between two types of surfactants. Colloidal solutions of a gold fine particle/DOAC/hexane system are so stable against heating or drying that the solvents are easily substituted.

In a coagulated metal ultrafine particle (UFP), the wave function of conduction electrons is presumed to diffuse between metal UFP's. The physical characteristics resulting from the electronic state of each metal UFP can be modified through this contact and be changed close to that of bulk materials according to the degree of contact.[1] On the contrary, metal UFP's in dispersions are expected to give physical properties and structural information concerning individual metal UFP more delicately than that in coagulation. We initiated a series of studies[2-5] in order to characterize the features of isolated metal UFP's dispersed into the liquid phase. In general, however, the preparation of stable dispersions of metal UFP in an organic liquid is difficult.

Some approaches to obtain stable dispersions of metal UFP have already been reported by several authors. The vacuum evaporation on running oil substrate (VEROS) method[6] is one of the available approaches for the preparation of dispersions of metal UFP. However, a severe restriction is imposed on the selection of solvents, i.e. oil with a very low vapor pressure must be selected. The chemical reaction method in a liquid phase is also a well-known technique in colloid chemistry for obtaining metal UFP dispersions.[7] However they are restricted to being almost only aqueous dispersions. Furthermore, several kinds of by-product, such as ions, remain in the solutions. The surface of metal UFP in these dispersions cannot be clearly defined because of considerable modifications, such as oxidation or chemisorption of several kinds of compounds. These techniques are, hence, not suitable for our purpose.

The authors have reported on methods for obtaining stable dispersions of UFP in pure organic liquids.[2] These methods were based on the evaporation technique in flow gas combined with matrix isolation techniques using frozen organic solvents (the gas flow-cold trap method) or cooled organic liquids (the gas flow-solution trap method) as a matrix. According to the combination of solvents with a high dielectric constant and metals with a high electron affinity, stable colloidal dispersions can be obtained by this method.[8] However, it is difficult to prepare stable dispersions for solvents with a low dielectric constant. We report here a method for obtaining stable colloidal dispersions of metal UFP in organic solvents with a low dielectric constant, employing the gas flow-cold trap method with the cationic surfactant of dimethyldioctadecylammonium chloride (DOAC). We tested the validity of this method with gold fine particles and hexane as the dispersed phase and dispersion medium, respectively. The surfaces of gold fine particles are considered to be free from oxidation, and hexane is one of the most poor solvents with respect to the formation of stable colloidal dispersions of metal UFP.[8] The colloidal solutions obtained by this method were found to be quite stable against such thermal processing as increasing temperature or freezing. Further, it was found that stable colloidal solutions are readily reproduced by exchanging the dispersion media after the drying process.

Experimental

Materials. Pure (99.99%) pieces of gold were purchased from Tanaka Kikinzoku Kougyou company. The dispersibility of the fine particles was examined for different types of surfactants, i.e. DOAC as a cationic surfactant and AOT (Aerosol OT, sodium 1,2-bis(2-ethylhexyloxycarbonyl)-ethanesulfonate) as an anionic surfactant. Both surfactants were of guaranteed grade and purchased from Tokyo Kasei Ltd. AOT was purified by a method reported by Kunieda et al.[9] A benzene solution of 15% AOT was washed three times with distilled water to remove water-soluble impurities. After evaporating benzene, AOT was dissolved into a 25% aqueous methanol solution and washed three times with petroleum ether to remove oil-soluble impurities. The solvents were removed by evaporation for 12

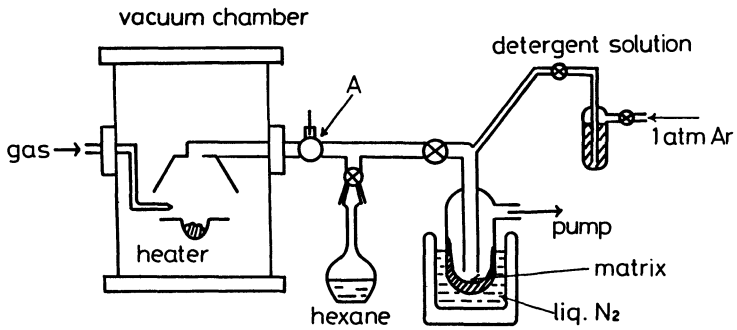

Fig. 1. The apparatus for the gas flow-cold trap method. Gas phase sampling of fine particles was performed at the point A by exposing Cu mesh with evaporated carbon film to the flow of carrier gas.

hours. AOT was then dissolved into methanol and shaken with hexane. Finally, AOT in the hexane phase was extracted and evacuated again for 12 hours. DOAC was recrystallized three times from dehydrated acetone and evacuated to dryness for 12 hours. Hexane solutions of both 0.1 wt% AOT and 0.01 wt% DOAC were prepared for the experiments. Since DOAC was hardly soluble in hexane, a cationic surfactant of (2-dodecylhexadecyl)trimethylammonium chloride (g-C28TAC)[10] was used for concentrated samples after the same purification process as DOAC. The solubility of g-C28TAC is sufficiently high due to a branched alkyl chain in this compound. g-C28TAC was kindly supplied by Mr. Kazuyuki Yahagi of Tokyo research laboratories, Kao corporation.

Preparation of Au UFP/Hexane Colloidal Solution. Au fine particles were formed and collected by the gas flow-cold trap method.[2] Figure 1 shows a schematic diagram of this method. The chamber was evacuated to 5.0×10^{-6} Torr prior to the introduction of inert gases (1 Torr≈133.322 Pa). The constant flow of He as a surrounding gas and Ar as a carrier gas were supplied around the heater. The particles in the gas stream were led to the trap which was cooled by liquid N_2. The partial pressures of He and Ar were 8 and 2 Torr, respectively. Purified and degassed hexane was vaporized into the gas stream from the chamber to the trap. Under an atmosphere of constant-flow inert gases, pieces of gold were heated in a tungsten wire heater and the UFP's produced were led to a frozen hexane matrix in the trap. After the accumulation of a sufficient amount of gold fine particles, liquid N_2 was removed. As soon as the matrix surface began to melt, a detergent solution was introduced on the matrix surface and the trap was filled with Ar gas at atmospheric pressure. Then, the trap was irradiated by ultrasonic waves. This ultrasonic wave treatment was continued for more than 5 minutes after a full melting of the matrix.

Characterization of Colloidal Solutions. The size distributions and the states of contact of UFP's were determined by a Hitachi H-500H type transmission electron microscope (TEM) of the laboratory of electron microscopy, the National Institute for Physiological Sciences at Okazaki. Specimens for TEM were obtained by dropping sample solutions on Cu grids coated by carbon film of 8 nm thickness. In order to obtain the size distribution of Au fine particles in the gas phase, Au fine particles were sampled at point A in Fig. 1, the location of which was the midpoint of the vacuum chamber and the solvent pool. A sample mesh for the electron microscope was exposed to the flow of the fine particles for about 1 second. The size distributions of Au fine particles were determined by TEM photographs using an Image analyzer (Kontron IBAS-1 of the Center for Analytical Instrument, the National Institute for Basic Biology at Okazaki).

recorded at room temperature just after the preparation of a colloidal solution. A conventional quartz cell was used.

Results

Figure 2(a) shows an electron micrograph of the particles sampled in the gas phase. A number of particles of about 2.5 nm in diameter can be seen in the photograph. The smallest particles are less than 1.0 nm. Figure 2(b) shows the size distribution determined from this picture. It can be seen that the evaporation method with a flow gas provides a size distribution with a sharp single peak. The maximum of this distribution curve was 2.5 nm. As reported in Ref. 5, almost all kinds of metallic fine particles, including Au, do not disperse in hexane at all without surfactants. Au fine particles coagulated as soon as the melting of a matrix and precipitated and were deposited within a few minutes. Figure 3(a) shows a TEM picture of these precipitates just after an ultrasonic treatment. Fine particles come into contact with each other to form larger aggregates. The boundaries of constituent particles become indistinct. It seems that particles coalesce to each other to some extent. A typical size-distribution curve of the system of Au UFP/hexane is shown in Fig. 3(b). Compared with a size histogram of these particles with those in the gas phase, it is easy to realize that further growth by coalescence proceeded in complex ways.

The effect of DOAC on the dispersibility of Au UFP is apparent. The colloidal solution prepared by the method described in the experimental section was colored rose-red and transparent, and scattering light through the solution was hardly observable in the visible region. A TEM picture of this solution is shown in Fig. 4(a). Most of the fine particles are observed in isolation in any photogram image. The diameter of the smallest particle observed in this figure is less than 1.0 nm, which is comparable to the size of particles sampled in the gas phase. Figure 4(b) shows a typical size histogram of Au fine particle/DOAC/hexane system. The maximum peak of this histogram is located at nearly the same place as those in the gas phase; however, the width of this histogram is somewhat larger. This fact means that coalescence growth can not be completely avoided, even when

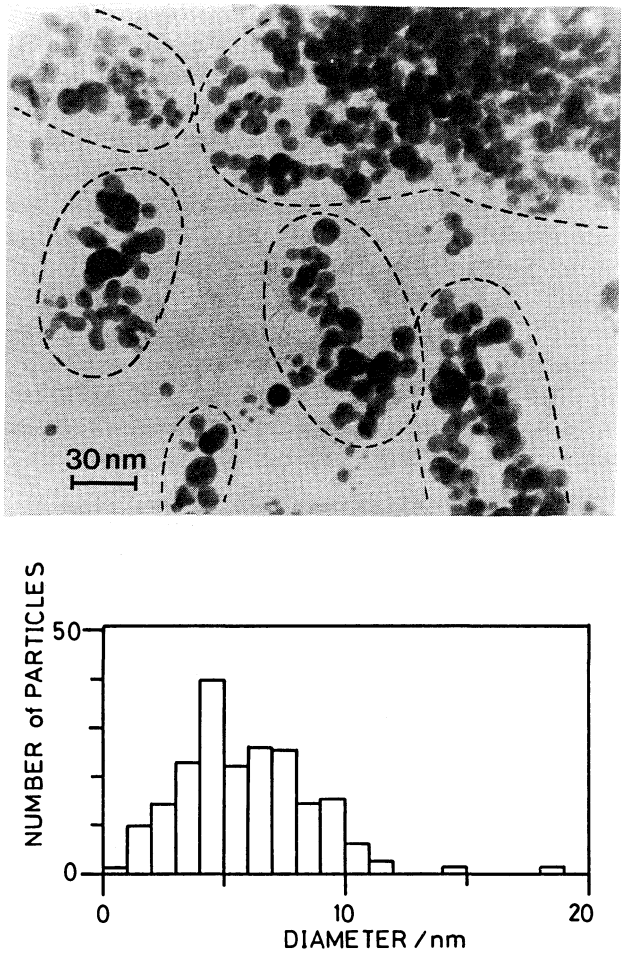

Fig. 5. (a) TEM micrograph of Au fine particles deposited from colloid solution of Au UFP's/AOT/hexane system. The encircled regions by broken lines represent the examples of aggregation unit of densely packed Au UFP's. (see discussion). (b) Size distribution of picture (a).

using the present method.

The effect of surfactants on the dispersibility of Au UFP depends on the ionic types of the hydrophilic part. The solution of the Au fine particle/AOT/hexane system is colored blue and is transparent just after the melting of the matrix. However, the colloidal dispersion of this solution is not stable. The Au UFP/AOT complexes fully precipitate within a few hours. Figure 5(a) shows a TEM picture of this system, sampled just after an ultrasonic treatment. The fine particles in this picture are anisotropic and irregular in shape more than those in Fig. 4(a). As is discussed later, this fact implies that the original Au UFP coalesce in an AOT/hexane system to a greater degree than in a DOAC/hexane system. However, it is worth noting that coalescent growth stopped at some stage. The boundaries of grown Au UFP can clearly be seen. From the size distribution of this colloidal system (Fig. 5(b)), one recognizes that AOT is also effective in preventing the coalescence growth process of fine particles to some extent, though coagulation does takes place.

Discussion

The size distributions of UFP strongly depend on the particle growth mechanism. Two growth processes have been proposed, i.e., the absorption and the coalescence growth processes.[5,11] In the absorption process, particle nuclei grow along with the absorption of metal atoms. The size distribution curve in this case is the normal distribution. In the coalescence growth process, however, particles grow by collisions of small clusters and the size distribution is the log-normal distribution. Graphical analyses make it possible to determine which mechanism takes place. Figure 6 shows logarithmic probability analyses of our samples. If the size distribution of particles is a log-normal one, a linear correlation is obtained between the cumulative percentage of particles with a certain size and the logarithm of the size of particles in a logalithmic probability plot. The size distribution of the gas-phase-particles by the gas-flow method is found to follow a log-normal distribution, as shown in Fig. 6. This is a rather surprising fact, since the coalescence growth process was derived by assuming a stationary state, whereas in the gas-flow method particles grow within a turbulent gas stream. The size distribution of a Au UFP/DOAC/hexane system also provides a linear correlation in the log-probability plot. In this case, the original features of the size distribution basically remained unchanged. The size distribution of a Au UFP/AOT/hexane system, how-

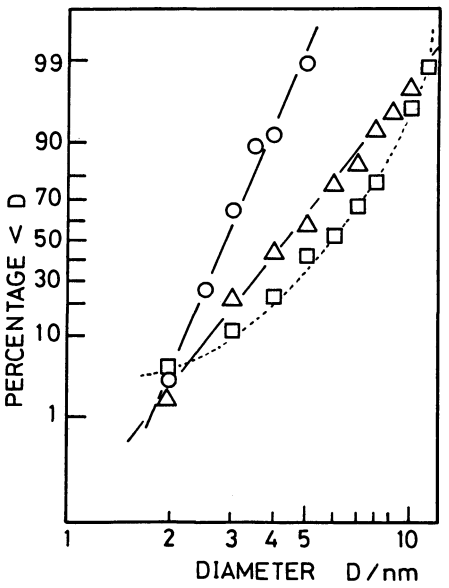

Fig. 6. Logarithmic probability plot of the size distribution of Au UFP's sampled from the gas phase (○), Au UFP/DOAC/hexane solution (△), Au UFP/AOT/hexane solution (□). The ordinate indicates the cumulative percentage of particles with diameters smaller than *D*.

ever, changes slightly from the log-normal distribution. This implies that particles in a Au UFP/AOT/hexane system grew in a more complex manner than in the Au UFP/DOAC/hexane system.

The optical properties of a colloidal solution sensitively reflect the dispersion state of the colloid, as was fully described by Kreibig.[12] He discussed and analyzed the visible absorption spectra of Au UFP taking into account the topography of the particle assembly, and introduced the fractal dimension as a relevant parameter for characterizing the metal UFP aggregate system.[13] Figure 7 shows the absorption spectra of (a) Au UFP/DOAC/hexane and (b) Au UFP/AOT/hexane solutions (those in Figs. 4 and 5, respectively) measured just after the ultrasonic treatment. The absorption spectra were characterized by a peak at 520 nm for (a) and 600 nm for (b), whereas a shoulder at 270 nm and an abrupt rise below 210 nm for both. The absorption spectrum in the visible region is mainly attributed to the surface plasma absorption of free electrons,[14] which has been well studied and is understood[15,16] in terms of Mie's scattering theory,[17] combined with Drude's free electron model. The ultraviolet spectrum reflects d-s interband transitions, the threshold of which is 2 eV.[14,15,18,19] The theoretical absorption spectra of a Au colloid solution was calculated according to the method of Doremus, in which the homogeneous dispersion was treated[15] within the framework of Mie's theory. Good agreement between the calculated and experimental absorption spectra was obtained in the case of the Au UFP/DOAC/hexane colloidal solution. This implies that DOAC is capable of dispersing Au UFP's ideally in hexane. This is not true for AOT. In the light of the classical free electron model for metal UFP, the maximum wavelength of a plasma absorption peak does not shift with the size of UFP when the size of the particles are sufficiently smaller than the wavelength, while the height and width of the peak are sensitive to the size.[15] Therefore, the differences in the average sizes and or the size distributions between Au UFP's of Au UFP/DOAC/hexane and of Au UFP/AOT/hexane systems could not explain the shift of the peak position from 520 to 600 nm (Fig. 7). A surface plasma peak is known to shift to the longer wavelength and to broaden when a volume fraction of colloid particles increases due to a dipolar interaction.[16,20,21] Since the total volume fraction of Au particles was nearly the same for both samples, the peak shift and broadening of the spectra must be explained in terms of the difference in the local colloidal state of the solutions. Actually, it is reported that a plasma resonance peak shifts to a longer wavelength and broadens when the colloid systems consist of well separated aggregates of densely packed particles.[12] In the TEM images of a Au UFP/AOT/hexane system, most particles are observed in aggregates of several tens or several hundreds of nanometers. An example of these units of aggregate is shown in Fig. 5(a). In the Au UFP/AOT/hexane colloidal system it is reasonably understood from the instability of the colloidal state that Au UFP's tend to form aggregates including AOT, even immediately after the matrix melts. The specificity to the ionic type of surfactants (i.e., the cationic surfactant disperses Au UFP's well, while the anionic surfactant does not) suggests a difference in the affinities of the surfactant to the surfaces of the Au UFP's between a cationic and an anionic surfactant. However, it is not clear at present why Au UFP's prefer DOAC to AOT. Further experiments for understanding the microscopic mechanism of the adsorption of the surfactants to the surfaces of Au UFP's are currently under way.

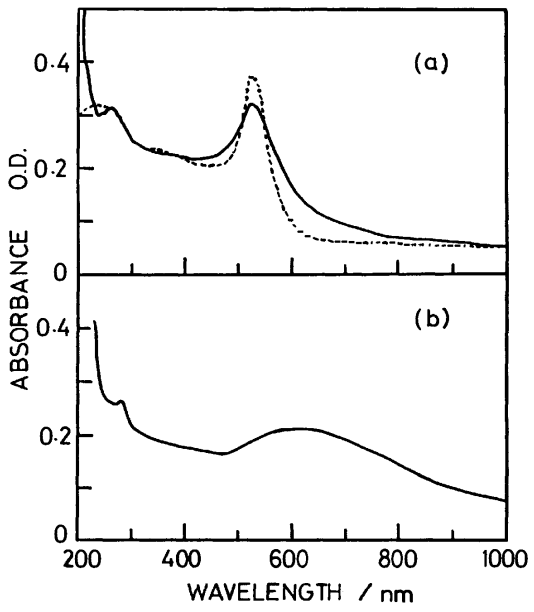

Fig. 7. (a) Optical absorption spectra of calculated (broken line) and Au UFP/DOAC/hexane colloidal solution (solid line). The calculated line was obtained from the first approximation of Mie's theory ($D \ll \lambda$; where D is diameter of UFP, λ, wavelength of light) using complex dielectric constants of Ref. 14.[15] (b) Absorption spectrum of Au UFP/AOT/hexane colloidal solution obtained just after the ultrasonic treatment.

When a Au UFP/DOAC/hexane solution is concentrated by evaporation, a phase separation occurs and Au UFP's precipitate with DOAC. It seems that the maximum concentration of Au UFP's in hexane is determined by the solubility of the surfactant into hexane. g-C28TAC, which has a much higher solubility in hexane than does DOAC due to the branched alkyl chain, is capable of stabilizing Au UFP's with more than a 100-times higher concentration.

The colloidal solutions stabilized by these cationic surfactants are quite stable against the passage of time, thermal processes (to the boiling point of hexane) and drying. In particular, the stability against drying makes it possible to exchange the type of solvent.

Hexane can be substituted for organic solvents with a dielectric constant less than ca. 10. The remarkable features of a colloidal solution of metal UFP's using a cationic surfactant for both the stability and changeability of the solvents are advantageous for future applications.

Light-Induced Oxidative Deposition of Polypyrrole on the Back Surface in the Dark of n-Type Silicon Wafer Photocatalysts

Hiroshi YONEYAMA,* Yoshihiro SHOJI, and Kei-ichi SUZUKI
Department of Applied Chemistry, Faculty of Engineering, Osaka University,
Yamada-oka 2-1, Suita, Osaka 565
(Received December 22, 1988)

A variety of surface conditions of n-type Si wafers were prepared by etching for different time damaged surfaces that were prepared by lapping with emery papers, and the effect of flaws in the wafer surfaces on photocatalytic deposition behaviors of polypyrrole and silver from acetonitrile containing pyrrole and $AgClO_4$ was investigated. It was found that if the front surface of the wafer to be illuminated contained a fairly high amount of defects and the back surface in the dark was defect-free, oxidative polymerization of pyrrole occurred on the back surface in the dark with the simultaneous deposition of silver on the front surface as long as the diffusion length of positive holes is greater than the thickness of Si wafers.

Flaws in semiconductor surfaces play an important role in semiconductor photocatalysis.[1-3] For example, high photocatalytic activities of n-type single crystal wafers appear when their illuminated surfaces are well-etched and their back surfaces in the dark are heavily damaged. The flaws have both favorable and unfavorable effects in semiconductor photocatalysis. The favorable effect is that the flaws produce in the forbidden zone of semiconductors intermediate energy states which serve as channels for transferring photogenerated electrons from the conduction band to electron scavengers in solution under upward bending of the bands,[1,4] while the unfavorable effect is that the flaws work as the recombination centers.[5-7]

Then it will be of interest to investigate how greatly the apparent photocatalytic activities of semiconductors are affected by changing the abundance of flaws either in illuminated front surfaces or in the back surfaces in the dark, or in both. The present study has been initiated to investigate this subject using n-type Si wafers. The reaction system chosen here was simultaneous deposition of polypyrrole and silver from acetonitrile containing pyrrole and silver perchlorate.[2,8] By using this reaction system, the effective cathodic sites and photoanodic sites of semiconductor surfaces can be recognized by observing the places where the silver and polypyrrole deposition take place, respectively. It will be shown that under special configurations of the front and back surfaces of the n-type Si wafers the positive hole-consuming polypyrrole deposition evidently takes place on the back surface of n-type Si wafers in the dark as a result of effective supply of the positive holes by diffusion only.

Experimental

n-type Si single crystal wafers were purchased from Osaka Titanium Co. Except where specially noted, the experiments were carried out using wafers of 0.6 mm thickness and of 2.4 Ω cm resistivity. The surface of the wafers was polished to mirror finish by the manufacturer. This surface is denoted here as mirror-finished surface. The mirror-finished surface was lapped with No. 500 emery papers when it was intended to prepare defect-containing surfaces. The surface prepared by this damaging is denoted here as damaged surface. The flaws produced in this way must have had the depth comparable to the particle size of the abrasives which was judged to be 34 μm on average.[9] The damaged surface was etched in a mixture of 1 part of 46% HF and 20 parts of 61% nitric acid for different time to remove the defects to different degrees. The etching rate was reported to be 13 $\mu m\ min^{-1}$ [10] for this etchant.

For the photocatalytic deposition experiments, edges and undesired parts of the Si wafers were coated with polyfluoroethylene oligomer (Difloil, #200, Daikin Industries), and after mounting in a flexible plastic frame, the Si wafers were hung in a deposition bath which consisted of 0.1 M pyrrole and 0.1 M $AgClO_4$ (1 M=1 $mol\ dm^{-3}$) dissolved in acetonitrile. For electrochemical experiments, the back face of the Si wafers was pasted by a Ga-In alloy to make ohmic contact where an electrical lead wire was attached with Dupont conducting silver paint. The Si wafer was then mounted in a Teflon electrode holder. The surface exposed to electrolyte solutions was 7 mm diameter.

Just prior to both photocatalytic experiments and photoelectrochemical experiments, the Si was immersed in 46% HF for more than 30 min to remove surface oxide films, followed by washing in a stream of deionized water. The electrolyte solutions and the deposition bath were bubbled by argon for more than 20 min to purge dissolved oxygen. The electrolytic cell had one compartment with a quartz window for illumination of the electrode. Cyclic voltammograms were obtained with the use of a potentiostat (Nikko Keisoku, DPGP-1), a potential sweeper (Nikko Keisoku, NPS-2) and an X-Y recorder (Yokogawa, Type 3077). The electrolyte solutions were prepared from re agent grade chemicals.

Illumination of the Si wafers was carried out using either a 500 W xenon lamp (Ushio, ULX-500-O) or a 25 mW He-Ne laser (NEC, GLG-5700). In the former case light from the lamp was passed through a Toshida glass filter L-39 to cut off wavelengths shorter than 390 nm. The illumination intensity was usually 0.45 $W\ cm^{-2}$.

The rate of simultaneous deposition of polypyrrole and silver was evaluated by determining the amount of the deposited silver as a function of the illumination time. For this purpose the deposited silver was dissolved with nitric

acid, neutralized with sodium hydroxide, and determined colorimetrically at 620 nm using dithizone as a complexing agent.

Results

Photoelectrochemical Properties of n-Type Si Having a Variety of Damages. The mirror-finished surface had smooth surface as judged from pictures taken by a scanning electron microscope (SEM) with magnification of 20000, while the damaged surface had irregular ditches with sharp edges as shown in Fig. 1(a). With increasing the etching time the sharp edges of the flaws became smooth as Figs. 1(b) to (d) show. Considering the depth of flaws of the dam-

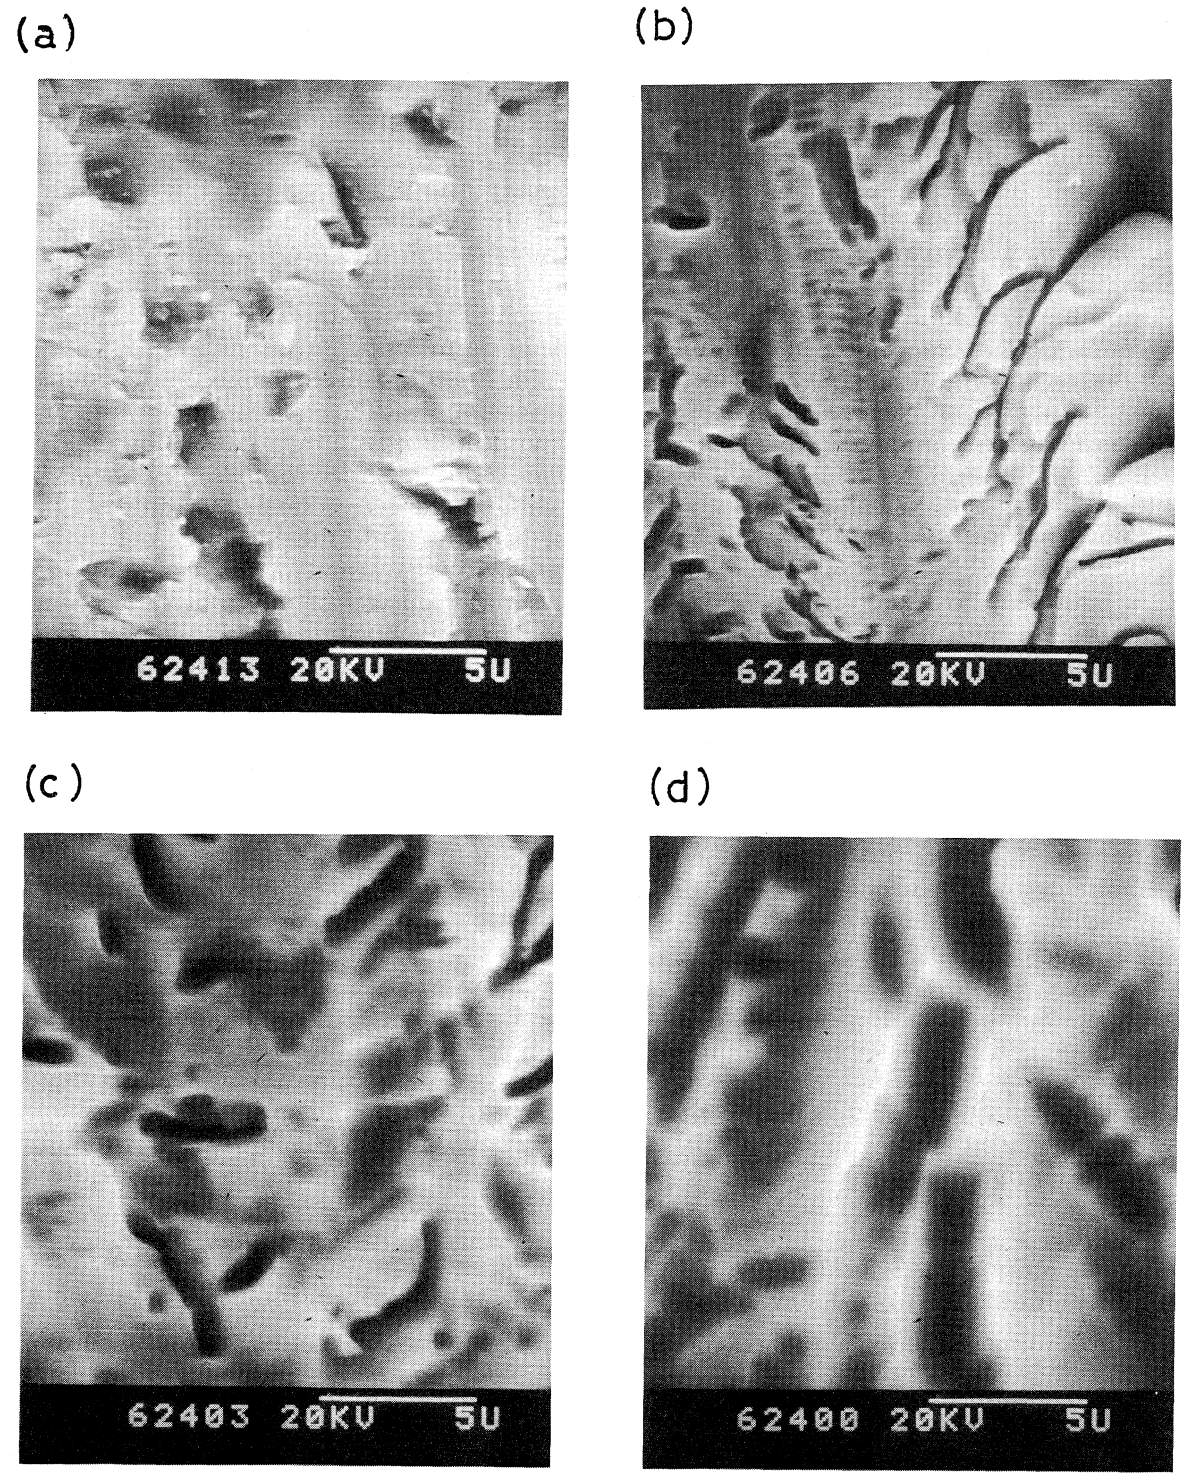

Fig. 1. Pictures of n-type Si surfaces containing a variety of damages. (a) Abraded with No. 500 emery papers (damaged surface), (b) etched of the damaged surface for 30 s, (c) etched for 60 s, and (d) etched for 5 min.

aged surface (34 μm) and the etching rate (13 μm min^{-1}), the flaws should be eliminated by the 3 min etching if the etching proceeds at the flaws only. However, the etching occurred not only in the flaws but also in the mirror-finished surfaces, it took much greater time to eliminate completely the flaws from the surface. According to the SEM pictures shown in Fig. 1, the 5 min etching of the damaged surface gave fairly smooth surface, and its electrochemical properties were found to be very close to those of the mirror-finished surface, as will be shown below.

Cyclic voltammograms of four kinds of n-type Si electrodes having different surface conditions, taken at an initial potential scan in propylene carbonate containing 10 mM ferrocene, are shown in Fig. 2. Illumination by the xenon lamp did not affect the shape of cyclic voltammograms at the damaged electrode, which behaved as if it were a metal electrode. In contrast, illumination caused photosensitized oxidation of ferrocene at the mirror-finished electrode, as shown in Fig. 2(d), though this electrode in the dark showed no appreciable reactivity for oxidation of ferrocene, as expected for n-type semiconductor electrodes.

The electrodes having different degrees of surface damages showed intermediate voltammetric behaviors between the mirror-finished and the damaged electrodes, depending on the degree of the surface damages. The onset potential of anodic photocurrents shifted negatively with increasing the etching of the damaged surface as shown in Fig. 3, and simultaneously anodic currents in the dark decreased; the onset potentials were not, however, affected by the etching. On the other hand, if the electrode contained a relatively high amount of defects in the electrode surface, the cathodic current was eventually the same as that at Pt electrodes, while if a large parts of surface flaws were eliminated, the onset potential was shifted towards negative potentials finally to reach the onset potential at the mirror-finished electrodes.

It is concluded from the results shown in Figs. 2 and 3 that the electrode surface prepared by etching the damaged surface for 15 s to 1 min possessed both semiconductor and metal electrode properties, because illumination caused negative shifts of anodic current onsets, but the onset potential of both anodic and cathodic currents in the dark were the same as those at the Pt electrodes.

The Effect of Surface Defects on the Photocatalytic Deposition Reactions. Figure 4 shows the amount of deposited silver with the illumination time, obtained when the front surface of the wafer was prepared by etching the damaged surface for different times and the back surface was the damaged one. The rate of the deposition reaction increased with the elimination of surface damages of the front surface, suggesting that the recombination of the photogenrated charge carriers in the illuminated surface controlled the rate of the deposition reaction. The silver deposition preferentially took place in the back damaged surfaces in the dark, and the polypyrrole deposited on the illuminated surfaces irrespective of whether this surface was mirror-finished or defective.

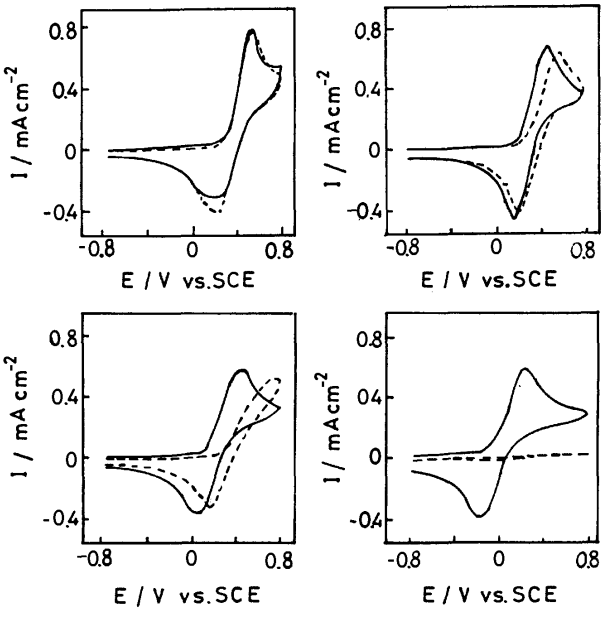

Fig. 2. Cyclic voltammograms of n-type Si electrodes in propylene carbonate containing 10 mM ferrocene and 0.1 M tetrabutylammonium perchlorate. The illumination intensity by the xenon lamp was 10 mW cm^{-2}. dE/dt=50 mV s^{-1}. Solid line: taken under illumination. Dashed line: taken in the dark. The electrodes were prepared by etching the damaged surface for (a) zero s, (b) 30 s, (c) 1 min, and (d) 5 min.

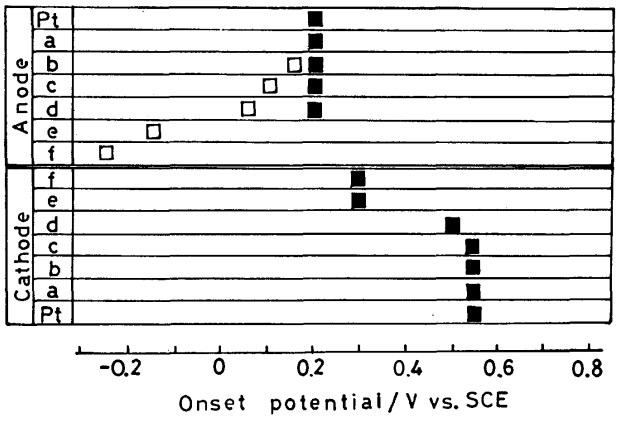

Fig. 3. The onset potential of anodic currents and cathodic currents, evaluated from cyclic voltammograms taken in a solution containing 10 mM ferrocene as shown in Fig. 1. (□) the onset potential of anodic currents under illumination of the electrode. (■) the onset potential in the dark. The etching time of the damaged Si electrode was (a) zero, (b) 15 s, (c) 30 s, (d) 1 min, (e) 5 min, (f) mirror-finished surface.

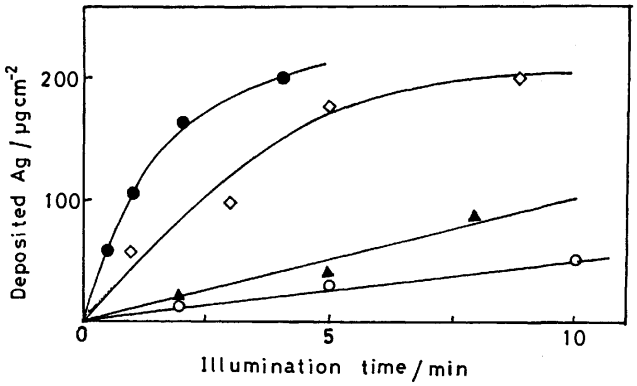

Fig. 4. Time course of silver deposition obtained when the front surface of n-type Si wafers contained flaws of different degrees, and the back surface was damaged. Solution: acetonitrile containing 0.1 M pyrrole and 0.1 M silver perchlorate. Illumination: 0.45 W cm^{-2} xenon light. The etching time of the damaged surface to prepare the front surface was (○) 1 min, (▲) 3 min, and (◇) 5 min. (●) well-etched front surface.

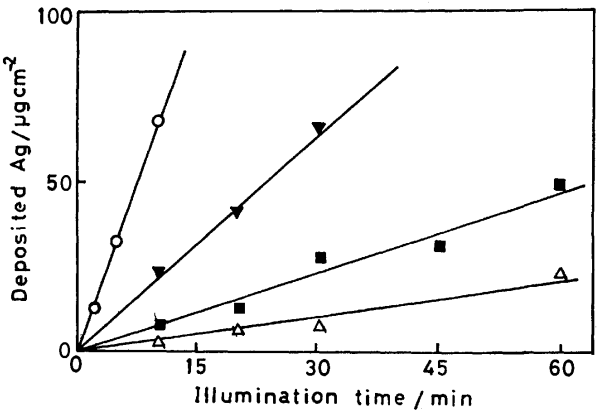

Fig. 5. As in Fig. 3, but for cases when both front and back surfaces of n-type Si wafer were in the same surface conditions. The etching time of the damaged surface for the preparation of each surface was (△) 30, s, (■) 1 min, and (▼) 5 min. (○) the well-etched surface.

Figure 5 shows the time course of silver deposition obtained when both the front and back surfaces were the same with respect to the defects. In such cases, the rate of the deposition reaction was increased by eliminating the surface damage. As shown in the figure, the highest rate was achieved when both the front and back surfaces were mirror-finished. However, the rate obtained was by far lower than that achieved when the front surface was mirror-finished and the back surface was damaged, as will be recognized by comparing Fig. 5 with Fig. 4. The deposition of both silver and polypyrrole took place in the illuminated front surface for the cases of 30 to 60 s etching of the damaged surfaces, but with further increase in the etching time, the silver deposition occurred on the back surface.

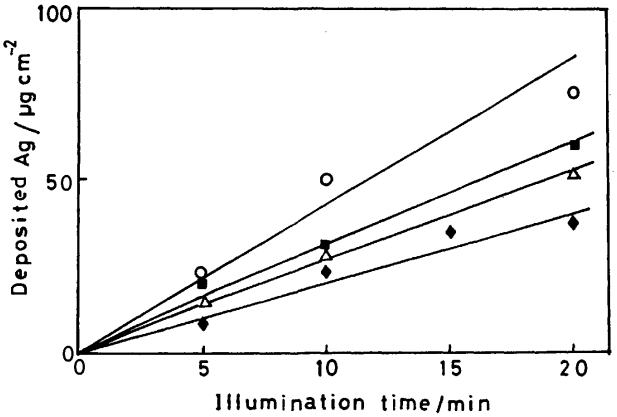

Fig. 6. As in Fig. 4, but for such surface conditions that the back surface was well-etched and the front surface was prepared by changing the etching time of the damaged surface for (■) 1 min, (△) 3 min, (◆) 5 min, and (○) 10 min.

Figure 6 shows the amount of deposited silver with illumination time for the case when the front surface was that prepared by etching the damaged surface for different time and the back surface was mirror-finished. The rate of silver deposition in that case was not so greatly influenced by the etching time of the damaged surface as that shown in Figs. 4 and 5. The interesting result obtained here is that the polypyrrole deposition took place on the mirror-finished back surface if the front surface was prepared by 30 to 60 s etching of the damaged surface, though the deposition on the front surface also took place with a less extent, as will be noticed from Fig. 7. In those cases, the silver deposition took place on the illuminated defective surface. With an increase in the etching time of the front surfaces, however, the polypyrrole deposition became to occur on the illuminated front surface. Simultaneously, the silver deposition became to take place on the back surface. It was found that the etching for 5 min was enough to change the major deposition place in such a manner as described above.

Figure 7 shows an example showing the occurrence of the polypyrrole deposition on the mirror-finished back surfaces as well as on the illuminated defective surface that was prepared by etching the damaged surface for 1 min. The illumination was made in that case by a He-Ne laser beam of ca. 0.5 mm diameter. According to this figure, there is a remarkable difference in the deposited patterns between the front surface and the back surface. In the front surface, the size of the deposition was near to that of the laser beam, but in the back surface the deposited polypyrrole occupied a much greater area. It seems important to remark here that if the front surface was unchanged but the back surface was changed from the mirror-finished surface to the damaged one, the polypyrrole deposition took place exclusively on the front

surface. Figure 8 shows the time course of the Ag deposition onto two kinds of n-type Si wafers whose front surfaces were the same and prepared by 1 min etching of the damaged surface, but whose back surfaces were different; one was mirror-finished and the other damaged. The deposition reaction at the Si wafer whose back surface was damaged stopped occurring at earlier illumination time than that at the wafer whose back surface was mirror-finished. The reason for this is that the photodeposition reaction does not proceed anymore when the deposited polypyrrole on the front surface becomes thick enough to absorb completely the incident photons, and such events are achieved more easily when the back surface of the wafer was damaged, because in that case the polypyrrole deposition took place exclusively on the front surface.

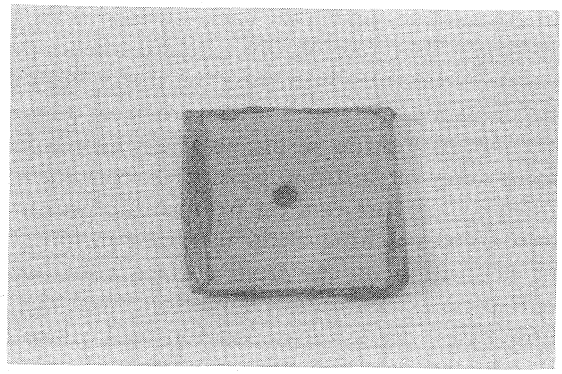

Fig. 7. Pictures showing the polypyrrole deposition on the well-etched back surface in the dark of n-type Si wafers of 0.6 mm thickness and of the resistivity of 2.4 Ωcm. The front surface was prepared by etching the damaged surfaces for 1 min, while the back surface was well-etched. Illumination was made by ca. 0.5 mm diameter He-Ne laser beam. (a) The back surface in the dark after illumination for 20 min, and (a′) the front surface at the same time.

The deposition of polypyrrole on the back surface in the dark of Si wafers was further investigated by using Si wafers of different resistivity and thickness. The experiments were carried out with almost the same surface configuration as that employed in the experiments whose results are given in Fig. 7; the front surface of the wafer was prepared by etching the damaged surface for 30 s and the back surface was mirror-finished. All the results including those shown in Fig. 7 are given in Table 1. It is recognized

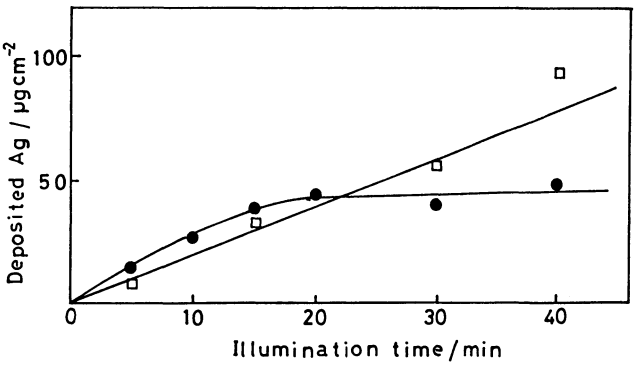

Fig. 8. Time course of the Ag deposition onto n-type Si wafers having different surface conditions in the back surfaces. The front surface was prepared by etching the damaged surface for 1 min for both cases, but the back surface was (□) well-etched and (●) damaged. Illumination: 0.45 W cm^{-2} xenon lamp.

Table 1. The Occurrence of Positive Hole-Consuming Polypyrrole Deposition on n-Type Si Wafers of Varous Resistivities and Thickness

Resistivity	Thickness	Deposition of polypyrrole		Diffusion length of positive hole
ohm cm	mm	Illuminated front surface	Back surface in the dark	mm
0.77	0.4	Occurred	Occurred	0.45
2.8	1.1	Occurred	Not occurred	0.63
2.8	0.9	Occurred	Not occurred	0.63
2.8	0.3	Occurred	Occurred	0.63
2.4	0.6	Occurred	Occurred	0.61

The front surface was prepared by etching the damaged surface for 30 s, while the back surface was well-etched. Illumination was made by a 25 mW He-Ne laser of ca. 0.5 mm beam diameter.

from the results shown in the table that the polypyrrole deposition on the mirror-finished back surface did not always take place.

Discussion

The most interesting result obtained in this study is that the oxidative deposition of polypyrrole occurred on the mirror-finished back surface if the front surface was prepared by etching the damaged surface for 30 to 60 s. Discussion on this result will be made first for the case of using the He-Ne laser as a light source.

The light penetration depth estimated from the inverse of the absorption coefficient at 632 nm is ca. 3.2 μm,[11] while the flaws in the surface prepared by ething the damaged surface for 30 to 60 s would leave the flaws of ca. 28 to 21 μm depth on average based on the assumption that the damaged surface originally contained flaws of 34 μm depth and the etching rate was 13 μm min^{-1}.[10] Accordingly, illumination of such surface will result in photogeneration of charge carriers in a surface region containing defects. Such speculation seems valid, judging from the SEM pictures of the electrode surfaces shown in Figs. 1(b) and (c), where fairly deep ditches are seen in the surfaces prepared by 30 to 60 s etching of the damaged surface. Photocurrent-potential bahaviors given in Figs. 2 and 3 also suggest that in cases of etching the damaged surface for 30 to 60 s the photogeneration of charge carriers occurred in the surface containing defects, because the onset potential of anodic photocurrens at the electrodes preprared by 30 to 60 s etching of the damaged surface was more positive than that at the mirror-finished surface.

The thickness of the space charge layer of n-type Si wafer having 2.4 ohm cm resistivity in the deposition bath is estimated to be 0.45 μm by using an well-established equation[12] under the assumption that the band bending is 0.4 V[2,3] and 2.4 Ωcm n-type Si contains 2.4×10^{15} cm^{-3} donors which is estimated from a donor concentration (N_d) vs. resistivity relation published as Fig. 5 of Ref. 13. The estimated space charge thickness is valid for well-etched surfaces and the values become small with an increase in the defect concentration.[5,7] The reviewer questioned why N_d was not determined by the Mott-Shottky plots of differential capacitances of the semiconductor electrodes. The Mott-Shottky plots may be a convenient way to determine N_d, but in many cases frequency dispersions appear in the plots, giving inaccurate determination of it. It has been shown for TiO_2 electrodes[14,15] that special surface treatments are necessary to eliminate the frequency dispersion in the plots.

It is known from the above estimation that the thickness of the Si wafers used in the present study was much greater than the sum of the light penetration depth and the space charge layer. Accordingly, positive holes must be supplied to the back surface by diffusion to cause the polypyrrole deposition there. To confirm this view, the diffusion length of positive holes (L_h) is estimated by inserting into Eqs. 1 and 2 the published data on the life time (τ_h)[16] and the mobility (μ_h)[17] both of which are available as a function of N_d.

$$L_h = (\tau_h D_h)^{1/2} \quad (1)$$

$$D_h = \mu_h kT/q \quad (2)$$

where D_h is the diffusion constant of positive holes. To estimate τ_h and μ_h, knowledge on N_d was required, and this was done from the resistivity values of the wafers using the published N_d vs. resistivity relation.[13] The estimated τ_h and μ_h of 2.4 Ω cm n-type Si, for example, were 3.4×10^{-4} s and 430 cm^2 V^{-1} s^{-1}, respectively. By using τ_h and μ_h estimated as a function of resistivities the diffusion length of positive holes is obtained also as a function of the resistivities, as shown in Fig. 9. In Table 1, the diffusion length of positive holes estimated in this manner is given. It is noticed from this table that the polypyrrole deposition took place on the mirror-finished back surface when the diffusion length of positive holes was greater than the thickness of the Si wafers used.

According to the above analysis, the thickness of Si samples used in the experiments whose results are given in Figs. 4 to 6 was shorter than the diffusion length of positive holes. Nevertheless, the polypyrrole deposition did not occur on the back surface if it was either damaged or contained a relatively high amount of defects. The main reason for this is that the presence of flaws in the back surface in the dark results in the annihilation of positive holes there. On the other hand, the presence of flaws is favorable for the silver deposition, as already described above. Furthermore, it must be remarked here that the polypyrrole deposition did not occur on the mirror-

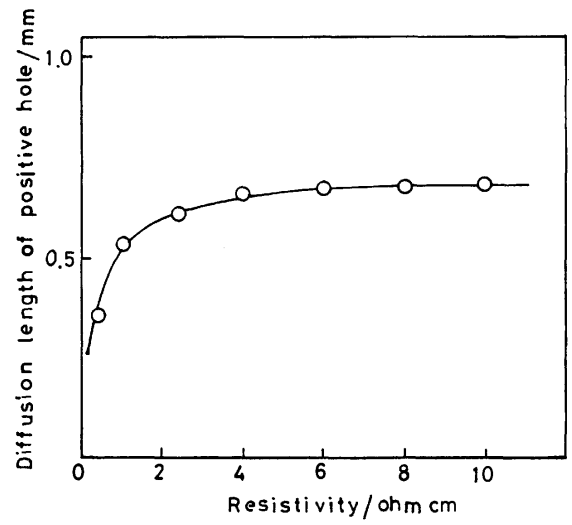

Fig. 9. The diffusion length of positive holes as a function of resistivity of n-type Si single crystals at 25 °C.

finished back surface if the front surface was also mirror-finished. Main reason for this is as follows. Since the bands are bent upward in the deposition bath, the energy structure of the illuminated mirror-finished surface is suited for the polypyrrole deposition there, but the photogenerated electrons are forced to move towards the bulk, where they recombine with positive holes that are supplied by diffusion. According to the results, the silver deposition took place on the back surface if both front and back surface were mirror-finished. Adsorbed silver ions may generate surface states which contribute to the silver deposition.[18] However, it is noticed that the rate was relatively low in that case, compared to that obtained when the front surface was mirror-finished and the back surface was damaged.

It is quite reasonable to consider that charge carriers supplied by diffusion contribute to heterogeneous reactions, but the present study have made clear that the contribution becomes appreciable under a special configuration of semiconductor surfaces; the back surface is mirror-polished and the front surface contains both anodic and cathodic sites. It is believed that the same should hold in photocatalysis of semiconductor powders.

Quantitative Mapping of Metal-Centered Dipolar Field in Hemin Dicyano Complex by Solution NMR

Yasuhiko YAMAMOTO,* Norishige NANAI, Yoshio INOUE, and Riichirô CHÛJÔ
Department of Biomolecular Engineering, Tokyo Institute of Technology, 12-1, 2-Chome, O-okayama, Meguro-ku, Tokyo 152
(Received December 23, 1988)

The metal-centered pseudo-contact shift contribution in the hyperfine shift of NMR resonance of paramagnetic hemin dicyano complex ([Fe^{III}(proto)$(CN)_2$]) in solution was quantitatively determined from the combined use of ^1H and ^{13}C NMR data. Taking advantage of the axially symmetric magnetic property for [Fe^{III}(proto)$(CN)_2$] in solution, the paramagnetic metal-centered dipolar field was quantitatively mapped. The highly solvent-dependent magnetic anisotropy, $(g^2_{//}-g^2_{\perp})$, of this complex in CD_3OD was estimated to be 7.2 and the obtained value is placed between the values in D_2O (4.4) and in $CDCl_3$ (9 .7).

Heme occupies the active sites of various hemoproteins and its electronic structure is crucially related to the functional properties of these proteins.[1] NMR presents potentially one of the most powerful spectroscopic techniques to investigate the structure-function relationship of hemoproteins in solution.[2-8] In the case of paramagnetic hemoproteins and hemin complexes, the hyperfine field due to the unpaired electron(s) of the heme iron provides a unique probe to characterize the electronic/molecular structure of the heme, because the hyperfine shifted NMR resonances arising from the heme and/or the surrounding amino acid residues in paramagnetic hemoproteins are extremely sensitive to the change in the heme molecular environments. The observed chemical shift of a hyperfine shifted resonance (δ_{obs}) is composed of three terms;[9,10] $\delta_{obs}=\delta_{dia}+\delta_c+\delta_{pc}$($\delta_c+\delta_{pc}$ is called the hyperfine shift (δ_{hf})), where δ_{dia} is the chemical shift of a suitable diamagnetic complex and δ_c and δ_{pc} are the contact and the metal-centered pseudo-contact shifts, respectively, which stem from the interaction of the nucleus with the unpaired electron(s). The δ_c value reflects the unpaired electron density delocalized into the s orbital of that nucleus and the δ_{pc} value can be interpreted in terms of the spatial relationship between that nucleus and the unpaired electron localized at the heme iron. Therefore the relative contributions of δ_c and δ_{pc} to δ_{hf} have to be determined in order to quantitatively analyze the δ_c value in terms of the unpaired spin delocalization, i.e., electronic structure of the heme, and the heme molecular structure.

Several procedures for separating δ_{hf} to δ_c and δ_{pc} have been proposed.[9,11-13] Those procedures usually start with the determination of magnetic anisotropy and the location of magnetic axes and, therefore, generally rely on the g-tensor measurements of either single crystal or frozen sample.[14-16] Even for ideal magnetic behavior, questions must remain about the application of those solid data to interpret solution NMR results. Goff[13,17] has demonstrated an approach to estimate the metal-centered pseudo-contact shift of fourfold symmetric iron(III) tetraphenylporphyrin derivative-imidazole complexes using solution NMR measurements with the assumption that the resonances from the peripheral phenyl groups experience predominantly metal-centered pseudo-contact shifts and, hence, their contact shifts are neglected. Since cyanide ion is the most frequently used as an external ligand for iron(III) hemoproteins to ensure a stable low-spin complex and the NMR spectral properties of iron(III) hemoprotein-cyano (met-cyano) complex are considerably different from those of iron(III) hemoprotein-imidazole (met-imidazole) complex, it is of interest to investigate the metal-centered dipolar field in met-cyano complex and to compare it with that in met-imidazole complex.

We present herein a novel method to quantitatively characterize the paramagnetic metal-centered dipolar field in paramagnetic low-spin hemin dicyano complex by making use of the difference in the δ_{pc} value between heme methyl carbon and attached proton nuclei. Since it has been proved that in-plane magnetic anisotropy of hemin dicyano complex in solution is averaged to zero,[18] the assumption of axially symmetric dipolar field can be confidently applied to analyze the metal-centered dipolar field of this complex. The proposed method can be useful to map the metal-centered dipolar field in paramagnetic low-spin hemin complexes and hemoproteins with insignificant in-plane magnetic anisotropy.

Experimental

Material; Hemin chloride and (protoporphyrinato IX) zinc(II) were purchased from Sigma Chemical Co. and Aldrich Chemical Co., respectively, and were dissolved in methanol-d_4(CD_3OD) with 5-fold excess of KCN and pyridine-d_5(C_5D_5N), respectively, for the NMR measurements. Concentration of both samples are ca. 20 mM.

Instrumentation; NMR spectra were recorded on a JEOL GX-270 FT NMR spectrometer operating in the quadrature mode (^1H and ^{13}C frequencies are 270 and 67.9 MHz, respectively). Typical ^1H spectra consisted of 256 transients with 32K data points over 5000 and 10000 Hz for

Zn and Fe complexes, respectively. Proton noise decoupled ^{13}C NMR spectra were recorded using a 10 mm diameter tunable probe, about 5000 transients, 16K data points over 30 kHz. The obtained free induction decay was apodized at 1—10 Hz. ^{1}H-^{13}C heteronuclear chemical shift correlated spectrum (^{1}H-^{13}C COSY spectrum) of (protoporphyrinato IX)zinc(II) ([Zn^{II}(proto)]) in C_5D_5N was recorded using the standard pulse sequences.[19] The time domain data matrix, 2K(^{13}C-15000 Hz)×128(^{1}H-4000 Hz) was expanded to the final matrix size 2K×512 by zero filling. The data matrix was apodized with a sine bell function in both dimensions and the spectrum is presented in the absolute value mode. Chemical shifts are given in parts per million (ppm) downfield from 2,2-dimethyl-2-silapentane-5-sulfonate (DSS).

Results and Discussion

Resonance Assignment in ^{1}H and ^{13}C NMR Spectra of [Zn^{II}(proto)]. ^{1}H-^{13}C COSY spectrum of diamagnetic [Zn^{II}(proto)] in C_5D_5N at 29 °C, together with the ^{1}H and ^{13}C NMR spectra attached along the F_1 and F_2 axes, respectively, is illustrated in Fig. 1. The individual ^{1}H signal assignment is obtained by a combined use of ^{1}H-^{1}H chemical shift correlated and nuclear Overhauser effect correlated spectroscopies (results not shown) and is shown with the ^{1}H spectrum in the figure. From the known ^{1}H assignment, the ^{13}C assignment is clearly established by the ^{1}H-^{13}C connectivities in the ^{1}H-^{13}C COSY spectrum. The resonances from the quaternary β-pyrrole carbon nuclei were assigned using the long-range ^{1}H-^{13}C COSY experiment (results not shown) and no attempt was made for assigning the quaternary α-pyrrole carbon resonances. The present assignments on both ^{1}H and ^{13}C spectra confirm the partial assignment previously reported[2,20] and are summarized in Table 1. Because of the presence of a pseudo-C_2 symmetry in [Zn^{II}(proto)] molecular structure, C_2 symmetric nature of its electronic structure with respect to the α,γ-meso axis is clearly reflected in the NMR spectra. The chemical shift values of [Zn^{II}(proto)] are used as the diamagnetic reference shift (δ_{dia}) in the analysis on the shifts of the paramagnetic hemin dicyano complex([Fe^{III}(proto)$(CN)_2$]) (see below).

complex has been reported previously.[21] The observed shifts for the heme methyl, meso, and quaternary β-pyrrole carbon resonances are plotted against reciprocal of absolute temperature in Fig. 3. Curvatures of the plots, especially in the plots of β-pyrrole carbon resonances, are apparently like the Curie plots for the ^{13}C resonances of iron(III) tetraphenylporphyrin derivative-imidazole complexes,[13,17] and, as reported previously,[2] ^1H data also exhibit some curvature in their Curie plots (results not shown). Nonlinear temperature dependence of the pseudo-contact shift[17] does not simply account for the degree of the curvature in their Curie plots because the curvature of the β-pyrrole carbon resonances is greater than that of the meso carbon resonances although the latter carbon nuclei are closer to the heme iron. Therefore the effects of aggregation[22] at low temperature might be responsible for the non-linear Curie plot. But the observed shifts of $[Fe^{III}(proto)(CN)_2]$ NMR resonances at 40 °C were essentially independent of concentration from 5 to 50 mmol dm^{-3}. The intercepts (at $T^{-1}=0$) of the Curie plots for all the resonances were calculated from the least-square fitting of the plots and are given in Table 1. The difference between the chemical shift value in $[Zn^{II}(proto)]$ and the intercept of the Curie plot, for the corresponding resonances, is relatively small for the heme side-chain carbon resonances and is large for the ^1H resonances, although the intercepts are close with each other among the resonances for the ^1H nuclei of same type.

Quantitative Mapping of Paramagnetic Metal-Centered Pseudo-Contact Field in $[Fe^{III}(proto)(CN)_2]$. The observed shifts of the heme methyl carbon resonances are plotted against those of the attached proton

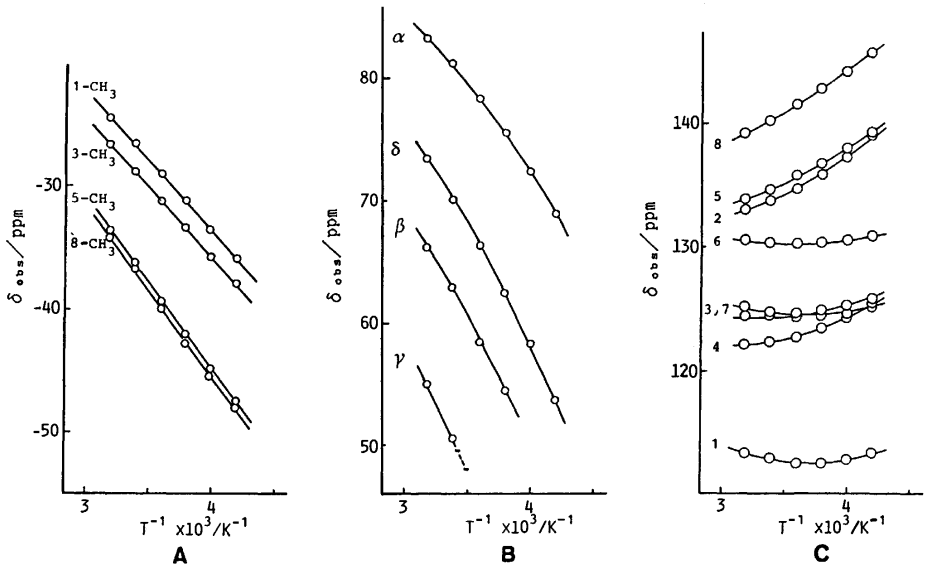

Fig. 3. Curie plot, the observed shift (δ_{obs}) vs. reciprocal of absolute temperature, for the heme methyl (A), meso (B), and β-pyrrole (C) carbon resonances. The curvature of the plots is most significant for the β-pyrrole resonances.

resonances, at various temperatures, in Fig. 4. As previously reported,[23] those plots give straight lines with a slope of $Q^{C}_{C'C}\gamma_H/Q^{H}_{CCH_3}\gamma_C$ for the system of axial symmetry ($Q^{C}_{C'C}$ and $Q^{H}_{CCH_3}$ are the parameters that account for the transfer of the unpaired spin density in the π orbital of the pyrrole carbon to directly-bonded carbon nucleus via the spin polarization and to the heme methyl proton nuclei through the hyperconjugation, respectively, and γ_H and γ_C are the gyromagnetic ratios of the proton and the carbon nuclei, respectively). The plots in Fig. 4 are straight and exhibit almost same slope over the temperature range examined, indicating $Q^{C}_{C'C}/Q^{H}_{CCH_3}$ is independent of temperature from −35—40 °C. The value of $Q^{C}_{C'C}=-39$ MHz reported for π-radical system[24] combined with the slope of the plots(=1.90) yield 82 MHz for $Q^{H}_{CCH_3}$.

For the limiting case of axial symmetry, δ_{pc} is expressed by Eq. 1,[10]

$$\delta_{pc}=\frac{(\chi_{//}-\chi_{\perp})}{3N}\frac{(3\cos^2\theta-1)}{r^3} \qquad (1)$$

where N is Avogadro's number. $\chi_{//}$ and $\chi_{\perp}$ are the components of the molecular susceptibility parallel and perpendicular to z axis of the hemin molecule (z axis is defined along the normal to the porphyrin plane). The quantity, $(3\cos^2\theta-1)/r^3$, is called axial geometric factor which defines the spatial position of the observed nucleus with respect to z axis and iron center of the hemin. Our procedure for mapping the paramagnetic metal-centered dipolar field relies on the assumption of axial symmetry in the magnetic property of [Fe^{III}(proto)$(CN)_2$]. But it has been verified for [Fe^{III}(proto)$(CN)_2$] that the in-plane anisotropy, which is present in the frozen glass state, is

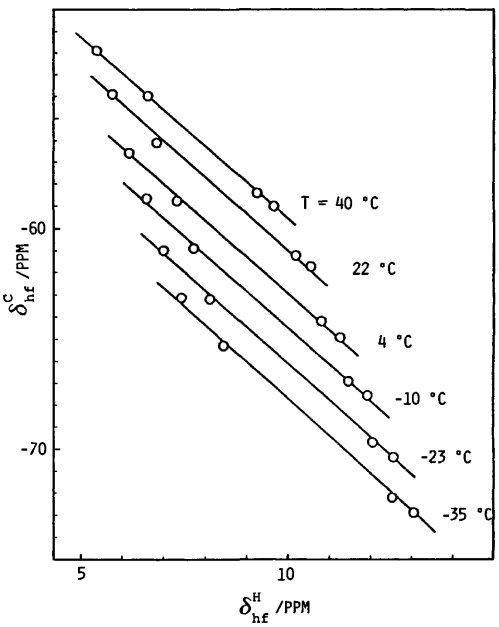

Fig. 4. The plots of heme methyl carbon hyperfine shift against the attached proton hyperfine shift at various temperatures. The plots strongly support that the in-plane magnetic anisotropy of [Fe^{III}(proto)$(CN)_2$] in solution is not significant and the $Q^{C}_{C'C}/Q^{H}_{CCH_3}$ is independent of temperature.

averaged to zero in solution.[18] The linear plots shown in Fig. 4 also prove the insignificant in-plane anisotropy of this complex.

Since the δ_c values of the heme methyl carbon and the attached proton resonances are proportional to the unpaired electron density in the π orbital of the pyrrole carbon to which the methyl group is attached, they vanish simultaneously as the density becomes

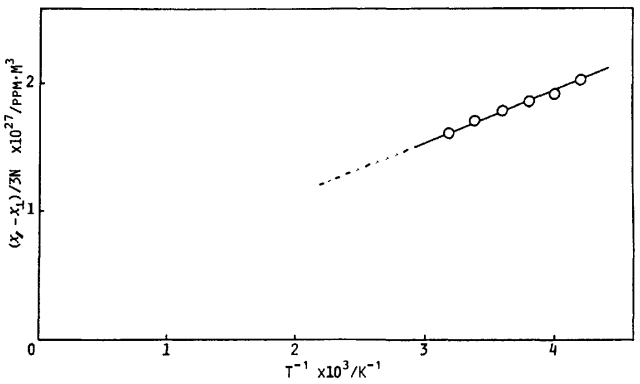

Fig. 5. The plots of $(\chi_{/\!/}-\chi_\perp)/3N$ against T^{-1}. The linear relationship indicates that the magnetic anisotropy is independent of temperature over the temperature range examined. Non-zero intercept would arise from unknown temperature dependence of $(\chi_{/\!/}-\chi_\perp)$ $(3\cos^2\theta-1)/r^3$.

0. Therefore the slope and intercept of the plots in Fig. 4 combined with the axial geometric factors[25] of heme methyl carbon and proton nuclei yield the coefficient of Eq. 1, $(\chi_{/\!/}-\chi_\perp)/3N$, and hence the axial metal-centered dipolar field given in Eq. 1 can be determined. δ_{pc} value of a given nucleus can be calculated from its axial geometric factor using the obtained equation.

The $(\chi_{/\!/}-\chi_\perp)/3N$ values are calculated at different temperatures and are plotted against T^{-1} in Fig. 5. The plot exhibits a straight line over the temperature range studied, supporting the validity of the present method for estimating δ_{pc}. The magnetic anisotropy appears to be essentially independent of temperature over the temperature range examined. If we assume that there is only a single spin state with insignificant second-order Zeeman contribution, $(\chi_{/\!/}-\chi_\perp)/3N$ is rewritten in terms of the g-factor as $\beta^2S(S+1)(g_{/\!/}^2-g_\perp^2)/9kT$ (β, S, and k are the Bohr magneton, total spin and Boltzmann constant, respectively).[10] The slope of the plot in Fig. 5 yields the value of 7.2 for the quantity, $g_{/\!/}^2-g_\perp^2$. It has been demonstrated that the magnetic anisotropy, $g_{/\!/}^2-g_\perp^2$, for [Fe^{III}(proto)$(CN)_2$] is highly solvent sensitive and is 4.4($g_{/\!/}\approx2.9$, $g_\perp\approx2.0$) in D_2O[26] and 9.7($g_{/\!/}\approx3.6$, $g_\perp\approx1.6$) in $CDCl_3$.[27] The value of 7.2 for CD_3OD solvent, obtained in the present study, is between those values and yields the δ_{pc} value of −14 ppm for the meso protons at 40 °C that is relatively large compared with the value previously estimated (−10 ppm) for met-imidazole complex,[13] but is comparable to the earlier estimation for [Fe^{III}(proto)(C_5H_5N)(CN)] complex.[11] Using −14 ppm for the δ_{pc} of meso proton resonances, the π-electron density(in percent) of −0.25, −0.33, −0.42, and −0.33(minus sign indicates negative spin density.) are calculated for the α, β, γ, and δ meso carbon nuclei, respectively, and +0.83, +0.88, +1.03, and +1.04 for 1, 3, 5, and 8-pyrrole carbons, respectively. Non-zero intercept of the plot shown in Fig. 5 would arise from unknown temperature dependence of $(\chi_{/\!/}-\chi_\perp)(3\cos^2\theta-1)/r^3$.

The present method can be applied to any paramagnetic low-spin iron(III) porphyrin complexes including hemoproteins for mapping the paramagnetic metal-centered dipolar field as long as their in-plane magnetic anisotropy is not so significantly large. The heme methyl carbon resonances have been observed in various paramagnetic low-spin hemoproteins.[23,28]

Thermal Isomerization of 1′,3′,3′-Trimethyl-8-nitrospiro-[2*H*-1-benzopyran-2,2′-indoline]-6-carboxylic Acid

Norio NISHIMURA,* Jun'ichi MIYAKE, and Yoshimi SUEISHI
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700
(Received January 5, 1988)

The rates of thermal isomerization of 1′,3′,3′-trimethyl-8-nitrospiro[2*H*-1-benzopyran-2,2′-indoline]-6-carboxylic acid (6-COOH-8-NO_2-SP) from its spiro form (SP) to its merocyanine form (MC) have been measured in some solvents and at high pressures. The equilibrium constants between these isomers at atmospheric pressure and at 30 °C are in the range of 0.25 to 2.52 depending on solvents. The activation volumes are 0.2—3.4 $cm^3 mol^{-1}$, while the reaction volumes are −7.9—−22.3 $cm^3 mol^{-1}$. Thus the volume profile was found to have a maximum, as predicted previously.

Thermochromic materials have attracted attention for many years. Recently, interest has been stimulated due to their practical applications to thermal copies, optical switches and displays. Spiropyrans belong to the most important class of the organic photochromic compounds which are used as light-sensitive materials. In spite of their practical interests, a little work focused on the mechanism of the photo and thermal isomerization of spiropyrans between SP and MC has been done.[1-5]

Recently we have studied the solvent and pressure effects on the rate of thermal conversion of 1′,3′,3′-trimethyl-6-nitrospiro[2*H*-1-benzopyran-2,2′-indoline] (6-NO_2-SP)[6] from MC to SP, and of 1′,3′,3′-trimethyl-spiro[2*H*-1-benzopyran-2,2′-indoline]-8-carboxylic acid (8-COOH-SP)[7] from SP to MC. The role of solvent-induced solute (MC) dipole has been discussed. The volume profile predicted with the help of these compounds has a maximum which is rarely found in chemical reactions. It has been concluded that these compounds probably isomerize via the same reaction path, i.e., via a transition state involving homolytic bond fission or bond formation, rather than via a heterolytic transition state.

The present work has been undertaken to ascertain if such a maximum really exists in the volume profile. We have used 6-COOH- 8-NO_2-SP for which SP and MC are in thermal equilibrium in the dark, and this made the estimation of equilibrium constant possible at any temperatures and pressures. The kinetic and thermodynamic quantities for the isomerization reaction are presented and the energy and volume profiles drawn.

Experimental

Materials. Utilizing the Reimer-Tiemann reaction, 3-formyl-4-hydroxybenzoic acid was prepared according to the method of Wynberg:[8] 4-hydroxybenzoic acid (0.1 mol) was refluxed for an hour with water (90 cm^3), KOH (1 mol), and chloroform (0.125 mol). After acidification and ether extraction, a brown solid 3-formyl-4-hydroxybenzoic acid was obtained. Nitration of this compound was carried out at temperatures between −5 and −10 °C. The precipitate, 3-formyl-4-hydroxy-5-nitrobenzoic acid, was recrystallized from 2-propanol; mp 217—219 °C. Equimolar amounts of this compound and 1,3,3-trimethyl-2-methylene indoline were dissolved into ethanol and the solution was refluxed for two hours. A dark precipitate 6-COOH-8-NO_2-SP was collected and dried. This compound is sparingly soluble in most solvents, and no further purification has been tried. However, its ^1H NMR spectrum in DMSO-d_6 showed that this compound is clearly an isomeric mixture of SP and MC in solution; δ=1.12, 1.25 (s, 3′-CH_3), 2.67 (s, >N-CH_3) for SP; δ=1.74 (s, 3′-CH_3), 3.91 (s, >N-CH_3) for MC. For spectral assignments, a report of Toppet et al. was referred.[9] Solvents used are of reagent grade and purified and dried in the usual manner.

Procedure. High pressure techniques and procedures for kinetic measurements were almost the same as those described before.[10] A sample solution (ca. 10^{-4} mol dm^{-3}) flushed with nitrogen gas was irradiated for a few seconds with a projection lamp. The thermal return from SP to MC was followed by monitoring the change in the absorbance in the vicinity of 560 nm using a Hitachi 139 spectrophotometer. The half life of the reaction was of the order of 10^3 s, and the absorbance at $t=\infty$ was estimated so that the first-order plot produced a best straight line. The photo and thermal isomerizations could be carried out reproducibly, and the apparent first-order rate constants (see Eq. 2 below) agreed within 5% error.

Results

Although conformational problems[3-5,11] remain for MC, the thermal equilibrium of 6-COOH-8-NO_2-SP between SP and MC can simply be represented as

$$\mathrm{SP} \underset{k_b}{\overset{k_f}{\rightleftarrows}} \mathrm{MC} \qquad (1)$$

Upon irradiation of the visible light, the equilibrium shifts to SP, and it returns to the original state in the dark.

In order to determine the concentrations of the isomers, it is necessary to know the molar absorptivity of MC. First, the equilibrium constant at 25 °C in DMSO-d_6 was estimated by means of ^1H NMR technique; the ratio of the integrated intensities of 3′-methyl protons in MC snd SP was regarded as the equilibrium constant (K=2.83 at 25 °C). From this

Table 1. Equilibrium Constants of 6-COOH-8-NO_2-SP between MC and SP at Various Pressures and Volumes of Reaction

Solvent	λ_{max}/nm	K (30 °C)						$\Delta V°$	ΔV_{solv}	$10^{11}q_p$ [a]	ΔV_{solv} [b]
	p/kgf cm^{-2} [c]	1	200	400	600	800	1200	cm^{3}mol^{-1}	cm^{3}mol^{-1}	Pa^{-1}	cm^{3}mol^{-1}
$CHCl_3$	573	0.250		0.312		0.383	0.454	−15.6	−30.6	15.9(30 °C)	−32.5
1,2-Dichloroethane	566	0.299		0.389		0.484	0.571	−18.6	−33.6	12.1(30 °C)	−24.7
Acetone	565	0.314		0.431		0.546	0.653	−22.3	−37.3	6.02(35 °C)	−12.3
DMSO	555	2.52	2.62	2.80	2.84			−7.9	−22.9	1.2 [d]	−1.8

a) Original q_p-values (Refs. 14,15) calculated on the basis of the Tait-type equation, $q_p=A/(B+p)$, are about twice as large as ours. We have estimated $(\partial\varepsilon/\partial p)_{T,p=0.1\ MPa}$ from the quadratic regression equation, $\varepsilon=ap^2+bp+c$. b) Calculated by using Eq. 7. c) 1 kgf cm^{-2}=9.81×10^4 Pa. d) Estimated by assuming $(\partial\varepsilon/\partial p)$= 3×10^{-8} Pa^{-1} (see text).

K-value and the absorbace at 555 nm (λ_{max} of MC), the molar absorptivity was estimated to be 33000 dm^{3}mol^{-1}cm^{-1}. This value could be used for other solvents without substantial danger, since the spectral shapes in the visible region in different solvents are almost the same.

It was found that the return rate follows the first-order kinetics, as expressed by Eq. 2.

$$d[MC]/dt = k_{obsd}([MC]_\infty - [MC]) \quad (2)$$

where $[MC]_\infty$ is the concentration of MC at equilibrium and k_{obsd} ($=k_f+k_b$) is the apparent rate constant. The equilibrium constant K is given by

$$K=[MC]_\infty/[SP]_\infty = k_f/k_b \quad (3)$$

Using K and k_{obsd}, k_f and k_b were calculated. These values at various pressures and temperatures are given in Tables 1—3.

The pressure dependence of the equilibrium constant was approximated by the following quadratic equation:

$$\ln K = ap^2+bp+c \quad (4)$$

Discussion

The reaction volumes ($\Delta V°$) at atmospheric pressure were estimated by

$$\Delta V° = (\partial \ln K/\partial P)_T \cong -bRT \quad (5)$$

and they are given in Table 1. The activation volumes for the forward and backward reactions (Eq. 1) estimated by similar equations are given in Table 2. Using the data in Tables 1—3, $\ln K$, $\ln k_f$, and $\ln k_b$ were plotted against $1/T$ in accordance with the van't Hoff and Arrhenius equations (Fig. 1, r=0.998 each). From these plots, thermodynamic parameters were estimated and they are given in Table 4. The equilibrium constant in DMSO, compared with those in other solvents (Table 1) is greater by about a factor of ten, indicating the increased stabilization of MC relative to SP. The band in the visible region shifts to a shorter wavelength as the solvent polarity increases (blue shift). This inclination was also observed for 6-NO_2-SP.[6] There are some spiropyrans which exhibit

Table 2. Pressure Dependence of the Rate Constants for the Forward and Backward Reactions at 30 °C

Solvent	10^4k_f / s^{-1}						$\Delta V^{\neq}$ / cm^{3}mol^{-1}

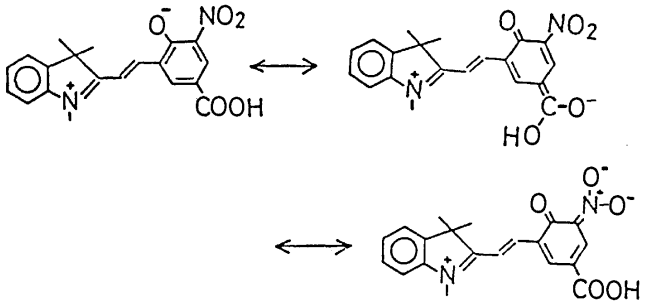
Table 4. Thermodynamic Quantities (303.2 K) for the Reaction SP ⇄ MC

Solvent	ΔH°	ΔS°	ΔV°	E_a	$\Delta S^{\neq}$	$\Delta V^{\neq}$	Remark
	kJ mol^{-1}	J mol^{-1} K^{-1}	cm^3 mol^{-1}	kJ mol^{-1}	J mol^{-1} K^{-1}	cm^3 mol^{-1}	
$CHCl_3$	−14.5	−59	−15.6	92.9	−13.9	1.0	Forward
				107.4	45.1	16.2	Backward
DMSO	−12.0	−32	−7.9	98.1	8.7	3.8	Forward
				109.7	40.3	8.3	Backward

the red shift.[12] Although this band may be assigned to the conjugation band (intramolecular charge-transfer band) through one of the possible conformations of MC,[5] the blue shift is contrary to the general trend of the π-π^* transition which exhibits the red shift. Therefore, the ground state of MC must be more polar than the excited state. In fact, the dipole moments of 6-NO_2-SP in the ground and excited states are reported to be 12.7 and 3.5 Debye (1 Debye= 3.34×10^{-30} mC), respectively.[13] A substantial contribution of the following zwitterionic structures in the ground state may be responsible for the above findings.



The Volume of Reaction. Volume change accompanied by chemical reactions is conventionally divided into two terms: an intrinsic volume change (ΔV_{int}) and a volume change arising from reorganization of solvent molecules (ΔV_{solv}), i.e.,

$$\Delta V^\circ = \Delta V_{int} + \Delta V_{solv} \quad (6)$$

Recent theoretical approach to the partial molar volume developed by Yoshimura and Nakahara,[14] enables us to understand its significance at the molecular level. However, the separate estimations of ΔV_{int} and ΔV_{solv} are rather critical, and must be done with great care.

Walling and Naiman[15] estimated the activation volumes of the Claisen rearrangement reaction in several solvents, and found that they fell in the range of −10—−15 cm^3 mol^{-1} with no obvious solvent dependence. They interpreted the results as consistent with rather tightly bonded cyclic transition state. This volume change could formally be ascribed to a 6-membered-ring-closure process. If we tentatively allot 15 cm^3 mol^{-1} for ΔV_{int} in the present case, then the "relative" values of ΔV_{solv} could be calculated. They are given in the 3rd column from the right in Table 1.

On the basis of the Kirkwood equation, ΔV_{solv} could be given by Eq. 7.

$$\Delta V_{solv} = N_A\left(\frac{\mu_{MC}^2}{r_{MC}^3} - \frac{\mu_{SP}^2}{r_{SP}^3}\right) q_P \quad (7)$$

where q_P is defined by Eq. 8.

$$q_P = \frac{3}{(2\varepsilon+1)}\left(\frac{\partial\varepsilon}{\partial p}\right)_{T,p=0.1\,MPa} \quad (8)$$

Using available ε-p data,[16,17] q_P-values were estimated (Table 1). Then, likely μ and r values(μ_{MC}=15 Debye, μ_{SP}=3 Debye, $r_{MC}=r_{SP}$=0.4 nm) were substituted into Eq. 7, together with the q_P-values (Table 1). The discrepancy between the observed ΔV_{solv} ($=\Delta V^\circ - \Delta V_{int}$) and calculated ΔV_{solv} becomes remarkable in the order chloroform <1,2-dichloroethane< acetone. This could be attributed to the enhanced polarization (increase of μ) within merocyanine molecule as the solvent polarity increases. Previously, we discussed this enhancement effect in some detail.[6,18,19] Unfortunately, no ϵ-p data are available for DMSO. However, judging from the $(\partial\varepsilon/\partial p)_T$-values for acetone and methanol[16,17] as polar solvents, $(\partial\varepsilon/\partial p)_T$-value for DMSO may not be far from 3×10^{-8} Pa^{-1}. Thus ΔV_{solv} in DMSO is presumed to be ca. −1.8 cm^3 mol^{-1}. It

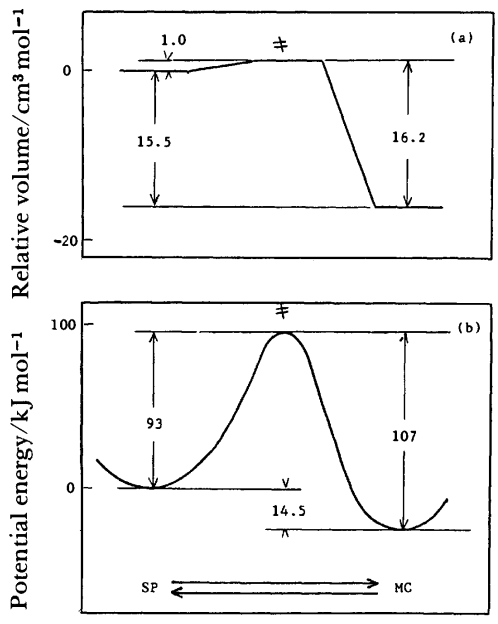


Fig. 2. Volume (a) and energy (b) profiles for the isomeric reaction of 6-COOH-8-NO_2-SP in $CHCl_3$.

could be said that the remarkable enhancement effect is involved in the case of DMSO, too.

Energy and Volume Profiles. In simple one-step reactions, the volume profiles are those having no extremum. This is in sharp contrast to the energy profile which has a maximum inevitably. According to le Noble,[20] extrema are usually the rule for stepwise reactions. However, there are some exceptions: sigmatropic shifts such as the Claisen rearrangement show minina.[21] Diels-Alder reactions participated by maleic anhydride as a dienophile also show minima.[22-24] The reaction of *p*-methoxystyrene with TCNE is another example which involves minima in the volume profile.[25] A maximum was observed in the degenerate Wagner-Meerwein shift[26] and the amide rotation of dipeptides.[27]

The energy and volume profiles are shown in Fig. 2. The activation volumes for the forward reaction are positive and small, while the reaction volumes are negative (Table 2). Therefore, it is hard to imagine a dipolar transition state where the second term in Eq. 6 would overwhelm the first one. A transition state which involves a homolytic bond stretching may be acceptable; a small volume increment is expected in this process. Therefore, it could be said that the transition state is located near the initial state in the sense that the nuclei are near the initial positions.

If the data in Table 4 are inspected, one may notice that both ΔH° and ΔS° are smaller in $CHCl_3$ than in DMSO. The same is true for E_a and ΔS^*, and ΔS° (ΔS^*) and ΔV° (ΔV^*) for the forward reaction. Although the reason is not clear, this compensation effect observed for $CHCl_3$ and DMSO are in line with the previous results.[7] It is notable that the entropy factor is as important as the enthalpy factor in determining the equilibrium. Leffler[28] exemplified the compensation effect for a variety of reaction series, and for reactions in solvents of varying polarity. The existence of the isokinetic temperature predicted from the linear free energy relationship was demonstrated by us.[29] Similarly, a rough linear correlation between $\Delta S^\circ(\Delta S^*)$ and $\Delta V^\circ(\Delta V^\circ)$ was also reported,[30-32] and the reason discussed by Kondo and Tokura.[33] Our results in this and previous investigations are in line with the findings of the above reports.

Ionic Partial Molar Volumes of Alkali Halides in Methanol as Evaluated from the Sedimentation Potentials

Hiromitu HIRAKAWA,* Hiroyasu NOMURA,† and Fumio KAWAIZUMI†
Department of Electronics, Faculty of Engineering, Kagoshima University, Kagoshima-shi 890
†Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya-shi 464
(Received December 3, 1988)

Sedimentation potential (SP) measurements were carried out for solutions of alkali halides dissolved in methanol. With the SP data thus obtained, the partial molar volumes V_2^∞ of alkali halide MX, V_2^∞ (MX), were divided into cationic V_2^∞ (M^+) and anionic V_2^∞ (X^-) parts. The ionic partial molar volumes evaluated showed a reasonable agreement with each other. These values of V_2^∞ (M^+) and V_2^∞ (X^-) are numerically compatible with those reported earlier by Kawaizumi and Zana using the ultrasonic vibration potential method and those given more recently by French and Criss based on the apportionment of the estimated V_2^∞ value for the large complex [Ph_4PBPh_4] (*J. Solution Chem.*, **11**, 625 (1982).) The magnitude of the concentration dependence of SP was evaluated theoretically by expressing the apparent molar volume, the transport number, and the density of a solution as functions of the solute concentration.

The evaluation of the anionic and cationic contributions to the properties of an electrolyte which consists of these ions has been one of the most important tasks in the physical chemistry of electrolytes and the goal of many studies. A thorough comparison of the properties of various ions is possible only after individual ionic properties have been evaluated in a convincing manner. For aqueous solvent media, the numerical values of the thermodynamic properties of ions evaluated by many investigators based on different methods are in good, or at least fair, agreement.

Conway[1] reviewed the earlier work related to the evaluation of ionic properties and discussed the reliability of the various methods and assumptions adopted up to that time for the assessment of the contribution of each ionic species to the physicochemical properties of the electrolyte as a whole. In his review, Conway judged that, in water, both the ultrasonic vibration potential (abbreviated hereafter as UVP) method[2-4] and the extrapolation method[5] can lead to excellent results for the division of the partial molar volume V_2^∞ of an electrolyte MX, V_2^∞ (MX), into cationic V_2^∞ (M^+) and anionic V_2^∞ (X^-) parts. Contrary to the other methods, the UVP method has been the only one that is completely free from any kind of extrathermodynamic assumption. However, because of the technical difficulty in the UVP method, no widespread use of this important method has yet been made.

For individual ionic properties in nonaqueous solvent systems, marked differences have often been observed among the reported values. These large differences may be attributed to the following three factors. First, the thermodynamic properties of an electrolyte are themselves determined less accurately in nonaqueous media than in aqueous media; hence, the ionic molar quantities derived from them necessarily contain much uncertainty. Second, in evaluating ionic contributions we are forced to rely upon assumptions and semiempirical relations that are physically questionable. Third, the paucity of various kinds of fundamental data prevents us from comparing the numerical values of individual ionic properties given by different authors. For these reasons, we are not certain which results are the more correct.

To date, the ionic division of the partial molar volume of an electrolyte in nonaqueous media using the UVP technique has been done by Zana and his co-workers for methanol,[6] ethanol,[7] DMF,[7] and DMSO.[8] An alternative to the UVP method is the sedimentation potential (abbreviated hereafter as SP) method. In the first paper[9] of this series, the present authors described an apparatus for measuring the SP designed by one of them (H. H) and the results of the SP measurements of a number of inorganic salts dissolved in water. With this apparatus we have previously measured the SP of aqueous solutions of bola-form electrolytes[10] and nitroamminecobalt(III) complexes,[11] as well as solutions of LiCl, NaCl, and KCl in mixed water-methanol solvents.[12]

In this paper, the results of the SP measurement of alkali halides in methanol will be presented. As has just been mentioned, the ionic partial molar volumes in methanol based on the UVP method[6] are available. More recently, French and Criss[13] compared the numerical values of the partial molar volume for the Br^- ion, V_2^∞ (Br^-), in water and in methanol; these values had been obtained by various methods. Based on the apportionment of the estimated V_2^∞ value for the large complex [Ph_4PBPh_4] between cationic and anionic parts in view of the charge effect, they suggested that V_2^∞ (Br^-)=19.7±2 $cm^3 mol^{-1}$ in methanol; their conclusion was that the V_2^∞ (Br^-) in methanol is between 17 and 20 $cm^3 mol^{-1}$. The method of apportionment gives results compatible with those of the UVP method, not only in aqueous systems but also in methanol systems. However, the values of V_2^∞ (Br^-) considered in the paper of French and Criss[13] are almost incredibly scattered, ranging from −30.5 to 21.7 $cm^3 mol^{-1}$. In view of this, it is of considerable inter-

est to measure the SP of simple electrolyte alkali halides in methanol and to determine the individual partial molar volumes of alkali metal ions and halide ions from the SP data

Experimental

Specimens. The solvent methanol used was of an extra pure grade, and it was used without further purification. Commercial products of alkali halide (guaranteed or extra-pure-grade regent) were dissolved in this methanol to prepare a stock solution at the concentration of 0.1 mol dm^{-3}. Sample solutions at each concentration were prepared by the dilution of the stock solution.

Sometimes the solution properties of nonaqueous solvent systems are significantly affected by the presence of a trace quantity of water. Fortunately, the SP measurements carried out in the mixed water-methanol solvents[12] indicate that it is unnecessary to use absolute methanol as solvent, so long as the water content in the solvent methanol is sufficiently low. In fact, in the UVP measurement,[6] the water in the methanolic electrolyte solution gave rise to no appreciable change in the potentials up to a water content of 1%.

Apparatus and Measurements. The experimental set-up and the procedures of the SP measurement are identical with those described before.[9] The SP measurements were carried out at 23 °C—25 °C.

Results and Discussion

SP Values Observed. Figure 1 shows the results of the SP measurements for alkali chlorides and bromides. The fluorides and iodides also showed a similar concentration dependence. The variation in SP with the salt concentration will be analyzed below. It will be seen there that the use of the logarithmic concentration scale in describing the concentration dependence of SP is acceptable.

The SP values at concentration ranges from 10^{-3} to 10^{-2} mol dm^{-3} were taken as the limiting SP values, and the partial molar volumes of the ions were calculated using these limiting values.

Partial Molar Volumes of Alkali Halides in Methanol. In the introduction, we mentioned that very large differences can be found in the literature values of the physical parameters of electrolytes in nonaqueous solvent systems. For the case of the partial molar volume, for example, the reported values of V_2^∞ for NaCl in methanol are scattered between −5.5[14] $cm^3 mol^{-1}$ and 2.0[15] $cm^3 mol^{-1}$. Such differences seem to arise from the facts that the density of a pure nonaqueous solvent varies during density measurements, because of the atmospheric humidity and that extrapolation to an infinite dilution is seldom carried out as is required by the Debye-Hückel theory.

In order for the evaluated ionic partial molar volumes to be reliable and comparable with other reported values on a common basis, we must rely upon the most reliable and "normalized" values of the partial molar volumes, V_2^∞, for which the additivity rule $V_2^\infty = V_+^\infty + V_-^\infty$ should hold (hereafter the subscripts + and − refer to the cation and the anion respectively). For this reason we adopted principally the V_2^∞ of the electrolyte obtained by adding the V_+^∞ and V_-^∞ values listed in the latest publication of French and Criss.[13] These V_2^∞ values generally agree with those given by different authors, within a precision of

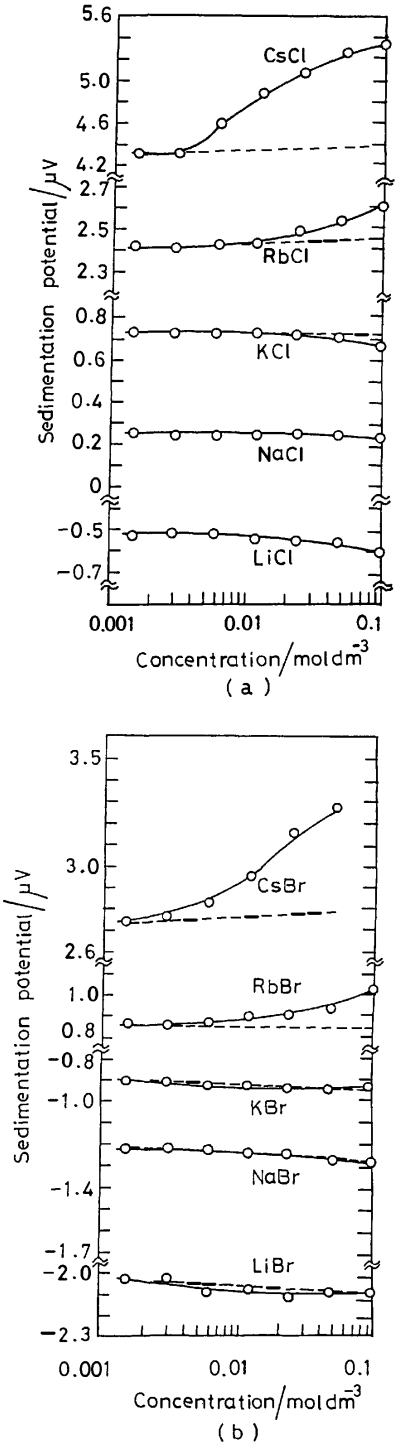

Fig. 1. Sedimentation potential in methanol for (a) chloride and (b) bromide as a function of concentration; —○— experimental; --------- calculated values obtained as explained in the text.

2 $cm^3 mol^{-1}$ or better. Only for CsCl does the difference in V_2^∞ value amount to 3.1 $cm^3 mol^{-1}$ (14.7 $cm^3 mol^{-1}$ by the additivity rule, while the value of 17.8 $cm^3 mol^{-1}$ is found in the literature[6]). Even for this case, we have used the value based on the results of French and Criss[13] in order to maintain the internal consistency of this work. However, they gave no value for the V_2^∞ of the Rb^+ ion, V_2^∞ (Rb^+), so this value was estimated by subtracting V_2^∞ (Cl^-), (Br^-), and V_2^∞ (I^-) from the respective values for rubidium salts found in the literature[6] and by then averaging the three resultant V_2^∞ (Rb^+) values.

Ionic Partial Molar Volumes in Methanol. As was done in our previous papers,[9-12] by solving simultaneously the additivity relation $V_2^\infty = V_+^\infty + V_-^\infty$ and Eq. 1; we can obtain numerical values of V_+^∞ and V_-^∞ which are free from any extrathermodynamic assumptions:

$$E = (ad/F)\cdot[(t_+/z_+)\cdot(m_+ - V_+^\infty\rho) - (t_-/z_-)\cdot(m_- - V_-^\infty\rho)] \quad (1)$$

Here, E is the SP; a, the acceleration; d, the distance between the two electrodes; F the Faraday constant; t, the transport number; z, the charge number; m, the molar mass of the ion, and ρ, the density. In our SP measurements the acceleration a is given as $\omega^2 x$, where ω is the angular frequency, and x, the amplitude of the oscillation generated in the SP apparatus. The partial molar volumes of the cation $V_+^\infty = V_2^\infty$ (M^+) and of the anion $V_-^\infty = V_2^\infty$ (X^-) evaluated for each alkali halide MX are summarized in Table 1, along with the values of t_+, t_-, and V_2^∞ used in the calculation.

Apparently the numerical values of V_2^∞ (M^+) and V_2^∞ (X^-) shown in Table 1 agree within the precision of SP measurements. The ionic partial molar volumes V_2^∞ (M^+) and V_2^∞ (X^-) given in Table 1 were averaged to give, respectively, the values for the M^+ and X^- ions in methanol. The results are shown in Table 2. In methanol, the transport numbers are known less accurately than in water. Differences of 5 units in the third decimal place of t_+ or t_- appear in different sources; this uncertsinty in the transport number alone will effect the ionic partial molar volumes by a little less than 1 $cm^3 mol^{-1}$. Therefore, Table 2 shows that the ionic partial molar volumes in methanol, as evaluated by three completely different methods agree well. Especially for V_2^∞ (Br^-), which was taken by French and Criss as a reference for ionic division, the agreement is better than we expected.

Analysis of the Concentration Dependence of SP. The experimental concentration dependences of the SP of the salts may be classified into three groups:
(1) salts with small concentration dependences; LiCl, NaCl, KCl, LiBr, NaBr, KRr, KI, RbI, and CsI.
(2) salts with moderate concentration dependences; NaF, KF, RbF, RbCl, RbBr, LiI, and NaI.
(3) salts with large concentration dependences; CsF, CsCl, and CsBr.

In our previous papers,[9-12] no attempt has been made to analyze the concentration dependence of SP. This has been done first in this work as follows: Equation 1 should describe the variation in SP with the concentration of the salts provided that the terms t_+, t_-, V_+, V_-, and d involved in Eq. 1 are given as functions of the solute concentration. As is well-known, these terms are satisfactorily expressed by the following relations:

$$t_\pm = \frac{\lambda_\pm^\infty - \frac{1}{2}B_2\sqrt{c}/(1+\kappa a_0)}{\Lambda^\infty - B_2\sqrt{c}/(1+\kappa a_0)} \quad (2)$$

$$V_\pm = V_\pm^\infty + \frac{3}{4}S_v\cdot c^{1/2} \quad (3)$$

and

$$\rho = \rho^0 + \frac{M - \rho^0 V_2^\infty}{1000} c + \frac{S_v \rho^0}{1000} c^{3/2} \quad (4)$$

In the above equations, the subscript ± is used instead of using separately the + or − sign to refer to a cation or an anion. The parameters have the following meanings; $\Lambda_\pm^\infty$ and $\lambda_\pm^\infty$ are, respectively, the limiting molar electric conductivities of an electrolyte and that of ions constituting the electrolyte; B_2 is a constant depending on the viscosity, the dielectric constant and the temperature of the solvent; κ is the reciprocal length of the ionic atmosphere; a_0 is the distsnce of the closest approach of two ions; S_v is the coefficient derived from the Debye-Hückel theory; c is the molar concentration (mol dm^{-3}) of the electrolyte; M is the molar mass, and the superscript 0 refers to a pure solvent. The a_0's in Eq. 2 were set equal to the sum of the hydrodynamic Stokes radius of cation and that of anion, which can be calculated from the ionic molar conductivities found in the literature.[16] For S_v, we adopted the value of 14.19[14] cm^3 mol$^{-3/2}$ dm$^{3/2}$. By inserting Eqs. 2—4 into Eq. 1 and using the V_+^∞ and V_-^∞ values listed in Table 1, we can see theoretically how the SP varies with the concentration. The results of this evaluation are represented in Fig. 1 by the dotted lines. As the $V_\pm^\infty$'s are calculated with the SP values at low concentrations, the dotted lines in Fig. 1 agree with the experimental observations in the lower concentration regions. For the salts with small cations (i.e., lithium, sodium, and potassium salts), the evaluated and observed SP variations agree well, while for rubidium salts the experimental SP values deviate upwards from the theoretical curve, and this deviation becomes much larger still for the largest cationic salts, CsCl and CsBr. Any further attempts at the analysis of the behavior of CsCl and CsBr seem to be speculative at present. The significance of the present analysis is that an increase or decrease in the SP with the salt concentration can be predicted in a qualitative manner from a combination of Eqs. 1 through 4. At any rate, the magnitude of the variation in the SP with the salt concentration is small; hence, the problem of selecting a concentration scale (an ordinary concentration scale or logarithmic concentration one) for representing the concentration dependence of SP is reduced to a matter of convenience.

Conclusion

The division of the partial molar volumes into cationic and anionic parts based on the results of SP measurements carried out for 1-1 type inorganic electrolytes dissolved in methanol leads to results which are completely in agreement with those of the UVP method used by Kawaizumi and Zana[6] and the apportionment between ionic parts of a complex salt with a large volume proposed by French and Criss.[13]

Comparison between Optical Properties of Sulfates and Hydrogensulfates in Halogen-Bridged Mixed-Valence Platinum(II, IV) Complexes

Nobuyuki MATSUSHITA,* Norimichi KOJIMA, Toshiro BAN, and Ikuji TSUJIKAWA
Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606
(Received January 17, 1989)

Syntheses and optical properties of some new halogen-bridged mixed-valence platinum complexes analogous to Wolffram's Red Salt, $[Pt(en)_2][PtBr_2(en)_2](HSO_4)_4$ (PBHS), $[Pt(en)_2][PtI_2(en)_2](HSO_4)_4 \cdot 4H_2O$ (PIHS), and $[Pt(en)_2][PtX_2(en)_2](SO_4)_2 \cdot 6H_2O$ {X=Br(PBSW), I(PISW)}, are reported. The powder X-ray diffraction pattern shows that PBHS is isomorphous with $[Pt(en)_2][PtCl_2(en)_2](HSO_4)_4$ (PCHS), and that PBSW and PISW are isomorphous. The hydrogensulfates PBHS and PIHS crystallize from an aqueous sulfuric acid solution, whereas the sulfates PBSW and PISW crystallize from an aqueous solution. The single crystal absorption spectra of PBHS, PIHS, PBSW, and PISW have been investigated at 4.2 K. The intense optical absorption due to intervalence charge-transfer transition from Pt(II) to Pt(IV) has been observed for the light polarized parallel to the Pt chain axis (E//chain). From the comparison of the energy of the intervalence charge-transfer absorption edges in PBHS, PBSW, and PISW, one can conclude that the influence of the substitution of the counterions HSO_4^- with SO_4^{2-} on the Pt(II)-Pt(IV) mixed-valence state is no less better than that of the substitution of the bridging halogen. The role of the counterion on the mixed-valence state is explained by the hydrogen bond network (Pt-NH···counterion···HN-Pt) on individual chains.

In recent years,[1-3] one-dimensional halogen-bridged mixed-valence complexes analogous to Wolffram's Red Salt (WRS) $[Pt(C_2H_5NH_2)_4][PtCl_2(C_2H_5NH_2)_4]Cl_4 \cdot 4H_2O$ have been investigated from viewpoints of physics and chemistry as a model of one-dimensional mixed-valence compounds. Many Wolffram's Red Salt Analogues (WRA) have ever been synthesized and studied, through the substitution of the in-plane ligand amines, bridging halogen and counterions. They comprise elongated octahedral $[Pt^{IV}X_2(AA)_2]^{2+}$ and square-planar $[Pt^{II}(AA)_2]^{2+}$ units alternately stacked along an axis, and counterions supporting the platinum complex columns, where AA denotes a bidentate amine or two monodentate amines etc., and X denotes a bridging halogen. Consequently, they comprise infinite platinum chains (···Pt^{II}···X-Pt^{IV}-X···) bridged by halogens which are not at the middle point between Pt(II) and Pt(IV), but closer to Pt(IV) than Pt(II). There is a charge-transfer interaction between an electronic state of Pt(II) and that of Pt(IV) through the bridging halogen.[4] The XPS measurement[5] suggests that the electronic state of Pt is not strictly divalence or tetravalence, and approaches that of Pt(III) by the medium of this interaction.

In WRS[4,6] and WRA,[6] the intervalence charge-transfer transition from an electronic state containing mainly d_{z^2} orbitals of Pt(II) to a state containing mainly d_{z^2} orbitals of Pt(IV) causes an intense optical absorption. This absorption appears in the spectral region from the visible to near-infrared, for light polarized parallel to the Pt chain axis (E//chain). Therefore, the single crystal spectrum for E//chain is a good probe of the Pt(II)-Pt(IV) mixed-valence state attributed to the charge-transfer interaction. Theoretical and experimental analyses of the above mentioned phenomena have been carried out on the basis of the extended Peierls-Hubbard model.[7,8]

The solid state properties in WRS and WRA have been investigated, mainly through the substitution of the metal atom (Pt, Pd, Ni) and the bridging halogen (Cl, Br, I).[8] Clark and Kurmoo[9] suggest that the hydrogen bond between a counterion and an in-plane ligand amine affects both the Pt(II)-Pt(IV) distances and the intervalence charge-transfer transition energies. Nevertheless, the influence of the hydrogen bond on the Pt mixed-valence state has not been investigated in detail by means of the substitution of the counterion. In order to elucidate the influence of the hydrogen bond on the Pt mixed-valence state we have investigated the WRA mixed-valence complexes comprising SO_4^{2-} and HSO_4^- as the counterions. Since the composition ratio of counterions for a platinum atom in the hydrogensulfate is twice as much as that in the sulfate, we can expect that the mixed-valence state of the complexes comprising SO_4^{2-} is clearly different from that of the complexes comprising HSO_4^-.

Layek and Papavassiliou[10] also reported the syntheses and Raman spectra of single crystals in WRA comprising SO_4^{2-} and HSO_4^-, $[Pt(en)_2][PtCl_2(en)_2](HSO_4)_4$ and $[Pt(en)_2][PtX_2(en)_2](SO_4)_2$ (X=Br, I), where en denotes ethylenediamine. We were able to prepare similar mixed-valence complexes, $[Pt(en)_2][PtBr_2(en)_2](HSO_4)_4$ (PBHS), $[Pt(en)_2][PtI_2(en)_2](HSO_4)_4 \cdot 4H_2O$ (PIHS), and $[Pt(en)_2][PtX_2(en)_2](SO_4)_2 \cdot 6H_2O$ {X=Br (PBSW), I (PISW)} which have different counterion composition and contain water of crystallization. In this paper, we report the syntheses and the optical properties of single crystals in PBHS, PIHS, PBSW, and PISW, and discuss the influence of the hydrogen bond on the Pt mixed-valence state.

Experimental

Preparation of the Constituent Complexes. The Pt(II) constituent complex $[Pt(en)_2]Cl_2$ was prepared by the procedure of Basolo et al.[11] The Pt(IV) constituent complexes $[PtBr_2(en)_2]Cl_2$ and $[PtI_2(en)_2]Cl_2$ were obtained by oxidation of $[Pt(en)_2]Cl_2$ in ethanol–water with Br_2 and I_2, respectively.

Preparation of the Mixed-Valence Complexes. The Pt(II)–Pt(IV) mixed-valence complexes were prepared by a procedure similar to that of Bekaroglu et al.[12] for $[Pt(en)_2][PtX_2(en)_2](ClO_4)_4$ (X=Br, I).

$[Pt(en)_2][PtBr_2(en)_2](HSO_4)_4$ (PBHS): $[Pt(en)_2]Cl_2$ (1.2 g) was dissolved in water (ca. 40 mL). This solution was divided into two equal parts. Water (ca. 100 mL) and ethanol (ca. 20 mL) were added into one of them, and Br_2 (ca. 0.1 mL) was dissolved in this solution with stirring. The color of the solution became pale yellow. The volume slowly reduced to ca. 70 mL on a hot plate. The solution, which had no odor of bromine, was then cooled and mixed with the other part of $[Pt(en)_2]Cl_2$ solution. A 62% aqueous sulfuric acid (ca. 3 mL) was then added. This solution was concentrated to ca. 10 mL on a water bath (ca. 40 °C) and then cooled. Green metallic lustrous needle-like crystals were obtained. They were filtered off and washed with diethyl ether; yield 1.6 g (87%). The single crystals were obtained by recrystallization from a dilute sulfuric acid solution. Found: C, 8.10; H, 3.00; N, 9.49; O, 21.96; S, 10.98; Br, 13.48%. Calcd for $C_8H_{36}Br_2N_8O_{16}Pt_2S_4$: C, 8.15; H, 3.08; N, 9.51; O, 21.72; S, 10.88; Br, 13.56%.

$[Pt(en)_2][PtI_2(en)_2](HSO_4)_4 \cdot 4H_2O$ (PIHS): $[Pt(en)_2]Cl_2$ (2.01 g) was dissolved in water (ca. 100 mL). This solution divided into two equal parts. An ethanol solution of I_2 (1.06 g/50 mL) was added to one of them. This solution was stirred overnight and evaporated to dryness by rotary evaporator to remove excess I_2. The residue was dissolved in water. This solution of Pt(IV) complex was added to the other part of $[Pt(en)_2]Cl_2$ solution, and the mixture was concentrated to ca. 40 mL on a hot plate. A 62% aqueous sulfuric acid (15 mL) was gradually added to the concentrated solution with stirring on an ice bath. Then, golden fine powdery solids were rapidly formed. This powder was filtered off, washed successively with a diethyl ether and sulfuric acid mixture (2:1, v/v), diethyl ether, and etanol; yield 2.59 g (74.2%). Plate-like single crystals were obtained by recrystallization from a dilute sulfuric acid solution. Found: C, 7.15; H, 3.06; N, 8.07; O, 23.87; I, 17.96%. Calcd for $C_8H_{44}I_2N_8O_{20}Pt_2S_4$: C, 7.15; H, 3.30; N, 8.33; O, 23.80; I, 18.87%.

$[Pt(en)_2][PtBr_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PBSW): A solution, which contains a mixture of $[Pt(en)_2]Cl_2$ and $[PtBr_2(en)_2]Cl_2$, was prepared by the same procedure employed for the preparation of PBHS, using $[Pt(en)_2]Cl_2$ (3.66 g) and Br_2 (ca. 0.3 mL). An aqueous solution of Na_2SO_4 (2.0 g/20 mL) was added to the Pt(II)–Pt(IV) solution. This was concentrated on a steam bath to ca. 120 mL and then cooled. Reddish-brown plate-like crystals were obtained. They were filtered off and washed with ethanol; yield 4.41 g (85.4%). Single crystals were obtained by recrystallization from an aqueous solution. Found: C, 8.93; H, 4.10; N, 10.35; O, 20.44; S, 5.93; Br, 14.63%. Calcd for $C_8H_{44}Br_2N_8O_{14}Pt_2S_2$: C, 8.81; H, 4.07; N, 10.27; O, 20.54; S, 5.88; Br, 14.65%.

$[Pt(en)_2][PtI_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PISW): A solution of $[Pt(en)_2]Cl_2$ and $[PtI_2(en)_2]Cl_2$ was prepared by the same procedure employed for the preparation of PIHS, using $[Pt(en)_2]Cl_2$ (3.17 g) and I_2 (2.0 g). To this solution, an aqueous solution of $NaHSO_4$ (1.9 g/10 mL) was added, and the mixture solution was concentrated on a steam bath to ca. 75 mL and then cooled. Golden lustrous plate-like crystals were obtained. They were filtered off and washed with a small amount of water; yield 3.13 g (64.4%). Single crystals were obtained by recrystallization from an aqueous solution. Found: C, 8.15; H, 3.70; N, 9.44; O, 18.77; I, 21.12%. Calcd for $C_8H_{44}I_2N_8O_{14}Pt_2S_2$: C, 8.11; H, 3.74; N, 9.46; O, 18.91; I, 21.43%.

$[Pt(en)_2][PtCl_2(en)_2](HSO_4)_4$ (PCHS): $[PtCl_2(en)_2]Cl_2$ (327 mg), which was obtained by oxidation of $[Pt(en)_2]Cl_2$ with an aqueous hydrogen peroxide solution, and $[Pt(en)_2]Cl_2$ (285 mg) were dissolved in water (ca. 20 mL). To this solution a 30% aqueous surfuric acid (ca. 2 mL) was added. This solution was slowly concentrated to a few milliliters at ca. 30 °C on a water bath. Red needle-like crystals obtained, were filtered off and dried in a desiccator containing silica gel. Yield 0.39 g (48%). Found: C, 8.78; H, 3.29; N, 9.82; O, 24.17; S, 11.77; Cl, 6.53%. Calcd for $C_8H_{36}Cl_2N_8O_{16}Pt_2S_4$: C, 8.82; H, 3.33; N, 10.28; O, 23.49; S, 11.77; Cl, 6.51%.

Elemental analysis was carried out by "The Laboratory for Organic Elemental Microanalysis" of Kyoto University.

Instrumental Measurements. Powder X-ray diffraction patterns were recorded at room temperature on a Rigaku diffractometer using the θ–2θ scan technique and graphite-monochromated Cu $K\alpha$ radiation (λ=1.5418 Å). For PBHS, PBSW, and PISW, lattice constants were obtained on a Rigaku four-circle diffractometer.

The TGA was performed on a Rigaku TG DTA 8112S apparatus in the temperature region from room temperature to 200 °C.

The absorption spectra of single crystals were measured at 4.2 K with a Jasco CT-100 spectrometer using a tungsten lamp for the light source and a Glan-Taylar prism for polarizing light. A lock-in system working with HTV R376 and R316 photomultipliers and a PbS photoconductive cell was used for detection. The sample was placed in glass Dewar's vessel and immersed in liquid helium to cool. The typical sizes of measured samples are 2×1×0.2 (mm^3) for PBHS, 3×2×0.06 (mm^3) for PIHS, 3×2×0.4 (mm^3) for PBSW, and 4×3×0.04 (mm^3) for PISW.

The absorption spectra of solutions were measured at room temperature with a Hitachi model 356 Double Beam Spectrophotometer.

Results and Discussion

Compounds. The complexes PBHS and PIHS are recrystallized from an aqueous sulfuric acid solution, and the PBSW and PISW are recrystallized from an aqueous solution. The result shows that the concentration of SO_4^{2-} and HSO_4^-, namely, the pH of the crystallizing solution dominates whether the hydrogensulfate or the sulfate crystallizes.

Table 1 shows the appearance of the single crystals of PCHS, PBHS, PIHS, PBSW, and PISW. Both the iodo-bridged mixed-valence complexes, PIHS and PISW, are golden in color. However, the bromo-

a) Weight percentages of water of crystallization in chemical formulas estimated from the elemental analysis.

bridged complexes, PBHS and PBSW, are different in color. Although PBHS and other bromo-bridged mixed-valence platinum complexes analogous to WRS are all metallic lustrous green in color, PBSW is similar to chloro-bridged complexes in color.

The powder X-ray diffraction pattern shows that PCHS and PBHS are isomorphous, and that PBSW and PISW are isomorphous. The X-ray pattern of PIHS is different from that of PCHS, PBHS, PBSW, and PISW. These results are consistent with the results of the elemental analysis.

Table 2 shows the lattice constants of PCHS,[13] PBHS,[14] PBSW,[15] and PISW.[15] The distance between Pt atoms on the chain can be preliminary estimated from the lattice constant of the Pt chain axis. The Pt-Pt distances of PCHS and PBHS are as long as that of other chloro- and bromo-bridged complexes with a univalence counterion.[16-18] On the other hand, the Pt-Pt distance of PBSW (5.747(2) Å) is longer than that of PBHS (5.518(5) Å), and that of PISW (5.831(1) Å) are also slightly longer than that of the iodo-bridged complexes with a univalence counterion and a bidentate amine.[18-20] The results show that the Pt-Pt distance of the complexes with a bivalence counterion is longer than that of the complexes with a univalence counterion.

For the WRA halogen-bridged mixed-valence complexes of which the structures were known, the chloro- and bromo-bridged complexes[16-18,21-25] are isomorphous each other, but are different from the corresponding iodo-bridged complex[19,20,26] in structure. The structures of the hydrogensulfates are classified into two groups in structure as same as above mentioned, namely the group of the chloro- and bromo-bridged complexes and the group of the iodo-bridged complex. For the sulfates, however, the bromo- and iodo-bridged complexes are isomorphous. It is the first example of the corresponding bromo- and iodo-bridged complexes belonging to the same group in structure, according to our knowledge.

Table 3 shows the results of TGA obtained from room temperature to 200 °C. The weight loss on heating of PIHS, PBSW, and PISW is consistent with the weight percentage of the water of crystallization in chemical formulas estimated from the elemental analysis. Thus, the complexes PIHS, PBSW, and PISW contain water of crystallization. In the hydrogensulfates PCHS, PBHS, and PIHS, only the iodo-bridged complex PIHS contains water of crystallization, which can be explained by the following considerations. The Pt-Pt distance of the iodo-bridged complexes is longer than that of the chloro- and bromo-bridged complexes, because iodide ion is the largest among the halide ions, (Cl^-, Br^-, and I^-). Thus, in the case that the framework of the halogen-bridged Pt complex column are only retained in the crystal structure of the halogen-bridged mixed-valence complexes, the cavity size between the halogen-bridged Pt chains of PIHS is larger than that of PCHS and PBHS. The water of crystallization of PIHS, therefore, is needed to occupy a free space which the counterions cannot occupy in the cavity between the Pt chains. Since the complexes PCHS and PBHS will not have the free space, they don't contain the water of crystallization. Similar mixed-valence complexes, $[Pt(NH_3)_4][PtX_2(NH_3)_4](HSO_4)_4$ (X=Cl,[16] Br[22,23]) and $[Pt(NH_3)_4][PtI_2(NH_3)_4](HSO_4)_4 \cdot 2H_2O$[26] were previously reported. For the hydrogensulfates of the ammonia complexes, equally, only the iodo-bridged complex contains the water of crystallization. For the water of crystallization in the sulfates PBSW and PISW, the

same explanation is given. Because the sulfates contain one-half of the counterions in the hydrogensulfates, the free space which the counterions don't occupy in the cavity between the Pt chains of the sulfates is larger than that of the hydrogensulfates. The sulfates PBSW and PISW, therefore, contain six molecules of water of crystallization per a chemical formula. We consider that whether or not the WRA mixed-valence complexes contain water of crystallization depends on the free space, namely, the relation between the volume of the counterion and the cavity between the Pt chains.

Similar WRA, $[Pt(en)_2][PtCl_2(en)_2](HSO_4)_4$, and $[Pt(en)_2][PtX_2(en)_2](SO_4)_2$ (X=Br, I) were previously reported by Layek and Papavassiliou.[10] Our chloro-bridged complex PCHS is the same as their chloro-bridged complex from the elemental analysis, whereas our bromo-bridged complexes PBHS and PBSW, and our iodo-bridged complexes PIHS and PISW are different from their bromo- and iodo-bridged complexes, respectively. Thus, our complexes PBHS, PIHS, PBSW, and PISW are new WRA halogen-bridged mixed-valence platinum complexes.

Spectra. Figures 1, 2, 3, and 4 show the absorption spectra of the single crystal in PBHS, PIHS, PBSW and PISW at 4.2 K and the corresponding spectra of aqueous solutions at room temperature, respectively.

The solution spectrum of PBHS is the same as that of PBSW, and that of PIHS is the same as that of PISW. In the solution, thus, an electronic state of the platinum complex in the hydrogensulfate is the same as that in the sulfate. This is consistent with the fact that the recrystallization of the hydrogensulfate and the sulfate depends on the pH of the recrystallizing solution as above mentioned.

The single crystal absorption spectra of the WRA mixed-valence complexes with univalence anions have been reported.[4,6,27] The single crystal absorption spectra of the WRA mixed-valence complexes with bivalence anions, however, have not yet been reported, except for our previous paper.[28] The absorption spectra of the single crystal in PBSW and PISW are reported for the first time in the WRA mixed-valence complexes with bivalence counterions.

Single crystals of PBHS, PIHS, PBSW, and PISW showed the strong absorption spectra in the region from visible to near-infrared. These spectra are attributed to the intervalence charge-transfer transition from Pt(II) to Pt(IV), which is a common feature of the WRA mixed-valence complexes, namely the class II mixed-valence compounds.[29] The single crystal spectra in this region showed a remarkable dichroism.

The strong absorption spectra for E//chain are due to the charge-transfer transition from the d_{z^2} of Pt(II) to the d_{z^2} of Pt(IV),[4,27] which is only allowed by selection rule for the light polarized parallel to the Pt chain axis. Absorption coefficients of the strong

absorption region in these single crystal spectra are saturated. The notation P in Figs. 1—4 shows the absorption edge of the low energy side of the absorption band due to the charge-transfer transition from the d_{z^2} of Pt(II) to the d_{z^2} of Pt(IV). The absorption band Q is due to the charge-transfer transition from an electronic state consisting mainly of d_{xz} and d_{yz} orbitals of Pt(II) to a state consisting mainly of d_{z^2} of Pt(IV).[27] This is allowed only for the light polarized perpendicular to the Pt chain axis ($E\perp$chain). However, this absorption band Q appears also in the spectrum with E//chain. We consider that the structure in the region of the saturated absorption coefficient for E//chain is attributed to a leakage of the spectrum for $E\perp$chain by a slight optical inhomogeneity, as previously reported.[8] Table 4 shows the energy of the absorption edges P and the bands Q of PBHS, PIHS, PBSW, and PISW. In the case of hydrogensulfates whose counterion is univalence, the energy of P of PBHS is higher than that of PIHS. Equally, in the case of sulfates whose counterion is bivalence, the energy of P of PBSW is higher than that of PISW. In both univalence and bivalence salts the energy of P of the bromo-bridged complex is higher than that of the iodo-bridged complex.

Comparison between PBHS and PBSW, and comparison between PBSW and PISW show that the energy shift of P by substituting counterion (i.e. PBSW → PBHS) is comparable to that by substituting bridging halogen (i.e. PBSW → PISW). Namely, the energy of the absorption edge of the iodo-bridged sulfate PISW with the bivalence counterion is as much as that of the bromo-bridged hydrogensulfate PBHS with the univalence counterion. Thus, one can conclude that an influence of the substitution of the univalence counterion HSO_4^- with the bivalence counterion SO_4^{2-} on the Pt(II)-Pt(IV) mixed-valence state is comparable to that of the substitution of the bridging halogen. The energy of the absorption edge of the bromo-bridged sulfate PBSW is comparable to WRS[4] and $[Pt(en)_2][PtCl_2(en)_2](ClO_4)_4$.[27]

Table 4. The Energy of the Intervalence Charge-Transfer Absorption Edges P and Bands Q at 4.2 K

Complex	P/10^3 cm^{-1}	Q/10^3 cm^{-1}
PBHS	8.4	15.6
PIHS	6.4	21.4
PBSW	17.7	21.1
PISW	9.5	20.9

We consider that the influence of substituting the counterion on these charge-transfer absorption edges is explained by the network of the hydrogen bonds which play a role of the bond between a platinum atom and an adjacent platinum on a chain by way of the amine (NH_2) and the counterion (Y) as shown in Fig. 5. The hydrogensulfates with the univalence counterion have more hydrogen bonds than the sulfates with the bivalence counterion, because the molar ratio of the counterions for a platinum atom in the hydrogensulfates is twice the ratio in the sulfates. Thus, the bond between a platinum atom and an adjacent platinum atom on a chain in the univalence counterion complexes is more strongly supported by the outerchain bridge of the hydrogen bond than that in the bivalence counterion complexes. The energy difference between the electronic states of Pt(II) and those of Pt(IV) in the univalence counterion complexes is smaller than that in the bivalence counterion complexes. Consequently, the energy of the absorption edge due to the charge-transfer transition from the d_{z^2} of Pt(II) to the d_{z^2} of Pt(IV) in the univalence counterion complexes is lower than that in the bivalence counterion complexes.

Furthermore, the result that the influence of the substitution of the counterion on the Pt mixed-valence state is comparable to the influence of the substitution of the bridging halogen, suggests that the formation of the WRA mixed-valence complexes can be interpreted by two contributions, as follows. (1)

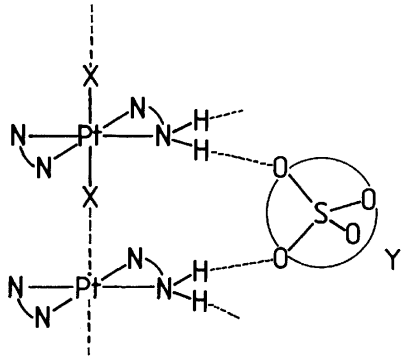

Fig. 5. The linkage between Pt(II) and Pt(IV) on a chain by hydrogen bonds through amines and counterions.

The charge-transfer interaction between the Pt(II) and Pt(IV) atoms becomes stronger in order of Cl, Br, and I which are the bridging halogen, because the energy of the intervalence charge-transfer absorption bands[7] and the energy distinction between the Pt(II) and Pt(IV) peaks in the XPS measurement[5] decrease in order of Cl, Br, and I. These results are in accordance with that the overlap integral between Pt(II) and Pt(IV) increase in the order of Cl, Br, and I. Accordingly, the ability to form the mixed-valence complexes increases in the order of Cl, Br, and I. (2) The charge-transfer interaction between the Pt(II) and Pt(IV) in the mixed-valence complexes having more counterions per a platinum atom is stronger than that in the complexes having less counterions, because the counterions link $[Pt^{IV}X_2(en)_2]^{2+}$ with $[Pt^{II}(en)_2]^{2+}$ on a chain by hydrogen bonds as shown in Fig. 5. Consequently, the charge-transfer interaction between the Pt(II) and Pt(IV) in the hydrogensulfates is stronger than that in the sulfates. In other words, the ability to form the mixed-valence complexes in the hydrogensulfates is larger than that in the sulfates.

In the energy region below the charge-transfer absorption edge P, weak absorption bands have been observed in the single crystal spectra of the sulfates PBSW and PISW for *E*//chain. This weak absorption band of PISW is noted by A in Fig. 4, and the weak absorption bands of PBSW are noted by A, B, and C in Fig. 3. The weak absorption band A of PISW, which has been recently reported partially in our previous paper,[28] and the weak absorption bands A, B, and C of PBSW will be attributed to the transition related to some kinds of defects, namely, Pt(III), Pt(IV)Pt(II)Pt(II)Pt(IV), and Pt(II)Pt(IV)Pt(IV)Pt(II) on individual Pt chains. In the case of the hydrogensulfats PBHS and PIHS, however, these weak absorption bands could not be observed. This result can be explained by the following consideration. In the hydrogensulfates, it is difficult to produce these defects, because the hydrogen bond network strongly links $[Pt^{IV}X_2(en)_2]^{2+}$ to $[Pt^{II}(en)_2]^{2+}$ on individual chains. On the other hand, in the sulfates, the defects are easily produced, because the hydrogen bond network weakly links the Pt atoms. Investigation of the dependence of the weak absorption bands on compounds will be also necessary.

The authors wish to thank Professor Tooru Taga of Kyoto University for obtaining the lattice constants of PBHS, and Dr. Koshiro Toriumi of I.M.S. for obtaining those of PBSW and PISW on a four-circle diffractometer. We are also indebted to Dr. Naohilo Watanabe of Kyoto University for his kind help and advice for data processing computer programs. This study was supported by the Grant-in-Aid for Scientific Research No. 63540485 from the Ministry of Education, Science, and Culture.

(Received June 17, 1988)

EXAFS (Extended X-ray Absorption Fine Structure) experiments on various polynuclear molybdate and tungstate compounds revealed the unusual phenomenon that Mo-O peaks which should appear at around 1.9 Å in Fourier transforms of the EXAFS spectra for $Mo_6O_{19}^{2-}$ and $PMo_{12}O_{40}^{3-}$ are hardly discernible, while the tungstates and other molybdates give the metal-oxygen peaks normally. It is concluded that the Debye-Waller factors for the metal-bridging oxygen bonds in $Mo_6O_{19}^{2-}$ and $PMo_{12}O_{40}^{3-}$ are exceptionally large ($\geqq$ 0.08 Å). The shape of the Raman bands for the $Mo_6O_{19}^{2-}$ pertaining to the vibration involving the bridging oxygens supports the large σ values estimated. EXAFS measurements were also performed for $AsMo_{12}O_{40}^{3-}$, $SiMo_{12}O_{40}^{4-}$, and $PMo_{12}O_{40}^{3-}$. The compounds with large Debye-Waller factors seem to be unstable against reductants.

EXAFS studies of molybdenum compounds have been attempted because of their interesting structures[1,2] and their reactivity as catalysts.[3]

The hexavalent molybdenum ion exists as a monomeric form of MoO_4^{2-} in a neutral or alkaline solution. In an acidic solution, the ion exists in the form of either $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$, or $Mo_6O_{19}^{2-}$, depending on the acidity of the solution. Heteropoly complexes of the Keggin structure, e.g., $PMo_{12}O_{40}^{3-}$, also exist in the presence of the PO_4^{3-} ion. Other heteropoly complexes are also known in which the P atom is replaced with Si, As, or Ge. Some of the Mo(VI) atoms in the polynuclear complexes can be reduced to form so-called molybdenum-blue. The polytungstates, e.g., $W_6O_{19}^{2-}$ and $PW_{12}O_{40}^{3-}$, with structures similar to those of the corresponding molybdenum complexes, are also known.

These molybdates and tungstates have been isolated as crystals, and their structures have been determined by the X-ray diffraction method. According to the literature, molybdenum in MoO_4^{2-} is coordinated by four oxygen atoms with the Mo-O distances of 1.75—1.78 Å.[4] $Mo_7O_{24}^{6-}$ and $Mo_6O_{19}^{2-}$ are composed of seven and six MoO_6 distorted octahedral units, respectively. In $Mo_6O_{19}^{2-}$ (Fig. 1a), the Mo-O bond distances have been reported to be 1.68 Å for terminal double bonds, 1.86—2.01 Å for bridging oxygens, and 2.32 Å for a central bridging oxygen.[5] The heteropoly compound, $PMo_{12}O_{40}^{3-}$ (Fig. 1b), has similar octahedral units around a central phosphorous atom.[6] Although the interatomic distances in the compounds of tungstates are not exactly the same as those in molybdates, the geometrical structures of the molybdenum and tungsten polynuclear compounds are quite similar to each other, e.g., $Mo_6O_{19}^{2-}$/$W_6O_{19}^{2-}$, and $PMo_{12}O_{40}^{3-}$/$PW_{12}O_{40}^{3-}$.

During the course of the EXAFS studies of these

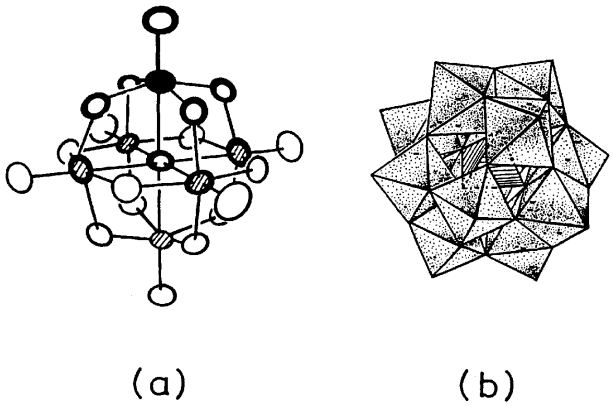

Fig. 1. (a) The structure of $Mo_6O_{19}^{2-}$ complex. The atoms circled with heavy line are included in the multiple scattering calculations. ◎ Molybdenum, ○ oxygen, and ● X-ray absorbing molybdenum atom. (b) The structure of Keggin type complex. Each octahedron represents MO_6 unit.

complexes in solution, we found the unusual phenomenon that the Mo-O peaks are hardly discernible in Fourier transforms for $Mo_6O_{19}^{2-}$ and $PMo_{12}O_{40}^{3-}$, while other molybdenum and tungsten compounds give normal peak intensities.[7] It is extremely important to know why the first shell atoms, which are normally the most easily detectable atoms by the EXAFS method, give almost no EXAFS peaks. Our lack of knowledge of the cause makes the use of the EXAFS technique too dangerous for structure analysis.

Since the anomalous peak intensities appear only for the samples of highly symmetrical $Mo_6O_{19}^{2-}$ and $PMo_{12}O_{40}^{3-}$, and not for low-symmetry samples (e.g., $Mo_7O_{24}^{6-}$), it is possible that this phenomenon is connected only to specified geometrical configurations. We must introduce a multiple-scattering the-

ory for the EXAFS analysis in order to discriminate between geometrical configurations, because the single-scattering theory treats only interatomic distances from the X-ray absorbing atom, i.e., the Mo-O and Mo-Mo distances. As far as Mo-O bonds are concerned, the single-scattering theory regards these complex polymers as simple MoO_6 octahedra. There is no room in the theory for the consideration of the symmetries of the complexes as to how the octahedral units are connected.

In the present paper, the origin for those anomalous peak intensities will be discussed from the points of view of the multiple-scattering effect and the Debye-Waller factor, which, of course, is a key parameter determining the peak intensities. Consequently, the large Debye-Waller factor for several molybdenum complexes are inferred and confirmed by the Raman spectroscopy.

Experimental

The $Na_2MoO_4 \cdot 2H_2O$, $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, and $Na_2WO_4 \cdot 2H_2O$ were purchased from Wako Pure Chemical Industries, Ltd., and the MoO_3, from the Merck Company. The $[(C_4H_9)_4N]_2Mo_6O_{19}$,[8] $[(C_4H_9)_4N]_2W_6O_{19}$,[9] $PMo_{12}O_{40}^{3-}$-TBA ($(C_4H_9)_4N^+$) salt, $AsMo_{12}O_{40}^{3-}$-TBA salt, $SiMo_{12}O_{40}^{4-}$-TBA salt, and $PW_{12}O_{40}^{3-}$-TEA($(C_2H_5)_4N^+$) salt were prepared according to the literature.[10] A partially reduced species of $PMo_{12}O_{40}^{3-}$, molybdenum-blue, was prepared by the reduction with ascorbic acid. The X-ray absorption spectra of Mo K-edge and W L_{III}-edge were obtained at BL-7C and 10B of the Photon Factory of the National Laboratory for High Energy Physics (KEK). The storage ring was operated at 2.5 GeV, and the ring current was between 150—200 mA. A Si(111) double-crystal monochromator and a Si(311) channel-cut crystal monochromator were used. The solid samples were powdered and loaded on adhesive tapes. The liquid samples were placed in a polyethylene pouch.

The Raman spectra of the powdered samples were measured with an Ar ion laser (5145 Å) at room temperature and at 88 K.

Data Analysis and Calculations

The EXAFS data treatments have been described in detail elsewhere,[11] and so they will be only briefly treated in this section. The EXAFS oscillation $\chi(k)$ is extracted from the absorption spectrum $\mu(k)$ as follows:

$$\chi(k)=[\mu(k)-\mu_0(k)]/\mu_0(k). \quad (1)$$

The background absorption $\mu_0(k)$ is obtained from the least-square fitting of the pre-edge region (about 300 eV) to the Victoreen formula, $a\lambda^3-b\lambda^4+c$, where a, b, and c are the constants and where λ is the wavelength of the incident X-ray. The c constant is introduced in order to correct the difference in the sensitivities of the ionization detectors for I and I_0. In order to remove low-frequency noises from $\chi(k)$, the following method is used. The second-order seven-point smoothing is applied to the $\chi(k)$ data until only the lowest-frequency component of significant signals remains. Subsequently, a base line is obtained by using a third-order natural spline method with which the center points of the oscillation in the smoothed spectrum are connected. Thus, the low-frequency noises are removed from $\chi(k)$ by subtracting the base line obtained. In the single-scattering approximation, the extracted EXAFS is described as:

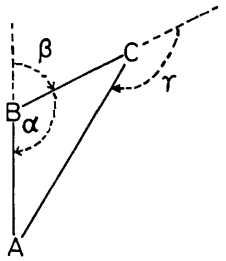

Fig. 2. Schematic representation of a triatomic system. A is the X-ray absorbing atom, and B and C are the scattering atoms.

$$\chi(k)=\sum_j S_j k^{-1} N_j r_j^{-2} f_j(k) \exp(-2r_j/\eta) \exp(-2k^2\sigma_j^2) \times \sin[2kr_j+\psi_j(k)], \quad (2)$$

where k is the photoelectron wave vector defined as:

$$k=[2m(E-E_0)]^{1/2}/\hbar. \quad (3)$$

E and E_0 are the photon energy and the threshold energy, respectively. S_j is the damping factor by the multielectron effect, m is the mass of an electron, N_j is the number of atoms located at distance r_j, η is the mean free path of the photoelectron, and σ_j is the root-mean-square displacement of r_j (the RMSRD or Debye-Waller factor). The backscattering amplitude $f_j(k)$ and the phase shift $\psi(k)$ calculated by Teo and Lee[12] are used for the Fourier transforms. The energy at the half height of the edge jump is used as the value of E_0.

The multiple-scattering calculations for EXAFS are performed according to the following equation for the triatomic model (A,B,C) shown in Fig. 2:[13,14]

$$\begin{aligned}\chi_{AC}(k)=&[(-1)^l/k]\{f_C(\pi)\exp(-2\sigma_{AC}^2k^2)\\ &\times\sin[2kr_{AC}+2\delta_l+\psi_C(\pi)]/r_{AC}^2+[2\cos(\gamma-\alpha)f_B(\beta)f_C(\gamma)/\\ &(r_{AB}r_{BC}r_{AC})]\exp[-(1-\cos\beta)^2k^2\sigma_{AB}^2/2]\\ &\times\exp[-(1-\cos\gamma)^2k^2\sigma_{AC}^2/\\ &2]\sin[k(r_{AB}+r_{BC}+r_{AC})+2\delta_l+\psi_B(\beta)\psi_C(\gamma)]+[f_B(\beta)^2f_C(\pi)/\\ &(r_{AB}^2r_{BC}^2)]\exp[-(1-\cos\beta)^2k^2\sigma_{AB}^2]\exp(-2k^2\sigma_{BC}^2)\\ &\times\sin[2k(r_{AB}+r_{BC})+2\delta_l+2\psi_B(\beta)+\psi_C(\pi)]\},\end{aligned} \quad (4)$$

where δ_l is the phase shift of the central atom with an angular momentum l and where ψ is that of the scattering atom. The muffin-tin potential of atoms with a neutral charge is assumed for the scattering field.

Results

EXAFS Spectra. Figure 3 shows the Fourier transforms of the Mo K-edge EXAFS for molybdenum com-

pounds and of the W L_{III}-edge EXAFS for tungsten compounds. The peak corresponding to Mo-O is present at 1.77 Å in the spectrum for MoO_4^{2-} (Fig. 3a). In the spectrum for MoO_3 (Fig. 3b), two peaks corresponding to Mo-O and Mo-Mo appear at 1.79 Å and 3.60 Å, respectively. Although several Mo-O bonds with different lengths are present in $Mo_7O_{24}^{6-}$, the bonds give only a single peak at 1.75 Å in the Fourier transform, and the Mo-Mo peak lies at 3.20 Å in the spectrum (Fig. 3c).

To our great surprise, we find quite an unusual phenomenon in the Fourier transform spectrum for $Mo_6O_{19}^{2-}$ (Fig. 3d). That is, the Mo-O peaks for the complex which should appear at somewhere around 1.9 Å are hardly discernible, while a high and sharp peak corresponding to the oxygen-bridged Mo-Mo distance appears at 3.26 Å. The X-ray diffraction results predict that both the Mo-O and Mo-Mo peaks for $Mo_6O_{19}^{2-}$ should be higher than those for $Mo_7O_{24}^{6-}$, since the structure of $Mo_6O_{19}^{2-}$ is highly symmetrical compared to $Mo_7O_{24}^{6-}$.[15] The EXAFS measurements were repeated at 20 K in order to study the effect of thermal vibration on the peak height for the Mo-O bonds. The result, shown as a broken line in Fig. 3d, is essentially the same as that obtained at room temperature. This indicates that the disappearance of the peak is not caused by the thermal vibration. In contrast to the result for $Mo_6O_{19}^{2-}$, the spectrum for $W_6O_{19}^{2-}$ is quite normal (Fig. 3f); there are two peaks corresponding to the terminal W=O (1.66 Å) and the bridging W-O (1.96 Å) bonds in addition to a W-W peak (3.45 Å).

An analogous phenomenon appears in heteropoly acids, as is shown in Fig. 4. The Mo-O peaks are very much obscured in the spectrum for $PMo_{12}O_{40}^{3-}$ (a), while peaks corresponding to W=O (1.60 Å) and W-O (1.98 Å) appear in that for $PW_{12}O_{40}^{3-}$(b). However, the Mo-O peak appears at 1.92 Å in the spectrum for the reduced $PMo_{12}O_{40}$ species (c).

$AsMo_{12}O_{40}^{3-}$ and $SiMo_{12}O_{40}^{4-}$ form the same structure as $PMo_{12}O_{40}^{3-}$. In the spectrum for $AsMo_{12}O_{40}^{3-}$ (d), the Mo-O peaks are poorly characterized, in a manner similar to that found for $PMo_{12}O_{40}^{3-}$ (a), whereas the Mo-O peak appears rather clearly at 1.85 Å in the spectrum for $SiMo_{12}O_{40}^{4-}$ (e).

Multiple-Scattering Calculation. The EXAFS analysis are normally done using a single-scattering theory. In this section we will study whether a photoelectron standing wave can be diminished for the system taking a special geometrical arrangement of scattering atoms due to a multiple-scattering effect, thus causing the peak in the Fourier transform to disappear. Figure 5 shows the calculated EXAFS oscillation spectra and their Fourier transforms, which were obtained by the use of the single-scattering (solid line) and multiple-scattering (broken line) theories. The atoms marked with a heavy line in Fig.

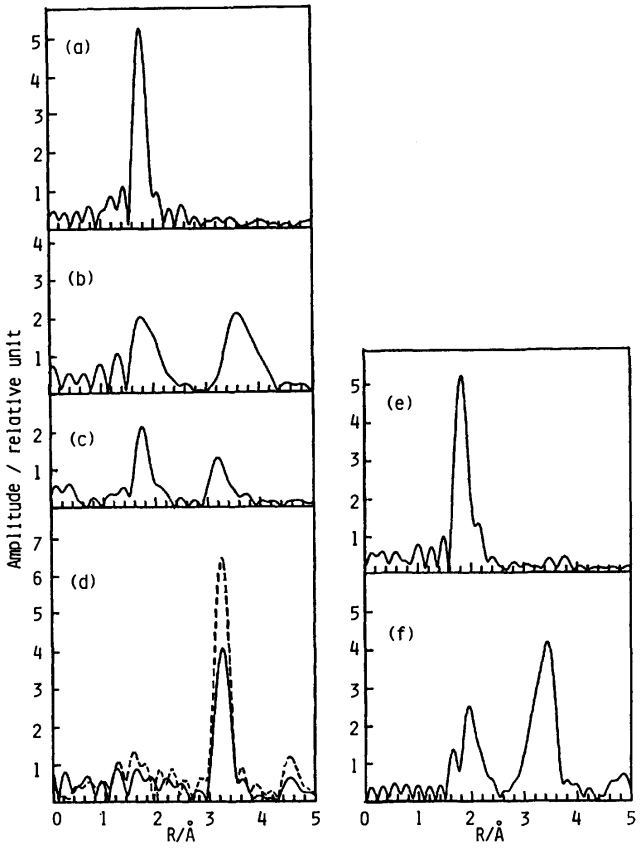

Fig. 3. Fourier transforms of Mo K-edge EXAFS for (a) $Na_2MoO_4 \cdot 2H_2O$, (b) MoO_3, (c) $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, (d) $[(C_4H_9)_4N]_2Mo_6O_{19}$, and WL_{III}-edge EXAFS for (e) $Na_2WO_2 \cdot 2H_2O$, and (f) $[(C_4H_9)_4N]_2W_6O_{19}$. Broken line in (d) represents that measured at 20 K.

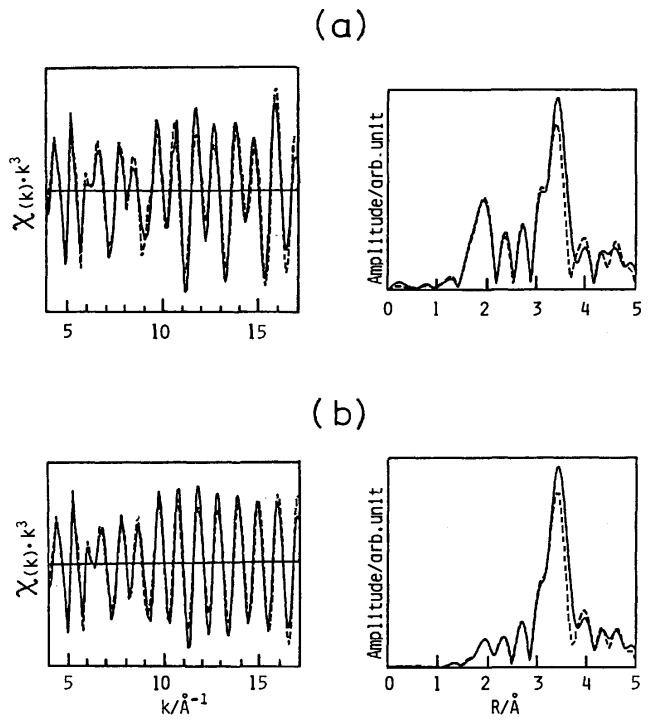

Fig. 5. Calculated EXAFS spectra and their Fourier transforms for the model compound for $Mo_6O_{19}^{2-}$. The σ values used for Mo-O are (a) 0.04 Å and (b) 0.08 Å. Solid line and broken line represent the result of the single scattering and multiple scattering calculations, respectively.

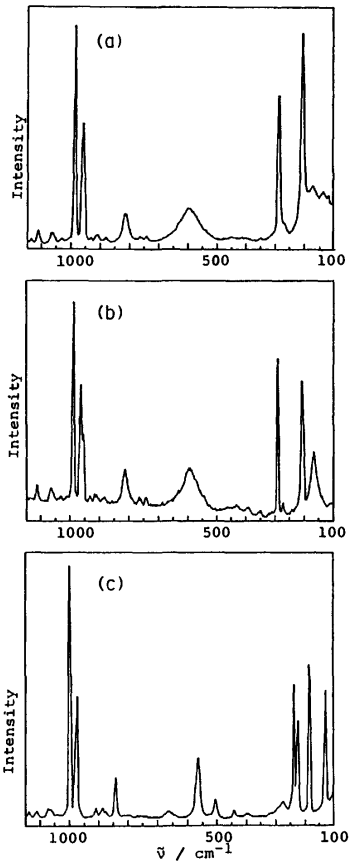

Fig. 6. Raman spectra for (a) $[(C_4H_9)_4N]_2Mo_6O_{19}$ at room temperature, (b) at 88 K, and (c) $[(C_4H_9)_4N]_2W_6O_{19}$ at room temperature.

1a constitute the MoO_6Mo_4 cluster used for the calculations of the model of $Mo_6O_{19}^{2-}$. The positions of the atoms are given from the crystallographic data.[5] Figure 5a shows the results obtained using the Debye-Waller factor σ of 0.04 Å for both Mo-O and Mo-Mo bonds. The value of 0.04 Å has been determined by Cramer et al.[1] in the case of the Mo(V) dimer. No significant difference can be observed between the single-scattering and multiple-scattering results. The calculations predict the Mo-O peaks at 1.7—2.0 Å and the Mo-Mo peak at 3.3 Å, as normal. Since the peak intensity depends upon the Debye-Waller factor, the simulation calculations were also performed using different σ values. Figure 5b shows the results for the case in which the σ value of 0.08 Å for the Mo-O bond is used. The value of 0.08 Å was selected according to the results of a Raman study, which will be discussed in the Discussion section below. The Mo-O peak at about 2.0 Å can no longer be distinguished from the ripple peaks.

Raman Spectra. A noteworthy difference in the Raman spectra is observed in the shape of the peak corresponding to the vibration involving the metal-bridging oxygen bond between the samples of $Mo_6O_{19}^{2-}$ and $W_6O_{19}^{2-}$. The Raman spectrum for $Mo_6O_{19}^{2-}$ at room temperature has a very broad peak at ca. 600 cm^{-1}, as is shown in Fig. 6a. Cooling the sample down to 88 K causes only a small reduction in the width of the peak, as is shown in Fig. 6b. According to the literature,[16] the peaks at ca. 600 cm^{-1} for $Mo_6O_{19}^{2-}$ and 570 cm^{-1} in Fig. 6c for $W_6O_{19}^{2-}$ have been assigned to correspond to the symmetrical stretching vibration of the bridging M-O-M bond (M=metal). It is remarkable that this peak for $Mo_6O_{19}^{2-}$ is significantly broader than that for $W_6O_{19}^{2-}$, while the peaks at ca. 1000 cm^{-1} due to the terminal M=O bonds are quite similar to each other. The peak at 167 cm^{-1} which has been assigned to the Mo-O-Mo bending vibration in the $Mo-O_4$ plane is also broad, and its width changes with the temperature.

Discussion

Our results definitely show that the anomalously low peak intensity for $Mo_6O_{19}^{2-}$ arises from the large Debye-Waller factor of the Mo-O bond in this compound. The theoretical calculations do not predict that the multiple-scattering effect works on the very specified symmetrical geometry of $Mo_6O_{19}^{2-}$ complex to diminish certain peaks. The calculations predict, instead, that the disappearance of the peaks can easily occur with larger σ values. The large σ value of the bond seems to be related to the anomalous peak shapes

in its Raman spectrum.

The σ value in the theory of EXAFS is given by:

$$\sigma^2 = \sigma^2_{stat} + \sigma^2_{vib.} \quad (5)$$

Thus, it is divided into static and vibronic contributions. The static factor represents the distribution of interatomic distances. As is obvious from the low symmetry of $Mo_7O_{24}^{6-}$, it is known from the X-ray diffraction study that the complex has Mo-O_{bridge} bonds with various lengths in it.[15] The bond lengths of Mo-O spread from 1.8 to 2.5 Å in $Mo_7O_{24}^{6-}$, while those in $Mo_6O_{19}^{2-}$ spread from 1.86 to 2.01 Å.[17] Therefore, the static factor must be much larger for $Mo_7O_{24}^{6-}$ than for $Mo_6O_{19}^{2-}$. Consequently, the present EXAFS results indicate that the apparent large σ value for $Mo_6O_{19}^{2-}$ comes not from the static part, but from the vibronic one. As for $W_6O_{19}^{2-}$, there are two reports which are inconsistent with each other with respect to the W-O bond lengths.[18,19]

Recently, the relationship between the Raman spectrum and the EXAFS Debye-Waller factor was studied by Lottici.[20] From his study of the nearest neighbor central force (NNCF) model, which is more exact than the Einstein model, he reported that the Debye-Waller factor can be related to the relative (or projected) density of vibrational states ρ_R. According to the Einstein model, the calculated σ_{vib} values of the M-O bond for $Mo_6O_{19}^{2-}$ and $W_6O_{19}^{2-}$ must be nearly equal because the vibrational frequencies for the M-O bonds in the two compounds are nearly equal. Thus, this model is not adequate for an attempt to find the cause of the difference in the character of the M-O bonds. The value of σ_{vib} is expressed[20] in terms of $\rho_R(\omega)$ according to the NNCF model as follows:

$$\sigma^2_{vib} = (\hbar/2\mu)\int[\rho_R(\omega)/\omega]\coth(\hbar\omega/2k_BT)d\omega. \quad (6)$$

The $\rho_R(\omega)$ is approximately related to the Raman scattering intensity $I(\omega)$ as follows:

$$I(\omega) = C\,\rho_R(\omega), \quad (7)$$

where C is the normalization constant. Now, using the above two relations, we can calculate the ratio of the σ_{vib} value of $Mo_6O_{19}^{2-}$ against that of $W_6O_{19}^{2-}$ with respect to the metal-bridging oxygen bonds from the Raman peaks of symmetrical stretching vibration at ca. 600 cm^{-1} and 570 cm^{-1}, respectively. The Raman intensities of the corresponding peaks are normalized by using one of the peaks due to the tetrabutylammonium ion at ca. 1060 cm^{-1}. The result of the calculation for the bridging oxygen gives a value of about 2 for the $\sigma_{vib}[Mo]/\sigma_{vib}[W]$ ratio. Therefore, once the σ_{vib} value of 0.04 Å for the W-O bond in $W_6O_{19}^{2-}$, which is a very typical value for metal complexes, is adopted for the EXAFS simulation calculation, the σ_{vib} value of 0.08 Å must be employed for the calculation of $Mo_6O_{19}^{2-}$. The EXAFS simulation calculations using these σ values show that the σ value of 0.04 Å is small enough to present the M-O peak in the Fourier transform, while the value of 0.08 Å is too large to present the peak, as is indicated in Fig. 5.

The EXAFS spectrum taken at 20 K for $Mo_6O_{19}^{2-}$ (Fig. 3d) indicates that the apparent σ value does not depend on the temperature. The same is true for the σ_{vib} value estimated from the Raman spectra taken at room temperature (Fig. 6a) and at 88 K (Fig. 6b). Equation 6 shows that, even at $T=0$, σ_{vib} has a finite value proportional to $\rho_R(\omega)/\omega$. The present study concludes that the Mo-O bond in $Mo_6O_{19}^{2-}$ has a large σ_{vib} value in which the temperature-independent contribution dominates. (As a matter of fact, for the vibration of ω=600 cm^{-1}, the value of $\coth(\hbar\omega/2k_BT)$ is almost 1 throughout all the range from $T=0$ to room temperature.)

We speculate that the large σ value for Mo-O bond is related to the rotational vibration on the axis of $O_{terminal}$-Mo-O_{center} (the rotation of the plane including four O_{bridge}'s); thus, the vibrational peaks corresponding to the Mo-O_{bridge} stretching vibration (at ca. 600 cm^{-1}) and the O_{bridge}-Mo-O_{bridge} bending (at ca. 160 cm^{-1}) are broad in the Raman spectrum because of the coupling of these vibrations to the rotational vibration. This interpretation is compatible with the EXAFS result of the clear appearance of the distant bond, Mo-Mo, in $Mo_6O_{19}^{2-}$ inspite of the disappearance of the shorter bond Mo-O_{bridge}, because the rotation does not change the Mo-Mo, but the Mo-O distance.

In concluding this section, it should be mentioned that there is something puzzling in the results of the X-ray diffraction analyses (XDA) of the complexes. None of the reported values of thermal parameters in XDA for Mo and W complexes contain any indication which can be connected to either the large σ values inferred from the EXAFS analyses or the broad band shapes in the Raman spectra. In either case in which static or vibronic disorder causes the peak disappearance in EXAFS of $Mo_6O_{19}^{2-}$, the values of the thermal parameters in XDA for O_{bridge} in it can be expected to be large. The incompatibility between the results of EXAFS and XDA requires further study in this regard.

Reactivity as Oxidants. It is interesting to note that $Mo_6O_{19}^{2-}$, $PMo_{12}O_{40}^{3-}$, and $AsMo_{12}O_{40}^{3-}$, for which the Mo-O peaks disappear in the Fourier transforms, are the most easily reducible species among the molybdenum complexes. According to the empirical classification by Pope,[21] the reactivity of $Mo_6O_{19}^{2-}$ as the oxidant is higher than that of $Mo_7O_{24}^{6-}$. Judging from the electrochemical redox potentials, the orders of reactivities are $PMo_{12}O_{40}^{3-} > PW_{12}O_{40}^{3-}$,[22] and $AsMo_{12}O_{40}^{3-} > PMo_{12}O_{40}^{3-} > SiMo_{12}O_{40}^{4-}$.[23] This is perfectly in accordance with the fact that $Mo_7O_{24}^{6-}$, $PW_{12}O_{40}^{3-}$, and $SiMo_{12}O_{40}^{4-}$ show the Mo-O peaks in their Fourier transforms. Thus, the compounds with high redox potentials are electrically unstable, even though they take highly symmetrical structures. It has also been reported that the redox reaction of

$PMo_{12}O_{40}^{3-}$ with hydrogen and isotopically labeled oxygen exchanges bridging oxygen atoms far more easily than the terminal oxygens.[24] Further, the Raman[24] and IR[25] spectroscopic studies and the Xα MO calculation[26] have indicated that the bridging oxygen atoms are more reactive than the terminal oxygens. From the point of view of reactivity as the oxidant, the intensity of the M-O peak in the Fourier transform seems to be small for a species with highly reactive bridging oxygen atoms. From the evidence in the present study, the M-O bonds in highly reactive molybdenum complexes can be considered to be "strained bonds" which may be created by the stress of the large framework of the polynuclear compounds. It has been reported that there is a correlation between the Debye-Waller factors determined from EXAFS experiments on aqua metal complexes and their ligand-water exchange-reaction rates.[27] The present study provides another example of the correlation between the Debye-Waller factor and the chemical reactivity.

Conclusion

Some of the molybdenum polynuclear compounds show almost no peaks corresponding to metal-oxygen bonds in their Fourier transforms of the EXAFS spectra. This very strange fact is the result of the large Debye-Waller factor of the corresponding bonds. This conclusion is supported by the theoretical simulation calculations and the results of the Raman spectroscopy. The metal-bridging oxygen bonds in those compounds must be deformed to make these compounds reactive toward a redox reaction.

The present authors wish to thank Drs. Tadashi Matsushita and Masaharu Nomura of the National Laboratory for High Energy Physics (KEK) for their help with the X-ray absorption measurements. The Syntheses of Ortho-, Meta-, and Paracyclophane-Type Thiacrown Compounds and Their Characteristics as Extractive-Spectrophotometric Reagents for Class *b* Metals–Silver and Copper

(Received June 30, 1988)

Ortho-, meta-, and paracyclophane-type thiacrown compounds bearing 4-(4-nitrophenylazo)phenol as a chromogenic group were synthesized, and their characteristics as extractive-spectrophotometric reagents for the class *b* metals, consisting of soft Lewis acids such as silver and copper(I), were examined. Silver and copper(I) were well extracted into chloroform with all of three reagents, though especially with the metacyclophane-type reagent. The absorption maxima of silver and copper(I) complexes with the orthocyclophane-type reagents are at the longest wavelengths among the three reagents. The orthocyclophane-type reagent is adequate for the extraction and spectrophotometric measurement of copper(I), and the metacyclophane-type reagent is suitable for that of silver. The extraction behavior of copper(II) with these three reagents has been studied in order to know if the hydroxyl group participates in the formation of the metal-thiacrown complexes.

Thiacrown ethers act as soft Lewis bases and react selectively with the class *b* metals of soft Lewis acids. The resulting thioether complex cations form ion pairs with appropriate anions, such as perchlorate and picrate, which are then extracted into suitable organic solvents.[1-7] The extractive-spectrophotometric determination of silver and copper with thiacrown ethers by the use of dye anions as the pairing anions has been reported.[8]

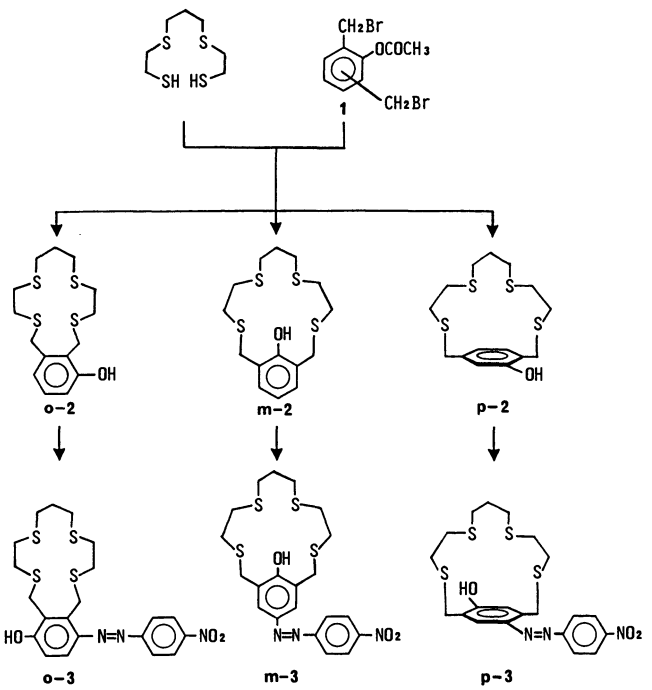
If a thiacrown ether compound itself has a chromogenic group which can function as a counter anion, that compound can be used as an extractive-spectrophotometric reagent for metal ions. Thus, the extraction with chromogenic thiacrown ethers, such as 4′-(pycrylamino)benzo-1,4,8,11-tetrathiacyclopentadec-13-ene (4′-PicNHBz-TTCP)[9] and those in which a nitro group in 4′-PicNHBz-TTCP is replaced by a trifluoromethyl group,[10] as well as thiacrown ethers containing a phenylazo group as a chromophore, have been reported.[11]

In the present study, in order to obtain more selective and sensitive thiacrown reagents, which contain the chromogenic group also functioning as a counter anion, new ortho-, meta-, and paracyclophane-type thiacrown ether reagents were synthesized, and their characteristics as extractive-spectrophotometric reagents for class *b* metals, such as silver and copper(I), were examined. Furthermore, as it seemed interesting to know how the hydroxyl groups of the ortho-, meta-, and paracyclophane-type thiacrown ethers participate in the formation of the metal-thiacrown complexes, the extraction behavior of copper(II) has been studied.

Results and Discussion

Syntheses of Reagents. Thiacrown ether containing a hyroxyl group may be expected to be obtained by the reaction of dithiol and bis(halogenomethyl)-phenol protected with a hydroxyl-protecting group such as tetrahydropyranyl ether. However, the synthesis of each isomer of bis(chloromethyl)phenol by chloromethylation into phenol or the direct bromination of dimethylphenol into the α position was very difficult. Fortunately, thiacrown ether containing a hydroxyl group **2** was obtained by the reaction of bis-(bromomethyl)phenyl acetate **1** and 3,7-dithianonane-1,9-dithiol, as shown in Scheme 1.

The cyclization reaction was achieved by the drop-by-drop addition of a benzene solution containing 1 molar equivalent of dibromide **1** and 1.5 molar equi-



Scheme 1.

valents of 3,7-dithianonane-1,9-dithiol to a sodium ethoxide solution by means of the high-dilution method. The cyclizations of *o*-, *m*-, and *p*-substituted dibromides with dithiol all produced satisfactory yields.

The reaction of hydroxy-substituted cyclophane **2** and *p*-nitrobenzenediazonium tetrafluoroborate was carried out in a dioxane-water solution under slightly alkaline conditions. The reaction mixture was acidified. A large quantity of water was added and then extracted with ethyl acetate. The solvent was removed, the residue was chromatographed on a silica-gel column, and the pure product was obtained by the recrystallization of the major band.

The orthocyclophane-type thiacrown ether **o-3** is moderately soluble in such organic solvents as chloroform, ethyl acetate, and acetone. The reagents **m-3** and **p-3** are soluble in chloroform or acetone. The proton NMR spectra of **o-3** and **m-3** are similar to each other except for that of aromatic protons, but that of **p-3** is very different from that of **o-3** or **m-3**. The benzyl proton signal of **p-3** separates into two quartets, indicating a two-AB pattern, although that of **o-3** is a doublet and that of **m-3** is a singlet. The protons of the thioether ring of **p-3** are shielded by a benzene ring and are probably affected by azo-group electrons. These proton NMR spectra are consistent with the desired configuration for each isomer; **m-3** is a symmetrical structure in which the thioether ring is coplanar for the benzene ring. **o-3** has an unsymmetrical thioether ring which is coplanar for the benzene ring. The thioether ring of **p-3** is an unsymmetrical structure and exists at the upper space of the benzene ring. It seems that the difference in the configuration of **p-3** from that of **o-3** or **m-3** causes the decrease in metal extraction to be described below.

Absorption Spectra of Three Reagents (o-3, m-3, and p-3) and of Their Silver Complexes in a 50% (v/v) Dioxane-Water Mixture. In Table 1, the absorption-spectra data for three reagents (**o-3**, **m-3**, and **p-3**), in a 50% (v/v) dioxane-water mixture are shown, along with those for their silver complexes. The absorption maxima of the three reagents in acidic media, which are present in the range of 384—400 nm, shift to longer wavelengths (537—545 nm) in alkaline media, and their molar absorptivities (ε) increase from 22000—24000 in acidic media to 34400—35800 in alkaline. These changes in the absorption spectra with the increase in the pH are almost the same as those of 4-(4-nitrophenylazo)phenol with the dimethyl substituent (2,3-dimethyl-; HL 394 nm, L^- 548 nm: 2,6-dimethyl-; HL 393 nm, L^- 556 nm: 2,5-dimethyl-; HL 398 nm, L^- 547 nm).

p-3	400	23600	538	34400	528	31200

Concentration of **3** and silver ions: 2.5×10^{-5} M.

In the presence of the silver ion, the absorption maxima of all three reagents shift to wavelengths shorter by 10—14 nm than those of L^-. It seems that the shift shows the decrease in the resonance of the azobenzene moiety by the shift of electrons from that of *p*-nitrobenzene to the thioether ring as a result of the coordination of the silver ion to the sulfur atoms. It is interesting that the molar absorptivities for **o-3** and **p-3** silver complexes decrease, but that for **m-3** increases, compared with L^-. This seems to indicate that the phenolate ion not only functions as a counter ion, but also takes part in the bonding of the silver ion.

Proton-Dissociation Constant. The acid dissociation constants of the reagents **3** were determined spectrophotometrically in a 50% (v/v) dioxane-water mixture, the effects of the silver ion on their pK_a values were also examined. The results are shown in Table 2. The pK_a values of **o-3** and **p-3** are similar, but that of **m-3** is somewhat small. In the presence of silver ions, the apparent pK_a value of every reagent decreases. Probably this is a result of the decrease in electron density on the phenolic oxygen atom when the electrons are shifted from the azobenzene moiety by the coordination of the silver ion. The large decrease in pK_a value for **m-3** suggests that the silver ion interacts directly with the hydroxyl group and

that, consequently, the proton is excluded by proton-silver ion repulsion.

Liquid-Liquid Extraction Behavior of Silver and Copper(I). (i) Absorption Spectra of Silver and Copper(I) Complexes for Reagents 3: The absorption spectra of **o-3**, **m-3**, and **p-3** and of those silver and copper(I) complexes extracted into chloroform are shown in Figs. 1—3.

The absorption bands of HL have their maxima at 378—385 nm (ε=21000—25000). The absorption maxima of silver complexes for **o-3** and **p-3** exist at 556 nm and 545 nm, which are longer than those of the corresponding silver complexes in a 50% (v/v) dioxane-water solution. However, that for **m-3** in chloroform exists at a shorter wavelength than those in a 50% (v/v) dioxane-water solution. This may be attributed to the larger decrease in the resonance of the azobenzene moiety by the coordination of silver. This influence may be weakened by a polar solvent, and the effect may be larger for **m-3** than for **o-3** and **p-3**. As shown in Table 3, the absorption maxima of silver complexes for **o-3** and **m-3** are shifted to the longer wavelengths with the increase in the solvent polarity and the shift for **m-3** is larger than that for **o-3**.

(ii) The Percentage of the Extraction of Silver and Copper(I) Complexes: The percentage of the extraction of silver and copper(I) with three reagents was also examined. The results are shown in Table 4. As has been reported in previous papers,[3,9,11] silver and copper(I) were well extracted with these thiacrown compounds. Similarly, those two metals were well extracted with these three reagents **3** at 20 times the metal concentration into chloroform, as shown in Table 4. Also, as shown in Table 5, these were well extracted with **m-3** in the same concentration is that of metal ions at pH 8.95. It seems that **m-3** has an intraannular hydroxyl group; therefore, a dissociated hydroxyl group exists at a preferable position compared with that of **o-3**. The extraction with **p-3** decreases to about a half. This decrease is presumed to be accounted for as follows: two sulfur atoms of the para-substituted benzyl group exist far apart, consequently, the silver or copper(I) ion can not be coordinated by those sulfur atoms-only two sulfur atoms bonded to the trimethylene group can be coordinated. In fact, it is obvious that the internal cavity of

p-3 is too small for silver or copper(I), as assumed by CPK model of the space-field type.

Liquid-Liquid Extraction of Copper(II). Among the metals belonging to class *ab* metals, Co^{2+}, Ni^{2+}, and Zn^{2+} were scarcely extracted at all with 4′-(2-hydroxy-5-chlorophenylazo)Bz-TTCP[11] and 4′-PicNHBz-TTCP.[9] Only Cu^{2+} was extracted appreciably with 4′-(2-hydroxy-5-chlorophenylazo)Bz-TTCP and not with 4′-PicNHBz-TTCP. It seemed interesting to determine whether or not copper(II) can be extracted with these three reagents **3**. The absorption spectra data of copper(II) complexes for the reagents **3** in chloroform are shown in Table 6. The percentage of extraction was examined, it is also shown in Table 6. Although the percentage of the extraction of copper(II) is less than those of silver or copper(I), copper(II) is extracted in an appreciable amount. In the previous paper, we presumed that the extraction of copper(II) with 4′-(2-hydroxy-5-chlorophenylazo)Bz-TTCP is performed by the complex formation of adjacent azo and hydroxyl groups, rather than the thioether ring. However, the results of the extraction with these reagents **3** strongly suggest the formation of copper(II) complexes with the thioether ring.

Experimental

Syntheses of Reagents. Bis(bromomethyl)phenyl Acetate 1: Dimethylphenyl acetate (8.2 g, 0.05 mol) was dissolved in carbon tetrachloride (100 ml) and *N*-bromosuccinimide (17.5 g, 0.1 mol), and then benzoyl peroxide (0.2 g) was added. The reaction mixture was refluxed for 2—3 h. After cooling, the precipitate was filtered and washed with a small amount of ether. The filtrate and the washings were combined, and the solvent was removed in vacuo. The solid was recrystallized from ethanol.

2,3-Bis(bromomethyl)phenyl Acetate: Mp 100—101 °C; yield, 5.6 g (34.6%). Found: C, 37.46; H, 3.19%. Calcd for $C_{10}H_{10}Br_2O_2$: C, 37.30; H, 3.13%. IR(KBr) 1760, 1220, 1210, 1190, 620 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 324 (M+2, 28), 322 (M^+, 58), 320 (29), 280 (98), 243 (98), 241 (98), 119 (100). ^1H NMR ($CDCl_3$) δ=2.35 (3H, s, CH_3), 4.60 (4H, s, CH_2Br), 6.95—7.35 (3H, m, aromatic H).

2,6-Bis(bromomethyl)phenyl Acetate: Mp 119—120 °C; yield, 7.3 g (45.6%). Found: C, 37.42; H, 3.10%. IR (KBr) 1760, 1220, 1210, 1180, 590 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 324 (M+2, 6), 322 (M^+, 12), 320 (6), 280 (88), 201 (100), 199 (98). ^1H NMR ($CDCl_3$) δ=2.40 (3H, s, CH_3), 4.35 (4H, s, CH_2Br), 7.00—7.50 (3H, m, aromatic H).

2,5-Bis(bromomethyl)phenyl Acetate: Mp 99—100 °C; yield, 4.9 g (30.1%). Found: C, 37.07; H, 3.00%. IR (KBr) 1760, 1230, 1200, 1190, 625 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 324 (M+2, 5), 322(M^+, 9), 320 (5), 243 (44), 241 (45), 199 (100). ^1H NMR ($CDCl_3$) δ=2.35 (3H, s, CH_3), 4.30—4.50 (4H, d, CH_2Br), 7.05—7.35 (3H, m, aromatic H).

Hydroxy-Substituted Cyclophane (Compounds o-2, m-2, and p-2). In absolute ethanol (360 ml) under nitrogen, sodium metal (0.83 g, 36 mmol) was dissolved. To this solution, an anhydrous benzene solution (450 ml) containing dibromide **1** (3.86 g, 12 mmol) and 3,7-dithianonane-1,9-dithiol (4.10 g, 18 mmol) was added dropwise during a 6-h period at 10—15 °C. After the mixture had then been stirred overnight, the solvent was removed until the volume has only about 100 ml, and then water was added. The mixture was acidified with dilute hydrochloric acid, extracted with ethyl acetate, washed with water, and dried. The solvent was then removed, and the residue was chromatographed on a silica-gel column with chloroform-ethyl acetate (20:1 v/v) (for ortho- and paracyclophanes) or benzene (for metacyclophane) as a eluting solvent. The major band was collected. The product was pure enough for the next process. Recrystallization gave an every purer product.

o-2: Yield, 3.11 g (74.9%). Recrystallization from methanol-methyl acetate (1 : 1); mp 112—113 °C. Found: C, 51.75; H, 6.30%. Calcd for $C_{15}H_{22}OS_4$: C, 51.98; H, 6.40%. IR (KBr) 3425, 1580, 1465, 1200, 765 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 348 (M+2, 5), 346 (M^+, 26), 211 (17), 167 (92), 107 (100). ^1H NMR ($CDCl_3$) δ=1.55—2.10 (2H, m, CH_2-CH_2CH_2), 2.50—3.10 (12H, overlapping t and s, CH_2-CH_2CH_2, CH_2CH_2), 3.75—4.10 (4H, d, CH_2Ar), 6.55—7.20 (3H, m, aromatic H).

m-2: Yield, 3.58 g (86.2%). Recrystallization from ethanol; mp 94—95 °C. Found: C, 51.99; H, 6.18%. IR(KBr) 3325, 1460, 1410, 1200, 750 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 348 (M+2, 22), 346 (M^+, 100), 286 (15), 184 (50), 120 (88), 91 (82). ^1H NMR ($CDCl_3$) δ=1.40—1.90 (2H, m, CH_2CH_2-CH_2), 2.30—2.75 (12H, overlapping t and s, $CH_2CH_2CH_2$, CH_2CH_2), 3.80 (4H, s, CH_2Ar), 6.65—7.30 (3H, m, aromatic H).

p-2: Yield, 3.49 g (84.0%). Recrystallization from acetonitrile; mp 96—97 °C. Found: C, 51.91; H, 6.31%. IR (KBr) 3245, 1580, 1430, 1230, 720 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 348 (M+2, 20), 346 (M^+, 97), 286 (8), 198 (16), 167 (96), 107 (100). ^1H NMR ($CDCl_3$) δ=1.25—1.80 (2H, m, $CH_2CH_2CH_2$), 2.15—2.65 (12H, overlapping t and s, $CH_2CH_2CH_2$, CH_2CH_2), 3.60—3.85 (4H, d, CH_2Ar), 6.80—7.25 (3H, m, aromatic H).

***p*-Nitrophenylazo Reagents 3 (Compounds o-3, m-3, and p-3).** Phenolic cyclophane **2** (1.04 g, 3.0 mmol) was dissolved in dioxane (60 ml), and then 0.05 M sodium hydroxide solution (60 ml) was added. To this solution, *p*-nitrobenzenediazonium tetrafluoroborate (0.77 g, 3.3 mmol) dissolved in water (150 ml) was added dropwise at 5—10 °C. During this addition, the reaction mixture was kept homogeneously at pH 8—9 by the use of dioxane and a dilute sodium hydroxide solution. Then the solution was stirred at room temperature for 1 h and acidified with dilute hydrochloric acid. A large quantity of water was added, the mixture was extracted with ethyl acetate and dried. The solvent was removed, and the residue was chromatographed on a silica-gel column with chloroform-ethyl ace-

tate (20:1 v/v) (for ortho- and paracyclophanes) or chloroform (for metacyclophane) as a eluting solvent. The major band was collected and recrystallized.

o-3: Recrystallization from acetonitrile; yield, 0.87 g (58.5%). Mp 219—220 °C. Found: C, 50.73; H, 4.90; N, 8.59%. Calcd for $C_{21}H_{25}N_3O_3S_4$: C, 50.88; H, 5.08; N, 8.48%. IR (KBr) 3280, 1580, 1330, 1280, 1240 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 495 (M^+, 3), 301 (16), 267 (32), 167 (68), 61 (100). ^1H NMR ($CDCl_3$:DMSO-d_6=1:1) δ=1.75—2.10 (2H, m, $CH_2CH_2CH_2$), 2.70—3.10 (12H, overlapping t and s, $CH_2CH_2CH_2$, CH_2CH_2), 4.10 (2H, s, CH_2Ar), 4.55 (2H, s, CH_2Ar), 6.85—6.95 (1H, d, aromatic H), 7.60—7.70 (1H, d, aromatic H), 7.95—8.20 (4H, q, aromatic H).

m-3: Recrystallization from acetonitrile; yield, 0.35 g (23.4%). Mp 162—163 °C. Found: C, 51.00; H, 4.97; N, 8.56%. IR (KBr) 3300, 1510, 1345, 1295, 1285 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 495 (M^+, 5), 269 (15), 194 (13), 107 (65), 61 (100). ^1H NMR ($CDCl_3$) δ=1.30—1.85 (2H, m, $CH_2CH_2CH_2$), 2.35—2.80 (12H, overlapping t and s, $CH_2CH_2CH_2$, CH_2CH_2), 3.90 (4H, s, CH_2Ar), 7.80—8.50 (6H, m, aromatic H).

p-3: Recrystallization from acetonitrile and water; yield, 0.49 g (33.0%). Mp 145—146 °C. Found: C, 50.77; H, 5.00; N, 8.57%. IR (KBr) 3450, 1525, 1340, 1280, 1260 cm^{-1}. MS (70 eV) *m/z* (rel intensity) 495 (M^+, 17), 301 (35), 268 (100), 167 (98), 107 (99). ^1H NMR (pyridine-d_5) δ=1.50—1.70 (2H, m, $CH_2CH_2CH_2$), 2.20—2.95 (12H, m, $CH_2CH_2CH_2$, CH_2CH_2), 3.78 and 4.48 (2H, AB-q, J=13.9, CH_2Ar), 3.80 and 5.17 (2H, AB-q, J=14.0, CH_2Ar), 7.51 (1H, s, aromatic H), 8.11 and 8.41 (4H, q, aromatic H), 8.25 (1H, s, aromatic H).

Reagent and Apparatus. Metal solution: Copper(II) sulfate, an analytical-grade reagent, was used to prepare the 1×10^{-2} M stock solution, which was then standardized by EDTA titration. A 1×10^{-2} M stock solution of silver nitrate commercially available for volumetric analysis was used.

The other reagents and all of the apparatus used were the same as have been described in a previous paper.[11]

Proton-Dissociation Constant. The proton dissociation constants of thiacrown ether reagents were determined spectrophotometrically in a 50% (v/v) dioxane-water mixture by means of a method similar to that described in the previous paper.[11] The ionic strength was adjusted to 0.1 with sodium sulfate.

Extraction of Metals. An aliquot (10 ml) of an aqueous solution containing the metal ion and the buffer solution was placed in a 20-ml cylindrical glass tube equipped with a stopper. The ionic strength was kept at 0.1 with sodium sulfate. To obtain a copper(I) solution, enough hydroxylamine sulfate was added to the copper(II) sulfate solution.

After the addition of 10 ml of the reagent **3** solution, the mixture was shaken for 30 min at 200 strokes/min and centrifuged for 5 min. The absorbance of the organic phase was measured at the wavelength of each absorption maximum against a reagent blank. The metal concentrations in the organic phase were determined as follows: 5 ml of the organic phase was taken and allowed to evaporate. The residue was dissolved with a small amount of concentrated nitric acid and diluted adequately with water, and then the metal ion was determined by means of atomic absorption spectrometry.

The authors wish to thank Professor Jun-ichi Oda, Dr. Yukio Yamamoto, and Dr. Naomichi Baba, Institute for Chemical Research, Kyoto University, for their useful suggestions for the syntheses of reagents and for obtaining the NMR spectra.

(Received September 19, 1988)

The oxidative addition of 2-(chloromethyl)pyridine to tetrakis(triphenylphosphine)palladium(0) in toluene at 100 °C gave [{PdCl(C_5H_4N-2-CH_2)PPh_3}$_2$] (**1a**), which was characterized by analytical, molecular-weight, and IR data as well as ^1H, ^{31}P, and ^{13}C NMR spectroscopy. The chloride ligand was readily replaced by other halides, whereas tertiary phosphines such as diphenylmethyl-, phenyldimethyl-, and triethylphosphines cleaved the bridge after substitution of triphenylphosphine to result in the monomeric *trans*-[PdCl(C_5H_4N-2-CH_2)(PR_3)$_2$] complexes. Reactions of **1a** with carbon monoxide and other reagents are also reported. The corresponding 3-picolyl complex [{PdCl(C_5H_4N-3-CH_2)PPh_3}$_n$] was also prepared, but could not be well characterized because of lower stability and solubility.

Organopalladium complexes have been investigated extensively,[1] since they play important parts in organic synthesis as catalysts and/or intermediates.[2] The benzylpalladium(II) complexes prepared by oxidative addition of benzyl halides to palladium(0)[3] have attracted special attention of many workers. Thus Stille and his collaborators revealed the S_N2 nature of the oxidative addition of benzyl chloride and related compounds to $Pd(PPh_3)_4$ and $PdCO(PPh_3)_3$ based on the stereochemical investigations.[4] Carbon monoxide is readily inserted into the Pd-C bond,[5] leading to synthesis of ketones[6] and esters.[7] Oxidative addition of benzyl chloride to palladium atoms yielded dimeric η^3-benzylchloropalladium(II),[8] and the same η^3-benzylpalladium(II) structure was also realized by the reaction of *trans*-benzylchlorobis(triethylphosphine)palladium(II) with sodium tetraphenylborate in ethanol.[9]

The benzylpalladium(II) complexes have thus been studied extensively, but investigation of the picolylpalladium(II) complexes are rather few, although several papers have appeared in reporting the picolyl complexes of Cr,[10] Co,[11] and other metals such as Mn, Mo, and Fe,[12] and their reactions with various electrophiles.[13] Roberts and Klabunde[8] obtained a picolylpalladium(II) complex by cocondensation of 2-(chloromethyl)pyridine with palladium vapors, but the exact structure has not been clarified. Recently Hiraki and his collaborators reported several 2-picolylpalladium(II) complexes.[14] As an extension of our studies on the σ-pyridyl complexes,[15-17] this paper reports on the properties and structures of some picolyl-palladium(II) complexes. A preliminary account and X-ray molecular structure of the 2-picolylpalladium(II) complex have previously been reported.[18]

Experimental

Air-sensitive compounds were handled in an atmosphere of nitrogen using solvents and reagents which had been redistilled under and purged with nitrogen, respectively. Tetrakis(triphenylphosphine)palladium(0), $Pd(PPh_3)_4$, was prepared according to literature.[19] 3-(Chloromethyl)-pyridine was prepared by treating the hydrochloride commercially available with triethylamine in diethyl ether. Tertiary phosphines and other reagents were purchased and used without further purification.

Preparation of the [Chloro(2- and 3-picolyl)(triphenylphosphine)palladium(II)] Complexes, [{PdCl(C_5H_4N-2-CH_2)PPh_3}$_2$] (1a) and [{PdCl(C_5H_4N-3-CH_2)PPh_3}$_n$] (4). To a solution of $Pd(PPh_3)_4$ (3.15 g, 2.73 mmol) in toluene (50 cm^3) was added 2- or 3-(chloromethyl)pyridine (3.48 g, 27.3 mmol) and the mixture was heated to 100 °C for 30 min. The mixture was then left standing at room temperature for 4 h to deposit a yellow-green precipitate, which was filtered and dissolved in dichloromethane (50 cm^3). After filtration, the solvent was distilled away under reduced pressure to obtain a yellow solid of **1a** or **4** in 73 and 15% yields, respectively, which was recrystallized from a mixture of dichloromethane and methanol (1 : 5 by volume).

Preparation of the Bis[chloro(2-picolyl)(diphenylmethyl- and phenyldimethylphosphine)palladium(II)] Complexes, [{PdCl(C_5H_4N-2-CH_2)PPh_2Me}$_2$] (1b) and [{PdCl(C_5H_4N-2-CH_2)$PPhMe_2$}$_2$] (1c). To a solution of **1a** (0.28 g, 0.28 mmol) in dichloromethane (10 cm^3) was added PPh_2Me (0.43 g, 2.2 mmol) or $PPhMe_2$ (0.30 g, 2.2 mmol) to change the color of solution from yellow to pale orange-yellow. After the reaction at room temperature for 3 h, the solution was concentrated to ca. 3 cm^3 by evaporation under reduced pressure. The concentrate was charged onto a column (30 cm×1.5 cm d) of Aluminiumoxid 60 PF_{254} (Type E, Merck). Petroleum ether (150 cm^3) was passed through the column to elute the excess phosphine, and dichloromethane (70 cm^3) was used as the developing solvent. The eluate was concentrated to 10 cm^3 again, and petroleum ether (50 cm^3) was added to the concentrate to precipitate yellow crystals of **1b** or **1c** in 62 and 45% yields, respectively, which were recrystallized from a mixture of dichloromethane and diethyl ether (1 : 6 by volume).

Preparation of the Bis[bromo- and iodo(2-picolyl)-(triphenylphosphine)palladium(II)] Complexes, [{PdX-(C_5H_4N-2-CH_2)PPh_3}$_2$], X=Br (1d) and I (1e). A methanol

solution (15 cm^3) of sodium bromide (0.309 g, 3.00 mmol) or iodide (0.450 g, 3.00 mmol) was added to a dichloromethane solution (30 cm^3) of **1a** (0.15 g, 0.15 mmol). The mixture was allowed to react at room temperature for 3 h and then concentrated to ca. 20 cm^3 by evaporation under reduced pressure to deposit a yellow (**1d**) or deep yellow (**1e**) precipitate in 80 and 65% yields, respectively. They were recrystallized from a mixture of dichloromethane and methanol (1 : 5 by volume).

Preparation of the *trans*-Chloro(2-picolyl)bis(triethylphosphine and phenyldimethylphosphine)palladium(II) Complexes, *trans*-[PdCl(C_5H_4N-2-CH_2)(PR_3)$_2$], PR_3= PEt_3 (2a) and $PPhMe_2$ (2b). To a solution of **1a** (0.35 g, 0.35 mmol) in dichloromethane (10 cm^3) was added PEt_3 (0.50 g, 4.2 mmol) or $PPhMe_2$ (0.59 g, 4.3 mmol), when color of the solution changed from yellow to pale orange-yellow. After the reaction at room temperature for 3 h, the solution was concentrated to ca. 1 cm^3 by evaporation under reduced pressure. Diethyl ether (30 cm^3) was added to the concentrate and the mixture was cooled to −78 °C to precipitate white to pale yellow crystals in 15 (**2a**) and 62% (**2b**) yields, respectively. They were recrystallized at the Dry Ice-methanol temperature from a mixture of dichloromethane and diethyl ether (1 : 10 by volume) containing a small amount of free phosphine.

Preparation of Chloro(2-pyridylacetyl-*C,N*)(triphenylphosphine)palladium(II), [PdCl(C_5H_4N-2-CH_2CO-*C,N*)PPh_3] (3). Carbon monoxide was bubbled at ambient temperature and pressure for 8 h through a suspension of **1a** (0.15 g, 0.15 mmol) in tetrahydrofuran (THF) (50 cm^3) to result in a pale yellow clear solution. Then the vessel was stoppered and the reaction was allowed to continue for further 4 h. Then the slightly reddish solution was concentrated to ca. 10 cm^3 by evaporation under reduced pressure to precipitate white crystals in a 47% yield. A mixture of dichloromethane and diethyl ether (1 : 5 by volume) was used for recrystallization.

Reaction of 1a with Phenyldimethylphosphine. Four different quantities of phenyldimethylphosphine (0.009 g (0.065 mmol), 0.027 g (0.0195 mmol), 0.032 g (0.23 mmol), and 0.054 g (0.39 mmol)) were added to four tubes of which each contained a solution of **1a** (0.065 g, 0.065 mmol) in CD_2Cl_2 (0.3 cm^3). Concentrations of $PPhMe_2$ were 0.22, 0.65, 0.77, and 1.3 mol dm^{-3}, respectively, **1a** being 0.217 mol dm^{-3} in each solution. These solutions were subjected to ^1H NMR assay of **1c** and **2b** formed.

Reaction of 1a with Hydrogen Chloride. A dichloromethane solution (15 cm^3) of hydrogen chloride (0.07 mol dm^{-3}) was added dropwise to a solution of **1a** (0.23 g, 0.23 mmol) in dichloromethane (20 cm^3) and the mixture was stirred at room temperature for 2 h. The solvent was then evaporated to dryness under reduced pressure and the residue was extracted with CD_3OD (0.7 cm^3). The solution was subjected to ^1H NMR measurement to identify 2-methylpyridine hydrochloride. No other organic compounds except triphenylphosphine were detected. The residue was further extracted with chloroform. The extract was evaporated to dryness to leave an orange solid, which was identified to be trans-[$PdCl_2(PPh_3)_2$] by IR spectroscopy[20] and elemental analysis (Found: C, 60.93; H, 4.08%. Calcd for $C_{36}H_{30}Cl_2P_2Pd$: C, 61.60; H, 4.31%) and the yield was 36%.

Reaction of 1a with Silver Acetate. Silver acetate (0.12 g, 0.72 mmol) was added to a suspension of la (0.29 g, 0.29 mmol) in benzene (20 cm^3) and the mixture was allowed to react at 40 °C for 3 h. The solvent was evaporated to dryness under reduced pressure. The residue was treated with dichloromethane (20 cm^3), and silver chloride and remaining silver acetate were filtered off. The yellow filtrate was again evaporated to dryness and the residue was extracted with diethyl ether (20 cm^3). The solvent was vaporized and the residue was dissolved in $CDCl_3$ (0.5 cm^3). A small amount of 2-picolyl acetate was identified on the ^1H NMR spectrum (CH_3, 2.16 s; CH_2, 5.27 s; H^6 of pyridine, δ 8.66 d). On the other hand the IR spectrum of residue suggests the presence of triphenylphosphine, picolyl and acetoxyl groups, and the elemental analysis (C, 52.03; H, 4.10; N, 2.47%) is near the values calculated for [{$PdOCOCH_3(C_5H_4N$-$CH_2)PPh_3$}$_2$] (C, 60.07; H, 4.65; N, 2.69%). The yield was 43%. Purification was not successful.

Reaction of 1a with Phenylacetyl Chloride. To a solution of **1a** (0.32 g, 0.32 mmol) in CD_2Cl_2 (0.5 cm^3) were added C_6D_6 (4 cm^3) and phenylacetyl chloride (0.10 g, 0.65 mmol), and the mixture was heated to 80 °C for 3 h, color of the solution changing from yellow to red. Then the solution was cooled and evaporated to ca. 2 cm^3 under reduced pressure. Red-orange crystals were filtered and the filtrate was subjected to ^1H NMR spectrometry. The organic compound giving proton signals at 3.83 d and 4.17 s ppm could not be identified. The crystals were identified as $Pd_2Cl_4(PPh_3)_2$ by elemental analysis (Found: C, 48.76; H, 3.29%. Calcd for $C_{36}H_{30}P_2Cl_4Pd_2$: C, 49.18; H, 3.44%) and comparison of the IR spectrum with that of an authentic sample and literature.[21] The yield of the dinuclear complex in the present reaction was 73%.

Derivation of Methyl 2-Pyridylacetate from 1a. Carbon monoxide was passed slowly through a suspension of **1a** (0.18 g, 0.18 mmol) in THF (30 cm^3) for 7 h. A methanol solution (5 cm^3) of sodium methoxide (0.023 g, 0.43 mmol) was added to the reaction mixture and CO bubbling was continued for further 2 h. The solvent was evaporated to dryness under reduced pressure and the residue was extracted with diethyl ether (20 cm^3), which was again vaporized. The residue was dissolved in $CDCl_3$ (0.5 cm^3) and shown by ^1H NMR assay to contain a small amount of methyl 2-pyridylacetate (CH_3 and CH_2 overlapping, 3.77 broad: H^6 of pyridine, δ 8.40).

Measurements. Infrared spectra were recorded in Nujol on a JASCO DS-701G spectrophotometer. A JEOL JNM MH-100 instrument was used to obtain ^1H NMR spectra at 100 MHz with tetramethylsilane as internal reference. ^{13}C NMR spectra were taken at 25.0 MHz on a JEOL JNM FX-100 spectrometer with tetramethylsilane as external reference and ^{31}P NMR spectra were recorded at 40.25 MHz on the same instrument with phosphoric acid as external reference. The molecular weight was determined in dichloromethane at 25 °C by vapor pressure osmometry with an instrument manufactured by Knauer in West Berlin, West Germany.

Results and Discussion

Although $Ni(PPh_3)_4$ reacted readily with 2-, 3-, and 4-(chloromethyl)pyridines, the expected picolylnickel(II) complexes could not be isolated, On the other hand, the reactions of $Pd(PPh_3)_4$ with these pyridine

Table 1. Analytical Data for the Picolyl Palladium(II) Complexes

Complex		Found (Calcd)

derivatives did not take place at room temperature, but occurred at 100 °C to finish after 30 min. The 2- and 3-picolylpalladium(II) complexes were isolated, but stability and solubility of the latter were not enough to allow full characterization. The 4-picolyl complex was not even isolated. Thus the stability of the picolylpalladium(II) complexes varies remarkably with the site of substitution on the pyridine ring.

Characterization of the Dinuclear Picolyl Complexes. The analytical and molecular-weight data in Table 1 indicate that complexes **1a** and **1b—1e** which were derived from **1a** by the ligand substitution reactions are dinuclear. As a dinuclear structure for the palladium(II) complexes the di-μ-chloro structure is most common.[21] However, X-ray analysis revealed that $[\{PdBr(C_5H_4N\text{-}C^2)PPh_3\}_2]$ has the pyridyl(C^2, N)-bridged structure.[22] If the picolyl ligand in the present dinuclear complexes also functions as a similar bridging ligand, the two structures depicted in Fig. 1 are conceivable. Structure A has a C_2 axis, while B being shown in the 2-litiomethyl-6-methylpyridine-tetramethylethylenediamine dimer[23] has a center of inversion. Hiraki and his co-workers proposed structure B,[14] but molecular models indicate that A is more favorable, since the bulky triphenylphosphine ligands experience a serious steric interference by the picolyl ligand in structure B. In fact X-ray analysis has confirmed that compound **1a** has structure A.[18]

The ν(Pd-Cl) frequencies observed for **1a—1c** (Table 2) are rather low for the terminal chloride, but are reasonable when located at the coordination site trans to carbon.[5] Table 3 lists ^1H NMR data for complexes **1a—1c**. The pyridyl ring protons are readily assigned by reference to the data for free 2-picoline[24] except the H^6 atoms of **1a** and **1b** of which signals are indiscernible because of overlapping with those for the phenyl-ring protons. Thus, the triplet signal at about δ 6.5 is assigned to H^5 and the doublet in the δ 6.7—7.0 region to H^3 which resonates at lower field than H^5 because of the anisotropic effect of the $(PPh_3)ClPdCH_2$ substituent.[25,17] The remaining triplet in the δ 7.0—7.3 region is attributed to H^4, H^6 of **1c** appearing as a doublet at δ 7.84.

Each of the pyridyl-ring protons except H^4 of the picolyl ligands resonates at a remarkably higher field than that of 2-(chloromethyl)pyridine (H^3 and H^5, around δ 7.6; H^4, 7.13; H^6, 8.56).[12a] In the case of $Fe(C_5H_4N\text{-}2\text{-}CH_2)(\eta^5\text{-}C_5H_5)(CO)_2$, the pyridyl-ring

protons show similar upfield shifts (H^3 and H^5, δ 6.90; H^4, 7.32; H^6, 8.28),[12a] which were considered to be caused by the electron-donating effect of the CH_2ML_n moiety.[11,12b] The phenyl-ring protons in **1a**, **1b**, and **1c** exhibit two multiplets at about δ 7.5 and 7.9, the former being assigned to the meta and para protons and the latter to the ortho protons.[26] The methyl protons of the phosphine in **1b** resonate as a doublet at δ 2.22 with ^2J(P-H)=ca. 12.5 Hz, but those in **1c** exhibit two doublets at δ 1.88 and 1.91 both with ^2J(P-H)=ca. 11 Hz (Fig. 2), showing that the two methyl groups of phenyldimethylphosphine in **1c** differ in their time-averaged magnetic environments. This indicates that there is no plane of symmetry through the Pd-P bond[27] in accordance with the dinuclear structure A in Fig. 1.

The methylene protons of the picolyl ligand in **1a**—**1c** are not equivalent as is seen in Fig. 1, but exhibit two separate signals in the δ 2.42—2.52 and 3.72—3.81 regions, respectively (Fig. 2 and Table 3). The higher-field signal is a triplet and the lower-field one doublet, both having the same coupling constant of about 9 Hz. Irradiation at the frequency of the triplet reduced the lower-field doublet to a singlet, and irradiation at the latter frequency reduced the triplet to a doublet, confirming the geminal coupling (J=ca. 9 Hz) of the methylene protons. The ^{31}P NMR spectrum of **1a** exhibits a signal at δ 36.06 downfield from H_3PO_4. Irradiation only at the region for the phenyl-ring protons gave a doublet shown in Fig. 3. The coupling constant is ca. 9 Hz, indicating that the phosphorus atom couples to one of the methylene protons which resonates as a triplet. As is seen in Fig. 2, the low-field doublet for **1c** splits due to ca. 3 Hz coupling to phosphorus. Thus one of the methylene protons in **1c** strongly couples to ^{31}P with J=ca. 9 Hz, while the other weakly with J=ca. 3 Hz.

Table 4 lists the ^{13}C chemical shifts and J(P-C) values for complex **1a** together with the corresponding data for uncoordinated triphenylphosphine[28] and 2-ethylpyridine[29] for comparison. Assignment for the phenyl carbons in **1a** was made on the basis of J(P-C)

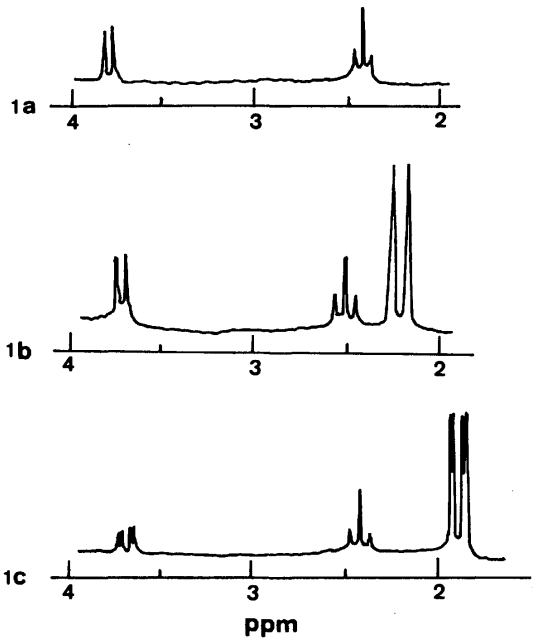

Fig. 2. Methyl and methylene signals in ^{1}H NMR spectra of [{PdCl(C_5H_4N-2-CH_2)L}$_2$] with PPh_3 (**1a**), PPh_2Me (**1b**) and $PPhMe_2$ (**1c**) as L.

values and by reference to uncoordinated PPh_3 and $[\{PdBr(C_5H_4\text{-}C^2)PPh_3\}_2]$.[16] The methylene carbon of the picolyl ligand in **1a** resonates at δ 28.47 and appears as a triplet of doublets under the off-resonance condition, ^2J(P-C) being ca. 7 Hz. The small coupling constant suggests that the methylene and phosphine ligands are mutually cis. Assignments for the pyridyl-ring carbons were made based on the off-resonance data and referring to $[\{PdBr(C_5H_4N\text{-}C^2)PPh_3\}_2]$.[16] As is shown by Table 4, the shielding of each carbon is quite similar to that of the corresponding ring carbon in 2-ethylpyridine, indicating that the $(PPh_3)ClPdCH_2$ moiety is functioning as an electron-donating group, but the effect is weaker than that of the $(PPh_3)BrPd$ group directly attached to the pyridyl ring in $[\{PPdBr(C_5H_4N\text{-}C^2)PPh_3\}_2]$.[16]

Table 4. ^{13}C Chemical Shifts δ (in ppm from external Me_4Si) and Coupling Constants J (in Hz) in CD_2Cl_2 at Room Temperature

Phenyl carbon in **1a**			Phenyl carbon in free PPh_3		
	δ	J(P-C)		δ	J(P-C)
C^1	130.98	51.5	C^1	138.3	21

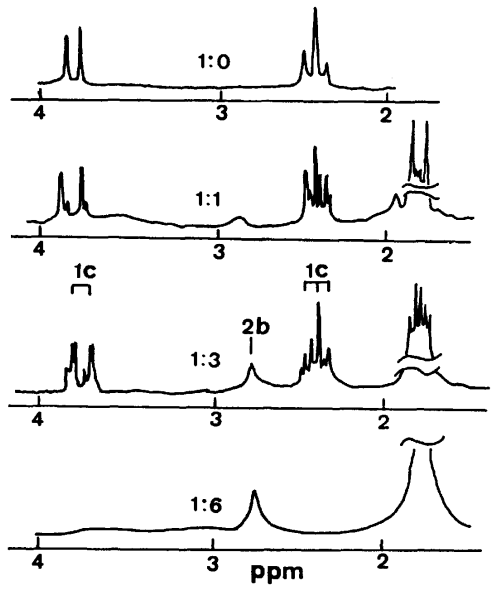
C^4	136.01		C^4	136.3	
C^5	117.7		C^5	121.9	
C^6	151.72		C^6	149.8	

Although the 3-picolyl complex **4** was prepared and isolated, it is less stable and less soluble in organic solvents than the 2-picolyl complex **1a** and its characterization has not been enough to allow the structure assignment. Results of the elemental analysis indicate that the complex is not mononuclear but may be polynuclear, since a dinuclear structure seems difficult.

Characterization of the Mononuclear Picolyl Complexes. The mononuclear picolyl complexes **2a** and **2b** were prepared by the reactions of **1a** with excess amounts of PEt_3 and $PPhMe_2$, respectively and isolated at low temperature. The analytical and molecular-weight data in Table 1 indicate that they are mononuclear and the ν(Pd-Cl) frequency of **2b** in Table 2 is quite similar to that recorded for *trans*-$[PdCl(CH_2Ph)(PPh_3)_2]$.[3] The ^1H NMR data for **2b** are included in Table 3. Contrary to the case of **1c**, the methyl protons of the phosphine ligands in **2b**



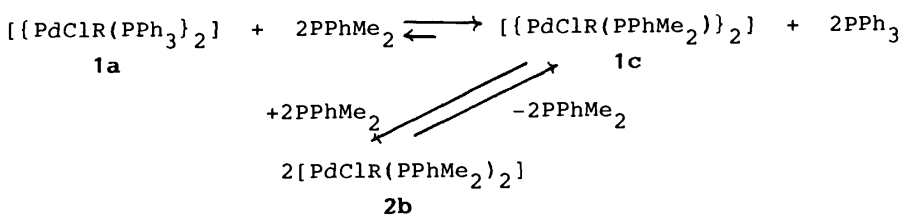


Fig. 4. The methylene-proton signals from $[\{PdCl(C_5H_4N\text{-}2\text{-}CH_2)PPh_3\}_2]$ (**1a**) in CD_2Cl_2 at room temperature in the absence and in the presence of one equivalent, three times, and six times molar amount of phenyldimethylphosphine. In the reaction scheme R represents the 2-picolyl ligand.

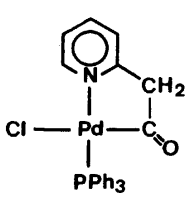
resonate as a singlet at δ 1.80 with no coupling to phosphorus, and the picolylic protons also exhibit a broad singlet at δ 2.78. The benzylic protons in *trans*-[PdCl(CH_2Ph)(PPh_3)$_2$] also lack coupling to phosphorus and the behavior was rationalized by the rapid phosphine exchange between the mononuclear complex and PPh_3 freed by the equilibrium $2[PdCl(CH_2Ph)(PPh_3)_2] \rightleftarrows [\{PdCl(CH_2Ph)PPh_3\}_2]+2PPh_3$.[3] Similar situation seems to be realized for **2b**. In fact the ^{1}H NMR spectrum of **2b** in CD_2Cl_2 at −40 °C exhibits two triplets at δ 1.83 and 2.74 assignable to the phosphine methyl (J=ca. 3 Hz) and picolyl methylene (J=ca. 8 Hz) protons, respectively, indicating that the rapid phosphine exchange is prohibited at lower temperature and that **2b** has the trans structure.[30]

The Phosphine Substitution and Bridge Cleavage Reactions of 1a with Phenyldimethylphosphine. Figure 4 compares the methylene-proton signals exhibited by solutions of **1a** in CD_2Cl_2 at room temperature containing various amounts of $PPhMe_2$. An equimolar mixture of **1a** and $PPhMe_2$ shows signals assignable mainly to **1a** and **1c** accompanied by a small amount of **2b** giving the signal at δ 2.78. When a three times molar amount of $PPhMe_2$ is added to **1a**, the predominant species is **1c** and the amount of **2b** is also increased. The last spectrum in Fig. 4, which is given by a 1:6 mixture of **1a** and $PPhMe_2$, is composed of broad signals assignable solely to **2b**. Such a sequence of spectra indicates that the phosphine substitution reaction of **1a** with $PPhMe_2$ to produce **1c** takes place prior to the bridge cleavage to result in a mononuclear complex **2b**.

As was described in the Experimental section, the mononuclear complexes **2a** and **2b** were obtained upon direct crystallization from the reaction mixture, but the dinuclear complexes **1b** and **1c** were isolated by virtue of the chromatographic separation of the mixture.

Characterization of the 2-Pyridylacetyl Complex 3. Complex **1a** reacted readily with carbon monoxide in THF to afford white crystals of **3**, which is shown to be mononuclear by the analytical and molecular-weight data in Table 1. A very strong IR band at 1690 cm^{-1} is assigned to the ν(C=O) vibration and a weak band at 330 cm^{-1} may be tentatively assigned to the ν(Pd-N) vibration. The ^{1}H NMR spectrum shows the methylene signal as a sharp singlet at δ 4.11. These spectral data for **3** conform with the following (*C,N*) chelate structure.



3

In this structure the pyridyl ring lies on the coordination plane and the methylene protons experience equal magnetic environment. Although the signals from the pyridyl-ring protons except H^6 are indiscernible because of overlapping with those from the phenyl-ring protons, H^6 resonates at δ 9.57. Such a remarkable downfield shift of H^6 may be caused by the deshielding anisotropic effect of the carbonyl group. Similar 2-pyridylacetyl complexes (C_5H_4N-2-CH_2CO)$Mn(CO)_4$ and (C_5H_4N-2-CH_2CO)$Mo(CO)_2$-(η^5-C_5H_5), to both of which the (C,N) chelate structure is proposed, show the methylene singlet at δ 4.00 and the pyridyl-ring H^6 doublet at δ 8.99 and 8.96, respectively.[12a]

Reactions of the Picolyl Ligand with Some Reagents. As was described in the Experimental section, reactions of the picolyl ligand with some reagents were examined. Hydrogen chloride decomposed **1a** in dichloromethane to produce 2-picoline hydrochloride and *trans*-$PdCl_2(PPh_3)_2$. The reaction of **1a** with silver acetate in benzene gave a small amount of 2-picolyl acetate and a complex which was presumed to be [{$PdOCOCH_3(C_5H_4N$-2-CH_2)-PPh_3}$_2$]. The acetato complex may be formed by the ligand substitution of **1a** and function as an intermediate for production of 2-picolyl acetate. Production of benzyl acetate by the reaction of *trans*-benzylchlorobis(triphenylphosphine)palladium(II) with silver acetate was similarly presumed to be preceded by replacement of chloride with acetate.[3] The reaction between **1a** and phenylacetyl chloride was tried with the aim of getting 2-picolyl benzyl ketone, but identification of organic products was unsuccessful, although [{$PdCl_2(PPh_3)$}$_2$] was obtained in a high yield. Carbonylation of **1a** followed by the reaction with methoxide gave methyl 2-pyridylacetate. This is analogous to the reactions reported for the benzylpalladium(II) complex.[4,7] Thus complex **1a** is a useful intermediate for preparation of various pyridine derivatives.

We wish to thank Mr. Junichi Gohda for elemental analysis and Mr. Tetsu Hinomoto of JEOL Co. Ltd. for measurements of the ^{13}C and ^{31}P NMR spectra.

(Received October 4, 1988)

The title complexes were synthesized and their crystal and molecular structures were determined by the X-ray diffraction method using their single crystals. The crystals of the former ten hexakis(isothiocyanato) complexes of lanthanum through dysprosium(III) and erbiun(III) are isomorphous with each other: monoclinic, space group $P2_1$, $Z=2$. The central metal atom is octa-coordinated, in a square-antiprism geometry, to six nitrogen atoms of thiocyanato (SCN) ions and two oxygen atoms of methanol and water molecules. The two oxygen atoms take the positions of the most approaching apexes of two squares. The latter three heptakis(isothiocyanato) complexes of dysprosium, erbium, and ytterbium are in another isomorphous form with each other: orthorhombic, space group $P2_1nb$, $Z=4$. The central metal atom is hepta-coordinated, in a deformed pentagonal-bipyramidal geometry, to seven nitrogen atoms of SCN ions.

The study of the molecular structures of the metal complexes of thiocynate (SCN) is one of the very interesting fields due to their variety of coordinated forms and bridging structures. The structure of tetrabutylammonium [hexakis(isothiocyanato)lanthanoidates(M)] (M=Pr—Yb, and Y) has already been elucidated by Martin and others.[1] It has a coordination number of six, although almost all lanthanoids have a coordination number 8—9 in almost all of thier complexes.

On the other hand, in anionic complexes of tetrapotassium [tetraaquatetrakis(isothiocyanato)lanthanoidates(M)] thiocyanates (M=Nd, Eu), reported by Lazarev, the coordination number of the central metal atom is eight (square-antiprism geometry).[2] The authors have already shown that in tetraethylammonium [aquaheptakis(isothiocyanato)lanthanoidates(M)] (M=La—Pr and Nd—Er) the central metal atom is in a cubic octa-coordination geometry.[3]

In this line of the study, the authors have tried to synthesize other types of thiocyanato complexes of lanthanoids, and have obtained the two series of the anionic complexes shown in the title. From now on, the former ten hexakis(isothiocyanato) complexes are called **A**-type complexes, while the latter three heptakis(isothiocyanato) complexes are called **B**-type.

In many cases a series of the isomorphous lanthanoid complexes were obtained only for a limited range of the members of the following series: for example, Sm—Yb for $[M(CH_3C_6H_4SO_3)_2(H_2O)_6](CH_3C_6H_4SO_3)\cdot 3H_2O$,[4] La—Gd for $[M\{(C_2H_5O)_2PS_2\}_2(C_6H_5CONH_2)_3][(C_2H_5O)_2PS_2]$,[5] La—Eu for $[\{M(ClCH_2CO_2)_3\}_3(H_2O)_5]$,[6] Gd—Yb for $[M_3(ClCH_2CO_2)_9(H_2O_4)]_n\cdot nH_2O$.[7] In a series of isomorphous lanthanoid complexes it was found that some structural detail changed, depending on the metal atomic number.[6,8,9] Since we had obtained ten members of isomorphous **A**-type complexes, we had planned to compare their detailed structures with each other. Moreover, by almost the same synthetic technique, the other type, **B**-type, complexes were obtained from the heavier lanthanoids. Therefore, a comparison of the **A**- and **B**-type complexes was also thought to be interesting.

Therefore, the authors investigated the crystal structures of the title two series of complexes by single-crystal X-ray diffraction.

Experimental

Synthesis of the A-Type Complexes: Tetramethylammonium [Aquamethanolhexakis(isothiocyanato)lanthanoidates(III)], $[(CH_3)_4N]_3[M(NCS)_6(CH_3OH)(H_2O)]$(M=La—Er). Lanthanoid(III) thiocyanates and tetramethylammonium thiocyanate were obtained by the metathetical reaction between lanthanoid(III) chlorides or tetramethylammonium chloride and potassium thiocyanate in methanolic medium, respectively (as reported previously), to obtain cadmium and other metal thiocyanates.[10,11] The obtained lanthanoid thiocyantes were stored as their methanolic solution (0.5 mol dm^{-3}) without drying.

To synthesize the lanthanum(III) complex, to the methanolic solution (7 cm^3) of lanthanum thiocyanate (1.0 mmol), tetramethylammonium thiocyanate (0.41 g, 3.1 mmol), and water (0.1 cm^3, 6 mmol) were added. The mixture was then warmed and stirred until complete dissolution occured. The solution was left standing for several days in a silica gel desiccator for drying to about 1 cm^3 at room temperature. A square plate form crystals were deposited. Yield: 0.55 g (0.72 mmol, 72 %).

Crystals were also obtained when the above-mentioned starting solution was left standing in chlorobenzene vapor. Yield, 0.25 g, 0.33 mmol, 33%, started from 1 mmol of the

metal salt.

The Ce through Dy complexes were obtained by the same technique in almost the same yield; even in the case of the Dy salt, only the **A**-type complex crystals were deposited, unless the starting solution was severely dried. (By the latter method, the **B**-type Dy complex was obtained.)

Both of the above-mentioned methods did not give the **A**-type erbium complex; only hexagonal thick plate crystals of the **B**-type complex were deposited within several days. The erbium complex was obtained by using a starting solution containing a little more water (0.5 cm^3 in place of 0.1 cm^3). The solvent was evaporated very slowly, over several months, at room temperature. Yield: 0.3 g (0.38 mmol, 38%) starting from 1.0 mmol of erbium thiocyanate.

All attempts to synthesize the **A**-type complex of ytterbium were unsuccessful. Even when more water was added to the starting solution, the **B**-type complex was always deposited.

Synthesis of the B-Type Complex: Tetramethylammonium Heptakis(thiocyanato)dysprosium(III), $[(CH_3)_4N]_4[M(SCN)_7]$ (M=Er, Yb). The dysprosium complex was synthesized as follows. To the methanol solution (10 cm^3) of dysprosium thiocyanate (2.0 mmol) and tetramethylammonium thiocyanate (1.06 g, 8.0 mmol), 10 cm^3 of ethanol and 10 cm^3 of benzene were added, and the mixture was evaporated to dryness by a vacuum rotary evaporator at about 80 °C. The same process was repeated three times so as to remove the water completely. The residue was dissolved into 10 cm^3 of methanol (GR grade reagent of Wako Pure Chemicals Industry Ltd.: it contains at most 0.3% of water). The solution was dried to 2 cm^3 by standing in a silica gel desiccator for several days: crystals were deposited. These were washed with a small portion of ethanol and dried in a silica gel desiccator. Yield: 1.21 g, 1.40 mmol 70%. By the same synthetic method **B**-type Er and Yb complexes were also obtained in almost the same yield.

B-type complexes of terbium and the lighter lanthanoids

were not obtained, even when a strictly dried starting solution was used.

The results of elemental analyses of the **A**- and **B**-type complexes are shown in Table 1.

X-Ray Structure Analysis. Crystallographic data and various experimental conditions for collecting intensity data are listed in Tables 2 and 3.

Reflections were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). In the case of the **A**-type complexes a ω-2θ scan technique was used, while for the **B**-type complexes a ω-scan was adopted. The intensities were corrected for the Lorentz and polarization factors, but not for absorption and extinction.

Structure Determination. The structure of the Nd complex in the **A**-type and that of the Yb complex in the **B**-type were solved by the heavy-atom method, respectively. The positions of the metal and some sulfur atoms were deduced from their three-dimensional Patterson maps; the other non-hydrogen atoms were located by successive Fourier syntheses. Their positional and thermal parameters were refined by a block-diagonal least-squares method. No hydrogen atoms were included in the structure factor calculations.

The structures of the other **A**-type complexes, Ce—Er complexes, were determined by starting from the final parameters of the neodymium complex. The structures of the **B**-type Dy and Er complexes were determined by starting from the final parameters of the ytterbium complex. In all cases, at the final cycle of the refinement the shifts of all the parameters were less than one third of the respective standard deviations.

Some thermal parameters of tetramethylammonium carbon atoms are relatively large in the **A**-type complexes, especially when the atomic number of the central lanthanoid atom is small. In the **B**-type complex the thermal parameters of some tetramethylammonium carbon atoms as well as the S(7) atom were large: the isotropic temperature factor was applied to the S(7) atom. Such large temperature factors of some atoms are also found in some other lanthanoid complexes, especially for their sulfur and carbon atoms, when they are loosely packed in the crystal.[12]

All calculations were carried out on a HITAC M-682H computer at the Computer Center of the University of Tokyo using a local version of the UNICS program.[13] The atomic scattering factors were taken from Ref. 14.

Infrared Absorption Spectrum Measurements. The infrared absorption spectra were obtained by means of a JASCO 202-A grating infrared spectrophotometer using paraffin oil and hexachloro-1,3-butadiene mull.

Results and Discussion

The final atomic positional and thermal parameters

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2)$. The B_{ij}'s are defined by: $T=\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}=2hkB_{12}+2hlB_{13}+2klB_{23})]$. b) The isotropic temperature factor was used for S(7) in the refinement. c) C (11—14; 21—24; 31—34, and 41—44) are the methyl carbon atoms bonded to the N(11, 21, 31, and 41) atoms, respectively.

(B_{eq}(Å)) of the **A**-type erbium(III) and of the **B**-type ytterbium(III) complexes are listed in Tables 4 and 5, and the selected bond lengths and bond angles of the **A**- and **B**-type complexes are given in Tables 6 and 7, respectively. Perspective drawings of the **A**-type Er complex as well as that of the **B**-type Yb complex are shown in Figs. 1 and 2, together with a numbering scheme of their atoms.

The crystal structures of the **A**-type Er and the **B**-type Yb complexes projected along the b-axis are shown in Figs. 3 and 4.[15]

The Structure of the A-Type Complexes. In the **A**-type erbium complex the central metal atom is octa-coordinated, in a square-antiprism geometry, to six nitrogen atoms of SCN ions, and two oxygen atoms of one water and one methanol molecules. The two ligated oxygen atoms take positions at the most approaching apexes of the respective bottom squares, obeying the empirical rule that the same kind of ligating atoms preferably take the neighboring posi-

tions.[17] A schematic presentation which shows the coordinating positions of the ligating atoms around the erbium atom is given in Fig. 5.

The complex, where an alcohol and a water molecules are coordinated to the same metal atom, had already been found in neodymium(III) 1-hydroxy-2-naphthoate;[16] however, it was readily decomposed in open air, missing the alcohol ligand. The crystal used for the intensity collection had to be sealed in a glass capillary. On the other hand, these **A**-type complexes are more stable in the open, and do not decompose in open air during the intensity collection process (about one week) without a cover.

Angle O(1)-Er-O(2) is 85.5°, and the Er-O(1) and Er-O(2) bonds are approximately directed to the next metal atoms in the a- and c-axis directions, respectively.

As shown in Table 6, the Er-O distance is 2.402 Å

(on the average), where Er-O(water) is 0.018 Å shorter than Er-O(methanol). Judging from these bond lengths, although methanol is coordinated to the metal atom more weakly than water, the diffence in the bond strengths does not seem to be great.

Although the Er complex is the last member of the **A**-type isomorphous complexes, the Er-N bond lengths are in the range 2.385(10)—2.419(10) Å (2.405 Å on the average): abnormally long bonds, which were found in some carboxylato complexes of lantha-

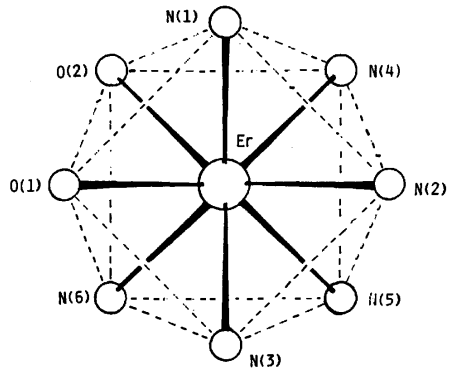

Fig. 5. Schematic presentation of the A-type erbium-(III) complex to show the coordination geometry around the metal atom.

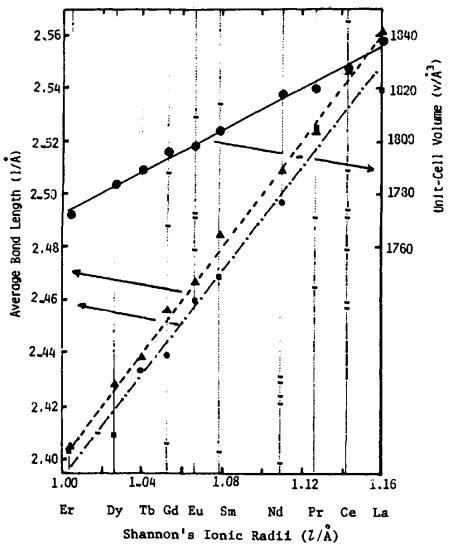

Fig. 6. The relation between the interatomic distances, M-N and M-O, as well as the unit cell volumes, and the Shannon's ionic radii of the central metal atom of the A-type complexes (unit cell volume (—●—); M-N bond length (---▲---); and average M-O bond length (-·-■-·-).

noids, do not exist.[6,18]

The sums of the Shannon's ionic radii are 2.35 and 2.46 Å for Er-O and Er-N (coordination number of Er is 8), respectively.[19] Therefore, the observed Er-O is longer and the observed Er-N, is shorter than the sums of the Shannon's ionic radii, respectively. In many carboxylato complexes of lanthanoids the M-O bond lengths are not much different from the sums of Shannon's ionic radii.[6,7,18] Therefore, in these complexes, the M-O bonds are a little weaker than those of the usual oxygen donor complexes. In the other aqua-isothiocyanato mixed complex, $K_4[M(SCN)_4(H_2O)_4](SCN)_3 \cdot nH_2O$ (M=Nd, Eu), the average Nd-O and Eu-O bonds are reported to be 2.60 and 2.51 Å, respectively, which are much longer than the sums of the Shannon's ionic radii, 2.46 and 2.42 Å.[2] The shortening of the Er-N bonds are also found in the

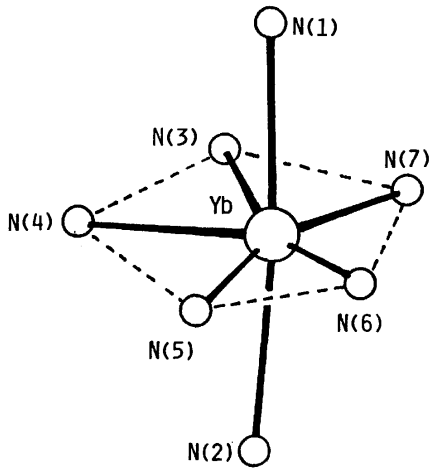

Fig. 7. Schematic presentation of the B-type ytterbium (III) complex to show the coordination geometry around the metal atom.

other isothiocyanato complexes. For example, the sums of the Shannon's ionic radii and the observed bond lengths of $[(C_2H_5)_4N]_4[Er(SCN)_7(H_2O)]$ are 2.46 and 2.36(3) Å, respectively.[3] However, in $[(C_4H_9)_4N]_3[Er(SCN)_6]$, these values are 2.35 and 2.34(2) Å, respectively, not much different from each other.[1]

The bond angles of Er-N-C and of N-C-S are 168.7° on the average (165.9(10)—172.8(10)°), and 177.3° on the average (175.8(11)—178.8(11)), respectively. They are not very far from 180°.

The relations between the Shannon's ionic radii of the central metal atom and the unit cell volume, as well as the average M-O and M-N bond lengths of the A-type complexes, are shown in Fig. 6. No irregular changes were found among the series of isomorphous complexes. However, the earlier members decomposed more easily than the later member ones when left standing in open air.

The Structure of the B-Type Coiplexes. In the B-type ytterbium complex, the central metal atom is hepta-coordinated in a deformed pentagonal-bipyramidal geometry to seven nitrogen atoms of SCN ions, as shown schematically in Fig. 7. The deviations of the atomic positions from the mean-square plane of the six atoms, five equatorially ligated SCN nitrogen atoms and the central metal atom, are 0.344 Å on the average (0.037—0.927 Å). The plane is approximately parallel to the ac-plane. The axis angle, N(1)-Yb-N(2), is 163.9(5)°, and the axis of the complex is directed approximately parallel to the b-axis.

The tetramethylammonium ions are approximately sandwitched between pentagon planes consisting of five equatorially coordinated SCN ions of the complexes, where the central nitrogen atoms of the cations are arranged on several layers parallel to the ac-plane and between the pentagon planes. Consequently, layers of the complexes and of the cations are piled up alternately in the b-axis direction.

The M-N bond lengths of the ytterbium complex are, as shown in Table 7, 2.331 Å on the average (2.302(12)—2.364(13) Å), which is much shorter than the sum of the Shannon's ionic radii, 2.39 Å,[19] as in the case of the **A**-type complexes.

The Yb-N-C and N-C-S bond angles are, on the average, 167.2 and 176.9°, respectively.

There are no systematic changes of the respective bond lengths and bond angles through the series of the **B**-type three complexes, except for the change of the M-N bond length due to a decrease in the metal ionic radii, depending on the metal atomic number. The three **B**-type complexes can be considered to have the same type structure. All members of the three **B**-type complexes are stable in open air for at least several weeks.

General Remark. Though the 6N-hexa-coordinated hexakis(thiocyanato) lanthanoidate(III) ion was found in its tetrabutylammonium salt,[1] deduced from the results of this and several related studies, the central metal atoms of thiocyanato complexs are not always in the hexa-coordination. Their coordination number can be seven or eight, depending on the kinds of counter cations, and of the included guest molecule, such as benzene, in the crystal,[20] or of the ligands other than the SCN ions of the complex.

Infrared Spectra. The general feature as well as the maximum wavenumbers of the infrared spectra of the **A**- and **B**-type complexes are not much different from each other, except for the strong ν(O-H) bands of the **A**-type complexes caused by including methanol and water, which appeared at about 3320—3350 cm^{-1}. The bands due to the N-bonded SCN ion appear almost in the same region as the other metal complexes:[21] ν(CN)(s), 2060 and 2100 cm^{-1} for the **A**-type, and 2060 and 2070 cm^{-1} for the **B**-type complexes; ν(CS), 730 cm^{-1}, and δ(SCN), 480 cm^{-1} for both type complexes. The bands due to the tetramethylammonium ion appear at 1488(s), 1433(m), 1163(m), 942(s), and 720(m) cm^{-1}. These bands are approximately the same as those found in the spectra of the other tetramethylammonium salts.

The authors wish to thank Shin-Etsu Chemical Ind. Co., Ltd., for presenting us the highly pure lanthanoid oxides.

Solvent Extraction of Indium with 3-Hydroxy-2-methyl-1-phenyl-4-pyridone

Hajime Ishii,* Shinji Numao,† and Tsugikatsu Odashima
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai, Miyagi 980
(Received September 17, 1988)

Extraction behavior of indium has been investigated with 3-hydroxy-2-methyl-1-phenyl-4-pyridone (HMPP) at 25 ± 0.1 °C and an ionic strength of 0.2. The values of the proton-dissociation constants, pK_{a1} and pK_{a2}, of HMPP were determined spectrophotometrically to be 3.02 and 9.56. The value of the partition coefficient, $\log K_D$, of HMPP between 1,2-dichloroethane and water was determined to be 1.35. Indium(III) was extracted into 1,2-dichloroethane by forming a 1 : 3 (metal : ligand) complex with HMPP. The extraction constant, K_{ex}, the overall formation constant, β_3, and the distribution constant, K_{DC}, of the indium(III)-HMPP complex were determined, their values being as follows: $\log K_{ex}=2.16$, $\log \beta_3=32.63$, and $\log K_{DC}=2.26$.

Since Herak and his co-workers[1] used 2-ethoxycarbonyl-5-hydroxyl-1-phenyl-4-pyridone and its analogues to the extraction and separation of tantalum(V) and niobium(V), 4-pyridones including 1-aryl-2-ethoxycarbonyl-5-hydroxy-4-pyridones and 1-aryl-3-hydroxy-2-methyl-4-pyridones[2,3] were synthesized and proposed as chelating and extracting reagents for various metal ions. As is apparent from their structures, these pyridones are *O,O*-donating chelating reagents, so they seem to be promising chelating and/or extracting reagents for metal ions classified into the hard acids including indium(III), gallium(III), and aluminium(III), investigations on the extraction of gallium(III) with some of these pyridones having already been done.[4,5]

On the other hand, indium is an element widely dispersed in nature, about 0.1 ppm of indium being contained in the earth's crust. Minerals containing indium as a major constituent are not known. Indium is usually recovered as a by-product in the zinc industry. Taking into consideration that indium is used not only as a constituent of corrosion-resisting alloys for bearings and a semi-conductor but also in many fields such as non-ferrous metallurgy, electric contacts and reflectors and so on, the separation and/or concentration of indium by solvent extraction with the above 4-pyridones are much attractive as well as of practical and theoretical importance.

Thus to start with, we investigated the extraction of indium(III) with 3-hydroxy-2-methyl-1-phenyl-4-pyridone (HMPP), the results of which are described in this paper.

Experimental

Reagents. All reagents used were of analytical-reagent grade unless stated otherwise. All aqueous solutions were prepared with distilled, deionized water.

HMPP solutions. Prepared by dissolving HMPP in 1,2-dichloroethane or 1,4-dioxane. The HMPP was synthesized by heating a mixture of 3-hydroxy-2-methyl-4-pyrone, aniline and water in a sealed, thick-walled glass tube for 46 h at 150 °C.[3]

Standard indium(III) solution, 5.0×10^{-2} M (1M=1 mol dm^{-3}). Prepared by dissolving the required mass of metallic indium (99.99 % pure), with heating, in a sufficient volume of nitric acid (1+1) to give an acidity of 0.1 M in the final solution. Working solutions were prepared by diluting this solution with water.

Buffer solutions. Buffers consisting of 1 M chloroacetic acid-1 M sodium chloroacetate, 1 M acetic acid-1 M sodium acetate, (0.2 M boric acid+0.05 M sodium chloride)-0.05 M sodium borate, 0.2 M tris(hydroxymethyl)aminomethane-0.2 M hydrochloric acid or 0.2 M sodium hydrogencarbonate-0.2 M sodium carbonate system was used according to the pH values required.

Apparatus. The following instruments were used: a Hitachi 139 spectrophotometer and a Hitachi 340 automatic recording spectrophotometer with 10-mm quartz cells, a Toa HM-5B pH meter, an Iwaki KM shaker and a Haake FK-2 thermoelectric circulating bath. All extractions were performed by shaking samples in 50-cm^3 separating funnels jacketed so that the system could be kept at a constant temperature (25±0.1 °C) by means of water circulated from the thermostatic bath.

Procedures. Proton Dissociation Constants: The proton dissociation constants of HMPP were determined spectrophotometrically[6] in aqueous dioxane of various concentrations (8—32% v/v) at 25±0.1 °C and at an ionic strength of 0.2. The ionic strength was adjusted with sodium chloride. Values of pH measured in aqueous dioxane solutions were not corrected because logarithmic values of U_H were very small (−0.03 at a dioxane concentration of 32% v/v), where U_H is a conversion factor in the equation proposed by Uitert et al.[7]

Partition of HMPP: A 10-cm^3 aliquot of an aqueous solution containing 2.7—5.3 cm^3 of 0.1 M sodium hydroxide solution and sodium nitrate to maintain the ionic strength to 0.2 was placed in a 50-cm^3 separating funnel along with 10 cm^3 of a 1.1×10^{-4} M HMPP solution in 1,2-dichloroethane. The funnnel was shaken for 30 min and allowed to stand for 15 min for the phase separation. The organic phase was transferred into a flask containing about 1 g of anhydrous sodium sulfate in order to dehydrate it. The absorbance of the organic phase was measured at 292 nm against 1,2-dichloroethane, the concentration of HMPP being calculated by using the molar absorptivity of HMPP in 1,2-dichloroethane, obtained beforehand. The equilibrium concentration of HMPP in the aqueous phase was calculated by subtracting the organic equilibrium concen-

† Present address: Research and Development Department, Showa Aluminum Corp., 6-224, Kaisan-cho, Sakai-shi, Osaka 590.

tration from the initial concentration.

Distribution of Indium: The distribution of indium between 1,2-dichloroethane and aqueous phases was determined as a function of the hydrogen ion concentration.

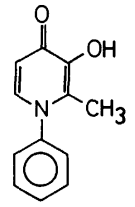
A 10-cm^3 aliquot of an aqueous solution containing 14.9 μg of indium (III), dilute perchloric acid to adjust the pH to the required value and potassium nitrate to maintain the ionic strength to 0.2 was placed in a 50-cm^3 separating funnel along with 10 cm^3 of 4.1×10^{-4} M HMPP solution in 1,2-dichloroethane. The funnel was shaken for 30 min and then allowed to stand for 15 min for the phase separation. The equilibrium concentration of indium in the organic phase was determined by measuring the absorbance of the extract at 319 nm against a reagent blank prepared under the identical conditions. The equilibrium concentration of indium in the aqueous phase was calculated by subtracting the organic equilibrium concentration from the initial concentration.

Formation Constant: To an aliquot containing 1.50 mg of indium(III) in a 25-cm^3 calibrated flask were added 10 cm^3 of a dilute nitric acid solution of 2.5×10^{-4} M HMPP, dilute perchloric acid to adjust the pH to the required value and sodium chloride to maintain the ionic strength to 0.2. Then the solution was diluted to the mark with water. After allowing to stand for 30 min at 25±0.1 °C, the absorbance of the solution was measured at 315 nm against water as a reference.

Results and Discussion

Proton Dissociation Constants, Species Distribution Diagram and Absorption Spectra of HMPP. HMPP is insoluble in water and practically insoluble in nonpolar organic solvents such as benzene and hexane, but very soluble in ethanol, dioxane, chloroform and 1,2-dichloroethane. It is also soluble in weakly acidic and alkaline solutions, but it decomposes in solutions of pH below 1 and above 12.5.

As is evident from the structure of HMPP shown in **I**, at least 3 species, H_2L^+, HL, and L^-, are involved in



(I)

its acid-base equilibria, the probable equilibria being as follows:

$$H_2L^+ \overset{K_{a1}}{\rightleftharpoons} HL \overset{K_{a2}}{\rightleftharpoons} L^- \qquad (1)$$

where L denotes the undissociable part of HMPP and, K_{a1} and K_{a2} are the proton dissociation constants. The value of K_{a2} is already determined by Herak et al.,[7] but that of K_{a1} is not determined yet. So both proton dissociation constants were determined by extrapolating the linear plot of apparent pK_a values obtained by the procedure stated already versus dioxane concentrations (8—32% v/v) to the intercept. The result was shown in Fig. 1. Values of apparent pK_{a1} decrease, whereas those of apparent pK_{a2} increase, with increasing the dioxane concentration. The values of pK_{a1} and pK_{a2} thus obtained were 3.02 and

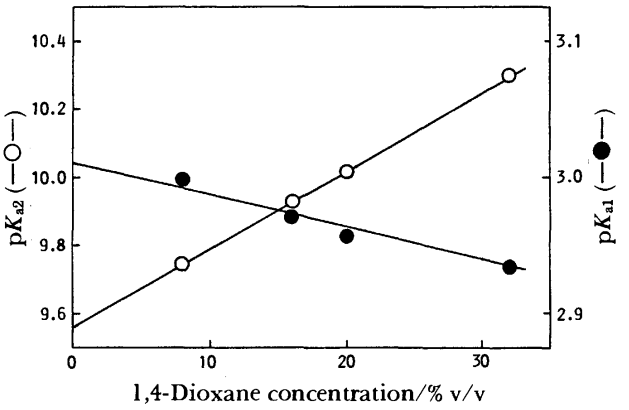


Fig. 1. Plots of pK_a values vs. 1,4-dioxane concentration.

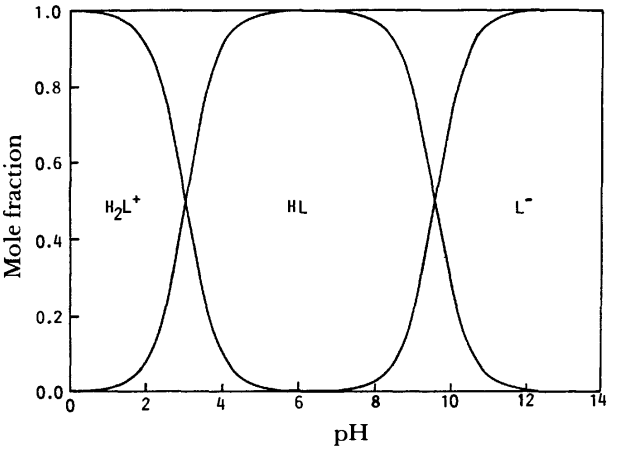

Fig. 2. Species distribution diagram.

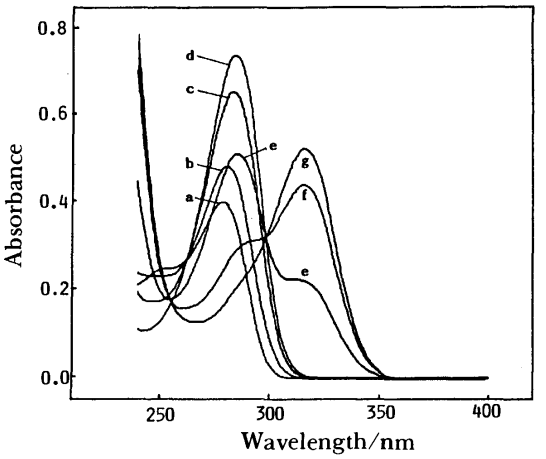

Fig. 3. Absorption spectra of HMPP in 8% v/v 1,4-dioxane. HMPP, 4.1×10^{-5} M; reference, 8% v/v 1,4-dioxane; pH—a, 1.1; b, 2.7; c, 3.7; d, 6.0; e, 9.6; f, 10.5; g, 12.0.

9.56, respectively. The latter value is near to the pK_{a2} value (9.88) reported by Herak et al.[8] K_{a1} and K_{a2} are considered to correspond to the deprotonations of the protonated pyridone-nitrogen and the hydroxyl group, respectively.

Figure 2 shows the species distribution diagram of HMPP prepared on the basis of the above results.

Figure 3 indicates absorption spectra of HMPP in 8% v/v dioxane solutions of various pHs. Spectra a, d, and g correspond to species of H_2L^+, HL, and L^-, respectively. The absorption maximum, λ_{max}, and the molar absorptivity, ε, of each species and the isosbestic points are summarized in Table 1.

Partition Coefficient of HMPP. The distribution ratio, D_L, of HMPP between an aqueous and a 1,2-dichloroethane phase can be expressed as Eq. 2 and is rewritten as Eq. 3 by using the proton dissociation constants and the partition coefficient K_D:

$$D_L = \frac{[HL]_{org}}{[H_2L^+]+[HL]+[L^-]} \quad (2)$$

$$D_L = \frac{K_D}{\frac{[H^+]}{K_{a1}} + 1 + \frac{K_{a2}}{[H^+]}} \quad (3)$$

where the subscript org denotes the concentration in the organic phase. When $[H^+] \ll K_{a1}, K_{a2}$, Eq. 3 can be approximated by Eq. 4 and rewritten as Eq. 5

$$D_L = \frac{K_D}{K_{a2}}[H^+] \quad (4)$$

$$\log D_L = \log K_D + pK_{a2} - pH \quad (5)$$

Equation 5 implies that the plot of $\log D_L$ against the pH gives a straight line with a slope of -1, the value of K_D being calculated from the intercept of this line. Such a relation was experimentally obtained as shown in Fig. 4, from which the value of 1.35 was obtained as $\log K_D$. This value is close to that (1.69) obtained in the chloroform-water system.[8]

Table 1. Spectral Characteristics of HMPP in 8% v/v 1,4-Dioxane

	H_2L^+	HL	L^-
Absorption maximum/nm	279	285	316
Molar absorptivity/M^{-1} cm^{-1}	9900	18000	13000
Isosbestic point/nm	264	256, 299	

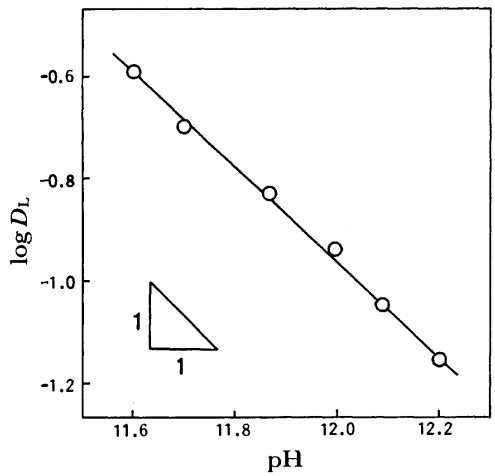

Fig. 4. Plot of $\log D_L$ vs. pH for the partition of HMPP between 1,2-dichloroethane and water at an ionic strength of 0.2 and at 25±0.1 °C. HMPP, 1.1×10^{-4} M; $V_{aq}/V_{org}=1$ ($V_{org}=10$ cm^3); shaking time, 30 min.

Absorption Spectra. Absorption spectra of HMPP and its indium(III) complex extracted into 1,2-dichloroethane are shown in Fig. 5 along with those of aluminium(III) and gallium(III) complexes measured for comparison. The absorption maxima of indium(III), gallium(III), and aluminium(III) complexes lie at nearly the same wavelengths, i.e., 319, 319, and 318 nm, respectively. The absorption maxima and the shape of the spectra did not vary in the pH range 2—12 and the molar ratio range of metal to ligand of 1:10—10:1, which suggests that only one species of each complex is extracted.

Shaking Time and Stability of the Extract. In general, as the shaking time needed to attain the extraction equilibrium increases with decreasing the pH, the influence of the shaking time on the extraction of the indium(III)-HMPP complex was examined at indium(III) and HMPP concentration of 1.3×10^{-5} and 4.1×10^{-4} M, respectively, and at pHs 2.7

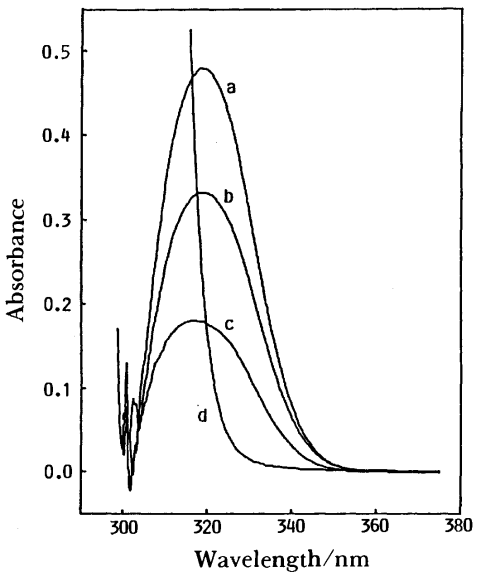

Fig. 5. Absorption spectra of HMPP and its metal complexes in 1,2-dichloroethane. HMPP, 4.1×10^{-4} M; In(III), 1.3×10^{-5} M; Ga(III), 1.1×10^{-5} M; Al(III), 9.9×10^{-6} M; a, In(III) complex; b, Ga(III) complex; c, Al(III) complex; d, HMPP alone (Reagent blank); reference—a,b,c, reagent blank; d, 1,2-dichloroethane.

and 1.9, by varying the shaking time from 15 to 60 min. The results revealed that shaking for 15 min is sufficient at either pH. The complex, once extracted, was very stable, the absorbance of the extract remaining unchanged for more than 2 h.

Influence of pH on Extraction. The degree of extraction of indium(III) with HMPP dissolved in 1,2-dichloroethane, as à function of the pH, is shown in Fig. 6 together with results on the extraction of gallium(III) and aluminium(III) carried out for comparison. Indium(III), gallium(III), and aluminium(III) were quantitatively extracted at pH above 2.6, 2.8, and 4.3, respectively, within 30 min, except for the extraction of indium(III) in the pH range 5—7 and that of gallium(III) in the pH range 4—6, where more than 14 hour's shaking was needed to attain equilibrium presumably because of hydrolysis of these ions. Values of half-extraction pHs, $pH_{1/2}$, for indium(III) and aluminium(III) were 2.16 and 3.15, respectively, but that for gallium(III) could not be obtained because no reliable extraction curve for gallium(III) was obtained below pH 1.7.

Extraction Constant of Indium. The overall reaction in the extraction of indium(III) with HMPP may be expressed as

$$In^{3+} + n\,HL_{org} \rightleftarrows InL_{n,org} + n\,H^+ \quad (6)$$

The extraction constant, K_{ex}, is defined as Eq. 7 and is rewritten as Eq. 8 by using the distribution ratio of indium, D_{In}, if it is assumed that (a) indium(III) forms no appreciable amounts of hydrolysis or anion coordination complexes, (b) the complex concentration in the aqueous phase is negligible, (c) the concentrations of intermediate complex species are negligible and (d) the volume of the organic phase is equal to that of the aqueous phase.

$$K_{ex} = \frac{[InL_n]_{org}[H^+]^n}{[In^{3+}][HL]^n_{org}} \quad (7)$$

$$\log D_{In} = \log K_{ex} + n \log [HL]_{org} + n\,pH \quad (8)$$

Equation 8 implies that the plot of $\log D_{In}$ against the pH at a constant HMPP concentration gives a straight line with a slope of n for indium(III), the value of K_{ex} being calculated from the intercept of this line. In fact, a linear relationship with a slope of about 3 was obtained experimentally as shown in Fig. 7, from which it can be concluded that only a 1:3 complex, InL_3, is extracted into 1,2-dichloroethane in this extraction system. The logarithmic value of K_{ex} was calculated to be 2.16 from the intercept of the line in Fig. 7.

Formation Constant of the Complex. Since HMPP and its indium(III) complex have enough solubilities in slightly and/or weakly acidic solution to investigate the complexation reaction in aqueous solution and in addition, the formation constant of the complex was expected to be large, the formation constant was determined in aqueous solution according to the same method as was used by Musha et al.[9]

On the basis of the results stated above, the overall complexation reaction may be written as

$$In^{3+} + 3\,HL \rightleftarrows InL_3 + 3\,H^+ \quad (9)$$

The equiliblium constant, K_{eq}, is defined as Eq. 10

$$K_{eq} = \frac{[InL_3][H^+]^3}{[In^{3+}][HL]^3} \quad (10)$$

In the pH region 2.5—3.5, where the experiment was carried out, HMPP exists as species of HL and

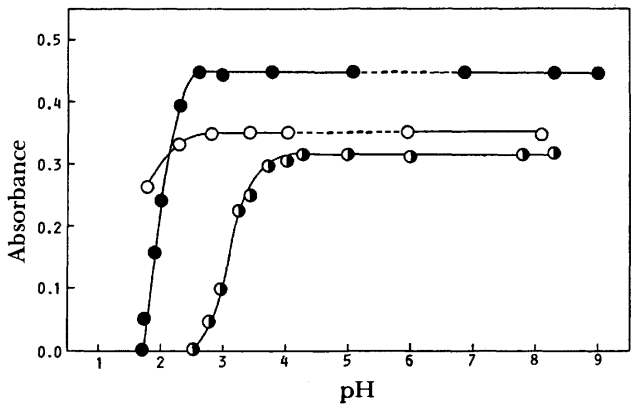

Fig. 6. Extraction curves for In(III)-, Ga(III)-, and Al(III)-HMPP complexes. HMPP, 4.1×10^{-4} M; $V_{aq}/V_{org}=1$ ($V_{org}=10$ cm^3); shaking time, 30 min; reference, reagent blank.

	Concentration/M	Wavelength/nm
—●— In(III)	1.3×10^{-5}	319
—○— Ga(III)	1.1×10^{-5}	319
—◑— Al(III)	9.9×10^{-6}	318

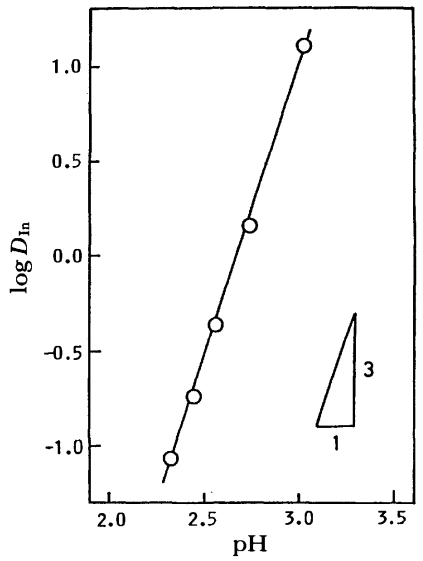

Fig. 7. Plot of $\log D_{In}$ vs. pH for the extraction of indium(III) with HMPP into 1,2-dichloroethane at an ionic strength of 0.2 and at 25±0.1 °C. In(III), 1.3×10^{-5} M; HMPP, 4.1×10^{-4} M; shaking time, 30 min; $V_{aq}/V_{org}=1$ ($V_{org}=10$ cm^3).

H_2L^+. So if the initial concentration of indium(III), C_{In}, is much higher than that of HMPP, C_{HL}, Eq. 10 can be expressed as

$$K_{eq}=x[H^+]^3\left(1+\frac{[H^+]}{K_{a1}}\right)^3/C_{In}(C_{HL}-3x)^3 \qquad (11)$$

where x is the equilibrium concentration of the complex formed. At a specified wavelength where the ligand, HMPP, shows no absorption, Eqs. 12 and 13 exist.

$$A=\varepsilon x \qquad (12)$$

$$A_\infty=\frac{1}{3}\varepsilon C_{HL} \qquad (13)$$

where ε is the molar absorptivity of the complex, A is the absorbance at a given pH of the solution containing indium(III) and HMPP and A_∞ is the limiting absorbance when all of the HMPP is complexed quantitatively with indium(III) at a higher pH. From Eqs. 11, 12, and 13, Eq. 14 can finally be obtained:

$$\log\frac{A}{27(A_\infty-A)^3}=\log C_{In}-2\log\varepsilon-pK_{eq}+3\log\frac{K_{a1}}{[H^+]^2+K_{a1}[H^+]} \qquad (14)$$

Equation 14 implies that at a constant value of C_{In} a plot of $\log A/27(A_\infty-A)^3$ vs. $\log K_{a1}/\{[H^+]^2+K_{a1}[H^+]\}$ should yield a straight line with a slope of 3. Such a relation was experimentally obtained as shown in Fig. 8. The pK_{eq} value was evaluated to be -3.95 by entering the value of $\log K_{a1}/\{[H^+]^2+K_{a1}[H^+]\}$ obtained when $\log A/27(A_\infty-A)^3$ is equal to zero in Eq. 14.

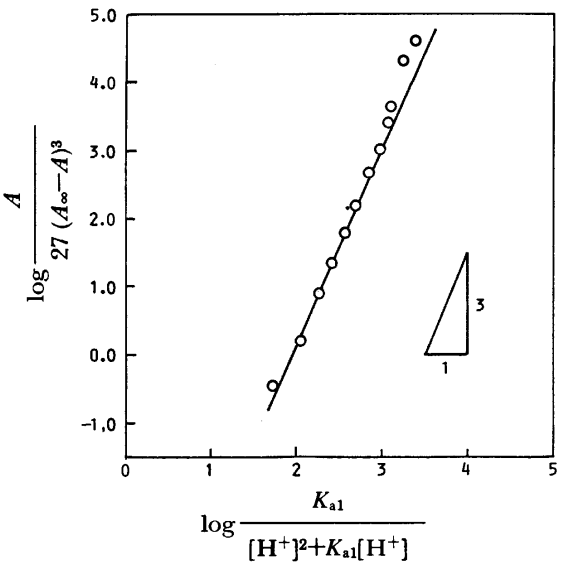

Fig. 8. Plot of $\log A/27(A_\infty-A)^3$ vs. $\log k_{a1}/\{[H^+]^2+K_{a1}[H^+]\}$ for the determination of the equilibrium constant, K_{eq}, at an ionic strength of 0.2 and 25±0.1 °C. In(III), 5.2×10^{-4} M; HMPP, 1.0×10^{-4} M; wavelength, 315 nm.

The overall formation constant, β_3, of this complex defined by

$$In^{3+}+3L^-\rightleftarrows InL_3$$
$$\beta_3=[InL_3]/[In^{3+}][L^-]^3 \qquad (15)$$

can be calculated from the values of K_{eq} and K_{a2} as follows:

$$\log\beta_3=3\,pK_{a2}-pK_{eq}=3\times9.56-(-3.95)=32.63 \qquad (16)$$

Distribution Constant of the Complex. The distribution constant of the indium(III) complex, K_{DC}, is defined by

$$InL_3\rightleftarrows InL_{3,org}$$
$$K_{DC}=[InL_3]_{org}/[InL_3] \qquad (17)$$

and K_{ex} is finally represented by

$$K_{ex}=K_{DC}K_{a2}^3\beta_3/K_D^3 \qquad (18)$$

From Eq. 18 the value of K_{DC} is calculated as follows:

$$\log K_{DC}=\log K_{ex}+3\log K_D-3\log K_{a2}-\log\beta_3=2.16+3(1.35)-3(-9.56)-32.63=2.26$$

Conclusion

From the results described above, it is concluded that the value of the overall formation constant of the indium(III)-HMPP complex is very large, but those of the partition coefficient of HMPP and the distribution constant of the complex are not so large as expected. So it is desirable to increase these two values, for example, by introducing a hydrophobic group into the HMPP molecule and enhance the practical usefulness of HMPP as an extractant, which is now in progress.

Single Crystal X-Ray and Optical Studies on Bis(1,5-diazacyclooctane)-copper(II) Nitrate, a Thermochromic Copper(II) Complex Involving Hydrogen Bonds between the Ligand and the Counter Ion

Naomi HOSHINO,† Yutaka FUKUDA,* Kozo SONE, Kiyoaki TANAKA,†† and Fumiyuki MARUMO††
Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
†† Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received September 27, 1988)

A thermochromic copper(II) complex of 1,5-diazacyclooctane (daco), $[Cu(daco)_2](NO_3)_2$, has been subjected to single-crystal X-ray and optical studies. This complex is orange as isolated, but it turns violet discontinuously when heated above 90 °C and returns to orange on cooling. Crystal structure of the low-temperature form has been determined at room temperature; the complex crystallizes in the monoclinic space group $P2_1/n$ with a=7.9040(7), b=15.694(1), c=7.0886(7) Å, β=95.36(1)°; V=875.5(1) Å^3, and Z=2. The CuN_4 chelate plane is planar and Cu-N coordination bonds are rather short. The structure has revealed the presence of weak hydrogen bonds bridging imino groups of the ligands with the nitrate ions and forming a macrocycle-like ring system, which results in enhancement of the ligand field strength. Single-crystal visible and infrared spectra for both low- and high-temperature forms have heen obtained and compared. A high-energy d-d transition band(s) causing the orange color at room temperature is in contrast to an extremely flattened broad band(s) for the violet form. The IR spectra of the two forms clearly differ in the intensity of ν_{NH} stretching peak, implying that the thermochromic phase transition involves a change in the nature of the hydrogen bonds of the imine ligands. On the basis of these observations and comparison to reported studies on a similarly thermochromic copper(II) complex, a mechanism is suggested involving dynamic fluctuation of the ligand field and geometry due to thermal motion of the anion/ligand hydrogen bond system.

Thermochromism and related chromotropic behaviors of inorganic compounds have been recently reviewed.[1] There exist a number of examples of thermochromic metal complexes and origins of the color changes are quite diverse. A certain class of materials show gradual color change over a wide temperature range, which is called continuous thermochromism.[2] Discontinuous thermochromism,[2] on the other hand, is a more abrupt or clearly visible color change over a small temperature range and manifests the onset of a first- or second-order phase transition. This latter phenomenon is not only interesting in its own right but also provides information on various factors determining coordination geometries and crystal structures of transition metal complexes.

We have previously reported that a copper(II) complex of 1,5-diazacyclooctane (daco), $[Cu(daco)_2](NO_3)_2$, shows reversible thermochromism between orange (at room temperature) and violet (above 90 °C) in solid state.[3] It was suggested at the moment that coordination of the nitrate ions to the copper center at elevated temperatures is responsible for the color change. On the other hand, Musker and Hussain have previously studied on bis(daco) complexes of copper(II) and nickel(II) and stated that the boat-chair conformation of the mesocyclic chelate ring would more or less shield the axial site of the central metal atom.[4,5] It was revealed later [6] that the nitrate ion in $[Cu(daco)_2](NO_3)_2$ is indeed far from accessible to the copper atom in the axial direction, and is rather interacting laterally with the daco ligands via a pair of hydrogen bonds. Thus the thermochromic mechanism appears to involve such ligand-anion interaction rather than the metal-anion bonding.

The purpose of this paper is to shed new light on the role of ligand-anion hydrogen bonding interaction in determining the structure, the ligand field strength, and the resulting physical properties of transition metal chelates. The crystal structure and optical spectra of $[Cu(daco)_2](NO_3)_2$, obtained for single crystals, are reported herein to show that the daco-nitrate interaction is really a key factor in the thermochromic phase transition of this complex.

Experimental

Materials. Synthesis of daco and $[Cu(daco)_2](NO_3)_2$ has been reported elsewhere.[3,7] Single crystals of the latter were grown by slow evaporation from an ethanol solution.

Physical Measurements. Single-crystal infrared absorption spectra were measured using an optical system consisting of a JASCO infrared radiation source, a JASCO CT-25C monochromator, an SBRC HgCdTe detector, and a PAR Model 124A lock-in amplifier. Visible absorption spectra were obtained with a similar system comprising a halogen-gas-filled tungsten incandescent lamp, an ISA Jobin Yvon Type HR1000 monochromator, and a Hamamatsu R376 photomultiplier. Polarized spectra were not obtained since the crystal faces were ill-defined.

The thermochromic transition temperature and enthalpy were determined using a Rigaku Thermoflex differential scanning calorimeter at a heating rate of 5 K min^{-1}.

X-Ray Analysis. An orange crystal was shaped into a sphere with a diameter of 0.22 mm on a wet filter paper under a microscope. Weissenberg photographs were taken with Cu$K\alpha$ radiation (λ=1.54184 Å) and the crystal was found to be monoclinic and has the space group $P2_1/n$.

† Present address: Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060.

Diffraction data were collected on a Philips automated four-circle diffractometer PW1100 having a maximum 2θ value of 90° with graphite monochromated Mo $K\alpha$ radiation (λ= 0.71073 Å). Cell constants (Table 1) were obtained from least-squares refinement, on the basis of setting angles of 67 reflections in the range $52° < 2\theta < 74°$, where separation of the $K\alpha$ doublet was clear and only the Mo $K\alpha_1$ reflections were used. A total of 3963 independent reflections were collected, and 2948 reflections (h=−13 to 13, k=0 to 29, and l=0 to 18) met the condition $I > 3\sigma(I)$ to be used for subsequent analysis. Three standard reflections (hkl=400, 080, and 004) were measured every 50 reflections and no significant variation was detected. Each reflection was measured up to 8 times until the total peak count exceeded 40000. Lorentz-polarization correction and absorption correction (factors ranging between 1.245 and 1.250) were applied to the data.

The structure was solved by the direct method with MULTAN78,[8] which yielded positions of all the nonhydrogen atoms. The structure was refined by the full-matrix least-squares method with the program LINKT80,[9] which minimizes the function $\sum(|F_o|-|F_c|)^2$; unit weight was assigned to each reflection. Hydrogen atoms were located on difference Fourier maps and their positions were refined with isotropic temperature factors, while anisotropic temperature factors were refined for nonhydrogen atoms. Anisotropic Type I extinction parameters were also refined.[10] The final values for R and R_w were 0.0311 and 0.0315, respectively. The maximum shift in the final cycle of the least-squares refinement was 0.15 for the isotropic temperature factor of H(12). The final difference Fourier map was featureless. Atomic scattering factors and dispersion terms were taken from the literature.[11] Tables of temperature factors and structure factors are deposited as Document No.8878 at the Office of the Editor of Bull. Chem Soc. Jpn.

Table 1. Crystallographic Data for $[Cu(daco)_2](NO_3)_2$

Results and Discussion

Crystal Structure of $[Cu(daco)_2](NO_3)_2$ at Room Temperature. This is the first example of bis(daco) complex of copper(II) for which the crystal structure has been solved. Figure 1 shows the structure, determined at room temperature, together with the numbering scheme. A stereoview showing crystal packing is given in Fig. 2. Table 2 lists atomic positional parameters, and selected interatomic distances and bond lengths and angles are summarized in Table 3.

The structure is centrosymmetric with the center of symmetry on the site of Cu and the CuN_4 chelate plane is planar. But it is not precisely square since two Cu-N coordination bonds of a daco ligand differ in length significantly (1.997(1) Å for Cu-N(1) and 2.034(1) Å for Cu-N(2)). These bond lengths, particularly of the former, are rather short for a Cu(II)-N(secondary amine) bond.[12] These facts agree with an enhanced ligand field strength suggested by the orange color which is rarely encountered among copper(II) com-

a) Hydrogen atoms H(3) through H(14) are numbered in the order of attached carbon atoms C(1) through C(6).

plexes. An important feature to note is that each $[Cu(daco)_2]^{2+}$ unit carries two NO_3^- ions which are hydrogen bonded to the amino nitrogens. These hydrogen bonds form a macrocycle-like ring system including a pair of N(1)-H(1)-[O(3)′-N(3)′-O(2)′]-H(2)″-N(2)″ bridges (dotted lines in Fig. 1). But these bonds are relatively weak; the interatomic distances 2.912(2) Å (N(1)···O(3)′) and 3.093(2) Å (N(2)″···O(2)′) are both in the range of weak hydrogen bond distances.[13] The positions of the hydrogen atoms which have been determined clearly demonstrate that these hydrogen bonds are not equivalent; the plane of NO_3^- is tilted by 68.2° relative to the CuN_4 chelate plane within which the O(3)′ atom and both of the hydrogen atoms H(1) and H(2)″ reside (Fig. 1, right), and so the N(1)-H(1)-O(3)′ hydrogen bond is rather straight (161(2)°) while the N(2)″-H(2)″-O(2)′ bond is bent (136(2)°). As a consequence of this unsymmetrical interaction of the anion to the ligand, not only the symmetry of the NO_3^- ion deviates from D_{3h} but also the two coordination bond lengths are significantly different as mentioned above; more linear and shorter hydrogen bond N(1)-H(1)-0(3)′ makes the related coordination bond Cu-N(1) shorter than the other.

Although the axial nitrate ions in Fig. 2 appear to have a close contact to the metal centers to form one-dimensional arrays of the chelate cations, such axial coordination does not exist, since even the shortest axial distance is 4.338(2) Å for Cu···O(2). This situation is well illustrated in the side view of the complex shown on the right in Fig. 1. The axial coordination appears to be precluded by chair and boat conformations of the chelate rings involving C(1)-C(2)-C(3) and C(4)-C(5)-C(6), respectively.

It is interesting to compare the structure with those of analogous species. Boeyens and Fox determined the structure of $[Ni(daco)_2](B(C_6H_5)_4)_2 \cdot 2DMSO$ and stated that the two solvent molecules, located aside the chelate plane, are interacting with the diamine nitrogen atoms through hydrogen bonding.[14] In addition, redetermination of the crystal structure of $[Ni(daco)_2](ClO_4)_2 \cdot 2H_2O$ by Boeyens et al. revealed that the water molecules also act as bridges between neighboring chelate cations through a set of O-H-N hydrogen bonds.[15] Thus the hydrogen bonding in crystals of daco complexes seems to be not uncom-

mon; as will be discussed below, we believe that the subtleness of this interaction is closely related to the thermochromic phase transition in the case of $[Cu(daco)_2](NO_3)_2$.

It would be desirable to have crystal structure of the high temperature form as well, but it has not been possible to date due to crystal disintegration on prolonged heating.

Optical and EPR Spectral Changes Associated with Thermochromism of $[Cu(daco)_2](NO_3)_2$. The reversible thermochromism of $[Cu(daco)_2](NO_3)_2$ can be visually observed as a distinct color change of a powdered

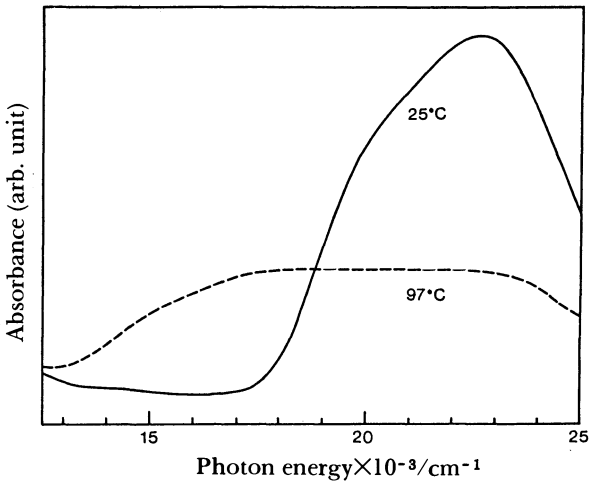

Fig. 3. Single-crystal visible spectral change associated with thermochromism of $[Cu(daco)_2](NO_3)_2$.

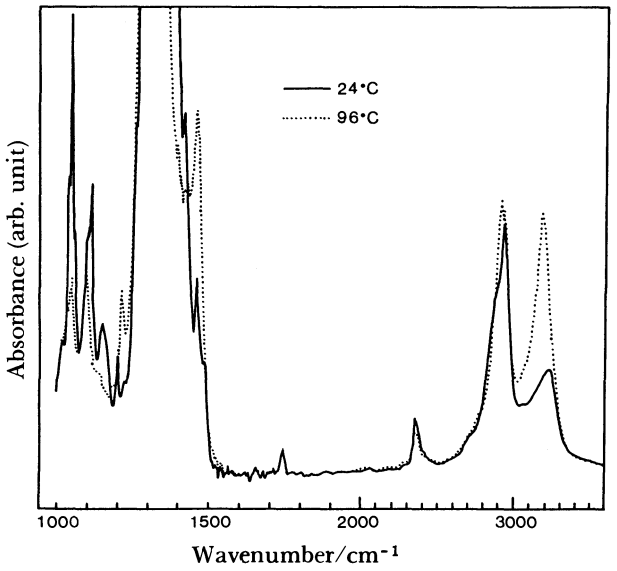

Fig. 4. Single-crystal infrared spectral change upon thermochromic transition of $[Cu(daco)_2](NO_3)_2$.

sample between orange and violet, as mentioned above. Powder reflectance spectral changes corresponding to this behavior were previously reported.[3] Single crystals have been used in this work in order to obtain absorption data which can be directly compared with each other. The results are shown in Figs. 3 and 4 for visible and infrared regions, respectively.

The visible absorption spectrum of $[Cu(daco)_2](NO_3)_2$ recorded at 25 °C exhibits a broad hand which peaks at 22.7×10^3 cm^{-1} and shows a shoulder at 20.0×10^3 cm^{-1}. As the crystal is heated with the peak intensity monitored, this band slightly diminishes at first and then suddenly drops to about one third of the original intensity at around 90 °C. The spectrum recorded at 97 °C indicates also that the absorption band is now widely spread (Fig. 3).

Royer et al. have investigated single-crystal polar-
