(Received April 20, 1988)

The spin-lattice relaxation times, T_1, of $H_2{}^{17}O$ have been measured for aqueous solutions of several pentoses, hexoses, di-, and trisaccharides as a function of the concentration at 25 °C. The coordination numbers, n_h, and the rotational correlation times, τ_c^h, of water molecules around the sugars were estimated and compared with that of pure water, τ_c°. The value of $\tau_c^h/\tau_c^\circ=4.10$ for glucose is largest, while that of $\tau_c^h/\tau_c^\circ=2.82$ for ribose is the smallest, among these sugars. The value of n_h ($\tau_c^h/\tau_c^\circ-1$) was defined as the dynamic hydration number. The dynamic hydration numbers showed a good correlation with the mean number of the equatorial OH groups and the limiting diffusion coefficients.

Several attempts have been made to elucidate the relation between the hydration and the conformation of carbohydrates in aqueous solutions,[1] since Kabayama and Patterson[2] proposed a model that the conformation of β-D-glucose well matches the tridymite structure in water. Special attention has been paid to the fact that the sugar hydration is affected by the mean value of the number of equatorial OH groups, $n(e\text{-OH})$, existing in the various conformers of sugar ususally found in solutions.[3,4]

Recently, we reported that the values of partial molar heat capacities at infinite dilution,[5] the relative increments in the ultrasonic velocity,[6] and the limiting diffusion coefficients[7] of many pentose, hexose, and oligomers in aqueous solutions correlate well with $n(e\text{-OH})$. It was found that the denaturation temperatures of lysozyme and ovalbumin increase almost linearly with the $n(e\text{-OH})$ of the added sugars.[8,9] The permeable velocity of some hexose through the red cell membrane is inversely proportional to their values.[4] These results show that e-OH groups play an important role in the equilibrium, transport, and biochemical properties of aqueous solutions of sugars.

To prove the effect of $n(e\text{-OH})$ on the hydration of sugars, the magnetic relaxation method of oxygen-17 is extremely powerful, since the sugars possess exchangeable protons. As far as we know, Tait et al.[3] have measured only the linewidth of the NMR spectra of ^{17}O-enriched water in concentrated solutions of several monosaccharides. In this work, we report the spin-lattice relaxation times of the natural abundance ^{17}O of water for aqueous solutions of pentose, hexose, and oligosaccharides as a function of the concentration at 25 °C. The concentration dependence of the water-^{17}O relaxation rates is interpreted in terms of the effect of the e-OH groups on the sugar hydration. Then we discuss the relation between the diffusion coefficients and the dynamic hydration numbers of sugars.

Experimental

All of the sugars studied were of G. R. (Tokyo Kasei Co.) and has been purified by the method which has been reported previously.[8,10]

Distilled and deionized water was used.

All natural-abundance oxygen-17 NMR experiments were performed using a JEOL GX-500 spectrometer operating at 6.7 MHz. The oxygen-17 T_1 was measured by using the inversion recovery sequence (180°~τ~90°). For the oxygen-17 relaxation in neutral water, $T_2<T_1$ is observed in consequence of ^{17}O-^1H spin-spin coupling.[11] Therefore, the water and all the solutions were maintained at pH 3.5 by adding p-hydroxybenzoic acid,[3] since at this pH value the proton exchange becomes sufficiently fast, making $T_2=T_1$ in pure water.

The temperature was maintained at 25±0.3 °C by means of gas-thermostating.

Results and Discussion

The value of the oxygen-17 T_1 of water was 7.3 ms at 25 °C, in agreement with the data reported by Hindman et al. (6.8 ms).[12] In Figs. 1—3, the values of T_1°/T_1 for $H_2{}^{17}O$ in aqueous solutions of sugars are plotted against their concentrations, where T_1° and T_1 are the spin-lattice relaxation times of ^{17}O in pure water and

solutions respectively.

The values of T_1°/T_1 for sugar solutions are adequately represented by the empirical equation of this form:

$$T_1^\circ/T_1 = 1 + Bm + Cm^2 \qquad (1)$$

where m is the molality of the sugar. Especially, the values of T_1°/T_1 for monosaccharide solutions are well represented by the linear equation of molality, as is shown in Figs. 1 and 2. The solid line in these figures are those calculated by the least-squares method. The correlation coefficients were in the range of 0.997—0.990. The values of $55.5B$ (see Eq. 6) for sugars are given in the third colum in the table. The numbers on the lines and curves in all the figures denote the same sugars as in the table.

In the extreme motional narrowing condition, we obtain for the oxygen-17 relaxation rate:[13]

$$\frac{1}{T_1} = \frac{3}{125}\left(1 + \frac{\eta^2}{3}\right)\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_c \qquad (2)$$

where η is an assymmetric parameter of the electrical field gradient, e^2qQ/h is the quadrupole coupling constant, and τ_c is the correlation time of molecular reorientation. The contribution of η will be omitted in the following discussion, since this value is usually small.[14] As the value of e^2qQ/h for pure water is 7.7 MHz,[3] we obtain τ_c°=2.4 ps from the value of T_1°; this is good agreement with the value (2.5 ps) which Hertz[14] obtained from the relaxation rate of the water protons.

In aqueous sugar solutions, the ^{17}O nuclei are distributed between two motional states with different intrinsic relaxation rates. If the exchange of water molecules between hydration water (mole fraction x_h) and bulk water is fast, the following relation is obtained;[15]

$$1/T_1 = (1 - x_h)/T_1^\circ + x_h/T_{1h} \qquad (3)$$

which, by the use of Eq. 2, can be rewritten as:[3,15]

$$\frac{T_1^\circ}{T_1} = 1 + n_h\left(K\frac{\tau_c^h}{\tau_c^\circ} - 1\right)\frac{m}{55.5} \qquad (4)$$

$$K \equiv (e^2qQ_h/\hbar)^2/(e^2qQ_0/\hbar)^2 \qquad (5)$$

where the subscripts h and zero refer to the water of the hydration sphere (cosphere) and bulk water respectively and n_h is the coordination number.[15] From a comparison of Eqs. 1 and 4, we obtain this relation;

$$55.5B = n_h\left(K\frac{\tau_c^h}{\tau_c^\circ} - 1\right) \qquad (6)$$

Then, if the value of n_h is known, we can estimate the value of τ_c^h/τ_c°. Since n_h is the number of the water molecule close to that of sugar, we supposed 6, 10, and 14 for mono-, di-, and trisaccharides respectively, according to Kabayama and Patterson's model.[2] Regarding the quadrupole coupling constant of hydration water, there are two viewpoints. It is usually assumed that e^2qQ/h is equal to that of pure water or ice. Generally, the former assumption is adopted in the case of electrolytes and nonelectro-

lytes.[14,15] On the other hand, Tait et al.[3] took the e^2qQ/h value of ice as that of glucose and ribose solutions. According to these two assumptions for the value of e^2qQ/h, the values of K in Eq. 5 were calculated to be 1 and 0.76 respectively.

We show in the table the values of $n(e\text{-OH})$, n_h, and τ_c^h/τ_c° for each sugar. For monosaccharides, a sugar with more e-OH groups shows the larger value of τ_c^h/τ_c°. This means that the thermal motion of water molecules around sugar is more restricted than in bulk water and that the degree of restriction depends on $n(e\text{-OH})$. Glucose has the largest stabilization effect on the water structure. It is worthy of notice that the values of τ_c^h/τ_c° for deoxyribose and ribose with smaller $n(e\text{-OH})$ values than those of other sugars are smaller; that is to say, water molecules around both sugars are more mobile. This means that the assumption that the e^2qQ/h value of water in the hydration sphere equals that of ice is not appropriate in the case of these sugars. Accordingly, we did not use this assumption in calculating the values of τ_c^h/τ_c° for ribose and deoxyribose.

As is shown in the table, the values of τ_c^h/τ_c° for di- and trisaccharides are nearly equal to those of the constituted monosaccharides. Suggett and Clark[16] measured the dielectric relaxation of the concentrated sugar solutions and obtained the values of the dielectric relaxation, τ_r of water molecules in the hydration sphere. The values for glucose, mannose, maltose, and sucrose were 22.0, 21.0, 21.6, and 21.6 ps respectively,[17] which agree with the results of τ_c^h/τ_c° reported in this study. Recently, we also obtained the same τ_c^h/τ_c° value for the monomers and dimers of sulfonate ions.[18]

Previously, we calculated the translational frictional coefficients of oligomers in aqueous solutions and pointed out that the microviscosity around the oligomer is almost the same as that around the monomer.[19] Since the microviscosity around a solute molecule is closely related to the rotational correlation time of the solvent in the cosphere, the above results strongly support our idea. Thus, there is little correlation between $n(e\text{-OH})$ and τ_c^h/τ_c° for oligosaccharides.

The values of $n_h(\tau_c^h/\tau_c^\circ-1)$, which is equal to $55.5B$, is considered to signify the dynamic state of the water molecule in the cosphere relative to the bulk water formed by the same number of water molecules as the cosphere, as is clear from Eqs. 3 and 6. In this context, $n_h(\tau_c^h/\tau_c^\circ-1)$ is defined as the dynamic hydration number. The dynamic state of water molecules in the cosphere of sugar molecule depends on the interaction between water and sugar molecules, which is itself affected by $n(e\text{-OH})$. The number of water molecules in the cosphere is in proportion to the number of OH groups in the sugar molecule, as has been mentioned above. The e-OH groups are able to interact with water in a manner which forms a long-lived hydration structure, since e-OH groups on pyranose sugars match the unperturbed water lattice.[2] We proposed that the sugar molecule, which has a larger number of e-OH groups in a molecule, has a stronger stabilizing effect on the water structure.[4] It is reasonable, therefore, to express the stabilizing effect in the dynamic hydration number. The relation of the dynamic hydration number to $n(e\text{-OH})$ is shown in Fig. 4. This good correlation clearly indicates that the hydration of sugar is essentially determined by the $n(e\text{-OH})$ value.

Recently, we found that the limiting diffusion coefficients, D_0, of sugars in water serve as a linear function of $n(e\text{-OH})$. Therefore, it is of interest to examine the correlation between the dynamic hydration number and the value of D_0. The straight line shown in Fig. 5 is expressed in the following equation by the least-square method:

$$10^{10}D_0 = 10.15 - 0.1872(55.5B)\ (m^2\ s^{-1}) \qquad (7)$$

The first term on the right-hand side of Eq. 7 indicates the diffusion coefficient of a hypothetical molecule, which has the same interaction as a water–water one. If this hypothetical molecule is a ring formed by

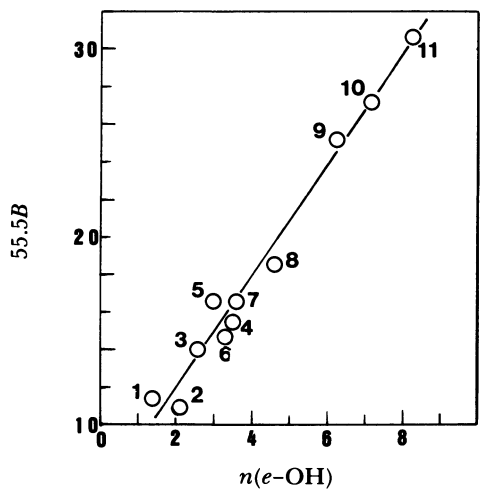

Fig. 4. The relation between $55.5B$ and $n(e\text{-OH})$. The numbers in figure denote the same sugar as in Table 1.

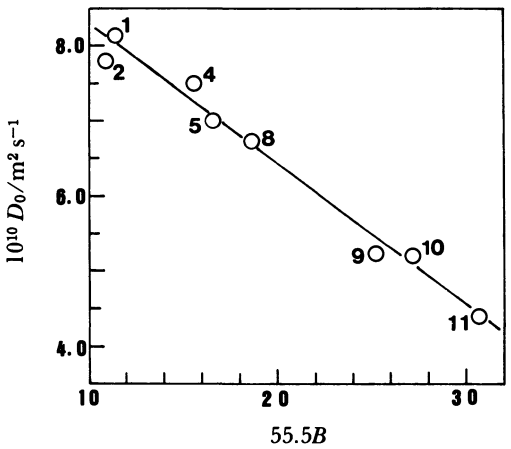

Fig. 5. The relation between D_0 and $55.5B$. The numbers in figure denote the same sugar as in Table 1.

several water molecules, we can calculate the D_0 value of the molecule by the use of the following equation:[19,20]

$$D_0 = D_w[11 \ln(L/r)/(6L/r)] \quad (8)$$

where D_w is the self-diffusion coefficient of pure water (2.3×10^{-9} m^{2}s^{-1} at 25 °C[21]). r is the radius of the water molecule, and L, the length of the ring. We obtain $D_0=10.4\times10^{-10}$ m^{2}s^{-1} for the ring consisting of four water molecules and $D_0=9.34\times10^{-10}$ m^{2}s^{-1} for the ring consisting of five such molecules. These results are reasonable in view of the model in which a molecule of monosaccharide is surrounded by six water molecules. Any other properties which depend on the sugar hydration may be consistently explained by the dynamic hydration number.

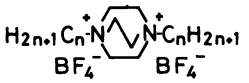
The Phase Transitions of 1,4-Dialkyl-1,4-diazoniabicyclo[2.2.2]octane Bis(tetrafluoroborate), C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$)

Tohru TERADA, Takashi NOGAMI,* and Yasuhiko SHIROTA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received May 27, 1988)

The phase transitions of a series of title compounds were investigated by means of DSC, IR absorption spectra, and measurements of ionic conductivities. All of the compounds exhibited phase transitions in the range of 77—110 °C. The IR absorption spectra clarified that conformational change in the alkyl chain occurred above the transition temperature. The temperature dependences of the ionic conductivities of BF_4^- showed conductivity jumps by a factor of 9—120 around the transition temperatures. A comparison of the DSC results and the ionic conductivities of BF_4-salts with those of the corresponding Br-salts showed that the former compounds have higher transition temperatures, smaller transition enthalpies (and, accordingly, smaller transition entropies), and smaller values of the conductivity jumps than the latter. These results show that BF_4-salts are more rigid than Br-salts in the low temperature phase and that the motion of the alkyl group of the former salts is less vigorous than the latter in the high-temperature phase. By observing the crystal with a polarization microscope under crossed Nicols condition, it was found that optical anisotropy was diminished gradually with the elevation of the temperature and disappeared completely above T_c without changing the crystal shape.

The phase transitions of various types of quaternary alkyl halide salts of 1,4-diazabicyclo[2.2.2]octane (DABCO) have been studied by means of measurements of the ionic conductivities of the halide anion, DSC, IR, and Raman spectroscopies.[1-7] Conductivity jumps of the halide anion by from two to three orders of magnitude were observed around the transition temperatures. The IR and Raman spectroscopies of the salts established that transitions are induced by the vigorous motion of the alkyl chain, accompanied with its conformational change.[8] Some of the unsymmetric bis(quaternary alkyl bromide) salts of DABCO gave a metastable state after having been heated above the transition temperature and then cooled.[4,5] The study of molecular motion in a solid is important as a model system for the melting of materials and the glass transition of polymers, etc. As an extension of the previous studies, we have investigated the phase transition of a series of symmetric bis(quaternary salts) of DABCO possessing the tetrafluoroborate anion. We adopted DABCO-BF_4 salts to see the effect of the different type of anion from the previous ones (spherical and monoatomic halide anion→tetrahedral and pentaatomic BF_4^-) on the phase transitions. The materials in this study will be abbreviated by the number of alkyl carbons. For example, 1,4-didodecyl-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate) is abbreviated to C_{12}-DABCO-C_{12}-$(BF_4)_2$. Thus, the materials in this study will generally be abbreviated as C_n-DABCO-C_n-$(BF_4)_2$.



C_n-DABCO-C_n-$(BF_4)_2$

Experimental

Materials. All of the materials were synthesized by treating the corresponding C_n-DABCO-C_n-Br_2[1,2] with tetrafluoroboric acid. Table 1 summarizes the reaction media and precipitation media of C_n-DABCO-C_n-Br_2 and C_n-DABCO-C_n-$(BF_4)_2$ ($1 \leqq n \leqq 22$), the solvents of recrystallization, and the yields of C_n-DABCO-C_n-$(BF_4)_2$ after one recrystallization. C_n-DABCO-C_n-Br_2 ($1 \leqq n \leqq 9$) could not be purified by recrystallization because of their hygroscopic properties; therefore, they were directly used, without recrystallization, for the synthesis of tetrafluoroborate.[9] A protonated salt, H-DABCO-H-$(BF_4)_2$, was synthesized by the reaction of DABCO with tetrafluoroboric acid in ethyl alcohol; it is denoted as $n=0$ in Table 1. C_n-DABCO-C_n-$(BF_4)_2$ ($1 \leqq n \leqq 9$) and H-DABCO-H-$(BF_4)_2$ were recrystallized five times, and C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$), three times, before the measurements. Most of the analytical data of C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$) were satisfactory.[10] All of the materials decomposed above 300 °C without melting.

The synthetic method will be described for C_{16}-DABCO-C_{16}-$(BF_4)_2$ as typical. The reaction was conducted in a Teflon beaker. C_{16}-DABCO-C_{16}-Br_2 (0.723 g, 1 mmol) was dissolved into ethyl alcohol (20 ml), and then two molar amounts of tetrafluoroboric acid (42%) was stirred in. The homogeneous solution was then stirred into benzene (180 ml), and the mixture was cooled by ice in order to precipitate the product. The white precipitate was collected, dried in a vacuum, and recrystallized three times from ethyl alcohol.

Measurements. The ionic conductivities, DSC, and IR absorption spectra were measured by methods reported previously.[1,2]

Results and Discussion

DSC Measurements. The DSC measurements were made with a scan speed of 5 °C min^{-1}. C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$) exhibited a single endothermic signal in the range of 77—110 °C. When they were

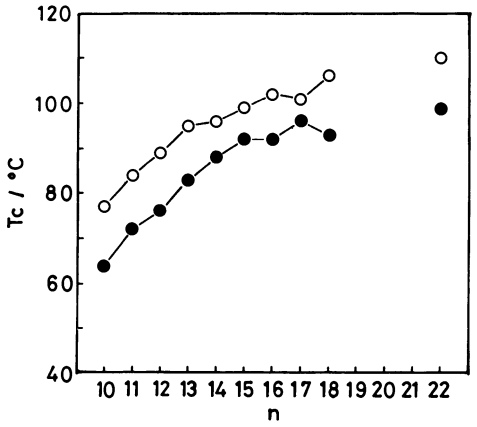

Fig. 1. The plot of the transition temperatures (T_c) against the carbon number of alkyl group (n) of C_n-DABCO-C_n-$(BF_4)_2$. The T_c-n plot of C_n-DABCO-C_n-Br_2 are also shown for the sake of comparison. ○ C_n-DABCO-C_n-$(BF_4)_2$, ● C_n-DABCO-C_n-Br_2.

cooled after having been heated above the transition temperature, they showed exothermic signals around the transition temperature. The values of the endothermic and exothermic heats of transition were almost equal, within the limits of experimental error. Thus, the phase transition is almost reversible. Part of Table 2 summarizes the transition temperatures, transition enthalpies, and transition entropies. The DSC signals expected for C_n-DABCO-C_n-$(BF_4)_2$ ($1 \leqq n \leqq 9$) were below the limit of sensitivity of the DSC apparatus. Figure 1 plots the transition temperatures (T_c) of C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$) against the carbon number (n) of the alkyl group. T_c was obtained by the onset of the endothermic signal. This figure also shows the T_c-n plot of C_n-DABCO-C_n-Br_2 ($10 \leqq n \leqq 22$)[2] for the sake of comparison. T_c tends to increase with the increase in the carbon number of the alkyl group. As will be described below, the phase transition is induced by the vigorous motion of the alkyl chain above T_c. The increase in T_c with the increase in n is caused by the fact that the van der Waals force between alkyl groups of the neighboring molecules becomes larger as n increases, while the

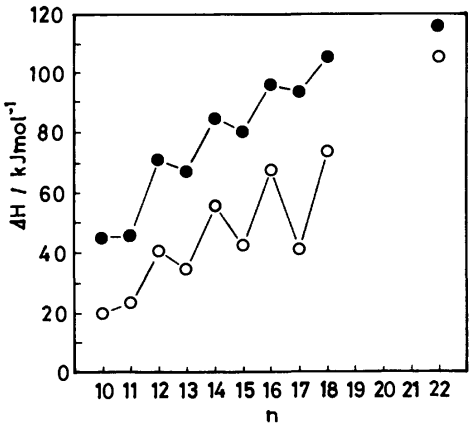

Fig. 2. The plot of the transition enthalpies (ΔH) against the carbon number of alkyl group (n) of C_n-DABCO-C_n-$(BF_4)_2$. The ΔH-n plot of C_n-DABCO-C_n-Br_2 are also shown for the sake of comparison. ○ C_n-DABCO-C_n-$(BF_4)_2$, ● C_n-DABCO-C_n-Br_2.

onset temperature of the motion of alkyl chain shifts to the higher temperature range with this increase. The transition temperatures of BF_4-salts were higher than those of the corresponding Br-salts. Thus, the former salts are harder than the latter in the low temperature phase. Figure 2 plots the transition enthalpies (ΔH) of C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$) against the carbon number of the alkyl group (n). This figure also shows the ΔH-n plot of C_n-DABCO-C_n-Br_2 for the sake of comparison. The ΔH values of BF_4-salts were smaller than those of the corresponding Br-salts. The even-odd number effect of alkyl carbon on ΔH was clearly seen for BF_4-salts as well as Br-salts, and this effect became larger with the increase in n in BF_4-salts. It is well known that the melting points of normal alkanes show such an even-odd number effect. Accordingly, the distinct even-odd number effect shown in Fig. 2 suggests that the alkyl group of DABCO-salt plays an important role in the phase transitions. The plot of the transition entropies (ΔS) sgainst the carbon number of the alkyl group (not shown here) also showed an even-odd number effect similar to that in Fig. 2. The ΔS values of the BF_4-salts were likewise smaller than those of the Br-salts; this suggests that the motion of the alkyl group of the former salts is less vigorous than that of the latter in the high-temperature phase.

IR Absorption Spectroscopy. The temperature dependence of the IR-absorption spectra of C_{17}-DABCO-C_{17}-$(BF_4)_2$ was measured by means of the KBr method in order to gain more detailed information on the phase transitions. Figure 3 shows the IR spectra measured below and above the transition temperature (12 and 115 °C). The strong absorption around 1000—1150 cm^{-1} is ascribable to BF_4^-. The spectrum at 12 °C (Fig. 3(a)) exhibits fine structures (shown by the arrows). These structures are assigned to band

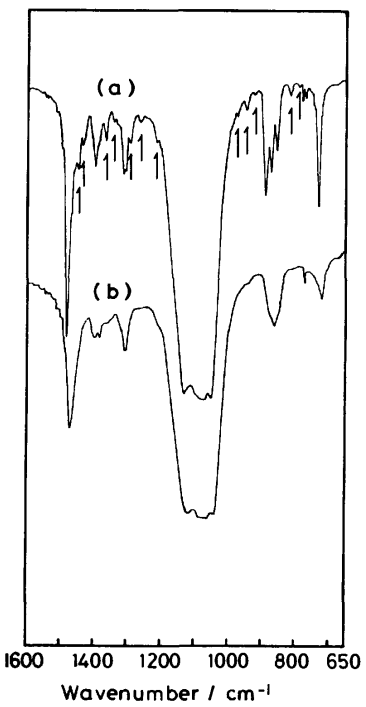

Fig. 3. IR absorption spectra of C_{17}-DABCO-C_{17}-$(BF_4)_2$.
(a) 12°C, (b) 115°C.

progressions of the alkyl chain[2] and are indicative of the trans-zigzag conformation of the alkyl chain in the low-temperature phase. Although a slight broadening was found, these band progressions were always observed with an elevation of the temperature up to the transition temperature. However, they disappeared suddenly around the transition temperature to give the structureless spectra shown in Fig. 3(b). The disappearance of the band progressions in the high-temperature phase indicates the conformational change in the alkyl chain induced by its vigorous motion in the solid.[2] Thus, the phase transitions of the present materials were attributable to be the same origin as C_n-DABCO-C_n-X_2 (X=Cl, Br, I).[1-7]

Ionic Conductivities. In the measurements of ionic conductivities, the charge carrier was usually determined by applying a DC voltage to the sample, while injecting the common carrier ion into the sample.[1,2] This was accomplished by mixing the authentic ionic conductor with the electrode material (graphite in many cases). Since the carrier concentration is maintained in such an experiment, the resistance of the sample does not change.[1] Unfortunately, since no BF_4^- conductor was reported, the above DC experiment could not be made for the present masterials. By analogy with previous studies,[1-7] C_n-DABCO-C_n-$(BF_4)_2$ is assumed to be the BF_4^- conductor. This assumption is plausible because, although the two candidates for the charge carrier[11] are quaternary DABCO cation and BF_4^-, the quaternary DABCO

cation is too big to transport in the solid. On the other hand, BF_4^- is much smaller than the quaternary DABCO cation, and can transport in the solid. In other words, if the quaternary DABCO cation, which occupies most of the volume of the material, could move in the solid, the materials would not remain solid, but would be converted into liquid, especially above T_c.

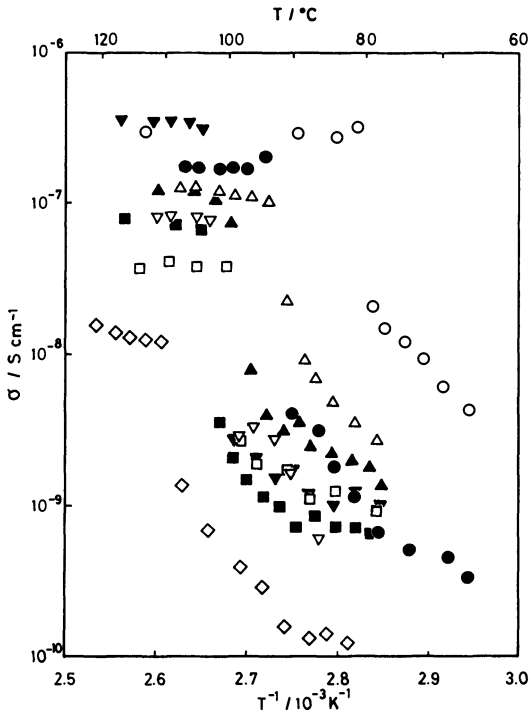

Fig. 4. Temperature dependence of the ionic conductivities of C_n-DABCO-C_n-$(BF_4)_2$.

The ionic conductivities were measured for compressed pellet samples by the AC method.[1,2] The temperature dependences of the ionic conductivities of C_n-DABCO-C_n-$(BF_4)_2$ are shown in Fig. 4. Conductivity jumps were observed within the temperature width of 1.7—5.7 °C[12] around the transition temperature[13] for all of the materials. Part of Table 2 summarizes the ratios of the ionic conductivities below (σ_l) and above (σ_h) the conductivity jumps. This table also shows the values of σ_h/σ_l in C_n-DABCO-C_n-Br_2 in parentheses for the sake of comparison. The σ_h/σ_l values of the BF_4-salts were found to be in the range of 9—120, whereas those of Br-salts were in the range of 850—3600.[2] Thus, the conductivity jumps of BF_4-salts were much smaller than those of Br-salts. This can be explained by the following reasons. The conductivity jumps proved to arise from the formation of voids (conduction channels) caused by the vigorous motion of the alkyl chain above T_c.[2-7] The DSC results showed that the motion of the alkyl chains of the BF_4-salts above T_c are less vigorous than those of the Br-salts. Therefore, the conduction channels of the BF_4^- are formed less effectively in the present materials than those of Br^- in C_n-DABCO-C_n-Br_2. Moreover, BF_4^- is a bigger anion than Br^-, and so the transport of BF_4^- is more retarded than that of Br^-. Accordingly, the ionic conductivities themselves of the BF_4-salts were lower than those of the Br-salts.[14] All of these effects lead to the smaller values of σ_h/σ_l for the BF_4-salts than those for the Br-salts. No correlation was found between the σ_h/σ_l values of C_n-DABCO-C_n-$(BF_4)_2$ ($11 \leqq n \leqq 22$) and those of the corresponding C_n-DABCO-C_n-Br_2 ($11 \leqq n \leqq 22$). Comparing the ionic conductivities themselves, C_n-DABCO-C_n-Br_2 showed almost identical values above T_c, irrespective of n,[2] although they were very different below T_c. On the other hand, the

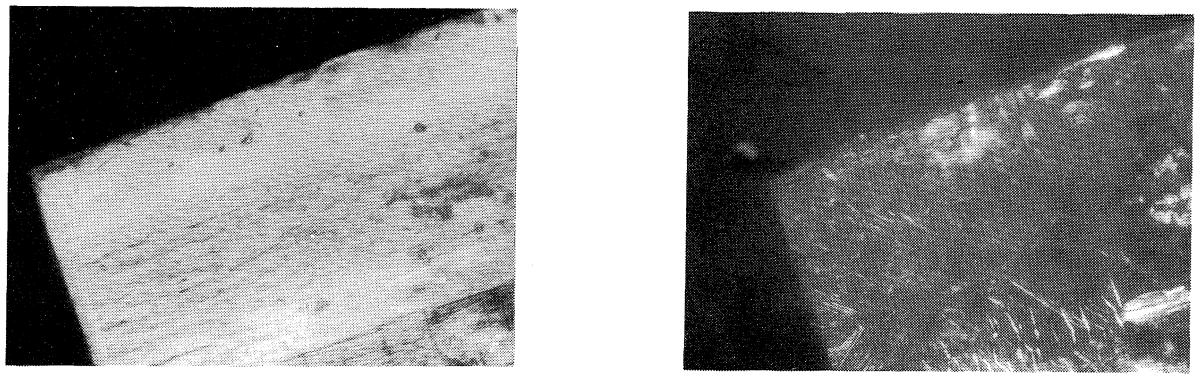

Fig. 5. Disapperance of optical anisotropy of C_{14}-DABCO-C_{14}-$(BF_4)_2$ observed by polarization microscope under a crossed Nicols condition.
(a) 60 °C, (b) 105 °C.

ionic conductivities of the present materials were very different below and above T_c. The reason for this remains to be clarified. The activation energies (ΔE) of the ionic conductivities were 0—13 and 16—94 kJ mol^{-1} above and below T_c respectively.[15] The small ΔE values of some of the materials above T_c suggest liquid-like anion transport in the solid.

Observation by Polarization Microscope. The IR absorption spectra of C_n-DABCO-C_n-$(BF_4)_2$ demonstrated a vigorous motion of the alkyl chain above T_c. The temperature dependence of the ionic conductivities of BF_4^- suggested a liquid-like anion transport above T_c. These phenomena can be visualized by observing the sample crystal under a polarization microscope. Figure 5 shows photographs of C_{14}-DABCO-C_{14}-$(BF_4)_2$ (T_c=96 °C) under a crossed Nicols condition at 60 and 105 °C as examples. The crystal looked bright far below T_c as a result of optical anisotropy (Fig. 5(a)). When the temperature of the sample was elevated, the optical anisotropy began to diminish around 80 °C, and it disappeared completely around 100 °C without changing the crystal shape (Fig. 5(b)). These phenomena were not so sharp as in the case of Br-salts.[16] In these cases, the disappearance of the optical anisotropy of the crystal occurred very sharply (within 1 °C). The wide temperature range of the disappearance of the optical anisotropy suggests that the movement of the alkyl group already begins below T_c and that it becomes more vigorous as the temperature is elevated. Although a single and sharp DSC signal was observed at T_c, it does not justify the simple picture that the movement of the alkyl group begins suddenly at T_c.[17]

Summary

The phase transitions of C_n-DABCO-C_n-$(BF_4)_2$ ($10 \leqq n \leqq 22$) were studied by means of DSC, the IR absorption spectra, and measurements of the ionic conductivities of BF_4^-. These materials exhibited conductivity jumps of BF_4^-, as in the cases of C_n-DABCO-C_n-X_2 (X=Cl, Br, I). The conductivity jumps were induced by the vigorous motion of the alkyl chain in the solid. A comparison of the conductivity jumps of BF_4-salts with those of Br-salts showed that the former gave smaller values of σ_h/σ_l by one to two orders of magnitude. When the T_c, ΔH, and ΔS values of BF_4-salts were compared with those of the corresponding Br-salts, the former were found to give higher T_c and smaller ΔH (and ΔS) than the latter. All of these experimental results led to the conclusions that BF_4-salts are harder than the corresponding Br-salts in the low-temperature phase and that the motion of the alkyl chain of the former salts is less vigorous than that of the latter in the high-temperature phase.

We are grateful to Professor Shigekazu Kusabayashi and Dr. Shunsuke Takenaka, Faculty of Engineering, Osaka University, for allowing us to use the DSC apparatus and the polarization microscope. The present work was supported by a Grant-in-Aid for Special Project Research on Chemical Sensors (No. 62217014) from the Ministry of Education, Science and Culture.

11) Since the samples were dried around 80 °C in a vacuum overnight before the measurements, the effect of the moisture on the ionic conductivity can be neglected.

12) The conductivity jumps were found to occur within the following temperature widths: 1.7 °C (n=11), 3.7 °C (n=12), 2.7 °C (n=13), 2.5 °C (n=14), 2.3 °C (n=15), 2.5 °C (n=16), 4.5 °C (n=17), 5.7 °C (n=18), 3.5 °C (n=22).

13) The transition temperatures of C_n-DABCO-C_n-$(BF_4)_2$, obtained by the use of the mid-points of the conductivity jumps, are as follows (they are close to those obtained by DSC (cf. Table 2)): 80 °C (n=11), 92 °C (n=12), 93 °C (n=13), 96 °C (n=14), 100 °C (n=15), 101 °C (n=16), 101 °C (n=17), 101 °C (n=18), 109 °C (n=22).

14) The ionic conductivities of BF_4-salts above T_c were by one to two orders of magnitude smaller than those of the Br-salts (cf. Ref. 2).

15) The activation energies (ΔE) of the ionic conductivities of C_n-DABCO-C_n-$(BF_4)_2$ are as follows (kJ mol^{-1}) (with the ranges of the temperature (°C) for the calculation of ΔE in the low-temperature phase shown in parentheses): Below

T_c: 55 (n=11, 67≦T≦79), 68 (n=12, 74≦T≦91), 56 (n=13, 79≦T≦89), 20 (n=14, 85≦T≦97), 32 (n=15, 79≦T≦98), 16 (n=16, 90≦T≦102), 94 (n=17, 87≦T≦98), 17 (n=18, 85≦T≦99), 65 (n=22, 88≦T≦107). Above T_c: 5 (n=11), 3 (n=12), 7 (n=13), 7 (n=14), 0 (n=15), 7 (n=16), 4 (n=17), 3 (n=18), 13 (n=22). The activation energies below the lower limit of the temperature shown in the parentheses are much smaller than those calculated especially for n=15, 16, 17, 18, and 22. The reasons for this remain to be clarified.

Effect of Additives on Selective Formation of Isobutene from the CO-H_2 Reaction over ZrO_2

Ken-ichi MARUYA,* Takeshi FUJISAWA, Akihiro TAKASAWA, Kazunari DOMEN, and Takaharu ONISHI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

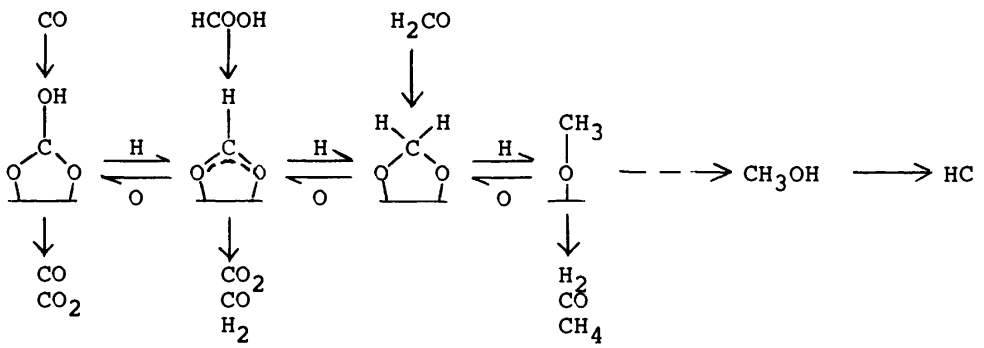
(Received June 22, 1988)

The CO-H_2 reaction over ZrO_2 was carried out in the presence of various organic additives. The addition of dimethyl ether, methylal, acetaldehyde, and dimethyl acetal showed the marked enhancement effects on the hydrocarbon formation keeping the high selectivity for isobutene. Ethylene was little effective. The addition of acetone, propanal, and propylene resulted in the decrease in the formation of isobutene and the increase in that of *n*-butenes. The presence of CO and H_2 was essential to the selective formation of isobutene. The formation pathways of isobutene and the other hydrocarbons are discussed.

The CO-H_2 reaction has been mostly performed using transition metal catalysts to produce a broad spectrum of compounds with linear carbon chains. Selective formation of saturated, branched-chain, aliphatic hydrocarbons has been carried out using the difficultly reducible oxide catalysts such as ThO_2[1] and Dy_2O_3[2] under very severe conditions and CdO catalysts combined with acid supports under mild conditions.[3] Recently, we found that the CO-H_2 reaction over ZrO_2 under mild conditions such as 673 K and atmospheric pressure produces isobutene selectively.[4,5]

The isosynthesis reaction[6] has been suggested to proceed via methanol which is formed as a primary product from CO and H_2.[1,2] He and Ekerdt[7,8] observed the appearance of methoxide species along with formate ion after the treatment of ZrO_2 with a mixture of CO and H_2 at reduced pressure and at reaction temperatures from 673 to 773 K followed by evacuation at 298 K, and proposed the following pathway for the formations of methanol and hydrocarbons from CO and H_2 over ZrO_2. This methanism is similar to that in the isosynthesis reaction, in that methanol is a precursor to hydrocarbons.

We have reported that the CO-H_2 reaction over ZrO_2 at 673 K forms the hydrocarbons consisting mainly of isobutene and that adsorbed species on the ZrO_2 surface during the reactions are both methoxide and formate species.[9] Therefore, the first question is how the methoxide species participates in the formation of hydrocarbons. We also reported that the formation path of isobutene is different from that of the other hydrocarbons such as C_2, C_3, and linear C_4 hydrocarbons on the basis of their different dependences on the reaction temperature and CO pressure,[5] i.e., the yields of C_2, C_3, and linear C_4 hydrocarbons are linearly plotted by the Arrhenius equation in the wide temperature range from 473 to 723 K, while that of isobutene increases rapidly above 573 K and the activation energy for the formation of isobutene is much higher than those of the other hydrocarbons. Furthermore, the formation rate of isobutene depends on the CO pressure nearly in the second order, while those of the other hydrocarbons do not. Therefore, the second question is how the formation of isobutene is correlated with that of the other hydrocarbons. Here we describe the relation of surface methoxide species to the formation of hydrocarbons and the effect of addition of various organic compounds having the carbon chain from C_1 to C_3 to the CO-H_2 reaction on the formations of isobutene and the other hydrocarbons.



Experimental

Materials. ZrO_2 was prepared as described previously.[5] H_2 was purchased from Showa Denko Co. CO, ethylene, and propylene were purchased from Takachiho Kagaku Kogyo K. K. Iron carbonyl in CO gas was removed by active carbon cooled at Dry Ice or liquid nitrogen temperature. Oxygenates were purchased from Kanto Chemical Co. and used without further purification.

Procedures. Reactions were carried out in a conventional flow system with a quartz reactor of 12 mm in diameter and a glass vacuum system with a gas-circulating pump. The flow reactions with organic additives were carried out at 1 atm total pressure and at the total flow rate of 100 ml·min^{-1}. Feed of dimethyl ether was controlled finely by two needle valves and its concentration was determined by G.C. The other organic compounds were added using syringe. The glass vacuum system was used for the investigation of time course of the CO–H_2 reaction. Products were analyzed by GC as described previously.[5]

Results

1) Reaction of Methanol. The reaction of methanol over isosynthesis catalysts at 723 K and 300 atm has been reported to form the products of the same hydrocarbon distribution as the CO–H_2 reaction.[1,2] On the other hand, the reaction of methanol over ZrO_2 under mild conditions such as 643 K and 0.23 kPa of the methanol partial pressure produced only dimethyl ether in the steady state. Since the CO–H_2 reaction in the presence of 0.25 kPa of water produced only CO_2 of 0.15 kPa, no formation of hydrocarbons in the methanol reaction over the ZrO_2 catalyst will be due to the inhibition of the further reaction of dimethyl ether for the hydrocarbon formation by water.

2) Reaction of Dimethyl Ether. Since dimethyl ether is an anhydride of methanol, the reaction of dimethyl ether is expected to occur without the inhibition by water. Table 1 shows the conversion of dimethyl ether and the distribution of hydrocarbons formed. Increasing the feed of dimethyl ether from 0.012 to 2.5 ml·min^{-1} decreases the conversion from 99 to 28% and the total yield of C_1 to C_6 hydrocarbons based on the dimethyl ether consumed from 72 to 6%. At the highest feed, 50% of dimethyl ether consumed decomposes into CO and H_2. One of the reasons why the increase in the feed of dimethyl ether results in the low yield of hydrocarbons is likely that the decomposition of dimethyl ether increases with an increase in the feed. The product distribution in Table 1 shows that the reaction of dimethyl ether alone yields a broad spectrum of hydrocarbons. Although the highest yield in the hydrocarbons is achieved in C_2 hydrocarbons, the yield is low.

The addition of H_2 to the dimethyl ether reaction leads to the higher yield of hydrocarbons, which

consist mainly of alkanes as shown in Table 1. The addition of CO instead of H_2 resulted in the rapid deactivation giving methane selectively.

3) Reaction of Dimethyl Ether in the Presence of CO and H_2. The conversion of dimethyl ether and the distribution of hydrocarbons formed in the presence of CO and H_2 are presented in Table 1. It is clear from the higher conversion of dimethyl ether and the higher yields of hydrocarbons that the presence of either CO or H_2 improves the reactivity of dimethyl ether. The main products are C_2 and C_4 hydrocarbons. The effect of CO and H_2 is particularly remarkable for the formation of C_4, because it is rather minor products in the absence of both CO and H_2. The yield of C_4 hydrocarbons in the absence of CO and H_2 is so low that it does not overcome the amount in the CO–H_2 reaction without dimethyl ether. The three reactant system of dimethyl ether, CO, and H_2 forms C_4 with much higher yield. The maximum yield is obtained at 2.2 ml·min^{-1} of the feed, above which the yield decreases with an increase in the feed.

Table 2 shows the isomer distribution in the C_4 hydrocarbons. In the absence of CO and H_2 the selectivity of isobutene increases, as the feed of dimethyl ether increases. In the presence of CO and H_2 the selectivity to isobutene is more than 90%.

At the dimethyl ether feed of 2.2 ml·min^{-1} in the three reactant system, the concentration of CO in the outlet of catalyst bed was higher by 4% than that in the inlet. This means that a large amount of dimethyl ether decomposes into CO and H_2 despite of the presence of CO and H_2. The carbon balance from CO formed and the hydrocarbons recovered shows that 16% of dimethyl ether consumed is still unrecovered, even though the decomposition into CO and H_2 is taken into account.

4) Relation between Formations of Methanol and Hydrocarbons. The enhancement effect of dimethyl ether on the isobutene formation mentioned above stimulated us to investigate the relation between the formation of methanol and hydrocarbons at low temperatures, where methanol is main in the products, the selectivity of isobutene in hydrocarbons is low,[5] and methoxide is one of the main adsorbed species on the catalyst surface.[9]

The time courses of the formation of methanol and dimethyl ether in the CO–H_2 reaction over ZrO_2 at 473 and 523 K are shown in Fig. 1. There are induction

a) Catalyst: 5.0 g, feed rate: 100 ml·min^{-1} ($CO/H_2/N_2$=40/40/20), temperature: 643 K. b) Acetaldehyde was used as a solution of methylal (12 μmol·min^{-1}).

times of 12 and 3 h for the formation of two oxygen-containing products at the temperatures, respectively. However, the induction times disappear in the repeated reaction after the reaction for 24 h followed by the evacuation for 30 min at the same temperatures.

At 523 K the CO-H_2 reaction was carried out for 1 h, during which no product was detected except for hydrocarbons by G.C. However, when the products trapped at liquid nitrogen temperature was dissolved into water and analyzed using GC-MS, a small amount of formaldehyde was detected. Almost the same amount of formaldehyde was found in the products collected from initial 1 to 2 h. Thus, within the induction time for methanol formation, hydrocarbons and formaldehyde were already formed.

On the other hand, the formation of hydrocarbons at 473 and 523 K is accompanied by no or a short induction time as shown in Fig. 2. The hydrocarbon distributions are rather similar to that in the reaction of dimethyl ether alone.

5) Effect of Organic Additives on the Formation of Isobutene. Table 3 shows the effect of the addition of ethylene and propylene to the CO-H_2 reaction. The addition of them seems to affect little the yield of hydrocarbons. However, in the addition of propylene, the main isomer in C_4 hydrocarbons changes into 1- and 2-butenes, although in the case of ethylene it is still isobutene.

Table 4 shows the effect of the addition of C_2 and C_3 oxygenates. The addition of diethyl ether only leads to produce mainly ethylene and C_4 hydrocarbons are minor. Acetaldehyde markedly enhanced the yield of hydrocarbons keeping the high selectivity for isobutene for initial few hours, after which the activity and selectivity were rapidly lowered to form yellow oily products. As it was very hard to control the amount of acetaldehyde added, dimethy acetal was used instead of C_2 aldehyde. The reaction was stable to form the higher yield of hydrocarbons with the high selectivity for C_4 hydrocarbons as shown in Table 4.

The addition of propanal leads to the decrease of C_4 hydrocarbons and the increase of the other hydrocarbons, especially C_5. The main isomer in C_4 hydrocarbons is changed from isobutene with the selectivity of 97% in the absence of propanal to 1- and 2-butenes with that of 75% in the presence of propanal. The addition of acetone also leads to the decrease of C_4 hydrocarbons. The most of acetone is converted to propylene.

Discussion

1) The Formation of C_2, C_3, and Linear C_4 Hydrocarbons. The treatment of ZrO_2 evacuated at 993 K with a mixture of CO and H_2 at room temperature results in the formation of some paraformaldehyde type adsorbed species.[5] The CO–H_2 reaction over ZrO_2 at 523 K produced formaldehyde in the initial stage of the reaction during the induction time for the formation of methanol and dimethyl ether. On the other hand, disappearance of induction time in repeated reaction shown in Fig. 1 may indicate that the induction time means the time taken to accumulate a surface intermediate which is not easily removed by evacuation at 523 K. Since formate and oxymethylene species on oxide surfaces are adsorbed forms of formyl and formaldehyde, respectively,[9–11] the formation of formaldehyde and methanol with and without induction time, respectively, may indicate the following relation of relative rates at the low temperatures,

$$CO + H_2 \longrightarrow CH_xO_y(a) \rightarrow \begin{cases} \xrightarrow{\text{fast}} CH_2O(g) \\ \xrightarrow{\text{slow}} CH_3O(a) \end{cases}$$

where $CH_xO_y(a)$ means adsorbed species such as formate, formyl, or formaldehyde.

On the other hand, the time course of hydrocarbon formations at 523 and 473 K shows no or a short induction time as shown in Fig. 2. Therefore, the hydrocarbons are not formed via methanol or methoxide species. Although dissociation of CO is possible for the common Fischer-Tropsch catalyst metals and polymerization of CH_2 formed from the carbon atoms and hydrogen is proposed as the mechanism of hydrocarbon formation,[12] there has been no report on the cleavage of C–O bond over oxide catalysts which requires a multiple catalyst site. We have no evidence for the cleavage also in the case of the reaction over ZrO_2. Since formaldehyde is formed without induction time, $CH_xO_y(a)$ is a possible candidate of the intermediate in the hydrocarbon formation. The formose reaction to form various carbohydrates having carbon-carbon bonds from formaldehyde in the presence of base catalysts[13] and the cleavage of carbon-oxygen bond of formaldehyde coordinated on zirconium complex[14] may suggest the possible pathway of direct hydrocarbon formation from the intermediate. Since the formation of C_2, C_3, and linear C_4 hydrocarbons are plotted by Arrhenius equation in the temperature range between 473 and 723 K, the formation path must be the same in the wide temperature range between 473 and 723 K.

2) The Formation of Isobutene. The formation of branched-chain hydrocarbons from CO and H_2 has been described by the pathway via the reaction of carbonyl of formaldehyde, acetaldehyde, and acetone coordinated on ZrO_2 with CO or methoxide species.[15,16] However, the present results that the addition of acetone or propanal to a mixture of CO and H_2 results in the decrease of C_4 hydrocarbons eliminate the formation of isobutene by either the carbonylation of acetone or propanal or the aldol condensation-type reaction of propanal.

The second order dependence of the isobutene formation on CO pressure[5] suggests that the formation of C_2 species from C_1 species is a slow process. The marked enhancement effect of C_2 oxygenate such as acetaldehyde or acetal on the isobutene formation may support the suggestion. On the other hand, the enhancement effect of dimethyl ether and the indispensability of CO and H_2 shown in Table 1 may suggest that methoxide or CH_xO_y species formed from dimethyl ether reacts with CO and H_2 to form the C_2 species. In the temperature range where isobutene is selectively formed, methanol and dimethyl ether are formed so fast as to be in equilibrium with a gas of CO and H_2. Thus, the following pathway is written. Further detailed mechanism is under investigation.

$$\left[\begin{matrix} CO + H_2 \\ \text{or} \\ CH_3OCH_3 \end{matrix}\right] \rightarrow \left[\begin{matrix} CH_xO_y(a) \\ \text{or} \\ CH_3O(a) \end{matrix}\right] \xrightarrow[CO + H_2]{\text{slow}} C_2 \text{ species}$$

$$\xrightarrow[CO + H_2]{\text{fast}} \xrightarrow[CO + H_2]{\text{fast}} CH_2{=}C(CH_3){-}CH_3$$

The Magnetic Predissociation of the $B^3\Pi_{0^+u}$ State of the Iodine Molecule

Masaaki BABA,* Misako KIMURA, Toshiyuki TSUBOI, Hajime KATÔ, and Saburo NAGAKURA†

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

†Institute for Molecular Science, Myodaiji, Okazaki 444

(Received July 4, 1988)

It is shown that the predissociation of I_2 excited to the $B^3\Pi_{0^+u}$ state can occur through the coupling with the $2431^1\Pi_u$ state by gyroscopic and Zeeman interactions. The interaction matrix elements between the $B^3\Pi_{0^+u}$ and $2431^1\Pi_u$ states are shown to be nonzero, for the $2431^1\Pi_u$ state is mixed significantly with the $2431^3\Pi_{1u}$ state by the spin-orbit interaction. The v, J dependence of the magnetic-quenching ratios of the $B^3\Pi_{0^+u}$–$X^1\Sigma_g^+$ fluorescence intensity has been measured and analyzed. The rate constants of the magnetic predissociation in the $B^3\Pi_{0^+u}$ state have also been evaluated. The magnetic-field dependence of the hyperfine structure has been measured by means of the Doppler-free intermodulated fluorescence method.

In 1913, Steubing[1] found the quenching of the $B^3\Pi_{0^+u}$–$X^1\Sigma_g^+$ fluorescence by an external magnetic field. Turner[2] suggested that it was due to magnetic predissociation in the $B^3\Pi_{0^+u}$ state. Van Vleck[3] suggested that the mixing of the $B^3\Pi_{0^+u}$ state with the repulsive $^3\Pi_{0^-u}$ state causes the magnetic predissociation. The rate constants were determined by studies of the magnetic quenching of the fluorescence intensity.[4,5]

The natural predissociation (predissociation in a zero magnetic field) of the $B^3\Pi_{0^+u}$ state was found by analyzing the fluorescence lifetime and the absorption strength.[6–9] The vibrational quantum-number dependence of the natural predissociation was very similar to that of the magnetic predissociation. The predissociation was attributed to the gyroscopic interaction (heterogeneous electronic-rotational perturbation) and the hyperfine interaction between the $B^3\Pi_{0^+u}$ and $2431^1\Pi_u$ states.[10] Vigue et al.[11,12] found an interference effect between the natural and magnetic predissociations. Both the natural and magnetic predissociations in the $B^3\Pi_{0^+u}$ state were consequently assigned as originating from the coupling with the $2431^1\Pi_u$ state.[12] However, this study is not yet complete because the matrix elements of the coupling between the $^3\Pi_{0^+u}$ and $^1\Pi_u$ states have been calculated to be zero for the gyroscopic and Zeeman interactions.

In this paper, we shall show that the matrix elements of the Zeeman interaction between the $B^3\Pi_{0^+u}$ and $2431^1\Pi_u$ states are not zero, for the $2431^1\Pi_u$ state is mixed with the $2431^3\Pi_{1u}$ state by the spin-orbit coupling.[13,14] We have measured the magnetic quenching ratios of completely resolved rotational lines. By using these results and the fluorescence lifetime,[12] we shall reexamine the rate constants of the magnetic predissociation in the $B^3\Pi_{0^+u}$ state. The magnetic-field dependence of the hyperfine structure has been measured by the Doppler-free intermodulated fluorescence method; these results shall also be discussed.

Experimental

A single-mode tunable ring dye laser equipped with an autoscan system (Coherent 699-29) was used for excitation. A small amount of solid iodine was sealed in a Pyrex cell after trap-to-trap purifications. The residual gas pressure was lower than 1×10^{-5} Torr (1 Torr≈133.322 Pa). The vapour pressure of the iodine was controlled by cooling the sidearm of the cell. The cell was placed in the center of an electric magnet. The laser light was linearly polarized and propagated with its polarization parallel to the applied magnetic field. The fluorescence was detected by a photomultiplier (Hamamatsu R712) through a glass filter (Toshiba R66) to block the scattered laser light. The output of the photomultiplier was phase-sensitively detected through a lock-in amplifier (PAR Model 128) by chopping the laser light at 960 Hz.

The magnetic-quenching ratio for a rotational level was determined by measuring the change in the peak intensity with the applied magnetic field. The Doppler-limited line shape did not change with the magnetic field. Therefore, the height of the maximum intensity was proportional to the integrated line intensity. The assignment of the rotational line was carried out using the molecular constants obtained by Luc.[15]

The hyperfine structure was obseved by means of the intermodulated fluorescence method.[16] The laser light was split into two counter propagating beams which were chopped at 390 Hz and 570 Hz and which crossed in the center of the cell. We obtained the Doppler-free spectrum by detecting the fluorescence intensity at 960 Hz through a lock-in amplifier. The linewidth was about 10 MHz at the laser power of 30 mW mm^{-2} and the vapour pressure of 30 mTorr (with the sidearm cooled at 0 °C).

Theoretical

As Mulliken defined,[14] we shall denote the MO (molecular orbital) electronic configuration of the valence-shell state of the $\sigma_g^2\sigma_u^2\sigma_g^m\pi_u^p\pi_g^q\sigma_u^n$ type with $m+n+p+q=10$ as $mpqn$. The basic determinant wavefunctions of the iodine molecule are given by:

$$|2440^1\Sigma_g^+> = |\pi_{g+1}\bar{\pi}_{g+1}\pi_{g-1}\bar{\pi}_{g-1}|,$$
$$|2431^3\Pi_{0^+u}> = (2)^{-1/2}(|\pi_{g+1}\pi_{g-1}\bar{\pi}_{g-1}\sigma_u| -$$

$$
\begin{aligned}
&+|\pi_{g+1}\bar{\pi}_{g+1}\bar{\pi}_{g-1}\bar{\sigma}_u|),\\
|2431^3\Pi_{1u+}> &= (2)^{-1/2}(|\pi_{g+1}\bar{\pi}_{g+1}\pi_{g-1}\bar{\sigma}_u|\\
&+|\pi_{g+1}\bar{\pi}_{g+1}\bar{\pi}_{g-1}\sigma_u|),\\
|2431^3\Pi_{1u-}> &= (2)^{-1/2}(|\pi_{g+1}\pi_{g-1}\bar{\pi}_{g-1}\bar{\sigma}_u|\\
&+|\bar{\pi}_{g+1}\pi_{g-1}\bar{\pi}_{g-1}\sigma_u|),\\
|2431^1\Pi_{u+}> &= (2)^{-1/2}(|\pi_{g+1}\bar{\pi}_{g+1}\pi_{g-1}\bar{\sigma}_u|\\
&-|\pi_{g+1}\bar{\pi}_{g+1}\bar{\pi}_{g-1}\sigma_u|),\\
|2431^1\Pi_{u-}> &= (2)^{-1/2}(|\pi_{g+1}\pi_{g-1}\bar{\pi}_{g-1}\bar{\sigma}_u|\\
&-|\bar{\pi}_{g+1}\pi_{g-1}\bar{\pi}_{g-1}\sigma_u|),
\end{aligned}
\tag{1}
$$

where MO without a bar indicates with an α-spin, where MO with a bar indicates with a β-spin, and where a determinant such as $|\sigma_g(1)\bar{\sigma}_g(2)\pi_{u+1}(3)\bar{\pi}_{u+1}(4)\pi_{u-1}(5)\bar{\pi}_{u-1}(6)\pi_{g+1}(7)\bar{\pi}_{g+1}(8)\pi_{g-1}(9)\bar{\pi}_{g-1}(10)|/(10!)^{1/2}$ is briefly denoted as $|\pi_{g+1}\bar{\pi}_{g+1}\pi_{g-1}\bar{\pi}_{g-1}|$ in Eq. 1 by omitting the common MOs of a low energy. MOs $\pi_{g\pm1}$ and σ_u in Eq. 1 are, respectively, of the form $5p_{\pm1}-5p_{\pm1}$ and $5p_0+5p_0$, where $5p_0=5p_z$ and $5p_{\pm1}=\mp2^{-1/2}(5p_x \pm i5p_y)$.

As a set of basis functions, we use wavefunctions of simple products, $|\Lambda>|S\Sigma>|v>|J\Omega M>$. The function $|\Lambda>|S\Sigma>|v>$ is a wavefunction for a nonrotating molecule, where Λ and Σ represent the projections of the total electronic orbital and the total electronic spin angular momenta along the molecular axis respectively, while v represents the vibrational quantum number. All of these are expressed in molecule-fixed coordinates. The wavefunction $|J\Omega M>$ associated with the molecular rotation is expressed in laboratory-fixed coordinates, where the quantum numbers J and M specify the total angular momentum and its projection along the laboratory-fixed Z axis respectively and where $\Omega=\Lambda+\Sigma$. The eigenfunctions for the levels of the unperturbed states $2440^1\Sigma_g^+$, $2431^3\Pi_{0^+u}$ $2431^3\Pi_{1u}$, and $2431^1\Pi_u$, are expressed, respectively, as:[17]

$$
\begin{aligned}
|2440^1\Sigma_g^+vJM> &= |0^+>|00>|v>|J0M>,\\
|2431^3\Pi_{0^+u}vJM> &= |0^+>|10>|v>|J0M>,\\
|2431^3\Pi_{1u\pm}vJM> &= 2^{-1/2}(|1>|10>|v>|J1M1>\\
&\pm|-1>|10>|v>|J-1M>),\\
|2431^1\Pi_{u\pm}vJM> &= 2^{-1/2}(|1>|00>|v>|J1M>\\
&\pm|-1>|00>|v>|J-1M>),
\end{aligned}
\tag{2}
$$

where the electronic wavefunctions $|0^+>|00>$, $|0^+>|10>$, $|1>|10>$, $|-1>|10>$, $|1>|00>$, and $|-1>|00>$ are equal to $|2440^1\Sigma_g^+>$, $|2431^3\Pi_{0^+u}>$, $|2431^3\Pi_{1u+}>$, $|2431^3\Pi_{1u-}>$, $|2431^1\Pi_{u+}>$, and $|2431^1\Pi_{u-}>$ of Eq. 1, respectively.

The spin-orbit interaction induces a mixing of the singlet and triplet wavefunctions, and it occurs between the same J levels. The perturbed wavefunctions of I_2 at the equilibrium distance R_e of the ground state were calculated by Mulliken[14] as:

$$
\begin{aligned}
|X^1\Sigma_g^+vJM> &= |2440^1\Sigma_g^+vJM>\\
&- 0.153|2341^3\Pi_{0^+g}vJM>,\\
|B^3\Pi_{0^+u}vJM> &= 0.916|2431^3\Pi_{0^+u}vJM>\\
&- 0.378|1342^3\Pi_{0^+u}vJM>\\
&- 0.064|1441^1\Sigma_u^+vJM>,\\
|A^3\Pi_{1u\pm}vJM> &= 0.908|2431^3\Pi_{1u\pm}vJM>\\
&+ 0.419|2431^1\Pi_{u\pm}vJM>,\\
|2431^1\Pi_{u\pm}vJM> &= 0.419|2431^3\Pi_{1u\pm}vJM>\\
&- 0.908|2431^1\Pi_{u\pm}vJM>.
\end{aligned}
\tag{3}
$$

The magnetic field was applied along the Z-axis in laboratory-fixed coordinates. The basic electronic orbital and spin wavefunctions are expressed in molecule-fixed coordinates. The Zeeman interaction energy in the molecule-fixed coordinates is written as:[17]

$$
H_Z = -[2^{-1/2}(\mu_+ D_{01}^1 - \mu_- D_{0-1}^1) + \mu_Z D_{00}^1]H, \tag{4}
$$

where H is the magnetic field. $\mu_+ = -\mu_B\sum_i(l_+ + 2s_+)_i$, $\mu_- = -\mu_B\sum_i(l_- + 2s_-)_i$, and $\mu_Z = -\mu_B\sum_i(l_Z + 2s_Z)_i$ are the components of the magnetic moment of the molecule, and D_{MN}^J is the rotation matrix. We shall always use the representations of the rotation group, the angular momenta, the coupling coefficients, and the tensors as defined by Brink and Satchler.[18] The matrix element of the Zeeman interaction is zero between different spin states in Eq. 2,while the nonzero matrix elements for $|2431^3\Pi_{0^+u}v'JM>$ are calculated to be:

$$
\begin{aligned}
&<2431^3\Pi_{0^+u}v'JM|H_Z|\,2431^3\Pi_{1u-}vJ-1\,M>\\
&\quad = 4\mu_B H<v'|v>[(J-1)(J-M)(J+M)/2J(2J-1)(2J+1)]^{1/2},\\
&<2431^3\Pi_{0^+u}v'JM|H_Z|\,2431^3\Pi_{1u+}vJ\,M>\\
&\quad = 4\mu_B H<v'|v>M/[2J(J+1)]^{1/2},\\
&<2431^3\Pi_{0^+u}v'JM|H_Z|\,2431^3\Pi_{1u-}vJ+1\,M>\\
&= -4\mu_B H<v'|v>[(J+2)(J+1-M)(J+1+M)\\
&\quad /2(J+1)(2J+1)(2J+3)]^{1/2}.
\end{aligned}
\tag{5}
$$

Thus, the $2431^3\Pi_{0^+u}$ state can couple with the $2431^3\Pi_{1u}$ state by the Zeeman interaction. The Zeeman interaction between the $B^3\Pi_{0^+u}$ and $2431^1\Pi_u$ states has nonvanishing matrix elements, as can be seen from Eqs. 3 and 5.

The Hamiltonian of the gyroscopic interaction is written as:

$$
H_G = -(\hbar^2/2\mu R^2)(J_+L_- + J_-L_+), \tag{6}
$$

where μ is the reduced mass and where R is the internuclear distance. It causes perturbation between states that differ by $\Delta\Omega=\Delta\Lambda=\pm1$ and $\Delta S=0$. The gyroscopic interaction between the $B^3\Pi_{0^+u}$ and $2431^1\Pi_u$ states arises through the nonzero matrix element:

$$
\begin{aligned}
&<2431^3\Pi_{0^+u}v'JM|H_G|2431^3\Pi_{1u+}vJM> =\\
&\quad -G<v'|\hbar^2/2\mu R^2|v>[J(J+1)]^{1/2},
\end{aligned}
\tag{7}
$$

where G is defined as $<0^+|L_-|1>=<0^+|L_+|-1>=2^{-1/2}G$. The predissociation of I_2 excited to the $|B^3\Pi_{0^+u}v'JM>$ level can occur through the gyroscopic interaction

with the $|2431^1\Pi_{u+}vJM\rangle$ level; the rate is proportional to:

$$G^2|\langle v'|\hbar^2/2\mu R^2|v\rangle|^2 J(J+1). \quad (8)$$

In the presence of the magnetic field H along the Z axis, the predissociation of I_2 excited to the $|B^3\Pi_{0+u}v'JM\rangle$ level can occur through the Zeeman interaction with the $|2431^1\Pi_{u-}vJ-1M\rangle$, $|2431^1\Pi_{u+}vJM\rangle$, and $|2431^1\Pi_{u-}vJ+1M\rangle$ levels, as can be seen from Eqs. 3 and 5. The predissociation through the interaction between the $|B^3\Pi_{0+u}v'JM\rangle$ and $|2431^1\Pi_{u+}vJM\rangle$ levels can occur by both gyroscopic and Zeeman interactions. The rate of predissociation from the excited level $|B^3\Pi_{0+u}v'JM\rangle$ is proportional to:

$$\begin{aligned}&8\mu_B^2H^2|\langle v'|v\rangle|^2(J-1)(J-M)(J+M)/J(2J-1)(2J+1)\\&+|4\mu_BH\langle v'|v\rangle M[2J(J+1)]^{-1/2}\\&-G\langle v'|\hbar^2/2\mu R^2|v\rangle[J(J+1)]^{1/2}|^2\\&+8\mu_B^2H^2|\langle v'|v\rangle|^2(J+2)(J+1-M)(J+1+M)\\&/(J+1)(2J+1)(2J+3)=k_{p(M)}.\end{aligned} \quad (9)$$

The $B^3\Pi_{0+u}-X^1\Sigma_g^+$ transition is allowed through the nonvanishing transition moments of $\langle^3\Pi_{0+u}|\mu|^3\Pi_{0+g}\rangle$ and $\langle^1\Sigma_u^+|\mu|^1\Sigma_g^+\rangle$, where μ is an electric dipole moment. The dependence on J and M is the same for both these transition moments. For an excitation by a plane-polarized light with the electric vector along the Z axis, which is the case in our experiment, the nonvanishing moment of the $B^3\Pi_{0+u}$ $(v'JM)-X^1\Sigma_g^+(v''JM)$ transition is given by:

$$\begin{aligned}&\langle B^3\Pi_{0+u}v'JM|\mu_Z|X^1\Sigma_g^+v''J-1M\rangle\\&\quad=\mu(B-X)\langle v'|v''\rangle[(J-M)(J+M)/(2J-1)(2J+1)]^{1/2},\\\text{and}\quad&\langle B^3\Pi_{0+u}v'JM|\mu_Z|X^1\Sigma_g^+v''J+1M\rangle\\&\quad=\mu(B-X)\langle v'|v''\rangle[(J+1-M)(J+1+M)/\\&(2J+1)(2J+3)]^{1/2},\end{aligned} \quad (10)$$

where $\mu(B-X)$ is the electric dipole transition moment of the $B^3\Pi_{0+u}-X^1\Sigma_g^+$ transition.

The rate of the predissociation following the optical excitation is proportional to:

$$\begin{aligned}k_p=&(2J+1)^{-1}\sum_M k_{p(M)}\mu(B-X)^2|\langle v'|v''\rangle|^2\\&\times[(J-M)(J+M)/(2J-1)(2J+1)\\&+(J+1-M)(J+1+M)/(2J+1)(2J+3)],\end{aligned} \quad (11)$$

The summation over M is equal to averaging over the molecular orientation; one thus obtains:

$$\begin{aligned}k_p=&\mu(B-X)^2|\langle v'|v''\rangle|^2[16\mu_B^2H^2|\langle v'|v\rangle|^2(J+1)(11J-5)\\&/(2J-1)(2J+3)+G^2|\langle v'|\hbar^2/2\mu R^2|v\rangle|^2J(J+1)/3],\end{aligned} \quad (12)$$

where the first term is the contribution from the Zeeman interaction, while the second term is that from the gyroscopic interaction. It should be noted that the interference term disappears upon the averaging; hence, the interference can not be observed in our experiment. Accordingly, the rate of predissociation due to the Zeeman interaction can be written as:

$$k_{mpr}=bH^2, \quad (13)$$

while the rate of predissociation due to the gyroscopic interaction can be written as:

$$k_{gpr}=g\,J(J+1), \quad (14)$$

where b and g are constants.

Experimental Results and Discussion

A portion of the fluorescence excitation spectrum of the iodine molecule,which includes the band origin of the $B^3\Pi_{0+u}(v'=6)-X^1\Sigma_g^+(v''=4)$ transition, is shown in Fig. 1. Most of the lines are rotationally resolved and can be easily assigned. However, the hyperfine structure is not resolved because of the Doppler-width. We measured the magnetic quenching ratio of the line intensity of each rotational level. Since the lifetime of the $B^3\Pi_{0+u}$ state is relatively long (an order of ~μs), the fluorescence intensity is sensitive to optical saturation and molecular collisions. Therefore, the measurement should be made at as low a laser power and as low a vapour pressure as possible. All the measurements were carried out at 1 mW mm^{-2} and 30 mTorr; it was thus confirmed that the quenching ratio under these conditions was almost independent of the laser power.

We also measured the magnetic-quenching ratio I_H/I_0 of each rotational line, where I_H and I_0 are, respectively, the fluorescence intensity at the magnetic

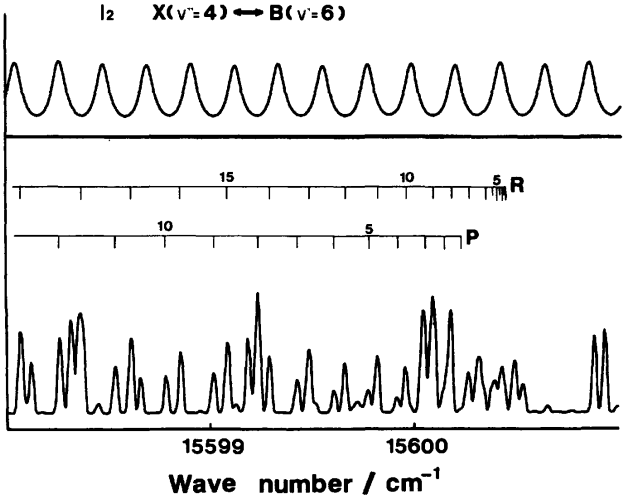

Fig. 1. Fluorescence excitation spectrum of I_2 around the band origin of the $B^3\Pi_{0+u}(v'=6)-X^1\Sigma_g^+(v''=4)$ transition. The assignment of each rotational line is shown above. The upper trace is the transmittance of the etalon (FSR=6.5 GHz) which is monitored to confirm the linearity of the scan and to detect a mode-hop of the laser line.

field H and at the zero magnetic field. The observed values of I_H/I_0 for J'=20—80 levels of v'=6 and 10 at H=0.78 and 1.67 T are shown in Fig. 2. The magnetic quenching ratio depends on the decay rate of the J' level. Hence, the values of the P and R lines of the identical J' are naturally the same. We measured the magnetic-field dependence of the quenching ratio for each rotational line. The ratios I_0/I_H of the P(35) lines of the $B^3\Pi_{0^+u}(v'=6)-X^1\Sigma_g^+(v''=4)$ and $B^3\Pi_{0^+u}(v'=10)-X^1\Sigma_g^+(v''=3)$ transitions are plotted against the square of the applied magnetic field in Fig. 3. The experimental error was ±1%.

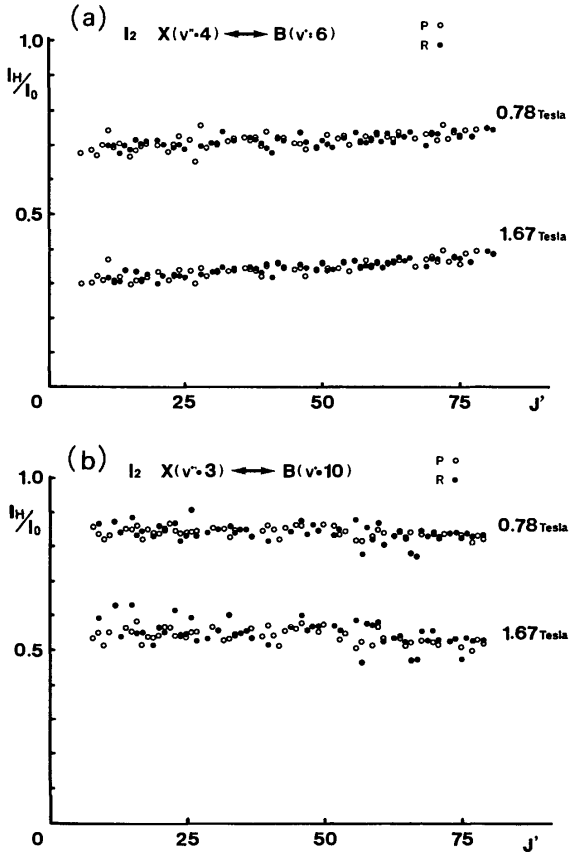

Fig. 2. The values of I_H/I_0 for J' levels of $B^3\Pi_{0^+u}$ (v'=6) at the magnetic field of 0.78 and 1.67 T are shown in (a). Those for J' levels of $B^3\Pi_{0^+u}(v'=10)$ are shown in (b).

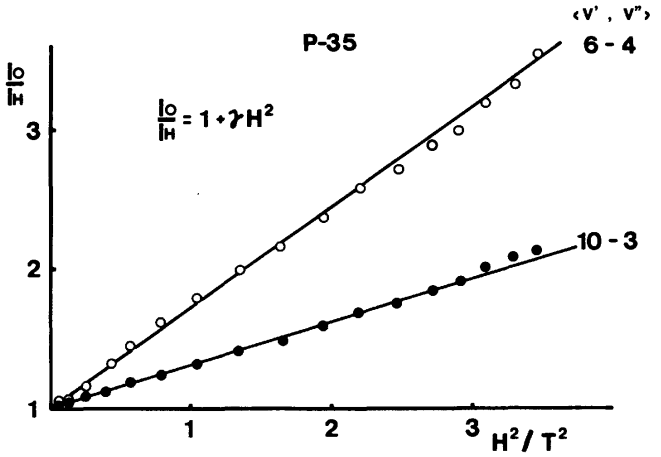

Fig. 3. Magnetic field dependence of the quenching ratio I_0/I_H of the P(35) lines of the $B^3\Pi_{0^+u}(v'=6)-X^1\Sigma_g^+(v''=4)$ and $B^3\Pi_{0^+u}(v'=10)-X^1\Sigma_g^+(v''=3)$ transitions.

The magnetic-quenching ratio of the fluorescence is expressed as:

$$I_H/I_0 = (k_{rad} + k_{col} + k_{npr}) / (k_{rad} + k_{col} + k_{npr} + k_{mpr}), \quad (15)$$

where k_{rad}, k_{col}, and k_{mpr} are, respectively, the rate of radiative decay, the rate of collisional quenching, and the rate of magnetic predissociation. k_{npr} is the rate of the natural predissociation, which is the sum of the rate of the gyroscopic predissociation k_{gpr} and the rate of the hyperfine predissociation k_{hpr}. The lifetime τ in the zero field is given by:

$$\tau = (k_{rad} + k_{col} + k_{npr})^{-1}. \quad (16)$$

From Eqs. 13, 15, and 16, one obtains:

$$I_0/I_H = 1 + \tau b H^2 = 1 + \gamma H^2. \quad (17)$$

One can determine the value of γ from the slope of I_0/I_H vs. H^2. We measured the J dependence of the magnetic-quenching ratios for various v' levels. The

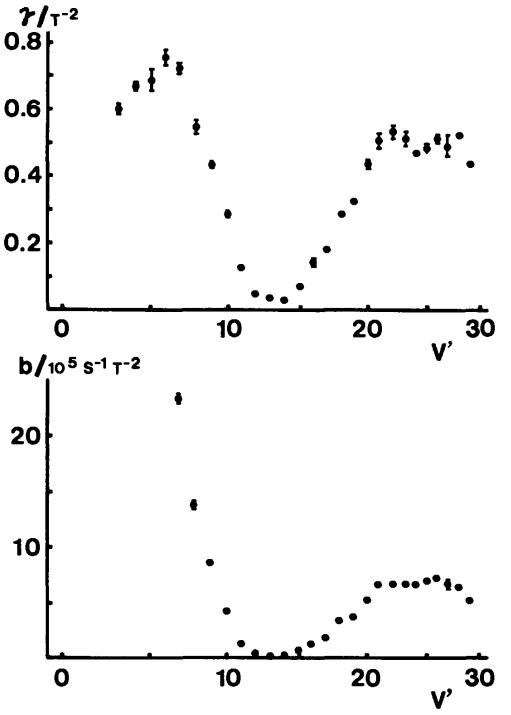

Fig. 4. Upper (a): Observed values of γ extrapolated to J=0 for various v levels. Lower (b): b values deduced from the observed γ values and the fluorescence lifetime at J=0 from Ref. 12.

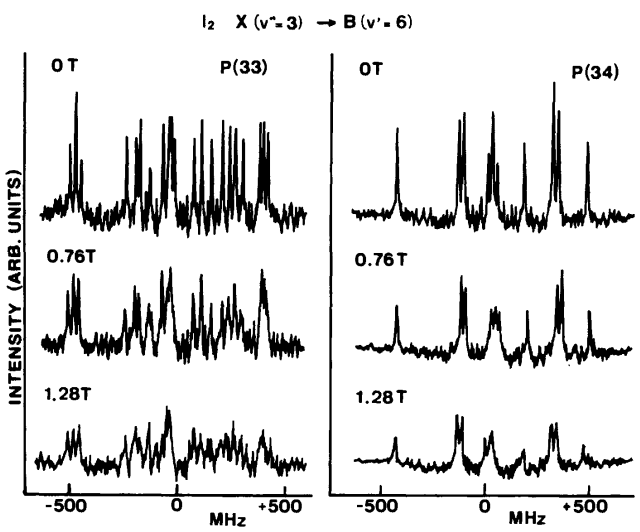

Fig. 5. Hyperfine structure of P(33) and P(34) lines of the $B^3\Pi_{0^+u}(v'=6)-X^1\Sigma_g^+(v''=3)$ transition, and the change with the magnetic field.

results of the extrapolation of the values of γ at $J=0$ are shown in Fig. 4(a). At $J=0$, the rate of the gyroscopic predissociation is zero. We evaluated the values of τ at $J=0$ by using the results obtained by Vigue et al.[12] Unfortunately, their results are limited for $v'>7$. Consequently we could obtain the b value at $J=0$ for $v'=7$—29; the b value obtained for each v' level is plotted in Fig. 4(b). The profile is very similar to that presented by Chapman et al.[5] and Vigue et al.,[12] but the absolute values are considerably different. We measured the magnetic-quenching ratio for many more rotationally resolved lines; hence, we could obtain more accurate values than the previous ones.

By using the intermodulated fluorescence technique,[16] we observed the hyperfine structure and the change with the magnetic field. The results for the P(33) and P(34) lines of the $B^3\Pi_{0^+u}(v'=6)-X^1\Sigma_g^+(v''=3)$ transition are shown in Fig. 5. The Pauli exclusion principle requires that odd J levels of the $B^3\Pi_{0^+u}$ state of $^{127}I_2$ can combine only with states of an even total nuclear spin ($I=0$, 2, and 4), while even J levels can combine only with states of an odd total nuclear spin ($I=1$, 3, and 5). Hence, 15 sublines are observed for an even J'' line and 21 sublines for an odd J'' line. In either the presence or absence of a magnetic field, no energy shift or line splitting of the hyperfine lines was observed. However, when a magnetic field was applied, a remarkable decrease of the intensity of each line was observed; the ratio of the change was almost the same for all lines.

The hyperfine structure could be explained by the nuclear electric quadrupole interaction and the nuclear spin-rotation interaction.[20,21] For a large value of $J(\gg I)$, the angular momentum $\boldsymbol{J}$ is almost parallel to $\boldsymbol{F}=\boldsymbol{J}+\boldsymbol{I}$. The Zeeman interaction energy with the nuclear spins may be expressed by:

$$E_{NZ} = g_I\mu_N(M_1 + M_2)H, \tag{19}$$

where M_i is the projection of the nuclear spin angular momentum of the nucleus i along the molecular-fixed z axis. g_I is a nuclear g-factor, and μ_N is the nuclear magneton. We used a linearly polarized light whose polarization was parallel to the magnetic field; hence,the transitions of $M'_F-M''_F=0$ are allowed by an electric dipole transition. The nuclear g-factors of the $B^3\Pi_{0^+u}$ and $X^1\Sigma_g^+$ states can be estimated to be almost the same, for no energy shift or line splitting of the hyperfine lines was observed when a magnetic field was applied.

Levenson and Schawlow[21] found that the nuclear spin-rotation interaction varied strongly with the vibrational quantum number v' of the $B^3\Pi_{0^+u}$ state. The coupling was found to increase rapidly near the dissociation limit of the $B^3\Pi_{0^+u}$ state. Broyer et al.[22] found that the lifetime extrapolated to $J=0$ shows a strong variation with v, very similar to that of b. They assigned the origin of this new predissociation to the hyperfine predissociation. In order to make this problem clear, more extensive studies of Doppler-free spectroscopy by using a molecular beam will be necessary.

A part of this work was supported by the Joint Studies Program (1987—1988) of the IMS. H. K. and M. B. wish to thank the Ministry of Education of Japan for a Grant-in-Aid for scientific research.

The Synthesis and Oxidation of Mixed Cobalt(III) Complexes with Dimethyldithiocarbamato and Diamine Ligands, and the Crystal Structure of $(+)^{CD}_{500}$-Dimethyldithiocarbamato-bis(ethylenediamine)cobalt(III) Bis[μ-(*R*,*R*)-tartrato]diantimonate(III) Pentahydrate

Masakazu KITA,*,† Kazuaki YAMANARI, and (the late) Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received October 9, 1987)

Dithiocarbamato complexes, $[Co(dtc)_{3-n}(diamine)_n]^{n+}$ (n=1 and 2 and dtc=dimethyldithiocarbamate) were newly prepared and characterized by means of their absorption, CD, and MCD spectra. $(+)^{CD}_{500}$-$[Co(dtc)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O$ crystallized in the monoclinic space group of $P2_1$ with a=14.630(3), b=9.300(1), c=12.023(5) Å, β=110.78(3)°, V=1529.4(8) Å^3, and Z=2. The refinement of 3346 reflections (Mo $K\alpha$ radiation) led to R=0.073. The dtc complex had a *Λ* configuration. The Co–N bond trans to the dtc sulfur atom was longer by 0.026 Å than the cis one. A novel oxidation derivative, $[Co\{(dimethylamino)thioxomethanesulfinato\text{-}O,S\}(en)_2]^{2+}$, was prepared and characterized by means of its XPS spectrum.

A large number of dithiocarbamato-metal complexes have been synthesized.[1] Several reports have been published on the crystal structures of dithiocarbamato cobalt(III) complexes: e.g., $[Co(S_2CNH_2)_3]$,[2] $[Co\{S_2CN(CH_3)_2\}_3]$,[3] and $[Co(S_2CN(C_2H_5)_2)_3]$.[4] No mixed chromophore systems of the $[Co(S)_2(N)_4]$ and $[Co(S)_4(N)_2]$ types have, however, been reported. The mixed chromophores are interesting in terms of their spectrochemistry because of the large difference in the ligand field strengths between dtc-sulfur and amine-nitrogen donors. Furthermore, sulfur donor groups with various chemical environments (thiolato, thioether, sulfenato, sulfinato, sulfito, thiosulfato, etc.) induce in cobalt(III) complexes the trans influence (structural trans effect) ranging in magnitude from 0.00 to 0.089 Å;[5] in contrast, however, no such trans influence of dithiocarbamato has yet been determined because the appropriate mixed complexes have not been synthesized.

This paper deals with the synthesis of a series of mixed cobalt(III) complexes with dimethyldithiocarbamate and diamine as the remaining ligands: $[Co(dtc)_{3-n}(diamine)_n]^{n+}$ (n=0, 1, and 2). The complexes were characterized by their electronic absorption, circular dichroism (CD), and magnetic circular dichroism (MCD) spectra. The X-ray crystal structure of $(+)^{CD}_{500}$-$[Co(dtc)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O$ was determined. The H_2O_2 oxidation of dithiocarbamato complexes was also attempted.

The following abbreviations of the ligands are used in this paper: Hdtc=dimethyldithiocarbamic acid $(CH_3)_2NCS_2H$; Hdtsi=(dimethylamino)thioxomethanesulfinic acid $(CH_3)_2NC(S)SO_2H$; Hmtz=2-mercapto-2-thiazoline $\overline{S\text{–}CH_2\text{–}CH_2N=C}\text{–}SH$; en=ethylenediamine $NH_2CH_2CH_2NH_2$; *R*-pn=(*R*)-propylenediamine $NH_2CH_2CH(CH_3)NH_2$.

Experimental

Preparation and Optical Resolution. (1) $[Co(dtc)(en)_2](ClO_4)_2$: To a solution of $Co(ClO_4)_2$ (0.018 mol) in 100 cm^3 of water we added a solution of ethylenediamine (2.2 g, 0.036 mol) in 100 cm^3 of methanol. To the mixture we then immediately added a solution of bis(dimethylthiocarbamyl) disulfide (2.2 g, 0.009 mol) in 200 cm^3 of ethanol, and the subsequent mixture was stirred at ca. 70 °C for 1 h. The resulting reddish purple precipitate was filtered off and washed with ethanol and diethyl ether. The precipitate was recrystallized by dissolving it in hot water (ca. 70 °C), filtering, and cooling to ca. 5 °C. The yield was 7.6 g (85%). Found: C, 16.75; H, 4.43; N, 13.81%. Calcd for $[Co(dtc)(en)_2](ClO_4)_2=C_7H_{22}N_5O_8S_2Cl_2Co$: C, 16.87; H, 4.45; N, 14.06%.

For optical resolution, to a solution of $[Co(dtc)(en)_2](ClO_4)_2$ (3.0 g, 0.006 mol) in 50 cm^3 of hot water we added a solution of $K_2[Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 3H_2O$ (1.9 g, 0.003 mol) in 50 cm^3 of hot water. After a few minutes, the red-plate diastereomer $(+)^{CD}_{500}$-$[Co(dtc)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O$ began to deposit; it was filtered off. The filtrate was cooled to induce the crystallization of $(-)^{CD}_{500}$-$[Co(dtc)(en)_2](ClO_4)_2$. The crystals were collected and recrystallized from hot water. Found for the less-soluble diastereomer: C, 19.64; H, 3.83; N, 7.58%. Calcd for $(+)^{CD}_{500}$-$[Co(dtc)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O=C_{15}H_{36}N_5O_{17}S_2CoSb_2$: C, 19.64; H, 3.92; N, 7.57%. Found for the $(-)^{CD}_{500}$-complex: C, 16.97; H, 4.48; N, 14.01%. Calcd for $(-)^{CD}_{500}$-$[Co(dtc)(en)_2](ClO_4)_2=C_7H_{22}N_5O_8Cl_2S_2Co$: C, 16.87; H, 4.45; N, 14.06%. An adequate amount of anion-exchange resin (QAE-Sephadex A-25, chloride form) was added to a suspension of the less-soluble diastereomer, $(+)^{CD}_{500}$-$[Co(dtc)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O$, in water, leading to a reddish brown supernatant. After the removal of the resin, sodium perchlorate was added to the filtrate; the crystals of $(+)^{CD}_{500}$-$[Co(dtc)(en)_2](ClO_4)_2$ were then deposited. Found: C, 16.80; H, 4.42; N, 13.98%. Calcd for $(+)^{CD}_{500}$-$[Co(dtc)(en)_2](ClO_4)_2=C_7H_{22}N_5O_8S_2Cl_2Co$: C, 16.87; H, 4.45; N, 14.06%.

(2) $[Co(dtc)_2(en)]ClO_4$: This green complex was obtained as a by-product (5%) from the mother liquor in the above preparation. The complex was also prepared in a

high yield by the following method. Bis(dimethylthiocarbamyl) disulfide (4.3 g, 0.0183 mol) was stirred into a solution of $Co(ClO_4)_2$ (0.036 mol) in 100 cm^3 of ethanol. To the mixture we then added a mixed solution of sodium dimethyldithiocarbamate dihydrate (6.4 g, 0.036 mol) and ethylenediamine (2.2 g, 0.036 mol) in 50 cm^3 of water. After a few minutes, the green precipitate began to deposit. The mixture was then stirred at ca. 70 °C for 1 h. The resulting green precipitate was filtered and washed with water (100 cm^3), ethanol (20 cm^3), chloroform (100 cm^3 each, three times), and then ether (100 cm^3). The water washings contained the complex $[Co(dtc)(en)_2](ClO_4)_2$, and the chloroform ones, $[Co(dtc)_3]$. The green precipitate was recrystallized by dissolving it in hot water–ethanol (2:1) and by then cooling it below 10 °C. The columnar green crystals were collected. The yield was 12 g (73%). Found: C, 20.80; H, 4.41; N, 12.17%. Calcd for $[Co(dtc)_2(en)]ClO_4=C_8H_{20}N_4O_4S_4ClCo$: C, 20.94; H,4.39; N, 12.21%.

(3) $(+)^{CD}_{580}$- and $(-)^{CD}_{580}$-$[Co(dtc)_2(R\text{-pn})]ClO_4$: The $[Co(dtc)_2(R\text{-pn})]ClO_4$ complexes were prepared by the same procedure as that used for $[Co(dtc)_2(en)]ClO_4$, except for the use of *R*-pn instead of en. The yield was 11 g (85%). The green crystals of $[Co(dtc)_2(R\text{-pn})]ClO_4$ were dissolved in a small amount of dimethyl sulfoxide (DMSO), adsorbed on a column of cation-exchange resin (SP-Sephadex C-25, Na^+ form), and eluted with a 0.5 M NaCl aqueous solution (1 M=1 mol dm^{-3}). The two green bands were eluted separately. The earlier eluate showed a negative CD at 17000 cm^{-1} and the latter one, a positive CD at 17000 cm^{-1}. Each perchlorate salt was obtained by adding a saturated aqueous solution of $NaClO_4$ to each eluate. Found for the $(-)^{CD}_{580}$-complex: C, 22.76; H, 4.70; N, 11.86%. Calcd for $(-)^{CD}_{580}$-$[Co(dtc)_2(R\text{-pn})]ClO_4=C_9H_{22}N_4O_4S_4ClCo$: C, 22.86; H, 4.69; N, 11.85%. Found for the $(+)^{CD}_{580}$-complex: C, 21.49; H, 4.86; N, 10.96%. Calcd for $(+)^{CD}_{580}$-$[Co(dtc)_2(R\text{-pn})]ClO_4\cdot 1.5H_2O=C_9H_{25}N_4O_{5.5}S_4ClCo$: C, 21.62; H, 5.04; N, 11.20%.

(4) $[Co(dtc)_3]$: This complex was obtained according to the method in the literature.[3] Found: C, 25.75; H, 4.37; N, 9.84%. Calcd for $[Co(dtc)_3]=C_9H_{18}N_3S_6Co$: C, 25.77; H, 4.32; N, 10.02%.

(5) $(-)^{CD}_{490}$-$[Co(dtsi)(en)_2](ClO_4)_2$: A mixed solution of 30% aqueous H_2O_2 (10 g) and 60% aqueous $HClO_4$ (10 g) was stirred into a solution of $(-)^{CD}_{500}$-$[Co(dtc)(en)_2](ClO_4)_2$ (5 g) in 50 cm^3 of DMSO below 5 °C to give an orange-red solution instantly. To the resulting solution we immediately added a mixture of diethyl ether (700 cm^3) and ethanol (300 cm^3). Orange-red crystals separated out on the inside of a beaker within a few minutes and were filtered off. The yield was ca. 1 g. Found: C, 16.19; H, 4.20; N, 13.18%. Calcd for $(-)^{CD}_{490}$-$[Co(dtsi)(en)_2](ClO_4)_2=C_7H_{22}N_5O_{10}S_2Cl_2Co$: C, 15.86; H, 4.18; N, 13.20%. The compound was stable in the solid state on exposure to light, but was unstable in an aqueous or DMSO solution, even in the dark, probably because of the solvolysis.

(6) $[Co(mtz)(en)_2](ClO_4)_2$: To a solution of $CoCl_2\cdot 6H_2O$ (4.8 g, 0.020 mol) in 40 cm^3 of ethanol–water (2:1) we added a solution of ethylenediamine (3.0 g, 0.050v mol) in 100 cm^3 of ethanol. To the mixture we then added a solution of 2-mercapto-2-thiazoline (2.4 g, 0.020 mol)[6] in 200 cm^3 of ethanol, after which the air oxidation was continued for 1 h. The resulting brown-purple precipitate was recrystallized by dissolving it in hot water, adding $NaClO_4$ (10 g), and cooling the mixture to ca. 5 °C. The yield was 2.5 g (25%). Found: C, 17.05; H, 4.11; N, 13.92%. Calcd for $[Co(mtz)(en)_2](ClO_4)_2=C_7H_{20}N_5O_8S_2Cl_2Co$: C, 16.94; H, 4.06; N, 14.11%.

For optical resolution, to a solution of $[Co(mtz)(en)_2](ClO_4)_2$ (0.5 g, 0.001 mol) in 20 cm^3 of hot water we added a solution of $K_2[Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 3H_2O$ (0.3 g, 0.0005 mol) in 30 cm^3 of hot water. After a few minutes, purple thin plate crystals $(+)^{CD}_{506}$-$[Co(mtz)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O$ began to deposit; they were filtered off. To the filtrate we added $NaClO_4$ (10 g), and then the crystals of $(-)^{CD}_{506}$-$[Co(mtz)(en)_2](ClO_4)_2$ deposited were collected and recrystallized from hot water. Found for the less-soluble diastereomer: C, 19.42; H, 3.94; N, 7.46%. Calcd for $(+)^{CD}_{506}$-$[Co(mtz)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O=C_{15}H_{38}N_5O_{17}S_2Cl_2CoSb_2$: C, 19.43; H, 4.13; N, 7.55%. Found for $(-)^{CD}_{506}$-complex: C, 16.87; H, 4.07; N, 13.73%. Calcd for $(-)^{CD}_{506}$-$[Co(mtz)(en)_2](ClO_4)_2=C_7H_{20}N_5O_8S_2Cl_2Co$: C, 16.94; H, 4.06; N, 14.11%.

Spectroscopic Determination. The visible and ultraviolet absorption spectra were measured on a Hitachi 330 spectrophotometer. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter, and the MCD spectra on the same instrument in a 1.5 T magnetic field. The absorption, CD, and MCD measurements were made in aqueous, DMSO, and/or $CHCl_3$ solution at room temperature. The XPS measurements were carried out on a Shimadzu HIPS 70 apparatus. The binding energies relative to the Fermi level were determined by referring to the values of the Na-2s (64.0 eV) and S-$2p_{3/2}$ (169.5 eV) of Na_2SO_4, mixed with an appropriate amount of each sample.

X-Ray Analysis. The X-ray analysis of $(+)^{CD}_{500}$-$[Co(dtc)(en)_2][Sb_2(R,R\text{-}C_4H_2O_6)_2]\cdot 5H_2O$ was also performed. Crystal Data: monoclinic, $P2_1$, a=14.630(3) Å, b=9.300(1) Å, c=12.023(5) Å, β=110.78(3)°, V=1529.4(8) Å^3, Z=2, D_{calcd}=2.01, D_{obsd}=2.00 g cm^{-3}. An orange-red crystal, of appropriate dimensions (0.375×0.250×0.075 mm), was used for X-ray work. The diffraction intensities were measured using a Rigaku four-circle diffractometer, with graphite monochromatized Mo $K\alpha$ radiation (λ=0.71069 Å). Their intensities decreased progressively with the length of X-ray exposure. Furthermore, the linear absorption coefficient is μ(Mo $K\alpha$)=25.08 cm^{-1}. Therefore the damage[7] and absorption[8] corrections were applied. Out of a total of 3654 reflections ($5°<2\theta<55°$), 3346 corresponded to those with $I>3\sigma(I)$. The atomic scattering factors of the neutral atoms were taken from Ref. 9 for all the atoms, both the $\Delta f'$ and $\Delta f''$ components of anomalous dispersion were included for all nonhydrogen atoms.

All the computations were performed on an ACOS-S700 apparatus at the Crystallographic Research Center, Institute for Protein Research, Osaka University. The computer programs used were ABSC,[8] MFPA,[10] HBLS V and RHO,[11] DAPH,[12] and ORTEP.[13] The structure was solved by the usual heavy-atom method: conventional Patterson, Fourier, and least-squares refinement techniques. The absolute configurations of the asymmetric carbon atoms of bis[μ-(*R*,*R*)-tartrato(4−)]diantimonate(III) ion were fitted to those reported previously.[14] Therefore, the absolute configuration of the cobalt(III) complex, $(+)^{CD}_{500}$-$[Co(dtc)(en)_2]^{2+}$, was determined definitely. All nonhydrogen atoms except one water oxygen atom, which could not be found by the last

a) The e.s.d. are shown in parentheses. The numberings are shown in Fig. 7. b) B is evaluated from the corresponding anisotropic thermal parameters according to Ref. 14. The isotropic thermal parameters are of the $\exp\{-B(\sin^2\theta/\lambda^2)\}$ form.

difference Fourier synthesis, were located and were assigned anisotropic parameters. The hydrogen atoms, except for those belonging to methyl-carbon atoms and water-oxygen atoms, were introduced into their geometrical positions,[15] but were not refined. The refinement of R and R_2 converged to 0.073 and 0.082 respectively.[16] The final positional parameters, the corresponding isotropic thermal parameters as calculated from the respective anisotropic parameters by Hamilton's method,[17] and their estimated standard deviations for nonhydrogen atoms are given in Table 1. The calculated positional parameters of the hydrogen atoms, the anisotropic thermal parameters for all the nonhydrogen atoms, and the complete list of $|F_o|$ and $|F_c|$ values are deposited as Document No. 8847 at the Office of the Editor of the Bull. Chem. Soc. Jpn.

Description of the Structure of $(+)^{CD}_{500}$-[Co(dtc)(en)$_2$]-[Sb$_2$(R,R-C$_4$H$_2$O$_6$)$_2$]·5H$_2$O and the Trans Influence Induced by the dtc Ligand. Figure 1 shows the numbering of the diastereomeric salt. Tables 2 and 3 show the nonhydrogen atom bond distances and angles respectively. Table 4 lists several selected plane equations, sets of deviations of atoms from the plane, and the dihedral angles between the pair of planes.

This dtc complex has the Λ-(δ,δ) configuration, judged from the asymmetric carbon atoms of the bis[μ-(R,R)-tartrato(4−)]diantimonate(III) ion.[14] The [Sb$_2$(R,R-C$_4$H$_2$O$_6$)$_2$]$^{2-}$ anion has reasonable bond distances and angles as compared with the results of an other structure analysis,[14] as is shown in Table 5. Table 6 shows the selected bond distances and angles of the present [Co(dtc)(en)$_2$]$^{2+}$ in comparison with those of [Co(dtc)$_3$].[4] There are no large differences between the two complexes concerning the dtc

ligand, the Co-S distances, and the bite angle, S-Co-S. The cobalt atom lies nearly on the plane of S_2CN (Table 4), but the S(1)-Co-S(2), S(1)-Co-N(2), and S(2)-Co-N(3) angles are 76.9, 169.9, and 172.4° respectively, accounting for the rather distorted octahedral structure shown in Table 2. More remarkable is the mean of the trans Co-N(2) and Co-N(3) distances, which is longer by 0.026 Å than the mean of cis Co-N(1) and Co-N(4). The magnitude of the trans influence induced by the dtc ligand is between those induced by the

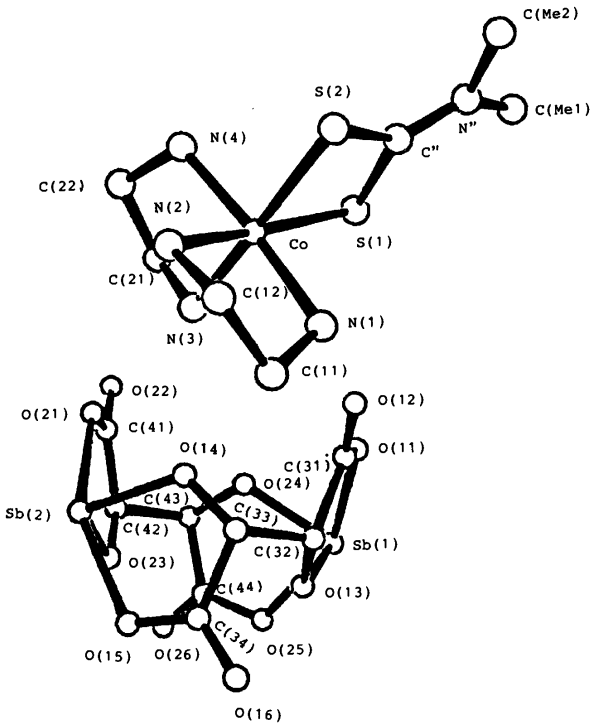

Fig. 1. A perspective view and numbering of $(+)^{CD}_{500}$-[Co(dtc)(en)$_2$][Sb$_2$(R,R-$C_4H_2O_6$)$_2$]·5H$_2$O (50% probability thermal ellipsoids).

thiolato and thiosulfato ligands: SO_3^{2-}(0.089)>RSO^-(0.072)>RSO_2^-(0.049)>RS^-(0.040)>dtc$^-$(0.026)>$S_2O_3^{2-}$(0.019)>RSR′, RSSR′, or $RSNH_2$(0.000),[5] where the figures in parentheses indicate the difference (Å) between the trans Co-N distance and the average of the cis distances in the [Co(S)(N)$_5$] type. The dtc sulfur donor atoms do not induce so large a trans influence, presumably because of the little overlapping between the σ(dtc) MO and metal dσ AO attributable to the 4-membered acute chelation.

Results and Discussion

Synthesis and Characterization of [Co(dtc)$_{3-n}$(diamine)$_n$](ClO$_4$)$_n$(n=0, 1, and 2, and diamine means en or *R*-pn). The reduction of dialkyl disulfide by 2-equiv cobalt(II) ions with 10-equiv amines yields several [Co(thiolato)(amine)$_5$]$^{2+}$-type complexes.[18] In the present series, [Co(dtc)$_{3-n}$(diamine)$_n$]$^{n+}$ (n=0, 1, and 2, and diamine means en or *R*-pn), such a redox reaction between the disulfide and cobalt(II) ions produced the desired complexes in high yields, as has been described in the Experimental section.

The absorption spectra of three complexes [Co(dtc)$_{3-n}$(en)$_n$](ClO$_4$)$_n$(n=0, 1, and 2) in a DMSO solution are shown in Fig. 2. The energies of both the spin-allowed first (15000—20000 cm^{-1}) and second (20000—25000 cm^{-1}) d-d bands decrease with the increase in the number of dtc ligands. Such shifts correspond the weaker ligand field of the dtc sulfur donor than that of the en nitrogen one. The observed increase in the band intensity can be accounted for through the partial release of the Laporte forbidden d-d transitions by the mixing between the dπ(Co) and n(dtc) or π(dtc) and by the distortion from the octahedral-site structure around the central cobalt(III)

ion because of the 4-membered chelation of the dtc ligand. In the higher energy region (25000—35000 cm^{-1}), the energy of ligand-to-metal charge-transfer (LMCT) band, dσ*(Co)←σ(dtc), decreases and the band is split and widened with the increase of the number of the dtc ligands. These features may result from the increase in the sets of combination of the σ MOs of the dtc ligands.

The absorption, MCD, and CD spectra of the complex compound $(-)^{CD}_{500}$-$[Co(dtc)(en)_2](ClO_4)_2$, which has a *cis*-$[Co(S)_2(N)_4]$ chromophore, are shown in Fig. 3, while the numerical data are listed in Tables 7, 8, and 9. The weak shoulders in the absorption spectrum at ca. 12000 cm^{-1} and ca. 15000 cm^{-1} can be assigned to the spin-forbidden d-d transitions, $^3T_1$ and $^3T_2$←$^1A_1$ (O_h) respectively. In the MCD spectra, the negative peak at 11360 cm^{-1} and the pair of the negative peak at 13700 cm^{-1} and the positive one at 17000 cm^{-1} correspond to the transitions of $^3T_1$ (the first peak) and $^3T_2$ (the latter two peaks)←$^1A_1$(O_h). The absorption band at 19400 cm^{-1}, the negative CD peak at 18300 cm^{-1}, and the negative MCD at 19900 cm^{-1} are assigned to the spin-allowed first d-d transition of $^1T_1$←$^1A_1$ (O_h), and the absorption band at 23700 cm^{-1} the negative MCD peak at 23200 cm^{-1}, and the positive CD one at 24500 cm^{-1}, to the second d-d transition of $^1T_2$←$^1A_1$. The intense absorption bands at 34300 cm^{-1} and at 41000 cm^{-1} can be assigned to the LMCT band σ*(Co)←σ(dtc or sulfur) and the intra-

ligand transition π^*(dtc or delocalized MO on S_2NC fragment)←n(dtc) respectively.

Figure 4 shows the absorption and MCD spectra of $[Co(dtc)_2(en)]ClO_4$, which has a *cis*-$[Co(S)_4(N)_2]$ chromophore. The first eluted $(-)^{CD}_{580}$-$[Co(dtc)_2(R$-pn$)]ClO_4$, which shows a negative CD at 17000 cm^{-1}, is assigned to the Δ absolute configuration by analogy with the assignment for $[Co(dtc)(en)_2](ClO_4)_2$. The CD curve due to the configurational contribution was calculated from these CD spectra on the basis of the assumed additivity of the CD contributions. It is noteworthy that the CD intensities of the bis-

a) Wavenumbers are given in 10^{-1} cm^{-1} units, the $\Delta\varepsilon$ (in parentheses) are given in mol^{-1} dm^3 cm^{-1} units, and sh indicates a shoulder.

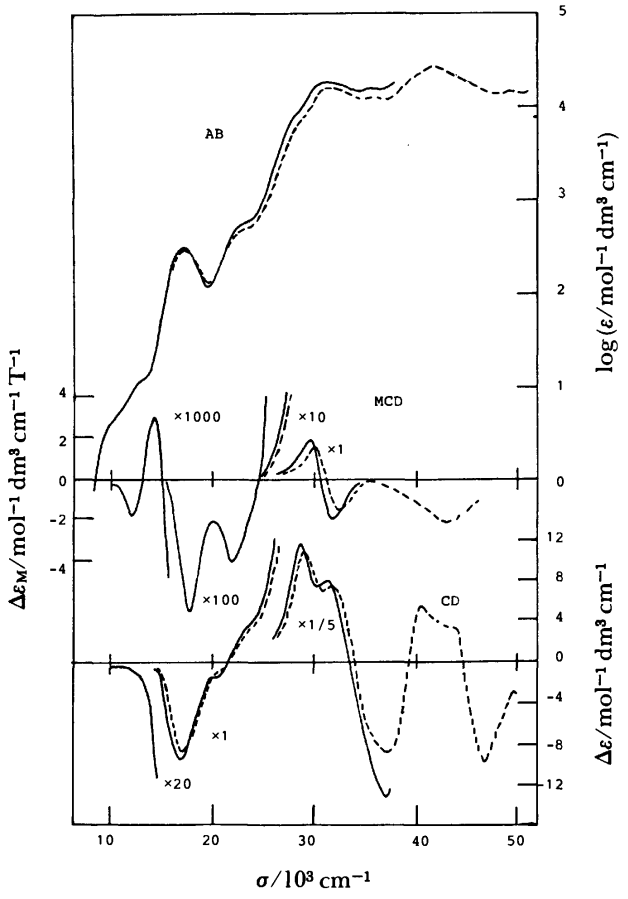

Fig. 4. Absorption and MCD spectra of [Co(dtc)$_2$(en)]-ClO$_4$, and CD curve of [(*Δ*-[Co(dtc)$_2$(*R*-pn)]ClO$_4$)−(*Λ*-[Co(dtc)$_2$(*R*-pn)]ClO$_4$)]/2 in DMSO (——) and H_2O (---) solutions.

(dithiocarbamate) complexes are about twice larger than that of the monodithiocarbamate one. This means the larger distortion from the octahedral-site structure is due to the increase in the numbers of the 4-membered dtc ligand. The shoulders of the absorption spectra at 10000 cm^{-1} and 13000 cm^{-1} are assigned to the spin-forbidden d–d transitions. A negative CD peak at 16900 cm^{-1} and a negative MCD peak at 17500 cm^{-1} are assigned to the splitting components of the first d–d transition. The two LMCT absorption bands at 27500 and 31300 cm^{-1} correspond to the two peaks of MCD at 29400 and 31700 cm^{-1} or to the two peaks of CD at 28700 and 31300 cm^{-1}. The absorption bands at 40000 and 41900 cm^{-1} are assigned to the dtc intraligand $\pi^*\leftarrow$n transitions. The vicinal contribution of asymmetric carbon or *R*-pn to the CD spectrum of [Co(dtc)$_2$(*R*-pn)]ClO$_4$ is shown in Table 9. It is interesting to note that the contribution depends significantly on the kind of solvent.

The absorption and MCD spectra of [Co(dtc)$_3$] with a [Co(S)$_6$] chromophore are shown in Tables 7 and 8. The absorption bands at 11200 and 12700 cm^{-1} are assigned to the spin-forbidden d–d transitions. The bands at 24100, 27200, and 29000 cm^{-1} are assigned to the LMCT transitions, and the band at 35900 cm^{-1}, to the dtc intraligand transitions. The positions of the absorption bands are the same as those of the MCD ones throughout the region observed.

The splitting components of the first d–d transition of the *cis*-S_2N_4- and *cis*-S_4N_2-type complexes were calculated semiempirically[21] on the basis of the observed d–d transition energies of [Co(en)$_3$]$^{3+}$ and

[Co(dtc)$_3$]. The calculated values are fairly consistent with the observed splittings: the energetically lower component corresponds to the CD peak, and the higher one, to the MCD extreme, as is shown in Table 10.

Synthesis and Characterization of the Oxidation Product [Co(dtsi)(en)$_2$](ClO$_4$)$_2$. The orange-red oxidation complex was prepared via the H_2O_2 oxidation of [Co(dtc)(en)$_2$](ClO$_4$)$_2$. The H_2O_2 oxidation of the coordinated dtc ligand in neutral aqueous solution was ineffective, but it was effective in acid media. Elemental analysis indicates that the calculated formula weight of the resulting species is consistent with two additional oxygen atoms compared with the starting material. Since it is reasonable to consider that the oxidation takes place at the sulfur moieties of the dtc ligand, there are two possibilities, $(CH_3)_2NC(SO)SO^-$ or $(CH_3)_2NC(S)SO_2^-$, as the oxidized dtc ligand. The XPS spectra of the [Co(dtc)(en)$_2$](ClO$_4$)$_2$ and [Co(dtsi)(en)$_2$](ClO$_4$)$_2$ are given in Fig. 5: they indicate the presence of two kinds of sulfur in the latter complex. The lower S-2p$_{3/2}$ binding energy (162.7 eV) in the dtsi complex is the same as that in the dtc complex. The higher peak (166.6 eV) is due to the oxidized sulfur atom with two oxygen atoms, for the S-2p$_{3/2}$ binding energy increases with the increase in

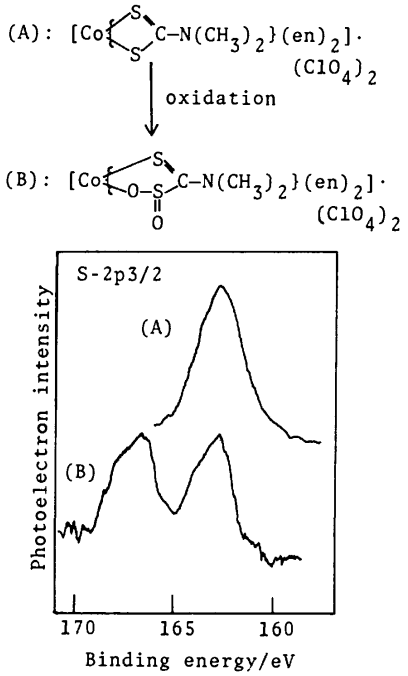

Fig. 5. XPS spectra of (A) [Co(dtc)(en)$_2$](ClO$_4$)$_2$ and (B) [Co(dtsi)(en)$_2$](ClO$_4$)$_2$ in the region of S-2p binding energy.

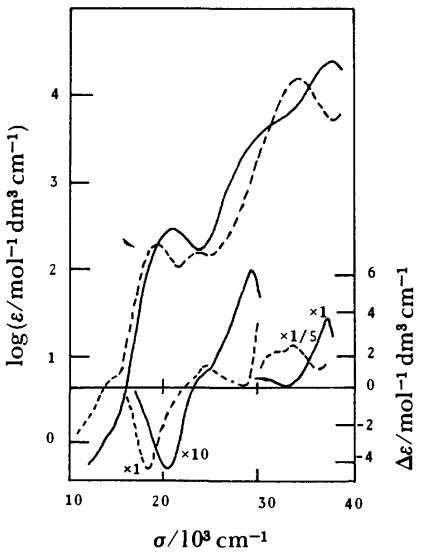

Fig. 6. Absorption and CD spectra of Δ-[Co(dtsi)(en)$_2$]-(ClO$_4$)$_2$ (——) and Δ-[Co(dtc)(en)$_2$](ClO$_4$)$_2$ (---) in DMSO solution.

the sulfur oxidation numbers.[22] Since the intensities of the lower and higher energy bands are approximately equal, the dtsi complex should have oxidized and nonoxidized sulfur atoms compared with those of the original dtc complex. Thus, the dtsi ligand is represented by this formula: $(CH_3)_2NC(S)SO_2^-$. The present dtsi complex exhibits a new absorption band at ca. 29000 cm^{-1} as a broad shoulder in addition to the $\sigma^*(Co)\leftarrow\sigma(S)$ LMCT band at 37000 cm^{-1}, as is shown in Fig. 6. The *O*-bonded sulfinato cobalt(III) complex, $[Co(NH_2CH_2CH_2SO_2\text{-}O,N)(en)_2]^{2+}$, shows a similar absorption band at 31000 cm^{-1} without the $\sigma^*(Co)\leftarrow\sigma(S)$ LMCT band.[5] This fact indicates that the dtsi ligand coordinates through the sulfinato oxygen and thiocarbonyl sulfur atoms. This indicates the occurrence of the chelate ring expansion from a four-membered ring to a five-membered one during the oxidation process. The optically active complex $(-)_{490}^{CD}$-$[Co(dtsi)(en)_2]^{2+}$ can be assigned to the *Δ*-configuration on the basis of the CD sign at 20400 cm^{-1} in the first d-d band region (Fig. 6). Therefore, the oxidation reaction proceeds with a retention of the initial configuration of *Δ*-$[Co(dtc)(en)_2]^{2+}$, whose configuration was determined by X-ray structure analysis as has been described in the preceding section.

^{125}Te and ^{129}I Mössbauer Spectroscopic Studies of the Tetragonal and Orthorhombic Forms of Tellurium(IV) Oxide

Hiroshi SAKAI* and Yutaka MAEDA
Research Reactor Institute, Kyoto University,
Kumatori-cho, Sennan-gun, Osaka 590-04
(Received May 11, 1988)

^{125}Te and ^{129}I Mössbauer spectra have been measured for the tetragonal (α) and orthorhombic (β) forms of TeO_2. The Mössbauer data show that there are no significant differences between the two modifications in either the electronic structure or the chemical bonding of the tellurium atoms; this is consistent with the crystallographic data. From a comparison of the Mössbauer data for ^{125}Te with those for ^{129}I, we have concluded that the ^{129}I daughter nucleus, produced by the nuclear β^- decay of ^{129}Te, is present in the same lattice environment as the parent ^{129}Te nucleus in TeO_2. A $Cu^{125}I$ crystalline compound has been used as the Mössbauer source of ^{125}Te, which emits a single line of resonance γ-ray. The values of the isomer shift and line width for the source are found to be -0.13 mm s^{-1} relative to the ZnTe standard absorber and 6.53 mm s^{-1} respectively.

Tellurium(IV) oxide (TeO_2) is known to have two crystalline forms, a colorless tetragonal (α) form and a yellow orthorhombic (β) form.[1] In both modifications the coordination about the tellurium atom is a slightly distorted trigonal bipyramid, with one corner of the equatorial triangle unoccupied. The four Te–O bond distances are 1.903 Å (equatorial) and 2.082 Å (axial) for the tetragonal form and from 1.88 to 2.19 Å for the orthorhombic form. These bond distances suggest a considerable covalent character of the Te–O bonds, since the sum of the covalent bond radius for each atom is 2.03 Å.[2] The surroundings of the Te sites (the bond distances and the bond angles) in the trigonal bipyramid are similar in the two modifications, although a weak Te–Te bond with the distance of 3.17 Å exists in the β-form. This fact suggests that there are no significant differences in the electronic structure and the chemical bonding of the Te atoms for the α- and β-forms. However, the results of ^{129}I Mössbauer emission investigations have exploded the expectations based on the coordination figures.[3,4] The isomer shift observed in the ^{129}I Mössbauer emission spectrum of the α-form is considerably larger than that in the β-form. Warren et al.[4] have concluded that the difference in the isomer shifts arises from differences in the s-character of the parent Te–O bonds is the two forms. If this conclusion is correct, a difference in the isomer shifts should be observed in the ^{125}Te Mössbauer absorption spectra for the two modifications.

In the present paper we wish to report our results on the ^{125}Te Mössbauer absorption spectra for the tetragonal (α) and orthorhombic (β) forms of TeO_2. Further, the ^{129}I Mössbauer emission spectra were measured for these compounds in order to compare their values with the previous data. Thus, the specimens were investigated both as absorbers and as sources.

Experimental

Materials. The commercially available TeO_2 (Wako Pure Chemical) was found by X-ray powder diffraction analysis using graphite monochromated Cu $K\alpha$ radiation to be the orthorhombic (β) phase. The tetragonal (α) form prepared by melt-quenching was also confirmed by X-ray diffraction. The diffraction patterns of the α- and β-forms are given in Fig. 1; they are in good agreement with the values in the literature (ASTM cards 1-0870, 1-0117).

Measurements. ^{125}Te Mössbauer Absorption Spectra: $Cu^{125}I$ crystalline powder, prepared from the standard form of $Na^{125}I$ in a 0.1 mol dm^{-3} NaOH solution (New England Nuclear Co.), was used as the Mössbauer source of ^{125}Te. The radioactive compound had first been used as the

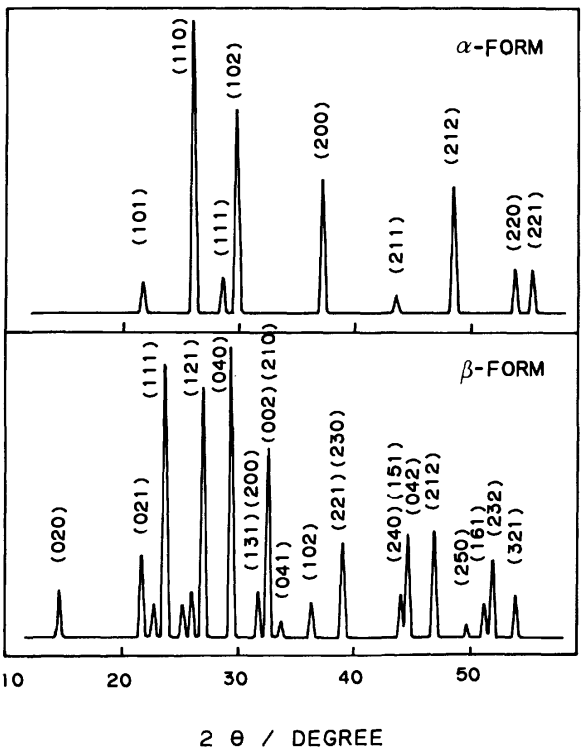

Fig. 1. X-Ray powder diffraction patterns of the tetragonal (α) and orthorhombic (β) forms of TeO_2 obtained by using graphiet monochromated Cu $K\alpha$ radiation.

γ-ray source for the ^{125}Te Mössbauer specitroscopy by Ambe and Ambe.[5] They found that the source emitted a single line of resonance γ-ray. In the present investigation, the source was also verified to be a single line from the spectra against a ZnTe absorber (2 mg cm^{-2} ^{125}Te) at 16 K and 77 K. The line width at half maximum was found to be 6.53 mm s^{-1} for the single absorption peak; this value was comparable to such other sources as ^{125}I or ^{125}Sb deposited on Cu foil and Zn^{125m}Te. The natural line width of ^{125}Te is calculated to be 5.20 mm s^{-1} from the lifetime of the 35.50 keV state. The Mössbauer spectra were measured in the transmission geometry by cooling the source and the absorber (each a modification of TeO_2; 3 mg cm^{-2} ^{125}Te) to 16 K by the use of a closed-cycle helium refrigerator. The 35.5 keV Mössbauer γ-ray was detected indirectly by counting the 5.8 keV escaped peak in a Xe-filled proportional counter. The velocity scale of the spectrometer was calibrated with a six-line spectrum of an Fe foil.

^{129}I Mössbauer Emission Spectra: About a 300-mg portion of each form of TeO_2 was used as a γ-ray source, irradiated at a thermal neutron-fluence rate of 2×10^{13} n cm^{-2} s^{-1} for 1 h in the Kyoto University Reactor (KUR). The Mössbauer experiments were performed with ^{129}I daughters produced by this nuclear reaction: ^{128}Te(n, γ) ^{129}Te$\xrightarrow{\beta^-}$ ^{129}I. The ^{128}Te abundance in natural tellurium is 31.8%, enough for it to serve as the source. A single line Cu^{129}I (10 mg cm^{-2} ^{129}I), used as a Mössbauer absorber, was prepared from Na^{129}I in a Na_2SO_3 solution in a manner similar to that used for Cu^{125}I. The absorber was checked, by means of a spectrum, against the standard ZnTe source at 16 K, in which the isomer shift and the line width were found to be -0.42 mm s^{-1} and 1.42 mms^{-1} respectively. Furthermore, the ^{129}I emission spectrum of the tellurium metal was measured at 16 K in order to calibrate the velocity scale of the spectrometer under the same experimental conditions; this was in addition to the measurement of the six-line spectrum of an Fe foil at room temperature. The Mössbauer measurements were carried out in the same way as those of ^{125}Te. The 27.8 keV γ-ray was detected by the use of a 1 mm-thick NaI(Tl) scintillation counter.

Results and Discussion

A. ^{125}Te Mössbauer Absorption Spectra. The ^{125}Te Mössbauer absorption spectra at 16 K of (a) ZnTe, (b) α-TeO_2, and (c) β-TeO_2 are shown in Fig. 2. The spectra were analyzed with Lorentzian curves by means of the least-squares method. The Mössbauer parameters, such as the isomer shift (δ) relative to the ZnTe standard absorber, the quadrupole splitting (2 ε), and the full width at half maximum (2Γ), are summarized in Table 1. Various δ values have been reported by different laboratories for the same Te compound, for example, TeO_2.[6] These discrepancies, as has been pointed out by Dobud and Jones,[7] seem to arise from the difficulties inherent in calibrating the spectrometer, for the ^{125}Te Mössbauer study requires a relatively high velocity region. Therefore, the standard Te compounds, such as Te metal and β-TeO_3, in addition to ZnTe, were measured under the same experimental conditions. The results are also given in Table 1, together with the δ values recommended by Stevens and Gettys.[8]

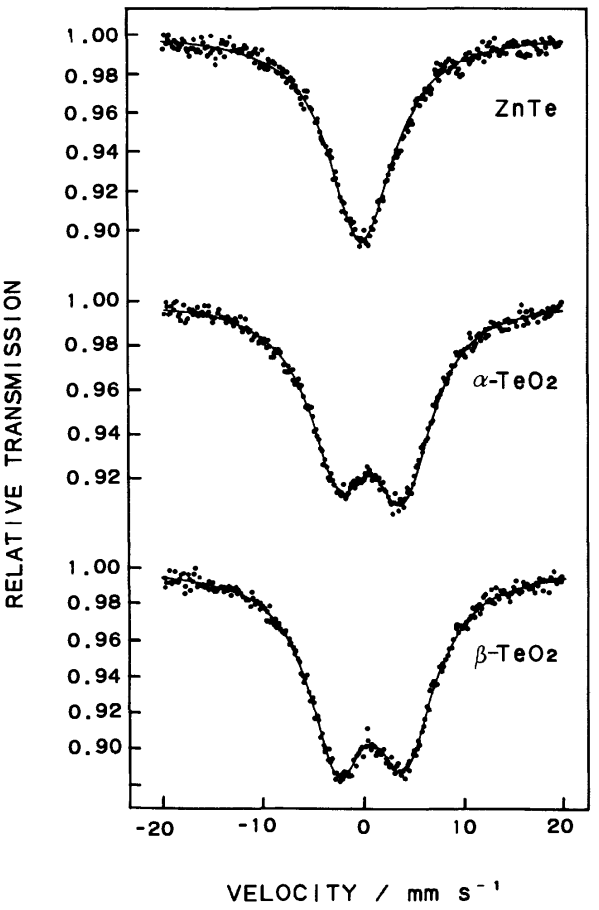

Fig. 2. ^{125}Te Mössbauer absorption spectra at 16 K of the ZnTe standard absorber, α-TeO_2, and β-TeO_2 against the Cu^{125}I source.

Table 1. ^{125}Te Mössbauer Parameters of α- and β-TeO_2, Te Metal, and β-TeO_3

	T	δ	2ε	2Γ
	K	mm s^{-1} ±0.08	mm s^{-1} ±0.08	mm s^{-1} ±0.10
α-TeO_2	16	0.73	6.48	7.25
β-TeO_2	16	0.70	6.80	7.10
Te metal	16	0.57 (0.66)	7.30	6.28
β-TeO_3	16	−1.11 (−1.11)	0	7.79
ZnTe	16	0	0	6.53

The δ values are relative to the ZnTe absorber. The δ values in parentheses are taken from Ref. 8.

The δ value of ZnTe against the Cu^{125}I source has been found to be +0.13 mm s^{-1}; this value is different from the recommended value (-0.02 mm s^{-1}) against the ^{125}I source deposited on a Cu foil.[8] The difference implies that the electronic structure of iodine in the CuI crystal is different from that in the Cu metal. As

will be shown below, the result we have obtained from the $Cu^{125}I$ source is reasonable, since the δ value of the $Cu^{129}I$ absorber against the $Zn^{129}Te$ source is about -0.4 mm s^{-1} in the ^{129}I Mössbauer study. It is of interest that the $Cu^{125}I$ source has given a single resonance line; that is, no anomalous charge state of ^{125}Te following the electron capture (EC) decay of ^{125}I has been observed for the spectrum. Violet and Booth[9] and Jung and Triftshäuser[10] observed four-line spectra for an $NaIO_3$ source. The latter authors concluded from the δ and 2ε values of two pairs of lines that the spectrum indicated the coexistence of Na_2TeO_3 and TeO_3, resulting from the K-capture decay of ^{125}I in $NaIO_3$ and the subsequent electron-rearrangements.

The ^{125}Te Mössbauer absorption spectra for the α- and β-forms of the TeO_2 crystal are similar to each other. The asymmetry in the spectrum of the α-form may be due to the preferred orientation of the specimen. The δ value of the α-form is in good agreement with that of the β-form, within the limits of experimental error. This result is apparently not in accord with that obtained from the ^{129}I Mössbauer emission spectra for both modifications. Warren et al.[4] have determined the isomer shift ratio, δ (^{125}Te)/ δ (^{129}I), for the ^{125}Te and ^{129}I nuclei in precisely the same lattices. They found this ratio to be $+0.29\pm0.03$ for several tellurium compounds. Therefore, if the ^{129}I resulting from the β^- decay of ^{129}Te finds itself in the same lattice environment as the parent TeO_2, the δ values relative to the ZnTe of the ^{129}I Mössbauer emission spectra should be observed to be about $+2.5$ mm s^{-1} for both modifications of the TeO_2 crystal, dividing the averaged δ value of ^{125}Te by 0.29. However, the δ values of ^{129}I for the α- and β-forms have been experimentally measured to be $+2.74\pm0.14$ mm s^{-1} and $+1.52\pm0.01$ mm s^{-1} respectively.[3,4] The deviation, in particular for the β-form, between the expected and measured δ values indicates that the resulting ^{129}I is no longer in the same lattice environment.

It is interesting to examine the δ value of the $Cu^{125}I$ source, for it is little used for ^{125}Te Mössbauer spectroscopy. The $Cu^{129}I$ absorber is often used for source experiments in the ^{129}I Mössbauer spetroscopy, and the δ value relative to the ZnTe source has been established as -0.41 mm s^{-1}.[11] Therefore, the δ value of the $Cu^{125}I$ source against the ZnTe absorber is estimated to be -0.12 mm s^{-1} from the isomer shift ratio for the ^{125}Te and ^{129}I nuclei; this value is in good agreement with the measured δ value (-0.13 mm s^{-1}). This implies that the ^{125}Te daughter nucleus, produced by the EC decay of ^{125}I, is present in the same lattice environment as the parent ^{125}I nucleus in the CuI crystal.

In the ^{125}Te Mössbauer absorption spectra, the quadrupole splitting $\{2\varepsilon=\frac{1}{2}e^2Qq(1+\frac{1}{3}\eta^2)^{1/2}\}$ of the α-form is slightly smaller than that of the β-form. This result also disagrees with that of the ^{129}I Mössbauer emission spectra, indicating that the quadrupole coupling constants (e^2Qq) for the α- and β-forms are $+812\pm21$ MHz and $+786\pm7$ MHz respectively.[3,4] Warren et al.[4] have determined the ratio of the quadrupole coupling constansts for ^{125}Te and ^{129}I nuclei, as well as the isomer shift ratio, in equivalent lattice sites as follows:

$$\frac{e^2Qq(^{125}\mathrm{Te})}{e^2Qq(^{129}\mathrm{I})}\left(1+\frac{1}{3}\eta^2\right)^{1/2}=0.45. \quad (1)$$

Langouche et al.[12] have also determined this ratio to be -0.48 ± 0.02 by means of a detailed examination of the ^{129}I and ^{125}Te Mössbauer spectra for several Te-thiourea compounds. Using this ratio and our result for 2ε of ^{125}Te, we can derive the e^2Qq values of ^{129}I for the α- and β-forms to be 773 MHz and 810 MHz respectively. The agreement between the measured and estimated e^2Qq values is insufficient.

It is important to note that in the ^{129}I Mössbauer emission measurements discrepancies in the values of δ and e^2Qq are often observed for an identical compound. For example, the δ and e^2Qq values for the tellurium metal have been reported to be $+0.71\pm0.03$ mm s^{-1} and -373 ± 6 MHz respectively by Pasternak and Bukshpan,[3] whereas they have been reported to be $+0.52\pm0.13$ mm s^{-1} and -349 ± 11 MHz respectively by Warren et al.[4] The values of δ and e^2Qq obtained in the present work are $+0.69\pm0.05$ mm s^{-1} and -403 ± 10 MHz respectively, values which are in good agreement with those of the more recent works of Langouche et al.[13] ($\delta=+0.77\pm0.04$ mm s^{-1}, $e^2Qq=-404\pm4$ MHz) and Kim and Boolchand[14] ($\delta=+0.80\pm0.03$ mm s^{-1}, $e^2Qq=-396\pm3$ MHz). Therefore, it is dangerous to conclude that the minor discrepancies in the reported and estimated δ and e^2Qq values for the two modifications of TeO_2 are to be attributed to the chemical effects accompanying the nuclear reaction and the β^- decay of the ^{129}Te nucleus.

B. ^{129}I Mössbauer Emission Spectra. ^{129}I Mössbauer emission spectra have been reinvestigated for both modifications of TeO_2 at 16 K, in order to examine in detail the chemical effects on the ^{128}Te (n, γ) ^{129}Te nuclear reaction and the β^- decay of the ^{129}Te and, furthermore, to clarify the origin of the large difference in the δ values of ^{129}I between the α- and β-forms previously reported. The spectra against the $Cu^{129}I$ standard absorber are shown in Fig. 3 (b) and (c); no anomalous peak is observed. These spectra were analyzed by the least-squares method using a single set of fitting parameters, δ, e^2Qq, the asymmetry parameter (η), the full width at half maximum (2Γ), each peak intensity, and the base line. The solid lines in the figures represent the best-fitting Lorentzian curves. The Mössbauer parameters obtained are given in Table

a) The δ values are relative to the ZnTe source.

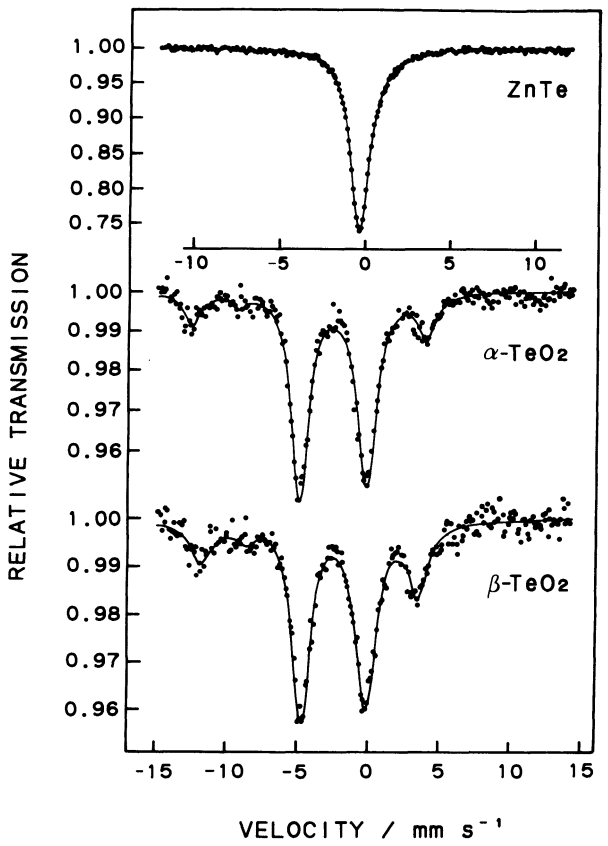

Fig. 3. ^{129}I Mössbauer emission spectra at 16 K of the ZnTe standard source, α-TeO_2, and β-TeO_2 against the $Cu^{129}I$ absorber.

2, together with the data of the previous works.[3,4] For the β-form of TeO_2, the measurements were independently carried out twice because of the large difference in the δ value between the previous data[3] and our data. The δ values are relative to a $Zn^{129}Te$ source, subtracting 0.42 mm s^{-1} (δ value for $Cu^{129}I$) from the actual δ values observed for the emission spectra.

The spectra observed in the present work are similar to the previously reported spectra independently measured by Pasternak and Bukshpan[3] and by Warren et al.[4] The values of e^2Qq and η for both modifications of TeO_2 are in good agreement with those reported by them, as may be seen in Table 2. However, the δ values, being close to each other for both modifications in this work, are different, especially for the β-form, from the previous data. The origin of the differences in the δ values is not clear. The differences might be attributable to the deviations between the ^{129}I spectra and ^{57}Fe calibrating spectra, since, in the ^{129}I Mössbauer measurements, the driving γ-ray source must be cooled in the cryostat, while the measurements of the ^{57}Fe calibrations are not accompanied by any such difficulty. One of the results obtained in the present investigation is that there are almost no differences in the δ values of ^{129}I for the α- and β-forms of TeO_2; this finding is consistent with that of the ^{125}Te absorption spectra. The isomer shift ratios of the ^{125}Te and ^{129}I nuclei are found to be 0.30 for both modifications of TeO_2. This value is very close to that to be expected when the ^{129}I daughter nucleus is present in the lattice site equivalent to the parent ^{129}Te site. On the other hand, the ratios of the quadrupole coupling constants of the ^{125}Te and ^{129}I nuclei are observed to be 0.46 for the α-form and 0.49 for the β-form. These values are in agreement with the value reported by Langouche et al.,[12] within the limits of experimental error of the ^{125}Te and ^{129}I Mössbauer measurements. Therefore, we have concluded, from a comparison of the values of δ and e^2Qq for ^{129}I with those for ^{125}Te, that the ^{129}I daughter nuclei, produced as a consequence of the nuclear β^- decay of ^{129}Te, are present in the same lattice environment as the parent ^{129}Te nuclei in both modifications of TeO_2.

C. Electronic Structures and Chemical Bondings. It is also of interest to consider the electronic structure and the chemical bonding of the tellurium atoms in the two forms of TeO_2. The tellurium atoms are present in a slightly distorted trigonal bipyramidal environment, and the Te–O bonds are predominantly covalent in character, judging from a consideration of the bond lengths. These crystallographic results

suggest that the bonding of the tellurium is characterized by sp^2 hybridization in the equatorial plane and by pd hybridization in the axial direction. Since, however, the $\angle$O-Te-O angles in the equatorial plane are 101°—102° for both modifications, the lone pair occupying one corner of the equatorial triangle may have significantly more s-character than that required in pure sp^2 hybridization. The contribution of the s-character to the bonding can be evaluated from the isomer shift (δ). The δ value reflects the s-electron density at the nucleus, $|\Psi_s(0)|^2$. Since the nuclear radius term $\Delta R/R$ is positive in sign for ^{125}Te, an increase in the s-electron density should lead to a more positive δ value. The 5s-electron density is shielded by outer 5p-electrons, therefore, δ is also dependent on the 5p-electron density. The removal of 5p-electrons of the tellurium atom in bonding will lead to an increase in the δ value, while the contribution of the 5s-electron to the bonding orbitals will directly decrease the δ value. These effects may be expressed quantitatively as follows:[15]

$$\delta = -2.6\,h_s + 0.44\,h_p - 0.16 \quad (2)$$
(mm s^{-1} for ZnTe reference material),

where h_s and h_p are the numbers of 5s- and 5p-electron holes respectively in the closed Te^{2-} configuration. The equation is obtained by multiplying the empirical formula of the ^{129}I Mössbauer isomer shift by 0.29, the isomer shift ratio, $\delta(^{125}Te)/\delta(^{129}I)$, described above.

The δ values observed for the two forms of TeO_2, smaller than those of the other Te(IV) compounds,[6] suggest that the s-electrons of the Te atoms take part in the bonding to some extent and that the Te-O bonds have a highly covalent character. Unfortunately, it is impossible to estimate independently the contribution of 5s-electrons to the bonding and the extent of the covalent character of the Te-O bonds. Dobud and Jones[7] have estimated the s-character in the bond to be about 9% for α-TeO_2, assuming that, in the absence of a 5s character, TeO_2 would have the same δ value as $TeCl_6^{2-}$ (+1.7 mm s^{-1}). The estimation has led to $5s^{1.6}$ $5p^{1.9}$ for the electronic configuration of the Te atom, i.e., an effective charge of +2.5 on the Te atom. It is thought that this estimated charge of +2.5 is the upper limit of the effective charge localized on the Te atom in the α-TeO_2, because the Te-O bonds would be expected, considering the Te-O and Te-Cl bond distances, to have a more covalent character than the Te-Cl bonds in $TeCl_6^{2-}$. The covalent character of the Te-Cl bond in $(NH_4)_2TeCl_6$ has been estimated to be 0.32 from the ^{35}Cl NQR measurements.[16] For the Te-O bonds in TeO_2 the covalent character would be larger.

It is important to assign the configuration of the iodine produced in α- and β-TeO_2 in order to examine the influence of the nuclear β^- decay of ^{129}Te. Since

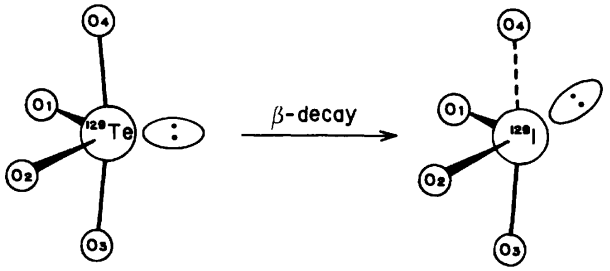

Fig. 4. Bonding configuration of the ^{129}I daughter atom produced by nuclear β^- decay of the ^{129}Te parent atom in TeO_2.

there are almost no differences in the values of δ, e^2Qq, and η between the two modifications, as has been described above, the resulting iodine species may be regarded to be identical. The values of δ, e^2Qq, and η observed for the iodine species in TeO_2 are very close to those for one iodine site (IO_3^-) in the I_2O_4 compound, consisting of two inequivalent iodine sites, IO^+ and IO_3^-.[17,18] The crystal structure of the I_2O_4 compound has not yet been established, but the IO_3^- part is believed to be similar to the configuration of HIO_3, judging from the similarity in the values of e^2Qq and η.[17] Therefore, we may infer that the iodine formed in TeO_2 is situated at a vertex of a distorted trigonal pyramid and that it has three nearest oxygen neighbors at an average distance of about 1.9 Å. The mean interbond angle O-I-O would be close to that of HIO_3 (98°). The formation of such an iodine species in the TeO_2 crystal can be understood as follows: one of the two axial Te-O bonds is severed by the β^- decay of ^{129}Te and subsequent electron rearrangements [see Fig. 4]. Such a process was also observed for the tellurium metal and tellurium atoms doped in the other elemental chalcogen hosts, in which the twofold coordination of tellurium involving π-bonding orbitals with two chalcogens-near-neighbors transforms into a nearly onefold coordination of iodine involving σ-bonding orbitals with a chalcogen-neighbor.[14]

In conclusion, the similarities between the Mössbauer spectra of the tetragonal (α) and orthorhombic (β) forms of TeO_2 indicate that there are no significant differences in the electronic structure and the chemical bonding of the tellurium atoms in the two modifications. In addition, the comparison of the Mössbauer data for ^{125}Te with those for ^{129}I indicates that the ^{129}I daughter nucleus, produced by the nuclear β^- decay of ^{129}Te, is present in the same lattice environment as the parent ^{129}Te nucleus in TeO_2.

We wish to thank Professor Sumio Ichiba and Dr. Kōji Yamada (Department of Chemistry, Hiroshima University) for the X-ray diffraction analysis. We are also grateful to Professor Takenobu Higashimura (Research Reactor Institute, Kyoto University) for his

useful discussions and encouragement. This work is partly supported by a Grant-in-Aid from the Ministry of Education (No. 62540330).

Solvent Effects on the Formation of Copper(II) Chloro Complexes in Acetonitrile-Dimethyl Sulfoxide Mixtures

Shin-ichi ISHIGURO,* Honoh SUZUKI, Bojana G. JELIAZKOVA,† and Hitoshi OHTAKI††
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227
††Coordination Chemistry Laboratories, Institute for Molecular Science, Myodaiji, Okazaki 444
(Received May 26, 1988)

Complexation of copper(II) with chloride ions has been calorimetrically and spectrophotometrically studied in various acetonitrile (AN)-dimethyl sulfoxide (DMSO) mixtures at 25 °C. Complexation of copper(II) ion with DMSO as a ligand in AN has also been investigated calorimetrically. It is indicated that the solvent effect on the thermodynamic parameters of the complexation is dominated by two factors, (1) the preferential solvation of copper(II) ion with DMSO that mainly affects the enthalpies, and (2) the change in solvent-solvent interactions in the bulk that strongly affects the corresponding entropies.

Complexation of copper(II) with chloride ions is enhanced in *N,N*-dimethylformamide (DMF),[1] dimethyl sulfoxide (DMSO)[2] and acetonitrile (AN)[3] over water, although the donicity of DMF or DMSO is stronger than that of water,[4] i.e. an energy to break copper(II)-solvent bonds is larger in DMSO or DMF than in water. The enhanced complexation in these aprotic solvents is generally due to large and positive entropies, in contrast to small or even negative entropies in water. It is also found that the difference in the complexation of copper(II) with chloride ions is significant even in these aprotic donor solvents. Although the donicities of DMSO and DMF are not largely different, the complexation of copper(II) ions is weaker in the former solvent than in the latter. The difference is also mainly ascribed to the entropies. These facts suggest that the solvent-solvent interaction in the bulk solvent molecules plays an important role for the complexation, as the entropy difference may reflect that solvent molecules coordinating to metal and ligand ions are liberated and enter the bulk solvent of different structures.[5]

In order to throw more light on the role of solvent structure in the bulk for complexation reactions, we have examined the complexation in AN-DMF mixtures.[6] Both AN and DMF solvents have so weak solvent-solvent interactions that they distribute practically at random in the liquid phase.[7] In contrast to DMF, DMSO is a strongly self-associated donor solvent in the liquid at room temperature.[8-10] Then, in this work we further investigated the complex formation of the same copper(II)-chloride system in AN-DMSO mixtures. The complexation of copper(II) ion with DMSO as a ligand in AN was also explored to elucidate preferential solvation of copper(II) ion with DMSO molecules in the mixtures.

Experimental

Reagents. All chemicals used were of reagent grade and were prepared or purified as described previously.[1-3]

Measurements. Calorimetric measurements were carried out in a room thermostated at 25±0.5 °C by using a computer assisted titration calorimetry system. In the copper(II) chloride system, acetonitrile-dimethyl sulfoxide mixtures of 0.05 and 0.1 mole fraction DMSO were used as solvents. The ionic strength of test solutions was kept constant at 0.2 mol dm^{-3} by using $(C_2H_5)_4NClO_4$ throughout measurements. A copper(II) perchlorate solution (100 cm^3) was placed in a Dewar vessel kept at 25.0±0.0001 °C, filled with dry nitrogen gas and isolated from moisture with a P_2O_5 drying-tube, and was titrated with a 0.2 mol dm^{-3} $(C_2H_5)_4NCl$ solution. The concentration of copper(II) ions in the initial test solution was varied over the range 10—30 mmol dm^{-3} in the mixtures. In the copper(II) DMSO system, an AN solution of copper(II) perchlorate (50 cm^3) was titrated with DMSO (0.5 mol dm^{-3}) in AN in which the ionic strength was kept at 0.1 mol dm^{-3} with $(C_2H_5)_4NClO_4$. In both systems, heats observed at each titration point were corrected for heat of dilution of the titrant, which had been determined by separate experiments and found to be very small in all the solutions examined.

Heats of solution of anhydrous $CuCl_2$ crystals were measured in the AN-DMSO mixtures of the same composition as that used for titration calorimetry. Details of the measurements were described elsewhere.[3]

Electronic spectra were measured with an MPS-2000 spectrophotometer (Shimadzu) equipped with a PC-9801 VM computer (NEC) which recorded data at 1 nm intervals over the wavelength range 250—500 nm. A flow-cell with the pathlength of 0.5 cm was connected with a titration vessel through Teflon and glass tubes. A copper(II) perchlorate solution (20 cm^3) was placed in the vessel under a dry nitrogen atmosphere and was titrated with a 0.2 mol dm^{-3} $(C_2H_5)_4NCl$ solution. The measurements were carried out in AN-DMSO mixtures of 0.025, 0.05, 0.10, and 0.5 mole fraction DMSO. Absorbance data at selected 50 wavelengths over the range 250—500 nm were used for a least-squares calculation of formation constants.

Data Analysis. Calorimetric and spectrophotometric data obtained were analyzed by the same method described

previously.[11]

Results and Discussion

Copper(II) Chloride Complexes. Calorimetric titration curves obtained in AN-DMSO mixtures of 0.05 and 0.1 mole fraction DMSO are depicted in Fig. 1. As the heat of reaction q at each titration point depends on the volume of an aliquot of the titrant added δv and the concentration of ligand ions in the titrant $C_{X,tit}$, the $-q/(\delta v C_{X,tit})$ values are plotted against the ratio of the total concentrations of the ligand to the metal ion in solution C_X/C_M. The titration curves are well explained in terms of the formation of mononuclear $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes in these mixtures, as well as in pure DMSO[2] and AN.[3] In Table 1 their formation constants and enthalpies simultaneously determined are summarized. The solid lines in Fig. 1 are calculated by using the constants in relevant mixtures in Table 1 and they well reproduce the experimental points over the whole range of C_X/C_M examined.

In Fig. 2 are shown typical electronic spectra measured in the AN-DMSO mixture of 0.025 mole fraction DMSO. The spectral changes with the concentration of chloride ions in the solution are similar in all the AN-DMSO mixtures examined.

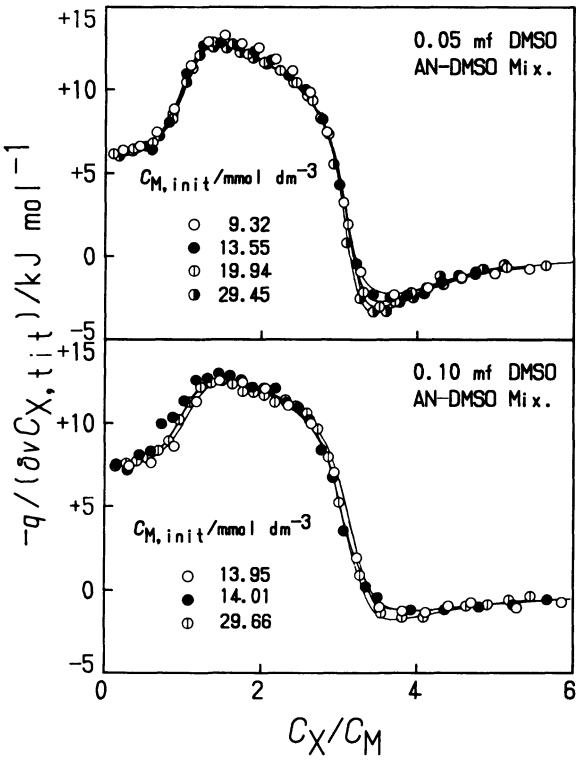

Fig. 1. Calorimetric titration curves for the copper(II) chloride system obtained in AN-DMSO mixtures at 25°C. Concentrations of copper(II) ions in the initial solutions $C_{M,init}$/mmol dm^{-3} are given. The solid lines show the curves calculated by using the constants in Table 1.

According to the analysis by the matrix rank method,[12] the number of species formed is five including the solvated copper(II) ion, each having appreciably different electronic spectra. The absorbance data are in fact satisfactorily explained in terms of the formation of $[CuCl_n]^{(2-n)+}$ (n=1—4) and their

formation constants were determined. The result is summarized in Table 2. The formation constants thus obtained by spectrophotometry in the 0.05 and 0.1 mole fraction DMSO mixtures are reasonably agreed with the respective values obtained by calorimetry in these solvents. The distribution of the species in these solutions, together with that in pure AN and DMSO, is shown in Fig. 3.

Extracted electronic spectra of the individual $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes are depicted in Fig. 4. The electronic spectra of each species in all the AN-DMSO mixtures examined are practically the same as those in DMSO[2] and in DMF.[1] In DMF the structure of the distorted octahedral $[CuCl(dmf)_5]^+$ and the distorted tetrahedral $[CuCl_3(dmf)]^-$ and $[CuCl_4]^{2-}$ complexes has been determined by X-ray diffraction.[13] It is therefore expected that the corresponding chloro complexes of copper(II) ion in DMSO and in the AN-DMSO mixtures have essentially the same coordination structures as those in DMF.

Copper(II) DMSO Complexes. Calorimetric titration curves obtained by titrating copper(II) perchlorate with DMSO in AN are depicted in Fig. 5, in which the values $-q/(\delta v C_{L,tit})$ are plotted against C_L/C_M, where L denotes DMSO. The calorimetric data were

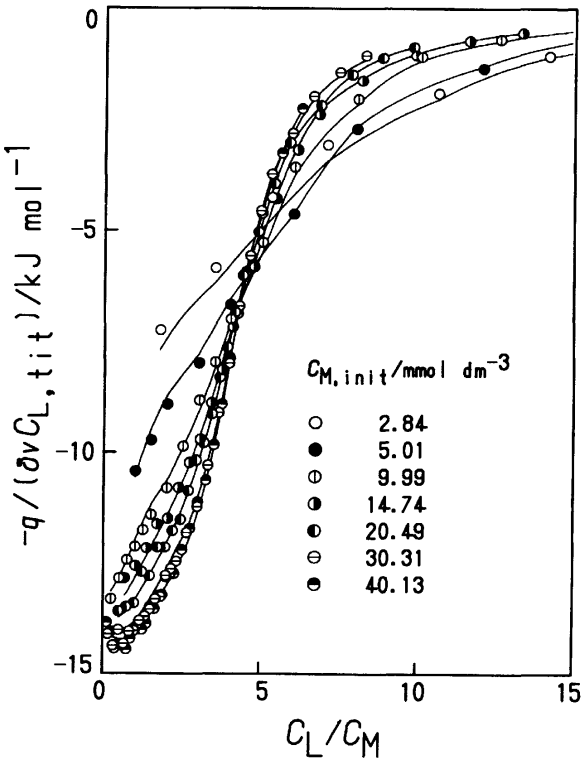

Fig. 5. Calorimetric titration curves for the copper(II) DMSO system in AN at 25 °C. Concentrations of copper(II) ions in the initial solutions $C_{M,init}$/mmol dm^{-3} are given. The solid lines show the curves calculated by using the constants for the set (1—6) in Table 3.

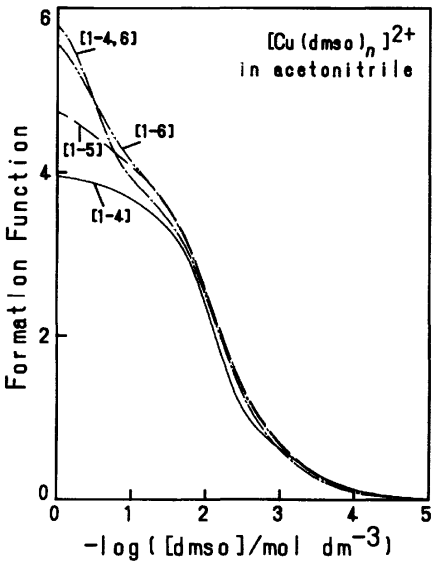

Fig. 6. Formation functions of $[Cu(dmso)_n]^{2+}$ for the various combinations of n's.

analyzed by assuming the formation of $[Cu(dmso)_n]^{2+}$ ($n \leqq 6$) complexes with various combinations of n's. The results of the least-squares analysis are summarized in Table 3. The Hamilton R factor for the set (1—4) assuming $[Cu(dmso)]^{2+}$, $[Cu(dmso)_2]^{2+}$, $[Cu(dmso)_3]^{2+}$ and $[Cu(dmso)_4]^{2+}$ only is appreciably larger than the values for the sets (1—5), (1—6) and (1—4,6). This evidently indicates that not only $[Cu(dmso)_n]^{2+}$ (n=1—4) but also higher species, $[Cu(dmso)_5]^{2+}$ and/or $[Cu(dmso)_6]^{2+}$, are formed in the solutions examined. The formation functions $\bar{n}$ calculated according to Eq. 1

$$\bar{n} = \Sigma n\beta_n[\text{dmso}]^n / (1 + \Sigma\beta_n[\text{dmso}]^n) \quad (1)$$

are shown in Fig. 6. The highest $\bar{n}$ reached in the present measurements is ca. 4.5, i.e., the formation of $[Cu(dmso)_5]^{2+}$ and/or $[Cu(dmso)_6]^{2+}$ is not extensive. In addition, the $\bar{n}$ curves for these sets are similar in the range $-\log([\text{dmso}]/\text{mol dm}^{-3}) > 1$, and thus it is hard to draw a unique conclusion for the formation of the pentakis- and/or hexakis(dimethyl sulfoxide) copper(II) complexes under the experimental conditions employed.

Enthalpies of Solution of Anhydrous $CuCl_2$ Crystal. By using the procedure described previously,[3] the enthalpies of solution for the following processes

$$CuCl_2(c) = Cu^{2+}(s) + 2Cl^-(s);\ \Delta H_s^\circ(Cu^{2+}, 2Cl^-) \quad (2)$$
$$CuCl_2(c) = [CuCl_2](s);\ \Delta H_s^\circ(CuCl_2) \quad (3)$$

where c and s stand for the crystalline and solution states, respectively, were determined in the AN–DMSO mixtures of 0.05 and 0.1 mole fraction DMSO. The result is given in Table 4. The $\Delta H_s^\circ(Cu^{2+}, 2Cl^-)$ values in the mixtures are significantly more negative than the value in AN, the fact also indicating that copper(II) ion is preferentially solvated with DMSO even in AN rich AN–DMSO mixtures. A similar trend, though much less marked, was found for the $\Delta H_s^\circ(CuCl_2)$ values.

Solvent Effects on the Formation of $[CuCl_4]^{2-}$. As seen in Table 5, the overall Gibbs energy value $\Delta G_{\beta 4}^\circ$ becomes less negative with an increase in the mole fraction of DMSO in the AN–DMSO mixtures. The $\Delta H_{\beta 4}^\circ$ value in any mixture is close to that in DMSO, but largely different from that in AN. The difference may be due to the preferential solvation of copper(II) ion with DMSO in the mixtures, i.e., an energy is needed to break Cu(II)–dmso bonds in the course of the reaction

$$[Cu(dmso)_6]^{2+} + 4Cl^- = [CuCl_4]^{2-} + 6dmso \quad (4)$$

in the mixtures. The values of $(\Delta H_{\beta 4}^\circ(AN) - \Delta H_{\beta 4}^\circ(mix))$ are −78.9 and −81.1 kJ mol^{-1} in the mixtures of 0.05 and 0.1 mole fraction DMSO, respectively, which are in fact close to the enthalpy of formation of $[Cu(dmso)_n]^{2+}$ (n=5 or 6) in AN. The result also implies that the solvation enthalpy of chloride ion may not be appreciably different in AN, DMSO, and their mixtures, as expected from the similar acceptor property of the solvents (the acceptor numbers are 19.3 for both DMSO and AN),[4] and the small enthalpy of transfer of chloride ion from AN to DMSO (−1.7 kJ mol^{-1}).[14]

It is known that DMSO molecules are associated in the liquid state at room temperature.[8–10] This is due to interactions between exposed dipoles at the molecular surface of DMSO[8] in contrast to embedded dipoles of AN, although these solvent molecules have similar dipole moments (μ_{AN}=12.9×10^{-30} C m, μ_{DMSO}=13×10^{-30} C m). A smaller molecular weight, or in other words, a smaller dispersion force, of AN than DMSO may also contribute to a weaker intermolecular interaction of the former. Donor–acceptor interactions between molecules may also be weaker in AN (the donor number D_N=14.1 and the acceptor number A_N=19.3) than in DMSO (D_N=29.8 and A_N=19.3). Consequently, AN is an unordered solvent with respect to pure DMSO. Dilute AN solutions of DMSO may be also unordered, i.e., DMSO–DMSO interactions are practically broken.

DMSO molecules solvate preferentially copper(II) ion to form $[Cu(dmso)_6]^{2+}$ in the AN–DMSO mixtures. The solvent molecules are liberated in the course of the complexation and enter the bulk solvent. As seen in Table 5 the $\Delta S_{\beta 4}^\circ$ values are all large and positive but significantly different. In AN, solvent molecules leave a relatively weak solvate structure for an unordered solvent, $\Delta S_{\beta 4}^\circ$ relatively low; in AN–DMSO mixtures, DMSO molecules leave a strong solvate structure for an unordered solvent, $\Delta S_{\beta 4}^\circ$ much larger; in DMSO, solvent molecules leave a strong solvate for an ordered solvent, again a low value of $\Delta S_{\beta 4}^\circ$, even lower than in AN. Thus, both solvate and solvent structures are responsible for the entropies of complexation.

Liberation of solvent molecules solvating chloride ion also occurs in the course of the complexation. However, the contribution of desolvation of chloride ion to the $\Delta S_{\beta 4}^\circ$ values may be small because of weak solvation of the ion in AN, DMSO, and their mixtures, as noted in a previous section.

The present work has been financially supported by Grant-in-Aid for Special Project Research No. 61134043 from the Ministry of Education, Science and Culture.

Aggregation of Complexes Coordinated with *N,N'*-Bis(5-alkylsalicylidene)-ethylenediamine: ^{1}H NMR Peak Shifts and Paramagnetic Broadening Investigations

Kazuo MIYAMURA,* Keiki SATOH, and Yohichi GOHSHI
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received May 27, 1988)

Nickel(II) complexes coordinated with *N,N'*-disalicylideneethylenediamine (salen) substituted by a series of *n*-alkyl side chains have been synthesized. Drastic improvement in the solubility towards chloroform brought about by the increase in alkyl side chain lengths realised an extremely high concentration of 0.5 mol·dm^{-3}. Due to aggregation, their ^{1}H NMR spectra in $CDCl_3$ were strongly dependent on the concentration especially in the high concentration region. The alkyl chain length has very little influence on the dependency, indicating that the aggregation is caused by the complex–complex interaction rather than by the hydrophobic interaction between the alkyl side chains. Assuming a monomer–dimer equilibrium, the aggregation constant is determined from the concentration dependence. Further, the structure of the aggregate is estimated by combining the results of the concentration dependence, and the paramagnetic broadening caused by adding the corresponding copper(II) complex. The paramagnetic broadening investigation also indicated a close contact of copper(II) complex to nickel(II) complex.

The importance of aggregation in the field of coordination chemistry has been recognized recently from the studies on chlorophylls,[1–4] vesicles,[5,6] and others.[7–9] In particular, the intensive studies on the chlorophyll aggregate suggested it has different properties from the monomeric species. This is effectively used in photosynthesis.[2] It can be said that the aggregation of the chlorophyll molecules alters their photochemical properties. It is also well-known that some properties in highly dense solutions are not the mere extrapolation of those in thin solutions. It is the phenomenon of aggregation that is responsible for these changes. The changes accompanying the aggregation phenomenon, which in many cases have been treated as experimental errors, are now under investigation and have increasing importance.

Complexes of *N,N'*-disalicylideneethylenediamine, usually abbreviated as salen, are known to form dimers in the crystalline state.[10,11] They have been studied extensively because of some interesting properties which they exhibit. For example, cobalt(II) complex of salen coordinates a dioxygen molecule reversibly similar to that observed for hemoglobin.[12] The chemistry of salen is interesting not only because of its porphyrin-like nature, but also for the simplicity in its synthesis. Thus, it is relevant to examine the aggregating nature of salen complexes, and to investigate the property changes due to the aggregation.

However, a problem arises in studying the aggregation of salen complexes because of their low solubilities. Generally, the phenomenon of aggregation becomes conspicuous in the high concentration region, because high concentration creates extra occasions for solute molecules to meet and aggregate. However, at high concentrations, precipitation tends to occur as a result of molecular aggregation, and this interferes with the investigation of aggregation in solution. Thus it is important to increase the solubility of the solute to investigate the phenomenon of aggregation. The introduction of alkyl chains causes an increase in their solubility towards organic solvents, such as chloroform, consequently providing us an opportunity to investigate their behaviour in the high concentration region.[13]

In a previous letter,[14] we have reported briefly that the chloroform-*d* solution of salen type complexes, substituted by hexyl groups, exhibit concentration dependence in ^{1}H NMR due to aggregation. Such a phenomenon is not observed for the unsubstituted complex because of its low solubility. In this paper, the equilibrium of aggregation and the aggregating structure are discussed, together with the experimental procedures.

Experimental

5-Alkylsalicylaldehydes (alkyl=ethyl, butyl, hexyl, octyl) were synthesized by the Reimer-Tiemann reaction[15] from the corresponding commercially available (Kantoh Chemical Co.) *p*-alkylphenols. 5-Dodecyl-and 5-decylsalicyclaldehydes were synthesized by the same procedure from the corresponding *p*-alkylphenols obtained by ordinary Friedel-Crafts acylation and Clemmensen reduction from phenol and the corresponding alkanoyl chlorides, the procedure for which is given elsewhere.[16] All other reagents used were commercially available and were of reagent grade.

[*N,N'*-Bis(5-hexylsalicylidene)ethylenediaminato]nickel(II) [Ni(1-6)]. Nickel acetate tetrahydrate (0.50 g, 2 mmol) and ethylenediamine (0.12 g, 2 mmol) were added to 100 cm^3 of ethanol in a 200 cm^3 flask with stirring. After the mixture had become a clear blue solution, 5-hexylsalicylaldehyde (0.83 g, 4 mmol) was added drop by drop to the solution. The reaction mixture was then refluxed for 3 h. The precipitate formed was filtered and recrystallized from chloroform-ethanol mixed solvents. The yield was 0.7 g

(71%)

Found: C, 68.15; H, 7.75; N, 5.90%. Calcd for $C_{28}H_{38}N_2NiO_2$: C, 68.15; H, 7.75; N, 5.70%. ^{1}H NMR ($CDCl_3$) δ=0.87 (3H, t, J=6.9 Hz, CH_3CH_2-) 1.28 (10H, m), 1.52 (2H, t, J=6.9 Hz, benzyl-CH_2), 3.41 (2H, s, H_c), 6.74 (1H, d, J=2.1 Hz, H_c), 6.93 (1H, d, J=8.9 Hz, H_a), 7.02 (1H, dd, J=2.2 and 8.7 Hz, H_b), 7.33 (1H, s, H_d).

Other [*N,N'*-Bis(5-alkylsalicyclidene)ethylenediaminato]-nickel(II) [Ni(1-*n*)](*n*=2,4,8,10,12). A series of [*N,N'*-bis(5-alkylsalicylidene)ethylenediaminato]nickel(II) (alkyl=ethyl, butyl, octyl, decyl, dodecyl) were obtained from the corresponding 5-alkylsalicylaldehydes by a similar procedure to [*N,N'*-bis-(5-hexylsalicylidene)ethylenediaminato]nickel(II) as described above. The yields of the complexes tend to decrease with the complexes of longer alkyl chains, but they were never under 40%.

Found for [Ni(**1-2**)]: C, 63.15; H, 5.90; N, 7.35%. Calcd for $C_{20}H_{22}N_2NiO_2$: C, 63.05; H, 5.80; N, 7.35%. Found for [Ni(**1-4**)]: C, 65.20; H, 6.85; N, 6.25%. [*N,N'*-Bis(5-hexylsalicylidene)ethylenediaminato]copper-(II) [Cu(1-6)]. Copper(II) acetate monohydrate (0.48 g, 2.4 mmol) and 5-hexylsalicylaldehyde (1.1 g, 5.3 mmol) were added to 100 cm^3 of ethanol in a 200 cm^3 flask with stirring. The mixture was then refluxed for 2 h. The green precipitate of bis(5-hexylsalicylaldehydato)copper(II) formed (0.8 g, 1.6 mmol) was filtered and dispersed again in ethanol. To this dispersion, ethylenediamine (0.11 g, 1.6 mmol) was added drop by drop. The reaction mixture was then refluxed for 3 h. The precipitate formed was filtered and recrystallized from hot ethanol. The yield was 0.4 g. (15%).

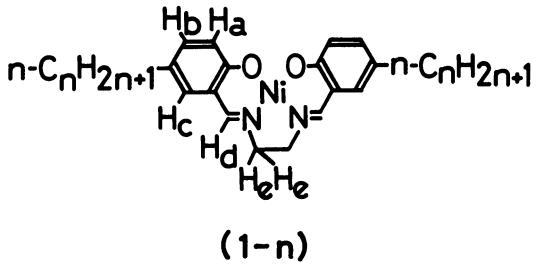
Found: C, 67.85; H, 7.20; N, 5.75%. Calcd for $C_{28}H_{38}CuN_2O_2$: C, 67.50; H, 7.70; N, 5.60%. Magnetic susceptibility μ_{eff}=1.89 B.M. (22 °C).

^{1}H NMR Measurements. The concentration dependence of ^{1}H NMR spectra was measured at 35 °C using a Hitachi R-40 90 MHz spectrometer. 400 MHz Superconducting ^{1}H NMR spectra were obtained with a JEOL spectrometer. The chloroform-d containing 1% of TMS supplied from Merck Japan Co., was used as solvent. A 5 cm^3 measuring flask was used to prepare the sample solution. The solutions of different concentration were prepared stepwise, adding the complex in small portions each time after the measurement had been completed.

Other Measurements. Visible absorption spectra were recorded with a Hitachi 340 spectrophotometer. Infrared spectra were obtained with a Jasoc IRA-2 spectrophotometer. Magnetic susceptibility measurements were performed with a Shimadzu torsion magnetometer MB-100 at Ochanomizu University.

Results and Discussion

The salen type ligands used in this paper have two alkyl (C_nH_{2n+1}) side chains of the same length, and are abbreviated as (**1-*n***). The results of elemental analyses accord well with the assumed structures. The IR spectra of nickel(II) and copper(II) complexes of (**1-*n***) exhibit a peak assignable to ν(C=N) at 1620 cm^{-1}, corresponding to the formation of a Schiff base in the complex.



(1-n)

The nickel(II) and copper(II) complexes of (**1-*n***) in chloroform (2×10^{-4} mol·dm^{-3}) exhibit almost an identical electronic spectra regardless of their alkyl chain length, and also, they do not show notable change either in peak positions or in absorption coefficients in the concentration region of 2×10^{-5} to 4×10^{-4} mol·dm^{-3}. Thus, the spectra of the (**1-6**) complexes are given in Fig. 1 as the representatives of the series, together with those of the unsubstituted complexes. The spectral profiles of alkyl-substituted complexes are similar to that of the unsubstituted complexes, which adopt the square-planar 4 coordination geometry. Thus it can be concluded that the complexes of (**1-*n***) also adopt the square-planar geometry. This is confirmed by the magnetic susceptibility measurements of the crystal of [Ni(**1-12**)]. It shows that the [Ni(**1-12**)] is diamagnetic as are most of the square-planar nickel(II) complexes. The μ_{eff} values for [Cu(**1-*n***)] (n=6, 12) are 1.89 and 1.91

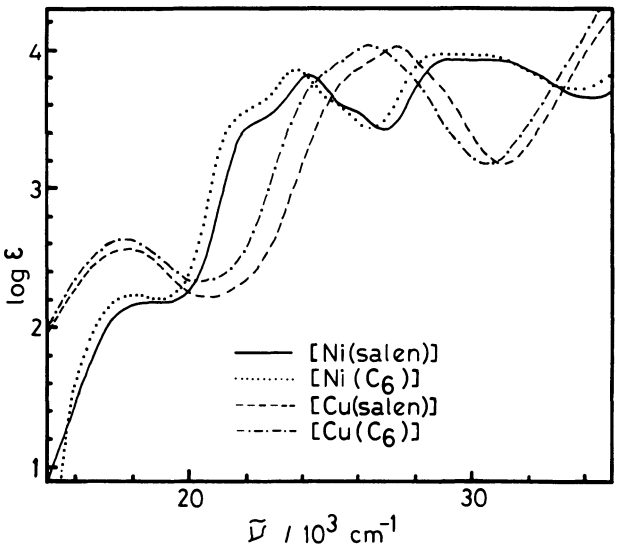


Fig. 1. Electronic spectra of [M(**1-6**)] and [M(salen)] (M=Ni, Cu).

B.M., which are in the range of normal monomeric copper(II) complexes.

However, a slight red shift on alkyl substitution can be noticed in the UV-region of the electronic spectra (Fig. 1). These red shifts are 500 and 1000 cm^{-1} for nickel(II) and copper(II) complexes, respectively. Similar red shifts are reported for the binuclear salen type complexes of (**2**).[17),18)] The shifts for nickel(II) and copper(II) complexes of (**2**) are 600 and 1200 cm^{-1} respectively. ESR study on the copper(II) complex of (**2**) revealed that the red shift is due to the interaction of two salen complex moieties in the complex. However, the concentration, at which the electronic spectra of (**1**-*n*) complexes are measured (2×10^{-4} mol·dm^{-3}), is far below the region of aggregation, as is shown later in this text. This means that the shift in electronic spectra of the (**1**-*n*) complexes cannot be attributed to the aggregation phenomenon dealt with in this paper. It can be considered that in (**1**-*n*), alkyl groups are directly attached to the benzene rings, possibly affecting the electronic state of salen moiety, while that is not the case in (**2**). It is, therefore, probable that the red shifts observed for the (**1**-*n*) complexes are due to the electronic effect of the substituted alkyl groups.

The Concentration Dependence in ^{1}H NMR. The ^{1}H NMR spectra of [Ni(**1**-*n*)] in chloroform-*d* are measured on a 400 MHz spectrometer, and almost all the peaks have been assigned. The assignment of the aromatic protons (H_a, H_b, and H_c) can be made by spin decoupling investigations. Geminal protons H_a and H_b split into doublets by the coupling, and a long-range coupling between H_b and H_c is also observed. Some other protons are also identified, on the basis of the assumed structure. ^{1}H NMR spectra of other nickel(II) complexes exhibit similar spectra and are assigned according to the same procedures. However, it is found that the positions of the peaks assigned to H_c and H_d differed slightly, each time one measures the ^{1}H NMR, although there are no differences in the sample solution except for their concentration.

On increasing the concentration, the signals assigned to the protons H_c and H_d, clearly showed up-field shifts. In Fig. 2 are given the concentration dependences of H_d for the nickel(II) complexes of (**1**-*n*). The shifts were observed only for H_c and H_d, and neither aliphatic protons nor the H_a and H_b protons of the benzene rings showed observable shifts. These up-field shifts become conspicuous above a concentration of ca. 10^{-3} mol·dm^{-3}, and, in the case of [Ni(**1**-**8**)], they move ca. 0.5 and 0.8 ppm upwards for H_c and H_d respectively, until the solution saturates at 0.51 mol·dm^{-3}.

The up-field shifts can be attributed to the aggregation of the complex, because there are no other interactions that are affected by the change in the concentration. It is well-known that the protons located above an aromatic ring exhibit a peak shift in

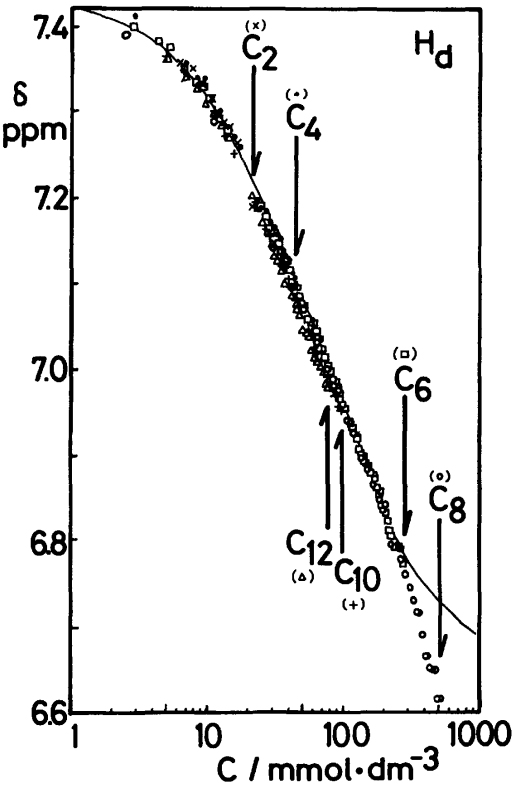

Fig. 2. Concentration dependence of ^{1}H NMR of [Ni(**1**-*n*)] in $CDCl_3$. Arrows indicate the concentration of saturation.

^{1}H NMR to an upper field due to the strong diamagnetic effect of the ring current formed in the aromatic ring.[19)] Thus, in the aggregate of [Ni(**1**-*n*)], the benzene ring of (**1**-*n*) is assumed to be placed above the protons H_c and H_d of another molecule of [Ni(**1**-*n*)], and vice versa. As the ^{1}H NMR spectrum of [Ni(**1**-*n*)] exhibits the shifts and not the splittings, a rapid equilibrium between the aggregate and the monomeric species is indicated.

The length of the alkyl chains have little effect on the concentration dependence. The major effect of the alkyl side chains is the modification of the solubility of the complex. The saturation concentration, which is indicated by arrows in Fig. 2, increases as the alkyl chain length increases, until it reaches its maxima for the (**1**-**8**) complex, and then decreases. The shift, on the other hand, has a slight tendency to increase with the alkyl length, but the amount is not large enough to be positively affirmed. However, it can be concluded that the complex-complex interaction rather than the hydrophobic interaction of the side chains is responsible for the aggregation.

Theoretical Treatment of the Concentration Dependences. The concentration dependence observed contains information on the distribution of the complex molecules present in the solution to the monomeric species and the aggregates. If the

aggregation occurs at low concentration, the shift of ^{1}H NMR should begin to appear at a low concentration. Therefore, the equilibrium constant of aggregate formation can be determined from the concentration dependence of the shift. At the primary stage of aggregation, i.e. in a relatively low concentration region, an equilibrium between the monomeric and dimeric species ought to be dominant in the solution. Assuming, therefore, an equilibrium between monomer and dimer for the first order approximation, the chemical shifts for a given proton (δ) at any concentration (C) are given as

$$\delta = \delta_d + (\delta_m - \delta_d)(\sqrt{1 + 8CK} - 1)/4CK$$

where K, δ_m, and δ_d stand for the equilibrium constant (=[dimer]/[monomer]^2), chemical shifts of monomer and dimer, respectively.[20] The shape of the curve for this equation is a sigmoidal curve, in which the δ value changes from δ_m (C=0) to δ_d (C=infinity).

Calculations to fit the theoretical curves to the observed data of H_c and H_d were performed, and the results are summarised in Table 1. The data for [Ni(**1-2**)] is insufficient to derive K and δ values, and the values calculated for [Ni(**1-4**)] are not accurate enough for the same reason. The curves given in Fig. 2 are those calculated for [Ni(**1-6**)]. The result shows that K, δ_m, and δ_d are almost identical regardless of the difference in the alkyl chain length. A slight increase of K in proportion to the chain length can be observed, but is not large enough to be confirmed. The calculated curves fit well to the data up to ca. 0.2 mol·dm^{-3}, but begin to drift apart from the data thereafter. In the case of [Ni(**1-8**)], the drift becomes extremely large because of the high concentration it reaches, and it shows completely different dependence from the theoretical curve. This is probably due to the formation of highly associated aggregates, such as trimers, etc.

Porphyrin complexes, including chlorophylls, also show this kind of up-field shifts.[20,21] The equilibrium constants for them are in the same order as the K values obtained here, indicating that the nickel complexes of (**1-*n***) are expected to have a similar aggregating ability to that of the porphyrin complexes. The differences between δ_m and δ_d for porphyrin complexes proved to be slightly larger than those observed for the (**1-*n***) complexes.

However, the ^{1}H NMR of the unsubstituted salen complex exhibited no observable shift. This is because the solubility of [Ni(salen)] (ca. 2×10^{-4} mol·dm^{-3}) is far lower than the concentration at which the salen type complex starts to aggregate. In other words, the crystallization takes place prior to the aggregation in [Ni(salen)]. It is apparent, therefore, that the effect of the aliphatic side chains is to increase the solubility of the complex, and to reveal the ability to aggregate in the solution, which is hidden in the complex of low solubility.

Paramagnetic Broadening Caused by Copper(II) Complex. Other information on aggregation phenomenon is obtained from the investigation of the paramagnetic broadening of ^{1}H NMR spectra caused by adding the corresponding copper(II) complex [Cu(**1-*n***)] to a $CDCl_3$ solution of [Ni(**1-*n***)]. In Fig. 3 is shown the spectral change of [Ni(**1-6**)] on adding [Cu(**1-6**)]. The change in the spectral profile becomes apparent on adding only 1% of the corresponding copper(II) complex. In Fig. 3, it is found that the peak at δ=3.4 (H_c) loses height drastically on the addition of the copper(II) complex. A similar phenomenon is also observed for the peaks at δ=6.6 (H_d) and 7.1 (H_c). Here again, the peaks of the protons H_c and H_d are broadened extensively, and in addition, the methylene protons of ethylenediamine moiety (H_e) are strongly affected. The intensity of the broadening observed is in the order of $H_c \approx H_d > H_e >$ other protons. It is found also that the peak width at half maxima and the amount of copper(II) complex added have a linear relation up to ca. 7%, although no special treatment such as deoxygenation was applied.

The paramagnetic broadening of ^{1}H NMR peaks is caused by the acceleration of the relaxation speed of activated protons placed near the unpaired electron of copper(II) complex (spin-spin relaxation).[22] Since the acceleration is due to the energy exchange between the spins of unpaired electrons of Cu^{2+} and ^{1}H nucleus, the observed paramagnetic broadening corresponds to the formation of [Ni(**1-6**)]-[Cu(**1-6**)] (abbr. Ni–Cu) aggregate. Protons subject to the intense

[Ni(**1-10**)]	10	6.81	6.12	7.46	6.43
[Ni(**1-12**)]	9.5	6.80	6.09	7.45	6.40

In $CDCl_3$ at 35°C.

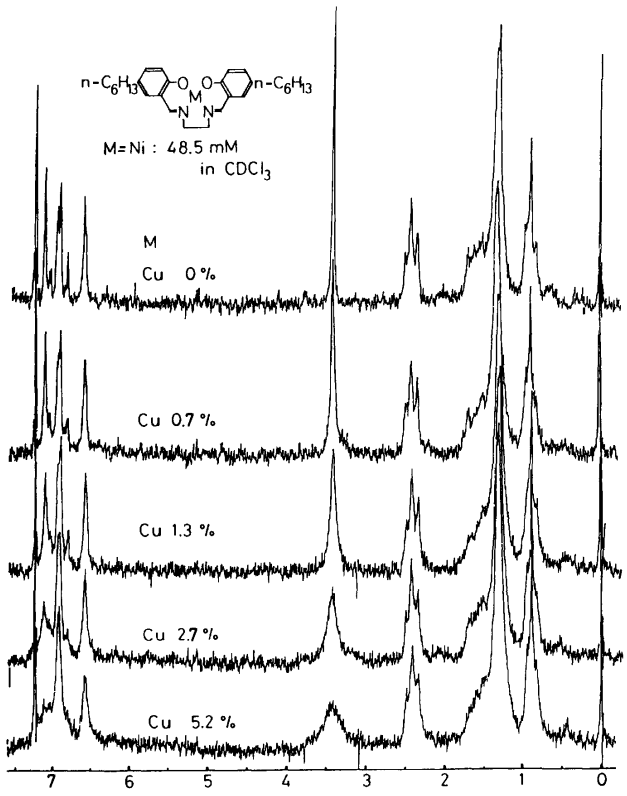

Fig. 3. Paramagnetic broadening of ^{1}H NMR spectra observed for [Ni(**1-6**)] by addition of [Cu(**1-6**)].

broadening, such as H_e and H_d, need to be placed near the Cu^{II} of [Cu(**1-6**)] in the Ni–Cu aggregate.

Paramagnetic broadening can also be caused by some other copper(II) complexes. Addition of bis(8-quinolinol)copper(II) or (*N,N'*-disalicylidene-1,3-propanediaminato)copper(II) also causes broadening in ^{1}H NMR spectrum of [Ni(**1-6**)]. This fact implies that [Ni(**1-6**)] aggregates with a variety of square-planar complexes. Thus, by observing the paramagnetic broadening, the structure of the heteronuclear aggregate of [Ni(**1-*n***)] and copper(II) complex can be investigated.

Structure of the Aggregate. The protons that are affected strongly in the peak shift (H_c and H_d) and paramagnetic broadening (H_c, H_d, and H_e), seem to be in the same part of the complex. These protons are all located around the imino groups. In other words, the spectral changes observed for Ni–Ni (abbr. for dimer of [Ni(**1-*n***)]) and Ni–Cu aggregates seem to be consistent with each other, implying similar structures for Ni–Ni and Ni–Cu aggregates. Assuming, therefore, that the structures of Ni–Ni and Ni–Cu aggregates are not very different, the structure of the aggregate in these systems can be evaluated from the amount and sign of the shift and broadening. The proposed structure for the aggregate in $CDCl_3$ solution is given in Fig. 4. In this aggregate, the protons H_c and H_d are placed above (and below) the aromatic rings, which lead to the

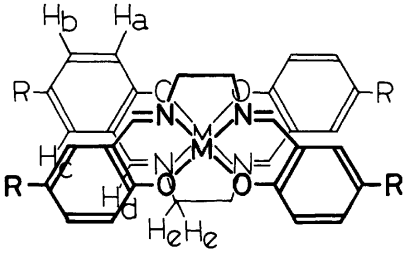

Fig. 4. Proposed aggregation structure (M=Ni, Cu).

shifts, and the protons H_c, H_d, and H_e are placed near to the Cu^{2+} of the neighbouring copper(II) complex, which cause broadening.

This structure of the dimer is different from that obtained for the crystal of [Cu(salen)]·$CHCl_3$ by the crystallographic study.[10] The dimer in the crystal has weak apical bonds between copper(II) of a [Cu(salen)] molecule and the coordinating oxygen atoms of another molecule in the dimer. This structure in the crystal does not explain the observation that the protons around the imino groups are strongly affected by aggregation. On the other hand, the proposed structure agrees well with that observed in [Co(salen)]·$CHCl_3$,[11] which is notable for its oxygen coordinating nature.[12] The result obtained here suggests that [Co(salen)]·$CHCl_3$ probably crystallizes in a dimeric form in $CHCl_3$.

Although an assumption that the homonuclear (Ni–Ni) and heteronuclear (Ni–Cu) aggregates take similar aggregating structures must be made, the combination of peak shift and broadening investigations proved effective in estimating the aggregating structure of the salen type complexes.

The authors thank Dr. Yutaka Fukuda of Ochanomizu University for his help in obtaining magnetic susceptibility data. The present work was partly supported by a Grant-in-Aid for Scientific Research No. 5950614 from the Ministry of Education, Science and Culture.

Studies on Mixed Chelates. XVI. Mixed Copper(II) Chelates with 1,2-Dipiperidinoethane and β-Diketonates[1)]

Yutaka FUKUDA,* Masako CHO, and Kozo SONE*
Department of Chemistry, Faculty of Science, Ochanomizu University,
Otsuka, Bunkyo-ku, Tokyo 112
(Received June 14, 1988)

1,2-Dipiperidinoethane (dipe) forms mixed chelates of the type $[Cu(dike)(dipe)]ClO_4$ with $Cu(ClO_4)_2$ and various β-diketonate ions (dike); however, hexafluoroacetylacetonate (hfac) forms $[Cu(hfac)_2(dipe)]$ instead. The strong solvatochromism of the former, and the high solubility and volatility of the latter, were compared with those of similar chelates studied so far.

1,2-Dipiperidinoethane (dipe; Fig. 1a) is a potential chelating agent which has been only little studied. Its chelate ring structure is similar to that of *N,N,N',N'*-tetramethylethylenediamine (tmen), but the substituent groups on its N atoms ($-(CH_2)_5-$) are much larger, and form bulky piperidine rings with the N atoms. It is, therefore, expected to be a weaker ligand than tmen, since (i) the bulkiness and rigidity of the piperidine rings will hinder the formation of chelate ring, and (ii) even when the chelate ring is formed, the bulky ligand will disturb the proper arrangement of other ligands, and destabilize the whole complex.

In spite of these expectations, however, we could recently prepare a number of fairly stable metallic complexes containing dipe. One of them is a dimeric copper(II) complex, $[Cu_2(OH)_2(dipe)_2](ClO_4)_2$, which is very similar to the dimeric complexes formed by tmen and related diamines.[2)] In this paper, the preparations and various interesting properties of mixed copper(II) complexes with β-diketonate ions (dike) are reported.

Experimental

Preparation of the Complexes. (1) $[Cu(dike)(dipe)]ClO_4$ (dike=Dipivaloylmethanate (dipm), Acetylacetonate (acac), Benzoylacetonate (bzac), Dibenzoylmethanate (dibm), or Trifluoroacetylacetonate (tfac)): To an ethanolic solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (10 mmol in 30 ml), a mixture of a β-diketone and KOH (10 mmol each) dissolved in 10 ml of ethanol (EtOH) is added, and dipe (Tokyo Kasei Co.; 10 mmol in 10 ml of EtOH) is dropped in it upon warming. The mixture is stirred for 10 minutes, filtered, and kept in a freezer overnight. The obtained precipitate is recrystallized from acetone. A similar complex with hexafluoroacetylacetonate (hfac) could not be obtained in this way, and a mixture of $[Cu(hfac)_2(dipe)]$ and unknown precipitate (maybe copper hydroxide) was obtained instead.

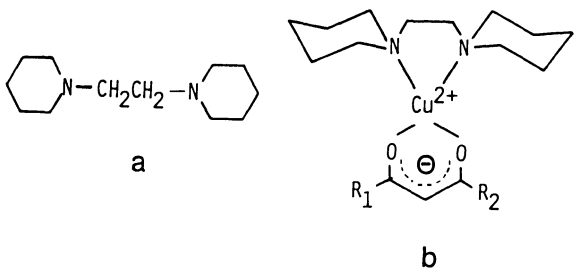

Fig. 1. Structures of dipe (a) and $[Cu(dike)(dipe)]^+$(b). The shape of the dipe moiety in (b) is assumed to be the same as that in $[Ni(NO_3)(acac)(dipe)]$, the structure of which was determined by an X-ray study (Y. Fukuda, C. Fujita, H. Miyamae, H. Nakagawa, and K. Sone, *Bull. Chem. Soc. Jpn.*, in press (1989)).

(2) $[Cu(hfac)_2(dipe)]$: To obtain this complex more easily, a mixture of hfacH and KOH (each 20 mmol, in 20 ml of EtOH) is added to an EtOH solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (10 mmol in 20 ml), and then dipe (10 mmol in 10 ml of EtOH) is dropped in it upon warming. The mixture is stirred for 10 minutes, filtered, and evaporated until green crystals begin to appear. The crystals obtained are recrystallized from 1,2-dichloroethane (DCE).

Physical Measurements. Regarding measurements of UV-visible and IR spectra, magnetic susceptibilities, electric conductivities, and TG-DTA curves of the complexes obtained, one should review Ref. 3.

Results and Discussion

(A) The Complexes $[Cu(dike)(dipe)]ClO_4$ (dike=dipm, acac, bzac, dibm, and tfac). The colors, analytical data and magnetic moments of these complexes are given in Table 1. The strong resemblance of these data and the spectral data (vide infra) to those of the mixed chelates of the type $[Cu(dike)(diam)]ClO_4$ (diam=*N,N'*-polyalkylethylenediamine, e.g., tmen) studied before[4–7)] indicates that these complexes should be formulated as the perchlorates of the chelate cations shown in Fig. 1b.

Spectral Data. As in the case of $[Cu(dike)(diam)]ClO_4$, all these complexes are strongly solvatochromic. Table 2 and Fig. 2 show the shifts of their d–d absorption band observed in various solvents, which are remarkably similar to the corresponding data for $[Cu(dike)(tmen)]ClO_4$[4)] and $[Cu(dike)(teen)]ClO_4$[5)] (teen=*N,N,N',N'*-tetraethylethylenediamine). As with the latter two series of complexes, the $\tilde{\nu}_{max}$ for a certain complex decreases with an increase in the solvent donor number (DN),[8)] i.e., in the order 1,2-dichloroethane (DCE)→nitromethane (NM)→acetone (Me_2CO)→methanol (MeOH)→*N,N*-dimethylformamide (DMF)→

a) Cf. Table 1. b) The DN values of the solvents a—g are, respectively, 29.8, 26.6, 19.1, 17.0, 14.1, 2.7, and 0.0.

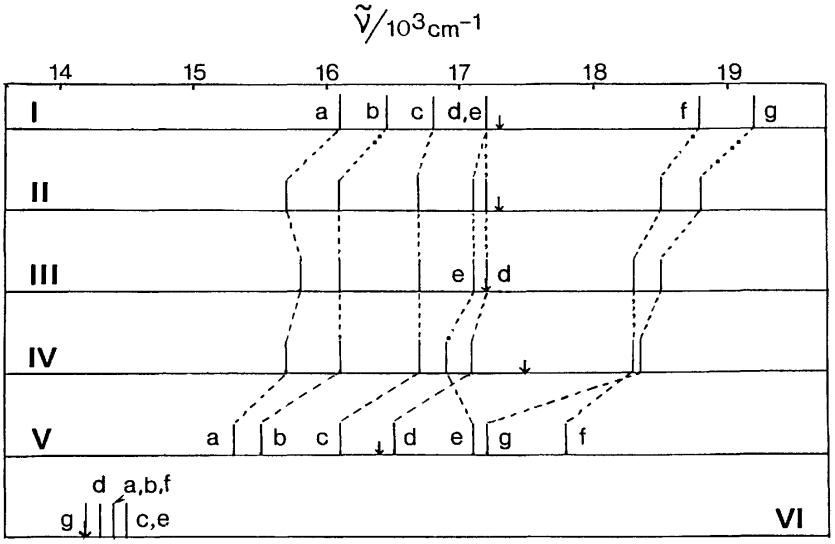

Fig. 2. Solvatochromism of the complexes: $\tilde{\nu}_{max}$ values of the complexes in various solvents. The $\tilde{\nu}_{max}$ in solid state are indicated by short arrows. As to the notations of the complexes (**I**—**VI**) and solvents (a—g), cf. Tables 1 and 2.

dimethyl sulfoxide (DMSO), while the $\tilde{\nu}_{max}$ in a certain solvent decreases with a decrease in the ligand field strength (l.f.s.) of dike, i.e., in the order dipm→acac→bzac→dibm→tfac. These resemblances prove, also in the present case, that the solvatochromism is caused by an axial coordination of solvent molecules onto the planar [Cu(dike)(dipe)]$^+$, which is strengthened by a decrease in the in-plane l.f.s. of the complex cation, as in the case of the tmen- and teen-containing complexes.[4,5]

An apparent exception from these general trends has now been found in the $\tilde{\nu}_{max}$ values in acetonitrile

(MeCN). The DN of this solvent (14.1) is sensibly lower than that of acetone (17.0), so that the $\tilde{\nu}_{max}$ in it should be higher than that in acetone. In fact, however, this is the case only with [Cu(tfac)(dipe)]-ClO_4, and with all other complexes (and also with the tmen- and teen-containing complexes, cf. Fig. 3), these two $\tilde{\nu}_{max}$ values are nearly equal, or slightly in the opposite order.

This spectral anomaly, which has been overlooked hitherto in this series of studies, may possibly be due to the slim, linear shape of MeCN molecule, and its "head-on" mode of coordination (i.e., the fact that $\angle$Cu–N–C=180°); these properties will facilitate the coordination of MeCN, especially when there is a steric hindrance, and so may make it an apparently stronger ligand than Me_2CO in certain cases. However, it may be due to another effect, i.e., the fact that the reacting particles in the present system (Cu^{2+} in the complex cation and MeCN) are rather "soft", and can form a "π-back bond" in the following way.

$$Cu^{2+} \longleftarrow N\equiv C-CH_3 \longleftrightarrow Cu^{2+} \overset{\pi}{\underset{\sigma}{\rightleftharpoons}} N=C-CH_3$$

Even a small contribution from this type of bonding will make the σ-bond synergetically stronger, and the apparent l.f.s. of MeCN notably higher. The sensitive dependence of the magnitude of the observed spectral anomaly on the electronic nature of dike, and similar spectral anomalies observed in MeCN solutions of [Ni(dike)(diam)]ClO_4,[9] seem to indicate the importance of the π-back bonding in the present case.

One more point of interest in Fig. 2 is a disappearance of the anomaly in DCE observed with [Cu(acac)(tmen)]ClO_4. It was formerly noted that the $\tilde{\nu}_{max}$ of this complex in DCE is apparently lower than that in NM, although the DN of DCE (=0) is lower than that of NM (=2.7). This anomaly was ascribed to the formation of ion pairs by means of an axial coordination of ClO_4^- in DCE; it was shown that the use of BPh_4^- instead of ClO_4^- eliminates this anomaly.[4,10]

Now this anomaly does not appear with [Cu(dipm)(dipe)]ClO_4 and [Cu(acac)(dipe)]ClO_4, and with [Cu(acac)(teen)]ClO_4, as shown in Fig. 3, i.e., $(\tilde{\nu}_{max})_{DCE} > (\tilde{\nu}_{max})_{NM}$ in every case. It is plausible that the bulky substituents on dipe and teen hinder the approach of ClO_4^- ions, and suppress ion-pair formation.

The values of $(\tilde{\nu}_{max})_{DCE}$ and $(\tilde{\nu}_{max})_{NM}$, however, get closer in going to [Cu(bzac)(dipe)]ClO_4 and [Cu(dibm)(dipe)]ClO_4, and in the case of [Cu(tfac)(dipe)]-ClO_4 the anomaly described above appears again more drastically. These facts, and the conductivity data shown below, lead to the following conclusion: the degree of ion-pair formation, which is low with the dipm and acac complexes, gradually increases in going to the bzac and dibm complexes, and then drastically in going to the tfac complex. In this last complex, in which the l.f.s. of tfac is the lowest among

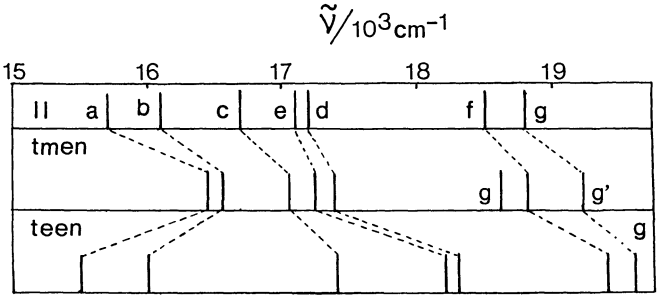

Fig. 3. Comparison of the solvatochromic changes of [Cu(acac)(dipe)]ClO_4, [Cu(acac)(tmen)]ClO_4, and [Cu(acac)(teen)]ClO_4. The notations of solvents are the same as those in Fig. 2. The $\tilde{\nu}_{max}$ of the tmen complex in DCE(g) is too low owing to the ion-pair formation (see text); the value for [Cu(acac)(tmen)]-BPh_4 (g') is therefore given for a better comparison.

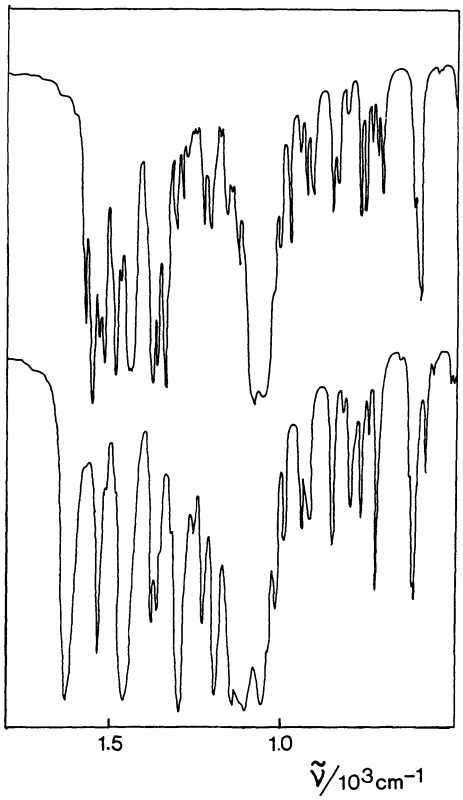

Fig. 4. Comparison of the IR spectra of [Cu(dipm)(dipe)]ClO_4 (above) and [Cu(tfac)(dipe)]ClO_4 (below).

the dike's used (or the positive charge on Cu(II) is highest), the bulkiness of dipe is seemingly insufficient to effectively hinder the coordination of ClO_4^-.

The coordination of ClO_4^- also occurs in crystals of the tfac complex. This can be seen from its IR spectrum, in which the peak of ClO_4^- near 1100 cm^{-1} is notably split, showing the deformation from T_d symmetry.[11] No such splitting takes place in the IR spectra of the other complex perchlorates. Figure 4 shows a part of the obtained spectra.[12]

Apart from such few anomalies, Fig. 2 may be taken

as a fairly regular array of solvents and dike ligands arranged in the order of their coordination abilities (DN of the solvents and l.f.s. of the dike's). In fact, these complexes of dipe (and those of teen, as reported before)[5,6] are even more strongly solvatochromic than [Cu(acac)(tmen)]ClO_4, which was often referred to as an excellent indicator of solvent DN.[7,13]

A comparison of the complexes of dipe, tmen, and teen given in Fig. 3 reveals some interesting trends. In going from tmen to teen, the d-d band moves to the blue in most solvents, except in solvents of very high DN (i.e., DMF and DMSO) where it moves to the red. This can be taken as an indication that (1) the thermal motion of the four ethyl groups of teen weakens the axial coordination of most solvents, making the complex more planar than in the case of tmen, while (2) strong solvent like DMF and DMSO can overcome this steric hindrance and get coordinated effectively, making the complex more regular octahedral, owing to the decreased in-plane l.f.s. produced by bulky teen, than in the case of tmen. On the other hand, in going from tmen to dipe, the d-d band of the complex [Cu(acac)(diam)]$^+$ moves to the red in all solvents, and the movement is larger in solvents of higher DN. In the dipe complex, the ends of the ethyl groups in teen are bound together in the form of piperidine rings, so that their free movements are strongly suppressed, and the movements toward axial directions become particularly difficult. The large steric hindrance to axial coordination in the teen complex is, thus, mostly lost in the dipe complex. Thus, it is probable that the spectral difference between the complex of dipe and that of tmen is mainly the result of the decreased l.f.s. of bulky and rigid dipe, which tends to make its complex more octahedral, in any solvent, than that of tmen.

Two factors which are expected to weaken the complexes of dipe were pointed out at the outset of this paper. The data in Fig. 3 indicate how the effects of both factors, i.e., the weakening of l.f.s. caused by large substituents, and steric hindrance to coordination of solvent molecules, can be recognized in solutions of the teen complex; however, only the first of them is apparent in those of the dipe complex, where the free motion of the substituent groups is restricted by ring formation.

Conductometric Data. Table 3a shows the molar conductivity values of the acac and tfac complexes in various solvents. They show, in general, that these complexes are 1:1 electrolytes.[14] One exception is the tfac complex in DCE; strong ion-pair formation is indicated here. Table 3b shows that the degree of ion-pair formation in DCE increases in the order dipm→acac→bzac→dibm→tfac, and also in the order teen→dipe→tmen. These results are in general agreement with the expectation from spectral data, if the ionic conductivities of the complex cations are reasonably assumed to be comparable to one another.

(B) The Complex [Cu(hfac)$_2$(dipe)]. When hfac is used as dike, no complex of the type (A) could be prepared, and a green, apparently 6-coordinated complex of this composition was obtained instead.[15] This complex is highly soluble in various nonpolar solvents, and it sublimes at ca. 175 °C (or at ca. 100 °C in vacuum) so that it can be purified by sublimation. The intermolecular attraction in this complex is therefore very weak; in this respect it is very similar to the complexes [Ni(dike)$_2$(diam)], and the corresponding Co(II) and Zn(II) complexes, studied before.[16,17]

The electronic spectra of this complex in organic solvents were also studied. Here, $\tilde{\nu}_{max}$ changes only slightly with solvent polarity, showing that there is no solvent molecule in the coordination sphere. A small shift to the blue, which occurs roughly in parallel with solvent acceptor number (AN),[8] is recognized. This may be due to an interaction of the solvent molecules, which now act as acceptors, with the twelve C-F groups covering the surface of the complex:

C—F·····Solvent (Acceptor).

A somewhat similar solvatochromism was recently observed in solutions of [Co(edta)]$^-$ and related

X-Ray Crystal Structures of *trans*-(Chloromethyl)bis(2,4-pentanedionato)-(aqua and methanol)chromium(III) Complexes. Evidence for a Trans Influence Exerted in the Carbon-Bonded Chromium(III) Complexes

Yoichi ABE and Hiroshi OGINO*
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Sendai 980
(Received July 2, 1988)

The crystal and molecular structures of alkylchromium(III) complexes, *trans*-[Cr(CH_2Cl)$(acac)_2(H_2O)$]·EtOH and *trans*-[Cr(CH_2Cl)$(acac)_2$(MeOH)] ($acac^-$=2,4-pentanedionate anion, EtOH=ethanol, MeOH=methanol), have been determined by X-ray structure analyses. Both crystals are triclinic and the space group $P\bar{1}$; Z=2 with a=9.935(2), b=10.606(2), c=9.399(2) Å, α=90.39(2), β=92.44(2), γ=115.54(1)° for the aqua complex, and Z=4 with a=11.402(6), b=16.780(7), c=8.543(3) Å, α=98.83(3), β=102.00(4), γ=83.03(4)° for the methanol complex. Each complex has trans configuration. The carbon-bonded CH_2Cl group elongates specifically the Cr–O bond trans to the Cr–C bond in the aqua complex (Cr–O(H_2O)=2.134(6) Å) and methanol complex (Cr–O(MeOH)= 2.156(6), 2.136(6) Å).

Recently, we synthesized and isolated dichloromethyl- and chloromethyl-bonded chromium(III) complexes, *trans*-[CrR$(acac)_2$L] (R=$CHCl_2$, CH_2Cl; L=H_2O, MeOH, py).[1,2] Remarkably rapid substitution reactions

$$\textit{trans}\text{-[CrR(acac)}_2\text{(MeOH)]} + \text{L} \rightleftharpoons \textit{trans}\text{-[CrR(acac)}_2\text{L]} + \text{MeOH}$$

were observed for the complexes, where L denotes pyridine and its analogs. The X-ray crystal structure determinations of [Cr($CHCl_2$)$(acac)_2$(py)] and [Cr(CH_2Cl)-$(acac)_2$(py)][2] revealed that the geometries of both complexes are trans and the carbon-bonded ligands lengthen specifically the Cr–N bonds trans to the Cr–C bonds in [CrR$(acac)_2$(py)]. Therefore, the labilized ligand substitution reactions are ascribed to a strong electronic effect of the alkyl group on the bond trans to the Cr–C bond. However, there has been no direct evidence that the geometries of [CrR$(acac)_2(H_2O)$] and [CrR$(acac)_2$(MeOH)] are trans. In this work the structural determinations for the [Cr(CH_2Cl)$(acac)_2$L] (L=H_2O, MeOH) are described. The structural features are compared with those of [CrR$(acac)_2$(py)] (R=$CHCl_2$, CH_2Cl).

Experimental

The syntheses of *trans*-[Cr(CH_2Cl)$(acac)_2(H_2O)$]·EtOH and [Cr(CH_2Cl)$(acac)_2$(MeOH)] were carried out by the methods reported previously.[2] The single crystals of the aqua and methanol complexes were obtained by the recrystallizations from H_2O–ethanol (1:5) and H_2O–methanol (1:3), respectively.

Intensity data were collected on a Rigaku AFC-6A four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). Crystallographic and experimental parameters for both complexes are listed in Table 1. During data collection, three standard reflections showed decrease in intensities of approximately 10% for both complexes. The reflection data were corrected for the decays as well as Lorentz and polarization factors. The structures were solved by the heavy-atom method and refined by the block-diagonal least-squares method. Refinement was carried out with anisotropic temperature factors for all non-hydrogen atoms. The positions of the hydrogen atoms of the chloromethyl groups and those of the methine groups of $acac^-$ ligands for both aqua and methanol complexes were calculated and fixed. All other hydrogen atoms were not included in the calculation. The atomic-scattering factors including the anomalous scattering factors were taken from Ref. 3 for non-hydrogen atoms and from Ref. 4 for hydrogen atom.

All the calculations were performed on Nippon Electric Co. ACOS-1000 and -2020 computers at the computer center of Tohoku University, using the Universal Crystallographic Computation Program System (UNICS III) and its local version.[5]

Results and Discussion

Positional and isotropic thermal parameters of the *trans*-[Cr(CH_2Cl)$(acac)_2(H_2O)$]·EtOH and [Cr(CH_2Cl)-$(acac)_2$(MeOH)] are listed in Tables 2 and 3,[6] respectively. The structures of the aqua and methanol complexes are shown in Figs. 1 and 2 with atom numbering schemes.

The geometries of *trans*-[Cr(CH_2Cl)$(acac)_2(H_2O)$]·EtOH and [Cr(CH_2Cl)$(acac)_2$(MeOH)] have been proved unequivocally to be trans by the crystal structure determinations. The ethanol molecule in *trans*-[Cr(CH_2Cl)$(acac)_2(H_2O)$]·EtOH is hydrogen-bonded to the coordinated water molecule (O(5)···O(6) 2.656(9) Å). The structures of two crystallographically independent molecules in *trans*-[Cr(CH_2Cl)$(acac)_2$(MeOH)] are almost the same, but different slightly in the orientation of the coordinated methanol molecules and the chloromethyl groups (Fig. 2).

Selected interatomic distances and angles are summarized in Tables 4 and 5. The most striking feature observed in the interatomic distances is that Cr–O-(H_2O) bond (2.134(6) Å) in the aqua complex is

considerably elongated, being compared to Cr–O(H_2O) bonds (1.975(4)—2.090(6) Å) in chromium(III) complexes which contain coordinated water molecules but have no Cr–C bonds.[7–12] This is also true for the methanol and pyridine complexes: The Cr–O(MeOH) bond (2.156(6) Å for molecule 1 and 2.138(6) Å for molecule 2) for the methanol complex and the Cr–N bond (2.201(4) Å) for the pyridine complex[2] are longer than those of *trans*-$[CrCl_2(MeOH)_4]^+$ (1.987 Å)[13] and *mer*-$[Cr(CF_3CO_2)_3(py)_3]$ (2.10 Å),[14] respectively. The trans influence exerted in the $[CrR(acac)_2L]$ complexes is responsible for the labilized ligand substitution rates.[2] It should be noted that similar ground-state distortion and kinetic effect are also observed for coenzyme B_{12} and related model complexes.[15–20]

a) The equivalent isotropic thermal parameters for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(\beta_{11}a^2+\beta_{22}b^2+\beta_{33}c^2+\beta_{12}ab\cos\gamma+\beta_{13}ac\cos\beta+\beta_{23}bc\cos\alpha)$. The β_{ij}'s are defined by $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+2hk\beta_{12}+2hl\beta_{13}+2kl\beta_{23})]$. b) O(6), C(2), and C(3) denote the oxygen, methylene carbon, and methyl carbon atoms of EtOH solvate, respectively.

The Cr–C bond lengths of $[Cr(CH_2Cl)(acac)_2L]$ (L=H_2O, MeOH, py) lie in the range of the values (2.01—2.11 Å) reported for those of other carbon-bonded chromium(III) complexes.[21–23] The Cr–C bond lengths of the present complexes show a slight but interesting dependence on the ligand L trans to the Cr–C bond; i.e. py (2.077(6) Å)>H_2O (2.06(1) Å)≥MeOH (2.049(9) Å for molecule 1 and 2.052(9) Å for molecule 2). This order appears to indicate that the electron donating trans ligand L affects the length of the Cr–C bond.

The existence of the Cr–C bond has no substantial influence on the equatorial ligands. Table 6 shows that Cr–O(acac) bond lengths in the $[CrR(acac)_2L]$ complexes are essentially the same as those of $[Cr(acac)_3]$[24,25] and related complexes.[26–28]

It has been reported that the pentane moieties of two $acac^-$ chelates in $[Cr(CH_2Cl)(acac)_2(py)]$ are bent toward the CH_2Cl group.[2] This seems to be due to the intermolecular repulsion between a hydrogen atom of a chloromethyl group and a methyl group. Similar bending modes are observed for the aqua and methanol complexes. The degree of the bending can be expressed by the dihedral angles between the plane 1 (the least-squares plane which is defined by a chromium atom and the four oxygen atoms of two

$acac^-$ chelates) and the plane 2 (the least-squares plane which is defined by the two oxygen atoms of a $acac^-$ chelate and three skeletal carbon atoms of the $acac^-$ chelate). The values of the dihedral angles are 164.7(1)° for the pyridine complex,[2] 169.4(3)—173.5(4)° for the methanol complex, and 174.1(4) and 173.6(5)° for the aqua complex. The bending of the $acac^-$ chelates is again due to the interaction of molecules in the crystal. In the aqua and methanol complexes, it is seen that the nearest intermolecular non-bonding distances between two methyl groups of different molecules are close to or slightly shorter than the sum

of the van der Waals radii for the methyl groups. In the aqua complex, there is an additional interaction between a chloromethyl group and the nearest methyl group of an ethanol. The inclination of the chloromethyl group may come from this repulsion.

This work was supported by a Grant-in-Aid for Scientific Research No. 60430011 from the Ministry of Education, Science and Culture.

Mössbauer spectra of $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics (x=0.003, 0.008, and 0.017) measured at room temperature show a superposition of three quadrupole doublets. An outermost doublet (δ=0—0.04 mm s^{-1}, Δ=1.94—1.98 mm s^{-1}) is ascribed to high-spin Fe^{4+} ions present at substitutional sites of Cu^{2+} ions (Cu(2) site). An intermediate doublet (δ=−0.03—0.02 mm s^{-1}, Δ=1.12—1.17 mm s^{-1}) is ascribed to intermediate-spin Fe^{3+} ions present at substitutional sites of Cu^{3+} ions (Cu(1) site). An innermost doublet is ascribed to Fe^{3+} ions (high spin) with tetrahedral symmetry, present along the b-axis. A decrease in T_c from 72 to 60 K, observed when iron content (x) is increased from 0.008 to 0.017, is explained by a lowered layer structure composed of "dimpled" CuO_4 planes, owing to a displacement of O(4) oxygen atoms sharing CuO_5 tetragonal pyramids and CuO_4 square planars. One-dimensional chains composed of CuO_4 square planars proved to be primarily affected by γ-ray irradiation, whereas no change of T_c was observed. Low-temperature Mössbauer measurements revealed that "partial Debye temperatures" are 330 and 740 K for the chains and layer structure, respectively.

Since Bednorz and Müller exhibited a possibility of high-T_c superconductivity in oxide ceramics,[1] Ln-Ba-Cu-O ceramics, where Ln indicates lanthanide elements, have attracted much attention. Important findings of superconducting Y-Ba-Cu-O ceramics by Wu et al.[2] and Hikami et al.[3,4] suggested several practical applications at higher temperatures than so-called "liquid nitrogen temperature," e.g., fiber and thin film.[5-9] In addition to the applications and studies of physical properties (e.g. T_c and J_c), structure of Y-Ba-Cu-O superconductors has been studied by several groups. Using an electron probe microanalyzer (EPMA), Iwata et al.[10] elucidated that black-colored phase having a composition of Y:Ba:Cu=1:2:3 causes the superconductivity. Crystal structure of high-T_c $YBa_2Cu_3O_{7-\delta}$ was studied by Hazen et al.[11] and LePage et al.[12] by means of powder X-ray diffraction. As a result, it was revealed that orthorhombic (*Pmmm*) phase and tetragonal (*P4/mmm*) phase are present in $YBa_2Cu_3O_{7-\delta}$ ceramics. Powder neutron diffraction study combined with Rietveld analysis revealed that an orthorhombic (*Pmmm*) phase is concerned with the superconductivity in $YBa_2Cu_3O_{7-\delta}$ ceramics.[13-16] Beno et al.[13] elucidated that the orthorhombic phase is composed of distorted CuO_5 tetragonal pyramids, constituting "dimpled" CuO_4 layers in the a-b planes, and CuO_4 square planars constituting one-dimensional fence-like chains in the b-c planes. It was reported that the distorted CuO_5 tetragonal pyramids also constitute semiconducting $YBa_2Cu_3O_{7-\delta}$ ceramics (δ>0.5).[13] Most of the copper atoms in "dimpled" CuO_4 layers (denoted by Cu(2)) were reported to be divalent,[14] being in contrast to Cu^{3+} ions constituting one-dimensional CuO_4 square planars in the b-c planes.[15] Jorgensen et al.[14] revealed that Cu^{3+} ions in CuO_4 square planar chains (Cu(1)) play an important role in the conduction mechanism and that a depression of superconductivity is due to a loss of Cu^{3+} ions and/or a disordering of the one-dimensional chains. Similar conclusion has been drawn by Izumi et al.[16,17] in neutron diffraction studies.

^{57}Fe-Mössbauer spectroscopy has been utilized for a structural study of superconducting $GdBa_2Cu_3O_{7-\delta}$,[18,19] $YBa_2Cu_3O_{7-\delta}$,[20-27] and $EuBa_2Cu_3O_{7-\delta}$[28,29] ceramics. In a Mössbauer study of $GdBa_2(Cu_{0.94}Fe_{0.06})_3O_{7-\delta}$ ceramic at room temperature,[18,19] the spectrum was analyzed into two types of quadrupole doublets with isomer shifts (δ) of −0.12 and −0.17 mm s^{-1} and quadrupole splittings (Δ) of 1.97 and 1.05 mm s^{-1}, respectively. The former doublet peak with larger quadrupole splitting was ascribed to the Fe^{3+} ions present at substitutional sites of Cu^{2+} ions at Cu(1) site, whereas the latter peak was ascribed to the absorption due to Fe^{3+} ions present at substitutional sites of Cu^{3+} ions at Cu(2) site. In these studies,[18,19] a homogeneous single phase was recognized by X-ray diffraction method when the substitution of iron for copper was less than 15% in the $GdBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics. Furthermore, a Mössbauer spectrum proved to show a magnetic splitting at 4.2 K when the substitution of iron for copper was greater than 3%. A peak assignment similar to the case of $GdBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$[18,19] ceramics was made for $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics by the same research group.[20] They indicated that T_c is decreased with increasing iron

content and that a superconductivity disappears when x is greater than 0.15. Isomer shift of $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramic (x=0.06) also proved to be located around 0 mm s^{-1} with respect to a stainless steel.[20] On the other hand, quite a reverse assignment was made by several groups.[21,22,24,25,28] Nasu et al.[21] indicated that an asymmetric outermost doublet peak corresponds to high-spin Fe^{3+} ions (S=5/2) present at substitutional sites of Cu^{2+} ions (Cu(2) site), and that an intermediate doublet peak corresponds to intermediate-spin Fe^{3+} ions (S=3/2) present at substitutional sites of Cu^{3+} ions (Cu(1) site). An innermost weak doublet (δ=0.27 mm s^{-1} and Δ=0.52 mm s^{-1}) was ascribed to octahedral Fe^{3+} ions of high spin state.[21] Takano and Takeda[22] showed that both the outermost and intermediate doublet peaks correspond to intermediate-spin Fe^{3+} ions (S=3/2).

Structural information obtained by Mössbauer spectroscopy seems to be very useful because it is directly concerned with the mechanism of superconductivity in these ceramics. The present ^{57}Fe-Mössbauer study was carried out in order to elucidate a local (short-range) structure in $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ superconductors and also a long-range structure in connection with lattice dynamics of lower-dimensional chain and layer structures composed of copper (Cu^{2+} or Cu^{3+}) and oxygen atoms. Mössbauer measurements of ^{60}Co-γ ray (ca. 10^8 R) irradiated $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ superconductor were also performed in order to elucidate a sensitivity to gamma rays in connection with a short- or long-range structure.

Experimental

Superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics, in which x was chosen to be 0.003, 0.008, and 0.017, were prepared from Y_2O_3, $BaCO_3$, CuO, and $^{57}Fe_2O_3$ (^{57}Fe=96.03%), of a guaranteed reagent grade. Each of the mixtures containing weighed quantities of these reagents was ground in an agate mortar and dehydrated at 110 °C for 1 h on an electric heater. Each mixture in an alumina crucible was then heated at 900 °C for 5 h in an electric muffle furnace. After being cooled to room temperature, the mixture was pressed into a pellet with a diameter of 6 mm, under a hydrostatic pressure of 200 kg cm^{-2}. Superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics were prepared by sintering each pellet at 900 °C for 35 h. After the sintering, temperature in the electric muffle furnace was cooled down to 200 °C with a rate of 70 °C h^{-1}. All the procedures were performed in ambient atmosphere. The $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics prepared in this way are black in color. Mössbauer measurements were performed on pulverized samples by using a metallic iron foil enriched with ^{57}Fe as a reference of isomer shift. The iron foil was also used for calibrating the velocity of spectrometer. Cobalt-57 (10 mCi) diffused into a sheet of palladium foil was used as a Mössbauer source. Gamma-Ray irradiation was performed at the Cobalt-60 Irradiation Facilities of Kyushu University at an ambient temperature. During the Mössbauer measurements and ^{60}Co-γ ray irradiations ranging from 10^6 to 10^8 R, each sample was placed in a polyethylene bag filled with dry nitrogen gas in order to prevent it from absorbing atmospheric moisture. DC resistivity measurements were performed by a four-terminal method. Magnetic susceptibility was measured between room temperature and 78 K. DTA measurements were performed between room temperature and 800 °C with a heating rate of 5 °C min^{-1}. In DTA measurements, powder of α-Al_2O_3 was used as a standard material.

Results and Discussion

Mössbauer spectra of $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics (x=0.017, 0.008, and 0.003) are demonstrated in Fig. 1. Each Mössbauer spectrum shows a superposition of three quadrupole doublet peaks; an outermost peak with a quadrupole splitting of 1.94—1.98 mm s^{-1} (doublet (a)), an intermediate peak with a quadrupole splitting of 1.12—1.17 mm s^{-1} (doublet (b)), and an innermost peak with a quadrupole splitting of 0.46—0.56 mm s^{-1} (doublet (c)). The isomer shift of doublets (a) and (b) are located at 0—0.04 and −0.03—0.02 mm s^{-1}, respectively. The isomer shift of doublet (c) is 0.27—0.29 mm s^{-1}. It should be noted that the linewidth of doublet (b) is 0.46—0.49 mm s^{-1}, whereas the linewidth of doublets (a) and (c) is in a range of 0.28—0.30 mm s^{-1}. The latter values are characteristic of the absorption due to iron in crystalline compounds. On the other hand, the large linewidth (0.46—0.49 mm s^{-1}) of doublet (b) indicates distributed bond lengths and bond angles between iron and oxygen atoms, as observed in several Mössbauer studies of inorganic glasses.[30-38] This suggests a non-crystalline character of steric configuration around the iron concerned with doublet (b). The isomer shift of doublet (b) (−0.03—0.02 mm s^{-1}) indicates a much increased s-electron density at iron nucleus compared with that of high-spin Fe^{3+} ions.[30-38] Therefore, doublet (b) is ascribed to the absorption due to either

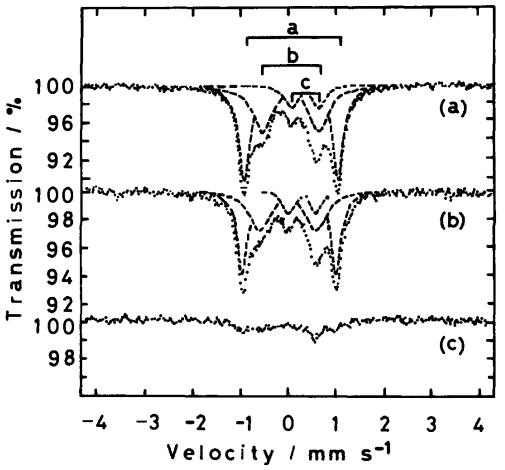

Fig. 1. Mössbauer spectra of superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics measured at room temperature. (a): x=0.017, (b): x=0.008, and (c): x=0.003.

high-spin Fe^{4+} ions or intermediate-spin Fe^{3+} ions ($S=3/2$).[39,40] If we take account of the small interatomic distance between Cu(1) and oxygen (O(1))[14,15] and therefore a strong ligand field at the copper (and also iron) site, we can speculate that iron is present at substitutional sites of Cu(1) in the form of intermediate-spin Fe^{3+} ($S=3/2$). In connection with this, Takano and Takeda[22] demonstrated a magnetically split peak at 1.5 K, which was assigned to Fe^{3+} ions of $S=3/2$, having an internal magnetic field (H_{int}) of about 33 T. A large linewidth of doublet (b) (0.46—0.49 mm s^{-1}), which is 30—75% greater than that of doublets (a) and (c), will reflect a decreased chain structure composed of CuO_4 chains in the b-c planes when Cu^{3+} (and small amounts of Cu^{2+}) ions are replaced by Fe^{3+} ions. In addition to the substitution of Fe^{3+} ions for Cu^{3+} (and also Cu^{2+}) ions, which preferentially conform CuO_4 square planars, incorporation of iron into $YBa_2Cu_3O_{7-\delta}$ ceramics will result in a formation of Fe^{3+}–oxygen polyhedra such as FeO_4 tetrahedra and FeO_6 octahedra. This will be discussed later.

Doublet (a) having a large quadrupole splitting is ascribed to Fe^{4+} ions present at substitutional sites of Cu^{2+} (and small amounts of Cu^{3+}) ions constituting CuO_5 tetragonal pyramids along the a-b planes. A bond length between copper (and also iron) present at Cu(2) site and an axial oxygen atom (O(4)), present at the apex of each pyramid, seems to be too longer[14,15] to form an intermediate spin state. Furthermore, isomer shift of high-spin Fe^{3+} ions present in tetragonal pyramids, having a coordination number 5, will be located around 0.4 mm s^{-1} with respect to metallic iron, i.e., between the isomer shift values of octahedra and tetrahedra.[30-40] A small isomer shift obtained for doublet (a) (0—0.04 mm s^{-1}) is explained by a decreased shielding effect of 4s-electron density by 3d-electrons when Fe^{3+} ($3d^5$) is oxidized to Fe^{4+} ($3d^4$). It seems that two-dimensional layers composed of "dimpled" CuO_4 planes constituting CuO_5 tetragonal pyramids along the a-b plane[13-17] will be less affected than one-dimensional chains composed of CuO_4 square planars (b-c plane), when Cu^{3+} and Cu^{2+} ions are replaced by Fe^{3+} and Fe^{4+} ions, respectively.

Doublet (c) having an isomer shift of 0.27—0.29 mm s^{-1} and a quadrupole splitting of 0.46—0.56 mm s^{-1} is ascribed to the absorption due to tetrahedral Fe^{3+} ions ($S=5/2$), because the isomer shift is characteristic of high-spin Fe^{3+} species with tetrahedral symmetry.[30-40] Magnetically-split Mössbauer spectra of $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics ($x=0.010$—0.067) observed at low temperatures, having an internal magnetic field (H_{int}) of about 49 T,[22,24,27] are consistent with the peak assignment described in this paper. In those papers, however, the magnetic peak was ascribed to octahedral Fe^{3+} ions.[22,24,27] It is generally known that H_{int} for octahedral Fe^{3+} species is greater than that of tetrahedral Fe^{3+} species, e.g. an H_{int} value of α-Fe_2O_3 at the corresponding temperature is about 54 T.[39] It seems that the FeO_4 tetrahedra are preferentially formed along the b-axis, because one-dimensional chain structure composed of CuO_4 square planars will be more favorable for the formation of FeO_4 tetrahedra than two-dimensional layer structure composed of CuO_5 tetragonal pyramids. The formation of FeO_4 tetrahedra along the b-axis will reduce a regular atomic arrangement, and some oxygen atoms will be located between one-dimensional chains composed of CuO_4 square planars. This will cause an increased unit cell length (lattice parameter a) along the a-axis, as reported by Maeno et al.[26] and Zhou et al.[27] If one-dimensional chains in the b-c planes carry supercurrent,[14-17,23] formation of FeO_4 tetrahedra along the b-axis will directly suppress the superconduction. As a result, a decrease in T_c will be observed. On the other hand, if two-dimensional layers in the a-b planes carry the supercurrent,[25,26] we have to consider a different mechanism concerning the decrease in T_c brought about by the formation of FeO_4 tetrahedra along the b-axis.

A decrease in T_c caused by increased iron content of superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics is shown in Fig. 2. By increasing iron content (x) from 0.008 (Fig. 2a) to 0.017 (Fig. 2b), it proved that T_c decreases from 72 to 60 K. These T_c's are lower than that of original $YBa_2Cu_3O_{7-\delta}$ ceramics (80 K) without iron.[2] Paramagnetic to diamagnetic transition around T_c is observed in $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ superconductor ($x=0.008$), as shown in Fig. 3. Temperature dependency of the magnetic susceptibility (χ) shows a good agreement with that of electrical resistivity shown in Fig. 2a. The formation of FeO_4 tetrahedra along the b-axis will lower the layer structure composed of "dimpled" CuO_4 planes (Cu(2) site), owing to a displacement of O(4) oxygen atoms sharing CuO_5 tetragonal pyramids and CuO_4 square planars. Therefore, if the superconduction is concerned with the a-b planes (Cu(2) site), displacement of O(4) oxygen will be the primary reason for the decrease in T_c. This is

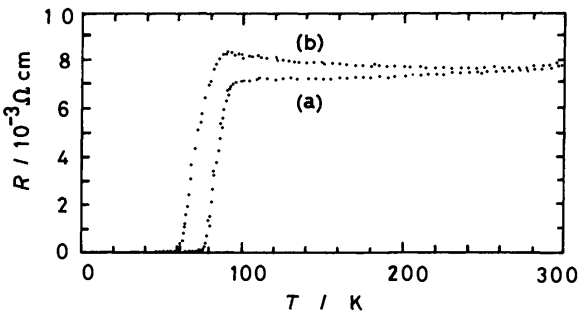

Fig. 2. Temperature dependency of electrical resistivity (R) of superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics. (a): $x=0.008$, (b): $x=0.017$.

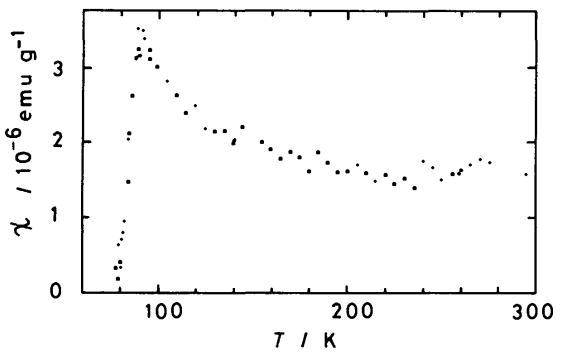

Fig. 3. Temperature dependency of magnetic susceptibility (χ) of superconducting $YBa_2(Cu_{0.992}Fe_{0.008})_3O_{7-\delta}$ ceramic.

also the case for the decrease in T_c observed in original $YBa_2Cu_3O_{7-\delta}$ ceramics when an oxygen content is decreased. Takano and Takeda,[22] reported that a relative absorption area corresponding to Cu(1) and Cu(2) sites depends on the oxygen content. This means that a decrease in T_c is not directly concerned with a relative occupation ratio of iron between Cu(1) and Cu(2) sites. Regarding the absorption and evolution of oxygen atoms, DTA measurements of superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramics (x= 0.008 and 0.003) revealed a single and wide exothermic peak ranging from room temperature to about 680 °C (x=0.008) and 660 °C (x=0.003), followed by a continuous endothermic peak at the higher temperatures. The exothermic peak having a maximum at about 430 °C indicates a continuous oxygen absorption in this temperature range. At temperatures higher than 660—680 °C, evolution of oxygen will become frequent, indicating a phase transition from orthorhombic to tetragonal at the temperatures.

Mössbauer parameters of superconducting $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ ceramic (x=0.017) irradiated with ^{60}Co-γ rays are summarized in Table 1. Mössbauer spectra and most of the parameters except an absorption area proved to be independent of the irradiation. Experimental error of the isomer shift is estimated to be ±0.01 mm s^{-1} and that of quadrupole splitting and linewidth is ±0.02 mm s^{-1}. These results indicate that a local structure and a chemical bond around iron are scarcely affected by the ^{60}Co-γ ray irradiations. Actually, no change of T_c was observed after the γ-ray irradiation of 10^8 R. This is quite in contrast to the result of several oxide glasses,[31,33] in which a quantitative reduction of Fe^{3+} to Fe^{2+} or a change of isomer shift and/or quadrupole splitting was observed when irradiated with γ-rays$\geqq 10^6$ R. These experimental results demonstrate that $YBa_2(Cu_{1-x}Fe_x)_3O_{7-\delta}$ and also $YBa_2Cu_3O_{7-\delta}$ ceramics are highly resistant to γ-rays so far as a local structure is concerned. On the other hand, Table 1 indicates a dose-dependent change of relative absorption area. This is illustrated in Fig.

Table 1. Mössbauer Parameters of $YBa_2(Cu_{0.983}Fe_{0.017})_3O_{7-\delta}$ Ceramic Irradiated with ^{60}Co-γ Rays

a) Isomer shift. b) Quadrupole splitting. c) Linewidth. d) Absorption area.

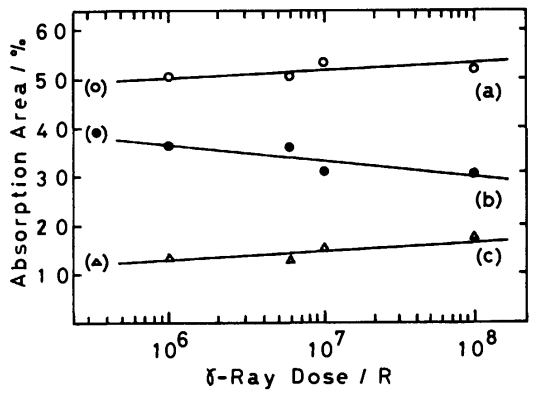

Fig. 4. Gamma-Ray dose dependency of relative absorption area (A) for superconducting $YBa_2(Cu_{0.983}Fe_{0.017})_3O_{7-\delta}$ ceramic. (a): doublet (a), (b): doublet (b), (c): doublet (c).

4, where plots in parentheses refer to the values before irradiation. We can understand from Fig. 4 that absorption area of doublet (b) decreases by the irradiation at the expense of absorption areas of doublets (a) and (c). This suggests a decrease in the recoil-free fraction f of Fe^{3+} ions present at substitutional sites of Cu(1) in one-dimensional chains. The reduced recoil-free fraction f will be closely concerned with the one-dimensional chain structure. This will be discussed later based on low-temperature Mössbauer measurements.

Mössbauer measurements of a superconducting $YBa_2(Cu_{0.992}Fe_{0.008})_3O_{7-\delta}$ ceramic were carried out at several temperatures ranging from room temperature to 78 K. As a result, no apparent spectral change was observed in any case. Temperature dependency of isomer shifts for the three doublets (a, b, and c) is shown in Fig. 5. It is obvious from Fig. 5 that all the isomer

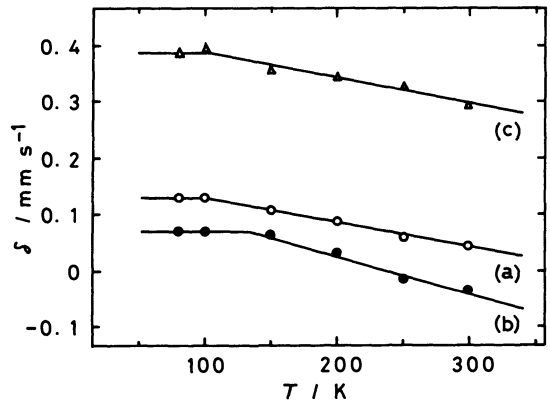

Fig. 5. Temperature dependency of isomer shift (δ). (a): doublet (a), (b): doublet (b), (c): doublet (c).

shift values are increased at lower temperatures owing to a decreased second-order Doppler effect. This suggests a decreased degree of atomic vibrations at iron and also copper sites, because a second-order Doppler shift is correlated with a mean square velocity of atomic vibration ($<v^2>$).[39] It can be known from Fig. 5 that a slope of doublet (b) is a little steeper than that of doublets (a) and (c). This means that a chemical bond between Fe^{3+} ion, present at substitutional sites of Cu(1) in one-dimensional chains, and four oxygen atoms is more affected by the lattice vibrations than two-dimensional Cu(2) sites or FeO_4 tetrahedra. In case of FeO_4 tetrahedra present along the b-axis, an atomic arrangement can be viewed to be three-dimensional because some oxygen atoms are located between two $Cu(1)O_4$ square planar chains, as described above. The experimental results shown in Fig. 5 are consistent with the result shown in Fig. 4. Another feature of Fig. 5 is that isomer shift is almost constant at 78 and 100 K. This result suggests that vibrational mode is changed at the onset of superconduction. The constant isomer shift values obtained at 78 and 100 K (and also at 150 K in case of doublet (b)) seem to suggest a retained amplitude (mean square velocity $<v^2>$) of lattice vibration, although we have only a few measuring points for each doublet peak. The present experimental results (Fig. 5) are consistent with the temperature dependencies of linewidth and absorption area shown in Figs. 7 and 8, respectively.

Figure 6 shows a temperature dependency of quadrupole splitting for each doublet peak. From Fig. 6, we can deduce on the average unchanged atomic configuration around Fe^{3+} or Fe^{4+} (and also Cu^{3+} or Cu^{2+}) ions and also unchanged 3d-electron configuration. In contrast to the quadrupole splitting values plotted in Fig. 6, linewidth (FWHM) of doublet (b) shows a significant decrease with increasing temperature (Fig. 7). The decrease in linewidth at higher temperatures is ascribed to a motional narrowing, which seems to be more frequent in case of one-

dimensional chains composed of CuO_4 square planars. A slight decrease in linewidth is observed in case of two-dimensional "dimpled" CuO_4 layers (doublet (a)). Figure 7 also indicates that a linewidth of doublet (c), corresponding to FeO_4 tetrahedra, is independent of the temperature.

Relative absorption area of three doublets is shown in Fig. 8. Characteristic feature of Fig. 8 is similar to

that of Figs. 5 and 7, i.e., absorption area of doublet (b) shows a pronounced decrease with increasing temperature. In contrast to this, absorption areas for doublets (a) and (c) are almost constant irrespective of the temperature, suggesting a high Debye temperature (Θ). A parameter of intermolecular force constant, Θ^2M, is calculated according to the formula,[41-43]

$$\Theta^2M = 3E^2/kc^2(-\mathrm{d}\ln f/\mathrm{d}T)^{-1}, \quad (1)$$

where M is the mass of Mössbauer nucleus and E is a Mössbauer transition energy. In Eq. 1, k and c are Boltzmann constant and velocity of light, respectively. When a very thin sample is measured, $\mathrm{d}\ln f/\mathrm{d}T$ can be approximated by $\mathrm{d}\ln A/\mathrm{d}T$,[41-43] where A and f are absorption area and recoil-free fraction, respectively. Several Θ^2M values have already been obtained for K_2O-GeO_2-SnO_2,[41] BaF_2-ZrF_4-FeF_2,[42] and K_2SO_4-$ZnSO_4$-$Fe_2(SO_4)_3$[43] glasses by Nishida et al. As a result, Θ^2M proved to be in a range of 1.9—8.7×10^6 in these glasses, depending on the composition and structure of the glass matrix. In case of BaF_2-ZrF_4-FeF_2 glasses,[42] a phase transition was observed around 225 K, where isomer shift and absorption area showed a different composition dependency. It is expected that Θ^2M of ionic compound will be much larger than those obtained for the glasses.[41-43] A Θ^2M value obtained from the total absorption area (Fig. 8d) amounts to 15.5×10^6, which corresponds to a Debye temperature (Θ) of 521 K if we substitute 57 for M. A little lower Debye temperatures have been obtained in Mössbauer studies of superconducting $YBa_2Cu_3O_{7-\delta}$[27] (455 K) and $EuBa_2Cu_3O_{7-\delta}$[28] (468 K) ceramics. Zhou et al.[27] reported that these Θ values are not exceptionally large. If we introduce a concept of "partial Debye temperature," which depends on each Mössbauer site, we can get some information corresponding to the amplitude of atomic vibrations at the individual sites. In this way, a Debye temperature of 330 K (Θ^2M= 6.2×10^6) is obtained from a slope of Fig. 8b. The relatively small Θ value is consistent with one-dimensional chains composed of $Cu(1)O_4$ square planars. On the other hand, "partial Debye temperature" amounts to 740 K (Θ^2M=31×10^6) in case of two-dimensional layers composed of "dimpled" $Cu(2)O_4$ planes (Fig. 8a). This higher Debye temperature will suggest a superconduction in the two-dimensional layers. "Partial Debye temperature" obtained from Fig. 8c (FeO_4 tetrahedra present along the b-axis) amounts to 1010 K (Θ^2M=58×10^6), for most of the absorption areas are almost constant irrespective of the temperature. Figure 8 indicates that an absorption area of each doublet measured at 78 K has the same magnitude as that measured at 100 K. Similar and more detailed results have recently been reported in case of ^{119}Sn-Mössbauer studies of $EuBa_2Cu_3O_{7-\delta}$[44] and $YBa_2Cu_3O_{7-\delta}$[45] superconductors doped with ^{119}Sn. In these studies,[44,45] it was suggested that phonons play an important role in electron pairing process. Temperature dependency of absorption area (Fig. 8) is similar to that of isomer shift shown in Fig. 5. It is understood from Figs. 5 and 8 that isomer shift is more sensitive to the change of temperature, because it is correlated with a square velocity ($\langle v^2 \rangle$) of atomic vibrations, as described above. Anyhow, when a superconduction occurs in $YBa_2Cu_3O_{7-\delta}$ ceramics, amplitude of atomic vibrations concerned with "dimpled" $Cu(2)O_4$ planes (and also $Cu(1)O_4$ square planars) will be retained in spite of the decrease in temperature. This will cause a strong phonon-electron coupling in the superconducting state.

The authors are grateful to Dr. Saburo Nasu of Osaka University and Prof. Yasukuni Matsumoto of Kinki University (Iizuka, Fukuoka) for useful comments and discussion. One of the authors (TN) is grateful to Kazuchika Ohkura Memorial Foundation for a financial support.

Syntheses of Acetyl-1-bromopyrenes

Masahiro MINABE,* Hidehiro MOCHIZUKI, Masaaki YOSHIDA, and Takashi TODA
Department of Applied Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321
(Received April 15, 1988)

The reaction of 1-bromopyrene with acetic anhydride in the presence of aluminium chloride afforded an *ipso*-substituted compound, 1-acetylpyrene, in addition to the expected compounds, 6-acetyl- and 8-acetyl-1-bromopyrene. 7-Acetyl-1-bromopyrene was prepared via the acetylation of 2-acetylamino-1-bromo-4,5,9,10-tetrahydropyrene. The structures of the acetylbromopyrenes were assigned according to the two-dimensional NMR spectra.

The chemistry of pyrene (**1**) is comparatively well-known in polycyclic aromatic hydrocarbons (PAHs).[1] An electrophilic substitution of **1** is known to take place preferentially at the 1-position,[2] and a second attack occurs at the 6- and 8-positions on bromination,[3] and at the 3-, 6-, and 8-positions on acetylation.[4] The isomeric 4- and 2-derivatives are easily obtained through the electrophilic substitutions of 1,2,3,6,7,8-hexahydropyrene[2,5,6] and of 4,5,9,10-tetrahydropyrene (**2**),[6-9] respectively. The reaction of 1-acetylpyrene (**3**)[2] with bromine afforded 1-bromoacetylpyrene as the main product.[10]

Recent development on synthetic programs of **1** has been classified into three categories: the first is the syntheses of derivatives of **1** as active metabolites.[11] Secondly, **1** is one of the useful starting materials to prepare PAHs for a carcinogenesis investigation and other purposes.[12,13] The third concerns the hydrogenated compounds of **1** as hydrogen donor solvents in the coal liquefaction process.[14]

During the course of the syntheses of indeno[1,2,3-*cd*]pyrenes, we have required some acetylbromopyrenes as precursors and for a consideration of the spectral characterization of indenopyrenes. The present paper deals with the Friedel–Crafts acetylation of 1-bromopyrene (**4**)[5] giving 6-acetyl- (**5**) and 8-acetyl-1-bromopyrene (**6**). The isomeric 7-acetyl-1-bromopyrene (**7**) was obtained from **2** through several steps. The structures of these isomers were assigned according to the NMR spectra.

Results and Discussion

The reaction of **4** with acetic anhydride in the presence of aluminium chloride yielded **3** (8%), **5** (23%), and **6** (34%), respectively, with the recovery of **4** (12%). The ratio of isomeric **5** and **6** was in fair agreement with the ratio on the diacetylation[4] of **1**. No detection of 1-acetyl-3-bromo isomer is similar to no isolation of 1,3-dibromopyrene in the bromination[3] of **4**, though different from the formation of 1,3-diacetylpyrene.[4] The formation of **3** is not due to the contaminating **1** in **4** because purity of **4** being over 98%: **3** was produced by the *ipso*-substitution of **4**.[15]

The first unknown compound in the sequence of the synthesis of **7** is 2-acetylamino-4,5,9,10-tetrahydropyrene (**8**): nitration of **2** with acetyl nitrate in acetic anhydride afforded 2-nitro derivative (**9**)[8] as the main product (74%), accompanied by 1-nitro isomer (**10**)[7] (8%). The resulting **9** was reduced to amine **11** by a procedure described elsewhere,[8] and the amino group was protected by the acetyl group to give **8**.

The synthesis of **7** from **8** is illustrated in Scheme 2. Bromination of **8** yielded, exclusively, 1-bromo derivative **12**. The Friedel–Crafts acetylation of **12** gave predominantly 7-acetyl derivative **13**: a steric repulsion

governs the regioselectivity of the acetylation giving no 3-acetyl isomer. Amine **14** was obtained by the hydrolysis of **13**, and a deamination of **14** gave 7-acetyl-1-bromo-4,5,9,10-tetrahydropyrene (**15**), followed by dehydrogenation to form **7**.

The IR and electronic spectra of **5** are very similar to those of **6**: carbonyl signals appear at 1668 cm^{-1} for **5** and 1664 cm^{-1} for **6**, and the absorption maxima were observed at 362 nm for **5** and 360 nm for **6**, respectively, having resemblance to those of **3** (389, 357, 285, 243, and 235 nm) (Fig. 1). On the contrary, those of **7** (1678 cm^{-1} and 345 nm) are significantly different from those of **5** and **6**. The absorptions at 345, 329, and 315 nm of **7** are very similar to those of **4** (347, 330, and 316 nm), showing a red shift from the parent **1** (337, 321, and 307 nm). This suggests that the 7-acetyl group of **7** can not conjugate effectively with an aromatic system, in comparison with those of **5** and **6**. This phenomenon should be similar to the "weak interaction" between the nitro group and the pyrenyl moiety of 2-nitropyrene.[6,11] These are ascribed to the different electron densities at the 1- and 2-position of parent **1**.[16]

The NMR signals of isomeric **5**, **6**, and **7** were assigned according to a 2D-NMR technique:[12,17] the chemical shifts and the ^3J coupling constants of ^1H NMR are summarized in Table 1. The characteristic peaks of **6**, compared with those of **5**, are a set of AB doublets at δ=8.09 and 8.10, corresponding to H_4 and H_5, respectively. The absorptions of peri and ortho protons to the acetyl group appear at 8.99 and 8.37 for **5** and 9.13 and 8.42 for **6**; these are in accord with those (ca. 9.0—9.1 and 8.4 ppm, respectively) for the diacetylpyrenes.[4] The signals of peri and ortho protons to the bromine absorb at 8.47 and 8.24 for **5**, at 8.57 and 8.29 for **6**, and at 8.48 and 8.29 ppm for **7**, respectively. The ^3J coupling constants of H_4/H_5 and H_9/H_{10} show large values upon substitutions of bromine and/or acetyl groups at the peri positions. It may demonstrate that the fairly good additivity by peri substituents is held on the coupling constants.

During a sequence of experiments, the nitration of **8** was examined in order to clarify the reactivity of **8**: the nitration of **8** gave two isomers, 2-acetylamino-1-nitro- (**16**) and 2-acetylamino-7-nitro-4,5,9,10-tetrahydropyrene (**17**), in a ratio of 60:40 (by HPLC). This finding is significantly different from the bromination of **8**: this is because of a higher regioselectivity of bromination than that of nitration.

Compound **16** was hydrolyzed to give free amine **18** followed by oxidation to yield 1,2-dinitro-4,5,9,10-tetrahydropyrene (**19**). The dehydrogenation of **19** afforded 1,2-dinitropyrene (**20**) (mp 246—248 °C, decomp). The NMR spectrum of **20** is the same as the reported values of the compound,[11,18] which was

Table 1. ^{1}H NMR of Acetyl-1-bromopyrenes, **5**, **6**, and **7**

Position in pyrene	Chemical shift δ/ppm (coupling const.[a]/Hz)		
	5	**6**	**7**

obtained by the nitration of 2-nitropyrene with nitric acid.

Experimental

All melting points are uncorrected. The NMR, IR, and electronic absorption spectra were recorded on a Varian VXR-300, a Jasco IR-G (KBr pellets), and a Hitachi U-3400 apparatus (EtOH). ^{1}H NMR were generally obtained using 3 mg of a sample dissolved in 0.62 ml of $CDCl_3$ in a 5 mm tube; ^{13}C NMR and 2D-NMR were measured using 11—14 mg of the specimen. Gas chromatograms were obtained by a Shimadzu GC-8AMP attached column (3 mm ID, 1 m) containing Dexsil 300 GC (5%) on Chromosorb WAW.

Materials. 1-Acetylpyrene (**3**) was obtained by the method described in the literature:[2] mp 87—90 °C (lit,[2] mp 88—90 °C); IR (C=O), 1660 cm^{-1}; ^{1}H NMR, δ=2.90 (3H, s), 8.04 (1H, t, J=7.7 Hz, H_7), 8.04 (1H, d, J=8.9 Hz, H_5), 8.14 (1H, d, J=8.1 Hz, H_3), 8.14 (1H, d, J=8.9 Hz, H_4), 8.21 (1H, d, J=9.5 Hz, H_9), 8.23 (1H, d, J=7.7 Hz, H_6), 8.24 (1H, d, J=7.7 Hz, H_8), 8.36 (1H, d, J=8.1 Hz, H_2), and 9.05 (1H, d, J=9.5 Hz, H_{10}); ^{13}C NMR, δ=30.5 (Me), 123.9 (C_3), 124.2 (C_{10c}), 124.9 (C_{10}), 125.0 (C_{10b}), 126.1 (C_5 or C_7), 126.3, 126.4, 127.0 (C_7 or C_5), 127.1 (C_2), 129.4 (C_{10a}), 129.6, 129.7, 130.4, 131.0, 131.8, 134.0 (C_1), and 202.1 (C=O).

1-Bromopyrene (**4**) was obtained by a method described in the literature:[5] mp 98.5—100.0 °C (lit,[5] mp 95—96.5 °C). Purity of **4** was determined to be over 98.0% (by GLPC, 245 °C) with contaminations of **1** (<0.2%) and dibromopyrenes (<1.8%). ^{1}H NMR of **4**, δ=7.99 (1H, d, J=8.1 Hz, H_3), 8.00 (1H, d, J=9.1 Hz, H_5), 8.02 (1H, t, J=7.5 Hz, H_7), 8.07 (1H, d, J=9.1 Hz, H_4), 8.15 (1H, d, J=9.3 Hz, H_9), 8.20 (1H, d, J=7.5 Hz, H_6 or H_8), 8.21 (1H, d, J=7.5 Hz, H_8 or H_6), 8.21 (1H, d, J=8.1 Hz, H_2), and 8.42 (1H, d, J=9.3 Hz, H_{10}); ^{13}C NMR, δ=119.9 (C_1), 124.0 (C_{10b}), 125.4 (C_5), 125.5 (C_8), 125.7 (C_6), 125.8 (C_{10c}), 125.9 (C_{10}), 126.5 (C_7), 127.1 (C_3), 127.7 (C_4), 128.9 (C_9), 129.6 (C_{10a}), 130.0 (C_2), 130.5 (C_{8a}), 130.9 (C_{5a}), and 131.1 (C_{3a}).

2-Nitro-4,5,9,10-tetrahydropyrene (**9**) was obtained by a method described elsewhere:[8] mp 108.5—110.5 °C (lit,[8] mp 110.8—111.6 °C); IR, 1528 and 1334 cm^{-1}; ^{1}H NMR, δ=2.9—3.0 (8H, m), 7.12 (2H, d, J=7.2 Hz, $H_{6,8}$), 7.22 (1H, t, J=7.2 Hz, H_7), and 7.95 (2H, s, $H_{1,3}$).

Isomeric **10** was isolated from the mother liquor of **9**: mp 142—144.5 °C; IR, 1518 and 1350 cm^{-1}; UV (CH_2Cl_2), λ_{max} 336, 279, and 271 nm; ^{1}H NMR, δ=2.8—3.0 (6H, m, $H_{4,5,9}$), 3.15 (2H, t, J=7.5 Hz, H_{10}), 7.13 (2H, d, J=7.5 Hz, $H_{6,8}$), 7.20 (1H, d, J=8.4 Hz, H_3), 7.22 (1H, t, J=7.5 Hz, H_7), and 7.73 (1H, d, J=8.4 Hz, H_2).

2-Amino-4,5,9,10-tetrahydropyrene (**11**) was obtained by a method described elsewhere:[8] mp 165.5—168 °C (decomp) (lit,[8] mp 168.8—169.6 °C); IR, 3390 and 3310 cm^{-1}; UV (CH_2Cl_2), λ_{max} 301 nm; ^{1}H NMR, δ=2.75—2.88 (8H, m, $H_{4,5,9,10}$), 3.65 (2H, bs, NH_2), 6.42 (2H, s, $H_{1,3}$), and 7.03 (3H, s, $H_{6,7,8}$).

Acetylation of 4. To a solution of **4** (323 mg, 1.2 mmol) in CH_2Cl_2 (5 ml) was added $AlCl_3$ (0.64 g, 4.8 mmol), and successively dropwise Ac_2O (0.49 ml, 5.2 mmol) over 3.5 h under ice-cooling. Upon stirring for an additional 0.5 h, the reaction mixture was quenched by an addition of ice. A small portion of the reaction mixture was analyzed by GLPC (at 245 °C with octacosane as an internal reference): **4** (retention time 5.6 min, 12.0%), **3** (7.9 min, 7.6%), **5** (19.7 min, 23.0%), and **6** (21.3 min, 34.0%) were confirmed to be contained.

The remaining part was percolated on silica gel (55 g) with PhH and separated into two fractions. The first eluate afforded a mixture (79 mg, mp 101—114 °C) of **1**, **4**, and dibromopyrenes. The second eluate gave a mixture (278 mg, mp 76—88 °C) of **3**, **5**, and **6**. The mixture was treated with LiChroprep Si-60 (E. Merck, 40—60 μm) using hexane-THF (95/5). The fraction between 1900—2200 ml gave 16 mg of **5**: mp 156.5—158.5 °C (from hexane); IR, 1668 cm^{-1}; UV, λ_{max} 390 (s, log ε 3.97), 362 (4.31), 285 (4.60), 244 (4.60), and 237 nm (s, 4.52); ^{13}C NMR, δ=30.5 (Me), 121.3 (C_1), 124.3 (C_{10c}), 124.5 (C_8), 125.2 (C_5), 125.4 (C_{10b}), 126.5 (C_3), 127.5 (C_7), 128.0 (C_{10}), 128.5 (C_9), 129.3 (C_4), 129.4 (C_{10a}), 129.5 (C_{5a}), 129.9 (C_{3a}), 130.6 (C_2), 132.6 (C_6), 133.6 (C_{8a}), and 202.1 (C=O); MS (70 eV), m/z 324, 322, 309, 307, 281, 279, and 200. Found: C, 66.76; H, 3.38%. Calcd for $C_{18}H_{11}OBr$: C, 66.89; H, 3.43%.

The fraction between 2400—2800 ml afforded 18 mg of **6**: mp 144—146 °C (hexane); IR, 1664 cm^{-1}; UV, λ_{max} 392 (log ε 4.01), 360 (4.39), 286 (4.47), 246 (4.60), and 238 nm (s, 4.53); ^{13}C NMR, δ=30.5 (Me), 121.2 (C_1), 124.3 (C_{10c}), 124.7 (C_6), 125.4 (C_{10b}), 126.5 (C_9), 126.7 (C_3), 127.3 (C_5), 127.5 (C_7), 128.1 (C_{10}), 129.0 (C_{10a}), 129.2 (C_4), 130.4 (C_{3a}), 130.5 (C_2), 130.6 (C_{8a}), 132.3 (C_8), 133.9 (C_{5a}), and 201.9 (C=O); MS (70 eV), m/z 324, 322, 309, 307, 281, 279, and 200. Found: C, 66.83; H, 3.40%. Calcd for $C_{18}H_{11}OBr$: C, 66.89; H, 3.43%.

2-Acetylamino-4,5,9,10-tetrahydropyrene (8). A mixture of **11** (4.972 g, 22 mmol) and Ac_2O (4.2 ml, 44 mmol) in PhH (100 ml) was refluxed for 1 h to give 5.797 g (99%) of **8**: mp 200.5—203.0 °C (decomp); IR, 3250, 1676, and 1648 cm^{-1}; UV, λ_{max} 314 (log ε 4.25), 300 (4.38), 290 (s, 4.28), and 237 nm

(3.70); ^{1}H NMR, δ=2.19 (3H, s, Me), 2.86 (8H, s, $H_{4,5,9,10}$), 7.04—7.14 (3H, m, $H_{6,7,8}$), 7.16 (1H, bs, NH), and 7.23 (2H, s, $H_{1,3}$); MS (20 eV), *m/z* 263, 221, and 200. Found: C, 81.84; H, 6.51; N, 5.22%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

Bromination of 2-Acetylamino-4,5,9,10-tetrahydropyrene (8). To a solution of **8** (1.315 g, 5 mmol) in $CHCl_3$ (180 ml) was added dropwise a solution of bromine (1.4 g, 7.8 mmol) in $CHCl_3$ (100 ml) under ice-cooling during a period of 2.5 h. Upon treatment with aq. $Na_2S_2O_3$ (3%), the organic layer afforded 1.55 g (91%) of **12**: mp 200.5—202.0 °C (decomp); IR, 3250 and 1660 cm^{-1}; UV, λ_{max} 296 (log ε 4.18) and 287 nm (4.19); ^{1}H NMR, δ=2.26 (3H, s, Me), 2.85—2.93 (6H, m, $H_{4,5,9}$), 2.98—3.06 (2H, m, H_{10}), 7.08 (1H, d, *J*=8.9 Hz, H_6 or H_8), 7.08 (1H, d, *J*=5.5 Hz, H_8 or H_6), 7.14 (1H, dd, *J*=5.5, 8.9 Hz, H_7), 7.73 (1H, s, NH), and 8.11 (1H, s, H_3); MS (20 eV), *m/z* 343, 341, 301, 299, and 262. Found: C, 62.98; H, 4.66; N, 4.08%. Calcd for $C_{18}H_{16}NOBr$: C, 63.17; H, 4.17; N, 4.09%.

Synthesis and Hydrolysis of 7-Acetyl-2-acetylamino-1-bromo-4,5,9,10-tetrahydropyrene (13). Aluminium chloride (7.04 g, 53 mmol) was added to a solution of **12** (3.762 g, 11 mmol) in CH_2Cl_2 (80 ml), and Ac_2O (1.7 ml, 18 mmol) was added dropwise at room temperature to the resulting mixture over 1 h. After the usual work-up, the crude materials were chromatographed on SiO_2 with CH_2Cl_2–AcOEt (8/2) to give 3.078 g (73%) of **13**: mp 248—250 °C (decomp); IR, 3260 and 1662 cm^{-1}; UV, λ_{max} 325 nm (log ε 4.37); ^{1}H NMR, δ=2.27 (3H, s, Me), 2.61 (3H, s, Me), 2.86—3.06 (8H, m, $H_{4,5,9,10}$), 7.68 (2H, s, $H_{6,8}$), 7.78 (1H, s, NH), and 8.18 (1H, s, H_3); MS (20 eV), *m/z* 385, 383, 343, 341, and 304. Found: C, 62.28; H, 4.55; N, 3.53%. Calcd for $C_{20}H_{18}NO_2Br$: C, 62.51; H, 4.72; N, 3.65%.

A mixture of **13** (1.215 g, 3.2 mmol), aq. HCl (20%, 25 ml), and EtOH (15 ml) was refluxed for 4.5 h to yield 825 mg (77%) of **14**: mp 176—177 °C (decomp); IR, 3460, 3340, and 1664 cm^{-1}; UV, λ_{max} 360 (log ε 4.35) and 246 nm (4.10); ^{1}H NMR, δ=2.60 (3H, s, Me), 2.75—3.05 (8H, m, $H_{4,5,9,10}$), 4.29 (2H, bs, NH_2), 6.57 (1H, s, H_3), and 7.66 (2H, d, *J*=1.8 Hz, $H_{6,8}$); MS (20 eV), *m/z* 343, 341, 328, and 326. Found: C, 62.80; H, 4.70; N, 3.91%. Calcd for $C_{18}H_{16}NOBr$: C, 63.17; H, 4.71; N, 4.09%.

7-Acetyl-1-bromopyrene (7). Amine **14** (724 mg, 2.1 mmol) was dissolved into a mixture of aq. HCl (18%, 20 ml) and THF (10 ml). The resulting mixture was diazotized with aq. $NaNO_2$ under ice-cooling, followed by stirring overnight with EtOH (16 ml) at room temperature. Upon a work-up by silica-gel column chromatography with CH_2Cl_2, **15** (448 mg, 65%) was obtained: mp 68—70 °C; IR, 1676 cm^{-1}; UV, λ_{max} 321 (s, log ε 4.35), 309 (4.39), 251 (s, 3.70), and 242 nm (3.89); ^{1}H NMR, δ=2.62 (3H, s, Me), 2.83—2.97 (6H, m, $H_{4,5,9}$), 3.02—3.07 (2H, m, H_{10}), 6.99 (1H, d, *J*=8.1 Hz, H_3), 7.43 (1H, d, *J*=8.1 Hz, H_2), and 7.69 (2H, s, $H_{6,8}$); MS (20 eV), *m/z* 328, 326, 313, 311, 203, and 202. Found: C, 65.97; H, 4.59%. Calcd for $C_{18}H_{15}OBr$: C, 66.07; H, 4.62%.

A mixture of **15** (115 mg, 0.35 mmol) and DDQ (397 mg, 1.75 mmol) in PhH (5 ml) was refluxed overnight, followed by column chromatography using alumina and PhH to give 62 mg (55%) of **7**: mp 157—159 °C; IR, 1678 cm^{-1}; UV, λ_{max} 406 (log ε 3.04), 385 (2.90), 345 (4.54), 329 (4.30), 315 (3.90), and 270 nm (4.71); ^{13}C NMR, δ=27.1 (Me), 120.4 (C_1), 124.8 (C_6), 124.9 (C_8), 125.2 (C_{10b}), 125.9 (C_3), 126.0 (C_{10c}), 126.6 (C_{10}), 127.8 (C_4), 128.0 (C_5), 129.2 (C_9), 130.1 (C_{10a}), 130.6 (C_{8a}), 130.9 (C_{5a}), 131.0 (C_{3a}), 131.1 (C_2), 134.4 (C_7), and 198.3 (C=O); MS (20 eV), *m/z* 324, 322, 309, 307, 281, 279, and 200. (Found: C, 66.28; H, 3.41%. Calcd for $C_{18}H_{11}OBr$: C, 66.90; H, 3.43%.)

Nitration of 8. A mixture of acetyl nitrate (4 mmol) in Ac_2O was added dropwise into a cold solution of **8** (526 mg, 2 mmol) in Ac_2O (50 ml); the reaction mixture was stirred for 40 min under ice-cooling. The resulting mixture was confirmed to contain **16** (48%), **17** (33%), and **8** (20%) by means of HPLC (LiChrosorb RP-18, CH_3CN). Upon work-up of the mixture with ice-water, the precipitate was chromatographed on SiO_2 with hexane–AcOEt (1/1) to give **16** (228 mg, 37%) and **17** (166 mg, 23%). **16**: mp 192—194 °C (decomp); IR, 3250, 1664, 1528, and 1368 cm^{-1}; UV, λ_{max} 288 (log ε 4.27) and 276 nm (s, 4.23); ^{1}H NMR, δ=2.22 (3H, s, Me), 2.8—3.0 (8H, m, $H_{4,5,9,10}$), 7.11 (2H, d, *J*=7.7 Hz, $H_{6,8}$), 7.19 (1H, d, *J*=7.7 Hz, H_7), 8.04 (1H, s, H_3), and 8.49 (1H, s, NH); MS (70 eV), *m/z* 308, 266, 250, and 249. Found: C, 70.19; H, 5.16; N, 9.07%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.11; H, 5.23; N, 9.09%.

17: mp 275—276 °C (decomp); IR, 3320, 1666, 1546, and 1334 cm^{-1}; UV, λ_{max} 370 (log ε 4.31), 261 (3.96), and 248 nm (3.96); ^{1}H NMR, δ=2.05 (3H, s, Me), 2.8—3.0 (8H, m, $H_{4,5,9,10}$), 7.40 (2H, s, $H_{1,3}$), 7.99 (2H, s, $H_{6,8}$), and 10.05 (1H, s, NH); MS (70 eV), *m/z* 308 and 266. Found: C, 70.26; H, 5.22; N, 9.04%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.11; H, 5.23; N, 9.09%.

In another experiment, **10** (263 mg, 1 mmol) was nitrated at a room temperature; in addition to 124 mg (40%) of **16**, 13 mg (4%) of 2-acetylamino-1,7-dinitro-4,5,9,10-tetrahydropyrene was isolated: mp 277 °C (decomp); IR, 3310, 1680, 1524, 1506, and 1348 cm^{-1}; ^{1}H NMR, δ=2.25 (3H, s, Me), 2.97—3.00 (8H, m, $H_{4,5,9,10}$), 7.99 (2H, s, $H_{6,8}$), 8.19 (1H, s, H_3), and 8.58 (1H, s, NH); MS (20 eV), *m/z* 353, 308, 294, and 249.

Synthesis of 1,2-Dinitro-4,5,9,10-tetrahydropyrene (19) and Dehydrogenation to 20. A mixture of **16** (681 mg, 2.2 mmol), aq. HCl (10%, 20 ml), and EtOH (35 ml) was refluxed for 2 h to give 515 mg (88%) of red needles of **18**: mp 159—161 °C; IR, 3470, 3370, 1514, and 1348 cm^{-1}; UV, λ_{max} 438 (log ε 3.04), 307 (s, 4.28), 296 (4.39), and 285 nm (4.37); ^{1}H NMR, δ=2.78—2.85 (6H, m, $H_{4,5,9}$), 3.00 (2H, t, *J*=6.6 Hz, H_{10}), 4.88 (2H, bs, NH_2), 6.62 (1H, s, H_3), and 7.04—7.15 (3H, m, $H_{6,7,8}$); MS (20 eV), *m/z* 266 and 249. Found: C, 72.06; H, 5.21; N, 10.48%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52%.

To a solution of **18** (300 mg, 1.1 mmol) in $CHCl_3$ (10 ml) was added dropwise a solution of *m*-chloroperbenzoic acid (876 mg, 5.6 mmol) in $CHCl_3$ (15 ml) under ice-cooling; the resulting mixture was stirred at a room temperature for 2 h to give 242 mg (72%) of **19**: mp 192—194 °C (decomp); IR 1544, 1528, and 1330 cm^{-1}; UV, λ_{max} 351 nm (log ε 4.07); ^{1}H NMR, δ=2.84—3.07 (8H, m, $H_{4,5,9,10}$), 7.18 (2H, d, *J*=7.5 Hz, $H_{6,8}$), 7.32 (1H, t, *J*=7.5 Hz, H_7), and 7.96 (1H, s, H_3); MS (20 eV), *m/z* 296, 204, 203, and 202. Found: C, 64.94; H, 3.97; N, 9.37%. Calcd for $C_{16}H_{12}N_2O_4$: C, 64.86; H, 4.08; N, 9.46%.

A solution of **19** (141 mg, 0.48 mmol) in PhH (6 ml) was refluxed overnight with DDQ (1.081 g, 4.8 mmol). After filtration, the filtrate was chromatographed on alumina with PhH to give 122 mg (87%) of **20**: mp 246—248 °C (decomp); IR, 1557, 1536, and 1344 cm^{-1}; UV, λ_{max} 418 (log ε

3.10), 369 (3.15), 343 (3.64), 292 (4.02), and 249 nm (3.78); ^{1}H NMR,[11] δ=8.06 (1H, d, J=9.5 Hz), 8.22 (1H, d, J=9.2 Hz), 8.26 (1H, t, J=7.8 Hz), 8.38 (1H, d, J=9.2 Hz), 8.39 (1H, d, J=9.5 Hz), 8.41 (1H, d, J=7.8 Hz), 8.44 (1H, d, J=7.8 Hz), and 8.87 (1H, s, H_3); ^{13}C NMR (only tertiary carbons), δ=119.7, 120.5, 126.9, 128.0, 128.4, 129.0, 131.7, and 132.8; MS (20 eV), m/z 292, 262, 216, and 200.

Present work was partially supported by a Grant-in-Aid for Scientific Research (No. 61470022) from the Ministry of Education, Science and Culture. One of us (M. M.) is particularly indebted to Professor Ronald G. Harvey, the University of Chicago, for useful suggestions concerning the chemistry of pyrene.

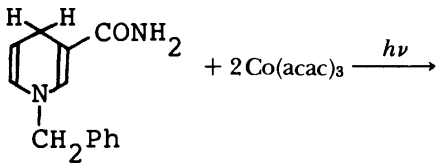
Methylviologen-Accelerated Photoreduction of Tris(acetylacetonato)cobalt(III) with 1-Benzyl-1,4-dihydronicotinamide

Kohichi YAMASHITA, Shûta KAJIWARA, and Katsutoshi OHKUBO*
Department of Applied Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received May 13, 1988)

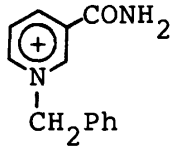
The photoreduction of tris(acetylacetonato)cobalt(III) ($Co(acac)_3$) by 1-benzyl-1,4-dihydronicotinamide (BNAH) was examined with or without methylviologen in the wavelength range of 340—410 nm. The reaction rate of electron transfer from BNAH to $Co(acac)_3$ was considerably enhanced by methylviologen, especially, in lower polar environments; The weaker the hydrophobic interaction between BNAH and the substrate become, the more effectively methylviologen acts as an electron mediator for the above photoreaction. The reaction mechanism is also discussed with particular reference to the participation of the electron mediator in the elementary steps of the present photoinduced reaction.

The photochemistry of organic or inorganic compounds including biological ones is of general interest because of their importance in relation to solar energy conversion, new methods of organic synthesis, biomimetic photoinduced reactions, etc.[1] Recently, one of the biologically interesting compounds related to coenzyme NAD(P)H, 1,4-dihydropyridines (absorption maxima at 300—400 nm) have received considerable attention, since their reactivities as a reductant are enhanced remarkably by photoirradiation.[2–6]

In our previous work,[3] the photoactivated 1-benzyl-1,4-dihydronicotinamide (BNAH) was found to be very reactive for the reduction of cobalt(III) complexes such as tris(acetylacetonato)cobalt(III) ($Co(acac)_3$), especially in the presence of surfactant micelles which accelerate the reaction through the lengthening of the lifetime of the photoexcited BNAH and through the concentrating of BNAH and the substrates on the micellar surface.



(BNAH)



$$+ 2Co(acac)_3 + 2acac^- + H^+ \quad (1)$$

BNAH has an absorption maxima of $\pi \rightarrow \pi^*$ excitation on the dihydropyridine ring at 360 nm and an oxidation potential of about −2 V (vs. SCE)[4,7] in its photoexcitation state.

The electron transfer from photoactivated BNAH (BNAH*) to the substrate in the reaction expressed by Eq. 1 might be accelerated by using a good electron mediator such as methylviologen (MV^{2+}) (reduction potential of −0.69 V vs. SCE[6]). This can effectively trap the activated electron from the short-living BNAH* (0.93 ns in methanol).[5,6] The cationic radical of the methylviologen (MV^{+}) formed by the reaction of MV^{2+} and BNAH* might donate the electron to the substrate directly or indirectly.[8]

This report describes how methylviologen behaves as an electron mediator in the photoinduced reduction of $Co(acac)_3$ by BNAH, based on a kinetic analysis of the reaction.

Experimental

Materials. 1-Benzyl-1,4-dihydronicotinamide (BNAH) was prepared according to the previous method.[9] The commercially available $Co(acac)_3$ was purified by recrystallization from petroleum ether–benzene. Satisfactory elemental analyses were obtained for both BNAH and $Co(acac)_3$. Methylviologen (MV^{2+}) was also commercially available as its chloride and was used without further purification. The solvents methanol and water were distilled and deoxygenated before use by purging with gaseous nitrogen.

Reaction Procedure. The homogeneous 20—90% (v/v) methanol–0.02 mol dm^{-3} borate buffer (pH 9.0) solution, containing BNAH (1.25×10^{-3} mol dm^{-3}), $Co(acac)_3$ (1.25×10^{-3} mol dm^{-3}), and MV^{2+} (0—3.13×10^{-2} mol dm^{-3}), was irradiated in a Pyrex cell using a 400 W mercury lamp in the wavelength range $410>\lambda>340$ nm with Toshiba glass filter UV-35 and UV-D35. The reaction temperature was kept at 30±0.5 °C by stirring with a thermostated cell holder. The reaction rates of the photoreduction of $Co(acac)_3$ with BNAH were followed by the spectrophotometric determination of the decreased amount of $Co(acac)_3$ at λ_{max}=595 nm and that of BNAH at λ_{max}=360 nm using a JASCO UVIDEC-430A spectrophotometer. The light intensities were determined by Reinecke's salt actinometry.[10] The fluorescence spectrum of BNAH was measured by means of the JASCO FP-550A fluorescence spectrophotometer. The lifetime (τ) of photoexcited BNAH in the present reaction media was estimated from τ=0.93 ns of BNAH* in methanol[5] by measuring the fluorescence quantum yield relative to that obtained in methanol. Reduction potentials of MV^{2+} and $Co(acac)_3$ were determined by the cyclic voltammetry measurements which were performed on a Hokuto Denko Model HA-301 potentiostat/galvanostat at 298—313 K in 20—90% (v/v) methanol–borate buffer solution, using a standard calomel reference electrode (SCE).

Results and Discussion

When the reaction of BNAH and $Co(acac)_3$ was carried out in the 20—90% (v/v) methanol-0.02 mol dm^{-3} borate buffer solution (pH 9.0), in a nitrogen atmosphere at 30 °C, the photoirradiation of the reaction mixtures immediately caused the decrease in the absorbance of $Co(acac)_3$ at 595 nm, while such an absorption change of $Co(acac)_3$ was not observed during the thermal reaction in the dark for 6 h. Such an absorption decrease at 595 nm in the present photoreduction of $Co(acac)_3$ by BNAH was considerably accelerated by the presence of MV^{2+} (Fig. 2). All the reactions in Fig. 1 obeyed a pseudo-first-order rate law. The pseudo-first-order rate constants (k_{obs}) increased with increasing the concentration of MV^{2+}. In the case of the molar ratio of $[MV^{2+}]/[BNAH]=25$, the rate constant (k_{obs}) increased in value tenfold as compared with that in the absence of MV^{2+} (Fig. 3). The photoirradiation of the methanol-borate buffer solution containg BNAH and MV^{2+} caused electron transfer from the former to the latter with the formation of new absorption maxima of a reduced MV^{2+} (viz., MV^{+}) at 400 nm and 602 nm. These two peaks immediately disappeared by exposure to O_2 through the reaction of MV^{+} and O_2; Such a MV^{+} formation is also recognized in the photoreaction of NADH and MV^{2+}.[5] Therefore, the methylviologen cation radical, MV^{+}, formed by the photoirradiation of the reaction mixtures present (BNAH, MV^{2+}, and $Co(acac)_3$) participated in the reduction of $Co(acac)_3$.

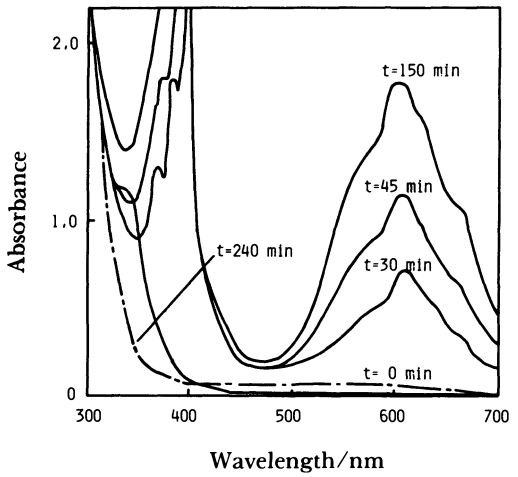


Fig. 1. Absorption spectral change during photoirradiation of BNAH and MV^{2+}. Broken line: O_2 bubling after t=240 min. $[BNAH]=1.25\times10^{-3}$ mol dm^{-3}, and $[MV^{2+}]=1.25\times10^{-3}$ mol dm^{-3} at 30 °C in 90% (v/v) methanol-borate buffer (pH 9.0) in a nitrogen atmosphere.

The quantum yield (Φ_{BNAH}) was evaluated on the basis of the amount of BNAH consumed by $Co(acac)_3$ or MV^{2+}. The Φ_{BNAH} value obtained in the present electron transfer reaction with MV^{2+} was characterized as the sum of the Φ_{BNAH} values evaluated in the reaction between BNAH* and MV^{2+} and in the reaction between BNAH* and $Co(acac)_3$. For instance, the presence of MV^{2+} in amounts equimolar with BNAH resulted in $\Phi_{BNAH}=7.31\times10^{-3}$, which was equal to the sum of the quantum yield for the reduction MV^{2+} by BNAH ($\Phi_{BNAH}=3.01\times10^{-3}$) and for the reduction of $Co(acac)_3$ by BNAH without MV^{2+} ($\Phi_{BNAH}=4.13\times10^{-3}$). Therefore, it is obvious that the photoinduced reduction of $Co(acac)_3$ by BNAH with MV^{2+} proceeds through the direct electron transfer from BNAH* to $Co(acac)_3$ and through the electron transfer from MV^{+}

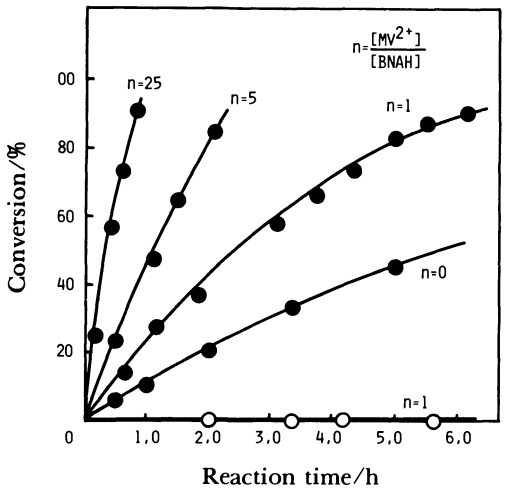

Fig. 2. Reduction of $Co(acac)_3$ with BNAH. Filled circle: Photoreduction, Empty circle: Thermal reduction. $n=[MV^{2+}]/[BNAH]$. $[BNAH]=1.25\times10^{-3}$ mol dm^{-3}, $[Co(acac)_3]=1.25\times10^{-3}$ mol dm^{-3}, at 30 °C in 90% (v/v) methanol-borate buffer (pH 9.0) in a nitrogen atmosphere.

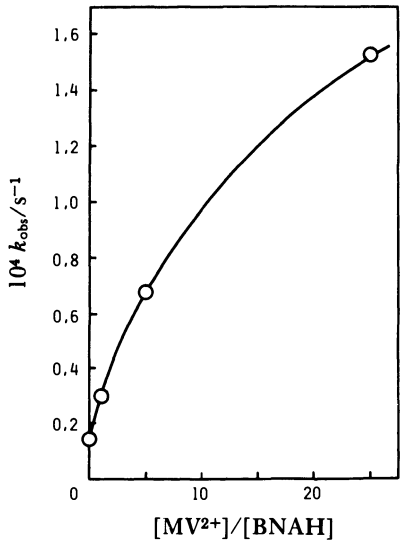

Fig. 3. The concentration effects of MV^{2+} on the pseudo-first-order rate constants in the photoreduction of $Co(acac)_3$ with BNAH. Reaction conditions are the same as Fig. 2.

(formed by the reaction of BNAH* and MV^{2+}) to $Co(acac)_3$. In this sense, the inactivation of BNAH* without the direct electron transfer to $Co(acac)_3$ is suppressed by the efficient electron mediator action of MV^{2+}.

In regard to the reaction mechanism of the present photoreduction of $Co(acac)_3$ by BNAH with MV^{2+}, the following multi-step electron transfer ($1e^-$, H^+, $1e^-$) mechanism (see Scheme) can be suggested as the most

$$\text{BNAH} \xrightarrow{h\nu} \text{BNAH}^* \quad (2a)$$

$$\text{BNAH}^* \xrightarrow{k_{ic}} \text{BNAH} \quad (2b)$$

$$\text{BNAH}^* \xrightarrow{k_f} \text{BNAH} + h\nu \quad (2c)$$

$$\text{BNAH}^* + MV^{2+} \xrightarrow{k_1} \text{BNAH}^{+\cdot} + MV^{+\cdot} \quad (2d)$$

$$\text{BNAH}^* + Co(acac)_3 \xrightarrow{k_1'} \text{BNAH}^{+\cdot} + Co(acac)_2 + acac^- \quad (2e)$$

$$\text{BNAH}^{+\cdot} \xrightarrow{k_2} \text{BNA}\cdot + H^+ \quad (2f)$$

$$\text{BNA}\cdot + MV^{2+} \xrightarrow{k_3} \text{BNA}^+ + MV^{+\cdot} \quad (2g)$$

$$\text{BNA}\cdot + Co(acac)_3 \xrightarrow{k_3'} \text{BNA}^+ + Co(acac)_2 + acac^- \quad (2h)$$

$$MV^{+\cdot} + Co(acac)_3 \xrightarrow{k_4} MV^{2+} + Co(acac)_2 + acac^- \quad (2i)$$

plausible mechanism.[6,11] In this mechanism, BNAH is activated to its singlet excited state, BNAH*, by photoirradiation (Reaction 2a), and the BNAH* once formed turns into a cationic radical ($BNAH^{+\cdot}$) by releasing one electron toward MV^{2+} or $Co(acac)_3$ via Reactions 2d, e, otherwise it is deactivated via Reactions 2b, c. A proton-releasing Reaction 2f is followed by the second electron-transfer step of the reaction between BNA· and the electron acceptor ($Co(acac)_3$ or MV^{2+}), as shown in Reaction 2g or 2h. The cationic radical ($MV^{+\cdot}$) formed by Reaction 2d and 2g donate the electron to $Co(acac)_3$ directly (Reaction 2i). These proton elimination and electron transfers might proceed very quickly because the pK_a value of $BNAH^{+\cdot}$ was 3.6 and the oxidation and reduction potentials (vs. SCE) of BNA·, MV^{2+}, and $Co(acac)_3$ were estimated to be -1.08, -0.47, and about -0.3 V respectively.[12,13] In practice, the accumulation of $MV^{+\cdot}$ ($\varepsilon_{max} \cong 12000$ mol^{-1} dm^3 cm^{-1} at 602 nm)[6] was not observed spectrophotometrically in the present photoreaction with MV^{2+}. It should be stressed that the amount of BNAH consumed by the thermal or photoinduced decomposition is negligibly small in comparison with that of BNAH reacted for the reduction of $Co(acac)_3$ and MV^{2+} in the present conditions (pH 9.0 at 30 °C), although 1,4-dihydropyridines such as BNAH undergo acid-catalyzed decomposition.[14]

From the reaction scheme (2a—i) the following Stern-Volmer equation (Eq. 3) was derived by a stationary state assumption of the concentration of BNAH*, $BNAH^{+\cdot}$, BNA·, and $MV^{+\cdot}$:

$$\frac{1}{\dfrac{1}{\Phi_{BNAH}} - 1} = \tau(k_1 MV^{2+} + k_1' Co(acac)_3) \quad (3)$$

where Φ_{BNAH}=quantum yield evaluated from the BNAH consumption and τ=lifetime of BNAH* in the absence of $Co(acac)_3$ and MV^{2+}. The Stern-Volmer equation (Eq. 3) can be rewritten as Eq. 4 or 5 for the present reaction without $Co(acac)_3$ and MV^{2+}, respectively.

$$\frac{1}{\Phi_{BNAH}} = \frac{1}{k_1\tau}\frac{1}{[MV^{2+}]} + 1 \quad (4)$$

$$\frac{1}{\Phi_{BNAH}} = \frac{1}{k_1' t}\frac{1}{[Co(acac)_3]} + 1 \quad (5)$$

As shown in Fig. 4, the linear relationship between $1/(1/\Phi_{BNAH}-1)$ and $[Co(acac)_3]$ was realized by the straight line of plots of $1/(1/\Phi_{BNAH}-1)$ vs. $[Co(acac)_3]$ for the photoreduction of $Co(acac)_3$ ($0.80-3.75\times10^{-3}$ mol dm^{-3}) with BNAH (1.25×10^{-3} mol dm^{-3}) in the presence of MV^{2+} (1.25×10^{-3} mol dm^{-3}); that is, the reaction sequences shown in scheme seems reliable for the present photoreactions. The k_1 and k_1' values in Eq. 3 were respectively estimated to be $(2.8\pm0.2)\times10^9$ and $(3.3\pm0.2)\times10^9$ mol^{-1} dm^3 s^{-1} from the above linear relationship by using the reported lifetime (τ=0.93 ns) value of BNAH*.[5] The relationship expressed by Eq. 4 or 5 was also satisfied in the photoreduction of $Co(acac)_3$ with BNAH or of MV^{2+} with BNAH (Fig. 5),

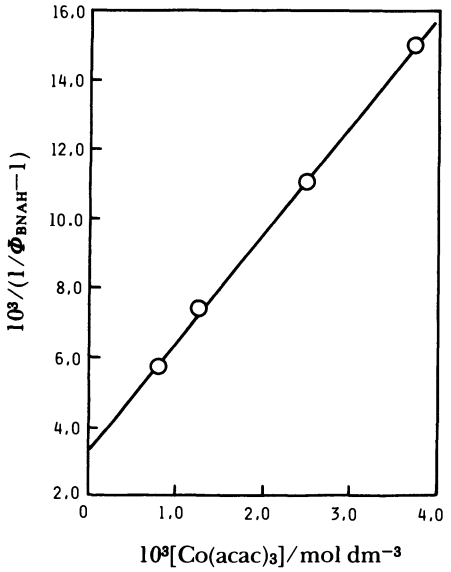

Fig. 4. Stern-Volmer plots for the photoreduction of $Co(acac)_3$ with BNAH in the presence of MV^{2+}. [BNAH]=1.25×10^{-3} mol dm^{-3}, and $[MV^{2+}]=1.25\times10^{-3}$ mol dm^{-3} at 30 °C in 90% (v/v) methanol-borate buffer (pH 9.0) in a nitrogen atmosphere.

and the straight lines in Fig. 5 resulted in $(3.0\pm0.2)\times10^9$ and $(3.4\pm0.2)\times10^9$ mol dm^{-3} s^{-1} for the k_1 and k_1' values, respectively. Notably, these two k_1 and k_1' values are approximately the same as those obtained from Eq. 3. This implies that both the electron-transfer reactions between BNAH and MV^{2+} and between BNAH and $Co(acac)_3$ are induced by the photoirradiation without interaction of $Co(acac)_3$ and MV^{2+} themselves.

The above-mentioned reaction mechanism suggests that the present photoreaction proceeds via the following photoactivation of such charge-transfer (CT) complexes as BNAH-MV^{2+}, if one takes account of the fact that 1,4-dihydropyridine compounds form CT-complexes with MV^{2+} in homogeneous or micellar solutions.[5]

$$\text{BNAH} + MV^{2+} \longrightarrow \text{BNAH-}MV^{2+} \quad (6)$$

$$\text{BNAH-}MV^{2+} \xrightarrow{h\nu} \text{BNAH-}MV^{2+*} \xrightarrow{Co(acac)_3} \text{BNAH}^{+} + Co(acac)_2 + MV^{2+} + acac^{-} \quad (7)$$

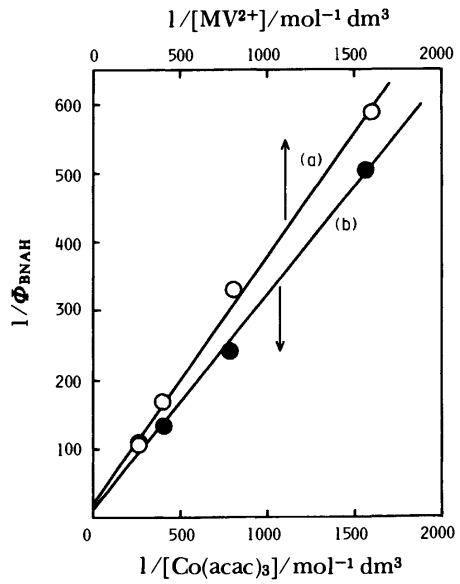

Fig. 5. Stern-Volmer plots for the photoreduction of (a) MV^{2+} and (b) $Co(acac)_3$ with BNAH. [BNAH]= 1.25×10^{-3} mol dm^{-3} at 30 °C in 90% (v/v) methanol-borate buffer (pH 9.0) in a nitrogen atmosphere.

However, such a CT-complex formation between BNAH and MV^{2+} can be negligible in the present reaction, because the present reaction did not generate the CT spectra of BNAH-MV^{2+} and the appreciable deviations of the observed data from the linear lines of the Stern-Volmer relationship by the CT-complex formation.

Since the lifetime (τ) of BNAH* and the reaction rate (k_1 or k_1') of BNAH* consumption by MV^{2+} or $Co(acac)_3$ might be affected by the reaction conditions, it is of interest to note how the present photoreduction of $Co(acac)_3$ by BNAH is dependent on the water content in the methanol-borate buffer solvent. As shown in Table 1, increasing the water content in the range of 10—80 vol.% accelerated Reaction 2e but retarded Reaction 2d. The reduction potentials of MV^{2+} and $Co(acac)_3$ seem not to be affected essentially by the increased water content. In a polar solvent the hydrophobic BNAH* can interact more easily with the hydrophobic $Co(acac)_3$ rather than with the hydrophilic MV^{2+}, so as to augment the k_1' value con-

siderably. However, the increased water content in the solvents shortened the lifetime of BNAH* (see Table 1), because BNAH* is inactivated by vibrational relaxation with water. Nevertheless, the increase of the water content in the solvents resulted in the slightly increased value of the pseudo-first-order rate constant (k_{obs}) of the overall reaction. This is probably because of the considerable acceleration of the elementary reaction between BNAH* and $Co(acac)_3$ at the higher water content in the solvents. In this sense, the extent of the contribution of MV^{2+} to the present photoreaction as an electron mediator via Reaction 2d is apparently large at low water contents of the solvents.

The present reaction also changes with the reaction temperature, as is shown in Table 2. The temperature elevation does not benefit the reaction in terms of the shortening of the lifetime of photoexcited BNAH* by increased vibrational relaxation of BNAH* in the solution.[15] However it does promote the electron transfer reactions expressed by Eqs. 2d and 2e , as reflected in the increased rate constants (k_1 and k_1') at higher temperatures. At any rate, the quantum yield (Φ_{BNAH}) given for the overall reaction in the presence of MV^{2+} decreased with increasing temperature, because the enhanced rate of BNAH* consumption by MV^{2+} or $Co(acac)_3$ did not affect the elevation of the Φ_{BNAH} value by overcoming the shortened lifetime of BNAH*. As reflected in the different extent of the rate change by the temperature difference between Reactions 2d and 2e, the magnitude of the contribution of MV^{2+} to the present reaction through the reaction with BNAH* suffers with the reaction temperature: the k_1 value (at 293 K) for the reaction between BNAH* and MV^{2+}, which was almost equal to the k_1' value (at 293 K) for the reaction between BNAH* and $Co(acac)_3$, was enhanced by the temperature elevation to a smaller extent as compared with the k_1' value in Reaction 2e; that is, the participation of MV^{2+} in the present reaction via Reaction 2d becomes less important at a temperature higher than 293 K.

Since linear Eyring relationships are obtainable from both the rate constants (k_1 and k_1') estimated at the temperature range of 293—313 K (Fig. 6), it is of interest to note the thermodynamic parameters (free energy of activation $\Delta G^{\neq}$, enthalpy of activation $\Delta H^{\neq}$, and entropy of activation $\Delta S^{\neq}$) for Reactions 2d and 2e.[16] Although the same $\Delta G^{\neq}$ values were obtained for Reactions 2d and 2e at 303 K, $T\Delta S^{\neq}$ value for Reaction 2e was less than that for Reaction 2e. This suggests that

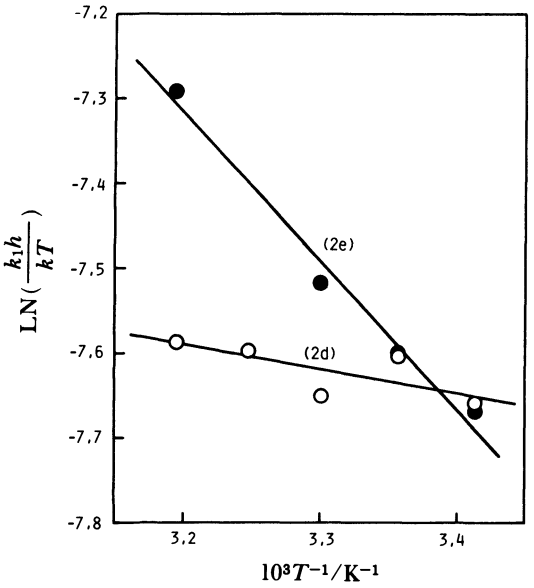

Fig. 6. Eyring relationships for the elementary reactions of 2d and 2e. Empty circle: Reaction 2d. Filled circle: Reaction 2e. [BNAH]=1.25×10^{-3} mol dm^{-3}, [MV^{2+}]=1.25×10^{-3} mol dm^{-3}, [$Co(acac)_3$]= 1.25×10^{-3} mol dm^{-3} in 90% (v/v) methanol-borate buffer (pH 9.0) in a nitrogen atmosphere.

BNAH and $Co(acac)_3$ react each other through a hydrophobic interaction as mentioned above.

Thus, it is concluded from the present study that the presence of hydrophilic MV^{2+} as an electron mediator in the photoreduction of hydrophobic $Co(acac)_3$ with hydrophobic BNAH accelerates the reaction considerably through the efficient acceptance of the electrons from the photoactivated BNAH*, especially in the lower polarity of the reaction conditions (viz., in the smaller content of water in the solvents in the present reaction) and, of course, through the smooth electron transfer from the electron mediator itself to $Co(acac)_3$.

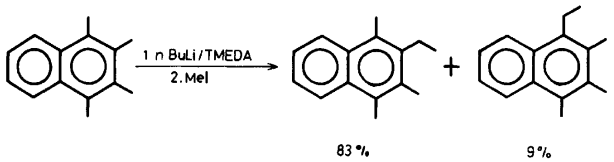
Selectivities of Aromatic Methyl Metalation.[1] Unexpectedly Strong Interactions of Carbanions with Aromatic Rings

Satoshi INAGAKI,* Takeo IMAI, and Yoshio MORI
Department of Chemistry, Faculty of Engineering, Gifu University,
Yanagido, Gifu 501-11
(Received May 25, 1988)

The site selectivities of the metalation reactions of dimethylnaphthalenes and dimethylanthracenes followed by MeOD quenching were investigated experimentally and theoretically. The 2(3)-methyl groups were found to be more effectively metalated than expected from the LUMO amplitudes of the aromatic rings. The MNDO calculations suggested that the naphthylmethyl and anthrylmethyl anions are not the aromatic rings perturbed by the carbanions, but the significantly different conjugated rings doubly bonded to the exocyclic carbon atoms. The unexpectedly strong interactions of the carbanion centers with the aromatic rings can account for the discrepancies between the selectivities and the LUMO amplitudes.

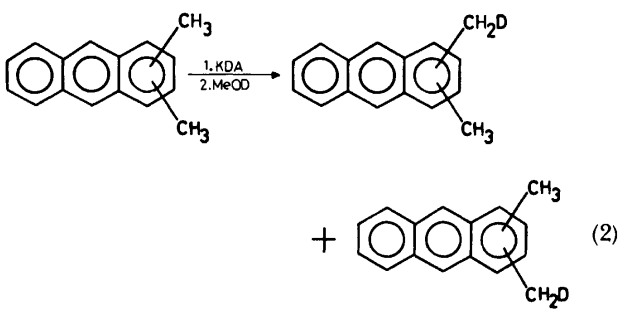
Aromatic compounds react with electrophiles (electron acceptors) and with nucleophiles (electron donors) at the positions where the HOMO and LUMO amplitudes are large, respectively. A similar expectation can be made for relative stabilities of aromatic compounds substituted by electron-releasing and -withdrawing groups. For example, aromatic compounds with an anionic center directly attached to the ring are expected to be stable when the LUMO amplitude is large on the substituted carbon atom. In fact, the acid dissociation constants[2] of isomeric naphthols and anthrols support the expectation: pK_a (H_2O, 20 °C)=9.85 for 1-naphthol and 9.93 for 2-naphthol; 9.88 for 1-anthrol and 9.92 for 2-anthrol. The LUMO of naphthalene and anthracene has greater extension at the 1- than 2-position (Fig. 1). However, the site-selectivity of the methyl metalation reactions of 1,2,3,4-tetramethylnaphthalenes observed by Dunkelblum and Hart[3] is opposite to the prediction based on the LUMO amplitudes. The metalation by butyllithium/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (*n*-BuLi/TMEDA) complex base preferentially occurs on the 2-methyl group (Eq. 1).



(1)

The anomaly was proposed[3] to come from steric origin: the C_2-methyls are closer to coplanarity with the naphthalene ring than the C_1-methyls, and *n*-BuLi/TMEDA, which is relatively large base, may attack the C_2-methyl to avoid the large steric interactions at the peri positions. A few years before, Kronzer and Sandel[4] estimated the kinetic parameters for the methylene rotation of the 1- and 2-naphthylmethyl (NM) organometallic compounds by the NMR spectroscopy. No appreciable difference was observed between the two isomers in the free energy of activation: ΔG^*(kcal mol^{-1}, 0 °C)=12.9±0.3 for 1-NM lithium and 12.8±0.5 for 2-NM lithium. In addition, Drakenberg et al.[5] reported the rotational barrier for the naphthoyl radicals. The barrier (ΔG^*) is lower for 1-naphthoyl radical (6.4 kcal mol^{-1}) than for 2-naphthoyl radical (8.2 kcal mol^{-1}). These rotational barriers throw a doubt on the steric explanation of the selectivity, rather than lend support to it.

We undertook experimental studies (Eq. 2) by employing 1,3-dimethylnaphthalene (DMN) and some dimethylanthracenes (DMA). The selectivity of the metalation reactions of the aromatic methyls was not always found to be in agreement with the LUMO amplitudes. The methyl metalations at the 2-positions of naphthalene and anthracene were shown to occur more preferentially than expected. The MNDO calculations suggested that methylnaphthalene and -anthracene, especially 2-methyl derivatives, might undergo more drastic structural change in the aromatic rings on metalation, which may account for the failure of the prediction based on the LUMO amplitudes.



(2)

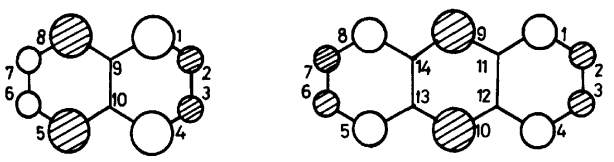


Fig. 1. The LUMO's of naphthalene and anthracene.

Results and Discussion

Selectivity. The metalation of 1,3-DMA preferentially occurred at the 3-methyl group, irrespective of the molar ratio of bases to the substrate (Fig. 2) and the reaction time (Fig. 3), although the LUMO amplitude is the smallest on C_3. For 1,10-DMA the 10-methyl metalation was preferred (Fig. 4). The LUMO amplitude is greater at the 9(10)-position(s). The selectivity is such as expected from the LUMO. The reactions of 2,9-DMA were not selective (Fig. 5), while the LUMO amplitude is much greater at the 9(10)-position(s). The absence of the selectivity is incompatible with the LUMO.

The reactions of 1,3-DMN were compared with 1,3-DMA. The 3-methyl metalation was preferred (Fig. 6). The selectivity is in good agreement with the observation by Dunkelblum and Hart.[3]

The selectivity consistent with the LUMO amplitude of the aromatic rings is only for 1,10-DMA. The other DMN and DMA examined here exhibited the opposite or inconsistent selectivities. The results present a striking contrast to the relative acidities of the isomeric naphthols and anthrols which can be explained in terms of the LUMO amplitudes.

MO Study. Molecular orbital study was undertaken to investigate the selectivity. Geometries of naphthylmethyl (NM) and anthrylmethyl (AM) carbanions were optimized by the MNDO molecular orbital calculations.[6] The relative stabilities of the isomeric anions are listed in Table 1.

Table 1. Relative Energies[a] of Naphthylmethyl (NM) and Anthrylmethyl (AM) Anions

1-NM	2-NM	1-AM	2-AM	9-AM
0.0	−0.77	0.0	−0.29	−2.44

a) The results of the MNDO calculations in kcal mol^{-1}.

Although the calculated energy differences between 1- NM and 2-NM and between 1-AM and 2-AM anions are small, the relative stabilities are unexpectedly compatible with the observed selectivities of 1,3-DMN and 1,3-DMA. The 9-AM anion was shown to be the most stable. This result is in agreement with the prediction based on the LUMO amplitude and with the preferential C_{10} methyl metalation of 1,10-DMA. However, the result conflicts with the comparable extents of the C_2 and C_9 methyl metalations of 2,9-DMA. As a result, the 2-methyl metalation was concluded to occur more preferentially than expected from the calculated relative stabilities of the intermediate carbanions and the LUMO amplitudes of the aromatic rings.

Some interesting features were found in the optimized geometries (Fig. 7). The exocyclic bonds are surprisingly among the shortest in each species. These structures are not regarded as the aromatic rings perturbed by the methyl anions, but as entirely different conjugated rings doubly bonded to the methyl carbon atoms. The unexpected structural features can account for the failure in predicting the selectivity on the basis of the frontier orbital theory. The interactions of the carbanion centers with the naphthalene and anthracene rings are suggested to be too strong to be treated by the perturbation approach. The discrepancy between the LUMO amplitudes and the selectivities of the aromatic methyl metalations

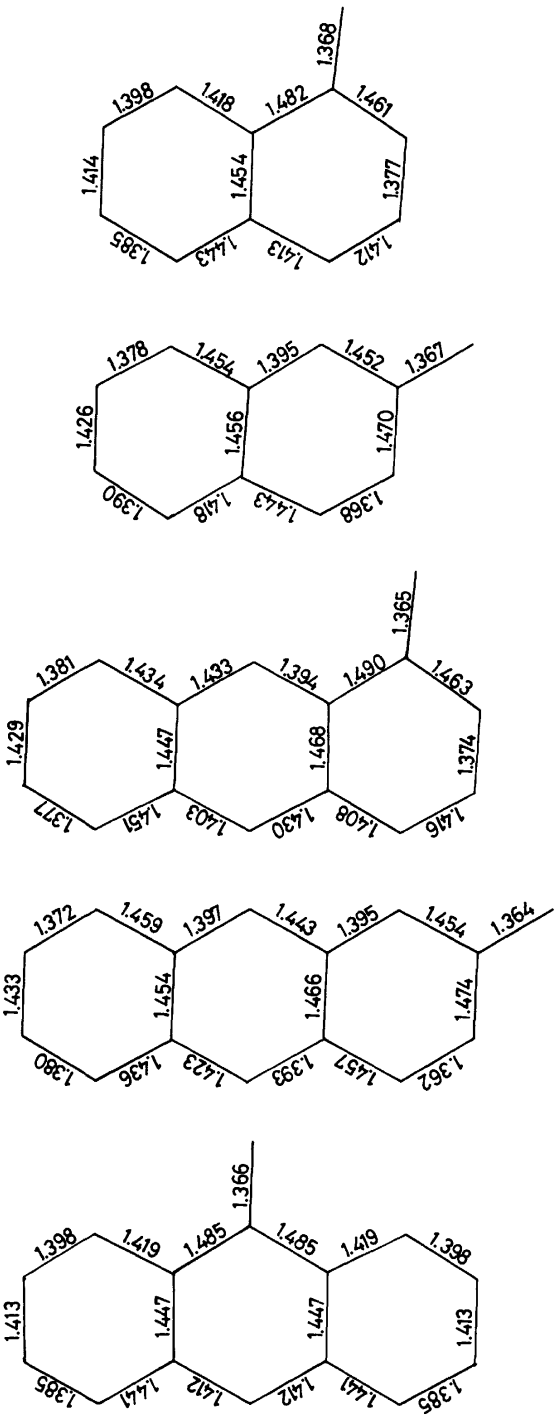

Fig. 7. The MNDO-optimized geometries of the naphthylmethyl (NM) and anthrylmethyl (AM) anions.

(the relative stabilities of the arylmethyl anions) is not necessarily incompatible with the success in explaining the relative acidities of the naphthols and anthrols. The oxy anions have n-orbitals at a lower energy level than the carbanions. The energy gaps between the n-orbitals and the LUMO of the aromatic rings are greater for the oxy anions. The frontier orbital interaction is weak enough to treat the

interactions of the oxy anions with the aromatic rings by the perturbational approach.

The bond alternations are remarkable all over the aromatic rings of the 2-NM and 2-AM anions. On the other hand, no appreciable bond alternation was found in the unsubstituted rings of the 1-NM, 1-AM, and 9-AM anions. The contrast was expected to give a clue to interpreting the preference of the 2-methyl metalation. Unfortunately, the explicit relation between the structural peculiarities and the selectivities still remains open to question.

Concluding Remarks

The selectivities of the methyl metalations of some dimethyl derivatives of naphthalene and anthracene were carried out under the same experimental conditions in order to examine the relation with the LUMO amplitudes of the aromatic rings. The preferential 3-methyl metalation of 1,3-DMN and 1,3-DMA is in conflict with the prediction from the LUMO amplitudes. The nonselective metalation of 2,9-DMA cannot be explained in terms of the LUMO which has much greater extension at the 9-position. The preference of the 10-methyl metalation of 1,10-DMA is in agreement with the LUMO amplitude. These results suggest that 2(3)-methyl group is more effectively metalated than expected from the LUMO amplitudes. The failure in predicting the selectivities from the LUMO presents a striking contrast to the success in predicting the acidities of the isomeric naphthols and anthrols.

The MNDO calculations suggested the strong interactions of the carbanions with the aromatic rings and the resulting double bond formation between them. The strong interaction rather than perturbation may be associated with the failure in the LUMO predictions of the relative stabilities of the isomeric arylmethyl anions or the selectivities of the aromatic methyl metalations. The successful explanation of the relative acidities of naphthols and anthrols can be understood in terms of weak interactions of the oxy anions with the aromatic rings due to lower n-orbital energies of the oxy anions.

Experimental

Materials. 1,3-, 1,4-, and 2,3-DMA's were prepared[7-9] from the anthraquinones.[10] 2,9- and 1,10-DMA's were obtained by Grignard synthesis from the anthrones.[11]

Metalation Reactions follwed by MeOD Quenching. DMA or DMN (0.1 g) was added to the KDA solution[12] which was prepared by mixing of t-BuOK into equimolar LDA in 10 ml of hexane under nitrogen atmosphere. The reaction mixtures immediately colored dark green for DMA and dark violet for DMN. The mixtures were stirred for a given period of time, and then quenched by a large excess of MeOD. After washing with dilute hydrochloric acid the organic layer was extracted by benzene and dried over sodium sulfate. The mixture was separated on the TLC. The ratios of methyl protons were determined by the 270 MHz FT-NMR spectroscopy on the basis of the 9- and 10-protons (2.0) for 1,3-DMA, the 9-proton (1.0) for 1,10-DMA, and the 10-proton (1.0) for 2,9-DMA.

The MNDO molecular orbital calculations were carried out on a HITAC M-680H computer, at the Institute for Molecular Science. NMR spectra were recorded on a JEOL JNM-GX 270 spectrometer, at the Center of Instrumentation, Gifu University. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Synthesis and Enantiomer Recognition of Dipodands and Crown Ethers Containing the 2,3:6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene Residue as the Chiral Subunit

Koichiro NAEMURA,* Rinkō FUKUNAGA, Masanori KOMATSU, Masatoshi YAMANAKA, and Hiroaki CHIKAMATSU
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received May 31, 1988)

Five new optically active crown ethers and six optically active dipodands are reported. The crown ethers were synthesized by using (+)-(1*S*,4*R*,5*S*,8*R*)-2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diol and (+)-(1*S*,4*R*,5*S*,8*R*)-4,8-bis(hydroxymethyl)-2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene as a chiral subunit and the dipodands contained the 2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene residue as a chiral anchor group. The enantiomer recognition behaviour of these compounds was evaluated by the enantiomer differential transport of methyl (±)-phenylglycinate and (±)-1,2-diphenylethylamine hydrochloride through bulk liquid membrane.

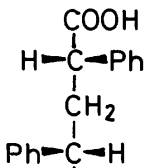
A large number of chiral crown ethers have been synthesized and numerous reports have described their chiral recognition properties.[1] Chiral discrimination of an open-chained equivalent of crown ether, to which Vögtle and Weber have suggested the term "podand",[2] is also interesting in the host–guest chemistry. Although a variety of optically active podands have been prepared,[1] as far as we know, little has been reported on their chiral recognition behavior.

In a recent publication,[3] we have reported on the preparation of optically active crown ethers and dipodands, and their chiral recognition properties. The crown ethers contained the *trans*-tetrahydrofuran-2,5-diylbis(hydroxymethylene) residue as a chiral subunit and dipodands contained the same residue as a chiral anchor group. All of the dipodands showed the enantiomer selectivity toward chiral primary ammonium salts examined and the dipodand having two 2,3-benzo-1,4,7-trioxa-2-octen-1-yl groups as a donor arm as well as the chiral tetrahydrofuran anchor group exhibited higher enantiomer selectivity than the crown ether having the same chiral subunit. It was also showed that the enantiomer selectivity of dipodands in transport was considerably changed by selection of the end group.

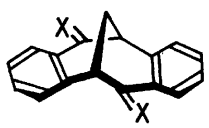
These recent results prompted us to examine the chiral recognition property of dipodands and crown ethers, and to acquire further information about the change of the enantiomer selectivity of dipodands produced by the variation in the structure of donor arm. In this paper, we report the preparation of optically active crown ethers and dipodands having a chiral anchor group. These compounds contained the 2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene residue as a chiral subunit. Their enantiomer recognition behavior was evaluated by the enantiomer differential transport of racemic primary ammonium salts through bulk liquid membrane.

Results and Discussion

(+)-(2*S*,4*S*)-2,4-Diphenylglutaric acid (**1**), $[\alpha]_D$ +81.3° (EtOH), was obtained by treatment of the sparingly soluble quinine salt with concentrated hydrochloric acid followed by recrystallization from ethanol.[4] The absolute configuration of the compound has been unambigously determined by a chemical correlation with (−)-(*R*)-3-phenylbutanoic acid.[4] Treatment of (+)-**1** with concentrated sulfuric acid at 80—90 °C for 1 h gave (−)-**2** in 77% yield, recrystallization of which from methanol provided the optically pure specimen **2**, mp 195—197 °C; $[\alpha]_D$ −340° (EtOH).[4] Reduction of (−)-**2** with $LiAlH_4$ in dry tetrahydrofuran (THF) yielded (+)-**4**, mp 192—194 °C; $[\alpha]_D$ +87.2° (EtOH), in 97% yield. Reaction of (+)-**4** with methyl *p*-toluenesulfonate and NaH in dry *N*,*N*-dimethylformamide (DMF) at 45 °C gave (−)-**11**, mp 169—170 °C; $[\alpha]_D$ +15.0° ($CHCl_3$), in 57% yield. The another chiral subunit (+)-**5** having two hydroxymethyl groups was prepared from (−)-**2** as follows. Wittig reaction of

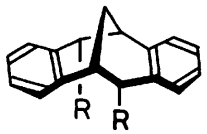


1



2 X = O

3 X = CH_2



4 R = OH

5 R = CH_2OH

(−)-**2** with methyltriphenylphosphonium bromide using potassium *t*-butoxide and THF[5] gave (−)-**3**, mp 126—127 °C; $[\alpha]_D$ −391° (EtOH), in 92% yield. Treatment of (−)-**3** with diborane in THF led to the corresponding organoborane which was converted into (+)-**5**, mp 170—172 °C; $[\alpha]_D$ +143° (EtOH), in 85% overall yield by oxidation with 30% H_2O_2 in THF followed by treatment with 3 M (1 M=1 mol dm^{-3}) aqueous sodium hydroxide.

Using the diols (+)-**4** and (+)-**5** as a chiral subunit, we prepared optically active crown ethers. One of the ethylene glycol unit of 18-crown-6 and 15-crown-5 was replaced by the chiral diol (+)-**4** to give the chiral crown ethers **6** and **7** respectively. High-dilution condensation of (+)-**4** with pentaethylene glycol ditosylate in the presence of NaH in refluxing THF provided the crown ether (−)-**6**,[6] mp 115—117 °C; $[\alpha]_D$ −1.5° ($CHCl_3$), in 16% yield after alumina chromatography followed by recrystallization from hexane-benzene, and the formation of the dimeric crown ether formed by the condensation of two molecules of the diol **4** with two ditosylate molecules was not detected. By use of the same procedure, (+)-**4** was condensed with tetraethylene glycol ditosylate to give the mixture of crown ethers. Alumina chromatography of the mixture furnished (+)-**7**,[6] mp 72—74 °C; $[\alpha]_D$ +42.6° ($CHCl_3$) and the dimeric crown ether (+)-**8**,[6] mp 166—168 °C; $[\alpha]_D$ +5.4° ($CHCl_4$), in 11% and 12% yield, respectively. Their structures were confirmed on the basis of their mass and ^{1}H NMR spectra as well as elemental analyses. Analogously, condensation of (+)-**5** with pentaethylene glycol and tetraethylene glycol ditosylate in the presence of NaH in THF gave (+)-**9**,[6] $[\alpha]_D$ +51.2° ($CHCl_3$), (a glassy solid 12% yield) and (+)-**10**,[6] $[\alpha]_D$ +24.0° ($CHCl_3$), (a glassy solid 11% yield), respectively. In both cases, the formation of dimeric crown ethers was not detected and the dehydrated product (−)-**3** was isolated.

Cation-binding abilities for alkali metal ions (Li^+, Na^+, K^+, and Rb^+) of the crown ethers **6** and **7** were estimated by solvent extraction of aqueous solution of metal picrates with a chloroform solution containing crown ether, and the results are given in Table 1. As

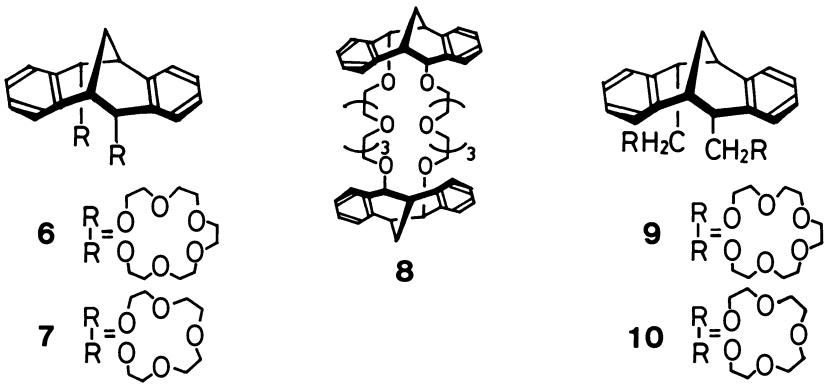
Table 1. Extraction of Alkali Metal Picrates with Crown Ethers **6** and **7**

Crown ether	Extractability/%			
	Li^+	Na^+	K^+	Rb^+
6	<0.1	6	2	1
7	<0.1	5	1	<0.1

can be seen from Table 1, both crown ethers show almost negligible extractabilities for any of the alkali metal ions examined in this study. The introduction of the chiral subunit (+)-**4** into 18-crown-6 and 15-crown-5 enlarges a cavity of the crown ether ring and this may be the major reason for the extremely low extractability of the crown ethers **6** and **7**.

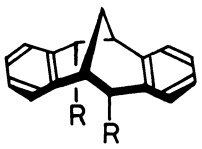
Our next task was the preparation of optically active dipodands having the 2,3:6,7-dibenzobicyclo[3.3.1]-nona-2,6-diene residue as a chiral anchor group. Condensation of (+)-**4** with 3-oxabutyl *p*-toluenesulfonate and NaH in dry DMF at 45—50 °C gave the dipodand (−)-**12** which possessed the methyl end group and two oxygen atoms in each donor arm. Both of the dipodands (−)-**13** and (−)-**14** contained two methyl end groups and they differed from each other in the number of donor atoms in a side chain. The dipodands (−)-**13** having three oxygen atoms in each side arm was prepared by condensation of (+)-**4** with 3,6-dioxaheptyl *p*-toluenesulfonate and the dipodand (−)-**14** having four oxygen atoms in each side arm was obtained from (+)-**4** and 3,6,9-trioxadecyl *p*-toluenesulfonate. The dipodands (−)-**15**, (−)-**16**, and (−)-**17**, all of which contained three oxygen atoms in a donor arm, differed from one another in the end group. Treatment of (+)-**4** with 3,6-dioxaoctyl, 3,6-dioxadecyl, and 7-phenyl-3,6-dioxaheptyl *p*-toluenesulfonate gave (−)-**15** having two ethyl end groups, (−)-**16** having two butyl end groups, and (−)-**17** having two benzyl end groups, respectively. All of the dipodands were obtained as a colorless oil and their structures were confirmed on the basis of their mass spectra as well as their ^{1}H NMR spectra.

Cation binding abilities of podands **13** and **14** were



examined, but both compounds extracted hardly any of the metal ions.

Next we turned attention to examine the enantiomer recognition behavior of these crown ethers and dipodands in transport[7] of (±)-1,2-diphenylethylamine and methyl (±)-phenylglycinate hydrochloride through bulk liquid membrane containing the optically active host molecules. The results are summarized in Table 2.



11 R = OCH_3

12 R = $O(CH_2)_2OCH_3$

13 R = $O(CH_2)_3OCH_3$

14 R = $O(CH_2)_4OCH_3$

15 R = $O(CH_2)_2OC_2H_5$

16 R = $O(CH_2)_2OC_4H_9$

17 R = $O(CH_2)_2OCH_2Ph$

As can be seen from Table 2, all crown ethers and dipodands transported dominantly 1,2-diphenylethylamine hydrochloride of the *S*-configuration and methyl phenylglycinate hydrochloride of the *R*-configuration. Entries 29 and 30 were carried out using the chloroform membrane which did not contain any host molecule. In these cases, methyl phenylglycinate hydrochloride scarcely transferred to the inner aqueous phase, but 4.0% of 1,2-diphenylethylamine hydrochloride moved to the receiving phase after 10 h. Entries 1, 2, 15, and 16 shows that the chiral compounds (+)-**4** and (−)-**11** containing no donor arm exhibited enantiomer selectivity, but their transportabilities were low. In Entries 3 and 4, the transport experiments were performed using the chloroform solution containing (+)-**4** and a small amount of achiral 18-crown-6. In these cases, the rate of transport of the guest molecules was obviously enhanced and the enantiomer selectivity was hardly changed by addition of 18-crown-6.

Table 2. Differential Transport of Enantiomeric Molecules through Bulk Liquid Membrane Containing Chiral Crown Ethers and Chiral Dipodands

Entry	Host	Guest[a]	Time	Transport	Configuration of dominant enantiomer	Optical purity
			h	%		%

28	(−)-**17**	b	48	11	*R*	3
29[c]	No	a	10	4.0	—	—
30[c]	No	b	72	1	—	—

a) a: (±)-1,2-Diphenylethylamine hydrochloride, b: methyl (±)-phenylglycinate hydrochloride. b) The chloroform solution contained (+)-**4** (0.005 M) and 18-crown-6 (0.0005 M). c) The chloroform solution did not contain any host molecule. d) Circular dichroism was not measured.

The enantiomer selectivity of (+)-**7** and (+)-**10**, the cavity of which is smaller than that of (+)-**6** and (+)-**9**, is higher than the selectivity of (+)-**6** and (+)-**9**. The enantiomer selectivity of (+)-**10** toward 1,2-diphenylethylamine hydrochloride is the highest in crown ethers examined here and comparable to that of biphenanthryl crown ether,[8] which has been known to be a crown ether having a high chiral recognition property. The crown ether (+)-**7** is nearly equal to biphenanthryl crown ether with regard to its enantiomer recognition behavior toward methyl phenylglycinate hydrochloride.

Entries 17—22 shows that, among dipodands (−)-**12**, (−)-**13**, and (−)-**14**, all of which have two methyl end groups, the enantiomer selectivity of (−)-**13** having three oxygen atoms in each side chain is the highest of all and comparable to that of (+)-**10**. Transportability of (−)-**12** having only two donor atoms in each side chain is low, and a significant difference was not found in transportabilities of (−)-**13** and (−)-**14**. In Entries 19, 20, and 23—28, among dipodands (−)-**13**, (−)-**15**, (−)-**16**, and (−)-**17**, all of which contain three oxygen atoms in each side chain, (−)-**13** having two methyl end groups has the highest enantiomer selectivity. The bulky end groups reduce the enantiomer selectivity of dipodand, but there is no significant difference in transportabilities of these dipodands.

As noted above, the degree of enantiomer selectivity of dipodands in transport varied widely with variation in the structure of the donor arms, and in the case of dipodands reported here, the 1,4,7-trioxaoctyl group is the best subunit as the donor arm of the chiral dipodands.

Experimental

Melting points are uncorrected. Infrared spectra were recorded on a Hitachi 260-10 spectrometer. Ultraviolet spectra were taken on a Hitachi 220A spectrophotometer and circular dichroism data were corrected with a JASCO J-40 spectropolarimeter. Optical rotations were measured with a JASCO DIP-40 automatic polarimeter. ^{1}H NMR spectra were obtained from a JNM-MH-100 and a JNM-C-60 and chemical shift are reported in parts per million (δ) down field from tetramethylsilane. Mass spectra were taken with a Hitachi RMS-4 spectrometer.

(−)-2,3:6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-dione (2). (+)-2,4-Diphenylglutaric acid (**1**) (6.00 g, 0.0211 mol) $[\alpha]_D^{22}$ +79.1° (EtOH), which was obtained from the sparingly soluble quinine salt, was stirred in concentrated sulfuric acid (40 mL) for 1 h at 80—90 °C. The mixture was cooled to room temperature, poured into an ice-water, and extracted with benzene. The extract was washed with aqueous solution of sodium hydrogencarbonate and water, dried over $MgSO_4$, and concentrated in vacuo to give **2** (4.00 g, 77% yield), which was recrystallized from methanol to furnish (−)-**2**, mp 195—197 °C; $[\alpha]_D^{22}$ −340° (*c* 0.0220, EtOH). Found: C, 82.01; H, 4.81%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.67%.

(−)-4,8-Bis(methylene)-2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (3). To a suspension of methyltriphenylphosphonium bromide[9] (36.0 g, 0.101 mol) in dry THF (450 mL) was added a suspension of potassium *t*-butoxide (11.3 g, 0.101 mol) in dry THF (190 mL), and then the mixture was stirred for 1 h at room temperature. A solution of (−)-**2** (5.00 g, 0.0202 mol); $[\alpha]_D$ −340°, in dry THF (30 mL) was added to the mixture and it was stirred for an additional 4 h at room temperature under nitrogen atmosphere. After water (15 mL) was added to the reaction mixture, it was stirred at room temperature for 1 h and an inorganic solid was filtered off. The filtrate was concentrated in vacuo and the residue was extracted with ether. The extract was washed with water, dried over $MgSO_4$, and concentrated in vacuo. After addition of hexane (200 mL) to the residue, the precipitated phosphine oxide was filtered off and the solvent was removed. The residue was chromatographed on alumina (eluted with hexane-benzene 1:1 v:v) to provide a solid, which was recrystallized from methanol to give (−)-**3** (4.52 g, 92% yield), mp 126—128 °C, $[\alpha]_D^{27}$ −391° (*c* 0.022, EtOH) (lit,[4] mp 124.2—124.6 °C; $[\alpha]_D$ +392° (EtOH)). Found: C, 93.25; H, 6.61%. Calcd for $C_{19}H_{16}$: C, 93.40; H, 6.60%.

(+)-2,3:6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diol (4). To a suspension of $LiAlH_4$ (1.60 g, 0.0421 mol) in dry THF (50 mL) was added a solution of (−)-**2** (2.65 g, 0.0107 mol) in dry THF (50 mL) at 0 °C and then the mixture was stirred for 1 h at room temperature. After addition of 10% sulfuric acid to the reaction mixture with ice-cooling, an inorganic solid was filtered off and the filtrate was concentrated in vacuo. The residue was extracted with chloroform. The extract was washed with diluted HCl, aqueous solution of sodium hydrogencarbonate, and water, and dried over $MgSO_4$. The solvent was removed in vacuo to give a solid, which was recrystallized from hexane-benzene to provide (+)-**4** (2.48 g, 92% yield), mp 192—194 °C; $[\alpha]_D^{22}$ +87.0° (*c* 0.159, EtOH). Found: C, 80.75; H, 6.36%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

(+)-4,8-Bis(hydroxymethyl)-2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (5). A freshly prepared solution of diborane (44.1 mL, 16.5 mmol) in THF was slowly added to a solution of (−)-**3** (4.04 g, 16.5 mmol) in dry THF (100 mL), and then the mixture was stirred for 1 h at room temperature under nitrogen atmosphere. After addition of a small amount of water, the reaction mixture was concentrated in vacuo to give a solid (7.78 g). The solid was dissolved in THF (100 mL), 3 M aqueous solution of sodium hydroxide (35 mL) was added, and the mixture was heated at 40 °C. 30% hydrogen peroxide (5.7 g) was added to the mixture and it was heated for an additional 2 h at this temperature. After water (50 mL) was added to the mixture, the organic phase was withdrawn and the aqueous solution was extracted with ether. The combined organic solutions were washed with water, dried over $MgSO_4$, and concentrated to give a solid, which was recrystallized from benzene to afford (+)-**5** (3.88 g, 85% yield), mp 170—172 °C; $[\alpha]_D^{27}$ +143° (*c* 0.524, EtOH); ^{1}H NMR (DMSO-d_6) δ=2.18 (2H, t J=3 Hz), 3.21 (2H, br s), 3.50 (2H, br s), 4.0—4.1 (4H, m), 4.70 (2H, br s), 6.9—7.5 (8H, m). Found: C, 81.20; H, 7.15%. Calcd for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

(−)-20,21:23,24-Dibenzo-2,5,8,11,14,17-hexaoxatricyclo-[16.3.3.1^{19,22}]pentacosa-20,23-diene (6). To a suspension of NaH (140 mg, 5.83 mmol) in dry THF (30 mL) was slowly

added a mixture of (+)-**4** (500 mg, 1.98 mmol) and pentaethylene glycol ditosylate[10] (1.20 g, 2.20 mmol) in dry THF (60 mL) over a period of 6 h under reflux in nitrogen atmosphere. After the mixture was refluxed for an additional 24 h, a small amount of water was added to the reaction mixture and the mixture was concentrated in vacuo. The residue was extracted with dichloromethane and the extract was washed with diluted HCl and aqueous solution of sodium hydrogencarbonate, and dried over $MgSO_4$. The solvent was evaporated in vacuo and the residue was chromatographed on alumina (eluted with chloroform) to give a solid, which was recrystallized from hexane-benzene to furnish (−)-**6** (140 mg, 16% yield), mp 115—117 °C; $[\alpha]_D^{26}$ −1.5°, $[\alpha]_{435}^{27}$ +30.7° (*c* 0.384, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.20 (2H, d *J*=3 Hz), 3.3—4.1 (22H, m), 4.67 (2H, d *J*=4.5 Hz), 6.9—7.5 (8H, m); MS *m/z* 454 (M^+). Found: C, 71.03; H, 7.44%. Calcd for $C_{27}H_{34}O_6$: C, 71.34; H, 7.54%.

(+)-17,18:20,21-Dibenzo-2,5,8,11,14-pentaoxatricyclo[13.3.3.1^{16,19}]docosa-17,20-diene (7) and (+)-35,36:38,39:40,41:42,43-Tetrabenzo-2,5,8,11,14,20,23,26,29,32-decaoxapentacyclo[31.3.3.2^{15,18}.2^{16,19}.1^{34,37}]tetratetracosa-35,38,40,42-tetraene (8). Condensation of (+)-**4** (500 mg, 1.98 mmol) with tetraethylene glycol ditosylate[10] (1.10 g, 2.19 mmol) and NaH (140 mg, 5.83 mmol) was carried out according to a similar procedure described for the preparation of **6**. After the same work-up, chromatography on alumina provided **7** (90 mg, 11% yield, eluted with benzene) and **8** (100 mg, 12% yield, eluted with benzene-chloroform 4:1 v:v).

7: Mp 72—74 °C (recrystallized from hexane-benzene); $[\alpha]_D^{25}$ +42.6° (*c* 0.402, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.18 (2H, t *J*=3 Hz), 2.7—3.7 (18H, m), 5.20 (2H,d *J*=7.5 Hz), 7.0—7.6 (8H, m); MS *m/z* 410 (M^+). Found: C, 72.80; H, 7.29%. Calcd for $C_{25}H_{30}O_5$: C, 73.14; H, 7.37%.

8: Mp 166—168 °C (recrystallized from benzene); $[\alpha]_D^{25}$ +5.4° (*c* 0.459, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.12 (4H, t *J*=3 Hz), 3.1—3.4 (4H, m), 3.6—4.1 (32H, m), 4.63 (4H, d *J*=4.5 Hz), 6.8—7.4 (16H, m); MS *m/z* 820 (M^+). Found: C, 72.85; H, 7.33%. Calcd for $C_{50}H_{60}O_{10}$: C, 73.14; H, 7.37%.

(+)-21,23:25,26-Dibenzo-3,6,9,12,15,18-hexaoxatricyclo[18.3.3.1^{21,24}]heptacosa-22,25-diene (9). To a suspension of NaH (130 mg, 5.42 mmol) in dry THF (30 mL) was added a mixture of (+)-**5** (500 mg, 1.81 mmol) and pentaethylene glycol ditosylate (1.10 g, 2.01 mmol) in dry THF (60 mL) over a period of 15 h under reflux and then the mixture was refluxed for an additional 29 h in nitrogen atmosphere. After the same work-up described for the preparation of **6**, the crude product was chromatographed on alumina. Fractions eluted with benzene gave (−)-**3** (53 mg, 12% yield) and fractions eluted with benzene-chloroform (9:1 v:v) gave (+)-**9** (100 mg, 12% yield) as a glassy solid, $[\alpha]_D^{23}$ +51.2° (*c* 0.775, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.20 (2H, br s), 3.2—4.0 (28H, m), 7.0—7.6 (8H, m); MS *m/z* 482 (M^+). Found: C, 71.80; H, 7.88%. Calcd for $C_{29}H_{38}O_6$: C, 72.17; H, 7.94%.

(+)-19,20:22,23-Dibenzo-3,6,9,12,15-pentaoxatricyclo[15.3.3.1^{18,21}]tetracosa-19,22-diene (10). The reaction of (+)-**5** (500 mg, 1.81 mmol) with tetraethylene glycol ditosylate (1.00 g, 1.99 mmol) and NaH (130 mg, 5.42 mmol) was performed by the same procedure described for the preparation of **6**. Alumina chromatography gave (−)-**3** (95 mg, 39% yield, eluted with benzene) and (+)-**10** (87 mg, 11% yield, eluted with benzene-chloroform 9:1 v:v) as a glassy solid, $[\alpha]_D^{24}$ +24.0° (*c* 0.566, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.20 (2H, m), 3.3—4.0 (24H, m), 7.0—7.6 (8H, m); MS *m/z* 402 (M^+). Found: C, 71.45; H, 8.35%. Calcd for $C_{24}H_{34}O_5$: C, 71.61; H, 8.51%.

General Procedure for the Preparation of Monotosylates. To a solution of 2-(2-methoxyethoxy)ethanol (5.00 g, 0.0416 mol) in pyridine (30 mL) was slowly added *p*-toluenesulfonyl chloride (11.9 g, 0.0624 mol) with ice-cooling, and the mixture was kept overnight in a refrigerator. The reaction mixture was poured into ice-water, acidified with hydrochloric acid, and extracted with benzene. The extract was washed with aqueous solution of sodium hydrogencarbonate and water, and dried over $MgSO_4$. The solvent was throughly removed in vacuo to give 10.2 g (90% yield) of 3,6-dioxaheptyl *p*-toluenesulfonate which was used in the next reaction without further purification. The other monotosylates were prepared by the same procedure described here.

(−)-4,8-Dimethoxy-2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (11). A mixture of (+)-**4** (302 mg, 1.20 mmol), NaH (115 mg, 4.79 mmol), and dry DMF (30 mL) was heated at 45 °C for 1 h. A solution of methyl *p*-toluenesulfonate (894 mg, 4.80 mmol) in dry DMF (20 mL) was added to the reaction mixture at 45 °C and then it was heated for an additional 48 h at 45—50 °C. After a small amount of water was added to the reaction mixture at room temperature, a solid was filtered off and the filtrate was concentrated in vacuo. To the residue was added diluted HCl and a precipitated solid was collected, washed with water, and recrystallized from ether-hexane to give (+)-**11** (190 mg, 57% yield), mp 169—170 °C; $[\alpha]_D^{25}$ +15.0° (*c* 0.360, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.29 (2H, t *J*=3 Hz), 3.3—3.5 (2H, m), 3.70 (6H, s), 4.54 (2H, d *J*=5.2 Hz), 7.0—7.5 (8H, m). Found: C, 81.20; H, 7.16%. Calcd for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

(−)-4,8-(1,3-dioxapentyl)-2,3:6,7-dibenzobicyclo[3.3.1]-nona-2,6-diene (12). To a suspension of NaH (144 mg, 6.00 mmol) in dry DMF (30 mL) was added (+)-**4** (378 mg, 1.50 mmol) and the mixture was stirred for 1 h at room temperature. A solution of 3-oxabutyl *p*-toluenesulfonate (863 mg, 3.75 mmol) in dry DMF (20 mL) was added to the reaction mixture and then it was stirred for 24 h at 45—50 °C in nitrogen atmosphere. After a small amount of water was added to the reaction mixture, the solvent was removed in vacuo. The residue was extracted with chloroform and the extract was washed with water, dried over $MgSO_4$, and concentrated in vacuo. The residue was chromatographed on alumina and fractions eluted with hexane-benzene (1:1 v:v) gave a solid, which was recrystallized from hexane to provide (−)-**12** (435 mg, 79% yield), mp 66—67 °C; $[\alpha]_D^{20}$ −10.3° (*c* 0.283, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.30 (2H, t *J*=3 Hz), 3.40 (6H, s), 3.3—4.3 (10H, m), 4.74 (2H, d *J*=5.2 Hz), 7.0—7.5 (8H, m). Found: C, 75.11; H, 7.70%. Calcd for $C_{23}H_{28}O_4$: C, 74.97; H, 7.66%.

(−)-4,8-Bis(1,4,7-trioxaoctyl)-2,3:6,7-dibenzobicyclo[3.3.1]-nona-2,6-diene (13). By using the same procedure described for the preparation of (−)-**12**, the compound **13** (650 mg, 86% yield) was obtained from (+)-**4** (470 mg, 1.66 mmol), 3,6-dioxaheptyl *p*-toluenesulfonate (1.14 mg, 4.15 mmol), and NaH (159 mg, 6.64 mmol) as a colorless oil after chromatography on alumina (eluted with hexane-benzene 1:1 v:v); $[\alpha]_D^{20}$ −34.0° (*c* 0.351, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.32 (2H, t *J*=3 Hz), 3.36 (6H, s), 3.3—4.2 (18H, m), 4.74 (2H, d *J*=5.2 Hz), 7.0—7.5 (8H, m); MS *m/z* 456 (M^+). Found:

C, 69.98; H, 7.90%. Calcd for $C_{27}H_{36}O_6$: C, 71.02; H, 7.95%.

(−)-4,8-Bis(1,4,7,10-tetraoxaundecyl)-2,3:6,7-dibenzobicyclo-[3.3.1]nona-2,6-diene (14). The compound **14** (205 mg, 25% yield) was obtained from (+)-**4** (378 mg, 1.50 mmol), 3,6,9-trioxadecyl *p*-toluenesulfonate (1.19 g, 3.75 mmol), and NaH (144 mg, 6.00 mmol) as a colorless oil after chromatography on alumina (eluted with hexane–benzene 1:1 v:v); $[\alpha]_D^{20}$ −10.5° (*c* 0.721, $CHCl_3$); ^1H NMR ($CDCl_3$); δ=2.19 (2H, t *J*=3 Hz), 3.30 (6H, s), 3.3—4.2 (26H, m), 3.73 (2H, d *J*=4.5 Hz), 6.9—7.5 (8H, m); MS *m/z* 544 (M^+). Found: C, 68.28; H, 8.08%. Calcd for $C_{31}H_{44}O_8$: C, 68.36; H, 8.14%.

(+)-4,8-Bis(1,4,7-trioxanonyl)-2,3:6,7-dibenzobicyclo[3.3.1]-nona-2,6-diene (15). (−)-4,8-Bis(8-phenyl-1,4,7-trioxaoctyl)-2,3:6,7-dibenzo-bicyclo[3.3.1]nona-2,6-diene (17). The compound **17** (339 mg, 25% yield) was prepared from (+)-**4** (378 mg, 1.50 mmol), 7-phenyl-3,6-dioxaheptyl *p*-toluenesulfonate (1.31 g, 3.75 mmol), and NaH (144 mg, 6.00 mmol) as a colorless oil after chromatography on alumina (eluted with benzene); $[\alpha]_D^{22}$ −5.91° (*c* 0.551, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.25 (2H, t *J*=3.2 Hz), 3.3—4.2 (20H, m), 4.72 (4H, d *J*=5.2 Hz), 7.0—7.5 (18H, m); MS *m/z* 608 (M^+). Found: C, 76.78; H, 7.15%. Calcd for $C_{39}H_{44}O_6$: C, 76.94; H, 7.29%.

Extraction Procedure. The aqueous solution (5 mL) of the metal picrate (2.4×10^{-4} M) and the chloroform solution (5 mL) containing the crown ether (2.4×10^{-4} M) were placed in a screw cap glass tube (30 mL) and the tube was shaken for 30 min at room temperature. Extraction of the picrate was followed by monitoring the absorbance at 357 nm of the aqueous phase.

Enantiomer Differential Transport. Enantiomer differential transport was carried out in a conventional apparatus which consisted of an outer cylindrical glass vessel (24.5 mm inner diameter) and a central glass tube (15.5 mm inner diameter). The 0.01 M chloroform solution of the optically active host molecule separated the inner aqueous phase (0.1 M hydrochloric acid) and the outer aqueous phase (0.08 M hydrochloric acid) which contained $LiPF_6$ (0.4 M) and the racemic guest molecule (0.08 M). The chloroform layer was gently stirred at a constant speed (60 rpm) at 20—25 °C, and transport was monitored by ultraviolet spectra and enantiomeric excess of the guest molecule transported was monitored by circular dichroism.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 61540372) from the Ministry of Education, Science and Culture.

(Received June 4, 1988)

The reaction of arenediazonium tetrafluoroborates with chlorotrimethylsilane in a tetrahydrofuran/*N*,*N*-dimethylformamide (DMF) (5v/3v) solution afforded the protodediazotization products in high yields. The reactions of the diazonium salts with halotrimethylsilanes in DMF were found to give the corresponding haloarenes. Among the halodediazotization reactions, the iododediazotization with iodotrimethylsilane proceeded smoothly at room temperature to give the iodoarenes in excellent yields. In a similar manner, a variety of azidoarenes were obtained in consistently high yields by the treatment of arenediazonium tetrafluoroborates with azidotrimethylsilane in a DMF solution.

The reaction of arenediazonium salts is among the first to be studied in organic chemistry, and it has since been extensively studied not only because of its fundamental importance but also because of its industrial importance.[1] Arenediazonium halides, which are usually unstable, are prepared in situ by the diazotization of arylamines with sodium nitrite in an aqueous solution containing a mineral acid at a low temperature; subsequent reactions are immediately conducted in the same solution. The reactions carried out in the aqueous solution, however, frequently give rise to some by-products besides the desired products. For the purpose of lowering the amount of undesired products, there has been an attempt to use an isolated arenediazonium tetrafluoroborate salt in a nonaqueous medium. However, most of the tetrafluoroborate salts are too stable to be decomposed, and they are less soluble in organic solvents. Therefore, the decomposition of the diazonium salts has been performed by the addition of a strong base,[2] metals such as powdered zinc,[3] copper,[4] and copper(I) oxide,[5] or organometallic compounds, such as rhodium complexes[6] and tributyltin hydride.[7] Crown ether compounds,[4] poly(ethylene glycol),[8] or phase-transfer catalysts[9] have been used to improve the low solubility of the diazonium salts in organic solvents.

We have found that arenediazonium tetrafluoroborates readily decompose in the presence of halo- and azidotrimethylsilanes in a *N*,*N*-dimethylformamide (DMF) solution to afford the corresponding reduction products or substituted arenes in satisfactory yields. We wish to report herein the protodediazotization and halodediazotization induced by halotrimethylsilanes. The preparation of azidoarenes by the reaction of arenediazonium tetrafluoroborates with azidotrimethylsilane will also be reported.

Results and Discussion

The decomposition of 2-fluorenediazonium tetrafluoroborate was attempted in the presence of chlorotrimethylsilane (CTMS) in organic solvents. The results are summarized in Table 1. The diazonium salt was readily decomposed in a tetrahydrofuran (THF) suspension in the presence of an equivalent of CTMS at 60 °C for 10 min to give fluorene in a 69% yield and a trace amount of 2-chlorofluorene. The evolution of nitrogen gas was completed within ten minutes at 60 °C. In contrast, the salt was stable under these conditions in the absence of CTMS. The protodediazotization product was obtained in only a 13% yield, even after the salt has been heated under reflux for 90 min in a THF medium. Therefore, CTMS appears to induce the decomposition of the diazonium tetrafluoroborate. The homogeneous reaction conducted in DMF, which dissolved the salt, did not improve the yield of the protodediazotization product. On using a DMF/THF combined medium, however, the product yield was remarkably increased. In an attempt to apply this procedure as a general method for a reductive dediazotization, some arenediazonium tetrafluoroborates were subjected to a decomposition reaction with CTMS in a solution of THF/DMF (5v/3v) at 60 °C for 1 h. The results are shown in Table 2. Consistently high yields of the reductive dediazotization product were observed in a variety of arenediazonium tetrafluoroborates.

The decomposition of 2-fluorenediazonium tetrafluoroborate with halotrimethylsilanes in DMF or *N*,*N*-dimethylacetamide (DMA) was attempted in the presence of a halogenating reagent. The results are shown in Table 3. Although the reaction of 2-fluorenediazonium tetrafluoroborate with CTMS in DMF afforded only 2% of 2-chlorofluorene, the addition of *N*-chlorosuccinimide (NCS) to the reaction mixture increased the formation of the chloride to a 39% yield. In the reaction carried out in a solution of DMA/car-

bon tetrachloride in the presence of NCS, the yield of the chloride was increased to 59%. Similarly, the diazonium salt was decomposed with bromotrimethylsilane in the presence of *N*-bromosuccinimide (NBS) in a DMA solution to give 2-bromofluorene in a 71% yield, while the decomposition without NBS gave the bromide and the reduction products in 41% and 51% yields respectively.

On the other hand, the drop-by-drop addition of iodotrimethylsilane to a solution of 2-fluorenediazonium tetrafluoroborate in DMF violently evolved nitrogen gas at room temperature to give 2-iodofluorene and the reduction product in 55% and 30% yields respectively. The addition of iodomethane into the reaction mixture increased the fomation of 2-iodofluorene. The yield of the iodide increased with an increase in the amount of iodomethane added. Finally, 2-iodofluorene was obtained in a 98% yield in the reaction using a medium of iodomethane mixed with a minimum amount of DMF to dissolve the diazonium salt.

This reaction procedure was also applied to the preparation of iodoarenes. Using the optimized conditions defined above, a variety of arenediazonium tetrafluoroborates were converted into the corresponding iodoarenes. The results are summarized in Table 4. 4-Iodobenzophenone, 1-iodo-4-nitronaphthalene, 4-iodo- and 3-iodo-1-nitrobenzenes, 4-iodobiphenyl, 7-bromo-2-iodofluorene, and 3-iododibenzofuran were obtained in excellent yields by this method.

When azidotrimethylsilane dissolved in DMF was

a) All the reactions were carried out in a solution of DMF in the presence of 1.2 equivalents of azidotrimethylsilane at room temperature for 1 h. b) Isolated yields.

added to a solution of 2-fluorenediazonium tetrafluoroborate in DMF at room temperature, nitrogen gas was immediately evolved to give 2-azidofluorene in an almost pure form in a 95% yield. No significant amount of the reduction product was observed. A variety of arenediazonium tetrafluoroborates were then reacted with azidotrimethylsilane in the DMF solution at room temperature. The yields and melting points of isolated azidoarenes are summarized in Table 5.

In all the cases examined here, the corresponding azidoarenes were obtained in satisfactory yields. The products, 2-azidofluorene, 4-azidobiphenyl, 4-azidobenzophenone, 3-azidodibenzofuran, 2-azido-7-bromofluorene, and 1-azido-4-nitronaphthalene, are new compounds. The IR spectra of these azides show the characteristic absorption peaks at 2180—2270 cm^{-1} due to the azide function. Their ^1H NMR spectral data are consistent with the desired structure.

Thus, halotrimethylsilanes (Cl, Br, I as the halide) and azidotrimethylsilane have been found to facilitate the decomposition of arenediazonium tetrafluoroborates to give the protodediazotization products or the corresponding haloarenes and azidoarenes. The acceleration effects of the trimethylsilyl compounds on the decomposition of 2-fluorenediazonium tetrafluoroborate in a DMF solution were in the sequence of: azido->iodo->bromo->chlorotrimethylsilanes. The ratio of halogenation to reduction products in the decomposition with halotrimethylsilanes was increased with the order of: iodo->bromo->chlorotrimethylsi-

lanes. According to the Hard and Soft Acids and Bases (HSAB) principle developed by Pearson,[15] the trimethylsilyl cation belongs to a hard acid group, while the halide ions, Br^- and I^-, and the azide ion, N_3^-, are classified as soft bases, the softness order being; $I^- > N_3^- > Br^- > Cl^-$. On the other hand, the tetrafluoroborate ion seems to be a hard base,[16] accounting for its good affinity to a hard acid, the trimethylsilyl cation. When CTMS is added to a solution of arenediazonium tetrafluoroborate in DMF, the hard acid species, the trimethylsilyl cation, would catch the hard-base anion, BF_4^-, to result in the formation of fluorotrimethylsilane, boron trifluoride, and arenediazonium chloride. This resultant diazonium chloride is usually less stable than the starting diazonium tetrafluoroborates, so it readily decomposes to give the corresponding chloroarenes or reduction products. The decomposition in the presence of the chlorinating reagent NCS increased the formation of chloroarenes. The addition of THF to the reaction medium DMF also remarkably increased the formation of the protodediazotization product. The decomposition appears to proceed by means of a radical mechanism. The decomposition with bromo-, iodo-, and azidotrimethylsilanes would also proceed by means of a process similar to that described above (Eqs. 2 and 3). The formation of fluorotrimethylsilane and boron trifluoride as well as the substituted arene was confirmed by ^1H NMR measurements of the reaction mixture of benzenediazonium tetrafluoroborate and azidotrimethylsilane in DMF/deuteriochloroform solutions. The full details of the confirmation will be given in the Experimental section.

$$ArN_2BF_4 + Me_3SiX \longrightarrow ArN_2X + Me_3SiF + BF_3 \quad (2)$$

$$ArN_2X \longrightarrow ArX + N_2 \quad (3)$$

The decompositions with iodo- and azidotrimethylsilanes proceed much more smoothly than that with CTMS. This may be due to the ease of both the exchange of the counter anion and the decomposition of the resultant diazonium salts.

In conclusion, halo- and azidotrimethylsilanes were found to be effective for the decomposition of arenediazonium tetrafluoroborates, which are usually difficult to decompose. Reduction products and haloarenes were obtained in satisfactory yields by the reaction of arenediazonium tetrafluoroborates with halotrimethylsilanes in a DMF solution. Azidoarenes were obtained in excellent yields by the reaction of arenediazonium tetrafluoroborates with azidotrimethylsilane. These reactions can be conducted in a DMF medium under mild conditions. There is no need to use any complex catalysts for the decompositions or any expensive additives to achieve dissolution in organic solvents. Thus, the reaction procedures described here will be useful for the preparation of arenes, haloarenes, and azidoarenes from arenediazonium tetrafluoroborates.

Experimental

Materials and Measurements. The melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S2 model infrared spectrophotometer. The ^1H NMR spectra were recorded on a JEOL-FX 270 FT-NMR spectrometer in deuteriochloroform solutions, with teramethylsilane as the internal standard. GLC analysis was carried out on a Hitachi GC Model 163 gas chromatograph equipped with a hydrogen-flame ionization detector and a stainless steel column (length 3 m, i.d. 3 mm) packed with 3% Dexil 300 GC on Chromosorb W.

Preparation of Arenediazonium Tetrafluoroborates. All the diazonium salts were prepared by standard techniques (Ref. 17). The following salts have not been found in the above references. The yields, decomposition temperatures, and IR data for them are as follows.

1-Pyrenediazonium Tetrafluoroborate: 100% yield; mp 135—137 °C (decomp); IR (KBr) 2200, 1620, 1470, and 851 cm^{-1}.

9-Methyl-2-carbazolediazonium Tetrafluoroborate: 88% yield; mp 161—163 °C (decomp); IR (KBr) 2210, 1578, 1452, and 750 cm^{-1}.

3-Dibenzofurandiazonium Tetrafluoroborate: 69% yield; mp 160—163 °C (decomp); IR (KBr) 2260, 1626, 1432, 1200, and 750 cm^{-1}.

9-Oxo-2-fluorenediazonium Tetrafluoroborate: 89% yield; mp 159—162 °C (decomp); IR (KBr) 2275, 1723, 1608, 1590, and 765 cm^{-1}.

7-Bromo-2-fluorenediazonium Tetrafluoroborate: 90% yield; mp 139—140 °C (decomp); IR (KBr) 2230, 1591, 1170, and 818 cm^{-1}.

Protodediazotization Reactions. One procedure for the protodediazotization of 2-fluorenediazonium tetrafluoroborate is described as typical. Into a solution of 2-fluorenediazonium tetrafluoroborate (0.200 g; 0.714 mmol) in DMF (3 mL) cooled in an ice water bath, we added portion by portion a solution of CTMS (0.093 g; 0.857 mmol) in THF (5 mL) with stirring. After the mixture has then been heated at 60 °C with stirring for 1 h, it was poured into water. The resulting solid was filtered and washed with water to give fluorene (0.117 g; 98% yield; mp 104—107 °C). The recrystallization of the solid from ethanol gave a product with the mp of 114—115 °C (lit,[10] mp 115—116 °C).

Halodediazotization Reactions. The iododediazotization of 2-fluorenediazonium tetrafluoroborate will be described as a typical method. To a solution of iodotrimethylsilane (0.171 g; 0.857 mmol) and iodomethane (1.5 mL), we added drop by drop a solution of 2-fluorenediazonium tetrafluoroborate (0.200 g; 0.714 mmol) in DMF (1.5 mL) at room temperature under a nitrogen stream. After this addition, the mixture was stirred for 1 h at room temperature, poured into ice water, and then extracted with dichloromethane. The organic layer was washed with water and dried over anhydrous sodium sulfate. After the evaporation of the solvent, crude 2-iodofluorene was obtained (0.198 g; 95% yield; mp 126—127 °C). The recrystallization of the product from 80% ethanol gave a product with the mp of 127—128 °C (lit,[11] mp 128 °C). In a similar manner, the following iodoarenes were prepared.

3-Iododibenzofuran: 95% yield; mp 143—144 °C (from 90% EtOH); IR (KBr) 1453, 1440, 1183, 868, 810, and 748 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.32—7.70 (m, 5H) and 7.90—9.93 (m, 2H).

Found: C, 48.85; H, 2.38%. Calcd for $C_{12}H_7OI$: C, 49.01; H, 2.40%.

7-Bromo-2-iodofluorene: 93% yield; mp 177—178 °C (from EtOH); IR (KBr) 1452, 1393, 1003, and 802 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.85 (s, 2H, CH_2) and 7.47—7.87 (m, 6H).

Found: C, 41.83; H, 2.17%. Calcd for $C_{13}H_8BrI$: C, 42.09; H, 2.17%.

By means of a similar procedure, chlorodediazotization and bromodediazotization reactions of 2-fluorenediazonium tetrafluoroborates with CTMS and bromotrimethylsilane were carried out in the presence of NCS and NBS respectively.

Preparation of Azidoarenes. Into a solution of 2-fluorenediazonium tetrafluoroborate (0.200 g; 0.714 mmol) in DMF (1.5 mL), we dropped a solution of azidotrimethylsilane (0.099 g; 0.857 mmol) in DMF (1.5 mL) at room temperature. After the mixture has then been stirred for 1 h at that temperature, it was poured into ice water (about 100 mL). The resulting precipitate was filtered, washed with water, and dried to give 2-azidofluorene (0.14 g; 95% yield; mp 102—104 °C). The recrystallization of the solid from 80% ethanol gave a product with the mp of 103—104 °C; IR (KBr) 2200, 1580, 1450, 1289, and 761 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.88 (s, 2H, CH_2), 7.03 (d, J=3.0 Hz, 1H), 7.20 (s, 1H), 7.25—7.40 (m, 2H), 7.52 (d, J=8 Hz, 1H), and 7.72 (d, J=3 Hz, 2H).

Found: C, 75.54; H, 4.08; N, 20.19%. Calcd for $C_{13}H_9N_3$: C, 75.35; H, 4.38; N, 20.28%.

By a similar procedure, the following azidoarenes were prepared.

4-Azidobenzophenone: 92% yield; mp 70—71 °C (70% EtOH); IR (KBr) 2200, 1645, 1598, 1280, and 713 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.12 (d, J=3 Hz, 2H), 7.46—7.60 (m, 3H), 7.77 (d, J=3 Hz, 2H), and 7.85 (d, J=3 Hz, 2H).

Found: C, 69.95; H, 4.17; N, 18.51%. Calcd for $C_{13}H_9N_3O$: C, 69.95; H, 4.06; N, 18.82%.

1-Azido-4-nitronaphthalene: 95% yield; mp 96—97 °C (80% EtOH); IR (KBr) 2270, 1573, 1285, and 761 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.27 (d, J=3 Hz, 1H), 7.63 (t, J=3 Hz, 1H), 7.78 (t, J=3 Hz, 1H), 8.23 (d, J=3 Hz, 1H), 8.34 (d, J=3 Hz, 1H), and 8.68 (d, J=3 Hz, 1H).

Found: C, 56.42; H, 2.64; N, 25.85%. Calcd for $C_{10}H_6N_4O_2$: C, 56.08; H, 2.82; N, 26.16%.

4-Azidobiphenyl: 99% yield; mp 74—75 °C (80% MeOH); IR (KBr) 2200, 1485, 1290, 833, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.09 (d, J=3 Hz, 2H), 7.31—7.45 (m, 3H), and 7.54—7.59 (m, 4H).

Found: C, 73.60; H, 4.77; N, 21.37%. Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.52%.

3-Azidodibenzofuran: 94% yield; mp 115—116 °C (70% EtOH); IR (KBr) 2200, 1602, 1453, 1288, and 779 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.03 (dd, J=3, 0.7 Hz, 1H), 7.23 (d, J=0.7 Hz, 1H), 7.34 (td, J=3, 0.4 Hz, 1H), 7.44 (td, J=3, 0.5 Hz, 1H), 7.55 (d, J=3 Hz, 1H), and 7.89 (d, J=3 Hz, 2H).

Found: C, 69.21; H, 3.52; N, 20.00%. Calcd for $C_{12}H_7N_3O$: C, 68.89; H, 3.37; N, 20.09%.

2-Azido-7-bromofluorene: 91% yield; mp 129—130 °C (80% EtOH); IR (KBr) 2200, 1613, 1457, 1293, and 798 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.85 (s, 2H, CH_2), 7.03 (dd, J=3, 0.7 Hz, 1H), 7.18 (s, 1H), and 7.47—7.70 (m, 4H).

Found: C, 54.45; H, 2.53; N, 14.54%. Calcd for $C_{13}H_8BrN_3$: C, 54.57; H, 2.83; N, 14.69%.

Confirmation of the Formation of Fluorotrimethylsilane and Boron Trifluoride. To a solution of benzenediazonium tetrafluoroborate (0.003 g) in DMF/deuteriochloroform (2v/8v) (1 mL) containing tetramethylsilane, we added a few drops of azidotrimethylsilane at 0—5 °C. After gas evolution had ceased, the mixture was subjected to ^1H NMR measurement at 27 °C. The NMR spectrum showed singlet peaks at 8.28, 3.36, 3.17, and 0.068 ppm in addition to the peaks due to DMF [7.99 (s, 1H), 2.96 (s, 3H), 2.85 (s, 3H)], azidobenzene [7.36 (t, 2H, J=7.3 Hz), 7.14 (t, 1H, J=7.3 Hz), 7.03 (d, 2H, J=8.3 Hz)], and azidotrimethylsilane [0.27 (s)]. The former three singlets (in a relative intensity of 1:3:3) were identified with those due to the DMF-boron trifluoride complex by comparing them with those observed in the ^1H NMR spectrum of a mixture of DMF and ethyl ehterboron trifluoride (1/1) in deuteriochloroform. The later singlet was identified as the peak due to fluorotrimethylsilane by being in accord with the chemical shift of that prepared from azidotrimethylsilane and KF in DMF/deuteriochloroform (2v/8v) solutions.

We wish to thank Fukui Chemical Industry Co. for its financial support of this work.

Organic Photochemical Reactions. XXXI.[1] Photosensitized Ring-Cleavage Reactions of 2,2-Diaryloxetanes by Aromatic Nitriles

Kenichi NAKABAYASHI, Jun-ichi KOJIMA, Kimiko TANABE, Masahide YASUDA, and Kensuke SHIMA*
Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Gakuen-Kibanadai, Miyazaki 889-21
(Received June 13, 1988)

Photosensitized reactions of 2,2-diaryloxetanes by 1,4-dicyanonaphthalene, 1-cyanonaphthalene, and 9,10-dicyanoanthracene, which give such ring-cleavage products as substituted benzophenones and alkenes, have been investigated. Quantum yields for the ring cleavage vary with the substituents on both the aryl group and oxetane ring. The quantum yield increases with increase in electron-donating ability of the oxetane. The limiting quantum yields in the case of 1,4-dicyanonaphthalene-photosensitized reaction of 2,2-di-*p*-tolyl- or 2,2-bis(*p*-methoxyphenyl)-3,3,4-trimethyloxetane exceed unity. The mechanism is discussed in terms of electron transfer from oxetanes to the excited singlet state of the sensitizer as well as the regeneration process of the oxetane cation radical involving the hole transfer from substituted benzophenone cation radicals to oxetanes in the chain process.

Cleavage of oxetane into carbonyl–olefin pairs is well-known to occur by the treatment with Brønsted acid or metal ion as well as by pyrolysis.[2] In these studies, the regio- and stereochemical control has been an interesting subject. On the other hand, photosensitized ring-cleavage reactions of such small ring compounds as cyclopropanes,[3] cyclobutanes,[4] oxiranes,[5] and aziridines[6] have received much attention from mechanistic and synthetic points of view. However, no photosensitized reactions of oxetanes have been reported. In order to develop the study of regioselective and efficient cleavage reactions of oxetanes, we attempted the ring cleavage of some 2,2-diaryloxetanes by photosensitization with such typical electron acceptor (S) as 1,4-dicyanonaphthalene (DCN), 1-cyanonaphthalene (CNN), and 9,10-dicyanoanthracene (DCA).

Results

Photoreaction. Photoreactions of 2,2-diaryloxetanes (**1a—h**) were carried out by irradiation of acetonitrile solutions at 313 nm for DCN and CNN runs and at 366 nm for DCA run, and the progress of the photoreactions was followed by gas chromatography. The photoproducts are shown in Scheme 1.

Pairs of substituted benzophenone (**2**) and alkenes (**3**) were formed by photosensitized reaction of **1a—h** with DCN. Such other products as 1,1-diaryl-2,2-dimethylethylene were not observed. The chemical yields of **2** and **3** in the photosensitized reaction with DCN are shown in Table 1. The formation of **2** occurred quantitatively whereas the yields of **3** were rela-

tively low in some cases except for the cases of **1d** and **1f**. DCN was recovered almost quantitatively except for the case of **1e** in which remarkable consumption of DCN was observed. Similarly, the photosensitized reaction of **1d** and **1f** with CNN or DCA proceeded to give **2** and **3** whereas no photosensitized reaction of **1a—c** with CNN or DCA occurred. The photosensitized reaction of **1f** with DCN and CNN did not proceed at all in less polar solvents such as benzene, dibutyl ether, dioxane, and tetrahydrofuran (THF) but proceeded slightly in ethyl acetate, 2-propanol, ethanol, and methanol. Acetonitrile was a better solvent for the occurrence of the efficient photoreactions. Moreover, it was confirmed that no reaction occurred at all in the dark or even upon direct irradiation of **1**.

Quantum Yields. The formation of **2** and **3** increased linearly with irradiation time up to 5% conversion. Limiting quantum yields were determined for the formation of **2** and **3** by the usual double-reciprocal plots of quantum yields (ϕ) vs. concentration of **1**. Figure 1 shows linear plots for the formation of **2** from DCN-photosensitized reaction of **1a—c,e,g**. Although such linear plots were also obtained from the formation of **3**, the slopes were steeper than those obtained from the formation of **2**, since the yields of **3** were lower than those of **2**. Such linear plots were not observed for the formation of **3b** from **1g**. Table 2 lists the intercept (I) and intercept-to-slope ratios (I/S) of the plots together with the limiting quantum yields for the formation of **2** and **3**. In the case of CNN and

a) Fluorescence lifetimes. b) The intercept (I) and the intercept-to-slope ratios (I/S) of the plots for the formation of **2** in Figs. 1 and 2. c) Not determined. d) In benzene. e) For the acetonitrile solution containing **1** [0.05 mol dm^{-3}] and CNN [0.01 mol dm^{-3}]. f) For the acetonitrile solutions containing **1** [0.05 mol dm^{-3}] and DCA [1×10^{-4} mol dm^{-3}].

DCA, the observed quantum yields at [1]=0.05 mol dm^{-3} are shown in Table 2. It should be noted that the limiting quantum yields for the formation of **2** and **3** from DCN-photosensitized reaction of **1d** or **1f** were more than unity as is shown in Fig. 2.

The quantum yields were measured for DCN-photosensitized reaction of **1d** in the presence of various concentrations of methanol and the plots of ϕ for the formation of **2** and **3** vs. [MeOH] are shown in Fig. 3. The ϕ_2 decreased to 0.38 when more than 0.4 mol dm^{-3} of methanol was added and ϕ_3 gradually decreased with increase of concentration of methanol.

Fluorescence Quenching. The fluorescence of aromatic nitriles was quenched by oxetanes following linear Stern-Volmer relationships (Eq. 1). Table 2 includes the Stern-Volmer constants (K_{SV}) and the fluorescence quenching rate constants (k_q) calculated from K_{SV} and the fluorescence life time (τ).[7-9]

$$I_F^0/I_F = 1 + K_{SV}[1] = 1 + k_q\tau[1] \quad (1)$$

Mass Spectrometry. The fragmentation of **1b—h** was studied by mass spectrometry at 70 eV. The relative intensities of the fragments are listed in Table 3 according to the fragmentation mode of Scheme 2 reported by Jones and McDonnell.[10]

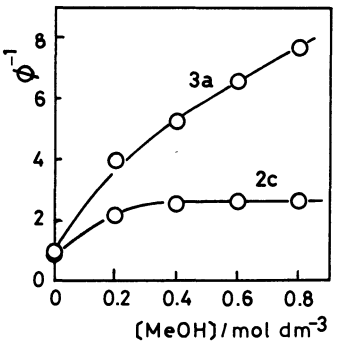

Fig. 3. Plots of the reciprocals of quantum yield for **2c** and **3a** vs. the concentration of methanol in DCN-photosensitized reaction of **1d**.

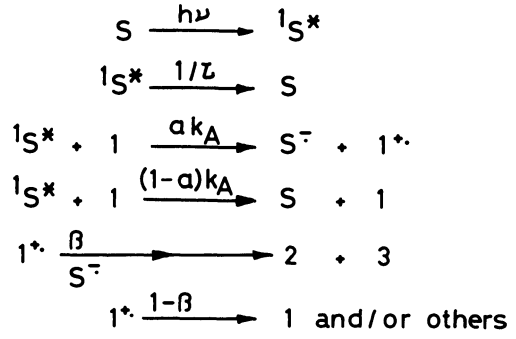
Discussion

Mechanism. There is no doubt that the photosensitization proceeds via the excited singlet state of aromatic nitriles since the rate constants for the fluorescence quenching of DCN by **1a—g** as well as the fluorescence quenching of DCA or CNN by **1f** are close to the diffusion-controlled rate in acetonitrile (2×10^{10} dm^3 mol^{-1} s^{-1}).[11] Moreover the intercept-to-slope ratio (I/S) obtained from quantum yield measurements shows reasonable agreement with the K_{SV} values for the fluorescence quenching in the case of DCN-**1a—c**. Table 4 lists the calculated free energy changes for the electron-transfer process from oxetanes to the excited singlet state of aromatic nitriles (^{1}S*) using the Rehm-Weller equation.[4,11] The calculated values for DCN-**1a—f** or DCA- and CNN-**1f** pairs are substantially negative. Therefore, it is strongly suggested that the electron transfer from oxetanes to ^{1}S* is responsible for the initiation process of photosensitized ring-cleavage reactions as reported for the photoreactions of some benzene derivatives with aromatic nitriles.[12] However, no photosensitized ring-cleavage reaction of **1f** with DCN or CNN in less polar solvents occur at all, though the fluorescence of S is efficiently quenched by **1f** in these solvents. From the above results, the cleavage of oxetane ring is suggested to proceed via the oxetane cation radical ($\mathbf{1}^{+\cdot}$) formed by the complete electron transfer from oxetanes to ^{1}S* rather than via exciplex formation. Consequently, mechanistic pathways for the photosensitized reaction with S are shown in Scheme 3. A usual kinetic treatment gives Eq. 2.

$$\phi^{-1} = \frac{1}{\alpha\beta}\left(1 + \frac{1}{k_A\tau[1]}\right) \qquad (2)$$

Since the oxidation potentials of 2,2-diaryloxetanes are similar to those of the corresponding benzene derivatives,[13] the positive charge in the photogenerated cation radicals of oxetanes is suggested to develop over the aryl groups. Therefore, the ring cleavage of $\mathbf{1}^{+\cdot}$ should be induced by the decrease of electron density in the C_2–C_3 σ bond through σ–π interaction between the aryl groups and the C_2–C_3 bond of the oxetane ring (Scheme 4). DCN-photosensitized reaction of *cis*-3,4-dimethyl-2,2-diphenyloxetane (**1h**) gave the mixture of *cis*- and *trans*-2-butene (**3c**) in 1:4—5 ratio and **2b** (Scheme 5). Such nonstereospecific cleavage of the oxetane ring arose from the stepwise bond-fission at C_2–C_3 of oxetane ring followed by free rotation around the C_3–C_4 bond. An alternative isomerization mechanism via the cation radical of **3c** is unlikely to operate in the photosensitized reaction of **1h**, since mass spectra of **1h** show that $\mathbf{3c}^{+\cdot}$ is scarcely produced from the fragmentation of $\mathbf{1h}^{+\cdot}$. Thus $\mathbf{2}^{+\cdot}$ and/or $\mathbf{3}^{+\cdot}$ are formed by the cleavage of the ring-opened cation radical and reduced with anion radical of S ($S^{-\cdot}$) to give **2** and **3**. The formation of $\mathbf{2}^{+\cdot}$ and/or $\mathbf{3}^{+\cdot}$ are also suggested by the fact that the quantum yields for the



Scheme 3.

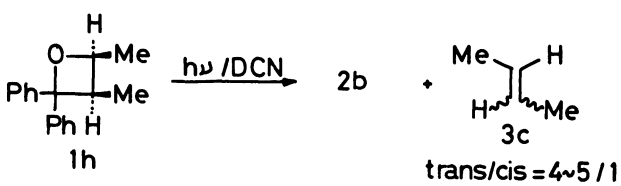

Scheme 5.

formation of **2** and **3** were diminished by the nucleophilic reaction of methanol in DCN-photosensitization of **1d** as shown in Fig. 3.

Consideration of Chain Mechanism. The chain mechanism should be taken into account in the case of **1d** and **1f** since the limiting quantum yields obtained from Fig. 2 exceed unity. The $2^{+\cdot}$ and $3^{+\cdot}$ generated from the cleavage of the oxetane cation radical are candidates for the chain carrier in the regeneration process of oxetane cation radicals. The hole transfer from $3^{+\cdot}$ to oxetanes is disadvantageous since the oxidation potentials of **3** are much lower than those of oxetanes showing that the hole-transfer process is substantially endothermic ($E^{ox}_{1/2}$=1.47 V for **3a** and 1.13 V for **3b**).[7] The hole transfer from $2^{+\cdot}$ to oxetane is conceivable for the regeneration pathways of $1^{+\cdot}$. Therefore, the reaction mechanism for DCN-photosensitization of **1d** and **1f** should include Eq. 3 in addition to Scheme 3. The I/S values for the chain process are much smaller than the K_{SV} values in Table 2. DCN-photosensitization of **1e** and **1g** in which I/S values are smaller than the K_{SV} values might proceed by a mechanism involving a chain mechanism.

$$2^{+\cdot} + 1 \longrightarrow 2 + 1^{+\cdot} \quad (3)$$

Jones and McDonnell reported that the fragmentation of the oxetane ring in mass spectra occurred according to the modes A, B, and C as is shown in Scheme 2.[10] Though the mass spectrometry features are different from those of photosensitized reactions, we can estimate the ratio of $2^{+\cdot}$ to $3^{+\cdot}$ generated from $1^{+\cdot}$ by the fragment intensity of mass spectra in mode A as shown in Table 3. It was found that the ratio of $2^{+\cdot}$ to $3^{+\cdot}$ in the case of **1d** and **1f** was greater than in the other cases. In other words, it is shown that the fragmentation of $1^{+\cdot}$ gives a pair of $2^{+\cdot}$ and **3** more than a pair of **2** and $3^{+\cdot}$ in the case of **1d** and **1f** in which the limiting quantum yield exceeds unity. Therefore, it is again indicated that $2^{+\cdot}$ plays an important role in the chain process.

In conclusion, the regioselective ring-cleavage reaction of oxetanes was accomplished by photosensitization with aromatic nitriles. The regioselectivity was caused by selective C_2–C_3 bond-fission of the oxetane cation radicals generated by photochemical electron transfer. Moreover, the reaction efficiencies were determined by the electron-donating abilities of oxetanes as well as by occurrence of chain processes.

Experimental

Instruments. Gas chromatography was performed on a Shimadzu GC-8A gas chromatograph using a 50 cm column of 2% OV-1 or 2% OV-17 on Chromosorb W for analyses of **1a**—h, **2a**—**d**, and DCN, a 3 m column of DC-550 on Uniport B for analyses of **3a**, a 1 m column of PEG-20M for analyses of **3b**, and a 2 m column of Unipak S (Gasukuro Kogyo) for analyses of **3c**. IR and ^{1}H NMR spectra were obtained on a Hitachi 260-50 spectrometer and a JEOL JNM60 spectrometer, respectively. The fluorescence quenching experiments were performed for degassed acetonitrile or benzene solutions (3 cm^3) containing DCN (1×10^{-3} mol dm^{-3}), CNN (1×10^{-3} mol dm^{-3}), or DCA (2×10^{-5} mol dm^{-3}) on a Hitachi MPF-4 spectrometer. Oxidation potentials of **1a**—**d**, f were determined by a Yanagimoto V10-PG cyclic voltammeter vs. Ag/$AgNO_3$ in acetonitrile using tetraethylammonium tetrafluoroborate as the supporting electrolyte.[14] Mass spectra were measured on a JEOL D-300S equipped with a JMA 2000 data analyzer.

Materials. Commercial 1-cyanonaphthalene was purified by the method described in a previous paper.[7] 9,10-Dicyanoanthracene was purified by repeated recrystallization from benzene. 1,4-Dicyanobenzene was prepared according to the literature method[15] and was purified by repeated recrystallization from benzene. The preparation of oxetanes was carried out by the irradiation of a benzene solution containing the substituted benzophenone and the alkene by high-pressure Hg lamp according to the procedure described in the literature.[16] The purification of the oxetanes was performed by column chromatography on silica gel and then by repeated recrystallization from methanol. Some data of oxetanes (**1a**—f) are as follows: **1a**, 80% of yield, mp 71—72 °C, ^{1}H NMR (CCl_4) δ=1.07 (s, 6H), 1.28 (d, 3H, J=6 Hz), 4.43 (q, 1H, J=6 Hz), 7.07—7.44 (m, 8H). **1b**, 88%, mp 104.5—105.5 °C, ^{1}H NMR (CCl_4) δ=0.98 (s, 6H), 1.18 (d, 3H, J=6 Hz), 2.17 (q, 1H, J=6 Hz), 6.92—7.43 (m, 10H). **1c**, 82%, mp 121.5—122 °C, ^{1}H NMR (CCl_4) δ=1.10 (s, 6H), 1.27 (s, 6H), 7.08—7.59 (m, 10H). **1d**, 77%, mp 99—100 °C, ^{1}H NMR (CCl_4) δ=0.95 (s, 6H), 1.15 (d, 3H, J=6 Hz), 4.34 (q, 1H, J=6 Hz), 6.79—7.30 (m, 8H). **1e**, 90%, mp 117—118 °C, ^{1}H NMR (CCl_4) δ=1.0 (s, 6H), 1.23 (s, 6H), 2.18 (s, 3H), 6.9 (d, J=8 Hz, 4H), 7.27 (d, J=8 Hz, 4H). **1f**, 87%, mp 91.5—92 °C, ^{1}H NMR (CCl_4) δ=0.97 (s, 6H), 1.20 (d, 3H, J=6 Hz), 4.40 (q, 1H, J=6 Hz), 6.55—7.42 (m, 8H). **1g**, 31%, mp 92—93 °C, ^{1}H NMR (CCl_4) δ=1.0 (s, 6H), 1.2 (s, 6H), 3.6 (s, 6H), 6.7 (d, J=8 Hz, 4H), 7.3 (d, J=8 Hz, 4H). **1h**, 75%, mp 87—88 °C, ^{1}H NMR (CCl_4) δ=0.83 (d, J=6 Hz, 3H), 1.3 (d, J=6 Hz, 3H), 3.03 (d-q, J=6 Hz, 6 Hz, 1H), 4.26 (d-q, J=6 Hz, 6 Hz, 1H), 6.9—7.26 (m, 10H).

Photoreactions and Determination of Quantum Yields. Photoirradiation was carried out with an Eikosha PIH-300 high-pressure Hg lamp under cooling with water using appropriate light filters and a "merry-go-round" turntable. A potassium chromate solution (0.2 g dm^{-3}, 10 mm path length) was used to isolate the 313-nm light, whereas the 366-nm light was obtained by the passage through a glass filter (Corning CS7-37) and 10% HCl aqueous solution of $BiCl_3$ (6.67 g dm^{-3}, 10 mm path length). A 2-hexanone actinometer and a trioxalatoferrate(III) actinometer were used for the determination of the quantum yields at 313 nm for the CNN and DCN-photosensitized reaction and at 366 nm for the DCA runs respectively.[17] The concentrations of DCN, CNN, and DCA were set in 0.02, 0.01, and 1×10^{-4} mol dm^{-3}, respectively. These were confirmed to be high enough for the complete absorption of the incident light during the photoreactions. Pyrex glass tubes (8 mm i.d.) were used as the common vessels for the photoreactions and actinometry.

The authors wish to thank Professor Chyongjin Pac, Osaka University, for his kind and helpful discus-

sions. We also thank Professor Toshinori Kokubu, Miyakonojo National College of Technology, for measurement of the oxidation potentials. This work was supported by a Grand-in-Aid for Scientific Research, No. 62550616, from the Ministry of Education, Science and Culture.

Diene-Containing Lipids as Probes for Phase-Transition Behavior of Lipids in Liposomes[1)]

Shinji TAKEOKA, Hidetaka IWAI, Hiroyuki OHNO, and Eishun TSUCHIDA*
Department of Applied Chemistry, Waseda University, Tokyo 160
(Received June 18, 1988)

The absorption maximum (λ_{max}) of 1,2-bis(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (DODPC), dispersed in an aqueous medium as liposomes, showed blue shift from 256.8 nm to 241.8 nm when these liposomes were cooled down from liquid crystalline state to gel state. The blue shift is explained to be due to stronger interaction between diene groups at gel state. This diene-containing lipid is examined to be an excellent membrane probe because it is typical phospholipid and miscible with several lipids. Furthermore, the dienoyl groups are known to be settled in the definite positions in bilayer membrane by suitable chemical modification. Phase transition behaviors of various 2,4-octadecadienoyl-containing phosphorylcholines as analogs for DODPC have also been investigated. Although they had similar spectral shifts at gel-to-liquid crystalline phase-transition temperature, their phase-transition temperatures and magnitude of λ_{max} shifts were revealed to be related directly and therefore be governed by the different packing of the diene groups in bilayer membrane. DODPC was mixed with 1,2-dipalmitoyl-*sn*-glycero-3-phosphorylcholine, or cholesterol, and phase behaviors of these mixed liposomes were also examined. Phase-transition of the mixed liposomes was detected easily by the shift of its λ_{max} with high sensitivity. Results were quite comparable to those obtained from other measurements, such as DSC, NMR, and so on.

We have already clarified various membrane properties through polymerization behaviors of polymerizable lipids as liposomes.[2-11)] 1,2-Bis(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (DODPC), which contains one diene group in every acyl chain, is effectively polymerized as liposomes with radical initiators. The polymerization profile was revealed to deeply depend on the characteristics of the applied radical initiators.[3,6)] However this monomeric lipid had polymerizable groups in the same 2,4-position in the 1- and 2-acyl chains, polymerization of diene groups in the 1-acyl chains was selectively initiated by azobis(isobutyronitrile) (AIBN) which was incorporated into a hydrophobic region of the bilayer membrane. On the contrary, the diene groups in the 2-acyl chains were polymerized by the addition of azobis(2-amidinopropane)dihydrochloride (AAPD), water-soluble radical initiators, suggesting that the diene groups in the 2-acyl chains were faced an aqueous phase.[3)] We also developed a new polymerization technique with which liposomes could be polymerized at any temperature.[10)] Polymerization was performed with AIBN and/or AAPD as photosensitizers and irradiating the UV-light of 360 nm at temperatures below or above the gel-to-liquid crystalline phase-transition temperature (T_c). Water-soluble AAPD penetrated lipid membrane at temperatures above T_c but not below.[10)] We prepared liposomes which possessed polymerized outer- or inner-half of bilayer with advantageous characteristics of impermeability of AAPD below the T_c.[10)] Change of microviscosity of lipid membrane at T_c was also analyzed with water-insoluble AIBN incorporated in hydrophobic region of the membrane. Initiation efficiency of the polymerization was affected by membrane microviscosity.[10)] We found that UV spectral shift for polymerizable lipids was attributed to the changes in lipid packing in the membrane. Here we describe this shift behavior in detail.

Experimental

Materials. 1,2-Bis(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (DODPC) was purchased from Nippon Oil & Fats Co., Ltd. 1-Palmitoyl-2-(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylchloline (POPC) was a gift from Toyo Soda Co., Ltd. 1,3-Bis(2,4-octadecadienoyl)-*rac*-glycero-2-phosphorylcholine (1,3-DPC) was synthesized according to the method as reported previously.[11)] 1,2-Dimyristoyl-*sn*-glycero-3-phosphorylcholine (DMPC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphorylcholine (DPPC) and cholesterol were purchased from Sigma. The purity of lipids was confirmed with thin-layer chromatography (Merck, silica-gel plates) with chloroform/methanol/water (65:35:5 by vol) to show a single spot.[3)]

***rac*-1-*O*-(2,4-Octadecadienoyl)-2-*O*-octadecylglycerol:** 2-Phenyl-1,3-dioxan-5-ol was obtained according to the procedure of Hibbert et al.[12)] The product was then allowed to react with 1-bromooctadecane yielding 2-octadecyloxy-1,3-propanediol according to the procedures of Arnold.[13)] 2-Octadecyloxy-1,3-propanediol (5.00 g, 14.5 mM; 1 M=1 mol dm^{-3}) and 0.95 g pyridine (12 mM) were dissolved into 250 ml dry dichloromethane, and added dropwise to 40 ml dry dichloromethane containing 2,4-octadecadienoyl chloride (10 mM) at room temperature. After addition of 4-(dimethylamino)pyridine, the mixture was stirred overnight at room temperature under nitrogen atmosphere. The mixture was washed successively with 1M HCl aqueous solution, then with saturated NaCl aqueous solution. The organic layer was dried over anhydrous sodium sulfate and evaporated in vacuo. The purification of the residual product was carried out by passing through a silica gel column with benzene/ether (10/1 by vol.) as an eluent. The desired fraction was collected and solvents were removed under reduced pressure. *rac*-1-*O*-(2,4-Octadecadienoyl)-2-*O*-octadecylglycerol (3.74 g) was obtained with 62% yield. R_f=0.25 (benzene/

ether=9/1 v/v); MS: 606 (M^+); IR in cm^{-1} (KBr): 1720 (ester carbonyl), 1640, 1620 (diene), 3400 cm^{-1} (OH); Elementaly Anal. (calcd value for $C_{39}H_{74}O_4$ in parenthesis): C 77.17 (77.17), H 12.87 (12.29%); ^{13}C NMR ($CDCl_3$, TMS) (in ppm): 62.7, 62.0, 77.8 (glycerol backbone), 70.6 (-C-O-C-), 118.5, 128.3, 145.4, 145.9 (diene), 167.2 (ester carbonyl); mp: 44.5 °C.

1-*O*-(2,4-Octadecadienoyl)-2-*O*-octadecyl-*rac*-glycero-3-phosphorylcholine (OOPC): *rac*-1-*O*-(2,4-Octadecadienoyl)-2-*O*-octadecylglycerol (3.60 g, 5.93 mM) and trimethylamine (0.72 g, 7.1 mM) were dissolved in 50 ml of dry benzene. 2-Chloro-1,3,2-dioxophosphorane 2-oxide (1.01 g, 7.1 mM) in 5 ml of dry benzene was slowly added to the solution at 10 °C. After the mixture was stirred at room temperature in the dark for 12 h, formed precipitates were removed by filtration. The filtrate was evaporated and the residue was dried in vacuo. It was allowed to react with dry trimethylamine (20 ml) in the mixture of *N,N*-dimethylformamide and benzene (15 ml/30 ml) in a pressure bottle at 60 °C for 4 h. Distilled acetone (0.2 ml) was then added to the mixture, the precipitate formed was collected, washed with dehydrated acetone and dried in vacuo. The residue was purified by passing through the zwitterion-type ion-exchange chromatography (Bio-Rad, AG501-x8(D)) with chloroform/methanol (20 ml/20 ml) as an eluent. The fractions having the same R_f value as that of egg york lecithin were collected. Solvent was removed and the residual product was lyophilized from dry benzene/dry methanol (5/1 v/v) to give 2.70 g of 1-*O*-(2,4-octadecadienoyl)-2-*O*-octadecyl-*rac*-glycero-3-phosphorylcholine (OOPC): yield 59%; FAB-MS: 772 (M+1); elementary anal. (calcd value for $C_{44}H_{86}NO_7P$ in parenthesis): N: 1.70 (1.81%); IR in cm^{-1} (KBr): 1710 (ester carbonyl), 1640, 1620 (diene), 1250 (P=O), 1090 and 970 (phosphorylcholine); ^{13}C NMR ($CDCl_3$, TMS) (in ppm): 54.3 (choline methyl), 64.4, 76.6 (glycerol backbone), 59.5, 66.3 (choline ethyl), 70.6 (-C-O-C-) 118.8, 145.6, 128.2, 145.1 (diene), 167.1 (ester carbonyl).

Methods. A total of 0.20 g of lipids was dissolved in dehydrated chloroform and was slowly evaporated in a rotating sample tube to prepare thin films on the inner surface of the tube, then 20 ml of distilled water was added. Small unilamellar liposome suspension was prepared by sonication (Tip type, Tomy Seiko UR-200P) at 60 W for 20 min under nitrogen atmosphere.[4] As disordered lipid packing perturbs accurate measurement on the characteristics of the oriented lipids in liposomes, freshly prepared liposomes were incubated at 8 °C to increase liposome size and to minimize the disordered molecular packing through liposomal fusion.[8,14] Accurately diluted liposome suspension was put into quartz cell, and the absorption maximum corresponding to the diene groups was analyzed with UV spectrometry (Shimadzu MPS-2000) under heating or cooling (1.0 °C min^{-1}).

Results

1,2-Bis(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (DODPC), which possesses 2,4-diene groups in both 1- and 2-acyl chains, shows the absorption maximum (λ_{max}) at 262.3 nm in chloroform solution at 25 °C. The λ_{max} was almost independent of temperature as shown in Fig. 1. When DODPC lipids were dispersed into water by sonication, they assembled to form liposomes. Though the λ_{max} of DODPC liposomes was found at 256.8 nm at 25 °C, a blue shift from 256.8 nm to 241.8 nm was observed when the suspension was cooled from 19 °C to 12 °C as also shown in Fig. 1. The maximum λ_{max} shift was found at about 16 °C corresponding to the gel-to-liquid crystalline phase-transition temperature (T_c) of DODPC (18 °C: with DSC).[8] The T_c is known to be influenced by liposome size especially for small unilamellar liposomes,[15] and λ_{max} shift behavior was observed in related to the liposome size (data not shown here). Small unilamellar liposomes (SUVs) prepared with

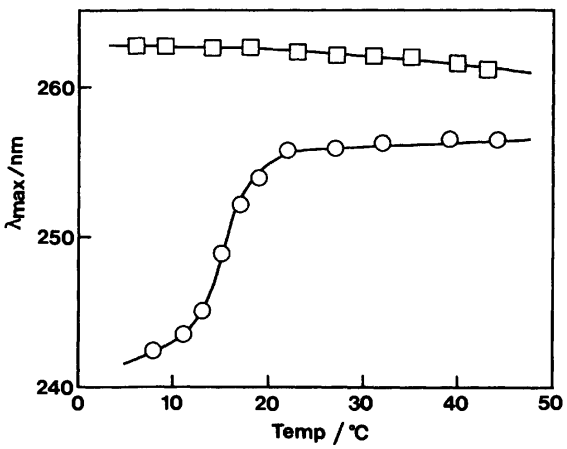

Fig. 1. Temperature dependence of wavelength at the absorption maximum for diene groups of DODPC. □: in chloroform. ○ in liposomes.

Table 1. λ_{max} and ε_{max} of Various Diene-Containing Lipid Liposomes at Temperatures below and above the Phase-Transition Temperature (T_c)

Lipid[a]	λ_{max}/nm		$\varepsilon_{max}\times10^{-4}$		T_{max}/°C	T_c/°C
	below T_c	above T_c	below T_c	above T_c		
DODPC	241.8	256.8	2.95	3.40	16.0	18.9
1,3-DPC	246.0	257.0	2.07	2.75	24.0	27.3
	(241.5	257.0	—	—	25.0)[b]	—
	(236.8	257.0	—	—	20.0)[c]	—
POPC	253.0	259.3	1.27	1.43	28.0	29.2
OOPC	245.0	255.0	1.48	1.70	39.0	40.1

a) Liposomes incubated at 8 °C for 12 h were used. b) Measured for the liposomes incubated for 7 days with elevating temperature. c) With lowering temperature.

sonication method were incubated at temperatures below T_c to prepare large unilamellar liposomes (LUVs) through liposomal fusion.[8,16] The LUVs with average radius of more than 35 nm are known to show almost the same phase-transition behavior.[8] The following measurements were therefore performed for LUVs with average radius of more than 35 nm. Those liposomes could be prepared by incubation at 8 °C for 12 h.

Spectral characteristics of other phospholipids having 2,4-octadecadienoyl group were also examined and summarized in Table 1. The temperature (T_{max}) which gave the maximum value of $d\lambda_{max}/dT$ was compared with a gel-to-liquid crystalline phase-transition temperature (T_c) obtained from DSC measurement. The blue shift of λ_{max} occurred at gel-to-liquid crystalline phase-transition temperature. The temperature dependence on the λ_{max} was normalized for all diene-containing lipids by drawing the relationship between $T-T_{max}$ and λ_{max} as summarized in Fig. 2. The absorption maxima of 1-palmitoyl-2-(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (POPC)[7] and 1-*O*-(2,4-octadecadienoyl)-2-*O*-octadecyl-*rac*-glycero-3-phosphorylcholine (OOPC) were measured in the temperature range from 5 °C to 60 °C. Though POPC or OOPC had one diene group in either 2- or 1-acyl chain, respectively, their λ_{max} shift behavior was quite different. In case of POPC, the λ_{max} shifted gradually from 253.0 nm to 259.3 nm on heating. The maximum shift was observed at 28 °C. While, OOPC showed a drastic shift from 245.0 nm to 255.5 nm at 39 °C. 1,3-Bis(2,4-octadecadienoyl)-*rac*-glycero-2-phosphorylcholine (1,3-DPC), an isomer of DODPC,[9] has 2,4-diene groups in 1- and 3-acyl chains. This 1,3-DPC also showed the λ_{max} shift from 246.0 nm to 257.0 nm at around 24 °C. However, 1,3-DPC liposomes were semistable and slowly changed their structure within a few days. When 1,3-DPC liposomes were incubated at 8 °C for 7 days, opalescent liposome dispersion was turbid indicating aggregation and fusion. In this system, λ_{max} changed from 241.5 nm to 257.0 nm (T_{max}=25 °C) with elevating temperature and from 257.0 nm to 236.8 nm (T_{max}=20 °C) with lowering temperature showing a hysteresis. This result was unique for 1,3-DPC liposomes.

The molar extinction coefficients (ε_{max}) of diene-containing lipid derivatives are also summarized in Table 1. ε_{max} for all lipids increased a little at temperatures above their phase-transition temperatures. As expected from the number of diene groups in one lipid molecule. ε_{max} of OOPC was almost identical as that of POPC and half of that of DODPC regardless of temperature.

The λ_{max} shift reflects the phase-transition temperature of diene-containing lipid liposomes. The ability of these lipids was also applied to analyze the phase-transition behavior of natural lipid assemblies. The λ_{max} shift for DODPC/DPPC (1:20 by mol) mixed liposomes was observed at 40 °C as shown in Fig. 3, corresponding to the gel-to-liquid crystalline phase-

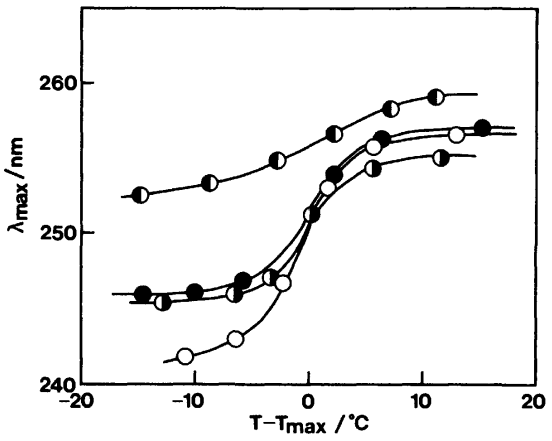

Fig. 2. Relationship betweeen $T-T_{max}$ and wavelength at the absorption maximum of DODPC (○), 1,3-DPC (●), OOPC (◑), and POPC (◐).

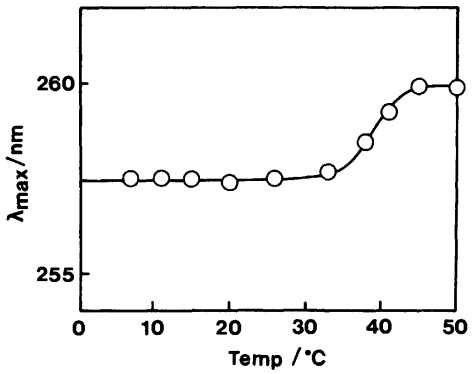

Fig. 3. Temperature dependence of wavelength at the absorption maximum of DODPC in DPPC/DODPC (20:1) mixed liposomes.

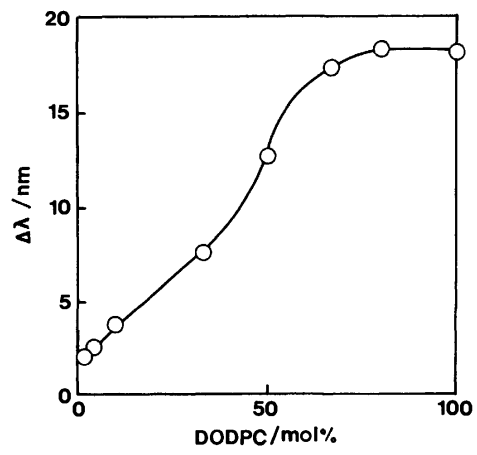

Fig. 4. Effect of DODPC mole fraction on the difference ($\Delta\lambda$) of wavelength between at the absorption maximum of DPPC/DODPC mixed liposomes at 5 °C and 260.0 nm. $\Delta\lambda$ at 0% of DODPC mole fraction corresponded to 258.5 nm.

transition temperature of DPPC, but not that of DODPC. The shift from 260.0 nm to 257.5 nm was different from that of DODPC (256.8 nm to 241.8 nm). This shift (2.5 nm) was very small compared with that of pure DODPC liposomes (15.0 nm). It is important to investigate λ_{max} shift behavior against composition of mixed liposomes. When DODPC fraction decreased, λ_{max} at temperatures below T_c significantly red-shifted while λ_{max} above T_c gradually saturated to 260.0 nm. The wavelength at 260.0 nm was considered to be limited value of longer wavelength. Differences ($\Delta\lambda$) between λ_{max} at gel state and that 260.0 nm against DODPC mole fraction were shown in Fig. 4. Since λ_{max} at 0% of DODPC mole fraction at gel state was 258.5 nm, the $\Delta\lambda$ was 1.5 nm. This increased with the DODPC composition and saturated to 18.2 nm when DODPC fraction exceeded 80%. In this case, T_{max} also reached the T_c of the pure DODPC liposomes. Furthermore, temperature range, at which the λ_{max} shift occurred, changed according to the composition of DODPC/DPPC mixed liposomes. There were two break points in the slope of temperature dependence of λ_{max}, namely, the onset and the offset blue shift. In mixed liposome system, temperatures of these two break points were significantly different. They were plotted against the molar ratio of DODPC to obtain an equilibrium phase diagram of DPPC and DODPC mixed liposome as shown in Fig. 5.[17] The temperature (T_f) of the onset blue shift drew the fluidus curve while the temperature (T_s) of the offset point did the solidus curve.

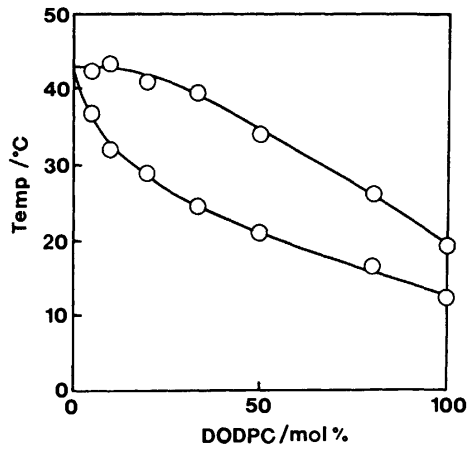

Fig. 5. Phase diagram of DODPC/DPPC mixed liposomes obtained from λ_{max} shift behavior. Upper curve was fluidus curve made of T_f and lower one was solidus curve made of T_s.

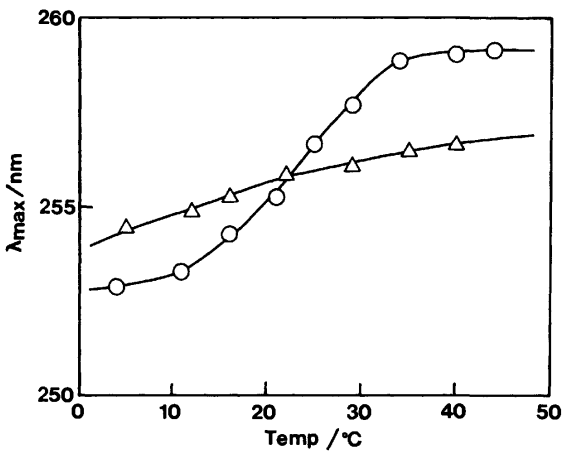

Fig. 6. Temperature dependence of the wavelength at the absorption maximum for diene groups of POPC (○) and POPC/cholesterol (1:1) mixed liposomes (△).

Effect of cholesterol on the phase-transition behavior was also analyzed with the λ_{max} shift. The λ_{max} for POPC/cholesterol (1:1 by mol) mixed liposome increased slightly from 254.2 nm to 256.7 nm when temperature was raised from 5 °C to 40 °C. The slope was smooth and continuous, and no distinct transition was found as shown in Fig. 6. This phenomenon can also be discussed in related to the well-known effect, so-called "Cholesterol Effect".[18,19]

Discussion

All diene-containing phospholipids analyzed here have at least one 2,4-dienoyl group in their acyl chains, and their absorption maximum was 262.3 nm in chloroform solution regardless of their structure. There was no temperature dependence on the λ_{max} in such a molecularly-dispersed homogeneous solution. Once these lipids formed molecular assemblies such as liposomes in an aqueous medium, the absorption maximum was observed at about 257 nm at temperatures above the gel-to-liquid crystalline phase-transition temperature (T_c) of corresponding lipid liposomes as shown in Table 1. All of diene-containing lipid liposomes showed blue shift of λ_{max} at temperatures below the T_c. The magnitude of λ_{max} shift at T_c was revealed to strongly depend on the chemical environment, acyl chain packing and conformation of dienoyl groups. Following three reasons can be presented to explain the blue shift of their λ_{max}.

(1) A structural change of conjugated dienoyl system may be induced at gel-to-liquid crystalline phase-transition temperature. If energy levels of electron orbitals for dienoyl group were changed by its structural change, the shift might occur.

(2) The λ_{max} for dienoyl groups is sensitive to solvent polarity. If polarity around dienoyl groups at temperatures below T_c was different from that above T_c because location of water molecules in bilayer membrane would change at T_c, the λ_{max} might therefore shift.

(3) The shifts in λ_{max} should be caused by the interaction of dienoyl groups in the lipid bilayer. In liquid-crystalline state, segmental motion of dienoyl groups is relatively high and they have more freedom

than those in the gel state. DODPC as liposomes in liquid-crystalline state showed a similar λ_{max} to that in homogeneous solution e.g. in methanol. Diene groups in gel state are oriented more regularly and interacted (stacked) with each other. It should therefore cause the blue shift of λ_{max}.[20]

To clarify the mean factor for this shift behavior, it is important to analyze the spectral characteristics for the diene group in the mixed bilayer membrane, where a little amount of diene-containing lipids is mixed with saturated normal lipids. In case of DPPC/DODPC (20:1 by mol) mixed liposomes (Fig. 3), the gel-to-liquid crystalline phase-transition temperature is almost the same as that of pure DPPC liposomes. However, the difference between λ_{max} below and above the T_c was much smaller than that of pure DODPC liposomes. If the λ_{max} shift was caused by the first and/or second reason, the mixed liposomes should have the same shift as that of the pure diene-containing lipid liposomes. In mixed liposome system, the wavelength of the absorption maxima at gel and liquid crystalline state approached to 258.5 nm and 260.0 nm, respectively in accordance with the increase of DPPC ratio as shown in Fig. 4. The wavelength of 258.5 nm was considered to be attributed to molecularly dispersed DODPC which had only intramolecular interaction of diene groups because the λ_{max} for not interacted diene group in bilayer membrane would be 260.0 nm. It was also supported from the result that the λ_{max} of molecularly-dispersed monodiene-type POPC was found at 260.0 nm at temperature below the T_c. The shift was therefore attributed to the direct interaction with diene groups of lipids. The third one is therefore concluded to be the most suitable explanation for this λ_{max} shift.

Generally, chromophores in stacked state show specific spectra reflecting their interaction. According to the molecular exciton model proposed by Kasha et al.,[13] direction and degree of λ_{max} shift were decided by inclination and distance among the transition dipoles. In bilayer membrane system, λ_{max} of chromophores, such as diene groups which constitute part of chains, is predicted to shift to a shorter wavelength because hydrocarbon chains extend perpendicularly to the membrane plane. The large blue shift however occurred only in gel state of the bilayer membrane as shown in Fig. 1. That was because the diene groups, packed closely with a good orientation manner in gel state, were disordered in liquid crystalline state. The λ_{max} shifted and approached to that of the molecularly dispersed diene-containing lipids (260.0 nm) at temperatures above T_c.

The λ_{max} shift for LUVs of some diene-containing lipids also reflected their structural characteristics as shown in Fig. 2. In case of DODPC, stacking of diene groups in the 1-acyl chains should be unequivalent with that in the 2-acyl chains because of their unsymmetrical chain packing in bilayer membrane.[4] The stacking between diene groups in the 1- and 2-acyl chains however also exists as described above. The comparison of the stacking of diene groups in the 1-acyl chains and that in the 2-acyl chains should be carried out with corresponding monodiene type lipids such as OOPC and POPC, respectively. λ_{max} of POPC was entirely longer than that of OOPC. This was attributed to the different orientation of diene groups of POPC to those of OOPC. Since diene groups in the 1-acyl chains of OOPC oriented perpendicularly to the membrane plane, stronger interaction was easily expected between these diene groups. While, those of POPC oriented with large inclination, and lots of dipoles aligned in the opposite direction with the same inclination. Interaction of 2,4-diene groups in the 2-acyl chains should therefore be very weak, leading to smaller blue shift of POPC than OOPC as shown in Fig. 2. The different packing of diene groups in the 1- and 2-acyl chains has already been shown from X-ray diffraction and D-NMR analyses on natural phospholipids.[21,22] It was also supported by our results on the selective polymerization of the 1- and 2-acyl chains by the addition of either water-soluble or -insoluble radical initiators.[4,6] Diene-groups in the 2-acyl chains of DODPC faced an aqueous phase while those in the 1-acyl chains located in a hydrophobic phase in consequence of perpendicular orientation of glycerol moieties to the liposome membrane plane. Diene-groups in the 2-acyl chains were therefore selectively polymerized with water-soluble radical initiators such as AAPD. POPC liposomes were accordingly polymerized with only water-soluble radical initiators.[7]

The spectral changes of azobenzene moieties of the assembled single chain amphiphiles have also been reported.[23] These amphiphiles are known to form bilayer structures in an aqueous medium, and the blue shift of λ_{max} was also found below the phase-transition temperature. This phenomenon was explained systematically with this exciton model in the one dimension because of card-like packing of azobenzene moieties in the membrane, and the λ_{max} shift was referred to the results from X-ray analyses.[24,25] In our system, the λ_{max} shift of diene groups was however smaller than those of azobenzene system. In the present paper, we discussed here the shift behavior with the two dimensional exciton model, i.e., molecular lamellar exciton model because diene group could be regarded as arrow.[26] We have to take the interaction of dipoles in two dimension into consideration. The treatment of interaction of dipoles with inclination to membrane plane is complicated because dipoles with the same inclination do not orient with the same direction in membrane plane.

Recently, O'Brien et al.[27] reported the shift of the absorption maxima for diene-containing lipids. They mentioned that the evidence for aggregation of diene

groups of DODPC and POPC in bilayer membrane could not be obtained from those lipids at 22 °C because those liposomes showed not so clear λ_{max} shift at that temperature. They should have taken the phase-transition temperature into account. The λ_{max} of around 260 nm for DODPC at 22 °C surely shifted to 243 nm at temperatures lower than the phase-transition temperature (16 °C) as shown in Fig. 1. In case of POPC, small shift of λ_{max} from 260.0 nm even below the phase-transition temperature (22 °C) occurred due to the different packing manner of diene groups in the 2-acyl chains as described above.

Temperature dependence of the absorption maxima was concluded to be essentially related to the lipid structure as shown in Table 1. Lipids having the same hydrophobic hydrocarbon number can be aligned in the following sequence by their T_c;

$$\text{DODPC}(18.9\,^\circ\text{C}) < \text{1,3-DPC}(27.3\,^\circ\text{C}) < \text{OOPC}(40.1\,^\circ\text{C}) < \text{DSPC}(55.0\,^\circ\text{C})$$

DSPC has two saturated acyl chains. OOPC has one diene group in 1-acyl chain. While DODPC or 1,3-DPC have two dienoyl groups in 1- and 2-acyl, or 1- and 3-acyl chains, respectively. This tendency has already been known for the natural lipids, i.e., the more the number of unsaturated bonds is, the lower the phase-transition temperature is. The difference of T_c between DODPC and 1,3-DPC was apparent to be due to the different lipid packing of these lipids in bilayer membrane. This lipid packing has already been analyzed with polymerization manner under the different point of view.[9] The diene-containing phospholipids are found to be applicable as probe molecules to analyze chemical environment of lipids in liposomes without disturbing the lipid packing. Furthermore, the position to be analyzed in bilayer membrane can be chosen by the location of diene groups in the acyl chains.

The molar extinction coefficient (ε_{max}) also shifted at gel-to-liquid crystalline phase-transition temperature. The ε_{max} decreased when temperature was set below the T_c. That was because the molar extinction coefficient of chromophore in a stacked stage was different (generally smaller) from that in the dispersed stage. The ε_{max} of POPC as liposomes was found to be smaller than that of OOPC as liposomes, though the ε_{max} values of POPC and OOPC were completely the same in organic solvents. It can be comprehended by the polarity around diene groups.[28] The absorption spectrum of diene group varies with solvent polarity. When the solvent polarity was higher, the ε_{max} tended to be smaller. The smaller ε_{max} of POPC indicated that the polarity of diene groups of POPC was higher than that of OOPC. The polarity of diene group in the 2-acyl chain is considered to be a little higher than that in the 1-acyl chain. These results strongly supported that 2,4-diene group of the 2-acyl chain faced an aqueous phase which had already been suggested from the analyses of polymerization behaviors of those lipids.[3,7] Furthermore, these spectroscopic analyses were quite suitable to measure the phase-transition of very dilute liposome suspension because the ε_{max} was large.

The λ_{max} for DPPC/DODPC (20:1 by mol) mixed liposomes shifted at 40 °C, corresponding to the T_c of this mixed liposome. The phase-transition temperature was almost the same as that of DPPC liposomes. Though diene-containing lipids can be used as membrane probe which detect the phase-transition temperature of lipid membrane, this probe itself is a lipid which has own phase-transition temperature. It is easy to reach the following conclusion that the present lipid system has effective to detect the T_c of the matrix membrane, it however has inevitable concentration dependence. It is favorable to use 5 mol% of the DODPC in order to detect the phase-transition of the matrix membrane because 5 mol% of DODPC is considered not to affect the phase-transition of the major component.[12] The shift for the mixed liposomes, however, was significantly smaller than that of pure diene-containing lipid liposomes. At this ratio, the shift was almost due to interaction of diene groups in 1- and 2-acyl chains of the lipid. Monodiene-type lipids therefore cannot be used as probes for phase-transition of matrix lipids. The lipid, having two diene groups which locate at the same position in bilayer membrane, is the best for this purpose because it is expected to be intramolecular interaction of diene groups.

When more than 5 mol% of DODPC was mixed to DPPC liposomes, λ_{max} shift also reflected the phase-transition of DODPC itself and it became broad.[29] It was a typical characteristic of mixed liposome systems. Two transition temperatures at which the onset and the offset of the blue shift occurred were related to T_f and T_s, respectively.[17] At temperatures above T_f, DODPC showed a constant value of λ_{max} because all of DODPC were in a liquid crystalline state. When the mixed liposome dispersion was cooled below T_f, gel phase of DODPC, which shows smaller λ_{max}, was formed in mixed liposomes. The portion of gel phase and the ratio of DODPC in the gel phase became larger by lowering temperature to T_s. It resulted that the value of λ_{max} gradually shifted to shorter wavelength. At temperatures below T_s, the mixed liposomes were totally in a gel state, showing a constant λ_{max} depending on the initial feed composition.

The phase-transition temperature is known to disappear by the addition of cholesterol, and slight temperature dependence of the λ_{max} was observed for cholesterol/POPC (1:1 by mol) mixed liposomes as shown in Fig. 6. The same phenomenon has already

been found with other measurements such as DSC,[18] NMR,[29] fluorescence spectroscopy[30] and so on. Cholesterol/POPC equimolar mixture system at 5 °C showed its λ_{max} at 254.2 nm which was longer wavelength than that for POPC (253.0 nm). Cholesterol shows an effect to fluidize the lipid membrane at temperatures below the T_c. It caused the decrease in the interaction between dienoyl groups of POPC below the T_c. The λ_{max} of cholesterol/POPC equimolar mixture liposomes (256.7 nm) at 40 °C, above the phase-transition temperature of POPC liposomes, was shorter than that of POPC liposomes (259.3 nm). That is considered to be the existence of some interaction of dienoyl groups due to less mobility of POPC in cholesterol containing lipid membrane. These spectral changes must be useful to detect the phase state of any lipid systems without disturbing their assembled structure.

Conclusion

The absorption maxima of diene-containing lipids as liposomes showed blue shift at gel state. The shift was resulted from the interaction of dienoyl groups, and it was explained by the exciton model. The different acyl chain packing of various diene-containing lipids was revealed to be the major factor to cause the temperature dependence of the absorption. The λ_{max} shift also reflected the phase-transition temperature of mixed liposomes. Besides the phase-transition temperature, the information about mobility and packing of diene groups were also obtained at any temperatures, which could not be observed by DSC measurement. The diene-containing lipids were concluded to be unique and quite potential compounds as membrane probes.

The authors thank Dr. Yoshihiko Nagata and Dr. Akira Akimoto of Toyo Soda Co. Ltd. for their kind supply of polymerizable lipid (POPC). This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Area "Macromolecular Complexes" from the Ministry of Education, Science and Culture.

Asymmetric Transformation of (*RS*)-Cysteine via Formation of (*RS*)-4-Thiazolidinecarboxylic Acids

Tadashi SHIRAIWA,* Kazuo KATAOKA, Shinji SAKATA, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received June 20, 1988)

Either (*R*)- or (*S*)-cysteine ((*R*)- or (*S*)-Cys) was efficiently obtained from (*RS*)-Cys by the asymmetric transformation via formation of (*RS*)-4-thiazolidinecarboxylic acid ((*RS*)-THC) or (*RS*)-2,2-dimethyl-4-thiazolidinecarboxylic acid ((*RS*)-DMT) and by using (2*R*,3*R*)- or (2*S*,3*S*)-tartaric acid ((*R*)- or (*S*)-TA), as a resolving agent, in acetic acid. The asymmetric transformation was carried out by combination of crystallization of less soluble salt of (*S*)-THC or -DMT with (*R*)-TA (or salt of (*R*)-THC or -DMT with (*S*)-TA) and epimerization of soluble diastereomeric salt. The (*R*)- and (*S*)-THCs from the less soluble salts gave approximately optically pure (*R*)- and (*S*)-Cys's, respectively, in 64% yield. The asymmetric transformation via formation of (*RS*)-DMT was more successfully achieved by adding 0.1 molar equivalent of salicylaldehyde; that is, hydrolysis of the obtained less soluble salt gave optically pure (*R*)- and (*S*)-Cys's, respectively, in 80% yield based on the (*RS*)-Cys used as the starting material.

(*RS*)-Cysteine (abbreviated as (*RS*)-Cys) has been optically resolved by preferential crystallization to obtain (*R*)-Cys, a useful material for medicines, food additives, and cosmetics, and (*S*)-Cys, a pharmaceutical material.[1-3] The optical resolution by preferential crystallization is useful for industrial purposes and gives both enantiomers. In many cases, only one enantiomer is demanded in large amounts, but the other is not in so large an amount. Asymmetric transformation has the possibility of converting a racemate solely into the desirable enantiomer. An asymmetric transformation has been carried out for (*RS*)-amino acid derivatives by combination of selective crystallization of a less soluble diastereomeric salt and epimerization of the other soluble one.[4-9] This paper describes an attempt to obtain either (*R*)- or (*S*)-Cys efficiently from (*RS*)-Cys.

(*R*)-4-Thiazolidinecarboxylic acid ((*R*)-THC), a material for antihypertensive agent, has been obtained by reacting (*R*)-Cys with formaldehyde.[10] We reported the asymmetric transformation of (*RS*)-THC via formation of its diastereomeric salts with equimolar (2*R*,3*R*)- or (2*S*,3*S*)-tartaric acid ((*R*)- or (*S*)-TA).[11] Although a treatment of (*R*)- or (*S*)-THC with hydroxylamine hydrochloride gives optically active Cys,[2,11] the overall yield based on initial (*RS*)-Cys is estimated to be 50%. It has been reported that optically active amino acids are racemized in the presence of aldehydes in an organic acid such as acetic acid.[12] If formation of (*RS*)-THC from (*RS*)-Cys, epimerization by excess formaldehyde of its soluble diastereomeric salt with TA, and crystallization of its less soluble salt take place simultaneously in one system, it is expectable to obtain optically active Cys in higher yield.

Optically active 2,2-dimethyl-4-thiazolidinecarboxylic acid (DMT) is rapidly formed by reacting optically active Cys with acetone in acetic acid and racemized simultaneously by excess acetone, as described in our previous paper.[13] DMT is more easily hydrolyzed in water to regenerate Cys than THC.[14,15] In addition, DMT seems to form easily the salt with equimolar TA similarly to THC.

On the basis of the above suggestions, the asymmetric transformation of (*RS*)-Cys was tried via formation of (*RS*)-THC and (*RS*)-DMT and by using optically active TA as a resolving agent.

Experimental

Materials. (*R*)- and (*RS*)-Cysteine hydrochloride monohydrates were purchased from Wako Pure Chemicals Ind. and Sigma Chemicals Co., respectively, and recrystallized from water. Aqueous solutions of the hydrochlorides were adjusted with concentrated aqueous ammonia to pH 6 to obtain (*R*)- and (*RS*)-Cys. (*R*)-Cys: $[\alpha]_D^{20}$ +6.5° (*c* 4.00, 5 mol dm^{-3} HCl). (*R*)- and (*S*)-TAs were purchased from Wako Pure Chemicals Ind.

Synthesis of 4-Thiazolidinecarboxylic Acid and 2,2-Dimethyl-4-thiazolidinecarboxylic Acid. (*RS*)- or (*R*)-Cys (0.0200 mol, 2.42 g) was dissolved in the presence of 1.62 g of 37% aqueous formaldehyde (0.0200 mol of formaldehyde) in 40 cm^3 of acetic acid at 50 °C, and the solution was cooled immediately to 30 °C. After stirring for 1 h at 30 °C, the solution was dried under reduced pressure at 40 °C. The THC obtained as the residue was washed thoroughly with methanol and dried. (*RS*)-THC: Yield 2.49 g (93.5%); mp 188—191 °C (decomp) (lit,[16] 183—184 °C, 195 °C (decomp)). (*R*)-THC: Yield 2.48 g (93.1%); mp 200—202 °C (decomp) (lit,[16] 196—197 °C, 205—209 °C (decomp); $[\alpha]_D^{20}$ −141° (*c* 0.500, water) (lit,[16] $[\alpha]_D$ −141° (water)).

(*R*)-DMT was obtained by reacting (*R*)-Cys with acetone in acetic acid and (*RS*)-DMT by racemization of (*R*)-DMT, as described in our previous paper.[13] (*R*)-DMT: Mp 144—145 °C (lit,[14] 138—140 °C); $[\alpha]_D^{20}$ −188° (*c* 0.100, acetone) (lit,[14] $[\alpha]_D$ −183° (acetone)). (*RS*)-DMT: Mp 150—152 °C.

Preparation of Standard Salts. A mixture of 0.0200 mol of (*R*)-Cys, 0.0200 mol of (*S*)-TA, and 0.0500 mol (2.90 g) of acetone in 10 cm^3 of acetic acid was refluxed for 30 min. After stirring the mixture for 30 min at room temperature, the formed salt of (*R*)-DMT with (*S*)-TA ((*R*)-DMT·(*S*)-TA salt) was collected by filtration, washed thoroughly with diethyl ether, and dried. The salt of (*R*)-DMT with (*R*)-TA

could not be obtained because the formed salt was strongly hygroscopic. The (*R*)-DMT·(*S*)-TA salt: Yield 5.95 g (95.6%); mp 172—174 °C (decomp); $[\alpha]_D^{20}$ −81.8° (*c* 0.500, methanol); Found C, 38.44; H, 5.47; N, 4.48% (Calcd for $C_{10}H_{17}NO_8S$: C, 38.58; H, 5.50; N, 4.50%).

The salt of (*R*)-THC with (*S*)-TA ((*R*)-THC·(*S*)-TA salt) and that of (*R*)-THC with (*R*)-TA ((*R*)-THC·(*R*)-TA salt) were prepared by the method described in our previous paper.[17] The (*R*)-THC·(*S*)-TA salt: Mp 171—173 °C (decomp); $[\alpha]_D^{20}$ −74.0° (*c* 0.500, water). The (*R*)-THC·(*R*)-TA salt: Mp 149—150 °C (decomp); $[\alpha]_D^{20}$ −55.8° (*c* 0.500, water).

Asymmetric Transformation. Procedure I: A mixture of 0.0200 mol of (*RS*)-Cys, 0.0200 mol of (*R*)- or (*S*)-TA, and 1.95 g of 37% aqueous formaldehyde (0.0240 mol of formaldehyde) in 40 cm³ of acetic acid was stirred for 0.5—2 h at 80 °C. After stirring the mixture for 15 min in an ice bath, the formed salt was collected by filtration, washed with diethyl ether, and dried. The salt was washed by stirring in 250 cm³ of ethanol for 1 h at 20 °C and then in 50 cm³ of methanol for 1 h to give (*R*)- or (*S*)-THC. The obtained (*R*)- and (*S*)-THCs (2.04 g) were treated with 1.5 molar equivalents of hydroxylamine hydrochloride in methanol to give 1.54 g of (*R*)- and (*S*)-Cys's, as described in our previous paper;[2] the yield based on 0.0200 mol of (*RS*)-Cys was 63.6%.

(*R*)-Cys (0.0200 mol) and 0.0200 mol of (*R*)-TA were dissolved in the presence of 1.62—2.44 g of 37% aqueous formaldehyde (0.0200—0.0300 mol of formaldehyde) in 40 cm³ of acetic acid at 70 °C. After stirring the mixture for 30 min at 30 °C and then for 1 h at 80 °C, the formed salt was filtered off and treated similarly to above.

Procedure II: A mixture of 0.0400 mol of (*RS*)-Cys, 0.0400 mol of (*R*)- or (*S*)-TA, and 0.200 mol of acetone in 15 cm³ of acetic acid was refluxed (approximately at 83 °C) for 2—10 h. The formed salt was filtered off, washed with diethyl ether, and dissolved in 80 cm³ of water. After refluxing for 2 h, the solution was dried under reduced pressure at 40 °C. The residue was stirred for 2 h in 100 cm³ of methanol to give (*R*)- or (*S*)-Cys.

Procedure III: After refluxing a mixture of 0.0400 mol of (*RS*)-Cys, 0.0400 mol of (*R*)- or (*S*)-TA, and 0.200 mol of acetone in 10 cm³ of acetic acid, 0.0040 mol of salicylaldehyde was added to the mixture. The mixture was refluxed (approximately at 77 °C) for 2—7 h and successively stirred for 30 min in an ice bath. The formed salt was filtered off, washed thoroughly with diethyl ether, and dried. The obtained salt was hydrolyzed to give (*R*)- or (*S*)-Cys and to recover TA. For example, 10.38 g of optically pure (*R*)-DMT·(*S*)-TA salt was added to a mixture of 10 cm³ of water and 100 cm³ of ethanol. After stirring the mixture for 1 h at 60 °C, crude (*R*)-Cys was filtered off: yield 5.61 g; $[\alpha]_D^{20}$ +4.7° (*c* 4.00, 5 mol dm⁻³ HCl). The (*R*)-Cys was washed by stirring for 30 min in 50 cm³ of methanol to give 3.88 g (80.1% yield) of optically pure (*R*)-Cys: $[\alpha]_D^{20}$ +6.5° (*c* 4.00, 5 mol dm⁻³ HCl) (lit,[18] $[\alpha]_D$ +6.5° (5 mol dm⁻³ HCl)). The ^{1}H NMR spectrum of the (*R*)-Cys in deuterium oxide showed no methyl protons. Drying of the above ethanol and methanol washings gave 4.96 g (82.6% recovery) of (*S*)-TA: $[\alpha]_D^{20}$ −12.1° (*c* 20.0, water) (lit,[19] (*R*)-TA $[\alpha]_D^{20}$ +11.98° (*c* 20%, water)).

Racemization Rate of (*R*)-2,2-Dimethyl-4-thiazolidinecarboxylic Acid. A mixture of 0.0200 mol of (*R*)-Cys and 30 cm³ of acetic acid was heated to 80 °C. After adding 0.100 mol of acetone and 0.0020 mol of acetaldehyde, benzaldehyde, 2-chlorobenzaldehyde, or salicylaldehyde, the resulting solution was stirred at 80 °C; (*R*)-Cys was dissolved completely by stirring for several minutes at 80 °C. One cm³ portions of the solution were pipetted out at 30 min intervals and diluted rapidly to 10 cm³ with acetic acid. The optical rotation at 589 nm was measured. The rate constant (k_R/h⁻¹) was calculated by the least-squares method from

$$\ln \alpha_0/\alpha_t = k_R t, \quad (1)$$

where α_t is the optical rotation at time *t* h and α_0 that extrapolated to zero time. The half-life period ($t_{1/2}$/h) was calculated on the basis of k_R values obtained by Eq. 1. The above solution was dried under reduced pressure after stirring for 3 h at 80 °C and the residue was washed thoroughly with diethyl ether. The ^{1}H NMR spectrum showed that the residue was DMT and not any 4-thiazolidinecarboxylic acid derivatives.

Measurements. Optical and specific rotations were measured by a Union Giken PM-101 digital polarimeter with a quartz cell of 0.50 dm path length. ^{1}H NMR spectra were recorded on a JEOL JNM—PMX 60 NMR spectrometer in deuterium oxide with no internal standard substance.

Results and Discussion

Asymmetric Transformation by Procedure I. (*RS*)-THC was easily formed by reacting (*RS*)-Cys with formaldehyde in acetic acid, as described in the experimental section. The diastereomeric salts of (*RS*)-THC with equimolar (*R*)-TA were separated into the less soluble (*S*)-THC·(*R*)-TA salt and the soluble (*R*)-THC·(*R*)-TA salt.[17] These results indicate a possibility that formation of (*RS*)-THC, selective crystallization of the (*S*)-THC·(*R*)-TA salt, and epimerization by excess formaldehyde of the (*R*)-THC·(*R*)-TA salt take place simultaneously in one system. The epimerization seems to be accelerated with an increase in amount of excess formaldehyde. However, the increase may result in dissolution of a part of the less soluble salt because 37% aqueous formaldehyde (37% FA) is employed. Optimization of the amount of 37% FA was conducted by stirring a mixture of 0.0200 mol of (*R*)-Cys, 0.0200 mol of (*R*)-TA, and 1.62—2.44 g of 37% FA (0.0200—0.0300 mol of formaldehyde) in acetic acid. These results are given in Table 1 and Fig. 1. The degree of transformation into the (*S*)-THC·(*R*)-TA salt in Fig. 1 was calculated by

$$\text{Degree of transformation}/\% = (\text{Yield}/\% \times \text{Optical purity}/\%)/100. \quad (2)$$

Although the use of 1.62 g of 37% FA (0.0200 mol of formaldehyde) gave the (*R*)-THC·(*R*)-TA salt, the salt was partially epimerized even by using equimole of formaldehyde to (*R*)-Cys, as indicated by its having 59.5% optical purity. The (*S*)-THC·(*R*)-TA salts with

a) (*R*)- or (*RS*)-Cysteine (Cys) 0.0200 mol; (2*R*,3*R*)- or (2*S*,3*S*)-tartaric acid (TA) 0.0200 mol; acetic acid 40 cm³; temperature 80 °C; THC 4-thiazolidinecarboxylic acid. b) 37% aqueous formaldehyde (1.62 g) corresponds to 0.0200 mol of formaldehyde. (c) (*R*·*R*) represented the salt composed of equimolar amounts of (*R*)-THC and (*R*)-TA (*S*·*R*) the salt of (*S*)-THC and (*R*)-TA, and (*R*·*S*) the salt of (*R*)-THC and (*S*)-TA. d) The yield was calculated on the basis of 0.0200 ml (5.67 g) of the salt. e) $[\alpha]_D^{20}$ (*c* 0.500, water). f) The optical purity was determined on the basis of the specific rotation of the (*S*·*R*)-salt ($[\alpha]_D^{20}$ +74.0° (*c* 0.500, water)) and that of the (*R*·*R*)-salt ($[\alpha]_D^{20}$ −55.8° (*c* 0.500, water)). g) The yield was calculated on the basis of 0.0200 mol (2.66 g) of Cys. h) The optical purity was determined on the basis of the specific rotation of (*R*)-THC ($[\alpha]_D^{20}$ −141 ° (*c* 0.500, water)).

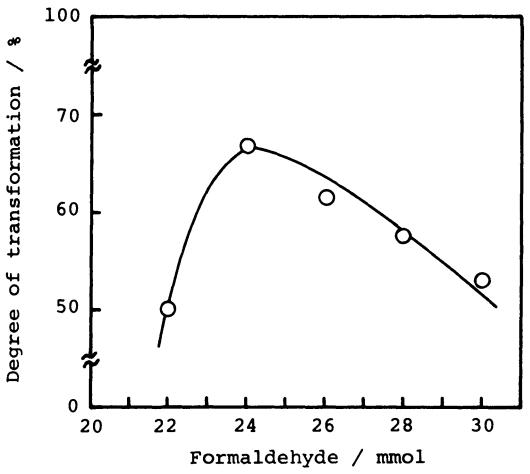

Fig. 1. Relationship between degree of transformation into salt of (*S*)-4-thiazolidinecarboxylic acid with (2*R*,3*R*)-tartaric acid and amount of formaldehyde. Conditions: (*R*)-Cysteine 0.0200 mol; (2*R*,3*R*)-tartaric acid 0.0200 mol; acetic acid 40 cm³; stirring time 1 h; temperature 80 °C; 1.62 g of 37% aqueous formaldehyde corresponds to 0.0200 mol of formaldehyde.

77—99% optical purity were obtained by using 1.79—2.44 g of 37% FA (0.0220—0.0300 mol of formaldehyde). As seen in Fig. 1, the (*S*)-THC·(*R*)-TA salt with 98.8% optical purity was obtained by using 1.95 g of 37% FA (0.0240 mol of formaldehyde) in the highest degree of transformation (66.7%). This salt gave (*S*)-THC with 99.3% optical purity in 63% yield based on the (*R*)-Cys used as the starting material.

Based on the above results, the asymmetric transformation was carried out by reaction of 0.0200 mol of (*RS*)-Cys, 0.0200 mol of (*R*)- or (*S*)-TA, and 1.95 g of 37% FA in 40 cm³ of acetic acid at 80 °C, as shown in Table 1. Although the asymmetric transformation was also attempted at 90 °C, the salt formed at lower temperature was dissolved on heating to 90 °C.

The (*R*)-THC·(*S*)-TA and (*S*)-THC·(*R*)-TA salts with approximately 100% optical purity were obtained in 83% yield by reaction for 1.5 and 2 h, respectively. These salts gave (*R*)- and (*S*)-THCs, respectively, in 77% yield. The obtained THCs were treated with hydroxylamine hydrochloride to give (*R*)- and (*S*)-Cys's, respectively, in 64% yield based on 0.0200 mol of (*RS*)-Cys.

Asymmetric Transformation by Procedure II. The asymmetric transformation by procedure I is more efficient than that described in our previous paper[11] in that it yields optically active Cys in higher yield. However, the treatment of THC with hydroxylamine hydrochloride is tedious and results in lowering of yield of the optically active Cys. Optically active DMT is racemized by acetone in acetic acid and hydrolyzed by adding water to reaction mixture to give (*RS*)-Cys in 97% yield.[13] The asymmetric transformation was tried for a mixture of 0.0400 mol of (*RS*)-Cys, 0.0400 mol of (*R*)-TA, and 0.200 mol of acetone in 15 cm³ of acetic acid under reflux (approximately at 83 °C), as shown in Table 2.

The salt of (*S*)-DMT with equimolar (*R*)-TA ((*S*)-DMT·(*R*)-TA salt) was crystallized as the less soluble diastereomeric salt and obtained in 61—75% yield with approximately 100% optical purity. Although the maximum yield was lower than that (83%) of the salt of THC obtained by procedure I, optically pure (*S*)-Cys was obtained in higher yield (71%) by hydrolysis in water. Therefore, DMT is a more favorable inter-

mediate than THC to obtain optically active Cys by the asymmetric transformation.

Racemization by Using Aldehydes as Catalyst. The (*S*)-DMT·(*R*)-TA salt seems to be insoluble in acetone and to be more soluble in acetic acid than the (*S*)-THC·(*R*)-TA and (*R*)-THC·(*S*)-TA salts. Therefore, a relative decrease in amount of acetic acid (or an increase of acetone) may result in an increase in yield of the (*S*)-DMT·(*R*)-TA salt or its enantiomeric salt. However, such a system is refluxed at lower temperature and hence the epimerization rate for the soluble salt is reduced.[12,13] As seen in Tables 1 and 2, procedure I gives the (*S*)-THC·(*R*)-TA or (*R*)-THC·(*S*)-TA salt with high optical purity in 80% yield by reaction for 1 h, whereas procedure II requires long reaction time (over 5 h) to give the (*S*)-DMT·(*R*)-TA salt in over 70% yield. Therefore, aldehydes seem to be more favorable catalysts for epimerization than ketones.

The racemization rate of (*R*)-DMT was measured at 80 °C in the presence of 0.1 molar equivalent of acetaldehyde, benzaldehyde, 2-chlorobenzaldehyde, or salicylaldehyde as the catalyst. Since an addition of a small amount of water to this system resulted in hydrolysis of the formed DMT,[13] 37% FA was not employed as the catalyst. The racemizations using acetaldehyde, salicylaldehyde, or no aldehydes are illustrated in Fig. 2.

Figure 2 shows that linear relationships exist between ln α_0/α_t and time (t/h); the correlation coefficients are over 0.99. Therefore, these racemizations can be regarded as first-order reactions. The rate constant (k_R/h^{-1}) and half-life period ($t_{1/2}$/h) were calculated by Eq. 1 and given in Table 3.

Although the addition of aldehydes tended to accelerate the racemization of (*R*)-DMT, any aldehydes other than salicylaldehyde showed no extremely pronounced catalysis. The k_R value in the case using

7	(*R*)	(*S*·*R*)	10.38[83.4]	+81.8	100	(*S*)	3.88[80.1]	100

a) (*RS*)-Cysteine ((*RS*)-Cys) 0.0400 mol; (2*R*,3*R*)- or (2*S*,3*S*)-tartaric acid 0.0400 mol; salicylaldehyde 0.0040 mol; acetone 0.200 mol; acetic acid 10 cm^3; temperature 77 °C. b) (*S*·*R*) represented the salt composed of equimolar amounts of (*S*)-DMT and (*R*)-TA and (*R*·*S*) the salt of (*R*)-DMT and (*S*)-TA. c) The yield was calculated on the basis of 0.040 mol (12.45 g) of the DMT·TA salt. d) $[\alpha]_D^{20}$ (*c* 0.500, methanol). e) The optical purity was determined on the basis of the specific rotation of the (*R*)-DMT·(*S*)-TA salt ($[\alpha]_D^{20}$ −81.8° (*c* 0.500, methanol)) and that of equimolar mixture of (*RS*)-DMT and (*S*)-TA ($[\alpha]_D^{20}$ −2.9° (*c* 0.500, methanol)). f) The yield was calculated on the basis of 0.0400 mol (4.85 g) of Cys. g) The optical purity was determined on the basis of the specific rotation of (*R*)-Cys ($[\alpha]_D^{20}$ +6.5° (*c* 4.00, 5 mol dm^{-3} HCl)).

salicylaldehyde is 2.2 times that in the absence of aldehyde.

Asymmetric Transformation by Procedure III. Based on the above suggestion, the asymmetric transformation of (*RS*)-Cys was achieved in the presence of 0.1 molar equivalent of salicylaldehyde as the catalyst under reflux (approximately at 77 °C), as shown in Table 4. The ^{1}H NMR spectra of the obtained salts showed methyl protons and no aromatic protons.

The (*S*)-DMT·(*R*)-TA salt with 96.6% optical purity was obtained in 75% yield even by reaction for 2 h. This salt gave (*S*)-Cys with 93.8% optical purity in 72% yield. This yield corresponds to that to be obtained at 6 h by procedure II. Therefore, the epimerization was accelerated by adding salicylaldehyde.

The (*S*)-DMT·(*R*)-TA and (*R*)-DMT·(*S*)-TA salts with 98—100% optical purity were obtained in over 80% yield by reaction for 4—7 h. These salts were hydrolyzed in water to give (*R*)- or (*S*)-Cys, respectively, with 98—100% optical purity in 80% yield based on the initial (*RS*)-Cys. Further, (*R*)- and (*S*)-TAs, respectively, were recovered easily from these salts in over 80% recovery.

Studies on Ferrocene Derivatives. V.[1] Oxidation Reaction of (*o*-Substituted phenyl)ferrocenes

Yutaka Okada,* Noriyuki Yamamoto, and Takatoshi Hayashi
Department of Chemistry, Faculty of Science and Engineering,
Ritsumeikan University, Kita-ku, Kyoto 603
(Received June 30, 1988)

The oxidation reactivity of (*o*-substituted phenyl)ferrocenes with air was measured in acidic solution. The reactivity of *o*-acetyl, *o*-methoxycarbonyl, and *o*-methoxy derivatives was higher than that of the corresponding *p*-isomers. On the other hand, for *o*-hydroxy and *o*-methyl derivatives, the reactivity was lower than that of *p*-isomers. It was considered that the reactivity of *o*-isomers is influenced by the coordination ability of proton to iron atom. The coordination ability is governed by both the I-effect and steric effect of substituent.

Ferrocene (Fc) is very stable in air, and the oxidation from Fe(II) to Fe(III) is difficult. However, in an acidic solution, Fc is readily oxidized to ferrocenium ion[2] with air.

Investigations on oxidation reaction of substituted ferrocenes with air (or oxygen gas) in acidic solution have been done by several workers.[3,4] It has been reported that the rate of the reaction is influenced by electron-donating ability of a substituent.[3] The reaction mechanism was considered as follows:[4] ferrocenonium ion[2] is formed by coordination of a proton to iron atom of Fc, and is converted continuously to ferrocenium ion with loss of hydrogen atom by attack of oxygen (Eq. 1). That is to say,

$$Fc \xrightarrow{H^+} [Fc\text{-}H]^+ \xrightarrow{O_2} Fc^+, \quad (1)$$

where the active species on the oxidation reaction is ferrocenonium ion (protonated ferrocene). Therefore, it was considered that the rate of the reaction depends on the values of pK_a of catalytic acid.[5] Ferrocenonium ion was observed in $BF_3 \cdot H_2O$ by means of ^1H NMR.[6] However, in trifluoroacetic acid, the species was not found,[6] and the concentration of ferrocenonium ion was quite low.[4] On the other hand, the second step reaction was reported as follows:[4] In ferrocenonium ion, Cp groups are tilted by formation of Fe–H bond, and the metal orbitals are exposed to attack by O_2.[7] The oxidation reaction proceeded via insertion of O_2 into the Fe–H bond, followed by loss of $\dot{H}O_2$ radical.[4]

In our previous papers,[8,9] conformational studies on (*o*-substituted phenyl)ferrocenes were carried out by ^1H and ^{13}C NMR. It was clarified that the degree and orientation of the twist of the bond between phenyl (Ph) group and cyclopentadienyl (Cp) group vary with the kind of ortho substituent. In the present work, the oxidation reaction of (*o*-substituted phenyl)ferrocenes with air in acidic solution has been studied. The results were compared with those of the corresponding *p*-isomers. For acetyl, methoxycarbonyl, and methoxy derivatives, the oxidation reactivity of *o*-isomers was higher than that of corresponding *p*-isomers. On the other hand, for hydroxy and methyl derivatives, the reactivity of *o*-isomers was lower than that of *p*-isomers. Namely, no linear relationship was recognized between the oxidation reactivity and electron-donating ability of ortho substituent. Hence, the relation between the reactivity and the conformation is discussed.

Experimental

Preparation of Materials. The preparation and physical properties of (substituted phenyl)ferrocenes were reported in a preceding paper.[8]

Measurements of Oxidation Reactivity. Small three-necked flask fitted with reflux condenser, thermometer, and dropping funnel were employed for oxidation reaction. Air was introduced from the top of the condenser (Fig. 1). (Substituted phenyl)ferrocene (0.3 mmol) and 1,2-dichloroethane (50 ml) were added in the flask. Trichloroacetic acid (57 mmol) was dissolved in 10 ml of 1,2-dichloroethane. This solution was added through the dropping funnel. When all the materials were added, the reaction measurement was started. Reaction temperature was 40.0±0.1 °C, and air was introduced at a rate of 25±1 ml min^{-1}. The reaction mixture was stirred at 500 rpm by a magnetic stirrer with 25 mm length stirring bar. Sampling of reaction mixture was carried out at a regular interval. The sample was added

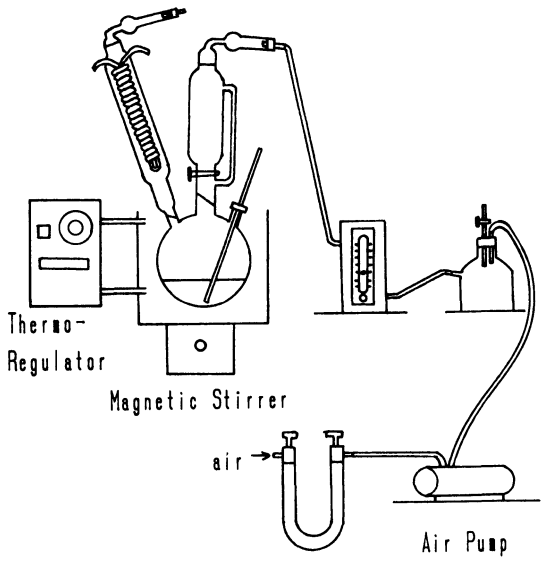

Fig. 1. Apparatus for oxidation reaction.

to water and vigorously stirred to stop the reaction. Then, the oxidation product (ferrocenium ion) was extracted in water; unreacted material and internal standard (nitrobenzene or 1,3,5-trichlorobenzene) remained in 1,2-dichloroethane layer. The amount of unreacted material in the presence of internal standard was determined by HPLC method. As mentioned above, the concentration of ferrocenonium ion in this solution was quite low.[4] Hence, it was considered that only ferrocenium ion was extracted in water. The conversion of the reaction is expressed by Eq. 2.

$$\text{Conversion} = ([Fc]_0 - [Fc])/[Fc]_0, \quad (2)$$

where [Fc] is the concentration of (substituted phenyl)ferrocene, and $[Fc]_0$ is the starting concentration. The rate constants were calculated as the pseudo-first order reaction about ferrocene derivatives; because the concentration of trichloroacetic acid was much higher than that of (substituted phenyl)ferrocene.

NMR Spectra. The method of NMR measurement was described in the preceding paper.[8]

IR Spectra. A JASCO IR-G type spectrometer was used. The measurements were done by the paste method (disperse medium: paraffin liquid).

Results and Discussion

Oxidation Reaction of (*p*-Substituted phenyl)ferrocenes. The conversions of the oxidation of (*p*-substituted phenyl)ferrocenes are shown in Fig. 2. The rate constants are presented in Table 1. The order of the reactivity was found as follows:

$$OH \fallingdotseq OCH_3 \fallingdotseq CH_3 > H > Cl > COCH_3 \fallingdotseq COOCH_3.$$

The order coincides approximately with that of electron-donating ability of para substituents. The relation between the Hammett constants[10] and the rate constants is shown in Fig. 3; a linear relationship was recognized. The reason was considered as follows. The electron density of the iron atom in the ferrocenes increased with an increase in electron-donating ability of para substituent. The coordination of catalytic proton to iron atom seems to be accelerated by higher electron density of iron atom. This order agrees with that of the polarographical oxidation potential value[11] of iron atom in ferrocene derivatives.

Oxidation Reaction of (*o*-Substituted phenyl)ferrocenes. The conversions of the oxidation of (*o*-substituted phenyl)ferrocenes are shown in Fig. 4. The rate constants are presented in Table 1. The order of the reactivity was found as follows:

$$OCH_3 > CH_3 \fallingdotseq COCH_3 > OH \fallingdotseq Cl \fallingdotseq COOCH_3.$$

The relation between the Hammett constants[10] and the rate constants is shown in Fig. 5. However, no linear relationship was recognized contrary to the case of the *p*-isomers.

The differences (Δk) of the rate constants between (*o*-substituted phenyl)ferrocenes and the correspond-

ing *p*-isomers are presented in the right column of Table 1. (Substituted phenyl)ferrocenes can be classified into three groups by the values of Δk. The first group (acetyl, methoxycarbonyl, and methoxy derivatives) has positive values of Δk, and the second group (methyl and hydroxy derivatives) has negative values. In the third group (chloro derivative), the value is very small. The reason will be discussed later.

[Acetyl-, (Methoxycarbonyl)-, and Methoxyphenyl]-ferrocene: In [acetyl-, (methoxycarbonyl)-, and methoxyphenyl]ferrocene, the values of Δk were positive (Table 1). That is to say, the oxidation reactivity of the *o*-isomer was higher than that of the corresponding *p*-isomer (Fig. 6). In particular, the reactivity of (*o*-methoxyphenyl)ferrocene was highest in all the derivatives measured in this study. The reason will be discussed below.

As mentioned in the preceding paper,[8] the bond between Ph group and Cp group of (*o*-substituted phenyl)ferrocene is twisted. The twist is mainly produced by a steric repulsion between ortho substituent and α-proton of Cp group. It was considered that the degree of the twist in acetyl and methoxy-

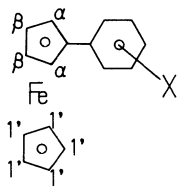
a) $\Delta\delta=\delta'-\delta$, where δ' is proton chemical shift value measured in the presence of equimolar trichloroacetic acid and δ is the value at normal conditions.



carbonyl derivative is almost equal.[8] On the other hand, the reactivity of acetyl derivative in *o*-isomer is higher than that of methoxycarbonyl derivative (Fig. 6). Therefore, it appears that the difference in this reactivity is not influenced by the I-effect which reflects on the twist of the bond between Ph group and Cp group, but depends on a different reason.

Proton chemical shift values of [acetyl- and (methoxycarbonyl)phenyl]ferrocene are shown in Table 2; the value of $\Delta\delta$ is defined as the difference between δ' and δ: δ' is the chemical shift value measured in the presence of equimolar trichloroacetic acid, and δ is the value at normal conditions. The value of $\Delta\delta$ was positive in all the protons of these derivatives. The values of $\Delta\delta$ of methyl groups in all the derivatives were larger than those of Cp groups. In Table 3, IR spectral data of (substituted phenyl)ferrocene are given. The values ν' measured in the presence of

Table 3. The Values of $\Delta\nu$ of [Acetyl- and (Methoxycarbonyl)phenyl]ferrocenes

	$\nu^{a)}/cm^{-1}$	$\nu'^{a)}/cm^{-1}$	$\Delta\nu^{b)}/cm^{-1}$
p-$COCH_3$	1666	1624	42

p-$COOCH_3$	1701	1686	15
o-$COOCH_3$	1710	1689	21

a) ν' is carbonyl streching frequency in the presence of trichloroacetic acid (ferrocene derivative: trichloroacetic acid=1 : 10) and ν is the value at normal conditions. b) $\Delta\nu=\nu-\nu'$.

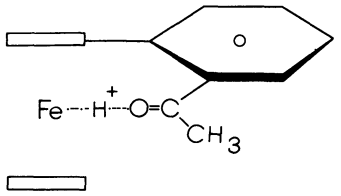

Fig. 7. Oxidation reaction of (*o*-acetylphenyl)ferrocene.

trichloroacetic acid were lower than the values ν measured at normal conditions. From these data, it was considered that coordination of proton occurs not only to iron atom but also to carbonyl oxygen. Hence, higher reactivity values of *o*-isomers are interpreted as follows: (i) Coordination of proton occurs to carbonyl oxygen at first. (ii) The proton was transferred to iron atom by formation of a chelate-like ring (Fig. 7). However, in *p*-isomer, the chelate-like ring is impossible to form.

If the oxidation reactions of [*o*-acetyl- and *o*-(methoxycarbonyl)phenyl]ferrocene are promoted by the chelating effect as shown in Fig. 7, the reactivity will be influenced by proton-coordinating ability or basicity of carbonyl oxygen. The basicity was examined by means of ^1H NMR.[12] The results indicate that basicity of acetyl group is higher than that of methoxycarbonyl group. Higher basicity of acetyl group was also shown by the IR spectral data in Table 3. (The values of $\Delta\nu$ of acetyl derivatives were larger than those of methoxycarbonyl derivatives.) Therefore, it was expected that the oxidation reactivity of (*o*-acetylphenyl)ferrocene is higher than that of methoxycarbonyl derivative. The experimental results agreed with this assumption. Namely, the difference in the reactivity between [*o*-acetyl- and *o*-(methoxycarbonyl)-phenyl]ferrocene can be explained by the chelating effect as shown in Fig. 7.

The unusually high reactivity of (*o*-methoxyphenyl)-ferrocene was considered by analogy. The values of $\Delta\delta$ of methyl groups in methoxy derivatives were positive (Table 2), whereas those in methyl derivatives were zero. Therefore, the oxidation reaction of this methoxy derivative seems to be promoted by the chelating effect as shown in Fig. 8. That is to say,

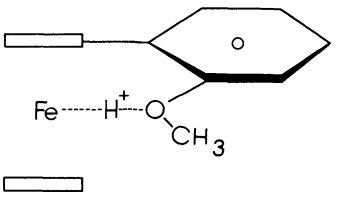

Fig. 8. Oxidation reaction of (*o*-methoxyphenyl)ferrocene.

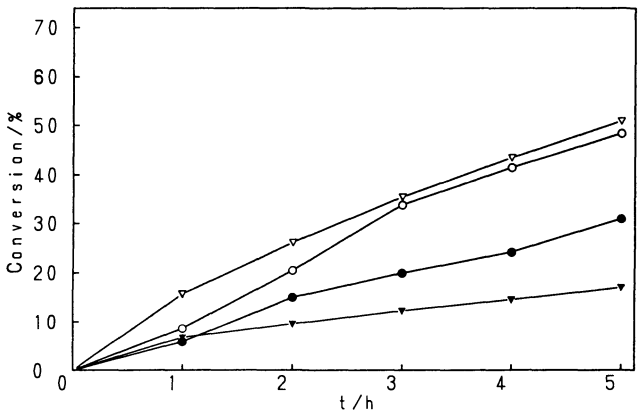

Fig. 9. Conversion of (hydroxy- and methylphenyl)-ferrocenes.
▽: *p*-OH-, ▼: *o*-OH-, ○: *p*-CH_3-, ●: *o*-CH_3-.

coordination of catalytic proton occurs at ethereal oxygen at first, and the proton transfer to iron atom follows by forming a chelate-like ring. Both the chelating effect of oxygen and the large I-effect of methoxyl group are presumed to raise the oxidation reactivity of (*o*-methoxyphenyl)ferrocene.

(Hydroxy- and Methylphenyl)ferrocene: In (hydroxy- and methylphenyl)ferrocene, the values of Δk were negative (Table 1), showing that the oxidation reactivity of the *o*-isomer is lower than that of the corresponding *p*-isomer (Fig. 9). The reason will be discussed below.

Displacing methyl group of (methoxyphenyl)ferrocene by hydrogen atom gives (hydroxyphenyl)ferrocene. The reactivity of two *o*-isomers, however, was strikingly different. Particular reactivity of methoxy derivative was mentioned above. The oxidation reactivity of (*o*-hydroxyphenyl)ferrocene was lowest in all the *o*-isomers examined in this study. The reason was considered in view of conformation of (*o*-hydroxyphenyl)ferrocene as follows. In this derivative, the degree of twist of the bond between Ph group and Cp group is distinctly large in spite of small size of hydroxyl group.[8] Furthermore, the endo conformation as in hydroxyl group is preferred than exo one. The driving force was suggested[8] to be an OH-d type hydrogen bond between hydroxyl group and d-electron of iron atom (Fig. 10). Therefore, it was considered that the electron density of iron atom in

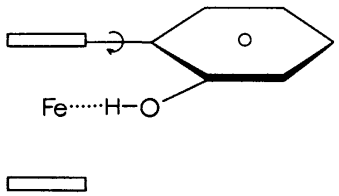

Fig. 10. Conformation of (*o*-hydroxyphenyl)ferrocene.

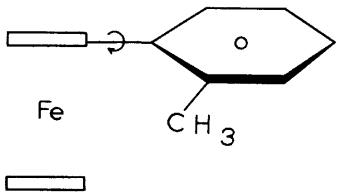

Fig. 11. Conformation of (*o*-methylphenyl)ferrocene.

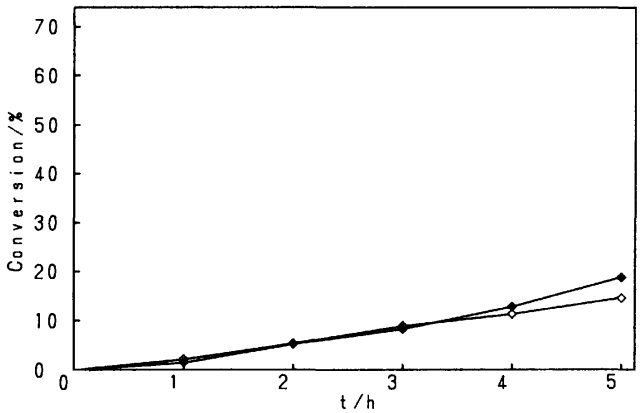

Fig. 12. Conversion of (chlorophenyl)ferrocene.
◇: *p*-Cl-, ◆: *o*-Cl-.

(*o*-hydroxyphenyl)ferrocene decreased strikingly by this hydrogen bond. Consequently, the oxidation reactivity of (*o*-hydroxyphenyl)ferrocene was remarkably low.

In (*o*-methylphenyl)ferrocene as well as hydroxy derivative, the endo conformation as in methyl group is preferred (Fig. 11).[8] The driving force to prefer the endo conformation is considered to be a CH-d type attractive interaction between methyl proton and d-electron of iron atom.[8] It is expected that the electron density of iron atom in (*o*-methylphenyl)ferrocene decreased slightly by this interaction. The CH-d type interaction will be weaker than the OH-d type hydrogen bond. Hence it seems that the electron density of iron atom in (*o*-methylphenyl)ferrocene is higher than that in (*o*-hydroxyphenyl)ferrocene. Consequently, the oxidation reactivity of methyl derivative was higher than that of hydroxy derivative.

(Chlorophenyl)ferrocene: In (chlorophenyl)ferrocene, the value of Δk was very small (Table 1),

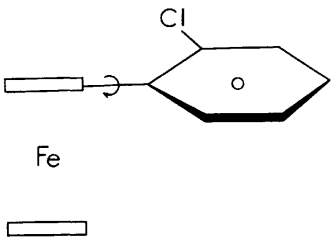

Fig. 13. Conformation of (*o*-chlorophenyl)ferrocene.

suggesting that no considerable difference exists in the reactivity between the *o*- and *p*-isomer (Fig. 12).

As mentioned in the previous paper,[8] the conformation of (*o*-chlorophenyl)ferrocene is considered as follows. The degree of twist of the bond between Ph group and Cp group is almost equal to that of (*o*-methylphenyl)ferrocene. However, in chloro derivative, the exo conformation (chlorine atom exists in exo position) is preferred (Fig. 13). The driving force to keep the exo conformation is considered to be an electronic repulsion between chlorine atom and d-electron of iron atom.[8] Therefore, it seems that the electron density of iron atom in chloro derivative does not decrease contrary to the case of methyl derivative. Consequently, the oxidation reactivity of (*o*-chlorophenyl)ferrocene was almost equal to that of *p*-isomer.

Conclusion

The reactivity of (substituted phenyl)ferrocene is influenced by the coordination ability of proton to iron atom. The coordination ability is governed by both the I-effect and the steric effect of the substituent.

Preparation of New Nitrogen-Bridged Heterocycles. 19.[1] Smooth Syntheses of Thieno[3,2-*a*]- and Thieno[2,3-*b*]indolizine Derivatives

Akikazu KAKEHI,* Suketaka ITO, Tuneo FUJII, Yuichiro MORIMOTO, Shin-ichi MATSUMOTO, and Morio SHIOHARA

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received June 30, 1988)

The reactions of 2-(ethoxycarbonylmethylthio)indolizines having an acyl and/or a cyano group at the 1- and 3-positions under several alkaline conditions were examined, and title compounds, thieno[3,2-*a*]- and thieno[2,3-*b*]indolizine derivatives were obtained in fairly good yields. The cyclization modes observed in these transformation reactions were in accord with those expected by the molecular orbital calculations using some model compounds and by the stereochemical consideration of starting indolizines. The alkylations of 3-hydroxythieno[3,2-*a*]- and 3-hydroxythieno[2,3-*b*]indolizines were also investigated and the corresponding *O*- and *C*-alkylated heterocycles were formed in good yields.

In our previous communication[2] we have reported the smooth intramolecular cyclizations of the indolizines possessing an ethoxycarbonylmethylthio group at the 2-position and a cyano or an ethoxycarbonyl group at 1- or 3-position to ethyl 3-aminothieno[3,2-*a*]indolizine-2-carboxylates or ethyl 3-hydroxythieno-[2,3-*b*]indolizine-2-carboxylates under alkaline conditions. The regiospecificity of the reactions and the high synthetic value for the preparations of new heterocyclic skeletons prompted us to investigate further these intramolecular cyclizations using various 2-(ethoxycarbonylmethylthio)indolizines from the theoretical and practical standpoints of view. In this paper we wish to describe the formation of some thieno[3,2-*a*]- and thieno[2,3-*b*]indolizine derivatives from the alkaline treatment of polyfunctionalized indolizines and the comparison of the cyclization modes observed in these reactions with those expected by the molecular orbital calculations using model compounds.

Results and Discussion

Preparations of 2-(Ethoxycarbonylmethylthio)indolizines. These 2-(ethoxycarbonylmethylthio)indolizine derivatives **4a—t** were prepared in moderate to good yields by the treatment of the pyridinium salts **3a—t**, readily obtainable from the *S*-alkylations of the corresponding pyridinium-*N*-methylides **1a—j** with bromoacetonitrile **2a** or ethyl bromoacetate **2b**, with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) at 0 °C followed by the addition of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) as a dehydrogenating agent to the resulting reaction solutions. In the reactions of pyridinium salts **3e—j**, **o—t** possessing an acetyl or a benzoyl group, the formations of tricyclic thieno[2,3-*b*]-indolizines **5**[3] were also formed, but their yields were very low (<3%) (Scheme 1).

The structures of indolizines **4a—t** were determined

a) These coupling constants are as follows: $J_{5,6}=J_{6,7}=7.0$, $J_{7,8}=9.0$, $J_{6,8}=2.0$, and $J_{Et}=7.0$ Hz. b) Overlapped with the phenyl proton signals. c) The signals due to these two ethoxycarbonyl groups could not be assigned.

by the analyses of their physical and spectral data and by the comparisons of their ^{1}H NMR (Table 1) and IR spectra (Table 4) with those of other indolizine derivatives prepared earlier by us[1,4] and other investigators.[5] For example, the elemental analyses of indolizines **4a—t** were in good accord with the proposed compositions and their ^{1}H NMR spectra showed distinct proton signals at near δ 1.15 (t, 3H, J=7.0 Hz, $OCH_2\underline{CH_3}$), 3.61—4.01 (s, 2H, SCH_2), and near 4.10 (q, 2H, J=7.0 Hz, $O\underline{CH_2}CH_3$) due to the 2-ethoxycarbonylmethylthio group, together with other proton signals on the indolizine ring. The presence of a saturated ester carbonyl group in the 2-substituent could be also confirmed by the absorption bands appeared at 1720—1740 cm^{-1} in their IR spectra. Interestingly, the up-field shift (10—30 cm^{-1}) of the absorption band of the carbonyl group at the 1-position in indolizines **4n**, **r** or at the 3-position in indolizines **4b**, **f**, **l**, **p** was observed. These shifts must be caused by the steric crowding of the carbonyl group with the 2-ethoxycarbonylmethylthio and the 5- or 8-methyl groups.

Preparations of Thieno[3,2-*a*]- and Thieno[2,3-*b*]-indolizines. Since these indolizines **4a—t** have an active methylene group in the 2-substituent and an acyl and/or a cyano group at the 1- or 3-position, the intramolecular reactions between these group should lead to the indolizine derivatives fused with a thiophene ring. Thus, the reactions of indolizines **4a—t** were examined under alkaline conditions in which the carbanion formation from the active methylene group could be expected.

Scheme 2.

The treatment of indolizines **4a**—g, **i**, **j** having the 1-cyano group with DBU in refluxing ethanol gave smoothly ethyl 3-aminothieno[3,2-*a*]indolizine-2-carboxylates **6a**—g, **i**, **j**, in 50—94% yields, respectively, while the similar reaction of indolizine **4h** afforded also ethyl 9-cyano-3,6,8-trimethylthieno[2,3-*b*]indolizine-2-carboxylate **7a** in ca. 65% yield, together with the expected ethyl 9-acetyl-3-amino-4,6-dimethylthieno[3,2-*a*]indolizine-2-carboxylate **6h** (ca. 18%). Apparently, the formation of amino compounds **6a**—**j** results from the nucleophilic addition of the carbanion generated in situ to the 1-cyano group of indolizines **4a**—**j**, and that of product **7a** from the nucleophilic attack of the same species to the 3-acetyl group (Scheme 2).

On the other hand, the reactions of diethyl 1,3-indolizinedicarboxylates **4k**—n with DBU did not afford any significant products, but their reactions

a) The coupling constants are as follows: $J_{5,6}=J_{6,7}=7.0$, $J_{7,8}=9.0$, $J_{6,8}=2.0$, $J_{Et}=7.0$ Hz. b) The proton signal due to the hydroxyl, methyl, methoxyl, or ethoxyl group. c) The signals due to these ethoxycarbonyl groups could not be assigned. d) Overlapped with the phenyl proton signals. e) The methyl signal on the C-2 position.

under the conditions for the Dieckmann reaction[6] gave the corresponding adducts: The treatment of indolizines **4k—m** with potassium *t*-butoxide in *N,N*-dimethylformamide (DMF) at room temperature followed by quenching the resulting mixture with diluted hydrochloric acid formed diethyl 3-hydroxythieno[2,3-*b*]indolizine-2,9-dicarboxylates **8a—c** in very good yields. Interestingly, similar reaction of compound **4n** did not give any compound of type **8**, but afforded only diethyl 3-hydroxy-4,6-dimethylthieno[3,2-*a*]indolizine-2,9-dicarboxylate **9a** in 89% yield. Analogously, the reactions of indolizines **4o—t** with potassium *t*-butoxide gave the corresponding cycloadducts **7b—d**, **7e+9b**, **7f**, and **7g**, respectively. Same products **7b**, **d**, **e**, were also obtained in 86, 74, and 59% yields by the reactions of indolizines **4o**, **q**, **r** with DBU. These results are shown in Scheme 3.

The structural assignments of thieno[3,2-*a*]indolizines **6a—j** and **9a**, **b** and thieno[2,3-*b*]indolizines **7a—g** and **8a—c** were accomplished mainly by their elemental and by ^{1}H NMR (Table 2 and 3) and IR (Table 5) spectral analyses. The structures of ethyl 3-aminothieno[3,2-*a*]indolizine-2-carboxylates **6a—j** could be easily decided by the appearances of two amino absorption bands (3300—3450 cm^{-1}) and the absence of the cyano band in their IR spectra and by the presence of amino proton signals (δ 5.95—6.37 (br s, 2H)) and the absence of the active methylene signals in their ^{1}H NMR spectra. Similarly, compounds **7a—g** were assigned to ethyl 3-methyl- or 3-phenylthieno[2,3-*b*]indolizine-2-carboxylates because the elimination of a water molecule from indolizines **4h**, **o—t** was confirmed by their elemental and by IR and ^{1}H NMR spectral analyses. On the other hand, the

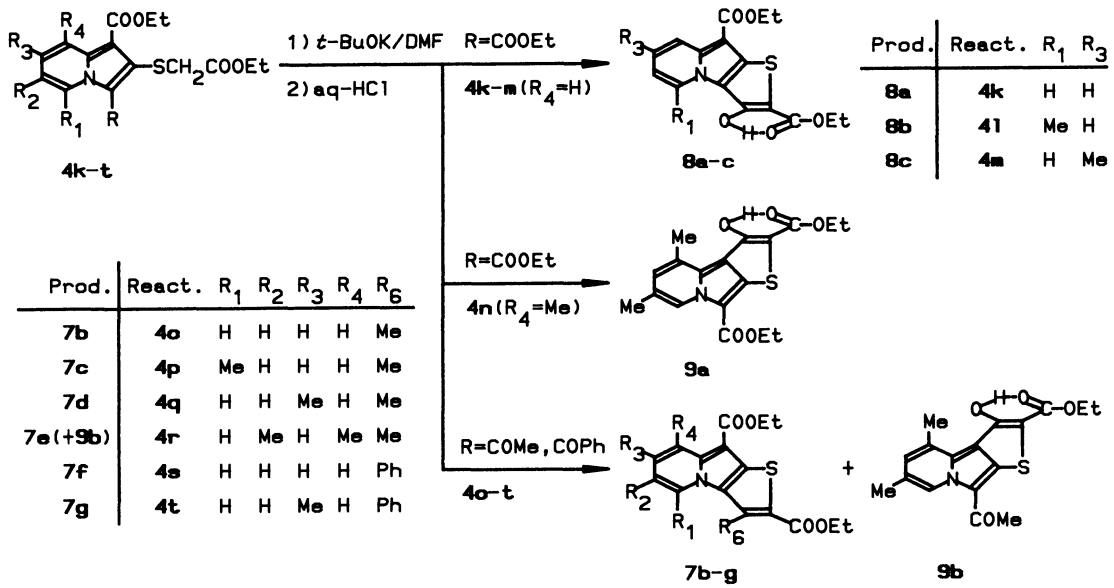
a) Starting materials. b) Satisfactory analytical data (within 0.3% for C, H, and N) were obtained for all new compounds.



Scheme 3.

structures of products **8a**—**c** and **9a**, **b** could be determined by considering in detail the presence or absence of the anisotropic effect of the carbonyl group participating with the cyclizations: In the ^{1}H NMR spectra of compounds **8a**—**c**, for example, the chemical shifts (δ 7.97—8.27) due to the 8-proton were very similar to those (δ 8.12—8.38) of the starting indolizines **4k**—**m**, but the values (δ 8.59 and 8.39) for the 5-proton of cycloadducts **8a**, **c** were largely different from those (δ 9.52 and 9.37) of indolizine derivatives **4k** and **4m**. On the contrary, the chemical shifts (δ 9.27 and 9.89) owing to the 7-proton of compounds **9a**, **b** were almost same value (δ 9.27 and 9.75) with the 5-proton of indolizine **4n**, **r**. These facts mean that the 3-ester group was attacked in the formers (**4k**—**m**) and the 1-ester group in the latters (**4n**, **r**). That is to say, the cyclization modes can be decided clearly by the largely diminished anisotropic effect (δ ca. 1 ppm) for the protons at the position peri to the carbonyl group disappeared during the reactions. Furthermore, the presence of an enolic hydroxyl proton signal at δ 8.70—11.44 (1H, br s) shows definitely that these compounds **8a**—**c** and **9a**, **b** have an aromatic thiophene ring.

Table 5. Some Data of Thieno[3,2-*a*]- and Thieno[2,3-*b*]indolizines

14a	**4n**, **10c**	C	87	152—153	1725	1700	1669		$C_{19}H_{21}NO_5S$

a) Satisfactory analytical data (within 0.3% for C, H, and N) were obtained for all new compounds except **6h**. b) Other physical and analytical data of compound **6h** (ca. 18%) could not be measured because of the inaccessibility of its pure sample. c) Cyano absorption band. d) Distinct hydroxyl absorption band did not appear in the range of 4000—3000 cm^{-1}.

Preparations of *O*- and *C*-Alkylated Thienoindolizines. Since facile and effective syntheses of 3-hydroxythieno[2,3-*b*]indolizines **8a—c** and 3-hydroxythieno[3,2-*a*]indolizine **9a** could be established, the preparations of some derivatives using them were examined. The treatment of indolizines **4k—n** with potassium *t*-butoxide in DMF at room temperature followed by the addition of dimethyl **10a** and diethyl sulfate **10b** yielded the corresponding *O*-methylated **11a—c** and **13a** and *O*-ethylated thienoindolizines **11d—f** and **13b** in 74—88% yields. On the other hand, the reactions of indolizines **4k—n** using methyl iodide **10c** as an alkylating agent gave compounds **11a**+**12a**, **12b**, **11c**+**12c**, and **14a** in good yields, and the *C*-methylated thienoindolizines **12a—c** and **14a** were major or exclusive (Scheme 4).

The structures of methoxy- and ethoxythienoindolizines **11a—f** and **13a, b** were determined by the presence of the methoxyl (δ 4.11—4.31 (3H, s)) or ethoxyl proton signals (δ near 1.40 (3H, t, J=7.0 Hz) and near 4.45 (2H, q, J=7.0 Hz)) in addition to other proton signals which were very similar to those of hydroxythienoindolizines **8a—c** and **9a, b** in their ^{1}H NMR spectra. On the other hand, compounds **12a—c** and **14a** were assigned by the indications of a methyl group (δ near 1.90 (3H, s)) and of an ethoxycarbonyl group (δ near 1.25 (3H, t, J=7.0 Hz) and near 4.25 (2H, q, J=7.0 Hz)) attached to the tetrahedral carbon and by the considerably increased down-field shift of the 5-proton signal (δ 8.93 (**12a**) and 8.81 (**12c**)) in their ^{1}H NMR spectra.

Reaction Mechanisms and Molecular Orbital (MO) Calculations. Possible mechanisms for these intramolecular cyclizations are shown in Scheme 5. As was expected, these thieno[3,2-*a*]- **6a—j** and **9a, b** and thieno[2,3-*b*]indolizine derivatives **7a—g** and **8a—c** must be formed via the nucleophilic attack of carbanion **15** generated in situ by the alkaline treatment of indolizines **4a—t** to the cyano or carbonyl group at the 1- or 3-position followed by the aromatizations through hydrogen shifts or with the elimination. The formations of *O*-alkylated **11a—f**

and **13a**, **b** and *C*-alkylated thienoindolizines **12a—c** and **14a** can be well-explained by the application of HSAB principle[7] to ambident anions **20** and **21**.

In order to obtain further information for the electrophilicity of the 1- and 3-substituents in the indolizine molecule, the MO calculations (PPP method)[8] of 1-cyano-3-indolizinecarboxylic acid **22a** and 1,3-indolizinedicarboxylic acid **22b** as models for

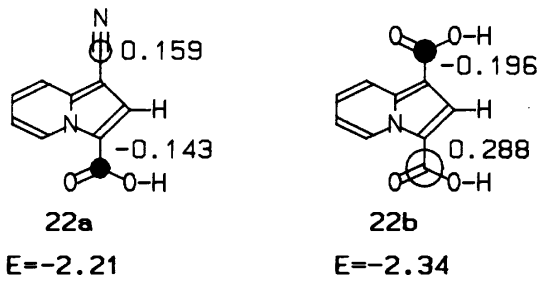

Fig. 1.

indolizines **4a**, **k** were carried out. The coefficients of the cyano and/or ester carbons at the 1- and 3-positions in the lowest unoccupied molecular orbitals (LUMO) of **22a**, **b** are shown in Fig. 1. Apparently, the order of the electrophilicity of the 1- and 3-substituent in these model compounds **22a**,**b** is 1-CN>3-COOH>1-COOH, and, except the cases of indolizines **4h**, n, **r**, parallel to that (1-CN>3-COMe or 3-COPh>3-COOEt>1-COOEt) observed. The formation of compound **7a** may be interpreted by considering the equilibrium (reversible) betweeen indolizine **4h** and 3-aminothieno[3,2-*a*]indolizine **6h** and an irreversible transformation of **4h** to **7a**. On the other hand, the nucleophilic attack leading to 3-hydroxythieno[3,2-*a*]indolizines **9a**, **b** can be explained in terms of the increased reactivity of the ester carbonyl carbon at the 1-position in indolizines **4n**, **r**, because the introduction of a 8-methyl group to the indolizine ring makes to shift the carbonyl absorption bands at the 1-position to considerably high (**4n**, 1716 cm^{-1}) and slightly high regions (**4r**, 1690 cm^{-1}).

Experimental

Melting points were measured with a Yanagimoto micromelting point apparatus and are uncorrected. The microanalyses were carried out on a Perkin-Elmer 240 elemental analyzer. The ^1H NMR spectra were determined with a Varian EM360A spectrometer in deuteriochloroform with tetramethylsilane as an internal standard and the chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 infrared spectrophotometer.

Materials. Pyridinium ylides **1a—j** were prepared according to the procedure appeared in the literature.[3,9] Some physical and spectral data of new compounds are as follows: **1a**, 78%, yellow needles (from $CHCl_3$-ether), mp 131—132 °C, IR ν (KBr) 1740 and 1645 cm^{-1} (CO). Anal. ($C_{14}H_{17}NO_4S_2$) C, H, N. **1b**, 91%, yellow needles (from $CHCl_3$-ether), mp 136—137 °C, IR ν (KBr) 1720 and 1652 cm^{-1} (CO). Anal. ($C_{15}H_{19}NO_4S_2$) C, H, N. **1c**, 84%, yellow needles ($CHCl_3$-ether), mp 148—150 °C, IR ν (KBr) 1737 and 1650 cm^{-1} (CO). Anal. ($C_{15}H_{19}NO_4S_2$) C, H, N. **1d**, 85%, yellow needles ($CHCl_3$-ether), mp 178—179 °C, IR ν (KBr) 1724 and 1645 cm^{-1} (CO). Anal. ($C_{16}H_{21}NO_4S_2$) C, H, N. **1f**, 52%, yellow needles ($CHCl_3$-ether), mp 98—100 °C, IR ν (KBr) 1720 and 1590 cm^{-1} (CO). Anal. ($C_{14}H_{17}NO_3S_2$) C, H, N. **1h**, 81%, yellow needles ($CHCl_3$-ether), mp 171—172 °C, IR ν (KBr) 1721 and 1595 cm^{-1} (CO). Anal. ($C_{15}H_{19}NO_3S_2$) C, H, N.

Preparations of Indolizines. General Method A: A chloroform solution (20 ml) of pyridinium ylide **1a—d** (2 mmol) and bromoacetonitrile or ethyl bromoacetate (**2**, 2.2 mmol) was kept on standing until the ylide was completely alkylated (ca. 1—6 d). The resulting mixture was concentrated under reduced pressure at 50—55 °C and the residue was washed three times with ether to remove excess alkylating agents. Pyridinium salt thus obtained was again dissolved in chloroform (30 ml). To the solution DBU (0.38 g, 2.5 mmol) was added dropwise in an ice bath, and after stirring for additional 10 min, DDQ (0.45 g, 2 mmol) was added. The mixture was allowed to react for further 6—12 h in an ice bath and then concentrated under reduced pressure. The residue was separated by column chromatography (alumina) using chloroform as an eluent, and recrystallization from ethanol afforded the corresponding ethyl 2-(ethoxycarbonylmethylthio)indolizine-3-carboxylates **4a—d**, **k—n**.

Method B: A chloroform solution (30 ml) of ylide **1e—j** (2 mmol) and an alkylating agent (2.2 mmol) was kept on standing at room temperature until the ylide was completely disappeared. Without the removal of excess alkylating agent, the resulting solution was allowed to react with DBU (0.38 g, 2.5 mmol) and then with DDQ (0.45 g, 2 mmol) in an ice bath for 6—12 h. The similar work-ups of resulting mixtures gave other indolizine derivatives **4e—j**, **o—t**.

These results and some data are listed in Tables 1 and 4.

In the reactions of ylides **1e—j** ethyl 9-thiocyanato- and 9-(ethoxycarbonylthio)thieno[2,3-*b*]indolizine-2-carboxylates **5** were also obtained in below 3% yields but the preparations of pure samples could not be successful because of their low yields and of their thermal instability.

The application of Method A for the reactions of ylides **1e—j** having an acetyl or a benzoyl group gave complex mixtures and considerably diminished yields of the expected indolizines **4e—j**, **o—t** were observed. In these reactions indolizines and thieno[2,3-*b*]indolizines derived from pyridinium salts via the cis-trans-isomerization of the vinyl group were also detected.

Preparations of Thieno[3,2-*a*] and Thieno[2,3-*b*]indolizines. General Method A: An ethanolic solution (30 ml) of indolizine (1 mmol) was heated under the reflux temperature for 1—4 h. The solution was chilled overnight in a freezer and the precipitated substance was collected by filtration. Recrystallization from chloroform gave the corresponding thienoindolizines.

Method B: To a DMF solution (5 ml) of indolizine (1 mmol) potassium *t*-butoxide (0.14 g, 1.25 mmol) was added at room temperature and the mixture was kept on standing for an additional 1 h. After the acidification of the solution with diluted hydrochloric acid the precipitated substances were collected by filtration, washed with two portions (each 10 ml) of water, and dried in vacuum desiccator for 1 d. The separation of crude product by column chromatography (silica gel) using chloroform and recrystallization from ethanol provided the corresponding thienoindolizines.

These results and some physical and spectral data are summarized in Tables 2, 3, and 5.

Alkylations of Thienoindolizines. General Method: To a DMF solution (5 ml) of indolizine (1 mmol) potassium *t*-

butoxide (0.14 g, 1.25 mmol) was added at room temperature and the resulting mixture was kept on standing for an additional 1 h. An alkylating agent (2 mmol) was then added dropwise under stirring. After stirring for 1 h, the reaction solution was heated to 60—70 °C for further 10 min to complete the reaction. The work-ups gave the corresponding *O*-alkylated and/or *C*-alkylated thienoindolizine derivatives.

These results and some data are listed in Tables 2, 3, and 5.

(Received July 7, 1988)

Treatment of a wide variety of 2-(2-arylhydrazino)tropones with ethanolic acid at 50—80°C readily gave the benzidine type rearrangement products, 2-amino-5-(4-aminoaryl)tropones, besides minor amounts of by-products of various type. The main products were conveniently led to the corresponding 5-aryltropolones. Similarly, 2-(2-arylhydrazino)tropones bearing an isopropyl and isopropenyl group at the 4-position afforded 4-substituted 2-amino-5-(4-aminoaryl)tropones as the main products, which were also led to 4-substituted 5-(4-acetamidoaryl)- and 5-(4-methoxyaryl)tropolones. Structural assignments of these products were made on the basis of ^{1}H NMR and other spectral data as well as of chemical transformations to known 5-phenyltropolone and also to 2-acetamido-8-hydroxy-10,10-dimethylcyclohept[*a*]inden-7(10*H*)-one. This synthetic scheme may possibly be utilized for a convenient synthesis of B-ring-open analogues of colchicine.

Colchicine (**1a**), a tricyclic natural troponoid, has attracted considerable attention owing to its marked antimitotic activity.[3] The total synthesis of **1a** has been accomplished so far by more than ten groups.[4] However, as all of these synthetic schemes involve lengthy multisteps and appear to lack general applicability particularly in large scale experiments, exploitation of a general, convenient synthetic method for colchicine analogues has been desired for the study of their structure-activity relationship.[5]

As for antimitotic agents, preparation of two types of the B-ring-open colchicine analogues **2** and **3**, (which can be derived from **1a** by the formal bond-disconnection at [a] and [b], respectively, see Scheme 1), was planned by one of us (T. N.) in order to obtain various information on tublinbinding sites. We have already reported the synthesis of various compounds of type **2**.[6] In the meantime, a synthetic approach for another, potentially useful compounds of type **3**, which are presumed to have a conformation close to that of **1a**, has been made as will be described below.

Although the tropolone nucleus is highly susceptible to various electrophilic substitutions (e.g., nitration, bromination, etc.), it does not undergo the Friedel–Crafts type alkylation and acylation by the usual method.[7,8] The reaction of organolithium or magnesium reagents with tropolones is known to afford C-3 and C-7 substitution products.[9] Thus, as for the preparation of 5-aryltropolones, only a few synthetic methods have been reported so far (see Scheme 2). Namely, 1) the permanganate oxidation of phenyltropilidene (**4**, derived from biphenyl) to give 5-phenyltropolone (**5**) in an extremely low overall yield (0.09%),[10] 2) the two-step conversion (amination and then hydrolysis) of a mixture of 4- and 5-phenyltropones (**7**, derived from phenyltropylium ion

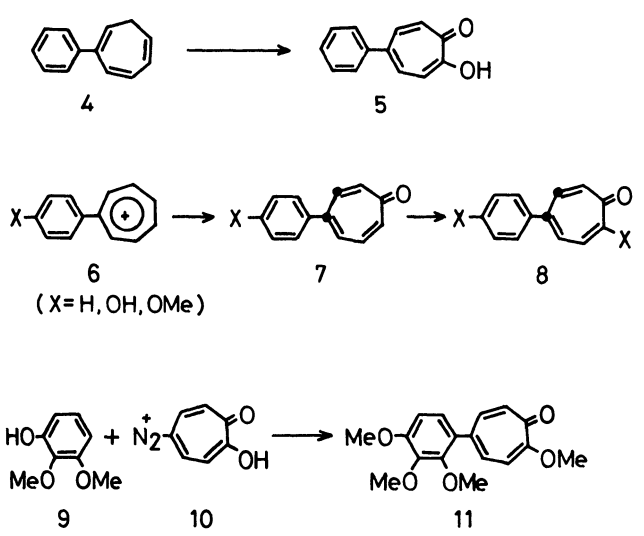

Scheme 2.

6)[11] to give, e.g., 2-methoxy-5-(4-methoxyphenyl)-tropone (**8**, X=OMe),[12] and 3) the thermolysis of 5-diazoniotropolone (**10**) either in benzene alone[7a] or in the presence of 2,3-dimethoxyphenol (**9**) to afford, after methylation, 2-methoxy-5-(2,3,4-trimethoxyphenyl)-tropone (**11**) (which exhibited an appreciable antimitotic activity).[3b,5a] However, all of these procedures have drawbacks either with respect to the low preparative yield or the regioselective control.[13] Thus, virtually no efficient, direct synthetic scheme has been established so far for preparation of 5-aryltropolones and much less tropolones having carbon substituents at both 4- and 5-positions.[13b]

Around 1973, Y. Sugimura[14] of Sankyo Co. (Tokyo) found that the treatment of some of 2-(2-phenylhydrazino)tropones **14** (see Scheme 3) with dilute hydrochloric acid readily afforded major products which he presumed to be derived through a benzidine-type

Scheme 3. Synthesis of 5-aryltropolones from 2-(2-arylhydrazino)tropones.

rearrangement. However, before establishing the precise structures of these products, the Sankyo research group had to interrupt this project for various reason and entrusted it to one of us (T. N.), who undertook further investigation in cooperation with the Tohoku Univ. research group. The structures of some of these acid-catalyzed products were then proved[2a] to be 2-amino-5-(4-aminophenyl)tropone (**15a**) and corresponding 5-(4-aminophenyl)tropones. Because of the Tohoku group's concentration on other research projects, the further study on this reaction was later carried out in cooperation with the Okayama and Kumamoto Univ. research groups.

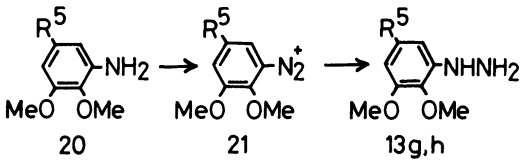
We now wish to describe in this paper our detailed but frequently interrupted studies on this novel benzidine type rearrangement of a wide variety of 2-(2-arylhydrazino)tropones (aryl stands for substituted phenyls or 1-naphthyl hereafter) with or without a carbon-substituent at the 4-position to give 4-substituted (or unsubstituted) 2-amino-5-(4-aminoaryl)-tropones, which can be readily led to various 5-aryltropolones. This method is expected to be applicable to a convenient synthesis of analogues of colchicine (**1a**), such as those of type **3**.

Results and Discussion

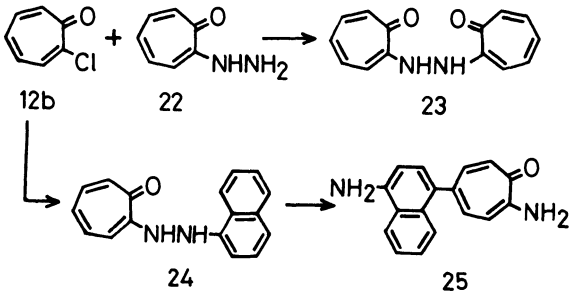
Preparation of 2-(2-Arylhydrazino)tropones. We have recently reported[1] a series of 2-(2-phenylhydrazino)tropones **14** available by the condensation of 2-tosyloxytropone (**12a**) with substituted phenylhydrazines **13** (Scheme 3). The preparations of some of the 2-(2-phenylhydrazino)tropones, **14a—d**, **14l**, and **14m**, have also been investigated presently by using another reactive troponoid, 2-chlorotropone (**12b**), but the yields were found to be somewhat less satisfactory for most of these products compared with the case[1] from **12a**. Thus, in order to closely examine the benzidine-type rearrangement of **14** we have prepared a variety of 2-(2-phenylhydrazino)tropones **14a—u** by the reaction of **12a** with **13a—m** (among which **13g** and **13h** were newly prepared from 2,3-dimethoxyanilines **20** via diazonium compounds **21**, see Scheme 4 and the Experimental section).

In addition, for a further examination of the scope of the rearrangement of 2-(2-arylhydrazino)tropone system other than phenyl ring in the moiety, we have also prepared 2,2′-hydrazobis(tropone) (**23**) and 2-[2-(1-naphthyl)hydrazino]tropone (**24**) by the reaction of **12b** with 2-hydrazinotropone (**22**) and 1-naphthylhydrazine, respectively (Scheme 5). Physical data for these new 2-hydrazinotropones are described in the Experimental section and are consistent with their structures.

The Benzidine Type Rearrangement of 2-(2-Arylhydrazino)tropones and Reactions of the Rearranged Products. It was then found that the rearrangement was best effected, in most cases, by



Scheme 4. Preparation of 2,3-dimethoxyphenylhydrazines. For R^5 of **13g**, **h**, see Scheme 3.



Scheme 5.

heating the arylhydrazinotropones **14a—u** at 50—80 °C in a ca. 1:10 mixture of 2 M hydrochloric acid (1 M=1 mol·dm^{-3}) and ethanol for 1—72 h under an inert atmosphere. The reactants were purified by recrystallization and/or silica-gel chromatography to yield 2-amino-5-(4-aminoaryl)tropones **15a—u** and other minor products **29—34** (see later), except for the case of the 2-(*p*-substituted phenylhydrazino)tropones **14d** and **14m**; the latter (**14m**) remained unchanged, while the former (**14d**) gave a mixture of several, air-sensitive products.[15] 2-[2-(1-Naphthyl)hydrazino]-tropone (**24**) similarly underwent the rearrangement to give 2-amino-5-(4-amino-1-naphthyl)tropone (**25**), whereas 2,2′-hydrazobis(tropone) (**23**) remained unchanged under the same acidic conditions (Scheme 5). The diamino compounds **15** stepwisely gave the monoacetyl and diacetyl derivatives as exemplified by treatment of **15a** with acetic anhydride in dichloromethane and in pyridine to give **15a′** and **15a″**, respectively (see Scheme 6).

Alkaline hydrolysis of **15** in ethanolic 2 M KOH under reflux for 10 h afforded 5-(4-aminophenyl)tropolones **16** (Scheme 3). As the 4-substituted 2-amino-5-(4-aminophenyl)tropones **15n—u** and tropolones **16n—u** were in general too air-sensitive to be isolated as pure compounds, they were immediately led to the *N,O*-diacetyl derivatives[16] **17n—u** and then 5-(4-acetamidophenyl)tropolones **18n—u** for characterization.

Structures of these newly isolated products **15—18** were established by spectroscopy [UV, IR, ^{1}H NMR, MS, and ^{13}C NMR (for some compounds, particularly **15a—c** and **25** in comparison with the spectra of the corresponding starting materials **14** and **24**)] and elemental analysis; their exact data and the rational assignments for the spectral parameters are described in the Experimental section. Yield of each product of

the above reactions is listed in Table 1.

The 4-aminophenyl substituent in **15** and **16** was confirmed to be on 5-position by converting a representative product **16a** into known 5-phenyltropolone[10,11] (**5**) upon treatment with nitrous acid, followed by reduction with phosphinic acid (Scheme 6). The unequivocal assignments of the isopropyl and isopropenyl groups of the rearranged products to the 4-position were based on the careful analysis of the 500 (or 200) MHz ^{1}H NMR data of **17** and **18n**—**u**, by taking into account the well-resolved parameters obtained presently for structurally related compounds, such as **1a**, colchiceine (**1b**), and tropolone itself (**12c**) (see Table 2). Characteristic features in the δ and J values for the representative examples of these 4,5-disubstituted tropolones **17** and **18** are summarized in Table 2, and these values have been effectively utilized in precisely determining the positions of substituents for the rest of the polysubstituted tropolones.

The conversion of the 4-acetamido group on the phenyl ring of **18** into 4-methoxyphenyl derivatives is exemplified by the transformations into **19n**, **p**, **q**, **u** upon treatment with ethanolic 1 M HCl under reflux and then with nitrous acid in aq methanol, followed by methylation with dimethyl sulfate in 1 M NaOH (Scheme 3).

Attempts to convert the 4-isopropyl and isopropenyl groups of **18** and **19** into the corresponding acetyl derivatives for the purpose of further manipulation[2b,6] of the functional group to suit more colchicine-like compounds have so far remained unsuccessful (Scheme 7). Namely, the selective ozonolysis of the isopropenyl group of **18o**, **p** was found to cause only profound decomposition in contrast to the successful conversion of 5-isopropenyltropolone to 5-acetyltropolone.[17] In order to obtain

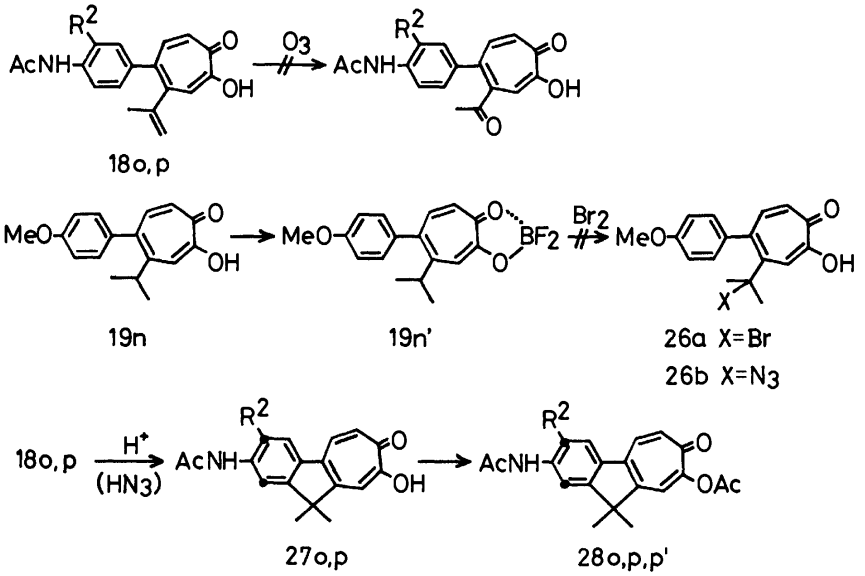
a) Chemical shifts are δ values and coupling constants (J) in Hz (see the Experimental section). The δ value without J indicates either the absence of coupling with other protons or only a small magnitude of J (<ca. 0.5 Hz). b) Although approximate or inadequate data for **1a** (at 270 MHz) and **1b** (at 60 MHz) were reported (Ref. 6f), more accurately resolved, reliable parameters obtained at 500 MHz are shown here. c) The numbering of the A and C rings of **1a** and **1b** corresponds to that of **17** and **18** for the purpose of comparison. d) For MeO-1. e) The proton signals on the B ring (note the numbering of these protons are shown in the formula **1a**): δ=1.86 (1H, brtd, $J_{6,6'}$=11.9, $J_{6',7}$=11.8, $J_{5,6'}$=6.6, $J_{5',6'}\simeq$1.3 Hz, H-6'), 1.98 (3H, s, AcN-7), 2.28 (1H, brsept, $J_{5,6}$=12.7, $J_{6,7}$=6.6, $J_{5',6}$=6.5 Hz, H-6), 2.40 (1H, brtd, $J_{5,5'}$=13.7 Hz, H-5), 2.53 (1H, brdd, H-5'), 4.64 (1H, brdt, $J_{7,NH}$=6.7 Hz, H-7), and 7.02 (1H, brd, HN-7). f) The proton signals on the B ring (note the numbering of these protons are shown in the formula **1b**): δ=1.90 (1H, brsept, $J_{6,6'}$=12, $J_{6',7}$=12, $J_{5,6'}$=6.5, $J_{5',6'}\simeq$4 Hz, H-6'), 2.03 (3H, s, AcN-7), 2.29 (1H, brsept, $J_{5,6}$=12, $J_{6,7}$=6.5, $J_{5',6}$=6 Hz, H-6), 2.34 (1H, brtd, $J_{5,5'}$=13 Hz, H-5), 2.52 (1H, brdt, H-5'), 4.66 (1H, brdt, $J_{7,NH}$=6 Hz, H-7), and 6.21 (1H, brd, HN-7). g) For HN-4'. h) Measured at 200 MHz. i) $J\simeq$1.4 Hz. j) $J\simeq$0.8 Hz.

4-(1-azido-1-methylethyl) derivatives (e.g., **26b**) to effect the Schmidt-type reaction[17,18] (to give the corresponding 4-acetyl compounds), preparation of the bromo derivative **26a** was first sought by converting **19n** to the difluoroborane complex **19n'** and then by treatment with bromine under a tungsten light. However, **19n'** did not give **26a** but remained unchanged, most likely owing to the steric congestion around the 4-isopropyl side chain. On the other hand, the treatment of **18o, p** with sodium azide–concd sulfuric acid in chloroform resulted in, instead of the anticipated rearrangement to yield the acetyl derivatives,[17] a surprisingly facile ring closure to give indenotropolones (cyclohept[*a*]inden-7(10*H*)-one derivatives) **27o, p** (Scheme 7), which were led to acetates[16] **28o—p'** for characterization (see the Experimental section). The intramolecular cyclization was confirmed to readily proceed in the absence of sodium azide at room temperature, further supporting the neighboring positions of the aryl and isopropenyl

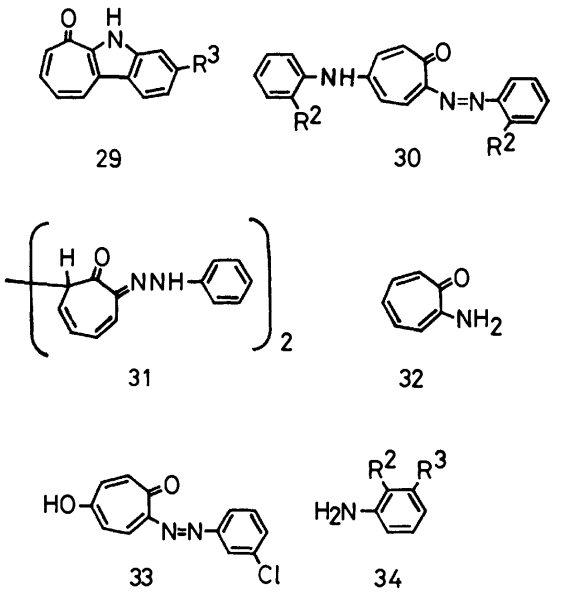


Scheme 7. Attempted preparations of 4-acetyl-5-aryltropolones. For R^2 of **18**, **27**, and **28o**, **p**, see Scheme 3.

groups on the tropolone ring in **18o—u**.

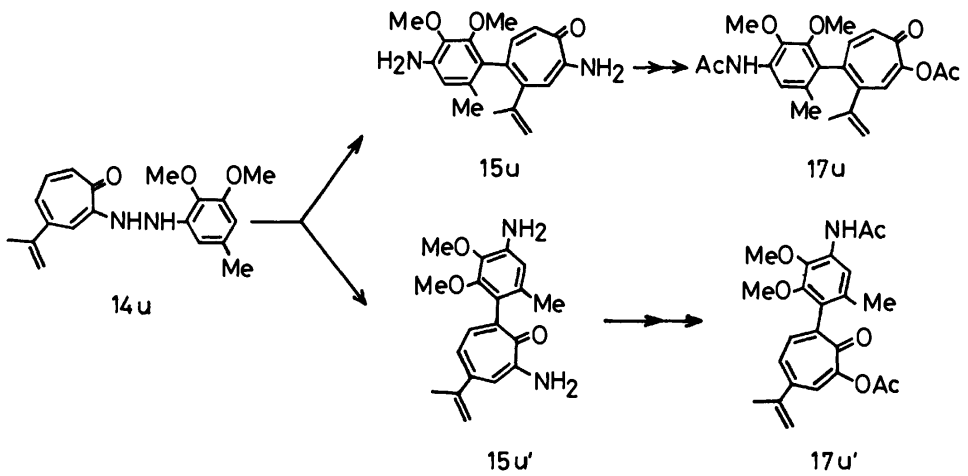
It is noteworthy that the rearrangement reactions of **14** resulted in the formation of minor amounts of by-products of various types. These were intensively studied in detail for the reactions of 2-(2-phenylhydrazino)tropones **14a—m**, and the following compounds were isolated (see Scheme 8):[15] a) The 3,*o*-type rearrangement products, indolotropones (6*H*-cyclohept[*b*]indol-6-one derivatives) **29**; b) the 5-semidine type rearrangement products, 5-anilino-2-arylazotropones **30**; c) the oxidative dimeric compound, 6,6'-bis(phenylhydrazono)-1,1'-[bi-2,4-cycloheptadien-1-yl]-7,7'-dione (**31**);[1] d) miscellaneous products, 2-aminotropone (**32**),[18] 2-arylazo-5-hydroxytropone (**33**), and *o*-[20] and *m*-nitroanilines[21] (**34**) (see Table 1 for yield of each compound).

Moreover, by a careful, chromatographic separation (after the alkaline hydrolysis and acetylation) of the reaction products of 2-[2-(2,3-dimethoxy-5-methylphenyl)hydrazino]-4-isopropenyltropone (**14u**), we isolated, besides the major 5,*p*-rearranged product **17u**, a minor amount of a by-product, whose structure was proved to be the 7,*p*-rearranged compound **17u'** by MS and ^{1}H NMR spectroscopy (see Scheme 9 and Table 2). It is noted that the signals due to 4-isopropenyl group in **17u'** were appreciably shifted to the downfield (ca. 0.5 ppm) from the corresponding signals of **17u** and appeared at δ 2.3 and 5.3—5.4 that coincide with the δ values of 4-isopropenyl group of β-dolabrin acetate,[22] thus supporting the assignment of the phenyl ring of **17u'** at the 7-position. This in turn shows the formation of a minor proportion of the corresponding 2-aminotropone **15u'** (Scheme 9) by the rearrangement of **14u**. Both **15u** and **15u'**, however, quickly turned into a dark tar during the attempted purification.



Scheme 8. Minor products of the rearrangement reaction. For R^2 and R^3 of **29**, **30**, and **34**, see Scheme 3.

Other remarks that would closely relate to the aspect of the reaction mechanism are as follows: 1) The presence of electron-donating substituents on the phenyl ring in **14** tends to accelerate the rearrangement, whereas that of an electron-withdrawing group markedly suppresses the reaction. 2) The rearrangement of **14o** proceeds much more smoothly than **14n**, suggesting that the presence of an electron-withdrawing group on the tropone ring of **14** appears to accelerate the reaction. 3) When substituent(s) is present at 3- (and 5-) position of the phenyl ring of **14**



Scheme 9. The 5,*p*- and 7,*p*-rearrangement of **14u**.

and becomes bulkier, the yield of the product **15** tends to decrease and the amount of by-products increases.[15]

Closer studies on the rearrangement products using more variety of 2-arylhydrazinotropones of type **14**, particularly in connection with precursors bearing suitable substituents (e.g., R^1=CH(Me)NHAc and R^5=Me), are in progress.[15] Nevertheless, these findings in the present rearrangement are believed to be of value from the viewpoint of the development of the fundamental chemistry of troponoids,[7] and also to give important suggestions on further clarification of the reaction mechanism of benzidine rearrangement in general, which is still considered to contain certain ambiguity in many respects.[23] Moreover, present work demonstrates an effective way for preparation of a wide range of 5-aryltropolones having carbon-substituents at 4-position that are otherwise hardly available, and this methodology is expected to be useful in the development of a new, convenient route to colchicine analogues.

Experimental

Melting points were determined with a Thomas Hover MR or Yanagimoto MP-S3 instrument and are uncorrected. All reactions were monitored by TLC (Merck silica gel 60F, 0.25 mm) with an appropriate solvent system (mostly with MeOH-$CHCl_3$, $CHCl_3$-AcOEt, and/or AcOEt-hexane). Preparative TLC and column chromatography were performed with Merck Kiesel Gel 60G and Wako C-200 silica gel, respectively. Yields of products **15**—**18** and **29**—**34** are given in Table 1. The UV spectra were recorded in MeOH with a Hitachi EPS-3T spectrophotometer. The IR spectra were taken as KBr disk (unless otherwise stated) with a Shimadzu IR-27G, Hitachi 215, or JASCO A-102 spectrometer. The ^{1}H NMR spectra were measured in $CDCl_3$ (unless otherwise stated) with a Hitachi R24, R24B, or R-600 (60 MHz), Varian HA-100 (100 MHz), JEOL-FX200 (200 MHz) or Varian VXR-500 instrument (500 MHz, the SC-NMR Lab., Okayama Univ.) at 27 °C. Chemical shifts are recorded as δ values relative to tetramethylsilane as the internal standard measured at 60 MHz (unless otherwise stated). The assignments of all signals were made by employing a first-order analysis with the aid of decoupling technique and the parameters were confirmed by a computer-assisted simulation analysis. ^{13}C NMR spectra were recorded with a JEOL FX-100 (25 MHz) in DMSO-d_6. Mass spectra were taken on a Hitachi M-52 low-resolution or JEOL JMX-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument and are given in terms of *m/z* (rel intensity) compared with the base peak.

Preparation of 2,3-Dimethoxy- (13g) and 2,3-Dimethoxy-5-methylphenylhydrazine (13h).[24] 2,3-Dimethoxyaniline[25] (15.9 g) was added dropwise to an ice-cooled 6 M HCl (40 cm^3), and then a solution of sodium nitrite (7.4 g) in water (20 cm^3) was added at 0—5 °C over a period of 30 min. Stirring was continued for 30 min at this temp. A solution of tin(II) chloride (110.6 g) in concd HCl (120 cm^3) was added at 0—5 °C over a period of 2 h. The mixture was stirred for 1 h at this temp and poured into an ice-cooled solution of NaOH (125.4 g) in water (314 cm^3). Black precipitates were filtered off and the filtrate was extracted with benzene. The combined organic layers were dried (Na_2SO_4) and concentrated in vacuo. The residue was distilled to give **13g** as pale yellow crystals (12.3 g, 75% yield): bp 122—124 °C/2 Torr (1 Torr=133.322 Pa), mp 78—82 °C; IR (neat) 3350 cm^{-1} (NH); ^{1}H NMR δ=3.72, 3.78 (3H each, 2s, MeO-2,3), 3.07—4.37 (3H, brm, $NHNH_2$), and 6.20—7.11 (3H, m, ArH*), *Aromatic H.

Anal. ($C_8H_{12}N_2O_2$) C, H, N.

Similar procedures starting with 2,3-dimethoxy-5-methylaniline[26] (20.9 g) afforded **13h** as a yellow viscous oil (16.1 g, 71%): bp 133—134 °C/3 Torr; IR (neat) 3400—3300 cm^{-1}; ^{1}H NMR δ=2.23 (3H, s, Me-5), 3.74, 3.80 (3H each, 2s, MeO-2,3), and 6.07—6.73 (2H, m, ArH).

Anal. ($C_9H_{14}N_2O_2$) C, H, N.

General Procedure for the Preparation of 2-(2-Arylhydrazino)tropones 14a—d, 14k, 14m, 23, and 24 from 2-Chlorotropone (12b). To a mixture of arylhydrazine **13** (1.2 mmol) and triethylamine (1.2 mmol, or 2.2 mmol when the arylhydrazine hydrochloride was used) in methanol (1 cm^3) was added **12b** (1.0 mmol) in methanol (2 cm^3) under nitrogen at room temp, and then the mixture was gently refluxed for 1.5—20 h; when the starting materials were not

soluble enough in MeOH alone, a certain amount of tetrahydrofuran (THF) was added as a co-solvent.

When the starting material **12b** almost disappeared (by TLC), the solvent was evaporated in vacuo. The residue was diluted with cold brine and extracted with $CHCl_3$ or CH_2Cl_2 (AcOEt or THF, if necessary). The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue (when it was a solid) was recrystallized from an appropriate solvent (see below) to give the corresponding product; the filtrate was concentrated in vacuo and the residue was chromatographed in a column of silica gel, giving an additional amount of the product.

2-(2-Phenylhydrazino)tropone[27,28] (14a). Yellow prisms (48% yield from **12b** and **13a**, cf. Ref. 1, 66% yield using **12a**); mp 168 °C (from benzene, lit,[27] mp 168 °C); UV λ_{max} 246 (log ε 4.52), 335 (4.04), and 400 nm (4.05); IR 3270 (NH) and 1598 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=6.6—7.4 (10H, m, ArH), 8.1 (1H, brm, NH-1'), and 9.0 (1H, brm, NH-2); ^{13}C NMR δ=109.3 (C-3), 112.3 (C-2', 6'), 119.4 (C-4'), 123.3 (C-5), 129.3 (C-3', 5'), 130.3 (C-7), 136.4 (C-4), 137.1 (C-6), 147.1 (C-1'), 156.2 (C-2), and 176.2 (C-1); MS *m/z* 212 (M^+; 78.5), 105 (4), 93 (100), and 77 (17).

2-[2-(*o*-Tolyl)hydrazino]tropone (14b): Yellow prisms (40% yield from **12b** and **13b** hydrochloride, cf. Ref. 1, 82% yield using **12a**); mp 90—91 °C (from benzene); UV λ_{max} 246 (log ε 4.25), 335 (3.78), and 400 nm (3.76); IR 3270, 3250 (NH), and 1590 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=2.26 (3H, s, Me-2'), 6.4—7.5 (9H, m, ArH), 7.59 (1H, brs, NH-1'), and 8.98 (1H, brs, NH-2); ^{13}C NMR δ=17.4 (Me-2'), 109.2 (C-3), 110.7 (C-6'), 119.5 (C-4'), 122.3 (C-2'), 123.1 (C-5), 126.7 (C-3'), 129.9 (C-5'), 130.3 (C-7), 136.4 (C-4,6), 145.2 (C-1'), 156.7 (C-2), and 176.0 (C-1); MS *m/z* 226 (M^+; 100), 107 (95), and 106 (80).

Anal. ($C_{14}H_{14}N_2O$) C, H, N.

2-[2-(*m*-Tolyl)hydrazino]tropone (14c): Yellow prisms (57% yield from **12b** and **13c** hydrochloride, cf. Ref. 1, 72% yield using **12a**); mp 148 °C (from benzene); UV λ_{max} 246 (log ε 4.37), 358 (4.05), and 400 nm (3.91); IR 3300, 3240 (NH), 1600, and 1590 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=2.18 (3H, s, Me-3'), 6.48 (1H, brd, $J_{4',5'}$=8 Hz, H-4'), 6.52 (1H, brs, H-2'), 6.56 (1H, brd, $J_{3,4}$=10 Hz, H-3), 6.6—7.1 (1H, m, H-5), 6.67 (1H, brd, $J_{5',6'}$=8 Hz, H-6'), 6.87 (1H, brt, H-5'), 7.00 (1H, brd, $J_{6,7}$=11.5 Hz, H-7), 7.24 (1H, brt, $J_{4,5}$=10.0, $J_{4,6}$=1.5 Hz, H-4), 7.28 (1H, ddd, $J_{5,6}$=9.5 Hz, H-6), 8.0 (1H, brs, NH-1'), and 9.0 (1H, brs NH-2); ^{13}C NMR δ=21.1 (Me-3'), 109.2 (C-3), 109.8 (C-2'), 112.8 (C-6'), 120.0 (C-4'), 123.2 (C-5), 129.0 (C-5'), 130.0 (C-7), 136.3 (C-4,6), 138.1 (C-3'), 147.6 (C-1'), 156.1 (C-2), and 176.0 (C-1); MS *m/z* 226 (M^+; 73.4) and 106 (100).

Anal. ($C_{14}H_{14}N_2O$) C, H, N.

2-[2-(*p*-Tolyl)hydrazino]tropone (14d): Yellow needles (53% yield from **12b** and **13d** hydrochloride, cf. Ref. 1, 63% yield using **12a**); mp 162—164 °C (from benzene); UV λ_{max} 245 (log ε 4.60), 335 (4.12), and 402 nm (4.10); IR 3260 (NH) and 1600 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=2.30 (3H, s, Me-4'), 5.7 (1H, brm, NH-1'), 6.6—7.4 (9H, m, ArH), and 8.3 (1H, brm, NH-2); MS *m/z* 226 (M^+; 100), 107 (80), and 106 (91).

Anal. ($C_{14}H_{14}N_2O$) C, H, N.

2-[2-(*m*-Nitrophenyl)hydrazino]tropone (14k): Yellow prisms (53% yield from **12b** and **13k**, cf. Ref. 1, 62% yield using **12a**); mp 188—190 °C (from $CHCl_3$-benzene); UV λ_{max} 246 (log ε 4.75), 335 (4.25), and 398 nm (4.28); IR 3260 (NH) and 1600 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=6.6—7.7 (9H, m, ArH), 8.7 (1H, brs, NH-1'), and 9.3 (1H, brs, NH-2); MS *m/z* 257 (M^+; 100), 138 (13), and 121 (7).

Anal. ($C_{13}H_{11}N_3O_3$) C, H, N.

2-[2-(*p*-Nitrophenyl)hydrazino]tropone (14m): Yellow prisms (53% yield from **12b** and **13m**, cf. Ref. 1, 51% yield using **12a**); mp 185 °C decomp (from benzene); UV λ_{max} 243 (log ε 4.26), 340 (4.01), and 398 nm (4.09); IR 3300, 3200 (NH), and 1600 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=6.75 (2H, brd, J=9 Hz, H-2',6'), 6.755 (1H, brd, $J_{3,4}$=10 Hz, H-3), 6.76 (1H, brdd, $J_{4,5}$=10, $J_{5,6}$=9 Hz, H-5), 7.03 (1H, brd, $J_{6,7}$=11.5 Hz, H-7), 7.26 (1H, brt, H-4), 7.34 (1H, brdd, H-6), 8.08 (2H, brd, J=9 Hz, H-3',5'), 9.31 (1H, brs, NH-1'), and 9.4 (1H, brs, NH-2); MS *m/z* 257 (M^+; 100) and 138 (5).

Anal. ($C_{13}H_{11}N_3O_3$) C, H, N.

2,2'-Hydrazobis(tropone) (23): Pale yellow crystals (70% yield from **12b** and **22**); mp 190 °C (from $CHCl_3$-benzene); UV λ_{max} 245 (log ε 4.58), 336 (4.16), and 404 nm (4.27); IR 3300 (NH), 1610, and 1590 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=6.60 (2H, brd, $J_{3,4}$=9.5 Hz, H-3), 6.77 (2H, brdd, $J_{4,5}$=10.0, $J_{5,6}$=8.5 Hz, H-5), 7.06 (2H, brd, $J_{6,7}$=11.5 Hz, H-7), 7.24 (2H, brdd, H-4), 7.36 (2H, ddd, $J_{4,6}$=1.5 Hz, H-6), and 9.36 (2H, brs, NH-2); MS *m/z* 240 (M^+; 100), 121 (21), and 105 (4).

Anal. ($C_{14}H_{12}N_2O_2$) C, H, N.

2-[2-(1-Naphthyl)hydrazino]tropone (24): Yellow prisms (15% yield from **12b** and 1-naphthylhydrazine); mp 150 °C (from $CHCl_3$-benzene); IR 3300, 3200 (NH), and 1597 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=6.55 (1H, dd, J=7, 2.5 Hz, H-2'), 6.65—7.6 (9H, m, ArH), 7.86 (1H, brdd, J=6.5, 3 Hz, H-5'), 8.28 (1H, brdd, J=6.5, 3 Hz, H-8'), 8.70 (1H, m, NH-1'), and 9.25 (1H, brs, NH-2); ^{13}C NMR δ=104.9 (C-2'), 109.1 (C-3), 119.2, 121.5, 122.2 (C-8'a), 123.2 (C-5), 124.6, 126.0, 126.4, 128.1, 130.1 (C-7), 133.9 (C-4'a), 136.6 (C-4), 136.8 (C-6), 142.5 (C-1'), 156.0 (C-2), and 176.1 (C-1); MS *m/z* 262 (M^+; 100), 143 (46), 142 (21), and 105 (27).

Anal. ($C_{17}H_{14}N_2O$) C, H, N.

General Procedure for the Benzidine-Type Rearrangement of 2-(2-Arylhydrazino)tropones 14, 23, and 24. A. Procedure for 14a—f,i,j,m, 23, and 24: A mixture of **14** (or **23** or **24**) (1 mmol) and 2 M HCl (6.3 cm^3, 12.5 mmol) in ethanol (50 cm^3) was heated at 50—80 °C for 1 h (for **14a—f**, **24**), or refluxed for 5—6 h (for **14m**, **23**) or 12 h (for **14i,j**) under nitrogen. The mixture was neutralized with cold 2 M NaOH solution and extracted with ethyl acetate. The extract was washed with water and then with brine. The organic layer was dried (Na_2SO_4) and concentrated. When crystals were separated, they were collected and recrystallized. The filtrate was concentrated and chromatographed on preparative TLC plates (with chloroform, ethyl acetate, or diethyl ether). When no crystals appeared on evaporation of the AcOEt extract, the residue was directly chromatographed.

B. Procedure for 14g,h: A mixture of **14** (0.2 mmol) and 2 M HCl (1.3 cm^3) in ethanol (10 cm^3) was refluxed for 2 h under nitrogen. The reaction mixture was similarly worked up.

C. Procedure for 14k,l: A mixture of **14** (1 mmol) and 2 M HCl (6.3 cm^3) in 3:2 dioxane-water (50 cm^3) was refluxed for 72 h under nitrogen. The reaction mixture was similarly worked up.

D. Procedure for 14l: A mixture of **14l** (1 mmol) and

2 M HCl (6.3 cm^3) in 1-butanol (50 cm^3) was refluxed for 72 h under nitrogen. The reaction mixture was similarly worked up.

E. Procedure for 14n—u: A mixture of a 4-substituted 2-(2-arylhydrazino)tropone **14** (50 mg), ethanol (10 cm^3), and 2 M HCl (2.5 cm^3) was refluxed under nitrogen for 1—3.5 h. When the starting material **14** almost disappeared (by TLC), the mixture was concentrated at 40—50 °C under reduced pressure. When crystals separated, they were filtered off and washed with benzene to give crude **15** (as hydrochloride). This was stirred with cold, saturated aq $NaHCO_3$ under nitrogen and extracted with ethyl acetate, giving unstable **15** after recrystallization. If the hydrochloride of **15** did not precipitate, the reaction mixture was taken to pH 8 with cold 2 M KOH and the solvent was concentrated in vacuo. The residue was extracted with CH_2Cl_2 or AcOEt. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo to give crude **15n—u**. As these products were not stable enough to be purified, they were immediately subjected to the next step (see later).

2-Amino-5-(4-aminophenyl)tropone (15a): Yellow prisms; mp 203—204 °C (from $CHCl_3$-benzene); UV λ_{max} 240 (log ε 4.44), 375 (4.28), and 402sh nm (4.20); IR 3450, 3300 (NH), and 1610 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=5.2 (2H, brs, H_2N-4′), 6.7 (2H, brd, J=8.5 Hz, H-3′,5′), 7.3 (2H, brd, J=8.5 Hz, H-2′,6′), 7.5 (2H, m, H_2N-2), and 6.9—7.8 (4H, m, H-3,4,6,7); ^{13}C NMR δ=113.0 (C-3), 114.5 (C-3′,5′), 127.9 (C-2′,6′), 129.3 (C-7), 129.9 (C-1′), 133.9 (C-4), 136.0 (C-5,6), 148.2 (C-4′), 156.7 (C-2), and 174.6 (C-1); MS m/z 212 (M^+; 75.6) and 184 (100).

Anal. ($C_{13}H_{12}N_2O$) C, H, N.

Compound **15a** (50 mg, 0.24 mmol) was treated with acetic anhydride (0.22 cm^3) in 3:5 dichloromethane–benzene (8 cm^3) at 40 °C for 3 h under nitrogen to give 2-amino-5-(4-acetamidophenyl)tropone (**15a′**, 60 mg, 100% yield): Yellow crystals; mp>300 °C; IR 3425, 3250 (NH), 1680 (amide), and 1605 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=2.20 (3H, s, AcN), 7.02 (2H, brd, J=9 Hz, H-3′,5′), 7.0—7.8 (8H, m, ArH, H_2N-2), and 10.1 (1H, brm, NH-4′); MS m/z 254 (M^+; 100), 212 (5), and 182 (97).

Treatment of **15a′** (21 mg) with Ac_2O–pyridine at 20 °C for 2 h under nitrogen gave 2-acetamido-5-(4-acetamidophenyl)-tropone (**15a″**, 24 mg, 97%): Yellow crystals; mp>300 °C; IR 3350, 3250 (NH), 1701, 1678 (amide) and 1600 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=2.10 (3H, s, AcN-4′), 2.20 (3H, s, AcN-2), 6.9—8.0 (8H, m, ArH), 9.1, and 9.2 (1H each, brm, 2NH); MS m/z 296 (M^+; 80.0), 253 (100), 223 (27), and 184 (57).

2-Amino-5-(4-amino-3-methylphenyl)tropone (15b): Yellow prisms; mp 204 °C (from benzene); UV λ_{max} 244 (log ε 4.56) and 382 nm (4.40); IR 3450, 3325 (NH), 1610, and 1600 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=2.14 (3H, s, Me-3′), 4.0 (2H, m, H_2N-4′), 6.70 (1H, brd, J=8.5 Hz, H-5′), 6.9—7.3 (4H, m, H-3,7,2′,6′), 7.32 (2H, brm, H_2N-2), and 7.49 (2H, brdd, J=12, 2 Hz, H-4,6); ^{13}C NMR δ=17.3 (Me-3′), 112.1 (C-3), 114.0 (C-5′), 121.1 (C-3′), 124.3 (C-2′), 128.1 (C-6′), 128.7 (C-7), 130.0 (C-1′), 133.2 (C-4), 135.7 (C-5,6), 145.4 (C-4′), 155.6 (C-2), and 174.2 (C-1); MS m/z 226 (M^+; 100) and 198 (75).

Anal. ($C_{14}H_{14}N_2O$) C, H, N.

2-Amino-5-(4-amino-2-methylphenyl)tropone (15c): Yellow prisms; mp 153—155 °C (from benzene); UV λ_{max} 249 (log ε 4.51), 362 (4.15), and 410 nm (4.02); IR 3400—3100 (NH) and 1605 cm^{-1} (C=O); ^1H NMR (100 MHz, DMSO-d_6) δ=2.08 (3H, s, Me-2′), 4.99 (2H, brs, H_2N-4′), 6.42 (1H, brd, $J_{5',6'}$=8 Hz, H-5′), 6.46 (1H, brs, H-3′), 6.84 (1H, brd, H-6′), 7.3 (2H, brm, H_2N-2), and 6.9—7.4 (4H, m, H-3,4,6,7); ^{13}C NMR δ=19.8 (Me-2′), 111.3 (C-3,3′), 115.6 (C-5′), 128.0 (C-6′), 129.3 (C-7), 131.3 (C-1′), 134.8 (C-2′), 136.1 (C-5), 136.7 (C-4), 138.4 (C-6), 147.2 (C-4′), 156.7 (C-2), and 174.4 (C-1); MS m/z 226 (M^+; 76.6) and 198 (100).

Anal. ($C_{14}H_{14}N_2O$) C, H, N.

2-Amino-5-(4-amino-3-methoxyphenyl)tropone (15e): Yellow prisms; mp 185 °C (from benzene); UV λ_{max} 244 (log ε 3.92) and 387 nm (3.78); IR 3395, 3270 (NH), and 1615 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=3.87 (3H, s, MeO-3′), 4.85 (2H, brm, H_2N-4′), 6.5—7.8 (7H, m, ArH), and 7.35 (2H, brm, H_2N-2); MS m/z 242 (M^+; 100), 214 (43), 199 (24), 172 (13), and 171 (59).

Found: m/z 242.1063. Calcd for $C_{14}H_{14}N_2O_2$: M, 242.1056.

2-Amino-5-(4-amino-2-methoxyphenyl)tropone (15f): Yellow prisms; mp 185—187 °C (from benzene); UV λ_{max} 245 (log ε 4.64) and 380 nm (4.41); IR 3400, 3245 (NH), and 1605 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=3.70 (3H, s, MeO-2′), 5.2 (2H, brm, H_2N-4′), 7.25 (2H, brm, H_2N-2), 7.25—7.45 (7H, m, ArH); MS m/z 242 (M^+; 100), 214 (67), and 199 (13).

Anal. ($C_{14}H_{14}N_2O_2$) C, H, N.

2-Amino-5-(4-amino-2,3-dimethoxyphenyl)tropone (15g): Yellow prisms; mp 166—167 °C (from benzene); IR ($CHCl_3$) 3400, 3355 (NH), and 1610 cm^{-1} (C=O); ^1H NMR δ=3.66 (3H, s, MeO-2′), 3.92 (3H, s, MeO-3′), 6.09 (2H, brm, H_2N-4′), 6.55 (1H, d, $J_{5',6'}$=9Hz, H-5′), 6.89 (1H, d, H-6′), 6.96 (1H, d, $J_{6,7}$=11 Hz, H-7), 7.15—7.65 (3H, m, ArH), and 7.35 (2H, brm, H_2N-2); MS m/z 272 (M^+; 100), 244 (63), and 229 (6).

Found: m/z 272.1176. Calcd for $C_{15}H_{16}N_2O_3$: M, 272.1161.

2-Amino-5-(4-amino-2,3-dimethoxy-6-methylphenyl)tropone (15h): Yellow prisms; mp 120—122 °C (from benzene); IR ($CHCl_3$) 3380, 3350 (NH), and 1610 cm^{-1} (C=O); ^1H NMR δ=2.00 (3H, s, Me-6′), 3.59 (3H, s, MeO-2′), 3.85 (3H, s, MeO-3′), 6.30 (2H, brm, H_2N-4′), 6.42 (1H, s, H-5′), 6.95—7.2 (4H, m, ArH), and 7.35 (2H, brm, H_2N-2); MS m/z 286 (M^+; 100), 271 (8), 254 (45), and 243 (11).

Found: m/z 286.1321. Calcd for $C_{16}H_{18}N_2O_3$: M, 286.1317.

2-Amino-5-(4-amino-3-chlorophenyl)tropone (15i): Yellow prisms; mp 230 °C decomp (from ethanol), UV λ_{max} 245 (log ε 4.49) and 378 nm (4.37); IR 3330, 3205 (NH), and 1610 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=5.35 (2H, brm, H_2N-4′), 6.90 (1H, brd, $J_{5',6'}$=8.5 Hz, H-6′), 7.0—7.7 (6H, m, ArH), and 7.45 (2H, brm, H_2N-2); MS m/z 248 (M+2; 31), 246 (M^+; 92), 220 (34), 218 (100), 182 (13), 154 (11), 109 (19), and 91 (25).

Found: m/z 246.0560. Calcd for $C_{13}H_{11}N_2OCl$: M, 246.0560.

2-Amino-5-(4-amino-2-chlorophenyl)tropone (15j): Yellow prisms; mp 161—162 °C (from chloroform); UV λ_{max} 248 (log ε 4.11) and 363 nm (3.86); IR 3345 (NH) and 1605 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=5.45 (2H, brm, H_2N-4′), 6.4—7.7 (7H, m, ArH), and 7.45 (2H, brm, H_2N-2); MS m/z 248 (M+2; 33), 246 (M^+; 99), 220 (34), 218 (100), 182 (17), 154 (11), and 109 (18).

Found: m/z 246.0537. Calcd for $C_{13}H_{11}N_2OCl$: M, 246.0560.

2-Amino-5-(4-amino-3-nitrophenyl)tropone (15k): Yellow prisms; mp 253—254 °C (from ethyl acetate); UV λ_{max} 247 (log ε 4.54) and 372 nm (4.49); IR 3445, 3290 (NH), and 1635 cm^{-1} (C=O); ^{1}H NMR (DMSO-d_6) δ=5.60 (2H, brm, H_2N-4′), 6.8—7.5 (5H, m, H-3,4,6,7,5′), 7.52 (2H, brm, H_2N-2), 7.70 (1H, dd, $J_{5',6'}$=8, $J_{2',6'}$=2 Hz, H-6′), and 8.14 (1H, d, H-2′); MS *m/z* 257 (M^+; 100), 229 (36), and 183 (41).

Found: *m/z* 257.0799. Calcd for $C_{13}H_{11}N_3O_3$: M, 257.0800.

2-Amino-5-(4-amino-2-nitrophenyl)tropone (15l): Yellow prisms; mp 246—247 °C (from ethyl acetate); UV λ_{max} 250 (log ε 4.45), 358 (4.20), and 409 nm (4.07); IR 3420, 3280 (NH), and 1620 cm^{-1} (C=O), ^{1}H NMR (DMSO-d_6) δ=5.85 (2H, brm, H_2N-4′), 6.6—7.3 (7H, m, ArH), and 7.65 (2 H, brm, H_2N-2); MS *m/z* 257 (M^+; 100), 240 (11), 212 (18), 201 (22), 197 (33), 185 (20), 184 (36), 183 (28), 182 (45), 169 (43), and 154 (31).

Found: *m/z* 257.0805. Calcd for $C_{13}H_{11}N_3O_3$: M, 257.0800.

2-Amino-5-(4-amino-1-naphthyl)tropone (25): Yellow prisms; mp 173 °C (from benzene); IR 3350 (NH) and 1603 cm^{-1} (C=O); ^{1}H NMR (100 MHz, DMSO-d_6) δ=4.4 (2H, brs, H_2N-4′), 5.8 (2H, brs, H_2N-2), 6.74 (1H, d, $J_{2',3'}$=8 Hz, H-3′), 6.98 (1H, d, $J_{3,4}$=12 Hz, H-3), 7.19 (1H, d, H-2′), 6.9—7.5 (4H, m, H-4,6,6′,7′), 7.67 (1H, brdd, $J_{5',6'}$=7, $J_{5',7'}$=3Hz, H-5′), and 8.13 (1H, brdd, $J_{7',8'}$=6.5, $J_{6',8'}$=3 Hz, H-8′); ^{13}C NMR δ=112.1 (C-3), 122.9 (C-4′a), 124.0, 125.3, 126.0, 128.0 (C-2′), 129.0 (C-7), 132.0 (C-1′), 135.8 (C-5), 138.0 (C-4), 139.7 (C-6), 144.6 (C-8′a), 157.7 (C-4′), 159.5 (C-2), and 175.2 (C-1); MS *m/z* 262 (M^+; 72.2), 234 (100), and 217 (54).

Anal. ($C_{17}H_{14}N_2O$) C, H, N.

6*H*-Cyclohept[*b*]indol-6-one (29a):[29] Yellow prisms; mp 267 °C (from benzene, lit,[29] 245—246 °C).

3-Methyl-6*H*-cyclohept[*b*]indol-6-one (29c): Yellow prisms; mp 226 °C (from benzene); UV λ_{max} 229 (log ε 4.49), 282 (4.44), 312 (4.38), 326 (4.33), 394 (4.86), and 410 nm (3.99); IR 3200 (NH) and 1605 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=2.45 (3H, s, Me-3), 6.9—7.8 (5H, m, ArH), 8.00 (1H, d, $J_{1,2}$=8 Hz, H-1), 8.16 (1H, d, $J_{9,10}$=10 Hz, H-10), and 12.3 (1H, brm, HN-5); MS *m/z* 209 (M^+; 100), 181 (92), 180 (78), and 152 (16).

Found: *m/z* 209.0833. Calcd for $C_{14}H_{11}NO$: M, 209.0841.

3-Methoxy-6*H*-cyclohept[*b*]indol-6-one (29f): Yellow prisms; mp 251—252 °C (from benzene); UV λ_{max} 228 (log ε 4.42), 281 (4.23), 317 (4.46), 390 (3.75), 410 nm (3.85); IR 3180 (NH) and 1625 cm^{-1} (C=O); ^{1}H NMR (DMSO-d_6) δ=3.82 (3H, s, MeO-3), 6.7—7.7 (5H, m, ArH), 8.18 (1H, d, $J_{1,2}$=9 Hz, H-1), 8.30 (1H, d, $J_{9,10}$=11 Hz, H-10), and 12.4 (1H, brm, HN-5).

Anal. ($C_{14}H_{11}NO_2$) C, H, N.

3-Chloro-6*H*-cyclohept[*b*]indol-6-one (29j): Yellow prisms; mp 191—192 °C (from benzene); UV λ_{max} 233 (log ε 4.42), 272 (4.37), 280 (4.38), 314 (4.36), 386 (3.84), and 404 nm (3.96); IR 3175 (NH) and 1615 cm^{-1} (C=O); ^{1}H NMR (DMSO-d_6) δ=6.9—7.8 (5H, m, ArH), 8.32 (1H, brd, $J_{9,10}$= 11 Hz, H-10), 8.35 (1H, d, $J_{1,2}$=8 Hz, H-1), and 12.4 (1H, brm, HN-5); MS *m/z* 231 (M+2; 25), 229 (M^+; 79), 203 (34), 201 (100), and 166 (45).

Found: *m/z* 229.0246. Calcd for $C_{13}H_8NOCl$: M, 229.0295.

3-Nitro-6*H*-cyclohept[*b*]indol-6-one (29l): Yellow crystals; mp>300 °C (from benzene-methanol); UV λ_{max} 249 (log ε 4.29), 310 (4.39), 336 (4.17), 404 (3.81), and 420 nm (3.90); IR 3180 (NH) and 1620 cm^{-1} (C=O); ^{1}H NMR (DMSO-d_6) δ=7.0—8.65 (7H, m, ArH) and 12.9 (1H, brm, HN-5); MS *m/z* 240 (M^+; 100), 212 (43), 166 (73), and 139 (55).

Found: *m/z* 240.0537. Calcd for $C_{13}H_8N_2O_3$: M, 240.0535.

5-Anilino-2-phenylazotropone (30a): Dark red needles; mp 183—184 °C (from benzene); UV λ_{max} 235 (log ε 4.38), 320 (4.25), and 495 nm (4.31); IR ($CHCl_3$) 3000 (NH) and 1590 cm^{-1} (C=O); ^{1}H NMR δ=6.6—7.0 [1H, m, H-4″ (PhN-5)], 7.1—7.6 (10H, m, ArH), 7.66 (1H, d, $J_{3,4}$=10 Hz H-3), 7.8—8.05 [2H, m, H-2′,6′ (PhN=N-2)], and 9.3 (1H, brm, NH-5); ^{13}C NMR δ=111.3 (C-3), 122.4, 123.5, 124.6, 125.9, 126.6, 129.1, 129.9 (C-4), 131.3 (C-7), 137.6, 138.0, 151.3 (C-1″), 152.9 (C-1′), 155.7 (C-2), and 172.0 (C-1); MS *m/z* 301 (M^+; 16), 272 (9), 196 (41), 181 (26), 167 (87), 115 (8), and 77 (100).

Anal. ($C_{19}H_{15}N_3O$) C, H, N.

5-(2-Chloroanilino)-2-(2-chlorophenylazo)tropone (30i): Dark red prisms; mp 176 °C (from benzene-hexane); UV λ_{max} 266 (log ε 4.33), 272 (4.36), and 490 nm (4.54); IR ($CHCl_3$) 3010 (NH) and 1620 cm^{-1} (C=O); ^{1}H NMR δ=6.3—8.0 (12H, m, ArH) and 9.56 (1H, brm, NH).

Anal. ($C_{19}H_{13}N_3OCl_2$) C, H, N.

2-(3-Chlorophenylazo)-5-hydroxytropone (33): Dark red microcrystals; mp 117 °C decomp (from benzene); UV λ_{max} 299 (log ε 3.92) and 502 nm (3.87); IR ($CHCl_3$) 3260 (OH) and 1590 cm^{-1} (C=O); ^{1}H NMR δ=6.6—8.2 (8H, m, ArH) and 9.4 (1H, brm, OH); MS *m/z* 262 (M+2; 24), 260 (M^+; 74), 232 (8), 141 (10), 139 (33), 121 (100), and 111 (95).

Found: *m/z* 260.0356. Calcd for $C_{13}H_9N_2O_2Cl$: M, 260.0353.

General Procedure for Hydrolysis of 2-Amino-5-(4-aminoaryl)tropones 15. Compound **15** (0.5 mmol) was dissolved in ethanol (8 cm^3) and 6 M KOH (3.5 cm^3); if necessary, some THF was added as a co-solvent. The mixture was refluxed under nitrogen for 3—12 h, brought to pH 7 with 2 M HCl, and then concentrated in vacuo. When **16** separated as crystals, they were filtered off and washed with cold water (and then with a little benzene). The filtrate was extracted with AcOEt or CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo to give additional **16**. The products **16n—u** were not stable enough for purification and therefore immediately acetylated (see later).

5-(4-Aminophenyl)tropolone (16a): Yellow prisms; mp 185—186 °C (from benzene-methanol); UV λ_{max} 238 (log ε 4.55), 256 (4.50), and 390 nm (4.38); IR 3440, 3360 (NH), 3150 (OH), and 1620 cm^{-1} (C=O); ^{1}H NMR δ=5.1 (3H, brm, H_2N-4′, HO-2), 6.70 (2H, brd, J=8.5 Hz, H-3′,5′), 7.1—7.2 (4H, m, ArH), and 7.25 (2H, brd, J=8.5 Hz, H-2′,6′); MS *m/z* 213 (M^+; 100) and 185 (98).

Anal. ($C_{13}H_{11}NO_2$) C, H, N.

Treatment of **16a** (54 mg) with cold nitrous acid, followed by reduction with phosphinic acid, gave 5-phenyltropolone (**5**)[10,11] as pale yellow plates (15 mg, 30% overall yield); mp 126 °C (lit,[10] 125—126 °C).

5-(4-Amino-3-methylphenyl)tropolone (16b): Yellow prisms; mp 157—158 °C (from benzene-methanol); UV λ_{max} 238 (log ε 4.50), 256 (4.44), and 393 nm (4.30); IR 3440, 3370 (NH), 3240 (OH), and 1615 cm^{-1} (C=O); ^{1}H NMR δ=2.20 (3H, s, Me-3′), 5.2 (3H, brm, H_2N-4′, HO-2), 6.69 (1H, brd, $J_{5',6'}$=9 Hz, H-5′), and 6.9—7.2 (6H, m, ArH).

Anal. ($C_{14}H_{13}NO_2$) C, H, N.

5-(4-Amino-2-methylphenyl)tropolone (16c): Yellow prisms; mp 115—117 °C (from benzene–methanol); UV λ_{max} 240sh (log ε 4.52), 251 (4.55), 358 (4.18), and 390sh nm (4.15); IR 3430 (NH), 3170 (OH), and 1615 cm^{-1} (C=O); ^1H NMR δ=2.15 (3H, s, Me-2′), 5.4 (3H, brm, H_2N-4′, HO-2), 6.50 (1H, brd, $J_{3',5'}$=2.5 Hz, H-3′), 6.51 (1H, brdd, $J_{5',6'}$=8.5 Hz, H-5′), 7.00 (1H, brd, H-6′), and 7.2—7.6 (4H, brs, ArH).

Anal. ($C_{14}H_{13}NO_2$) C, H, N.

5-(4-Amino-3-methoxyphenyl)tropolone (16e): Yellow prisms; mp 155—157 °C (from benzene–methanol); UV λ_{max} 238 (log ε 4.61), 257 (4.50), and 398 nm (4.37); IR 3460, 3320 (NH), 3200 (OH), and 1620 cm^{-1} (C=O); ^1H NMR δ=3.90 (3H, s, MeO-3′), 5.60 (3H, brm, H_2N-4′, HO-2), 6.67 (1H, brd, $J_{5',6'}$=8.5 Hz, H-5′), 6.84 (1H, brs, H-2′), and 7.1—7.8 (5H, brs, ArH).

Anal. ($C_{14}H_{13}NO_3$) C, H, N.

***5-(4-Amino-2-methoxyphenyl)tropolone* (16f):** Yellow prisms; mp 167—169 °C (from benzene–methanol); UV λ_{max} 237 (log ε 4.58), 256 (4.55), and 397 nm (4.30); IR 3470, 3380 (NH), 3200 (OH), and 1610 cm^{-1} (C=O); ^1H NMR δ=3.76 (3H, s, MeO-2′), 5.05 (3H, brm, H_2N-4′, HO-2), 6.15—6.45 (2H, m, H-3′,5′), 7.05 (1H, brd, $J_{5',6'}$=8 Hz, H-6′), and 7.2—7.65 (4H, m, ArH).

Anal. ($C_{14}H_{13}NO_3$) C, H, N.

5-(4-Amino-2,3-dimethoxyphenyl)tropolone (16g): Yellow prisms; mp 110—111 °C (from benzene); IR 3465, 3350 (NH), 3200 (OH), and 1605 cm^{-1} (C=O); ^1H NMR δ=3.69 (3H, s, MeO-2′), 3.84 (3H, s, MeO-3′), 5.45 (3H, brm, H_2N-4′, HO-2), 6.72 (1H, d, $J_{5',6'}$=8.5 Hz, H-5′), 7.0—7.65 (4H, m, ArH), and 7.03 (1H, d, H-6′).

Anal. ($C_{15}H_{15}NO_4$) C, H, N.

5-(4-Amino-2,3-dimethoxy-6-methylphenyl)tropolone (16h): Yellow prisms; mp 98—100 °C (from benzene); IR 3470, 3360 (NH), 3200 (OH), and 1610 cm^{-1} (C=O); ^1H NMR δ=2.06 (3H, s, Me-6′), 3.72 (3H, s, MeO-2′), 3.86 (3H, s, MeO-3′), 5.20 (3H, brm, H_2N-4′, HO-2), 6.72 (1H, s, H-5′), and 7.05—7.7 (4H, m, ArH).

Anal. ($C_{16}H_{17}NO_4$) C, H, N.

5-(4-Amino-3-chlorophenyl)tropolone (16i): Yellow prisms; mp 136—138 °C (from benzene–methanol); UV λ_{max} 238 (log ε 4.49), 256 (4.42), and 376 nm (4.32); IR 3450, 3350 (NH), 3200 (OH), and 1620 cm^{-1} (C=O); ^1H NMR δ=5.60 (3H, brm, H_2N-4′, HO-2), 6.76 (1H, brd, $J_{5',6'}$=8.5 Hz, H-5′), and 7.0—7.6 (6H, m, ArH).

Anal. ($C_{13}H_{10}NO_2Cl$) C, H, N.

5-(4-Amino-2-chlorophenyl)tropolone (16j): Yellow prisms; mp 161—163 °C (from benzene–methanol); UV λ_{max} 240sh (log ε 4.58), 256 (4.61), 355 (4.30), 358 (4.30), and 390sh nm (4.23); IR 3460, 3370 (NH), 3240 (OH), and 1605 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=5.10 (3H, brm, H_2N-4′, HO-2), 6.60 (2H, m, H-3′,5′), and 7.1—7.2 (5H, m, ArH).

Anal. ($C_{13}H_{10}NO_2Cl$) C, H, N.

5-(4-Amino-3-nitrophenyl)tropolone (16k): Yellow prisms; mp 272—275 °C (from chloroform–ethyl acetate); UV λ_{max} 241sh (log ε 4.49), 256 (4.52), 367 (4.41), and 390sh nm (4.36); IR 3480 (NH), 3180 (OH), and 1620 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=5.10 (3H, brm, H_2N-4′, HO-2) and 7.1—7.8 (7H, m, ArH).

Anal. ($C_{13}H_{10}N_2O_4$) C, H, N.

5-(4-Amino-2-nitrophenyl)tropolone (16l): Yellow prisms; mp 250—253 °C (from chloroform–ethyl acetate); UV λ_{max} 352 (log ε 4.58), 356 (4.31), 360 (4.32), and 394sh nm (4.25); IR 3480, 3380 (NH), 3180 (OH), and 1620 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=5.05 (3H, brm, H_2N-4′, HO-2) and 7.0—7.9 (7H, m, ArH).

Anal. ($C_{13}H_{10}N_2O_4$) C, H, N.

Acetylation of 5-(4-Aminoaryl)tropolones 16 to 5-(4-Acetamidoaryl)tropolone Acetates 17. A mixture of **16** (50 mg), pyridine (2.5 cm^3), and acetic anhydride (0.16 cm^3) was stirred overnight at 20 °C under argon. The volatile material was evaporated in vacuo and the residue was purified in a column of silica gel to give **17**. The complete characterization of **17n—t** was made as the corresponding tropolones **18n—t** after hydrolysis (see later).

5-(4-Acetamidophenyl)tropolone Acetate (17a): Yellow prisms; mp 215 °C (from benzene); UV λ_{max} 247 (log ε 4.07) and 354 nm (4.02); IR 3320—3200 (NH), 1755, 1695 (amide), and 1590 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) δ=2.10 (3H, s, AcN-4′), 2.30 (3H, s, AcO-2), 7.1—8.0 (8H, m, ArH), and 10.0 (1H, brm, NH); MS *m/z* 297 (M^+; 24.0), 254 (100), 226 (13), 212 (11), and 184 (65).

Anal. ($C_{17}H_{15}NO_4$) C, H, N.

5-(4-Acetamidophenyl)-4-isopropyltropolone Acetate (17n): Yellow oil; ^1H NMR δ=1.01 (6H, d, J=7 Hz, Me_2C-4), 2.09 (3H, s, AcN-4′), 2.40 (3H, s, AcO-2), 2.75 (1H, sept, HC-4), 7.1—7.8 (7H, m, ArH), and 10.1 (1H, brs, NH).

5-(4-Acetamidophenyl)-4-isopropenyltropolone Acetate (17o): Yellow oil; ^1H NMR δ=1.56 (3H, brs, MeC-4), 2.18 (3H, s, AcN-4′), 2.36 (3H, s, AcO-2), 5.06 (2H, brs, H_2C=C-4), 7.1—7.8 (7H, m, ArH), and 8.43 (1H, brm, NH).

5-(4-Acetamido-3-methylphenyl)-4-isopropenyltropolone Acetate (17p): Yellow syrup; ^1H NMR δ=1.58 (3H, brs, MeC-4), 2.20 (3H, s, AcN-4′), 2.28 (3H, brs, Me-3′), 2.35 (3H, s, AcO-2), 5.05 (2H, brs, H_2C=C-4), and 7.1—8.0 (7H, m, ArH, NH).

5-(4-Acetamido-2-methylphenyl)-4-isopropenyltropolone Acetate (17q): Yellow syrup; ^1H NMR δ=1.59 (3H, brs, MeC-4), 2.16 (6H, brs, AcN-4′, Me-2′), 2.36 (3H, s, AcO-2), 4.92 (2H, brs, H_2C=C-4), and 7.05—7.85 (7H, m, ArH, NH).

5-(4-Acetamido-3-methoxyphenyl-4-isopropenyltropolone Acetate (17r): Yellow oil; ^1H NMR δ=1.59 (3H, brs, MeC-4), 2.23 (3H, s, AcN-4′), 2.37 (3H, s, AcO-2), 3.88 (3H, s, MeO-3′), 5.07 (2H, brs, H_2C=C-4), 6.2—7.57 (6H, m, ArH), and 7.82 (1H, m, NH).

5-(4-Acetamido-2-methoxyphenyl)-4-isopropenyltropolone Acetate (17s): Yellow oil; ^1H NMR δ=1.65 (3H, brs, MeC-4), 2.18 (3H, s, AcN-4′), 2.37 (3H, s, AcO-2), 3.78 (3H, s, MeO-2′), 4.90 (2H, brs, H_2C=C-4), and 6.95—8.1 (7H, m, ArH, NH).

5-(4-Acetamido-2,3-dimethoxyphenyl)-4-isopropenyltropolone Acetate (17t): Yellow oil; ^1H NMR δ=1.70 (3H, brs, MeC-4), 2.22 (3H, s, AcN-4′), 2.37 (3H, s, AcO-2), 3.73 (3H, s, MeO-2′), 3.89 (3H, s, MeO-3′), 4.92 (2H, brs, H_2C=C-4), 6.92 (1H, d, $J_{5',6'}$=8.5 Hz, H-6′), 7.12 (1H, d, $J_{6,7}$=11.0 Hz, H-7), 7.18 (1H, s, H-3), 7.39 (1H, d, H-6), 7.9 (1H, brm, NH), and 8.18 (1H, brd, H-5′).

5- and 7-(4-Acetamido-2,3-dimethoxy-6-methylphenyl)-4-isopropenyltropolone Acetates (17u,u′): A mixture (3:2 by ^1H NMR) of **17u** and **17u′** (respectively) was obtained as a yellow oil, which was rechromatographed in a prepacked silica-gel column (Merck Lobar, Size A) with 1:3 AcOEt–hexane to give only small proportions of pure **17u** and **17u′** (besides mostly overlapping fractions).

17u: Colorless prisms; mp 161.5—163 °C (from AcOEt–hexane); ^{1}H NMR (500 MHz), see Table 2; MS *m/z* 412 (M+1; 10.8) 411 (M^+; 40.7), 370 (26), 369 (100), 354 (22), 338 (15), 327 (13), 326 (16), 312 (44), 296 (44), 284 (15), 268 (21), 253 (16), and 252 (15).

Found: *m/z* 411.1666. Calcd for $C_{23}H_{25}NO_6$: M, 411.1682.

17u′: A pale yellow syrup; ^{1}H NMR (500 MHz), see Table 2; MS *m/z* 411 (M^+; 10.3), 381 (11), 380 (40), 369 (14), 354 (15), 340 (28), 339 (27), 338 (100), and 281 (10).

Found: *m/z* 411.1640. Calcd for $C_{23}H_{25}NO_6$: M, 411.1682.

Hydrolysis of 5-(4-Acetamidoaryl)tropolone Acetates 17 to 5-(4-Acetamidoaryl)tropolones 18. Compound **17** (50 mg) was treated with 1:1 1 M KOH–ethanol (4 cm^3) at 20 °C overnight. The solvent was evaporated in vacuo. The residue was diluted with cold water, taken to pH 4 with dil HCl, and extracted with CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was chromatographed in a column of silica gel to provide **18**.

5-(4-Acetamidophenyl)-4-isopropyltropolone (18n): Yellow needles; mp 250 °C decomp (from AcOEt); IR 3300 (OH, NH), 1675 (amide), and 1600 cm^{-1} (C=O); ^{1}H NMR δ=1.09 (6H, d, J=7 Hz, Me_2C-4), 2.09 (2H, s, AcN-4), 2.85 (1H, sept, HC-4), 7.1—7.8 (8H, m, ArH, OH), and 10.1 (1H, brs, NH); MS *m/z* 297 (M^+; 70.2), 282 (100), 254 (61), and 240 (15).

Found: *m/z* 297.1342. Calcd for $C_{18}H_{19}NO_3$: M, 297.1365.

5-(4-Acetamidophenyl)-4-isopropenyltropolone (18o): A pale yellow crystalline powder: mp 119—121 °C (from AcOEt–hexane); ^{1}H NMR δ=1.62 (3H, brd, J=1.5 Hz, MeC-4), 2.22 (3H, s, AcN-4′), 5.03, 5.06 (1H each, both brs, H_2C=C-4), 5.5 (1H, brm, HO-2), 7.25 (1H, d, $J_{6,7}$=11.5 Hz H-7), 7.26 (2H, brd, $J_{2',3'}=J_{5',6'}$=8 Hz, H-2′,6′), 7.39 (1H, d, H-6), 7.44 (1H, s, H-3), 7.49 (2H, brd, H-3′,5′), and 7.8 (1H, brm, NH); MS *m/z* 295 (M^+; 81.2), 280 (100), 252 (41), 238 (18), 210 (73), and 195 (31).

Found: *m/z* 295.1205. Calcd for $C_{18}H_{17}NO_3$: M, 295.1208.

5-(4-Acetamido-3-methylphenyl)-4-isopropenyltropolone (18p): Yellow prisms; mp 172—174 °C (from AcOEt–benzene, cf. Ref. 2b, mp 85 °C decomp[30]); ^{1}H NMR (500 MHz) δ=1.60 (3H, s, MeC-4), 2.23 (3H, brs, AcN-4′), 2.27 (3H, brs, Me-3′), 5.01, 5.05 (1H each, both brs, H_2C=C-4), 7.03 (1H, brm, NH), 7.13 (1H, brd, $J_{2',6'}$=1.7 Hz, H-2′), 7.15 (1H, brdd, $J_{5',6'}$=8.3 Hz, H-6′), 7.26 (1H, d, $J_{6,7}$=11.6 Hz, H-7), 7.38 (1H, d, H-6), 7.42 (1H, s, H-3), and 7.87 (1H, brd, H-5′); MS *m/z* 309 (M^+; 97.8), 294 (100), 266 (26), 252 (31), 238 (20), 224 (66), and 209 (46).

Found: *m/z* 309.1353. Calcd for $C_{19}H_{19}NO_3$: M, 309.1365.

5-(4-Acetamido-2-methylphenyl)-4-isopropenyltropolone (18q): Yellow prisms; mp 177—179 °C (from AcOEt–benzene); ^{1}H NMR (500 MHz) δ=1.63 (3H, brs, MeC-4), 2.12 (3H, brs, Me-2′), 2.19 (3H, brs, AcN-4′), 4.90 [1H, brs, (*E*)-HC=C-4], 4.94 [1H, brquint, J=1.3 Hz, (*Z*)-HC=C-4], 7.03 (1H, brd, $J_{5',6'}$=8.3 Hz, H-6′), 7.20 (1H, brm, NH), 7.23 (1H, d, $J_{6,7}$=11.7 Hz, H-7), 7.25 (1H, d, H-6), 7.31 (1H, brdd, $J_{3',5'}$=1.9 Hz, H-5′), 7.39 (1H, s, H-3), and 7.42 (1H, brd, H-3′); MS *m/z* 309 (M^+; 36.6), 294 (40), 266 (21), 250 (21), 224 (64), 222 (100), and 209 (40).

Found: *m/z* 309.1336. Calcd for $C_{19}H_{19}NO_3$: M, 309.1365.

5-(4-Acetamido-3-methoxyphenyl)-4-isopropenyltropolone (18r): Pale yellow needles; mp 169—171 °C (from AcOEt–hexane); ^{1}H NMR (500 MHz), see Table 2; MS *m/z* 325 (M^+; 100), 310 (20), 282 (82), 268 (94), 254 (52), 240 (66), 223 (28), 209 (24), 197 (15), and 195 (16).

Found: *m/z* 325.1296. Calcd for $C_{19}H_{19}NO_4$: M, 325.1314.

5-(4-Acetamido-2-methoxyphenyl)-4-isopropenyltropolone (18s): Pale yellow needles; mp 108—110 °C (from light petroleum); ^{1}H NMR (200 MHz), see Table 2; MS *m/z* 325 (M^+; 100), 310 (12), 282 (76), 268 (91), 254 (42), and 240 (53).

Found: *m/z* 325.1332. Calcd for $C_{19}H_{19}NO_4$: M, 325.1314.

5-(4-Acetamido-2,3-dimethoxyphenyl)-4-isopropenyltropolone (18t): Pale amber fine prisms: mp 159—159.5 °C (from AcOEt–cyclohexane); ^{1}H NMR (200 MHz) δ=1.73 (3H, brs, MeC-4), 2.22 (3H, s, AcN-4′), 3.63 (3H, s, MeO-2′), 3.88 (3H, s, MeO-3′), 4.83, 4.92 (1H each, both brs, H_2C=C-4), 6.85 (1H, d, $J_{5',6'}$=8.3 Hz, H-6′), 7.22 (1H, d, $J_{6,7}$=11.5 Hz, H-7), 7.33 (1H, s, H-3), 7.34 (1H, d, H-6), 7.79 (1H, brs, NH), and 8.06 (1H, brd, H-5′); MS *m/z* 355 (M^+; 16), 324 (19), 312 (11), 298 (12), and 43 (100).

Found: *m/z* 355.1435. Calcd for $C_{20}H_{21}NO_5$: M, 355.1420.

5- and 7-(4-Acetamido-2,3-dimethoxy-6-methylphenyl)-4-isopropenyltropolones (18u,u′): Pale yellow needles (a 3:2 mixture of **18u** and **18u′**, respectively, which were not separable even repeating chromatography); mp[§] 75 °C (from AcOEt–hexane).

18u: ^{1}H NMR[§] (500 MHz) see Table 1; MS[§] *m/z* 369 (M^+; 51), 338 (85), 326 (100), and 312 (31).

Found: *m/z* 369.1555. Calcd for $C_{21}H_{23}NO_5$: M, 369.1576.

18u′: ^{1}H NMR[§] (500 MHz) see Table 2.

General Procedure for the Preparation of 4-Substituted 5-(4-methoxyaryl)tropolones 19. A mixture of 5-(4-acetamidoaryl)-tropolone **18** (50 mg), ethanol (6 cm^3), and 2 M HCl (3 cm^3) was refluxed under argon for 12—36 h. The solvent was evaporated in vacuo. The residue was diluted with water (1 cm^3), EtOH (0.5 cm^3), and 2 M HCl (0.16 cm^3) at 0 °C, to which was slowly added, at 0 °C, sodium nitrite (1.2 equiv mol) dissolved in water (0.4 cm^3). The mixture was stirred at 5 °C for 2 h, diluted with water (50 cm^3), and then refluxed for 2 h under argon. The solvent was evaporated in vacuo. The residue was diluted with cold water and extracted with CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was suspended in cold water (1.5 cm^3) and 1 M NaOH (0.5 cm^3), and dimethyl sulfate (0.036 cm^3) was added. The mixture was stirred under argon at 5 °C for 30 min and then 70 °C for 1 h. After cooling, it was extracted with AcOEt and then with CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was chromatographed in a column of silica gel with benzene to provide **19**.

4-Isopropyl-5-(4-methoxyphenyl)tropolone (19n): Colorless needles (42% yield from **18n**); mp 114—115 °C (from

§ For specimen consisting of a ca. 3:2 mixture of **u** and **u′** form, because their separation could not be achieved.

benzene–cyclohexane); ^{1}H NMR δ=1.19 (6H, d, J=7.0 Hz, Me_2C-4), 3.01 (1H, brsept, J=7.0 Hz, HC-4), 3.89 (3H, s, MeO-4′), 6.93 (2H, brd, J=8.5 Hz, H-3′,5′), 7.11 (2H, brd, J=8.5 Hz, H-2′,6′), 7.19 (1H, d, $J_{6,7}$=12.0 Hz, H-7), 7.38 (1H, d, H-6), 7.43 (1H, s, H-3), and 7.45 (1H, brm, OH); MS m/z 270 (M^+; 100), 242 (36), 227 (43), 212 (11), and 196 (11).

Found: m/z 270.1224. Calcd for $C_{17}H_{18}O_3$: M, 270.1256.

4-Isopropyl-5-(4-methoxyphenyl)tropolone Difluoroborane Complex (19n′). Treatment of **19n** with an equivalent amount of boron trifluoride etherate in benzene–ether at 5 °C for 1 h, followed by purification using column chromatograhy on silica gel gave **19n′**: Colorless fine prisms (90% yield); mp 214—215 °C (from benzene–cyclohexane); ^{1}H NMR δ=1.20 (6H, d, J=7.0 Hz, Me_2C-4), 3.20 (1H, sept, J=7 Hz, HC-4), 3.88 (3H, s, MeO-4′), 7.01 (2H, brd, $J_{2',3'}=J_{5',6'}$=8.5 Hz, H-3′,5′), 7.18 (2H, brd, H-2′,6′), 7.62 (1H, d, $J_{6,7}$=11 Hz, H-6), 7.90 (1H, s, H-3), and 7.99 (1H, d, H-7); MS m/z 318 (M^+; 100), 290 (12), 275 (45), and 260 (11).

Found: m/z 318.1215. Calcd for $C_{17}H_{17}O_3BF_2$: M, 318.1239.

4-Isopropenyl-5-(4-methoxy-3-methylphenyl)tropolone (19p): Yellow needles (51% yield from **18p**); mp 146—147 °C (from ether–light petroleum); ^{1}H NMR δ=1.60 (3H, s, MeC-4), 2.22 (3H, s, Me-3′), 2.6 (1H, brm, OH), 3.86 (3H, s, MeO-4′), 5.04 (2H, brs, H_2C=C-4), 6.78 (1H, brd, $J_{5',6'}$=8.5 Hz, H-5′), 7.04 (1H, brs, H-2′), 7.06 (1H, brd, H-6′), 7.23 (1H, d, $J_{6,7}$=12.0 Hz, H-7), 7.40 (1H, d, H-6), and 7.42 (1H, s, H-3); MS m/z 282 (M^+; 100), 267 (80), 239 (71), 224 (51), 208 (22), and 181 (20).

Found: m/z 282.1198. Calcd for $C_{18}H_{18}O_3$: M, 282.1256.

4-Isopropenyl-5-(4-methoxy-2-methylphenyl)tropolone (19q): Pale yellow needles (40% yield from **18q**); mp 131—132 °C (from light petroleum); ^{1}H NMR δ=1.64 (3H, brs, MeC-4), 2.12 (3H, s, Me-2′), 3.85 (3H, s, MeO-4′), 4.93 (2H, m, H_2C=C-4), 6.71 (1H, brd, $J_{5',6'}$=8.5 Hz, H-5′), 6.77 (1H, brs, H-3′), 6.98 (1H, brd, H-6′), 7.20 (1H, d, $J_{6,7}$=12.0 Hz, H-7), 7.30 (1H, d, H-6), and 7.40 (1H, s, H-3); MS m/z 282 (M^+; 100), 267 (79), 239 (53), 224 (25), and 208 (9).

Found: m/z 282.1250. Calcd for $C_{18}H_{18}O_3$: M, 282.1256.

4-Isopropenyl-5- and 7-(2,3,4-trimethoxy-6-methylphenyl)-tropolone (19u,u′): A mixture (3:2) of **19u** and **19u′** (respectively) was obtained as a yellow syrup (49% yield from **18u,u′**), which was chromatographically inseparable.

19u: ^{1}H NMR[§] (500 M Hz) δ=1.25 (brs, HO-2), 1.74 (3H, brs, MeC-4), 2.00 (3H, brs, Me-6′), 3.69 (3H, s, MeO-2′), 3.87, 3.878 (3H each, 2s, MeO-3′,4′), 4.88 (2H, brs, H_2C=C-4), 6.50 (1H, brs, H-5′), 7.22 (1H, d, $J_{6,7}$=11.7 Hz, H-7), 7.27 (1H, d, H-6), and 7.38 (1H, s, H-3); MS[§] m/z 342 (M^+; 88), 327 (27), 312 (100), 311 (73), 292 (72), 281 (99), 268 (64), 253 (82), and 238 (81).

Found:[§] m/z 342.1428. Calcd for $C_{20}H_{22}O_5$: M, 342.1463.

19u′: ^{1}H NMR[§] (500 MHz) δ=1.25 (brs, HO-2), 2.04 (3H, brs, Me-6′), 2.20 (3H, brs, MeC-4), 3.69 (3H, s, MeO-2′), 3.88, 3.89 (3H each, 2s, MeO-3′,4′), 5.32, 5.45 (2H, 2brs, H_2C=C-4), 6.62 (1H, s, H-5′), 7.12 (1H, dd, $J_{5,6}$=10.7, $J_{3,5}$=1.7 Hz, H-5), 7.31 (1H, d, H-6), and 7.57 (1H, d, H-3).

2-Acetamido-8-hydroxy-10,10-dimethylcyclohept[*a*]inden-7(10*H*)-one (27o) and Its Acetate (28o). To a solution of **18o** (10 mg) in $CHCl_3$ (1 cm^3) was successively added concd sulfuric acid (0.5 cm^3) and sodium azide (3 mg) at 5 °C. The mixture was heated under argon at 70 °C for 2 h. The solvent was evaporated in vacuo. The residue was diluted with cold water, taken to pH 3 with $NaHCO_3$, and extracted with CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo to give **27o** as a pale amber crystalline powder (6 mg, 60%): mp 295—300 °C decomp (from EtOH–AcOEt–benzene); ^{1}H NMR δ=1.50 (6H, s, Me_2C-10), 2.20 (3H, s, AcN-2), 7.36 (1H, brd, $J_{3,4}$=8.5 Hz, H-4), 7.42 (1H, d, $J_{5,6}$=11.5 Hz, H-6), 7.51 (1H, s, H-9), 7.62 (1H, brd, H-3), 7.63 (1H, d, H-5), and 7.72 (1H, brs, H-1); MS m/z 295 (M^+; 100), 280 (6), 267 (8), 253 (17), 225 (26), 210 (22), and 182 (8).

Found: m/z 295.1174. Calcd for $C_{18}H_{17}NO_3$: M, 295.1208.

The above reaction was effected in the absence of sodium azide at 20 °C within 5 h.

27o (6.0 mg) was dissolved in pyridine (1 cm^3) and acetic anhydride (0.5 cm^3), and the mixture was stirred overnight at 20 °C under argon. The volatile material was evaporated in vacuo and the residue was purified in a column of silica gel with AcOEt–hexane as an eluant, giving **28o** as amber prisms (5.1 mg, 74% yield): ^{1}H NMR (500 MHz) δ=1.47 (6H, brs, Me_2C-10), 2.22 (3H, s, AcN-2), 2.38 (3H, s, AcO-8), 7.32 (1H, d, $J_{5,6}$=10.6 Hz, H-6), 7.38 (1H, brs, H-9), 7.38 (1H, brd, $J_{3,4}$=8.4 Hz, H-4), 7.43 (1H, brm, NH), 7.46 (1H, brd, H-5), 7.62 (1H, brd, H-3), and 7.78 (1H, brs, H-1); MS m/z 337 (M^+; 11), 296 (90), 295 (100), 280 (21), 267 (29), 253 (53), 238 (14), 225 (63), 224 (27), 210 (48), 181 (30), 180 (21), and 43 (22).

Found: m/z 337.1285. Calcd for $C_{20}H_{19}NO_4$: M, 337.1314.

2-Acetamido-8-hydroxy-1,10,10- (and 3,10,10)-trimethylcyclohept[*a*]inden-7(10*H*)-one (27p) and Their Acetates (28p,p′). The similar treatment of **18p** (10 mg) as those for **27o** and **28o** gave the products as isomeric mixtures with regard to the 1- and 3-methyl group.

27p: A yellow powder (5 mg, 50% yield); ^{1}H NMR δ=1.49, 1.60* (6H, s, Me_2C-10), 2.21 (3H, brs, AcN-2), 2.35, 2.40* (3H, brs, Me-1,3), 6.9—8.2 (ca. 7H, m, ArH, NH, OH);* signals presumably due to the minor 1-methyl isomer (ca. 30%) in the chromatographically inseparable mixture; MS m/z 309 (M^+; 100), 294 (10), 268 (15), 267 (18), 239 (13), and 225 (10).

28p (3,10,10-trimethyl isomer): Yellow fine prisms (40% yield from **27p**) after separation from the minor product **28p′** (see below) by silica-gel column chromatography with 1:1 AcOET–hexane; mp 233—235 °C (from AcOEt); ^{1}H NMR δ=1.47 (6H, s, Me_2C-10), 2.22 (3H, brs, AcN-2), 2.35 (3H, brs, Me-3), 2.37 (3H, s, AcO-8), 7.30 (1H, d, $J_{5,6}$=11.0 Hz, H-6), 7.35 (1H, brs, H-9), 7.36 (1H, brs, H-4), 7.43 (1H, brd, H-5), 7.50 (1H, brs, H-1), and 8.05 (1H, brm, NH); MS m/z 351 (M^+; 5.2), 309 (100), 297 (10), 294 (9), 268 (13), 267 (15), 265 (11), 239 (17), 225 (16), 209 (10), and 43 (60).

Found: m/z 351.1452. Calcd for $C_{21}H_{21}NO_4$: M, 351.1471.

28p′ (1,10,10-trimethyl isomer): A yellow solid (25% yield from **27p** after the chromatographic purification); ^{1}H NMR δ=1.59 (6H, s, Me_2C-10), 2.21 (3H, brs, AcN-2), 2.38 (3H, s, AcO-8), 2.42 (3H, brs, Me-1), 7.32 (1H, d, $J_{5,6}$=11 Hz, H-6), 7.39 (1H, brs, H-9), 7.47 (1H, brd, $J_{3,4}$=8.5 Hz, H-4), 7.55 (1H, brd, H-5), 7.62 (1H, brd, H-3), and 7.95 (1H, brm, NH); MS m/z 351 (M^+; 3.3), 309 (100), 297 (18), 267 (18), 239 (15), 225 (11), 209 (10), and 43 (45).

Found: m/z 351.1445. Calcd for $C_{21}H_{21}NO_4$: M, 351.1471.

We are very indebted to Dr. Yukio Sugimura (Sankyo Co., Ltd., Tokyo) for his generously entrusting the early part of this study to us and also to Dr. Ko Hojo and Miss Masami Tsutsumi (Tokyo Kasei Kogyo Co., Ltd.) for kindly preparing the new phenylhydrazines **13g** and **13h** and supplying to us. Thanks are also due to Professor Hitoshi Takeshita (Kyushu Univ.) for the measurement of the ^{13}C NMR spectrum, Mr. Shin-ichi Takekuma (Kinki Univ.) for 200 MHz ^{1}H NMR and MS, and Dr. Hiromichi Matsuura (Wakunaga Pharmaceutical Co., Ltd.) for the high-resolution mass spectra. The present work was partially supported by Grant-in-Aids for Scientific Research Nos. 60540331 (to H. Y.), 60540336, and 61540381 (to K. I.) from the Ministry of Education, Science and Culture.

Triethylborane-Induced Hydrodehalogenation of Organic Halides by Tin Hydrides

Katsukiyo MIURA, Yoshifumi ICHINOSE, Kyoko NOZAKI, Keigo FUGAMI, Koichiro OSHIMA,* and Kiitiro UTIMOTO
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received July 7, 1988)

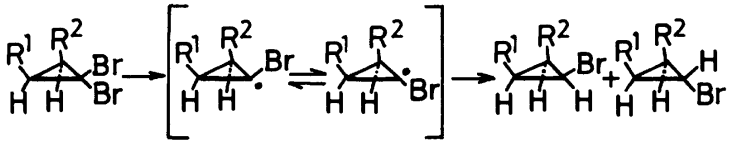
The reduction of organic halides with tributyltin hydride in the presence of a catalytic amount of triethylborane has been studied. (1) Alkyl iodides and alkyl bromides reacted easily with tin hydride at −78°C to give the corresponding hydrocarbons, while alkyl chlorides were sluggish to react and recovered unchanged. (2) The reduction of alkenyl halides such as 1-deuterio-1-iodo-1-dodecene and 1-iodo-1-triethylsilyl-1-dodecene proceeded nonstereospecifically. (3) The reduction of aryl halides with *n*-Bu_3SnH–Et_3B system was not so effective as the reduction of alkyl halides and alkenyl halides. Whereas aryl iodides were reduced at room temperature with *n*-Bu_3SnH, aryl bromides hardly reacted with *n*-Bu_3SnH even at 80 °C.

The free radical halogen abstraction from a C–Hal bond opens a broad variety of synthetic possibilities.[1,2] The simplest version is trapping of the outcoming radical by tin hydride, providing us with a facile route to replacement of halogen by hydrogen at the same carbon atom. The reactions are initiated by generation of tin radicals, which are produced mostly by radical initiators such as azobisisobutyronitrile (AIBN) or benzoyl peroxide. Recently we have found that Et_3B is an efficient radical initiator for generation of tin radicals from tin hydrides and applied this methodology to a couple of organic syntheses.[3] We would now like to report on a more detailed study on the reduction of organic halides with R_3SnH in the presence of Et_3B under mild reaction conditions.

Reduction of Alkyl Halides. A number of organic halides were reduced with *n*-Bu_3SnH–Et_3B system and the results are summarized in Table 1. Treatment of a solution of 1-bromododecane and tributyltin hydride in toluene with a catalytic amount of Et_3B (hexane solution, 10 mol%) gave dodecane quantitatively. It is worth noting that the reaction proceeded at low temperature such as −78 °C. Without Et_3B, 1-bromododecane was recovered quantitatively after treatment with *n*-Bu_3SnH in toluene at −78 °C for 3 h. Secondary bromoalkane and tertiary bromides were also easily reduced. The reactivity of the halides depends on the nature of the halogen. Iodides and bromides reacted easily with tin hydride in the presence of Et_3B, while chlorides were sluggish to react and were recovered practically unchanged. Heating a benzene solution of 1-chlorododecane with *n*-Bu_3SnH or Ph_3SnH in the presence of a catalytic amount of Et_3B at 70 °C for 5 h resulted in a recovery of the starting 1-chlorododecane quantitatively. Taking advantage of the difference in reactivity between bromide and chloride, it was possible to reduce one halogen in the presence of the other (Run 10).

Reduction of halides containing other functional groups such as ether, hydroxyl, or carbonyl proved that these functionalities could be present in the molecule without perturbing the course of reduction, although the nature of the functional group slightly influences the development of the reaction. For example, β-bromopropiophenone (Run 7) and ethylene acetal (Run 13) were reduced slowly at −78 °C. The reaction mixture was allowed to come to room temperature and then stirred for several hours to complete the reduction. 11-Bromo-1-undecanol could not be reduced at low temperature because of its low solubility in toluene and the reaction was perpformed at 0 °C.

Monodehalogenation of alkyl-substituted *gem*-dibromocyclopropanes with *n*-Bu_3SnH–Et_3B proceeded easily at −78 °C to provide stereoisomeric mixtures of monobromocyclopropanes. The isomeric ratios were almost the same as those obtained by reported ordinary procedure (without Et_3B).[4] The formation of *endo*- or *cis*-bromocyclopropanes as major products is explained as follows: (1) Tin radical attacks bromine to give a radical, (2) the intermediate radical equilibrates faster than hydrogen is transferred, (3) finally the less hindered approach of tin hydride provide endo or cis isomer selectively (Scheme 1). Reduction of monobromocyclopropanes to cyclopropanes did not proceed at −78 °C and it took prolonged reaction time (10 h) at



Scheme 1.

Table 1. Reduction of Alkyl Halides with n-Bu_3SnH–Et_3B

Run	Substrate	Reaction conditions Temp °C	Time h	Procedure	Yield of alkane %

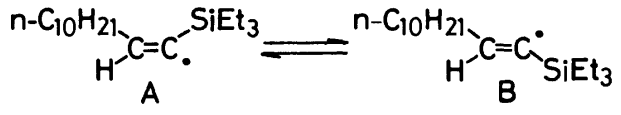
a) Isomeric ratio (cis/trans). b) 2.2 mol of n-Bu_3SnH was employed. c) Isomeric ratio (endo/exo).

room temperature to complete the reaction. Treatment of dibromocyclopropanes with 2.2 mol of tin hydride at room temperature for 15 h afforded cyclopropanes directly in high yields.

β-Elimination has been achieved by treatment of *vic*-dibromoalkanes with n-Bu_3SnH–Et_3B system. *meso*-1,2-Dibromocyclododecane gave a mixture of *trans*- and *cis*-cyclododecene in an 1:1 ratio (Run 18).

Reduction of Alkenyl Halides. The reduction of alkenyl iodides and bromides was also examined in the presence of a catalytic amount of Et_3B. Whereas iodides reacted easily with tin hydrides at −78 °C, bromides reacted slowly compared with iodides and it took 10 h to complete the reduction at room temperature. The effectiveness of Et_3B catalyst was confirmed by the fact that treatment of a solution of (*E*)-1-bromo-1-dodecene with n-Bu_3SnH in the absence of Et_3B at room temperature for 15 h resulted in quantitative recovery of (*E*)-1-bromo-1-dodecene. The typical results are summarized in Table 2. Treatment of (*E*)-1-deuterio-1-iodo-1-dodecene or (*Z*)-isomer with n-Bu_3SnH–Et_3B at −78 ° resulted in a formation of similar isomeric mixtures of (*E*)- and (*Z*)-1-deuterio-1-dodecene (*E*:*Z*=61:39—63:37). Thus, the reduction proceeded nonstereospecifically. Same stereochemical results were obtained with n-Bu_3SnH–AIBN system. The reaction of (*E*)- or (*Z*)-1-deuterio-1-iodo-1-dodecene with n-Bu_3SnH in the presence of AIBN at 50 °C

provided similar isomeric mixtures of (*E*)- and (*Z*)-1-deuterio-1-dodecene (*E*:*Z*=60:40). The reduction of alkenyl halides having silyl group on the same carbon bearing iodine also followed non-stereospecific course (Runs 6 and 7). (*E*)-1-Iodo-1-triethylsilyl-1-dodecene (**1**) gave a mixture of (*Z*)-1-triethylsilyl-1-dodecene and (*E*)-isomer (*Z*:*E*=56:44) and (*Z*)-isomer **2** afforded a Z:*E*=57:43 mixture upon treatment with *n*-Bu_3SnH–Et_3B at −78 °C.[5] The results have been explained by fast equilibration of two configurations of the alkenyl radical before hydrogen transfer (Scheme 2).



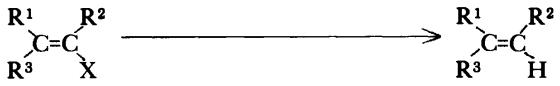
Scheme 2.

gem-Dibromoalkene provided monobromoalkene. For instance, reduction of 1,1-dibromo-1-dodecene gave an 1:1 mixture of 1-bromo-1-dodecene.

Reduction of Aryl Halides. The reduction of aryl iodides and bromides proceeded slowly with *n*-Bu_3SnH–Et_3B system.[6] 1-Iodonaphthalene reacted at room temperature, while 1-bromonaphthalene were inert. Aryl bromides were reduced at 80 °C, however, when more reactive Ph_3SnH was employed. The reaction was successively applied to the cyclization reaction. For instance, a mixture of five-membered ring and six-membered ring products was obtained upon treatment of aryl iodide **3** with *n*-Bu_3SnH–Et_3B (Scheme 3).

The Et_3B-induced reaction has following characteristics compared to ordinary reaction. (1) Tributyltin radical or triphenyltin radical can be generated at low

Table 2. Reduction of Alkenyl Halides with *n*-Bu_3SnH–Et_3B



Run	Substrate	Reaction conditions Temp/°C	Time/h	Yield of alkene/%
1		20	0.5	1-Dodecene 77

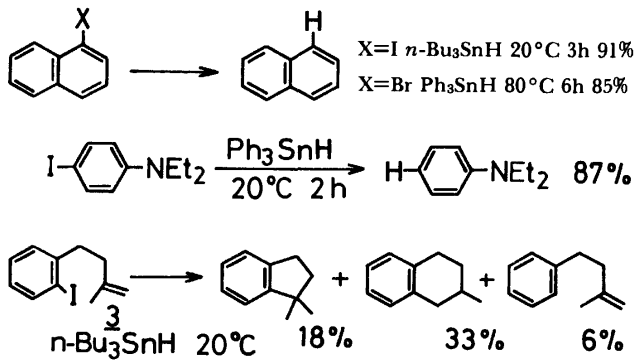
6	 **1**	−78	0.5	 95 (*Z*/*E*=56/44)
7	 **2**	−78	0.5	 98 (*Z*/*E*=57/43)
8		−78	0.5	 80 (*Z*/*E*=1:1)



Scheme 3. Triethylborane-catalyzed reduction of aryl halides.

temperature such as −78 °C and thereby the reduction of organic halides (iodides and bromides) proceeds at lower temperature than that with *n*-Bu_3SnH–AIBN (or dialkyl peroxide) system. The mildness of the reaction will offer promising possibilities for selective reduction. (2) The reduction of organic halides with *n*-Bu_3SnH–Et_3B system takes place easily to give the corresponding hydrocarbons in comparable yields to previously reported procedure.

Triethylborane proved to be an effective radical initiator in the presence of trace amount of oxygen. Other role of Et_3B, however, is not clear. We are studying on this point from the intrinsic mechanistic interest.

Experimental

Distillation of the products was performed by use of Kugelrohr (Büchi), and boiling points are indicated by an air-bath temperature without correction. ^1H NMR and ^{13}C NMR spectra were taken on a Varian XL-200 spectrometer, $CDCl_3$ was used as solvent unless otherwise noted, chemical shifts being given in δ with tetramethylsilane as an internal standard. IR spectra were determined on a JASCO IR-810 spectrometer. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Purification of products was performed by silica gel (Wakogel C-100) column chromatography.

Tributyltin Hydride and Triphenyltin Hydride. These compounds were prepared according to the reported procedure.[7]

Preparation of Alkyl Halides. Commercially available organic halides such as 1-bromododecane, 2-bromododecane, 1-iodododecane, 1-bromoadamantane, and α-bromo-γ-butyrolactone were used without further purification. Methyl 11-bromo undecanoate,[8] β-bromopropiophenone,[9] and 4,5-dihydro-5-iodomethyl-4-phenyl-2(3*H*)-furanone[10] were prepared according to the literature. *gem*-Dibromocyclopropanes were generated following the literature.[4] *vic*-Dibromides were prepared by treatment of 1-dodecene and *trans*-cyclododecene with bromine in ether.

3-Bromopropyl 4-Chlorobutyrate. A solution of 4-chlorobutyryl chloride (1.4 g, 10 mmol) in ether (10 ml) was added dropwise to a solution of 3-bromo-1-propanol (1.39 g, 10 mmol) and pyridine (1.6 g, 20 mmol) in ether (10 ml) at 0 °C under an argon atmosphere. The resulting mixture was stirred for 15 min at 0 °C, then for 2 h at room temperature. The mixture was diluted with ethyl acetate (20 ml) and poured into 1 M HCl (1 M=1 mol dm^{-3}) solution. Organic layer was separated and washed with 1 M HCl (2×20 ml) and brine (2×20 ml). Concentration of the dried (Na_2SO_4) organic layer gave a crude oil which was purified by silica-gel column chromatography followed by distillation to provide the title compound (1.8 g) in 74% yield. Bp 120 °C (bath temp, 2 Torr, 1 Torr=133.322 Pa); IR (neat) 2960, 1733, 1442, 1421, 1391, 1364, 1298, 1174, 1146, 1090, 1050, 1009, 785, 650 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.00—2.26 (m, 4H), 2.53 (t, J=7.3 Hz, 2H), 3.48 (t, J=6.5 Hz, 2H), 3.62 (t, J=6.3 Hz, 2H), 4.21 (t, J=6.1 Hz, 2H). Found: C, 34.68; H, 5.05%. Calcd for $C_7H_{12}O_2ClBr$: C, 34.52; H, 4.97%.

Preparation of Alkenyl Halides. (*E*)-1-Iodo-1-dodecene or (*E*)-1-bromo-1-dodecene were prepared by hydroalumination followed by treatment with iodine or bromine.[11]

(*E*)-1-Deuterio-1-iodo-1-dodecene. The compound was generated by hydroalumination of 1-deuterio-1-dodecyne followed by iodination. ^1H NMR ($CDCl_3$) δ=0.80—1.00 (m, 3H), 1.20—1.50 (m, 16H), 2.00—2.15 (m, 2H), 6.53 (tm, J=7.5 Hz, 1H).

(*Z*)-1-Deuterio-1-iodo-1-dodecene. Hydroalumination of 1-trimethylsilyl-1-dodecyne in hexane–ether (1:1) followed by the addition of D_2O gave (*Z*)-1-deuterio-1-trimethylsilyl-1-dodecene.[12] Iododesilylation[13] of alkenylsilane gave the title compound. ^1H NMR ($CDCl_3$) δ=0.75—0.95 (m, 3H), 1.10—1.50 (m, 16H), 2.00—2.20 (m, 2H), 6.18 (t, J=7.0 Hz, 1H).

2-Iodo-2-tridecene. The compound was prepared by iododesilylation according to the reported procedure.[13] A solution of iodine (0.25 g, 1.0 mmol) in dichloromethane (5.0 ml) was added to a solution of (*Z*)-2-trimethylsilyl-2-tridecene generated from 1-trimethylsilyl-1-dodecyne (0.25 g, 1.0 mmol)[14] in dichloromethane (5.0 ml) at 25 °C and the resulting mixture was stirred for 1 h. Work-up followed by purification by TLC (silica gel) gave 2-iodo-2-tridecene (0.20 g) in 65% yield as an isomeric mixture (*E*:*Z*=4:6). ^1H NMR ($CDCl_3$) δ=0.75—0.95 (m, 3H), 1.20—1.50 (m, 16H), 2.00 (m, 2H), 2.33 (s, 1.8H), 2.45 (s, 1.2H), 5.38 (tq, J=6.8, 1.5 Hz, 0.4H), 6.15 (tq, J=7.5, 1.7 Hz, 0.6H).

(*E*)-1-Iodo-1-triethylsilyl-1-dodecene and (*Z*)-1-Iodo-1-triethylsilyl-1-dodecene. These compounds were prepared from 1-triethylsilyl-1-dodecyne following the reported procedure.[12]

1,1-Dibromo-1-decene. The title compound was prepared from decanal, carbon tetrabromide, and triphenylphosphine.[15]

General Procedure for the Reduction of Alkyl Halides. (a) Procedure A: The hydrodehalogenation of 1-bromododecane is representative of procedure A. A dry 30-ml flask was equipped with septum inlet, a stirring bar, and three-way stop cock. One end of stop cock was connected to a balloon which was filled with argon. The inner atmosphere of the apparatus was replaced by argon. The flask was charged with a solution of 1-bromododecane (0.25 g, 1.0 mmol) in toluene (4.0 ml) and cooled to −78 °C with an Dry Ice–methanol bath. A solution of tributyltin hydride (0.33 g, 1.1 mmol) in toluene (4.0 ml) and a hexane solution of Et_3B (1.0 M, 0.1 ml, 0.1 mmol) was added successively. The solution was stirred

for 30 min at −78 °C. The disappearance of the starting material was confirmed by thin layer chromatographic assay. The resulting mixture was transferred into 100 ml round-bottomed flask using 25 ml of methanol. The solvent was evaporated as an azeotropic mixture to afford a crude oil which was submitted to silica-gel column chromatography (hexane as an eluant) to give dodecane (0.17 g) quantitatively. **(b) Procedure B:** The procedure was used for the reduction of the compounds which have polar functional groups such as hydroxyl or carbonyl in the molecule. The reduction of 11-bromo-1-undecanol to 1-undecanol is representative. A solution of tributyltin hydride (0.33 g, 1.0 mmol) in toluene (4.0 ml) was added to a solution of 11-bromo-1-undecanol (0.25 g, 1.0 mmol) in toluene (4.0 ml) at 0 °C. Et_3B (1.0 M hexane solution, 0.1 ml, 0.1 mmol) was added and the resulting mixture was stirred at 0 °C for 30 min. The reaction mixture was diluted with EtOAc (20 ml) and saturated aqueous potassium fluoride (2 ml) and anhydrous potassium fluoride (1.0 g) were added to remove tributyltin bromide.[16] The mixture was stirred for another 30 min and the precipitated tributyltin fluoride was removed by filtration and washed with ethyl acetate. Combined filtrates were washed with brine and dried over anhydrous sodium sulfate and concentrated in vacuo. The residual oil was purified by silica-gel column chromatography (hexane/ethyl acetate=5/1 as an eluant) to give 1-undecanol (0.16 g) in 94% yield.

General Procedure for the Reduction of Alkenyl Halides. The reactions were performed following the procedure A described for the reduction of alkyl halides. A solution of tributyltin hydride (0.33 g, 1.1 mmol) in toluene (4.0 ml) and Et_3B (1.0 M hexane solution, 0.1 ml, 0.1 mmol) were added successively to a solution of 1,1-dibromo-1-decene (0.30 g, 1.0 mmol) in toluene (4.0 ml) at −78 °C and the resulting mixture was stirred at −78 °C for 30 min. Concentration followed by purification by silica-gel column chromatography gave 1-bromo-1-decene (0.18 g) in 80% yield as an isomeric mixture (*E*/*Z*=1/1).

Reduction of Aryl Halide 3 with *n*-Bu_3SnH-Et_3B. A solution of *n*-Bu_3SnH (0.35 g, 1.2 mmol) in benzene (2.0 ml) was added dropwise over 2 h by syringe pump to a solution of aryl iodide **3** (0.24 g, 1.0 mmol) and Et_3B (1.0 M hexane solution, 0.1 ml, 0.1 mmol) in benzene (10 ml) at 20 °C. The resulting mixture was stirred more than 1 h after the completion of the addition. Work-up followed by purification by preparative TLC on silica gel gave a mixture of 1,1-dimethylindan (18%), 2-methyl-1,2,3,4-tetrahydronaphthalene (33%), and (3-methyl-3-butenyl)benzene (6%), whose spectra were identical with those of authentic samples.[17,18]

Aromatic Hydroxylation with an Iron(III)-Catechol-H_2O_2 System. Mechanistic Implication of the Role of Catechol

Seizo TAMAGAKI, Kenji SUZUKI, and Waichiro TAGAKI*
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3, Sumiyoshi-ku, Osaka 558
(Received July 8, 1988)

The role of catechol in benzene hydroxylation with Fe^{3+}/catechol/H_2O_2 system, the so-called Hamilton system, has been mechanistically investigated by using tiron as a substitute for pyrocatechol. The yield of phenol progresses linearly with reaction time. The phenol yield is dependent on the mole ratio of Fe^{3+} relative to tiron, and the ratio of more than unity is particularly important for the effective functioning of the catalyst system. The *o*-, *m*-, and *p*-product isomer distributions for a few aromatic hydrocarbons are nearly identical with those of the Fenton reaction. These and the separate experimental results are consistent with the mechanism involving the rate-limiting redox reaction between tiron and Fe^{3+} and then the follow-up radical chain sequence as in the Fenton reaction.

Since the first report of Udenfriend,[1] an enormous number of model peroxidase systems such as the Udenfriend[2] and Hamilton systems[3] have received considerable attention thus far. However, the reaction mechanisms for the majority of those systems are the least understood and quite speculative. This paper describes the results of detailed reexamination of mechanistic aspects of the aromatic hydroxylation by the Hamilton system consisting of Fe^{3+}, a catechol, and H_2O_2. The hydroxylation of aromatic hydrocarbons by this system has been studied in details by Hamilton.[3] The rate of the reaction was found to be first order in iron(III), H_2O_2, and catechol concentrations at a low concentration of catechol (2×10^{-4} M; 1 M=1 mol dm^{-3}). At higher concentrations of catechol, however, there was observed a decrease in rate, which may be due to the function of higher complexes of catechol with Fe^{3+} that is less reactive than the 1:1 complex. It has been postulated by Hamilton[4a] and has hitherto been cited in the literature and books[4b] that the reaction involves an *o*-quinone–iron oxide complex (**1**), which serves as an active oxidant to form a reactive intermediate **2**.

2

Recently, Richter and Waddell[5] have reported the evidence of a radical chain mechanism for the hydroxylation of a substrate, benzoic acid, with H_2O_2 in the presence of catalytic iron ion and 5-methyldihydrophenazine (H_2O_2/Fe^{3+}/MPH system) and have proposed the mechanism essentially resembling the classical Fenton reaction except that the new system requires the organic mediator (5-methyldihydrophenazine) to get the oxidized catalyst metal back to its original state. Thus, they classified this new system as the nonclassical Fenton system together with the Hamilton system. However, the mechanism for the Hamilton hydroxylation system is not yet perfectly understood, since no convincing evidence has been given; in particular, the functional roles of a catechol have not been exactly determined. In an attempt to find a mechanistic version of this reaction, we have replaced ordinarily used catechol by disodium catechol-3,5-disulfonate (tiron) which seems better suited for the mechanistic study of the Hamilton system with twofold reasons. (1) It is a bidentate ligand to form a deep blue Fe^{3+} complex, relatively far stable compared to the complex of catechol in a reaction pH range 2.0—3.5 and (2) it shows remarkable resistance to oxidative destruction during the reaction due to its bearing the aromatic ring highly substituted with two strongly electronegative sulfonato groups.

Experimental

Materials: Substituted catechols were commercially available as special grade and used without further purification.

Hydroxylation of Benzene: The hydroxylation were generally perfomed at ambident temperature in an aqueous solution of pH 3 adjusted with H_2SO_4 under nitrogen. A standard reaction was carried out in a two-phase system of H_2O (50 ml) and benzene (1 ml), containing $Fe_2(SO_4)_3$ (0.05 mmol) and tiron (0.1 mmol). Benzene was used in excess to minimize the further oxidation of product phenol. H_2O_2 (0.5 M, 2 ml, 1 mmol) was then added to the solution all at once. The mixing was performed with a mechanical shaker for 2.5 h. Analysis of products was done according to those described in the previous paper.[6] In any case, phenol

was obtained as the major product. No appreciable amount of by-products such as biphenyl, catechol, and quinone (if any, less than 1%) was detected. All the phenol yields were based on H_2O_2 added. Under the standard conditions the phenol yield was 38%.

Kinetics: The rate of decomposition of a Fe^{3+}-catechol complex in water was determined as follows: The equal volumes of the stock solutions of Fe^{3+} and a catechol (8×10^{-4} M each) was pipetted out and placed into a UV cell and the disappearance of the blue color due to the complex (λ_{max} shown in Table 1) was monitored with a Hitachi 220 spectrometer. The k_{obs} thus obtained was also listed in the third column of Table 1.

Table 1. Absorption Maximum and Redox Reaction Rate for Catecholate-Fe^{3+} Complexes (pH 3.0, 25 °C)

Catechol	λ_{max}/nm	k/min^{-1}
	660(ε=1780)	0.018
	660	0.075
	650	0.14
	720	9.1
	720	too fast

Conditions: [Fe^{3+}], 4×10^{-4} M; [catechol], 4×10^{-4} M.

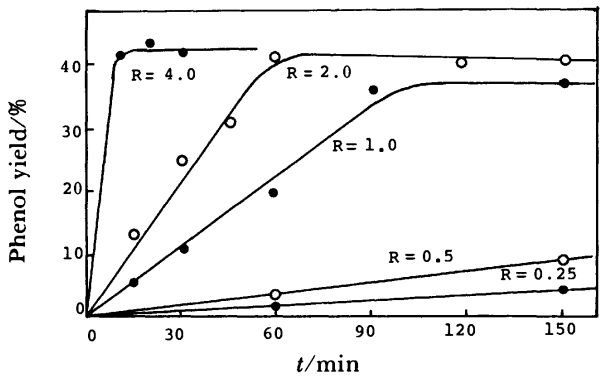

Fig. 1. Yield vs. time profile at varying [Fe^{3+}]/[tiron] ratio. R=[Fe^{3+}]/[tiron]. [Fe^{3+}]=2×10^{-3} M.

Results and Discussion

Time Course of Hydroxylation: First, the time courses for the hydroxylation were determined at varying mole ratios of Fe^{3+} to tiron, keeping the Fe^{3+} concentration fixed. Figure 1 shows the results. The yield of phenol increases linearly with time, indicating zero-order dependence of the rate on H_2O_2 concentration. Thus, H_2O_2 is not involved in the rate-limiting step.

Furthermore, a comparison of the rates at different mole ratios of Fe^{3+}/tiron, keeping the concentration of the Fe^{3+} constant, shows that the reaction at the ratio of 0.5 runs slower than that at 2.0, in spite of formation of a two-fold amount of the complex in the former; namely, the rate is independent of the quantities of the complex formed in solution, clearly demonstrating that, as opposed to the suggestion of Hamilton,[3] the Fe^{3+}-catechol complex itself can not be an active catalyst.

Effect of Fe^{3+}/Tiron Ratio on Phenol Yield. The effect of altering ratios of Fe^{3+}/tiron on the phenol yield was examined. The results are illustrated in Fig. 2. A plot of the phenol yield versus the mole ratio produces the characteristic sigmoidal profile; the phenol yield is quite low (<10%) in the ratio range below unity. This is not a result of formation of a lot of by-products but a result of no reaction, since the consumption of H_2O_2 was not observed.

The phenol yield begins to steeply rise as the ratio being close to unity, and then finally approaches a limiting value 40% when a slight excess of Fe^{3+} relative to tiron is added, suggesting that free Fe^{3+} is required for the activation of the catalyst system. As mentioned in the introductory section, tiron binds with Fe^{3+} to form only a 1:1 stable complex with an equilibrium constant $K\fallingdotseq10^4$ M^{-1} rather than highly coordinated Fe^{3+} complexes even at a large excess of tiron over

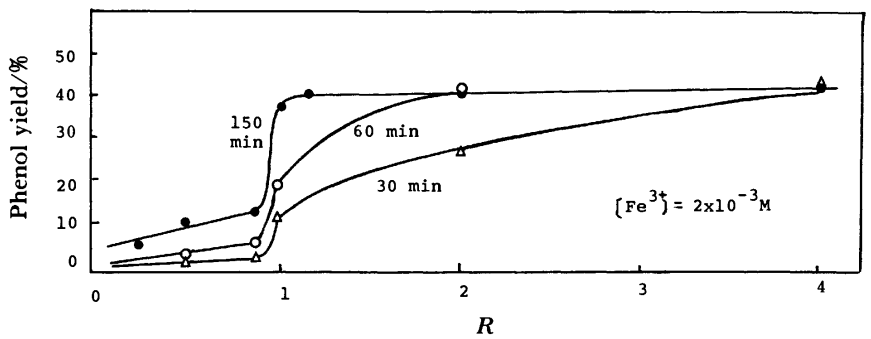

Fig. 2. Plots of phenol yield vs. [Fe^{3+}]/[tiron]. Reaction time: 30 (△); 60 (○); 150 min (●).

Fe^{3+} concentrations. Therefore, addition of an slight excess (less than 1.5 fold) of tiron brings about the complete lack of free Fe^{3+} in solution and would thus remarkably depress the phenol yield.

Kinetics of Tiron Oxidation with Fe^{3+}: In order to confirm further the above conclusion, the oxidation of tiron with iron(III) was kinetically examined at an Fe^{3+}/tiron mole ratio (R) of 1:1 by monitoring the disappearance of the absorption band of the tiron-Fe^{3+} complexes, holding the tiron concentration constant. The rate constants thus obtained are plotted as a function of R. Figure 3 shows those results. The rate is dependent on the ratio in the same characteristic fashion as observed in the benzene hydroxylation. That is, the reaction is extremely slow in the ratio range less than unity, while very fast in the range larger than unity. In the latter range, in particular, the rate increases linearly with increasing Fe^{3+} concentrations, explicitly demonstrating that an excess of Fe^{3+} over tiron is essential for the tiron oxidation as well as for the hydroxylation, and hence these two reactions commonly involve the oxidation of tiron by uncomplexed Fe^{3+} leading to a semiquinone and then to a quinone.

In Table 1 are listed the λ_{max} values of the complexes

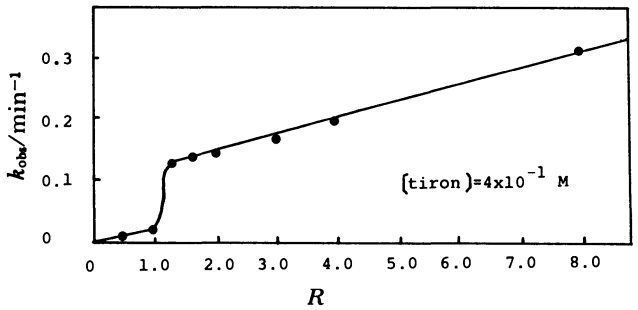

Fig. 3. Plot of the rate of the complex decomposition vs. $[Fe^{3+}]/[tiron]$. Varying concentrations of Fe^{3+} (0—3.2×10^{-3} M) in unbuffered solution (pH 3) changed the reaction pH from 3.0 to 2.6. In a separate experiment, however, such a pH change had no significant effect on the rate. Therefore, the solution was not buffered here. Rate/min^{-1} (pH): 0.14 (3.05); 0.151 (3.00); 0.148 (2.91); 0.150 (2.75); 0.145 (2.5); 0.104 (1.9); 0.060 (1.7).

due to the catecholate-to-Fe(III) charge-transfer band along with the rate constants for disappearance of their absorption bands (650—720 nm depending on catechols) at a 1:1 Fe^{3+}/catechol ratio.[7] The substitution of electron-donating groups on the catechol ring resulted in a red shift of the CT band and acceleration of the rate, as would be generally expected for oxidation reactions, while the electron-withdrawing ones decelerated the rates. Of these catechols studied here, tiron was the most stable with regard to its oxidation reaction.

Table 2 provides further evidence for the mechanism of tiron oxidation, i.e., the preequilibrium formation of the semiquinone, followed by the rate-determining semiquinone oxidation. According to this mechanism, an increase of Fe^{2+} in the reaction solution would move the equilibrium to the left, which should be attributable to the common ion effect of Fe^{2+} ion on the catechol-semiquinone preequilibrium. In fact, addition of foreign Fe^{2+} ion to the reaction system resulted in marked rate drop.

Baxendale et al.[8] undertook the kinetic study of the reaction between Fe^{3+} and catechol in detail and observed the deviation (Eq. 1) from the second-order kinetics attributable to the reverse reaction of Fe^{2+} with an intermediate. A mechanism (Scheme 1) involving a preequilibrium formation of the semiquinone intermediate was proposed there.

Scheme 1.

***o*-, *m*-, and *p*-Products Distribution.** In order to understand the nature of hydroxylating species, the *o*-, *m*-, and *p*-isomer distributions in phenols derived from a few aromatics were examined under various conditions. The results are summarized in Table 3. The hydroxylating species generated from the present system reacts with phenylacetic acid and anisole to afford *o*-, *m*-, and *p*-hydroxyphenylacetic acids and anisoles with isomeric distributions of 49:29:22% and 82:8:10%, respectively.

Meanwhile, use of the modified Fenton reagent,[9] consisting of H_2O_2 and a stoichiometric amount of Fe^{2+} in the presence of Cu^{2+}, afforded 47:30:23 and 87:3:10%, respectively. The Fenton reagent has been established to produce hydroxyl radicals as the reactive hydroxylating species.[9] Therefore, a close parallelism between tiron and Fenton's systems in the patterns of isomeric distributions strongly supports that OH

radicals are reactive species common to these two hydroxylations.

Mechanism. The kinetic and yield data presently available are accounted for by the following reaction sequence in which elemental steps 1—5 combine to form an overall catalytic cycle. (Scheme 2)

The similarity in shape of the curvatures obtained on the hydroxylation (Fig. 2) and the redox reaction (Fig. 3) clearly indicates that both reactions take place through the same sequence up to the rate-determining step of the reaction. As Fig. 3 shows, the pseudo-first-order rate constant, k_{obs}, increases linearly with increasing [Fe^{3+}] in the range of the [Fe^{3+}]/[tiron] ratio>1, supporting that there is the reversible breakdown of the Fe^{3+}–tiron complex, yielding one semiquinone radical and one Fe^{2+} (1b), then followed by rate-determining attack of a second Fe^{3+} on the semiquinone radical, giving an *o*-quinone and Fe^{2+} (1c). The reversibility of step 1b is substantiated further by the observation of the common ion effect of foreign Fe^{2+} ions on the rate of the step 1b. The step 1c must be more rapid than the disproportionation of the semiquinone radical to the corresponding quinone and catechol (5), because the breakdown of the complex needs a second Fe^{3+}.

Fe^{2+} so formed triggers the Fenton reaction to yield an OH radical, immediately followed by steps 3 and 4, in which the OH radical attacks an aromatic ring giving rise to 1-hydroxycyclohexadienyl radical at a rate of almost diffusion control (10^{10} M^{-1} s^{-1}) and then the hexadienyl thus formed is oxidized by a quinone to phenol. The finding that quinones are good oxidants for such carbon radicals was reported by Steenken and Raghavan;[10] they estimated the rates of electron transfer between 1-methoxy-2-, 3-, and 4-hydroxycyclohexadienyl radical and *p*-benzoquinone to be 1.2×10^9, $<8\times10^5$, 4.4×10^9 M^{-1} s^{-1}, respectively. Thus, quinones are reduced back to the semiquinones or further to hydroquinones before the cyclohexadienyl radicals bimolecularly collapse to biphenyl, a coupling product. Actually, in sharp contrast to the original Fenton system, the present system gave no appreciable amount of biphenyl to be detected by HPLC analysis. The lifetime of an intermediate carbocation thus produced is $<1\times10^{-6}$ s[10] and hence phenol may be formed synchronously with the reduction of *p*-benzoquinone.

Meanwhile, the data of Table 4 shows that the isomer distribution is not appreciably affected by the presence

Table 3. Isomer Distributions in Phenolic Products from Phenylacetic Acid and Anisole

Catechol	Total yield %	*o*	*m* /%	*p*
Anisole				
(a) Tiron	9.4	82	8	10
(b) Catechol	18.4	67	3	30

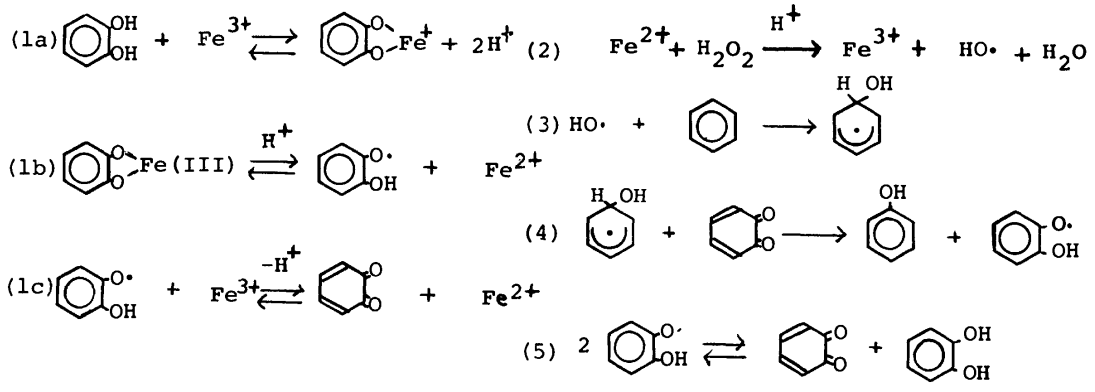
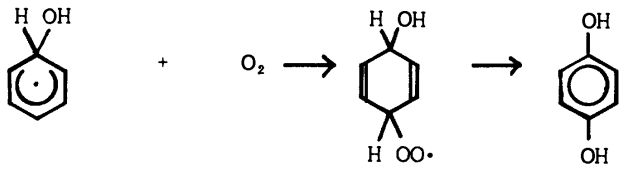
a) Tiron, 0.1 mmol; Fe^{3+}, 0.1 mmol; H_2O_2, 1.0 mmol; benzene, 2 ml; H_2O, 50 ml. b) Conditions were the same as a), except the substrate (1 mmol of methyl phenylacetate).



Scheme 2.

or absence of air. Under such a relatively low oxygen pressure the hexadienyl radical is more quickly oxidized to phenol than trapped by molecular oxygen. On the contrary, replacing air for the atmospheric pressure of oxygen considerably depressed the phenol yield more than 20%. This yield depression indicates the occurring of a concomitant irreversible trapping by molecular oxygen of the hexadienyl radical giving an intermediate 4-hydroxy-2,3-cyclohexadienylperoxyl radical, which would terminate the radical chain cycle; formation of such an intermediate in metal-catalyzed aromatic hydroxylation under an oxygen atmosphere was reported elsewhere.[11]



Thus, the overall mechanistic picture for the tiron system and related systems are basically similar to that for the MPH/Fe^{3+}/H_2O_2 system reported by Richter and Waddell. A catechol displays dual functions as a reductant toward Fe^{3+} and as an oxidant toward a 1-hydroxycyclohexadienyl radical through shuttling between catechol and quinone.

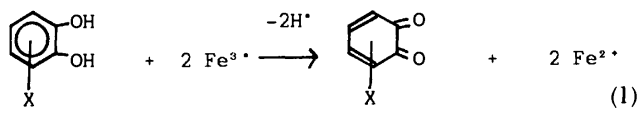
Fe(III)-Catalyzed Aromatic Hydroxylation with H_2O_2 in the Presence of a Variety of Electron-Transfer Agents

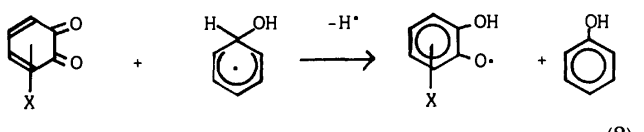
Seizo TAMAGAKI, Masaaki SASAKI, and Waichiro TAGAKI*
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3, Sumiyoshi-ku, Osaka 558
(Received August 4, 1988)

Electron-transfer agents such as *N,N,N',N'*-tetramethylphenylenediamine (TMPD), ferrocenes, and phenothiazines have been found to mediate the hydroxylation of benzene with H_2O_2 in the presence of Fe^{3+}. Of these, TMPD catalyst is the most effective to provide phenol in 80% or better yield based on added H_2O_2 under the optimized conditions. A general mechanism, involving the rate-determining reduction of Fe^{3+} to Fe^{2+} with such mediators, is suggested.

Since the initial report of Udenfriend,[1] many workers have studied the scope and mechanism of a number of non-enzymic hydroxylation systems, described by Udenfriend, Grinstead,[2] Hamilton,[3] and Ullich.[4] Richter and Waddell[5] studied the decomposition of H_2O_2 and hydroxylation of benzoic acid in the presence of catalytic Fe^{3+} and 5-methyldihydrophenazine (MPH) and have proposed that the oxidant inducing the aromatic hydroxylation is the hydroxyl radical produced in an iron-catalyzed one-electron reduction of H_2O_2. The rate was found to be expressed as $-d[H_2O_2]/dt=k[MPH]([Fe^{3+}]+\alpha)$. Recently, we have also shown that catechol-3,5-disulfonate, a substitute for catechol (CT), mediates electron transfer in the catalytic hydroxylation. Most of the phenomenon appears to be accounted for by the general features proposed by Richter and Waddell. The rate-determining step has been confirmed to be the redox reaction of Fe^{3+} with the catechol (Eq. 1), and the quinone or semiquinone thus formed is used to oxidize the 1-hydroxycyclohexadienyl radical intermediate (**8**) to phenol (Eq. 2). The catechol displays dual functions as a reductant toward Fe^{3+} and as an oxidant toward 1-hydroxycyclohexadienyl radical through shuttling between catechol and quinone.



(1)



8 (2)

A set of these hydroxylating systems, referred to as a nonclassical Fenton reaction, have been suggested to commonly require catalytic electron-transfer agents (mediators) to return the oxidized Fe^{3+} to its reduced state.[5] However, only a limited number of mediators have been recognized so far; of these, the reduced 5-methylphenazinium cation has frequently been utilized in biological studies. The use of catechols has been reported by Hamilton[3] and by us.[6] We have recently reported 1,2-naphthoquinone-4-sulfonate to mediate the aromatic hydroxylation with H_2O_2 to produce phenols in 40% yields.[7]

In order to fully understand these hydroxylations, we consider it of interest to extend our studies to other new mediators. In this paper we present the results of a thorough kinetic study of the mediator-dependent hydroxylations.

Experimental

Materials. TMPD (**1**), (dimethylaminomethyl)ferrocene (DAMF, **2**), catechol (CT, **3**), hydroquinone (HQ), promethazine (PMZ, **4**), phenothiazine (PTZ, **5**), Methylene Blue (MB, **6**), thianthrene, *N*-methylacridinium iodide and ascorbic acid (AsH_2, **7**) were all commercially available as special grade and used as received. 10-Methyl-9,10-dihydroacridine (MDA) and the reduced Methylene Blue were prepared by the reduction of *N*-methylacridinium iodide and Methylene Blue, respectively. Moreover, 1,3,10-trimethyl-1,5-dihydroisoalloxazine (TMDIA) were synthesized according to the method described in the literature.[8]

5 **6** **7**

Hydroxylation of Benzene. A standard hydroxylation procedure was effected as follows: Fe^{3+} (0.01 mmol, 0.2 mM; 1 M=1 mol dm^{-3}), an appropriate organic mediator (0.01 mmol, 0.2 mM), and benzene (1 ml) were added to 50 ml of H_2O adjusted with H_2SO_4 to pH 3. The air in the vessel was purged with nitrogen gas, and H_2O_2 (1 mmol, 2 mM) was

then added all at once. After mechanical shaking for 2.5 h, the solution was thoroughly extracted with ether and then the amount of phenol in the ether was determined with HPLC using anisole as an internal standard at 270 nm. The product yields are all based on an added amount of H_2O_2. When the yield was less than 5%, the reaction was examined again by increasing the amounts of Fe^{3+} and/or the mediator each ten-fold to obtain convenient rates. The results thus obtained are collected in Tables 1—5 along with Fig. 1.

Kinetics of the Reaction between Organic Mediator and Fe^{3+}. For the very fast redox reaction, the reaction rate was determined with a stopped flow apparatus with two mixing chambers (Union Giken Model RA 401) by monitoring the appearance of the absorption of the final products (radical cations), namely, at 610 nm for TMPD and at 615 nm for DAMF.[9] For PMZ having a relatively slow rate, a Hitachi 220 spectrophotometer equipped with temperature-controlled cell-holders was used to monitor the appearance of an increasing absorption at 513 nm. The initial concentrations of TMPD and DAMF were 5×10^{-5} and 1.25×10^{-4} M, respectively. The concentrations of Fe^{3+}(as $Fe_2(SO_4)_3$) were changed in the range 2.5—25×10^{-4} M, depending on mediators.

Isomer Distribution. The hydroxylation procedure was as usual except for employing methyl phenylacetate instead of benzene; conditions: TMPD, 0.01 mmol; Fe^{3+}, 0.01 mmol; H_2O_2, 1 mmol; methyl phenylacetate, 1 mmol in 50 ml of H_2O (pH 3) at 25 °C. The products were analyzed by using HPLC (Nihon Bunko Uniflow-221) with Packed Column SS-05 eluted with hexane/methyl acetate/methanol 9:1:1 at 290 nm. *o*-Methoxyphenol was an internal standard.

Results

It is clear from Table 1 that the optimum pH is about 3, just similar to that for the catechol-catalyzed hydroxylation reported previously by Hamilton.[3]

Table 2 shows that thianthrene, 10-methyl-9,10-dihydroacridine (MDA), ascorbic acid (AsH_2), and a pteridine are all ineffective even at a high level (2 mM) of catalyst concentrations. On the other hand, TMPD, DAMF, and CT work well even at a low level (0.2 mM) of these concentrations. The reaction solutions are

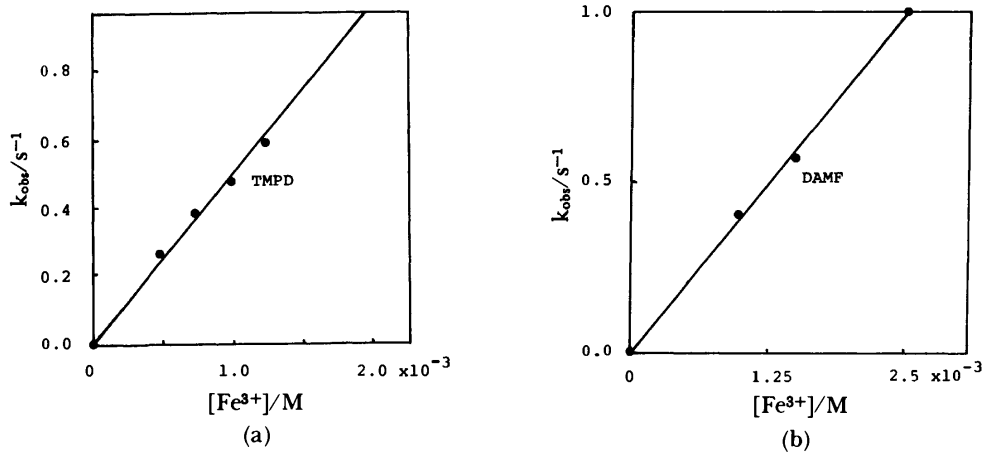

Fig. 2. Effect of concentration of Fe^{3+} on the redox rate. For reaction conditions, see text.

very clean and the formation of neither appreciable amount of by-products such as biphenyl and hydroquinone (<1%) nor dark deposit was observed. These mediators are at least an order of magnitude more active than TMDIA, PMZ, and PTZ. Figure 1 illustrates the profiles of the time courses of the reactions. Thus, the mediator dependency of the hydroxylation rate is obvious. The rate follows the order: TMPD>DAMF>CT>HQ>TMDIA>PMZ=PTZ. The phenol yields are found to increase linearly with reaction time and reach a limiting value irrespective of changing mediators. This linearity indicates that H_2O_2 is not involved in the rate-determining step of the reaction.

The highest reactivity of TMPD seems to be due to the fast redox reaction between Fe^{3+} and TMPD giving rise to Fe^{2+} and the TMPD radical cation. In order to ascertain this speculation, the kinetic experiments on the reaction of Fe^{3+} with TMPD and some other mediators was done under pseudo-first-order conditions in the presence of a 10-fold excess of Fe^{3+} in unbuffered aqueous solution of pH 2.5 at 25 °C by means of a stopped flow apparatus. In every case examined, the reaction is first-order with respect to each reactant and obeys strictly bimolecular kinetics; only representative data are shown in Fig. 2 and the second-order rate constants are given in Table 3. The rate is obviously mediator-dependent and follows the order: TMPD>DAMF>CT>HQ>PMZ. With regard to these effective mediators, this dependency clearly parallels the rate order for the hydroxylation, unambiguously indicating that the reduction of Fe^{3+} to Fe^{2+} takes place in the rate-determining step in these

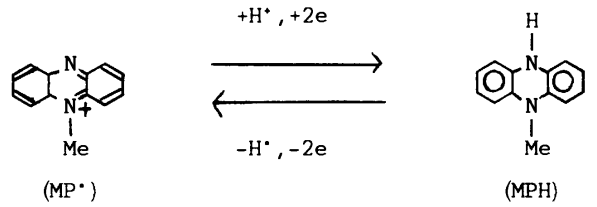
hydroxylation reactions.

Meanwhile, addition of 1,10-phenanthroline, 2,2′-bipyridine, and EDTA, typical metal-chelating agents, in an excess over Fe^{3+} completely inhibited the progress of both the redox and the hydroxylation reactions, but pyridine and quinoline only slightly did it (Table 4). The implication is that the strong complexation of Fe^{3+} with, for example, EDTA leads to substantial lowering of the reduction potential of ferric ion from +0.7 to +0.17 (pH 4),[10] so that the redox reaction in question might not occur. Actually, in the presence of EDTA, no consumption of H_2O_2 was observed. The details will be discussed later.

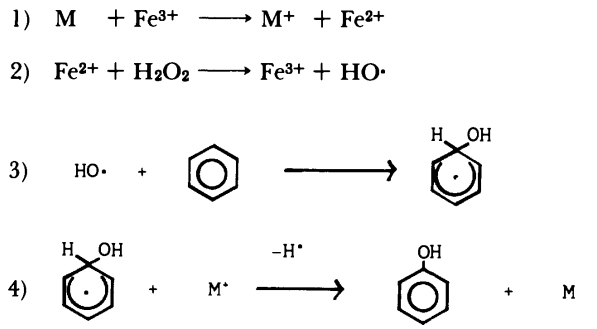
In order to further elucidate reaction mechanisms whether OH radicals are formed, an examination of isomer distributions in the product phenols was carried out. In Table 5 are compared the *o*-, *m*-, and *p*-isomer distibutions for the present hydroxylating systems with that for the Fenton system. Methyl phenylacetate was the substrate. These *o*-, *m*-, and *p*-distributions are roughly the same for all mediators although far from a statistically random distribution of 2:2:1, supporting the occurrence of the hydroxyl radical as the reactive oxidant.

Discussion

The kinetic and yield data available could be accounted for by the essential steps 1)—4), as illustrated in Scheme 1, which combine to form a catalytic cycle; 1) the rate-determining reaction between Fe^{3+} and a reduced mediator giving Fe^{2+} and the corresponding oxidized mediator. 2) The production of an OH radical by the reaction of H_2O_2 with Fe^{2+}, followed by the subsequent phenol-forming steps 3) and 4) which include the 1-hydroxycyclohexadienyl radical as the key intermediate. Since TMPD and DAMF have no labile proton, Scheme 1, unlike the reaction mechanism proposed by Richter and Waddell, involves no protonation and deprotonation events accompanying the redox reaction; for example,



Scheme 1.



(M denotes an organic mediator in the reduced state.)

As can be seen from Table 2, MDA and AsH_2 are catalytically inactive. The two-electron redox potentials of MDA^{2+}/MDA (0 V) and dAs/AsH_2 (+0.17 V at pH 4; +0.06 V at pH 7)[10,11] are negative enough to reduce Fe^{3+}; nevertheless, those potentials seem to be too low to oxidize the 1-hydroxycyclohexadienyl radical to phenol. As for MDA, therefore, the one-electron oxidation by MDA^{2+} of the 1-hydroxylcyclohexadienyl redical (step 4) seems to be endothermic. The same argument can be given for catalytically inactive anthraquinonesulfonates[7] bearing a relatively low potential ($E°<-0.1$ V).[10,12] However, there is another explanation for the inactivity of ascorbic acid; dehydroascorbic acid (dAs) exists in hydrated form as the 2,3-bis-(gem-diol) in aqueous solution, which has no ability to oxidize the 1-hydroxycyclohexadienyl radical.

PMZ has a rather low activity, because it has a higher one electron-oxidation potential ($E°$=+0.86 V at pH 7)[13] than Fe^{3+}/Fe^{2+} couple ($E°$=+0.771 V; +0.74 at pH 3); hence, the reaction between Fe^{3+} and PMZ (step 1) is slightly endothermic. The lack of catalytic activity of thianthrene is due probably to the same reason.

Meanwhile, an organic mediator which possesses a redox potential somewhere between the $E°$ values of the Fe^{3+}/Fe^{2+} and 1-hydroxycyclohexadienyl radical/phenol couples, particularly, in the favorable range of about +0.2 and about +0.6 V, is quite effective. TMPD (+0.27 V), DAMF (+0.44 V), CT(+0.55 V), and HQ (+0.46 V)[13] meet well this requirement. These reactions follow the same mechanistic pattern. In addition, the oxidation potential of the 1-hydroxycyclohexadienyl radical is roughly estimated to lie somewhere between +0.1 and −0.1 V. Electrochemical potentials of various redox pairs are summarized in Fig. 3.

The effect of metal-chelating agents is quite interesting. The hydroxylations were inhibited by the addition of EDTA and 1,10-phenanthroline (Table 4) and no consumption of H_2O_2 was observed in both cases. However, the mechanistic features of the inhibition appear to be different with each chelating agent, because the redox potentials of iron–EDTA and iron–phenanthroline differ much: Since a redox potential of the iron–EDTA complex is far low compared to that of the standard Fe^{3+}/Fe^{2+} couple, the complexation with EDTA stabilizes the Fe(III) rather than Fe(II) state and thus would stop the progress of the Fe(II) formation (step 1). On the contrary, 1,10-phenanthroline complex (+1.03 V) stabilizes the Fe(II) rather than Fe(III) state to inhibit the generation of the OH radical (step 2). The hydroxylation in the presence of metal-chelating agents has been investigated by many workers.[14] Their roles have received much attention, but has not yet been fully understood and further studies will be needed.

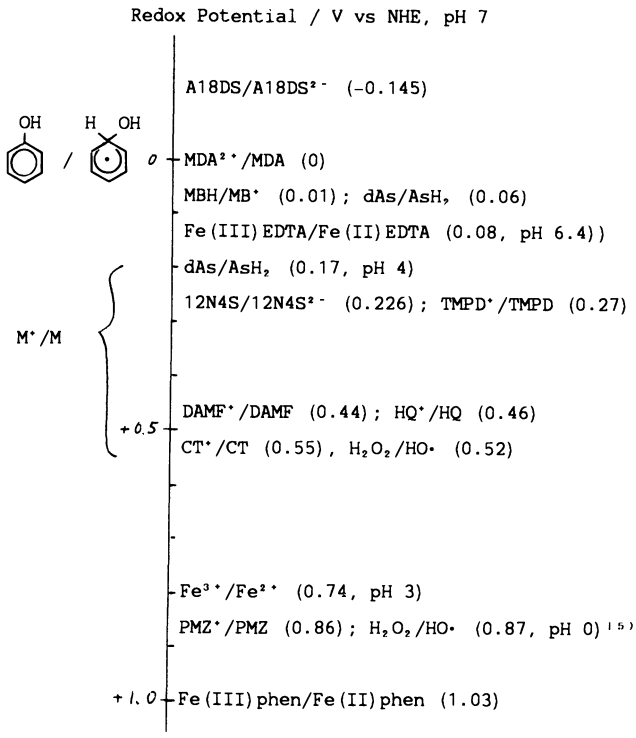


Fig. 3. Redox potentials (Volt vs. NHE, pH 7).

Table 6. Effect of Amounts of Benzene and H_2O_2 on Phenol Yield with $Fe^{3+}/TMPD/H_2O_2$

Benzene/ml	H_2O_2/mmol	Phenol yield/%
1	1	41.7
5	1	49.7
10	1	50.4
20	1	48.8
5	0.5	64.4
5	0.25	70.6
5	0.125	80.9

Reaction conditions: TMPD, 0.01 mmol; Fe^{3+}, 0.01 mmol; pH 3, 25 °C.

$$\underset{E°(V)\ 1.03}{\text{Fe(II)phen}} + H_2O_2 \xrightarrow{H^+,\ -H_2O} \underset{0.87}{\text{Fe(III)phen}} + HO\cdot$$

Finally, it is worth mentioning that, under the standard conditions, as Fig. 1 shows, the phenol production reaches about 40% regardless of used mediators. Although we can not offer a conclusive explanation for this observation, it should be noted, however, that the final phenol yield is substantially dependent on the initial concentration of added H_2O_2. Actually, as inspection of the data of Table 6 reveals, the TMPD-catalyzed reaction affords phenol in more than 80% yields, when, in order to maximize the conversion of H_2O_2 to phenol by minimizing further oxidation of product phenol and side reactions of H_2O_2, a five-fold excess of benzene and an eight-fold decreased amount of H_2O_2 were employed. Obviously, the presence of too much H_2O_2 is the major cause to decrease the phenol yield. Perhaps, a reaction shown below effectively competes with Reaction 3. It is well-known that the hydroperoxy radical will not participate in the hydroxylation of aromatic hydrocarbons.

$$H_2O_2 + HO\cdot \longrightarrow HOO\cdot + H_2O$$

Use of less Fe^{3+} improves the yield but only slightly. To our knowledge, more than 80% yield is the highest yet attained in the hydroxylations of unactivated aromatic hydrocarbons by hydroxyl radicals.

The Catalytic Role of a Flavin Analogue for Aromatic Hydroxylation with the Udenfriend System

Seizo TAMAGAKI, Masaaki SASAKI, and Waichiro TAGAKI*
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3, Sumiyoshi-ku, Osaka 558
(Received August 11, 1988)

A new combination of the Udenfriend reagent and a flavin analogue was found to hydroxylate benzene to phenol. Effects of temperature and concentrations of reaction components, i.e., iron(II), flavin, and ascorbate, on the phenol yield were examined. In particular, decreasing ascorbate concentration increased the yield of phenol. Thus, 68% of the yield was obtained under better conditions. The mechanism of action of ascorbic acid and the flavin was discussed.

The Udenfriend system (Fe^{2+}/EDTA/ascorbate/O_2),[1] a model peroxidase, is a general method for the addition of a hydroxyl group into an aromatic substrate. Grinstead has examined the hydroxylation of benzoic and salicylic acids and has suggested a chain mechanism in which a hydroxyl radical is the reactive species that takes part in hydroxylation.[2] The reaction is relatively mild compared to other methods,[3] and the products obtained with the Udenfriend system in vitro are identical with that from the same compound in vivo. From a biomimetic or mechanistic viewpoint, the Udenfriend and related systems are still worthy of further investigations.[4]

Nevertheless, these systems usually afford only 3 to 25% yields depending on the substrate, the metal ion, and the complexing agent. Particularly, the hydroxylation of benzene gave rise to only less than 5% yield of phenol even under better conditions. This suggests that the Udenfriend system itself has yet a critical disadvantage of electron accepting/transferring relay in the catalytic cycle.

We report here that the 1,10-ethanoisoalloxazinium cation (a flavin analogue **1**)[5] markedly enhances the catalytic efficiency of the Udenfriend system. In this work, benzene was selected as a diagnostic substrate and for ease of the quantitative analysis of the product phenol.

Experimental

Materials. EDTA, ascorbic acid, 1,10-phenanthroline, iron(II) sulfate were purchased from commercial suppliers and used without further purification. Flavins (**1**—**4**) were prepared by literature procedures.[6]

Hydroxylation. The standard hydroxylation was performed in a benzene (1 ml)-water (50 ml) two-phase system, containing 2 mM (1 M=1 mmol dm^{-3}) of Fe^{2+}, 2 mM of **1**, and 20 mM of ascorbic acid, at 50 °C under constant bubbling of oxygen through two needles with mechanical shaking. The pH of the reaction medium was initially adjusted to 3.0 with H_2SO_4. As the rate of the reaction is slow compared to dissolution of oxygen, the solution was assumed to be saturated with oxygen at all times. Benzene in excess of saturation was employed to keep the benzene concentration in the aqueous layer constant. The amount of phenol produced was determined with HPLC by using anisole as an internal standard as described previously.[7] All the percent yields are based on the added amount of ascorbate. Under the standard conditions (90 min), the yield was 31.0%. The results thus obtained are summarized in Figs. 1—4 and Tables 1—3. Unlike the original Fenton

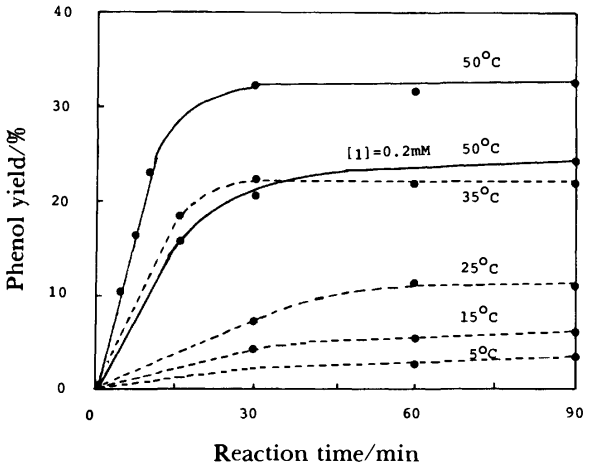

Fig. 1. Time courses of hydroxylation with Fe^{2+}/**1**/AsH_2/O_2.
Conditions: Fe^{2+}(2 mM)/**1**(2 mM)/AsH_2(20 mM) under O_2 at pH 3.

system, no biphenyl was detected by HPLC analysis in any cases. However, 10% of hydroquinone was produced.

Kinetics. The rate of reaction of **1** with ascorbic acid under N_2 at 25 °C was followed by the disappearance of the absorption peak due to **1** (λ_{max} 365 nm; ε 13500 in H_2O). Typical UV traces are shown in Fig. 5.

Results and Discussion

Figure 1 depicts the time plots for the benzene hydroxylation with the Fe^{2+}/**1**/ascorbic acid/O_2 system at various temperatures. The reaction is strongly temperature-dependent, and the phenol yield increases steadily with reaction time and reaches a limiting value at each reaction temperature. Table 1 compares the effect of changing structures of flavins on the yield under the standard conditions. The phenol yield for unblocked flavin **4** is only 1.1% and as poor as that for the control reaction in the absence of any flavins. On the other hand, flavin **1**, blocked with an ethano bridge at N-1 and N-10, afforded more than 30% yield. Further blocking at N-5 position (**2**) is far less effective than is the blocking at N-1 and N-10. Hemmerich and Massey[8] have studied the flavin-dependent molecular oxygen activation and have concluded that: (1) the more planar is the structure of a flavin molecule, the greater the reactivity toward O_2, (2) the substitution of 5-position with an alkyl group lowers the catalytic activity. On the basis of these criteria, the catalytic activity is expected to be in the order, **1**>**2**>**3**, just as was observed here.

A mechanism shown in Scheme 1 can be tentatively proposed for this reaction on the basis of this and other research. There are two catalytic cycles in the sequence; one is for the generation of hydrogen peroxide (Reactions 1, 2), the other for the production of phenol (Reactions 3—6). Although this mechanism is basically analogous to that previously reported for the nonclassical Fenton reaction (Fe^{3+}/MPH/O_2/NADH system),[9] the role of ascorbic acid (AsH_2) is somewhat different from that of NADH which has been proposed to reduce solely 5-methylphenazinium cation (MP^+). The details will be discussed later. In this mechanism, we presume the catalytic function of a flavin as follows; its fully reduced form (Fl_{red}) would be involved in formation of H_2O_2 from molecular oxygen via Reaction 2, while the oxidized form (Fl_{ox}) would be involved in phenol formation via Reaction 6 in which Fl_{ox} is converted to Fl_{sem} by abstracting one electron from the 1-hydroxycyclohexadienyl radical (**5**). The carbon cation thus formed is converted into phenol immediately after its formation (Reaction 6).[10] The Fl_{ox} could be reconverted to Fl_{red} either via disproportionation of Fl_{sem} (Reaction 7) or reduction with ascorbic acid (Reaction 1).

Thus, the lack of catalytic activity of unblocked flavin **4** is explained by its lower redox potential than that of ascorbic acid; hence, Reaction 1 is substantially endothermic. An altenative explanation may be possible. Reaction 6 would be also too endothermic to propagate the radical chain reaction, for the redox potential of **4** (Fl_{ox}) was estimated to be much lower than that of the hexadienyl radical.[7]

$$Fl_{ox} + AsH_2 \underset{(0.5)}{\overset{-H^+}{\rightleftharpoons}} Fl_{red}^- + dAs \quad (1)$$

$$Fl_{red} + O_2 \xrightarrow[(10^3)^{6)}]{+H^+} Fl_{ox} + H_2O_2 \quad (2)$$

$$2\,Fe(III) + AsH_2 \xrightarrow[(10^2)^{2)}]{-2\,H^+} 2\,Fe(II) + dAs \quad (3)$$

$$Fe(II) + H_2O_2 \xrightarrow[(50)^{13)}]{+H^+} Fe(III) + HO\cdot \quad (4)$$

Table 1. Hydroxylation of Benzene by Fe^{2+}–AsH_2–O_2 in the Presence of Various Flavin Analogs[a]

Flavin	Phenol yield/%[b]
None (Udenfriend's conditions)	1.1
1	31.9
2	7.1
3	16.2
4	1.8

a) Conditions: Fe^{2+}(2.0 mM)/flavin(2.0 mM)/AsH_2(20 mM); reaction pH 3, 50 °C under O_2 for 90 min. b) Phenol yield based on added AsH_2.

In order to obtain better yields of phenol and to establish the reaction mechanism further, studies of variation of pH and concentrations of reaction components such as iron(II), flavin **1**, and ascorbic acid, and of effect of coordinating additives were performed. As **1** was found to be the most effective of all flavins at pH 3 (Table 2), only **1** was used for

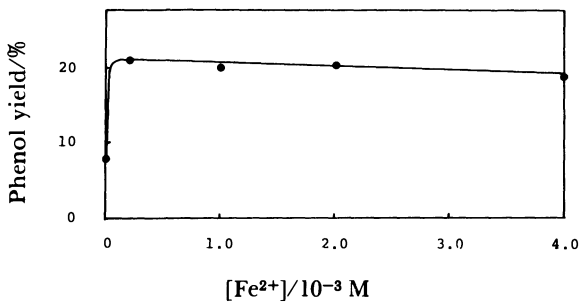

Fig. 2. Effect of Fe^{2+} concentration on phenol yield. Conditions: **1**(2 mM)/AsH_2(20 mM) under O_2 at pH 3 for 90 min.

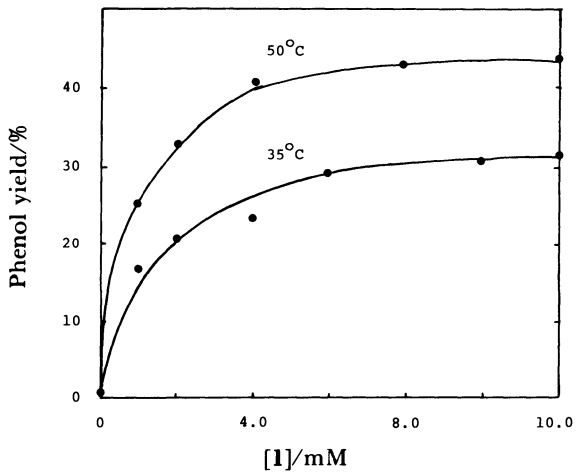

Fig. 3. Effect of concentration of **1** on phenol yield. Conditions: Fe^{2+}(2 mM)/AsH_2(20 mM) under O_2 for 90 min.

Table 2. Dependence of Phenol Yield on Reaction pH

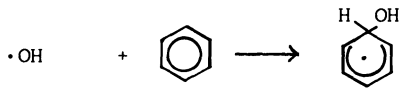
pH\Flavin	Yield/%		
	1	**2**	**3**
1	23.3	6.0	24.0
3	31.9	7.1	16.2
5	11.8	2.6	9.2

Conditions: Fe^{2+}(2.0 mM)/flavin(2.0 mM)/AsH_2 (20.0 mM) under O_2 at 50°C for 90 min.

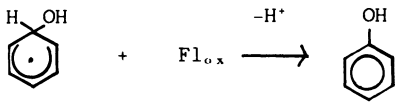
further investigations. The results are collected in Figs. 2 and 3. Figure 2 shows that the yield appears to be virtually independent of Fe^{2+} concentrations beyond 0.1 mM, indicating that neither the reduction (Eq. 3) nor the oxidation of metal ion (Eq. 4)[11] is rate-determining under the standard conditions. Moreover, the same Figure shows that even adventitious iron ion (no added Fe^{2+}), although less efficient, is capable of continuing the catalytic chain cycle. In these respects the present reaction follows a reaction pattern characteristic of the Fe^{3+}/MPH/O_2/NADH system.[9]

As can be seen from Table 3, the Fe^{2+}/**1**/H_2O_2 hydroxylating system, in which hydrogen peroxide is itself a reactant, is inhibited by addition of metal-complexing agents such as EDTA and 1,10-phenanthroline. Particularly, effect of EDTA is quite interesting. As was reported in the previous paper,[7] the mechanism for that hydroxylation is as indicated by the reaction sequence in Scheme 2. EDTA prevents the reaction of Fl_{red} (Fl_{sem}) with Fe^{3+} (Eq. 11) by markedly lowering the redox potential of Fe^{3+} below that of Fl_{red} (Fl_{sem}).

$$Fe(II) + H_2O_2 \xrightarrow[-H_2O]{+H^+} Fe(III) + \cdot OH \quad (8)$$



(9)



(10)

$$Fl_{red}(Fl_{sem}) + Fe(III) \longrightarrow Fl_{sem}(Fl_{ox}) + Fe(II) \quad (11)$$

$$2\,Fl_{sem} \underset{-H^+}{\overset{H^+}{\rightleftharpoons}} Fl_{red} + Fl_{ox} \quad (12)$$

On the other hand, EDTA in the present system had a little or no inhibitory effect on the phenol production, indicating that ascorbate must be used for

Table 3. Effect of Metal Ion-Chelating Agents (pH 3; 50°C)

Hydroxylating system	Fe^{2+}	**1**	% Phenol yield

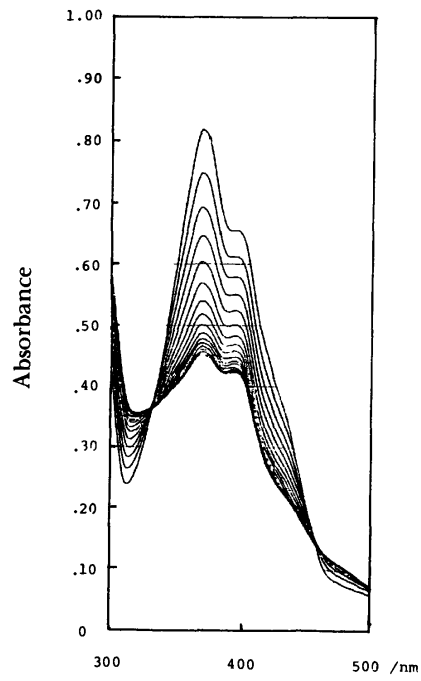

Fig. 4. UV traces for reaction of **1** with AsH_2 under N_2 at 25 °C at pH 3. The time interval is kept constant at 3 min. [**1**]=0.067 mM; $[AsH_2]_0$=2.68 mM.

reducing not only Fe^{3+} but also even the Fe(III)–EDTA chelate (Eq. 3). The Fe(II)–EDTA chelate have been well-known to react with H_2O_2 much more rapidly than the haxaaquairon(II) ion to produce reactive oxidants (Eq. 4).[11] As opposed to EDTA, 1,10-phenanthroline almost completely inhibited the production of phenol. This is probably because complexation of Fe^{3+} with 1,10-phenanthroline significantly stabilizes the Fe(II) rather than Fe(III) state and hence surpresses the generation of OH radical (Eq. 13).

$$\underset{E°(V)\ 1.03}{\text{Fe(II)-phen}} + H_2O_2 \not\longrightarrow \underset{0.72}{\text{Fe(III)-phen}} + HO\cdot \qquad (13)$$

Figure 3 illustrates the plots of the phenol yield as a function of varying concentrations of **1** over its concentration range 0—10 mM under the standard conditions, unless otherwise stated. With increase of the flavin concentrations, the yield increases steadily and approaches a limiting value of 32% at flavin concentrations greater than 4 mM. Similarly, comparison of time plots at 50 °C, shown as solid lines (a and b) in Fig. 1, reveals that the hydroxylation rate is proportional to the concentration of the catalyst flavin. These findings suggest again that either step associated with the formation of H_2O_2, i.e., Reaction 1 or 2, seems rate-determining. According to Bruice's calculation of the Gibbs free energy,[6] Reaction 2 is significantly exothermic as opposed to Reaction 1. Thus, the rate-determining step should be Reaction 1 rather than 2. Actually, this is evidenced further by

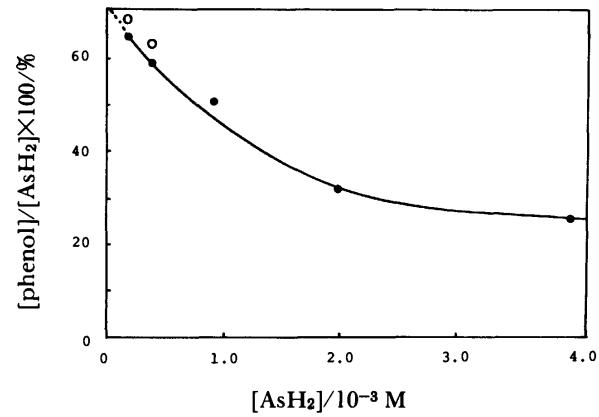

Fig. 5. Plots of phenyl yield vs. initial concentration of AsH_2. The yield is based on the initially added amount of AsH_2.
Conditions: (●) Fe^{2+}(2 mM)/**1**(2 mM); (○) Fe^{2+}(0.2 mM)/**1**(2 mM) under O_2 at pH 3 for 90 min.

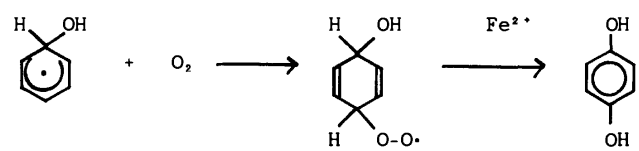
Fig. 4, which illustrates the kinetic feature of reduction of Fl_{ox} with ascorbic acid in a 40-fold excess under nitrogen. The absorbance at λ_{max} 365 nm due to **1** decreases and finally the equilibrium is attained; as would be expected, the decreased peak returns to the original peak as soon as air has been introduced into the solution. The apparent 2nd-order rate constant for the reduction of Fl_{ox} thus obtained is 0.5 $M^{-1}\,s^{-1}$. This figure shows that the reduction in question is the slowest of all the reactions in Scheme 1. It is quite probable, therefore, that Reaction 1 is the rate-limiting step of the hydroxylation.

Meanwhile, the effect of altering ascorbic acid concentrations is particularly suggestive (Fig. 5). The yield of phenol increased steadily as the concentration of ascorbic acid is decreased; namely, the eight-fold decrease of ascorbic acid increases the yield up to 67.7%. This means that the presence of too much ascorbic acid in solution is a major important factor diminishing the phenol yield, where side reactions such as Reactions 14 and 15 might participate.

$$AsH_2 + \cdot OH \longrightarrow AsH\cdot + H_2O \qquad (14)$$

$$AsH_2 + H_2O_2 \longrightarrow dAs + 2\,H_2O \qquad (15)$$

Another inevitable side reaction would be ascribed to the reaction of the 1-hydroxycyclohexadienyl radical itself. As have often been reported by many workers,[12] the cyclohexadienyl radical will be trapped by molecular oxygen to give eventually hydroquinone. In fact, 10.0% of hydroquinone was produced under the standard conditions.



In conclusion, we have found that certain flavins markedly improve the Udenfriend hydroxylation system; a flavin plays versatile roles as catalyst for accepting and transferring electron(s). Ascorbic acid is merely the reductant toward Fl_{ox} and Fe^{3+}.

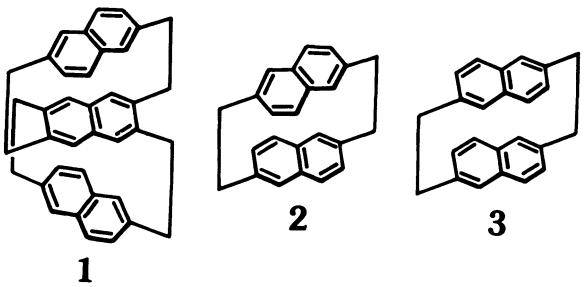
(Received July 11, 1988)

The title compound was synthesized in a similar manner to a simple access to triple-layered [2.2][2.2]paracyclophane. Its structure was elucidated by X-ray crystallographic analysis. The outer naphthalene rings are bent into a boat form and the inner naphthalene ring is bent into a twist form. These naphthalenes are stacked in layers within van der Waals contact. Therefore, there is a strong transannular π-electronic interaction between them, which brings about characteristic bathochromism, hyperchromism, and broadening in the electronic spectrum. These effects are more prominent than those of the double-layered homologue.

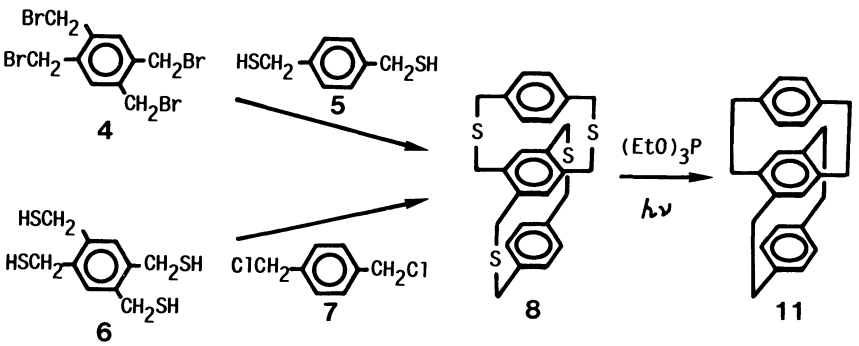
Multilayered cyclophanes are one of the most interesting compounds in the field of cyclophane chemistry.[2)] They show more unusual physical and chemical properties than double-layered phanes because their transannular π-electronic interactions between aromatic nuclei increase with an increase of the layers.[3)] However, the previous study has been limited only to benzene series.[2)] The extensive studies to fused aromatic ring series might be helpful in a comprehensive understanding of the transannular electronic interactions of cyclophanes which serve as an excimer model.[4)] In this report, we would like to present triple-layered [2.2][2.2]naphthalenophane (**1**) as the first example of multilayered phanes composed of fused aromatic nuclei. There have been some double-layered [2.2]naphthalenophanes of different stacking types mainly depending on the substitution mode of the bridging ethylenes. Haenel and Staab reported chiral [2.2](2,6)naphthalenophane (**2**), in which two aromatic rings were bridged at the 2- and 6-positions and obliquely overlapped each other.[5)] Blanck and Haenel later reported achiral isomer (**3**), which had the exact overlap of the two aromatic rings and accordingly was less stable than **2**.[6)] A study of a series of multilayered [2.2]paracyclophanes revealed that there was observed a dramatic enhancement in the electronic interaction with an increase in stacking layers from double to triple.[3)] Therefore, triple-layered naphthalenophane (**1**) is expected to show characteristic properties as compared to double-layered one **2** or **3**.



1 **2** **3**

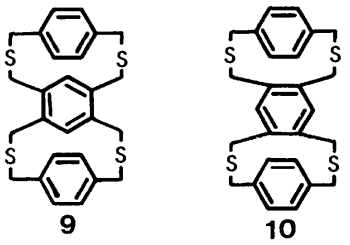
Results and Discussion

Synthesis. Multilayered cyclophanes were previously synthesized in multisteps via double-layered ones.[3,7)] The same pathway is inapplicable to fused aromatic phanes because the functionalized double-layered intermediates are not readily accessible. Boekelheide et al., however, reported that a termolecular coupling of 1,2,4,5-tetrakis(bromomethyl)benzene



Scheme 1.

and 2 equiv of 2,6-bis(mercaptomethyl)pyridine followed by ring contraction using the Wittig rearrangement led to triple-layered pyridinoparacyclophane.[8] Such a termolecular reaction appears to provide a direct entry to triple-layered phanes, though it has a possibility of not only a low yield but also the formation of some regioisomers. Then, we have first examined its approach to triple-layered [2.2][2.2]paracyclophane (**11**) prior to the present target molecule **1**. As shown in Scheme 1, a termolecular coupling reaction of 1,2,4,5-tetrakis(bromomethyl)benzene (**4**) and 2 equiv of 1,4-bis(mercaptomethyl)benzene (**5**) in ethanol solution containing potassium hydroxide at room temperature gave triple-layered tetrathia[3.3][3.3]paracyclophane (**8**) in only 4.2% yield. On the other hand, a reaction of 1,2,4,5-tetrakis(mercaptomethyl)benzene (**6**) and two 1,4-bis(chloromethyl)benzenes (**7**) in refluxing ethanol gave the same compound **8** in 12% yield. There was no evidence for the formation of the other possible isomers **9** and **10**.



9 **10**

The photoinduced desulfurization of **8** with triethyl phosphite smoothly proceeded to give the desired compound **11** in 93% yield. The coupling yield is quite low, but the steps are few and the reactants **4**—**7** are readily available. As a result, this access constitutes the simplest one to **11**.

A similar method was applied to the synthesis of triple-layered [2.2][2.2]naphthalenophane (**1**) (Scheme 2). 2,3,6,7-Tetramethylnaphthalene (**12**) was prepared from 2,3-dimethylsuccinic anhydride and *o*-xylene according to the procedure of Dozen and Hatta[9] and brominated with *N*-bromosuccinimide to 2,3,6,7-tetrakis(bromomethyl)naphthalene (**13**) in 69% yield. A termolecular coupling reaction of **13** and two 2,6-bis(mercaptomethyl)naphthalenes (**14**) gave triple-layered tetrathia[3.3][3.3]naphthalenophane (**17**) in 9% yield. Alternatively, **13** on treatment with thiourea followed by alkaline hydrolysis was converted to 2,3,6,7-tetrakis(mercaptomethyl)naphthalene (**15**), which was coupled with two 2,6-bis(bromomethyl)naphthalenes (**16**) to give the same product **17** in 17% yield. The ^{1}H NMR spectrum demonstrates that the inner naphthalene protons resonate as a multiplet at δ 6.1—6.4. This indicates that **17** consists of an isomeric mixture of **17a—c**, which are quite difficult to separate. Another possible isomer **18** with a different substitution mode was not detected. The inner aromatic protons of **18** might be situated just above the outer naphthalene rings, so that the ^{1}H NMR spectrum should show a characteristic

Scheme 2.

upfield shift like H_a protons (δ 5.82) of 2,15-dithia[3.3](2,6)(2,7)naphthalenophane (**19**) as a double-layered homologue.[10] The photolytic sulfur extrusion of **17** with triethyl phosphite gave the desired product **1** in 32% yield. Its structure was characterized by elemental analysis, spectroscopic measurements, and finally X-ray crystallographic analysis. No desulfurized isomers corresponding to the stacking types of **17b** and **17c** were observed. Probably a ring rotation occurred during the C–S bond fission on photolysis, leading to the sole formation of the more stable isomer **1**.

Molecular Structure. The crystal of **1** is triclinic with space group $P\bar{1}$ and the unit cell contains four molecules which form two distinct enantiomeric pairs. Table 1 lists final atomic parameters for the molecules (I) and (II). No essential difference in structure between the two distinct molecules is observed, so that only molecular structure I is discussed below. Figure 1 shows the side view of the ORTEP drawing. The three naphthalenes diagonally overlap each other and, on the whole, take a spiral structure. As seen from the top view of Fig. 2, the diagonal angle between the neighboring ones is 34°. The bridging ethylene bonds are torsional to avoid the eclipsing form. The torsional angle around C(1)–C(2) bond is 39°. Table 2 summarizes the C–C bond lengths and C–C–C bond angles. As a whole, they hold values close to normal except for a little elongation of the bridged ethylene bonds. On the other hand, Figs. 3 and 4 demonstrate that the outer naphthalene rings are bent into a boat form and the inner naphthalene ring is bent into a twist form. A mean plane (A) defined by C(4), C(5), C(11), and C(12) atoms inclines by 8.1° from a plane (molecular horizon) defined by C(5), C(6), C(10), and C(11), a plane (B) defined by C(3),

a) $B_{eq}=(4/3)\sum_{ij}\beta_{ij}(a_i \cdot a_j)$.

C(4), and C(12) atoms makes a dihedral angle of 7.9° with the plane A, and the C(2)–C(3) bond makes an angle of 9.7° with the plane B. These values are fairly smaller than the bending angles of [2.2]paracyclophane[11] or the multilayered homologues,[12] indicating that the outer naphthalene effectively disperses a strain throughout the fused system. On the other hand, the twist angle of the inner naphthalene, defined by the dihedral angle between mean planes of the two

benzene rings, is 15.4° so that a considerable strain exists in it. In addition, Fig. 3 shows the nearest nonbonded atomic distances between the neighboring aromatic rings to be situated in 2.8—3.1 Å. These values are quite smaller than van der Waals contact, causing a strong transannular interaction between the naphthalenes.

Spectroscopic Properties. The ^{1}H NMR spectra of cyclophanes are characterized by the magnetic anisotropic effect of the adjacent aromatic rings.[13] When the chemical shifts of three kinds of the aromatic protons in [2.2](2,6)naphthalenophane (**2**), δ 6.41 (noncoupled α-ArH), 6.83 (coupled β-ArH), and 7.09 (coupled α-ArH) are compared to the corresponding ones of 2,6-dimethylnaphthalene, δ 7.57, 7.24, and 7.64, the upfield shift on the noncoupled α-protons is marked, because they are more subject to a shielding

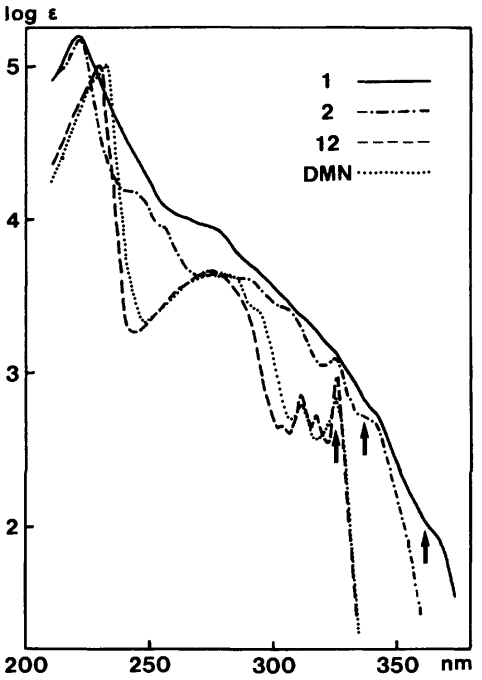

Fig. 5. The electronic spectra of triple-layered naphthalenophane (**1**), double-layered naphthalenophane (**2**), 2,3,6,7-tetramethylnaphthalene (**12**), and 2,6-dimethylnaphthalene (DMN) in tetrahydrofuran. The positions of the longest absorption bands are marked by arrows.

effect owing to the obliquely stacking structure.[5] The NMR spectrum of **1** suffers the additional anisotropy of the third naphthalene ring. The spiral stacking structure forces the noncoupled α-protons (δ 6.17) of the outer naphthalene to appear at a higher field than the coupled α-protons (δ 6.69) and β-protons (δ 6.91). The inner naphthalene protons are sandwiched between the two outer naphthalenes and accordingly the upfield shift of the signal (δ 5.55) relative to that (δ 7.44) of 2,3,6,7-tetramethylnaphthalene is especially large and corresponds to almost twice that for the α-protons of **2**.

The transannular π-electronic interactions of layered cyclophanes can be best understood by electronic spectroscopy. Figure 5 shows the electronic spectra of naphthalenophanes **1** and **2** in tetrahydrofuran. When 2,6-dimethylnaphthalene (DMN) or 2,3,6,7-tetramethylnaphthalene (**12**) is chosen as a standard, both compounds demonstrate common spectral characteristics of layered cyclophanes, i.e., bathochromism, hyperchromism, and broadening.[3] These effects are more eminent with an increase of the layers. For example, the longest absorption peaks of 2,6-dimethylnaphthalene and 2,3,6,7-tetramethylnaphthalene appear at 326 and 325 nm, respectively. In contrast, **2** has a shoulder at 336 nm as the longest band. Further, **1** has its band at 362 nm, indicating a stronger transannular π-electronic interaction as expected from the above crystal structure.

The strong transannular π-electronic interaction of **1** was also confirmed by its charge-transfer absorption with tetracyanoethylene (TCNE) as an electron acceptor. 2,6-Dimethylnaphthalene with TCNE exhibited two broad CT bands at λ_{max} 478 and 609 nm in dichloromethane. On the other hand, **2** showed the corresponding CT bands at 500(sh) and 644 nm, and **1** at 514 and 683 nm. Evidently, the bathochromic shifts for these naphthalenophanes indicate the enhancement of their donor abilities due to the transannular electronic interactions, which is more eminent in **1** than in **2**.

Experimental

General. Elemental analyses were determined by Mr. H. Iwatani, Microanalytical Laboratory of Department of Applied Chemistry, Hiroshima University. Melting points are uncorrected. NMR measurements were made on a JEOL PMX-60 instrumet (60 MHz) using deuteriochloroform as a solvent with tetramethylsilane as an internal standard. Mass spectra were taken on a JEOL JMS-DX 300 spectrometer at 70 eV using a direct insertion technique. Visible and ultraviolet spectra were measured with a Shimadzu UV-160 spectrophotometer.

1,2,4,5-Tetrakis(mercaptomethyl)benzene (6). A mixture of 1,2,4,5-tetrakis(bromomethyl)benzene (**4**)[14] 1.35 g (3 mmol) and thiourea 0.99 g (13 mmol) was refluxed in 20 cm³ of 95% ethanol for 5 h. The resulting tetrakis(thiouronium salt) was collected by filtration and washed with ethanol, 2.21 g. It was then refluxed with potassium hydroxide (4 g) in 15 cm³ of water for 4 h under nitrogen. The reaction mixture was acidified with 50% sulfuric acid on ice-cooling and extracted with dichloromethane. The extract was washed with brine, dried ($MgSO_4$), and evaporated. Recrystallization of the residue from benzene gave colorless needles 0.65 g (83%), mp 132—133 °C. ^{1}H NMR δ=1.83 (t, J=7 Hz, 4H, SH), 3.80 (d, J=7 Hz, 8H, CH_2), 7.21 (s, 2H, ArH). Calcd for $C_{10}H_{14}S_4$: C, 45.76; H, 5.38%. Found: C, 45.74; H, 5.38%.

Triple-Layered Tetrathia[3.3][3.3]paracyclophane (8). A solution of 1,2,4,5-tetrakis(mercaptomethyl)benzene (**6**) 1.048 g (4 mmol) and 1,4-bis(chloromethyl)benzene (**7**) 1.40 g (8 mmol) in 200 cm³ of benzene was slowly added into a refluxing solution of ethanol (1 dm³) containing potassium hydroxide (1.44 g) in a nitrogen atmosphere. The addition took one and a half day. After treated under reflux for additional half a day, the reaction mixture was concentrated in vacuo. The residue was taken up in dichloromethane and chromatographed on silica gel with dichloromethane. Recrystallization of the solid in the first eluate gave colorless plates of **8**, 228 mg (12%), decomp 210 °C. ^{1}H NMR δ=3.57 (d, J=14 Hz, 4H, CH_2), 3.66 (s, 8H, CH_2), 4.16 (d, J=14 Hz, 4H, CH_2), 6.26 (s, 2H, ArH), 6.71 (ABq, J=8 Hz, 8H, ArH). MS m/z 466 (M^+). Calcd for $C_{26}H_{26}S_4$: C, 66.91; H, 5.61%. Found: C, 67.17; H, 5.29%.

The same product (**8**) was obtained from a similar coupling reaction of 1,2,4,5-tetrakis(bromomethyl)benzene (**4**) 1.80 g (4 mmol) and 1,4-bis(mercaptomethyl)benzene (**5**) 1.36 g (8 mmol) at RT, yield 77 mg (4.2%).

Triple-Layered [2.2][2.2]Paracyclophane (11). A mixture of compound **8** 77 mg, triethyl phosphite 20 cm³, and benzene 20 cm³ was placed in a quartz tube and irradiated with a high-pressure mercury lamp (300 W) for 5 h in a nitrogen atmosphere. It was concentrated in vacuo, and the residue was chromatographed on silica gel with benzene to give the desired product **11** in the first eluate, 52 mg (93%). Recrystallization from carbon tetrachloride–acetone (1:3) gave colorless prisms, decomp 230 °C. It was consistent with the authentic sample in all respects.

2,3,6,7-Tetrakis(bromomethyl)naphthalene (13). 2,3,6,7-Tetramethylnaphthalene (**12**)[9] 3.68 g (20 mmol) was refluxed with *N*-bromosuccinimide 15.6 g (88 mmol) and a catalytic amount of benzoyl peroxide in 300 cm³ of carbon tetrachloride for 30 min under sunlight. The mixture was concentrated to about 50 cm³. The resulting solid was collected by filtration and thoroughly washed with hot water. The remainder was essentially pure product **13**, which was recrystallized from benzene to give colorless fine crystals, decomp 230 °C, 6.87 g (69%). ^{1}H NMR δ=4.85 (s, 8H, CH_2), 7.83 (s, 4H, ArH). Calcd for $C_{14}H_{12}Br_4$: C, 33.64; H, 2.42%. Found: C, 33.67; H, 2.36%.

2,3,6,7-Tetrakis(mercaptomethyl)naphthalene (15). 2,3,6,7-Tetrakis(bromomethyl)naphthalene (**13**) 6.87 g (13.7 mmol) was refluxed with thiourea 5.03 g (66 mmol) in 100 cm³ of 95% ethanol. The resulting tetrakis(thiouronium salt) was collected by filtration and washed with ethanol, 7.85 g. It was refluxed with potassium hydroxide (18 g) in 200 cm³ of water for 6 h under nitrogen. After the insoluble material was removed by filtration, the filtrate was acidified with 50% sulfuric acid on ice-cooling. The resulting solid was collected by filtration and recrystallized from chloroform to give colorless scales, 2.64 g (62%), mp 181—182 °C. ^{1}H NMR δ=1.83 (t, J=7 Hz, 4H, SH), 4.04 (d, J=7 Hz, 8H, CH_2), 7.69 (s, 4H, ArH). Calcd for $C_{14}H_{16}S_4$: C, 53.80; H, 5.16%. Found: C, 53.52; H, 5.02%.

Triple-Layered Tetrathia[3.3][3.3]naphthalenophane (17). A solution of 2,3,6,7-tetrakis(mercaptomethyl)naphthalene (**15**) 312 mg (1 mmol) and 2,6-bis(bromomethyl)naphthalene (**16**)[5] 646 mg (2.06 mmol) in 400 cm³ of benzene was slowly added into a refluxing solution of ethanol (800 cm³) containing potassium hydroxide (0.6 g) in a nitrogen atmosphere. The addition took 3 days. The solution was concentrated in vacuo, and the residue was chromatographed on silica gel with dichloromethane to give the desired product **17** in the first eluate, 52 mg (17%), colorless plates from chloroform, decomp 250 °C. ^{1}H NMR δ=3.5—4.5 (m, 16H, CH_2), 6.14, 6.21, 6.35 (each bs, 4H, inner ArH), 6.7—7.0 (m, 17H, outer ArH). MS m/z 616 (M^+). Calcd for $C_{38}H_{32}S_4$: C, 73.98; H, 5.23%. Found: C, 73.71; H, 5.27%.

A similar coupling reaction using 2,3,6,7-tetrakis(bromomethyl)naphthalene (**13**) 200 mg (0.4 mmol) and 2,6-bis(mercaptomethyl)naphthalene (**14**)[5] 167 mg (0.76 mmol) gave the same product **17**, 21 mg (9%).

Triple-Layered [2.2][2.2]Naphthalenophane (1). Triple-layered tetrathia[3.3][3.3]naphthalenophane (**17**) 72 mg, triethyl phosphite 20 cm³, and benzene 30 cm³ were placed in a quartz tube. The suspension was irradiated with a high-pressure mercury lamp for 12 h in a nitrogen atmosphere. It was evaporated, and the residue was purified by column chromatography on silica gel with benzene and then gel-permeation liquid chromatography with chloroform to give the desired product **1**, 18 mg (32%), colorless prisms from benzene, decomp 285 °C. ^{1}H NMR δ=2.3—3.3 (m, 16H,

CH_2), 5.55 (s, 4H, inner ArH), 6.17 (s, 4H, outer ArH), 6.69 (d, J=8 Hz, 4H, outer ArH), 6.91 (d, J=8 Hz, 4H, outer ArH). MS m/z 488 (M^+). Calcd for $C_{38}H_{32}$: C, 93.40; H, 6.60%. Found: C, 93.24; H, 6.71%.

Crystal Structure Analysis. The X-ray diffraction data were collected by using a Rigaku automated four-circle diffractometer with Cu $K\alpha$ radiation monochromatized by a graphite plate. Independent reflections 5750 with 2θ values up to 126° ($|F_o| \geqq 3.0\sigma(F_o)$) were used for analysis. Crystal data are as follows; colorless prism, $C_{38}H_{32}$, M=488.68, triclinic, space group $P\bar{1}$, a=13.515(3), b=18.748(3), c=11.143(2) Å, α=90.38(2), β=101.62(2), γ=110.30(1)°, V=2584.8(9) Å^3, D_m=1.237, D_c=1.256 g cm^{-3} for Z=4, u=4.574 cm^{-1}, crystal size 0.18×0.18×0.23 mm^3. The structure was solved by the Monte Carlo direct method[15] using the MULTAN-78 program system[16] and refined on F^2 by the full-matrix least-squares method with the analytical absorption correction.[17] Atomic scattering factors were taken from International Tables for X-ray Crystallography.[18] Anisotropic temperature factors were used for the refinement of carbon atoms. All H atoms were located from difference Fourier maps and their coordinates were refined with the isotropic temperature factors equivalent to that of the bonded carbon atoms. The R value converged to 0.066. Computations were carried out partly at the Information Processing Center of Hiroshima University and mainly at the Computation Center of Nagoya University using the library program of CRYSTAN system. Tables of structure factors, anisotropic thermal parameters, and coordinates of hydrogen atoms are deposited as Document No. 8850 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Synthesis of 4-[(*E*)-1-Alkenyl]-2-hydroxybutanolides and (*Z*)-4-Alkylidene-2-butenolides through Cycloadditions Using a Phosphorus-Functionalized Nitrile Oxide

Shuji KANEMASA,* Norihiko NAKAGAWA, Hiroyuki SUGA, and Otohiko TSUGE*

Kyushu University, Kasugakoen, Kasuga 816
(Received July 15, 1988)

A sequence of cycloadditions of (diethoxyphosphinyl)acetonitrile oxide with α,β-unsaturated esters, the Raney Ni reduction of the resulting cycloadducts, the Horner–Emmons olefination, and the carbonyl reduction with sodium borohydride leads to 5-[(*E*)-1-alkenyl]-3-hydroxy-4,5-dihydro-2(3*H*)-furanones which can be converted into (*Z*)-5-alkylidene-2(5*H*)-furanones in two steps.

Unsaturated five-membered lactones, butenolides, are often the central skeletons of naturally occurring oxygen heterocycles.[1] Among the numerous reported syntheses of 2-butenolides,[2] the route by dehydration of 2-hydroxybutanolides is not familiar since availability of the starting 2-hydroxybutanolides[3] or their related derivatives[4] is quite narrow.

On the other hand, 2-isoxazoline-5-carboxylates which can be formed as cycloadducts in the cycloadditions of nitrile oxides with conjugated esters are synthetically equivalent to the α-hydroxy-γ-oxo ester functionality by a simple one-step procedure involving reductive N–O bond cleavage and hydrolysis. This cleavage can be conveniently and effectively carried out by the aid of Raney Ni.[5] Application of this sequence to the nitrile oxide bearing a functional group utilizable for olefination would lead to 2-hydroxy-4-oxo-5-alkenoates. These alkene esters must be the promising starting materials in the synthesis of 4-(1-alkenyl)-2-hydroxybutanolides (or 5-(1-alkenyl)-3-hydroxy-4,5-dihydro-2(3*H*)-furanones) and further 4-alkylidene-2-butenolides (or 5-alkylidene-2(5*H*)-furanones).

The present article describes a new synthetic method of butanolides and butenolides through the cycloaddition route using a phosphorus-functionalized nitrile oxide. Hereafter only the nomenclature as well as the compound numbering based on heterocyclic systems is employed in order to avoid confusion.

Results and Discussion

We have already reported that (diethoxyphosphinyl)-acetonitrile oxide (**1**) serves as a synthetically useful phosphorus-functionalized nitrile oxide[6,7] which undergoes regioselective cycloaddition with methyl acrylate to produce methyl 3-[(diethoxyphosphinyl)methyl]-2-isoxazoline-5-carboxylate (**2**).[8,9] Methyl 5-(diethoxyphosphinyl)-2-hydroxy-4-oxopentanoate (**3**)[9] can be obtained in a satisfactory yield via the Raney Ni reduction of the cycloadduct **2** in the presence of boric acid.

Though Horner–Emmons olefinations of 4-hydroxy-2-oxoalkylphosphonates are often accompanied by competitive dehydration and/or retro-aldol reaction, use of the combination of triethylamine (or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)) and lithium bromide as a weak base system on the *O*-unprotected substrates was found effective enough to suppress these undesired side reactions.[10]

Under the equivalent conditions (lithium bromide–DBU in dry THF at 0 °C for 24 h), highly functionalized phosphonate **3** was smoothly converted into 2-hydroxy-4-oxo-5-alkenoates **4a—c** (Scheme 1). These olefinations were highly *E*-selective for all the aldehydes employed, no contamination by *Z*-isomers being observed. It should be emphasized that the reactions with aliphatic aldehydes provided the olefins in better yields than that with an aromatic aldehyde (**4a**: 80%; **4b**: 82%; **4c**: 52%).

Reduction of the conjugated carbonyl group at the 4-position of **4** with sodium borohydride was impracticably sluggish in ethanol at 0 °C and that at room

Scheme 1.

temperature resulted in a complex mixture of many products. However in methanol a smooth reduction took place at 0 °C.[11] The reduction was carefully monitored on thin-layer chromatography (TLC) and as soon as the reduction was complete the crude reaction mixture containing the dihydroxy esters was subjected to lactonization without purification. Treatment of the crude reduction products with a catalytic amount of *p*-toluenesulfonic acid in dichloromethane at room temperature produced 5-(1-alkenyl)-3-hydroxy-4,5-dihydro-2(3*H*)-furanones **5a—c** as about 1 : 1 mixtures of 3,5-cis and 3,5-trans isomers. Although these two isomers can be separated from each other through careful column chromatography and in the present research their separation was actually carried out for characterization, this separation step may be omitted only for the purpose of synthesizing 2-butenolides.

As direct dehydration of **5a** by the aid of either of dicyclohexylcarbodiimide–copper(I) chloride (reflux in benzene for 5 h)[12] or methyltriphenoxyphosphonium iodide (at 80 °C for 1 h in hexamethylphosphoric triamide (HMPA))[13] ended in the formation of complex mixture, the hydroxyl group was replaced with a more effective leaving group such as mesyl, tosyl, or bromo substituent.

Though *O*-mesylation of **5a** with methanesulfonyl chloride–triethylamine (at 0 °C in dichloromethane) gave the mesylate **8** in a moderate yield, the product obtained on treating **5a** with *p*-toluenesulfonyl chloride–pyridine at room temperature was not the expected tosylate **10** but the chloride **9** (77%). On the other hand, only 18% yield of bromide **6a** was prepared by reacting **5a** with tribromophosphine–pyridine.

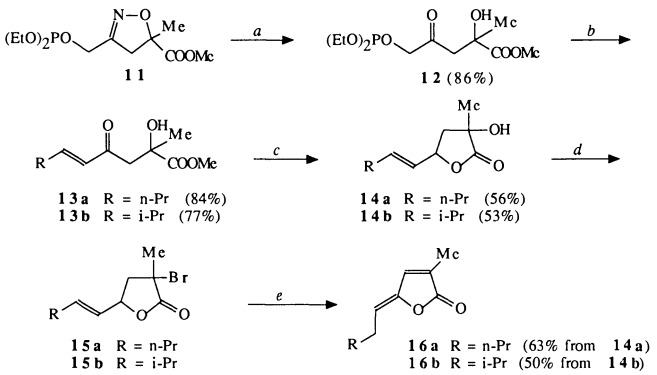
Base-induced dehydrohalogenation of chloride **9** and bromide **6a** was all unsuccessful (with triethylamine under reflux in diethyl ether, dichloromethane, or THF; with pyridine at 80 °C). Only when mesylate **8** was heated with DBU under reflux in THF, a low yield (5%) of the expected 2-butenolide **7a** was obtained. After some efforts, it was found that treating bromide **6a** with DBU under reflux in THF provided 2-butenolide **7a** in 58% yield. The structure of **7a** will be discussed below.

Therefore an effective synthetic route to bromides **6a—c** was searched. The aforementioned high-yield formation of chloride **9** in the attempted tosylation of **5a** indicates a possibility of the ready nucleophilic substitution of the tosylate **10** with a halide nucleophile under the quoted conditions. Accordingly hydroxy lactones **5a—c** were first mesylated and the crude mesylates were allowed to react with lithium bromide in THF at room temperature to give good yields of the expected bromides **6a—c** (Scheme 1). Since the starting hydroxy lactones **5a—c** were all mixtures of 3,5-cis and 3,5-trans isomers, **6a—c** were not stereochemically pure.

Dehydrobromination of bromides **6a—c** was carried out with DBU under reflux in THF where a catalytic amount of hydroquinone was used to inhibit the polymerization of products.[14] Though the 3-bromo-4,5-dihydro-2(3*H*)-furanones **6a—b** underwent smooth dehydrobromination, the phenyl-substituted analog **6c** led to complex mixture under all the employed conditions.

The structures of **7a—b** were assigned as *Z*-isomers of 5-alkylidene-2(5*H*)-furanones on the basis of spectral data where there newly appeared three olefin (3-, 4-, and 1′-Hs) and a pair of methylene (2′-H) protons and disappeared one set of trans-olefin. The *Z*-stereochemistry was confirmed by comparison of the chemical shifts of 1′-H (**7a**: δ=5.32; **7b**: 5.34) with those of *E*- and *Z*-isomers of 5-butylidene-2(5*H*)-furanone (*E*-isomer: 5.70; *Z*-isomer: 5.22),[3b] 5-ethylidene-3-methyl-2(5*H*)-furanone (*E*-isomer: 5.67; *Z*-isomer: 5.20),[15,16] or 3-methyl-5-(2-methylpropylidene)-2(5*H*)-furanone (*E*-isomer: 6.23; *Z*-isomer: 5.43).[17]

One application of the above furanone synthesis using nitrile oxide **1** enables the introduction of a methyl group at the 3-position of 5-alkylidene-2(5*H*)-furanones as shown in Scheme 2.



a Raney Ni / $B(OH)_3$ in aq EtOH at rt

Scheme 2.

Regioselective cycloaddition of nitrile oxide **1** with methyl methacrylate and subsequent Raney Ni reduction of the cycloadduct **11** afforded ester phosphonate **12** (Scheme 2). Horner–Emmons olefination of **12** mediated by lithium bromide–DBU led to (*E*)-olefins **13a,b**. Sodium borohydride reduction of **13** proceeded in a stereoselective fashion to give 3-hydroxy-3-methyl-4,5-dihydro-2(3*H*)-furanones **14a,b** after acid-catalyzed lactonization. Three transformations consisting of mesylation of **14a,b**, bromination of the mesylates with lithium bromide, and the final dehydrobromination of the bromides **15a,b** were carried out in one procedure

without separation of the intermediate products to produce (*Z*)-3-methyl-5-pentylidene-2(5*H*)-furanone (**16a**) and (*Z*)-3-methyl-5-(3-methylbutylidene)-2(5*H*)-furanone (**16b**). No sign of the regioisomeric dehydrobromination leading to 2-methylenebutanolide was even observed.[18]

In conclusion, the cycloaddition route using the phosphorus-functionalized nitrile oxide **1** offers a useful preparation method of 3-hydroxy and 3-halo derivatives of (*E*)-5-(1-alkenylidene)-4,5-dihydro-2(3*H*)-furanones and (*Z*)-5-alkylidene-2(5*H*)-furanones. By a set of appropriate choices of conjugated esters in the cycloaddition step, carbonyl compounds in the olefination step, and nucleophiles in the functional group interconversion of the 3-hydroxyl moiety, this method can be further applied to their families bearing a variety of substitution patterns. Alkylation adjacent to the phosphinyl moiety of 2-isoxazolines **2** and **11** can be also combined.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 spectrometer. ^{1}H NMR spectra were recorded on a JEOL GSX-270 instrument (270 MHz), and ^{13}C NMR on a JEOL FX-100 (25.05 MHz) or a JEOL GSX-270 spectrometer (67.94 MHz). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. High-resolution mass spectra were obtained on the same instrument. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Materials and Solvents. Generation of nitrile oxide **1**, its cycloaddition with methyl acrylate leading to 2-isoxazoline **2**, Raney Ni reduction of **2** furnishing **3**, its Horner-Emmons olefination with benzaldehyde giving **4c** were all previously reported.[8-10] Methyl methacrylate was distilled prior to use. Lithium bromide, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), and hydroquinone are commercially available and were used without further purification. Tetrahydrofuran (THF) and dichloromethane were purified immediately before use by distillation from lithium aluminum hydride and calcium hydride, respectively, under nitrogen.

Methyl (*E*)-2-Hydroxy-4-oxo-5-nonenoate (4a). To a solution of lithium bromide (0.377 g, 3.88 mmol) in dry THF (5 ml) was added a solution of **3** (1.095 g, 3.88 mmol) in THF (5 ml). After stirring at room temperature for 10 min under nitrogen, a solution of DBU (0.561 g, 3.69 mmol) in THF (5 ml) was added dropwise at 0 °C. After 1 h at 0 °C, butanal (0.56 g, 7.76 mmol) was added, the mixture was stirred at 0 °C for 24 h, poured into ice water, and then extracted with dichloromethane (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed on silica gel by using hexane–ethyl acetate (3:1 v/v) to give **4a** (0.624 g, 80%) as a single isomer (by ^{1}H NMR): Colorless liquid; IR (neat) 3480, 1740, 1660, 1620, 1430, 1200, 1100, 1030, and 975 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.95 (3H, t, J=7.3 Hz, *n*-Pr), 1.51 (2H, sx, J=7.3 Hz, *n*-Pr), 2.22 (2H, dt, J=7.3 and 7.0 Hz, *n*-Pr), 3.08 (1H, d, J_{3-2}=10.3 Hz, one of 3-H), 3.09 (1H, d, J_{3-2}=5.5 Hz, the other of 3-H), 3.50 (1H, br s, OH), 3.78 (3H, s, COOMe), 4.57 (1H, dd, J_{2-3}=10.3 and 5.5 Hz, 2-H), 6.11 (1H, d, J_{5-6}=16.1 Hz, 5-H), and 6.89 (1H, dt, J_{6-5}=16.1 and J_{6-7}=7.0 Hz, 6-H); ^{13}C NMR ($CDCl_3$) δ=13.69, 21.30, 34.57 (each *n*-Pr), 43.27 (3-C), 52.49 (COOMe), 67.19 (2-C), 130.42 (5-C), 149.11 (6-C), 174.28 (COOMe), and 197.70 (CO); MS *m/z* (rel intensity, %) 200 (M^+, 11), 141 (16), 97 (base peak), and 55 (57). HRMS Found: *m/z* 200.1050. Calcd for $C_{10}H_{16}O_4$: M, 200.1048.

Methyl (*E*)-2-Hydroxy-7-methyl-4-oxo-5-octenoate (4b). A similar procedure using lithium bromide (0.353 g, 4.06 mmol) in THF (5 ml), **3** (1.147 g, 4.06 mmol) in THF (5 ml), DBU (0.588 g, 3.86 mmol) in THF (5 ml), and 2-methylpropanal (0.586 g, 8.13 mmol) at 0 °C for 1 h after column chromatography on silica gel with hexane–ethyl acetate (3:1 v/v), gave **4b** (0.667 g, 82%) as a single isomer (by ^{1}H NMR): Colorless liquid; IR (neat) 3480, 1740, 1660, 1620, 1440, 1360, 1270, 1210, 1100, 1030, and 980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (6H, d, J=7.0 Hz, *i*-Pr), 2.3—2.7 (1H, m, *i*-Pr), 3.0—3.2 (2H, m, 3-H), 3.4—3.5 (1H, m, OH), 3.76 (3H, s, COOMe), 4.55 (1H, dd, J_{2-3}=10.0 and 5.5 Hz, 2-H), 6.04 (1H, dd, J_{5-6}=16.1 and J_{5-3}=1.5 Hz, 5-H), and 6.84 (1H, dd, J_{6-5}=16.0 and J_{6-7}=6.0 Hz, 6-H); ^{13}C NMR ($CDCl_3$) δ=21.18, 31.23 (each *i*-Pr), 43.27 (3-C), 52.50 (COOMe), 67.11 (2-C), 127.45 (5-C), 155.24 (6-C), 174.24 (COOMe), and 198.06 (CO); MS *m/z* (rel intensity, %) 200 (M^+, 5), 141 (14), 97 (base peak), 96 (13), 69 (11), and 41 (22). HRMS Found: *m/z* 200.1048. Calcd for $C_{10}H_{16}O$: M, 200.1048.

3-Hydroxy-5-[(*E*)-1-pentenyl]-4,5-dihydro-2(3*H*)-furanone (5a). To a solution of **4a** (0.787 g, 3.93 mmol) in methanol (10 ml) was added sodium borohydride (0.149 g, 3.93 mmol). After stirring at room temperature for 10 min, acetone (5 ml) was added at 0 °C. The mixture was stirred at 0 °C for 10 min, poured into ice water, and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was dissolved in dichloromethane (10 ml) containing *p*-toluenesulfonic acid (0.075 g, 0.393 mmol), the mixture was stirred at room temperature for 3 h, poured into ice water, and then extracted with dichloromethane (20 ml×2). After dried over magnesium sulfate, the combined extracts were evaporated in vacuo and the residue was chromatographed on silica gel with hexane–ethyl acetate (2:1 v/v) to give **5a** (0.447 g, 67%) as a 1:1 mixture of two diastereomers (by ^{1}H NMR) which could be separated from each other by a careful column chromatography.

3,5-*trans*-5a: Colorless liquid; IR (neat) 3400, 1770, 1670, 1450, 1320, 1180, 1120, 970, and 940 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, t, J=7.3 Hz, *n*-Pr), 1.41 (2H, sx, J=7.3 Hz, *n*-Pr), 2.04 (2H, dt, J=7.3 and 7.0 Hz, *n*-Pr), 2.3—2.5 (2H, m, 4-H), 3.6—3.8 (1H, br s, OH), 4.53 (1H, dd, J_{3-4}=7.7 and 7.3 Hz, 3-H), 5.0—5.2 (1H, m, 5-H), 5.48 (1H, dd, $J_{1'-2'}$=15.0 and

$J_{1'-5}$=7.0 Hz, 1'-H), and 5.80 (1H, dt, $J_{2'-1'}$=15.0 and $J_{2'-3'}$=7.0 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=13.59, 21.91, 34.11 (each *n*-Pr), 36.47 (4-C), 67.32 (3-C), 78.74 (5-C), 127.14 (1'-C), 135.52 (2'-C), and 178.06 (2-C); MS (25 eV) *m/z* (rel intensity, %) 170 (M^+, 2), 98 (29), 83 (base peak), 82 (58), 81 (68), 70 (28), and 55 (21).

3,5-*cis*-5a: Colorless liquid; IR (neat) 3400, 1770, 1670, 1450, 1310, 1190, 1120, 960, and 900 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.3 Hz, *n*-Pr), 1.43 (2H, sx, J=7.3 Hz, *n*-Pr), 1.9—2.1 (3H, m, *n*-Pr and one of 4-H), 2.06 (1H, ddd, J_{gem}=12.5, J_{4-3}=8.0 Hz, and J_{4-5}=5.4 Hz, the other of 4-H), 3.6—3.8 (1H, br s, OH), 4.55 (1H, m, 3-H), 4.76 (1H, ddd, J_{5-4}=10.8, 5.4, and $J_{5-1'}$=7.7 Hz, 5-H), 5.50 (1H, dd, $J_{1'-2'}$=15.4 and $J_{1'-5}$=7.7 Hz, 1'-H), and 5.86 (1H, dt $J_{2'-1'}$=15.4 and $J_{2'-3'}$=7.0 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=13.95, 21.86, 34.11 (each *n*-Pr), 37.70 (4-C), 68.61 (3-C), 77.79 (5-C), 126.88 (1'-C), 137.27 (2'-C), and 177.88 (2-C); MS (25 eV) *m/z* (rel intensity, %) 170 (M^+, 1), 113 (47), 98 (24), 83 (base peak), 82 (47), 81 (59), and 70 (21).

No satisfactory analytical data were obtained due to hygroscopic nature of the both isomers of **5a**.

3-Hydroxy-5-[(*E*)-3-methyl-1-butenyl]-4,5-dihydro-2(3*H*)-furanone (5b). A similar procedure using **4b** (0.231 g, 1.15 mmol) in methanol (5 ml), sodium borohydride (0.044 g, 1.15 mmol), and *p*-toluenesulfonic acid (0.022 g, 0.115 mmol) in dichloromethane (5 ml) gave **5b** (0.135 g, 69%), after silica-gel column chromatography with hexane–ethyl acetate (5:1 v/v), as a 1:1 mixture of two diastereomers (by ^{1}H NMR). These two isomers could be separated from each other through a careful column chromatography.

3,5-*trans*-5b: Colorless prisms; mp 30—32 °C; IR (KBr) 3400, 1780, 1670, 1470, 1180, 1120, 1030, and 930 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.00 (6H, d, J=7.7 Hz, *i*-Pr), 2.2—2.5 (1H, m, *i*-Pr), 2.37 (1H, ddd, J_{gem}=13.2, J_{4-3}=7.7, and J_{4-5}=4.4 Hz, one of 4-H), 2.41 (1H, ddd, J_{gem}=13.2, J_{4-5}= 7.7, and J_{4-3}=7.3 Hz, the other of 4-H), 4.20 (1H, br s, OH), 4.55 (1H, ddd, J_{3-4}=7.7, 7.3, and J_{3-OH}=3.3 Hz, 3-H), 5.06 (1H, ddd, J_{5-4}=7.7, 4.4, and $J_{5-1'}$=7.0 Hz, 5-H), 5.43 (1H, ddd, $J_{1'-2'}$=15.4, $J_{1'-5}$=7.0, and $J_{1'-3'}$=1.5 Hz, 1'-H), and 5.78 (1H, ddd, $J_{2'-1'}$=15.4, $J_{2'-3'}$=6.6, and $J_{2'-5'}$=1.1 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=21.89, 30.65 (each *i*-Pr), 36.47 (4-C), 67.33 (3-C), 78.80 (5-C), 124.07 (1'-C), 142.41 (2'-C), and 177.98 (2-C); MS *m/z* (rel intensity, %) 142 (M^+—CO, 1), 99 (11), 95 (28), 93 (16), 84 (17), 83 (51), 82 (base peak), 81 (14), 73 (11), and 70 (41).

3,5-*cis*-5b: Colorless prisms; mp 36—38 °C; IR (KBr) 3400, 1780, 1660, 1460, 1320, 1180, 1120, 1030, 930, and 800 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.01 (6H, d, J=7.0 Hz, *i*-Pr), 2.03 (1H, ddd, J_{gem}=12.8, J_{4-3}=11.4, and J_{4-5}=10.6 Hz, one of 4-H), 2.2—2.5 (1H, m, *i*-Pr), 2.72 (1H, ddd, J_{gem}=12.8, J_{4-3}=8.1, and J_{4-5}=5.1 Hz, the other of 4-H), 4.12 (1H, s, OH), 4.60 (1H, ddd, J_{3-4}=11.4, 8.1, and J_{3-OH}=4.4 Hz, 3-H), 4.75 (1H, ddd, J_{5-4}=10.6, 5.1, and $J_{5-1'}$=7.7 Hz, 5-H), 5.45 (1H, ddd, $J_{1'-2'}$=15.4, $J_{1'-5}$=7.7, and $J_{1'-3'}$=1.5 Hz, 1'-H), and 5.83 (1H, dd, $J_{2'-1'}$=15.4 and $J_{2'-3'}$=6.6 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=21.84, 30.70 (each *i*-Pr), 37.74 (4-C), 68.64 (3-C), 77.91 (5-C), 123.94 (1'-C), 144.11 (2'-C), and 177.91 (2-C); MS *m/z* (rel intensity, %) 170 (M^+, 1), 95 (44), 93 (32), 84 (22), 83 (65), 82 (base peak), 81 (19), 79 (11), 77 (12), 73 (19), and 70 (35).

No satisfactory analytical results were obtained due to hygroscopic nature of the both isomers of **5b**.

3-Hydroxy-5-[(*E*)-2-phenylethenyl]-4,5-dihydro-2(3*H*)-furanone (5c). A similar procedure was applied to **4c** under the following conditions: **4c** (0.171 g, 0.73 mmol) in methanol (5 ml), sodium borohydride (0.028 g, 0.73 mmol), 10 min at 0 °C, acetone (2 ml), 10 min at room temperature, hydrolytic workup and extraction with dichloromethane, *p*-toluenesulfonic acid (0.014 g., 0.073 mmol) in dichloromethane (10 ml), 20 min at room temperature, hydrolytic workup and extraction with dichloromethane, silica-gel column chromatography with hexane–ethyl acetate. A 1:1 mixture (by ^{1}H NMR) of two diastereomers of **5c** (0.128 g, 86%) was obtained. These isomers could be separated through a careful column chromatography.

3,5-*trans*-5c: Colorless prisms (dichloromethane–hexane); mp 100—103 °C; IR (KBr) 3420, 1750, 1310, 1230, 1180, 1120, 930, 800, 750, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.49 (1H, ddd, J_{gem}=13.2, J_{4-3}=8.1, and J_{4-5}=2.2 Hz, one of 4-H), 2.51 (1H, ddd, J_{gem}=13.2, J_{4-3}=8.1, and J_{4-5}=4.8 Hz, the other of 4-H), 3.58 (1H, br s, OH), 4.59 (1H, t, J_{3-4}=8.1 Hz, 3-H), 5.28 (1H, ddd, $J_{5-1'}$=6.2, J_{5-4}=4.8, and 2.2 Hz, 5-H), 6.17 (1H, dd, $J_{1'-2'}$=15.8 and $J_{1'-5}$=6.2 Hz, 1'-H), 6.67 (1H, d, $J_{2'-1'}$=15.8 Hz, 2'-H), and 7.2—7.4 (5H, m, Ph); MS *m/z* (rel intensity, %) 204 (M^+, 9), 131 (12), 129 (12), 128 (16), 117 (15), 115 (30), 105 (17), 104 (base peak), 103 (14), 102 (13), 91 (32), 77 (18), 76 (40), 63 (14), and 51 (26). Found: C, 70.47; H, 5.92%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

3,5-*cis*-5c: Colorless prisms (dichloromethane–hexane); mp 135—138 °C; IR (KBr) 3450, 1750, 1320, 1200, 1120, 970, 910, 800, 760, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.12 (1H, ddd, J_{gem}=12.5, J_{4-5}=11.0, and J_{4-3}=10.8 Hz, one of 4-H), 2.84 (1H, ddd, J_{gem}=12.5, J_{4-3}=8.1, and J_{4-5}=5.5 Hz, the other of 4-H), 3.22 (1H, br s, OH), 4.61 (1H, dd, J_{3-4}=10.8 and 8.1 Hz, 3-H), 4.98 (1H, ddd, J_{5-4}=11.0, 5.5, and $J_{5-1'}$=7.3 Hz, 5-H), 6.19 (1H, dd, $J_{1'-2'}$=15.8 and $J_{1'-5}$=7.3 Hz, 1'-H), 6.72 (1H, d, $J_{2'-1'}$=15.8 Hz, 2'-H), and 7.2—7.4 (5H, m, Ph); MS *m/z* (rel intensity, %) 204 (M^+, 6), 129 (21), 128 (12), 117 (19), 115 (37), 104 (base peak), 103 (11), 91 (30), 78 (14), 77 (16), and 51 (22). Found: C, 70.47; H, 5.92%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.91%.

3-Bromo-5-[(*E*)-1-pentenyl]-4,5-dihydro-2(3*H*)-furanone (6a). To a solution of **5a** (0.06 g, 0.35 mmol) in dry dichloromethane (2 ml) were added, at 0 °C under nitrogen, triethylamine (0.043 g, 0.42 mmol) and methanesulfonyl chloride (0.055 g, 0.42 mmol). After stirring at 0 °C for 2 h, the mixture was poured into saturated aqueous ammonium chloride and extracted with dichlomethane (15 ml×2). The combined extracts were washed with saturated aqueous sodium hydrogencarbonate and dried over magnesium sulfate. The residue obtained by evaporation of the dichloromethane in vacuo was dissolved in dry THF (2 ml). After lithium bromide (0.061 g, 0.71 mmol) was added, the mixture was stirred at room temperature for 20 h under nitrogen, poured into water, and extracted with dichloromethane (15 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed on silica gel with hexane–ethyl acetate (7:1 v/v) to give **6a** (0.058 g, 71%) as a 1:1 mixture (by ^{1}H NMR) of two diastereomers which could be separated from each other through a careful column chromatography.

3,5-*trans*-6a: Colorless liquid; IR (neat) 1780, 1670, 1460, 1430, 1380, 1320, 1180, 1030, 970, and 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.3 Hz, *n*-Pr), 1.43 (2H, sx, J=7.3 Hz, *n*-Pr), 2.07 (2H, dt, J=7.3 and 6.6 Hz, *n*-Pr),

2.47 (1H, ddd, J_{gem}=14.7, J_{4-5}=7.3, and J_{4-3}=6.6 Hz, one of 4-H), 2.59 (1H, ddd, J_{gem}=14.7, J_{4-5}=5.5, and J_{4-3}=2.2 Hz, the other of 4-H), 4.44 (1H, dd, J_{3-4}=6.6 and 2.2 Hz, 3-H), 5.14 ((1H, dt, J_{5-4}=$J_{5-1'}$=7.3, and J_{5-4}=5.5 Hz, 5-H), 5.50 (1H, dd, $J_{1'-2'}$=15.4 and $J_{1'-5}$=7.3 Hz, 1'-H), and 5.92 (1H, dt, $J_{2'-1'}$=15.4 and $J_{2'-3'}$=6.6 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=13.58, 21.81, 34.14 (each *n*-Pr), 38.96 (4-C), 40.16 (3-C), 80.31 (5-C), 125.65 (1'-C), 137.71 (2'-C), and 172.42 (2-C); MS *m/z* (rel intensity, %) 234 (M^++2, 18), 232 (M^+, 20), 191 (47), 189 (50), 153 (75), 109 (58), 81 (28), 78 (21), 69 (23), 67 (base peak), and 55. HRMS Found: *m/z* 232.0093. Calcd for $C_9H_{13}O_2Br$: M, 232.0099.

3,5-*cis*-6a: Colorless liquid; IR (Neat) 1780, 1660, 1450, 1320, 1265, 1160, 970, and 930 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, t, J=7.3 Hz, *n*-Pr), 1.43 (2H, sx, J=7.3 Hz, *n*-Pr), 2.07 (2H, dt, J=7.3 and 6.6 Hz, *n*-Pr), 2.38 (1H, ddd, J_{gem}=13.9, J_{4-5}=8.6, and J_{4-5}=8.4 Hz, one of 4-H), 3.02 (1H, ddd, J_{gem}=13.9, J_{4-3}=8.4, and J_{4-5}=6.2 Hz, the other of 4-H), 4.56 (1H, t, J_{3-4}=8.4 Hz, 3-H), 4.89 (1H, ddd, J_{5-4}=8.6, 6.2, and $J_{5-1'}$=7.7 Hz, 5-H), 5.60 (1H, dd, $J_{1'-2'}$=15.4 and $J_{1'-5}$=7.7 Hz, 1'-H), and 5.87 (1H, dt, $J_{2'-1'}$=15.4 and $J_{2'-3'}$=6.6 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=13.59, 21.80, 34.10 (each *n*-Pr), 37.91 (4-C), 39.77 (3-C), 79.98 (5-C), 126.49 (1'-C), 137.56 (2'-C), and 172.51 (2-C); MS *m/z* (rel intensity, %) 234 (M^++2, 43), 232 (M^+, 39), 191 (34), 189 (34), 153 (37), 109 (52), 78 (25), 67 (base peak), and 55 (84). HRMS Found: *m/z* 232.0086. Calcd for $C_9H_{13}O_2Br$: M, 232.0099.

3-Bromo-5-[(*E*)-3-methyl-1-butenyl]-4,5-dihydro-2(3*H*)-furanone (6b). A similar procedure was applied to **5b** under the following conditions: **5b** (0.287 g, 1.69 mmol) in dry dichloromethane (3 ml), triethylamine (0.205 g, 2.02 mmol), and methanesulfonyl chloride (0.263 g, 2.02 mmol) at 0 °C for 3 h, hydrolytic workup and extraction with dichloromethane (20 ml×2), lithium bromide (0.293 g, 3.37 mmol) in THF (3 ml), stirring at room temperature for 24 h, hydrolytic workup and extraction with dichloromethane, column chromatography on silica gel with hexane-ethyl acetate (7:1 v/v). A 1:1 mixture of two diastereomers of **6b** (by ^{1}H NMR, 0.315 g, 80%) was obtained by this procedure, which could be separated from each other through a careful column chromatography.

3,5-*trans*-6b: Colorless liquid; IR (neat) 1780, 1670, 1460, 1430, 1320, 1290, 1180, 1030, 970, and 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.02 (6H, d, J=7.0 Hz, *i*-Pr), 2.2—2.5 (1H, m, *i*-Pr), 2.49 (1H, ddd, J_{gem}=14.7, J_{4-5}=8.8, and J_{4-3}=6.2 Hz, one of 4-H), 2.59 (1H, ddd, J_{gem}=14.7, J_{4-5}=5.5, and J_{4-3}=1.8 Hz, the other of 4-H), 4.45 (1H, dd, J_{3-4}=6.2 and 1.8 Hz, 3-H), 5.12 (1H, ddd, J_{5-4}=8.8, 5.5, and $J_{5-1'}$=7.3 Hz, 5-H), 5.45 (1H, dd, $J_{1'-2'}$=15.4 and $J_{1'-5}$=7.3 Hz, 1'-H), and 5.90 (1H, dd, $J_{2'-1'}$=15.4 $J_{2'-3'}$=5.5 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=21.79, 30.71 (each *i*-Pr), 38.98 (4-C), 40.16 (3-C), 80.36 (5-C), 122.67 (1'-C), 144.47 (2'-C), and 172.39 (2-C); MS *m/z* (rel intensity, %) 234 (M^++2, 3), 232 (M^+, 3), 191 (38), 189 (41), 153 (53), 109 (96), 81 (27), 69 (92), 67 (51), and 55 (base peak). HRMS Found: *m/z* 232.0081. Calcd for $C_9H_{13}O_2Br$: M, 232.0099.

3,5-*cis*-6b: Colorless liquid; IR (neat) 1780, 1670, 1470, 1325, 1170, 975, and 930 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.02 (6H, d, J=7.0 Hz, *i*-Pr), 2.2—2.5 (1H, m, *i*-Pr), 2.37 (1H, ddd, J_{gem}=13.6, J_{4-3}=9.2, and J_{4-5}=8.8 Hz, one of 4-H), 3.02 (1H, ddd, J_{gem}=13.6, J_{4-3}=8.4, and J_{4-5}=6.2 Hz, the other of 4-H), 4.57 (1H, dd, J_{3-4}=9.2 and 8.4 Hz, 3-H), 4.88 (1H, dd, J_{5-4}=8.8, 6.2, and $J_{5-1'}$=7.3 Hz, 5-H), 5.54 (1H, dd, $J_{1'-2'}$= 15.4 and $J_{1'-5}$=7.3 Hz, 1'-H), and 5.85 (1H, dd, $J_{2'-1'}$=15.4 and $J_{2'-3'}$=6.6 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=21.77, 30.71 (each *i*-Pr), 37.82 (4-C), 39.80 (3-C), 80.04 (5-C), 123.54 (1'-C), 144.32 (2'-C), and 172.43 (2-C); MS *m/z* (rel intensity, %) 234 (M^++2, 2), 232 (M^+, 2), 191 (22), 189 (21), 153 (57), 109 (67), 81 (24), 79 (23), 69 (base peak), 67 (54), 56 (21), and 55 (94). HRMS Found: *m/z* 232.0074. Calcd for $C_9H_{13}O_2Br$: M, 232.0099.

3-Bromo-5-[(*E*)-2-phenylethenyl]-4,5-dihydro-2(3*H*)-furanone (6c). A similar procedure was applied to **5c** under the following conditions: **5c** (0.099 g, 0.048 mmol) in dichloromethane (3 ml), triethylamine (0.054 g, 0.53 mmol), and methanesulfonyl chloride (0.061 g, 0.53 mmol) in dichloromethane (1 ml) at −20 °C, stirring at 0 °C for 2 h, hydrolytic workup and extraction with dichloromethane (20 ml×2), lithium bromide (0.084 g, 0.97 mmol) in THF (2 ml), at room temperature for 24 h, hydrolytic workup and extraction, column chromatography on silica gel with hexane-ethyl acetate (7:1 v/v). A 1:1 mixture (by ^{1}H NMR) of two diastereomers of **6c** (0.09 g, 70%) was obtained, which could be separated from each other through a careful column chromatography.

3,5-*trans*-6c: Colorless liquid; IR (neat) 1770, 1490, 1440, 1370, 1305, 1170, 1030, 970, 920, and 760 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.5—2.8 (2H, m, 4-H), 4.48 (1H, dd, J_{3-4}=6.6 and 2.2 Hz, 3-H), 5.33 (1H, dt, J_{5-4}=8.8, 7.3, and $J_{5-1'}$=7.3 Hz, 5-H), 6.17 (1H, dd, $J_{1'-2'}$=15.8 and $J_{1'-5}$=7.3 Hz, 1'-H), 6.76 (1H, d, $J_{2'-1'}$=15.8 Hz, 2'-H), and 7.2—7.5 (5H, m, Ph).

3,5-*cis*-6c: Colorless liquid; IR (neat) 1770, 1480, 1440, 1380, 1330, 1165, 970, 920, and 750 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.49 (1H, ddd, J_{gem}=13.9, J_{4-3}=8.8, and J_{4-5}=7.7 Hz, one of 4-H), 3.12 (1H, ddd, J_{gem}=13.9, J_{4-3}=8.4, and J_{4-5}=6.6 Hz, the other of 4-H), 4.60 (1H, dd, J_{3-4}=8.8 and 8.4 Hz, 3-H), 5.11 (1H, ddd, J_{5-4}=7.7, 6.6, and $J_{5-1'}$=7.3 Hz, 5-H), 6.28 (1H, dd, $J_{1'-2'}$=15.8 and $J_{1'-5}$=7.3 Hz, 1'-H), 6.73 (1H, d, $J_{2'-1'}$= 15.8 Hz, 2'-H), and 7.2—7.5 (5H, m, Ph).

(*Z*)-5-Pentylidene-2(5*H*)-furanone (7a). To a solution of **6a** (0.276 g, 1.18 mmol) in dry THF (12 ml) were added hydroquinone (0.013 g, 0.118 mmol) and DBU (0.36 g, 2.37 mmol) in THF (8 ml). The mixture was heated under reflux for 2 h, poured into saturated aqueous ammonium chloride, and extracted with diethyl ether (20 ml×2). The combined ethers were washed with saturated aqueous sodium chloride, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed on silica gel with hexane-ethyl acetate (5:1 v/v) to give **7a**[3b] (0.105 g, 58%) as a single isomer (by ^{1}H NMR): Pale yellow liquid; IR (neat) 1780, 1670, 1550, 1460, 1180, 1120, 1100, 1060, 940, 870, and 830 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, t, J=7.0 Hz, *n*-Bu), 1.2—1.6 (4H, m, *n*-Bu), 2.41 (2H, dt, J=8.1 and 7.0 Hz, *n*-Bu), 5.32 (1H, t, $J_{1'-2'}$=8.1 Hz, 1'-H), 6.14 (1H, d, J_{3-4}=5.5 Hz, 3-H), and 7.35 (1H, d, J_{4-3}=5.5 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=13.79, 22.36, 26.18, 31.04 (each *n*-Bu), 117.81 (1'-C), 118.90 (3-C), 143.72 (4-C), 149.74 (5-C), and 170.20 (2-C); MS *m/z* (rel intensity, %) 152 (M^+, 13), 109 (28), 81 (36), 80 (39), 68 (26), 67 (27), 55 (85), and 41 (base peak). HRMS Found: *m/z* 152.0839. Calcd for $C_9H_{12}O_2$: M, 152.0837.

(*Z*)-5-(3-Methylbutylidene)-2(5*H*)-furanone (7b). A similar prodedure was applied to **6a** under the following conditions: **6a** (0.34 g, 1.46 mmol), hydroquinone (0.016 g, 0.146 mmol), and DBU (0.444 g, 2.92 mmol) in dry THF (25 ml), heating under reflux for 2 h, hydrolytic workup and

extraction with diethyl ether (25 ml×2), column chromatography on silica gel with hexane–ethyl acetate (5:1 v/v). A single isomer (by ^{1}H NMR) of **7b** (0.111 g, 50%) was obtained: Pale yellow liquid; IR (neat) 1780, 1670, 1560, 1330, 1210, 1145, 1110, 1080, 950, 890, and 820 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.95 (6H, d, J=6.6 Hz, *i*-Bu), 1.7—1.9 (1H, m, *i*-Bu), 2.35 (2H, dd, J=8.1 and 6.6 Hz, *i*-Bu), 5.34 (1H, t, $J_{1'-2'}$=8.1 Hz, 1'-H), 6.15 (1H, d, J_{3-4}=5.5 Hz, 3-H), and 7.37 (1H, d, J_{4-3}=5.5 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=22.33, 28.57, 35.32 (each *i*-Bu), 116.58 (1'-C), 118.96 (3-C), 143.65 (4-C), 150.22 (5-C), and 170.22 (2-C); MS *m/z* (rel intensity, %) 152 (M^+, 4), 81 (25), 80 (23), 56 (53), 55 (53), and 42 (base peak). HRMS Found: *m/z* 152.0835. Calcd for $C_9H_{12}O_2$: M, 152.0837.

3-(Methylsulfonyloxy)-5-[(*E*)-1-pentenyl]-4,5-dihydro-2(3*H*)-furanone (8). To a solution of **5a** (0.071 g, 0.42 mmol) in dry dichloromethane (2 ml) were added dropwise, at 0 °C under nitrogen, methanesulfonyl chloride (0.057 g, 0.5 mmol), and then triethylamine (0.046 g, 0.46 mmol). After stirring for 2 h at 0 °C, the mixture was poured into saturated aqueous ammonium chloride and extracted with dichloromethane (20 ml×2). The combined extracts were washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed on silica gel with hexane–ethyl acetate (3:1 v/v) to give **8** (0.066 g, 63%) as a 1:1 mixture of two diastereomers (by ^{1}H NMR) which could be separated from each other through a careful column chromatography.

***3,5-trans*-8:** Colorless liquid; IR (neat) 1780, 1670, 1460, 1370, 1170, 970, and 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.3 Hz, *n*-Pr), 1.43 (2H, sx, J=7.3 Hz, *n*-Pr), 2.07 (2H, ddt, J=7.3, 6.6, and 1.5 Hz, *n*-Pr), 2.50 (1H, ddd, J_{gem}=13.9, J_{4-3}=8.1, and J_{4-5}=4.8 Hz, one of 4-H), 2.67 (1H, dt, J_{gem}=13.9, J_{4-3}=J_{4-5}=7.0 Hz, the other of 4-H), 3.25 (3H, s, Me), 5.0—5.2 (1H, m, 5-H), 5.29 (1H, dd, J_{3-4}=8.1 and 7.0 Hz, 3-H), 5.48 (1H, ddt, $J_{1'-2'}$=15.4, $J_{1'-5}$=7.0, and $J_{1'-3'}$=1.5 Hz, 1'-H), and 5.86 (dt, $J_{2'-1'}$=15.4 and $J_{2'-3'}$=6.6 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=13.58, 21.79, 34.05 (each *n*-Pr), 35.09 (Me), 39.42 (4-C), 74.09 (3-C), 79.05 (5-C), 126.29 (1'-C), 136.77 (2'-C), and 171.25 (2-C); MS *m/z* (rel intensity, %) 153 (M^+—OMs, 1), 97 (13), 83 (11), 81 (35), 79 (57), 69 (13), 67 (35), and 55 (base peak).

Methyl 3-[(Diethoxyphosphinyl)methyl]-5-methyl-2-isoxazoline-5-carboxylate (11). To a solution of (diethoxyphosphinyl)acetaldehyde oxime (7.81 g, 40 mmol) in dry DMF (50 ml) was added dropwise at −20 °C a solution of NBS (14.2 g, 80 mmol) in dry DMF (50 ml). After stirring at −20 °C for 1 h and at 0 °C for 30 min, the mixture was diluted with dry diethyl ether (50 ml). A mixture of methyl methacrylate (8.01 g, 80 mmol) and triethylamine (4.05 g, 40 mmol) in diethyl ether (50 ml) was slowly added, the resulting mixture was stirred at room temperature for 18 h, poured into ice water, and extracted with dichloromethane (50 ml×2). The combined extracts were washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed on silica gel with hexane–ethyl acetate (5:1 v/v) to give **11** (7.62 g, 65%): Pale yellow liquid; IR (neat) 1740, 1670, 1440, 1390, 1340, 1250, 1020, 960, and 790 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.33 (6H, t, J=7.0 Hz, OEt), 1.60 (3H, s, Me), 2.95 (2H, d, J_{H-P}=22.0 Hz, PCH_2), 3.01, 3.59 (each 1H, dd, J_{gem}=18.0 and J_{H-P}=4.0 Hz, 4-H), 3.76 (3H, s, COOMe), and 4.11 (4H, dq, J=7.0 and J_{H-P}=8.0 Hz, OEt); ^{13}C NMR ($CDCl_3$) δ=16.39 (d, J_{C-P}= 5.9 Hz, OEt), 23.35 (Me), 26.26 (d, J_{C-P}=140.9 Hz, PCH_2), 47.04 (4-C), 52.89 (COOMe), 62.63 (d, J_{C-P}=5.9 Hz, OEt), 85.9 (5-C), 151.44 (d, J_{C-P}=9.8 Hz, 3-C), and 172.31 (COOMe); MS *m/z* (rel intensity, %) 293 (M^+, 1), 234 (base peak), 206 (28), 178 (59), and 160 (16). Satisfactory analytical result was not obtained because of its hygroscopic nature.

Methyl 5-(Diethoxyphosphinyl)-2-hydroxy-2-methyl-4-oxopentanoate (12). To a solution of **11** (7,62 g, 26 mmol) in

aqueous ethanol (17%, 78 ml) were added Raney Ni (W-2, suspension in ethanol, 6 ml) and boric acid (6.43 g, 104 mmol). The mixture was stirred at room temperature under hydrogen (1 atm) for 14 h. After removal of the catalyst by filtration through Celite 545, the filtrate was diluted with water and extracted with dichloromethane (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed on silica gel with ethyl acetate to give **12** (6.6 g, 86%): Colorless liquid; IR (neat) 3340, 1740, 1710, 1450, 1390, 1250, 1020, 970, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.34 (6H, t, J=7.0 Hz, OEt), 1.41 (3H, s, Me), 3.04 (1H, d, J_{gem}=17.6 one of 3-H), 3.11 (2H, d, J_{H-P}=22.7 Hz, 5-H), 3.28 (1H, d, J_{gem}=17.6 Hz, the other of 3-H), 3.76 (3H, s, COOMe), 3.82 (1H, s, OH), and 4.14 (4H, dq, J=7.0 and J_{H-P}=7.5 Hz, OEt); ^{13}C NMR ($CDCl_3$) δ=16.31 (d, J_{C-P}=6.8 Hz, OEt), 26.26 (Me), 43.18 (d, J_{C-P}=127.2 Hz, PCH_2), 52.71 (COOMe), 52.86 (3-C), 62.72 (d, J_{C-P}=5.9 Hz, OEt), 72.45 (2-C), 176.01 (COOMe), and 200.79 (d, J_{C-P}=5.9 Hz, 4-C); MS m/z (rel intensity, %) 296 (M^+, 0.3), 237 (base peak), 167 (22), 139 (42), 123 (30), 42 (54), and 30 (20). HRMS Found: m/z 296.1023. Calcd for $C_{11}H_{21}O_7P$: M, 296.1023.

Methyl (*E*)-2-Hydroxy-2-methyl-4-oxo-5-nonenoate (13a). Under nitrogen, a solution of **12** (0.727 g, 2.45 mmol) in dry THF (5 ml) was added to a solution of lithium bromide (0.213 g, 2.45 mmol) in THF (2 ml). After stirring at room temperature for 10 min, a solution of DBU (0.355 g, 2.33 mmol) in THF (5 ml) was added at 0 °C, stirring was continued for 1 h, and then butanal (0.354 g, 4.19 mmol) was slowly added. After stirring at 0 °C for 24 h, the reaction mixture was poured into ice water and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed on silica gel by using hexane–ethyl acetate (3:1 v/v) as an eluent to give **13a** (0.443 g, 84%): Colorless liquid; IR (neat) 3510, 1750, 1670, 1630, 1460, 1380, 1300, 1210, 1120, and 990 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (3H, t, J=7.3 Hz, n-Pr), 1.43 (3H, s, Me), 1.50 (2H, sx, J=7.3 Hz, n-Pr), 2.21 (2H, dq, J=7.3 and 1.5 Hz, n-Pr), 2.91, 3.26 (each 1H, J_{gem}=17.2 Hz, 3-H), 3.76 (3H, s, COOMe), 4.00 (1H, s, OH), 6.07 (1H, dt, J_{5-6}=15.8 and J_{5-7}=1.5 Hz, 5-H), and 6.88 (1H, dt, J_{6-5}=15.8 and J_{6-7}=7.3 Hz, 6-H); ^{13}C NMR ($CDCl_3$) δ=13.68, 21.24, 34.54 (each n-Pr), 26.28 (Me), 48.83 (3-C), 52.64 (COOMe), 72.74 (2-C), 130.29 (5-C), 149.24 (6-C), 176.32 (COOMe), and 199.00 (4-C); MS m/z (rel intensity, %) 214 (M^+, 5), 155 (27), 97 (base peak), 55 (62), 43 (51), and 41 (24). HRMS Found: m/z 214.1207. Calcd for $C_{11}H_{18}O_4$: M, 214.1208.

Methyl (*E*)-2-Hydroxy-2,7-dimethyl-4-oxo-5-octenoate (13b). A similar procedure was applied under the following conditions: **12** (1.439 g, 4.86 mmol) in dry THF (9 ml), lithium bromide (0.422 g, 4.86 mmol) in THF (2 ml), 10 min at room temperature, DBU (0.702 g, 4.61 mmol) in THF (9 ml) at 0 °C, stirring at 0 °C for 1 h, 2-methylpropanal (0.701 g, 9.71 mmol), stirring at 0 °C for 24 h, hydrolytic workup and extraction with dichloromethane (20 ml×2), column chromatography on silica gel with hexane–ethyl acetate (3:1 v/v). This procedure gave **13b** (0.805 g, 77%): Colorless liquid; IR (neat) 3500, 1740, 1670, 1630, 1460, 1370, 1200, 1120, and 990 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (6H, d, J=7.0 Hz, i-Pr), 1.43 (3H, s, Me), 2.3—2.6 (1H, m, i-Pr), 2.92, 3.26 (each 1H, d, J_{gem}=17.2 Hz, 3-H), 3.76 (3H, s, COOMe), 3.99 (1H, s, OH), 6.02 (1H, dd, J_{5-6}=16.1 and J_{5-7}=1.5 Hz, 5-H), and 6.84 (1H, dd, J_{6-5}=16.1 and J_{6-7}=6.6 Hz, 6-H); ^{13}C NMR ($CDCl_3$) δ=21.17, 31.17 (each i-Pr), 26.25 (Me), 48.97 (3-C), 52.50 (COOMe), 72.61 (2-C), 127.45 (5-C), 155.06 (6-C), 176.25 (COOMe), and 199.07 (4-C); MS m/z (rel intensity, %) 214 (M^+, 4), 155 (29), 97 (base peak), 43 (34), and 41 (24). HRMS Found: m/z 214.1212. Calcd for $C_{11}H_{18}O_4$: M, 214.1204.

3-Hydroxy-3-methyl-5-[(*E*)-1-pentenyl]-4,5-dihydro-2(3*H*)-furanone (14a). A single isomer of **14a** (0.347 g, 56%) was obtained by a procedure similar to that employed for the preparation of **5a** from **4a** under the following conditions: **13a** (0.723 g, 3.37 mmol) in methanol (8 ml), sodium borohydride (0.128 g, 3.37 mmol), stirring at 0 °C for 10 min, acetone (4 ml), stirring at 0 °C for 10 min, hydrolytic workup and extraction with dichloromethane (20 ml×2), the crude product and p-toluenesulfonic acid (0.064 g, 0.337 mmol) in dichloromethane (8 ml), stirring at room temperature for 2 h, hydrolytic workup and extraction with dichloromethane (20 ml×2), column chromatography on silica gel with hexane–ethyl acetate (5:1 v/v): Colorless prisms; mp 49—51 °C; IR (KBr) 3400, 1750, 1440, 1380, 1320, 1180, 1120, 960, 920, and 600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.3 Hz, n-Pr), 1.42 (2H, sx, J=7.3 Hz, n-Pr), 1.49 (3H, s, Me), 1.91 (1H, dd, J_{gem}=13.6 and J_{4-5}=8.4 Hz, one of 4-H), 2.05 (2H, q, J=7.3 Hz, n-Pr), 2.50 (1H, dd, J_{gem}=13.6 and J_{4-5}=6.2 Hz, the other of 4-H), 3.71 (1H, br s, OH), 5.05 (1H, ddd, J_{5-4}=8.4, 6.2, and $J_{5-1'}$=7.3 Hz, 5-H), 5.46 (1H, dd, $J_{1'-2'}$=15.1 and $J_{1'-5}$=7.3 Hz, 1'-H), and 5.84 (1H, dt, $J_{2'-1'}$=15.1 and $J_{2'-3'}$=7.3 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=13.59, 21.91 (each n-Pr), 23.92 (Me), 34.17 (n-Pr), 43.37 (4-C), 73.66 (3-C), 78.64 (5-C), 127.28 (1'-C), 136.22 (2'-C), and 178.54 (COOMe); MS m/z (rel intensity, %) 167 (M^+—OH, 0.4), 97 (20), 81 (34), 71 (26), 67 (19), 58 (17), 55 (18), and 43 (base peak). Found C, 64.92; H, 9.00%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

3-Hydroxy-3-methyl-5-[(*E*)-3-methyl-1-butenyl]-4,5-dihydro-2(3*H*)-furanone (14b). A similar procedure was applied to **13b** under the following conditions: **13b** (0.747 g, 3.49 mmol) in methanol (7 ml), sodium borohydride (0.132 g, 3.49 mmol) stirring at 0 °C for 10 min, acetone (3 ml), stirring at 0 °C for 10 min, hydrolytic workup and extraction with dichloromethane (15 ml×2), the crude product and p-toluenesulfonic acid (0.066 g, 0.349 mmol) in dichloromethane (7 ml), stirring at room temperature for 1 h, hydrolytic workup and extraction with dichloromethane (15 ml×2), silica-gel column chromatography with hexane–ethyl acetate (5:1 v/v). From this procedure was obtained a single isomer of **14b** (0342 g, 53%) which was contaminated by a trace amount of an unidentified product: Colorless prisms; mp 85—87 °C; IR (KBr) 3420, 1750, and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (6H, d, J=7.0 Hz, i-Pr), 1.50 (3H, s, Me), 1.92 (1H, dd, J_{gem}=13.6 and J_{4-5}=8.4 Hz, one of 4-H), 2.50 (1H, dd, J_{gem}=13.6 and J_{4-5}=6.2 Hz, the other of 4-H), 3.76 (1H, m, OH), 5.05 (1H, ddd, J_{5-4}=8.4, 6.2, and $J_{5-1'}$=7.0 Hz, 5-H), 5.41 (1H, dd, $J_{1'-2'}$=15.4 and $J_{1'-5}$=7.0 Hz, 1'-H), and 5.82 (1H, dd, $J_{2'-1'}$=15.4 and $J_{2'-3'}$=6.2 Hz, 2'-H); ^{13}C NMR ($CDCl_3$) δ=21.89 (i-Pr), 23.99 (Me), 30.71 (i-Pr), 43.34 (4-C), 73.66 (3-C), 78.67 (5-C), 124.26 (1'-C), 143.06 (2'-C), and 178.50 (2-C); MS m/z (rel intensity, %) 167 (M^+—OH, 8), 95 (21), 81 (49), 71 (22), 55 (34), and 43 (base peak).

(*Z*)-3-Methyl-5-pentylidene-2(5*H*)-furanone (16a). To a solution of **14a** (0.23 g, 1.25 mmol) in dry dichloromethane

(5 ml) were added, at 0 °C under nitrogen, triethylamine (0.152 g, 1.5 mmol) and methanesulfonyl chloride (0.171 g, 1.5 mmol). After stirring at 0 °C for 3 h, the mixture was poured into saturated aqueous ammonium chloride and extracted with dichloromethane (15 ml×2). The combined extracts were washed with saturated aqueous sodium hydrogencarbonate, dried over magnesium sulfate, and evaporated in vacuo. The residue was dissolved in dry THF (5 ml) and lithium bromide (0.217 g, 2.5 mmol) was added. The mixture was refluxed under nitrogen for 1 h, poured into water, and extracted with dichloromethane (15 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was filtered through a short column packed by silica gel. The fraction eluted with hexane–ethyl acetate (5:1 v/v) was evaporated in vacuo to give crude **15a** (0.183 g). This product was disolved in dry THF (1 ml) and were added hydroquinone (0.014 g, 0.125 mmol) and DBU (0.38 g, 2.5 mmol). This mixture was refluxed under nitrogen for 1 h, poured into saturated aqueous ammonium chloride, and extracted with diethyl ether. The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed on silica gel by using hexane–diethyl ether (5:1 v/v) to afford **16a** (0.131 g, 63%): Colorless luquid; IR (neat) 1780, 1670, 1620, 1460, 1050, 990, 890, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.0 Hz, *n*-Bu), 1.2—1.5 (4H, m, *n*-Bu), 1.99 (3H, d, J_{Me-4}=1.5 Hz, Me), 2.37 (2H, dt, J=7.7 and 7.0 Hz, *n*-Bu), 5.17 (1H, t, $J_{1'-2}$=7.7 Hz, 1'-H), and 7.02 (1H, q, J_{4-Me}=1.5 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=10.47 (Me), 13.81, 22.36, 25.89, 31.26 (each *n*-Bu), 114.81 (1'-C), 128.85 (3-C), 137.91 (4-C), 148.43 (5-C), and 171.27 (2-C); MS *m/z* (rel intensity, %) 166 (M^+, 16), 123 (58), 110 (35), 96 (31), 95 (23), 81 (32), 69 (20), 68 (60), 67 (20), 60 (28), and 55 (base peak). HRMS Found: *m/z* 166.0990. Calcd for $C_{10}H_{14}O_2$: M, 166.0993.

(*Z*)-3-Methyl-5-(3-methylbutylidene)-2(5*H*)-furanone (16b). A similar procedure was performed under the following procedure: **14b** (0.339 g, 1.84 mmol) in dry dichloromethane (7 ml), addition of triethylamine (0.223 g, 2.21 mmol) and methanesulfonyl chloride (0.253 g, 2.21 mmol) at 0 °C, stirring at 0 °C for 3 h under nitrogen, hydrolytic workup and extraction with dichloromethane, the crude product and lithium bromide (0.32 g, 3.68 mmol) in THF (5 ml), heating under reflux for 1 h, hydrolytic workup and extraction with dichloromethane, filtration through a short column, the crude product (0.297 g) and hydroquinone (0.02 g, 0.184 mmol) and DBU (0.56 g, 3.68 mmol) in THF (4 ml), heating under reflux for 1 h, hydrolytic workup and extraction with diethyl ether, a silica-gel chromatography with hexane–diethyl ether (5:1). Thus a single isomer of **16b** (0.153 g, 50%) was obtained: Colorless liquid; IR (neat) 1770, 1680, 1620, 1460, 1060, 1040, 990, 890, and 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (6H, d, J=6.6 Hz, *i*-Bu), 1.6—1.9 (1H, m, *i*-Bu), 1.99 (3H, d, J_{Me-4}=1.5 Hz, Me), 2.27 (2H, dd, J=8.1 and 7.3 Hz, *i*-Bu), 5.17 (1H, t, $J_{1'-2'}$=8.1 Hz, 1'-H), and 7.01 (1H, q, J_{4-Me}=1.5 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=10.48 (Me), 22.32, 28.65, 35.06 (each *i*-Bu), 113.57 (1'-C), 128.95 (3-C), 137.76 (4-C), 148.89 (5-C), and 171.30 (2-C); MS *m/z* (rel intensity, %) 166 (M^+, 12), 123 (85), 111 (21), 95 (36), 68 (44), 67 (24), 56 (88), 54 (22), and 40 (base peak). HRMS Found: *m/z* 166.0992. Calcd for $C_{10}H_{14}O_2$: M, 166.0993.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 61470095) from the Ministry of Education, Science and Culture.

Acid-Catalyzed Transformation of α-Hydroxy-γ-oxo Acetals to γ-Oxo Esters. A Novel Deconjugation of 4-Oxo-2-alkenal Acetals

Shuji KANEMASA,* Norihiko NAKAGAWA, Hiroyuki SUGA, and Otohiko TSUGE*

(Received July 15, 1988)

Under acid catalysis, α-hydroxy-γ-oxo acetals which are readily available from the nitrile oxide cycloaddition route are smoothly converted into γ-oxo esters. This unusual and high-yield transformation involves rare acid-catalyzed deconjugation of the intermediary 4-oxo-2-alkenal acetals and is influenced by a substituent at the 5-position.

A sequence of cycloadditions of (diethoxyphosphinyl)acetonitrile oxide with olefins or acetylenes and reductive N–O bond cleavage of the cycloadducts provides 4-hydroxy-2-oxoalkylphosphonates.[1] The resulting functionalities are synthetically important when they are utilized in organic synthesis either separately, all together, or together with an additional function introduced from dipolarophiles.[2]

We were investigating a possibility of acid-catalyzed one-step transformation of 2-hydroxy-4-oxo-5-alkenal acetals into 5-alkylidene-2(3*H*)-furanones which are important heterocycles often seen in natural products.[3] During this investigation we came across an unusual and high-yield transformation of the acetals to γ-oxo esters. All the results with respect to this novel transformation and its reaction mechanism are discussed in the present article.

Results and Discussion

Acid-catalyzed ring closure of 2-hydroxy-4-oxo-5-alkenal acetals must be useful as a direct synthetic way to 5-alkylidene-2(3*H*)-furanones[4] when the starting acetals are easily available. Since we previously tested the synthetic value of Horner–Emmons olefination of 4-hydroxy-2-oxoalkylphosphonates,[5] its applications to the synthesis of 5-alkylidene-2(3*H*)-furanones were aimed.

(*E*)-6,6-Diethoxy-5-hydroxy-1-phenyl-1-hexen-3-one (**3**) as a starting compound, can be prepared by Horner–Emmons olefination of diethyl 5,5-diethoxy-4-hydroxy-2-oxopentylphosphonate (**2**) which is available by a sequence of 1,3-dipolar cycloaddition of (diethoxyphosphinyl)acetonitrile oxide with 3,3-diethoxypropene and Raney Ni reduction of the cycloadduct, 5-(diethoxymethyl)-3-[(diethoxyphosphinyl)-methyl]-2-isoxazoline (**1**).[1,5]

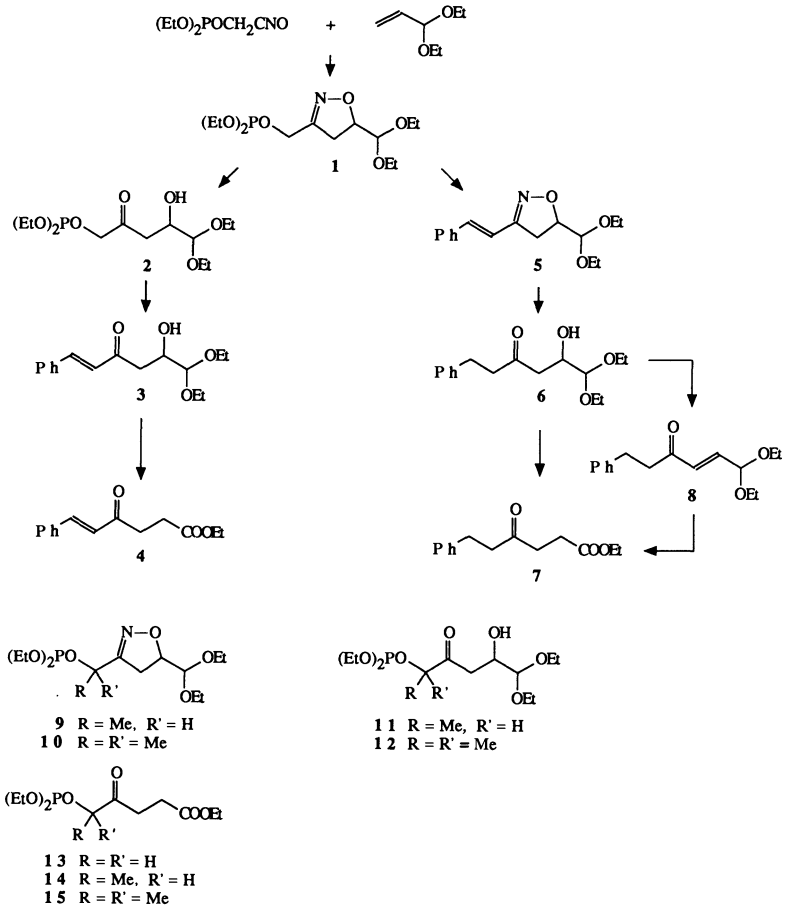
Treatment of **3** with hydrogen chloride in chloroform at room temperature unexpectedly led to quantitative formation of ethyl (*E*)-4-oxo-5-hexenoate (**4**) (Scheme 1). This reaction can be complete in 20 min at 0 °C and the same product **4** was obtained in 89% yield. Ester **4** showed quite high stability against acid. For example, **4** stayed unchanged even when heated under reflux in chloroform together with hydrogen chloride for a long time (18 h). This quantitative ester formation contrasts with the reported example[4] where an analogous acetal, 6-hydroxy-2,6-dimethyl-7,7-dimethoxy-2-hepten-4-one, gives 3-methyl-5-(2-methylpropylidene)-2(3*H*)-furanone in 72% yield under the comparable conditions. Although there are known several ring-closure reactions of γ-oxo esters or acids leading to 2-furanone derivatives,[1,6] the high stability of ester **4** indicates that the furanone synthesis cited in Ref. 4 has proceeded not via the corresponding γ-oxo ester intermediate.[7]

To see whether the double bond of **3** is requisite or not for this novel transformation, the saturated ketone **6** was prepared from **1**. The Horner–Emmons olefination of 2-isoxazoline **1** with benzaldehyde gave 5-(diethoxymethyl)-3-[(*E*)-2-phenylethenyl]-2-isoxazoline (**5**) in 82% yield, which was reductively cleaved on Raney Ni to provide 6,6-diethoxy-5-hydroxy-1-phenyl-3-hexanone (**6**) in 69% yield.

Similar treatment of **6** with hydrogen chloride in chloroform gave γ-oxo ester **7** albeit in a moderate yield (58%), indicating that the essential skeleton for the γ-oxo ester formation is an α-hydroxy-γ-oxo acetal framework. However, it should be emphasized that the double bond at the 5-position of **3** has certainly contributed to some stabilization of the corresponding intermediate. This will be discussed later.

As the reaction for α-hydroxy-γ-oxo acetal **6** most likely to undergo under acid catalysis would be dehydration, treatment of the dehydrated derivative, (*E*)-6,6-diethoxy-1-phenyl-4-hexen-3-one (**8**), with an acid was next examined. Compound **8** is readily obtained in 85% yield through a sequence of *O*-mesylation and triethylamine-mediated β-elimination. When **8** was allowed to react with hydrochloric acid, the expected γ-oxo ester **7** was obtained in 57% yield, confirming the intermediacy of 4-oxo-2-alkenal acetal **8**.

It was disappointing that phosphonate **2** as a pre-

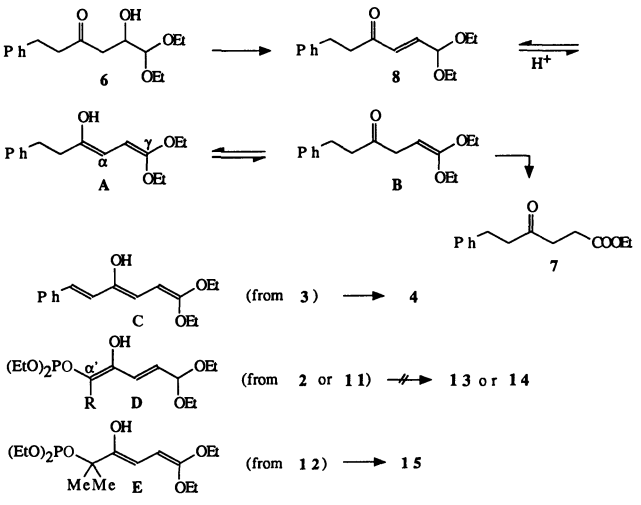


Scheme 1.

cursor of **3** underwent no such transformation into the corresponding γ-oxo ester **13** under similar conditions or even at −78 °C. The introduction of an alkyl moiety adjacent to the phosphinyl group (5-position) was of no use either. Thus phosphonate **2** as well as the methylated derivative **11** led to mixture of complex products.

Two methyl moieties were introduced adjacent to the phosphinyl moiety of **2** via 3-(1-phosphinyl-1-methylethyl)-2-isoxazoline **10** to give 2-(diethoxyphosphinyl)-6,6-diethoxy-5-hydroxy-2-methyl-3-hexanone (**12**). It was our delight to find that the dimethylated ketone **12** was smoothly converted into the corresponding γ-oxo ester **15** in 78% yield.

On the basis of the above results and observations, a possible reaction mechanism is illustrated in Scheme 2. Under acidic conditions the initial acid-catalyzed dehydration of **6** leads to enone **8** which then reversibly isomerizes into dienol intermediate **A**. Formation of **A** is facilitated by stabilization effect from the two ethoxyl groups attached at one end of the dienol conjugation. Since protonation occurs at the less congested α-position rather than the hindered γ-position, the isomerization equilibrates in favor for deconjugation leading to **B**. Under the reaction conditions, intermediate **B** is irreversibly hydrolyzed into γ-oxo ester **7**.



Scheme 2.

Although many synthetically useful examples are known for deconjugation processes under base catalyst[8] and under irradiation,[9] acid-catalyzed deconjugation was less important. As acid-catalyzed deconjugation is always a reversible reaction and often leads to a mixture of conjugated and deconjugated carbonyl compounds,[10] an irreversible step has to be involved for the process to be a useful synthetic reaction. In the

present case, the equilibrating intermediate **B** is irreversibly hydrolyzed by the water formed in the step of **6** to **8** under the applied conditions so that the equilibrium moves in favor for deconjugation.

The preexisting double bond of **3** provides some additional stabilization of the enolized intermediate **C** as a trienol. This is a reason why quantitative conversion of **3** into **4** has been achieved.

Since both the phosphonates **2** and **11** bear at least one highly acidic hydrogen at the α'- position, their enolization occurs exclusively at this position to form phosphorus-stabilized dienol intermediates **D** (R=H or Me) so that there is little chance for deconjugation. Only α',α'-dialkylated phosphonate **12** can undergo smooth conversion into γ-oxo ester **15** via dienol intermediate **E**.

In conclusion, 4-oxo-2-alkenal acetals are converted under acidic conditions into γ-oxo esters through a sequence of dehydration, enolization, deconjugation, and hydrolysis. Since both 3-(phosphinylmethyl)-2-isoxazoline **1** and 2-oxoalkylphosphonate **2** can be successfully employed for the introduction of a wide pattern of substituents by the aid of the phosphinyl moiety,[1] this transformation offers a general synthetic method of γ-oxo esters.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a JEOL FX-100 (100 MHz) or a JEOL GSX-270 instrument (270 MHz), and ^{13}C NMR on a JEOL FX-100 (25.05 MHz) or a JEOL GSX-270 spectrometer (67.94 MHz). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. High resolution mass spectra were obtained on the same instrument. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Materials and Solvents. 2-Oxoalkylphosphonate **2** and enone **3** were prepared according to the reported method starting from 2-isoxazoline **1**.[1,5] Tetrahydrofuran (THF) was distilled from lithium aluminum hydride under nitrogen immediately prior to its use.

Ethyl (*E*)-4-Oxo-6-phenyl-5-hexenoate (4): To a saturated solution of hydrogen chloride in chloroform (20 ml) was added dropwise a solution of **3** (0.067 g, 0.24 mmol) in chloroform (5 ml). The resulting solution was stirred at room temperature for 4 h, poured into ice water, and then extracted with chloroform (15 ml×2). The combined chloroform was washed with saturated aqueous sodium hydrogencarbonate, dried over anhydrous magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate (5:1 v/v) to give **4** (0.055 g, 98%). Similar reaction at 0 °C for 20 min afforded 89% of **4** and under reflux for 18 h 97%: Pale yellow liquid; IR (neat) 1730, 1680, 1660, 1610, 1575, 1490, 1445, 1360, 1200, 1160, 1100, 750, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.24 (3H, t, J=7.0 Hz, COOEt), 2.68, 3.01 (each 2H, t, J=6.5 Hz, 2- and 3-H), 4.14 (2H, q, J=7.0 Hz, COOEt), 6.73 (1H, d, J_{5-6}=16.0 Hz, 5-H), 7.1—7.8 (5H, m, Ph), and 7.57 (1H, d, J_{6-5}=16.0 Hz, 6-H); ^{13}C NMR ($CDCl_3$) δ=14.20 (COOEt), 28.24 (2-C), 35.26 (3-C), 60.62 (COOEt), 125.90, 128.32, 128.95 (each Ph), 130.52 (5-C), 134.44 (Ph), 142.86 (6-C), 172.87 (COOEt), and 198.04 (CO); MS m/z (rel intensity, %) 232 (M^+, 11), 131 (base peak), 103 (40), and 77 (30). HRMS Found: m/z 232.1107. Calcd for $C_{14}H_{16}O_3$: M, 232.1099.

5-(Diethoxymethyl)-3-(*E*)-2-phenylethenyl-2-isoxazoline (5): To a solution of **1** (0.522 g, 1.61 mmol) in dry THF (4 ml) was added, at −78 °C under nitrogen, butyllithium (15% in hexane, 1.14 ml, 1.78 mmol). After 1 h, benzaldehyde (0.343 g, 3.23 mmol) was added and the mixture was stirred at room temperature for 18 h. Saturated aqueous ammonium chloride was added to the mixture which was then extracted with dichloromethane (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was subjected to column chromatography over silica gel with hexane–ethyl acetate (5:1 v/v) to give **5** (0.363 g, 82%): Pale yellow liquid; IR (neat) 1630, 1495, 1450, 1370, 1060, 960, 900, 750, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20, 1.25 (each 3H, t, J=7.0 Hz, OEt), 3.18 (1H, dd, J_{gem}=16.2 and J_{4-5}=10.6 Hz, one of 4-H), 3.28 (1H, dd, J_{gem}=16.2 and J_{4-5}=7.0 Hz, the other of 4-H), 3.5—3.9 (4H, m, OEt), 4.52 (1H, d, J_{CH-5}=4.8 Hz, $CH(OEt)_2$), 4.71 (1H, ddd, J_{5-4}=10.6, 7.0, and J_{5-CH}=4.8 Hz, 5-H), 6.76 (1H, d, J=16.5 Hz, -CH=), 7.06 (1H, d, J=16.5 Hz, PhCH=), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.28, 15.36 (each OEt), 34.46 (4-C), 63.45, 64.43 (each OEt), 81.45 (5-C), 102.23 ($CH(OEt)_2$), 117.69 (-CH=), 126.97, 128.84, 128.89 (each Ph), 135.82 (Ph), 136.60 (PhCH=), and 157.85 (3-C); MS m/z (rel intensity, %) 275 (M^+, 4), 230 (10), 103 (base peak), 75 (47), and 47 (22). Found: C, 69.79; H, 7.69; N, 5.09%. Calcd for $C_{16}H_{21}NO_3$: C, 69.97; H, 7.93; N, 4.98%.

6,6-Diethoxy-5-hydroxy-1-phenyl-3-hexanone (6): To a solution of **5** (0.363 g, 1.32 mmol) in aqueous ethanol (17%, 7.2 ml) were added Raney Ni (W-2, suspension in ethanol, 0.5 ml) and boric acid (0.326 g, 5.27 mmol). The mixture was stirred at room temperature under hydrogen (1 atm) for 12 h. All insoluble materials were filtered off by the aid of Celite 545. The filtrate was diluted with water and extracted with dichloromethane (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate (5:1 v/v) to give **6** (0.256 g, 69%): Colorless liquid; IR (neat) 3430, 1705, 1600, 1490, 1445, 1370, 1060, 745, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20, 1.22 (each 3H, t, J=7.3 Hz, OEt), 2.6—3.0 (7H, m, 1-, 2-, 4-H, and OH), 3.4—3.9 (4H, m, OEt), 4.09 (1H, dt, J_{5-4}=7.7, 4.8, and J_{5-6}=4.8 Hz, 5-H), 4.38 (1H, d, J_{6-5}=4.8 Hz, 6-H), and 7.1—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.32, 15.35 (each OEt), 29.47 (2-C), 44.15 (1-C), 45.18 (4-C), 63.51, 63.93 (each OEt), 68.74 (5-C), 104.03 (6-C), 126.07, 128.30, 128.46 (each

Ph), 140.97 (Ph), and 209.63 (3-C); Ms *m/z* (rel intensity, %) 235 (M^+—OEt, 4), 105 (37), 104 (27), 103 (base peak), 91 (63), 74 (56), 47 (58), and 43 (35). Found: C, 68.29; H, 8.94%. Calcd for $C_{16}H_{24}O_4$: C, 68.55; H, 8.63%.

Ethyl 4-Oxo-6-phenylhexanoate (7): A procedure similar to that employed for the formation of **4** from **3** was applied to **6** (0.093 g, 0.33 mmol). The reaction at room temperature for 2 h and the followed workup (silica-gel chromatography with hexane–ethyl acetate (7:1 v/v)) gave **7** (0.045 g, 58%). Compound **7** was also obtained by a similar procedure on **8** (room temperature for 1 h, in 57% yield): Pale yellow liquid; IR (neat) 1725, 1495, 1450, 1410, 1370, 1185, 1100, 1030, 750, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.24 (3H, t, *J*=7.3 Hz, COOEt), 2.57, 2.69, 2.78, 2.91 (each 2H, t, $J_{2-3}=J_{5-6}$=7.0 Hz, 2-, 3-, 5-, and 6-H), 4.12 (2H, q, *J*=7.3 Hz, COOEt), and 7.1—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.17 (COOEt), 27.99 (2-C), 29.69 (3-C), 37.23 (5-C), 44.26 (6-C), 66.65 (COOEt), 126.13, 128.29, 128.51 (each Ph), 140.96 (Ph), 172.79 (COOEt), and 208.00 (CO); MS *m/z* (rel intensity, %) 234 (M^+, 16), 105 (48), 101 (29), 91 (base peak), 76 (22), and 30 (30). HRMS Found: *m/z* 234.1254. Calcd for $C_{14}H_{18}O_3$: M, 234.1255.

***(E)*-6,6-Diethoxy-5-hydroxy-1-phenyl-4-hexen-3-one (8):** To a solution of **6** (0.1 g, 0.36 mmol) in dry dichloromethane (1 ml) were added, at −15 °C under nitrogen, triethylamine (0.108 g, 1.07 mmol) and methanesulfonyl chloride (0.049 g, 0.43 mmol). After stirring at −15 °C for 1 h and then at room temperature for 4 h, the reaction mixture was poured into ice water and then extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane–ethyl acetate (7:1 v/v) to provide **8** (0.08 g, 85%): Colorless liquid; IR (neat) 1680, 1640, 1605, 1500, 1450, 1370, 1330, 1130, 1060, 750, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (6H, t, *J*=7.0 Hz, OEt), 2.9—3.0 (4H, m, 1- and 2-H), 3.4—3.8 (4H, m, OEt), 5.03 (1H, d, J_{6-5}=4.4 Hz, 6-H), 6.35 (1H, d, J_{4-5}=16.1 Hz, 4-H), 6.63 (1H, dd, J_{5-4}=16.1 and J_{5-6}=4.4 Hz, 5-H), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.19 (OEt), 29.83 (2-C), 41.96 (1-C), 61.50 (OEt), 99.54 (6-C), 126.12, 128.35, 128.48 (each Ph), 131.49 (Ph), 141.00, 141.35 (4- and 5-C), and 199.30 (CO); MS *m/z* (rel intensity, %) 262 (M^+, 1), 105 (24), 103 (base peak), 91 (93), 84 (30), 83 (21), 77 (22), 75 (33), 55 (34), and 47 (26). Found: C, 73.21; H, 8.83%. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%.

5-(Diethoxymethyl)-3-[1-(diethoxyphosphinyl)ethyl]-2-isoxazoline (9): To a solution of **1** (0.53 g, 1.64 mmol) in dry THF (4 ml) was added, at −78 °C under nitrogen, butyllithium (15% in hexane, 1.15 ml, 1.8 mmol). After 30 min at −78 °C, methyl iodide (0.465 g, 3.28 mmol) was added and the mixture was stirred at room temperature for 18 h. It was then poured into saturated ammonium chloride and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was subjected to column chromatography over silica gel by using hexane–ethyl acetate (5:1 v/v) to give **9** (0.388 g, 70%) as a 1:1 mixture (by ^{13}C NMR) of two diastereomers: Pale yellow liquid; IR (neat) 1610, 1440, 1390, 1375, 1250, 1160, 1120, 1060, 1020, 960, 885, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20, 1.23 (each 3H, t, *J*=7.0 Hz, OEt), 1.34 (6H, t, *J*=7.0 Hz, OEt), 1.42, 1.49 (3H, each d, *J*=7.3 Hz, Me), 3.0—3.3 (3H, m, PCH and 4-H), 3.5—3.8 (4H, m, OEt), 4.15 (4H, dq, *J*=7.3 (HP) and 7.0 Hz, OEt), 4.44 (1H, d, *J*=5.1 Hz, $CH(OEt)_2$), and 4.5—4.7 (1H, m, 5-H); ^{13}C NMR ($CDCl_3$) δ=15.29 (Me), 15.33, 15.36 (each OEt), 16.46 (*J*=5.9 (CP) Hz, OEt), 32.09, 32.24 (each *J*=140.9 (CP) Hz, PCH), 36.47, 37.16 (each 4-C), 62.45, 62.50 (each *J*=6.9 (CP) Hz, OEt), 63.25, 63.37, 64.15, 64.33 (each OEt), 80.86, 80.89 (each 5-C), 102.17, 102.32 (each $CH(OEt)_2$), and 156.66 (*J*=6.9 (CP) Hz, 3-C); MS *m/z* (rel intensity, %) 292 (M^+—OEt, 26), 103 (base peak), 75 (50), and 47 (37). No satisfactory analytical result was obtained due to the hygroscopic nature of **9**.

5-(Diethoxymethyl)-3-[1-(diethoxyphosphinyl)-1-methylethyl]-2-isoxazoline (10): A similar procedure was employed under the following conditions: **1** (1.402 g, 4.34 mmol) in THF (9 ml), butyllithium (15% in hexane, 5.96 ml, 9.54 mmol) at −78 °C for 30 min, methyl iodide (2.462 g, 17.3 mmol), at room temperature for 17 h, silica-gel column chromatography with hexane–ethyl acetate (5:1 v/v). The dialkylated product **10** was obtained in 40% (0.61 g) yield: Pale yellow liquid; IR (neat) 1610, 1460, 1440, 1390, 1320, 1250, 1050, 1025, 960, 890, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.19, 1.23 (each 3H, t, *J*=7.0 Hz, OEt), 1.33 (6H, t, *J*=7.0 Hz, OEt), 1.44, 1.50 (each 3H, Me), 3.0—3.3 (2H, m, 4-H), 3.5—3.8 (4H, m, OEt), 4.14 (4H, dq, *J*=7.3 (HP) and 7.0 Hz, OEt), 4.43 (1H, d, *J*=5.5 Hz, $CH(OEt)_2$), and 4.5—4.7 (1H, m, 5-H); ^{13}C NMR ($CDCl_3$) δ=15.32 (OEt), 16.49 (*J*=4.9 (CP) Hz, OEt), 21.47, 21.69 (each Me), 36.72 (4-C), 37.64 (*J*=158.5 (CP) Hz, PC), 62.72 (*J*=7.8 (CP) Hz, OEt), 63.37, 64.16 (each OEt), 81.22 (5-C), 102.32 ($CH(OEt)_2$), and 160.32 (*J*=5.9 (CP) Hz, 3-C); MS *m/z* (rel intensity, %) 306 (M^+—OEt, 7), 103 (base peak), 75 (37), and 47 (24). No satisfactory analytical result was obtained due to the hygroscopic nature of **10**.

6,6-Diethoxy-2-(diethoxyphosphinyl)-5-hydroxy-3-hexanone (11): A procedure similar to that used to prepare **6** from **5** was employed to **9** under the following conditions: **9** (0.388 g, 1.15 mmol) in aqueous ethanol (17%, 9 ml), Raney Ni (W-2, suspension in ethanol, 0.5 ml), boric acid (0.284 g, 4.6 mmol), under hydrogen (1 atm) at room temperature for 12 h, silica-gel column chromatography with ethyl acetate. A 1:1 mixture (by ^{13}C NMR) of two diastereomers of **11** (0.271 g, 69%) was given: Colorless liquid; IR (neat) 3400, 1710, 1440, 1390, 1370, 1240, 1060, 1020, and 960 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—1.3 (6H, m, OEt), 1.33 (6H, t, *J*=7.0 Hz, OEt), 1.3—1.5 (3H, m, 1-H), 2.8—3.1 (3H, m, 2- and 4-H), 3.5—3.8 (4H, m, OEt), 4.13 (4H, dq, *J*=7.3 (CP) and 7.0 Hz, OEt), 4.0—4.2 (2H, m, 5-H), and 4.3—4.5 (1H, m, 6H); ^{13}C NMR ($CDCl_3$) δ=15.38 (1-C and OEt), 16.39 (*J*=5.9 (CP) Hz, OEt), 44.88 (4-C), 47.48, 47.57 (each *J*=126.2 (CP) Hz, 2-C), 62.55, 62.58 (each *J*=6.8 (CP) Hz, OEt), 63.44, 63.47, 63.97, 64.06 (each OEt), 68.78, 69.10 (each 5-C), 104.,04, 104.10 (each 6-C), 205.41, and 206.05 (each *J*=3.9 (CP) Hz, CO); MS *m/z* (rel intensity, %) 295 (M^+—OEt, 1), 236 (15), 103 (base peak), 74 (35), and 47 (23). No satisfactory analytical result was obtained due to the hygroscopic nature of **11**.

6,6-Diethoxy-2-(diethoxyphosphinyl)-5-hydroxy-2-methyl-3-hexanone (12): A procedure similar to that used to prepare **6** from **5** was employed to **10** under the following conditions: **10** (0.6 g, 1.71 mmol) in aqueous ethanol (17%, 10 ml), Raney Ni (W-2, suspension in ethanol, 2 ml), boric acid (0.422 g, 6.83 mmol), under hydrogen (1 atom) at room temperature for 22 h, silica-gel column chromatography with hexane–ethyl acetate (1:5 v/v). A 49% yield of **12** (0.298 g) was obtained and then the unreacted **10** was recov-

ered (0.132 g, 22%). **12**: Colorless liquid; IR (neat) 3400, 1710, 1460, 1450, 1395, 1370, 1240, 1025, 960, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—1.4 (6H, m, OEt), 1.32 (6H, t, J=7.0 Hz, OEt), 1.41, 1.47 (each 3H, 1-H and 2-Me), 2.8—3.1 (2H, m, 4-H), 3.5—3.9 (4H, m, OEt), 4.14 (4H, dq, J=7.3 (HP) and 7.0 Hz, OEt), 4.0—4.3 (2H, m, 5-H), and 4.42 (1H, d, J_{6-5}=4.8 Hz, 6-H); ^{13}C NMR ($CDCl_3$) δ=15.38 (OEt), 16.43 (J=5.9 (CP) Hz, OEt), 20.12, 20.19 (each 1-C and 2-Me), 40.92 (4-C), 50.79 (J=130.1 (CP) Hz, 2-C); 62.77 (J=6.8 (CP) Hz, OEt), 63.35, 63.84 (each OEt), 68.82 (5-C), 104.00 (6-C), and 208.73 (CO); MS m/z (rel intensity, %) 309 (M^+—OEt, 5), 251 (21), 180 (11), 123 (11), 103 (base peak), 76 (32), and 47 (22). No satisfactory analytical result was obtained due to the hygroscopic nature of **12**.

Ethyl 5-(Diethoxyphosphinyl)-2-methyl-4-oxohexanoate (15): A procedure similar to that used for the preparation of **4** from **3** was employed under the following conditions: **12** (0.092 g, 0.26 mmol) in chloroform (15 ml) saturated with hydrogen chloride, at room temperature for 5 h, silica-gel column chromatography with ethyl acetate. A 78% yield of **15** (0.062 g) was obtained: Colorless liquid; IR (neat) 1730, 1700, 1460, 1380, 1370, 1240, 1170, 1050, 1020, 960, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (6H, t, J=7.0 Hz, OEt), 1.32 (6H, t, J=7.0 Hz, COOEt), 1.43, 1.49 (each 3H, s, 5-Me), 2.56, 3.05 (each 2H, t, J_{2-3}=6.6 Hz, 2- and 3-H), 4.12 (4H, q, J=7.0 Hz, COOEt), and 4.14 (4H, dq, J=7.3 (HP) and 7.0 Hz, OEt); ^{13}C NMR ($CDCl_3$) δ=14.20 (COOEt), 16.44 (J=5.9 (CP) Hz, OEt), 20.37, 20.45 (each 5-Me), 28.42 (2-C), 34.31 (3-C), 50.11 (J=131.1 (CP) Hz, 5-C), 60.55 (COOEt), 62.81 (OEt), 172.78 (COOEt), and 207.13 (CO); MS m/z (rel intensity, %) 308 (M^+, 5), 263 (20), 180 (base peak), 138 (41), 124 (21), 123 (43), 111 (20), 109 (45), 101 (36), 81 (46), 70 (25), 65 (23), and 55 (24). HRMS Found: m/z 308.1400. Calcd for $C_{13}H_{25}O_6P$: M, 308.1387.

The present work was partially supported by a Grand-in-Aid for Scientific Research (No. 61470095) from the Ministry of Education, Science and Culture. The authors thank Professor Akira Mori, Institute of Advanced Material Study, Kyushu University, for his useful suggestion to the reaction mechanism study.

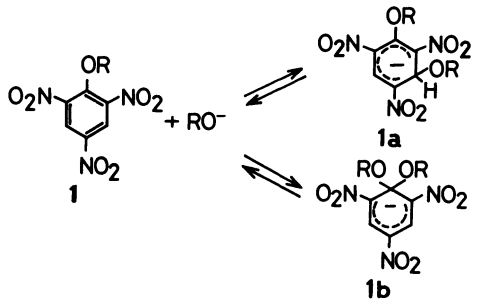
Stopped-Flow Kinetics of the Formation and Decomposition of 2,4- and 4,4-Disubstituted Meisenheimer Complexes in the Reaction of 4-Piperidino-1,3-dinitrophenanthrene with Potassium Methoxide in Dimethyl Sulfoxide-Methanol[1)]

Hiroyuki TAKAHASHI, Takao HIRAIDE, Yohji HASHIDA, and Shizen SEKIGUCHI*
Department of Synthetic Chemistry, Tenjin-cho, Kiryu, Gunma 376
(Received July 21, 1988)

The formation of 2,4-disubstituted anionic σ complex, followed by the formation of 4,4-disubstituted one was confirmed by means of absorption and NMR spectra in the reaction of 4-piperidino-1,3-dinitrophenanthrene with potassium methoxide in DMSO–CH_3OH. The rates and activation parameters were determined by kinetic studies using stopped-flow and conventional spectrophotometers. It was found, compared with the previous results on the naphthalene system that the presence of H^5 of the title compound affects the rates differently.

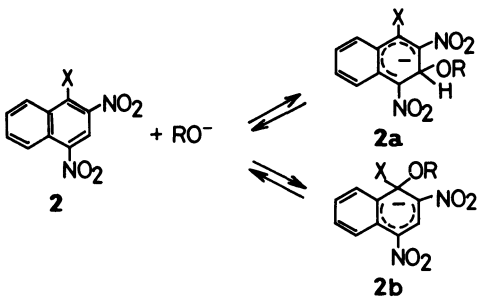
Many Jackson–Meisenheimer complexes (anionic σ complex) have been prepared by nucleophilic attack on polynitroaromatic compounds (Eqs. 1a and 1b), in



(1a)

(1b)

which at first **1a** (R: alkyl; hereafter called 1,3-disubstituted complex) is formed (kinetically controlled), subsequently rearranging into **1b** (hereafter called 1,1-disubstituted complex) (thermodynamically controlled.)[2)] Although many 1,3-disubstituted anionic σ complexes such as **1a** have been identified in the benzene or heteroaromatic systems, only a few ones such as **2a** (1,3-disubstituted complex) have been found in the naphthalene system (Eqs. 2a and 2b).[3–5)] The

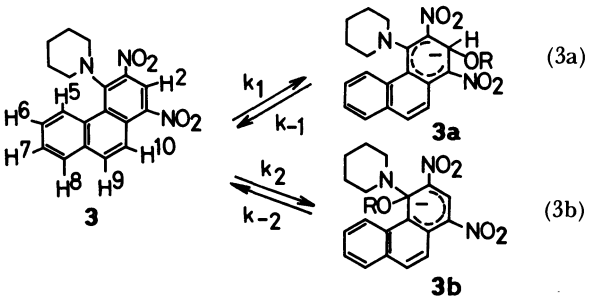


(2a)

(2b)

fact that **2a** (X; alkoxyl) is difficult to confirm in the reactions of **2** (X; alkoxyl) with alkoxide ions can be ascribed to its less stability than **1a**, mainly because the presence of nitro group para to the reaction site (C-3) stabilizes **1a** to much greater extent.[2)]

On the other hand, in the reactions with various nucleophiles, especially amines, the steric effects exerted by the structures of substrates or bulkiness of nucleophiles on the reaction mechanism have attracted much attention.[6–9)] In order to elucidate the effect of the structure of a substrate on the reaction rate, therefore, at first, we tried the reaction of 4-piperidino-1,3-dinitrophenanthrene (**3**) with potassium methoxide (CH_3OK) in DMSO–CH_3OH (90:10 v/v) (Eqs. 3a and 3b). We patterned the present experiments



(3a)

(3b)

on those of the previous work.[5)]

This paper reports the stopped-flow kinetics of the formation of 2,4-disubstituted complex (**3a**) and of its decomposition or the formation of 4,4-disubstituted complex (**3b**), corresponding to **1b** and **2b**, and the comparison of the results with those for the naphthalene systems.[5)]

Results

General Features. Upon addition of excess CH_3OK to a DMSO–CH_3OH solution of **3**, Curve b appeared instantly, and then changed into Curve c at a relatively slow rate (Fig. 1), where the former could be attributed to **3a**, and the latter to **3b**.[4–7)] The results indicate that the reaction consists of the two seperate stages, i.e., the first rapid formation of **3a** and the second relatively slow decomposition of **3a** or the formation of **3b**.

NMR technique is expected to be useful for

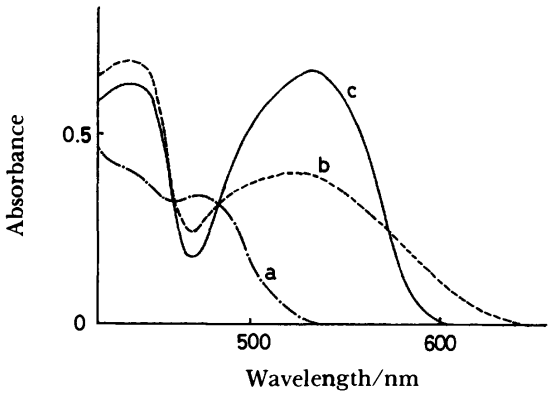


Fig. 1. Spectral change relevant to the reaction of 4-piperidino-1,3-dinitrophenanthrene (**3**) with CH_3OK in DMSO-CH_3OH (90:10, v/v); (a) **3** (3.87×10^{-5} M [M=mol dm^{-3}]) at room temperature; (b) just after addition of CH_3OK (2.95×10^{-2}); (c) 60 min.

elucidating the assignment mentioned above. Just after addition of methanolic CH_3OK (1.40×10^{-4} mol) to a DMSO-CH_3OH solution (0.5 ml) of **3** (1.40×10^{-4} mol), the solution turned red, suggesting the formation of a complex. Just upon addition of CH_3OK, H^2 sharp singlet (δ 8.25) of **3** shifted to δ 6.25, with a small singlet at δ 9.23, attributed to H^2 of **3b**, indicating the formation of **3a** (Eq. 3a) (sweep time 20 cps). This upfield shift is well-known to be characteristic of 2,4-disubstituted complex such as **3a**, corresponding to **2a** (1,3-disubstituted complex).[2] The H^2 singlet (δ 9.23) of **3b** increased in strength at the expense of the singlet at δ 6.25, which disappeared in 60 min. These results support the reaction path as shown in Eqs. 3a and 3b very well. It can be expected, therefore, that the separate kinetics of formation and decomposition of **3a** is possible.

Kinetics. Let us rewrite Eqs. 3a and 3b in a form convenient for quantitative discussion as Eq. 4. In the

$$3 + {}^-OCH_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{3a} \quad (4a)$$

$$\mathbf{3a} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathbf{3b} \quad (4b)$$

$$K_1 = \frac{k_1}{k_{-1}}, \quad K_2 = \frac{k_2}{k_2}$$

kinetics on Stage I, Stage II can be neglected, since the former reaction is completed in several thousandths seconds, making contamination by the latter negligible from considering the time scale of reaction.

Stage I. The pseudo-first-order rate constant, k_ψ, for the attainment of an equilibrium is the sum of forward and reverse components.[8,9] Therefore, the following expression should hold:

$$k_\psi = k_1([{}^-OCH_3] + [\mathbf{3}]) + k_{-1} \quad (5)$$

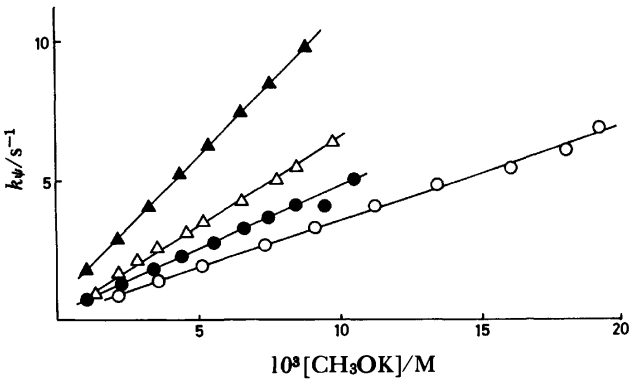

Fig. 2. Relationship between k_ψ and $[CH_3OK]$ in Stage I; $[\mathbf{3}]_0$ 1.53×10^{-4} M; μ 0.05 M ($KClO_4$); ○ 25 °C; ● 30 °C; △ 35 °C; ▲ 45 °C.

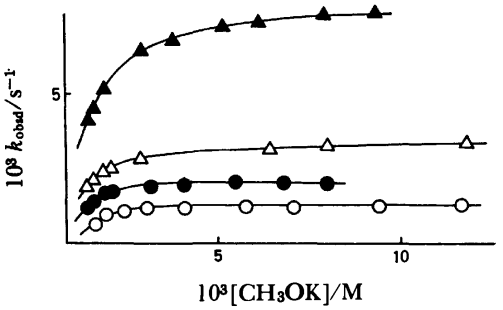

Fig. 3. Relationship between k_{obsd} and $[CH_3OK]$ in Stage II; $[\mathbf{3}]_0$ 1.99—6.00×10^{-5} M; μ 0.05 M ($KClO_4$); ○ 25 °C; ● 30 °C; △ 35 °C; ▲ 45 °C.

Under the usual conditions ($[{}^-OCH_3] \gg [\mathbf{3}]$), Eq. 5 is simplified to

$$k_\psi = k_1[{}^-OCH_3] + k_{-1} \quad (6)$$

As a result, dependence of k_ψ on $[{}^-OCH_3]$ would afford a linear relationship, and k_1 and k_{-1} are estimated from the slope and the intercept, respectively. The results in Fig. 2 are compatible with Eq. 6. Although the k_1 value can be exactly estimated from the slope, the k_{-1} one is very small relative to k_1, and has a large error. As a result, the k_{-1} value was calculated by the method described in the following paragraph.

Stage II. In considering the kinetics on Stage II, Stage I can be dealt with as a mobile equilibrium, lying almost entirely on the right under the conditions. Putting $[\mathbf{3}]_{st}=[\mathbf{3}]+[\mathbf{3a}]$ and K_1 the equilibrium constant for Stage I reaction, one obtains the following expression.

$$k_{obsd} = k_{-2} + \frac{k_2[{}^-OCH_3]}{1 + K_1[{}^-OCH_3]}, \quad (7)$$

where k_{obsd} is the pseudo-first-order rate coefficient for Stage II reaction, and k_2 and k_{-2} are the rate coefficients for forward and reverse reactions. Consequently, de-

a) $K_1=k_1/k_{-1}$. b) $K_2=k_2/k_{-2}$. c) $M^{-1}=dm^3\,mol^{-1}$.

pendence of k_{obsd} on [$^-OCH_3$] would afford a curvilinear relationship (convex upward), in which the curve would not pass through the origin (Fig. 3).

The exact k_2, k_{-2}, and k_1 values were estimated in the following way. First, k_1, k_{-1}, and K_1 ($=k_1/k_{-1}$) are obtained from the slope and intercept (Fig. 2), although k_{-1} has some extent of error. Second, in the plateau (Fig. 3) $K_1[^-OCH_3]\gg 1$, so the following relationship holds. In Eq. 8 it is clear from the previous work[5] that $k_2/k_1\gg k_{-2}$.

$$k_{obsd} = k_{-2} + \frac{k_2}{K_1} \qquad (8)$$

As a result, k_2 can be calculated by using the K_1 value obtained just above. Once k_2 and K_1 are estimated, k_{-2} can be calculated from Eq. 7 by using appropriate experimental values of k_{obsd} and methoxide concentration. Third, by substituting these values into Eq. 7 as initial values and using a nonlinear least squares method (Gauss-Newton Method), the optimum K_1, k_2, and k_{-2} values can be obtained, which are listed in Table 1.

From K_1 and k_1, k_{-1} can be estimated (Table 1). Calculated k_ψ and k_{obsd} obtained by substituting the values in Table 1 into Eqs. 6 and 7 are in agreement with the observed ones almost within <2% in almost all runs.

The rate and equilibrium constants and activation parameters, obtained by the Arrhenius plot are summarized in Table 2, together with those for the naphthalene system.[5]

Discussion

Stage I. The k_1 value is smaller for the phenanthrene system than for the naphthalene one, depending on $\Delta S_1^{\neq}$ rather than $\Delta H_1^{\neq}$. Such a result would stem from the following steric reason. When a methoxide ion attack C-2 of **3** or C-3 of **2**, the negative charge donated by the ion is delocalized over the ring to a larger extent for the phenanthrene system than the naphthalene one, which is reflected on $\Delta H_1^{\neq}$. This delocalization, however, would make $\Delta S_1^{\neq}$ decrease for the phenanthrene system as follows: both ortho-nitro groups to the reaction site could assume coplanarity to the ring upon delocalization, since the negative charge donated by the ion ($^-OCH_3$) delocalizes especially over these two nitro groups in the transition state of k_1 step.[6,7,10] The coplanarity of 3-nitro group of **3** would make the steric interference among 3-nitro, 4-piperidino, and H^5 groups severer than that of 2-nitro group of **2** would do among 2-nitro, 1-piperidino, and H^8 groups, and make the piperidyl ring almost perpendicular to the phenanthrene one, resulting in less freedom.

In k_{-1} step, both $\Delta H_{-1}^{\neq}$ and $\Delta S_{-1}^{\neq}$ are slightly unfavorable for the phenanthrene system, since **3a** is more stable by ca. 0.5 kcal mol^{-1} ($\Delta\Delta G^0=\Delta\Delta H^0-T\Delta\Delta S^0$) than **2a** owing to more extensive delocalization and, as a result, the reverse reaction is unfavorable. The fact the ΔG^0 is −3.6 and −3.1 kcal mol^{-1} for **3a** and **2a** respectively is very interesting indicating that **3a** and **2a** are more stable than **3** and **2** ($\Delta G^0=\Delta H^0-T\Delta S^0$), respectively.

Stage II. The k_2 value is larger for the phenanthrene system than for the naphthalene one, depending on

$\Delta H_2^{\neq}$ rather than $\Delta H_2^{\neq}$. The $\Delta\Delta H_2^{\neq}$ value ($=\Delta H_2^{\neq}$ for **2** $-\Delta H_2^{\neq}$ for **3**) is 0.7 kcal mol^{-1}, which makes k_2 for **3** ca. 3.3 times larger than k_2 for **2**, whereas the observed ratio is ca. 1.1 (Table 2). As a result, it can be seen that $\Delta S_2^{\neq}$ for **3** unfavorably affects k_2 to make the rate ratio of ca. 3.3 depending on $\Delta H_2^{\neq}$ reduce to ca. 1.1, although the $\Delta S_2^{\neq}$ values have large errors. In the transition state of k_2 step for the phenanthrene system, H^5 protrudes over between the piperidino and methoxyl (nucleophile) groups, and consequently the steric interference among H^5, piperidino, and 3-nitro groups would be relieved to some extent, compared with the transformation of **2** to **2b**, which is expected to lower the potential energy barrier between the reactants and transition state. This effect, however, would decrease $\Delta S_2^{\neq}$ to a larger extent for the phenanthrene system. In addition, delocalization of the negative charge donated by a methoxide ion is more extensive for the phenanthrene system than for the naphthalene one, and the larger resonance inhibition between the unshared electron pair on the piperidino nitrogen and the phenanthrene ring would make the nucleophilic attack on C-4 of a methoxide ion easier than for the naphthalene system. These effects would lower $\Delta H_2^{\neq}$ for the phenanthrene system.

Although the k_{-2} values can not be rigorously discussed because of large error in the case of **2**, they can be said to be much less smaller than the k_2 ones for the two systems. The large K_2 values indicate that **3b** and **2b** are very stable, compared with the reactants.

In conclusion it is found that H^5 of **3** exerts steric interference to the reaction site indirectly (Stage I) or directly (Stage II) in the reaction of 4-piperidino-1,3-dinitrophenanthrene (**3**) with $KOCH_3$ in DMSO–CH_3OH (9:1 v/v), which is very different from the fimilar reaction of the naphthalene analogue.

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer and UV-VIS absorption spectra on a Hitachi Model 200-10 spectrophotometer.

Materials. 4-Piperidino-1,3-dinitrophenanthrene (**3**) was prepared from 4-chloro-1,3-dinitrophenanthrene (CDNP) and piperidine according to the method described previously.[11] The compound (CDNP) was prepared from 1,3-dinitro-4-phenanthrol, *p*-toluenesulfonyl chloride, and *N*,*N*-diethylaniline according to the method described previously.[10] Commercial dimethyl sulfoxide and methanol were purified according to the method described previously.[5] Commercial potassium perchlorate of special grade was used without further purification to keep the ionic strenght at 0.05 mol l^{-1} in rate measurements.

Rate Measurement. As regards the kinetics of formation of 2,4-disubstituted complex, an increase in the absorbance at 532 nm due to the complex was followed in order to estimate the apparent rate constants (k_ψ) with a thermostatted stopped-flow spectrophotometer (Otsuka Denshi Co.). In order to estimate k_{obsd}, a decrease in the absorbance at 600 nm due to 2,4-disubstituted complex was followed with a thermostatted Hitachi Model 200-10 spectrophotometer.

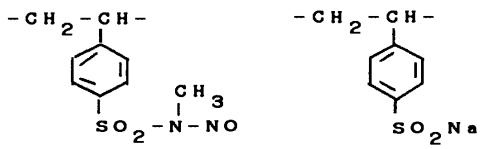
Polymer Reagents Derived from Sodium *p*-Styrenesulfonate: *N*-Methyl-*N*-nitroso-*p*-styrenesulfonamide and *p*-Styrenesulfinic Acid Polymers

Hiroyoshi KAMOGAWA* and Tomoo KITAMURA
Department of Applied Chemistry, Yamanashi University, Kofu 400
(Received July 25, 1988)

N-Methyl-*N*-nitroso-*p*-styrenesulfonamide (**1**) was synthesized starting with sodium *p*-styrenesulfonate (**3**). Monomer **1** and sodium *p*-styrenesulfinate (**2**), also synthesized starting with **3**, were polymerized and polymer of **2** was converted to corresponding free acid (**9**). The function of polymer of **1** as the reagent attaching the CH_2 group to the carbonyl carbon by insertion and that of polymer **9** as the catalyst for cis→trans isomerization were investigated for various compounds, including cyclohexanone and benzaldehyde and ethyl oleate. The effects of these polymer reagents as compared with those of the corresponding model compounds were discussed.

Sodium *p*-styrenesulfonate, now commercially available, is a versatile reagent for the syntheses of a variety of polymer reagents.[1-4] In the present article, we wish to report the synthesis of *N*-methyl-*N*-nitroso-*p*-styrenesulfonamide (**1**) polymer as a novel polymer reagent, together with *p*-styrenesulfinic acid polymer as a novel polymer catalyst, both being derived from sodium *p*-styrenesulfonate.

Thus, monomer **1** and sodium *p*-styrenesulfinate (**2**) were synthesized and homo- and copolymerized with *N*-vinyl-2-pyrrolidone (VP), respectively, to afford soluble polymers in appropriate solvents. VP was employed here to get copolymers soluble in reaction solvents.



Polymer of 1 Polymer of 2

The CH_2 insertion and cis→trans isomerization reactions with polymer of **1** and the acid form of polymer of **2** were investigated, respectively.

Results and Discussion

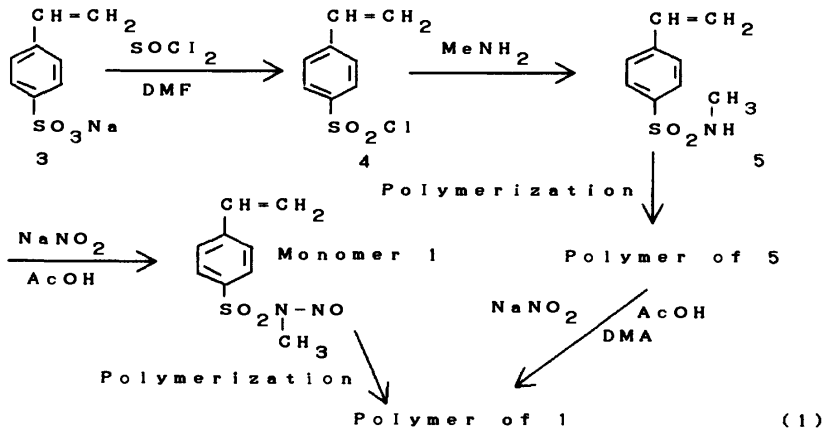
Monomer **1** was synthesized starting with sodium *p*-styrenesulfonate (**3**) in the following manner (Eq. 1).

Compound **4** was synthesized from **3** in a high yield (91%) at 20 °C or below, without danger of polymerization.[1] Addition of an excess of methylamine to **4** provided **5** in a moderate yield (64%). Compound **5** in acetic acid was treated with aqueous sodium nitrite to afford crude monomer **1**. Reprecipitation from benzene–hexane by cooling followed by silica-gel column chromatography provided the purified monomer **1** in 62% yield. Analytical data (^{1}H NMR, IR, mass, and CHN) were all satisfactory.

Monomer **2** was synthesized also starting with **3**, as described in a previous paper.[2]

Monomer **1** was polymerized with α,α'-azobisisobutyronitrile (AIBN) in *N*,*N*-dimethylformamide (DMF) with 72% conversion to afford polymer of **1**, which was soluble in a ternary mixture of *N*,*N*-dimethylacetamide (DMA), ethanol, and water and suitable for the investigation of its function.

Polymer of **1** could also be prepared by means of the polymer reaction using the copolymerization product



(1)

of **5** with VP in DMF (conversion, 70%) and consisting of nitrosation in a mixture of DMA, acetic acid, and water (conversion, 62%), as shown in Eq. 1.

Polymer of **2** was prepared by the copolymerization of **2** with VP in ethanol (conversion, 88%). Polymer of **2** in aqueous solution was converted to its acid form by acidification with concd HCl to produce polymer **9**, which was soluble in dioxane, the cis-trans reaction solvent, and immediately used as catalyst.

The functions adopted for homopolymer of **1** and polymer **9** were the same as those for the corresponding low-molecular-weight compounds, *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide and *p*-toluenesulfinic acid (Eqs. 2 and 3).[5,6] However, separations of polymers **7** and **9** from products were easier.

Conversion from **6a—e** to **8a—e** and the extent of cis→trans isomerization were determined gas-chromatographically for the purified reaction mixtures, except for **6f—8f** and **6g—8g** mixtures, in which no standard samples of **8f,g** were available and the reaction products (**8f** and **8g**) were identified by IR, mass, and ^{1}H NMR and determined by ^{1}H NMR.

It can be seen in Table 1 that cyclic ketones such as **6a** and **6b** provided particularly low conversions under these conditions, presumably due to the poor accessbility of these bulky ketones to the functional portions of polymer molecules. *N*-Methyl-*N*-nitroso-*p*-toluenesulfonamide, the corresponding low-molecular-weight compound, afforded results similar to those observed for polymer of **1**. **8g**, a different kind of

6a	**8a**	13(20[b])
6b	**8b**	17(23[b])
6c	**8c**	35(38[b])
6d	**8d**	35
6e	**8e**	65(65[b])
6f	**8f**[c]	67[d]
6g	**8g**[c]	57[d]

a) As for experimental conditions, see Experimental Section. b) For reference sample, *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide. c) The identity of the product was determined only by ^{1}H NMR, IR, and mass spectra. d) Determined by ^{1}H NMR.

Table 2. Function of Polymer **9** According to Eq. 3[a]

Reactant	Product	Conversion/%
10a	**11a**	80(83[b])
10b	**11b**	83(88[b])

a) As for experimental conditions, see Experimental section. b) For reference sample, *p*-toluenesulfinic acid, as catalyst.

product from others, was the same as that obtained from **6g** with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide.[5]

Recycle of polymer of **1** could be carried out by the alkaline hydrolysis of polymer **7** to polymer containing **3** units, followed by conversion to polymer containing **1** units, which showed an enough function. This recycle could be repeated at least three times.

Table 2 also shows the results with polymer **9** according to Eq. 3. Conversions obtained with polymer **9** were also similar to those with the corresponding low-molecular-weight compound, *p*-toluenesulfinic acid. In this case, polymer **9** was not appreciably changed during the reaction and could be reused, if properly stored.

It is concluded from these results that, in the cases of the styrene polymers containing *N*-methyl-*N*-nitrososulfonamide and sulfinic acid functional groups, polymers bahave in reactions almost similarly to the corresponding low-molecular-weight reagents, but with more readiness of the separation of products from reagents as well as the possibility of recycling.

Experimental

The infrared (IR), ^{1}H NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX60 spectrometer, and a Hitachi M808MS spectrometer, respectively, under standard conditions. Elemental analyses were made with a Perkin-Elmer 240 instrument. Gas chromatography was carried out with a Hitachi 164 gas chromatograph fitted with a SE-30 column under helium stream (30 ml min^{-1}).

***N*-Methyl-*p*-styrenesulfonamide (5).** A large excess of aqueous methylamine (25%; 10 ml, 80 mmol) was added dropwise to a stirred solution of *p*-styrenesulfonyl chloride (**4**; 4.4 g, 20 mmol), prepared from sodium *p*-styrenesulfonate (**3**) according to the method described in a previous report,[1] in ether (40 ml), cooled with an ice bath. Stirring was continued further for one hour, the resulting reaction mixture was extracted with ether (160 ml), and the organic layer was rinsed with water and dried over anhydrous sodium sulfate, followed by concentration on a rotary evaporator below 40 °C to leave a fluid in 64% yield. Found: C, 54.70; H, 5.65; N, 6.91%. Calcd for $C_9H_{11}NSO_2$: C, 54.75; H, 5.58; N, 7.09%. IR ($CHCl_3$) 3400 (NH), 1320, 1140 (SO_2), 990, 910 (vinyl) cm^{-1}. ^{1}H NMR (CCl_4) δ=2.5 (d, 3H, Me), 5.1—5.9 (m, 3H, CH_2=+NH), 6.7 (q, 1H, CH=), 7.5 (q, 4H, ArH). MS *m/z* 197 (M^+).

***N*-Methyl-*N*-nitroso-*p*-styrenesulfonamide (1).** A solution of sodium nitrite (0.84 g, 12 mmol) in water (2 ml) was added dropwise to a stirred solution of **5** (2.0 g, 10 mmol) in acetic acid (10 ml) containing a small quantity of water in an ice bath. Stirring was continued further for one hour. The reaction mixture was poured into aqueous sodium hydrogencarbonate (excess) containing ice, immediately followed by extraction with ether. The organic layer was washed thoroughly with water, dried over anhydrous sodium sulfate, and concentrated on the rotary evaporator to give crude **1**, which was reprecipitated from benzene (or ether)-hexane by cooling down to −20 °C, then subjected to silica-gel column chromatography to afford a purified fluid in 62% yield. Single spot by TLC. Found: C, 47.58; H, 4.46; N, 12.23%. Calcd for $C_9H_{10}N_2SO_3$: C, 47.79; H, 4.42; N, 12.40%. IR ($CHCl_3$) 1560, 1490 (N=O), 1360, 1110 (SO_2), 980 (vinyl) cm.$^{-1}$ ^{1}H NMR ($CDCl_3$) δ=3.2 (s, 3H, Me), 5.8 (q, 2H, CH_2=), 6.7 (q, 1H, CH=), 7.9 (q, 4H, ArH). MS *m/z* 196 (M^+—NO).

Preparation of Polymer of 1. (a) By Homopolymerization. A solution of monomer **1** (0.5 g) and purified α,α'-azobisisobutyronitrile (AIBN; 0.03 g) in DMF (1 ml) was put into a glass ampule, which was evacuated and sealed in the conventional manner. The ampule was then let stand at 50 °C for 72 h to effect polymerization. The content of the ampule was poured into a large amount of ether to afford precipitate in 72% conversion. $[\eta]$=0.06 dl g^{-1} (DMF, 25 °C). IR for polymer of **1** deposited on a KRS cell indicated the absorptions characteristic of the *N*-methyl-*N*-nitrososulfonamide portion of polymer, together with those at 2930—2860 cm^{-1} attributable to the vinyl polymer backbone.

(b) By Polymer Reaction Using Polymer of 5. Alternatively, polymer of **1** was prepared by a polymer reaction applied to polymer of **5**.

(i) Polymer of 5. A solution of **5** (1.0 g, 5 mmol), VP (10.0 g, 92 mmol), and AIBN (0.5 g) in DMF (20 ml) was gently stirred at 80 °C for 48 h under a nitrogen atmosphere. The resulting solution was diluted with DMF and poured into ether to afford precipitate in 70% conversion. $[\eta]$=0.21 dl g^{-1} (DMF, 25 °C). IR was satisfactory and the **5** to VP ratio in copolymer was 1:5.5 from the result of elemental analysis.

(ii) Polymer Reaction. To the stirred solution of polymer of **5** (5 g), prepared above, in a mixture of DMA (10 ml) and acetic acid (5 ml) cooled with an ice bath was added dropwise a solution of sodium nitrite (0.42 g, 6 mmol) in water (1 ml), followed by stirring for 2 h. The reaction mixture was

precipitated into ether to afford a sticky solid. IR was satisfactory and the conversion calculated from the results of elemental analysis was 62%.

Preparation of Polymer 9. (a) Polymer of 2. A solution of sodium *p*-styrenesulfinate (**2**; 0.2 g), prepared also starting with **3** as reported in a previous paper,[2] VP (1.0 g), and AIBN (0.06 g) in ethanol (2 ml) was put into an ampule, which was evacuated and sealed in the conventional manner and let stand at 70 °C for 72 h. The resulting viscous solution was precipitated into ether to afford polymer of **2** in 88% conversion. $[\eta]$ in water at 25 °C was 0.78 dl g^{-1} and the **2**/VP ratio in copolymer was 0.17 from elemental analysis.

(b) Polymer 9. A solution of polymer of **2** (0.5 g) prepared above in a small amount of water was acidified with concd HCl to afford precipitate, which was dried under reduced pressure (yield, 29%) and employed immediately for the reaction indicated in Eq. 3.

Function of Polymer of 1 According to Eq. 2. To a solution of polymer of **1** (0.5 g, 2 mmol), prepared by homopolymerization of monomer **1** as described above, in DMA (5 ml) were added with vigorous stirring ethanol (5 ml) and a carbonyl compound (**6a—g**; 2 mmol). To the resulting solution cooled in an ice bath, a solution of potassium hydroxide (0.2 g) in water (5 ml) was further added dropwise, followed by 3-h stirring of the resulting alkaline mixture below 20 °C. The reaction mixture was poured into an ice-water mixture, followed by ether extraction and conventional work up to afford a sample for gas chromatography. Polymer **7** remaining after the ether extraction as insoluble residue was hydrolyzed with 1 mol l^{-1} NaOH at 20 °C overnight to afford polymer of **3**, which was subjected to a reaction sequence analogous to that in Eq. 1 to recover polymer of **1**.

The position of peaks and their areas in the gas chromatograms of samples (column temperature: 80—100 °C) were compared with those of standard compounds to determine the **6a—e→8a—e** conversions. The results thus obtained are satisfactory and shown in Table 1. In the cases of **6f—g→8f—g** combinations, no standard compounds of **8f** and **8g** were available, so that quantitative comparison was not made by GC, but made by ^{1}H NMR. Conversions using a low-molecular-weight compound, *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide, instead of polymer of **1**, were also determined and compared with the results obtained with polymer.

The result of recycle or polymer was 12 (1st), 10 (2nd), and 10% (3rd) in conversion for **6a→8a** in Table 1.

Function of Polymer 9 According to Eq. 3. A solution of polymer **9** (2.4 g, 2 mmol as $-SO_2H$), prepared above and a cis compound (**10a,b**; 2 mmol) in dry dioxane (10 ml) was heated under nitrogen stream. Reaction temperatures and times were 100 °C and 1 h and 70 °C and 6 h, respectively. Upon cooling, the reaction mixture was diluted with hexane to precipitate polymer **9**, which was removed by filtration and ready to another use. The filtrate was washed twice with sat. aq. NaCl, dried over anhyd. $MgSO_4$, and concentrated on a rotary evaporator to leave a sample for gas chromatography. The comparison of the positions and areas of peaks in the gas chromatogram with those for the corresponding standard compound was successfully done and provided the **10a,b→11a,b** conversion. The results thus obtained are shown in Table 2, in which the results with *p*-toluenesulfinic acid instead of polymer **9** are also given. Column temperatures were 210 and 80 °C for samples **10a** and **10b**, respectively.

The result of recycle of polymer was 75 (1st), 74 (2nd), and 70% (3rd) in conversion for **10a→11a** in Table 2.

Replacement of an 11-Carbonyl Group of 11-Oxo Steroid by an Oxygen Atom. A New Partial Synthesis of 11-Oxaprogesterone[1)]

Hiroshi SUGINOME* and J. B. WANG
Organic Synthesis Division, Department of Chemical Process Engineering,
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received July 28, 1988)

We describe the transformation of commercially available 3α-hydroxy-5β-pregnane-11,20-dione acetate (**1**) into 11-oxaprogesterone (**15**) in 11 steps including the regioselective β-scission of an alkoxyl radical as a key step.

Among oxamodification of steroids, the synthesis of 11-oxasteroids has been extensively investigated by Engel and his colleagues. In 1968 they achieved the transformation of hecogenin into the first oxasteroid, 11-oxaprogesterone (**15**) having a significant biological activity, in 22 steps.[2,3)] They have also reported the synthesis and biological evaluation of several related 11-oxasteroids.[4,5)] Recently, the partial synthesis of 11-oxaestradiol via dye-sensitized photooxygenation of a 3-hydroxy-1,3,5(10),9-estratetraen-17-one methyl ether has also been reported by Bonet and his colleagues.[6)]

We ourselves have reported new general methods for transforming steroidal five- and six-membered cyclic alcohols or cyclic ketones as starting materials into oxasteroids with the same ring size in 2 or 4 steps[7-9)] and synthesized 1-oxa-, 3-oxa-, 4-oxa-, 6-oxa-, 7-oxa-, 16-oxa-, and 17-oxasteroids effectively by these methods. We have also recently shown that the synthesis of 11-oxasteroids can be achieved by our general method by which cyclic ketones are transformed into the corresponding cyclic ethers and that the synthesis of 11-oxa-5β-pregnan-3α-ol can be achieved by the replacement of the 11-carbonyl group of a commercially available 3α-hydroxy-5β-pregnane-11,20-dione acetate (**1**).[10)]

We wish to describe here the partial synthesis of 11-oxaprogesterone (**15**) from pregnane dione **1** based on our method by which cyclic ketones are transformed into cyclic ethers.

Results

A selective reduction of the 20-carbonyl group of a commercially available pregnane derivative **1** with $NaBH_4$ at room temperature followed by acetylation by the standard method gave a mixture of 3α,20α- and 3α,20β-dihydroxy-5β-pregnan-11-one 3,20-diacetate (**3**) in 94% yield. The preparations of this mixture of epimers by the reduction of 5β-pregnane-3,11,20-trione or 3α-hydroxy-5β-pregnane-11,20-dione with $NaBH_4$ followed by acetylation,[11,12)] have been reported to give the 20β-epimer as the predominant product.[12)]

A Baeyer–Villiger oxidation of diacetates **3** with potassium peroxodisulfate in glacial acetic acid containing concd sulfuric acid for 10 days at room temperature led to a regio- and stereoselective oxidation of the carbonyl group and gave a crystalline mixture of 3α,20α- and 3α,20β-dihydroxy-11-oxa-*C*-homo-5β-pregnane-12-one 3,20-diacetate (**4**) in a 56% yield. The ratio of the 20β-isomer and 20α-isomer was estimated to be approximately 1.7:1 based on the area ratio of the signals due to the two 9α-protons of the

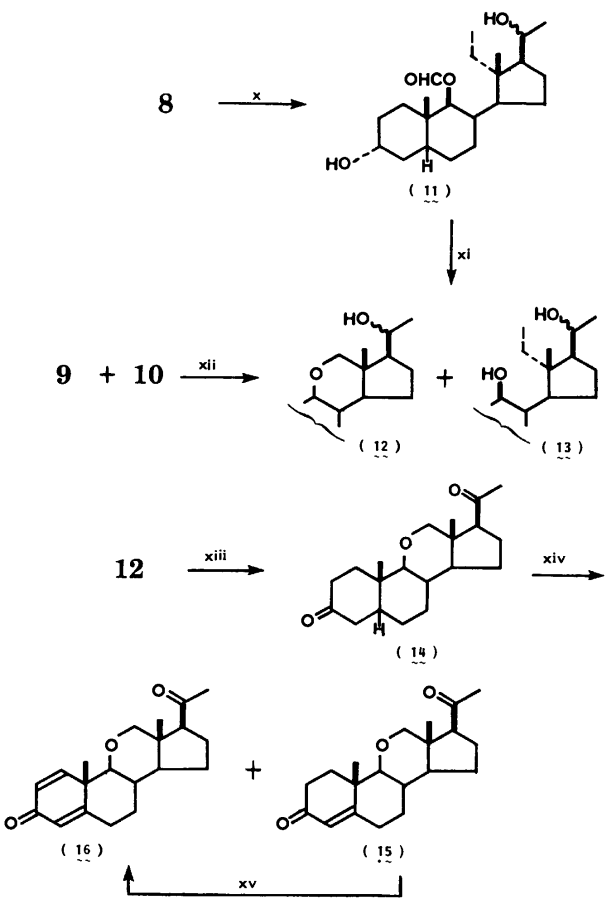
Scheme 1. ^{1}H NMR spectrum. To the best of our knowledge, no successful formation of lactones from 11-oxosteroids by means of the Baeyer–Villiger oxidation has previously been reported and the present example seems to be the first one. Examination of the oxidation product by means of TLC indicated that neither 9β-isomers nor 12-oxa-isomers of lactones **4** were present in the product. Its ^{1}H NMR spectrum exhibited two clear doublets at δ 4.27 and 4.38 with J=9.62 and 10.62 arising from the 9α-H of the 20-isomers.

Before transforming the lactone **4** into the corresponding lactols, the replacement of the 3α- and 20-acetyl groups by an MEM† group was necessary. The diacetate was therefore treated with sodium carbonate in aq methanol under reflux for 18 h to give the corresponding diol **5** in a 78% yield. The ratio of the two isomers with regard to the 20 position was 1:1.5. The treatment of diols **5** with [(2-methoxyethoxy)-methyl]triethylammonium chloride in acetonitrile under reflux for 16 h gave the corresponding MEM ether **6** in 76% yield. The dihydroxylactones protected by the MEM group was then transformed into the corresponding lactols **7** in a 73% yield by a treatment with DIBAL†† in toluene for one day at room temperature. The lactols **7** were then subjected to a regioselective homolytic cleavage of the 12,12a-carbon–carbon bond according to the procedure reported previously;[8] the lactols **7** in benzene were first transformed into the corresponding hypoiodite with 3 molar equivalents each of mercury(II) oxide and iodine and the solution was irradiated with a 100-W Hg arc for 4 h through a Pyrex to give iodo formates **8** in a 73% yield. Signals due to the formyloxy groups of the 20α-isomer and 20β-isomer in the ^{1}H NMR spectrum appeared at δ 8.23 and 8.33 as two singlets. The ratio of the two epimers estimated by the area ratio of these two singlets was 1:1.6.

The first attempt to cyclize the iodo formates **8** into the corresponding oxasteroids was made by heating the formates **8** in THF with $NaBH_4$ under reflux for 2 days. This procedure resulted, however, in only a low yield of oxasteroid **10** with an accompanying formation of 11β-ol **9** arose from hydrolysis. The crude oxasteroid **10**, isolated by means of preparative TLC, was immediately subjected to the removal of the protecting MEM group to give a mixture of 11-oxa-5β-pregnane-3α,20α- and 3α,20β-diol (**12**) by the standard method. The overall yield of oxasteroids **12** from iodo formates **8** was only 16%.

We obtained a much higher yield of oxasteroids **12**, however, by the initial removal of the MEM group of iodo formates **8** to iodo formates **11** followed by cyclization, although the intramolecular displacement of the iodo formates **8** in dichloromethane with $TiCl_4$ at room temperature gave a mixture of two epimers of iodo formates **11** in a 96% yield. The ratio of the two epimers estimated by the signal areas due to their 9α-H in the ^{1}H NMR was 1.1:1. The heating of iodo formates **11** in THF under reflux for 3 days gave a mixture of 11-oxa-5β-pregnane-3α,20α- and 3α,20β-diol (**12**) in a 51% yield with an accompanying formation of triols **13**.

Oxidation of 20-epimers of dihydroxyoxasteroids **12** in dichloromethane with PCC††† gave 11-oxa-5β-pregnane-3,20-dione (**14**) in a 84% yield. Further oxidation of dione **14** in dioxane with DDQ afforded 11-oxaprogesterone (**15**) and 11-oxapregna-1,4-diene-3,20-dione **16** in 11% and 31% yields. The transformation of the latter into the former by means of selective homogeneous hydrogenation with tris(triphenylphosphine)chlororhodium as a catalyst has already been achieved in 85% yield by Engel and his colleagues.[2]



Scheme 2. Reagents: x) CH_2Cl_2, $TiCl_4$, 0°C, 20 min; xi) THF, $NaBH_4$, reflux, 3 d; xii) CH_2Cl_2, $TiCl_4$, 0°C, 40 min; xiii) CH_2Cl_2, PCC, 0°C, 12 h; xiv) dioxane, DDQ, reflux, 23 h; xv) benzene, H_2, $(Ph_3P)_3RuCl$, 20°C, 5 h.

† MEM; (2-methoxyethoxy)methoxy.

†† DIBAL; diisobutylaluminium hydride.

††† PCC; pyridinium chlorochromate.

Experimental

Mps were recorded with a Yanagimoto micro mp apparatus and are uncorrected. IR spectra were determined for Nujol mull with a JASCO IR 810 infrared spectrophotometer. ^{1}H NMR spectra were determined with JEOL JNM-FX 270 high-resolution FT-NMR spectrometer (270 MHz) (Solvent $CDCl_3$; $SiMe_4$ as internal standard) (Faculty of Pharmaceutical Sciences of this University). TLC was carried out on a Merck Kieselgel 60 PF_{254}. The high- and low-resolution mass spectra were determined with a JEOL JMA-D 300 spectrometer (70 eV) (Faculty of Agriculture or Faculty of Pharmaceutical Sciences of this University). Optical rotations were measured with a JASCO DIP-360 digital polarimeter.

3α,20α- and 3α,20β-Dihydroxy-5β-pregnan-11-one 3,20-Diacetates (3). Commercially available 3α-hydroxy-5β-pregnane-11,20-dione 3-acetate (**1**) (5 g) in ethanol (350 ml) was reduced with $NaBH_4$ (1 g) at room temperature for 5 h by the standard procedure to yield a mixture of 3α,20α- and 3α,20β-dihydroxy-5β-pregnan-11-one 3-acetates (**2**). The crude 20-ols **2** were immediately acetylated with acetic anhydride (25 ml) and pyridine (50 ml) for 35 h at room temperature. The solution was poured into water and the crystals were collected by filtration, washed with water and dissolved in dichloromethane. The solution was worked up in the usual way to yield 3,20-diacetates **3** (5.94 g). Recrystallization of the diacetates with hexane–ethyl acetate gave a stereoisomeric mixture of 3,20-diacetates **3** (5.24 g, 94%). Mp 161.5—163.0 °C (lit,[11] 160.5—161.0 °C)

Baeyer-Villiger Oxidation of 3α,20α-Dihydroxy-5β-pregnan-11-one 3,20-Diacetates. The diacetates (1.59 g), potassium peroxodisulfate (7 g) and concd sulfuric acid (7 ml) in glacial acetic acid (39 ml) in a vessel covered by aluminum foil was set aside for 10 days at room temperature. The reaction mixture was extracted with chloroform (ca. 40 ml× 5). The combined extracts were washed with 5% aqueous sodium thiosulfate, brine and water and dried over $MgSO_4$. The work-up of the solution gave a residue which was subjected to preparative TLC with 1:1 hexane–ethyl acetate to yield two fractions. The less polar fraction (1.06 g) was the starting material. The more polar fraction (300 mg) was a crude lactone **4** which was recrystallized from hexane–ethyl acetate. Mp 192—195 °C. (Found: M$^+$, 434.2676. $C_{25}H_{38}O_6$ requires M, 434.2668); IR 1727 (OAc and lactone C=O), 1244 and 1039 cm^{-1}; ^{1}H NMR δ=0.75 (3H, s, 18-H of 20α- and 20β-isomer), 1.08 (s, 19-H of 20α- and 20β-isomer), 1.17 (d, J=5.86 Hz, 21-H), 2.03 (s, OAc of 20α-isomer), 2.04 (s, OAc of 20β-isomer), 2.10 (s, OAc of 20β-isomer), 2.14 (s, OAc of 20α-isomer), 2.39 and 2.66 (each d, J=14.2 Hz, 12a-H of 20α-isomer), 2.51 and 3.22 (each d, J=13.9 Hz, 12a-H of 20β-isomer), 4.27 (d, J=9.52 Hz, 9aα-H of 20β-isomer), 4.38 (d, J=10.62 Hz, 9α-H of 20α-isomer), and 4.77 (m, 3β-H and 20-H of 20α- and 20β-isomers). EIMS m/z 434 (M$^+$, 4.8%). 374 [(M−CH_3CO_2H)$^+$, 11.4], 324 [(M−2CH_3COOH)$^+$, 18.6], and 43 (100).

3α,20α- and 3α,20β-Dihydroxy-5β-C-homo-11-oxapregnan-12-one (5). To the lactone **4** (270 mg) in methanol (20 ml), aq. saturated sodium carbonate (2 ml) was added. The solution was heated under reflux for 18 h. The removal of the solvent gave a residue which was dissolved in dichloromethane, then washed with a 5% hydrochloric acid, brine and water and dried over $MgSO_4$. The usual work-up gave a product (223 mg) which was purified by means of preparative TLC with ethyl acetate to give diol **5** as an amorphous solids (169 mg, 78%). (Found: M$^+$, 350.2471. $C_{21}H_{34}O_4$ requires M, 350.2457); IR 3380 (OH), 1708 (lactone C=O) and 1041 cm^{-1} (C-O-C); ^{1}H NMR δ=0.87 (s, 18-H of 20α-isomer), 0.93 (s, 18-H of 20β-isomer), 1.06 (s, 19-H of 20β-isomer), 1.07 (s, 19-H of 20α-isomer), 1.00 (d, J=6.23 Hz, 21-H of 20β-isomer), 1.16 (d, J=6.23 Hz, 21-H of 20α-isomer), 2.46 and 3.61 (each d, J=13.6 Hz, 12a-H of 20α-isomer), 2.52 and 3.26 (each d, J=13.6 Hz, 12a-H of 20β-isomer), 3.70 (2H, m, 3β-H and 20α- and 20β-H), 4.30 (d, J=9.89 Hz, 9α-H of 20α-isomer), and 4.40 (d, J=9.89 Hz, 9α-H of 20α-isomer); EIMS m/z 350 (M$^+$, 18.9), 322 [(M−H_2O)$^+$, 51.4], 341 [(M−2H_2O)$^+$, 50.0], and 81 (100%).

3α,20α- and 3α,20β-Dihydroxy-5β-C-homo-11-oxapregnan-12-one 3,20-MEM Ether (6). To diol **5** (163 mg) in dry acetonitrile (10 ml), MEM triethylammonium chloride (400 mg) was added. The solution was heated under reflux for 16 h and the solvent was removed under vacuum. The residue was dissolved in dichloromethane–acetone. The solution was washed with aq 5% sodium hydrogencarbonate, brine and then water and dried over $MgSO_4$. The usual work-up gave a crude MEM ether. Since the IR spectrum indicated the presence of the starting diol in this product, the crude MEM ether was again subjected to the above procedure to transform the starting diol into MEM ether. The product was purified by means of preparative TLC with ethyl acetate to give oily MEM ether **6** (187 mg, 76.3%). (Found: M$^+$, 526.3493. $C_{29}H_{50}O_8$ requires M, 526.3503); IR 1735 (lactone C=O), 1119 (C-O-C) and 1048 cm^{-1} (C-O-C); ^{1}H NMR δ=0.80 (s, 18-H of 20α-epimer), 0.83 (s, 18-H of 20β-epimer), 1.05 (s, 19-H of 20α-epimer), 1.06 (s, 19-H of 20β-epimer), 3.38 (s, OMe), 3.39 (s, OMe), 3.56—3.74 (m, -OCH_2CH_2O-), 4.28 (d, J=9.80 Hz, 9α-H of 20β-epimer), 4.38 (d, J=9.80 Hz, 9α-H of 20β-isomer), and 4.68—4.89 (4H, m, -OCH_2O-), EIMS: m/z 526 (M$^+$, 0.1), 89 (95.6), and 59 (100%).

Reduction of 3α,20α- and 3α,20β-Dihydroxy-5β-C-homo-11-oxapregnan-12-one 3,20-MEM Ether (6) with DIBAL. To lactone MEM ether **6** (195 mg) in dry toluene (10 ml), a DIBAL solution (0.53 ml) (1 M in toluene) was added dropwise at −78 °C in an atmosphere of nitrogen. The solution was stirred for 1 day at room temperature. After the solution had again been cooled to −78 °C, a more DIBAL solution (0.2 ml) was added and the solution stirred for 4 h at room temperature. The reaction was quenched by the addition of iced water and the solution was filtered. After the addition of chloroform and acetone, the solution was washed with brine and then with water and dried over $MgSO_4$. The usual work-up gave a product which was purified by means of preparative TLC with ethyl acetate to give only lactol **7** (143 mg, 73%). [Found: (M−H_2O)$^+$, 510.3573. $C_{29}H_{50}O_7$ requires M, 510.3557]: IR 3442 (OH), 1099 (C-O-C) and 1043 cm^{-1} (C-O-C); ^{1}H NMR δ=3.85 (d, J=9.52 Hz, 9α-H of 20α-epimer), 3.97 (d, J=9.65 Hz, 9α-H of 20α-epimer), 5.14 (m, 12-H of 20β-epimer), and 5.33 (m, 12-H of 20α-epimer); EIMS m/z 510 [(M−H_2O)$^+$, 0.19] and 59 (100%).

Preparation of 3α,20α- and 3α,20β-Bis[3-(2-methoxyethoxy)methoxy]-11-iodo-9,11-seco-C-nor-5β-yl Formates (8). Lactol **7** (155 ml) was dissolved in dry benzene (20 ml) containing pyridine (0.2 ml). To this solution mercury(II) oxide (200 mg) and iodine (230 mg) were added. The solution was then flashed with nitrogen and irradiated with a

100-W high-pressure Hg arc for 4 h. The solution was then filtered and the filtrate was washed with aq 5% sodium thiosulphate, brine and then water successively and dried over $MgSO_4$. The usual work-up of the solution gave a residue (193 mg) which was subjected to preparative TLC with a 1:2 hexane–ethyl acetate. The most mobile fraction (140 mg, 73%) was two 20-epimers of iodo formates **8**. IR 1721 (OCHO) and 1025—1175 (C-O-C); ^{1}H NMR δ= 0.93 (s, 18-H of 20α-epimer), 0.95 (s, 18-H of 20β-epimer), 1.04 (s, 19-H of 20α-epimer), 1.06 (s, 19-H of 20α-epimer), 3.39 (s, OMe), 3.51—3.78 (m, $-OCH_2CH_2O-$), 4.74—4.81 (m, $-OCH_2O-$), 5.21 (d, J=10.99 Hz, 9α-H of 20β-epimer); 5.32 (d, J=9.16 Hz, 9α-H of 20α-epimer), 8.23 (s, OCHO of 20α-epimer), and 8.33 (s, OCHO of 20β-epimer); EIMS: m/z 549 [(M−OMEM)$^+$, 0.14], 397 (2.1), 89 (100), and 59 (80.1%).

Preparation of 3α,20α- and 3α,20β-Dihydroxy-11-iodo-9,11-seco-*C*-nor-5β-pregnan-9β-yl Formate (11). To iodo formate **8** (50 mg) in dichloromethane (3 ml), titanium tetrachloride (0.2 ml) was slowly added at 0 °C. After the solution had been stirred for 20 min at 0 °C, concd aq ammonia was added. The combined organic layers were washed with brine and then with water and dried over $MgSO_4$. The usual work-up gave an oily product (50 mg) which was purified by means of preparative TLC with ethyl acetate to give amorphous formate **11** (35 mg, 96%). [Found: (M−HI−H_2O)$^+$, 332.2321, $C_{21}H_{32}O_3$ requires M 332.2351]; IR ($CHCl_3$) 3410 (OH), 1719 and 1189 (-OCHO); ^{1}H NMR δ=5.20 (d, J=10.99 Hz, 9α-H), 5.30 (d, J=10.99 Hz, 9α-H), 8.30 (s, OCHO), and 8.35 (s, OCHO); EIMS m/z 415 [(M−OCHO−H_2O)$^+$, 0.22], 332 [(M−HI−H_2O)$^+$, 2.8], 305 [(M−HCHO−I)$^+$, 2.3], 287 [(M−OCHO−H_2O)$^+$, 84.3], 269 [(M−HCHO−I−2H_2O)$^+$, 56.4], and 95 (100%).

11-Oxa-5β-pregnane-3α,20α and 3α,20β-diol (12). To iodo formates **11** (90 mg) in dry THF (10 ml), $NaBH_4$ (180 mg) was added and the solution was heated under reflux for 3 days. The removal of the solvent gave a residue which was dissolved in dichlorormethane. The solution was washed with brine and then with water and dried over anhydrous $MgSO_4$. The usual work-up of the solution gave a product (80 mg) which was subjected to preparative TLC with a 2:1 ethyl acetate–hexane to give three fractions. The most mobile fraction (10 mg) was the starting iodo formates **11**. The next mobile fraction (31 mg, 51%) was the amorphous epimers **12** of oxasteroid. (Found: M$^+$, 322.2523. $C_{20}H_{34}O_3$ requires M, 322.2508); IR 3280 (OH), 1114, 1085, and 1072 cm^{-1}; ^{1}H NMR δ=(the predominant epimer of the 20α- and 20β-isomers), 0.86 (3H, s, 18-H), 1.02 (3H, s, 19-H), 3.12 (1H, d, J=9.89 Hz, 9α-H), 3.18 (1H, d, J=10.63 Hz, 12-H), 3.61—3.75 (2H, m, 3β-H and 20ξ-H) and 4.15 (1H, d, J=10.63 Hz, 12-H).

The most polar fraction (30 mg, 35%) was an oily 11-iodo-*C*-nor-9,10-seco-5β-pregnane-3α,9β,20α- and 3α,9β,20β-triols. IR ($CHCl_3$) 3392 (OH) and 1094 cm^{-1} (C-O); ^{1}H NMR δ=3.04 (d, J=10.63 Hz, 11-H), 3.34 (d, J=9.90 Hz, 9α-H); 3.56—3.74 (m, 3α-H, 11-H, 20α-H, and 20β-H); the epimer, δ=3.26 (d, J=10.26 Hz, 11-H), 3.77 (d, J=10.26 Hz, 11-H), and 3.94 (d, J=9.90 Hz, 9α-H), ^{1}H NMR m/z 433 (0.27), 415 (1.08), 397 (0.68), 322 [(M−HI)$^+$, 36.1], 304 [(M−HI−H_2O)$^+$, 35.4], and 44 (100%).

Preparation of 11-Oxa-5β-pregnane-3,20-dione (14). To diol **13** (30 mg) in dichloromethane (5 ml), PCC (100 mg), and Celite (100 mg) were added at 0 °C and the solution was stirred for 12 h at room temperature. After the addition of diethyl ether, the solution was filtered. The removal of the solvent from the filtrate gave a residue which was purified by means of preparative TLC with a 2:3 hexane–ethyl acetate to give crystals of dione **14** (25 mg, 84%). The specimen for analysis was obtained by recrystallization from hexane–ethyl acetate. Mp 153.5—155.0 °C. (Found: C, 75.47; H, 9.60%. $C_{20}H_{30}O_3$ requires C, 75.43; H, 9.50%); $[\alpha]_D^{22}$ +48° (c 1, $CHCl_3$); IR 1715 and 1703 (C=O), 1078 and 1071 (C-O-C); ^{1}H NMR δ=0.77 (3H, s, 18-H), 1.10 (3H, s, 19-H), 2.07 (3H, s, 21-H), 3.26 (1H, d, J=9.53 Hz, 9α-H), 3.47 (1H, d, J=10.26 Hz, 12-H), and 4.16 (1H, d, J=10.26 Hz); EIMS: m/z 318 (M$^+$, 52.2), 300 (6.9), 288 (9.9), 233 (37.4), and 43 (100%).

Preparation of 11-Oxa-5β-pregnane-3,20-dione (14) from Iodo Formate 8 via 10 and 12. Iodo formate **8** (139 mg) in dry THF (6 ml) containing $NaBH_4$ (139 mg) was heated under reflux for 1 day in an atmosphere of dry nitrogen. To the solution a further amount (50 mg) of $NaBH_4$ was added and the solution was heated under reflux for 1 day. After the removal of the solvent the residue was dissolved in dichloromethane. The solution was washed with brine and then with water and dried over anhydrous $MgSO_4$. The removal of the solvent gave an oily product (120 mg) which was subjected to preparative TLC with a 1:1 hexane–ethyl acetate to give an oily product (80 mg). To the product in dichloromethane (5 ml), titanium tetrachloride (0.28 ml) was added and the solution was stirred for 40 min at 0 °C. To the solution concd aq ammonia was added and the organic layer was washed with brine and then with water and dried over anhydrous $MgSO_4$. The usual work-up of the solution gave a product (60 ml) which was subjected to preparative TLC with a 1:2 hexane–ethyl acetate to give oxasteroid **12** (15 mg) and triol **13** (35 mg). Oxasteroid **12** was oxidized with PCC to give a new dione **14** (11 mg) as described previously. The overall yield from **8** to **12** was 16%.

Synthesis of 11-Oxaprogesterone (15) and 11-Oxapregna-1,4-diene-3,20-dione (16). 11-Oxasteroid **14** (28 mg) in dry dioxane (3 ml) containing DDQ (30 mg) was heated under reflux for 23 h in an atmosphere of nitrogen. After the removal of the solvent, the residue was dissolved in acetone and the solution was filtered through aluminum oxide. The removal of acetone gave a yellow product which was subjected to preparative TLC (Merck, silica gel 60 F_{254}) with a 1:1 hexane–ethyl acetate to give three fractions. The most mobile fraction (10 mg) was the starting material. The second mobile fraction was crystals of 11-oxaprogesterone (**15**) (2 mg, 11% based on the converted oxasteroid **14**) which was recrystallized from dichloromethane–diethyl ether. Mp 179—180 °C (lit,[2] 181—182 °C). ^{1}H NMR δ=0.80 (3H, s, 18-H), 1.26 (3H, s, 19-H), 2.07 (3H, s, 21-H), 2.59 (1H, J=9.98 Hz, 9α-H), 3.44 (1H, J=10.26 Hz, 12-H), 4.16 (1H, J=10.26 Hz, 12-H), and 5.78 (1H, s, 4-H). EIMS m/z 316 (M$^+$, 28), 193 (84), and 43 (100%).

The most polar fraction (6 mg, 31% based on the converted starting steroid) was 11-oxapregna-1,4-diene-3,20-dione which was recrystallized from dichloromethane–diethyl ether to give a pure specimen. Mp 193—196 °C (lit,[2] 195—196 °C), $[\alpha]_D^{22}$ +104.8° (c 0.8 in $CHCl_3$) [lit,[2] $[\alpha]_D^{22}$ +104.3° (c 1.0 in $CHCl_3$)]. ^{1}H NMR δ=0.83 (3H, s, 18-H), 1.32 (3H, s, 19-H), 2.07 (3H, s, 21-H), 2.63 (1H, d, J=9.52 Hz, 9α-H), 3.48 (1H, d, J=10.26 Hz, 12-H), 4.18 (1H, d, J=10.26 Hz, 12-H), 6.12 (1H, s, 4-H), 6.25 (1H, d, J=10.3 Hz, 2-H), and 7.26 (1H, s, J=10.3 Hz, 1-H), EIMS: m/z 314 (M$^+$, 16.5), 286 (5.8), 193 (42.3), and 42 (100%).

Design and Synthesis of Macromonocyclic Polyamines Composed of Natural Methylene Arrays

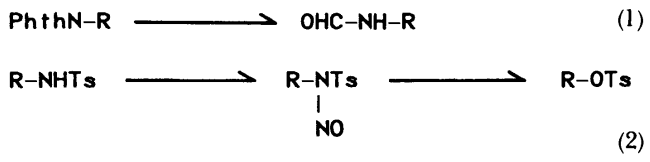
Masaaki IWATA* and Hiroyoshi KUZUHARA
RIKEN (The Institute of Physical and Chemical Research),
Wako, Saitama 351-01
(Received August 4, 1988)

A general synthetic method applicable to acyclic and cyclic polyamines was developed. The methodology was exemplified by systematical synthesis of twelve macromonocyclic polyamines, **1** ([17]N_4) through **12** ([35]N_8), composed of the combination of four natural polyamine segments, spermidine, spermine, thermine, and thermospermine. These twelve designed macrocycles are exhausted numbers of possible structures defined by three arbitrarily chosen criteria concerning with methylene chain arrays and nitrogen content (four to eight). The common elements of the structural characteristics were analyzed and were found to be reduced to readily available three classes of simple *N,N'*-ditosylalkanediamines derived from diamines and triamine. Nitrogen content was increased systematically through the reaction of *N,N'*-ditosylalkanediamine with one of three ω-phthalimidated electrophiles followed by regeneration of the same functionality at symmetrical both terminals as the starting materials via a series of transformation reaction, in excellent yields. Tractable formamide intermediate profits the facile synthesis of acyclic polyamines with long chains. Cyclization was achieved, under high dilution conditions, through the reaction of α,ω-bis(tosylamide) with α,ω-ditosylates in DMF in the presence of cesium carbonate. The cyclization occurred in practical synthetic yields even in the formation of multi-membered ring when the shorter electrophile and the longest α,ω-bis(tosylamide) reacted.

Knowledge of biological importance of natural polyamines as one of substances controlling cell functions[1] has stimulated much interest in intrinsic biological role of amino groups involved in, through the synthesis of selectively modified spermidines[2a] or through the studies on biological activities of polyamine analogues.[2b,c] Ubiquitous natural polyamines, spermidine and spermine, and rare species-specific polyamines, thermine[3a] and thermospermine,[3b] are correlated structurally in a sense of disposition of methylene chain blocks, in which both types of polyamines are composed, mysteriously, of the combination of the contiguous three and/or four methylene chain blocks. Difference lies only in the order of the methylene block disposed along the polyamine chain. Biosynthetically, this implys only the limited numbers of amino acid sources, methionine and ornithine. However, profound nature of their sequence might be concealed in their biological function because of their species-specific beings.

Cyclic polyamines, in which the studies had been initiated based on the interest in complexing reagents with high stability and/or selectivity for metal ions,[4a,b] have extended recently their subject fields in search of functions such as molecule or ion receptors, analogous to but much more different from crown ethers, which effect such functions as recognition, regulation, transport, and catalysis for guest molecules or ions.[4c] Since these functions are highly dependent on the molecular design of the macrocycles, synthetic feasibility of a given molecular architecture is crucial to access for investigation. The strategy in most cases has been to elaborate the substituted acyclic polyamine backbone from a simple amine and then close macrocycle late in the synthesis. Prior derivatization of a polyamine building block has resorted to rather limited methods.[2a,4d,e,f] Presently, the most effective molecular architecture for designed cyclic polyamines has been carried out through four main processes; (a) the synthesis of acyclic polyamines with α,ω-bis(tosylamide)s as nucleophiles, and (b) of electrophiles with electron-withdrawing groups at both terminals, followed by (c) cyclization between nucleophiles and electrophiles, and, finally, (d) deprotection of the protecting groups on the amino groups.[5] All the presently known methods, however, suffer from some synthetic drawback especially, in (a), (b), and (c) steps for efficient and generally adaptable architecture. In (a) step, it is desirable to accommodate every type of methylene chain blocks and to regenerate efficiently the same nucleophilic functionality in the shortest procedure.[2a] In (b) step, it is ideal to accommodate the tosyloxy group at both terminals.[6] In addition, when designed macrocycles might be constructed through several couples of α,ω-nucleophiles and α,ω-electrophiles in (c) step, it is ideal to select readily best couples according to a certain guiding principle.

Recently, we have developed two elemental reactions; the transformation reaction of phthalimides to formamides[7] (Eq. 1) and the rearrangement reaction of *N*-nitroso sulfonamides, which are quantitatively prepared by nitrosation of the corresponding sulfonamides, to tosylate[8] (Eq. 2). Through the



preliminary investigations concerning with applicability of the elemental reactions,[9] a new plan of molecular architecture for macromonocyclic polyamines was emerged. In the plan, firstly, our concern

was to provide cyclic polyamines, in which all the methylene blocks in the ring are composed of natural methylene arrays. This effort might provide functionally unique macrocycles which may reveal the biological significance of mysterious natural methylene arrays and of biological role of primary amino groups. Secondary, our concern was to elongate chain as long as possible, in order to know how much extent the elemental reactions could be tenable in polyamine synthesis. Therefore, most of the problems involved in the conventional methods are expected to be solved through the present study.

Results and Discussion

Concept of Design and Specification: In design of cyclic polyamines, three criteria, concerning with methylene chain arrays and amine content, were defined to limit arbitrariness of the structures and to reduce numbers of targets; i) every two or three contiguous methylene blocks bisected by nitrogen atoms are comparable to one of natural polyamine segments, spermidine, spermine, thermine, and thermospermine, ii) the cycle includes these four natural polyamine arrays at least once in the chain, and iii) four through eight nitrogen atoms exist in the chain. These three criteria generate logically twelve polyamines, **1** ([17]N_4) through **12** ([35]N_8), as exhausted numbers of possible structures to be synthesized. In order to minimize synthetic steps of the defined macrocycles, the common elements of the structural characteristics were analyzed; according to their

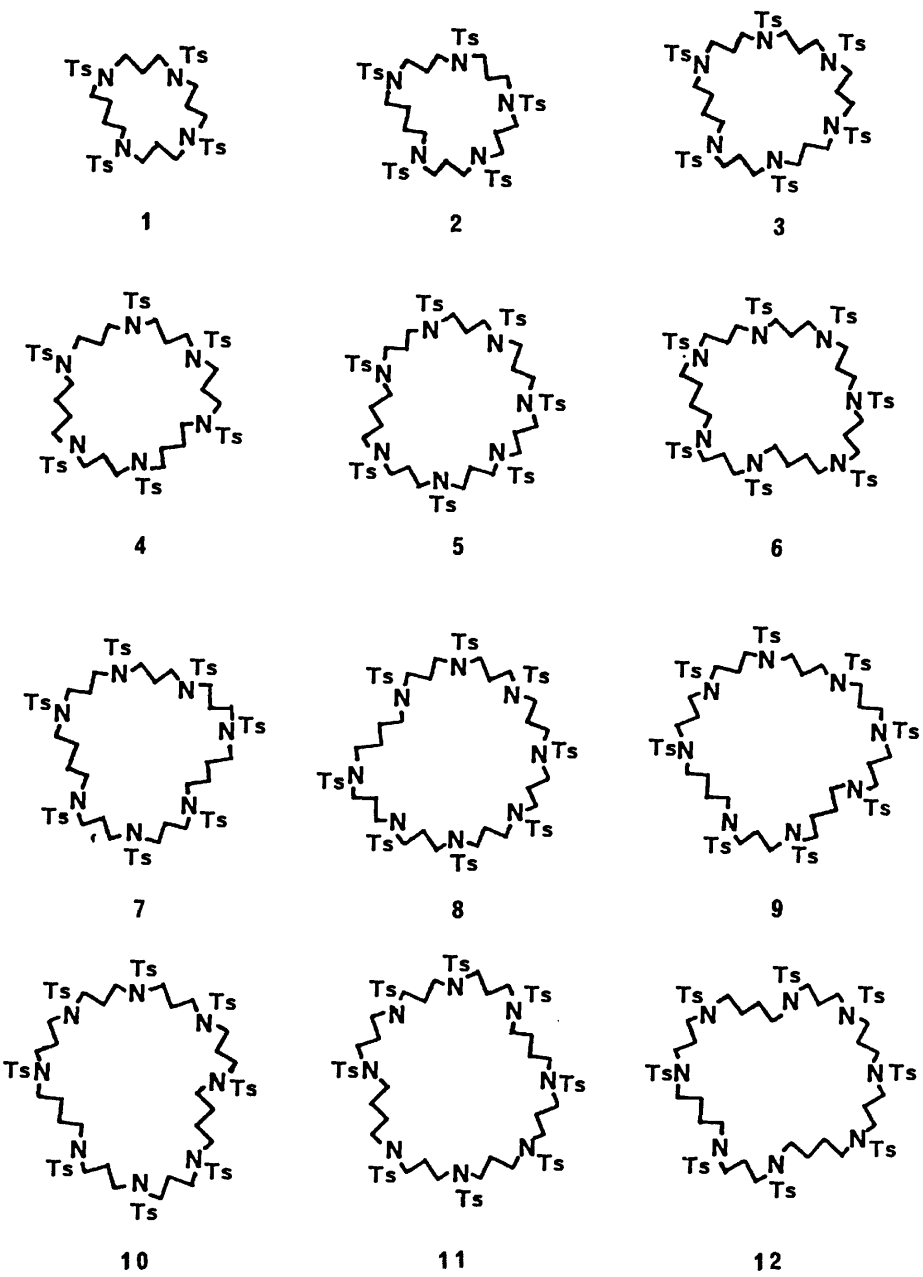


Table 1. The Flow Chart of Hierarchical Synthetic Design of Tosylated Acyclic and Cyclic Polyamines[a)]

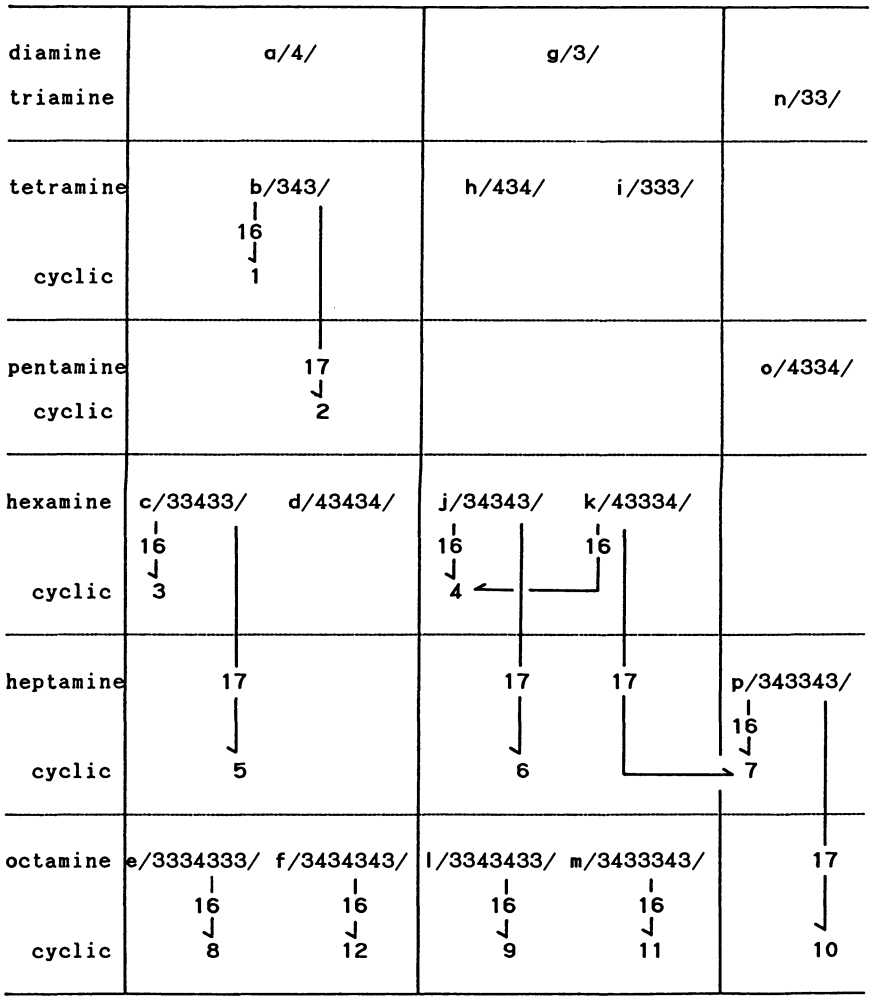
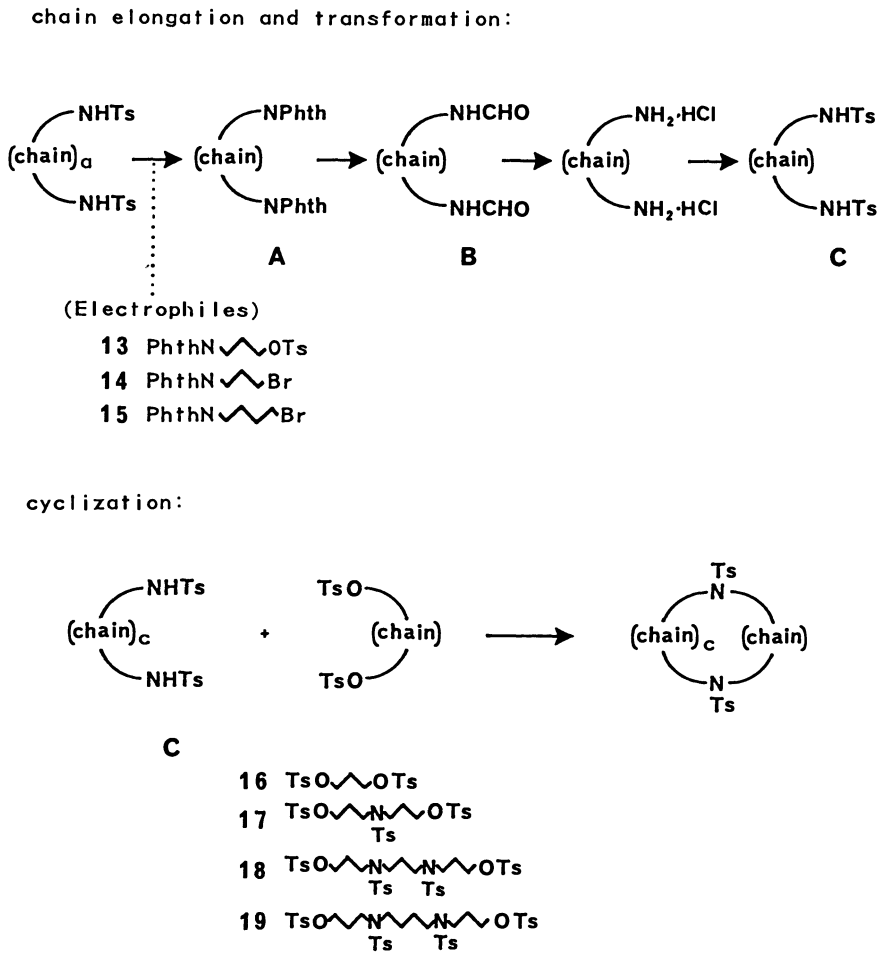


a) The chain type is shown by gothic alphabet and the chain composition is indicated by the contiguous methylene chain blocks in Arabic numerals with the default of nitrogen atoms between slant lines. Arrows in Table indicate a formal route from the acyclic to cyclic polyamines by use of α,ω-ditosylates (**16**, **17**) indicated in the arrow intermitted.

molecular symmetry, these twelve macrocycles designed were found to be divided into three classes. Starting from *N*,*N*′-ditosyl-1,4-butanediamine (**a**) as one core chain, six macrocycles, **1**, **2**, **3**, **5**, **8**, and **12** could be derived. Likewise, *N*,*N*′-ditosyl-1,3-propanediamine (**g**) as another core chain emerges four macrocycles, **4**, **6**, **9**, and **11**. N^1,N^7,4-Tritosyl-4-azaheptane-1,7-diamine (**n**) could be the other core for two macrocycles, **7** and **10**. Owing to their molecular symmetry, two macrocycles, **4** and **7**, might be synthesized through alternative combination.

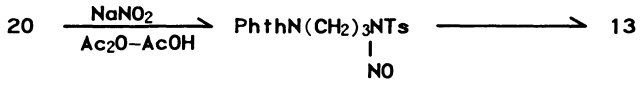
Molecular Architecture: As shown in Table 1, nitrogen content could be increased hierarchically, for synthetic convenience, at both terminals with the same electrophiles. For example, diamine chains (**a**, **g**) will be source for tetramine chains, which, then, be source for hexamine and octamine chains. Thus, heptamine chain (**p**) will be derived from pentamine chain (**o**), which might have been derived from triamine chain (**n**). We expected that chain elongation from the lower to the higher nitrogen content and transformation to regenerate the same functionality at symmetrical both terminals as the starting α,ω-bis(tosylamide)s would be provided through the processes illustrated in Scheme 1; the reaction of α,ω-bis(tosylamide)s, **a**, **g**, or **n**, with ω-phthalimidated electrophiles, **13**, **14**, or **15**, will provide α,ω-diphthalimides (**A**) which then be transformed to α,ω-diformamides (**B**) and subsequently to α,ω-bis(tosylamide)s (**C**) to give **b**, **h**, or **o**, respectively, with the higher nitrogen content. The processes were expected to be recyclizable. Cyclization was expected to be achieved by the conventional process,[6)] using **C** and α,ω-ditosylated electrophiles, **16**, **17**, **18**, or **19**. As a result, in the strategy of our molecular architecture (in Table 1 and Scheme 1),



Scheme 1.

synthetic feasibility will be judged from the efficacy of repeated three reactions, chain elongation, **A** to **C** transformation, and cyclization. Therefore, efficient synthesis of electrophilic synthons, ω-phthalimidated electrophiles (**13**, **14**, **15**) and, α,ω-ditosylates (**16**, **17**, **18**, **19**), required for chain elongation and cyclization, should be the first issue.

Synthesis of Electrophiles: Elongative introduction of three methylene chain would be accommodated by *N*-(3-tosyloxypropyl)phthalimide (**13**) or *N*-(3-bromopropyl)phthalimide (**14**), and four methylene chain would be accommodated by *N*-(4-bromobutyl)phthalimide (**15**). It should be noted, as pointed previously,[9a] that the tosyloxy group is about five-fold more reactive than the bromo group. Thus, efficient synthesis of **13** was pursued. According to *N*-nitroso sulfonamide–sulfonate rearrangement reaction,[8a] *N*-(3-tosylaminopropyl)phthalimide (**20**) could be a precursor for **13**. Compound **20** was prepared via independent two routes; one route was via tosylation of commercially available 3-bromopropylamine hydrobromide (**21**) followed by condensation with potassium phthalimide (route A). The other route started with diphthalimidation of commercially available 1,3-dibromopropane (**23**) followed by treatment with hydrazine hydrate to afford a unique heterocycle, 3,4-dihydro-2*H*-pyrimido[2,1-*a*]isoindol-6-one (**25**).[10] After hydrolysis of **25**, tosylation in the presence of triethylamine gave **20** in quantitative yield (route B). Both routes proceeded in excellent yields. In economical point of view, compound **21** is expensive. Nitrosation of **20** proceeded quantitatively[8b] and the nitrosated product was rearranged in hot benzene to give **13** in 80% conversion yield. For the pur-



pose of reactivity comparison with **13**, compound **14** was prepared in 88% yield through the modification of the Gabriel method[11a] via the reaction of 1,3-dibromopropane with phthalimide. Since *N*-(4-tosyloxybutyl)phthalimide (**27**) has been unavailable in practical scale,[12] *N*-(4-bromobutyl)phthalimide (**15**), employed for accommodation of four methylene block throughout, was prepared in 68% yield through

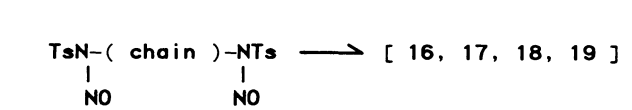
modification of the Gabriel method[11b] via the reaction of 1,4-dibromobutane (**28**) with phthalimide.

α,ω-Ditosylates, **16**, **17**, **18** and **19**, were prepared from the corresponding α,ω-bis(tosylamide)s, **Cg**, **Cn**, **Ci**, and **Cb**, respectively, through the nitrosation[8b] followed by the rearrangement reaction.[8a]



Chain Elongation and Transformation: Presently, three methods have been available for the condensation of electrophiles with α,ω-tosylamides (**C**) in synthetic polyamine chemistry; conventional use of potassium carbonate as base trigger in *N,N*-dimethylformamide (DMF), activation of α,ω-bis(tosylamino) groups via the formation of the corresponding Na salt,[6] and use of cesium carbonate[13] in DMF. When cesium carbonate was employed for the reaction of **Ca** with **13** in DMF at ambient temperature, the product **Ab** was obtained almost quantatively though the reaction proceeded very slowly (a day long). When the reaction temperature was elevated up to 80 °C for acceleration of the condensation, the reaction was not accelerated but decomposition of **13** turned out remarkable.

In preliminary experiments, tosylates were found to be decomposed considerably during the slow condensation reaction with potassium carbonate, probably due to the prolonged reaction time. When the reaction temperature was elevated, decomposition of the tosylate was accelerated as well as in the case of the use of cesium carbonate, resulting in marked decrease in product yield. When the Na salt of tosylamide of **Ca** reacted with **13** in DMF, the condensation occurred rapidly but yield of **Ab** never exceeded 40% in several runs. Therefore, in sacrifice of the reaction time, cesium carbonate was employed as a base for chain elongation throughout the present study. In addition, difference in reactivity between the tosyloxy group and the bromo group was not apparent due, probably, to mild reaction conditions. Thus, both **13** and **14** were employed for introduction of three methylene chains without intention and **15**, for accommodation of four methylene chains. Since the bromo group is more tough against base than the tosyloxy group, in a general sense, and more feasible in scaled-up synthesis, compound **14** was employed more often than **13**. Furthermore, it was an idea that ω-phthalimidated electrophile was added in slight excess amount so as to supply its amount lost by its decomposition during prolonged reaction time.

The transformation reaction of phthalimides to formamides[7] was applied satisfactorily to the conversion of α,ω-diphthalimides (**A**) to α,ω-diformamides (**B**) without exception and the yield of **B** became optimal when 20 mol equiv hydrazine hydrate to **A** was employed in hot DMF. Compound **B** was hydrolyzed with hot 2 M HCl (1 M=1 mol dm^{-3}) to give the corresponding hydrochloride salt. It was optional to isolate hydrochloride salt mostly as crystals. However, for the present purpose, the hydrochloride was treated, without neutralization, directly with tosyl chloride in pyridine in the presence of triethylamine to afford α,ω-bis(tosylamide) (**C**).

These series of reactions were found to be repeated successfully without decrease in product yields even if the chain was elongated to octamines. The results in repeated manipulation, **A** through **C**, are summarized in Table 2. Tractable formamide intermediate (**B**) profits greatly the facile synthesis of acyclic poly-

amines. In addition, operationally simplified tosylation by in situ neutralization of hydrochloride salt with triethylamine was found to be advantageous for increased yields of tosylamide (**C**) and decreased decomposition of unstable free amine.

Macrocyclization: The same three methods as those shown in the section of chain elongation and transformation have been available for cyclization reaction of the electrophiles with nucleophiles. Since the product yield in the chain elongation turned out optimal when cesium carbonate was used as a base, the same base seemed to be the best choice upon macrocyclization as well. Under high dilution conditions, α,ω-bis(tosylamide) and α,ω-ditosylate (1.2 mol equiv) reacted in the presence of cesium carbonate (2.5 mol equiv) in DMF (a day long). The results obtained are listed in Table 3. Compound **1** ([17]N_4) and **2** ([21]N_5) were obtained almost quantitatively. Since compound **1** had been prepared previously in 56% yield by the reaction of **Ci** with 1,4-dibromobutane in the presence of potassium carbonate in DMF at 120 °C,[13] the present method turned out to improve the product yield of cyclization to great extent. The difference in yields suggests how important the choice of base, reaction time, and types of electrophiles is for macrocyclization. The other cyclic polyamines, **3** through **12** containing six to eight nitrogens in the ring, were prepared in rather excellent yields for such large ring sizes. There was no by-product in any case. Unreacted nucleophile **C** was retrieved. However, α,ω-ditosylated electrophile was not retrieved but decomposed completely. This implys that conversion yield based on nucleophile **C** was quantitative in all cases. Thus, it is suggestive as for the conditions of optimal cyclization that yield will be elevated further if α,ω-ditosylated electrophile is added intermittently in a suitable time during the reaction.

Compounds **7** ([30]N_7), **9** ([33]N_8), and **11** ([34]N_8) were prepared, for comparison, by two sets of electrophile and nucleophile. The results reveal that a coupling of the electrophile with the shortest chain length and the nucleophile with the longest chain

Table 2. Product Yields (%) of α,ω-Diphthalimides (**A**), α,ω-Diformamides (**B**), and α,ω-Bis(tosylamide)s (**C**) in the Chain Elongation and Transformation Reactions (in Scheme 1)

length gives far better yield in each case.

Spectral Characteristics: Chemical shifts in ^{1}H NMR spectra are summarized in Tables 4 through 7. Table 4 includes all protons for macrocycles, **1** through **12**. Table 5 includes protons in the methylene region for α,ω-diphthalimide (**A**). Table 6 includes protons in the methylene region and the formamido group for typical α,ω-diformamide (**B**). Table 7 includes protons in the methylene region and tosylamino group for α,ω-bis(tosylamide) (**C**). All signals were perfectly assigned by ^{1}H–^{1}H spin decoupling technique.

^{1}H NMR spectra provide certain information about the ring flexibility in cyclic polyamines since FIN- and TIN-protons[15] indicate marked dependence on

the ring size. In comparison of **1** and **12**, the difference in chemical shift values between them is 0.14 for FIN-protons and 0.1 for TIN-protons, respectively (Table 4). Since chemical shift values for all protons in **12** are almost the same as those for open-chain polyamines (**A**) to (**C**), compound **1** is fairly a rigid molecule. In viewpoint of the ring flexibility on the basis of chemical shift value, cyclic polyamines, **6** and **7** with thirty-membered ring, are the boundary ring size whether or not the ring is flexible. Thus, the macrocycles, **2** through **5**, are rather rigid molecules in comparison with the macrocycles, **8** through **12**. It is reasonable to predict that the trend observed is related closely to the nitrogen function in the molecule; that is, latent amine nitrogens involved in the polyamines, **8** through **12**, might behave equivalently, while each of those in polyamines, **1** through **5**, would function differently. Averaged chemical shift values for the terminal tosylamide proton (NHTs) in **C**, and the formamide proton (NHCHO) and the formyl proton in **B** are δ 5.30, 6.33, and 8.16, respectively.

Conclusion

Synthetic availability of the recently developed transformation reaction of phthalimides to formamides[7] and tosylamides to tosylates via *N*-nitrosotoluenesulfonamide intermediates[8] for polyamine synthesis was investigated through molecular architecture for designed polyamines with natural methylene arrays. Since chain elongation, transformation, and cyclization reactions proceeded very effectively, the present route provides a new adaptable method generally applicable to polyamine synthesis. Several problems involved in the traditional synthetic processes for cyclic polyamines has now been overcome perfectly. In addition, a guiding principle for the choice of better couple of nucleophiles and electrophiles upon cyclization has now been discovered. In the present synthesis, all the amino nitrogens are protected by the tosyl group, which makes it advantageous to monitor the proceeding reaction and isolation as well. Since effective detosylation methods are available for *N*-tosylated polyamines,[5,16] formal synthesis of acyclic and cyclic polyamines has now been established.

Experimental

The ^{1}H NMR spectra were recorded on JEOL GSX-500S (500 MHz) instrument with Me_4Si as the internal standard in $CDCl_3$ unless otherwise mentioned; chemical shifts (δ) and coupling constants (J) are in parts per million and hertz, respectively. Infrared spectra (IR) were obtained on a Shimadzu IR-27 apparatus. Merck silica gel 60 (Art. 7734, 0.063—0.02) was used for column chromatography, and fragmented Merck precoated silica gel 60 F_{254} plates (Art. 5715, 20×20 cm), for thin-layer chromatography (TLC). Product spots on TLC were detected either with UV-lamp or in an iodine vapor bath. The uncorrected melting points were measured in a bilayered coverglass (18 m/m, thickness 0.13—0.17 mm) with a micro melting point apparatus (Yanagimoto Seisakusho, Serial No. 2647).

Materials. *N*,*N*-Dimethylformamide (DMF) was dried over Molecular Sieves (Type A). Phthalimide, 3-bromopropylamine hydrobromide (**21**), 1,3-dibromopropane (**23**), and 1,4-dibromobutane (**28**) are commercially available. Potassium phthalimide was prepared according to the described method.[17] 1,3-Diphthalimidopropane (**24**)[11a] was prepared by the reaction of **23** with phthalimide in the presence of potassium carbonate in DMF. 3,4-Dihydro-2*H*-pyrimido[2,1-*a*]isoindol-6-one (**25**) was prepared from **24** through newly developed method.[10] *N*-(3-Bromopropyl)phthalimide (**14**) and *N*-(4-bromobutyl)phthalimide (**15**) were prepared by the reaction of **23** and **28**, respectively, with phthalimide in 88 and 68% yields respectively;[11] **14**, mp 73—75 °C (lit,[11a] mp 72—73 °C); **15**, mp 81—82 °C (lit,[11b] mp 80.5 °C). Synthesis of α,ω-

ditosylates, **16**, **17**, **18**, and **19**, from the corresponding α,ω-bis(tosylamide)s will be described elsewhere. *N,N'*-Ditosyl-1,4-butanediamine (**a**) and *N,N'*-ditosyl-1,3-propanediamine (**g**) were prepared from the correspoding diamines via the method previously reported.[18]

Synthesis of *N*-(3-Tosylaminopropyl)phthalimide (20). Route A; compound **21** (15 g, 69 mmol) and tosyl chloride (29.6 g, 1.5 mol equiv) pyridine (150 mL) was stirred at 0—5 °C for 2 h. The mixture was poured into water and extracted with chloroform. The chloroform layer was washed several times with 2 M HCl and, then, dried over $MgSO_4$. Chloroform was removed and the residue was chromatographed on a silica-gel column eluted with chloroform–acetone (95:5 v/v) to give 11.92 g (99% yield) of *N*-tosyl-3-bromopropylamine (**22**). A mixture of **22** (2.93 g, 10 mmol) and potassium phthalimide in DMF (50 mL) was heated at 80 °C for 3 h. The mixture was poured into brine and resulting precipitate was collected by filtration. The precipitate was recrystallized from ethanol to give 2.665 g (74% yield) of **20**.

Route B; compound **25** (1.23 g, 6.6 mol) was heated with 2 M HCl (28 mL) containing ethanol (5 mL) at 75 °C for 5 h. Solvents were removed under reduced pressure and the residue was recrystallized from ethanol to give 1.55 g (98% yield) of *N*-(3-aminopropyl)phthalimide hydrochloride (**26**); mp 192—194 °C. Calcd for $C_{11}H_{13}O_2N_2Cl$; C, 54.89; H, 5.44; N, 11.64; Cl, 14.73%. Found; C, 54.79; H, 5.45; N, 11.48; Cl, 15.02%. IR (KBr) ν 2400—2800 (NH_3^+), 1780 and 1710 (C=O) cm^{-1}.

Compound **26** (1.5 g, 6.2 mmol) and tosyl chloride (1.54 g, 1.3 mol eguiv to **26**) in pyridine (45 mL) and triethylamine (1 mL) were stirred at ambient temperature for 4 h. Solvents were removed and the residue was chromatographed on a silica-gel column eluted with chloroform–acetone (9:1 v/v) to afford 1.46 g (98% yield) of **20**; mp 170—171 °C. Calcd for $C_{18}H_{18}O_4N_2S$: C, 60.32; H, 5.06; N, 7.82; S, 8.95%. Found: C, 60.13; H, 5.08; N, 7.71; S, 8.91%. IR (KBr) ν 3290 (NH), 1770, 1705 (C=O), 1340, 1160 (SO_2) cm^{-1}. ^1H NMR; δ=1.83 (2H, quin, J=6.35, phthN-CH_2-CH_2-), 2.40 (3H, s, ArMe[15]), 3.74 (2H, t, J=6.35, phthN-CH_2-CH_2-), 3.93 (2H b-m, -CH_2-CH_2-NHTs), 5.25 (1H, b-t, NHTs), 7.27 (2H, d J=8.30, ArHme[15]), 7.75 (2H, d, J=8.30, ArHs[15]), 7.73 (2H, m, aromatic protons meta to phthaloyl carbonyl), 7.82 (2H, m, aromatic protons ortho to phthaloyl carbonyl).

Synthesis of *N*-(3-Tosyloxypropyl)phthalimide (13). Compound **20** (1.5 g, 4.2 mmol) was treated with sodium nitrite (0.713 g, 2 mol equiv to **20**) in a mixture of acetic anhydride (15 mL) and acetic acid (3 mL) at below 5 °C for 3 h. The mixture was poured into water and the resulting crystalline precipitate was collected by filtration. After dried in Drierite desiccator, the nitrosated compound was heated with benzene (80 mL) at 80 °C for 20 h. Solvent was removed and the residue was chromatographed on a silica-gel column eluted with chloroform–acetone (95:5 v/v) to give 0.87 g (59% yield) of **13**; mp 92—94 °C. Calcd for $C_{18}H_{17}O_5NS$: C, 60.15; H, 4.77; N, 3.90; S, 8.92%. Found: C, 60.15; H, 4.78; N, 4.25; S, 8.68%. IR (KBr) ν 1773, 1710 (C=O), 1357, 1188, 1175 (SO_2) cm^{-1}. ^1H NMR; δ=2.06 (2H, quin, J=6.83, phthN-CH_2-CH_2-), 2.44 (3H, s, ArMe[15]), 3.74 (2H, t, J=6.83, phthN-CH_2-CH_2-), 4.11 (2H, t, -CH_2-CH_2-OTs), 7.33 (2H, d, J=8.30, ArHme[15]), 7.78 (2H, d, J=8.30, ArHs[15]), 7.72 (2H, m, aromatic protons meta to phthaloyl carbonyl), and 7.83 (2H, m, aromatic protons ortho to phthaloyl carbonyl).

General Procedure for the Synthesis of α,ω-Diphthalimides (A) by the Reaction of α,ω-Tosylamides (C) with ω-Phthalimidated Electrophilies (13,14,15). A mixture of α,ω-bis(tosylamide) (**C**), one of ω-phthalimidated electrophiles (**13**,**14**,**15**) (2.2 mol equiv to **C**), and cesium carbonate (2.5 mol equiv to **C**) in DMF was stirred at ambient temperature for two days. The mixture was filtered through Celite and, then, the solvent was removed under reduced pressure. The residue was chromatographed on a silica-gel column eluted with chloroform–acetone (95:5 v/v) to give α,ω-diphthalimide (**A**).

General Procedure for the Synthesis of α,ω-Diformamides (B) from α,ω-Diphthalimides (A). To a solution of α,ω-diphthalimide (**A**) in DMF, hydrazine hydrate (20 mol equiv to **A**) was added and the mixture was heated at 75 °C for 23 h. After removal of DMF, the residue was chromatographed on a silica-gel column eluted with chloroform–methanol (9:1 v/v) to give α,ω-diformamide (**B**).

General Procedure for the Synthesis of α,ω-Bis(tosylamide)s (C) from α,ω-Diformamides (B). To a solution of α,ω-diformamide (**B**) in a small amount of ethanol, 2 M hydrochloric acid was added and heated at 80 °C for 4 h. Solvents were removed and the residue was stirred with tosyl chloride (2.6 mol equiv to **B**) in pyridine containing a small amount of triethylamine at ambient temperature for 4 h. Solvents were evaporated under reduced pressure and the residue was chromatographed on a silica-gel column eluted with chloroform–acetone (9:1 v/v) to give α,ω-bis(tosylamide)s (**C**).

***N,N'*-Bis(3-phthalimidopropyl)-*N,N'*-ditosyl-1,4-butanediamine (Ab).** By the reaction of a with either **13** or **14**, compound **Ab** was obtained as crystals; mp 201—202 °C (recryst. from ethanol–acetone). Calcd for $C_{40}H_{42}O_8N_4S_2$: C, 62.32; H, 5.49; N, 7.27; S, 8.32%. Found: C, 62.11; H, 5.47; N, 7.18; S, 8.36%. IR (KBr) ν 1770, 1720 (C=O), 1340, 1155 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

***N,N'*-Bis(3-formamidopropyl)-*N,N'*-ditosyl-1,4-butanediamine (Bb).** By the reaction of **Ab** with N_2H_4 in DMF, compound **Bb** was obtained as viscous liquid; Calcd for $C_{26}H_{38}O_6N_4S_2$: C, 55.10; H, 6.76; N, 9.89; S, 11.32%. Found: C, 54.99; H, 6.72; N, 9.98; S, 11.11%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

***N,N'*-Bis[3-(tosylamino)propyl]-*N,N'*-ditosyl-1,4-butanediamine (Cb).** Through treatment of **Bb** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cb** was obtained as viscous liquid; Calcd for $C_{38}H_{50}O_8N_4S_4$: C, 55.72; H, 6.15; N, 6.84; S, 15.66%. Found: C, 55.71; H, 6.29; N, 6.70; S, 15.55%. IR (KRS) ν 3280 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,8,13,17-Tetratosyl-N^1,N^1:N^{20},N^{20}-diphthaloyl-4,8,13,17-tetraazaeicosane-1,20-diamine (Ac). By the reaction of **Cb** with either **13** or **14**, compound **Ac** was obtained as amorphous powder; Calcd for $C_{60}H_{68}O_{12}N_6S_4$: C, 60.34; H, 5.74; N, 7.04; S, 10.75%. Found: C, 60.14; H, 5.84; N, 6.87; S, 10.52%. IR (KBr) ν 1770, 1720 (C=O), 1340, 1155 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,8,13,17-Tetratosyl-N^1,N^{20}-diformyl-4,8,13,17-tetraazaeicosane-1,20-diamine (Bc). By the reaction of **Ac** with N_2H_4 in DMF, compound **Bc** was obtained as amorphous

powder; Calcd for $C_{46}H_{64}O_{10}N_6S_4$: C, 55.84; H, 6.52; N, 8.50; S, 12.97%. Found: C, 56.10; H, 6.43; N, 8.73; S, 12.87%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

N^1,N^{20},4,8,13,17-Hexatosyl-4,8,13,17-tetraazaeicosane-1,20-diamine (Cc). Through treatment of **Bb** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cc** was obtained as amorphous powder; Calcd for $C_{58}H_{76}O_{12}N_6S_6$: C, 56.10; H, 6.17; N, 6.77; S, 15.50%. Found: C, 55.92; H, 6.15; N, 6.53; S, 15.36%. IR (KRS) ν 3290 (NH), 1330, 1155 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

5,9,14,18-Tetratosyl-N^1,N^1:N^{22},N^{22}-diphthaloyl-5,9,14,18-tetraazadocosane-1,22-diamine (Ad). By the reaction of **Cb** with **15**, compound **Ad** was obtained as viscous liquid; Calcd for $C_{62}H_{72}O_{12}N_6S_4$: C, 60.96; H, 5.94; N, 6.88; S, 10.50%. Found: C, 60.72; H, 5.86; N, 7.16; S, 10.36%. IR (KBr) ν 1770, 1710 (C=O), 1340, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

5,9,14,18-Tetratosyl-N^1,N^{22}-diformyl-5,9,14,18-tetraazadocosane-1,22-diamine (Bd). By the reaction of **Ad** with N_2H_4 in DMF, compound **Bd** was obtained as viscous liquid; Calcd for $C_{48}H_{60}O_{10}N_6S_4$: C, 56.67; H, 6.74; N, 8.26; S, 12.61%. Found: C, 56.78; H, 6.74; N, 8.04; S, 12.75%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

N^1,N^{22},5,9,14,18-Hexatosyl-5,9,14,18-tetraazadocosane-1,22-diamine (Cd). Through treatment of **Bd** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cd** was obtained as amorphous powder; Calcd for $C_{60}H_{80}O_{12}N_6S_6$: C, 56.75; H, 6.35; N, 6.62; S, 15.15%. Found: C, 56.61; H, 6.22; N, 6.56; S, 15.04%. IR (KBr) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,8,12,17,21,25-Hexatosyl-N^1,N^1:N^{28},N^{28}-diphthaloyl-4,8,12,17,21,25-hexaazaoctacosane-1,28-diamine (Ae). By the reaction of **Cc** with **14** compound **Ae** was obtained as amorphous powder; Calcd for $C_{80}H_{94}O_{16}N_8S_6$: C, 59.46; H, 5.86; N, 6.94; S, 11.91%. Found: C, 59.34; H, 5.79; N, 6.68; S, 11.75%. IR (KBr) ν 1770, 1710 (C=O), 1340, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,8,12,17,21,25-Hexatosyl-N^1,N^{28}-diformyl-4,8,12,17,21,25-hexaazaoctacosane-1,28-diamine (Be). By the reaction of **Ae** with N_2H_4 in DMF, compound **Be** was obtained as amorphous powder; IR (KBr) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}.

N^1,N^{28},4,8,12,17,21,25-Octatosyl-4,8,12,17,21,25-hexaazaoctacosane-1,28-diamine (Ce). Through treatment of **Be** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Ce** was obtained as amorphous powder; Calcd for $C_{78}H_{102}O_{16}N_8S_8$: C, 56.29; H, 6.18; N, 6.73; S, 15.42%. Found: C, 55.95; H, 6.15; N, 6.54; S, 15.30%. IR (KBr) ν 3290 (NH), 1330, 1155 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,9,13,18,22,27-Hexatosyl-N^1,N^1:N^{30},N^{30}-diphthaloyl-4,9,13,18,22,27-hexaazatriacontane-1,30-diamine (Af). By the reaction of **Cd** with **14**, compound **Af** was obtained as amorphous powder; Calcd for $C_{82}H_{98}O_{16}N_8S_6$: C, 59.90; H, 6.01; N, 6.82; S, 11.70%. Found: C, 59.60; H, 5.96; N, 6.86; S, 11.49%. IR (KBr) ν 1770, 1710 (C=O), 1340, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,9,13,18,22,27-Hexatosyl-N^1,N^{30}-diformyl-4,9,13,18,22,27-hexaazatriacontane-1,30-diamine (Bf). By the reaction of **Af** with N_2H_4 in DMF, compound **Bf** was obtained as amorphous powder; IR (KBr) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}.

N^1,N^{30},4,9,13,18,22,27-Octatosyl-4,9,13,18,22,27-hexaazatriacontane-1,30-diamine (Cf). Through treatment of **Bf** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cf** was obtained as amorphous powder; IR (KBr) ν 3290 (NH), 1330, 1155 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

***N*,*N*′-Bis(3-phthalimidopropyl)-*N*,*N*′-ditosyl-1,3-propanediamine (Ah).** By the reaction of **g** with either **13** or **14**, compound **Ah** was obtained as amorphous powder; Calcd for $C_{39}H_{40}O_8N_4S_2$: C, 61.89; H, 5.33; N, 7.40; S, 8.47%. Found: C, 61.76; H, 5.36; N, 7.20; S, 8.37%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

***N*,*N*′-Bis(3-formamidopropyl)-*N*,*N*′-ditosyl-1,3-propanediamine (Bh).** By the reaction of **Ah** with N_2H_2 in DMF, compound **Bh** was obtained as viscous liquid; Calcd for $C_{25}H_{36}O_6N_4S_2$: C, 54.32; H, 6.57; N, 10.14; S, 11.60%. Found: C, 54.10; H, 6.67; N, 9.97; S, 11.40%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

***N*,*N*′-Bis[3-(tosylamino)propyl]-*N*,*N*′-ditosyl-1,3-propanediamine (Ch).** Through treatment of **Bh** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Ch** was obtained as viscous liquid; Calcd for $C_{37}H_{48}O_8N_4S_4$: C, 55.20; H, 6.01; N, 6.96; S, 15.93%. Found: C, 55.56; H, 5.98; N, 6.93; S, 15.97%. IR (KRS) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

***N*,*N*′-Bis(4-phthalimidobutyl)-*N*,*N*′-ditosyl-1,3-propanediamine (Ai).** By the reaction of **g** with **15**, compound **Ai** was obtained as amorphous powder; Calcd for $C_{41}H_{44}O_8N_4S_2$: C, 62.73; H, 5.65; N, 7.14; S, 8.17%. Found: C, 62.59; H, 5.68; N, 7.06; S, 8.14%. IR (KBr) 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

***N*,*N*′-Bis(4-formamidobutyl)-*N*,*N*′-ditosyl-1,3-propanediamine (Bi).** By the reaction of **Ai** with N_2H_4 in DMF, compound **Bi** was obtained as viscous liquid; Calcd for $C_{27}H_{40}O_6N_4S_2$: C, 55.84; H, 6.94; N, 9.65; S, 11.04%. Found: C, 55.61; H, 6.83; N, 9.57; S, 10.78%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

***N*,*N*′-Bis[4-(tosylamino)buty]-*N*,*N*′-ditosyl-1,3-propanediamine (Ci).** Through treatment of **Bi** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Ci** was obtained as viscous liquid; Calcd for $C_{39}H_{52}O_8N_4S_4$: C, 56.22; H, 6.29; N, 6.73; S, 15.40%. Found: C, 55.94; H, 6.24; N, 6.76; S, 15.15%. IR (KRS) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,9,13,18-Tetratosyl-N^1,N^1:N^{21},N^{21}-diphthaloyl-4,9,13,18-tetraazaheneicosane-1,21-diamine (Aj). By the reaction of **Ci** with either **13** or **14**, compound **Aj** was obtained as amorphous powder; Calcd for $C_{61}H_{70}O_{12}N_6S_4$: C, 60.67; H, 5.84; N, 6.96; S, 10.62%. Found: C, 60.59; H, 5.77; N, 6.56; S, 10.39%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,9,13,18-Tetratosyl-N^1,N^{21}-diformyl-4,9,13,18-tetraazaheneicosane-1,21-diamine (Bj). By the reaction of **Aj** with N_2H_4 in DMF, compound **Bj** was obtained as amorphous powder; Calcd for $C_{47}H_{66}O_{10}N_6S_4$: C, 56.26; H, 6.63; N, 8.38; S, 12.78%. Found: C, 55.92; H, 6.73; N, 8.57; S, 12.66%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

N^1,N^{21},4,9,13,18-Hexatosyl-4,9,13,18-tetraazaheneicosane-

1,21-diamine (Cj). Through treatment of **Bi** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cj** was obtained as amorphous powder; Calcd for $C_{59}H_{78}O_{12}N_6S_6$: C, 56.43; H, 6.26; N, 6.69; S, 15.32%. Found: C, 56.71; H, 6.19; N, 6.54; S, 15.29%. IR (KBr) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

5,9,13,17-Tetratosyl-N^1,N^1:N^{21},N^{21}-diphthaloyl-5,9,13,17-tetraazaheneicosane-1,21-diamine (Ak). By the reaction of **Ch** with **15**, compound **Ak** was obtained as viscous liquid; Calcd for $C_{61}H_{70}O_{12}N_6S_4$: C, 60.67; H, 5.84; N, 6.96; S, 10.62%. Found: C, 60.40; H, 5.83; N, 6.93; S, 10.56%. IR(KRS) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

5,9,13,17-Tetratosyl-N^1,N^{21}-diformyl-5,9,13,17-tetraazaheneicosane-1,21-diamine (Bk). By the reaction of **Ak** with N_2H_4 in DMF, compound **Bk** was obtained as viscous liquid; Calcd for $C_{47}H_{66}O_{10}N_6S_4$: C, 56.26; H, 6.63; N, 8.38; S, 12.78%. Found: C, 55.98; H, 6.63; N, 8.19; S, 12.76%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

N^1,N^{21},5,9,13,17-Hexatosyl-5,9,13,17-tetraazaheneicosane-1,21-diamine (Ck). Through treatment of **Bk** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Ck** was obtained as amorphous powder; Calcd for $C_{59}H_{78}O_{12}N_6S_6$: C, 56.43; H, 6.26; N, 6.69; S, 15.32%. Found: C, 56.38; H, 6.05; N, 6.40; S, 15.37%. IR (KBr) 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,8,13,17,22,26-Hexatosyl-N^1,N^1:N^{29},N^{29}-diphthaloyl-4,8,13,17,22,26-hexaazanonacosane-1,29-diamine (Al). By the reaction of **Cj** with **14**, compound **Al** was obtained as amorphous powder; Calcd for $C_{81}H_{96}O_{16}N_8S_6$: C, 59.68; H, 5.94; N, 6.88; S, 11.80%. Found: C, 59.60; H, 5.80; N, 6.79; S, 11.52%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,8,13,17,22,26-Hexatosyl-N^1,N^{29}-diformyl-4,8,13,17,22,26-hexaazanonacosane-1,29-diamine (Bl). By the reaction of **Al** with N_2H_4 in DMF, compound **Bl** was obtained as viscous liquid; IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. It was very hard to obtain analytically pure sample by chromatography. Thus, the sample was directly subjected to the next reaction.

N^1,N^{29},4,8,13,17,22,26-Octatosyl-4,8,13,17,22,26-hexaazanonacosane-1,29-diamine (Cl). Through treatment of **Bl** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cl** was obtained as amorphous powder; Calcd for $C_{79}H_{104}O_{16}N_8S_8$: C, 56.54; H, 6.25; N, 6.68; S, 15.29%. Found: C, 56.80; H, 6.09; N, 6.48; S, 15.17%. IR (KBr) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,9,13,17,21,26-Hexatosyl-N^1,N^1:N^{29},N^{29}-diphthaloyl-4,9,13,17,21,26-hexaazanonacosane-1,29-diamine (Am). By the reaction of **Ck** with **14**, compound **Am** was obtained as amorphous powder; Calcd for $C_{81}H_{96}O_{16}N_8S_6$: C, 59.68; H, 5.94; N, 6.88; S, 11.80%. Found: C, 59.55; H, 5.82; N, 6.73; S, 11.88%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,9,13,17,21,26-Hexatosyl-N^1,N^{29}-diformyl-4,9,13,17,21,26-hexaazanonacosane-1,29-diamine (Bm). By the reaction of **Al** with N_2H_4 in DMF, compound **Bm** was obtained as viscous liquid; IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. It was very hard to obtain analytically pure sample by chromatography. Thus, the sample was directly subjected to the next reaction.

N^1,N^{29},4,9,13,17,21,26-Octatosyl-4,9,13,17,21,26-hexaazanonacosane-1,29-diamine (Cm). Through treatment of **Bm** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cm** was obtained as amorphous powder; Calcd for $C_{79}H_{104}O_{16}N_8S_8$: C, 56.54; H, 6.25; N, 6.68; S, 15.29%. Found: C, 56.47; H, 6.18; N, 6.50; S, 15.49%. IR (KBr) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

N^1,N^1:N^7,N^7-Diphthaloyl-4-tosyl-4-azaheptane-1,7-diamine (An). By the reaction of **13** with **20** in the presence of cesium carbonate, compound **An** was obtained as crystals; mp 227—228 °C (recryst. from ethanol). Calcd for $C_{29}H_{27}O_6N_3S$: C, 63.84; H, 4.99; N, 7.70; S, 5.88%. Found: C, 63.85; H, 4.99; N, 7.66; S, 5.91%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

N^1,N^7-Diformyl-4-tosyl-4-azaheptane-1,7-diamine (Bn). By the reaction of **Al** with N_2H_4 in DMF, compound **Bm** was not obtained and, thus, was prepared via the separate path; the reaction of *N*-formyl-*N'*-tosyl-1,3-propanediamine[7] with **14** in the presence of cesium carbonate in DMF gave N^1-formyl-N^7-phthaloyl-N^4-tosyl-4-azaheptane-1,7-diamine in 93% yield, which was, then, treated with hydrazine hydrate in DMF to afford **Bn** in 98% yield; viscous liquid. Calcd for $C_{15}H_{23}O_4N_3S$: C, 52.76; H, 6.79; N, 12.31; S, 9.39%. Found: C, 52.81; H, 6.87; N, 12.20; S, 9.21%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

N^1,N^7,4-Tritosyl-4-azaheptane-1,7-diamine (Cn). Through treatment of **Bn** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cn** was obtained as amorphous powder; Calcd for $C_{27}H_{35}O_6N_3S_3$: C, 54.61; H, 5.94: N, 7.08; S, 16.20%. Found: C, 54.29; H, 5.99; N, 7.03; S, 16.04%. IR (KBr) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

5,9,13-Tritosyl-N^1,N^1:N^{17},N^{17}-diphthaloyl-5,9,13-triazaheptadecane-1,17-diamine (Ao). By the reaction of **Cn** with **15**, compound **Ao** was obtained as amorphous powder; Calcd for $C_{51}H_{57}O_{10}N_5S_3$: C, 61.48; H, 5.77; N, 7.03; S, 9.66%. Found: C, 61.66; H, 5.71; N, 7.06; S, 9.55%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_3) cm^{-1}. ^1H NMR, shown in Table 5.

5,9,13-Tritosyl-N^1,N^{17}-diformyl-5,9,13-triazaheptadecane-1,17-diamine (Bo). By the reaction of **Ao** with N_2H_4, compound **Bo** was obtained as viscous liquid; Calcd for $C_{37}H_{53}O_8N_5S_3$: C, 56.11; H, 6.75; N, 8.84; S, 12.15%. Found: C, 55.90; H, 6.78; N, 8.79; S, 11.99%. IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 6.

N^1,N^{17},5,9,13-Pentatosyl-5,9,13-triazaheptadecane-1,17-diamine (Co). Through treatment of **Bo** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Co** was obtained as amorphous powder; Calcd for $C_{49}H_{65}O_{10}N_5S_5$: C, 56.35; H, 6.27; N, 6.71; S, 15.35%. Found: C, 56.30; H, 6.15; N, 6.64; S, 15.36%. IR (KBr) ν 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

4,9,13,17,22-Pentatosyl-N^1,N^1:N^{25},N^{25}-diphthaloyl-4,9,13,17,22-pentaazapentacosane-1,25-diamine (Ap). By the reaction of **Co** with **14**, compound **Ap** was obtained as amorphous powder; Calcd for $C_{71}H_{83}O_{14}N_7S_5$: C, 60.10; H, 5.90; N, 6.91; S, 11.30%. Found: C, 60.33; H, 6.06; N, 6.76; S, 11.18%. IR (KBr) ν 1770, 1710 (C=O), 1335, 1150 (SO_2) cm^{-1}. ^1H NMR, shown in Table 5.

4,9,13,17,22-Pentatosyl-N^1,N^{25}-diformyl-4,9,13,17,22-penta-

azapentacosane-1,25-diamine (Bp). By the reaction of **Ap** with N_2H_4, compound **Bp** was obtained as viscous liquid; IR (KRS) ν 3350 (NH), 1670, 1520, 1450 (NHCHO), 1330, 1150 (SO_2) cm^{-1}. It was very hard to obtain analytically pure sample by chromatography. Thus, the sample was directly subjected to the next reaction.

***N*¹,*N*²⁵,4,9,13,17,22-Heptatosyl-4,9,13,17,22-pentaazapentacosane-1,25-diamine (Cp).** Through treatment of **Bp** with 2 M hydrochloric acid and, then, with tosyl chloride, compound **Cp** was obtained as amorphous powder; Calcd for $C_{79}H_{104}O_{16}N_8S_8$: C, 56.49; H, 6.25; N, 6.68; S, 15.30%. Found: C, 56.47; H, 6.10; N, 6.66; S, 15.28%. IR (KBr) 3290 (NH), 1330, 1160 (SO_2) cm^{-1}. ^1H NMR, shown in Table 7.

General Procedure for the Synthesis of Macromonocyclic Polyamines, (1) through (12). A mixture of α,ω-bis(tosylamide) (**C**), α,ω-ditosylate (**16**, **17**, **18**, or **19**) (1.2 mol equiv to **C**), and cesium carbonate (2.5 mol equiv to **C**) in DMF was stirred at ambient temperature for a day or two. The mixture was filtered through Celite and the solvent was, then, evaporated under reduced pressure. The residue as chromatographed on a silica-gel column eluted with chloroform–acetone (95:5 v/v) to afford cyclic polyamine.

1,5,9,13-Tetratosyl-1,5,9,13-tetraazacycloheptadecane (1): [17]N_4. By the reaction of **16** with **Cb**, compound **1** was obtained as amorphous powder. Compound **1** had been prepared via alternative route in less yield.[14] IR (KBr) ν 1335 and 1150 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17-Pentatosyl-1,5,9,13,17-pentaazacycloheneicosane (2): [21]N_5. By the reaction of **16** with *N*¹,*N*¹⁶,4,8,13-pentatosyl-4,8,13-triazahexadecane-1,16-diamine (**Cq**), which was derived from tosylated spermidine in similar series of procedure to those for **Co** preparation from **An**, compound **2** was obtained as amorphous powder; Calcd for $C_{51}H_{67}O_{10}N_5S_5$: C, 57.22; H, 6.31; N, 6.54; S, 14.98%. Found: C, 56.89; H, 6.27; N, 6.32; S, 15.23%. Amorphous powder. IR (KBr) ν 1335 and 1150 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17,21-Hexatosyl-1,5,9,13,17,21-hexaazacyclopentacosane (3): [25]N_6. By the reaction of **16** with **Cc**, compound **3** was obtained as amorphous powder; Calcd for $C_{61}H_{80}O_{12}N_6S_6$: C, 57.16; H, 6.29; N, 6.56; S, 15.01%. Found: C, 57.18; H, 6.29; N, 6.46; S, 15.08%. IR (KBr) ν 1335 and 1150 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,18,22-Hexatosyl-1,5,9,13,18,22-hexaazacyclohexacosane (4): [26]N_6. By the reaction of **16** with **Cj**, compound **4** was obtained as amorphous powder; Calcd for $C_{62}H_{82}O_{12}N_6S_6$: C, 57.47; H, 6.38; N, 6.49; S, 14.85%. Found: C, 57.63; H, 6.40; N, 6.12; S, 14.52%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17,21,25-Heptatosyl-1,5,9,13,17,21,25-heptaazacyclononacosane (5): [29]N_7. By the reaction of **17** with **Cc**, compound **5** was obtained as amorphous powder; Calcd for $C_{71}H_{93}O_{14}N_7S_7$: C, 57.11; H, 6.28; N, 6.57; S, 15.03%. Found: C, 57.21; H, 6.30; N, 6.42; S, 14.85%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17,22,26-Heptatosyl-1,5,9,13,17,22,26-heptaazacyclotriacontane (6): [30]N_7. By the reaction of **17** with **Cj**, compound **6** was obtained as amorphous powder; Calcd for $C_{72}H_{95}O_{14}N_7S_7$: C, 57.38; H, 6.35; N, 6.51; S, 14.90%. Found: C, 57.12; H, 6.42; N, 6.21; S, 14.64%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,18,22,26-Heptatosyl-1,5,9,13,18,22,26-heptaazacyclotriacontane (7): [30]N_7. In order to examine the effect on cyclization yield by changing in a couple of electrophile and nucleophile, two couples were tested; by the reaction of **17** with **Co**, compound **7** was obtained as amorphous powder in 66% yield. Alternatively, by the reaction of **19** with **Cq**, compound **7** was obtained in 47% yield. Calcd for $C_{72}H_{95}O_{14}N_7S_7$: C, 57.38; H, 6.35; N, 6.51; S, 14.90%. Found: C, 57.52; H, 6.68; N, 6.14; S, 14.58%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17,21,25,29,-Octatosyl-1,5,9,13,17,21,25,29-octaazacyclotritriacontane (8): [33]N_8. By the reaction of **16** with **Ce**, compound **8** was obtained as amorphous powder; Calcd for $C_{81}H_{106}O_{16}N_8S_8$: C, 57.08; H, 6.27; N, 6.58; S, 15.05%. Found: C, 57.14; H, 6.35; N, 6.31; S, 14.78%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17,21,26,30-Octatosyl-1,5,9,13,17,21,26,30-octaazacyclotetratriacontane (9): [34]N_8. In order to examine the effect on cyclization yield by changing in a couple of electrophile and nucleophile, two couples were tested; by the reaction of **16** with **Cl**, compound **9** was obtained as amorphous powder in 86% yield. Alternatively, by the reaction of **18** with **Cj**, compound **9** was obtained in 37% yield. Calcd for $C_{82}H_{108}O_{16}N_8S_8$: C, 57.31; H, 6.34; N, 6.52; S, 14.93%. Found: C, 56.98; H, 6.36; N, 6.18; S, 14.54%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,17,22,26,30-Octatosyl-1,5,9,13,17,22,26,30-octaazacyclotetratriacontane (10): [34]N_8. By the reaction of **17** with **Cp** compound **10** was obtained as amorphous powder; Calcd for $C_{82}H_{108}O_{16}N_8S_8$: C, 57.31; H, 6.34; N, 6.52; S, 14.93%. Found: C, 56.99; H, 6.34; N, 6.26; S, 14.92%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,18,22,26,30-Octatosyl-1,5,9,13,18,22,26,30-octaazacyclotetratriacontane (11): [34]N_8. In order to examine the effect on cyclization yield by changing in a couple of electrophile and nucleophile, two couples were tested; by the reaction of **16** with **Cm**, compound **11** was obtained as amorphous powder in 64% yield. Alternatively, by the reaction of **19** with **Cc**, compound **11** was obtained in 38% yield. Calcd for $C_{82}H_{108}O_{16}N_8S_8$: C, 57.31; H, 6.34; N, 6.52; S, 14.93%. Found: C, 56.99; H, 6.38; N, 6.34; S, 14.62%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

1,5,9,13,18,22,27,31-Octatosyl-1,5,9,13,18,22,27,31-octaazacyclopentatriacontane (12): [35]N_8. By the reaction of **16** with **Cf**, compound **12** was obtained as amorphous powder; Calcd for $C_{83}H_{110}O_{16}N_8S_8$: C, 57.54; H, 6.40; N, 6.47; S, 14.81%. Found: C, 57.45; H, 6.46; N, 6.29; S, 14.78%. IR (KBr) ν 1335 and 1155 (SO_2) cm^{-1}. ^1H NMR data, listed in Table 4.

We are indebted to Dr. Hiroshi Yamazaki and his staff in RIKEN for performing elemental analyses and to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu in RIKEN for measurement of ^1H NMR spectra. M. I. is grateful to Dr. Hideki Nagashima in RIKEN for helpful discussion in the molecular design and to the Ministry of Education, Science and Culture for a financial support by a Grant-in-Aid for Scientific Research (No. 62540397).

A Mechanistic Study on the Reaction of Iminothiadiazolines with Activated Acetylenes: Competitive Pathway through Hypervalent Sulfurane and Zwitterion

Yohsuke YAMAMOTO,† Tohru TSUCHIYA, Masahide OCHIUMI, Shin-ichi ARAI, Naoki INAMOTO,* and Kin-ya AKIBA*,†

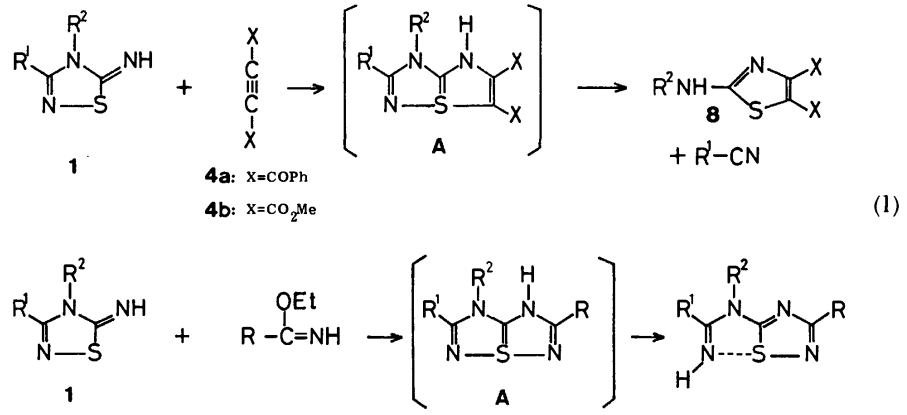
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 5, 1988)

The reaction of 3-aryl-5-benzoyl-2-imino-2,3-dihydro-1,3,4-thiadiazoles (**6**) with dimethyl acetylenedicarboxylate (**4b**) gave the corresponding thiazole (**8**) and benzoyl cyanide through sulfurane (**B**) by 1,3-dipolar cycloaddition and cis- (**9**) and trans-vinyl (**10**) compounds through zwitterion (**C**) by simple addition. Two types of addition reactions competed each other and the ratio of the two [R=**B**/**C**] depended solely on the solvent polarity (E_T). Dibenzoylacetylene behaved similarly. Several iminothiazolines and iminothiadiazolines reacted with activated acetylenes and the selectivity for the two types of addition reactions for each system was shown to be affected by quite subtle balance of electron-withdrawing ability of each heterocycle.

Many kinds of five-membered sulfur heterocycles have been used for cycloadditions as masked 1,3-dipoles. For example, aminothiatriazole,[1] dithiolanthiones,[2] dithiolethiones[3] and its aza-,[4] oxa-,[5] selena-[6] analogues have been reported to react with activated olefins, acetylenes, nitriles, and heterocumulenes. During our research on the role of hypervalent sulfur for ring-transformation,[7] we also reported the reaction of 5-imino-4,5-dihydro-1,2,4-thiadiazole (**1**) with activated acetylenes to give the corresponding 2-aminothiazole and nitrile and also that of the same compound with imidates to afford the corresponding adduct which has an aromatic 1,2,4-thiadiazole ring via hydrogen shift.[4g,7c] The characteristic feature of these reactions is that bond switching takes place at the central sulfur atom and the resulting products are adducts accompanied by ring-transformation or new heterocycles produced by elimination of small molecules from the adducts. Although almost all reactions are assumed to proceed through hypervalent sulfuranes, for example **A**, only a few mechanistic studies have been presented. Goerdeler reported the cycloaddition of 3-imino-3*H*-1,2,4-dithiazoles (**2**) with activated olefins,[4b] and found that fumarate and maleate reacted stereospecifically, which indicated that the reaction proceeded in a concerted manner. Another example is the reaction of cis- and trans-disubstituted dithiolanthiones (**3**) with activated acetylenes (**4**),[2a] and the former compound produced cis-olefin and vice versa (Scheme 2, Eqs. 2 and 3). The result also shows that any discrete polar or radical intermediate is not involved through the process.

During our study on the scope of these reactions, we found some complexity of the product depending on the change of electronic nature of the starting iminothiadiazolines. Closely related 2-imino-2,3-dihydro-1,3,4-thiadiazoles **5** and **6a** reacted with dibenzoylacetylene (**4a**: X=PhCO) to give different types of compounds as main product, that is, **7a** (81%) and **8d** (98%), respectively (vide infra, Scheme 3, Eqs. 4 and 5). Hence, there is still to be elucidated on mechanism of the reaction of activated acetylenes



Scheme 1.

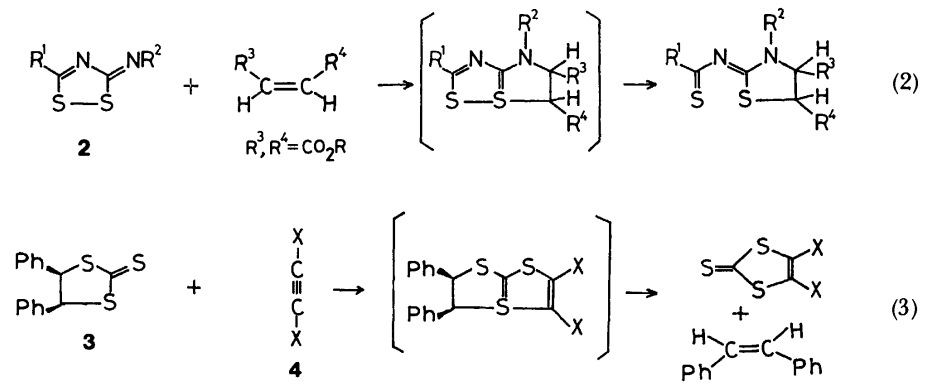
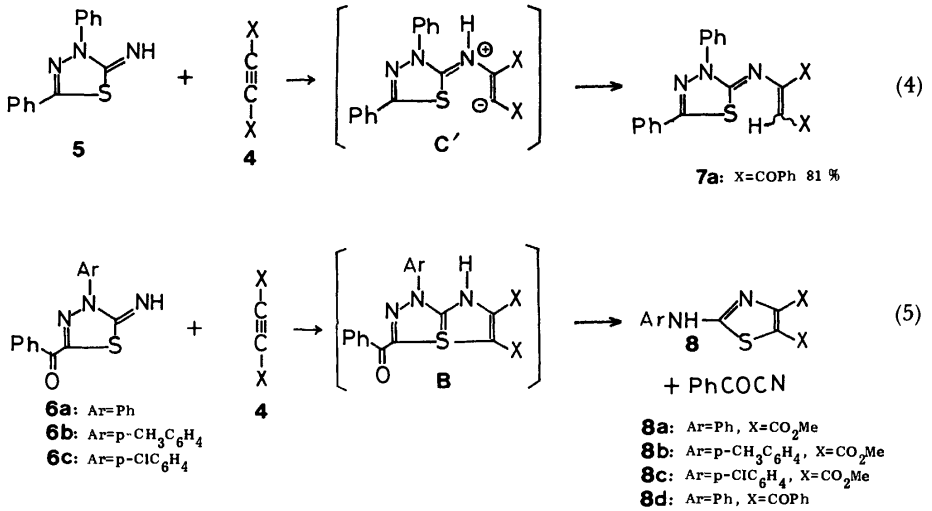


Scheme 2.

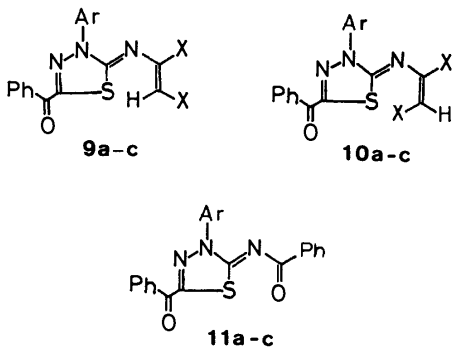


Scheme 3.

with those compounds. We examined the reaction of Eq. 5 in detail in comparison with Eq. 4 to obtain mechanistic insight of the reaction. It was concluded that the difference of the reaction course could be explained on the basis of competitive reactions which proceeded through two intermediates, sulfurane (**B**) and zwitterion (**C**).

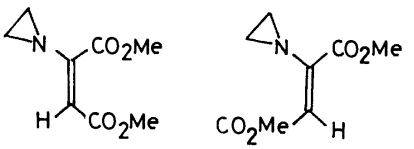
Results and Discussion

Products of the Reaction of 6 with 4b. The reaction of 3-aryl-5-benzoyl-2-imino-2,3-dihydro-1,3,4-thiadiazoles (**6**) with dimethyl acetylenedicarboxylate (**4b**) was carried out in a variety of solvents at 50 °C for several hours (Eq. 5). In all cases examined, the main product was the thiazole (**8**), which could be recrystallized from the reaction mixture. When the reaction was carried out in nonpolar solvents the yield of **8** always amounted to ca. 90%. In order to scrutinize the reaction the products were separated by dry column chromatography (SiO_2) using dichloromethane as an eluent. Besides the thiazole (**8**), three products **9**, **10**, **11**, and benzoyl cyanide were obtained. The structure of **11** was confirmed by comparison with authentic samples prepared from **6** and benzoyl



chloride. Structural assignment of **9** and **10** are based on the elemental analyses, ^1H NMR and mass spectra. ^1H NMR clearly shows that both products have an olefinic proton, and isomerization from **9** to **10** was observed by addition of a catalytic amount of chloroacetic acid. Therefore these are geometrical

isomers. By comparison of the ^{1}H NMR spectra of **9** and **10**, rather large difference was noticed between chemical shifts of olefinic protons (δ 5.5—5.7 and 6.2—6.4). As it is known that a greater deshielding of the vinyl proton occurs in fumarate ester than in maleate, the former compound with vinyl proton at higher field should be cis-vinyl **9** and the latter is trans-vinyl **10**.[8] By the same reason Dolfini[9] assigned structure of adduct (**12**) of aziridine with **4b** that **12** with a vinyl proton at higher field (δ 5.31) is **12a** and the another at lower field (δ 6.15) is **12b**. We were surprised to see that the thiazole (**8**), which is expected to result from sulfurane **B**, and vinyl compounds **9** and **10**, which should be produced through zwitterion **C**, were obtained together in aprotic solvents. Therefore we next examined the solvent and substituent effects on the reaction.



12a **12b**

Solvent and Substituent Effects on the Reaction of 6 with 4b. Reactions of **6b** with **4b** were carried out in eleven solvents to examine the solvent effect on the ratio of these products. A mixture of **4b** (1.2—1.4 mmol) and **6b** (0.99—1.01 mmol) in 50 ml of a dry solvent was heated at 50.0 °C for several hours. The reaction proceeded cleanly and four products were separated by chromatography. Total yield was almost quantitative (95—100%) and Table 1 shows the ratio of the four products. The formation of **11** is ascribed to the secondary reaction of **6b** with benzoyl cyanide which is produced together with **8** during the reaction. This was actually confirmed by a separate experiment.

Table 1. Solvent Effect on the Reaction of **6b** with **4b**[a]

Solvent	E_T	**8**	**9**	**10**	**11**	R[b]
PhH	34.5	86.4	2.1	0.9	10.6	28.8
CCl_4	32.5	90.6	3.3	0.1	6.0	26.6
THF	37.4	91.6	3.7	0.5	4.2	21.8
AcOEt	38.1	84.1	3.1	1.3	11.5	19.1
MeCOMe	42.2	72.8	6.3	1.6	19.2	9.2
Me_2SO	45.0	76.3	9.4	3.4	11.0	6.0
MeCN	46.0	73.9	14.7	1.5	9.9	4.6
t-BuOH	43.9	79.0	5.7	4.0	11.3	8.1
i-PrOH	48.6	71.9	5.3	12.4	10.4	4.1
EtOH	51.9	68.7	13.8	15.8	1.7	2.32
MeOH	55.5	41.8	38.5	18.9	0.8	0.73

a) Sum of the isolated yields of the four products were 95—100% and these values were normalized to correspond to the total yield of 100%. b) R=**8**/(**9**+**10**).

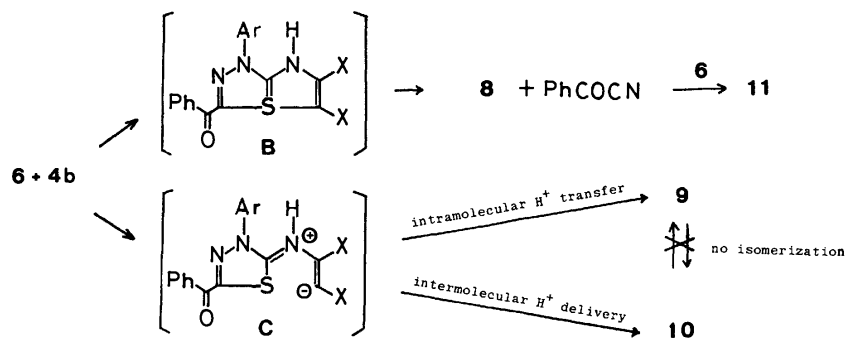
Important informations can be extracted from Table 1: (i) The yield of the main product **8** decreases and that of total vinyl compounds (**9**+**10**) increases according to the increase of polarity of solvents (E_T),[10] i.e., R ([**8**/(**9**+**10**)])[11] decreases according to the increase of E_T, (ii) vinyl compounds are produced even in nonpolar aprotic solvents and cis-vinyl (**9**) is the major one in all the aprotic solvents, (iii) ratio of cis-vinyl (**9**) to trans-vinyl (**10**) is dependent on the kind of alcohols used.

When log R was plotted against the parameter E_T, good linear relationship was observed (corr. coeff. 0.980) for all of the solvents (Fig. 1). This means that the ratio of **8** to total vinyl compounds (**9**+**10**) is determined solely by the polarity of the solvent irrespective of the participation of alcoholic protons in the formation of **9** and **10**. These can be explained by competitive reactios (Scheme 4), that is, the vinyl compounds and the thiazole are formed through different intermediates, i.e., nonpolar sulfurane (**B**) and polar one, zwitterion (**C**), the ratio of which is determined by the solvent polarity.

Table 2. Substituent Effect on the Reaction of **6** with **4b** in Methanol[a]

Ar	**8**	**9**	**10**	**11**	R[b]
p-MeC_6H_4	41.8	38.5	18.9	0.8	0.61
C_6H_5	45.3	35.6	18.9	0.2	0.83
p-ClC_6H_4	48.8	26.5	23.4	1.3	0.98

a) Sum of the isolated yields of the four products were 95—100% and these values were normalized to correspond to the total yield of 100%. b) R=**8**/(**9**+**10**).



Scheme 4.

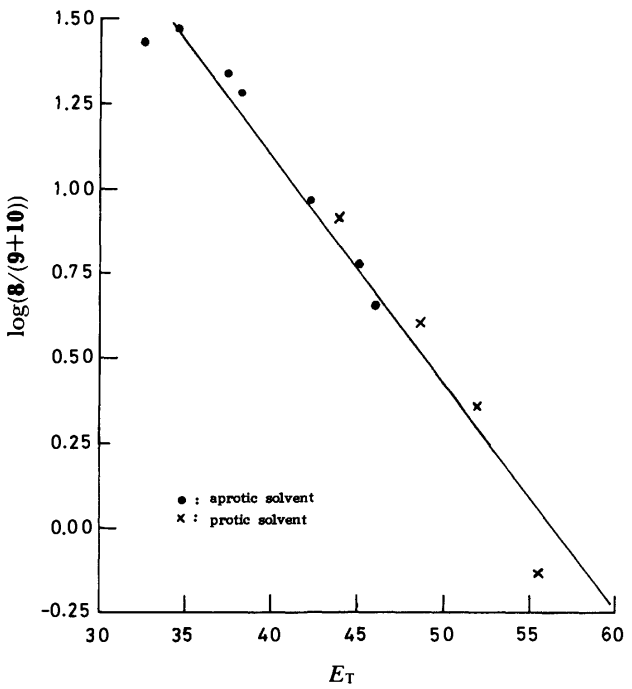


Fig. 1. Relationship between product distribution and solvent polarity E_T.

Substituent effect of the aryl group was examined in methanol as a solvent and results are shown in Table 2. These indicate that the ratio R increased according to the increase of the electron-withdrawing ability of substituent Ar. It is reasonable that formation of sulfurane (**B**) is favored and stability of zwitterion (**C**) is disfavored by increasing electron-withdrawing ability of Ar.

The cis–trans ratio of vinyl compounds (**9** and **10**) remained constant under the reaction conditions and workup procedure. The cis–trans ratio of vinyl compounds in methanol was examined at appropriate intervals by ^{1}H NMR and no change of the ratio was observed at 20, 25, 45, 70, and 138 h. In addition the isomerization during workup was carefully checked by subjecting the isolated vinyl compounds again to chromatography and no change of the ratio was confirmed. Therefore, it is concluded that the ratio of the vinyl compounds (**9** and **10**) was actually determined by the reaction. Such a ratio of vinyls is consistent with that of aziridine with **4b**.[9,12] It was reported that cis adduct **12a** formed via intramolecular path was exceedingly formed in aprotic solvent and trans adduct was predominant in methanol because intermolecular protonation by the solvent became favored. Also in our result, cis-vinyl **9** was invariably preferred to trans-vinyl **10** in aprotic solvents, which probably results from intramolecular prototropy. Ratios of **9** to **10** in protic solvents were quite different from those in aprotic ones, for example, the dramatic difference exists between acetonitrile (**9**/**10**=14.6/1.5) and 2-propanol (5.3/12.4) which have similar polarity (E_T). The ratios in alcohols seem to depend on bulkiness of alkyl groups and to acidity of alcohols. The result indicates that alcohols participate to form vinyl compounds (**9** and **10**) from **C**.

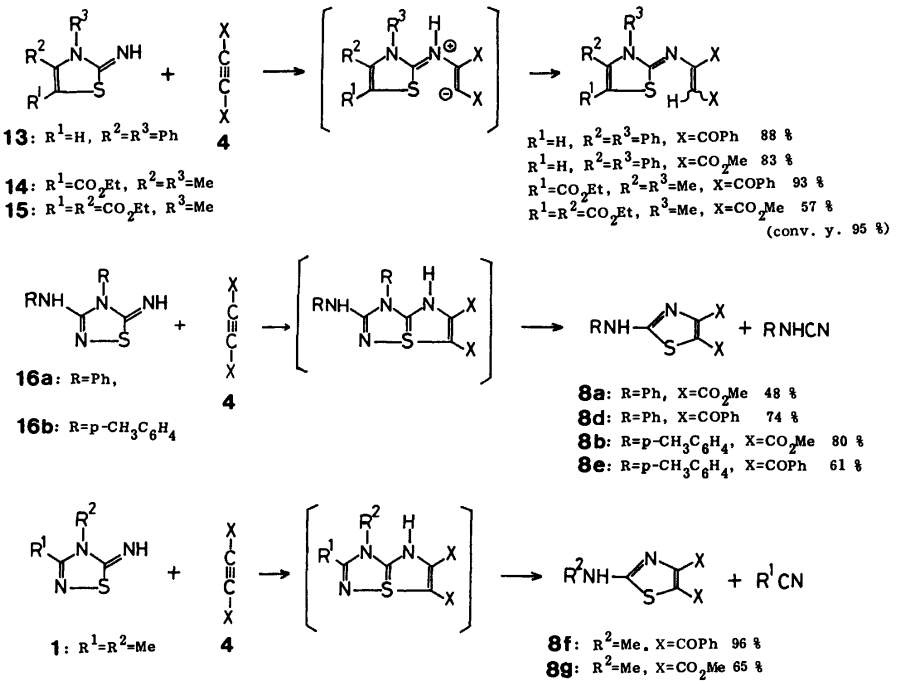
Reaction of Closely Related Thiazolines and Thiadiazolines with Activated Acetylenes. Now it is interesting to compare the results with closely related systems. We examined six types of compounds, **1**, **5**, **13**—**16** in addition to **6**. All these compounds reacted smoothly with activated acetylenes **4a** and **4b** at room temperature or at 50 °C within several hours. Results are summarized in Scheme 5. Reaction course was not affected by using either **4a** or **4b**.

In thiazolines (**13**—**15**), any ring-transformed thiazole was not obtained but only simple adduct was formed in high yield even in nonpolar aprotic solvents. On the other hand, 1,2,4-thiadiazolines, **1** and **16a** (Hector's base) reacted with dibenzoyl acetylene to give only ring-transformed thiazole in 96 and 74% yields and the same kind of results was obtained with dimethyl acetylenedicarboxylate. It is noteworthy here that the reaction of 1,3,4-thiadiazoline **6** with **4a** gave the ring-transformed thiazole as a main product (vide supra), but only simple adduct **7a** was obtained from **4a** and **5**, in which the benzoyl group at 2 position was substituted by a phenyl group (Scheme 3, Eqs. 4 and 5).

All these results can be interpreted by competitive reactions similarly to Scheme 4. That is, relative stability of the intermediate sulfurane **D** and zwitterion **E** determines the reaction course. It is well-known that the hypervalent bond, i.e., three-center four-electron bond, is stabilized by electronegative groups at apical positions.[13] In sulfurane **D** the hypervalent bond corresponds to 1, 6a, 6 bond, so that the groups at 1 and 6 positions are most important in order to form the sulfurane by 1,3-dipolar cycloaddition. In 1,2,4-thiadiazolines **1** and **16** (Hector's base) sulfurane **D** was formed due to the presence of an electronegative nitrogen atom at position-M. In three thiazolines, **13**—**15**, less electronegative carbon than nitrogen should come to position-M, thus not sulfurane (**D**) but zwitterion (**E**) was generated as an intermediate. In 1,3,4-thiadiazolines the nitrogen at position-L has electron-withdrawing effect but the effect is not so much as the nitrogen at position-M in 1,2,4-thiadiazolines. Thus the group at position-M became important in 1,3,4-thiadiazolines. The benzoyl group attached at position-M was electronegative enough to let **6** participate in cycloaddition to generate sulfurane **D** but the phenyl group was not enough so and **5** gave vinyl compounds via zwitterion **E**.

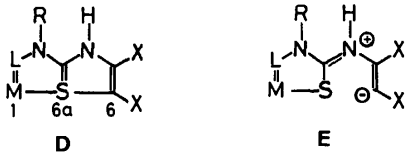
Conclusion

The reaction of iminothiadiazolines and 2-imino-4-



Scheme 5.

thiazolines with activated acetylenes can be understood by competitive reactions, invoking the formation of sulfurane **D** by concerted 1,3-dipolar cycloaddition and that of zwitterion **E** by simple addition. Selectivity between the two reactions stands on quite subtle balance of electron-withdrawing ability of the heterocycles. It is not yet clear whether sulfurane **D** can open to zwitterion **E** or **E** can close to **D** during the reaction, however, the presence of the two intermediates was verified for the present case, i.e., **6**+**4a**.



Experimental

IR spectra were recorded on a Hitachi EPI-G2 spectrometer. ^{1}H NMR spectra were determined with a Hitachi R-24B or a Hitachi R-20B spectrometer. UV spectra were measured with a EPS-G3 spectrometer. Mass spectra were obtained with a Hitachi RMU-6 and JEOL D-300 spectrometer. All melting points are uncorrected. All solvents employed in the reaction were purified as follows; methanol and ethanol were distilled from magnesium alkoxide. 2-Propanol, *t*-butyl alcohol, and benzene were distilled from sodium. Carbon tetrachloride and ethyl acetate were distilled from phosphorus pentaoxide and redistilled from anhydrous potassium carbonate. Acetone was treated with potassium permanganate and redistilled from potassium carbonate. Tetrahydrofuran was distilled from sodium/benzophenone. Dimethyl sulfoxide was distilled over calcium hydride. Acetonitrile was spectral grade stored over 4-A Molecular Sieves. Dibenzoyl acetylene (**4a**)[14] and dimethyl acetylenedicarboxylate (**4b**)[15] were prepared by the reported procedure.

5-Benzoyl-2-imino-3-phenyl-2,3-dihydro-1,3,4-thiadiazole (6a) was prepared from phenacyl thiocyanate and benzenediazonium chloride in ethanol-water-tetrahydrofuran solution at pH 4.[16]

6a: Yield 50%; mp 94—96 °C (lit, 89—90 °C);[16] UV (CH_2Cl_2) λ_{max} 265 (log ε=4.28), 375 nm (4.15); IR (KBr) 3310, 1640, 1600 cm^{-1}.

5-Benzoyl-2-imino-3-*p*-tolyl-2,3-dihydro-1,3,4-thiadiazole (6b). Yield 60%; mp 123—124 °C (lit, 112 °C);[16] UV (CH_2Cl_2) λ_{max} 265 (log ε=4.24), 377 nm (4.09); IR (KBr) 3250, 1640, 1600 cm^{-1}.

5-Benzoyl-2-imino-3-(*p*-chlorophenyl)-2,3-dihydro-1,3,4-thiadiazole (6c). Yield 60%; mp 139.5—141 °C (lit, 127 °C);[16] IR (KBr) 3300, 1640, 1600 cm^{-1}.

Reactions of 6 and 4b. General Procedure: A solution of **4b** (1.2—1.4 mmol) and **6** (0.99—1.01 mmol) in 50 ml of dry solvent was heated at 50 °C for several hours. After disappearance of **6** was checked by TLC, the solvent was evaporated. The reaction mixture was subjected to dry column chromatography (SiO_2) with chloroform as an eluent. This column was divided into four fractions, each of which was composed of **8**, **9**, **10** an **11**.

4,5-Bis(methoxycarbonyl)-2-(phenylamino)thiazole (8a). Mp 115—116 °C; IR (KBr) 3150, 3125, 1745, 1720, 1590 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.70 (s, 3H), 3.80 (s, 3H), 7.2—7.5 (m, 5H), 9.5 (brs, 1H); MS, *m/z* (relative intensity) 292 (M^+, 100), 232 (72). Calcd for $C_{13}H_{12}N_2O_4S$: C, 53.43; H, 4.14; N, 9.59%. Found: C, 53.37; H, 3.98; N, 9.33%.

4,5-Bis(methoxycarbonyl)-2-(*p*-tolylamino)thiazole (8b). Mp 173.5—175.5 °C; IR (KBr) 3200, 3150, 1730, 1690,

1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.40 (s, 3H), 3.80 (s, 3H), 3.85 (s, 3H), 7.1—7.4 (m, 4H), 8.85 (brs, 1H); MS, *m/z* (relative intensity) 306 (M^+, 100), 246 (87). Calcd for $C_{14}H_{14}N_2O_4S$: C, 54.90; H, 4.61; N, 9.15%. Found: C, 54.96; H, 4.61; N, 9.24%.

4,5-Bis(methoxycarbonyl)-2-(*p*-chlorophenylamino)thiazole (8c). Mp 191—192 °C; IR (KBr) 3220, 3170, 1730, 1690, 1600 cm^{-1}. Calcd for $C_{13}H_{11}N_2O_4SCl$: C, 47.79; H, 3.39; N, 8.51; S, 9.81; Cl, 10.85%. Found: C, 47.79; H, 3.53; N, 8.31; S, 9.97; Cl, 10.68%.

5-Benzoyl-3-phenyl-2-[[(*E*)-1,2-bis(methoxycarbonyl)vinyl]-imino]-2,3-dihydro-1,3,4-thiadiazole (9a). Mp 121.5—122.5 °C; UV (CH_2Cl_2) λ_{max} 272 (log ε=4.17), 318 (4.24), 381 nm (4.10); ^1H NMR ($CDCl_3$) δ=3.69 (s, 3H), 3.80 (s, 3H), 5.56 (s, 1H), 7.2—8.4 (m, 10H); MS, *m/z* (relative intensity) 423 (M^+, 4), 105 (100). Calcd for $C_{21}H_{17}N_3O_5S$: C, 59.57; H, 4.05; N, 9.93%. Found: C, 59.59; H, 3.91; N, 10.21%.

Compound 9b. Mp 123.5—124.5 °C; UV (CH_2Cl_2) λ_{max} 270 (log ε=4.21), 319 (4.16), 386 nm (4.09); ^1H NMR ($CDCl_3$) δ=2.35 (s, 3H), 3.70 (s, 3H), 3.85 (s, 3H), 5.65 (s, 1H), 7.1—8.4 (m, 9H); MS, *m/z* (relative intensity) 437 (M^+, 4), 105 (100). Calcd for $C_{22}H_{19}N_3O_5S$: C, 60.40; H, 4.38%. Found: C, 60.32; H, 4.37%.

Compound 9c. Mp 121.0—122.5 °C; ^1H NMR ($CDCl_3$) δ=3.75 (s, 3H), 3.90 (s, 3H), 5.70 (s, 1H), 7.2—8.4 (m, 9H). Calcd for $C_{21}H_{16}N_3O_5SCl$: C, 55.09; H, 3.52; N, 9.18%. Found: C, 54.51; H, 3.33; N, 8.90%.

5-Benzoyl-3-phenyl-2-[[(*Z*)-1,2-bis(methoxycarbonyl)vinyl]-imino]-2,3-dihydro-1,3,4-thiadiazole (10a). Mp 131.5—132.5 °C; UV (CH_2Cl_2) λ_{max} 272 (log ε=4.33), 380 nm (4.06); ^1H NMR ($CDCl_3$) δ=3.67 (s, 3H), 3.76 (s, 3H), 6.23 (s, 1H), 7.2—8.4 (m, 10H); MS, *m/z* (relative intensity) 423 (M^+, 18), 105 (100). Calcd for $C_{21}H_{17}N_3O_5S$: C, 59.57; H, 4.05; N, 9.93%. Found: C, 59.72; H, 4.07; N, 9.66%.

Compound 10b. Mp 148.5—149.5 °C; UV (CH_2Cl_2) λ_{max} 272 (log ε=4.34), 383 nm (4.03); ^1H NMR ($CDCl_3$) δ=2.40 (s, 3H), 3.71 (s, 3H), 3.80 (s, 3H), 6.35 (s, 1H),7.1—8.5 (m, 9H); MS, *m/z* (relative intensity) 437 (M^+, 5), 105 (100). Calcd for $C_{22}H_{19}N_3O_5S$: C, 60.40; H, 4.38; N, 9.61%. Found: C, 60.41; H, 4.11; N, 9.35%.

Compound 10c. Mp 161—162 °C; ^1H NMR ($CDCl_3$) δ=3.70 (s, 3H), 3.80 (s, 3H), 6.35 (s, 1H), 7.2—8.4 (m, 9H). Calcd for $C_{21}H_{16}N_3O_5SCl$: C, 55.09; H, 3.52; N, 9.18%. Found: C, 55.66; H, 3.70; N, 9.43%.

5-Benzoyl-2-benzoylimino-3-phenyl-2,3-dihydro-1,3,4-thiadiazole (11a) was prepared by the reaction of **6a** with benzoyl chloride in quantitative yield. Mp 202.5—204 °C. Calcd for $C_{22}H_{15}N_3O_5S$: C, 68.56; H, 3.92; N, 10.91%. Found: C, 68.56; H, 3.77; N, 10.79%.

Compound 11b. Mp 233.0—233.5 °C. Calcd for $C_{23}H_{17}N_3O_5S$: C, 69.15; H, 4.29; N, 10.52%. Found: C, 69.69; H, 4.18; N, 10.62%.

Compound 11c. Mp 216—217.5 °C. Calcd for $C_{22}H_{14}N_3O_2SCl$: C, 62.93; H, 3.36; N, 10.01%. Found: C, 62.91; H, 3.24; N, 9.92%.

Reaction of 6a with 4a. In 30 ml of THF **6a** (435 mg, 1.55 mmol) was mixed with **4a** (467 mg, 1.99 mmol). After stirring for 4 h at room temperature, the reaction mixture was recrystallized from benzene to give 4,5-dibenzoyl-2-(phenylamino)thiazole (**8d**) in 98% yield. Mp 173.5—175 °C; IR (KBr) 3200, 3150, 1680, 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.0—7.9 (m, 15H), 8.75 (brs, 1H); MS, *m/z* (relative intensity) 384 (M^+, 100), 279 (29). Calcd for $C_{23}H_{16}N_2O_2S$: C, 71.87; H, 4.20; N, 7.29%. Found: C, 71.60; H, 3.95; N, 7.04%.

2-Imino-3,5-diphenyl-2,3-dihydro-1,3,4-thiadiazole (5) was prepared from a reported method.[17] Mp 99.5—101 °C (lit, 97 °C).[17]

Reaction of 5 with 4a. In 5 ml of THF **5** (33 mg, 0.13 mmol) was mixed with **4a** (113 mg, 0.48 mmol) at room temperature and heated at 50 °C for 2 h. The reaction mixture was submitted to TLC (SiO_2) with chloroform to give 52 mg (81%) of simple addition product. Mp 141—142.5 °C; IR (KBr) 1680, 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.0 (s, 1H), 7.4—8.6 (m, 20H); MS, *m/z* (relative intensity) 487 (M^+, 10), 382 (71), 105 (100). Calcd for $C_{30}H_{31}N_3O_2S$: C, 73.90; H, 4.34; N, 8.62; S, 6.58%. Found: C, 73.92; H, 4.30; N, 8.32; S, 6.50%.

5-Imino-4-phenyl-3-phenylamino-4,5-dihydro-1,2,4-thiadiazole (16a). Hector's bases were prepared from the corresponding arylthioureas by oxidation with acidic hydrogen peroxide.[18] Yield 54%; mp 181—182 °C (lit, 181 °C).[18]

Compound 16b. Yield 47%; Mp 126—127 °C (lit, 127 °C).[18]

Reaction of 16a and 4b. To a stirred solution of **16a** (1.34 g, 5.01 mmol) in 100 ml of chloroform, **4b** (0.93 g, 6.6 mmol) in 20 ml of chloroform was added dropwise during 7 h at room temperature. After being stirred for 3 h, the reaction mixture was subjected to dry column chromatography (alumina) to give **8a** in 48% yield.

Reaction of 16a with 4a. To a solution of **16a** (1.34 g, 5.01 mmol) in 100 ml of chloroform, **4a** (1.53 g, 6.5 mmol) was added portionwise. After the mixture was stood for 1 h, the solvent was evaporated. The residual oil was crystallized from benzene-hexane to give 4,5-dibenzoyl-2-(phenylamino) thiazole (**8d**) in 74% yield.

4,5-Dibenzoyl-2-(*p*-methylphenylamino)thiadiazole (8e). Yield 61%; mp 203—204 °C; IR (KBr) 3200, 3150, 1680, 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.3 (s, 3H), 7.0—7.8 (m, 14H), 8.7 (brs, 1H); MS, *m/z* (relative intensity) 398 (M^+, 97), 293 (23).

3,4-Dimethyl-5-imino-4,5-dihydro-1,2,4-thiadiazole (1) was prepared from a similar method described in the literature.[19] Mp 64—69 °C (lit, 66 °C);[19] IR (KBr) 3200, 1595, 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.25 (s, 3H), 3.28 (s, 3H), 5.85 (brs, 1H).

Reaction of 1 with 4a. The solution of **4a** (1.07 g, 4.58 mmol) in 5 ml of THF was added dropwise to a solution of **1** (495 mg, 3.83 mmol) in 10 ml of THF. After stirring overnight at room temperature, the reaction mixture was crystallized from ethanol to give 4,5-dibenzoyl-2-(methylamino)thiazole (**8f**) in 96% yield. Mp 197—198.5 °C; IR (KBr) 3200, 1680, 1620 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.87 (bd, *J*=6 Hz, 3H), 7.2—7.8 (m, 10H), 8.4 (brm, 1H). Calcd for $C_{18}H_{14}N_2O_2S$: C, 67.06; H, 4.38; N, 8.69; S, 9.95%. Found: C, 67.10; H, 4.22; N, 8.68; S, 9.94%.

Reaction of 1 with 4b. To a solution of **1** (126 mg, 0.98 mmol) in 5 ml of hexane **4b** (142 mg, 1.00 mmol) was added dropwise at 0 °C. The reaction occurred exothermally to form precipitates. After 1 h, the solvent was evaporated and the residue was submitted to TLC (SiO_2, ether). 4,5-Bis(methoxycarbonyl)-2-(methylamino)-thiazole (**8g**) was obtained in 65% yield. Mp 156.5—158 °C

(recrystallized from benzene-hexane); IR (KBr) 3200, 3100, 1730, 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.97 (d, J=6 Hz, 3H), 3.84 (s, 3H), 3.95 (s, 3H), 8.27 (bs, 1H); MS, m/z (relative intensity) 230 (M^+, 100), 199 (81), 172 (28). Calcd for $C_8H_{10}N_2O_4S$: C, 41.73; H, 4.38; N, 12.17; S, 13.93%. Found C, 41.62; H, 4.65; N, 12.05; S, 14.09%.

2-Imino-3,4-diphenyl-4-thiazoline (13) was prepared from a similar method described in the literature.[20] Mp 112—113 °C (lit, 111 °C).[20]

Reaction of 13 with 4a. To a solution of **13** (1.27 g, 5.05 mmol) in 50 ml of chloroform, **4a** (1.52 g, 6.51 mmol) was added portionwise at room temperature. After the mixture was stood overnight, the solvent was evaporated. The residual oil was crystallized from ethanol to give 3,4-diphenyl-2-[(1,2-dibenzoylvinyl)imino]-4-thiazoline in 88% yield. Mp 183.5—185.5 °C; IR (KBr) 1670, 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.4 (s, 1H), 6.9 (s, 1H), 6.8—8.1 (m, 20H); MS, m/z (relative intensity) 486 (M^+, 14), 381 (65), 279 (100).

Reaction of 13 with 4b. To a stirred solution of **13** (1.26 g, 5.01 mmol) in 50 ml of chloroform, **4b** (933 mg, 6.57 mmol) in 50 ml of chloroform was added portionwise After the mixture was stood overnight, the solvent was evaporated. The residue was crystallized from ethanol to give 3,4-diphenyl-2-[[1,2-bis(methoxycarbonyl)vinyl]imino]-4-thiazoline in 83% yield. Mp 162—163 °C; IR (KBr) 1740, 1710, 1685 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.7 (s, 3H), 3.8 (s, 3H), 5.7 (s, 1H), 6.5 (s, 1H), 7.1—7.6 (m, 10H); MS, m/z (relative intensity) 394 (M^+, 78), 335 (94), 303 (100). Calcd for $C_{21}H_{18}N_2O_4S$: C, 63.95; H, 4.60; N, 7.10%. Found: C, 64.15; H, 4.67; N, 7.13%.

5-Ethoxycarbonyl-3,4-dimethyl-2-imino-4-thiazoline (14) was prepared by methylation of 2-amino-5-ethoxycarbonyl-4-methylthiazole[21] with trimethyloxonium tetrafluoroborate in 32% yield. Mp 76—77 °C; ^1H NMR ($CDCl_3$) δ= 1.30 (t, J=6 Hz, 3H), 2.50 (s, 3H), 3.30 (s, 3H), 4.20 (q, J=6 Hz, 2H), 6.85 (brs, 1H); High resolution MS, Calcd for $C_8H_{12}N_2O_2S$: 200.0617. Found: m/z 200.0496.

4,5-Bis(ethoxycarbonyl)-2-imino-3-methyl-4-thiazoline (15) was prepared by methylation of 2-amino-4,5-bis(ethoxycarbonyl)thiazole[22] with trimethyloxonium tetrafluoroborate in 35% yield. Oil; ^1H NMR ($CDCl_3$) δ=1.30 (t, J= 6 Hz, 3H), 1.40 (t, J=6 Hz, 3H), 3.30 (s, 3H), 4.20 (q, J= 6 Hz, 2H), 4.40 (q, J=6 Hz, 2H), 7.0—7.5 (brs, 1H); High resolution MS, Calcd for $C_{10}H_{14}N_2O_4S$: M, 258.0673. Found: m/z 258.0632.

Reaction of 14 with 4a. A mixture of **14** (418 mg, 2.09 mmol) and **4a** (554 mg, 2.37 mmol) in 25 ml of benzene was heated at 50 °C for one day. The reaction mixture was chromatographed (dry column chromatography, SiO_2) with dichlorometane as an eluent to give a vinyl compound in 93% yield. ^1H NMR ($CDCl_3$) δ=1.40 (t, J=6 Hz, 3H), 2.60 (s, 3H), 3.45 (s, 3H), 4.30 (q, J=6 Hz, 2H), 7.00 (s, 1H), 7.2—8.1 (m, 10H).

Reaction of 15 with 4b. A mixture of **15** (340 mg, 1.32 mmol) and **4b** (218 mg, 1.53 mmol) in 40 ml of methanol was heated at 50 °C for 5 h. About 1:1 mixture of vinyl compounds were obtained after chromatographic separation in 57% yield (And 40% of **15** was recovered). To the $CDCl_3$ solution was added chloroacetic acid, resulting in isomerization and the ratio of the compounds changed to 5:1. cis-vinyl: ^1H NMR ($CDCl_3$) δ=1.30 (t, J=7 Hz, 3H), 3.44 (s, 3H), 3.70 (s, 3H), 3.88 (s, 3H), 4.0—4.5 (m, 4H), 5.60 (s, 1H). trans-vinyl: ^1H NMR ($CDCl_3$) δ=1.41 (t, J=7 Hz, 3H), 3.44 (s, 3H), 3.70 (s, 3H), 3.81 (s, 3H), 4.1—4.6 (m, 4H), 6.29 (s, 1H).

Anodic Oxidation of (Trimethylsilyl)methanes with π-Electron Substituents in the Presence of Nucleophiles

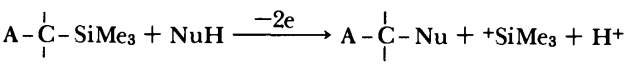
Toshio KOIZUMI, Toshio FUCHIGAMI,* and Tsutomu NONAKA*
Department of Electronic Chemistry, Tokyo Institute of Technology,
4259 Nagatsuta, Midori-ku, Yokohama 227
(Received March 12, 1988)

It was found that oxidation potentials of methanes with π-electron substituents were decreased by introduction of a trimethylsilyl group. The anodic oxidation of benzyl-, allyl-, aryl(or alkyl)thiomethyl-, and aryloxymethyl-substituted trimethylsilanes smoothly proceeded in the presence of nucleophiles, e.g. alcohols and carboxylic acids, to eliminate the trimethylsilyl groups giving the corresponding alkoxylated and carboxylated products in moderate or high yields without full optimization of electrolytic conditions, while aminomethylsilanes did not undergo such a kind of anodic oxidation.

Anodic oxidation of organic compounds involves mostly a proton elimination step which sometimes governs overall efficiency and/or selectivity of the reaction. For instance, the anodic substitution of toluene involves the proton elimination from the methyl or phenyl group which is substituted by a nucleophile. The proton elimination step is generally influenced by reaction conditions, and in fact it has been found that the product selectivity of the toluene oxidation is sensitively affected by electrolytic conditions such as acidity/basicity of anolyte and anode material.[1-6]

In this work, it was attempted to control the proton elimination on the basis of a different principle in which the methyl group of toluenes was modified by a cationic leaving group. As leaving species more favorable than proton, NO^+, RCO^+, and I^+ have sometimes been used.[7] However, these are electron-withdrawing groups, which cause increases in the oxidation potential of the mother compounds. This should be a disadvantage for efficient anodic oxidation. In this work, a trimethylsilyl group was used as a cationic leaving group for the following reasons:[8] (a) A trimethylsilyl substituent increases HOMO energy level of π-electron system at β-position,[14-17] (b) a C–Si bond is more easily cleaved than a C–H one[18] (Bonding energy: CH_3–$SiMe_3$, 89.4 kcal mol^{-1}; CH_3–H, 104.8 kcal mol^{-1}[19]), (c) a silicon atom is more easily attacked by nucleophiles than a hydrogen one,[18] (d) silyl substituents contribute to stabilize β-carbocations, comparably to alkoxy ones,[18,20] (e) a C–Si bond is chemically stable,[18] and (f) trimethylsilyl compounds are easily prepared using trimethylsilyl chloride.[21]

The following anodic substitution reaction of (trimethylsilyl)methanes with π-electron substituents was examined in the presence of nucleophiles, e.g. alcohols and carboxylic acids.



A: π-Electron substituent
NuH: Nucleophile

Results and Discussion

Trimethylsilylated compounds[(trimethylsilyl)methanes] such as benzyl-, allyl-, thiomethyl-, oxymethyl-, and aminomethyl-trimethylsilane (**1**—**5**), and related unsilylated compounds were used as the starting materials of the anodic oxidation.

Oxidation Potentials of Trimethylsilanes. Benzyl- and thiomethyl-trimethylsilanes (**1a**, **b**, and **3a**, **c**) gave irreversible cyclic voltammetric waves at a platinum anode in 0.1 M (1 M=1 mol dm^{-3}) Bu_4NBF/MeCN (Scan rate, 100 mV s^{-1}). As shown in Table 1, their oxidation peak potentials (E_p^{ox}) are significantly less noble than those of the unsilylated parent compounds. Similar decreases in oxidation potentials of allyl- and aminomethyl-silanes have been found by Yoshida et al.[11] and Cooper and Owen,[22] respectively. These facts suggest that the decreases in oxidation potentials of the π-electron compounds can be induced by introduction of silyl groups to the α-positions.

Anodic Oxidation of Benzylsilanes (1a—c). Oxidation in Methanol: Benzylsilanes (**1a**, **b**) were oxidized at platinum and graphite anodes in methanol containing $NaClO_4$ to give mixtures of α-monomethoxy-

Table 1. Oxidation Potentials of Benzyl- and [Aryl(or alkyl)thiomethyl]trimethylsilanes, and Their Unsilylated Parent Compounds

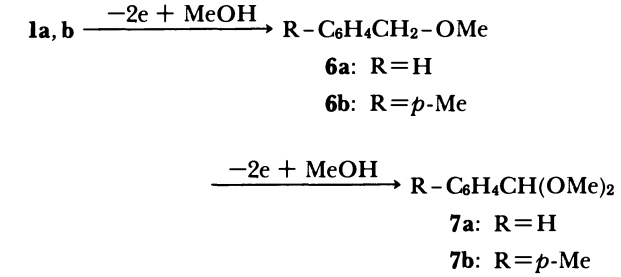
toluenes (**6a, b**) and α,α-dimethoxytoluenes (**7a, b**) in good combined yields (Table 2). Any nucleus-methoxylated products were not formed. At smaller amounts of charge passed, the platinum anode seems somewhat favorable to the formation of **6**. Increases in charge passed resulted in evident decreases and increases in the yields of **6** and **7**, respectively. This fact suggests that **7** forms via **6**.



It is interesting to note that Yoshida et al.[11] have obtained **6** (R=H and *p*-Cl) as single products in high yields in the anodic oxidation of **1** at a graphite anode in Et_4NOTs/MeOH, though any reasoning for such a difference from the above result can not be made at present.

Oxidation in Dichloromethane: Allyl alcohol is easily oxidized because of its low oxidation potential.[23] Therefore, the anodic allyloxylation hardly takes place in general, since the oxidation of allyl alcohol itself occurs preferably to substrates to be allyloxylated. However, the benzylsilanes, of which the oxidation potentials are decreased by the introduction of trimethylsilyl groups, could be anodically allyloxylated in moderate yields under unoptimized conditions (Table 3: Runs 9 and 10).

The anodic substitution is reasonably affected by natures of nucleophiles used. In fact 2,2,2-trifluoroethanol, whose nucleophilicity should be extremely low due to the strongly electron-withdrawing CF_3 group, did not give the corresponding trifluoroethoxylated product (Run 11). On the other hand, somewhat nucleophilic trifluoroacetate ion gave benzyl trifluoroacetate along with benzyl alcohol as a by-product in the oxidation of **1a** (Run 12). The formation of benzyl alcohol may be due to water as a contaminant in the electrolyte or to hydrolysis of the main prodct during the work-up procedure. In Run 13 without any nucleophile added, **1a** itself played a role of nucleophile and benzyl(trimethylsilylmethyl)benzene was formed in 30% yield. In a quaternary ammonium tosylate solution (Run 14), tosylate ion did not act as a nucleoplile, but products such as bibenzyl and toluene were formed, probably, via benzyl radical intermediate species.

From the above results, a mechanistic scheme (Scheme 1) can be postulated as below. In the scheme, the elimination of trimethylsilyl cation from the cation radical intermediate species occurs superiorly to that of protons and the radical coupling process proceed under certain conditions.

In an acetonitrile solution (Run 15), **1a** was anodically acetamidated to give *N*-benzylacetamide in a low yield.

Anodic Oxidation of Allylsilanes (2a, b). Allyltrimethylsilane (**2b**) was anodically trifluoroethoxylated in a low yield in a divided cell (Table 4: Run 16), while benzyltrimethylsilane (**1b**) was not in an undivided cell (Run 11). Reasoning for this difference has not been clearly made, but it is likely that the trifluoroethoxylation is accelerated by acid electrogenerated

in the anode chamber of the divided cell. In fact, the yield was increased by addition of TsOH (Run 17).

Although benzylsilane (**1a**) did not give the corresponding tosylate but underwent the radical process as described above (Run 14), allyl tosylate was formed in the oxidation of allylsilane (**2a**) under similar conditions (Run 18). This may be rationalized due to a stronger electrophilicity of allyl cation than benzyl one

Table 3. Anodic Oxidation of Benzyltrimethylsilanes in Dichloromethane in the Presence and Absence of Nucleophiles[a]

a) 2.5 mmol of **3** was electrolyzed by passing 2×96500 C mol^{-1} of charge at 1.0 A dm^{-2} of current density at a graphite anode in 0.60 M Et_4NOTs/MeCN containing 50 mmol of ROH in an undivided cell. b) Isolated yield. c) At 0.5 A dm^{-2} of current density. d) Used as solvent. e) Determined by GLC. f) At 1.5 A dm^{-2} of current density. g) By-products: $(CF_3CH_2O)_2$-CHPh (16%) and $(MeS)_2CHPh$ (32%).

whose positive charge is more highly delocalized. The anodic trifluoroacetoxylation of **2a** (Run 19) occurred as well as that of **1a**.

The reaction scheme of allylsilanes can be presented similarly to that of benzylsilanes (Scheme 1). Yoshida et al. reported interesting results from a mechanistic aspect and proposed a more detailed mechanism.[11]

Anodic Oxidation of [Aryl(or alkyl)thiomethyl]silanes (3a—c). Oxidation in the Presence of Alcohols: It is known that α-methoxylated sulfides can be obtained by the anodic methoxylation of sulfides.[24,25] However, the existence of electron-withdrawing groups at the α-positions of sulfide molecules seems to be necessary to accelerate deprotonation from cation radical intermediate species and to result in successful methoxylation. In fact, it was confirmed that methyl phenyl sulfide was anodically methoxylated in only 1% yield.

As shown in Table 5, [aryl(or alky)lthiomethyl]-trimethylsilanes (**3a—c**) could be alkoxylated in the anodic oxidation in the presence of a variety of alcohols such as primary (Runs 20—23, 26, 28, 30—33), secondary (Runs 24, 27) and tertiary (Run 25) alcohols. In most cases, the yields were considerably good, though reaction conditions were not fully optimized. Phenol (Run 29) and trifluoroethanol (Run 31) did not give satisfactory results due to their low nucleophilicities.

Although arylthiometyl ethers (**8**) are versatile synthetic reagents for C_1 homologation,[26] it is not so easy to prepare them except for methyl and aryl arylthiomethyl ethers.[27] The anodic alkoxylation should provide an efficient and useful method for the preparation of **8**.

It is noteworthy that the allyloxylation of (thiomethyl)silanes can be performed by the anodic method, though allyl alcohols have considerably less noble oxidation potentials. The anodic methoxylation of phenyl trifluoroethyl sulfide proceeds very efficiently (in 93% yield) by contribution of the electron-withdrawing trifluoromethyl group,[24] while the allyloxylation did not. This fact should clearly indicate a sufficient effect of the modification of sulfides by trimethylsilyl groups on the allyloxylation. It is expected that **8** with allyl groups are converted into the corresponding β,γ-unsaturated ketones by the [2,3]Wittig rearrangement using bases. In fact, **8** derived from **3c** and allyl alcohol in Run 32 gave the ketone in a good yield as follows:

$$MeS\text{-}\underset{|}{\overset{Ph}{C}}H\text{-}OCH_2CH{=}CH_2 \xrightarrow[-80\text{—}-20^\circ C]{LDA/THF} Ph\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH_2CH{=}CH_2 \quad (74\%)$$

Oxidation in the Presence of Carboxylic Acids: As shown in Table 6, the anodic carboxylation of **3a** could smoothly proceed using a few kinds of aliphatic carboxylic acids. It is interesting to note that an unsilylated

Table 6. Anodic Oxidation of Phenylthiomethylsilane in the Presence of Carboxylic Acids[a]

$$\underset{\textbf{3a}}{\text{Ph-S-CH}_2\text{-SiMe}_3} \xrightarrow{-2e + \text{RCOOH}} \underset{\textbf{9}}{\text{Ph-S-CH}_2\text{OCOR}}$$

Run	RCOOH	Yield[b] of 9/%
34	MeCOOH	66
35[c]	MeCOOH	20
36	$Me_2CHCOOH$	61

a) 2.5 mmol of **3a** was electrolyzed by passing 2× 96500 C mol^{-1} of charge at 1.0 A dm^{-2} of current density at a graphite anode in 0.60 M Et_4NOTs/MeCN containing 50 mmol of RCOOH in an undivided cell. b) Isolated yield. c) At a Pt anode in 0.6 M MeCOONa/MeCOOH.

sulfide, $PhSCH_2CH_3$, was not acetoxylated at all under the same conditions.

A reaction scheme involving sulfenium ions as key intermediates would be written for the anodic alkoxylation and carboxylation of **3** analogously to Scheme 1.

Anodic Oxidation of Aryloxymethyl (4) and Aminomethyl (5) Silanes. (Phenoxymethyl)trimethylsilane (**4**), which is an oxygen analogue of **3a**, was anodically methoxylated (52% yield) under conditions presented in Table 5.

[(*N*-Methylbenzylamino)methyl]trimethylsilanes (**5**) did not undergo the alkoxylation,[28] but gave a diamine (**10**) in 40—68% yields in the presence of either methanol or ethanol. The diamine (**10**) was also formed chemically from *N*-methylbenzylamine and formaldehyde along with dimethyl or diethyl ether.

Experimental

Materials. Anodes: Platinum and graphite anodes were polished with fine alumina powder and emery paper, respectively, and then washed with acetone.

Solvents: Acetonitrile, dichloromethane, and methanol were dried using P_2O_5-CaH_2, CaH_2, and sodium metal, respectively, and then distilled in an atmosphere of nitrogen.

Benzyltrimethylsilanes (1a—c): A general method developed for preparing aryltrimethylsilanes[29] was applied. **1a**: Bp 84—85 °C (26 mmHg) (1 mmHg=133.322 Pa) [lit,[30] 93 °C) (35 mmHg)]. **1b**: Bp 84—85 °C (14 mmHg) (lit,[31] 211.5 °C). **1c**: Bp 82—83 °C (9 mmHg) (lit,[32] 210—211 °C.

Allyltrimethylsilanes (2a, b): The silane **2a** was prepared by the method of literature.[29] Bp 86—87 °C (lit,[29] 85 °C). The silane **2b** was also prepared similarly to **2a**. Bp 103—105 °C (10 mmHg); ^{1}H NMR [$CDCl_3$, relative to $Si(CH_3)_3$] δ=0.00 (s, 9H, $Si(CH_3)_3$), 1.5—1.7 (m, 2H, CH_2-Si), 6.1—6.4 (m, 2H, CH=CH), and 7.0—7.4 (m, 5H, C_6H_5).

[Aryl(or alkyl)thiomethyl]trimethylsilanes (3a—c): The silanes were prepared by methods of literatures. **3a**:[33,34] Bp 136—137 °C (32 mmHg) [lit,[35] 158.5 °C (52 mmHg)]. **3b**:[35] Bp 150—151 °C (30 mmHg) [lit,[35] 83—85 °C (1 mmHg)]. **3c**:[37] Bp 99—100 °C (8 mmHg); ^{1}H NMR ($CDCl^3$, relative to $Si(CH_3)_3$) δ=0.00 (s, 9H, $Si(CH_3)_3$), 1.87 (s, 3H, S-CH_3), 3.31 (s, 1H, CH), and 7.1—7.3 (m, 5H, C_6H_5).

Phenoxymethyltrimethylsilane (4): The silane was prepared by the method of literature.[38] Bp 86—87 °C (9 mmHg) (lit,[38] 83—84 °C (8 mmHg)).

[*N*-(Methylbenzylamino)methyl]trimethylsilane (5): The silane was prepared by the method of literature[39] and purified by column chromatography (Silica gel, hexane-ether (1:1)).

Electrolysis. The electrolysis was galvanostatically carried out at room temperature using a platinum (7.7 cm^2) or graphite (5.0 cm^2) anode in a divided (anolyte, 35—50 cm^3) or undivided (electrolyte, 15 cm^3) cell. Detailed electrolytic conditions are shown in the text.

Separation and Analysis of Products. After electrolysis, the electrolytic solution was poured into a saturated sodium chloride solution and extracted with ether or dichloromethane. The extract was dried over anhydrous sodium sulfate and concentrated under reduced pressure. The products were analyzed by GLC (2 m PEG 20 M and 2.25 m Silicone HV grease columns) and isolated by column chromatography (silica gel, hexane-dichloromethane (4:1) or benzene). Molecular structures of all the products were determined by ^{1}H NMR, MS and IR spectra, and/or elemental analysis. Data for the identification of some special products are given below.

[(Benzylphenyl)methyl]trimethylsilane: IR (neat) 3070, 3030, 2960, 2900, 1600, 1505, 1490, 1450, 1250, 1215, 1155, 850, 725, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$, relative to $SiCH_3$) δ=0.00, 0.02 (s, 9H, $Si(CH_3)_3$), 2.07, 2.13 (s, 2H, -CH_2-Si), 3.95 (s, 2H, C_6H_5-CH_2-C_6H_4), and 6.47—6.77 (m, 9H, C_6H_5-CH_2-C_6H_4); MS (70 eV) *m/z* (M^+); GLC 2 peaks with almost equal area, probably for *o*- and *p*-benzyl isomers.

3-Phenylallyl 2,2,2-Trifluoroethyl Ether: ^{1}H NMR ($CDCl_3$, TMS) δ=3.90 (q, 2H, CH_2CF_3), 4.35 (d, 2H, =CH-CH_2-O), 6.1—6.7 (m, 2H, CH=CH) and 7.2—7.6 (m, 5H, C_6H_5).

Methyl Phenylthiomethyl Ether:[40] IR (neat) 3070, 3000, 2940, 2900, 2830, 1590, 1480, 1440, 1185, 1080, and 900 cm^{-1}; ^{1}H NMR ($CDCl_3$, TMS) δ=3.47 (s, 3H, O-CH_3), 5.00 (s, 2H, S-CH_2-O), and 7.2—7.6 (m, 5H, C_6H_5); MS (70 eV) *m/z* 154 (M^+).

Ethyl Phenylthiomethyl Ether: IR (neat) 3070, 2990, 2940, 2900, 1590, 1480, 1440, 1080, 1015, 840, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$, TMS) δ=1.22 (t, 3H, CH_2CH_3), 3.67 (q, 2H, CH_2CH_3), 4.98 (s, 2H, S-CH_2-O), and 7.1—7.5 (m, 5H, C_6H_5); MS (70 eV) *m/z* 168 (M^+). Found: C, 64.29; H, 7.25%. Calcd for $C_9H_{12}SO$: C, 64.25; H, 7.19%.

Isopropyl Phenylthiomethyl Ether: ^{1}H NMR ($CDCl_3$, TMS) δ=1.17 (d, 6H, CH_3), 3.8—4.3 (m, 1H, CH), 5.00 (s, 2H, S-CH_2-O), 7.1—7.6 (m, 5H, C_6H_5); MS (70 eV) *m/z* 182 (M^+). Found: C, 65.58; H, 7.60%. Calcd for $C_{10}H_{14}SO$: C, 65.89; H, 7.74%.

***t*-Butyl Phenylthiomethyl Ether:** IR (neat) 3070, 2980, 2930, 1585, 1480, 1440, 1395, 1365, 1055, 1025, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$, TMS) δ=1.25 (s, 9H, CH_3), 4.87 (s, 2H, S-CH_2-O), and 7.1—7.5 (m, 5H, C_6H_5); MS (70 eV) *m/z* 196 (M^+). Found: C, 67.20; H, 8.18; S, 16.39%. Calcd for $C_{11}H_{16}SO$: C, 67.30; H, 8.22; S, 16.33%.

Allyl Phenylthiomethyl Ether: IR (neat) 3070, 3030, 2990,

2900, 2860, 1585, 1480, 1440, 1060, 1000, and 930 cm^{-1}; ^1H NMR ($CDCl_3$, TMS) δ=4.17 (d, 2H, O-C<u>H</u>$_2$-CH=), 5.00 (s, 2H, S-CH_2-O), 5.0—5.5 (m, 2H, CH=C<u>H</u>$_2$), 5.6—6.2 (m, 1H, C<u>H</u>=CH_2), and 7.2—7.6 (m, 5H, C_6H_5); MS (70 eV) *m/z* 180 (M^+). Found: C, 66.32; H, 6.86; S, 18.25%. Calcd for $C_{10}H_{12}SO$: C, 66.63; H, 6.71; S, 17.79%.

1-Methylallyl Phenylthiomethyl Ether: IR (neat) 3070, 2990, 2940, 2910, 1740, 1585, 1480, 1440, 1060, 1040, 1025, 995, and 930 cm^{-1}; ^1H NMR ($CDCl_3$, TMS) δ=1.26 (d, 3H, CH_3), 4.35 (quintet, 1H, O-C<u>H</u>(CH_3)CH=), 4.91 (s, 2H, S-CH_2-O), 5.1—5.3 (m, 2H, =CH_2), 5.5—5.9 (m, 1H, -CH=), and 7.2—7.5 (m, 5H, C_6H_5); MS (70 eV) *m/z* 194 (M^+). Found: C, 68.01; H, 7.30; S, 16.47%. Calcd for $C_{11}H_{14}SO$: C, 68.00; H, 7.26; H, 16.50%.

3-Methyl-2-butenyl Phenylthiomethyl Ether: IR (neat) 3060, 3030, 2980, 2910, 2880, 1670, 1585, 1480, 1440, 1200, 1060, 900, and 735 cm^{-1}; ^1H NMR ($CDCl_3$, TMS) δ=1.69 (s, 3H, CH_3), 1.75 (s, 3H, CH_3) 4.17 (d, 2H, O-C<u>H</u>$_2$-CH=), 5.00 (s, 2H, S-CH_2-O), 5.36 (t, 1H, CH_2-C<u>H</u>=), and 7.2—7.7 (m, 5H, C_6H_5). Found: C, 69.11; H, 7.79%. Calcd for $C_{12}H_{16}SO$: C, 69.19; H, 7.74%.

Allyl (*p*-Methylphenylthio)methyl Ether: IR (neat) 3075, 3030, 2980, 2920, 2900, 2860, 1640, 1595, 1490, 1060, 1000, and 920 cm^{-1}; ^1H NMR ($CDCl_3$, TMS) δ=2.33 (s, 3H, CH_3), 4.20 (d, 2H, O-C<u>H</u>$_2$-CH=), 5.00 (s, 2H, S-CH_2-O), 5.1—5.5 (m, 2H, CH=C<u>H</u>$_2$), 5.6—6.3 (m, 1H, C<u>H</u>CH_2), 7.08 (d, 2H, C_6H_4), and 7.38 (d, 2H, C_6H_4); MS (70 eV) *m/z* 194 (M^+). Found: C, 68.29; H, 7.68%. Calcd for $C_{11}H_{14}SO$: C, 68.00; H, 7.26%.

2,2,2-Trifluoroethyl Phenyl(methylthio)methyl Ether: ^1H NMR ($CDCl_3$, TMS) δ=1.98 (s, 3H, CH_3), 3.90 (q, 2H, -CH_2-), 5.73 (s, 1H, S-CH-O), and 7.4—7.8 (m, 5H, C_6H_5).

[Di(methylthio)]phenylmethane: ^1H NMR ($CDCl_3$, TMS) δ=2.10 (s, 6H, CH_3), 4.77 (s, 1H, S-CH-S), and 7.4—7.8 (m, 5H, C_6H_5).

Di(2,2,2-trifluoroethoxy)phenylmethane: ^1H NMR ($CDCl_3$, TMS) δ=3.90 (q, 2H, -CH_2-), 5.87 (s, 1H, O-CH-O), 7.12 (s, 5H, C_6H_5).

Allyl Phenyl(methylthio)methyl Ether: IR (neat) 3080, 3040, 3000, 2930, 2870, 1640, 1600, 1490, 1455, 1070, 1010, and 915 cm^{-1}; ^1H NMR ($CDCl_3$, TMS) δ=1.87 (s, 3H, CH_3), 4.1—4.3 (m, 2H, O-C<u>H</u>$_2$CH=), 5.1—5.6 (m, 2H, CH=C<u>H</u>$_2$), 5.60 (s, 1H, S-CH-O), 5.7—6.4 (m, 1H, C<u>H</u>=CH_2), and 7.1—7.6 (m, 5H, C_6H_5); MS (70 eV) *m/z* 194 (M^+). Found: C, 68.59; H, 7.53%. Calcd for $C_{11}H_{14}SO$: C, 68.00; H, 7.26%.

3-Methyl-2-butenyl Phenyl(methylthio)methyl Ether: IR (neat) 3075, 3040, 2995, 2930, 2870, 1670, 1605, 1495, 1455, 1080, 1060, 1030, and 725 cm^{-1}; ^1H NMR ($CDCl_3$, TMS) δ=1.70 (s, 3H, =C-CH_3), 1.78 (s, 3H, =C-CH_3), 1.90 (s, 3H, S-CH_3), 4.22 (d, 2H, O-C<u>H</u>$_2$-CH=), 5.47 (t, 1H, CH_2-C<u>H</u>=), 5.63 (s, 1H, S-CH-O), and 7.2—7.7 (m, 5H, C_6H_5). Found: C, 70.12; H, 8.27%. Calcd for $C_{13}H_{18}SO$: C, 70.23; H, 8.16%. The product **10** was also identified with an independently synthesized sample[41] by comparing their physical properties.

[2,3]Wittig Rearrangement Reaction of Allyl Phenyl(methylthio)methyl Ether. A THF solution (1 cm^3) of the titled ether (0.203 g, 1.0 mmol) was dropwise added to a mixed solution of diisopropylamine (2.2 mmol), 1.50 M butyllithium/hexane (1.5 cm^3, 2.2 mmol) and THF (5 cm^3) at −80 °C. The temperature was gradually elevated and reached to −20 °C after 4 h. The reaction mixture was poured into a saturated ammonium chloride solution and extracted with ether. The extract was dried over anhydrous sodium sulfate and evaporated under reduced pressure. Allyl phenyl ketone was isolated from the residue by preparative thin layer chromatography (Silica gel, hexane–chloroform (1 : 1)): Yield 0.108 g (74%). The ketone was converted into the 2,4-dinitrophenylhydrazone to be identified. IR (KBr) 3300, 3090, 1610, 1595, 1580, 1505, 1485, 1330, 1310, 1135, 1100, 980, and 920 cm^{-1}; MS (70 eV) *m/z* 326 (M^+). Found: C, 58.79; H, 4.18; N, 17.06%. Calcd for $C_{16}H_{14}N_4O_4$: C, 58.89; H, 4.32; N, 17.17%.

The authors are grateful to Dr. Junichi Yoshida (Osaka City University) for helpful discussion.

The Ab Initio Modeling of Hammett-Type Correlations. The Separation of Inductive Effects from Mesomeric Effects in Aromatic Systems

Jun NIWA
College of General Education, Nagoya University, Chikusa, Nagoya 464-01
(Received April 13, 1988)

Substituent effects have been modeled using both substituted hydrogens and substituted benzenes perturbed with point charges in order to separate the inductive (field) effect from the mesomeric effect with the use of ab initio techniques. Several pure dipole 'substituents' have been introduced to derive the scale of inductive effects common to both aliphatic and aromatic systems. In the above systems the interaction energies have been estimated by dividing into electrostatic interaction and polarization. Calculations with the use of 4-31G basis set show satisfactory correlations with the experimentally determined substituent constants. The propriety of the present approach has also been examined for the gas-phase acidities of phenols.

Recently substituent effects in Hammett correlations have been investigated by Streitwieser et al. with the use of STO-3G basis set ab initio techniques,[1] where substituted benzenes are perturbed with pure point charges in order to model the nonbonded reaction center. They have concluded that most substituents have essentially the same polarizability and that they are, therefore, independent of the reaction-center-charge type.

They have, however, made no explicit estimate of the electrostatic interaction (ES) and polarization (PL) between substituent and probe. Comparison with experimentally determined substituent constants has also shown serious discrepancies in the substituents, such as Cl, CF_3, CHO, and $COCH_3$.

On the other hand, years of analyses of Hammett-type correlations have led to a separation of the inductive (field) effects from the mesomeric (resonance) effects in aromatic systems.[2] It has a priori been based on an implicit consensus that the inductive effect of a substituent is uniformly transmitted to the reaction center independently of any structure variation in the parent compounds throughout aliphatic and aromatic systems, while the mesomeric effect varies greatly depending on the extent to which the reaction center interacts with the substituent.

Several experimental and theoretical attempts have been made to derive the standard scale of the inductive effect inherent in each substituent itself.[2,3] Inconsistencies between the scales appear to be a consequence of how well the interactions other than the electrostatic interaction between substituent and reaction center or probe (namely, such effects as resonance, hyperconjugation, and polarization) are eliminated in the aliphatic systems adopted to derive the scale.

One of the major problems remaining in separating the inductive effects from mesomeric effects is to clarify theoretically whether or not such a standard scale of inductive effect inherent in each substituent can be derived. In order to settle this problem using ab initio techniques, we have chosen isodesmic reactions for the systems of substituted hydrogens, HX, and substituted benzenes, C_6H_5X, perturbed with point charges (+)/and(−)···HX (**1**) and (+)/and(−)····C_6H_5X (**2**), respectively, where point charges are located on the molecular axis in the former and in the para-direction in the latter.

The advantage of Systems **1** and **2** as the reference systems is that the HX molecules in System **1** contain no mesomeric interactions and that no mesomeric effects can be due to direct mesomerc interactions with the perturbing site in System **2**.

In the above systems, several pure dipole 'substituents' carrying different charges have been introduced in order to model pure 'inductive' (field) effect substituents and to make a standard scale of the inductive effect, one common to both aliphatic and aromatic systems. The electronic interactions between substituent and probe have been estimated by dividing into electrostatic interaction (ES) and polarization (PL) by utilizing the energy decomposition analysis.[4]

Furthermore, in order to ascertain the propriety of our approach we have attempted to separate the inductive effect from the mesomeric effect in the gas-phase acidities of phenols,[5] in which there exist strong direct mesomeric interactions between the substituent and the reaction center.

Calculation Methods

Calculations were performed using the IMSPAK series[6] of the computer program at the 4-31G basis level, in which the procedure of energy-decomposition analysis[4] was included. The procedure may be briefly described as follows. We express the Hartree–Fock (HF) wave function for the isolated molecule as ψ^0 and its energy as E_0. If we denote the HF wave function of the molecule perturbed with a point charge and its energy as ψ^1 and E_1 respectively, the HF total interaction energy, ΔE_{SCF}, is given by:

$$\Delta E_{SCF} = E_1 - E_0$$

The electrostatic interaction (ES) is the interaction

between the undistorted electron distribution of the molecule and the point charge. In our scheme, ES is calculated as the difference between E_2 and E_0, E_2 being the energy associated with the wave function ψ^0:

$$ES = E_2 - E_0$$

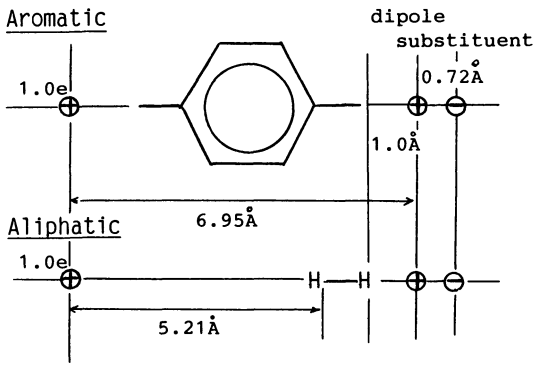
The polarization (PL) is the effect of the distortion of the electron distribution of the molecule by the point charge. Then the difference E_1-E_2 corresponds to the energy change due to the polarization by the point charge:

$$PL = E_1 - E_2$$

The geometries of the benzenoid rings were maintained constant for each substituent; r_{C-C}=1.39 Å r_{C-H}=1.083 Å, and all angles=120°. The geometries of the substituent groups were taken from the experimentally determined values.[7] In the geometry of a pure dipole 'substituent', we have taken the same geometry as Streitwieser et al.[1] used; that is, a positive pole carrying a charge (1.0e) was located at 1 Å from the hydrogen atom of the parent compound, and the distance between positive and negative poles was taken to be 0.72 Å so as to coincide with the dipole moment experimentally determined for nitromethane (3.5 D). The other dipole substituents were set up to carry 0.3e and 0.5e respectively.

The unit point charge of the probe was located at 1 Å from the hydrogen atom along the C-H bond in the para-position in C_6H_5X and at 5.21 Å in HX molecules so as to make their values equal to the distance from the positive pole of the dipole substituent in System **2** (see the Scheme 1 below).

As the means of evaluating the substituent effects on the above perturbed molecules, the following isodesmic reaction was used:



Scheme 1.

$$\underset{A}{RX} + (\pm)\cdots\underset{B}{RH} \rightarrow \underset{C}{RH} + (\pm)\cdots\underset{D}{RX} \quad (1)$$

where X represents a substituent, and RH, a parent compound. The total change in the energy($\delta\Delta E_{SCF}$) for the isodesmic reaction was obtained using Eq. 2. It corresponds to a substituent effect for the perturbed system:

$$\delta\Delta E_{SCF}=(E_C + E_D) - (E_A + E_B)=(E_D - E_A) - (E_B - E_C)=\Delta E_{subst} - \Delta E_H \quad (2)$$

A negative value in $\delta\Delta E_{SCF}$ corresponds to the energy which is stabilized compared with that of the parent compound.

Results and Discussion

The total energies, E_0, E_1, and E_2, are summarized in Tables 1 and 4. The respective energy changes, $\Delta E_{SCF}(\Delta E_{subst})$, are summarized in Tables 2 and 5, where they are also shown divided into electrostatic interactions (ES) and polarization (PL). As may clearly be seen from the tables, the contributions of PL

to the total interaction energies, ΔE_{SCF}, are small compared with those of ES, except for X=H and CH_3 in Systerm **1**, while those of PL are much more than those of ES in System **2**. However, the contributions of PL to the isodesmic energies ($\delta\Delta E_{SCF}$) (Tables 3 and 6) are almost the same in magnitude in the two systems; as a whole, their contributions to the substituent effects are small compared with those of ES.

According to the comments of Streitwieser et al.[1] the original assumptions for the Hammett equation were that the susbstituent constants are independent of the nature of the reactions and that a different charge center changes only the sign of the reaction constant. Strictly speaking, these assumptons are valid only in an approximate sense. The latter assumption should be restricted only to the electrostatic interactions because the contributions of PL act as a disturbing factor for the assumption, even in the present model systems, which are perturbed only with point charges.

Figure 1-(a) shows plots of the $\delta\Delta E_{SCF}$ values in System **1** perturbed with positive and negative charges, where the dotted line of a unit slope is drawn through the points for the δ ES values. The deviations from the line show the contributions of PL to the substituent effects. Such contributions can almost be ignored in System **1**. The solid line shows the correlation between the $\delta\Delta E_{SCF}$ values of the systems (the value of slope: −0.99, correlation coefficient: r=0.998, goodness of 'fit':[8] f=0.03). These results practically satisfy the original assumptions for the Hammett equation including the dipole 'substituents'; this means that System **1** can be used as a reference system to derive a standard scale of the inductive effect independent of the charge type of the probe. On the other hand, the contributions of PL to the substituent effects in System **2** are rather too large to ignore (Fig.1-(b)), and those perturbed with positive point chrges are a little larger than those perturbed with negative point charges (r=0.985, f=0.13). These results imply that the standard σ^0 values experimentally derived in cationic

systems must be somewhat different from those derived in anionic systems. Therefore, in order to derive experimentally the 'inherent' substituent constants, it is necessary to choose the system in which there exists no polarization contribution arising from charged probe centers and in which complicating solvent effects have been eliminated as much as possible. Recently several attempts have been performed to derive 'inherent' substituent constants by utilizing gas-phase reactions.[9] However, all the reactions thus far examined have carried charged probe centers and also contained additive resonance interactions between the substituents and the reaction center.

Therefore, up to the present, the σ_R^0 values redefined

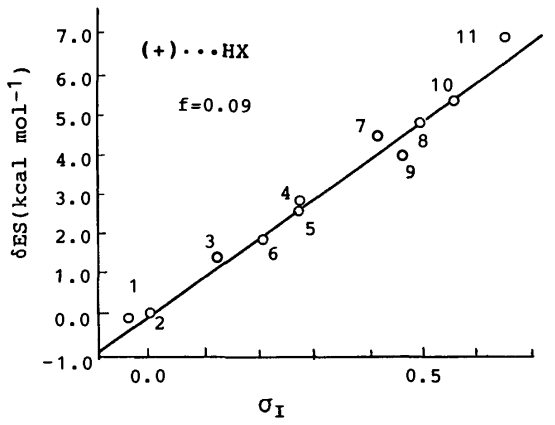

Fig. 2. Plots of δES against σ_I for the positive point charge perturbed substituted hydrogens (HX). The numbering corresponds to that in Table 3.

by Taft et al.[10] appear to be the nearest to the original assumptions for the Hammett equation; they have been determined on the basis of the substituent chemical shift, ^{13}C, at the para-position (C_p-SCS) of monosubstituted benzenes in diluted 'inert' solvents and, therefore, the ^{13}C 'probe' is a part of the 'neutral' aryl ring unperturbed by the charge. In the present analysis we will define the experimental 'inherent' substituent constants σ^0 (inh) using σ_I and σ_R^0 values determined by Taft et at.,[10] that is, $\sigma^0(\text{inh})=\sigma_I+\sigma_R^0$ (Table 2 in Ref. 10).

Figure 2 shows plots of the δ ES in System **1** against the σ_I values determined by Taft et al.,[10] where representative eleven substituents are chosen. The δES values obtained at 4-31G show a 'good' fit (r=0.989, f=0.09), while those at STO-3G show serious discrepancies in the substituents F, Cl, CF_3, CHO, and $COCH_3$.

Theoretical approaches to derive the field-effect parameter (σ_F) have also been performed by several workers, using the isodesmic reactions (NH_4^+/HX), measuring the polarization of a bond produced in an isolated moloecule by the HX molecule (HH/HX), and using the electrostatic potentials ($EP_{(HX)}$) obtained from the interaction of a positive charge at a determined geometry from a HX molecule, and so on.[3b] The third approach is essentially identical with that of Streitwieser et al.[1] The $\sigma_{F(theo)}$ values recommended by Topsom are summarized in Ref. 3b (Table 19 on p. 166). The correlation of δES and $\sigma_{F(theo)}$ values showed a 'good' fit (r=0.988, f=0.10, n=11), while that of δES and $EP_{(HX)}$ was properly excellent (r=0.997, f=0.05, n=9).

Figure 3 shows plots of the δES against values $\sigma^0(\text{inh})=(\sigma_I+\sigma_R^0)$[10] in System **2**. The δES values obtained at 4-31G also show a 'fair' fit for the eleven substituents (r=0.988, f=0.13). In this case, too, values obtained at STO-3G show serious discrepancies for the substituents, CF_3, CHO, $COCH_3$, and Cl. The correla-

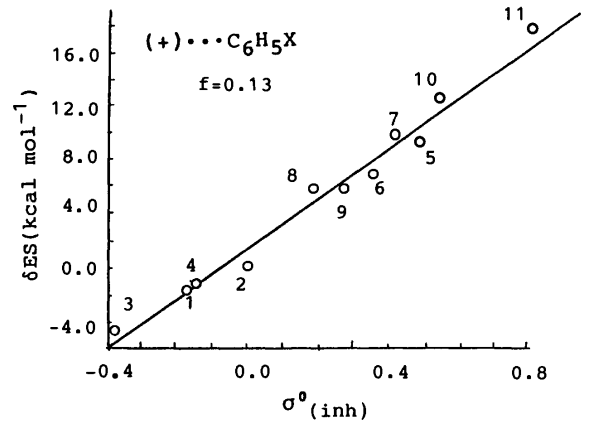

Fig. 3. Plots of δES against σ^0(inh)($=\sigma_I+\sigma_R^0$) for para-substituted benzenes (C_6H_5X). The numbering corresponds to that in Table 6.

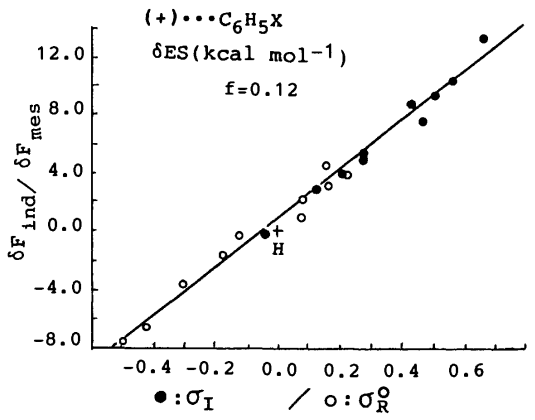

Fig. 5. Correlation between δF_{ind} and δF_{mes} against $\sigma_{I(inh)}$ and σ_R^0, respectively, on the same regression line.

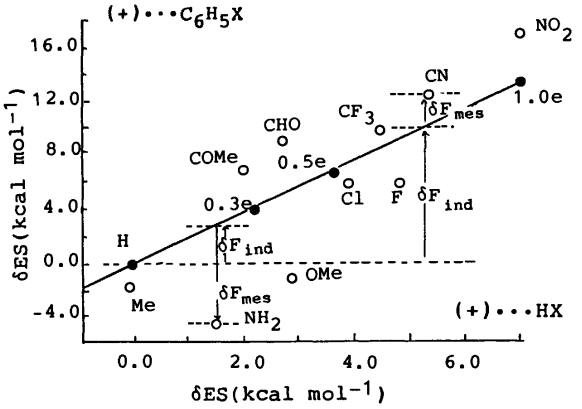

Fig. 4. Separation of inductive effects from mesomeric effects. Plots of δES for the positive point charge perturbed substituted hydrogens (HX) and benzenes (C_6H_5X). A regression line shows the correlation between hydrogen and dipole substituents. The deviations from the line (δF_{ind} and δF_{mes}) correspond to the inductive and mesomeric contributions of substituents in C_6H_5X.

tion between the $\delta\Delta E_{SCF}$ values which contain the contribution of PL and σ^0(inh) also shows a 'fair' fit (r=0.985, f=0.16 and r=0.988, f=0.13 for both systems, perturbed with positive and negative point charges respectively).

Figure 4 shows plots of the δES values in System **2** against those in System **1** perturbed with the positive point charge, where the correlation line is drawn for three 'dipole' substituents and hydrogen to derive the scale of inductive effects in aromatic systems (r=0.999, f=0.03). The intersecting point of a perpendicular line drawn from a substituent with the correlation line corresponds to its inductive effect, because it contains no mesomeric interactions and it is a quantity directly proportional to the inductive effect in System **1**. Points above the line correspond to π-destabilizing groups, while points below the line correspond to π-stabilizing groups. Thus, deviations from the correlation line correspond to the 'mesomeric effects' in the Hammett equations.

There can not be any direct mesomeric interactions between a substituent and a probe in System **2**. Therefore, the mesomeric contribution must be attributed to the field effect caused by the distribution of charges on the molecule, a distribution which stems from a strong interaction between the π-system of the benzene ring and suitable orbitals on the substituent group. Hereafter, we will abbreviate the former effect as δF_{ind}, and the latter, as δF_{mes}. The latter is expected to be proportional to the experimentally determined σ_R^0 values. The values of δF_{ind} and δF_{mes} are summarized in Table 9, while those of σ_I, σ_R^0, and σ_R^- (g)[5] are cited in Table 10.

Figure 5 shows plots of δF_{ind} against σ_I and those of δF_{mes} against σ_R^0. The correlation shows a 'fair' fit (r=0.991, f=0.12) on the same correlation line; no substituents examined show any serious deviations from the correlation line.

The theoretical σ_R^0 values have also been derived by the calculation of the overall π-electron transfer, $\sum q_\pi$, in monosubstituted benzenes and ethylenes.[3b] The correlation of δF_{mes} with the $\sigma_{R(theo)}^0$ values was 'fair' (r=0.986, f=0.18, n=11), while δF_{mes} was well correlated with the experimental σ_R values summarized by Topsom (Table 1 in p. 16 of Ref. 3b) (r=0.992, f=0.13, n=11).

Strictly speaking from the experimental point of view, a common scale of inductive effects exists, of course, only in an approximate sense. In the present approach, a common scale of inductive effects throughout the aliphatic and aromatic systems has been obtained by the introduction of the pure dipole 'substituents'. Our results imply that the hypothetical dipole of the substituent group in the aromatic system which corresponds to that of the aliphatic system can be estimated from the correlation line. Although the pure dipole 'substituents' are undoubtedly not actual,

the existence of the common scale is guaranteed since they are intrinsically of an abstract nature.

The propriety of the present approach has further been investigated for the gas-phase acidities of *p*-substituted phenols.[5] The corresponding isodesmic reaction is:

$$XC_6H_4OH + C_6H_5O^- \rightarrow XC_6H_4O^- + C_6H_5OH \quad (3)$$

where the geometries of the parent compounds, C_6H_5OH and $C_6H_5O^-$, were optimized by means of the energy-gradient method at the 3-21G level,[11] while those of the substituent groups were taken from the experimentally determined values.

The total energies calculated at 4-31G for *p*-substituted phenols and phenoxide ions are summarized in Table 7. The isodesmic energies ($\delta\Delta E_{SCF}$) are summarized in Table 8 and compared with the experimentally obtained values.[12] The calculations considerably overestimated the observed substituent effects ($\delta\Delta G^0$ (g) kcal mol^{-1}). As may clearly be seen from Fig. 6, however, the correlation between observed and calculated values shows almost a 'good' fit (r=0.993, f=0.11) for all the substituents measured.

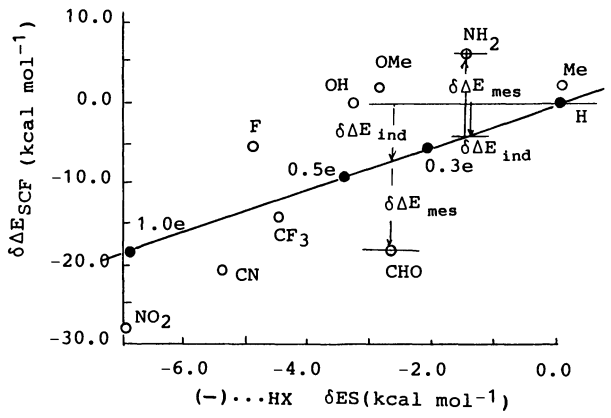

Fig. 7. Separation of inductive effects from mesomeric effects. Plots of the isodesmic energy changes ($\delta\Delta E_{SCF}$) for *p*-substituted phenols against δES for negaitive point charge perturbed hydrogens. A regression line shows the correlation between hydrogen and dipole substituents. The deviations from the line ($\delta\Delta E_{ind}$ and $\delta\Delta E_{mes}$) correspond to the inductive and mesomeric contributions of substituents.

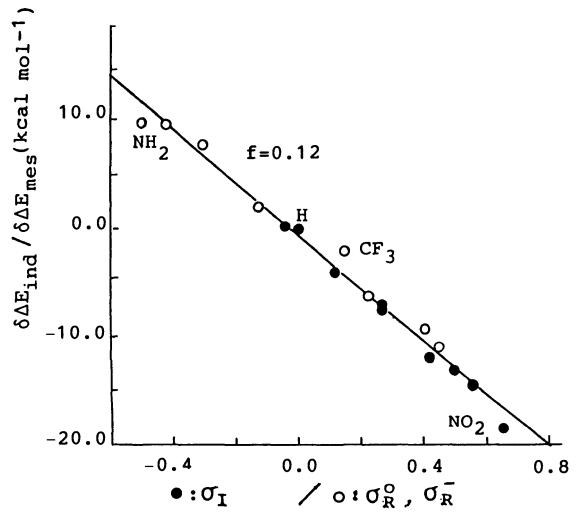

Fig. 8. Correlation between $\delta\Delta E_{ind}$ and $\delta\Delta E_{mes}$ against σ_I and σ_R^0(for EDG)/σ_R^-(g)(for EWG), respectively, on the same correlation line.

is drawn for three dipole 'substituents' and hydrogen. The correlation is very good (r=1.000, f=0.001). By the same procedure as that described in System **2**, the inductive effects ($\delta\Delta E_{ind}$) can be estimated. The points above the line correspond to π-destabilizing groups (electron donating groups; EDG), while the points below the line correspond to π-stabilizing groups (electron withdrawing groups; EWG). Thus, deviations from the correlation line correspond to mesomeric effects ($\delta\Delta E_{mes}$). Therefore, the deviations above the line may be expected to be proportional to the σ_R^0 values, while the downward deviations may be expected to be proportional to the σ_R^- (g) values.

Figure 8 shows plots of $\delta\Delta E_{ind}$ against σ_I and also plots of $\delta\Delta E_{mes}$ against σ_R^0 for EDG and against σ_R^- (g) for EWG. The correlation shows a 'fair' fit (r=0.992, f=0.12) on the same correlation line.[13]

The present approach provides us with theoretical grounds for the separation of the inductive effect from the mesomeric effect in aromatic systems. It can also be applied to gas-phase reactions in which the reaction center carries a positive charge. We will present the results of analyses of these in succeeding papers.

The numerical calculations were carried out on a FACOM M-382 computer at the Nagoya University Computation Center.

12) Calculations were also performed for some phenoxide ions with 4-31+G, where a diffuse sp function (exponent: 0.068) is taken into account. Althoguh the total energies were improved (for example, X=H; −304.54540, X=NO_2; −507.72919 (hartree)), the isodesmic energy was not so much affected ($\delta\Delta E_{SCF}$ for X=NO_2: −26.1 kcal mol^{-1}).

13) When σ_R^- (g) values were used for the EDG, the correlation partly collapsed for F and NH_2 (r=0.986, f=0.16).

Effective Doping of Polymer Anion during Chemical Polymerization of Pyrrole Using $Fe(OH)_3$ Oxidant

Akira OHTANI† and Takeo SHIMIDZU*
Division of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
†Central Research Laboratory, Nitto Electric Industrial Co., Ltd., Ibaraki, Osaka 567
(Received May 16, 1988)

Polypyrroles were prepared by the chemical polymerization of pyrrole using various combinations of Fe^{3+} oxidants and electrolytes. The morphology and yield of the resulting polymers were affected by the property of the electrolyte anion in the oxidative solution. The size of the particles of the resulting polymers was decreased by using a high-molecular-weight polymer anion as the electrolyte anion. Both the polymer anion and Cl^- were incorporated as a dopant into the polypyrrole matrix during the chemical polymerization of pyrrole, using an aqueous solution containing both $FeCl_3$ and the polymer anion. On the contrary, the polymer anion was effectively incorporated as a dopant into the polypyrrole matrix during the chemical polymerization of pyrrole, using an aqueous solution containing both $Fe(OH)_3$ and the polymer acid. A novel type of chemical preparation of the polypyrrole-polymer anion composite using the $Fe(OH)_3$ oxidant and the polymer acid was developed.

Conducting polypyrrole (PPy)[1-6] has applications in such equipment as electronic devices,[7,8] electrochromic displays,[9-11] polymer batteries,[12-15] polymer modified electrodes,[16] and functional membranes.[17-20] An electrochemical polymerization, a chemical polymerization, and a photo-electrochemical polymerization of pyrrole easily provided conducting PPy. Moreover, many hydridization procedures of PPy have been developed so as to improve the properties of PPy.[21-40] In electrochemical polymerization, dopant anions are freely chosen, since they act as supporting electrolytes. Many kinds of PPy-functional anion composites have been prepared.[21-23,32,33] The functional anions to be doped were such as electrochromic molecules, photosensitive molecules, nucleic acids, amino acids, tenside anion, and polymer anions. In the chemical polymerization of pyrrole in a solution containing both an oxidant and a functional anion, an anion of oxidant, e.g. Cl^- of $FeCl_3$, is easily incorporated as a dopant into the PPy matrix, though the doping of the functional anion is not efficient. However, chemical polymerization is a useful method for preparing of large amount of conducting polymers, since it is performed without electrodes.[41-45] In this study, $Fe(OH)_3$ was chosen as an oxidant; and discussions are presented concerning the effective doping of the polymer anion into the PPy matrix during the chemical polymerization of pyrrole in H_2O containing the $Fe(OH)_3$ oxidant and the polymer acid.

Experimental

Materials. Pyrrole (Aldrich Chemical) was distilled and stored under a N_2 atmosphere. $FeCl_3 \cdot 6H_2O$ (Wako Chemical), $Fe_2(SO_4)_3$ (Wako Chemical), sodium 1-propanesulfonate (PSNa) (Nakarai Chemical), and 1-propanesulfonic acid (PSH) (Kodak) were used without further purification. $Fe(OH)_3$ was prepared by adding a $FeCl_3$ aqueous solution to a NaOH aqueous solution; then, the precipitate of $Fe(OH)_3$ was filtered to remove Na^+ and Cl^-. Sodium polyethylenesulfonate (PESNNa) was prepared by the polymerization of sodium ethylenesulfonate (Tokyo Kasei), using a combination of potassium peroxodisulfate (Wako Chemical) and sodium hydrogensulfite (Wako Chemical) as a redox-initiator in H_2O. The degree of polymerization was controlled by varying the polymerization time. Polyethylenesulfonic acid (PESNH) and polystyrenesulfonic acid (PSSH) were obtained by an ion-exchange treatment of PESNNa and sodium polystyrenesulfonate (Toyo Soda) through ion-exchange column (DOWEX 50W-12; Dow Chemical), respectively.

Preparation of PPy. Reaction of Pyrrole with $FeCl_3$ and $Fe_2(SO_4)_3$ Aqueous Solutions: Pyrrole (0.187 ml) was added to a 10 ml $FeCl_3$ aqueous solution (0.54 mol dm^{-3}) or in 10 ml $Fe_2(SO_4)_3$ aqueous solution (0.27 mol dm^{-3}); the solution instantly acquired a black color as the PPy precipitate was formed. After 2 hours at room temperature, the mixture was filtered and the precipitate was washed with distilled water. After a final rinse with acetone, the black powder was dried in vacuo.

Reaction of Pyrrole with $FeCl_3$ Aqueous Solution Containing Polymer Anion: Pyrrole (0.187 ml) was added in 10 ml $FeCl_3$ aqueous solution (0.54 mol dm^{-3}) containing 1.62 mol dm^{-3} PESNNa; the solution instantly acquired a black color as the PPy precipitate was formed. After 2 hours at room temperature, the mixture was filtered and the precipitate was washed with distilled water. After a final rinse with acetone, the black powder was dried in vacuo.

Reaction of Pyrrole with $Fe(OH)_3$: An acid (PSH, PESNH, or PSSH) (0.0162 mol) was added to 10 ml of H_2O containing pyrrole (0.0027 mol) and suspended $Fe(OH)_3$ (0.0054 mol); the solution instantly acquired a black color. After 2 hours at room temperature, the mixture was filtered and the precipitate was washed with distilled water (in the case that the precipitate was obtained). On the contrary, when a precipitate was not obtained, the mixture was centrifuged at 3000 rpm; then, the supernatant was disposed of. The remaining mixture was filtered and the precipitate was washed with distilled water. After a final rinse with

acetone, the black powder was dried in vacuo.

Measurements. The conductivity was measured by using a standard van der Pauw method. The PPy powder was molded into a disk by pressing. Scanning and transmission electron microscopic (SEM and TEM) observations were carried out with a Hitachi S-450 and a Hitachi H-800, respectively. The preparation of ultrathin sections of the resulting polymers used for TEM observations was carried out by cutting the PPy powder dispersed PET film, which was embedded in epoxy resin (Polysciences), with an ultra microtome (Sorvall, MT-6000). An elementary analysis of Fe atoms in the PPy matrix was carried out with an X-ray Microanalyzer attachment (Hitachi H-8010).

Results and Discussion

Table 1 shows the conditions of the chemical polymerization of pyrrole using various Fe^{3+} oxidants and electrolytes, as well as the characteristics of the resulting polymers. Pyrrole was polymerized by $FeCl_3$ and $Fe_2(SO_4)_3$ aqueous solutions containing no other electrolyte. The resulting polymers (PPy/Cl^- and PPy/SO_4^{2-}) were precipitated, and black powders were obtained by filtration. On the contrary, pyrrole was not polymerized by $Fe(OH)_3$ suspended H_2O containing no electrolyte. Upon adding an electrolyte, PSNa or PESNNa, into the $Fe(OH)_3$ suspended H_2O, pyrrole was not polymerized either. It was considered that $Fe(OH)_3$ cannot oxidize pyrrole. Upon adding an acid, PSH, PESNH, or PSSH, into the $Fe(OH)_3$ suspended H_2O, $Fe(OH)_3$ was dissolved and pyrrole was polymerized. When PSH and low-molecular-weight PESNH (η_{inh}=0.05) were used as an electrolyte, the resulting polymers (PPy/PS^- and PPy/$PESN^-$(1)) were precipitated. In contrast, when high-molecular-weight PESNH (η_{inh}=0.19 and 0.24) and PSSH (η_{inh}=0.77) were used as an electrolyte, the resulting polymers (PPy/$PESN^-$(2), PPy/$PESN^-$(3), and PPy/PSS^-) were suspended. On the other hand, the resulting polymer (PPy/mix.) prepared by $FeCl_3$ aqueous solution containing PESNNa (η_{inh}=0.19) was precipitated. PPy/PS^-, PPy/mix., and PPy/$PESN^-$(1) were easily obtained by filtration. On the contrary, PPy/$PESN^-$(2) and PPy/$PESN^-$(3) were obtained by a combination of centrifugation (3000 rpm) and filtration. Particles of these polymers did not precipitate perfectly. The PPy/PSS^- did not precipitate upon centrifugation (3000 rpm). These results indicate that the size of the particles of the resulting polymer depended on the property of the electrolyte anion.

Table 2 shows elementary analysis and conductivity data of the resulting polymers. These PPy had as high conductivity (ca. 10^0 S cm^{-1}) as PPy prepared by electrochemical polymerization in H_2O.[37] The Cl/N and the S/N ratios allowed us to estimate the ratio of incorporated anions to the pyrrole moiety (f). As for the polymer anion, the present f-value does not necessarily indicate the doping ratio, since the existence of

PPy/$PESN^-$ (3)	3.93	43.22	10.79	9.33	0	0	0.378	0.378	0.18

a) f=Cl/N+S/N. b) f=S/N×2.

the undoped sulfonate moiety in the PPy matrix was observed (as mentioned below). PPy/PESN$^-$ had a higher f-value than PPy/Cl$^-$ and PPy/SO_4^{2-}. As for PPy/mix., because of the existence of Cl and S atoms in the PPy matrix, both Cl$^-$ and PESN$^-$ seemed to be incorporated as a dopant into the PPy matrix. Interestingly, the f-value of PESN$^-$ was 4-times larger than that of Cl$^-$, in spite of the same concentration of the two anions in the oxidative solution. A similar behavior was observed for the PPy prepared by electrochemical polymerization in H_2O containing both the polymer anion and ClO_4^- as an electrolyte anion.[46] This result indicates that the polymer anion was easily incorporated, compared with the small anion, owing to a multi-negative charge. However, doping by only the polymer anion was not expected when $FeCl_3$ was used as an oxidant. When $Fe(OH)_3$ was used as an oxidant, on the contrary, effective doping by the polymer anion seemed to be achieved, since only S atoms existed in the PPy matrix. Because the $Fe(OH)_3$ oxidant and PESN$^-$ gave the PESN-Fe and H_2O, the polymer anion was the only anionic species in the oxidative solution. Therefore, the polymer anion could be incorporated as a dopant into the PPy matrix.

Table 3 shows the molecular weight (MW) per residue of the resulting polymer and yield. The MW per residue was calculated by using the f-value, the MW of pyrrole moiety, and the MW of anion:

$$\text{MW per residue} = (\text{MW of pyrrole moiety}) + (\text{MW per one anion moiety}) \times f. \quad (1)$$

Assuming that the f-value corresponds to the real doping ratio, the theoretical yield was calculated in terms of the moles of the oxidant used, the f-value, and the MW per residue. $(2+f)$ electrons were consumed

Table 3. Molecular Weight per Residue of the Resulting Polymer and Yield

PPy	MW per residue	Theoretical yield/g	Experimental yield/g	Yield/%
PPy/Cl$^-$	72.2	0.177	0.180	102
PPy/SO_4^{2-}	75.8	0.184	0.180	98
PPy/mix.	82.3	0.203	0.208	102
PPy/PESN$^-$ (1)	106.9	0.241	0.233	97
PPy/PESN$^-$ (2)	103.9	0.238	0.176	74
PPy/PESN$^-$ (3)	106.0	0.241	0.158	66

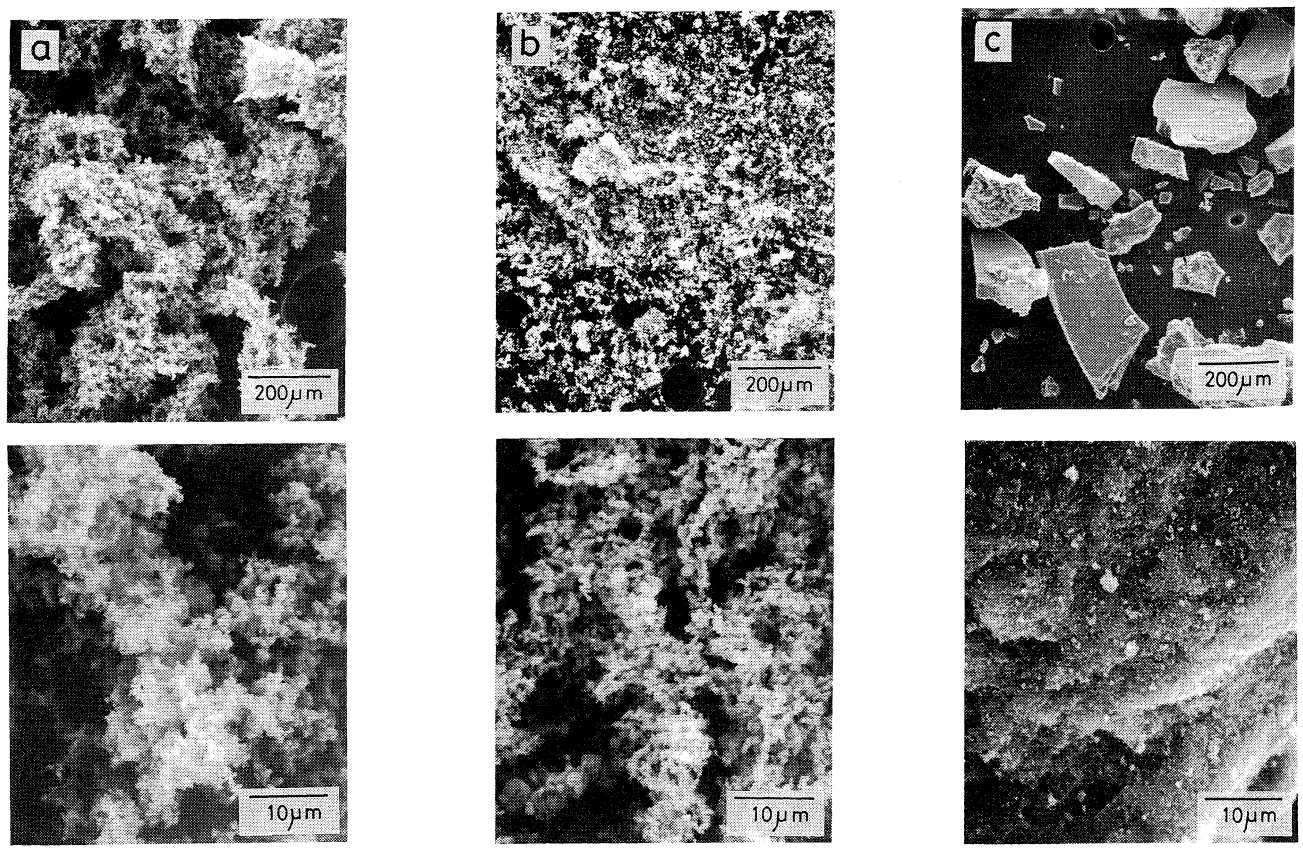

Fig. 1. Typical SEM photographs of the resulting polymers. Accelerating voltage was 15 kV. (a) PPy/SO_4^{2-}, (b) PPy/PESN$^-$(1), (c) PPy/PESN$^-$(3).

during the oxidative polymerization of one pyrrole. Thus,

$$\text{(mole of oxidant used)/(mole of pyrrole consumed)} = [2(x-1)+(fx)]/x;$$

$$\text{if } x \text{ is large,} \quad \simeq 2+f.$$

Here, x denotes the degree of polymerization. Accordingly,

$$\text{Theoretical yield} = [\text{(mole of oxidant used)}/(2+f)] \times \text{(MW per residue)}. \quad (2)$$

The yields for PPy/Cl^-, PPy/SO_4^{2-}, PPy/mix., and PPy/PESN$^-$(1), which were precipitated, were ca. 100%. The yields for PPy/PESN$^-$(2) and PPy/PESN$^-$(3), which were suspended, were low.

Figures 1(a)—(c) show typical SEM photographs for the resulting polymers. The morphology of the resulting polymers was affected by the size of the dopant. Powders of PPy with a small-size anion and PPy with a low-molecular-weight polymer anion have clusters of globules with void spaces between, as shown in Fig. 1(a) and (b). On the other hand, powders of PPy with a high-molecular-weight polymer anion were curds composed of very small particles, as shown in Fig. 1(c). Figures 2(a)—(d) show typical TEM photographs of the resulting polymers. The size of particles estimated by TEM photographs were 2800—4000 Å, 2000—2800 Å, 800—1200 Å, and 200—400 Å for PPy/Cl^-, PPy/mix., PPy/PESN$^-$(2), and PPy/PSS^-, respectively. The higher molecular-weight of the polymer anion seems to give a smaller size of PPy particle. PPy/mix. showed an intermediate property between PPy/Cl^- and PPy/PESN$^-$(2). These photograph observations indicates that the polymer anion, which has a multi-negative charge, acted as an inhibitor for the growth of PPy particles. The existence of a small amount of Fe atom was observed in the PPy matrix in the X-ray microanalysis measurement. The present Fe atom was considered to be a counter cation of sulfonic acid of the polymer anion, since it was removed from the PPy matrix by washing

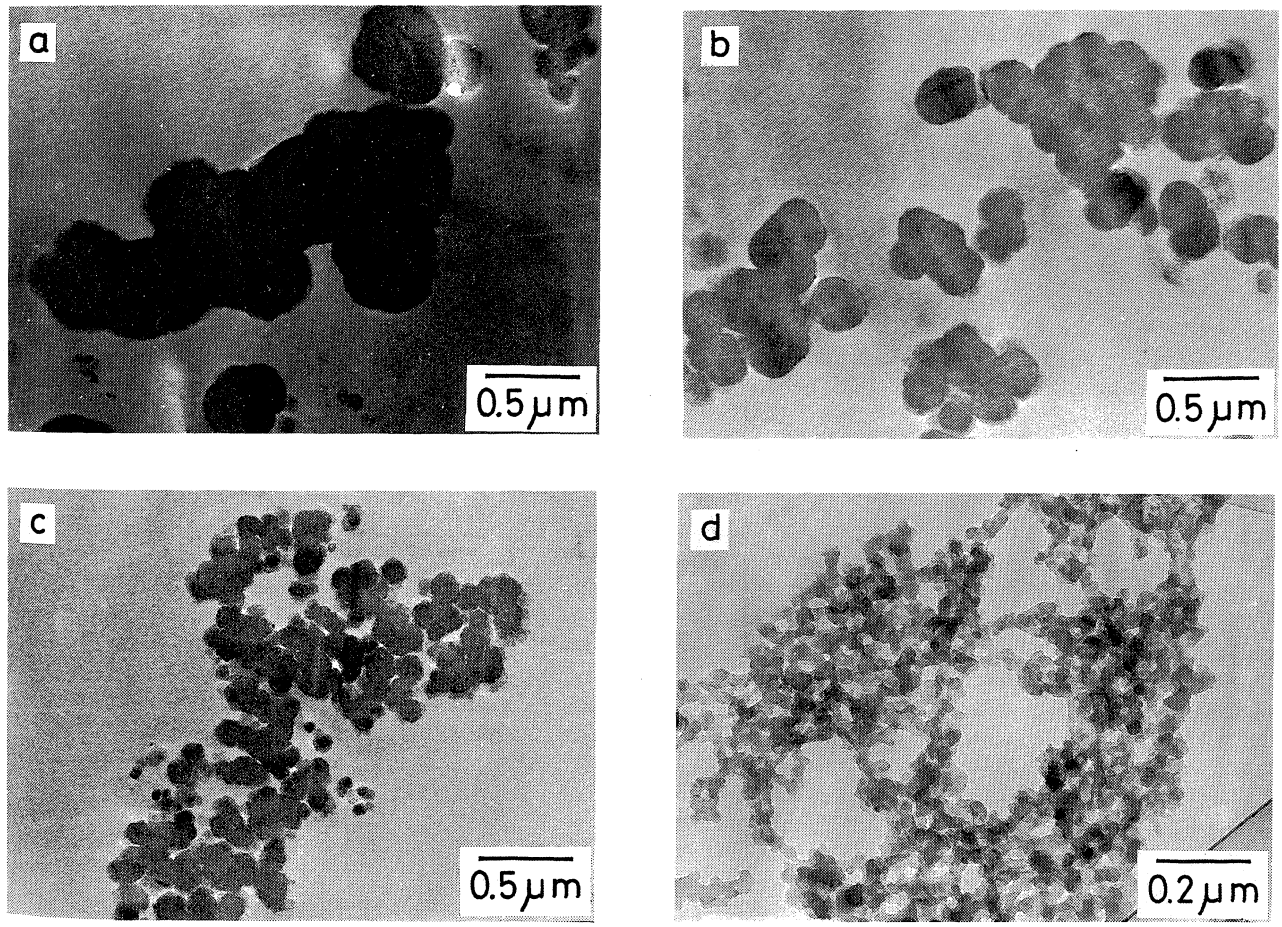

Fig. 2. Typical TEM photographs of the resulting polymers. Accelerating voltage was 100 kV. Ultra-thin section of (a) PPy/Cl^-, (b) PPy/mix., and (c) PPy/PESN$^-$(2), and dispersion of (d) PPy/PSS^-.

using an HCl aqueous solution. Moreover, PPy/PESN$^-$ had a higher doping ratio than PPy/Cl^- and PPy/SO_4^{2-}, as mentioned above. Thus, it was considered that there are a considerable amount of undoped polymer anions in the PPy matrix. It is speculated that during the chemical polymerization of pyrrole, the partly incorporated polymer anion into PPy has a considerable amount of free, undoped sulfonic acid, so that PPy was prevented from aggregation, owing to the high charge density of the remaining undoped sulfonic acid. Low yields of PPy/PESN$^-$(2) and PPy/PESN$^-$(3) could be explained by the unrecovered smaller particle of PPy. It was concluded that the $Fe(OH)_3$ oxidant has a capability to effectively dope the acid and that the morphology of the resulting polymers can be controlled by the property of the electrolyte anion.

The present method, using an $Fe(OH)_3$ oxidant and an acidic solution, is considered to be one of the effective hybridization procedures in conducting polymer syntheses.

We thank Mr. Hajime Tsuchiya, Nitto Technical Information Center, for his TEM observations.

Highly Stereoselective Palladium(0)-Catalyzed Allylation of Active Methylene Compounds with Allyl Imidates under Neutral Conditions

Osamu SUZUKI, Seiichi INOUE, and Kikumasa SATO*
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received July 22, 1988)

In the presence of a catalytic amount of Pd(0), active methylene compounds were allylated by allyl imidates under neutral conditions. In allylation with 3,3-disubstituted allyl imidates, e.g., geranyl and neryl imidate the effect of solvent and ligand to the *E/Z* ratio are investigated. The reaction in dimethyl sulfoxide by addition of diphosphine, e.g., 1,2-bis(diphenylphosphino)ethane, or large excess of triphenylphosphine as additive ligand gave best results. In these conditions, various active methylene compounds were allylated stereoselectively, especially complete retention of starting olefin geometry was achieved with neryl imidate.

Palladium-catalyzed allylation of carbanions is one of the useful methods for carbon–carbon bond formation; allyl acetates are commonly used as precursors of π-allylpalladium intermediates in the presence of a stoichiometric amount of bases such as NaH for the generation of a carbanion to be allylated.[1] It would be more valuable if the reaction could be carried out without addition of a base. Allylation using allyl carbonates under neutral conditions has also been reported.[1c]

Many bioactive compounds which have *trans*-isoprene units are known, and in recent years several kinds of polyprenols containing *cis*-isoprene units such as betulaprenols,[2,3] undecaprenol,[4] dolichols,[5] and others[6] have been isolated. An efficient method for stereoselective introduction of isoprene units is strongly desired, but stereoselective allylation via π-allylpalladium species had not been achieved until we recently reported that active methylene compounds were allylated by *O*-(allyloxycarbonyl)oximes with high stereoselectivity in the presence of catalytic amounts of bases.[7]

The present paper describes the highly stereoselective allylation of various active methylene compounds with allyl imidates under neutral conditions.

Results and Discussion

Although stoichiometric amounts of the bases were needed, palladium catalyzed allylic alkylation to active methylene compounds took place with allyl acetates smoothly. We anticipated that allylimidates **1**, imine analogues of esters, would be reactive toward palladium to generate π-allylpalladium species[8] and would also be capable of liberating imidate anions which are basic enough to generate carbon nucleophiles from active methylene compounds (Scheme 1).

A series of imidates was prepared by either the reaction of imidoyl chloride with alkoxide[9] or the reaction of ethyl imidate with allylic alcohols.[10]

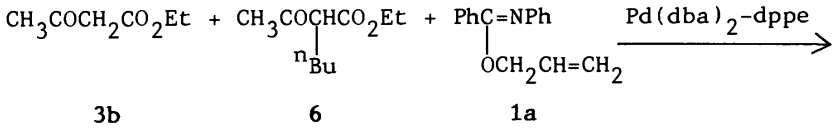
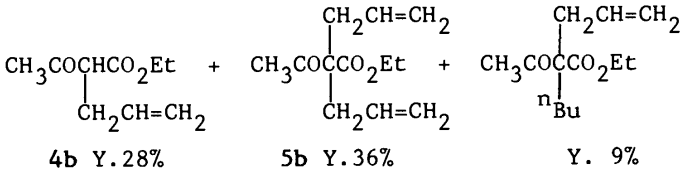
a) The reaction was carried out by using 2 mol% of Pd(dba)$_2$-dppe in DMF at r.t. Ts=*p*-$CH_3C_6H_4SO_2$. b) Isolated yield. c) PPh_3 (4 equiv to Pd(0)) was used instead of dppe. d) The reaction was carried out at 85 °C.





Scheme 3.

(R^1=Ph, R^2=Ph) with various active methylene compounds **3** was found to proceed smoothly in the presence of bis(dibenzylideneacetone)palladium (Pd(dba)$_2$) (2 mol%) and 1,2-bis(diphenylphosphino)ethane (dppe) (2 mol%) in *N*,*N*-dimethylformamide (DMF) to yield a mixture of monoallylated **4** and diallylated compounds **5** in good combined yields (Scheme 2). The results are summarized in Table 1. The ratio of diallylation to monoallylation products decreased in almost the reverse order of the acidity of active methylene compounds. Various kinds of imidates **1** (R^1=Ph, H, Me, R^2=Ph, H) were similarly effective for this allylation reaction. Tetrahydrofuran (THF), chloroform, benzene, acetonitrile, dimethyl sulfoxide (DMSO), and hexamethylphosphoric triamide (HMPA) were also effective as solvents; the addition of triphenylphosphine (PPh_3) or dppe is absolutely necessary, but the allylation did not take place with tributylphosphine, trimethyl phosphite, or tri-*o*-tolylphosphine.

To examine the concurrent formation of the diallylation products a competition experiment was conducted. When an equimolar mixture of ethyl acetoacetate (**3b**) and ethyl 2-butyl-3-oxobutanoate (**6**) was treated with imidate **1a**, the allylation of **6** took place only to a small extent (9% yield) in comparison with the formation of the diallylation product **5b** from **3b** in 36% yield (Scheme 3). These results imply that the allylation does not proceed by a simple mechanism. Hence, use of a large excess of active methylene compound was effective at suppressing the diallylation; when 10 equiv of **3b** was used, monoallylation product was obtained in 77% yield and the diallylated product was no longer formed.

The regiochemistry of allylation with unsymmetrically substituted allylic systems is an important problem from both synthetic and mechanistic viewpoints. The results of allylation of *p*-tolylsulfonylacetone (**3e**) with several substituted allyl imidates are summarized in Table 2. It is noteworthy that diallylated products were no longer detected. The less substituted site of the allylic system in the imidate reacted preferentially, and prenyl imidate **2d** gave only one regioisomer **7d**. Moreover, the 2-butenylated product **7b** was a pure trans isomer irrespective of the structure of the starting imidate **2b** or **2c**.

The stereochemistry of allylation with 3,3-disubstituted allyl imidates was next examined using geranyl imidate **2e** and neryl imidate **2f** (Scheme 4). In these types of allylation good yields were obtained only in polar solvents; in chloroform, benzene, or THF, the yields were poor or the reaction did not take place. In general, the reaction of the π-allylpalladium complex is strongly influenced by the solvent and the

ligand.[1] However, few reports have been given with respect to the stereochemistry.[11] Therefore, initially, the effect of the solvent to the *E/Z* ratio of products was examined in detail (Table 3). When geranyl imidate **2e** was used in combination with dppe, the greater the donor number[12] of the solvent, the higher was the stereoselectivity. On the other hand complete retention of the stereochemistry of the starting neryl imidate **2f** was attained by the use of DMSO as solvent. It is well-known that the pathway for isomerization of the allyl moiety involves π-allyl to σ-allyl interconversion and bond rotation,[13] and this higher selectivity indicates that nucleophilic attack is faster than syn-anti isomerization. Indeed, the allylation proceeded most rapidly in DMSO among the solvent tested. When PPh$_3$ was used as ligand, the amount of PPh$_3$ was crucial for the stereoselectivity. No stereoselectivity (*Z*:*E*=50:50) was observed with 2 equiv. of PPh$_3$ to Pd(0) in allylation of diethyl malonate (**3c**) with **2f** in DMSO, satisfactory results were obtained with 8 equiv. of PPh$_3$ (*Z*:*E*=90:10). Notably complete retention of stereochemistry was attained by using a large excess (15 equiv to Pd(0)) of PPh$_3$. Similarly, no stereoisomer was formed with a large excess of methyldiphenylphosphine.

Table 4 shows the results of allylation of various active methylene compounds with geranyl imidate (**2e**) and neryl imidate (**2f**) in DMSO. Ethyl acetoacetate (**3b**) was allylated with **2e** and **2f** with complete retention of the olefin geometry to yield, after hydrolysis and decarboxylation, stereochemicaly pure geranylacetone

and nerylacetone in 71% and 73% yield, respectively. Substituted ethyl acetoacetates **4b**, **6** and diethyl malonate (**3c**), and diethyl allylmalonate (**4c**) were also allylated stereoselectively, especially with **2f**, no stereoisomer was observed. Sulfonylacetone **3e** and ethyl *p*-tolylsulfonylacetate (**3f**) were also allylated stereoselectively by using a large excess of PPh_3 as ligand.

In other neutral allylations, e.g., allylation with allyl carbonates, complete retention of stereochemistry was not achieved, especially the reaction of neryl carbonate with methyl acetoacetate which gave almost equal amounts of geranylacetone and nerylacetone.[1c] Therefore the present allylation with allyl imidates is thought to be valuable as a method for the stereoselective introduction of trisubstituted allylic moieties under neutral conditions.

Experimental

General. Boiling points are uncorrected. IR spectra were measured on a Hitachi 260-10 spectrometer. ^1H NMR spectra were obtained with a JEOL JNM-C-60M or a JEOL FT-90-Q using $CDCl_3$ as solvent and with tetramethylsilane as internal standard. Column chromatography was normally effected with Wakogel C-200 (Wako Pure Chemical Industries). GLC analyses were performed on a Shimadzu GC-9A chromatograph using a column packed with Silicone OV-17 (3 mm×2 m), and the peak areas were calculated on a Shimadzu chromatopack C-R3A.

Materials. $Pd(dba)_2$ was prepared according to a literature method.[14] The structure of the known compounds were established on the basis of their spectroscopic properties and from descriptions in the literature. Allylic imidates were prepared by methods described in the literature.[9] The following new compounds were prepared by the method of Roberts.[10]

3-Methyl-2-butenyl *N*-Phenylformimidate (2d): Bp 91—92 °C/0.45 mmHg (1 mmHg≈133.322 Pa); IR(neat) 1650, 1190, 770, and 700 cm^{-1}; ^1H NMR δ=1.71 (6H, s), 4.63 (2H, d, J=7 Hz), 5.35 (1H, t, J=7 Hz), 6.7—7.2 (5H, m), 7.47 (1H, s).

Found: C, 76.38; H, 7.68; N, 7.56%. Calcd for $C_{12}H_{15}NO$: C, 76.16; H, 7.99; N, 7.40%.

(*E*)-3,7-Dimethyl-2,6-octadienyl *N*-Phenylformimidate (2e): Bp 139—141 °C/0.38 mmHg; IR (neat) 1640, 1185, 760, and 700 cm^{-1}; ^1H NMR δ=1.59, 1.65, and 1.71 (9H, each s), 2.01 (4H, bs), 4.64 (2H, d, J=7 Hz), 4.98 (1H, bs), 5.33 (1H, t, J=7 Hz), 6.6—7.1 (5H, m), and 7.44 (1H, s).

Found: C, 79.15; H, 9.32; N, 5.29%. Calcd for $C_{17}H_{23}NO$: C, 79.33; H, 9.01; N, 5.44%.

(*Z*)-3,7-Dimethyl-2,6-octadienyl *N*-Phenylformimidate (2f): Bp 141—143 °C/0.35 mmHg; IR (neat) 1640, 1185, 760, and 700 cm^{-1}; ^1H NMR δ=1.59, 1.65, and 1.75 (9H, each s), 2.10 (4H, bs), 4.64 (2H, d, J=7 Hz), 5.01 (1H, bs), 5.37 (1H, t, J=7 Hz), 6.7—7.2 (5H, m), and 7.50 (1H, bs).

Found: C, 79.58; H, 9.20; N, 5.58%. Calcd for $C_{17}H_{23}NO$: C, 79.33; H, 9.01; N, 5.44%.

General Procedure for Allylation of Active Methylene Compounds. To a stirred mixture of active methylene compound (0.4 mmol), $Pd(dba)_2$ (5 mg, 2 mol%), and dppe (3 mg, 2 mol%) in DMF (10 ml), was added a solution of imidate (0.4 mmol) in DMF (2 ml). The resulting mixture was stirred at 85 °C under nitrogen, poured into water, and extracted with diethyl ether. The organic layer was washed with brine and dried over $MgSO_4$. After filtration, the solvent was removed and the residue was purified by column chromatography (silica gel; hexane/ethyl acetate).

Reaction of 2-Propenyl *N*-Phenylbenzimidate (1a) with Ethyl Acetoacetate (3b) and Ethyl 2-Butyl-3-oxobutanoate (6). To a stirred mixture of **3b** (406 mg, 3.1 mmol), **6** (581 mg, 3.1 mmol), $Pd(dba)_2$ (36 mg), and dppe (25 mg) in DMF (10 ml), was added a solution of **1a** (740 mg, 3.1 mmol) in DMF (2 ml). The resulting mixture was stirred at room temperature for 2 h and treated according to the general procedure, affording **4b** (149 mg, 28%), **5b** (118 mg, 36%) and ethyl 2-butyl-2-(2-propenyl)-3-oxobutanoate (64 mg, 9%).

Allylation of *p*-Tolylsulfonylacetone (3e) with Substituted Allyl Imidate (Table 2). Substituted allyl imidate (0.4 mmol) and **3e** (85 mg, 0.4 mmol) were stirred in DMF (10 ml) at 85 °C under nitrogen in the presence of $Pd(dba)_2$ (5 mg, 2 mol%) and dppe (3 mg, 2 mol%). Allylated sulfones were obtained according to the general procedure. The ratio of **7b** and **7c** was determined by GLC (column 230 °C, **7b**; retention time=7.6 min, **7c**; retention time=6.5 min).

Allylation of Diethyl Malonate (3c) with 2e and 2f in Several Polar Solvents (Table 3). To a stirred mixture of **3c** (311 mg, 1.9 mmol), $Pd(dba)_2$ (22 mg, 2 mol%), and dppe (15 mg, 2 mol%) in solvent (20 ml), was added a solution of imidate **2e** or **2f**. The resulting mixture was stirred at 85 °C under nitrogen, and treated according to the general procedure. The E/Z ratio was determined by GLC (column 180 °C, **8a**; retention time=9.9 min, **8b**; retention time=8.7 min).

Allylation toward Various Active Methylene Compounds with 2e and 2f (Table 4). To a stirred mixture of the active methylene compound (1.9 mmol), $Pd(dba)_2$ (22 mg, 2 mol%), and dppe (15 mg, 2 mol%) in DMSO (20 ml) was added a solution of imidate **2e** or **2f**. The resulting mixture was stirred at 85 °C under nitrogen, and treated according to the general procedure. The following new compound were obtained using the above procedure.

Ethyl (*E*)-2-(3,7-Dimethyl-2,6-octadienyl)-2-(2-propenyl)-3-oxobutanoate: IR (neat) 1735, 1710, 1215, and 920 cm^{-1}; ^1H NMR δ=1.26 (3H, t, J=7 Hz), 1.60 (6H, s), 1.68 (3H, S), 2.00 (4H, bs), 2.12 (3H, s), 2.58 (4H, d, J=7 Hz), 4.19 (2H, q, J=7 Hz), 4.8—5.1 (4H, m), 5.62 (1H, ddt, J=18, 9, 7 Hz).

Found: C, 74.57; H, 9.78%. Calcd for $C_{19}H_{30}O_3$: C, 74.47; H, 9.87%.

Ethyl (*Z*)-2-(3,7-Dimethyl-2,6-octadienyl)-2-(2-propenyl)-3-oxobutanoate: IR (neat) 1735, 1710, 1215, and 920 cm^{-1}; ^1H NMR δ=1.25 (3H, t, J=7 Hz), 1.60, 1.68 (6H, each s), 2.03 (4H, bs), 2.11 (3H, s), 2.57 (2H, d, J=7 Hz), 4.18 (2H, q, J=7 Hz), 4.88 (1H, t, J=7 Hz), 5.10 (1H, bs).

Found: C, 74.39; H, 10.64%. Calcd for $C_{20}H_{30}O_3$: C, 74.49; H, 10.63%.

Diethyl (*Z*)-2-(3,7-Dimethyl-2,6-octadienyl)-2-(2-propenyl)-malonate: IR (neat) 1730, 1220, and 920 cm^{-1}; ^1H NMR δ=1.24 (3H, t, J=7 Hz), 1.60 (3H, s), 1.68 (6H, s), 2.03 (4H, bs), 2.62 (H, d, J=7 Hz), 4.17 (4H, q, J=7 Hz), 4.9—5.2 (4H, m), 5.68 (1H, ddt, J=18, 9, 7 Hz).

Found: C, 71.68; H, 9.39%. Calcd for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59%.

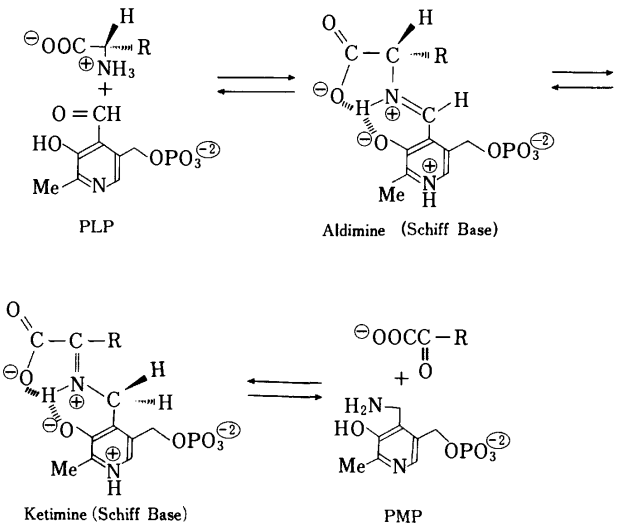
Synthesis and Reaction of a New Chiral Pyridoxamine Analogue; Some Doubt about the Stereochemical Process Tentatively Proposed for a Nonenzymatic Transamination Reaction

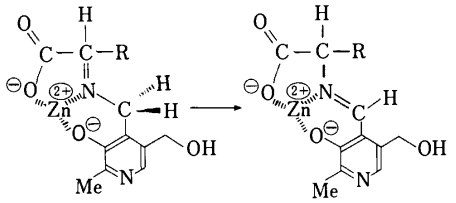
Makoto ANDO* and Hiroyoshi KUZUHARA*
Riken (The Institute of Physical and Chemical Research),
Wako-shi, Saitama 351-01
(Received August 8, 1988)

A pyridoxamine analogue-like chiral pyridinophane with two sulfonyl groups in the bridging chain, (*S*)-15-aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-tetraoxide ((*S*)-**7**), was prepared by oxidation of the sulfide precursor, (*S*)-**2**. The amino group was successfully transferred from (*S*)-**7** to several 2-oxo carboxylic acids in methanol at room temperature in the presence of one-half equimolecular zinc(II) ion, giving (*R*)-amino acids in excess. The reaction rates of this nonenzymatic transamination using chiral (*S*)-**7** were much smaller than those of the corresponding reaction using chiral (*S*)-**2**. The enantiomeric excess of the amino acids obtained through the reactions of (*S*)-7 was compared with those of (*S*)-**2**, showing that (*S*)-**7** was more efficient than (*S*)-**2** for the preparation of (*R*)-alanine, but was less than that of (*S*)-**2** for the preparations of (*R*)-valine, (*R*)-leucine, and (*R*)-phenylalanine. These results aroused some doubt about the previous explanation of the stereochemical features of such nonenzymatic transamination reactions.

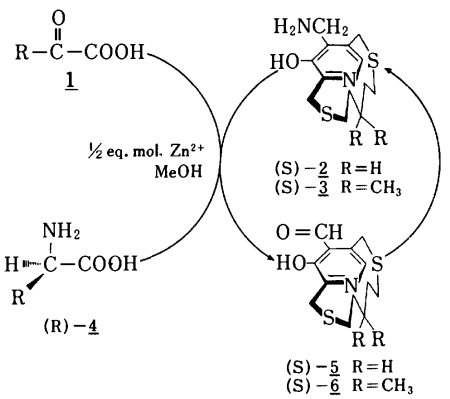
Transaminases, as well as other vitamin B_6-dependent enzymes, play a crucial role in amino acid metabolism, catalyzing the transfer of an amino group between amino acids and 2-oxo carboxylic acids. Two coenzymes, pyridoxal phosphate (PLP) and pyridoxamine phosphate (PMP), mediate the transfer of amino groups in such enzymatic reactions by forming Schiff bases with substrates, that undergo subsequent equilibration between their aldimine and ketimine forms (Scheme 1). The pioneering work of Snell[1] demonstrated that, in the simple model systems (in the absence of apoprotein), pyridoxal and pyridoxamine (with or without phosphate groups) duplicate the reaction of transaminases, and that the reaction rate is considerably increased when polyvalent metal cations are present. Martell[2] presented the first example of zinc(II) catalysis of a model transamination reaction in nonaqueous solvents, in which a simple isomerization from the ketimine to the aldimine reached near completion in the absence of large excesses of reagents (Scheme 2). Utilizing these fundamental discoveries, several groups[3] have pursued further development of new transaminase models capable of enantioface differentiation. We have succeeded in the preparation of pyridoxamine analogues with planar chirality, the (*R*) and (*S*) enantiomers of 15-aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane (**2**)[4] and 15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9]-(2,5)pyridinophane (**3**).[5] Stereoselective transamination from chiral **3** (and **2** in a few cases) to various 2-oxo carboxylic acids (**1**) in methanol in the presence of



Scheme 1.



Scheme 2.



Scheme 3.

zinc(II), successfully produced α-amino acids (**4**) with enantiomeric excesses (e.e.) ranging from 60 to 96% depending on the substrates employed.[6] Interesting stereochemical features were observed in these transamination reactions. First, the reduction of the molar ratio of zinc(II) vs. chiral **3** from 1/1 to 0.5/1 resulted in a remarkable increase of the e.e. values of **4** produced, without affecting their chemical yields (about 70% in most cases). Second, the employment of the (*S*) enantiomer of **3** gave the (*R*) enantiomer of **4** in excess, and vice versa. In order to rationalize these phenomena, we tentatively proposed an octahedral zinc(II) chelate complex coordinated with two equimolecular Schiff base ligands as the key intermediate.[7] As is seen in Fig. 1,[8] a kinetically controlled stereoselective protonation would take place on one of the enantiofaces of the carbanion. The other enantioface is sterically hindered by one of the bulky sulfur atoms (circled in Fig. 1). If this hypothetical view is applicable to other cases, the replacement of the sulfur atoms of **3** (or **2**) with bulkier groups would result in the increase of the e.e. values of **4** produced by the model transamination reaction.

This paper describes syntheses of the racemate and the (*S*)-enantiomer of 15-aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-tetraoxide (**7**) from **2**, and the zinc(II)-catalyzed transamination reactions of chiral **7** and chiral **2** with various kinds of **1**. The sulfonyl group in **7** is much bulkier than the thio group in **2** and would be expected to have little tendency to chelate metal ions, which is a necessary condition for the model transamination reactions to proceed smoothly. Although it has been shown that **3** shows higher efficiency in asymmetric induction than **2**,[6] the derivatives of **3** were generally much less soluble than those of **2**. Consequently, the asymmetric transaminations from **7** were compared with those from **2**, but not the sulfonyl analogue of **3** with **3**.

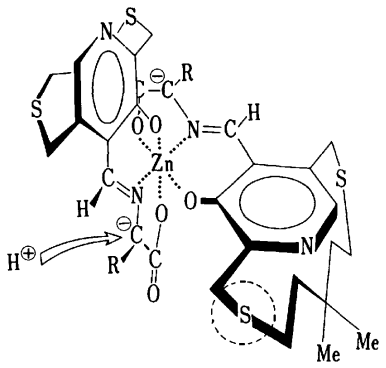


Fig. 1. *Λ*-Isomer of the octahedral zinc(II) chelate complex containing (*S*)-**3** Schiff base.

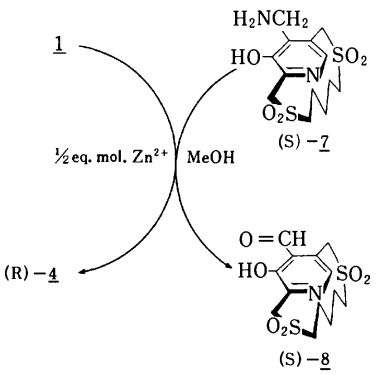
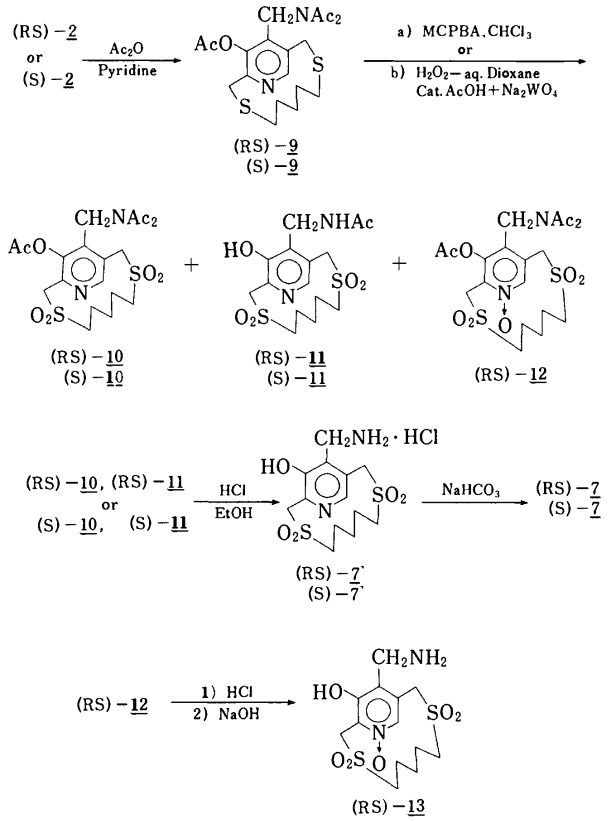
Synthesis of 7. Initially, racemic **7** was prepared for model studies. Acetylation of (*RS*)-**2** with acetic anhydride and pyridine at 100 °C gave crystalline 14-acetoxy-15'-diacetylamino derivative, (*RS*)-**9**, which revealed three carbonyl absorptions at 1690, 1710, and 1780 cm^{-1} but no NH absorption in the IR spectrum. Its ^1H NMR spectrum also revealed methyl protons of three acetyl groups around δ 2.30. In the spectrum, all gem-protons of the three pyridylmethylene groups appeared with the same characteristic pattern; i.e., one proton as a sharp doublet but the other as a broad doublet, suggesting that all acetyl groups undergo restricted rotation, and each rotamer influences one of the gem-protons in a different way. Oxidation of (*RS*)-**9** with *m*-chloroperbenzoic acid in chloroform gave almost equal amounts of two products in 82% total yield, which were separable by silica-gel chromatography. Both compounds revealed two absorption



Scheme 4.



Scheme 5.

peaks of sulfonyl groups, at 1120—1130 and 1310—1320 cm^{-1} in their IR spectra. Elemental analyses of these products suggested that the less polar one was the expected (*RS*)-14-acetoxy-15-[(diacetylamino)methyl]-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-tetraoxide ((*RS*)-**10**), and the other was *N,S,S,S',S'*-pentaoxide, (*RS*)-**12**. This identification was in good agreement with the results of our previous model oxidation experiment.[9] When the ^1H NMR spectrum of (*RS*)-**10** was compared with that of (*RS*)-**9**, four protons of 1- and 9-pyridylmethylene groups showed downfield shifts, appearing in the region of δ 4.36—5.24. One of the gem-protons of the (diacetylamino)methyl group, that appeared at 5.08 ppm as a broad doublet in the spectrum of **9**, was split into three sharp doublets at δ 5.07, 5.15, and 5.22 in the spectrum of **10**, with peak ratio 1:3:1. This presumably reflects the geometric proportion of the acetyl groups undergoing the restricted rotation. The ^1H NMR spectrum of (*RS*)-**12** revealed that one of the protons of the methylene group existing between the pyridine ring and the sulfonyl groups was missing, suggesting its easy replacement with the deuterium of the solvent (DMSO-d_6). Selective oxidation of the sulfur atoms in **9** to the corresponding sulfone was achieved by employing hydrogen peroxide as the oxidant. Although this oxidation also gave two compounds, the by-product was not **12** but **11**, a partially deacetylated derivative of **10**. Thus, when (*RS*)-**9** was treated in aqueous dioxane with hydrogen peroxide in the presence of catalytic amounts of acetic acid and sodium tungstate, (*RS*)-**10** and (*RS*)-15-[(acetylamino)-methyl]-14-hydroxy-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-tetraoxide ((*RS*)-**11**) were obtained in a total yield of 62% with a ratio dependent on the reaction conditions employed. Both racemic **10** and **11** were deacetylated by treatment with hydrochloric acid, giving the same product, the racemic hydrochloride of **7** ((*RS*)-**7'**), which was quantitatively converted to the free base, (*RS*)-**7**, by neutralization with aqueous sodium hydrogencarbonate. In the ^1H NMR spectrum of (*RS*)-**7** using DMSO-d_6 as the solvent, all gem-protons of the pyridylmethylene groups appeared as three sets of sharp AB quartets, one of which was characteristic in showing a large difference of the chemical shifts between the A and B doublets (δ 3.97 and 4.98). (*RS*)-**12** could also be deprotected in a similar way, giving (*RS*)-**13**.

Chiral **7** was prepared from the corresponding **2** in the same way as the racemate model preparation. Thus, (*S*)-**2** was changed to (*S*)-**9**, which was oxidized by using the hydrogen peroxide–acetic acid–sodium tungstate system. Acidic hydrolysis of (*S*)-**10** and (*S*)-**11** gave (*S*)-**7'**, which was neutralized to give free (*S*)-**7** with the specific rotation of −352° at 589 nm.

Transamination Reactions. Transaminations from (*S*)-**7**, and from (*S*)-**2** were conducted employing four kinds of **1** as the reactants. The reaction conditions employed were the same, as those of the previous experiments mainly using chiral **3**,[6] except for the reaction time. A methanol solution containing the sodium salt of **1** (sodium pyruvate), (*S*)-**7** (or (*S*)-**2**), and one-half equivalent of zinc(II) was allowed to stand at room temperature, and the progress of the reaction was monitored by the change in its electronic absorption spectra with time (Fig. 2). The decrease in the initial absorption at 329 nm, due to the ketimine Schiff base zinc chelate complex, occurred simultaneously with an increase in the corresponding aldimine absorption at 390 nm. The time required for completion of the reaction reflected a large difference in the rate of the reactions of **2** and **7**. In the case of **2**, the isomerization from the ketimine to the aldimine was complete within 1 day, whereas it took more than 10 days in the reaction of **7**.

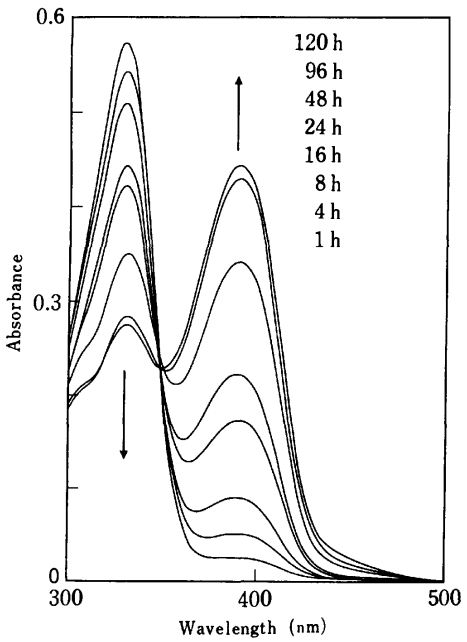


Fig. 2. Changes of the electronic absorption spectra with time for a methanol solution of (*S*)-**7** (0.1 mM), zinc perchlorate (0.05 mM), and sodium pyruvate (0.2 mM).

Various modifications of the procedures previously employed[6] were also required for isolation of amino acids from the zinc(II) chelate complexes of aldimine Schiff bases between **4** and **8** (Scheme 4). We have previously reported that the chelated aldimine intermediate derived from (*S*)-**2** was readily decomposed at room temperature by addition of dilute hydrochloric acid to the methanol solution of the reaction mixture. After extraction of (*S*)-**5** and excess of **1** with organic solvent, ion-exchange chromatography of the remaining aqueous solution gave (*R*)-**4**. Unexpectedly, this method failed in the present case, and the chelated aldimine intermediate derived from (*S*)-**7** resisted

a) The values in the parentheses are the calculated ones on the basis of the amount of (*S*)-**7** consumed.

hydrolysis with dilute hydrochloric acid at room temperature, giving no amino acids. As the initial electronic absorption at 390 nm disappeared by addition of dilute hydrochloric acid it was replaced by a new stable absorption which appeared at 300 nm. It is possible that only zinc(II) ion was removed, leaving the acid-stable aldimine Schiff base in the solution. Therefore, the mixture in methanol–hydrochloric acid was evaporated and the residue redissolved in 1 M (1 M=1 mol dm^{-3}) hydrochloric acid. After heating at 100 °C for 5 h, extraction with ethyl acetate removed (*S*)-**8** and the excess of **1**. The aqueous solution was placed on a Dowex 50 W (H^+) column and successively eluted with water and aqueous ammonia to remove inorganic salts. In contrast to the case of transamination using (*S*)-**2**, concentration of the aqueous ammonia solution precipitated (*S*)-**7** unchanged. After filtration, the filtrate containing the amino acid **4** was passed through an Amberlite CG 50 (H^+) column, for complete removal of (*S*)-**7**. The combined yield of (*S*)-**7** recovered was in the range of 10—30%, depending upon the bulkiness of **1** employed. A small amount of brown-colored unidentified impurity was finally removed from the aqueous amino acid solution, using a LOBAR column.

Chemical yields and e.e. values of the amino acids isolated were determined on the basis of their weights and specific rotations measured. All results of the transamination reaction are tabulated in Table 1. The behavior of the *N,S,S,S',S'*-pentaoxide **13** in the transamination reaction is interesting, but no transamination was observed with (*RS*)-**13**.

Discussion

As mentioned above, the transamination reactions of (*S*)-**7** were different from those of (*S*)-**2** in several respects. For example, in the preparation of valine, the transamination using (*S*)-**2** was completed within 24 h and no (*S*)-**2** was left; whereas 31% of (*S*)-**7** was recovered even after standing for 10 days. Nevertheless, as the change of electronic absorption spectra showed, the reaction pattern producing chiral amino acids was essentially the same for both cases. The chemical yields of the amino acids produced by transamination using (*S*)-**2** or (*S*)-**7** did not differ much, when they

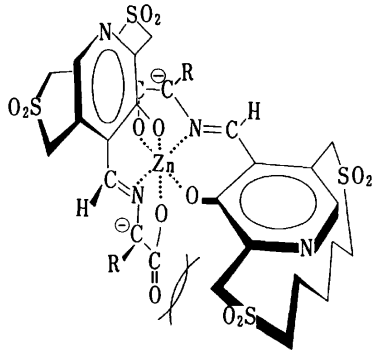

Fig. 3.

were calculated on the basis of the chiral pyridoxamine analogues consumed (the values in the parentheses for (*S*)-**7** in Table 1). The major enantiomer of amino acids obtained was *R* in all cases, suggesting that the transamination reaction using chiral **7** also obeys the rule established by the previous experiments using chiral **3** (and **2** in part); i.e., use of the (*S*)-enantiomer of the pyridoxamine analogues gives the (*R*)-amino acids in excess, and vice versa.[6] Contrary to the previous expectation of generally higher e.e. value by using (*S*)-**7** instead of (*S*)-**2**, it was actually so only in the single case of alanine. In the preparation of other amino acids such as valine, leucine, and phenylalanine, the efficiency of asymmetric induction by (*S*)-**7** was at most nearly equal to or lower than (*S*)-**2**. These unexpected results might be still rationalized with our view of the hypothetical reaction intermediate like Fig. 1, as described in the following. When the alkyl group in **1** is small like pyruvic acid (R=CH_3), the ketimine Schiff base resulted from its condensation with (*S*)-**7** might behave similarly to the Schiff base of (*S*)-**2**, forming a six-coordinated octahedral zinc(II) chelate complex. Isomerization from the ketimine to the aldimine involving the kinetically controlled stereoselective protonation would also take place within such chelate complex (see Fig. 1). These situations should have been considerably disturbed in the syntheses of other amino acids having bulkier alkyl groups (R in **1**). Namely, steric interaction should exist between the two bulky groups, R and sulfonyl group, as shown in

Fig. 3. This would labilize such zinc(II) chelate structure coordinated with two equimolecular Schiff base ligands. As a result, the geometry most favorably fixed for the ketimine-aldimine isomerization would be partially destroyed, lowering the steric effect of the sulfonyl group for enantioselectivity. This situation would lead not only to the increase of the amount of unchanged (*S*)-**7** but also to the decrease of the e.e. value of the amino acids.

The above speculative rationalization has been presented without any evidence. Therefore, an alternative process involving four- or five-coordinated zinc(II) chelate complex might better explain the whole stereochemical features of the nonenzymatic transamination reactions. Consideration of these possibilities and accumulation of the evidences for them will be made hereafter.

Experimental

General Procedures. Melting points were determined in a capillary tube using a Büchi melting point apparatus and are uncorrected. IR and UV-VIS absorption spectra were obtained with a Shimadzu IR 27G and a Varian-Cary 2290 spectrometer, respectively. Specific rotations were measured by using a Perkin-Elmer 241 polarimeter with a 1 dm 5 mL or a 1 dm 1 mL cell at room temperature. ^{1}H NMR spectra were obtained with a JEOL JNM GSX 500 s (500 MHz) using tetramethylsilane or sodium 3-(trimethylsilyl)propionate-d_4 as the internal references. Thin-layer chromatography (TLC) used precoated aluminium sheets from E. Merck (silica gel 60 F_{254}, 0.2 mm-thick for pyridinophanes, and cellulose F_{254}, 0.1 mm-thick for amino acids). The solvent systems used were as follows: chloroform–methanol for silica gel and 1-butanol–acetic acid–water for cellulose. The pyridinophanes on the silica gel layer were observed under a UV lamp or visualized by iodine vapor. The amino acids on the cellulose layer were visualized by ninhydrin–1-butanol and heating. Silica-gel column chromatography was performed using Merck silica gel 60 (0.063—0.200 mm in particle size) with solvent systems specified. Dowex 50 W×8 (100—200 mesh) and Amberlite CG 50 (Type 1) were purified in the usual way prior to use. Reversed-phase silica-gel column chromatography was carried out with a prepacked Merck LOBAR Column (Li Chroprep RP-8, 40—60 μm in particle size and 10×240 mm in column size) using water as the eluent. Ultrafiltration was performed using a Millex GS (0.22 μm in pore size and 4 cm^2 in effective area of filtration) purchased from Millipore, Japan Ltd.

(*RS*)-14-Acetoxy-15-[(diacetylamino)methyl]-2,8-dithia[9](2,5)pyridinophane ((*RS*)-9). A solution of (*RS*)-2[4] (10.00 g) in pyridine (100 mL) and acetic anhydride (100 mL) was stirred at 100 °C for 16 h, concentrated in vacuo at 70 °C, and poured into ice-water. The mixture was extracted with ethyl acetate and the extract was washed successively with aqueous sodium hydrogencarbonate and water, dried ($MgSO_4$), and concentrated in vacuo. The residual matter was chromatographed on silica gel with 100:1 (v/v) $CHCl_3$–MeOH as the eluent, giving (*RS*)-**9** (14.37 g, quantitative), mp 127—128 °C; UV ($CHCl_3$) 289 nm (ε 4.0×10^3); IR (KBr) 1780 (O-C=O) and 1710 and 1690 cm^{-1} (N-C=O); ^{1}H NMR (DMSO-d_6) δ=2.28 (s, 3H, $OCOCH_3$), 2.32 (s, 6H, N-$(COCH_3)_2$), 3.52 (d, 1H, J=13.0 Hz, =CCH_2S), 3.75 (broad, d, 1H, J=ca. 13 Hz, =CCH_2S), 3.87 (d, 1H, J=13.7 Hz, =CCH_2S), 4.01 (broad, d, 1H, J=ca. 14 Hz, =CCH_2S), 4.87 (d, 1H, J=16.2 Hz, =CCH_2N), 5.08 (broad, d, 1H, J=ca. 16 Hz, =CCH_2N), and 8.42 (s, 1H, N=CH). Found: C, 55.43; H, 6.38; N, 6.73; S, 15.62%. Calcd for $C_{19}H_{26}N_2O_4S_2$: C, 55.59; H, 6.38; N, 6.82; S, 15.62%.

(*S*)-14-Acetoxy-15-[(diacetylamino)methyl]-2,8-dithia[9](2,5)pyridinophane ((*S*)-9). The same treatments of (*S*)-**2** as those of the racemate described above resulted in (*S*)-**9** in 87% yield: mp 147—148 °C; $[\alpha]_D^{27}$ −42.6° (*c* 0.384, $CHCl_3$). Found: C, 55.57; H, 6.36; N, 6.85; S, 15.48%. Calcd for $C_{19}H_{26}N_2O_4S_2$: C, 55.59; H, 6.38; N, 6.82; S, 15.62%.

Oxidation of (*RS*)-9. (a) With *m*-Chloroperbenzoic Acid: A solution of *m*-chroroperbenzoic acid (85% purity, 7.50 g, 37 mmol) in chloroform (75 mL) was added dropwise at 5—10 °C for 1 h with stirring to a solution of (*RS*)-**9** (2.00 g, 4.9 mmol) in chloroform (100 mL), giving a precipitate. The mixture was stirred at 5—10 °C for another 1 h and at room temperature overnight. Meanwhile the precipitate completely dissolved. After addition of 20—30 mL of 5% aqueous sodium hydrogensulfite, the mixture was extracted with aqueous sodium hydrogencarbonate for removal of *m*-chlorobenzoic acid. The chloroform layer was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on silica gel, using 100:1 (v/v) $CHCl_3$–MeOH as the eluent, giving (*RS*)-**10** (0.95 g, 41%) and (*RS*)-**12** (0.97 g, 41%) in this elution order. (*RS*)-**10**: mp 202—204 °C; UV ($CHCl_3$) 282 nm (ε 4.2×10^3); IR (KBr) 1790 (O-C=O), 1710 and 1690 (N-C=O), and 1320 and 1120 cm^{-1} (SO_2); ^{1}H NMR (DMSO-d_6) δ=2.31 (s, 3H, $COOCH_3$), 2.32 (s, 6H, N$(COCH_3)_2$), 4.36—4.92 (m, 5H, =CCH_2S and =CCH_2N), 5.07 (d, 0.2H, J=17 Hz, =CCH_2N), 5.14 (d, 0.6H, J=16 Hz, =CCH_2N), 5.22 (d, 0.2H, J=17 Hz, =CCH_2N), and 8.81 (s, 1H, N=CH). Found: C, 47.74; H, 5.51; N, 5.68; S, 13.64%. Calcd for $C_{19}H_{26}N_2O_8S_2$: C, 48.09; H, 5.52; N, 5.90; S, 13.51%.

(*RS*)-**12:** Mp 201—202 °C (decomp); UV ($CHCl_3$) 287 nm (ε 11.9×10^3); IR (KBr) 1780 (O-C=O), 1710 and 1690 (N-C=O), 1310 (SO_2), 1290 (N→O), and 1130 cm^{-1} (SO_2); ^{1}H NMR (DMSO-d_6) δ=2.31 (s, 3H, $OCOCH_3$), 2.32 (s, 6H, N-$(COCH_3)_2$), 4.51 (d, 1H, J=13.5 Hz, =CCH_2S), 4.84 (d, 1H, J=14.2 Hz, =CCH_2S), 4.85 (d, 1H, J=15.9 Hz, =CCH_2N), 4.90 (d, 1H, J=14.2 Hz, =CCH_2S), 5.14 (d, 1H, J=15.9 Hz, =CCH_2N), and 8.81 (s, 1H, N=CH). Found: C, 46.33; H, 5.32; N, 5.67; S, 12.97%. Calcd for $C_{19}H_{26}N_2O_9S_2$: C, 46.52; H, 5.34; N, 5.71; S, 13.07%.

(b) With Hydrogen Peroxide: Aqueous hydrogen peroxide (30%, 2.43 mL, 24.5 mmol) was added dropwise with stirring at 60—65 °C for 30 min to a solution of (*RS*)-**9** (2.00 g, 4.9 mmol), acetic acid (ca. 15 mg), and sodium tungstate dihydrate (ca. 5 mg) in dioxane–water (2:1 v/v, 30 mL). The mixture was heated at 80—85 °C for 1 h, cooled, diluted with aqueous sodium hydrogensulfite (5%, 5—10 mL), and extracted with chloroform. The extract was dried ($MgSO_4$), concentrated, and chromatographed on silica gel with 100:1 (v/v) $CHCl_3$–MeOH as the eluent, giving (*RS*)-**10** (1.15 g, 50%). Further elution with 25:1 (v/v) $CHCl_3$–MeOH gave (*RS*)-**11** (0.22 g, 12%); mp>280 °C; UV ($CHCl_3$) 282 nm (ε 4.2×10^3); IR (KBr) 3350 (broad, NH, OH), 1650 (NHCO), and 1310 and 1140 cm^{-1} (SO_2); ^{1}H NMR

(DMSO-d_6) δ=1.87 (s, 3H, $NCOCH_3$), 4.34 (d, 1H, J=13.3 Hz, $=CCH_2S$), 4.35 (dd, 1H, J=14.8 and 6.1 Hz, $=CCH_2N$), 4.57 (dd, 1H, J=14.8 and 6.1 Hz, $=CCH_2N$), 4.67 (d, 1H, J=14.1 Hz, $=CCH_2S$), 4.95 (d, 1H, J=13.7 Hz, $=CCH_2S$), 5.00 (d, 1H, J=13.3 Hz, $=CCH_2S$), 8.37 (s, 1H, N=CH), 8.82 (t, 1H, J=5.8 Hz, NH), and 10.82 (s, 1H, OH). Found: C, 45.36; H,5.57; N, 6.89; S, 16.41%. Calcd for $C_{15}H_{22}N_2O_6S_2 \cdot 1/2H_2O$: C, 45.10; H, 5.80; N, 7.01; S, 16.05%.

Oxidation of (*S*)-9 with Hydrogen Peroxide. The same treatment of (*S*)-**9** with hydrogen peroxide-acetic acid-sodium tungstate gave a mixture of (*S*)-**10** and (*S*)-**11** in 33% and 30% yields, respectively. (*S*)-**10**: mp 204—205 °C; $[\alpha]_D^{31}$ −78° (c 0.363, $CHCl_3$). Found: C, 47.12; H, 5.40; N, 5.70; S, 13.45%. Calcd for $C_{19}H_{26}N_2O_8S_2 \cdot 1/2H_2O$: C, 47.19; H, 5.63; N, 5.79; S, 13.26%.

(*S*)-**11**: Mp 266—267 °C (decomp); $[\alpha]_D^{29}$ −168 ° (c 0.321, pyridine). Found: C, 43.97; H, 5.38; N, 6.68; S, 15.96%. Calcd for $C_{15}H_{22}N_2O_6S_2 \cdot H_2O$: C, 44.11; H, 5.92; N, 6.86; S, 15.70%.

(*RS*)-15-Aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-Tetraoxide ((*RS*)-7) via Monohydrochloride of 7 ((*RS*)-7'). **(a) From (*RS*)-10:** A solution of (*RS*)-**10** (3.00 g, 7.3 mmol) in ethanol (15 mL) and 6 M hydrochloric acid (15 mL) was heated under reflux for 3 h and concentrated in vacuo. The residue was dissolved in a small amount of hot water, treated with charcoal, and diluted with ethanol, giving (*RS*)-**7'** (1.94 g, 80%): mp>280 °C; UV (H_2O) 333 (ε 3.7×10³), 301 (ε 4.1×10³), and 255 nm (ε 3.7×10³); IR (KBr) 3000, 1580, and 1500 (OH, $NH_2 \cdot HCl$) and 1320 and 1110 cm^{-1} (SO_2). Found: C, 40.56; H, 5.58; Cl, 8.85; N, 7.13; S, 16.54%. Calcd for $C_{13}H_{20}N_2O_5S_2 \cdot HCl$: C, 40.57; H, 5.50; Cl, 9.21; N, 7.28; S, 16.66%.

To a solution of (*RS*)-**7'** (1.414 g, 3.7 mmol) in water was added aqueous sodium hydrogencarbonate (310 mg, 3.7 mmol) and the mixture was stirred at room temperature for 30 min, giving (*RS*)-**7** (1.223 g, 91%) as a precipitate: mp 175—202 °C (decomp); UV (dioxane) 300 nm (ε 2.9×10³); IR (KBr) 3500 and 3350 (NH_2, OH) and 1300 and 1130 cm^{-1} (SO_2); ^{1}H NMR (DMSO-d_6)[10] δ=3.97 (d, 1H, J=12.4 Hz, $=CCH_2S$), 4.07 (d, 1H, J=15.6 Hz, $=CCH_2N$), 4.13 (d, 1H, J=15.3 Hz, $=CCH_2N$), 4.42 (d, 1H, J=14.0 Hz, $=CCH_2S$), 4.65 (d, 1H, J=13.7 Hz, $=CCH_2S$), 4.98 (d, 1H, J=12.4 Hz, $=CCH_2S$), and 7.78 (s, 1H, N=CH). Found: C, 42.58; H, 5.50; N, 7.57; S, 17.47%. Calcd for $C_{13}H_{20}N_2O_5S_2 \cdot H_2O$: C, 42.61; H, 6.05; N, 7.64; S, 17.50%.

(b) From (*RS*)-11: A solution of (*RS*)-**11** (0.85 g, 2.1 mmol) in ethanol (10 mL) and 6 M hydrochloric acid (10 mL) was heated under reflux for 3 h and worked up in the same way as described in (a), giving (*RS*)-**7'** (0.71 g, 86%), which was neutralized with sodium hydrogencarbonate to give (*RS*)-**7** (0.61 g, 90%).

(*S*)-15-Aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane *S,S,S',S'*-Tetraoxide ((*S*)-7) via Monohydrochloride of 7 ((*S*)-7'). Either (*S*)-**10** or (*S*)-**11** was treated with hydrochloric acid in the same way as the hydrolysis of the corresponding racemate, giving (*S*)-**7'** in 74% and 85% yields, respectively: mp>280 °C; $[\alpha]_D^{29}$ −317 ° (c 0.293, H_2O). Found: C, 40.40; H, 5.56; Cl, 9.10; N, 7.20; S, 16.59%. Calcd for $C_{13}H_{20}N_2O_5S_2 \cdot HCl$: C, 40.57; H, 5.50; Cl, 9.21; N, 7.28; S, 16.66%.

Neutralizing (*S*)-**7'** with equimolecular amount of sodium hydrogencarbonate similarly to the case of the racemate gave (*S*)-**7** in quantitative yield: mp 196—199 °C (decomp); $[\alpha]_D^{19}$ −352 ° (c 0.241, pyridine). Found: C, 42.69; H, 5.51; N, 7.52; S, 17.55%. Calcd for $C_{13}H_{20}N_2O_5S_2 \cdot H_2O$: C, 42.61; H, 6.05; N, 7.64; S, 17.50%.

(*RS*)-15-Aminomethyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane *N,S,S,S',S'*-Pentaoxide ((*RS*)-13). A solution of (*RS*)-**12** (1.92 g, 5.3 mmol) in ethanol (20 mL) and 6 M hydrochloric acid (20 mL) was heated under reflux for 3 h, treated with charcoal, and concentrated in vacuo. The residue was dissolved in a minimum amount of water and adjusted to pH 3 by addition of aqueous sodium hydroxide, giving (*RS*)-**13** (1.38 g, 97%) as a precipitate: mp>280 °C; UV (1 M HCl) 327 (ε 4.8×10³), 276 (ε 9.0×10³), and 240 nm (ε 23.7×10³); IR (KBr) 3400 (broad, NH_2, OH), 1360 (SO_2), 1280 (N→O), and 1130 cm^{-1} (SO_2); ^{1}H NMR (DCl-D_2O)[11] δ=3.86 (s, 2H, $=CCH_2N$), 4.20 (d, 1H, J=15.0 Hz, $=CCH_2S$), 4.46, (d, 1H, J=14.6 Hz, $=CCH_2S$), 4.50 (d, 1H, J=14.6 Hz, $=CCH_2S$), 5.02 (d, 1H, J=14.6 Hz, $=CCH_2S$), and 7.92 (s, 1H, N=CH). Found: C, 42.57; H, 5.58; N, 7.44; S, 17.43%. Calcd for $C_{13}H_{20}N_2O_6S_2$: C, 42.85; H, 5.53; N, 7.69; S, 17.65%.

Transamination Reactions. (a) Using (*S*)-2: A solution of (*S*)-**2** (85 mg, 0.3 mmol), sodium salts of **1** (0.6 mmol), and zinc perchlorate hexahydrate (56 mg, 0.15 mmol) in methanol (150 mL) was stirred at room temperature for 24 h. After addition of 1 M hydrochloric acid (6 mL), the resulting mixture was concentrated to dryness in vacuo. The residue was extracted with a mixture of water and ethyl acetate. The aqueous extract was concentrated to ca. 10 mL and put on a column packed with Dowex 50 W×8 (100—200 mesh,H^+ form, 50 mL). The column was successively eluted with water (1 L) and 0.1 M aqueous ammonia. The latter eluate was concentrated to give a residue, which was put on a column packed with Amberlite CG 50 (100—200 mesh, H^+ form, 20 mL). The column was eluted with water to collect the amino acid-containing fractions, and evaporated. Optical purities of **4** obtained were calculated on the basis of its measured optical rotations.

(b) Using (*S*)-7: The same reaction conditions were employed except for the longer reaction time. A solution of (*S*)-**7** (110 mg, 0.3 mmol), sodium salt of **1** (0.6 mmol), and zinc perchlorate hexahydrate (56 mg, 0.15 mmol) in methanol (150 mL) was stirred at room temperature, monitoring the reaction by the change of the electronic absorption spectrum. The reaction time employed was 5 days for preparations of alanine (from pyruvate) and phenylalanine (from phenylpyruvate), whereas 10 days were necessary for the preparation of valine (from 3-methyl-2-oxobutyrate) and leucine (from 4-methyl-2-oxovalerate). After the reaction was over, 1 M hydrochloric acid (6 mL) was added and the mixture was concentrated to dryness; the residue was dissolved again in 1 M hydrochloric acid (20 mL) and heated at 100 °C for 5 h. Concentration in vacuo followed by dilution with water was repeated several times to remove hydrochloric acid as much as possible. The final residue was extracted with a mixture of water and ethyl acetate. The aqueous extract was concentrated to a volume of 10 mL and put on a column packed with Dowex 50 W×8 (100—200 mesh, H^+ form, 50 mL). The column was successively eluted with water (1 L) and 0.1 M aqueous ammonia. The latter eluate was concentrated to a volume of 5 mL to give (*S*)-**7** unreacted as a precipitate, which was filtered off. The filtrate was put on a column packed with Amberlite CG 50

(100—200 mesh, H^+ form, 20 mL) and eluted with water. The amino acid-containing fractions were collected, concentrated, and put on a LOBAR column RP-8 (10×240 mm), which was eluted with water. Concentration of the eluate gave **4**. Before measurement of the optical rotations, the aqueous solutions of **4** obtained were passed through a membrane filter.

The authors wish to express their thanks to Miss Mutsuko Yoshida and her coworkers of this Institute for elemental analyses and to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu of this Institute for the measurements of ^1H NMR spectra.

This study was performed through Special Coordination Funds of the Science and Technology Agency of the Japanese Government.

The Electric Birefringence and Dichroism of a Nonlinear Optical Compound, 4-[2-[4-(Dimethylamino)phenyl]ethenyl]-1-ethylpyridinium Iodide, in the Presence of Poly(*p*-styrenesulfonate) and Poly(L-α-glutamate) in Solutions

Kiwamu YAMAOKA* and Yasumori HINO
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received June 11, 1988)

The pulsed electric birefringence at 633 nm and dichroism at 462 nm of the title cationic compound (DAES) were measured at 20 °C over a wide electric field strength range (0.1—24 kV cm^{-1}) in the presence of poly(*p*-styrenesulfonate)(NaPSS) and poly(L-α-glutamate) (PGA) in aqueous solutions at various mixing ratios (*P/D*) of the polymer to the ligand. The steady-state electric birefringence δ of NaPSS–DAES complexes was positive, while that of NaPSS was negative. The optical anisotropy factor of bound DAES was responsible for the sign reversal. The reduced electric dichroism of NaPSS–DAES at a *P/D* of 1.9 was +0.38 at infinitely high fields. A value of ±50° was found for the average angle between the orientation axis of the complex and the direction of the optical transition moment at 462 nm of bound DEAS chromophores. No appreciable permanent dipole moment was present in any of the NaPSS–DAES systems. The field orientation was due mostly to counterion-induced moments. The rotational relaxation time was determined from the decay signals. For PAG–DAES and PGA at pH 6.4 and 4.1, the sign of δ was always positive, the magnitude differing from each other by only 10—20%.

4-[2-[4-(Dimethylamino)phenyl]ethenyl]-1-ethylpyridinium iodide (DAES) is one of the well-known nonlinear optical materials which exhibit a marked second harmonic generation (SHG) phenomenon, due mostly to their large hyperpolarizability in the crystalline state.[1] Attempts have been made to observe SHG in some stilbene derivatives in the dissolved state with a strong Nd:YAG laser beam.[2] The static electric field-induced SHG of the π-electronic conjugated system is generally weak; therefore, a high external field strength of about 100 kV cm^{-1} or more is required. If nonlinear optical compounds were oriented unidirectionally at much lower electric fields, as in the crystalline state, the SHG measurement could be facilitated with less powerful but easily available laser diodes as the light source; hence, a variety of practical applications would thus become feasible. This idea may be realized if the nonlinear materials are attached either covalently or electrostatically to the appropriate polymeric matrices, which are easily orientable by an external force. The electric field is particularly useful because the field orientation is fast and reversible, which would enable us to develop an on-off switching device.

In order to achieve the above objectives, a series of systematic studies will be necessary to determine the electrooptical properties of polymer-nonlinear optical material complexes. In this work, the field orientation behavior of DAES, a cationic stilbene derivative with a large permanent dipole moment, was studied in the presence of poly(sodium *p*-styrenesulfonate) (NaPPS)[3–8] and poly(sodium L-α-glutamate) (PGA),[9–11] both of which are known to be oriented easily in an aqueous solution by means of an external electric field. The interaction of polymer–ligand complexes is best studied by pulsed electric birefringence and electric dichroism, which measure the anisotropic electric, optical, and hydrodynamic properties.[3–14] Since a large change in permanent dipole moments between the ground and excited states of the nonlinear optical ligand effects an SHG phenomenon,[1] lower ratios of the polymer site to the ligand are chosen in this work.

Experimental

Materials. The DAES was purchased from Nippon Kankoh Shikiso Kenkyusho (Okayama) and was used without further purification. This compound was insensitive to the irradiation of the 320—450 nm light from a 150-W quartz-iodine lamp. The NaPSS was kindly supplied by the Tosoh Co. and was fractionated by the precipitation method. The weight-average molecular weight was estimated to be 1.63×10^6 from the intrinsic viscosity of 2.61 dl g^{-1} in 0.2 M (1 M=1 mol dm^{-3}) NaCl at 25 °C.[15] The PGA was a gift of Dr. Hiroshi Sato of the Mitsubishi Rayon Co. and was fractionated by successive precipitation. The weight-average molecular weight was estimated to be 1.04×10^5 from the intrinsic viscosity of 1.02 dl g^{-1} in 2 M NaCl at 25 °C. The polymer–DAES solution was prepared by adding the DAES solution to the polymer solution at a desired mixing ratio (denoted as *P/D*), which was expressed in terms of the polymer residue-to-DAES concentrations. The polymer concentration was kept constant at all *P/D* values, since the polymer conformation without added salt or at a low ionic strength is concentration-dependent.

Measurements. The absorption spectra in the absence of electric field were measured on a Shimadzu Model UV-250 recording spectrophotometer at 20 °C with quartz cells 0.3 and 1.0 cm in path length. The electric birefringence was measured at 20 °C on a high-speed, high-voltage He–Ne laser (632.8 nm) apparatus constructed in this laboratory. The electric dichroism was determined at 20 °C and at an absorption maximum of 462 nm of DAES on an instrument

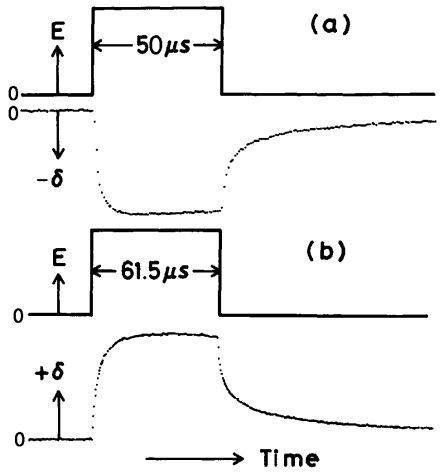

Fig. 1. Transient electric birefringence signals and applied electric square-pulse fields. (a) NaPSS: E=16.83 kV cm^{-1} and δ=−6.19° and (b) NaPSS-DAES at P/D=1.9: E=16.78 kV cm^{-1} and δ=+21.67°. Birefringence signal δ in (a) is an average of four accumulations, while the signal in (b) is the response to a single pulse. The sampling time of the signal detecting system was set at 200 ns. The instrumental time constant was adjusted to 100 ns for the buildup (or the rise) and 300 ns for the decay signal.

previously reported.[5,12] The output signals were digitized and processed with the transient wave memory-microcomputer system.[16] Figure 1 shows examples of the transient electric birefringence signals of NaPPS and its DAES complex.

Results and Discussion

Isotropic Absorption Spectra. Figure 2 shows the isotropic absorption spectra of DAES in the presence of NaPSS and PGA, together with those of DAES alone (P/D=0). The spectra of DAES in the presence of NaPSS differ from the reference spectrum of DAES, whose maximum at 450 nm is shifted toward red by 25 nm at higher P/D values, but shifted back to ca. 430 nm at a low P/D of about 1 probably because of the metachromatic effect of bound DEAS.[17] These changes are a strong indication of the formation of a complex by the electrostatic interaction between the anionic sulfonato group and the quarternized ring nitrogen of DAES.[17] The spectra of DAES in PGA differ only slightly from the DAES spectra at two pH's; thus, the binding of DAES to PGA appears to be very weak, regardless of the backbone conformations of PGA (helix at pH 4.1 and random coil at pH 6.4).

Steady-State Electric Birefringence. Figure 3 shows the steady-state birefringence of NaPSS-DAES complexes, expressed in terms of the optical phase retardation δ. Since DAES exhibits no electric birefringence in the absence of NaPSS over a field strength range of $E \leq 22.4$ kV cm^{-1}, the observed signals are all due to the NaPSS-DAES complex. It should be noted that the

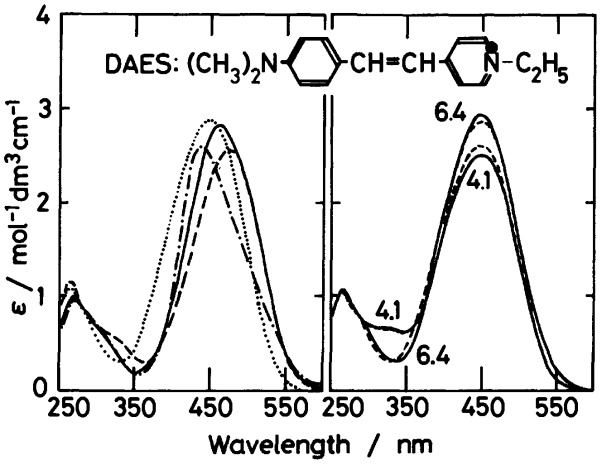

Fig. 2. Isotropic absorption spectra of DAES in the presence and the absence of NaPSS (left) and PGA (right). P/D for NaPSS at pH 6.4: 7.1 (——), 1.9 (——), 0.94 (—·—·—), and 0 (·····). P/D for PGA: 9.8 (——) and 0 (-----) at pH 4.1 and 5.4 (——) and 0 (-----) at pH 6.4; the numerals denote pH values. The molar absorption coefficient ε was expressed in terms of the concentration of DAES. The residue concentrations of polymers are constant: [NaPSS]= 0.202 mM containig 0.8 mM NaCl, [PGA]=0.389 mM.

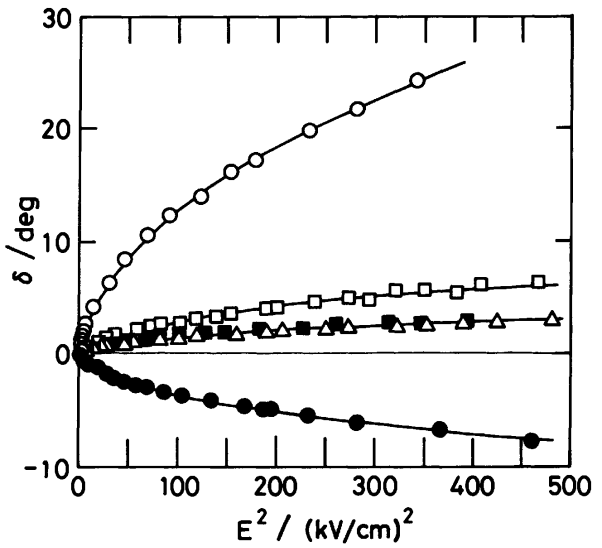

Fig. 3. The steady-state electric birefringence δ of NaPSS-DAES complexes and NaPSS versus the square of applied external electric field strength E^2. P/D: 7.1 (■), 4.7 (□), 1.9 (○), 0.94 (△), and ∞ (●). [NaPSS]=0.202 mM in 0.8 mM NaCl. Solid lines are theoretically calculated SUSID orientation functions (see text).

sign of δ for the complex is reversed to positive, while the sign is negative for NaPSS itself.[3,4,6-8] A large contribution of the bound DAES moiety to the observed δ values is evident. Since more than half of DAES present in solution are unbound at a low P/D ratio of 0.94, the δ values are much less than those of complexes at P/D=7.1—1.9, probably because of the

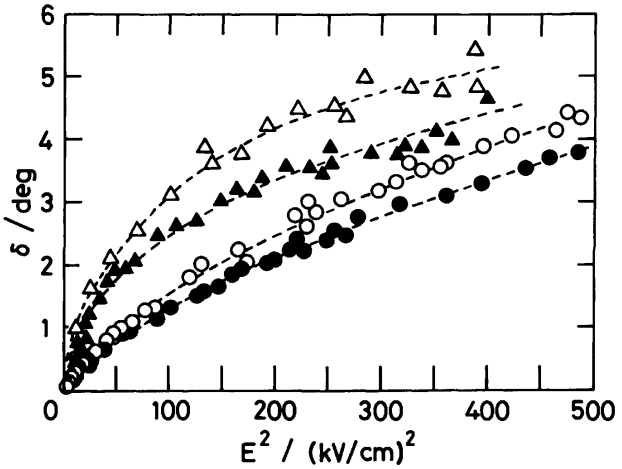

Fig. 4. The steady-state electric birefringence δ of PGA in the presence and the absence of DAES versus the square of field strength E^2. pH at 4.1: P/D=9.8 (○) and ∞ (●). pH at 6.4: P/D=5.4 (△) and ∞ (▲). [PGA]=0.389 mM.

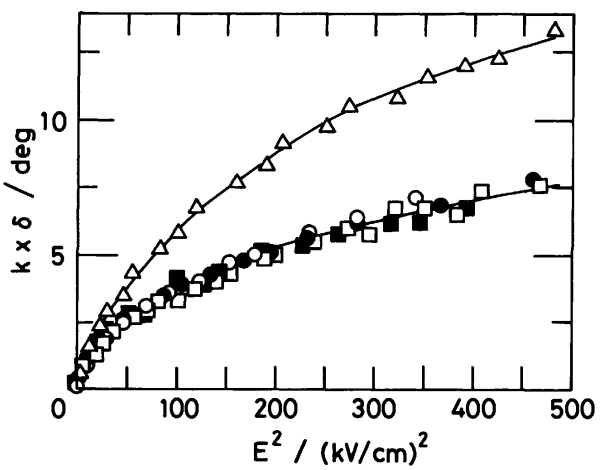

Fig. 5. The field strength dependence of δ multiplied by a normalization factor k for NaPSS-DAES complexes. k=−1.0 (∞), 2.3 (7.1), 1.3 (4.7), 0.29 (1.9), and 4.0 (0.94), P/D values being given in the parentheses. The symbols and other conditions are all the same as in Fig. 3.

presence of unbound DEAS in the solution.

Figure 4 shows the steady-state birefringence of DAES in the presence of PGA at pH 4.1 and 6.4. The magnitude of δ for DAES in the presence of PGA was found to differ from that of PGA by only 10—20% over the 0.1—22.4 kV cm^{-1} range, the sign of δ being positive in all cases. Hence, no appreciable DAES ions are oriented jointly with PGA by an applied field. It is now clear that, though positively charged at those pH's, DAES is not bound tightly to the side-chain carboxylate of PGA, as is also indicated by the spectral changes (cf. Fig. 2).

Electric birefringence is expressed by the product of the optical, $\Delta g/n$, and electric, $\Phi(E)$, terms; it is given as $\delta=(4\pi^2 C_v d/\lambda)(\Delta g/n)\Phi(E)$, where C_v is the volume fraction of orientable solutes (i.e., the NaPSS-DAES complex), d is the path length of a Kerr cell (1.0 cm), λ is the wavelength of the incident light (632.8 nm), Δg is the optical anisotropy factor, n is the refractive index of the solution, and $\Phi(E)$ is the orientation function, which describes the dependence of δ on the field strength.[7] If the field orientation of the NaPSS-DAES complexes and NaPSS is described by a common orientation function, the observed δ vs. E^2 plots in Fig. 3 should all be brought to coincide with one another. In such a case, $\delta \times k=\Phi(E)$, where k is a constant, since the optical term is independent of the field strength. Figure 5 shows that all the δ vs. E^2 plots except for P/D=0.94 are now brought into a good coincidence with the appropriate constants, k, evaluated in the low field region. This indicates that a single orientation function is sufficient to describe the field orientation of NaPSS (P/D=∞) and the complexes (P/D=7.1, 4.7, 1.9).

It has been shown that NaPSS is oriented because of its large induced dipole moment.[3,4,8] The results shown in Fig. 5 indicate that NaPPS-DAES complexes also possess practically no net permanent dipole moment μ along the molecular axis of field orientation. If all the DEAS molecules in a solution are bound, the average number of DEAS molecules bound on each NaPSS polyanion would be about 1110(at P/D=7.1)—4150(at P/D=1.9). Because of the permanent dipole moment of ca. 7 Debye units for each DAES molecule, the vectorial sum of μ would be roughly as large as 7000—29000 Debyes if all bound DAES moieties were aligned in parallel fashions like an arrow along a rodlike NaPSS backbone. This case is inconsistent with the present results. Possible explanations are: (1) the bound DAES molecules are so arranged that the individual dipole moments, μ_{DAES}, cancel each other out and/or (2) the overall conformation of the complexes is not rigidly rodlike, but coiled, so that the net moment μ is negligibly small.

In order to analyze the experimentally obtained δ vs. E^2 plots for ionized polymers, which are lacking in the permanent dipole moment and are, therefore, oriented by induced dipole moment(s), a new orientation function is needed. For this purpose, a theoretical function was recently derived on the assumption that an ionized polymer possesses both saturable ($\Delta\sigma E$) and unsaturable ($\Delta\alpha E$) induced dipole (SUSID) moments.[18] These two types of induced dipole moments are responsible for the interaction with the electric field. The former ($\Delta\sigma E$) is induced by the counterion and is saturated at the critical electric field E_0, while the latter ($\Delta\alpha E$) is partly electronic and partly ionic. Here, $\Delta\alpha$ is the electronic polarizability anisotropy, and $\Delta\sigma$ is the ionic polarizability anisotropy (the details are given in Ref. 18). The theoretical curves based on the SUSID mechanism (solid lines) in Fig. 3 reproduce all

a) The optical phase retardation at infinitely high fields. b) Values are estimated by curve-fitting. c) The reduced optical anisotropy factor contributed by DAES, defined as [((Δg/n) of NaPSS-DAES complex)−(Δg/n) of NaPSS)]/(DAES concentration).

the observed δ vs. E^2 plots quite well. The degree of orientation at a high field of 22.4 kV cm^{-1} is calculated from those theoretical curves to be 0.53 for NaPSS and for NaPSS-DAES at P/D=7.1—1.9 and 0.56 for NaPSS-DAES at P/D=0.94; these values constitute strong evidence for the ease of the orientation of these polymer systems by external pulse fields. Table 1 shows the optical and electric properties, which were evaluated by means of the curve-fitting.[18] It is interesting to note in Table 1 that the reduced optical anisotropy factor ($\Delta g/n$) of the NaPSS-DAES complexes varies greatly with the P/D ratio, while the ($\Delta g/n$) value per DAES molecule, $(\Delta g/n)_{DAES}$, remains nearly constant in the P/D range of 7.1—1.9, where the DAES molecules in the solution are probably almost all bound to NaPSS.[17]

Relaxation Time from Decay Signal. Figure 6 shows the birefringence-average relaxation time of the NaPSS and NaPSS-DAES complexes, $\langle\tau\rangle_{EB}$, which was obtained by means of the area method from the decay signal upon the removal of the applied pulse field (cf. Fig. 1).[19] The values of $\langle\tau\rangle_{EB}$ rapidly decrease in the low field region; however, they reach constant levels at higher pulse fields ($E \geq 10$ kV cm^{-1}). This feature is mostly due to the polydispersity of the NaPSS sample.[20] The value of $\langle\tau\rangle_{EB}$ at infinitely high fields is reduced to the weight-average relaxation time τ_w which is given in Table 1. The τ_w value of 27 μs for NaPSS is the largest, while it is only 4 μs for NaPSS-DAES at P/D=0.94. Considering that the weight-average degree of polymerization is 7890, the contour length of NaPSS would be as long as 19700 Å (=2.5 Å×7890). For a rigidly rodlike model with this length and a radius of 9 Å, the rotational relaxation time should be ca. 52.6×10^3 μs, as calculated with the aid of the Broersma equation.[7,21] A comparison of this value of 52.6×10^3 μs with the observed value of 27 μs reveals that the backbone chain is probably folded and that the overall shape of NaPSS and its DAES complex may be approximated by an ellipsoid.[7] The apparent length l (=2a) is given in Table 1 for this model, with a probable semi-minor axis b of 32 Å,[7] as calculated with the Perrin equation: $\tau^{-1}=(9kT/4\pi\eta_0 a^3)\cdot[\ln(2p)-0.5]$, where η_0 is the viscosity of the solvent, $p=a/b$ (the axial ratio), and a is the semi-major axis.

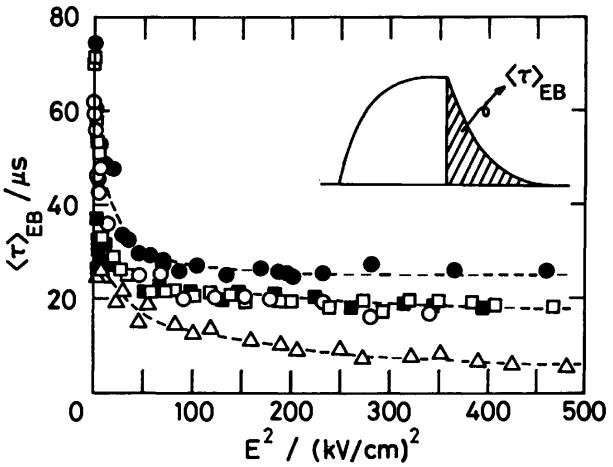

Fig. 6. The birefringence-average relaxation time $\langle\tau\rangle_{EB}$ of NaPSS and NaPSS-DAES complexes. Symbols are all the same as in Fig. 3.

(In this calculation, the NaPSS sample was assumed to be monodisperse.) The most likely reason for the absence of the net permanent dipole moment μ in the DAES-bound NaPSS is the extensive folding of the polymer chain.[7] The whole shape, approximated by an ellipsoid, apparently becomes more compact with the decrease in the P/D values.

Electric Dichroism of the NaPSS-DAES Complex. Since the value of $\Delta g/n$ was positive for the NaPSS-DAES complexes, in contrast with the case of NaPSS (cf. Table 1), the DAES chromophore is probably bound to the ionized sulfonate group in such a way that the angle θ between the orientation axis of the complex and the optical transition moment direction of the 462-nm absorption band of bound DAES is less than ±54.7°.[5,12] In order to confirm this inference, the steady-state electric dichroism of the NaPSS-DAES complex at P/D=1.9 was measured over a wide field-strength range. Figure 7 shows the field-strength dependence of the reduced dichroism $\Delta A/A$ at 462 nm, which is given as $\Delta A/A=(A_{/\!/}-A_\perp)/A=(3/2)(3\cos^2\theta-1)\times\Phi(E)$, where A is the absorbance at 463 nm of the solution in the absence of an applied field.[12] As in the case of the electric birefringence shown in Fig. 3, the experimental plot was fitted to a SUSID theoretical

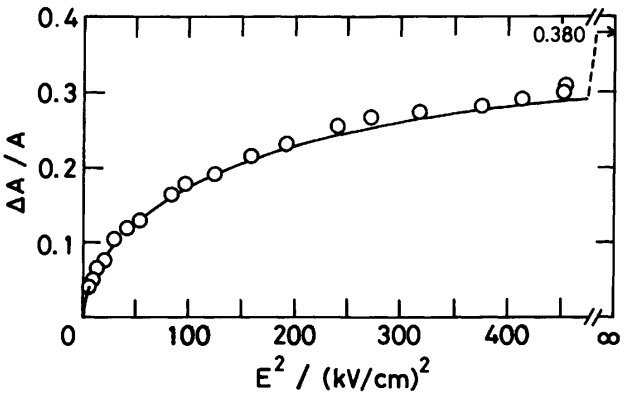

Fig. 7. The field strength dependence of the steady-state reduced electric dichroism $\Delta A/A$ at 462 nm of NaPSS-DAES complex at P/D=1.9. [NaPSS]= 0.10l in 0.4 mM NaCl. Circles are experimentally obtained. Solid line is calculated with the SUSID orientation function with the following values: $\Delta\alpha=4.4\times10^{-33}$ F m², $\Delta\sigma=4.4\times10^{-31}$ F m², $\Delta\sigma E_0$=4000 Debyes, and E_0=0.3 kV cm^{-1}.

curve in order to estimate the intrinsic or saturated reduced dichroism, $(\Delta A/A)_s=(3/2)(3\cos^2\theta-1)$, at infinitely high fields. This value was found to be +0.38, from which the angle θ was calculated to be ±50°. The 462-nm transition moment is directed along the long axis of the DAES molecule, which, therefore, makes an angle of ±50° with respect to the orientation axis of the complex. (This angle represents an *average* of all the bound DAES chromophores and should not be construed as meaning that each and every DAES molecule is bound at this fixed angle.)

The positive $\Delta g/n$ value (cf. Fig. 3 and Table 1) is now verified to result from the angle θ, which is less than ±54.7° (where $(\Delta A/A)_s=0$)[12] for all NaPSS-DAES complexes. It is also clear that the angle is nearly constant over P/D values from 7.1 to 1.9, as is indicated by the $(\Delta g/n)_{DAES}$ values in Table 1. The average angle of ±50° of bound DAES chromophores indicates that the component of the ground-state permanent dipole moment μ_3 along the orientation axis of the NaPSS-DAES complex (the 3-axis)[7] should amount to approximately 4.5 (=7cos50°) Debyes per bound DAES. Considering the number of DAES on each NaPSS chain, the total moment of μ_3 might be expected to make a large contribution to the field orientation, but the experimental finding is contrary, as has been discussed above. If the conformational deformation of the whole NaPSS-DAES complex backbone or the local motion of the bound DAES moiety should occur as the result of an applied electric field, the $\Delta A_{/\!/}/A=-2\Delta A_\perp/A$ relationship generally breaks down between the parallel $\Delta A_{/\!/}$ and prependicular $\Delta A_\perp$ dichroism (Eq. 3 of Ref. 12). This relationship was confirmed to hold up to $E\leq22.4$ kV cm^{-1} in the present work; therefore, in this field range no electrochromic effect[22] is expected in NaPSS-DAES complexes.

The steady-state dichroism signal of DAES at 450 nm was very small in the presence of PGA either at pH 4.1 or at 6.4, again indicating that the interaction between DAES and PGA is weak.

Conclusion

In brief summary, NaPSS-DAES complexes can be oriented by external electric fields to exhibit considerable electric birefringence and dichroism signals, but a complete orientation is still difficult to attain at a practical field strength of about 25 kV cm^{-1}. The overall permanent dipole moment of the complex is nearly zero; the cooperative addition of individual moments of DAES did not occur upon binding to NaPSS. A host polymeric matrix with a larger electric moment must be explored to improve the degree of field orientation. The contribution of the first-order hyperpolarizability anisotropy of the NaPSS-DAES complex to the field orientation seems to be of no special significance. The orientation behavior can be described satisfactorily by the interaction between the electric (linear) polarizability anisotropies $\Delta\alpha$ and $\Delta\sigma$ of the NaPSS chain and the applied field E.

PGA is a rigid and rodlike helix in the low pH region, each residue having a permanent dipole moment of 5—4 Debye units;[9-11] thus, it was thought to be very suitable as the host to cationic DAES and other 2-styrylpyridinium derivatives which show optical nonlinearity.[1] Unfortunately, no appreciable binding occurs in these host-ligand systems, probably because of the weak basicity of the quarternary ring nitrogen atom of DAES and also the weak acidity of the carboxylate of the glutamyl residue. In order for bound optically nonlinear materials to show a larges SHG effect, a smaller molecular weight and rigidly rodlike NaPSS, and other host polyelectrolytes may have to be explored. At the same time, the bound ligands may have to be arranged in such a manner that their permanent dipole moments are additive. In this fashion, a large difference in the excited and ground state moments can be expected; this is one of the conditions for the optical SHG phenomenon.[1]

(Received July 4, 1988)

Incorporation of polypeptides with hydrophobic side groups into lipid bilayers was achieved by the polymerization of *N*-carboxy anhydrides of γ-dodecyl L-glutamate and of γ-benzyl D-glutamate in DMPC liposomal membrane under reduced pressure and normal pressure. The effects of polypeptide conformations on the barrier properties of liposomal membrane incorporating polypeptide were examined. There was little difference in the trapping volume when liposomes prepared under reduced pressure and normal pressure were compared. The incorporation of polypeptides into the membrane bilayer had a tendency to decrease the volume trapping efficiencies. It was found that in the membrane-free aqueous phase, polymerization of *N*-carboxy amino acid anhydrides promoted formation of β-structure and in the membrane bilayer formation of α-helix structure was enhanced. The content of α-helical polypeptide was maximum for liposomes prepared under reduced pressure. The activation energies for water permeation across the liposomal membrane were lowered by the incorporation of polypeptdes into the membrane bilayer. The incorporation of α-helical polypeptide was more ceffective than that of β-structured one for the lowering of activation energies. The permeability barrier properties of liposomal membrane were larger for liposome incorporating poly(γ-dodecyl L-glutamate) (PDOLG) than for liposome incorporating poly(γ-benzyl D-glutamate)(PBDG). This seems to be due to a difference in miscibilities with lipid in the membrane bilayer.

The interactions of liposomes with a variety of polypeptides have been studied as attractive models for the molecular interactions occuring in biological membranes. The interactions cause major changes in the permeability of the membrane bilayer,[1-3] the polypeptide conformation,[4,5] and the morphology of the liposomes.[6] Poly(L-glutamic acid) interacts on the surface of the phosphatidylcholine liposomes and remains in random coil configuration upon complexation with the liposome.[7] Poly(L-lysine) goes from a random coil to an α-helix when it interacts with phosphatidylserine.[5] The copolypeptide lysine–tyrosine has only a small effect on the membrane conductance and it gives a β-structure upon interaction with phosphatidylserine or phosphatidylcholine liposome.[4] Most results so far reported have been obtained by the use of a variety of water-soluble polypeptides that were adsorbed by electrostatic interaction to the outer surface of liposomal membrane. It is now well-recognized that nonpolar interactions play a major role in the determination of protein tertiary structure, catalytic activity, and ligand binding activities and it is to be anticipated that such interactions would also play an important role in lipid-proton interactions of the cell membrane. Our attention has been focused on the incorporation of hydrophobic polypeptide into the membrane bilayer and the effects of their conformations.[8]

In the present study, polypeptides with nonpolar side groups were used as a lipophilic protein model which was embedded into the hydrophobic domain of the membrane. Incorporation of polypeptides with hydrophobic side groups into the membrane bilayer was achieved by polymerization of *N*-carboxy anhydrides of γ-dodecyl L-glutamate and of γ-benzyl D-glutamate in DMPC liposomal environment under reduced pressure and normal pressure. The effects of conformation and hydrophobic side group of polypeptides on the water permeability of liposomal membrane incorporating polypeptide were studied by the osmotic method.

Experimental

Materials. Dimyristoylphosphatidylcholine (DMPC) and dihexadecyl hydrogenphosphate (DHP) were obtained from Sigma. *N*-Carboxy anhydrides of γ-dodecyl L-glutamate (DOLG-NCA) and γ-benzyl D-glutamate (BDG-NCA) were prepared by the method of Blout and Karlson.[9] Diethyl ether and dichloromethane were distilled under nitrogen atmosphere. Water was distilled, the second time from alkaline potassium permanganate solution.

Preparation of Liposome. Large unilamellar liposomes were prepared according to the ether injection method of Deamer and Bangham[10] with some modifications. Injecting lipid solution was prepared by solubilizing DMPC, DHP, and *N*-carboxy amino acid anhydride in mixture of diethyl ether and dichloromethane (3:2 (v/v)) at an appropriate molar ratio (1:0.1:1). This solution was gradually injected with the aid of a mechanical drive through a needle into an aqueous phase, located within the internal chamber of the modified Liebig condenser. 45 ml of the lipid solution (2.5 μmol ml^{-1}) was injected into 6 ml distilled water at 60 °C under normal pressure. For the preparation of liposomes under reduced pressure the apparatus was placed under water vacuum. The temperature of the aqueous phase inside the water vacuum line was maintained at 35 °C for 460 mmHg (1 mmHg≈133.322 Pa) and 45 °C for 510 mmHg. *N*-Carboxy amino acid anhydride represents a class of high-energy amino acid derivatives which polymerize to form

polypeptides. Since the negative-charged portion on the liposomal surface was expected to be favorable for the spontaneous polymerization of *N*-carboxy amino acid anhydrides,[11] the preparation of liposome was evolved for DMPC liposome containing 10 mol% of DHP.

Isolation of Polypeptides from Liposomes. The liposome suspension prepared was filtered through gel column (Cellulofine-GC-700) to remove residual organic solvent, non-incorporated monomer and polymer. To isolate polypeptide from liposomes incorporating polypeptide (150 μmol DMPC), the liposome suspension was first lyophilized and the residue was added to 10 ml diethyl ether or methanol. After shaking, a dispersed precipitant appeared. The precipitated polypeptide was filtered off, washed with methanol, and dried in vacuo.

Osmotic Shrinkage Measurements. For the osmotic shrinkage measurements the liposome suspension was mixed quickly by using a rapid mixing device (Otsuka Electronics MX-7) with hypertonic glucose solution (100 mM) and a 1:1 mixing ratio. The osmotic shrinking of liposomes was followed by the time-course of turbidity change at 450 nm. For osmometers with membrane completely impermeable to the solute a proportionality exists betweem the volume change and the difference in osmotic pressure of the outer and inner volume. Since the initial volume change is directly proportional to the relative initial shrinkage rate (initial absorbance change), r_0, the following relation holds:[12,13]

$$r_0 = 1/A_0(\mathrm{d}A/\mathrm{d}t) = k(\mathrm{d}V/\mathrm{d}t) = kP_wSRT\Delta C \qquad (1)$$

where $1/A_0(\mathrm{d}A/\mathrm{d}t)$ is the initial shrinkage rate, $\mathrm{d}V/\mathrm{d}t$ is the volume change with time, P_w is the permeability coefficient for water, S is the area occupied by the membrane, R is the gas constant, T is the absolute temperature, and ΔC is the concentration difference in the permeable solutes between the inside and outside the liposome, respectively. On the assumption that permeability coefficients could be expressed in the form of Arrhenius's equation

$$P_w = P_w^0 \exp(-\Delta E_a/RT) \qquad (2)$$

one can obtain from Eqs. 1 and 2:

$$r_0/T = 1/A_0\,(\mathrm{d}A/\mathrm{d}t)/T = KP_w^0 \exp(-\Delta E_a/RT) \qquad (3)$$

where K ($=kSR\Delta C$) is a constant at fixed ΔC. An activation energy, ΔE_a, for water permeation across the liposomal membrane could be determined by plotting the logarithms of r_0/T as a function of the reciprocal of absolute temperature.

Results and Discussion

Effects of Conditions for Preparing Liposome on Trapping Volume. Polypeptides isolated from the liposomes prepared under reduced pressure and normal pressure were in yields of 20% and 14% for PDOLG and of 12% and 9% for PBDG. The incorporation of these polypeptides into the liposomal membrane tends to be somewhat larger for reduced pressure (460 mmHg) than for normal pressure.

A parameter we have used to characterize ether injection liposomes is the trapping volume, calçulated by the solute diffusion method.[14] Table 1 summarizes the typical values of volume trapping efficiencies of the liposomes with the without polypeptide prepared under reduced pressure and normal pressure. We observed little difference between the trapping volume of the liposomes prepared under reduced pressure polypeptides into the bilayer tended to decrease volume trapping efficiencies. The values of the trapping volume ranged from 8 to 11 l mol^{-1} and were larger than the values for the typical sonicated liposome by a factor of about 10.

Conformation of Polypeptides Prepared in Membrane Bilayer. Figures 1 and 2 show the infrared spectra for PDOLG and PBDG isolated from liposomes prepared under reduced pressure (460 mmHg) and normal pressure, together with that for the same polypeptides obtained by polymerizing *N*-carboxy amino acid anhydrides in membrane-free aqueous phase. The spectra which are characteristic of poly-

peptide having α-helix structure show major diagonostic at about 1650 cm^{-1} for the amide I band and 1550 cm^{-1} for the amide II band. The β-structure gives rise to a strong band at lower frequecy (about 1635 cm^{-1} for the amide I band and 1520 cm^{-1} for the amide II band) than the α-helix structure. The contents of α-helix structure and β-structure are qualitatively estimated by the comparison of the peak height between 1650 and 1635 cm^{-1} for the amide I band. The conformations of PDOLG and PBDG polymerized in the membrane-free aqueous phase were enhanced in the β-structure (Figs. 1-a and 2-a). Taking into account the fact that both PDOLG and PBDG polymerized in organic solvent (dioxane or anisole) take the α-helix structure,[8] the hydrophilic environments for the polymerization of *N*-carboxy amino acid anhydrides may promote the formation of the β-structure. Yaron et al.[15] have reported that the helical structure of poly[N^5-(3-hydroxypropyl)-L-glutamine] was stabilized under hydrophobic environments such as methanol or *N*,*N*-dimethylformamide and that the addition of water into this solution resulted in a lowering of the helix content. Apparently the presence of water as a protein solvent is not necessarily the most favorable environment for helical structures of polypeptide. On the other hand, polymerization of DOLG-NCA and of BDG-NCA in the membrane bilayer under normal pressure increased the α-helical content (Figs. 1-b and 2-b) and under reduced pressure led to further increase of the α-helix structure (Figs. 1-c and 2-c). Although the α-helicities of PDOLG and PBDG have a tendency to change with the reaction environments, PDOLG differs from PBDG in the α-helix content of polypeptides prepared under different conditions. The polymerization of DOLG-NCA in the membrane-free aqueous phase gave spectra of the β-configuration. PDOLG prepared in the bilayer under normal pressure was enhanced in α-helix, and under reduced pressure the α-helix structure was present in much larger quantities. For the polymerization of BDG-NCA in the membrane-free aqueous phase, on the other hand, the spectra showed mostly β-structure, similar to that of DOLG-NCA. The content of α-helix for PBDG prepared in the bilayer under normal pressure was nearly equal to that of the β-structure, and under reduced pressure the helical content again became much larger than that of the β-structure.

From the results mentioned above, it is found that in the membrane-free aqueous phase the polymerization of *N*-carboxy anhydrides of γ-dodecyl L-glutamate and of γ-benzyl D-glutamate promotes the formation of the β-structure, while in the lipid bilayer membrane the α-helix structure predominates. The content of α-helical polypeptide was maximum for liposomes prepared under reduced pressure. Considering these results, we suggest that the hydrophobic anchor side groups of these *N*-carboxy anhydrides are embedded locally with some degree of translational or rotational freedom into the lipid bilayer matrix of liposomes, and functional groups of *N*-carboxy anhydrides may be brought into positions favorable to the formation of spiral arrangements of the molecules. Consequently, this will induce the formation of the α-helical structure. It is important to delineate the factors affecting the conformation of biological macromolecules. The force dictating the conformation of polypeptide can arise from intramolecular forces, from intermolecular forces, from the solvent, or from surrounding dissimilar medium (environments), which represents a special type of intermolecular interaction. The liposomal environments found to be favorable for the preparation of α-helical polypeptide.

Water Permeation through Liposomal Membrane. The water permeability of liposomal membrane incorporating polypeptide is a sensitive function of the extent of interaction between polypeptides and membrane lipids, and was studied by the measurements of initial osmotic shrinkage rates.

Figures 3, 4, and 5 show the experimental data for the polypeptide-free liposome, and the polypeptide incorporating liposomes prepared under reduced pressure (460 and 500 mmHg) and normal pressure. A linear relationship between the logarithms of r_0/T and the reciprocal of absolute temperature as in Eq. 3 was obtained in all cases investigated. The activation energies estimated from the gradient in Figs. 3—5 are given in Table 2. The values listed in columns 2 and 3 are the pressure and the temperature of the aqueous phase, respectively.

The activation energies for water permeation which

Table 2. Activation Energies for Permeation of Water across Liposomal Membranes under Different Conditions

Composition	P	T	ΔE_a
	mmHg	°C	kcal mol^{-1}
DMPC:DHP	760	60	9.6
	510	45	10.3
	460	35	9.5
DMPC:DHP:	760	60	8.6
DOLG-NCA	510	45	8.3
	460	35	7.2
DMPC:DHP:	760	60	7.6
BDG-NCA	510	45	7.1
	460	35	6.3

DMPC:DHP=1:0.1(mol/mol). DMPC:DHP:NCA=1:0.1:1(mol/mol).

laid in the range 6.3—10.3 kcal mol^{-1} were dependent of the conditions for preparing liposomes. The preparation of polypeptide incorporating liposomes under reduced pressure tended to increase α-helical polypeptide in membrane bilayer as shown in Figs. 1 and 2. This lowers the activation energies for water permeation through polypeptide incorporating liposomal membrane. That is to say, the incorporation of α-helical polypeptide was more effective than that of β-structured one for the lowering of activation energies. Another reason why the activation energies are lowered in the presence of polypeptide is in miscibility between polypeptide and DMPC. Much information has been gained by the recognition of analogies between monomolecular films and biological membranes.[16] PDOLG and PBDG form a monomolecular film at the air-water interface, and the surface-pressure-area (π-A) curves are shown in Fig. 6. The curves of PDOLG with alkyl side groups and PBDG with benzyl side groups have differences related to hydrophobic side chain interactions and side chain flexibility.[17,18] Therefore, the difference in properties of monomolecular films must be reflected in the orientation and the packing of DMPC in polypeptide incorporating membrane bilayer which is associated in permeability barrier properties. Actually, we obtained the results that the permeability barrier properties were larger for liposome incorporating PDOLG than for that incorporating PBDG (Table 2).

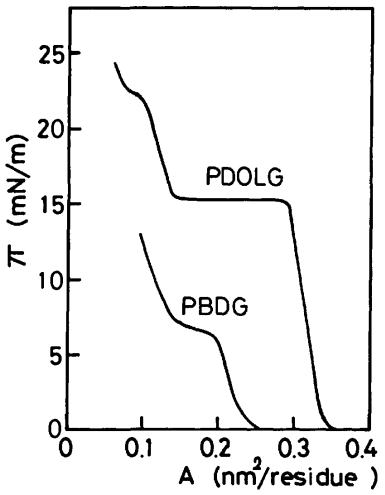

Fig. 6. Surface pressure-area (π-A) curves of poly-(γ-dodecyl L-glutamate) and poly(γ-benzyl D-glutamate).

Conclusion

Incorporation of polypeptides with hydrophobic side groups into lipid bilayers was achieved by the polymerization of DOLG-NCA and BDG-NCA in DMPC liposomal membrane under reduced pressure and normal pressure. Polymerization of *N*-carboxy amino acid anhydrides in the liposomal membrane promoted formation of the α-helix structure. The presence of polypeptides in membrane bilayer resulted in a lowering of activation enegries for permeation of water across the liposomal membrane, and the lowering was maximum for incorporation of α-helical polypeptide.

Studies of the Hydrous Niobium(V) Oxide Ion Exchanger. V. Effect of Heat Treatment on the Sodium Isotopic Exchange Rates between Hydrous Niobium(V) Oxide in Na^+ Form and Aqueous Solutions

Yasushi INOUE,* Hiromichi YAMAZAKI, and Mitsuji IKEDA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received April 15, 1988)

The effect of a heat treatment was studied on the sodium isotopic exchange rate between the hydrous niobium(V) oxide in the Na^+ form and aqueous solutions. The rate was controlled by the particle diffusion of sodium ions and increased with the heat-treatment temperature. The increase in the rate for the exchanger heat-treated at 200 °C was due to a decrease in the effective particle radius brought about by cracks which developed in the particles. A further increase in the rate at temperatures higher than 200 °C could be explained in terms of an increase in the Na^+-diffusion coefficient, which was produced by an increase in the pore size responsinble for the movement of sodium ions.

A radiochemical experiment was previously undertaken in order to measure the isotopic exchange rate of sodium ions between hydrous niobium(V) oxide in the Na^+ form and aqueous solutions of sodium salts, indicating that the rate in Na^+ solutions higher than 0.1 mol dm^{-3} was controlled by the particle diffusion.[1] On the other hand, this material may be useful for applications at high temperatures, since it is appreciably stable under heat treatment.[2] This aroused the interest of the present authors regarding a study of the effect of a heat treatment on the ion-exchange rate of this material. In addition, this study will greatly contribute to an understanding of the ion-exchange mechanism of hydrous niobium(V) oxide by clarifying the relation between the properties of the exchanger matrix and the ion-exchange rates.

The present paper describes the effect of a heat treatment in air on the isotopic exchange rates of sodium ions between the hydrous niobium(V) oxide and aqueous solutions, and discusses the important properties of the material which strongly governs the isotopic exchange rate.

Experimental

Sample Preparation. The hydrous niobium(V) oxide prepared by the previously recommended method was classified into four particle sizes by using Japan Industrial Standard sieves (mesh size; −48+60, −70+80, −100+120, −145+200) and then converted to the H^+ form.[1,3]

Two- to four-gram portions of the exchanger were heated in air to a constant weight at constant temperature (200, 350, and 450 °C). After being cooled, the exchanger was immersed in water overnight, followed by drying to a constant weight in a desiccator containing a saturated NH_4Cl solution (relative humidity, 79%).

The exchanger was then converted to the Na^+ form by treating it with a 0.05 mol dm^{-3} $Na_2B_4O_7$ buffer solution at pH 9.3. The buffer solution was used for preventing any part of the exchanger from dissolving, since the exchanger is chemically unstable in strong basic solutions. The particale size was again made uniform by using sieves, since the exchanger would be broken down during a heat treatment. The exchanger was then labeled with ^{22}Na by equilibrating it with a ^{22}Na-solution having the same chemical composition as the above-mentioned solution for 2d at room temperature. After having been washed with a 0.05 mol dm^{-3} $Na_2B_4O_7$ solution (free from ^{22}Na), the exchanger was used for a rate meassurement.

Properties of the Exchangers. The properties of each sample were all referred to the exchanger in the H^+ form dried in the desiccator. The average particle radius was estimated by approximating the particle shape by a sphere, from the particle-size distribution measured in an 83 wt% glycerol solution by using a Seishin Enterprise Micron-Photo-Sizer, Model SKC-2000S. The specific surface area of the sample, after heated at 110 °C to a constant weight, was determined by the BET method (N_2 adsorption at −196 °C) using a Yanagimoto Surface Area Measuring Apparatus (Model GSA-10). The pore-size distribution and the pore volume of each sample were calculated by Inkley's method from the adsorption isotherm of N_2 at −196 °C.[4] The density of the exchanger was measured in the usual manner by using a 25-cm^3 pycnometer. The exchange capacity of the sample for Na^+ ions was measured in a 0.05 mol dm^{-3} $Na_2B_4O_7$ solution (pH 9.3) by a column method. The water content was determined from the weight loss of the exchanger heated at 850 °C. X-Ray diffraction patterns were obtained by means of a Shimadzu X-ray diffraction unit, Model XD-3A, using Ni-filtered Cu $K\alpha$-radiation.

Measurement of the Isotopic Exchange Rate. All the rate measurements were performed in a nitrogen atmosphere by using the same apparatus as described earlier.[5] The rate was measured in solution with the same compositions as those used for converting the exchanger to the Na^+ form. A portion less than 0.2 gram of the sample was placed in a cage and immersed in 200 cm^3 of a solution of a desired composition while the cage was being rotated. The solution had been adjusted in advance to a constant temperature (within ±0.1 °C). Aliquots of the solution (0.2 cm^3) were taken out at appropriate time intervals in order to measure the radioactivity with a well-type NaI(Tl)-scintillation counter (Aloka Model ARC-361). The time of contact of the exchanger with the solution was taken as the elapsed time between immersing

the cage and withdrawing an aliquot of the solution. The fractional attainment of equilibrium, $F(t)=C_t/C_\infty$, was calculated from these results; here, C_t is the total radioactivity of the solution at time t and C_∞ at $t=\infty$. C_∞ was calculated using $C_\infty=C_iM/(M+m)$, where C_i is the initial total radioactivity of the exchanger, and m and M the total amounts of Na^+ in the exchanger and in solution, respectively. Although the rate was measured by a batch method, the infinite solution-volume approximation was closely obeyed under the present experimental conditions: less than 0.2 g of the exchanger per 200 cm^3 of the solution.

Results and Discussion

Analysis of the Results. The exchange rate for the exchanger without heat treatment was confirmed to be controlled by the diffusion of ions in the spherical particles.[1] When the infinite solution volum approximation is obeyed, as is the case in the present experimental condition, Bt vs. t plots must give a straight line passing through the point of origin,and the slope of the line, i.e., B, is inversely proportional to the square of particle radius. Here,

$$B = \pi^2 D/r^2, \quad (1)$$

where D is the self-diffusion coefficient of the ions in the exchanger and r refers to the radius of the particles. Bt can be calculated from the measured values of the fractional attainment of equilibrium ($F(t)$) by using the equation derived by Reichenberg:

$$Bt = 2\pi - \frac{\pi^2}{3}F(t) - 2\pi\left(1 - \frac{\pi}{3}F(t)\right)^{1/2}. \quad (2)$$

This equation gives a fairly good approximation in the region where $F(t)$ is less than 0.85.[6] In putting the rate data in order, therefore, Bt values were plotted against t.

Effect of Heat Treatment on the Properties of the Exchanger. Table 1 shows some properties of the exchanger in the H^+ form heat-treated in air, together with those without heat treatment (designated sample as R.T.). These results were obtained for the sample of −145+200 mesh, but were essentially the same for those of differrent particle sizes.

When the samples were heated at 200 °C, the exchange capacity and the water content, respectively, decreased to about 60 and 70% of the original values, and then gradually decreased with temperature. The density increased with temperature, reaching a constant value at 350 °C. The specific surface area decreased with temprature, but the fractional pore volume was independent of the temperature of the heat treatment. Figure 1 shows distribution curves of the pore size as form of the frequency polygon, in which the percentage of the volume of pores of each size to the total pore volume is shown at intervals of 1 nm of the diameter. The distribution curves gradually shifted to the lager-pore side with increasing temperature during a heat treatment and became considerably broadened at 450 °C. The reason for the broad distribution curve for a sample heat-treated at 200 °C is not clear, but may be attributable to an incomplete relaxation of the distortion of the structure of the exchanger matrix, by considering an increase in the density of the exchanger at a heat treatment temperature between 200 and 350 °C.

Effect of Heat Treatment on the Exchange Rate. The Na^+-isotopic exchange rates for samples heat-treated at various temperatures, together with those for sample

Temperature, 5.1 °C; 0.10 mol dm^{-3} Na^+; temperature for heat treatment, ◑: R.T., □: 200 °C, △: 350 °C, ○: 450 °C. Particle size/mesh, 2-a:−48+60, 2-b:−70+80, 2-c:−100+120, 2-d:−145+200.

R.T., are shown in Figs. 2-a through 2-d. These figures indicate that the heat treatment enhanced the exchange rate in such different ways as to depend on the particle size; the rate increased monotonously with temperature in −48+60 mesh, but abruptly between 200 and 350 °C in −145+200 mesh. These figures also show that plots of Bt vs. t gave straight lines passing through the point of origin, irrespective of the heat-treatment temperature. Hence, the exchange rate is controlled by the rate of diffusion of sodium ions in the exchanger particles.

When this is true, the slopes of the straight lines (B) must be inversely proportional to the square of the particle radii (r). As is shown in Fig. 3, however, the exchangers which were heat-treated did not follow this relation, unlike sample R. T. This inconsistency may be ascribed to a dependence of the effective particle radius responsible for the diffusion of sodium ions or of the diffusion coefficient of Na^+ ions, on the apparent particle size. The latter is improbable for the following reason. As shown in Fig. 2, when the samples were heat-treated at 200 °C, an exchanger of small particle size (−145+200 mesh) showed the same rate as sample R. T. whereas the heat treatment appreciably increased the rate in the case of exchangers of large particle size. We can, therefore, conclude that the effective radius of the exchanger particles was decreased from the apparent radius estimated from the particle size distribution.

The decrease in the effective particle size is considered to be brought about by cracks developed during heating in the particles which are stressed due to a condensation of the hydroxyl groups. Naturally, the cracks build up more in large than in small particles; that is, the ratio of the effective to apparent radius becomes smaller when

Table 2. Particle Size of Samples Heat-Treated at 200 °C

Particle size	Apparent particle radius (r)	B_0[a]	B'[b]	Effective[c] particle radius (r')	Volume[d] ratio
mesh	μm	$\times 10^{-2}$ s^{-1}	$\times 10^{-2}$ s^{-1}	μm	%
−48+60	145±4	0.67±0.02	0.84±0.04	130±5	72±4
−70+80	107±3	1.24±0.02	1.56±0.05	95±3	71±3
−100+120	74±2	2.13±0.09	2.54±0.11	68±3	77±5
−145+200	52±2	4.45±0.13	4.67±0.22	51±2	94±5

a) Slope of Bt vs. t plot for the sample R.T. b) Slope of Bt vs. t plot for the sample heated at 200 °C. c) Effective radius of the exchanger heated at 200 °C, determined by the equation: $r'=(B_0/B')^{1/2}r$. d) Ratio of the effective volume to the apparent volume determined from particle size distribution.

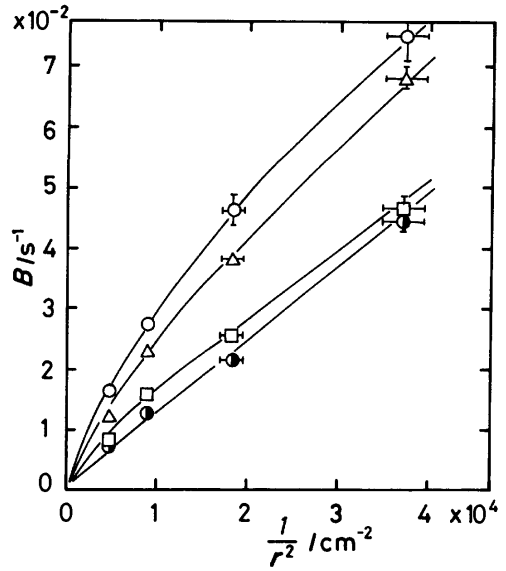

Fig. 3. Relationship between B and $1/r^2$.
Temperature, 5.1 °C; 0.10 mol dm^{-3} Na^+; temperature for heat treatment, ◑: R.T., □: 200 °C, △: 350 °C, ○: 450 °C.

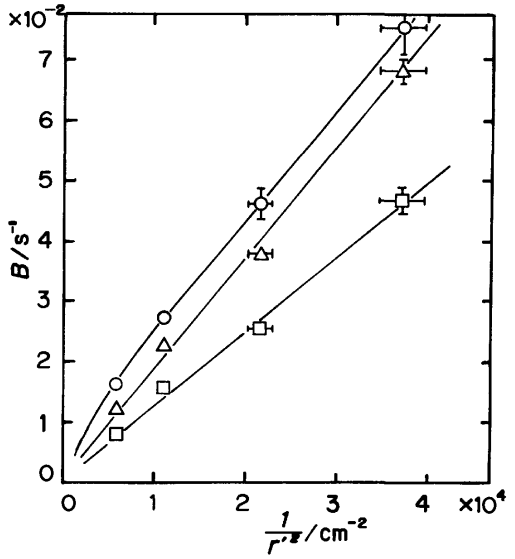

Fig. 4. Relationship between B and $1/r'^2$.
Temperature, 5.1 °C; 0.10 mol dm^{-3} Na^+; temperature for heat treatment, □: 200 °C, △: 350 °C, ○: 450 °C.

the apparent radius is larger. Based on this view, by assuming a constant Na^+-diffusion coefficient, the effective particle radius (r') was calculated by using the equation $r'/r=(B_0/B')^{1/2}$, where B_0 and B', respectively, are the B values for samples without a heat treatment and those heat-treated at 200 °C; where r refers to the apparent particle radius of the exchanger. Table 2 shows the effective particle radii of exchangers heated at 200 °C of various apparent particle sizes. This table reveals that, although the effective radius of the exchanger particle of −145+200 mesh heated at 200 °C was nearly the same as its apparent radius, those of larger particles decreased considerably with heating at 200 °C.

By using the r' estimated for samples heat-treated at 200 °C (Table 2), B vs. $1/r'^2$ plots were made for samples heat-treated at higher temperatures, together with those for the samples heated at 200 °C for a comparison (Fig. 4). In the case where a sample was heated at 350 °C, the plot followed a straight line passing through the point of origin. Therefore, it is considered that cracking does not proceed further and that the effective particle radii are unchanged when the temperature for a heat treatment is raised from 200 to 350 °C. The larger slopes of the straight lines for the samples heated at 350 °C than at 200 °C indicate an increasing D with temperature on account of Eq. 1. At 450 °C, the factors contributing to an increase of the rate cannot be unequivocally determined, because a precise proportionality does not hold between B and $1/r'^2$, but may be a combination of the two factors mentioned above.

If we consider the situation microscopically, the hydrous niobium(V) oxide consists of two phases: the solid framework and the interstitial pore phase. Ions diffuse mainly through the pore phase, since a very large specific surface area of the samples (Table 1) indicates that the solid framework occupies only a small fraction of the exchanger particle. The diffusion is necessarily slower in the medium of the pore phase than in a homogeneous phase having the same medium as the pore phase. This is the situation for two reasons. First, the diffusion path is obstructed by the framework and is, thus, tortuous rather than straight. Secondly, the movement of the diffusing species in the pore phase

may be reduced by friction or other interactions with the pore walls, together with a retarding effect of the electrostatic interaction between the ions and the exchange sites. The change of the Na^+-diffusion coefficient by heat treatment can be explained by one or combinations of these factors.

As was shown in Table 1, the fractional pore volume of the exchanger was unchanged upon heat treatment. Therefore, an increase in the diffusion coefficient in the exchanger with heating at 350 °C cannot be explained by a diminution in the tortuosity of the diffusing path or in the obstruction by the matrix. The retarding effect due to the electrostatic interaction between the ions and the exchange sites is also not effective, since changes of the exchange capacity for sodium ions and the electronic density on the fixed ionic groups of the exchanger have no influence on the exchange rate, as was described in a preceding report.[1] Collisions of ions and their friction with pore walls slow down the movement of the ions in the pore phase when the pores are not large enough compared to the size of the ions. From the large water content and fractional pore volume of the exchanger, sodium ions are considered to exist as hydrated ions in the exchangers. The diameter of hydrated sodium ions has been reported to be 1.2 to 1.4 nm.[7] Pores of dimeter smaller than 2.4 to 2.8 nm, therefore, strongly interrupt the movement of ions. On the other hand, such a retarding effect must be relaxed in pores lager than such a boundary value. As shown in Fig. 1, the peak, appearing in the vicinity of this boundary, of the distribution curve of the pore size in the exchanger heated at 200 °C shifted to the larger side of the boundary when the sample was heated at 350 °C. The large value of the Na^+-diffusion coefficient in the exchanger heated at 350 °C, therefore, is attributable to the large pore size, twice as large as the diameter of hydrated sodium ion, though some ambiguity remains concerning the effect of the broadness of the distribution curves. The further increase of the exchange rate for a sample heated at 450 °C may be partly due to a further increase in the diffusion coefficient produced by an increase in the pore diameter to 6.5 nm. Figure 5 shows the X-ray diffraction patterns of the samples, indicating an enhanced crystallization of the exchanger heated at 450 °C. If the retarding effect of pore walls on the diffusion of ions is small in a well-ordered exchanger matrix, the effective diffusion coefficient of ions may be increased by crystallization. As an example, Nancollas reported that the effective diffusion coefficient of sodium ions in hydrons thorium(IV) oxide was increased by the crystallization of the matrix.[8]

The effect of heating on the isotopic exchange rates of sodium ions for the hydrous niobium(V) oxide can be summarized as follows.

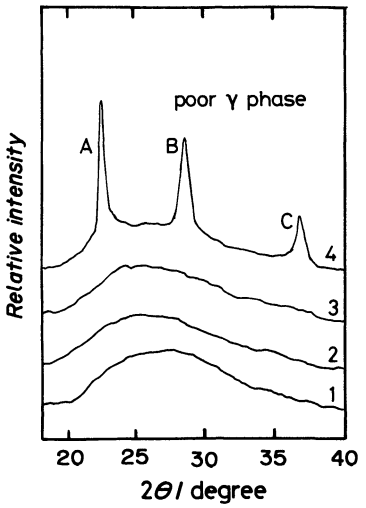

Fig. 5. X-Ray diffraction patterns.
Temperature of treatment, 1: R.T., 2: 200 °C, 3: 350 °C, 4: 450 °C. Interplaner distance/nm, A: 0.393, B: 0.315, C: 0.246.
γ-Niobium(V) oxide: low temperature phase of the compound reported by Brauer[9] and by Holtzberg et al.[10]

When an exchanger of large particle size is heated at 200 °C, the effective radius of the exchanger particle is decreased due to cracks which develop in the exchanger particles, resulting in an increased rate in the exchange reaction. A further increase in the exchange rate, when samples are heated at temperatures higher than 200 °C, can be explained in terms of an increase in the diffusion coefficient of sodium ions due to a reduction of the interactions between the ions and the pore walls, and the collisions of ions in the pores.

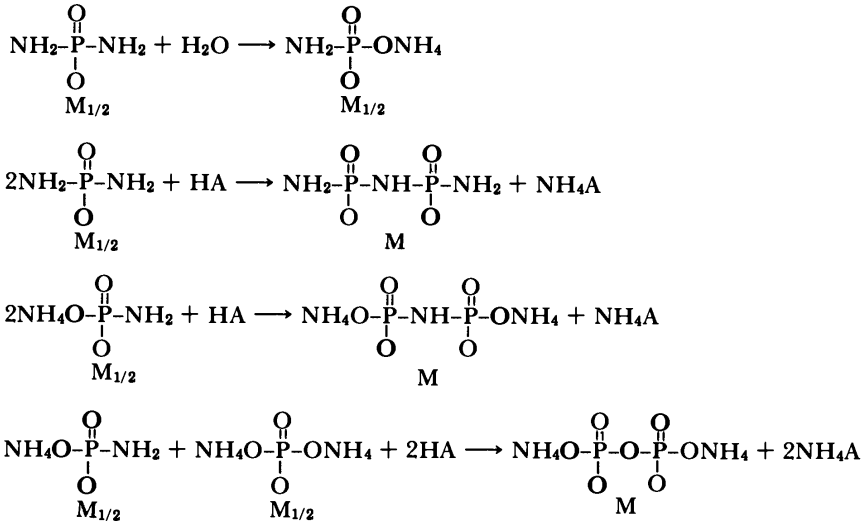
The Synthesis and Chemical Reaction of Magnesium and Calcium Bis(phosphorodiamidates) with Acids

Shoji SATO, Takao TAKAYANAGI, and Makoto WATANABE*
Department of Industrial Chemistry, Chubu University,
Matsumoto-cho, Kasugai, Aichi 487
(Received June 30, 1988)

Magnesium bis(phosphorodiamidate) hexahydrate and calcium bis(phosphorodiamidate) dihydrate were made by adding an aqueous solution of magnesium chloride or calcium chloride to a sodium phosphorodiamidate solution. These phosphorodiamidates reacted with the water of crystallization and/or adsorbed water to produce phosphoramidate and orthophosphate. They also reacted with HCl gas, acetic acid, and oxalic acid to make polyphosphates and phosphates with amino and/or imino groups. Several typical reactions are as follows:



where M and HA stand for alkaline earth metal and acid respectively.

There are many kinds of phosphorus-nitrogen compounds. Among these compounds, the phosphazenes may be the best known and the most intesively studied ones. These compounds have attracted much attention from the theoretical, synthetic, mechanistic, and technological points of view.[1] There are a series of phosphorus-nitrogen compounds which have amino groups on a phosphorus atom. These compounds can be used as fertilizers, flame retarders, and starting materials for the preparation of organic and inorganic phosphorus compounds.[2] The present authors have previously reported the syntheses and thermal behavior of several phosphoramidates.[3-8] When the phosphoramidates were heated in air at a moderately high temperature (100—1000 °C), they mainly produced ortho- and polyphosphates, although a small amount of polyphosphates containing imino groups was also formed. The present authors also studied the synthesis and thermal behavior of sodium phosphorodiamidate.[9] The phosphorodiamidate was finally converted to sodium metaphosphate when it was heated in air above 300 °C. An amino group on these phosphoramidates was, accordingly, thermally unstable in air, and it was difficult to prepare phosphates containing imino groups from phosphoramidates by means of thermal condensation. The chemical reactions of alkaline earth bis(phosphorodiamidates) with hydrogen chloride, acetic acid, and oxalic acid have now been carried out in order to study the condensation and decomposition of the amino groups in the phosphorodiamidates.

Experimental

Preparation of Phosphorodiamidates. Sodium phosphorodiamidate pentahydrate was made by the method described in our previous paper.[9] The phosphorodiamidate (20.8 g) was dissolved in 100 cm^3 of water, and then 100 cm^3 of a 0.5-mol dm^{-3} solution of magnesium chloride or calcium chloride was added. Acetone (500 cm^3) was put into the resulting mixed solution, and a white precipitate was filtered off. The product was dissolved in 150 cm^3 of water, and the residue was removed by filtration. The product was recrystallized by adding 300 cm^3 of acetone to the solution. The recrystallized product was filtered off, washed with 75 Vol%-aqueous acetone, and then dried in a silica-gel desiccator at room temperature for several days.

Reaction of Phosphorodiamidates with Hydrogen Chloride. About 3—4 g of a phosphorodiamidate sample was placed in a reaction glass tube. The air in the tube was replaced with

dried nitrogen gas. Dried hydrogen chloride, which had been prepared by adding concentrated hydrochloric acid to concentrated sulfuric acid and by then passing the resulting gas through concentrated sulfuric acid, was introduced into the reaction tube. The reaction product was washed quickly with ethanol to remove the HCl gas adsorbed on the product.

Reaction of Phosphorodiamidates with Acetic Acid. Magnesium phosphorodiamidate (5 g) or calcium phosphorodiamidate (4 g) was placed in a mixed solution of 2 cm^3 of acetic acid and 20 cm^3 of chloroform. The mixture was then heated at 25 or 60 °C in a water bath while being stirred. The solid product was filtered off and washed with ethanol.

Reaction of Phosphorodiamidates with Oxalic Acid. Phosphorodiamidate (2 g) and oxalic acid (3 g) were added to 100 cm^3 of ethanol. The mixture was then heated at 25 or 60 °C in a water bath, after which the solid product was filtered off and then washed with ethanol.

Chemical Analysis. Alkaline earth cations, phosphorus, and nitrogen in a sample solution were determined by, respectively, the EDTA (disodium dihydrogen ethylenediaminetetraacetate dihydrate) titration method with a BT indicator, Molybdenum Blue colorimetric analysis, and the Kjeldahl technique.

The Paper Chromatography and Colorimetry of Phosphates. A sample (0.1 g) was dissolved in 10 cm^3 of a 6% EDTA solution by adjusting the pH of the solution to 9—10. The paper-chromatographic separation and colorimetric determination of the phosphate species in the solution were carried by the methods described in our previous paper.[3] A modified stock solution of a molybdenum(V)-molybdenum(VI) reagent was used.[10]

HPLC Technique. The HPLC analysis which was developed by Yoza was employed to separate and determine the phosphate species in a sample.[11] A separation column (2.6 mm×500 mm) with TSK-GEL (SAX-F0011), a Shimadzu spectrophotometer (UV-110-02), and KCI eluents (0.20 and 0.40 mol dm^{-3}) were used for the analysis. About 10 mg of a sample was dissolved in 10 cm^3 of water or a 6% EDTA solution, and 200 mm^3 of the solution was injected into the column.

X-Ray Diffractometry. An X-ray diffraction diagram of a powder sample was taken with nickel-filtered Cu $K\alpha$ radiation using a Rigaku X-ray diffractometer, RAD-1B.

IR Spectrophotometry. An IR spectrum of a sample was recorded on a JASCO IR spectrophotometer, A-3, using the KBr disc method.

^{31}P NMR Measurement. A sample was dissolved in water or a 6% EDTA solution. The ^{31}P NMR spectrum of the sample solution was taken by means of a JNM-GX 270 spectrograph. The chemical shifts are reported relative to external 85%-orthophosphoric acid, with the positive shifts being downfield.

Results and Discussion

Composition of Phosphorodiamidates. The phosphorodiamidates gave a single ^{31}P NMR peak at +14.4 ppm at pH 9. (The peak shifted to +8.5 ppm at pH 5—4.) Found for magnesium salt: Mg, 7.5; P, 19.7; N, 17.5%. Found for calcium salt: Ca, 15.1; P, 23.5; N, 21.1%. Calcd for $Mg[PO_2(NH_2)_2]_2 \cdot 6H_2O$: Mg, 7.5; P, 19.2; N, 17.4%. Calcd for $Ca[PO_2(NH_2)_2]_2 \cdot 2H_2O$: Ca, 15.1; P, 23.3; N, 21.1%. Accordingly, the products are magnesium bis(phosphorodiamidate) hexahydrate and calcium bis(phosphorodiamidate) dihydrate. The yields of the products were about 80%. The magnesium phosphorodiamidate was stable below 5 °C, but it gradually decomposed above room temperature (15—25 °C). On the other hand, the calcium phosphorodiamidate was stable at room temperature.

Reaction with Hydrogen Chloride. When hydrogen chloride gas was introduced into the reaction tube, an elevation of the temperature in the tube was observed. The highest temperature was about 50—60 °C. The analytical data of the nitrogen content and the X-ray diffraction analysis of the reaction products are given in Table 1. (Since the paper-chromatographic separation between phosphate species in the products could not be achieved with the developing solvents employed in this experiment, the analytical data of the composition of the products as obtained by paper chromatography are not given in the table.) According to the results shown in the table, the magnesium phosphorodiamidate reacted with HCl gas to produce an ammonium ion. In the case of the reaction of the calcium phosphorodiamidate, the reaction rate seemed much slower than that of the magnesium salt. The IR spectral data in Fig. 1 show the absorption of NH_4^+ at 1400 cm^{-1} in good agreement with the results in Table 1. The IR spectra of the products also give peaks due to P–O–P and/or P–NH–P linkages at 920 and 730 cm^{-1}. This means that the phosphorodiamidates produce polymers associated with P–O–P and/or P–NH–P linkages by the reaction with HCl gas. The

Table 1. Nitrogen Content and X-Ray Diffraction Data of the Reaction Products of Phosphorodiamidates with HCl Gas

Phosphorodiamidate	Reaction time/min	Total N/%	N as NH_4^+/%	X-Ray dif.
$Mg[PO_2(NH_2)_2]_2 \cdot 6H_2O$	60	17.4	8.4	NH_4Cl, UK
	180	15.8	9.5	NH_4Cl, UK
	300	15.5	9.3	NH_4Cl, UK

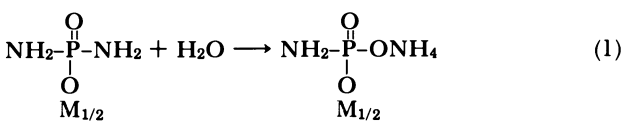
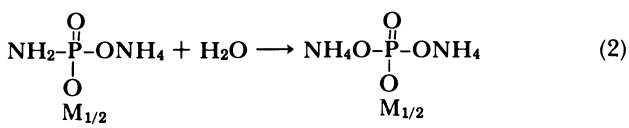
and/or imino groups.[12] The HPLC profile of the products in Fig. 3 indicates that the products contain phosphorodiamidate, phosphoramidate, orthophosphate, diphosphate, imidodiphosphate, triphosphate, and higher-chain and ring polyphosphates with P–O–P and P–NH–P linkages. According to the results, the following reaction processes can be written for the reaction systems:

(1) Decomposition



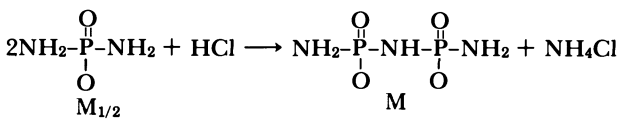
(1)



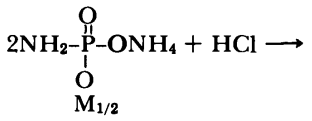
(2)

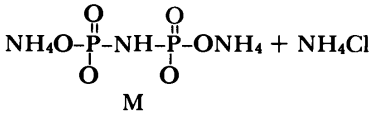
The water in the above reaction can come from the water of crystallization and/or the adsorbed water of the phosphorodiamidates and from the slight amount of water in the gas in the reaction systems.

(2) Condensation

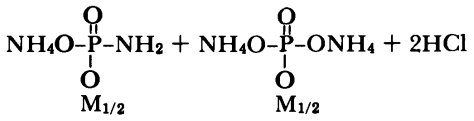


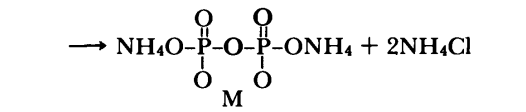
(3)



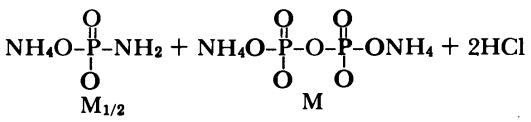


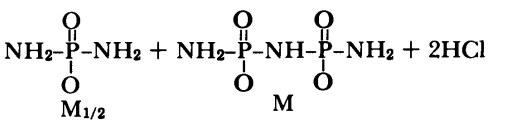
(4)



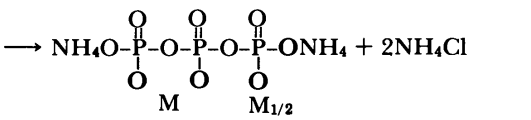


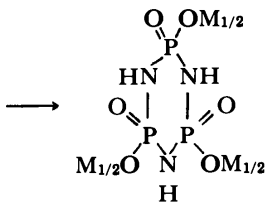
(5)



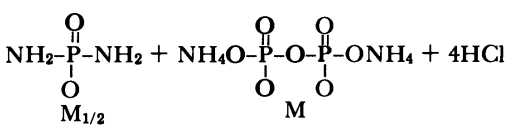


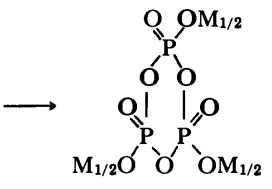
(6)





+2NH4Cl (7)

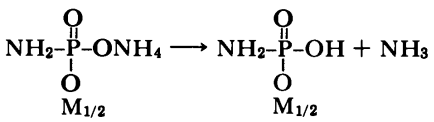




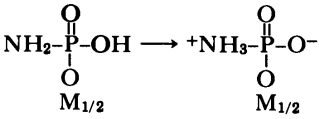
+4NH4Cl (8)

where M stands for alkaline earth metal. (Only typical reactions are shown above.)

The phosphoramidate with an OH group was considered to from a zwitterion:[2]

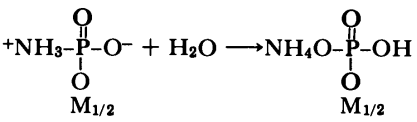


(9)

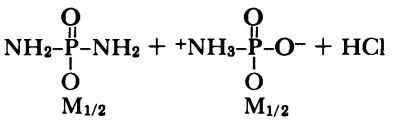


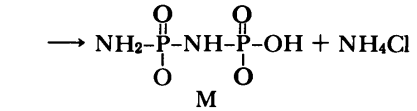
(10)

The zwitterion is very active and can react with water, phosphoramidates, and phosphates to produce orthophosphate, polyphosphates, and phosphates with amino and/or imino groups:

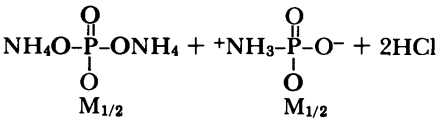


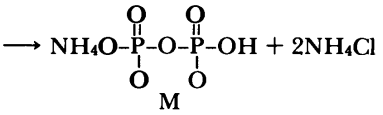
(11)





(12)





(13)

It was difficult, however, to obtain exact information about the zwitterion, so it is impossible to decide which process is most reasonable for the reaction systems.

Reaction with Acetic Acid. The nitrogen content and the results of the X-ray diffraction analysis of the reaction products of the phosphorodiamidates with acetic acid are listed in Table 2. The results show that the amino group in the phosphorodiamidates was converted to an ammonium ion by the reaction with acetic acid. The IR spectra of the products in Fig. 4 exhibit an absorption of an NH_4^+ ion at 1400 cm^{-1}. The results agree well with those in Table 2. The IR spectra also show that the products have P-O-P and/or P-NH-P linkages by means of the absorption at 920 cm^{-1}. The ^{31}P NMR spectra of the reaction products in Fig. 5 give peaks due to orthophosphate, phosphoramidate, and an end-PO_4 group, a middle-PO_4 group, and unknown materials. As has been men-

tioned above, the peaks in the magnetic fields lower than that of orthophosphate seemed to be attributable to the peaks of phosphates associated with amino and/or imino groups. The HPLC profiles of the products in Fig. 6 give peaks of orthophosphate, phosphoramidate, diphosphate, imidodiphosphate, triphosphate, and higher-chain and ring polyphosphates containing P–O–P and/or P–NH–P linkages. Accordingly, the same decomposition reactions as in Eqs. 1 and 2 can be given for the reaction systems. The following condensations of phosphate species with acetic acid can be described for the systems:

(Only a few typical reaction models are described here.)

Reaction with Oxalic Acid. The chemical analysis of the nitrogen content and X-ray diffraction data of the products in Table 3 show that the phosphorodiamidates react little with oxalic acid at 25 °C. The amino group in the phosphorodiamidates is converted to an ammonium ion at 60 °C. The IR spectra of the reaction products in Fig. 7 show an absorption of NH_4^+ at 1400 cm^{-1} and support the results in Table 3. The ^{31}P NMR spectra of the products of the magnesium phosphorodiamidate in Fig. 8 indicate large peaks of orthophosphate, phosphoramidate, an end-PO_4 group, a middle-PO_4, group, and unknown species. The ^{31}P NMR spectra of the other reaction products gave a large peak of phosphorodiamidate and very small peaks of the other species. This means that the rates of the reactions other than that of the magnesium salt at 60 °C are very small. These results are well supported by the HPLC data in Fig. 9. According to the above results, one can write the same decomposition reactions as Eqs. 1 and 2, and the condensation reaction processes similar to those of acetic acid for the reactions with oxalic acid, thus:

Hydrothermal Synthesis of Gallium Orthophosphate Crystals

Shin-ichi HIRANO* and Pan-chae KIM
Department of Applied Chemistry, Faculty of Engineering, Nagoya University,
Furo-cho, Chikusa-ku, Nagoya 464
(Received July 27, 1988)

Synthesis and crystal growth of $GaPO_4$ have been carried out in order to elucidate the properties of gallium orthophosphate. Single crystals were hydrothermally grown in the low temperature range from 150 to 180 °C. Solubility of $GaPO_4$ was measured under hydrothermal conditions, and the temperature coefficient of solubility was found to be negative in H_3PO_4 solution. Single crystals have morphologies bounded by the major rhombohedral $(10\bar{1}1)$ faces under lower temperature and pressure conditions. Polymorphs of $GaPO_4$ exist corresponding to low quartz type, low and high cristobalite types.

On the study of orthophosphate crystals M(III)PO_4, with M=Al, Ga, Fe, or Mn, compared with the extensive studies on berlinite ($AlPO_4$), little has been done on other crystals. It is well known that the single crystal of $AlPO_4$ has a larger piezoelectric coupling constant than quartz.[1] Single crystals of $GaPO_4$ which have a similar structure to $AlPO_4$ have potential as a promising material with interesting piezoelectric properties. However, the synthesis and properties of $GaPO_4$ single crystals have not been well investigated. This work describes the following studies; (1) synthesis of $GaPO_4$ particles as a single phase, (2) measurement of solubility of $GaPO_4$ in 4 mol dm^{-3} H_3PO_4 hydrothermal solution, (3) growth of $GaPO_4$ single crystals in H_3PO_4 solution at low temperatures below 180 °C, (4) phase transition of $GaPO_4$ single crystals.

Experimental

The starting particles of $GaPO_4$ were prepared by the solid state reaction of a stoichiometric mixture of Ga_2O_3 (99.99% purity) and $NH_4H_2PO_4$ (>99.0% purity) at 1000 °C for 24 h, and subsequently by the hydrothermal treatment at 180 °C and 14.7 MPa for 24 h in 4 mol dm^{-3} H_3PO_4 solution.[2,3] The hydrothermal runs were carried out in a test-tube type pressure vessel. The temperature was controlled with a calibrated chromel-alumel thermocouple set in the pressure vessel. The pressure was measured with a calibrated Heise gauge with an accuracy of ±0.5%. The solubility was determined by the weight loss method with a gold capsule of about 0.4 cm^3 in inner volume with recrystallized powders. The powders and H_3PO_4 solution were sealed hermetically in the gold capsule, and placed in a pressure vessel. Solubility runs were carried out at desired temperatures and pressures. Equilibrium was achieved after 3 d. Therefore, the solubility was measured by experimental runs for longer than 3 d, which were found to be enough to reach the equilibrium by preliminary experiments. The pressure vessel was quenched into cold water, the capsule was cut-open, and the powders were rinsed on a filter, dried and weighed. Synthesis runs of $GaPO_4$ single crystals were carried out by the following two methods because of its negative temperature coefficient of solubility; runs were performed by an inverse method with the nutrient in a lower temperature region and the others by the temperature increase method. The hydrothermal growth conditions are a temperature of 150—180 °C, a pressure of 14.7 MPa, a solvent of 4 mol dm^{-3} H_3PO_4 and a run duration of 3—7 d. The morphology of the grown single crystals was observed by optical microscopy. Phase transitions of $GaPO_4$ single crystals were investigated by DTA and XRD.

Results and Discussion

Synthesis of the Starting Particles. In order to investigate the solid state reaction process between Ga_2O_3 and $NH_4H_2PO_4$, DTA-TG analysis was carried out at a heating and cooling rate of 10 °C min^{-1} (Fig. 1). Endothermic peaks at about 200 and 300 °C are ascribed to the two step decomposition reactions of $NH_4H_2PO_4$.[2] The partial reaction of Ga_2O_3 with P_2O_5 produced from $NH_4H_2PO_4$ took place at about 450 °C to form $GaPO_4$, associated with amorphous $Ga(H_2PO_4)_3$ compound. The XRD indicated the formation of crystalline $GaPO_4$. Amorphous $Ga(H_2PO_4)_3$ decomposed to $Ga(PO_3)_3$ at about 550 °C. $GaPO_4$ was formed in a highly crystallized state associated with evaporation of P_2O_5 above about 850 °C. The formation of $GaPO_4$ crystalline powders took place by the decomposition of $Ga(PO_3)_3$ to loose P_2O_5, at which a little weight loss occurred. The products reacting up to 800 °C were consist with Ga_2O_3, P_2O_5, $GaPO_4$, and $Ga(PO_3)_3$. The formation reaction of $GaPO_4$ completed above 800 °C. The prepared powders treated at 1000 °C for 24 h and then cooled to room temperature were composed of the low temperature type $GaPO_4$, P_2O_5 glass and the high

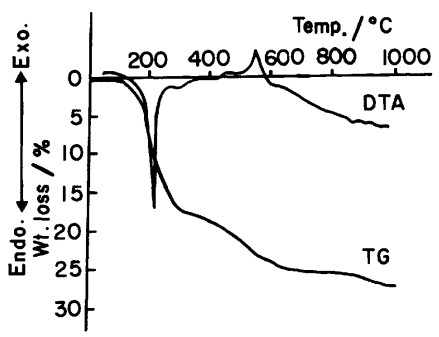

Fig. 1. Thermogravimetric and differential thermal analysis of the reaction product between Ga_2O_3 and $NH_4H_2PO_4$.

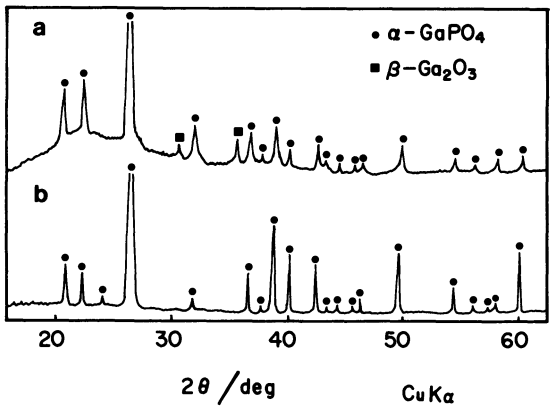

Fig. 2. X-Ray diffraction profiles of Ga_2O_3-$NH_4H_2PO_4$ mixture, (a) reacted twice at 1000 °C for 24 h, and (b) hydrothermally treated at 180 °C and 14.7 MPa for 24 h in 4 mol dm^{-3} H_3PO_4 solution.

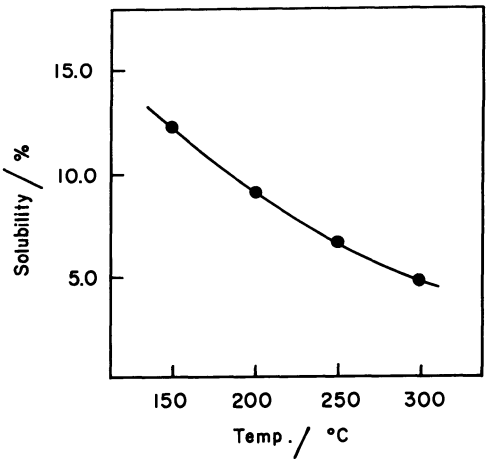

Fig. 3. Weight percent solubility of $GaPO_4$ as a function of temperature at 14.7 MPa in 4 mol dm^{-3} H_3PO_4 solution.

temperature type Ga_2O_3 as shown in Fig. 2 (a). The above results indicate a solid state reaction process to form $GaPO_4$ as follows:

$$2NH_4H_2PO_4 \rightarrow P_2O_5 + 2NH_3\uparrow + 3H_2O\uparrow \text{ (200 and 300 °C)}$$

$$Ga_2O_3 + 3P_2O_5 + 6H_2O \rightarrow 2Ga(H_2PO_4)_3 \text{ (ca. 450 °C)}$$
$$(Ga_2O_3 + P_2O_5 \rightarrow 2GaPO_4)$$

$$Ga(H_2PO_4)_3 \rightarrow Ga(PO_3)_3 + 3H_2O\uparrow \text{ (ca. 550 °C)}$$

$$Ga(PO_3)_3 \rightarrow GaPO_4 + P_2O_5\uparrow \text{ (>800 °C)}$$

In order to prepare the $GaPO_4$ particles as a single phase, these mixture powders were hydrothermally treated at 180 °C and 14.7 MPa for 24 h in 4 mol dm^{-3} H_3PO_4 solution. As shown in Fig. 2 (b), it was confirmed that only the low temperature type of $GaPO_4$ formed as a single phase. Single phase $GaPO_4$ particles were used for the solubility measurement and crystal growth.

Solubility. Solubilities in 4 mol dm^{-3} H_3PO_4 hydrothermal solution were measured as a function of temperature and pressure over the range 150—300 °C and 14.7—44.1 MPa. Figure 3 shows the solubility of $GaPO_4$ as a function of temperature at 14.7 MPa in 4 mol dm^{-3} H_3PO_4 solution. In turns out that the temperature coefficient of solubility at constant pressure, $(\partial S/\partial T)_p$, is negative over the range 150—300 °C. This fact indicated several features of importance to crystal synthesis, i.e. it is eventually required to proceed the crystal growth with supersaturation provided by a temperature difference under hydrothermal conditions where the nutrient was sustained in the low temperature region of the pressure vessel. The solubility was re-plotted as a relation of log (solubility) with $1/T$, in order to investigate the dissolution behavior of $GaPO_4$ in 4 mol dm^{-3} H_3PO_4

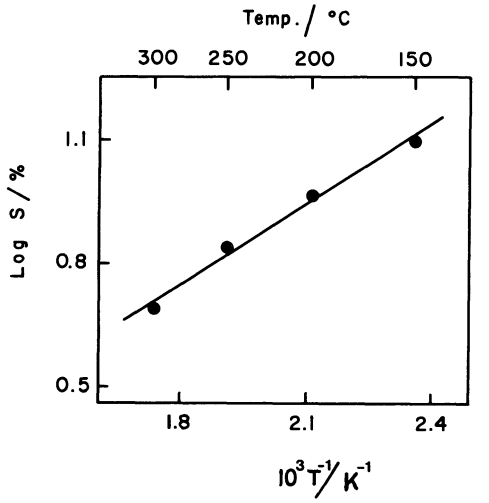

Fig. 4. Log solubility (Log S) of $GaPO_4$ as a function of $1/T$ at 14.7 MPa in 4 mol dm^{-3} H_3PO_4 solution.

$$S = \frac{\text{Wt. of dissolved } GaPO_4}{\text{Wt. of } H_3PO_4 \text{ solution}} \times 100\ (\%)$$

hydrothermal solution at 14.7 MPa (Fig. 4). The figure reveals that the van't Hoff equation was well obeyed. From the slope of Fig. 4, the heat of dissolution with the solvent, ΔH, was calculated to be about −5.4 kJ mol^{-1}. Figure 5 shows the solubility of $GaPO_4$ as a function of pressure in 4 mol dm^{-3} H_3PO_4 solution at constant temperature. The result indicates that the solubility increases with pressure under these conditions. Therefore, the general solubility behavior of $GaPO_4$ at low concentrations of H_3PO_4 solution is similar to that at relatively high concentrations.[3] However, as far as the growth experiment is concerned, the concentration of hydrothermal solvent must be especially considered because the viscosity of H_3PO_4 solution increases with increase of concentra-

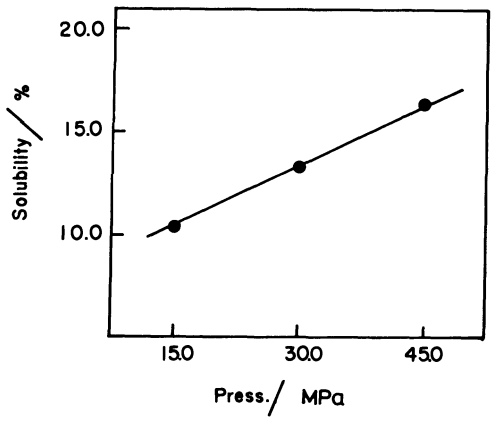

Fig. 5. Weight percent solubility of $GaPO_4$ as a function of pressure at 180 °C in 4 mol dm^{-3} H_3PO_4 solution.

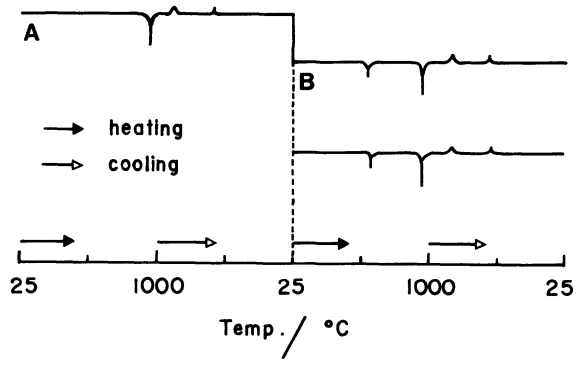

Fig. 7. Typical differential thermal analysis curves of $GaPO_4$ heated and cooled at 10 °C min^{-1}, (A) the first $GaPO_4$ run, and (B) the second $GaPO_4$ run of reverse changes.

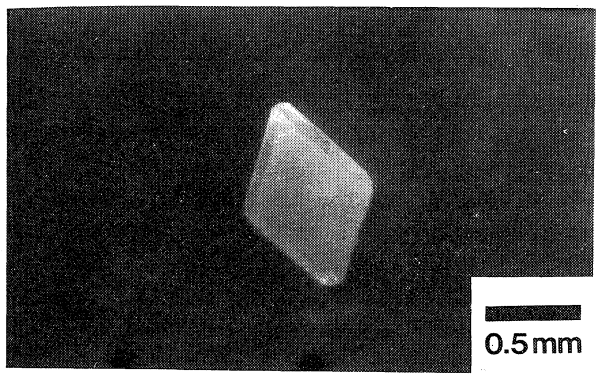

Fig. 6. Microscopic photograph of an α-quartz type $GaPO_4$ single crystal grown hydrothermally in 4 mol dm^{-3} H_3PO_4 solution at 150—180 °C and 14.7 MPa for 3 d.

tion such as 4 mol dm^{-3} H_3PO_4 solution; 4.5×10^{-3} Pa s, 6 mol dm^{-3} H_3PO_4 solution; 5.0×10^{-3} Pa s and 7.25 mol dm^{-3} H_3PO_4 solution; 5.6×10^{-3} Pa s. It becomes more difficult to avoid taking up the highly viscous solution within grown single crystals in highly concentrated solution.

Synthesis of $GaPO_4$ Single Crystals. Based on the results of solubilities, preliminary synthesis runs were carried out under the following conditions: temperature, 150—180 °C; heating rate, 10 °C d^{-1}; pressure, 14.7 MPa; run duration, 3 d; solvent, 4 mol dm^{-3} H_3PO_4 solution. Under these conditions, synthesis of single crystals was achieved by heating the saturated solution at the constant heating rate, i.e. the temperature increase method. As a result, spontaneously nucleated crystals were obtained at the lower part of the gold capsules (higher temperature region) and a typical grown crystal is shown in Fig. 6. At lower growth temperature in 4 mol dm^{-3} H_3PO_4 solution, typical grown crystals tended to be bounded by well developed major rhombohedral ($10\bar{1}1$) faces. The alternative technique was applied to grow $GaPO_4$ crystals, i.e. the inversely placed method, at 180 °C and 14.7 MPa in 4 mol dm^{-3} H_3PO_4 solution for 7 d. In a gold capsule, nutrient was set in a basket at the upper (cooler) part and the seeds were placed at the lower (hotter) part. Consequently, seeds were suspended in the hotter region and the excess nutrient in the cooler region. Also, a modified technique was used, that is the combination of the temperature increase method with inversely placed arrangement under several conditions. The growth features of the crystals did not depend on the growth method, but varied with the growth condition, e.g. at 240 °C and 25 MPa in 7.25 mol dm^{-3} H_3PO_4 solution, the crystals tended to be bounded by prism ($10\bar{1}0$) faces and terminated by small major rhombohedral ($10\bar{1}1$) faces and minor rhombohedral ($01\bar{1}1$) faces.[3]

Phase Transition of $GaPO_4$ Single Crystals. A few studies of phase transition on $GaPO_4$ have been reported.[4-6] However, the transition behavior has not been clarified yet with use of single crystals. In this work, the phase transitions of $GaPO_4$ single crystals were studied by the X-ray diffraction method and by the differential thermal analysis technique. The starting single crystals of $GaPO_4$ were identified by X-ray diffraction at room temperature. It was confirmed to consist of only the low temperature quartz type of $GaPO_4$. Typical differential thermal analysis curves for $GaPO_4$ single crystals are shown in Fig. 7. In the curve (A) of the first cycle run, the transition temperature with endothermic peak was observed at about 976 °C on the heating cycle, and those with exothermic peaks at about 915 and 576 °C on cooling. In the second heating cycle (B), the transition temperature with endothermic peaks were observed at about 608 and 957 °C on heating, and those with exothermic peaks at about 928 and 576 °C on cooling, respectively. The behavior of phases at the transition temperature was investigated by X-ray diffraction on the quenched

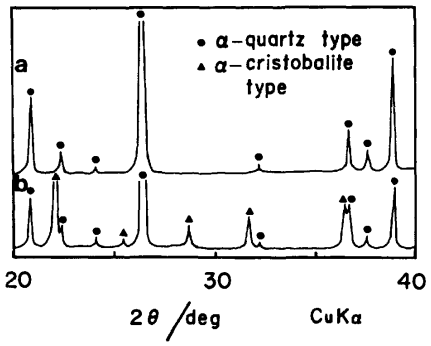

Fig. 8. X-Ray diffraction profiles of the starting $GaPO_4$, (a) the first $GaPO_4$ form, and (b) the second $GaPO_4$ form (in the data of Fig. 7).

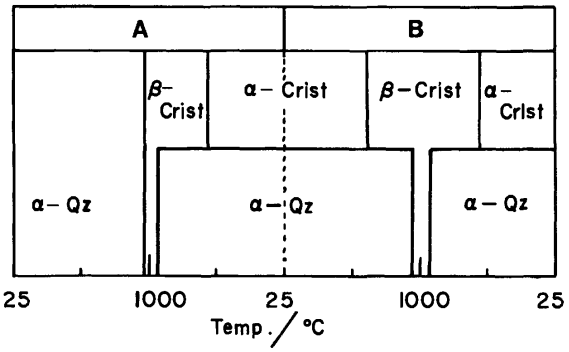

Fig. 9. The phase transition scheme of $GaPO_4$, (A) curve A, and (B) curve B of differential thermal analysis (in the data of Fig. 7).
α-Qz; low temperature quartz type, α-Crist; low temperature cristobalite type, β-Crist; high temperature cristobalite type.

specimens. In the curve (A) of the first run, it is shown that the phase transition from α-quartz type to β-cristobalite type $GaPO_4$ at around 970 °C on heating occurs, while on cooling, β-cristobalite type $GaPO_4$ was partially transformed to α-quartz type $GaPO_4$ and β-cristobalite type remained untransformed was subsequently transformed to α-cristobalite type $GaPO_4$. In the curve (B) of the second run, the phase transition from α-cristobalite type to β-cristobalite type $GaPO_4$ was observed at 608 °C. The α-quartz type transformed to β-cristobalite type $GaPO_4$ at 957 °C on heating, and the phase transition behavior on cooling was similar to the curve (A). From the above results, the starting phase of the first run was composed only of α-quartz type $GaPO_4$ of a single phase as shown in Fig. 8 (a). After cooled to room temperature from 1000 °C, α-quartz type and α-cristobalite type $GaPO_4$ coexisted, as shown in Fig. 8 (b). The results of these phase transitions were summarized in Fig. 9 on cycles.

Conclusion

α-Quartz type $GaPO_4$ particles were synthesized as a single phase by the solid state reaction of Ga_2O_3 with $NH_4H_2PO_4$ and subsequent hydrothermal treatment. Solubilities of α-quartz type $GaPO_4$ were measured under hydrothermal conditions over the range 150—300 °C and 14.7—44.1 MPa, and the temperature coefficient was found to be negative in 4 mol dm^{-3} H_3PO_4 solution. The solubility increased with increase of pressure in 4 mol dm^{-3} H_3PO_4 solution. The solubility of $GaPO_4$ obeyed the van't Hoff equation. The heat of dissolution with the solvent, ΔH, was about −5.4 kJ mol^{-1}. α-Quartz type $GaPO_4$ single crystals could be grown at lower temperature, pressure and concentration of solution, i.e. at 150—180 °C and 14.7 MPa in 4 mol dm^{-3} H_3PO_4 solution. Typical grown single crystals were bounded by well developed major rhombohedral ($10\bar{1}1$) faces. On heating, the phase transition from α-quartz type to β-cristobalite type $GaPO_4$ occurred at about 976 °C. On cooling, β-cristobalite type transformed to α-quartz type $GaPO_4$ at about 915 °C, and subsequently transformed to α-cristobalite type $GaPO_4$ at about 576 °C. On heating in successive runs, the phase transition from the α-cristobalite type to the β-cristobalite type $GaPO_4$ occurred at about 608 °C, and the α-quartz type which remained untransformed was transformed to the β-cristobalite type $GaPO_4$ at about 957 °C. On cooling, the β-cristobalite type transformed to the α-quartz type $GaPO_4$ at about 928 °C, and subsequently transformed to the α-cristobalite type $GaPO_4$ at about 576 °C.

A Calorimetric Study on the β' Phase in the System Tin-Antimony. Enthalpies of Mixing and Formation

Walid Ahmad BADAWI
Department of Chemistry, Faculty of Science, Al-Fateh University, Tripoli, Libya
(Received July 15, 1987)

Calorimetric studies on the behavior of the enthalpy of formation at 573 K in the system tin-antimony have been carried out at the compositions 44, 50, 57 at-% Sb using a presently constructed calorimeter. The enthalpy of mixing at 943 K has been determined in the whole range of composition. The relation of the behavior of mixing to that of formation is found as predicted earlier. The enthalpy of formation displays a pronounced temperature dependence above 623 K. The thermodynamic properties of the alloy SnSb at the three compositions exclude a transformation from β to β' phase around 600 K. Also estimated entropy terms indicate the absence of such a transformation. Earlier reported additional β phase in the system Sn-Sb seemed therefore not to be present.

In our previous studies[1,2] on the enthalpy of formation in the systems Bi-Sb and Sn-Sb, it was observed that the enthalpy of formation depends insignificantly on the temperature. On the other hand, Wittig and Schöffl[3] reported a pronounced temperature dependence of the heat of formation in the systems Al-Ag and Al-Zn. Such a temperature dependence was claimed to be a typical property of all metallic alloys. In order to determine the range of temperature for which this statement could be valid we have again been studying the system Sn-Sb, however, using a different procedure and a presently constructed isoperibolic calorimeter. This should also confirm the results obtained from our study[2] on the enthalpy of formation in this system and consequently test the accuracy of our calorimeter.

The phase boundaries in the system Sn-Sb have not yet been precisely predicted and diverging opinions and results exist with regard to the structures of the phases present and their transformations. Hansen and Anderko[4] rerported the existence of β and β' phases in the system Sn-Sb. According to their studies the transformation from β to β' phase should be accompanied by a change in the structure so that the β phase with a NaCl-structure exists above 598 K, while the β' phase with a distorted rhombohedral structure appears below 598 K in the region 42—58% Sb.

The present study on the system tin-antimony has been carried out in order to determine the existence of the β phase and its transformation. This would be possible by studying the thermodynamic properties of this system.

Experimental

Sample. The metals used were of extra purity grade (Riedel de Haen Co.). The preparation, treatment, and testing of the samples were all the same as reported earlier.[2]

High Temperature Diffraction Study. X-Ray (powder) photographs for samples at the compositions 58 and 50 at-% Sb were taken at 598 and 698 K (Table 1). They revealed nearly the same values for the lattice constant as those at room temperature.[2]

High Temperature Calorimetry. The calorimeter operates quasi-isothermally and represents an isoperibolic type of calorimeter. The cylindrical calorimeter of Thermax steel (Thermax 10, production No. 4742, Ger.) with a mass of 202 g is used as a sample container. The hollow space of the calorimeter is coated with a layer of aluminium oxide and its purpose was to prevent reaction of the sample with the calorimeter. The cover of the calorimeter, also coated with a layer of Al_2O_3, has three wells for the tube of the drop device, stirrer (made of ceramic) and Pt-to-(Pt+10 mass per cent Rh) thermopile. The calorimeter is suspended inside a metallic shield system of V2A steel which contains two cylindrical compensating systems of Thermax steel placed below and above the calorimeter. The lower compensating body has wells of each 3.5 mm diameter for the twelve differential thermopiles. The whole assembly is placed in a vertical tube furnace (R=41 Ω). Another tube furnace (R=35 Ω) is placed above the cooling system which in turn was placed at the mouth of a tube of silica glass containing the whole assembly. The purpose of the second tube furnace was to warm the sample before its final drop in the calorimeter.

The temperature difference between the calorimeter and lower compensating system are measured by means of a set of twelve differential thermopiles. These were calibrated on a standard Pt-PtRh thermopile. The accuracy obtained was found to be ±0.1 K. The thermal potential of the thermopiles is measured by means of a digital millivoltmeter (Hewlett-Packard 2401 C). The temperature drifts of the calorimeter from the lower compensating system are of negligible importance. The observed short-term fluctuation of the null-point is measured to 2×10^{-4} K min^{-1}. Excellent regulation of the temperature was obtained by means of a p-regulator.[5] The derived temperatures are judged to correspond with the IPTS-68 within 0.01 K at 500 K and 0.1 K at 1000 K. In fact the precision is considerably better, and the temperature increments are measured to 0.0003 K.

The calibration of the calorimeter occured on exactly measured enthalpy of tin sample.[3] The calibration factor is determined with an accuracy of 0.3% to an average value: ϕ=85.0±0.31 mV^{-1} min^{-1}.

The operation with this calorimeter can be explained with the aid of Table 2 and Fig. 1 which describe the process and evaluation of a measurement on alloy sample as follows:
Using the quasi-isothermal procedure, the calorimeter equation of 1st order becomes

$$Q = k \cdot \int_0^n (\vartheta - \bar{\vartheta}_v)\mathrm{d}t = K \cdot A \qquad (1)$$

where Q is the heat produced in the calorimeter in J, K the constant of heat interchange in $W K^{-1}$, ϑ the difference between the temperature of the calorimeter and that of the thermostat (compensating system) in the main period which represents the sum of all reads in the main period, and $\bar{\vartheta}_v$ the average value of all reads in the null-point periods: $\bar{\vartheta}_v=(\vartheta_v+\vartheta_n)/n$. A refers to the area under the curve as shown in Fig. 1 and t to the time in second. The determination of A and calculation of the heat content of an alloy sample are illustrated in Table 2: Subtraction of the average value of $\bar{\vartheta}_v$ and ϑ_n from all reads in the main period yields a reduced quantity which represents the deviations in the temperature of the calorimeter from the null-point in the pre- and post-period. The reduced quantity will be integrated according to the trapezoidal rule: The sum of the first and last reads in the main period will be devided by 2. Addition of this result to the sum of all reads between the first and last one gives the area A.

at the temperature T through the equations

$$-(1-x_2)\cdot \mathrm{Sn}(l,T) - x_2\mathrm{Sb}(l,T) + \mathrm{Sn}_{1-x_2}\mathrm{Sb}_{x_2}(l,T) = 0 \quad (2)$$

$$h^{\mathrm{M}} = -(1-x_2)\cdot h_1(T) - x_2 h_2(T) + h_3(T) \quad (3)$$

where h^{M} is the enthalpy of mixing of liquid tin and liquid antimony, h_3 the enthalpy of the alloy at the mole fraction of antimony x_2.

The enthalpy of mixing has been determined at 943 K in the whole range of composition (Table 3).

The enthalpy of formation is the special form of the enthalpy of reaction evolved by the formation of the substance from the elements. In the case of the tin-antimony alloy, the formation reaction is

$$-(1-x_2)\cdot \mathrm{Sn}(\mathrm{s},T_0) - x_2\cdot \mathrm{Sb}(\mathrm{s},T_0) + \mathrm{Sn}_{1-x_2}\mathrm{Sb}_{x_2}(\mathrm{s},T_0) = 0. \quad (4)$$

The enthalpy of formation is then

$$h^{\mathrm{F}} = -(1-x_2)\cdot h_1(T_0) - x_2\cdot h_2(T_0) + h_3(T_0) \quad (5)$$

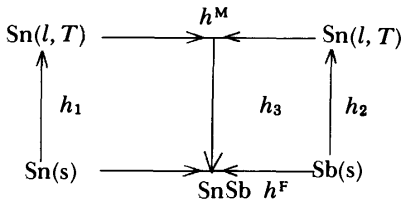
Indices 1, 2, and 3 refer to tin, antimony, and the alloy, respectively.

Subtraction of Eq. 5 from Eq. 3, yields

$$h^{\mathrm{M}} - h^{\mathrm{F}} = -(1-x_2)[h_1(T) - h_1(T_0)] - x_2[h_2(T) - h_2(T_0)] + [h_3(T) - h_3(T_0)] = {}^{\mathrm{e}}h(T) - {}^{\mathrm{e}}h(T_0) \quad (6)$$

where ${}^{\mathrm{e}}h(T)-{}^{\mathrm{e}}h(T_0)$ is the difference in the excess enthalpy of the alloy. The term $h_3(T)-h_3(T_0)$ is the enthalpy difference of the alloy; this was measured at even temperature interval of 10 K in the range 298.15 K to 923 K and tabulated together with the difference of the excess enthalpy at even temperature interval of 50 K in the same range of temperature. The enthalpy difference of tin and antimony are measured accurately (Table 4). All these heat contents have been measured using the present technique: The solid sample can be tempered at any temperature using a pre-furnace (see the description of the calorimeter) before the drop in a liquid phase of the same substance and composition existing inside the calorimeter. In this case the pre-dissolving of the sample is not required since the melting occurs in a liquid phase having the same composition as that of the sample so that the complications of the solution-calorimetry can be avoided. This also enables us to obtain the enthalpy difference between the solid and liquid phases.

The procedure for measurement of the enthalpy of formation (refer to Eq. 6) can be illustrated with reference to the following schema:



The non-measurable process of the enthalpy of formation will be substituted by (1) heating of tin and antimony at T, (2) measurement of the enthalpy of mixing at T, and (3) measurement of the enthalpy difference of the single miscible phase between T_0 and T. The value of h^{F} has been determined at three compositions (Table 7) employing the present procedure.

Results and Discussion

(i) Lattice Constant. Results of the lattice constant determinations at 598 and 698 K for the compositions 50 and 58 at-% Sb in the system Sn-Sb are presented in Table 1. They compare surprisingly well with those at room temperature.[2] These results are compatible to those expected for a β' phase with distorted rhombohedral structure.[4] This gives the first signal for the non-existence of further β phase claimed to be present in the phase diagram of the system SnSb.[4]

(ii) Enthalpy of Mixing. In Table 3 are listed the values of the enthalpy of mixing as determined in the present study. The results have been least squares fitted by a polynomial expression with a standard deviation of 0.3% for a single measurement. The present value of h^{M} is in good agreement with that by Hultgren et al.[6] and Wittig.[7] Also the result by Kleppa[8] who gives an accuracy of 1% for his measurements is in reasonable agreement with the present one.

(iii) Enthalpies. Table 4 illustrates values for $h_1(T)-h_1(298.15\ \mathrm{K})$ and $h_2(T)-h_2(298.15\ \mathrm{K})$ as measured in the present study. The average error of the individual measurements was found to be 0.32%, while the deviation for a single measurement of earlier reported data[6] was estimated to be 1—2%.

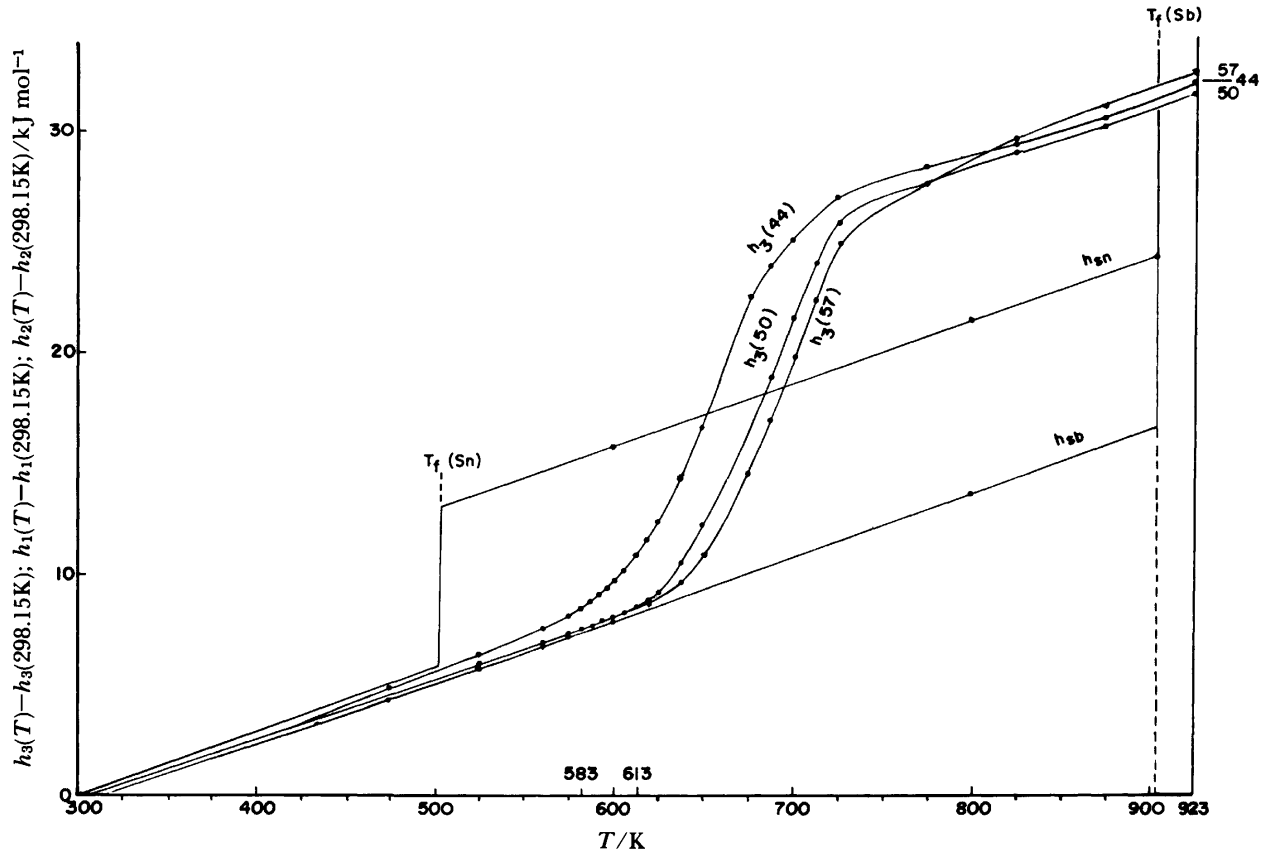

Fig. 2. Dependence of the enthalpy difference of Sn, Sb, and the alloy at the compositions 44, 50, and 57 at-% Sb on the temperature T.

In Table 5 are listed the present values of the enthalpy and excess enthalpy differences of the alloy SnSb in the region 298.15 to 923 K. The estimated standard deviation is 0.35% for a single measurement. Figure 2 shows the curves of the enthalpy differences of Sn and Sb against temperature in the range 300 to 923 K together with those for the enthalpy differences of the alloy at 44, 50, and 57 at-% Sb in the same range of temperature. The values of $h_3(T)-h_3(298.15\,K)$ for the three compositions in the region 583 to 618 K (as a part of the whole range 298.15 to 923 K) are obtained from a separate series of experiments using the present calorimeter and Wittig's one[7] for C_p measurements. The purpose of these additional measurements was to find

thorough trace for the trends of $h_3(T)-h_3(298.15\,K)$ around 600 K in order to detect any phase transformation which should occur around this temperature.[4]

In the case of a phase transformation, the curve of h_3 should indicate an abrupt rise in a form of a sharp bent around 600 K. Since this is not observed experimentally, such a transformation can be excluded (refer to Fig. 2).

(iv) Thermodynamic Properties of the Alloy. Table 6 represents values of C_p, $h_3^\circ(T)-h_3^\circ(298.15\,K)$, and $S^\circ(T)-S^\circ(298.15\,K)$ of the alloy SnSb at the compositions 44, 50, and 57 at-% Sb for selected temperatures in the range 298.15 to 923 K. The C_p for the composition 44 at-% Sb indicates a somewhat significant increasing trend due to the partially melting of the alloy in accordance with the phase diagram of the system Sn-Sb, while C_p for 50 and 57 at-% Sb increases insignificantly with the temperature. This is due to the fact that the alloy at the last two compositions can persist until 618 K. Since C_p at 698 K dose not display an abruptly increasing trend which could point out phase transformation, the β phase seems not to be producible.

Further important evidence for the absence of a transformation from β' to β phase is obtained from the quantitative information of the entropy terms: With reference to Table 6, the increase in the entropy change between 597 and 600 K is 0.45 J K^{-1} mol^{-1} for 44 at-% Sb, and 0.04 J K^{-1} mol^{-1} for 50 and 57 at-% Sb; and that between 593 and 600 K is 0.47, 0.39, and 0.39 J K^{-1} mol^{-1} for 44, 50, and 57 at-% Sb, respectively. Also the increase in the entropy change between 593 and 603 is not much larger 1.04, 0.54, and 0.54 J K^{-1} mol^{-1} for 44, 50, and 57 at-% Sb, respectively). Such a very small increase in the entropy change corresponds to usual increase in the enthalpy due to the rise in the temperature but not due to phase transformation.

(v) Enthalpy of Formation. The data in Table 7 represent values for the integral and partial molar enthalpy of formation at 573 K as obtained from the present study for the compositions 44, 50, and 57% Sb. A number in parenthesis is the estimated standard deviation (esd). The present data of h^F could confirm those obtained earlier[2] by using the Wittig's calorimeter.[7] This means that the present calorimeter could be useful for measurements of heat contents with an accuracy of 0.8% and reproducibility of 0.3%.

Table 7. Integral and Partial Molar Enthalpies of Formation in the System Tin-Antimony at 573 K in $J\,mol^{-1}$. Estimated Standard Deviations in Parenthesis

x_2	$-h^F$	$-h_1^F$	$+h_2^F$
0.44	3986(13)	9242	2606
0.50	3216(12)	10158	3752
0.57	2152(11)	11506	4924

From curve-fitting calculations, the following polynomial function for h^F is derived:

$$h^F = -5.655 - 4.101\,x_2 + 18.01\,x_2^2 \quad (7)$$

This equation would produce a curve for h^F similar to that one illustrated in Figs. 2 and 3 in the previous study.[2]

For the partial molar enthalpies of formation of tin and antimony, the following equations are derived:

$$h_1^F = -5.655 - 18.01\,x_2^2 \quad (8)$$

$$h_2^F = 8.254 - 18.01\,(x_2 - 1)^2 \quad (9)$$

These equations would also produce nearly the same curves as shown earlier.[2] The behavior of the enthalpy of formation and its partial quantities in relation to the composition has been discussed previously.[2] Also the behavior of the enthalpy of mixing and its partial quantities in relation to that of the enthalpy of formation is found as predicted earlier.[2] The discussion on the data of h^F will be here restricted to the dependence of h^F on the temperature and the transformation from β' to β phase.

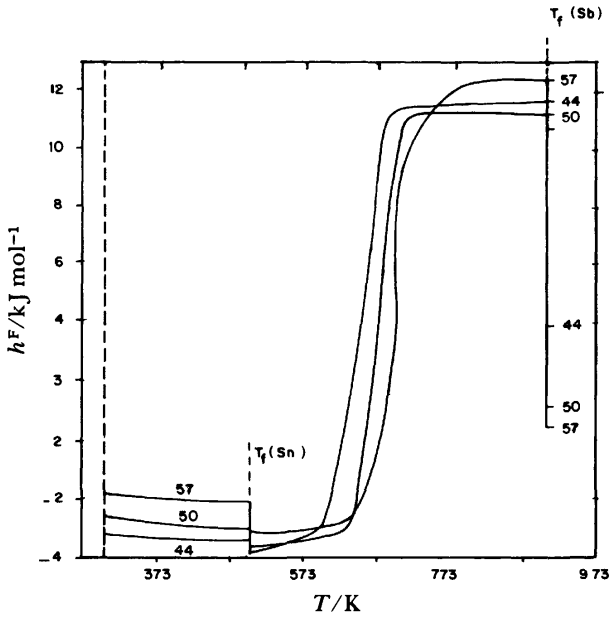

Fig. 3. Dependence of the enthalpy of formation, h^F, at the compositions 44, 50, and 57 at-% Sb on the temperature T.

With reference to the previous data,[2] the enthalpy of formation depends insignificantly on the temperature. This is only valid for the range 298.15 to 504 K. As shown in Fig. 3, h^F changes abruptly at the same temperatures around 505 and 904 K at the three compositions 44, 50, and 57 at-% Sb. This is due to the melting of Sn and Sb. Figure 3 also illustrates that h^F displays a pronounced temperature dependence above 623, 648, and 668 K at 44, 50, and 57 at-% Sb, respectively. This is due to the fact that the alloy can not persist until 623 K but partially melts in accordance with the phase diagram. The continuous formation of the liquid phase should be accompanied with continuous increasing enthalpy of formation. After completion of the liquid formation and disappearing of the β' phase, h^F increases insignificantly and drops finally due to the melting of antimony at 904.02 K (see Fig. 3).

Assuming that a β phase could exist at 598 K in equilibrium with the original one (β' phase), the entropy change for the sample with x_2=0.44 at 598 K would be

$$\Delta S = S(\beta) + S(\text{liquid}) - S(\beta') = n_s \cdot S^F_{x_s} + n_l[(1 - x_l)S^{fus}_{Sn} + x_l \cdot S^{fus}_{Sb} + S^M_{x_l}] - S^F_{x_2} \quad (10)$$

where $S^F_{x_s}$ and $S^F_{x_2}$ are the entropies of formation at the mole fractions of the solid x_s and antimony x_2, respectively. S^{fus}_{Sn} and S^{fus}_{Sb} refer to the entropies of Sn and Sb, respectively. $S^M_{x_l}$ is the entropy of mixing at the mole fraction of the liquid x_l.

With reference to the phase diagram of the system Sn-Sb[4] and applying the level rule, the number of moles of the liquid will be $n_l = \frac{x_2 - x_s}{x_l - x_s} = 0.132$ mol, and that of the solid is $n_s = 1 - n_l = 0.868$ mol (x_l=0.216; x_s=0.474; x_2=0.44).

Substitution of these values in Eq. 10 together with the entropy terms, yields

$$\Delta S = [(-0.868 \times 5.644) + 0.132\{(0.784 \times 13.916^{6}) + (0.216 \times 21.589^{6}) - 2.408^{7}\} + 6.366]\ \text{J K}^{-1}\ \text{mol}^{-1}$$

$$\Delta S = [3.205]\ \text{J K}^{-1}\ \text{mol}^{-1}.$$

The value of ΔS (3.205 J K^{-1} mol^{-1}) seems to be too large compared with that obtained for the increase in the change of the entropy between 593 and 603 K as 1.04 J K^{-1} mol^{-1} (see, Table 6 and p. 283). This means that our assumption of the existence of further β phase in equilibrium with the β' phase was incorrect and hence the first one seems not to be present. These views together with the above cited ones (C_p and [$h_3(T) - h_3$(298.15 K)] behavior around 598 K (the transformation temperature), estimated entropy terms and the results of the high temperature diffraction study) exclude a transformation from β to β' phase. It is also noteworthy that some strong views support the existence of only one phase.[9]

Behaviors of the Enthalpies of Mixing and Formation in the System Lead-Indium

Walid Ahmad BADAWI
Department of Chemistry, Faculty of Science, Al-Fateh University, Tripoli, Libya
(Received January 5, 1988)

The paper presents results of calorimetric studies on the enthalpies of mixing and formation in the system lead-indium. The enthalpy of formation is negative and becomes more negative at higher composition. The partial enthalpy of formation of lead is negative but increases at higher composition. The partial enthalpy of formation of indium is also negative and decreases with increasing the composition. The enthalpy of formation displays a considerable temperature dependence which seems to be smaller than that observed for the enthalpy of formation in other systems.

The studies of the behavior of the enthalpy of formation, $\Delta_f H°$, in binary systems begun in the previous papers[1,2] are now continued with another system, namely lead-indium. The phase diagram of this system has been previously studied by Hansen[3] and Elliott.[4] Also the enthalpy of solution has been measured by Hultgren et al.[5] However, no determination of the enthalpy of formation in the system Pb-In seems to be reported so far. Hence we report here values for the enthalpy of formation at 298.15 K and 423 K.

The studies by Wittig and Schöffl[6] on the enthalpy of formation in the systems Al-Ag and Al-Zn revealed a pronounced temperature dependence of $\Delta_f H°$. Such a temperature dependence was claimed to be a general property of all metallic alloys. On the other hand, the increase of the heat of formation due to an increase in the temperature was attributed to lattice defects of greater expansion of aluminum lattice in the alloys compared with the expansion in pure aluminum metal. However, such a lattice defect caused by the increase in the temperature is not common to all metallic solid solutions. Thus, further studies on other systems are required in order to decide if a pronounced temperature dependence of $\Delta_f H°$ is general property of all metallic alloys. For this reason, we have been studying the system Pb-In which was selected due to its large range of miscibility in the solid state.

Experimental

Sample. The metals used were of extra purity grade (Riedel de Haen Co.). The preparation, treatment, and testing of the samples were all the same as described before.[1] The samples were tempered for 6 h at 420 K, 6 h at 350 K, and 190 h at 320 K. The procedure adopted was similar to that used earlier.[2] In the measurement process, the samples of different masses (1.352—1.525 g) were dropped in a liquid phase (having the same composition and material as that of the solid sample) existing inside the calorimeter.

Apparatus. The calorimeter operates quasi-isothermally and represents an isoperibolic calorimeter. Figure 1 shows the apparatus which consists of a cooling system (10) in which a tube of silica glass (20), of 85 mm diameter and 800 mm height, with lower closed end was fixed by means of sealing-wax. The tube of silica glass contains a cylindrical shield system of V2A steel (13) being connected to a ring of brass by means of three rods of V2A steel. The ring of brass is placed in the lower part of the cooling system.

A set of plates of Nickel (12) are connected to the cover of the shield by means of three rods of V2A steel and their purpose was to distribute the heat radiation.

The cylindrical shield (ϕ_c=80 mm, ϕ=68 mm, h=200 mm) contains two cylindrical compensating systems of Thermax steel (14, 18) placed below and above a calorimeter also of Thermax steel (Thermax 10, production no. 4742, Germany). The hollow space of the calorimeter (16) is coated with a layer of aluminum oxide in order to provide better

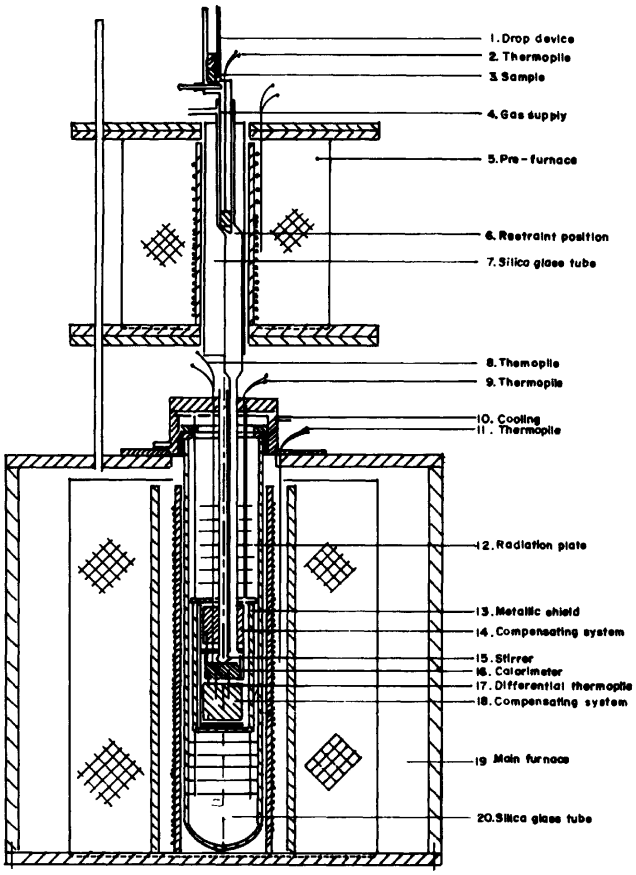

Fig. 1. Apparatus.

interchange of heat and to prevent reaction with the sample since the calorimeter was used as a sample container. The lower compensating system (18) was connected to a plate of V2A steel by means of two rods of the same material. This plate was used as a cover of the shield.

The change of the calorimeter after completion of a series of experiments occurs by moving the upper compensating system upwards.

The lower compensating system is connected to the calorimeter by means of a set of twelve differential Pt-to-(Pt+10 mass per cent Rh) thermopiles. These were calibrated on a standard Pt-PtRh thermopile. The cover of the calorimeter (sprayed with Al_2O_3) has three wells for the thermopile of the calorimeter (8), stirrer made of ceramic (15) and the silica glass tube of the drop device.

The upper compensating system (14) having the same dimensions as those of the lower one is placed on three studs made of ceramic. The differential thermopiles (17) and other ones have leeds which go through wells in the cover of the cooling system. These are sealed by means of lip sealing in form of rubber rings.

The whole assembly is placed in a vertical tube furnace (19) of 41 Ω resistance. Another vertical tube furnace (5) of 35 Ω resistance is placed above the cooling system. The role of the second furnace was to warm the sample before its final drop in the calorimeter. The drop of the sample to a position lying close to the center of the upper tube furnace occurs by means of a drop device (1). The restrain development (6) allows the sample to be tempered at any temperature. The final drop of the samle occurs by moving the upper part of the drop device upwards. The drop device is connected with argon gas supply (4) being connected with a purification and distribution device. The role of Ar gas is to prevent oxidation.

The temperature differences between the calorimeter and the lower compensating system were measured by means of a set of twelve differentical Pt-PtRh thermopiles. The sensibility of the thermopiles was increased due to isolation of their soldered joints with a layer of aluminum oxide instead of tubes of ceramic. This also reduced the dead time of the calorimeter. Excellent regulation of the temperature of the furnace was obtained by means of p-regulator.[7] The temperature of the guard body is kept 0.2 K below that of the shield, while the temperature of the furnace is kept 5 K lower to secure satisfactory operation of the control units. The calibration of the calorimeter was conducted measuring the enthalpy of a standard sample of tin.[8] The calibration factor was determined with an accuracy of 0.3%. The time needed to reach equilibrium was registered to 300 s. The calorimeter sensibility is 625 $\mu V\,K^{-1}$. The short-term fluctuation of the null point was measured to 2.1×10^{-2} K min^{-1}. The temperature drifts of the calorimeter from the lower compensating system were of negligible importance. The derived temperatures are judged to correspond with the IPTS-68 to within 0.01 K at 500 K and 0.1 K at 1000 K. In fact, the precision is considerably better and, the temperature increments were measured to 0.0003 K. The measurement of the thermal potential of the thermopiles occured by means of a digital millivoltmeter (Hewlett-Packard 2401 C).

Results and Discussion

(i) Enthalpies. Table 1 presents values of $H_1^\circ(T)-H_1^\circ(298.15\,K)$; $H_1^\circ(T)-H_1^\circ(423\,K)$ and $H_2^\circ(T)-H_2^\circ(298.15\,K)$; $H_2^\circ(T)-H_2^\circ(423\,K)$ as determined in the present study. The average error of the individual measurements was found to be 0.34% while the deviation for a single measurement of earlier reported data[5] was estimated to 1%.

Table 2 summarizes values of $[H_3^\circ(670\,K)-H_3^\circ(298.15\,K)]$ and $[H_3^\circ(720\,K)-H_3^\circ(423\,K)]$. The deviation is 0.32% for a single measurement.

(ii) Enthalpy of Mixing. The enthalpy of mixing of lead-indium at the temperature T_1 has been determined according to the following equations:

$$-(1-x_2)\cdot \mathrm{Pb}(l,T_1) - x_2\cdot \mathrm{In}(l,T_1) + \mathrm{Pb}_{1-x_2}\mathrm{In}_{x_2}(l,T_1) = 0 \quad (1)$$

$$\Delta_m H^\circ = -(1-x_2)H_1^\circ(T_1) - x_2H_2^\circ(T_1) + H_3^\circ(T_1) \quad (2)$$

where $\Delta_m H^\circ$ is the enthalpy of mixing of liquid Pb-In and H_3° is the enthalpy of the alloy at the mole fraction of indium x_2.

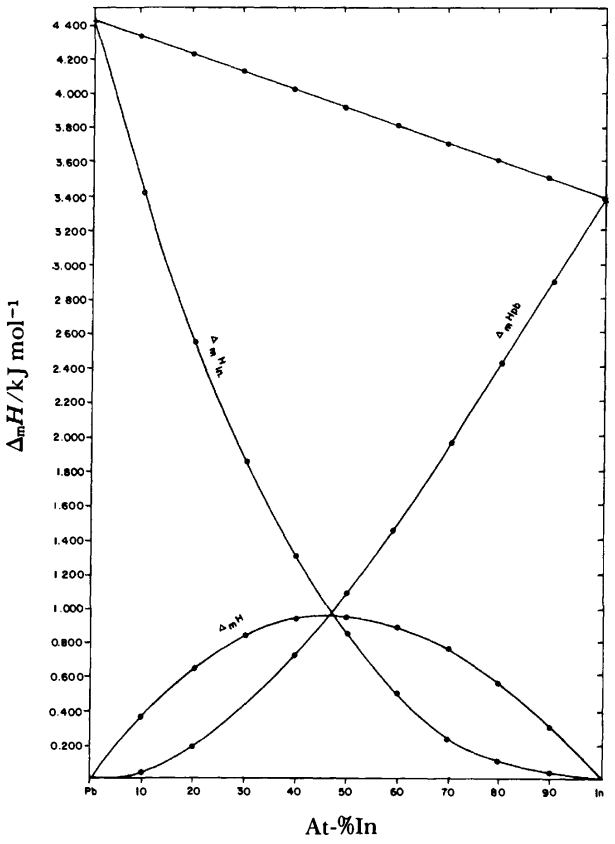

Fig. 2. The integral and partial molar enthalpies of mixing; the ξ-function at 670 K in the system Pb-In.

Table 3 collects the values of the integral and partial molar enthalpy of mixing and the ξ-values at 670 and 720 K in the whole range of composition. A number within parenthesis is the estimated standard deviation (esd). The accuracy obtained is 1% for $\Delta_m H°$ at 670 K and 0.6% for $\Delta_m H°$ at 720 K. The present value is in acceptable agreement with that by Hultgren et al.[5] From curve-fitting calculations, the following polynomial functions for $\Delta_m H$ are derived:

$T = 670$ K;

$$\Delta_m H° = 4.438x_2 - 5.467x_2^2 + 1.029x_2^3, \quad (3)$$

$T = 720$ K;

$$\Delta_m H° = 5.129x_2 - 6.363x_2^2 + 1.224x_2^3. \quad (4)$$

The curve of $\Delta_m H°$ against the composition is shown in Figs. 1 and 2. Figure 2 illustrates the trend of $\Delta_m H°$ at 670 and 720 K. From the data in Table 3 one may conclude that the enthalpy of mixing is small compared with that for other systems e.g. Sn-Sb.[2] This is due to excellent mixing of Pb with In. The enthalpy of mixing is positive and increases with the increase of indium mole fraction to reach a maximum at x_{In}=0.5 (Figs. 1, 2); after that the enthalpy of mixing decreases with the increase of the composition. The partial molar quantities of an integral thermodynamic property, Y, is given by

$$y_1 = Y - x_2 \cdot (\partial Y/\partial x_2)_{T,p} \quad (5)$$

and

$$y_2 = Y - (x_2 - 1) \cdot (\partial Y/\partial x_2)_{T,p} \quad (6)$$

Using Eqs. 3, 4, 5, and 6, we obtain

$T = 670$ K;

$$\Delta_m H_1^\circ = 5.467x_2^2 - 2.058x_2^3, \quad (7)$$

1.000	0	3.409	0	3.409	0	3.905	0	3.905

$$\Delta_m H_2^\circ = 4.438 - 10.934x_2 + 8.554x_2^2 - 2.058x_2^3. \quad (8)$$

$T = 720$ K;

$$\Delta_m H_1^\circ = 6.353x_2^2 - 2.448x_2^3, \quad (9)$$

$$\Delta_m H_2^\circ = 5.129 - 12.706x_2 + 10.025x_2^2 - 2.448x_2^3. \quad (10)$$

Table 3 also illustrates the ξ-values. For $\xi\,(T)$, the following equation was used:

$$\xi(T) = \Delta_m H^\circ(T)/x_2 \cdot (1 - x_2). \quad (11)$$

The polynomial functions for $\Delta_m H^\circ(T)$ were employed together with Eq. 11 to derive the following relations for ξ:

$$\xi(670\,\text{K}) = 4.438 - 1.029x_2, \quad (12)$$

$$\xi(720\,\text{K}) = 5.129 - 1.224x_2. \quad (13)$$

With reference to these equations, $\xi(T)$ exhibits a linear function. Figure 3 represents the experimentally determined values for ξ.

(iii) Enthalpy of Formation. The enthalpy of formation is the special form of the enthalpy of reaction evolved by the formation of the substance from the elements. In the case of lead-indium alloy, the formation reaction is

$$-(1 - x_2)\cdot \text{Pb(s, } T_0) - x_2 \cdot \text{In(s, } T_0) + \text{Pb}_{1-x_2}\text{In}_{x_2}\text{(s, } T_0) = 0 \quad (14)$$

where T_0 is the intial temperature.

The enthalpy of formation is then

$$\Delta_f H^\circ = -(1 - x_2)\cdot H_1^\circ(T_0) - x_2 \cdot H_2^\circ(T_0) + H_3^\circ(T_0) \quad (15)$$

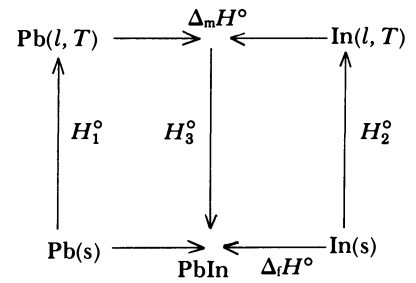
The indices 1, 2, and 3 indicate lead, indium, and the alloy, respectively.

Subtraction of Eq. 15 from Eq. 2, yields

$$\Delta_m H^\circ - \Delta_f H^\circ = -(1 - x_2)\cdot[H_1^\circ(T_1) - H_1^\circ(T_0)] - x_2 \cdot [H_2^\circ(T_1) - H_2^\circ(T_0)] + [H_3^\circ(T_1) - H_3^\circ(T_0)]. \quad (16)$$

The term $[H_3^\circ(T_1) - H_3^\circ(T_0)]$ which appears in Eq. 16 is the enthalpy difference of the alloy; this was measured between 298.15 and 670 K; between 423 and 720 K. The enthalpy differences $[H_1^\circ(T) - H_1^\circ(T_0)]$ and $[H_2^\circ(T) - H_2^\circ(T_0)]$ are measured accurately (see Table 1).

The following schema illustrates the above given procedure for determining of $\Delta_f H^\circ$:



The non-measurable process of the enthalpy of formation will be substituted by (1) heating of lead and indium at T_1, (2) measurement of the enthalpy of mixing at T_1, and (3) measurement of the enthalpy difference of the single miscible phase between T_0 and T_1. Employing this procedure, the enthalpy of formation at 298.15 and 423 K has been determined at four compositions.

The integral and partial molar enthalpies of formation at 298.15 and 423 K are presented in Table 4 for four compositions. A number within parenthesis is the estimated standard deviation (esd). The average error of the individual measurement was found to be 0.2% for T=298.15 K and 0.3% for T=423 K. Using the

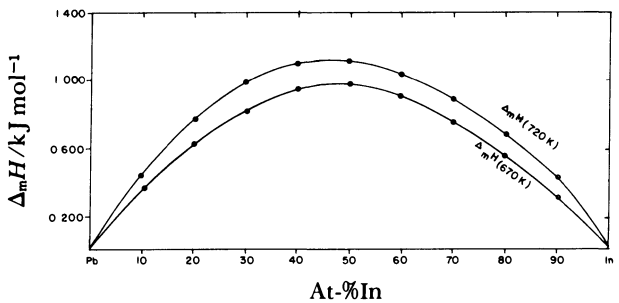


Fig. 3. The enthalpies of mixing at 670 and 720 K in the system Pb–In.

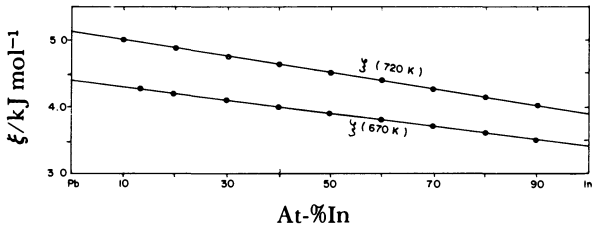

Fig. 4. The ξ-function at 670 and 720 K in the system Pb–In.

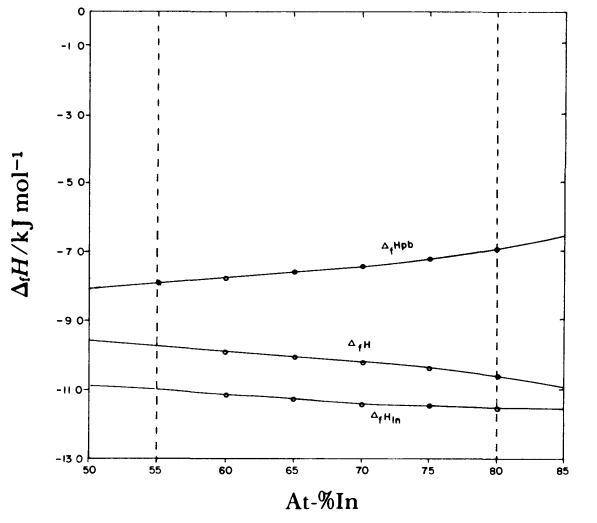

Fig. 5. The integral and partial molar enthapies of formation at 298.15 K in the system Pb–In.

Table 4. Integral and Partial Molar Enthalpy of Formation of the β-Phase in the System Lead-Indium in kJ mol^{-1}. Estimated Standard Deviations in Parenthesis. M(Pb)=207.2 g mol^{-1}; M(In)=114.82 g mol^{-1}

x_{In}	T=298.15 K			T=423 K		
	$-\Delta_f H°$	$-\Delta_f H_1°$	$-\Delta_f H_2°$	$-\Delta_f H°$	$-\Delta_f H_1°$	$-\Delta_f H_2°$
0.600	9.868(18)	7.827	11.228	8.081(21)	6.426	9.219
0.650	10.044(1)	7.642	11.339	8.247(1)	6.247	9.310
0.700	10.227(10)	7.442	11.517	8.628(14)	6.110	9.389
0.750	10.444(28)	7.227	11.517	8.628(53)	5.933	9.456

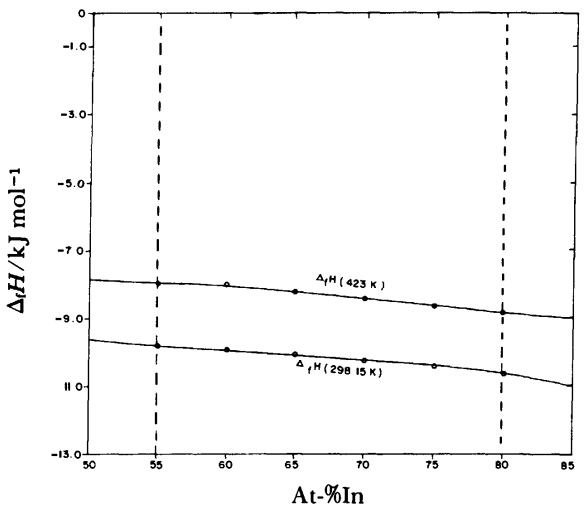

Fig. 6. The enthalpies of formation at 298.15 and 423 K in the system Pb-In.

data in Table 4, it was possible to derive equations which produce the curves shown in Fig. 5 as follows:

$$\Delta_f H°(298.15\,K) = -8.886 + 0.119x_2 - 2.908x_2^2 - 0.028x_2^3, \quad (17)$$

$$\Delta_f H°(423\,K) = -7.296 + 0.098x_2 - 2.388x_2^2 - 0.023x_2^3. \quad (18)$$

It is apparent that the enthalpy of formation displays a somewhat pronounced temperature dependence. However, it appears that $\Delta_f H°$ in other systems e.g. Al-Zn[6] exhibits larger temperature dependence.

The enthalpy of formation in the system Pb-In is negative and becomes more negative at higher composition. This is due to the insertion of the smaller indium atom in the structure of PbIn which becomes more stable at higher mole fraction of indium.

With reference to the definitions of the partial quantities (Eqs. 5 and 6), and using Eqs. 17 and 18, the following equations for $\Delta_f H_1°$ and $\Delta_f H_2°$ are derived:

T = 298.15 K;

$$\Delta_f H_1° = -8.886 + 2.908x_2^2 + 0.056x_2^3, \quad (19)$$

$$\Delta_f H_2° = -8.767 - 5.816x_2 + 2.824x_2^2 + 0.056x_2^3. \quad (20)$$

T = 423 K;

$$\Delta_f H_1° = -7.296 + 2.388x_2^2 + 0.046x_2^3, \quad (21)$$

$$\Delta_f H_2° = -7.198 - 4.776x_2 + 2.319x_2^2 + 0.046x_2^3. \quad (22)$$

The curve in Fig. 4 shows that the partial enthalpy of formation of lead is negative but increases at higher composition. However, $\Delta_f H_1°$ is always negative. This means that the structure remains stable even when the composition increases. The partial molar enthalpy of formation of indium is also negative and becomes more negative at higher composition. For a heteropolar behavior, the delivery of electrons from indium to lead would increase with the increase of indium mole fraction so that the partial molar enthalpy of formation of indium should increase with the increase of the composition.

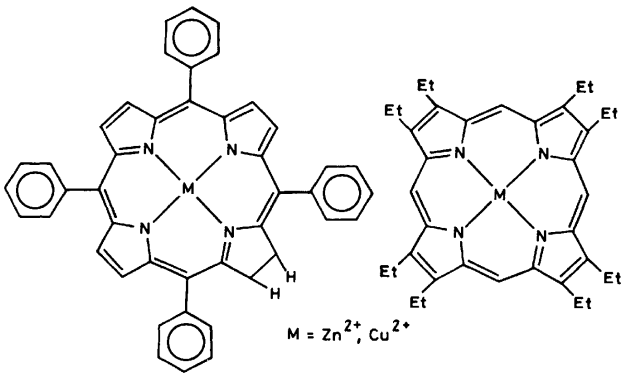
Optical and Magnetic Resonance Studies of the Interaction of Metallotetraphenylchlorin and Octaethylporphyrin with Trinitrofluorenone

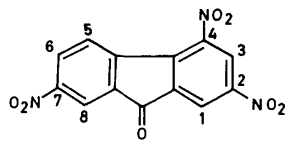
Biswajit CHOUDHURY and T. K. CHANDRASHEKAR*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received November 2, 1987)

The interaction of metallo derivatives of tetraphenylchlorin (TPC) and octaethylporphyrin (OEP) with 2,4,7-trinitrofluorenone (TNF) is described in terms of 1 : 1 molecular complexes. The binding constants vary as CuOEP>ZnOEP>CuTPC>ZnTPC and this variation is accounted in terms of the structure of the macrocycle and the substituents present on it. ESR studies of the complexes reveal that the π-complexation results in changes in the electronic structure of the central metal ion. The magnitude of different proton shifts of the acceptor in ^{1}H NMR spectra of the complexes are used to arrive at the possible solution structure of the complexes.

Molecular complexation of macrocyclic tetrapyrrole pigments with organic molecules has been the subject of numerous studies because of their presence and participation in many reactions of chemical and biochemical interest.[1-3] It has been shown that the major source of stabilization in such complexes is π-π interaction between the donor and acceptor and charge transfer forces contribute to a small extent to the binding strength.[4,5] The recent X-ray crystallographic work on the photosynthetic bacterial reaction center has revealed that the orientation of the donor and the acceptor relative to each other is crucial in such complexes to prevent back electron transfer.[6] Thus a systematic study of the molecular complexes of porphyrins and related macrocycles with electron acceptors is important to get information about the factors and forces responsible for stability of such complexes in a particular orientation. We have been interested in the molecular complexation behavior of tetrapyrrole pigments and our earlier studies have indicated that the stability of the complexes depends both on the metal ion present in the cavity of the macrocycle as well as on the compatibility in sizes of the donor and acceptor.[7-9] In the present study the metal derivatives (Cu and Zn) of tetraphenylchlorin (TPC) and octaethylporphyrin (OEP) were employed as donors and 2,4,7-trinitro-9-fluorenone (TNF) as an acceptor (Fig. 1). Electronic absorption spectral method was used to evaluate the bindig constants while the ^{1}H NMR and ESR measurements were recorded to ascertain the site of interaction in these complexes. The results of this study were used to derive information regarding the relative orientation of the donor and acceptor in the complexes in solution.



Tetraphenylchlorin Octaethylporphyrin



2,4,7-Trinitro-9-fluorenone

Fig. 1. Structure of metallomacrocycles and 2,4,7-trinitro-9-fluorenone.

Experimental

TPC was prepared from tetraphenylporphyrin (TPP) following the literature procedure.[10] OEP and TPP were obtained from Strem Chemicals, USA. TNF was procured from Aldrich Chemicals, USA. The metal derivatives of OEP and TPC were synthesized by refluxing the corresponding metal acetate with the macrocycle in DMF.[11] The purity was checked by NMR and optical spectra. All the solvents employed in the study were distilled before use. The preparation of the solutions and all the manipulations were carried out in dim light. The spectra of the solutions were recorded immediately after mixing.

The electronic absorption method employed for the evaluation of association constants involved the measurement of absorbance of the Q-bands of the porphyrins in the solvent $CHCl_3$ on increasing addition of TNF. The concentration of the donor was held constant (approx. 10^{-5} M; 1 M=1 mol dm^{-3}) and the range of concentration of TNF employed was 1.0×10^{-4} to 2.0×10^{-2} M.

The optical absorption spectra were recorded on Shimadzu double beam spectrophotometer. The ^{1}H NMR spectra of the complexes were recorded on a Bruker WH 400 FT NMR spectrometer usig $CDCl_3$ as solvent and TMS as internal standard. The ESR spectra were recorded on a Varian E-109 ESR spectrometer using toluene as solvent. The spectra were recorded at about 100 K using liquid nitrogen. The IR spectra of the complexes were recorded on

a Perkin Elmer 580/7358 IR spectrometer. The 1:1 complexes for ^{1}H NMR, ESR, and IR studies were prepared as follows. To a solution of porphyrin [10^{-3} M] in $CHCl_3$, TNF [10^{-3} M] was added and the mixture was stirred for an hour. Slow evaporation of solvent over a water bath gave the required complex. The air-dried complex was dissolved in appropriate solvents and used for spectral studies.

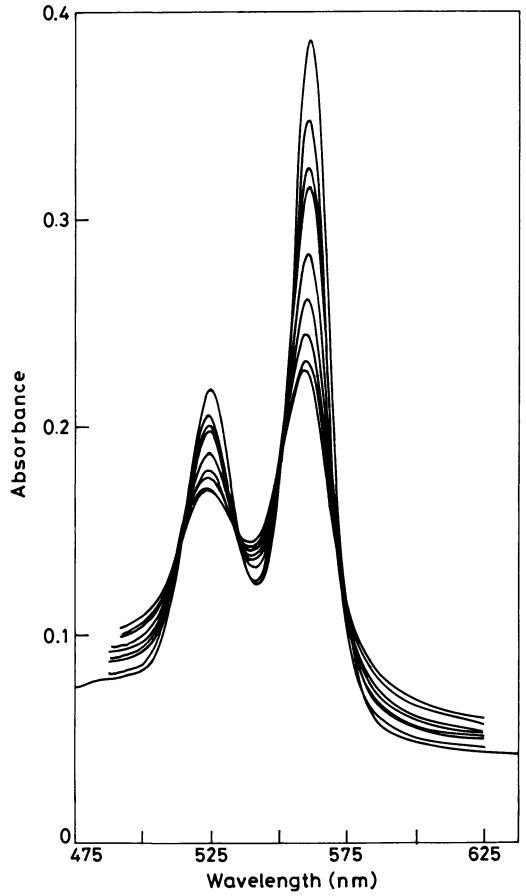


Fig. 2. Visible absorption spectra of CuOEP [1.06×10^{-5} M] containing increasing amounts of TNF [1.356×10^{-4}—2.712×10^{-3} M].

Results and Discussion

The metal derivatives of TPC and OEP exhibited intense absorption bands (Q-bands) in the visible region (500—600 nm) in $CHCl_3$. The acceptor, TNF, did not absorb in this region and showed intense absorption only in UV region. Addition of increasing amounts of TNF to $CHCl_3$ solutions of MTPC and MOEP derivatives progressively decreased the intensity of the Q-bands of the donors with the appearance of isosbestic points (Fig. 2). These observations are consistent with the formation of molecular complexes between TNF and the macrocycle.[12] The decrease in absorbance of donor upon increasing concentrations of the acceptor was analyzed for the calculation of association constant (K) using Nash equation.[13] The linearity of the plots of $d^0/(d^0-d)$ versus $1/C_A$, where d^0 and d denote the absorbance values of donor in the absence and presence of TNF and C_A is the concentration of the acceptor, indicated that the predominant species that existed in solution is the 1:1 complex (Fig. 3). The possible existence of 1:2 (donor-acceptor) complexes in solution was then analyzed using the method of Bent and French.[14] The slopes of the logarithmic plots yielded values in the range from 0.9—1.7 indicating the existence of higher order complexes.[15] It was difficult to quantify the stability constants of these higher order complexes as they were present in only very low concentrations. However, the presence of these complexes did not alter the magnitudes of K-values calculated for 1:1 complexes appreciably. The association constants determined for 1:1 complexes are listed in Table 1.

An inspection of Table 1 reveals that the values of K vary as CuOEP>ZnOEP>CuTPC>ZnTPC. A comparison of these K values with other structurally similar macrocycles is also made in the table. The increase in K-values upon going from OEP to TPC derivatives can be attributed to the presence of eight strong electron-donating ethyl groups as the pyrrole

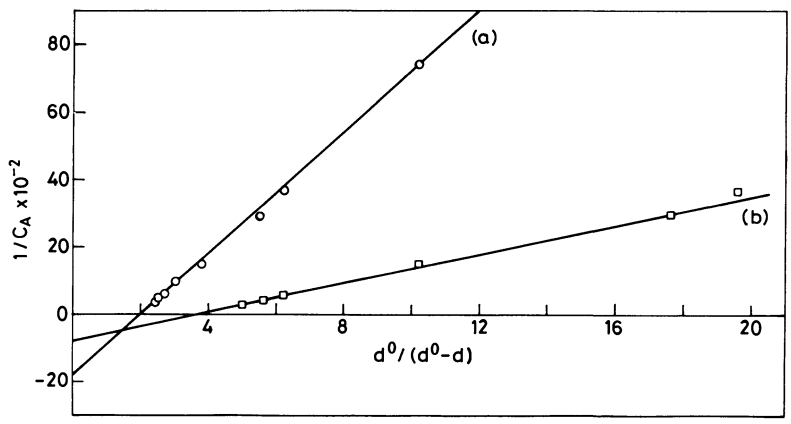

Fig. 3. Plot of $1/C_A$ versus $d^0/(d^0-d)$ for (a) CuOEP-TNF and (b) ZnOEP-TNF at 30°C.

substituents in OEP relative to TPC. Also, the presence of one reduced pyrrole ring in TPC decreases the conjugation thereby decreasing its donating ability. It should be mentioned here that the recent ESR study on the charge transfer complexation between OEP and TPP metal derivatives indicates that the effects of the interaction are generally much larger for OEP complexes than for TPP complexes, supporting our observation.[16] The higher values of K for pheophytin may arise due to the presence of an additional electron-rich cyclopentanone ring in pheophytin relative to chlorin. The limited study made here did not allow us to quantify the role of metal ions on the magnitude of K-values.

The ESR spectra of CuTPC and CuOEP and their 1:1 complexes in toluene at 100 K displayed characteristic features in parallel and perpendicular regions permitting evaluation of ESR parameter (Table 2).[17] The observed effects on ESR parameters upon complexation with TNF are (i) a small decrease in $g_{\parallel}$ and $g_{\perp}$, and $A_{\parallel}^{Cu}$ values and (ii) a small increase in $A_{\perp}^{Cu}$, $A_{\parallel}^{N}$, and $A_{\perp}^{N}$ values. These effects were consistent with the formation of molecular complex.[18] It was anticipated that the π-complexation would lead to a small change in the distribution of π-electrons over the macrocycle perturbing the electronic levels of central metal orbitals. Indeed, Iwaizumi et al.[16] in their recent EPR and ENDOR studies on OEP and TPP complexes of Co and Cu have shown that the charge transfer complex formation with π-acceptors perturbs the metal d-orbital states. If this is true, then one would expect the covalency of the (Cu-N) σ-bond to get perturbed upon complexation. Therefore, bonding parameter α^2 of the (Cu-N) σ-bond was calculated using the $A_{\parallel}^{Cu}$ hyperfine tensor using the equation:[19]

$$\alpha^2 = -\left(\frac{A_{\parallel}^{Cu}}{P}\right) + (g_{\parallel} - 2) + \frac{3}{7}(g_{\perp} - 2) + C$$

A value of P=0.0354 cm^{-1} was used for copper complexes. From Table 2 it can be seen that the α^2 value decreases slightly upon complexation with TNF for both CuTPC and CuOEP. This decrease in α^2

value indicates an increase in the covalency of the (Cu–N) σ-bond. This was also supported by the experimental observation of a slight increase in both $A_{\parallel}^{N}$ and $A_{\perp}^{N}$ values upon interaction with TNF. These two observations qualitatively indicated that there is a slight rearrangement in the electronic environment of the central metal ion upon π-complexation.

In view of the observation that the interactions are essentially localized in the π-system of macrocycles, the ^{1}H NMR spectral studies were undertaken to arrive at the relative orientations of the molecules in solution. We examined the effect of complexation from proton resonance shifts experienced by acceptor and donors (ZnOEP and ZnTPC). Figure 4 shows the ^{1}H NMR of TNF and ZnTPC–TNF (1:1) complex. The assignment of TNF proton resonance was made according to the literature.[20] It is seen from the spectra that all the protons of TNF are upfield shifted in the complexes relative to pure TNF indicating that the TNF is positioned in the diamagnetic shielding zone of the macrocycle. A similar shielding of the acceptor proton resonances have been observed in the charge-transfer complexes with aromatic donors.[21] The proton resonance of donor [β-pyrrole, *o*-, *m*-, and *p*-hydrogens of aryl groups in TPC and ethyl substituents in OEP] also showed both upfield and downfield shifts. The magnitude of shifts were very small (0.15—0.2 ppm). The shifts observed for different proton resonances of TNF upon complexation are listed in Table 3. Examination of Table 3 clearly reveals that the magnitude of shifts observed for TNF protons is much higher for ZnOEP complex than those observed for ZnTPC complex. This may be due to the stronger donating capacity of OEP relative to TPC. This was also reflected in the magnitude of *K*-values. Moreover, the table also illustrates that among the different protons of TNF, the upfield shift experienced by H_5 and H_6 are relatively large compared to other protons [H_3, H_1, and H_8] consistent with the observation made by Hill et al. for the interaction of Co(II) and Ni(II) mesoporphyrin dimethyl ester with TNF.[20] These results indicate that the protons H_5 and H_6 are closer to the π-system of the macrocycle relative to other protons of TNF.

The spectral data obtained in the present study provides some insight into the proposition of possible overlap structures of donor and the acceptor in solution. The observation that the strong IR vibrations of

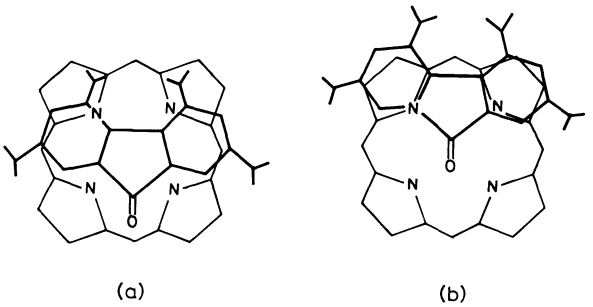

Fig. 5. Possible overlap pictures of the donor and the acceptor in solution. (a) The C_4 axis of the porphyrin is coincident with the C_5 axis of the fluorenone skeleton and (b) the carbonyl group of the fluorenone is tilted away from the metal ion (see text). For clarity the double bonds and the substituents on porphyrin are omitted.

the acceptor [ν(CO) and ν(NO_2)] were not perturbed upon complexation clearly rules out any possibility of coordinative type of interaction of the acceptor with the metal. Thus the major stabilization for the complexes arises from the π–π interaction of the donor and acceptor. Several structures could be perceived by juxtapositioning the acceptor over the macrocycle keeping the intermolecular distance at van der Waals interaction level. CPK models indicate that one can visualize two structures in terms of plane to plane overlap.

In structure (a), the acceptor can be placed over the porphyrin plane such that the axis passing through the five membered ring of the fluorenone is coincident with the C_4 axis of the porphyrin. This would dispose TNF protons over the porphyrin core. In this case all the protons of TNF would experience a uniform shielding since both the planes are exactly parallel. In the alternate structure, (b), the acceptor can be displaced over the porphyrin plane such that the carbonyl group of TNF is tilted away from the metal center (Fig. 5). This will bring H_5 and H_6 protons of TNF near to the porphyrin core. In this case the protons H_5 and H_6 of TNF are expected to shield more relative to other protons. ^{1}H NMR shift data seems to support the structure (b).[5,18,20] These proposed overlap structures are in general agreement with the only reported X-ray crystallographic structure for the 1:2 [porphyrin–acceptor] charge transfer complex[23] of a nickel porphyrin with tetranitrofluorenone. In this structure the porphyrin and the fluorenone rings are both approximately planar and the angle between the porphyrin and the fluorenone ring is 11.4°. The only difference between the proposed structure in the present study and the X-ray study lies in the fact that the carbonyl oxygen is tilted towards the metal ion while in the present case it is tilted away from the metal ion. This difference might arise from the fact that the X-ray structure reported is for a 1:2 complex while our data is for a 1:1 complex. Secondly, the choice of the

porphyrin is different from the reported structural study. In conclusion, the solution structure described here is strongly supported by experimental data presented. Further confirmation of the structure must come from X-ray crystallographic studies.

Spectral Studies on the Cooperative Binding Mechanism of Evans Blue to Poly(*N*-vinyl-2-pyrrolidone)

Meenakshi MARUTHAMUTHU* and E. SUBRAMANIAN
Department of Physical Chemistry, University of Madras,
Guindy Campus, Madras 600025, India
(Received March 7, 1988)

The binding of Evans Blue (EB) to poly(*N*-vinyl-2-pyrrolidone) (PVP) was studied at two pH's 7.2 and 11.2 spectrophotometrically by absorbance change method. At pH 7.2, the absorption spectrum of EB changed unusually on adding PVP and this indicated the formation of two types of spectroscopically distinguishable PVP–EB complexes. At very low [PVP], a weak complex was formed which got converted into a strong complex at high [PVP]. Positive cooperativity was found to be operative in this conversion and in the strong complex at higher [PVP]. Scatchard, Hill, and Schwarz methods were employed to analyze this cooperativity and to determine the binding parameters. The analysis revealed: (i) the binding constants for the weak and strong complexes were of the order of 10^4 and 10^5 dm^3 mol^{-1} respectively; (ii) positive cooperativity at higher [PVP] was due to the interaction of neighboring binding sites on different polymer chains. At pH 11.2, only one type of complex was formed with higher affinity. But the binding behavior remained the same as at pH 7.2.

Evans Blue, a bisazo dye (C. I. No. 23860) is employed in blood volume determination. The basis behind this is its high binding affinity to plasma albumin. Resembling with serum albumin in many respects, for example, in binding behavior and in having amide linkage, the water-soluble synthetic polymer, poly(*N*-vinyl-2-pyrrolidone) (abbreviated as PVP) is physiologically and pharmaceutically an important macromolecule. In our earlier study,[1] the binding of the dye, Evans Blue (EB) to PVP was analyzed using a simple method, namely the Klotz's spectrophotometric method.[2] The significant finding of the study was that the dye binds mainly through electrostatic interaction. In the present work, employing absorbance change method[3] instead of the Klotz's method, we have attempted to investigate the cooperative binding mechanism, the binding forces and the nature of binding. Further, the unusual spectral change of EB with PVP, an interesting observation, has been found to be due to the formation of two types of spectroscopically distinguishable complexes. Thus all these features inspired us to make a thorough investigation of the system.

Experimental

Materials. PVP (average molecular weight=40000) and EB were purchased from Loba Chemie Indo Austranal Co., India. Urea, sodium chloride, and buffer reagents used were of analytical grade.

Method. The binding experiments were carried out at pH 7.2 in KH_2PO_4–Na_2HPO_4 buffer and at pH 11.2 in Na_2HPO_4–Na_3PO_4 buffer, both of 0.05 mol dm^{-3} concentration. All spectroscopic measurements were made at room temperature (ca. 25 °C) using Carl Zeiss Specord UV VIS spectrophotometer with matched 1 cm path length quartz cuvettes. The measuring pipettes and the cuvettes were prerinsed with the dye solution to reduce its concentration loss by adsorption onto the walls. Viscosities of PVP and PVP–EB solutions were measured at 30 °C with an Ubbelohde suspended level viscometer which has a flow time of 141 s for water.

For the binding studies, a dye concentration range of 7.5 to 25.0 μmol dm^{-3} was selected as admitted by the Beer-Lambert's law and PVP was employed in a wide concentration range from 1.11×10^{-7} mol dm^{-3} to 2.78×10^{-4} mol dm^{-3}, expressed in terms of polymer molecular weight. Urea and NaCl were used as additives in a range with maximum concentrations of 4.0 mol dm^{-3} and 1.6 mol dm^{-3} respectively.

Results and Discussion

Since the studies were conducted at two different pH's 7.2 and 11.2 and the binding behavior is almost the same at both the pH's, at first, the results obtained at pH 7.2 have been discussed in detail.

Quantification of Binding. The spectral shift of EB, at pH 7.2, from the λ_{max} of 609 nm to 639 nm on adding PVP forms the basis for the absorbance change method adopted in the present work. The absorbances of the dye were measured at 639 nm (at 609 nm when the pH is 11.2) (i) in the unbound or free condition (D_1), (ii) in the fully-bound condition (D_2) i.e., at the highest [PVP] and (iii) in the partially bound condition (D). Substituting all these values in Eq. 1, the bound dye concentration, C_B was calculated.

$$C_B = \frac{(D_1 - D)}{(D_1 - D_2)} \times C_T \qquad (1)$$

C_T is the total initial dye concentration, a known quantity. The conditions proposed for the application of the absorbance method are: (i) obeying of Beer-Lambert's law by both the free and the bound dye and (ii) the constancy of the molar extinction coefficient value of the complex with the variation of [dye]/[polymer] ratios. These have been found to be fulfilled in the present system and hence the dye-aggregation in the free as well as in the complexed states has been ruled out. Nonoccurrence of any blueshifts in the spectrum of EB with PVP also excludes, as pointed out by Takagishi et al.,[4] the association of dye molecules.

Scatchard method,[5] for which the equation is given

below, was followed to determine the binding parameters for the PVP–EB system.

$$\frac{r}{C_F} = nK - rK \qquad (2)$$

where r = the ratio, in moles, of bound dye to total polymer,
C_F = the unbound or free dye concentration,
n = the total number of binding sites per mole of polymer,
and K = the intrinsic binding constant, a measure of the strength of binding.

From the slope and intercept of the Scatchard plot, the binding parameters were calculated both in the absence and in the presence of the additives, 2.0 mol dm^{-3} urea and 0.4 mol dm^{-3} NaCl. Table 1 displays these values and Fig. 1 illustrates the representative Scatchard plots. Freedman and Johnson[6] have reported the K value of 4×10^5 dm^3 mol^{-1} for the human serum albumin–Evans Blue system at pH 7.3 in buffer–NaCl (0.12 mol dm^{-3}) mixture. This literature value is comparable with that of the PVP–EB system ($K=1.03\times10^5$ dm^3 mol^{-1}) in 0.4 mol dm^{-3} NaCl, admitting the fact that we have used a higher [NaCl] which has certainly a binding-reducing effect.

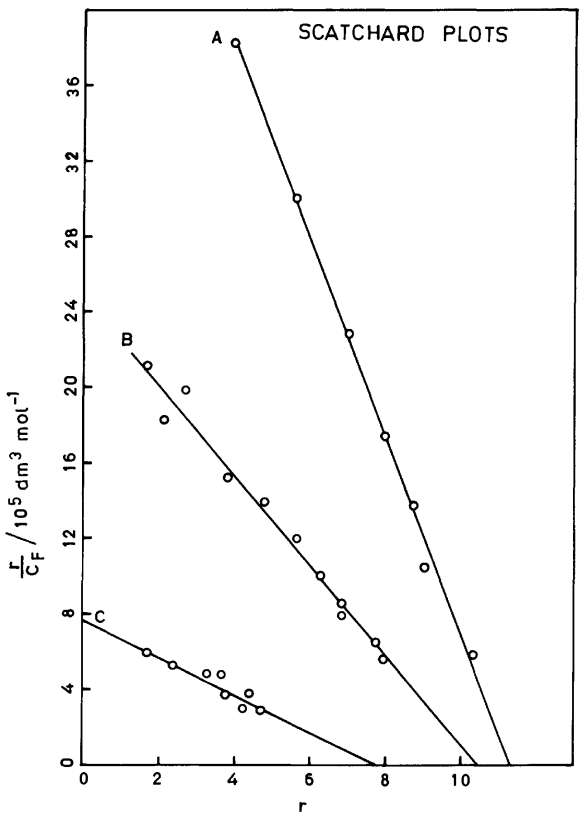

Fig. 1. Scatchard plots for the PVP–EB system at pH 7.2.
(A) PVP+2.0 mol dm^{-3} urea; (B) PVP only; (C) PVP+0.4 mol dm^{-3} NaCl, [PVP]=1.39 μmol dm^{-3} for B and C and 1.0 μmol dm^{-3} for A with varying [EB].

Spectroscopically Distinguishable Complexes. The spectrum of the dye, EB undergoes a peculiar shift (Fig. 2) when PVP is added from the lowest to the highest concentration of the range specified earlier. First, at very low [PVP], absorption at the λ_{max} of the free dye (609 nm or 16.42×10^3 cm^{-1}) decreases without any shift and it continues upto a [PVP] of 0.53 μmol dm^{-3}. In this condition, as evident from the isosbestic point at 635 nm, only two kinds of spectral species—the unbound dye and a weak PVP–EB complex—are existing in solution, maintaining equilibrium between themselves. When the added [PVP] is higher than 0.53 μmol dm^{-3}, two things happen: (i) spectral shifting to 639 nm (or 15.64×10^3 cm^{-1}) starts and (ii) the decreased absorption at 609 nm begins to increase with the disappearance of the isosbestic point. This drastic change indicates the

formation of the strong PVP-EB complex by the conversion of the weak one.

Figure 3 illustrates clearly the change in absorbance of the dye (20 μmol dm^{-3}) with [PVP] at the two wavelengths 609 nm and 639 nm. Upto [EB]/[PVP]$\geqslant$25, i.e, until log([EB]/[PVP]) reaches a value of 1.4, ΔA i.e., ($D_1 - D$) at 609 nm (ΔA_{609}) increases while ΔA_{639} first remains constant and then decreases. Since the changes of ΔA occur in two opposite directions upto the ratio of 25, it indicates the presence of two types of PVP-EB complexes in solution under equilibrium condition. Below the ratio of 25, change in ΔA_{609} as well as ΔA_{639} occurs in one direction only, i.e., a decrease and then constancy. This points out the existence of one complex i.e., the strong complex. Since all the experiments for determining the binding parameters in Table 1 were carried out at sufficiently high [PVP], the ratio [EB]/[PVP] is always less than 25 and hence the data correspond to the strong complex only. The designations 'strong' and 'weak' given to the complex, are purely relative and have been assigned only on the basis of the binding constant values.

Cooperativity and [PVP] Effect. Generally in ligand-polymer binding studies, cooperativity will be manifested at high [ligand]/[polymer] ratios only. Because, at this condition the number of available free sites will be much less than the free ligand concentration. Reeves et al.[7] have noticed cooperative binding at high dye concentrations only in 4-phenylazo-1-naphthol-2-sulfonate and the corresponding disulfonate-PVP systems. But on the contrary, in the present system cooperativity is explicit at the low [EB]/[PVP] ratio only i.e., a high [PVP] induces cooperativity. This is clearly seen from the convex Scatchard plots of Fig. 4 drawn for the set of a fixed [EB] with varying [PVP]. These plots obviously show that the operation of positive cooperativity is a function of [PVP]. This inference is again confirmed

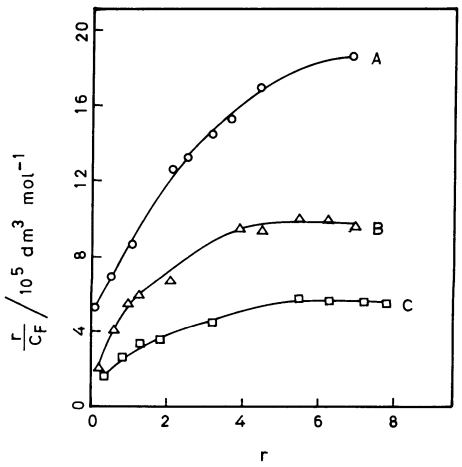

Fig. 4. Convex Scatchard plots for the PVP-EB system at pH 7.2. [PVP]=0.11 to 278.0 μmol dm^{-3}; [EB] (in μmol dm^{-3})=(A) 7.5; (B) 15.0 and (C) 25.0.

by the sigmoidal shape binding isotherm also i.e., r versus C_F plot (figure not shown). Figure 4 apparently shows that as the [EB]/[PVP] ratio is increased (e.g., at [EB]=25 μmol dm^{-3}), the extent of convexity is reduced. Therefore if we had used a still higher dye concentration, we would have obtained a concave Scatchard plot also indicative of negative cooperativity. But the experimental constraints did not allow us to do so. However in the reverse approach i.e. fixing the [PVP] constant and varying the dye concentration, an inverted 'U' shaped Scatchard plot (figure not shown) was obtained, suggesting the operation of both the positive and negative cooperativities.

The alternate inference from the afore-mentioned Scatchard plots is the ligand-mediated and ligand-facilitated association of polymer molecules. This possibility is ruled out on the grounds that the shapes and intersection of the theoretical Scatchard plots proposed by Cann[8] for the association of polymer

molecules do not coincide with that for the PVP-EB system. Moreover the values of the binding constants should be raised, if the polymer molecules were to associate through ligands. This was also not observed in the present system. Hence the above scatchard plots indicate only the operation of a 'mixed' cooperativity i.e., positive cooperativity at lower [EB]/[PVP] ratios and negative cooperativity at higher ratios. If the [PVP] is much less, the upward rising portion of the Scatchard curve disappears and only a linear down-ward plot (Fig. 1) is obtained, implying a simple model of binding.

Analysis of Cooperativity. Two methods—the well-known Hill method[9] and the Schwarz method[10]—have been employed for the analysis of cooperativity. Molyneux and Lentzos[11] have already applied these methods. For the use of both the methods an essentially accurate n value should have been known. The n value of 10.36 in Table 1 was verified by the difference spectrum method.[12] The difference spectrum of EB (20 μmol dm^{-3}) in varying [PVP] was recorded with the dye solution of same concentration as reference. The λ_{max} of the spectrum (661.4 nm) does not change upto a [PVP] of 2 μmol dm^{-3} and above this, it blueshifts to 651.5 nm. This observation demonstrates that one mole of PVP, on an average, can bind 10 moles of EB without any change in the nature of the complex. A higher [PVP] promotes a less polar environment around the already existing complex resulting in the blue-shift.

In Fig. 5 are shown the Hill plots constructed according to the Eq. 3.

$$\log\left(\frac{r}{n-r}\right) = \log K_a + n_H \log C_F \qquad (3)$$

Where K_a is the apparent binding constant and n_H the Hill coefficient. Figure 5 (Plot A) which exhibits clearly the operation of positive cooperativity in binding is the plot of the data obtained from a set of experiments with [EB]=7.5 μmol dm^{-3} and varying [PVP]. This plot is linear for 5 to 66% saturation of the binding. The curved portions at very low and very high degrees of saturation which reflect the single-site binding are extrapolated back to the abscissa to evaluate the first (K_1) and the last (K_n) ligand binding constants. These were used in calculating the

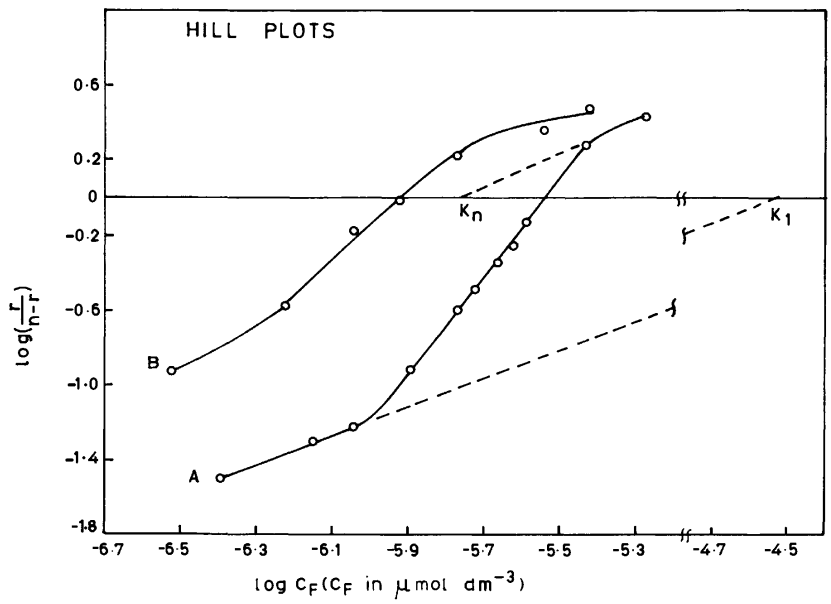

Fig. 5. Hill plots for the PVP-EB system.

interaction energy,[13] ΔG_{int} as given by Eq. 4.

$$\Delta G_{int} = RT \ln \frac{K_n}{K_1} \quad (4)$$

The values of the Hill parameters are presented in Table 2. When [EB] is increased from 7.5 μmol dm^{-3} to 25 μmol dm^{-3}, the Hill plot becomes linear for the entire data (3—76% saturation) and here K_a has a lower value. It is obvious from Table 2 that as [EB] is increased, the extent of positive cooperativity is diminished and thereby it supplements the Scatchard plots in Fig. 4. The values of the Hill coefficient imply that there is a constructive interaction between the two neighboring binding sites and that it is this interaction which promotes positive cooperativity. In the other experimental approach i.e., keeping the [PVP] constant and varying [EB], the Hill equation is not obeyed indicating the operation of a mixed cooperativity. PVP-EB system has an interaction energy of 1.69 kcal mol^{-1} (1 cal=4.184 J) or 163 cal/site which is less relative to the hemoglobin-O_2 system (3.0 kcal mol^{-1} or 750 cal/site).[13] This marked difference reflects the poor elevation of the binding strength in the PVP-EB system on each successive step of ligand binding.

Figure 6 shows the Schwarz isotherm at the [EB]=7.5 μmol dm^{-3}. The linearity of the plot suggests the obeying of the Schwarz equation given below:

$$\frac{(1-2\theta)\sqrt{C_F}}{\sqrt{\theta(1-\theta)}} = \frac{1}{\sqrt{K_0}} - \alpha C_F \sqrt{K_0} \quad (5)$$

Here θ = the fractional occupancy i.e., r/n,
K_0 = the intrinsic binding constant for a site when the sites on either side of it are unoccupied,
and α = the cooperativity parameter i.e., the increment in K_0 when one neighboring site is filled.

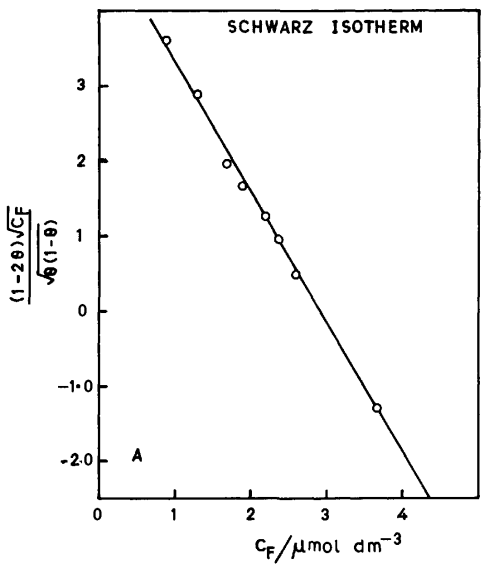

Fig. 6. Schwarz isotherm for the PVP-EB system at pH 7.2.
[EB]=7.5 μmol dm^{-3}; [PVP]=0.28 to 22.2 μmol dm^{-3}.

From the slope and intercept, α and K_0 were calculated and are given in Table 3 along with the Hill parameters. Table 3 shows that K_0 and K_1 are comparable as well as αK_0 and K_a, within the limits of experimental error. Thus the two methods, by virtue of their nature, provide the binding constant value (K_0 and K_1) of the PVP-EB weak complex also. Obeying of Schwarz model in the present system implies that at the lowest [PVP] (i.e. [EB]/[PVP]>25), when every polymer chain has only one EB molecule bound to the site, the complex exists as a weak one. But when further PVP is added, site-site interaction of two neighboring binding sites occurs leading to the conversion of the weak complex into the strong one.

Thus it is brought out from the above discussion that positive cooperativity is exhibited at two instances: (i) in the conversion of the weak to the strong complex and (ii) in the strong complex at higher [PVP]. But at the low [PVP] in the strong complex, no cooperativity is observed. Incorporating all these features, the following mechanism is proposed:

$$\underset{\text{(at the lowest concentration)}}{\text{PVP}} + \text{EB} \rightleftharpoons \text{Weak complex} \quad (6)$$

$$\text{Weak complex} + \text{PVP} \overset{\text{Cooperativity}}{\rightleftharpoons} \text{Strong complex} \quad (7)$$

$$\text{Strong complex} + \text{PVP} \overset{\text{Cooperativity}}{\rightleftharpoons} \text{Cooperative PVP-EB Strong complex} \quad (8)$$

Nature of the Complexes. The nature of the complexes formed depends on the structures of the polymer and the dye. PVP consists of nonpolar methylene and methine (CH) groups and the polar amide linkage. Due to the operation of keto-enol tautomerism, the heterocyclic N and the carbonyl O atoms acquire fractional positive and negative charges respectively to the extent of 0.37 units.[14] EB is a bisazo dye with two phenyl-substituted hydroxyl groups at

Table 3. Binding Parameters from the Schwarz and Hill Methods. pH=7.2; [EB]=7.5 μmol dm^{-3}; Varying [PVP]; Temperature=25 °C

Schwarz	Hill
$\frac{K_0}{\text{dm}^3\,\text{mol}^{-1}} = 3.89 \times 10^4$	$\frac{K_1}{\text{dm}^3\,\text{mol}^{-1}} = 3.33 \times 10^4$
$\alpha = 8.83$	
$\frac{\alpha K_0}{\text{dm}^3\,\text{mol}^{-1}} = 3.44 \times 10^5$	$\frac{K_a}{\text{dm}^3\,\text{mol}^{-1}} = 3.36 \times 10^5$

the ortho positions with respect to the azo groups. It also has hydrophilic ($-SO_3H$, $-NH_2$) and hydrophobic (biphenyl) groups in its structure (refer to Scheme 1). Two other structurally similar dyes, Trypan Blue (TB) and Benzopurpurin 4B (BP) have been chosen to determine the nature of the PVP–EB complexes. TB is a positional isomer of EB, the difference being in the position of the four sulfonato groups. In TB, two of the four sulfonato groups are very near to the azo groups i.e., at the ortho positions; the other two sulfonato groups are meta to the amino groups. This difference in position of the sulfonato groups between EB and TB reflects in the binding constant value also (as shown in the ensuing discussion). BP has the same basic skeleton as of EB and TB but without two hydroxyl and two sulfonato groups.

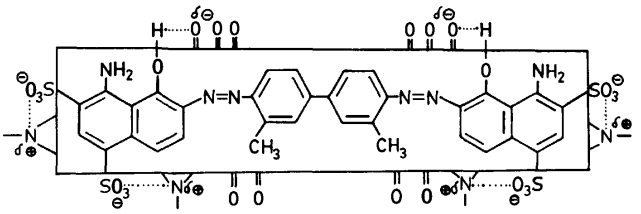
A comparison of the spectral behavior of these dyes at pH 7.2 shows that except BP, EB and TB exhibit, at first a decreased absorption at their respective λ_{max}'s with very low [PVP] and then a red shift at higher [PVP]. BP, on the other hand, shows only a redshift. At pH 11.2, the spectral behavior of EB (Fig. 9) gets changed from that at pH 7.2 and resembles that of BP. The reason for this is the ionization of the two phenolic hydroxyl groups at this alkaline pH. Correlation of these observations with the structures of the dyes leads to the interpretation that the initial decrease in absorption of EB and TB is mainly due to the -OH group of the dye and hence the formation of the weak complex. A similar decrease in absorption is also observed when NaCl is added to EB. From this, it is concluded that the formation of weak complex produces a polar environment around the dye, relative to that present with the dye alone. When urea is added to the weak complex the decreased absorption begins to increase at 0.5 mol dm^{-3} urea and at 4.0 mol dm^{-3}, the spectrum of the complex coincides with that of the free dye, suggesting the total collapse of the weak complex. Thus the urea effect, coupled with the above spectral studies indicates that the hydrogen bonding is the main force in the weak complex formation.

A brief description about the weak complex, emerging from the foregoing discussion is as follows: Since the [PVP] is very low, the polymer molecules would exist as single entities only. Hydrogen bonding interaction from the two -OH groups and the electrostatic interaction from the two sulfonato groups (far from the azo groups) favor its formation. Both the azo groups and the other two sulfonato groups (para to the amino groups) do not seem to involve in binding but get exposed to the solvent medium. Thereby they make the environment of the complex more polar.

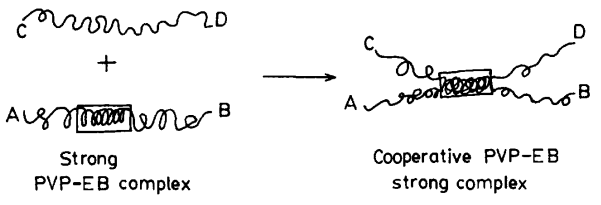
In the strong complex, the electrostatic interactions originating from the two remaining sulfonato groups, the dipolar and the hydrophobic interactions from the biphenyl part are the additional interacting forces. Now the azo group is present in a less polar environment as indicated by the redshift of the spectrum. Since the [PVP] is high, the PVP chains would be in somewhat coiled form and thereby make a less polar environment. All these features strengthen the PVP–EB attachment and hence the binding constant is enhanced by 7 times the value of the weak complex. Scheme 1 illustrates the model for the PVP–EB strong complex. In this model, the rectangle represents the PVP binding site with coiled chain.

The two sulfonato groups para to the amino groups are near to the azo groups, when compared to the other two sulfonato groups. The former sulfonato groups start interacting with PVP, only in the strong complex but not in the weak complex. This conclusion was made because of the following inference. The interaction from the anionic groups nearer to the azo group appears to contribute significantly to the binding affinity. The supporting evidences for this are: (i) $-O^-$ rather than -OH is the stronger interacting group, as revealed by the studies at pH 11.2; (ii) the PVP–TB strong complex has been observed to have a higher binding constant value than the PVP–EB strong complex. Since the azo group interaction is more pronounced in the strong complex only, the above logical conclusion was arrived at.

Further addition of PVP to the strong complex e.g., at a [PVP] of 10 or 20 μmol dm^{-3}, the polymer coils of the unoccupied sites interact hydrophobically, create a still less polar environment and thereby induces the site–site cooperative interaction. This is possible because at higher [PVP], intermolecular interactions such as polymer entanglement or interpenetration of polymer chains are unavoidable and therefore the site–site interaction is feasible. Creation of nonpolar environment and hence the positive cooperativity is proved by (i) change in λ_{max} of the difference spectrum, (ii) effect of urea on binding at higher [PVP] (discussed



Scheme 1. PVP–EB strong complex.



Scheme 2. Cooperative interaction in the strong PVP–EB complex.

later) and (iii) cooperativity as a function of [PVP] previously illustrated by Scatchard and Hill plots. Scheme 2 pictorially represents the cooperative interaction. In this model AB and CD are two different polymer chains and the rectangle denotes the bound dye molecule.

The question of positive cooperativity due to the interaction between adjacent sites on the same polymer chain rather than on different polymer chains is ruled out because, if it were the case, we should have observed cooperativity at the very low [PVP] also. But it is not the case. Further cooperativity of sites on the same polymer chain would facilitate the dye binding on a single macromolecule resulting in the overall conformational change. This was also not encountered as indicated by the viscosity data in Table 4. Thus from the foregoing arguments, it is clear that the observed positive cooperativity in the strong complex is exclusively due to the interaction between the sites on different polymer chains. The viscosity data also reveal the absence of coulombic repulsion between the bound dye molecules and hence the chain elongation.

Influence of Additives on Binding. In our previous article[1] we have reported that both urea and NaCl reduce the binding constant values at higher [PVP]. But at lower [PVP], urea enhances the binding constant while NaCl decreases it. In other words, urea plays a dual role while NaCl has only one effect i.e., the binding reducing effect. The trend at lower [PVP] is observed in the present work also (Table 1). The explanation for this is based on the effect of these additives on the formation of weak and strong complexes. Decrease in absorbance at 609 nm (D^{609}) and the increase in absorbance at 639 nm (D^{639}) of the PVP-EB mixture, relative to the absorbance of the free dye (D_1) have been considered as to signify the formation of the weak and strong complexes respectively. Therefore if the addition of urea or NaCl decreases the value of D^{609}, it is considered as to favor the formation of the weak complex. If D^{609} is increased, it indicates the inhibition of the weak complex formation. Oppositely, the increase in D^{639} represents the facile formation of the strong complex and the decrease in D^{639}, the inhibition.

Figure 7 exhibits clearly the urea effects (4.0 mol dm^{-3}) in terms of the plot ΔA or $(D-D_1)$ versus [EB] at both the wavelengths. At the [PVP] of 0.4 μmol dm^{-3},

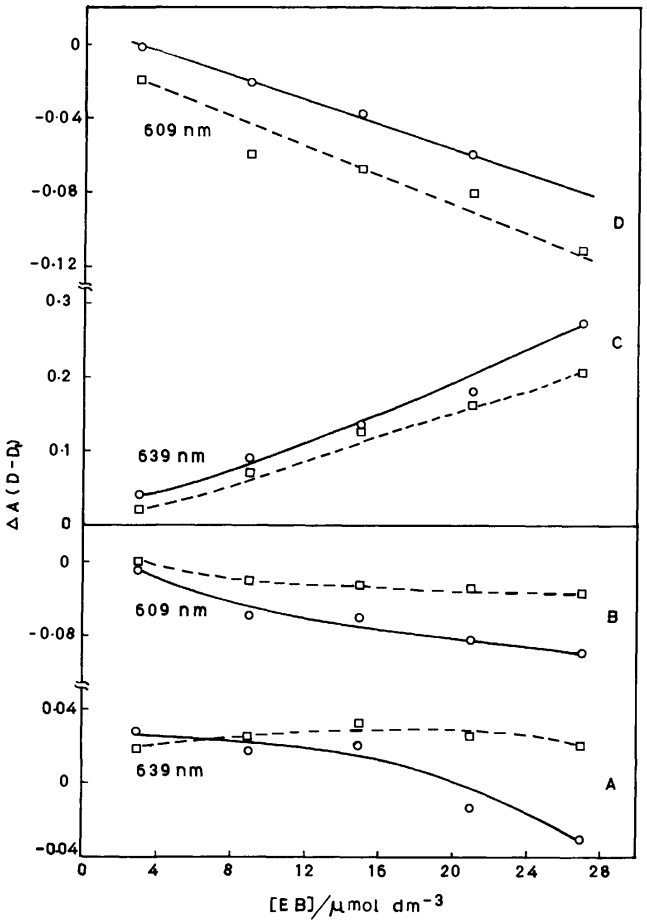

Fig. 7. Difference in absorbance, ΔA and urea effects at pH 7.2, [urea]=4.0 mol dm^{-3}.
For A and B [PVP]=0.4 μmol dm^{-3} and for C and D [PVP]=50.0 μmol dm^{-3}. Solid line: PVP+EB; dotted line: PVP+EB+urea. D=absorbance of the complex; D_1=absorbance of the free dye; $\Delta A = D-D_1$.

addition of urea to PVP-EB mixture increases the absorbance at both the wavelengths. This means that the strong complex formation is favored at the decay of the weak complex. But at higher [PVP] (50 μmol dm^{-3}), urea produces the opposite effect i.e., absorbances are decreased at both the wavelengths. This decrease in absorbance at 609 nm of the PVP+EB mixture by urea (the set of two lines D in Fig. 7) should not be taken as an indication of the formation of weak complex. Because, at this higher [PVP], as already stated, only one type of complex i.e., the strong complex alone can exist. Therefore, this decreased absorbance at 609 nm, as already discussed in the nature of the PVP-EB weak complex, could be considered only as reflecting a more polar environment around the PVP-EB strong complex. Thus at higher [PVP], the strong complex formation is hindered by urea, as a result of the change in polarity of the binding environment.

The underlying principle for both the urea effects is

the water-structure breaking action. It has been already established that for the effective interaction of different polar groups in aqueous solution in close proximities, the water structure around these groups is an inhibiting factor. As already mentioned, in the conversion of weak to strong complex, additional electrostatic and dipolar interactions from the sulfonato, azo, and biphenyl groups begin to operate. Therefore the breaking of water structure around the hydrophilic groups by urea in the weak complex favors an effective interaction between PVP and EB and facilitates the conversion of weak to strong complex. Conversely at higher [PVP], the nonpolar interactions operating between different polymer chains in the cooperative PVP–EB strong complex is disfavored to some extent by urea through the destruction of iceberg structure of water. This type of inhibition of hydrophobic interactions by urea has already been noticed in many studies.[15] This effect leads to the exposure of the PVP–EB strong complex to a relatively less nonpolar environment and hence reduces the binding affinity. Now the urea effect is summarized as follows:

$$\text{At lower [PVP] : Weak complex} \xrightarrow{\text{Urea}} \text{Strong complex} \quad (9)$$

$$\text{At higher [PVP] : Strong complex (in nonpolar environment)} \xrightarrow{\text{Urea}} \text{Strong complex (in less nonpolar environment)} \quad (10)$$

Thus these two types of effects are responsible for the dual role played by urea.

On the contrary to urea, NaCl decreases the absorbances of the complex at both the wavelengths at all PVP concentrations. This means that the strong complex formation is hindered by NaCl, irrespective of the [PVP] employed. Since the present work is mainly concerned with the strong complex, the observed effect of NaCl is only a reduced binding at all PVP concentrations. This effect may be caused in two ways: (i) the water-structure breaking action and (ii) the interaction of Na^+ ions with the hydrophilic groups e.g. the sulfonato and the azo groups. The latter way appears to be the predominant one because, the strong complex formation to which the contribution from the electrostatic interaction is very much, is hindered.

Binding Forces. The forces involved in binding need not be discussed in detail because the operation of electrostatic forces, hydrogen bonding and hydrophobic interaction in the system has already been mentioned. Besides these, the dipolar forces may also operate between the easily polarizable aromatic moieties and the >C=O group in PVP. Figures 8A and 8B illustrate respectively the UV spectra of PVP and EB in the presence of the other component. The $n\rightarrow\pi^*$ transition of both the components get redshifted with decreased intensity. This clearly demonstrates the creation of a less polar environment and in turn the mutual delocalization of electrons and the ground state stabilization. All these aspects facilitate the polar interactions.

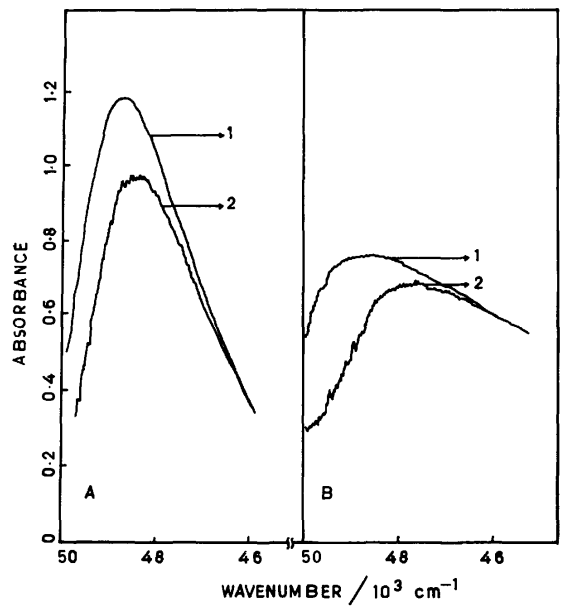

Fig. 8. UV spectra of PVP and EB at pH 7.2. [PVP]=1.0 μmol dm^{-3} and [EB]=20.0 μmol dm^{-3}. A: (1) Spectrum of PVP alone (λ_{max}=205.2 nm); (2) Spectrum of PVP in the presence of EB (λ_{max}=206.4 nm). B: (1) Spectrum of EB alone (λ_{max}=205.3 nm); (2) Spectrum of EB in the presence of PVP (λ_{max}=210 nm).

Studies at pH 11.2. At this alkaline pH, the two phenolic hydroxyl groups are ionized ($pK_a \simeq 10$) and the dye acquires 6 negative charges. Unlike at pH 7.2, only one type of complex is formed at pH 11.2. This is shown in Fig. 9 with the spectral change in only one direction. The free dye has λ_{max} at 570 nm and the bound dye at 609 nm. Because of this spectral shift, a very attractive instantaneous color change can be seen, when one drop of PVP solution is added to the dye solution. The isosbestic point at 573.4 nm is an additional proof for the existence of only one type of complex. Since the λ_{max} of the bound dye coincides with that of the free dye at pH 7.2 (609 nm), it is concluded that the EB molecule in the PVP–EB complex, at the alkaline pH, should be present with the two phenoxide anions involved in ion-pair formation with the fractionally positively charged N atom of the pyrrolidone ring. This ion-pair formation is very much facilitated because of the nonpolar environment provided by the PVP molecular chains. Such ion-pair formation as this, has already been

Table 5. Binding Parameters for the PVP-EB System at pH 11.2. Temperature=25 °C

K=8.14×10^5	K_n=8.17×10^5	K_0=2.78×10^5
n=11.49	n_H=1.75	α=2.91
		αK_0=8.11×10^5

All the binding constants are in dm^3 mol^{-1} unit. a) [PVP]=1.0 μmol mol^{-3} with varying [EB]. b) [EB]=12.5 μmol dm^{-3} with varying [PVP].

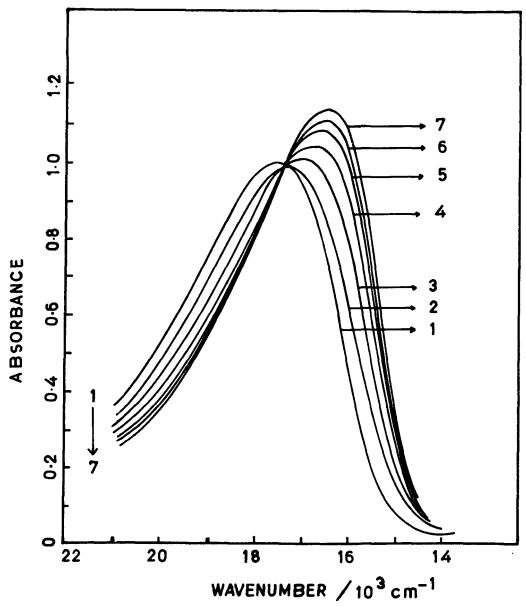

Fig. 9. Spectra of EB and PVP-EB complex at pH 11.2.
[EB]=27.5 μmol dm^{-3}. (1) EB only (λ_{max}=570 nm); (2—7): EB+PVP (λ_{max} for 7=609 nm) with [PVP] (in μmol dm^{-3})=0.5, 1, 2, 5, 10 and 25 respectively. Isosbestic point for the PVP-EB complex=573.4 nm.

reported in the bovine serum albumin-Methyl Orange system.[16]

Eventhough only one type of complex is formed, the entire binding behavior is the same as in pH 7.2. The binding parameters determined from various methods are given in Table 5. Extrapolations in the Hill plot (plot B; Fig. 5) to evaluate K_1 and K_n were not possible under the experimental conditions at pH 11.2. The dye has higher affinity at this pH and this is due to the involvement of two more electrostatic interacting sites ($-O^-$ ions) in binding. The cooperativity parameter α is one-third of the value at pH 7.2 and this may be due to the absence of weak complex in initial stage. Incorporating all these, the following mechanism is put forward.

$$\text{PVP} + \text{EB} \rightleftharpoons \text{Complex} \quad (11)$$

$$\text{Complex} + \text{PVP} \overset{\text{Cooperativity}}{\rightleftharpoons} \text{Cooperative PVP-EB complex} \quad (12)$$

Comparison of the binding studies at the two pH's points out that the two phenolic hydroxyl groups play the key role in establishing the binding behavior in the PVP-EB system. From the whole study the conclusion arrived at is that although a synthetic polymer, PVP can be placed in equal rank with the protein molecules as the former is also able to exhibit a cooperative mechanism like the biomacromolecules in the binding of ligands.

The financial assistances offered by CSIR and UGC, New Delhi are gratefully acknowledged. Sincere thanks are due to Dr. P. Molyneux, Macrophile Associates, London, for his help.

Behavior of the Enthalpies of Dissolution and Formation in the System Silver-Indium

Walid Ahmad BADAWI*,† and Ahmed M. OUN
Department of Chemistry, Faculty of Science, Al-Fateh University, Tripoli, Libya
(Received March 28, 1988)

The enthalpy of dissolution in the system Ag-In has been measured at 1100 K in the whole range of composition. The behavior of the enthalpy of dissolution points out the existence of the compound Ag_3In in the liquid state. The enthalpy of formation in the range of the γ phase has also been determined at 623 and 773 K. The enthalpy of formation is negative. The partial molar enthalpy of formation of silver is negative but increase with the increase of the composition, and that of indium is negative and decreases with increasing composition. The enthalpy of formation depends insignificantly on the temperature. A pronounced temperature dependence of the enthalpy of formation seemed not to be a general property of all metallic alloys as reported earlier.

The behavior of the thermodynamic functions of alloys depends on (1) the ratio of the atomic radii of the components, (2) the electronegativity and (3) the valence electron concentration (C_{ve}) which is given by

$$C_{ve} = v_1 + x_2 \cdot (v_2 - v_1), \quad (1)$$

where v_1 is the valence of the first component in the binary alloy. x_2 and v_2 refer to the mole fraction and the valence of the second component, respectively. Based upon these factors, it was possible to derive systematic statements for the behavior of the enthalpy of mixing in liquid alloys.[1,2] The quantity C_{ve} (Eq. 1), and in some cases the above given factors (2) and (3) contribute in determining the trend of the enthalpy of formation. However, solid solutions differ from liquid ones in that they include miscibility gaps and phases of different structures. This led to a need of more detailed information on common factors which are responsible for predicting the behavior of the enthalpy of formation in solid solutions. Hence, we now extend our previous studies[3–5] to include more observations on the properties of the enthalpy of formation by studying the system silver-indium which has been selected due to its somewhat large range of miscibility in the solid state, and due to the existence of a γ phase[6] which has not been studied before.

Another point of interest is to see if the enthalpy of formation displays a pronounced temperature dependence and to decide if this temperature dependence is a general property of all metallic alloys as claimed by Wittig and Schöffl.[7]

Experimental

Sample. The metals used were: indium of extra purity grade (E. Merck Co.) and 99.88 mass percent silver (Riedel de Haen Co., Germany). The preparation, treatment and testing of the samples were all the same as described before.[1] The samples were tempered for 10 h at 773 K, and 170 h at 623 K. In the measurement process of the enthalpy of dissolution, the solid samples of silver with different masses (12.970—0.160 g) were dropped in liquid samples of indium (1.534 g) being heated at 1100 K. For measurement of the enthalpy difference of the single miscible phase, the solid alloy samples with masses lying between 1.435 and 1.545 g were dropped at 623 and 773 K in a liquid phase (having the same composition as that of the solid alloy sample) which exists at 1100 K inside the calorimeter.

Calorimetric Technique. The calorimeter used in the present study has been described in detail elsewhere.[5] The cylindrical calorimeter of Themax steel which represents a sample container has a hollow space coated with a layer of aluminum oxide. The role of this Al_2O_3 layer is to prevent reaction of the sample with the calorimeter. The cover of the calorimeter, also coated with a layer of aluminum oxide, has three wells for the tube of the drop device, stirrer (made of ceramic) and the thermocouple. The calorimeter is suspended inside a metallic shield system of V2A steel. This contains two cylindrical compensating systems of Thermax steel placed below and above the calorimeter. The lower compensating system has wells of each 3.5 mm diameter for the twelve differential Pt-to-(Pt+10 mass percent Rh) thermocouples. The whole assembly is placed in a vertical tube furnace. Another vertical tube furnace is placed above the cooling system which in turn was placed at the mouth of a silica glass tube which contains the whole assembly. The role of the second tube furnace was to temper the sample at any high temperature before its final drop in the calorimeter. The calibration of the thermocouples used was based on a standard Pt-PtRh thermocouple. A digital millivoltmeter (Hewlett-Packard 2401 C) was used for a registration of the thermal potential of the thermocouples. The temperature drifts of the calorimeter caused by the lower compensating body were negligible. The derived temperatures are judged to correspond with the IPTS-68 to within 0.01 K at 500 K and 0.1 K at 1000 K. The temperature was regulated by means of a p-regulator.[8]

The calibration of the calorimeter was conducted by measuring the enthalpy of a standard tin sample.[9] The calibration factor is determined with an accuracy of 0.3%.

Results and Discussion

(i) Enthalpies. Values of $[H_1^\circ(T)-H_1^\circ(623\text{ K})]$; $[H_1^\circ(T)-H_1^\circ(773\text{ K})]$ and $[H_2^\circ(T)-H_2^\circ(623\text{ K})]$; $[H_2^\circ(T)-H_2^\circ(773\text{ K})]$ are presented in Table 1. The deviation for a single measurement is 0.35%.

Table 2 collects values for the enthalpy differences of the alloys: [H_3°(1100 K)$-H_3^\circ$(623 K)] and [H_3°(1100 K)$-H_3^\circ$(773 K)] as measured in the present study. The deviation is 0.4% for a single measurement.

(ii) Enthalpy of Dissolution. The enthalpy of dissolution of solid silver in liquid indium at the temperature T_1 can be determined according to the following equations:

$$-(1-x_2)\cdot \mathrm{Ag(s}, T_1) - x_2\cdot \mathrm{In}(l, T_1) + \mathrm{Ag}_{1-x_2}\mathrm{In}_{x_2}(l, T_1) = 0, \quad (2)$$

$$\Delta_s H^\circ = -(1-x_2)\cdot H_1^\circ(T_1) - x_2\cdot H_2^\circ(T_1) + H_3^\circ(T_1), \quad (3)$$

where $\Delta_s H^\circ$ is the enthalpy of dissolution of Ag in In, and H_3° is the enthalpy of the alloy at the mole fraction of indium x_2. Table 3 summarizes the values of the integral and partial molar enthalpies of dissolution at 1100 K in the whole range of composition. A number within parenthesis is the estimated standard deviation (esd). The accuracy

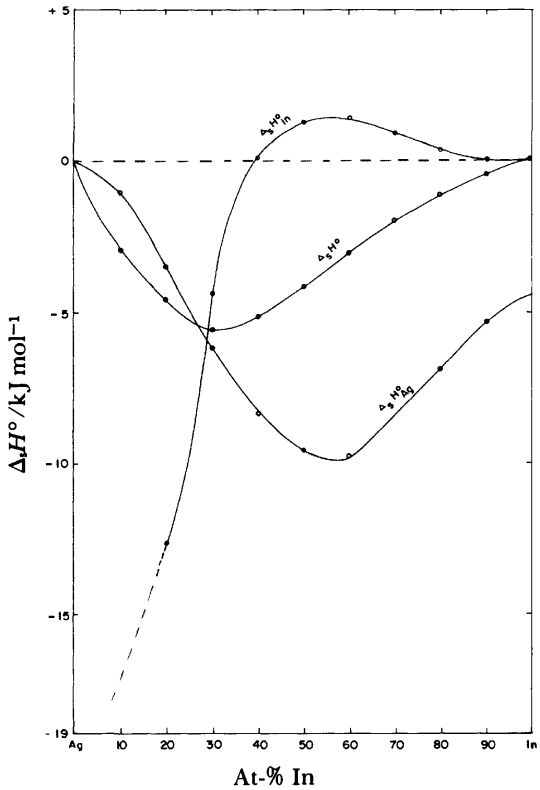

Fig. 1. The integral and partial molar enthalpies of dissolution at 1100 K in system Ag-In.

obtained is 0.8%. The present value is in excellent agreement with that obtained by Hultgren et al.[6]

From curve-fitting calculations, the following polynomial function for $\Delta_s H^\circ$ is derived:

$$\Delta_s H^\circ = -48.448x_2+132.302x_2^2-123.876x_2^3+40.022x_2^4. \quad (4)$$

Figure 1 shows the plot of the integral and partial molar enthalpies of dissolution $\Delta_s H^\circ$, $\Delta_s H_{Ag}^\circ$, $\Delta_s H_{In}^\circ$,

against the composition. The integral enthalpy of dissolution is negative and decreases with the increase of the composition to reach a minimum at x_2=0.3; after that the enthalpy of dissolution increases with the increase of indium mole fraction. This behavior of $\Delta_s H°$ with a minimum lying at x_2=0.3 points out the existence of a compound with the form Ag_3In. This may be quantitatively explained by using the Wagner effect:[10] assuming that we have to deal with a heteropolar system with the compound Ag_3In, the minimum of $\Delta_s H°$ should lie at the composition of the compound: $x_{In}=1-3/(1+3)=0.25$, where Ag is considered to be the donor and In the acceptor (see Ref. 11). With reference to Eq. 4, $\Delta_s H°$ at x_2=0.3 is equal to -5.648 kJ mol^{-1}, while $\Delta_s H°$ at x_2=0.25 is equal to -5.622 kJ mol^{-1}. The deviation between the two values (26 J mol^{-1}) is not much larger than the value expected from the experimental uncertaintities (14—18 J). It is also possible that the Wagner effect is overlapped by another dissolution effect so that the minimum of the enthalpy of dissolution is shifted to the composition x_2=0.3. This means that we have to deal with a non-ideal Wagner effect (see Ref. 11). It is also noteworthy that such behavior of the enthalpy of dissolution which suggests the existence of a compound at x_2=0.3 indicates that the maximum of the volume of dissolution may also lie at x_2=0.3.

With reference to the definition of the partial molar quantities:

$$y_1 = Y - x_2 \cdot (\partial Y/\partial x_2)_{T,p}, \quad (5)$$

$$y_2 = Y - (x_2 - 1) \cdot (\partial Y/\partial x_2)_{T,p}, \quad (6)$$

and using Eq. 4, we obtain:

$$\Delta_s H_1^\circ = -132.302x_2^2 + 247.752x_2^3 - 120.066x_2^4, \quad (7)$$

$$\Delta_s H_2^\circ = -48.448 + 264.604x_2 - 503.930x_2^2 + 407.840x_2^3 - 120.066x_2^4. \quad (8)$$

Figure 1 shows the partial molar enthalpies of dissolution of silver and indium against the composition. The partial molar enthalpy of dissolution of silver $\Delta_s H^\circ_{Ag}$ is negative and takes a minimum at the composition 58 at-% In. This is due to the delivery of electrons from silver to indium. Such a delivery of electrons increases with the increase of indium mole fraction so that $\Delta_s H^\circ_{Ag}$ becomes more negative to reach a minimum at equilibrium being established at the maximum of the C_{ve} which lies at x_2=0.58. The partial molar enthalpy of dissolution of indium, $\Delta_s H^\circ_{In}$ is negative in the range 0 to 40 at-% In but increases with the increase of the composition to take positive values above 40 at-% In with a maximum at x_2=0.58. This behavior is also understandable: The insertion of the somewhat larger indium atom in the structure causes a positive deformation work which increases with increasing composition since the lattice suffers higher tension. The maximum of $\Delta_s H^\circ_{In}$ at x_2=0.58 (the same composition of $\Delta_s H^\circ_{Ag}$ minimum) also represents the maximum of C_{ve} at equilibrium.

(iii) Enthalpy of Formation. The enthalpy of formation can be calculated from the enthalpy of dissolution using the method as described before.[2] The procedure can be explained through the following equations:

$$-(1 - x_2) \cdot \mathrm{Ag(s, } T_0) - x_2 \cdot \mathrm{In(s, } T_0) + \mathrm{Ag_{1-x_2}In_{x_2}(s, } T_0) = 0. \quad (9)$$

This reaction represents the formation reaction of the alloy from Ag and In at the initial temperature T_0. The enthalpy of formation of the alloy AgIn is:

$$\Delta_f H° = -(1 - x_2) \cdot H(T_0) - x_2 \cdot H_2^\circ(T_0) + H_3^\circ(T_0). \quad (10)$$

The indices 1, 2, and 3 indicate silver, indium, and the alloy, respectively.

Subtraction of Eq. 10 from Eq. 3, yields:

$$\Delta_s H° - \Delta_f H° = -(1 - x_2) \cdot [H_1^\circ(T_1) - H_1^\circ(T_0)] - x_2 \cdot [H_2^\circ(T_1) - H_2^\circ(T_0)] + [H_3^\circ(T_1) - H_3^\circ(T_0)]. \quad (11)$$

The term $[H_3^\circ(T_1)-H_3^\circ(T_0)]$ which appears in Eq. 11 is the enthalpy difference of the alloy; this was measured between 623 and 1100 K and between 773 and 1100 K. The differences $[H_1^\circ(T)-H_1^\circ(T_0)]$ and $[H_2^\circ(T)-H_2^\circ(T_0)]$ are measured accurately (Table 1).

Table 4 presents values for the integral and partial molar enthalpies of formation at 623 and 773 K. A number within parenthesis is the estimated standard deviation (esd). The average error of the individual measurement was found to be 0.6% for the enthalpy of formation at 623 K and 0.36% for that at 773 K. There exists no report on the enthalpy of formation in the

Table 4. Integral and Partial Molar Enthalpies of Formation of the γ Phase in the System Silver-Indium in kJ mol^{-1}. Estimated Standard Deviations in Parenthesis M(Ag)=107.868 g mol^{-1}; M(In)=114.82 g mol^{-1}

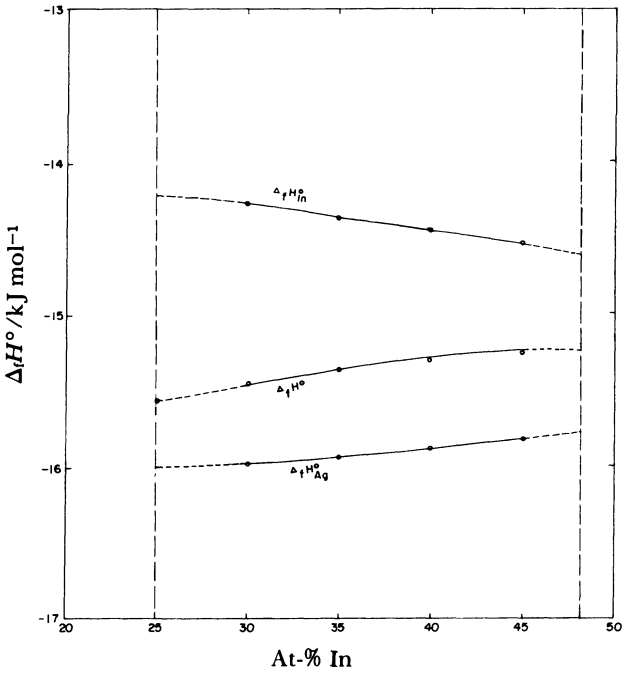

Fig. 2. The integral and partial molar enthalpies of formation at 623 K in the range of the γ phase in the system Ag–In.

literature, hence a comparison with the present data can not be made.

From curve-fitting calculations it was possible to derive equations for the relation of the enthalpy of formation to the mole fraction of indium:

$$\Delta_f H^\circ(623\ \mathrm{K}) = -16.117 + 2.641x_2 - 1.506x_2^2 + 0.050x_2^3, \quad (12)$$

$$\Delta_f H^\circ(773\ \mathrm{K}) = -15.914 + 2.607x_2 - 1.486x_2^2 + 0.049x_2^3. \quad (13)$$

These equations produce the curves of the enthalpies of formation against the temperature as shown in Fig. 3. It is clearly observable that the enthalpy of formation depends insignificantly on the temperature. This is a somewhat surprising observation since Wittig and Schöffl[7] claimed in their study on the system Al–Zn that a pronounced temperature dependence of the enthalpy of formation is a typical property of all metallic alloys. However, it appears that Wittig's conclusion was incorrect: The pronounced temperature dependence of the enthalpy of formation in the system Al–Zn was attributed to lattice defects of greater expansion of aluminum lattice in the alloy compared with the expansion in pure aluminum metal. Since such a lattice defect in the structure due to an increase in the temperature is not common to all metallic alloys, a pronounced temperature dependence of the enthalpy of formation (which is not observed on the system Ag–In) seemed

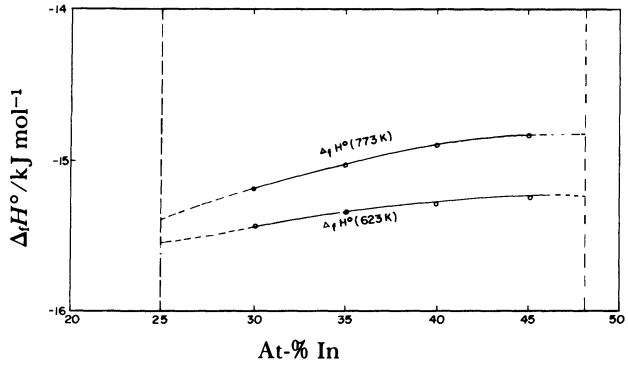

Fig. 3. The enthalpies of formation at 623 and 773 K in the range of the γ phase in the system Ag–In.

not to be a general property of all metallic alloys. The relation of the enthalpy of formation to temperature depends on the type of the system and on the range of temperature and composition in which the phase can exist. This was deduced from our study on the system Sn–Sb[5] where the pronounced temperature dependence was attributed to the continuous formation of liquid from the solid solution (the β' phase) in accordance with the phase diagram.

As illustrated in Table 4 and Figs. 2 and 3, the enthalpy of formation is negative and increases slightly with the increase of the composition due to the insertion of indium atom in the structure. The insertion of indium atom which is not much larger than silver atom in the structure leads to a small positive deformation work so that the enthalpy of formation depends slightly on the composition. The charging of the Brillouin zones is always the reason for the increase of the enthalpy of formation with the increase of the composition (see Ref. 3).

With reference to the definition of the partial molar quantities (Eqs. 5 and 6), we obtain through Eqs. 12 and 13 the following equations for $\Delta_f H_1^\circ$ and $\Delta_f H_2^\circ$:

$T = 623$ K

$$\Delta_f H_1^\circ = -16.117 + 1.506x_2^2 - 0.100x_2^3, \quad (14)$$

$$\Delta_f H_2^\circ = -13.476 + 3.012x_2 + 1.356x_2^2 - 0.100x_2^3 \quad (15)$$

and

$T = 773$ K

$$\Delta_f H_1^\circ = -15.914 + 1.486x_2^2 - 0.098x_2^3, \quad (16)$$

$$\Delta_f H_2^\circ = -13.307 - 2.972x_2 + 1.486x_2^2 - 0.098x_2^3. \quad (17)$$

Figure 2 shows that the partial molar enthalpy of silver is negative and becomes more negative at higher composition. A hypothetical illustration of this behavior is probably that a poor fraction of silver s-electrons forms a weak bond with indium ions. At higher composition, the equilibrium shifts for the benefit of the delivery of further electrons on indium.

The partial molar enthalpy of formation of indium is also negative, but increases at higher composition. The negative trend in the whole range of the γ phase indicates the stability of the structure. However, this stability decreases at higher composition due to the insertion of the somewhat larger indium atom in the structure: the structure exhibits a higher tension resulting from a small deformation work which is associated with the insertion of the indium atom in the structure.

Conductimetric Studies of Ionic Association of Tetraalkylammonium Halides and Tetraphenylborate in *N,N*-Dimethylformamide-Methyl Ethyl Ketone Mixtures at 25 °C

Nurul Islam,* S. B. A. Zaidi, and Aijaz Ahmad Ansari
Department of Chemistry, Aligarh Muslim University, Aligarh-202002, India
(Received April 18, 1988)

The molar conductivities of Et_4NBr, n-Pr_4NBr, n-Bu_4NBr, and n-Bu_4NBPh_4 have been measured in *N,N*-dimethylformamide–methyl ethyl ketone (DMF–MEK) mixtures ($34.5 \geqslant D \geqslant 20.10$) over the maximum concentration range ($2 \times D^3 \times 10^{-7}$ mol dm^{-3}) along with the densities and viscosities of the solvent mixtures at 25 °C. The conductance data have been analyzed by using the Fuoss-1978 (F78) conductance equation and the results compared with those obtained from the Justice (J) and the Fuoss-Onsager-Skinner (FOS) equations. The molar conductivities at infinite dilution (Λ_0), the thermodynamic association constant (K_A) and the distance or the ion-size parameter (R or $a°$) are evaluated from these data. A better fit of the parameters was provided by the F78 equation which yielded K_A and R values. The Λ_0 and the K_A values are found to increase with decrease in the dielectric constant of the medium and in a given solvent mixture they follow the order $Et_4NBr > n$-$Pr_4NBr > n$-$Bu_4NBr > n$-Bu_4NBPh_4.

Extensive studies on the electrolytic conductivities in various pure and mixed aprotic solvents have been made[1–8] to examine the magnitude and the nature of ion–ion and ion–solvent interactions in terms of the limiting molar conductance, the ion-size parameter and the ionic association constant. The solvent properties like the viscosity and the dielectric constant have also been taken into account in determining the extent of ionic association and the solute–solvent interactions which enabled many to interpret the unique structure of the solvent.

The present study deals with the mixtures of *N,N*-dimethylformamide and methyl ethyl ketone (DMF–MEK) both of which are dipolar aprotic and in the pure state have no tendencies[9–11] to self-association through the dipole–dipole interactions. Recently,[12] it has been reported that the physical properties of DMF–MEK mixtures over the entire composition range show an ideal behavior for the physicochemical investigations in the cases of 1:1 electrolytes. Consequently, the investigation of conductance behavior of tetraalkylammonium halides and tetraphenylborate has been undertaken with a view to examining the suitability of the F78[13,14] conductance equation over those of the Justice[15] and the FOS[16] conductance equations.

Experimental

Methyl ethyl ketone was treated several times with saturated potassium carbonate solution to remove the acid impurities and the two layers thus obtained were separated. After removing most of the water by distillation, the ketone was dried over sodium sulfate and anhydrous potassium carbonate for several days. The decanted liquid was fractionally distilled several times until the measured density (0.7999 kg m^{-3}), viscosity (0.379 kg m^{-1} s^{-1}) and specific conductance: (2—3.5)$\times 10^{-8}$ S cm^{-1} at 25 °C were found to be comparable with those of the corresponding literature values.[12,17]

N,N-Dimethylformamide was purified by keeping it over anhydrous sodium carbonate for 24 hours and was then distilled under reduced pressure in a dry nitrogen atmosphere and the fraction distilling at 73 °C/57 mmHg (1 mmHg≈133.322 Pa) was collected. The purified solvent had a density: 0.9443 kg m^{-3}; viscosity: 0.795 kg m^{-1} s^{-1} and specific conductance: (1—2)$\times 10^{-7}$ S cm^{-1}, which agree well with those of the reported[18,19] values.

Tetrabutylammonium tetraphenylborate (n-Bu_4NBPh_4) was prepared[20] by dissolving sodium tetraphenylborate in conductivity water (2% solution) and filtered to remove a small amount of insoluble impurities. To this, an equivalent amount of tetrabutylammonium bromide in 2% aqueous solution was slowly added. The bulky white precipitate thus obtained was washed five times by decantation. After preliminary drying, the product was recrystallized four times from 1:3 water–acetone mixture and finally dried for several days at 40 °C and 10^{-4} mmHg pressure (mp 223—225 °C).

The pure samples of Et_4NBr, n-Pr_4NBr (both, Fluka, AG), and n-Bu_4NBr (Eastman, AG) procured from the supplier were used as such.

Conductance measurements were carried out by the IMPEDENCE BRIDGE, 1608-A (General Radio & Co., U.S.A.) at a constant frequency of 1 kHz with an accuracy of ±0.05—0.005%. The Pyrex conductivity cell (cell constant, 0.7891 cm^{-1}) having bright platinum disc electrodes was used. The cell was calibrated by the method of Lind and co-workers[21] using the decinormal potassium chloride solutions. The overall reproducibility of the conductance measurement was found to be within ca. ±0.025%.

The solvent mixtures were prepared by weight and in each case initially a concentrated electrolytic solution ($C_{max} = 2 \times D^3 \times 10^{-7}$)[22] of the salt was prepared and several solutions of different concentrations were prepared by the method of dilution. Dielectric constants of the solvent mixtures were taken from the literature.[12]

All the measurements were carried out in an atmosphere of pure and dry nitrogen at 25±0.01 °C in a thermostated oil bath.

Results and Discussion

The physical properties of the solvents employed in computation are listed in Table 1. The molar conductivities, Λ(S cm^2 mol^{-1}) of dilute electrolytic solutions of varying concentrations, C(mol dm^{-3}) of Et_4NBr, n-Pr_4NBr, n-Bu_4NBr, and n-Bu_4NBPh_4 in mixtures of DMF–MEK are recorded at 25 °C (Table 2).

The concentration dependence of the above conductance data has been analyzed in terms of the F78 equation[13,14] and the parameters thus obtained are compared with those obtained by employing the J and the FOS equations.[15,16]

The F78 equation[13,14] based on the concept of diffusion controlled steady state approach is of the form,

$$\Lambda = [1 - \alpha(1 - \gamma)][\Lambda_0(1 + \Delta x/x) + \Delta\Lambda_e] \quad (1)$$

where Λ_0 is the limiting equivalent conductance, the term $\Delta x/x$ represents the relaxation effect, $\Delta\Lambda_e$ the electrophoretic effect, while γ denotes the fraction of solute present as free ions and α is the contact pair parameter. Both Δx and $\Delta\Lambda_e$ depend on the values of the diameter of the Gurney cosphere, R, the dielectric constant and the viscosity of the medium. The parameters and the auxilliary variables are related by a set of the following equations:

$$K_R = (1 - \alpha)(1 - \gamma)/C\gamma^2 f^2 = (4\pi NR^3/3000)\exp(\beta/R) \quad (2)$$

$$K_S = \alpha/(1 - \alpha) \quad (3)$$

The conductometric association constant, K_A is given by

$$K_A = (1 - \gamma)/C\gamma^2 f^2 = K_R/(1 - \alpha) \quad (4)$$

while the activity coefficient, f, is

$$-\ln f = \beta\kappa/2(1 + \kappa R) \quad (5)$$

in which $\beta = e^2/DkT$ and $\kappa^2 = 8\pi\beta\gamma n = \pi\beta NC/125$. The relevant terms have their usual significance. For this purpose, the PARACOND[23] computer program designed for the symmetrical electrolytes has been used.

Similarly, each set of conductance data has been analyzed using Justice's modification[15] of the Fuoss-Hsia equation[24] and the relevant constants derived by employing the Fernandez-Prini equation.[1] The Fuoss-Hsia equation is given by,

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + E\gamma C\ln(C\gamma) + J_1 C\gamma - J_2(C\gamma)^{3/2} - \Lambda C f_\pm^2 \gamma K_A \quad (6)$$

where γ is the degree of dissociation, $f_\pm$ the mean molar activity coefficient, and all other terms have their usual significance. The thermodynamic association constant is given by

$$K_A = (1 - \gamma)/C\gamma^2 f_\pm^2 \quad (7)$$

in which the activity coefficient for the neutral ion pair is taken as unity. The activity coefficients are obtained using the Debye–Hückel equation,

$$\ln f_\pm = -A(\gamma C)^{1/2}/\{1 + BR_j(C\gamma)^{1/2}\}. \quad (8)$$

As proposed by Justice,[15] the distance parameter, R_j of Eq. 8 has been taken as the Bjerrum critical distance, q ($=e^2/2DkT$). The analysis of the data in terms of Eq. 6 has been carried out by a pit-mapping method[25] in which Λ_0, R_j, and K_A are varied until a minimum is located for the standard error of estimate. This latter quantity, σ_Λ is defined by

$$\sigma_\Lambda = \{\sum(\Lambda_{obs} - \Lambda_{calc})^2/(N - 3)\}^{1/2}. \quad (9)$$

Finally, the above set of conductance data (Table 2) has been analyzed in terms of the FOS equation,[16]

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma\log(6E'_1 C\gamma) + LC\gamma - C\gamma f_\pm^2 \Lambda K_A \quad (10)$$

for associated electrolytes. The symbols used have their usual meaning. Kay's computer program[26] based on the least square method of calculation is employed here.

The values of the best fit parameters of Λ_0, K_A, and the distance or the ion-size parameter (R or a°)

corresponding to the minimum standard deviations from the relevant (F78, J and FOS) equations are listed in Tables 3-I, 3-II, and 3-III, respectively.

The above calculations have been carried out on a VAX-11/780 computer.

A comparison of the applicability of the above three equations to the conductance is made here. The computed values of Λ_0 for the salts under study in various DMF–MEK mixtures obtained using the F78, the J and the FOS equations are found to be close to each other. On the one hand, these Λ_0 show the usual decrease in their values with increase in the size of the ions in the order: $Et_4\overset{+}{N}>n\text{-}Pr_4\overset{+}{N}>n\text{-}Bu_4\overset{+}{N}>Ph_4B^-$ in accord with the trend in the behavior of their parent Λ values. On the other hand, the Λ_0 values are found to increase with decrease in the dielectric constant of the solvent mixtures. Such a situation has also been reported earlier for several pure[11,27] and mixed aprotic solvents[28,29] and has been attributed to a number of effects such as the solvent structure and the ion–solvent interactions. The solvent structure effects are apparently reflected by the viscosity behavior which is marked by its increase with increase in the mol% of DMF. The excess thermodynamic parameters[12] of the present system show an ideal mixing which suggest the absence of intermolecular interactions in DMF–MEX mixtures similar to those observed for the DMF–acetone system.[6]

The K_A values (Table 3) obtained using the F78 equation are found to be ca. 23.26% and ca. 30.38% higher than those obtained from the J and the FOS equations, respectively. An increase in the K_A values with decrease in the dielectric constant of the medium is in accordance with those reported earlier[27–33] for similar system. The applicability of the various theories of ion association can be examined in terms of the dependence of $\log K_A$ upon $1/D$ (Fig. 1). The nonlinearity of the plot suggests the applicability of the F78, FOS and Justice theories of ionic association.

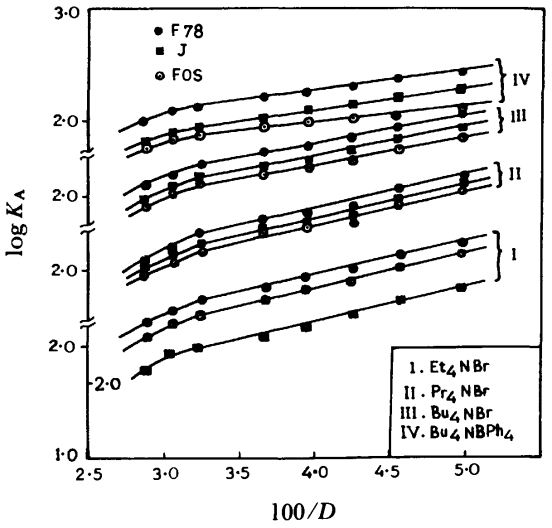

Fig. 1. $\log K_A$ vs. $100/D$.

Further, it is evident from Table 3 that the K_A values for all the salts in a given dielectric constant decrease with the increasing size of the cations in the order, $Et_4\overset{+}{N}>n\text{-}Pr_4\overset{+}{N}>n\text{-}Bu_4\overset{+}{N}\approx BPh_4^-$, similar to those observed earlier[11,30,34,35] due to apparent decrease in the ion–dipole interaction.

The distance or the ion-size parameter (R or $a°$) values obtained using different equations are compared with the crystallographic radii of the salts under study. The values of R_j or $a°$ obtained using the J and the FOS equations in some of the solvent mixtures (Tables 3-II and 3-III) are less than the corresponding crystallographic radii of the ion pairs and are, therefore, not understandable. The F78 equation, on the other hand, predicts meaningful values of R as 11.40 to 17.55 Å in the media of $34.50\geqslant D\geqslant 20.10$ which are also more than the Bjerrum critical distance, q ($=e^2/2DkT$) unlike the R_j or $a°$ values (of J or the FOS equations) which are found to be less than the q values. It may, however, be noted that the J equation

yields higher values of R_j ($25.40 \geqslant D \geqslant 20.10$) than the crystallographic radii of the ion pairs. Although not too much can be deduced from the best-fit R values as they are particularly susceptible to the choice of conductance equation. However, some generalization can be made about the R values obtained from the F78 equation since this presupposes that ion pairs may be of solvent-separated or contact ion pair variety. For a contact ion pair (CIP), R is simply taken as the sum of the ionic radii whereas for the solvent separated ion pair (SSIP), $R=\bar{a}+ds$, where $\bar{a}$ is taken as the sum of the ionic radii and ds is the diameter of solvent molecules. The ds value estimated to be 4.98 Å for MEK and 5.03 Å for DMF. Consequently, the resultant association constant is greater for smaller ions than those for the larger ones because the smaller ion prefers to form an additional CIP with the formation of SSIP in DMF-MEK mixtures and it is apparent from Table 3-I that the SSIP formation constant, K_R increases and CIP formation constant, K_S

decrease with increasing the size of the cations in a given dielectric constant of the medium.

Thus, in view of the above findings the F78 equation seems to be better suited for explaining the conductance behavior of the present system. The successful applicability of this equation seems to stem from the consideration of the solvated radii of ions present in solution in the diffuse steady state and consequently gives significantly better fit parameters compared to the other available conductance equations.

We are grateful to Prof. R. M. Fuoss, Prof. R. L. Kay, and Prof. J. C. Justice for sending the details of their equations and computer programs. One of us (S.B.A.Z.) thanks the U.G.C., Government of India for financial assistance.

Infrared and Raman Studies of the $[VO(O_2)_2F]^{2-}$ Ion

E. M. Nour*,††, A. B. El-Sayed,† and S. A. Sadeek
Department of Chemistry, Faculty of Science, Zagazig University, Zagazig, Egypt
†Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt
(Received January 5, 1988)

The IR and Raman spectra of $Cs_2[VO(O_2)_2F]$ are recorded. The spectra are interpreted on the basis of C_s symmetry of the $[VO(O_2)_2F]^{2-}$ ion. The ν(V=O), ν_s(O-O), and ν_{as}(O-O) are assigned at 950, 890, and 875 cm^{-1}, respectively. The calculated values of the force constants $f_{V=O}$, f_{O-O}, f_{V-O}, $f_{V-O'}$, and f_{V-F} are 670, 298, 262, 273, and 248 N m^{-1}, respectively. The band assignments and the force constant values are discussed in view of the bonding and structure of the $[VO(O_2)_2F]^{2-}$ ion.

In recent years the study of the peroxovanadium chemistry has attracted considerable interest and growing importance,[1-7] since the compounds have much relation to the various types of metal-centered biological systems such as the oxygen carriers as well as the peroxidase and catalase enzymes.[8-10] Most of these studies on peroxovanadium compounds are concerned mainly with their syntheses and structures and in some cases along with vibrational qualitative assignments of the bands, relatively few detailed vibrational works have been elucidated.

Although the reaction between vanadium(V) and H_2O_2 is complicated and pH dependent, many peroxovanadium(V) species have recently been prepared in pure forms. In 1980 Jere and Kaushik[4] reported the isolation of the first fluoro-peroxo species of vanadium(V), $K_2[VO(O_2)_2F]$. A general method for the preparation of different alkali fluorooxodiperoxovanadates(V), $A_2[VO(O_2)_2F]$, was later reported by Chaudhuri and Ghosh.[11].

In previous communications[12-14] detailed vibrational studies have been successfully carried out for many peroxometal species. In this work we report the quantitative vibrational assignments for an oxodiperoxovanadium species based on the IR and Raman spectra of $Cs_2[VO(O_2)_2F]$ and with the aid of normal coordinate analysis. The force constant values for the different bonds and angle bends are calculated. This enable an assessment of the type of bonding and structure inherent in this type of oxodiperoxo compounds.

Experimental

The soild oxodiperoxo compound $Cs_2[VO(O_2)_2F]$ was prepared according to the published method.[11] The chemical composition and IR spectrum agreed with the literature data.[11]

Spectroscopic Measurements. The Raman spectrum of $Cs_2[VO(O_2)_2F]$ was measured using a Carry Model 82 spectrometer and a Coherent Radiation Innova 12 argon ion laser with excitation lines 488.0 and 514.5 nm. To prevent photochemical and thermal decomposition by the laser beam, the sample, as a pressed disc, (20% by weight in KBr), was spun at approximately 2000 rpm in a conventional rotating disc holder. The IR spectrum of the compound was recorded for the sample as a KBr disc using a Pye Unicam SP 2000 spectrometer.

Results and Discussion

The IR spectrum of $Cs_2[VO(O_2)_2F]$ is shown in Fig. 1, and its Raman spectrum recorded using the

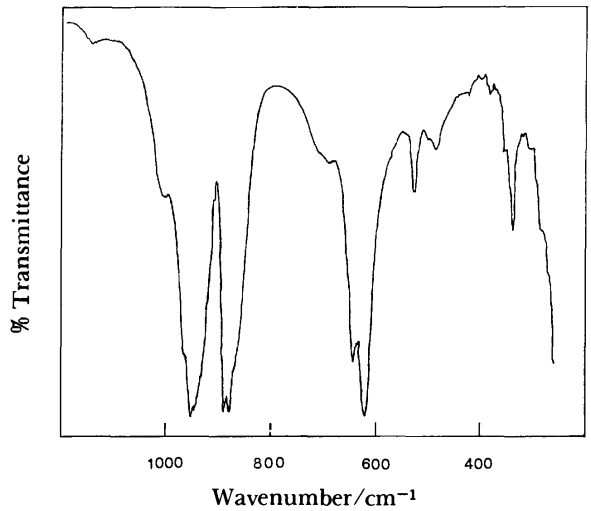

Fig. 1. Infrared spectrum of $Cs_2[VO(O_2)_2F]$.

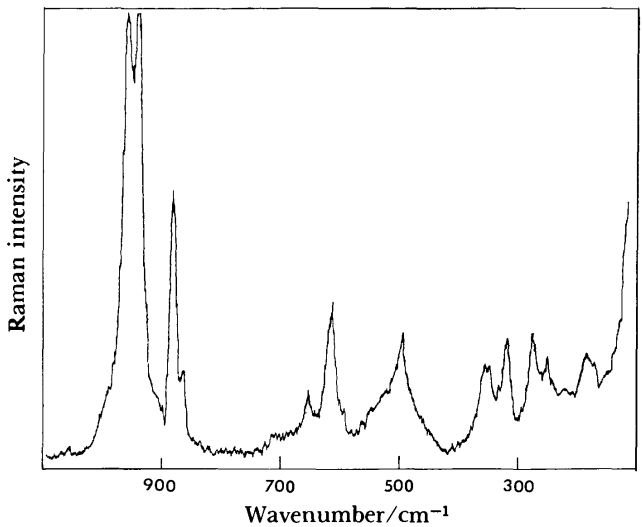

Fig. 2. Raman spectrum of $Cs_2[VO(O_2)_2F]$.

†† Present address: Department of Chemistry, Qatar University, Doha 2713, Qatar (Arabian Gulf).

488.0 nm excitation line is shown in Fig. 2. Before discussing the assignments of these spectra, the geometry of the ion $[VO(O_2)_2F]^{2-}$ must be considered. Here, the vanadium is six coordinate and from the IR and Raman band activities of the O_2^{2-} groups (Table 2), it is clear that each of the peroxy groups acts as a bidentate ligand forming a triangular shape with a vanadium. In this case two structures for the $[VO(O_2)_2F]^{2-}$ are possible. In the first structure both the vanadyl oxygen and the fluoride occupy the two axial positions while the two peroxo groups occupy the four equatorial positions. In this case the ion belongs to the C_{2v} symmetry. The other possible structure contains the two peroxo groups and the fluoride coordinated to vanadium in one plane with the vanadyl oxygen perpendicular to such a plane (Fig. 3). In this case the $[VO(O_2)_2F]^{2-}$ ion belongs to the C_s symmetry. This C_s structure may be the most probable one based on the fact that the reported crystal structure[7] of the related species $NH_4[VO(O_2)_2(NH_3)]$ indicates that the vanadium(V) is bonded to five oxygens and one nitrogen atoms: the coordination structure can best be described as a pentagonal pyramid. The four oxygens of the two peroxo groups, which are related by the mirror plane, and the ammonia nitrogen form the base of a distorted pyramid, and the vanadyl oxygen occupies the apical position. The V-O, V=O, V-N, and O-O bond lengths are 1.883, 1.606, 2.110, and 1.472 Å, respectively. Moreover, the predicted C_s structure for $[VO(O_2)_2F]^{2-}$ ion is also related to those of $[CrO(O_2)_2py]$ and $[CrO(O_2)_2(H_2O)]$.[15,16] Accordingly, the modes of vibrations of $[VO(O_2)_2F]^{2-}$ ion with the pentagonal pyramidal structure in the C_s symmetry, are distributed amongst the vibrational representation: $9A'+6A''$. This gives 15 non-degenerate modes, all are being both infrared and Raman active. From the fifteen fundamentals two modes of the type A′ belong to V=O and V-F bond stretches. The diperoxovanadium unit, $V(O_2)_2$ which possesses a local symmetry of C_{2v}, has six modes of bond vibrations, $3A'+3A''$. These are designated as ν(O-O); A′, ν(O-O); A″, ν(V-O); 2A′, and ν(V-O); 2A″. The remaining seven modes, 4A′ and 3A″ are associated with the different angle bends.

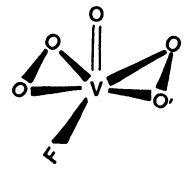

Fig. 3. Geometry of the $[VO(O_2)_2F]$ ion.

Table 1. Force Constants for $[VO(O_2)_2F]^{2-}$ Ion

Symbol	Description	Value[a]

a) Stetching constants in N m^{-1}, bending constants in N m^{-1} Rad.^{2}.

Band Assignments. The observed IR and Raman bands are quantitatively assigned as indicated in Table 2 based on the C_s symmetry and the band intensities and with the aid of a complete normal coordinate analysis. This analysis was carried out on the basis of Wilson's GF matrix method;[17] a general quadratic potential energy function was applied utilizing no nonbonded interactions. A version of the Schachschneider programs[18] was used in the computation process. The details of the calculations are similar to those described previously.[19,20] However, in the calculation we faced with the problem that the number of the force constants exceeds the number of the observed frequencies which made it difficult to determine a complete set of force constants for $[VO(O_2)_2F]^{2-}$ ion. Therefore, the force field was simplified to include only the most effective interaction constants beside the diagonal constants. The initial set of force constants involved only the diagonal constants was first introduced and these were chosen in comparison with the known values of related peroxo compounds.[12] These values were systematically refined to obtain the best fit between the observed and calculated frequencies. The next step was to determine the effective off-diagonal constants by studying the effect of change in the value of each of the interaction force constants on values of the calculated frequencies as well as the physically acceptable potential energy distributions as shown in Table 2. This type of simplifying the force field has been successfully used by many workers.[21,22] The final set of the force constant values and their description are given in Table 1. The ν(V=O); A′ is assigned to the IR band at 952 cm^{-1} and to the Raman doublet at 955 and 942 cm^{-1}. This doublet structure may infer the existence of solid-solid interaction between the vanadyl oxygen of one ion and the vanadium of another.[7] This assignments for ν(V=O) agree well with the known values reported for other vanadyl species.[4,11,23]

Normalized to total 100 for the diagonal force constant distributions. Vibrations with more than 5% contribution are only listed.

The O–O bond vibrations are assigned to the bands around 890 and 875 cm^{-1} due to the ν_s(O–O); A′ and ν_{as}(O–O); A″, respectively. The observation of these two modes in both the IR and Raman spectra supports the triangular structure of $V(O_2)$ units (Fig. 3). Under such a structure, ν_s(O–O) and ν_{as}(O–O) belong to A′ and A″ symmetries, respectively, and both should be IR and Raman active. These values of ν(O–O) occur at much higher frequencies compared with that of the simple peroxide salts. The ν(O–O) in Li_2O_2 occurs at 802 cm^{-1}.[24] The higher value of ν(O–O) in our ion $[VO(O_2)_2F]^{2-}$ may be due to the π-donation from the filled π^* orbitals of the O_2^{2-} to the empty d-orbitals of vanadium(V); the peroxide bond order, and hence its frequency should be increased. However, we believe that such π-donation from the peroxide should be much stronger than that reflected as an increase in the ν(O–O) value. This conclusion is based on the P.E.D. values (Table 2) which demonstrate a relatively strong coupling between the ν(O–O) and the ν(V–O) vibrations; the coupling is expected to lower the ν(O–O) value. The assignments of the other ν(V–O) and ν(V–F) frequencies are rather difficult. This arises from the very strong coupling between these motions as indicated from the P.E.D. values for each band as shown in Table 2. This type of strong mixing is expected from the closed system of $V(O_2)_2$ beside the existence of all of these atoms in one plane. However, the ν_s(V–O) and ν_{as}(V–O) could be assigned to the infrared and Raman bands observed around 650 and 620 cm^{-1}, respectively. The corresponding frequencies for the V–O′ bond vibrations are 485 and 526 cm^{-1}. The ν(V–F) is assigned to the Raman band at 495 cm^{-1}.

The calculated force constant values for the O–O and V=O bonds are 298 and 670 N m^{-1} respectively, while the average value of the V–O bonds is 268 N m^{-1}.

The higher value of the $f_{V=O}$ agrees with the double bond character of the vanadyl bond. Using the bond stretching force constant as an approximate measure of the relative equilibrium bond strength, it appears that the vanadyl link is ≈2.5 times stronger than the vanadium-peroxo link.

We are grateful to Professor J. Laane of Texas A & M University for the Raman facilities.

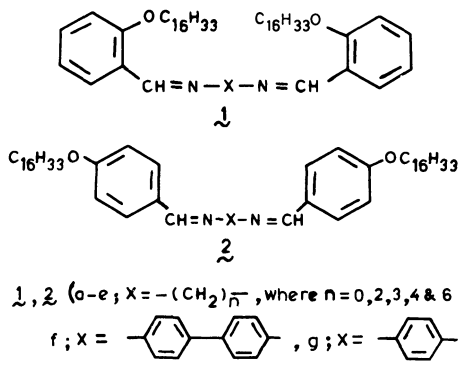
Synthesis and Spectral Analysis of Some Schiff Bases Containing Long Alkyl Chains

Sushree SENAPATI, Bijaya Kumar MISHRA, Gopa Bandhu BEHERA,* and Prem Prakash MAHENDROO†
Centre of Studies in Surface Science and Technology, Department of Chemistry,
Sambalpur University, Burla 768 019, India
†Alcon Laboratories, Inc., 6201 South Freeway, Fort Worth, Texas 76134, U.S.A.
(Received July 30, 1987)

Schiff bases containing hydrophobic alkyl chains have been synthesized and the IR, ^{1}H NMR, ^{13}C NMR, and mass spectral data of some of the compounds have been reported.

In view of the biological importance[1-5] of the Schiff bases, we have reported in this paper the synthesis of Schiff bases (**1** and **2**) from hexadecyloxybenzaldehydes and diamines and have discussed the IR, ^{1}H NMR, ^{13}C NMR, and mass spectra of some of these compounds. Recently Becker et al.[6] have also reported the synthesis of a similar Schiff base derived from 11-*cis*-retinal and have studied their photophysical and photochemical behavior in nonionic micellar solutions.



Experimental

General. Melting points were determined on a sulfuric acid bath and are uncorrected. IR (KBr) spectra were recorded on a Perkin-Elmer 398 spectrophotometer (Table 1). ^{1}H NMR (Table 2) and ^{13}C NMR (Table 3) spectra of the compounds (**1a,b,d** and **2b—e**) were recorded in $CDCl_3$ using TMS as an internal standard. Mass spectra of the compounds (**1a,b** and **2b,d**) were obtained from CDRI Lucknow.

***p*-(Hexadecyloxy)benzaldehyde:** About 0.5 g (0.02 mol) of sodium was dissolved in 50 ml ethanol and to it a solution of *p*-hydroxybenzaldehyde (2.44 g, 0.02 mol) in 20 ml ethanol were added with stirring. To this, hexadecyl bromide (10 ml, 0.02 mol) was added gradually and the total mixture was refluxed at 120 °C for 15 h. A solid separated after cooling the reaction mixture to 0 °C. It was then washed with water, extracted from ether, and crystallized from acetonitrile. Yield 45%; mp 50 °C, IR 2910, 2840 (CH_2), 1690 cm^{-1} (CH=O).

o-(Hexadecyloxy)benzaldehyde was prepared similarly by treating salicylaldehyde with hexadecyl bromide. Yield 45%; mp 46 °C; IR 2910, 2840 (CH_2), 1680 cm^{-1} (CH=O).

***N,N'*-Bis[*p*-(hexadecyloxy)benzylidene]diamines (2b):** A solution of *p*-(hexadecyloxy)benzaldehyde (0.692 g, 0.002 mol) and ethylenediamine (0.06 ml, 0.001 mol) in ethanol (20 ml) was refluxed for 30 min in presence of one to two drops of piperidine. A white compound obtained at room temperature was then crystallized from absolute ethanol. Yield 80%; mp 91 °C.

Other Schiff bases (**1** and **2**) were prepared similarly by treating appropriate diamines with *o*- or *p*-(hexadecyloxy)-benzaldehyde, respectively, with varying reflux time. Compounds **2a, f, g** were crystallized from benzene and the rest were from ethanol. Compound **1c** was found to be gummy and could not be crystallized. The diamines used for the synthesis of Schiff bases together with mp, analytical, and IR data of the compounds are given in Table 1.

Results and Discussion

IR Spectra: The IR spectra of all the compounds exhibit characteristic absorption in the range of 2920—2840 cm^{-1} for the $-CH_2-$, 1635—1570 cm^{-1} for the -C=N-, 1255—1240 cm^{-1} for the C-O-C, and 770—720 cm^{-1} for the aromatic -C-H. The IR absorption of the C=N group occurs at a lower energy region for compounds **a, f, g**, of both series, which may be due to extended conjugation in the molecule. The absorption due to aromatic C-H groups for Schiff bases **2**

appears at a lower energy region than that for **1**.

^{1}H NMR Spectra: The ^{1}H NMR spectral data of the compounds are given in Table 2. The chemical shift values indicate that the influence of the 'O' and 'N' atoms is not observed beyond three bonds (i.e. about 4 Å distance). The 'q' and the 'y' protons in the compounds **1d**, **2d**, and **e** appear at the same δ value. Hence, the extent of inductive effect due to the 'O' and 'N' atoms is same at the second carbon (i.e., by a bond distance of about 3 Å). The 'y' protons for the compound **2c**, however, appear at a down field because these protons experience the inductive effect from both the nitrogen atoms to an equal extent whereas in **2d** and **2c** the influence is due to one nitrogen only. The signal due to the methine protons ($-CH_w$=N) is generally shifted downfield for the ortho series

Table 2a. ^{1}H NMR Chemical Shifts (δ) of Schiff Bases **1**

Compound	Nature of X	Positions of proton[a)]

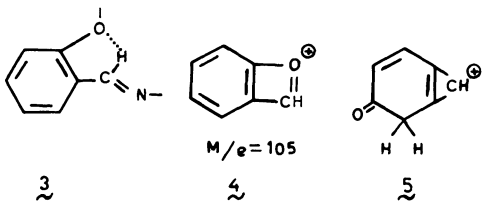
C_{26}	—	—	—	27.149

compared to that for para series because of the possibility of hydrogen bond formation (**3**) in the former. The signal is further shifted downfield in **1a** because its most probable conformation is the H-bonded structure.

^{13}C NMR Spectra: The assignment of the chemical shift values to the carbon atoms has been worked out by applying additive rules proposed by Lindman and Adam.[7] The substituents used are the $-OCH_3$ in place of the $-OC_{16}H_{33}$ and the $-CH=CH_2$ in place of the -C=N- due to unavailability of data and similarity in behavior. The calculated values (given in parentheses) fit well with the observed values within an error of ±0.7 ppm.

Mass Spectra: None of the compounds show a molecular ion peak but the fragmentation pattern conforms to the expected structures of the compounds. The fragmentation pattern due to a straight alkyl chain, peaks at m/z=43 due to $C_3H_7^+$, at 105 due to **4** (for ortho series) and **5** (for para series), a prominent peak at 223 (Scheme 1) for all compounds are discernible. The fragmentation pattern of the compounds **1b** and **2b** are given in Scheme 2.



3 **4** **5**

The authors thank the University Grants Commission, New Delhi for funding the project, CDRI Lucknow for mass spectra and Sambalpur University for laboratory facilities.

Studies on Tetramethyldithizone Isomers and Their Reactions with Metal Ions

A. M. KIWAN,* F. M. HASSAN, and W. HAMDAN
Department of Chemistry, University of Kuwait, P. O. Box 5969 Safat, 13060 Safat, Kuwait
(Received February 17, 1988)

Six bis(dimethylphenyl) analogues of dithizone are prepared, characterized and their reactions with metal ions in a two phase system are reported. The extraction equilibria of their complexes with Cd(II), Co(II), Hg(II), Pb(II), Tl(I), Zn(II), and Bi(III) as well as their spectral characteristics are described. Complete extraction of these metal chelates requires higher pH's than those needed for the unsubstituted dithizone. The molar absorptivities of Bi(III) complexes with bis(3,4-dimethylphenyl)-, and bis(3,5-dimethylphenyl) analogues are higher than the corresponding value of Bi(III) dithizonate. The molar absorptivities of Cu(II) and Hg(II) (in CCl_4) complexes with bis(3,5-dimethylphenyl) analogue are also higher than the corresponding values of the unsubstituted dithizone complexes.

Dithizone (3-mercapto-1,5-diphenylformazan) is a well-known sensitive analytical reagent used for the determination of many metals in various substances.[1] It is also effective for the separation and preconcentration of traces of metals from different materials prior to their determination by highly sensitive methods.[2] The sensitivity and/or selectivity of dithizone are affected by introducing substituents in the phenyl rings. In a preceding paper, the effects of introducing four chlorine atoms (as electron-withdrawing groups) into the phenyl rings of dithizone on the extraction parameters and spectral characteristics of six new tetrachlorodithizone isomers and their metal complexes were reported.[3]

This paper describes the effects of introducing four methyl groups (as electron-releasing groups) into the phenyl rings of dithizone and their spectral characteristics as well as those of their metal complexes.

Results and Discussion

Visible Spectra of Tetramethyldithizone Analogues. These compounds are black crystalline solids which are insoluble in water. They are fairly soluble in

a) Position of methyl substituents on both phenyl rings. b) Molar absorptivity (l mol^{-1} cm^{-1}). c) $\Delta R=R_s-R_u$ where R_s and R_u are the peak ratios for the substituted and unsubstituted dithizone, respectively. d) Ref. 4. e) Ref. 7. f) Ref. 1. g) Ref. 5. h) Ref. 6.

organic solvents such as chloroform and carbon tetrachloride to give green solutions with two distinct absorption bands in the visible region. The positions and intensities of these bands were found to depend on the position of methyl groups in the phenyl rings as well as on the nature of solvents (Table 1). The solutions of these compounds were found to be stable for about one week if they are kept refrigerated.

Inspection of the spectral data in Table 1 shows the following:

1) Both $\lambda_{max,1}$ and $\lambda_{max,2}$ of all tetramethyldithizone isomers (except bis(2,6-dimethylphenyl) analogue of dithizone) are shifted towards longer wavelengths. This trend is qualitatively similar to what was found with dimethyldithizone isomers[4-7] and also with the tetrachlorodithizone isomers.[8]

2) The $\varepsilon_{max,1}$ values of all tetramethyldithizone derivatives (except that of bis(2,6-dimethylphenyl) analogue) have increased, whereas the $\varepsilon_{max,2}$ values have decreased. This effect is the opposite to what was found with the tetrachlorodithizone analogues whose $\varepsilon_{max,1}$ values have generally decreased.[8]

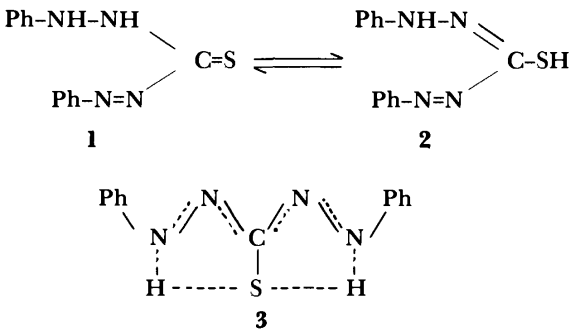
3) As a result of the effects on $\varepsilon_{max,1}$ and $\varepsilon_{max,2}$ mentioned above, all peak ratio (R) values ($= \varepsilon_{max,1}/\varepsilon_{max,2}$) of all tetramethyldithizone derivatives are higher than the corresponding value of the unsubstituted dithizone. Substituent effects on the R values of dimethyldithizone analogues were observed[4-7] where opposite effects on the R values of tetrachlorodithizone analogues has been found.[8]

The existence of two absorption bands in the visible spectra of dithizone solutions in organic solvents are generally attributed to thione–enethiol tautomerism.[1,3,9] The longer wavelength band is attributed to the thione (**1**) whereas the shorter wavelength band corresponds to the thiol tautomer (**2**). It has been also suggested that the peak ratio, R, represents the relative concentration of the two tautomers. The findings that the R values of all tetramethyldithizone isomers are higher than the corresponding values of the unsubstituted dithizone, may then be accounted for by the shifting of equilibria towards the thione tautomer.

However, some authors have attempted to reconsider the thione–enethiol hypothesis of dithizone; firstly by the preparation of *S*-methyl derivative of dithizone and comparing its spectrum with that of the parent compound. This failed, for while authentic *S*-methyldithizone have been synthesized by Irving and Bell,[10] its initially permanganate pink solution in chloroform (λ_{max} 270 and 550 nm, ε_{550} 1225 $m^2\,mol^{-1}$) isomerizes rapidly by first-order kinetics to a yellow isomer (λ_{max} 280, 420, and 540 nm, ε_{420} 1775 $m^2\,mol^{-1}$) the band at 550 nm becoming less intense as that at 420 nm increases.

Some of the doubts concerning the existence and structure of thiol and thione tautomers of dithizone would be also resolved if *N*-methyl derivatives such as PhNH–N(CH_3)–C(=S)–N=N–Ph or PhN(CH_3)–NH–C(=S)–N=N–Ph could be prepared. Many authors have attempted such syntheses but without success.[11-13]

The ^1H and ^{13}C NMR spectroscopy has also been applied by some authors[14-17] to examine the thione–enethiol hypothesis. Owing to its low solubility in organic solvents, Coleman et al.[14] examined the more soluble analogue 1,5-bis(2-ethylphenyl) thiocarbazone in $CDCl_3$. They observed δ 1.4 (6H, triplet, CH_3), 3.0 (4H quartet, CH_2), 7.3, 8.1 (8H, multiplet, ArH), and 12.0 (1.6H, singlet, NH). The latter resonance which disappeared on addition of CH_3OD, showed no signs of splitting over the range of +50 to −45 °C, and the authors ruled out the hypothesis of tautomeric equilibrium in favor of a single symmetrical species **3** essentially that subsequently established for the solid-state structure by X-ray crystallography.[18]



1 **2**

3

Hutton[17] has recently investigated the ^1H and ^{13}C NMR spectroscopy of dithizone and seven of its alkyl-substituted analogues and his results showed that their NH singlets at ca. δ 12.50—12.80, always integrated for 2 protons, i.e. confirming Coleman's results.[14]

On the other hand, Wagler and Koch[19] have recently reported a mathematical analysis of the spectra of dithizone in four organic solvents which supports the thione–enethiol tautomerism. Their analysis allowed the calculation of the individual thione and thiol forms and also estimation of the position of tautomeric equilibria in different organic solvents. However, despite that thione–enethiol tautomerism is still unresolved, dithizone (as well as some of its analogues) remains among the best known sensitive analytical reagents.

Visible Spectra of Metal Complexes: The metal complexes of tetramethyldithizone analogues are highly colored and their electronic spectra are characterized by strong absorption bands in the visible region. Table 2 summarizes their spectral characteristics which indicate the following main features:

1) The metal complexes of bis(2,3-, 2,4-, 2,5-, and 2,6-(dimethylphenyl) analogues of dithizone exhibit λ_{max}'s at shorter wavelengths and have lower values of ε_{max} than the corresponding values of unsubstituted

dithizone metal complexes.

2) On the other hand, almost all complexes of bis(3,4- and 3,5-dimethylphenyl) analogues of dithizone exhibit λ_{max}'s at longer wavelengths and have relatively higher ε_{max} values than the corresponding complexes of the unsubstituted dithizone.

3) The molar absorptivities of Bi(III) complexes with bis(3,4-dimethylphenyl)-, and bis(3,5-dimethylphenyl) analogues are higher than the corresponding value with the unsubstituted dithizone. The molar absorptivities of Cu(II) and Hg(II) (in CCl_4) complexes with bis(3,5-dimethylphenyl) analogue are also higher than the corresponding values of the unsubstituted dithizone complexes.

2,4-	143	65.45	6.38	3440, 2915, 1605, 1505, 1435, 1385, 1215, 1165, 1145 1095, 805
2,5-	136	65.27	6.45	3440, 2910, 1630, 1465, 1450, 1250, 1230, 1190, 1145, 1095, 805, 585, 450
2,6-	138	65.18	6.40	3410, 3280, 3175, 2960, 1290, 1260, 1200, 1150, 1095, 1020, 930, 860, 790, 765, 630, 575, 510, 465
3,4-	125	65.52	6.27	3420, 2910, 1485, 1450, 1315, 1255, 1215, 1175, 1140, 815, 460
3,5-	128	65.15	6.42	3440, 2910, 1600, 1490, 1315, 1245, 1190, 1160, 1120, 840, 770, 660, 475

a) The theoretical results are 65.35% C, and 6.45% H.

Extraction Equilibria. The metal extraction equilibria may be represented by the following general equation:

$$n(CH_3)_4H_2Dz + M^{n+} \rightleftharpoons M[(CH_3)_4HDz]_n + nH^+$$

Table 3 lists the extraction data from which the following conclusions may be drawn:

i) The extraction constants, K_{ext} of tetramethyldithizone metal complexes are considerably smaller than those of the unsubstituted dithizone or the tetrachlorodithizone complexes.[8]

ii) Complete extraction of the metal chelates require higher pH's than those needed for the unsubstituted dithizone complexes as suggested by their higher $pH_{1/2}$.

iii) Unlike bis(2,6-dichlorophenyl) analogue of dithizone,[8] the bis(2,6-dimethylphenyl) analogue of dithizone can extract Cu(II) rather more efficiently than the other tetramethyldithizone isomers (except bis(3,4-dimethylphenyl) analogue.

iv) Bis(3,5-dimethylphenyl) analogue seems more efficient than the unsubstituted dithizone in the separation of Cd(II) from Zn(II).

Experimental

Reagents and Chemicals: The bis(2,3-, 2,4-, 2,5-, 2,6-, 3,4-, and 3,5-dimethylphenyl) analogues of dithizone were prepared from the corresponding arylamines by the nitroformazyl method.[20] The nitroformazan derivatives were converted to the tetramethyldithizone analogues and were finally purified by crystallization from chloroform–cyclohexane mixtures. The elemental analysis data, melting points and some characteristic IR frequencies are given in Table 4.

Deionized water was used throughout, and the usual precautions were taken as with dithizone.[3,21,22]

Procedures. The spectral characteristics (λ_{max} and ε_{max}) of the tetramethyldithizone isomers and their metal complexes were determined in the usual way.[3,21,22] The composition of metal complexes and their extraction constants were also determined as described elsewhere.[8]

The visible spectra of ligands and their complexes were recorded on a Unicam SP8000 spectrophotometer and the infrared spectra on a Unicam SP1000, a Radiometer 64 pH-meter was used for pH measurements. The elemental analyses were done at the Alfred Bernhardt Mikroanalytisches Laboratorium, Elbach, F. R. G.

The authors are grateful to the Research Council of the University of Kuwait for the financial support (SC026) of this work.

On the Relationship between the Chemical Structure and the Carcinogenicity of Polycyclic Aromatic Compounds and Heterocyclic Nitrogen Compounds, as Studied by ^{13}C NMR

Yohko SAKAMOTO* and Yuko SAKAMOTO
School of Pharmaceutical Sciences, Toho University, Funabashi, Chiba 274
(Received May 25, 1988)

Synopsis. The relationship between the chemical structure and the carcinogenicity of eighty polycyclic aromatic compounds and heterocyclic nitrogen compounds was investigated by ^{13}C NMR. The averaged chemical shifts of the carcinogenic polycyclic aromatic compounds were within the range from δ 126.80 to 127.87, while those of the carcinogenic heterocyclic nitrogen compounds were within the range from δ 129.48 to 132.12. The carcinogenicity of several compounds were predicted according to the index.

The information on the electronic structure and electronic state of polycyclic aromatic compounds was obtained by the calculation of the averaged chemical shifts for all the carbons in the ring structure of the molecules, as has been described previously.[1]

The purpose of this paper is to confirm the previous "carcinogenic index" in eighty polycyclic aromatic compounds, either carcinogenic, noncarcinogenic or undetermined.

Polycyclic Aromatic Hydrocarbons 1—51: It has been reported that compounds **1** and **2** are carcinogenic.

The averaged chemical shifts of these carcinogenic compounds are within the index range from δ 127.11 to 127.87, as has reported in a previous paper.[1]

The averaged chemical shift of two other carcinogenic compounds, **3** and **4**, were δ 126.99 and 126.80 respectively. Thus, we can expand the upper limit of the "carcinogenic index" at a high field from δ 127.11 to 126.80.

Compounds **5—8** and **10—13**, previously reported to be noncarcinogenic,[2,3] were confirmed to be out of the "carcinogenic index".

All the fluorene compounds **10—13** can similarly be expected to be noncarcinogenic.

Compounds **14—22**, **24**, **31**, and **37—46** have been reported to be either carcinogenic or noncarcinogenic, depending on the reports.[2-4] According to the "index range", the possibility that compounds **15**, **16**, **18**, **19**, **24**, **31**, **37**, **39**, **42**, and **46** are carcinogenic is high. On the other hand, the possibility that compounds **14**, **17**, **20—22**, **38**, **40**, **41**, and **43—45** are carcinogenic is low.

Compound **9**, previously reported to be noncarcinogenic,[3] fell in the borderline region of the "carcinogenic index", where the judgement of carcinogenicity was difficult.

Heterocyclic Nitrogen Componds 52—80: The averaged chemical shifts in the carcinogenic compounds **52—60** were within the range from δ 129.48 to 132.12.

a) − for noncarcinogenic and + for carcinogenic. b) Carcinogenicity reported previously. It may be based on biochemical evidence or molecular orbital calculation. −: for noncarcinogenic, +: for carcinogenic, ±: for either noncarcinogenic or carcinogenic. c) (−): the carcinogenicities of these compounds were assigned by adopting the noncarcinogenic range for the chlorinated monocyclic aromatic compounds.

The carcinogenicity of the other compounds **61—80** have not been determined. Compounds **72**, **73**, and **74** may be expected to be carcinogenic, according to the above "index range". The "carcinogenic index" of the heterocyclic nitrogen compounds (δ 129.48—132.12) was similar to that of chlorinated monocyclic aromatic compounds (δ 127.76—132.64);[1] both were shifted to a lower field than that from the polycyclic aromatic compounds (δ 126.80—127.87).

There have been no reports on attempts to determine the noncarcinogenic range of noncarcinogenic heterocyclic nitrogen compounds.

However, compounds **61—71** and **75—80** may be expected to be noncarcinogenic by analogy with the chlorinated monocyclic aromatic compounds.

The polar atoms attract the electrons in the ring by the δ-I effect. Thus, the averaged chemical shifts of heterocyclic and chlorinated compounds move downfield as a whole compared with those of polycyclic aromatic compounds, resulting in the difference in the "carcinogenic index" between the two types of compounds.

The present study, like the previous report,[1] shows a close relationship among the carcinogenicity, the averaged chemical shifts, and the electronic structure in aromatic hydrocarbons. Thus, the "index" will be useful in predicting whether or not compounds are carcinogenic.

The authors are heartily grateful to Professor Taichi Ohmoto of Toho University for his encouragement.

(Received April 1, 1988)

Synopsis. The ion-association equilibrium of tetrabutylammonium chloride, bromide, and iodide in the titled solvents has been investigated by solvent extraction at 298 K. In each solvent the association constants have been found to be of similar magnitude among these three salts. This is explained in terms of the larger degree of hydration in the smaller anions. The influence of coextracted water on the equilibrium is discussed.

Solvent extraction has been applied to studies on equilibrium in water-immiscible solvents.[1,2] The solvent is, however, intrinsically saturated with water and even though its amount is usually small, it may cause some effects on the equilibrium. In some solvent extraction systems a certain amount of water is extracted together with the substance in question and the coextraction of water is attributed to the hydration of the chemical species in the organic phase.[3–6] In the present study, the distribution of tetrabutylammonium halides (TBAX; X=Cl, Br, and I) is measured between an aqueous solution and three aprotic solvents; 1,1-dichloroethane (1,1-DCE, relative permittivity[7] ε_r=9.90), 1,2-dichloroethane (1,2-DCE, ε_r=10.37), and 4-methyl-2-pentanone (MIBK, ε_r=13.11); and the association constant of these salts in the organic phase is calculated. The water content of the equilibrated 1,1- and 1,2-DCE is also measured in order to compare the degree of hydration of the salts in these solvents.

Experimental

The reagents employed were of reagent grade. Both 1,1- and 1,2-DCE were washed with aqueous sodium hydrogencarbonate and then water. The former solvent was distilled and the middle distillate was used. MIBK was washed with diluted perchloric acid, an aqueous sodium hydroxide solution, and then water. Tetrabutylammonium halides were recrystallized from ethanol and ether. Their stock solutions were titrated with a standardized silver nitrate solution using uranine as the indicator.

A portion of an aqueous TBAX solution and an equal volume of an organic solvent were mechanically agitated for half an hour in a thermostated room at 298 K. The TBA^+ in the organic phase was stripped with water. When the stripping was not quantitative with water only, a certain amount of carbon tetrachloride (to DCE) or hexane (to MIBK) was added. TBA^+ both in the stripping solution and in the equilibrated aqueous phase was extracted into chloroform as its picrate, and the concentration was determined by spectrophotometry. The water content in the equilibrated 1,1- and 1,2-DCE solutions was measured with a Karl Fischer titrator. Since the extraction of TBACl was poor, the aqueous chloride-ion concentration was enhanced to 2 mol dm^{-3} by adding lithium chloride in order to attain a measurable amount of coextracted water.

Since the salt concentrations in both the aqueous and organic solutions were low, formation of ion pairs in the aqueous phase and any association of ions other than one-to-one adducts in the organic phase are assumed to be negligible. The equilibria and distribution ratio can then be written as follows using the extraction constant, K_{ex}, and the association constant, K_{as}.

$$TBA^+_{(aq)} + X^-_{(aq)} \rightleftarrows TBA^+X^-_{(org)}$$

$$K_{ex} = [TBA^+X^-]_{org}[TBA^+]_{aq}^{-1}[X^-]_{aq}^{-1}f_{\pm}^{-2} \quad (1)$$

$$TBA^+_{(org)} + X^-_{(org)} \rightleftarrows TBA^+X^-_{(org)}$$

$$K_{as} = [TBA^+X^-]_{org}[TBA^+]_{org}^{-1}[X^-]_{org}^{-1} \quad (2)$$

$$D = ([TBA^+X^-]_{org} + [TBA^+]_{org})/[TBA^+]_{aq} \quad (3)$$

Using the charge balance in both phases, $[TBA^+]_{aq} = [X^-]_{aq}$ and $[TBA^+]_{org} = [X^-]_{org}$, Eq. 4 can be obtained.

$$D/f_{\pm} = K_{ex}[TBA^+]_{aq}f_{\pm} + (K_{ex}/K_{as})^{1/2} \quad (4)$$

The mean activity coefficient in the aqueous solution, $f_{\pm}$, was calculated using Debye-Hückel's expression with the closest ion-ion distance 0.6 nm. The activity coefficient of the ionic species in the organic phase is considered to be unity because the dissociated amount of the salts in it should be very small. The distribution data were treated by a least squares program.

Since TBA^+ can be regarded as anhydrous in 1,1-DCE as well as in 1,2-DCE,[3,5] the coextracted water interacts with the anions and the apparent mean hydration number of the anion in the solvents, n_h, is calculated by Eq. 5;

$$n_h = (w_t - w_0)/[TBAX]_{org,total} \quad (5)$$

where w_t and w_0 represents the water concentrations in the organic phase equilibrated with an aqueous solution containing and without containing TBAX, respectively.

Results and Discussion

The distribution data are given in Fig. 1 and the calculated constants are shown in Table 1. The ion-association equilibrium of tetraalkylammonium salts has often been studied by several methods. The association constant for the present salts and solvents is available in the literature only for the iodide in DCE. By electrolytic conductivity the values for dry and water-saturated 1,1-DCE have been compared as; 7.30×10^4 (dry) and 6.54×10^4 (wet), and for 1,2-DCE, 6.70×10^3 (dry) and 5.83×10^3 (wet).[8] Another value for dry 1,2-DCE is reported to be 8.0×10^3 [9] From the solvent extraction data in Ref. 10, it can be calculated to be 5.37×10^4 for 1,1-DCE and 5.89×10^3 for 1,2-DCE, respectively.

The amount of the water uptake of the salts is shown in Fig. 2. After agitation with pure water, 1,1-DCE and 1,2-DCE contained 0.066 mol dm^{-3} and 0.126 mol dm^{-3} of water, respectively. These values were used as w_0 in the calculation of the hydration number for the iodide and the bromide. When equilibrated with 2 mol dm^{-3} of aqueous lithium chloride solution, 1,1-DCE contained 0.060 mol dm^{-3} of water and 1,2-DCE did 0.120 mol dm^{-3}. These were used in the calculation of n_h for the chloride. The extraction of lithium chloride was negligible. The difference of the water concentration between these two experiments is caused by the decrease of water activity in the lithium chloride solution.[11] However, since the initial concentration of TBAX was at most 0.1 mol dm^{-3}, the water activity change should be slight in each aqueous TBAX solution so that each w_0 is valid for the different concentrations of TBAX. In Fig. 2 the plots for the chloride in 1,1-DCE show upper deviation with increasing salt concentration. In this case the extrapolated value onto the lower concentration was taken as its n_h. The obtained values of n_h are given in Table 1.

A wet solvent can be regarded as a mixed solvent with water. Since water has large relative permittivity (78.3), the wet solvents discussed here have larger permittivity than the dry ones. Assuming the linear contribution of water to the permittivity of the solution and using w_0 and the relative permittivity values of pure solvent and water, the permittivity of the water-saturated 1,1-DCE is calculated to be 10.2 instead of 9.9 for the pure solvent. Similar calculations give 10.8 for the water-saturated 1,2-DCE instead of 10.4.[12] The experimentally observed enhancement for 1,2-DCE is, however, reported to be only 0.105 (10.387 instead of 10.282) when it contains 0.118 mol dm^{-3} of water which is close to saturation.[13] On the basis of Fuoss's expression,[14] the decrease in the association constant caused by the change of the permittivity of the water-saturated solvents is estimated to be around 10% both for 1,1-DCE (for the increase from 9.9 to 10.2) and for 1,2-DCE (from 10.3 to 10.4).[15] Ito et al.[8] have compared the association constants of TBAI between several dry and wet solvents and concluded that the saturated amount of water reduces the association constants around 15% irrespective of the solvents examined. Therefore, even when the permittivity change by the coexisting water seems to be small, it should be considered in a precise discussion.

The values of n_h in Table 1 are in the order chloride>bromide>iodide in both solvents. This order is that of the hydration tendency of the anions. It means that the organic solvent molecules solvate weakly and the hydrated water molecules are only partially replaced. For three anions the n_h values are always smaller in 1,1-DCE than in 1,2-DCE. This has been explained by Diamond[5] in terms of the acidity of the solvent, namely, the capability of hydrogen-bond formation with the anions which is stronger in 1,1-DCE. Water dissolves into MIBK up to 0.8 mol dm^{-3}, which interferes with the determination of a

reliable hydration number of the anions in this solvent. Since MIBK is a basic solvent, water will react as an acid with the MIBK molecules. This may also change the properties of the solvent.

As seen in Table 1, the association constants of TBAX in MIBK are almost equal for the three salts. This is totally different from the order observed in dry basic aprotic solvents;[16] for example in acetone, the association constant of TBA^+ salts is 435 for the chloride, 264 for the bromide, and 143 for the iodide. It is also known that the order of K_{as} for halide salts in solvating type solvents such as alcohols is chloride<bromide<iodide.[16] Not only for MIBK, none of the K_{as} in Table 1 follow the two typical orders. Considering the n_h values together, this may be explained by the opposite tendency being overlapped; the hydrated water gives a solvating effect and the bulk solvent remains almost inert. In other words, the effective radius of the anions in each solvent should be similar in the three halide ions by hydration. If the ion-ion distance of the ion pairs is similar, whatever ions are solvated or hydrated, the association constants should be of similar magnitude.

The influence of the coextracted water will be larger for the extraction of the more hydrating species and, in the opposite extreme, comparison of the behavior of anhydrating substances in wet and dry solvents will give information about the net change of the physical properties of the solvent induced by the coexisting water.

15) The association constant is expressed in Ref. 14 as;

$$K_{as} = (4\pi N\mathring{a}^3/3000)\cdot\exp(e^2/\mathring{a}\varepsilon_r kT)$$

where $\mathring{a}$ is the distance of the ions in a pair in the unit of cm. At 298 K we obtain the following equation.

$$\log K_{as} = 21.40 + 3\log\mathring{a} + 2.43\times10^{-6}/\mathring{a}\varepsilon_r$$

If the value of $\mathring{a}$ is supposed to be constant, e.g. 5×10^{-8} cm, the final term of the above equation is about $50/\varepsilon_r$. Assuming the $\mathring{a}$ value to be constant, we can estimate the $\log K_{as}$ values for different ε_r with this equation.

Photochemical Reaction of Benzophenones with Allylic Silanes

Akio TAKUWA,* Naomi FUJII, Hiroyuki TAGAWA, and Hidetoshi IWAMOTO
Department of Chemistry, Faculty of Science, Shimane University,
Nishikawatsu-cho, Matsue 690
(Received June 20, 1988)

Synopsis. Photocycloaddition and hydrogen abstraction reactions between benzophenones and allylic silanes have been investigated. The high regioselective oxetane formations were explained in terms of an additional stability due to the σ_{Si-C}–p_π hyperconjugation of β-silyl radicals in diradical intermediates. Allyl radical substituted by a trimethylsilyl group, which was generated from a hydrogen abstraction reaction, recombined with benzophenone ketyl radical at the γ position. No electron transfer products were observed in the reactions.

Although a photochemical reaction of allylic silanes has been recently developed, most of them are focused on a photoinduced electron-transfer reaction between allylic silanes and electron acceptors such as iminium salts,[1] cyano aromatics,[2] and imides,[3] in which a cation radical generated by an electron transfer from allylic silanes readily undergoes desilylation; the resulting allyl radical attacks the substrates to afford allylated products. However, little is known about the reactivity of allylic silanes as an olefin[4] to the photoexcited carbonyl group. In this paper we wish to describe the Paterno-Büchi reaction and the hydrogen abstraction reaction between benzophenones and allylic silanes.

Results and Discussion

Irradiation of a N_2-purged acetonitrile solution of benzophenone (**1a**, 1 equiv) and allyltrimethylsilane (**2a**, 6 equiv) with a high-pressure Hg lamp through a Pyrex filter afforded a regioisomeric mixture of oxetanes (**3a** and **4a**, 41%) and (*E*)-1,1-diphenyl-4-trimethylsilyl-3-buten-1-ol (**5a**, 26%), and benzopinacol (**6a**, 15%). These products were separated by preparative thin-layer chromatography on silica gel. Each regioisomer of oxetanes could be separated into **3a** and **4a** by medium-pressure liquid chromatography. The structural identification of these isolated products was elucidated by spectral analyses and chemical transformation.

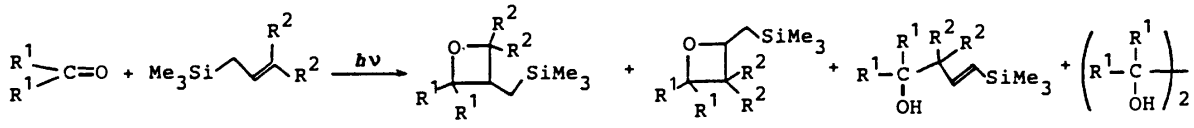
The configuration of the oxetanes, **3a** and **4a**, was determined by ^{1}H NMR (270 MHz): the signals at δ 3.85 (m), 4.38 (dd, J=5.1 and 5.4 Hz), and 4.82 (dd, J=5.4 and 8.3 Hz) were assignable, respectively, to Ha and Hb or Hc of 2,2-diphenyl-3-(trimethylsilylmethyl) oxetane (**3a**), whereas 2,2-diphenyl-4-(trimethylsilylmethyl)oxetane (**4a**) showed the signals at δ 2.94 (dd, J=7.6 and 9.9 Hz, Hb′ or Hc′), 3.32 (dd, J=6.7 and 9.9 Hz, Hb′ or Hc′), and 4.98 (m, Ha′). The isomeric distribution of the oxetanes was estimated by integrations of these signals before separation. The catalytic hydrogenation of the hydrogen abstraction product (**5a**) gave 1,1-diphenyl-4-trimethylsilyl-1-butanol. The *E* configuration of **5a** was confirmed by the coupling constant (J=18 Hz) between the olefinic protons. The irradiation of other benzophenones with **2a** under similar conditions afforded **3**—**6**; the results are summarized in Table 1.

Unsymmetrical allylic silane, (3-methyl-2-butenyl)-trimethylsilane (**2b**) also reacted with the benzophenones to afford oxetanes, hydrogen abstraction product, and benzopinacol (see Table 1).

It is well-known[5] that electronically excited benzophenones in the triplet state react with olefins to yield [2+2]cycloadducts (oxetanes) and, in fewer cases, allyl alcohols (reduction products), formed by the abstraction of an allylic hydrogen from the olefin by photoexcited benzophenone and a recombination of the two resulting radicals. This reaction pattern also holds for the present reactions, as shown in Scheme 1.

An extremely high regioselectivity of oxetane formation was observed in a reaction of **1** with **2a** (**3**:**4**=24—32:1, see Table 1); this is noteworthy. The regioselectivity of oxetane formation is usually predicted in terms of stability of diradical intermediates.[5] However these high regioselectivities in the present reactions could not be simply explained on the

Table 1. Photochemical Reaction of Benzophenones with Allyl- and (3-Methyl-2-butenyl)trimethysilanes



1 2 3 4 5 6

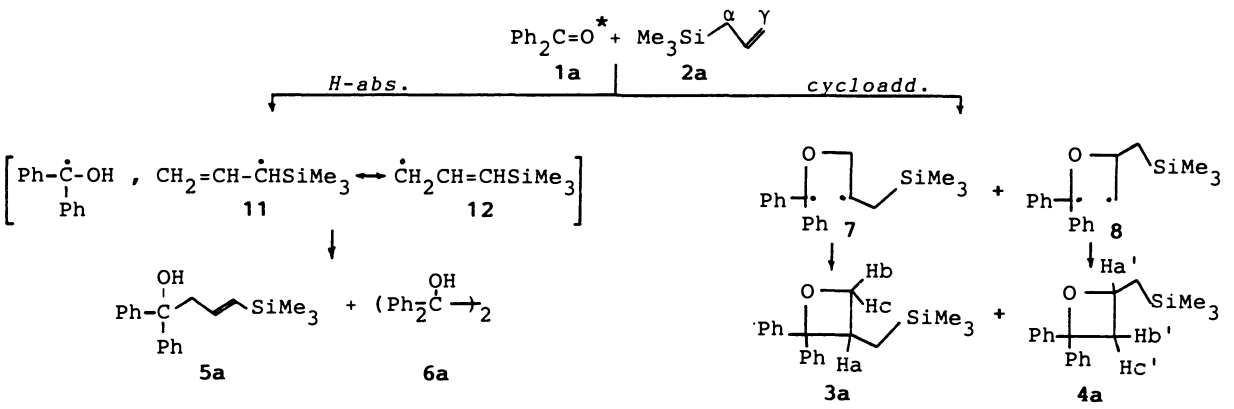
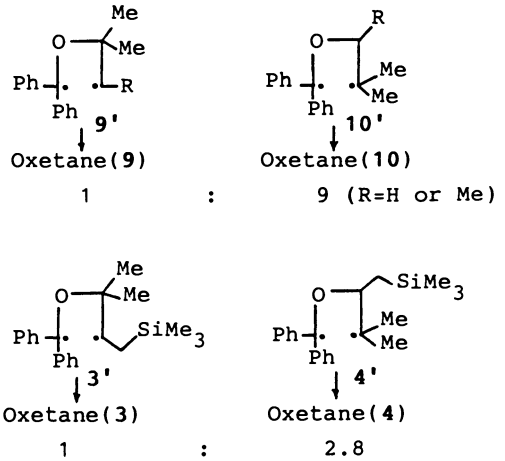


Scheme 1.

basis of the stability differences of primary and secondary radicals, because Yang et al.[6] reported that 1:9 mixtures of oxetanes (**9**:**10**) were produced in the photocycloaddition of benzophenone with isobutene or 3-methyl-2-butene. The diradical **7** could be more stabilized than expected, probably due to a σ_{Si-C}–p_π hyperconjugation.[7]

This additional stabilizing effect by the σ_{Si-C}–p_π conjugation was further supported by the isomeric distribution of oxetanes formed in the reaction with **2b**. Although isomer **4** predominates, the selectivity (**3**:**4**=1:2.8, see Table 1) is less than that which we had expected (1:9)[6] from the results of oxetane formation between **1** and isobutene. This also clearly indicates that the diradical **3'** is more stable than the diradical **9'** (R=H) owing to the σ_{Si-C}–p_π conjugation of β-silyl radical.



A 1-(trimethylsilyl)-2-propenyl radical formed by an H-abstraction of **1a** from **2a** recombined exclusively at the γ position with ketyl radical to give **5a**; nevertheless, radical **11** can be expected to be more stable than radical **12**. This suggests that the coupling at the α position is strongly hindered by a steric interaction between the trimethylsilyl and phenyl groups. 1-(Trimethylsilyl)-3-methyl-2-butenyl radical generated from **2b** also coupled at the γ position with a ketyl radical.

We recently reportred a photoinduced electron-transfer reaction between benzophenones and allylic stannanes,[8] however, no electron-transfer reaction products (homoallyl alcohols) could be detected in the present reactions. This is understandable on the bases of the endothermicity of the present reactions, since the free energy changes calculated by Rehm–Weller equation[9] for an electron transfer from allylsilane to photoexcited triplet benzophenones were estimated to be positive (+0.88—+1.21 eV).

Experimental

^{1}H NMR spectra were recorded on a JEOL MH-100 or GX-270 spectrometer using TMS or chloroform as the internal standard in deuteriochloroform. Infrared spectra were taken with a Hitachi 260-50 spectrometer. Medium-pressure liquid chromatography was performed on a Yamazen FFLC-254 chromatograph equipped with a Lobar column (Merck Si-60). Mass spectra were recorded with a ESCO EMD-05A spectrometer. Elemental analyses were carried out using a Yanaco MT-2 CHN corder. Benzophenones and allyltrimethylsilane were commercially available and used after recrystallization or distillation. (3-Methyl-2-butenyl)trimethylsilane was prepared by a method described in the literature.[10]

General Procedure. After a N_2-purged acetonitrile or benzene solution (15 ml) of a benzophenone (0.5 mmol) and allylic silane (3 mmol) was irradiated with a high-pressure Hg lamp through a Pyrex filter for 15 h, the solvent was evaporated, and products were separated by preparative TLC (ether–hexane). The isomeric mixture of oxetanes could be separated into each isomer by liquid chromatography. The yields of the products are shown in Table 1. Benzopinacols (**6a**—**6c**) gave satisfactory spectroscopic data.

Identification of the Products. 2,2-Diphenyl-3-(trimethylsilylmethyl)oxetane (3a): Oil; ^{1}H NMR δ=−0.03 (s, 9H), 0.41 (t, 1H, J=14 Hz), 0.65 (dd, 1H, J=3 and 14 Hz), 3.85 (m, 1H), 4.38 (dd, 1H, J=5.1 and 5.4 Hz), 4.82 (dd, 1H, J=5.4 and 8.3 Hz), and 7.25—7.43 (m, 10H); IR (CCl_4) 2945, 2853, 1487, 1442, 1245, 980, 860, 840, and 700 cm^{-1}; MS m/z 296 (M^+). Found: C, 76.59; H, 8.22%. Calcd for $C_{19}H_{24}OSi$: C, 76.97; H, 8.16%.

2,2-Diphenyl-4-(trimethylsilylmethyl)oxetane (4a): Oil; ^{1}H NMR δ=0.01 (s,9H), 1.18 (dd, 1H, J=10.5 and 13.5 Hz), 1.32 (dd, 1H, J=5.4 and 13.5 Hz), 2.94 (dd, 1H, J=7.6 and 9.9 Hz), 3.32 (dd, 1H, J=6.7 and 9.9 Hz), 4.98 (m, 1H), and 7.16—7.49 (m, 10H); IR(CCl_4) 2945, 2905, 1490, 1445, 1245, 940, 860, 838, and 700 cm^{-1}; MS m/z 296 (M^+). Found: C, 76.81; H, 7.79%. Calcd for $C_{19}H_{24}OSi$: C, 76.97; H, 8.16%.

(*E*)-1,1-Diphenyl-4-trimethylsilyl-3-buten-1-ol (5a): Oil; ^{1}H NMR δ=0.01 (s, $SiMe_3$), 2.54 (s, OH), 3.14 (t, CH_2, J=2.7 Hz), 5.87 (m, CH=CH), and 7.22—7.46 (m, aromatic protons); IR ($CHCl_3$) 3550, 2997, 2945, 1605, 1440, and 1245 cm^{-1}. Found: C, 77.12; H, 8.03%. Calcd for $C_{19}H_{24}OSi$: C, 76.97; H, 8.16%. The alcohol (24 mg, 0.08 mmol) was hydrogenated in methanol (5 ml) in the presence of 5% Pd-C (3 mg) to give 1,1-diphenyl-4-trimethylsilyl-1-butanol: oil(63%); ^{1}H NMR δ=0.00 (s, $SiMe_3$), 0.60 (t, CH_2, J=8.3 Hz), 1.38 (m, CH_2), 2.19 (s, OH), 2.36 (t, CH_2, J=8.8 Hz), and 7.25—7.49 (m, aromatic protons); IR ($CHCl_3$) 3600, 3010, 2950, 1450, and 1250 cm^{-1}; MS m/z 298 (M^+).

2,2-Bis-(*p*-chlorophenyl)-3-(trimethylsilylmethyl)oxetane (3b): Oil; ^{1}H NMR δ=−0.05 (s, 9H), 0.38 (t, 1H, J=14 Hz), 0.55 (dd, 1H, J=4.6 and 14 Hz), 3.66 (m, 1H), 4.24 (t, 1H, J=5.9 Hz), 4.70 (dd, 1H, J=5.9 and 8.2 Hz), and 7.30 (8H); MS m/z 365 (M^+). Found: C, 62.66; H, 5.70%. Calcd for $C_{19}H_{22}OCl_2Si$: C, 62.46; H, 6.07%.

2,2-Bis(*p*-chlorophenyl)-4-(trimethylsilylmethyl)oxetane (4b): Oil; ^{1}H NMR δ=0.01 (s, 9H), 1.20 (dd, 1H, J=9.3 and 14 Hz), 1.37 (dd, 1H, J=4.7 and 14 Hz), 2.83 (dd, 1H, J=8.4 and 10.2 Hz), 3.23 (dd, 1H, J=8.4 and 11.2 Hz), 5.20 (m, 1H), and 7.33 (8H); MS m/z 365 (M^+).

(*E*)-1,1-Bis(*p*-chlorophenyl)-4-trimethylsilyl-3-buten-1-ol (5b): Oil; ^{1}H NMR δ=−0.01 (s, $SiMe_3$), 2.51 (s, OH), 3.04 (d, CH_2, J=6 Hz), 5.77 (dt, C-CH=C, J=6 and 18 Hz), 5.89 (d, C=CH-Si, J=18 Hz), and 7.21—7.46 (m, aromatic protons); MS m/z 365 (M^+). Found: C, 62.22; H, 5.91%. Calcd for $C_{19}H_{22}OCl_2Si$: C, 62.46; H, 6.07%.

2,2-Di-*p*-tolyl-3-(trimethylsilyl)methyloxetane (3c): Oil; ^{1}H NMR δ=−0.02 (s, 9H), 0.44 (t, 1H, J=14 Hz), 0.64 (dd, 1H, J=2.9 and 14 Hz), 2.36 (s, 6H), 3.74 (m, 1H), 4.30 (dd, 1H, J=5.5 and 7.8 Hz), 4.73 (dd, 1H, J=5.5 and 8.3 Hz), and 7.18—7.26 (m, 8H); MS m/z 324 (M^+). Found: C, 78.00; H, 8.77%. Calcd for $C_{21}H_{28}OSi$: C, 77.72; H, 8.70%.

2,2-Di-*p*-tolyl-4-(trimethylsilylmethyl)oxetane (4c): Oil; ^{1}H NMR δ=0.03 (s, 9H), 1.22 (dd, 1H, J=10.3 and 13.5 Hz), 1.38 (dd, 1H, J=5.3 and 13.5 Hz), 2.36 (s, 6H), 2.85 (dd, 1H, J=7.4 and 11.2 Hz), 3.23 (dd, 1H, J=7.4 and 11.2 Hz), 4.96 (m, 1H), and 7.15—7.26 (m, 8H); MS m/z 324 (M^+).

1,1-Di-*p*-tolyl-4-trimethylsilyl-3-buten-1-ol (5c): Oil; ^{1}H NMR δ=0.07 (s, $SiMe_3$), 2.38 (s, Me), 2.55 (s, OH), 3.16 (br.s, CH_2), 5.95 (br.s, CH=CH), and 7.17 (d, 4H, J=8.3 Hz), and 7.37 (d, 4H, J=8.3 Hz); IR ($CHCl_3$) 3550, 3000, 2955, 2925, 1613, 1508, 1250, 860, and 837 cm^{-1}; MS m/z 324 (M^+). Found: C, 77.96; H, 9.00%. CalCd for $C_{21}H_{28}OSi$: C, 77.72; H, 8.70%.

2,2-Dimethyl-4,4-diphenyl-3-(trimethylsilylmethyl)oxetane (3d): Oil; ^{1}H NMR δ=0.04 (s, 9H), 0.45 (dd, 1H, J=12 and 15 Hz), 0.52 (dd, 1H, J=4 and 15 Hz), 1.26 (s, 3H), 1.35 (s, 3H), 3.38 (dd, 1H, J=4 and 12 Hz), and 7.09—7.36 (m, 10H); IR ($CHCl_3$) 2995, 2950, 1445, 1370, 1250, 1000, 875, and 860 cm^{-1}; MS m/z 324 (M^+). Found: C, 77.54; H, 8.87%. Calcd for $C_{21}H_{28}OSi$: C, 77.72; H, 8.70%.

3,3-Dimethyl-2,2-diphenyl-4-(trimethylsilylmethyl)oxetane (4d): Needles from methanol; mp 88 °C ^{1}H NMR δ=0.13 (s, 9H) 0.69 (dd, 1H, J=5.4 and 14.2 Hz), 0.99 (s, 3H), 1.00 (s, 3H), 1.02 (dd, 1H, J=10.3 and 14.2 Hz), 4.51 (dd, 1H, J=5.4 and 10.3 Hz), and 7.11—7.63 (m, 10H); IR (KBr) 2950, 1490, 1460, 1445, 1245, 1000, 940, 860, and 710 cm^{-1}; MS m/z 324 (M^+). Found: C, 77.59; H, 8.86%. Calcd for $C_{21}H_{28}OSi$: C, 77.72; H, 8.70%.

2,2-Dimethyl-2,2-diphenyl-4-trimethylsilyl-3-buten-1-ol (5d): Oil; ^{1}H NMR δ=0.07 (s, $SiMe_3$), 1.17 (s, Me), 2.46 (s, OH), 5.84 (d, C-CH=C, J=19.3 Hz), 6.34 (d, C=CHSi, J=19.3 Hz), and 7.21—7.55 (m, aromatic protons); IR ($CHCl_3$) 3600, 2955, 1605, 1495, 1450 1255 870, and 842 cm^{-1}. Found: C, 77.46; H, 8.99%. Calcd for $C_{21}H_{28}OSi$: C, 77.72; H, 8.70%.

2,2-Dimethyl-4,4-di-*p*-tolyl-3-(trimethylsilylmethyl)oxetane (3e): Oil; ^{1}H NMR δ=−0.03 (s, 9H), 0.47 (dd, 1H, J=12 and 15 Hz), 0.54 (dd, 1H, J=4 and 15 Hz), 1.30 (s, 3H), 1.40 (s, 3H), 2.37 (s, 6H), 3.40 (dd, 1H, J=4 and 12 Hz), and 7.05—7.33 (m, 8H); IR ($CHCl_3$) 2980, 2950, 1370, 1245, 1155, 1005, and 860 cm^{-1}; MS m/z 352 (M^+). Found: C, 78.39; H, 8.88%. Calcd for $C_{23}H_{32}OSi$: C, 78.35; H, 9.15%.

3,3-Dimethyl-2,2-di-*p*-tolyl-4-(trimethylsilylmethyl)oxetane (4e): Prisms; mp 79—80 °C; ^{1}H NMR δ=0.13 (s, 9H), 0.71 (dd, 1H, J=4.9 and 14 Hz), 1.00 (s, 6H), 1.01 (dd, 1H, J=10 and 14 Hz), 2.28 (s, 3H), 2.29 (s, 3H), 4.50 (dd, 1H, J=5.1 and 10 Hz), and 7.06—7.49 (m, 8H); IR (KBr) 2945, 2910, 1605, 1460, 1245, 993, 945, 860, and 815 cm^{-1}; MS m/z 352 (M^+). Found: C, 78.60; H, 9.00%. Calcd for $C_{23}H_{32}OSi$: C, 78.35; H, 9.15%.

2,2-Dimethyl-2,2-di-*p*-tolyl-4-trimethylsilyl-3-buten-1-ol (5e): Oil; ^{1}H NMR δ=0.10 (s, $SiMe_3$), 1.20 (s, Me), 2.23 (s, Me), 2.38 (s, OH), 5.80 (d, C=CH-Si, J=19 Hz), 6.45 (d, C-CH=C, J=19 Hz), and 7.05—7.40 (m, aromatic protons); IR ($CHCl_3$) 3590, 2990, 2945, 1605, 1500, 1245, 863, and 840 cm^{-1}; MS m/z 352 (M^+). Found: C, 78.21; H, 9.46%. Calcd for $C_{23}H_{32}OSi$: C, 78.35; H, 9.15%.

(Received June 22, 1988)

Synopsis. Cyclic trithiocarbonates, such as 1,3-dithiolane-2-thiones and 1,3-dithiane-2-thiones, were conveniently synthesized by treating 1,2- or 1,3-dihaloalkanes with sodium trithiocarbonate in the presence of a phase-transfer catalyst.

Much attention has been paid to the synthesis of cyclic trithiocarbonates, which are very important intermediates for the preparation of insecticides,[1] biologically active compounds[2] and the donor of a superconductor.[3] Many procedures for the synthesis of cyclic trithiocarbonates have hintherto been developed: for example, a reaction of potassium *O*-methyl dithiocarbonate or carbon disulfide with epoxide[4,5] a reaction of potassium *O*-methyl dithiocarbonate with 2-chloroethanols,[6] a reaction of sodium trithiocarbonate with 1,3-trimethylene dimesylates,[2] and a reaction of ammonium trithiocarbonates with α,ω-dithioalkanes.[7] These procedures have, however, some problems reparding the availability of the starting materials. In the course of our investigations on the synthesis of alkanediyl and alkyl aryl trithiocarbonates,[8] we found a convenient synthesis of cyclic trithiocarbonates, 1,3-dithiolane-2-thione (**2a—d**) and 1,3-dithiane-2-thione (**4a—c**), from 1,2- or 1,3-dihaloalkanes with sodium trithiocarbonate in phase-transfer catalyst (PTC) systems (Eqs. 1 and 2).

Trioctylmethylammonium chloride (TOMAC) was employed as a phase-transfer catalyst. As shown in Table 1, 1,3-dithiolane-2-thione (**2a**) was obtained in high yield from 1,2-dibromoethane (Run 4). The reaction in the absence of PTC resulted in a poor yeild of 4-methyl-1,3-dithiolane-2-thione (**2b**) (Runs 8—10). Surprisingly, 1,2-ethanedithiol also afforded 1,3-

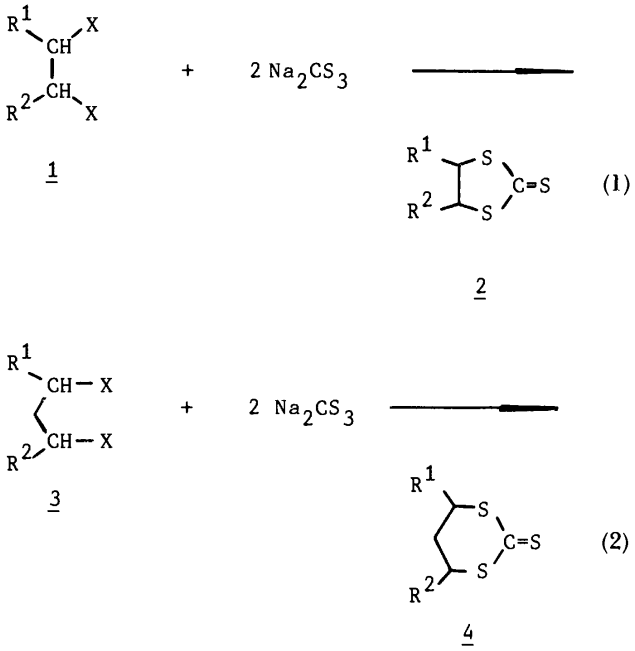

Table 1. Reaction of Substituted 1,2-Dihaloethane and Sodium Trithiocarbonate in the Presence of PTC

a) 1,2-Dihaloethane, 2 mmol; Na_2CS_3, 6 mmol. b) Isolated yield based on substrate. c) 1,2-Ethanedithiol, 2 mmol; CS_2, 6 mmol; NaOH, 2.5 mmol. d) Products were ethene derivatives.

dithiolane-2-thione (**2a**) in high yield upon treating with carbon disulfide and sodium hydroxide, as shown in Table 1 (Run 5). It should be noted that the treatment of 1,2-diiodoethane and 1,2-dibromo-1,2-diphenylethane with sodium trithiocarbonate gave *trans*-1,2-diphenylethene, since the ethene was a dehalogenates product from the diiodide or dibromide (Runs 7 and 12).[9] Interestingly, 4-mercaptomethyl-1,3-dithiane-2-thione (**5**) was obtained in good yield upon treating 2,3-dibromo-1-propanol (59%) and 1,3-dibromo-2-propanol (37%) with sodium trithiocarbonate. The formation of **5** may be interpreted in terms of a substitution of the hydroxyl group with trithiocarbonate followed by cyclization as depicted in Scheme 1. The novel thiolane **5** is conceived to be a useful intermediate for the synthesis of biologically active compounds, based on previous results.[2]

Next, we studied the synthesis of 4-methyl-1,3-dithiane-2-thione (**4b**) by a reaction of 1,3-dibromobutane (**3**) with sodium trithiocarbonate in the presence of PTC. As shown in Table 2, three 1,3-dithiane-2-thiones (**4a—c**) were obtained in moderate yields. The treatment of 1,4-dibromobutane with sodium trithiocarbonate by the above-mentioned method was not prepared seven-membered cyclic trithiocarbonate.

As mentioned above, 1-3-dithiolane-2-thione **2** and 1,3-dithiane-2-thione **4** were synthesized in satisfactory yields by a reaction of the corresponding 1,2- or 1,3-dihaloalkanes with sodium trithiocarbonate in the presence of PTC. A plausible pathway for this reaction may be considered to be an internal nucleophillic attack of the thiolate anion of intermediate (**6**) as shown in Scheme 2. This novel method for the preparation of cyclic trithiocarbonates has a great advantage from the point of synthetic convenient and utility.

Experimental

All melting points were uncorrected. IR spectra were obtained on a Jasco IR-G spectrophotometer and NMR spectra

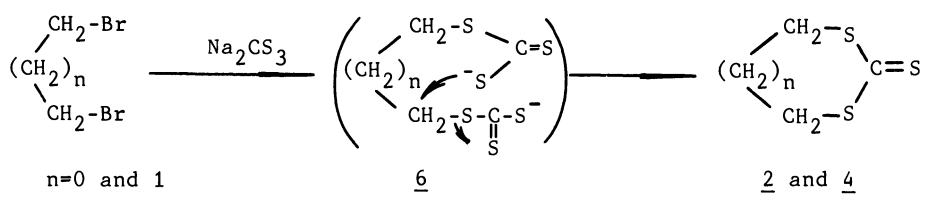

Scheme 2.

were measured with a Varian Gemine-200 spectrophotometer (200 MHz) in $CDCl_3$ using TMS as in internal standerd. Elemental analyses were determined with a Yanagimoto MT-3.

General Procedure. To a solution of 1,2-dibromoethane (2 mmol) in benzene (5 ml) were added Na_2CS_3 30% aqueous solution (6 mmol) and trioctylmethylammonium chloride (0.08 mmol); then, the mixture was heated with stirring at 60 °C for 8 h. After completion of the reaction, the benzene layer was washed with water and then dried on sodium sulfate. A yellow oil obtained by the evaporation of benzene was chromatographed on silica gel using dichloromethane–hexane (3:1) as an eluent to give the desired 1,3-dithiolane-2-thione (**2a**) in a yield of 97%. The structures of the products were characterized by ^1H NMR, IR, MS, and elemental analyses. The physical and spectral data of thione **2a**, **4a**, and **4b** were identified with those of authentic samples.[2,9,10]

4-Methyl-1,3-dithiolane-2-thione (2b): Oil; IR (neat) 1032, 1048, and 1077 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.65 (d, 3H, J=6,6 Hz, CH_3), 3.70 (q, 1H, J=11.8, 7.4 Hz, CH), 4.04 (q, 1H, 7.4, 5.7 Hz, CH), and 4.55 (m, 1H, J=11.8, 6.6, and 5.7 Hz, CH). Found ; C, 32.19; H, 4.09%. Calcd for $C_4H_6S_3$: C, 31.96; H, 4.02%.

4-Ethyl-1,3-dithiolane-2-thione (2c): Oil; IR (neat) 1048 and 1088 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.09 (t, 3H, J=7.4 Hz, CH_3), 1.99 (m, 2H, CH_2), 3.72 (q, 1H, J=12.0, 7.6 Hz, CH), 4.00 (q, 1H, J=12.0, 5.6 Hz, CH), and 4.34 (m, 1H, CH). Found: C, 36.70; H, 4.97%. Calcd for $C_5H_8S_3$: C, 36.54; H, 4.91%.

4,5-Dimethyl-1,3-dithiolane-2-thione (2d): Oil; IR (neat) 1050, 1065, and 1090 cm^{-1}; ^1H NMR ($CDCl_3$) (mixture of cis and trans) δ=1.52, 1.60 (d, 6H, CH_3) and 4.10, 4.50 (m, 2H, CH). Found: C, 36.69; H, 4.66%. Calcd for $C_5H_8S_3$: C, 36.54; H, 4.91%.

4,6-Dimethyl-1,3-dithiane-2-thione (4c): Oil; IR (neat) 930, 990, and 998 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.46 (d, 6H, J=7.0 Hz, CH_3), 2.19 (t, 2H, J=6.0 Hz, CH_2), and 3.64 (m, 2H, J=7.0, 6.0 Hz, CH_2). Found: C, 40.65; H, 5.76%. Calcd for $C_6H_{10}S_3$; C, 40.40; H, 5.63%.

4-Mercaptomethyl-1,3-dithiolane-2-thione (5): Oil; IR (neat) 2500 and 1060 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.77 (t, 1H, J=9.0 Hz, SH), 3.05 (m, 2H, CH_2), 3.99 (q, 1H, J=12.2, 4.4 Hz, CH), 4.19 (q, 1H, J=12.2, 5.4 Hz, CH), and 4.36 (m, 1H, CH). Found: C, 26.45; H, 3.32%. Calcd for $C_4H_6S_4$: C, 26.34; H, 3.32%.

The β-Sheet Structure-Disrupting Potential of Electron-Donor and -Acceptor Solvents and Role of Mixed Solvents in Solvation of Peptides[1)]

Mitsuaki NARITA,* Shinya HONDA, and Satoshi OBANA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received July 27, 1988)

Synopsis. The β-sheet structure-disrupting potential of hydrogen-donor and -acceptor solvents was in the good relationship with their electron-acceptor and -donor numbers (AN and DN), respectively. As AN and DN of solvents are larger, their β-sheet structure-disrupting potential becomes higher. Based on the results of the β-sheet structure disruption in the three component solvent system, it can also be clarified that combinations of homogeneous solvents are suitable for peptide and protein synthesis, but those of heterogeneous ones are not effective. The results of this study are of quite significance for the search for effective solvents in peptide and protein synthesis.

The elucidation of dissolution mechanism of peptides in organic solvents is of practical significance because the insolubility of peptide intermediates, protected peptides, is a serious obstacle in peptide and protein synthesis.[2,3)] In previous papers,[4–10)] we showed that the insolubility of peptides in high-polar organic solvents such as DMF, NMP, DMSO, and HMPA was caused by a β-sheet aggregation formed by peptide chains of equal to or larger than an octa- or nonapeptide sequence. Furthermore, in a recent paper,[11)] we demonstrated that the hydrogen donating and accepting ability of solvent played an important role in disrupting a β-sheet aggregation, and that strongly hydrogen-donating HFIP had a high peptide-solubilizing potential.

In this paper, using a solvent-titration technique,[12)] we first demonstrate that the β-sheet structure-disrupting potential of hydrogen-donor and -acceptor solvents is in the good relationship with their electron-acceptor and -donor numbers (AN and DN),[13)] respectively. Next, we examine the β-sheet structure disruption in the three component solvent system and discuss the criteria to search for effective solvents in peptide and protein synthesis.

Experimental

Materials. The sample of Boc-Val-Gly-Phe-Gly-Leu-Ile-Leu_2-OBzl is that prepared before.[4)] The purity of the peptide was confirmed by elemental and amino acid analyses. It gave a single peak on high-performance liquid chromatography.

IR Measurements. The IR absorption spectra of the sample in CH_2Cl_2 were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer by employing 0.5 mm-path length cells with sodium chloride windows. The concentration of the peptide was kept 1.0×10^{-3} M (1 M=1 mol dm^{-3}).

Results and Discussion

The β-Sheet Structure-Disrupting Potential of Electron-Donor and -Acceptor Solvents. As a β-sheet structure of peptides is disrupted by hydrogen bonding between solvents and peptide main chains such as N-H···O=C, N-H···O=S, N-H···O=P, and C=O···H-O, the β-sheet structure-disrupting potential of hydrogen-acceptor solvents such as DMF, NMP, DMSO, and HMPA is expected to correlate with their DN. Actually, as shown in Fig. 1, plots of log $[S_{0.5}]_0$ vs. DN for HMPA, DMSO, TMP, and PC gave a straight line. The apparent molarity of titrating solvents, $[S_{0.5}]_0$, corresponds to that at the half value of the initial intensity of 1630-cm^{-1} band in the solvent-titration curves of Boc-Val-Gly-Phe-Gly-Leu-Ile-Leu_2-OBzl[11)] when molarity of titrating solvents is used as abscissa instead of vol-%.

In this paper, we further investigated the relationship between the β-sheet structure-disrupting potential and AN of electron-acceptor solvents. As expected from the result of electron-donor solvents, the fine straight line relationship between log $[S_{0.5}]_0$ and AN for AcOH, MeOH, EtOH and *i*-PrOH was also obtained by the solvent titration curves of the peptide in CH_2Cl_2 using electron-acceptor solvents as titrating solvents (Fig. 1). As AN and DN of titrating solvents are larger, their β-sheet structure-disrupting potential clearly becomes higher. The straight lines observed between log $[S_{0.5}]_0$ and AN or DN indicate that AN and DN of solvents are a measure of their solvating power for peptide C=O and N-H bonds, respectively, and that the hardness of a peptide C=O bond as a base and a

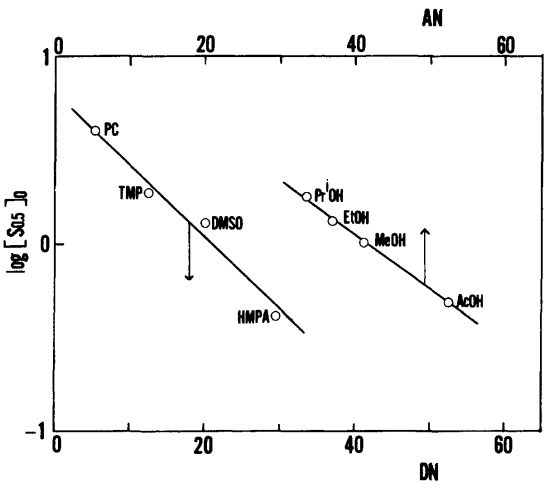

Fig. 1. Plots of log $[S_{0.5}]_0$ vs. AN for AcOH, MeOH, EtOH, and *i*-PrOH and DN for HMPA, DMSO, TMP, and PC.

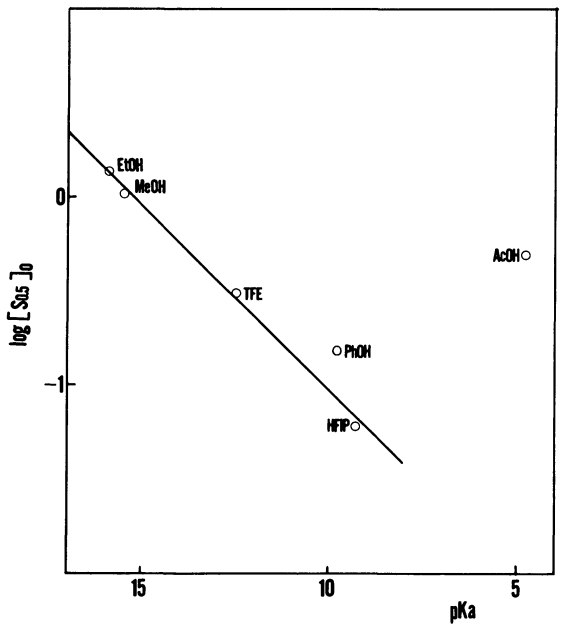

Fig. 2. The linear relationship between $\log[S_{0.5}]_0$ and pK_a values of hydrogen-donor solvents.

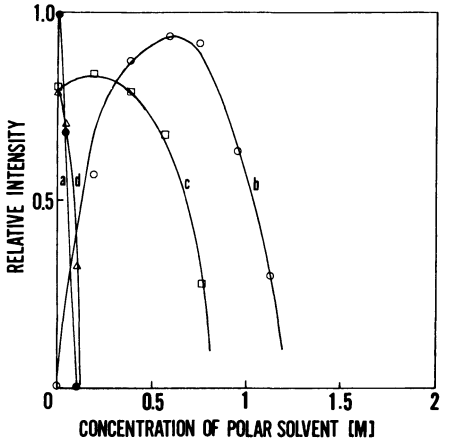

Fig. 3. The solvent-titration curves of the peptide in CH_2Cl_2 (a), HMPA-CH_2Cl_2 (b), DMSO-CH_2Cl_2 (c), and EtOH-CH_2Cl_2 (d) using HFIP as a titrating solvent. Each molar concentration of DMSO, HMPA, and EtOH in CH_2Cl_2 was 0.7 M.

peptide N–H bond as an acid is similar to that of triethylphosphine oxide and antimonyl(V) chloride, respectively.[13] Furthermore, although the AN values using triethyphosphine oxide as an electron donor are not reported for HFIP, PhOH, TFE, and *n*-BuOH, the linear relationship observed by AcOH, MeOH, EtOH, and *i*-PrOH suggests that the values of $[S_{0.5}]_0$ for HFIP (0.05), PhOH (0.14), TFE (0.33), and *n*-BuOH (1.5) give their AN values in the case that peptide C=O bonds act as an electron donor. Thus, from Fig. 1, the AN values are estimated to be 88 for HFIP, 70 for PhOH, 59 for TFE, and 36 for *n*-BuOH, respectively.

Figure 2 shows the fine correlation of the β-sheet structure-disrupting potential of hydrogen donor solvents with their pK_a values. The β-sheet structure-disrupting potential of hydrogen-donor solvents except AcOH has the linear relationship with their pK_a values, being in the following order: HFIP>PhOH>TFE>AcOH>MeOH>EtOH>*n*-BuOH>*i*-PrOH, and the lower the pK_a value of hydrogen-donor solvents is, the higher their β-sheet structure-disrupting potential becomes. The straight line observed between $\log[S_{0.5}]_0$ and pK_a values also indicates that pK_a values of hydrogen-donor solvents are a measure of their solvating power for a peptide C=O bond. Since AcOH is predominantly present in the dimeric form in CH_2Cl_2, AcOH has the potential lower than that expected from its pK_a value. In fact, the IR spectrum of AcOH in CH_2Cl_2 shows bands stronger at 1720—1708 cm^{-1} (dimer) than at 1760 cm^{-1} (monomer).

The β-Sheet Structure Disruption in the Three Component Solvent System. In peptide and protein synthesis, a mixture of aprotic high-polar solvents such as NMP, DMSO, and HMPA is generally used for coupling reactions between large peptide fragments because the solubilizing potential of their mixture is higher than that of them alone. Therefore, it is of practical significance to clarify why mixed solvents were more effective in peptide and protein synthesis.

On the other hand, the fine correlation of the β-sheet structure-disrupting potential of hydrogen-donor and -acceptor solvents with their AN and DN strongly suggests that combinations of homogeneous solvents are suitable for peptide and protein synthesis but those of heterogeneous ones are not effective. For example, in CH_2Cl_2, HMPA functions as a strong electron donor and HFIP, as a strong electron acceptor. Thus, in a mixture of HMPA and CH_2Cl_2, addition of HFIP is estimated to interrupt hydrogen bonding of HMPA to a peptide N–H bond and to reduce the peptide-solubilizing potential of a mixture of HMPA and CH_2Cl_2. Therefore, the investigation of the β-sheet structure-disrupting behavior in the three component solvent system is expected to offer significant information for the search for effective solvents in peptide and protein synthesis. Thus, we examined the β-sheet structure-disrupting behavior of the peptide in the three component solvent systems. Figure 3 shows the solvent-titration curves of the peptide in DMSO-CH_2Cl_2, HMPA-CH_2Cl_2, and EtOH-CH_2Cl_2 using HFIP as a titrating solvent. Figure 4 presents the solvent-titration curves of the peptide in DMSO-CH_2Cl_2 and EtOH-CH_2Cl_2 using HMPA as a titrating solvent. In Figs. 3 and 4, the molar concentration of each high-polar solvent was 0.7 M.

In Fig. 3, the curve b gives a clear-cut role of HMPA and HFIP in the β-sheet structure disruption. In the absence of HFIP, the peptide is completely solvated by HMPA in the HMPA-CH_2Cl_2 solution, being free from the β-sheet aggregation, and successive addition of HFIP induces the onset and increase in the β-sheet aggregation. These phenomena signify that HFIP counteracts hydrogen bonding between peptide N–H bonds and HMPA P=O bonds, and that HFIP functions as a strong hydrogen donor not for peptide C=O bonds but for HMPA P=O bonds since the DN of

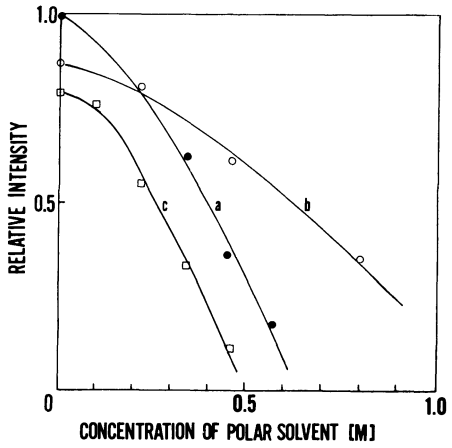

Fig. 4. The solvent-titration curves of the peptide in CH_2Cl_2 (a), EtOH-CH_2Cl_2 (b), and DMSO-CH_2Cl_2 (c) using HMPA as a titrating solvent. Each molar concentration of EtOH and DMSO in CH_2Cl_2 was 0.7 M.

a HMPA P=O bond is higher than that of amide C=O bonds.[13] Further addition of HFIP clearly causes the β-sheet structure disruption. In the DMSO-CH_2Cl_2 solution, HFIP also functions as a strong hydrogen donor for DMSO S=O bonds (Fig. 3, c). These results show that a mixture of electron-donor and -acceptor solvents is not suitable for disruption of the β-sheet structure in peptide and protein synthesis. On the other hand, successive addition of HFIP to the EtOH-CH_2Cl_2 solution induces a remarkable decrease in the 1630-cm^{-1} band due to disruption of the β-sheet structure (Fig. 3, d). In this case, HFIP and EtOH act independently as hydrogen donors for peptide C=O bonds since the DN of EtOH and HFIP is estimated to be lower than that of peptide C=O bonds. Similarly, a combination of HMPA and DMSO, which are strong hydrogen acceptors for peptide N-H bonds, showed effective disruption (Fig. 4, c) since no competition between HMPA and DMSO takes place by mixing. In addition, in the HFIP-EtOH-CH_2Cl_2 and HMPA-DMSO-CH_2Cl_2 solvent systems, each solvent can independently play an important role in effective solvation of peptide side chains in peptide and protein synthesis. We have the view that the results in this study clarify the criteria of the search for effective solvents in peptide and protein synthesis.

The authors wish to thank Central Glass Co., Ltd., for generous gift of HFIP and TFE.

Temperature Dependence of Conductivities and Ion-Association Constants of Potassium Sulfate in Water

Haruhiko YOKOYAMA* and Tomoko OHTA
Department of Chemistry, Yokohama City University, 22-2 Seto, Kanazawa-ku, Yokohama 236
(Received May 13, 1988)

Synopsis. From the temperature dependence of the ion-association constants between K^+ and SO_4^{2-} at 0 to 50 °C, the contact ion-pair formation and short-range interactions are discussed while considering the hydration of the anion. The limiting molar conductivities of SO_4^{2-} are expressed as a cubic equation of the temperature.

In a previous conductivity study[1] of $KClO_4$ and KNO_3 in water, we found that their ion-association constants have minimum values at certain temperatures between 0 and 50 °C. This phenomenon was explained as indicating the presence of specific interactions within contact ion pairs, the formations of which were considered to be helped by a weak hydration of the ions. The sulfate ion, one of the oxoacid anions, also has been known to associate with the potassium ion.[2] It is of interest to examine the temperature dependence of the ion-association constant between these ions, especially whether the specific interactions are characteristic of oxoacid anions.

Although a sulfate ion is one of the most usual types of inorganic anions, details concerning the temperature dependence of its limiting molar conductivity have not yet clarified.[3,4] In the present study, the precise conductivities of potassium sulfate in aqueous solutions were measured at eleven temperatures between 0 and 50 °C in order to clarify these problems.

Experimental

Materials. Potassium sulfate (Wako Pure Chemical Industries, reagent grade) was recrystallized twice from conductivity water and then air-dried at room temperature. It was further dried at about 150 °C and kept over diphosphorus pentaoxide in a desiccator under reduced pressure. This salt was confirmed to be anhydrous by the Karl-Fischer method with an AQ-5 Aquacounter of Hiranuma Sangyo Co. The quantity of adsorption water was less than 0.003 wt%.

Solutions. All solutions were made by weight and the molar concentration at each temperature was calculated by using the solution densities estimated from those at 25 °C (as previously described).[1,5] The conductivity of the water used[1] was always lower than 1×10^{-7} S cm^{-1} at 25 °C after dissolved carbon dioxide was removed. Eight solutions of 0.00025 to 0.0023 mol dm^{-3} were examined.

Measurements. Conductivity measurements were made with a Fuso 360 linear-bridge conductometer in a manner described previously.[1,5] The change of the cell constant (0.13720 cm^{-1} at 25 °C) with temperature was corrected to be regarded as −0.0014% for an elevation of 1 °C.[1] The reproducibility of conductivity measurements was within 0.05%. The precision of temperature measurements was ±0.003 °C and the accuracy of the temperature was ±0.01 °C.

Results and Discussion

Analysis of Conductivity Data. The observed molar conductivities, $\Lambda(K_2SO_4/2)$,[6] were analyzed by assuming the following ion-association (ion-pair formation) equilibrium between the ions, as made by Jenkins and Monk:[2]

$$K^+ + SO_4^{2-} \rightleftharpoons K^+SO_4^{2-}.$$

Representing the fraction of the free sulfate ion as α and the ionic molar conductivity as λ, we can express $\Lambda(K_2SO_4/2)$, based on the mixed rule, by

$$\Lambda(K_2SO_4/2) = \alpha[\lambda(K^+) + \lambda(SO_4^{2-}/2)] + (1-\alpha)[\lambda(K^+) + \lambda(K^+SO_4^{2-})]/2 = \alpha\Lambda_{12} + (1-\alpha)\Lambda_{11}/2,$$

where Λ_{12} and Λ_{11} correspond to the molar conductivities of hypothetical 1:2 and 1:1 electrolytes completely dissociated. In the present study Λ_{12} and Λ_{11} were expressed by means of the Robinson-Stokes equation[3] as follows:

$$\Lambda_{12} = [\lambda^\infty(K^+) + \lambda^\infty(SO_4^{2-}/2)] - S\sqrt{I}/(1 + Ba\sqrt{I}) \quad (1)$$

and

$$\Lambda_{11} = [\lambda^\infty(K^+) + \lambda^\infty(K^+SO_4^{2-})] - S\sqrt{I}/(1 + Ba\sqrt{I}), \quad (2)$$

where λ^∞ is the limiting molar ionic conductivity, a is the closest distance of approach of ions, S and B have their usual meanings[3] and I is the ionic strength, $I=c(1+2\alpha)$, where c is the molar concentration of the salt. According to the treatment of Jenkins and Monk,[2] the $\lambda^\infty(K^+SO_4^{2-})$ was approximated as $0.6\lambda^\infty(SO_4^{2-}/2)$ and S in Eqs. 1 and 2 were taken as those in hypothetical solutions for $\alpha=1$ and 0, respectively. The activity coefficients of the ions, y_i, were expressed by the Debye-Hückel equation involving a.[3] The values of a were assumed to be 3.66 Å, considering the crystallographic radius of K^+ (1.33 Å)[3] and the effective ionic radius of SO_4^{2-} (2.33 Å), which was estimated from its ionic partial molar volume by means of Glueckauf's equation.[1,5] The values of $\lambda^\infty(K^+)$ were obtained from the following cubic equation in which parameters had been given by Harned and Owen:[1,4]

$$\lambda^\infty(t\,°C) = \lambda^\infty(25\,°C) + a(t-25) + b(t-25)^2 + c(t-25)^3. \quad (3)$$

On these assumptions, the $\lambda^\infty(SO_4^{2-}/2)$ and the ion-association constant,

$$K = (1-\alpha)/[c\alpha(1+\alpha)y_{2-}],$$

were determined by a least-squares procedure, minimizing σ, where $\sigma^2=\sum[\Lambda(\text{obsd})-\Lambda(\text{calcd})]^2/(n-2)$. Further details of the calculation have been described

previously.[1,5]

Ion-Association Constants and Their Temperature Dependence. The obtained values of K, $\lambda^\infty(SO_4^{2-}/2)$ and σ are shown in Table 1 together with the used values of $\lambda^\infty(K^+)$.[7] The results at 25 °C are in practical agreement with those of Jenkins and Monk:[2] K=9 dm³ mol⁻¹ and $\lambda^\infty(SO_4^{2-}/2)$=79.98 S cm² mol⁻¹.[8] The values of K are apparently comparable to the theoretical ones:[9] K/dm³ mol⁻¹=7.75 (0 °C), 8.08 (10 °C), 8.48 (20 °C), 8.93 (30 °C), 9.45 (40 °C), and 10.05 (50 °C) for a=3.66 Å. However, as shown in Fig. 1, the difference in the temperature dependence between the theoretical and experimental values is found, especially at lower temperatures, even if the scattering of the experimental values is taken into consideration. The full line fitted to the log K values in Fig. 1 was drawn by using the following equation:[1]

$$\log K = p(t - t_{min})^2 + \log K_{min}, \quad (4)$$

with $p=(3.9\pm0.8)\times10^{-5}K^{-2}$, $t_{min}=6.4\pm3.7$ °C, and $\log K_{min}=0.899\pm0.001$ (obtained by a least-squares calculation). The standard enthalpy and entropy of ion association, $\Delta H°$ and $\Delta S°$, were estimated by the use of Eq. 4 and are shown for several temperatures in Table 2, compared with the theoretical values.[9] The experimental and theoretical values ($\Delta H°$ and $\Delta S°$) are close to each other at higher temperatures. However, the experimental values deviate more with decreasing temperature.

The temperature dependence of K between K^+ and SO_4^{2-} is similar to that for KNO_3 and $KClO_4$, for which the K values were considerably larger than the theoretical ones and became minimum at higher

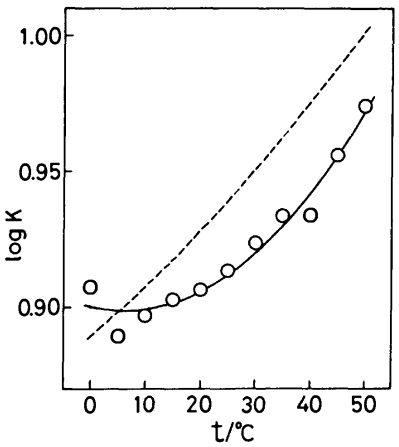

Fig. 1. Temperature dependence of the ion-association constants: experimental (O) and theoretical (----) values.

temperatures: 30 °C for KNO_3 and 36 °C for $KClO_4$.[1] These results have been explained as indicating the presence of specific short-range interactions within the contact ion pairs of which formations were helped by the weak hydration of the ions.[1] The present results can be explained by considering the relatively strong hydration of SO_4^{2-} compared to that of NO_3^- and ClO_4^-.[10] The appearance of t_{min} may suggest the presence of short-range interactions within contact ion pairs,[11] as observed for KNO_3 and $KClO_4$.[1] The lower t_{min} is due to the relatively large energy requirement for the partial release of hydration water molecules around SO_4^{2-} by the contact ion-pair formation. The

not so large values of K (in spite of the possibility of the presence of specific interactions) is due to a strong hydration of SO_4^{2-}, which hinders contact ion-pair formation. A similar hydration effect has been found concerning the ion association between Na^+ and SO_4^{2-}, of which the K value, 6.7 $dm^3 mol^{-1}$,[2] is relatively small compared to that for K^+. This has been attributed to a stronger hydration of Na^+ than of K^+.[10]

The Temperature Dependence of Limiting Molar Conductivities of SO_4^{2-}. Equation 3 was used to represent the temperature dependence of $\lambda^\infty(SO_4^{2-}/2)$. The parameters were determined to be as follows: $\lambda^\infty(25\,°C)$=79.83 S $cm^2 mol^{-1}$, a=1.7027 S $cm^2 mol^{-1} K^{-1}$, b=6.70×10^{-3} S $cm^2 mol^{-1} K^{-2}$, and c=−5.4×10^{-6} S $cm^2 mol^{-1} K^{-3}$. By using Eq. 3 with these parameter values, the experimental $\lambda^\infty(SO_4^{2-}/2)$ could be reproduced with an average deviation of ±0.03 S $cm^2 mol^{-1}$.

Selective Formation of Ethene from CO Hydrogenation Reaction over In_2O_3-CeO_2, -La_2O_3, and -Y_2O_3 Mixed Oxide Catalysts

Toru ARAI, Ken-ich MARUYA,* Kazunari DOMEN, and Takaharu ONISHI*
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,

(Received June 9, 1988)

CO hydrogenation over mixed oxides of 3A and 4A Groups (Y_2O_3, La_2O_3, CeO_2, and ZrO_2) with 3B Group (Al_2O_3, Ga_2O_3, and In_2O_3) was carried out. The addition of Ga_2O_3 or In_2O_3 to Y_2O_3, La_2O_3, and CeO_2 enhances the formation of light alkenes. An In_2O_3-CeO_2 catalyst shows the highest selectivity (43%) for ethene with the lowest selectivity (0.5%) for ethane in total hydrocarbons produced. The addition of In_2O_3 to CeO_2 results in an increase in activity for the CO hydrogenation reaction. From the results of an ethene hydrogenation reaction over mixed oxide catalysts, the high selectivity for alkene formation over In_2O_3-containing catalysts is due to a suppression of alkene hydrogenation by the addition of In_2O_3. Indium in CeO_2 is highly dispersed while keeping an oxidation state of +1 or +3 under the reaction conditions.

The selective, direct formation of light alkenes from CO hydrogenation has been studied over specifically supported metal catalysts under limited conditions. Propene is selectively formed over an Al_2O_3-supported $Fe_3(CO)_{12}$ catalyst at the initial stage of the reaction,[1,2] and also over a Co-zeolite catalyst reduced by Cd vapor.[3] Ott et al.[4] reported that the formation of ethene and propene proceeds with selectivity of 25% over freshly reduced Fe-Ru alloys. Vannice et al.[5-7] found that ethene is formed with a selectivity of 25—30% over K-promoted Fe-Mn cluster catalysts; however, the activity decreases rapidly upon carbon deposition due to a CO disproponation reaction. These metal catalysts are generally not so stable as to keep the high activity for a long-time reaction and are not selective for ethene formation.

On the other hand, CO hydrogenation over oxide catalysts, such as ThO_2, known as an iso-synthesis catalyst, proceeds to form branched hydrocarbons selectively under severe conditions such as at 723—743 K and 30—60 MPa.[8] Maehashi et al.,[9] reported that isobutene is selectively formed over ZrO_2 under moderate conditions, such as at 623—673 K and 67—2000 kPa. The formation of branched hydrocarbons with specific selectivity[10] is a characteristic of oxide catalysts on the CO hydrogenation reaction.

In this paper, we report on the CO hydrogenation reaction over mixed oxide catalysts: 3A and 4A group metal oxides with 3B Group metal oxides and the role of In_2O_3, which is the most effective for the selective formation of ethene among the added 3B Group oxides.

Experimental

Catalyst Preparation. Oxide catalysts (CeO_2, La_2O_3, Y_2O_3, and ZrO_2) were prepared as follows: Metal hydroxide was precipitated by the hydrolysis of each metal(III) nitrate with a 5% aqueous ammonia solution, washed with distilled water, dried overnight at 393 K, and then calcined to form oxide at 773 K for 3 h. Mixed oxide catalysts were prepared by co-precipitation from a mixed aqueous solution of each metal nitrate via the same procedure as that of the oxide. The atomic ratios of M_I (Al, Ga, and In) to M_{II} (Y, La, Ce, and Zr) were 1 : 10. All catalysts used were evacuated at 973 K for 3 h before the reaction, except for La_2O_3 and its mixed oxides which were evacuated at 973 K for 1 h.

Chracterization. The surface areas of the used catalysts were measured by the BET method. The crystal structures were determined by X-ray diffraction (Rigaku geigerflex rad-B system). Surface analyses of the catalysts were conducted by using an X-ray photoelectron spectrometer equipped with a glovebox (Shimadzu ESCA-750). The binding energies were corrected by Au $4f_{7/2}$ (83.8 eV).

Procedure. CO hydrogenation reactions were carried out over catalysts in a closed circulation system. A typical reaction was performed at 673 K and the initial pressure was 67 kPa (H_2 : CO=3 : 1).

Ethene hydrogenation reactions were carried out over catalysts at 195 and 273 K, and 60 kPa (H_2 : C_2H_4=20 : 1). The activities were obtained from the initial rate of ethane formation.

Analyses. Products, except for methane, were collected by a liquid-nitrogen trap. Quantitative analyses were conducted by a GC equipped with a Porapak-Q column for hydrocarbons, CO_2, and H_2O, VZ-7 and VZ-10 columns for C_2 and C_3 hydrocarbons and isomers of C_4 hydrocarbons, and a Molecular Sieve-5A column for CH_4 and CO.

Results and Discussion

CO Hydrogenation over Oxide and Mixed Oxide Catalysts. Table 1 shows the activity and selectivity for hydrocarbon formation over catalysts which were stable for 17.5 h, except for In_2O_3 and Ga_2O_3. The products were hydrocarbons, CO_2, H_2O, and a small amounts of oxygenates, such as methanol and dimethyl ether.

Y_2O_3, La_2O_3, CeO_2, and ZrO_2 showed a relatively high selectivity for C_4, C_5, and C_6 hydrocarbons which consist mainly of branched alkenes, while Ga_2O_3 produced only CH_4. In_2O_3 was rapidly reduced to metallic indium under the reaction conditions and produced large amounts of CO_2 and H_2O with no hydrocarbons from CO hydrogenation. The addition of In_2O_3 or Ga_2O_3 to CeO_2, La_2O_3, and Y_2O_3 resulted in an

a) The amounts of catalysts used were 1.5 g except CeO_2 and CeO_2 mixed oxide catalysts (0.5 g) and the atomic ratios of Al_2O_3, Ga_2O_3, and In_2O_3 to Y_2O_3, La_2O_3, CeO_2, and ZrO_2 were 1/10. b) The values are the average rates from initial 2.5 to 17.5 h in carbon-base $\mu mol \cdot g\text{-cat.}^{-1} \cdot h^{-1}$. c) $m^2 \cdot g^{-1}$. d) Parentheses show the specific activity based on surface area in carbon-base $\mu mol \cdot m^{-2} \cdot h^{-1}$. e) Parentheses show the selectivity for alkenes. f) In_2O_3 was reduced to metallic indium under the reaction conditions.

increase in the selectivity for C_2 and C_3 hydrocarbons, while CH_4, C_4, C_5, and C_{6+} hydrocarbons decreased. The alkene selectivities in C_2 and C_3 hydrocarbons also increased. Especially, the In_2O_3-CeO_2 catalyst exhibited the highest selectivity (43%) for C_2 hydrocarbons which consist of 99% ethene. The addition of Al_2O_3, Ga_2O_3, or In_2O_3 to ZrO_2 resulted in an increase in the selectivity for methane. In_2O_3-Al_2O_3 produced methane only. These results indicate that In_2O_3- or Ga_2O_3-combined 3A group oxides are effective for the selective formation of ethene and that In_2O_3 is the most effective among the additives.

The catalytic activity, based on the surface area of the oxide and mixed oxide catalysts (Table 1), show that CeO_2 and its mixed oxides exhibit a high specific activity. Especially, In_2O_3-CeO_2 indicates the highest value among them and the addition of In_2O_3 to CeO_2 leads to an enhancement of the activity for hydrocarbon formation. The activity of In_2O_3-Y_2O_3 and In_2O_3-La_2O_3 are nearly equal to that of Y_2O_3 and La_2O_3, respectively.

The Effect of In_2O_3 Addition to CeO_2, La_2O_3, and Y_2O_3 on the Hydrocarbon Formation. The product distribution change upon the addition of In_2O_3 suggests that the role of In_2O_3 is to retard the rate of carbon-carbon bond formation and to accelate the rate of the hydrogenation of surface species. However, the facts that the addition of In_2O_3 does not increase the selectivity for methane and that it retards alkane formation seem to be inconistent with the above-mentioned suggestion. Although there is a little difference among the three oxides, it may be a common feature that the addition of In_2O_3 to 3A Group oxides results in the retardation of the carbon-carbon bond formation and alkane formation, including methane, without lowering the activity for hydrocarbon formation.

CO Hydrogenation Reaction over In_2O_3-CeO_2 and Effect of In_2O_3 Addition. Figures 1 and 2 show the time course of the activity and selectivity for hydrocarbon formation over In_2O_3-CeO_2, respectively. The constant catalytic activity and the selectivity for hydrocarbon formation were observed during 2—48 h reactions. Large amounts of CO_2 and H_2O (totally 600 $\mu mol\ g^{-1}$) were formed at the initial stage (0—1 h), but decreased remarkably after 1 h, the reaction proceeded with a good material balance during 2—48 h reactions.

Figure 3 shows the dependence of the reaction temperatures on the selectivity over In_2O_3-CeO_2 and CeO_2 catalysts. In_2O_3-CeO_2 shows the high selectivity (40—45%) for C_2 hydrocarbons, which consist of 98—99% ethene in the temperature range 573—723 K.

In the case of a single CeO_2 catalyst, the selectivity for C_2 hydrocarbons is only 4% at 573 K, and the ethene content in C_2 hydrocarbons is 71%; however, these values increase to 36 and 96%, respectively, at 723 K.

The activity of the In_2O_3-CeO_2 catalyst based on the surface area is remarkably high in comparision with that of CeO_2 at temperatures below 673 K, as shown in Fig. 4. Thus, the addition of In_2O_3 to CeO_2 leads to an

increase in the activity for hydrocarbon formation, the selectivity for C_2 hydrocarbons, and the selectivity for alkene. These effects become clearer at lower reaction temperatures.

C_2H_4 Hydrogenation Reaction over Single and In_2O_3-Containing Mixed Oxides. The rates of C_2H_4 hydrogenation at 195 and 273 K over CeO_2, La_2O_3, and Y_2O_3 and their mixed oxides with In_2O_3 are shown in Table 2. The rates of C_2H_4 hydrogenation over CeO_2 and In_2O_3-CeO_2 are much slower than those over the other oxide catalysts. The addition of In_2O_3 results in a decrease in the rate of C_2H_4 hydrogenation. The catalysts which have the lower rate for the C_2H_4 hydrogenation show a higher selectivity for alkene, as shown in Fig. 5. This indicates that the high selectivity for alkene formation over CeO_2 and In_2O_3-containing mixed oxides is due to the low rate of alkene hydrogenation as a side reaction of CO hydrogenation.

Among single oxides, CeO_2 shows the lowest and

La_2O_3 shows the highest activity for ethene hydrogenation, respectively, as reported by Minachev et al.[11] To the contrary, the activity for a CO hydrogenation reaction is highest over CeO_2 and lowest over La_2O_3. These facts show that there is a great difference between the hydrogenation reactions of C_2H_4 and CO. These results suggest the following possibilities: (1) a key step of hydrocarbon formation from CO and H_2 is neither the step of hydrogenation nor the activation of H_2, (2) the activation site or process of CO is different from that of C_2H_4, and (3) the hydrogen species which reacts with CO or intermediates to form hydrocarbons is different from that which reacts with ethene.

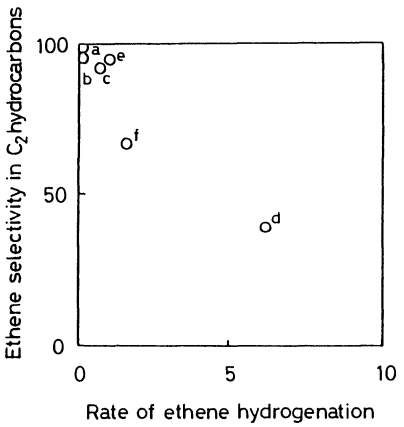

Fig. 5. Correlation between the ethene selectivity (%) in C_2 hydrocarbon on CO hydrogenation reaction at 673 K and the rate (10^3 μmol g-cat.$^{-1}$ h^{-1}) of ethene hydrogenation at 195 K.

Table 2. Rate of Hydrogenation of C_2H_4

Catal.[a]	Rate (μmol g-cat^{-1} h^{-1})	
	273 K	195 K
CeO_2	20	0(0)[b]
In_2O_3-CeO_2	3	0(0)
La_2O_3	fast	6100(360)
In_2O_3-La_2O_3	fast	680(40)
Y_2O_3	fast	1500(30)
In_2O_3-Y_2O_3	fast	940(20)

a) Catalysts of 0.1 g (La_2O_3, Y_2O_3, and their In_2O_3-containing mixed oxides) or 0.5 g (CeO_2 and In_2O_3-CeO_2) were used on C_2H_4 hydrogenation reaction as maintaining the conversion below ca. 30%. b) Parentheses show the activity based on specific surface area, μmol m^{-1} h^{-1}.

The addition of In_2O_3 to CeO_2 enhances CO hydrogenation while supressing C_2H_4 hydrogenation. Therefore, the role of added In_2O_3 is different in the hydrogenation of CO and alkene.

Characterization of In_2O_3-Containing Mixed Oxides. XRD and XPS results of the oxides and In_2O_3-containing mixed oxides are shown in Table 3. For In_2O_3-CeO_2, only the diffraction patterns of CeO_2 (fluorite type) were observed, although the catalyst contained 10% In_2O_3. On the other hand, a slight amount of $LaInO_3$ and $YInO_3$ in addition to La_2O_3 and Y_2O_3 were observed for In_2O_3-La_2O_3 and In_2O_3-Y_2O_3, respectively. However, no peaks due to In_2O_3 appeared for all In_2O_3-containing mixed oxides. The binding energies of In $3d_{5/2}$ for the mixed oxides after the reaction were observed between 444.4 and 444.7 eV. The values are higher than that at 443.3 eV for metallic indium. Indium in the mixed oxides still kept the higher oxidation state under the reaction conditions.

The surface composition on the In_2O_3-CeO_2 catalyst was estimated from the peak area of Ce3d and In3d and corrected by the ionization cross section[13] and escape depth[14] using formula,[15]

$$\frac{C_{In}}{C_{Ce}} = \frac{A_{In}}{A_{Ce}} \times \frac{I_{Ce}}{I_{In}} \times \frac{D_{Ce}}{D_{In}}$$

where C, A, I, and D denote the surface concentration, peak area, total ionization cross section, and escape depth, respectively.

It was found that the surface ratio of In/Ce is close to the bulk ratio, as shown in Table 3.

From these results, it can be seen that indium in CeO_2 is highly dispersed as small crystalline forms of

Table 3. Characterization of the Oxides and In_2O_3-Containing Mixed Oxides

Catal.	XRD	XPS	
		Binding energy of In $3d_{5/2}$ (eV)	Surface ratio (%) of In to M (Ce, La, or Y)

La_2O_3	La_2O_3	—	—
In_2O_3-La_2O_3	La_2O_3+($LaInO_3$)	444.5	9
Y_2O_3	Y_2O_3	—	—
In_2O_3-Y_2O_3	Y_2O_3+($YInO_3$)	444.7	5
In_2O_3	In_2O_3	444.4	—
In[a]	—	443.3	—

a) Commercial metallic indium (99.99%) was spattered by Ar ion bomberdment before the measurement, and the binding energy obtained for $In3d_{5/2}$ agreed with the literature.[12]

In_2O_3 or as a substitutional solution state, and that indium in La_2O_3 and Y_2O_3 exists partialy as mixed oxide compounds of $LaInO_3$ and $YInO_3$, while keeping the oxidation state under the reaction conditions. To the contrary, single In_2O_3 is rapidly reduced to metallic indium and forms no hydrocarbons from a mixture of CO and H_2 under the above-stated reaction conditions. The valency of indium could not be determined by XPS, since the binding energies of In^+ and In^{3+} are close to each other. On the other hand, In_2O_3-CeO_2 produces large amounts of CO_2 and H_2O (total ca. 600 $\mu mol\,g^{-1}$) during the initial stage (0—1 h). It is known that In_2O_3 is easily reduced[16] and that CeO_2 is partially reduced to CeO_{2-x} (x=0—0.5)[17] to form Ce^{3+},[18] under the reductive conditions, such as the CO hydrogenation reaction. Single CeO_2 forms relative small amounts of CO_2 and H_2O (totally ca. 50 $\mu mol\,g^{-1}$) during the initial stage of the reaction at 673 K. These facts indicate that the In_2O_3 addition to CeO_2 enhances the reduction of the catalyst to form In^+ and/or Ce^{3+}. CeO_2 exhibits a high activity and selectivity for ethene formation, similar to In_2O_3-CeO_2, at a high reaction temperature of 723 K (Figs. 3 and 4). This means that the active centers for hydrocarbon formation exist on cerium ions in In_2O_3-CeO_2. Details concerning the active center for CO hydrogenation reaction over In_2O_3-CeO_2 will be published elsewhere.

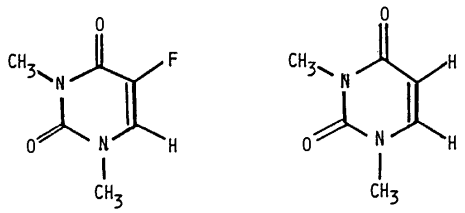
Intermolecular Interactions of Fluorine Atoms in the Crystal of 1,3-Dimethyl-5-fluorouracil and Its Mixed Crystal with 1,3-Dimethyluracil

Tooru TAGA,* Noriko YAMAMOTO, and Katsunosuke MACHIDA
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Yoshidashimoadachi-cho, Kyoto 606
(Received June 20, 1988)

A crystal of 1,3-dimethyl-5-fluorouracil can be used to solve large amounts of 1,3-dimethyluracil as a solid-solution crystal. The crystal structure has been determined by an X-ray method. The planar molecules are arranged in a parallel sheet, and the molecules within the same sheet interact with each other through short CH···O and CH···F contacts. The short intermolecular C···F distance is 2.999(6) Å. The stability of a mixed crystal could be explained in terms of intermolecular interactions around the fluorine atom.

A mixed crystal of organic compounds is generally formed in the case that two component molecules have similar sizes and shapes.[1] On the other hand, the similarity of the atomic sizes between a fluorine atom and a hydrogen atom is one of the important characteristics for fluorine-substitution effects.[2] Thus, a rigid organic compound and its fluorine substituent have a high possibility to form a mixed crystal. We therefore tried to form a mixed crystal between 1,3-dimethyluracil (DMU) and 1,3-dimethyl-5-fluorouracil (DNFU), and obtained fairly stable mixed crystals over a wide range of their mixing ratios. The DMU and DMFU compounds were obtained by methylations of uracil and 5-fluorouracil. The 5-fluorouracil is a well-known antitumor-active agent, and its fluorine-substitution effects have received special attention.[2] The crystal structure of DMU had already been reported by Banerjee et al.[3] However, the crystal structure of DMFU was unknown, and the mixed crystal was isomorphic to the DMFU crystal. Thus, the present X-ray analyses of the DMFU and mixed crystals were performed in order to study the fluorine-substitution effects in the mixed crystals.



Scheme 1.

Experimental

Structure Determination of DMFU. The colorless single crystals of DMFU were obtained from an ethanol solution and a crystal (0.1×0.3×0.3 mm) was mounted on a Rigaku AFC-5RU diffractometer with graphite-monochromated Cu$K\alpha$ radiation (λ=1.54178 Å). The crystal data were $C_6H_7N_2O_2F$, M_r=158.13, orthorhombic, $P2_12_12_1$, a=6.605(2), b=8.455(2), c=12.621(2) Å, V=704.8 Å^3, Z=4, D_x=1.490 Mg m^{-3}. Intensity data of 638 reflections were collected within $2\theta<120°$ (h 0—6, k 0—8, l 0—14) in a 2θ-ω scan mode with a scan width of $0.8°+0.5°\tan\theta$ and scan speed 2° ω/min. The intensity fluctuation during data collection was less than 2% for three standard reflections measured at every 56 reflections. Intensities were corrected for Lorentz and polarization factors, but no absorption correction was applied (μ=11.54 cm^{-1}). The structure was solved by MULTAN78[4] and refined by a full-matrix least-squares method using a modified version of the program ORFLS.[5] The minimized quantity was $\sum w(|F_o|-k|F_c|)^2$, where k is a scale factor and w is a weight equal to $[\sigma(F_o)+(0.023\ F_o)^2]^{-1}$. All hydrogen atoms were located on a difference Fourier map. The refinement of C, N, O and F atoms with anisotropic temperature factors and of H atoms with isotropic temperature factors converged an R value to 0.047 (wR=0.057) for 541 unique reflections with $F_o>2\sigma(F_o)$, in which (200) reflection was omitted due to a large extinction effect.

Mixed Crystal Formed between DMFU and DMU. Condensed ethanol solutions of DMFU-DMU mixtures with 1 : 1, 2 : 3, 1 : 2, and 1 : 5 molar ratios for DMFU : DMU were prepared at room temperature (27 °C). Transparent columner crystals were obtained by cooling the solution in a refringerator (5 °C) for a few days. The HPLC analyses using a Shimadzu LC-3A apparatus equipped with an SPD-2A UV detector showed that the molar content of DMU in the obtained crystals were 0.36, 0.50, 0.61, and 0.77, corresponding to the above-mentioned solutions. Preliminary microscopic and X-ray photographic studies indicated that the mixed crystals were isomorphic to the DMFU crystal. The mixed crystal obtained from a 1 : 1 DMFU : DMU solution was subjected to a single-crystal X-ray analysis. The crystal size was 0.3×0.3×0.3 mm, and the unit cell dimensions were a=6.634(1), b=8.439(1), and c=12.530(1) Å, V=703.6 Å^3. The calculated crystal density was 1.425 Mg m^{-3} for Z=4. Data collections and structure refinements were performed in the same way as in the case of the DMFU crystal. Intensity data of 652 reflections (h 0—6, k 0—8, l 0—14) were collected. Disorders of the F(5) and H(5) atoms were assumed in the structure, and an occupancy of 0.6 was assigned for the F(5) atom. The disordered structre was refined to R=0.075 (wR=0.125) for 540 reflections with $F_o>3\sigma(F_o)$.

The atomic scattering factors used for all atoms were obtained from the International Table for X-ray Crystallography.[6] All computations were undertaken on a FACOM M382 in the Data Processing Center of Kyoto University,

using the program KPPXRAY.[7]

Results and Discussion

Molecular Structure of DMFU. The atomic coordinates and thermal parameters for nonhydrogen atoms are listed in Tables 1 and 2.[8] A perspective view of the DMFU molecule with the atomic numbering is given in Fig. 1. The molecule is planar within 0.04 Å, except for the hydrogen atoms of the methyl groups. Bond distances and bond angles, except for the C(4)-C(5)-C(6) angle (Table 3), agree well with those

of the usual uracil derivatives.[9] The C(5)-F(5) bond distance of 1.348(3) Å is close to the usual values, but the C(4)-C(5)-C(6) bond angle of 123.4(3)° is significantly larger than the average value of 120.7° for those of other uracil derivatives. A similar trend regarding such a large bond angle has been observed in several compounds which have a conjugated ring substituted with a fluorine atom, e.g. fluorobenzens[10] and *m*-, *o*-, *p*-fluorobenzoates.[11-13]

Molecular Packing of DMFU. The planar DMFU molecules form a sheet parallel to the *bc* plane. Such sheets cross the *a*-axis at $a=1/4$ and 3/4 with the interplaner distance of 3.3 Å. The projection of the molecular stacking along the *a*-axis is shown in Fig. 2. The molecules related by the 2_1-axis along the *a*-axis are close to each other, the short van der Waals distances being 3.32(1) Å between C(4) and C(6), 3.33(1) Å between C(2) and F(5), 3.37(1) Å between N(3) and F(5), and 3.40(1) Å between N(3) and C(5). The molecular stacking pattern is different from those of other uracil crystals. However, the molecular overlapping, such as the fluorine atom which lies near the adjacent uracil ring, resembles those observed in purine and halogenated pyrimidine complexes.[14] This type of molecular stacking may be favorable for dipole-induced dipole interactions between the fluorine atom and the conjugated ring.

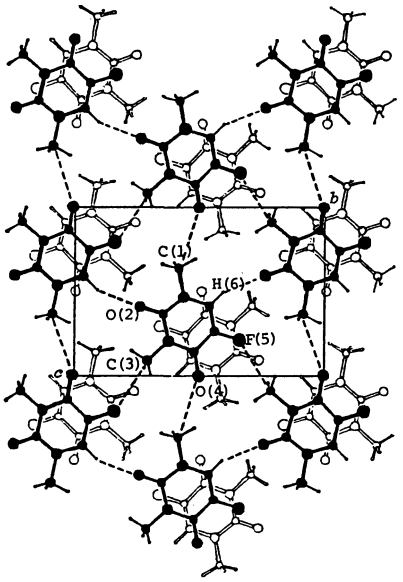

Fig. 2. Projection of the crystal structure viewed along the *a*-axis.

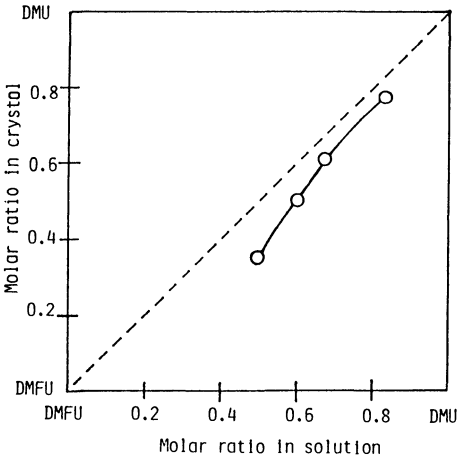

Fig. 3. Plots of the molar ratios in the prepared solutions and in the crystals.

CH ··· O Hydrogen Bonds. As shown in Fig. 2, one DMFU molecule is surrounded by six neighbor molecules within the same sheet; very short intermolecular contacts, C(6)H ··· O(2) (C ··· O 3.190(4) Å and H ··· O 2.28(3) Å) and C(1)H_3 ··· O(4) (C ··· O 3.245(5) Å and H ··· O 2.63(4) Å) were observed within the sheet. The C ··· O and H ··· O distances are significantly shorter than the sum of the van der Waals radii, 1.75, 2.0, 1.50, and 1.20 Å for C, CH_3, O, and H, respectively.[15] Similar short NCH_3 ··· O contacts have been observed in the DMU crystal,[3] and similar short C(aromatic)-H ··· O contacts have been also observed in the benzoquinone crystal.[16] The short CH ··· O interactions may be classified into the CH ··· O hydrogen-bonds[17–19] which strongly bind to the planar molecules in the sheet.

Mixed Crystal Formation between DMFU and DMU. The crystal structure of DMFU is quite different from that of DMU, and the mixed crystal has an isomorphic form to the DMFU crystal. A comparison of the molar ratios in the prepared solutions and in the obtained mixed crystals are given in Fig 3. The observed line is located below the dotted diagonal line, and the DMU amounts in the mixed crystal are smaller than those in the solution. However, very large amounts of DMU can be mixed into a DMFU crystal. Even if the DMU molar ratio is 77%, the mixed crystal has the same DMFU form. In this mixed crystal, the larger the amounts of DMU molecules are solved, the more the unit cell volume of the mixed crystal decreases, though the decrement of the unit cell volume is smaller than the expected value for the DMU amounts; for instance, a volume decrement of 1.2 $Å^3$ for a mixed crystal with a 0.4 DMU/DMFU molar ratio corresponds to about half of the volume change estimated from the van der Waals volumes. Thus, the small volume change is one of the unique properties of this mixed crystal. Usually a mixed crystal formed without any volume change is classified into a block solution in which impurity molecules occupy defect sites of the crystal or are located at the boundaries of mosaic blocks. However, in the present case it must be a true substitutional solid solution in which the host molecules are replaced with guest molecules at random. The structure of such a solid solution model was successfully refined by a least-squares method for the 0.4 molar ratio DMU mixed crystal. The refined structure was essentially the same as that of the DMFU crystal, although the C-F bond in the mixed crystal seems to be slightly shortened.

Intermolecular NCH_3 ··· F Interaction. The fluorine atom in the DMFU crystal has a short intermolecular contact to the methyl group of the neighbouring molecule with an F(5) ··· C(3) distance of 2.999(6) Å. According to Nyburg and Faerman,[20] the van der Waals radius for a fluorine atom varies from 1.30 to 1.38 Å, depending on the directions of the intermolecular contacts. The present F ··· C distance is shorter than the van der Waals sum of the smallest F radius (1.30 Å) and the C radius (1.75 Å), and it is the shortest in the resemble F ··· CH_3 contacts observed so far.[21,22] The Coulomb interaction between the approached F and CH_3 is attractive; the interaction energy is about -11 kJ mol^{-1} for a simple point charge model with net charges of -0.195 a.u. on F and 0.124 a.u. on CH_3. Thus, the replacement of F by H in a mixed crystal will cause a loss of Coulomb energy. On the other hand, the van der Waals interaction between the F and CH_3 is repulsive in the DMFU crystal because of the very short F ··· CH_3 distance. Thus, the replacement of F by H will decrease the van der Waals energy; the estimated energy gain is about 2.7 kJ mol^{-1} for the coefficients by Williams and Houpt.[23] The entropy effect, owing to a mixing of two components, also decreases the free energy of the mixed crystal, though

this contribution (maximum -3 kJ mol^{-1} for an ideal case) is small if the mixing ratio is different from 1 : 1.

In conclution, the DMFU crystal consists of very stable sheets of planar DMFU molecules which are bonded by CH $\cdots$ O hydrogen bonds. Repulsive van der Waals interactions at short F $\cdots$ CH_3 contacts cause the DMFU crystal to become a stable solid solution for DMU over a wide range of mixing ratios. Such easy replacement of fluorine substituents must be one of the important properties of a fluorine atom in considering the fluorine-substitution effects.

The authors wish to thank Professor Kenji Osaki for his motivation of this work. They also thank Dr. Takashi Harayama and Dr. Reiko Yanada for their kind supply of 1,3-dimethyl-5-fluorouracil.

Photochromic Properties of a New Spirobenzothiopyran Compound

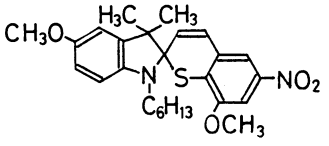
Shin-ichiro TAMURA,* Nobutoshi ASAI, and Jun'etsu SETO
Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240
(Received July 26, 1988)

Photochromic processes of 1'-hexyl-5',8-dimethoxy-3',3'-dimethyl-6-nitrospiro[2*H*-1-benzothiopyran-2,2'-indoline] were investigated with laser flash techniques. Photocoloration was found to proceed via the excited singlet state, and the quantum yield of coloration was an order of magnitude smaller than those of ordinary spirobenzopyrans. The main route of the decoloration was found to be the thermal reaction. Remarkably different solvent effects for the thermal fading rate of the colored form were observed, which indicates that the zwitterionic structure is more significant for the new spirobenzothiopyran than ordinary spirobenzopyrans. Repetitive cycles of photocoloration and thermal fading were achieved.

Photochromism of spirobenzothiopyran was first reported by Becker and Kolc.[1] They synthesized 1',3',3'-trimethylspiro[2*H*-1-benzothiopyran-2,2'-indoline], and observed its colored form at 77 K. The colored form was thermally unstable, and bleached at elevated temperatures. The photochemical processes of coloration and decoloration have not as yet been investigated.

Recently, a new series of spirobenzothiopyrans was synthesized.[2] The thermal stability of the colored forms observed at room temperature upon irradiation with UV light of these new compounds was improved by introducing a nitro group in the benzothiopyran ring. The absorption spectra of the colored forms in a polymer matrix are reported to extend to wavelengths as long as 900 nm, and application as optical recording media for laser is expected.

In the present work, the photochromic reactions of a typical compound of the new spirobenzothiopyrans, 1'-hexyl-5',8-dimethoxy-3,3'-dimethyl-6-nitrospiro-[2*H*-1-benzothiopyran-2,2'-indoline] (Scheme 1), were investigated with laser flash techniques. The solvent effect on the fading rate and the absorption spectrum was also studied in order to assign the structure of the colored form.



Scheme 1.

Results and Discussion

Coloration and Decolortation Processes. The absorption spectrum of the colorless form is independent of the kind of solvent, and has maxima at 310 nm and 400 nm. Fluorescence was not detected at room temperature, which is in agreement with the result of Becker and Kolc.[1] Although they attempted to observe emission at 77 K, no emission characteristics of 1',3',3'-trimethylspiro[2*H*-1-benzothiopyran-2,2'-indoline] was detected.

The photocoloration process was investigated in aerated and degassed solutions of ethanol (EtOH) and *N*,*N*-dimethylformamide (DMF). The colorless form was excited at 360 nm. Figure 1 shows the transient absorption spectra in aerated and degassed EtOH solutions, measured immediately after the laser pulse. There is no significant difference between the two spectra. The shape of the spectrum was that of the colored form, and no reaction intermediates were detected. Similar results were obtained in aerated and degassed DMF solutions.

Kinetic measurements of the coloration process were made at the wavelength of the absorption maximum of the colored form (620 nm in EtOH, 660 nm in DMF). The absorbance of the colored form was proportional to the laser energy, indicating a single photon process. Figure 2 shows the result of the kinetic measurements of the coloration process in EtOH solution. The time that the absorption change lags behind the time-integrated laser intensity is very small. We assumed a linear response of the reaction to the laser pulse, and obtained a good fit of the experimental results with the calculated absorption changes using various rate constants. The coloration proceeds by first-order kinetics, and the colorlation rates were determined to be 7×10^7 s^{-1} in EtOH and 8×10^7 s^{-1} in DMF. No significant

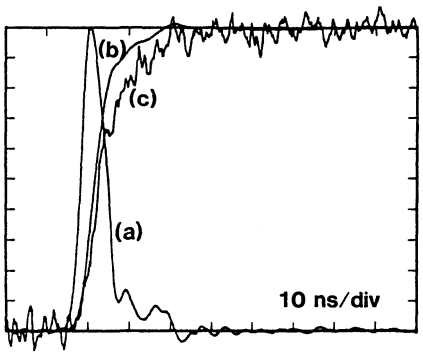

Fig. 2. The photocoloration process in ethanol solution. The laser profile(a), its time-integrated intensity(b), and the absorption change of the colored form(c) are shown. Each curve is normalized to unity.

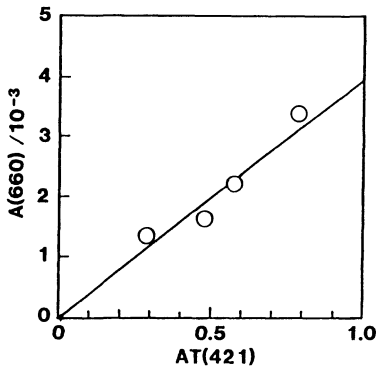

Fig. 3. The plot of the absorption of the colored form in degassed DMF, $A(660)$ vs. the triplet-triplet absorption of anthracene, $AT(421)$.

difference was found in the observed rate constants for degassed and aerated solutions, or for aprotic and protic solvents.

In order to determine the reaction state of the coloration process, we performed triplet quenching experiments on the photoexcited colorless form in degassed EtOH solution using ferrocene (triplet energy 159 kJ mol^{-1} [3]) as a quencher. It is reasonable to assume that the triplet energy level of the colorless form is much higher than that of ferrocene, so the triplet-triplet energy transfer from the colorless spirobenzothiopyran to ferrocene may proceed with the diffusion-controlled rate constant, k_d ($=9.2\times10^9$ s^{-1} [4]). The observed rate of the coloration, k, is given by $k=k_0+k_d$ [Ferr], where k_0 is the coloration rate constant in the absence of ferrocene. However, even when ferrocene was added up to a concentration of 1×10^{-1} mol dm^{-3}, the observed rate of the coloration was not changed. These results indicate that the coloration does not proceed via the triplet state of the uncolored form. Therefore, the reaction state must be the excited singlet state.

Quantum yields of the coloration reaction were determined in degassed solutions of EtOH and DMF by using the triplet-triplet absorption of anthracene in degassed EtOH solution as a relative standard as described in Ref. 5. Figure 3 shows the relationship between the absorption of the colored form at 660 nm, $A(660)$, in degassed DMF and the triplet-triplet absorption of anthracene at 421 nm, $AT(421)$. The quantum yield is estimated from the slope of the plot, and is 4.8×10^{-2} in EtOH and 1.8×10^{-2} in DMF. These values are an order of magnitude smaller than those of the ordinary spirobenzopyrans,[6] which indicates that the deactivation process due to the sulfur atom is efficient for the new spiro compound.

We also carried out laser flash experiments on the decoloration reaction, in which the colored form was excited in the wavelength region on the longer wavelength side of the absorption spectrum. In aerated solutions, decoloration was observed, while, in degassed solutions, no decoloration of the colored form was observed under these experimental conditions. Therefore, the photodecoloration observed in aerated solution was due to photooxidation, and the conversion of the colored form to the colorless form mainly occurs by way of a thermal reaction in the ground state.

Solvent Effect. The thermal stability of the colored form is affected by the solvent polarity. A number of studies have been made for the ordinary spirobenzopyrans, and the colored forms are best regarded as zwitterionic species.[7] The logarithm of the fading rate constant decreases linearly with increasing Kosower's Z or Brownstein's S values. However, the plot against the $(D-1)/(D+2)$ gives a nonlinear graph, and is different for protic and aprotic solvents, where D is the dielectric constant of the solvent. These results can be interpreted in terms of the hydrogen bonding between the colored form and protic solvents.[7]

For the new spirobenzothiopyran, the thermal fading rate, k_T, at 25 °C and the wavenumber of the absorption maximum of the colored form, $\tilde{\nu}_{max}$ was measured in methanol (MeOH), ethanol (EtOH), isobutyl alcohol (i-BuOH), tetrahydrofuran (THF), N,N-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO), and summarized in Table 1. Remarkably different solvent effects for the thermal fading rate were observed for this compound. Figure 4 shows the plot of the logarithm of k_T against Dimroth's E_T

Table 1. Effects on the Solvent Polarity on the Rate Constant of Thermal Fading, k_T, (25 °C) and the Wavenumber of the Absorption Maximum of the Colored Form, $\tilde{\nu}_{max}$

Solvent	Dielectric constant(D)	E_T	k_T	$\tilde{\nu}_{max}$
		kJ mol^{-1}	s^{-1}	cm^{-1}
MeOH	32.6	232	2.8×10^{-4}	1.66×10^4
EtOH	24.3	217	6.9×10^{-3}	1.61×10^4
i-BuOH	15.2	196	9.4×10^{-3}	1.59×10^4
DMSO	48.9	188	4.3×10^{-4}	1.56×10^4
DMF	36.7	183	2.8×10^{-3}	1.51×10^4
THF	7.93	156	3.1×10^{-1}	1.39×10^4

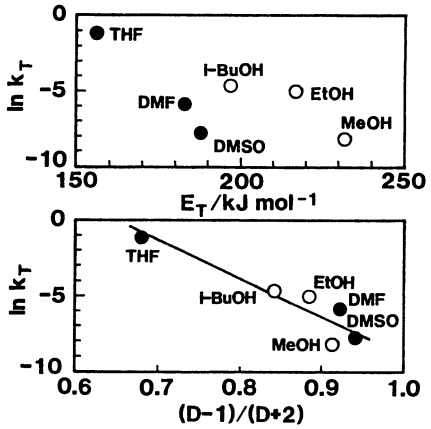

Fig. 4. The plots of ln k_T vs. E_T (upper half) and $(D-1)/(D+2)$ (lower half). The solid circle represents the aprotic solvent, and the open circle protic solvent.

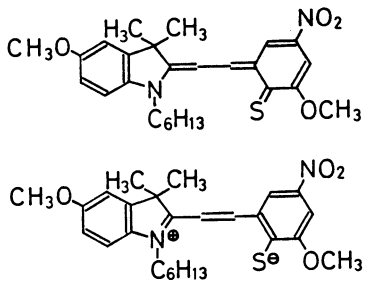
values[8] (E_T is linearly related to the S and Z values) and $(D-1)/(D+2)$. With increasing value of E_T and $(D-1)/(D+2)$, k_T decreases. A linear relationship was obtained against $(D-1)/(D+2)$, rather than against E_T, which is contrary to the ordinary spirobenzopyrans. For the new spirobenzothiopyran, the hydrogen bonding effect on the thermal stability of the colored form in protic solvents as observed in the ordinary spiropyran was not marked.

For the structure of the colored form of the new spirobenzothiopyran, two resonance forms, the thione structure **I** and the zwitterionic structure **II** (Scheme 2) are considered. Becker and Kolc assigned the structure of the colored form of a spirobenzothiopyran to be similar structure to **I**, by comparing the spectral characteristics at 77 K with the colored forms of the chromenes, 2*H*-1-benzothiopyrans, and spiro[benzopyran-2,2′-indolines].[1]

However, the dependence of k_T on the $(D-1)/(D+2)$ value can not be explained in terms of the thione structure **I**. The k_T value for the new spirobenzothiopyran is on the same order (ca. 10^{-4} s^{-1}) as that for the ordinary spirobenzopyran[7] in a highly polar solvent such as MeOH. On the other hand, k_T for the new spirobenzothiopyran in THF is about 10 times larger than that for the ordinary spirobenzopyran, and the colored form of the new spirobenzothiopyran becomes very



Scheme 2.

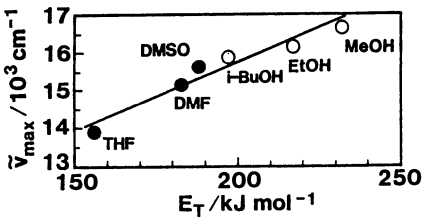


Fig. 5. The plots of $\tilde{\nu}_{max}$ vs. E_T. The solid circle represents the aprotic solvent, and the open circle the protic solvent.

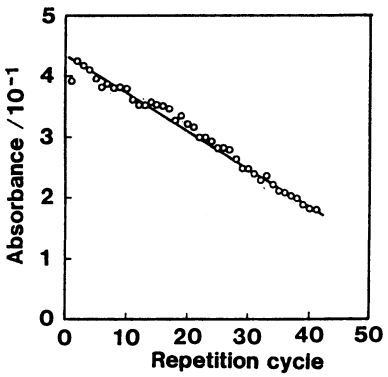

Fig. 6. The absorption decay of the colored form on the repetitive UV coloration and thermal fading cycles.

unstable in a solvent with a small $(D-1)/(D+2)$ value. These results imply that the contribution of the zwitterionic structure is even larger for the new spirobenzothiopyran than for the ordinary spirobenzopyran.

Figure 5 shows the plots of the wavenumber of the absorption maximum of the colored form, $\tilde{\nu}_{max}$, against the Dimroth's E_T value. $\tilde{\nu}_{max}$ increases with increasing value of E_T, and a hypsochromic effect was observed. A linear plot was obtained against the E_T value. This result indicates that the polarity of the colored form in the excited state is lower than that in the ground state, which can be interpreted in terms of the zwitterionic structure **II**.

Cycle Lifetime and Recording Characteristics. The new spirobenzothiopyran could be repetitively colored and bleached by irradiating with UV and by thermal treatment respectively. We performed repetitive coloration and decoloration in degassed DMF solution containing 10^{-4} mol dm^{-3} of the spirobenzothiopyran. With 2 minutes of UV irradiation, more than 30 cycles were achieved before the absorption of the colored form at the maximum decreased to 50% of the initial value (Fig. 6). The value of the cycle lifetime is on the order of 10 even in a dilute solution, which is promising with regard to practical application.

We examined the recording characteristics of a disk medium with a multilayer structure, in which the new spirobenzothiopyran was used as the sensitive material. The recording was carried out with a laser diode lasing at 780 nm. A carrier-to-noise ratio of more than

54 dB was achieved with a carrier frequency of 1 MHz.[9]

In conclusion, we first investigated the photochromic processes of a spirobenzothiopyran compound, and found that photocoloration proceeds via the excited singlet state, and the quantum yield of coloration is an order of magnitude smaller than those of ordinary spirobenzopyrans. The main route of the decoloration was found to be the thermal reaction. Remarkably different solvent effects for the thermal fading rate were observed, and the zwitterionic structure was significant for the new spirobenzothiopyran than for ordinary spirobenzopyrans.

Experimental

The spirobenzothiopyran was synthesized as described elsewhere.[1] All the solvents used methanol (MeOH), ethanol (EtOH), isobutyl alcohol (*i*-BuOH), tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO)) were spectral-grade. Typical concentration of the spiropyran was 1×10^{-4} mol dm^{-3}.

Photochemistry of the coloration and decoloration process was investigated in aerated and degassed solution of EtOH and DMF. Excitation was from a pulsed dye laser (FWHM>8 ns, output>10 mJ) optically pumped by a XeCl excimer laser. The absorption change was detected by a K-367 laser kinetic spectrometer (Applied Photophysics). The photomultiplier signal was recorded on a Tektronix 7912AD programmable digitizer, and analyzed by using a personal computer. Quantum yields of coloration were determined by using the triplet-triplet absorption of anthracene in degassed EtOH solution as a relative standard. The values used were 5.2×10^{4} dm^{3}mol^{-1} cm^{-1} for the molar extinction coefficient[10] and 0.7 for the triplet yield.[11] The molar absorption coefficient of the spiropyran was estimated by the extrapolation of the coloration curves in degassed solutions to be 8.5×10^{3} dm^3 mol^{-1} cm^{-1} (620 nm) in EtOH and 8.0×10^{3} dm^3 mol^{-1} cm^{-1} (660 nm) in DMF.

The solvent effect on the thermal fading and the absorption spectra in various solvents were monitored with a Hitachi 320 spectrophotometer. A 500 W high pressure mercury lamp with a Toshiba UV-D36 and a IRA-25S glass filters was used for the coloration source for the repetitive coloration and thermal fading experiments.

The X-Ray Photoelectron Spectra of 1:1 and 1:2 Salts Formed from Triethylammonium and 7,7,8,8-Tetracyanoquinodimethane

Jun Okubo, Toshihiko Hoshi,* Isao Ono, Kaori Karube, and Michio Kobayashi†

(Received July 27, 1988)

The X-ray photoelectron spectra of the 1:1 and 1:2 salts formed from the triethylammonium cation ($TEAH^+$) and 7,7,8,8-tetracyanoquinodimethane (TCNQ) have been measured and analyzed in order to investigate the electronic structures and conformations of the salts. The N 1s band (398.2 eV) degenerated in the free TCNQ molecule splits into two bands (398.4 eV and 400.3 eV) in the 1:1 salt. This is due to the unequal interactions of the nitrogen atoms of the TCNQ anion radical ($TCNQ^{\cdot-}$) with $TEAH^+$. In the 1:2 salt, the degenerated N 1s bands of two free TCNQ molecules split into three bands (398.5, 400.0, and 401.8 eV). This implies that the negative charge is inhomogeneously distributed over two TCNQ molecules, supporting the idea that the electronic structure of the 1:2 salt can be represented approximately as $TEAH^+$-$TCNQ^{\cdot-}$-$TCNQ^0$. It is found that, in the 1:2 salt, the neutral TCNQ molecule ($TCNQ^0$) is weakly bound to the TCNQ anion radical ($TCNQ^{\cdot-}$) of the strongly bound 1:1 salt, with their molecular planes parallel.

7,7,8,8-Tetracyanoquinodimethane (TCNQ) is a strong electron-acceptor and easily forms CT (charge transfer) complexes with such electron donors as tetrathiafulvalene and *p*-phenylenediamine.[1-13] Melby et al. have synthesized salts of TCNQ with many electron donors and investigated their physicochemical properties.[1] The ion-radical salt of TCNQ with triethylammonium ($TEAH^+$) was also synthesized by them, and its EPR, IR and UV spectra were measured. The analyses of these spectra have revealed that the electronic structure of the 1:1 salt between $TEAH^+$ and TCNQ can be described as $TEAH^+$-$TCNQ^{\cdot-}$; i.e., the TCNQ molecule exists as an anion radical in the crystal. Kobayashi et al. have determined the crystal structure of the 1:2 salt between $TEAH^+$ and TCNQ by means of X-ray diffraction and have shown that the TCNQ in the crystal has two kinds of electronic structures, $TCNQ^{\cdot-}$ and $TCNQ^0$; i.e., the negative charge is inhomogeneously distributed over two TCNQ molecules.[2] In contrast, Filhol et al. showed, by means of the neutron diffraction, that the electronic structure of the 1:2 salt is $TEAH^+$-$TCNQ^{-1/2}$-$TCNQ^{-1/2}$.[3a] However, they have since corrected the results to $TEAH^+$-$TCNQ^{-3/5}$-$TCNQ^{-2/5}$;[3b] i.e., the two TCNQ molecules in the 1:2 salt are not equivalent, but the negative charge is delocalized significantly over the two TCNQ molecules.

In this investigation we have measured and analyzed the X-ray photoelectron spectra (XPS) of the 1:1 and 1:2 salts formed from $TEAH^+$ and TCNQ in order to investigate the electronic structures and conformations of these salts.

Experimental

Commercial triethylamine hydrochloride (TEA-HCl) (Wako Pure Chemical Industries, Ltd.) was purified by sublimation after several recrystallizations from ethyl alcohol. Commercial TCNQ (Tokyo Kasei Co., Ltd.) was purified by sublimation in vacuo (0.28 mmHg/220 °C; 1 mmHg=133.322 Pa). The 1:1 and 1:2 salts of $TEAH^+$ and TCNQ were synthesized according to the procedure reported by Melby et al. and purified by recrystallization from acetonitrile.[1] The salts thus obtained were identified by means of their IR and UV spectra and elemental analysis. The XPS spectra were measured with a Shimadzu ESCA-750 apparatus, employing Mg $K\alpha$ (1253.6 eV) radiation as the X-ray source. Powdered samples are fixed on an adhesive tape put on the holder. The binding energies for the XPS bands were calibrated by the use of that for the $4f_{7/2}$ band of Au powder.

MO Calculation

MO calculation for the π-electron system of TCNQ was performed by using a modified PPP method[14] which can deal, at the same time, with mutually perpendicular π and π' systems as presented in the triple bonds of the cyano groups of TCNQ.

Results and Discussion

The XPS spectra for TEA-HCl, TCNQ, and the 1:1 salt between $TEAH^+$ and TCNQ are compared in Fig. 1, while the spectrum for the 1:2 salt is shown in Fig. 2. According to Ikemoto et al., the N 1s band of the TCNQ salt changes in shape upon X-ray irradiation.[4] In order to confirm this fact, we have measured the XPS spectra of the TCNQ salts at various accumulation times. As a result, the shape of the spectra was found not to change within three accumulation times, but the band shape did vary slightly at five accumulation times. Thus, in this investigation, the spectra accumulated three times are used. The dotted lines shown for each XPS band are the reduced spectra, which are obtained assuming Gaussian curves. The peak positions and integrated intensities (in percent) of these reduced spectra are summarized in Table 1 for all of the compounds investigated here.

XPS Spectra of TEA-HCl and TCNQ. TEA-HCl shows a fairly wide C 1s band at 285.4 eV, the half-width being 2.5 eV. This band consists, therefore, of

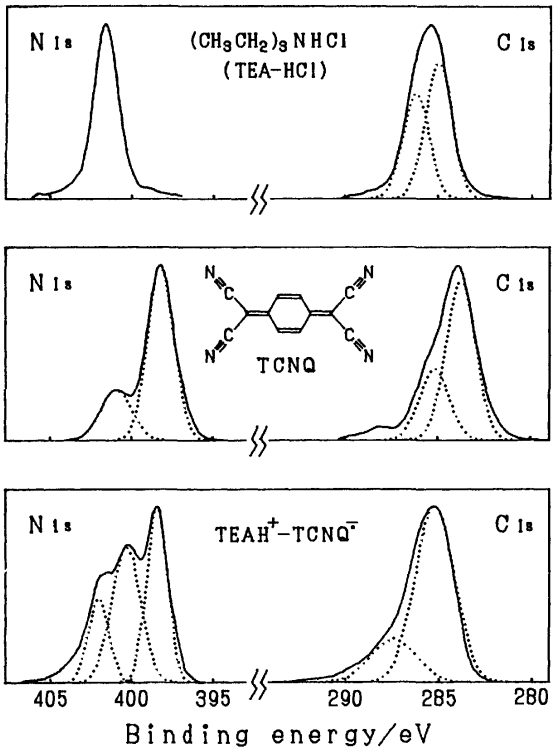

Fig. 1. Comparison of XPS spectra of TEA-HCl, TCNQ, and the 1:1 salt between $TEAH^+$ and TCNQ.

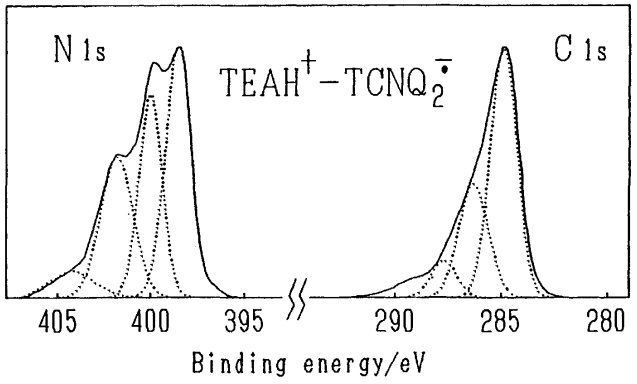

Fig. 2. XPS spectrum for the 1:2 salt between $TEAH^+$ and TCNQ.

two bands with nearly equal intensities whose peak positions are, as determined from the reduced spectra, at 285.0 and 286.2 eV. The higher-energy band at 286.2 eV is assigned to the 1s orbital of the electron-deficient carbon atom adjacent to the electron-withdrawing nitrogen atom with the higher electronegativity, and the lower energy band at 285.0 eV, to that of the outer methyl carbon atom. The N 1s band of TEA-HCl is positioned at 401.6 eV, with a narrow half width.

TCNQ has a C 1s band consisting of a main peak at 283.8 eV and a weak band (a shoulder in the original spectrum) at 285.2 eV. To assign these bands in the reduced spectrum, we have performed a modified PPP

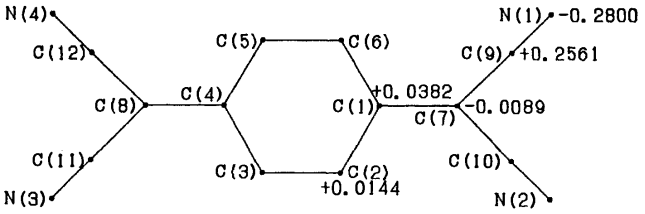

Fig. 3. The formal charge on each atom of TCNQ estimated by a modified PPP calculation.

Table 1. The C 1s and N 1s Binding Energies and Intensities for TEA-HCl, TCNQ, $TEAH^+$-$TCNQ^{\cdot}$, and $TEAH^+$-$TCNQ_2^{\cdot}$, as Estimated from the Reduced Spectra

Compound	Core level	Binding energy/eV	Intensity (in percent)
TEA-HCl	C 1s	288.0	57
		286.2	43
	N 1s	401.6	100
TCNQ	C 1s	283.8	69
		285.2	31
	N 1s	398.2	74
		400.9	26
$TEAH^+$-$TCNQ^{\cdot}$ (1:1)	C 1s	285.2	78
		287.4	22
	N 1s	398.4	37
		400.3	40
		402.0	17
$TEAH^+$-$TCNQ_2^{\cdot}$ (1:2)	C 1s	284.8	60
		286.2	31
		278.6	9
	N 1s	398.5	39
		400.0	27
		401.8	27
		404.2	7

calculation (as explained in the previous section) and have estimated the formal charge on each atom of TCNQ, the results being illustrated in Fig. 3. The formal charges on the central carbon atoms C(1)-C(8) constituting the quinodimethane skeleton are small in magnitude, but those on carbon atoms C(9)-C(12) constituting the cyano groups are large (positive values). From the viewpoint of potential depth, the lower-energy band at 283.8 eV and the higher-energy band at 285.2 eV are assigned to carbon atoms C(1)-C(8) and C(9)-C(12), respectively. This assignment predicts the intensity ratio of the 283.8 eV band to the 285.2 eV band (which is equal to the ratio of the numbers of carbon atoms assigned to each band) to be 2:1, in considerable agreement with the observed value (69:31) given in Table 1.

The N 1s band of TCNQ consists of a main band at 398.2 eV and a sub-band at 400.9 eV. The band contour and band positions agree well with those reported by Ikemoto et al.[5] They have suggested that the sub-band is attributable to a shake-up process involving intramolecular transitions between the π-electron

molecular orbitals.

XPS Spectrum of the 1 : 1 Salt between $TEAH^+$ and TCNQ. As may be seen from Fig. 1, the N 1s band of the 1 : 1 salt shows a complex band contour not explained by the simple addition of the N 1s band of $TEAH^+$ to that of TCNQ; i.e., an extra or new N 1s band has emerged on the formation of the salt. This extra band is too intense to be assigned to only a shake-up band,[4,5] i.e., the shake-up band is considered to be buried in the intense extra band. It is, therefore, demonstrated that the N 1s band is sensitive to the salt formation; in other words, the interaction between $TEAH^+$ and $TCNQ^{\cdot-}$ in the 1 : 1 salt is manifest in the behavior of the N 1s band. This may be due to the fact that the salt is in such a conformation that $TEAH^+$ interacts entirely with the nitrogen atoms located on the outer part of the TCNQ molecule, as will be discussed below in detail. The N 1s band of the 1 : 1 salt consists of three bands —at 398.4, 400.3, and 402.0 eV (Table 1) which are now assigned on the basis of the previously proposed ionic structure ($TEAH^+$-$TCNQ^{\cdot-}$) of the salt.[1]

From the viewpoint of the potential depth on atoms for the free molecule, it is natural to expect that the N 1s band of the triethylammonium cation ($TEAH^+$) is positioned on a higher-energy side than that of the TCNQ anion radical ($TCNQ^{\cdot-}$). Therefore, the highest-energy band at 402.0 eV can be assigned to the N 1s band originating from the $TEAH^+$ of $TEAH^+$-$TCNQ^{\cdot-}$. The N 1s band originating from the $TEAH^+$ of $TEAH^+$-$TCNQ^{\cdot-}$ is on a somewhat higher-energy side than that of $TEAH^+$-Cl^-. This may be due to the fact that the effective positive charge of the proton in $TEAH^+$-$TCNQ^{\cdot-}$ is larger than that in $TEAH^+$-Cl^-; this is because the ionic radius of $TCNQ^-$ is larger than that of Cl^-. Thus, the other two N 1s bands —at 398.4 and 400.3 eV— of the salt can be attributed to the ionization from the N 1s orbital of $TCNQ^{\cdot-}$. This implies that the N 1s bands of free $TCNQ^{\cdot-}$, which are degenerated, are split into two bands because $TEAH^+$ interacts with the nitrogen atoms of $TCNQ^{\cdot-}$ unequally. The unequal interaction of $TEAH^+$ with the nitrogen atoms of $TCNQ^{\cdot-}$ just mentioned may be possible when the configuration of $TEAH^+$ and $TCNQ^{\cdot-}$ is linear in the 1 : 1 salt, as is illustrated in Fig. 4a. The N 1s bands (398.4 and 400.3 eV) of the $TCNQ^{\cdot-}$ of the 1 : 1 salt are positioned on a higher-energy side than that (398.2 eV) of the free TCNQ. This fact is rather surprising, since, in general, an XPS band of a neutral molecule is on a higher-energy side than that of negatively charged species.

As is well-known, the position of the XPS band is dependent on the potential depth on the atom. In the present case, the potential depth may be influenced by two factors: the effects of the π-electron density, and the positive charge of the proton. The increase in the binding energy of the N 1s bands of the $TCNQ^{\cdot-}$ of the 1 : 1 salt in comparison with that of the free TCNQ molecule may indicate that the effect of the proton is superior to that of an extra odd electron. Thus, the 400.3 eV band is assigned to the N 1s band of the nitrogen atoms 1 and 2, which interact with the proton of $TEAH^+$ directly, and the 398.4 eV band to those of the nitrogen atoms 3 and 4 (Fig. 4a). In conformity with these assignments, the observed intensity ratio (37 : 40 : 17) of the N 1s bands is in good agreement with the theoretical one (2 : 2 : 1) estimated from the number of nitrogen atoms assigned to each N 1s band. It is interesting to notice here that the 400.3 eV N 1s band of the salt has a wide half width. We have considered that this band broadening is derived from the singlet-triplet splitting due to the biradical nature of the ionized state of $TCNQ^{\cdot-}$ and/or from superimposition of the shake-up band.[5] The unpaired electron in $TCNQ^{\cdot-}$ may be localized mainly at nitrogen atoms 1

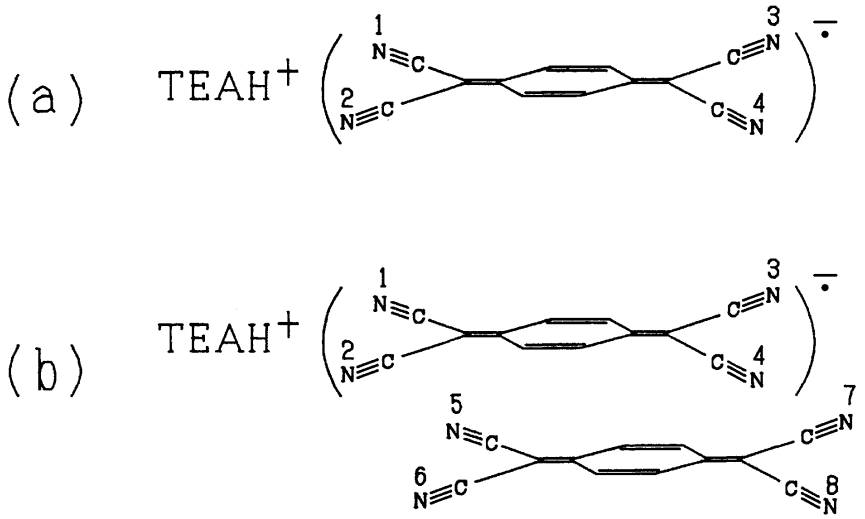

Fig. 4. Conformations of (a) the 1 : 1 salt ($TEAH^+$-$TCNQ^{\cdot-}$) and (b) the 1 : 2 salt ($TEAH^+$-$TCNQ^{\cdot-}$-$TCNQ^0$).

and 2 through the electrostatic attraction by $TEAH^+$, resulting in the concentration of the biradical nature of the ionized state of $TCNQ^-$ on nitrogen atoms 1 and 2 (Fig. 4a). This may be the reason why only the 400.3 eV N 1s band of the salt, which stems from the ionization of the nitrogen atoms 1 and 2, is broadened. The band broadening mentioned above may, therefore, be evidence for the presence of an unpaired electron in the CT-structure ($TEAH^+$-$TCNQ^-$) of the 1 : 1 salt.

In contrast to the N 1s band, the C 1s band of the 1 : 1 salt has a broad and rather structureless band shape; i.e., the C 1s bands of donor and acceptor are not separated, but are overlapped to give a broad band, demonstrating that the C 1s band is insensitive to the salt formation. The broad C 1s band of the 1 : 1 salt can, however, be decomposed into two bands of the Gaussian type positioned at 285.2 and 287.4 eV, whose intensity ratio is 78 : 22 (Table 1), as is shown in Fig. 1. The intense band at 285.2 eV results, as has been explained above, from a complete overlap of the band originating from the 283.8 eV C 1s band of the free TCNQ molecule, which is assigned to the central carbon atoms C(1)-C(8) of TCNQ (Fig. 3), and that originating from the C 1s band of TEA-HCl. The weak band at 287.4 eV may originate from the 285.2 eV C 1s band of the free TCNQ molecule, which is assigned to the carbon atoms C(9)-C(12) of TCNQ; this assignment is based on the fact that the theoretical intensity ratio (7 : 2) is in good agreement with the observed one (78 : 22). According to these assignments of the C 1s bands of the salt, the two C 1s bands at 283.8 and 285.2 eV of the free TCNQ molecule are shifted to energies higher by 1.4 and 2.2 eV respectively by the formation of the salt. This rather surprising result may be also explained by the same reason as that presented for the higher-energy shift of the N 1s band of $TCNQ^-$.

XPS Spectrum of the 1 : 2 Salt between $TEAH^+$ and TCNQ. The N 1s band of the 1 : 2 salt shows, like that of the 1 : 1 salt, a complex band contour not explained by the simple addition of N 1s bands of the cation and the anion; i.e., at least, an additional N 1s band has emerged on the formation of the salt. Indeed, it has shown, as will be discussed below, that the splitting pattern of the N 1s bands is a good indicator of the donor-acceptor interaction in the salt or of the conformation and electronic structure of the salt.

The N 1s band of the 1 : 2 salt consists of four bands —at 398.5, 400.0, 401.8, and 404.2 eV, with the intensity ratio of 39 : 27 : 27 : 7 (Table 1). The assignment of these bands is the basis for the study of the donor-acceptor interaction in the 1 : 2 salt and for the verification of the previously proposed models for the electronic structure of the 1 : 2 salt. By analogy with the case of the 1 : 1 salt, the N 1s band of $TEAH^+$ may be expected to shift to a higher-energy side on forming the 1 : 2 salt, the 401.8 or 404.2 eV band being a candidate for the N 1s band of $TEAH^+$ in the salt. We have considered that the 401.8 eV N 1s band can not be assigned to the N 1s band of $TEAH^+$ for the following two reasons: (1) the band has, as will be discussed later, a wide half width and, hence, resembles the 400.3 eV N 1s band of the $TCNQ^-$ of the 1 : 1 salt, and (2) the intensity of the band is too large to be assigned to $TEAH^+$. Thus, the 404.2 eV N 1s band is assigned to $TEAH^+$, while three N 1s bands at 398.5, 400.0, and 401.8 eV must be assigned to the two TCNQ molecules in the 1 : 2 salt. In other words, it has been demonstrated that the degenerated N 1s bands of two free TCNQ molecules are split into three bands in the 1 : 2 salt. This splitting pattern of the N 1s bands is possible only when the following two conditions are fulfilled: (a) the negative charge is inhomogeneously distributed over two TCNQ molecules, and (b) the unequal, in the same sense as in the 1 : 1 salt, interaction of $TEAH^+$ with the nitrogen atoms of the one TCNQ molecule is stronger (or weaker) than that with the nitrogen atoms of the other TCNQ molecule. The first condition is necessary for the second one to be fulfilled, rather supporting the electronic structure of $TEAH^+$-$TCNQ^-$-$TCNQ^0$ previously determined by means of X-ray diffraction.[2] The second condition may be fulfilled when the 1 : 2 salt is in the conformation illustrated in Fig. 4b. As may be seen from Fig. 4b, $TEAH^+$ interacts strongly with $TCNQ^-$ with just the same conformation as that of the 1 : 1 salt, and $TCNQ^0$ interacts weakly with $TCNQ^-$, with their molecular planes parallel.

The conformational model shown in Fig. 4b makes possible a further assignment of the three N 1s bands at 398.5, 400.0, and 401.8 eV. There seem to be formally two alternative assignments for the lowest-energy band at 398.5 eV: one is the assignment to the four nitrogen atoms of the $TCNQ^0$ positioned at 5—8, and the other, to the nitrogen atoms at 3, 4, 7, and 8 (Fig. 4b). Following the latter assignment, the highest-energy band at 401.8 eV is assigned to the nitrogen atoms 1 and 2, which are bound with the proton of $TEAH^+$ most strongly, and the band at 400.0 eV to the nitrogen atoms 5 and 6. As a result, the energy difference between the two split bands of $TCNQ^-$ in the 1 : 2 salt amounts to 3.3 (=401.8—398.5) eV, which is very different from that (1.9 eV) in the 1 : 1 salt; thus, the latter assignment can be ruled out. Since, however, the 401.8 eV band is assigned to the nitrogen atoms 1 and 2, and the 400.0 eV band, to the nitrogen atoms 3 and 4, the former assignment reasonably predicts the above-mentioned energy difference to be 1.8 (=401.8—400.0) eV, which corresponds well to the value (1.9 eV) observed in the 1 : 1 salt. The theoretical intensity ratio (2 : 1 : 1) for the three N 1s bands assigned as above is also in agreement, though only qualitatively, with the observed one (39 : 27 : 27). It is interesting to note that the two split N 1s bands of $TCNQ^-$ in the 1 : 2 salt are both shifted to a higher-energy side by ca. 1.5 eV compared with those in the 1 : 1 salt. This may be because a small amount of the unpaired electron of $TCNQ^-$

migrates to $TCNQ^0$, for that $TCNQ^0$ is bound to $TCNQ^{\cdot-}$ via the weak CT-type interaction ($TCNQ^{\cdot-}$ behaves as an electron donor with respect to $TCNQ^0$). The unique similarity between the N 1s bands of the 1 : 2 salt and those of the 1 : 1 salt is the existence of the broad band assigned to the nitrogen atoms (1 and 2) of $TCNQ^{\cdot-}$ directly interacting with $TEAH^+$. That is, the 401.8 eV N 1s band of the 1 : 2 salt, which is assigned to the nitrogen atoms (1 and 2) directly interacting with $TEAH^+$, exhibits a band broadening based on the same mechanism as that in the 1 : 1 salt. This is a further confirmation of the band assignment based on the conformation and electronic structure of the 1 : 2 salt presented in Fig. 4b.

The C 1s band of the 1 : 2 salt shows an ill-resolved band shape which is very similar, in spite of the presence of $TCNQ^{\cdot-}$ in the salt, to that of the C 1s band of the free TCNQ molecule. Indeed, the two lower-energy reduced bands at 284.8 and 286.2 eV, which are assigned, respectively, to the central carbon atoms of $TCNQ^{\cdot-}$ and $TCNQ^0$ and to the carbon atoms constituting the cyano groups of $TCNQ^{\cdot-}$ and $TCNQ^0$, have an energy separation of 1.4 eV and an intensity ratio of 60 : 31, comparable to those values (1.3 eV and 69 : 31) for the C 1s band of the free TCNQ molecule (see Table 1). It can, therefore, be understood that the C 1s-band positions of $TCNQ^{\cdot-}$ coincide, following the electronic structure of $TEAH^+$-$TCNQ^{\cdot-}$-$TCNQ^0$ for the 1 : 2 salt, with those of $TCNQ^0$. We have considered this coincidence to be a further confirmation of the already mentioned general tendency for the core level of the carbon atom to be scarcely affected by valence electrons.[5] The C 1s band of $TEAH^+$ in the 1 : 2 salt might be buried under the C 1s bands of $TCNQ^{\cdot-}$ and $TCNQ^0$.

Spectroscopic Evidence of α,α-Dihydroxy Ketone in Biacetyl Aqueous Solutions

Kaori MIYATA, Kenichi NAKASHIMA,† and Motohiko KOYANAGI*
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received July 27, 1988)

From the analysis of emission, excitation, absorption, and ^{1}H NMR spectra of 2,3-butanedione (i.e., biacetyl), it has been established that about two thirds of the molecule in aqueous solutions exists as 3,3-dihydroxy-2-butanone (i.e., a hydrated form of biacetyl). For the first time, two different types of emission are discriminated: Emission is mostly due to the fluorescence spectrum of the monoketone upon irradiation of light with a shorter wavelength than 320 nm while it is due to the strong phosphorescence spectrum of biacetyl itself upon irradiation of light with a longer wavelength than 350 nm. The almost stoichiometric molecular rearrangement from the hydrated (monoketone) form in a water phase to the ordinary (diketone) form in a hydrocarbon phase has been found to take place.

The molecule, 2,3-butanedione (i.e., biacetyl; hereafter abbreviated as BA), has extensively been studied both on the energy decay dynamics[1-9] and on the electronic and molecular structures in the excited states.[10-14] Its substantially high phosphorescence quantum yield in fluid solutions still gives intriguing problems to molecular spectroscopists. The fundamental interpretations of the photochemical and photophysical processes were reviewed earlier.[15,16] Many optical studies thereof have so far been carried out in nonaqueous solvents or in the free molecule, on one hand. From the spectroscopic interest of cage effects, on the other hand, room temperature phosphorescence materials (including BA) in cyclodextrins and in micelles have recently come to attract attention;[17,18] the surrounding environments being water for these cases.

At an early stage of the ^{1}H NMR instrumental development, Greenzaid et al. observed the spectra of several aliphatic aldehydes and ketones in aqueous solutions and found that there, more or less, exists equilibrium between the hydration-dehydration reaction for each molecule.[19] Further, unusual absorption behavior was found for BA in water.[20-25] Substantial hydration was pointed out to occur in such solutions although several other photochemical processes were suggested.[22] Spectroscopically, no further developed optical study has been pursued from this point of view despite its importance: In fact, several authors seem to encounter similar problems recently.[17,18,23-25] Most all these works are thus likely to contain some erroneous conclusions because they did not necessarily take into account this molecular rearrangement reaction in the water phase.

The purpose of this paper is to give an additional piece of evidence for the equilibrium by means of the usual emission technique.

Experimental

The materials (i.e., BA, acetone, 3-hydroxy-2-propanone, 3-hydroxy-2-butanone, and 1,3-dihydroxy-2-propanone: all Tokyo Kasei GR grade reagents) were several times distilled in vacuo. The absorption and emission spectra were recorded on a Hitachi Absorption Spectrometer EPS-2 and on a Hitachi Fluorometer F-3000, respectively. The NMR spectra were measured on a 400 MHz Japan Electric NMR Spectrometer type JNM-GX400 using D_2O and C_6D_6 (both E. Merck reagents). The other solvents were all Dotite spectroscopic grade reagents. Dioxane (DX) and tetrahydrofuran (THF) were used immediately after the neat solvents were purged with nitrogen gas for several minutes.

Results and Discussion

Absorption Spectra. To our knowledge, there is not a suitable solvent which is miscible with water and is of an "inert" nature. As the next best choice, DX and THF were employed although these never fulfilled the latter requirement. In order to obtain reproducible (and thus reliable) spectral data, we measured the absorption spectra immediately after the sample solutions were prepared. Further, we paid a special caution to prevent the solutions from coming into contact with air under room light. The absorption spectra of BA at a constant concentration in THF-H_2O mixed solvents were measured with changing the molar fraction of H_2O. The results are partially shown in Fig. 1. An increase in absorption intensity around 260 nm with a decrease in H_2O concentration may largely be attributed to peroxides which still coexist in THF.

First we consider a chemical equilibrium between the hydration-dehydration reaction as follows:

$$BA + n\,H_2O \leftrightarrow BA[H_2O]_n. \quad (1)$$

Then we obtain a stoichiometric equation by using an analytical method[26,27] as follows:

$$\frac{1}{\varepsilon - \varepsilon_A} = \frac{1}{(\varepsilon'_A - \varepsilon_A)KC^n} + \frac{1}{\varepsilon'_A - \varepsilon_A} \quad (2)$$

where ε'_A and ε_A are the molar extinction coefficients of the hydrated (monoketone) form and the diketone form of BA, respectively; ε an apparent absorption

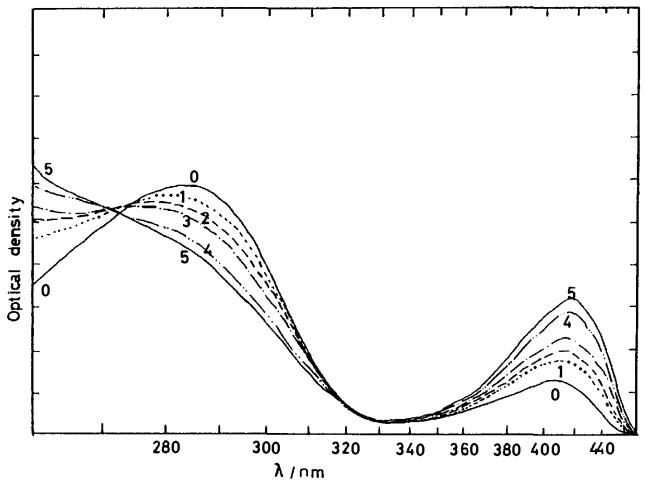

Fig. 1. Absorption spectra of BA in H_2O–THF mixed solvents at 25 °C. BA concentration is fixed at 2.6×10^{-2} mol dm^{-3}. H_2O concentrations (in mol dm^{-3} units) are: (0)55, (1)38.5, (2)33, (3)27.5, (4)16.5, and (5)11.

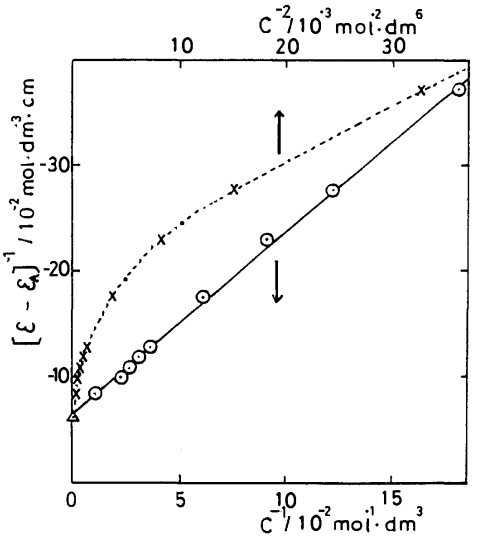

Fig. 2. Plots of $(\varepsilon-\varepsilon_A)^{-1}$ against C^{-n} (C: H_2O concentrations; and n=1,2) at 410 nm. For ○, n=1; for ×, n=2; and for △, see text.

coefficient of the system as a function of wavelengths; and C the total concentration of water. Plots of $(\varepsilon-\varepsilon_A)^{-1}$ against C^{-n} may give a straight line as far as Eq. 1 holds. In Fig. 2, $(\varepsilon-\varepsilon_A)^{-1}$ at 410 nm was plotted against C^{-1} and C^{-2}. It should be noted that a linear relation was obtained for case n=1, but not for n=2 (and also not for n=0.5). The hydration number n is thus 1. From the slope and the intercept of the straight line in Fig. 2, the values of K and ε'_A were estimated to be 3.61×10^{-2} dm^3 mol^{-1} and ca. 0 dm^3 mol^{-1} cm^{-1}, respectively. As shown in Table 1, the obtained K value is close to that evaluated by Bell et al. for another solvent system at 25 °C under the assumption that the 420 nm absorption system is completely due to the $S_1(n\pi^*)\leftarrow S_0$ transition of the ordinary diketone form of

Table 1. Equibrium Constant K at 25 °C

Solvent system[a]	Means[b]	$K/10^{-2}$ dm^3 mol^{-1}	α[c]
H_2O-DX	Abs.	3.8±0.5	0.48±0.07

a) DX: dioxane; THF: tetrahydrofuran; EtOH: ethanol. b) Abs.: absorption. c) Molecular ratio: [unhydrate]/[hydrate]. d) Taken from Ref. 19. e) Calculated from the reported α-value by using 55.4 mol dm^{-3} for pure water at 25 °C. f) Taken from Ref. 21.

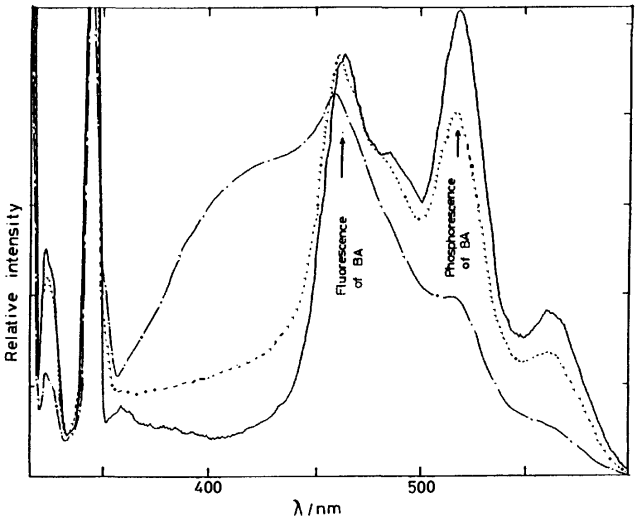

Fig. 3. Emission spectra of ca. 10^{-3} mol dm^{-3} BA in H_2O–THF mixed solvents at 20 °C. Water concentrations are: (——), 0 vol%; (----), 5 vol%; and (-·-·-), 10 vol%. Several sharp bands in the 330—350 nm range are due to Raman lines of the solvents. λ_{exc}=313 nm; slit widths (in light wavelength units): 1.5 nm.

BA.[21] The present (more general) treatment confirms that Bell and McDougall's assumption is almost acceptable because of the obtained $\varepsilon'_A\approx 0$ in the 380—430 nm range. The same method was applied to the 270—320 nm absorption system. However, no reliable correlation was obtained for n=1 (and n=2).

Emission Spectra. When BA in aqueous solutions is irradiated with light monochromated at 313 nm, a broad emission spectrum appears around 420 nm, near the absorption maximum of the $S_1(n\pi^*)\leftarrow S_0$ absorption of BA (see also Fig. 1). This band shows an increase in intensity with an increase in water concentration (see Fig. 3) while no such an anomalous emission was observed for ca. 10^{-3} mol dm^{-3} BA in nonaqueous solvents such as toluene, methylcyclohexane, and hexane. With a further increase in water concentration, the intensity of the 420 nm band comes to surpass those of the three bands at 457 nm (fluorescence of BA), at 512 nm (phosphorescence of BA), and at 560 nm (phosphorescence of BA). Such an example (in ca. 100% H_2O) is shown in Fig. 4 (see the solid line

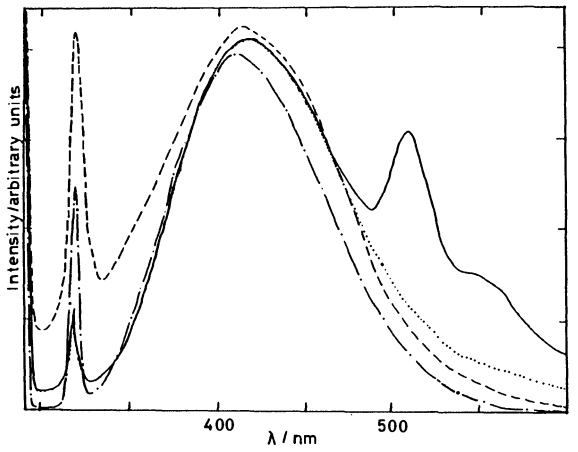

Fig. 4. Emission spectra of ca. 10^{-3} mol dm^{-3} ketones in aqueous solutions at 20°C. λ_{exc}=313 nm. Slit widths: 1.5 nm. (——) and (– – – –): BA in the absence and existence of oxygen, respectively; (– – –): 3-hydroxy-2-propanone; and (–·–·–): 3-hydroxy-2-butanone (acetoin). Bands around 320 nm are attributed to Raman lines of H_2O.

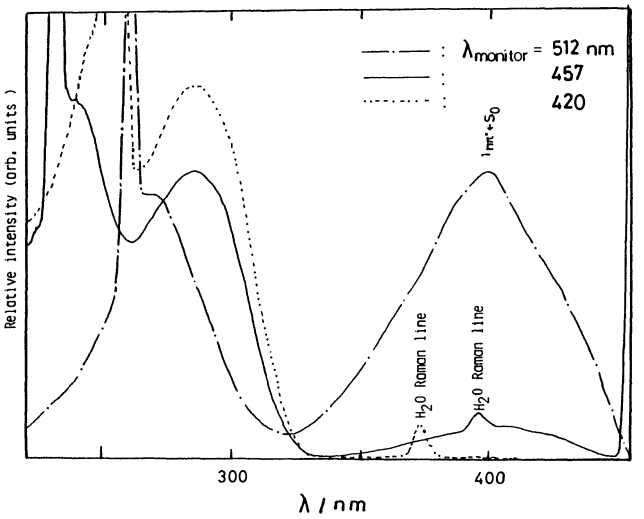

Fig. 5. Excitation spectra of ca. 10^{-3} mol dm^{-3} BA in aqueous solutions at 20°C. Slit widths: 1.5 nm. Note that 2nd order excitation light appears with large intensity below 260 nm since no light filter was employed.

curves). For comparison, fluorescence spectra of the four monoketones (i.e., 3-hydroxy-2-propanone (hydroxyacetone), 3-hydroxy-2-butanone (acetoin), 1,3-dihydroxy-2-propanone (dihydroxyacetone), and acetone) were measured at 20°C in aqueous solutions. Excitation light was all the same. For space saving, the spectra of the former two are shown in Fig. 4. A similarity between the 420 nm emission spectrum of BA in aqueous solutions and the fluorescence spectrum of each monoketone strongly suggests that the former is due to the monoketone species (namely, the hydrated form of BA, $CH_3C(OH)_2CO\text{-}CH_3$). Several other optical properties (such as band width, emission quantum yield, Stokes shift, etc.) resemble the general optical features of monoketones.[28,29]

Excitation Spectra. In order to identify this additional species more clearly, we observed several excitation spectra of BA in aqueous solutions at various wavelengths of the emission spectra monitored. Only three spectra are shown in Fig. 5. Obviously, there are big differences in the spectral locations and in the intensity distribution patterns when emission is monitored at 512 nm (the peak wavelength of the normal phosphorescence) and at 420 nm (that of the anomalous fluorescence): In between is the remainder which was measured at $\lambda_{monitored}$=457 nm (the peak wavelength of the normal fluorescence spectrum of BA). The different spectral dependence is a manifestation that there are chemically different emitting species: one with an absorption maximum at 400 nm and another with that at 285 nm.

Further, we studied the emission, absorption, and excitation spectra of the four monoketones, loc. cit., in aqueous solutions at 20°C. Although small spectral shifts of the absorption maxima were found from molecule to molecule, these emission spectra were very

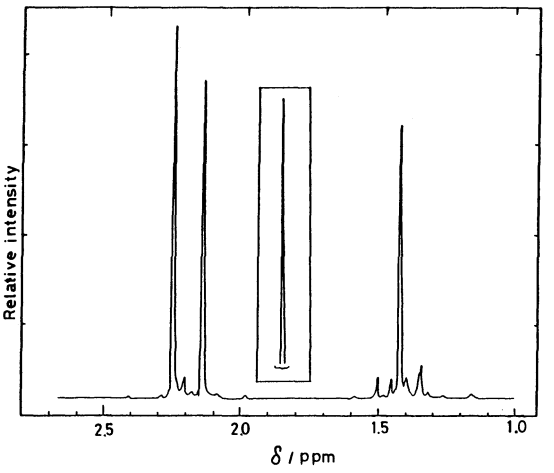

Fig. 6. 400 MHz ^{1}H NMR spectra of 1.5×10^{-2} mol dm^{-3} BA in D_2O at 20°C. The inserted shows only one peak obtained from BA in C_6D_6.

similar to each other (vide supra). It was confirmed that each excitation spectrum showed a close correlation to the corresponding absorption spectrum. All these results lead us to the conclusion that the 420 nm emission in BA aqueous solutions is due to the hydrated form of BA.

^{1}H NMR Spectra. The ^{1}H chemical shifts and integrated intensities of BA were measured for two solvent systems: D_2O and C_6D_6. The concentration of BA was of ca. 10^{-2} mol dm^{-3} for each case. The results are shown in Fig. 6. Three prominent peaks were observed in D_2O solutions while only one prominent peak in C_6D_6 solutions. Without doubt, the strong single peak at δ 1.86 in C_6D_6 solutions is due to the six equivalent protons of $C^1H_3COCOC^1H_3$. The relative integrated intensity ratio among the three prominent

peaks in D_2O solutions was approximately 1.8 (for the peak at δ 2.25): 1.0 (for the peak at δ 2.14): 1.0 (for the peak at δ 1.42). That the integrated intensities of the latter two peaks are almost equal to each other allows the assignment to be the same as proposed by Greenzaid et al.:[19] the peak at δ 2.25 as the six equivalent protons in the ordinary diketone form of BA; and the peak at 2.14 ppm as the three equivalent protones of C^1H_3CO- and the peak at δ 1.42 as the three remainder (i.e., $C^1H_3C(OD)_2-$) in the hydrated form. Many small peaks are due to several impurities produced photochemically during the experimental procedure.

Greenzaid et al. found that the molecular ratio of the dehydrated to the hydrated form of BA in H_2O was 0.50,[19] a little bit smaller value with reference to 0.54 for our BA-D_2O system. This small difference is, however, within the experimental errors ($\pm$0.05).

Reversibility of the Molecular Rearrangement and Equilibrium Constants. Another important aspect is that the hydration-dehydration reaction takes place in equilibrium on going from one phase to another. We confirmed this by measuring the ^1H NMR spectra of BA first in aqueous solution (phase 1), secondly in C_6D_6 solution (phase 2) after extraction of the BA from the phase 1 solution by fresh perdeuterated benzene, and lastly in D_2O solution (phase 3) after extraction of the BA from the C_6D_6 (phase 2) solution by fresh heavy water. Apart from the contaminated ^1HDO signal at δ 4.74 in D_2O and at δ 1.60 in C_6D_6 solution, the triplet to singlet and the singlet to triplet signal pattern changes were well reproduced. This means that the BA molecule exists extensively as the hydrated form in the water phase while they are almost completely as the ordinary diketone form in the benzene phase.

This equilibrated molecular rearrangement was also confirmed by measuring emission and excitation spectra of two-phases-forming (i.e., unmiscible) H_2O-methylcyclohexane (MCH) solution systems. The chemical treatments are the same as mentioned above, but for a system of H_2O and MCH instead that of D_2O and C_6D_6. Both the emission and excitation spectra are almost completely ascribed to the ordinary diketone form of BA in the MCH phases while those are due to the both forms in the water phases.

The equilibrium constants obtained for the hydration-dehydration reaction of BA in several aqueous solvent systems are briefly summarized in Table 1 together with the data reported previously by other investigators.[19,21] Apart from some differences in the K-values, all the data establish that there occurs an extensive hydration reaction of BA in such aqueous solutions. An interesting issue may arise on this molecuar rearrangement and on the decay dynamics of BA around an interface of oil-water as well as around those of micelle-water and cyclodextrin-water. This reversibility in the molecular rearrangement strongly suggests that there is a possibility of BA (as well as benzil[30]) to become a new probing reagent for studies of such hydrophobic/hydrophilic macromolecular phenomena. At least, this polymorphous nature of BA should fully be taken into account on the discussion of the dynamics and structures in micelles,[17,18] in cyclodextrins,[18] and in water-contained organic solvents.[23,24]

The authors are thankful to Professor Ryoichi Shimada for his encouragement and to Miss Kayoko Ogi for her kind assistence in obtaining the ^1H NMR spectra. This work was in part supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 62540358).

30) Benzil is well-known to emiss both phosphorescence and fluorescencence with remarkable emission yields in fluid solutions (e.g., see Ref. 31). Very recently, we have studied absorption spectra of benzil in various solvents. In contrast to the results obtained thereof (Ref. 32), no anomalous absorption intensification of BA was observed in hydrogen donating solvents. The environmental intensification scheme of BA thus seems to be close to the cases of acetone and cyclopentanone (Ref. 33). Reversely, no evidence of the reactions of hydration and methylation has not been obtained for benzil.

(Received August 8, 1988)

The electronic properties of charge-transfer (CT) complexes based on a new organic donor MTDTPY with TCNQ and *p*-benzoquinone derivatives (fluoranil (FLL), chloranil (CHL), bromanil (BRL), and DDQ) have been investigated by means of electrical conductivity, thermoelectric power, ESR, and band calculation. β-MTDTPY-TCNQ, MTDTPY-CHL, and MTDTPY-BRL show a metallic electrical conduction. MTDTPY-CHL and MTDTPY-BRL are the first organic metals among the CT complexes with *p*-benzoquinone derivatives. The metal-insulator (M-I) transition takes place around 110, 240, and 125 K for β-MTDTPY-TCNQ, MTDTPY-CHL, and MTDTPY-BRL, respectively. The sharp ESR linewidth and large anisotropy of the transfer integral for β-MTDTPY-TCNQ and MTDTPY-CHL suggest a one-dimensional electronic property. Thus, the M-I transition for these complexes is considered to be caused by a Peierls instability. MTDTPY-CHL undergoes a first-order phase transition in the semiconducting phase. This phase transition disappears by applying pressure.

The findings of metallic conductivity in TTF-TCNQ and superconductivity in $(TMTSF)_2PF_6$ have attracted the interest of many chemists and physicists dealing with organic conductors. These new phenomena have mainly been discovered in charge-transfer (CT) complexes based on TTF and its derivative donors. It is required to explore a new class of donors for the purpose of extending the range of research for organic conductors. It is well known that polycyclic aromatic hydrocarbons form CT complexes with various acceptors. Among them, a perylene-bromine complex is famous for the first organic semiconductor with a high conductivity of $\rho_{RT}\approx 1\ \Omega$ cm.[1] Thereafter, metallic conductivities down to 200 K have been observed in perylene-X (X=PF_6 and AsF_6) crystals obtained using an electrochemical technique.[2]

For the development of a new class of donors based on polycyclic aromatic hydrocarbons, we intended to introduce sulfur atoms in perylene and pyrene skeletons in order to increase the polarizability and decrease the ionization potential. 3,10-Dithiaperylene (DTPR) and 1,6-dithiapyrene (DTPY) were synthesized on the basis of such a molecular design. Most of their CT complexes were semiconductors, despite relatively high conductivities.[3] Bechgaard et al. prepared a single crystal of DTPY-TCNQ and found metallic conductivity down to 4 K.[4,5] In order to enhance the dimensionality through interchain interactions, we synthesized 2,7-bis(methylthio)-1,6-dithiapyrene (MTDTPY) substituted with two methylthio groups to DTPY. The molecular structure of MTDTPY is illustrated in Fig. 1. We reported on the synthesis and gave a brief of the physical properties of MTDTPY and their CT complexes in a previous paper,[6] which

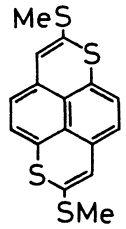

Fig. 1. Molecular structure of MTDTPY.

presents the metallic conductivities of MTDTPY complexes with TCNQ, chloranil (CHL), and bromanil (BRL). In this paper, we present the experimental results of electrical conductivity, thermoelectric power, ESR, and band calculation for MTDTPY complexes with TCNQ, fluoranil (FLL), CHL, BRL, and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) and discuss the electronic structures in relation to their dimensionalities. The difference in electronic properties between DTPY-TCNQ and MTDTPY-TCNQ is also discussed.

Experimental

Single crystals of MTDTPY with TCNQ were prepared by a diffusion method in a CH_3CN solution. Two kinds of black needle crystals were obtained as lustrous crystal and lusterless crystal. X-Ray studies have shown that each crystal phase has a different crystal structure, where the former (α-form) is monoclinic and the latter (β-form) is triclinic.[6] The black needle crystals of MTDTPY complexes with FLL, CHL, and BRL were prepared by a slow concentration of the mixed solutions of the donor and the acceptor in CH_2Cl_2. MTDTPY-DDQ was obtained as black needle crystal by a diffusion method in a C_6H_5CN solution. All the complexes were shown to have a composition of 1 : 1 from elemental analyses. The electrical conductivity for all complexes along the long crystal axis, which corresponds to the stacking axis for β-MTDTPY-TCNQ and MTDTPY-CHL, was meas-

† Present address: Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152.

ured by a two-probe method for α-MTDTPY-TCNQ and a four-probe method for the other complexes using gold paste as electrical contacts. The conductivity under pressure up to 10 kbar for MTDTPY-CHL was carried out by means of a BeCu clamp cell with a manganin pressure sensor using Idemitsu Daphne oil #7373 as a pressure fluid medium. The thermoelectric power for β-MTDTPY-TCNQ and MTDTPY-CHL along the long crystal axis was measured by the Chaikin and Kwak method.[7] An ESR measurement was performed using a conventional X-band spectrometer Varian E112 equipped with a continuous-flow helium cryostat Oxford ESR9. A static magnetic field was applied perpendicular to the long axis of the crystals with dimensions of about 1×0.1×0.03 mm^3 for β-MTDTPY-TCNQ and about 2×0.2×0.03 mm^3 for MTDTPY-CHL. The absolute value of the spin susceptibility was determined with DPPH as a reference. Molecular orbital calculations for β-MTDTPY-TCNQ and MTDTPY-CHL were performed by the extended Hückel method.[8,9] The intermolecular overlap integral was calculated between the conduction molecular orbitals which correspond to the highest occupied molecular orbital (HOMO) for a donor and the lowest unoccupied molecular orbital (LUMO) for an acceptor. The energy band structure was obtained using the tight-binding approximation.

Results

MTDTPY-TCNQ. α-MTDTPY-TCNQ shows a simple semiconductive behavior with a resistivity at room temperature ρ_{RT} of 2.7×10^5 Ω cm and an activation energy E_a of 0.26 eV. This result can be easily understood in terms of a mixed stack structure by an X-ray diffraction study and a small degree of charge transfer of 0.3—0.4 estimated by IR and X-ray procedures.[6] On the contrary, β-MTDTPY-TCNQ with a segregated stack structure and a partial CT of 0.6—0.7[6] shows a metallic conduction with $\rho_{RT}=9.5\times10^{-3}$ Ω cm (Fig. 2). The resistivity gradually decreases down to 275 K, where it shows a broad minimum. Below 150 K, the resistivity increases steeply with an inflection in the slope around 110 K. The activation energy below 90 K is estimated to be 0.056 eV. The temperature dependence of the thermoelectric power S for β-MTDTPY-TCNQ is also shown in Fig. 2. S is almost constant down to 200 K with a negative value of −8.5 μV K^{-1} at room temperature, and it then gradually increases. Its sign changes to a positive side around 150 K. Then, S shows a maximum at 110 K and decreases rapidly.

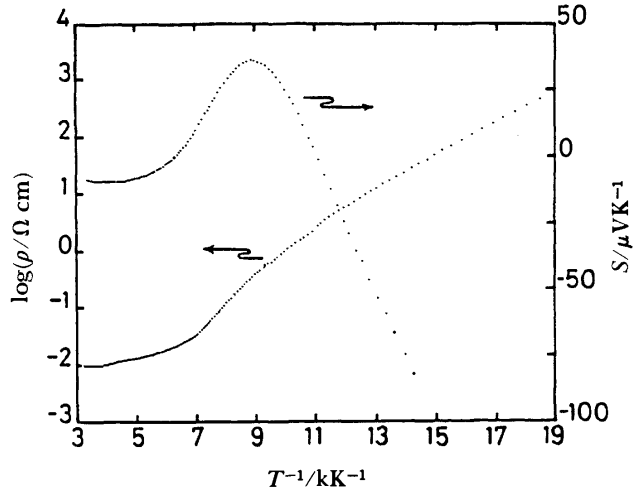

Fig. 2 .Temperature dependence of the resistivity and the thermoelectric power for β-MTDTPY-TCNQ.

β-MTDTPY-TCNQ shows a sharp ESR spectrum with a Lorentzian line shape with a g-value of 2.0024 and a linewidth of 0.87 G (1G=10^{-4} T) at room temperature. The g-value is independent of the temperature down to 110 K (Fig. 3). The ESR spectra split into two components below 110 K. The g-value of one component remains unchanged down to 50 K, around the g-value of the spectra above 110 K, while that of the other component gradually increases to 2.0034 at 50 K. Below 50 K, the two signal components approach each other. The signal with a smaller g-value is assigned to electron spins on TCNQ molecules, since its value is very close to 2.0025 of the reported value for $TCNQ^-$ anion in the LiTCNQ salt.[10] The signal with a larger g-value is assigned to electron spins on MTDTPY molecules, since the large g-shift ($\delta g=g-g_0$, g_0: g-value for free electron spin) is caused by a large spin-orbit coupling due to sulfur atoms in an MTDTPY molecule. The temperature dependence of the linewidth is also shown in Fig. 3. The linewidth decreases linearly with decreasing temperature in the metallic region. Below 110 K at the biginning of the splitting in the

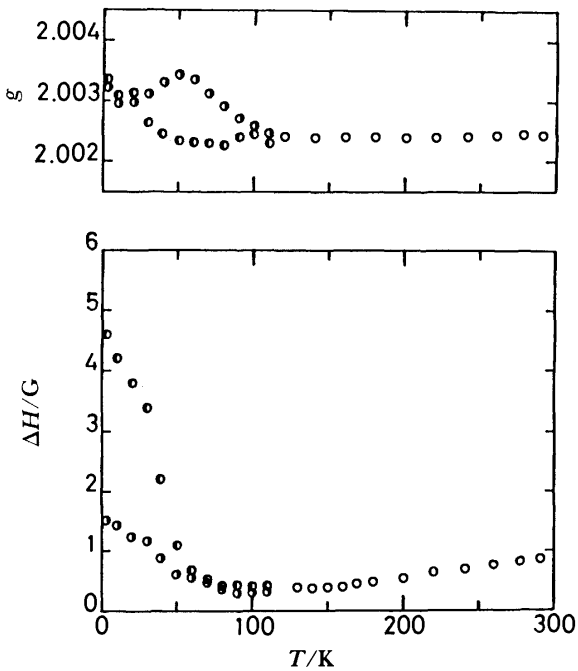

Fig. 3. Temperature dependence of the g-value and the linewidth (ΔH) in ESR spectra for β-MTDTPY-TCNQ. The half-open circles indicate the g-value and the linewidth of two components of the ESR spectra deconvoluted by a computer simulation (◑: MTDTPY, ●: TCNQ).

spectra, the linewidths for two signal components increase with lowering temperature. The signal for TCNQ chains becomes broader than that for MTDTPY chains, where 4.5 G for the former signal and 1.5 G for the latter signal at 3 K. Figure 4 shows the temperature dependence of the spin susceptibility χ_s for β-MTDTPY-TCNQ. χ_s gradually decreases in the metallic region and then decreases steeply below 150 K. Below 110 K, it decreases exponentially and has a Curie tail due to lattice irregularities below 50 K. The estimated concentrations of localized spins are about 0.04 and 0.07% for MTDTPY and TCNQ molecules, respectively.

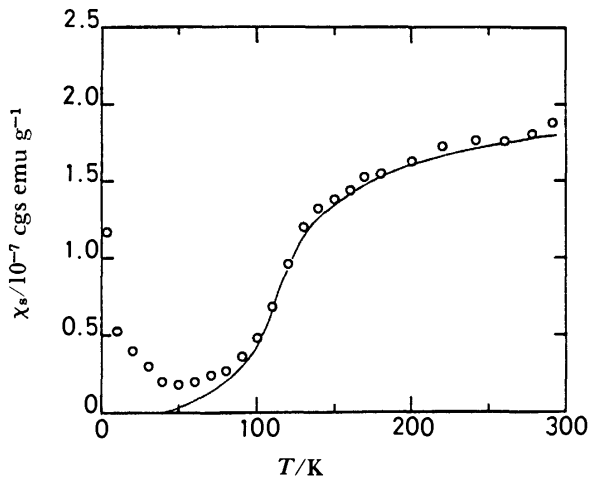

Fig. 4. Temperature dependence of the spin susceptibility (χ_s) for β-MTDTPY-TCNQ. The solid line is obtained after a subtraction of the Curie tail at low-temperatures.

Figure 5 shows the charge distribution of the HOMO in an MTDTPY molecule. The charge density on the inner sulfur atom is ten times as large as that on the outer sulfur atom. Table 1 summarizes the calculated intermolecular overlap integrals for the HOMO of MTDTPY, the LUMO of TCNQ, and the HOMO-LUMO between MTDTPY and TCNQ in β-MTDTPY-TCNQ. Both MTDTPY and TCNQ molecules have the largest overlap integrals along the stacking direction parallel to the c-axis. The ratio ($t_{\parallel}/t_{\perp}$) between intrachain and interchain transfer integrals is 24 and 44 for MTDTPY and TCNQ columns, respectively. According to IR and X-ray studies, β-MTDTPY-TCNQ has a degree of charge-transfer of 0.6—0.7.[6] The energy band structure under the degree of CT of 0.6 is shown in Fig. 6. The upper energy band corresponds to TCNQ, while the lower one corresponds to MTDTPY. Both MTDTPY and TCNQ sheets display completely one-dimensional band structures having an energy dispersion only along the stacking axis and almost flat Fermi surface.

a) The definition of the crystal axes is described in Ref. 6.

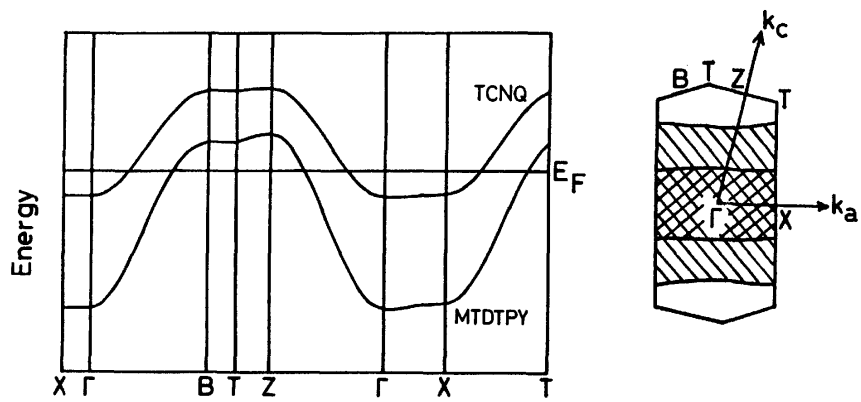

Fig. 6. Energy band structure and Fermi surface of β-MTDTPY-TCNQ. The regions shaded with // slashes and \\ slashes indicate the electron-like parts for MTDTPY and TCNQ, respectively.

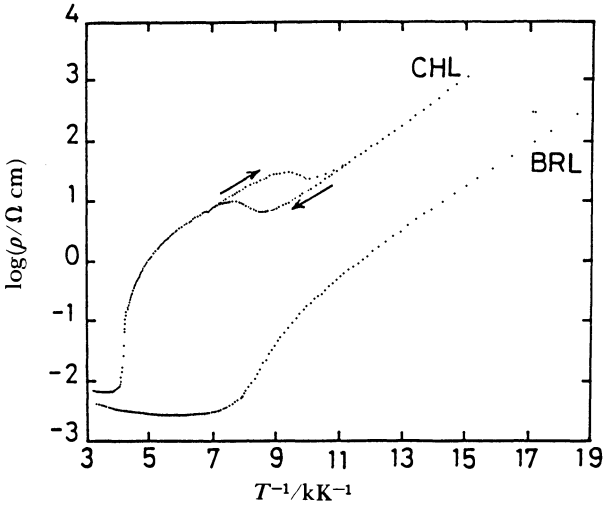

Fig. 7. Temperature dependence of the resistivities for MTDTPY-chloranil (CHL) and MTDTPY-bromanil (BRL). The arrows indicate the cooling and heating runs.

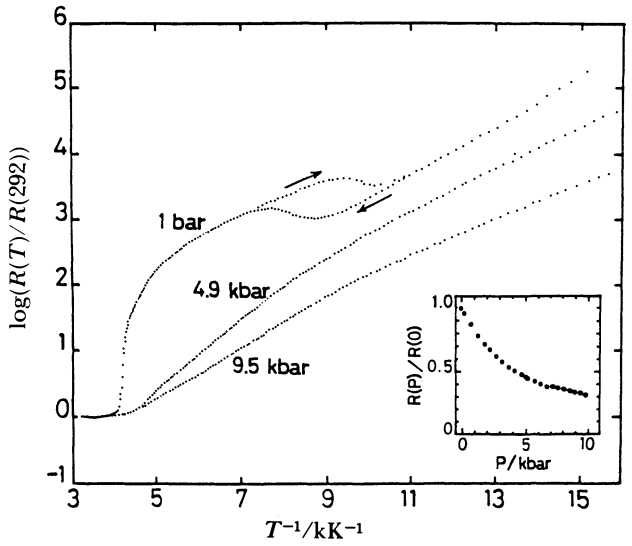

Fig. 8. Temperature dependence of the resistivities under 1 bar, 4.9 kbar, and 9.5 kbar for MTDTPY-chloranil. The inset shows the pressure dependence of the resistance at room temperature.

FLL shows a simple semiconductive behavior with E_a=0.13 eV in spite of fairly low resistivity with ρ_{RT}=5.5×10^{-2} Ω cm. MTDTPY-DDQ is also a semiconductor with ρ_{RT}=5.4 Ω cm and E_a=0.14 eV. On the other hand, MTDTPY-CHL shows a metallic conduction with ρ_{RT}=7.0×10^{-3} Ω cm (Fig. 7). The resistivity slowly decreases down to 280 K, where it shows a broad minimum. Then, the resistivity suddenly increases at 240 K. A hysteresis of the resistivity is observed around 110 K. The results of the resistivity under pressure for MTDTPY-CHL are shown in Fig. 8. The pressure dependence of the resistance at room temperature is shown in the inset. The resistance decreases monotonously with increasing pressure and the resistance at about 10 kbar becomes about one-third of that at 1 bar. Under 4.9 kbar, the metal-insulator transition temperature (T_{MI}) is lowered to 220 K compared with 240 K under 1 bar. What is noticeable is that the hysteresis of the resistivity disappears above this pressure. The activation energy E_a is 0.10 eV just below the M-I transition under 4.9 kbar. When the pressure increases to 9.5 kbar, T_{MI} is unchanged and E_a just below the M-I transition decreases to 0.078 eV due to a reduction of the band gap by pressure.

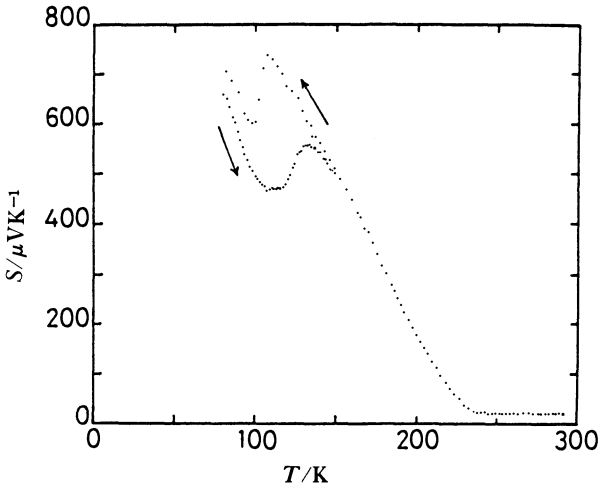

Fig. 9. Temperature dependence of the thermoelectric power for MTDTPY-chloranil. The arrows indicate the cooling and heating runs.

Figure 9 shows the temperature dependence of the thermoelectric power S for MTDTPY-CHL. S is steadily constant down to 240 K and then increases steeply. The hysteresis in the thermoelectric power is observed around the same temperature as that in the resistivity.

MTDTPY-CHL shows an ESR spectrum with a Lorentzian line shape with a g-value of 2.0059 and a linewidth of 2.2 G at room temperature. The splitting of the ESR spectra was not observed over the entire temperature region, unlike β-MTDTPY-TCNQ. The g-value is entirely independent of the temperature. Figure 10 shows the temperature dependence of the linewidth ΔH and the spin susceptibility χ_s for MTDTPY-CHL. ΔH gradually decreases down to about 120 K and then increases to 2.9 G at 3 K. χ_s gradually decreases down to 240 K, and below this temperature it decreases exponentially. Below 80 K, χ_s shows a Curie tail due to lattice irregularities in the crystal. The concentration of localized spins is about 0.03%.

Table 2 summarizes the intermolecular overlap integrals for MTDTPY-CHL. The overlap integrals along the stacking axis are largest for both donor and acceptor columns. $t_{\parallel}/t_{\perp}$ is 7 and 45 for MTDTPY and CHL columns, respectively. The degree of CT of MTDTPY-CHL has not been determined precisely.

From X-ray analysis, the bond lengths of C=C and C=O of a CHL molecule in MTDTPY-CHL are larger than those of a neutral CHL. These values are close to those in TMPD (*N,N,N',N'*-tetramethyl-1,4-phenylenediamine)-CHL with a degree of CT of ca. 0.6.[6] Figure 11 shows the energy band structure of MTDTPY-CHL, assuming that the degree of CT is 0.6. The energy bands for MTDTPY and CHL show a one-dimensional character with a strong dispersion along the stacking direction. They cross each other and the band gaps come out at the crossing points. This manner is in contrast with the parallel bands in

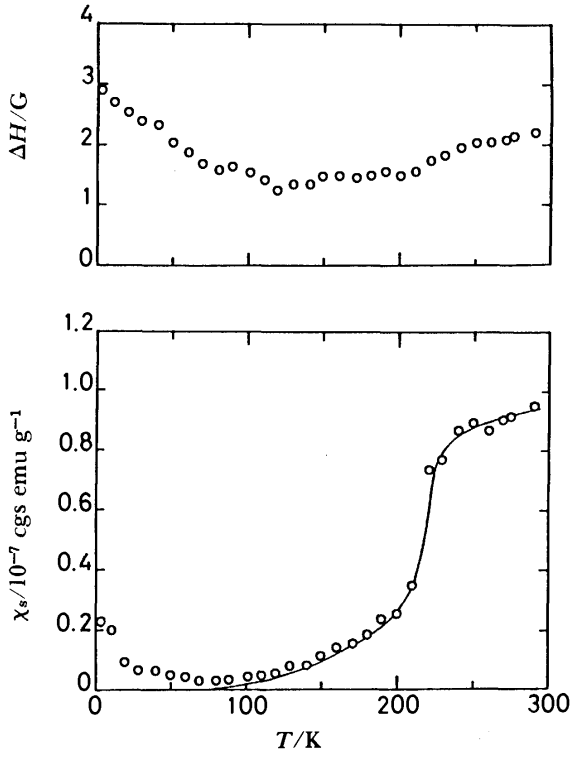

Fig. 10. Temperature dependence of the linewidth (ΔH) and the spin susceptibility (χ_s) for MTDTPY-chloranil. The solid line is obtained after a subtraction of the Curie tail at low-temperatures.

β-MTDTPY-TCNQ. The band structure is semimetallic with electron and hole carriers at the Fermi energy. Accordingly, electron and hole pockets coexist at the Fermi surface in the Brillouin zone.

Next, we present the results concerning the electrical property of MTDTPY-BRL. As shown in Fig. 7, MTDTPY-BRL has a metallic character down to 125 K. The resistivity at room temperature is 4.3×10^{-3} Ωcm, which is lower than 7.0×10^{-3} Ωcm of MTDTPY-CHL. The resistivity decreases gradually down to 175 K and shows a broad minimum, and then increases gradually. Thereafter, the resistivity increases sharply below 125 K, which suggests the occurrence of a metal-insulator transition. This transition temperature is lower compared with 240 K of MTDTPY-CHL. MTDTPY-BRL does not show any hysteresis in the resistivity, dissimilar to MTDTPY-CHL.

Discussion

β-MTDTPY-TCNQ. In a β-MTDTPY-TCNQ crystal, MTDTPY and TCNQ molecules are segregately stacked to form uniform columns along the c-axis with interplanar spacings of 3.48 Å for MTDTPY stacks and 3.27 Å for TCNQ stacks.[6] The degree of CT was evaluated to be 0.6—0.7 from the CN stretching frequency and the bond length in a TCNQ molecule. Such a segregated stack structure and partial CT, which are favorable for realizing organic metals, give a

Table 2. Overlap Integrals of the HOMO, the LUMO, and the HOMO-LUMO in MTDTPY-Chloranil

Molecules	Crystal direction[a]	Overlap integral $\times10^{-3}$
MTDTPY-MTDTPY	c	−6.81
MTDTPY-MTDTPY	a+b+c	−1.01

metallic conductivity. β-MTDTPY-TCNQ has a two-chain conducting system due to a partial CT from MTDTPY to TCNQ. A thermoelectric power measurement is useful for determining which carrier is dominant in electrical conduction. The negative thermoelectric power at high-temperature means that the electron carriers on TCNQ columns predominate in electrical conduction. The shift of its sign below 150 K implies that the sort of carriers which play the main role of electrical conduction changes from electron carriers on TCNQ columns to hole carriers on MTDTPY columns. The change of the main conduction path affects the electronic properties, since the resistivity starts to increase steeply below 150 K.

A band calculation presents a one-dimensional electronic structure with large anisotropy of the transfer integral between MTDTPY molecules and between TCNQ molecules, and weak intermolecular interaction between MTDTPY and TCNQ molecules. The sharp ESR linewidth of 0.87 G at room temperature is also suggestive of the one-dimensionality of this complex. The linewidth with the Lorentzian line shape can be expressed by the inverse of the spin-lattice relaxation time. The linewidth observed in a one-dimensional metal is extremely narrow, since spin-lattice relaxation through spin-orbit coupling based on the Elliott mechanism is prohibited due to the lack of interchain hopping for pure one-dimensional conductors.[11,12] The spin susceptibility gradually decreases in the metallic region, which deviates from temperature-independent Pauli paramagnetic behavior seen in simple metals. The temperature-dependent Pauli susceptibility has been observed in typical one-dimensional organic metal TTF-TCNQ.[13] The Pauli susceptibility χ_P is related to the density of states at the Fermi energy $N(E_F)$ in the equation $\chi_P=\mu_B{}^2N(E_F)$. For a one-dimensional system, a Peierls gap as a fluctuation already exists in the metallic state and reduces $N(E_F)$. Since the fluctuation is enhanced with lowering temperature, the spin susceptibility shows a decreasing behavior with temperature, even in the metallic region.

β-MTDTPY-TCNQ undergoes an M-I transition around 110 K, judging from an activated behavior in the spin susceptibility χ_s and a decrease proportional to T^{-1} in the thermoelectric power below this temperature. The exponential decrease in χ_s suggests a stabilization of a singlet ground state below T_c. The magnetic activation energy Δ is evaluated to be 0.042 eV with the equation $\chi_s=(C/T)\exp(-\Delta/T)$. This value is in good agreement with E_a of 0.056 eV in the resistivity. The thermoelectric power for intrinsic semiconductors can be approximately expressed in the Boltzmann-transport theory by

$$S = -\frac{k}{|e|}\left(\frac{b-1}{b+1}\cdot\frac{E_a}{kT}+A\right),$$

where b is the mobility ratio μ_e/μ_h between electron and hole carriers, and A is a constant term.[14] The mobility ratio b is calculated to be 2.8 from the slope below 110 K using E_a value of 0.056 eV in the resistivity. This fact means that electron carriers move faster than hole carriers in the semiconductive phase. In the metallic phase, the ESR spectra show a single absorption line due to motional narrowing through interchain coupling between donor and acceptor. Below T_c, the ESR spectra split into two signal components. The splittings of the spectra in the semiconducting phase are attributed to a reduction of the interchain electron hopping rate. The hopping rate is evaluated to be ca. 2×10^{-7} s at 110 K with an absorption line shape simulation for electron hopping model between two sites.[15,16] This rate is quite slow, which means that the interactions between MTDTPY and TCNQ columns are very weak. (The hopping rate for TTF-TCNQ metal is estimated to be 3.7×10^{-12} s from an NMR experiment by Soda et al.[17])

We now discuss the differences in the electronic properties between DTPY-TCNQ and β-MTDTPY-TCNQ. Both complexes possess segregated stacks of donor and acceptor molecules in their crystals. The significant difference is the manner of interatomic contact between an S atom in a donor molecule and an N atom in a TCNQ molecule. DTPY-TCNQ has a contact of 3.40 Å (van der Waals distance: 3.35 Å) between S atom with the high charge density and N atom,[4,5] while β-MTDTPY-TCNQ has a contact of 3.50 Å between the outer S atom with the low charge density and N atom.[6] According to our band calculation of DTPY-TCNQ, the intermolecular overlap integrals are -3.7×10^{-3} for DTPY stacks, 32.1×10^{-3} for TCNQ stacks, and -6.0×10^{-3} between DTPY and TCNQ stacks. Noticeably, the intermolecular overlapping between DTPY and TCNQ molecules is perceptibly large, which is comparable to that for DTPY stacks and is one-fifth of that for TCNQ stacks. The enhancement of the dimensionality through interchain interactions between DTPY and TCNQ stacks is considered to suppress the Peierls transition in the DTPY-TCNQ system. In the case of β-MTDTPY-TCNQ, the intermolecular interaction between MTDTPY and TCNQ stacks is very weak with a minute overlap integral. The marked one-dimensionality may give rise to the Peierls transition at a higher temperature.

MTDTPY-CHL. The electronic property in the metallic state of MTDTPY-CHL closely resembles that of β-MTDTPY-TCNQ. According to an X-ray diffraction study, the MTDTPY-CHL crystal possesses a uniform segregated stack structure with interplanar distances of 3.47 Å for MTDTPY stacks and 3.22 Å for CHL stacks.[6] The bond lengths of CHL in MTDTPY-CHL complex suggest a partial CT state. These facts realize a metallic conduction in this complex. A theoretical calculation exhibits the semimetal-

lic band structure with electron and hole carriers. The positive thermoelectric power of 20 $\mu V K^{-1}$ at room temperature tells that the electrical conduction is dominated by hole carriers. The one-dimensional nature of this complex is shown in the narrow ESR linewidth of 2.2 G at room temperature, the large $t_{\parallel}/t_{\perp}$ for both MTDTPY and CHL stacks and the weak interchain interaction between MTDTPY and CHL stacks. Hence, the Pauli susceptibility depends on the temperature, even in the metallic state, due to a one-dimensional fluctuation.

MTDTPY-CHL is considered to have a Peierls transition at 240 K, since below this temperature the resistivity increases abruptly and the thermoelectric power increases proportionally to T^{-1} and the spin susceptibility decreases in an activated manner with Δ=0.091 eV. Characteristically, MTDTPY-CHL shows a first-order phase transition with the hysteresis in the resistivity and the thermoelectric power around 110 K, which suggests the presence of some transformation in the crystal structure. This first-order phase transition is smeared out upon applying pressure above ca. 5 kbar.

Finally, we briefly mention of the relation between the conductivity and the ionicity of the complex. The ionicity of the complex is mainly goverened by the difference (I_p−E_A) between an ionization energy I_p of a donor and an electron affinity E_A of an acceptor. A small (I_p−E_A) gives an ionic complex, while a large one gives a neutral complex. A complex with a partial CT is realized under the condition (I_p−E_A)≈E_M (E_M: crystal Madelung energy).[18] As to *p*-benzoquinone derivatives used in this work, the ability of an acceptor increases in BRL≈CHL≪DDQ. MTDTPY-BRL and MTDTPY-CHL show high conductivities owing to a partial CT of ca. 0.6. MTDTPY-DDQ shows the highest resistivity, 5.4 Ωcm, since the ionicty of the complex approaches the ionic state with a decrease of (I_p−E_A).

Summary

α-MTDTPY-TCNQ, MTDTPY-FLL, and MTDTPY-DDQ are semiconductors, whereas β-MTDTPY-TCNQ, MTDTPY-CHL, and MTDTPY-BRL show metallic conductivity. X-Ray diffraction studies confirm that metallic conductions in β-MTDTPY-TCNQ and MTDTPY-CHL are owing to uniform segregated stacks and a partial charge-transfer state. MTDTPY-CHL and MTDTPY-BRL are the first organic metals among the *p*-benzoquinone derivatives complexes ever known. Theoretical calculations give one-dimensional electronic structures for β-MTDTPY-TCNQ and MTDTPY-CHL. ESR measurements also suggest one-dimensionality with a narrow linewidth and temperature-dependent Pauli susceptibility. Thus, the origin of the metal-insulator (M-I) transitions at 110 and 240 K for β-MTDTPY-TCNQ and MTDTPY-CHL, respectively, can be attributed to a Peierls instability. These complexes show novel behaviors in the semiconducting region. In the case of β-MTDTPY-TCNQ, the ESR spectra are separated into two components below T_{MI}. The splittings of the spectra can be explained by a slow interchain hopping rate of electrons between MTDTPY and TCNQ molecules. MTDTPY-CHL has a first-order phase transition around 110 K. This phase transition is easily suppressed by pressure above ca. 5 kbar. MTDTPY-BRL, without a first-order phase transition, shows a lower M-I transition temperature of 125 K.

β-MTDTPY-TCNQ and MTDTPY-CHL have two-dimensional networks in the crystals through interchain S-S contacts less than the van der Waals distance.[6] However, their electronic properties are one-dimensional, as presented in the results of ESR and band calculation. The selection of the other acceptors or another chemical modifications will be needed to achieve an intention for enhancing the dimensionality to stabilize a metallic state.

The authors are grateful to Dr. Shunji Bandow of Institute for Molecular Science for his helpful support in the ESR simulation.

A computer simulation method for gel filtration chromatography (GFC), based on plate theory and mass action law, is developed for rapidly self-associating systems and compared with asymptotic theory. For ovalbumin, a non-associable protein, whose elution volume increases linearly with increasing concentration, the leading boundary is predicted to be broader than the trailing. Computer simulations are used to estimate the aggregation numbers and the equilibrium constants for dimerization of carbonylhemoglobin and hexamerization of α-chymotrypsin. The concentration, C_{min}, at the plateau region of the trailing boundary is shown to be close to cmc by asymptotic theory. The present computer simulation and derivative GFC patterns serve to estimate monomer concentration and micellar size of surfactants from analysis of GFC data.

Gel filtration chromatography (GFC) is routinely used for separation of materials different in size and for estimation of the molecular weights of proteins and synthetic polymers. GFC patterns for self-associating or complex forming systems are often complicated and troublesome for the above purposes. An appropriate analysis of these systems, however, may provide useful information on molecular association. The dissociation of the hemoglobin subunits is an instance for such applications.[1] Since the assumption of a sharp (no broadening) boundary simplifies the analysis of complicated patterns for chemically reacting systems, this assumption (hereafter called asymptotic theory) has been used for analyses of GFC, sedimentation velocity,[2] and electrophoretic data. These analyses have established the stoichiometry of the reactions by using mass action law.[1-4] Furthermore, these transport properties are often represented as derivative patterns. These patterns have been analyzed by the asymptotic theory.[2-4]

The GFC method has also been used to investigate the aggregation properties of surfactants,[5] such as the aggregation number,[6] monomer concentration,[7,8] micellar size,[8-10] and mixed micelle formation.[11,12] However, since the aggregation number of surfactants is usually much larger than that of proteins, GFC elution curves of the surfactants have been analyzed on the basis of phase separation model intuitively,[8] by the asymptotic theory,[7] or by plate theory.[12,13] As a result, different analyses have been done for surfactants and proteins. For micellization of surfactants, mass action model is superior to the phase separation model; e.g., it is suggested by GFC that monomer concentration of a surfactant increases with increasing surfactant concentration above the critical micelle concentration (cmc).[7,8] Therefore the above-mentioned results for surfactants[5-13] should be analyzed in terms of the mass action model by reference with those of proteins. Furthermore, derivative GFC profiles often provide more detailed information than original profiles. No derivative GFC pattern except ours has been reported for surfactants.[10]

The major advantage of the asymptotic theory is that analytical solutions of the characteristic constants of self-associating systems are obtained from the elution curve and its derivative. Therefore this theory has been applied to surfactants and proteins.[1-7] Computer simulation procedures of transport properties (including GFC) of self-associating systems have been published.[14] These procedures require a number of parameters involved in column beds and materials used. Plate theory[15] based on the phase separation model has been applied to surfactants.[12,13] This theory is superior to the asymptotic theory, since the former predicts a more realistic profile than the latter. Another advantage of the plate theory over other theories[14] is that the adjustable parameter for the column characteristics is only the number of plates.

In the present work, we developed plate theory based on mass action model, demonstrated its usefulness for simulations of GFC profiles of proteins and surfactants, and revealed the scope and limitations of the asymptotic theory.

Computational Methods

Plate Theory. A gel column is assumed to be composed of n plates as shown schematically in Fig. 1. Each plate consists of the mobile and stationary phases. The total volume of the mobile phase equals to the void volume V_0 of the column. When a solution of volume of V_f is applied from the "zero-th" plate (the top) of the column, the mobile phase of volume V_f is flown down to the nearest neighboring plate throughout the column till another solution of the same volume flows from the n-th plate (the bottom). Then we assumed a rapid establishment of the partition equilibrium of the solute between the mobile and stationary phases at each plate.[12,13,15]

When the partition equilibrium has been established after addition of a solution of volume iV_f, the total amount of the solute at the j-th plate may be written as

$$(M_{i,j}+S_{i,j})V_f=(M_{i-1,j-1}+S_{i-1,j})V_f. \quad (1)$$

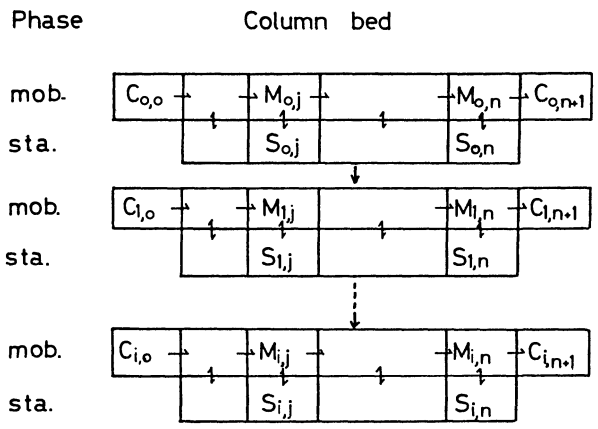

Fig. 1. Schematic elution process based on plate theory. The integers i and j indicate the numbers of transfer and plate, respectively.

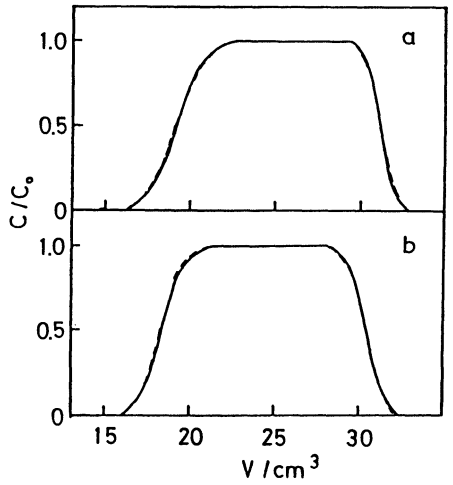

Fig. 2. Effects of concentration dependence of elution volumes upon the protein distribution for ovalbumin at (a) 12.0 g dm^{-3} and (b) 1.6 g dm^{-3}. The observed results (solid lines) are taken from Ref. 19 and the dashed lines are calculated from plate theory by using the following parameters; V_0=12.53 cm^3, n=250, and P=0.00638C_0+0.45092.

Here $M_{i,j}$ and $S_{i,j}$ are "concentrations" at the j-th plate in terms of the volume of the mobile phase (V_f). The same equilibration is made for all plates (j=1 to n). In Eq. 1, for the first plate (j=1) $M_{i-1,0}=C_{i-1,0}$ and for the n-th plate $M_{i-1,n}=C_{i,n+1}$. This procedure is repeated for different numbers of transfer (i=1 to i) starting from zero. The relation between $C_{i,n+1}$ and iV_f presents the theoretical elution curve. The partition ratio, P, of a solute between the stationary and mobile phases may be written as

$$P=S_{i,j}/M_{i,j}=(V_e-V_0)/V_0, \tag{2}$$

where V_e is the elution volume of the solute.

For analysis of GFC data two methods for charging a sample are used, viz., the small size (zonal) method and the large sample size (frontal) method.[16] The latter examples are shown in Fig. 2. When an enough volume of solution at concentration C_0 is charged, the solution of the same concentration C_0 appears on the elution curve. If a small volume of the sample is charged, the sample is diluted during elution in the column. Therefore, since the zonal method cannot be used for quantitative analysis of elution curves for self-associating systems,[9] we will consider only the frontal method. For the frontal method we may assume $C_{i,0}=C_0$ for $1\leqq i\leqq k$ and $C_{i,0}=0$ for $i>k$, where k is sufficiently large to produce the plateau region on the elution curve, as shown in Fig. 2.

For the self-associating system, monomer$\rightleftarrows m$-mer, we may write the equilibrium constant K in the mobile phase as

$$K=C_m/C_1^m, \tag{3}$$

where C_1 and C_m denote concentrations of the monomer and m-mer on a monomer basis. The total concentrations in the mobile and stationary phases may be written as

$$M_{i,j}=C_1+C_m=C_1+KC_1^m \tag{4}$$

and

$$S_{i,j}=P_1C_1+P_mC_m=P_1C_1+P_mKC_1^m, \tag{5}$$

where P_1 and P_m are the partition ratios for the monomer and m-mer.

Assuming appropriate values for V_0, n, P_1, P_m, K, m, and C_0, we can simulate the theoretical elution curve (C vs. V) and its first-derivative curve (dC/dV vs. V). The derivative curve provides useful information on self-associating systems.[4,10,17,18]

Asymptotic Theory. As Fig. 2 shows for the frontal method, the boundaries at the initiation (leading) and termination (trailing) of solute elution are diffuse. Approximately we may assume that the equivalent sharp boundary for the solute zone leading or trailing boundary is the first moment (centroid) of the elution profile and satisfies the relationships:

$$V_C=\int_0^{C_0} V\mathrm{d}C/C_0 \qquad \text{(leading boundary)} \tag{6}$$

and

$$V_C'=\int_0^{C_0} V\mathrm{d}C/C_0+S \qquad \text{(trailing boundary)}. \tag{7}$$

Here S is the charged volume of the sample. For these determinations the volume coordinate V is assigned a zero value when the leading boundary of the charged sample enters the column bed. This theory predicts the elution profile of a rectangle (C_0 in height and S in width) for the non-associating system.[4,16]

When this theory is applied to the self-associating system, monomer$\rightleftarrows m$-mer, we may determine the aggregation number m from the trailing boundary and the equilibrium constant K from either the leading or trailing boundary. At $m\geqq 3$, the derivative profile for the trailing boundary is expected to exhibit a min-

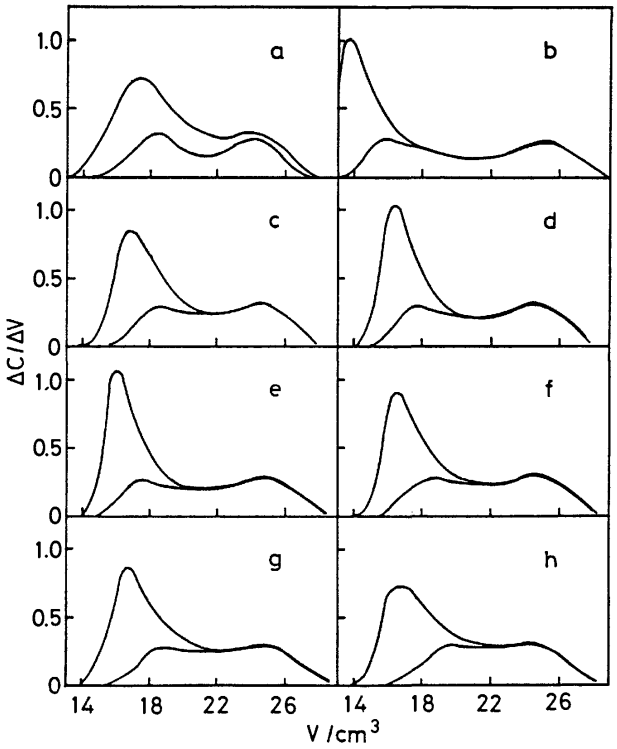

Fig. 3. Derivative chromatograms of α-chymotrypsin at concentrations of 5.0 g dm^{-3} (upper curve) and 2.4 g dm^{-3} (lower curve); Fig. a is observed[17] and Figs. b–h are calculated by using the parameters shown in Table 2.

imum (V_{min}) and two maxima ($V_{1p}>V_{mp}$), as shown in Fig. 3, and m and K may be evaluated from

$$m=(3V_{min}-V_1-2V_m)/(3V_{min}-2V_1-V_m) \quad (8)$$

and

$$K=(m-2)\{2(m^2-1)\}^{m-1}/[\{(m(2m-1)\}^m(C_{min})^{m-1}]. \quad (9)$$

Here C_{min} may be taken as the concentration corresponding to the minimum on the derivative curve and V_1 and V_m are the centroid elution volumes of the monomer and m-mer, respectively. At $m=2$, only one maximum (V_{max}') is expected for the derivative curve in the trailing boundary and K may be evaluated from

$$K=\lambda(m+\lambda)^{m-1}/(m^m C_e^{m-1}). \quad (10)$$

Here C_e may be taken as the concentration at the maximum and $\lambda=(V_1-V_{max}')/(V_{max}'-V_m)$.

For the leading boundary the centroid volume V_e may be written as

$$V_e=\alpha V_1+(1-\alpha)V_m, \quad (11)$$

where α is the weight fraction of monomeric species in the plateau region. Substitution of $C_1=C_0\alpha$ and $C_m=C_0(1-\alpha)$ into Eq. 3 yields

$$K=(1-\alpha)/(C_0^{m-1}\alpha^m), \quad (12)$$

where α may be taken as $(V_e-V_m)/(V_1-V_m)$ from Eq. 11.[3-5,16] Thus, the main advantage of the asymptotic theory over the plate theory is to provide the analytical solutions for m and K. However, the values of m and K estimated from the asymptotic theory may be used as a first approximation.

Results and Discussion

Concentration Dependence of Elution Volumes. Generally speaking, the elution volume increases with increasing solute concentration slightly.[16] In the case where the elution volume of a nonassociable solute increases with increasing concentration, the leading boundary becomes broader than the trailing one.[19] This elution pattern is the reverse found for self-associating solutes.[17]

Figure 2 shows the elution curves for ovalbumin at 1.6 g dm^{-3} and 12 g dm^{-3}. From such results V_e (and V_e') has been determined as a function of C_0:

$$V_e=18.18+0.080C_0. \quad (13)$$

In the experiments $S=12.0$ cm^3 and $V_0=12.53$ cm^3 (estimated in this work). Substitution of these values and Eq. 13 into Eq. 2 yields

$$P=0.00638C_0+0.45092. \quad (14)$$

Based on the plate theory by using P (Eq. 14), V_0 (12.53 cm^3), C_0 (1.6 or 12 g dm^{-3}) and $n=250$, we can simulate the elution curve. These theoretical curves are drawn by the dashed lines. At the low concentration of the protein, the leading and trailing boundaries are almost symmetric, whereas at the high concentration the leading boundary is broader than the trailing. These results are well reproduced, showing the utility of the plate theory to predict the shape of the elution pattern. Asymptotic theory always predicts a rectangular elution pattern for a non-associable solute. The results of Fig. 2 have also been explained by the Houghton theory.[19,20] This theory is applicable for the system where the concentration dependence of V_e is small.

Table 1. Comparison between the Observed and Theoretical Values of V_e for Dimerization of Human Carbonylhemoglobin as a Function of Concentration

C_0	V_{obsrd}[a]	V_{calc}[b]			
		Asymptotic theory		Plate theory	
mmol dm^{-3}	cm^3	K=0.25	K=0.31	K=0.25	K=0.31
0.3×10^{-6}	37.8	37.79	37.75	37.79	37.75

14	36.2	36.15	36.06	36.17	36.07

a) Taken from Ref. 3. b) $V_1=38.0$ cm^3, $V_m=34.9$ cm^3, and $V_0=15.6$ cm^3 were used. c) Average of two or three data.

Dimerization of Carbonylhemoglobin. The equilibrium constant of dimerization of human carbonylhemoglobin has been determined from Sephadex G-200 column experiments.[3] In Table 1 the observed and theoretical V_c values from the leading boundary are shown as a function of protein concentration. From the experiments at 10^{-8} mol dm^{-3} and 10^{-3} mol dm^{-3}, the V_c values for the monomer and dimer have been estimated to be 38.0 and 34.9 cm^3, respectively. These values may be regarded as independent of concentration. The void volume has been determined to be 15.6 cm^3 from V_c of tobaco mosaic virus.[3]

By substituting m=2, the observed values of V_m, V_1, and C_0, and an assumed K value in Eq. 12, we can calculate the theoretical V_c value for dimerization. In Table 1 the calculated V_c values for two K values are shown; a K value of 0.25 dm^3 mmol^{-1} has been reported by the original workers[3] and 0.31 dm^3 mmol^{-1} is our best fitted value. A K value of 0.28 dm^3 mmol^{-1} has been estimated from porous disk diffusion measurements for the same protein.[3] Agreement between the K values estimated from the two methods is very good, showing that these values are reliable.

From the plate theory we can calculated V_c by using the observed values of V_0, V_1, and V_m and assumed values of K and n. The V_c values for the cases n=200 and K=0.25 and 0.31 are included in Table 1. Agreement between the asymptotic and plate theories is excellent.

Hexamerization of Chymotrypsin at Neutral pH. Winzor and Scheraga have reported frontal elution patterns and their derivatives for α-chymotrypsin at pH 7.9.[17] In the elution curve the leading boundary was sharper than the trailing. This feature is common for self-associating systems and is in contrast with nonassociating concentration-dependent systems, as shown in Fig. 2. This characteristic has been explained by the asymptotic theory[16] and is also explicable on the basis of the plate theory (computed results are omitted).

The derivative trailing patterns for several protein concentrations have been reported.[17] The data at two concentrations of them, 5.0 and 2.8 g dm^{-3}, are shown in Fig. 3, since most of the main features appear herein. Extrapolation of the monomer elution volume to C_0=0 permits us to estimate a value of V_1=25.0 cm^3.[3] One of the main problems encountered in the use of GFC patterns to characterize self-associating systems is the absence of the definite value of V_m.[16] As expected from Table 2, one of the estimation methods is to choose the gel phase from which the polymer is excluded.[4] Then V_m may be identified with V_0, the void volume of the column bed. By this reasoning Ackers and Thompson have taken V_m as 11.9 cm^3.[3] Substituting these values in Eq. 8, together with an estimate of V_{min}=21.5 cm^3 (inferred from Fig. 3a), they estimated a value of m=6.[3] Furthermore a C_{min} value of 1.4 g dm^{-3} has been inferred[4] from the size of the more slowly migrating part of the bimodal trailing boundary reported by Winzor and Scheraga. By using these m and C_{min} values, a K value of 0.015 dm^{15} g^{-5} has been estimated from Eq. 9.[4] However, we should be alert to the above analysis since an estimated V_0 value has been used. In this connection it is noted that the sedimentation velocity patterns of Massey et al.[21] yielded a slightly higher estimate of C_{min} (1.8 g dm^{-3}), from which a value of K=0.004 dm^{15} g^{-5} has been obtained on the basis of asymptotic theory.[4]

Table 2. Seven Sets of the Parameters to Simulate Polymerization of α-Chymotrypsin at Neutral pH on the Basis of Plate Theory[a]

Set	m	K / g^{m-1} dm^{3m-3}	V_1 / cm^3	V_m / cm^3
b	6	0.015	25.0	11.9
c	6	0.010	23.9	15.5
d	6	0.010	23.9	14.0+0.298C_m
e	6	0.009	24.5	13.2+0.357C_m
f	5	0.014	24.5	13.2+0.357C_m
g	5	0.015	24.5	14.5
h	4	0.020	24.5	12.0+0.357C_m

a) n=100 is used for simulation.

Taking these uncertainties of K and V_m values into consideration, we made simulations for many sets of the values of m, V_1, V_m, K, and n. Seven sets of them are shown in Table 2. In the following calculations, we used n=100. In set b, the values used in the above analysis based on the asymptotic theory are employed. As Fig. 3b shows, the polymer peaks have much smaller V_m values than the observed ones (Fig. 3a). This discrepancy may be ascribed to inadequate values for V_m or V_0 (or both) suggested by Ackers and Thompson. The most uncertain parameter in this simulation is V_m. Therefore we considered larger V_m values and their concentration dependences (sets c—e). Determann and Nichel reported a calibration relation between molecular weights and elution volumes for many proteins from the literature.[22] From this relation we can estimate a value of V_0=13.1 cm^3. The V_m values in Table 2 are chosen by taking this V_0 value into consideration. As Figs. 3c—e show, the simulated polymer peak at 5 g m^{-3} is slightly sharper than the observed one. Therefore we considered smaller aggregation numbers. As Fig. 3f shows, the simulated curve at C_0=2.4 g dm^{-3} gives a slightly broader peak than the observed. A value of m=5 (Figs. 3f and 3g) gives as good fittings as m=6. None of the simulations (b—h) very well reproduce the experimental result (a). This discrepancy may be ascribed to the inaccuracy in both the experimental result and the plate theory. Asymptotic theory predicts unrealistic derivative patterns.[4]

Comparison between Asymptotic and Plate Theories. In application of Eq. 8 the practical upper limit

lies in the region $m<10$, since the denominator of Eq. 8 approaches experimental errors in the determination of the elution volume.[3] Therefore we made model calculations in the case of hexamerization to compare the two theories.

For these theories we used the same parameters, viz., V_1=230.0, V_m=130.0, V_0=100.0, and K=1. Concentration dependence of these parameters was neglected. Substitution of these values and m=6 in Eqs. 8 and 9 yielded V_{min}=203.3 and C_{min}=0.649. According to the asymptotic theory, these values should be independent of C_0. Furthermore V_c for the leading boundary can be calculated from Eq. 12 and is shown in Table 3.

From the plate theory, we also calculated the frontal elution curve and its derivative, by assuming n=100. From these curves we determined several characteristic values. These are shown in Table 3. The equilibrium monomer concentration C_1 was calculated from Eq. 3 and included herein. In this table V_{mp} and V_{lp} are the elution volumes at maxima ($V_{mp}<V_{lp}$) in the trailing boundary of the derivative curve.

The V_{min} value calculated from the plate theory increases with increasing concentration, in contrast with concentration independence expected from the asymptotic theory. The experimental V_{min} data on chymotrypsin support the prediction of the plate theory (e.g., see Fig. 3). Therefore the estimation of m from Eq. 8 may be generally regarded as a first approximation. The value of C_{min} from the plate theory is also concentration-dependent and is smaller than that of the asymptotic theory. It is notable that C_{min} is smaller than C_1. Combination of Eqs. 9 and 12 yields

$$C_e/C_0=\{(m-2)(2m-2)^{m-1}\alpha^m\}^{1/(m-1)}/\{(2m^2-m)(1-\alpha)\}^{1/(m-1)}. \quad (15)$$

At the limit $m\to\infty$

$$C_{min}\to C_0\alpha=C_1. \quad (16)$$

Here the equation $C_e=C_{min}$ is used since $m\geqq 3$. The same conclusion (Eq. 16) was obtained from the plate theory based on phase separation model for micelle formation.

Table 3 shows that the plate theory predicts the increase of V_1 and the decrease of V_m with increasing concentration. Concentration dependence of the elution volume of the monomer and m-mer does not always indicate size changes of these species. These results are consistent with the experimental data on chymotrypsin.[17]

The difference between the V_c values calculated from the two theories is 0.5, regardless of C_0. Since this difference (close to $V_0/2/n$) decreases with increases in n, we can conclude that the two theories predict the same V_c value for the leading boundary. This conclusion may justify applications of the asymptotic theory to leading boundary data for self-associating systems, such as hemoglobin[1] and carbonylhemoglobin (Table 1).

Implications to Micellization of Surfactants. The above results may be useful for quantitative analyses of GFC data on surfactants. The aggregation number of surfactants is usually larger than that of proteins, e.g., typically $m>50$. Hence phase separation model ($m=\infty$) has been used to analyze GFC data for pure and mixed surfactants.[11-13] This model is useful, but is less accurate than mass action model since m is a definite value. Furthermore, most of the GFC data on surfactants have been analyzed on the basis of the asymptotic theory.[6-8]

The monomer concentration C_1 for hexaethylene glycol dodecyl ether ($C_{12}E_6$) has been estimated by two interpretations of GFC data. First approach[7] used Eq. 11 and second approach assumed the equality of $C_{min}=C_1$.[8] As expected, the former approach yielded greater C_1 values than the latter.[7,8] However, both approaches must be reconsidered, as shown below.

According to Phillips' definition of the cmc, the cmc is a C_0 value which satisfies the equation $d^3(C_1+C_m/m)/dC_0^3=0$.[23] By using this definition and Eq. 3, we can obtain

$$\text{cmc}=[Km(2m-1)/(m-2)]^{1/(1-m)}. \quad (17)$$

This equation can be also obtained from the equation $d^3C_1/dC_0^3=0$.[24] On the other hand, we can write C_{min} at $m\geqq 3$ from Eq. 9 as

$$C_{min}=\left\{\frac{K[m(2m-1)]^m}{(m-2)[2(m^2-1)]^{m-1}}\right\}^{1/(1-m)} \quad (18)$$

When m is large enough, we can thus obtain

$$C_{min}\cong\text{cmc}\cong(2Km)^{1/(1-m)}. \quad (19)$$

This equation provides the physical meaning of C_{min} and a GFC method for cmc determination without interpolation of any property. The C_{min} value for $C_{12}E_6$ increased with increasing C_0, whereas the plate theory

Table 3. Comparison between Two Theories in Hexamerization[a]

C_0	C_1	Plate theory[b]					Asymptotic theory[c]
		C_{min}	V_{min}	V_{mp}[d]	V_{lp}[d]	V_c	V_c

a) V_1=230.0, V_m=130.0, V_0=100.0, and K=1 are used for calculations. b) n=100 is used. c) C_{min}=0.649 and V_{min}=203.3 were obtained from Eqs. 8 and 9, regardless of C_0. d) These values are the volumes at maxima in the derivative elution curves. e) Not observed.

predicts a slight decrease of C_{min} (e.g., see Table 3) and the asymptotic theory predicts the constancy. This discrepancy between theory and experiment may be ascribed to the increase of m with increasing C_0 for $C_{12}E_6$.[8,10]

In GFC, generally, large particles have smaller elution volumes than small ones. For self-associating systems, however, the elution volume depends on C_0 as well as size of species. As Fig. 3 shows, the polymer peak shifts toward smaller volume side with increasing C_0. This is not due to the increase of m. For $C_{12}E_6$, the elution volume of the micelle decreased with increasing C_0. This decrease has all been ascribed to the increase of m. The V_m value in Eq. 11 should correspond to true size of the micelle, and is not equal to the elution volume of the micelle at the concentration of the solution used.[10]

Conclusion

To demonstrate the scope and limitations of asymptotic theory and plate theory based on mass action law for self-associating systems, we investigated the elution patterns for ovalbumin (nonassociable protein), dimerization of carbonylhemoglobin, hexamerization of chymotrypsin, and micellization of surfactants. The asymptotic theory has an advantage of giving analytical expressions (V_c, C_{min}, V_{min}, and others) for elution patterns of self-associating systems. Equation 11, which was supported by the plate theory, gives the basis for the estimation of monomer concentrations of such systems. For surfactants C_{min} is very close to the cmc (Eq. 19). The plate theory has an advantage of requiring only a limited number of parameters over other theories.[14] It correctly predicts that the trailing boundary becomes sharper with increasing C_0 when the elution volume of a nonassociable solute increases linearly with C_0. Derivative elution profiles of self-associating systems were well simulated to make possible estimation of m and K and prediction of concentration dependence of V_{min} and C_{min}. These predictions will be useful to analyze experimental GFC data on surfactants.[18]

Photoelectrochemical Properties of Thin Films of Zinc Porphyrin Derivatives with Pyridyl Group

Kohshin TAKAHASHI,* Teruhisa KOMURA, and Hiroto IMANAGA
Department of Chemistry and Chemical Engineering, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920
(Received August 8, 1988)

The cathodic photocurrents of the film electrodes of $ZnPyP_3P(3)$ and $ZnPyP_3P(4)$, ($PyP_3P(n)$, 5-(2-, 3-, and 4-pyridyl)-10,15,20-triphenylporphyrin, where (n) denotes the position of free bond of pyridyl group), were almost four times larger than that of ZnTPP (TPP, 5,10,15,20-tetraphenylporphyrin) in 0.01 mol dm^{-3} quinhydrone aqueous solution at pH 5. On the other hand, the very small anodic photocurrent was observed with the film electrodes of ZnTPyP(3) and ZnTPyP(4) (TPyP(n),5,10,15,20-tetra(2-, 3-, and 4-pyridyl)porphyrin). The photoelectrochemical properties of $ZnPyP_3P(2)$ and ZnTPyP(2) were distinct from those of other structural isomers, but approximately similar to those of ZnTPP. The conductivities of $ZnPyP_3P(n)$ films were about three oders of magnitude larger than those of ZnTPP and ZnTPyP(n) films. It was found from the absorption and resonance Raman spectra that the pyridyl group in porphyrin coordinated to zinc in another porphyrin in the solid films as well as in toluene and dichloromethane solutions. The molecular arrangement of zinc porphyrin in the solid film probably influenced the photoelectrochemical properties and the conductivity.

Much attention has been drawn to the photoelectrochemical properties of metalloporphyrin films from the standpoint of the conversion of solar to chemical and/or electrical energy.[1-8] The cathodic photocurrent is observed with the metalloporphyrin film electrode because of the formation of the blocking contact between a p-type semiconductor such as the metalloporphyrin film and an electrolytic solution.[1] The photocurrent quantum yield increases with a decrease in the first ring oxidation potential of metalloporphyrins,[2-5] and also with an increase in π-π interactions between neighbouring molecules.[5] On the other hand, the film of 5,10,15,20-tetra(3-pyridyl)porphyrin acts as an n-type semiconductor.[6]

In the present paper, the photoelectrochemical properties of zinc porphyrins as illustrated in Fig. 1 are investigated in a quinhydrone solution and compared with those of ZnTPP. We report that the pyridyl group in zinc porphyrins plays an important role in the photoelectrochemical behavior because of its coordination to zinc in another porphyrin.

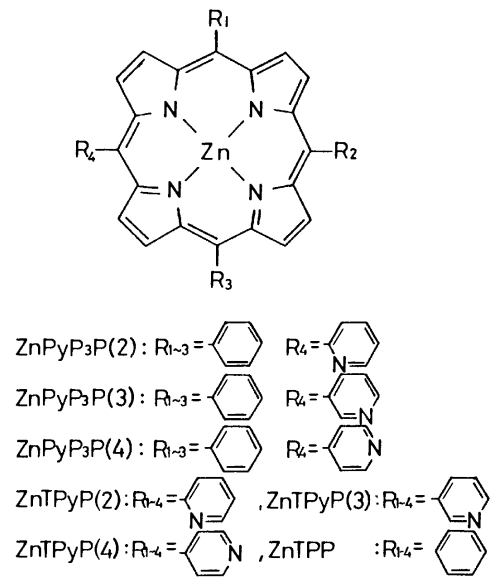

Fig. 1. Structures and abreviations of zinc porphyrins.

Experimental

H_2TPP, and $H_2PyP_3P(n)$ as well as $H_2TPyP(n)$ were synthesized and purified by the literature method.[9-11] Contamination with chlorine was oxidized by 2,3-dichloro-5,6-dicyano-*p*-benzoquinone.[12] ZnTPP and $ZnPyP_3P(n)$ as well as ZnTPyP(n) were synthesized by the literature method.[13] The products were purified by column chromatography on alumina. *p*-Benzoquinone was used after sublimation. Potassium chlorid and tetraethylammonium perchlorate (Et_4NClO_4) were used after double recrystallization from water. Toluene and dichloromethane were purified twice by distillation. *N*,*N*-Dimethylformamide (DMF) was twice distilled under reduced pressure in a N_2 atmosphere after dehydration by Molecular Sieves (4A 1/16) and barium oxide. Pyridine was twice distilled after dehydration by KOH. Other chemicals (reagent grade) were used without purification. All aqueous solutions were prepared with twice distilled water.

Absorption and second-derivative absorption spectra were taken on a Hitachi U-3210 spectrophotometer. The exciting radiation for resonance Raman spectra was provided by a Ar^+ laser (488 nm, Nippon Denki GSL3200). The scattering radiation was dispersed by a double monochromator (Jobin Yovon Ramanor HG2S), and detected by a cooled photomultiplier tube (Hamamatsu Photonics R464) and a photon-counter (Hamamatsu Photonics C1230). Porphyrin films were prepared on a Pt or glass plate by sublimation at pressure 4×10^{-3} Pa. Film electrodes were insulated from the electrolyte with epoxy resin except for the portion to be exposed to light (1 cm^2). A 500W xenon arc lamp (Ushio UXL-500D-O) was used as a white light source. The light was passed through a color filter (Toshiba L-39) and water (1 cm), and irradiated onto a film electrode in a N_2-purged solution thermostated at 25 °C. The light source for photo-

current action spectra measurements consisted of a 750 W halogen-tungsten lamp and a monochromator (Jasco CT-10). Monochromatic light intensity was measured with a chemical actinometer of $K[Cr(NH_3)_2(NCS)_4]$.[14] Photocurrent-voltage curves of the film electrodes were measured by using a potentiostat (Nikko Keisoku NPG-301), a potential sweeper (Nikko Keisoku NPG-2), and a three-electrode configuration. An X-Y plotter (Riken Denshi F-3B) was used to record current-voltage curves. A platinum wire (30 cm^2) was used as a counter electrode and a commercially available Ag/AgCl (in 3.33 M KCl aqueous solution, 1 M=1 mol dm^3) as the reference electrode. The conductivity of a surface-type cell of the solid film in vacuum was determined from a linear relationship between voltage and current. The measurements of current and voltage were performed by a picoammeter and a DC voltage source (Yokogawa Hewlet Packard 4140B). Cyclic voltammetry was performed in a N_2-purged solution by a Pt disk (diameter, 1 mm) as the working electrode, a Pt wire as the counter electrode, and Ag/0.01 M $AgNO_3$ in acetonitrile as the reference electrode. Half-wave potentials were measured with the scan rate of 100 mV s^{-1}, and as the average of cathodic and anodic peak potentials.

Results and Discussion

Dimerization of (ZnPyP$_3$P(n)) in Toluene and CH_2Cl_2. In nonbonding solvents such as toluene and CH_2Cl_2, $ZnPyP_3P(n)$ was slightly soluble and ZnTPyP(n) was insoluble, but in coordinating solvents such as DMF and pyridine, $ZnPyP_3P(n)$ and ZnTPyP(n) were soluble. The addition of pyridine to ZnTPP in toluene gave rise to a red shift of the absorption peak in the B and Q regions because of the formation of a monopyridine complex.[15] On the other hand, the absorption peak in the Q region of $ZnPyP_3P(2)$ in toluene was observed at a longer wavelength than that of ZnTPP in toluene, and the addition of pyridine gave rise to a blue shift of the Q band of $ZnPyP_3P(2)$. The Soret band of $ZnPyP_3P(2)$ in toluene and CH_2Cl_2 exhibited very broad spectra with very small molar extinction coefficients at the absorption peak (about 3×10^5 M^{-1} cm^{-1}) in comparison with those of other zinc porphyrins such as ZnTPP, $ZnPyP_3P(3)$ and $ZnPyP_3P(4)$, but in the solution containing pyridine, the sharp Soret band was observed with $ZnPyP_3P(2)$ as well as other zinc porphyrins. It was found from the second-derivative absorption spectra that the Soret band of $ZnPyP_3P(2)$ in CH_2Cl_2 consisted of two components and the peak wavelengths were 418 and 436 nm. The $Q_{1.0}$ bands of $ZnPyP_3P(n)$ in toluene and CH_2Cl_2 were broad. It was found from the second-derivative absorption spectra that the broad $Q_{1.0}$ bands consisted of two components and the peak wavelengths were near 550 and 565 nm. However, the absorption spectra in solution containing pyridine exhibited only one component near 560 nm. The absorption spectra of ZnTPP and $ZnPyP_3P(2)$ are shown in Fig. 2, and the absorption spectra features of zinc porphyrin derivatives are summarized in Table 1.

The absorption spectra of $ZnPyP_3P(n)$ in toluene distinctly changed in the range of 25 to 65 °C although that of ZnTPP hardly changed. Figure 3 shows the temperature-dependence of the absorption and second-

derivative spectra in the Q region of $ZnPyP_3P(2)$ in toluene. The absorption spectra indicated two isobestic points at 530 and 557 nm. The minima of second-derivative absorption spectra corresponded to the absorption peaks, and thus two absorption peaks were present in the $Q_{1,0}$ region of the toluene solution at relatively high temperature. The absorbances of the absorption peaks at 568 and 613 nm decreased with an increase in temperature, while that at 551 nm increased.

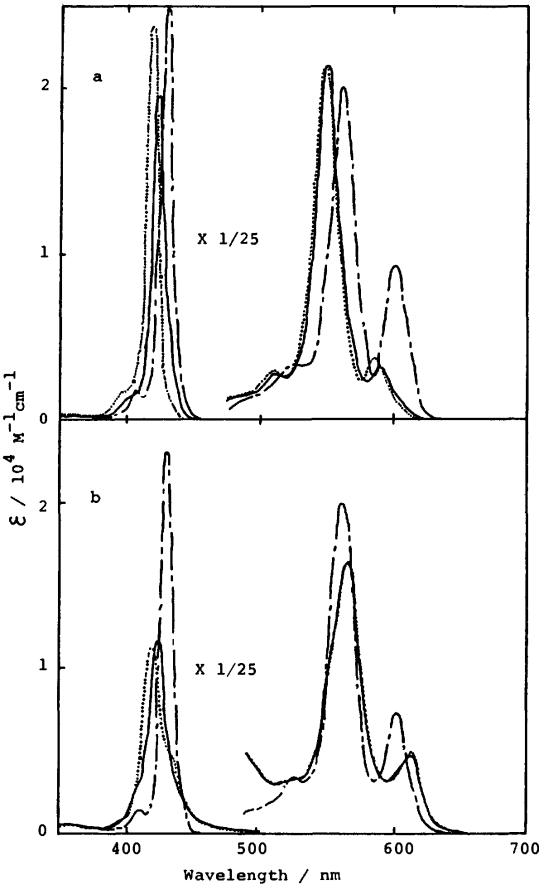

Fig. 2. Absorption spectra of ZnTPP(a) and $ZnPyP_3P(2)$(b) in toluene (——), CH_2Cl_2 (----), and toluene containing 1.2 M pyridine (-·-·-) at 25 °C.

The above results suggested that the pyridyl group in porphyrin coordinated to zinc in another porphyrin in nonbonding solvents such as toluene and CH_2Cl_2. However, the absorption spectra of $ZnPyP_3P(n)$ in toluene exhibited the temperature-dependence because the coordination bond between porphyrin molecules was relatively weak. Kirksey et al. demonstrated by means of ^1H NMR that the exchange between coordinated and uncoordinated pyridine was rapid in the solution of ZnTPP.[16] It was therefore presumed that the exchange between coordinated and uncoordinated $ZnPyP_3P(n)$ occurred in the toluene and CH_2Cl_2 solutions. Further, the dimer and monomer probably coexisted in the solution of $ZnPyP_3P(n)$ because the

absorption spectra at different temperatures passed through isobestic points. On the other hand, the Soret band of $ZnPyP_3P(2)$ in toluene and CH_2Cl_2 was especially broad in comparison with those of $ZnPyP_3P(3)$ and $ZnPyP_3P(4)$. Figure 4 shows typical schematic dimer models of $ZnPyP_3P(n)$. The π-π interaction between porphyrin rings in a dimer of $ZnPyP_3P(2)$ was probably large because only $ZnPyP_3P(2)$ can form a dimer of the face-to-face type. Therefore, the Soret band of $ZnPyP_3P(2)$ was broadened considerably.

The Photoelectrochemical Properties of Zinc Porphyrin Films. The photovoltaic effect was observed with the film electrodes of zinc porphyrin derivatives in a quinhydrone aqueous solution. Figure 5 shows the dependence of the short circuit photocurrent on the film thickness. The film electrodes of $ZnPyP_3P(3)$ and $ZnPyP_3P(4)$ exhibited the maximum cathodic photocurrent at the film thickness of 70 nm (about -12 $\mu A\ cm^{-2}$), and above 70 nm the photocurrent slightly decreased with an increase in film thickness. The film electrodes of $ZnPyP_3P(2)$, ZnTPyP(2), and ZnTPP exhibited the maximum cathodic photocurrent at the film thickness of 40—80 nm (-3—-8 $\mu A cm^{-2}$), and then the photocurrent suddenly decreased with an increase in film thickness. On the other hand, the film electrodes of ZnTPyP(3) and ZnTPyP(4) generated the very small anodic photocurrent (about 1 $\mu A cm^{-2}$). The dependence of the photocurrent of $ZnPyP_3P(2)$ and ZnTPyP(2) on the film thickness was distinct from that of other structural isomers, but approximately similar to that of ZnTPP. The film electrodes were consequently classified into three groups, (a) $ZnPyP_3P(3)$ and $ZnPyP_3P(4)$, (b) $ZnPyP_3P(2)$, ZnTPP, and ZnTPyP(2), (c) ZnTPyP(3) and ZnTPyP(4). The film electrode of each group indicated the different dependence of photocurrent on the film thickness because porphyrin of each group in the solid film may be oriented in different pattern. The molecular arrangement for porphyrin in the solid film will be discussed later. Figure 6 shows the photocurrent-voltage curves of the film electrodes of $ZnPyP_3P(4)$ and ZnTPyP(3) in 0.01 M quinone and hydroquinone solutions containing 0.2 M KCl at pH 5. The cathodic photocurrent was observed with $ZnPyP_3P(4)$ below the electrode potential of 0.5—0.6 V vs. AgCl/Ag in the quinone solution, and also the small anodic and cathodic photocurrents were observed in the hydroquinone solution because of the increase of conductivity of a zinc porphyrin film under irradiation. The onset potential of cathodic photocurrent in the quinone solution was larger than the reduction potential of quinone. The film electrodes of groups (a) and (b) indicated similar photocurrent-voltage curves to $ZnPyP_3P(4)$. These film electrodes consequently behaved as p-type semiconductors. The very thin film electrode of ZnTPyP(3) exhibited the anodic photocurrent above the electrode potential of -0.05 V vs. AgCl/Ag in the hydroquinone solution, and also the film electrode of ZnTPyP(4) (group (c)) indicated a similar photocurrent-voltage curve to ZnTPyP(3). Thus the film electrodes of group (c) exhibited different photocurrent-voltage curves from those of groups

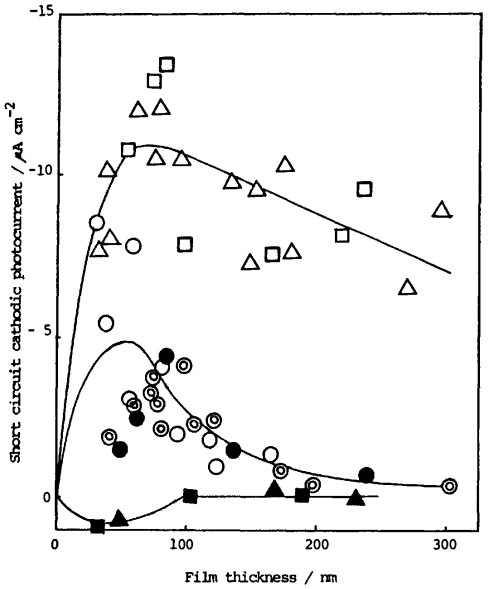

Fig. 5. Dependence of short circuit photocurrents of zinc porphyrins on film thickness in 0.01 M quinhydrone aqueous solution containing 0.2 M KCl at pH 5. A white light source was a 500 W xenon lamp.

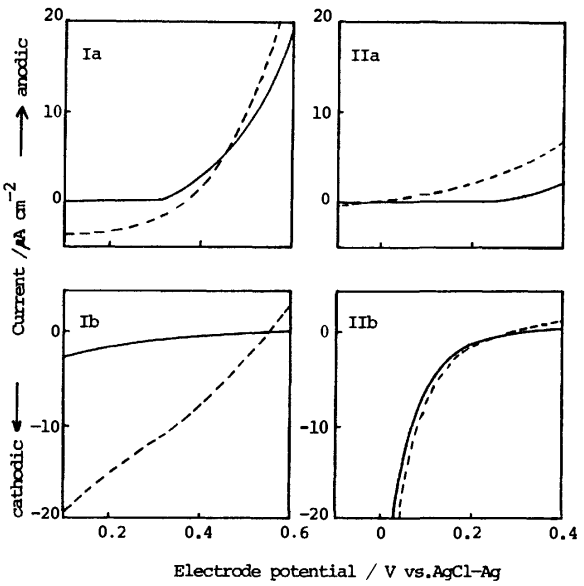

Fig. 6. Current-voltage curves of film electrodes of $ZnPyP_3P(4)$ (I, thickness 140 nm) and ZnTPyP(3) (II. thickness 30 nm) in 0.01 M hydroquinone(a) and quinone(b) aqueous solutions containing 0.2 M KCl at pH 5. A white light source was a 500 W xenon lamp.
——, in dark; ----, under irradiation.

(a) and (b). Figure 7 shows the short circuit photocurrent action spectrum of $ZnPyP_3P(4)$ film electrode in 0.01 M quinhydrone solution containing 0.2 M KCl at pH 5. The photocurrent was normalized in such a way that the incident light on the film electrode was constant (300 $\mu W\,cm^{-2}$). The photocurrent quantum yield of $ZnPyP_3P(4)$ was 0.16% at the irradiation wavelength of 440 nm. The action spectra were approximately the same as the absorption spectrum of the film. Therefore, the result suggested that the excited state of a zinc porphyrin molecule took part in the generation of the photocurrent.

The conductivities of $ZnPyP_3P(2)$, $ZnPyP_3P(3)$, and $ZnPyP_3P(4)$, which have only one pyridyl group in a molecule, were 8.3×10^{-11}, 6.6×10^{-10}, and 3.4×10^{-10} $S\,cm^{-1}$, respectively, and larger than that of ZnTPP (3×10^{-13} $S\,cm^{-1}$). On the other hand, the conductivities of ZnTPyP(n), which has four pyridyl groups in a molecule, were nearly equal to that of ZnTPP. The photoconductivity was observed with these films. The conductivities of zinc porphyrin films are summarized in Table 2. The pyridyl group in a porphyrin molecule was probably concerned with the molecular arrangement of porphyrin in the solid film because the conductivity was dependent on the number of the pyridyl group.

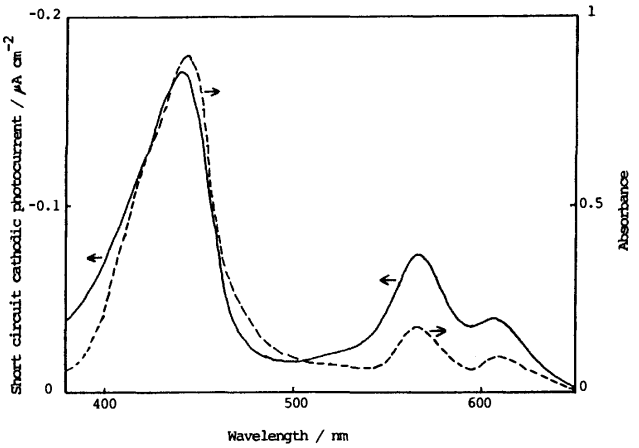

Fig. 7. Absorption(----) and photocurrent(——) action spectra of $ZnPyP_3P(4)$ film electrode (thickness 80 nm). An electrolytic solution was 0.01 M quinhydrone aqueous solution containing 0.2 MKCl at pH 5.

The photocurrent quantum yield of porphyrin film electrodes may be influenced by the following factors,[4] (i) the ease of charge carrier formation, (ii) packing of porphyrin molecules in the solid film, and (iii) the extent of π-π overlap between the porphyrin rings. The charge carrier may be easily formed with a decrease in the first ring oxidation potential of metalloporphyrins.[2-4] Table 3 summarizes the redox potentials of zinc porphyrin derivatives. ZnTPyP(n) was easily reduced but not oxidized in comparison with ZnTPP because of electron withdrawing of the pyridyl group in porphyrin. However, the redox potential of $ZnPyP_3P(n)$ was nearly equal to that of ZnTPP. Therefore, the difference of the photoelectrochemical properties of zinc porphyrin derivatives was not attributable to that of redox potentials. On the other hand, factors (ii) and (iii) presumably facilitated energy and electron transfers.[4]

The absorption peaks in the Q region of $ZnPyP_3P(n)$ and ZnTPyP(n) films were observed at longer wavelengths than that of a ZnTPP film (Table 1). The resonance Raman spectra were observed with zinc porphyrin films. We presumed that the signals in the range of 382 to 395 cm^{-1} were greatly ascribed to the stretching vibration of Zn-N (pyrole). The signals of $ZnPyP_3P(n)$ and ZnTPyP(n) were observed at lower wavenumbers than that of a ZnTPP film at 395 cm^{-1}

Table 2. Conductivities in the Dark (σ_d) and under Irradiation (σ_i)[a] of Zinc Porphyrin Films at Room Temperature

Porphyrin	σ_d/S cm^{-1}	σ_i/S cm^{-1}
ZnTPP	3×10^{-13}	9×10^{-12}
$ZnPyP_3P(2)$	8.3×10^{-11}	1.1×10^{-9}
$ZnPyP_3P(3)$	6.6×10^{-10}	5.3×10^{-9}
$ZnPyP_3P(4)$	3.4×10^{-10}	2.8×10^{-9}
ZnTPyP(2)	5×10^{-13}	1.5×10^{-11}
ZnTPyP(3)	8×10^{-13}	1.4×10^{-11}
ZnTPyP(4)	6×10^{-13}	4×10^{-12}

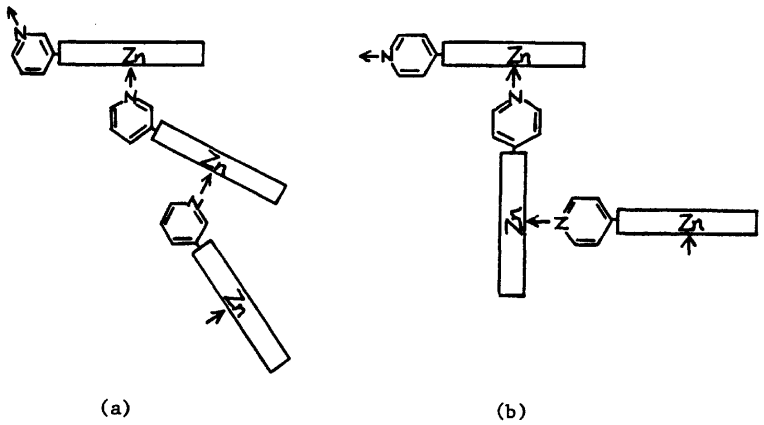

Fig. 8. Typical schematic models of molecular arrangement of $ZnPyP_3P(3)$ (a) and $ZnPyP_3P(4)$ (b) in a solid film.
▭ Denotes porphyrin ring, and N→Z coordination between Zn and N (pyridyl group).

(difference, 8—13 cm^{-1}). The results suggested that the pyridyl group in porphyrin coordinated to zinc in another porphyrin in the solid film as well as in the toluene and CH_2Cl_2 solutions. $ZnPyP_3P(3)$ and $ZnPyP_3P(4)$ can form linear polymers as shown in Fig. 8 because the porphyrins have only one pyridyl group in a molecule, but ZnTPyP(3) and ZnTPyP(4) can form cross-linked polymers because of four pyridyl groups in a molecule. A linear polymer in porphyrin film facilitated the energy and electron transfers, but a cross-linked polymer interfered these transfers. On the other hand, $ZnPyP_3P(2)$ and ZnTPyP(2) can not form a polymer because of dimer formation of the face-to-face type (Fig. 4) and/or the steric hindrance by the porphyrin ring although a oligomer can be formed. Therefore, the absorption peaks in the Soret region of $ZnPyP_3P(2)$ and ZnTPyP(2) films were observed at shorter wavelengths than those of other structural isomer films, and at the same wavelength as that of ZnTPP film (Table 1). The film electrodes of $ZnPyP_3P(2)$ and ZnTPyP(2) consequently exhibited the same photoelectrochemical properties as a ZnTPP film electrode.

High-resolution ^{13}C NMR spectra of a variety of (1→3)-β-D-glucans were recorded in the solid state after lyophilization from DMSO solution in order to study resulting conformations free from the triple-helix conformation. Lyophilization from DMSO solution caused conformational change of laminaran from *Laminaria species* ($\overline{Dp}$=38) from the triple helix to the oligomer-type form (form I). On the contrary, single-chain conformation (form II) of high molecular-weight curdlan was unchanged before and after lyophilization from DMSO solution. Further, DMSO induced conformational change of both single-chain (form II) and triple-helical (form III) conformations of acid-degraded curdlan ($\overline{Dp}$=14) to the form I. These findings support our view that the single-chain conformation is a major form in curdlan powder. We found that these three forms are distinguished by either the ^{13}C spin-lattice relaxation times (T_1^C's) of the laboratory frame or proton spin-lattice relaxation times in the rotating frame ($T_{1\rho}^H$). In particular, the form I was distinguishable from others by its prolonged T_1^C values (3.5—12 s) of C-6 carbon. In addition, the $T_{1\rho}^H$ of the triple helix of annealed curdlan was one order of magnitude longer than that of the single chain, reflecting their difference in the manner of molecular packing.

Linear or branched (1→3)-β-D-glucans function as structural components in cell walls of plant cell or microorganism and also act as reserve polysaccharides.[1] Such function depends on secondary structure of polysaccharides, single or triple helix or others, which is strongly affected by a number of structural and physical parameters such as the degree of polymerization and/or of branching, the extent of annealing, etc. In this connection, it appears that conformational elucidation of these polysaccharides in the solid state is essential for better understanding in their function as well as solution properties. However, conformational characterization by X-ray diffraction is not feasible for noncrystalline samples which are in many instances important in relation to their solution/gel properties.

For this purpose, we have demonstrated that high-resolution solid-state ^{13}C NMR spectroscopy can be conveniently used as an alternative means for characterization of secondary structures of a number of molecular systems,[2-4] because this method is equally applied to noncrystalline as well as crystalline substances. In fact, we demonstrated that three types of conformations, form I (laminaripentaose or laminariheptaose), form II (curdlan-type) and form III (laminarn-type), are readily distinguishable for (1→3)-β-D-glucans in the solid, on the basis of the conformation-dependent displacements of ^{13}C chemical shifts (up to 8 ppm).[5-7] Most of samples adopting these conformations were obtained by lyophilization or spray-drying, except for the annealed curdlan. Nevertheless, we found that conformations of the forms I and II are not always completely disordered as anticipated, because the C-3 ^{13}C NMR peaks of these forms (δ 91.2±0.4 and 89.6±0.5 for the forms I and II, respectively) are significantly displaced downfield by 5—6 ppm as compared from those of disordered state achieved in aqueous solution (δ 84.5).[5] This finding is in contrast to the case of amorphous (1→4)-α-D-glucans whose C-1 peak is so broad and shows a remarkably large chemical shift range (δ 94—106). Further, the weighted average of amorphous C-1 shift is similar to the chemical shift in aqueous solution.[8] Accordingly, these forms should be considered as locally ordered conformations as judged by ^{13}C NMR spectroscopy, which is sensitive to change of the local conformations, although they are disordered as determined by X-ray diffraction.

In this connection, we previously proposed the existence of *single*-helix[9] conformation in (1→3)-β-D-glucans of higher molecular-weight (curdlan and pachyman) obtained by spray-drying or lyophilization,[5,6] although this form might not be always straightforwardly acceptable, as an energetically stable form on the basis of calculation of molecular mechanics.[10] It is easily recognized, however, that this sort of form could be isolated as anhydrous form as a result of lyophilization. The evaluation of relative proportion of such single chains is very important to clarify molecular architecture of their resulting gel networks and gelation mechanism.[11-16] Then, it is expected that single-stranded chains can be obtained if (1→3)-β-D-glucans dissolved in DMSO solution are lyophilized, because DMSO molecules tend to disperse the triple-helical chains into single chains and to yield conformations free from the triple-helix form. As a result, direct evidence as to the existence of the single chain is available by means of the conformation-dependent ^{13}C chemical shifts.

In the present article, we aimed to study conformational change of various types of (1→3)-β-D-glucans lyophilized from DMSO solution. In addition, we measured ^{13}C spin-lattice relaxation times in the laboratory frame (T_1^C's)[17] and proton spin-lattice relaxation time in the rotating frame ($T_{1\rho}^H$'s)[18] to gain

information as to dynamic features of these three kinds of conformations.

Experimental

Curdlan powder ($\overline{Dp}$=540) was provided by Takeda Chemical Industries, Osaka, Japan. Laminaran from *Laminaria species* ($\overline{Dp}$=38) was purchased from Nutritional Biochemistry Corporation, Ohio, USA. Laminaran from *Eisenia araborea* was purchased from Nakarai Chemical Industry, Kyoto, Japan (Lot. No. M6G2275). Preparation of acid-degraded curdlan, $\overline{Dp}$=14, was described in our previous paper.[5] Laminaripentaose and laminariheptaose were purchased from Seikagaku Kogyo, Tokyo (Lot No. 407191). Lentinan and HA-β-glucan, branched (1→3)-β-D-glucans,[5] were generous gift from Dr. G. Chihara and Dr. Y. Yoshioka of this Institute, respectively. Lyophilized solid samples from DMSO solution were prepared by dissolving the glucans in DMSO or DMSO-d_6, followed by lyophilization in vacuo.

High-resolution ^{13}C NMR spectra in the solid state were recorded on a Bruker CXP-300 spectrometer by means of cross polarization-magic angle spinning (CP-MAS) method. Samples were contained in a ceramic rotor used for the double air-bearing type MAS system and spun as fast as 3—3.5 kHz. The duration of 90° pulse was 4 μs. The contact, sampling and repetition times were 1 ms, 20—30 ms, and 4 s, respectively. The ^{13}C chemical shifts were referred to TMS through the peak position of the glycine carboxyl group (δ 176.0).

The ^{13}C spin-lattice relaxation times were measured by the method of cross polarization enhancement, with an inversion of proton-spin temperature.[17] The peak intensity $M_{net}(t)$ at the delay time t after turning off the ^{13}C H_1 field decays exponentially from its initial value, $2M_{cp}(0)$ as shown by Eq. 1,

$$M_{net}(t)=2M_{cp}(0)\exp(-t/T_1^C) \quad (1)$$

Thus, the T_1^C values were obtained by a semilog plot of the peak-intensity against the delay time t. Carbon-resolved proton spin-lattice relaxation times in the rotating frame ($T_{1\rho}^H$'s) were obtained from the exponential decrease in ^{13}C NMR peak-intensity of longer contact time.[18] Namely, the ^{13}C peak-intensity $M(t)$ is given by

$$M(t)\approx M_0\exp(-t/T_{1\rho}^H)/(1-T_{CH}/T_{1\rho}^H) \quad (2)$$

where M_0 and T_{CH} stand for the maximum peak-intensity and cross polarization relaxation time, respectively. Thus, we obtained the $T_{1\rho}^H$ values from a semilog plot of $M(t)$ vs. t.

The proton spin-lattice relaxation times of the laboratory frame (T_1^H's) were measured by the pulse sequence via ^{13}C CP-MAS, in which 180° pulse and variable delay time were inserted prior to standard cross polarization.[19] So, the T_1^H values were obtained by a semilog plot of ^{13}C NMR intensity vs. t, as in a similar manner to the inversion-recovery measurement in liquid state.

Results

Figure 1 shows that the C-3 ^{13}C NMR peak of laminaran from *Laminaria species* lyophilized from DMSO solution (δ 90.8) (Fig. 1B) is displaced downfield by 3.9 ppm from that of untreated sample[6] (δ 86.9; form III, triple helix) (Fig. 1A). These ^{13}C chemical shifts of (1→3)-β-D-glucans in the solid state were assigned on the basis of the data recorded in DMSO-d_6 solution, as summarized in Table 1. The relative peak-positions

of the C-5 and C-2 carbons in the form III were previously confirmed by measurements of the ^{13}C spin-lattice relaxation times of the laboratory frame,[6] although these are obscured in the form II due to overlap of peaks. The C-3 NMR peak-position of laminaran lyophilized from DMSO solution is very close to that of the form II (single-chain conformation; δ 89.6±0.5[5]) but is resonated slightly at a low-field position (90.8 ppm), corresponding to that of the form I[5,6] (δ 91.2±0.4) (Table 1). In contrast to the above-mentioned water-soluble species, the ^{13}C NMR peak-positions of water-insoluble laminaran from *Eisenia araborea* (Fig. 1C) are similar to those of curdlan powder (form II; Fig. 2B), although the individual peaks of the former were considerably broadened as compared with those of the latter, reflecting the enhancd extent of disorder. Figure 2 illustrates the ^{13}C NMR spectra of curdlan and its acid-degraded fraction ($\overline{Dp}$=14) lyophilized from DMSO solution, together with those of annealed curdlan (at 180°) and curdlan powder as reported previously.[5,6] Again, the ^{13}C NMR spectrum of acid-degraded fraction ($\overline{Dp}$=14) lyophilized from DMSO solution is found to be very similar to that of laminaripentaose or laminariheptaose (form I), as judged from the C-3 peak-positions and the splitting pattern of the C-5, C-2, and C-4 peaks (Fig. 2D and 2E). However, the ^{13}C NMR pattern of curdlan powder (high molecular-weight) is unchanged

before and after lyophilization from DMSO solution (form II, Figs. 2B and 2C). Obviously, the ^{13}C NMR pattern of the triple-helix (form III) is readily distinguishable from those of the forms I and II. The DMSO-induced conformational change of (1→3)-β-D-glucans as described above was summarized in Table 2.

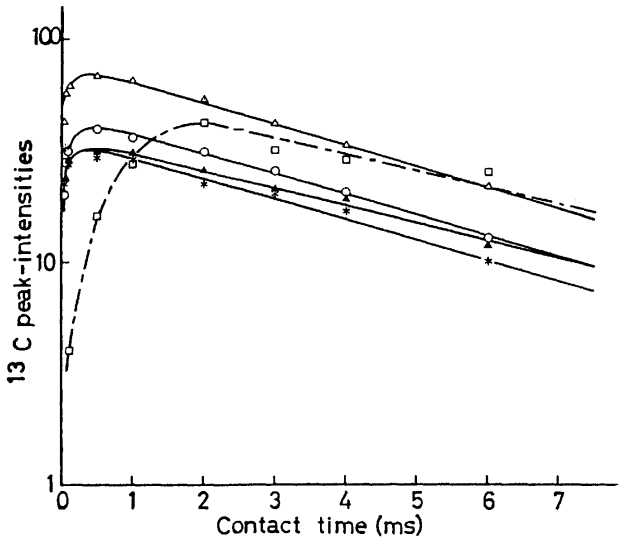

Fig. 5. Plot of the ^{13}C peak-intensities of curdlan lyophilized from DMSO against the contact time: (○) C-1; (*) C-3; (△) C-5,2; (●) C-6; (□) CH_3

As demonstrated in Fig. 3, the methyl ^{13}C NMR signal of perdeuterated DMSO is clearly visible (with approximate 30% peak-intensity as compared with that of protonated DMSO: see Figs. 3B and C) in spite of the absence of nearby protons. The peak-intensity of the methyl signal is enhanced by increasing the contact time from 1 ms to 2 ms (Fig. 3A). Figure 4 illustrates a typical stacked plot of the ^{13}C NMR spectra of curdlan lyophilized from DMSO solution for measurements of the ^{13}C spin-lattice relaxation times. It is evident from Fig. 4 that the methyl, C-6 and other ^{13}C signals decay with different time constant. The T_1^C values based on these stacked plots were summarized in Table 3.

Figure 5 illustrates a typical plot of the ^{13}C peak-intensity vs. the contact time for curdlan lyophilized from DMSO solution. The maximum peak-intensity of curdlan polymer was achieved at the contact time of 500 μs, whereas the maximum peak of DMSO was at 2 ms. Carbon-resolved $T_{1\rho}^H$ and T_1^H values were summarized in Table 4.

Discussion

Conformation of (1→3)-β-D-Glucans Lyophilized from DMSO Solution. Linear (1→3)-β-D-glucans are not soluble in aqueous media when the degree of polymerization ($\overline{Dp}$) is larger than 14.[20] This is a

consequence of adopting regular secondary structure which causes aggregation of polymer chains in aqueous media. In particular, we previously showed that (1→3)-β-D-glucans with $\overline{Dp}$=14—131 take considerable fraction of the triple helix conformation (ca. 40%).[5] On the contrary, relative fraction of the triple helix is reduced to less than 10%[5] for the glucans with $\overline{Dp}$ larger than ca. 200, which possess gel-formig ability.[20] Branched glucans such as lentinan and schizophyllan, on the other hand, form soft gel when the glucans of higher concentration are dissolved in aqueous media.[21] In any cases, ^{13}C NMR peak-intensity of these gel samples is suppressed partially or completely,[21] depending on the extent of polymer chains participated in formation of the triple helix.

On the other hand, full peak-area is observed in DMSO solution due to complete disruption of the triple-helix conformation.[22] As a result, the high-field shoulder or peak at δ 87.0 arising from the triple-helix coformation (form III) (approximately 10, 40, and 100% contribution for curdlan, acid-degraded fraction ($\overline{Dp}$=14), and laminaran, respectively) disappeared almost completely for preparations lyophilized from DMSO solution. In fact, (1→3)-β-D-glucans take effectively disordered conformation in DMSO solution, as substantiated from the displacement of peaks as well as relaxation parameters.[22] This view was also supported by the data of light scattering, viscosity and refractometry as applied to DMSO solution of schizophyllan, a branched glucan.[23,24]

Nevertheless, it is interesting to note that the lyophilized samples from DMSO solution do not necessarily take completly disordered conformation but adopt local regular secondary forms, either the forms I or II, depending on their chain-lengths, as judged from the peak-position of the C-3 signal which exhibits conformation-dependent displacement (see Figs. 1 and 2).[3-7] In general, lyophilization results in retaining ordered solution conformation in the solid state, if solvent molecules do not play dominant role to adopt ordered conformation in solution, as demonstrated previously for a number of sequential polypeptides and silk fibroin.[25,26] On the contrary, the present finding indicates that rather regular secondary structure (at least as viewed as a local conformation) is formed during the course of freezing followed by lyophilization, even if solution conformation is completely disordered as in DMSO solution. This situation is not unexpected, because conformational freezing around the minimum conformational energy could occur during the freezing step of lyophilization. Similar result was obtained for formation of silk I-like form by lyophilization from disordered aqueous fibroin solution (unpublished). As summarized in Table 2, achieved conformations differ as in the single chain or form I, depending on $\overline{Dp}$ of the glucans. It is emphasized that the latter form is also single-stranded by taking the condition for formation into account. In any cases, the present result demonstrates that DMSO causes conformational change of (1→3)-β-D-glucans from the triple helix to the form I or form II (single chain) These findings clearly support our view about the existence of the single chains in gel-forming linear glucans such as curdlan. On the contrary, the reverse conformational change from the single chain to triple helix is associated with hydration or hydration/annealing of samples, as illustrated schematically in Fig. 6. In other word, it is seen that the present conformational transitions are mainly caused by either hydration or dehydration process.

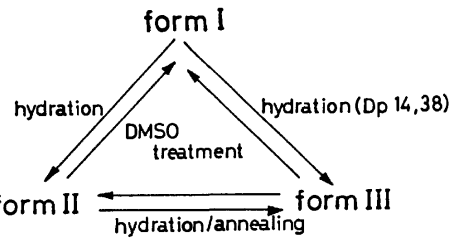

Fig. 6. Schematic representation of conformational changes.

It is interesting that DMSO molecules are always present in lyophilized samples from DMSO solution (less than 1/2 DMSO molecules per single residue), as seen by the methyl ^{13}C NMR signal from DMSO (Figs. 1—3). This is again true for the ^{13}C NMR peak of DMSO-d_6, in spite of the absence of nearby proton. This means that build-up of the DMSO signal is caused by intermolecular cross-polarization with protons from the glucan due to short proton-carbon distance (the order of 10 Å or less).[27]

Conformational Characterization by Spin-Lattice Relaxation Times. As pointed out previously, noncrystalline samples characterized by X-ray diffraction are not necessarily motionally disordered, because there appears no distinction of the ^{13}C T_1 values between curdlan powder and annealed curdlan[6] (see Table 3). In many instances, it appears that the presence of methyl or hydroxymethyl groups, undergoing rapid reorientational motions with correlation time at the order of 10^{-8} s, strongly affects the spin-lattice relaxation times of nearby carbons due to dipolar coupling, instead of slow overall motions ineffective to the T_1 process of the laboratory frame.[6,28-30] In fact, very long T_1^C values (50—800 s) were reported for highly crystalline cellulose samples where there exists no rapid reorientation in the C-6 hydroxymethyl groups.[31,32] Thus, the T_1^C values of the C-4 and C-5 carbons in the single-chain (form II) and triple-helical (form III) conformations are appreciably shortened by the dipolar couplings to the C-6 hydroxymethyl protons undergoing rapid internal rotation (Table 3),[6] since the extent of the dipolar couplings is proportional to r^{-6} where r is the interatomic distance. On the contrary, the corresponding C-6 T_1^C values in the oligomer-type form (form I) (3.5—12 s) are much

longer than those (1.0—1.6 s) of the above-mentioned polymers adopting the forms II and III. Therefore, the T_1^C values of the oligomers are generally longer than those of the polymer samples. For this, it is tempted to explain that this is simply caused by difference in molecular packing. However, these two types of samples were not obtained by crystallization but by lyophilization. Thus, it is reasonable to assume that conformation of the olilgomer-type (form I) is altered, especially at the site of C-6 hydroxymethyl group, from the single-chain conformation. In this connection, it is worthwhile to take into account the plausible conformational diversity at C-6 as viewed from the C-6 ^{13}C chemical shifts which are sensitive to C-6 conformation (i.e. tg, gt, or gg).[33,34] No such differences, however, are found for the spectra and therefore there is no evidence for conformational diversity at C-6. Thus, the longer T_1^C values for the oligomers may reflect a closer-packed, more immobile local structure.

Interestingly, very short ^{13}C spin-lattice relaxation times (0.4—0.6 s) arose from the methyl carbons of DMSO molecules which undergo rapid rotational reorientation in the solid state (Table 3). It is rather surprising to note, however, that the presence of such rapid motion of the methyl groups in DMSO is not effective for shortening of the T_1^C's of nearby carbons from the glucans as a fast relaxation center for dipolar couplings. In fact, there appear no significant differences in the T_1^C values between samples with and without DMSO. The most probable explanation is that DMSO molecules are not closely located at a short (2—3 Å) distance to any of carbons in the glucans, as an effective center for further shortening of the T_1^C values, even if they are bound to either the hydroxyl groups at the C-2, C-4, or C-5 carbons.

In contrast, only averaged values are observed for both proton spin-lattice relaxation times in the laboratory and rotational frame due to efficient spin diffusion[35] (Table 4). The $T_{1\rho}^H$ values of the single-chain (1→3)-β-D-glucans are almost the same among three kinds of glucans (4—5 ms), irrespective of differences in the primary structures. However, the $T_{1\rho}^H$'s of triple-helical annealed curdlan are almost one order of magnitude longer than those of the single-chain conformation. In the case of a branched glucan adopting the triple helix (HA-β-glucan), the $T_{1\rho}^H$ values are not substantially prolonged as in the annealed curdlan but are still prolonged as compared with those of the single-chain glucans (Table 4). Such distinction seems to be accounted for by differences in molecular packing: the latter molecules are not crystalline but lyophilized. In general, the T_1^H's are sensitive to spatially dependent proton-proton spin diffusion as well as spectral density of ^1H dipolar modulation. In this connection, it appears that the above-mentioned difference between the triple and single helix is a consequence of differential motional state rather than spin-diffusion process.

Conclusion

We have shown that (1→3)-β-D-glucans lyophilized from DMSO solution undergo substantial conformational change from the triple helix to single-chain or oligomer-type form, depending on their chain lengths. The present finding supports our view about the existence of the single chains in gel-forming high molecular-weight (1→3)-β-D-glucans. Further, we found that three types of conformations are distinguishable by either ^{13}C spin-lattice relaxation times in the laboratory frame or proton spin-lattice relaxation times in the rotating frame.

The authors are grateful to Drs. Goro Chihara and Yûko Yoshioka for their generous gift of lentinan and HA-β-glucan, respectively.

9) In our previous series of papers,[5-7] form II conformation was ascribed to the "single helix" form based on the similarity of peak positions between the powder and gel sample. However, we found on the basis of ^{13}C NMR data that the single-helix conformation as seen in the gel state is the same as that of the "swollen form" (A. J. Stipanovic and P. J. Giammatteo, "Industrial Polysaccharides: Genetic Engineering, Structure/Property Relations and Applications," ed by M. Yalpani, Elsevier, Amsterdam, (1987), p. 281), rather than the form II (to be published). For this reason, it is more appropriate to ascribe the form II to "single chain" form.

16) It was shown that intense ^{13}CNMR signals are visible (70—80%) in curdlan gel at the temperature of swelling (54 °C; translucent low set gel) by conventional high-resolution spectrometer (Ref. 11). The conformation of such a portion is not a random coil but an ordered form (single helix) with increased flexibilty of chains as viewed from the significant displacements of the C-3 signals from those of aqueous solution and condition of acquisition of spectra, in contrast to the cases of a variety of gels formed by chemically cross-linked synthetic polymers. This means that major conformation of starting curdlan powder is not the triple-helical but single-chain form (form II), in contrast to the expectation based on the previous X-ray diffraction studies (Refs. 10 and 15). In fact, conversion from the single to triple helix is at most 50%, even if annealing of the gel sample is made at 150—180° and resulting samples were cooled rapidly (Ref. 6).

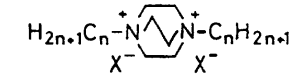
(Received August 25,1988)

Temperature dependence of ^{1}H NMR spin-lattice relaxation time was measured in solid 1,4-didecyl-1,4-diazoniabicyclo[2.2.2]octane dibromide and diiodide (C_{10}-DABCO-C_{10}-Br_2 and C_{10}-DABCO-C_{10}-I_2). ^{79}Br NMR spin-lattice relaxation time and chemical shift measurements in the high-temperature phase were also performed in C_{10}-DABCO-C_{10}-Br_2. It was found that the cation rotates isotropically, while the anion diffuses at a correlation time of ca. 10^{-8} s in the high-temperature phase of C_{10}-DABCO-C_{10}-Br_2. The activation energies for these modes are 30 and 34 kJ mol^{-1}, respectively. Methyl reorientation is activated in the low-temperature phase (E_a=11.8 kJ mol^{-1} in C_{10}-DABCO-C_{10}-Br_2 and E_a=12.0 kJ mol^{-1} in C_{10}-DABCO-C_{10}-I_2). Near the phase-transition temperature some motion of decyl chain is observed (E_a=57 kJ mol^{-1} in C_{10}-DABCO-C_{10}-Br_2 and E_a=35.5 kJ mol^{-1} in C_{10}-DABCO-C_{10}-I_2).

A series of symmetric bis(quaternary alkyl halide) salts of 1,4-diazabicyclo[2.2.2]octanes (DABCO) exhibit first order solid-solid phase transitions above room temperature.[1,2] For these compounds the halide anion conductivities in the high-temperature phases are higher than those in the room-temperature phases by two or three orders of magnitude.[1,2] This characteristic phase transition has been studied extensively by DSC, IR, and powder X-ray diffraction.[1,2] It was revealed that the longer the alkyl chain, the higher the transition temperature becomes in both bromide and iodide salts. If the carbon number of alkyl groups is the same, the transition temperature rises in the order of chloride, bromide, and iodide. Temperature dependence of the IR spectra shows abrupt disappearance of the band progressions[1] above the transition temperatures. These results indicate that the phase transition is accompanied by a conformational change of the alkyl chains. In the case of the unsymmetric bis(quaternary alkyl halide) salts of 1,4-diazabicyclo[2.2.2]octanes, similar phase transitions have been observed.[3,4]

The conductivities of these compounds are of the order of 10^{-5} $(\Omega\,cm)^{-1}$ in the high-temperature phases, being considerably low compared with typical superionic conductors in which conductivities of the order of 10^{-1} to 10^{-3} $(\Omega\,cm)^{-1}$ have been observed. However, they possess the characteristic feature which is not seen in the other ionic conductors, i.e., the conductivity as well as the transition temperature to the conductive phase can be controlled by changing the length and the assortment of side alkyl chains. Therefore, the compounds of DABCO series are potential candidates of new type of electrical conductors which possess highly controllable characteristics. The extensive works on this series will thus open a new area of the molecular design.

Althougth we have been engaged in a number of experimental work as mentioned above, the microscopic mechanisms of the phase transitions and of the high electrical conduction in the high-temperature phases of DABCO series compounds have not yet been clarified. In order to shed light upon these points, we conducted measurements of ^{1}H NMR spin-lattice relaxation times in 1,4-didecyl-1,4-diazoniabicyclo-[2.2.2]octane dibromide (C_{10}-DABCO-C_{10}-Br_2) and 1,4-didecyl-1,4-diazoniabicyclo[2.2.2]octane diiodide (C_{10}-DABCO-C_{10}-I_2), and ^{79}Br NMR spin-lattice relaxation times and chemical shift in C_{10}-DABCO-C_{10}-Br_2.



C_n-DABCO-C_n-X_2(X=Br, I)

Experimental

C_{10}-DABCO-C_{10}-Br_2 and C_{10}-DABCO-C_{10}-I_2 were synthesized by the method described in a previous paper.[1] ^{1}H NMR spin-lattice relaxation times (T_1) were measured with the saturation-τ-$\pi/2$ pulse sequence by a MATEC pulsed spectrometer between 77 and 400 K. The resonance frequencies were 20.5 MHz for C_{10}-DABCO-C_{10}-Br_2 and 19.5 MHz for C_{10}-DABCO-C_{10}-I_2.

The specimen were sealed in a glass ampoule with a small amount of helium gas for heat exchange. The sample temperatures were measured with Chromel-*P*-Constantan thermocouples and controlled to within 0.1 K during each run.

^{79}Br NMR spin-lattice relaxation time (T_1) and line shape measurements were carried out by a MATEC pulsed spectrometer with a wide-bore (130 mmϕ) Oxford superconducting magnet (4.72 T). The sample temperature was regulated by using a home-made cryostat of liquid flow type. T_1 was measured after 256 signal accumulation by using the saturation-τ-$\pi/2$ pulse sequence. The line shape was determined by the Fourier transformation after the 1024 accumulation of FID signals (sampling interval=2 μs and sampling points= 2048). The aqueous solution of NaBr and powder NaBr

were used as standard reagents of ^{79}Br NMR.

Results and Discussion

Temperature dependence of ^1H NMR spin-lattice relaxation times (T_1) for both compounds is shown in Fig. 1. T_1's change abruptly at 337 K in C_{10}-DABCO-C_{10}-Br_2 and at 361 K in C_{10}-DABCO-C_{10}-I_2. These temperatures agree well with the transition temperatures determined by DSC within the experimental error.[1,2]

The T_1 minima around 150 K are attributed to reorientation of terminal methyl groups for the following reasons. The spin-lattice relaxation rate due to methyl reorientation is expressed[5] by

$$T_1^{-1} = A \cdot B(\omega_0 \cdot \tau_c)\,\omega_0^{-1},$$

where

$$A = \frac{3}{5}\gamma^4 \hbar^2 r^{-6} I(I+1),$$

$$B(\omega_0 \cdot \tau_c) = \frac{\omega_0 \cdot \tau_c}{1+(\omega_0 \cdot \tau_c)^2} + \frac{4\omega_0 \cdot \tau_c}{1+4(\omega_0 \cdot \tau_c)^2},$$

and

$$\tau_c = \tau_0 \exp(E_a/kT)$$

where ω_0 is the nuclear Larmor frequency, τ_c is the correlation time, r is the interproton distance within the methyl group, I is the spin quantum number, and E_a is the activation energy. Using A as an adjustable parameter, we can reproduce T_1 as shown in Fig. 1. The activation energies obtained are given in Table 1. According to the BPP theory,[5] the methyl reorientation contributes to A by an amount of $8.9\times10^8\,s^{-2}$ assuming that all methylene protons are rigid and do not undergo any relaxation, and that the spin-temperature approximation holds in the present system. This value agrees very well with the experimental ones (8.5×10^8 s^{-2} in C_{10}-DABCO-C_{10}-Br_2 and 8.0×10^8 s^{-2} in C_{10}-DABCO-C_{10}-I_2). We found also that the above experimental results satisfy well an empirical relation between E_a and the temperature at which T_1 minimum occurs[6] for both compounds. The T_1 minima around 150 K are, therefore, attributed to the terminal methyl group reorientation.

Temperature dependence of T_1 near the phase-transition temperature is shown in Fig. 2. In the low-

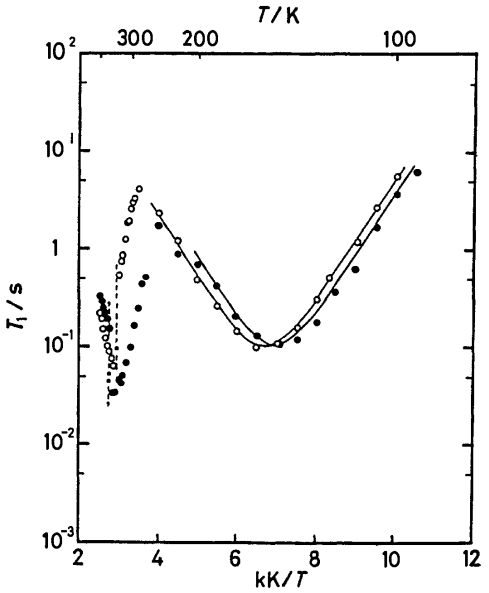


Fig. 1. Temperature dependence of ^1H NMR spin-lattice relaxation times (T_1) in C_{10}-DABCO-C_{10}-Br_2 (○) and C_{10}-DABCO-C_{10}-I_2 (●). The measuring frequencies are 20.5 and 19.5 MHz for C_{10}-DABCO-C_{10}-Br_2 and C_{10}-DABCO-C_{10}-I_2, respectively. Solid lines are the theoretical curves by assuming the methyl reorientations. The phase-transition temperatures are indicated by vertical broken lines.

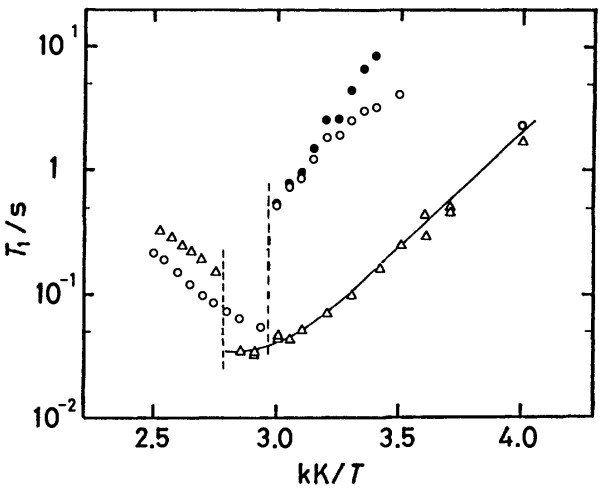

Fig. 2. Temperature dependence of ^1H NMR spin-lattice relaxation times (T_1) near the phase-transition temperatures in C_{10}-DABCO-C_{10}-Br_2 (○) and C_{10}-DABCO-C_{10}-I_2 (△). For C_{10}-DABCO-C_{10}-Br_2 T_1 is contributed by the methyl reorientation and another undefined mode (●). The measuring frequencies are 20.5 and 19.5 MHz for C_{10}-DABCO-C_{10}-Br_2 and C_{10}-DABCO-C_{10}-I_2, respectively.

Table 1. Activation Energies in C_{10}-DABCO-C_{10}-Br_2 and C_{10}-DABCO-C_{10}-I_2

	Low-temperature phase		High-temperature phase
	CH_3 rotation	Large angle oscillation?	Overall rotation
	E_a/kJ mol^{-1}	E_a/kJ mol^{-1}	E_a/kJ mol^{-1}
C_{10}-DABCO-C_{10}-I_2	12.0	35.5	28.0
C_{10}-DABCO-C_{10}-Br_2	11.8	57	30

temperature phase near the phase-transition point, the T_1 decreases with increasing temperature. For C_{10}-DABCO-C_{10}-Br_2 T_1 is contributed by two components in this temperature region. One is the contribution of methyl reorientation mentioned above. The other component discussed here is also shown in Fig. 2 as solid circles. The mechanism of this relaxation can not be pinned down at present stage: A large angle oscillation of the decyl chain is the most probable candidate. The activation energies for this mode are 57 kJ mol^{-1} for C_{10}-DABCO-C_{10}-Br_2 and 35.5 kJ mol^{-1} for C_{10}-DABCO-C_{10}-I_2. In the high-temperature phases, the T_1's become longer with increasing temperature with apparent activation energies of 30 kJ mol^{-1} for C_{10}-DABCO-C_{10}-Br_2 and 28 kJ mol^{-1} for C_{10}-DABCO-C_{10}-I_2. The free induction decays (FID) are shown in Fig. 3 where T_2*=33 μs in the high-temperature phase in comparison with T_2*=8 μs in the room-temperature phase. In the high-temperature phase the line widths, which are equal to the inverse of T_2*, are relatively wide and comparable with those often encountered in liquid crystalline phase or plastic phase. In addition, the polarizing microscope study[1] gave an evidence that the high-temperature phase is isotropic. The IR spectra showed that the ordered trans-zigzag conformation of the alkyl chain is lost in the high-temperature phase.[2] All these facts suggest that overall rotation of the cation is excited in the high-temperature phase.

In the high-temperature phase, the activation energies for these two compounds are almost the same. This fact suggests strongly that the cations in both materials are in similar environment. On the other hand, the activation energy for large-amplitude motion in the low-temperature phase is significantly lower in C_{10}-DABCO-C_{10}-I_2 than in C_{10}-DABCO-C_{10}-Br_2, due probably to larger void space available to the cations, which is brought about by larger size of

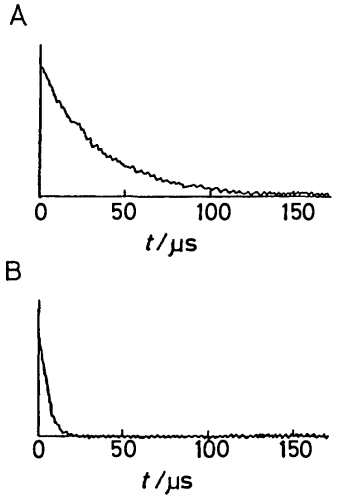

Fig. 3. Free induction decays of ^{1}H NMR in C_{10}-DABCO-C_{10}-Br_2 (A) in the high-temperature phase and (B) in the room-temperature phase.

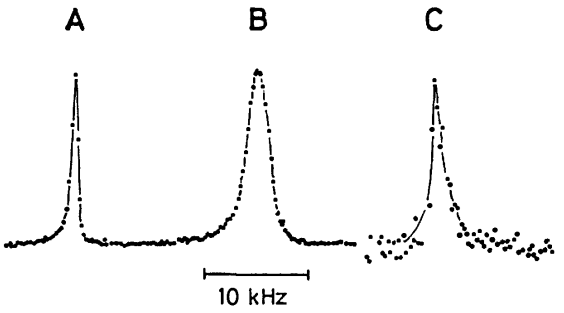

Fig. 4. ^{79}Br FT-NMR spectra A) in NaBr water solution, B) in NaBr powder, and C) in C_{12}-DABCO-C_{12}-Br_2.

the anion in the former material. Since the cationic motion is highly excited in C_{10}-DABCO-C_{10}-I_2, the difference in the Gibbs energy in low- and high-temperature phases is certainly small compared with C_{10}-DABCO-C_{10}-Br_2 and the transition temperature of C_{10}-DABCO-C_{10}-I_2 is significantly higher than that of C_{10}-DABCO-C_{10}-Br_2.

^{79}Br NMR of C_n-DABCO-C_n-Br_2 (n=10, 12, 14) were observed only in the high-temperature phases. The line shape in C_{12}-DABCO-C_{12}-Br_2 at 363 K is shown in Fig. 4 together with those in aqueous solution of NaBr and powdered NaBr. The line shapes and the line widths in C_{10}-DABCO-C_{10}-Br_2 and C_{14}-DABCO-C_{14}-Br_2 are nearly the same as those in C_{12}-DABCO-C_{12}-Br_2. In NaBr crystals Br nuclei are located at the sites of cubic symmetry so that the electric field gradient (EFG) at the Br site vanishes. Hence one expects neither first order splitting nor second order shift of the ^{79}Br resonance in NaBr. The finite line width in this compound shown in Fig. 4 is due probably to imperfection of the crystal lattice and to the magnetic dipole interaction which can be hardly estimated because of the lack of the crystal-structure data. The resonance frequency in NaBr crystals coincides with that in aqueous solution of NaBr listed in Table 2. The line width in C_n-DABCO-C_n-Br_2 (Fig. 4) is narrower than that in powdered NaBr, indicating that the EFG at the Br site vanishes and moreover, any extrinsic EFG due to lattice imperfection and magnetic dipole interaction are averaged out due to rapid translational diffusion of Br^- as will be discussed later. In the low-temperature phases the ^{79}Br NMR could not be observed due to large quadrupolar line broadening. The most remarkable point in Table 2 is that C_n-DABCO-C_n-Br_2 (n=10, 12, or 14)

Table 2. ^{79}Br NMR Frequencies, Line Widths, and Chemical Shifts

System	ν/MHz	$\Delta\nu$/kHz	δ/ppm
C_n-DABCO-C_n-Br_2 (n=10, 12, 14)	50.5360	1.5	3660
NaBr powder	50.3517	3.0	0
NaBr solution	50.3517	1.0	0

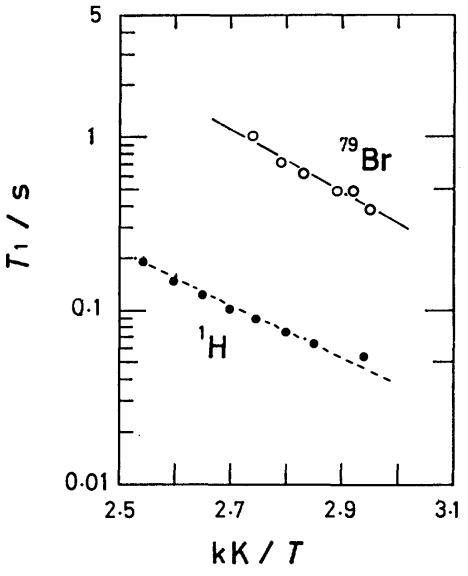

Fig. 5. Temperature dependence of ^{79}Br (50.5 MHz) and ^{1}H NMR (20.5 MHz) T_1's in the high-temperature phase of C_{10}-DABCO-C_{10}-Br_2.

show a very large down-field chemical shift. The interpretation by a second-order quadrupole effect is ruled out because of very narrow, symmetric line shape as shown in Fig. 4. Thus one must consider that there exists some special mechanism to generate a large paramagnetic term in the DABCO series compounds. At present we cannot identify the origin of such a large paramagnetic shift.

The temperature dependence of ^{79}Br and ^{1}H T_1's in C_{10}-DABCO-C_{10}-Br_2 are shown in Fig. 5. ^{79}Br T_1 is longer than ^{1}H T_1 by an order of magnitude, and its temperature slope is slightly larger. ^{79}Br T_1 (solid line in Fig. 5) shows that $\omega_0\tau_c<1$ and leads to E_a=34±3 kJ mol^{-1} which can be attributed to the translational diffusion of Br^- anions. Since the overall rotation of cations as well as anionic diffusion is highly excited in the isotropic high-temperature phase, this phase can be classified as an ionic plastic crystal. NH_4NO_3,[7] $TlNO_3$,[8] CH_3NH_3I[9] have been considered to belong to this category.

In conclusion, the methyl reorientation is first activated in the low-temperature phase (E_a=11.8 kJ mol^{-1} in C_{10}-DABCO-C_{10}-Br_2 and E_a=12.0 kJ mol^{-1} in C_{10}-DABCO-C_{10}-I_2). On further increase in temperature the large angle oscillation of the decyl chains may govern the relaxation mechanism (E_a=35.5 kJ mol^{-1} and 57 kJ mol^{-1} in C_{10}-DABCO-C_{10}-I_2 and C_{10}-DABCO-C_{10}-Br_2). In the high-temperature phase the overall rotation of cations are excited (E_a=28.0 kJ mol^{-1} and 30 kJ mol^{-1} in C_{10}-DABCO-C_{10}-I_2 and C_{10}-DABCO-C_{10}-Br_2). Furthermore, the anions diffuse at a rate higher than 10^8 s^{-1} with an activation energy of E_a=34 kJ mol^{-1}.

The Electrocapillary Curves of the Phosphatidylcholine Monolayer at the Polarized Oil-Water Interface. II. Double Layer Structure of Dilauroylphosphatidylcholine Monolayer at the Nitrobenzene-Water Interface

Takashi KAKIUCHI, Masatoshi NAKANISHI, and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 25, 1988)

Electrocapillary curves have been measured at the polarized nitrobenzene-water interface in the presence of dilauroylphosphatidylcholine (DLPC) in the nitrobenzene phase. DLPC formed a saturated monolayer when the concentration of DLPC was above 10 μmol dm^{-3}. The area occupied by a DLPC molecule in the saturated monolayer was 0.93 nm^2, indicating that the monolayer was in the liquid-expanded state. The stability of the monolayer was strongly affected by the electrical potential difference across the interface. The monolayer was stable when the interface was negatively polarized, i.e., the potential in the aqueous phase was negative with respect to that in the oil phase. The potential of zero charge shifted to a negative potential as the adsorption of DLPC increased, which indicated the specific adsorption of lithium ions in the aqueous phase to the head group of the DLPC molecules exposed to the aqueous phase. When the interface was positively polarized, the adsorption of DLPC abruptly decreased and the monolayer appeared to be disrupted.

Phospholipid monolayers formed at the air-water interface and at the oil-water interface have been extensively used to study the surface properties of the monolayers, which are expected to represent, to some extent, the surface properties of phospholipid bilayers as well as those of biological membranes.[1,2] Among those monolayers, the monolayer formed at the polarizable oil-water interface is particularly suitable for studying the electrochemical properties of phospholipid monolayers, since the potential drop across the interface can be accurately controlled externally at this interface.[3] Thus, the monolayer at the polarized oil-water interface enables us to study its electrochemical properties in detail, e.g., the double layer structure in the vicinity of the monolayer and the ion-transfer reaction across the monolayer. The electrochemical study of the retardation of the ion transfer across the oil-water interface in the presence of a phospholipid monolayer has been reported by Koryta et al.,[4] Girault and Schiffrin,[5] and Cunnane et al.[6] However, the properties of the monolayer, itself, formed at these interfaces are not yet fully understood. To make full use of the advantage of the monolayer at the polarized interface, it is important to elucidate the properties of the phospholipid monolayers formed at the polarized interface. For example, knowledge regarding the double layer structure seems indispensable to correctly interpret the measured change of the rate constant of the ion-transfer reaction, e.g., taking account of the Frumkin correction.[7] Several attempts have been made to characterize the phospholipid monolayer at the polarized oil-water interface. We reported the conditions of the monolayer formation of L-α-dilauroylphosphatidylcholine (DLPC) at the nitrobenzene-water interface after measuring the double layer capacitance of the interface.[8] Although double layer capacitance is a sensitive measure which can be used to detect any structural change of the interface, the basic properties of the interface, such as the absolute amount of adsorbed substances and the excess surface charge density, can be estimated thermodynamically only through electrocapillary curve measurements. Girault and Schiffrin have studied the electrocapillary curves at the 1,2-dichloroethane-water interface in the presence of egg york phosphatidylcholine and phosphatidylethanolamine.[9] They have also studied the effect of pH in the aqueous side of the interface on the electrocapillary curves at different concentrations of phosphatidylcholine.[10] However, a detailed analysis of the electrocapillary curves has not yet been reported. In Part I of this study, we found that an equilibrium electrocapillary curve can be obtained for the DLPC monolayer at the polarized nitrobenzene-water interface in the potential range where the potential of the aqueous phase was negative with respect to that in the nitrobenzene phase.[11] In the present communication, we will focus our attention mainly on the electrocapillary curves in this potential region of the interface recorded at various concentrations of DLPC.

Experimental

The interfacial tension was measured at 25±0.05 °C using a computer-aided pendant drop method.[12,13] Details of this method were described in Part I.[11] In the measurement, the drop of an aqueous solution was formed in the nitrobenzene phase to make sure that the amount of the DLPC was sufficient to make up a saturated monolayer. A laboratory-made four-electrode potentiostat of the type proposed by Samec et al.[14] was used to control the potential drop across the polarized interface. The nitrobenzene used as a solvent of the oil phase was distilled and then treated with active alumina. DLPC was purchased from Sigma and was used without further purification. DLPC was dissolved in a 3:2 toluene-chloroform mixture as a stock solution. The nitrobenzene solution of DLPC for the measurement was prepared so that the final concentration of a 3:2 toluene-chloroform mixture in nitrobenzene was 10% (v/v). The

methods for the preparation of tetrapentylammonium tetraphenylborate (TPnATPB) and of the tetrapentylammonium chloride (TPnACl) solution have been described elsewhere.[15] All other chemicals were of reagent grade. The nitrobenzene solution was equilibrated with an aqueous solution of lithium chloride prior to a measurement.

Results

The electrochemical cell employed in the present study was

I	II	III	IV	V	VI	VII
Ag	AgCl	0.02 M† TPnACl (W)	0.1 M TPnATPB + $x\mu$M DLPC (NB)	0.05 M LiCl (W)	AgCl	Ag

The interface between Phases IV and V was a polarized nitrobenzene-water interface. The other nitrobenzene-water interface between Phases III and IV was a nonpolarized interface.[15] The potential of the right hand side of cell with respect to the left is denoted as E^{W-}_{O+}, where the super- and subscripts, W− and O+, indicate that the right-hand side and left-hand side reference electrodes are reversible to an anion (Cl^-) in Phase V and a cation ($TPnA^+$) in Phase IV, respectively. The electrocapillary curves were recorded between x=0 and 50 in the cell two hours after the formation of an interface in order to ensure the establishment of adsorption equilibrium.[11]

The potential of zero charge, E_{pzc}, of this system was found to be 0.32 V (Fig. 2) when x=0. Since at E_{pzc} the Galvani potential difference between the nitrobenzene and the aqueous phases is very small in the absence of specific adsorption,[16] the potential referring to E_{pzc} at x=0 can be taken as a convenient measure of the Galvani potential difference, $\Delta^W_O\phi$. As we have shown in Part I, the DLPC monolayer gives an equilibrium electrocapillary curve when $\Delta^W_O\phi<0$, i.e., in Region I (see Fig. 1). In the more positive potential range, Region II, the interfacial tension, γ, abruptly increased and the data in this region were much less reproducible (Fig. 1). Below, we mainly deal with the electrocapillary curves measured in Region I.

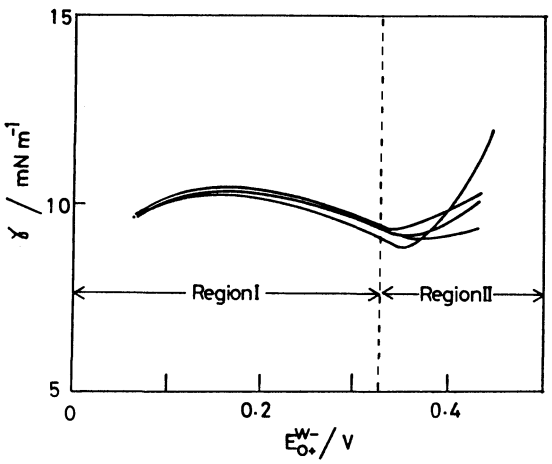

Fig. 1. The reproducibility of the electrocapillary curve when c_{DLPC}=10 μmol dm^{-3}.

The electrocapillary curves at x=0, 0.5, 1, 2, 5, 10, 20, and 50 are shown in Fig. 2. Each point represents the average value of triplicate measurements. For the electrocapillary curves at the four higher concentrations, only data from Region I are plotted. In Region I, the interfacial tension decreased as the concentration of DLPC was increased. Here, γ is plotted against the logarithm of the concentration of DLPC in the nitrobenzene phase, $\ln c_{DLPC}$, at different values of E^{W-}_{O+} (Fig. 3). At a higher concentration of DLPC, the γ vs. $\ln c_{DLPC}$ curve at any value of E^{W-}_{O+} gave a straight line. This

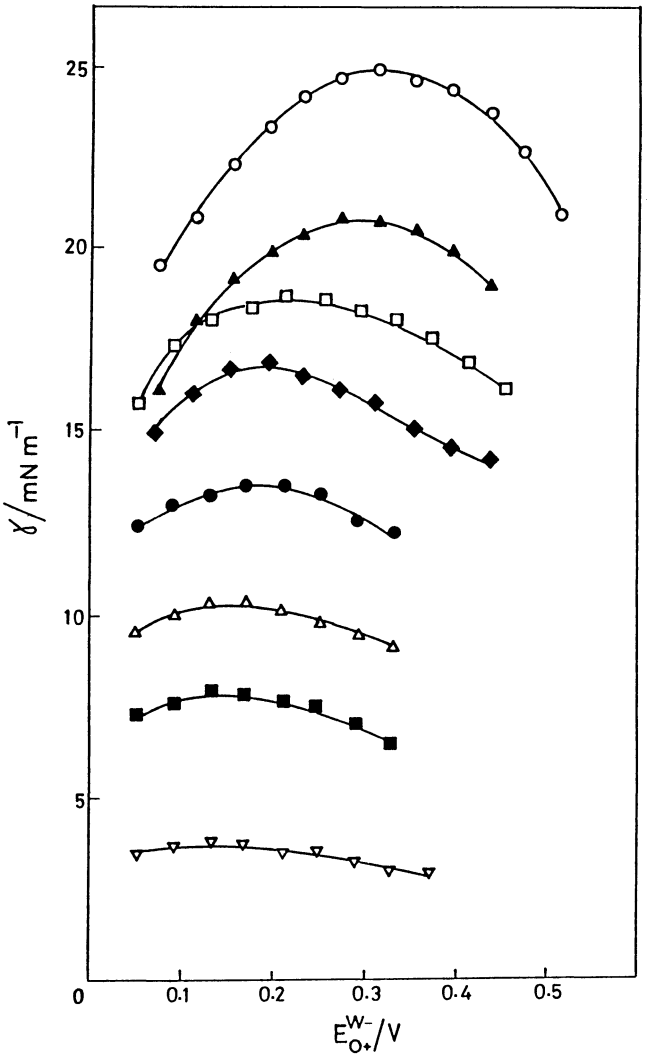

Fig. 2. The electrocapillary curves at 25°C for the interface between the nitrobenzene solution of 0.1 mol dm^{-3} TPnATPB and the aqueous solution of 0.05 mol dm^{-3} LiCl in the presence of x μmol dm^{-3} DLPC in the nitrobenzene phase: x=0(○), 0.5(▲), 1(□), 2(◆), 5(●), 10(△), 20(■), and 50(▽).

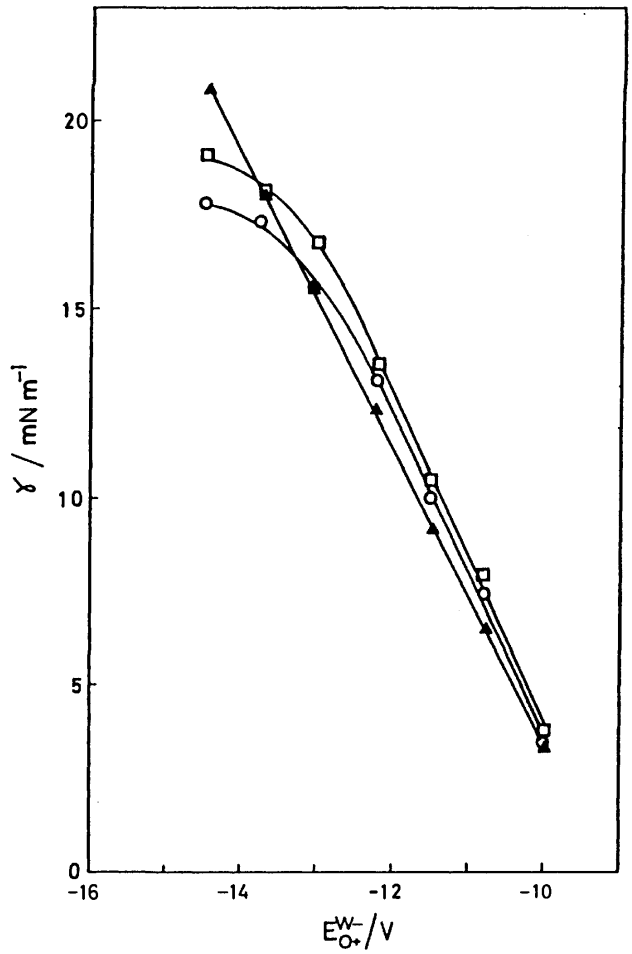

Fig. 3. γ vs. ln c_{DLPC} curves at E^{W-}_{O+}=0.09(▲), 0.15(□), and 0.33(○) V.

linear dependence indicates the formation of a saturated monolayer of DLPC at the interface. The possibility of micelle formation of the DLPC in the nitrobenzene phase is excluded within the concentration range studied, because of the lack of a break point in the curves. The adsorbed amount of DLPC was calculated from the slope of the curves in Fig. 3 using the thermodynamic relation based on the electrocapillary equation at the polarized oil-water interface:[17]

$$\Gamma_{DLPC} = -\frac{1}{RT}(\partial\gamma/\partial \ln a^{NB}_{DLPC})_{E^{W-}_{O+},\mu_i}, \quad (1)$$

where Γ_{DLPC} is the relative surface excess of DLPC, a^{NB}_{DLPC} the activity of the DLPC in the nitrobenzene phase, R the gas constant, and T the absolute temperature. The subscripts of the parenthesis in the right-hand side of Eq. 1 indicate that the derivative must be taken while keeping E^{W-}_{O+} and the chemical potentials of components except for DLPC constant. In the calculation, a^{NB}_{DLPC} was taken to be equal to the concentration of DLPC in the nitrobenzene phase, c_{DLPC}. Since the concentration of the DLPC in the nitrobenzene phase is small, Γ_{DLPC} can be equated to the adsorbed amount of DLPC at the interface. The adsorption isotherm of DLPC at E^{W-}_{O+}=0.210 V is shown in Fig. 4. The maximum adsorption of DLPC, Γ^{m}_{DLPC}, calculated from the limiting slope of the γ vs. lnc_{DLPC} curves was plotted as a function of E^{W-}_{O+} in Fig. 5. Γ^{m}_{DLPC} was independent of E^{W-}_{O+} between E^{W-}_{O+}=0.08 and 0.280 V; the monolayer was stable in this potential range. This is in accordance with our previous results, obtained from differential capacitance measurements of the DLPC monolayer at the same interface.[8] The Γ^{m}_{DLPC} in this potential range was found to be 1.76×10^{-10} mol cm^{-2}, which corresponds to the value of the occupied area of a DLPC molecule (0.93 nm^2). The isotherm fitted well to the Frumkin isotherm (Fig. 4). The solid curve in Fig. 4 is a regression curve using the Frumkin isotherm:[18]

$$Bc_{DLPC} = \frac{\theta}{1-\theta}\exp(-2a\theta), \quad (2)$$

where B is the adsorption coefficient, $\theta=\Gamma_{DLPC}/\Gamma^{m}_{DLPC}$, and a is the interaction parameter. In the regression

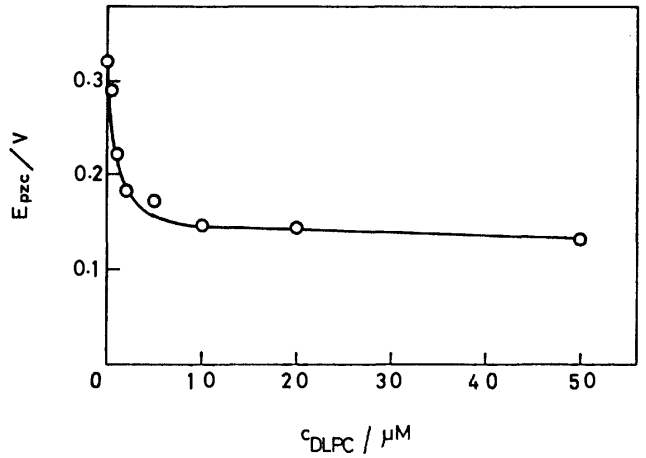

Fig. 7. Shift of the potential of zero charge, E_{pzc}, with the increase of the DLPC concentration.

analysis, the value of Γ^{m}_{DLPC}, estimated from the limiting slope of the γ vs. lnc_{DLPC} plot, was employed. The adsorption isotherm in Fig. 4 ensures the absence of multi-layer formation at the interface. The logarithm of B and a are plotted in Fig. 6 as a function of E^{w-}_{o+}. As can be seen in Fig. 2, the potential of zero charge, E_{pzc}, shifted to a negative potential with the increase of c_{DLPC} (Fig. 7). The shift reached 170 mV when the saturated monolayer was formed.

Discussion

Figures 3, 4, and 5 clearly manifest the formation of a saturated DLPC monolayer at the polarized nitrobenzene-water interface. The monolayer was stable when the $\Delta^{w}_{o}\phi$ was negative. This confirms our previous conclusion concerning the monolayer formation of DLPC obtained from capacitance measurement.[8] The value of the area occupied by a DLPC molecule in the saturated monolayer, 0.93 nm^2, is 20% greater than the value estimated from the capacitance measurements using the spread monolayer technique.[8] If we take account of the uncertainty intrinsic to the spread method, i.e., the necessary extrapolation of the capacitance value to the value at t=0,[8] the values from the two independent methods agree with each other and suggest that the saturated monolayer is in the liquid-expanded state.[19] The ln$B$ was weekly dependent on the applied potential (Fig. 6) and decreased with a positive increase in the potential. The value of ln$B$ at E^{w-}_{o+}=0.22 V was 12.5, corresponding to an adsorption free energy of 31 kJ mol^{-1}. This is in agreement with the value estimated from the capacitance measurement at the same polarization.[8] Wandlowski et al. reported a similar value from the capacitance measurements.[20] The a parameter was also varied with the applied potential, yet the value of a was always positive.

The negative shift of the E_{pzc} with an increase in the DLPC adsorption (Fig. 7) means that there exists a Galvani potential difference at the E_{pzc}, such that the inner potential in the aqueous phase becomes more negative with respect to the inner potential in the nitrobenzene phase. There are four possible sources for this shift of the E_{pzc}: the nitrobenzene and the water molecules at the interface, the head group and the carbonyl group of the adsorbed DLPC molecules, and the specific adsorption of ions in the presence of the monolayer. The contribution from the first factor would be very small, because the $\Delta^{w}_{o}\phi$ at the E_{pzc} in the absence of the specific adsorption of ions at the interface is very small.[16] The second and third factors are the permanent dipole moments of the DLPC molecules oriented at the interface. The phosphatidylcholine molecule has a zwitterion group, whose isoelectric point is at pH=5.5.[19] The pH of the aqueous solution studied was typically 5.8, and, hence, all the head groups exposed to the aqueous side of the interface were in zwitterionic form. The dipole moment of the zwitterion group is so large that even its minute orientation normal to the interface should give rise to large dipole potential. However, neutron diffraction studies of the phosphatidylcholine bilayer have demonstrated a coplaner arrangement of the choline segment, i.e., with the P-N dipole approximately parallel to the plane of the bilayer.[21] A similar conclusion has been reached in a study of the phosphatidylcholine monolayer at the air-water interface.[22] Moreover, since the phosphate group is directly attached to the glyceride part of the phosphatidylcholine and the trimethylammonio group is away from it, the deviation of the orientaion of the zwitterionic group from the parallel position, if any, should result in a shift of the pzc to the positive direction, which is at variance with the

present results. On the other hand, the C=O bond of the carbonyl group in the phosphatidylcholine monolayer at the air-water interface is oriented with its oxygen atom pointing toward the aqueous phase and with the angle of C=O axis being within 20° with respect to the interface.[23] If the carbonyl group is oriented similarly in the polarized nitrobenzene-water interface, the contribution of this oriented dipole is estimated to be 70 mV at the saturation coverage. This contribution to the surface potential, however, can explain only part of the shift of the E_{pzc} observed experimentally. Consequently, the above-mentioned three possible contributions arising from the oriented dipoles cannot fully account for the observed shift of 170 mV. The remaining factor that can account for the observed change of the E_{pzc} is the specific adsorption of an Li^+ ion in the aqueous phase to the hydrophilic head group of the adsorbed monolayer. This specific adsorption should result in a potential difference in the aqueous phase, such that the potential at the inner Helmholtz plane (IHP) where the Li^+ ion is specifically adsorbed, ϕ_1, is positive with respect to the bulk of the aqueous phase. This direction of the shift is in harmony with the observed trend of E_{pzc}. The specific adsorption of Li^+ ions to the phospholipid surface has been found in the liposomes made of phosphatidylcholine.[24] Pospisil et al. reported the specific effect of Li^+ ion on the phase transition of dipalmitoylphosphatidylcholine adsorbed at the mercury-solution interface.[25] The specific binding of Li^+ ion to a lipid bilayer made of a phosphatidylserine membrane was found to significantly affect its physicochemical properties and physiological functions.[26]

If the specific adsorption of Li+ does occur at the interface, the shift of E_{pzc} is expected to depend on the concentration of Li^+ ion in the aqueous phase. Figure 8 shows that the shift of E_{pzc} with the LiCl concentration exceeds the shift attributable to a change in the potential of the reference electrode in the aqueous phase (dotted line). The latter change was calculated using the Davies equation[27] for an evaluation of the mean ionic activity of LiCl. The observed large shift of E_{pzc} with the Li^+ ion concentration (solid line) confirms the presence of the specific adsorption of Li^+. If we make a simplified assumption, that the distribution of the nonspecifically adsorbed ions in the aqueous phase follows the Gouy-Chapman theory, we can estimate the degree of the Li^+ ion binding to the interface. The shift of E_{pzc}, after subtracting the potential drop due to the oriented carbonyl group, which was assumed to be 70 mV irrespective of the $\Delta_o^w\phi$ and of the LiCl concentration, should correspond to ϕ_1. Although ϕ_1 is in general larger than the potential at the outer Helmholtz plane (OHP), ϕ_2, which passes through the center of the nonspecifically adsorbed Li^+ ion at its closest approach to the interface, the error would be small if we equate ϕ_1 with ϕ_2, because some of the nonspecifically adsorbed ions can enter beyond the OHP due to the sparse distribution of the adsorbed DLPC molecules(cf. Figs. 9a and 9b). Then, by using the Gouy-Chapman theory, the surface charge density corresponding to the ϕ_2 potential at a given concentration of LiCl can be calculated. This surface charge density may be taken as the specifically adsorbed amount of Li+ ions, since the potential is at the E_{pzc} and there is no excess surface charge density in the nitrobenzene phase. The specifically adsorbed amount of Li^+ ion, ${}^i\Gamma_{Li}$, and the degree of the counterion binding, $\alpha={}^i\Gamma_{Li}/\Gamma_{DLPC}$, thus obtained, are listed in Table 1. The Γ_{DLPC} was assumed to be constant over the concentration range of LiCl studied.

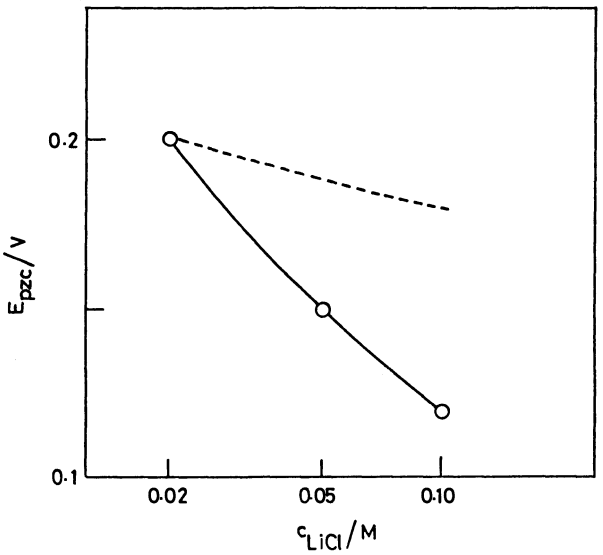

Fig. 8. Shift of the potential of zero charge with the concentration of DLPC in the nitrobenzene phase. The dotted line is the expected curve in the case of no specific adsorption.

In the case of the phosphatidylcholine bilayer, lipophilic anions are much more strongly adsorbed at the membrane surface than lipophilic cations.[28] Flewelling and Hubbell attributed this asymmetric adsorbability to the potential drop across the membrane surface and then estimated for the egg yolk phosphatidylcholine membrane that the potential at the membrane surface is 240±70 mV positive with respect to the bulk solution.[29] It is interesting that this magnitude of the membrane potential is comparable with the amount of the shift of the E_{pzc} found in the present study. The double-layer structure of the nitrobenzene-water interface in the presence of the satu-

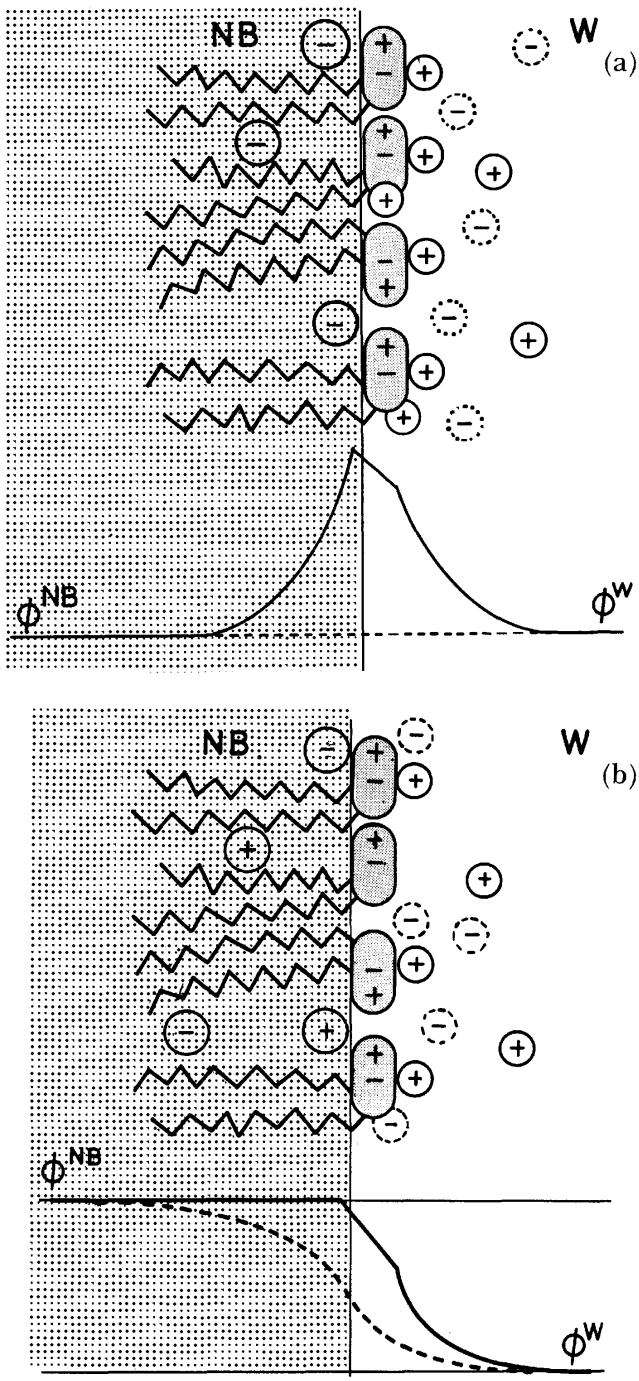

Fig. 9. Schematic representation of the double layer structure and the potential profile of the interface between the nitrobenzene solution of TPnATPB and the aqueous solution of LiCl in the presence (——) and in the abscence (----) of DLPC adsorption: a) at the E_{pzc} for the base electrolyte, b) at the E_{pzc} for the saturated DLPC monolayer.

rated DLPC monolayer, deduced from the present analysis, is illustrated in Fig. 9a at E_{O+}^{W-}=0.32 V ($\Delta_O^W\phi\simeq 0$) and in Fig. 9b at the E_{pzc} for the saturated DLPC monolayer, respectively. The inner Helmholtz plane in the aqueous phase was postulated to lie on the line passing through the centers of the specifically adsorbed Li^+ ions. Also, schematically illustrated are the penetration of $TPnA^+$ and TPB^- ions in the nitrobenzene phase into the hydrocarbon part of the DLPC monolayer and the random orientation of the zwitterion group in the plane parallel to the interface.

The abrupt increase in the interfacial tension (Fig. 1) when the potential was increased from Region I to II would predict the appearance of a peak on the corresponding equilibrium capacitance vs. potential curve. However, experimentally no such peak at this potential was observed on the differential capacitance vs. potential curves.[8,20,30] In the presence of the adsorption of a surface active substance, the capacitance, $C=(\partial q/\partial E)_c$, is generally composed of two terms:[31]

$$\left(\frac{\partial q}{\partial E}\right)_c = \left(\frac{\partial q}{\partial E}\right)_\Gamma + \left(\frac{\partial q}{\partial \Gamma}\right)_E \left(\frac{\partial \Gamma}{\partial E}\right)_c , \qquad (3)$$

where q is the excess surface charge density, E the electrical potential difference, c the bulk concentration of the adsorbate, and Γ the surface excess of the adsorbate. The first term on the right-hand side of Eq. 3 is a quantity called "true capacitance" and the second term is the "adsorption pseudocapacitance." In Region I, the Γ_{DLPC} is practically independent of E_{O+}^{W-} (Fig. 5) and, hence, the second term makes no significant contribution to the total capacitance. On the other hand, in Region II, the desorption of DLPC from the interface certainly takes place, judging from the recovery of the interfacial tension (Fig. 1). Then, the $(\partial\Gamma/\partial E)_c$ term in Eq. 3 is not generally negligible. When the adsorption is a diffusion limited process, which is likely to be the case for the DLPC adsorption, because of the low value of c_{DLPC}, the second term in Eq. 3 may be rewritten as[31]

$$\left(\frac{\partial q}{\partial \Gamma}\right)_E \left(\frac{\partial \Gamma}{\partial E}\right)_c = \left(\frac{\partial q}{\partial \Gamma}\right)_E \left(\frac{\partial \Gamma}{\partial E}\right)_{c,\omega=0} \frac{b+2}{(b+1)^2+1} , \qquad (4)$$

where $(\partial\Gamma/\partial E)_{c,\omega=0}$ is $(\partial\Gamma/\partial E)_c$ at $\omega\to 0$, $\omega=2\pi f$ is the angular frequency, and f is the ac frequency employed in a capacitance measurement. The b is given by

$$b=(2\omega/D)^{1/2}(\partial\Gamma/\partial c)_E, \qquad (5)$$

where D is the diffusion coefficient of the adsorbate. Only when b is small, can the measured capacitance be seen as being the thermodynamic capacitance.[32] In the case of the Frumkin isotherm,

$$(\partial\Gamma/\partial c)_E = \frac{\Gamma_m}{c}\,\frac{\theta(1-\theta)}{1-2a\theta(1-\theta)} . \qquad (6)$$

If we assume that the diffusion coefficient of the DLPC in the nitrobenzene is the same as that of dilauroylphosphatidylethanolamine, 3.8×10^{-6} cm^2 s^{-1},[33] we obtain $b=6.38\sqrt{\omega}$ when c=10 μmol dm^{-3}, a=1, and θ=0.5. Accordingly, even at f=1 Hz the last factor of the right hand side of Eq. 4 is significantly smaller than 1, resulting in the disappearance of the expected peak on a measured capacitance vs. potential curve. If the adsorption-desorption process is sluggish giving a

"frozen" monolayer, the second term in Eq. 3 is again smaller than the equilibrium value. Thus, the measured capacitance in Region II is in any case smaller than the equilibrium capacitance and the integration of the measured capacitance vs. potential curve would not give the excess surface charge density.

The abrupt increase of the interfacial tension in the adsorption of egg yolk phosphatidylcholine at the 1,2-dichloroethane-water interface has been suggested to be due to the protonation of the phosphatidylcholine molecules at the interface.[9] In the experimental conditions employed in the present study, this protonation model is not applicable. The pK_a of the phosphate group of phosphatidylcholines at the air-water interfaces is of the order of 3.0.[34] On the other hand, in the present study the ϕ_2 potential in the aqueous phase does not exceed 30 mV,[16] even in the positive extreme of Region II, because of the relatively high concentration of LiCl. Accordingly, the surface pH is not lower than 4.5 and, hence, practically all the DLPC molecules at the interface should be in a zwitterionic form,[34] even when the change of pH in the vicinity of the interface is taken into account. A probable explanation of the abrupt rise of γ would be a desorption of the DLPC molecules from the interface accompanied by the process of the facilitated Li^+ ion transfer in Region II.

Surface Adsorption and Micelle Formation of Dodecyltrimethylammonium Chloride and Decylammonium Chloride Mixture

Norihiro IKEDA,* Eiji SHIOTA, Makoto ARATONO, and Kinsi MOTOMURA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received September 13, 1988)

The surface tension of the aqueous solution of dodecyltrimethylammonium chloride (DTAC) and decylammonium chloride (DeAC) mixture was measured as a function of the total molality and composition of the surfactants at 298.15 K under atmospheric pressure. To make clear the miscibility of surfactants, the compositions in the mixed adsorbed film and micelle were calculated by use of the thermodynamic equations developed previously. The results indicated that both adsorbed film and micelle are richer in DTAC molecules than the bulk solution. Furthermore, the composition in the adsorbed film at the critical micelle concentration (cmc) was evaluated and compared with that in the micelle. It was found that the composition of DeAC in the micelle is smaller than that in the adsorbed film. This forms a striking contrast to the previous observation of dodecylammonium chloride (DAC)-DeAC mixture. It was concluded that the structure and size of polar head group of surfactants have a significant influence on the miscibility of surfactants.

In our previous paper on the subject of the adsorption of dodecylammonium chloride (DAC) and decylammonium chloride (DeAC) mixture from its micellar solution, we have evaluated thermodynamically the compositions of the surfactants in the mixed adsorbed film and micelle.[1] It has been proved that they, though fairly similar with each other, are remarkably different from that in the solution.

Now another combination of surfactants will give us an information about the miscibility of surfactants in the adsorbed film and micelle and make sure of the usefulness of our thermodynamic treatment. In the present study we choose the dodecyltrimethylammonium chloride (DTAC)-DeAC mixture because (i) we have already investigated the adsorption of DTAC from the micellar solution, the effect of *N*-methylation of DAC on the adsorption and micelle formation, and the phase transition of the adsorbed film of DTAC and DeAC mixture at a low concentration,[2-4] (ii) the critical micelle concentration (cmc) of DTAC is smaller than that of DeAC while the surface tension at the cmc is larger, and (iii) an information is expected to be provided about the influence of the chemical structure of polar head group of surfactant on the miscibility.

The surface tension of the aqueous solution of DTAC-DeAC mixture is measured as a function of the total concentration and composition of the mixture at concentrations around the cmc at constant temperature under atmospheric pressure and analyzed by use of the thermodynamic equations advanced by the authors.[1,4,5] Further, the results are compared with those of the DAC-DeAC system.

Experimental

Dodecyltrimethylammonium chloride and decylammonium chloride were synthesized and purified by the method described previously.[6,7] Water was distilled triply, the second and third stages being from dilute alkaline permanganate solution. Surface tension was measured under atmospheric pressure at 298.15 K by the drop volume method described in the previous paper.[8] The surface tension values were reproducible to ± 0.05 mN m^{-1}.

Results and Discussion

To obtain the compositions in the adsorbed film and micelle in equilibrium with the aqueous solution of surfactant mixture, the total molality m of surfactants in the solution defined by

$$m = m_1 + m_2 \quad (1)$$

and the composition of the surfactant 2 in the total surfactant defined by

$$X_2 = m_2/m \quad (2)$$

were adopted as the experimental variables at constant temperature and pressure.[1,4,5] Here m_i is the molality of surfactant i.

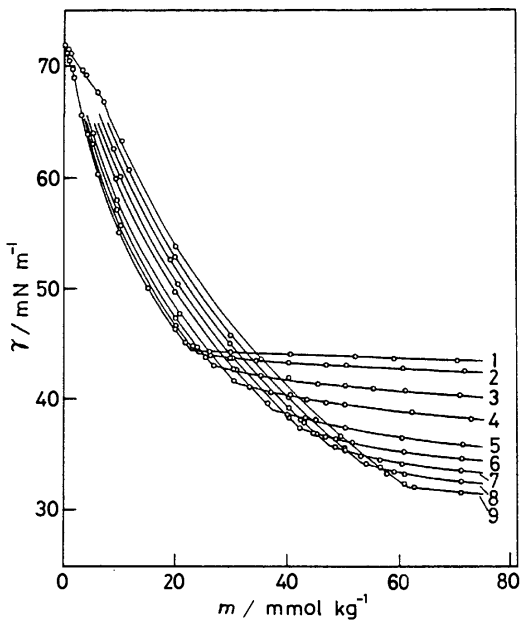

Fig. 1. Surface tension vs. total molality curves at constant composition: (1) X_2=0; (2) 0.1000; (3) 0.3017; (4) 0.5002; (5) 0.7021; (6) 0.8026; (7) 0.8932; (8) 0.9506; (9) 1.

The surface tension of the aqueous solution of dodecyltrimethylammonium chloride and decylammonium chloride mixture was measured as a function of m at fixed composition X_2 of DeAC and at 298.15 K under atmospheric pressure. The results are shown in Fig. 1. It is seen that the γ vs. m curve changes its shape gradually with X_2 from the curve of DTAC to that of DeAC. The curve has a distinct break point arising from the formation of micelles; the concentration at the break point is referred to as the critical micelle concentration (cmc). The cmc value increases with increasing X_2 and the surface tension at the cmc γ^{cmc} decreases. Here, it should be noted that the slope of γ vs. m curve of the micellar solution of mixture has a larger absolute value than those of pure DTAC and DeAC.

Taking up the γ values at a given m value from Fig. 1, the γ vs. X_2 curves are obtained and shown in Fig. 2 together with the γ^{cmc} vs. X_2 curve. It is seen that the value of γ increases with increasing X_2 while that of γ^{cmc} decreases. On the other hand, the m vs. X_2 curves at a given surface tension obtained from Fig. 1 are shown in Fig. 3 with the cmc vs. X_2 curve. It is found that both values of m and cmc increase with X_2.

Now let us evaluate the total surface density of surfactant mixture Γ^H defined by

$$\Gamma^H=\Gamma_1^H+\Gamma_2^H, \tag{3}$$

where Γ_i^H is the surface excess number of moles per unit area of surfactant i with respect to the two dividing planes chosen so as to make the surface excess numbers of moles of water and air zero. Assuming that the solution is ideal, the total surface density is calculated by use of the equation

$$\Gamma^H=-(m/2RT)(\partial\gamma/\partial m)_{T,p,X_2}, \tag{4}$$

where T is the temperature, p the pressure, and R the gas constant. The evaluated values of Γ^H are plotted against m at various compositions in Fig. 4. It should be noted that the value of Γ^H increases with decreasing the composition at low concentrations, while it decreases at high concentrations. Taking into account that the DTAC molecule has a larger head group than the DeAC molecule, the large size of the polar head group of DTAC molecule is said to reduce considerably the adsorption of surfactants at a high surface density even though the DTAC molecule has a longer

hydrocarbon chain.

It has been shown that the plots of γ at constant m and of m at constant γ against the composition of DeAC in the adsorbed film X_2^H provide us the useful information to examine the miscibility of surfactants in the mixed adsorbed film. Here the composition X_2^H is defined by

$$X_2^H = \Gamma_2^H / \Gamma^H. \tag{5}$$

The values of X_2^H at constant m are calculated by applying the relation

$$X_2^H = X_2 - [(1-X_2)X_2/RT\Gamma^H](\partial\gamma/\partial X_2)_{T,p,m} \tag{6}$$

to the γ vs. X_2 curves given in Fig. 2 with the Γ^H values of Fig. 4 and those at constant γ by applying the relation

$$X_2^H = X_2 - [2(1-X_2)X_2/m](\partial m/\partial X_2)_{T,p,\gamma} \tag{7}$$

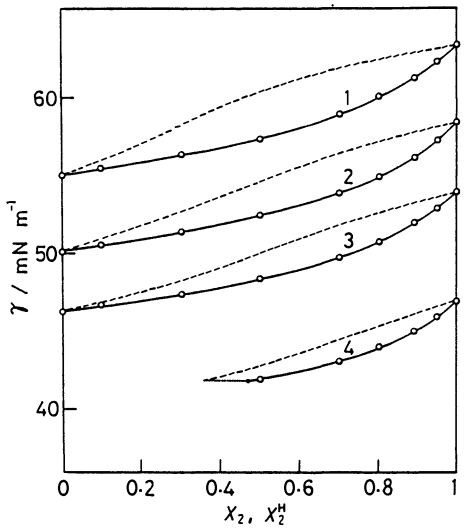

Fig. 5. Surface tension vs. composition curves at constant total molality; (1) m=10 mmol kg^{-1}; (2) 15; (3) 20; (4) 30; (●) γ^{cmc}; (——) X_2; (----) X_2^H.

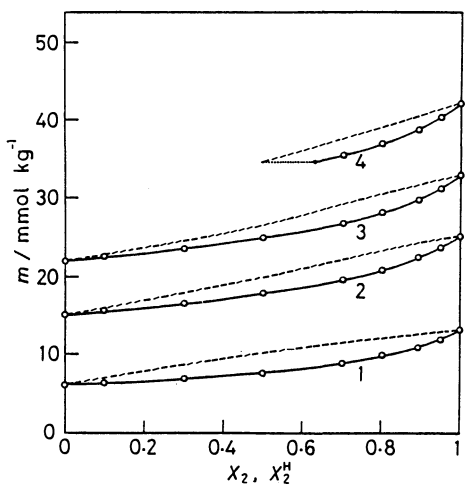

Fig. 6. Total molality vs. composition curves at constant surface tension: (1) γ=60 mN m^{-1}; (2) 50; (3) 45; (4) 40; (●) cmc; (——) X_2; (----) X_2^H.

to the m vs. X_2 curves given in Fig. 3.[1,4] Both results are respectively shown in Figs. 5 and 6. These diagrams take the shape of cigar and are similar to the three-dimensional phase diagram of an ideal system. Therefore we can say that the DTAC and DeAC molecules are perfectly miscible in the adsorbed film. It is also seen that the adsorbed film is richer in DTAC molecules. This implies that the mixed adsorbed film abounds in the surfactant having a lower surface tension at a given concentration. Further the qualitative feature of the diagram is almost the same as that of the DAC-DeAC mixture.[1] However, the diagrams in Fig. 5 seem to be thinner than the corresponding ones of the DAC-DeAC mixture. This is visualized by plotting the difference in composition between the solution and the adsorbed film $X_2 - X_2^H$ against X_2 (Fig. 7); the differences of the DTAC-DeAC mixture are much smaller than those of the DAC-DeAC mixture both at a given γ and at a given m. Taking into account that the DTAC and DAC molecules are different only in the structure and size of the polar head group, it is concluded that the large head group of DTAC increases the composition of DeAC and decreases the total surface density remarkably at high concentrations.

Next, let us discuss the miscibility of the surfactants in the mixed micelle. We define the thermodynamic quantity of micelle as the excess one in reference to the spherical dividing surface which makes the excess number of moles of water zero[5] and the composition of DeAC in the mixed micelle X_2^M as

$$X_2^M = N_2^M/(N_1^M+N_2^M), \tag{8}$$

where N_i^M is the number of surfactant i in the micelle particle. The value of X_2^M is calculated by application of the relation[1,5]

$$X_2^M = X_2 - [2(1-X_2)X_2/\mathrm{cmc}]\,(\partial \mathrm{cmc}/\partial X_2)_{T,p} \tag{9}$$

to the cmc vs. X_2 curve given in Fig. 3. The cmc vs. X_2^M

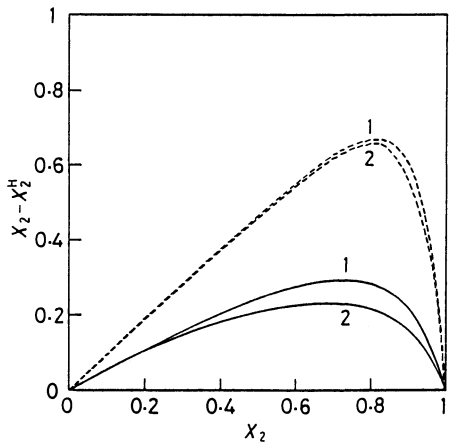

Fig. 7. Difference in composition between the solution and the adsorbed film vs. composition curves at constant molality and constant surface tension: (1) m=14 mmol kg^{-1}; (2) γ=50 mN m^{-1}; (——) DTAC-DeAC system; (----) DAC-DeAC system.

curve is depicted together with the cmc vs. X_2 curve in Fig. 8. It is seen that the diagram has the shape of a swollen cigar and the micelle is richer in DTAC molecules than the solution. Since the mixed adsorbed film is in equilibrium with the bulk solution containing the micelles at a concentration above the cmc, it is useful to compare the compositions in the micelle and adsorbed film. The composition in the adsorbed film at the cmc $X_2^{H,cmc}$ is obtained by virtue of the equation

$$X_2^{H,cmc} = X_2^M - [(1-X_2)X_2/RT\Gamma^{H,cmc}]\,(\partial\gamma^{cmc}/\partial X_2)_{T,p}, \quad (10)$$

where $\Gamma^{H,cmc}$ is the total surface density at the cmc.[1] By applying this equation to the γ^{cmc} vs. X_2 curve given in Fig. 2 and using the X_2^M value in Fig. 8, the values of $X_2^{H,cmc}$ were evaluated; the results are also depicted in

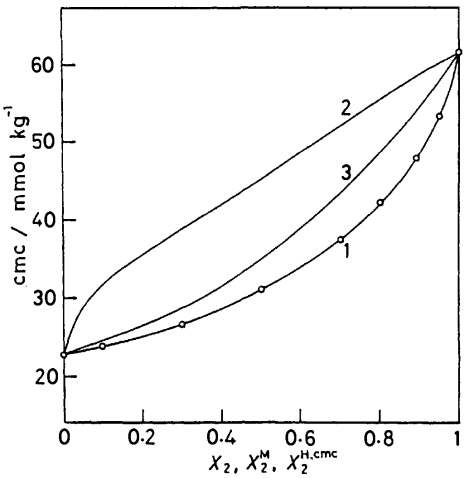

Fig. 8. Critical micelle concentration vs. composition curves: (1) cmc vs. X_2; (2) cmc vs. X_2^M; (3) cmc vs. $X_2^{H,cmc}$.

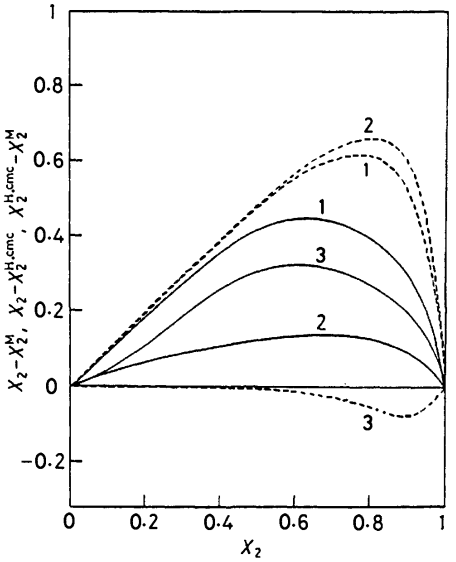

Fig. 9. Difference in composition vs. composition curves at the cmc: (1) $X_2-X_2^M$ vs. X_2; (2) $X_2-X_2^{H,cmc}$ vs. X_2; (3) $X_2^{H,cmc}-X_2^M$ vs. X_2; (——) DTAC-DeAC system; (----) DAC-DeAC system.

the form of the cmc vs. $X_2^{H,cmc}$ curve in Fig. 8. We can see that the adsorbed film at the cmc is also richer in DTAC molecules than the bulk solution. However, it is noteworthy that the composition of DeAC in the adsorbed film is larger than that in the micelle. This behavior forms a striking contrast to that of the DAC-DeAC system.[1]

Now let us consider the values of $X_2-X_2^M$, $X_2-X_2^{H,cmc}$, and $X_2^{H,cmc}-X_2^M$ to elucidate the relation among the compositions in the bulk, surface, and micelle. They are plotted against X_2 in Fig. 9. It is clearly seen that the $X_2-X_2^M$ value is considerably large compared with the $X_2-X_2^{H,cmc}$ value. However, on looking at the corresponding ones of the DAC-DeAC system depicted also in Fig. 9, we notice that the $X_2-X_2^M$ and the $X_2-X_2^{H,cmc}$ values are not so different than each other. This fact indicates that the difference in composition between the adsorbed film and micelle stems from that in geometrical shape when the polar head groups of surfactants are different in shape and size. Furthermore, taking into account that the $X_2-X_2^{H,cmc}$ values of the two systems are fairly different though the $X_2-X_2^M$ values are relatively close to each other, it is concluded that the miscibility in the adsorbed film is influenced more significantly by the structure of polar head group than that in the micelle. A similar conclusion has been drawn from the effect of the *N*-methylation of dodecylammonium chloride on the entropies of interface and micelle formation.[3] There is one more important difference between the two systems; that is, the value of $X_2^{H,cmc}-X_2^M$ is positive for the present system, while negative for the DAC-DeAC system. We can say therefore that the bigger head group is favorable to the micelle formation.

Finally, it is possible to show that the γ^{cmc} vs. composition diagram is helpful to understand the variation of the surface tension of surfactant mixture in the range of concentration above the cmc. It is seen from Fig. 10 that as the total molality m of surfactant mixture increases at a given overall composition X_2, the composition X_2^M in the mixed micelle increases and

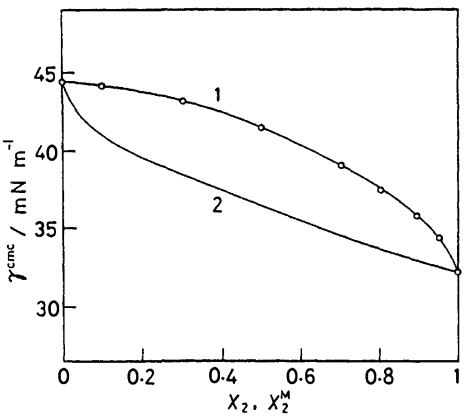

Fig. 10. Surface tension at the cmc vs. composition curves: (1) γ^{cmc} vs. X_2; (2) γ^{cmc} vs. X_2^M.

approaches X_2 at an infinite m. Consequently the surface tension of the micellar solution of mixture is expected to decrease gradually with increasing m. Inspecting Fig. 1, the γ vs. m curve of mixture is found to have a larger negative slope than those of pure DTAC and DeAC at concentrations above the cmc. This is consistent with the above expectation.

In-Situ X-Ray Diffraction Study of Metal Hydride Formation in Palladium and Palladium-Based Alloy Electrodes under Cathodic Hydrogen Charging

Ken-ichi MACHIDA† and Michio ENYO*
Research Institute for Catalysis, Hokkaido University, Sapporo 060
(Received September 28, 1988)

An in situ X-ray diffraction (XRD) technique reported earlier was improved and employed to study the hydride formation in Pd and Pd-Au alloy foils and amorphous Pd-Zr alloy ribbons during cathodic hydrogen charging or its reverse process. The phase transformation from α- to β-PdH_x in the Pd electrode, accompanied by an increase in the cell volume, was demonstrated to take place by the formation of a β phase domain in the bulk during the cathodization. The lattice constant was discontinuously changed from $a \simeq 3.92$ to 4.04 Å and such a discontinuous change was observed on the $Pd_{90}Au_{10}$ alloy as well. However, no phase transformation was observed on the Pd-Au alloys with the Pd content of 70 at.% or below, where the lattice constant increased continuously with an increase in the negative potential for the cathodic polarization. No crystallization in the amorphous Pd-Zr alloy ribbon electrodes was detected after hydrogen charging.

Electrochemical oxidation/reduction reactions are often accompanied by the occlusion of electrolysis products into the electrode, which may cause a phase transformation or formation of other phases. A typical example is the hydride formation due to hydrogen absorption into electrodes of some metals or alloys.[1] An X-ray diffraction (XRD) technique may be used to detect such changes. A set of ex situ XRD measurements on a relationship between the α and β phases of Pd and its alloys has demonstrated that the phase transformation proceeds even electrochemically and also is modified by the alloying element and its content.[2-4] However, the measurements should preferably be made in situ, as the new phases formed may be unstable when the electrodes are taken out of the system in which the electrochemical environment has been controlled.

Uno Falk et al.[5] have reported, by using an in situ XRD technique, clear phase changes during charging and discharging of Cd, Fe, or Ni electrode in Jungner and Edison secondary cells. Recently, Nazri and Müller[6] have applied this technique to a Li electrode in nonaqueous solutions. The present authors also have reported the phase transformation accompanied by the hydride formation in Pd electrodes.[7] In this work, the in situ XRD technique is improved for accepting samples with low crystallinity and applied to the study of hydride formation in Pd, Pd-Au, and amorphous Pd-Zr alloy electrodes as a function of the cathodization conditions.

Basic Relations in Hydrogen Electrode Reaction. The hydrogen electrode reaction on Pd, Pd-Au, or amorphous Pd-Zr alloy electrodes has been shown to proceed via the Volmer-Tafel reaction scheme.[8-10] In this mechanism, the equivalent hydrogen pressure $\overline{P}_{H_2}$ during the polarization as referred to its value $\overline{P}_{H_2,o}$ at equilibrium potential is related to the overpotential component η_2' for the Tafel step, $2H(ads) \rightarrow H_2$, by the relation,[8]

$$-\eta_2' = (RT/2F) \ln (\overline{P}_{H_2}/\overline{P}_{H_2,o}) \quad (1)$$

This overpotential component can readily be evaluated from electrode potential-time transient curves.[8] Although this relation has been substantiated by various analyses, a direct demonstration under an in situ condition is desirable. The in situ XRD analysis by monitoring the η_2' may be expected to give conclusive information about the metal hydride phase relation in hydrogen absorbing metal or alloy electrodes under cathodic polarization.

Experimental

Electrodes. The test electrodes used were Pd foil and $Pd_{100-x}Au_x$ (x=10, 30, 45, and 60) alloy foils of 10×10 mm in size and 12.5 or 50 μm in thickness which were spot-welded to Ta wires sealed beforehand into glass tubings. Similarly, an amorphous $Pd_{35}Zr_{65}$ ribbon (0.8 mm wide and ca. 20 μm in thickness) was cut to pieces of 10 mm long, which were spot-welded on a Ta net of 10×10 mm, followed by etching in dilute HF solution for several ten seconds in order to remove a catalytically inactive ZrO_2 surface layer.

Apparatus and Method. A syringe-type electrochemical cell[11] consisting of the working electrode, a Pt net counter electrode, a Ag/AgCl reference electrode, and a window of Kapton foil (polyimid sheet) for X-ray observations[7] was used (Fig. 1). In order to make the cell applicable to samples of low crystallinity (e.g. oxides or, particularly, amorphous-like samples), a modification was introduced to minimize the background signal from the Kapton foil window, especially in a low 2θ angle region, in such a way that X-ray beams passed vertically through the window over the whole scan angle. The glass cell was mounted on a Rigaku θ-θ scan goniometer which had a fixed and horizontal sample stage, rotatable X-ray source and a detector. The X-ray radiation used was Mo $K\alpha$ (λ=0.71069 Å) monochromatized with a graphite plate. All the electrochemical measurements were carried out at room temperature (about 293 K) in 0.5 M H_2SO_4 (M=mol dm^{-3}) under H_2 atmosphere. The XRD data obtained were calibrated by using silicon powder comounted with epoxy resin on the electrode. All potentials were

represented based on a reversible hydrogen electrode potential.

Results and Discussion

Pd Foil Electrodes. The in situ XRD patterns obtained on a Pd foil electrode under polarization are shown in Fig. 2. The conditions for polarization were chosen in such a way that η_2' was shifted in sequence towards more negative potentials. This process leads to adsorption of hydrogen into the Pd electrode bulk (the absorption hemicycle). The patterns on Pd foil electrode before the polarization or polarized at $\eta_2'>50$ mV were assigned to α phase of the Pd-H system, viz. a cubic system with space group of $Fm3m$. The lattice constant is gradually increased from $a\simeq3.89$ to 3.91 Å along with the negative shift of the polarization potential.

At the η_2' value of 49 mV, the β phase (which belongs to the same cubic system as the α phase) of the Pd-H system started to appear, leading to the α-β coexistence phase. The presence of signals of both α and β phases indicates that the transformation takes place by the partial formation of β-PdH_x domain in the Pd foil electrode. The lattice constants of the specimen at $\eta_2'=49$ mV were 3.92 and 4.40 Å for the α and β phase, respectively. The η_2' value of 49 mV is equivalent to $\overline{P}_{H_2}\simeq2.5$ kPa according to Eq. 1, which is in agreement with that usually observed in the process of gaseous hydrogen charging into Pd.[12] Nevertheless, the complete transformation to β phase at $\eta_2'=46$ or 49 mV needed a long time of polarization and the condition of $\eta_2'=0$ or -38 mV was suitable to achieve a uniform β phase. In addition, the specimen polarized at $\eta_2'=-38$ mV gave rise to enlargement of the lattice constant ($a=4.08$ Å). This clearly indicates that the hydrogen content x in the β-PdH_x further increased with cathodic polarizations at more negative potentials.

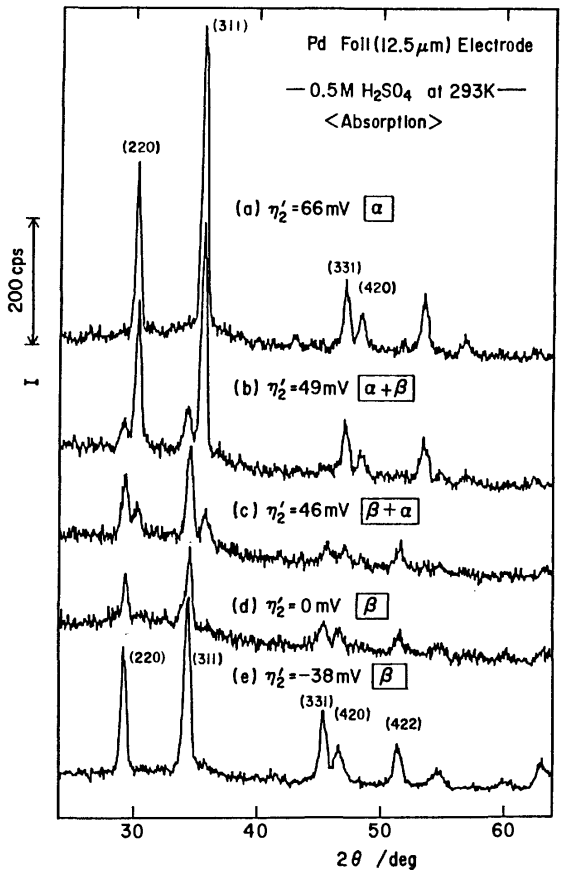

Fig. 2. In situ XRD patterns observed on a Pd foil electrode at various η_2' values during the hydrogen absorption hemicycle. The polarization time was 0.5 h for $\eta_2'=-38$ and 0 mV or 3 h for $\eta_2'=46$, 49, and 66 mV. 0.5 M H_2SO_4.

Figure 3 shows the in situ XRD patterns obtained on a Pd foil electrode under polarization, together with that under a blank condition. The data were collected

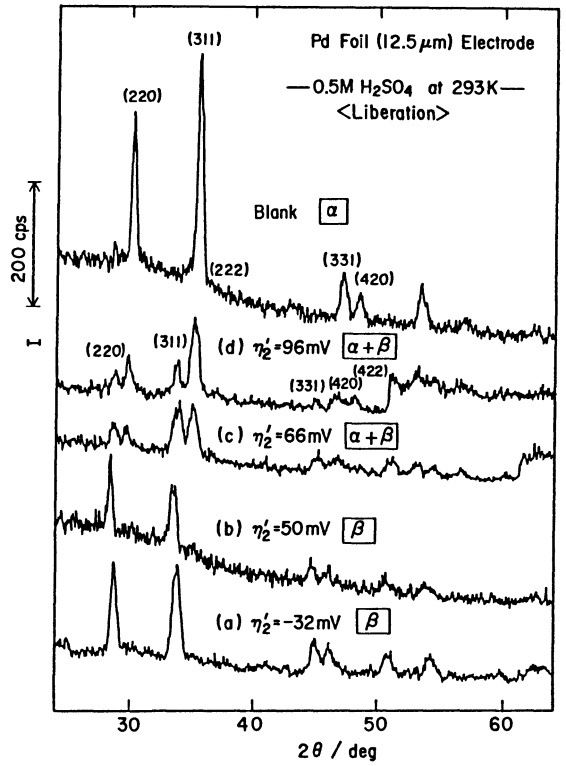

Fig. 3. In situ XRD patterns observed on a Pd foil electrode at various η_2' values during the hydrogen liberation hemicycle. Polarization time was 0.5 h for η_2'=−32 mV or 3 h for η_2'=50, 66, and 96 mV. 0.5M H_2SO_4.

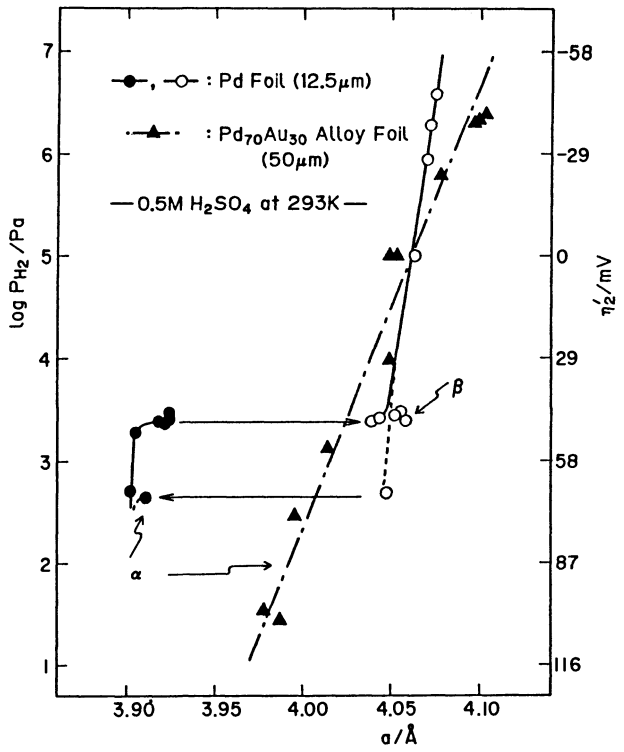

Fig. 4. Relationships between the η_2' (or $\overline{P}_{H_2}$) and lattice constant observed for α and β phases on the Pd-H and $Pd_{70}Au_{30}$-H systems.

under the condition in which electrode potential was shifted stepwise to more positive potentials up to η_2'=96 mV (a hydrogen liberation hemicycle). The β phase in the Pd foil electrode was kept even under the polarization of η_2'=50 mV, but it was partly retransformed to α phase at η_2'= 66 mV, giving the XRD signal originated from α phase which has a comparable intensity with β phase. The amount of α phase increased with increase of the potential for polarization, viz. η_2'=96 mV. On the other hand, no retransformation to α phase was observed at the potential in the α-β transformation region during the hydrogen absorption hemicycle (η_2'=50 mV), even after a longer

Table 1. Lattice Constants for a Series of $Pd_{100-x}Au_x$ Alloy Foils before and after Cathodic Polarization (in 0.5 M H_2SO_4)

Alloy	Lattice constant/Å	
	before	after[a)]
$Pd_{90}Au_{10}$	3.90	4.07
$Pd_{70}Au_{30}$	3.93	4.05
$Pd_{55}Au_{45}$	3.95	4.04
$Pd_{40}Au_{60}$	3.97	4.03

a) Cathodization potential η_2'=ca. −5 mV.

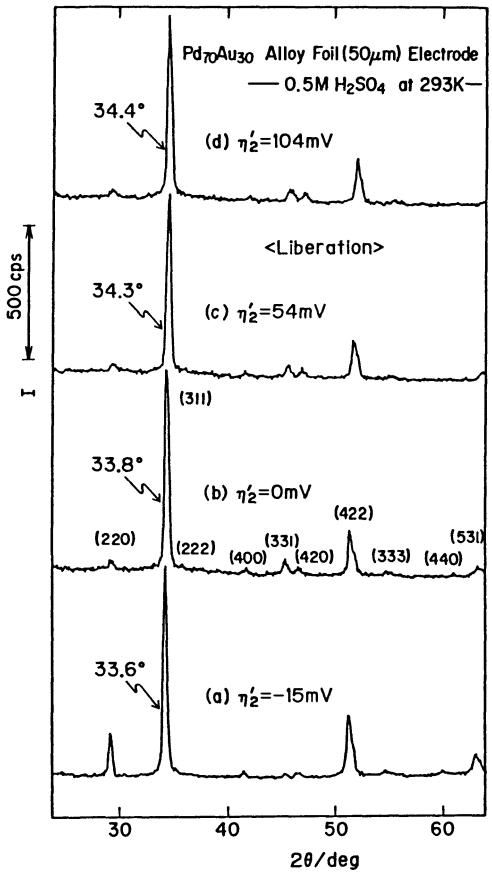

Fig. 5. In situ XRD patterns observed on a $Pd_{70}Au_{30}$ alloy foil electrode at various η_2' values during the hydrogen liberation hemicycle. Polarization time was 0.5 h. 0.5 M H_2SO_4.

polrization period, e.g. 20 h.

The relationship between the η_2' (or $\overline{P}_{H_2}$) and lattice constant observed on the Pd foil are shown in Fig. 4. A clear hysteresis is seen on the hydrogen pressure versus hydrogen content curves between the hydrogen liberation and absorption hemicycles. Such a hysteresis well corresponds to that observed in the hydrogen charging-discharging cycle in gaseous H_2,[12] with the extent dependent on the duration of the polarization.

Pd-Au Alloy Foil Electrodes. The lattice constants of a series of Pd-Au alloy electrodes before and after the polarization at $\eta_2' \simeq -5$ mV are summarized in Table 1. The increase of the Au content in the Pd-Au alloys resulted in an enlargement of the lattice constants (see data in Table 1), while the inverse tendency was observed after the cathodic polarization. This indicates that the Pd-Au alloys become difficult to absorb hydrogen with an increase in the Au content. This observation agrees with results obtained on Pd alloyed with Au[3] or the other group IB metals.[4]

In Fig. 5, the in situ XRD patterns obtained on the $Pd_{70}Au_{30}$ electrode in the hydrogen liberation hemicycle are shown. There was no discontinuous change in the lattice constant obtained at various η_2' values and, instead, the 2θ value of (311) reflection from the α phase changed continuously from 33.6 to 34.4° as indicated in the figure, which gave the lattice constant of 3.986—4.078 Å. In this way, the α-β phase transformation such as that observed on Pd foils did not take place in the $Pd_{70}Au_{30}$ alloy foil electrode. This result is in good agreement with similar characters observed in the case of absorption of hydrogen into Pd-Au alloys.[3]

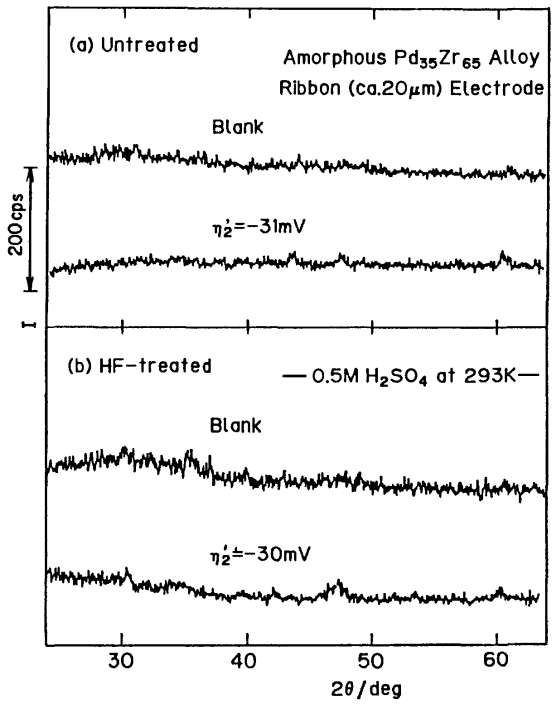

Fig. 6. In situ XRD patterns observed on an amorphous $Pd_{35}Zr_{65}$ ribbon electrode at various η_2' during the hydrogen absorption hemicycle. Polarization time was 1 h. 0.5 M H_2SO_4.

Amorphous $Pd_{35}Zr_{65}$ Alloy Ribbon Electrodes. Figure 6 shows in situ XRD patterns observed on amorphous $Pd_{35}Zr_{65}$ alloy ribbon electrodes before and after the etching treatment in dilute HF solution. Both the untreated and HF-treated specimens before the polarization gave no peak in the XRD patterns originating from crystalline phases (see blank one). Further, no XRD peak corresponding to hydrides was detected even under the cathodic polarization conditions (η_2'=ca. −30 mV). This result may be important in suggesting that the amorphous alloy materials are not likely to encounter hydrogen embrittlement due to recrystallization even under strong hydrogen charging conditions such as the one in the electrochemical cathodic polarization, and thus they may be used in hydrogen storage-type batteries.

Conclusion

An in situ XRD technique was developed and applied to the studies of phase changes during metal hydride formation in Pd and Pd-Au alloy foil and amorphous Pd-Zr ribbon electrodes. The technique may be applicable to studies of composition or structure changes in other electrochemical processes. The α-β phase transformation in PdH_x or no such phase changes in Au-rich Pd-Au alloy foils and amorphous Pd-Zr alloy ribbons were indicated.

The present work has been partly supported by Grants-in-Aid for Scientific Reseasrch from the Ministry of Education, Science and Culture.

Ionization and Dissociation of Picric Acid in 4-Methyl-2-pentanone Solutions at Various Water Concentration

Tatsuya SEKINE* and Hirochika NAGANAWA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 26, 1988)

The spectrum of picric acid in 4-methyl-2-pentanone solutions which contained the acid and water at several concentrations was determined in the wavelength range from 330 to 500 nm and the data were statistically analyzed. It was concluded that picric acid molecules formed ion pairs together with four water molecules in these solutions and the ion pairs thus formed dissociated partially. Both of the ion pairs and dissociated picrate ions in these solutions had strong absorption in the visible range where no absorption was found with the acid molecules but the spectra of these two species were different. The formation and dissociation constants of the ion pairs were also calculated from the data and the role of water in these chemical reactions was considered.

In a previous paper,[1] the dissociation of picric acid in water-saturated 4-methyl-2-pentanone was studied by a liquid-liquid distribution method and the results were compared with those of perchloric and nitric acid. It was concluded that picric acid in this medium was a weak acid (pK_a=4.7) which was weaker than perchloric acid (pK_a=3.5) but stronger than nitric acid (pK_a=6.0). An acid in the undissociated form in such organic solvents may be present in two different chemical forms; the acid molecule and the ion pair. However, it was not possible to know only from these liquid-liquid distribution data whether the undissociated picric acid was in one of these chemical forms or it was a mixture of both. In the present study, the spectrum of picric acid in 4-methyl-2-pentanone solutions was determined at various concentrations of the acid and water. The data were statistically analyzed and the spectrum of the ion pairs was estimated. Furthermore, the molar ratio of the two chemical forms of undissociated acid species was calculated. The formation constant of the ion pairs from the acid molecules as well as the dissociation constant of the ion pairs thus formed were determined at several water concentrations and the role of water for these reactions was considered.

Experimental

All the materials were of a reagent grade. A small amount of picric acid was stored in a reduced pressure desiccator. The 4-methyl-2-pentanone was distilled twice. All the procedures were carried out in a thermostated room at 298 K. A picric acid solution of water-saturated 4-methyl-2-pentanone was prepared by shaking the solvent with an aqueous solution which contained a certain amount of the acid. In order to prepare a picric acid solution of 4-methyl-2-pentanone at a certain acid concentration and a desired water concentration, a water-saturated solution containing the acid was mixed with a calculated amount of dry solvent in a stoppered polypropylene tube. Use of glass vessels was found to be unfavorable for the experiments. When glass vessels were used, the reproducibility of the data was poor but by use of polypropylene vessels, it was much improved. This is probably due to that a part of water and/or the acid are adsorbed on the surface of glass. The absorbance of the picric acid solutions which contained water was measured from 330 to 500 nm. The acid concentration was determined as follows. A portion of the solution was transferred into another tube and ten times volume of hexane was added in order to make the back extraction of the acid more easily. Then the solution was shaken with a 1×10^{-3} mol dm^{-3} aqueous sodium hydroxide solution and the optical absorption of the aqueous phase at 380 nm where the molar absorptivity was 1.34×10^4 was measured. The spectrum of tetrabutylammonium picrate of 4-methyl-2-pentanone solutions at different water concentrations was determined in a similar manner as previously reported.[2] Quartz cells of 1 to 10 mm optical path were used for this spectrophotometry. The water concentration in the solution was determined by the Karl-Fischer titration. A spectrophotometer (Hitachi 556 type) which was connected with a personal computer (NEC 9801 VM type) through a 12 bit interface (Microscience Co. DAS-1898BPC type) was used throughout the experiments.

Data Analysis

In a 4-methyl-2-pentanone solution, picric acid may be present in three forms; an acid molecule ($Hpic(H_2O)_p$), an ion pair ($H^+pic^-(H_2O)_q$), and a picrate ion ($pic^-(H_2O)_r$) which has released a proton ($H^+(H_2O)_s$). Each of the value of p, q, r, and s in the above chemical formulas could be different when the water concentration is different but these values can not be determined in the present study. Thus the total concentration of picric acid in the solution may be written as;

$$[\mathrm{Acid}]_{\mathrm{total}} = \sum[Hpic(H_2O)_p] + \sum[H^+pic^-(H_2O)_q] + \sum[pic^-(H_2O)_r] \quad (1)$$

The water concentration experimentally determined is the sum of the associated and unassociated water with the acid. However, since the water concentration in the present study (0.5 to 0.8 mol dm^{-3}) is in a large excess to the acid, the concentration of total water could be regarded as that of the unassociated water. The ionization of acid is caused by the water in the medium. If the number of water molecules which are necessary for the formation of an ion pair from an acid molecule is always the same even when the water concentration in the medium is different, the following

statistical treatments are possible. Under such conditions, each of p, q, r, and s could be treated as a fixed value in the equations in order to make a simpler expression. The equilibrium for the formation of ion pairs from the acid molecules may generally be written as;

$$Hpic(H_2O)_p + n\ H_2O \rightleftarrows H^+pic^-(H_2O)_q$$

$$K_{ip} = \frac{[H^+pic^-(H_2O)_q]}{[Hpic(H_2O)_p]\,[H_2O]^n} \quad (2)$$

Part of the ion pairs may undergo dissociation. The equilibrium can be written as;

$$H^+pic^-(H_2O)_q \rightleftarrows H^+(H_2O)_s + pic^-(H_2O)_r$$

$$K_{dis} = \frac{[H^+(H_2O)_s]\,[pic^-(H_2O)_r]}{[H^+pic^-(H_2O)_q]} \quad (3)$$

Since several properties of the medium such as the dielectric constant etc. could be different when the water concentration is different, the value of dissociation constant of the ion pairs may be affected by the change in the concentration of water.

The overall acid dissociation constant in the medium may be written as;

$$K_a = \frac{[H^+(H_2O)_s]\,[pic^-(H_2O)_r]}{[Hpic(H_2O)_p] + [H^+pic^-(H_2O)_q]} \quad (4)$$

This can also be rewritten as;

$$K_a = \frac{K_{dis}\,K_{ip}[H_2O]^n}{1 + K_{ip}[H_2O]^n} \quad (5)$$

The absorbance of the solution, A, may be written as;

$$A = \varepsilon_{mol}[Hpic(H_2O)_p] + \varepsilon_{ip}[H^+pic^-(H_2O)_q] + \varepsilon_{ion}[pic^-(H_2O)_r] \quad (6)$$

where ε_{mol}, ε_{ip}, and ε_{ion} is the molar absorptivity of acid molecules, ion pairs, and dissociated picrate ions, respectively, at a certain wavelength.

From Eqs. 1 to 6, the following equation is obtained;

$$A = \frac{1}{2}K_a(\sqrt{1 + 4K_a^{-1}[Acid]_{total}} - 1) \times \left\{\frac{1}{2}\varepsilon_u(\sqrt{1 + 4K_a^{-1}[Acid]_{total}} - 1) + \varepsilon_{ion}\right\} \quad (7)$$

where ε_u is the molar absorptivity of the acid in the undissociated form which can be written as;

$$\varepsilon_u = \frac{\varepsilon_{ip}K_{ip}[H_2O]^n + \varepsilon_{mol}}{1 + K_{ip}[H_2O]^n} \quad (8)$$

When the water concentration is different, the value of ε_u should not be the same as seen from this equation.

In the present study, the spectra of solutions were determined at various acid and water concentrations and the data were analyzed by a successive approximation method using a least squares computer program.

Results

In the present study, the spectra of the following 98 sample solutions were measured. The water concentration was 0.801 (water saturated), 0.751, 0.701, 0.651, 0.601, 0.551, and 0.501 mol dm^{-3} and the total picric acid concentration was 14 different values from 5×10^{-6}

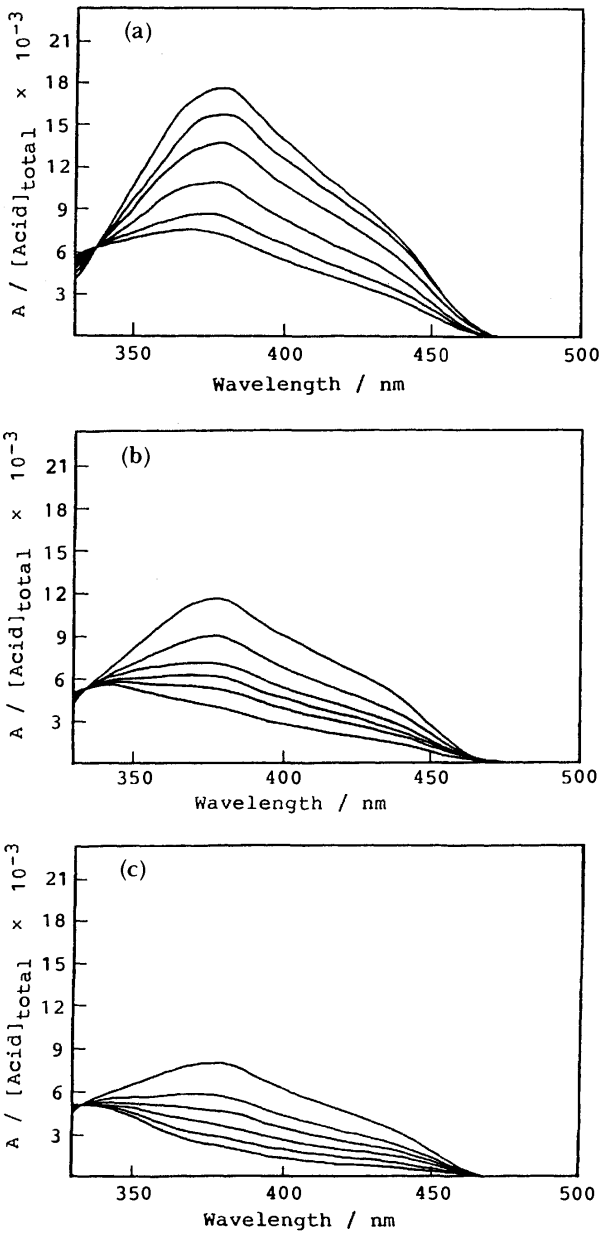

Fig. 1. Examples of spectra of picric acid in 4-methyl-2-pentanone which contained water. The total acid concentration, $[Acid]_{total}$, for each curve in the figures is from the top to the bottom in the right side. (a) $[H_2O]_{total}$ is 0.801 mol dm^{-3} (water saturated) and $[Acid]_{total}$ is 4.77×10^{-6}, 1.45×10^{-5}, 2.90×10^{-5}, 8.25×10^{-5}, 2.03×10^{-4}, and 3.45×10^{-4} mol dm^{-3}. (b) $[H_2O]_{total}$ is 0.651 mol dm^{-3} and $[Acid]_{total}$ is 1.96×10^{-5}, 4.94×10^{-5}, 1.10×10^{-4}, 1.60×10^{-4}, 2.50×10^{-4}, and 6.02×10^{-4} mol dm^{-3}. (c) $[H_2O]_{total}$ is 0.501 mol dm^{-3} and $[Acid]_{total}$ is 2.10×10^{-5}, 5.25×10^{-5}, 9.39×10^{-5}, 1.84×10^{-4}, 3.29×10^{-4}, and 8.05×10^{-4} mol dm^{-3}.

to 1×10^{-3} mol dm^{-3} for each water concentration. Figures 1(a) to 1(c) give the spectra obtained when the water concentration was 0.801, 0.651, and 0.501 mol dm^{-3} as examples of the experimental data.

The absorbance of the 14 solutions of the same water concentration but different $[Acid]_{total}$ was measured from 330 to 500 nm at an interval of 1 nm. Since the absorbance due to the solvent could not be canceled out when the wavelength was lower than 330 nm, no optical data were obtained in this lower wavelength range. From these data, the value of ε_u was determined on the basis of Eq. 7 for each wavelength to give the best-fit with the optical data at a certain given value of K_a. By repeating these procedures, a value of K_a which was common for the data of all the wavelengths and a value of ε_u for each wavelength (total 171 values of ε_u in the above wavelength range) were calculated for each given water concentration. Table 1 lists the values of K_a for the seven water concentrations thus obtained. The spectra of the undissociated species were calculated as shown in Fig. 2. When the water concentration in the medium was very low, for example, such as 5×10^{-3} mol dm^{-3}, no absorption due to the ion pairs and/or due to the dissociated picrate ions was found in the visible range and the spectrum from 330 to 500 nm was essentially similar to that of picric acid in cyclohexane obtained by separate experiments. For this reason, it was concluded that only the spectrum of the acid molecules was observed under such conditions. This spectrum is also given in Fig. 2. It was found that the spectrum of 1×10^{-5} mol dm^{-3} of tetrabutylammonium picrate in 4-methyl-2-pentanone was not affected by water in the concentration range of the present study. The salt could be regarded to dissociate nearly completely at this concentration at least in the water-saturated medium.[2] From these, it could be assumed that the molar absorptivity of the dissociated picrate ions, ε_{ion}, is not affected by water under the conditions of the present study.

The above results indicate that water is indispensable for the formation of ion pairs in the medium. From the values of ε_u, the value of n and of K_{ip} were calculated on the basis of Eq. 8 by the successive approximation method. After trials, the number of water molecules which were necessary to form the ion pairs from acid molecules in 4-methyl-2-pentanone, n in Eq. 2, was found to be 4.0. The value of K_{ip} is found to be $10^{-0.35}$ as given in Table 1. Furthermore, the value of K_{dis} at each water concentration was determined by introducing a set of values of K_a, K_{ip}, and n into Eq. 5 as listed in Table 1. Figure 3 gives the spectra of the three chemical species of picric acid. The spectrum of ion pairs was obtained by the above calculation but that of acid molecules and of dissociated picrate ions were obtained by separate experiments under conditions where only one of these species was found in the solution.

Table 1. Summary of the Values Obtained by Analysis of Data

$[H_2O]_{total}$	log K_a	log K_{ip}[a]	log K_{dis}	n[b]	R[c]
0.801	−4.51	−0.35	−3.70	4.0	0.156
0.751	−4.61	−0.35	−3.71	4.0	0.125
0.701	−4.73	−0.35	−3.72	4.0	0.098
0.651	−4.87	−0.35	−3.74	4.0	0.075
0.601	−5.01	−0.35	−3.75	4.0	0.056
0.551	−5.15	−0.35	−3.75	4.0	0.040
0.501	−5.33	−0.35	−3.77	4.0	0.028

a) In the successive approximation procedures of data analysis, K_{ip} in Eq. 2 was assumed to be constant even when the water concentration was different. The range of error for this value obtained is ±0.07. b) The number of water molecules which are necessary to form an ion pair from one acid molecule. The range of error for this value obtained is ±0.14. c) The molar ratio of ion pairs to the acid in the undissociated form; $R=[H^+pic^-]/([Hpic]+[H^+pic^-])$.

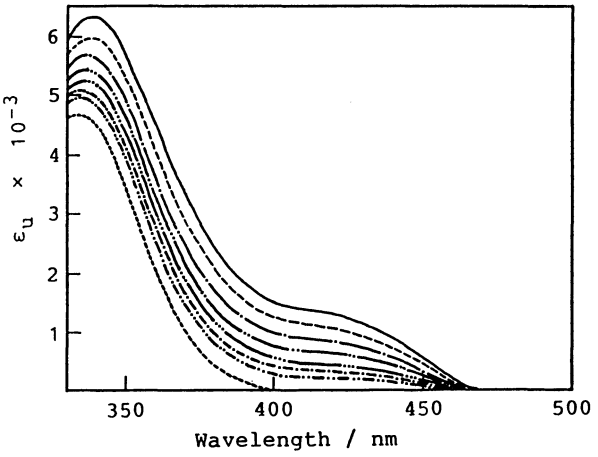

Fig. 2. Calculated spectrum of picric acid in the undissociated form when the $[H_2O]_{total}$ is different. The $[H_2O]_{total}$ is 0.801, 0.751, 0.701, 0.651, 0.601, 0.551, 0.501, and 5.0×10^{-3} mol dm^{-3} from the top to the bottom.

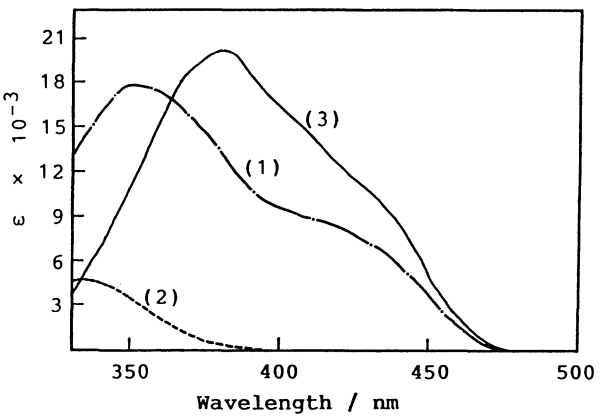

Fig. 3. Absorption spectrum of (1) ion pairs obtained by calculation and that of (2) acid molecules and (3) dissociated picrate ions obtained by separate experiments. The solvent is 4-methyl-2-pentanone containing water.

Discussion

In the previous paper,[1] the dissociation constant of picric acid in water-saturated 4-methyl-2-pentanone was determined by a liquid-liquid distribution method to be $10^{-4.7}$. This value is approximately similar to that in the water-saturated medium obtained by the spectrophotometry in the present study, $10^{-4.51}$. The water concentration in the solvent was the same throughout the experiments and no spectrophotometric measurements were made in this previous liquid-liquid distribution study. For this reason, the chemical form of the undissociated acid and the role of water for the acid dissociation could not be concluded. However, the following conclusions can be drawn from the results in the present study. (i) Since the spectrum of picric acid in this solvent at lower water concentrations is quite similar to that in cyclohexane, all the acid should be in the form of acid molecule under these conditions. Thus the change in the spectrum by the change in the water concentration in 4-methyl-2-pentanone can well be explained in terms of ion-pair formation from one acid molecule with four water molecules and that of the dissociation of ion pairs thus formed. In other words, water is an essential base which has an electron donating oxygen atom and causes the ion-pair formation. However, 4-methyl-2-pentanone should be a too weak base for this. (ii) Since the value of K_{dis} was not affected very much by the change in the water concentration as is seen from Table 1, the change in the physical properties of the medium should be only slight in the concentration range of water of the present study. (iii) The overall acid dissociation constant, K_a in Eq. 4, is dependent on the water concentration but the dissociation constant of the ion pairs, K_{dis} in Eq. 3, is only slightly dependent on it. Thus the dependence of the overall acid dissociation constant on the water concentration is an apparent effect. This is because although the ionization of the acid is caused by water, K_a in Eq. 4 does not contain the term of water concentration. The effect of water can be normalized by Eq. 5. (iv) The value of K_{dis} in water-saturated solvent ($10^{-3.70}$) is similar to that of the dissociation constant of sodium and potassium salt of this acid ($10^{-3.60}$ for sodium salt and $10^{-3.61}$ for potassium salt) in the same medium as reported in the previous paper.[2] This indicates that the degree of dissociation of the ion pairs is rather similar to that of sodium or potassium salt of this acid in the same medium. Furthermore, the spectrum of the ion pairs in Fig. 3 is quite similar to that of the ion pairs of sodium or potassium picrate in water-saturated 4-methyl-2-pentanone.[2] Both of the spectrum of lithium picrate in the ion-pair form and in the dissociated ion form in 2-butanone previously reported by Gilkerson and Roberts[3] are quite similar to that of picric acid in the corresponding chemical form obtained in the present study. (v) Since four water molecules should hydrate a proton when the acid is ionized, the cation, $H_9O_4^+$, may be formed in such a medium like in aqueous solutions[4,5]. This cation could be present in the dissociated form or in the ion-pair form with a picrate ion in 4-methyl-2-pentanone.

Iwachido, Oosawa, and Tôei studied the dissociation of picric acid in 4-methyl-2-pentanone, 2-butanone, and acetone by spectrophotometry and by vapor-pressure osmometric method.[6] In this previous paper, the dissociation equilibrium in the following equation was considered.

$$HA_{x(H_2O)} + nH_2O \rightleftarrows H^+_{y(H_2O)} + A^-_{z(H_2O)}$$

From Fig. 1 in this previous paper, the pK_a in water-saturated 4-methyl-2-pentanone can be read as $10^{-4.3}$. Furthermore, the hydration number of proton was concluded to be 4.0 in this previous study. However, as seen from Fig. 2 in the present study, the spectrum of the undissociated acid, which is the cumulative spectrum of both the acid molecules and ion pairs, is dependent on the water concentration. This is due to the difference in the proportion of the ion pair species in the undissociated acid when the water concentration is different. Thus when the acid dissociation is determined by spectrophotometry and when the formation of ion pairs is not taken into account, the fraction of ion pairs is not involved in the fraction of the undissociated acid but it is involved in the fraction of the dissociated picrate ions. This should cause an overestimation of the acid dissociation. Furthermore, as seen from Fig. 3, the spectra of ion pairs and dissociated picrate ions are different and this causes an error in the estimation of the dissociation constant when the wavelength to be used for the data analysis is different. Table 1 also gives the calculated molar ratio of the ion pairs to the undissociated acid at each water concentration. This ratio should be independent from the acid concentration when the water concentration is the same as seen from Eq. 2. When ion pairs are formed, a careful correction for this species should be made for the determination of the acid dissociation constant by spectrophotometry. Such a correction should not be necessary when the medium is high dielectric as water or it is low dielectric as cyclohexane. This is because in the former, the formation of ion pairs is negligible and in the latter, the dissociation of the ion pairs is negligible. However, in a moderately dielectric medium as in 4-methyl-2-pentanone (dielectric constant=13.1, dry solvent at 293 K), consideration on the effect for the optical absorption due to the ion pairs is important under certain conditions. This should be necessary in order to make a reasonable estimation of the dissociation equilibrium of the acid.

The authors are grateful to Dr. Satoshi Kusakabe for his valuable discussion.

Syntheses, and Crystal and Molecular Structures of Tetraethylammonium, and Tetrapropylammonium Tris(thiocyanato)cadmates(II), $[R_4N][Cd(SCN)_3]$, ($R=C_2H_5$, C_3H_7)

Masahiro TANIGUCHI* and Akira OUCHI
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received July 23, 1988)

The title complexes have been synthesized and their crystal and molecular structures determined by a single crystal X-ray diffraction technique. $[(C_2H_5)_4N][Cd(SCN)_3]$ (**1**) is orthorhombic with a space group of $A2_1am$; $a=10.773(2)$, $b=16.574(4)$, $c=9.871(2)$ Å, and $Z=4$, while $[(C_3H_7)_4N][Cd(SCN)_3]$ (**2**) is triclinic with a space group of $P\bar{1}$; $a=10.297(5)$, $b=11.542(5)$, $c=9.374(3)$ Å, $\alpha=90.10(3)$, $\beta=91.61(4)$, $\gamma=80.94(4)°$, and $Z=2$. In **1**, the metal atom has a 3*N*,3*S*-hexa-coordinated octahedral geometry, and three ligated N atoms take *fac*-configuration. Each pair of a metal atoms are bridged by three thiocyanate (SCN) ions, where two SCN ions are *S*-coordinated, while the other is *N*-coordinated to the same side metal atom, forming a linear polymeric form. In **2**, the metal atom is in a 3*N*,2*S*-penta-coordinated trigonal-bipyramidal geometry, where one non-bridging SCN ion is *N*-coordinated equatorially, while four bridging SCN ions are ligated with two N (axially), and two S atoms (equatorially), respectively. Each pair of metal atoms is bridged by two SCN ions, forming a linear polymeric form. The respective tetraalkylammonium ions in **1** and **2** are not bridged to the complex anions, but are bonded only electrostatically. The final *R* values obtained are: **1**, 0.042 and **2**, 0.052.

Several reports about the thiocyanato complexes of cadmium, in which the metal atoms are bridged by thiocyanate (SCN) ions, have already been published.[1-9] Many of the complexes are the neutral Lewis base adducts of cadmium(II) thiocyanates,[1-7] but there are some, not many, anionic thiocyanato complexes where the central cadmium atoms are coordinated only to SCN ions.[8,9] These anionic complexes have their own polymeric form, respective types of bridging structures. The $M[Cd(SCN)_3]$ type tris(thiocyanato)-cadmates of rubidium,[9] cesium,[9] and tetramethylammonium[8] are in two-, three-, and one-dimensional polymeric form, respectively. Moreover, in the case of the tetramethylammonium salt, we could obtain another type of thiocyanatocadmate, $[(CH_3)_4N]_2[Cd(SCN)_4]$, which has a different type of polymeric chain.[8] Therefore, it was thought to be very interesting to synthesize and to clarify the structures of the other kinds of tetraalkylammonium thiocyanatocadmates.

From this aspect, we have synthesized the title two new complexes, and their crystal and molecular structures were determined by the single-crystal X-ray diffraction method.

Experimental

Synthesis of Tetraethylammonium and Tetrapropylammonium Tris(thiocyanato)cadmates(II). Cadmium(II) thiocyanate, as well as tetraethyl- and tetrapropylammonium thiocyanates were obtained by metathetical reactions between their chlorides and potassium thiocyanate in methanol, respectively, by the method of Singh.[10]

The tetraethylammonium salt, $[(C_2H_5)_4N][Cd(SCN)_3]$ (**1**), was obtained as follows. Cadmium thiocyanate (0.57 g, 2.5 mmol) was dissolved into 10 cm^3 of methanol, and the acetone solution (5 cm^3) of tetraethylammonium thiocyanate (0.47 g, 2.5 mmol) was added. The mixture was stirred and was left standing for about 1 h at ambient temperature; the crystalline product precipitated. Yield: 0.56 g (1.34 mmol, 54%). Found: Cd, 26.88; C, 31.63; H, 4.76: N, 13.29%. Calcd for $CdC_{11}H_{20}N_4S_3$: Cd, 26.96; C, 31.69; H, 4.84; N, 13.44%.

The tetrapropylammonium salt, $[(C_3H_7)_4N][Cd(SCN)_3]$ (**2**), was obtained almost by the same method as that for **1**, using an aqueous solution of cadmium thiocyanate (0.57 g, 2.5 mmol, in 5 cm^3 of water) and the acetone solution of tetrapropylammonium thiocyanate (0.61 g, 2.5 mmol, in 7 cm^3 of the solvent). Yield: 0.60 g (1.27 mmol, 51%). Found: Cd, 23.83; C, 37.85; H, 5.88; N, 11.85%. Calcd for $CdC_{15}H_{28}N_4S_3$: Cd, 23.76; C, 38.09; H, 5.97; N, 11.84%.

Intensity Data Collection. The crystallographic data as well as various experimental conditions used to obtain the intensity data of both complexes are listed in Table 1. The used crystals of both complexes were colorless. The reflections were collected on a Rigaku AFC-6A automated 4-circle X-ray diffractometer with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). The observed intensities were corrected for Lorentz and polarization factors, but not for absorption and extinction.

Structure Determination. The structures were solved by the heavy-atom method. The positions of the metal, sulfur, and some other atoms were deduced from their three-dimensional Patterson maps; the other non-hydrogen atoms were located by means of successively Fourier syntheses. Their positional, isotropic and then anisotropic thermal parameters were refined by means of a block-diagonal least-squares method.

In a crystal of **1**, the ab-plane is a mirror plane, and the cadmium atom as well as one bridging SCN ion, S(2)–C(2)–N(2), are on it, while the other two bridging SCN ions are arranged on both sides of the plane, since one is the mirror image of the other (Fig. 3).

The N(3) atom of the tetraethylammonium ion is also in the mirror plane. Although only one set of its carbon atoms are shown in Fig. 3, another set of carbon atoms also exists at the respective mirror image positions, and the occupancy factors of each pair should be equal, 0.5, except for those of C(4) and C(6), 1.0, which are in the mirror plane.

As the respective electron clouds of the pairs of C(3) and $C(3^i)$, as well as of C(5) and $C(5^i)$, which are on both sides of

$R_w=[\sum w(|F_o|-|F_c|)^2/\sum wF_o^2]^{1/2}$, where $w=1/[\{\sigma(|F_o|)\}^2+(F_w\times F_o)^2]$
R_r (R_{rw}): The R_r and R_{rw} values for the structure of inversed chirality. As these values are higher than the normal ones, they are not adopted. Moreover, as the differences between the corresponding values of the normal and inversed chirality are only a little, any more stereochemical investigations were not attempted.

the mirror plane symmetrically, are hardly separated, they are too large to be regarded as being at one position in the mirror plane. Therefore, in the final step of refinement, as a device to converge their positional parameters, two of their thermal parameters, B_{23} and B_{13}, were fixed to be 0, and were refined as usual. No such problem was found concerning the C(7) and C(9) atoms. An attempt to separate the C(8) atomic position into two was not successful: probably their positions are too close to be distinguished from each other.

All of the calculations were carried out on a HITAC M-682H or M-680H computer at the Computer Center of the University of Tokyo, using the UNICSIII program.[11] The atomic scattering factors were taken from Ref. 12.

Infrared Spectrum Measurement. The infrared spectra of these complexes were obtained by means of a JASCO 202-A infrared spectrophotometer, using liquid paraffin and hexachloro-1,3-butadiene mull.

Results and Discussion

The final atomic parameters of **1** and **2**, together with their isotropic equivalent temperature factors, are listed in Tables 2 and 3; their bond lengths and bond angles are tabulated in Tables 4 and 5, respectively.[13] A perspective drawing of the skeletons of complexes **1** and **2**, together with the numbering scheme of the atoms, are shown in Figs. 1 and 2. Projections of the unit cell of **1** and **2** along c-axis are given in Figs. 3 and 4. The numbering scheme of the tetraalkylammonium cations of **1** and **2** are shown in Figs. 3 and 4,

respectively.

In **1**, each cadmium atom, which is in the mirror plane, has a 3*N*3*S*-hexa-coordinated octahedral geometry: the nitrogen atoms as well as sulfur atoms are in the *fac*-configuration, respectively. Each pair of cadmium atoms is bridged triply by three SCN ions, where the ions are coordinated to one side of the metal atom with 2N and 1S atoms, while to the other side of the metal atom with 1N and 2S atoms, respectively. This type of triple SCN bridging structure is only found in this complex, **1**, and in $[(CH_3)_4N][Cd(SCN)_3]$ (**3**);[8] it is never found in any other metal thiocyanato complexes.

The complex is linked approximately linearly along the a-axis. The cadmium atoms lie along the planes

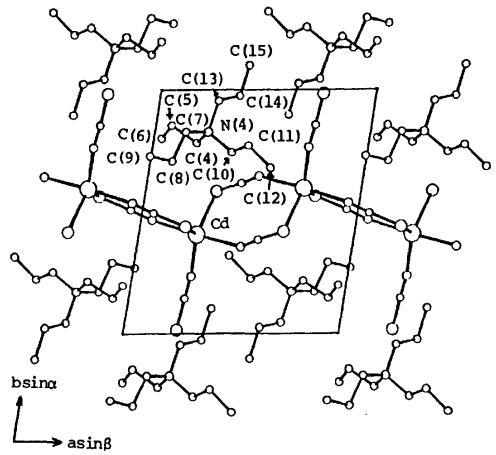

Fig. 4. A projection of the unit cell of $[(C_3H_7)_4N][Cd(SCN)_3]$ along c-axis.

parallel to the bc-plane, which cross the a-axis at 0 and 0.5.

As shown in Table 4, the average Cd-S and Cd-N bond lengths are shorter than the sum of the Shannon's ionic radii of Cd-S and Cd-N.[14] The average Cd-S and Cd-N bond lengths of **3**, 2.720 and 2.334 Å,[8] are not much different from the corresponding ones of **1**.

Similar to the Cd-N-C angles of **3** (155.5(7), 145.6(10), and 144.5(11)°),[8] the corresponding bond angles of **1**, Cd^{iv}-N(1)-C(1) (iv, 0.5+x, $-y$, z) and Cd-N(2)-C(2) (147.1(7) and 157.2(8)°), are much smaller than the angles of common thiocyanato complexes, 160—180°.

On the other hand, the Cd-S-C bond angles of **1** are in the range of the common angle of the other cadmium thiocyanato complexes (90—100°).[1-9]

The Cd··· Cd^{iv} distance is 5.442(1) Å, which is not much different from that of **3**, 5.373(3) Å, but a little shorter than the values found in the other double-SCN-chain neutral cadmium thiocyanate adducts.[1-7]

However, the chains of complexes **1** and **3** are a little different from each other. As shown in Fig. 3, all complex chains of **1** are exactly parallel, while those of **3** are not, because their neighboring chains are different in their zigzag bending structure from each other. Consequently, their corresponding SCN ions are not exactly parallel.

Complex **1** is less closely packed than **3**. Their unit-cell volumes are; **1**, 1762.5(7), and **3**, 1370(7) Å^3, respectively, where both of them are Z=4, and their respective D_x are: **1**, 1.57 and **3**, 1.75.

In **2**, the cadmium atom is 3*N*2*S*-penta-coordinated trigonal bipyramidal geometry: two nitrogen atoms, N(1) and $N(3^{ii})$, are at the axial positions, while two sulfur, $S(1^{i})$ and S(3), and one nitrogen, N(2), atoms are ligated equatorially. The angle N(1)-Cd-$N(3^{ii})$ is 176.1(3)°, which is approximately a straight line, while the positional deviation of the Cd atom from the plane of N(2), S(3), and $S(1^{i})$ atoms is only 0.04 Å.

Since, the complex **2** has a smaller coordination number, 5, than the octahedral ones, the Cd-S as well as the Cd-N bond lengths are expected to be shorter than the latter type complexes. In fact, Shannon's ionic radii of divalent cadmium in coordination number 6 and 5 are 0.95 and 0.87 Å, respectively.[14] Really the Cd-S lengths of **2** (2.573 Å on the average are shorter than those of **1** (2.745 Å on the averge). However, against expectation, the Cd-N length of **2** (2.288 Å on the average) is not much different from those of **1** (2.295 Å on the average). In **2**, the axially bridging Cd-N(1), and Cd-$N(3^{ii})$ bond lengths (2.351 Å on the average) are longer than that of the equatorially coordinated non-bridging SCN ion, Cd-N(2) (2.163(7) Å). This fact is probably due to a steric hindrance caused by packing SCN-bridging complexes in the crystal, which may originate for the same reason, since their Cd-N-C bond angles are abnormally small (143.1(6) and 160.9(6)°), compared with the corresponding angles of any common thiocyanato complexes, 180—160°. The angle of Cd-N(2)-C(2) is 169.5(7)°, which is less deviated from 180°, and which is expected to be less hindered (sterically) in the crystal.

Each pair of cadmium atoms is bridged by two SCN ions, forming a linear polymeric chain laid approximately parallel to the a-axis: Cd··· Cd^{i} and Cd··· Cd^{ii} are 5.373(3) and 5.855(3) Å, respectively. Two cadmium atoms, the central one and the next one in the line, and the atoms of two SCN ions, which bridge the two metal atoms, form an eight-membered ring. The rings on both sides of a metal atom, are in the respective planes: the deviations of the atomic positions of the rings from the respective mean-square planes are less than 0.1 Å. The dihedral angle between the two planes is 78.1°.

Some temperature factors of propyl carbon atoms of **2** are a little large; however, no clear disorder was found.

This type of penta-coordinated complex is the first example in the anionic thiocyanato complexes of cadmium. Even among the neutral adducts of cadmium(II) thiocyanates, only one example, bis(thiocyanato)-{tri(*m*-tolyl)phosphine}cadmium(II) (**4**), has been reported.[1] In **4**, one S and one N atom of SCN ions are ligated to the axial directions, while one each of P(phosphine), S(SCN), and N(SCN) atoms occupy the equatorial positions. The axial Cd-S and Cd-N bond lengths are 2.792(2) and 2.297(6) Å, while the equatorial ones are, 2.595(2) and 2.256(6) Å. Compared with the corresponding bond lengths of **2**, in **4**, the Cd-S (equatorial) is about the same, while Cd-N (equatorial) is not so short as that of **2**. This fact is probably because of the steric hindrance of the large size phosphine ligand, as well as because of the fact that the equatorial SCN ion is a bridging one in **4**.

The infrared spectra of **1** and **2** were examined. The ν(CN) band at 2100 cm^{-1} of **1** is approximately a sin-

glet, although some fine structure of the peak was recognized. On the other hand, the band of **2** appeared in two peaks (2100 and 2140 cm^{-1}), other than the additional fine structures of both peaks. The splitting of the band of **2** is probably due to the existence of two types of SCN ions as above mentioned. The ν(CS) (760 cm^{-1}), and δ (SCN) (458 cm^{-1}) bands were found in both spectra of **1** and **2**: both of them are singlets and no clear wavenumber differences were recognized between the corresponding peaks of **1** and 2.

Preparation of Crystalline $LiNb_xTa_{1-x}O_3(0 \leqq x \leqq 1)$ Films from Metal Alkoxide Solutions

Shin-ichi HIRANO* and Kazumi KATO
Department of Applied Chemistry, Faculty of Engineering, Nagoya University,
Furo-cho, Chikusa-ku, Nagoya 464
(Received August 3, 1988)

Crystalline $LiNb_xTa_{1-x}O_3(0 \leqq x \leqq 1)$ films were prepared from complex alkoxide solutions, controlling the ratio of Nb to Ta by means of a dip-coating method. The present work revealed the dependence of the film thickness on the concentration of the solution and the speed of the withdrawal of the substrate from the solution, the effects of water on the crystallization of the films, and the effects of the structures of the substrates on the crystallinity of the prepared films.

$LiNbO_3$ and $LiTaO_3$ are very attractive materials for use in piezoelectric and electrooptic devices. They have the same crystal structure and form a solid solution. The growth of single crystals had been studied mainly by means of the Czochlarski method for a long time. In both the Li_2O-Nb_2O_5 system and the Li_2O-Ta_2O_5 system, there are solid solution ranges around the stoichiometric compositions. Single crystals could be grown not from the stoichiometric melts, but from the congruent melts. The congruent compositions of $LiNbO_3$ and $LiTaO_3$ are 48.45 mol% Li_2O[1] and 48.75 mol% Li_2O[2] respectively. For SAW devices and integrated optics, $LiNbO_3$ and $LiTaO_3$ thin films were prepared by several techniques, including RF sputtering,[3-7] vapor transport,[8] epitaxial growth by melting (EGM),[9] and the liquid-phase epitaxial (LPE) growth,[10-13] in which the chemical composition has hitherto been quite difficult to control. The precise control of the composition is important in these systems, though, since their properties depend greatly on the Li_2O composition.

We ourselves previously reported the synthesis of stoichiometric $LiNbO_3$ powders and $LiNbO_3$ films by the controlled hydrolysis of carefully prepared alkoxide.[14-16] By this method, we could synthesize stroichiometric crystalline fine powders of $LiNbO_3$ at temperature as low as 250 °C,[14] and also crystalline $LiNbO_3$ films on Si and sapphire substrates.[15,16] It was found that the crystallinity of the initial thin film coating of $LiNbO_3$ affected the crystallization of films deposited subsequently. By crystallizing the initial thin film at 400 °C on a sapphire substrate, the subsequently coated film on it could be made to crystallize, even at 250 °C, without any cracks. Films on sapphire substrates crystallized with the preferred orientation, but not these on Si substrates. Several workers[17,18] have followed us in the preparation of $LiNbO_3$ films and $LiTaO_3$ films by this method because this method is a promising chemical technique by which highly pure products with desiable composition can be synthesized at low temperatures.

In this paper, we will discuss the conditions desirable for preparing $LiNbO_3$ and $LiTaO_3$ films with and without the preferred orientation from alkoxide solutions by means of the dip-coating method, we will also examine the crystallization process of these prepared films. This paper will also focus on the preparation of $LiNb_xTa_{1-x}O_3(0 \leqq x \leqq 1)$ films.

Experimental

Lithium ethoxide (99.99% pure), niobium pentaethoxide (99.999% pure), and tantalum pentaethoxide (99.9999% pure) were used as sources. Both $LiOC_2H_5$ and $M(OC_2H_5)_5$ (M=Nb,Ta) in the molar ratio of 1 : 1 were dissolved in absolute ethanol; then the mixture was stirred and refluxed carefully at 78.5 °C for 24 h in order to prepare a complex alkoxide solution.[14] For the partial hydrolysis of this solution, an adequate amount of CO_2-free, distilled water with ethanol was dropped in slowly. After the mixture had then been stirred and refluxed for 24 h, it was concentrated in order to adjust the viscosity and the density of the solutions by measuring with a rotational viscometer and a picnometer.

Optically polished Si and sapphire (α-Al_2O_3) with various crystallographic orientations (such as (100) and (111) for Si and (012), (110), and (001) for α-Al_2O_3) were used as substrates. These substrates were cleaned by ethanol before the dipping procedure.

Substrates were dipped into the solutions and withdrawn at fixed rates. Thin films formed on the substrates after they had dried for several minutes at room temperature. The coated substrates were then heated up to various temperatures at the rate of 2 °C min^{-1} and kept for 1 h at that temperature in a flow of a water-vapor and oxygen mixture, after while they were heated further for 0.5 h in dry oxygen. To examine the effect of the atmosphere on the crystallization during heat treatment, the entire heating procedure was also carried out in a flow of dry oxygen.

The crystallization of films was examined by means of XRD and FT-IR. The film thicknesses were determined by means of ellipsometry, while the morphologies of the films were observed by means of SEM.

Results and Discussion

The parameters which influenced the homogeneity, the thickness, the crystallization, and the crystallinity of the films prepared by the dip-coating method were as follows; the partial hydrolysis of alkoxide solutions, the concentration of alkoxide solutions, the speed of the withdrawal of substrates from the solutions, the crystal system and the crystallographic orientation of

the substrates, and the heating conditions.

Effects of Concentration of Alkoxide Solution and Withdrawal Speed on Film Thickness. For the composition of Li_2O-Nb_2O_5, homogeneous, transparent, and stable solutions were prepared after a partial hydrolysis of the double alkoxide solution. An amount of water equal to the amount of the double alkoxide, $R_w(H_2O/LiNb(OEt)_6)=1.0$, was essential for the partial hydrolysis if we were to prepare a stable homogeneous alkoxide solution. The viscosities and the densities of the solutions for various concentrations are shown in Table 1. Homogeneous gel films could be prepared not from a 1.3 mol dm^{-3} solution, which was almost saturated, but from solutions of up to 1.0 mol dm^{-3}. Figure 1 shows the thickness of $LiNbO_3$ films crystallized at 400 °C as a function of the concentration of the solution. It was found that the film thickness changed linearly with the concentration of the solution. Another parameter which determined the film thickness was the withdrawal speed. Figure 2 shows the effect of the withdrawal speed (U) on the thickness (t) of $LiNbO_3$ films crystallized at 400 °C. Linear relationships are observed for the log t-log U plots. This linear relation has also been observed for a solution of styrene and hexyl methacrylate in toluene,[19] for alkoxy-derived films,[20] and for $BaTiO_3$ films from alkoxide solutions.[21] In the present work on $LiNbO_3$ films, a slope of 0.45—0.54 has been observed.

Table 1. Viscosities and Densities of Solutions for Preparation of $LiNbO_3$ Films (20 °C)

	Withdrawal speed / mm s^{-1}		
	0.6	1.5	2.4
0.2	27	40	50
0.6	86	126	180

The alkoxide solution with the Li_2O-Ta_2O_5 composition was more sensitive to water than the solution with the Li_2O-Nb_2O_5 composition. Even though a very small amount of water (R_w=1/4) was added, the solution came to be opaque colloidal, which was not appropriate for the dip-coating. Therefore, $LiTaO_3$ films were prepared from the double alkoxide solution without partial hydrolysis. The viscosities and the densities of the solutions are shown in Table 2. The saturated concentration of the solution with the Li_2O-Ta_2O_5 composition was about 0.7 mol dm^{-3}. Therefore, the relationships between the concentration of the solution and the thickness of films crystallized at

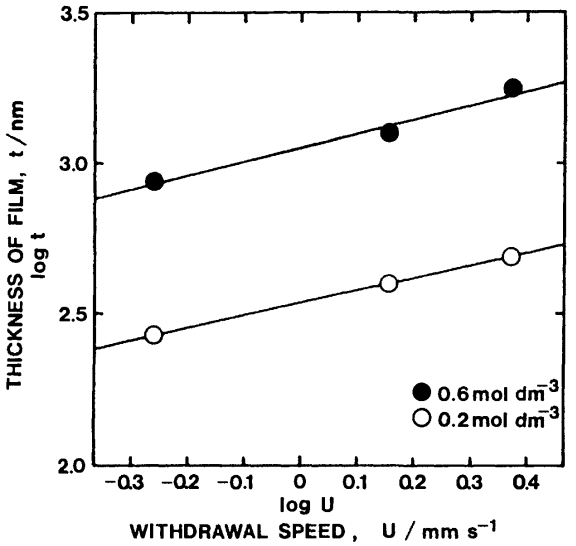

Fig. 3. Change of film thickness (t) with withdrawal speed (U) for $LiTaO_3$ films crystallized at 500 °C expressed in logarithmic scale.

500 °C, and the withdrawal speed and the film thickness, were measured for the solutions up to 0.7 mol dm^{-3} (Table 3 and Fig. 3). The film thickness was found to increase linearly with the concentration of the solution, also, it depended on the withdrawal speed to a power in the range from 0.41 to 0.47.

Effect of Water on Crystallization of Films. The as-prepared $LiNbO_3$ films on Si substrates, which had been prepared from the solution with R_w=1.0, were amorphous. Figure 4(a) shows the FT-IR spectra of films heated in the flowing of a water vapor and oxygen mixture. The as-prepared film showed an absorption band at 540 cm^{-1} attributable to a Nb-O bond. The band shifted to the higher frequency side because of the strengthening of the Nb-O bond with the crystallization of the film, and the film heated at 400 °C showed a strong absorption band at 590 cm^{-1}. It has been confirmed by the electron-diffraction method that the film heated at 250 °C was polycrystalline, and the film crystallized at 400 °C on Si showed the same XRD pattern as did crystalline $LiNbO_3$ powders.[15] On the contrary, a $LiNbO_3$ film which had been prepared from a solution without partial hydrolysis (R_w=0) and then heated to 400 °C showed a broader absorption band on the lower-frequency side, as is shown in Fig. 4(b). From the XRD pattern of this film, the crystallinity was found to be lower than that of films prepared from the solution with the partial hydrolysis. This result clearly indicates the importance of controlled partial hydrolysis for the crystallization of films.

Figures 5(a) and (b) show the FT-IR spectra of $LiTaO_3$ films heated in the flow of a water vapor and oxygen mixture, and in one of dry oxygen, respectively. The films which were crystallized at 500 °C in the flow of a water vapor and oxygen mixture showed

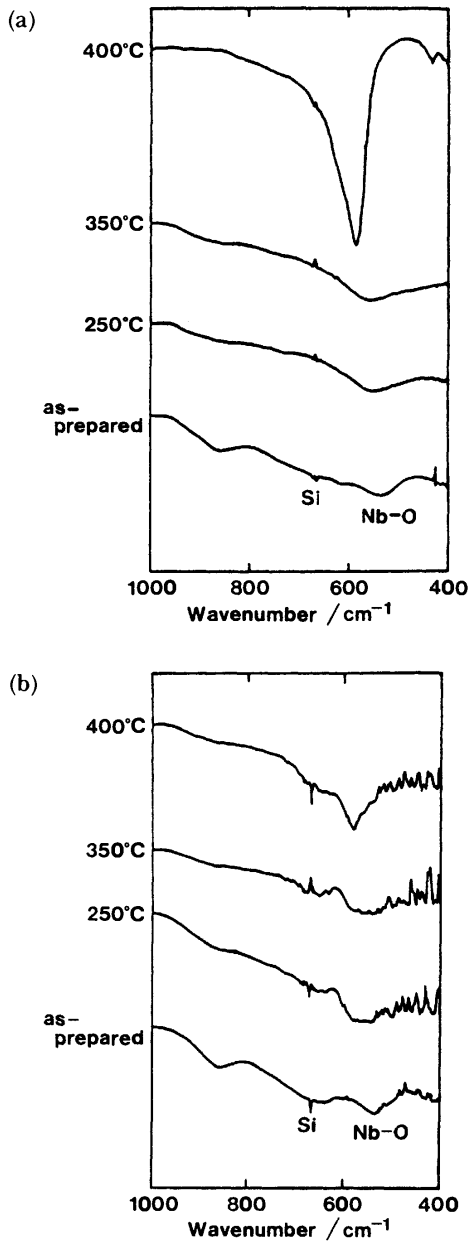

Fig. 4. FT-IR spectra of $LiNbO_3$ films, which were prepared from (a) solution with the partial hydrolysis (R_w=1.0) and (b) solution without partial hydrolysis (R_w=0), heated in a flowing mixture of water vapor and oxygen on Si.

a strong absorption band at 590 cm^{-1} attributable to a Ta-O bond. In contrast with this film, the film heat-treated at 500 °C in a flow of dry oxygen showed only a broad absorption band on the lower-frequency side, plus another absorption band on 860 cm^{-1} attributable to the residual CO_3^{2-} groups. Figure 6 shows the XRD profiles of $LiTaO_3$ films on Si(111) substrates heated in the flow of a water vapor and oxygen mixture, which revealed the occurrence of the crystallization. However, the film heated in the flow of a dry oxygen without water vapor stream did not crystallize at the same temperature of 500 °C.

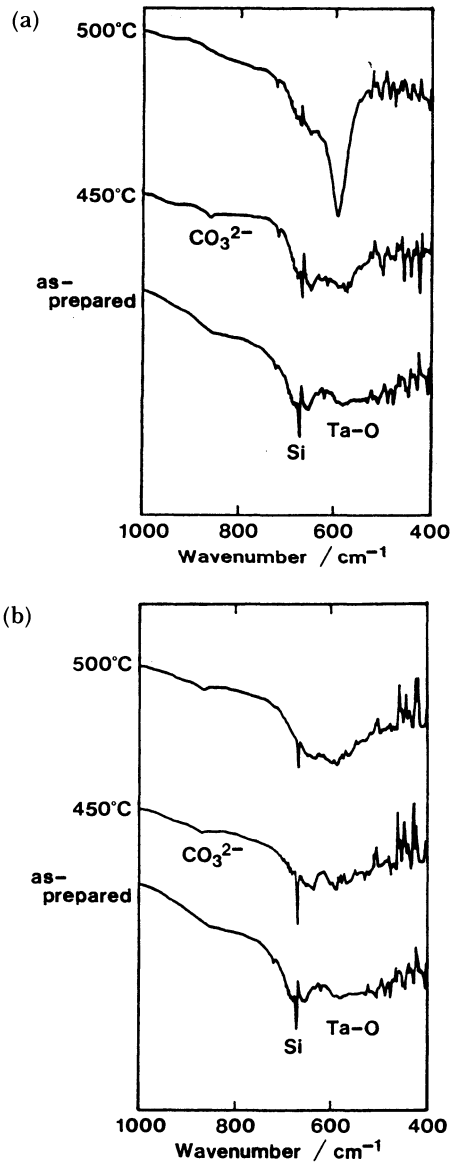

Fig. 5. FT-IR spectra of $LiTaO_3$ films on Si heated in flow (a) of water vapor and oxygen mixture and (b) of dry oxygen.

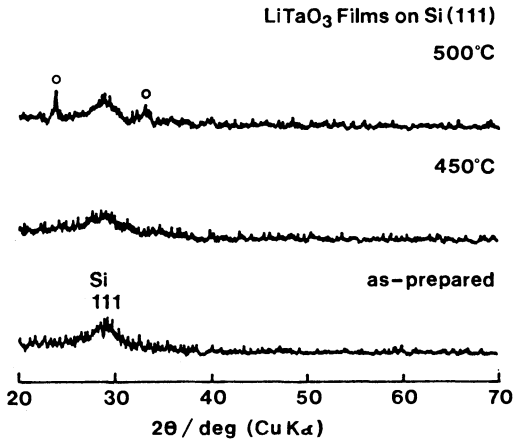

Fig. 6. XRD profiles of $LiTaO_3$ films heated in flow of water vapor and oxygen mixture on Si(111) substrates.

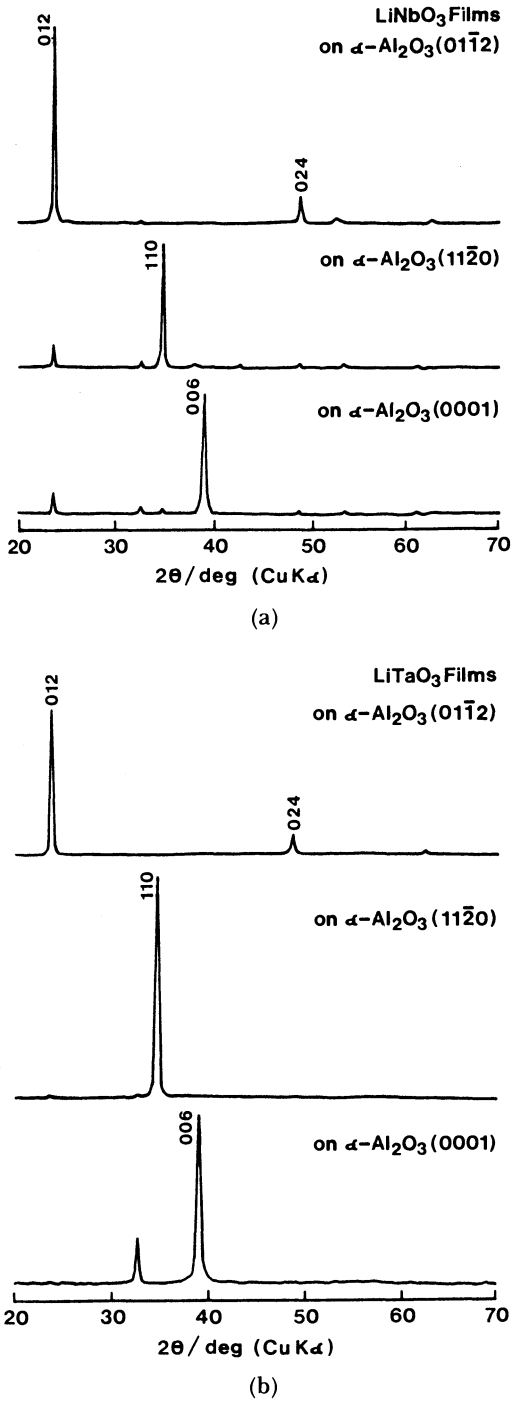

Fig. 7. XRD profiles of (a) $LiNbO_3$ films crystallized at 400 °C on sapphire substrates and (b) $LiTaO_3$ films crystallized at 500 °C on sapphire substrates.

Effects of Substrates on Crystallinity. Both $LiNbO_3$ films and $LiTaO_3$ films on Si substrates were polycrystalline and showed the same XRD profiles as those of $LiNbO_3$ powders and $LiTaO_3$ powders respectively. On the contrary, these films on sapphire substrates, which have the same type of oxygen packing as $LiNbO_3$ and $LiTaO_3$, crystallized with the preferred orientation along each orientation, such as (012), (110), and (001) sapphire. Figures 7(a) and (b) show

the XRD profiles of $LiNbO_3$ films crystallized at 400 °C on sapphire substrates, and of $LiTaO_3$ films crystallized at 500 °C on sapphire substrates, respectively. The crystallographic orientation of the sapphire substrates controls the preferred orientation of the crystallized $LiNbO_3$ and $LiTaO_3$ films.

Formation of $LiNb_xTa_{1-x}O_3(0 \leqq x \leqq 1)$ Films. Complex alkoxide solutions with a stoichiometric composition were prepared by controlling the molar ratio of niobium pentaethoxide to tantalum pentaethoxide. The alkoxide solutions without partial hydrolysis were used for the preparation of films in order to prevent any deviation from the nominal ratio of the composition. Typical XRD profiles of $LiNb_{0.5}Ta_{0.5}O_3$ films crystallized at 500 °C on sapphire substrates are shown in Fig. 8. These films also showed the preferred orientation as the films of the edge compounds, just like $LiNbO_3$ and $LiTaO_3$. Figure 9 shows the relationships between the composition and the lattice constants of films crystallized at 500 °C on sapphire (110) and (001) substrates. The *a* lattice constant increased slightly while the *c* lattice constant decreased, with the composition. These data obey Vegard's law. That such behavior of the lattice parameter changes with the composition could also be observed by Peterson et al.[22,23] and Fukuda et al.[24]

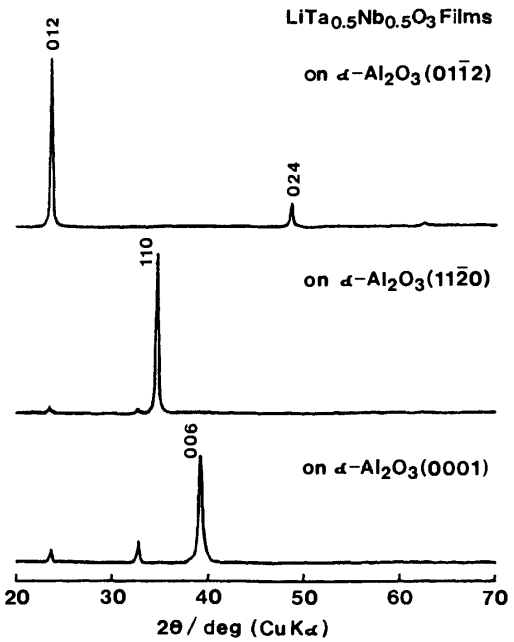

Fig. 8. XRD profiles of $LiNb_{0.5}Ta_{0.5}O_3$ films crystallized at 500 °C on sapphire substrates.

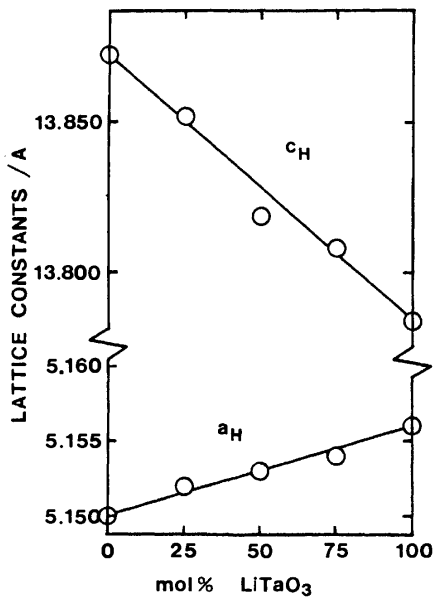

Fig. 9. Change of lattice constants of $LiNb_xTa_{1-x}O_3(0 \leqq x \leqq 1)$ with composition.

Conclusion

Crystalline $LiNbO_3$ films and $LiTaO_3$ films were prepared from double alkoxide solutions by the dip-coating method at lower temperatures. The film thickness could be controlled by adjusting the concentration of the solution and the withdrawal speed from the solution. The water for the partial hydrolysis and the water vapor stream during the heat treatment were found to be very effective for the decomposition and the elimination of organic groups and is promoting the crystallization. The crystallinity of the films was affected by the kind of substrate and the crystallographic orientation. $LiNbO_3$ films and $LiTaO_3$ films on sapphire substrates showed the preferred orientation along each orientation, such as (012), (110), and (001), whereas these films on Si(100) and (111) had the same crystallinity as $LiNbO_3$ and $LiTaO_3$ powders, without any preferred orientation. Solid solution $LiNb_xTa_{1-x}O_3(0 \leqq x \leqq 1)$ films could also be prepared from the complex alkoxide solutions. The composition of the films were found to be controlled by the formation of the complex alkoxide solution and could be strictly monitored from the linear relationships between the compositions and the lattice constants of the films.

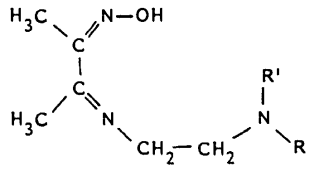
Synthesis and Properties of Copper(II) Halide Complexes with Imino Oximes

Songping WAN,* Wasuke MORI,† Shoichiro YAMADA,† and Shun-Ichi MURAHASHI
Faculty of Engineering Science, Osaka University, Toyonaka 560
†College of General Education, Osaka University, Toyonaka 560
(Received August 22, 1988)

Two types of imino oxime copper(II) complexes were obtained by the reactions of copper(I) halides CuX (X=Br, I) with imino oximes (3-[2-[(alkylamino)ethyl]imino]-2-butanone oximes or 3-[2-[(dialkylamino)ethyl]-imino]-2-butanone oximes, abbreviated as Hdox-enRR′). One type contains the binuclear complexes $[Cu_2(dox\text{-}enRR')_2]^{2+}$ and uncoordinated halide anions. The magnetic susceptibilities measured over the temperature range 77—320 K show a strong antiferromagnetic spin coupling interaction through the N-O bridge in these complexes. The magnetic behavior can be explained by using the Bleaney-Bowers equation. It is assumed that the complexes of the other type consist of copper(I) and copper(II) in 2:1 ratio without spin-coupling interaction between the copper ions. The plot of the reciprocal magnetic susceptibilities versus temperatures is linear.

Previous reports on the metal complexes with imino oximes **1** have shown a variety of structural and magnetic properties, which depend upon the substituents R and R′, metal ions and counter anions.[1-5] For



1a Hdox-enR(R′=H,R=alkyl)
1b Hdox-enR$_2$(R′=R=alkyl)
1

example, the reactions of nickel(II) with imino oximes **1** gave two types of complexes, namely hexa-coordinated and tetra-coordinated nickel(II) complexes. These results show a significant effect of the counter anions.[1] We have extended similar studies to several other metals and found that in the copper(II) thiocyanato complexes, imino oximes **1** are coordinated to copper(II) ion as a bridging quadridentate ligand, and the thiocyanate anion is coordinated through nitrogen atom to form a group of penta-coordinated binuclear copper(II) complexes.[4] It is worthwhile to investigate the effect of the anions on the structure and the bonding of copper(II) complexes formed. Reported here are the results of some of our work with the copper(II) halide complexes, together with their comparison with the corresponding nickel(II) complexes and thiocyanato copper(II) complexes.

Experimental

Materials. Biacetyl monoxime, *N*-alkylethylenediamine, *N,N*-dialkylethylenediamine, and copper halides CuX (X= Br, I) were commercially available and used as received.

Synthesis. Cu(dox-enMe)I (R′=H,R=Me; 2a). A mixture of biacetyl monoxime (1.01 g, 0.01 mol) and *N*-methylethylenediamine (0.74 g, 0.01 mol) in ethanol (40 cm^3) was heated at 60 °C for 2.5 h. Copper(I) iodide (0.95 g, 0.005 mol) was added to the solution at 50 °C, stirred for several hours and filtered off. The solution was evaporated spontaneously at room temperature and a dark-green precipitate was collected by filtration and washed with ethanol to give the complex (0.5 g) in 27% yield. Mp: 147 °C. Found: C, 25.99; H, 4.91; N, 11.37%. Calcd for $C_7H_{14}N_3OCuI \cdot 1/2EtOH$: C, 25.74; H, 4.55; N, 11.29%.

Cu(dox-enR$_2$)I (R′=R=Me, Et; 2b, 2c). These complexes were prepared by the method similar to that for Cu(dox-enMe)I except that *N,N*-dimethylethylenediamine and *N,N*-diethylethylenediamine, respectively, were used instead of *N*-methylethylenediamine. On adding a small amount of ether and ethanol when the reaction solution was almost evaporated nearly to dryness, complex **2b** (0.6 g) and complex **2c** (0.6 g) were obtained as dark-green crystals in 33% yield and 31% yield, respectively. Mp: **2b**, 141 °C; **2c**, 142 °C. Found: C, 26.40; H, 4.48; N, 11.42%. Calcd for $C_8H_{16}N_3OCuI$ (**2b**): C, 26.64; H, 4.47; N, 11.65%. Found: C, 31.20; H, 5.24; N, 10.70%. Calcd for $C_{10}H_{20}N_3OCuI$ (**2c**): C, 30.90; H, 5.19; N, 10.81%.

Cu(dox-enBu$_2$)I (R′=R=Bu; 2d). A mixture of biacetyl monoxime (1.11 g, 0.011 mol) and copper(I) iodide (0.95 g, 0.005 mol) in methanol (40 cm^3) was heated at 70 °C for 1 h. *N,N*-dibutylethylenediamine (1.72 g, 0.01 mol) was added and the mixture was stirred for 1 h. Addition of a small amount of ether and ethanol, followed by evaporation of the solvent almost to dryness, gave dark-green crystals (0.5 g) of the complex **2d** in 23% yield. Mp: 124 °C. Found: C, 37.90; H, 6.39; N, 9.44%. Calcd for $C_{14}H_{28}N_3OCuI$: C, 37.80; H, 6.34; N, 9.45%.

Cu(dox-enRR′)Br (R′=R=Me, Et; 2e, 2f). To a solution of copper(I) bromide (0.36 g, 0.0025 mol) in ethanol (20 cm^3) was added the ligand Hdox-enRR′ (0.005 mol) which was prepared beforehand.[1] The mixture was stirred at 70 °C for 1.5 h. The solution was filtered and evaporated spontaneously at room temperature. On adding a small amount of ether when the solution was almost evaporated nearly to dryness, the complex **2e** (0.2 g) and complex **2f** (0.63 g) were obtained as dark-green crystals in 24% yield and 66% yield respectively. Mp: **2e**, 150 °C; **2f**, 137 °C. Found: C, 29.12; H, 5.45; N, 12.65%. Calcd for $C_8H_{16}N_3OCuBr \cdot H_2O$ (**2e**): C, 28.91; H, 5.47; N, 12.67%. Found: C, 34.50; H, 6.03; N, 12.04%. Calcd for $C_{10}H_{20}N_3OCuBr \cdot 1/2H_2O$ (**2f**): C, 34.24; H, 6.03; N, 11.98%.

Cu$_3$(dox-enPr$^i_2$)$_3$I (R′=R=Pr^i; 3a). A mixture of bi-

acetyl monoxime (1.11 g. 0.011 mol) and copper(I) iodide (0.95 g, 0.005 mol) in ethanol (40 cm^3) was heated at 60 °C for 2 h. *N,N*-Diisopropylethylenediamine (1.44 g, 0.01 mol) was added to the solution and the mixture was stirred for 1 h. On concentrating the solution to 20 cm^3, a green precipitate (0.1 g) was obtained in a very low yield. Mp>300 °C. Found: C, 41.19; H, 7.09; N, 11.64%. Calcd for $C_{36}H_{72}N_9O_3Cu_3I \cdot 3H_2O$ C, 41.15; H, 7.48; N, 12,00%.

Cu_3(dox-enPr$^i_2$)$_3$Br (R′=R=Pr^i; 3b). A mixture of biacetyl monoxime (1.11 g, 0.011 mol) and CuBr (0.72 g, 0.005 mol) in methanol (50 cm^3) was heated at 60 °C for 3 h. At room temperature a solution of *N,N*-diisopropylethylenediamine (1.44 g, 0.01 mol) in ethanol (10 cm^3) was added to the reaction mixture above, and the mixture was heated at 60 °C for several hours. Evaporation of the filtered solution at room temperature gave a green precipitate (0.7 g) in 14% yield. Mp>300 °C. Found: C, 44.49; H, 7.55; N, 12.73%. Calcd for $C_{36}H_{72}N_9O_3Cu_3Br \cdot H_2O$: C, 44.69; H, 7.60; N, 13.03%.

Measurements. Electronic absorption spectra were measured at room temperature with a Shimadzu MPS 5000 spectrophotometer. Infrared absorption spectra were recorded as Nujol mulls on a Perkin-Elmer 938G infrared spectrophotometer. Room temperature magnetic moments were determined with the Gouy-method using H_2O as a susceptibility standard, and magnetic susceptibilities at temperatures 77 K to 320 K were measured by the Faraday method in a manner as described previously.[6] Pascal's constants were used to estimate the diamagnetic corrections for imino oximes, Br, I, and Cu.[7]

Results and Discussion

Synthesis of the Copper(II) Halide Complexes with Imino Oximes. In the present work, the reactions of copper(I) salts CuX (X=I, Br) with the imino oximes (Hdox-enRR′; **1**) gave two types of copper(II) complexes depending on the nature of R and R′:

i) Cu(dox-enRR′)X (**2**; R′=H, R=Me, X=I; R′=R=Me, Et, X=I, Br; R′=R=Bu, X=I).

ii) Cu_3(dox-enPr$^i_2$)$_3$X (**3**; X=I, Br)

The following features are to be noted about the synthesis of these complexes:

i) By the reactions of copper(I) halides CuX (X=I, Br) with 3-[[2-(alkylamino)ethyl]imino]-2-butanone oximes (**1a**), the complex Cu(dox-enMe)I (**2a**) was obtained exclusively. Attempts to isolate copper(II) complexes by the reactions of copper(I) chloride with imino oximes (Hdox-enRR′) have so far been unsuccessful. It seems to be difficult to crystallize out the desirable copper(II) complexes because of their high solubilities in an organic solvent.

ii) Using copper(I) halide salts CuX (X=I, Br) as a starting material, we succeeded in preparing the imino oxime copper(II) complexes (**2**). In this method, the copper(I) ion was oxidized by atmospheric oxygen under the reaction conditions employed. This method has been applied with success to the preparation of other copper(II) complexes.[4] By similar procedures, using copper(II) bromide in place of copper(I) bromide, the desirable copper(II) complex could not be isolated as solid. The following equations can be considered:

$$CuX + \text{Hdox-enRR}' \xrightarrow{O_2} \text{Cu(dox-enRR}')X + H_2O \quad (1)$$

$$CuX_2 + \text{Hdox-enRR}' \longrightarrow \text{Cu(dox-enRR}')X + HX \quad (2)$$

According to the Eq. 2, the reaction of copper(II) salt with imino oximes produces HX, which induced the decomposition of ligand Hdox-enRR′ and hence the formation of the complexes Cu(dox-enRR′)X becomes unfavorable; however using copper(I) salt as starting substance, beside the desirable complexes only H_2O is formed as shown in Eq. 1.

iii) As shown in the experimental section, the crystals of complexes were obtained by adding a small amount of ether when the reaction solution was evaporated nearly to dryness. It also reflects the high solubility of these complexes in alcohol.

Characterization of the Copper(II) Halide Complexes (2) of Imino Oximes. As discussed later in more detail, d-d bands and magnetic properties indicate that the complexes **2** isolated are copper(II) complexes. The composition determined by the elemental analysis indicates that the imino oximes lose a proton on coordination to the copper(II) ion.

Infrared spectra of the complexes **2** exhibit no vibrations in 3140—3253 cm^{-1}, showing that the deprotonated imino oxime monoanions are coordinated to the copper(II) ion, in agreement with the assumption that the complexes **2** are copper(II) complexes. Moreover, the bands due to imino oxime C=N (Table 1) are shifted from the vibration of the free ligand at 1623—1630 cm^{-1}, indicating that the nitrogen atom of imino oxime C=N is bound to the copper(II) ion.

Electronic absorption spectra of the copper(II) complexes **2** show one broad band in the visible region (Table 1), where d-d bands of square planar copper(II) complexes are expected to be occur.[8,9] Since the magnetic moments of these coeper(II) complexes at room temperature are subnormal, the spin-coupling interaction between copper(II) ions is presumed to be present. In the light of previous studies on the corresponding thiocyanato copper(II) complexes,[4,5] a similar binuclear structure $[Cu_2(\text{dox-enRR}')_2]^{2+}$ (shown in **2**) may

Table 1. The Main Data for Copper(II) Halide Complexes of Imino Oximes

$[Cu_2(dox\text{-}enRR')_2]^{2+}$
2

also be proposed for the copper(II) halide complexes in the present work. Since the coordination ability of halide anions, particularly iodide anion, is much lower than that of thiocyanate, it is reasonable to assume that the halide anions are not coordinated to copper(II) ion in the complexes **2**. In agreement with this seems to be the finding in the present work that the d-d bands of the copper(II) halide complexes shift to higher energy region, as compared with those of thiocyanato copper(II) complexes.[4] It is well-known that the d-d bands of the square-planar copper(II) complex undergo a bathochromic shift when the fifth ligand is bound to the planar copper(II) ion.[8,9]

Investigation on the temperature dependence of the magnetic susceptibility of copper(II) complex is very important and useful for understanding the nature of spin-coupling interaction and the structure of complexes. There have been many studies on the magnetic properties of copper(II) complexes, which have binuclear structures and show spin-coupling interaction between two copper(II) ions through the bridging oxygen atom[10-12] or bridging group N-O.[13,14] As discussed above, the magnetic moments of the complexes **2** are much smaller than that of the normal $3d^9$ system, showing that there exists a spin-coupling interaction between two copper(II) ions. Magnetic susceptibilities of complexes **2** were measured over the temperature range 77—320 K. One of the examples is shown in Fig. 1. The temperature dependence of the magnetic susceptibility shows the presence of a strong spin-coupling interaction between copper(II) ions in these binuclear complexes. The magnetic behaviors can be explained using the Bleaney-Bowers equation (Eq. 3)

$$\chi_A = \frac{Ng^2\beta^2}{kT}\frac{1}{3+\exp(-2J/kT)} + N\alpha \qquad (3)$$

or its modification (Eq. 4)

$$\chi_A = \frac{Ng^2\beta^2}{kT}\frac{1}{3+\exp(-2J/kT)}\cdot(1-p) + \frac{Ng^2\beta^2}{4kT}\cdot p + N\alpha \qquad (4)$$

The symbols in Eqs. 3 and 4 have their usual meanings. Figure 1 exhibits the good agreement between the experimental and calculated values. The exchange parameters for the halide copper(II) complexes **2** are given in Table 2. It is interesting that the values of $-2J$ of the halide copper(II) complexes are greater than those of the thiocyanato copper(II) complexes. This result implies that the spin-coupling interaction between two copper(II) ions is stronger in the halide complexes than that in the thiocyanato complexes, and may be considered to arise from the apical bonding of the thiocyanate anion to the copper(II) ion in the latter. Thus all the findings combined are consistent with the assumption that the complexes **2** adopts a binuclear structure $[Cu_2(dox\text{-}enRR')_2]^{2+}$ and that there exists a strong antiferromagnetic interaction between two copper(II) ions through two bridging N-O groups. This result is in contrast to that of similar nickel(II) complexes, in which there is little interaction between two nickel(II) ions having d^8 system.[1]

Depending upon the nature of ligand and the steric conditions, copper(II) ion would form various complexes with different coordination numbers and different structures. The results of the present work show that although the main skeleton of copper(II) complexes was determined by imino oximes used, the different anions form the complexes with different coordination numbers and structures.[4,5,15]

Characterization of Complexes 3. The characterization of complexes **3** was investigated in the same way as that for complexes **2**. The composition of the elemental analysis leads to the empirical formula

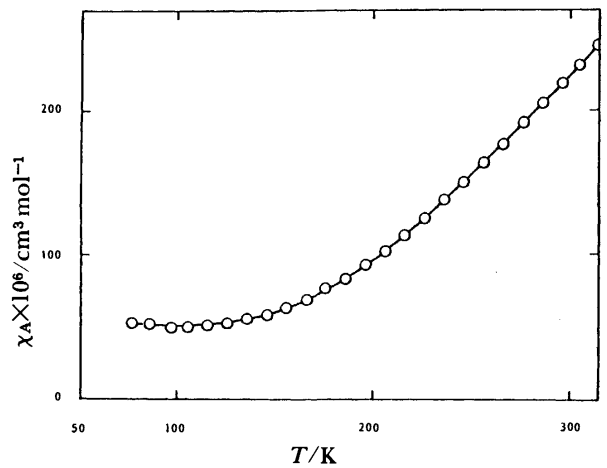

Fig. 1. Temperature dependence of the magnetic susceptibilities for $Cu(dox\text{-}enMe_2)Br$. The solid line was calculated from Eq. 3 with $2J/k=-1060$ K, $N\alpha=46\times10^{-6}$ cm^3mol^{-1}.

Table 2. Magnetic Susceptibilities at Room Temperature and Magnetic Parameters of Copper(II) Halide Complexes of Imino Oximes

2f	−0.09	2.26	1240	68	

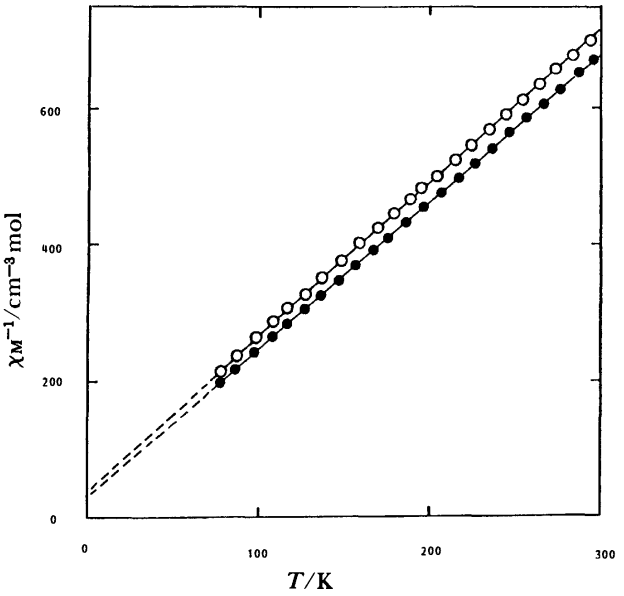

Fig. 2. Reciprocal susceptibility vs. temperature for $Cu_3(dox\text{-}enPr^i_2)_3$ Br (○) and $Cu_3(dox\text{-}enPr^i_2)_3$ I (●). The susceptibility is calculated per formula unit, e.g., for three copper ions. The curves show the theoretical susceptibilities calculated by the Curie-Weiss equation with the parameters described in the text.

$Cu_3(dox\text{-}enPr^i_2)_3X \cdot nH_2O$ (X=I, Br), which is significantly different from that of the complexes **2**. This formulation, which involves the imino oxime monoanion as ligand, requires that copper be present as a mixture in 1+ and 2+ oxidation states. It is also noted that the imino oxime C=N infrared vibrations of complexes **3** occur at wavenumbers around 1624 cm^{-1} distant from the corresponding ones of **2** showing that the structure of **3** differs from that of **2**. The d-d bands (Table 1) indicate that the coordination geometry around copper(II) ion is square-planar. No specific feature of the electronic spectrum could be assigned as an intervalence transfer transition. This difference between complexes **2** and **3** probably arises from the presence of the bulky diisopropylamino groups $-N(Pr^i)_2$ in **3**, which may interfere with the coordination of the $-N(Pr^i)_2$ part. More direct evidence for the existence of a mixed-valence copper complex comes from measurements of the magnetic susceptibility. The magnetic moment calculated per copper ion is μ_{eff}=1.06—1.08 BM (BM=9.274×10^{-24} JT^{-1}). This value is consistent with the presence of Cu(I) and Cu(II) in 2 : 1 ratio without spin-coupling interaction between the copper ions. Variable temperature magnetic susceptibility measurements are also consistent with the existence of copper(I) and almost magnetically independent copper(II) centers. Over the temperature range 77—300 K the plot of reciprocal susceptibility versus temperature is linear (Fig. 2). The data fit well to the Curie-Weiss law (Eq. 5), with C=0.443 emu K mol^{-1} and θ=−18 K for X=Br, and C=0.462 emu K mol^{-1} and θ=−14 K for X=I, where C and θ are Curie and Weiss constant, respectively.

$$\chi^{-1} = C^{-1}(T-\theta) \quad (5)$$

Thus the present compounds are considered to be class I mixed-valence compounds, which contain noninteracting copper(I) and copper(II) sites.[16] Precise structure for these complexes must await further studies using X-ray methods. In any case, however, it is evident that the structure of copper complexes with imino oxime $Hdox\text{-}enPr^i_2$ is different from that of the corresponding dialkylamino analogues. The present study thus demonstrates one of those cases, in which the *N*-isopropyl-substituted ligands tend to form metal complexes with structure different from that of the corresponding normal alkyl analogues, owing to the bulky isopropyl groups.[17]

(Received May 18, 1988)

The reaction of arenes with benzyltrimethylammonium tribromide or benzyltrimethylammonium dichloroiodate in acetic acid in the presence of $ZnCl_2$ at room temperature or at 70 °C gave bromo- or iodo-substituted arenes in good yield, respectively.

The aromatic bromination of arenes (**1**) with molecular bromine has usually been brought about in the presence of a catalytic amount of iodine or iron filings.[2] The reaction of **1** with NBS and aqueous sulfuric acid gives bromo-substituted arenes (**2**).[3] Reactive **1** can be (mono)brominated by the use of NBS in DMF.[4] Trifluoroacetyl hypobromite (CF_3COOBr),[5] which is prepared by a reaction of bromine with silver trifluoroacetate, and copper(II) bromide[6] have also been used as brominating agents for arenes.

A direct iodination of **1** using I_2 can be accomplished with the use of HNO_3[7] or HIO_3/H_2SO_4[8] to oxidize HI to I_2 and so displace the equilibrium. A mixture of I_2 and $HIO_4 \cdot 2H_2O$ is conveniently used for the direct iodination of polyalkylbenzenes.[9] Iodoarene (**3**) have also been synthesized by a reaction of **1** with I_2 and an equimolecular mixture of $AlCl_3$ and $CuCl_2$.[10] Activated **1** can be iodinated by the use of I_2 and $Cu(OAc)_2$ in acetic acid.[11]

We have recently shown that quaternary ammonium polyhalides, such as benzyltrimethylammonium tribromide (BTMA Br_3)[12] or benzyltrimethylammonium dichloroiodate (BTMA ICl_2),[13] are useful brominating or iodinating agents for reactive aromatic compounds. In this paper, we wish to report on the bromination and iodination of **1** by the use of BTMA Br_3-$ZnCl_2$ and BTMA ICl_2-$ZnCl_2$, respectively.

Results and Discussion

The reaction of **1** with a calculated amount of BTMA Br_3 and $ZnCl_2$ or BTMA ICl_2 and $ZnCl_2$ in acetic acid (at room temperature or at 70 °C) gave **2** or **3** in good yields, respectively. The results are summarized in Table 1.

While such reactive aromatic compounds as phenols, aromatic amines, aromatic ethers, and acetanilides have been easily brominated by BTMA Br_3 in dichloromethane in the presence of methanol, the reaction of **1** (less reactive compounds) with BTMA Br_3 in dichloromethane-methanol did not proceed at all, even under reflux for many hours. However, **1** could be smoothly brominated by use of this reagent in acetic acid with the aid of the Lewis acid $ZnCl_2$. Thus, the combined effect of BTMA Br_3 and $ZnCl_2$ in acetic acid provides a new excellent bromination procedure for **1**.

BTMA ICl_2 is slightly soluble in acetic acid at room temperature. However, an addition of $ZnCl_2$ makes this reagent soluble in acetic acid, and the iodination reaction of **1** readily proceeds under mild conditions.

In these cases, it turned out that an equimolar amount of $ZnCl_2$ was required for BTMA Br_3 or BTMA ICl_2. We, thus, assumed the existence of complexes formed from the polyhalides and $ZnCl_2$ as active species, and proposed that a reaction scheme which affords **2** (mono-bromoarenes) or **3** (mono-iodoarenes) may be described according to the following equations:

$$PhCH_2(CH_3)_3N^+XY_2^- + ZnCl_2 \longrightarrow [PhCH_2(CH_3)_3N]^+[ZnCl_2Y_2]^{2-}X^+ \quad (1)$$

$$\underset{\mathbf{1}}{Ar\text{-}H} + [PhCH_2(CH_3)_3N]^+[ZnCl_2Y_2]^{2-}X^+ \longrightarrow \underset{\mathbf{2}\text{ or }\mathbf{3}}{Ar\text{-}X} + PhCH_2(CH_3)_3N^+Y^- + ZnCl_2 + HY. \quad (2)$$

That is, the reaction appeared to occur in accord with the following stoichiometry:

$$\underset{\mathbf{1}}{H\text{-}Ar} + PhCH_2(CH_3)_3N^+XY_2^- \xrightarrow{ZnCl_2} \underset{\mathbf{2}\text{ or }\mathbf{3}}{Ar\text{-}X} + PhCH_2(CH_3)_3N^+Y^- + HY. \quad (3)$$

(X=Y=Br for BTMA Br_3; X=I, Y=Cl for BTMA ICl_2)

Incidentally, we found that $ZnCl_2$ was a more effective Lewis acid catalyst than other $AlCl_3$, $AlBr_3$, $FeCl_3$, and $ZnBr_2$.

As shown in Table 1, the bromination of **1** using BTMA $Br_3/ZnCl_2$ proceeded more easily than the iodination of **1** using BTMA $ICl_2/ZnCl_2$. Avramoff et al. have already reported the bromination of **1** with tetramethylammonium tribromide (TMA Br_3) in acetic acid under reflux.[44] However, TMA Br_3 is not easy to handle, compared with stable BTMA Br_3 due to its hygroscopic character. Unfortunately, by our method the bromination of benzene did not proceed

a) Yield of isolated product. b) Reaction was carried out by shading the light in order to prevent a side chain bromination. c) 1,2-Dichloroethane-methanol was used as solvent instead of acetic acid contained $ZnCl_2$.

and the bromination of toluene gave a mixture of *o*-, *p*-bromo and dibromo derivatives.

The reaction of **1** with equimolar amount of BTMA ICl_2 and $ZnCl_2$ at room temperature usually gave monoiodoarenes, and with 2-equiv of BTMA ICl_2 and $ZnCl_2$ at 70 °C usually gave diiodoarenes. Thus, the objective mono-, or diiodoarenes could be obtained selectively from **1** by the use of a calculated amount of BTMA ICl_2 and $ZnCl_2$ in acetic acid. However, by our method the iodination of less reactive benzene hardly proceeded; otherwise, the iodination of monoalkylbenzenes, such as toluene and ethylbenzene, gave a mixture of *o*-, *p*-iodo and diiodo derivatives, respectively, with nonselective manners. In the case of *t*-butylbenzene (**1a**), only a *p*-iodo compound **3a-1** was obtained, owing to a steric hindrance of the large *t*-butyl moiety.

Keefer et al. have reported the iodination of **1** such as 1,3,5-trimethylbenzene (**1g**) and 1,2,3,4,5-pentamethylbenzene (**1j**) by the use of ICl and $ZnCl_2$ in acetic acid.[27] However, it takes a long time to obtain the iodo compound, compared with our iodination method. Furthermore, ICl is not easy to handle quantitatively because of its viscous character.

Experimental

All melting points are uncorrected. The ^1H NMR spectra were recorded on a JMN-MH-100 spectrometer with tetramethylsilane as an internal standard.

Benzyltrimethylammonium Tribromide (BTMA Br_3). A partially improved preparative method is as follows: Benzyltrimethylammonium chloride (9.3 g, 50 mmol) and sodium bromate (3.8 g, 25 mmol) was dissolved in water (80 ml); dichloromethane (50 ml) was then added to the aqueous solution. To an ice-cold mixture of the above-mentioned solution was added dropwise 47% hydrobromic acid (30.2 g, 175 mmol) under stirring over a period of 15 min. The dichloromethane layer (dark red) was separated and the water layer was extracted with dichloromethane (20 ml×3). The combined organic solution was dried over magnesium sulfate and evaporated in vacuo to give a residue which was recrystallized from dichloromethane-ether (5:1) affording BTMA Br_3 as orange crystals; yield 16.6 g (85%); mp 100—101 °C (lit,[45] mp 100—101 °C).

2,5-Dimethyl-1-bromobenzene (2d-1). Typical Procedure of Bromination at Room Temperature: To a solution of 1,4-dimethylbenzene (**1d**) (0.50 g, 4.71 mmol) in acetic acid (30 ml) was added BTMA Br_3 (1.84 g, 4.71 mmol) and $ZnCl_2$ (0.7 g, 5.13 mmol). The mixture was stirred for 2 h at room temperature until the initial orange color faded. To the mixture was added water (20 ml) and 5% aq. solution of $NaHSO_3$ (10 ml). The mixture was extracted with hexane (40 ml×4). The organic layer was dried over magnesium sulfate and passed through a short alumina-column. The elute (hexane solution) was concentrated in vacuo to give **2d-1** as colorless oil; yield 0.74 g (84%); bp 203—204 °C/760 mmHg (lit,[20] bp 205 °C/760 mmHg; 1 mmHg≈133.322 Pa).

1-Bromo-4-*t*-butylbenzene (2a-1). Typical Procedure of Bromination at 70 °C. To a solution of *t*-butylbenzene (**1a**) (0.50 g, 3.73 mmol) in acetic acid (20 ml) was added BTMA Br_3 (1.60 g, 4.10 mmol) and $ZnCl_2$ (0.7 g, 5.13 mmol). The mixture was stirred for 2 h at 70 °C until the initial orange color faded. A subsequent work-up as mentioned above gave **2a-1** as colorless oil; yield 0.75 g (95%); bp 228 °C/760 mmHg (lit,[14] bp 228—229 °C/740 mmHg).

1-Iodo-2,4,6-trimethylbenzene (3g-1). Typical Procedure of Iodination: To a solution of 1,3,5-trimethylbenzene (**1g**) (0.50 g, 4.16 mmol) in acetic acid (20 ml) was added BTMA ICl_2 (1.45 g, 4.17 mmol) and $ZnCl_2$ (0.6 g, 4.40 mmol). The mixture was stirred for 3 h at room temperature. The yellow color of the solution gradually changed to light brown. To the mixture was added water (20 ml) and 5% aq. solution of $NaHSO_3$ (10 ml). Then, the mixture was extracted with hexane (50 ml×3). The organic layer was dried over $MgSO_4$ and passed through a short alumina-column in order to remove any trace amount of acetic acid. The hexane solution was concentrated in vacuo to give **3g-1** as colorless crystals; yield 0.92 g (90%); mp 30.5—31 °C (lit,[27] mp 30.5—31 °C).

1,2-Dibromo-3-iodo-4,5,6-trimethylbenzene: This compound was obtained as colorless crystals; mp 223—224 °C (from ethanol). ^1H NMR ($CDCl_3$) δ=2.30, 2.45, and 2.58 (9H, three s, three CH_3). Found: C, 27.00; H, 2.05%. Calcd for $C_9H_9IBr_2$: C, 26.77; H, 2.25%.

1-Bromo-3-iodo-2,4,6-trimethylbenzene: Mp 42—43 °C (from ethanol-water (1:3)). ^1H NMR ($CDCl_3$) δ=2.30, 2.35, and 2.70 (9H, three s, three CH_3), and 6.88 (1H, s, 5-H). Found: C, 33.27; H, 3.01%. Calcd for $C_9H_{10}IBr$: C, 33.26; H, 3.10%.

1-Bromo-3,5-diiodo-2,4,6-trimethylbenzene: This compound was obtained as colorless crystals; mp 184—185 °C (from ethanol). ^1H NMR ($CDCl_3$) δ=2.77 (6H, s, 2- and 6-CH_3), and 2.93 (3H, s, 4-CH_3). Found: C, 24.25; H, 2.01%. Calcd for $C_9H_9I_2Br$: C, 23.98; H, 2.01%.

2,7-Diiodofluorene (3o-2): Mp 214—215 °C (from ethanol-water (1:1)). (lit,[43] mp 155.5 °C). ^1H NMR ($CDCl_3$) δ=3.80 (2H, s, CH_2) and 7.4—8.0 (6H, m, Harom). Found: C, 37.29; H, 1.87%. Calcd for $C_{13}H_8I_2$: C, 37.35; H, 1.93%.

We wish to thank Dr. Mamoru Nakai and Mr. Katsumasa Harada, Ube Laboratory, Ube Industries, Ltd., for elemental analysis.

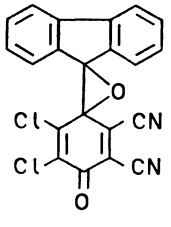
The title reaction gave 3′,4′-dichloro-1′,6′-dicyanospiro[fluorene-9,7′-[3′]norcarene]-2′,5′-dione (**2**) in a good yield. Recrystallizations of **2** from solvents such as benzene, dioxane, acetonitrile, and acetone gave each molecular complex consisting of a **2**/solvent molar ratio of 1 : 1. The structure of **2** was determined by the use of one complex, **2**·CH_3COCH_3, by an X-ray crystallographic analysis, which revealed that an interaction between **2** and acetone was not very strong. Such a host-guest interaction was shown also from ^1H NMR spectroscopy and a differential thermal analysis of the complex. Compound **2** afforded the corresponding spiroacetals of 9-fluorenone through reactions with ethylene glycol and 1,3-propanediol.

Diazoalkanes are best represented as resonance hybrids comprising linear structures with opposing dipoles.[1a,b] They react with electrophiles (largely at carbon) and with nucleophiles (at nitrogen).[1c] Furthermore, these diazo compounds behave as 1,3-dipoles[2] or carbene precursors.[3] On the other hand, quinones have conjugated two carbonyl groups and two carbon-carbon double bonds and can be considered as being dipolarophiles.[4] In particular, the quinones substituted by electronegative groups, such as halogen and/or cyano group(s),[5] become strong electron acceptors.[6] Thus, the reactions of diazoalkanes with quinones have aroused wide interest from mechanistic or synthetic points of view and have been described by various authors.[7]

Generally speaking, diazoalkanes achieve 1,3-dipolar cycloaddition to the carbon-carbon double bonds of *p*-benzoquinone and of incompletely blocked *p*-quinones to give pyrazoline derivatives,[8] while the diazo compounds attack the carbonyl group(s) of completely blocked *p*-quinones to afford oxiranes[8c,d,9], with the evolution of nitrogen. Needless to say, the oxirane formation from the former quinones[8e,9a] and the pyrazoline formation from the latter[8f,10] have also been reported.

In a previous paper,[11] we stated that we had obtained 2,3-dichloro-5,6-dicyanodispiro[2,5-cyclohexadiene-1,2′-oxirane-3′,9″-fluoren]-4-one (**1**) through a reaction of 9-diazofluorene (9-DF) with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ). The instability of the 9-fluorenylidene-DDQ adduct in an acetone-d_6 solution precluded its characterization by ^{13}C NMR spectroscopy. However, chemical support of the structure (**1**) was deduced from the seemingly straightforward formation of acetals by reactions of the adduct with alcohols (as described hereinafter). We recently undertook an X-ray analysis of a crystal which included acetone used for recrystallization of the adduct, and determined its structure to be that of 3′,4′-dichloro-1′,6′-dicyanospiro[fluorene-9,7′-[3′]-norcarene]-2′,5′-dione (**2**) rather than that of **1**.

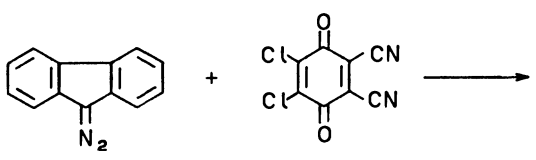


1

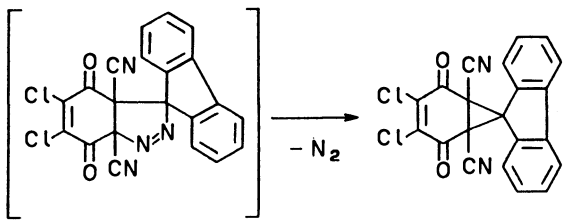
Results and Discussion

Reaction of 9-DF with DDQ. A solution of 9-DF in acetonitrile was added drop by drop with stirring into a solution of DDQ of acetonitrile at room temperature. The evolution of nitrogen was immediately observed and an orange substance was obtained, accompanied by 9,9′-bifluorenylidene (**3**). The substance, upon standing under vacuum for several hours, turned from orange to a yellow powder, **2**.

Regarding the formation of **2** from 9-DF and DDQ, the following routes can be suggested: (A) 1,3-Dipolar cycloaddition of the diazo compound to a quinone carbon-carbon double bond takes place to give substituted 3a,4,7,7a-tetrahydro-3*H*-indazole-4,7-dione (**4**), and then the loss of nitrogen gives **2**. In fact, such dipolar cycloadducts have been isolated in the many

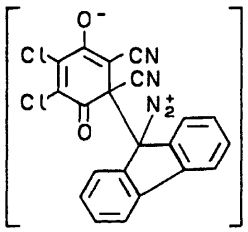


9-DF DDQ



4 2

reactions of diazo compounds and quinones.[8] It has been reported that the reactions of 9-DF with *p*-benzoquinone and with 1,4-naphthoquinone give the dihydroxy-3*H*-indazole derivatives.[12] On the other hand, it has been noted that, upon sufficiently raising the temperature in these reactions (in refluxing benzene), a dipolar reaction and a loss of nitrogen occur to give cyclopropanes while the dienolization to form dihydroxy-3*H*-indazole derivatives can be effectively avoided.[13] In our reaction system of 9-DF with DDQ bearing electron-withdrawing groups, the 3*H*-indazole was not isolated because of its instability, even under the present reaction condition. Cycloaddition, however, was observed to occur in the double bond of the cyano group site in DDQ in preference to that of the chloro site. This finding can be explained according to a difference in electron-withdrawing ability between the chloro and the cyano groups. (B) A direct nucleophilic attack of the diazo carbon on the carbon atom adjacent to the cyano group in DDQ leads to the for-



5

mation of a diazonium betain intermediate (**5**), which gives **2** through a loss of nitrogen and a ring closure. This route may be ruled out for the formations of indazole derivatives from diazo compounds and quinones. (C) A charge-transfer complex of DDQ and 9-DF may be formed as the first step, followed by the formation of a radical ion pair prior to the free radical ions,[14] which may combine to give the pyrazoline (**4**) as a precursor of **2**. The 1 : 1 charge-transfer complexes of DDQ with durene[15] and with *p*-phenylenediamine[16] have been isolated. The formations of a DDQ radical anion in a DDQ–diphenyldiazomethane system[17] and of a radical ion pair for DDQ and 9-DF[14] have been observed by means of their electron spin resonance and electronic absorption spectra. From the point of view of the one-electron redox potentials, $E_{1/2}$(+0.51[18] and +1.21[19] V vs. SCE in acetonitrile for DDQ and 9-DF, respectively), it seems unlikely to us that the above-mentioned pyrazoline formation proceeds through the radical ions.

Inclusion of Some Solvents. Upon recrystallization from acetone, **2** slowly precipitated as big yellowish-orange columnar crystals, which exhibited the values of elementary analysis for a molecular compound consisting of one molecule of **2** and one molecule of acetone. The mass spectra of the molecular complex (**2**·CH_3COCH_3) revealed *m/z* 390 (M^+ −58 (C_3H_6O)) as the highest peak. The ^1H NMR spectra (in $CDCl_3$) of **2**·CH_3COCH_3 were all similar to superimposed spectra of the components; none of the peak shifts were observed. This finding shows that **2**·CH_3COCH_3 completely dissociates into the components in the solvent because of a week interaction between **2** and the ketone. When the big crystals of **2**·CH_3COCH_3 were stored in a dry-seal desiccator, their surfaces gradually changed to yellow powder. When crushed crystals of **2**·CH_3COCH_3 were kept in vacuo by use of a rotary oil pump for one hour or so, they completely changed to yellow powder, **2**. The recrystallization of **2** or **2**·CH_3COCH_3 from ethyl methyl ketone gave a new molecular complex (**2**·$C_2H_5COCH_3$) having a molar ratio of **2** to the ethyl methyl ketone of 1 : 1 in either case; the complex showed the same behavior as those of **2**·CH_3COCH_3 in its characterization by mass and ^1H NMR spectroscopy. In addition, **2** forms crystalline molecular complexes of 1 : 1 stoichiometry with a variety of guest molecules such as benzene, tetrahydrofuran, dioxane, and acetonitrile. Furthermore, these host-guest compounds make a change in the guests upon recrystallization from the other solvents,[11] as mentioned above regarding the conversion of **2**·CH_3COCH_3 into **2**·$C_2H_5COCH_3$. Differential thermal analyses (DTA) of each host-guest compound gave endothermic peaks at respective temperatures between 74 and 107 °C (for six kinds of samples), all of the compounds recorded the start of exothermic peaks at temperature 185—187 °C.[11] Although the host-guest compounds with polar additives (acetonitrile and ketones) have a tendency to indicate higher DTA endothermic peak points than the boiling points of these additives, the

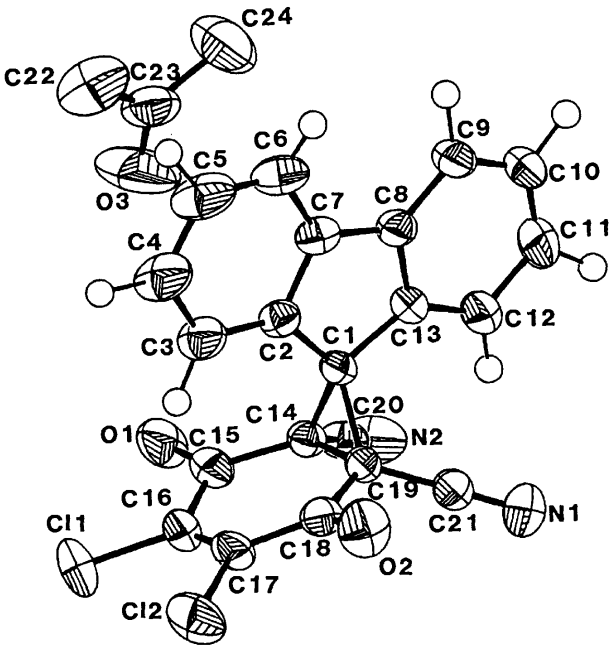


Fig. 1. ORTEP drawing of **2**·CH_3COCH_3.

relationship of the peak points to the natures of the additives is not clear.

X-Ray Crystal Structure. A perspective view of a complex, **2**·CH_3COCH_3, is shown in Fig. 1 by an ORTEP drawing[20] together with the atomic numberings. The bond distances and the bond angles are listed in Tables 1 and 2, respectively.

The cyclopropane ring of **2** is formed with a short bond, C14-C19 (1.505 Å), and two longer bonds, C1-C14 (1.542 Å) and C1-C19 (1.556 Å). The bond angles in the cyclopropane ring are 58.1° (C14-C1-C19), 61.4° (C1-C14-C19) and 60.5° (C1-C19-C14), respectively. These facts show a cyclopropane ring having a tendency to be an isosceles triangle.

Table 1. Bond Distances (in Å) of **2**·CH_3COCH_3 with Estimated Standard Deviations in Parentheses

Bond	Distance	Bond	Distance	Bond	Distance
C1-C2	1.518(4)	C2-C3	1.379(4)	C3-C4	1.390(5)

C23-C24	1.485(7)				

The projected view of the crystal structure of the complex, **2**·CH_3COCH_3, is represented in Fig. 2. The shortest distance between the acetone molecule and **2** is that of O2-C22 (X, $1+Y$, Z) (3.286 Å). This distance reveals the existence of a hydrogen bond,[21] though it is very weak, judging from the sum (3.40 Å[21]) of the van der Waals radii of a methyl group and an oxygen atom.

Reaction of 2 with Diols. It was found that, in acetonitrile at room temperature, **2** reacted with diols to give spiroacetals (**6**). Besides **6**, an almost quantitative amount of 2,3-dichloro-5,6-dicyanohydroquinone ($DDQH_2$) was isolated along with 9-fluorenone (**7**). The formation of the by-product, **7**, can be ascribed to the action of residual water present in the used solvent and/or of the water used in the treatment of the reaction mixture.

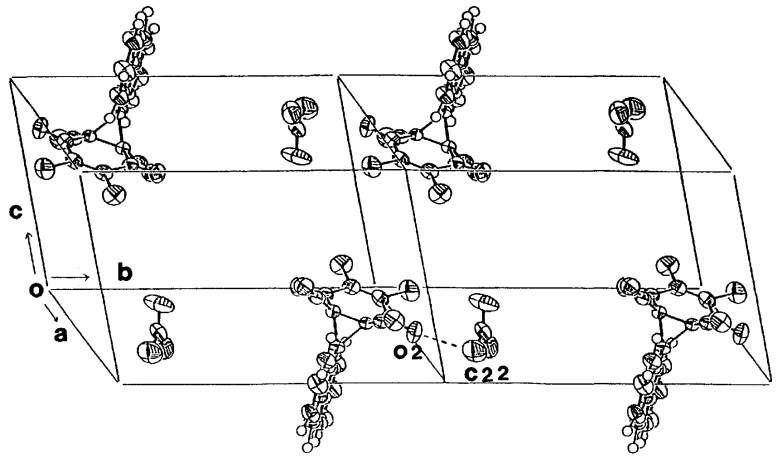

Fig. 2. The projected view of the crystal structure of **2**·CH_3COCH_3.

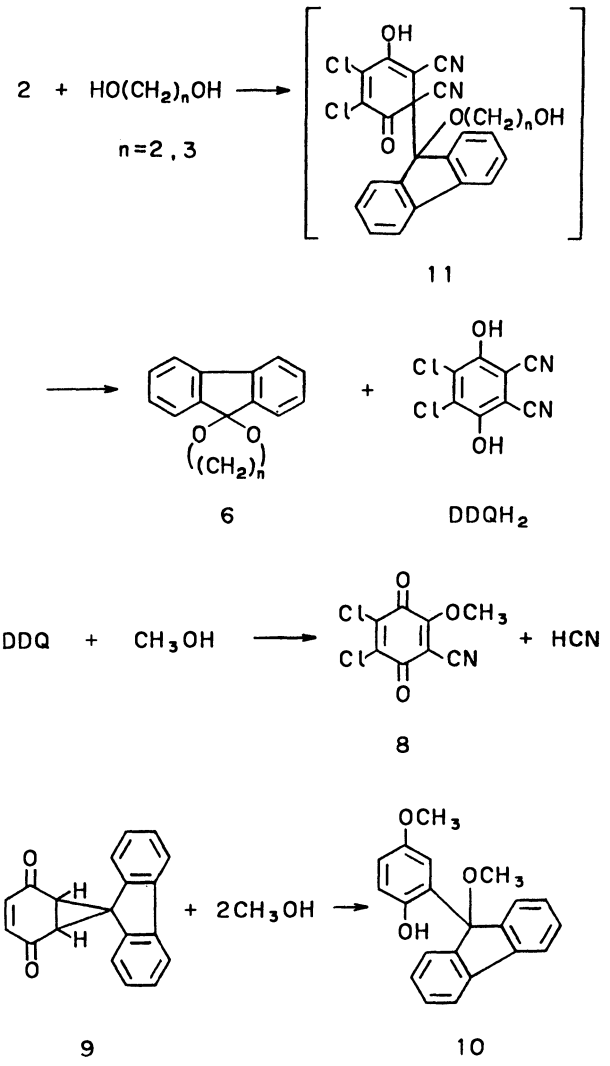

The nucleophilic displacement of the cyano group in DDQ by methanol proceeds to give 2,3-dichloro-5-cyano-6-methoxy-*p*-benzoquinone (**8**) at room temperature,[22] and the nucleophilic ring opening of the cyclopropane in spiro[fluorene-9,7′-[3′]norcarene]-2′,5′-dione (**9**) by methanol proceeds to afford 4-methoxy-2-(9-methoxy-9-fluorenyl)phenol (**10**).[13] In respect that the reaction of **2** with the diols has led to the production of the corresponding acetals and $DDQH_2$; the intermediate (**11**) represented above may be formed prior to the acetals. The cyclopropane ring of **2** provides electron-withdrawing cyano, carbonyl, and 9-fluorenylidene groups as well as strains inherent in a three-membered cyclic alkane. A nucleophilic attack of the diol takes place on the spiro carbon atom, leading to the ring opening; the follow-up proton migration occurs from the resulting oxonio hydrogen to the carbonyl oxygen to give **11**. In this intermediate, because of the strong electron-withdrawal of the DDQ moiety, the 9-fluorenylidene site is most likely subject to an internal nucleophilic attack by the other alcohol oxygen atom. Thus, an internal acetalization and an aromatization of the DDQ moiety provide **6** and $DDQH_2$. Here, it is left as a possibility that **11** undergoes an intermolecular nucleophilic attack with another molecule of the diol to give the corresponding noncyclic acetal. However, the noncyclic acetals could not be isolated also in the presence of more excess diols than those in the above-mentioned runs.

As mentioned above, a small amount of 9,9′-bifluorenylidene (**3**) was obtained in the reaction of 9-DF and DDQ. Whereas, from a stirred acetonitrile solution of **2** and 9-DF, **3** was not detected by means of high-performance liquid chromatography, both of the starting materials were recovered unchanged. Such a result was also shown by employing diphenyldiazomethane instead of 9-DF. Mechanistically, **3** could be derived from the diazonium betain intermediate, which had been provided by a nucleophilic attack of the diazo carbon on one carbonyl oxygen in DDQ, as described for the stilbene derivative formation in the reactions of aryldiazomethanes with chloranil.[9c,d]

Experimental

The melting points were determined on a Laboratory Devices Melt-Temp instrument and uncorrected. The infrared spectra were recorded on a Hitachi 260-10 spectrometer. The ^1H NMR spectra were taken on a Varian EM-390 spectrometer (90 MHz) and the ^{13}C NMR spectra were taken on a JEOL FX-200 spectrometer at 50.10 MHz (measured at NMR Application Laboratory, Nippon Denshi LTD., Tokyo, Japan) by the use of tetramethylsilane as an internal standard in acetone-d_6 or chloroform-d_3. Mass spectral data were obtained with a Hitachi RUM-6E mass spectrometer at an ionization potential of 70 eV. The DTA was accomplished with a Shimadzu DTA-system (thermal analysis instrument 30-series), all the samples being heated at a rate of 10 K min^{-1} from room temperature to 190 °C.

Materials. 9-Diazofluorene[23] and diphenyldiazomethane[24] were prepared by oxidation of the corresponding hydrazones with yellow mercury(II) oxide, the former; mp 99 °C[25] (from ether), the latter; mp 29—30 °C[26] (from light petroleum). Although 9-DF can be preserved for a long time in a refrigerator, the diazomethane must be prepared just before use. Benzene, acetone, ethyl methyl and diethyl ketones, acetonitrile, and dioxane were used after the commercial reagents had been purified according to the published directions.[27] DDQ was obtained from a commercial source and recrystallized from dichloromethane; mp 213—214 °C.[28] The diols were distilled under reduced pressure before use after the commercial materials were dried over Molecular Sieves 3A.

Reaction of 9-DF with DDQ. To a stirred solution of DDQ (3.63 g, 16 mmol) in acetonitrile (100 ml) was added dropwise over 40 min at 22—27 °C a solution of 9-DF (2.88 g, 15 mmol) in acetonitrile (50 ml); the evolution of nitrogen began immediately. Stirring was allowed to continue until the gas evolution was no longer observed after completing the addition. The evolved nitrogen was almost the theoretical amount, based on the diazo compound used. The orange-yellow flocculent precipitate formed under stirring was collected and washed with a small quantity of cold acetonitrile. A further crop was obtained by concentrating the

mother liquor under reduced pressure. The combined products were crystallized from dichloromethane to give **2** (5.45 g, 93%) as a yellow powder. Evaporating the acetonitrile mother liquor, treating the residue with ether, and cooling yielded red crystals of **3** (0.10 g, 2%). Upon employing acetone, dichloromethane, and benzene as the reaction solvent, the yield of **2** (70—90%) decreased with an increase in the yield of **3**. 3′,4′-Dichloro-1′,6′-dicyanospiro[fluorene-9,7′-[3′]norcarene]-2′,5′-dione (**2**): Mp 183 °C (decomp). Found: C, 64.39; H, 2.12; N, 7.16%. Calcd for $C_{21}H_8N_2O_2Cl_2$: C, 64.47; H, 2.06; N, 7.16%. MS *m/z* 390 (M^+). IR (KBr) 2250 (C≡N), 1710 (C=C), 1450, 1280, and 730 cm^{-1}. ^{13}C NMR ($(CD_3)_2CO$) δ=40.97 (s, fluorenylidene 9-C), 53.93 (s, C-CN), 112.60 (s, CN), 134.41 (s, CCl), 175.73 (s, CO), 136.43, 142,09, 144.27, 147.39 (each s), 122.37, 123.50, 123.83, 126.66, 129.37, 130.24 (each d), and 132.70 (d, 2C). 9,9′-Bifluorenylidene (**3**): Red needles (from ether); mp 189—190 °C. Found: C, 95.00; H, 4.88%. Calcd for $C_{26}H_{16}$: C, 95.09; H, 4.91%. MS *m/z* 328 (M^+). IR (KBr) 3050, 1600 (C=C), 1440, 1340, 760, and 720 cm^{-1}.

Host-Guest Compounds. A general method is exemplified in the adduct formation of **2** with ethyl methyl ketone as follows. The powder of **2** was dissolved in 10 ml of the ketone placed in a 30-ml Erlenmeyer flask at about 40 °C. The top of the flask was covered by a piece of powder paper which had been perforated with a pin; the saturated solution was left to stand at room temperature for crystallization, which gave big yellowish-orange columnar crystals. The adduct, **2**·$C_2H_5COCH_3$, was filtered off before use: Found: C, 64.81; H, 3.48; N, 6.05; Cl, 15.31%. Calcd for $C_{25}H_{16}N_2O_3Cl_2$: 64.79, H, 3.31; N, 5.90; Cl, 15.21%. MS *m/z* 390 (M^+−72). ^1H NMR ($CDCl_3$) δ=1.20 (t, $CH_2C\underline{H}_3$), 2.12 (s, CH_3), 2.44 (q, CH_2), and 7.0—8.2 (8H, aromatic H).

All of the following adducts made in this way revealed the mass spectra having the highest peak at *m/z* 390 and the ^1H NMR spectra (in $CDCl_3$) having peaks attributable to the fluorenylidene protons and the original peaks of their respective guests.

2·CH_3COCH_3: Found: C, 64.02; H, 3.13; N, 6.16%. Calcd for $C_{24}H_{14}N_2O_3Cl_2$: C, 64.16; H, 3.14; N, 6.24%.

2·CH_3CN: Found: C, 64.10; H, 2.42; N, 9.70%. Calcd for $C_{23}H_{11}N_3O_2Cl_2$: C, 63.90; H, 2.57; N, 9.72%.

2·Tetrahydrofuran: Found: C, 64.70; H, 3.46; N, 6.12%. Calcd for $C_{25}H_{16}N_2O_3Cl_2$: C, 64.81; H, 3.48; N, 6.05%.

2·1,4-Dioxane: C, 62.58; H, 3.38; N, 5.90%. Calcd for $C_{25}H_{16}N_2O_4Cl_2$: C, 62.64; H, 3.37; N, 5.85%.

2·Benzene: Found: C, 68.88; H, 3.00; N, 6.01%. Calcd for $C_{27}H_{14}N_2O_2Cl_2$: C, 69.09; H, 3.01; N, 5.97%.

2·Tetrahydropyran: Found: C, 65.22; H, 3.78; N, 5.80%. Calcd for $C_{26}H_{18}N_2O_3Cl_2$: C, 65.42; H, 3.80; N, 5.87%.

2·$C_2H_5COC_2H_5$: Found: C, 65.51; H, 3.90; N, 5.68%. Calcd for $C_{26}H_{18}N_2O_3Cl_2$: C, 65.42; H, 3.80; N, 5.87%.

As for a change of the guests, for example, **2**·$C_2H_5COCH_3$ was recrystallized from acetonitrile, by a manner similar to that described above, to give the **2**·CH_3CN adduct as orange columnar crystals.

Spiro Acetals. To a solution of 1.00 g (2.6 mmol) of **2** in acetonitrile (30 ml) was added 1.00 g (16 mmol) of ethylene glycol; the solution was then stirred for 4 h at room temperature. The removal of the solvent under reduced pressure gave a pale-yellow oil. To the residue was added benzene (30 ml or so), and insoluble $DDQH_2$ was filtered off and washed with benzene. The washing and filtrate parts were combined, washed with a 5% solution of sodium carbonate (15 ml×3), followed by rinsing with a saturated solution of sodium chloride (15 ml×3) and drying over anhydrous magnesium sulfate. The concentration of the benzene solution gave an oily substance, which was chromatographed on alumina (about 300 mesh). Careful successive elution gave **7** (0.12 g, 26%) with benzene-ether (5 : 1) and a spiro acetal, **6a**, (0.32 g, 56%) with benzene-ether (1 : 1). The reaction of **2** with 1,3-propanediol, by the same method as described above, gave **7** (0.17 g, 37%) and **6b** (0.31 g, 51%) besides $DDQH_2$. The structures of $DDQH_2$ and **7** were assigned

upon comparisons with the authentic samples.

Spiro[1,3-dioxolane-2,9′-fluorene] (6a): Mp 133—134 °C (from ether). Found: C, 80.26; H, 5.41%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%. MS *m/z* 224 (M^+). IR (KBr) 2860, 1440, 1110, 1060, 980, 935, 760, and 725 cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.35 (s, 4H) and 7.1—7.7 (m, 8H).

Spiro[1,3-dioxane-2,9′-fluorene] (6b): Mp 172—173 °C (form ether). Found: C, 80.44; H, 5.92%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%. MS *m/z* 238 (M^+). IR (KBr) 2880, 1450, 1082, 1010, 960, 930, 770, and 740 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.9—2.2 (m, 2H), 4.35 (t, 4H, J=5.4 Hz, OCH_2), and 7.1—7.8 (m, 8H).

Crystallographic Measurements. The crystal of $2 \cdot CH_3COCH_3$ was sealed in a Lindemann glass capillary with the mother liquor, because it gradually lost acetone molecules. Three dimensional X-ray data were collected using a crystal (0.4×0.3×0.2 mm) by Ni-filtered Cu $K\alpha$ radiation on a Rigaku automated four-circle diffractometer. The ω-2θ scan mode was employed at a rate of 10 ° min^{-1} (in ω). The backgrounds were counted for 2 s before and after each scan. A total of 3751 reflections was collected up to 2θ=125° and 2989 ($|F_o|>3\sigma|F_o|$) reflections were used in the analyses. The structure was solved by the direct method (MULTAN 74)[29] and refined by a block-diagonal least squares method (HBLS-V).[30] Anisotropic temperature factors were used for nonhydrogen atoms. The positions of the hydrogen atoms were calculated based on the molecular geometry. The methyl hydrogen atoms of the acetone molecule were neglected. These hydrogen atoms with isotropic temperature factors were included in further refinement. The final R and R_w values were 0.057 and 0.076, respectively. The weighting scheme used was $w=1/(\sigma(F_o)^2+0.0015(F_o)+0.0001(F_o)^2)$. The atomic scattering factors for all atoms were taken from Ref. 31. The final atomic coordinates are listed in Table 3†.

Crystal Data: $C_{24}H_{14}N_2O_3Cl_2$, F.W.=449.3, triclinic, space group $P\bar{1}$, a=9.848(1), b=13.972(1), c=9.222(1) Å, α=101.27(1), β=117.78(1), γ=71.96(1), V=1065.5(2) $Å^3$, D_c=1.401 $g \cdot cm^{-3}$, Z=2.

All the computations were carried out on an ACOS computer at the Computation Center, Osaka University, and on an ACOS S-850 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

† Tables of anisotropic temperature factors, and of observed and calculated structure factors are deposited as Document No. 8848 at the office of Bull. Chem. Soc. Jpn.

Selective Synthesis of Halogeno Derivatives from 5-Acetoxytropolone

Tomohiro NAGAO, Akira MORI,† and Hitoshi TAKESHITA*,†
Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
†Institute of Advanced Material Study, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received June 25,1988)

5-Acetoxytropolone was successfully halogenated by means of benzyltrimethylammonium tribromide and sulfuryl chloride to give 3-halotropolones and 3,7-dihalotropolones which were converted to the corresponding halogenated *p*-tropoquinone derivatives. From 3,7-dihalo-*p*-tropoquinones, 3,4,7-trichloro-5-hydroxytropolone was prepared in good yields via a Thiele-type addition reaction with hydrochloric acid. By a similar treatment, 5-hydroxytropolone gave a complex mixture.

Recently, we have shown that tropolones polysubstituted with acetoxyl group and/or halogens undergo reductive dehydrohalogenation during acetyl trifluoroacetate (ATA)-mediated acetolysis.[1] This was particularly interesting in connection to the reduction of *p*-tropoquinones to 5-hydroxytropolones by heating in acetic acid which suffered an oxidative decarboxylation.[2,3] Previous attempts of electrophilic bromination of 5-hydroxytropolone (**1**)[4] have so far been unsuccessful: a treatment of **1** with bromine has been known to give an intractable material.[5] Refluxing acetic acid of **1** with bromine,[2] however, gave 2,10-dihydroxydicyclohepta[*b,d*]furan-3,9-dione and its dibromo derivatives and dibromo-5-hydroxytropolones, which were a mixture of 3,6-, 3,7-, and 4,6-dibromo derivatives, indicating the operation of an oxidation-addition mechanism via tropoquinones.[6]

Herein, we discuss the electrophilic substitution reactions of the derivatives of **1** with benzyltrimethylammonium tribromide (**2**)[7] and sulfuryl chloride (**3**) halogenations to selectively form 3-halo or 3,7-dihalotropolones.

First of all, **1** was acetylated to 5-acetoxytropolone (**4**)[4] and treated with two molar equivalents of **2** to form product (**5**) in quantitative yield. The structure of **5** was deduced to be 5-acetoxy-3,7-dibromotropolone by conversion to known 3,7-dibromo-5-hydroxytropolone (**6**).[6]

The reaction was mild and selective. The present procedure gave 3,7-dibromo derivatives selectively. However, an excess amount of **2** resulted in the formation of cyclohexadienones; probably, the product, **5**, was oxidized with **2** to 3,7-dibromo-*p*-tropoquinone (**7**) or its equivalent which further ring-contracted via a benzil-benzilic acid rearrangement, in a protic solvent to 3,5-dibromo-4-hydroxy-4-methoxycarbonyl-2,5-cyclohexadienone (**8**).[6] On the other hand, a monobromo derivative, 5-acetoxy-3-bromotropolone (**9**), was obtained in good yield by the use of a controlled amount of **2**. A mild acid hydrolysis of **9** in aqueous acetic acid gave 3-bromo-5-hydroxytropolone (**10**).

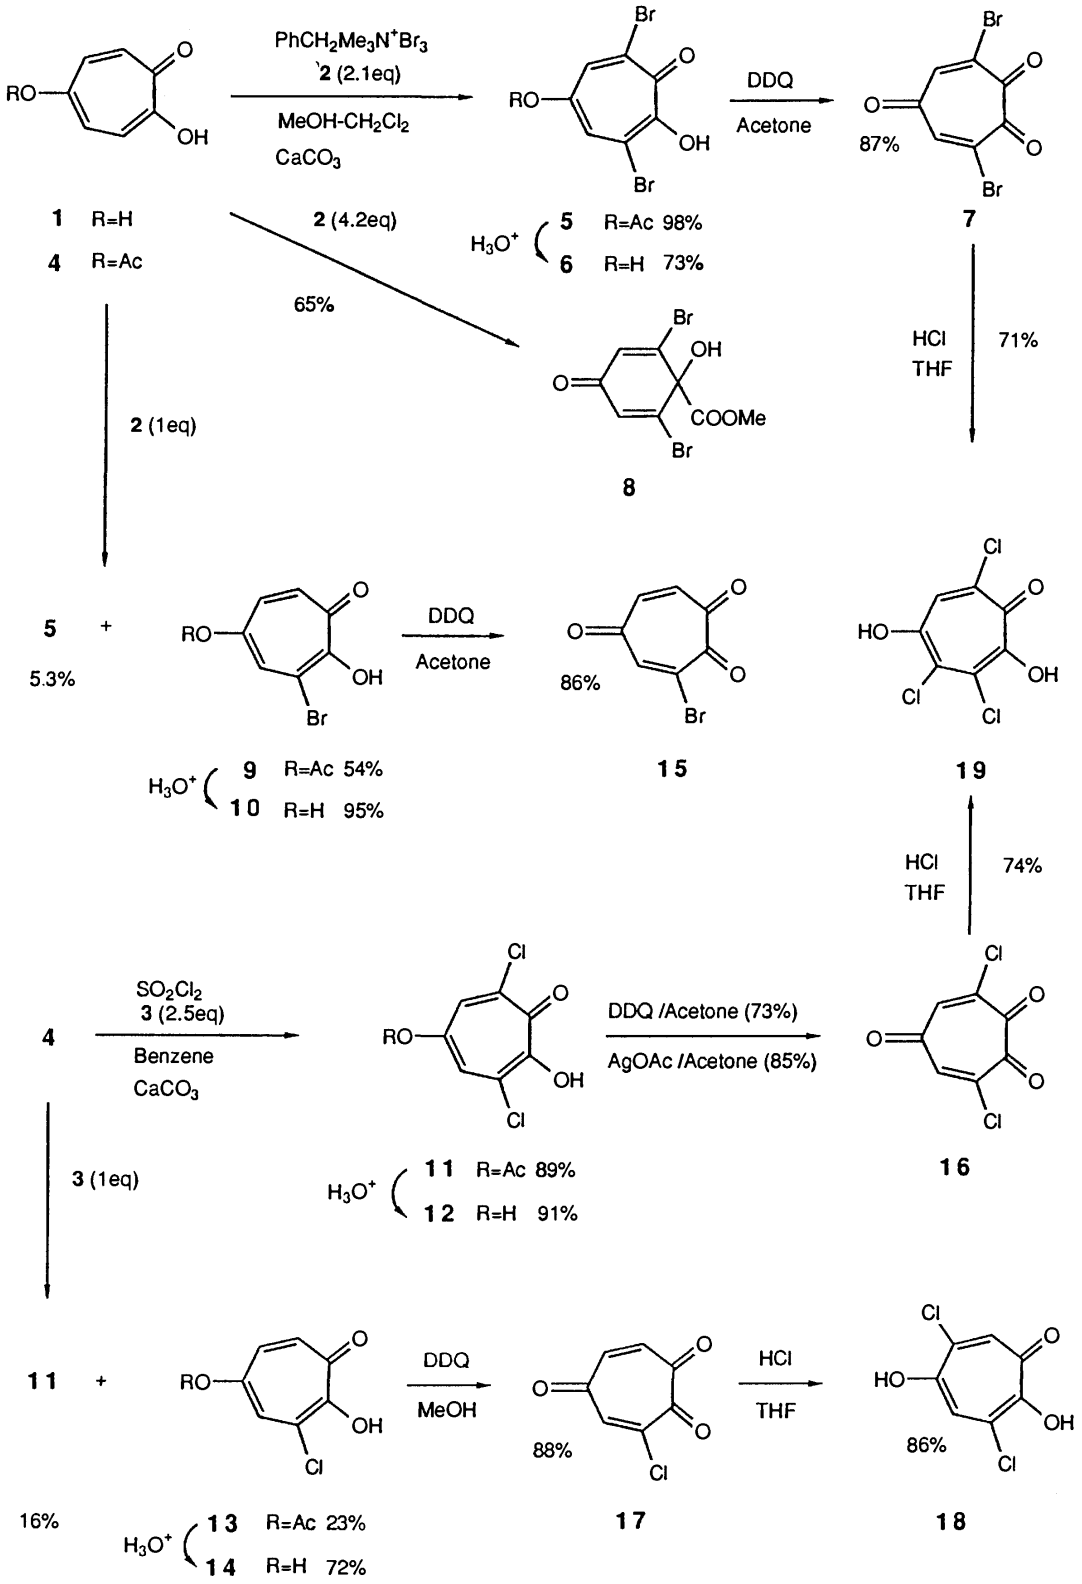
In parallel, chlorination of **4** was also successful by use of **3**: A treatment of **4** with **3** in benzene gave 5-acetoxy-3,7-dichlorotropolone (**11**), which could be quantitatively hydrolyzed to 3,7-dichloro-5-hydroxytropolone (**12**). The controlled chlorination of **4** yielded 5-acetoxy-3-chlorotropolone (**13**) together with an accompanied formation of 16% of **11**. An acid hydrolysis of **13** gave 3-chloro-5-hydroxytropolone (**14**).

The DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone)-oxidation of these halogenated compounds, **6**,[6] **10**, **12**, and **14**, afforded the corresponding *p*-tropoquinone derivatives (**7**,[6] **15**, **16**, and **17**) in high yields. A comparable result could be obtained by silver acetate-oxidation[6] of the 5-hydroxytropolones, as verified, in the case of **6** to **7**. As predicted, concd hydrochloric acid treatment of **17** and **16** in tetrahydrofuran (THF) gave 3,6-dichloro-5-hydroxytropolone (**18**) and 3,4,7-trichloro-5-hydroxytropolone (**19**). The **7** also gave **19** via a halogen exchange. Interestingly, **6** or **10** did not react with concd hydrochloric acid to **12** or **14**; the exchange should be operative only with quinones, prior to the Thiele-type addition step. Further, DDQ-oxidation of **19** was unsuccessful.

In conclusion, we have now obtained products of electrophilic substitution reactions of the derivative of **1** with halogens. Related studies concerning the development of the functional materials starting these troponoids are progressing.

Experimental

Bromination of 4 to 5-Acetoxy-3,7-dibromotropolone (5). A 1 : 1-mixture of MeOH and CH_2Cl_2 (10 cm^3) containing **4** (100 mg) was treated with **2** (476 mg) and $CaCO_3$ (120 mg) at room temperature for 1 h. The mixture was then treated with 1 M HCl (1 M=1 mol dm^{-3}), extracted with EtOAc, and dried over $MgSO_4$. Silica-gel column chromatography of the organic material obtained by removal of the solvent afforded **5** [greenish-yellow needles, mp 188—190 °C, 187 mg; 98%. Found: C, 31.85; H, 2.00%. Calcd for $C_9H_6O_4Br_2$: C, 31.99; H, 1.79%. ^{1}H NMR[8] δ=2.27 (3H, s) and 7.95 (2H, s). ^{13}C NMR δ=21.1, 123.9 (2C), 135.5 (2C), 139.4, 172.4 (2C), and 175.1. IR ν: 3155, 1760, 1615, 1595, 1565, 1330, 1195, 1155, 915, 810, and 760 cm^{-1}. UV λ_{max}^{MeOH}: 267 nm (ε=29300), 335 (9000, sh), 346 (12200), 418 (9400, sh), and 438 (14400)].



Hydrolysis of 5 to 3,7-Dibromo-5-hydroxytropolone (6). An aqueous AcOH solution (50%, 9 cm^3) of **5** (75 mg) was heated at 100 °C for 6 h. The mixture was then heated in vacuo to remove the solvent and the separated crystals were collected by filtration to give **6** [yellow needles, mp 232—234 °C (decomp) (lit,[6] 166—167 °C), 49 mg; 73%] together with the recovered **5** (17 mg; 23%).

Formation of 3,5-Dibromo-4-hydroxy-4-methoxycarbonyl-2,5-cyclohexadienone (8) by Treatment of 4 with Excess of 2. A 1 : 1-mixed solution consisted of MeOH and CH_2Cl_2 (5 cm^3) of **4** (50 mg) was treated with **2** (458 mg, 4.2 mol equiv) in the presence of $CaCO_3$ (60 mg) at room temperature for 1 h. The same work-up of the mixture gave **8** [colorless prisms, mp 161—162 °C, 59 mg; 65%. Found: C, 29.72; H,

2.05%. Calcd for $C_8H_6O_4Br_2$: C, 29.48; H, 1.86%. ^{1}H NMR δ=3.90 (3H, s) and 6.78 (2H, s). ^{13}C NMR δ=55.6, 77.4, 131.1 (2C), 142.8 (2C), 168.8, and 181.1. IR ν: 3350, 1750, 1650, 1600, 1300, 1225, 1115, 900, and 705 cm^{-1}. UV λ_{max}^{MeOH}: 249 nm (ε=14400) and 280 (4100)].

Controlled Bromination of 4 to 5-Acetoxy-3-bromotropolone (9). To an MeOH solution (20 cm^3) of **4** (200 mg) and $CaCO_3$ (60 mg), a CH_2Cl_2 solution (20 cm^3) of **2** (433 mg) was added drop by drop at room temperature for 2 h. After being stirred for another 2 h, the mixture was acidified with dil HCl, extracted with EtOAc, and dried over $MgSO_4$. Silica-gel column chromatography of the organic material afforded **9** [pale-yellow needles, mp 152—154 °C, 155 mg; 54%. Found: C, 41.86; H, 2.66%. Calcd for $C_9H_7O_4Br$: C, 41.73; H, 2.72%. ^{1}H NMR δ=2.33 (3H, s), 7.15 (1H, dd, J=11.4, 2.6 Hz), 7.30 (1H, d, J=11.4 Hz), and 7.96 (1H, d, J=2.6 Hz), ^{13}C NMR δ=20.9, 118.5, 128.3, 130.2, 137.5, 146.7, 164.3, 169.3, and 169.9. IR ν: 3245, 1765, 1610, 1565, 1210, 1150, 915, and 810 cm^{-1}. UV λ_{max}^{MeOH}: 258 nm (ε=29300), 318 (6200, sh), 335 (9700), 342 (9500, sh), 373 (4600, sh), 391 (5500), and 420 (4800)] together with **5** (20 mg; 5.3%) and the recovered **4** (35 mg; 18%).

Hydrolysis of 9 to 3-Bromo-5-hydroxytropolone (10). Similarly, **9** (93 mg) was treated with aqueous AcOH (33%, 10 cm^3) at 100 °C for 6 h to afford **10** [yellow needles, mp 226—228 °C (decomp), 74 mg; 95%. Found: C, 38.52; H, 2.30%. Calcd for $C_7H_5O_3Br$: C, 38.74; H, 2.32%. ^{1}H NMR δ=7.37 (1H, dd, J=11.7, 2.9 Hz), 7.67 (1H, d, J=11.7 Hz), and 8.15 (1H, d, J=2.9 Hz). ^{13}C NMR δ=127.6, 128.2, 134.2, 134.4, 161.7, 162.1, and 164.9. IR ν: 3300—2300, 1605, 1510, 1465, 1315, 1215, 1080, 870, and 760 cm^{-1}. UV λ_{max}^{MeOH}: 253 nm (ε=14700), 346 (6800), 389 (4900, sh), 401 (5100), and 431 (2800, sh)].

Chlorination of 4. Formation of 5-Acetoxy-3,7-dichlorotropolone (11). An anhydrous benzene suspension (10 cm^3) of **4** (2.0 g) and $CaCO_3$ (560 mg) was treated with SO_2Cl_2 (3.75 g) and refluxed for 2 h. After removing the solvent, the residue was acidified with dil HCl and extracted with $CHCl_3$. Silica-gel column chromatography of the organic material afforded **11** [greenish-yellow crystals, mp 168—170 °C, 2.46 g; 89%. Found: C, 43.12; H, 2.40%. Calcd for $C_9H_6O_4Cl_2$: C, 43.40; H, 2.43%. ^{1}H NMR δ=2.29 (3H, s) and 7.77 (2H, s). ^{13}C NMR δ=20.7, 133.9 (2C), 134.2 (2C), 144.9, 165.7 (2C), and 171.0. IR ν: 3200, 1765, 1600, 1575, 1340, 1200, 1155, and 855 cm^{-1}. UV λ_{max}^{MeOH}: 251 nm (ε=22400, sh), 262 (32600), 333 (9500, sh), 344 (12300), 396 (4100, sh), 412 (6800, sh), and 436 (10000)].

Hydrolysis of 11 to 3,7-Dichloro-5-hydroxytropolone (12). An aqueous acetone solution (33%, 15 cm^3) of **11** (1.84 g) was refluxed for 4 h. Silica-gel column chromatography of the residue, obtained from the mixture, afforded **12** [yellow crystals, mp 253—255 °C (decomp), 1.39 g; 91%. Found: C, 40.91; H, 2.06%. Calcd for $C_7H_4O_3Cl_2$: C, 40.61; H, 1.95%. ^{1}H NMR δ=7.50 (2H, s). ^{13}C NMR δ=127.4 (2C), 136.9 (2C), 154.8, and 162.8 (2C). IR ν: 3400—2400, 1605, 1575, 1530, 1420, 1360, 1220, 1110, 860, and 760 cm^{-1}. UV λ_{max}^{MeOH}: 255 nm (ε=25500), 349 (8800), 395 (6400, sh), 412 (7300), and 438 (4800, sh)].

Controlled Chlorination of 4. Formation of 5-Acetoxy-3-chlorotropolone (13). To an anhydrous benzene suspension (100 cm^3) of **4** (3.0 g), an anhydrous benzene solution (20 cm^3) of SO_2Cl_2 (2.24 g) was added drop by drop for 1 h. After being refluxed for another 2 h, the mixture was heated in vacuo to remove the solvent. The residue was chromatographed on a silica-gel column to give recovered **4** (1.05 g; 35%), **11** (645 mg; 16%), and **13** [pale-yellow needles, mp 148—150 °C, 834 mg; 23%. Found: C, 50.49; H, 3.25%. Calcd for $C_9H_7O_4Cl$: C, 50.37; H, 3.29%. ^{1}H NMR δ=2.33 (3H, s), 7.13 (1H, dd, J=11.4, 2.6 Hz), 7.32 (1H, d, J=11.4 Hz), and 7.73 (1H, d, J=2.6 Hz). ^{13}C NMR δ=20.9, 118.3, 129.9, 134.5, 136.8, 146.6, 164.7, 169.2, and 169.5. IR ν: 3270, 1750, 1610, 1575, 1220, 1155, 920, 845, and 775 cm^{-1}. UV λ_{max}^{MeOH}: 215 nm (ε=29900), 314 (6200, sh), 332 (10000), 342 (9200, sh), 373 (4700, sh), 390 (5500), and 415 (3700)].

Hydrolysis of 13 to 14. An aqueous acetone solution (33%, 15 cm^3) of **13** (300 mg) was refluxed for 4 h. The mixture was then heated in vacuo to remove the solvent; the residue was crystallized from EtOH to give **14** [pale-yellow crystals, mp 218—220 °C (decomp) (lit,[6] 221—223 °C (decomp)). ^{1}H NMR δ=7.03 (1H, d, J=11.4, 2.6 Hz), 7.35 (1H, d, J=11.4 Hz), and 7.70 (1H, d, J=2.6 Hz)].

DDQ-Oxidation of 6. Formation of 3,7-Dibromo-*p*-tropoquinone (7). An acetone suspension (2 cm^3) of **6** (100 mg) was treated with DDQ (93 mg) at room temperature for 30 min. The mixture was then heated in vacuo to remove the solvent; the residue was chromatographed on a silica-gel column to give **7** [yellow crystals, mp 93—95 °C (lit,[6] 96—97 °C (decomp)), 86 mg; 87%].

DDQ-Oxidation of 10 to 3-Bromo-*p*-tropoquinone (15). Similarly, an acetone solution (5 cm^3) of **10** (40 mg) was treated with DDQ (42 mg) at room temperature for 30 min. The mixture was then heated in vacuo to remove the solvent; the residue was chromatographed to give **15** [yellow crystals, mp 59—61 °C, 34 mg; 86%. Found: C, 39.25; H, 1.53%. Calcd for $C_7H_3O_3Br$: C, 39.10; H, 1.41%. ^{1}H NMR δ=6.78 (2H, d, J=0.7 Hz) and 7.53 (1H, t, J=0.7 Hz). ^{13}C NMR δ=133.8, 136.5, 138.5, 141.1, 181.9, 184.6, and 185.2. IR ν: 3045, 1670, 1640, 1610, 1595, 1320, and 1160 cm^{-1}].

DDQ-Oxidation of 12. Formation of 3,7-Dichloro-*p*-tropoquinone (16). An acetone suspension of **12** (200 mg) was treated with DDQ (200 mg) at room temperature for 1 h. After removing the solvent, the residue was chromatographed on a silica-gel column to give **16** [yellow crystals, mp 53—55 °C, 145 mg; 73%. Found: C, 41.50; H, 1.15%; M$^+$, 203.9414. Calcd for $C_7H_4O_3Cl_2$: C, 41.01; H, 0.98%; M, 203.9381. ^{1}H NMR δ=7.30 (2H, s). ^{13}C NMR δ=136.9 (2C), 142.5 (2C), 180.3, and 181.5 (2C). IR ν: 1695, 1630, 1610, 1330, 1190, and 895 cm^{-1}].

AgOAc-Oxidation of 12. An acetone suspension (5 cm^3) of **12** (100 mg) was treated with AgOAc (160 mg) at room temperature for 1 h with stirring. After removing the solvent in vacuo, the residue was passed through a short Celite column and chromatographed on a silica-gel column to give **16** (84 mg; 85%).

Concentrated HCl-Treatment of 16 to 3,4,7-Trichloro-5-hydroxytropolone (19). A THF solution (5 cm^3) of **16** (145 mg) and concd HCl (0.03 cm^3) was stirred at room temperature for 30 min. After removing the solvent in vacuo, the residue was washed with $CHCl_3$ and recrystallized from MeOH to give **19** [greenish-yellow crystals, mp 190 °C (decomp), 126 mg; 74%. Found: C, 34.98; H, 1.25; Cl, 43.90%. Calcd for $C_7H_3O_3Cl_3$: C, 34.82; H, 1.25; Cl, 44.06%. ^{1}H NMR δ=7.59 (1H, s). ^{13}C NMR δ=123.7, 133.3, 135.9, 137.8, 151.4, 161.2, and 163.3. IR ν: 3200—2400, 1510, 1430, 1310, 1190, 1140, 870, and 835 cm^{-1}. UV λ_{max}^{MeOH}: 263 nm (ε=23600), 329 (2900, sh), 355 (6200), 370 (6300), 397 (6400, sh), 416 (7500), and 440 (5800, sh)].

Concentrated HCl-Treatment of 7. Formation of 19. Similarly, a THF solution (5 cm^3) of **7** (195 mg) was treated with concd HCl (0.03 cm^3) at room temperature for 30 min. After removing the solvent, the residue was washed with $CHCl_3$ and recrystallized from MeOH to give **19** (114 mg; 71%). Its identity with the sample obtained from **12** was confirmed by a direct comparison.

DDQ-Treatment of 14. Formation of 3-Chloro-*p*-tropoquinone (17). An MeOH solution (4 cm^3) of **14** (150 mg) was treated with DDQ (200 mg) at room temperature for 30 min. The mixture was then chromatographed on a silica-gel column to give **17** [yellow crystals, mp 68—69 °C (lit,[6] 73—74 °C), 130 mg; 88%].

Concentrated HCl-Treatment of 17 to 3,6-Dichloro-5-hydroxytropolone (18). A THF solution (5 cm^3) containing concd HCl (0.03 cm^3) of **17** (130 mg) was stirred at room temperature for 1 h. After removing the solvent, the residue was recrystallized from EtOH to give **18** [pale-yellow crystals, mp 181—183 °C (decomp), 136 mg; 86%. Found: C, 40.52; H, 2.02%. Calcd for $C_7H_4O_3Cl_2$: C, 40.61; H, 1.95%. ^1H NMR δ=7.70 (1H, s) and 7.96 (1H, s). ^{13}C NMR δ=124.6, 129.6, 130.9, 139.7, 153.5, 159.2, and 168.1. IR ν: 3400—2800, 1525, 1450, 1335, 1220, 1130, and 830 cm^{-1}. UV λ_{max}^{MeOH}: 255 nm (ε=27000), 351 (8100), 365 (8200), 391 (8900, sh), 408 (9800), and 434 (6400, sh)].

Attempted DDQ-Oxidation of 19. An anhydrous acetone solution (5 cm^3) of **19** (100 mg) was treated with DDQ(85 mg) at room temperature for 1 h. After removing the solvent in vacuo, the residue was chromatographed on a silica-gel column to give 14 mg of solid material, whose ^1H NMR spectrum indicated a mixture. Despite the intensive effort, no compound was isolable, and the absence of starting **19** in the mixture was assured by mass spectrometry.

Novel Synthesis of Carbamic Ester from Carbon Dioxide, Amine, and Ortho Ester

Shigeru Ishii, Hidenobu Nakayama, Yasuhiko Yoshida,* and Tadataka Yamashita
Department of Applied Chemistry, Faculty of Engineering, Toyo University, Kujirai, Kawagoe, Saitama 350
(Received June 30, 1988)

Carbon dioxide reacted with aliphatic amines and ortho esters to form carbamic esters in good yields. The influence of different ortho esters on the carbamate synthetic reaction is described. In the case of orthocarbonates, carbamic esters were obtained in high yields. The reaction of carbon dioxide, amines, and ortho esters may involve a competitive reaction between the esterification of carbamic acid produced by a reaction of carbon dioxide with amine, and the alkylation of amine.

In recent years, great efforts have been made to find alternative raw materials for organic syntheses, instead of using diminishing fossil fuel. Carbon dioxide is hoped to be made available as a potential carbon source for future use since it is an almost inexhaustible resource. However, it has a great disadvantage due to its inertness in chemical reactions.

A large number of the fixation reactions of carbon dioxide has so far been studied. Especially, recent interest in the fixation of carbon dioxide has been leading to a starting material for the direct synthetic reactions of carbamic esters.[1-9] The usual synthetic methods for carbamic esters[10] are the reaction of alcohol with isocyanate or carbamoyl chloride, and the reaction of amine with chloroformate. However, a new process for preparing carbamic esters without these compounds should be developed, since these reagents are very toxic. Carbamic esters have not been obtained by a direct esterification of carbamic acid, since carbamic acid has been known only as a transient intermediate in the reaction of isocyanate with water, or the hydrolysis of carbamic ester,[11] and is not isolable.

Carbamic acid can also be obtained by a reaction of carbon dioxide with aliphatic amine (Eq. 1). However, carbon dioxide is not fixed by only the reaction with amine, because of an easy dissociation to carbon dioxide and amine.[12]

$$R_2NH + CO_2 \rightleftarrows R_2NCOOH \qquad (1)$$

We reported previously the following reactions using carbamic acid as the reaction intermediate: the reaction of carbon dioxide and amines with epoxides to obtain 2-hydroxyalkyl carbamates in high yields,[3] the reaction with vinyl ethers to form 1-alkoxyalkyl carbamates selectively,[2] and the reaction with alkyl halides to yield the corresponding alkyl carbamates.[5] In the course of our studies concerning the fixation of carbon dioxide, a direct esterification of carbamic acid using ortho esters was found.

In this paper we describe this reaction of carbon dioxide, aliphatic amines, and ortho esters to afford directly carbamic esters.

Results and Discussion

Carbon dioxide reacted with amines and ortho esters to give carbamic esters in good yields, depending on the reactivities of amines and ortho esters, and the reaction conditions.

$$CO_2 + R_2NH + R'C(OR'')_3 \longrightarrow R_2NCOOR'' \qquad (2)$$

yield upon the reaction temperature in a reaction of diethylamine, carbon dioxide, and trimethyl orthoformate for 45 h. The yield of methyl diethylcarbamate was 3% at 60 °C, though the yield increased with the reaction temperature. The yield of methyl diethylcarbamate was 43% at 120 °C.

The relation between the reaction time and the yield of methyl diethylcarbamate is shown in Fig. 2. In this case, a longer reaction time enhanced the carbamate yield to 60% after 72 h.

The results for the reaction of carbon dioxide, various amines, and ortho esters at 120 °C for 45 h are summarized in Table 1. While aliphatic amines gave the carbamic esters in good yields (Table 1, Nos. 1—10), aromatic amine, such as *N*-methylaniline, did not give the carbamic ester (Table 1, No. 11). It appeared that aromatic amine does not react with carbon dioxide, since the basicities of aromatic amines are lower than those of aliphatic amines.

A reaction using orthoacetate gave a carbamic ester in higher yield than that of orthoformate (Nos. 1 and 2.). With orthocarbonates, the yields of methyl and ethyl carbamates were 127 and 156%, respectively (Nos. 4 and 5)

The reaction with ethyl ortho esters gave the corresponding carbamic esters in higher yields than those of methyl ortho esters (Nos. 2—9), even in the case of using any of the aliphatic secondary amines. The primary aliphatic amine reacted with methyl ortho ester to give the corresponding carbamic ester in a good yield (No. 10).

In order to obtain more details concerning the reaction mechanism, the by-products of the reaction with amines, carbon dioxide, and ortho esters at 120 °C for 45 h were studied in greater detail. The results are summarized in Table 2. The reaction of diethylamine, carbon dioxide, and triethyl orthoformate gave ethyl diethylcarbamate in 83% yield with *N*,*N*-diethylformamide, ethyl alcohol, and triethylamine as by-products in 93, 186, and 6%, respectively (Table 2, No. 1). From these results, the reaction mechanism is considered to be as follows. At first, carbamic acid, formed from a reaction of carbon dioxide with amine (Eq. 1), reacted with ortho ester to form carbamic ester, alcohol, and

Table 2. Reaction Mixture Obtained by the Reaction of CO_2, Amines, and Ortho Esters[a]

a) Amine; 0.2 mol, ortho ester; 0.1 mol, CO_2; 40 atm, 120 °C, 45 h. b) Yield based on ortho ester by GLC.

carboxylic ester corresponding to ortho ester (Eq. 3). Then, the formed carboxylic ester reacted with amine (being present in large excess into the reaction system) to give the corresponding amide and alcohol (Eq. 4). The alkylation of amine by ortho ester also occurred to form tertiary amine (Eq. 5).

$$R_2NCOOH + R'C(OR'')_3 \longrightarrow R_2NCOOR'' + R''OH + R'COOR'' \quad (3)$$

$$R'COOR'' + R_2NH \longrightarrow R_2NCOR' + R''OH \quad (4)$$

$$R_2NH + R'C(OR'')_3 \longrightarrow R_2NR'' + R''OH + R'COOR'' \quad (5)$$

Using methyl orthoformate, the alkylation of morpholine was preferred to the esterification of carbamic acid to give *N*-methylmorpholine in good yield (No. 2). The reaction with ethyl orthoformate gave the carbamic ester in higher yield (No. 3).

When tetraethyl orthocarbonate was used in the synthetic reaction of the carbamic ester, ethyl diethylcarbamate was formed in a yield over 100%, based on the amount of ortho ester. The reaction of carbamic ester with tetraethyl orthocarbonate is considered to give ethyl diethylcarbamate, diethyl carbonate and ethyl alcohol in equimolar amounts (Eq. 6). Diethyl carbonate easily reacted with the amine to form carbamic ester (Eq. 7),[13-15] which corresponded to the amide obtained by reactions with orthoformate or orthoacetate.

$$R_2NCOOH + C(OR')_4 \longrightarrow R_2NCOOR' + (R'O)_2CO + R'OH \quad (6)$$

$$(R'O)_2CO + R_2NH \longrightarrow R_2NCOOR' + R'OH \quad (7)$$

The reaction of amines, carbon dioxide, and ortho esters is considered to involve competitive reactions between the esterification of carbamic acid and the alkylation of amine,[16,17] depending on the reactivities of the amines and ortho esters.

In conclusion, aliphatic amines react with carbon dioxide and ortho esters to give carbamic esters in good yields, though aromatic amines give no products at all. The reactions of carbon dioxide and amines with ethyl ortho esters give the carbamic esters selectively in high yields.

Experimental

Material. Commercially available amines and ortho esters were purified by employing the usual procedures and stored under a nitrogen atmosphere. Commercially high-purity carbon dioxide gas was introduced into an autoclave directly from a gas cylinder without further purification.

Measurements. IR spectra were recorded on Hitachi EPG-G3 and 260-50 equipment. NMR spectra on a Hitachi 24B spectrometer operating at 60 MHz and JEOL FX90Q at 90 MHz, using hexamethyldisiloxane (HMDS) as an internal standard. The GC-MS spectra were recorded on a Shimadzu QP1000 GC-MS spectrometer. Gas liquid chromatography (GLC) analyses were performed on a Shimadzu GC-4C apparatus with a thermal conductor, using a 3 mm×5 m column packed with Silicon OV-17 with helium as the carrier gas.

Syntheses of Carbamic Esters. Ethyl Diethylcarbamate: The typical reaction of amines and carbon dioxide with ortho esters is noted as follows. The mixture of diethylamine (0.2 mol; 20.7 cm^3) and triethyl orthoformate (0.1 mol; 16.6 cm^3) was added into a 100 cm^3 stainless autoclave, and carbon dioxide gas was introduced directly from a gas cylinder until the pressure reached 40 atm (4.05×10^6 Pa). After the autoclave was allowed to stand in an oil bath controlled at 120 °C for 45 h, an excess of carbon dioxide gas was released. The reaction mixture was subjected to fractional distillation under reduced pressure in order to isolate the product, ethyl diethylcarbamate (bp 60.8—61.2 °C/13 mmHg, (1 mmHg≈133.322 Pa) 11.0 g, 76%).

Preparations of other carbamic esters were carried out by a similar manner.

Identification of the Carbamic Ester. Methyl Diethylcarbamate: Bp 155—156 °C (lit,[18] bp 154—155 °C); IR (neat) 1695 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.99 (6H, t, $(C\underline{H}_3CH_2)_2N$), 2.88 (4H, q, $(CH_3C\underline{H}_2)_2N$), 3.21 (3H, s, CH_3O).

Ethyl Diethylcarbamate: Bp 60.8—61.2 °C/13 mmHg (lit,[19]; Bp 62—63 °C/14 mmHg); IR (neat) 1700 cm^{-1} ((C=O), ^1H NMR ($CDCl_3$) δ=1.1 (9H, t, CH_3), 3.24 (4H, q, $(CH_3C\underline{H}_2)_2N$), 4.12 (2H, q, $OC\underline{H}_2CH_3$).

***N*-Methoxycarbonylpiperidine:** Bp 101.0—101.5 °C/30 mmHg (lit,[20] bp 100 °C/30 mmHg); IR (neat) 1700 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.4 (6H, m, methylenes of piperidine ring), 3.2 (4H, m, CH_2N), 3.46 (3H, s, CH_3O).

***N*-Ethoxycarbonylpiperidine:** Bp 57.7—58.0 °C/1.5 mmHg (lit,[20] bp 55—56 °C/0.9 mmHg); IR (neat) 1705 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.97 (3H, t, $C\underline{H}_3CH_2O$), 1.3 (6H, m, methylene of piperidine ring), 3.2 (4H, m, CH_2N), 3.75 (2H, q, $CH_3C\underline{H}_2O$).

Electronic Control of Stereoselectivity in the Metal Hydride Reductions of 1,2,3,4-Tetrahydro-1,4-methanonaphthalen-9-ones[1]

Keiji Okada,* Seiji Tomita, and Masaji Oda*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received July 11, 1988)

Stereoselectivity in the metal hydride reduction of a series of substituted 1,2,3,4-tetrahydro-1,4-methanonaphthalen-9-ones was investigated in relation to their homoconjugation character. The observed stereoselectivity sequence was found to be parallel with the homoconjugation sequence: the portion of anti-attack increases as the benzene ring becomes electron-rich. The results are rationalized in terms of the transition state model proposed by Cieplak or of the contribution of the nonclassical carbocation in the transition state.

Since Dauben, Fonken, and Noyce presented a rationalization of "product development control" for the predominant axial attack of nucleophiles on cyclohexanones in 1956,[2] a number of ingenious rationalizations as well as many experimental investigations on the nucleophilic addition to cyclic ketones have appeared.[3] 7-Norbornenone has also attracted attention in its relationship to the homoconjugation character between the carbonyl group and the endocyclic double bond. Brown and Muzzio originally expected that the anti/syn-stereoselectivity towards 7-norbornenone might reflect the homoconjugation property. Such interaction would lead to the preferential anti-attack. However, the opposite selectivity was observed.[4] Experimental data so far available show that the nucleophiles stereoselectively attack the carbonyl group from the syn-side of the double bond. For example, the reactions with sodium borohydride,[4] Grignard reagents,[5,6] alkyllithium reagents,[7] diazomethane,[8] and with sulfonium[9] or sulfoxonium[6] ylides gave the products of syn-attack in a stereoselective or stereospecific manner. Exceptions can be seen in the reaction with vinyllithium[10] and phenyllithium.[11] Mechanistic problems as to whether the observed stereoselectivity is due to steric or electronic effects are controversial. Attack from the anti-side of the double bond seems to be slightly more hindered owing to the steric repulsion between the exo-protons of ethano-bridge and the incoming nucleophiles. An empirical calculation evaluating congestion or torsion-corrected congestion, however, suggests that attack from the side of the double bond is slightly more hindered, leading to a consideration that the stereoselectivity may be due to a chelating effect of the double bond rather than a steric or torsional effect.[12] A similar electronic interpretation was also proposed by Bly and Bly.[6] An insight into this selectivity can be drawn by the experiments reported by Tanida who investigated the metal hydride reductions of monosubstituted benzonorbornenones **1** as a reference for the solvolysis experiments of the corresponding anti-brosylates. A maximum variation for the selectivity of anti/syn-alcohol was obtained in the disiamylborane reduction (52/48 for Z=Cl, 45/55 for Z=H, 36/64 for Z=OMe). However, the author argued the selectivity in terms of the subtle change of steric environment because the change of stereoselectivity was too small in comparison with the large variation of solvolysis rates.[13] For demonstration of the electronic effect, much widely variable selectivity is desirable. We wish to report the metal hydride reductions of a series of substituted 1,2,3,4-tetrahydro-1,4-methanonaphthalen-9-ones (9-benzonorbornenones),[14] **2a—f**. Because of simplicity, the name "9-benzonorbornenone" is used in the text hereafter.

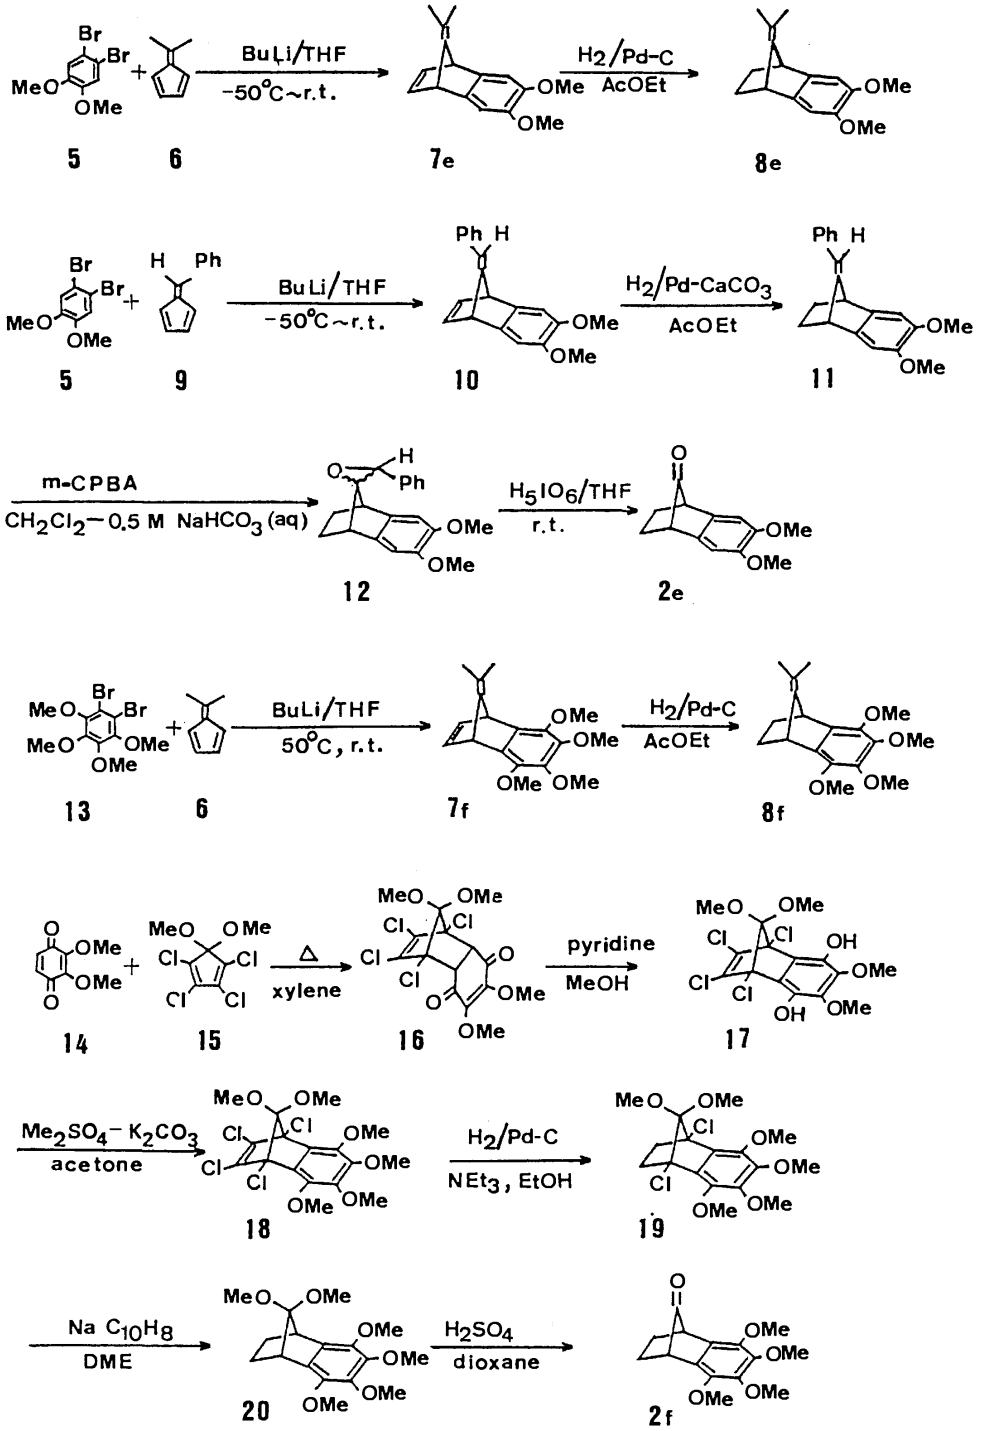
Results and Discussion

Synthesis. Compounds **2a**, **2b**, **2c**, and **2d** were synthesized according to the literature procedures.[15,16] Dimethoxy derivatives **2e**, **8e** and tetramethoxy derivatives **2f** and **8f** are new compounds. At first, we attempted the syntheses of **2e** and **2f** from the corresponding isopropylidene derivatives **8e** and **8f**, which were prepared by cycloaddition of 6,6-dimethylfulvene (**6**) with the appropriate benzynes, followed by reduction of the endocyclic double bond, in total yields of 38 and 44%, respectively (Scheme 1). Ozonolysis or oxidative cleavage ($KMnO_4$-$NaIO_4$, OsO_4-$NaIO_4$) of the isopropylidene derivatives gave **2e** and **2f** in very poor yields because of facile oxidation of the benzene rings. More rewarding routes to **2e** and **2f** are also outlined in Scheme 1. Cycloaddition of 6-phenylfulvene (**9**) with 4,5-dimethoxybenzyne gave the adduct **10** in 24% yield. Reduction of the endocyclic double bond and



Scheme 1.

successive epoxidation followed by oxidative cleavage with H_5IO_6 in THF produced the desired **2e** in 28% yield from **10**. Compound **2f** was synthesized by a modification of the reported method.[16] Cycloaddition of 2,3-dimethoxy-*p*-benzoquinone (**14**) with 5,5-dimethoxy-1,2,3,4-tetrachlorocyclopentadiene (**15**) gave **16** in 97% yield. Enolization followed by *O*-methylation afforded dimethyl acetal **18** in 78% yield. Direct transformation of **18** to **20** with metal reduction (Li/*t*-BuOH-THF) failed and a mixture of the dimethoxy and trimethoxy derivatives was obtained instead. This conversion was achieved by two step reduction with use of H_2/Pd-C-Et_3N-EtOH and sodium naphthalenide/DME. Acidic hydrolysis of **20** gave **2f** in 85% yield.

Stereochemistry of Anti- (3a—f) and Syn-Alcohols (4b—f). ^{1}H NMR data of the produced anti- (**3a—f**) and syn-alcohols (**4b—f**) are listed in Table 1. Stereochemistry of the anti- and syn-alcohols were determined by use of a NMR shift reagent, Eu(fod)$_3$. The

a) Measured in $CDCl_3$ (ca. 25—30 mg/0.3 ml). b) In parenthesis; averaged values determined by successive addition of 5 mg of $Eu(fod)_3$ up to ca. 25 mg. c) An averaged value of the two kind of protons.

relative shift values (1.00 for $H_{1,4}$-protons in both alcohols) induced by $Eu(fod)_3$ for $H_{2,3}$- and other protons are also summarized in Table 1. It is clear that $H_{2,3}$-exo protons in anti-alcohols (**3b—f**) have larger relative shifts (0.76—1.20) than those (0.35—0.42) of syn-alcohols (**4b—f**). The same trend is observed for $H_{2,3}$-endo protons. These results clearly elucidate the stereochemistry of the alcohols as assigned in the text. Although the partial coordination of $Eu(fod)_3$ onto methoxyl groups is also recognizable from the table, this coordination would not much affect the shift of $H_{2,3}$-protons for the relatively long distance between these protons and the coordinated metal center. The assignment is also supported by the fact that H_9-methine protons of anti-alcohols appear in higher field (δ ca. 3.7—3.92) than those of syn-alcohols (δ 4.06—4.20) because of the anisotropy effect of the benzene rings. Similarly, hydroxyl protons of anti-alcohols have lower chemical shifts (δ 1.87—2.12) than those (δ 1.58—1.76) of syn-alcohols in usual concentration (ca. 25—30 mg/0.3 ml $CDCl_3$). It is interesting to note that the shift of aromatic protons of **3e** and **4e** is larger than those of **3d** and **4d** upon the contact with $Eu(fod)_3$. This may suggest that the two adjacent methoxyl groups might form a better ligand for $Eu(fod)_3$ than the two methoxyl groups at *p*-position. It may be also interesting to refer to GC retention time (column; OV-17) of these alcohols: syn-alcohols have shorter retention time than anti-alcohols in all cases. This may be a reflection of the expected hydrogen bond between the hydroxyl group and the benzene π-bond. This relation might be used as a convenient method of stereochemical assignment for the related compounds.

Homoconjugation Interaction of the Carbonyl Group and the Benzene Ring. Although the expectation that anti/syn-stereoselectivity may reflect the homoconjugation interaction in 7-norbornenone was rather disappointing,[4] it is worthy to reconsider the possibility that the same expectation may be realized in a series of substituted 9-benzonorbornenones. Before entering the section of stereoselective metal hydride reduction, the donating ability of the substituted benzene rings is discussed here in relation to the homoconjugation property. As to 7-norbornenone, extensive studies by means of ^{13}CNMR,[17] PES,[18] and CD (for unsymmetrically deutrated or substituted derivatives)[19] spectra have shown the homoconjugation interaction between the endocyclic double bond and the carbonyl group. The similar homoconjugation interaction is expectable if the endocyclic double bond is replaced by the benzene ring. Electron-donating substituents on the benzene ring of 9-benzonorbornenones (**2a—f**) would decrease the double bond character of the carbonyl group. Therefore, the homoconjugation in **2a—f** may be revealed in IR stretching frequency of the carbonyl groups. Initially, we thought that electron-donating property would increase in the sequence of **2a**→**2b**→**2c**→**2d**→**2e**→**2f**. However, the observed frequency for **2f** falls in the range between **2b** and **2c**: [IR(CCl_4, $\nu_{C=O}$); 1793 for **2a**: 1786 ($CHCl_3$) for **2b**: 1782 for **2c**: 1781 for **2d**: 1778 for

2e: 1785 cm^{-1} for **2f**]. This may suggest that tetramethoxybenzo moiety may not be an effective electron donor, contrary to our initial expectation. To elucidate this point, other reliable methods to evaluate the electron-donating ability of the substituted benzene rings favorably using the related molecules were sought. 9-Isopropylidenebenzonorbornenes are known to be homoconjugated compounds.[16,20,22] In these compounds, it has been established that the degree of homoconjugation can be evaluated by ^{13}C NMR parameter, $\Delta\delta$ (C_9–C_{10})[20,22] and also by the anti/syn-stereoselectivity in the reaction with singlet oxygen and other electrophiles.[22] For these reasons, 9-isopropylidene analogues **8e** and **8f** were prepared and their ^{13}C NMR and the reactions with singlet oxygen were examined. Table 2 shows the results together with the reported data.[16,22] Both $\Delta\delta$ (C_9–C_{10}) and the anti/syn-attack selectivity indicate the poor electron-donating ability of tetramethoxybenzene ring: the ^{13}C NMR parameters and the stereoselectivities for **8a—f** are roughly lined in the order of **8a**≃**8b**→**8f**→**8c**→**8d**→**8e**. This is the same sequence with that the IR experiments showed for **2a—f**. From these results, we conclude that the donating ability of the substituted benzene rings increases in the order of **2(8)a**≃**2(8)b**→**2(8)f**→**2(8)c**→**2(8)d**→**2(8)e**. The poor electron-donating property in **2(8)f** is probably due to nonplanar conformation of tetramethoxybenzo moiety arising from the steric congestion of four adjacent methoxyl groups.

Stereoselective Metal Hydride Reductions of 9-Benzonorbornenones. The reductions of substituted 9-benzonorbornenones (**2a—f**) with various metal hydrides gave the corresponding anti- (**3a—f**) and syn-alcohols (**4b—f**) in high yields (71—99%). The produced alcohols can be separated by the preparative TLC or gas chromatography. Table 3 summarizes the results of the reductions with various typical reagents along with the reaction conditions. In spite of considerably different sizes and reactivities of the reagents, the portion of anti-attack (syn-alcohol) increases in the order of **2a**→**2b**→**2f**→**2c**→**2d**→**2e** with slight deviation. Especially, the reduction with diisobutylaluminum hydride (DIBALH), and bis(1,2-dimethylpropyl)-borane (common name "disiamylborane" is used hereafter) follows this sequence. A small change in the sequence is observed for other reagents. In addition, the following features are notable from Table 3. (1) **2a**

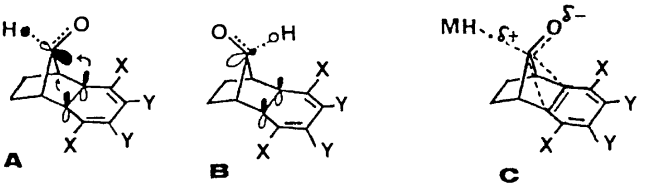
and **2b** show high syn-selectivity toward all the reagents giving anti-alcohols. (2) High selectivity of syn-attack is observed in the reduction with tri-*t*-butoxyaluminum hydride for all the substrates. (3) The anti/syn-selectivity is widely varied in the reduction with lithium aluminum hydride in THF, diisobutylaluminum hydride, and disiamylborane: in these cases, the main product is switched from anti- to syn-alcohol when the benzene ring becomes electron-donating. Obviously, steric effect of the substituents on the benzene ring or the $H_{2,3}$-exo protons do not provide a rationalization for the observed stereoselectivity sequence. On the other hand, this sequence is the one that was discussed in homoconjugation interaction, strongly indicating the importance of electronic effects.

Several electronic factors have been previously reported on the stereoselectivity in the nucleophilic addition to cyclic ketones. Especially with regard to cyclohexanones, the origin of the selectivity is highly controversial: product development control, torsional strain,[23] orbital interaction,[24] antiperiplanar interaction with axial hydrogen,[25] steric effect of axial hydrogen at C_4,[26] and electrostatic potential field[27] have been proposed. Recently, Hudec and Giddings reported a new view of "twist-angle," which is determined by the relative signs of coefficients of $p_{x,y,z}$-orbitals of carbonyl carbon in LUMO of ketones, to rationalize the stereoselectivity in the nucleophilic addition to cyclic ketones including 7-norbornenone.[28] For 7-norbornenone, they predicted that the endocyclic double bond facilitates the syn-attack and rationalized the result of syn-attack in sodium borohydride reduction. However, our experiments clearly show that anti-attack increases when the electron-donating substituents are situated on the benzene ring. Therefore, the model proposed by Hudec and Giddings cannot explain our results. A related but more successful transition state model has been recently reported by Cieplak.[29] He assumed that the incipient C-Nu bond is weak and essentially electron-deficient and therefore can be characterized as a σ^*-orbital. In his model, nucleophiles preferably attack the carbonyl group from the direction such that the σ^*-orbital can interact with the electron-donating orbitals neighboring the carbonyl group. Le Noble and co-workers recently reported that the model developed by Cieplak reasonably explained the stereoselectivity of a series of substituted adamantanones.[30] Participation of donor orbitals on the stabilization of polarized carbonyl group of the adamantanones may be supported by the recent X-ray study of the complex, 5-phenyl-2-adamantanone-pentachloroantimony reported by Laube and Stilz.[31]

Application of Cieplak's model to our system gives a satisfactory rationalization. Qualitative transition models are illustrated in **A** for anti-attack and in **B** for syn-attack. In **A**, the transition state is much stabilized



by the large bonding overlap of back side lobe of σ^*-orbital with benzene π-orbital, compared with the transition state in **B**. Thus, increase of electron-donating character of the benzene ring would increase the anti-attack. Furthermore, Cieplak predicts that coordination of metal ions to the carbonyl oxygen would decrease the energy of σ^*-orbital, so that higher stereoselectivity would be observed. This can explain higher anti-attack for **2d** and **2e** in the reduction with diisobutylaluminum hydride and disiamylborane, both of which have a Lewis acid character and would coordinate onto the carbonyl oxygen in the transition state. Lithium ion in THF is also known to coordinate onto carbonyl groups.[32] Thus, Cieplak's model satisfactorily explains our results.

However, similar rationalization is also provided by the contribution of nonclassical carbocation. As Cieplak pointed out that the incipient C-H bond is electron-deficient and polarized in nature, some positive charge remains on the carbonyl carbon to a greater extent than in the ground state. Coordination onto the carbonyl oxygen must assist this polarization. When the benzene ring becomes electron-rich, the transition state for anti-attack would be stabilized as shown in **C**. Thus, the explanations with Cieplak's and nonclassical carbocation models lead to the similar conclusion in this system. We do not have choice of one from the two explanations because of their totally different languages.

It is interesting to compare the results of anti/syn-stereoselectivity in metal hydride reduction of **2a—f** with that in singlet oxygen addition to isopropylidene derivatives **8a—f**. As can be recognized from Tables 2 and 3, higher selectivity of anti-attack for the substrates which have the same substituents on the benzene ring is observed in the reaction with singlet oxygen (e.g. anti/syn-attack for singlet oxygen; 76/24 for **8c**, for LAH reduction with THF; 38/62 for **2c**). High anti-selectivity of addition of other electrophiles to **8** have been reported.[16,22] The different selectivity in the two systems is probably related to the difference of the approach of the reagents to the C=C and C=O bond. Electrophiles would attack from the center of C=C in the transition state because of the bonding nature of HOMO of C=C. Whereas nucleophiles would attack the carbonyl group from the side of carbonyl carbon with obtuse angle of Nu-C-O[33] because of the anti-bonding nature of LUMO of C=O. From this consideration, nucleophilic attack toward 9-benzonorbornenones or 7-norbornenone would involve much severe steric repulsion with $H_{2,3}$-exo protons in com-

parison with electrophilic addition to the corresponding 9-isopropylidene analogues. High selectivity of syn-attack in the reduction with very bulky tri-*t*-butoxyaluminum hydride for all the substrates may be ascribed to this factor. In this case, the contribution of the electronic factor would be minimized.

Higher syn-selectivity toward **2a** and **2b** for all the metal hydrides may be due to several factors. The expected small electronic contribution via Cieplak's model or nonclassical carbocation as well as steric repulsion with $H_{2,3}$-exo protons, which would be similar in all the substrates, would suggest more or less syn-attack. However exclusive syn-attack for **2a** may indicate that certain level of special electronic factor such as electrostatic potential field is exerted. Such field calculation in the related isopropylidene system has been reported by Paquette and Gleiter et al.[16,22]

In summary, we have demonstrated electronic control of stereoselectivity in the metal hydride reductions of a series of 9-benzonorbornenones: anti-attack prevails when benzene ring becomes electron-rich. Brown's original expectation that anti/syn-stereoselectivity in the nucleophilic addition may reflect the homoconjugation character is realized in this paper. Rationalizations are provided by Cieplak's model or by the contribution of nonclassical carbocation. Since both explanations are related to HOMO-LUMO interaction between *p*-orbital of the polarized carbonyl carbon with benzene π-orbital in the transition state, the observed stereoselectivity must be lined parallel with the homoconjugation interaction which is related to the interaction of weakly polarized C=O and benzene π-orbitals in the ground state. A steric effect of $H_{2,3}$-exo protons must be also important for the metal hydride reductions. However, such effect is very similar in the series of 9-benzonorbornenones for the given metal hydrides. High syn-selectivity of **2a** is probably due to the special electrostatic potential field effect.

Experimental

General. Melting points were measured on a Mettler FP2 apparatus and are uncorrected. IR spectra were recorded with a Hitachi EPI-G3 grating spectrophotometer and wavenumbers were corrected with use of polystyrene film. The wavenumbers of the carbonyl stretching for **2a**—f were directly read from the spectrophotometer at their maximum absorptions. ^{1}H NMR spectra were obtained at 90 MHz on a JEOL FX-90Q, or 100 MHz on a Varian XL-100. ^{13}C NMR spectra were taken with a JEOL FX-90Q (22.5 MHz). Mass spectra were measured on a JEOL JMS-01SG-2 mass spectrometer. GLC analyses were performed on a Hitachi 063 gas chromatography with a glass column packed with Silicone OV-17 (3%) on Chromosorb W AW DMCS (1 m). Column chromatography was carried out with Merck Kieselgel 60 or Merck Aluminiumoxide 90 and preparative TLC with Merck Kieselgel GF_{254} (Type 60). Lithium aluminum hydride, sodium borohydride, lithium tri-*t*-butoxyaluminum hydride, and diisobutylaluminum hydride were commercial products and used without purification. Diborane and disiamylborane were generated in situ prior to use.[34] Compounds **2a**,[15] **2b**,[15] **2c**,[15] and **2d**[16] were prepared according to the reported methods. All the solvent were distilled before use.

1,4-Dihydro-9-isopropylidene-6,7-dimethoxy-1,4-methanonaphthalene (7e). In a 300 ml three-necked round bottom flask equipped with a dropping funnel was placed 100 ml of dry THF, 10.0 g (33.9 mmol) of 1,2-dibromo-4,5-dimethoxybenzene (**5**) and 4.70 g (44.3 mmol) of 6,6-dimethylfulvene (**6**). The mixture was flashed with nitrogen, cooled to −50 °C, and magnetically stirred while 55 mmol of butyllithium in 34 ml hexane solution (1.63 M; 1 M=1 mol dm^{-3}) was slowly added over 40 min from the dropping funnel. The solution was stirred at −50—−34 °C for 1 h, and allowed to come up slowly to ambient temperature. After being stirred for 1 h, the mixture was treated dropwise with 80 ml of water and then 60 ml of ether. The separated organic layer was dried, filtered, and concentrated. Chromatography over 50 g silica gel (eluent; hexane : ethyl acetate=10 : 1) gave 3.08 g (37%) of **7e**. Recrystallization from hexane gave colorless prisms; mp 79—80 °C; IR (KBr) 2930, 2900, 1603, 1488, 1462, 1295, 1208, 1086, 1050, 754 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=1.53 (s, 6H), 3.80 (s, 6H), 4.30 (dd, 2H, J=1.8, 1.8 Hz), 6.83—6.95 (m, 4H); MS (75 eV) m/z (%) 242 (M^+; 40), 227 (7), 188 (14), 115 (100). Found: C, 79.27; H, 7.49%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

1,2,3,4-Tetrahydro-9-isopropylidene-6,7-dimethoxy-1,4-methanonaphthalene (8e). To a 50 ml two-necked flask containing 50 mg of 5% Pd on charcoal was added 4.00 g (16.5 mmol) of **7e** dissolved in 20 ml of ethyl acetate. The suspension was flashed with hydrogen (1 atm) and stirred for 3 h at 0 °C. Filtration through Celite and evaporation of the solvent produced almost pure **8e**. Recrystallization from hexane gave colorless prisms; mp 82—84 °C; IR (KBr) 2945, 2860, 1601, 1499, 1468, 1458, 1323, 1312, 1287, 1252, 1215, 1196, 1110, 1103, 1088, 1020, 794 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ= 1.18 (m, 2H), 1.59 (s, 6H), 1.86 (m, 2H), 3.69 (dd, 2H, J= 1.8, 1.8 Hz), 3.80 (s, 6H), 6.75 (s, 2H); ^{13}C NMR ($CDCl_3$) δ=27.34, 43.78, 56.30, 109.74, 139.73, 147.89. Found: C, 78.29; H, 8.21%. Calcd for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25%.

1,4-Dihydro-6,7-dimethoxy-9-benzylidene-1,4-methanonaphthalene (10). To a solution of 6.00 g (20.3 mmol) of 1,2-dibromo-4,5-dimethoxybenzene (**5**) and 4.70 g (30.5 mmol) of 6-phenylfulvene (**9**) in 60 ml of dry THF cooled to −50 °C under nitrogen was added 16.2 ml (26.2 mmol) of a hexane solution of butyllithium (1.62 M) dropwise via syringe over 25 min. After being stirred at −50—−60 °C for 1 h, the solution was gradually warmed up to room temperature and further stirred for an additional 1 h. Ether (40 ml) and water (50 ml) were added to the mixture. The separated organic layer was dried, filtered, and concentrated under reduced pressure. Column chromatography over 80 g silica gel (eluent; hexane : ethyl acetate=5 : 1) afforded 1.42 g (24%) of **10**. Recrystallization from ethanol gave colorless prisms; mp 123—125 °C; IR (KBr) 3000, 2935, 2900, 2830, 1680, 1603, 1490, 1297, 1219, 1095, 1074, 1054, 853, 771, 712 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=3.81 (s, 3H), 3.82 (s, 3H), 4.20 (m, 1H), 4.70 (m, 1H), 5.49 (s, 1H), 6.89—7.04 (m, 4H), 7.08—7.41 (m, 5H); MS (75 ev) m/z (%) 290 (M^+; 100), 275 (11), 259 (14). Found: C, 82.40; H, 6.31%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

1,2,3,4-Tetrahydro-6,7-dimethoxy-9-benzylidene-1,4-methanonaphthalene (11). A solution of 1.06 g (3.66 mmol)

of **10** in 10 ml of ethyl acetate in the presence of 100 mg of 1.2% Pd on calcium carbonate[35] was stirred under hydrogen (1 atm) at 0 °C. During hydrogenation, the absorption of volume of hydrogen was measured. After 16 h, the solution was filtered and evaporated under reduced pressure. Recrystallization of the crude product from ethanol gave 0.977 g (92%) of **11** as colorless needles; mp 56—58 °C; IR (KBr) 2930, 2860, 1690, 1610, 1498, 1470, 1327, 1316, 1285, 1220, 1104, 1088, 1020, 793, 706 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.32 (m, 2H), 2.05 (m, 2H), 3.58 (m, 1H), 3.82 (s, 3H), 3.84 (s, 3H), 4.14 (m, 1H), 5.92 (s, 1H), 6.82 (s, 1H), 6.84 (s, 1H), 7.09—7.42 (m, 5H); Found: C, 81.89; H, 6.96%. Calcd for $C_{20}H_{20}O_2$: C, 82.16; H, 6.90%.

1,2,3,4-Tetrahydro-6,7-dimethoxy-1,4-methanonaphthalen-9-one (2e). To a solution of 450 mg (1.54 mmol) of **11** in 15 ml of dichloromethane was added 5 ml of aqueous sodium hydrogen carbonate (0.5 M) and *m*-chloroperbenzoic acid (310 mg, 1.79 mmol). The mixture was stirred for 2 h at room temperature. The progress of the reaction was followed by TLC. To this mixture was further added 100 mg (0.578 mmol) of *m*-chloroperbenzoic acid. After 1 h of stirring, dichloromethane (15 ml) was added to the mixture and the organic layer was washed with 20 ml of 10% sodium hydrogensulfite solution, 20 ml of saturated sodium hydrogencarbonate solution, and brine prior to drying over magnesium sulfate. After filtration and evaporation of the solvent, the mixture was passed through a short alumina column to give a mixture of epoxides **12** (284 mg; 60%, anti : syn=7 : 1 from NMR analysis). The mixture of epoxides was used for the next step without separation. To a stirred solution of 230 mg (1.01 mmol) of periodic acid in dry THF (3 ml) at 0 °C was added a solution of 284 mg (0.922 mmol) of **12** in 6 ml of dry THF. After 1 h, ether (15 ml) was added to the mixture. The organic layer was washed with saturated sodium hydrogencarbonate, dried and evaporated. Chromatography over 18 g of silica gel (eluent; hexane : ethyl acetate=5 : 1) of the crude products gave 100 mg (50%) of **2e**. Recrystallization from hexane-benzene gave colorless prisms; mp 142—143 °C; IR (CCl_4) 2975, 1778, 1493, 1466, 1321, 1278, 1225, 1078, 1013, 856 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ= 1.34 (m, 2H), 2.18 (m, 2H), 3.30 (dd, 2H, J=1.8, 1.8 Hz), 3.86 (s, 6H), 6.89 (s, 2H); ^{13}C NMR ($CDCl_3$) δ=23.01, 47.49, 56.35, 106.22, 132.93, 148.69; MS (75 eV) *m/z* (%) 218 (M^+; 14), 190 (100), 175 (32). Found: C, 71.32; H, 6.44%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

1,4-Dihydro-9-isopropylidene-5,6,7,8-tetramethoxy-1,4-methanonaphthalene (7f). To a stirred solution of 3.36 g (9.44 mmol) of 1,2-dibromo-3,4,5,6-tetramethoxybenzene (**13**) and 2.00 g (18.8 mmol) of 6,6-dimethylfulvene (**6**) in 25 ml of dry THF cooled at −50 °C under nitrogen was added dropwise butyllithium (12 mmol) in 7.6 ml of hexane solution (1.62 M) over 10 min via syringe. The mixture was stirred for 1 h at −50—−44 °C and slowly allowed to come up to room temperature. After 1 h of stirring, water (20 ml) and ether (20 ml) was added. The separated organic layer was dried and evaporated under reduced pressure. Chromatography over 70 g silica gel (eluent; hexane : ethyl acetate=15 : 1) afforded 1.38 g (48%) of **7f**. Recrystallization from hexane gave colorless prisms; mp 51—53 °C; IR (KBr) 2990, 2965, 2925, 1471, 1451, 1409, 1402, 1350, 1262, 1190, 1116, 1071, 1027, 1020, 973, 959, 751 cm^{-1}. ^1H NMR (90 MHz, $CDCl_3$) δ=1.55 (s, 6H), 3.86 (s, 12H), 4.60 (dd, 2H, J=1.8, 1.8 Hz), 6.90 (dd, 2H, J=1.8, 1.8 Hz); MS (75 eV) *m/z* (%) 302 (M^+; 100), 287 (50). Found: C, 71.39; H, 7.33%. Calcd for $C_{18}H_{22}O_4$: C, 71.50; H, 7.33%.

1,2,3,4-Tetrahydro-9-isopropylidene-5,6,7,8-tetramethoxy-1,4-methanonaphthalene (8f). According to the similar procedure with the preparation of **11**, 1.00 g (3.31 mmol) of **7f** was converted to the hydrogenated **8f** (936 mg, 3.08 mmol, 93%). Recrystallization from ethanol-water gave as colorless plates; mp 55—59 °C; IR (KBr) 2980, 2950, 2920, 1471, 1449, 1410, 1360, 1291, 1268, 1120, 1108, 1081, 1060, 1025, 1007, 966 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.32 (m, 2H), 1.63 (s, 6H), 1.86 (m, 2H), 3.87 (s, 12H), 3.97 (dd, 2H, J=1.8, 1.8 Hz); ^{13}C NMR ($CDCl_3$) δ=19.89, 27.10, 40.43, 61.23, 61.28, 110.09, 135.15, 142.73, 144.30. Found: C, 70.87; H, 8.00%. Calcd for $C_{18}H_{24}O_4$: C, 71.03; H, 7.95%.

1,2,3,4-Tetrahydro-5,6,7,8-tetramethoxy-1,4-methanonaphthalen-9-one (2f). A solution of 702 mg (4.18 mmol) of 2,3-dimethoxy-1,4-benzoquinone (**14**) and 1.60 g (6.06 mmol) of 5,5-dimethoxy-1,2,3,4-tetrachlorocyclopentadiene (**15**) in 5 ml of xylene was refluxed for 20 h with stirring under nitrogen. After evaporation of the solvent under reduced pressure, the mixture was separated with chromatography over 40 g silica gel (eluent; hexane : ethyl acetate=2 : 1) to give 1.76 g (97%) of the endo adduct **16**. Recrystallization from hexane-benzene gave colorless prisms; mp 121—122 °C; IR (KBr) 2950, 2845, 1698, 1680, 1594, 1458, 1330, 1294, 1259, 1247, 1189, 1148, 1121, 1044, 1015, 1009, 979, 957, 910, 815, 623 cm^{-1}. ^1H NMR (100 MHz, $CDCl_3$) δ=3.57 (s, 5H), 3.66 (s, 3H), 3.97 (s, 6H); MS (75 eV) *m/z* (%) 434 (M^++4, 4), 432 (M^+ +2, 8), 430 (M^+, 5), 401 (5), 399 (34), 397 (95), 395 (100). Found: C, 41.80; H, 3.29; Cl, 32.61%. Calcd for $C_{15}H_{14}O_6Cl_4$: C, 41.70; H, 3.27; Cl, 32.82%. A solution of 800 mg (1.85 mmol) of **16** and 0.3 ml (3.7 mmol) of pyridine in 10 ml dry methanol was refluxed for 20 h. To the cooled solution were added 30 ml of dichloromethane and 20 ml of hydrochloric acid (1 M). The separated organic layer was washed with brine, dried, and concentrated. Separation with chromatography over 30 g silica gel (eluent; hexane : ethyl acetate=2 : 1) gave 625 mg (78%) of **17**. Recrystallization from hexane-benzene gave colorless plates; mp 144—145 °C; IR (KBr) 3490, 3390, 2950, 2845, 1603, 1477, 1438, 1305, 1260, 1190, 1131, 1078, 1007, 950, 781, 763, 699, 682, 664 cm^{-1}. ^1H NMR (100 MHz, $CDCl_3$) δ=3.52 (s, 3H), 3.64 (s, 3H), 3.91 (s, 6H), 5.67 (s, 2H). Found: C, 42.01; H, 3.32; Cl, 32.73%. Calcd for $C_{15}H_{14}O_6Cl_4$: C, 41.70; H, 3.27; Cl, 32.82%. A solution of 460 mg (1.06 mmol) of **17** in 10 ml of dry acetone containing 0.20 ml (2.1 mmol) of dimethyl sulfate and 3.1 g (22 mmol) of anhydrous potassium carbonate was refluxed for 15 h with vigorous stirring. The cooled solution was treated with 20 ml of water and stirred for 30 min at room temperature. The mixture was extracted with 20 ml of ether twice, and the ethereal layer was washed with brine and dried. Evaporation of ether afforded almost pure **18**. Recrystallization from hexane gave colorless prisms; mp 99—100 °C; IR (KBr) 2930, 2820, 1607, 1471, 1410, 1348, 1273, 1184, 1100, 1026, 1004, 987, 964, 940, 822, 771, 693, 682, 653 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=3.50 (s, 3H), 3.66 (s, 3H), 3.82 (s, 6H), 3.92 (s, 6H). Found: C, 44.41; H, 3.91; Cl, 30.96%. Calcd for $C_{17}H_{18}O_6Cl_4$: C, 44.37; H, 3.94; Cl, 30.82%. A solution of 2.43 g (5.28 m mol) of **18** in a mixture of triethylamine (25 ml) and ethanol (50 ml) containing 300 mg of 5% palladium on charcoal was stirred for 3 h under hydrogen (1 atm) at room temperature. Filtration through Celite and evaporation of the solvent gave almost pure **19** (1.88 g,

91%). Recrystallization from hexane afforded colorless prisms; mp 113—115 °C; IR (KBr) 2925, 2820, 1470, 1410, 1359, 1291, 1253, 1189, 1105, 1067, 1040, 997, 977, 933, 842, 810, 710, 620 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.77 (m, 2H), 2.50 (m, 2H), 3.53 (s, 3H), 3.73 (s, 3H), 3.83 (s, 6H), 3.92 (s, 6H). Found: C, 51.87; H, 5.64; Cl, 18.16%. Calcd for $C_{17}H_{22}O_6Cl_2$: C, 51.92; H, 5.64; Cl, 18.03%. To a solution of 2.00 g (15.6 mmol) of naphthalene in 30 ml dry DME under nitrogen at 0 °C was added sodium (290 mg, 12.6 mmol). To this sodium naphthalenide solution was added dropwise at 0 °C a solution of 1.00 g (2.54 mmol) of **19** in 10 ml of dry DME. After 30 min, the mixture was slowly treated with 10 ml of ethanol, 60 ml of water, and extracted with 70 ml of ether twice. The ether layer was washed with brine and dried. Purification with chromatography over 30 g silica gel (eluent; hexane : ethyl acetate=6 : 1) afforded 750 mg (91%) of acetal **19**. Recrystallization from hexane gave colorless prisms; mp 69—70 °C; IR (KBr) 2945, 2825, 1472, 1413, 1369, 1302, 1277, 1179, 1138, 1089, 1064, 1031, 958, 801 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.16 (m, 2H), 2.12 (m, 2H), 3.12 (s, 3H), 3.29 (s, 3H), 3.50 (dd, 2H, J=1.8, 1.8 Hz), 3.83 (s, 6H), 3.88 (s, 6H). Found: C, 62.92; H, 7.45%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46%. To a solution of 666 mg (2.06 mmol) of **19** in 10 ml of dioxane was added a solution of 20% aqueous sulfuric acid (20 ml) at 0 °C. After 11 h of stirring at 50 °C, the solution was cooled, poured into 30 ml of water, and extracted with 50 ml of ether twice. The combined ether layer was washed with brine, dried, and concentrated. Purification with chromatography over 10 g silica gel (eluent; hexane : ethyl acetate=5 : 1) afforded 485 mg (85%) of **2f**. Recrystallization from hexane gave colorless prisms; mp 92—94 °C; IR (CCl_4) 2925, 1785, 1481, 1420, 1410, 1360, 1302, 1272, 1121, 1084, 1063, 1032, 1012 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.43 (m, 2H), 2.24 (m, 2H), 3.54 (dd, 2H, J=1.8, 1.8 Hz), 3.86 (s, 6H), 3.90 (s, 6H); ^{13}C NMR ($CDCl_3$) δ=22.59, 44.02, 61.38, 61.49, 127.50, 144.16, 145.65; MS (75 eV) m/z (%) 278 (M+; 23), 250 (100), 235 (80), 207 (16). Found: C, 64.70; H, 6.52%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Prototypical Procedure for Reductions with Lithium Aluminum Hydride. To a suspension of 28 mg (0.74 mmol) of lithium aluminum hydride in 5 ml of dry ether under nitrogen at 0 °C was added dropwise a solution of 100 mg (0.63 mmol) of **2c** in 5 ml of dry ether. After 30 min, the reaction was quenched by addition of 0.1 ml of water. The ether layer was dried over magnesium sulfate and directly subjected to GLC analysis (**3c** : **4c**=81 : 19). Separation with preparative TLC gave 80 mg (0.50 mmol) of **3c** and 20 mg (0.13 mmol) of **4c** in total yield of 99%. The yields for other derivatives were as follows; in ether: 96% for **2a**, 79% for **2b**, 99% for **2d**, 89% for **2e**, and 80% for **2f**, in THF: 98% for **2a**, 71% for **2b**, 97% for **2c**, 99% for **2d**, 91% for **2e**, and 90% for **2f**. The anti/syn ratio of the alcohols are listed in Table 3. A large volume (80—100 ml) of solvents were used to dissolve 100 mg of **2b**. Physical data for the alcohols **3a**—f and **4b**—f are as follows; **3a**: colorless prisms from hexane; mp 122—124 °C; IR (KBr) 3300, 2905, 1500, 1482, 1301, 1139, 1032, 951, 888, 777 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.22 (m, 2H), 1.90—2.38 (m, 3H), 3.42 (m, 2H), 3.82 (m, 1H). Found: C, 56.79; H, 3.43%. Calcd for $C_{11}H_8OF_4$: C, 56.90; H, 3.47%. **3b**: colorless needles from hexane; mp 133—135° C; IR (KBr) 3255, 2920, 1371, 1294, 1101, 1065, 678 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.23 (m, 2H), 2.02 (br s, 1H), 2.24 (m, 2H), 3.46 (m, 2H), 3.92 (m, 2H). **4b**: colorless needles from hexane; mp 162—165 °C; IR (KBr) 3260, 2945, 1374, 1309, 1132, 1122, 1070 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$): δ=1.18 (m, 2H), 1.76 (br s, 1H), 2.08 (m, 2H), 3.52 (m, 2H), 4.20 (br s, 1H). Found: C, 44.14; H, 2.72; Cl, 47.41%. Calcd for $C_{11}H_{18}OCl_4$: C, 44.34; H, 2.71; Cl, 47.59%. **3c**:[13,24] colorless needles from hexane; mp 103—105 °C; IR (KBr) 3250, 2970, 1350, 1337, 1105, 1080, 747 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.18 (m, 2H), 1.87 (br s, 1H), 2.10 (m, 2H), 3.11 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.80 (br s, 1H), 7.06 (s, 4H). **4c**:[13,23,24] colorless needles from hexane; mp 114—115 °C; IR (KBr) 3250, 2970, 1458, 1370, 1271, 1151, 1124, 1068, 750 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ= 1.11 (m, 2H), 1.58 (br s, 1H), 1.96 (m, 2H), 3.16 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 4.10 (br s, 1H), 6.99—7.30 (m, 4H). **3d**: colorless needles from hexane; mp 107—108 °C; IR (KBr) 3560, 3530, 2950, 2835, 1508, 1468, 1459, 1446, 1298, 1260, 1165, 1093, 1065, 969, 811, 800, 717 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.17 (m, 2H), 1.95—2.21 (m, 3H), 3.11 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.72 (s, 6H), ca 3.7 (m, 1H), 6.54 (s, 2H). Found: C, 70.69; H, 7.28%. Calcd for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32%. **4d**: colorless needles from hexane; mp 68—70 °C; IR (KBr) 3945, 3920, 2945, 2880, 1502, 1463, 1302, 1259, 1168, 1075, 1032, 961, 794, 715 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.12 (m, 2H), 1.63 (br s, 1H), 1.92 (m, 2H), 3.40 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.73 (s, 6H), 4.06 (t, 1H, J=1.8), 6.61 (s, 2H). Found: C, 70.83; H, 7.28%. Calcd for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32%. **3e**: colorless needles from hexane; mp 118—119 °C; IR (KBr) 3520, 2930, 1499, 1463, 1331, 1248, 1216, 1097, 1069, 771 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.14 (m, 2H), 1.97—2.23 (m, 3H), 3.07 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.81 (m, 1H), 3.82 (s, 6H), 6.77 (s, 2H). Found: C, 71.00; H, 7.41%. Calcd for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32%. **4e**: colorless prisms from hexane-benzene; mp 107—108 °C; IR (KBr) 3325, 2965, 1500, 1491, 1461, 1328, 1282, 1121, 1092, 1074, 1039, 783 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.08 (m, 2H), 1.72 (br d, 1H, J=ca. 9.0 Hz), 1.94 (m, 2H), 3.11 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.86 (s, 6H), 4.11 (m, 1H), 6.89 (s, 2H). Found: C, 70.82; H, 7.38%. Calcd for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32%. **3f**: colorless needles from hexane; mp 105—106 °C; IR (KBr) 3315, 2970, 2940, 1478, 1417, 1319, 1295, 1126, 1065, 1027, 1005 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.03 (m, 2H), 1.93—2.27 (m, 2H), 3.34 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.82 (m, 1H), 3.83 (s, 6H), 3.86 (s, 6H). Found: C, 63.96; H, 7.14%. Calcd for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19%. **4f**: colorless needles from hexane; mp 121—124 °C; IR (KBr) 3320, 2935, 1472, 1413, 1364, 1309, 1089, 1068, 1032, 1020, 973 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=1.18 (m, 2H), 1.58 (d, 1H, J=9.0 Hz), 2.00 (m, 2H), 3.42 (ddd, 2H, J=1.8, 1.8, 1.8 Hz), 3.85 (s, 6H), 3.90 (s, 6H), 4.11 (dt, 1H, J=9.0, 1.8 Hz); Found: C, 64.00; H, 7.17%. Calcd for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19%.
