Figure 5 shows TG-DTA curves of hydrogen molybdenum bronzes. [U] indicates an unwashed sample which was filtrated and immediately sucked dry. [W] indicates a sample washed with 2—3 M HCl, then washed with water and sucked dry. [U] of Type-I shows an exothermic peak at 263.6 °C and an endothermic peak at 709.4 °C. While [W] of Type-I shows the exothermic peak at 148.6 °C. The exothermic peak of [W] is lower than that of [U]. Each

			Type II
	100.4 ----	91.0	----------
			Type III
	75.7 ----	47.2	----------
			Type IV

[U] of all phases of hydrogen bronzes show an endothermic peak at near 710 °C; [W] does not. Exothermic peaks of all phases of [U] arise at higher temperature than those of [W]. All peak temperatures are shown in Table 1. DTA curves of [U] give more distinct separate peaks than those of [W]. According to chemical analysis, [U] contains a small amount of residual Zn^{2+} and Cl^- ions, and [W], no residual ion. However, according to the X-ray results and chemical analysis, there are no difference in crystal structure and hydrogen contents between [U] and [W]. This suggests that the endothermic peak at near 710 °C and the exothermic peaks at higher temperature of [U] should be due to residual ions.

As has been reported[6,7] Type-I is decomposed by vacuum heating to the nonstoichiometric oxide with the rhombic MoO_3 structure by evolution of H_2O.

$$H_{0.30}MoO_3 \longrightarrow H_{0.21}MoO_{2.95}{}^{22)}$$

$$\longrightarrow H_{0.06}MoO_{2.88}{}^{23)} \longrightarrow MoO_{2.85}{}^{23)}$$

It is very important to know the decomposition of bronzes in air. As mentioned above, there are no differences in the crystal structure and hydrogen contents between [U] and [W]; however, [U] gives more distinct exothermic peaks than does [W]. Type-I treated at about 150 °C shows the original orthorhombic crystal structure, but that treated at about 330 °C shows the rhombic MoO_3 structure. The compositions of all phases heated at the temperature before and after exothermic peaks (marked by arrows (⟶) in Fig. 5) are shown in Table 1. This result suggests that the hydrogen molybdenum bronze changes successively from a bronze with a higher hydrogen content to one with a lower hydrogen content upon heating: Type-IV⟶Type-III⟶Type-II⟶Type-I⟶MoO_3.

The weight loss of samples can be calculated from TG curves. [U] gives a clear phase separation, though it contains a small amount of residual Zn^{2+} and Cl^- ions. It is therefore not reasonable to obtain gravimetric results. The total weight losses are obtained from the TG results of [W] by substracting the adsorbed water molecules (Table 2). Under vacuum heating, the decomposition of Type-I takes place by an evolution of H_2O. Usually, the decomposition of a bronze can occur by the following two ways.

$$H_xMoO_3 \longrightarrow \frac{x}{2} H_2 + MoO_3 \quad (1)$$

and

$$H_xMoO_3 \longrightarrow \frac{x}{2} H_2O + MoO_{3-x/2} \quad (2)$$

The weight loss can be lead to the conclusion if the decomposition should proceed by Eq. 1 or 2. Since the hydrogen contents of Type-I, Type-II, Type-III, and Type-IV were determined to be x=0.21, 0.91, 1.55, and 1.90, respectively, the theoretical weight losses were calculated from the above equations (Table 2). Comparing these results, the observed weight loss from TG is very close to the theoretical weight loss calculated from Eq. 1. This means that the bronzes decompose upon heating in air by the evolution of H_2. DTA and X-ray results also support the idea that the decomposition of bronzes change from a higher hydrogen content to a lower hydrogen content. It is therefore reasonable to conclude that the bronzes decompose in air through Eq. 1 as follows:

Table 2. Weight Loss of Bronzes

x	Weight loss/%		
	H_2	H_2O	Observed
0.21	0.15	1.31	0.40
0.91	0.63	5.65	0.89
1.55	1.06	9.59	1.38
1.90	1.30	11.73	1.29

$$\text{Type IV} \xrightarrow[\text{ca. 47 °C}]{H_2\uparrow} \text{Type III} \xrightarrow[\text{ca. 91—99 °C}]{H_2\uparrow} \text{Type II}$$

$$\xrightarrow[\text{ca. 123—131 °C}]{H_2\uparrow} \text{Type I} \xrightarrow[\text{ca. 149—157 °C}]{H_2\uparrow} MoO_3$$

Precise thermal studies are in progress.

Dielectric Dispersion and Intermolecular Association for 28 Pure Liquid Alcohols. The Position Dependence of Hydroxyl Group in the Hydrocarbon Chain

Toshiomi SHINOMIYA†
School of Pharmaceutical Sciences, Kitasato University,
Shirokane, Minato-ku, Tokyo 108
(Received September 10, 1988)

The dielectric constants and losses of 28 linear alcohols, 1-alkanol (n=3—10), 2-alkanol (n=3—10), 3-alkanol (n=5—10), 4-alkanol (n=7—10), and 5-alkanol (n=9 and 10), have been measured at the frequencies from 1.35 to 4500 MHz at 15, 25, and 35 °C. The Kirkwood-Fröhlich equation was modified so that it could be applied to each dispersion region calculated. The concentration C_1 of linear hydrogen-bonded chain polymers, which primary dispersion originates, was evaluated by means of this modified equation. The C_1 decreases as the hydroxyl group approaches the center of a molecule, except for propanols and butanols, and also decreases with increasing temperature. For isomeric decanols, for example, the percentages of C_1 ($C_1 \times 100/C_0$) against alcohol gross stoichiometric concentration C_0 at 15, 25, and 35 °C are about 71, 63, and 53% for 1-decanol, 52,40,and 29% for 2-decanol, 22, 17, and 12% for 3-decanol, 11, 7, and 6% for 4-decanol, and 8, 6, and 5% for 5-decanol, respectively. The thermodynamic parameters, ΔF^*, ΔH^*, and ΔS^*, were obtained for dipole relaxation and viscous flow. The $\Delta F\tau^*$ decreases, although the $\Delta H\tau^*$ and $\Delta S\tau^*$ increase, as the hydroxyl group approaches the center of a molecule. The $\Delta F\eta^*$ increases linealy with the molecular volume, irrespective of the position of the hydroxyl group.

The liquid structure of alcohols has been the subject of many investigations because of its having a possible hydrogen bonding between adjacent molecules. Studies of the dielectric relaxation processes[1-3] have estimated the existence of monomers and hydrogen-bonded molecular species in pure liquid alcohols. The magnitude of the primary dispersion is usually much greater than that of the higher dispersion. Its relaxation time is long and strongly temperature dependent. Therefore, this process is considered to be attributed to the characteristic of linear hydrogen-bonded chain polymers.[2-4] A clear detailed molecular model has, however, still not been realized. It is interesting to investigate relationship between the magnitude of primary dispersion and molecular geometry. In isomeric alcohols, the magnitude of dispersion may depend on the positions of the hydroxyl and methyl groups in a chain. It is considered that any difference in their dielectric behaviors must be due entirely to a difference in the extent of intermolecular association, since these isomers have approximately the same dipole moment and the same molecular volume. The formation of a linear hydrogen-bonded chain polymer changes according to the amount of shielding of the hydroxyl group and/or to the steric hindrance of the alkyl group. In the present study, therefore, 28 pure alcohols were selected to investigate the influences due to the position of the hydroxyl group in a chain.

Wide-range measurements indicated two or three different dispersion regions at low temperature and room temperature.[2-6] No theory can satisfactorily interpret the co-existence of the two or three dispersion regions observed. Experimental data concerning the dielectric dispersion for water and liquid alcohols have usually been analyzed by means of Kirkwood-Fröhlich theory,[7-9] which was developed on the basis of a single relaxation process. This theory can not interpret the large value of the Kirkwood correlation factor. Although this equation is still used to obtain information concerning the configuration for neighboring dipole moments, there are doubtful problems in the application of this equation to data of the dielectric dispersion for liquid alcohols. Their equation was, therefore, modified; then the concentration of the primary dispersion region was calculated.

Experimental

Purification of Materials. The commercial alcohols were fractionally distilled under reduced pressure at a very high reflux ratio. About 80% of the middle fraction was distilled again by the same method. Two distillation systems were used, one consisting of a 1 m adiabatic column packed with glass-helix packings and the other consisting of a 60 cm adiabatic column with a Teflon spinning band with a rotation speed variable from 1000 to 6000 rpm. Both systems have 200—300 theoretical plates. A Molecular Sieve of 3A or 5A was used as a drying agent. The middle portion was finally distilled in a grease-free apparatus under reduced pressure before use.

Apparatus. The dielectric constants and losses were measured by making use of the following three types of apparatus over the frequency range from 1.35 to 4500 MHz.

Low Frequency Range: A Boonton Radio RX meter (Type 250A) was used for measurements at frequencies of 1.35, 6.3, 17, 30, and 45 MHz. An adaptor (GR 900-QNP) and a T-type adaptor (which is joined to an inductor) were put between a cell and a terminal of RX meter's bridge. The necessary corrections of coaxial transmission line were made

† Present address: 207-52, Shirahata kami-cho, Kanagawa-ku, Yokohama 221.

according to the transmission line formulas by the use of the terminations (Type GR 900-W50, GR 900-W200, and GR 900-WO4) and the reference air lines (Type GR 900-LZ) as standard equipments. Two dielectric cells were carefully made of a GR Precision Inner-Conductor Rod, an Outer-Conductor Tube, and a GR 900-BT connector. The temperature of the cell was kept constant within ±0.1 °C of the specified values by circulation of water from a thermostat through a jacket around the cell.

Middle Frequency Range: Measurements at frequencies 60, 80, 100, 150, 200, 250, 300, 400, and 480 MHz were made with a Hewlet-Packard VHF Bridge which comprised a VHF Signal Generator (Model 608C), a VHF Detector (Model 417A), a VHF Bridge (Model 803A), an SWR meter (415E), and a frequency counter. This apparatus was described in detail by Komooka.[10] The frequencies of the RX meter and VHF Bridge were controlled to be within ±0.01% of the specified values.

High Frequency Range: A General Radio Precision Slotted Line (Type 900-LB) was used for measurements at frequencies of 600, 750, 1000, 1400, 2000, 3000, and 4500 MHz. This equipment has a slotted section of 9/16-inch and is a precision coaxial transmission line with a characteristic impedance of 50.0 ohm±0.1%. The signal sources were a Modulating Power Supply (Type 1264-B) and a VHF Oscillator (Type 1362), a Modulating Power Supply (Type 1264-B) and a Lockable Oscillator (Type 1218-BV), and a HP Signal Generator (Type 8616A). The line was fitted with a movable carriage which provides a mount for a detector diode, a tuning stub, an adjustable probe, and a Type 874 output connector which was connected with an SWR meter (415E). Two cells were identical to those used in the measurement of the low-frequency range described above.

Calculation of Dielectric Parameters. In general, the dielectric constant ε' and loss ε'' are described by

$$\varepsilon_j' = \varepsilon_\infty + \sum_{i=1}^{n}\left(\frac{\varepsilon_{i-1}-\varepsilon_i}{2}\left(1-\frac{\sinh\theta_i}{\cosh\theta_i+\sin\left(\frac{\pi}{2}h_i\right)}\right)\right)$$

and

$$\varepsilon_j'' = \sum_{i=1}^{n}\left(\frac{\varepsilon_{i-1}-\varepsilon_i}{2}\left(\frac{\cos\left(\frac{\pi}{2}h_i\right)}{\cosh\theta_i+\sin\left(\frac{\pi}{2}h_i\right)}\right)\right),$$

where ε_∞ is the limiting high-frequency dielectric constant. $\theta_i=(1-h_i)\ln(f_j/fr_i)$. h_i is constant, $0\leqq h_i<1$. When $0<h_i<1$, the dispersion is a Cole–Cole like, depressed-center semicircular arc. In the limit $h_i=0$, it reduces to a Debye-like, semicircular arc. $\varepsilon_{i-1}-\varepsilon_i$ is a magnitude and fr_i is a relaxation frequency of the i-th dispersion. ε_j' and ε_j'' are experimental values at frequency f_j. The dielectric parameters were calculated by the equations with the least-squares method.

Results and Discussion

Dielectric Relaxation. The Cole–Cole plots are shown in Fig. 1 for isomeric pentanols and in Fig. 2 for isomeric decanols, respectively. Primary dispersion is quantitatively described by a Debye-like semicircular arc, though it is also evident that the data

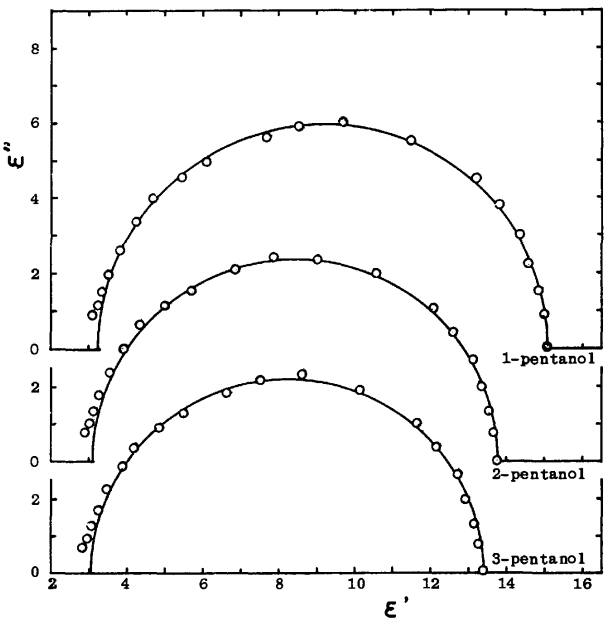

Fig. 1. Cole–Cole plots for isomeric pentanols at 25 °C.

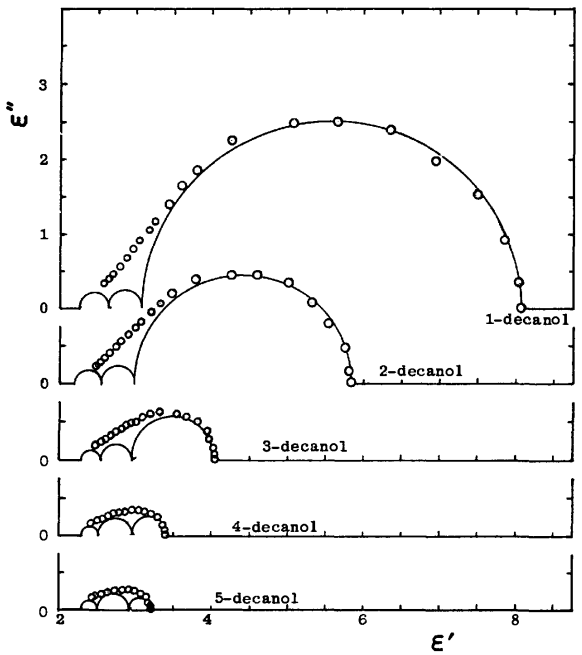

Fig. 2. Cole–Cole plots for isomeric decanols at 25 °C, together with calculated behavior for the three dispersion regions.

can not be satisfactorily fitted in the high-frequency region of the dispersion. At first glance it looks as if the Cole–Cole plots can be grouped into three dispersion types. The first one is best described by several overlapping Debye-like semicircular arcs, $\varepsilon^*-\varepsilon_\infty=(\varepsilon_0-\varepsilon_\infty)/(1+i\omega\tau)$, such as isomeric pentanols in Fig. 1 and 1-decanol in Fig. 2. The second one by Davidson–Cole skewed arc, $\varepsilon^*-\varepsilon_\infty=(\varepsilon_0-\varepsilon_\infty)/(1+(i\omega\tau))^\beta$,

such as 3-decanol in Fig. 2. The third one by Cole–Cole depressed-center semicircular arc, $\varepsilon^*-\varepsilon_0=(\varepsilon_0-\varepsilon_\infty)/(1+(i\omega\tau)^\alpha)$, such as 5-decanol in Fig. 2. ε^* is the complex dielectric constant, ε_0 and ε_∞ are the limiting low- and high-frequency dielectric constants, ω is the angular frequency, τ the relaxation time, and α and β are parameters, $0<\alpha$ or $\beta<1$. However, the loci of these compounds are temperature dependent and will change probably from a Debye type to a Davidson–Cole type or a Cole–Cole type by a decrease in the magnitude of the primary dispersion region in comparison with those of other dispersion regions. We assumed, therefore, that the dielectric absorption for each compound was the sum of several overlapping Debye-like dispersion regions. The dielectric parameters of the primary dispersion calculated are listed in Table 1, together with refractive indices, densities, and with viscosities.

The magnitude, $(\varepsilon_0-\varepsilon_1)T/C_0$, of primary dispersion region is plotted in Fig. 3 against the alcohol gross concentration C_0. T is the absolute temperature. Figure 3 shows that the curves from 1-propanol to 1-decanol and from 2-propanol to 2-decanol indicate a maximum at about 11 mol dm^{-3}, in the vicinity of butanols, respectively. The dielectric properties of higher alcohols (at lower alcohol concentration than the maximum) are often different with those of lower alcohols (such as propanols and butanols). For higher alcohols, the value of the magnitude decreases with decreasing alcohol concentration and becomes extremely small as the hydroxyl group approaches the center of a molecule. The magnitude of 5-decanol is 13 K mol^{-1} dm^3, being about 5% of that of 1-decanol. These isomers differ remarkably from each other in the average value of magnitude per one hydroxyl group. The difference leads us to anticipate that the magni-

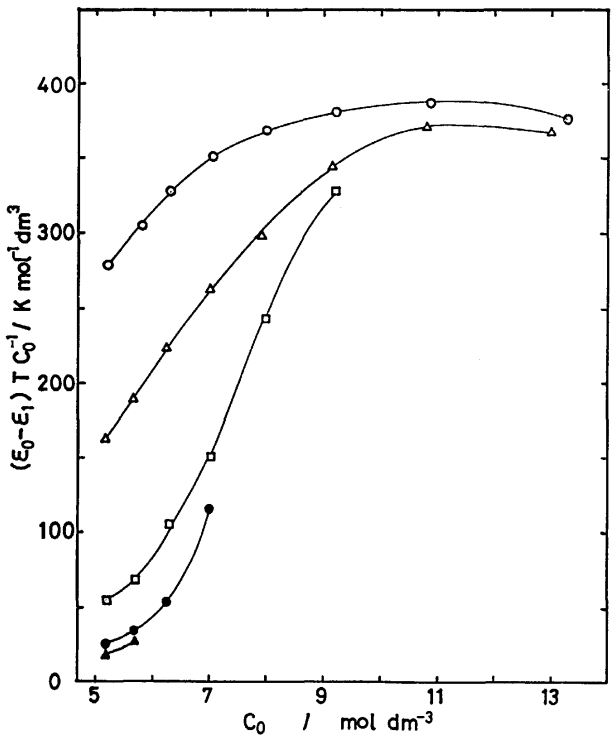

Fig. 3. The magnitude of primary dispersion region as a function of alcohol gross concentration C_0 at 25 °C.

tude is intimately related to the extent of hydrogen bonding and to the existence of a nonpolar cyclic polymer. It is desired to examine the equilibrium between linear chain polymers and nonpolar cyclic polymers.

Concentration of Primary Dispersion Region. Experimental data concerning the dielectric dispersion have usually been analyzed by means of the Kirkwood-Fröhlich equation:[8,9]

$$\varepsilon_0 - n_D^2 = \frac{3\varepsilon_0}{2\varepsilon_0 + n_D^2} = \left(\frac{n_D^2+2}{3}\right)^2 \frac{4\pi N_0 \mu_0^2}{3kT} g, \quad (1)$$

where n_D is the refractive index, N_0 the number of molecule per unit volume, and μ_0 the dipole moment of the molecule in vacuum. From Eq. 1, in which 1.05 n_D^2 was used in place of n_D^2,[11] the Kirkwood correlation factors g were calculated to be 3.14, 3.19, 3.15, 3.07, 2.97, 2.83, 2.70, and 2.56 at 25 °C for pure normal alcohols from propyl through decyl, respectively. These g factors are much greater than 2.39 obtained by Oster and Kirkwood[8,12] for a model of an infinite hydrogen-bonded chain of alcohol molecules with free rotation about the hydrogen bonds. For isomeric decanols at 25 °C, the respective g factors are 2.56 for 1-decanol, 1.77 for 2-decanol, 1.00 for 3-decanol, 0.70 for 4-decanol, and 0.62 for 5-decanol. The observation that the g factor is less than unity has been interpreted as being due to an antiparallel alignment of near-neighbor dipole moments. The g factor increases with decreasing temperature and becomes 4.7 for an infinitely long chain of 6-methyl-3-heptanol at a very low temperature.[11] The large values of the g factor can not be interpreted satisfactorily for liquid alcohols. Dannhauser[13] proposed a partial hindrance of the rotation in place of the free rotation about the hydrogen bonds described in the Kirkwood model.[8] We believe that the large value of the g factor is attributed to the value of 1.05 n_D^2 which is usually less than the limiting high-frequency dielectric constant and that a concentration factor should be introduced instead of the molecular volume into the Kirkwood-Fröhlich equation[8,9] in the same manner that the existence of a nonpolar cyclic polymer is considered when the g factor is less than unity. If their equation is applied to the data of liquid alcohols, we must take care concerning the following four points: 1) The dispersion of liquid alcohols can be resolved into some overlapping relaxation processes; 2) therefore, the choice of n_D^2 must be corrected for each dispersion region calculated; 3) alcohol molecules must be assigned to each dispersion region; and 4) if nonpolar cyclic polymers exist, their concentrations must be neglected in order to not contribute to the dispersion. According to the Kirkwood-Fröhlich theory, therefore, we propose that the cavity field G inside a spherical cavity with dielectric constant ε_i instead of the n_D^2 must be replaced by $G=3\varepsilon_0 E/(2\varepsilon_0+\varepsilon_i)$. E is the macroscopic field. The dipole moment μ in the Kirkwood equation can be expressed by making use of the vacuum moment μ_0 for a spherical molecule as follows: $\mu=(\varepsilon_i+2)\mu_0/3$. In order to apply the Kirkwood-Fröhlich equation to the some overlapping dispersion regions, this equation was modified as follows:

$$\varepsilon_{i-1} - \varepsilon_i = \frac{3\varepsilon_{i-1}}{2\varepsilon_{i-1}+\varepsilon_i}\left(\frac{\varepsilon_i+2}{3}\right)^2 \frac{4\pi N_A \mu_0^2}{3\times 10^3 kT} C_i g_i. \quad (2)$$

Where

$$C_0 = \sum_{i=1}^{k} C_i + C_{ring}, \quad (3)$$

$$g = 1, \text{ if } n = 1 \text{ and } g = 1 + Z\sum_{m=2}^{n} f(\cos^2\frac{\theta}{2})^{m-1}, \text{ if } n \geqq 2, \quad (4)$$

$$f = \frac{(\mu_H + \mu_R)(\mu_H + \mu_R\cos\theta)}{\mu_H^2 + \mu_R^2 + 2\mu_H\mu_R\cos\theta}.$$

In this equations, ε_{i-1} and ε_i are the limiting low- and high-frequency dielectric constants of the i-th dispersion, N_A Avogadro's number, C_0 the gross stoichiometric concentration in mol dm^{-3} of all alcohol molecules, C_i the alcohol concentration which the i-th

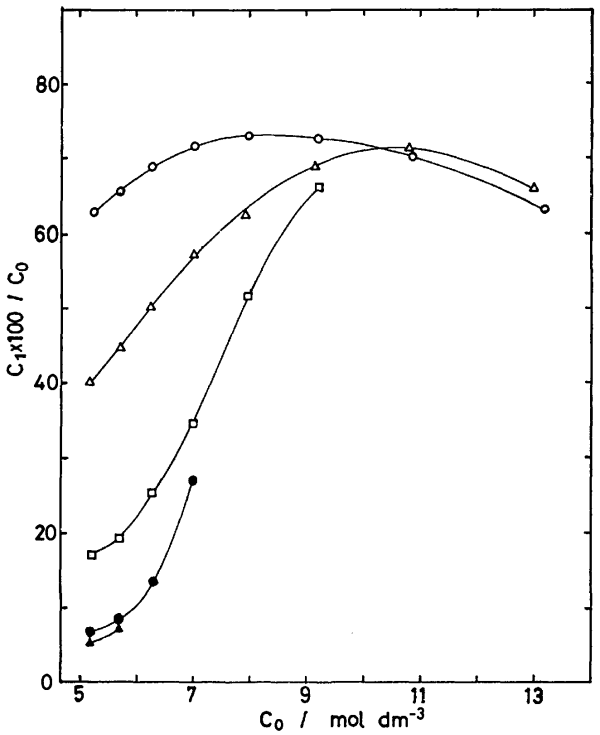

Fig. 4. The concentration (%) of primary dispersion region as a function of alcohol gross concentration C_0 at 25 °C.
○: 1-propanol-1-decanol, △: 2-propanol-2-decanol, □: 3-pentanol-3-decanol, ●: 4-heptanol-4-decanol, ▲: 5-nonanol and 5-decanol.

dispersion originates, C_{ring} that of a nonpolar cyclic polymer, and Z the coordination number. Additionally, μ_H and μ_R are the components of the dipole moment of alcohol molecule ROH along the O–H and O–R bonds, respectively, θ is the angle between O–H and O–R bonds, m represents m-th molecule, and n is the number of alcohol molecule in the linear chain polymer. It was assumed in Eqs. 2—4 that Z=2, μ_H=1.53 D, μ_R=1.20 D, μ_0=1.68 D, and θ=105° for the liquid alcohols investigated. The g_1 of the primary dispersion was calculated from Eq. 4, as being 1.87 if n=2, 2.31 if n=4, and 2.38 if n is greater than 6, respectively. If g_1 is assumed to be 2.38, the concentration of C_1 which the primary dispersion region originates can be calculated from Eq. 2 by making use of the experimental values of ε_0 and ε_1. The percentage of C_1, $C_1 \times 100/C_0$, against the gross stoichiometric concentration is shown in Fig. 4 at 25 °C. Figure 4 shows, for example, that the respective percentages of C_1 for isomeric decanols are 63% for 1-decanol, 40% for 2-decanol, 17% for 3-decanol, 7% for 4-decanol, and 6% for 5-decanol at 25 °C. Six percent of the gross concentration for 5-decanol is only associated with the formation of linear hydrogen-bonded chain polymers which the primary dispersion region originates. The other 94% for 5-decanol must exist as a monomer and some hydrogen-bonded short linear chains and nonpolar cyclic species. The C_1 generally decreases with increasing temperature. The percentages of C_1 for isomeric hexanols at 15, 25, and 35 °C are 76, 73, and 66% for 1-hexanol, 73, 62, and 53% for 2-hexanol, and 67, 52, and 41% for 3-hexanol, respectively. It may be that the depolymerization of linear hydrogen-bonded chain polymers occurs as the temperature increases.

Thermodynamic Parameters. The thermodynamic parameters, the free energy of activation ΔF^*, the heat of activation ΔH^*, and the entropy of activation ΔS^*, were calculated by the Eyring's equations,[14,15] which are described for dipole relaxation and for viscous flow as follows:

$$\tau = \frac{h}{kT}\exp\left(\frac{\Delta F\tau^*}{RT}\right) = \frac{h}{kT}\exp\left(-\frac{\Delta S\tau^*}{R}\right)\exp\left(\frac{\Delta H\tau^*}{RT}\right)$$

and

$$\eta = \frac{Nh}{V}\exp\left(\frac{\Delta F\eta^*}{RT}\right) = \frac{Nh}{V}\exp\left(-\frac{\Delta S\eta^*}{R}\right)\exp\left(\frac{\Delta H\eta^*}{RT}\right)$$

Here, τ is the relaxation time, h Planck's constant, RT the thermal energy, η the viscosity, and V is the molecular volume. ΔH^* and ΔS^* were calculated by the least-squares method in the temperature range 15—35 °C and ΔF^* was obtained at 25 °C. The thermodynamic parameters calculated are given in Table 2.

Table 2 shows that $\Delta H\tau^*$ increases with increasing alkyl chain length for normal alcohols and is nearly equal for secondary alcohols irrespective of length of alkyl chain, except for lower alcohols. $\Delta H\tau^*$ also increases as the hydroxyl group approaches the center of a molecule for isomeric alcohols, namely being expressed as 1-<2-<3-<4-<5-ol. $\Delta S\tau^*$ indicates the same tendency as the behavior of $\Delta H\tau^*$. $\Delta S\tau^*$ becomes large as the hydroxyl group approaches the center of a molecule. Therefore, it is noticeable that $\Delta F\tau^*$ increases with increasing alkyl chain length, being the same as that described for $\Delta H\tau^*$, but varies inversely as $\Delta H\tau^*$ in order to be a large value of $\Delta S\tau^*$ for isomeric alcohols, namely being expressed as 1->2->3->4->5-ol. It seems that the reorientation of a dipole moment of an alcohol molecule requires the rupture of hydrogen bondings and the rearrangement of some surrounding dipole moments, so that both $\Delta H\tau^*$ and $\Delta S\tau^*$ have large values. It is interesting that increases in $\Delta H\tau^*$ and $\Delta S\tau^*$ are strongly associated with the amount of shielding of the hydroxyl group in the hydrocarbon chain.

Table 2 shows that the $\Delta H\eta^*$ and $\Delta S\eta^*$ of normal alcohols increase with increasing alkyl chain length, being smaller than those of secondary alcohols. The $\Delta H\eta^*$ and $\Delta S\eta^*$ of secondary alcohols are nearly

Aryliminodimagnesium Reagents. XV.[1] Condensation with Nitrobenzene. Formation of Unsymmetrical Azobenzenes Favored by Long-Chain *p*-Alkoxy-Substituted Reagents

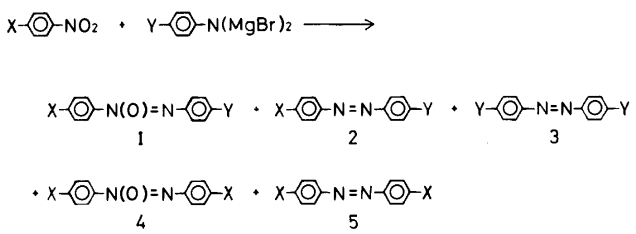
Masao Ōkubo,* Koji Matsuo, and Akira Yamauchi
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received September 28, 1988)

In the reaction of *p*-$MeC_6H_4N(MgBr)_2$ with *p*-alkoxynitrobenzene, no effect of alkoxyl chain length on the relative yields of azoxy and azo products was observed. In contrast, in the reaction of *p*-alkoxy-$C_6H_4N(MgBr)_2$ with *p*-nitrotoluene, C_{12}- and C_{18}-alkoxyl chains led to the corresponding unsymmetrical azobenzenes in unexpectedly high yields. This result, arising from efficient condensation and deoxygenation processes, was explained in terms of cooperation of reagent molecules through their aggregation assisted by a novel tying effect of their long chains.

The most important reaction of aryliminodimagnesium ($ArN(MgBr)_2$, IDMg) is the condensation with nitroarenes (Scheme 1). The *ONN* and *NNO* isomers of the unsymmetrical azoxyarene (**1**) are prepared by interchange of the substituents X and Y,[2] and the lack of interconversion of the isomers in the presence of IDMg is of significance for synthetic purposes. The reaction is applied to functionalization of azoxy- and azoarenes. If the compound **1** having a long chain alkyl or alkoxyl group (X or Y) is photoconverted into *o*-hydroxyazoarene,[3] it will be a useful chelating agent in micelle systems. The compound **2** having a long chain substituent will also be useful in micelle systems, by means of *Z–E* photoisomerization, as a probe for physicochemical studies.[4]

By use of molar excess of IDMg in the reaction with nitrobenzene (Scheme 1), the compound **1** is formed and successively deoxygenated to give **2**.[5] Single electron transfer (SET) from reagent to substrate is involved, and causes formation of minor coupling products: **3** frequently via oxidation of IDMg,[2,6] and **4** and **5** occasionally via reduction of nitroarene.[7] The coupling of nitroarene to give **4** is expected from the basic nature of IDMg because the coupling in basic medium[8] is well-known. The principal factor governing the relative yield of major and minor products is the relative SET efficiency estimated by oxidation and reduction potentials of reactants.[9,10] The precise mechanism remains to be studied.

In this study, the effect of the *p*-alkoxy (RO) chain length on the relative yield of **1** and **2** was examined using the combination of *p*-$ROC_6H_4NO_2$ with *p*-MeC_6H_4-IDMg (X=RO, Y=Me) and that of *p*-$MeC_6H_4NO_2$ with *p*-ROC_6H_4-IDMg (X=Me, Y=RO). Interestingly, "the long chain of the IDMg reagent was proved to be efficient for the formation of **2**." The reason for the variation of product yields will be discussed in this paper.



Scheme 1.

Results and Discussion

Product yields obtained by a typical treatment with 4.2 molar equivalents of IDMg (8.4 mmol in 50 ml THF at 55 °C for 3 h) are summarized in Table 1 (S1—S6 and R1—R10), which includes those affected by reaction conditions (R11—R14). Relative yields of **1**—**3** in the same combinations with S1 and R1[2] were reproduced.

The relative yield of **1**—**3** in S1—S6 (S-series) is essentially unaffected by the chain length of *p*-$ROC_6H_4NO_2$. The results of R1—R10 (R-series) using *p*-ROC_6H_4-IDMg are different from those of S-series, and are distinguished by two features. The first feature is the presence of *p,p'*-Me_2-azoxy- and -azobenzenes (**4** and **5**) in some cases of R-series (R1—R5, R7—R9), in contrast to the absence of the corresponding *p,p'*-$(MeO)_2$ products in S-series. The estimated relative SET efficiency in the combination of R1 is higher than that in S1,[2,9,10] and the electron-donating ability of *p*-ROC_6H_4-IDMg must be comparable to that of *p*-MeO reagent. Thus, the presence of **4** (or **5**) in R-series is ascribed to the rapid SET and not to any effect of chain length.

The second feature relates to the peculiar results of R6 and R10 among R-series. By use of the C_{12} and C_{18} alkoxy-substituted reagents, the yields of **2** are unusually elevated (at the expense of **1**) and concurrently the yields of **3**—**5** are reduced. The absense of **1** indicates its efficient deoxygenation to give **2**, and the appreciable yields of **3**—**5** arise usually from rapid SET.[2,10] It is thus recognized that the unusual reduction of the yields of **3** and **4** (or **5**) in R6 and R10, in spite of rapid SET (vide supra), accompanies the efficient formation of **2**. "The novel effect of reagent's chain length on the efficiency of condensation and deoxygenation processes"

is discussed in what follows.

The conditions efficient for the two processes were reported. In the reaction with o-MeO- and o-halonitrobenzenes,[1] "normal addition" of them to a large molar excess of IDMg favors the condensation giving **1** and **2** (cf. Scheme 1), whereas "reverse addition" of a small molar excess of IDMg to the substrate favors, instead, the replacement of substituents leaving the nitro group unchanged. In order to deoxygenate azoxybenzenes to sufficient degree, the treatment with a 5-fold molar excess of the strongly electron-donating p-$MeOC_6H_4$-IDMg at 55 °C for 3 h[5,11] is needed. Even under these conditions, azoxybenzenes having a p-MeO-C_6H_4 group remote to the azoxy nitrogen (electronically resembling **1** formed in R-series) are sluggishly deoxygenated. The cited results reveal that high concentration in the proximity of nitro and/or azoxy groups is required for all the processes leading to **1** and **2**. At the usual concentrations (3—10 mmol in 50 ml THF), at least a part of IDMg molecules aggregate and "cooperate" for the condensation and also for the deoxygenation.

The aggregation arises from the equilibrium between monomeric and dimeric (or oligomeric) species of IDMg (Scheme 2a) resembling that in Grignard solution proposed early by Schlenk (Scheme 2b).[12] The deposition of IDMg crystals by cooling of the clear solution (of the concentration used in the previous[2,5] and present studies) to 0 °C is due to the formation of -Br···Mg< coordination bond, and indicates the presence of an equilibrium involving the bond formation and breaking, i.e., ligand exchange with

THF molecule. Since a molecular model of p-alkoxyaniline shows that its C^{10} atom can locate close to the amino nitrogen of the same molecule, it is suggested that a long p-alkoxyl chain having more than eleven methylenes twists around the -$N(MgBr)_2$ group of the other molecule to tie the dimer (or oligomer); i.e., the dissociation is prevented and the

a) Undetermined.

self-aggregation is assisted. Figure 1 shows a tentative depiction of a dimeric aggregate tied by the *p*-octadecyloxyl group causing an ideal cooperation responsible for the high yield of **2** in R10. The cooperation will be initiated by efficient binding of nitroarene molecule with the IDMg aggregate through the coordination of nitro (and/or azoxy) oxygen to Mg atoms.

The effect of even-numbered chains (R6, R10) is somewhat different from that of odd-numbered ones (R5, R7—R9) probably due to different conformations more or less favoring the twist. Another mode of twist, i.e., that of a reagent's long chain around a substrate molecule seems possible, but may be excluded by the notable formation of **4** in R7—R9 (probably arising from a dissociation, after SET, of σ-complex formed at the initial stage of reaction[10]). The twist of substrate's long chain around a reagent molecule is excluded by the lack of chain length effect in S-series. Physical evidence for IDMg aggregation was difficultly obtained by means of the expected shift of n-π^* elecronic absorption band or ^1H NMR signal. An advanced measurement of ^{14}N and/or ^{15}N NMR spectra, which may be hopeful, remains to be carried out. However, the suggestion of IDMg cooperation and some previous observations (vide infra) are supported, as shown below, by the variation of the yields of C_{12}-substituted **1** and **2** in R11—R14, the reaction conditions being changed from that of R6.

The use of 2.0 molar equivalents of reagent in R11 leads expectedly[2] to the fair amount of recovery (34%), but the suggestion is supported by the still much higher yield (33%) of **2** than that (2%) of **1**. Fair yields of **1** at the expense of **2** were obtained by use of four-fold volume of solvent (200 ml, R12) and by use of shorter time of heating (0.5 h, R13; the mixture is the same with R6). The result of R12 indicates the effect of reduced population of dimer (or oligomer) due to left-hand side shift of the equilibrium of Scheme 2a by dilution. The result of R13 supports a previous observation,[5] i.e., sluggish deoxygenation of **1** compared to its formation. In spite of the great amount of recovery (89%) in R14 due to quite a low conversion after stirring (the mixture is the same with R6) for 10 min at room temperature,[2] a low yield (7%) of **2** is still accompanied by an undetectable amount of **1**.

As discussed above, the major factor (relative SET efficiency), governing a variety of both Grignard and IDMg reactions,[10] was modified by the effect of cooperation of reagent molecules as one of the minor factors. The effect evokes a similar cooperation proposed from structures and behavior of intermediates

of Grignard addition to benzil and benzophenone,[14] and the unified view of reactions of the two magnesium reagents[10] will be elaborated. The other minor factor, based on the effect of coordination of substrate's oxygen to reagent's Mg,[10,13] was disclosed owing to the mild electron-donating ability of IDMg.[9] The major and minor factors, determining the product yields, will be utilized for mechanistic and synthetic studies.

Experimental

Materials and Procedures. The *p*-alkoxynitrobenzenes were prepared by treatment of dried potassium *p*-nitrophenolate with appropriate alkyl bromides in refluxing cyclopentanone.[15] The *p*-alkoxyanilines were prepared in yields higher than 80% by the reduction of the corresponding nitrobenzenes by zinc powder in refluxing ethanol.[16] Longer times of refluxing are needed for efficient reduction of nitrobenzenes having longer alkoxyl chains: 1 h for C_6 and C_8, 2 h for C_{10} and C_{11}, 3 h for C_{12} and C_{13}, 4 h for C_{15}, and 5 h for C_{17} and C_{18}. By heating C_6 nitrobenzene for 3 h, some decomposition leading to 38% yield was observed. Some attempts to reduce *p*-$C_8H_{17}O$-nitrobenzene by use of $NaBH_2S_3$[17] gave poor results.

A preparation of IDMg reagents from the corresponding anilines and their reaction with nitrobenzenes were carried out according to the reported procedures.[2] The products were separated by column and thin-layer chromatographies on silica gel (Wako Gel C-200 and C-300 and Merck Kieselguhr 60G). In Table 2, the melting points (uncorrected) and ^1H NMR data of **1** (obtained in S2—S6 and R2—R10) are summarized. The other products are known.

The authors thank Miss Takae Ura for the preparation of *p*-octyloxyaniline and the reaction of its IDMg reagent. A part of this work was financially supported by Grants-in-Aid for Scientific Research (Nos. 60470026 and 63540405).

Quadrupole Coupling Constants in the Symmetric Tetrasubstituted Germanes

Toshie HARAZONO, Katsumi TANAKA, and Yoshito TAKEUCHI*
Department of Chemistry, The College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received June 21, 1988)

Synopsis. The quadrupole coupling constants in the symmetric tetrasubstituted germanes, GeR_4 (R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, Cl, and Br) were obtained by measuring the ^{73}Ge spin-lattice relaxation times (T_1) and the reorientational correlation times (τ_c) of the chloroform solutions. Quadrupole coupling constants of GeR_4 were in the range of 0.72 MHz (R=n-C_4H_9) to 1.51 MHz (R=CH_3), and these decreased slightly as the molecular radius increased.

Very little had been reported on the relaxation mechanism of ^{73}Ge nuclei (I=9/2)[1,2] when we[3] started to study this subject. Since then we analyzed the relaxation mechanism of ^{73}Ge in such symmetrical tetrasubstituted germanes as GeR_4 (R=H, CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, Cl, Br, and I).[4-6] We demonstrated that the spin-lattice relaxation of ^{73}Ge in all compounds investigated and the spin-spin relaxation of ^{73}Ge in compounds except GeH_4, $GeCl_4$, $GeBr_4$, and GeI_4 occur solely via the quadrupole relaxation mechanism. The spin-spin relaxation of ^{73}Ge in GeH_4, $GeCl_4$, $GeBr_4$, and GeI_4 were found to occur via a combination of quadrupole and scalar coupling relaxation mechanisms.

During this investigation we noticed that very few quadrupole coupling constants have so far been reported for organogermanium compounds.[1] The quadrupole coupling constants in the crystal or powder states are generally obtained from Mössbauer or NQR (nuclear quadrupole resonance) spectra. If electric field gradients occur at the central germanium nuclei, and if correlation times are obtainable in the symmetric tetrasubstituted germanes mentioned above, the quadrupole coupling constants of ^{73}Ge in the liquid state can be estimated from the relaxation times and the correlation times. In this paper we describe our attempts along this line.

Experimental

Preparation of Compounds. Tetraalkylgermanes were prepared by the procedures described in the literature.[7] $GeCl_4$, guaranteed reagent grade, was purchased from Sumitomo Metal and Mines Co., Ltd. $GeBr_4$ (bp 82—83 °C/32 mmHg; 1 mmHg≈133.322 Pa) was synthesized by the procedures described in the literature.[8] The purity of the compounds were confirmed by ^1H NMR spectra (Varian EM-390) and/or GLC (Shimadzu GC-3BT). GeR_4 were dissolved in $CDCl_3$ (50% v/v). The solution was taken in an egg shaped cell and degassed by the freeze-thaw method.

Germanium-73 NMR Spectra. The ^{73}Ge NMR spectra were recorded by JEOL FX-90Q equipped with a low frequency insert NM-IT10LF at 3.10 MHz. T_1 was determined by the inversion-recovery method. The error in T_1 thus determined was estimated to be about or less than 5%. Other conditions of the measurements have been described in previous papers.[5,6]

Measurement of Viscosity. For the measurement of viscosity of GeR_4, the sample was dissolved in $CHCl_3$ (50% v/v). The procedure of the measurement has been described in the previous papers.[5,6]

Estimation of Molecular Radius. The radius of GeR_4 (R=alkyl) is defined as the distance between the germanium nucleus and the terminal hydrogen atom plus van der Waals radius of terminal hydrogen atom. The germanium-hydrogen distance was obtained from the structure of the alkylgermanes optimized by the molecular mechanics calculations[9] while for GeR_4 (R=halogen) the reported values for germanium-halogen distance were used.[10,11]

Results and Discussion

Origin of Relaxation. It is generally accepted that if electric field gradients occur at the nucleus site, the quadrupole relaxation times, T_1 and T_2, of nuclei with nuclear spin $I>1/2$ are related to the reorientational correlation time τ_c at the extreme-narrowing limit as given below:[12]

$$\pi\Delta\nu_{1/2} = \frac{1}{T_1} = \frac{1}{T_2} = \frac{3\pi^2}{10}\,\frac{2I+3}{I^2(2I-1)} \times \left(\frac{e^2Qq}{h}\right)^2\left(1+\frac{\zeta^2}{3}\right)\tau_c \qquad (1)$$

where e^2Qq/h is quadrupole coupling constant and ζ is asymmetry parameter.

Since tetrasubstituted germanes of the type GeR_4 have tetrahedral symmetry, the electric field gradient at the germanium nuclei must be zero, which is expected to make the relaxation time of germanium nuclei infinitely long. The fact is, however, that the relaxation time is finite.

Some authors have proposed a theory to account for the quadrupole relaxation of symmetric molecules. Brown and Colpa suggested that the quadrupole relaxation occurs by the vibration and/or rotation,[13] while Osten and Jameson attributed the effect to the collision among molecules.[14] The electric field gradient generated at the germanium nuclei of symmetric tetrasubstituted germanes is averaged to zero but it has a non vanishing mean square, i.e., $(e^2Qq/h)^2\neq 0$.[14] Osten and Jameson calculated the relaxation rate of neat $GeCl_4$ at 300 K by using the collision model as $1/T_1=2\ s^{-1}$ comparable with the observed rate ($1.2\ s^{-1}$).[2] Sekatsis et al. suggested that the non-zero electric field gradient is induced by the deformation of the molecular orbitals during molecular collisions.[1] Tarasov et al.[2] suggested that the quadrupole relaxation of $GeCl_4$ and $GeBr_4$ was affected by the vibrationally-induced electric field gradients. We have also shown in previous papers[3-6] that T_1 of ^{73}Ge compounds investigated are predominantly governed by the quadrupole relaxation mechanism. If the reorientational correlation time can, for instance, be determined from the viscosity

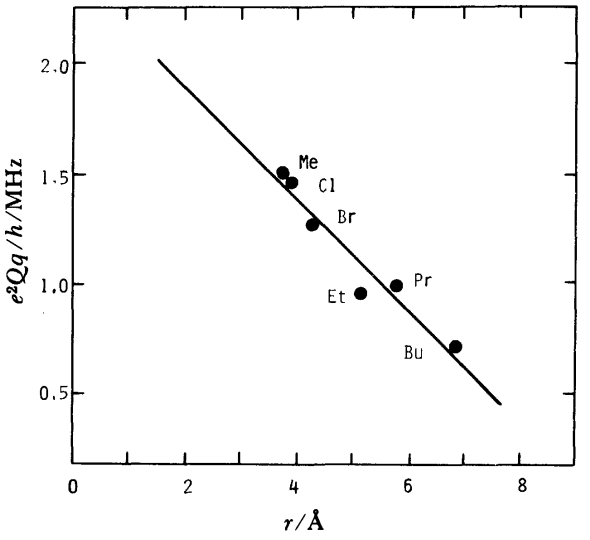

Fig. 1. Plot of e^2Qq/h. vs. radius of GeR_4.

data, it is tempting to employ Eq. 1 as a means to estimate the quadrupole coupling constants of organogermanium compounds in solution. Some authors have interpreted the quadrupole relaxation data associated with highly symmetric nuclei, such as $^{55}Mn(CNR)_6^{+ \text{ or } 2+}$, (R=*i*-$C_3H_7$ and *t*-C_4H_9),[15] aqueous tetrahedral oxoacid anions MO_4^{X-} (M=^{51}V, ^{53}Cr, ^{97}Mo, ^{183}W, ^{55}Mn, ^{99}Tc, ^{185}Re, ^{189}Os, X=1, 2, 3),[16,17] and chloride ion[18–20] and halide ions[21] by Eq. 1.

At the moment, we believe that Eq. 1 may be extended to the assessment of the quadrupole coupling constants of highly symmeteric molecules as has previously been done by several investigators[15–21] mentioned above.

Quadrupole Coupling Constants. We estimated the quadrupole coupling constants of GeR_4 with the aid of Eq. 1. The values of the concentration, density (ρ), viscosity (η), and radius (r) of tetrasubstituted germanes are shown in Table 1. The correlation time, τ_c is given by Eq. 2,[22]

$$\tau_c = 4\pi r^3 \eta f / 3kT \quad (2)$$

where k is the Boltzmann constant, T the absolute temperature, and f a microviscosity which is described in the previous papers.[5,6,22] The mean radius of solvent molecule $CHCl_3$ was estimated as 3.13 Å.

The quadrupole coupling constants for GeR_4 were found in the range of 0.72 to 1.7 MHz as shown in Table 2. For $Ge(CH_3)_4$ and $Ge(C_4H_9)_4$ in $CDCl_3$, the values of quadrupole coupling constants have been reported as 1.7 and 1.1 MHz, respectively,[1] in which τ_c was calculated from dipole–dipole interaction of CH_3 group. This discrepancy of the quadrupole coupling constants may be due to the different methods of determining τ_c values.

Since the relaxation rate is proportional to the correlation time and to the square of the quadrupole coupling constant, it is interesting to determine which of the two mainly determines the relaxation rate.

We found that the difference of relaxation rate is mainly governed by the correlation time rather than by the quadrupole coupling constant from the data for GeR_4 shown in Table 2.

A linear relationship exists between ln τ_c and the molecular radius as shown in the previous paper.[6] On the other hand, the value of quadrupole coupling constant slightly decreases as the molecular radius increases. In Fig. 1 a plot of the quadrupole coupling constants vs. molecular radius, r is given. The larger is the radius, the smaller is the quadrupole coupling constant. It seems that in symmetrical germanium compounds investigated the smaller complex molecule will be instantaniously distorted by the molecular vibrations and rotations, or collisions. On the other hand, for octahedral manganese isocyanide complexes, the differences in the line widths were attributed to variable values of quadrupole coupling constants under the assumption that the correlation time is essentially independent on the shape and size of similar molecules.[15] Indeed, Nielson et al. showed that wider half widths were observed for the complexes with larger ligands whereas molecules with large complex ligands tend to distort due to vibrational and rotational movements.[15]

The authors wish to thank Professor Hiroshi Watanabe, Department of Chemistry, the College of Arts and Sciences, the University of Tokyo for his help in the measurement of viscosity, Professor Isao Ando and Woo-Sik Jung, The Tokyo Institute of Technology, for valuable discussions. Thanks are also due to ASAI Germanium Research Institute and the Ministry of Education for financial support.

Prediction of Soil Sorption Coefficients of Hydrophobic Organic Pollutants by Adsorbability Index

Shoichi OKOUCHI* and Hisayoshi SAEGUSA
Chemistry Laboratory, College of Engineering, Hosei University,
Koganei, Tokyo 184
(Received August 31, 1988)

Synopsis. The adsorbability index proposed by Abe et al. to predict the activated carbon adsorption of organic compounds from aqueous solution was well correlated with the soil sorption coefficients of polycyclic aromatic hydrocarbons (PAHs), alkylbenzenes, chlorobenzenes, chlorinated alkanes and alkenes, heterocyclic and substituted PAHs, and halogenated phenols. The adsorbability index was also found to be well correlated with the first-order molecular connectivity index and the total molecular surface areas of these compounds.

The adsorbability index, AI, has recently been proposed by Abe et al.[1] from a quantitative structure–activity relationship analysis based on the molecular refraction to predict the activated carbon adsorption of 157 compounds from aqueous solutions (Freundlich adsorption constant: K). Their results indicated the good linear relationship between $\log K$ and AI with the correlation coefficient, r, of 0.986. Then, we investigated whether the adsorbability index was applicable to predict the soil sorption as well as the activated carbon adsorption. As a quantitative measure of the soil adsorption a soil sorption coefficient, K_{om},[2–15] has been used, which is defined as the ratio between the concentrations of a given chemical sorbed by the soil and dissolved in the soil water normalized to the total organic carbon content of the soil. The soil sorption coefficient, K_{om}, is also one of the important parameters to describe the environmental fate of chemicals. Besides the experimental determination of K_{om}, the values of K_{om} can be estimated from the water solubility[4,7,8,11,13–15] or 1-octanol/water partition coefficient,[4,7–11] but the estimation needs their accurate data.

Recently, Sabljić[2] showed the first-order molecular connectivity index, χ, as a good structure parameter that described most adequately a relationship between the molecular structure of 72 hydrophobic organic compounds and their adsorption by soil. Furthermore, he indicated that χ was well correlated with the total molecular surface areas, TSA, of the compounds. Then, attempts were made to determine a relationship between AI and TSA of the 72 hydrophobic organic compounds reported by Sabljić,[2] which included polycyclic aromatic hydrocarbons (PAHs), alkylbenzenes, chlorobenzenes, chlorinated alkanes and alkenes, heterocyclic and substituted PAHs, and halogenated phenols.

Results and Discussion

The adsorbability index, AI, of a given molecule can be readily calculated from Eq. 1[1] by adding the values of A and I shown in Table 1,

$$\mathrm{AI} = \Sigma A + \Sigma I \tag{1}$$

where A and I indicate the factors of the respective increasing and decreasing adsorbabilities of the atom or functional group in the molecule onto the activated carbon from aqueous solution.

The AI values calculated from Eq. 1 are shown in Table 2 for the 72 hydrophobic organic compounds.[2] The AI values in Table 2 are obtained by only the A values, since the I values can be ingnored for the compounds used in this work. The logarithm of K_{om} was expressed by the following regression equation:

$$\log K_{om} = 0.62\,\mathrm{AI} + 0.16 \quad (r = 0.967,\ s = 0.341), \tag{2}$$

where s is the standard deviation. The graphical representation of this fit is given in Fig. 1. This led to the conclusion that the adsorbability index gave good prediction of the soil sorption coefficients as well as

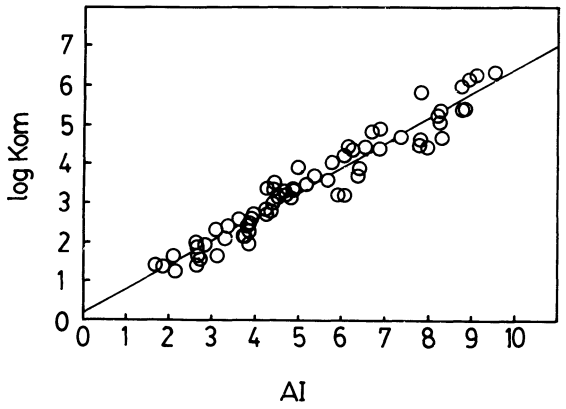

Fig. 1. Relationship between log K_{om} and adsorbability index, AI.

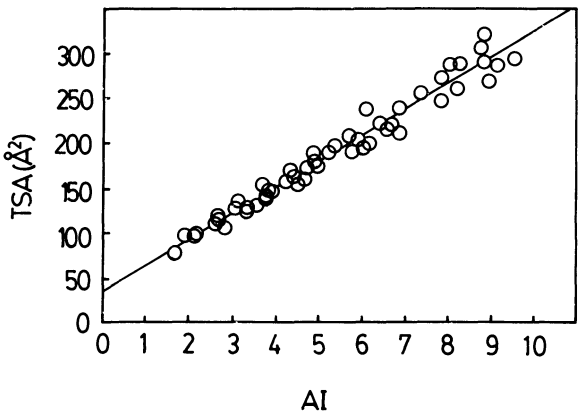

Fig. 2. Relationship between total molecular surface areas, TSA, and adsorbability index, AI.

the first-order connectivity index (χ) as shown by Eq. 3.[2]

$$\log K_{om} = 0.53\chi + 0.54 \quad (3)$$
$$(r = 0.976,\ s = 0.298)$$

Therefore, the adsorbability index for prediction of the activated carbon adsorption was also found to be effective for prediction of the soil adsorption coefficient.

On the other hand, the regression analysis showed that the relationships between AI, TSA, and χ were expressed as the following linear functions:

$$TSA = 29.4AI + 35.3 \quad (4)$$
$$(r = 0.985,\ s = 10.9)$$

$$\chi = 1.16AI - 0.68 \quad (5)$$
$$(r = 0.988,\ s = 0.377)$$

$$TSA = 24.1\chi + 58.5 \quad (6)$$
$$(r = 0.956,\ s = 19.4),$$

The AI index was well correlated with both TSA and χ. The correlation of TSA with AI (Eq. 4) was superior to that of TSA with χ (Eq. 6) reported by Sabljić.[2] Figure 2 shows the relationship between TSA and AI according to Eq. 4. The adsorbability index was found to be a parameter that strongly depends on the total molecular surface areas.

(Received September 8, 1988)

Synopsis. Low-frequency Raman bands of the [$^1H_4$]- and [$^2H_4$]pyrazine crystals were studied at various temperatures between 4.2 and 300 K. All six rotational lattice vibrations were identified based on the isotopic factor (the ratio of the vibrational frequency of the [$^1H_4$]- and [$^2H_4$]pyrazine crystals) of the individual vibrations. Classification of the rotational lattice vibrations into symmetry species was made through the polarization measurement of the Raman bands in single crystals.

The rotational lattice vibrations of pyrazine crystal were first studied by Ito and Shigeoka.[1] They observed five low-frequency Raman bands due to the rotational lattice vibrations and gave assignments for these bands on the basis of the normal coordinate calculation assuming intermolecular force constants of the pyrazine crystal. Their calculation indicated that the lowest vibrational frequency of the rotational lattice vibration would be about 20 cm^{-1} and they considered that the Raman band due to this lattice vibration could not be observed under their experimental conditions. Pasquier et al. also observed the low-frequency Raman bands of pyrazine crystal and determined the six rotational lattice vibrations based on the normal coordinate calculation,[2] although their assignments given for some bands are different from those given by Ito et al.

In this work the low-frequency Raman bands of the [$^1H_4$]- and [$^2H_4$]pyrazine crystals are reinvestigated and the assignments of the six rotational lattice vibrations are discussed based on the isotopic factor and the polarization behavior of the bands.

Experimental

Material. [$^2H_4$]Pyrazine was synthesized by exchange reaction of [$^1H_4$]pyrazine with D_2O using palladium asbestos as a catalyst.[3] The isotopic purity of the product was confirmed by nuclear magnetic resonance measurement. The samples were purified by repeated vacuum distillations.

Optical Measurements. Low-frequency Raman bands of the pyrazine crystals were observed with a SPEX 1402 doublemonochromator at 4.2 K and with a JEOL 400T laser Raman spectrophotometer at various temperatures between 77 and 300 K. The polarization behavior of the Raman bands was observed in the following way. It is known that the pyrazine crystal grows along the b axis and the crystal is twinned on the cleavage (101) plane.[4] A well-grown single crystal obtained by the Bridgman method was cut along the cleavage plane, which will be referred to as bc′ plane, where the c′ axis is inclined counterclockwise by 57.6° from the c axis in the ac plane, and was sealed in a small rectangular glass cell with the bc′ plane attaching to the cell face. The crystal in the cell was excited with the 514.5 nm beam from an Ar^+ ion laser. The power of the laser beam was adjusted low enough because of high sublimation property of the pyrazine crystal. The propagation direction of the excitation light beam was set to be parallel to the c′ axis or perpendicular to the bc′ plane. In this alignment the a′a′, bb, c′c′, a′b, and bc′ polarized Raman spectra were obtained by the back scattering method, where the a′ axis is taken to be perpendicular to the c′ axis in the ac plane and the first and second letters refer to the polarization directions of the excitation and scattering lights, respectively.

Results and Discussion

Pyrazine crystallizes in the orthorhombic space group P_{mnn} (D_{2h}^{12}) with two molecules in the unit cell.[4] The six rotational lattice vibrations are distributed among the four symmetry species: $1A_g+1B_{3g}+2B_{1g}+2B_{2g}$. The rotational modes of the molecule around the z axis give rise to the A_g and B_{3g} lattice vibrations and the rotational modes around the x and y axes give rise to the B_{1g} and B_{2g} lattice vibrations as shown in Table 1.[1] The x axis is taken to be perpendicular to the molecular plane and the y and z axes in the plane with the z axis passing through the nitrogen atoms.

The Raman spectra of the [$^1H_4$]- and [$^2H_4$]pyrazine crystals in the low-frequency region observed at 4.2 K are shown in Fig. 1. Seven Raman bands were clearly observed and their frequencies are given in Fig. 1 and Table 2. In this table the frequencies and assignments of the rotational lattice vibrations of the [$^1H_4$]pyrazine crystal determined by Ito et al.[1] and Pasquier et al.[2] are also given. The Raman band at 56 cm^{-1} observed by Ito et al. at 4.2 K resolved into two bands at 57 and 58 cm^{-1} and a weak additional Raman band was clearly observed at 116 cm^{-1}. No bands could be observed in the low frequency region around 20 cm^{-1} contrary to the prediction given by Ito et al. The observed Raman bands can be ascribed to the rotational lattice vibrations, if the isotopic factor of the bands ($\tilde{\nu}[^1H_4]/\tilde{\nu}[^2H_4]$) is equal to the value of $\{I_r[^2H_4]/I_r[^1H_4]\}^{1/2}$, where $\tilde{\nu}$ is the Raman frequency and I_r is the moment of inertia of the molecule about the axis r(=x, y, z). Using the values of the moments of inertia of the

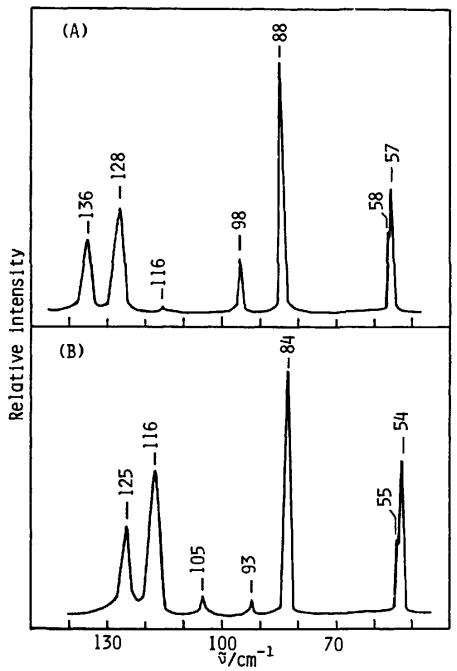

Fig. 1. The Raman spectra of the [$^1H_4$]- (A) and [$^2H_4$]pyrazine (B) crystals in the low-frequency region observed at 4.2 K.

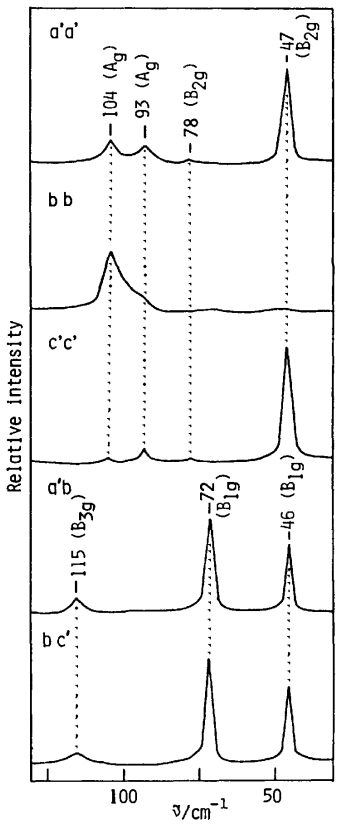

Fig. 2. The polarized Raman spectra of the [$^1H_4$]-pyrazine single crystal in the low-frequency region observed at 300 K.

[$^1H_4$]- and [$^2H_4$]pyrazine molecules calculated based on the molecular structure determined by Wheatley,[4] the isotopic factors were calculated to be 1.069, 1.036, and 1.105 for the rotational lattice vibrations about the x, y, and z axes, respectively.

The structures of the Raman spectra observed at various temperatures between 300 and 77 K are the same as that observed at 4.2 K except for the band width, which increases with increasing temperature. This indicates that no apparent phase transition takes place between 300 and 4.2 K. The polarized Raman spectra of the [$^1H_4$]pyrazine single crystal observed at 300 K are given in Fig. 2. According to Table 1, the lattice vibrations belonging to the symmetry species A_g will be observed in the aa, bb, and cc spectra and those belonging to the B_{1g}, B_{2g}, and B_{3g} species in the ab, ac, and bc spectra, respectively. The a'a' and c'c' spectra include the aa, cc, and ac spectra, while the a'b and bc' spectra include the ab and bc spectra because the a' and c' axes are in the ac plane. Therefore, the Raman bands observed in the bb spectrum should be assigned to the A_g species, those in the a'a' and c'c' spectra to the A_g or B_{2g} species, and those in the a'b and bc' spectra to the B_{1g} or B_{3g} species. The band at 115 cm^{-1}, whose isotopic factor is 1.11, was observed in the a'b and bc' spectra and the band at 104 cm^{-1} giving the isotopic factor of 1.11 was observed in the a'a', bb, and c'c' spectra. Therefore, these bands were assigned to the rotational lattice vibrations of the B_{3g} and A_g species about the molecular z axis, respectively. The

lowest wavenumber band could not resolve into doublet at 300 K. However, careful observation showed that the frequency of the bands observed in the a'a' and c'c' spectra was 47 cm^{-1} and that observed in the a'b and bc' spectra was 46 cm^{-1}. This observation indicates that the 47 and 46 cm^{-1} bands should be assigned to the vibrations belonging to the different symmetry species. The 46 and 47 cm^{-1} bands correspond to the 57 and 58 cm^{-1} bands observed at 4.2 K, respectively. The observed isotopic factors of the bands at 46, 47, 72, and 78 cm^{-1} ranges between 1.06 and 1.04 and thus these bands are to be assigned to the rotational modes about the molecular x and y axes. The 72 cm^{-1} band showed the a'b and bc' polarization and the 78 cm^{-1} band the a'a' and c'c' polarization behavior. Therefore, the 46 and 72 cm^{-1} bands were assigned to the B_{1g} species and the 47 and 78 cm^{-1} bands to the B_{2g} species although Ito et al. and Pasquier et al. gave different assignments for the 72 and 78 cm^{-1} bands as shown in Table 2. The band at 93 cm^{-1} showing the a'a', bb, and c'c' polarization behavior and giving the isotopic factor of 1.09 was assigned to the overtone vibration of the 46 and/or 47 cm^{-1} bands although Pasquier et al. assigned this band to the B_{1g} vibration. These assignments are given in Table 2.

The polarization behavior of the Raman bands of the [$^2H_4$]pyrazine crystal is exactly the same as that of the [$^1H_4$]pyrazine crystal. The assignments for the low-frequency Raman bands of the [$^2H_4$]pyrazine crystal are also given in Table 2. We believe that the polarization behavior of the Raman bands in single crystals gives clear and definite experimental justification for the vibrational assignments and the six rotational lattice vibrations of the [$^1H_4$]- and [$^2H_4$]-pyrazine crystals determined in this work are quite reasonable. The isotopic factors measured for the individual bands also confirm the reliability of the assignments.

The tetramethylpyrazine crystal hydrates quite easily with moisture in the air and the Raman bands due to the hydrated crystal were observed in the intramolecular and lattice vibrations.[5] In order to study the effect of hydration on the intramolecular and lattice vibrations of the pyrazine crystal, the Raman spectra of wet pyrazine crystal prepared by adding water to the pyrazine crystal were observed, but no distinct change of the spectral structure and vibrational frequencies were observed untill the pyrazine crystal deliquesces by water.

(Received September 16, 1988)

Synopsis. The ultraviolet spectrum observed in γ-irradiated liquid nitrogen containing a small amount of oxygen has been ascribed to ozone. The εG value was obtained. The dose rate effect on the yield of ozone was observed. The value of $\varepsilon_m G$ was inversely proportional to the square root of the dose rate. This allowed us to discuss the formation mechanism of ozone in liquid nitrogen.

It is well-known that ozone is produced in irradiated liquid nitrogen containing a small amount of oxygen and that the decomposition of such ozone sometimes leads to incidental explosions during the irradiation with γ-rays[1] electron beams[2] or reactor radiation.[3] The yield of ozone as a function of oxygen concentration in γ-irradiated liquid nitrogen has been measured by an indirect method.[4]

Although the optical absorption spectrum of gaseous ozone was previously reported,[5,6] there is no report of the ultraviolet absorption spectrum of ozone produced in γ-irradiated liquid nitrogen as far as we are aware. In the ultraviolet region there often appear the absorption bands due to ionic species or radicals when organic substances are irradiated in liquid nitrogen. So, if one uses the same cryostat for both irradiation and optical measurement, it becomes indispensable to distinguish the ultraviolet spectrum of the species from that of ozone.

In this study we report the ultraviolet spectrum of ozone produced in γ-irradiated liquid nitrogen. We also discuss the formation mechanism of ozone in connection with the effect of dose rate on the yield of ozone.

Experimental

Liquid nitrogen supplied by the Osaka Sanso Co. was used. Oxygen concentration in liquid nitrogen was measured by a zirconia type oxygen gas sensor and a gas chromatography. Although the concentration of oxygen in liquid nitrogen stored in a 3000 dm^3 storage tank was about 0.3 ppm, it amounted to 160±30 ppm after liquid nitrogen was transferred in air from a 5 dm^3 container to an optical cryostat. This nitrogen in the cryostat was used for both γ-irradiation and optical absorption measurement. Nitrogen gas evaporated inside the cryostat was released into atmosphere after passing through silicon oil in a gas wash bottle which was attached to the cryostat. This device prevented the outside air being dissolved in liquid nitrogen.

Liquid nitrogen was irradiated by γ-rays with various dose rates (163 Gy h^{-1}—1602 Gy h^{-1}). The total dose was always 801 Gy. Optical absorption measurements were carried out with a Shimadzu double beam spectrophotometer. Optical absorption spectra were recorded in the ultraviolet region of 210 nm$<\lambda<$320 nm and in the absorbance region of $0<A<4$.

Results and Discussion

The ultraviolet spectrum of liquid nitrogen recorded after the γ-irradiation with the dose rate of 1602 Gy h^{-1} is shown in Fig. 1(A), where ε is the molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$) and G is the G-value (molecules formed/100 eV absorbed). The spectrum shows the wavelength of the absorption maximum (λ_{max}) of 255 nm, the half-height width ($W_{1/2}$) of 6.6×10^3 cm^{-1} and a vibrational band structure near the absorption maximum.

The apparent absorption intensity of the spectrum increased as the amount of liquid nitrogen in the cryostat decreased owing to the natural evaporation. The reciprocal plots of the absorption intensity against the evaporation time after the irradiation were linear for an extended period of time, e.g. 4 hours. This can be explained on the assumption that liquid nitrogen in the cryostat evaporates at a constant rate and that the species responsible for the absorption does not evaporate together with nitrogen, being dissolved in the remaining liquid nitrogen.

After liquid nitrogen in the cryostat was completely evaporated, the absorption measurement was again carried out in order to see if there is any absorption due to the residual gas inside the cryostat. The absorption

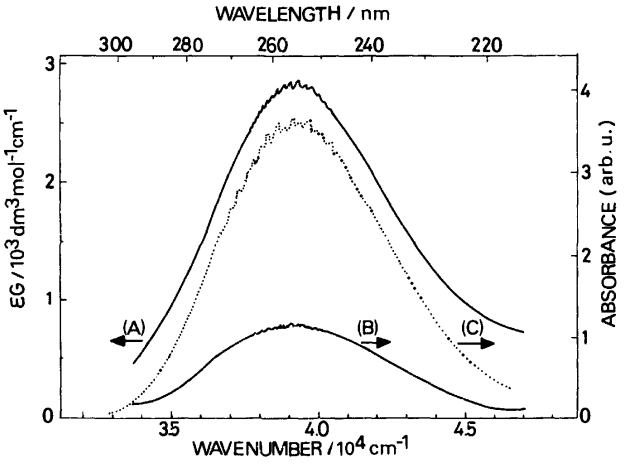

Fig. 1. The ultraviolet absorption spectra of ozone: (A) observed in γ-irradiated liquid nitrogen containing 160 ppm oxygen, (B) observed after liquid nitrogen was completely evaporated, and (C) reported spectrum of gaseous ozone (Ref. 5). The γ-irradiation was carried out at the dose rate of 1602 Gy h^{-1}. The total dose was 801 Gy.

spectrum thus recorded is shown in Fig. 1(B). The values of λ_{max} and $W_{1/2}$ of spectrum (B) were the same as those of spectrum (A). Opening the frange of the cryostat, we could smell irritatingly. The smell was characteristic of ozone. The ultraviolet spectrum of ozone at 300 K which was reported previously by other authors[6] is shown in Fig. 1(C), where the Hartley band structure is clearly seen near the absorption maximum. The values of λ_{max} and $W_{1/2}$ of spectra (A) and (B) were almost the same as those of spectrum (C). From these observations, we ascribe spectra (A) and (B) to ozone formed by γ-irradiation of liquid nitrogen containing the small amount of oxygen. The value of ε at $\lambda=\lambda_{max}$, ε_m, reported for ozone at 300 K[6] is 2900 $dm^3\,mol^{-1}\,cm^{-1}$. If we use this value for the present case, we obtain the G-value of ozone, $G(O_3)=1.0$ for the dose rate of 1602 Gy h^{-1}. It is reported, however, that the value of ε depends on temperature at temperatures higher than 300 K.[7] If this is also true at 77 K, the calculated $G(O_3)$ is not correct. Instead, if the empirical relationship between the value of ε and temperature[7] is extrapolated to 77 K, the value of ε becomes about 3500 $dm^3\,mol^{-1}\,cm^{-1}$ at 77 K so that $G(O_3)=0.83$ is obtained. Matumoto et al.[4] used the method of the stoichiometric reaction between ozone and nitrogen monoxide in order to determine $G(O_3)$. According to their results, one can estimate $G(O_3)=6.0$ under the conditions of the oxygen concentration of 160 ppm and the γ-dose rate of 1.1×10^4 Gy h^{-1}. Their value is much larger than ours. This may partly due to an enhanced reaction of oxygen atom with the quartz wall of the cryostat in our case. However, the discrepancy between the reported $G(O_3)$ and ours cannot be elucidated by the present knowledge.

A dose rate effect on the yield of ozone was observed. This is demonstrated in Fig. 2. It is seen from Fig. 2 that the plots of log ($\varepsilon_m G$) against log (dD_a/dt), where dD_a/dt is the dose rate, gave a straight line with the gradient of $-1/2$.

It was reported that N_3^+ ion is one of the major radiolytic products of nitrogen gas and that N_3^+ ion reacts with O_2 to give rise to oxygen atom.[8,9] On this basis, we put forward the following reaction mechanism for the formation of ozone in the γ-irradiated liquid nitrogen containing a small amount of oxygen:

$$N_2 \longrightarrow N_3^+ \quad (1)$$

$$N_3^+ + e^- \longrightarrow \text{neutralization} \quad (2)$$

$$N_3^+ + O_2 \longrightarrow O + NO^+ + N_2 \quad (3)$$

$$O + O_2 + N_2 \longrightarrow O_3 + N_2 \quad (4)$$

$$O + \text{wall} \longrightarrow 1/2O_2 + \text{wall} \quad (5)$$

The formation rate of N_3^+ ion is given by $\{G(N_3^+)/100N_0\}(dD_a/dt)$, where $G(N_3^+)$ is the G-value of N_3^+ ion, N_0 the Avogadro constant and dD_a/dt is the dose rate in the unit of eV $dm^{-3}\,s^{-1}$. During γ-irradiation the steady-state conditions of $d[N_3^+]/dt=d[e^-]/dt=d[O]/dt=0$ must be satisfied, where $[N_3^+]$, $[e^-]$, and $[O]$ are the concentration of N_3^+ ion, the excess electron, and oxygen atom. The rate constants of the Reactions 2 and 3, k_2 and k_3, are in the ranges of 10^{-6} and 10^{-10} $cm^3\,s^{-1}$ respectively.[10,11] The values of $\{G(N_3^+)/100N_0\}(dD_a/dt)$ and $[O]$ are in the ranges of 10^{-7} mol $dm^{-3}\,s^{-1}$ and 10^{-3} mol dm^{-3}, respectively in the present case. These values result in $\{G(N_3^+)/100N_0\}(dD_a/dt)\gg\{k_2[O^2]\}$.[2] Under this condition we obtain

$$G(O_3) = \{G(N_3^+)\}^{1/2} f([O_2],k_2,k_3,k_4,k_5)(dD_a/dt)^{-1/2}, \quad (6)$$

where k_4 and k_5 are the rate constants of the Reactions 4 and 5, respectively and $f([O_2],k_2,k_3,k_4,k_5)$ is given by

$$f = (100N_0)^{1/2} k_3 k_4 [O_2]^2 / \{(2k_2)^{1/2}(k_4[O_2] + k_5)\}. \quad (7)$$

Equation 6 shows that the yield of ozone is inversely proportional to the square root of the dose rate. Thus the observed dependence of log ($\varepsilon_m G$) on log (dD_a/dt) is explained by the proposed mechanism.

Matumoto et al.[4] investigated the effect of oxygen concentration on the yield of ozone in liquid nitrogen and proposed a mechanism for the formation of ozone in liquid nitrogen. According to their mechanism, the excited state of nitrogen molecule undergoes the reaction with oxygen molecule to produce oxygen atom. However, they did not discuss the mechanism in detail, since they did not investigate other effects e.g. the dose rate effect.

It may be instructive to mention the following. If the excited nitrogen molecules react with themselves or with other transient species which concentration is proportional to that of the excited nitrogen molecules and if the reaction is competitive to the reaction with oxygen molecule, one can obtain an equation which is essentially the same as Eq. 6. In this context it is beyond our present knowledge whether N_3^+ ion or an excited state of nitrogen is responsible for the formation of ozone in liquid nitrogen.

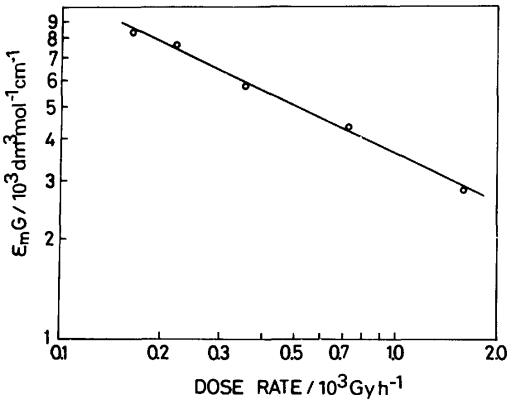

Fig. 2. Effect of the dose rate on $\varepsilon_m G$ of ozone produced in liquid nitrogen. The total dose was 801 Gy.

The authors are greatly indebted to Prof. Kenji Fueki, Nagoya University, for his valuable suggestions. The authors are greatful toi Messrs. Kenzo Kawamoto, Hisao Kodaka, and Kiyomi Miyata of Research Reactor Institute, Kyoto University for the measurement of oxygen concentration in liquid nitrogen.

(Received May 9, 1988)

Synopsis. Variable temperature ^{1}H NMR suggests that the metal-carbon bonded Pt(II) complex of 1,1,2,2-tetraacetylethane(dahd=3,4-diacetyl-2,4-hexadiene-2,5-diol), [Pt(dahd-C^3,O')(SEt_2)$_2$] undergoes two distinct rearrangements at the sulfides, one of which is accompanied by an anomalous dissociation process. From a comparison of the estimated kinetic parameters for inversion, an arrangement of the two sulfides in planar geometry is proposed.

A number of studies concerning internal exchange processes of pyramidal sulfur have been done on Pt(II) and Pt(IV) complexes with symmetry.[1-6] ^{1}H NMR spectral change of methylene hydrogens from the AB(ABCD) to the A_2 spin system in *trans*-[MCl_2{S-(CH_2SiMe_3)$_2$}$_2$] (M=Pd, Pt),[3] [MCl_2{S(Ph)(CH_2SiMe_3)}$_2$] (M=Pd, Pt),[3] *cis*-[$PtCl_2(SEt_2)_2$][6] has been sufficiently explained by the inversion process on the assumption of fast M-S and S-C bond rotations. Still, sulfur inversion in a Pt(II) complex with low symmetry is relatively elusive.

The authors have recently prepared several anomalous 1,1,2,2-tetraacetylethane Pd(II) and Pt(II) complexes, in which the ligand links a metal with the (*C,O'*)-chelate; [M(dahd-C^3,O')L_2]{M=Pd, L_2=1,10-phen;[7] M=Pt, L=SEt_2, PMe_2Ph, L_2=2,9-R_2-1,10-phen (R=H, Me)}.[8] They have formerly been characterized by means of ^{1}H, ^{13}C NMR {^1J(^{195}Pt-C^3)=489 Hz} and Fast Atom Bombardment Mass Spectroscopy (M^+=572).[8] Of them, ^{13}C NMR of [Pt(dahd-C^3,O')(SEt_2)$_2$] at the ambient temperature unexpectedly shows an absence of ^{195}Pt satellites in resonances due to one SEt_2. These findings led us to investigate the rearrangement dynamics of pyramidal sulfides arranged unsymmetrically in square planar geometry, one of which may possibly proceed via some dissociation.

This note will deal with the inversion processes of two distinct sulfides in [Pt(dahd-C^3,O')(SEt_2)$_2$], as studied by variable-temperature ^{1}H NMR; moreover, from a comparison of the activation parameter of inversion, an arrangement of the sulfides will also be discussed.

Results and Discussion

^{1}H NMR pattern of [Pt(dahd-C^3,O')(SEt_2)$_2$] in $CDCl_3$ changes with the temperature, as is shown in Fig. 1. The changes are remarkable in resonances due to methylene hydrogen of SEt_2 (δ 2.4—3.3). Throughout the temperature change, two distinct resonance patterns (S^1, S^2) were obtained. This finding is, as expected, consistent with no mutual exchange of the sulfides. The signals arising from S^1 show a quartet with no ^{195}Pt satellite at 308 K, consistent with its ^{13}C NMR. On the other hand, the resonances arising from S^2 obviously show the ^{195}Pt satellite {J(^{195}Pt-H)=28.8Hz}, though the coupling constant is relatively small compared with those of 46.4 and 37.2 Hz

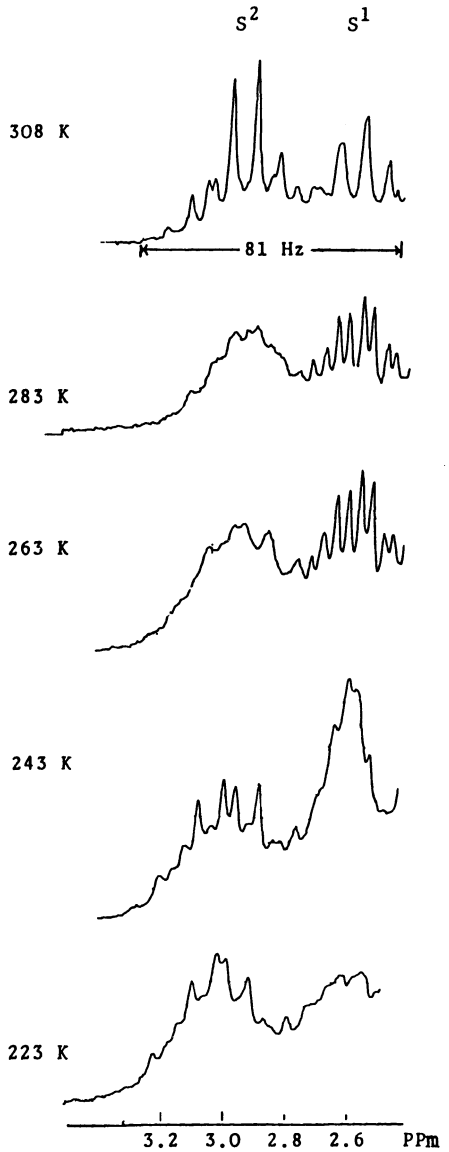

Fig. 1. Variable temperature ^{1}H NMR (resonances due to methylene proton of SEt_2) of Pt(dahd-C^3,O')(SEt_2)$_2$ in $CDCl_3$. The spectra were recorded using Hitachi R-90H FT NMR (90.04 MHz) operating Fourier transform mode. Deviation of temperature control was ±2%±1° on the centigrade temperature scale.

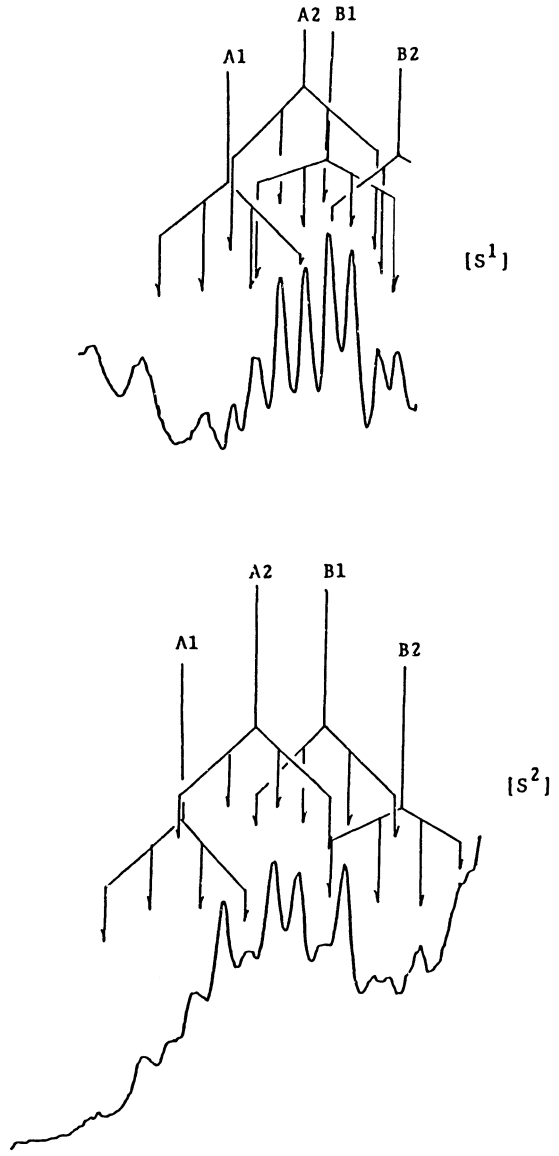

Fig. 2. AB part of ABM_3 spin system assigned to methylene hydrogen at; S^1 at 263 K and S^2 at 243 K.

found for *cis*- and *trans*-$[PtCl_2(SEt_2)_2]$[6] respectively over the coalescence temperature.

The resonances due to S^2 at 283 K are very close to coalescence, but below 283 K the resonaces separate. At 243 K, four predominant quartets could be discerned with $J(H,H')=7.2$ Hz, although the complete analysis of $J(^{195}Pt-H)$ could not be performed. However the spectrum is in good agreement with the simulated lines of ABM_3 spin system with $J_{AB}=11.7$ and $J_{AM}=J_{BM}=7.2$ Hz. A spin-system change, $ABM_3 \rightleftarrows A_2M_3$, thus arising from S^2 corresponds to an averaging process of two pairs of methylene hydrogen. This mutual exchange of methylene hydrogen cannot be explained by rotation about the Pt-S and S-C bonds. The only process causing such an exchange is inversion at the pyramidal sulfur atom. The effect of inversion is shown in Fig. 3 as a preferred conformation, [A] or [B]. The symmetry plane bisecting the pyramidal sulfide ligand for both conformations is in coplanar with the coordination plane where the two conformations are enantiometrically related and where the methylene protons between the two groups are indistinguishable magnetically. The [B] conformation is obtained by the inversion of S^2 in [A] together with a 180° rotation about the Pt-S^2 bond and 120° rotation about the S^2-C bond; the net effect is a mutual exchange of methylene hydrogen. Concerning the so-called hindered rotation, no firm spectral evidence has been obtained in the Pt(II) and Pd(II) complexes so far

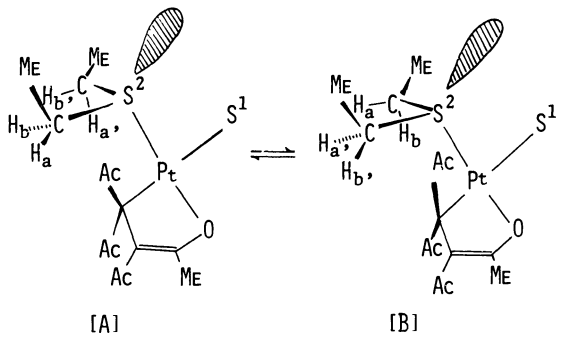

Fig. 3. A conformation [B] is obtained by inversion at S^2 in [A] together with 180° rotation about Pt-S bond and 120° rotation about S-C bond.

Table 1. Variable-Temperature ^1H NMR Data

T/K	$\Delta\nu$/Hz[a]		J_{AB}/Hz[b]		ΔG^*/kJ·mol^{-1}[c]		k/s^{-1}[d]	
	S^1	S^2	S^1	S^2	S^1	S^2	S^1	S^2
308					67.7			
	}[T_c]				|		}21.7(±0.4)	
283		[T_c]			62.0	65.8(±0.1)		45.0(±0.2)
263	9.70(±0.2)		11.3(±0.5)					
243		20.1(±0.1)		11.7(±0.1)				

a) Spacing estimated by $\sqrt{(A1-B2)(A2-B1)}$, where A1, A2, B1, and B2 are the chemical shifts due to the ABM_3 spin system observed for methylene hydrogen in the order of low-field resonances. b) Coupling constant $J_{H,H}$ within the methylene group. c) Calculated by the use of $\Delta G^*/RT_c=22.96+\ln(T_c/\Delta\nu)$, where ΔG^* is the activation parameter for the inversion of sulfide at the coalescence temperature; R. J. Abraham and P. Loftus, "Proton and Carbon-13 NMR spectroscopy-An Integrated Approach," Heydon and Son (1978). d) Inversion rate calculated by the use of $k=RT_c/Nh \exp(-\Delta G^*/RT_c)$. e) Coalescence may exist between 283—308 K, and its ΔG^* was arbitrarily estimated, with 283 K as its lower limit and 308 K as its upper limit. f) Coalescence temperature.

studied even at 213 K,[3] which can be assumed to be fast. In the present case also, the rotation about Pt–S^2 bond is tentatively presumed to be fast in the NMR time scale. The activation parameter for the inversion process at S^2 was thus estimated to be $\Delta G^*(T_c=283\ K)=65.8\ kJ\cdot mol^{-1}$ and k (inversion rate at T_c)$=45.0\ s^{-1}$. These activation parameters obtained for [Pt(dahd-C^3,O')(SEt_2)$_2$] are comparable with those of $\Delta G^*=70.3\ kJ\cdot mol^{-1}$ and $k=64.7\ s^{-1}$ ($T_c=333$ K) found for *cis*-[$PtCl_2(SEt_2)_2$] and those of $58.2\ kJ\cdot mol^{-1}$ and $k=36.4\ s^{-1}$ ($T_c=274$ K) for its trans form.

On the other hand, low-temperature ^1H NMR (resonances arising from S^1Et_2) shows an analogous and more explicit spectral change, while its ^{13}C NMR at the ambient temperature exhibits no ^{195}Pt satellites. The coalescence temperature is in the vicinity of 300 K. The resonances at 263 K, which seem to be two quartets overlapping, are, however, assigned to the AB part of the ABM_3 spin system; the spectrum accords well with lines simulated using the five-spin system with $J_{AB}=11.3$ and $J_{AM}=J_{BM}=7.2$ Hz. We could not, unfortunately, obtain precise information whether or not ^{195}Pt–H coupling exists at that temperature. The spin system change thus arising from S^1, $ABM_3 \rightleftarrows A_2M_3$, corresponds to an averaging process of methylene hydrogen and can also be explained only by an inversion process. However, this inversion cannot proceed intramolecularly, because the lack of ^{195}Pt–H and ^{195}Pt–C couplings indicates a bond breakage of the sulfide, S^1. In fact, on the addition of the free ligand SEt_2 into [Pt(dahd-C^3,O')(SEt_2)$_2$], only the broad resonances arising from S^1, whose spectrum is close to the coalescence temperature, became a sharp and single quartet with an increase in the intensity, while its chemical shift did not change. For the spectral change with the temperature due to S^1, T_c has not definitely been fixed. The activation free energy was arbitrarily estimated at the two temperatures, 283 and 308 K, to be 62.0 and $67.7\ kJ\cdot mol^{-1}$ respectively. Although such a rough estimation for ΔG^* gives a fair deviation, the inversion rates k thus derived at both temperatures eventually approach $21.7\ s^{-1}$, unaccompanied by any significant deviations. Accordingly, the inversion rate of S^1 estimated at 283 K can be compared with that of S^2, which unexpectedly results in one half of the rate of S^2. As has been established formerly,[8] S^1 in [Pt(dahd-C^3,O')(SEt_2)$_2$] is readily displaced by PPh_3 to give [Pt(dahd-C^3,O')(PPh_3)(S^2Et_2)], in which PPh_3 is arranged trans to C^3\{$J(^{31}P-C^3)=60$ Hz\}. By accounting for the trans labilizing effect: C(3)(from $acac^-$)> O(from $acac^-$),[8,9] S^1 undergoing rearrangement via a bond breakage should be arranged trans to C(3) from the $dahd^{2-}$. If an analogous intramolecular rearrangement can be presumed, the inversion of S^1 should proceed much faster than that of S^2. In contrast to this expectation, the inversion rate of S^1, accompanied by bond dissociation, is comparatively much slower than that of S^2. It is most likely that the rearrangement of S^1 proceeds via an intermolecular pathway.[10]

One of the present authors (S. Y.) wishes to thank Yasuko Tanaka (Applied Engineering Center, Hitachi, Ltd., Ibaragi) for obtaining the NMR spectra.

(Received August 4, 1988)

Synopsis. X-Ray photoelectron spectroscopy (XPS) was applied to three binuclear molybdenum(V) complexes of di-μ-oxo-, μ-oxo-μ-sulfido-, and di-μ-sulfido-bis[(cysteinato)-oxomolybdate(V)]$^{2-}$, $[Mo_2(\mu\text{-}O)_x(\mu\text{-}S)_yO_2(cys)_2]^{2-}$ (x=2, y=0; x=y=1; and x=0, y=2), and the electronic state for Mo atom of the $(\mu\text{-}O)_2$ bridge, $(\mu\text{-}O, \mu\text{-}S)$ bridge and $(\mu\text{-}S)_2$ bridge complexes was studied. It has been found that the binding energy of the Mo $3d_{5/2,3/2}$ peaks shifts to a lower value by at most 0.5 eV with increasing the number of μ-S bridges from 0 to 2. On the other hand, those of O 1s, C 1s, N 1s, and S 2s peaks are not significantly affected by bridge substitution. The change in the electronic state of Mo atoms is discussed in terms of the low electronegativity of the S atom.

The structures of binuclear molybdenum(V)–cysteine complexes with oxo and sulfide bridges, $[Mo_2(\mu\text{-}X)(\mu\text{-}Y)O_2(cys)_2]^{2-}$ (X,Y=O or S, cys: $SCH_2CH(NH_2)CO_2$), have been examined though X-ray analyses (Fig. 1) by several investigators, Knox et al.[1] have determined the structure of $Na_2[Mo_2(\mu\text{-}O)_2O_2(cys)_2]\cdot 2H_2O$ (abbreviation: $(\mu\text{-}O)_2$ bridge), Brown et al.[2] have dealt with

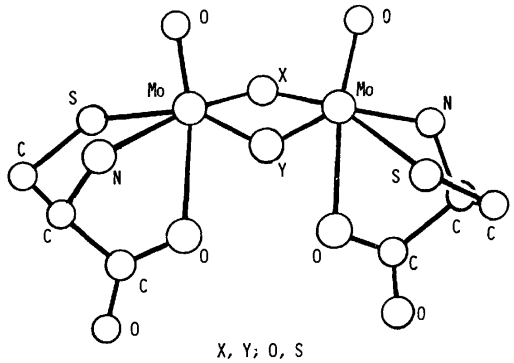

Fig. 1. The structure of $[Mo_2(\mu\text{-}X)(\mu\text{-}Y)O_2(cys)_2]^{2-}$.

$Na_2[Mo_2(\mu\text{-}S)_2O_2(cys)_2]\cdot 5H_2O$ (abbreviation: $(\mu\text{-}S)_2$ bridge), and Shibahara et al.[3] have elucidated the structure of $Ca[Mo_2(\mu\text{-}O)(\mu\text{-}S)O_2(cys)_2]\cdot 3H_2O$ (abbreviation: $(\mu\text{-}O)(\mu\text{-}S)$ bridge). A comparison of data between $(\mu\text{-}O)_2$ and $(\mu\text{-}S)_2$ bridge complexes for the structure allows us to recognize that a complex with a $(\mu\text{-}S)_2$ bridge has longer distances between Mo–Mo and Mo–O_{cys}, and a shorter distance between Mo–O_t than does a complex with a $(\mu\text{-}O)_2$ bridge. This may be due to a difference in the electronic state of Mo atoms between these two complexes.

The present paper deals with the electronic state of the $(\mu\text{-}O)_2$ bridge, the $(\mu\text{-}O)(\mu\text{-}S)$ bridge and $(\mu\text{-}S)_2$ bridge complexes by XPS measurements.

Experimental

Preparation of Complexes. $Na_2[Mo_2(\mu\text{-}O)(\mu\text{-}O)O_2(cys)_2]\cdot 5H_2O$, $Na_2[Mo_2(\mu\text{-}O)(\mu\text{-}S)O_2(cys)_2]\cdot 4H_2O$ and $Na_2[Mo_2(\mu\text{-}S)(\mu\text{-}S)O_2(cys)_2]\cdot 5H_2O$ were prepared according to published procedures.[4]

Measurements. XPS measurements were carried out in a vacuum of around 1.3×10^{-7} Pa with irradiation of Mg $K\alpha$ X-rays ($h\nu$=1253.6 eV) to the sample mounted on a holder with Au-mesh, using a VG ESCA 3 electron spectrometer. The binding energes (E_B) of all peaks was corrected by taking the kinetic energy ($=h\nu-E_B$) of the Na KLL Auger peak to be 990.0 eV, in order to avoid any ambiguity in accurately determining the value of E_B of broad C 1s peaks.

Results and Discussion

In spectra for $Na_2[Mo_2(\mu\text{-}O)(\mu\text{-}O)O_2(cys)_2]\cdot 5H_2O$, $Na_2[Mo_2(\mu\text{-}O)(\mu\text{-}S)O_2(cys)_2]\cdot 4H_2O$, and $Na_2[Mo_2(\mu\text{-}S)(\mu\text{-}S)O_2(cys)_2]\cdot 5H_2O$, there appeared to be O 1s, C 1s, N 1s, S 2p, S 2s, Mo $3d_{5/2}$, Mo $3d_{3/2}$, Mo $3p_{3/2}$, and Mo $3p_{1/2}$ ESCA-peaks and O(KLL), and Na(KLL) Auger-peaks. The binding energy (E_B) and the full width at half

Table 1. Binding Energy (E_B)[a] and Full Width at Half Maximum (FWHM)[b] of Peaks Obtained for Binuclear Molybdenum(V)–Cysteine Complexes

Complex		C 1s	O 1s	S 2p	N 1s	Mo 3d		Mo 3p	
						5/2	3/2	3/2	1/2

	FWHM (eV)	3.4	2.7	2.8	2.5	3.0	2.4	3.4	3.3
$Na_2[Mo_2(\mu\text{-}O)(\mu\text{-}S)O_2(cys)_2]\cdot 4H_2O$	E_B (eV)	285.2	531.6	162.4	400.2	231.2	234.4	396.9	414.5
	FWHM (eV)	3.2	2.6	2.7	2.6	3.0	2.2	3.8	3.4
$Na_2[Mo_2(\mu\text{-}S)(\mu\text{-}S)O_2(cys)_2]\cdot 5H_2O$	E_B (eV)	285.4	531.6	162.3	400.1	230.8	233.9	396.6	414.3
	FWHM (eV)	3.3	2.6	2.6	2.7	2.8	2.0	3.7	3.4

a) The value of E_B for all peaks was corrected by using the kinetic energy of Na KLL Auger peak to be 990.0 eV.
b) The value of FWHM for N 1s, Mo $3d_{5/2}$, Mo $3d_{3/2}$, and Mo $3p_{3/2}$ was obtained by a peak deconvolution with computer analysis.

maximum (FWHM) of the ESCA-peaks are shown in Table 1. All of the examined complexes have relatively broad C 1s peaks, because of a difference in E_B of C 1s between hydrocarbon and carbonyl group in the cysteine ligand. Each complex shows relatively sharp peaks of N 1s, O 1s, and S 2p; these peaks have similar values of E_B and FWHM. This suggests that the O and S atoms included in a different functional group have similar electronic states, and that the electronic states of N, O, and S atoms are not significantly affected by bridge substitution.

The binding energy of Mo $3d_{5/2}$ and Mo $3d_{3/2}$ peaks for the $(\mu\text{-S})_2$ complex is lower by about 0.4 and 0.5 eV than those for the $(\mu\text{-O})(\mu\text{-S})$ and $(\mu\text{-O})_2$ complexes, respectively, and Mo $3p_{3/2,1/2}$ peaks also show about 0.3 eV of chemical shift to the lower binding energy side by substituting $(\mu\text{-S})_2$ for a $(\mu\text{-O})_2$ bridge.[5] This strongly suggests that the electron density for Mo atoms in a $(\mu\text{-S})_2$ complex is higher than that in $(\mu\text{-O})(\mu\text{-S})$ and $(\mu\text{-O})_2$ complexes. The lower electronegativity of the S atom, compared with that of the O atom, could make the electron density for Mo atoms higher, leading to an enhancement of the covalent bonding characteristics of the bridge.

Recently, similar effects of the S atom have been reported for other type of complexes. Ikari et al.[6] examined $[M_2(\mu\text{-X})(\mu\text{-Y})O_2(edta)]^{2-}$ complexes (M: Mo or W; X, Y: O or S) by XPS. They reported that E_B of Mo $3d_{5/2}$ peak for the $(\mu\text{-O})(\mu\text{-S})$ complexes is lower by 1.2 eV than that for the $(\mu\text{-O})_2$ complex, and that W $4f_{7/2}$ peak shifts 1.1 eV lower by substituting $(\mu\text{-S})_2$ bridge for $(\mu\text{-O})_2$ bridge. Shibahara et al.[7] showed a decrease of ca. 2 eV in E_B of the Mo $3d_{5/2}$ peak by replacing O-bridge with S-bridge for $[Mo_3O_{4-n}S_n(NCS)_9]^{5-}$ (n=0—3). Ansari et al.[8] reported that E_B of W $4d_{5/2}$ for $[W_2O_2(\mu\text{-S})_2(S_2CNEt_2)_2]$ is higher by 0.5 eV than that for $[W_2S_2(\mu\text{-S})_2(S_2CNEt_2)_2]$. The chemical shift of the Mo 3d peak observed in this investigation by the bridge substitution seems to be smaller than that reported for the other type of complexes stated above. Thus, the electronic state of the central metal atoms can be appreciably affected by the electronic effect, steric effect, coordination number or configuration of the coordinated ligands in complexes.

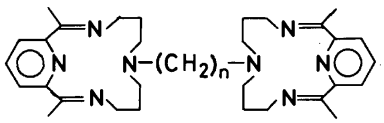
Synthesis of Heterobinuclear Cu(II)Ni(II) Complexes with Bis(tetraazamacrocycle)

Katsura MOCHIZUKI* and Yumiko ENDOH
Department of Chemistry, Yokohama City University, Yokohama 236
(Received September 7, 1988)

Synopsis. A new series of heterobinuclear Cu(II)Ni(II) complexes with bis(tetraazamacrocycle), i.e., 7,7′-polymethylenebis[2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),2,11,13,15-pentaene]copper(II)nickel(II) perchlorates with polymethylene bridges with a length of 2—6-C, were synthesized by a template reaction.

Metal–metal interactions of homobinuclear Cu(II)-Cu(II)[1-4] and Ni(II)Ni(II)[3-6] complexes with bis(tetraazamacrocycle) have been actively studied by means of the ESR spectroscopical,[1-4] magnetical,[1] and electrochemical methods.[2-6] Recently we synthesized the Ni(II)Ni(II) complexes with several ligands, 7,7′-polymethylenebis[2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),2,11,13,15-pentaene](polymethylene = ethylene (L^2), trimethylene (L^3), tetramethylene (L^4), pentamethylene (L^5), and hexamethylene (L^6)), in which two of the same tetraazamacrocycles are linked by polymethylene bridges of various lengths.[6] Our electrochemical study of the Ni(II)Ni(II) complexes revealed that the metal–metel interaction operates when the polymethylene bridge is shorter than that of tetramethylene.[6]



L^2 : n = 2
L^3 : n = 3
L^4 : n = 4
L^5 : n = 5
L^6 : n = 6

In order to investigate the metal–metal interaction of two different metals, a series of heterobinuclear complexes with L^2—L^6 is required. To the best of our knowledge, however, no such heterobinuclear complex has yet been synthesized except for one compound, $[Cu^{II}Ni^{II}(bis(cyclam))]^{4+}$,[4] which was prepared by the addition of Ni(II) and Cu(II) ions to an aqueous solution of a presynthesized ligand, bis(cyclam), i.e., by a complexation reaction.

In this paper we will describe the synthesis of a series of heterobinuclear Cu(II)Ni(II) complexes with L^2—L^6 by the use of a template reaction; this is the first example of the preparation of heterobinuclear complexes with bis(tetraazamacrocycle) by a template reaction.

In seeking for the proper reaction conditions for the preparation of heterobinuclear Cu(II)Ni(II) complexes, the following characteristic results were obtained. (1) When *N,N,N′,N′*-tetrakis(3-aminopropyl)-1,4-butanediamine, hereafter termed a branched polyamine, was added to a solution containing both Cu(II) and Ni(II) ions and 2,6-diacetylpyridine, the mixture immediately turned blue, indicating that the Cu(II) ion is more favorable for the template reaction than the Ni(II) ion. In fact, after the mixture had been kept at 60 °C for 6 h, the homobinuclear Cu(II)Cu(II)[1] complex was isolated as the major product, and the Cu(II)Ni(II) and Ni(II)Ni(II)[6] complexes, as minor ones. (2) When the template reaction was performed without the Cu(II) ion under the conditions used for the preparation of Cu(II)Ni(II) complexes (see Experimental), the expected monomacrocyclic Ni(II) complex, formed by the template reaction on a single side of the branched polyamine, could not be obtained, but the bismacrocyclic Ni(II)Ni(II) complex was. These results suggest that it is difficult to stop the second cyclization reaction and/or to isolate the monocyclic Ni(II) complex. (3) When a solution including equimolar amounts of the Ni(II)Ni(II) complex and the Cu(II) ion was heated at 50 °C for 3 h, no changes occurred, suggesting that the Ni(II) ion in the complex is not replaced by the Cu(II) ion. On the basis of these results, the procedures described in the experimental section were employed for the preparation of Cu(II)-Ni(II) complexes.

Because the template reaction always afforded a mixture of Cu(II)Cu(II),[1] Cu(II)Ni(II), and Ni(II)-Ni(II)[6] complexes, its products should be separated by column chromatography of SP-Sephadex C-25 ion-exchange resin, followed by elution with an aqueous solution of 0.5 mol dm^{-3} NaCl. In every instance of chromatography, the blue Cu(II)Cu(II) complex was eluted first, the reddish-violet Cu(II)Ni(II) complex second, and the orange Ni(II)Ni(II) complex last. This clear separation of the three bands indicates that the second band is not a mixture of the Cu(II)Cu(II) and Ni(II)Ni(II) complexes.

In fact, the complexes isolated from the second band, the Cu(II)Ni(II) complexes, were characterized as follows.

In the IR spectra, all the complexes show distinct bands at about 1620 ($\nu_{C=N}$) and 1580 cm^{-1} (the skeletal vibration of pyridine), but no bands corresponding to $\nu_{C=O}$ and the vibrations of the free amines, indicating a formation of the cyclic ligand by the condensation of diacetylpyridine with branched polyamines.

The presence of Cu(II) and Ni(II) ions in a ratio of 1:1 was determined by polarography. The complexes were decomposed with H_2O_2–H_2SO_4; the subsequent solutions, containing a NH_3–NH_4^+ buffer (pH 10),

showed three waves, at −0.02, −0.32, and −0.87 V vs. Hg-pool, which were assigned to the Cu^{II}/Cu^{I}, Cu^{I}/Cu^{0}, and Ni^{II}/Ni^{0} couples respectively. By a comparison of these wave heights with those of a standard solution containing both Cu(II) and Ni(II) ions, the amounts of the metals were determined (see the elemental analyses in Experimental).

The absorption spectra and differential pulse polarograms (DP) show that the products have two macrocycles of Cu(II) and Ni(II) complexes in the same molecule. Figure 1 shows the absorption spectrum of $[Cu^{II}Ni^{II}(L^4)]^{4+}$ in an aqueous solution; it is practically equal to the sum of the spectrum of $[Ni^{II}_2(L^4)]^{4+}$ and that of $[Cu^{II}_2(L^4)]^{4+}$. The same conclusion was also obtained by differential pulse polarography. Figure 2 shows the DP observed in the oxidation of $[Cu^{II}Ni^{II}(L^4)]^{4+}$ in acetonitrile. The peak of the Ni^{II}/Ni^{III} couple (ca. 1.2 V) is symmetrical, suggesting that the electrode process is quasi-reversible;

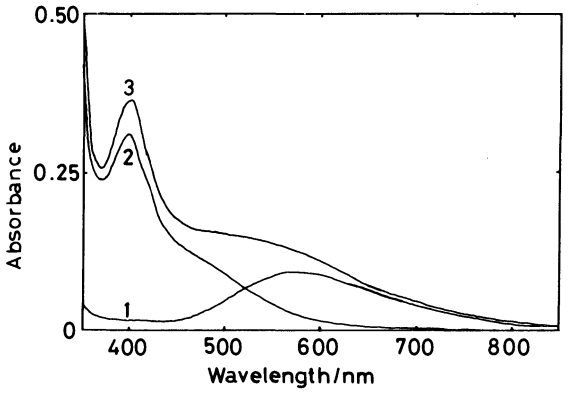


Fig. 1. Absorption spectra of the aqueous solution of $[MM'(L^4)]^{4+}$: 2×10^{-4} mol dm^{-3} M=M'=Cu(II) (1), 2×10^{-4} mol dm^{-3} M=M'=Ni(II) (2), 4×10^{-4} mol dm^{-3} M=Cu(II) and M'=Ni(II) (3). T=25 °C.

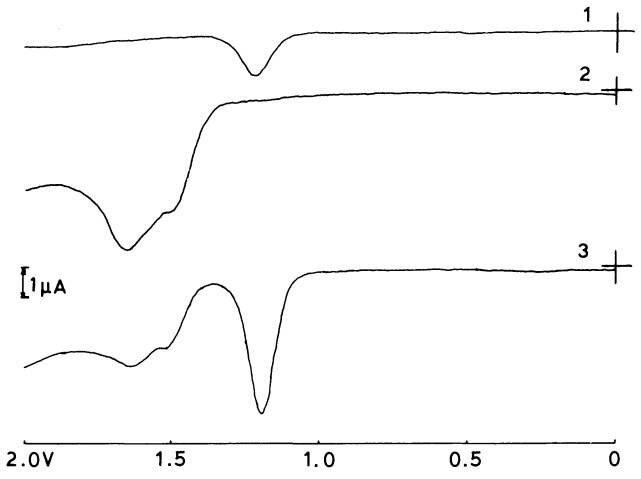

Fig. 2. Differential pulse polarograms (scan rate: 1 mV s^{-1}; pulse amplitude: 10 mV) of $[MM'(L^4)]^{4+}$ in acetonitrile: M=M'=Ni(II) (1), M=M'=Cu(II) (2), M=Cu(II) and M'=Ni(II) (3). V vs. $Ag-Ag^+$ (0.01 mol dm^{-3} $AgNO_3$). Glassy carbon electrode.[11] T= 25 °C.

also, it is well-separated from that of the Cu^{II}/Cu^{III} couple. The DP of $[Cu^{II}Ni^{II}(L^4)]^{4+}$ is again equal to the sum of the DP of $[Cu^{II}_2(L^4)]^{4+}$ and that of $[Ni^{II}_2(L^4)]^{4+}$. Similar results in the absorption spectra and DPs were obtained for the other binuclear complexes prepared herewith.

Thus, the desired heterobinuclear Cu(II)Ni(II) complexes were successfully obtained.[7]

Experimental

Materials. A typical procedure for the preparation of the heterobinuclear complexes was as follows.

2,6-Diacetylpyridine (3.26 g, 0.02 mol) and nickel(II) acetate tetrahydrate (2.49 g, 0.01 mol) were dissolved in 200 cm^3 of ethanol-water (1:1, v/v). To this solution we then added 100 cm^3 of ethanol-water (1:1, v/v) containing *N,N,N',N'*-tetrakis(3-aminopropyl)-1,4-butanediamine (3.22 g, 0.0102 mol) which had been neutralized with acetic acid just before the addition. After the solution had then been stirred for 3.5 h at 60 °C, 100 cm^3 of an ethanol-water (1:1, v/v) solution containing copper(II) acetate monohydrate (2.00 g, 0.01 mol) was added. The mixture was stirred for 4.5 h at 60 °C, left to stand at room temperature for 1 h, evaporated to half of its original volume, and then filtered. To the filtrate we added a saturated aqueous sodium perchlorate solution to obtain dark brown precipitates. The precipitates were suspended in a small amount of water and then the suspension was passed through a column of Cl-form anion-exchange resin (Amberlite IRA410, ϕ=30 mm, l=300 mm) to exchange the counter ions. The resulting clear solution was chromatographed with a cation-exchange column (SP-Sephadex C-25, ϕ=30 mm, l=1250 mm), with 0.5 mol dm^{-3} sodium chloride solution as the eluant, to give three well-separated bands. The first, blue-violet band and the third, reddish-yellow one were assigned to the homobinuclear Cu(II)Cu(II)[1] and Ni(II)Ni(II)[6] complexes respectively by comparison with authentic samples. The second, dark-reddish-purple eluate was concentrated to ca. 20 cm^3. The sodium chloride then precipitated by the addition of ethanol to the solution was filtered off. The same procedure was repeated five times in order to remove all the sodium chloride. The residue thus obtained was dissolved in a minimum amount of water, to which was added a saturated aqueous sodium perchlorate solution to yield microcrystalline precipitates. After dissolving the precipitates in a small amount of hot water, the addition of a small amount of $HClO_4$ gave crystals, which were then washed well with water and dried over P_2O_5 in a vacuum. The absence of chloride ions in the complex was checked by the use of $AgNO_3$.

The physical data of the new compounds are given below. $[Cu^{II}Ni^{II}(L^4)](ClO_4)_4\cdot2H_2O$: Yield: 8%.[8] Found: C, 36.28; H, 4.49; N, 9.91; Cu, 5.5; Ni, 5.1%. Calcd for $C_{34}H_{50}N_8CuNiCl_4O_{16}\cdot2H_2O$: C, 36.24; H, 4.83; N, 9.94; Cu, 5.64; Ni, 5.21%. IR (KBr): 1619 (C=N) and 1580 cm^{-1} (py).

The hexamethylene, pentamethylene, and trimethylene derivatives were prepared by the same procedure except that for using *N,N,N',N'*-tetrakis(3-aminopropyl)-1,6-hexanediamine, *N,N,N',N'*-tetrakis(3-aminopropyl)-1,5-pentanediamine, and *N,N,N',N'*-tetrakis(3-aminopropyl)-1,3-propanediamine were used instead of *N,N,N',N'*-tetrakis(3-aminopropyl)-1,4-butanediamine. In the case of ethylene derivative (*N,N,N'N'*-tetrakis(3-aminopropyl)-1,2-ethanediamine), however, a longer reaction time (8 and 9 h after the addition of the Ni(II) and Cu(II) ions respectively) was required, because only small amounts of macrocyclic products were obtained under the conditions described

above.

$[Cu^{II}Ni^{II}(L^6)](ClO_4)_4 \cdot 2H_2O$: Yield: 10%.[8] Found: C, 37.53; H, 4.72; N, 9.65; Cu, 5.8; Ni, 4.8%. Calcd for $C_{36}H_{54}N_8CuNiCl_4O_{16} \cdot 2H_2O$: C, 37.44; H, 5.06; N, 9.70; Cu, 5.50; Ni, 5.08%. IR (KBr): 1615 (C=N) and 1575 cm^{-1} (py).

$[Cu^{II}Ni^{II}(L^5)](ClO_4)_4 \cdot 2H_2O$: Yield: 8%.[8] Found: C, 36.51; H, 4.64; N, 9.58; Cu, 5.8; Ni, 5.1%. Calcd for $C_{35}H_{52}N_8CuNiCl_4O_{16} \cdot 2H_2O$: C, 36.85; H, 4.95; N, 9.82; Cu, 5.57; Ni, 5.14%. IR (KBr): 1615 (C=N) and 1575 cm^{-1} (py).

$[Cu^{II}Ni^{II}(L^3)](ClO_4)_4 \cdot 2H_2O$: Yield: 8%.[8] Found: C, 35.63; H, 4.44; N, 10.04; Cu, 5.3; Ni, 4.9%. Calcd for $C_{33}H_{48}N_8CuNiCl_4O_{16} \cdot 2H_2O$: C, 35.62; H, 4.71; N, 10.07; Cu, 5.71; Ni, 5.27%. IR (KBr): 1620 (C=N) and 1580 cm^{-1} (py).

$[Cu^{II}Ni^{II}(L^2)](ClO_4)_4$: Yield 27%.[8,9] Found: C, 36.19; H, 4.29; N, 10.38; Cu, 5.5; Ni, 5.1%. Calcd for $C_{32}H_{46}N_8CuNiCl_4O_{16}$: C, 36.16; H, 4.36; N, 10.54; Cu, 5.78; Ni, 5.34%. IR (KBr): 1615 (C=N) and 1585 cm^{-1} (py).

Measurements. The infrared and visible absorption spectra were measured with Hitachi 260-10 and Hitachi 340 spectrophotometers respectively. The electrochemical measurements were performed according to the method described in our previous paper.[10]

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 62740352) from the Ministry of Education, Science and Culture.

7) The product ratios of the Cu(II)Cu(II):Cu(II)Ni(II):Ni(II)Ni(II) complexes were as follows: 0.30:1:0.18 (L^2); 0.12:1:1.1(L^3); 0.23:1:1.0(L^4); 0.48:1:1.2(L^5); 0.28:1:1.4(L^6). If there is no difference in reactivity between Cu(II) and Ni(II) ions, the product ratio can be expected to be 1:2:1. However, the experimental results did not agree with this surmise.

8) The overall yield (isolated after recrystallization) is calculated by assuming that the reaction gave the Cu(II)-Ni(II) complex only.

9) The conditions employed for the preparation of the complexes with L^3—L^6 gave only small amounts of the macrocyclic products. Prolonging the reaction time considerably increased the yield of $[Cu^{II}Ni^{II}(L^2)]^{4+}$. These results might be explained as indicating that the electrostatic repulsion between two metal ions which are located close to each other during the reactions is serious in the case of the ethylene derivatives, thus retarding the template reaction.

Preparation of Bismuth Sulfide Thin Films by Solution Pyrolysis of Bismuth Dithiocarbamate Complexes

Ryoki NOMURA,* Kouichi KANAYA, and Haruo MATSUDA
Department of Applied Chemistry, Faculty of Engineering,
Osaka University, Yamada-Oka, Suita, Osaka 565
(Received October 8, 1988)

Synopsis. Solution pyrolysis of $Bi(S_2CNRR')_3$ in *p*-xylene or chloroform on a glass substrate at 350 °C under Ar atmosphere gave polycrystalline and low resistive (10^2 Ω cm in dark) bismuth sulfide thin films which showed large photoelectric effect.

Bismuth sulfide (Bi_2S_3) is the direct band gap material with E_g of 1.3 eV[1] and useful for photodiode arrays or photovoltaics.[2,3] Preparation of photoconducting Bi_2S_3 thin layers has so far been limited to the physical methods such as vacuum evaporation[4] or sintering.[5] However, to develop the chemical thin film process has been considered to be indispensable to produce large area chalcogenide layers in low cost.[6,7] Thus, some chemical processes such as dip-dry method,[2] chemical liquid deposition (CLD)[7,8] and solution-gas interface technique[9] have already examined, but they generally supplied highly resistive and amorphous Bi_2S_3 films. Recently, we have reported the preparation of several polycrystalline oxide or sulfide thin films via a "solution pyrolysis" technique (printing method) using organometallics[10] and/or metal dithiocarbamate complexes.[11] The printing method is the most convenient procedure for the preparation of thin layers,[11] however, the method remains unemployable state yet bacause of a lack of suitable precursor compounds for Bi_2S_3 layers. Therefore we attempted to prepare Bi_2S_3 films via the solution pyrolysis using bismuth dithiocarbamate complexes ($Bi(S_2CNRR')_3$) on the basis of their thermal analysis data.

Experimental

General. Characterization of the obtained bismuth sulfide films were performed with a Rigaku Rota-flex X-ray diffractometer (Cu $K\alpha$, 40 kV), a Shimadzu ESCA 650B, a Hitachi S-405 type scanning electron microscope (SEM), and a Shimadzu UV-200S spectrophotometer. Resistivity was measured by means of four probe method using a Tycoon 841 type apparatus. Thermal analysis of the bismuth dithiocarbamate complexes was done with a SEIKO TG/DTA 20 type thermal analyzer. Commercial bismuth(III) oxide (Mitsuwa, purity >99.9%) was used without purification. Other reagents and solvents were used after distillation.

Preparation of $Bi(S_2CNRR')_3$. Preparation of $Bi(S_2CNRR')_3$ was conducted with the procedure reported previously.[12] Into a suspension of Bi_2O_3 (6 mmol) in methanol (20 ml), carbon disulfide (50 mmol), and amines (40 mmol) were added dropwise in this order. The mixture was stirred for 19—48 h at room temperature and the resulting yellow precipitates were recrystallized from methanol or chloroform. **$Bi(S_2CNEt_2)_3$**: Mp 194—196 °C (lit,[13] 194—195 °C); IR (KBr) 1490 cm^{-1}. **$Bi(S_2CNBu^n_2)_3$**: Mp 98—99 °C; IR (KBr) 1480 cm^{-1}; Found: C, 39.42; H, 6.60; N, 5.11; S, 23.42%. Preparation of Bismuth Sulfide Films by Solution Pyrolysis Method. A detailed technique for the solution pyrolysis was reported previously.[10,11] About a 100 μl of 10 wt-% solution of $Bi(S_2CNRR')_3$ in the prescribed solvent was dropped onto a glass substrate (IWAKI Code 2926 WSLID-P, 76×26 mm) and spread over the whole surface by tipping. Thus the substrate was heated in a quartz tube under Ar atmosphere. A heating sequence was as follows: 1) 100 °C for 1 h, 2) cooling to room temperature, 3) 250—350 °C for 1 h. Chloroform and *p*-xylene were selected as the solvents for $Bi(S_2CNEt_2)_3$ and for $Bi(S_2CNBu^n_2)_3$ and $Bi(S_2CNHex^n_2)_3$, respectively.

Results and Discussion

We first investigated on the thermal properties of $(BiS_2CNRR')_3$, in order to optimize the process for

$Bi(S_2CNHBu^i)_3$	100	218	55.6 (60.7)	146

a) Conditions: instrument, SEIKO TG/DTA 20; N_2 flow; heating program, 10 °C min^{-1}, rt—500 °C. b) Values of total %-weight loss are presented. Calcd means the weight loss to give Bi_2S_3 and is indicated in the parentheses. c) Underlined temperatures showed the melting points.

preparation of Bi_2S_3 films, and the results are summarized in Table 1. It was found that the $Bi(S_2CNRR')_3$ employed here decomposed with endotherms. Three dialkyl derivatives decomposed at around 310—330 °C and gave Bi_2S_3 powders quantitatively till 350 °C. While $Bi(S_2CNHBu^i)_3$ decomposed at ca. 150 °C and also gave Bi_2S_3 powders. Although $Bi(S_2CNHBu^i)_3$ seemed to be a more suitable precursor for the preparation of Bi_2S_3 only from its decomposition temperature, it decomposed with a significant degree of vaporization, and its solubility was too low to use in the solution pyrolysis. Therefore, we investigated to prepare Bi_2S_3 films using the dialkyldithiocarbamate complexes.

If the solution on the substrate was directly heated at the pyrolysis temperatures (250—350 °C), only Bi_2S_3 powders deposited and no film was obtained. While, a "preheating" at 100 °C for 1 h which preceded the calcination was found to be effective to inhibit the formation of powders and the two step heating process gave smooth and homogeneous thin layers. In the following discussion, the term "temperature" will indicate the second step temperature.

The X-ray diffraction patterns of the obtained films are displayed in Fig. 1. The intensities of the diffraction peaks increased with temperature rising from 250 to 350 °C. The Bi_2S_3 films obtained from $Bi(S_2CNBu^n_2)_3$ at 350 °C possessed the polycrystalline texture as shown in Fig. 2. The surface morphology of this film rather resembled the vacuum-evaporated Bi_2S_3 films[9] than those obtained by CLD method.[7a] Observation by ESCA on the surface and the cross sectional composition indicated that the film was the stoichiometric Bi_2S_3.

Generally, it is well-known that the Bi_2S_3 films prepared by the chemical process show high resistivity (10^6—10^{13} Ω cm) and low sensitivity of the photoelectric response.[2,3,7] In contrast, the Bi_2S_3 films obtained by the solution pyrolysis of $Bi(S_2CNRR')$ in this study possessed relatively low resistivity (10^{2-3} Ω cm in dark) as shown in Table 2. It is obvious that the degree of the photoelectric effect increases with an increase of the crystallinity. The specimen prepared from $Bi(S_2CNBu_2)_3$ at 350 °C showed the largest photoelectric response and the difference of the dark and the light resistivities was found to be more than two orders of magnitude. In addition, optical band gap energy $(E_g)_{opt}$ of this sample was also estimated to be 1.40 eV by UV-visible spectrometry, which was lower than those of the Bi_2S_3 films obtained by other chemical method (1.47—1.65 eV)[3,5] and slight larger than the value for single crystal (1.3 eV).[1]

Thus, polycrystalline and low resistive Bi_2S_3 thin films can be conveniently prepared from bismuth

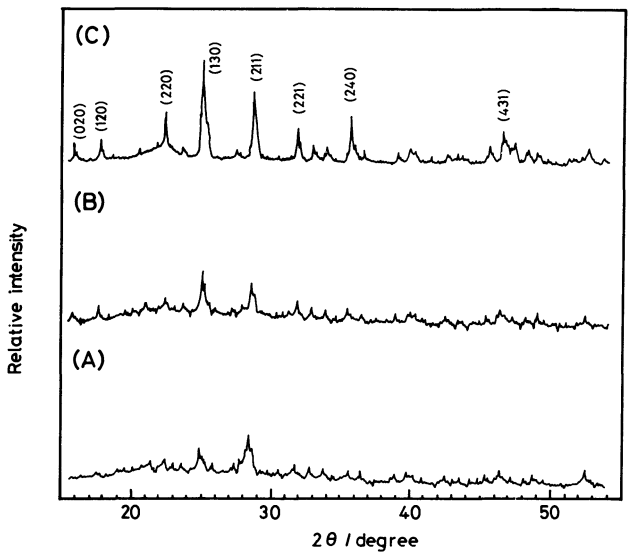

Fig. 1. Typical X-ray diffraction patterns of as-deposited bismuth sulfide thin films obtained by solution pyrolysis of $Bi(S_2CNBu^n_2)_3$ at 250 °C (A), 300 °C (B), and 350 °C (C), under Ar atmosphere for 1 h.

dithiocarbamate complexes by solution pyrolysis at 350 °C under Ar atmosphere. In addtion, preparation of Bi_2S_3 films is now feasible under the innert atmosphere such as Ar without the use of the hazardous sulfuration reagents such as H_2S and CS_2 which are necessary in other chemical process to maintain the Bi_2S_3 stoichiometry.[2,3,7,8]

Asymmetric Hydrogenation Using Diphenylphosphinite Derivatives of Carbohydrates as the Chiral Ligand of Rhodium Catalysts

Mitsuji YAMASHITA,* Manabu NAOI, Hiroyuki IMOTO, and Tatsuo OSHIKAWA
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
(Received March 26, 1988)

Synopsis. Diphenylphosphinite derivatives of carbohydrates (L-rhamnose, D-mannitol, and cellulose), which have asymmetric centers on the skeletons were synthesized. Asymmetric hydrogenations of prochiral substrates using rhodium catalysts with the prepared chiral phosphinite ligand were carried out to obtain chiral substances in 8—78% optical yield.

Monosaccharides have several chiral carbon atoms in their skeletons, however, their applications to homogeneous asymmetric hydrogenation are found only in several papers.[1-6] Cellulose, which widely exists in nature, is one of the most important naturally occurring resources and will work as a functional polymer, however, the investigation to apply the chirality to asymmetric induction are very much limited. As the result, the application of a bisphosphinite of cellulose to a chiral ligand for the rhodium catalyst was reported.[7]

In our preceding paper we reported the asymmetric hydrogenation of prochiral unsaturated acid derivatives to afford the corresponding saturated acid derivatives in an optical yields up to 100%, where methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphino)-α-L-rhamnopyranoside was revealed to be a good ligand for di-μ-chloro-bis(cyclooctadiene)dirhodium(I) catalyst.[6b] In this note we tried to clarify the efficiency of asymmetric hydrogenation catalysts in comparison with the preparative methods for the catalyst as well as the structure to spread the utility of carbohydrate ligands for asymmetric inductions.

Results and Discussion

Synthesis of Carbohydrate Ligands. Methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphino)-α-L-rhamnopyranoside (**1**) was prepared by the reaction of the anion of methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside with diphenylphosphinous chloride in ether, compound **1** thus prepared being agreed with that reported.[6b] 1,2:5,6-Di-*O*-isopropylidene-3,4-di-*O*-(diphenylphosphino)-D-mannitol (**2**) was prepared from 1,2:5,6-di-*O*-isopropylidene-D-mannitol by an action of diphenylphosphinous chloride in the presence of triethylamine (Eq. 1). 2,3,6-Tri-*O*-(diphenylphosphino)cellulose (**3**) was prepared from cellulose and diphenylphosphinous chloride in the presence of pyridine (Eq. 2).

1 4

Asymmetric Hydrogenation of Prochiral Substrates. Asymmetric hydrogenation of prochiral substrates such as (*Z*)-α-acetylaminocinnamic acid, methyl (*Z*)-α-acetylaminocinnamate, (*Z*)-α-benzoylaminocinnamic acid, itaconic acid, dimethyl itaconate, tiglic acid, and acetophenone was carried out. The hydrogenation using rhodium(I) perchlorate catalyst **4** proceeded in 100% chemical yield for such a substrate as (*Z*)-α-acetylaminocinnamic acid to afford *N*-acetylphenylalanine ethyl ester. The optical yield was 54% with *R* configuration, being improved in optical yield over the previous work.[6b] The results are shown in Table 1. The complex was effective enough for the asymmetric hydrogenation, however, the chemical yields were not improved.

The asymmetric hydrogenation of prochiral olefins using di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and mannitol **2** or cellulose **3** gave the results summarized in Table 2.

These results suggest that the cellulose ligand seems not to bring about a good asymmetric induction enough toward prochiral olefins owing mainly to its poor coordinating power to the rhodium catalyst because of its bulkiness, which cancels the merit of cellulose ligand in the hydrogenation procedure. Asymmetric hydrogenation of prochiral olefins with rhodium(I) catalysts having a cyclic carbohydrate ligand was expected to proceed excellently, because the tetrahydropyran ring has more rigid conformation

Table 1. Asymmetric Hydrogenation of Prochiral Substrates with $\{Rh(C_8H_{12})[1]_2\}^+ClO_4^-$ (4)[a]

Substrate	Product	Chemical yield/%	$[\alpha]_D$/° (Solvent)	Optical yield/%[b]	(Configuration)
(*Z*)-α-Acetylaminocinnamic acid	*N*-Acetylphenylalanine ethyl ester[c]	100	−7.4 (*c* 0.85, EtOH)	54	(*R*)
Methyl (*Z*)-α-acetylaminocinnamate	*N*-Acetylphenylalanine methyl ester	50	−6.8 (*c* 1.02, MeOH)	32	(*R*)
(*Z*)-α-Benzoylaminocinnamic acid	*N*-Benzoylphenylalanine	53	+12.5 (*c* 0.28, MeOH)	31	(*R*)
Itaconic acid	Methylsuccinic acid	50	−13.3 (*c* 0.84, EtOH)	78	(*S*)
Dimethyl itaconate	Dimethyl methylsuccinate	96	−4.5 (*c* 0.96, EtOH)	73	(*S*)
Tiglic acid	2-Methylbutyric acid	60	+1.5 (*c* 0.77, EtOH)	8	(*R*)
Acetophenone	1-Phenylethanol	21	+19.4 (*c* 0.33, CH_2Cl_2)	37	(*R*)

a) The ratio of the substrate to the Rh complex was 25:1. All hydrogenations were carried out in 2 ml of benzene–ethanol (1:1) for 24 h at room temperature under atmospheric pressure of hydrogen in the presence of Et_3N (0.04 ml). b) Calculated on the basis of reported values of specific rotation for the optically pure compouds: (*S*)-*N*-acetylphenylalanine ethyl ester,[9] (*S*)-*N*-acetylphenylalanine methyl ester,[9] (*S*)-*N*-acetylphenylalanine,[10] (*S*)-*N*-benzoylphenylalanine,[11] (*R*)-methylsuccinic acid,[1] dimethyl (*R*)-methylsuccinate,[12] (*S*)-2-methylbutyric acid,[13] and (*S*)-1-phenylethanol.[14] c) Ethyl esterification proceeded at the deionization process of the catalyst with Dowex 50W (H^+).

Table 2. Asymmetric Hydrogenation of Prochiral Olefins with $[Rh(C_8H_{12})Cl]_2$ and Ligand **2** or **3**[a]

Substrate	Ligand	Product	Chemical yield/%	$[\alpha]_D$/° (Solvent)	Optical yield/%[b]	(Configuration)
(*Z*)-α-Acetylaminocinnamic acid[c]	**3**	*N*-Acetylphenylalanine	100	−3.8 (*c* 0.32, EtOH)	8.2	(*R*)
Methyl (*Z*)-α-acetylaminocinnamate[c]	**3**	*N*-Acetylphenylalanine methyl ester	100	+3.4 (*c* 1.39, MeOH)	16	(*S*)
(*Z*)-α-Benzoylaminocinnamic acid[c]	**3**	*N*-Benzoylphenylalanine	43	−3.6 (*c* 0.73, MeOH)	9.0	(*S*)
Itaconic acid	**2**	Methylsuccinic acid	50	−13.3 (*c* 0.84, EtOH)	78	(*S*)
Dimethyl itaconate[c,d]	**3**	Dimethyl methylsuccinate	100	+2.3 (*c* 1.00, EtOH)	38	(*R*)
Dimethyl itaconate	**2**	Dimethyl methylsuccinate	50	−1.2 (*c* 0.50, EtOH)	20	(*S*)

a) The ratio of the ligand to the Rh complex was 4:1. The reaction conditions were the same as that of Table 1 except otherwise noted. b) Calculated on the basis of the reported values of specific rotation for the optically pure compounds in Table 1. c) Conducted in 4 ml of the solvent. d) Conducted at 30°C under 50 atm of hydrogen.

than cyclohexane ring.[7] Ligands with less rigid and/or less soluble framework in solvents did not afford any good results in the asymmetric hydrogenation.

Experimental

Measurements. ^1H NMR spectra were measured on a Hitachi R-24B (60 MHz) spectrometer with tetramethylsilane as an internal standard, mass spectra were measured on a Hitachi RMU 7MG GC-MS spectometer, and IR spectra on a Japan Spectroscopic Co., Ltd. A-3 infrared spectrophotometer. Optical rotations were measured on Japan Spectroscopic Co., Ltd. DIP-4 digital polarimeter. Melting and boiling points were uncorrected.

Materials. The following materials were synthesized according to reported methods: di-μ-chloro-bis(cyclooctadiene)dirhodium(I),[6a] methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside,[6a] and 1,2:5,6-di-*O*-isopropylidene-D-mannitol.[8]

Synthesis of (Cyclooctadiene)bis[methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphino)-α-L-rhamnopyranoside]rhodium(I) Perchlorate (4). To a mixture of di-μ-chloro-bis(cyclooctadiene)dirhodium(I) (0.30 g) in dichloromethane (6 ml) and sodium perchlorate (0.15 g) in water (6 ml) was added methyl rhamnopyranoside **1** (1.0 g). The mixture was stirred for 5 h at room temperature. The reaction mixture was washed with water (6 ml×3) and the organic layer was dried over anhydrous sodium sulfate. Concentration of the solvent up to 2 ml followed by addition of cyclohexane (30 ml) gave precipitates (0.18 g), which was filtered off. Concentration of the mother liquid up to 2 ml followed by addition of hexane (20 ml) gave the cationic rhodium catast (**4**, 0.13 g) in 13% yield, mp 135 °C.

^1H NMR ($CDCl_3$) δ=1.0—1.7 (m, 18H, $2C(CH_3)_2$, $2CHCH_3$), 2.0—2.4 (m, 8H, C_4H_8), 3.4—4.3 (m, 8H, $2C_{2,3,4,5}$-H), 4.4—5.0 (m, 4H, C_4H_4), 5.35 (s, 2H, $2C_1$-H), 7.1—8.2 (m, 20H, 4Ph).

Synthesis of 1,2:5,6-Di-*O*-isopropylidene-3,4-di-*O*-(diphenylphosphino)-D-mannitol (2). Reaction of 1,2:5,6-di-*O*-isopropylidene-D-mannitol (0.50 g, 1.9 mmol) with diphenylphosphinous chloride (0.42 g) (0.92 mmol) in the presence of triethylamine (2 ml) for 48 h at room temperature followed

by filtration and evaporation gave **2** (0.50 g) in 44% yield.

^{1}H NMR ($CDCl_3$) δ=1.25, 1.35 (2s, 12H, $2C(CH_3)_2$), 3.5—4.3 (m, 8H, $2CH_2CHCH$), 7.0—8.2 (m, 20H, 4Ph); Found: C, 46.11; H, 6.23%. Calcd for $C_{36}H_{40}O_6P_2$: C, 46.46; H, 6.39%.

Synthesis of 2,3,6-Tri-*O*-(diphenylphosphino)cellulose (3). Reaction of cellulose (1.0 g) with diphenylphosphinous chloride (3.7 g) in pyridine (30 ml) for 8 d at room temperature followed by washing the reaction mixture with ethanol, separation of the product by successive centrifuging and decantation, and evaporation of the solvent in vacuo gave **3** (1.8 g) in 43% yield.

IR ν_{max} (neat, cm^{-1}) 1440 (P-Ph), 1020 (P-O-C), but no OH absorption.

Asymmetric Hydrogenation of *N*-Acetylaminocinnamic Acid with Cationic Rhodium(I) Perchlorate Catalyst 4. Asymmetric hydrogenation of *N*-acetylaminocinnamic acid (1.0 g) was carried out in dried benzene–ethanol (1:1 v/v, 2 ml) in the presence of rhodium catalyst **4** (21.8 mg, 0.82 mmol) and triethylamine (0.04 ml) for 24 h at room temperature under hydrogen atmosphere. Removal of the rhodium catalyst from the reaction mixture with ion-exchange resince Dowex 50 W (H^+ form, 10 g), where ethyl esterification proceeded quantitatively, followed by decolorization with active charcoal and evaporation of the solvent in vacuo afforded *N*-acetylphenylalanine ethyl ester (0.12 g) in 100% conversion. The structure of the product was confirmed by ^{1}H NMR,[6a] $[\alpha]_D^{13}$=−7.4° (*c* 0.85, EtOH), optical yield 54% with *R* configuration [lit,[9] for (*S*)-*N*-acetylphenylalanine ethyl ester $[\alpha]_D^{20}$=+13.8° (*c* 2.0, 95% EtOH)].

Asymmetric Hydrogenation of *N*-Acetylaminocinnamic Acid with Di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and Cellulose 3. Asymmetric hydrogenation of *N*-acetylaminocinnamic acid (1.0 g) was carried out in dried benzene–ethanol (1:1 v/v, 4 ml) in the presence of di-μ-chloro-bis(cyclooctadiene)dirhodium(I) (1.0 mg, 0.020 mmol), cellulose **3** (29 mg), and triethylamine (0.04 ml) for 24 h at 30 °C under 50 atm of hydrogen in autoclave. Removal of the rhodium catalyst from the reaction mixture by filtration followed by decolorization with active charcoal and evaporation of the solvent in vacuo afforded *N*-acetylphenylalanine (0.077 g) in 100% conversion. The structure of the product was confirmed by ^{1}H NMR,[6b] $[\alpha]_D^{12}$=−3.8° (*c* 0.32, EtOH), optical yield 8.2% with *R* configuration [lit[10] for (*S*)-*N*-acetylphenylanine $[\alpha]_D^{26}$=+46.0° (*c* 2.0, EtOH)].

Hydrolysis of Spiro Derivatives that Undergo No Shrinkage on Polymerization

Hirotaka TAGOSHI† and Takeshi ENDO*
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227
†Oita Research Laboratory, Showa Denko K. K., 2 Nakanosu, Oita-shi 870-01
(Received June 4, 1988)

Synopsis. Acid-catalyzed hydrolyses of spiroorthoeters (**1**, **2a**, **2b**, and **2c**) and spiroorthocarbonates (**3** and **4**) were carried out to give the corresponding ring-opening reaction products. The ring-cleavage modes of these spiro derivatives depended on the structure of intermediate cations.

Cationic ring-opening polymerization of spiroorthoesters (SOE)[1,2] and spiroorthocarbonates (SOC),[3-6] which undergo no shrinkage in volume on polymerization, affords the poly(ester–ether)s and poly(carbonate–ether)s, respectively. Radical ring-opening polymerization, and polyaddition of unsaturated spiroorthoesters (USOE)[7] or spiroorthocarbonates (USOC)[8] have been reported. Although, each of SOE, SOC, USOE, and USOC is rather labile to moisture, there is few report on the hydrolysis of them, i.e. hydrolysis of cyclic dialkoxy orthoesters by Deslongchamps and et al.[13] and that of benzospiroorthoesters via dialkoxycarbocation intermediate by McClelland and Moreau.[14]

In this paper, we describe hydrolyses of some spiro derivatives in order to demonstrate the stability of these spiro monomers to water, and to clear the ring-cleavage mode of USOE and USOC.

Results and Discussion

As indicated in Scheme 1, there are two possible modes (a and b) of decomposition of intermediates (**6a** and **6b**) producing hydroxy esters **7a**, **7b**, and lactone **8** in hydrolysis of SOE. Actually, the mixture of **7a** and **7b** was obtained by the hydrolysis of SOE **1**, but **8** not at all. This result shows that the reaction proceeds via mode a only and further lactonization of the produced hydroxy esters does not occur.

In the hydrolysis of USOE **2**, there are two possible initial intermediates **9** and **13**. The former may give hydroxy ester **12**, and the latter, ester **16** via mode a (Scheme 2). The exclusive formation of **12** (Table 1) suggests that the intermediate **9** is more stable than **13** because of conjugate structure of cation.

There are two possible modes of decomposition of intermediate **11** which eventually affords **12** via mode a or lactone **17** and hydroxyacetone **18** via mode b. The hydrolysis of **2a** produced immediately corresponding **12a** accompanied by large amount of **17a**. **12a** can give the lactone under the similar conditions, but this

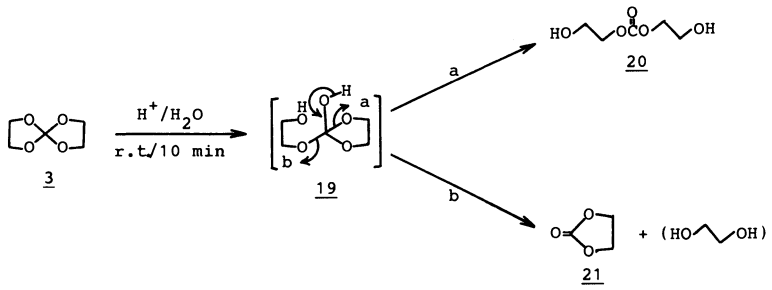
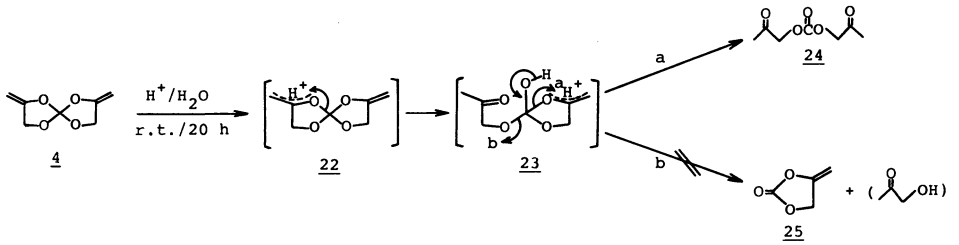


Scheme 3.



Scheme 4.

process is relatively slow.[15)] Therefore, the hydrolysis of **2a** proceeds via both modes a and b. The hydrolysis of **2b** initially (60 min) gave the corresponding hydroxy ester **12b**, but finally (20 h) lactone **17b** quantitatively. Meanwhile, the hydrolysis of **2c** produced only **12c**. In conclusion, the mode of the hydrolysis of USOE including subsequent lactonization depends upon the structure (possibly upon the ring size) of spiro derivatives.

The hydrolysis of SOC **3** was completed in 10 min to give **20** and **21** in 24% and 56% yields, respectively (Scheme 3). This behavior of **3** is very similar to that of SOE (Scheme 1). The less selectivity in this hydrolysis is in good accordance with the results of cationic ring-opening polymerization of **3** which afforded a mixture of poly(ether-carbonate) and polyether with the elimination of **21**.[3)]

In contrast to **3** USOC **4** having bidenticle exomethylene groups was hydrolyzed to give only **24** via mode a. As shown in Shceme 4, decomposition of intermediate **23** take place via protonation of vinyl ether group followed by ring cleavage.

Experimental

Preparation of Spiroorthoester Derivatives. SOE **1** and USOEs (**2a**, **2b**, and **2c**) were prepared by the method reported earlier.[7,16)]

2b: colorless liquid; bp 52—54 °C/0.4 mmHg (1 mmHg= 133.322 Pa); IR (neat) 1693 (C=C), 1284, 1188, 1168, 1141, 1115, 1068, 1041, and 1018 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.7—4.3 (3H, m), 4.0—3.7 (3H, m), 2.1— 1.8 (2H, m), 1.0—1.7 (3H, m), and 0.99 (3H, d, J=6.3 Hz); ^{13}C NMR ($CDCl_3$) δ=155.3, (121.2*), 120.8, 79.7, (79.2*), (66.5*), 65.3, (64.5*), 64.4, 39.6, 32.8, (28.0*), 27.9, and 21.7 (*: chemical shift of

minor isomer); Anal. ($C_9H_{14}O_3$) C, H.

Preparation of Spiroorthocarbonate Derivatives. The preparation of **3**[17] and **4**[11] was carried out according to the procedure reported previously.

Hydrolysis (General Procedure). A solution of spiro derivative and a few drops of aq HCl (6 mol dm^{-3}) in THF or THF-H_2O were stirred at ambient temperature. The reaction was monitored by GC. The reaction mixture was quenched by adding a few drops of saturated aq $NaHCO_3$, dried over $MgSO_4$, and evaporated.

7a and 7b: separated by silica gel preparative TLC (ethyl acetate as eluent); quantitative yield; IR (neat) 3400 and 2940 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.23 (2H, d, J=7 Hz)*, 4.22 (2H, d, J=6 Hz)*, 4.08 (1H, m) 3.68 (2H, t, J=7 Hz), 3.64 (2H, d, J=6 Hz), 3.12 (1H, br s, -OH), 2.40 (2H, t, J=7 Hz)**, 2.32 (2H, t, J=7 Hz)**, 1.92 (1H, br s, -OH), and 1.2—1.8 (6H, m) (*, **: chemical shift of **7a** or **7b**). **12a**: colorless liquid, 15%; bp 125 °C/0.55 mmHg (Kugelrohr); IR (neat) 3400 and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.68 (2H, s), 3.68 (2H, t, J=6 Hz), 2.73 (1H, br s), 2.56 (2H, t, J=7 Hz), 2.17 (3H, s), and 1.91 (2H, tt, J=7 Hz, 6 Hz); ^{13}C NMR ($CDCl_3$) δ=202.0, 173.1, 68.2, 61.4, 30.4, 27.6, and 26.0; HRMS Found: m/z 160.0730. Low-Temperature Coal Liquefaction in Basic Nitrogen Compounds

Hideyuki TAGAYA,* Akira SAITO, and Koji CHIBA*
Department of Applied Chemistry, Faculty of Engineering,
Yamagata University, Jonan, Yonezawa 992
(Received August 1, 1988)

Synopsis. A high conversion (75%) of Taiheiyo coal was attained using indole at 300 °C. Morpholine and tetrahydroquinoline were also effective solvents although quinoline, aniline, and triethylamine were not effective as well as tetralin and 1-methylnaphthalene. Extraordinarily high SRC yields and their molecular weight distributions suggested the presence of a solvent dimer and hydrogen donation.

We have already reported that the conversion exceeded 80% when the Taiheiyo coal was liquefied at 300 °C for 10 h using butylamine as a solvent.[1] The presence of low molecular weight compounds in coal has been proven by the fact that coal solubilization was proceeded by mild alkylation.[2a] It was suggested that the substitution reaction of butylamine with hydroxyl groups of coal contributed to the rupture of non covalent bonds, such as hydrogen bonds between coal molecules. The undesirable condensation or polymerization reactions of coal fragments can be avoided by liquefaction at low temperatures,[3] and the chemical structures of liquefaction products which were obtained at mild conditions provide important information about coal structure.[2]

We examined the coal-liquefaction reaction with basic nitrogen compounds other than butylamine to obtain information about a liquefaction mechanism at low temperature.

Experimental

Coal Samples and Solvents. Four coals were used in this study. Analyses of these coals are given in Table 1. The coals were ground so as to pass through a 100 mesh (149 m) screen and dried at 107 °C in a nitrogen atmosphere. Reagent-grade tetralin was used after distillation under reduced pressure. Various solvents were reagent grade.

Coal Liquefaction Procedure. Coal (6 g) and solvent (18 g) were placed in a 100 ml magnetically stirred autoclave and pressurized to 3 MPa with nitrogen. Materials remaining in the autoclave after liquefaction were extracted with benzene. Any benzene-insoluble material was further extracted with tetrahydrofuran (THF). Conversion to a THF-extractable material was calculated according to the following equation:

conversion (wt%, daf basis) = 100 × (weight of coal charged−weight of THF-insoluble material)/weight of daf coal

The liquefaction solvent was recovered from the benzene extract by vacuum distillation at 240 °C and 933 Pa. The distillation residue was weighed as a solvent-refined coal (SRC):

SRC yield (wt%, daf coal basis) = 100 × weight of SRC/weight of daf coal

Analysis of SRC. For the measurement of molecular weight distributions of SRC, gel permeation chromatography (GPC) was used. In the GPC measurement, THF was used as the liquid phase and a refractometer and a UV detector (254 nm) were used for monitoring the effluents from the columns.

Results and Discussion

The conversion of Taiheiyo coal at 300 °C are shown in Fig. 1. We already reported that tetralin scarcely donated hydrogen to coal at 300 °C.[1] Tetralin seems to act only as a diluent. Furthermore, conversions using 1-methylnaphthalene, quinoline, aniline, and triethylamine as solvents were almost the same with that using tetralin. However, higher conversions than these were obtained when indole was used as the solvent. The conversion reached to 75% for a liquefaction of 10 h. Conversions using tetrahydroquinoline and morpholine were also higher than that using tetralin, although they were lower than that using indole.

The liquefaction of subbituminous coal (Wyodak coal) using indole and a high conversion of the coal (62% at 375 °C, 20 min) have already been reported by Padrick and Lockwood, although the reaction temperature was higher than 300 °C.[4] When butylamine was used as the liquefaction solvent, coal conversion depended upon the hydroxyl oxygen content of coal,[1] as shown in Table 2. The conversion tended to increase, generally, with an increase in the hydroxyl content of coal in the case of butylamine. We tried to liquefy different kinds of coal using indole. The

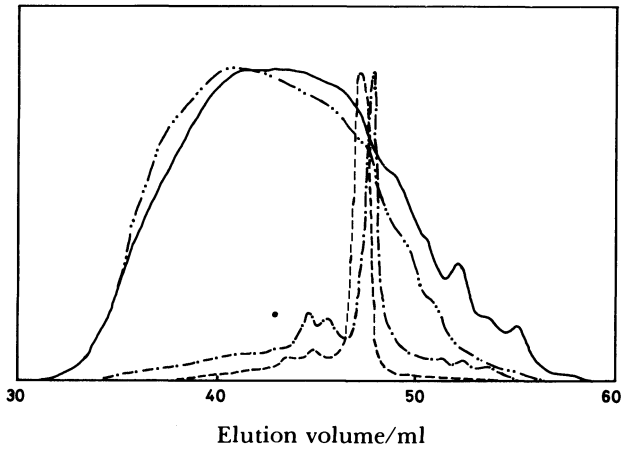

Fig. 2. Molecular distributions of Taiheiyo coal SRCs measured by a GPC UV detector. Solvents were tetralin (————), indole (— — — —), tetrahydroquinoline (— — — —), morpholine (— · — · —).

results are also given in Table 2. Coal conversions using indole at 300 °C for 1 h liquefaction were in the range from 23—30% and scarcely affected by coal rank. Indole was a more effective solvent than butylamine for Miike coal liquefaction, whose hydroxyl content was the smallest in four coals. This fact indicated that the liquefaction mechanism in indole was different from that in butylamine.

SRC yields using indole were higher than the conversions and exceeded 100% when Taiheiyo coal was liquefied for 5 and 10 h; the yields were 120 and 177%, respectively. The extraordinarily large SRC yields indicate the presence of an incorporation reaction of indole to coal or the oligomerization of indole. The molecular weight distributions of the SRCs are shown in Fig. 2. The SRCs were obtained in the liquefaction of Taiheiyo coal at 300 °C using tetralin, indole, tetrahydroquinoline, and morpholine; the yields (reaction time and conversion) were 3.0 (1 h, 5.7%), 90.3 (1 h, 23.5%), 95.5 (10 h, 40.4%), and 86.3% (10 h, 43.6%), respectively. Smooth molecular weight distributions were observed when tetralin and morpholine were used as the solvents and the same with that when butylamine was used.[1] However, clear peaks which did not arise from the solvents themselves were observed when indole and tetrahydroquinoline were used.

Padrick and Lockwood reported the presence of a new peak in the product distribution of coal using indole, and concluded that the peak could be assigned as a complex between two indole molecules and one coal molecule with a molecular weight of 400.[4] However, we could not believe the above mechanism since the liquefaction products of coal had a wide range molecular weights.

It had already been reported that the heating of indole with sulfur produced an indole dimer.[5] We tried a reaction of indole and sulfur and confirmed that the elution volume of the dimer corresponded with that of the peak in Fig. 2. Furthermore, from the mass spectroscopy of the SRC the presence of the indole dimer was confirmed; its molecular weight was 232. This indicated that two indoles dimerized, evolving two hydrogen. The dimerization was also supported from the H/C values of the SRCs. The H/C of SRC in indole was 0.86; this value was fairly smaller than 1.15 in tetralin and also than 0.88 of indole itself. We could not determine the structure of indole dimer;[6] however, the presence of a dimer suggested that indole donated hydrogen to coal and dimerized. The same mechanism should be applied to liquefaction using tetrahydroquinoline. The presence of biquinoline in the reaction products under liquefaction conditions had already been reported.[7] The peak in Fig. 2 must be due to biquinoline.

To clarify the mechanism, the hydrogen donor ability of indole was measured using anthracene as a

hydrogen acceptor.[8] When indole (3 g) and anthracene (3 g) was reacted at 300 °C for 1 h, 6% of the anthracene was hydrogenated to dihydroanthracene, although no anthracene was hydrogenated when tetralin was reacted with anthracene at 300 °C for 1 h.[8b] ESR studies of Petrakis and Grandy indicated that the radical concentration increased from low temperatures at 300 °C.[9] It is suggested that coal fragmentation at low-temperature occurred. It was considered that some part of the coal fragmented even at 300 °C and that the fragments were stabilized by the hydrogen donation of indole.

We already confirmed that the hydrogen donor ability of butylamine was not so large.[1] The molecular weight distribution of SRC in morpholine was smooth (Fig. 2) as with that in butylamine. An incorporation reaction in preference to dimerization was suggested because the SRC yields were larger than coal conversion and no dimer was observed by GPC and mass spectroscopy analysis. The same liquefaction mechanism as that in butylamine was considered.

In the low-temperature liquefaction of coal using butylamine, it was suggested that the substitution reaction of butylamine with hydroxyl groups in coal caused the rupture of noncovalent bonds in coal.[1] The same liquefaction mechanism was suggested in liquefaction using morpholine as a solvent. Furthermore, Mayo et al. carried out extractions and reactions of coals below 100 °C and proposed that pyridine and several amines cleaved some of the coal network to a soluble material.[10] This study suggested that the hydrogen donor abilities of basic nitrogen compounds, like indole and tetrahydroquinoline, were higher at low temperatures (like 300 °C) than expected. It was considered that at low temperature, coal solubility was attained by the complex actions of basic nitrogen compounds expressed above, such as a disruption of noncovalent bonds between coal molecules by a substitution reaction and hydrogen donation to coal fragments.

The authors would like to express their gratitude to Mr. Jouji Sugai for his technical assistance.

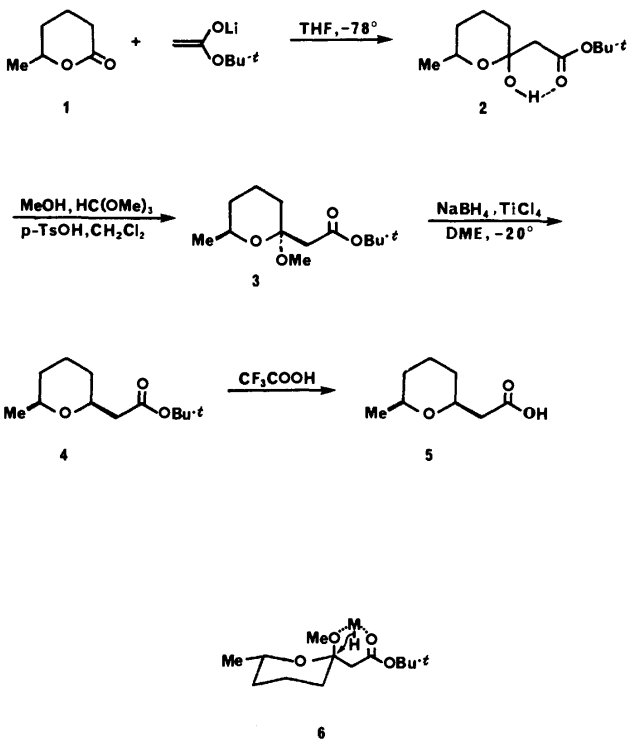
A Simple Synthesis of (±)-*cis*-(6-Methyltetrahydro-2-pyranyl)acetic Acid, a Constituent of Civet

Kazuhiro KOBAYASHI* and Hiroshi SUGINOME
Organic Synthesis Division, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received August 12, 1988)

Synopsis. The title compound was synthesized stereoselectively starting with readily available 5-hexanolide in a 47% overall yield.

cis-(6-Methyltetrahydro-2-pyranyl)acetic acid (**5**) was isolated as a minor constituent of civet, which is utilized in perfumery, by Mauer et al. in 1979.[1] Since then, several synthetic methods for the preparation of **5** have been reported.[2] We now wish to report a more simple synthesis of **5**, which involves a stereoselective reduction of the cyclic acetal **3**.

t-Butyl (2-methoxy-6-methyltetrahydro-2-pyranyl)-acetate (**3**) was prepared from the reaction of 5-hexanolide with the lithium enolate of *t*-butyl acetate[3] followed by the subsequent treatment of the cyclic hemiacetal **2** with methanol and trimethyl orthoformate in dichloromethane in the presence of a catalytic amount of *p*-toluenesulfonic acid. The magnesium enolate of *t*-butyl acetate[4] also could be used for the preparation of **2**. Although the yield was slightly reduced, the reaction proceeded under milder conditions. In each case **3** was obtained in stereochemically pure form. The stereochemistry of **3** was determined on the basis of the reported ^{1}H NMR examination.[5]



The sodium borohydride reduction of **3** to **4** was found to be feasible using titanium tetrachloride as a catalyst. Thus, **3** was allowed to react with 1 equivalent of sodium borohydride in the presence of 1.5 equivalent of the catalyst in 1,2-dimethoxyethane at −20 °C, and the reduced product **4** was produced stereoselectively in an 80% isolated yield. The reaction occurred immediately and cleanly, and the ester moiety was not affected under the present conditions.[6] The use of excess sodium borohydride or the catalyst, prolonged reaction time, and elevated reaction temperature led to complicated mixture of products arising from the reduction of the ester moiety. 1,2-Dimethoxyethane was essential for the reaction, and the use of diethyl ether, THF, benzene, and dichloromethane was not effective. The use of lithium aluminum hydride instead of sodium borohydride was also ineffective.

The specific formation of **4** in the reduction of **3** may be explained in terms of the involvement of the intermediate **6**.[7]

The ester cleavage of **4** was carried out in trifluoroacetic acid to give **5** in a 79% yield. Since the present method is operationally simple and highly selective, it offers advantages over the porevious methods for the preparation of **5**.[2]

Experimental

The IR spectra were recorded on a Hitachi 285 spectrometer. The ^{1}H NMR spectra were recorded on a Hitachi R-90B spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. The high and low resolution mass spectra were determined with a JEOL JMS-D300 spectrometer. Thin-layer chromatography was performed using Merck Silica Gel 60 GF_{254}. All solvents were dried over appropriate agents and distilled under nitrogen prior to use. All reactions were carried out in a nitrogen atmosphere.

***t*-Butyl (2-Hydroxy-6-methyltetrahydro-2-pyranyl)acetate (2).** To a stirred solution of lithium diisopropylamide (LDA) (10 mmol), which was prepared by the treatment of diisopropylamine (1.0 g, 10 mmol) with butyllithium (10 mmol, 1.5 M† in hexane solution) in THF (20 ml) at −78 °C, was added *t*-butyl acetate (1.2 g, 10 mmol). After stirring for 20 min at the same temperature 5-hexanolide[2c] (1.1 g, 10 mmol) was added to the reaction mixture and it was stirred for additional 4 h. The resulting mixture was quenched by adding aqueous ammonium chloride and extracted with ether three times. The combined extract was washed with brine, dried over anhydrous magnesium sulfate, and evaporated to give a crude **2** (2.2 g), which was not further purified and used in the next step. Compound **2** was alternatively prepared as follows. Diisopropylamine (4.1 g, 40 mmol) was added to an ethereal solution (30 ml) of ethylmagnesium bromide (20 mmol) at 0 °C and the mixture was stirred for 1 h at the same temperature. To the resulting turbid solution were successively added *t*-butyl acetate (1.2 g,

† 1 M=1 mol dm^{-3}.

10 mmol) and 5-hexanolide (1.1 g, 10 mmol), and the mixture was stirred for additional 30 min. The resulting mixture was quenched by adding aqueous ammonium chloride and extracted with ether three times. The combined extract was dried over anhydrous magnesium sulfate, and concentrated in vacuo. The resulting crude product was not further purified and used in the next step.

***t*-Butyl (2-Methoxy-6-methyltetrahydro-2-pyranyl)acetate (3).** A solution of the crude **2** (2.2 g), trimethyl orthoformate (2 ml), methanol (1 ml), and *p*-toluenesulfonic acid (95 mg, 0.5 mmol) in dichloromethane (20 ml) was stirred at room temperature overnight. The resulting mixture was washed with aqueous sodium hydrogencarbonate and dried over anhydrous sodium sulfate. Evaporation of the solvent gave a crude oil which was distilled using Kugelrohr to afford **3** (1.8 g, 75% from **1**). Bp 110 °C (bath temperature)/0.1 Torr[††]; IR (neat) 1725 cm^{-1}; ^1H NMR δ=1.12 (d, J=6.2 Hz, 3H), 1.45 and 1.3—2.0 (s and m, combined 15H), 2.38 (d, J=13.4 Hz, 1H), 2.67 (d, J=13.4 Hz, 1H), 3.25 (s, 3H), 3.4—3.8 (m, 1H); MS, m/z (rel intensity) 244 (M^+, 0.2), 213 (6.2), 119 (95.8), 57 (100). Found: m/z 244.1666. Calcd for $C_{13}H_{24}O_4$: M, 244.1675.

***t*-Butyl *cis*-(6-Methyltetrahydro-2-pyranyl)acetate (4).** To a stirred suspension of sodium borohydride (0.19 g, 5 mmol) and **3** (1.2 g, 5 mmol) in 1,2-dimethoxyethane (20 ml) was added dropwise titanium tetrachloride (0.43 g, 7.5 mmol) at −20 °C. An exothermic reaction immediately occurred and the suspension turned to a green solution, which was poured into aqueous ammonium chloride and extracted with ether three times. The combined extract was washed with brine, dried over anhydrous sodium sulfate, and concentrated in vacuo. Distillation of the residue gave **4** (0.86 g, 80%). Bp 95 °C (bath temperature)/0.2 Torr; IR (neat) 1725 cm^{-1}; ^1H NMR δ=1.14 (d, J=6.2 Hz, 3H), 1.44 and 1.3—1.9 (s and m, combined 15H), 2.25 (dd, J=14.8, 6.2 Hz, 1H), 2.47 (dd, J=14.8, 6.8 Hz, 1H), 3.3—3.9 (m, 2H); MS, m/z (rel intensity) 214 (M^+, 0.1), 199 (0.8), 99 (84), 57 (100). Found: 214.1573. Calcd for $C_{12}H_{22}O_3$: M, 214.1569.

***cis*-(6-Methyltetrahydro-2-pyranyl)acetic Acid (5).** To a solution of **4** (0.21 g, 1 mmol) in dichloromethane (4 ml) was added trifluoroacetic acid (0.2 ml), and the mixture was stirred at room temperature overnight. Evaporation of the solvent gave a crude solid which was recrystallized from petroleum ether to afford **5** (0.13 g, 79%). Mp 51—52 °C (lit,[2a] 50—52 °C).

[††] 1 Torr=133.322 Pa.

Synopsis. Particle size of the metal catalysts controlled the stereoselectivity in the hydrogenation of methylenecyclohexanes. No effect of particle size, on the contrary, was observed in the hydrogenation of substituted 3-methylenetetrahydropyran and 5-methylene-1,3-dioxane which contain oxygen atom/atoms in the molecule.

Explanations of the stereochemistry in catalytic hydrogenation have been dominated by ideas concerning the manner in which a given unsaturated compound may best be fitted onto a planar surface from which hydrogen is abstracted; cis addition is the consequences.[1] However, the effect of the steric interaction of substrates with the metallic surface on the product distribution is still complicated.

In order to investigate the correlation between the stereochemistry of hydrogenation and the interaction of the substrate with the catalyst surface, 1-*t*-butyl-4-methylenecyclohexane (**1**), 3,3,5-trimethyl-1-methylenecyclohexane (**2**), 2-*t*-butyl-5-methylenetetrahydropyran (**3**), and 2-*t*-butyl-5-methylene-1,3-dioxane (**4**) were hydrogenated over several transition metal catalysts whose particle sizes of the metal were controlled.

Results and Discussion

The catalysts used in the present study were a Rh and Os colloid in a matrix of poly(*N*-vinylpyrrolidone), and highly dispersed Rh on a SiO_2 surface. Two types of Rh colloid were prepared by the method of Hirai (one type is tentatively named colloid A and the other is colloid B).[2] The average particle diameter of colloid A was reported to be 9 Å and that of colloid B to be 20 Å. The observed particle size of the latter was 27 Å by electron microscope at a magnification of 200000. Two types of Os colloid were similarly prepared as Rh. These Os colloids were highly dispersed and the particle sizes were distributed in very narrow ranges. The average particle diameters of these two types of colloid were 30 Å (colloid A) and 40 Å (colloid B). Three types of Rh supported on SiO_2 were also used as the catalysts. These were 1.0, 4.7, and 14.2% Rh on SiO_2, the average particle sizes of which are 14, 28, and 48 Å, respectively.[3] In some cases, a small amount of endo-cyclic olefins, which were derived by the double bond migration of the original substrates, appeared during the hydrogenation (see Table 1). since the rate of hydrogenation of these endo-cyclic olefins is very slow compared with the original substrates (the apparent rate of hydrogenation of endo-cyclic olefins was less than 1/10 of that of the oiriginal substrates), the appearance of these isomerized olefins with the progress of the reaction seemed to have little influence

Table 1. The Product Distribution of Hydrogenation of Substituted Methylenecyclohexanes, -tetrahydropyran, and -dioxane

Catalyst	Average diameter (Å)	(axial methyl isomer in saturated product (%)) (1)	(2)	(3)	(4)
Rh colloid A	9	58(14)[a]	50(9)	96(0)	98(3)
Rh colloid B	27	80(12)	83(6)	97(0)	98(3)
Rh black		90(4)	84(6)	94(0)	98(1)
Os colloid A	30	73(2)	88(1)	97(0)	98(1)
Os colloid B	40	74(2)	93(1)	97(0)	95(1)
Os black		91(2)	89(1)	92(*t*)[b]	92(*t*)
1.0% Rh/SiO_2	14	65(12)	65(7)	94(0)	95(1)
4.7% Rh/SiO_2	28	71(12)	69(8)	95(0)	96(2)
14.2% Rh/SiO_2	48	78(13)	77(10)	95(0)	96(1)

on the epimeric ratios of the saturated products from the original substrates in the early stage of the reaction. The product distribution of the hydrogenation is summarized in Table 1.

The stereochemistry of the hydrogenation of **1** depended on the particle size of the catalyst metal. The ratios of the axial methyl product to the equatorial tend to decrease in the order; black catalyst, colloid B, colloid A on Rh catalyst and those eventually approached unity. A similar trend was observed with Os colloid catalyst. This means that a decrease in the average particle size of the metal colloid gives a decrease in the ratio of the axial methyl isomer. The hydrogenation of **2** also showed the same trend as that of **1**.

Siegel and his co-workers discussed the hydrogenation of cyclic olefins in terms of Horiuti–Polanyi mechanism and proposed that the change in the product-controlling step coincides with a change in the ratio of the products.[4] The distribution of stereoisomeric products will depend upon which of the elementary reactions is product-controlling because the geometry and/or composition of the several possible transition states differ from one another. When the product-controlling step is the adsorption of the substrate on the catalyst or the first hydrogen transfer from the catalyst to the adsorbed species, the stereochemistry of the reaction is controlled by the interaction between the substrate and the catalyst surface.

Since it has been known that the hydrogenation of **1** over noble metal black catalysts always gave cis product,[5] the stereochemistry of the product is considered to be determined by the steric interaction between the substrate and the catalyst surface. Taking into account the average particle size of the catalyst metal together with the product distribution obtained in the present study, the geometries of the adsorption states on the catalyst are illustrated as in Fig. 1, in which the stereochemical correlation of the substrate with the catalyst is imagined. The product distribution leads to the tentative conclusion that (1) the compressional stress of the axial and the equatorial side of a six-membered ring is not very different on the catalyst whose particle size is rather small, so that the attack of hydrogen from either the axial or the equatorial side is roughly equal. This results in the low stereoselectivity of hydrogenation. (2) It is clear from the drawings that the difference of the compressional stress between the axial and the equatorial side increases with increasing particle size of the catalyst metal, so that the adsorption of the substrate becomes easier from the equatorial side than from the axial side. An extremely high axial methyl selectivity is responsible for the overwhelmingly equatorial addition of hydrogen on the metal black catalyst whose particle size of the metal is considered to be macroscopically infinite.

Of particular interest are the results for **3** and **4** which contain the oxygen atom/atoms in the molecule. The compounds containing a polar substituent or atom such as an oxygen or a nitrogen near a reducible double bond are known to exert special directing effect. Presumably, some type of attractive interaction has bound the polar group or atom to the catalyst surface during the hydrogenation so as to enforce the addition of hydrogen from the same side.[6] On the other hand, when the polar atom and the unsaturated group are placed at an appropriate position in the molecule, the directing effect is no longer predominant. For instance, the stereochemistry of the hyrogenation of 2-substituted 5-methylene-1,3-dioxanes over Group VIII transition metal black catalysts made a sharp contrast with that of 4-substituted 1-methylenecyclohexanes. A high cis selectivity was observed in the former, while the latter exhibited a wide variety of diastereomeric product distribution depending on the catalyst metals.[7,8] If the directing effect of the oxygen atom operates, hydrogens should be incorporated from the axial side to give the equatorial methyl isomer. Hydrogen, however, transfers stereoselectively to the unsaturated bond from the opposite side of oxygen lone pairs (Scheme 1). Such high stereoselectivity was interpreted in terms of the presence of the intramolecular interaction between the n orbital of the oxygen atom and the π_{cc} orbital in these compounds.[7,8] In the present study, **3** and **4** gave more than 92% cis product irrespective of the characteristics of the catalysts. This strongly supports that the product distribution of the hydrogenation of these compounds is not controlled

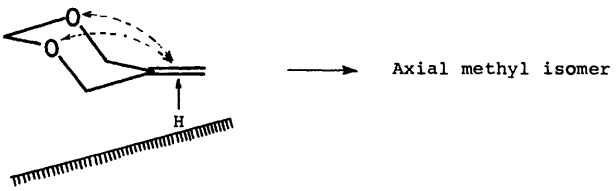
Directing effect of oxygen



Intramolecular $n_O-\pi_{CC}$ interaction

Scheme 1.

by the particle size of the catalyst at all. In other words, the stereochemistry of the hydrogenation seems not to be determined by the steric and/or directing effect, but by the intramolecular orbital interaction.

Experimental

Materials. Compound **3**[8] was prepared by the Wittig reaction[9] of 6-*t*-butyltetrahydropyran-3-one which was obtained by the pyridinium dichromate oxidation of 6-*t*-butyltetrahydropyran-3-ol.[10] Compound **4** has been previously reported.[11]

Catalysts. Rh colloids were prepared by the method of Hirai et al.[2] Os colloid A: OsO_4 (8.5 mg) and poly(*N*-vinylpyrrolidone) (150 mg) were separately dissolved in two portions of methanol (22.5 ml for each). Both solutions were combined and refluxed. After refluxing for 30 min, a methanol solution (5 ml) of sodium hydroxide (6.7 mg) was added dropwise to the solution under reflux, resulting in rapid color change of the solution to dark brown, which corresponded to the formation of Os particles. After further refluxing for 10 min, a dark brown solution of colloid A was obtained. Os Colloid B: OsO_4 (8.5 mg) and poly(*N*-vinylpyrrolidone) (150 mg) were separately dissolved in two portions of ethanol (22.5 ml for each). Both solutions were combined and refluxed. After refluxing for 3 h, a dark brown solution of colloid B was obtained.

Catalytic Hydrogenation. The substrate (0.5 mmol) was stirred in a hydrogen atmosphare in 5 ml methanol (colloid A and black catalysts) or ethanol (colloid B and silica supported catalysts) at room temperature over a weighed catalyst (colloid: substrate/catalyst; 120—250 mol/g-atom, black catalyst: 5 mg, silica supported catalyst: 50 mg). The reaction was followed gas chromatographically by analyzing aliquots of the reaction mixture at appropriate time intervals.

A Practical Method for Optical Resolution of 1,1′-Binaphthyl-2,2′-dicarboxylic Acid via 1-Phenylethylamides

Shuichi Ôi, Yutaka Matsuzaka, Junzo Yamashita,† and Sotaro Miyano*
Department of Biochemistry and Engineering, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
†Chemical Research Laboratory, Tokyo Medical College, 1-1, 6-Chome, Shinjuku-ku, Tokyo 160
(Received September 9, 1988)

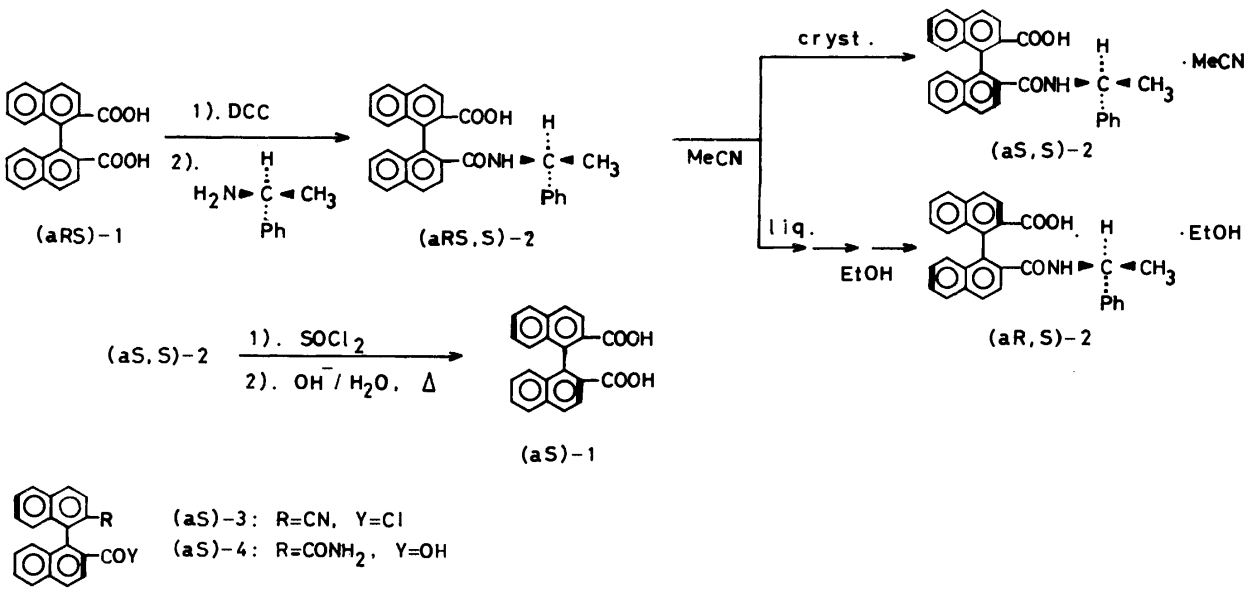
Synopsis. Both enantiomers of 1,1′-binaphthyl-2,2′-dicarboxylic acid (100% ee's by HPLC) were conveniently obtained in high yields (ca. 80% of the theory) via fractional crystallization of the (*S*)-1-phenylethylamide diastereomers of the racemic acid followed by treatment with thionyl chloride and then alkaline hydrolysis.

Since Kuhn and Albrecht first resolved 1,1′-binaphthyl-2,2′-dicarboxylic acid **1** in 1928,[1] optically active **1** has been widely utilized for the preparation of various axially chiral binaphthyl derivatives.[2,3] Recently increasing attention has been centered on **1** as it has become to be known that **1** shows characteristic features not only as chiral host for selective inclusion of enantiomeric alcohols[4] but also as chiral stationary phase for direct discrimination of various enantiomers.[5] The enantiomers of **1** have conventionally been obtained by means of an optical resolution through its quinine salt. But the procedure is rather tedious, and efficiency of resolution was low.[2,6] Quite recently Suda and his co-workers have reported an improved optical resolution of **1**, while it still requires to use highly toxic brucine as the resolving agent.[7]

In this paper, we report another practical method for optical resolution of **1** in substantial quantities via 1-phenylethylamide diastereomers (Scheme 1). Treatment of (a*RS*)-**1**[8] with dicyclohexylcarbodiimide (DCC) gave acid anhydride(s),[9] which in turn allowed to react with ca. 1.2 equiv of (*S*)-1-phenylethylamine to give the pair of the diastereomeric mono amides ((a*R*,*S*)- and (a*S*,*S*)-**2**) in quantitative yield. Upon trying various solvents, we have eventually found that acetonitrile is the specific medium to crystallize (a*S*,*S*)-**2** from the mixture. The (a*S*,*S*)-**2** was obtained as fine crystals of a 1:1 clathrate with acetonitrile; the yield amounted to 86% based on one of the enantiomers of **1** with more than 99% diastereomeric excess (de) as evidenced by HPLC. The filtrate was recrystallized twice from ethanol to give the (a*R*,*S*)-counterpart as a 1:1 clathrate with ethanol in a 81% yield and here again in essentially diastereomerically pure state.

The amide bond of **2** was intact by treatment with aqueous sodium hydroxide or sulfuric acid. Eventually, diastereomeric **2** was first treated with thionyl chloride to give the nitrile **3** (the von Brawn reaction),[10] which was then hydrolyzed to the free diacid ((a*R*)- or (a*S*)-**1**) without any appreciable racemization nevertheless rather severe reaction conditions.

Although the resolution method disclosed here requires amides formation followed by regeneration of the free acids, the procedure is operationally simple and straightforward, and applicable to obtain substantial quantities of optically pure **1**, using rather inexpensive enantiomeric 1-phenylethylamine as the resolving agent. Another merit of the procedure is that diastereomeric purity of **2** is readily checked by HPLC to ensure the obtention of enantiomerically pure **1**.[11]



Scheme 1.

Experimental

Instruments. HPLC measurements were carried out on a JASCO TRIROTAR-III equipped with a JASCO UVIDEC-100-III ultraviolet detector (254 nm). IR spectra were measured on a Shimadzu IR-430 grating spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL JNM-FX 60 instrument with tetramethylsilane as an internal standard. Optical rotations were recorded on a Union PM-101 automatic digital polarimeter in a 1-cm cell at 23—25 °C. Melting points were measured on a Yamato MP-21 apparatus and are uncorrected.

Materials. (a*RS*)-**1** was obtained according to the literature procedure;[2,12] mp 271—272.5 °C; IR (KBr) 3500—2300, 1690, 1280, 1240, and 1130 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=12.2 (2H, br, s, -COOH) and 6.6—8.2 (12H, m, ArH). (*S*)-1-Phenylethylamine ([α]$_D$=−38.0 ° (*c* 2, ethanol)) and DCC were used as purchased. Thionyl chloride and recrystallization solvents (acetonitrile and ethanol) were distilled before use.

Preparation and Separation of Diastereomeric Amides from (*S*)-1-Phenylethylamine and (a*RS*)-1. To a stirred solution of (a*RS*)-**1** (15.0 g, 43.8 mmol) in THF (150 ml) was added a solution of DCC (9.04 g, 43.8 mmol) in THF (100 ml) at room temperature for 1 h under a nitrogen atmosphere. The mixture was stirred for another 2 h at that temperature, and then heated at reflux for 4 h. After triethylamine (5 ml) and (*S*)-1-phenylethylamine (6.37 g, 52.6 mmol) were added to the hot mixture, it was refluxed for 3 h. The mixture was allowed to cool to room temperature, precipitated *N,N'*-dicyclohexylurea was filtered off, and the solids were rinsed with small portions of THF. The solvent was removed from the filtrate under reduced pressure, and the residue was dissolved in 200 ml of chloroform. The solution was washed with concd HCl (200 ml×2) and then with water (200 ml×4), dried over $MgSO_4$ in the presence of activated charcoal. After filtration, the solvent was evaporated in vacuo to give crude (a*RS,S*)-**2**.

The (a*RS,S*)-**2**, which was contaminated with a small amount of *N,N'*-dicyclohexylurea, was directly dissolved in 1000 ml of acetonitrile, and then 700 ml of the solvent was distilled off under atmospheric pressure. The remaining solution was kept overnight at 4 °C to give 9.14 g (85.8% yield, >99% de by HPLC[13]) of (a*S,S*)-**2** clathrated with 1 mol of acetonitrile; mp 190.5—192 °C; [α]$_D$=−123.3 ° (*c* 1.04, chloroform); IR (KBr) 3500—2500, 3260, 1703, 1595, and 1565 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=0.99 (3H, d, -CH$_3$), 2.05 (3H, s, acetonitrile), 4.6 (1H, m, CH), and 6.3—8.5 (18H, m, NH and ArH). Found: C, 79.27; H, 5.67; N, 5.29%. Calcd for $C_{30}H_{23}NO_3 \cdot C_2H_3N$: C, 78.99; H, 5.39; N, 5.76%.

The solvent of the mother liquor from the above crystallization was removed under reduced pressure. The residue was dissolved in 260 ml of ethanol with warming, and then 150 ml of which was distilled off under atmospheric pressure. The remaining solution was kept overnight at 4 °C. The precipitated crystals were recovered by filtration (9.12 g), and were again dissolved in 250 ml of ethanol. The solvent was distilled (108 ml) until just prior to causing cloudiness of the solution. The solution was kept overnight at 4 °C to give 8.68 g (80.6% yield, >99% de by HPLC) of (a*R,S*)-**2**; mp 260—261 °C; [α]$_D$=+183.2 ° (*c* 1.01, chloroform); ^{1}H NMR (DMSO-d_6) δ=0.79 (3H, d, -CH$_3$), 1.0 (3H, t, ethanol -CH$_3$), 3.4 (2H, q, ethanol -CH$_2$-), 4.6 (1H, m, CH), 6.6—8.2 (17H, m, ArH), and 8.3 (1H, d, NH). Found: C, 78.25; H, 6.09; N, 2.91%. Calcd for $C_{30}H_{23}NO_3 \cdot C_2H_6O$: C, 78.19; H, 5.95; N, 2.85%.

Regeneration of Axially Homochiral (a*S*)-1. To the 9.14 g (18.8 mmol) of (a*S,S*)-**2** were added 100 ml of thionyl chloride and one drop of DMF, and the mixture was refluxed for 3 h. The excess of thionyl chloride was distilled out, and the residue was dried at 70 °C under vacuum to give (a*S*)-**3**, which was substantiated by IR as methyl ester by treatment with methanol; IR (KBr) 2200 and 1715 cm^{-1}. The crude (a*S*)-**3** was directly dissolved in 130 ml of ethanol with warming, and 10 g of KOH in 30 ml of water was added and then refluxed for 5 h to give amide (a*S*)-**4** as evidenced by IR; (KBr) 3500—2500, 3400, 1700, and 1640 cm^{-1}. After volatiles were removed under reduced pressure, the residue was suspended in a solution of 50 g of NaOH in 400 ml of water and heated at reflux; the mixture became almost clear solution after 10-h heating, and the reaction was continued for another 30 h to ensure complete hydrolysis, while almost all the hydrolysis seemed to be completed by 20-h heating. After cooling to room temperature, 200 ml of water was added and washed with ether (200 ml×2) to remove nonacidic compounds. The aqueous solution was acidified with concd HCl and the precipitate was extracted with ethyl acetate (150 ml×3). The combined organic layer was dried over $MgSO_4$ in the presence of activated charcoal. After filtration, the solvent was evaporated in vacuo and recrystallization from toluene gave 5.84 g (91% yield) of (a*S*)-**1**, which was of essentially 100% ee as evidenced by HPLC; a small sample of the acid was converted to the bis(butylamide) and subjected to HPLC analysis on a chiral stationary phase as reported before;[14] mp 165—167 °C;[15] [α]$_{546}$=−126.2 ° (*c* 1.05, 0.1 mol dm^{-3} NaOH) (lit,[7] [α]$_{546}$=−127 ° (*c* 1.0, 0.1 mol dm^{-3} NaOH)).

(a*R*)-2: Similar treatment of 8.68 g (17.7 mmol) of (a*R,S*)-**2** gave 5.69 g (94% yield, 100% ee by HPLC) of (a*R*)-**1**.

Sommelet-Hauser Rearrangement of Oxygen and Sulfur Containing Heteroaromatic Sulfonium Ylides

Makoto YAMAMOTO,* Madoka KAKINUMA, Shigeo KOHMOTO, and Kazutoshi YAMADA
Department of Industrial Chemistry, Faculty of Engineering, Chiba University,
1-33 Yayoi-cho, Chiba-shi 260
(Received September 16, 1988)

Synopsis. A Sommelet-Hauser rearrangement of sulfonium ylides of 4*H*-pyran-4-ones, furan, and thiophenes are discussed. The sulfonium halides which were prepared from excess dimethyl sulfide with corresponding halides were treated with NaH or NaOR in a polar solvent to give moderate to good yields of rearranged products.

Allyl and arylsulfonium ylides undergo an orbital-symmetry allowed [2.3] sigmatropic rearrangement, commonly known as the Sommelet-Hauser rearrangement.[1] The Sommelet-Hauser rearrangement of acyclic sulfonium ylides[1] and its aromatic analogues[2] can be widely quoted. However, the rearrangement of heteroaromatic ylides has been sparsely reported.[3]

We wish to report here on the Sommelet-Hauser rearrangement of 4-pyranones, furan and thiophene derivatives. Many methods for the preparation of a sulfonium ylide are known, such as sulfonium salt-base,[4] carbene insertion,[5] and nitrene addition.[6] We prepared the sulfonium ylides via the sulfonium salt-base, which we found to be a simple method.

In general, a Sommelet-Hauser rearrangements of heteroaromatic compounds were carried out by treating the substrates in an inert atmosphere with an excess of dimethyl sulfide, followed by treatment with a base (MeONa-MeOH, EtONa-EtOH, or NaH). Following this procedure, 2,6-dimethyl-3-methylthiomethyl-4*H*-pyran-4-one (**2a**) was obtained in 92% yield from 2-bromomethyl-6-methyl-4*H*-pyran-4-one (**1a**).[7] In this reaction none of the [1.2] rearranged product was detected. Compound **2a** was also prepared by treating the sulfonium salt of **1a** with sodium hydride in refluxing THF or dioxane in 84 and 55% yields, respectively.

(3)

The halopyrans, **1b** and **1c**, gave the corresponding rerranged products, **2b** and **2c**, in 87 and 73% yields, respectively. In contrast, a treatment of the branched bromide **1d** gave only 3% of the desired product **2d**, together with 52% of 2-methyl-6-(1-methylthiomethyl)-4*H*-pyran-4-one (**3**).

2-(Chloromethyl)furan (**4**) gave **5** in 34% yield. However, the sulfonium salt of **4** and the rearranged product **5** were unstable and easily decomposed to a black tar.

3-(Bromomethyl)thiophene (**6**) afforded rearranged product **7** in 67% yield. Compound **7** was also

obtained in 60% yield when the sulfonium bromide of **6** was treated with sodium ethoxide in ethanol at room temperature and in 22% yield when the same reaction was carried out at 0 °C. Interestingly, the reaction in refluxing ethanol gave 24% of the ethyl ether **8** in addition to 12% of **7**. A similar result was obtained in the case of sodium methoxide in refluxing methanol (**7**: 19%, **9**: 19%). The mechanisms for the formation of **8** and **9** are sitll not clear.

The sulfonium bromide of 2-(bromomethyl)benzo[*b*]thiophene (**10**)[8] gave the desired product **11** in 57% yield.

We have thus demonstrated that the heteroaromatic ylides undergo an efficient Sommelet–Hauser rearrangement. Moreover, the methylene of a newly formed methylthiomethyl group can be used as a d^1-synthon. Applications of the aforementioned synthetic potentialities of this reaction are presently being studied in the laboratory. Results will be communicated separately.

Experimental

2,6-Dimethyl-3-methylthiomethyl-4*H*-pyran-4-one (2a): A mixture of **1a** (2.03 g, 10 mmol) in 5 ml of chloroform and excess dimethyl sulfide (3.72 g, 60 mmol) was stirred overnight at room temperture under nitrogen. The resulting precipitate was collected by filtration and, without further purification, the precipitate was added to an equimolar amount of sodium methoxide in 20 ml of methanol. The mixture was heated to reflux for 2 h, cooled, neutralized with diluted hydrochloric acid and worked up as usual to give a crude product which was purified by silica-gel column chromatography using benzene–ethyl acetate (2:1) as an eluent to give colorless plates of **2a** (1.69 g, 92%), mp 56—58 °C (from benzene–hexane=1:3).

Sulfonium bromide of **1a** (1.02 g, 5 mmol) was treated with sodium hydride (132 mg, 5.5 mmol) in refluxing THF (15 ml) or in refluxing dioxane (12 ml) for 2 h under nitrogen to give **2a** in 773 mg (84%) or 506 mg (55%), respectively. Similarly, rearranged products **2b** (87%; mp 77—78 °C), and **2c** (73%; pale yellow liquid) were obtained. Spectral data are listed in Table 1.

Attempted Rearrangement of the Branched Sulfonium Ylide: A mixture of **1d** (2.31 g, 9.43 mmol) prepared from 2-butyl-6-methyl-4*H*-pyran-4-one[9] and excess dimethyl sulfide (1.84 g, 13.0 mmol) in chloroform (8 ml) was treated according to the procedure mentioned above; the products were purified similarly to give **2d** (52 mg, 3%) and **3** (975 mg, 52%). ^{1}H NMR of **2d** (CCl_4, δ): 0.92 (t, 3H), 1.20—1.87 (m, 4H), 2.00 (s, 3H), 2.25 (s, 3H), 2.60 (t, 2H), 3.60 (s, 2H) and 5.40 (s, 1H). ^{1}H NMR of **3** ($CDCl_3$, δ): 0.97 (t, 3H), 1.10—1.80 (m, 4H), 2.00 (s, 3H), 2.25 (s, 3H), 3.34 (t, 1H) and 5.90 (s, 2H). MS of **3**: Found: *m/z* 212.0876, Calcd as $C_{11}H_{16}O_2S$: M, 212.0870. *m/z* 212 (M^+, 100), 141 (33), 85 (90) and 43 (60).

3-Methylthiomethyl-2-methylfuran (5): A mixture of 2-(chloromethyl)furan (**4**; 816 mg, 7.0 mmol) and dimethyl sulfide (1.28 g, 21 mmol) was kept at room temperature overnight. The resulting brown paste was stirred with sodium ethoxide (7.7 mmol) in ethanol (40 ml) at 0 °C for 3.5 h. The reaction mixture was quenched with water (12 ml), extracted with ether, dried over anhydrous magnesium sulfate, concentrated, and purified by silica-gel column chromatography with hexane to give **5** (338 mg, 34%) as a colorless oil. The spectral data are listed in Table 1.

3-Methyl-2-(methylthiomethyl)thiophene (7): 3-(Bromomethyl)thiophene (**6**; 1.04 g, 5.9 mmol), which was prepared from 3-methylthiphene with NBS and benzoyl peroxide in refluxing benzene,[7] was mixed with dimethyl sulfide (733 mg, 11.8 mmol) the mixture was kept overnight at room temperature. The resulting brown paste was washed several times with ether and dried to give a crude sulfonium bromide (959 mg, 68%). This sulfonium bromide in THF (25 ml) was treated with sodium hydride (106 mg, 4.4 mmol) with stirring at room temperature for 22 h. The reaction mixture was quenched with water, extracted with ether, dried, concentrated and purified by silica-gel column chromatography with hexane to give **7** (628 mg, 67%) as a colorless oil. The sulfonium bromide of **6** (720 mg) was treated with sodium ethoxide in refluxing ethanol (20 ml) for 2 h to give **7** (57 mg, 12%) and 3-ethoxymethyl-2-(methylthiomethyl)thiophene (**8**; 146 mg, 24%). IR (neat) of **8**: 3100, 2990, and 1090 cm^{-1}. ^{1}H NMR (CCl_4, δ) of **8**: 1.20 (t, 3H, J=7.0 Hz), 2.04 (s, 3H), 3.45 (q, 2H, J=7.0 Hz), 3.82 (s, 2H), 4.41 (s, 2H), 6.88 (d, 1H, J=5.2 Hz) and 7.07 (d, 1H, J=5.2 Hz). MS of **8**: Found: *m/z* 202.0474, Calcd as $C_9H_{14}OS_2$: M, 202.0474. ^{13}C NMR ($CDCl_3$, δ) of **8**: 14.96 (q), 15.45 (q), 30.27 (t), 65.64 (t), 65.74 (t), 123.3 (d), 128.8 (d), 136.2 (s), and 138.4 (s).

The sulfonium bromide of **6** (720 mg) was also treated with sodium methoxide in refluxing methanol (20 ml) for 2 h to give **7** (90 mg, 19%) and 3-methoxymethyl-2-(methylthiomethyl)thiophene (**9**; 108 mg, 19%). ^{1}H NMR (CCl_4, δ) of **9**: 2.04 (s, 3H), 3.30 (s, 3H), 3.82 (s, 2H), 4.38 (s, 2H), 6.88 (d, 1H, J=5.0 Hz) and 7.08 (d, 1H, J=5.0 Hz).

2-Methyl-3-(methylthiomethyl)benzo[*b*]thiophene (11): A solution of 2-(bromomethyl)benzo[*b*]thiophene (**10**)[8] (2.37 g, 10.4 mmol) in chloroform (1 ml) was added to dimethyl sulfide (1.97 g, 31.7 mmol); the mixture was kept overnight at room temperature. The resulting white precipitate was filtered, washed several times with ether, dried to give crude sufonum bromide of mp 132—133 °C (2.45 g, 81%). To a solution of this sulfonium bromide (941 mg, 3.33 mmol) in THF (15 ml) was added sodium hydride (184 mg, 3.5 mmol) the mixture was heated to reflux for 5 h. The reaction mixture was quenched with 1 M-hydrochloric acid (1M=1 mol dm^{-3}), extracted with benzene, dried, concentrated and purified by silica-gel column chromatography with benzene–ethyl acetate (9:1) to give **11** (365 mg, 57%) as yelow paste. Spectral data are listed in Table 1.

Production of L-Tryptophan from γ-Glutamaldehydic Acid

Hirozumi ETO,* Chikahiko EGUCHI, and Teruhiko KAGAWA
Central Research Laboratories, Ajinomoto Co., Inc. 1-1,
Suzuki-cho, Kawasaki-ku, Kawasaki 210
(Received September 17,1988)

Synopsis. Labile γ-glutamaldehydic acid (**1**) was first converted to tryptophan via its phenylhydrazone; no racemization occurred during the reaction. The stability of **1** was shown to be remarkably enhanced in the presence of additives.

The production of L-tryptophan (L-Trp) has been extensively investigated after its positive effects as a feed additive became recognized.[1] We focused our attention on obtaining L-Trp by a combination of a fermentation and chemical synthesis. Practical synthetic methods for the production of L-Trp generally require an optical resolution of the racemic form, followed by the racemization of D-Trp.[2] Our process dose not necessitate these steps since optically active starting material prepared by fermentation is used.

γ-Glutamaldehydic acid (GAA, **1**) and its cyclic imine form, 3,4-dihydro-2*H*-pyrrole-2-carboxylic acid, were known to be labile intermediates in the biosynthesis of proline from glutamic acid.[3-5] GAA (**1**) was likely to be a suitable starting material of the nonprotected L-Trp synthesis by a Fischer indole formation. GAA (**1**), however, has neither been isolated in a pure form nor has it been used as a useful synthetic intermediate, probably because of its instability. The stability of **1** depended on its concentration; 30% of **1** in a 50-mM neutral solution (1 M=1 mol dm^{-3}) was reported to decompose within 1 hour.[6] On the other hand, none of these changes were observed in a 1-mM solution.[6] In the course of our practical research toward the establishment of a production method for L-Trp, 1) the possibility of chemical conversion of **1** to Trp, 2) the stereochemistry during the reaction, and 3) the way for preservation of **1** in neutral solution, were investigated.

In order to mimic the combination of biosynthesis of **1** and chemical conversion of it to Trp, GAA (**1**) was conveniently generated by the acidic hydrolysis of GAA dimethyl acetal (**5**), because L-**1** was not currently available by a fermentative production.[8] Since the phenylhydrazone (**6**) did not quantitatively precipitate due to its solubility, phenylhydrazone formation and indole synthesis were carried out consecutively. *N*-Ac-GAA (**3**) and GAA-hydantoin (**4**) were reported to afford the corresponding protected Trp in good yield under mild reaction conditions: [0.1 M HCl, reflux, 1 equiv of phenylhydrazine].[9] Meanwhile, for the case of **1**, Trp was provided in poor yield under the same conditions as mentioned above. The yield was shown to depend on the acidity and the amount of phenylhydrazine (Table 1). When 15 equiv of phenylhydrzine and 0.45 M (1 M=1 mol dm^{-3}) sulfuric acid was used, the result was remarkably improved (85% yield). GAA (**1**) in a

Table 1. Synthesis of Trp from **5** under Various Conditions

neutral solution provided the same results (85% yield) under optimum reaction conditions.

The previously mentioned successful observation suggested that L-**1** in a fermentation broth was able to be effectively converted to L-Trp. We therefore investigated whether isomerization took place during the course of the reaction. Optically active **5** was prepared by enzymatic deacylation of racemic *N*-acetyl-**5**. Compound L-**5** was subjected to the aforementioned Trp synthesis followed by esterification. The optical purity of the obtained L-Trp methyl ester (L-Trp-OMe) was examined by ^1H NMR using a chiral shift reagent. The ^1H NMR spectra of the reaction products were compared to the spectra of a mixture (95:5) of L- and D-Trp-OMe in the presence of tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III).[10] Since no signal corresponding to D-Trp-OMe was detected in the reaction product (Fig. 1), it was concluded that isomerization did not occur during the reactions.

Since an accumulation of **1** in the fermentation broth with a high concentration is desired in order to produce L-Trp on an industrial scale, we investigated the enhancement of the stability of **1** in a neutral environment.

When a 230-mM solution of **1** (pH 7) was left at 31 °C for several hours, followed by treatment with phenylhydrazine in acidic solution, Trp formation at an appropriate time decreased linearly with a time (Fig. 2). Meanwhile, reagents which generally react with aldehydes such as phenylhydrazine, sodium hydrogensulfite, hydroxylamine, and semicarbazide were added to a neutral solution of **1** before left standing, in order to form a stable adduct. As expected, no substantial decrease in Trp formation was observed, even after 15 hours. This meant that **1** could be preserved under standard fermentation conditions (pH 7, 31 °C). A stable form was exhibited to have the same chemical reactivity as **1** from the Trp synthesis.

These results strongly indicate the possibility of accumulating L-**1** by fermentation without decomposition and conversion to L-Trp. This process is highly straightforward and practically attractive. Further, progress in the fermentative production of L-**1** and its conversion to L-Trp will be reproted elsewhere.[8]

Experimental

High performance liquid chromatography (HPLC) was obtained with a Hitachi 635 fitted with a 500 mm×2.1 mm column containing Hitachi cation resin #2610. The eluent was a phosphate buffer (0.1 M KH_2PO_4: 0.1 M Na_2HPO_4= 16:1) at a flow rate of 0.5 ml min^{-1}. The temperature was 52 °C and detection was at 274 nm. IR and NMR spectra were recorded on a JASCO Infrared Spectrometer Model IR-S and Varian NMR Spectrometer XL-100A, respectively. The optical rotation was determined on a JASCO Digital Polarimeter DIP-140. Melting points are uncorrected. Racemic GAA dimethyl acetal (**5**) was prepared according to the procedure reported by Okuda.[7] Aminoacylase derived from *Aspergillus oryzae* was purchased from Amano Pharmaceutical Co.

Trp (general procedure). **Method A.** To the solution of phenylhydrazine hydrochloride (2.46 g, 17.0 mmol) in 0.9 M sulfuric acid (6 ml) was added **5** (201 mg, 1.1 mmol) in water (6 ml) dropwise under reflux. The reaction was carried out for 1 hour and analyzed by HPLC (85% yield). **Method B.** To a cooled solution of 1 M hydrochloric acid (10 ml) in an ice bath was added **5** (201 mg, 1.1 mmol). The mixture was stirred for 30 minutes and neutralized to pH 7 by adding 1 M aq. sodium hydroxide solution. This solution was added to a refluxing solution of phenylhydrazine hydrochloride (2.45 g, 17.0 mmol) in 0.9 M sulfuric acid (15 ml). The reaction mixture was refluxed for 1 hour and analyzed by HPLC (85% yield).

L-γ-Glutamaldehydic Acid Dimethyl Acetal (L-5). To a solution of **5** (3.39 g, 1.9 mmol) in 0.44 M aq. sodium hydroxide (50 ml) was added acetic anhydride (2.5 g,

25 mmol) while keeping the pH at 9 by the occasional addition of aq. sodium hydroxide at room temperature. The mixture was stirred for 1 hour and lyophilized after the pH was adjusted to 7. The residue was dissolved in water (80 ml) and 10 mM cobalt(II) chloride solution (4 ml) and amino-acylase (198.5 mg) were added. The enzymic reaction was carried out for 92 hours at 37 °C and the pH was kept in the range of 7.5 to 8.0. Inorganic salts were removed by adding a cation-exchange resin (IRC-50) and an anion-exchange resin (IR-45). The solvent was evaporated under reduced pressure and the residue (1.2 g) in water (400 ml) was charged to a sirotherm resin (supplied by Japan Sirotherm Co., Inc.) (80 ml) in column in order to remove any unreacted *N*-acetylated **3**. The column was washed with water (250 ml) at 0 °C and then eluted with water (300 ml) at 80 °C. The eluent was lyophilized and the residue was recrystallized from water (1 ml) and ethanol (1 ml) and diethyl ether (2 ml) to afford 93.3 mg (0.53 mmol) of L-**5**. $[\alpha]_D^{25}$ −1.07 (*c* 0.93, water).

L-Trp-OMe. L-**5** (93.3 mg, 0.3 mmol) was converted to L-Trp as previously described. The resultant solution was adjusted to pH 9.5 and washed with benzene and diethyl ether to remove phenylhydrazine. The aqueous phase was neutralized and concentrated to dryness. The residue was dissolved in methanol (20 ml) and esterified by bubbling HCl gas for 1.5 hours at room temperature. The solvent was removed and the residue, dissolved in chloroform, was washed with aq. sodium hydrogencarbonate, water and dried to give L-Trp-OMe (46.5 mg, 0.21 mmol).

Determination of Optical Purity of L-Trp-OMe. The Kainosho method was used.[10]

Stability of γ-Glutamaldehydic Acid (1). GAA dimethyl acetal (**5**, 280 mg, 1.58 mmol) was treated with 1 M HCl (7 ml) at 5 °C overnight. The mixture was allowed to warm to room temperature and then neutralized by adding aq. sodium hydroxide. To this solution of **1** was added equimolar amounts of reagents ($PhNHNH_2 \cdot HCl$, $NaHSO_3$, $NH_2OH \cdot HCl$, $H_2NCONHNH_2 \cdot HCl$). The pH was then adjusted to 7 and the volume adjusted to 10 ml. The mixture was left at 31 °C for an appropriate time and then converted to tryptophan using optimum reaction conditions. The yield of tryptophan was compared to the yield when nothing was added to a solution of **1**.

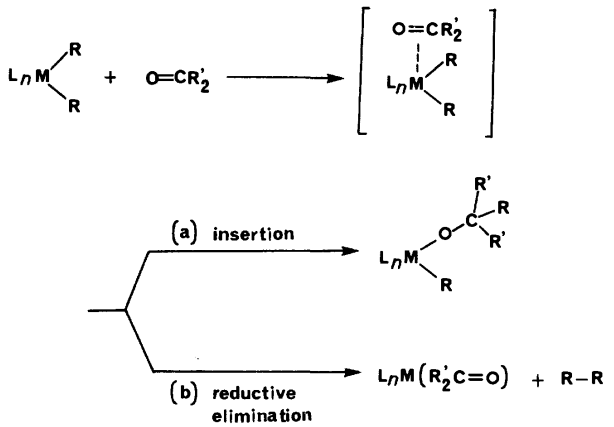
Synopsis. Reactions of hexafluoroacetone and 2,2,2-trifluoroacetophenone with dialkylnickel complexes cause extrusion of the alkyl ligands to give nickel complexes having an η^2-coordinated ketone and an auxiliary ligand such as bpy (2,2′-bipyridine) or dpe (1,2-bis(diphenylphosphino)ethane).

In comparison to a rich variety of η^2-olefin-coordinated transition metal complexes,[1] examples of η^2-ketone-coordinated transition metal complexes are still scarce.[2-5] We report here preparation and characterization of new ketone-coordinated nickel complexes derived from dialkylnickel complexes by reactions with fluorinated ketones.

Ketones with electron-withdrawing groups may cause two types of reactions with transition metal alkyls or hydrides. One is insertion of the carbonyl group in ketones into a metal–alkyl or metal–hydrogen bond to give transition metal alkoxides and the other is ketone coordination which induces reductive elimination of transition metal alkyls or hydrides. A similar effect of olefins with electron-withdrawing groups to promote reductive elimination of dialkylnickel complexes is well known.[6]

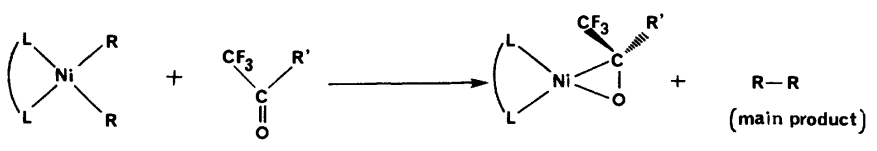


In our previous communication we have observed facile insertion of the carbonyl group in hexafluoroacetone and 2,2,2-trifluoroacetophenone into a metal–hydrogen bond of cobalt, ruthenium and rhodium hydride complexes to give stable alkoxides of these late transition metals.[7]

In the course of our recent study on the chemistry of nickel and palladium alkoxide complexes,[8] we examined reactions of fluorinated ketones with dialkyl nickel(II) complexes. We observed extrusion of the alkyl groups and formation of nickel complexes with the fluorinated ketones bonded in a side-on manner to the nickel center. Some of the ketone-coordinated nickel complexes prepared in the present study by treatment of dialkylnickel complexes with the fluorinated ketones have been previously prepared by displacement of olefin or tertiary phosphine ligands coordinated to Ni(0) center.[2-5] The present method provides an alternative route to the ketone-coordinated complexes, which have attracted less attention than the olefin-coordinated complexes.

Results and Discussion

Dialkylnickel complexes, $NiMe_2(bpy)$, $NiEt_2(bpy)$, and $NiMe_2(dpe)$ (dpe=1,2-bis(diphenylphosphino)-ethane), react smoothly with hexafluoroacetone to give $Ni(\eta^2\text{-}(CF_3)_2CO)(bpy)$ **1** and $Ni(\eta^2\text{-}(CF_3)_2CO)(dpe)$ **3**. The reaction of $NiMe_2(dpe)$ with the fluorinated ketone gives mixtures of CH_4 and C_2H_6 as gaseous products, while similar reactions of $NiR_2(bpy)$ (R=Me, Et) give reductive elimination products R–R exclusively. Complexes **1** and **3** have been prepared from reactions of the ketone with $Ni(cod)_2$ (bis(1,5-cyclooctadiene)-nickel) in the presence of the auxiliary ligands, bpy and dpe, respectively.[4] The products obtained in the present study show the IR spectra almost identical to those in the literature.[4] A similar reaction of $NiEt_2(bpy)$ with 2,2,2-trifluoroacetophenone gives a nickel–ketone complex $Ni(\eta^2\text{-}CF_3COPh)(bpy)$ **2** with



R = Me, Et.

1 L⌣L = bpy, R′ = CF_3;

2 L⌣L = bpy, R′ = Ph;

3 L⌣L = dpe, R′ = CF_3;

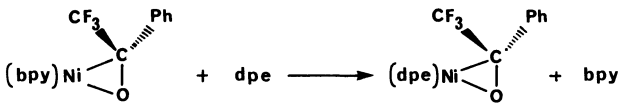
4 L⌣L = dpe, R′ = Ph.

Table 1. Reactions of Fluoro Ketones with Dialkylnickel Complexes

NiR_2L_2 (mmol)	Fluoro ketone (mmol)	Conditions[a]		Products (Yield/%)[b]	
		Temp	Time		
$NiMe_2$(bpy) (0.36)	CF_3COCF_3 (0.36)	25 °C	1 h	C_2H_6 (92)	**1** (62)
$NiEt_2$(bpy) (0.40)	CF_3COCF_3 (0.40)	25 °C	1 h	C_2H_6 (2), C_4H_{10} (85)	**1** (77)
$NiEt_2$(bpy) (0.42)	CF_3COPh (0.42)	40 °C	1 h	C_4H_{10} (86)	**2** (63)
$NiMe_2$(dpe) (0.40)	CF_3COCF_3 (1.00)	40 °C	10 h	CH_4 (23), C_2H_6 (42)	**3** (53)
$NiMe_2$(dpe) (0.42)	CF_3COPh (2.00)	50 °C	18 h	CH_4, C_2H_6[c]	**4** (23)

a) Reactions were carried out in THF under reduced pressure. b) Yields by GC for gaseous products. c) The formation was confirmed by GC, but the yields were not measured.

evolution of C_4H_{10}. Conversion of $NiMe_2$(dpe) to Ni(η^2-CF_3COPh)(dpe) **4** requires more severe conditions. Stirring a THF solution of $NiMe_2$(dpe) with CF_3COPh for 18 h at 50 °C gave **4** in a 23% yield. Complex **4** can be independently prepared by reactions of the CF_3COPh-coordinated nickel complex with bipyridine ligand, **2**, with an equimolar amount of dpe in a higher yield. In

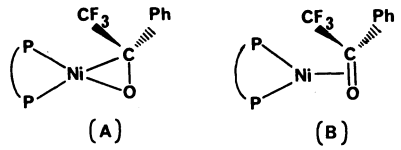


2 4

general, dpe coordinates to a nickel center more tightly than bpy, and $NiMe_2$(bpy) undergoes a facile ligand exchange with dpe to give $NiMe_2$(dpe).[9] Products of these reactions are summarized in Table 1.

New complexes **2** and **4** obtained in these reactions were characterized by IR and NMR spectroscopy and elemental analysis as well as chemical reactions. IR spectrum of **2** shows a ν(C–F) band at 1140 cm^{-1} and a ν(C–O) band at 1080 cm^{-1}, the latter band being shifted by ca. 650 cm^{-1} lower than that of the uncoordinated ketone. ^1H NMR spectrum of **2** shows signals only in the aromatic hydrogen region, indicating the absence of alkyl ligand in the complex. Complex **2** reacts with an equimolar amount of I_2 to give 2,2,2-trifluoroacetophenone (83%) and NiI_2(bpy).

The ^1H NMR of complex **4** shows signals due to hydrogens of dpe ligand and of the phenyl group in the coordinated ketone. $^{31}P\{^1H\}$ NMR spectrum shows two doublet signals, each of which is split into a quartet due to coupling with three fluorine atoms (see Experimental). $^{13}C\{^1H\}$ NMR spectrum of **4** shows signals due to the carbonyl carbon atom at δ=79.42 as a doublet of quartets by coupling with three fluorine and one phosphorus nuclei. The low value of the chemical shift of the signal and the low frequency of the ν(C–O) vibration in the IR spectrum suggest that complex **4** may be better formulated as a σ-bonded Ni(II) oxametallacycle (**A**) rather than a π-bonded Ni(0) complex (**B**).[10] These spectroscopic features indicate that complex **4** has a square planar coordination with a carbon, an oxygen, and two phosphorus ligating atoms around the nickel center.[11]



(A) (B)

Experimental

All manipulations were carried out under nitrogen or argon atmosphere. Dialkylnickel complexes were prepared by the methods in the literature.[12,13] Hexafluoroacetone was purchased from PCR Inc. and introduced to the reaction flask by means of a vacuum line technique.[14] 2,2,2-Trifluoroacetophenone was purchased from Tokyo Kasei Co., Ltd.

Preparation of the Complexes 1, 2, and 3. To a THF (3 cm^3) solution of diethyl(bipyridine)nickel (110 mg, 0.40 mmol), hexafluoroacetone (66 mg, 0.40 mmol) was added at room temperature. Complex **1** was immediately precipitated as a red solid which was filtered, washed with hexane several times, and dried in vacuo (113 mg, 77%).

Complexes **2** and **3** were prepared analogously.

Complex 2: Mp 147—150 °C (decomp); ^1H NMR (CD_3COCD_3) δ=7.7—8.9 (m, $C_{10}H_{10}N_2$ and C_6H_5); ^{19}F NMR 12.6 ppm (downfield from external CF_3COOH, s). Found: C 54.7; H 3.1; N 6.9%. Calcd for $C_{17}H_{13}F_3N_2ONi$: C 54.2; H 3.4; N 7.4%.

Preparation of 4. A toluene (5 cm^3) solution of **2** (180 mg, 0.47 mmol) and dpe (90 mg, 0.47 mmol) was stirred for 1 h at room temperature to cause precipitation of a yellow solid of **4**, which was filtered and recrystallized from THF (52%).

Complex **4** was also obtained in a lower yield from the reaction of 2,2,2-trifluoroacetophenone with $NiMe_2$(dpe) at 50 °C for 18 h.

Complex 4: Mp 153—156 °C (decomp); ^1H NMR (C_6D_6) δ=1.6—2.1 (4H, m, CH_2) and 7.0—8.3 (25H, m, C_6H_5); ^{31}P NMR (CD_2Cl_2) 58.16 ppm (downfield from external PPh_3 qd, J_{P-F}=4 Hz, J_{P-P}=51 Hz) and 51.56 ppm (qd, J_{P-F}=13 Hz, J_{P-P}=51 Hz); ^{19}F NMR (CD_2Cl_2) 12.8 ppm (downfield from external CF_3COOH, dd); ^{13}C NMR (CD_2Cl_2) δ=28.51 (dd, CH_2, J_{P-C}=18, 11 Hz), 24.40 (dd, CH_2, J_{P-C}=29, 11 Hz) 79.42 (qd, CO, J_{P-C}=27 Hz, J_{C-F}=33 Hz), and 117.10 (q, CF_3, J_{C-F}=292 Hz). Found: C 64.4; H 4.5%. Calcd for $C_{34}H_{29}F_3OP_2Ni$: C 64.7; H 4.6%.

This work was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of

Education, Science and Culture (No. 63470079). The authors are grateful to Toyo Stauffer Chemical Co. for their kind donation of $AlMe_3$ and $AlEt_2(OEt)$.

Reaction of Triarylchloroallenes with Nucleophiles under Solvolytic Conditions

Tsugio KITAMURA,* Sumiya MIYAKE, Shinjiro KOBAYASHI, and Hiroshi TANIGUCHI*
Department of Applied Chemistry, Faculty of Engineering, Kyushu University 36,
Hakozaki, Fukuoka 812
(Received September 24, 1988)

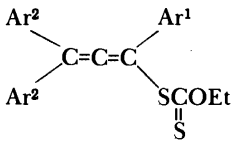
Synopsis. Solvolytic reactions of triarylchloroallenes in the presence of thiocyanate and *O*-ethyl dithiocarbonate anions gave the corresponding allenyl derivatives, while the reaction in the presence of cyanate anion afforded the corresponding propargyl derivative. These results are interpreted in terms of a steric factor of the nucleophiles.

Since allenyl cations were first suggested in solvolysis by Jacobs and Fenton,[1] much work has been done about the chemistry of allenyl cations; especially Schiavelli and co-workers have revealed intervention of the allenyl cations in their detail mechanistic studies.[2] One of the most interesting features is an ambident character of allenyl cations, which can provide allenyl and/or propargyl derivatives. However, most works on solvolysis of allenyl halides indicate that nucleophiles attack on the γ-position of the resulting allenyl cations unless bulky substituents are present on the γ-position.[3]

On the other hand, we have studied photolysis of arylvinyl halides and disclosed that the photogenerated vinyl cations react with various nucleophiles to give substituted ethylenes and heterocyclic compounds.[4] This successful vinylic substitution led us to examine the reaction of the extended unsaturated carbenium ions, allenyl cations. Here we report a high regioselectivity depending on nucleophiles in the reaction of triarylchloroallenes under solvolytic conditions.

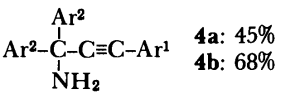
Results and Discussion

1,3,3-Triphenylchloroallene (**1a**) solvolyses under mild conditions: the half-life period $t_{1/2}$=1.0 h at 26.1 °C in 70:30 acetone water (v/v).[3] The solvolysis was carried out in the presence of KSCN, KS_2COEt, and KNCO in a similar manner as conducted by Schiavelli and co-workers.[3] In contrast to the reported results,[3] solvolytic reaction of chloroallenes **1a—c** with potassium thiocyanate gave allenyl thiocyanates **2a—c** in high yields. In the IR spectra of **2a—c** were observed a sharp absorption of the thiocyanato group at 2150 cm^{-1} and a weak absorption of the allenyl bond at 1920—1930 cm^{-1}, but the latter was obscured by overlapping with aromatic ring absorptions. The strong evidence for the allenyl structure was obtained from the ^{13}C NMR spectra. The allenyl carbons of triphenylallenyl thiocyanate (**1a**) resonated at 207 ppm for the β carbon, and at 99 and 118 ppm for γ and α carbons, respectively.[5] The carbon of thiocyanato group resonated at 110 ppm.[6] Similar substitution at the α carbon observed in the presence of potassium *O*-ethyl dithiocarbonate as a nucleophile. Solvolytic reaction of chloroallenes **1a** and **1b** led to formation of the corresponding allenyl *O*-ethyl dithiocarbonates **3a** and **3b** in 73 and 57% yield, respectively.

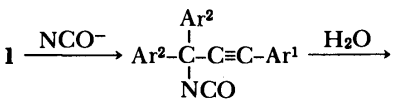


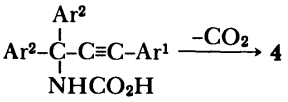
3a: 73%
3b: 57%

However, when potassium cyanate was used as a nucleophile, the cyanate anion attacked on the γ-position to give propargyl derivatives **4**. The IR spectrum of the crude product showed the absorpotion at 3340—2700 and 1700—1645 cm^{-1}, which were assignable to propargylcarbamic acids **5**. However, the compounds **5** could not be isolated because of their instability. Instead, propargyl amines **4** were isolated after treatment of the crude product with an alkaline solution.



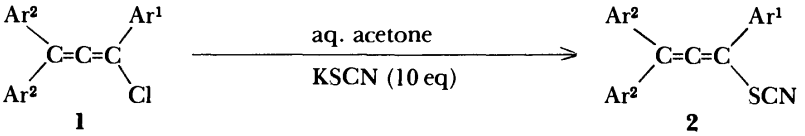
4a: 45%
4b: 68%





5

These results indicate that the reaction manner can be controlled by choice of nucleophiles. From the kinetic[3] and theoretical[7] studies, it is predicted that



a: Ar^1=Ar^2=Ph
b: Ar^1=Ph, Ar^2=*p*-MeC_6H_4
c: Ar^1=*n*-Bu, Ar^2=Ph

2a: 98%
2b: 88%
2c: 72%

nucleophiles react at the propargyl position of the allenyl cation. However, when the γ-position bears a sterically hindered substituent a nucleophile should attack on the allenyl position.[8] Such a steric factor may be operative for a bulky nucleophile. Among the nucleophiles used in this study, thiocyanate and *O*-ethyl dithiocarboate anions are greater in size than cyanate anion because sulfur atom has much larger van der Waals radius than nitrogen or oxygen atom does.[9] The larger nucleophile prefers to attack the allenyl position which has less steric congestion, while the smaller nucleophile prefers the propargyl position which is more reactive than the allenyl position.[3,7] Thus, a high regioselectivity of nucleophiles toward triarylallenyl cations can be explained in terms of the capacity and reactivity of the reacting position and the size of the nucleophiles.

Experimental

Chloroallene 1. Chloroallenes **1** were prepared according to the method prepared by Jacobs and Fenton,[1] from the corresponding propargyl alcohols.[1,3]

Solvolytic Reaction of Chloroallenes 1 in the Presence of Nucleophiles (KSCN, KS_2COEt, and KNCO). To a solution (100—200 ml) of 70:30 acetone-water (v/v) were added chloroallene **1** (1 mmol) and a nucleophile (10 mmol; KSCN, KS_2COEt, or KNCO) and the mixture was stirred for 12—48 h at 25 °C. The reaction mixture was poured into water and the products were extracted with ether. The organic layer was washed with water, saturated sodium chloride solution, and then dried over anhydrous sodium sulfate. After evaporation of the ether, the products were separated by column chromatography on silica gel or alumina using ether–hexane eluent. In the case of potassium cyanate, the crude product obtained by extraction with ether was refluxed for 12 h in a solution of sodium hydroxide (5 mmol) in ethanol (20 ml), benzene (10 ml), and water (20 ml). The product was extracted with ether–benzene and separated by column chromatography on silica gel.

The products obtained are as follows. 1,3,3-Triphenylallenyl thiocyanate (**2a**): mp 115—116 °C (benzene–hexane); ^{1}H NMR ($CDCl_3$) δ=7.20—7.60 (m, ArH); ^{13}C NMR ($CDCl_3$) δ=98.60 (C-3), 110.06 (SCN), 118.01 (C-1), 126.72, 128.95, 129.13, 131.83, 134.12 (aromatic carbons), and 206.90 (C-2); IR (Nujol) 2150 (m, SCN) and 1920 cm^{-1} (m). Found: C, 80.74; H, 4.65; N, 4.20%. Calcd for $C_{22}H_{15}NS$: C, 81.20; H, 4.65; N, 4.30%. 3,3-Bis(*p*-methylphenyl)-1-phenylallenyl thiocyanate (**2b**): Mp 114—115 °C (benzene–hexane); ^{1}H NMR ($CDCl_3$) δ=2.37 (s, Me) and 7.05—7.63 (m, ArH); IR (Nujol) 2150 (m, SCN) and 1920 cm^{-1} (m). Found: C, 81.40; H, 5.41; N, 3.98%. Calcd for $C_{24}H_{19}NS$: C, 81.55; H, 5.42; N, 3.96%. 1-Butyl-3,3-diphenylallenyl thiocyanate (**2c**): Oil; ^{1}H NMR ($CDCl_3$) δ=0.80—2.73 (m, *n*-Bu) and 7.10—7.70 (m, ArH); IR (neat) 2150 (s, SCN) and 1930 cm^{-1} (m). Found: C, 78.55; H, 6.32; N, 4.62%. Calcd for $C_{20}H_{19}NS$: C, 78.65; H, 6.27; N, 4.59%. 1,3,3-Triphenylallenyl *O*-ethyl dithiocarbonate (**3a**): Oil; ^{1}H NMR ($CDCl_3$) δ=1.12 (t, *J*=7 Hz, Me), 4.47 (q, *J*=7 Hz, CH_2), and 6.75—7.70 (m, ArH); ^{13}C NMR ($CDCl_3$) δ=13.35 ($OCH_2\underline{C}H_3$), 70.12 ($O\underline{C}H_2CH_3$), 102.24 (C-3), 112.95 (C-1), 126.65, 128.06, 128.37, 128.72, 129.01, 129.66, 134.13, 134.77 (aromatic carbons), 211.01, and 211.31 (C-2 and C=S); IR (neat) 1930 (w), 1220, 1100, and 1030 cm^{-1} (S_2CO). 3,3-Bis(*p*-methylphenyl)-1-phenylallenyl *O*-ethyl dithiocarbonate (**3b**): Oil; ^{1}H NMR (CCl_4) δ= 1.12 (t, *J*=7 Hz, Me), 2.31 (s, Me), 4.44 (q, *J*=7 Hz, CH_2), and 6.55—7.62 (m, ArH); IR (neat) 1920 (m), 1230, 1115, and 1040 cm^{-1} (S_2CO). **3a** and **b** were not satisfied with their elemental analyses because of their instability. 3-Amino-1,3,3-triphenylpropyne (**4a**): mp 90—91 °C (EtOH–benzene); ^{1}H NMR ($CDCl_3$) δ=2.25 (s, NH_2) and 7.13—7.78 (m, ArH); ^{13}C NMR ($CDCl_3$) δ=59.06 (C-3), 85.12 (C-2). 95.18 (C-1), 123.24, 126.42, 127.30 128.36, 131.71, and 146.19 (aromatic carbons); IR (Nujol) 3370, 3300 (NH_2), and 2200 cm^{-1} (w, C≡C). Found: C, 88.69; H, 6.22; N, 4.92%. Calcd for $C_{21}H_{17}N$: C, 89.01; H, 6.05; N, 4.94%. 3-Amino-3,3-bis(*p*-methylphenyl)-1-phenylpropyne (**4b**): Mp 101—103 °C (EtOH–benzene); ^{1}H NMR (CCl_4) δ=2.18 (s, NH_2), 2.29 (s, Me), and 6.99—7.64 (m, ArH); IR (Nujol) 3300 and 3350 cm^{-1} (NH_2). Found: C, 88.54; H, 6.58; N, 4.65%. Calcd for $C_{23}H_{21}N$: C, 88.71; H, 6.80; N, 4.50%.

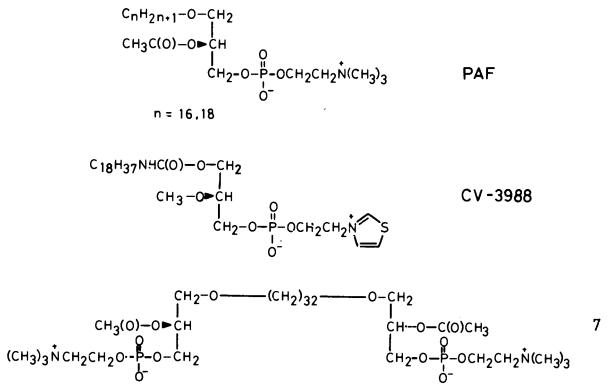
Synopsis. A dimer of platelet activating factor (PAF), 1,1′-(1,32-dotriacontanediyl)bis[2-acetyl-*sn*-glycero(3)phosphocholine] (**7**), was synthesized and examined for platelet aggregation and antihypertension activities. The compound **7** showed both activities with the maximum levels of 1/50—1/100-fold of those of PAF, but the antihypertension effect of **7** persisted much longer and appeared with time lag of 1—3 min. The unique expression of the activities was discussed in conjunction with the molecular structure.

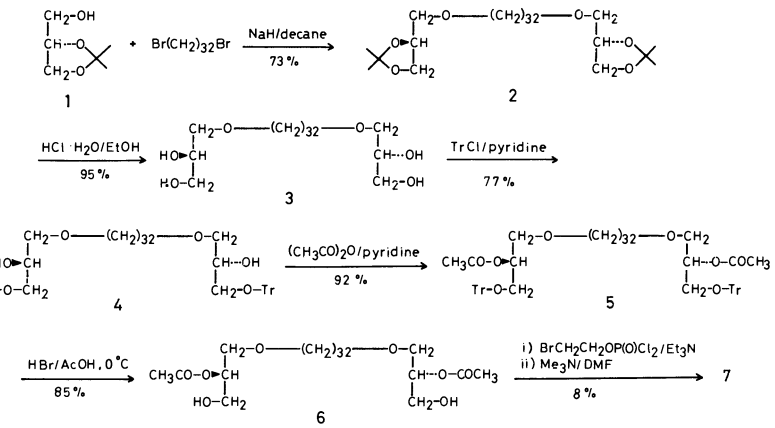
1-Alkyl-2-acetyl-*sn*-glycero(3)phosphocholine (alkyl: C_nH_{2n+1}, n=16 and 18) is released from IgE-sensitized basophiles. The lipids are potent platelet activating factor (PAF)[1,2] and serve as chemical mediators in physiological processes such as anaphylaxis and inflammation.[3] Various agonists have been synthesized to reveal the following structural features for the biological activity;[4] (a) a long chain-alkyl ether linkage at the *sn*-1-O atom,[5,6] (b) short chain acylation (C_{2-4}) at the *sn*-2-O atom,[7,8] and (c) a quaternary ammonium residue as small as $(CH_3)_3N^+$ of the phosphorylcholine moiety at the *sn*-3 position.[9,10] In this paper we wish to report preparation and biological activities (platelet activation and antihypertension) of a new agonist of PAF, 1,1′-(1,32-dotriacontanediyl)bis[2-acetyl-*sn*-glycero(3)phosphocholine] (**7**). The bis(glycerophospholipid) may be considered as a dimeric version of PAF.



Experimental

Synthesis. 2,3-Isopropylidene-*sn*-glycerol (**1**), after conversion into the sodium alkoxide, was heated with 1,32-dibromodotriacontane in decane at 140 °C. The resulting **2** was transformed via **3** and **4** into **5** by a series of usual reactions including acid catalyzed deisopropylidenation, tritylation and acetylation in an overall yield of 73%. Removal of the trityl groups of **5** required considerable experimentation since the acetyl group at the *sn*-2-O position tended to rearrange into the *sn*-3-O position.[11] A treatment of a benzene–ethyl acetate solution of **5** with 25% hydrogen bromide–acetic acid at 0 °C for 50 s was satisfactory to generate **6**, which was isolated by means of Sephadex LH-20 gel column chromatography. A subsequent treatment of **6** with 2-bromoethyl phosphorodichloridate in the presence of triethylamine at room temperature overnight and a reaction of the resulting phosphate with trimethylamine in *N*,*N*-dimethylformamide at 55 °C for 4 d provided **7**, which was isolated and purified by a combination of silica-gel and Sephadex LH-20 gel column chromatographies: 400 MHz ^{1}H NMR ($CDCl_3$–CD_3OD, 2:1 v/v; 7.26 ppm-singlet of $CHCl_3$ as an internal standard) δ 1.14 [coherent peak, 60H, $(CH_2)_{30}$], 2.45 (s, 6H, 2×*sn*-2-CH); IR (KBr) 1735 (C=O), 1240 and 1095 (P-O-C) cm^{-1}. Table 1 lists physical constants of **2**—**7**.

Biological Assays. (i) **Platelet Aggregation.** A 9:1 volumetric mixture of male New Zealand white rabbit blood and 3.8% trisodium citrate was centrifuged at 1100 rpm for



10 min at room temperature. The upper layer, platelet-rich plasma (PRP), was collected. Then, the residual blood sample was centrifuged at 3000 rpm for 10 min at 4 °C to provide platelet-poor plasma (PPP). Platelet count in PRP was measured by Systemax Platelet Counter PL-100, and adjusted to 5×10^8/ml by appropriate dilution with PPP. Platelet aggregation was initiated by adding 30 μl of **7** in a 0.025 M (1 M=1 mol dm^{-3}) tris-HCl buffer (pH 7) containing 0.13 M NaCl into 270 μl of PRP. The assay was conducted according to the turbidimetric procedure of Born and Cross.[13] In the experiment to know the effect of *rac*-3-[*N*-(octadecyl)carbamoyloxy]-2-methoxypropyl 2-(3-thiazolino)-ethyl phosphate (CV-3988)[12] on test compound-induced platelet aggregation, PRP was pretreated with 100 μM of CV-3988 for 3 min. Typical results are displayed in Fig. 1.

(ii) Antihypertension. Wister male rats (weight, 254—276 g) were anesthetized with sodium pentobarbitol (60 mg/kg, i.p.). Appropriate amounts of **7** dissolved in saline or PAF in 0.05 M tris-HCl–0.15 M NaCl buffer (pH 7) was then injected intravenously, and the blood pressure in jugular vein was measured for 15 min by the use of a pressure-transducer, a Nippon Hatsuden model RMP-6018. The results are shown in Fig. 2.

Results and Discussion

It was found that dimerization of PAF into **7** resulted in modifying the platelet aggregation and antihypertension activities in a unique manner; e.g., although the maximum levels of both activities of **7** were 1/50—1/100-fold of those of PAF (Fig. 1a and 1b; Fig. 2) and appeared to be dose-dependent in the examined range (10^{-1}—1 μM for platelet aggregation and 10—100 μg/kg of rat for antihypertension), the antihypertension effect was exhibited with time lag of

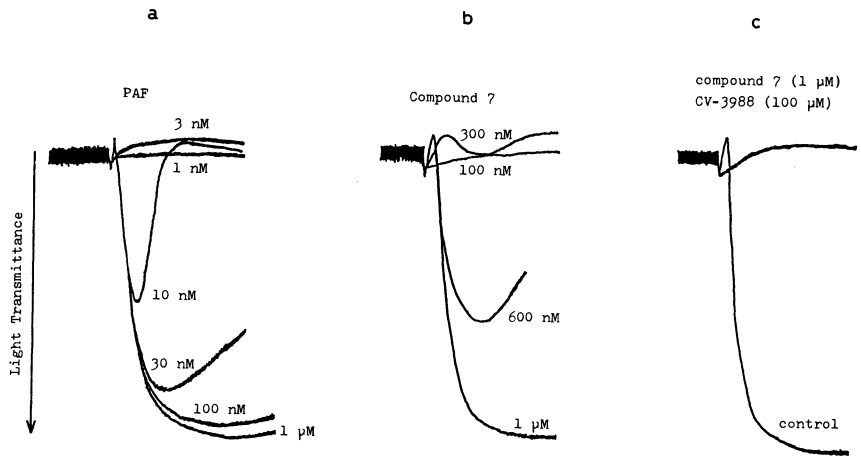


Fig. 1. Typical patterns of PAF- and compound **7**-induced rabbit platelet aggregation (a and b), and inhibitory effect (c) of CV-3988 on the compound **7**-induced aggregation.

1—3 min and seemed to persist for a period much longer than PAF (Fig. 2). By contrast, the effect of PAF was transient and became inactive rapidly within a few minutes after administration. The integrated biological activity over the effective time, though examined only qualitatively, may thus be comparabale with or surpass that of PAF. A mechanism of the PAF-effect has not been understood well.[12,14–16] The compound **7**, however, was seemed to act on platelets in a manner similar to PAF because (i) **7** resembled with PAF in aggregation pattern and (ii) the activity of **7** was inhibited competitively by an antagonist of PAF, CV-3988[14] (typical aggregations: Fig. 1a—c). The decreased magnitudes in the biological activities of **7** may be attributed to conformational or steric effect of the 1,32-dotriacontanediyl residue and/or the increased polarity due to two phosphorylcholine residues. Such a structural modulation would result in slow metabolism leading to long duration of the activities, and the time lag as well, which might be ascribed to slow accommodation of **7** to PAF-receptors on platelets.

Active Sites of a Reduced Molybdena-Alumina Catalyst. A Transient Study of Hydrodenitrogenation of Carbazole and Acridine

Masatoshi NAGAI* and Takashi MASUNAGA†
Department of Chemical Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received October 7, 1988)

Synopsis. A response study of the hydrodenitrogenation of acridine and carbazole on a reduced MoO_3/Al_2O_3 catalyst was performed at 300 °C and 10.1 MPa total pressure. Acridine was strongly adsorbed on the acidic sites of the catalyst surface for hydrogenation, while carbazole was weakly adsorbed not only on the same sites as acridine, but also on the terminal oxygen anion sites in the presence of strong bases.

Molybdena–alumina catalysts have been extensively investigated in an effort to understand the nature of their catalytically active sites for hydrogenation and hydrogenolysis. The chemisorption of NO,[1] oxygen,[2] and pyridine[3,4] has been applied to reduced and sulfided molybdena–alumina catalysts at reduced pressure. The chemisorptions were correlated with the hydrogenation activity and coordinatively unsaturated sites (Lewis acid sites) of the pretreated molybdena surface.

However, hydrodenitrogenation (HDN), hydrogenolysis of a carbon–nitrogen bond of polynuclear aromatic nitrogen compounds, proceeds at high pressure and high reaction temperature.[5–7] The nature of the active sites for HDN should be determined under these reaction conditions. Our recent poisoning studies at 10.1 MPa of the total pressure revealed that both hydrogenation and denitrogenation sites exist on the surface of the molybdenum catalysts.[6,7] The active sites of a sulfided $NiMo/Al_2O_3$ catalyst for hydrogenation were correlatable with the gas-phase basicity of the nitrogen compound,[8] which was proportional to their proton affinity; therefore, hydrogenation takes place on the Brönsted acid sites of molybdenum atoms of the catalyst. Furthermore, the active sites of the catalysts for denitrogenation were related with the gas-phase acidity of the sulfur and oxygen compound;[9] therefore, denitrogenation occurs on the terminal oxygen anion sites which exist on the reduced catalyst as well as desulfurization.[7,9]

A polynuclear nitrogen compound contains two types of nitrogen compounds: a basic (acridine) and nonbasic (carbazole) polynuclear aromatic nitrogen compound. The non-basic nitrogen compound becomes the basic nitrogen compound during hydrogenation. This observation suggested that the adsorption sites of a reduced molybdenum catalyst were different for the two typical nitrogen compounds.

In this work, a transient response study of the HDN of these two typical nitrogen compounds has been applied in order to facilitate an understanding of the nature of the active sites of a reduced Mo/Al_2O_3 catalyst for the HDN of carbazole and acridine at 300 °C and 10.1 MPa.

Experimental

The reagents, the catalyst, and the reactor used in this study are shown elsewhere.[6] Two grams of the 12.5% MoO_3/Al_2O_3 catalyst were placed in the reactor during a typical series of experiments. The catalyst was oxidized in air at 450 °C for more than 24 h and then reduced in hydrogen for 4 h at 400 °C before a run. After reduction, the reactor was cooled to the desired temperature by a flowing hydrogen stream. A solution containing a mixture of 0.013 mol L^{-1} of carbazole and 0.013 mol L^{-1} of acridine in xylene was injected at 20 ml h^{-1}. A steady state was usually reached within 3 h. The reaction products, having higher boiling points than xylene, were analyzed by F.I.D. gas chromatography (Dexsil 400, 2.5%). The lower boiling point products, such as NH_3 and any light cracking products, were not determined because the amounts formed during reactions were negligible.

Results and Discussion

In previous studies,[6,7] acridine was easily hydrogenated to produce perhydroacridine and octahydroacridine on the Brönsted acid sites. The major denitrogenated compound was dicyclohexylmethane by the C–N scission of perhydroacridine on the terminal oxygen anion sites. Carbazole was difficult to hydrogenate to tetrahydrocarbazole. Other hydrogenated carbazole compounds were barely formed at any of the other reaction temperatures. The major denitrogenated product was 1,1′-bicyclohexyl together with 2-ethylbicyclo[4.4.0]decane and hexylcyclohexane.

The transient experiment provided two different aspects for the HDN of acridine and carbazole with different basicities. The HDN of acridine on the reduced Mo/Al_2O_3 catalyst at 300 °C and 10.1 MPa in the presence and absence of carbazole is shown in Fig. 1. A transient response occurred during the first 2.5 h; the HDN reaction then reached a steady state. The addition of carbazole increased the amount of octahydroacridine formed and decreased both dicyclohexylmethane and benzylcyclohexane amounts. This result showed that the addition of carbazole hindered the hydrogenation of octahydroacridine to perhydroacridine. This result suggested that carbazole was adsorbed and hydrogenated on the same active site as both acridine and octahydroacridine.

The concentration of perhydroacridine initially jumped for the first 2.5 h upon the addition of carbazole and, then, gradually decreased again to its initial concentration before the addition of carbazole. This implied that the addition of carbazole expelled

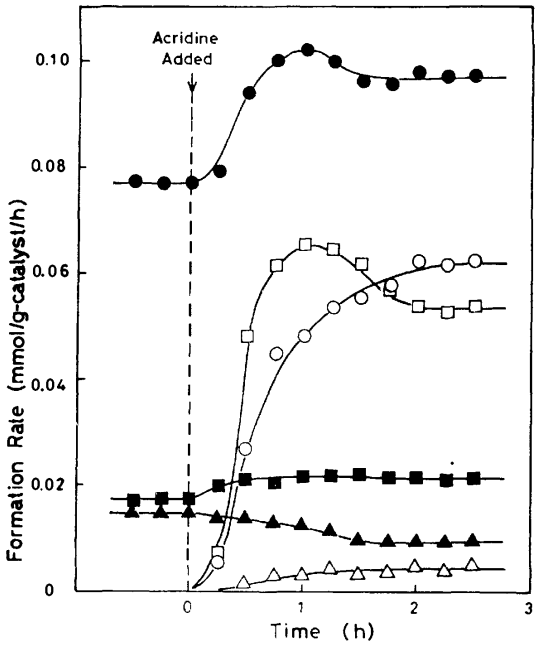

Fig. 2. The addition of acridine to the HDN of carbazole on the reduced Mo/Al_2O_3 catalyst at 300 °C and 10.1 MPa total pressure. The symbols are the same as those in Fig. 1.

the perhydroacridine adsorbed from the active site of the catalyst. The amount of perhydroacridine adsorbed was calculated as being 11.8 μmol g^{-1} on the basis of the area of the increased perhydroacridine. This observation indicated that carbazole was also adsorbed on the same active site where perhydroacridine was adsorbed. Since perhydroacridine was adsorbed on the terminal oxygen anion sites, carbazole was competitively adsorbed on the same anion sites as perhydroacridine as well as on the Brönsted acid sites.

On the other hand, for the addition of acridine to carbazole HDN, there was no similar observation to that when perhydroacridine was desorbed by the addition of carbazole. Figure 2 shows that the addition of acridine to carbazole HDN decreased 1,1′-bicyclohexyl and then 5.7 μmol g^{-1} of both carbazole and tetrahydrocarbazole were released to the solution from the catalyst surface in 2.5 h. The addition of acridine appears to have inhibited the hydrogenations of tetrahydrocarbazole to perhydrocarbazole. In addition, 5.8 mol g^{-1} of both acridine and the hydrogenated compounds were adsorbed on the catalyst's surface. The adsorbed amount of acridine hydrogenated compounds was almost equal to the released amount of the carbazole hydrogenated compounds. Therefore, acridine was adsorbed and hydrogenated on the Brönsted sites of the catalyst, but not adsorbed on the anion sites. Acridine is also competitively hydrogenated with the resulting hydrogenated acridine compounds on the same sites. On the other hand, carbazole is actually a very weak base, but carbazole turns to a basic compound during the reaction; therfore carbazole is weakly adsorbed on the same sites as acridine, and even adsorbed on the terminal oxygen anion sites in the presence of a stong base.

Estimating the amount of denitrogenation sites on which perhydroacridine and carbazole were adsorbed found that the 12.5 wt% MoO_3 catalyst (N_2 BET surface area: 188 $m^2 g^{-1}$) contains 5.16×10^{18} Mo molecules/m^2. The amount of perhydroacridine (11.8 μmol/g-cat) released from denitrogenation sites corresponds to 3.7×10^{16} molecules/m^2. The number is two orders of magnitude smaller than the total molybdenum available on the catalyst. It could be estimated that 0.72% of the molybdenum sites have become active sites.

Suarez et al.[4] studied the adsorption of pyridine on reduced Mo/Al_2O_3 (7.48 wt% Mo, BET 211 $m^2 g^{-1}$) at 400 °C. The amount of adsorbed pyridine (Lewis acid site) was 0.18×10^{18} molecules/m^2 when the catalyst was exposed for 6 h. When the value was converted to that on the 12.5 wt% Mo/Al_2O_3, it was 0.3×10^{18} Mo molecules/m^2, which was three times that obtained in this study. They reported that adsorbed pyridine (Brönsted acid site) barely exists on the surface of the reduced catalyst. Furthermore, Segawa and Hall[2] found that the Brönsted acidity could be eliminated by a reduction of the catalyst; Lewis acid sites were present on both the molybdenum and alumina portions of the catalyst's surface. The reduced catalyst held many Lewis acid sites, but rarely Brönsted acid sites under reduced pressure. Thus, there was a great gap between the results of our study at high hydrogen pressure and that of the adsorption experiment under reduced pressure. The acidity and number of active sites on the surface of the Mo/Al_2O_3 catalyst during the reaction would be expected to be different from those measured

under vacuum. It is suggested that molybdenum Lewis acid sites turned to Brönsted sites at high hydrogen pressure.

A Conductometric Study on the Phenylglyoxylic Acid-Strychnine Complex

Yasuzo SAKAI, Kenichi SATO, Ikuko ITO, and Fujio TAKAHASHI*
Department of Applied Chemistry, Faculty of Engineering, Utsunomiya University, Utsunomiya 321
(Received June 27, 1988)

In order to elucidate the mechanism by which phenylglyoxylic acid (PGA) is reduced electrochemically in the presence of strychnine (SC) to form mandelic acid (MA), which exhibits an optically active property, conductometric studies were carried out. The formation of a 1 : 1 complex between PGA (or MA) and SC was suggested from the results that equimolar mixture of PGA (or MA) and SC showed a maximum decrease of conductivity. Equilibrium constants of the 1 : 1 complex of PGA-SC or MA-SC were determined from the results of conductivity measurements at various temperatures. The thermodynamic data were calculated. ΔH and ΔS were found to be +22 kJ mol^{-1} and +1.1×10^2 J K^{-1} mol^{-1} for both the PGA-SC complex and MA-SC complex.

There have been many papers concerning asymmetric electrochemical reaction occurring in the presence of optically active substances such as alkaloids used as inductors.[1-6] It is known that phenylglyoxylic acid (PGA) is reduced electrochemically under the influence of strychnine (SC) to form mandelic acid (MA), which exhibits a dextrorotatory property.[1,2] However, the reaction mechanism remains unclear at present. Therefore, we presumed that PGA might combine with SC to form a complex, which was adsorbed onto the surface of the electrode,[7] and reduced to form the MA-SC complex. For the first step towards verifying our presumption, in this paper, we present the results of conductometric studies to determine equilibrium constants, and then calculate thermodynamic data for complexes of PGA-SC and MA-SC. On the basis of these results, we speculate about a possible formation of the complex for the asymmetric electrochemical reduction.

Theoretical

Let K be an equilibrium constant, if PGA or MA reacts with SC to form a 1 : 1 complex. Also let concentrations of free PGA (or MA), free SC and 1 : 1 complex be [P], [S], and [PS], and total concentrations of PGA (or MA) and SC be P_T and S_T, then,

$$\mathrm{P} + \mathrm{S} \rightleftarrows \mathrm{PS}, \tag{1}$$

$$K = \frac{[\mathrm{PS}]}{[\mathrm{P}]\,[\mathrm{S}]}, \tag{2}$$

$$P_T = [\mathrm{P}] + [\mathrm{PS}], \tag{3}$$

$$S_T = [\mathrm{S}] + [\mathrm{PS}], \tag{4}$$

In the case of an equimolar mixture, we define a ratio of [PS] to C as α,

$$\alpha = \frac{[\mathrm{PS}]}{C}, \tag{5}$$

where

$$P_T = S_T = C. \tag{6}$$

From Eqs. 2—6, the following equation was derived.

$$\frac{\alpha}{(1-\alpha)^2} = KC. \tag{7}$$

From plots of $\alpha/(1-\alpha)^2$ against C, we may obtain a straight line, the slope of which is equal to K.

The value of α will be obtained by the measurement of conductivity as follows:

Let the conductivity of each individual solution of PGA (or MA) and SC, and the conductivity of mixture of PGA (or MA) and SC be κ_P, κ_S, κ_{PS}, and their molar conductivities be Λ_P, Λ_S, Λ_{PS}, then

$$\kappa_P = P_T\Lambda_P, \tag{8}$$

$$\kappa_S = S_T\Lambda_S, \tag{9}$$

$$\kappa_{PS} = [\mathrm{P}]\Lambda_P + [\mathrm{S}]\Lambda_S + [\mathrm{PS}]\Lambda_{PS}. \tag{10}$$

Eq. 10 is acceptable at very low concentrations of PGA (or MA) and SC, unless other species of complex may exist in the solution. The difference of conductivity, $\Delta\kappa$, is

$$\Delta\kappa = (\kappa_P + \kappa_S) - \kappa_{PS}. \tag{11}$$

The 1 : 1 complex may exhibit less ionic property, because a carboxyl group of PGA (or MA) and a heterocyclic nitrogen (not an indolizine nitrogen) of SC are locked inside the complex by the formation of an ionic bond. Therefore, it is reasonable to assume that

$$\Lambda_{PS} \ll \Lambda_P \text{ or } \Lambda_{PS} \ll \Lambda_S. \tag{12}$$

If we neglect Λ_{PS}, then, the following equation is introduced from Eqs. 5 and 8—12.

$$\frac{\Delta\kappa}{\kappa_P + \kappa_S} = \alpha. \tag{13}$$

The values of α are determined at every concentration of equimolar mixtures of PGA (or MA) and SC by Eq. 13 from the measurement of conductivity. Then, we can obtain K from the slope at zero with respect to concentration on plots of $\alpha/(1-\alpha)^2$ against C according to Eq. 7. If a 1 : 1 complex exists in the mixture, a maximum difference of $\Delta\kappa$ must appear at $P_T = S_T$ in relation between the molar ratio and $\Delta\kappa$, when

P_T+S_T=constant. This can be demonstrated by the derivation in the same manner as Jop's consecutive variation method,[8] except that absorption is replaced by conductivity. This modified Jop's method is valuable for the determination of the equilibrium constants of molecular complexes, which is obtained by ionic bond formation with conductivity change and without absorption change.

Experimental

PGA, MA, and SC sulfate used were commercially available reagent grade. SC sulfate was used in place of free SC, which is less soluble in water. These compounds were dissolved in deionized water to prepare a 1—60 mol dm^{-3} solution.

The conductivities were measured with a TOA conductometer CM-30ET at 20—35 °C

Results and Discussion

The sample solutions were prepared with various concentrations of individual solution of PGA, MA, and SC, and those of equimolar mixture of PGA (or MA) and SC. The conductivities were measured at 20—35 °C. The results are shown in Figs. 1 and 2.

In order to verify the presence of a 1 : 1 complex, sample solutions were prepared with various molar

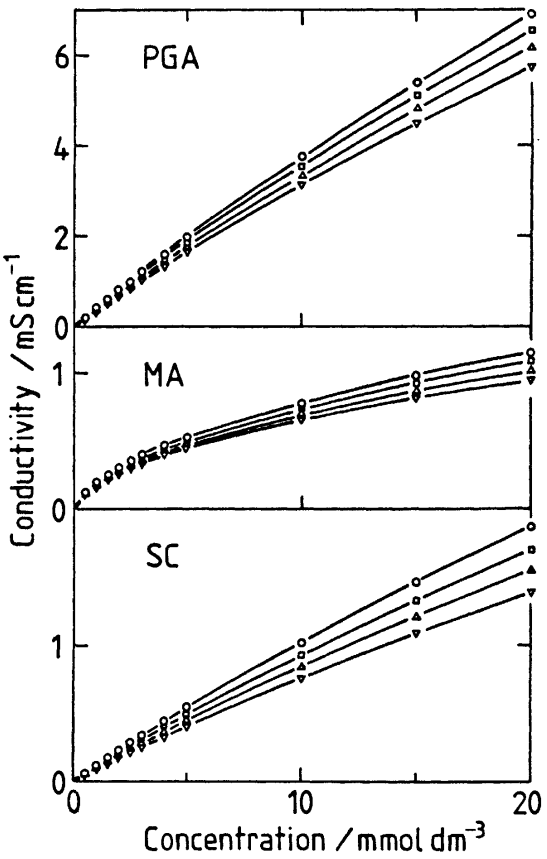

Fig. 1. The conductivities of individual solution of PGA, MA, or SC. —▽—: 20 °C, —△—: 25 °C, —□—: 30 °C, and —○—: 35 °C.

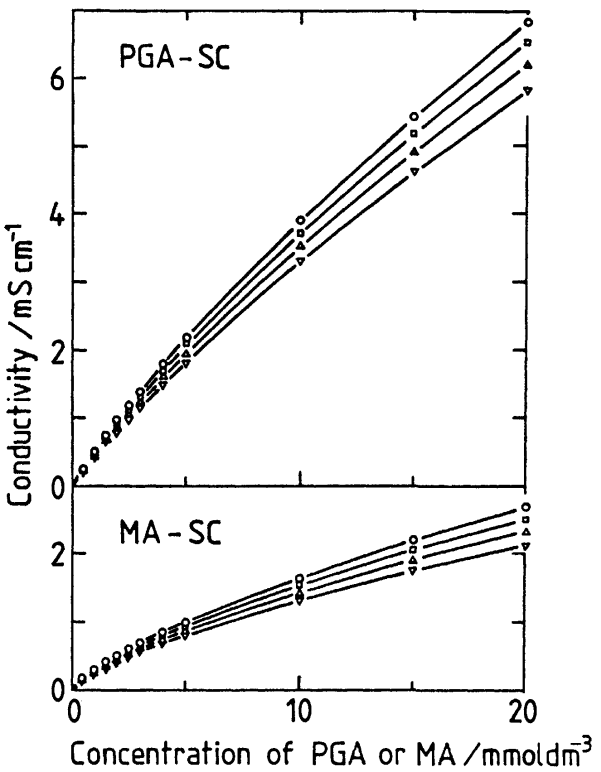

Fig. 2. The conductivities of equimolar mixture of PGA and SC, or MA and SC. The same symbols as those in Fig. 1 are used.

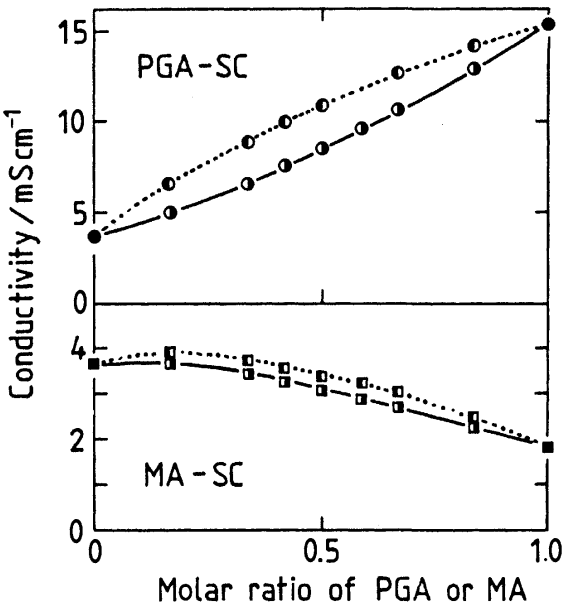

Fig. 3. Plots of conductivity against molar ratio on PGA-SC and MA-SC systems (25 °C). Total concentrations of PGA (or MA) and SC were maintained at 60 mmol dm^{-3}. Solid lines; conductivity of mixture of PGA (or MA) and SC at each molar ratio. Dotted lines; sum of conductivities of individual solution of PGA (or MA) and SC at corresponding concentration.

ratio of PGA (or MA) and SC under the conditions that the total concentration of the two components was kept constant, and these conductivites were measured at 25 °C. We have many data on the relation between conductivity and molar ratio. In order to avoid duplication we present here only two plots at 60 mmol dm^{-3} of total concentration as typical results in Fig. 3.

In Fig. 3, plots on solid lines show the conductivity of a mixture of PGA (or MA) and SC at each molar ratio, and plots on dotted lines show the sum of conductivities of individual solution of PGA (or MA) and SC at the corresponding concentration. The sum of conductivities was calculated from the data in Fig. 1. The gaps between the solid lines and dotted lines are equal to $\Delta\kappa$s. It was found that the maximum gap ($\Delta\kappa$) was obtained at a molar ratio of 0.5.

It must be considered that SC sulfate might be dissociated into SC and sulfate ion completely at infinite dilution in water. The same consideration is applied in the case of a mixture of PGA (or MA) and SC, when the conductivity of the sulfate portion may be offset by the subtraction of the mixture from the sum of indvidual solutions.

This consideration sustains our presumption of the presence of a 1 : 1 complex in the mixture of PGA (or MA) and SC. The conductivity of the mixture was smaller than the sum of the conductivities of the individual solution of PGA (or MA) and SC. This is because the concentrations of free carboxyl group and free base decrease on the formation of an ionic bond.

The values of α were calculated by Eq. 13 and in turn those of $\alpha/(1-\alpha)^2$ were obtained. Plots of $\alpha/(1-\alpha)^2$ against concentration of PGA (or MA) are shown in Fig. 4. This indicates that Eq. 7 is effective at very low the concentrations. The slopes, which should be equal to the equilibrium constant, K, were determined at zero extrapolation on every curve in Fig. 4. It was found, on the other hand, that plots according to Kohlrausch's equation, $\Lambda=\Lambda_\infty-A\sqrt{C}$, with the data in Figs. 1 and 2 fell on straight lines in lower regions of concentration of individuals and mixtrues of PGA and SC as shown in Fig. 5. The values of α in the case of the PGA-SC mixture in the region of very low concentration were recalculated by using values obtained from the straight lines in Fig. 5. The dotted lines in Fig. 4 in the case of the PGA-SC mixtures were obtained by using values, α from Fig. 5. Equilibrium constants, K, were determined from the slopes at every temperature. In the case of MA solutions, no straight line is obtained from the Kohlrausch plots (Fig. 6). This is because MA is a weak acid. Therefore, we made slopes in Fig. 4 in the case of MA-SC mixture by a rough estimate. The values of K are summarized in Table 1, larger error in the case of MA-SC than PGA-SC should be considered in Table 1.

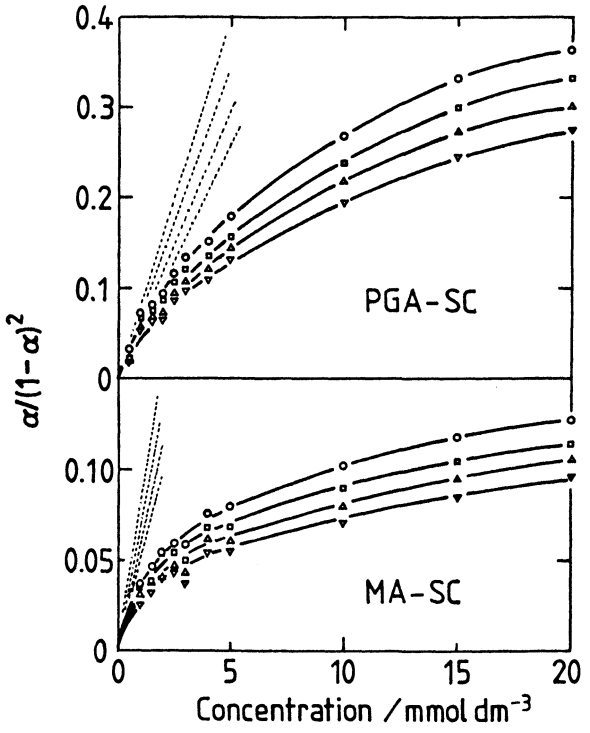

Fig. 4. Plots of $\alpha/(1-\alpha)^2$ against concentration of PGA (or MA). The same symbols as those in Fig. 1. are used. Dotted lines show the slopes of each curve at the zero concentration.

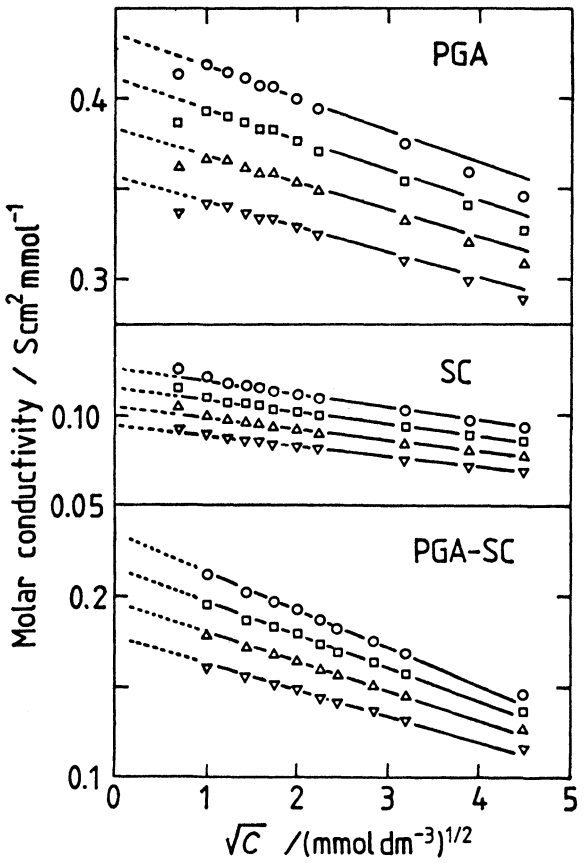

Fig. 5. Plots according to Kohlrausch's equation on PGA, SC, and PGA-SC solutions. The same symbols as those in Fig. 1 are used.

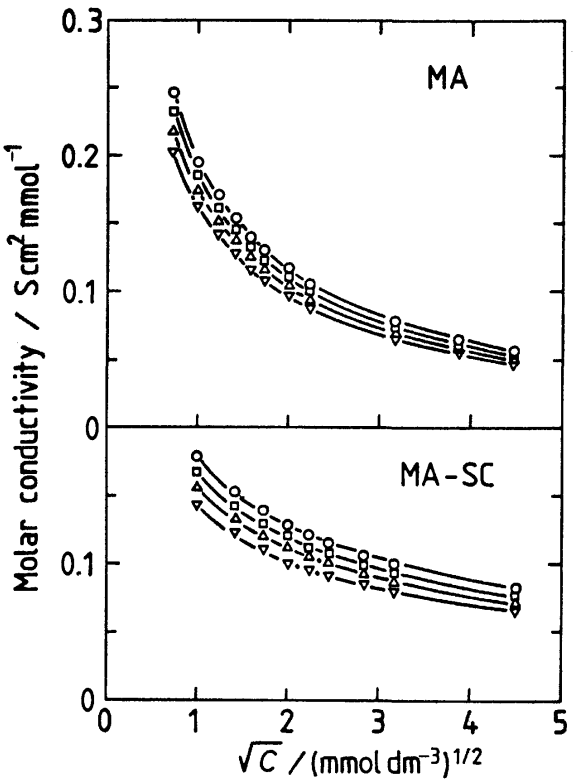

Fig. 6. Plots according to Kohlrausch's equation on MA and MA-SC solutions. The same symbols as those in Fig. 1 are used.

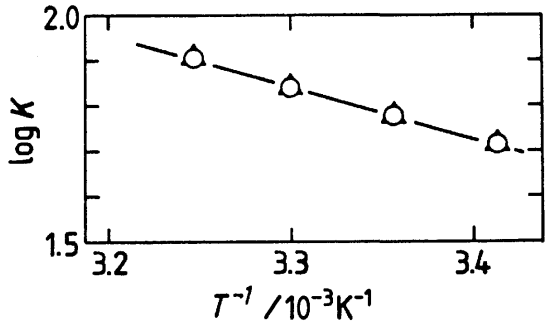

Fig. 7. Plots of $\log K$ against $1/T$ on PGA-SC and MA-SC systems. —○—: PGA-SC system and —△—: MA-SC system.

From plots of $\log K$ against $1/T$, we obtained straight lines as shown in Fig. 7. Thermodynamic data, ΔH and ΔS, were calculated with slopes in Fig. 7 by the equation, $\ln K=(-\Delta H/R)\ (1/T)+(\Delta S/R)$, as shown in Table 1.

Positive values of ΔH and ΔS suggest the existence of hydrophobic interaction in the process of 1 : 1 complex formation in aqueous solution. It is plausible that a phenyl group of PGA (or MA) may contact with a hydrophobic group supposed to be a benzene ring of SC by excluding water molecules from hydrated PGA (or MA) and hydrated SC.

Table 1. Equilibrium Constants and Thermodynamic Data for Both PGA-SC and MA-SC Systems. The Same Data Were Obtained on Both Systems as in Table 1

Equilibrium constant/$dm^3\,mol^{-1}$	52±5 (293 k) 60±5 (298 K) 69±5 (303 K) 80±5 (308 K)
$\Delta H°/J\,mol^{-1}$	$+2.2\times10^4$
$\Delta S°/J\,K^{-1}\,mol^{-1}$	$+1.1\times10^2$

The values of ΔH and ΔS show almost no difference in both the PGA-SC complex and the MA-SC complex. It seems that the difference of molecular structure between PGA and MA may change little with the ratio of complex formation.

The equilibrium constant of the PGA-SC complex is consistent with that of the MA-SC complex in the region of 20—35 °C. Therefore, it is possible that the PGA in the PGA-SC complex is replaced by MA to form the MA-SC complex. As the PGA-SC complex is reduced to form the MA-SC complex on the surface of the electrode, the following process must be repeated:

$$\text{PGA} + \text{SC} \rightleftarrows \text{PGA-SC} \xrightarrow{2H^+,\,2e} \text{MA-SC} \rightleftarrows \text{MA} + \text{SC}. \quad (14)$$

A Theoretical Study of the Ionized State of Polymers with the Localized Molecular Orbital Method

Akira IMAMURA,* Kehong YE, and Masahiro TAKETOSHI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received August 1, 1988)

A localized molecular orbital method for the investigation of the ionized state of polymers is presented. It is based on the Crystal Orbital Method(CO). By performing a super-cell method and Edmiston and Ruedenberg's LMO method, the Bloch function was transformed into a nearly completely localized Wannier function. Furthermore, the calculation of the configuration interaction was introduced to obtain more reasonable results. The present method was applied to polyacetylene (PA), polyethylene (PE), and polypropylene (PP). Ionization potentials of these polymers were calculated and compared with experimental and other theoretical results. All the calculations were performed using the CNDO/S approximation.

Interest in the theoretical studies of organic polymers has grown considerably in recent years. As the result of the remarkable development of computers, it has become possible to investigate the electronic structure of huge molecules or complicated systems which could not be treated before. Consequently, many theoretical methods have been proposed, and many calculated results have been reported. Most of these calculations, however, have been carried out on the ground state of polymers. Not many attempts have been done to investigate the ionized state of polymers. We carried out this study for the following two main reasons. One is that suitable theory has not yet been established. The second reason is the lack of precise experimental values, which makes the comparison between experimental and theoretical results defficult, sometimes even impossible.

It is known that, for the species in which the interaction between segments is very weak, the exciton model is useful, while for the species in which the interaction is very strong, the crystal orbital method provides a good description. However, for the species in which the interaction is between the above two, the theory seems not to be established. Therefore, the purpose of this study is to present a theoretical method for the investigation of the ionized state of polymers. In our method, by using a super-cell method[1] and Edmiston and Ruedenberg's LMO method[2,3] a nearly completely localized Wannier function can be obtained from Bloch's function. We can calculate the ionization potential from this Wannier function directly or after carrying out the configuration interaction procedure. We applied the method to polyacetylene, polyethylene, and polypropylene. The results seem to be in somewhat good agreement with the experimental values.

Method of Calculations

In the tight-binding approximation, one electron-crystal orbital for a linear-periodic polymer is given by Bloch's function as follows:[4]

$$\psi_{ks}(\boldsymbol{r}) = (1/N)^{1/2} \sum_{j=1}^{N} \sum_{t=1}^{n} C_{ks,jt} \chi_t \{\boldsymbol{T}^j(\boldsymbol{r} - \boldsymbol{r}_t - j\boldsymbol{a})\} \quad (1)$$

$$C_{ks,jt} = \exp(ikj) C_{ks,t} \quad (2)$$

$$k = 2\pi p/N \quad (p = 0, 1, 2 \cdots\cdots N-1) \quad (3)$$

where j denotes a cell in the polymer; t, an atomic orbital in the j-th cell; $\boldsymbol{r}_t$, its vector from the center of a segment; $\boldsymbol{T}$, the rotational operator around the helical axis, and $\boldsymbol{a}$, the unit vector of the translational symmetry which is paralled to the helical axis. N and n specify the total number of cells and the number of atomic orbitals in an unit cell, while the s value, ranging from 1 to n, indicates an energy band. $C_{ks,jt}$ can be rewritten as Eq. 2; here i denotes the imaginary number. The k value in Eq. 3 corresponds to the wavenumber vector defined by the solid state physics.

A localized molecular orbital (LMO) can be obtained in several ways. In the case of polymers, the Wannier transformation is well known. The Wannier function has a particular property: if the overlap integrals between neighbouring segments are very small, the MO coefficients, C_k's, do not depend on the wavenumber vector, k. That is, the MOs obtained are localized in a certain segment. However, in general, a nearly completely localized molecular orbital can not be expected by using the Wannier transformation only. Therefore, in order to get a well-localized molecular orbital for polymers, we considered two procedures before the Wannier transformation. One is called the super-cell method, and second, a modification of the Edmiston and Ruedenberg's LMO procedure which was performed for the wave function of super cells in each wavenumber vector. By performing these two procedures, the overlap integrals between corresponding localized orbitals in neighbouring segments become very small; that is, well-localized MOs can be expected with the two procedures, followed by the Wannier transformation.

The details of the super-cell method can be found in Ref. 1. Here we will give just a simple outline. It assumed that, in a linea-periodic polymer system, several units can be considered as big units, named "super cells", if the relation between such a super cell and the

unit cells satisfies the following equations:

$$k' = mk - 2\pi j \quad (j: \text{integer}) \tag{4}$$

$$C_{k's,t}(l) = C_{ks,t} \exp\{i(l-1)k\} \tag{5}$$

where k' and $C_{k's,t}$ denote the wave vector and the MO coefficient of the super cell, while k and $C_{ks,t}$ are those of the unit cells. The integer j in Eq. 4 must be chosen so that the value of k is in the range of the first Brillouin zone (0—2 π); l indicates the l-th cell in the super cell.

After the super cells were created, as has been mentioned above, we treated the super cell thus obtained in each wavenumber vector with the modification of the Edmiston and Ruedenberg's energy-localized MO method. In general, however, the wave functions of polymers are complex; so in this procedure we completed the LMO by considering three kinds of transformations, which will be described in detail below.

1. Orthogonal transformation:

$$\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} \cos\gamma & \sin\gamma \\ -\sin\gamma & \cos\gamma \end{pmatrix} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} \tag{6}$$

where u_1, u_2, and ψ_1, ψ_2 are the complex functions. After the transformation, the sum of the diagonal elements is given by the following equations:

$$D(u) = D(\psi) + A_{12} + (A_{12}+B_{12})^{1/2} \cos 4(\gamma-\alpha) \tag{7}$$

$$2A_{12} = [\psi_1^*\psi_2 + \psi_1\psi_2^* | \psi_1^*\psi_2 + \psi_1\psi_2^*] - [\psi_1\psi_1^* - \psi_2\psi_2^* | \psi_1\psi_1^* - \psi_2\psi_2^*] \tag{8}$$

$$B_{12} = [\psi_1\psi_1^* - \psi_2\psi_2^* | \psi_1^*\psi_2 + \psi_1\psi_2^*] \tag{9}$$

$$\tan 4\alpha = -B_{12}/A_{12} \tag{10}$$

In Eq. 7, when the value of $\gamma=\alpha+(n\pi/2)$, $D(u)$ reaches a maximum. By placing the Bloch function, Eq. 1, into Eqs. 8 and 9 and by using the periodic boundary condition and the CNDO/S[5] approximation, Eqs. 8 and 9 can be rewritten as follows:

$$2A_{k,12} = 1/N \sum_{t=1}^{n}\sum_{u=1}^{n} \{(C_{k1,t}^* C_{k2,t} + C_{k1,t} C_{k2,t}^*)(C_{k1,u}^* C_{k2,u} + C_{k1,u} C_{k2,u}^*) - (C_{k1,t}^* C_{k1,t} - C_{k2,t} C_{k2,t}^*)(C_{k1,u} C_{k1,u}^* - C_{k2,u} C_{k2,u}^*)\} \sum_{j=1}^{N} \gamma_{tu}^{0j} \tag{11}$$

$$B_{k,12} = 1/N \sum_{t=1}^{n}\sum_{u=1}^{n} (C_{k1,t} C_{k1,t}^* - C_{k2,t} C_{k2,t}^*)(C_{k1,u}^* C_{k2,u} + C_{k1,u} C_{k2,u}^*) \sum_{j=1}^{N} \gamma_{tu}^{0j} \tag{12}$$

$$\gamma_{tu}^{0j} = [\chi_t \chi_t | \chi_u(\boldsymbol{T}^j\boldsymbol{r} - j\boldsymbol{a}) \chi_u(\boldsymbol{T}^j\boldsymbol{r} - j\boldsymbol{a})] \tag{13}$$

2. Transformation between the real part of one MO and the imaginary part of the other MO:

$$\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} \cos\gamma & i\sin\gamma \\ i\sin\gamma & \cos\gamma \end{pmatrix} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} \tag{14}$$

In this case, the sum of the diagonal elements has the following forms:

$$D(u) = D(\psi) + A_{12} + (A_{12}+B_{12})^{1/2} \cos 4(\gamma-\alpha) \tag{15}$$

$$2A_{12} = [\psi_1^*\psi_2 - \psi_1\psi_2^* | \psi_1^*\psi_2 - \psi_1\psi_2^*] - [\psi_1\psi_1^* - \psi_2\psi_2^* | \psi_1\psi_1^* - \psi_2\psi_2^*] \tag{16}$$

$$B_{12} = [\psi_1\psi_1^* - \psi_2\psi_2^* | \psi_1^*\psi_2 - \psi_1\psi_2^*] i \tag{17}$$

$$\tan 4\alpha = -B_{12}/A_{12} \tag{18}$$

By using the same procedures as in Transformation 1, Eqs. 16 and 17 become:

$$2A_{k,12} = -1/N \sum_{t=1}^{n}\sum_{u=1}^{n} \{(C_{k1,t}^* C_{k2,t} - C_{k1,t} C_{k2,t}^*)(C_{k1,u}^* C_{k2,u} - C_{k1,u} C_{k2,u}^*) + (C_{k1,t} C_{k1,t}^* - C_{k2,t} C_{k2,t}^*)(C_{k1,u} C_{k1,u}^* - C_{k2,u} C_{k2,u}^*)\} \sum_{j=1}^{N} \gamma_{tu}^{0j} \tag{19}$$

$$B_{k,12} = i/N \sum_{t=1}^{n}\sum_{u=1}^{n} (C_{k1,t} C_{k1,t}^* - C_{k2,t} C_{k2,t}^*)(C_{k1,u}^* C_{k2,u} - C_{k1,u} C_{k2,u}^*) \sum_{j=1}^{N} \gamma_{tu}^{0j} \tag{20}$$

Well-localized MOs can be obtained by carrying out the above two transformations iteratively for every wavenumber vector. Finally, to rearrange the MO coefficients to similar types for all k values, a third transformation will be performed.

3. Transformation between real part and imaginary part in the same MO:

$$u_1 = \{a(a^2+b^2)^{1/2} - ib(a^2+b^2)^{1/2}\}\psi_1 \tag{21}$$

The LMO of the super cell completely obtained can be expressed in the following form:

$$\psi_{ks}(\boldsymbol{r}) = (1/N)^{1/2} \sum_{j=1}^{N}\sum_{t=1}^{n} \exp(ikj) C_{ks,t}(\text{LMO}) \chi_t(\boldsymbol{T}^j\boldsymbol{r} - j\boldsymbol{a}) \tag{22}$$

Using the above formula, we can derive the Wannier function easily. It is well-known that the Wannier function[6] is described as follows:

$$a_s(\boldsymbol{r}-l) = (1/N)^{1/2} \sum_{k} \exp(-ikl)\psi_{ks}(\boldsymbol{r}) \tag{23}$$

where l is the l-th segment of the Wannier function. By inserting Eq. 22 into Eq. 23, we obtain:

$$a_s(\boldsymbol{r}-l) = \sum_{j=1}^{N}\sum_{t=1}^{n} A_{ls,jt} \chi_t(\boldsymbol{T}^j\boldsymbol{r} - j\boldsymbol{a}) \tag{24}$$

$$A_{ls,jt} = (1/N) \sum_{k} \exp\{ik(j-l)\} C_{ks,t}(\text{LMO}) \tag{25}$$

In order to calculate the ionization potential from the Wannier function, four kinds of calculation models were considered; the ionization was assumed to arise from the central cell of the Wannier function. Next, we will give an outline for each model.

Model 1. The ionization energy is calculated from the above-obtained Wannier function directly:

$$I.P = E(M) - E(M^+) = H_{m0} + \sum_{l=1}^{N}\sum_{s=1}^{n} (2J_{ls,m0} - K_{ls,m0}) \tag{26}$$

where M corresponds to the ground state, and M^+ to the ionized state.

$$H_{m0} = [a_m(\boldsymbol{r}_1) | \hat{h} | a_m(\boldsymbol{r}_1)] \tag{27}$$

$$J_{ls,m0} = [a_s(\boldsymbol{r}_1 - l) a_m(\boldsymbol{r}_2) | 1/r_{12} | a_s(\boldsymbol{r}_1 - l) a_m(\boldsymbol{r}_2)] \tag{28}$$

$$K_{ls,m0} = [a_s(\boldsymbol{r}_1 - l) a_m(\boldsymbol{r}_2) | 1/r_{12} | a_m(\boldsymbol{r}_1) a_s(\boldsymbol{r}_2 - l)] \tag{29}$$

Using the Wannier function, the one electron term in Eq. 26 becomes:

$$H_{m0} = \sum_{tt'}\sum_{jj'} A_{m0,jt}^* A_{m0,j't'} [\chi_t(\boldsymbol{T}^j\boldsymbol{r} - j\boldsymbol{a}) | \hat{h} | \chi_{t'}(\boldsymbol{T}^{j'}\boldsymbol{r} - j'\boldsymbol{a})] \tag{30}$$

while the two electron term is:

$$\sum_l \sum_s (2J_{ls,m0}-K_{ls,m0}) = 2\sum_{tt'}\sum_{jj'} A^*_{m0,j't'}A_{m0,j't'}\gamma^{jj'}_{tt'} \sum_l \sum_s A^*_{js,jt}A_{ls,jt} - \sum_{tt'}\sum_{jj'} A^*_{m0,j't'}A_{m0,jt}\gamma^{jj'}_{tt'} \sum_l \sum_s A^*_{js,jt}A_{ls,j't'} \quad (31)$$

Model 2. In order to get even more reliable results, that is, results more comparable with the experimental values, in this model we introduced a configuration interaction treatment and carried it out in a unit cell of the polymer.

In the present work, a complete singly excited configuration interation (SECI) was considered. The elements of matrix for SECI can be simply expressed in the following way:

Diagonal elements:

$$H_{kk}=-\{h_{kk}+\sum_i (2J_{ik}-K_{ik})\} \quad (32)$$

Non-diagonal elements:

$$H_{kl}=-h_{kl}-\sum_i \{2(kl|ii)-(ki|ii)\}-(kl|kk)-(kl|ll) \quad (33)$$

Using the Wannier function and the parameters of the CNDO/S approximation, the ionization potential can be obtained by diagonalizing the above matrix.

Model 3. It is known that, in the CI calculation, the more configurations interact, the better results can be obtained. In this case, therefore, we extended the above CI calculation to a super cell. The CI matrix in this model is similar to that in Model 2.

Model 4. Generally speaking, ionization can be considered as arising from a rather localized state. However, due to some disagreements between the theoretical and experimental results, a question arises: is the excitation of a polymer limited in a particular space or does it arise from a more extended space? In other words, can the ionized state move along the polymer chain or not? In an attemp to answer this question, in this model, based on the concept of exciton, we change the above CI matrix into a new hermit matrix by using the following equation, which satisfies the periodic boundary condition.

$$H^{(0,0)}_{tu}=H^{(0,0)}_{tu}+\sum_{m=1} \cos mk(H^{(0,m)}_{tu}+H^{(0,-m)}_{tu}) + i\sum_{m=1} \sin mk(H^{(0,m)}_{tu}-H^{(0,-m)}_{tu}) \quad (34)$$

Also, the ionization potential of a polymer can be obtained by diagonalizing the new matrix.

Results and Discussion

We applied the present method to polyacetylene, polyethylene, and polypropylene. The structures of these polymers are shown in Fig. 1. The ionization potentials were calculated by using the four models of calculation described in the previous section.

In order to compare the polymers, first we calculate the ionization energies of some small molecules. These molecules can be considered as oligomers of the corresponding polymers. The results are shown in Table 1. The values obtained seem to be in good agreement with the experimental results. This means that the present method is suitable for investigating the ionized state of oligomers; consequently, it may also be suitable for polymers. From ethane to isobutane, as the number of carbons in the molecule increases, the corresponding values decrease. Table 1 shows that the ionization energies of alkenes are lower than those of corresponding alkanes because of the existence of a double bond in the molecules. This

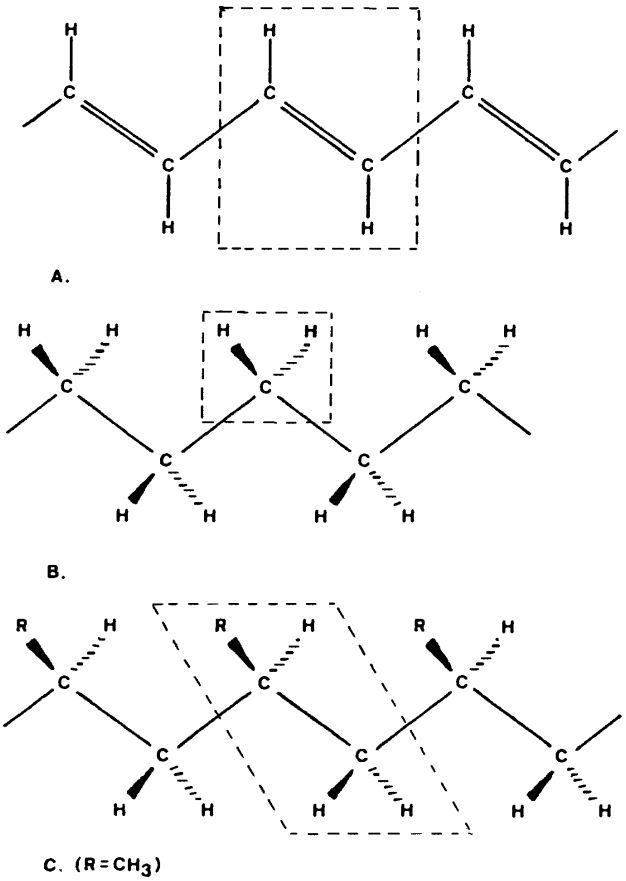

Fig. 1. Structures of *all-trans*-polyacetylene (A), polyethylene (B), and polypropylene (C). Unit cells are surrounded by broken lines.

Table 1. Ionization Energies of Some Small Molecules (eV)

Molecule	Symmetry	This work	Experiment
Ethane	Ag	14.898	12.1
	Eg	14.196	13.6
	Eu	19.167	15.4
Propane	A1	13.778	12.1
	B2	13.579	12.7
	A2	15.914	13.5
Isobutane	E	12.923	11.4
	A1	12.923	12.1
	A2	13.243	12.8
Ethylene	B3u	10.796	10.5
Butadiene	Bg	9.369	9.03
	Au	12.696	11.46

suggests that the ionization energy of polyacetylene is smaller than that of polyethylene. In fact, this is true, as can be seen from Tables 4 and 7. Consequently, the CNDO/S parameters are adequately reliable for the calculation of the ionization energies of the polymers under consideration.

Polyacetylene (PA). First, the MO's coefficient will be considered. The results are listed in Tables 2 and 3. These tables show that the molecular orbitals obtained are quite localized on the central cell. With the number of unit cells contained in a super cell increased from 3 to 4, the MO's coefficients undergo a little change, but not a very large one. For example, in the case of C-C (π), the difference is about 0.0003. We can expect that such a small difference would not affect the values of the ionization potential. Also, this means that, in our calculation for PA, taking the number of unit cells in a super cell as 3 or 4 is sufficient.

Next, let us compare our results with those obtained by experiments and other theoretical calculations.[7-10] The results are shown in Table 4. Peak 1 corresponds to the C-C π bonding orbital; the value given by Model 1 is larger than the others. The reason for this disagreement can be understood as follows. π-electrons, generally, are considered as moving in a broad space. However, in this method they are described as localized upon a particular bond. This may produce the disagreement. Peaks 2 and 3 in Model 1 also give very large values; these ionization arise from C-H bonds. The most probable explanation may be that these ionization arise from a more delocalized space instead of a localized one; that is, ionization occurs not just in a limited bond, but in a broader space extending to the neighboring bonds. The results would be improved if the CI procedure is introduced. In fact, this can be seen by comparing Model 1 with Models 2—4. For Peak 2, the result obtained from Model 4 is rather good, while the value given by Model 2 is desirable for Peak 3. This also means that the delocalized space in Peak 2 is broader than that in Peak 3. Finally, Peaks 4 and 5 are related to the C-C σ orbitals; the results of Model 1 are in good agreement with the experimental values and some other theoretical ones.

are shown in Tables 5 and 6. Table 5 shows the MO's of the C-H bonding orbital, and Table 6, those of the C-C bond. We can see that the MO coefficients are localized completely on the central cell and are almost independent of the numbers of unit cell, contained in a super cell. Therefore, taking 3 or 4 unit cells for a super cell is enough for our treatment.

Next, it is interesting to compare our results with other theoretical and experimental ones.[11-13] The results are shown in Table 7. First, let us examine Peak 1, which is obtained from the ionization that arise from one C-H bond. The value given by Model 1 is very large, even greater than the result of CNDO/2. This may suggest that the ionization arises from a more delocalized space, similar to Peaks 2 and 3 in PA discussed above. On the other hand, Model 4 gives a reasonable result. This may be due to the fact that CI was taken into account. From Model 2 to Model 4, as the space of configuration interaction is extended, the results seem to be improved greatly. Next, as for Peak 2, the value from Model 1 seems greater than the others, but not very large, and it is degenerate when compared with Peak 1. The results given by Models 2 and 3 show a very good agreement with the ESCA's, while Model 4 gives an overestimated value. Finally, in the case of Peak 3, Model 1 gives a very good result. This may imply that, for the high-energy region, an ionized state can be well described by a localized model.

Table 10. Ionization Energies of Polypropylene (eV)

	Peak 1	Peak 2	Peak 3	Peak 4	Peak 5
Model 1	21.49	21.51	21.59	21.60	22.20
Model 2	15.07	16.33	17.63	18.11	18.97
Model 3	9.80	13.41	13.85	14.45	16.68
Model 4	7.69	9.89	12.83	15.95	19.01
Band model	7.51	11.80	13.17	13.69	17.78

Polypropylene (PP). Some of the Mo's coefficients of PP are given in Tables 8 and 9. In this case, we just consider the super cell that contains only 3 unit cells. From these tables, we can see that, as with PA and PE, the molecular orbitals are well localized. For PP, unfortunately, we can not find any related experimental results at present. Therefore, our results are shown in Table 10 just with those obtained by the use of the Band model. The values given by Model 1 also seem to be too large, especially in Peak 1 to Peak 3, they were improved by introducing the CI calculation from Model 2 to Model 4. Therefore, it seems that the general tendency of the ionization of PP is the same as those of PA and PE.

Conclusion

The present method seems to be applicable to the investigation of the ionized state of one-dimensional periodic polymers such as PE and PA. The localized model (Model 1) described ionizations from the high-energy region quite well, but failed to explain those from the low-energy region. By introducing the models including configuration interaction (Model 2 to Model 4), the results of ionization from the low-energy region were improved and became comparable with the experimental values. Therefore, we concluded that, in the high-energy region, ionizations arise from a rather localized space, so Model 1 is suitable. In the low-energy region, especially in the first ionization potential, ionization occurs from a more delocalized space; here, Model 4 is excellent, In the middle region, ionized states can be well described by Models 2 and 3.

We are very grateful to Dr. Kazuhiko Seki for his useful discussions. All the calculations were performed in the Information Processing Center of Hiroshima University, to which we express our gratitude.

Solubilities and Dissolution States of a Series of Symmetrical Tetraalkylammonium Salts in Water

(Received August 26, 1988)

The solubilities of a series of symmetrical tetraalkylammonium salts, R_4NX ($R=CH_3$—n-C_8H_{17}, including i-C_4H_9 and i-C_5H_{11}; X=Cl, Br, I, NO_3, and ClO_4), in water have been determined over the temperature range between 5 and 45 °C. The solubilities of these salts were found to be strongly dependent upon both the chain length of R of the R_4N^+ cation and upon the partial molar volume of the X^- anion. It has been concluded that these solubilities are closely related with the stability of a "cage-like" water structure, which is presumably formed around the R_4N^+ cation in the solution. A thermodynamic interpretation of the solubility of the R_4NX salts was made by using some thermodynamic properties obtained by a differential scanning calorimetry, together with the enthalpy of the solution calculated from the temperature dependence of the solubility.

It has been pointed out that one of the most important factors which contributes to the stability of a tetraalkylammonium cation in an aqueous solution is the formation of a "cage-like" or "clathrate-like" water structure around its nonpolarizable moieties.[1] This explanation is closely related to a phenomenon in which many tetrabutylammonium salts (or tetraisopentylammonium salts) form unique hydrates having a large number of moles of water.[2] Single-crystal X-ray examinations[3-5] by Jeffrey and his coworkers on these hydrates showed that the central N atom lies at a common vertex of four large polyhedra, which are either tetrakaidecahedra or pentakaidecahedra; each of the four alkyl chains extends into one of the polyhedral cages. Furthermore, other experimental results[6] suggest that such short alkyl chains as $R=C_2H_5$ and $R=n$-C_3H_7 are stably accommodated within a pentagonal dodecahedron. Thus, a "cage-like" water structure around R_4N^+ cations with $R=C_2H_5$—n-C_4H_9, and i-C_5H_{11}, is expected to be fairly stable and to contribute to the elevation of the solubilities in water.

The effect of an anion X^- on the solubility of a R_4NX salt has not been fully discussed. However, the most important effect of an anion X^- on the dissolution state of the R_4NX salts in water may be considered to be a deformative or destructive effect on the "cage-like" water structure around the R_4N^+ cation, owing to the large molar volume of the anion. This consideration comes from the fact that the melting points of the hydrates formed by a series of salts $(n\text{-}C_4H_9)_4NX$ with X=F, Cl, Br, IO_3, NO_3, and ClO_3 decrease almost linearly with increasing the partial molar volume of the X^- anion.[7]

In this study, in order to determine whether the above-mentioned effects of both R_4N^+ cations and X^- anions on the solubilities of the R_4NX salts are generally adequate, the solubilities of various R_4NX salts in water have been measured, especially for salts whose solubility data are not available in literature. Furthermore, some attempts were made at a thermodynamic interpretation of these solubility data.

Experimental

Materials. Most of the symmetrical tetraalkylammonium salts, R_4NX, used were prepared from the corresponding tetraalkylammonium iodides, R_4NI. The iodides with $R=CH_3$—n-C_3H_7 were purchased from Tokyo Kasei Kogyo Co., Ltd. and purified by repeated recrystallization from pure water. The iodides with $R=n$-C_4H_9—n-C_8H_{17}, i-C_4H_9, and i-C_5H_{11}, were sythesized and purified by the same procedure previously reported.[8] Aqueous solutions of all the chlorides and the bromides having $R=i$-C_5H_{11}, n-C_6H_{13}, and n-C_8H_{17} were prepared by neutralizing each tetraalkylammonium hydroxide solution with either a HCl or HBr solution. The hydroxide solution was obtained by treating the tetraalkylammonium iodide with freshly prepared silver hydroxide in water with vigorous shaking, followed by filtration of silver iodide in a CO_2-free atmosphere.[9] Tetraalkylammonium nitrates were obtained by reacting each R_4NI with silver nitrate either in water (for $R=CH_3$—n-C_4H_9) or in acetone-water mixture (for $R=n$-C_5H_{11}—n-C_8H_{17}), followed by filtration of silver iodide and evaporation of the solvent using a rotary evaporator. These nitrates, except for $(n\text{-}C_8H_{17})_4NNO_3$, were purified by recrystallization from water and $(n\text{-}C_8H_{17})_4NNO_3$ from diethyl ether. Tetraalkylammonium perchlorates, R_4NClO_4, with $R=CH_3$—n-C_3H_7 were purchased from Tokyo Kasei Kogyo Co., Ltd. Since the solubilities of tetraalkylammonium perchlorates with long alkyl chains ($R=n$-C_4H_9—n-C_8H_{17}) were quite low, these solubilities were determined by measuring the radioactivity of ^{36}Cl-labeled perchlorates, $R_4N^*ClO_4$. Two radioactive perchlorates with $R=n$-C_4H_9 and n-C_5H_{11} were obtained in the following manner: nonradioactive perchlorate, which was obtained as a precipitate by mixing an aqueous R_4NCl solution with an aqueous solution of $NaClO_4$ and purified by repeated recrystallization from water, was dissolved in hot water containing a small amount of radioactive K^*ClO_4. The radioactive perchlorate solid was then obtained by cooling the solution. The other two radioactive perchlorates, $(n\text{-}C_6H_{13})_4N^*ClO_4$ and $(n\text{-}C_8H_{17})_4N^*ClO_4$, were obtained by the neutralization of each nonradioactive hydroxide solution, which was prepared by the same procedure as men-

tioned above, with an aqueous solution of $HClO_4$ containing a small amount of K^*ClO_4.

Procedure. The solubilities were determined in the following manner. In a measuring cell (3-cm diameter and 10-cm high) immersed in a constant-temperature bath, each salt was saturated in 10—20 cm^3 of water by vigorous stirring with a magnetic stirrer for 5—30 h. It took more than 20 h until a saturation equilibrium was attained for a sparingly soluble salt like $(n\text{-}C_8H_{17})_4NClO_4$. Then, a given amount of each saturated solution was withdrawn and analyzed by one of the methods listed below according to the magnitude of the solubility values and the types of cations and anions of the samples: (1) determination of the water content using the Karl Fischer titration method; (2) evaporation of water to dryness; (3) titration of either $(n\text{-}C_4H_9)_4N^+$ cation or $(i\text{-}C_5H_{11})_4N^+$ cation with a sodium tetraphenylborate solution;[7] (4) colorimetric determination of the ClO_4^- ion by Methylene Blue-ClO_4^- complex formation;[10] (5) potentiometry using an electrode responding to I^- ion; and (6) an efficiency tracing technique applied to a radioactive ^{36}Cl atom. The Karl Fischer titration was carried out on a MK-II apparatus manufactured by Kyoto Electronics Manufacturing Co. The radioactivity was measured using the TRI-CARB 460C Automatic Liquid Scintillation System manufactured by Packard Instrument Co., Inc. in the same manner as described in the previous papers.[11,12]

The melting points and transition temperatures as well as enthalpies of melting and of transitions were measured using a differential scanning calorimeter, DSC 10 with SSC 580 thermal controller manufactured by Seiko Instruments and Electronics Ltd.

Results and Discussion

(1) Solubilities of a Series of Tetraalkylammonium Salts in Water at 25 °C. The measured solubilities of a series of tetraalkylammonium salts, R_4NX, in water at 25 °C are summarized in Table 1, together with those available in the literature.[8,13-16] For both chlorides and bromides, the solubilities of those with R=$i\text{-}C_5H_{11}$, $n\text{-}C_6H_{13}$, and $n\text{-}C_8H_{17}$, were newly measured in this study. The solubilities of $(i\text{-}C_5H_{11})_4NCl$ and of $(i\text{-}C_5H_{11})_4NBr$ are considerably low compared, for example, with those of $(n\text{-}C_5H_{11})_4NCl$ and of $(n\text{-}C_5H_{11})_4NBr$ since the solid phase which is in equilibrium with a saturated aqueous solution at 25 °C is a clathrate hydrate, $(i\text{-}C_5H_{11})_4NCl(ca.\ 39)H_2O$ and $(i\text{-}C_5H_{11})_4NBr(ca.\ 39)H_2O$,[8] respectively. Three systems, $(n\text{-}C_6H_{13})_4NCl\text{-}H_2O$, $(n\text{-}C_6H_{13})_4NBr\text{-}H_2O$, and $(n\text{-}C_8H_{17})_4NCl\text{-}H_2O$, become a two-liquid phase equilibrium at 25 °C, in which a fairly dilute aqueous solution is in equilibrium with a fairly concentrated solution. The concentrations of both phases are also listed in Table 1. The solubilities of the iodides reported in Table 1 are somewhat different from those reported earlier: 0.0622 $mol \cdot kg^{-1}$ for $(n\text{-}C_4H_9)_4NI$;[17] 2.50×10^{-3} $mol \cdot kg^{-1}$ for $(n\text{-}C_5H_{11})_4NI$.[17]

The solubilities of all the nitrates, R_4NNO_3, were determined for the first time. In all cases, a solid phase was found to be anhydrous through the Karl Fischer titration method. It is interesting to note that the solubilities of nitrates with R=CH_3—$n\text{-}C_4H_9$ are quite high, whereas those of nitrates with R longer than C_5 are quite low. As a result, the solubility of $(n\text{-}C_4H_9)_4NNO_3$ is about 700-times that of $(n\text{-}C_5H_{11})_4NNO_3$. The reason for this will be discussed below.

The solubilities of perchlorates with R=CH_3—$n\text{-}C_4H_9$ are in good agreement with those reported earlier: 0.0747,[15] 0.075,[18] and 0.0753[19] $mol \cdot kg^{-1}$ for $(CH_3)_4NClO_4$; 0.232[15] and 0.217[18] $mol \cdot kg^{-1}$ for $(C_2H_5)_4NClO_4$; 0.0204[18] and 0.0197[19] $mol \cdot kg^{-1}$ for $(n\text{-}C_3H_7)_4NClO_4$; 0.0100[20] and 0.0103[19] $mol \cdot kg^{-1}$ for $(n\text{-}C_4H_9)_4NClO_4$. However, the values reported by Deno et al.,[18] 6.7×10^{-4} $mol \cdot kg^{-1}$ for $(n\text{-}C_5H_{11})_4NClO_4$ and 4.4×10^{-4} $mol \cdot kg^{-1}$ for $(n\text{-}C_6H_{13})_4NClO_4$, are fairly different from our values listed in Table 1. Our values seem to be more exact since a radio tracer technique is appropriate for a determination of such low solubility. The solid phase, which was in equilibrium with the saturated aqueous solution and analyzed by the Karl Fischer titration method, was shown to be anhydrous in all cases. In Table 1, it should be noted that the solubilities of $(i\text{-}C_4H_9)_4NClO_4$ and of $(i\text{-}C_5H_{11})_4NClO_4$

This work, except where indicated

a) Solid phase is a clathrate hydrate. b) Two-liquid phase system.

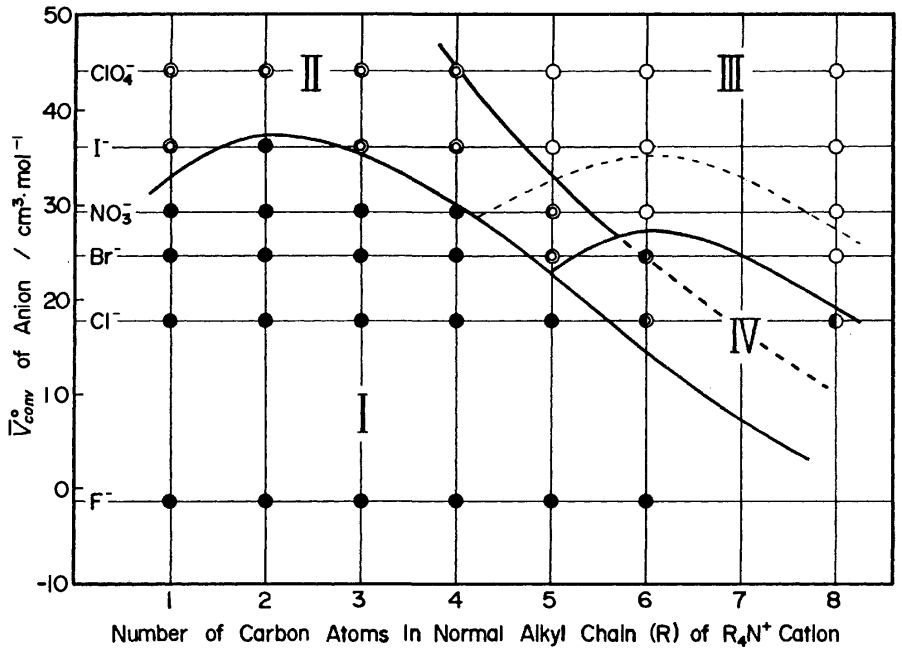

Fig. 1. The relationship between the solubilities of a series of symmetrical tetraalkylammonium salt, R_4NX, in water at 25 °C and the number of carbon atoms in a normal alkyl chain R of the R_4N^+ cation and a conventional partial molar volume of the anion X^- at 25 °C, $\bar{V}^\circ_{conv}$. The solubility of the R_4NX salt is divided into three ranges: ●: higher than 1.0 mol·kg^{-1}; ◎: 0.01—1.0 mol·kg^{-1}; ○: lower than 0.01 mol·kg^{-1}. Three marks ●, ◎, and ○ form the region I, II, and III in this order. The region IV represents a liquid-liquid equilibrium. Precise explanation about the simbols is given in the text.

are about 6.5-times and 3.6-times higher than that of $(n\text{-}C_4H_9)_4NClO_4$ and of $(n\text{-}C_5H_{11})_4NClO_4$, respectively.

The effect of the alkyl chain, R, of the R_4N^+ cation and of the type of the X^- anion on the solubilities of the R_4NX salts in water will be discussed in the following manner. The solubility values are tentatively classified into three concentration ranges: higher than 1.0 mol·kg^{-1}; 0.01—1.0 mol·kg^{-1}; and less than 0.01 mol·kg^{-1}. Using notations ●, ◎, and ○, in this order, all the solubilities of the R_4NX salts, including some fluorides,[8] are represented in Fig. 1. The ordinate of this figure is a conventional partial molar anionic volume at 25 °C, $\bar{V}^\circ_{conv}$, and the abscissa is the number of carbon atoms of a normal alkyl chain R of the R_4N^+ cation. The conventional partial molar anionic volume, i.e., a partial molar anionic volume at infinite dilution based on the assumption that the partial molar volume of a hydrogen ion at infinite dilution is equal to 0, are used as an indication of the effective volume of an anion in a saturated aqueous solution. The values of $\bar{V}^\circ_{conv}$ for the anions discussed in this study are taken from the literature.[21] Symbols ◐ and ◐ in Fig. 1 represent a liquid-liquid phase equilibrium: the mark ◐ indicates a system in which a fairly concentrated solution (in the range of ●, defined above) is in equilibrium with a fairly dilute solution (in the range of ◎); similarly, ◐ indicates a liquid-liquid equilibrium in which the concentration of a dilute solution phase is in the range of ○. It is interesting to note that each symbol (●, ◎, ○, and ◐+◐) gathers within a limited area and forms four domains (I—IV) as shown in Fig. 1. This figure clearly demonstrates the following: (1) that the solubilities of a variety of R_4NX salts in water can be interpreted in terms of two factors, i.e., the chain length of R of the R_4N^+ cation and the molar volume of the X^- anion; (2) as a general trend, the solubility decreases with increasing both the chain length of R and the anionic volume; and (3) the two liquid phase region (IV) appears between region I and III (or II) when the chain length of R becomes fairly long. At 60 °C, for example, domain IV extends to the region shown by a thin dotted line. Tetrahexylammonium salts are most liable to be in a liquid-liquid equilibrium. This would be, at least partly, due to the fact that, for the same kind of anion, the melting points of tetrahexylammonium salts are lower than those both of tetrapentylammonium salts and of tetraoctylammonium salts, as shown below (Table 3).

In Fig. 2, the logarithm of the solubilities (m_{sat}) at 25 °C, given in Table 1, is plotted against the conventional partial molar anionic volumes, $\bar{V}^\circ_{conv}$, for a series of salts having the same R_4N^+ cations. The mark in parenthesis indicates the concentration of a water-rich

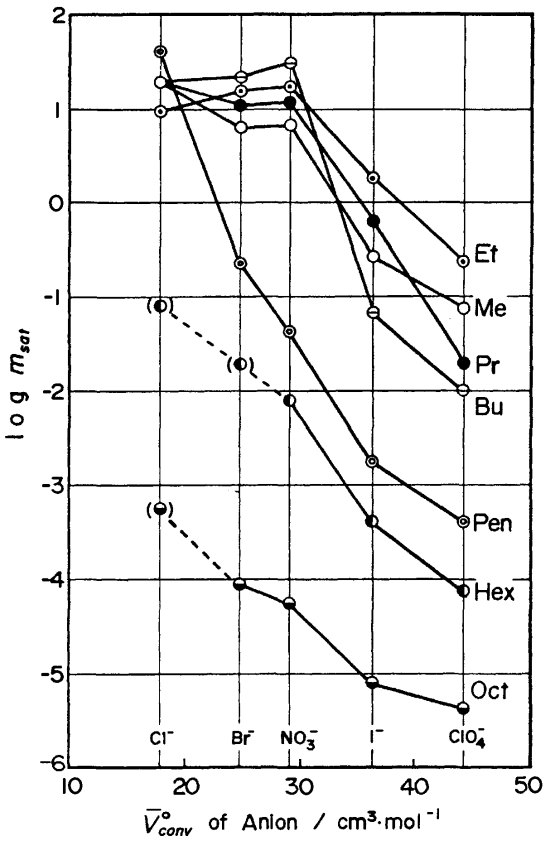

Fig. 2. The relations between the logarithm of the solubilities, m_{sat} (in molality), of a series of R_4NX salts at 25 °C and the conventional partial molar volume of the X^- anion, $\bar{V}^{\circ}_{conv}$. ○: R=CH_3; ⊙: R=C_2H_5; ●: R=n-C_3H_7; ○: R=n-C_4H_9; ◎: R=n-C_5H_{11}; ◐: R=n-C_6H_{13}; ◒: R=n-C_8H_{17}. The symbol in parenthesis represents the concentration of a water-rich phase in a liquid-liquid equilibrium.

phase in a liquid-liquid equilibrium. Generally, as can be seen for tetrahexylammonium and tetraoctylammonium salts, the solubilities of the R_4NX salts decrease with increasing the $\bar{V}^{\circ}_{conv}$. However, it is noteworthy to point out that (1) the solubilities of tetraethylammonium and tetrapropylammonium salts, except for $(C_2H_5)_4NCl$ and $(n\text{-}C_3H_7)_4NClO_4$, are higher than those of tetramethylammonium salts, in consistent with the observation that the "cage-like" water structure (may be pentagonal dodecahedron) around C_2H_5 and n-C_3H_7 group is more stable than that around a CH_3 group. This is verified by the relationship between the melting points of a series of clathrate-like hydrates of $(n\text{-}C_4H_9)_4NOOCR'$ and the chain length of the R′ group.[6] (2) The solubilities of three tetrabutylammonium salts, $(n\text{-}C_4H_9)_4NCl$, $(n\text{-}C_4H_9)_4NBr$, $(n\text{-}C_4H_9)_4NNO_3$, and of $(n\text{-}C_5H_{11})_4NCl$, are extremely high as compared with the values expected from a monotonous relation between log m_{sat} vs. $\bar{V}^{\circ}_{conv}$, in perfect coincidence with the fact that all of these salts can form a stable clathrate-like hydrate.[7,8] In conclusion, the high solubility of R_4NX salts always corresponds to the ability of a clathrate-like hydrate formation. This suggests that the formation of a stable "cage-like" water structure around the R_4N^+ cation greatly contributes to the high solubility of the R_4NX salt.

In Fig. 3, log m_{sat} is plotted against the number of carbon atoms in a normal alkyl chain R in the R_4N^+ cation for a series of salts with voluminous anions NO_3^-, I^-, and ClO_4^-, respectively. Except for $(n\text{-}C_4H_9)_4NNO_3$, whose solubility is remarkably high, all the other salts cannot form a clathrate-like hydrate;[7]

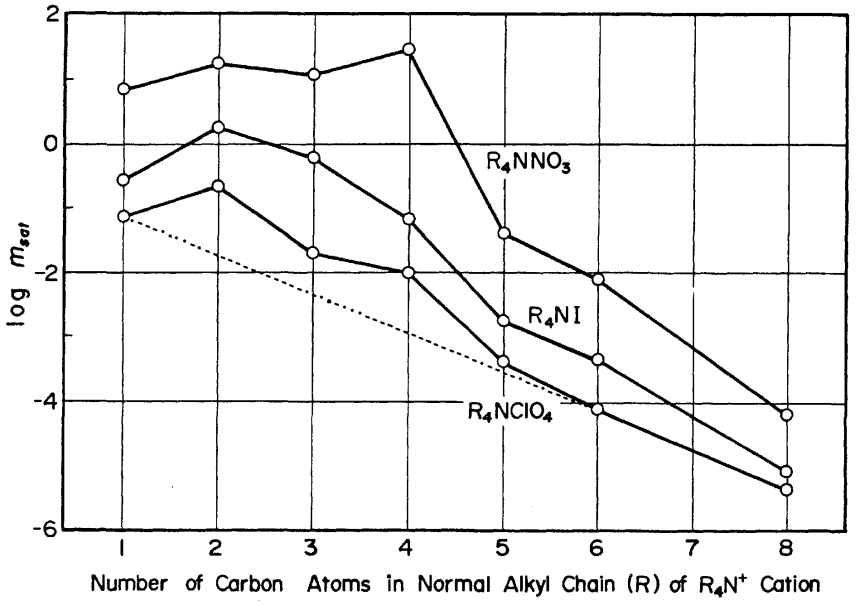

Fig. 3. The relations between the logarithm of the solubilities of a series of R_4NX salts at 25 °C, m_{sat} (in molality), and the number of carbon atoms in a normal alkyl chain R of the R_4N^+ cation. The points corresponding to the salts with the same anions (X=NO_3, I, and ClO_4) are connected by a full line. A dotted line is explained in the text.

Table 2. Solubilities of Symmetrical Tetraalkylammonium Salts, R_4NX, in Water at Various Temperatures

Salt	Solubility m_{sat}/mol·kg^{-1}			
	5 °C	15 °C	35 °C	45 °C
$(i\text{-}C_5H_{11})_4NI$	—	7.60×10^{-3}	1.02×10^{-2}	1.26×10^{-2}

$(n\text{-}C_8H_{17})_4NNO_3$	5.16×10^{-5}	5.46×10^{-5}	6.44×10^{-5}	—
$(CH_3)_4NClO_4$	3.60×10^{-2}	5.17×10^{-2}	0.111	0.148
$(C_2H_5)_4NClO_4$	0.121	0.164	0.318	0.452
$(n\text{-}C_3H_7)_4NClO_4$	1.43×10^{-2}	1.67×10^{-2}	2.59×10^{-2}	3.24×10^{-2}
$(n\text{-}C_4H_9)_4NClO_4$	1.01×10^{-2}	9.95×10^{-3}	1.15×10^{-2}	1.31×10^{-2}
$(i\text{-}C_4H_9)_4NClO_4$	4.51×10^{-2}	5.15×10^{-2}	7.71×10^{-2}	8.74×10^{-2}
$(n\text{-}C_5H_{11})_4NClO_4$	2.59×10^{-4}	3.04×10^{-4}	5.50×10^{-4}	7.66×10^{-4}
$(i\text{-}C_5H_{11})_4NClO_4$	1.37×10^{-3}	1.43×10^{-3}	1.77×10^{-3}	2.25×10^{-3}
$(n\text{-}C_6H_{13})_4NClO_4$	4.85×10^{-5}	5.92×10^{-5}	9.23×10^{-5}	1.40×10^{-4}
$(n\text{-}C_8H_{17})_4NClO_4$	3.27×10^{-6}	3.91×10^{-6}	6.13×10^{-6}	8.01×10^{-6}

i.e., in these solutions a voluminous anion seems to prevent the formation of a stable "cage-like" water structure around the R_4N^+ cation. For the perchlorates, a dotted line is drawn by connecting the point corresponding to R=CH_3 with the points to R=n-C_6H_{13} and n-C_8H_{17}. Generally, for a sparingly soluble salt solution, log m_{sat} is approximately proportional to $\mu_s-\mu^\circ$ divided by $2.303RT$, where μ_s is the chemical potential of a solid salt and μ° is the standard chemical potential of the salt dissolved in water at a hypothetical concentration of 1 mol·kg^{-1}. If a specific phenomenon such as the formation of a "cage-like" water structure around the R_4N^+ cation does not occur, log m_{sat} will change monotonously upon increasing the number of carbon atoms in R, since both μ_s and μ° are expected to change monotonously with the chain length of R. However, the points corresponding to R=C_2H_5, n-C_3H_7, and n-C_4H_9, deviate remarkably from the dotted line. This clearly indicates that the formation of a "cage-like" water structure around such cations as $(C_2H_5)_4N^+$, $(n\text{-}C_3H_7)_4N^+$, and $(n\text{-}C_4H_9)_4N^+$ contributes to the elevation of their solubility. A similar discussion can essentially be made for the behavior of the other two lines for R_4NI and R_4NNO_3 in Fig. 3.

(2) Temperature Dependence of the Solubilities of Symmetrical Tetraalkylammonium Salts in Water. The solubilities of a few tetraalkylammonium iodides and of various nitrates and perchlorates over the temperature range 5—45 °C are listed in Table 2. The values at 25 °C are omitted from this table since they are already listed in Table 1. The solid phases of all the salts were found to be anhydrous from Karl Fischer titration. The system $(n\text{-}C_6H_{13})_4NNO_3$-$H_2O$ became a liquid-liquid equilibrium at temperatures higher than 28.9 °C. In Fig. 4, the logarithm of the solubilities (expressed in molality, m_{sat}) is plotted against the

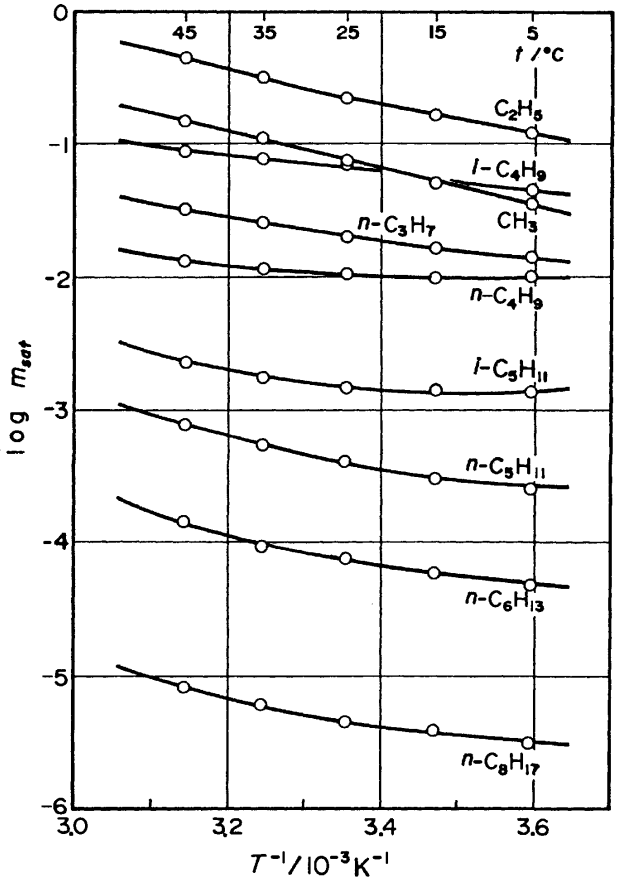

Fig. 4. Temperature dependence of the solubilities of a series of tetraalkylammonium perchlorates, R_4NClO_4, in water. The logarithm of the solubility, m_{sat} (in molality), is plotted against the reciprocal of the absolute temperature. The alkyl group R is shown by each line. The temperature expressed in ordinary Celsius units is shown on the upper side of the figure.

reciprocal of the absolute temperature for a series of tetraalkylammonium perchlorates. A similar plot for the nitrates shows an analogous behavior. This figure clearly indicates that (1) a pronouncely high solubility of tetraethylammonium perchlorate, found at 25 °C as shown in Table 1, is also the case for those at all the temperatures examined; and (2) the slopes $-\partial \log m_{sat}/\partial(1/T)$ for the perchlorates with R=n-C_3H_7, n-C_4H_9, i-C_4H_9, and i-C_5H_{11} at low temperatures are relatively small as compared with those of the other perchlorates, indicating that the enthalpies of solution of these four perchlorates are somewhat small. This may be due to the evolution of heat owing to the formation of a stable "cage-like" water structure around cations like $(n\text{-}C_3H_7)_4N^+$, $(i\text{-}C_4H_9)_4N^+$, $(n\text{-}C_4H_9)_4N^+$, and $(i\text{-}C_5H_{11})_4N^+$ over the temperature range studied. It is interesting to note that this behavior is not eminent for $(C_2H_5)_4NClO_4$ notwithstanding a stable "cage-like" water structure around the $(C_2H_5)_4N^+$ cation is expected as mentioned above. Precise discussion will be impossible since for such a very soluble salt an activity should be used instead of the solubility itself.

(3) Thermodynamic Analysis of the Solubilities of Symmetrical Tetraalkylammonium Salts in Water. If we use a hypothetical liquid supercooled below its melting point as the standard state, the chemical potential of a solid substance at T, μ_2^s, is given by

$$\mu_2^s = \mu_2^l + RT\ln a_2, \quad (1)$$

where μ_2^l is the chemical potential of the standard state, a_2 is the activity of the solute, and R is the gas constant. The quantity $RT\ln a_2$ can be expressed by[22]

$$RT\ln a_2 = -\Delta H_m^F(1-T/T_m) + \Delta C_p(T_m-T) + T\Delta C_p\ln(T/T_m), \quad (2)$$

in which ΔC_p ($=C_p^l-C_p^s$) is the difference of the molar heat capacities between liquid and solid state, and ΔH_m^F is the molar enthalpy of melting at the melting point, T_m.

Under equilibrium conditions between a solid and a saturated aqueous solution,

$$\mu_2^s = \mu_2 = \bar{H}_2 - T\bar{S}_2, \quad (3)$$

where $\bar{H}_2$ and $\bar{S}_2$ are partial molar enthalpy and entropy of a solute, respectively, in a saturated solution. Thus, from Eqs. 1 and 3, together with the relation $\mu_2^l = H_2^l - TS_2^l$, we may write

$$(\bar{H}_2 - H_2^l) - T(\bar{S}_2 - S_2^l) = RT\ln a_2. \quad (4)$$

The enthalpy term in Eq. 4 can be written as

$$\bar{H}_2 - H_2^l = \Delta H_s(\text{sat}) - \Delta H_m^F + \Delta C_p(T_m - T) \quad (5)$$

The term $\Delta H_s(\text{sat})$ ($=\bar{H}_2-H_2^s$) represents the molar enthalpy of solution of a solid substance in a saturated solution.

The entropy term in Eq. 4 may be expressed by[23]

$$\bar{S}_2 - S_2^l = -R\{\nu_+\ln(X_+^{sat}/X_+^l) + \nu_-\ln(X_-^{sat}/X_-^l)\} + S_2^E, \quad (6)$$

where X_+^{sat} and X_-^{sat} is the mole fraction of the cation and the anion, respectively, in a saturated solution, and similarly, X_+^l and X_-^l in a hypothetical melt of a solute. The ν_+ and ν_- are the number of moles of cations and anions, respectively, when one mole of a solute dissociates in the solution. S_2^E is the excess entropy of the solution and Eq. 6 may be regarded as the definition of S_2^E.

By inserting $X_+^{sat}=(\nu_+\cdot m_{sat})/(M+\nu\cdot m_{sat})$, $X_-^{sat}=(\nu_-\cdot$

Table 3. Melting Point (t_m), Transition Temperature (t_{tr}), Enthalpy of Melting (ΔH_m^F), and of Transition(ΔH_{tr}) of Symmetrical Tetraalkylammonium Salts

Salts	t_m / °C	ΔH_m^F / kJ·mol^{-1}	t_{tr} / °C	ΔH_{tr} / kJ·mol^{-1}
$(n\text{-}C_3H_7)_4NNO_3$	>250	—	57.6	8.97

$m_{sat})/(M+\nu\cdot m_{sat})$, $X_+^l=\nu_+/\nu$, and $X_-^l=\nu_-/\nu$ into Eq. 6, we can get

$$\bar{S}_2-S_2^l=-\nu R\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}+S_2^E, \quad (7)$$

where $\nu=\nu_++\nu_-$, M=55.51, and m_{sat} is the solubility expressed in molality. Thus, from Eqs. 2, 4, 5, and 7, the following relation is obtained:

$$-\nu RT\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}=$$
$$\Delta H_s(sat)-\Delta H_m^F(T/T_m)-T\Delta C_p\ln(T/T_m)-TS_2^E. \quad (8)$$

Furthermore, since most of the symmetrical tetraalkylammonium salts discussed here have transition temperatures (as shown later, Table 3) between room temperature and their melting points, the term $-\sum_{tr}\Delta H_{tr}(T/T_{tr})$ should be added to the right side of Eq. 8, where ΔH_{tr} is the molar enthalpy of a transition at a transition temperature, T_{tr}, and summation is carried out with respect to all the transitions when a solid has more than one transition point between T and T_m. Then Eq. 8 becomes,

$$-\nu RT\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}=$$
$$\Delta H_s(sat)-\Delta H_m^F(T/T_m)-\sum_{tr}\Delta H_{tr}(T/T_{tr})-T\Delta C_p\ln(T/T_m)-TS_2^E. \quad (9)$$

In the following discussion, the term containing ΔC_p is omitted for the following reasons: (1) precise information about the values of ΔC_p is not available and (2) the melting points (Table 3) of the salts discussed here are lower than 150 °C, except for $(n\text{-}C_3H_7)_4NClO_4$ and $(n\text{-}C_4H_9)_4NClO_4$, so that the quantity of $\ln(T/T_m)$ is smaller than 0.41 at T=298.15 K. Thus, we use the following equation:

$$-\nu RT\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}=$$
$$\Delta H_s(sat)-\{\Delta H_m^F(T/T_m)+\sum_{tr}\Delta H_{tr}(T/T_{tr})\}-TS_2^E. \quad (10)$$

The melting points, transition temperatures, the enthalpy of melting, and the enthalpy of transition which are determined by differential scanning calorimetry are listed in Table 3, together with some of the melting points reported in the literature. The errors inherent in the determination of the enthalpies of melting and transition are of the order of 5—10 per cent, since calibration of the apparatus was carried out at the melting point of In alone (156.6 °C, and ΔH_m^F=3.3 kJ·mol^{-1}). No transition temperatures and enthalpy data had been reported earlier. For the salts whose ΔH_s(sat) data are available, each term in Eq. 10 at 298.15 K can be calculated from the data given in Tables 1—3; these are listed in Table 4. The ΔH_s(sat) values in Table 4 are either the values obtained by Krishnan et al.[24] or values calculated from the relation $\Delta H_s(sat)=-2R\partial\ln m_{sat}/\partial(1/T)$ using the data shown in Tables 1 and 2. This calculation is reasonable, at least to a first approximation, since this relation was only applied to sparingly soluble salts. The values obtained by Krishnan et al.[24] are based upon the enthalpies of solution in propylene carbonate and the enthalpy of transfer from propylene carbonate to water. Therefore, these values are not exactly equal to the enthalpy of solution of the solid salt at its saturation concentration. However, we use these values as approximate values of ΔH_s(sat) since there are no data available and the other terms listed in Table 4, especially the one containing ΔH_m^F and ΔH_{tr}, are not so accurate.

It is interesting to note that, for the most iodides and perchlorates, the quantity ΔH_s(sat) is almost compensated for by the quantity $\Delta H_m^F(T/T_m)+\sum_{tr}\Delta H_{tr}(T/T_{tr})$, resulting in a large positive value of the $-\nu RT\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}$ term corresponds roughly to a large negative value of the excess entropy TS_2^E. In case of the nitrates, not only the values of the ΔH_s(sat) term are generally smaller than the term $\Delta H_m^F(T/T_m)+\sum_{tr}\Delta H_{tr}(T/T_{tr})$, but also the term $-\nu RT\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}$ is rather small compared with those of iodides

Table 4. Each Term in Eq. 10 and Calculated Values of Excess Entropy at 298.15 K for Some Symmetrical Tetraalkylammonium Salts

Salt	(A)[a]	ΔH_s(sat)	(B)[b]	S_2^E	S_2^E/n
	kJ·mol^{-1}			J·K^{-1}·mol^{-1}

a) (A)$=-\nu RT\ln\{(\nu\cdot m_{sat})/(M+\nu\cdot m_{sat})\}$. b) (B)$=\Delta H_m^F(T/T_m)+\sum_{tr}\Delta H_{tr}(T/T_{tr})$.

and perchlorates with the same type of cation because of relatively high solubility of the nitrates (Table 1). Eventually, this situation also results in a large negative excess entropy. The values of S_2^E calculated from Eq. 10 are also listed in Table 4. It is interesting to note that (1) the S_2^E becomes more negative upon increasing the number of carbon atoms of the R_4N^+ cation and (2) for the same kind of cation S_2^E has almost a similar value, irrespective of the kind of anion. This result suggests that the value of S_2^E is mainly determined by the number of carbon atoms of the R_4N^+ cation. Tentatively, if we calculate the excess entropy per mole of carbon atoms, S_2^E/n, n being the total number of carbon atoms of the R_4N^+ cation, this value has almost a similar value ranging from -8 to -10 $J \cdot mol^{-1} \cdot K^{-1}$ for all the salts examined here. This value is also listed in the last column of Table 4. The simple average of S_2^E/n is -8.8 $J \cdot mol^{-1} \cdot K^{-1}$. Although a quantitative discussion about the behavior of the excess entropy is impossible at present, the behavior of S_2^E (or of S_2^E/n) found in this study will undoubtedly reflect a restricted motion of the carbon chain of the R_4N^+ cation in the solution due to the water networks surrounding the R_4N^+ cation. Unfortunately, it is impossible to discuss the relation between a "cage-like" water structure and the excess entropy defined here, since S_2^E cannot be calculated (for the reasons mentioned below) for many tetraalkylammonium salts to which the existence of a stable "cage-like" water structure in its aqueous solution is expected. The reasons are: (1) a value for ΔH_s(sat) is not available in the literature and its estimation from the temperature dependence of the solubility is inadequate because of the high solubility of the salt concerned, and (2) in general, such a salt has a fairly high melting point and sometimes gradually decomposes at high temperatures, so that accurate values of T_m and ΔH_m^F (and T_{tr} and ΔH_{tr}) cannot be obtained by thermal analyses.

(Received August 31, 1988)

A useful method for computing the rate constants of reversible, first-order, triangular network reactions ($\mathbf{B}_1 \rightleftarrows \mathbf{B}_2$, $\mathbf{B}_2 \rightleftarrows \mathbf{B}_3$, $\mathbf{B}_3 \rightleftarrows \mathbf{B}_1$) is developed. It gives the best-fit set of the rate constants from the experimental data of the equilibrium constants and the mole fraction-time curves through an iterative least-squares method. This type of reaction can be classified into three categories for different shapes of the mole fraction-time curves. The method was successfully applied to determining the rate constants of the rearrangement reactions among the three isomers of [Ru(acac)(tfpb)$_2$] (acac$^-$=acetylacetonate ion, tfpb$^-$=4,4,4-trifluoro-1-phenyl-1,3-butanedionate ion) in *N,N*-dimethylformamide at 90 °C. The direct conversion between the *de,fc*-bis(tfpb) isomer and the *cf,ed*-bis(tfpb) isomer was forbidden. The twist mechanisms are incompatible with this fact.

The simplest network reaction is a first-order reversible reaction of three components with a triangular scheme, exemplified by isomerization of butene[1] and cobalt complexes.[2,3] A theory of the triangular network reaction has been fully developed by Wei and Prater.[1] Numerical methods for determining rate constants have been presented in a detailed review.[4] Since the differential equations for the kinetics is linear, the solution is composed of a sum of exponential terms.[5] In order to evaluate rate constants from experimental data through combinations of exponential functions, it is necessary to linearize the equation. The numerical method of Wei and Prater[1] is essentially based on the linearization around the equilibrium. Consequently, a number of accurate data points near the equilibrium are required for the determination of rate constants. Such data are difficult to obtain when the experimental precision is limited by the presence of side reactions or for other reasons; besides, a sufficient number of such data are rarely available if the reaction is very slow. Furthermore, this numerical method does not give the absolute values of the rate constants, but only their ratios. It is desirable to explore a technique that gives the absolute values of rate constants making use of all the experimental points.

This report is devoted to development of a numerical technique based on nonlinear regression and to the evaluation of the rate constants of the triangular network of a set of the isomers of β-diketonato-ruthenium(III) complexes.

Theoretical

Figure 1 illustrates the reaction scheme of the triangular network, where k_{ij} is the rate constant of the reaction $\mathbf{B}_i \rightarrow \mathbf{B}_j$. We denote the mole fraction of species $\mathbf{B}_j$ by x_j. Then kinetic equations for the triangular reaction are

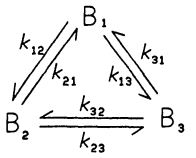

Fig. 1. Model of the triangular network reversible reaction. The equilibrium constants are defined in Eq. 5.

$$dx_1/dt = -(k_{12}+k_{13})x_1 + k_{21}x_2 + k_{31}x_3 \quad (1)$$
$$dx_2/dt = k_{12}x_1 - (k_{21}+k_{23})x_2 + k_{32}x_3 \quad (2)$$
$$dx_3/dt = k_{13}x_1 + k_{23}x_2 - (k_{31}+k_{32})x_3, \quad (3)$$

where t is the time since the beginning of the reaction. The initial conditions are given by

$$t=0: x_1=x_1^0,\ x_2=x_2^0,\ x_3=x_3^0. \quad (4)$$

Here x_j^0 is the initial mole fractions of species $\mathbf{B}_j$. We define the following three equilibrium constants:

$$K_{12} = x_2^e/x_1^e = k_{12}/k_{21}$$
$$K_{23} = x_3^e/x_2^e = k_{23}/k_{32} \quad (5)$$
$$K_{31} = x_1^e/x_3^e = k_{31}/k_{13}.$$

The superscript e means the equilibrium. An alternative form of Eq. 5 is

$$x_1^e = (1+K_{12}+1/K_{31})^{-1}$$
$$x_2^e = (1+K_{23}+1/K_{12})^{-1} \quad (6)$$
$$x_3^e = (1+K_{31}+1/K_{23})^{-1}.$$

Obviously only two of the three equilibrium constants are independent because $K_{12}K_{23}K_{31}=1$. Hence the following relation holds:

$$k_{12}k_{23}k_{31} = k_{13}k_{32}k_{21}, \quad (7)$$

The initial problem of Eqs. 1—4 can be solved by means of a conventional method, e.g., the Laplace transformation, although it is cumbersome to elim-

inate two of the three dependent variables. The solution is expressed by

$$x_j = x_j^e + r_j e^{-pt} + s_j e^{-qt}, \quad (j=1, 2, 3) \tag{8}$$

with

$$p = \{\alpha - (\alpha^2 - 4\beta)^{1/2}\}/2 \tag{9}$$

$$q = \{\alpha + (\alpha^2 - 4\beta)^{1/2}\}/2 \tag{10}$$

$$r_j = (x_j^0 p - \kappa_j + \lambda_j/p)/(p-q) \tag{11}$$

$$s_j = (x_j^0 q - \kappa_j + \lambda_j/q)/(q-p),$$

where

$$\kappa_1 = x_1^0(k_{21}+k_{23}+k_{32}+k_{31}) + x_2^0 k_{21} + x_3^0 k_{31} \tag{12a}$$

$$\kappa_2 = x_1^0 k_{12} + x_2^0(k_{12}+k_{13}+k_{31}+k_{32}) + x_3^0 k_{32} \tag{12b}$$

$$\kappa_3 = x_1^0 k_{13} + x_2^0 k_{23} + x_3^0(k_{12}+k_{21}+k_{23}+k_{13}) \tag{12c}$$

$$\lambda_1 = k_{31}k_{21} + k_{23}k_{31} + k_{32}k_{21} \tag{13a}$$

$$\lambda_2 = k_{12}k_{32} + k_{31}k_{12} + k_{13}k_{32} \tag{13b}$$

$$\lambda_3 = k_{23}k_{13} + k_{12}k_{23} + k_{21}k_{13} \tag{13c}$$

$$\alpha = k_{12}+k_{21}+k_{23}+k_{32}+k_{31}+k_{13} \tag{14}$$

$$\beta = k_{12}k_{23}/x_3^e + k_{23}k_{31}/x_1^e + k_{31}k_{12}/x_2^e. \tag{15}$$

A characteristic of Eq. 8 is that the arguments of the exponential are common to the three species. A set of these equations are essentially the same as Wei and Prater's matrix expression.[2]

Examples of the x_j-t curves calculated for the case where $K_{12}=K_{23}=K_{31}$, $x_1^0=1$, and $x_2^0=x_3^0=0$ are shown in Fig. 2. Here the three sets of the curves represent the following typecal cases:

(A) When the values of k_{ij} is comparative (the solid curves), x_2 and x_3 increase monotonically at the sacrifice of x_1 and then approach the equilibrium values. The rate of the decrease of x_1 is almost the same as the sum of the rates of the increase of x_2 and x_3. A special case is that all the values of k_{ij} are the same. Then Eq. 8 reduces to

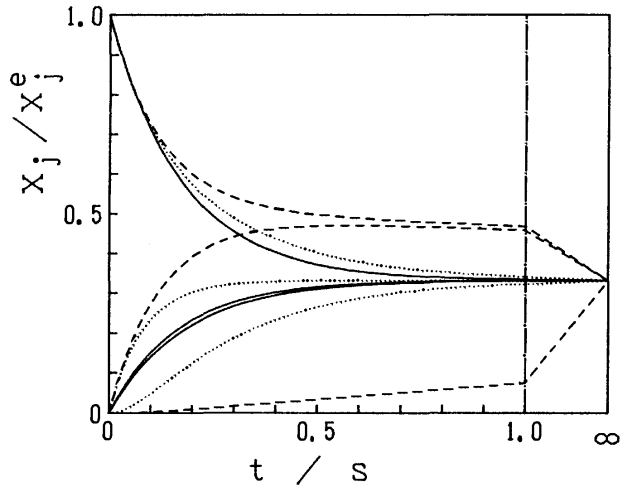

Fig. 2. Variations of x_j (j=1,2,3) with time at K_1=K_2=K_3=1 calculated from Eqs. 8—15 for (k_{12}, k_{23}, k_{31})=(2.0, 2.0, 1.8)(——), (4.0, 4.0, 0.0)(·····) and (4.0, 0.2, 0.0)(-----). The initial conditions are x_1^0=1.0, x_2^0=0, and x_3^0=0.

$$x_j = 1/3 + (x_j^0 - 1/3)\exp[-3k_{ij}t]. \tag{16}$$

Then the overall relaxation time is $1/(3k_{ij})$.

(B) When both k_{12} and k_{23} are large and k_{31} is small (the dotted curves), $\mathbf{B}_3$ is generated through $\mathbf{B}_2$ without direct supply from $\mathbf{B}_1$. The increase of x_3 is slower than that of x_2. Since x_3 increases very slowly at the beginning, the curve for x_3 is a sigmoid. In an extreme case where $k_{31}=k_{13}=0$, the network reduces to a two-step consecutive reaction.

(C) When k_{12} is large and both k_{23} and k_{31} are small (the dashed curves), $\alpha^2 \gg 4\beta$ or $q \gg p$. Then the mole fractions vary mainly with $\exp(-\alpha t)$ or $\exp[-(k_{12}+k_{21})]$. In this case, x_1 and x_2 converge before reaching the equilibrium value.

Let us explore a technique of determining the rate constants from a set of experimental x_j curves. It is assumed that the equilibrium constants are known in advance. Then the unknown parameters are k_{12}, k_{23}, and k_{31}. It is possible to use any other three independent parameters composed of adequate combinations of k_{12}, k_{23}, and k_{31}: for example (α, β, κ_1) or (p, q, r_1). Choice of the independent parameters is important for successful curve fitting. We chose (p, q, r_1), because this set is directly connected with the shape of the x_j-t curves.

A convenient numerical technique of curve fitting is the least squares method.[6] Since Eq. 8 is nonlinear with respect to p, q, and r_1, it has to be linearized. The Taylor expansion of Eq. 8 is carried out around a set of tentative values of p', q', and r_j'. Retaining only the linear terms, one has

$$x_j = x_j^e + (x_j^0 - x_j^e)e^{-q't} - (e^{-p't} - e^{-q't})r_j + r_j' te^{-p't}(p-p') - (x_j^0 - x_j^e + r_j')te^{-q't}(q-q'). \tag{17}$$

The sum of squares of the differences between Eq. 17 and the experimental values for each x_j-t curve is $\sum(x_j - x_{jn})^2$, where x_{jn} is the value of x_j at the n-th experimental point. The minimum condition for the total sum of squares of a set of three x_j-t curves is give by Eq. 18 (note that the adjustable parameters are p, q, r_1, r_2, and r_3).

$$\sum_{j=1}^{3}[\partial\sum_n(x_j - x_{jn})^2/\partial p + \partial\sum_n(x_j - x_{jn})^2/\partial q + \partial\sum_n(x_j - x_{jn})^2/\partial r_j] = 0. \tag{18}$$

The values of p, q, r_1, r_2, and r_3 that minimize the total sum of squares for a given set of p', q', r_1', r_2', and r_3' are determined by solving Eq. 18. These values are inserted into Eq. 17 in place of p', q', r_1', r_2', and r_3'. By solving the resultant equation, a new set of p, q, r_1, r_2, and r_3 that gives a better fitting will be obtained. This procedure is repeated until the values of these parameters converge. The convergence naturally depends on how the values of the first set of p', q', r_1', r_2', and r_3' are close to the final values; too unrealistic initial values may result in divergence. A method of determining the initial values will be described in

Results and Discussion. Equation 18 is rewritten as

$$\mathrm{D}\begin{pmatrix} p \\ q \\ r_1 \\ r_2 \\ r_3 \end{pmatrix} = \mathrm{F}\begin{pmatrix} p' \\ q' \\ r_1' \\ r_2' \\ r_3' \end{pmatrix} \quad (19)$$

Here D is a symmetric square matrix with five columns. The element of D at the h-th column and the m-th line is given by $\sum_n \sum_j a_h a_m$ (j=1,2,3; h=1,2,···,5; m=1,2,···,5), where

$$\begin{aligned} a_1 &= -r_j' t_n \exp(-p' t_n) \\ a_2 &= -\{x_j^0 - x_j^e - r_j'\} t_n \exp(-q' t_n) \\ a_3 &= a_4 = a_5 = \exp(-p' t_n) - \exp(-q' t_n) \end{aligned} \quad (20)$$

and F is a diagonal matrix the element of which at the m-th column, b_m (m=1,2,···,5) is given by

$$b_m = \sum_{j=1}^{3} \sum_n [x_j^e + r_j' \exp(-p' t_n) - x_{jn} + \{x_j^0 - x_j^e - r_j'\} \exp(-q' t_n)] a_m. \quad (21)$$

Equation 19 is the simultaneous equation for p, q, r_1, r_2, and r_3. Its solution and the iteration can be executed on a personal computer. An example of estimation of the initial values of p', q', r_1', r_2', and r_3' is given below.

Experimental

Chemicals. The following three geometrical isomers of acetylacetonatobis(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)ruthenium(III) were prepared and isolated according to the procedure described previously:[7] *ab*-acetylacetonato-*de*,*fc*-bis(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)ruthenium(III) (**B**$_1$), *ab*-acetylacetonato-*cf*,*de*-bis(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)ruthenium(III) (**B**$_2$), and *ab*-acetylacetonato-*cf*,*ed*-bis(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)ruthenium(III) (**B**$_3$). Deionized water (Barnstead, NANOpure) was used, and the other solvents were of liquid-chromatographic grade unless otherwise stated.

Chromatography. High-pressure liquid chromatography was conducted on a Toyo Soda CCPM liquid chromatograph with a Toyo Soda UV-8000 ultraviolet-visible detector operating at 304 nm. The three isomers were separated on a silanised silica gel column (250 mm length, 4 mm internal diameter; Merck LiChrosorb RP-18, particle size 5 μm) by a mixture or methanol-water-acetonitrile (8:3:2 by volume) at a flow rate of 1 cm^3 min^{-1}. Retention time were 19 min for **B**$_3$, 20 min for **B**$_2$, and 23 min for **B**$_1$.

The peak area (defined as the product of the peak hight and the half-peak width) was proportional to the amount of each isomer. The mole fractions of the isomers in the reaction mixtures were determined by means of calibration curves drawn for a standard series of mixtures prepared gravimetrically from the isolated samples of the isomers.

Kinetic Measurement. Each of the isomers (**B**$_1$, 3.87×10^{-5} mol; **B**$_2$, 4.02×10^{-5} mol; **B**$_3$, 2.29×10^{-5} mol) was dissolved in 50 cm^3 of *N*,*N*-dimethylformamide (DMF) of the spectrophotometric grade (Dojindo Laboratories, Dotite Spectrosol). Forty five 0.1 cm^3 aliquots of each solution were transferred into glass tubes of 1.5 mm internal diameter. After the contents were deoxygenated by passing argon through a glass capillary for 1 min, the tubes were sealed in a flame and mounted on a holder. During these operations, the solutions were cooled with ice-water. The reaction was started by immersing the holder with 135 tubes into an oil bath (Thomas Kagaku Thermostatic Oil Bath, T-201) maintained at (90±0.1) °C. Three tubes, one for each starting isomer, were removed from the oil bath at certain time intervals and immediately quenched in ice-water. Each tube was then cut open, and a 2 mm^3 portion of its content was injected into the chromatograph.

The mole fractions of the three isomers under equilibrium conditions were determined in a similar manner when the reaction mixtures were allowed to stand at 90 °C until no further change was detected (2—3 days).

No indication of any side reactions was observed.

Results and Discussion

The three equilibrium constants are presented in Table 1. They were independent of the starting species and are not far from the statistical values (4:1:2).

Figures 3a, 3b, and 3c show variations of x_j with the time when starting species are **B**$_1$, **B**$_2$, and **B**$_3$, respectively. Evidently, the reactions **B**$_1$→**B**$_3$ and **B**$_3$→**B**$_1$ are slower than the other reactions, and the reaction **B**$_2$→**B**$_3$ is slower than the reaction **B**$_2$→**B**$_1$. The curves in Fig. 3a are essentially similar to the dotted curves in Fig. 2, suggesting that the reaction belongs to case (B).

The initial values of parameters p', q', r_1', r_2', and r_3' were determined as follows. If $q \gg p$, plot of $\ln(x_{jn} - x_j^e)$ against t_n at long times should fall on a straight line, of which slope and intercept give approximate values of p and r_j, respectively. The plots for the three curves with x_j^0=1 in Figs. 3a, 3b, and 3c are straight lines (Fig. 4), although their slopes are not quite the same. We took the slope of the line corresponding to Fig. 3a (circles in Fig. 4) as the initial value of p' and its intercepts as the initial value of r_1'. The initial value of q' was set to be twice the initial value of p' and r_2'=r_3'=0 (there was no particular reason for this choice). The values of p, q, r_1, r_2, r_3 for the data of Fig. 3a were successfully determined by inserting these initial values into Eqs. 19—21 and executing the iteration.

The same procedure was applied to the data of Figs. 3b and 3c. Values of the five parameters thus obtained are listed in Table 2. From these values, three sets of κ_j were calculated by means of the following equation:

Table 1. Equilibrium Constants[a)]

Starting species	$K_{12}=x_2^e/x_1^e$	$K_{23}=x_3^e/x_2^e$	$K_{31}=x_1^e/x_3^e$	Number of runs
B$_1$	1.820 (0.059)	0.677 (0.018)	0.813 (0.014)	3
B$_2$	1.799 (0.086)	0.665 (0.044)	0.839 (0.037)	4
B$_3$	1.823 (0.054)	0.694 (0.044)	0.792 (0.027)	2
Average	1.811 (0.064)	0.675 (0.034)	0.820 (0.032)	

a) Values in the parentheses are standard deviations.

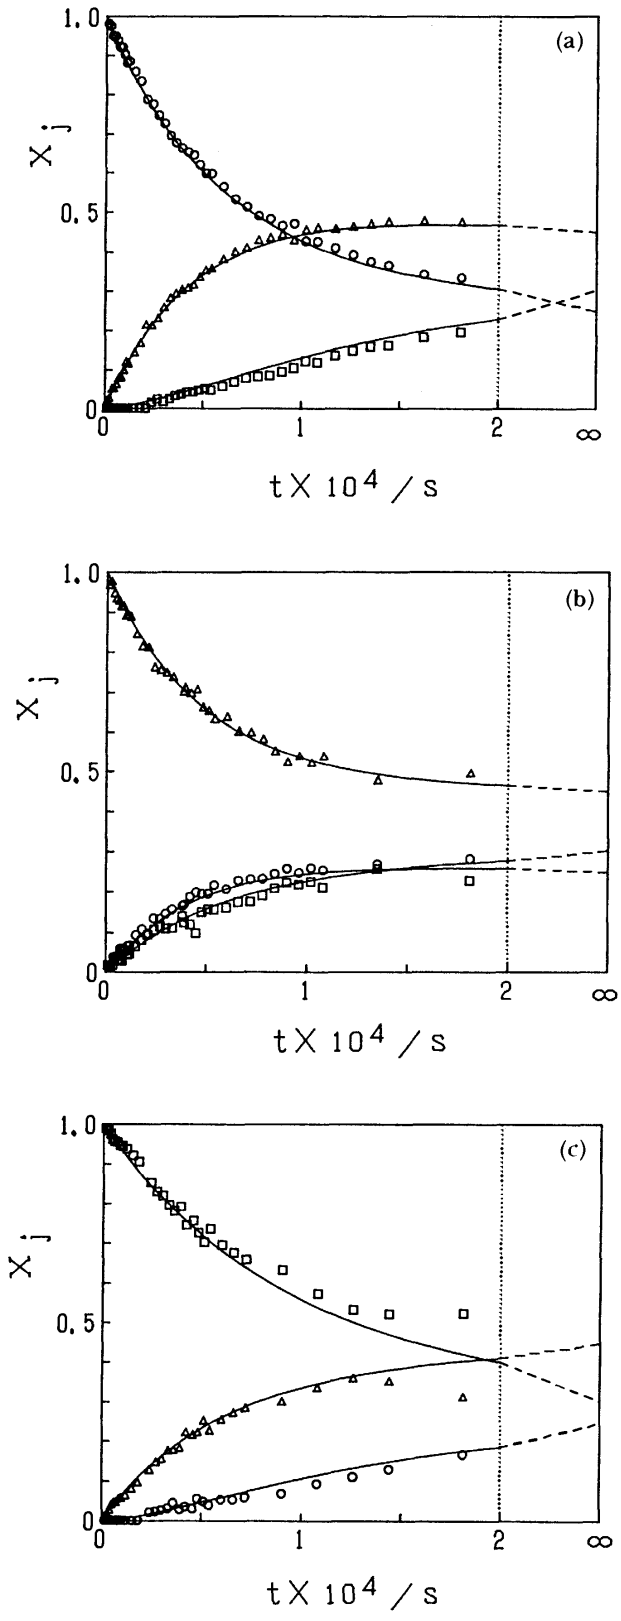

Fig. 3. Variations of mole fractions, x_j (j=1,2,3), for $\mathbf{B}_1$(○), $\mathbf{B}_2$(△), and $\mathbf{B}_3$(□) with time. Starting species are $\mathbf{B}_1$(a), $\mathbf{B}_2$(b), and $\mathbf{B}_3$(c). Solid lines are simulated curves calculated from Eqs. 8—15 at the following values: K_{12}=1.811, K_{23}=0.675, K_{31}=0.820, k_{12}=1.228×10^{-4} s^{-1}, k_{23}=0.476×10^{-4} s^{-1}, and k_{31}=0.027×10^{-4} s^{-1}.

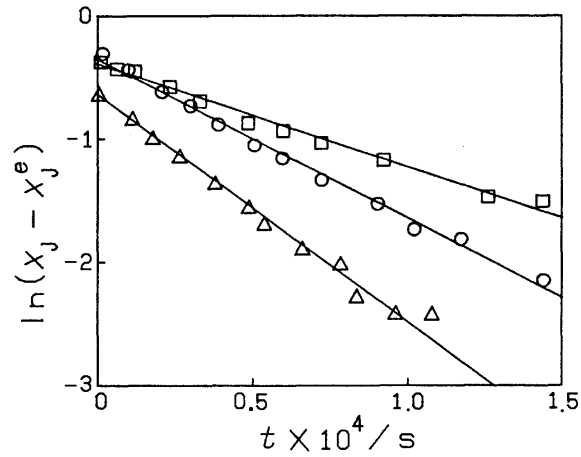

Fig. 4. Logarithmic plots of deviation of the mole fraction from the equilibrium against the time. Symbols ○, △, and □ correspond respectively to data ○ in Fig. 3a, data △ in Fig. 3b, and data □ in Fig. 3c.

Table 2. Auxiliary Kinetic Parameters Required for Determination of k_{ij}

Starting species	$p\times10^4$ / s^{-1}	$q\times10^4$ / s^{-1}	r_1	r_2	r_3
$\mathbf{B}_1$	0.863	2.116	0.333	0.177	−0.510
$\mathbf{B}_2$	0.681	2.266	0.078	0.066	−0.144
$\mathbf{B}_3$	0.584	2.875	−0.286	−0.236	0.522

Table 3. Linearly Combined Rate Constants, κ_j

Starting species	$\kappa_1\times10^4$ / s^{-1}	$\kappa_2\times10^4$ / s^{-1}	$\kappa_3\times10^4$ / s^{-1}
$\mathbf{B}_1$	1.805	1.171	0.002
$\mathbf{B}_2$	0.685	1.803	0.459
$\mathbf{B}_3$	0.058	0.750	2.650

$$\kappa_j = x_j^0(p+q) - pr_j - q(x_j^0 - x_j^e - r_j), \qquad (22)$$

which has been derived from Eq. 11 by eliminating λ_j. The values of κ_j are listed in Table 3. Since κ_j is the linear combinations of k_{12}, k_{23}, and k_{31} (Eq. 12), the rate constants can be immediately estimated: κ_2 for $\mathbf{B}_1$ (1.2×10^{-4} s^{-1}) is $x_1^0k_{12}$, while κ_1 for $\mathbf{B}_2$ (0.68×10^{-4} s^{-1}) is $x_2^0k_{21}$, and so forth. However, the k values obtained in this way are not consistent. For example, the calculated values of k_{12} and k_{21} do not satisfy k_{12}/k_{21}=1.811 (=K_{12}). There are nine known values for κ_j from which three k's are to be determined. This redundancy can be effectively utilized for increasing the precision of the computation in the following way.

Let us consider a three-dimensional space (k_{12}, k_{23}, k_{31}). Each κ_j value is represented as a plane in this space. The most probable values of k_{12}, k_{23}, and k_{31} will be given by the coordinates of the center of the polyhedron defined by the nine κ_j planes. The center is the point where the total sum of squares of the distances between that point and the nine planes is a

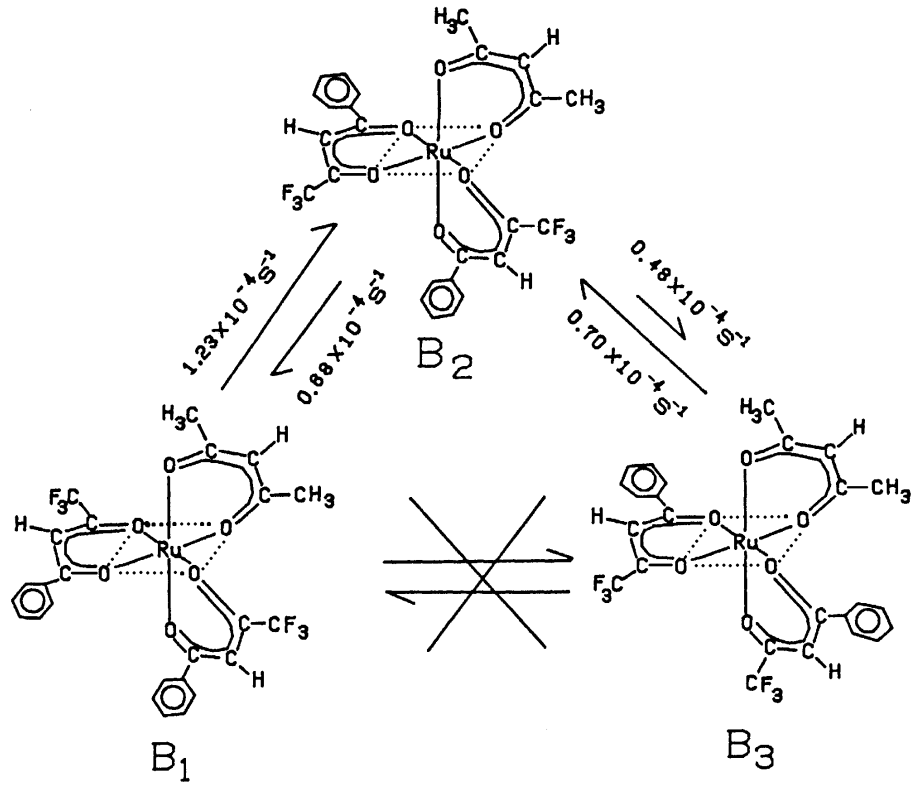

Fig. 5. Kinetic parameters for the isomerization of [Ru(acac)(tfpb)].

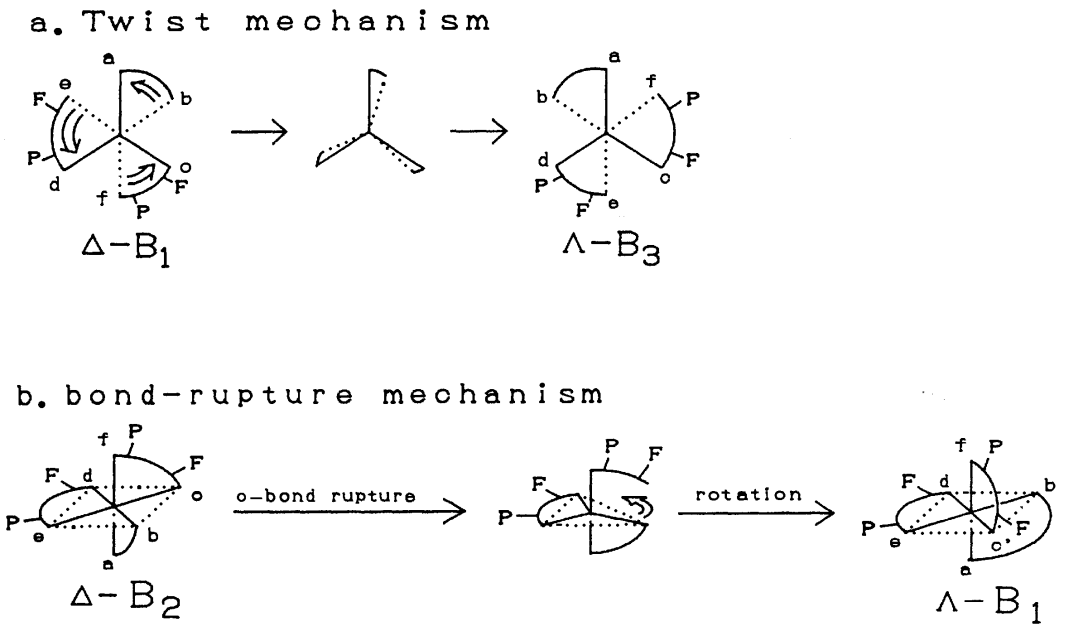

Fig. 6. Examples of twist mechanism (a) and bond-rupture mechanism (b).

minimum. This least squares method leads to the following values: $k_{12}=1.22_8\times10^{-4}$ s^{-1}, $k_{23}=0.47_6\times10^{-4}$ s^{-1}, and $k_{31}=0.02_7\times10^{-4}$ s^{-1}. The standard deviation is $0.05_3\times10^{-4}$ s^{-1}. The curves in Fig. 3 are calculated from Eq. 8 with these k values. They are in good agreement with the experimental data. The deviation of the points from the calculated curves for $t>$ca. 1.5×10^4 s is attributable to experimental errors. Noteworthy is the fact that the direct conversion between **B**$_1$ and **B**$_3$ was forbidden. Isomerization reactions of octahedral tris-chelate complexes are generally interpreted in terms of two basic pathways: twist mechanisms and bond-rupture mechanisms.[8] The twist mechanisms are not compatible with this fact because

the rotation around two of the possible four axes allows the conversion between $\mathbf{B}_1$ and $\mathbf{B}_3$ (for example, Fig. 6a). On the contrary, certain types of bond-rupture pathways[9] (for example, Fig. 6b) are in accord with the absence of the direct conversion between $\mathbf{B}_1$ and $\mathbf{B}_3$. More detailed discussion will be presented in a subsequent paper.

The technique of determining the rate constants presented above has the following advantages: 1) absolute values of the rate constants can be obtained; 2) all the experimental points, not only those near the equilibrium, are effectively utilized; 3) the rate constants are determined consistently from all the available data; 4) the requirement of the precision of the data is not too strict.

The authors' thanks are due to Dr. S. F. Howell, Sophia University, for correcting the manuscript.

Stabilities in Water and Transfer Activity Coefficients from Water to Nonaqueous Solvents of Benzo-18-crown-6-Metal Ion Complexes

Yasuyuki TAKEDA,* Rie KOHNO, Yoshihiro KUDO, and Naoaki FUKADA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 260
(Received September 5, 1988)

Formation constants in water of 1 : 1 benzo-18-crown-6 (B18C6)-metal ion complexes and the B18C6 solubility in water were determined at 25 °C by conductometry or potentiometry with ion-selective electrodes and spectrophotometry, respectively. The selectivity sequences of B18C6 for metal ions in water are $Pb^{2+} > Ba^{2+} > Sr^{2+} > Ag^+ > K^+ > Tl^+ > Na^+ > Rb^+$. In each case of alkali and alkaline earth metal ions, the more closely a metal ion fits into the B18C6 cavity, the more stable is the B18C6-metal ion complex. Although the solvation power of water for an alkali metal ion is not the largest of all solvents, the formation constant of a given B18C6-alkali metal ion complex in water is by far the smallest of all solvents. The transfer activity coefficients (γ) from water to nonaqueous solvents of the B18C6-metal ion complexes were then calculated from the formation constants of the B18C6 complexes, γ values of B18C6 (obtained from solubilities of B18C6), and γ values of the uncomplexed metal ions. The γ value of B18C6 is larger than those of B18C6-alkali metal ion complexes. This shows that when B18C6 forms a complex with an alkali metal ion, the B18C6 complex becomes more soluble in nonaqueous solvents than in water, compared with uncomplexed B18C6.

The formation constants in water and transfer activity coefficients from water to nonaqueous solvents of crown ether-metal ion complexes provide valuable information on effects of water on the stabilities and aspects of hydration of crown ether complexes, respectively, where the transfer activity coefficients of the crown ether complexes are calculated by using the formation constants of the crown ether complexes. The formation constants[1] in water and the transfer activity coefficients[2-4] from water to nonaqueous solvents of 18-crown-6 (18C6)- and dibenzo-18-crown-6 (DB18C6)-metal ion complexes have been reported. However, no data on the stabilities of benzo-18-crown-6 (B18C6)-metal ion complexes in water[1] have been reported.

In this study, the formation constants in water and the transfer activity coefficients from water to nonaqueous solvents of B18C6-metal ion complexes were determined at 25 °C. Effects on the stabilities in water and the aspects of hydration of the B18C6-metal ion complexes are discussed in detail.

Experimental

Materials. Benzo-18-crown-6 was prepared according to a method of Pedersen.[5] The product was recrystallized four times from hexane and dried in a vacuum oven at room temperature. Its purity was checked by melting point (mp 44—45 °C), elemental analysis, NMR, and conductometry.

Extremely pure NaCl, KCl, RbCl, CsCl, $Sr(NO_3)_2$, $Ba(NO_3)_2$, and analytical grade $TlNO_3$ were obtained from Merck Japan Ltd. They were used without further purification. Analytical grade $AgNO_3$ and $Pb(NO_3)_2$ were purchased from Wako Pure Chemicals Ltd. The purities of $AgNO_3$ and $Pb(NO_3)_2$ were determined by means of KCl and EDTA titration, respectively. The conductivity of water was less than $4\times10^{-7}\ \Omega^{-1}\ cm^{-1}$.

Apparatus and Procedure. The conductance measurements were made on a Fuso conductivity apparatus (model 362B) in a water bath thermostated at 25±0.005 °C. Two cells with cell constants of 0.05823 and 0.08135 cm^{-1} were used. The experimental procedure to obtain the formation constants of B18C6-metal ion complexes was almost the same as that described in a previous paper.[6]

The emf measurements were carried out with a Denki Kagaku Keiki ion meter apparatus (model IOC-10) in a water bath thermostated at 25±0.05 °C. For Na^+ and K^+, a Horiba 1512A-06T Na^+-selective electrode and a Toko Kagaku 1200 K^+-selective electrode were used, respectively. The Denki Kagaku Keiki 7080 Ag^+-selective electrode and the 7180 Pb^{2+}-selective electrode were used for Ag^+ and Pb^{2+}, respectively. Horiba 2535A-06T (Ag|AgCl electrode) and Denki Kagaku Keiki 4083 (Ag|AgCl electrode) were used as references for Na^+, K^+ measurements, and for Ag^+, Pb^{2+} measurements, respectively. Experiments for obtaining the formation constants of B18C6-metal ion complexes were performed according to the method of Frensdorff.[7]

Solubility of B18C6. A B18C6 suspension in water was stirred at 25±0.02 °C for 3 days; then, the solution saturated with B18C6 was filtered under nitrogen. The B18C6 concentration of the aqueous solution was determined spectrophotometrically (at 273 nm). The solubility of B18C6 in water (average of seven measurements) at 25 °C was 0.94±0.02 M (1 M=1 mol dm^{-3}).

Results and Discussion

The analysis of conductometric data for obtaining the formation constants (K_{ML}) of complexes of B18C6 with K^+, Rb^+, Tl^+, Sr^{2+}, and Ba^{2+} was the same as that described elsewhere.[6] Here, $K_{ML}=[ML^{m+}]/[M^{m+}][L]$; M^{m+} and L are a metal ion and a crown ether, respectively. The analysis of potentiometric data for obtaining K_{ML} values of complexes of B18C6 with Na^+, K^+, Ag^+, and Pb^{2+} was the same as that described by Frensdorff.[7] In this study, it is assumed that the association between a cation and an anion is negligible and that B18C6 forms a 1 : 1 complex with a metal ion. The log K_{ML} values are compiled in Table 1.

Stability Constants. It can be seen from Table 1 that the selectivity sequence of B18C6 for alkali metal ions

in H_2O is $K^+ > Na^+ > Rb^+$ ($> Cs^+$). The selectivity tendency in H_2O of B18C6 for alkali metal ions other than Na^+ agrees completely with those of 18-crown-6 (18C6) and dibenzo-18-crown-6 (DB18C6); namely, the more closely the metal ion fits into the B18C6 cavity (18C6 cavity radius: 1.38 Å[18]), the more stable is the B18C6-metal ion complex (size-fit concept). A similar selectivity trend of 18C6, B18C6, and DB18C6 for K^+, Rb^+, and Cs^+ was observed in nonaqueous solvents.[14] The sodium ion-selective tendency of B18C6 in H_2O is consistent with that of DB18C6, but is different from that of 18C6. This may be attributed largely to the higher ligand-ring rigidity of B18C6 caused by the benzo group, compared with 18C6. It has been reported that a complexation reaction of Na^+ with a flexible crown ether causes a large ligand-ring conformational change, resulting in a great entropy-destabilization of the Na^+ complex.[14] The K_{ML} (K^+)/K_{ML} (Na^+) ratio of B18C6 varies somewhat with the solvent, in comparison with DB18C6; however, the $K_{ML}(K^+)/K_{ML}(Na^+)$ ratio of 18C6 varies greatly. Kolthoff and Chantooni, Jr.[2] reported that, from the K_{ML} (K^+)/K_{ML} (Na^+) ratios of 18C6 and DB18C6, the conformation of L in ML^+ seemed to be more affected by the solvent when L is 18C6 than when it is DB18C6. It, thus, appears from this that the conformation of B18C6 in ML^+ is somewhat greater, and is less affected by the solvent, compared with DB18C6 and 18C6, respectively.

A K^+ ion fits most nicely into the B18C6 cavity, whereas the size of a Ag^+ ion is smaller than that of the B18C6 cavity; though the Gibbs-free energy of hydration ($\Delta G_h°$) of Ag^+ is smaller than that of K^+ (Table 3), the B18C6 forms a slightly more stable complex with Ag^+ than K^+ in water (Table 1). Although the ionic sizes of Tl^+ and Rb^+ are almost the same and $\Delta G_h°$ of Tl^+ is slightly smaller than that of Rb^+, the Tl^+-B18C6 complex is more stable than the Rb^+-B18C6 complex in water.

From Table 1, the $\log K_{ML}$ value of a B18C6-Ba^{2+} complex in water is larger than that of a B18C6-Sr^{2+} complex; this tendency is entirely consistent with the size-fit concept. The same is true for the cases of 18C6 and DB18C6. A Pb^{2+} ion has a less suitable size for the B18C6 cavity than does a Ba^{2+} ion; though $\Delta G_h°$ of Ba^{2+} is larger than that of Pb^{2+} (Table 3), the Pb^{2+}-B18C6 complex is somewhat more stable than the Ba^{2+}-B18C6 complex in water. The unexpected behavior of B18C6 complexes with Ag^+, Tl^+, and Pb^{2+} may be ascribed to different binding forms of Ag^+, Tl^+, and Pb^{2+} with ether oxygen atoms of B18C6 from those of s-block metal ions.

Ba^{2+} and K^+ are nearly identical in size; though $\Delta G_h°$ of Ba^{2+} is very much smaller than that of K^+ (Table 3), Ba^{2+} forms a more stable complex with B18C6 than K^+ in water. The ionic radii of Sr^{2+} and Pb^{2+} are approx-

imately equal to that of Ag^+; though ΔG_h° of Sr^{2+} and Pb^{2+} are very much smaller than that of Ag^+, Sr^{2+}- and Pb^{2+}-B18C6 complexes are more stable than a Ag^+-B18C6 complex in water. The same trend is found for 18C6 and DB18C6, except for the cases of Sr^{2+}- and Ag^+-DB18C6 complexes (Table 1).

On account of the higher basicity of an aliphatic ether oxygen atom compared with an aromatic ether oxygen atom, it can be expected that the stabilities of the complexes of a given metal ion with the three crown ethers in water decrease in the order 18C6> B18C6> DB18C6. The data on water given in Table 1 are consistent with this expectation, except for the cases of Na^+ and Ag^+. For each case of Na^+ and Ag^+, the B18C6 complex is more stable than the DB18C6 complex in water, which is in accord with the expectation; however, the stability sequence of the 18C6 complex among these three crown ether complexes is unexpected. On account of the smaller size of the metal ion compared with the 18C6 cavity-size and the higher ligand-ring flexibility of 18C6, the metal ion with higher charge density may cause a large conformational change upon complexation. Thus, the 18C6 complex is entropy-destabilized, resulting in the unexpected stability sequence.

Although the solvation power of water for an alkali metal ion (i.e., relative solubility of the alkali metal ion), which is derived from the data on transfer activity coefficients of the alkali metal ion,[2] is the third largest of all the solvents listed in Table 1, the log K_{ML} value of a given B18C6-alkali metal ion complex in water is by far the smallest of all the solvents. The same tendency was observed for the cases of 18C6- and DB18C6-alkali metal-ion systems.[14] It appears from this finding that the hydrogen bonds between ether oxygen atoms of the crown ether and water molecules cause the much lower stability of the crown ether-alkali metal ion complex in water than all the other solvents.

Benzo-18-crown-6 forms much more unstable complexes with Sr^{2+} and Ba^{2+} in water than in methanol (Table 1). The much stronger solvation of Ba^{2+} in water than in methanol[20] is probably responsible for the much lower stability of the Ba^{2+} complex in water than in methanol.

Transfer Activity Coefficient. The logarithm of the transfer activity coefficient ($\log {}^{s_1}\gamma^{s_2}(ML^{m+})$[21]) of a B18C6-metal ion complex between solvent s_1 and solvent s_2 is calculated as follows:

$$\log {}^{s_1}\gamma^{s_2}(ML^{m+}) = (\log K_{ML})_{s_1} - (\log K_{ML})_{s_2} + \log {}^{s_1}\gamma^{s_2}(L) + \log {}^{s_1}\gamma^{s_2}(M^{m+}), \quad (1)$$

where ${}^{s_1}\gamma^{s_2}(L)$[21] and ${}^{s_1}\gamma^{s_2}(M^{m+})$[21] refer to the transfer activity coefficients of B18C6 and a metal ion between solvent s_1 and solvent s_2, respectively. Further, $(\log K_{ML})_s$ denotes the $\log K_{ML}$ value in solvent s. When $\log {}^{s_1}\gamma^{s_2}(ML^{m+})$ is positive, it can be considered that the complex, ML^{m+}, undergoes stronger solvation in s_1 than in s_2. The transfer activity coefficient values of ML^{m+}, M^{m+}, and L when s_1=H_2O are compiled in Table 2.

$\log {}^{H_2O}\gamma^s(L)$ values of benzo-15-crown-5 (B15C5) at 25 °C are −1.24, −1.04, and −0.56, when s=CH_3CN (AN), propylene carbonate (PC), and methanol, respectively.[26] In each case of s=AN and PC, the $\log {}^{H_2O}\gamma^s(L)$ value of B18C6 is larger than that of B15C5; the $\log {}^{H_2O}\gamma^{CH_3OH}(L)$ value of B18C6 is slightly greater than that of B15C5. This shows that, from B15C5 to B18C6, the crown ether is more soluble in water than in the nonaqueous solvents. The size of B18C6 is larger than that of B15C5 by an ether oxygen atom and an ethylene group. Thus, the additional hydrogen bonding between the added ether oxygen atom of B18C6 and water may be responsible for the higher $\log {}^{H_2O}\gamma^s(L)$ values of B18C6 compared with B15C5. The $\log {}^{H_2O}\gamma^s(L)$ value of B18C6 is larger than the corresponding $\log {}^{H_2O}\gamma^s(L)$ value of DB18C6; $\log {}^{H_2O}\gamma^{CH_3OH}$ (18C6) is greater than $\log {}^{H_2O}\gamma^{CH_3OH}$(B18C6) (Table 2). This reveals that with more benzo groups, the crown ether is more soluble in nonaqueous sol-

vents than in water. This is due to the lipophilicity of the benzo group.

Generally, $\log {}^{H_2O}\gamma^s$ values of B18C6-K^+ and -Rb^+ complexes for a given solvent s are approximately equal; but, $\log {}^{H_2O}\gamma^s$ values of B18C6-K^+ and -Rb^+ complexes are somewhat different from those of B18C6-Na^+ and -Cs^+ complexes. This indicates that the nature of solute-solvent interactions of the B18C6-K^+ and -Rb^+ complexes is almost the same; however, this is different from the nature of the solute-solvent interactions of the B18C6-Na^+ and -Cs^+ complexes. This reflects the fact that both K^+ and Rb^+ have more suitable sizes for the B18C6 cavity than do Na^+ and Cs^+.

The $\log {}^{H_2O}\gamma^s(M^{m+})$ value is larger than the corresponding $\log {}^{H_2O}\gamma^s(ML^{m+})$ value of B18C6. This shows that when a M^{m+} ion forms a complex with B18C6, the M^{m+} ion complexed with B18C6 becomes less soluble in water than in nonaqueous solvents, compared with the free M^{m+} ion; namely, B18C6 plays a role in enhancing the lipophilicity of the M^{m+} ion. When s=AN, PC, DMF, and DMSO, $\log {}^{H_2O}\gamma^s(ML^+)$ value of a given alkali metal ion decreases in the order B18C6>DB18C6 (3.7—4.4, 2.4—2.7, 3.6, and 2.7—3.4 units, respectively); the $\log {}^{H_2O}\gamma^{CH_3OH}(ML^{m+})$ value sequence of a given metal ion is 18C6>B18C6>DB18C6 (the differences: 1.5—2.1 and 0.8—1.6 units, respectively). Similar differences are observed for the cases of free 18C6, B18C6, and DB18C6. It can be concluded from this finding that the more the number of benzo groups is, the more hydrophobic (lipophilic) the crown ether-M^{m+} complex is, regardless of a variety of the metal ions. This may be ascribed largely to the hydrophobic entropy effect[3] caused by the enforcement of a hydrogen-bonded structure of water against the benzo group.

For a given solvent s, $\log {}^{H_2O}\gamma^s$(B18C6) is larger than $\log {}^{H_2O}\gamma^s$ of B18C6-alkali metal-ion complexes; the same is true for the cases of 18C6 and DB18C6. This shows that when B18C6 forms a complex with an alkali metal ion, the B18C6 complex becomes more soluble in nonaqueous solvents than in water, compared with uncomplexed B18C6. Chantooni, Jr. and Kolthoff[3] have reported that upon the complexation of a crown ether with a M^{m+} ion, hydrogen bonding to the ether oxygen atoms is greatly decreased as a result of ionic M^{m+}-O bonding. The considerably reduced strength of hydrogen bonding between ether oxygen atoms and water may cause an enforcement of the hydrogen-bonded structure of water for a bulky crown ether complex, resulting in a higher hydrophobicity of the complex, compared with an uncomplexed crown ether. The solvation power of DMF and DMSO for an alkali metal ion is greater than that of water.[27] When s=DMF and DMSO, both the effect of the reduced strength of hydrogen bonding and the stronger interaction between the complexed alkali metal ion and solvents may be responsible for the result, $\log {}^{H_2O}\gamma^s(L) > \log {}^{H_2O}\gamma^s(ML^+)$. Although water has a stronger solvation power for an alkali metal ion than do acetonitrile, propylene carbonate, and methanol,[27] $\log {}^{H_2O}\gamma^s(L)$ is larger than the corresponding $\log {}^{H_2O}\gamma^s(ML^+)$. The solvation power of water for an alkali metal ion is not so large as that of DMF or DMSO.[27] Thus, the superiority of the effect of reduced strength of hydrogen bonding between ether oxygen atoms and water over the effect of the stronger solvation power of water may result in $\log {}^{H_2O}\gamma^s(L) > \log {}^{H_2O}\gamma^s(ML^+)$. The above discussion is supported by a large difference in $\log {}^{H_2O}\gamma^s(L) - \log {}^{H_2O}\gamma^s(ML^+)$ for the same alkali metal ion and crown ether between a group of AN, PC, CH_3OH and that of DMF, DMSO.

$\log {}^{H_2O}\gamma^{CH_3OH}$ of a B18C6-Ba^{2+} complex is larger than that of a free B18C6. The same is true for the cases of 18C6 and DB18C6. This is different from the cases of alkali metal ions, which is due to a difference in the charge density between Ba^{2+} and M^+. Since Ba^{2+} is much more strongly solvated in water than in methanol, compared with an alkali metal ion (log ${}^{H_2O}\gamma^{CH_3OH}(Ba^{2+})=3.2$ in Table 2), the effect of a very much stronger interaction with water of the Ba^{2+} ion in the crown ether complex than with methanol probably surpasses the effect of the reduced strength of hydrogen bonding between ether oxygen atoms and water, resulting in $\log {}^{H_2O}\gamma^{CH_3OH}(BaL^{2+}) > \log {}^{H_2O}\gamma^{CH_3OH}(L)$.

These data on the transfer activity coefficients strongly support the conclusion in the preceding section that the unexpected lowest stability of the crown ether-metal ion complex in water of all the solvents can be attributed to the very strong hydrogen bonding between the ether oxygen atoms of the uncomplexed crown ether and water molecules.

Although the solvation power of water for an alkali metal ion is the third largest of all the solvents listed in Table 2,[27] that of water for a B18C6-alkali metal ion complex is the smallest. The same tendency is found for 18C6- and DB18C6-alkali metal ion complexes. This can probably be ascribed to the above-mentioned effect produced by the greatly reduced strength of hydrogen bonding between ether oxygen atoms and water on a bulky crown ether-alkali metal ion complex.

From Table 2, a B18C6-Ba^{2+} complex is slightly more soluble in water than in methanol; the reverse is

Table 3. Gibbs Free Energy of Hydration ($\Delta G_h°$) of Metal Ions at 25 °C[19]

Ion	$-\Delta G_h°$/kJ mol^{-1}
Na^+	411.3
K^+	338

Ba^{2+}	1318
Pb^{2+}	1497

true for the B18C6-alkali metal ion complexes. The very much stronger interaction of Ba^{2+} with water than with methanol, compared with the cases of alkali metal ions, may be responsible for the slightly higher solubility of the B18C6-Ba^{2+} complex in water than in methanol.

Photocatalytic Decomposition of 2-Ethoxyethanol on Titanium Dioxide

Sadamu YAMAGATA,* Ryo BABA, and Akira FUJISHIMA
Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 13, 1988)

The reaction mechanism of the photocatalytic oxidation of 2-ethoxyethanol (Ethyl Cellosolve, $EtOCH_2CH_2OH$) on TiO_2 powder was investigated by gas chromatography-mass spectrometry (GC-MS), infrared (IR) spectroscopy, and electron spin resonance (ESR) with spin trapping technique. Irradiation of TiO_2 powder with UV light in the presence of $EtOCH_2CH_2OH$ under air led to the formation of ethyl formate, ethanol, acetaldehyde and carbon dioxide. The main product, ethyl formate was different from the product through the reaction pathway proposed before for primary alcohols. It was also different from the product of electrolysis on Pt. Reaction mechanism is proposed based on IR and ESR studies.

There have been many studies on the photocatalytic reactions of organic substances on illuminated semiconductor powders.[1] However, detailed mechanisms of the reactions have not been well understood so far. Therefore, this work was undertaken to investigate the reaction mechanism of photocatalytic oxidation of an organic substance on TiO_2 powder, using mainly IR spectroscopy. There have been many studies on the IR spectra of surface species on TiO_2[2-5] but studies on the photocatalytic reactions of organic substances on TiO_2 powder by IR spectroscopy are relatively few. Filimonov reported the IR spectra of the adsorbed species produced by the photocatalytic reaction of some alcohols and alkanes on TiO_2.[6] Kawai et al. studied the photocatalytic hydrogen evolution from various alcohols and water adsorbed on Pt/TiO_2 and proposed that two processes are involved in the reaction based on an IR study.[7] One was a direct reaction of alcohols with the photoproduced hole in the valence band and the other was the $\cdot OH$ formation from the reaction of the hole with an adsorbed H_2O on the photocatalyst.

The organic substance we employed was 2-ethoxyethanol ($EtOCH_2CH_2OH$) which is widely used as an organic solvent. In order to keep the environment clean and safe it is usually necessary to remove from the air the volatile organic solvents such as $EtOCH_2CH_2OH$ exhausted from manufacturing plants. A photocatalytic reaction is in principle available to treat poisonous chemical species such as CN^- in an aqueous solution[8] or stinking molecules in the air, though the reaction mechanism is not clear yet. From a practical point of view it is quite promising to employ photocatalysis for the treatment of $EtOCH_2CH_2OH$.

Furthermore, we are interested in the oxidative reaction of alkoxyethanols such as $EtOCH_2CH_2OH$ because they have two functional groups, i.e. alcoholic hydroxyl (-OH) and etheric oxy (-O-) groups. It is quite interesting from the viewpoint of organic chemistry to get information as to which group is oxidized first by the photocatalyst. For example, Nishimoto et al. investigated the photocatalytic degradation and polymerization of poly(oxyethylene) on TiO_2 powder in aqueous solution and concluded that both functional groups, alcoholic hydroxyl and etheric oxy, were oxidizable depending on the surface condition of TiO_2.[9] Ross et al. reported that 2-methoxyethanol, a homologous compound of $EtOCH_2CH_2OH$, was oxidized on a platinum and a carbon electrode through the electron transfer at the etheric oxy group rather than the hydroxyl group.[10] Sugawara studied the oxidation of a series of alkoxyethanols on a Pt electrode.[11] The oxidations of alkoxyethanol by pyrolysis[12] and permanganate[13] have also been studied. These investigations on the decomposition of alkoxyethanols showed that the reaction products were different depending on the oxidation processes. The photocatalytic reaction of 1,1-diphenylethylene on the illuminated TiO_2 powder was reported to give products different from those of the electrolysis on Pt.[14] Taking these into consideration the photocatalytic oxidation of $EtOCH_2CH_2OH$ on semiconductor powders seems quite interesting in terms of its reaction pathway and products.

In this study the photocatalytic oxidation of $EtOCH_2CH_2OH$ on TiO_2 powder was investigated, using GC-MS, IR spectroscopy, and ESR with a spin trapping method.

Experimental

Materials. TiO_2 (Nippon Aerosil, P-25) was used as a photocatalyst without pretreatments. Photoirradiation on CdS (Wako Chemicals), ZnS (Wako Chemicals), Al_2O_3 (Wako Chemicals), SnO_2 (Furuuchi Chemicals), and MnO_2 (Kanto Chemicals) powders were carried out for references. All organic reactants in the present experiments were reagent grade (Tokyo Kasei).

Products Analysis. Reaction products in the gas/solid reaction were sampled from a circulating system (volume 800 ml). This system had a fan to vaporize the organic liquid and to circulate the sample gas. It was also equipped with a Pyrex glass reactor with a flat bottom (area 50 cm^2) to support the photocatalyst. The catalyst powder (0.5 g) was evenly spread over the transparent bottom of the reactor and was irradiated from beneath with a 500 W high-pressure mercury lamp. The concentration of the organic substance in the gas phase was about 3000 ppm. Reaction products in the gas phase were analyzed periodically by the gas chroma-

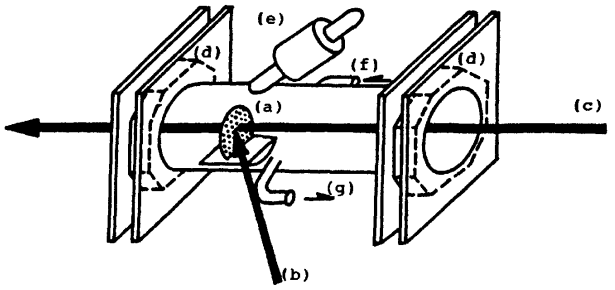

Fig. 1. The IR cell used for the simultaneous IR measurement and GC analysis; (a): TiO_2 pellet; (b): UV light for excitation; (c): IR for monitor; (d): NaCl plate; (e): tube for gas sampling; (f): gas inlet; (g): gas outlet.

tography (Hitachi 163; column: PEG 4000 for organic gases and silica gel for CO_2).

In order to identify the products by GC-MS, photocatalytic reaction of TiO_2 slurry in liquid $EtOCH_2CH_2OH$ was carried out because a gas/solid reaction in the present system did not supply a sufficient amount of the products for a qualitative analysis by GC-MS. The TiO_2 powder (500 mg) dispersed in a given 2-alkoxyethanol (5 ml) saturated with air was irradiated for 5 h in a flask which was installed with an internal high-pressure Hg lamp. The products in liquid phase were collected by distillation and then analyzed by GC-MS (Shimadzu QP1000 with a 30 m OV101 column).

IR Studies. The measurement of IR transmittance of the adsorbed species on the photocatalyst was performed with self-supporting TiO_2 disks. The TiO_2 powder was exposed overnight to the air which was saturated with the organic compound in the dark at room temperature and then the powder (50 mg) was pressed into a disk of 20 mm in diameter and about 0.1 mm in thickness. The IR spectrum was recorded after periodic UV-irradiation with a 500 W Xe-lamp through a water filter to reduce the heating effect. The IR spectrum of liquid $EtOCH_2CH_2OH$ was also recorded by a liquid film method using NaCl plates. A cell was used to analyze the gas phase which is shown in Fig. 1. The cell was first evacuated slowly after the TiO_2 disk which was adsorbed with $EtOCH_2CH_2OH$ was placed inside, and then an air saturated with $EtOCH_2CH_2OH$ was introduced into the cell. An inlet and an outlet of the cell were closed with screw cocks and then the IR measurement and the gas phase analysis were carried out after periodical UV-irradiation under the atmospheric pressure.

ESR Studies. Spin trapping method for an ESR measurement was applied to the present system. The experimental procedure was previously mentioned.[15] 5,5-Dimethyl-4,5-dihydro-3*H*-pyrrole *N*-oxide (DMPO) was used as a spin trapping reagent.

Results

Products Analysis. The gas chromatography analysis of the products in gas/solid reaction showed four peaks, three of which had the same retention times with those of acetaldehyde, ethyl formate, and ethanol, respectively, but the fourth peak which had a longer retention time than $EtOCH_2CH_2OH$ has not been identified yet. This substance was different from ethyl-

ene glycol and was supposed to be such an ether as produced from $EtOCH_2CH_2OH$ by photoreaction in the presence of $TiCl_4$.[16] Carbon dioxide was also detected in a separate experiment. Figure 2 shows the gas chromatogram of the products and the time profile of each product.

CdS and ZnS also gave the same products upon irradiation but were found to be less active than TiO_2. SnO_2, and Al_2O_3 powders did not photocatalyze the decomposition of $EtOCH_2CH_2OH$ because of their large bandgap energies compared with the UV light employed.

Decomposition of $EtOCH_2CH_2OH$ did not occur either when the catalyst was illuminated with a light of a longer wavelength than the bandgap of TiO_2 or when the system temperature was raised up to 353 K in the dark. In the absence of molecular oxygen, photoirradiation caused the reduction of TiO_2 and turned its color blue, and the amount of detected products was insignificant. When the sample gas was flowed over an oxidizing agent, e.g. MnO_2 powder, in the dark, the same gaschromatogram was obtained as when the UV-irradiated photocatalysts were employed. These results suggest that the reaction on the illuminated TiO_2 proceeded through a photocatalytic oxidation involving molecular oxygen in gas phase upon the bandgap illumination of the TiO_2.

A qualitative analysis of the products in liquid/solid reaction by GC-MS showed only one peak, mass spectrum of which agreed well with that of ethyl for-

mate,[17] in addition to the out-of-scale $EtOCH_2CH_2OH$ peak which was in contrast to the results in the gas/solid experiment. There have been some reports mentioning that chemisorbed species react at low pressure gas/solid reactions while physisorbed species become important at high pressure of gas/solid and liquid/solid reactions.[18,19] In our conditions the pressure of $EtOCH_2CH_2OH$ is high enough and the physisorbed molecules react as in the case of liquid/solid phase. Therefore, the difference in the products was ascribed to the surface concentration of $EtOCH_2CH_2OH$ on TiO_2. $EtOCH_2CH_2OH$ is oxidized much easier than ethyl formate in the present conditions, which leads to the production of only ethyl formate under high concentration of $EtOCH_2CH_2OH$.

Alkyl formate is produced from alkoxyethanol by the dissociation of the C-C bond between the two oxygen atoms followed by the subsequent oxidation of one of these carbon atoms. Indeed, when 2-methoxyethanol, 2-isopropoxyethanol, or 2-butoxyethanol was used as a reactant, it was found by GC-MS that the corresponding formate was produced in each case. This result suggests that the C-C bond between the two oxygen atoms of alkoxyethanol is photocatalytically dissociated on the illuminated TiO_2 surface.

IR Studies. Adsorption of $EtOCH_2CH_2OH$ on TiO_2 in the Dark: Infrared spectra of bare TiO_2 (a), liquid $EtOCH_2CH_2OH$ (b), $EtOCH_2CH_2OH$ adsorbed on TiO_2 (c), and ethyl formate adsorbed on TiO_2 (d) are shown in Fig. 3. Bare TiO_2 has broad bands at 650—1100, 1500—1700, and 3000—3600 cm^{-1}, which are assigned to H_2O and OH groups on TiO_2. A comparison of the IR spectrum of $EtOCH_2CH_2OH$ in liquid phase with that of adsorbed $EtOCH_2CH_2OH$ on TiO_2 powder shows that the absorption band of $EtOCH_2CH_2OH$ at 1380 cm^{-1} decreased in intensity more than the bands at 1360 and 1450 cm^{-1} after the adsorption of $EtOCH_2CH_2OH$ onto TiO_2. The decrease of the band at 1380 cm^{-1} indicates that this

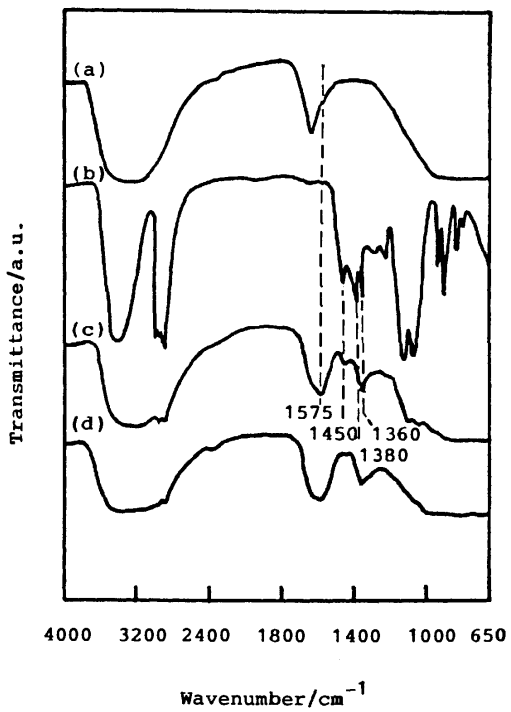

Fig. 3. Infrared spectra of bare TiO_2 (a), liquid phase $EtOCH_2CH_2OH$ (b), $EtOCH_2CH_2OH$ adsorbed on TiO_2 (c), and ethyl formate adsorbed on TiO_2 (d).

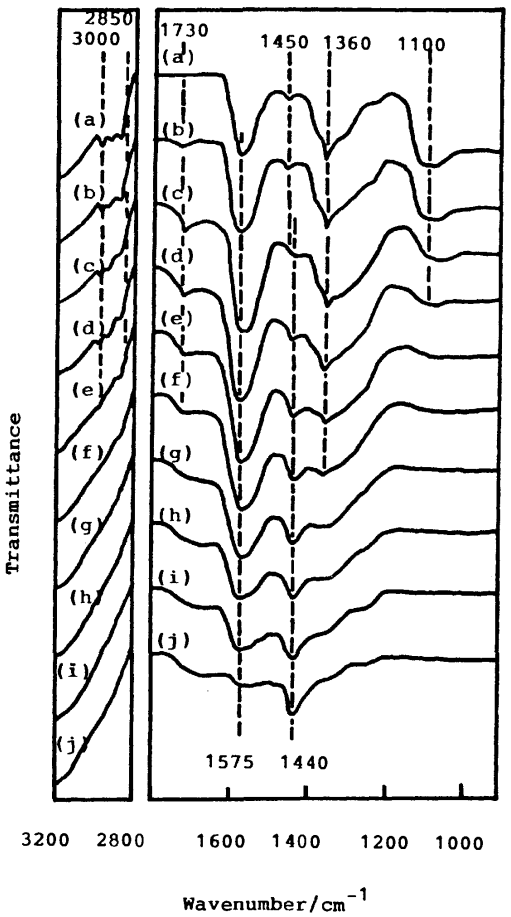

Fig. 4. The time profile of the IR spectrum of adsorbed species upon UV irradiation. Each curve shows the spectrum after the following minutes of UV irradiation (a) 0; (b) 5; (c) 10; (d) 20; (e) 40; (f) 60; (g) 90; (h) 120; (i) 150; (j) 240. The spectra were recorded with the reference of untreated TiO_2 for the wavenumbers from 650—1800 cm^{-1}.

band is due to -OH in $EtOCH_2CH_2OH$, because alcohols are reported to be adsorbed onto TiO_2 forming alkoxides, i.e. losing their -OH groups.[20] It is worth noting that the new band appearing at 1575 cm^{-1} is different from that of the surface formate species reported by Nakajima et al.[20] (Table 1). This band was ascribed to the surface complex produced from the adsorbed $EtOCH_2CH_2OH$ and oxygen species (Fig. 7 (**VI**)), which will be discussed later.

Time Dependence of IR Spectrum of the Adsorbed Species on TiO_2 Powder upon UV Irradiation: The IR spectrum of $EtOCH_2CH_2OH$ adsorbed on the TiO_2 disk showed a time dependence upon UV-irradiation as shown in Fig. 4. That is, the irradiation of the disk with UV light for the first 20 minutes caused an increase in the band intensity at 1575 and 1360 cm^{-1} and a decrease in the band intensity at 1100, 1450, and 2850—3000 cm^{-1}. In addition, new bands appeared, which are at 1440 and 1730 cm^{-1}. A prolonged UV-irradiation caused the band at 1440 cm^{-1} to increase, and the bands, at 1730, 1575, and 1360 cm^{-1} to decrease.

The band at 1440 cm^{-1} was assigned to the surface acetate species[20] (Table 1). The other band at 1530 cm^{-1} due to the surface acetate species reported by Nakajima et al. was obscured by a strong band at around 1575 cm^{-1}. The stable adsorption of the acetate species was reported[20,21] and was also evidenced in the present study by the existence of the band at 1440 cm^{-1} even after 240 minutes of UV-irradiation.

The band at around 1730 cm^{-1} is assigned to the physisorbed ethyl formate (Fig. 7 (**VII**)) which will be further photocatalytically oxidized to ethanol, acetaldehyde, and acetate as will be discussed below.

Simultaneous Measurement of an Adsorbed Species and a Gas-Phase Product: The time profiles of the intensity of the IR band at 1575 cm^{-1} and that of the amount of ethyl formate in gas phase analyzed by GC during UV-irradiation are shown in Fig. 5. The maxima occurred at 40 minutes and 25 minutes of UV-irradiation for the IR absorbance at 1575 cm^{-1} and for the amount of produced ethyl formate in the gas phase, respectively. This result suggests that the surface species which has IR band at 1575 cm^{-1} may be different from ethyl formate because the maxima are different.

Radical Detection by Spin Trapping Method: Figure 6 shows the ESR spectrum observed after 20 seconds of UV-irradiation of the TiO_2 slurry in $EtOCH_2CH_2OH$ with DMPO. The hyperfine splitting constants (a_N=14.6 G and a_H=20.6 G; 1 G=10^{-4} T) indicate that a carbon-centered radical[22] was produced by the photocatalytic reaction of $EtOCH_2CH_2OH$ on TiO_2.

Discussion

Based on the experimental results we propose a reaction mechanism of the photocatalytic decomposition of $EtOCH_2CH_2OH$ on TiO_2 as shown in Fig. 7 and the details of it will be discussed in this section.

Reaction Products. The formation of ethyl formate from $EtOCH_2CH_2OH$ on the photoexcited TiO_2 powder is interpreted through the dehydration and the subsequent oxidation of the double bond according to the oxidation mechanism proposed by Djeghri and Teichner.[23] They have studied the photocatalytic oxidation of primary, secondary, and tertiary alcohols on TiO_2 and concluded that there are two oxidation pathways; one is a direct oxidation which produces aldehydes and ketones from primary and secondary alcohols, respectively. The other is dehydration of alcohols into alkenes which are oxidized at the double bond, forming carbon dioxide and aldehydes or ketones with less carbon atoms than the original alcohols. Applying their reaction mechanisms to the photocatalytic oxidation of $EtOCH_2CH_2OH$ on the illuminated TiO_2 powder, ethoxyacetaldehyde (through direct oxidation) and ethyl formate (through dehydra-

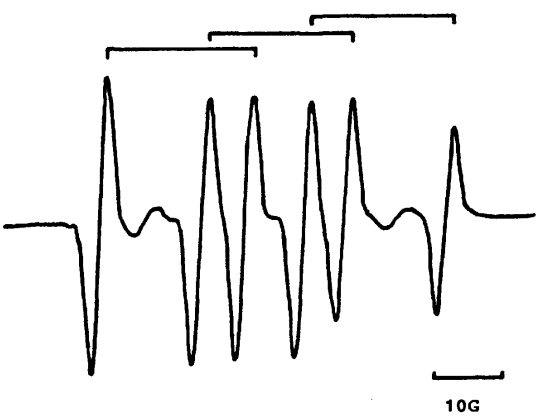

Fig. 6. ESR spectrum of the spin adduct obtained after 20 second UV irradiation of TiO_2 slurry in $EtOCH_2CH_2OH$ with DMPO.

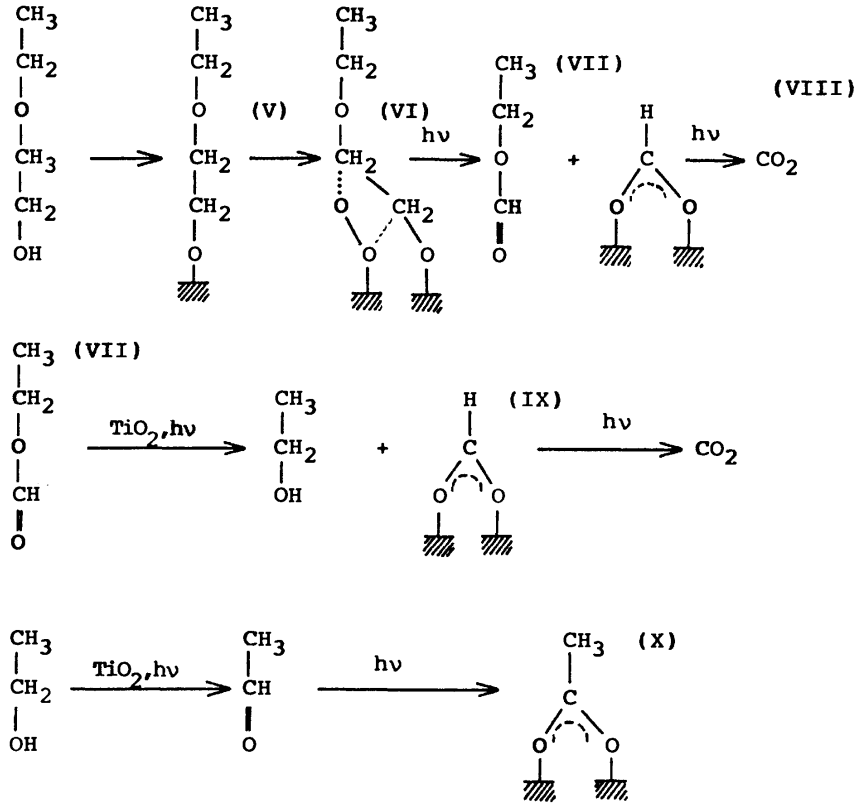

Fig. 7. The reaction scheme of the photocatalytic oxidation of $EtOCH_2CH_2OH$ on TiO_2.

tion-oxidation) are expected to be reaction products. However, only ethyl formate was detected in the present experiment, even though $EtOCH_2CH_2OH$, a primary alcohol, might tend to be oxdized directly into ethoxyacetaldehyde.

No production of ethoxyacetaldehyde may be ascribed to the molecular structure of $EtOCH_2CH_2OH$, i.e., the configuration of the oxygen atom at the β-position of the carbon atom which has the alcoholic -OH. Indeed, the indirect oxidation of alkoxyethanol was previously reported by Sugawara on a Pt electrode.[11] He investigated the electrochemical oxidation of a series of alkoxyethanols and proposed the following mechanism: Discharge occurs at an alcoholic oxygen which is followed by the fission of the C-C bond between the two oxygen atoms, producing a cation **I** and a formaldehyde **II**. This path corresponds to the step between **VI** and **VII** in Fig. 7. The cation **I** is then subjected to the C-O bond fission, producing an alcohol **III** and a formaldehyde **IV**.

$$ROCH_2CH_2OH \xrightarrow{-e,\,-H^+} ROCH_2CH_2O\cdot \xrightarrow{-e} \overset{+}{R}OCH_2\ (\mathbf{I}) \xrightarrow{+H_2O,\,-H^+} ROH\ (\mathbf{III}) + H_2CO\ (\mathbf{II}) \qquad + H_2CO\ (\mathbf{IV})$$

Scheme 1.

Our experimental results indicate that the first two steps of Scheme 1 occurred on the irradiated TiO_2 surface. The subsequent C-O bond fission, however, did not occur. Instead, oxidation of the carbon atom of **I** took place, yielding ethyl formate.

Adsorption of $EtOCH_2CH_2OH$ on TiO_2 in the Dark. We assigned the IR bands at 1575 and 1360 cm^{-1} which appeared after the adsorption of $EtOCH_2CH_2OH$ on TiO_2, to the surface species produced from adsorbed $EtOCH_2CH_2OH$ and oxygen species on TiO_2 (Fig. 7 (**VI**)). Although these bands are in good accordance with those at 1560 and 1360 cm^{-1} of the formate species on TiO_2 prepared from 2-propanol and oxygen at 523 K,[20] it is concluded that the adsorption of $EtOCH_2CH_2OH$ onto TiO_2 surface at room temperature in the dark did not produce the surface formate species. This is because raising the temperature of the TiO_2 powder with $EtOCH_2CH_2OH$ up to 353 K did not release any decomposed products which would be formed along with the surface formate species. In our experimental conditions molecular oxygen was adsorbed on the TiO_2 surface before the introduction of $EtOCH_2CH_2OH$. Molecular oxygen is reported to accept an electron from TiO_2, producing surface O_2^- which is stable at room temperature and can react with organic substances when they are introduced at higher temperatures.[24] Taking this into consideration we propose that the preadsorbed oxygen molecule accepts an electron from TiO_2 and reacts with $EtOCH_2$-

CH_2OH to form a surface formate-like species (Fig. 7 (**VI**)) which has IR bands at 1575 and 1360 cm^{-1}.

Surface Species on TiO_2 during the UV-Irradiation. The UV-irradiation caused an increase in intensity of the band at 1575 cm^{-1} (Figs. 4, 5). We assigned this band to the surface formate species (Fig. 7 (**VIII**)) for the following two reasons: (1) the bands at around 2850—3000 cm^{-1} due to $-CH_3$, and $-CH_2-$ disappeared while the band at 1575 cm^{-1} increased upon irradiation (Fig. 4). This result indicates that the species which has band at 1575 cm^{-1} produced upon UV-irradiation is neither adsorbed $EtOCH_2CH_2OH$ nor ethyl formate on TiO_2 because both of them have the IR bands at 2850—3000 cm^{-1} (Fig. 3 (c),(d)), (2) the simultaneous measurement of the intensity of the IR transmittance at 1575 cm^{-1} and the amount ot ethyl formate in gas phase (Fig. 5) showed that the production of ethyl formate precedes the surface species. This result can be interpreted as follows; surface formate species is produced from the C_1-species which is formed concomitantly with ethyl formate through the C-C cleavage.

Gonzalez et al. assigned the IR band at 1730 cm^{-1} to a surface ketene species (Table 1), which was produced by the thermal reaction of acetic acid on TiO_2.[21] This surface ketene species was produced by the dehydrogenation of a surface acetate species, which indicated that the ketene species was in a more oxidized state than the acetate species. In our experiment the band at 1730 cm^{-1} appeared only in the early stage of the illumination and it did not increase in intensity upon the prolonged UV-irradiation, which was in contrast to the progressive increase of the band at 1440 cm^{-1} with irradiation time. From this result, it is reasonable to assign the band at 1730 cm^{-1} not to the ketene species but to a precursor of an acetate species. Since free aldehyde has an IR band at around 1730—1740 cm^{-1} due to C=O stretching,[25] the formation of physisorbed aldehyde may be responsible for the IR band at 1730 cm^{-1}. When ethyl formate (Fig. 3 (d)) or acetaldehyde was adsorbed on TiO_2 in the dark, the band due to C=O was shifted to lower wavenumbers because aldehyde was chemisorbed on TiO_2. But carboxylate species such as formates and acetates were reported by Gonzalez et al. to have a dislodging effect on oxygen species bound to Ti^{4+},[21] which allowed aldehyde to physisorb onto the TiO_2 surface. Hence, we concluded that the band at 1730 cm^{-1} was due to the physisorbed ethyl formate (Fig. 7 (**VII**)) which has a formyl group in it.

Based on the results from the IR studies and products analysis we propose a reaction pathway for the photocatalytic oxidation of $EtOCH_2CH_2OH$ on TiO_2 surface, as shown in Fig. 7; $EtOCH_2CH_2OH$ is adsorbed on TiO_2 to yield surface alkoxide **V** and then reacts with the adsorbed O_2^- to produce formate-like species **VI** which has a strong IR band at 1575 and 1360 cm^{-1}. This surface species decomposes upon UV irradiation into ethyl formate **VII** in gas phase and the surface formate species on TiO_2 **VIII**. The surface formate species is oxidized further to CO_2. Further, the ethyl formate is oxidized photocatalyticaly to ethanol, acetaldehyde, and acetate species when the surface concentration of $EtOCH_2CH_2OH$ is low.

Intermediate Radical Species. The ESR experiment revealed that carbon-centered radical was produced from $EtOCH_2CH_2OH$ on TiO_2 upon UV-irradiation. Assuming that the electron transfer from the alcoholic OH of the adsorbed $EtOCH_2CH_2OH$ takes place in the primary step of the reaction, analogous to the case of Pt electrode, the photocatalytically produced radical **XI** will be converted to 2-ethoxy-1-hydroxyethyl radical **XII** or ethoxymethyl radical (**XIII**) by the subsequent β fragmentation, as shown in Scheme 2. This process corresponds to the step between **VI** and **VII** in Fig. 7.

$$EtOCH_2CH_2\dot{O}\overset{+}{H}\ (\mathbf{XI}) \begin{cases} \nearrow\ EtOCH_2\dot{C}HOH\ (\mathbf{XII}) + H^+ \\ \searrow\ EtOCH_2\dot{C}\ (\mathbf{XII}) + H_2CO + H^+ \end{cases}$$

Scheme 2.

Both of the radicals (**XII** and **XIII**) are carbon-centered. The former corresponds to the intermediate in the direct oxidation and the latter corresponds to the intermediate in the indirect oxidation.[23] From the reaction product, ethyl formate, a radical species **XIII** is supposed to be produced in the present experiment. We have already reported that alcohols with an α-hydrogen does not give a high concentration of spin adducts with DMPO in the irradiated TiO_2 suspension of alcohol. This is because the intermediate radicals immediately inject another electron into the conduction band of TiO_2, inducing a current doubling phenomenon.[15] Although $EtOCH_2CH_2OH$ is an alcohol with α-hydrogens and hence can bring about a current doubling,[26] $EtOCH_2CH_2OH$ gave experimentally a rather high concentration of a spin adduct in comparison with methanol or ethanol. The radical species **XIII** is more stable than those produced from methanol , ethanol, and 2-propanol.

Conclusion

The photocatalytic reaction of $EtOCH_2CH_2OH$ on TiO_2 powder gives ethyl formate as the primary product. The reaction product is different from the one expected from the reaction mechanism proposed for primary alcohol before. Base on our experimental results, we conclude that $EtOCH_2CH_2OH$ adsorbs on TiO_2 and reacts with the adsorbed O_2^- on the TiO_2 surface to produce a surface formate-like species . This surface species is photocatalytically oxidized to give ethyl formate and surface formate species. The former is further oxidized to ethanol, acetaldehyde, and acetate species by prolonged UV-irradiation. The photocatalytic oxidation of $EtOCH_2CH_2OH$ on TiO_2 is another example in which the products are different

from those from the electrolysis on a Pt electrode.[14]

Mr. Haru Sakashita of Faculty of Engineering, University of Tokyo is acknowledged for GC-MS analysis.

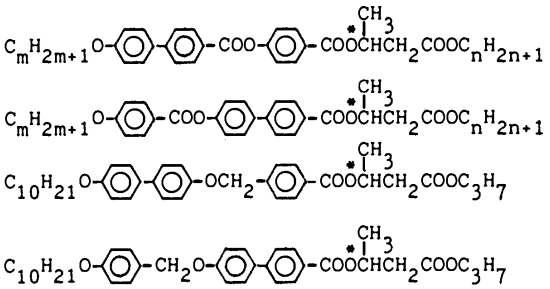
(Received Sepetmber 16, 1988)

The following series of novel ferroelectric liquid crystals, derived from normal alkyl esters of (*R*)-3-hydroxybutanoic acid, have been synthesized, and several factors determining their mesomorphic properties have been investigated:



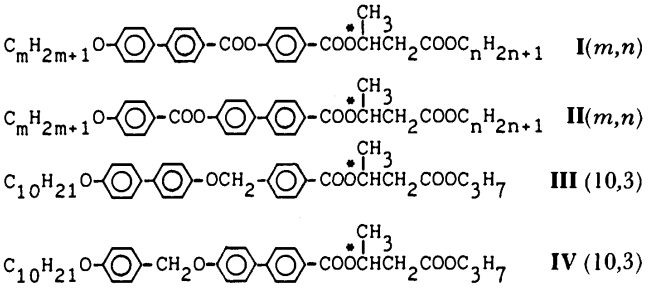
The smectic polymorphism for these compounds with three aromatic rings is strongly affected by the position and kind of the linkage groups in the core. The effects of the lengths of the two terminal chains (*m*,*n*) and the linkage groups in the core on the thermal stability of the smectic A and chiral smectic C phases have been discussed from the structural points of view.

Very many compounds with a chiral smectic C(Sm*C) phase have been synthesized since the invention of high-speed switching devices based on these compounds' ferroelectric properties.[1] Their common structural features are a rigid core consisting of at least two aromatic rings and two terminal chains at the ends of the core, one of which contains at least one chiral group.

There have been many studies of the effects of molecular structure of the core and the length of the achiral terminal chain on the mesomorphic properties of the liquid crystals.[2] However, the correlation between the molecular structure and the mesomorphic properties still remains insufficiently understood. Especially, there have been few investigations of the effect of the length of terminal chain at the chiral part on the mesomorphic properties because of the limited number of chiral reagents used in experiments.

Systematic investigations of the effect of the lengths of the two terminal chains on the mesomorphic properties have been made by Goodby and Gray employing homologues of the normal alkyl esters of 4′-alkoxy-1-biphenylcarboxylic acids. They have shown that the SmC phase appears when both the terminal chains have an appropriate chain length,[3] although these compounds do not have chiral groups in their molecular structures.

We have selected normal alkyl esters of (*R*)-3-hydroxybutanoic acid as chiral reagents and have synthesized novel ferroelectric liquid crystals with three aromatic rings in the core. Their general molecular structures are as follows:



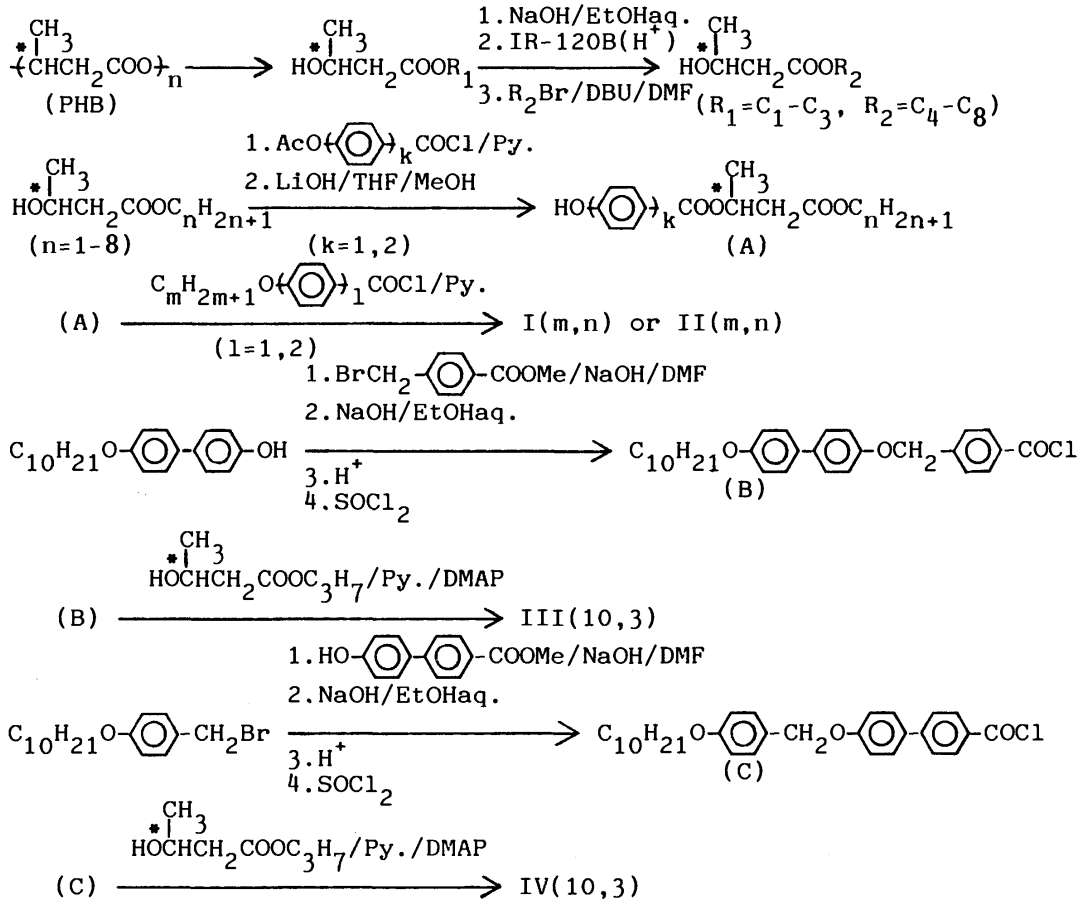
One of these compounds **I**(8,2) has already been synthesized and its ferroelectric property reported by Taniguchi et al.;[4] however, no systematic investigations of the mesomorphic properties of the homologous series have yet been done.

In the present paper, we discuss the effect of the lengths of two terminal chains and of the position and kind of the linkage groups in the core on the thermal stability of the mesophase.

Experimental

Preparation of Materials. The homologous series, **I**(*m*,*n*) and **II**(*m*,*n*), and the analogues, **III**(10,3) and **IV**(10,3), were synthesized by Scheme 1.

In order to obtain highly optically pure reagents, poly-((*R*)-3-hydroxybutanoic acid) (PHB) (Imperial Chemical Industry Co., Ltd.) was chosen as the starting material. The normal alkyl esters of (*R*)-3-hydroxybutanoic acid were eas-



Scheme 1.

ily prepared by the following method. The lower alkyl (R_1: methyl, ethyl, propyl) esters of (*R*)-3-hydroxybutanoic acid were synthesized by the alkolysis of PHB in the corresponding dry alcohols, using conc. H_2SO_4 as the catalyst. Sugai et al. reported that the optical purity of ethyl (*R*)-3-hydroxybutanoate synthesized by a similar method was 100% e.e. ($[\alpha]_D^{21}=-43.4°$ in $CHCl_3$).[5] The specific rotation $[\alpha]_D^{23}$ of the ethyl (*R*)-3-hydroxybutanoate prepared by our method was −44.7°; therefore, its optical purity was estimated to be 100% e.e. The higher alkyl (R_2: butyl, pentyl, octyl) esters of (*R*)-3-hydroxybutanoic acid were prepared by an esterification reaction of (*R*)-3-hydroxybutanoic acid obtained by the hydrolysis of the ethyl (*R*)-3-hydroxybutanoate with the corresponding alkyl bromides in *N*,*N*-dimethylformamide (DMF), using 1,8-diazabicyclo[5.4.0.]-7-undecene (DBU) as the catalyst. The esters of 4-hydroxybenzoic acid or 4′-hydroxy-1-biphenylcarboxylic acid with the normal alkyl esters of (*R*)-3-hydroxybutanoic acid were prepared by reacting 4-acetoxybenzoyl chloride or 4′-acetoxy-1-biphenylcarbonyl chloride with normal alkyl (*R*)-3-hydroxybutanoates in dry pyridine, followed by the hydrolysis of acetoxyl group selectively in a mixed solvent of tetrahydrofuran (THF) and methanol containing equimolar 1 mol dm^{-3} LiOH. The homologous series, **I**(*m*,*n*) and **II**(*m*,*n*), were synthesized by esterifying the (A) compounds with the corresponding 4-alkoxybenzoyl chlorides or 4′-alkoxy-1-biphenylcarbonyl chlorides in dry pyridine. Compounds **III**(10,3) and **IV**(10,3) were prepared by reacting propyl (*R*)-3-hydroxybutanoate with Compounds **B** and **C** respectively in dry pyridine containing 10 wt% 4-dimethylaminopyridine (DMAP). All the final products were purified by silica-gel column chromatography, followed by two recrystallizations from ethanol.

Their elementary analysis data are listed in Table 1.

Measurement of Thermal Properties. The mesophase was identified using a Nikon polarizing microscope equipped with a Mettler FP-52 heating stage. the transition temperatures were measured using a Daini Seikosha SSC-560 differential scanning calorimeter (DSC) at a scanning rate of 2.5 °C min^{-1} under N_2 atomosphere.

Results and Discussion

The melting points and the mesomorphic transition temperatures for the homologous series, **I**(*m*,*n*) and **II**(*m*,*n*), are summarized in Table 2. The mesomorphic trends of **I**(*m*,3) and **II**(*m*,3) are shown in Figs. 1 and 2. As can be seen in the figures, both of the series show the phase sequence of isotropic(Iso)-smectic A(SmA)-chiral smectic C(Sm*C)-unidentified smectic phase(Sm3)-crystal(Cryst). The Sm3 phase for **I**(*m*,3) appears monotropically below the Sm*C in the homologues with shorter alkoxyl chains (*m*=7—11). This phase shows a broken and banded focal-conic fan texture or a pseudo-homeotropic or schlieren texture which resembles photomicrographs of the reference sample reported by Gray and Goodby.[6] The transi-

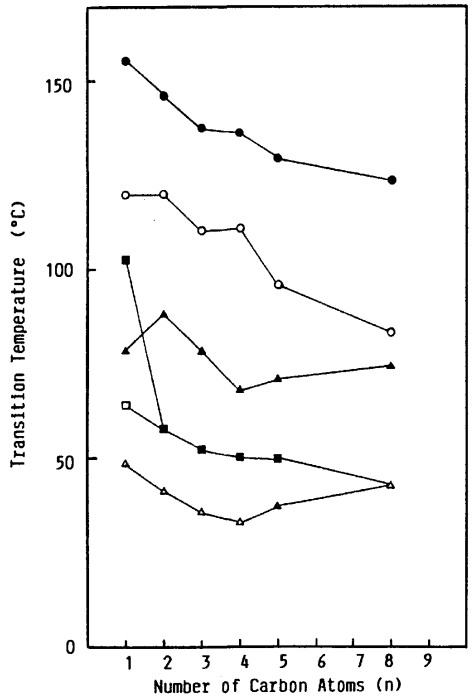

Fig. 3. Plots of transition temperatures against the number of carbon atoms (n) in the alkyl ester chain of homologous series **I** (10,n): mp (—▲—); Iso-SmA (—●—); SmA-Sm*C (—○—); Sm*C-Sm3 (—■—); Sm3-Sm4 (—□—); Sm3,Sm4-Cryst(—△—).

tion enthalpies measured by DSC are about 0.86—1.5 kJ mol^{-1}. On the other hand, the Sm3 phase for **II**(m,3) appears monotropically below the Sm*C in the homologues with heptyloxyl, decyloxyl, and tetradecyloxyl chains and shows a focal-conic fan texture or a homeotropic texture formed from the broken focal-conic fan or the schlieren textures of the Sm*C phase, respectively. Moreover, the transition bars across the backs of the fans are observed at the transition from the Sm3 phase to the Sm*C. The transition enthalpies are about 1.5—4.5 kJ mol^{-1}. From these findings, we speculate that the Sm3 phases of **I**(m,3) and **II**(m,3) may be chiral smectic I(Sm*I) and smectic B(SmB), respectively; however, more detailed study by the X-ray diffraction method and the misibility test will be necessary for the assignment of these phases.

The Iso-SmA transition temperaturs for **I**(m,3) and **II**(m,3) show normal trends, that is, an odd-even alternation and a gentle falling as the series ascend. On the other hand, the SmA-Sm*C transition temperatures show significantly different features. The Sm*C phase for **I**(m,3) appears enantiotropically, and the SmA-Sm*C transition temperatures do not change very much in respect to the length of the terminal alkoxyl chain, whereas the Sm*C phase for **II**(m,3) appears monotropically in the region of the shorter alkoxyl chains (m=7—10) and becomes enantiotropic in the region of the longer alkoxyl chains (m=12—16). Their transition temperatures gradually increase with the length of the terminal alkoxyl chain, leading to the decrease in the temperature range of the SmA phase.

There are some characteristic features in the phase transition from the Sm*C phase to the Sm3 phase for **I**(m, 3) and **II**(m, 3). The Sm*C-Sm3 transition for **I**(m,3) appears as a monotropic transition in the homologues with shorter alkoxyl chains (m=7—10), and the transition temperatures decrease with the length of the terminal alkoxyl chain. On the other hand, the Sm*C-Sm3 transition for **II**(m,3) appears as a monotropic one, and the transition temperatures seem to increase with the length of the terminal alkoxyl chain in the region of the shorter chains and to slightly decrease in the region of the longer chains. However, the correlation between the molecular structure and these Sm3 phases cannot be found at this stage because the assignment of these phases has not yet been accomplished.

Figures 3 and 4 present the mesomorphic trends of the homologous series, **I**(10,n) and **II**(10,n). These homologous series show phase sequences similar to those of the corresponding homologous series **I**(m,3) and **II**(m,3). The Sm3 phases again appear monotropically in all the homologues except **I**(10,8). All the Sm3 phases for **I**(10,n) and **II**(10,n) except that for **I**(10,1) exhibit a texture similar to those of the **I**(m,3) and **II**(m,3); therefore, the Sm3 phases of **I**(10,n) and **II**(10,n) may be Sm*I and SmB, respectively. The Sm3 phase of the **I**(10,1) homologue shows a broken focal-

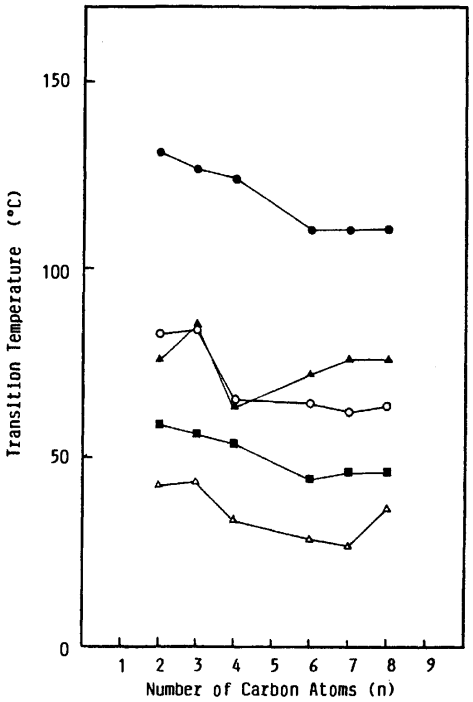

Fig. 4. Plots of transition temperatures against the number of carbon atoms (n) in the alkyl ester chain of homologous series **II** (10,n): mp(—▲—); Iso-SmA (—●—); SmA-Sm*C (—○—); Sm*C-Sm3 (—■—); Sm3-Cryst (—△—).

conic fan whose back is "L"-shaped and which has highly coloured patches or pseudo-homeotropic textures. The transition enthalpy is too small to be estimated from the DSC chart. From these findings, we speculate that this phase may be chiral smectic F(Sm*F); however, more detailed studies employing the X-ray diffraction method will be necessary for the assignment of this phase.

The effects of the terminal chain length for the chiral part on the thermal stability of the mesophase are a little different from those of the other terminal alkoxyl chain. The Iso-SmA transition temperatures for **I**(10,n) and **II**(10,n) show a gentle falling with the terminal chain length (n), although the odd-even alternation is not clear. The SmA-Sm*C transition temperatures for **I**(10,n) and **II**(10,n) also decrease with the terminal chain length (n), unlike those of the corresponding homologous series, **I**(m,3) and **II**(m,3) where the other terminal chain varies. This tendency probably means that the thermal stability of the Sm*C phase is reduced as the difference in length between the two terminal chains is small. Such a tendency has also been reported by Goodby and Gray in the homologous series of n-alkyl esters of 4-alkoxy-1-biphenylcarboxylic acids, in which the SmC phase has been observed only with the alkoxyl chain from hexyloxyl to tetradecyloxyl and with the alkyl ester chains from propyl to decyl. However, in comparison with the homologous series of the normal alkyl esters of 4-alkoxy-1-biphenyl carboxylic acids, there are some differences in

Table 3. Phase Sequence and Transition Temperature

the effects of the terminal chains on the thermal stability of the Sm*C phase for the homologous series, **I**(m,n) and **II**(m,n), with three aromatic rings in the core. According to McMillan,[7] de Jeu,[8] and Patel and Goodby,[9] the thermal stability of the Sm*C phase is strongly affected by the polar groups in the core. In the cases of **I**(m,n) and **II**(m,n), the only structural difference between them is the position of -COO- linkage in the core. This means that the effects of the terminal chain length on the thermal stability of Sm*C phase are quite different only if the position of the linkage group is changed in the core.

To investigate the effects of the linkage groups in the core with three aromatic rings on the mesomorphic properties in more detail, the mesomorphic properties of two further analogues with the same terminal chains will be examined (Table 3).

In comparison with **I**(10,3) and **II**(10,3), the **III**(10,3) and **IV**(10,3) analogues with a $-CH_2O-$ linkage in the core have the phase sequences of Iso-Sm*C-Sm2-Sm3-Cryst and of Iso-SmA-Sm*C-Cryst, respectively. The Sm2 phase of **III**(10,3) shows a broken-fan or a schlieren texture under a polarizing microscope, and the transition enthalpy is 1.4 kJ mol^{-1}; therefore, this phase may be Sm*I. The microscopic texture of the Sm2 phase changes slightly at the Sm2-Sm3 transition and turns into another broken-banded fan or schlieren texture in the Sm3 phase, and the transition enthalpy is 2.1 kJ mol^{-1}; however, this phase cannot be speculated on at this stage. As is evident from these results, the smectic polymorphism for the homologous series with three aromatic rings in the core is strongly influenced by the position and kind of the linkage groups in the core.

There are also some characteristic tendencies for the mesomorphic transition temperatures among these four analogues. The Iso-SmA or Iso-Sm*C transition are in the order of: **I**(10,3)>**II**(10,3)≈**III**(10,3)>**IV**(10,3). As is to be expected from Gray's report,[2] the thermal stability of the smectic phase depends on the rigidity and planarity of the central linkage in the core. Con-

traty to the -COO- linkage, the $-CH_2O-$ linkage has no double-bond character; therefore, the Iso-Sm*C and Iso-SmA transition temperatures for **III**(10,3) and **IV**(10,3) should be lower than those for **I**(10,3) and **II**(10,3). Judging from the data, this speculation seems to be valid; however, the Iso-SmA transition temperature for **II**(10,3) (126.5 °C), is almost the same as the Iso-Sm*C transition temperature for **III**(10,3) (127.0 °C), and the difference in the Iso-smectic transition temperature between **I**(10,3) and **II**(10,3) is only 11.4 °C, whereas that between **III**(10,3) and **IV**(10,3) is 33.4 °C. These facts cannot be explained only by the difference in the flexibility of the linkage groups. In the core moiety containing three aromatic rings, the biphenyl ring is known greatly to enhance the thermal stability of the smectic phase because of its lath-like shape. On the other hand, the chiral part with a protruding 1-methyl branch in the molecule significantly reduces the thermal stability of the smectic phase. If the biphenyl ring is connected to the chiral part with 1-methyl branch through the -COO- linkage, as is **II**(10,3) and **IV**(10,3), they could not form a parallel arrangement with one another because of the steric hindrance of the 1-methyl branch. In the cases of **I**(10,3) and **III**(10,3), the biphenyl ring is connected to the chiral part through the $-COO-C_6H_4-COO-$ or the $-OCH_2-C_6H_4-COO-$ linkage. In these two analogues, the biphenyl rings could be packed parallel with one another more easily than those in **II**(10,3) and **IV**(10,3), because the effect of the protruding 1-methyl branch on the packing of the biphenyl ring is diluted through the linkage groups, thus leading to Iso-smectic transition temperatures higher than the corresponding analogues **II**(10,3) and **IV**(10,3). Additionally, compared with the biphenyl ring in **I**(10,3), that in **III**(10,3) is connected to the $-C_6H_4-COO^{*}CH(CH_3)-CH_2COOC_3H_7$ through the $-OCH_2-$ linkage, which is more flexible than the -COO- linkage, so that the biphenyl ring in **III**(10,3) could form the parallel arrangement most easily in the smectic phase, with the result that **III**(10,3) has a comparatively higher Iso-Sm*C transition temperature among these four analogues.

The authors would like to thank Dr. Hiroshi Sato for his hearty encouragement throughout this work and also to thank Dr. Toshio Yoshihara for his useful suggestions. The authors also wish to thank Mr. Teruyuki Yamada, Mr. Shigeo Kamimura, Mr. Yoshihiro Sako, and Mrs. Mioko Uematsu for their assistance in the experiments.

(Received September 26, 1988)

Monodispersed α-iron(III) oxide (hematite) particles were produced from an iron(II) chloride/2,2′-bipyridine system in the presence of potassium nitrate at elevated temperatures, 90—100 °C. An aqueous solution of 2,2′-bipyridineiron(II) complex directly gave spherical hematite particles (0.35 μm in size with a relative standard deviation of 0.09) under the conditions of 1.0×10^{-3} mol dm^{-3} $FeCl_2$, 3.0×10^{-3} mol dm^{-3} 2.2′-bipyridine, 6.0×10^{-3} mol dm^{-3} HCl, and 5.0×10^{-2} mol dm^{-3} KNO_3 at 100 °C for 8 h. The oxidation of iron(II) ions would be slower than the dissociation of the complex and precipitation during the course of aging. The hematite particles grew through the polynuclear layers mechanism. Iron(II) sulfate/2,2′-bipyridine mixed solutions were also capable of yielding monodispersed particles, though they were a mixture of hematite and α-iron(III) hydroxide oxide (goethite). The points of zero charge (PZC) of these particles were estimated as pH 7.7 and 7.5 for those obtained from the iron(II) chloride and sulfate/2,2′-bipyridine systems, respectively.

The preparation and characterization of monodispersed particles of metal oxide and hydrous oxide have been extensively studied by forced hydrolyses.[1-8] Monodispersed α-iron(III) oxide (hematite) particles have been prepared by aging acidified iron(III) salt solutions at elevated temperatures through the conversion of β-iron(III) hydroxide oxide, β-FeOOH, previously deposited.[2,4,5] On the other hand, an iron(III) chloride/glycine system directly gave monodispersed hematite particles through forced hydrolysis.[9,10] In the latter case, the glycinatoiron(III) complex acts as a soluble reservoir for hydroxoiron(III) complexes at higher temperatures.

In the present work, monodispersed iron(III) oxide and hydroxide oxide particles were prepared by the forced hydrolysis of 2,2′-bipyridineiron(II) complex solutions in the presence of potassium nitrate as an oxidizing agent. Furthermore, the growth process and surface characterization of the monodispersed particles are discussed.

Experimental

Materials. All of the reagents used in this work were of guaranteed grade and employed without further purification. A small amount of iron(III) species in iron(II) chloride and sulfate solutions was reduced with iron of 99.9% in purity (≈200 mesh) and corresponding acid. An aliquot of the iron(II) salt solution was passed through a column charged with an H-type cation-exchange resin (Amberlite IR 120B). Then a concentration of acid, thus replaced, was titrated in order to determine the total number of moles of iron(II) and acid. The concentration of the iron(II) species was determined spectrophotometrically with 2,2′-bipyridine. All of the solutions were previously filtered through a Membrane filter (0.2 μm in pore size) and then deoxygenated by bubbling nitrogen before use.

Procedures. A mixed solution of iron(II) salt, 2,2′-bipyridine, corresponding acid, and potassium nitrate was tightly sealed in a screw-capped glass tube at specified concentrations and then aged at 100±1 and and 90±1 °C for 8—72 h in a thermostatted air oven. The produced particles were centrifuged at 1160 g and washed repeatedly with doubly distilled water using ultrasonic equipment. The morphology and size of the particles were observed with a scanning electron microscope (model ALPHA-10S). The particles were identified using an X-ray diffractometer (model Geigerflex RAD IIIA).

The mixed solution was also aged at 100±0.5 °C for 14 h in an oil bath in order to study the growth process of monodispersed hematite particles from the concentration changes of the iron species remaining in the solution. The aged solution was quenched to room temperature at regular intervals and centrifuged to remove precipitates, followed by filtration through a Membrane filter (0.1 μm in pore size). The total concentration of the iron(II) and (III) species was determined spectrophotometrically with 2,2′-bipyridine after reducing the iron(III) species to iron(II) with hydroxylamine hydrochloride. The concentration of the iron(II) species was separately determined after masking the iron(III) ions with sodium ethylenediaminetetraacetate.

A specific surface area was measured using a modified BET analyzer (model SA1000). The surface charge density of the particles was determined by ordinary potentiometric titration as follows: a sample of 0.40 g was suspended in 50.0 cm^3 of 4.00×10^{-3} mol dm^{-3} potassium hydroxide solution. The suspension was titrated very slowly (≈30 h) with 5.00×10^{-3} mol dm^{-3} nitric acid at 25±0.1 °C under an ionic strength of 0.10 mol dm^{-3} (KNO_3) in a nitrogen atmosphere.

A surface analysis was carried out in order to identify the species adsorbed on the surface of particles using an X-ray photoelectron spectroscope (XPS), model ESCALAB Mk II.

Results

Formation of Monodispersed Hematite Particles from Iron(II) Chloride/2,2′-Bipyridine System. Figure 1 shows the concentration domain of iron(II) chloride and hydrochloric acid for making iron(III) oxide particles by forced hydrolysis at 100±1 °C for 24 h under fixed concentration ratios of [bpy]/[$FeCl_2$]=3.0 and [KNO_3]/[$FeCl_2$]=50, respectively. Monodispersed spherical particles were directly produced under a

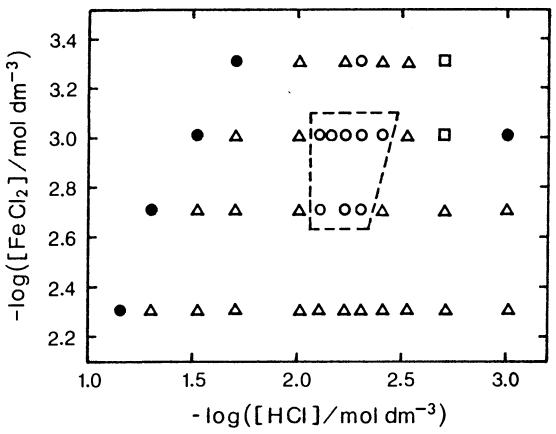

Fig. 1. Concentration domain of $FeCl_2$ and HCl for making hematite particles by forced hydrolysis at 100°C for 24 h. Conditions: [bpy]/[$FeCl_2$]=3.0, [KNO_3]/[$FeCl_2$]=50. Symbols: ○; spherical, □; flower-like, △; irregular, ●; no precipitation. A dashed line indicates the composition range for monodispersed spherical particles.

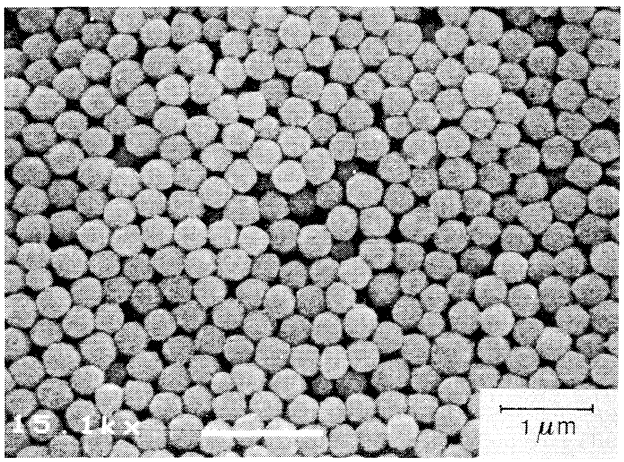

Fig. 2. Scanning electron micrograph of monodispersed spherical hematite particles prepared by forced hydrolysis at 100°C for 8 h. Conditions: [$FeCl_2$]=1.0×10^{-3}, [bpy]=3.0×10^{-3}, [HCl]=6.0×10^{-3}, [KNO_3]=5.0×10^{-2} mol dm^{-3}.

limited set of conditions (indicated by ○). No particles were observed, even after aging for 72 h, in the region indicated by ●.

Figure 2 shows an example of monodispersed spherical particles obtained at 100±1 °C for 8 h under the conditions given in the figure (an initial pH 2.2 and a final pH 2.3). The average size of these particles was estimated as being 0.35 μm, with a relative standard deviation of 0.09. The spherical particles would be polycrystals or aggregates of well-crystallized fine hematite[11] particles, judging from X-ray powder diffractometry and their morphology. On the other hand, flower-like particles (Fig. 3) were produced under the conditions shown by □, which consisted of mixtures of α-iron(III) hydroxide oxide (goethite)[12] and hematite.

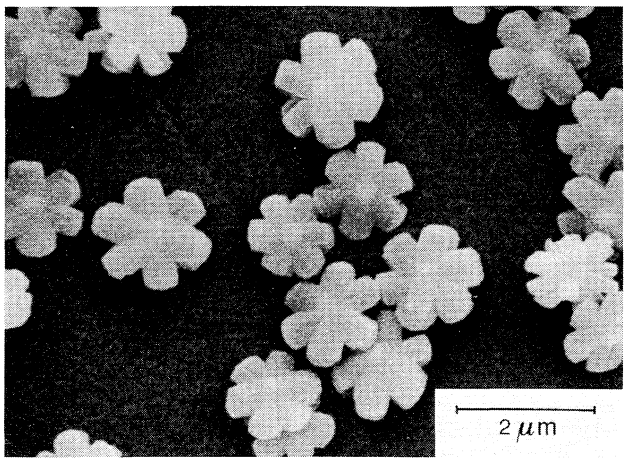

Fig. 3. Scanning electron micrograph of flower-like partilces obtained at 100°C for 24 h. Conditions; [$FeCl_2$]=5.0×10^{-4}, [bpy]=1.5×10^{-3}, [HCl]=2.0×10^{-3}, [KNO_3]=2.5×10^{-2} mol dm^{-3}.

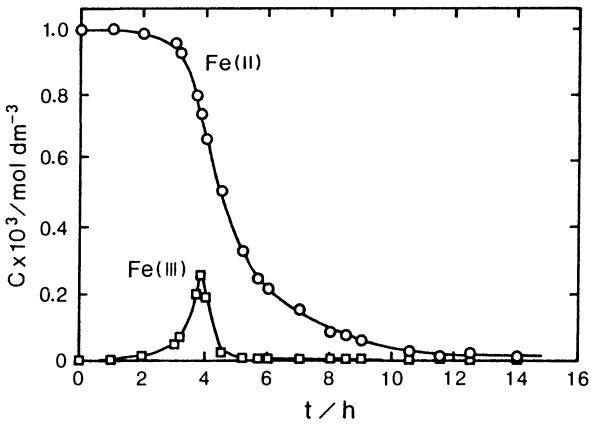

Fig. 4. Concentration changes in Fe(II) and (III) species in supernatant solution during forced hydrolysis at 100°C in 2,2′-bipyridine/iron(II) chloride system. Conditions: [$FeCl_2$]=1.0×10^{-3}, [bpy]=3.0×10^{-3}, [HCl]=6.0×10^{-3}, [KNO_3]=5.0×10^{-2} mol dm^{-3}.

Concentration Change in Iron Species during Growth of Monodispersed Spherical Hematite Particles in Iron(II) Chloride/2,2′-Bipyridine System. The concentrations of iron species in a supernatant solution were determined at 100±0.5 °C for 14 h in order to elucidate the growth process of monodispersed hematite particles under the conditions given in Fig. 2. Figure 4 shows the concentration changes in both the iron(II) and iron(III) species as a function of the aging time. The concentration of iron(II) species decreased after 1.7 h, as the release and oxidation of iron(II) ions were enhanced. However, the iron(III) species steeply increased up to a maximum value, 2.5×10^{-4} mol dm^{-3}, at 3.8 h and then drastically decreased. At the same time, the particles were generated, following a rapid decrease in the total iron concentration. The concentration of iron(III) species reached a critical supersaturation for spontaneous and rapid nucleation at 3.8 h,

followed by a negligibly small concentration of iron (III) species after 4.5 h. The oxidation of iron(II) to the trivalent state, in general, takes place slowly in the presence of nitrate ions, even in a neutral solution.[13] Thus, this process would be a rate-determining step during the growth of hematite particles after iron(II) ions have been released through the dissociation of the 2,2′-bipyridineiron(II) complex.

It has been confirmed that hydroxoiron(III) complexes act as the precursors of iron(III) oxide particles.[14,15] An appropriate supersaturation of hydroxoiron(III) complexes should be maintained in order to produce monodispersed particles[16,17] without secondary nucleation. Thus, the conditions given in the present work would satisfy the above criteria.

Growth Process of Spherical Hematite Particles. The growth process of the spherical hematite particles was examined by following the total concentration of iron species in the supernatant solution during the course of aging (Fig. 4). The reaction degree, α, is defined as

$$\alpha=(C_0-C)/(C_0-C_f), \quad (1)$$

where C_0, C_f, and C are the initial and final concentrations of the iron species, and that at reaction time t, respectively.

Nielsen[18] has proposed that a change in the reaction degree, $d\alpha/dt$, can be expressed by the following equation for the growth of particles through a polynuclear layers mechanism as:

$$d\alpha/dt=KC^{(m+2)/3}\alpha^{2/3}, \quad (2)$$

where the parameters, K and m, stand for the apparent rate constant under the given conditions and the exponent of the concentration dependence for the surface nucleation, respectively.

Parameters m and K[19] were numerically estimated as being 3.53 and 8.53×10^5 by a least-squares method using logarithmic values of $d\alpha/dt$, C, and α. Figure 5 shows the results calculated from Eq. 2 by the Runge-Kutta method using the parameters obtained above. The values, thus obtained (solid curve), agreed well with those observed in a rather wide range of the reaction degree from around 0.1 to 0.9. Similar numerical treatments were also made for the mononuclear layer and diffusion mechanisms. However, calculated values for both the mechanisms did not fit with the experimental ones. Thus, the monodispersed spherical hematite particles would grow through the polynuclear layers mechanism in the iron(II) chloride system, though they were polycrystals or aggregates.

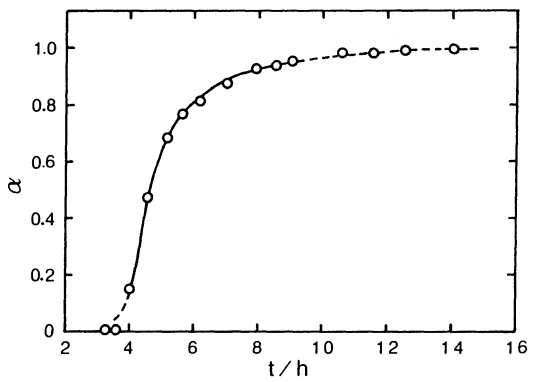

Fig. 5. Change in reaction degree during forced hydrolysis at 100 °C. Conditions: $[FeCl_2]=1.0\times10^{-3}$, $[bpy]=3.0\times10^{-3}$, $[HCl]=6.0\times10^{-3}$, $[KNO_3]=5.0\times10^{-2}$ mol dm^{-3}.

Precipitation of Iron(III) Hydrous Oxide Particles from Iron(II) Sulfate/2,2′-Bipyridine System. Mixed solutions were aged at 100±1 °C for 24 h under the fixed conditions of 5.0×10^{-3} mol dm^{-3} iron(II) sulfate and $[KNO_3]/[FeSO_4]$ ratio of 50, varying concentrations of sulfuric acid from 1.0×10^{-3} to 1.0×10^{-1} mol dm^{-3} and 2,2′-bipyridine from 5.0×10^{-3} to 2.0×10^{-2} mol dm^{-3}.

Spherical particles of a reasonably narrow size distribution were obtained only in a narrow composition range of sulfuric acid from 4.0×10^{-3} to 5.0×10^{-3} mol dm^{-3} (an initial pH 2.2—2.3) and $[bpy]/[FeSO_4]$ ratios between 2.7 and 3.3. Figure 6 shows an example of the particles comprising a mixtures of hematite and goethite, in contrast to the particles obtained in the iron(II) chloride system. Their average size was estimated as being 2.9 μm with a relative standard deviation of 0.12, much larger than those obtained in the chloride system.

Sulfate ions, in general, promote the polymerization of hydroxometal complexes, while the condensation reaction is much slower than the former.[20] Thus, hydroxoiron(III) complexes easily generate the goethite partly framed by -OH- bridges with the aid of sulfate ions, which lead to coprecipitated larger particles.

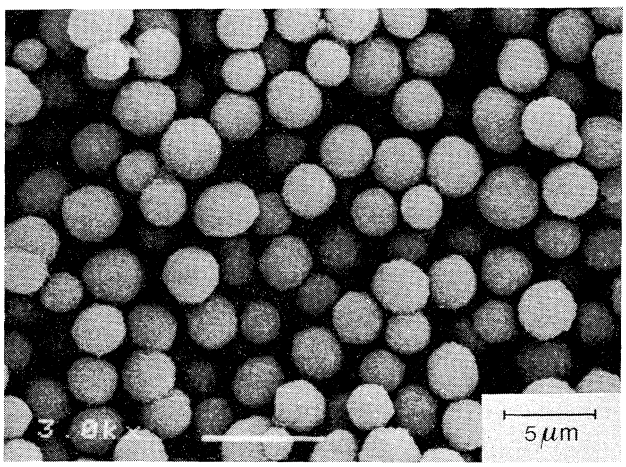

Fig. 6. Scanning electron micrograph of spherical particles obtained from 2,2′-bipyridine/iron(II) sulfate mixed solution at 100 °C for 8 h. Conditions: $[FeSO_4]=5.0\times10^{-3}$, $[bpy]=1.5\times10^{-2}$, $[H_2SO_4]=5.0\times10^{-3}$, $[KNO_3]=2.5\times10^{-1}$ mol dm^{-3}.

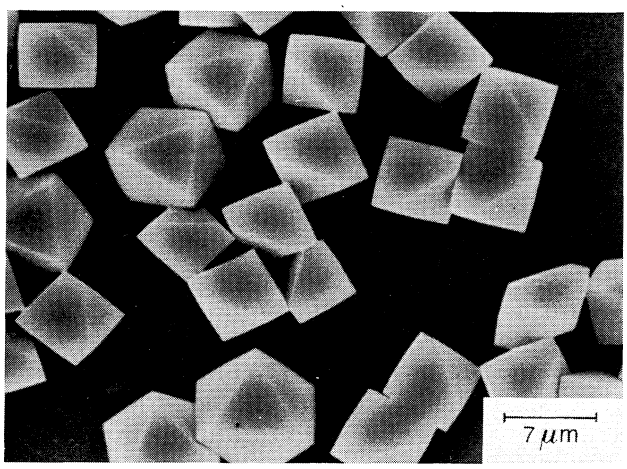

Fig. 7. Scanning electron micrograph of hydronium jarosite particles produced from 2,2′-bipyridine/iron (II) sulfate mixed solution at 100 °C for 72 h. Conditions: $[FeCl_2]=5.0\times10^{-3}$, $[bpy]=5.0\times10^{-3}$, $[H_2SO_4]=7.1\times10^{-2}$, $[KNO_3]=2.0\times10^{-1}$ mol dm^{-3}.

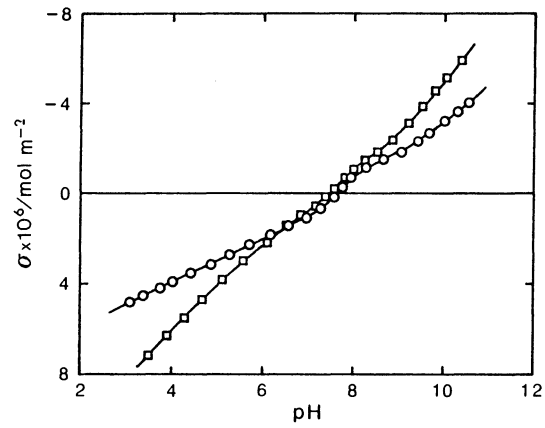

Fig. 8. Surface charge densities of spherical particles at 25 °C and I=0.1 mol dm^{-3}. Symbols: O; hematite particles obtained from iron(II) chloride system, □; mixed particles of hematite and goethite obtained from iron(II) sulfate system.

On the other hand, well-crystallized particles (Fig. 7) were created at rather higher sulfuric acid concentrations (from 5.0×10^{-2} to 7.1×10^{-2} mol dm^{-3}, an initial pH 1.1—1.2), independently of the [bpy]/[$FeSO_4$] ratio. They were identified as hydronium jarosite, $Fe_3(SO_4)_2(OH)_5\cdot2H_2O$,[21,22] by X-ray powder diffractometry, in analogy with that reported.[1] According to the formation constant and enthalpy change of protonation of 2,2′-bipyridine,[23,24] iron(II) ions would hardly form a complex with this ligand in such a low pH range (1.1—1.2). However, iron(II) ions can easily produce the sulfato complex in the presence of a large amount of sulfate ions due to their affinity.[25] Thus, these complex ions generate hydronium jarosite, independently of the [bpy]/[$FeSO_4$] ratio.

Spherical particles of reasonably narrow size distribution were also obtained at 90±1 °C under the same conditions given in Fig. 6, of which the average size was 2.0 μm with a relative standard deviation of 0.11. The composition of these particles varied depending on the duration of aging. Only goethite precipitated as spherical particles at 90±1 °C, while the particles changed to a mixture of goethite and hematite by prolonged aging for 120 h.

Goethite is irreversibly converted to hematite through topotatic dehydration due to similar oxygen stackings in their crystal structure.[26] However, the goethite scarcely changes to hematite in a solution after the former has been deposited, even though -O- bridge is more stable than -OH- bridge.[27,28] Thus, the hematite that becomes incorporated with the goethite would be directly generated during the prolonged aging at 90 °C and not through the conversion of the previously deposited goethite.

Surface Characterization of Monodispersed Spherical Particles. Surface charge densities of the particles were determined by an ordinary potentiometric titration for those obtained from the iron(II) chloride and sulfate systems. The particles were washed twenty times with doubly distilled water using ultrasonic equipment. Then they were further treated with a 1.0×10^{-4} mol dm^{-3} potassium hydroxide solution, followed by washing again twenty times with doubly distilled water. Figure 8 shows the surface charge densities of the particles as a function of pH.

The points of zero charge (PZC) were estimated as being of almost the identical pH (7.7 and 7.5) for particles prepared from the iron(II) chloride and sulfate systems, respectively. However, the PZC of the particles made from the latter was apparently found to be as low as pH 3.7 if the alkali-treatment had not been carried out, whereas that of the particles prepared from the former was approximately the same pH (7.5).

It has been reported that sulfate ions are strongly adsorbed on the surfaces of goethite particles, depending on the pH.[29] The sulfate ions would be easily replaced by hydroxide ions in an alkaline solution. Actually, the titration on the particles (the sulfate system) indicated much lower pH values, especially during the early stage of titration, as a result of the consumption of hydroxide ions. Thus, the value of PZC was apparently found to be as low as pH 3.7. According to the XPS, sulfur was detected from the surface of these particles, in contrast with those prepared from the iron(II) chloride system. A trace amount of sulfur was still detectable, even after these particles had been alkali-treated, as mentioned above, and by etching them with Ar^+ ions for 10 min in the XPS instrument. This result indicated that sulfate ions were also internally included, not only on the surfaces of the particles.

Discussion

Hydroxoiron(III) complexes have been proposed to serve as the precursors of iron(III) oxide.[15] An

enthalpy change for the formation of 2,2′-bipyridineiron(II) complex has been determined as −105—−131 kJ mol^{-1}.[23,30,31] Thus, this complex should dissociate at elevated temperatures. Figure 9 shows the absorption spectra of the 2,2′-bipyridineiron(II) complex at different temperatures. The intensity of the spectra markedly decreased with increasing temperature. These facts confirmed the above consideration.

A direct oxidation of 2,2′-bipyridineiron(II) complex is unlikely because the formal oxidation-reduction potential, $E^{0\prime}$, of the $[Fe(bpy)_3]^{3+}/[Fe(bpy)_3]^{2+}$ couple (+1.120 V)[32] is much larger than that of the Fe(II)/Fe(III) couple (+0.74 V in 0.2 mol dm^{-3} HNO_3).[33] Furthermore, 2,2′-bipyridineiron(III) species would quickly oxidize iron(II) ions (a rate constant, k=2.7×10^4 l mol^{-1} s^{-1} at 25 °C),[34] even if the direct oxidation of 2,2′-bipyridineiron(II) took place.

The stability of 2,2′-bipyridine, itself, was examined under the conditions given in this work using its own absorption band from 250 to 300 nm. A solution contained 1.5×10^{-2} mol dm^{-3} 2,2′-bipyridine, 5.0×10^{-3} mol dm^{-3} sulfuric acid, and 2.5×10^{-1} mol dm^{-3} potassium nitrate was heat-treated at 100 °C for 24 h. Little change in the intensity of the absorption band indicated that 2,2′-bipyridine scarcely decomposed under these conditions.

These facts clearly indicated that the iron(II) ions were released by only the dissociation of the complex, not by the degradation of the ligand at higher temperatures. Then, iron(II) ions were oxidized to the trivalent state by coexisting nitrate ions, followed by forced hydrolysis. Thus, the 2,2′-bipyridineiron (II) complex acted as a soluble reservoir of hydroxoiron(III) complexes for the iron(III) oxide and hydroxide oxide particles.

Monodispersed spherical particles were obtained at almost the same pH range (2.2—2.4) in both the iron (II) chloride and sulfate systems. Hydroxoiron(III) complexes should be controlled at a suitable supersaturation for making monodispersed oxide particles by adjusting the iron(II) salt concentration and pH of the starting solution. The kind of anions present also affect the shape, size, and chemical composition of the particles.[3-6] As mentioned above, the optimum conditions were limited to within a relatively narrow range.

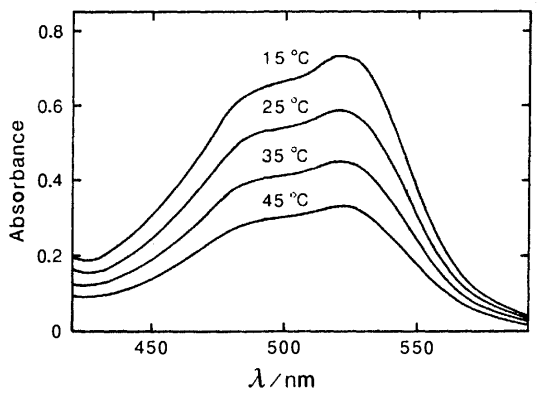

Fig. 9. Spectra of 2,2′-bipyridineiron(II) complex solution at different temperatures. Conditions: $[FeSO_4]$=1.6×10^{-4}, [bpy]=4.8×10^{-4}, $[H_2SO_4]$=5.0×10^{-3} mol dm^{-3}.

Table 1. Effect of Potassium Nitrate Concentration on Formation of Hematite Particles at 100°C[a]

Sample	$\frac{[KNO_3]}{[FeCl_2]}$	d / μm	RSD[b]	Morphology
A	5			Irregular
B	10	1.11	0.21	Spherical
C	25	0.61	0.16	Spherical
D	50	0.39	0.14	Spherical
E	100	0.32	0.17	Spherical

a) $[FeCl_2]$=1.0×10^{-3}, [bpy]=3.0×10^{-3}, [HCl]=6.0×10^{-3} mol dm^{-3}; aging time: 94 h (A), 24 h (B—E). b) Relative standard deviation.

The oxidation rate of iron(II) ions is also an important factor for making monodispersed particles. One effect of the oxidant concentration on the morphology and size of the particles was examined by varying the concentration ratio, $[KNO_3]/[FeCl_2]$, from 5 to 100. As shown in Table 1, spherical particles of the narrowest size distribution could be obtained at a concentration ratio of 50 under these experimental conditions, whereas the average size normally decreased from 1.11 to 0.32 μm owing to a rapid oxidation of iron(II) species as the concentration ratio increased from 10 to 100. Thus, this concentration ratio of 50 was taken in the present work.

Nitrate ions, in general, scarcely coordinate with iron(III) ions, so that they hardly affect the nucleation and growth rates by surface complexation but by oxidation. On the other hand, much faster oxidation makes longer nucleation periods, leading to polydispersed particles.

The concentration ratio of 2,2′-bipyridine to iron(II) ions was also sensitive for making monodispersed particles, especially in the iron(II) sulfate system. It is well known that 2,2′-bipyridine coordinates with iron(II) ion at a molar ratio of 3 : 1. Therefore, the stability of this complex would be greatly dependent on the ratio, [bpy]/[Fe(II)], and the pH of the solution.

Charge-Transfer Rates in Thin Polyelectrolyte Films Incorporating a Redox Molecule with Two Separate Electroactive Centers Having Different Redox Potentials. An Alizarine Red S-Cationic Perfluoropolymer Film System

Takeo OHSAKA, Youko TAKAHIRA, Osamu HATOZAKI, and Noboru OYAMA*
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received October 13, 1988)

The diffusion coefficients for the charge-transport processes through 9,10-dihydro-3,4-dihydroxy-9,10-dioxo-2-anthracenesulfonate (Alizarine Red S, **1**)-incorporating cationic perfluoropolymer (CPFP) polyelectrolyte films on electrodes undergoing oxidation or reduction of two separate electroactive centers with different redox potentials, i.e., the two-electron reduction of **1** to 3,4,9,10-tetrahydroxy-2-anthracenesulfonate (**2**) and the two-electron oxidations of **2** to **1** and **1** to 3,4,9,10-tetrahydro-3,4,9,10-tetraoxo-2-anthracenesulfonate (**3**) were measured by potential-step chronoamperometry and chronocoulometry. The apparent diffusion coefficients for **1** to **2**, **2** to **1**, and **1** to **3** processes where the first two processes are reversible and the **1** to **3** process is irreversible, represented as $D_{app}^{rev}(1\rightarrow2)$, $D_{app}^{rev}(2\rightarrow1)$ and D_{app}^{irrrev} $(1\rightarrow3)$, respectively, decreased with increasing the concentration (C_{film}) of **1** (or **2**) in the CPFP film, and for a given C_{film} they were found to be in the following order: $D_s' \gg D_{app}^{rev}(1\rightarrow2) \sim D_{app}^{rev}(2\rightarrow1) > D_{app}^{irrev}(1\rightarrow3)$, where D_s' represents the diffusion coefficients corresponding to the diffusion of supporting electrolyte ions coupled to electron transfer and molecular motion of reactant itself. It became apparent that the difference in $D_{app}^{rev}(1\rightarrow2)$ (or $D_{app}^{rev}(2\rightarrow1)$) and D_{app}^{irrev} $(1\rightarrow3)$ can be attributed to different contributions of electron exchange between electroactive centers to the overall charge-transport rates. The results demonstrate that the contributions from molecular motion of reactant itself and electron exchange between reactants to the overall charge-transport rates can be estimated depending upon which redox center is employed in an electrochemical measurement of diffusional rates.

Charge transport through thin films (thicknesses are typically ca. 10^{-6}—10^{-3} cm) of redox polymers with electroactive mobile reactants or fixed sites, which are coated on electrode surfaces and are well-swollen with solvent/electrolyte, has been a subject of much interest in recent years.[1-20] The mechanisms of charge transport are generally reasonably well-understood, but in any particular case it is often difficult to determine the rate-determining step, especially in the case[2a,3,4f,5,6a,9,12,14,15,17] where the electroactive reactants incorporated in films are not part of the polymeric structure or permanently attached to functional groups present in the films. In this case, the diffusion of electroactive reactants within the polymeric matrix can include contributions from both molecular motion[1b,2a-c,3a,b,d,e,g,4b,c,f,g,5,9,12,14,15] and electron exchange between adjacent pairs of the oxidized and reduced reactants.[1a,b,2c-e,3b,c,f,g,4a,d,e,5g-i,12,21,22] The diffusion is also usually accompanied by migration of electrolyte ions to maintain electroneutrality, motion of solvent and segmental motion of polymeric chain. Thus, it has been generally known that the rates of charge transport, which has been proved to be treated in many cases[1-5,7a,8a,9a,b,12-15,17-20] as a Fickian diffusion process, depend on the polymer matrix, the electroactive reactant incorporated into it, the concentration of the reactant, the supporting electrolyte and its concentration, pH of solution, solvent, etc.

A variety of redox polymer film systems have been ever used as models for the fundamental elucidation of charge-transfer process within thin films on electrodes.[1-9,12,14,15,17-20] Among these, a system, where a molecule with two separate electroactive centers having different redox potentials is incorporated in a polyelectrolyte film on electrodes, is of particular interest as originally pointed out by Tsou and Anson,[3f] because one could obtain new information on charge transport that is not obtained or is different from that obtained for cases where a kind of redox species is incorporated in a film or two kinds of redox species are simultaneously incorporated in it. Tsou and Anson have measured the diffusion coefficients of the hetero-binuclear metal complex $(NH_3)_5RuC_5H_4N$-$CH_2NHC(=O)$-$CpFeCp$ (C_5H_4N=4-pyridyl, Cp=cyclopentadienide or substituted cyclopentadienide) within Nafion coatings in all three of its possible redox states (i.e., $Ru^{II}LFe^{II}$, $Ru^{III}LFe^{II}$, $Ru^{III}LFe^{III}$) and have explained successfully possible origins of the differences of the diffusional rates corresponding to these three oxidation states and their concentration dependences on the basis of intermolecular electron self-exchange, single-file diffusion and electrostatic cross linking. More recently, we[23] also have reported the preliminary results concerning the charge-transport rates for the oxidation and reduction of the two separate electroactive centers-containing molecule/thin polymer film system, i.e., 9,10-dihydro-3,4-dihydroxy-9,10-dioxo-2-anthracenesulfonate (which is often called Alizarine Red S dye and is abbreviated as ARS in this paper)-incorporating perfluoropolymer (CPFP) film system. ARS contains two separate electroactive centers, i.e., 3,4-dihydroxy and 9,10-dioxo groups, and the electrode reactions of 3,4-dihydroxy and 9,10-dioxo groups are irreversible and reversible, respectively.[23,24] Thus, if the electron exchange between electroactive centers contributes significantly

to the overall charge-transport rates, we could observe different charge-transport rates for the oxidation (or reduction) process of these two kinds of the electroactive centers. This is the first reason why we chose ARS as an electroactive molecule to be incorporated in films. The electroinactive functional group (i.e., SO_3^- group) serves as a counter anion site of the fixed cationic quaternized ammonio groups of CPFP and the net charge on ARS does not change before and after the oxidation or reduction of the electroactive centers. This is another reason for using ARS. In a previous paper,[23] it has been suggested that the contributions from molecular motion of reactant itself and electron exchange between reactants to the overall charge-transport rates can be estimated depending upon which redox center is employed in an electrochemical measurement of diffusional rates.

In this study, in addition to the fundamental redox behavior of ARS incorporated in CPFP films, we examined in more detail the charge-transport process within ARS-incorporating CPFP films undergoing oxidation or reduction of 3,4-dihydroxy and 9,10-dioxo groups, e.g., the dependences of the diffusional charge-transport rates on the concentration of ARS in films and the differences between these rates and the diffusional rates corresponding to the physical diffusion of counter ions which is necessarily, for charge neutrality, coupled to electron transfer (i.e., the homogeneous oxidation-reduction reaction of the electroactive groups in the CPFP films). The results obtained are reported in this paper.

CPFP

Experimental

Materials. 9,10-Dihydro-3,4-dihydroxy-9,10-dioxo-2-anthracenesulfonate (abbreviated as ARS) of reagent grade was obtained from Wako Pure Chemical Industries, Ltd., and was recrystallized three times from H_2O-C_2H_5OH mixture (volume ratio=1 : 1), then dried at 100 °C. A stock solution of cationic perfluoropolymer (abbreviated as CPFP) was prepared as described previously.[25] The concentration of CPFP stock solution (solvent: H_2O-C_2H_5OH-2-propanol (volume ratio=1 : 1 : 1)) was 10.5 mg ml^{-1}. $[Co(tpy)_2]Cl_2 \cdot 2H_2O$ (tpy: 2,2′ : 6′,2″-terpyridine) was prepared and purified according to the literature.[26] NaI was of reagent grade (Tokyo Kasei Co., Ltd.). Basal-plane pyrolytic graphite (BPG, Union Carbide Co.) and In-Sn oxide conducting glass (ITO, Matsuzaki Shinku Co.) were used as working electrodes. Unless otherwise noted, the areas of BPG and ITO electrodes used were 0.19 and 0.25 cm^2, respectively. A platinum wire was used as a counter electrode. The supporting electrolyte solutions were 0.2 M (1 M=1 mol dm^{-3}) CF_3COONa, prepared from CF_3COOH (Aldrich) and NaOH, adjusted to the desired pH's with CF_3COOH, NaOH and/or the commonly used buffer solutions: citric acid/Na_2HPO_4 buffer solutions (at pH 3, 5, and 7), $Na_2B_4O_7$/HCl buffer solution (pH 9) and Na_2HPO_4/NaOH buffer solution (pH 11). Aqueous solutions were prepared from doubly distilled water. Other chemicals were of reagent grade and were used as received.

Apparatus and Procedures. A standard three-electrode, electrochemical cell was used for all the electrochemical experiments. The electrode assembly consisted of an uncoated or a CPFP film-coated BPG (or ITO) as the working electrode, a sodium chloride saturated calomel electrode (SSCE) as the reference electrode, and a platinum wire as the counter electrode.

For cyclic voltammetry (CV), potential-step chronoamperometry (PSCA) and potential-step chronocoulometry (PSCC), a homemade instrument was employed. Positive feedback circuitry was employed to compensate the resistances associated with the polymer films as much as possible. PSCA and PSCC data (i.e., current-time responses and charge-time responses) were monitored and stored on a Nicolet digital oscilloscope (model 3091). These data were then transferred to the laboratory's minicomputer (NEC, PC-9801VE), where calculation was performed, and then graphically presented on an X-Y recorder (Graphtec Co.). Rotating-disk voltammograms were obtained with standard, previously described procedures and apparatus.[27]

The preparation of CPFP film-coated electrodes and the measurement of the film thickness (typically 1.0 μm) were carried out by the same procedure as before.[25] The CPFP film-coated electrodes were equilibrated with 0.01—0.1 mM solutions (pH 1.0) (containing 0.2 M CF_3COONa) of ARS in order to achieve the incorporation of desired quantities of ARS into the films. During the incorporation of several hours, the electrode potential was repeatedly cycled between −0.6 and 0.2V vs. SSCE, and simultaneously the solution was stirred. The quantity (Γ) of ARS incorporated into the CPFP films on the electrodes was estimated (in mol cm^{-2}) by measuring the area of cyclic voltammograms for the oxidation of ARS obtained at slow potential scan rates (1—5 mV s^{-1}). In this case, the electrode potential was held at −0.6 V vs. SSCE for ca. 5—20 min and then the potential was scanned from −0.6 to 0.2 V vs. SSCE. The concentration (in mol cm^{-3}) of the incorporated ARS was calculated from the Γ value thus obtained using the measured film thickness. All experiments were run under a nitrogen atmosphere at laboratory temperature (25±1 °C). The potentials were measured and are quoted with respect to the SSCE.

Results

Incorporation of ARS into CPFP Films Coated on Electrodes. Figure 1 shows typical cyclic voltammograms demonstrating the incorporation of ARS into the CPFP film (thickness: 1.0 μm) coated on an ITO electrode in a 0.2 M CF_3COONa aqueous solution (pH 1.0) containing 0.1 mM ARS. The incorporation of ARS by anion exchange with Cl^- ions, which are initially present in the film as the counteranions of the fixed cationic quaternized ammonio groups, continued for about 90 min (Fig. 1B). No further increases

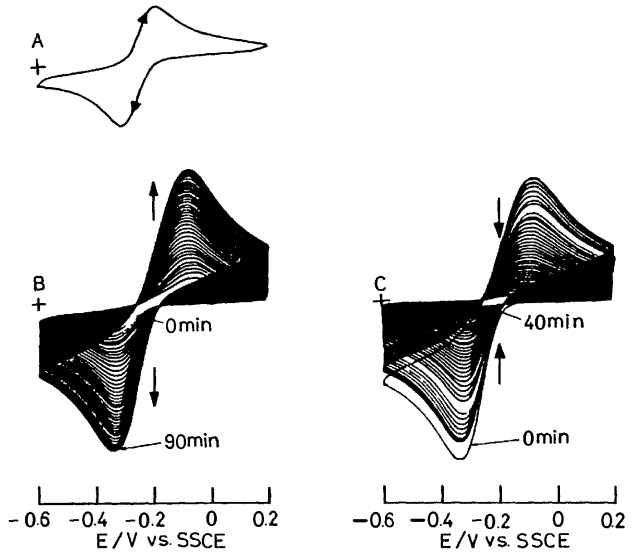

Fig. 1. (A) Cyclic voltammogram of ARS at an uncoated ITO electrode in 0.2 M CF_3COONa solution (pH 1.0) containing 0.1mM ARS. (B) Cyclic voltammograms demonstrating the incorporation of ARS into the CPFP film coated on an ITO electrode in the same solution as used in A. Thickness of the CPFP film: 1.0 μm. Volume concentration of the quaternized ammonium site in the CPFP film: 1.7 M. (C) Cyclic voltammograms obtained when the electrode used in B was transferred to a 0.2 M CF_3COONa solution (pH 1.0). Immersion time is indicated on the voltammograms. In every case, scan rate was 50 mVs^{-1} and electrode area was 0.25 cm^2.

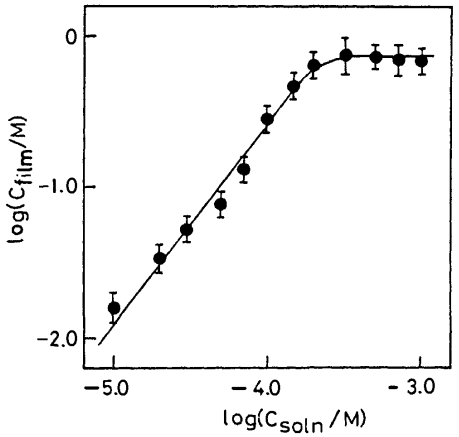

Fig. 2. Equilibrium distribution curve of ARS in the bulk of 0.2 M CF_3COONa solutions (pH 1.0) and in the CPFP films (thickness: 1.0 μm) coated on electrodes. C_{soln} and C_{film} refer to the concentrations of ARS in the bulk of CF_3COONa solution and the CPFP film, respectively.

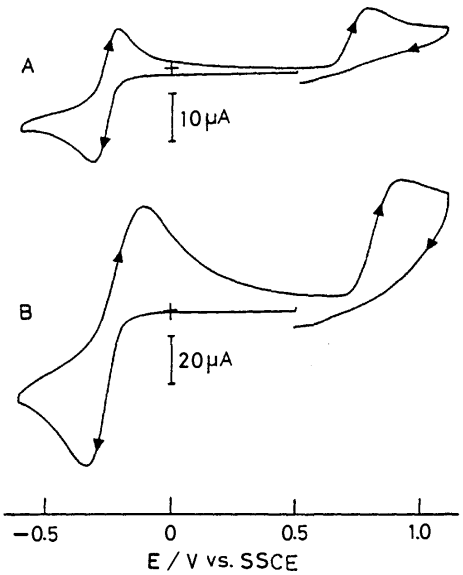

Fig. 3. (A) Cyclic voltammogram of ARS at an uncoated ITO electrode in 0.2 M CF_3COONa solution (pH 1.0) containing 0.1 mM ARS. Scan rate: 20 mVs^{-1}. (B) Cyclic voltammogram of ARS confined in the CPFP film (thickness: 1.0 μm) coated on ITO electrode in the same solution as used in A. Scan rate: 50 mVs^{-1}. In both cases, the electrode areas were 0.22 cm^2.

in peak current were observed with scanning time longer than 90 min. The peak current at the coated electrode was about 2.5 times that at an uncoated electrode (Fig. 1A), and the concentration of the incorporated ARS was 0.46 M. This indicates that the quantity of the incorporated ARS corresponds to ca. 27% of the total amount (1.7 M)[25] of the quaternized ammonium site in the CPFP film. When the CPFP-coated electrode was removed from the incorporating solution and replaced in the pure supporting electrolyte, the ARS anions leached gradually from the CPFP film, and thus the peak current decreased with scanning time. After about 40 min, most of the ARS anions were lost from the film (Fig. 1C). However, the steady-state currents shown in Fig. 1B remained substantially unchanged in the incorporating solution containing 0.1 mM ARS for a period of several hours, even when the electrode was rotated at rotation rates of 100—4900 rpm in the hydrodynamic voltammetric experiments using rotating-disk electrodes (as mentioned below).

The equilibrium distribution curve for ARS partitioned into the CPFP film from 0.2 M CF_3COONa solution (pH 1.0) is shown in Fig. 2, where the logarithm of the concentration (C_{film}) of ARS incorporated into the films is plotted against the logarithm of the concentration (C_{soln}) of ARS in the incorporating solutions over the concentration range 10^{-5} to 10^{-3} M. It is apparent from this figure along with Fig. 1 that ARS is incorporated and concentrated into CPFP film on electrode. The C_{film} vs. C_{soln} plot is almost linear at $C_{soln}<0.14$ mM and the equilibrium distribution coefficients, defined as C_{film}/C_{soln}, are estimated to be (1—3) $\times 10^3$ at $C_{soln}=10^{-5}$—10^{-4} M.

Cyclic Voltammetry of ARS in Solution and CPFP Film. The cyclic voltammetric behavior of ARS confined in CPFP film was found to be essentially the

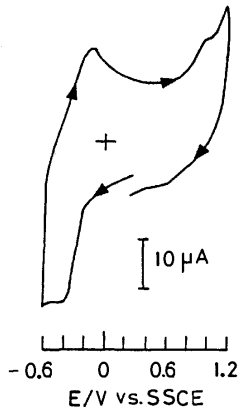

Fig. 4. Cyclic voltammogram for ARS confined in the CPFP film (thickness: 1.0 μm) coated on ITO electrode in 0.2 M CF_3COONa (pH 1.0) containing 0.025 mM ARS. Scan rate: 10 Vs^{-1}.

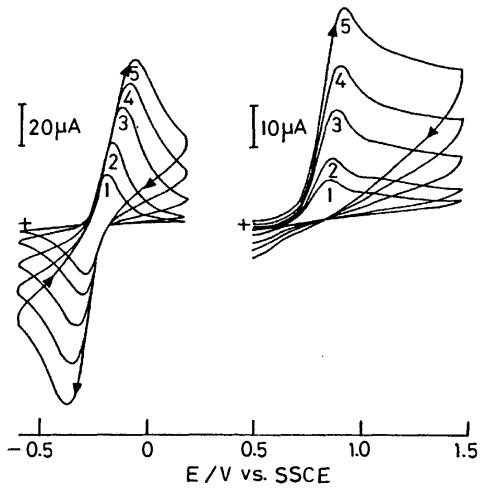

Fig. 5. Cyclic voltammograms of ARS confined in the CPFP film coated on ITO electrode in 0.2 M CF_3COONa solution containing 0.1 mM ARS at various potential scan rates. Concentration of ARS in the CPFP film (thickness: 1.0 μm): 0.46M. Electrode area: 0.25 cm^2. Scan rates: (1) 10, (2) 20, (3) 50, (4) 100, and (5) 200 mVs^{-1}.

same as dissolved in solution, as shown in Fig. 3. That is to say, the reversible and irreversible redox responses can be observed at ca. −0.27 and ca. 0.8 V vs. SSCE, which correspond to the oxidation-reduction reaction of 9,10-dioxo group and the oxidation of 3,4-dihydroxy group, respectively. The data in Fig. 3 were obtained with ITO electrodes. Almost similar results were also obtained with BPG electrodes, but in this case an adsorption of ARS on uncoated BPG electrode substrates was observed. The reversibility of the electrode reactions of 9,10-dioxo and 3,4-dihydroxy groups seemed essentially unchanged on the time scale (ca. 1—40 ms) of the potential-step experiments from which the diffusion coefficients for the diffusional charge-transport processes were obtained (mentioned below), as seen from the cyclic voltammograms shown in Fig. 3 and obtained at a scan rate of 10 Vs^{-1} (Fig. 4). The time scale of 10 Vs^{-1} at CV approximately corresponds to ca. 1 ms at PSCA and PSCC.[28] Plots of the peak currents (i_p) for the oxidation and/or reduction of 9,10-dioxo and 3,4-dihydroxy groups of ARS incorporated in the CPFP film against the square root of potential scan rate, $v^{1/2}$, were nearly linear in the range of v from 10 to 200 mVs^{-1} (as shown typically in Figs. 5 and 6), indicating that charge transport through the CPFP film is apparently diffusional and obeys Fick's law.[28]

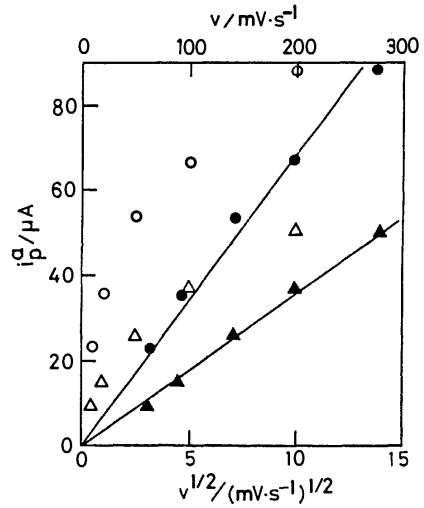

Fig. 6. Dependences of the anodic peak currents, i_p^a, for the oxidations of ARS confined in the CPFP film upon potential scan rate, v. The plots correspond to the data used in Fig. 5. (○, △): i_p^a vs. v plots, (●, ▲): i_p^a vs. $v^{1/2}$ plots. (○, ●): oxidation of **2** to **1**, (△, ▲): oxidation of **1** to **3**.

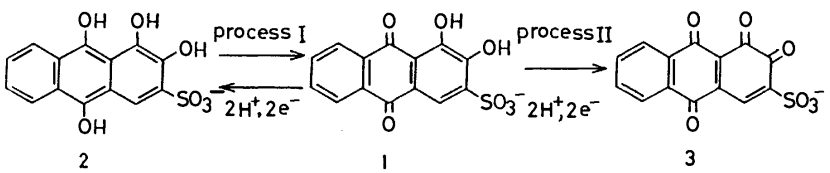
The formal redox potentials ($E^{o\prime}$) (estimated as the average of the anodic and cathodic peak potentials) for the oxidation-reduction reaction of the 9,10-dioxo group of ARS in both solution and CPFP film shifted to negative potentials with increasing pH, and the slope of the $E^{o\prime}$ vs. pH plot was about −56 mV/pH. Thus, protons and electrons were found to take part in the electrode reaction in a 1/1 ratio. On the basis of the above-mentioned and previously reported results,[23,24] the mechanism of the electrode reaction of ARS confined in the CPFP film on electrodes can be represented as follows.



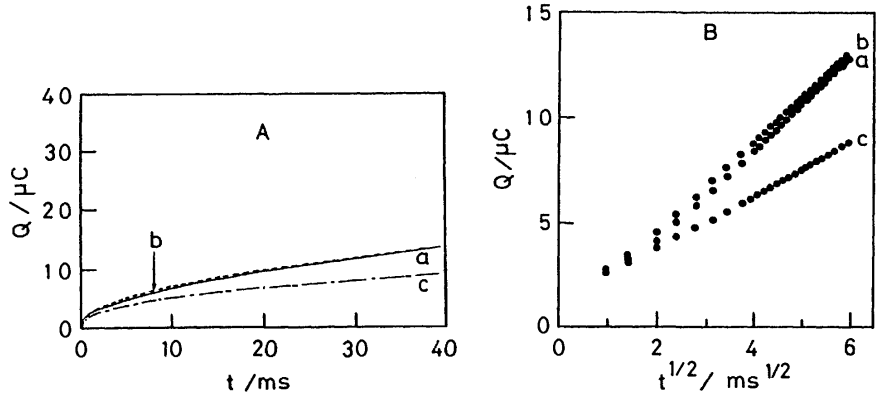


Fig. 7. (A) Typical potential-step chronocoulometric responses for (a) the reduction of **1** to **2**, and the oxidations of (b) **2** to **1** and (c) **1** to **3** of ARS confined in the CPFP film coated on ITO electrode (0.25 cm^2) in 0.2 M CF_3COONa solution (pH 1.0) containing 0.01 mM ARS. Concentration of ARS in the CPFP film (thickness: 1.0 μm): 35 mM. The electrode potentials were stepped from (a) 0.2 to −0.6, (b) −0.6 to 0.2, and (c) 0.2 to 1.3 V vs. SSCE. (B) Chronocoulometric Cottrell plots for the data in A.

Potential-Step Chronoamperometry and Chronocoulometry. Figure 7A shows typical potential-step chronocoulometric responses for an ITO/CPFP, ARS electrode where the electrode potentials were stepped from (a) 0.2 to −0.6, (b) −0.6 to 0.2, and (c) 0.2 to 1.3 V vs. SSCE. Responses a and b correspond to process I and response c corresponds to process II. The chronocoulometric Cottrell plots (i.e., Q vs. $t^{1/2}$ plots) are shown in Fig. 7B. The data gave almost linear Q-$t^{1/2}$ plots in the examined range of t from ca. 1 to 40 ms, and thus the slopes of these plots yielded the apparent diffusion coefficients (D_{app}) for the diffusion-like charge-transport processes within the films. The D_{app} values were also obtained by potential-step chronoamperometry. The results thus obtained are summarized in Fig. 8 and Table 1. In this paper, for convenience, we will represent D_{app}'s for the reversible process I and the irreversible process II as D_{app}^{rev} and D_{app}^{irrev}, respectively. It should be noted that the D_{app} values changed slightly from one electrode to another, even when the experimental conditions (e.g., C_{film} and step-potential in PSCA and PSCC experiments) were the same. For this reason, the values of D_{app}^{rev}, D_{app}^{irrev}, and κD_s (D_s: diffusion coefficients for I^- and $[Co(tpy)_2]^{2+}$ in CPFP films, κ: partition coefficient, mentioned below)

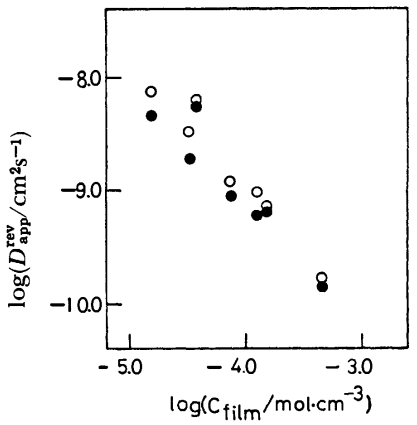

Fig. 8. Dependence of D_{app}^{rev} on C_{film}. CPFP film thickness: 1.0 μm. Supporting electrolyte: 0.2 M CF_3COONa (pH 1.0). (○): oxidation of **2** to **1**; (●) reduction of **1** to **2**.

at a given C_{film}, summarized in Table 1, were obtained at the same electrode. From Fig. 8 and Table 1, we can see that D_{app}^{rev} and D_{app}^{irrev} decrease with increasing C_{film} and that $D_{app}^{rev} > D_{app}^{irrev}$ for a given C_{film}.[35]

Rotating-Disk Voltammetry. In order to estimate the diffusion coefficients coresponding to the diffusion of supporting electrolyte ions which is necessarily, for

charge neutrality, coupled to electron transfer (i.e., redox reactions of electroactive groups of ARS), the redox ions, which are electroactive in such a potential region (ca. 0—0.7 V vs. SSCE) that the redox response of ARS is not substantially observed, are required owing to electroinactivity (under the experimental conditions employed in this study) of the supporting electrolyte ions used (Na^+ and CF_3COO^-). For this purpose, I^- and $[Co(tpy)_2]^{2+}$ were chosen. Figure 9 shows typical steady-state current-potential curves for the oxidation of I^- at both bare and CPFP film-coated rotating BPG disk electrodes in a 0.2M CF_3COONa solution (pH 1.0) containing 0.01 mM ARS and 0.5 mM NaI. In this case, the CPFP film-coated electrode was previously equilibrated with a 0.01 mM ARS solution containing no I^-, and then the hydrodynamic voltammetric experiments were conducted. Note that the oxidation of I^- is not thermodynamically mediated by ARS incorporated in the CPFP film, as seen from the comparison of formal redox potentials ($E^{\circ\prime}$'s) of ARS and I_2/I^- couple, i.e., the $E^{\circ\prime}$'s of ARS (for process I) and I_2/I^- couple are −0.27 and 0.44 V vs. SSCE, respectively, in 0.2 M CF_3COONa aqueous solution (pH 1.0). The oxidation of I^- might be mediated by the I_2/I^- couple present within the CPFP film, since it is an anion-exchanging film and thus the trapping of I^- in the film is possible. However, this possibility may be ignored from the following fact. After the above-mentioned rotating-disk voltammetric experiments, the electrode was transferred into a 0.2 M CF_3COONa solution (pH 1.0) containing no ARS and I^- and the cyclic voltammetric response was examined as soon as possible. Consequently, we observed a well-defined redox response of ARS, but no redox response corresponding to I_2/I^- couple was obtained. Thus, the observed anodic currents correspond to the oxidation of I^- ions that penetrate the ARS-containing CPFP films to reach the electrode surface. Figure 10A shows the Levich plots[29] of limiting current, i_{lim} vs. (rotation rate, ω)$^{1/2}$ obtained from the steady-state current-potential curves such as those shown in Fig. 9. The deviations of the limiting currents with CPFP-coated electrodes from the straight line obtained with a bare BPG electrode reflect the different diffusion rates of I^- ion in the bulk of the solution and the swollen, ARS-containing CPFP films.

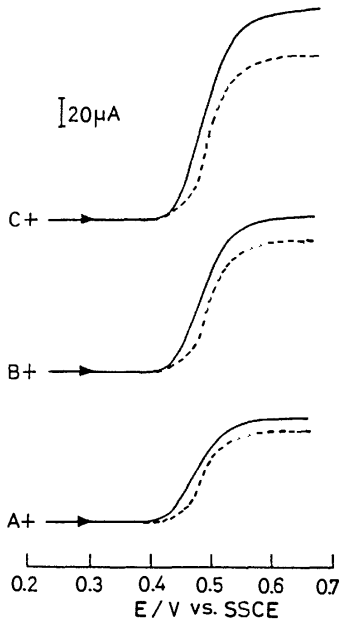

Fig. 9. Typical steady-state current-potential curves for the oxidation of iodide ion at uncoated and ARS-containing CPFP film-coated BPG disk electrodes. (——): at an uncoated BPG electrode in 0.2 M CF_3COONa solution (pH 1.0) containing 0.5 mM NaI; (----): at an ARS-containing CPFP film-coated BPG electrode in 0.2 M CF_3COONa solution (pH 1.0) containing 0.01 mM ARS and 0.5 mM NaI. Concentration of ARS in the CPFP film (thickness: 1.0 μm): 35 mM. Electrode areas: 0.19 cm^2. Potential scan rate: 2 mVs^{-1}. Electrode rotation rate: (A) 400, (B) 900, (C) 1600 rpm.

The quantitative analysis of this problem was made according to the Koutecky-Levich equation as described previously:[28,30]

$$\frac{1}{i_{lim}} = \frac{1}{i_{Lev}} + \frac{1}{i_s} \tag{1}$$

with

$$i_{Lev} = 0.62\, nFAD_{soln}^{2/3}\, \nu^{-1/6}\, C_{soln}\, \omega^{1/2} \tag{2}$$

$$i_s = nFA\kappa C_{soln} D_s \phi^{-1} \tag{3}$$

where i_{Lev} is the Levich current,[29] i_s is the "permeation current"[7c,28,31,32] of I^- ion through the CPFP film, D_{soln} is the diffusion coefficient of I^- ion in a bulk solution, D_s is the diffusion coefficient of I^- ion in the film, ν is the kinematic viscosity of the solution, C_{soln} is the bulk concentration of I^- ion, ϕ is the film thickness, and κ is the partition coefficient of I^- ion between in the film and in the bulk of the solution. The Koutecky-Levich plots of i_{lim}^{-1} vs. $\omega^{-1/2}$ for the data of Fig. 10A were linear, as expected from Eq. 1, and the slopes matched that at a bare electrode (Fig. 10B). Thus, from the data shown in Fig. 10B, the values of D_{soln} and κD_s for I^- ion were estimated (Table 1).

The values of D_{soln} and κD_s for $[Co(tpy)_2]^{2+}$ ion ($E^{\circ\prime}$ of $[Co(tpy)_2]^{2+/3+}$ couple=0.035 V vs. SSCE in 0.2 M CF_3COONa solution (pH 1.0)) were also estimated according to the same way as mentioned above (Table 1). We can see that the diffusion rates of I^- and $[Co(tpy)_2]^{2+}$ ions in the swollen CPFP film of a given C_{film} are different and that they change with C_{film}.

Discussion

Dependence of D_{app}^{rev} on C_{film}. The decrease of apparent diffusion coefficients (D_{app}) for charge-transport processes within electroactive films with increasing the concentration (C_{film}) of electroactive species confined in the films has been previously

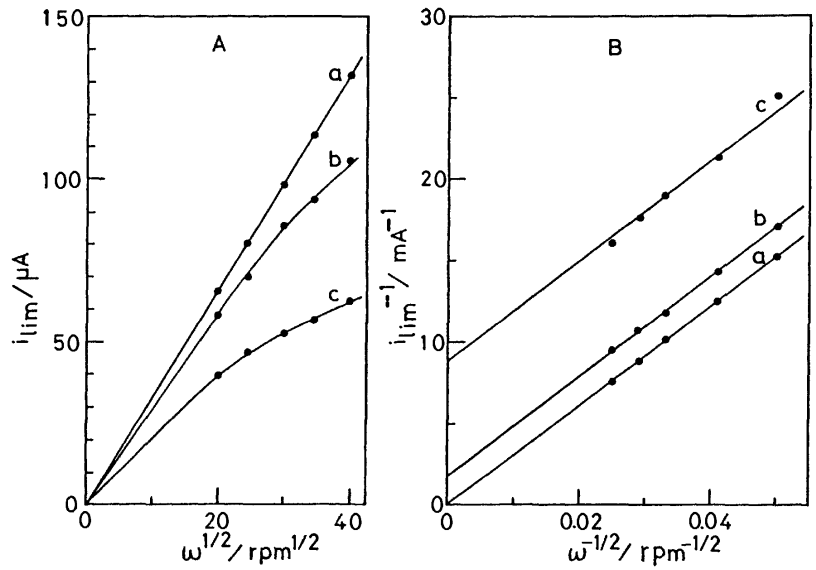

Fig. 10. (A) Levich plots of limiting current, i_{lim}, vs. (rotation rate, ω)$^{1/2}$ for the oxidation of iodide ion at (a) uncoated and (b,c) ARS-containing CPFP film-coated BPG electrodes. (B) Koutecky-Levich plots of i_{lim}^{-1} vs. $\omega^{-1/2}$ for the data used in A. Solution compositions: (a) 0.2 M CF_3COONa (pH 1.0)+0.5 mM NaI; (b) 0.2 M CF_3COONa (pH 1.0)+0.5 mM NaI+0.01 mM ARS; (c) 0.2 M CF_3COONa (pH 1.0)+0.5 mM NaI+0.1 mM ARS. Other experimental conditions are the same as in Fig. 9.

observed in many cases[3,5a-f,j] where multiply-charged electroactive species are electrostatically confined in oppositely charged polymer films. In these cases, the decrease of D_{app} with increasing C_{film} has been explained in terms of an electrostatic cross-linking of the polymer film[2,3,4b-c-f,g,5a-f,j-25] and a single-file diffusion.[3c-f,33,34] That is to say, an increase of the electrostatic cross linking with increasing C_{film} causes a decrease in the diffusion rate of electroactive species itself as well as decreases in the rates of the charge-compensating counterion motion which is necessarily coupled to electron transfer, the motion of solvent and/or the segmental motion of the polymeric chain. Also, the diffusion species which must move between more or less fixed sites within a polymeric matrix are considered to have their rate of motion limited by the decreasing availability of sites as C_{film} of diffusing species increases ("single-file diffusion effect"[34]). These result in the decrease of the overall rate of the charge transport with an increase in C_{film}.

However, the same explanation seems not to be straightforwardly applicable to the case of the ARS-CPFP film system examined in this study (though the decrease of D_{app}^{rev} with increasing C_{film} was observed (Fig. 8), because ARS bears only a single negative charge as SO_3^- group and thus replacing Cl^- anions initially present in the film by ARS anions can not be expected to produce a cross linking based on an electrostatic interaction alone. A possible explanation for the result obtained is that a hydrophobic interaction between the aromatic ring of ARS and the large fluorocarbon component of the CPFP coating as well as an electrostatic interaction between the SO_3^- group and the cationic quaternized ammonio group in the film concurrently contribute to the trapping of ARS anion in the film and such a combined interaction operates in the same manner as an electrostatic interaction[3,5a-f,j] between multiply-charged species and oppositely charged polyelectrolyte films. A similar hydrophobic interaction has been realized in the incorporation of electroactive compounds into polyelectrolyte films on electrode surfaces.[3c,h,33,36] A relatively high concentration of ARS anions into the CPFP coating (shown in Figs. 1 and 2), which is almost comparable to that of multiply-charged species into polyelectrolyte films by electrostatic interactions,[3,5a-f,j] may support this explanation.

Differences in Rates of Various Diffusional Processes and Their Physical Significance. Prior to considering differences in rates of various diffusional processes, it seems to be useful in developing the discussion to mention some reasons for use of ARS as an electroactive species incorporated in the CPFP film on electrodes: (i) ARS contains two separate electroactive centers with different $E^{\circ\prime}$'s and different reversibility of their electrode reactions, (ii) the electroinactive functional group (i.e., SO_3^- group) other than the electroactive ones (i.e., 3,4-dihydroxy and 9,10-dioxo groups) serves as a counteranion site of the fixed cationic quaternized ammonio groups in the CPFP film domain, and (iii) the net charge on ARS does not change before and after the oxidation or reduction of

the electroactive centers.

As can be seen from Table 1, the diffusion coefficients for processes I and II and for the physical diffusion of I^- and $[Co(tpy)_2]^{2+}$ in the film are in the following order: $\kappa D_s \gg D_{app}^{rev}$ (1→2)~D_{app}^{rev} (2→1)>D_{app}^{irrev}(1→3), where D_{app}^{rev} (1→2), D_{app}^{rev} (2→1), and D_{app}^{irrev} (1→3) correspond to **1** to **2**, **2** to **1**, **1** to **3** processes, respectively. The diffusion coefficients (D_s') for the diffusion of supporting electrolyte ions used (Na^+ and CF_3COO^-) in the CPFP film have been unknown. The diffusion coefficients (D_s) of I^- and $[Co(tpy)_2]^{2+}$ in the ARS-containing CPFP film were estimated by hydrodynamic voltammetry using rotating disk electrodes. These ions were chosen based on the fact that they are electroactive in the potential region where the redox response of ARS is not substantially observed. The mean ionic diameters (a) of Na^+ and CF_3COO^- ions can be assumed to be between those of I^- and $[Co(tpy)_2]^{2+}$ ions: a's of I^-, Na^+, CF_3COO^- and $[Co(tpy)_2]^{2+}$ are roughly considered to be ca. 3, 4.5, 5, and >6 Å, respectively.[37] Thus, D_s's for I^- and $[Co(tpy)_2]^{2+}$ ions were obtained as a rough measure of D_s''s for Na^+ and CF_3COO^- ions. Based on these considerations and the obtained values of κD_s, D_{app}^{rev}, and D_{app}^{irrev}, it can be expected that $D_s' \gg D_{app}^{rev} > D_{app}^{irrev}$. This suggests that the rate of the charge transport in the film is not substantially controlled by motion of the counterion (supporting electrolyte ion) in the polymer matrix which is coupled to electron transfer and molecular motion of ARS itself undergoing electrolysis.

The different values of D_{app}^{rev} and D_{app}^{irrev} seem to be instructive in understanding the charge transport mechanism as pointed out in a previous paper.[23] In general, the D_{app} value can include contributions from both molecular motion (physical diffusion of reactant in film) and electron exchange between reactants, which will be represented as D_o and D_{ex} (in units of $cm^2 s^{-1}$), respectively:[2d,e,3b,c,f,4c,d,5h,21-23]

$$D_{app} = D_o + D_{ex} \quad (4)$$

According to Dahms and Ruff,[21,22] D_{ex} is expressed by Eq. 5.

$$D_{ex} = (\pi/4)\, k_{ex} \delta^2 C \quad (5)$$

where k_{ex} is the second-order electron-exchange rate constant for the redox couple, δ is the distance between the reactants when the electron transfer occurs, and C is the concentration of reactants (the sum of the concentrations of the oxidized and reduced forms of the redox couple). In **1** to **2** and **1** to **3** processes, the contribution (D_o) from molecular motion should be the same, because the same molecule takes part in both processes. Thus, based on Eq.4 the difference in D_{app}^{rev} (1→2) and D_{app}^{irrev} (1→3) at a given C_{film} may be considered to originate from that in D_{ex}'s. As can be readily seen from Eq.5, the degree of the contribution from electron exchange to the overall charge-transport rate depends on the electron self-exchange rate constant between electroactive reactants, i.e., homogeneous electron self-exchange rate constant (k_{ex}): The larger k_{ex} is, the larger is D_{ex}, and thus the larger is the contribution of electron exchange. Alternatively, k_{ex} can be correlated to the heterogeneous electron-transfer rate constant (k°)[38], i.e., in a qualitative sense to the reversibility of the electrode reaction: For the redox system with large k_{ex}, the k° value is large. As seen from Fig. 3, process I is reversible, while process II is irreversible. Thus, the k° value for process I should be larger than that for process II. Based on these considerations, the difference in D_{app}'s for processes I and II can be attributed to different contributions of electron exchange between electroactive centers to the overall charge-transport rates.

(Received October 24, 1988)

The physicochemical properties of the α,ω-type (bolaform) surfactant, bis(triethylammonium) 1,20-eicosanediyl disulfate (α,ω $C_{20}N_2Et_6$), in aqueous solution have been investigated by means of surface tension, electrical conductivity, dye solubilization and time-resolved fluorescence quenching. The critical micelle concentration of α,ω $C_{20}N_2Et_6$ was 1—1.3×10^{-3} mol dm^{-3}. The micelle ionization degree of the surfactant was larger than a conventional surfactant having the same head group. From surface tension measurements, the molecular area of α,ω $C_{20}N_2Et_6$ at the air-water interface was found to be about twice as large as that of a normal type surfactant, such as sodium dodecyl sulfate (SDS). This reveals that α,ω $C_{20}N_2Et_6$ probably forms vertical looping ("wicket-like" conformation) at the air-water interface. By time-resolved fluorescence quenching measurements, the aggregation number of α,ω $C_{20}N_2Et_6$ micelle was found to be strongly dependent on the concentration, but only slightly dependent on the temperature. At low concentrations the aggregation number is close to half that corresponding to a normal type surfactant having a chain length that is that of the bolaform. The solubilizing power of a micellar solution of α,ω $C_{20}N_2Et_6$ toward Orange OT was 7.6×10^{-3} mol of dye per mol of surfactant, that is, a value smaller than that of SDS.

α,ω-Type (bolaform) surfactnts have hydrophilic head groups at both ends of the hydrophobic alkyl chain. Interest in bolaform surfactants has increased steadily in recent years from the stand points of both fundamental investigations and applications.[1-14] The investigations of α,ω-type surfactants in aqueous solutions have shown the following. First, the propensity of micelle formation of the α,ω-type surfactants is generally lower, the size of their micelles is smaller,[8,9,11-13] and their cmc is generally higher than that of single head surfactants of comparable chain length.[7-9] Second, the α,ω-type surfactants have been shown to adopt a folded, wicket-like, conformation at the air-water interface.[6,8] Third, it was suggested that these surfactants may exist in a predominantly folded conformation in micelles.[9c] As regards to the last point, a study for providing direct evidence on the conformation of these surfactants in micellar solutions, performed by using ^{13}C and ^{14}N NMR relaxation techniques,[13] suggested that bolaform surfactant chains adopt a predominantly stretched form in micelles. Recently, we have reported on the properties of α,ω-type cationic surfactant.[12,13] However, there have been a few reports about other types α,ω surfactant, i.e. the anionic or nonionic type.

In this study, as one of the systematic investigations with α,ω-type surfactants, the physicochemical properties of the anionic surfactant bis(triethylammonium) 1,20-eicosanediyl disulfate in aqueous solution have been investigated by means of surface tension, electrical conductivity, dye solubilization and time-resolved fluorescence.

Experimental

Materials. Bis(triethyl ammonium) 1,20-eicosanediyl disulfate was synthesized by using eicosanedioic acid (Okamura Oil Mill Ltd.) as the starting material via 1,20-eicosanediol. Eicosanedioic acid was reduced to 1,20-eicosanediol by using borane-THF complex (Aldrich Chem. Co.). The diol was recrystallized twice from benzene and dried for 48 h under vacuum. Its purity was confirmed by IR spectroscopy. The diol was reacted with chlorosulfuric acid to give 1,20-eicosanedisulfonic acid which was neutralized with triethylamine. The bolaform was recrystallized three times from an acetone-ethanol mixture and three times from an ethyl acetate-ethanol mixture; it was then washed twice with diethyl ether and dried for more than 72 h under vacuum. The white crystalline product was found to be more than 99% pure by elemental analysis, isotachophoresis (IP-3A: Shimadzu Co., Ltd.), NMR, and surface tension. *N*-Phenylbenzoylacetamide (BZAA), ammonium 8-anilino-1-naphthalenesulfonate (ANS) (Wako Pure Chemical Industries. Ltd.) and benzoylacetone (BZA) (Tokyo Kasei Co.) were used without further purification. Yellow OB and Orange OT (Tokyo Kasei Co., recrystallized twice from ethanol) were used as dyes.

Measurements and Methods. The surface tensions of aqueous surfactant solutions were measured by a Wilhelmy-type surface tensiometer (Shimadzu ST-1) at 25 °C. The establishment of equilibrium was checked by repeated measurements in 5-minute intervals. The electrical conductivity of the solution was measured by means of a conductivity meter (Model CM-30ET Toa Denpa Co.) at 25±0.1 °C. The fluorescence and UV spectra of each sample were measured with a fluorescence spectrophotometer (Hitachi 650-10S) and a UV spectrophotometer (Hitachi 220A). The emission and excitation slits were set at 10 nm for ANS and at 1 nm for pyrene. Pyrene and ANS were excited at 335 and 365 nm, respectively. The concentrations of these probes were kept at 5.0×10^{-5} mol dm^{-3} for ANS and 1.6×10^{-6} mol dm^{-3} for pyrene. The emission intensity was measured from 350 to 600 nm.

The solubilization measurements of water-insouble dyes

were carried out as follows. After an excess amount of water-insoluble dye was added to the surfactant solutions, the solutions were shaken for 48 h in order to reach a solubilization equilibrium. After centrifugation (5000 rpm, 30 min) of these suspensions, the supernatant solutions were taken, and diluted by ethanol. The optical density of the solution at each absorption maximum was measured with a UV spectrophotometer; the dye concentration was determined from calibration curves.

Prior to fluorescence measurements the solutions were bubbled with argon for about 20 min for deoxygenation. The fluorescence decay experiments were performed with the same photon-counting apparatus as in our previous studies,[15] modified by the use of an amplifier and single-channel analyzer (Ortec, type 590), which ensured rejection of multiphoton events and, thus, permitted a higher count rate. The measurements were performed at concentrations of 0.05, 0.1, 0.197, 0.296, 0.302 mol dm^{-3}. The fluorescence decay curves were determined at low pyrene concentration (generally around 10^{-5} mol dm^{-3}) in the absence and in the presence of the quencher *N*-dodecylpyridinium chloride (DPCl) at a concentration such that the [DPCl]/[micelle] molar concentration ratio, *R*, was around 1. The decay curves were computer-fitted to Eqs. 1 and 2 in both absence and presence of the DPCl:

$$I = I(0)\exp(-t/\tau_0) \quad (1)$$

and

$$I = I(0)\exp[-A_2 t - A_3(1-\exp(-A_4 t))], \quad (2)$$

respectively, after convolution with a lamp curve, using a nonlinear weighted least-squares procedure. The fitting yielded τ_0, fluorescence lifetime of micelle-solubilized pyrene in the absence of quencher and constants A_2, A_3, and A_4. In general, it was found that $\tau_0 > A_2^{-1}$. This result indicated that the quencher was not completely immobile on the fluorescence timescale. However, the use of the full expressions of A_2, A_3, and A_4 values in such a situation[16] yielded $A_3 = R$ because of the high concentration of quencher used in the experiments in view of the small aggregation number of the bolaform micelles. The aggregation number *N* was obtained from

$$N = R(C - \text{cmc})/[\text{DPCl}], \quad (3)$$

where *C* is the concentration of the surfactant and cmc its critical micelle concentration

The aggregation number of α,ω $C_{20}N_2Et_6$ micelles was also determined by the static fluorescence quenching method.[26] The quenching of the fluorescence emission (at 372 nm) of micelle-solubilized pyrene by *N*-hexadecylpyridinium chloride (CPCl) was measured at increasing contents of quencher and constant concentration of pyrene (1×10^{-5} mol dm^{-3}) and surfactant. The slope of the line obtained by plotting $\ln I_0/I$ (where *I* and I_0 are the fluorescence intensities with and without a quencher) versus the quencher concentration yields the micelle aggregation number.

Results and Discussion

Surface Tension. Figure 1 shows a plot of the equilibrium surface tension, γ, versus the log of the concentration *C* (in molarity) of an α,ω $C_{20}N_2Et_6$ aqueous solution. The γ_{cmc} value of α,ω $C_{20}N_2Et_6$ was

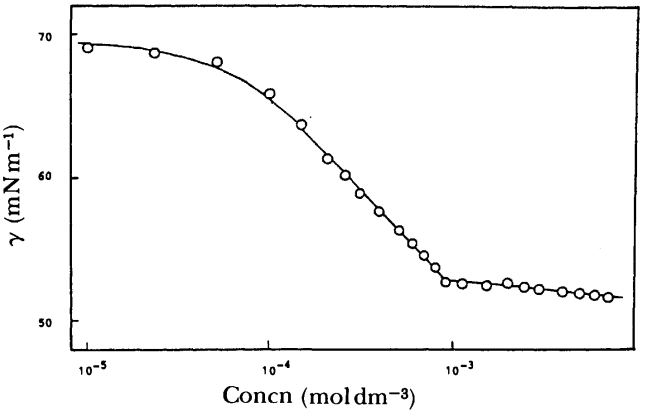

Fig. 1. Plot of surface tension, γ, against log concentration

slightly higher than those for the corresponding normal-type surfactants, i.e., alkyl hydrogensulfate. Figure 1 shows that the break in the γ vs. log *C* curve at the cmc is nearly as sharp as for normal-type surfactants such as sodium dodecyl sulfate (SDS). However, there appears to be a small decrease of γ upon increasing *C* at above 3×10^{-3} mol dm^{-3}. The critical micelle concentration of α,ω $C_{20}N_2Et_6$ from the surface tension was 1.0×10^{-3} mol dm^{-3}. Surface area calculations were based on the Gibbs adsorption equation,

$$\Gamma = -(1/nRT)(\partial\gamma/\partial \ln a), \quad (4)$$

where γ, Γ, and *a* denote the surface tension in mN m^{-1}, the surface excess in mol cm^{-2}, and the activity of the surfactant, respectively. The factor $n=3$ in the denominator is applicable for a 2:1 electrolyte with no added salt; and for a dilute solution *a* is substituted for by the concentration, *C*. In Eq. 5, where N_A is Avogadro's number,

$$A = 10^{16}/\Gamma N_A \quad (5)$$

gives the surface area *A* in Å^2 per molecule. The surface area was calculated from γ vs. log *C* plots. α,ω $C_{20}N_2Et_6$ had a surface area of 66.1 Å^2/molecule, which is very close to twice the value of 33.0 Å^2/molecule for SDS obtained by other workers.[17] Therefore, α,ω $C_{20}N_2Et_6$ seems to form vertical looping, "wicket-like" conformation, at the air-water interface. This picture is consistent with that suggested by other reports.[2,6,8]

Conductivity. The variations of the conductivity κ with concentration *C*, and of the equivalent conductivity *Λ* with the square root of the concentration expressed in equivalent per liter $(2C)^{1/2}$ are shown in Fig. 2. Each plot shows a sharp break at a concentration corresponding to the critical micelle concentration (cmc): 1.3×10^{-3} mol dm^{-3} from the κ-plot and 1.25×10^{-3} mol dm^{-3} from the *Λ*-plot. The slope of the *Λ* vs. $(2C)^{1/2}$ plot is close to the limiting slope expected for a 2:1 electrolyte in the range 3×10^{-4}—10^{-3} mol dm^{-3} (below 3×10^{-4} mol dm^{-3}, the error on κ is too large for meaningful calculations of *Λ*-values.) The

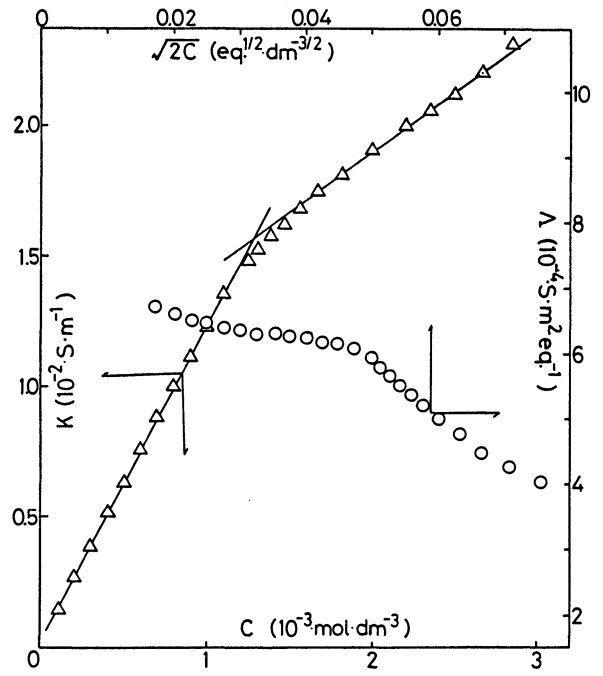

Fig. 2. Electrical conductivity-concentration of α,ω $C_{20}N_2Et_6$ (△) and equivalent conductivity-(concentration)$^{1/2}$ (○) curves.

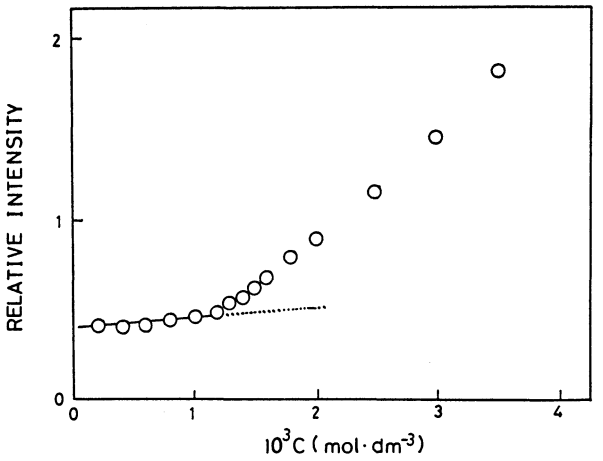

Fig. 3. Variation of the intensity of fluorescence of ANS as a function of α,ω $C_{20}N_2Et_6$ concentration.

micelle ionization degree, α=0.38, was obtained as the ratio of the slopes of the κ vs. C plots above and below cmc. This value is slightly larger than that of SDS micelles: 0.32, obtained as part of this work from the κ vs. C plot for this surfactant.

Solubilization of Dyes. The solubilization properties of aqueous solutions of α,ω $C_{20}N_2Et_6$ were studied by using ANS, BZA, BZAA, pyrene, Yellow OB, and Orange OT. The absorption and fluorescence spectra of organic compounds solubilized in micelles provide information about micellar properties. ANS is an indicator for the determination of the cmc of a surfactant because the quantum yield of this fluorescence probe is much higher in a nonpolar medium than in a

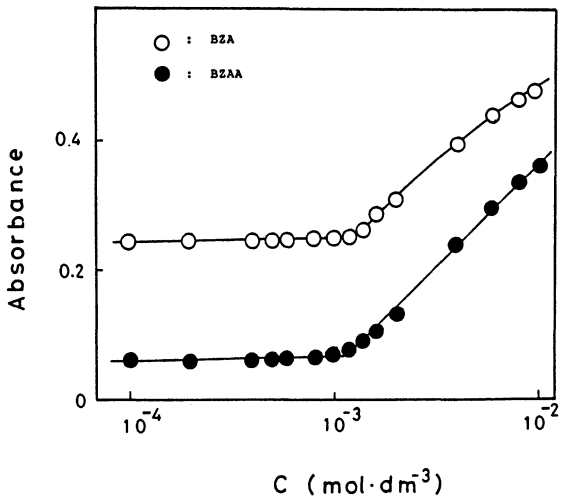

Fig. 4. UV absorbance of BZA and BZAA as a function of α,ω $C_{20}N_2Et_6$ concentration.

Table 1. cmc of α,ω $C_{20}N_2Et_6$ at 25 °C

Method	10^3cmc/mol dm^{-3}
Surface tension	1.0
Equivalent conductivity	1.3
Solubilization (ANS)	1.25
(BZA)	1.2
(BZAA)	1.2

polar solvent like water.[8,18,19] Figure 3 shows that the fluorescence intensity of ANS increased steadily at C above 1.25×10^{-3} mol dm^{-3}, which can be considered as the cmc of α,ω $C_{20}N_2Et_6$. This cmc value agrees with those obtained by electrical conductivity and surface tension.

The keto-enol tautomerisms of BZAA and BZA were also used to probe for micelle formation. The keto-form structure is predominant when the probe is in water. The change from a keto-form to an enol-form structure occurs when the polarity of the probe environment is decreased.[20] The cmc value (1.2×10^{-3} mol dm^{-3}) determined from the change of the probe absorbance, associated with this conformational transition (Fig. 4) agrees with those from other methods. All the cmc values obtained by several methods are listed in Table 1.

The fluorescence probe pyrene was used to investigate the polarity of α,ω $C_{20}N_2Et_6$ micelles. The ratio I_1/I_3 of the intensities of the first and third vibronic peaks of pyrene increases upon going from aliphatic to polar solvents and can be used as an indicator of the effective local polarity of the pyrene solubilization site in the micelles.[21] Figure 5 shows that I_1/I_3 decreases with an increasing α,ω $C_{20}N_2Et_6$ concentration from a value above 1.8 below cmc to a value of 1.42 at a concentration of 0.1 mol dm^{-3}, well above cmc. This last value is well above that found with normal-type surfactants, such as SDS, and indicates that pyrene senses

a fairly polar environment in α,ω $C_{20}N_2Et_6$ micelles. These micelles may not be as well organized as a normal-type surfactant micelle and allow somewhat more extensive pyrene-water contacts in the micelle palisade layer where pyrene preferentially resides.[21]

The molar concentrations of Yellow OB and Orange OT solubilized in α,ω $C_{20}N_2Et_6$ solutions are plotted against the surfactant concentration in Fig. 6. The solubilities of Yellow OB and Orange OT increased rapidly and linearly above the cmc. The slope of the line yields the number of moles of solubilized dye per

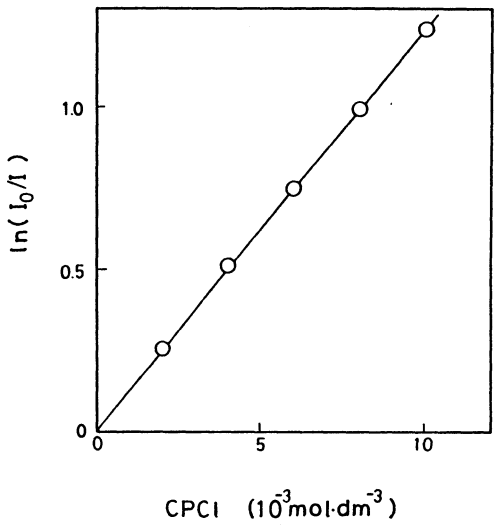

Fig. 7. Variation of $\ln I_0/I$ with the CPCl concentration in a 2×10^{-2} mol dm^{-3} solution of α,ω $C_{20}N_2Et_6$.

mole of micellar surfactant, i.e., the solubilizing power. For α,ω $C_{20}N_2Et_6$ micelles, the solubilizing power was 4.49×10^{-2} and 7.64×10^{-3} mol of dye per mol of surfactant for Yellow OB and Orange OT, respectively. The value for Orange OT was smaller than that of the conventional surfactant micelles such as SDS: 9.90×10^{-3} for Orange OT. If the solubilizing power is expressed in moles of solubilized dye per mole of surfactant head groups, the value of α,ω $C_{20}N_2Et_6$ then appears to be much smaller than that of SDS. However, the solubilizing power of different surfactants should be compared at a constant solubilizing volume, which is proportional to the alkyl chain length, that is the number of carbon atoms, to the third power. The solubilizing power of α,ω $C_{20}N_2Et_6$ expressed in moles of dye per mole of surfactant head groups was thus found to be 6.6×10^3 when corrected by the factor $(12/10)^3$, that is a little smaller than for SDS.

Aggregation Number. Table 2 lists the values of the micelle aggregation number, N, at several temperatures and surfactant concentrations, obtained from time-resolved fluorescence quenching experiments. Static fluorescence quenching experiments using pyrene as probe and *N*-hexadecyl pyridinium chloride (CPCl) as quencher yielded a linear $\ln I_0/I$ vs. quencher concentration plot (see Fig. 7) from which the value $N=15$ was obtained by using Eq. 3 in Ref. 22,

at $C=2\times10^{-2}$ mol dm^{-3} (25 °C), in good agreement with the results in Table 2. The aggregation number greatly increased with concentration. This increase is somewhat comparable to that found for SDS, where N increases from 65 to 110 when the concentration goes from 0.1 to 0.6 mol dm^{-3}.[23] Notice that a 0.3 mol dm^{-3} α,ω-type surfactant corresponds to 0.6 mol dm^{-3} of a classical surfactant with an alkyl chain equal to half that of the α,ω-type surfactant. Studies with another bolaform surfactant, 1,20-bis(triethylammonio)eicosane dibromide, referred to as $C_{20}Et_6$, have yielded an aggregation number which showed only little dependence on the concentration.[25] This difference with α,ω $C_{20}N_2Et_6$ may be due to the fact that the head-group size in $C_{20}Et_6$ is much larger than in α,ω $C_{20}N_2Et_6$. It will, thus, form small micelles and will have a lesser tendency to grow upon increasing concentration since its stacking parameter[24] (volume/surface area per head group × alkyl chain length) is smaller. On the other hand, it is noteworthy that $C_{20}Et_6$ and α,ω $C_{20}N_2Et_6$ have nearly the same aggregation numbers at low concentration: 17—20, and that these values are close to that calculated with the oil drop model for a classical surfactant with a 10 carbon atom alkyl chain. Finally, Table 2 shows that the aggregation number of α,ω $C_{20}N_2Et_6$ in an aqueous solution depends little on the temperature in comparison with normal type surfactants. Dodecyltrimethylammonium chloride (DTAC), dodecyltrimethylammonium bromide (DTAB), and SDS show a linear, or nearly linear, decrease of N upon increasing temperature.[26-28] For normal-type surfactants, the larger the value of N at low temperature, the steeper the decrease of N upon increasing the temperature.

One last point must be made. From the analysis of the pyrene fluorescence decay curve in presence of DPCl, we have been able to extract the rate constant k^- for the exit of the quencher dodecylpyridinium ion from α,ω $C_{20}N_2Et_6$ micelles. Although these values are fairly inaccurate, because of the small magnitude of k^- with respect to the quantity A_4, they all turned out to be in the range $1-2\times10^5$ s^{-1}. The residence time of the probe in the bolaform micelle is, thus, 5 to 10 μs. This value is comparable to that for other surfactants having the same chain length.[29]

The authors are grateful to Okamura Oil Mill Ltd. for the gift of a number of eicosanedioic acids.

Interaction between Disodium 1,14-Tetradecanediyl Disulfate and Sodium Dodecyl Sulfate or Poly(oxyethylene) Nonyl Phenyl Ether on Alumina

Kunio ESUMI,* Yuki ASANO, Yuichi SAKAMOTO, and Kenjiro MEGURO
Department of Applied Chemistry, Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku,Tokyo 162
(Received October 25, 1988)

The interactions between disodium 1,14-tetradecanediyl disulfate ($\alpha,\omega C_{14}$) and sodium dodecyl sulfate (SDS) or poly(oxyethylene) nonyl phenyl ether (NP 7.5) on α-alumina have been studied by measuring the zeta potential, the mean particle size, the amounts of surfactants adsorbed, and the fluorescence spectra of pyrene. When $\alpha,\omega C_{14}$, SDS, or NP 7.5 as a second additive is added to alumina previously flocculated by the addition of SDS or $\alpha,\omega C_{14}$, as a first additive, the flocculated alumina redisperses in the $\alpha,\omega C_{14}$-SDS and $\alpha,\omega C_{14}$-NP 7.5 systems. For the $\alpha,\omega C_{14}$-SDS and $\alpha,\omega C_{14}$-NP 7.5 systems, the redispersion of alumina proceeds in such a manner that the hydrophobic parts of SDS or NP 7.5 are in contact with the $\alpha,\omega C_{14}$-coated alumina and the hydrophilic polar groups direct out to aqueous solution, resulting in the formation of mixed bilayers on the alumina, while for the $\alpha,\omega C_{14}$-SDS system the adsorption of SDS on the $\alpha,\omega C_{14}$-coated alumina is not enough to attain the redispersion of alumina. The measurement of the ratio I_1/I_3 of intensities of the first and third vibrionic bands of the pyrene monomer fluorescence spectra indicates that pyrene is solubilized in a much lower polar site for the $\alpha,\omega C_{14}$-SDS mixed bilayer than for the mixed bilayer of $\alpha,\omega C_{14}$-NP 7.5.

Recently, we have studied the properties of mixed bilayers[1-3] of surfactants formed on monodispersed ferric hydro sols and on alumina by measuring the zeta potential, the mean particle size, the amounts of surfactants adsorbed, and the fluorescence spectra of pyrene. The formation of the mixed bilayers depends on the combination of surfactants used: the mixed bilayers are more preferentially formed for anionic hydrocarbon-nonionic hydrocarbon surfactants than for anionic fluorocarbon-anionic hydrocarbon surfactants. All of the studies of the mixed bilayers have been limited to combinations of conventional surfactants consisting of a straight-hydrocarbon chain or a fluorocarbon chain and one hydrophilic group.

A bolaform surfactant is composed of a hydrocarbon chain with one ionic or polar head group attached at each of its two ends. Ionic bolaform surfactants show several important differences from conventional surfactants with the same head group.[4-8] The bolaform surfactants have been reported to take a folded, wicket-like conformation at the air-water interface.[5,8] Zana et al.[9] have reported the mixed micellization in mixtures of α,ω-bis(trimethylammonio)alkane dibromide and alkyltrimethylammonium bromide, and they have found that the mixed micellization depends on the matching of the hydrocarbon chain length between bolaform and conventional surfactants, and on their concentrations. This study would lead the possibility of the formation of a mixed bilayer between bolaform and conventional surfactants on particle surfaces.

This work will extend the above approach to the solid/aqueous solution interface. In this paper, the interactions between disodium tetradecanediyl disulfate ($\alpha,\omega C_{14}$) and sodium dodecyl sulfate (SDS) or poly(oxyethylene) nonyl phenyl ether (NP7.5) will be studied through the redispersion behavior of alumina by measuring the zeta potential, the mean particle size of alumina, the amounts of surfactants adsorbed, and the fluorescence spectra of pyrene.

Experimental

Materials. The disodium 1,14-tetradecanediyl disulfate was synthesized as follows. Tetradecanedioic acid supplied by the Tokyo Kasei Co. was reduced to 1,14-tetradecanediol with borane-THF complexes following the esterization of the diol with chlorosulfuric acid. The product was then neutralized by the addition of sodium hydrogencarbonate. The final product was recrystallized twice with mixtures of 2-propanol-water and then with diethyl ether. Sodium dodecyl sulfate was also synthesized and purified. Poly(oxyethylene) nonyl phenyl ether with average oxyethylene chains of 7.5 was obtained from the Nikko Chemicals Co., Ltd., and was used without further purification.

The water used in all experiments was purified by passing it through a Mill-Q system (Nihon Millipore Co.) until its specific conductivity fell below $10^{-7}\ \Omega^{-1}\ cm^{-1}$.

The alumina used was α-alumina of a 99.995% purity supplied by Showa Denko K.K. The specific surface area and the average particle diameter of the alumina were 10.1 $m^2\ g^{-1}$ and 500 nm respectively.

Procedure. As the alumina had an isoelectric point of pH 9.0, the alumina flocculated upon the addition of anionic surfactants at pH 3.5, where the alumina showed an appropriate positive zeta potential value. Then, a second surfactant, different from the first one, was added to the flocculated alumina. After the mixture had reached an adsorption equilibrium, the interaction between first and second surfactants on the alumina was characterized by measuring the zeta potentials and the particle size of the alumina. The zeta potential of alumina was measured using an electrophoresis apparatus (Pen Kem, Laser Zee 500). The particle size of alumina was measured using photocorrelation spectroscopy (Autosizer, Malvern Co.). Further, after the centrifugation of the suspension, the concentrations of all the surfactants except NP7.5 in the supernatant were determined by means of an isotachophoresis method. The concentration of NP7.5, which has an absorption band at 275 nm, was determined by means of a UV spectrophotometer. The amounts

of surfactants adsorbed on the alumina were determined from the difference in the concentration before and after the adsorption.

For the measurement of the fluorescence spectra, the suspension was added to a flask in which pyrene dissolved in ethanol had first been introduced, after which the solvent had been allowed to evaporate. The steady-state emission spectra of the suspensions were obtained using a Hitachi 650-10S fluorescence spectrophotometer. The concentration of pyrene ranged from 1×10^{-6} to 1×10^{-7} mol dm^{-3}. The excitation wavelength of pyrene was at 335 nm.

In order to keep the ionic strength constant, all the measurements were carried out at 25 °C in 10 mmol dm^{-3} sodium nitrate. Nitric acid was used to adjust the pH of the suspension.

Results and Discussion

Figure 1 shows the adsorption isotherms of SDS and $\alpha,\omega C_{14}$ on the alumina. The amounts of SDS and $\alpha,\omega C_{14}$ adsorbed increased at first gradually and then sharply, following a plateau level. This adsorption behavior has been reported by many workers.[10-13]

In order to study the dispersion state of the alumina upon the addition of SDS or $\alpha,\omega C_{14}$, the zeta potentials and the mean particle sizes of the alumina were measured.

Figure 2 shows that the zeta potentials of the alumina decrease with the concentration of both SDS and $\alpha,\omega C_{14}$, then they are reversed, the zeta potential of the alumina upon the addition of SDS being much smaller than that upon the addition of $\alpha,\omega C_{14}$. The mean particle size measurement suggests that the alumina is flocculated by the addition of $\alpha,\omega C_{14}$ above 0.5 mmol dm^{-3} and that it is not redispersed anywhere in the whole concentration region studied, whereas the alumina is flocculated and then redispersed with an increase in the concentration of the SDS additive. By the addition of $\alpha,\omega C_{14}$, the alumina might be covered with $\alpha,\omega C_{14}$ molecules orienting their hydrocarbon chains toward the aqueous solution, resulting in the hydrophobic surface of the alumina and flocculation. This mechanism may be supported by the view that α,ω surfactants generally adopt a folded, wicket-like conformation at an air-water interface.[5,8] On the other hand, SDS molecules are adsorbed on the alumina, orienting their hydrophobic chains toward the aqueous solution, and with an increase in the concentration the bilayer of SDS[14] on the alumina is formed, resulting in a redispersion of the alumina. In this study, it is found that the optimum flocculation con-

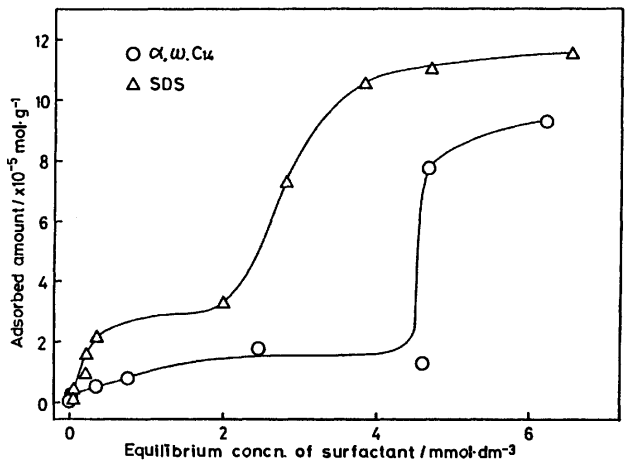

Fig. 1. Adsorption isotherms of SDS and α,ω C_{14} on alumina at 25 °C.

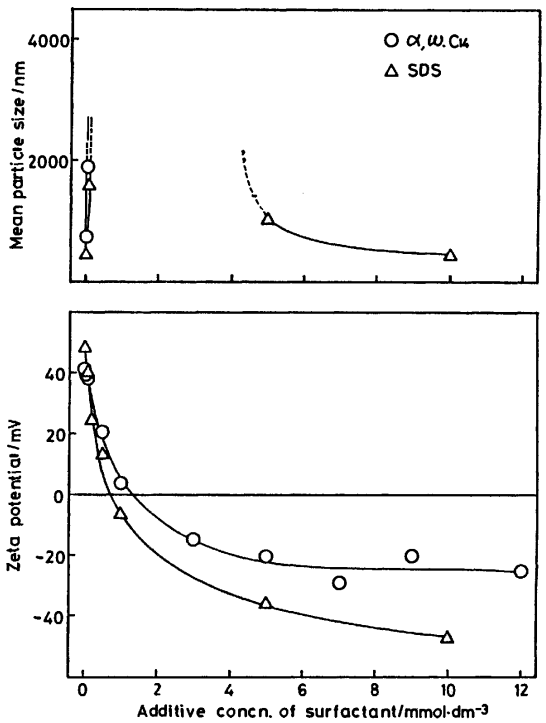

Fig. 2. Changes in mean particle size and zeta potential of alumina with additive concentration of SDS or $\alpha,\omega C_{14}$.

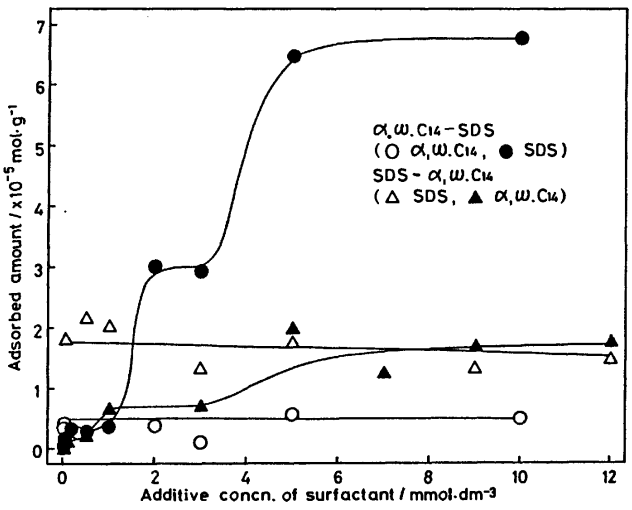

Fig. 3. Amount adsorbed of SDS and α,ω C_{14} on alumina with additive concentration of anionic surfactant for SDS-$\alpha,\omega C_{14}$ and $\alpha,\omega C_{14}$-SDS systems.

centrations of SDS and $\alpha,\omega C_{14}$ for the alumina are about 1 mmol dm^{-3}.

In order to elucidate the interaction between $\alpha,\omega C_{14}$ and SDS or NP7.5 on the alumina, SDS, $\alpha,\omega C_{14}$ or NP7.5 was added to alumina which had been flocculated by the addition of SDS or $\alpha,\omega C_{14}$ at its optimum flocculation concentration.

Figure 3 shows the amounts of SDS and $\alpha,\omega C_{14}$ adsorbed on the alumina for the SDS-$\alpha,\omega C_{14}$ and $\alpha,\omega C_{14}$-SDS systems. Here, the SDS-$\alpha,\omega C_{14}$ system means that in which the alumina is flocculated by the addition of 1 mmol dm^{-3} SDS as a first additive and then $\alpha,\omega C_{14}$ as a second additive to the flocculated alumina. The other systems are studied by the same procedure as the SDS-$\alpha,\omega C_{14}$ system. In the SDS-$\alpha,\omega C_{14}$ system, it is clear that the amount of SDS adsorbed is nearly constant after the addition of $\alpha,\omega C_{14}$, while the amount of $\alpha,\omega C_{14}$ adsorbed is relatively small. This result may imply that the hydrophobicity of the hydrocarbon chain of $\alpha,\omega C_{14}$ is not strong enough to form hydrophobic bonding between SDS and $\alpha,\omega C_{14}$. On the contrary, in the $\alpha,\omega C_{14}$-SDS system, the amount of $\alpha,\omega C_{14}$ adsorbed is almost constant, while the amount of SDS adsorbed increases gradually with the concentration of the SDS additive, suggesting that, with the concentration of the SDS additive, SDS is adsorbed on the hydrocarbon chains of $\alpha,\omega C_{14}$ covering on the alumina, resulting in the formation of a mixed bilayer between SDS and $\alpha,\omega C_{14}$. These differences in adsorption behavior between $\alpha,\omega C_{14}$ and SDS as the second additive may be supported by the fact that the surface activity of a bolaform surfactant[9] is considerably smaller than that of alkyl hydrogensulfate because of the lower hydrophobicity of the bolaform surfactant.

Figure 4 shows that the amount of $\alpha,\omega C_{14}$ adsorbed on the alumina is nearly constant, even after the addition of various concentrations of NP7.5, while the amount of NP7.5 adsorbed increases with an increase in the concentration of the NP7.5 additive. These results imply that with an increase in the concentration of the NP7.5 additive, the $\alpha,\omega C_{14}$ adsorbing on the alumina is not replaced by NP7.5, but a subsequent adsorption of NP7.5 forms mixed bilayers of $\alpha,\omega C_{14}$-NP7.5 on the alumina. This mixed bilayer is probably formed in such a manner that the hydrophobic parts of NP7.5 are in contact with the $\alpha,\omega C_{14}$-coated alumina and the hydrophilic polar groups, i.e., oxyethylene chains, directed out toward the aqueous solution.

Furthermore, in order to characterize the properties of layers adsorbed between $\alpha,\omega C_{14}$ and SDS or NP7.5, pyrene fluorescence experiments were carried out. The pyrene fluorescence fine structure has been found to be remarkably dependent on the solvent: the intensity ratio of I_1/I_3 (I_1, first vibrionic, and I_3 third vibrionic bands at 373 and 383 nm respectively) is sensitive to the solvent polarity.[15] Typically, the I_1/I_3 ratio for pyrene

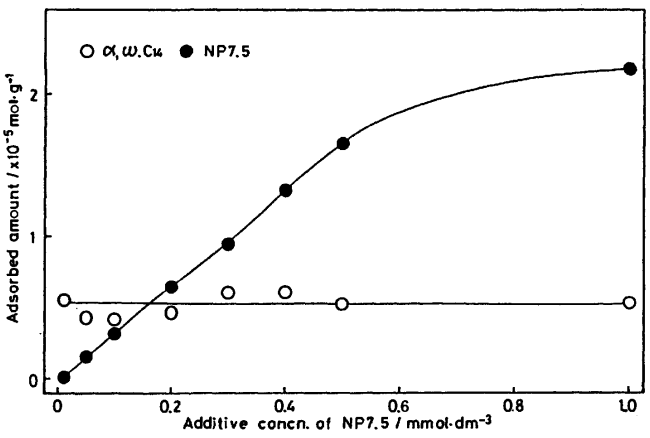

Fig. 4. Amount adsorbed of α,ω C_{14} and NP7.5 on alumina with additive concentration of NP7.5.

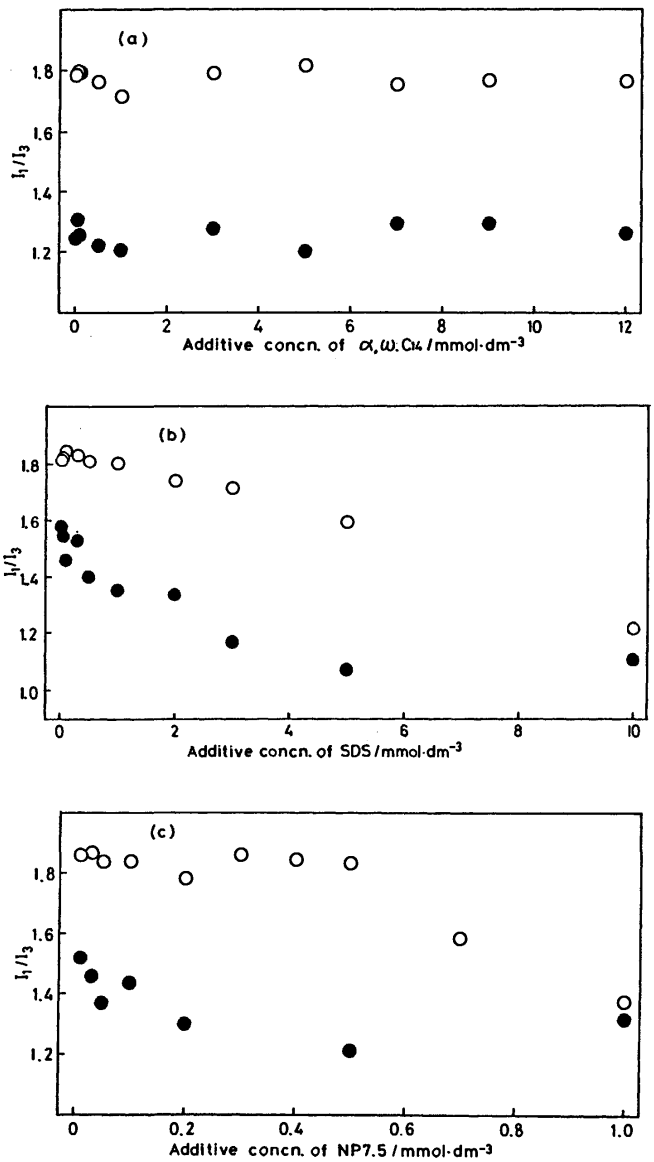

Fig. 5. Changes in I_1/I_3 value of pyrene for(a) SDS-α,ω C_{14}, (b) α,ω C_{14}-SDS, and (c) α,ω C_{14}-NP7.5 systems: open mark, in supernatant; closed mark, in suspension.

changes from 1.8 in water to 0.6 in hydrocarbon media.[16] This fluorescence technique, when applied to an aqueous system[17-20] containing solid particles, has given useful information on the microenvironmental properties of surfactants adsorbed on particles. Figures 5(a) and (b) show the changes in the I_1/I_3 values of pyrene for the SDS-$\alpha,\omega C_{14}$ and $\alpha,\omega C_{14}$-SDS systems. It may be seen that in the SDS-$\alpha,\omega C_{14}$ system, the I_1/I_3 values of the suspension are nearly constant, i.e., 1.2—1.3, even after the addition of various concentrations of $\alpha,\omega C_{14}$ while the I_1/I_3 values of the supernatant range from 1.8 to 1.7. This result indicates that the pyrene is located in hydrocarbon chain of SDS adsorbed on the alumina, for the I_1/I_3 values are very close to that in the SDS micelles. On the other hand, in the $\alpha,\omega C_{14}$-SDS system, the I_1/I_3 values of the suspension decreased from 1.6 to about 1.1 with an increase in the concentration of the SDS additive, while the I_1/I_3 values of the supernatant decreased gradually, reaching about 1.2 at the concentration of the SDS additive, 10 mmol dm^{-3}. This result can be interpreted by the view that pyrene, solubilized in hydrocarbon chains of $\alpha,\omega C_{14}$ adsorbed on the alumina, becomes located at the hydrocarbon chains of SDS, taking into consideration the fact that the I_1/I_3 values of pyrene are about 1.6 for $\alpha,\omega C_{14}$ micelles[8] and about 1.1—1.2 for SDS micelles. It is noteworthy that, on the redispersion state of alumina, the I_1/I_3 values of the suspension are much lower than that of the supernatant, indicating that the mixed bilayer of $\alpha,\omega C_{14}$ and SDS formed on the alumina is much more compact than in the case of the micelle in an aqueous solution.

Figure 5(c) shows that,in the $\alpha,\omega C_{14}$-NP7.5 system, the I_1/I_3 values of pyrene for the suspension decrease with the concentration of the NP7.5 additive until they reach a constant value (1.3), while those for the supernatant also decrease. Above 0.2 mmol dm^{-3} of NP7.5, the mixed bilayer of $\alpha,\omega C_{14}$-NP7.5 begins to be formed, but the amount of NP7.5 adsorbed is not enough to obtain a redispersion state of the alumina below 1 mmol dm^{-3} of NP7.5. In the redispersion state of alumina, the I_1/I_3 values of the suspension are not very different from those of the supernatant, suggesting that the compactness in the mixed bilayer and the mixed micelle is almost the same. The comparison with the I_1/I_3 values for the bilayers shows that the I_1/I_3 value for the $\alpha,\omega C_{14}$-SDS bilayer is lower than that for mixed bilayer of $\alpha,\omega C_{14}$-NP7.5, indicating that the pyrene is solubilized in much a lower polar site for the former than for the latter.

In order to ensure a dispersion state of the alumina for the three systems, the zeta potential and the mean particle size of the alumina were measured. Figure 6 shows that, in the $\alpha,\omega C_{14}$-SDS system, the zeta potential of the alumina decreases with an increase in the concentration of the SDS additive, reaching about −50 mV, while above the concentration of 5 mmol dm^{-3}, the mean particle size is detectable by the Auto-

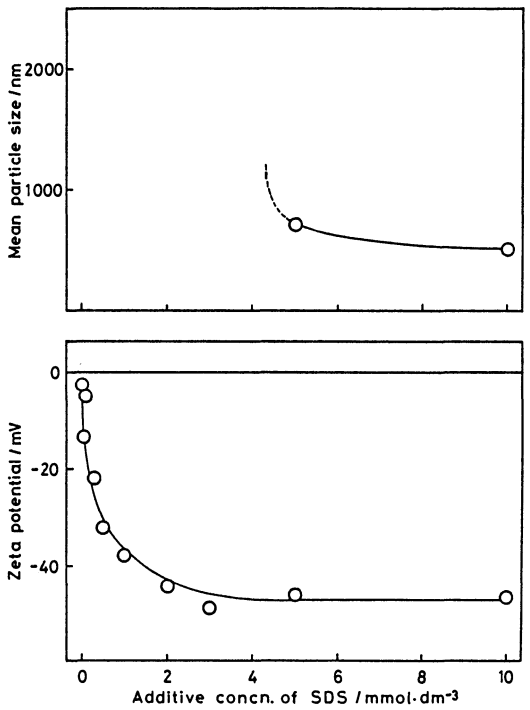

Fig. 6. Changes in zeta potential and mean particle size of alumina with additive concentration of SDS for $\alpha,\omega C_{14}$-SDS system.

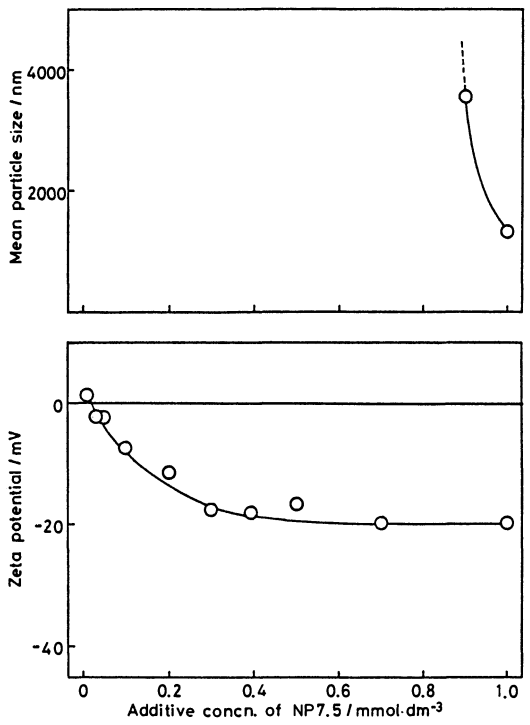

Fig. 7. Changes in zeta potential and mean particle size of alumina with additive concentration of NP7.5 for $\alpha,\omega C_{14}$-NP7.5 system.

sizer. The redispersion state of the alumina is found to be achieved by the concentration of the SDS additive above 5 mmol dm^{-3}. However, although not shown in the figure, in the SDS-$\alpha,\omega C_{14}$ system, the mean parti-

cle size of the alumina could not be measured because of the flocculated alumina, and the zeta potential value of the alumina was not significantly changed. Figure 7 demonstrates that,in the $\alpha,\omega C_{14}$-NP7.5 system, the mean particle size of the alumina decreases with the concentration of the NP7.5 additive, while the zeta potential also decreases. The reason why the zeta potential value is negative, although NP7.5, which is a nonionic surfactant, is adsorbed on the $\alpha,\omega C_{14}$-covered alumina, can not be explained at the present time. It is found that the redispersion state of the alumina can be attained by the addition of more than 1 mmol dm^{-3} of NP7.5.

Thus, these changes in the zeta potential and the mean particle size of the alumina are well correlated with those in the amounts of surfactants adsorbed and in the I_1/I_3 values for the three systems.

This study shows that the alumina previously flocculated by the addition of $\alpha,\omega C_{14}$ redisperses upon the addition of SDS and NP7.5 due to the formation of mixed bilayers of $\alpha,\omega C_{14}$-SDS and $\alpha,\omega C_{14}$-NP7.5 on the alumina, while the alumina previously flocculated by the addition of SDS hardly redisperses upon the addition of $\alpha,\omega C_{14}$ judging from the measurements of the zeta potential, the mean particle size of alumina, and the amounts of surfactants adsorbed. From the measurement of the I_1/I_3 ratio of pyrene, it is found that pyrene is solubilized in a much lower polar site of the $\alpha,\omega C_{14}$-SDS mixed bilayer than in the mixed bilayer of $\alpha,\omega C_{14}$-NP7.5.

Photocatalytic Hydrogen Evolution from Aqueous Solutions of Sodium Sulfite Using Platinum-Loaded $CdS_{1-x}Se_x$ Mixed Crystal Powder

Toshio UCHIHARA,† Hirohisa ABE, Michio MATSUMURA, and Hiroshi TSUBOMURA*
Laboratory for Chemical Conversion of Solar Energy and Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received November 10, 1988)

The $CdS_{1-x}Se_x$ mixed-crystal powder was prepared for the purpose to reduce the band gap of CdS and expand the effective wavelength region of the photocatalyst. Hydrogen evolution was observed from an aqueous solution of 1 M sodium sulfite by use of the mixed-crystal photocatalyst loaded with platinum under illumination at wavelengths longer than 520 nm, where neither the platinum-loaded CdS nor CdSe photocatalyst is active. However, when the mixed-crystal catalysts were illuminated at wavelengths longer than 390 nm or with an AM 1 solar simulator, the rate of the hydrogen evolution was lower than that of CdS. The energy levels of the electronic bands in the mixed-crystals have been clarified from the results of the electrochemical studies, and the fact that the mixed-crystal powder has lower photocatalytic activity than CdS powder has been ascribed to the downward shift of the conduction band edge. These findings are useful in designing photocatalysts for hydrogen production.

Photocatalytic hydrogen evolution on semiconductor particles has been attracting much attention in view of solar energy utilization.[1] Among various semiconductor materials most frequently studied, cadmium sulfide (CdS) is known to have a spectral response in the visible region.[2-8] For the purpose of solar energy utilization, however, semiconductors having smaller band gaps are more suitable because they can convert light energy in a wider spectral region. As a candidate we may take up cadmium selenide (CdSe) because its band gap (1.7 eV) is smaller than that of CdS (2.4 eV) and its physical and chemical properties are similar to those of CdS. It is known, however, that CdSe does not cause hydrogen evolution.[9] We have therefore undertaken to study the photocatalytic properties of the $CdS_{1-x}Se_x$ mixed-crystal powder for the purpose of obtaining efficient photocatalysts working under sun light. The results were analyzed based on the electrochemical measurements of the $CdS_{1-x}Se_x$ sinter electrodes.

The photoelectrochemical properties of the $CdS_{1-x}Se_x$ mixed-crystal electrodes have been reported by some groups.[10-14] Kawai et al.[15] studied the photocatalytic hydrogen evolution from aqueous solutions containing ethanol or formic acid on $CdS_{1-x}Se_x$ powder and concluded that the photocatalytic activity was mainly determined by the energy value of the valence band and the transport property of the photogenerated carriers in the mixed crystal. In this paper, we will emphasize the importance of the height of the conduction band energy for the hydrogen evolution based on our results on the electrochemical measurements.

Experimental

The $CdS_{1-x}Se_x$ powder was prepared by grinding CdS and CdSe powders purchased from Fruuchi Chem. Co., Ltd. in an agate mortar and, then, heating at 750 °C for 20 h under a nitrogen atmosphere in an electric furnace. The ratio of S and Se in the powder was controlled by changing the quantities of the CdS and CdSe powders. The preparation of the $Cd_{1-x}Zn_xSe$ powder from CdSe and ZnSe powders was also attempted in a similar manner. The semiconductor powder thus prepared was loaded with 3 wt% platinum powder by shaking the semiconductor powder and platinum powder in a glass flask.[4] The X-ray diffraction (XRD) patterns of the powder specimens were obtained with a Shimadzu VD-1 diffractometer using the Cu $K\alpha$ radiation. The diffuse reflection spectra were obtained with a Shimadzu UV-360 spectrophotometer equipped with an integrating sphere.

Photocatalytic hydrogen evolution was studied in a 100 ml glass flask containing 30 ml of an aqueous solution of 1 M (M=mol dm^{-3}) sodium sulfite and 300 mg photocatalyst. The pH of the solution was adjusted to 8.0 by addition of boric acid and sodium hydroxide. After the air in the flask was evacuated, the suspension was illuminated with a 500 W xenon lamp combined with a Toshiba L-39 or VO-52 cut-off glass filter, or with an AM 1 (100 mW cm^{-2}) solar simulator (Wacom Co., Ltd.). Hydrogen was the only gaseous product and its amount was determined from the pressure in the glass flask and the total volume of the flask plus the vacuum line used for the pressure measurements.

The sintered disks of CdS, CdSe, ZnSe, and the mixed-crystal materials were prepared by pressure-sintering at 850 °C, applying a pressure of 1.25×10^7 Pa for 10 h under a nitrogen atmosphere. The densities of CdS and CdSe sintered disks prepared by this method were 96 and 89% of the single crystals, respectively, being considerably higher than those obtained by sintering under ambient pressure. The electrodic properties of these disks were studied in a three-electrode cell having such a semiconductor electrode, a platinum counter electrode, and a saturated calomel electrode (SCE). The potential of the semiconductor electrode was controlled with a potentiostat (Nikkokeisoku, NPGS-301). The intensity of incident light was measured with a thermopile (Eppley Lab.).

Results and Discussion

1. Photocatalytic Activity of the $CdS_{1-x}Se_x$ Powder. The XRD pattern of the mixture of CdS and CdSe

† On leave of absence from Department of Chemistry, College of Science, University of the Ryukyus, Nishihara, Okinawa 903-01.

powders without heat treatment consists of diffraction peaks of pure CdS and CdSe powders as seen in Fig. 1a. By heating it at 750 °C for 2 h, the peaks due to CdS and CdSe become weak and new peaks appear at intermediate positions between the corresponding peaks of CdS and CdSe (Fig. 1b). Only the new peaks are observed after heating for 20 h (Fig. 1c), and the positions of the new peaks change continuously with the mole fraction of CdSe (X). These results indicate that homogeneous crystalline particles are formed by heating for a time longer than 20 h at 750 °C. After the heat treatment, the particle size increased to about 3 μm from the original size of the CdS and CdSe particles, about 1 μm.

The reflection spectra of the mixed crystal specimens also changed continuously from that of CdS to that of CdSe along with the fraction X. The reflection spectra were analyzed according to the Kubelka-Munk's equation,[16]

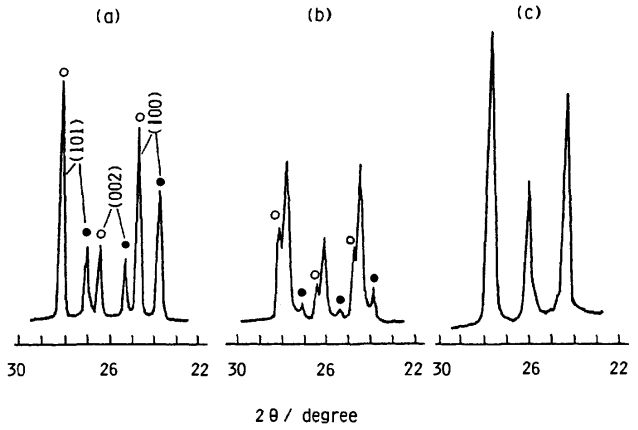

Fig. 1. XRD patterns for the CdS-CdSe mixed powder containing 40 wt% CdSe, before heat treatment (a) and after heat treatment at 750 °C for 2 h (b) and 20 h (c). Open and closed circles denote the peaks assigned to CdS and CdSe, respectively.

$$f(R_d) = \alpha/S = (1-R_d)^2/2R_d \quad (1)$$

where R_d is the relative diffuse reflectance, α the absorption coefficient, and S the coefficient of light diffusion. The $f(R_d)$ calculated is plotted against wavelength in Fig. 2. The $f(R_d)$ value of pure CdS and CdSe powders at the wavelengths corresponding to their band gap energy of 2.4 and 1.7 eV are 4.0 and 3.7 (denoted by points A and B in Fig. 2). Accordingly, the band gaps of the $CdS_{1-x}Se_x$ mixed-crystal specimens are determined from the wavelengths corresponding to the intersections of the curves of the $CdS_{1-x}Se_x$ specimens with the straight line passing through A and B as shown in Fig. 2. The band gaps thus obtained are plotted against X in Fig. 3.

The $CdS_{1-x}Se_x$ mixed-crystal powder was loaded with 3 wt% platinum, and the photocatalyzed hydrogen evolution from an aqueous solution of 1 M sodium sulfite at pH 8.0 was measured under illumination with a 500 W xenon lamp combined with a glass filter. In the solution of sodium sulfite, the platinized CdS photocatalyst was stable[17] and generated hydrogen with quantum efficiencies higher than 20% under illumination at wavelengths shorter than 500 nm.[4,18] When light in the region shorter than 520 nm was eliminated with a cut-off glass filter (VO-52), hydrogen did not evolve on CdS because CdS does not absorb light in the region longer than 520 nm. The CdSe photocatalyst did not evolve hydrogen from the same solution in spite of the fact that it does absorb light in this region. Nevertheless, the $CdS_{1-x}Se_x$ mixed-crystal powder caused hydrogen evolution, the rate showing a plateau at X values from about 0.1 to 0.3 as indicated by the solid line in Fig. 4. As shown by the broken line, higher rates of hydrogen evolution were obtained when the cut-off wavelength was lowered to 390 nm by use of a L-39 glass filter, where pure CdS showed the highest rate. Similar results were

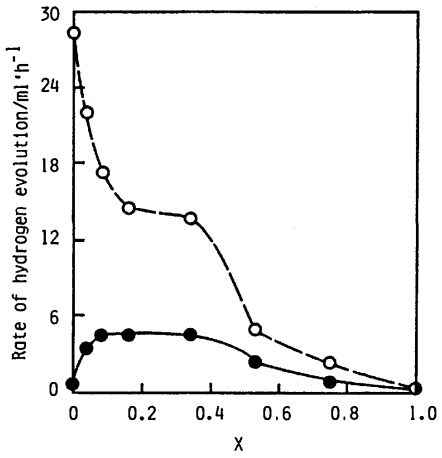

Fig. 4. The Rate of the photocatalytic hydrogen evolution from an aqueous solution of 1 M sodium sulfite (pH 8.0) by use of the $CdS_{1-x}Se_x$ mixed-crystal powder as a function of X. Illumination was made through cut-off glass filters, Toshiba L-39 (○) and VO-52 (●), which showed 50% transparency at 390 and 520 nm, respectively.

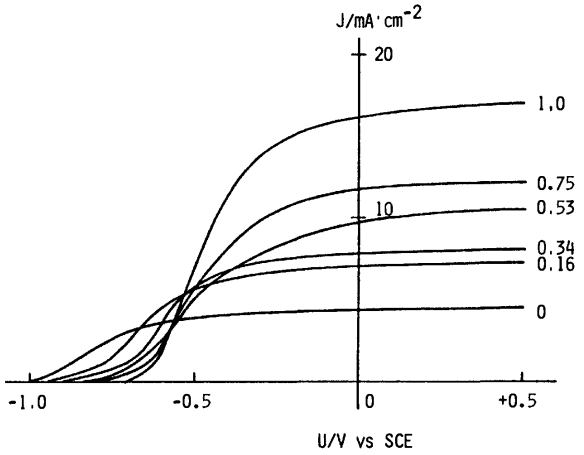

Fig. 5. The J-U curves for the $CdS_{1-x}Se_x$ sinter electrodes in a solution of 1 M sodium sulfite (pH 8.0). Illumination was carried out with an AM 1 solar simulator. The numbers on curves denote X.

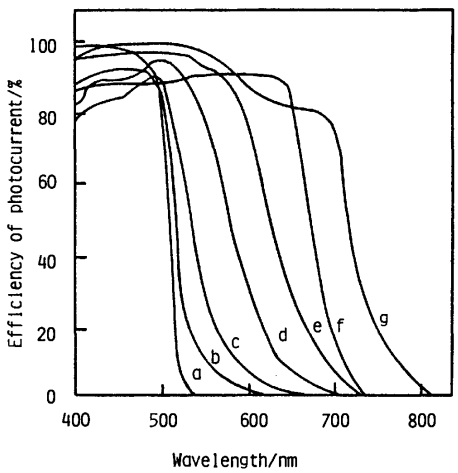

Fig. 6. The photocurrent quantum efficiency spectra for the $CdS_{1-x}Se_x$ sinter electrodes in an aqueous solution of 1 M sodium sulfite under anodic polarization (at +0.5 V vs. SCE) for X values 0 (a), 0.08 (b), 0.16 (c), 0.34 (d), 0.53 (e), 0.75 (f), and 1.0 (g).

obtained when AM 1 solar simulator was used, the pure CdS photocatalyst having the highest activity for hydrogen evolution. Thus, the trial to enhance the reaction efficiency under sun light by use of $CdS_{1-x}Se_x$ mixed-crystals was unsuccessful, although the effective region of wavelengths was expanded.

2. Photoelectrochemical Measurements of the $CdS_{1-x}Se_x$ Sinter Electrodes. For the further understanding of the photocatalyst properties, photoelectrochemical measurements were carried out by use of the $CdS_{1-x}Se_x$ mixed-crystal sinter electrodes, which were prepared by the pressure-sintering of mixed CdS-CdSe powder at 850 °C. The XRD pattern and the reflection spectra revealed that the sintered disks have a homogeneous mixed-crystal structure. Under simulated AM 1 illumination for the electrodes containing various amounts of Se in a solution of 1 M sodium sulfite, the saturated photocurrent density increased with the fraction of Se as shown in Fig. 5. This is explained well on account of the matching of band gaps of the mixed-crystal electrodes with the AM 1 spectrum. Another remarkable feature observed is that the photocurrents start at more positive potentials as the Se fraction increases.

In the absence of sulfite ions in the solution, the photocurrents due to the dissolution of the electrodes rose up from more positive potentials and decayed during illumination for all cases of the $CdS_{1-x}Se_x$ electrodes. That the onset potentials of the photocurrents are more negative in the presence of sulfite ions indicates that sulfite ions react well with positive holes photogenerated in the valence band of the mixed-crystal electrodes and prevent the electrode from corroding. The photocurrents measured in the solution of 1 M sodium sulfite were stable when the electrodes were illuminated at potentials more negative than the onset potential of the photoanodic dissolution currents.

The action spectra for the photocurrents of the mixed-crystal electrodes measured in aqueous solutions of 1 M sodium sulfite under anodic polarization are shown in Fig. 6. The photocurrents rise up at wavelengths corresponding to the band gaps obtained from the reflection spectra. The photocurrent quantum efficiencies of all specimens having various Se fractions showed nearly the same saturation values at short wavelengths, 80 to 95% without correction of the light losses due to the reflection on the electrode surface and the cell window.

The Mott-Schottky plots of the pure CdS sinter electrodes measured in an aqueous solution of 1 M sodium sulfite at 1 kHz gave straight lines and the flat band

potential was deteremined to be −1.01 V vs. SCE, nearly in agreement with the onset potential of the photocurrents. On the other hand, for the case of the $CdS_{1-x}Se_x$ electrodes having X values larger than 0.2, the Mott-Schottky plots did not show straight lines probably because they were porous, so that no flat band potential was determined by this method. So, we used the onset potential of the photocurrents of the $CdS_{1-x}Se_x$ electrodes in the 1 M sodium sulfite solution as a measure of the flat band potentials of the electrodes. It is conceivable that the difference between the Fermi level and the bottom of the conduction band is negligibly small for this case, because the semiconductors are rather highly doped. The solid line in Fig. 7 shows the position of the conduction band thus determined against the X value. The position of the valence band determined by subtracting the band gap energy from the energy level of the conduction band is also shown by the broken line in the figure. The results indicate that the conduction band energy goes down and the valence band energy goes up as the Se fraction increases in the mixed-crystal electrodes. The fact mentioned above that all the $CdS_{1-x}Se_x$ electrodes are fairly well stabilized by sulfite ions in the solution shows that the reactivity of the photogenerated holes in the valence band with sulfite ions is not spoiled by the upward shift of the valence band of the mixed crystal with increasing Se fraction.

When the CdSe electrode was short-circuited with a Pt electrode and illuminated in an aqueous solution of 1 M sodium sulfite, practically no photocurrent was observed. This is explained by taking into account the fact that the conduction band of CdSe is very close to the hydrogen evolution potential (Fig. 7). The bands

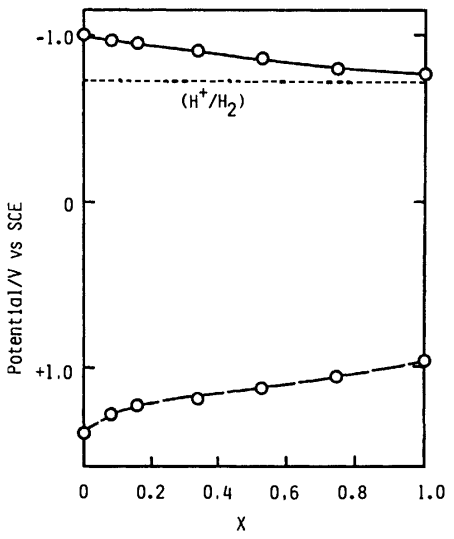

Fig. 7. The estimated energy levels of the conduction band of the $CdS_{1-x}Se_x$ mixed-crystal (solid line) and those of the valence band (broken line) as a function of X in an aqueous solution of 1 M sodium sulfite. The dotted line represents the potential for the hydrogen evolution in the same solution.

are therefore flattened under illumination, leading to very rapid recombination of the photogenerated electrons and holes. This result is in harmony with the inactivity of the CdSe photocatalyst for the hydrogen evolution (Fig. 4). On the other hand, for the case of a CdS electrode connected to a Pt electrode, electron-hole separation occurs efficiently and a photocurrent of 2.3 mA cm^{-2} is observed under AM 1 (100 mW cm^{-2}) illumination.

The highest quantum efficiency of the photocatalytic reaction on Pt-loaded CdS photocatalyst measured in our previous work was about 35%.[18] The efficiency limitation most probably arises from insufficient band bending of the photocatalyst at the working condition.[18] The downward shift of the conduction band by the incorporation of Se into the photocatalyst further weakens the band bending and lowers the efficiency of the photocatalytic reaction. This unfavorable effect caused by the incorporation of Se overcomes the positive effect of expanding the available wavelength region of the photocatalyst and makes the photocatalyst less active under illumination with the solar simulator or the similar light sources.

Kawai et al.[15] observed the lowering of the activity of the $CdS_{1-x}Se_x$ photocatalysts with the increase of X for the hydrogen evolution from aqueous solutions of alcohols. They attributed the reason for this to the upward shift of the valence band, disregarding the change of the energy level of the conduction band. Our results reveal that the energy level of the conduction band is largely changed by the incorporation of Se and this is the main reason for the lowering of the efficiency of the hydrogen evolution.

Noufi et al.[10] and Fujishima et al.[12] reported that the flat band potential of the $CdS_{1-x}Se_x$ mixed crystal electrodes determined from the onset potentials of the photocurrents became the maximum at an intermediate X values between 0.1 to 0.5 in alkaline solutions with and without sulfide ions. However, in our experiments, no maximum was observed for the flat band potential. This is consistent with the result that the band position changes linearly with the electronegativity of the elements of which the semiconductor is made.[19]

3. Characterization of CdSe-ZnSe Mixed Powders. Based on the above consideration, it is expected that the reaction efficiency under sun light may be enhanced if one can find a mixed crystal having a higher conduction band. It has been reported that the conduction band energy of ZnS is much higher than that of CdS and its photocatalytic activity is high under illumination in UV region.[20] From the results obtained so far, it is expected that the conduction band energy will move upward by incorporating a small amount of ZnSe (E_g 2.7 eV) into CdSe. However, the CdSe-ZnSe mixed-powder prepared by us showed very poor photocatalytic activity for the hydrogen production in an aqueous solution of 1 M sodium sulfite.

The reflection spectra of the CdSe-ZnSe mixed-powder samples heat-treated at 750 °C for 20 h showed that CdSe and ZnSe diffuse into each other to some extent. However, the spectra showed more broad tailing at the reflection edge than those of the $CdS_{1-x}Se_x$ powder. The XRD patterns of the heat-treated CdSe-ZnSe mixed powder showed new peaks ascribable to the CdSe-ZnSe mixed phase. They were broader than those of the $CdS_{1-x}Se_x$ mixed-crystal powder. These results suggest that the inhomogeneity of the CdSe-ZnSe mixed powder was not well removed by the heat treatment. The sintered disks of the mixture of CdSe and ZnSe powders prepared by pressure-sintering showed no photocurrents in a photoelectrochemical cell. These results can be explained by assuming that the mixed crystals have too many defect states, causing rapid recombination of the photogenerated carriers.

††Faculty of Textile Science, Kyoto Institute of Technology, Sakyo-ku, Kyoto 606
(Received May 27, 1988)

The extraction behavior of cobalt(II) into 1,1,2,2-tetrachloroethane (TCE) with 8-quinolinol (HQ) from an aqueous solution in the presence of various inorganic anions (X^-) such as perchlorate, nitrate, and chloride ions was studied themodynamically. The extraction equation can be written as

$$2Co^{2+} + 6HQ_{(o)} + X^- \rightleftarrows Co_2Q_3(HQ)_3{}^+{}_{(o)} + X^-_{(o)} + 3H^+$$

The ion-pair of the binuclear complex (complex ion-pair) dissociates to a complex cation and an inorganic anion in the organic phase. The extraction constant increases in proportion to the radius of the counter anion. Changes in the enthalpy and entropy are negative for the overall extraction of cobalt with 8-quinolinol. These thermodynamic parameters were compared with those of zinc and cadmium. The temperature effect on the extraction behavior of cobalt with 8-quinolinol was also investigated in a chloroform system for comparison.

In recent years a number of studies have been carried out concerning the various factors affecting the solvent extraction of a metal chelate. However, only a few thermodynamic studies have been carried out.[1-5] Nakayama[6,7] studied the effect of temperature on the extraction of 8-quinolinol itself and copper, zinc and cadmium chelate of 8-quinolinol into TCE. Yamada et al.[8] clarified the mechanism of a synergistic solvent extraction of metal diphenylcarbazonate using thermodynamic data. It is thought that thermodynamic data provide valuable information regarding extraction mechanisms.

The extraction behavior of cobalt with 8-quinolinol into chloroform has been studied by several investigators.[9-13] It was reported that the species extracted into chloroform is the self-adduct, such as $CoQ_2(HQ)_2$[9,10] or CoQ_2HQ.[11,12] While Sekido et al.[13] found that an ion-pair complex containing a large anion, such as perchlorate, $Co_2Q_3(HQ)_3X$, is extracted below pH 5.1.

In this study, the temperature effects on the extraction behavior of cobalt with 8-quinolinol were investigated in both TCE and chloroform systems.

Experimental

Reagents. 8-Quinolinol was recrystallized twice from ethanol. Cobalt chloride ($CoCl_2 \cdot 6H_2O$) was used to prepare a stock solution of cobalt. A ^{60}Co solution (1 mCi) was obtained from the Japan Radio-isotope Association. Sodium Salts of perchlorate, nitrate and chloride as well as other chemicals were all of analytical grade.

Apparatus. Extraction was carried out in a cylindrical glass tube with a magnetic stirrer in a Yamato BH-71 water bath regulated at a temperature of ±0.05 °C. The cobalt concentration in the aqueous phase was determined by a Rigaku Denki energy dispersive X-ray fluorescence spectrometer Ultra-trace system according to a previously reported method.[14] In the case of $[Co]_{init.} = 10^{-8}$ M ($[Co]_{init.}$ is the initial concentration of cobalt in the aqueous phase, 1M=1 mol dm^{-3}), the concentration of cobalt was determined by measuring the γ-radio-activity of aliquots of both phases with a Packard Auto-Gamma 5100 single-channel pulse-height analyzer. For pH measurements, a Philips PW 9422 pH meter was used.

Extraction Procedure. A 30 ml portion of a buffered cobalt solution was stirred with a 10 ml portion of the 8-quinolinol solution of organic solvent standing in a constant-temperature bath for 30 min (a time period required to attain equilibrium). The initial aqueous solution was adjusted to the desired pH with a small amount of an acetic acid-acetate buffer solution, and to an ionic strength of 0.1 with sodium perchlorate, sodium nitrate or sodium chloride.

After stirring, the pH of the aqueous phase measured in situ was taken as the equilibrium pH. After phase separation, the concentration of cobalt in the aqueous phase was determined by an X-ray fluorescence spectrometer after concentrating cobalt as a diethyldithiocarbamate (DDTC) complex on a Millipore filter. Measurements were carried out by using a Mo anode and a Ge secondary target under excitation conditions of 35 kV-30 mA. The data-accumulation time was usually 100 s and the Co $K\alpha$ line intensity was used throughout the analytical calculations. The equilibrium concentration of cobalt in the organic phase was calculated from the aqueous equilibrium concentration and the initial concentration. The volume of the aqueous phases was corrected for temperature with values of the water density in the Smithsonian tables. The volumes of the organic phases were corrected for temperature using an experimentally determined density function. The density of TCE at any desired temperature employed could be obtained using the formula $1.597 - 1.562 \times 10^{-3}(t-20)$, where t is the temperature in degrees centigrade.

Results and Discussion

Extraction of Cobalt into TCE with 8-Quinolinol in the Presence of Various Inorganic Anions. All investigations were carried out below pH 6.0, because the species containing no anion, $Co_2Q_4(HQ)_2$, may be extracted in higher pH ranges.[13]

Plots of log D vs. pH at 25 °C in the presence of perchlorate, nitrate and chloride ions are shown in Fig. 1. The slopes of 1.5 indicate that the ratios Co : Q^- are 2 : 3, since the predominant species of cobalt in the aqueous phase is considered to be Co^{2+}. The order of the distribution ratios is ClO_4^->NO_3^-> Cl^-. In Figs. 2—4 the relationship between log D vs. log$[HQ]_o$ at various temperatures is shown for perchlorate, nitrate and chloride ions, respectively. In a perchlorate system, the slopes are 3 up to 70 °C. In a nitrate system, the slopes are 3 up to 55 °C. At 70 °C the slope is nearly down to 2. In a chloride system, the slopes change from 3 to nearly 2 above 55 °C. These facts suggest that the extracted species is 1 : 3 chelate at room temperatures and 1 : 2 chelate at sufficiently high temperatures for the nitrate and chloride systems. The effects of the concentration of the inorganic anions (ClO_4^-, NO_3^-, and Cl^-) on the distribution of cobalt in TCE were examined. Here, the ionic strength of the aqueous phase was adjusted to 0.1 with sodium sulfate. All of the plots of log D vs. log$[X^-]$ indicate a slope of nearly 0.5. This suggests that the ratios Co : X^- are 2 : 1.

From the slope analysis stated above, the extracted species is considered to be $Co_2Q_3(HQ)_3X$. In addition, the plots of log D vs. log$[Co]_{aq}$ are constant in the cobalt concentration range from 10^{-6} M to 10^{-4} M. This is generally accepted as being evidence for the existence of a mononuclear complex in the organic phase. However, our analysis of the results suggests

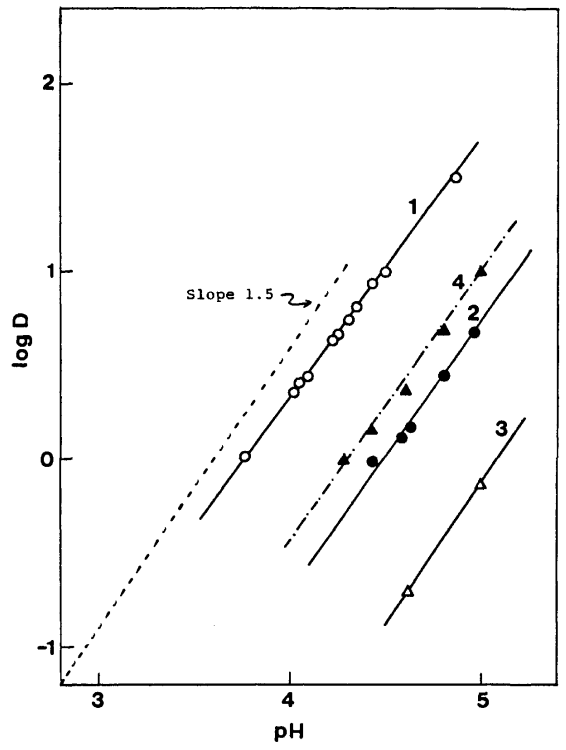

Fig. 1. Effect of pH on the distribution ratio of cobalt between TCE and water in the presence of various inorganic anions at 25 °C.

that the binuclear complex of cobalt dissociates in TCE in a way similar to the case of cadmium and zinc, as previously stated.[6,7]

Therefore, the extraction equation can be given as

$$2Co^{2+} + 6HQ_{(o)} + X^- \rightleftharpoons Co_2Q_3(HQ)_{3(o)}^{+} + X^-_{(o)} + 3H^+. \quad (1)$$

where o refers to the species in the organic phase. The extraction constant is

$$K_{ex} = \frac{[Co_2Q_3(HQ)_3^+]_o\,[X^-]_o\,[H^+]^3}{[Co^{2+}]^2\,[HQ]_o^6\,[X^-]}. \quad (2)$$

To maintain electrical neutrality in the organic phase, $[Co_2Q_3(HQ)_3^+]_o = [X^-]_o$, Eq. 2 can be transformed into

$$K_{ex} = \frac{[Co_2Q_3(HQ)_3^+]_o^2\,[H^+]^3}{[Co^{2+}]^2\,[HQ]_o^6\,[X^-]}. \quad (3)$$

The distribution ratio, D, can be given as

$$D = 2K_{ex}^{1/2}[HQ]_o^3[H^+]^{-3/2}[X^-]^{1/2}. \quad (4)$$

This equation means that plots of $\log D$ vs. $\log[HQ]_o$ show a slope of 3; plots of $\log D$ vs. pH show a slope of 1.5; and plots of $\log D$ vs. $\log[X^-]$ show a slope of 0.5. Thus, the assumption that the ion-pair of the binuclear complex would dissociate in the organic phase agrees well with the experimental results. It is, therefore, apparent that the extraction mechanism of cobalt with 8-quinolinol into TCE is similar to those of cadmium and zinc. The dissociation of an ion-associated complex in an organic solvent whose dielectric constant is relatively large, such as nitrobenzene (34.8), has already reported. However, the dielectric constant of TCE is 8.2 (at 20 °C). In order to certify the dissociation of the binuclear complex in TCE, the conductivities of the extract of zinc into TCE were measured. The results of conductivity measurements support the assumption that the ion-pair of the binuclear complex dissociates into a complex cation and an inorganic anion in TCE.[15] It has already been reported that many compounds, for example triarylmethyl chloride, dissociate in chlorinated ethanes such as 1,2-dichloroethane and TCE whose dielectric constants are not very large.[16,17]

Plots of $\log K_{ex}$ vs. $1/T$ in the presence of perchlorate, nitrate and chloride are shown in Fig. 5. The distribution ratios decrease remarkably with an increase in the temperature for each anion. This trend is more remarkable for a larger anion, such as perchlorate. The slopes of $\log K_{ex}$ vs. $1/T$ plots become gentle for smaller anions, such as chloride. Changes in the slope of $\log K_{ex}$ vs. $1/T$ suggest that the extracted species in high-temperature ranges are different from those in low-temperature ranges. This is supported by the fact that the slopes of plots of $\log D$ vs. $\log[HQ]_o$ become smaller than 3 at high temperatures, especially for the smaller anions as stated above. At high temperatures, the extraction of anhydrous chelate CoQ_2 may occur in a manner similar to zinc extraction with 2-methyl-8-quinolinol.[15] In a perchlorate system, the extractable ion-associated compound is formed even at high temperatures because the ionic redius of perchlorate is fairly large.

The value of the enthalpy change, ΔH, was calculated from the slope. The value of the entropy change, ΔS was calculated from the corresponding ΔH and K_{ex}

values. The results are listed in Table 1. The data show that the extraction of the complex ion-pair is an exothermic reaction. Extraction in the perchlorate system is mainly enthalpy controlled, resulting in a positive $\log K_{ex}$ value. In nitrate and chloride systems, negative enthalpy changes are canceled by large negative entropy changes, resulting in negative $\log K_{ex}$ values. In a nitrate system, the contribution of the entropy is larger than that in a perchlorate system. Plots of ΔG and ΔH of ion-pair extraction of cobalt vs. ΔG and ΔH of hydration of perchlorate, nitrate and chloride ions are shown in Fig. 6. These indicate that the dehydration of perchlorate, nitrate and chloride ions plays an important role in ion-pair extraction. These thermodynamic parameters were compared with those of zinc and cadmium, since the extraction mechanism of cobalt is similar to those of zinc and cadmium. The ΔH values of the extraction of cobalt, zinc and cadmium are listed in Table 2.[7] In perchlorate and nitrate systems, the larger the size of metal ion, the more exothermic is the ion-pair extraction (Co^{2+} 0.72 Å, Zn^{2+} 0.74 Å, Cd^{2+} 0.97 Å[19]). In a chloride system, ΔH values for all metal ions are almost the same.

Extraction of Cobalt into Chloroform with 8-Quinolinol in the Presence of Perchlorate Ion. The extraction behavior of cobalt with 8-quinolinol into chloroform was studied at various temperatures for a comparison with that in the TCE system. The concentration ratio of perchlorate to metal ion in chloroform was 0.5. Plots of $\log D(1+D)$ vs. pH are shown in Fig. 7. Here, the slopes are 3. The distribution decreases with a rise in temperature, which is similar to the case of TCE. Plots of $\log D(1+D)$ vs. $\log [HQ]_o$ are straight lines with slopes of 6. Plots of log D vs. $\log [Co]_{aq}$ give a straight line with a slope of 1 in the vicinity of $[Co]_{init.}=10^{-4}$—10^{-5} M. These results suggest that the extracted binuclear complex of cobalt would almost associate in chloroform, unlike the case in the TCE system. This is probably attributable to the fact that the dielectric constant of chloroform (4.9) is lower than that of TCE. Nevertheless, the dissociation of a com-

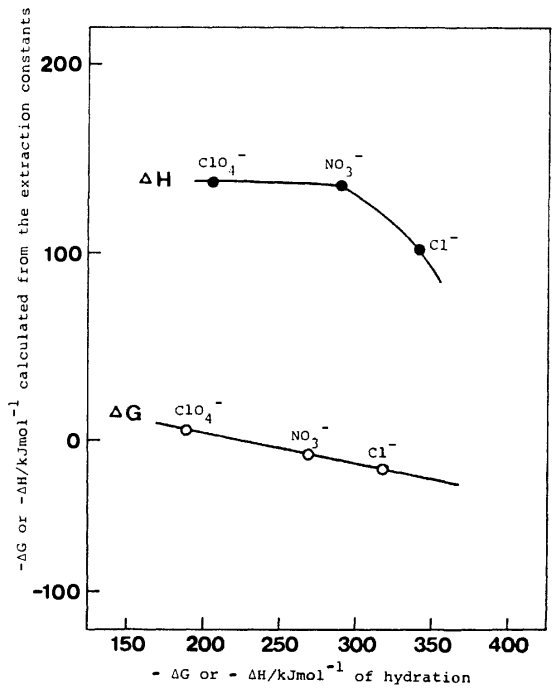

Fig. 6. Relationship between thermodynamic parameters for extraction of cobalt chelates with 8-quinolinol into TCE in the presence of various inorganic anions and hydration energies of those anions.

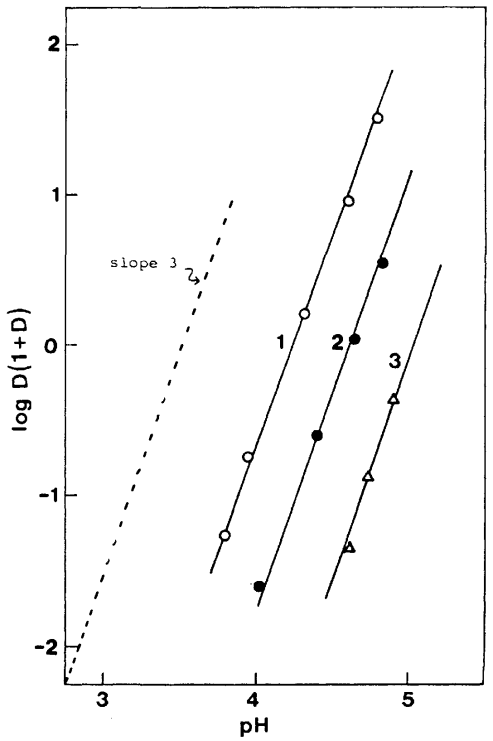

Fig. 7. Effect of pH on the distribution ratio of cobalt between chloroform and water in the presence of perchlorate.
1; 10 °C 2; 25 °C 3; 40 °C.

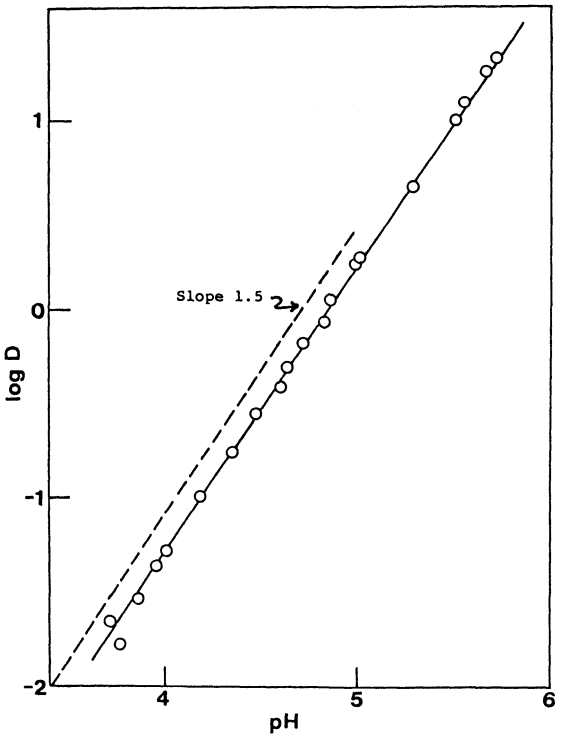

Fig. 8. Effect of pH on the distribution ratio of cobalt between chloroform and water in the presence of perchlorate ion in the case of low $[Co]_{init.}$. $[Co]_{init.}=10^{-8}$ M, $[HQ]_o=10^{-2}$ M, 0.09 M $NaClO_4$ +0.01 M AcOH-AcONa buffer, temp=20°C.

plex ion-pair is expected, even in a chloroform system when $[Co]_{init.}$ is sufficiently low. Figure 8 shows the plots of log$D$ vs. pH in the case of $[Co]_{init.}=10^{-8}$ M. This experiment was conducted by using ^{60}Co as a cobalt tracer. The slope of 1.5 indicates that cobalt is extracted into chloroform by a similar mechanism occurring in the TCE system. Sekido et al. suggested that cobalt is extracted into chloroform as a monomeric complex of 8-quinolinol when $[Co]_{init.}$ is lower than 10^{-6} M from the fact that the log D values are independent of $[Co]_{init.}$ in this concentration range.[13] Our result, however, demonstrates that the dissociation of the complex ion-pair is more likely than the extraction of the monomeric complex.

When $[Co]_{init.}$ is more than 10^{-5} M, the extraction equation can be written as

$$2Co^{2+}+6HQ_{(o)}+ClO_4^- \rightleftharpoons Co_2Q_3(HQ)_3(ClO_4^-)_{(o)}+3H^+. \quad (5)$$

The extraction constant is given by

$$K_{ex}=\frac{[Co_2Q_3(HQ)_3(ClO_4^-)]_o[H^+]^3}{[Co^{2+}]^2[HQ]_o^6[ClO_4^-]}. \quad (6)$$

The distribution ratio, D, is represented by

$$D=2K_{ex}[Co^{2+}][HQ]_o^6[H^+]^{-3}[ClO_4^-]. \quad (7)$$

Since $[Co^{2+}]=[Co]_{init.}/(1+D)$, Eq. 7 can be transformed to

$$D(1+D)=2K_{ex}[Co]_{init.}[HQ]_o^6[H^+]^{-3}[ClO_4^-]. \quad (8)$$

The logK_{ex} values are 4.04, 2.85, and 1.61 at 10, 25, and 40°C, respectively. The logK_{ex} value at 25°C agrees with the value given by Sekido et al.[13] (2.60). Thermodynamic data at 25°C are $\Delta G=-16.3$ kJ mol^{-1}, $\Delta H=-137$ kJ mol^{-1} and $\Delta S=-405$ J K^{-1} mol^{-1}. The values of enthalpy and entropy changes for chloroform are negative, similar to those for ion-pair extraction.

Comparing the extraction mechanism of cobalt 8-quinolinol complex into TCE with that into chloroform, the extracted binuclear complex of cobalt almost dissociates in TCE, while it almost associates in chloroform. Accordingly, it is considered that the difference in the thermodynamic parameters between TCE and chloroform systems would depend on the difference in the thermodynamic parameters of the distribution of 8-quinolinol and its cobalt complex and of the dissociation of the extracted binuclear cobalt complex in TCE. The values of logK_{DR}, ΔH, and ΔS for the distribution of 8-quinolinol are 2.64, −5.02 kJ mol^{-1}, and 33.5 J K^{-1} mol^{-1} for TCE[6] and 2.63, −9.02 kJ mol^{-1}, and 20.0 J K^{-1} mol^{-1} for chloroform,[4] respectively. The difference in the ΔH values for the distribution constant between TCE and chloroform is small. Moreover, the difference in ΔH values for the distribution of binuclear cobalt complex between TCE and chloroform systems may be small because the distribution species of cobalt for TCE is similar to that for chloroform.[15] Then, since the ΔH values for the extraction constant have almost the same values for both solvents, the ΔH value for the dissociation of an extracted binuclear cobalt complex in TCE would not be so large.

This work was supported in part by a Grant-in-Aid for Scientific Research Nos. 58740256 and 59740275 from the Ministry of Education, Science and Culture.

Inversion and Deuteration at the Chiral Nitrogen Centers of [Co(acac or ox)$_2$(Me-en or Me$_3$en)]$^{+or-}$ (acac=2,4-Pentanedionate Ion; ox=Oxalate Ion; Me-en=*N*-Methylethylenediamine, Me$_3$en=*N,N,N'*-Trimethylethylenediamine)

Guilin MA, Tomomi HIBINO, Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464-01
(Received July 15, 1988)

The rates of the base-catalyzed proton exchange (deuteration, k_D) and isomerization (epimerization, k_{ep}) at the chiral amine nitrogen centers of [Co(acac or ox)$_2$(Me-en or Me$_3$en)]$^{+or-}$ in aqueous solutions were measured at 34.0 °C, and the results were compared with one another and with those of related complexes. The deuteration rate is affected more by the nature of coexisting ligands than the overall charge on the complex. The uninegative ox complexes have larger k_D values than the unipositive acac complexes. The k_{ep} values of the ox complexes are ca. 10^4 times as large as those of the acac complexes. For both ox and acac complexes, the complexes with Me$_3$en have larger k_D and k_{ep} values than the complexes with Me-en. The deuteration rates are ca. 10^4—10^5 and ca. 10^2 times greater than the inversion rates for the acac and ox complexes, respectively.

In a previous paper,[1] we reported that the rates of OH^--catalyzed isomerization (epimerization, k_{ep}) and proton exchange (deuteration, k_D) at the chiral nitrogen center of [Co(acac)$_2$(Me-en)]$^+$ are unusually slow, the rates being ca. 10^4 times as small as those of [Co(NH$_3$)$_4$(Me-en)]$^{3+}$.[2] The rates of the same reactions of the sarcosinate ion (sar) in [Co(sar)(Hbg)$_2$]$^{2+}$ (Hbg: biguanide=NH$_2$C(=NH)NHC(=NH)NH$_2$)[3] are also ca. 10^3—10^4 times as small as those of [Co(sar)(NH$_3$)$_4$]$^{2+}$.[4] These results suggest that the rates are largely affected by the nature of coexisting ligands, although deuteration rates at the coordinated amine nitrogen centers are known to increase with an increasing positive charge on the complex.[5] Thus it is interesting to compare the rates of [Co(acac)$_2$(diamine)]$^+$ with those of [Co(ox)$_2$(diamine)]$^-$; both complexes belong to the CoO_4N_2-type, but they have charge of different signs.

In this paper, we report the rates of epimerization and deuteration at chiral nitrogen centers of [Co(acac or ox)$_2$(Me-en or Me$_3$en)]$^{+or-}$. The paper also describes the preparation and some properties of oxalato complexes with related diamines.

Experimental

[Co(acac)$_2$(Me$_3$en)]ClO$_4$ (Me$_3$en=*N,N,N'*-trimethylethylenediamine) was prepared and separated into the two isomers, *Λ*(*R*)*Δ*(*S*) and *Λ*(*S*)*Δ*(*R*), as described previously.[6] Absorption and ^{1}H NMR spectra were measured on a Hitachi 323 spectrophotometer and a Hitachi R-90H spectrometer, respectively.

Λ(R)Δ(S)-Na[Co(ox)$_2$(Me-en)]·H$_2$O, Λ(S)Δ(R)-Na[Co(ox)$_2$(Me-en)]·H$_2$O, Na[Co(ox)$_2$(*N,N*-Me$_2$en)]·0.5NaCl·0.5H$_2$O (*N,N*-Me$_2$en=*N,N*-Dimethylethylenediamine), Λ(RR)Δ(SS)-Na[Co(ox)$_2$(*N,N'*-Me$_2$en)]·2H$_2$O (*N,N'*-Me$_2$en=*N,N'*-Dimethylethylenediamine), Λ(RS)Δ(SR)-Na[Co(ox)$_2$(*N,N'*-Me$_2$en)]·2H$_2$O, and Λ(SS)Δ(RR)-Na[Co(ox)$_2$(*N,N'*-Me$_2$en)]. These complexes were prepared by a similar method to that for Na[Co(ox)$_2$(en)] (en=ethylenediamine).[7] Yield: 20—50%. For Me-en and *N,N'*-Me$_2$en complexes, the complexes were epimerized in dil Na_2CO_3 solution (pH 8—9) for 30 min at room temperature, and then the isomers were separated by Dowex 1×8 column chromatography (eluent: 0.05 mol dm^{-3} NaCl-0.01 mol dm^{-3} HCl). Anal. ($C_7H_{12}N_2CoNaO_9$=*Λ*(*R*)*Δ*(*S*)- and *Λ*(*S*)*Δ*(*R*)-Na[Co(ox)$_2$(Me-en)]·H$_2$O) C,H,N. ($C_8H_{13}N_2Cl_{0.5}CoNa_{1.5}O_{8.5}$=Na[Co(ox)$_2$(*N,N*-Me$_2$en)]·0.5NaCl·0.5H$_2$O) C,H,N. ($C_8H_{16}N_2CoNaO_{10}$=*Λ*(*RR*)*Δ*(*SS*)- and *Λ*(*RS*)*Δ*(*SR*)-Na[Co(ox)$_2$(*N,N'*-Me$_2$en)]·2H$_2$O) C,H,N. ($C_8H_{12}N_2CoNaO_8$=*Λ*(*SS*)*Δ*(*RR*)-Na[Co(ox)$_2$(*N,N'*-Me$_2$en)]) C,H,N.

Λ(R)Δ(S)-Na[Co(ox)$_2$(Me$_3$en)]·H$_2$O and Λ(S)Δ(R)-Na[Co(ox)$_2$(Me$_3$en)]·3H$_2$O. To an aqueous solution (80 cm^3) of K$_3$[Co(ox)$_3$]·3H$_2$O (3.7 g, 9.4 mmol) was added an aqueous solution (20 cm^3) of Me$_3$en (1.35 g, 11.3 mmol). The mixture was stirred for 25 h at room temperature and then filtered. The purple filtrate was diluted with water (1 dm^3), and applied on a column (ϕ2.6 cm×20 cm) of Dowex 1×8 (200—400 mesh). By elution with 0.15 mol dm^{-3} NaCl, a purple, a pink (probably a cobalt(II)-ox complex), and a green ([Co(ox)$_3$]$^{3-}$) band developed in this order. From the purple eluate the complex (a mixture of the two isomers) was isolated as the sodium salt. Yield: 2.6 g (73%). The complex was epimerized and separated into the two isomers, *Λ*(*R*)*Δ*(*S*) and *Λ*(*S*)*Δ*(*R*), in the ratio of 5.2 : 1 by the same method as for the Me-en complex. Anal. ($C_9H_{16}N_2CoNaO_9$=*Λ*(*R*)*Δ*(*S*)-Na[Co(ox)$_2$(Me$_3$en)]·H$_2$O) C,H,N. ($C_9H_{20}N_2CoNaO_{11}$=*Λ*(*S*)*Δ*(*R*)-Na[Co(ox)$_2$(Me$_3$en)]·3H$_2$O) C,H,N.

Na[Co(ox)$_2$(Me$_4$en)]·4H$_2$O (Me$_4$en=*N,N,N',N'*-Tetramethylethylenediamine). This complex was prepared by a method similar to that described for the Me$_3$en complex in a yield of 37% (violet crystals). Anal. ($C_{10}H_{24}N_2CoNaO_{12}$) C,H,N.

Deuteration Studies. The rates of deuteration at the chiral nitrogen centers of [Co(ox)$_2$(Me-en)]$^-$, [Co(ox)$_2$(Me$_3$en)]$^-$, and [Co(acac)$_2$(Me$_3$en)]$^+$ were followed by monitoring N-CH$_3$ signal changes in the ^{1}H NMR spectra as described previously.[1] [Co(acac)$_2$(Me$_3$en)]ClO$_4$ was converted into the more soluble chloride with a Dowex 1×8 anion exchanger in the chloride form. The rates for [Co(ox)$_2$(Me-en)]$^-$ and [Co(acac)$_2$(Me$_3$en)]$^+$ were measured in a phosphate buffer (pD 5.7—7.1) at 34.0 °C, while that for [Co(ox)$_2$(Me$_3$en)]$^-$ in a phthalate buffer (pD 4.3—6.5) at 34.0 °C. The empirical formula, pD=pH meter reading+0.4, was used to calculate

$[OD^-]$.[8]

Epimerization Studies. The rates of epimerization for $[Co(ox)_2(Me\text{-}en)]^-$, $[Co(ox)_2(Me_3en)]^-$, and $[Co(acac)_2(Me_3en)]^+$ in aqueous solutions at 34.0 °C were followed by the same method as that described previously.[1,9] It involves separation of two isomers of the complexes by a high-performance liquid chromatographic method, and analysis of chromatograms changed with reaction time.

Results and Discussion

Two, three, and two isomers (racemic pairs of diastereomers) are possible for $[Co(ox)_2(Me\text{-}en)]^-$, $[Co(ox)_2(N,N'\text{-}Me_2en)]^-$, and $[Co(ox)_2(Me_3en)]^-$, respectively (Fig. 1). All these isomers were separated by Dowex 1×8 column chromatography under acidic conditions. The aqueous solutions should be kept acidic to avoid isomerization (inversion at the chiral nitrogen centers, vide infra). The structures of the complexes were assigned on the basis of the ^1H NMR spectra taking magnetic anisotropy of the carboxyl group into consideration; a complex which shows a doublet attributable to the *N*-methyl group at a higher magnetic field is assigned to the $\Lambda(S)\Delta(R)$-isomer (Table 1).

The distributions of the isomers at equilibrium (34 °C) were analyzed by the reversed-phase high-performance liquid chromatographic technique, and the results are given in Table 1. Table 1 also gives the absorption spectral data for the complexes. Both distributions of the isomers and positions of the d-d absorption bands seem to be related with the steric crowding involved in the isomers. For example, the $\Lambda(S)\Delta(R)$-isomer of $[Co(ox)_2(Me\text{-}en)]^-$, in which the *N*-methyl group is situated over one of the ox ligands and larger steric crowding will be involved than the $\Lambda(R)\Delta(S)$-isomer, is formed less and exhibits the d-d absorption bands at lower energy than the $\Lambda(R)\Delta(S)$-isomer (Fig. 1 and Table 1). The $[Co(ox)_2(Me_4en)]^-$ complex exhibits the d-d absorption bands at the lowest energy in the present complexes (Table 1). The low ligand field strength of the Me_4en ligand was also reported for $[Co(acac)_2(Me_4en)]^+$ and was ascribed to the steric crowding which occurs in the complex.[6,10]

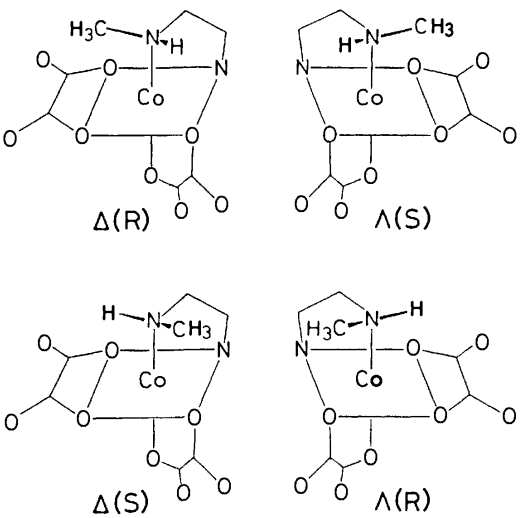

Fig. 1. The four possible isomers of $[Co(ox)_2(Me\text{-}en)]^-$.

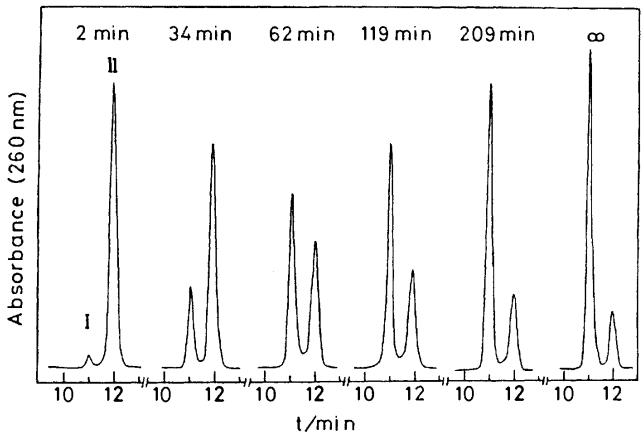

Fig. 2. Change in the elution curve during the epimerization of $\Lambda(S)\Delta(R)$-$[Co(ox)_2(Me_3en)]^-$ at pH 6.03 and 34.0 °C (I: $\Lambda(R)\Delta(S)$ isomer, II: $\Lambda(S)\Delta(R)$ isomer). Chromatographic conditions: column, JASCO Finepack SIL C_{18}, ϕ 0.46 cm×25 cm; eluent, 5×10^{-3} mol dm^{-3} Bu_4NCl in CH_3CN-H_2O (11:89 v/v); flow rate, 2.0 cm^3 min^{-1}; UV detection, 260 nm.

Table 2. A Comparison of Data for the Deuteration and Inversion at Chiral Nitrogen Centers of [Co(ox)$_2$L]$^-$ (L=Me-en, Me$_3$en) and [Co(acac)$_2$L]$^+$ at 34.0 °C

Complex	Isomer	k_D/M^{-1} s^{-1} [b]	k_{ep}/M^{-1} s^{-1}	(k_1 or k_{-1})/M^{-1} s^{-1}	k_D/(k_1 or k_{-1})
[Co(ox)$_2$(Me-en)]$^-$	$\Lambda(R)\Lambda(S)$	2.2×10^4	8.4×10^2	k_{-1}: 2.7×10^2	8.1×10
	$\Lambda(S)\Lambda(R)$	1.8×10^5		k_1: 5.7×10^2	3.2×10^2
[Co(ox)$_2$(Me$_3$en)]$^-$	$\Lambda(R)\Lambda(S)$	1.2×10^5	1.2×10^4	k_{-1}: 2.1×10^3	5.7×10
	$\Lambda(S)\Lambda(R)$	8.1×10^5		k_1: 9.9×10^3	8.2×10
[Co(acac)$_2$(Me-en)]$^+$ [a]	$\Lambda(R)\Lambda(S)$	[c]	1.3×10^{-1}	k_{-1}: 5.9×10^{-2}	
	$\Lambda(S)\Lambda(R)$	8.9×10^3		k_1: 7.1×10^{-2}	1.3×10^5
[Co(acac)$_2$(Me$_3$en)]$^+$	$\Lambda(R)\Lambda(S)$	2.4×10^3	1.0	k_{-1}: 3.4×10^{-1}	7.1×10^3
	$\Lambda(S)\Lambda(R)$	1.1×10^4		k_1: 6.6×10^{-1}	1.7×10^4

a) From Ref. 1. b) 1M=1 mol dm^{-3}. c) The data could not be obtained because of the overlapping of the N-CH$_3$ and C-CH$_3$ signals.

Kinetic studies of reversible isomerization (epimerization) between the two isomers of [Co(ox)$_2$(Me-en)]$^-$, [Co(ox)$_2$(Me$_3$en)]$^-$, and [Co(acac)$_2$(Me$_3$en)]$^+$ were performed in aqueous solutions at 34.0 °C by observing the change in chromatograms with reaction time. Figure 2 shows a typical set of elution curves obtained at intervals after $\Lambda(S)\Lambda(R)$-[Co(ox)$_2$(Me$_3$en)]$^-$ had been dissolved in water at pH 6.03 and 34.0 °C. The pseudo-first-order rate constant, $k_{ep(obsd)}$ was obtained by the method described previously.[1,9] The $k_{ep(obsd)}$/[OH$^-$] ($=k_{ep}$) values are constant at 34.0 °C in the pH range 5.7—6.7 indicating that the reaction is first order in [OH$^-$]. Thus, the rate law was the same as that for racemization (epimerization) of other chiral amine complexes, $R=k_{ep}$[complex][OH$^-$].[11] The runs starting from either of the isomers gave the same result within the experimental error. From these observations, the reaction can be expressed as

$$\Lambda(S)\Lambda(R) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \Lambda(R)\Lambda(S)$$

The forward and reverse second-order rate constants, k_1 and k_{-1}, were obtained from k_{ep} ($k_{ep}=k_1+k_{-1}$) and the equilibrium constant ($K_{eq}=k_1/k_{-1}$) as given in Table 2.

The rates of deuteration at chiral amine nitrogen centers of [Co(ox)$_2$(Me-en)]$^-$, [Co(ox)$_2$(Me$_3$en)]$^-$, and [Co(acac)$_2$(Me$_3$en)]$^+$ were followed by monitoring siganl changes in the ^{1}H NMR spectra. From the changes, the pseudo-first-order rate constants for deuteration, $k_{D(obsd)}$ were obtained by a method similar to that for epimerization. The rate law for the deuteration reaction was the same as that obtained previously for other amine complexes, $R=k_D$[complex][OD$^-$].[11] The k_D values are given in Table 2.

In the deuteration reactions, the term in [OD$^-$] is interpreted as removal of H$^+$ from the coordinated amine to leave a pyramidal center.[4,11] The pyramidal nitrogen center is followed by formation of a trigonal planar amide which leads to the inversion of the nitrogen center (epimerization of the complex).[4,11] Thus the k_{ep} values will be related to both the rate of deuteration and the stability of the trigonal planar amide in the transition state. The k_D values for the $\Lambda(S)\Lambda(R)$ isomers of the present complexes are ca. 5—8 times as large as those for the $\Lambda(R)\Lambda(S)$ isomers. The rate differences can be attributed to a difference in steric effect between the isomers. As is seen in Fig. 1 the secondary amine hydrogen in the $\Lambda(R)\Lambda(S)$ isomer, which is situated over one of the ox ligands, will be more effectively hindered by the ox ring from atacking of OH$^-$ than the hydrogen in the $\Lambda(S)\Lambda(R)$ isomer. The same interpretation is given for the rate difference between the isomers of [Co(acac)$_2$(Me$_3$en)]$^+$.

For both ox and acac complexes, the complexes with Me$_3$en have larger k_D values than the complexes with Me-en. The result seems to be related with a difference in electron density on the secondary amine hydrogen atoms as suggested in the ^{1}H NMR spectra. For example, as one goes from $\Lambda(S)\Lambda(R)$-[Co(ox)$_2$(Me-en)]$^-$ to $\Lambda(S)\Lambda(R)$-[Co(ox)$_2$(Me$_3$en)]$^-$, the amine proton signal (N<u>H</u>(CH$_3$)) is shifted from δ 5.92 to 6.45, suggesting a decrease in electron density at the hydrogen atom in line with the increase in k_D value (Tables 1 and 2). The k_{ep} values for the Me$_3$en complexes are also larger than those for the Me-en complexes.

It is known that deuteration rates increase with an increasing positive charge on the complex (ca. 10-fold for each unit of charge).[5] Thus the unipositive acac complexes are expected to give larger k_D values than the uninegative ox complexes. However, the inverse has been found. The difference in k_{ep} values between the ox and acac complexes is much more pronounced; the k_{ep} values for the ox complexes are ca. 10^4 times as large as those for the corresponding acac complexes. Kawaguchi et al.[3] reported that [Co(sar)(Hbg)$_2$]$^{2+}$ also gives much smaller k_D (ca. 10^4 mol^{-1} dm^3 s^{-1} at 39.6 °C) and k_{rac} ($=k_{ep}$, 13.8 mol^{-1} dm^3 s^{-1} at 35.0 °C) values than those (k_D=1.2 ×10^8 mol^{-1} dm^3 s^{-1} and k_{rac}=3.3×10^4 mol^{-1} dm^3 s^{-1} at 33.3 °C) of the corresponding ammine complex [Co(sar)(NH$_3$)$_4$]$^{2+}$.[4] These results suggest that the reactivity of coordinated secondary amine nitrogen center is affected more by the kind of coexisting ligands than the overall charge on the complex. The reason for the small rates of the acac and Hbg complexes remains unknown. However, it is worth noting that both acac and Hbg ligands form a chelate ring with delocalized π-electrons.

The $k_D/(k_1$ or $k_{-1})$ ratios (retention ratios) for $[Co(acac)_2(Me\text{-}en$ or $Me_3en)]^+$ (ca. 10^4—10^5) are similar to that for $[Co(NH_3)_4(Me\text{-}en)]^{3+}$ (2.5×10^5 at 34.3 °C),[2] and the values imply that the configuration about the chiral nitrogen atom (pyramidal configuration) is retained most of the time that the proton is off the quarternary N site. On the other hand, the retention ratios for $[Co(ox)_2(Me\text{-}en$ or $Me_3en)]^-$ (ca. 10^2) and $[Co(sar)(Hbg)_2]^{2+}$ (10^2—10^3) are small. The smaller retention ratios may result from an increased stabilization of the trigonal planar amide in the transition state.[2,12] However, the factors governing the retention ratio for the above complexes are not clear at the moment. More kinetic data will be needed to elucidate the effect of coexisting ligands on the reactivity of coordinated amine nitrogen center.

(Received August 18, 1988)

An X-ray diffraction study of the title complex has been carried out, along with spectroscopic measurements and thermal analyses. The crystal is orthorhombic, space group $P2_12_12_1$, Z=4, a=9.978(2), b=12.624(3), c=7.129(1) Å, U=898.0(3) Å^3. Block-diagonal least-squares refinements have led to the final R value of 0.032. The structure consists of a one-dimensional polymer chain bridged by a carboxylato group of an *N,N*-diethylglycinato ligand. One oxygen atom in the carboxylato group is coordinated to two copper atoms, and the other is coordinated to one of these two copper atoms. This is the same bridging form as in aquachloro(4-hydroxy-L-prolinato)copper(II). The copper atom reveals a distorted five-coordination: the copper atom is surrounded by three carboxylato oxygen atoms, one nitrogen atom, and one chlorine atom. The infrared spectra of the title complex and of aquachloro(4-hydroxy-L-prolinato)copper(II) both show the characteristic pattern at the peaks assigned to the vibrations of the carboxylato group. The peaks can be an indicator of the bridging form.

The amino acids with a pyrrolidine ring, 4-hydroxy-L-proline (Hhpro) and L-proline (Hpro) (their anion ligands abbreviate to hpro and pro, respectively), have slightly different structural features from other α-amino acids. Some interesting properties of their metal complexes are reported. To give an example, the solution of Cu^{II} complex with an L-amino acid, in general, exhibits a negative circular dichroism (CD) band at near 600 nm, and that of a D-amino acid has a positive one. But those of L-pro and L-hpro both exhibit a positive CD band at near 600 nm.[1,2] Another example is as follows. The four possible isomers, *Λ-fac, Λ-fac, Δ-mer*, and *Λ-mer*, are all obtained in the tris amino acid complexes of Co^{III} with L-alanine, L-valine and L-leucine. However, in the L-pro complex only three isomers can be isolated, and *Λ*-mer isomer can not be obtained.[3] These facts are based on the characteristic structures of Hhpro and Hpro. Therefore studies about syntheses, properties, and structures of some metal complexes with Hhpro and Hpro have been carried out in our group.[4-8]

A complex was prepared from $CuCl_2$ and Hhpro ([CuCl(hpro)(H_2O)]),[5] and its crystal structure was discussed.[8] In this work, a complex was prepared from $CuCl_2$ and *N,N*-diethylglycine (Hdeg; the anion ligand abbreviates to deg); its structure was determined and its spectroscopic data and thermal behavior were investigated, in order to compare the results with those of [CuCl(hpro)(H_2O)]. The aim of this study is to confirm whether the interesting bridging form existing in [CuCl(hpro)(H_2O)] is characteristic for amino acid ligands having a pyrrolidine ring (e.g. hpro), or whether it can also be formed by other *N*-substituted amino acids like Hdeg.

Experimental

Preparation of Chloro(*N,N*-diethylglycinato)copper(II). To an ethanol solution (100 cm^3) of 1.53 g (0.01 mol) of sodium *N,N*-diethylglycinate, 1.34 g (0.01 mol) of dichlorocopper(II) was added. As $CuCl_2$ was dissolved, sodium chloride was precipitated. As soon as $CuCl_2$ was dissolved completely, centrifugation of the solution was carried out until NaCl was removed. Dark blue crystals were obtained from the solution by keeping it at room temperature for several days. The crystals were recrystallized from methanol. Found: C, 31.53; N, 5.97; H, 5.22%. Calcd for $CuCl(C_6H_{12}NO_2)$: C, 31.44; N, 5.97; H, 5.28%.

X-Ray Measurements and Structure Determination. The crystal data are as follows. The crystal is orthorhombic, space group $P2_12_12_1$, Z=4, a=9.978(2), b=12.624(3), c=7.129(1) Å, U=898.0(3) Å^3, D_m=1.67 g cm^{-3}, D_m=1.70 g cm^{-3}, μ(Mo $K\alpha$)=27.7 cm^{-1}. The size of the crystal used for the measurement was 0.15×0.16×0.14 mm^3. The reflection intensities were collected by the ω-2θ scan technique (measured range 3—60° (2θ); scan width 1.30° (θ); scan speed 4° min^{-1} (θ)) on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The measured reflections were 1598, of which 1255 ($|F_o|>3\sigma(|F_o|)$) were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but not for absorption and extinction.

The structure was solved by a heavy-atom method. The positions of the copper and chlorine atoms were deduced on a three-dimensional Patterson map; other atoms were located by successive Fourier syntheses. Their positional, isotropic and then anisotropic thermal parameters (except for hydrogen atoms) were refined by the block-diagonal least-squares method. Isotropic temperature factors for hydrogen atoms of -CH_3 in -CH_2CH_3 were assumed to be 4.0 Å^2. All the calculations were carried out on a HITAC M-680H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS program.[9] The atomic scattering factors were taken from Ref. 10. The final R value was 0.032 and R_w was 0.038.[11]

The Other Measurements. The simultaneous thermogravimetric (TG) and differential thermal (DTA) analyses were carried out with a Rigaku Denki "Thermoflex" M-8075 using a sample weighing about 7.8 mg; the heating rate was 5 °C min^{-1} in air; α-alumina was used as the reference.

The infrared spectra of the sample were obtained by means

of a Hitachi 295 type infrared spectrophotometer, using Nujol mull and KBr disks.

Visible and ultraviolet spectra were measured on a Hitachi U-3200 Spectrophotometer.

The magnetic moment was obtained for the solid sample by the Gouy method at room temperature, using Hg[Co(SCN)$_4$] as a calibration standard.

Results and Discussion

The final atomic parameters are listed in Table 1, the interatomic distances in Table 2, and the bond angles in Table 3.[12] The perspective drawing of the complex and the numbering scheme of the atoms are shown in Fig. 1.

Table 1. Final Positional Parameters ($\times10^5$ for Cu and $\times10^4$ for the Other Non-Hydrogen Atoms) and Equivalent Isotropic Temperature Factors (B_{eq}/Å^2), with the Estimated Standard Deviations in Parentheses

Atom	x	y	z	B_{eq}[a]
Cu	19430(5)	38573(4)	28463(7)	2.02
Cl	1828(1)	2325(1)	1390(2)	3.46
O(1)	2239(3)	4935(3)	4756(4)	2.73
O(2)	1230(3)	5844(2)	6984(4)	2.63
N	1(3)	3908(3)	3755(5)	2.11
C(1)	1209(4)	5244(3)	5605(6)	2.14
C(2)	−136(4)	4882(4)	4855(6)	2.60
C(3)	−978(4)	3874(4)	2170(7)	2.91
C(4)	−739(5)	4713(4)	710(8)	3.94
C(5)	−244(5)	2968(4)	4972(7)	3.20
C(6)	748(5)	2837(4)	6528(8)	4.08

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2)$.

Key to symmetry operations: I. 0.5−x, 1.0−y, −0.5+z; II. 0.5−x, 1.0−y, 0.5+z.

The structure of the complex consists of a one-dimensional polymer chain bridged by only one carboxylato group of deg. One carboxylato oxygen atom of the deg is coordinated to two copper atoms to form an oxygen bridge, and the other is coordinated to one of these two copper atoms. Therefore the carboxylato group forms a four-membered chelate ring. It is the same bridging form as that of the hpro in [CuCl(hpro)(H$_2$O)] forms.[8]

The copper atom is surrounded by five atoms: three carboxylato oxygen atoms, one nitrogen atom, and one chlorine atom. The coordination type can not be assigned to a typical five-coordination polyhedron, a trigonal-bipyramid or a square-pyramid. It may be an extremely distorted tetrahedron, if the whole of the carboxylato group (forming the four-membered chelate ring) is regarded as an unidentate ligand.

The bond length of Cu-Cl, 2.199(1) Å, is a common value as a bond of Cu-Cl(terminal), which is different from Cu-Cl in [CuCl(hpro)(H$_2$O)]. The other bond lengths are common values except for Cu-O(1)^{I}, 2.801(4) Å. The rather long distance of Cu-O(1)^{I}, however, is not very surprising as discussed previously.[8]

In this complex, one of the two types of the chelate rings, the four-membered ring formed by Cu, O(1)^{I}, C(1)^{I}, and O(2)^{I}, is a fairly flat plane: the deviations from the least-squares plane are: Cu^{II} (0.007 Å), O(1)^{I}

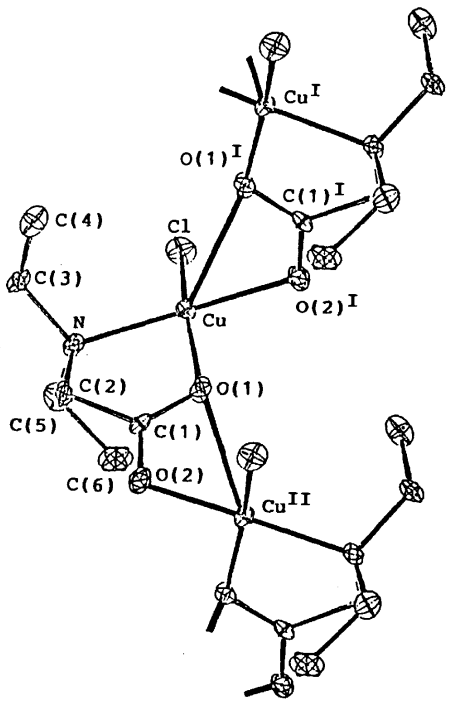

Fig. 1. The perspective drawing of [CoCl(deg)] and the numbering scheme of the atoms. Thermal ellipsoids are drawn at 30% probability level.
Key to symmetry operations: I. 0.5−x, 1.0−y, −0.5+z; II. 0.5−x, 1.0−y, 0.5+z.

(−0.013 Å), C(1)^{I} (0.028 Å), O(1)^{I} (−0.022 Å). The other, five-membered ring formed by Cu, O(1), C(1), C(2), and N, is slightly distorted; C(2) and N deviate from the plane formed by the five atoms in opposite directions. The distortion is not found in [CuCl(hpro)(H_2O)].[8] The difference of the five-membered chelate ring between [CuCl(hpro)(H_2O)] and [CuCl(deg)] is likely to be based on the difference of the positions of N and C(2) in each amino acid ligand. In hpro, N and C(2) belong to a pyrrolidine ring. On the other hand, N and C(2) in deg can be shifted more easily than those of hpro. The N and C(2) in deg, may deviate from the above mean plane in order to avoid the steric hindrance by ethyl groups connected to the nitrogen atom. The ethyl groups may also play a role of preventing coordination of a solvent molecule.

The projection of the structure along the c axis is given in Fig. 2. The polymer chains arrange in parallel with the c axis. There is no hydrogen bond, since the complex does not have any hydrogen donors, different from [CuCl(hpro)(H_2O)]: in [CuCl(hpro)(H_2O)], there are two types of hydrogen bonds, inter- and intrachain hydrogen bonds, between the water oxygen and chlorine atoms.

The structure of [CuCl(deg)] has the same bridging form as that of [CuCl(hpro)(H_2O)], though the coordination environment of the copper atom and the formation of the hydrogen bonds are different, as mentioned above. The bond lengths of Cu-N in [CuCl(deg)] and in [CuCl(hpro)(H_2O)] are 2.044(3) Å and 2.024(5) Å, respectively. Both of them are slightly longer than that common for Cu-N. It is suggested that the interesting bridge is formed when the nitrogen atom in an amino acid ligand makes the longer bond to the metal, because of steric hyndrance due to *N*-substituted groups. The coordination number of a metal or hydrogen bonding is not a principal cause of the formation of the bridging.

The magnetic moment of [CuCl(deg)] is 1.86 B.M. This is close to the value of [CuCl(hpro)(H_2O)], 1.89 B.M. The value is a little lower than those of the common octahedral copper(II) complexes, but the apparent Cu-Cu interaction is not considered. The result is supported by Cu-Cu atomic distances: 4.72 Å in [CuCl(deg)], and 4.46 Å in [CuCl(hpro)(H_2O)].

Infrared spectra of [CuCl(deg)] and [CuCl(hpro)(H_2O)] are shown in Fig. 3. There is a characteristic large split peak around 1600 cm^{-1} in both complexes, and near 1400 cm^{-1} a slightly split peak (in [CuCl(hpro)(H_2O)]) or a peak with a shoulder (in [CuCl(deg)]). These peaks are assigned to COO^- antisymmetric and symmetric stretching vibrations, respectively. The shapes of the peaks reflect the coordination form of the carboxylato group. Therefore the peaks can be an indicator of this coordination type, without reference to whether the amino acids have a pyrrolidine ring or not. The bis-chelate complex, [Cu(deg)$_2$(H_2O)$_2$], has the peak at 1617 cm^{-1} (COO^- antisymmetric). This agrees well with the higher frequency peak of the COO^- antisymmetric split peaks of [CuCl(deg)]. Moreover, the COO^- symmetric vibration of [Cu(deg)$_2$(H_2O)$_2$] has the same frequency (1381 cm^{-1}) as that of [CuCl(deg)].[13] These similarities are also found for [Cu(hpro)$_2$] and [CuCl(hpro)(H_2O)]: [Cu(hpro)$_2$] has the peaks at 1592 cm^{-1} and 1407 cm^{-1} and they agree with the higher frequency peaks between the respective corresponding split peaks of [CuCl(hpro)(H_2O)]. Therefore, in the interesting carboxylato bridging, the COO^- anti- and symmetric vibrations which are also shown in the normal amino acid chelate are kept and the new vibrations are added.

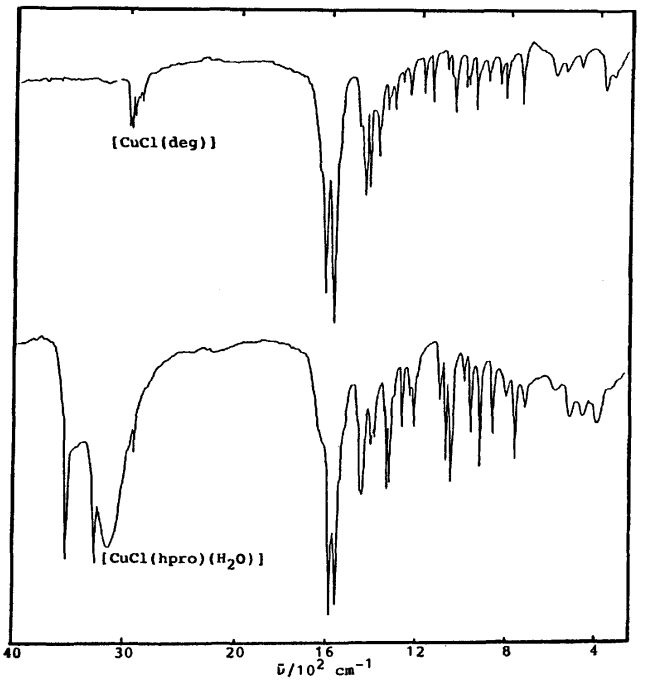

Fig. 3. Infrared spectra of [CuCl(deg)] and [CuCl(hpro)(H_2O)].

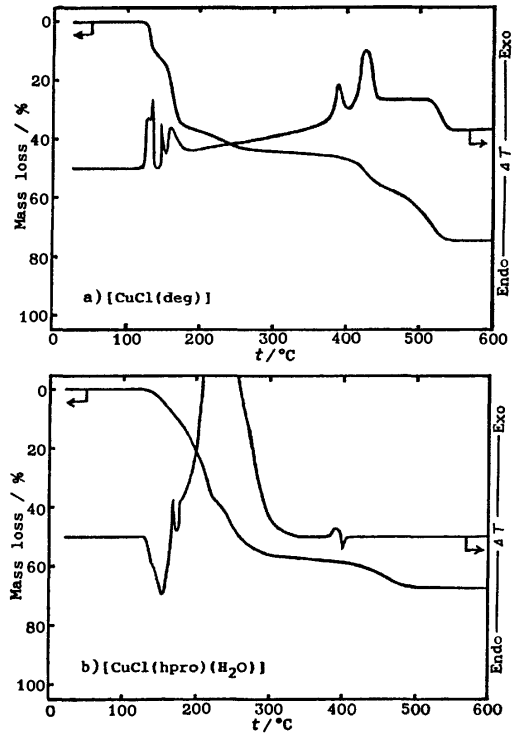

Fig. 4. The thermogravimetric and differential thermal analysis curves of [CoCl(deg)] and [CuCl(hpro)(H_2O)].

(756 nm ($\log\{\varepsilon/mol^{-1}\,dm^3\,cm^{-1}\}$=1.87), 266 nm (3.74)) is different from the powder diffuse reflection spectrum (609 nm (shoulder ca. 750 nm))[14] in [CuCl(deg)], which is similar to that observed in [CuCl(hpro)(H_2O)]. The deg complex is also likely to change into a six-coordinated Cu^{II} complex cation in the solution. The peak in the methanol solution, 756 nm, is closer to that in the powder diffuse reflection spectrum in [CuCl(hpro)(H_2O)] rather than to the corresponding peak of the electronic spectrum in [CuCl(hpro)(H_2O)]. The fact may indicate that the coordination polyhedron is not a typical shape, i.e. an elongate-octahedral symmetry due to coordination of solvent molecules along the axis normal to the molecular plane, but a widely different shape from an octahedron. The effect of the difference in solvent could not be checked, because the deg complex is hydrolyzed in the aqueous solution.

The results of the simultaneous TG and DTA of [CuCl(deg)] and of [CuCl(hpro)(H_2O)] are shown in Fig. 4. In the former, the decomposition began at about 130 °C, with some exothermic peaks on the DTA, and beyond 540 °C, black ash was obtained. In [CuCl(hpro)(H_2O)], after the elimination of water molecules (endothermic reaction), the decomposition began immediately and the black ash was obtained at the final stage. Both complexes change into CuO in the last place, but the process of the decomposition of each amino acid is different. It appears that the deg in [CuCl(deg)] decomposes through some steps, but in [CuCl(hpro)(H_2O)] the hpro decomposes at once. The difference may be based on the difference of the structure of the amino acid: the deg has two flexible ethyl groups, while the hpro has a rigid pyrrolidine ring.

The authors wish to express their thanks to Professor Akira Ouchi of The University of Tokyo and Associate Professor Mamoru Shimoi of Tohoku University for X-ray diffractometer measurements. They gratefully acknowledge the assistance on the structure-analysis calculations given by Mr. Kimitake Aoyagi of Sophia University. Thanks are due to Associate Professor Yoshio Masuda of Niigata University for TG and DTA measurements. They would also like to thank Dr. F. S. Howell of Sophia University for correcting this manuscript.

The Solubility of (Biphenyl, Naphthalene)-(Benzene, Cyclohexane, 1-Octanol) Binary Mixtures in Water

Isao SANEMASA,* Masaya KUMAMARU, Kazunari ISHIBASHI, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received August 23, 1988)

The solubility in water at 25 °C of binary mixed solutes, combinations of biphenyl and naphthalene with benzene, cyclohexane, and 1-octanol, was measured using a shake-flask method. As a function of biphenyl or naphthalene mole fraction, activity coefficients of biphenyl and naphthalene in benzene, cyclohexane, and 1-octanol, and those of benzene in biphenyl-benzene and naphthalene-benzene binary systems have been determined.

The solubility of hydrocarbons in water is still an important physicochemical property, and a large number of data have been accumulated. Most of the available data are concerned with the solubility of pure compounds, and there are only a few reports concerning the aqueous solubility of mixed solutes. For a better understanding of natural environment, it is essential to study mixed solute systems, since mixed organic compounds rather than a single solute is what we encounter in reality, e.g., spilled oil on water surface.

The study of aqueous solubility of binary organic solutes is also important in considering partition of an organic solute between aqueous and organic phases. The partition coefficient of a chemical is thought to be a measure of its relative hydrophobicity and considered to be a significant factor of bioaccumulation: the chemical with a large partition coefficient is likely to be accumulated into fish body.[1-3]

The object of this work is to determine activity coefficients of biphenyl and naphthalene in benzene, cyclohexane, 1-octanol, and water by measuring the solubility of these solid solutes in water.

Experimental

Materials. Deionized redistilled water was used throughout this work. Biphenyl, naphthalene, benzene, cyclohexane, and 1-octanol were of analytical reagent grade and used without further purification.

Apparatus and Procedures. Aqueous solutions saturated with binary solute mixtures were prepared in a glass vessel consisting of two parts. The upper part (300 cm^3 capacity) and the lower part (200 cm^3 capacity) were connected by a ground glass joint with stopcock. A side-arm with a stopcock was attached to the lower bottle at 2 cm above the bottom. The binary solute mixture (20—30 cm^3) was placed with 100 cm^3 of water in the lower bottle and the vessel was immersed up to above the stopcock of the joint in a water bath thermostated at 25.0±0.1 °C. The stopcock was closed and the contents were stirred for at least 24 h by a Teflon-coated magnet in the bottom. The vessel was then allowed to stand for at least 24 h without stirring and taken out of the bath. The upper part of the vessel was lightly evacuated through a stopcock attached to the top of the vessel. The top stopcock was closed, then the middle one with the joint was temporarily opened to reduce pressure inside the lower bottle, and air was carefully introduced into the bottle through the side arm by operating its stopcock to remove any solute droplets present inside the side arm. Then, the vessel was immersed again in the bath and stood for 24 h. A portion of the aqueous solution was withdrawn via the side arm, weighed, and extracted with cyclohexane.

The UV absorption of the extract was examined for biphenyl, naphthalene, and benzene at 247.5, 285, and 254 nm, respectively, on a Hitachi 100-50 spectrophotometer. The absorbance of benzene at 285 nm is practically negligible, while that of naphthalene at 254 nm cannot be neglected. Correction for naphthalene absorbance was made on benzene measurements; the contribution of naphthalene amounted to 3—20% depending on the relative concentration of naphthalene and benzene in the cyclohexane extract.

Because of a relatively high solubility of benzene in comparison with biphenyl, the absorbance of benzene at 247.5 nm is very strong, and hence, biphenyl cannot be determined directly on the cyclohexane extract. We overcame this problem by making use of the fact that in the presence of β-cyclodextrin the volatilization rate of benzene from aqueous into gaseous phase is much larger than that of biphenyl: Biphenyl forms more stable 1:1 complex with β-cyclodextrin than benzene does.[4] A 20 cm^3 portion of the aqueous solution containing biphenyl and benzene was taken into a cylindrical test tube (100 cm^3), to which 5 cm^3 of β-cyclodextrin (10^{-2} mol dm^{-3}) was added. The test tube was immersed in a water bath at 25.0±0.1 °C, and nitrogen was bubbled in the solution through a sintered glass ball at a rate of 500 cm^3 min^{-1} for 30 min. The content was diluted with water to 80 cm^3, and extracted with cyclohexane. Under the N_2 bubbling condition, 98.0% of benzene present initially was driven out of the solution, while 62.0% of biphenyl remained in the solution.

The absorbance of biphenyl at 254 nm cannot be neglected, and its correction was made on benzene measurements: the contribution of biphenyl was in 3—30% range.

Results and Discussion

Solubility in water of benzene, biphenyl, and naphthalene in binary mixtures was measured at 25 °C, but that of cyclohexane and 1-octanol was not measured. The results are shown in Figs. 1 and 2 as a function of biphenyl or naphthalene mole fraction. These solubility data were treated by the curve-fitting method as follows:

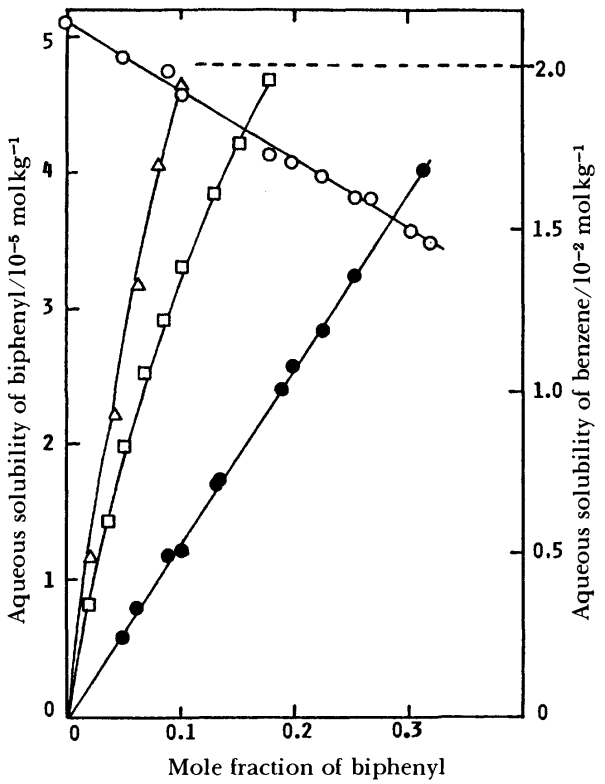

Fig. 1. Biphenyl-(benzene, cyclohexane, 1-octanol) binary systems at 25 °C. Aqueous solubility of biphenyl; ●: benzene system, □: cyclohexane system, △: 1-octanol system. Aqueous solubility of benzene; ○: biphenyl-benzene system. The dotted horizontal line shows the aqueous solubility of biphenyl determined at 25 °C for the solid solute.

where X_w is the aqueous solubility in mole fraction and X_o is mole fraction of biphenyl or naphthalene in the binary system. The results are summarized in Tables 1 and 2.

From equilibrium thermodynamics, the activity of a given solute is equal in both phases, then,

$$X_w\gamma_w=X_o\gamma_o, \quad (1)$$

where γ_w and γ_o are activity coefficients of a solute in the aqueous and the organic solvent phases, respectively. According to the literature,[5-8] the biphenyl-benzene system shows very small positive deviation from Raoult's law. It is, however, difficult to discriminate this small deviation from solubility measurements, because a relatively large error is unavoidable in solubility measurements. The X_w vs. X_o plots being linear, we assume this system as an ideal one: the γ_o values for benzene and biphenyl in the binary system are taken to be unity. From the reciprocal slope of the straight line, activity coefficients of biphenyl and benzene in water at 25 °C are evaluated to be 4.33×10^{5} and 2.58×10^{3}, respectively. Using these values as γ_w, the activity coefficient of biphenyl in the binary system with cyclohexane or 1-octanol and that of benzene in the binary system with naphthalene can be determined at any composition, X_o, with the aid of Eq. 1. The results are given in Table 2.

On the other hand, though there is a report from vapor pressure measurements of benzene to support that naphthalene forms an ideal solution with benzene,[9] it seems reasonable to consider from the data

on the solubility of naphthalene in benzene[10,11] that this system is not ideal, but exhibits more positive deviation from Raoult's law in comparison with the biphenyl-benzene system. We, therefore, determined γ_w for naphthalene from the equation,[12]

$$\ln(X_w\gamma_w) = \ln(f_s/f_l) = \Delta H_f(T_m^{-1} - T^{-1})R^{-1}, \quad (3)$$

where f_s and f_l are the fugacity of pure solid naphthalene and its supercooled liquid, ΔH_f is the heat of fusion of naphthalene, T_m is the melting temperature, T is the temperature of the system, and R is the gas constant. The data are available in the literature,[13] ΔH_f=18.979 kJ mol^{-1} and T_m=353.43 K, then, the activity coefficient of naphthalene in water is evaluated to be 6.68×10^4 at 25 °C using 4.52×10^{-6} as X_w. Using this value, activity coefficients of naphthalene in benzene, cyclohexane, and 1-octanol are determined from Eq. 1. The results are given in Tables 1 and 2.

The activity coefficient of a solute in binary mixtures has been usually determined by measuring vapor pressure of the constituent solute. In the system, however, where a solid solute is concerned, as in the pres-

a) Mole fraction of biphenyl or naphthalene in cyclohexane or 1-octanol. b) The aqueous solubility and the activity coefficient of biphenyl or naphthalene shown in the parentheses are those correspond to X_o^*, mole fraction of biphenyl or naphthalene in 1-octanol saturated with water. c) See footnote. d) In Table 1.

ent cases, the vapor pressure of the solid solute is too low to be accurately measured, and hence, only that of the solvent is measured. Then, the activity coefficient of the other less volatile component is estimated indirectly by means of the Gibbs-Duhem transformation. In contrast to this, the present approach gives direct information concerning the solid solute. There is, however, inevitable disadvantage in the present method that the system is not binary in a strict sense but ternary, because water itself participates more or less in the system. This seems not to be a serious problem when benzene or cyclohexane is used as a constituent component of binary systems.[14,15] This is, however, not the case for 1-octanol because the solubility of water in 1-octanol is very high.

The solubility of water in 1-octanol is reported to be 0.25 mole fraction at 25 °C.[16] This water content being considered, the mole fraction of a solute in water-free 1-octanol, X_o, should be corrected: $X_o = X_o^*/(0.75+0.25X_o^*)$,[17] where X_o^* refers to the mole fraction in water-saturated 1-octanol. Activity coeficients, corrected for water in 1-octanol, are given in Table 2.

The 1-octanol/water partition coefficient, $K_{o/w}$, is commonly defined as follows:

$$K_{o/w} = C_o/C_w = \gamma_w^* \bar{V}_w^*/(\gamma_o^* \bar{V}_o^*), \quad (4)$$

where C_o and C_w denote the molar concentration of a solute in 1-octanol saturated with water and that in water saturated with 1-octanol, respectively. The activity coefficient of a solute in water saturated with 1-octanol, γ_w^*, can be made equal to γ_w, and the partial molar volume of water saturated with 1-octanol, $\bar{V}_w^*$, can also be made equal to the molar volume of water,[18] because the solubility of 1-octanol in water is low. Using 0.018 $dm^3 mol^{-1}$ as $\bar{V}_w$ and 0.12 $dm^3 mol^{-1}$ as $\bar{V}_o^*$,[18] log $K_{o/w}$ values are found to be 4.1 for biphenyl and 3.5 for naphthalene. Here we used γ_o^* of 4.74 for biphenyl and 2.96 for naphthalene, which are estimated at infinite dilution of X_o^*, that is, $(\gamma_o^*)_{X_o^* \to 0}$. These log $K_{o/w}$ values obtained are comparable with those in the literature, 4.09 (biphenyl) and 3.36 (naphthalene).[18]

The authors wish to thank the Ministry of Education, Science and Culture for a financial support, a Grant-in-Aid for Scientific Research (No. 62540445).

Stereoselective Isomerization Reaction of (Iminodiacetato)-(ethylenediamine-*N*-acetato)cobalt(III), [Co(ida)-(edma)], in a Basic Aqueous Solution

Hiroshi KAWAGUCHI,* Hideko MIYAMOTO, Tomoharu AMA, and Takaji YASUI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received August 29, 1988)

Isomerization reactions among four geometrical isomers (pink, violet, brown, and light-brown) of [Co(ida)(edma)] were studied in a basic aqueous solution. In a reaction of $(-)^{CD}_{554}$-pink, three isomers of $(+)^{CD}_{563}$-violet, $(+)^{CD}_{565}$-brown (with a low optical purity), and racemic light-brown formed simultaneously. The major products in reactions of $(+)^{CD}_{563}$-violet and $(+)^{CD}_{565}$-brown were $(+)^{CD}_{565}$-brown and $(+)^{CD}_{563}$-violet, respectively. Light-brown mainly isomerized to brown at a rapid rate. Moreover, it was found that $(+)^{CD}_{563}$-violet racemized at a considerable rate. These stereoselective reactions are discussed in connection with those for $[Co(edma)_2]^+$ and $[Co(ida)_2]^-$.

Over the last few years we have been investigating the structure-reactivity pattern of octahedral complexes, particularly the isomerization of the bis(terdentate)cobalt(III) complexes. In previous papers,[1,2] we reported the preparation and characterization of four geometrical isomers of [Co(ida)(edma)] (Fig. 1),[3] and also a determination of the absolute configurations of the three isomers containing facially coordinated ligands. The possible configurations and CD signs for the three isomers are shown in Table 1. We describe here the isomerization reaction of the [Co(ida)(edma)] system, which is discussed on the basis of the previous studies on the related complexes, $[Co(ida)_2]^-$[4] and $[Co(edma)_2]^+$.[5]

Table 1. Possible Configurations and CD Signs of [Co(ida)(edma)]

Geometrical isomer	Possible configuration and CD sign	
mer(O)trans(N_c) (brown)	$(+)^{CD}_{565}$-$\Lambda\Lambda(S)$	$(-)^{CD}_{565}$-$\Delta\Delta(R)$
mer(O)cis(N_c) (violet)	$(+)^{CD}_{563}$-$\Lambda\Delta\Lambda(S)$	$(-)^{CD}_{563}$-$\Delta\Lambda\Delta(R)$
fac(O) (pink)	$(+)^{CD}_{554}$-$\Lambda\Delta\Lambda(S)$	$(-)^{CD}_{554}$-$\Delta\Lambda\Delta(R)$

Experimental

Complexes and Reagents. The complexes examined here were prepared and optically resolved according to methods described in our previous papers.[1,2] They are $(+)^{CD}_{565}$-*mer(O)trans*(N_c)-[Co(ida)(edma)] (abbreviation: $(+)^{CD}_{565}$-brown), $(+)^{CD}_{563}$-*mer(O)cis*(N_c)-[Co(ida)(edma)]·H_2O ($(+)^{CD}_{563}$-violet), $(-)^{CD}_{554}$-*fac(O)*-[Co(ida)(edma)] ($(-)^{CD}_{554}$-pink), and *mer(ch)*-[Co(ida)(edma)]·H_2O (light-brown). All the chemicals used were of a reagent grade, and the deionized water was degassed before use.

Isomerization. $(+)^{CD}_{563}$-Violet Isomer: This isomer (0.2211 g) was dissolved in 100.0 cm^3 of water in a reaction vessel kept in a thermostated bath at 40.0 °C. The reaction was started by stirring 100.0 cm^3 of a buffer solution [Na_2CO_3(0.5606 g)-$NaHCO_3$(0.2241 g)] previously kept at 40.0 °C into the reaction vessel. The reaction conditions were as follows: Complex concentration, 3.4×10^{-3} M (M= mol dm^{-3}); pH, 10.30±0.03; temperature, 40.0±0.1 °C. The temperature and pH of the reaction solution were checked with a thermistor thermometer (Takara D221) and a pH meter (Toa TSC-10A), respectively, throughout the kinetic run. At a prescribed time, the reaction solution was acidified to pH 5 in order to stop the reaction. (Such kinetic runs with different reaction times were carried out repeatedly.) The acidified solution was concentrated under reduced pressure at 35—40 °C and then applied to a column (3.0 cm×80 cm) of Sephadex G-10 in order to remove salts.[6] The eluate containing the isomers of [Co(ida)(edma)] was concentrated again and chromatographed on a column (3.7 cm×80 cm) of QAE-Sephadex A-25 [$Sb_2(d\text{-tart})_2^{2-}$ form] using water as an eluent; three bands of el 1 [$(+)^{CD}_{565}$-brown and violet], el 2 [$(-)^{CD}_{565}$-brown and light brown], and el 3 [pink]. The three eluates were collected separately and concentrated to appropriate constant volumes. The amount and optical purity of each isomer were determined from absorption and CD data measured by a Hitachi 557 spectrophotometer and a JASCO J-22 spectropolarimeter, respectively. The amounts of the two isomers and the optical purity of violet in el 1 were estimated from binary-curve analyses of the absorption and CD spectra. The amounts of the two isomers in el 2 were also estimated by a procedure similar to that described above.

In these curve analyses, the spectral data at 20 points in the visible region were used; the analyses were carried out on an NEC PC-9801F computer using a least-squares method.

$(+)^{CD}_{565}$-Brown, $(-)^{CD}_{554}$-Pink, and Light-Brown Isomers: The isomerization reaction of $(+)^{CD}_{565}$-brown was carried out by a procedure similar to that used for $(+)^{CD}_{563}$-violet. The reaction conditions were the same as those in the case of $(+)^{CD}_{563}$-violet.

The solubility of $(-)^{CD}_{554}$-pink was low. Thus, the saturated solution (180 cm^3) of $(-)^{CD}_{554}$-pink, which was obtained by stirring the powder of the isomer in water at 40.0 °C for 10 min, and a buffer solution (20 cm^3) containing 0.5653 g of Na_2CO_3 and 0.2241 g of $NaHCO_3$ were prepared for the isomerization reaction. The procedure of the reaction was the same as that in the case of $(+)^{CD}_{563}$-violet. The reaction conditions were as follows: Complex concentration, 2.8×10^{-3} M (It was determined from the absorption data at the start of the reaction.); pH, 10.30±0.02; temperature, 40.0±0.1 °C.

The isomerization study of light-brown could not be carried out sufficiently, since the preparation of the isomer was very difficult. Only one isomerization run using light-brown as a starting material was carried out on a small scale (1/4 of the scale for violet), and the isomer proportions at one hour after the start of the reaction were determined by a procedure similar to that in the case of $(+)^{CD}_{563}$-violet.

In weak acidic and neutral solutions at room temperature, the absorption and CD spectral changes of each isomer were not observed for about one day. Therefore, progress of the isomerization and/or racemization reaction during such procedures as chromatographic separation and concentration under reduced pressure should be negligible.

Results and Discussion

Base-Catalyzed Isomerization Reaction. $(-)^{CD}_{554}$-Pink Isomer: The isomerization reaction of $(-)^{CD}_{554}$-pink was followed over a period of 12 h under the conditions of pH 10.30 and 40.0 °C. Figure 2 shows the changes in the proportions of the starting material and reaction products. A part of the numerical data are listed in Table 2, together with the enantiomer excess percentage of each isomer. The isomerization reaction of pink is faster than the reactions of violet and brown. The half-life period (with regard to the decrease in pink) is about 40 min under the conditions described above. In this reaction, three products — $(+)^{CD}_{563}$-violet, $(+)^{CD}_{565}$-brown, and racemic light-brown — were simultaneously formed. Throughout the reaction, no other products were detected by the present experimental method. The brown isomer increased in amount with the passage of time and was a major species after a prolonged reaction time. The concentrations of light-brown and violet were maximal at about 45 min and about 4 h after the reaction start, respectively; thereafter, they decreased. At longer reaction times (>ca. 4 h), the amount of light-brown was almost negligible.

As shown in Table 2, $(-)^{CD}_{554}$-pink (starting material) retained a high optical purity until about 2 h; at that time most of the pink had already isomerized to other isomers. This fact probably indicates that the racemization of $(-)^{CD}_{554}$-pink, itself, is negligible. During the initial stage of the reaction, $(+)^{CD}_{563}$-violet formed from $(-)^{CD}_{554}$-pink retained an optical purity of about 100%. The isomerization path of $(-)^{CD}_{554}$-pink → $(+)^{CD}_{563}$-violet

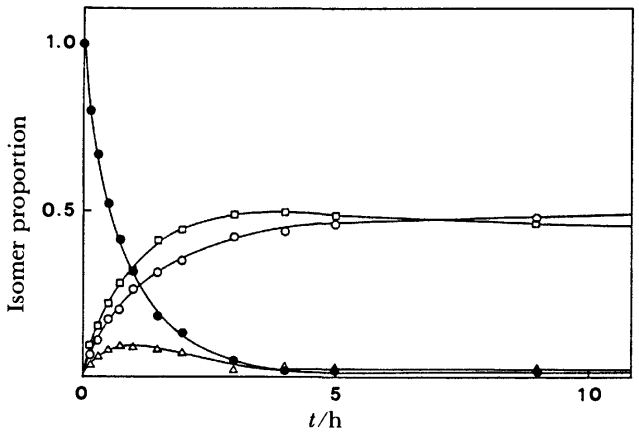

Fig. 2. The changes of the isomer proportions in the isomerization reaction of $(-)^{CD}_{554}$-pink (40.0 °C, pH 10.30); pink (-●—●-), violet(-□—□-), brown (-○—○-), and light-brown (-△—△-).

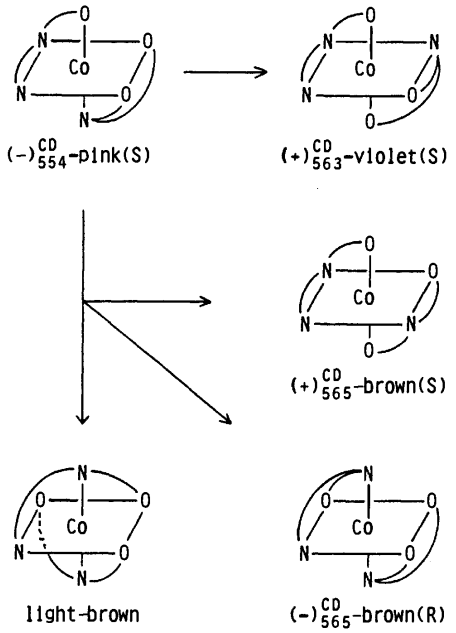
change is thus highly stereoselective. However, the optical purity of the formed $(+)^{CD}_{563}$-violet decreased with the passage of time. The $(+)^{CD}_{565}$-brown formed in the same reaction showed a low optical purity (ca. 10 %). Moreover, the value of the optical purity was nearly constant throughout the present reaction (12 h). Accordingly, it is thought that $(-)^{CD}_{554}$-pink isomerizes to $(+)^{CD}_{565}$- and $(-)^{CD}_{565}$-brown with a constant ratio (55 : 45%).

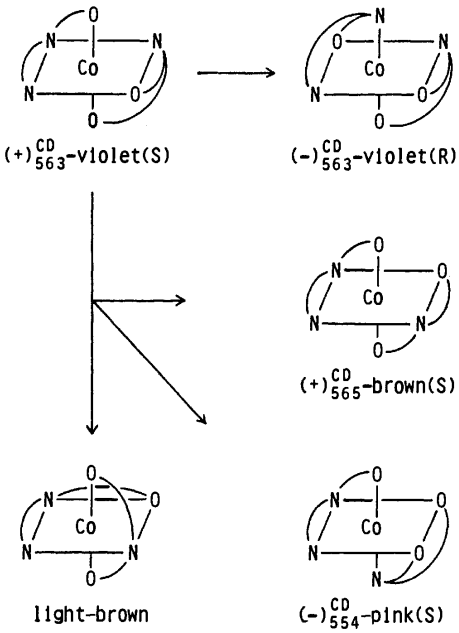
In an isomerization reaction among three geometrical isomers of $[Co(ida)_2]^-$, the reaction scheme was found to be *u-fac* ⇄ *mer* ⇄ *s-fac*.[4] However, in the $[Co(edma)_2]^+$ system, the isomerization from the *fac*-type isomers to the *mer* isomer was not observed. Isomerization among *fac*-type isomers of $[Co(edma)_2]^+$ accompanies inversion at one of two secondary nitrogen (sec-N) centers of the coordinated edma ligands. The inversion is thought to be caused by a coordination-site exchange between the sec-N and carboxylato oxygen of a coordinated edma ligand.[5] If [Co(ida)(edma)] has a reactivity that is similar to those of both $[Co(ida)_2]^-$ and $[Co(edma)_2]^+$, the reaction paths shown in Scheme 1 should be expected for the isomerization of $(-)^{CD}_{554}$-pink: Three paths from $(-)^{CD}_{554}$-pink to $(+)^{CD}_{563}$-violet, $(+)^{CD}_{565}$-brown, and $(-)^{CD}_{565}$-brown are proposed by considering the isomerization mechanism for the $[Co(edma)_2]^+$ system (coordination-site exchange between the sec-N and O of the coordinated ida or edma ligand), and the $(-)^{CD}_{554}$-pink → light-brown path is proposed on the basis of the assumption that the reaction proceeds by a process similar to that for the $[Co(ida)_2]^-$ system. The experimental results described above, namely the simultaneous formation of $(+)^{CD}_{563}$-violet, approximately racemic brown, and light-brown are well explained with the simultaneous occurence of four paths in Scheme 1. The light-brown obtained in this isomerization reaction was racemate. This does not mean that the $(-)^{CD}_{554}$-pink → light-brown change is not stereoselective. Even though the change is stereoselective, the optically active light-brown formed from $(-)^{CD}_{554}$-pink must racemize very rapidly under the present reaction conditions, judging from the racemization rates of *mer*-[Co(ida)(dien)]$^+$,[7] *mer*-[Co(edma)(dien)]$^{2+}$,[8] and *mer*-$[Co(dien)_2]^{3+}$.[9] The decrease of the optical purities in $(+)^{CD}_{563}$-violet and $(-)^{CD}_{554}$-pink with the passage of time are explained in the later section.

$(+)^{CD}_{563}$-Violet Isomer: The isomerization reaction using $(+)^{CD}_{563}$-violet as a starting material was also carried out in a carbonate buffer (pH 10.30) at 40 °C, and a part of the data are listed in Table 2. In the initial stage of the reaction, three products — $(+)^{CD}_{565}$-brown, $(-)^{CD}_{554}$-pink, and light-brown (racemate) — were formed. The amounts of pink and light-brown little increased even though the reaction was allowed to proceed for a long time, indicating that the subsequent isomerizations from these isomers to brown and/or violet occurred. While, brown increased in its amount with the passage of time and was a major species in the final stage of the reaction.

As shown in Table 2, the optical purity of the starting material — $(+)^{CD}_{563}$-violet — decreased more rapidly compared with the rate of its concentration decrease. This fact means that $(+)^{CD}_{563}$-violet, itself, racemized at a considerable rate. $(-)^{CD}_{554}$-Pink and $(+)^{CD}_{565}$-brown, which were formed from $(+)^{CD}_{563}$-violet, showed optical purities of about 100 and about 70%, respectively, during the initial stage of the reaction. These two isomerization paths are, thus, stereoselective. However, the optical purities of these two products decreased with the passage of time. The results may be attributed to a rapid



Scheme 1.



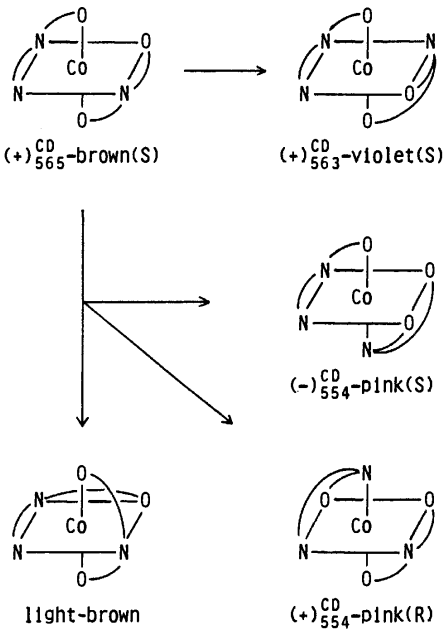
Scheme 2.

racemization of the starting material; $(-)^{CD}_{563}$-violet formed in the racemization of the starting material [$(+)^{CD}_{563}$-violet] produces $(+)^{CD}_{554}$-pink and $(-)^{CD}_{565}$-brown.

The isomerization of $(+)^{CD}_{563}$-violet can also be explained in a manner similar to that in the isomerization of $(-)^{CD}_{554}$-pink. If the isomerization due to the mechanism proposed for the $[Co(edma)_2]^+$ system occurs in $(+)^{CD}_{563}$-violet, three isomers — $(-)^{CD}_{563}$-violet, $(+)^{CD}_{565}$-brown and $(-)^{CD}_{554}$-pink — must be formed, as shown in Scheme 2. This proposal is consistent with the experimental results except for the minor formation of $(-)^{CD}_{554}$-pink. In the $[Co(edma)_2]^+$ system, it is found that the inversion at the sec-N center trans to the ligating nitrogen [*trans*(*N*)-sec-N] occurs slowly and that the inversion at the *trans*(*O*)-sec-N center occurs rapidly.[5] If such phenomenon as observed in the $[Co(edma)_2]^+$ system is expected to occur in the reaction of $(+)^{CD}_{563}$-violet, the experimental results, namely, the fast racemization of $(+)^{CD}_{563}$-violet and the minor formation of $(-)^{CD}_{554}$-pink, can be rationalized: The $(+)^{CD}_{563}$-violet → $(-)^{CD}_{563}$-violet change (racemization) accompanies the inversion at *trans*(*O*)-sec-N center, therefore, its rate is fast, and the $(+)^{CD}_{563}$-violet → $(-)^{CD}_{554}$-pink change accompanying the inversion at *trans*(*N*)-sec-N center occurs slowly. The formation rate of brown from $(+)^{CD}_{563}$-violet is relatively faster than that of pink in the same reaction, even though the $(+)^{CD}_{563}$-violet → $(+)^{CD}_{565}$-brown change accompanies an inversion at *trans*(*N*)-sec-N center. This fact may be ascribed to additional isomerization paths, such as $(+)^{CD}_{563}$-violet → $(-)^{CD}_{554}$-pink → $(+)^{CD}_{565}$-brown and $(+)^{CD}_{563}$-violet → light-brown → brown.

$(+)^{CD}_{563}$-Violet isomerized to racemic light-brown in a small amount. This indicates the existence of isomerization due to a mechanism similar to that in the $[Co(ida)_2]^-$ system, even though it is a minor path in the isomerization of $(+)^{CD}_{563}$-violet.

$(+)^{CD}_{565}$-Brown Isomer: The isomerization reaction of $(+)^{CD}_{565}$-brown proceeded slowly. The major product was $(+)^{CD}_{563}$-violet, of which the optical purity was high during the initial stage of the reaction (Table 2). $(-)^{CD}_{554}$-Pink with low optical purity and light-brown were also formed in a small amount; their amounts did not increase with time. This result can be rationalized using the same idea as used for the isomerization of $(+)^{CD}_{563}$-violet. If the isomerization of $(+)^{CD}_{565}$-brown proceeds on the mechanism of the coordination-site exchange between the sec-N and O of the edma or ida ligand, three products of $(+)^{CD}_{563}$-violet and $(-)^{CD}_{554}$- and $(+)^{CD}_{554}$-pink may be formed (Scheme 3). Two sec-N atoms in brown are located at the trans positions to each other [*trans*(*N*)-sec-N]; therefore, the isomerization of brown is expected to be slow. This expectation coincides with the present experimental result. The formation of light-brown can be explained by assuming an isomerization path similar to that proposed for the $[Co(ida)_2]^-$ system, even though it is a minor path in this reaction.



Scheme 3.

Light-Brown Isomer: The isomerization study of light-brown was not sufficient, since the preparation of its isomer was very difficult. The absorption spectrum of light-brown changed more rapidly, compared with the spectral changes of other isomers. From this spectral change, the formations of brown (major) and violet (minor) were presumed. Light-brown was allowed to react for one hour under the conditions of pH 10.28 at 40.0 °C; the proportions of the starting material and products in the reaction solution were chromatographically obtained. As shown in Table 2, the major product was brown (83% of the total amount of the products) one hour after the reaction started.

In the previous section it was described that $(+)^{CD}_{565}$-brown with a very low optical purity was obtained in the isomerization reaction of $(-)^{CD}_{554}$-pink. The result has been explained by the occurrence of two different N-O displacement processes (Scheme 1). The formation of racemic brown from $(-)^{CD}_{554}$-pink was also expected through the successive path of $(-)^{CD}_{554}$-pink → light-brown → brown (with a rapid rate). This path is similar to the isomerization process in the $[Co(ida)_2]^-$ system. It may be sure that the pink → light-brown → brown change contributes to the isomerization of pink to a considerable extent.

(Received September 13, 1988)

The molecular structures of three racemic pairs of diastereomers, *ΔRR*(*ΔSS*)-, *ΔSR*(*ΔRS*)-, and *ΔSS*(*ΔRR*)-*trans*(*N*-Ph, *N*-Ph)-[Co(pd)(Ph-en)$_2$]$^{2+}$ and of one racemic pair of diastereomers, *ΔSS*(*ΔRR*)-*trans*(*N*-Ph, *N*-Ph)-[Co(ox) (Ph-en)$_2$]$^+$ (pd=2,4-pentanedionate ion, ox=oxalate ion, Ph-en=*N*-phenylethylenediamine) were determined by the single-crystal X-ray diffraction method in order to study the intramolecular interactions between π-systems in the ligands. For the *ΔSS*(*ΔRR*)-isomer of [Co(pd)(Ph-en)$_2$]$^{2+}$, three kinds of crystal structures **3a**, **3b**, and **3c** were investigated. The crystal data and final R values are: *ΔRR*(*ΔSS*)-[Co(pd)(Ph-en)$_2$](ClO$_4$)$_2$·H$_2$O (**1**), orthorhombic, *Pbca*, a=32.472(9), b=11.120(3), c=15.303(4) Å, V=5526(3) Å^3, Z=8, R=0.065 for 2113 observed unique reflections. *ΔSR*(*ΔRS*)-[Co(pd)(Ph-en)$_2$](ClO$_4$)$_2$ (**2**), orthorhombic, $P2_12_12_1$, a=19.440(8), b=16.406(8), c=8.407(3) Å, V=2681(2) Å^3, Z=4, R=0.038 for 2205 reflections. *ΔSS*(*ΔRR*)-[Co(pd)(Ph-en)$_2$]-Cl$_2$·H$_2$O (**3a**), monoclinic, $P2_1/c$, a=12.475(3), b=11.590(2), c=19.054(4) Å, β=117.18(2)°, V=2450.6(9) Å^3, Z=4, R=0.035 for 2164 reflections. *ΔSS*(*ΔRR*)-[Co(pd)(Ph-en)$_2$](ClO$_4$)Cl·H$_2$O (**3b**), triclinic, $P\bar{1}$, a=11.847(5), b=13.584(4), c=8.367(2) Å, α=103.57(2), β=91.85(3), γ=84.25(3)°, V=1302.1(8) Å^3, Z=2, R=0.087 for 1374 reflections. *ΔSS*(*ΔRR*)-[Co(pd)(Ph-en)$_2$](ClO$_4$)Cl (**3c**), triclinic, $P\bar{1}$, a=11.660(5), b=14.028(3), c=8.308(7) Å, α=108.00(8), β=101.57(9), γ=92.47(13)°, V=1258(3) Å^3, Z=2, R=0.052 for 1118 reflections. *ΔSS*(*ΔRR*)-[Co(ox)(Ph-en)$_2$] Br·6H$_2$O (**4**), orthorhombic, $Pna2_1$, a=15.804(1), b=15.646(1), c=10.428(2) Å, V=2578.5(4) Å^3, Z=4, R=0.065 for 1496 reflectios. The numbers of phenyl rings of the Ph-en ligands that overlap with the pd π system in the complex cation are 0, 1, and 2 for **1**, **2**, and **3** respectively. The ox ligand of **4** is ill-sandwiched by the two phenyl rings, whereas the pd ligand is well-sandwiched in **3a**. The arrangements of the phenyl groups relative to the pd differ slightly from one another in the crystals of **3a**, **3b**, and **3c**. The dihedral angles between the pd (or ox) and phenyl rings range from 25 to 35°.

Three isomers of *trans*(*N*-Ph, *N*-Ph)-[Co(pd)(Ph-en)$_2$]$^{2+}$ were prepared and characterized.[1] Their absorption spectra are different from each other, although the structures differ simply in the absolute configurations of the coordinated secondary N atoms. The greater the number of Ph rings placed over the pd chelate ring, the lower the energy of the first absorption band.[1] X-Ray crystal structure analyses have been done to verify their relative configurations, as assigned on the basis of the ^{1}H NMR spectra, and to investigate the intramolecular interaction of the π systems. The *ΔSS*(*ΔRR*)-*trans*(*N*-Ph,*N*-Ph)-[Co(ox)(Ph-en)$_2$]$^+$ complex has also been prepared and its structure examined in order to compare the results with those for the pd complexes.

Experimental

Preparation of [Co(ox)(Ph-en)$_2$]Br·6H$_2$O. The procedure was carried out under an atmosphere of nitrogen until the complex was formed. To a deaerated solution (180 cm^3) of K$_3$[Co(ox)$_3$]·3H$_2$O (2.8 g, 7.1 mmol) in dimethyl sulfoxide-water (4:5 v/v) we added deaerated *N*-phenylethylenediamine (1 g, 7.34 mmol). The mixture was warmed at 30 °C for 3 h. The resulting dark purple solution was diluted with water (1500 cm^3) and placed in a column (ϕ2.8 cm ×20 cm) of Dowex 1×8 (Cl$^-$ form) to remove the anionic species. The column was then washed with water, and the red effluent was placed in a column (ϕ2.8 cm×20 cm) of Dowex 50W×8 (Na$^+$ form). By elution with 0.6 mol dm^{-3} NaBr-0.01 mol dm^{-3} HBr, two red bands and a brown band developed in this order, the brown one remaining at the top of the column. The eluate containing the fastest-moving red band (main band) was collected and evaporated to dryness under reduced pressure. The residue was shaken with methanol to extract the complex, and the solvent was removed under reduced pressure. The residue was dissolved in a small amount of 0.01 mol dm^{-3} HBr and then allowed to stand overnight in a refrigerator. The red crystals were collected by filtration and washed with water and then methanol. Yield: 0.93 g (23%). UV-VIS spectrum (0.01 mol dm^{-3} HBr) 18.55 (log ε 2.32), 28.59 (4.72), and 42.72×10^3 cm^{-1} (4.87).

The slower-moving red band seemed to contain another isomer (racemic pair of the diastereomers) of [Co(ox)(Ph-en)$_2$]$^+$. The complex was not isolated, however, since it was unstable and the amount was very small. The complex showed the first absorption band at 18870 cm^{-1}. The abundance of the first band relative to that of the second band was ca. 30:1 when the two isomers were assumed to have the same molar absorption coefficient.

Crystal-Structure Determination. Crystals of **1**, **2**, and **3** were grown from acetone-HCl and HClO$_4$ mixtures to avoid epimerization.[1] Compound **4** was recrystallized from water. The experimental conditions and refinement information are listed in Table 1. The intensities were measured using graphite monochromatized Mo$K\alpha$ radiation (λ=0.71073 Å) on an automated Rigaku four-circle diffractometer AFC-5. The θ-2θ scan technique was employed at a scan rate of 6° min^{-1} in θ. The lattice constants were determined from

Table 1. Crystal Data, Experimental Conditions, and Refinement Details

15—34 2θ values ($20<2\theta<30°$). Absorption corrections were made except for the small crystal of **3c**. The positions of the heavy atoms were determined from the Patterson function, while the other nonhydrogen atoms were located by means of Fourier syntheses and were refined anisotropically. The ratios of the number of H atoms located by the difference synthesis are **1** 24/31, **2** 24/31, **3a** 30/31, **3b** 16/31, **3c** 27/31, and **4** 12/24. The other H atoms were calculated and refined isotropically. The function, $\sum w||F_o|-|F_c||^2$, was minimized with $w^{-1}=\sigma^2(|F_o|)+(0.015|F_o|)^2$ by the block-diagonal least-squares method. Complex neutral-atom scattering factors were used.[2] The calculations were carried out on a FACOM M380R computer at Keio University using the computation program system UNICS-III.[3] The final atomic parameters are listed in Table 2, and the bond lengths and bond angles within the complex cations, in Table 3.[4] The following points are worth mentioning. The structure of **1** is difficult to solve because the Co and two Cl atoms lie nearly on the glide planes, as shown in Fig. 1. The statistics of the intensity data showed that *hkl* with *h* or *l* odd is weak, suggesting pseudo translational symmetries of *a*/2 and *c*/2. The positions of the heavy atoms were determined by direct methods with MULTAN78[5] using a single overall scale factor in the normalization. The coordinated N and O atoms were deduced by means of Fourier synthesis utilizing the Co-ligand vectors found in the Patterson function. The

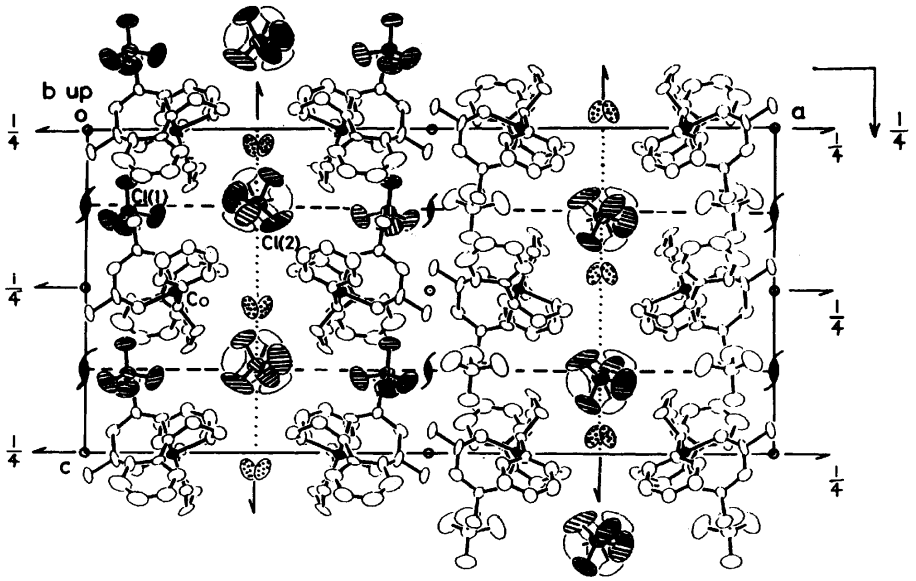

Fig. 1. A projection of the crystal structure of **1** along *b*.

space group of **2** is $P2_12_12_1$, indicating spontaneous resolution. The absolute structure was determined by anomalous-scattering techniques. The enantiomeric structure converged to R=0.0387 and wR=0.0449, slightly larger than the values of 0.0380 and 0.0441 for the adopted structure. In **3a**, the water molecules are disordered. The population parameters of three possible positions of O(W) were estimated by the trial-and-error method in such a way that the isotropic thermal parameter took nearly equal values. The Cl^- ion and water molecules in **3b** are disordered. The difference synthesis gave nine positions with peak heights greater than 1.0 e Å^{-3}. Since the disordered water molecules can not be distinguished from the disordered Cl^- ions, those peaks were tentatively assumed to be Cl^- ions and their population parameters were estimated by the trial-and-error method. The relatively large R value of **3b**, 0.087, may be attributed to this disorder. As the crystal of **3c** was too small to collect sufficient number of reflections, the carbon atoms were refined isotropically. The systematic absences of **4** indicated that the space group was $Pna2_1$ (No. 33) or the $ac\bar{b}$ setting of *Pnma* (No. 62). Since Z=4 and the complex cation has no mirror plane and no inversion center, the space group was determined to be $Pna2_1$.

Results and Discussion

The atomic parameters of **1**, **3**, and **4** in Table 2 were selected to represent the absolute configuration *Δ* for convenience of comparison with **2**. The bond lengths and bond angles within the complex cations are listed in Table 3, while the short intramolecular distances and hydrogen bonds are listed in Tables 4 and 5 and

Symmetry code: (i) x, 1/2−y, z−1/2, (ii) 1/2−x, −y, z+1/2, (iii) 1/2−x, −y, z−1/2, (iv) −x, y+1/2, −z−1/2, (v) −x,−y, 1−z, (vi) −x, y−1/2, 1/2−z, (vii) 1−x, −y, −z, (viii) 1−x, 1−y, −z, (ix) x, y, z+1.

perspective drawings of the complex cations are presented in Fig. 2. The combinations of two asymmetric N atoms of the $[Co(pd)(Ph\text{-}en)_2]^{2+}$ complexes agree with the assignments based on the ^1H NMR spectra:[1] **1** *ΔRR*, **2** *ΔSR*, and **3** *ΔSS*. Only one of the diastereomers was isolated for the $[Co(ox)(Ph\text{-}en)_2]^+$ complex, the **4** *ΔSS* isomer. The two Ph-en ligands in the pd complexes take the lel ob conformation, which breaks the twofold symmetry of the *ΔRR* and *ΔSS* isomers. For the ox complex **4**, however, the Ph-en ligands take ob_2 configuration, which retains a twofold symmetry. The difference in the structures may be attributed to the difference in the O-Co-O chelate angles, 95.3(2)—96.3(2)° and 86.7(4)° for pd and ox respectively. The pd complexes are isomerized in a neutral aqueous solution with this equilibrium distribution ratio; *ΔRR*(*ΔSS*): *ΔSR*(*ΔRS*): *ΔSS*(*ΔRR*)=5 : 78 : 17 at 20 °C.[1] The N-Ph bonds in the most stable isomers **2** and **4** take a conformation equatorial to the en chelate ring. The Co atom lies almost on the pd or ox plane in each complex, in contrast to the bent Co-pd chelate ring in $(+)^{GD}_{531}$-$[Co(pd)(RR\text{-}chxn)(edpp)](ClO_4)_2$.[6] The dihedral angles between the pd or ox chelate ring and phenyl groups range from 25 to 35° (see Table 6). There are no significantly close contacts between the phenyl groups and methyl groups of pd. Comparing

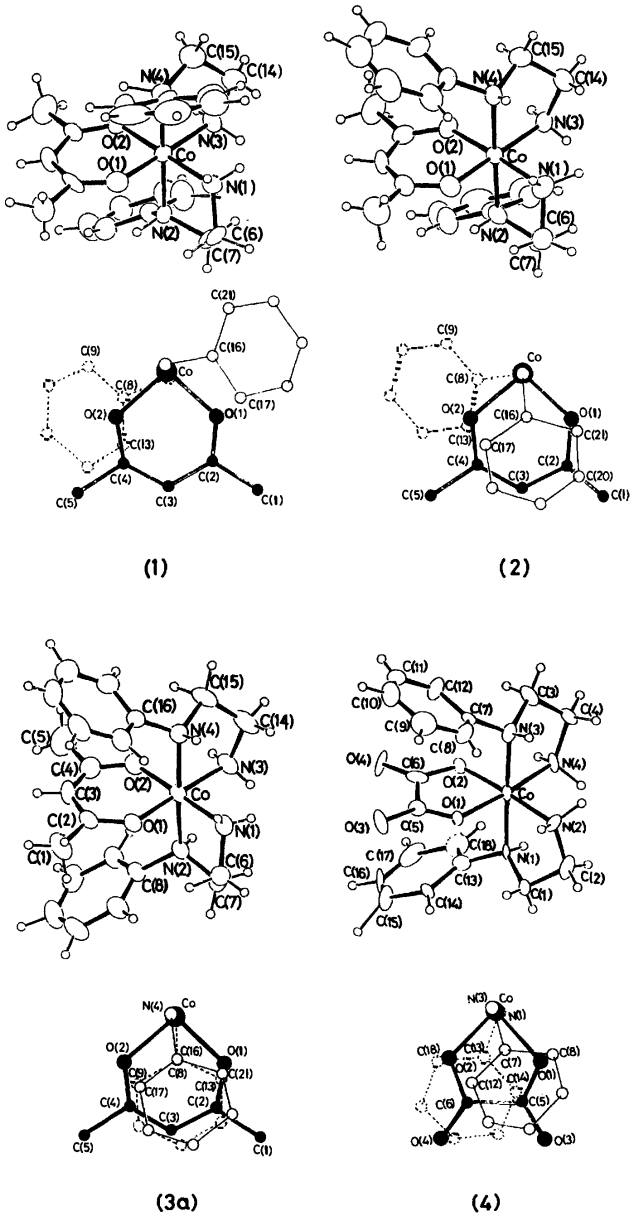

Fig. 2. Molecular structures, and projections of the Ph rings on the least squares plane through the pd or ox ligand for **1**, **2**, **3a**, and **4**. The Ph rings above and below the projection plane are drawn with solid and broken lines, respectively.

Table 6. Dihedral Angles (°) between the pd or ox Chelate Ring and Ph Rings Involving C(8) and C(16) Atoms

	C(8)	C(16)
1	25.6	27.9
2	28.7	29.8
3a	30.7	28.7
3b	27.5	33.5
3c	28.4	35.3
4	24.5	30.7

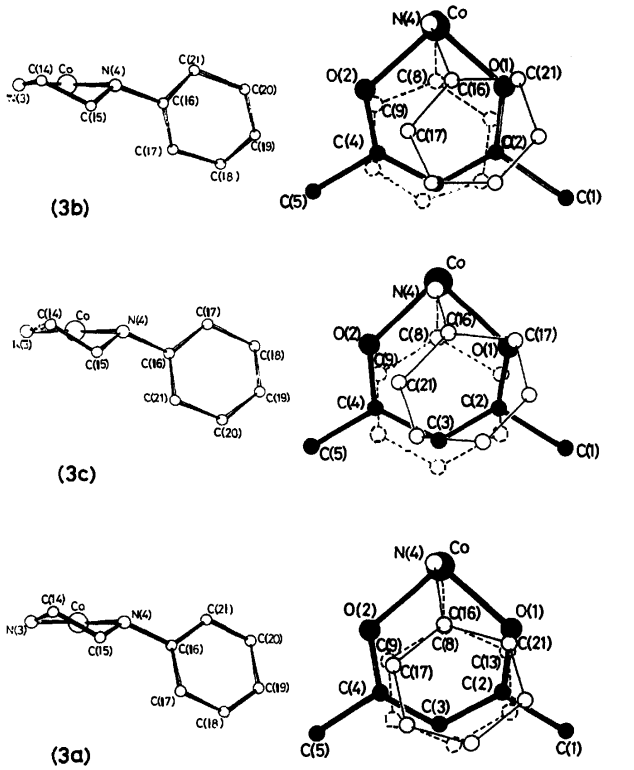

Fig. 3. Comparison of the Ph-en chelate ring conformations in *ΔSS*-$[Co(pd)(Ph\text{-}en)_2]^{2+}$ ions of **3b**, **3c**, and **3a**. The left half shows a projection along the line through the Co atom and the midpoint of the N(3)-N(4) axis. The right half shows a projection of the Ph rings on the pd chelate ring. The projections are arranged in a sequence that vividly illustrates the smooth change in the Ph-en chelate ring conformation in different crystal field.

the projections of the Ph rings to the least-squares plane through the pd in **3a** with that through the ox in **4** (see Fig. 2), the Ph rings of **3a** may be seen to overlap more with the pd π system than in **4**. However, the flexibility of the Ph-en chelate ring was revealed by the difference in the structures of **3a**, **3b**, and **3c**, as is shown in Fig. 3. The orientation of one of the Ph groups to the pd ligand alters with a different conformation of the five-membered chelate ring. After all, the orientation of the Ph group is altered along with the chelate-ring conformation of the Ph-en ligand, which is itself primarily determined by the coordination geometry around the Co atom. Molecular packing stabilization is a secondary condition, while the minor conditions are the intramolecular interactions between the π systems. The difference in the energy of the first absorption band of the three diastereomers of the pd complex[1] could not be explained by the structural data; no significant differences in the Co-N and Co-O bond lengths are observed among these diastereomers (see Table 3). The Co-N(HPh) bond distance is longer than the Co-N(H_2) distance by 0.06—0.07(1) Å, which corresponds to the fact that the ligand-field strength of Ph-en is weaker than that of en.[7]

Preparation and Crystal Structure of New Gold(I) Complexes Linked to Pyrimidines

Takashi AMAGAI, T. Ken MIYAMOTO,* Hikaru ICHIDA, and Yukiyoshi SASAKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 4, 1988)

Two new gold(I) complexes linked to pyrimidines, (5-fluoro-2′-deoxyuridinato-N^3)(triphenylphosphine)-gold(I) (**1**) and [5-fluoro-1-(tetrahydro-2-furanyl)-2,4(1*H*,3*H*)-pyrimidinedionato-N^3](triphenylphosphine)gold(I) (**2**) were synthesized and characterized by ^{31}P, ^1H NMR and IR spectra. The structure of **2** was determined by an X-ray diffraction method. A linear, two-coordination around gold(I) has been shown. In order to estimate the possible alteration of **1** and **2** in vivo, several factors such as the effect of pH, and reactions with thiol, thiophenol, and imidazole were examined.

For a long time, gold(0) have been used as anti-rheumatoid drugs.[1] Recent progress in medicinal chemistry has led to a new finding that auranofin [(2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranosato-*S*)-(triethylphosphine)gold(I)] has not only antirheumatoid but anticancer activities.[2,3] Other gold(I) phosphine complexes, e.g. [bis[1,2-bis(diphenylphosphino)-ethane]gold(I) chloride] also show anticancer activities.[4] In these gold(I) compounds, a lot of thiolate or chloride complexes have been investigated extensively;[5] however, antitumor activities of gold(I) complexes containing nitrogen ligands have been not well-characterized.

Organic derivatives of 5-fluorouracil have been widely known as anticancer drugs. They contain nitrogen atoms, which can coordinate to metal atoms. By using these ligands, we have successfully synthesized new compounds.

In this paper, the preparation and crystal structure of these compounds are described. Additionally, the reactions of the complexes to thiol and imidazole are also mentioned.

Experimental

Materials. Chloro(triphenylphosphine)gold(I) were prepared by the literature method,[5] and further recrystallized from tetrahydrofuran (THF). Two pyrimidines, e.g., 5-fluoro-2′-deoxyuridine (5FdUrd) and 5-fluoro-1-(tetrahydro-2-furanyl)-2,4(1*H*,3*H*)-pyrimidinedione (tegafur) were offered by Mitsui Pharmaceutical Inc. Reagent grade solvents were used without further purification.

Measurements. Elemental analysis were carried out by analytical technicians in this department. ^{31}P NMR spectra at 36.4 MHz were recorded with a JEOL FX90Q in 10 mm-tubes using a 85% H_3PO_4 solution as an external reference. ^1H NMR spectra at 60 MHz were obtained with a Hitachi R24B in 5 mm-tubes. IR spectra were measured with a Hitachi 260-30.

Preparation of (5-Fluoro-2′-deoxyuridinato-N^3)(triphenylphosphine)gold(I) (1). All procedures were performed under an Ar atmosphere. Chloro(triphenylphosphine)-gold(I) 1.87 g (3.78 mmol), 5FdUrd 1.94 g (7.89 mmol) and KOH 0.43 g (7.66 mmol) were dissolved in H_2O (30 ml)/THF (30 ml). The solution was stirred at 50—60 °C; then the product was obtained as precipitation by evaporation of THF. The solid was filtered off and recrystallized from THF with addition of diethyl ether. (2.23 g; 83.8% yield) Calcd for $C_{27}H_{25}N_2O_5AuFP$ (M.W.=704.45): C, 46.04; H, 3.58; N, 3.98%. Found: C, 45.87; H, 3.79; N, 3.81%.

Preparation of [5-Fluoro-1-(tetrahydro-2-furanyl)-2,4-(1*H*, 3*H*)-pyrimidinedionato-N^3](triphenylphosphine)gold(I) (2). The complex was prepared by the same procedure as that of **1**. From chloro(triphenylphosphine)gold(I) 3.06 g (6.19 mmol), tegafur 2.98 g (14.9 mmol) and KOH 0.74 g (13.2 mmol), 2.53 g of **2** were obtained. (62.1% yield) Calcd for $C_{26}H_{23}N_2O_3AuFP$ (M.W.=658.42): C, 47.43; H, 3.52; N, 4.25%. Found: C, 47.05; H, 3.55; N, 3.96%.

Crystal Structure Determination. X-Ray diffraction intensities were measured on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation at room temperature. Calculations were carried out with UNICS3 programs on a HITAC M-680H/M-682H computer at the Computer Centre of the University of Tokyo.[7]

Crystal dimensions were 0.6×0.15×0.15 mm. Intensities were collected for $4° \leqq 2\theta \leqq 55°$ by the ω-2θ scan technique. Independent 2722 points were collected and 2470 reflections with $F_o \leqq 2.5\sigma(F_o)$ were used for calculation. The position of the Au atom was determined by the heavy-atom method. Other atoms, except for H atoms, were located from subsequent Fourier syntheses. The positional and thermal parameters were refined by a block-diagonal least-squares method. The final R-value was 0.076.

Crystallographic data of **2** are as follows: Formula $C_{26}H_{23}N_2O_3AuFP$ (F.W.=658.42), monoclinic, space group $P2_1/n$, a=10.200(2) Å, b=26.115(5) Å, c=9.344(2) Å, β=102.05(3)°, V=2434 Å^3, D_x=1.797 g cm^{-3}, Z=4, μ=61.34 cm^{-1}. The atomic parameters are listed in Table 1. The complete F_o-F_c data are deposited as Document No. 8866 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Examination of the Chemical Stability. A. Effect of pH. Since each complex has an extremely low solubility in H_2O, reactions were performed in two-layer solvents ($CHCl_3$-H_2O). A solution of each complex (0.2 mmol) in $CHCl_3$ (10 ml) was added to excess hydrochloric acid (pH=2, 40 ml), excess amount of aqueous KOH (pH=12, 40 ml) or 10 ml of distilled H_2O (pH=6). The solution was shaken vigorously for ten minutes in a separatory funnel. The organic layer was separated. The organic solution was evaporated to dryness and the residue was characterized by the ^1H NMR and IR spectra.

B. Reaction of 1 and 2 with Methanethiol, *p*-Toluenethiol, or Imidazole. Ethanethiol (0.4 mmol), *p*-toluenethiol (0.4 mmol), or imidazole (0.4 mmol) was added to a chloro-

form solution (10 ml) containing each complex (0.2 mmol). The solution was shaken vigorously for 10 minutes. Unreacted methanethiol, *p*-toluenethiol or imidazole was extracted into the aqueous KOH phase as potassium salts. The products in $CHCl_3$ were isolated by evaporation and characterized by the ^1H NMR and IR spectra.

Results and Discussion

Preparation and Characterization of 1 and 2. Compound **1** was obtained as a powdery solid, while **2** was obtained as colorless transparent pillar crystals. We also tried to prepare analogous (triethylphosphine)gold(I) derivatives; however, preparations of the products were unsuccessful under the present exprimental conditions.

Coordination of 5-fluorouracil derivatives to gold(I) in **1** and **2** was confirmed by the ^{31}P, ^1H NMR and IR spectra.

^{31}P NMR of **1** (δ 31.7 in $CDCl_3$-THF) and **2** (δ 31.8 $CDCl_3$), proved to be upfield shifts, compared with that of chloro(triphenylphosphine)gold(I) (δ 33.4 in $CDCl_3$). The ^{31}P upfield shifts were also observed for other (triethylphosphine)gold(I)-(nitrogen ligand) compounds.[8,9] Thus, ^{31}P shifts imply that the nitrogen atom links to the gold(I) atom.

^1H NMR spectral data of **1** and **2** are summarized in Table 2. For **1**, the peak of pyrimidine H(6) proton shows an upfield shift, compared to that of free 5FdUrd, and overlaps with that of fifteen phenyl protons. While, for **2**, the peak of pyrimidine H(6) proton also shows an upfield shift compared with that of free tegafur, it does not overlap with fifteen phenyl protons. ^1H NMR results suggest again that those upfield shifts are caused by a coordination of the pyrimidines.

IR data of **1** and **2** are shown in Table 3. Characteristic absorption bands due to C=O were found in the range 1530—1660 cm^{-1} in these compounds. The C=O absorption peaks shift to a lower frequency than those of the free 5FdUrd or tegafur in the range 1650—1720 cm^{-1}. These results mean that the C=O bonds increase the single-bond character by the coordination, i.e., a part of bond electrons of C=O move toward nitrogen-gold(I) link.

Structure of 2. The molecular structure of **2** is illustrated in Fig. 1 by the use of ORTEP program.[10] Selected bond lengths and angles are listed in Table 4. Au(I) has almost a linear coordination. The lengths of Au-N and Au-P, and the angle of P-Au-N, agree with those of (phthalimidate)(triethylphosphine)gold(I) and (adeninate)(triethylphosphine)gold(I).[8,9] A deformation of ligands resulting through coordination is not found, except that the N(2) atom is slightly pulled toward the Au(I) atom; also, tetrahydrofuranyl moiety rotates around C(23)-N(1) bond. This rotation is

C(3)-C(26)-C(25)	104.2(28)

caused by stacking of the bulky triphenylphosphine group in the crystal. Substituent fluorine has only little effect on the molecular structure of pyrimidine skeleton.[11]

Examination of the Chemical Stability of 1 and 2. Compound **1** was stable against neutral or alkaline solutions (pH=12; aqueous KOH), but under acidic conditions (pH=2; hydrochloric acid), **1** was transformed to chloro(triphenylphosphine)gold(I). Compound **2** was stable under the above conditions. The instability of **1** is attributable to the existance of hydroxyl groups in **1**; polar hydroxyl groups may accelerate the reactions by hydrogen bond or proton affinity.

Both **1** and **2** reacted with methanethiol, *p*-toluenethiol or imidazole. In each case, the corresponding phosphine thiolate gold(I) complexes or phosphine imidazolato gold(I) complex were formed. These facts suggest that **1** and **2** have a possibility to react with a protein containing a cysteine or histidine residue in vivo.

Antitumor Activity. Preliminary antitumor antimal tests against Mouse Leukemia L1210 were carried out using female CDF_1 mice. While **2** showed comparable activity to tegafur, compound **1**, however, indicated an enhanced activity, compared with 5FdUrd. Further animal tests by use of Lymphocytic Leukemia P388 are in progress.

This work was supported in part by Grand-in-Aid for Cancer Research from the Ministry of Health and Welfare of Japan. Thanks are also given to Mr. Shizuo Shimada (Institute of Biological Sciences, Mitsui Pharmaceuticals Inc.) for the antitumor activity test against L1210 Leukemia.

(Received October 24, 1988)

Palladium(II) acetate reacts with benzene in the presence of dialkyl sulfides at 70 °C to afford novel diphenyltripalladium(II) complexes of $[(R^1SR^2)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(R^1SR^2)]$ (**1a**; R^1=Bu^t, R^2=CH_2Bu^t: **1b**; R^1=R^2=Bu^t: **1c**; R^1=R^2=Pr^i: **1d**; R^1=R^2=Et). Adducts, $[Pd(MeCO_2)_2(Bu^tSCH_2Bu^t)_2]$ and $[Pd(MeCO_2)_2(SPr^i_2)_2]$, prepared by the reactions of palladium(II) acetate and the corresponding dialkyl sulfides in benzene at 5—10 °C, change to **1a** and **1c**, respectively, on heating in benzene at 70 °C. In contrast, reactions of palladium(II) acetate with toluene or thiophene in the presence of diisopropyl sulfide afford no isolable tolyl- or thienyl-palladium species, but coupling products, i.e. bitolyls or bithienyls, are detected by GLC analysis. Treatment of **1b** with styrene produces *trans*-stilbene, whereas **1c** reacts with carbon monoxide as well as carbon dioxide to yield benzoic acid. When palladium(II) acetate and *t*-butyl phenethyl sulfide are heated at 80 °C in benzene, an adduct $[Pd(MeCO_2)_2(Bu^tSCH_2CH_2Ph)_2]$ is formed, in sharp contrast with the case of benzyl *t*-butyl sulfide, which gives a cyclopalladated complex under the same reaction conditions.

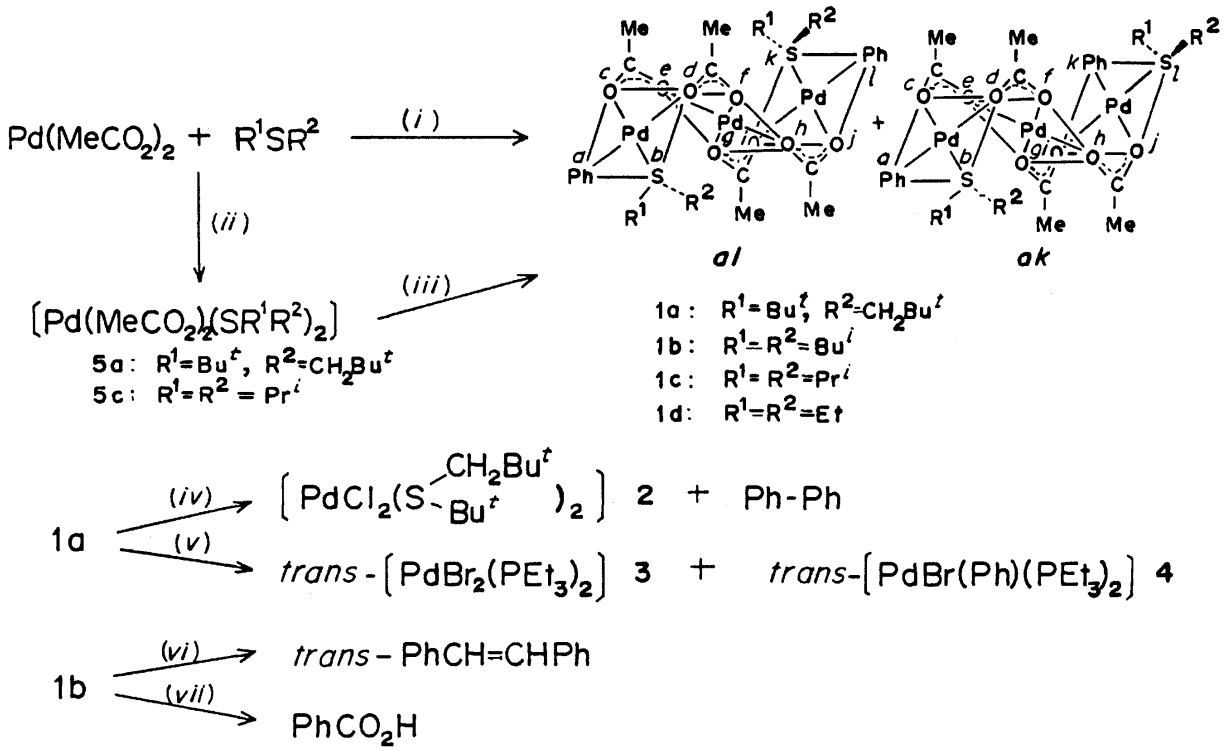
Although the metallations of arenes with non-transition metal compounds such as thallium[1] and mercury compounds[2] are well-known, the activation of arene C-H bonds by transition metals is a subject undergoing current research in organometallic chemistry. Up to date, mainly two types of the preparations of σ-aryl complexes directly from arenes and transition metal compounds have been reported. The first type is the oxidative addition of arene C-H bonds to coordinatively unsaturated species which are photochemically generated from dihydridometal complexes such as $[W(\eta^5\text{-}C_5H_5)_2H_2]$[3] and $[M(\eta^5\text{-}C_5Me_5)H_2(PMe_3)]$ (M=Rh,[4] Ir[5]) or thermally generated from $[M(2\text{-naphthyl})H(Me_2PCH_2CH_2PMe_2)_2]$ (M=Fe, Ru).[6] The second type is electrophilic substitution of arenes by metal complexes such as $AuCl_3$,[7] H_2PtCl_6,[8] and [Rh(octaethylporphyrinato)Cl]-Ag salt.[9]

It was proposed that σ-arylpalladium(II) complexes were formed in the arylation of olefins,[10] or carbonylation[11] and carboxylation[12] of arenes by palladium(II) acetate, but such the complex had never been isolated. Previously, we reported preliminary results about novel diphenyltripalladium(II) complexes isolated from palladium(II) acetate-dialkyl sulfide systems in benzene.[13] Here, we wish to report both the details of the C-H bond activation of arenes by the same systems and by a few additional ones and characterization of the resulting diphenyltripalladium(II) complexes.

Results and Discussion

Reactions of Palladium(II) Acetate with Dialkyl Sulfides in Benzene. Palladium(II) acetate reacted with *t*-butyl neopentyl sulfide in benzene at 70 °C to give yellow-brown crystals of **1a** and biphenyl (70% yield). The IR spectrum of **1a** showed newly a ν(C-H) frequency of the aromatic ring at 3040 cm^{-1}, together with the bands due to bridging acetato ligands at 1570, 1555, 1410, and 1395 cm^{-1}. The NMR data (^{1}H and ^{13}C; see below) of **1a** in C_6D_6 confirmed the presence of phenyl groups as well as acetato and *t*-butyl neopentyl sulfide ligands. The molecular weight was determined to be 1055 by osmometry in benzene at 42 °C (Calcd for $C_{38}H_{62}O_8Pd_3S_2$: M, 1030.28). On the basis of these results and elemental analysis, **1a** was assigned as diphenyltripalladium(II) complex with four μ-acetato ligands, $[(Bu^tSCH_2Bu^t)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(Bu^tSCH_2Bu^t)]$. The ^{1}H NMR spectrum of **1a** exhibited the phenyl proton signals at δ 8.14 (d), 8.05 (d), and 6.95—7.5 (m). In addition, the acetatomethyl protons appeared as four singlets at δ 1.63 (3H), 1.73 (3H), 1.84 (3H), and 1.93 (3H), whereas the methyl protons of the sulfide moieties resonated as three singlets at δ 1.31 (18H, $CH_2C\underline{Me}_3$), 1.39 (9H, $SC\underline{Me}_3$), and 1.46 (9H, $SC\underline{Me}_3$). These data indicated that **1a** consisted of two geometrical isomers, *al-* and *ak*-diphenyl types (Scheme 1) in a population ratio of 1 : 1. In the $^{13}C\{^1H\}$ NMR spectrum,[14] signals due to the two isomers were observed almost separately.

Complex **1a** reacted with lithium chloride in acetone to give an adduct $[PdCl_2(Bu^tSCH_2Bu^t)_2]$ (**2**) but not a phenylpalladium species. However, biphenyl was detected in 70% yield based on **1a** by GLC analysis of the reaction mixture. In contrast, when **1a** was treated with triethylphosphine and lithium bromide in acetone, both *trans*-$[PdBr_2(PEt_3)_2]$ (**3**) and *trans*-$[PdBr(Ph)(PEt_3)_2]$ (**4**) were isolated in 61% and 14% yields, respectively. These results confirmed that **1a** contained phenylpalladium moieties as well as '$Pd(MeCO_2)_2$' moiety. The formation of trinuclear palladium(II) complexes containing four μ-acetato ligands has been found in $[Pd_3(\eta^3\text{-allyl})_2(\mu\text{-}MeCO_2)_4]$,[15]



Scheme 1. Reactions of palladium(II) acetate with dialkyl sulfides in benzene and the reactivities of complexes **1a** and **1b**. (i) Benzene, 70 °C. (ii) Benzene, 5—10 °C. (iii) Benzene, 70 °C. (iv) LiCl. (v) PEt_3, LiBr. (vi) $PhCH{=}CH_2$. (vii) CO or CO_2.

Table 1. Yields, Melting Points, IR, and Analytical Data of the Complexes

Complex	Yield %	Mp[a] θ_m/°C	IR/cm^{-1} ν(CH aromatic)	IR/cm^{-1} ν(COO)	Found (Calcd)(%) C	Found (Calcd)(%) H
1a	29 45[b]	139	3040	1570, 1555 1410, 1395	43.62(44.30)	5.94(6.07)

a) With decomposition. b) Yield from **5a**. c) Yield from **5c**.

$[Pd_3(CH_2CMe_2CH_2NMe_2)_2(\mu\text{-}MeCO_2)_4]$,[16] and $[Pd_3(CH_2C_6H_4NMe_2\text{-}o)_2(\mu\text{-}MeCO_2)_4]$,[17] which were produced by the reactions of palladium(II) acetate with monoolefins, *N,N*-dimethylneopentylamine, and *N,N*-dimethyl-*o*-toluidine, respectively.

It is also found that when palladium(II) acetate was treated with benzene at 70 °C for 2 h in the presence of each of diisobutyl, diisopropyl, and diethyl sulfides, the corresponding diphenyltripalladium(II) complexes $[(R^1SR^2)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(R^1SR^2)]$ (**1b**, $R^1{=}R^2{=}Bu^i$; **1c**, $R^1{=}R^2{=}Pr^i$; **1d**, $R^1{=}R^2{=}Et$) were obtained with the formation of biphenyl in 12, 22, and 39% yields, respectively. The complexes **1b—1d** were characterized by means of elemental analyses (Table 1) and spectroscopic data (Tables 1 and 2). Complexes **1b—1d** were also composed of two isomers *al*- and *ak*-diphenyl types in population ratios of about 1 : 0.8.

Complexes **1a—1d** were fairly stable in solid state, but decomposed gradually in solution to give metallic palladium. Any good single crystal suitable for X-ray structural analysis could not be obtained owing to their instability in solution. It should be noted that

the benzene molecule was directly activated by palladium(II) acetate in the presence of dialkyl sulfides to give the diphenyltripalladium(II) complexes of **1a**—**1d**.

When di-*t*-butyl sulfide or tetrahydrothiophene was heated in benzene at 70 °C for 2 h with palladium(II) acetate, the corresponding diphenyltripalladium(II) complex like **1** could not be isolated in both cases. However, biphenyl was detected in 19% (in the case of SBu^t_2) and 40% yields [in the case of $S(CH_2)_4$] based on palladium(II) acetate by GLC analysis of the reaction mixtures. When palladium(II) acetate was treated with benzene at 70 °C for 2 h in the absence of dialkyl sulfide, no biphenyl was detected. Taking these facts into consideration, it seemed likely that benzene was also activated in the cases of di-*t*-butyl sulfide and tetrahydrothiophene.

The reactions of palladium(II) acetate with *t*-butyl neopentyl sulfide and diisopropyl sulfide, carried out in benzene at 5—10 °C, produced mononuclear addition complexes, $[Pd(MeCO_2)_2(Bu^tSCH_2Bu^t)_2]$ (**5a**) and $[Pd(MeCO_2)_2(SPr^i_2)_2]$ (**5c**), respectively. Complex **5a** was heated in benzene at 70 °C for 2 h to give yellow-brown crystals, which was ascribed to the diphenyltripalladium(II) complex **1a**, but not to a binuclear palladium(II) species such as $[(Bu^tSCH_2Bu^t)PhPd(\mu\text{-}MeCO_2)_2PdPh(Bu^tSCH_2Bu^t)]$. Similarly, **5c** was converted to **1c** under the same conditions.

Reactivity of the Diphenyltripalladium(II) Complex $[(Bu^i_2S)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(SBu^i_2)]$ (1b). The complex **1b** reacted with styrene in THF at room temperature to produce *trans*-stilbene in 94% yield. When carbon monoxide was bubbled through a THF solution of **1b** at room temperature and the reaction mixture was treated with sodium hydrogencarbonate and hydrochloric acid, benzoic acid was obtained in 64% yield by GLC analysis. Benzoic acid was also produced in 9% yield (GLC analysis) by treating **1b** with 4.4×10^6 Pa of carbon dioxide in a THF-$MeCO_2H$ (4:1) mixed solvent in an autoclave at 60 °C. Furthermore, very small amount of phenol was obtained by treating **1b** with pressurized mixture of dioxygen and carbon monoxide.[18]

It was reported that benzene was carbonylated with carbon monoxide (1.52×10^6 Pa) and was also carboxylated with carbon dioxide (3.04×10^6 Pa) in the presence of palladium(II) acetate to give benzoic acid in 26% and 13% yield, respectively.[11,12] The facts that *trans*-stilbene and benzoic acid were obtained from **1b** are important in elucidating the mechanisms for the arylation of alkenes[10] and carbonylation[11] as well as carboxylation of arenes[12] by palladium(II) acetate.

Reaction of Palladium(II) Acetate with Dialkyl Sulifde in Toluene or in Thiophene. Treatment of palladium(II) acetate with diisobutyl sulfide in toluene at 80 °C for 2 h gave only an intractable oil. However, GLC analysis of the reaction mixture revealed the presence of bitolyls composed of six isomers [2,2′:(2,3′+2,4′):3,3′:3,4′:4,4′=6:6:22:45:21] in 25% yield based on palladium(II) acetate. The above reaction carried out in thiophene also afforded an intractable oil, but bithienyls consisting of three isomers [2,2′:(2,3′+3,3′)=9:1] were detected in 25% yield based on palladium(II) acetate by GLC analysis. On the other hand, no coupling product was detected in a toluene or thiophene solution heated only with palladium(II) acetate at 80 °C for 2 h. In consideration of these facts, it seemed likely that tolyl- and thienylpalladium species were formed during the reactions as intermediates, and that diisobutyl sulfide enhanced the coupling reactions of aromatic compounds.

Reactions of Palladium(II) Acetate with Phenyl-Substituted Dialkyl Sulfides, $Ph(CH_2)_nSBu^t$ (n=1,2) in Benzene. It is interesting to investigate whether palladium(II) acetate could activate the C-H bond of benzene intermolecularly even in the presence of phenyl-substituted dialkyl sulfides or activate the ortho C-H bond of the phenyl group in the sulfides intramolecularly. The reaction of benzyl *t*-butyl sulfide with palladium(II) acetate in benzene at 80 °C afforded a cyclopalladated complex $[\{Pd(\mu\text{-}MeCO_2)(C_6H_4CH_2SBu^t\text{-}C^1,S)\}_2]$ (**6**), whose IR and ^1H NMR spectra were identical with those of the authentic sample.[19] In contrast, *t*-butyl phenethyl sulfide afforded only an adduct, $[Pd(MeCO_2)_2(Bu^tSCH_2CH_2Ph)_2]$ (**7**) under the same reaction conditions. Prolonged heating of **7** in benzene at 50 °C for 20 h gave neither a cyclopalladated species nor a phenylpalladium one, but only **7** was recovered from the reaction mixture. Up to date, there has been only one report concerning the formation of six-membered cyclopalladated complexes of sulfur ligands.[20,21] In these cases, the sulfur-containing six-membered cyclopalladated structures were reinforced by the double chelations or a five-membered C-S or C-N chelate.[20] It seemed likely that *t*-butyl phenethyl sulfide was also hard to be cyclopalladated and form a simple six-membered palladacycle $Pd\text{-}C_6H_4CH_2CH_2\text{-}SBu^t\text{-}C^1,S$.

Experimental

t-Butyl neopentyl sulfide,[22] benzyl *t*-butyl sulfide,[23] and *t*-butyl phenethyl sulfide[24] were prepared according to the literatures. Diisobutyl, diisopropyl, diethyl, and di-*t*-butyl sulfides and tetrahydrothiophene were commercial samples. Gas chromatographic analyses were made with a Shimadzu GC-4B gas chromatograph using helium as a carrier gas on columns of Apieson Grease L and Silicone OV-17. Identification of the reaction products was performed by coinjection with authentic samples on the columns and by a Nichiden-Varian TE-600 gas chromatograph-mass spectrometer. For determination of yields, the following internal standards were used: naphthalene for biphenyls, bitolyls, and bithienyls, and hexamethylbenzene for benzoic acid. Other procedures were as described previously.[25]

Preperations of $[(R^1SR^2)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2\text{-}PdPh(R^1SR^2)]$ (1a; R^1=Bu^t, R^2=CH_2Bu^t: 1b; R^1=R^2=Bu^i: 1c; R^1=R^2=Pr^i: 1d; R^1=R^2=Et). A mixture containing palladium(II) acetate (250 mg, 1.11 mmol) and *t*-butyl neopentyl sulfide (119 mg, 0.742 mmol) in 10 cm^3 of benzene was heated at 70 °C for 90 min. After filtration, the filtrate was concentrated under reduced pressure and diluted with hexane to give 79 mg of **1a** as beige crystals. Complexes **1b**, **1c**, and **1d** were prepared similarly.

Reation of 1a with Lithium Chloride. Lithium chloride (103 mg, 2.43 mmol) in water (2 cm^3) was added to an acetone solution (15 cm^3) of **1a** (250 mg, 0.243 mmol), and the resulting mixture was stirred at room temperature for 6 h. After the mixture was evaporated to dryness, the residue was extracted with benzene. The extract was diluted with hexane to give 50 mg of $[PdCl_2(Bu^tSCH_2Bu^t)_2]$ (**2**) as a yellow powder.

Reaction of 1a with Triethylphosphine and Lithium Bromide-Water (1/1). Triethylphosphine (124 mg, 1.05 mmol) in acetone (5 cm^3) was added to **1a** (150 mg, 0.146 mmol) in acetone (15 cm^3), and the mixture was stirred at room temperature for 4 h. To the resulting yellow solution, lithium bromide-water (1/1) (507 mg, 5.84 mmol) was added. Stirring was further continued for 20 h, and then the mixture was evaporated to dryness. The residue was chromatographed on a silica-gel column (200 mesh, 1.8×16 cm). A yellow fraction eluted by benzene was collected and evaporated to dryness to give 44 mg of *trans*-$[PdBr_2(PEt_3)_2]$ (**3**). Another yellow fraction eluted by CH_2Cl_2/Et_2O (3/1) afforded 28 mg of *trans*-$[PdBr(Ph)(PEt_3)_2]$ (**4**).

Reactions of Palladium(II) Acetate with Di-*t*-butyl Sulfide or Tetrahydrothiophene in Benzene. A mixture containing palladium(II) acetate (250 mg, 1.11 mmol) and di-*t*-butyl sulfide (108 mg, 0.738 mmol) or tetrahydrothiophene (65 mg, 0.738 mmol) in benzene (15 cm^3) was heated at 70 °C for 2 h. After the reaction mixture was filtered, the filtrate was concentrated under reduced pressure and diluted with hexane to give only dark brown oil in both cases.

Preparation of the Adduct $[Pd(MeCO_2)_2(SR^1R^2)_2]$ (5a; R^1=Bu^t, R^2=CH_2Bu^t: 5c; R^1=R^2=Pr^i). A benzene solution (5 cm^3) of *t*-butyl neopentyl sulfide (857 mg, 5.34 mmol) was added to a benzene solution (10 cm^3) of palladium(II) acetate (400 mg, 1.78 mmol) at 5—10 °C. After stirring for 4 h at 10 °C, the resulting yellow solution was concentrated under reduced pressure and diluted with hexane to yield 180 mg of **5a**. Similarly, **5c** was prepared.

Reactions of 5a or 5c with Benzene. A benzene solution (10 cm^3) of **5a** (150 mg, 0.275 mmol) was heated at 70 °C for 2 h and then filtered. The filtrate was concentrated under reduced pressure and diluted with hexane to afford 43 mg of **1a**. Complex **5c** was similarly converted to **1c**.

Reactions of 1b with Styrene, Carbon Monoxide, or Carbon Dioxide. (i) **With Styrene.** Styrene (44 mg, 0.42 mmol) was added to a THF solution (10 cm^3) of **1b** (200 mg, 0.200 mmol), and the resulting mixture was stirred at room temperature for 1 h. The mixture was filtered to remove the precipitated palladium black, and the filtrate was chromatographed on a silica-gel column (200 mesh, 1.8×30 cm). A fraction eluted by benzene/hexane (1/1) was collected and evaporated to dryness to give 68 mg of *trans*-stilbene as white crystals, whose IR, mp, and ^1H NMR spectrum were identical with those of the authentic sample.

(ii) **With Carbon Monoxide.** Carbon monoxide was bubbled through a THF solution (30 cm^3) of **1b** (100 mg, 0.100 mmol) for 3 h at room temperature. Precipitated palladium black was filtered, and the filtrate was added to a saturated sodium hydrogencarbonate solution (10 cm^3). Then, diethyl ether (15 cm^3) was added. The water layer was separated and acidified with concentrated HCl and the organic product was extracted with diethyl ether (15 cm^3). The ethereal layer was dried by Na_2SO_4 and after evaporation of the solvent, the product was analyzed and identified as benzoic acid by GLC analysis (64% based on **1b**), mp, and IR.

(iii) **With Carbon Dioxide.** In a 200-cm^3 autoclave was placed a 100-cm^3 beaker containing **1b** (213 mg, 0.213 mmol), THF (20 cm^3), and acetic acid (5 cm^3). The autoclave was closed, flushed with carbon dioxide, and pressurized to 4.4×10^6 Pa. The mixture was heated at 60 °C with stirring for 20 h. The resulting mixture was filtered and the filtrate

was similarly treated as described in (ii). The organic products detected by GLC analysis were benzoic acid (9% yield) and biphenyl (1% yield).

Reactions of Palladium(II) Acetate with Diisobutyl Sulfide in Toluene or Thiophene. A mixture containig palladium(II) acetate (150 mg, 0.668 mmol) and diisobutyl sulfide (65 mg, 0.445 mmol) in 10 cm^3 of toluene or thiophene was heated at 70 °C for 2 h, and then filtered. The filtrate was concentrated under reduced pressure and diluted with hexane to give dark brown oil in both cases.

Reactions of Palladium(II) Acetate with Phenyl-Substituted Dialkyl Sulfides $Ph(CH_2)_nSBu^t$ (n=1,2) in Benzene. (i) With $PhCH_2SBu^t$. A mixture containing palladium(II) acetate (150 mg, 0.670 mmol) and benzyl *t*-butyl sulfide (145 mg, 0.804 mmol) in benzene (10 cm^3) was heated at 80 °C for 4 h, and then filtered. The filtrate was diluted with hexane to afford 50 mg of $[\{Pd(\mu\text{-}MeCO_2)(C_6H_4CH_2SBu^t\text{-}C^1, S)\}_2]$ (**6**) as a yellow powder.

(ii) With $PhCH_2CH_2SBu^t$. A mixture containing palladium(II) acetate (200 mg, 0.890 mmol) and *t*-butyl phenethyl sulfide (380 mg, 1.96 mmol) in benzene (20 cm^3) was heated at 80 °C for 4 h, and then filtered. The filtrate was diluted with hexane to give 110 mg of $[Pd(MeCO_2)_2(Bu^tSCH_2CH_2Ph)_2]$ (**7**) as yellow crystals.

The authors wish to thank the Asahi Glass Foundation for Industrial Technology for financial support to this study and acknowledge Mrs. Hisako Mazume for her technical assistance.

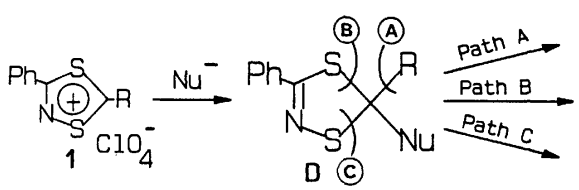
Reaction of 1,4,2-Dithiazolium and 1,3-Dithiolium Salts with Malononitrile

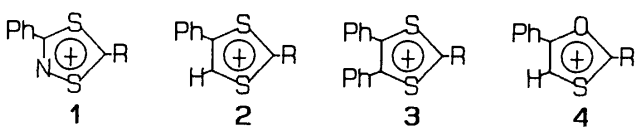
Katsumi YONEMOTO,* Isao SHIBUYA,* and Kazumasa HONDA
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received July 27, 1988)

The reaction of 5-substituted 3-phenyl-1,4,2-dithiazolium salts with malononitrile gave not only 5-dicyanomethylene-3-phenyl-1,4,2-dithiazole and an isothiazole derivative, but 4-amino-5-cyano-2-(1-cyano-2-dialkylamino-2-mercaptovinyl)-6-phenylpyrimidines (**6**) and a butadiene derivative, depending on substituents at C-5 and bases used. The structure of **6** was confirmed by X-ray crystallographic analysis of its methylated derivative. These results are well explained by assuming three possible fission modes of the initial adduct: liberation of substituents at C-5 (Path A), ring opening-ring closure reaction (Path B), and fragmentation of dithiazole ring (Path C). On the other hand, 2-dialkylamino-4,5-diphenyl-1,3-dithiolium salts were allowed to react with malononitrile to afford 2-amino-3-cyano-5,6-diphenyl-1,4-dithiin (**13**) and 4-amino-3-cyano-2-dicyanomethylene-5,6-diphenyl-2*H*-thiin (**14**) as well as 2-dicyanomethylene-4,5-diphenyl-1,3-dithiole (**12**). In a separate experiment, both **13** and **14** were formed by the reaction of **12** with malononitrile. This pathway can be interpreted in terms of considerable contribution of polar structure of **12** due to the push-pull effect of sulfur atoms and cyano groups. Furthermore, the reaction of 2-substituted 4-phenyl-1,3-dithiolium salts with malononitrile also gave 2-dicyanomethylene-4-phenyl-1,3-dithiole and thiophene derivatives.

Five-menbered heteroaromatic-cation compounds have attracted much attention on their reactivity to serve as versatile intermediates in organic synthesis.[1-3] In particular, it is well known that the reactions of 1,3-dithiolium cations (**2**)[3a,d] and 1,3-oxathiolium cations (**4**)[1b,3] with various kinds of nucleophiles lead to a wide range of heterocyclic compounds. The preparation of 1,4,2-dithiazolium cations (**1**) was recently established by three independent groups, and the reaction of **1** with a few nucleophiles was also reported.[4] We have shown in a previous paper that the reaction of **1** with various amino compounds can be classified into three types (Paths A, B, and C) depending on three possible fission modes (A, B, and C in Scheme 1) of the initial adduct (**D**), leading to 5-imino-1,4,2-dithiazole, 1,3,4-thiadiazole, and thiourea derivatives, respectively.[5] In our continuing investigation into the chemistry of **1**, we carried out the reaction of **1** with malononitrile, one of highly reactive methylene compounds, in the presence of various bases. For comparison, the behavior of 4-phenyl- and 4,5-diphenyl-1,3-dithiolium cations (**2** and **3**), carba-analogues of **1**, toward malononitrile was also examined, and some interesting information on their reactivity was obtained.



Scheme 1.



Results and Discussion

When 5-dimethylamino-3-phenyl-1,4,2-dithiazolium perchlorate (**1a**) was treated with malononitrile in the presence of Et_3N at room temperature, the reaction gave a yellow compound as the sole product (Entry 1 in Table 1). On the grounds of its elemental analysis and spectral data, i.e., mercapto, amino, and two cyano bands in IR spectrum, the signals attributable to dimethylamino and phenyl groups in ^1H NMR spectrum, and the molecular ion peak in mass spectrum, the pyrimidine derivative (**6a**) was proposed as the structure of this compound. The reaction of **1b** with malononitrile in the presence of Et_3N and γ-picoline also afforded this type of compound **6b** (Entries 2 and 3). Since the structure of the above products cannot be unequivocally determined from the present data, it was examined by X-ray crystallographic analysis of **7** which was obtained by methylation of **6b**. It proved the proposed pyrimidine structure; an ORTEP illustration of **7** is given in Fig. 1. It shows that the ring skeleton of starting material **1** is divided into sections

with elimination of one sulfur atom, into which two malononitrile molecules are consequently incorporated.

Detailed mechanism of the present reaction is not clear, but the formation of **6** is most likely rationalized by the pathway shown in Scheme 2. The initial adduct **D** formed by reaction of **1** with malononitrile undergoes ring opening (Path B) and subsequent ring closure leading to the intermediate **E**, which then brings about ring expansion with sulfur extrusion to give six-membered intermediate **F**; another malononitrile molecule attacks on C-2 position of **F** to afford intermediate adduct **G**, which then undergoes ring opening and ring closure to lead to the final products **6**.

The reaction of **1b** with malononitrile was carried out in NaH/THF or NaH/EtOH, i.e., EtONa/EtOH. In both cases, 2-amino-4-diethylamino-4-mercapto-1,1,3-tricyano-1,3-butadiene (**8**) was formed (Entries 4 and 5). On the other hand, in the case of using the combinations of **1** with relatively weak bases such as pyridine and γ-picoline (Entries 6—8), the reaction of **1** with malononitrile in MeCN at room temperature gave 5-dicyanomethylene-3-phenyl-1,4,2-dithiazole (**5a**). The formation of **8** and **5a** can be explained as follows. The initial adduct **D** (in Scheme 2) undergoes ring cleavage leading to intermediate **H** together with benzonitrile and sulfur (via Path C), which then reacts with another malononitrile to give **8**; **D** is alternatively converted into **5a** with liberation of dialkylamino or methylthio groups (via Path A).

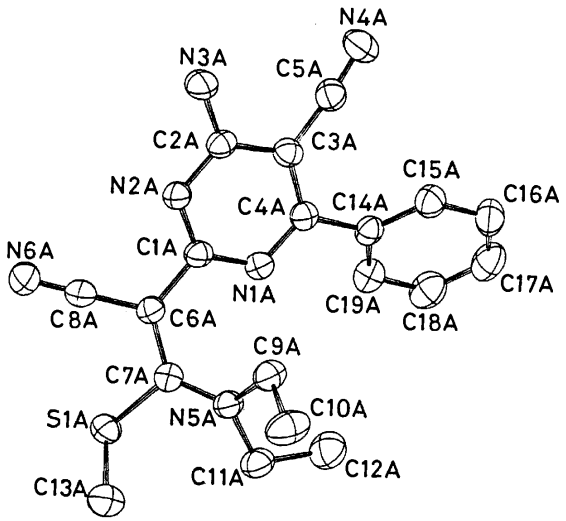

Fig. 1. Molecular structure[15] of **7** with the numbering system for the non-hydrogen atoms. Thermal ellipsoids are drawn at 40% probability.

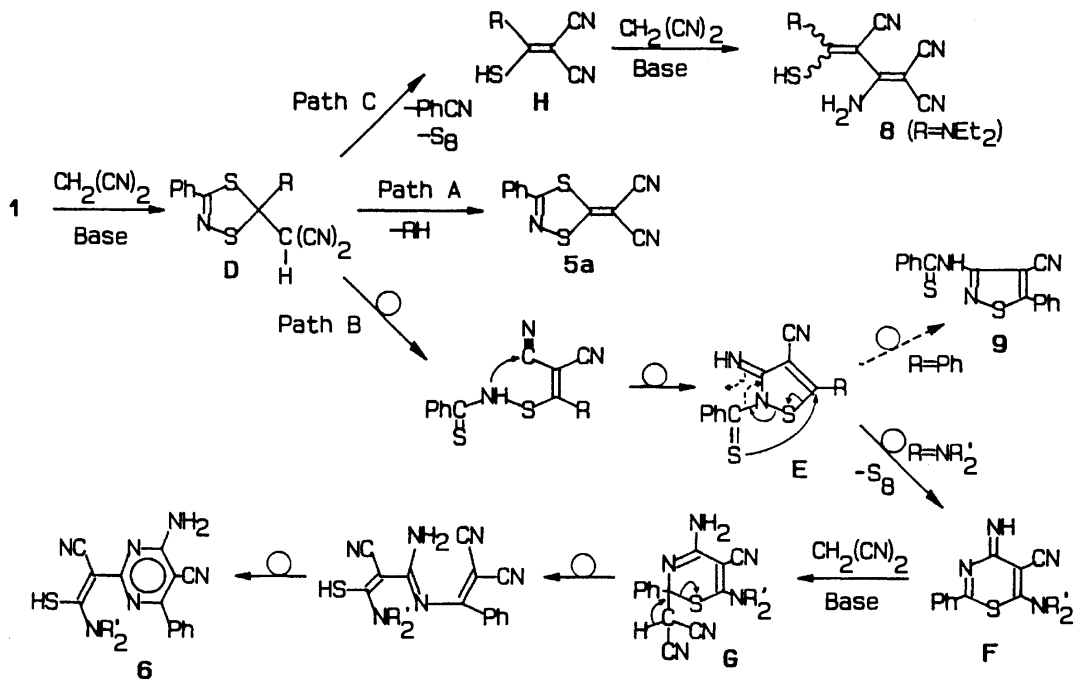

Scheme 2.

5-Phenyl form **1e** was allowed to react with malononitrile in the presence of Et_3N to give only 4-cyano-5-phenyl-3-(thiobenzoylamino)isothiazole (**9**) in 58% yield (Entry 9). The result was well explained in terms of [1,3]-shift of thiobenzoyl group in the intermediate **E** (in Path B).

From the above results, except the case of Entry 3, **5a** is preferentially formed (via Path A) in the presence of weaker bases such as pyridine and γ-picoline, whereas, in the presence of stronger bases such as Et_3N, NaH, and EtONa, the reaction undergoes ring opening (via Path B) or ring fragmentation (via Path C) resulting in the preferential formation of **6**, **8**, or **9**. In our previous work, a similar trend has been shown in the reaction of **1** with *p*-substituted aniline derivatives in the presence of various bases.[5]

On the other hand, the reactions of **1** with dimethyl malonate and Meldrum's acid in the presence of Et_3N have been reported, which lead to only 5-alkylidene-1,4,2-dithiazole derivatives (via Path A in Scheme 1).[4b,d] In order to examine generality of reaction courses corresponding to Path B (ring opening) or Path C (ring fragmentation), the reaction of **1a** with other active methylene compounds such as phenylsulfonylacetonitrile and benzoylacetonitrile in the presence of Et_3N was attempted; but the products other than 5-alkylidene-1,4,2-dithiazole derivatives **5b** and **5c** were not obtained.

In order to obtain additional information on the reactivity of five-membered heteroaromatic cations toward malononitrile, the reaction of 4-phenyl- and 4,5-diphenyl-1,3-dithiolium salts (**2** and **3**) bearing different substituents at C-2 position was carried out in the presence of different bases.[6] The results are presented in Tables 2 and 3, respectively.

The reaction of 2-diethylamino-4-phenyl-1,3-dithiolium perchlorate (**2a**) with malononitrile in the presence of γ-picoline (weak base) gave only 2-dicyanomethylene-4-phenyl-1,3-dithiole (**10**)[3d] (Entry 10), whereas, in the presence of Et_3N (strong base), **2a** afforded 3-amino-4-cyano-5-diethylamino-2-thiobenzoylthiophene (**11a**) (Entry 11). However, 2-dimethylamino form **2b** afforded only **10** (Entry 12) even under the same conditions as used in Entry 11. On the other hand, the sole formation of thiophene derivative **11b** by reaction of **2d** (Entry 14) is associated with the fact that phenyl group at C-2 has no leaving ability. Thus the reactivity of **2** seems to depend delicately on both substituents at C-2 position and bases used. The similar effects of base strength on reactivity have been observed in the reaction of 1,3-oxathiolium salts **4** with active methylene compounds; the reaction leads to 2-alkylidene-1,3-oxathioles (1,4-oxathiafulvenes) and open chain compounds which often undergo ring closure reaction to afford thiophene derivatives.[3b]

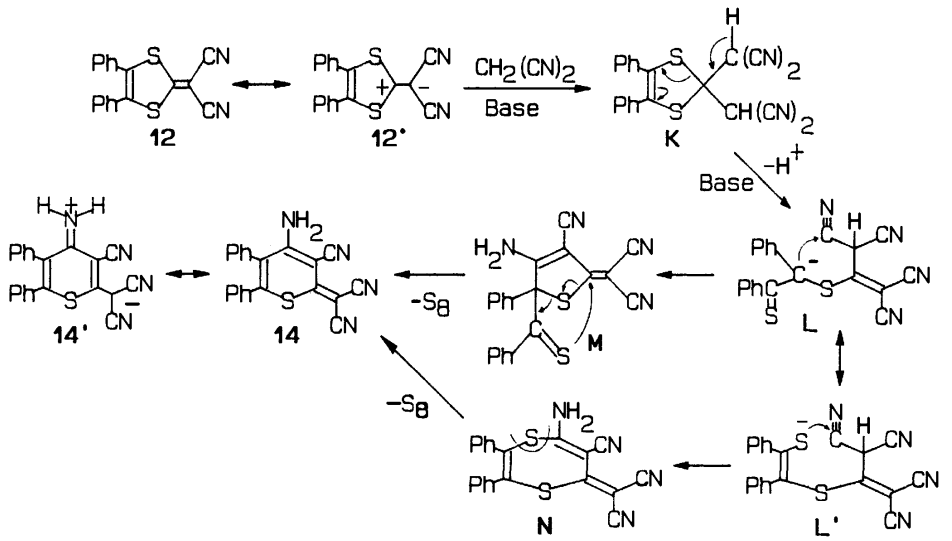
a) Isolated yield. b) Products **13** and **14** were detected only on TLC.



Scheme 3.

1,3-dithiolium perchlorates (**3a** and **3b**) were subjected to react with 2 equiv of malononitrile in the presence of Et_3N in MeCN at room temperature for 1.5 h to give three products (Entries 15 and 16). Their spectral data (IR, ^1H NMR, and MS) and elemental analyses suggested that the main product is the expected 2-dicyanomethylene-4,5-diphenyl-1,3-dithiole (**12**), and that the others are 2-amino-3-cyano-5,6-diphenyl-1,4-dithiin (**13**) and 4-amino-3-cyano-2-dicyanomethylene-5,6-diphenyl-2*H*-thiin (**14**). Characteristically, the ^1H NMR signals of two amino protons of **14** were magnetically unequivalent and broad, indicating large contribution of the polar structure **14'** as shown in Scheme 3.

The same reaction as in Entry 16, except prolonged standing (1 day), resulted in disappearance of **12** and improvement of yields of both **13** and **14**, the ratio of which was almost unchanged (Entry 17). In the case of using γ-picoline (weaker base) instead of Et_3N, neither **13** nor **14** was formed (Entry 18). Under the forced conditions, i.e., NaH/THF system (Entry 19), **12** was preferentially obtained in a short reaction time. Therefore, the formation of **13** and **14** is speculated to go via initially-formed **12**. In fact, the reaction of **12** with malononitrile under the same conditions as those used in Entry 17 gave **13** (42%) and **14** (26%) with no recovery of **12**.

These results are well explained by assuming considerable contribution of the polar structure **12'**, which takes the push-pull effect of two electron-donating sulfur atoms in hetero-ring and two electron-withdrawing cyano groups as shown in Scheme 3. Nucleophilic attack of malononitrile on C-2 position of **12'** leads to intermediate adduct **K** which then undergoes ring opening-ring closure reaction and subsequent rearrengement with sulfur extrusion to give **14** (via intermediates **L** and **M**). This pathway is similar to Path B in Scheme 2 and product **14** corresponds to intermediate **F**. Thus, the isolation of **14** seems to be an evidence for the transient existence of **F** in the proposed reaction pathway. On the other hand, we cannot exclude the possibility that intermediate **L'**, a tautomer of **L**, undergoes ring closure and sulfur extrusion via seven-membered intermediate **N** to give **14**. However, in the case of the reaction of **1**, the pathway similar to that via **L'** and **N** cannot be probable for Path B, because the corresponding seven-membered intermediate 1,4,2-dithiazepine derivative, aza-analogue of **N**, could not afford 1,3-thiazines **F** but 1,2-thiazines. A mechanism of the formation of **13** still remains uncertain.

In summary, the reaction of 1,4,2-dithiazolium salts **1** with malononitrile gave **5a** and **9** in similar manners to the reactions of 1,3-dithiolium salts **2** and **3** leading to **10**, **11**, and **12**,[3] whereas, via novel courses, **1** gave **6** and **8**, depending on substituents at C-5 position and bases used. It is known that the reaction manner of malononitrile to heteroaromatic cations is often different from that of other active methylene compounds.[2a,7] In this study, this tendency was shown again. Detailed studies on the behavior of fulvene-type compounds such as **5a**, **10**, and **12** toward various kinds of nucleophiles are currently under way.

Experimental

All the melting points were uncorrected. The ^1H NMR spectra were recorded on a HITACHI R-40 or a JEOL FX-90A spectrometer using TMS as an internal standard. The IR spectra were measured on a JASCO A-302 spectrometer using KBr disks. The low-resolution mass spectra were taken on a HEWLETT PACKARD 5995A spectrometer by electron impact ionizing technique at 70 eV.

1,4,2-Dithiazolium salts **1a**—**c**[4a] and **1b**,[4b] and 4-phenyl-1,3-dithiolium salts **2a**—**d**[8] were prepared according to the procedures in the literatures. The salt **1e** was prepared from dithiobenzoate in three steps utilizing the similar procedure

for **1a**—**c**.[9] 4,5-Diphenyl-1,3-dithiolium salts **3** were prepared from the reaction of dithiocarbamate and 2-bromo-2-phenylacetophenone in a similar manner to that described in Ref. 8. Other commercially available reagents and bases were used without any purification.

Reaction of 1,4,2-Dithiazolium Salts 1 with Malononitrile. 1,4,2-Dithiazolium perchlorates **1** (1 mmol) were added with stirring to the solution (6 ml) of malononitrile (2 mmol) and bases (2 mmol): the combinations of bases and solvents are listed in Table 1. The reaction mixture was stirred for 6 h at room temperature. In some cases, the products were recrystallized out and filtered off. The crude product was extracted with dichloromethane after addition of dil HCl. After the solvent was removed in vacuo, the residue was purified by column chromatography on silica gel and recrystallized from appropriate solvents. The yields of products are presented in Table 1.

5-Dicyanomethylene-3-phenyl-1,4,2-dithiazole (5a): Pale yellow powder. Mp 160.0—162.0 °C (CH_2Cl_2-hexane). ^{1}H NMR ($CDCl_3$) δ=7.5—7.7 (3H, m), 7.8—8.0 (2H, m). IR ν 2208, 1535, 1469, 1239 cm^{-1}. MS m/z (rel intensity) 243 (M^+, 29), 103(100). Found: C, 53.99; H, 2.10; N, 17.14; S, 26.25%. Calcd for $C_{11}H_5N_3S_2$: C, 54.30; H, 2.07; N, 17.27; S, 26.35%.

4-Amino-5-cyano-2-(1-cyano-2-dimethylamino-2-mercaptovinyl)-6-phenylpyrimidine (6a): Yellow powder. Mp 270.5—271.5 °C (DMF-water). ^{1}H NMR (DMF-d_7) δ=3.35 (6H, s), 7.5—7.7 (3H, m), 7.9—8.1 (2H, m). IR ν 3416, 3308, 3180, 2600(br), 2224, 2204, 1644, 1558 cm^{-1}. MS m/z (rel intensity) 322 (M^+, 63), 289 (21), 88 (100). Found: C, 59.39; H, 4.35; N, 25.68; S, 9.94%. Calcd for $C_{16}H_{14}N_6S$: C, 59.61; H, 4.38; N, 26.07; S, 9.94%.

4-Amino-5-cyano-2-(1-cyano-2-diethylamino-2-mercaptovinyl)-6-phenylpyrimidine (6b): Yellow powder. Mp 266.0—268.0 °C (DMF-water). ^{1}H NMR (DMSO-d_6) δ=1.25 (6H, t, J=7.2 Hz), 3.87 (4H, q, J=7.2 Hz), 7.6—7.8 (3H, m), 7.8—8.0 (2H, m). IR ν 3372, 3176, 2600, 2216, 2188, 1658, 1558 cm^{-1}. MS m/z (rel intensity) 350 (M^+, 26), 317 (8), 253 (86), 116 (31). Found: C, 61.58; H, 5.39; N, 24.16; S, 8.87%. Calcd for $C_{18}H_{18}N_6S$: C, 61.69; H, 5.18; N, 23.98; S, 9.15%.

(*Z*)- and (*E*)-2-Amino-4-diethylamino-4-mercapto-1,1,3-tricyano-1,3-butadiene (8): It is difficult to distingush between *Z*- and *E*-forms: a 3:2 isomeric mixture from comparison of the relative areas of ^{1}H NMR signals (diethylamino group). Yellow powder. Mp 178.5—179.5 °C (DMF-MeCN). ^{1}H NMR (DMSO-d_6) δ=1.18 (6H, t, J=7.2 Hz) and 3.46 (4H, q, J=7.2 Hz) for the major isomer, 1.32 (6H, t, J=7.2 Hz) and 3.86 (4H, q, J=7.2 Hz) for the minor isomer. IR ν 3412, 3192, 2226, 2196, 2136, 1652, 1566, 1444 cm^{-1}. MS m/z (rel intensity) 247 (M^+, 24), 230 (100), 175 (45). Found: C, 53.39; H, 4.92; N, 28.06; S, 12.96%. Calcd for $C_{11}H_{13}N_5S$: C, 53.42; H, 5.30; N, 28.32; S, 12.96%.

4-Cyano-5-phenyl-3-(thiobenzoylamino)isothiazole (9): Orange yellow powder. Mp 183.5—184.5 °C (CH_2Cl_2-ether). ^{1}H NMR ($CDCl_3$) δ=7.4—7.7 (8H, m), 7.8—8.0 (2H, m). IR ν 3176, 2224, 1543, 1443, 1418, 1386 cm^{-1}. MS m/z (rel intensity) 321 (M^+, 11), 320 (11), 121 (100). Found: C, 62.99; H, 3.43; N, 12.96; S, 19.91%. Calcd for $C_{18}H_{12}N_2SO$: C, 63.53; H, 3.45; N, 13.07; S, 19.95%.

Reaction of 1,4,2-Dithiazolium Salt 1a with Other Active Methylene Compounds. The salt **1a** (1 mmol) was added to stirred dichloromethane solution (6 ml) of active methylene compounds (1.5 mmol) and Et_3N (1.5 mmol). The reaction mixture was refluxed for 6 h. Subsequent work-up and purification were accomplished according to a similar procedure to the reaction of **1** with malononitrile.

5-[Cyano(phenylsulfonyl)methylene]-3-phenyl-1,4,2-dithiazole (5b): Yield 45%. Mp 201.5—203.0 °C (MeCN-$CHCl_3$). ^{1}H NMR ($CDCl_3$) δ=7.4—7.9 (8H, m), 8.0—8.2 (2H, m). MS m/z (rel intensity) 358 (M^+, 11), 135 (24). Found: C, 53.63; H, 2.77; N, 7.80; S, 26.83%. Calcd for $C_{16}H_{10}N_2S_3O_2$: C, 53.61; H, 2.81; N, 7.82; S, 26.83%.

5-(Benzoylcyanomethylene)-3-phenyl-1,4,2-dithiazole (5c):

Yield 56%. Mp 176.5—177.0 °C (DMF). ^{1}H NMR ($CDCl_3$) δ=7.6—7.8 (6H, m), 8.0—8.2 (4H, m). MS *m/z* (rel intensity) 322 (M^+, 11), 105 (51). Found: C, 63.26; H, 3.12; N, 8.64; S, 19.85%. Calcd for $C_{17}H_{10}N_2S_2O$: C, 63.33; H, 3.13; N, 8.69; S, 19.89%.

Methylation of 6b. To an ice-cooling suspension of sodium hydride (1.1 mmol) in abs tetrahydrofuran (4 ml) was added **6b** (1 mmol) to give a clear solution. Methyl iodide (3 mmol) was added to the mixture, which was stirred at room temperature for 1 h and then refluxed for 30 min. The mixture was quenched with dil HCl and the product was extracted with dichloromethane. The residue was purified by preparative TLC and recrystallized from dichloromethane-hexane to give **7** as yellow needles of mp 168.5—169.0 °C in 63% yield.

4-Amino-5-cyano-2-(1-cyano-2-diethylamino-2-methylthiovinyl)-6-phenylpyrimidine (7): ^{1}H NMR ($CDCl_3$) δ=1.26 (6H, t, *J*=7.7 Hz), 2.59 (3H, s), 3.67 (4H, q, *J*=7.7 Hz), 5.65 (2H, br. s), 7.4—7.6 (3H, m), 7.9—8.1 (2H, m). IR ν 3432, 3316, 3200, 2192, 1638, 1524, 1395 cm^{-1}. Found: C, 62.42; H, 5.50; N, 23.10; S, 8.65%. Calcd for $C_{19}H_{20}N_6S$: C, 62.61; H, 5.53; N, 23.06; S, 8.80%.

Reaction of 1,3-Dithiolium Salts 2 and 3 with Malononitrile. 1,3-Dithiolium salts **2** and **3** (1 mmol) were added to stirred solution (4 ml) of malononitrile (2 mmol) in the presence of bases (2 mmol) at room temperature. Other reaction conditions are listed in Tables 2 and 3. Subsequent work-up and purification were accomplished by a similar procedure to the reaction of **1**.

3-Amino-4-cyano-5-diethylamino-2-thiobenzoylthiophene (11a): Orange powder. Mp 245.0—246.0 °C (DMF-MeCN). ^{1}H NMR ($CDCl_3$) δ =1.30 (6H, t, *J*=7.2 Hz), 3.58 (4H, q, *J*=7.2 Hz), 7.3—7.4 (5H, br. s). IR ν 3332, 2196, 1602, 1553, 1499, 1458 cm^{-1}. MS *m/z* (rel intensity) 315 (M^+, 85), 243 (100), 121 (78). Found: C, 60.82; H, 5.36; N, 13.38; S, 20.37%. Calcd for $C_{16}H_{17}N_3S_2$: C, 60.92; H, 5.43; N, 13.32; S, 20.33%.

3-Amino-4-cyano-5-phenyl-2-thiobenzoylthiophene (11b): Orange powder. Mp 190.5—191.5 °C (MeCN-ether). ^{1}H NMR ($CDCl_3$) δ=7.3—7.6 (8H, m), 7.7—7.8 (2H, m), 8.3 (2H, br. s). IR ν 3372, 2208, 1602, 1422, 1334 cm^{-1}. MS *m/z* (rel intensity) 320 (M^+, 65), 319 (100), 287 (15), 243 (29), 121 (61). Found: C, 67.08; H, 3.75; N, 8.76%. Calcd for $C_{18}H_{12}N_2S_2$: C, 67.47; H, 3.77; N, 8.74%.

2-Dicyanomethylene-4,5-diphenyl-1,3-dithiole (12): Pale yellow powder. Mp 170.5—171.0 °C (CH_2Cl_2-MeCN). ^{1}H NMR ($CDCl_3$) δ=7.2—7.5 (10H, m). IR ν 2196, 1489, 1435, 1073 cm^{-1}. MS *m/z* (rel intensity) 318 (M^+, 100), 210 (48), 165 (86), 121 (51). Found: C, 67.73; H, 3.13; N, 8.84; S, 19.90%. Calcd for $C_{18}H_{10}N_2S_2$: C, 67.90; H, 3.17; N, 8.80; S, 20.14%.

2-Amino-3-cyano-5,6-diphenyl-1,4-dithiin (13): Yellow powder. Mp 191.0—192.0 °C (MeCN). ^{1}H NMR ($CDCl_3$) δ= 5.1 (2H, br. s) 7.0—7.2 (10H, m). IR ν 3384, 3260, 3176, 2188, 1618, 1542, 1440, 1310 cm^{-1}. MS *m/z* (rel intensity) 308 (M^+, 100), 276 (30), 242 (21), 178 (78), 121 (98). Found: C, 65.91; H, 3.93; N, 9.29%. Calcd for $C_{17}H_{12}N_2S_2$: C, 66.21; H, 3.92; N, 9.08%.

4-Amino-3-cyano-2-dicyanomethylene-5,6-diphenyl-2*H*-thiin (14): Yellow powder. Mp 258.5—260.0 °C (MeCN). ^{1}H NMR ($CDCl_3$) δ=5.8 (1H, br.), 6.7 (1H, br.), 7.0—7.5 (10H, m). IR ν 3432 (br.), 3332 (br.), 2204, 1635, 1441 cm^{-1}. MS *m/z* (rel intensity) 352 (M^+, 29), 178 (15), 121 (36), 55 (100). Found: C, 71.43; H, 3.40; N, 15.91; S, 9.12%. Calcd for $C_{21}H_{12}N_4S$; C, 71.57; H, 3.43; N, 15.90; S, 9.10%.

Reaction of 12 with Malononitrile. 2-Dicyanomethylene-4,5-diphenyl-1,3-dithiole **12** (1 mmol) was added to stirred acetonitrile solution (4 ml) of malononitrile (1 mmol) in the presence of Et_3N (1 mmol). The reaction mixture was stirred for 1 d at room temperature and worked up as described above to give **13** (42%) and **14** (26%).

Single-Crystal X-Ray Analysis of 7. Crystal data: $C_{19}H_{20}N_6S$; MW 364.48; monoclinic; space group $P2_1/c$; a=16.170 (4), b=14.822 (2), and c=16.276 (5) Å and β=101.27 (5)°; U=3826(1) Å^3; D_m=1.3 and D_c=1.27 g cm^{-3}, Z=8; μ(Mo $K\alpha$)= 1.85 cm^{-1}. Intensity data were collected on a Rigaku AFC-4 four-circle diffractometer by using graphite monochromated Mo $K\alpha$ radiation (λ=0.71069 Å) in the 2θ-ω scan mode with a scan width of $\Delta\omega$=(1.0+0.5 tan θ)° and a scan speed of 4.0° min^{-1} over the range of 2θ values of 2° up to 55°. Three standard reflections monitored every 50 reflections showed no significant X-ray damage or crystal decay. Intensities of 9446 reflections were measured and 4707 independent reflections ($|F_o|>3.0\,\sigma(|F_o|)$ were obtained and used for the analysis. The intensities were corrected for the Lorentz and polarization factors, but no correction were made for the absorption and extinction.

The structure was solved by MULTAN 78 program.[10] The positions of hydrogen atoms were obtained from the difference Fourier synthesis. Anisotropic thermal parameters and isotropic thermal parameters were assumed for non-hydrogen atoms and for hydrogen atoms, respectively. The structural parameters were refined by a full-matrix least-squares method to the final R value of 0.056 and the R_w=0.054 in conjunction with the weighting scheme of w=(40(sin θ/λ)^2−30 (sin θ/λ)+9)$^{-1}$. The atomic scattering factors for non-hydrogen atoms and for hydrogen atoms were taken from Refs. 11 and 12, respectively. All the computations were carried out on a FACOM M-380 and a M-780 computer using UNICS III system.[13] The final atomic parameters for non-hydrogen atoms are given in Table 4[14] and the molecular structure with the numbering system for non-hydrogen atoms is shown in Fig. 1.

The authors are grateful to Dr. Masayasu Kurahashi and Mrs. Midori Goto for helpful discussions with regard to the X-ray crystallographic analysis.

Rotational Isomerism in Fluorene Derivatives. XV.[1] Conformational Equilibria of 2-Substituted and 2,7-Disubstituted 9-(2′-Dimethylaminophenyl)-fluorene Derivatives and the Effects of Acid on Them

Akiko NISHIDA, Makoto TAKESHITA, Nobuaki KAWANO, Shizuo FUJISAKI, and Shoji KAJIGAESHI*
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received July 29, 1988)

Several 9-(2′-dimethylaminophenyl)-9-fluorenols (**2**) and 9-(2′-dimethylaminophenyl)fluorenes (**3**), which had electron-attracting or electron-releasing groups at 2- or 2,7-positions of the fluorene ring, were synthesized. The conformational equilibria (anti⇄syn) of **2** and **3** in $CDCl_3$ lay near to their syn sides. However, the equilibria of **2** in DMSO-d_6 inclined to the anti side. By the addition of trifluoroacetic acid to the solution of **3** in $CDCl_3$, *anti*-**3** salts were formed and stabilized by the N-H···π interaction between the dimethylammonio group and the fluorene ring. In this case, the intensities of the N-H···π interaction were affected by the magnitudes of the π-electron density of the fluorene ring.

During the course of an investigation on the conformational equilibria (anti⇄syn)[2] in 9-(2′-substituted phenyl)fluorenes, we recently recognized the presence of the N-H···π interaction between the dimethylammonio group and the fluorene ring in the anti-form of ammonium trifluoroacetate of 9-(2′-dimethylaminophenyl)fluorene (**3a**).[3] In the present paper, we wish to report on the syntheses of several 2-substituted and 2,7-disubstituted 9-(2′-dimethylaminophenyl)fluorene derivatives having electron-attracting or releasing groups as substituents, and on the investigation of the effects of these substituents on their conformational equilibria in $CDCl_3$, DMSO-d_6, and trifluoroacetic acid.

Results and Discussion

Preparation of 2-Substituted and 2,7-Disubstituted 9-(2′-Dimethylaminophenyl)fluorenes (3). The reaction of 2-substituted or 2,7-disubstituted fluorenones (**1**) with 2-dimethylaminophenylmagnesium bromide in ether gave the corresponding fluorenols (**2**) (**2b—2f** in Scheme 1). The reduction of **2b—2d** with hydrogen iodide in acetic acid in the presence of red phosphorus gave the desired fluorenes **3b—3d**. The same treatment of **2e** and **2f** with hydrogen iodide and red phosphorus

Table 1. Syntheses of 2-Substituted and 2,7-Disubstituted 9-(2′-Dimethylaminophenyl-9-fluorenols (**2**) and 2-Substituted and 2,7-Disubstituted 9-(2′-Dimethylaminophenyl)fluorenes (**3**)

a) Light yellow liquid.

in acetic acid afforded a mixture of **3e** and 2-hydroxy compound (**3g**), and a mixture of **3f** and 2,7-dihydroxy compound (**3h**), respectively. Pure **3e** and **3f** were obtained by the treatment of each mixture with dimethyl sulfate in methanol. The mp's, yields, and NMR data of **2** and **3** are shown in Table 1.

Conformational Equilibria of 2 and 3 in $CDCl_3$. As shown in Table 1, dimethylamino protons and 6'-protons of **2b—2f** and **3b—3f** in $CDCl_3$ appeared at δ ca. 2.8—3.0 as singlets or broad singlets and at δ ca. 6.3—6.6 as broad doublets, respectively, as in the cases of **2a** and **3a**. For compound **2a** and **3a**, their conformational equilibria (anti⇄syn) have been investigated by the behavior of the chemical shifts of dimethylamino groups and 6'-protons, and these compounds have been confirmed to exist predominantly as the syn-form at room temperature.[3] From the similarity for the appearance of these chemical shifts as shown in the Table, it can be claimed that the equilibria of **2b—2f** and **3b—3f** are also inclined to the syn-form (Fig. 1).

DNMR spectra of **3b—3f** were observed in $CDCl_3$. However, the anti-signals were scarcely recognized at low temperature (−20 °C) because the equilibria lay close to the syn side. Furthermore, since **3b—3f** were almost insoluble in $CDCl_3$, the activation parameters of the internal rotation (anti⇄syn) of these compounds were not measured.

Conformational Equilibria of 2 in DMSO-d_6. We have already indicated the existence of intramolecular hydrogen bonding in **2a**[3] and 9-(2'-methoxyphenyl)-9-fluorenol[4] by the examination of their IR spectra in CCl_4 and their NMR spectra in $CDCl_3$ or DMSO-d_6. Accordingly, it was proved that the intramolecular hydrogen bonding between the hydrogen atom of the 9-hydroxyl group and the nitrogen atom of 2'-dimethylamino group stabilized the syn-form of **2** in $CDCl_3$ (Fig. 2).

In the compound **2a** in DMSO-d_6, particularly, the dimethylamino proton was observed at δ 1.96 as a singlet. That is, it could be noted that the equilibrium of the rotamer of **2a** lay near to the anti side.[3] The dimethylamino protons of **2b—2f** were similarly observed at δ 1.7—2.1 in DMSO-d_6. In these cases, intermolecular hydrogen bonding, which formed between the hydrogen atom of the 9-hydroxyl group and the oxygen atom of dimethyl sulfoxide, should stabilize the anti-form. Thus, the anti-form of **2** was exclusively predominant in DMSO-d_6 (Fig. 2).

As can be seen from Table 1, the chemical shifts of the dimethylamino protons in DMSO-d_6 were affected by the nature of the 2- or 2,7-substituents on the fluorene ring, and their increasing order of chemical shift was shown as follows; **2c<2b<2a<2d<2e<2f**. Each chemical shift was a specific values for compounds **2a—2f**, respectively. That is, these chemical shifts of **2** having stronger electron-attracting substituent appeared at higher magnetic field. In fact an electron-attracting substituent decreased the π-electron density of the fluorene ring. The repulsion between the fluorene ring and an unshared electron pair on the nitrogen atom in the dimethylamino group should be decreased. Thus, the magnitudes of the electron pair $\cdots$ π repulsive interaction in **2** can be given in the following order; **2c<2b<2a<2d<2e<2f**.

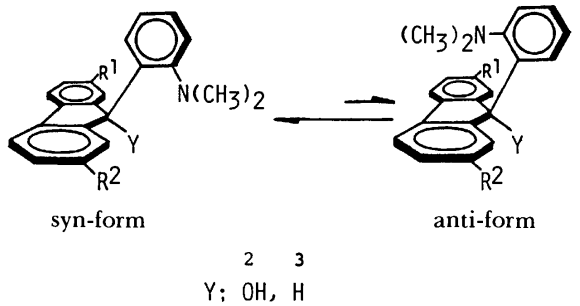

Fig. 1. Conformational equilibria between syn and anti forms of **2** and **3** in $CDCl_3$.

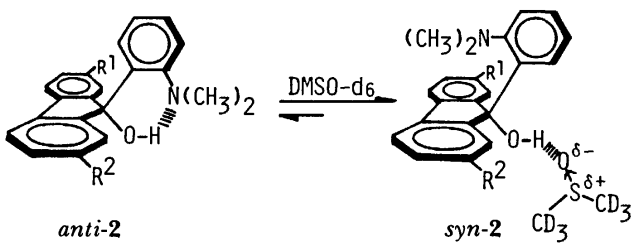

Fig. 2. Interconversion between syn and anti conformers of **2** in DMSO-d_6.

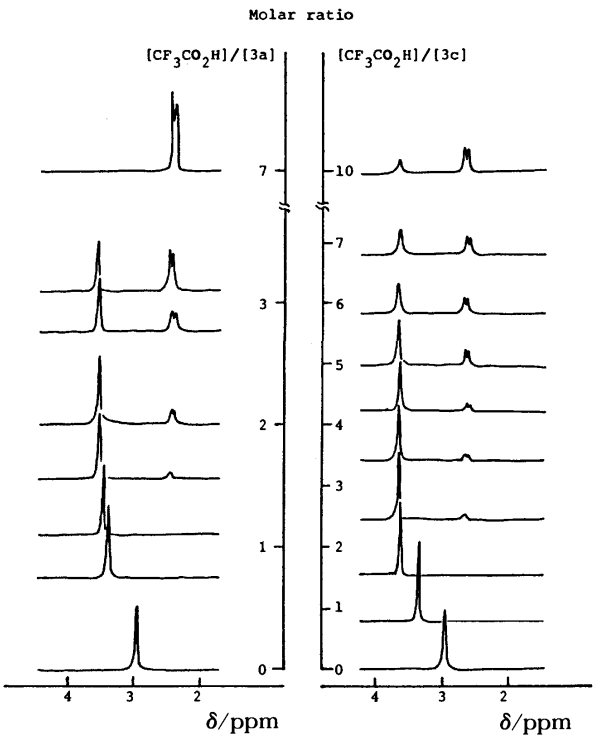

Fig. 3. Isomerization of **3a** and **3c** by addition of trifluoroacetic acid at 0 °C.

N-H···π Interaction of Ammonium Trifluoroacetates of 3. As shown in the previous paper,[3] we recognized that an N-H···π interaction between the dimethylammonio group and the fluorene ring stabilized the anti-form of **3a**-trifluoroacetate. Accordingly, it is interesting to investigate the influence of the π-density of the fluorene ring for the N-H···π interaction in **3**. In 2-substituted and 2,7-disubstituted 9-arylfluorene derivatives, the substituents should not affect the rotation about C(9)-C(Ar) bonds and the stabilization of the syn form. The electronic properties of these substituents change the π-density of the fluorene ring.

The variation of the ^{1}H NMR signals of the dimethylamino groups was followed upon addition of trifluoroacetic acid in $CDCl_3$ solution of **3b—3f**. For an example, the examination for **3c** was illustrated as compared with that of **3a** in Fig. 3.

The methyl signal (singlet) of *syn*-**3c** moved to a lower field on increasing the amount of acid added. When excess equivalent of acid was added ($[CF_3CO_2H]/[\mathbf{3c}]\approx3$), the methyl signal (doublet) of the anti-salt appeared. Further added acid ($[CF_3CO_2H]/[\mathbf{3c}]>10$) reversed the intensities of the anti- and syn-signals, and the syn-signal then almost disappeared. The methyl signal of **3a** in $CDCl_3$ also behaved in the similar manner on adding acid.[3] However, the anti-signal of the **3a**-salt has already appeared when $[CF_3CO_2H]/[\mathbf{3a}]\approx1.5$ (see Fig. 3).

Thus, the intensities of the two methyl signals (syn and anti) of the **3c**-salt changed more slowly compared with those of **3a**-salt. These experimental results should be attributed to the weaker N-H···π interaction in the **3c**-salt than in the **3a**-salt. Accordingly, the π-electron density of the fluorene ring of the **3c**-salt should be smaller than that of the **3a**-salt. This phenomenon can be understood from the fact that the electron-attracting property of bromine decreases the π-electron density of the fluorene ring in **3c**.

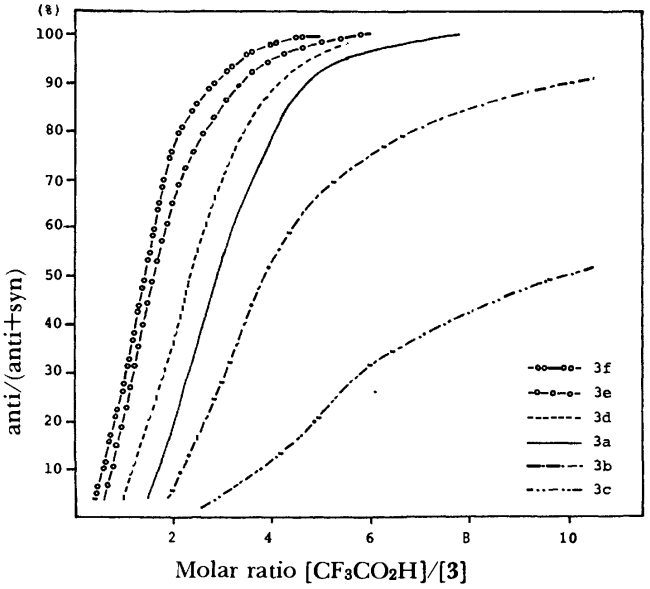

Fig. 4. Proportion of *anti*-**3** salt depend on the molar ratio of CF_3CO_2H vs. **3** ($[\mathbf{3}]/[CDCl_3]$=ca. 5×10^{-5} mol/0.4 ml).

On the other hand, in compound **3f**, the rate of variation of the conformational equilibria following the addition of trifluoroacetic acid was much faster than that of **3a**. The relationship between the variation of the conformational equilibria and the concentration of the acid in **3b—3f** are shown together with that in **3a** in Fig. 4.

It is apparent that the larger is the π-electron densities of the fluorene ring, the stronger is the N-H···π interaction; the magnitudes of the N-H···π interactions in *anti*-**3**-salts are given in the following order; **3f>3e>3d>3a>3b>3c**.

Experimental

^{1}H NMR spectra were recorded on a JEOL-MH-100 spectrometer with a JEOL model JES-VT-3 variable temperature controller. The chemical shifts are expressed in ppm, with tetramethylsilane as an internal standard. Mass spectra were recorded on a JEOL JMS-D spectrometer. The IR spectra were measured on a JASO IRA-1 spectrometer. All melting points are uncorrected.

2,7-Dibromo-9-(2′-dimethylaminophenyl)-9-fluorenol (2c). Typical Procedure. A solution of 2,7-dibromofluorenone (4.0 g, 12 mmol) in dry benzene was added to the Grignard reagent which was prepared from magnesium turnings (0.5 g, 12.5 mmol) and *o*-bromo-*N*,*N*-dimethylaniline (2.5 g, 12.5 mmol). The mixture was refluxed for 1 h. After cooling, the solution was poured into dil. hydrochloric acid. The solid precipitate was alkalized with sodium hydroxide solution and extracted with chloroform. The organic layer was dried with magnesium sulfate and distilled off in vacuo, leaving a residue which was recrystallized from chloroform to give **2c** as colorless prisms; yield 2.9 g (51%), mp 262—263 °C. Found: C, 54.90; H, 3.60; N, 3.05%. Calcd for $C_{21}H_{17}NOBr_2$: C, 54.93; H, 3.73; N, 3.05%.

2-Bromo-9-(2′-dimethylaminophenyl)-9-fluorenol (2b). Yield 50%; colorless crystals; mp 160—161 °C (from chloroform). Found: C, 66.21; H, 4.74; N, 3.52%. Calcd for $C_{21}H_{18}NOBr$: C, 66.33; H, 4.77; N, 3.68%.

2-Methyl-9-(2′-dimethylaminophenyl)-9-fluorenol (2d). Yield 41%; colorless needles; mp 153—155 °C (from chloroform). Found: C, 83.54; H, 6.75; N, 4.43%. Calcd for $C_{22}H_{21}NO$: C, 83.78; H, 6.71; N, 4.44%.

2-Methoxy-9-(2′-dimethylaminophenyl)-9-fluorenol (2e). Yield 59%; colorless crystals; mp 195—196 °C (from benzene). Found: C, 79.47; H, 6.18; N, 4.06%. Calcd for $C_{22}H_{21}NO_2$: C, 79.78; H, 6.39; N, 4.23%.

2,7-Dimethoxy-9-(2′-dimethylaminophenyl)-9-fluorenol (2f). Yield 80%; colorless crystals; mp 191—192 °C (from benzene). Found: C, 76.66; H, 6.53; N, 3.65%. Calcd for $C_{23}H_{23}NO_3$: C, 76.43; H, 6.41; N, 3.88%.

2,7-Dibromo-9-(2′-dimethylaminophenyl)fluorene (3c). Typical Procedure. To a solution of **2c** (1.4 g, 3mmol) in acetic acid (10 ml) was added red phosphorus (0.3 g, 10 mmol) and hydriodic acid (57%, 6.0 g, 50 mmol), and the mixture was refluxed for 4 h. After cooling, red phosphorus was filtered off and the solvent distilled off in vacuo. The

residue was alkalized by sodium hydroxide solution, extracted with benzene and the extract dried with magnesium sulfate. The solution was evaporated in vacuo, leaving a residue which was recrystallized from chloroform to give **3c** as colorless crystals; yield 0.8 g (62%), mp 191—193 °C. Found: C, 56.68; H, 3.78; N, 3.31%. Calcd for $C_{21}H_{17}NBr_2$: C, 56.91; H, 3.87; N, 3.16%.

2-Bromo-9-(2′-dimethylaminophenyl)fluorene (3b). Yield 55%; colorless crystals; mp 133—135 °C (from chloroform). Found: C, 69.11; H, 4.88; N, 3.94%. Calcd for $C_{21}H_{18}NBr$: C, 69.24; H, 4.98; N, 3.84%.

2-Methyl-9-(2′-dimethylaminophenyl)fluorene (3d). Yield 56%; oil; MS *m/z*: 219 (M^+).

2-Methoxy-9-(2′-dimethylaminophenyl)fluorene (3e). Hydriodic acid (57%, 6 g, 50 mmol) and red phosphrous (0.3 g, 10 mmol) were added to a solution of **2e** (1 g, 3 mmol) in acetic acid (20 ml) and refluxed for 3 h. The reaction mixture was concentrated in vacuo and the residue was treated with sodium hydrogensulfite. The solid precipitate was collected by filtration and dissolved in methanol. To the solution was added dimethyl sulfate (0.76 g, 6 mmol) and sodium hydroxide (0.36 g, 9 mmol), and the mixture was refluxed for 1 h. After cooling, the precipitate was washed with water and recrystallized from methanol to give **3e** as colorless crystals; yield 0.26 g (27%), mp 86—87 °C. Found: C, 83.89; H, 6.46; N, 4.37%. Calcd for $C_{22}H_{21}NO$: C, 83.78; H, 6.71; N, 4.44%.

2,7-Dimethoxy-9-(2′-dimethylaminophenyl)fluorene (3f). To a solution of **2f** (0.44 g, 1.2 mmol) in acetic acid (10 ml) was added hydriodic acid (57%,3 g, 25 mmol) and the mixture was refluxed for 2 h. The reaction mixture was worked up as described for the preparation of **3e**, to give **3f** as colorless crystals; yield 0.22 g (52%), mp 90—91 °C. Found: C, 80.17; H, 6.68; N, 4.12%. Calcd for $C_{23}H_{23}NO_2$: C, 79.97; H, 6.71; N, 4.05%.

The authors wish to thank Professor Masashi Tashiro, Institute of Advanced Material Study, Kyushu University, for the elemental analyses.

(Received August 23, 1988)

Seven ω-hydroxy carboxylic acids bearing 2—5 ether oxygens with or without aromatic rings and five ω-alkoxy carboxylic acids bearing 2—6 ether oxygens with aromatic rings were employed as carriers for the active transport of alkaline earth metal ions as well as alkali metal ions through 1,2-dichloroethane or 1-hexanol as an organic liquid membrane. The relatively hydrophobic ω-hydroxy and ω-alkoxy carboxylic acids ($\log P>7$) exhibited a high M^{2+} transport ability and selectivity over M^+ through 1,2-dichloroethane, regardless of the number of ether oxygen. However, a marked selectivity among alkaline earth metal ions (Mg^{2+}, Ca^{2+}, Ba^{2+}) was not observed. The less hydrophobic carboxylic acids ($\log P<6$) did not transport Ba^{2+} through 1,2-dichloroethane. Ba^{2+} transport ability of the hydrophobic acids through 1-hexanol was lower than that through 1,2-dichloroethane. Linoleic acid in the presence of oligo- and polyethylene glycols showed efficient Ba^{2+} transport through 1,2-dichloroethane, although a long-chain fatty acid was not able to transport Ba^{2+} by itself.

Naturally occurring carboxylic acid ionophores have ether linkages in the framework and hydroxyl group at the other end. The ionophore forms a pseudo-cavity by head-to-tail hydrogen bonding between carboxyl and hydroxyl groups. When the ionophore forms a salt with a cation, the cation is trapped in the cavity and is coordinated with ether oxygen atoms of ionophores. The cation was thereby lipophilized and transported through biological and organic liquid membranes.[2] Each ionophore exhibits a particular ion selectivity. A few of the ionophores, such as lasalocid and A 23187, which are able to complex and transport divalent cations as well as monovalent ones, are called divalent polyether antibiotics.[2,3] Their backbones are considerably shorter than those of monovalent polyether antibiotics. Despite the short chain length, the coordination of two ionophore anions to M^{2+} makes the complex lipophilic.

We synthesized polyether carboxylic acids, the structures of which were analogous to the natural carboxylic ionophores (as mentioned above). These synthetic ionophores were employed for the transport of alkali metal ions through an organic liquid membrane in order to investigate the relationship between the primary structures of ionophores and the transport ability and selectivity.[1a,4] We report here the transport of alkaline earth metal ions by synthetic carboxylic ionophores with a variety of chain lengths, the carboxylic acid moiety at the terminal, and the structure at the other terminal. Although a few synthetic ionophores have already been reported for the transport of alkaline earth metal ions,[5] the purpose of this study is to use a series of our synthetic carboxylic ionophores for the transport of divalent ions as well as monovalent ones for a comparison. The cooperative transport of alkaline earth metal ions with carboxylic acid and polyether in separate molecules is also described.

Results and Discussion

Synthetic ionophores employed in this study are shown in the order of numbers of hydroxyl and ethereal oxygens in Scheme 1. Some of the compounds (**2**, **5**, **7**, **9**—**14**) have already been reported for the transport of alkali metal ions,[1a] and the rest of them (**1**, **3**, **4**, **6**, **8**) are newly synthesized for this study (as described in the experimental sections).

Transport of Alkaline Earth Metal Ions by Synthetic Carboxylic Ionophores. The stoichiometry of **10** and metal ions in chloroform was investigated (Fig. 1). It was revealed that at pH ca. 7, neither K^+ nor Ba^{2+} was incorporated into organic layer, but that at higher pH, 1 : 1 and 2 : 1 complexes of **10** were formed with K^+ and Ba^{2+}, respectively. Compound **10** containing one carboxyl group forms a neutral 1 : 1 complex of a potassium carboxylate, whereas divalent Ba^{2+} was complexed with two ionophore anions. This is consistent with the stoichiometry of complex for natural carboxylic ionophores.[3b,6] A 2 : 1 complex of ionophore and alkaline earth metal ion, where the cation is surrounded by two ionophore carboxylate molecules, is anticipated to be more hydrophobic than the corresponding 1 : 1 complex with alkali metal ion. This would result in an easy incorporation of M^{2+} into the organic layer, compared with M^+.

	—	—	—	—	52	41	93

a) No ion is transported without ionophore.

The competitive transport of alkali and alkaline earth metal ions by **10** and **7** through 1,2-dichloroethane was carried out as shown in Table 1. Both ionophores exhibited K^+ selectivity among Li^+, Na^+, and K^+, as previously reported.[1a] Divalent cations (Ba^{2+}, Ca^{2+}, and Mg^{2+}) were transported in preference to monovalent cations. Among the divalent cations, little selectivity was observed.

Through a 1-hexanol membrane mono- and divalent ions were transported by **10** (Table 2). Compared with 1,2-dichloroethane the 1-hexanol membrane lowered the transport ability and the selectivity of the ionophore. From these results, it can be presumed that the ionophore functions only as an anionic ligand of the carboxylate in 1-hexanol, and that a cation in the salt is solvated by 1-hexanol molecules instead of ether oxygens of the ionophore.

Ionophores which have fewer ether oxygens or fewer aromatic rings than **10** were employed for Ba^{2+} transport through 1,2-dichloroethane. Table 3 shows the results together with the hydrophobicity parameter ($\log P$) of the ionophores.[1a] Compounds with $\log P$ of less than 6 (**6**, **2**, **5**, and **3**) did not transport Ba^{2+}. Ionophores with $\log P$ greater than 7 (**1**, **4**, **7**, **10**) transported Ba^{2+}, except for linoleic acid. Even **1**, bearing only two ether oxygens, has a high transport ability. In the case of ionophores with a low $\log P$ value, the salt complex formed at the interface is too hydrophilic to diffuse into the organic layer. Compounds, **6**, **2**, **5**,

and **3** ($\log P<6$) are not sufficiently hydrophobic to be an ion carrier. For more lipophilic compounds ($\log P>7$) two ether oxygens are sufficient for Ba^{2+} transport.

Ba^{2+} and Ca^{2+} were transported separately through 1,2-dichloroethane by **10** and its analogues (Table 4). For a comparison, K^+ transport was also carried out. Compounds **11** and **12**, hydroxyalkylated derivatives of **10**, revealed a comparable transport ability to **10**. Compounds **13** and **14**, *m*- and *p*-substituted isomers of **10**, were employed for Ba^{2+} transport. While neither **13** nor **14** transported K^+, both ionophores exhibited as high a transport ability for Ba^{2+} as **10**. A 2 : 1 complex of ionophore and M^{2+} seems to have a less rigid structure than the 1 : 1 complex does.[1b] In the 2 : 1 complex, ether oxygens of even *m*- and *p*-isomers are able to coordinate M^{2+} to be solubilized in the organic layer. These results show that if a ionophore has a carboxyl group and ether oxygens, the substituted position of the carboxyl group does not affect M^{2+} transport through 1,2-dichloroethane, in contrast to M^+ transport.

When 1-hexanol was used as a liquid membrane, linoleic acid had a similar transport ability to those of **10** and its isomers (Table 4). As mentioned above, the carboxylate anion of the ionophore interacts with the cation electrostatically and neither oxygens are very important for the transport of M^{2+}, compared to that of M^+. Water molecules are replaced out of the hydration sphere by 1-hexanol to solvate the divalent cation.

Transport of Alkaline Earth Metal Ions by Carboxylic Acids and Polyethers. As mentioned above, and reported previously,[1a] **10** exhibited the ability to transport monovalent ions through 1,2-dichloroethane, while its *m*- and *p*-substituted isomers, **13** and **14**, transported no alkali metal ion. On the other hand, divalent ions were transported by both **10** and its isomers. For alkaline earth metal ion transport, the relative position of the carboxyl group of ionophore to polyether linkages should not be important. It was expected that a simple carboxylic acid could transport M^{2+} in the presence of another polyether molecule. When a mixture of linoleic acid and diol **8**, each of which could not transport M^{2+}, was employed, 85% of Ba^{2+} was transported through 1,2-dichloroethane at 35 °C for 5 days. Under the same conditions, no K^+ was transported. A mixed system of carboxylic acid and ether was found to transport M^{2+} selectively. A mixture of diol **8** with various carboxylic acids as well as linoleic acid was applied to the transport of Ba^{2+}. The results are shown in Table 5. The hydrophobicity of the acids corresponds to the transport ability. Hydrophilic acids such as acetic, adipic, benzoic, hexanoic, and decanoic acids did not transport Ba^{2+}. A long-chain fatty acid such as lauric, myristic, palmitic, and linoleic acids transported Ba^{2+} in the presence of **8**. The transported amount of Ba^{2+} increased with an increase in the lipophilicity at acids. Unless the carboxylic acid was fully hydrophobic, the mixed system of carboxylic acid and **8** had no transport ability. Barium salts of hydrophilic carboxylic acids should be dissolved in an aqueous layer. Even if the salt is coordinated with polyether at the interface, the complex is not sufficiently hydrophobic to be incorporated into the organic layer. On the other hand, barium salts of lipophilic acids stayed mainly at interface, then, the replacement of water molecules out of the hydration sphere by the oxygens of **8** dissolved Ba^{2+} into the organic layer.

Table 5. Ba^{2+} Transport through 1,2-Dichloroethane Using Various Carboxylic Acids and **8**

Carboxylic acid	log *P*	Transported Ba^{2+} (%)
CH_3COOH	−0.2	0
$HOOC(CH_2)_4COOH$	0.7	0
PhCOOH	1.6	0
$CH_3(CH_2)_4COOH$	1.9	0
$CH_3(CH_2)_8COOH$	3.9	0
$CH_3(CH_2)_{10}COOH$	4.9	19
$CH_3(CH_2)_{12}COOH$	5.9	72
$CH_3(CH_2)_{14}COOH$	6.9	52
Linoleic acid	7.3	85

The effect of the polyether structure on ion transport was examined. Ba^{2+} transport by using linoleic acid together with various polyether compounds is shown in Table 6. Glycols and their derivatives were used as polyether. Ba^{2+} was not transported by ethylene glycol and the transported amount of Ba^{2+} increased with an increase in the oxyethylene units. Since a short-chain glycol is, itself, slightly soluble in an organic solvent, the coordinated glycol with Ba^{2+} of the salt is not sufficiently lipophilic to be incorporated into the organic layer. However, a stable complex of the salt with a long-chain glycol, such as tetraethylene glycol and polyethylene glycols, results in an increase in Ba^{2+} transport. Methyl ether derivatives (diglyme, tetraglyme, and **9**) exhibited a much lower transport ability

Table 6. Ba^{2+} Transport through 1,2-Dichloroethane by Linoleic Acid and Polyethers

than the corresponding glycols. The terminal hydroxy groups of the glycols seem to play an important role in the transport of Ba^{2+}.

Experimental

Methods. IR spectra were run with a Jasco IR-G spectrophotometer. ^1H NMR spectra were recorded with a JEOL JNM-PMX 60 instrument. UV spectra were recorded on a Hitachi 124 spectrophotometer. Mass spectra were obtained on a Hitachi M-80 mass spectrometer operating at 30 eV. Elemental analyses were performed on a Yanaco Model MT-3. Atomic absorption and flame spectrochemical analyses were performed with Hitachi 170—30 Atomic Absorption Spectrophotometer.

Materials. Unless stated otherwise reagent grade reactants and solvents were obtained from commercial suppliers and used without further purification.

Compound **1** was synthesized from 2-benzyloxyphenol[7] and with methyl 2-bromomethylbenzoate similar to synthesis of **7** previously reported.[1a]

2-[2-(2-Benzyloxyphenoxy)methyl]benzoic Acid (1). Yield (0.70 g, 48%). IR(KBr) 1685 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=5.2 (s, 2H, benzyl), 5.6 (s, 2H, benzyl), 6.9 (s, 4H, phenylene), 7.2—8.3 (m, 9H, phenyl and aromatic of toluic acid). Calcd for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43%. Found: C, 75.60; H, 5.45%.

Compound **3** was prepared from **2** and methyl iodide and **4** was prepared from **2** and benzyl chloride by the same procedure as that for **11**.[1a]

2-[[2-(2-Methoxyethoxy)phenoxy]methyl]benzoic Acid (3). Yield (0.35 g, 75%). IR(KBr) 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.45 (s, 3H, CH_3O), 3.83 (m, 2H, CH_2OMe), 4.20 (m, 2H, CH_2OAr), 5.51 (s, 2H, benzyl), 6.90 (s, 4H, phenylene), 7.3—8.1 (m, 4H, aromatic of toluic acid). High-resolution mass spectrum for $C_{17}H_{18}O_5$, Calcd 302.1154, Found 302.1116.

2-[[2-(2-Benzyloxyethoxy)phenoxy]methyl]benzoic Acid (4). Yield (0.13 g, 33%). IR(KBr) 1675 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.9 (m, 2H, CH_2), 4.3 (m, 2H, CH_2), 4.7 (s, 2H, benzyl), 5.6 (s, 2H, benzyl), 6.9 (s, 4H, phenylene), 7.3—8.3 (m, 8H, aromatic of toluic acid). Calcd for $C_{23}H_{22}O_5$: C, 73.00; H, 5.86%. Found: C, 72.54; H, 5.81%.

14-Hydroxy-3,6,9,12-tetraoxatetradecanoic Acid (6). Small pieces of Na (9.2 g, 0.4 mol) were by portions added to tetraethylene glycol (120 ml) (distilled under reduced pressure) under a nitrogen atmosphere. The mixture was heated at 100 °C for 6 h. Chloroacetic acid (18.9 g, 0.2 mol) in tetraethylene glycol (40 ml) was added dropwise to the alkoxide solution and the mixture was heated at 100 °C for 3 h. Excess of tetraethylene glycol was distilled under reduced pressure. To the residue was added concd HCl (100 ml) to form a white precipitate. The solid was removed by suction and the filtrate was evaporated under reduced pressure to remove water and HCl. The residue was distilled under vacuum to afford **6** (30 g, 60%). Bp 148—151 °C/1 mmHg (1 mmHg=133.322 Pa). IR(neat) 1740 cm^{-1} (C=O); ^1H NMR (CD_3OD) δ=3.65 (m, 16H, OCH_2COOH and CCH_2OC), 4.19 (t, 2H, CH_2OH, J=6 Hz). Calcd for $C_{10}H_{20}O_7$: C, 47.61; H, 7.99%. Found: C, 47.42; H, 8.27.

1,2-Bis[2-(2-methoxyethoxy)phenoxy]ethane (9). 1,2-Bis-[2-(2-hydroxyethoxy)phenoxy]ethane (3.4 g, 10 mmol) and 60% NaH (0.8 g, 20 mmol) in dry DMF (30 ml) were stirred at room temperature for 30 min. To this was added dropwise methyl iodide (2.9 g, 20 mmol) in dry DMF (20 ml); the mixture was stirred at room temperature for 2 h. DMF was removed in vacuo and the residue, dissolved in chloroform, was washed with water. The organic layer dried over sodium sulfate was evaporated and applied to a silica-gel column (chloroform/methanol=100/1) to afford 1,2-bis[2-(2-methoxyethoxy)phenoxy]ethane (2.9 g, 80%). ^1H NMR ($CDCl_3$) δ=3.40 (s, 6H, CH_3O), 3.73 (m, 4H, $OCH_2CH_2OCH_3$), 4.16 (m, 4H, $OCH_2CH_2OCH_3$), 4.38 (s, 4H, $ArOCH_2CH_2$), 6.90 (s, 8H, aromatic).

Stoichiometry of Complex of 10 and Metal ion in Chloroform. Chloroform saturated with water and water saturated with chloroform were used. A 10-ml chloroform solution of 5×10^{-5} mol of **10** and a 5-ml aqueous tris buffer solution (pH 7—9) containing $BaCl_2$ (0.05 M) or KCl (0.1 M) (1 M=1 mol dm^{-3}) in a 30-ml vial were vigorously shaken 60 times by hand. The vial was allowed to stand for 1 day in order to separate the organic layer from the aqueous layer. At higher pH, a metal hydroxide solution at an appropriate concentration was used instead of a tris buffer solution. A part of the organic layer (5 ml) was transferred to another 30-ml vial. To this was added a 5-ml HCl solution (0.2 M). The mixture was vigorously shaken 60 times by hand. The vial was allowed to stand for 1 day in order to separate the layers. The organic solution was diluted 100 times to determine the concentration of **10** by UV spectroscopy (273 nm). The aqueous solution was diluted 10 times to determine the concentration of K^+, or Ba^{2+} by flame spectrochemical analysis or atomic absorption analysis.

Ion Transport Experiment. Ion transport was carried out in U-type or H-type cells[4b] at 35±1 °C for 5 days with stirring at 200 rpm. Donor phase-I contains a 10-ml aqueous solution of an alkaline earth metal hydroxide (0.05 M). Acceptor phase -II contains a 10-ml aqueous solution of HCl (0.1 M) and an alkaline earth metal chloride (0.05 M). In the case of competitive ion transport, both the donor and acceptor phases also contain alkali or alkaline earth metal chlorides at the same concentration. Organic phase-III contains a 20-ml organic solution of a 10^{-4} mol carboxylic acid (and a 10^{-4} mol polyether). An aqueous solution at acceptor phase was diluted to an appropriate volume. The concentration of ions (10—100 ppm for M^+, 20—140 ppm for Ba^{2+} and Ca^{2+}, 1—20 ppm for Mg^{2+}) was determined to be c_0 and c_1 before and after the transport experiment by a flame spectrochemical analysis for alkali metal ions and by an atomic absorption analysis for alkaline earth metal ions. The transported ions (%) were calculated by $[(c_1-c_0)/c_0]\times100$.

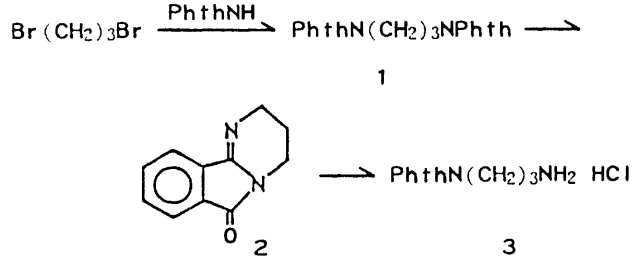
Efficient Synthetic Method for Differentially Protected Naturally Occurring Acyclic Polyamines

Masaaki IWATA* and Hiroyoshi KUZUHARA
RIKEN (The Institute of Physical and Chemical Research), Wako, Saitama 351-01
(Received August 25, 1988)

A new systematic route to threefold protected natural polyamines, spermidine, spermine, thermine, and thermospermine, was developed through alternate regioselective manipulation on the terminal primary amino groups, starting from *N,N*-phthaloyl-1,3-propanediamine hydrochloride (**3**). When **3** was tosylated at the amine terminal and the phthaloyl terminal was subjected to transformation to the formamido group followed by substitution at the tosyl terminal with, e.g., *N*-(4-bromobutyl)phthalimide, threefold protected spermidine was obtained in excellent yield. After hydrolysis of the formamido group to amine salt, a sequence of the reactions was satisfactorily repeated to afford various types of threefold protected natural tetramines.

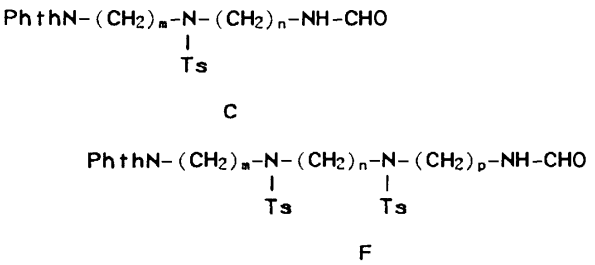
Feasible synthetic methods for differentially protected natural acyclic polyamines play the crucial role in the total synthesis of polyamine conjugates[1] since the polyamine moiety has to be introduced regiospecifically at the proper step of the synthesis. In particular, in unsymmetrical natural polyamine-derived conjugates such as spermidine and thermospermine conjugates, the terminal primary amino groups have to be differentiated essentially for orientated introduction. In the literature survey, practical methods hitherto devised for discrimination of amino group have relied on (i) the reactivity difference in amino groups,[2] (ii) stoichiometric control of reactants in the level of triamine formation,[3] and (iii) the extension of differential protection generated in the level of diamine formation through the traditional way of stepwise synthesis.[4] Since the first method depends on the intrinsic nature of reactivity difference in amino groups of expensive spermidine as a starting material, it is inadequate for a large scale synthesis and for versatile synthetic utility.

We have recently found the novel transformation reaction[5] specific for *N,N:N′,N′*-diphthaloyl-1,3-propanediamine (**1**). In the transformation reaction *N,N*-phthaloyl-1,3-propanediamine hydrochloride (**3**) is readily obtained quantitatively passing through the fused heterocycle (**2**) prepared in high yield from **1**.[6]



Since the transformation reaction indicates facile discrimination of the terminal primary amino groups in two steps, exemplification of synthetic feasibility of **3** was planned for molecular design of differentially protected polyamines, combining with another transformation reaction of phthalimides to formamides as follows;[7]

We set synthetic targets of threefold protected triamines (**C**) and tetramines (**F**) with the following types of functional groups;



in which the primary amino groups at both ends are protected differently by the base- and hydrazine-sensitive phthaloyl group and by the acid-sensitive and reducible formyl group, respectively, and the secondary amino groups, by the photo-,[8] alkali metal- and HBr-sensitive tosyl group.[9]

The synthetic plan is shown in Scheme 1, which is characterized by alternate regioselective manipulation on the terminal primary amino groups in a systematic way as follows; to start with tosylation of **3** followed by the transformatlon of the phthalimido group to formamido group (**A**→**B**). Then, the tosylamino group at the other ω-terminus functioning as nucleophile reacts with ω-phthalimidated compounds, either **4**, **5**, or **6** (**B**→**C**). The formamido group is hydrolyzed to give ω-*N,N*-phthaloylated α,ω-diamine hydrochloride, which disposes the same functional groups as those of the starting **3** in a reversed order. Therefore, a series of the reactions will be repeated for construction of tetramines in a similar fashion, disposing the primary amino group outside in (**D**→**E**→**F**). Since there has been no report on nucleophilic reactivity of formamido nitrogen, **A** to **B** or **E** to **F** steps are crucial in the present plan in which the terminus of diamine **B** or **E**, bearing both tosylamino and formamido groups, reacts with ω-phthalimidated compound (**4**).

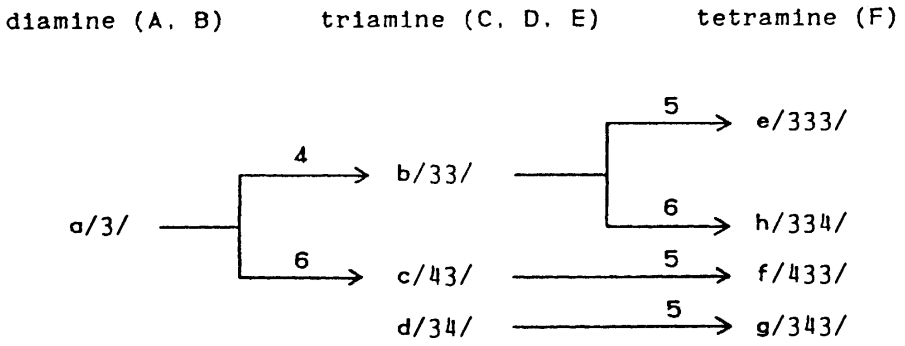


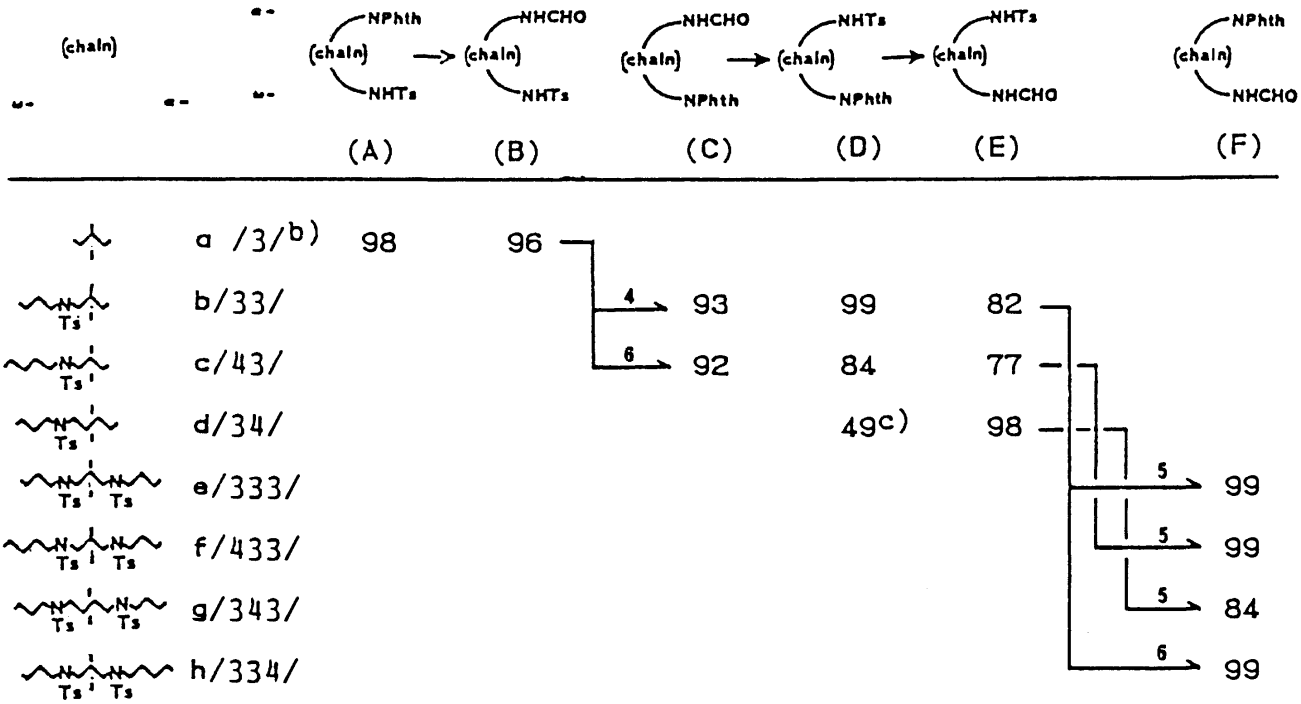
Scheme 1.

Results and Discussion

In the presence of triethylamine, **3** was tosylated with tosyl chloride in pyridine to give **Aa**,[10] which was treated with hydrazine hydrate in DMF to afford **Ba**. Alternatively, nitrosation of **Aa** followed by the rearrangement reaction in benzene gave **4**.[6,11] Condensation of **Ba** with **4** was best carried out by the use of cesium carbonate in DMF[6] to give the aimed threefold protected **Cb** exclusively. This reveals that the formamido nitrogen is far less reactive as nucleophile than the tosylamino nitrogen. Likewise, threefold protected spermidine (**Cc**) was obtained by the reaction of **Ba** with **6**. Hydrolysis of **C** in a mixed solvent of ethanol and 2 M HCl was completed at 75 °C for 3 h to yield the corresponding hydrochloride salts, which

were satisfactorily tosylated with tosyl chloride in pyridine in the presence of triethylamine to afford **D**. Since the present strategy is started with **3**, it is impossible to prepare **Dd** which bears the same functional groups at each primary amines in the opposite order to those of **Dc**. Therefore, **Dd** was supplied by the reaction of *N,N'*-ditosyl-1,4-butanediamine with **4**. All the **D** series of compounds were subjected to the transformation with hydrazine hydrate in DMF,[7] in the same way as **A** to **B** conversion, to afford **E** series. At this stage, we were ready to carry out the *N*-alkylation at the α-terminus with ω-phthalimidated compounds, **5** and **6**, to construct the second series of threefold protected natural tetramines (**F**). Symmetrical thermine derivative,[12a] **Fe**, was prepared by the reaction of **Eb** with **5** in DMF in the presence of cesium carbonate. Likewise, two isomers of unsymmetrical thermospermine derivatives,[12b] **Ff** and **Fh**, were prepared by the

Table 1. Product Yield(%) of Systematic Differential Protection of Amino Groups[a]



a) The transformation/substitution products are correlated by the arrow, the number on which corresponds to a electrophile employed in Scheme 1. b) the abbreviated chain symbol in the second column stands for the contiguous methylene chain blocks in Arabic numerals with default of nitrogen atoms between slant lines. In the first column, ω-terminus is placed at the left side and α-terminus, at the right side. These termini were arbitrarily chosen, independent of the nomenclature rule. c) **Dd**, obtained as by-product in the separate route (see Experimental).

a) See Ref. 13 for the significance of abbreviated designation.

reaction of **Ec** with **5** and **Eb** with **6**, respectively. Threefold protected spermine derivative, **Fg**, was prepared from **Ed** and **5** as well. Relationshlp between starting materials and products are shown together with all the product yields in Table 1. Tables 2 and 3 are implicated to chemical shifts of all the protons in ^{1}H NMR spectra for **B** through **F** series of compounds.

In viewpoint of regioselectivity of the chain elongation and transformation and excellent product yields in each step, the present method for differential protection provides a new synthetic approach to polyamine conjugates. According to the present method, natural polyamines differentially modifiable at each terminus are supplied in a large scale from the cheap starting materials.

Experimental

General: The ^{1}H NMR spectra were recorded on JEOL GSX-500S (500 MHz) instrument with Me_4Si as an internal standard in $CDCl_3$ unless otherwise mentioned; chemical shifts (δ) and coupling constants (J) are in parts per million and hertz, respectively. Infrared spectra (IR) were obtained on a Shimadzu IR-27 apparatus. Merck sllica gel 60 (Art. 7734, 0.063—0.02) was used for column chromatography, and fragmented Merck precoated silica gel 60 F_{254} plates (Art. 5715, 20×20 cm), for thin layer chromatography (TLC). Product spots on TLC were detected either with UV-lamp or in an iodine vapor bath. The uncorrected melting points were measured in a bilayered coverglass (18 m/m, thickness 0.13—0.17 mm) with a micro melting point apparatus (Yanagimoto Seisakusho, Serial No. 2647).

Materials: *N,N*-Dimethylformamide (DMF) was dried over molecular sieves (Type A). Pyridine, triethylamine, tosyl chloride, hydrazine hydrate, anhydrous cesium carbonate, and sodium nitrite are purchased and employed without further purifIcation. The preparation of *N,N:N′,N′*-diphthaloyl-1,3-propanediamine (**1**) and its transformation to 3,4-dihydro-2*H*-pyrimido[2,1-*a*]isoindol-6-one (**2**) have been reported recently.[5] Hydrolysis of **2** to *N,N*-phthaloyl-1,3-propanediamine hydrochloride (**3**) and its tosylation to give *N,N*-phthaloyl-*N′*-tosyl-1,3-propanediamine (**Aa**) have been described in the preceding report.[6] ω-Phthalimidated electrophiles, **4**, **5**, and **6**, were prepared by the method in the preceding report.[6,11] N^1,N^1-Phthaloyl-4,N^8-ditosyl-4-azaoctane-1,8-diamine (**Dd**) was prepared as by-product in the following procedure; to a stirred mixture of Na-salt of *N,N′*-ditosyl-1,4-butanediamine[14] in DMF, **4** (2.6 mol equiv) in DMF was added dropwise at 80 °C. After workup, the residue was chromatographed on a silica-gel column to give *N,N′*-bis(3-phthalimidopropyl)-*N,N′*-ditosyl-1,4-butanediamine as a crystal in 44% yield[6] and **Dd** in 49% yield as viscous liquid; **Dd**, Found: C, 59.40; H, 5.71; N, 7.17; S, 10.71%. Calcd for $C_{29}H_{33}O_6N_3S_2$: C, 59.67; H, 5.70; N, 7.20; S, 10.99%. IR (KRS), ν 3290 (NH), 1770 and 1710 (CO), and 1330 and 1150 (SO_2) cm^{-1}.

General Procedure for Formation of Formamides (B and E) from Phthalimides (A and D): To a solution of phthalimide (**A** or **D**) in DMF, hydrazine hydrate (10 mol equiv) was added and the mixture was heated at 75 °C for more than 18 h. After removal of DMF under reduced pressure, the residue was chromatographed on a silica-gel column eluting with chloroform–methanol (9:1 v/v) to give formamide (**B** or **E**).

General Procedure for the Chain Elongation Reaction from ω-Formyl-α-*p*-toluenesulfonamides (B and E) to ω-Formyl-α-phthalimides (C and E): A mixture of formamidated *p*-toluenesulfonamide (**B** or **E**), one of appropriate ω-phthalimidated electrophile (**4**, **5**, or **6**) (1.1 mol equiv to **B** or **E**), and cesium carbonate (1.2 mol equiv) in DMF was stirred at ambient temperature for two days. The mixture was filtered through Celite, then the solvent was removed under reduced pressure. The residue was chromatographed on a silica-gel column eluting with chloroform–acetone (95:5 v/v) to give formamidated phthalimide (**C** or **F**).

General Procedure for Hydrolysis and Tosylation of α-Formy-ω-phthalimide (C) to Form α-Tosylamino-ω-phthalimide (D): To a solution of **C** in a small amount of ethanol, 2 M hydrochloric acid was added and heated at 80 °C for 4 h. The solvents were removed under reduced pressure and the residue was stirred with tosyl chloride (1.5 mol equiv to **C**) in pyridine containing a small amount of triethylamine at ambient temperature for 4 h. The solvents were evaporated under reduced pressure and the residue was chromatographed on a silica-gel column eluting with chloroform–acetone (9:1 v/v) to afford **D**.

N^1-Formyl-N^3-tosyl-1,3-propanediamine (Ba): viscous

The Photoinduced Removal of Nitro Groups from Steroidal 6-Membered α,α′-Dinitro Cyclic Ketones[1)]

Hiroshi SUGINOME* and Yoshitaka KUROKAWA
Organic Synthesis Division, Department of Chemical Process Engineering,
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received September 2, 1988)

2,4-Dinitro-5α- and 5β-cholestan-3-ones were prepared by dinitration of the parent 3-ones by a modified standard method. Spectroscopy indicated that in ethanol these α,α′-dinitro ketones exist in their enol forms. Photolysis of these dinitro ketones in ethanol gave diosphenols arising from the removal of their two nitro groups. On the basis of the results of the irradiation of hypothesized intermediate obtained by synthesis, we suggest the path likely to lead to the removal of the nitro groups.

In our previous paper,[2)] we reported the results of the photoreaction of several steroidal 6-membered cyclic α-nitro ketones in ethanol. The investigation disclosed that steroidal 6-membered cyclic α-nitro ketones, which exist in ethanol in their enol form, give the corresponding α-hydroxyimino ketones arising from a hydrogen abstraction by the excited nitro group and the corresponding α-diketone arising from the nitro-nitrite rearrangement, while irradiation of 6-membered cyclic α-nitro ketones, which exist in ethanol in their keto forms, gave the corresponding α-hydroxyimino ketones without any accompanying formation of the corresponding α-diketones. An anomalous formation of 5α-cholestane-2,3-dione was found when 2-nitro-5α-cholestan-3-one, which in ethanol exists exclusively in its enol form was photolyzed. We then suggested the probable paths for the formation of all these products in the photolysis.

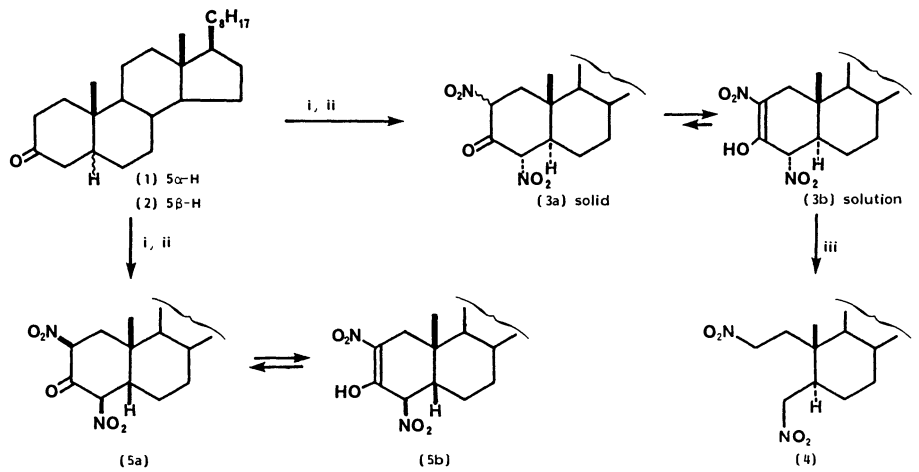
In this paper, we wish to report the results of the photoreaction of two steroidal 6-membered cyclic α,α′-dinitro ketones, 2,4-dinitro-5α-cholestan-3-one (**3**) and its 5β-epimer (**5**).

Preparation of the α,α′-Dinitro Ketones 3 and 5. The α,α′-dinitro ketones **3** and **5** chosen for the present study were prepared by α,α′-dinitration of 5α-and 5β-cholestan-3-one (**1** and **2**) with alkyl nitrate and potassium *t*-butoxide in *t*-butyl alcohol.[3)]

We found that the potassium salts of 2,4-dinitro-5α-cholestan-3-one (**3**) and 2,4-dinitro-5β-cholestan-3-one (**5**) readily gave the corresponding α,α′-dinitro ketones **3** and **5** with no accompanying formation of α,ω-secosteroids when the *dried* potassium salts dissolved in glacial acetic acid were poured into a large volume of iced water instead of being treated with HCl in a diethyl ether suspension.[3)] On the other hand, we found that the above treatment of the potassium salts contaminated with water led to the formation of α,ω-dinitro secosteroids[3-5)] (e.g., **4**).

We also found that the α,α′-dinitro ketone **3** is readily hydrolysed to α,ω-dinitro alkanes when **3** is heated in acetic acid-water under reflux for 3 h, is passed through a silica-gel column,[4)] or is subjected to preparative TLC on silica gel.

The IR spectrum of α,α′-dinitro-5α-cholestan-3-one (**3**) in Nujol indicated that in the mull it exists in a keto form **3a**. Its ^{1}H NMR spectrum in $CDCl_3$, however, exhibited two doublets at δ 2.32 and 2.78 (J=16.6 Hz) and a doublet at δ 5.08 (J=11.2 Hz) assignable to the C-1 methylene and the 4β-H of the enol form, 2,4α-dinitro-5α-cholest-2-en-3-ol (**3b**). The IR spectrum of



i) $CH_3CH_2CH_2ONO_2$–$(CH_3)_3COK$ ii) CH_3COOH iii) CH_3COOH–H_2O–reflux or SiO_2–H_3O^+

Scheme 1.

the solution ($CHCl_3$) and the UV spectra (hexane or ethanol) also indicated that in the solution it exists entirely in the enol form **3b**.

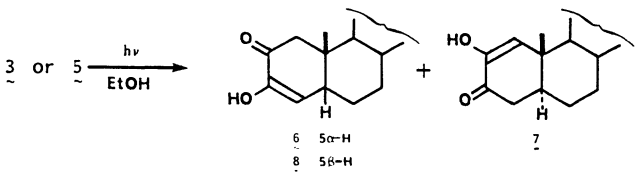
In contrast to the behavior of α,α'-dinitro-5α-cholestan-3-one (**3**), the IR spectrum of the 5β-epimer **5** in Nujol indicated that in the mull its keto and enol forms are in equilibrium. ^{1}H NMR spectrum of **5** in $CDCl_3$ exhibited a series of signals assignable both to the keto form, 2β,4β-dinitro-5β-cholestan-3-one (**5a**) and to the enol form, 2,4β-dinitro-5β-cholest-2-en-3-ol (**5b**). The ratio of the signal areas indicated that the ratio of the two forms was approximately 1 to 1 in $CDCl_3$ (see Experimental).

Photochemistry of α,α'-Dinitro-5α- and 5β-cholestan-3-ones (3 and 5). The photolysis of the two nitro ketones **3** and **5** was carried out in ethanol and in *t*-butyl alcohol under the conditions established for 6-membered cyclic α-nitro ketones reported in our previous paper.[2]

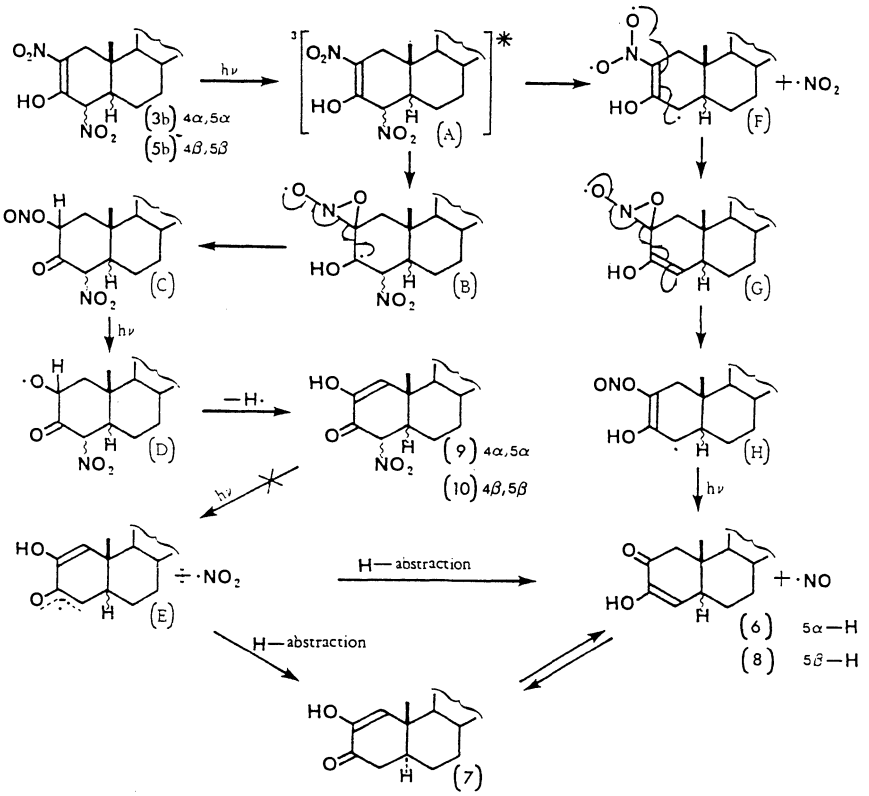
Photolysis of 2,4α-dinitro-5α-cholest-2-en-3-ol (**3b**) in ethanol with a Hanovia 450-W high-pressure mercury arc through a Pyrex filter in an atmosphere of nitrogen gave a product mixture from which a mixture of diosphenols, 3-hydroxy-5α-cholest-3-en-2-one **6** and its isomer **7**[2] was obtained in a 55% yield. Its purification by means of preparative TLC gave a 1 : 1 crystalline mixture of **6** and **7**. Essentially the same results were obtained when the photolysis was carried out in a less hydrogen-donating protic solvent, *t*-butyl alcohol.

Similar photolysis of an equilibrium mixture of 2β,4β-dinitro-5β-cholestan-3-one (**5a**) and 2,4β-dinitro-5β-cholest-2-en-3-ol (**5b**) gave a product in a 48% yield. Spectroscopy confirmed that the structure of the crystalline produt **8** was 3-hydroxy-5β-cholest-3-en-2-one (**8**). The diosphenol has been prepared by Sandmeier and Tamm only as a mixture of diosphenol **8** and 2-hydroxy-5β-cholest-1-en-3-one.[6]

The photochemistry of cyclic α,α'-dinitro ketones has never previously been reported.[7,8] Our present experiments show that the photolysis of α,α'-dinitro ketones in alcohol results in the efficient removal of the two nitro groups to give the corresponding α-diketones. Two probable paths leading to the α-diketones are outlined in Scheme 3. Thus, the first probable path would involve the removal of the 2-nitro group from an excited nitro ketone **A** through the species B, C, and D through a nitro nitrite rearrangement[8,9] to give 4-nitro-2,3-diketone **9** as in the case of the 6-membered cyclic α-nitro ketones reported in our previous paper.[2] A photoinduced homolysis of the C-N bond of 4-nitro-2,3-diketone **9** followed by the



Scheme 2.



Scheme 3.

hydrogen abstraction from the solvent might then give the α-diketones **6**, **7**, and **8**.

A second possible path, on the other hand, would involve an initial homolysis of the C-N bond[10] of the 4-nitro group to give a nitrite radical **H** through an oxaziridine **G**. The homolysis of the C-N bond is considered to be especially facile since the generated species **F** is a stabilized allylic radical. In order to distinguish these two paths, we prepared 2-hydroxy-4α-nitro-5α-cholest-1-en-3-one **9** and carried out its photolysis.

Thus, nitration of 5α-cholestane-2,3-dione with butyl nitrate and potassium *t*-butoxide in THF gave mononitro-5α-cholestane-2,3-dione **9** in a 30% yield. The IR, NMR, and mass spectra confirmed that the structure was the desired 2-hydroxy-4α-nitro-5α-cholest-1-en-3-one (**9**). The IR spectra exhibited two bands at 1695 and 1648 cm^{-1} assignable to the α,β-unsaturated carbonyl group and a strong band at 1560 cm^{-1} due to the unconjugated nitro group. The ^1H NMR spectrum exhibited a singlet (1H) at δ 6.60 assignable to the proton attached to the C-1 and a doublet at δ 5.29 with J=13.55 Hz assignable to the 4β-proton.

We found that nitro ketone **9** is recovered unchanged when it is subjected to photolysis in ethanol for 3 h under the same conditions established for the photolysis of α,α'-dinitro ketone **3**. The result excludes the first path involving the intermediates **C** and **D** in the formation of α-diketones **6**, **7**, and **8**. The α-diketones are therefore very likely to be formed through intermediates **F**, **G**, and **H**, whose formations are triggered by the homolysis of the C_4-NO_2 bond.

Experimental

For the instruments used and the general procedure see Ref. 2.

Preparation of 2ξ,4α-Dinitro-5α-cholestan-3-one (3). Freshly sublimed potassium *t*-butoxide (4.0 g) was dissolved by heating in dry *t*-butyl alcohol (68 ml) in a nitrogen atmosphere. The solution was cooled to 19 °C and 5α-cholestan-3-one (**1**) (2.0 g) was dissolved in it. To the solution propyl nitrate (4 ml) was added over the course of 10 min and the solution was stirred for 20 h at 18—20 °C, after which the solution was poured into iced water. The separated potassium salt of dinitrocholestane was filtered off and dried. The yield of potassium salt was 2.468 g. The potassium salt was dissolved in glacial acetic acid and the solution was poured into iced water. The separated crystals of 2,3-dinitro-5α-cholestan-3-one (**3**) (2.3 g) were collected by filtration and recrystallized from ethyl alcohol. Mp 199—201 °C. IR (Nujol) 1737 (C=O) and 1558 cm^{-1} (NO_2); IR ($CHCl_3$) 1642 (C=C) and 1562 (4α-NO_2) and 1530 (br, 2-NO_2); (Found: C, 67.90; H, 9.37; N, 5.70%; Calcd for $C_{27}H_{44}N_2O_5$: C, 67.90; H, 9.31; N, 5.88%); UV (hexane), λ_{max} 308.5 nm (ε; 5790); (ethanol), 353 nm (ε; 8570); (ethanol and 1 equiv mol of sodium ethoxide), 345.5 nm (ε; 12170); ^1H NMR ($CDCl_3$), δ=0.67 (3H, s, 18-H), 0.87 (3H, s, 19-H), 2.32 (1H, d, J=16.60 Hz, 1-H), 2.78 (1H, d, J=16.60 Hz, 1-H), and 5.08 (1H, d, J=11.23 Hz, 4β-H); MS m/z (rel intensity) 476 (M^+, 87.8%), 430 (M^+-NO_2, 13.3), 322 (73.8), 321 (91.4), 69 (86.8), 57 (96.4), 55 (97.2), and 43 (100).

2,4-Dinitro-2,3-seco-*A*-nor-5α-cholestane (4). 2,4-Dinitro-5α-cholestan-3-one (**3a**) (50 mg) dissolved in glacial acetic acid (17 ml) and water (6 ml) was heated under reflux for 3 h. After the addition of hot water, the solution was extracted with dichloromethane three times. The combined solution was washed with water several times and dried over anhydrous sodium sulfate. The usual work-up gave a dinitro compound (63 mg), mp 165—169 °C. (lit,[5] 169—172 °C). UV, λ_{max} (EtOH) 277 nm (ε; 64); MS m/z (rel intensity) 450 (M^+, 23.8), 433 (M^+-NO_2, 9.8), 420 (19.8), 402 (15.5), 329 (18.3), and 55 (100%).

Preparation of 2,4-Dinitro-5β-cholestan-3-one (5a). Freshly sublimed potassium *t*-butoxide (3.0 g) was dissolved by heating in dry *t*-butyl alcohol (50 ml) in a nitrogen atmosphere. The solution was cooled to 20 °C and 5β-cholestan-3-one (**2**) (1.5 g) was added. To the solution, propyl nitrate (2 ml) was then added over a period of 10 min. More propyl nitrate (1 ml) was added after 30 min and the solution was stirred for 15 h at 16—20 °C. The solution was poured into iced water, and the mixture was made acidic (pH 3) with acetic acid. The orange colored precipitates were collected by filtration. The dried precipitates (2.0 g) were dissolved in glacial acetic acid (150 ml) and iced water (300 ml) was added to the solution. The colorless solid (1.83 g) was collected by filtration and dried. The dinitro ketone **5a** was recrystallized from ethanol to give crystals (698 mg, 37.2%), mp 177—179 °C. (Found: C, 68.03; H, 9.31; N, 5.85%. Calcd for $C_{27}H_{44}N_2O_5$: C, 68.03; H, 9.31; N, 5.88%); UV (EtOH) 353 nm (ε; 1060); IR (Nujol) 1751 (C=O) and 1655 (C=C) and 1548 (NO_2); ^1H NMR; the keto form, δ=0.66 (s, 18-H), 1.19 (s, 19-H), 5.33 (dd, J=12.4 and 5.12 Hz, 2α-H), and 5.58 (d, J=10.25 Hz, 4α-H), the enol form, 0.69 (s, 18-H), 1.26 (s, 19-H), 2.31 (d, J=17.09 Hz, 1-H), 3.08 (d, J=17.09 Hz, 1-H), and 5.71 (d, J=12.7 Hz, 4α-H); MS m/z (rel intensity) 476 (M^+, 18.7), 430 (M^+-NO_2, 31.9), 412 (19.5), 383 (36.4), 57 (100), and 55 (99.0%).

Photolysis of 2ξ,4α-Dinitro-5α-cholestan-3-one (3). (a) In Ethanol. α,α'-Dinitro ketone **3**, (300 mg, 0.63 mmol) in absolute ethanol (450 ml) was irradiated for 3 h with a Hanovia 450-W high-pressure mercury arc through a Pyrex filter in an atmosphere of dry nitrogen. Removal of the solvent under reduced pressure gave an oily residue (325 mg) which was subjected to preparative TLC with dichloromethane to give a mixture of diosphenols **6** and **7** (139 mg, 55.2%). This mixture was again purified by means of preparative TLC to give diosphenols (59 mg, 23.5%). This was recrystallized from methanol-water to give crystals of a 1 : 1 mixture of **6** and **7** (32 mg, 12%), mp 119—155 °C.

(b) In *t*-Butyl Alcohol. α,α'-Dinitro ketone **3** (300 mg) in dry *t*-butyl alcohol (350 ml) was similarly irradiated for 3 h. A similar work-up of the solution gave a mixture of diosphenols **6** and **7** (89 mg, 34.3%). This mixture was recrystallized from methanol to give crystals at a 1 : 1 mixture of **6** and **7** (26 mg, mp 129—155 °C).

Photolysis of 2,4-Dinitro-5β-cholestan-3-one (5). α,α'-Dinitro ketone **5**, (300 mg, 0.63 mmol) in absolute ethanol (400 ml) was irradiated for 6 h with a Hanovia 450-W high-pressure mercury arc through a Pyrex filter in an atmosphere of dry nitrogen. Removal of the solvent under a reduced pressure gave an oily residue (341 mg) which was subjected

to preparative TLC with dichloromethane to give diosphenol **8** (124 mg, 47.8%). This was recrystallized from diethyl ether-methanol to yield the specimens for analysis (74 mg), mp 157—162 °C. (Found: C, 80.94; H, 11.07%. Calcd for $C_{27}H_{44}O_2$: C, 81.00; H, 11.29%); IR (Nujol) 3528 and 2438 (OH), 1666 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=0.64 (3H, s, 18-H), 1.11 (3H, s, 19-H), 2.23 (1H, d, J=16.6 Hz, 1β-H), 2.71 (1H, d, J=16.6 Hz, 1α-H), 5.75 (1H, d, J=2.93 Hz, 4-H) and 5.81 (1H, s, OH); MS, m/z (rel intensity) 400 (M^+, 100), 385 [$(M-Me)^+$, 7.9], 314 (38.9), 287 (37.7), 274 (18.3), 269 (18.3), 220 (15.4), 159 (25.0), 137 (43.5), 95 (42.1), 81 (38.0), 69 (36.8), 55 (47.7), and 43 (45.4).

Synthesis of 2-Hydroxy-4α-nitro-5α-cholest-1-en-3-one (9). To a solution of potassium *t*-butoxide (0.42 g) in THF (10 ml) at −40 °C, a solution of 5α-cholestane-2,3-dione[5] (0.5 g) in THF (10 ml) was added dropwise. To this solution, propyl nitrate (0.38 ml) was added and the temperature of the solution was then neutralized with glacial acetic acid and poured into iced water. The aqueous solution was extracted with diethyl ether. The organic layer was washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent left a product (599 mg) which was recrystallized from methanol to give 4α-nitro-2-hydroxy-5α-cholest-1-en-3-one (**9**) (165 mg, 30 %), mp 157—161 °C. The specimen for analysis was obtained by recrystallization from methanol. Mp 159—161 °C. IR (Nujol) 3404 (OH), 1695 (C=O), 1648 (C=C), and 1560 cm^{-1} (NO_2); ^1H NMR (270 MHz) δ=0.69 (3H, s, 18-H), 1.13 (3H, s, 19-H), 5.29 (1H, d, J=13.55 Hz, 4β-H) and 6.60 (1H, s, 1-H); MS m/z (rel intensity) 445 (M^+, 9.8), 429 [$(M-O)^+$, 8.6], 415 [$(M-NO)^+$, 31.6], 398 [$(M-NO_2H)^+$, 100], 387 (27.9), and 137 (80%); UV (EtOH) λ_{max} 270 nm (ε; 7850); (Found; C, 72.46; H, 9.77; N, 2.90%. Calcd for $C_{27}H_{43}NO_4$; C, 72.77; H, 9.73; N, 3.14%).

Attempted Photolysis of 2-Hydroxy-4β-nitro-5α-cholest-1-en-3-one (9). Nitro enone **9** (50 mg) in absolute ethanol (50 ml) was irradiated through a Pyrex-filter in an atmosphere of nitrogen with a Hanovia 450-W Hg arc for 2 h. Removal of the ethanol gave an oil (47 mg). Examination of this oil by preparative TLC and ^1H NMR indicated that it was virtually the pure recovered starting material; this was confirmed by spectroscopy after purification.

Inclusion Properties of Acyclic *p*-Substituted Phenol-Formaldehyde Oligomers

Tyo SONE,* Yoshihiro OHBA, and Hajime YAMAZAKI
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received September 2, 1988)

Acyclic para-substituted phenol-formaldehyde oligomers (R=H, Me, *n*-Bu, *t*-Bu, and cyclohexyl; the number of phenol units=3—6) form host-guest complexes with various organic compounds. The inclusion property of the acyclic oligomers is greatly influenced by the *p*-substituents of phenol and the number of phenol units in the oligomers; for example, a) while the *t*-butyl tetramer is effective, the corresponding butyl tetramer has a poor ability for the complex formation, and b) the tetramers and pentamers are good hosts for organic compounds, forming 2:1 (host:guest) complexes in many cases.

Cyclic *p*-substituted phenol-formaldehyde oligomers with methylene bridges in positions ortho to the phenolic hydroxyl group, named "calixarene," are well-known to have the property of forming host-guest complexes with organic molecules.[1] The corresponding acyclic oligomers have also been found to form stable complexes, although only a few examples are available. For example, the trimer based on phenol (phenol trimer; **3e**) forms a complex with benzene;[2] the *p*-cresol tetramer (**4a**) forms complexes with $ClCH_2CH_2Cl$[3] or toluene;[4] the *p*-*t*-butylphenol tetramer (**4b**) forms a complex with cyclohexane.[5] It has been shown by X-ray analysis that the cyclic and acyclic oligomers are quite different from each other in conformation in the crystalline state[1,2] which plays an important role in the complex formation. This suggests that the inclusion property of acyclic oligomers differ from that of cyclic ones. There has, however, been no systematic study on the inclusion property of acyclic oligomers. We have investigated the subject and found that *p*-substituents of phenol and the number of phenol units in the oligomers have a striking effect on the inclusion property. The results will be reported.

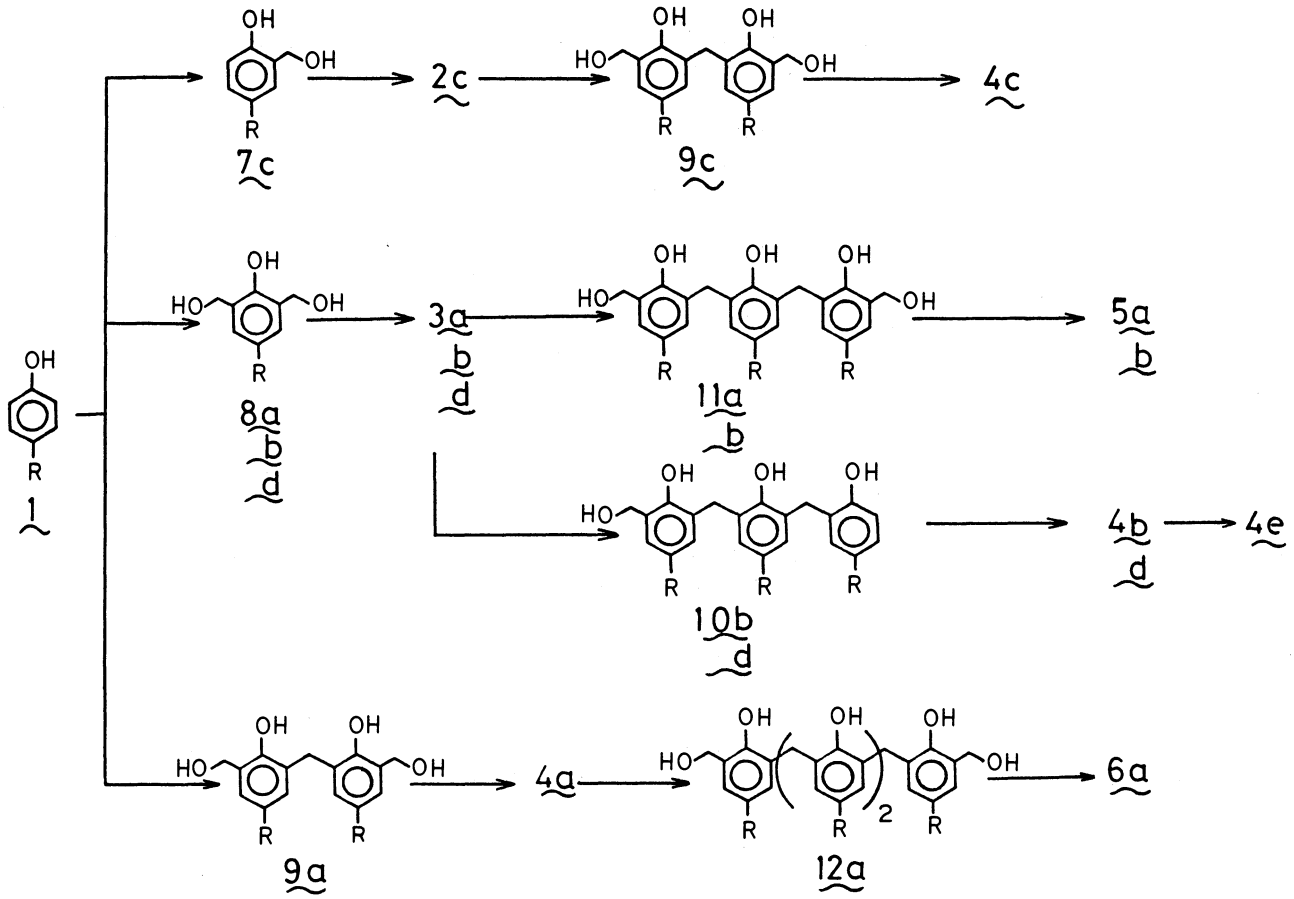
Results and Discussion

Synthesis of Oligomers. In general, *p*-substituted phenol-formaldhyde oligomers are synthesized by the stepwise procedure[6,7] based on repeated hydroxymethylation-arylation reaction sequences on phenolic substrates. Except for the *p*-butylphenol tetramer (**4c**) and *p*-cyclohexylphenol tetramer (**4d**), all oligomers used in this study have been known. However, some of the oligomers could not be obtained in satisfactory yields by the reported procedures. Therefore, the synthetic routes were modified in such cases. For example, the tetramers **4a** and **4b** have been synthesized by the condensation of the bis(hydroxymethyl) dimer (**9a** or **9b**) with the corresponding phenol **1a** or **1b**. But **9b** could not be obtained in one step by the base-induced hydroxymethylation of *p*-*t*-butylphenol (**1b**) as described in the literature.[5] Such is also the case with the bis(hydroxymethyl) dimers **9c** and **9d**. The HCl-catalyzed condensation of **8b** with 10 molar equiv of **1b** gave the trimer **3b** in good yield. The NaOH-induced hydroxymethylation of **3b** with aq formaldehyde yielded the mono(hydroxymethyl) trimer **10b**, which was reacted with **1b** to afford **4b**. The tetramer **4d** was obtained by a similar method. On the other hand, the tetramer **4c** was synthesized by starting with 4-butyl-2-(hydroxymethyl)phenol (**7c**); the dimer **2c** which has been prepared by treating **7c** with excess *p*-butylphenol (**1c**) was hydroxymethylaled under basic conditions and the resultant bis(hydroxymethyl) dimer **9c** was again reacted with excess **1c** to afford **4c**. The phenol tetramer (**4e**) was easily produced by the debutylation of **4b** with $AlCl_3$, the procedure being analogous to that employed in the synthesis of unsubstituted calixarenes.[8] The synthetic pathway of the oligomers is illustrated in Scheme 1.

Inclusion Properties. Inclusion ability of oligomers toward organic molecules was examined by recrystallization of oligomers from various organic solvents. It was found that the oligomers had an ability to form complexes with a variety of molecules and that the complexation was dependent upon substituents in the *p*-position of phenol and the number of phenol units in the oligomers. While calixarene has been reported to form 1:2 (host:guest) or 1:1 complexes,[8-15] the corresponding acyclic oligomers form 2:1 complexes in many cases, suggesting that modes of host-guest association are quite different between



Scheme 1.

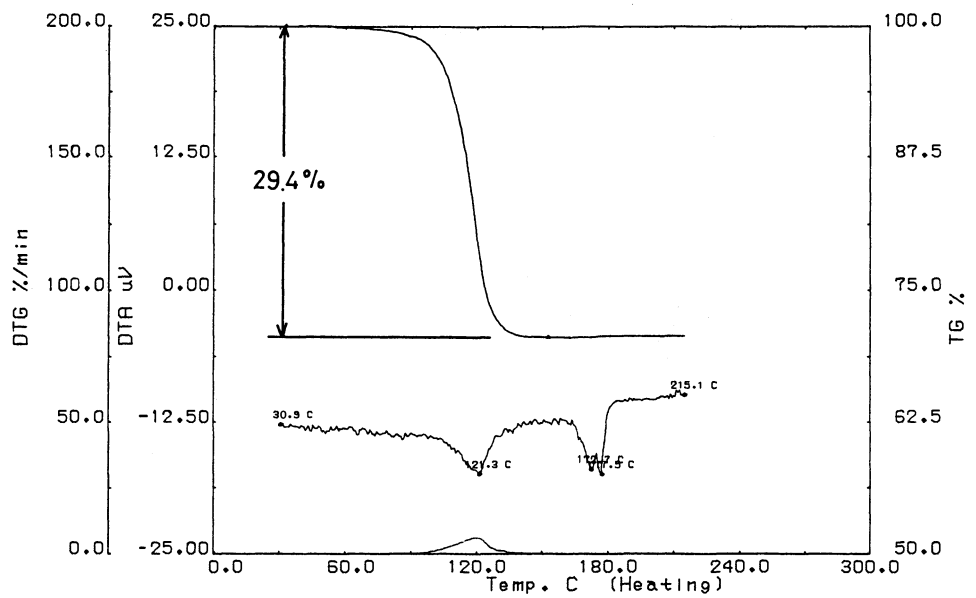


Fig. 1. TG-DTA curves of the complex of **4a** with 1,2-dibromoethane.

the cyclic and acyclic oligomers. The results are summarized in Tables 1 and 2.

The host-guest ratio was determined by ^{1}H NMR spectroscopy and thermogavimetry (TG). The TG-DTA (differential thermal analysis) patterns of a complex obtained from the tetramer **4a** and 1,2-dibromoethane are shown in Fig. 1 as an example. The TG curve indicates that the complex is stable up to 80 °C and the crystal morphology of the complex seems to change on heating. The weight loss corresponds accurately to the 1,2-dibromoethane content of the 1 : 1 complex of **4a** with 1,2-dibromoethane. The

stoichiometric ratio was ascertained by ^{1}H NMR integration as well as elemental analysis.

Table 1 shows that the inclusion properties of tetramers **4a—e** are greatly influenced by the *p*-substituent of phenol. The methyl-substituted tetramer **4a** forms host-guest compounds mainly with halogenated hydrocarbon compounds and not with aromatic compounds except for benzene. The unsubstituted tetramer **4e** is similar to **4a** in forming complexes with haloganated hydrocarbons but fails to form complexes with benzene. On the other hand, the *p*-*t*-butyl-substituted tetramer **4b** preferentially includes benzene and its alkyl derivatives. The host : guest molar ratios (2 : 1 and 1 : 1) suggest that different modes of complexation are expected between the benzene and toluene complexes. On the contrary, the butylphenol tetramer (**4c**) has a poor ability for the complex formation. The only difference between **4b** and **4c** is in the bulkiness of the butyl groups. These facts suggest that the linear and flexible butyl group at the *p*-position prevents the incorporation of the guest molecules into the crystalline lattice. The cyclohexyl-substituted tetramer **4d** differs from the others in forming complexes with ketones. Furthermore, **4d** gives a complex only with *o*-xylene among the isomeric xylenes.

Table 2 shows that the number of the phenol units also affects inclusion properties. The *p*-cresol (**4a**) and *t*-butylphenol tetramers (**4b**) and the corresponding pentamers (**5a** and **5b**) form efficiently complexes with many organic guests; the tetramer and the correspond-

ing pentamer include similar guests in each series. On the other hand, the trimers (**3a** and **3b**) exhibit almost no inclusion properties, and guests of the hexamer **6a** are rather limited. These results suggest that the molecular size of the trimers is not large enough to form lattice voids appropriate for the complex formation, whereas that of the hexamer is too large to form voids.

Besides the guests listed in the tables, the cresol tetramer (**4a**) forms complexes with chloroform (1 : 1), tetrahydrofuran (1 : 1), diethylamine, triethylamine (1 : 1), and chlorobenzene (2 : 1), but not with isopropyl alcohol, acetonitrile, cyclohexene, or aniline. None of the oligomers gave inclusion compounds with hexane or thiophene.

It should be noted that not a few molecules which possess no group to participate in hydrogen bonding are included by the oligomers; hydrogen bonding between hosts and guest molecules is not primarily responsible for complex formation. This makes a sharp contrast with the situation for many other phenolic hosts.[16-18]

Finally, in an attempt to estimate the thermal stability of host-guest complexes, some kinetic parameters for the dissociation of the complexes (host : guest=2 : 1) of **4a**, **4b**, and **5a** with benzene were obtained from their dissociation rates (Table 3). The thermal stability is dependent upon the substituents in the *p*-position or the size of the oligomers. For the tetramers methyl group is more favorable than *t*-butyl group for the formation of stable complex, whereas for the cresol oligomers the tetramer **4a** is more favorable than the pentamer **5a**.

Experimental

All melting points are uncorrected. NMR spectra were obtained on a Hitachi R-600 spectrometer at 60 MHz, using TMS as an internal reference. IR and mass (70 eV) spectra were recorded on a Hitachi EPI-S2 and a Hitachi UMU-6MG spectrometer, respectively. TG/DTA curves were recorded on a Seiko TG/DTA30 instrument with a heating rate of 10 °C min^{-1} under air stream.

The following oligomers were prepared according to the methods reported in literatures. **3a**: mp 214—215 °C (lit,[19] mp 215 °C). **4a**: mp 174—178 °C (lit,[5] mp 173 °C). **5a**: mp 127—128 °C (lit,[19] mp 130 °C). **6a**: mp 215—216 °C (lit,[19] 217 °C). **3b**: mp 221—222 °C (lit,[20] 220—221 °C). **5b**: mp 218—219 °C (lit,[20] 217—218 °C).

Synthesis of 2-[3-[3-(5-*t*-Butylsalicyl)-5-*t*-butylsalicyl]-5-*t*-butylsalicyl]-4-*t*-butylphenol (4b). Formalin (37%; 1.3 g, 16.1 mmol) was added with stirring over a period of 30 min to a mixture of **3b** (7.7 g, 16.1 mmol), 10% aqueous NaOH solution (30 ml), and methanol (30 ml) at 60 °C under an N_2 atmosphere. After stirring under reflux for 35 h, the reaction mixture was cooled to room temperature, acidified to pH 4 with 50% acetic acid, and extracted with chloroform. The organic layer was washed with water and dried over Na_2SO_4. The solvent was evaporated and the residue was chromatographed on silica gel (hexane/ethyl acetate=3/1) to give **10b** (2.7 g, 34%; mp 187—189 °C (lit,[5] mp 188.5—189 °C)), and **11b** (1.0 g, 12%; mp 143—145 °C (lit,[5] mp 140—145 °C)) together with unchanged **3b** (2.5 g, 33%).

A solution of **10b** (1.25 g, 2.48 mmol), *p*-*t*-butylphenol (**1b**; 20 g, 0.133 mol), and *p*-toluenesulfonic acid (45 mg) in benzene (30 ml) was stirred under reflux for 24 h; the water produced during the reaction was removed by azeotropic distillation using a Dean-Stark condenser. The benzene was evaporated and excess **1b** was removed by steam distillation. The residual mass was crystallized from cyclohexane to give the **4b**-cyclohexane complex (**4b**: cyclohexane=1 : 2) as a white powder (1.3 g, mp 105 °C (lit,[5] mp 105 °C)). This complex was heated at 80 °C under reduced pressure (1 mmHg; 1 mmHg=133.322 Pa) for 8 h to give cyclohexane-free **4b** as white powder (1.0 g, 64%; mp 210—211 °C (lit,[5] mp 212—213 °C)).

Synthesis of 2-[3-[3-(5-Butylsalicyl)-5-butylsalicyl]-5-butylsalicyl]-4-butylphenol (4c). To a mixture of *p*-butylphenol (**1c**; 10.0 g, 67 mmol) and formalin (5.4 g, 67 mmol) 10% aqueous NaOH solution (33 ml) was added with stirring under ice-cooling, and the reaction mixture was stirred at 50 °C for 6 h under an N_2 atmosphere. Then, another 5.4 g of formalin was added to the mixture, and the mixture was stirred for an additional 1 h. After being cooled to room temperature, the mixture was acidified with 50% acetic acid (pH 5) and extracted with benzene. After a usual work-up, the product was chromatographed on silica gel (Wako C-200; hexane/ethyl acetale=2/1) to give 4-butyl-2-(hydroxymethyl)phenol (**7c**; 2.0 g, 17%) and 4-butyl-2,6-bis(hydroxymethyl)phenol (**8c**; 7.5 g, 54%) together with unreacted **1c** (3.0 g, 30%).

7c: white plates; mp 79—80.5 °C; IR (KBr) 3450 (OH stretching) and 815 cm^{-1} (trisubstituted phenyl); ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, t, J=5 Hz), 1.10—1.90 (4H, m), 2.30—2.75 (2H, m), 4.80 (2H, s), and 6.60—7.30 (3H, m); MS m/z 180 (M^+, 42%); Anal. ($C_{11}H_{16}O_2$) C, H.

8c: colorless prisms, mp 65—66 °C; IR (KBr) 3400, 3280 (OH stretching), and 880 cm^{-1} (tetrasubstituted phenyl); ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, t, J=5 Hz), 1.10—1.95 (4H, m), 2.35—2.80 (2H, m), 3.80 (2H, s, OH), 4.40—5.00 (4H, m), 6.80 (2H, s), and 8.2 (1H, s, Ar-OH); MS m/z 210 (M^+, 34%); Anal. ($C_{12}H_{18}O_3$) C, H.

Hydrochloric acid (2 ml) was added to a mixture of **7c** (3.0 g, 17 mmol) and **1c** (7.7 g, 51 mmol), and the mixture was stirred at 110 °C for 6 h. After removing excess **1c** from the

reaction mixture by steam distillation, the residue was extracted with chloroform. A usual work-up gave a crude product, which was purified by medium-pressure column chromatography on silica gel (Kieselgel 60, 230—400 mesh; hexane/ethyl acetate=4/1) to give the *p*-butylphenol dimer (**2c**; 4.2 g, 79%).

2c: colorless powder; mp 66.5—67.0 °C; IR (KBr) 3250 (OH stretching) and 820 cm^{-1} (trisubstituted phenyl); ^1H NMR ($CDCl_3$) δ=0.90 (6H, t, J=5 Hz), 1.10—1.95 (8H, m), 2.30—2.75 (4H, m), 3.85 (2H, s), and 6.55—7.25 (6H, m); MS m/z (rel intensity) 314 (M^+, 100); Anal. ($C_{21}H_{28}O_2$) C, H.

To a mixture of **2c** (4.1 g, 13 mmol), 20% aqueous KOH solution (15 ml), and dioxane (20 ml), formalin (40 ml, 0.53 mol) was added over a period of 1 h under ice-cooling. The mixture was stirred at 60 °C for 20 h under an N_2 atmosphere. After being cooled to room temperature, the mixture was acidified with 50% acetic acid (pH 4) and extracted with benzene. After a usual work-up, the crude product was separated by medium-pressure liquid chromatography on silica gel (Kieselgel 60, 230—400 mesh; ethyl acetate/hexane=1/2) and recrystallized with chloroform-hexane to give the bis(hydroxymethyl) derivative (**9c**; 1.6 g, 33%) of **2c**.

9c: white powder; mp 123—124 °C; IR (KBr) 3375 (OH stretching) and 870 cm^{-1} (tetrasubstituted phenyl); ^1H NMR ($CDCl_3$) δ=0.90 (6H, t, J=5 Hz), 1.10—1.90 (8H, m), 2.00—2.80 (4H, m), 3.80 (2H, s), 4.70 (4H, s), and 6.60—7.30 (4H, m); MS m/z 372 (M^+, 14%); Anal. ($C_{23}H_{32}O_4$) C, H.

A mixture of **9c** (1.4 g, 3.7 mmol), **1c** (5.6 g, 37 mmol), and HCl (1 ml) was stirred at 100 °C for 3.5 h. Excess **1c** was removed by steam distillation and the residue was extracted with chloroform. After a usual work-up, the crude material was recrystallized from hexane to give **4c** (1.8 g, 75%).

4c: white powder; mp 117—118 °C; IR (KBr) 3250 (OH stretching), 875 (tetrasubstituted phenyl), and 820 cm^{-1} (trisubstituted phenyl); ^1H NMR ($CDCl_3$) δ=0.90 (12H, t, J=5 Hz), 1.10—2.00 (16H, m), 2.25—2.80 (8H, m), 3.80 (6H, s), and 6.75—7.30 (10H, m); MS m/z 636 (M^+, 76%); Anal. ($C_{43}H_{56}O_4$) C, H.

Synthesis of 2-[3-[3-(5-Cyclohexylsalicyl)-5-cyclohexylsalicyl]-5-cyclohexylsalicyl]-4-cyclohexylphenol (4d). A mixture of *p*-cyclohexylphenol (**1d**; 5.0 g, 28 mmol), 20% KOH (20 ml), and formalin (50 ml) was heated with stirring at 60 °C for 30 h under an N_2 atmosphere. The reaction mixture was cooled to room temperature, acidified to pH 5 with 10% aqueous HCl (50 ml), and extracted with chloroform (100 ml). After a usual work-up, the product was subjected to silica-gel column chromatography (hexane/ethyl acetate=2/1) to give 4-cyclohexyl-2,6-bis(hydroxymethyl)-phenol **8d** (5.7 g, 82%, mp 112—113 °C (lit,[21] 106—107 °C)).

A mixture of **8d** (2.7 g, 11.4 mmol), **1d** (10.0 g, 56.7 mmol), and HCl (2 ml) was stirred at 130 °C for 8 h. A work-up similar to the one described for the synthesis of **4c** from **9c** afforded the *p*-cyclohexylphenol trimer (**3d**), which was recrystallized from toluene to give pure **3d** (3.6 g, 57%).

3d: colorless needles; mp 186—188 °C; IR (KBr) 3300 (OH stretching), 865 (tetrasubstituted phenyl), and 810 cm^{-1} (trisubstituted phenyl); ^1H NMR ($CDCl_3$) δ=0.80—2.70 (33H, m), 3.90 (4H, s), and 6.60—7.30 (8H, m); MS m/z 552 (M^+, 21%); Anal. ($C_{38}H_{48}O_3$) C, H.

The hydroxymethyl derivative **10d** of **3d** was synthesized from **3d** in 33% yield in a similar manner as described for the synthesis of **10b** from **3b**.

10d: colorless needles; mp 156—157 °C; IR (KBr) 3280 (OH stretching), 865 (tetrasubstituted phenyl), and 815 cm^{-1} (trisubstituted phenyl); ^1H NMR ($CDCl_3$) δ=0.80—2.80 (33H, m), 3.80 (4H, s), 4.70 (2H, s), and 6.50—7.30 (7H, m); MS m/z 582 (M^+, 8%); Anal. ($C_{39}H_{50}O_4$) C, H.

A mixture of **10d** (1.2 g, 2.1 mmol), **1d** (4.0 g, 22.7 mmol), *p*-xylene (2 ml), and HCl (3 ml) was stirred at 130 °C for 12 h. After a usual work-up, the product was subjected to medium-pressure column chromatography on silica gel (Kieselgel 60, 230—400 mesh; hexane/ethyl acetate=5/1) to give **4d** (0.9 g, 58%).

4d: white powder; mp 179—182 °C; IR (KBr) 3250 (OH stretching), 870 (tetrasubstituted phenyl), and 815 cm^{-1} (trisubstituted phenyl); ^1H NMR ($CDCl_3$) δ=1.80—2.60 (44H, m), 3.85 (6H, s), and 6.60—7.30 (10H, m); MS m/z 740 (M^+, 0.1%); Anal. ($C_{51}H_{64}O_4$) C, H.

Synthesis of 2,2'-Methylenebis[6-(2-hydroxybenzyl)phenol] (4e). The procedure is a modification of the method used for the synthesis of calix[4]arene from *p-t*-butylcalix[4]arene.[8] Aluminum chloride (1.1 g, 8.2 mmol) was added to a solution of **4b** (1.0 g, 1.57 mmol) in toluene (50 ml), and the mixture was stirred at 50 °C for 2 h. The reaction mixture was cooled to 5 °C, and then dilute HCl (3%, 25 ml) was added to this mixture. A work-up and medium-pressure column chromatography (Kieselgel 60, 230—400 mesh, hexane/ethyl acetate=2/1) gave **4e** (0.42 g, 65%; mp 158—159 °C (lit,[2] mp 163 °C)).

Preparation of Inclusion Complex (General Procedure). The host oligomer (0.3 g) was dissolved in a minimum amount of organic solvent (guest) by heating and the solution was cooled to room temperature. The precipitates were filtrated, where necessary, washed with hexane, and dried at room temperature for 12 h. The guest-host ratio was determined by ^1H NMR (solvent $CDCl_3$) and/or TG measurements.

Kinetic Study. The weight decreasing rate of a complex was measured at four points using Al_2O_3 as an reference. The programmed temperature was raised at a rate of 10 °C min^{-1} up to each temperature. Based on the rate constants thus obtained, $\ln A$ and E_a values were calculated by the least-squares method. The results are shown in Table 3.

The authors are grateful to Professor Kenzo Matsuki and Mr. Takashi Endo for TG/DTA measurements. They also wish to thank Mr. Kazuaki Sato for elemental analyses and Mr. Kazuhiko Moriya and Miss Chikako Kobayashi for their assistance in some experiments.

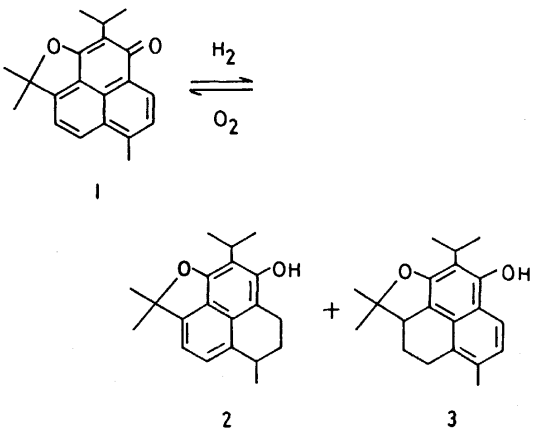
Synthesis of Salvilenone, a Diterpenoid Phenalenone of *Salvia miltiorrhiza*

Guo-Chi ZHENG and Hiroshi KAKISAWA*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received September 8, 1988)

Salvilenone **1**, a phenalenone diterpene isolated from the roots of *Salvia miltiorrhiza* Bunge, was synthesized in thirteen steps from resorcinol dimethyl ether. Dihydrophenalenol derivative **19**, a key intermediate, was treated with aqueous hydrobromic acid to give salvilenone accompanied by the formation of a hydroxy diketone **20**.

Salvilenone is a diterpenoid found in the roots of *Salvia miltiorrniza* Bunge. The dried root of this plant, Dan-shen, is a traditional medicine in China used for the treatment of blood difficulties, hemorrhages, miscarriages and viral hepatitis.[1,2] Recently, it is also used for the treatment of heart disease as a clinically important drug.[3]

The main constituents of this folk medicine were thoroughly studied to find many diterpenoid naphthoquinones and phenanthrenequinones possessing a norabietane carbon skeleton.[4] In the course of our studies on the minor constituents of Dan-shen, a bright yellow compound salvilenone was isolated in a trace amount, and the structure was determined to be a diterpenoide phenalenone **1** different from the known naphthoquinones and phenanthrenequinones of this medicine.[5] The low availability of this compound and scarce distribution of phenalenone derivatives in nature[6] prompted us to investigate its synthesis. The present paper describes in detail the synthesis of salvilenone.[7]



Scheme 1.

It was found in the course of the structural determination that on hydrogenation salvilenone **1** gave unstable products **2** and **3**, which were smoothly autooxidized to the original pigment.[5] On the basis of this observation, dihydrophenalenol derivative **3** was chosen as a key intermediate for the synthesis.

A dihydrophenalenone derivative **16a** was synthesized from resorcinol dimethyl ether (**4**) by an eleven step process.

The reaction of the dihydrophenalenone derivative **16a** with lithium acetylide-ethylenediamine complex proceeded smoothly to give an ethynyl derivative **17** in good yield.[9] Treatment of this ethynyl-substituted alcohol with mercury(II) sulfate and sulfuric acid at 55 °C under Rupe reaction conditions resulted in the formation of acetylphenalenone **18**[12] with concomitant demethylation in these mild conditions. This reaction confirmed the remarkably facile formation of phenalenone from a dihydrophenalenol as observed in the structural determination of salvilenone.

Because selective conversion of the acetyl group of

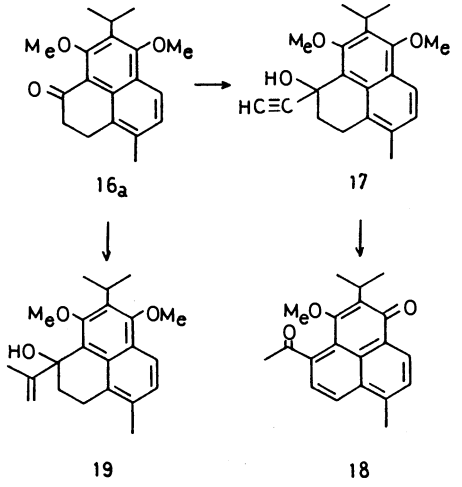
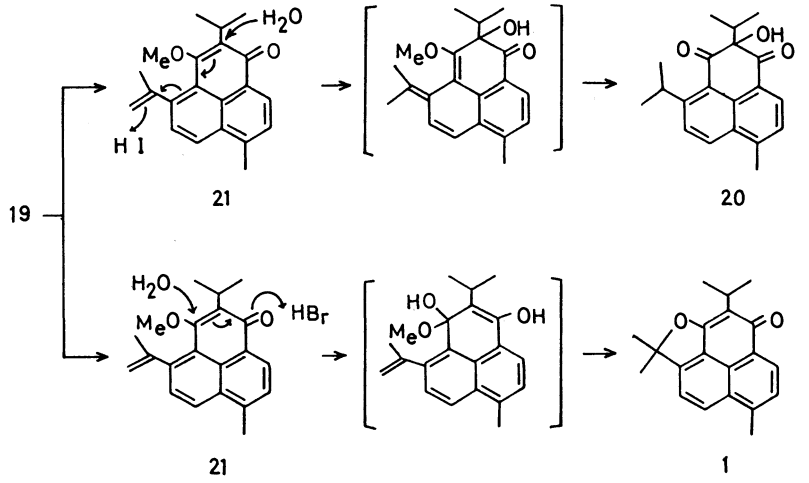


Scheme 3.

18 to an isopropenyl group was unsuccessful, isopropenyllithium[10] was allowed to react with dihydrophenalenone **16a** to obtain the intermediate **19**.

Treatment of the isopropenyl-substituted alcohol **19** with 47% aqueous hydrobromic acid[11] in boiling acetic acid for 48 h afforded salvilenone **1**, accompanied by the formation of a by-product hydroxy diketone **20**. Synthetic salvilenone **1** was identical with an authentic sample in ^{1}H NMR, ^{13}C NMR, IR spectra, and TLC. The structure of the by-product ($C_{20}H_{22}O_3$) was determined to be **20** by spectral analyses. The ^{1}H NMR spectrum showed the presence of two isopropyl groups, an aromatic methyl, and two adjacent aromatic protons. Two of three oxygen atoms of the by-product were considered to comprise two carbonyl groups from ^{13}C NMR signals at δ 193.2 and 197.7, and



Scheme 4.

the remaining one was hydroxyl group from ^{1}H NMR signal at δ 9.67 and IR absorption at 3460 cm^{-1}. The presence of an asymmetric carbon atom was infered from the nonequivalence of the methyl groups in the two isopropyl groups in the NMR spectra [0.95 (3H, d), 0.97 (3H, d), 1.35 (3H, d), and 1.47 (3H, d)].

Although salvilenone **1** and the hydroxy diketone **20** were produced from the intermediate **19** by treatment with hydrobromic acid, on treating with hydriodic acid the intermediate **19** afforded the hydroxy diketone **20** as the sole product, and heating of **19** with iodine in carbon tetrachloride afforded a methoxyphenalenone **21**.[12] The hydroxy diketone **20** is considered to be produced from methoxyphenalenone **21**; protonation by hydriodic acid (a soft acid) may take place preferably at the isopropenyl terminal of **21** rather than at the carbonyl oxygen. Subsequent hydrolysis affords hydroxy diketone **20**. Salvilenone **1** is assumed to be produced by protonation at the carbonyl oxygen atom of the same intermediate **20** by rather hard acid, hydrobromic acid.

Experimental

Melting points were recorded on a Yamato capillary melting point apparatus. Proton magnetic resonance (^{1}H NMR) spectra were recorded on either a JEOL JNM-PMX60si or a JEOL FX90Q spectrometer or, where specified, on a Bruker AM500 spectrometer with chemical shifts given in parts per million (δ) downfield from tetramethylsilane as an internal standard. Deuteriochloroform was used as solvent unless otherwise noted. Carbon magnetic resonance (^{13}C NMR) spectra were recorded at 22.5 MHz on a JEOL EX90Q instrument. Infrared (IR) spectra were measured on a Hitachi 215 or a JASCO FT/IR-3 spectrophotometer. Mass spectra (MS) were obtained on a Hitachi RMU-6H GC/MS instrument at 70 eV. Elemental analyses were performed by the University of Tsukuba Chemical Analysis Center. Ultraviolet (UV) spectra were recorded on a Hitachi EPS-3T spectrophotometer. Gas chromatography (GLC) data were obtained with a 063 Hitachi gas chromatography (1.7 m/3 mm i.d. glass column packed with 5% SE-30). High-pressure liquid chromatography (HPLC) was carried out with a Waters ALC/GPC 202/401 instrument (1/4 in/1 ft column packed with RP-18). Wako C-300 silica gel was used for flash column chromatography. Merck Kieselgel 60 F_{254} Art 5744 (0.25 mm) and Merck Kiesel gel 60 F_{254} Art 5744 (0.5 mm) were used for analytical and preparative thin-layer chromatography.

1,3-Dimethoxy-2-(1-hydroxy-1-methylethyl)benzene (5). To a solution of resorcinol dimethyl ether **4** (3.2 g, 0.023 mol) in dry tetrahydrofuran, a solution of butyllithium in hexane (1.39 M, 20 ml, 0.028 mol; 1 M=1 mol dm^{-3}) was added dropwise and stirred under an argon atmosphere. After refluxing for 2 h, the solution was chilled to room temperature and a solution of dry acetone (1.6 g, 0.028 mol) in tetrahydrofuran was added dropwise. The mixture was heated under reflux for 3 h, cooled, and poured into ice water followed by extraction with ether. The organic layer was washed with water and then dried over sodium sulfate, evaporated under reduced pressure; distillation afforded a colorless oil **5** (2.9 g, 64%). Bp 120—124 °C/4Torr (1 Torr≈ 133.322 Pa). ^{1}H NMR ($CDCl_3$) δ=1.58 (6H, s, CH_3×2), 3.73 (6H, s, OCH_3×2), 4.95 (1H, brs, OH), 6.3—7.1 (3H, m, AB_2, ArH). Found: C, 67.47; H, 8.18%. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

1,3-Dimethoxy-2-isopropylbenzene (6). A solution of **5** (0.64 g, 3.26 mmol), 3 M hydrochloric acid (0.1 ml), PtO_2 (0.05 g), and glacial acetic acid (20 ml) was stirred under H_2 for 3 h at room temperature. After filtration of the catalyst, the solution was evaporated under reduced pressure, and distillation of the residue afforded a colorless oil **6** (0.58 g, 99%). Bp 70—71 °C/0.5 Torr, IR ($CHCl_3$) 2940, 1580, 1450, and 1360 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.25 (6H, d, J=8 Hz, CH_3×2), 3.60 [1H, sept, J=8 Hz, $(CH_3)_2\underline{CH}$], 3.85 (6H, s, OCH_3×2), and 6.2—7.2 (3H, m, AB_2, ArH). Found: C, 73.32; H, 8.94%. Calcd for $C_{11}H_{16}O_2$: C, 73.29; H, 8.94%.

4-(2,4-Dimethoxy-3-isopropylphenyl)-4-oxobutyric Acid (7). To a solution of **6** (1 g, 5.5 mmol) and succinic anhydride (0.55 g, 5.5 mmol) in dry nitrobenzene (50 ml), cooled in an iced water bath, a powdered anhydrous aluminum chloride (878 mg, 6.6 mmol) was added with stirring under an argon atmosphere. After stirring for 70 h at room temperature, the mixture was poured to ice water containing concentrated hydrochloric acid (10:1 v/v). The mixture was extracted with ether (5×50 ml), from which an acid product was obtained by the usual method as a solid (1.26 g, 82%). The crude product was recrystallized from benzene to give colorless plates, mp 91.5—93 °C; IR ($CHCl_3$) 2950, 1705, 1670, 1580, 1450, 1400, and 1360 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 1.31 (6H, d, J=8 Hz, CH_3×2), 2.72 (2H, t, J=7 Hz, $COCH_2$), 3.26 (2H, t, J=7 Hz, -CH_2COO), 3.51 [1H, sept, J=8Hz, $(CH_3)_2CH$], 3.67 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), 6.60 (1H, d, J=8.5 Hz, ArH), 7.46 (1H, d, J=8.5 Hz, ArH), and 12.65 (1H, s, COOH). Found: C, 64.04, H, 7.15%. Calcd for $C_{15}H_{20}O_5$: C, 64.27, H, 7.19%.

4-(2,4-Dimethoxy-3-isopropylphenyl)butanoic Acid (8). A mixture of acid **7** (0.42 g, 1.5 mmol), 10% Pd/carbon (0.07 g), and perchloric acid (70%, 0.1 ml) in acetic acid (20 ml) was stirred under H_2 at room temperature. After 70 h the solution was filtered. To the filtrate was added NaOAc (0.5 g) and the resulting gray ppt was filtered off. The neutralized filtrate was evaporated under reduced pressure to about 5 ml, water was added and the mixture thoroughly extracted with ether. The organic layer was washed with water and dried over magnesium sulfate. The solvent was evaporated to give yellow oil. Recrystallization from benzene/hexene afforded **8** (0.39 g, 97%) as bright yellow needles, mp 64—65.5 °C; IR (KBr) 2940, 1690, 1590, 1480, 1450, 1405, and 1335 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.34 (6H, d, J=7 Hz, CH_3×2), 1.7—2.8 (6H, m, $CH_2CH_2CH_2COO$), 3.45 [1H, sept, J=7 Hz, $CH(CH_3)_2$], 3.70 (3H, s, OCH_3), 3.79 (3H, s, OCH_3), 6.57 (1H, d, J=8.5 Hz, ArH), 6.96 (1H, d, J=8.5 Hz, ArH), and 10.35 (1H, brs, COOH). Found: C, 67.57; H, 8.30%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.32%.

5,7-Dimethoxy-6-isopropyl-α-tetralone (9). Phosphorus pentaoxide (3.8 g) was added to vigorously stirred phosphoric acid (3.1 g) at a temperature below 60 °C and the resulting mixture stirred for 5 h at 84 °C. A solution of **8** (0.32 g, 1.2 mmol) in dichloromethane (2 ml) was added to the polyphosphoric acid with vigorous stirring at 60—70 °C. After 30 min, the resulting reddish solution was cooled in an ice bath and 20 ml ice-water added. The mixture was extracted with three 30 ml portions of ether. The combined

ethereal extracts were successively washed with water, a 5% $NaHCO_3$ solution, water, and a saturated sodium chloride solution and dried over sodium sulfate. The ethereal solution was concentrated to afford a neutral oil. The oily mixture was distilled under reduced pressure to give **9** (0.28 g. 94%) as a colorless liquid (bp 135 °C/0.4 Torr). IR ($CHCl_3$) 2950, 1662, 1590, 1560, 1445, and 1405 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.32 (6H, d, J=7 Hz, CH_3×2), 1.90—2.93 (6H, m, $COCH_2CH_2CH_2$), 3.62 (1H, sept, J=7 Hz, CH), 3.68 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), and 7.30 (1H, s, ArH). Found: C, 72.56; H, 8.20%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.11%.

5,7-Dimethoxy-6-isopropyl-2-methyl-α-tetralone (10). A solution of magnesium methoxide was prepared from magnesium (0.06 g) and 5 ml of anhydrous methanol. The bulk of the methanol was evaporated from the solution under reduced pressure with stirring at 50—55 °C. The anhydrous *N,N*-dimethylformamide (5 ml) was added. The resulting suspension was stirred vigorously while a stream of anhydrous carbon dioxide was passed into the reaction system. When the suspended magnesium methoxide changed into a clear solution, the flow of carbon dioxide was stopped. A solution of 0.15 g (0.6 mmol) of tetralone **9** in *N,N*-dimethylformamide (5 ml) was added and the reaction mixture refluxed for 2 h. The mixture was cooled to room temperature, and 0.34 g of iodomethane added dropwise. After the mixture was stirred for 10 h at 50 °C, it was poured into 1 M aqueous hydrochloric acid (10 ml) followed by extraction with ether. The combined organic extracts were washed with 5% aqueous $NaHCO_3$, saturated aqueous NaCl, and dried and finally evaporated to give a yellow oil. Distillation of this material gave 0.12 g of methyltetralone **10** as a colorless oil (74% 160 °C/0.3 Torr). IR ($CHCl_3$) 2930, 1665, 1590, 1450, 1410, 1360, and 1310 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.24 (3H, d, J=6.5 Hz, $COCHCH_3$), 1.37 (6H, d, J=7 Hz, CH_3×2), 1.78—3.20 (5H, m, CH_2CH_2CH), 3.51 [1H, sept, J=7 Hz, $(CH_3)_2\underline{CH}$], 3.70 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), and 7.35 (1H, s, ArH). ^{13}C NMR ($CDCl_3$) δ=15.5(q), 20.8(q), 20.8(q), 22.6(t), 26.0(d), 31.3(t), 42.3(d), 55.4(q), 61.1(q), 104.9(d), 130.6(s), 131.5(s), 135.8(s), 155.8(s), 158.1(s), and 200.2(s); MS m/z 262 (M^+), 247 (M^+-CH_3), and 219 ($M^+-C_3H_7$). Found: C, 73.50; H, 8.41%. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%. Further distillation of the residue afforded 0.009 g (5%) of 5,7-dimethoxy-2,2-dimethyl-6-isopropyl-α-tetralone as white needles (182—185 °C/0.3 Torr): ^1H NMR ($CDCl_3$) δ=1.20 (6H, s, CH_3×2), 1.32 (6H, d, J=8 Hz), 1.93 (2H, t, J=6 Hz, CH_2), 2.90 (2H, t, J=6 Hz, CH_2), 3.50 [1H, sept, J=8 Hz, $(CH_3)_2\underline{CH}$], 3.72 (3H, s, OCH_3), 3.83 (3H, s, OCH_3), and 7. 34 (1H, s, ArH); MS m/z 277 (M^++1), 276 (M^+), 261 (M^+-CH_3), and 246 (M^+-2CH_3). Found: C, 73.67; H, 8.89%. Calcd for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75%.

1-(3-Butenyl)-5,7-dimethoxy-6-isopropyl-2-methyl-1,2,3,4-tetrahydro-1-naphthol (11). Magnesium metal shavings (0.24 g) were placed in a flask equipped with a reflux condenser and a dropping funnel. The system was flushed with nitrogen before addition of anhydrous ether (12 ml). The flask was cooled in an ice bath and a small volume of 4-bromo-1-butene was added to the stirred solution. Once the reaction had started, the remainder of the bromide (1 ml) in ether solution (2 ml) was added at below 20 °C. After 3 h the solution was cooled to 0 °C with ice bath, the α-methyl tetralone **10** (1 g, 3.8 mmol) in ether was added dropwise and the mixture was refluxed for 3 h. The reaction mixture was poured into ice cooled ammonium chloride solution and extracted with ether. The combined extracts were dried over anhydrous sodium sulfate. Evaporation of the solvent and flash chromatography of the residue on silica gel with 8:2 hexane/ethyl acetate afforded **11** as a pale yellow oil (1.03 g, 85%). IR ($CHCl_3$) 3580, 2920, 1595, 1565, 1440, 1400, and 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (3H, d, $COHCHCH_3$), 1.42 [6H, d, J=7.5 Hz, $CH(CH_3)_2$], 1.50—2.90 (8H, m, $CH_2CH_2CH_2CH_2$), 3.51 [1H, sept, J=7.5 Hz, $C\underline{H}(CH_3)_2$], 3.71 (3H, s, OCH_3), 3.79 (3H, s, OCH_3), 4.12 (1H, m, $CHCH_3$), 4.81—6.08 (3H, m, CH_2=CH), and 6.91, 7.00 (1H, ArH). Found: C, 75.44; H, 9.52%. Calcd for $C_{20}H_{30}O_3$: C, 75.43; H, 9.49%. Further elution affords 0.15 g of reduced product, 5,7-dimethoxy-6-isopropyl-2-methyl-1,2,3,4-tetrahydro-1-naphthol as colorless needles (8%). IR ($CHCl_3$) 3580, 2920, 1600, and 1565 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (3H, d, $COHCHCH_3$), 1.31 (6H, d, J=7.5 Hz), 1.62 (1H, s, OH), 1.60—3.00 (4H, m, CH_2CH_2), 3.50 [1H, m, J=7.5 Hz $C\underline{H}(CH_3)_2$], 3.70 (3H, s, OCH_3), 3.76 (3H, s, OCH_3), 4.32 (1H, brs, $C\underline{H}OH$), and 6.78 (1H, s, ArH); MS m/z 265 (M^++1), 264 (M^+), 249 (M^+-CH_3), and 246 (M^+-H_2O). Found: C, 72.81; H, 9.32%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%.

1-(3-Butenyl)-5,7-dimethoxy-6-isopropyl-2-methyl-3,4-dihydronaphthalene (12). The alcohol **11** (0.739 g, 2.3 mmol) was added to 50 ml of dry benzene containing *p*-toluenesulfonic acid hydrate (0.24 g, 1 mmol) and calcium chloride (0.2 g). The solution was stirred at room temperature for 30 min. The mixture was filtered and the filtrate was washed with 20% aqueous $NaHSO_3$ and water until neutral, it was then dried over sodium sulfate. The solvent was evaporated under reduced pressure to give **12** as a yellow oil in 95% yield (0.65 g). This material was used directly for the next step without purification. An analytical sample was purified by chromatography: IR ($CHCl_3$) 2920, 1590, 1440, 1400, and 1310 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.31 [6H, d, J=8 Hz, $CH(CH_3)_2$], 1.88 (3H, brs, $=CCH_3$), 1.98—2.82 (8H, m, CH_2CH_2, CH_2CH_2), 3.60 [1H, sept, J=8 Hz, $CH(CH_3)_2$], 3.73 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 4.78—6.10 (3H, m, CH_2=CH), and 6.57 (1H, s, ArH); MS m/z (rel intensity, %) 301(24), 300(M^+, base), 286(9), 285(42), 247(8), 246(34), and 194(66). Found: C, 80.11; H, 9.18%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

1-(3-Butenyl)-5,7-dimethoxy-6-isopropyl-2-methylnaphthalene (13). A mixture of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (1 g, 4 mmol) and **12** (0.65 g, 2.2 mmol) in benzene (40 ml) was stirred for 15 h at room temperature under argon. The resulting solution was filtered through a column of Celite. Evaporation of the solvent afforded **13** as a bright yellow oil (0.6 g, 93%). The oil was used without further purification for the next reaction. The analytical sample was obtained by flash chromatography. IR ($CHCl_3$) 2930, 1615, 1590, and 1120 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.39 [6H, d, J=7.5 Hz, $CH(CH_3)_2$], 2.46 (3H, s , $ArCH_3$), 2.1—3.7 (5H, m, $CHCH_2CH_2$), 3.83 (3H, s, OCH_3), 3.87 (3H, s, OCH_3), 4.86—6.28 (3H, m, CH_2=CH), 6.98 (1H, s, ArH), and 7.06, 7.72 (2H , ABq, J=8 Hz, ArH). MS m/z (rel intensity) 299 (6), 298 (M^+, 23), 245 (18), 244 (base), 214 (4). Found: C, 80.55; H, 8.76%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

3-(5,7-Dimethoxy-6-isopropyl-2-methyl-1-naphthalene)-propionic Acid (14). To a solution of **13** (0.118 g, 0.4 mmol) in 40 ml of dioxane was added a mixed solution made from 0.52 g of KIO_4, 33.5 mg of $KMnO_4$, 16.8 mg of Na_2CO_3 and 20 ml of water. The mixture was stirred for 15 h at room

temperature. The excess reagent was decomposed by the addition of 5% aqueous H_2O_2 under ice cooling and most of the dioxane was evaporated, the residual solution was acidified with concentrated hydrochloric acid and extracted with dichloromethane. The organic layer was extracted three times with 5% sodium hydroxide solution. The combined alkaline extracts were acidified with concentrated hydrochloric acid and extracted thoroughly with ether. The organic layer was washed with water, dried over sodium sulfate, and evaporated to give an oil. Recrystallization from benzene/hexane afforded 0.101 g (80%) of **14** as white needles: mp 160—162 °C; IR (KBr) 3400—3500, 2950, 1700, and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.42 [6H, d, J=7.5 Hz, $CH(CH_3)_2$], 2.47 (3H, s, $ArCH_3$), 2.50—3.54 (4H, m, CH_2CH_2), 3.71 [1H, sept, J=7.5 Hz, $CH(CH_3)_2$], 3.84 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 7.09 (1H, s, ArH), 7.06, 7.73 (2H, ABq, J=8.5 Hz), and 10.23 (1H, brs, COOH). Found: C, 71.91; H, 7.63%; Calcd for $C_{19}H_{24}O_4$: C, 72.12; H, 7.64%.

7,9-Dimethoxy-8-isopropyl-4-methyl-1*H*-phenalen-1-one (16a). To a stirred suspension of phosphorus pentachloride (113 mg, 0.54 mmol) in dry benzene (2 ml), a solution of the propionic acid **14** (150 mg, 0.48 mmol) in benzene was added dropwise at room temperature under argon. When the vigorous reaction subsided, more benzene (2 ml) was added and the mixture warmed to 50—60 °C for 30 min. The clear solution was chilled in an ice bath and a solution of tin(IV) chloride (10 mg) in benzene (1 ml) was added dropwise with stirring while keeping the temperature below 5 °C. After being maintained for 2 h more at 5 °C, the dark solution was decomposed by the slow addition of 1 : 1 (v/v) hydrochloric acid/water (1 ml) while avoiding a rise in temperature above 15 °C. The clear red solution was separated and washed thoroughly with dilute hydrochloric acid, then water. Removal of benzene left a clear mobile oil which after chromatography (hexane/ethyl acetate 3 : 1) gave an oil (97 mg, 68%) of **16a**. IR ($CHCl_3$) 2950, 2850, 1670, 1605, and 1570 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 [6H, d, J=7.5 Hz, $CH(CH_3)_2$], 2.47 (3H, s, $ArCH_3$), 2.77—2.98 (2H, m, J=8 Hz, $ArCH_2$), 3.19—3.38 (2H, m, J=8 Hz, $COCH_2$), 3.68 [1H, sept, J=7.5 Hz, $CH(CH_3)_2$], 3.93 (6H, s, OCH_3×2), and 7.29, 7.86 (2H, ABq, J=8.5 Hz, ArH). MS m/z (rel intensity) 298 (M^+, 91), 284 (23), 283 (base), 281 (35), and 265 (52). Found: C, 76.24; H, 7.44%; Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

1-Ethynyl-7,9-dimethoxy-8-isopropyl-4-methyl-2,3-dihydro-1*H*-phenalen-1-ol (17). To a solution of lithium acetylide-ethylenediamine complex (0.138 g, 1.5 mmol) in anhydrous tetrahydrofuran (30 ml), a solution of **16a** (46 mg, 0.15 mmol) in dry tetrahydrofuran (10 ml) was added with stirring under an argon atmosphere. The reaction mixture was stirred for 18 h at room temperature. The mixture was poured into 5% ammonium chloride solution and extracted with ether. The combined ether extracts were washed with 2% HCl solution and water, dried over $MgSO_4$ and concentrated in vacuo. Purification of the residue by flash silica-gel chromatography gave white crystals **17** (46 mg, 92%). Mp: 123—126 °C; IR(CCl_4) 3480, 3300, 2950, 1600, 1485, 1440, and 1380 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.42 (3H, d, J=8.5 Hz, $CHCH_3$), 1.50 (3H, d, J=8.5 Hz, $CHCH_3$), 2.43 (3H, s, $ArCH_3$), 2.60 (1H, s, C≡CH), 2.00—3.35 (4H, m, CH_2CH_2), 3.50 [1H, m, J=8.5 Hz, $CH(CH_3)_2$], 3.93 (3H, s, OCH_3), 4.05 (3H, s, OCH_3), 6.38 (1H, s, OH), and 7.24, 7.75 (2H, ABq, J=9 Hz). MS m/z (rel intensity) 325 (7), 324 (M^+, 40), 307 (30), 306 (base), and 291 (23). Found: C, 77.93; H, 7.56%. Calcd for $C_{21}H_{24}O_3$: C, 77.75; H, 7.46%.

4-Acetyl-2-isopropyl-3-methoxy-7-methyl-1*H*-phenalen-1-one (18). To a solution of 1.4 ml of water, 0.16 ml of concentrated sulfuric acid and 0.1 ml of methanol, was added 1 mg of mercury(II) sulfate in 1 ml methanol. A solution of **17** (13 mg, 0.04 mmol) in 1 ml of MeOH was added to the solution at 50 °C with rapid stirring. The temperature was maintained at 50—55 °C throughout the reaction. After the reaction was completed (1 h), the reaction mixture was cooled to room temperature, 5 ml of water added and the product extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent followed by chromatography on silica gel with hexane/ethyl acetate (8 : 2) afforded 8.2 mg (68%) of **18** as bright yellow orange needles. Mp: 114—116 °C; ^1H NMR ($CDCl_3$) δ=1.43 [6H, d, J=7 Hz, $CH(CH_3)_2$], 2.52 (3H, s, CH_3CO), 2.82 (3H, J=1 Hz, $ArCH_3$), 3.34 (1H, sept, J=7 Hz), 3.65 (3H, s, OCH_3), 7.33, 8.19 (2H, ABq, J=8.5 Hz), and 7.58, 8.49 (2H, ABq, J=7.7 Hz); MS m/z (rel intensity) 309 (14), 308 (M^+, 60), 294 (21), 293 (base), 279 (10), 278 (11), and 265 (48). Found: C, 77.65, H, 6.79%; Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%.

1-Isopropenyl-8-isopropyl-7,9-dimethoxy-4-methyl-2,3-dihydro-1*H*-phenalen-1-ol (19). A solution of isopropenyllithium in tetrahydrofuran was prepared by addition of butyllithium (0.8 M in hexane, 1 ml) to 2-bromopropene (0.1 ml) in 1 ml of dry tetrahydrofuran at −78 °C under argon followed by stirring for an additional 1 h at −78 °C. A ketone **16a** (85 mg, 0.29 mmol) in 0.5 ml tetrahydrofuran was added slowly to the stirred solution via a syringe. The reaction mixture was stirred for 2.5 h at −78 °C under argon, and the mixture was allowed to warm to 0 °C. Saturated aqueous sodium chloride was added to the reaction mixture, and the phases were separated. The aqueous phase was extracted with three 20 ml portions of ether. The combined organic phases were dried over anhydrous sodium sulfate and concentrated under vacuum to yield the crude product. Flash chromatography of the crude oil on silica gel with hexane/ether (8 : 1) afforded 87 mg (90%) of **19** as a pale yellow oil. IR ($CHCl_3$) 3430 and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.39 (3H, d, J=7.3 Hz), 1.49 (3H, d, J=7.3 Hz), 2.02 (3H, s, CH_3), 2.40 (3H, s, $ArCH_3$), 2.60—3.70 (4H, m, CH_2CH_2), 3.42 [1H, sept, J=7.3 Hz, $CH(CH_3)_2$], 3.77 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 4.89 (2H, brs, CH_2=), and 7.20, 7.76 (2H, ABq, J=8.7 Hz, ArH); ^{13}C NMR ($CDCl_3$) δ=18.5, 20.0, 22.6, 23.2, 24.1, 26.3, 34.1, 62.5, 63.0, 77.8, 114.0, 119.1, 125.5, 128.1, 128.6, 130.5, 131.3, 132.2, 132.8, 151.7, 153.8, 156.5; MS m/z (rel intensity) 340 (M^+, 33), 323 (26), 322 (63), 307 (18), 306 (7), 300 (29), and 299 (base). Found: C, 77.80; H, 8.34%; Calcd for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29%.

9-Isopropyl-2,2,5-trimethylphenaleno[1,9-*bc*]furan-8(2*H*)-one (Salvilenone, 1) and 20. A mixture of alcohol **19** (30 mg, 0.088 mmol), acetic acid (4 ml), and 47% hydrobromic acid (1 ml) was heated under reflux for 48 h. The reaction mixture was evaporated in vacuo, and ether added to the residue. The ethereal solution was washed with 5% sodium carbonate solution and water, and dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure. The residue was separated by preparative TLC (silica gel, was developed twice with 8 : 2 hexane/ethyl acetate) to give **1** (17 mg, 66%) and hydroxy diketone **20** (5.4 mg, 20%). Hydroxy diketone was recrystallized from hexane: mp 134—136 °C; IR 3460, 1712, and 1677 cm^{-1}. ^1H NMR ($CDCl_3$) δ=

0.95 (3H, d, J=6 Hz, $CHCH_3$), 0.97 (3H, d, J=6 Hz), 1.35 (3H, d, J=7 Hz), 1.47 (3H, d, J=7 Hz), 2.34 [1H, sept, J=6 Hz, $CH(CH_3)_2$], 2.80 (3H, s, $ArCH_3$), 4.10 [1H, sept, J=7 Hz, $ArCH(CH_3)_2$], 7.53 (1H, d, J=8 Hz, ABq), 7.79 (1H, d, J=9 Hz, ABq), 8.27 (1H, d, J=9 Hz, ABq), 8.35 (1H, d, J=8 Hz, ABq), and 9.67 (1H, brs, OH). MS m/z 311 (M^++1) 310 (M^+), 292 (M^+−18), and 267 (M^+−43); UV (EtOH): 208 (21080), 238 (44950), 325 nm (8060). ^{13}C NMR (125 MHz, $CDCl_3$) δ= 16.6(q), 17.0(q), 20.2(q), 23.3(q), 24.7(q), 29.3(d), 36.1(d), 101.6(s), 126.0(d), 126.7(s), 126.8(s), 127.2(d), 129.0(d), 129.7(d), 130.3(s), 131.8(s), 142.9(s), 152.8(s), 193.2(s), and 197.7(s). Found: C, 77.20; H, 7.16%; Calcd for $C_{20}H_{22}O_3$: C, 77.39; H, 7.14%.

2-Hydroxy-2,4-diisopropyl-7-methyl-1*H*-phenalene-1,3 (2*H*)-dione (20). A mixture of 7 mg of alcohol **19**, 2 ml of glacial acetic acid, and 1 ml of 50% hydriodic acid solution was heated under reflux for 35 h. The reaction mixture was concentrated in vacuo., and extracted with ether. The ether extracts were filtered through celite until the filtrate became clear. The combined filtrates were washed with 10% $NaHCO_3$ and water, dried, and concentrated. The residue was purified by chromatography on silica gel using hexane/ethyl acetate (7:3) as eluent to give 3.9 mg (59%) of a white solid, which was identical with the hydroxy diketone **20** obtained in the preceding experiment.

4-Isopropenyl-2-isopropyl-3-methoxy-7-methyl-1*H*-phenalen-1-one (21). A mixture of 7 mg (0.02 mmol) of alcohol **19** and iodine in 6 ml of carbon tetrachloride was stirred for 17 h at room temperature. The iodine was decomposed by addition of $Na_2S_2O_3$. After the precipitates were removed, the solution was washed with water, dried over sodium sulfate, and evaporated to give a yellow solid. Purification of the crude product by preparative TLC (hexane/ethyl acetate 6:49) gave 3.4 mg (54%) of **21** as an orange yellow solid. Mp 120—122 °C; ^1H NMR ($CDCl_3$) δ=1.42 [6H, d, J=7 Hz, $CH(CH_3)_2$], 2.01 (3H, s, $CH_3C{=}CH_2$), 2.81 (3H, s, $ArCH_3$), 3.44 [1H, sept, J=7 Hz, $CH(CH_3)_2$], 3.70 (3H, s, OCH_3), 5.1 (2H, m, $CH_3C{=}CH_2$), 7.27 (1H, d, J=9 Hz), 7.63 (1H, d, J=8 Hz), 8.12 (1H, d, J=9 Hz), and 8.48 (1H, d, J=8 Hz). MS m/z 360 (M^+). Found: C, 82.44; H, 7.33%. Calcd for $C_{21}H_{22}O_2$: C, 82.32; H, 7.23%.

Reduction of 2-Carboxy-4′-dimethylaminoazobenzene by *Bacillus* Diaphorase

Chizuko YATOME,* Toshihiko OGAWA, Toshihiko OGAWA, and Hideki HAYASHI
Department of Chemistry, Faculty of Engineering, Gifu University, Yanagido 1-1, Gifu 501-11
(Received September 14, 1988)

2-Carboxy-4′-dimethylaminoazobenzene (CDMAB) was reductively cleaved into its two component primary arylamines by *Bacillus* diaphorase together with NADH (pH 6.1, 25 °C). The reductive cleavage was found to proceed stoichiometrically by a spectrofluorometric assay of fluorescent *o*-aminobenzoic acid and a fluorescent product formed between *N*,*N*-dimethyl-*p*-phenylenediamine and fluorescamine. Parallel lines were obtained in Lineweaver-Burk plots of initial rate vs. CDMAB concentration for the reduction. This experimentally observed kinetic behavior is consistent with a reaction scheme in favor of the Ping Pong mechanism in which CDMAB is reduced by a reduced form of diaphorase. From a kinetic formula, the apparent K_m(CDMAB), K_m(NADH), and V_{max} values are 2.14×10^{-5} mol dm^{-3}, 7.35×10^{-5} mol dm^{-3}, and 1.8×10^{-7} mol dm^{-3} min^{-1} per mg of protein, respectively.

Most azo compounds are reduced into their parent primary arylamines by azoreductase in rat liver microsomes[1] and liver cytosol preparations.[2] Microbial reduction of water-soluble sulfonated azo compounds has been widely investigated, and it has been reported that microbial azoreductase was much more effective than liver microsomal azoreductase for a reduction of azo compounds.[3] However, there are few reports about the microbial reduction of slightly water-soluble and water-insoluble azo compounds.[4] As a part of studies on the microbiological treatment of wastewater containing various azo compounds, it is desirable to investigate on the microbial reduction (both in vivo and in vitro) of slightly water-soluble and water-insoluble azo compounds.

In this paper, the stoichiometry and kinetics of the enzymatic reduction of 2-carboxy-4′-dimethylaminoazobenzene by *Bacillus* diaphorase was followed.

Experimental

Chemicals. *Bacillus* diaphorase and NAD(P)H were purchased from Boehringer Mannheim GmbH and Wako Pure Chemical Industries, Ltd., respectively. These enzyme and chemicals were used without purification. The apparent specific activity of *Bacillus* diaphorase was about 15 units/mg (25 °C; with NADH and 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyltetrazolium chloride; pH 8.8). The prosthetic group of the enzyme was FMN. 2-Carboxy-4′-dimethylaminoazobenzene (CDMAB) was purchased from Nakarai Chemicals Ltd. and recrystallized from ethyl alcohol. The purity was verified by thin-layer chromatography using several systems.

Methods. Reduction of CDMAB by Diaphorase together with NADH: Suitable conditions for the reduction of CDMAB by diaphorase were examined as follows. A reaction mixture containing 0.5 cm^3 of 0.2 mmol dm^{-3} CDMAB aqueous solution, 0.02 cm^3 of 1 mg cm^{-3} diaphorase solution, and 0.5 cm^3 of 0.5 mmol dm^{-3} NADH solution in a final volume of 2 cm^3 of 0.07 mol dm^{-3} potassium phosphate buffer was incubated under an atmosphere of nitrogen in an ampule at a prescribed temperature (10—37 °C) and pH (5.5—7.5). The amount of protein was determeined by the method of Layne.[5] The reaction was terminated by addition of potassium hydroxide (0.1 mol dm^{-3}, 1 cm^3) and the residual CDMAB in the mixture was extracted with butyl alcohol. The disappearance of CDMAB was determined using a spectrophotometric assay based on the decrease in the absorbance of CDMAB at 435 nm (λ_{max} 435 nm in butyl alcohol saturated with water).

The azoreductase activity of diaphorase was determined as follows. A solution containing 19.8 to 72.8 nmol of CDMAB and 20 μg of diaphorase in 1.7 cm^3 of 0.07 mol dm^{-3} potassium phosphate buffer (pH 6.1) was placed in a spectrophotometric Thunberg cuvette. A solution containing 0.24 to 2.4 μmol of NADH in 0.3 cm^3 of 0.07 mol dm^{-3} potassium phosphate buffer was placed in the stopper of the Thunberg cuvette. Two solutions were bubbled independently with nitrogen gas for about 10 min. The reaction was initiated by mixing the two solutions. The mixture was incubated at 25 °C. The activity of diaphorase was determined in a spectrophotometer by recording the decrease in the absorbance of CDMAB at 430 nm (λ_{max} 430 nm in potassium phosphate buffer solution; pH 6.1) for 0—2 min and using the molar absorptivity of CDMAB (21.8 dm^3 mmol^{-1} cm^{-1}).

Assay of Reduction Products of CDMAB by Diaphorase: The products, *o*-aminobenzoic acid (*o*-ABA) and *N*,*N*-dimethyl-*p*-phenylenediamine (DMPA), were determined using a gas chromatographic-mass spectrometric (GC-MS) and a spectrofluorometric assay.

The reaction mixture was similar to that described above. The reaction (3 cm^3, pH 11) was terminated by addition of potassium hydroxide and the mixture was charged into a column of Extrelut 3 (purchased from Merck Co., Inc.) in an atmosphere of nitrogen and in the dark. Hexane (15 cm^3) was passed through the column after 10—15 min. Only one of the products, DMPA, was extracted into the hexane under these conditions with a recovery of about 90%. Then, 25 cm^3 of ether containing 0.1 cm^3 of acetic acid was passed through the column. Unreduced CDMAB was first extracted into the ether. Subsequently, the other product, *o*-ABA, was extracted into the ether with a recovery of about 100%.

The hexane of the extract containing DMPA was slowly removed by aspiration. To the residue (1), ethyl acetate and trifluoroacetic anhydride (TFAA) were added and the mixture was allowed to stand for 5 d at room temperature or for 6

h at 50 °C. Then 0.001 cm^3 was injected onto the GC-MS. On the other hand, the hexane extract containing DMPA was back extracted into 2 cm^3 of sodium acetate buffer (pH 4.0) and the upper hexane layer was carefully removed by aspiration in the dark. Fluorescamine solution (0.2 mg of fluorescamine in 1 cm^3 of acetone, 1 cm^3) was added to the aqueous phase with vigorous mixing. After 30 min, the fluorescence of the product formed between DMPA and fluorescamine was measured at 25 °C in a spectrofluorometer using excitation and emission wavelengths of 400 and 488 nm, respectively. A standard curve of DMPA was prepared by runs of the entire procedure with known amounts of authentic sample passed through the column of Extrelut 3.

The ether extract containing *o*-ABA was dehydrated by adding a few drops of 2,2-dimethoxypropane (DMP), and then the ether was evaporated under reduced pressure. To the residue (2), ethyl acetate and TFAA were added and 0.001 cm^3 was injected onto the GC-MS.[6] On the other hand, to the residue (2), 2 cm^3 of 0.07 mol dm^{-3} potassium phosphate buffer (pH 6.1) was added, and then the fluorescence of *o*-ABA was measured at 25 °C in a spectrofluorometer using excitation and emission wavelengths of 355 and 429 nm, respectively. A standard curve of *o*-ABA was prepared from the authentic sample subjected to the entire procedure.

Apparatus and Conditions: Visible spectra: a Hitachi Spectrophotometer Model 330 was used. Fluorescent spectra: a Hitachi Spectrofluorometer Model 650-10 was used. GC-MS: a Hitachi Mass Spectrometer Model M-52 was used; a 1 m×3 mm glass column was packed with Silicone OV-17 (2%) on Chromosorb WAW DMCS (80—100 mesh); samples were 0.001 cm^3. Operational conditions: column temperature 110—140 °C; carrier gas He; chamber voltage 20 eV.

Results and Discussion

Conditions for the Reduction of CDMAB by Diaphorase. The azoreductase activity of diaphorase was investigated using either NADH or NADPH as electron donor. Through the investigation it has been proved that the activity is supported favorably by NADH. Suitable conditions for the reduction of CDMAB by diaphorase together with NADH are as follows: (1) the optimum pH is 6.1; (2) the optimum temperature is 25 °C. The representative result is shown in Fig. 1.

Stoichiometry of the Reduction of CDMAB by Diaphorase together with NADH under Anaerobic Conditions. The stoichiometry of the reduction of CDMAB by diaphorase together with NADH was determined using a spectral assay based on the decrease in concentration of CDMAB and a spectrofluorometric assay based on the increase in amount of reduction products.

The magnitude of spectral change at 430 nm was initially proportional to the amount of NADH added. After addition of 250, 500, or 750 nmol of NADH to a solution containing 250 nmol of CDMAB, the spectral change (ΔA_{430}) was 0.17, 0.34, or 0.35, respectively. These results indicate that the reduction of 1 mol of CDMAB requires 2 mol of NADH under anaerobic conditions as reported by Huang et al.[2]

Reduction products were detected by GC-MS. The products were found having the same m/z (rel intensity) 215 (M^+; 26) and 146(100) with the TFA derivative of authentic *o*-ABA and the same m/z (rel intensity) 328 (M^+; 47), 231(45), and 162(100) with the TFA derivative of authentic DMPA. It has been confirmed from these results that CDMAB is reduced by diaphorase together with NADH to form two primary arylamines, *o*-ABA and DMPA.

The products, *o*-ABA and DMPA, in the reaction mixture could be simultaneously determined by spectrofluorometry since a satisfactory separation of the

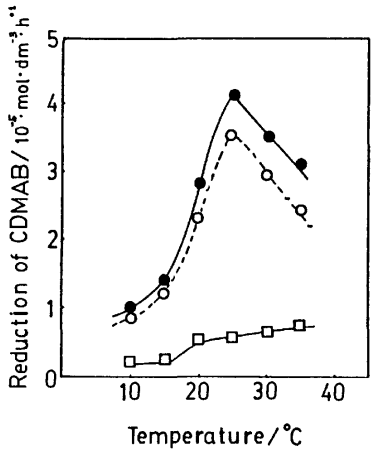

Fig. 1. Effect of temperature on reduction of CDMAB (5×10^{-5} mol dm^{-3}) by NADH (1.25×10^{-4} mol dm^{-3}) in the presence of diaphorase (10 $\mu g\,cm^{-3}$).

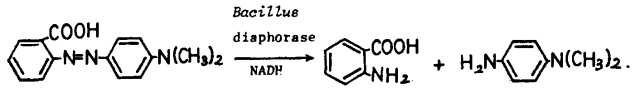
products was achieved using the column of Extrelut. The result is shown in Fig. 2. The expected stoichiometry for the reduction of the azo linkage of CDMAB by diaphorase together with NADH has been demonstrated. The reaction was completed within 120 min under the conditions adopted. Consequently these results indicate that *Bacillus* diaphorase consumes 2 mol of NADH as electron donor when 1 mol of CDMAB is reduced to *o*-ABA and DMPA under the present experimental conditions. The reduction of CDMAB by diaphorase is summarized as follows:



CDMAB *o*-ABA DMPA

Hydrazo intermediates are presumably formed in the reduction of azo compounds.[1,7] While CDMAB can be reduced to the hydrazo intermediate with sodium sulfite, at pH 5—8 CDMAB is known to be reduced to the amines via a four-electron reaction by electrode reaction.[8] The hydrazo intermediate was not detected in the present experiment.

Kinetic Studies. Under the conditions minimizing the non-enzymatic reduction (the non-enzymatic reaction was made not to occur during 2 min), the amounts of diaphorase used were selected so that the reaction rate was significant but small enough to remain linear for at least 2 to 3 min. Initial slopes of recorder tracings were taken as initial rates. Parallel lines were obtained in the Lineweaver-Burk plot of initial rate vs. CDMAB concentration at fixed enzyme and various NADH concentrations, as shown in Fig. 3. The result can be explained by the Ping Pong mechanism; Alberty,[9] suggested two kinds of mechanisms, Sequential and Ping Pong, as a result of inspection of double reciprocal plots of initial rate vs. substrate concentration (Lineweaver -Burk plot). In theory, lines in Lineweaver-Burk plots for the Ping Pong mechanism are parallel in contrast with the Sequential mechanism which exhibits converging lines. The feature of the Ping Pong mechanism is that the enzyme reacts with one of the substrates to form a complex, which in turn breaks down to yield a modified enzyme with dissociation of the product before the second substrate binds the enzyme. On the basis of the stoichiometry of reduction of CDMAB previously described, the result can therefore be summarized as the following reaction scheme, where E is the enzyme, diaphorase, and Eox and Ered are the oxidized and reduced forms of the enzyme, respectively:

$$\mathrm{Eox} + 2\mathrm{NADH} + 2\mathrm{H^+} \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} \mathrm{Eox\text{-}(NADH)_2\text{-}(H^+)_2},$$

$$\mathrm{Eox\text{-}(NADH)_2\text{-}(H^+)_2} \underset{k_{-2}}{\overset{k_{+2}}{\rightleftharpoons}} \mathrm{Ered} + 2\mathrm{NAD^+},$$

$$\mathrm{Ered} + \mathrm{CDMAB} \underset{k_{-3}}{\overset{k_{+3}}{\rightleftharpoons}} \mathrm{Ered\text{-}CDMAB},$$

$$\mathrm{Ered\text{-}CDMAB} \underset{k_{-4}}{\overset{k_{+4}}{\rightleftharpoons}} \mathrm{Eox} + \mathrm{DMPA} + o\text{-}\mathrm{ABA},$$

Eox: E-$(FMN)_2$, Ered: E-$(FMNH_2)_2$.

This mechanism leads to the following expression as for the Bi Bi Uni Uni Ping Pong mechanism using Cleland's nomenclature,[10] in which the initial reaction rate in a steady-state treatment depends on the square of the concentration, $[NADH]^2$, in the form[11,12]

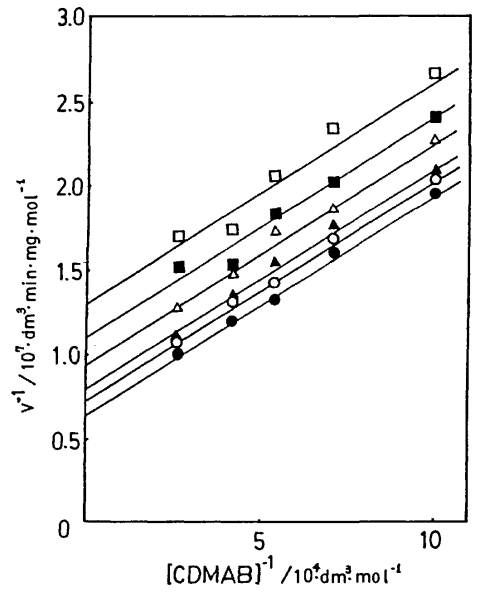


Fig. 3. Relationship between reciprocal intial reaction rate and reciprocal concentration of CDMAB (Lineweaver-Burk plots).
Concentration of diaphorase; 10 $\mu g\,cm^{-3}$. Concentration of NADH ($\times 10^{-5}$ mol dm^{-3}). —●— 120, —○— 60, —▲— 30, —△— 24, —■— 18, —□— 12.
The reaction mixture containing CDMAB, NADH and diaphorase was incubated under anaerobic conditions in a spectrophotometric Thunberg cuvette at 25°C, pH 6.1.

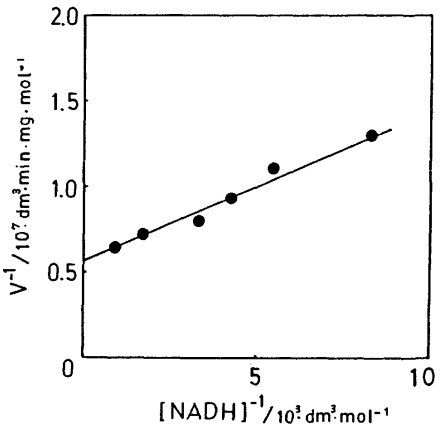

Fig. 4. Relationship between intercepts on the ordinate of Fig. 3 and reciprocal of concentration of NADH (Lineweaver-Burk plots).

$$\frac{V}{v} = 1 + \frac{K_m(\text{coen.})\,K'_m(\text{coen.})}{[\text{coen.}]^2} + \frac{2K_m(\text{coen.})}{[\text{coen.}]} + \frac{K_m(\text{dye})}{[\text{dye}]} \quad (1)$$

where

coen.: NADH, dye: CDMAB,

$$V = \frac{k'_{+2}\,k_{+2}\,k_{+4}}{k'_{+2}\,k_{+2} + k'_{+2}\,k_{+4} + k_{+2}\,k_{+4}}\,E_0\,,$$

$$K_m(\text{dye}) = \frac{k'_{+2}\,k_{+2}(k_{-3} + k_{+4})}{k_{+3}(k'_{+2}\,k_{+2} + k'_{+2}\,k_{+4} + k_{+2}\,k_{+4})}\,,$$

$$K_m(\text{coen.}) = \frac{k_{+2}\,k_{+4}(k_{-1} + k'_{+2})}{k_{+1}(k'_{+2}\,k_{+2} + k'_{+2}\,k_{+4} + k_{+2}\,k_{+4})}\,,$$

$$K'_m(\text{coen.}) = \frac{k'_{-1}}{k'_{+1}}\,.$$

The square term in Eq. 1 becomes negligible, provided [NADH] $\gg K_m$(NADH) or K'_m(NADH). Equation 1 may be rearranged to

$$\frac{V}{v} = 1 + \frac{2K_m(\text{coen.})}{[\text{coen.}]} + \frac{K_m(\text{dye})}{[\text{dye}]}\,. \quad (2)$$

Equation 2 predicts that a plot of v^{-1} vs. $[\text{NADH}]^{-1}$ will be linear. [NADH] under the present experimental conditions was varied in the range $12-120\times10^{-5}$ mol dm^{-3}. These conditions are higher than the tentative K_m(NADH) value, 7×10^{-5} mol dm^{-3}. In Fig. 4 data are presented to show that a secondary plot of the intercepts of the Lineweaver-Burk plots of Fig. 3 vs. NADH concentration gives a straight line. Equations 1 and 2 are in good agreement with the data in Figs. 3 and 4. Thus the experimental data suggest the correctness of the above reaction scheme that in the sequence of substrate binding and product release, CDMAB is reduced by a reduced form of the enzyme.

Dehydrooligopeptides. XI. Facile Syntheses of Various Kinds of Dehydrodi- and tripeptides, and Dehydroenkephalins Containing ⊿Tyr Residue by Using *N*-Carboxydehydrotyrosine Anhydride[1)]

Chung-gi SHIN,* Takumi OBARA, Shuji TANIGUCHI, and Yasuchika YONEZAWA
Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received September 17, 1988)

Several kinds of *N*-free and protected *N*-carboxydehydrotyrosine anhydride (⊿Tyr·NCA) derivatives, derived by both the cyclization of the corresponding *N*-benzyloxycarbonyldehydrotyrosine derivatives and the protection of the resulting ⊿NCA, were employed for a one-pot dehydrooligopeptide (DHP) synthesis. As a result, various kinds of DHPs with a wide variety of combinations of sequences could be synthesized in fairly good yields. In addition, by utilizing the obtained information, two kinds of leucine-dehydroenkephalins containing a ⊿Tyr[1] and both ⊿Tyr[1] and ⊿Phe[4] residues were also synthesized.

In a previous paper,[2)] we reported in detail the syntheses of various kinds of *N*,*O*-diprotected dehydrotyrosine (⊿Tyr) derivatives from mainly two routes. That is to say, the ⊿Tyr derivatives were derived by the condensation of *O*-protected *p*-hydroxybenzaldehyde with *N*-acyl-2-(diethoxyphosphinyl) glycine[3)] and by the reaction of *N*-carboxydehydrotyrosine anhydride (⊿Tyr·NCA), derived by the cyclization of *N*-benzyloxycarbonyl (Cbz)-dehydrotyrosine with $SOCl_2$, with methanol. On the other hand, recently, various modes of coupling of *N*-carboxy-α-dehydroamino acid anhydride (⊿NCA) with an amino (*N*-), carboxy (*C*-) or both two components of AA were carried out to give a number of dehydrooligopeptides (DHP) in fairly good yields.[4,5)] However, there has only been a few reports concerning a useful synthetic method for DHP containing a ⊿Tyr residue,[6)] although the hydrogenated one, namely L-tyrosine (Tyr) residue, is often an important bioactive site in opioid peptides, such as cholecystokinin-8.[7)]

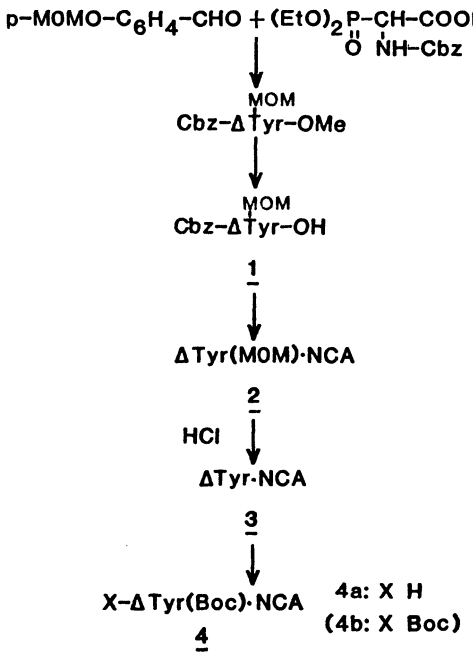
In this paper we wish to report on convenient syntheses of various kinds of DHP containing (*Z*)-configurational ⊿Tyr residues blocked with available *N*- and *O*-protecting groups, such as Cbz, *t*-butoxycarbonyl (Boc), and methoxymethyl (MOM), by the so-called ⊿NCA method.[4,8–10)]

Moreover, in order to chemically modify naturally occurring peptides, leucine-enkephalin (Leu-Enk), as one of the numerous neuropeptides, was chosen and Tyr[1] or both Tyr[1] and phenylalanine (Phe[4]) residues were replaced by the corresponding ⊿Tyr and dehydrophenylalanine (⊿Phe) to obtain Δ^1 and $\Delta^{1,4}$-dehydroenkephalin derivatives (Δ^1Enk and $\Delta^{1,4}$Enk).[11)]

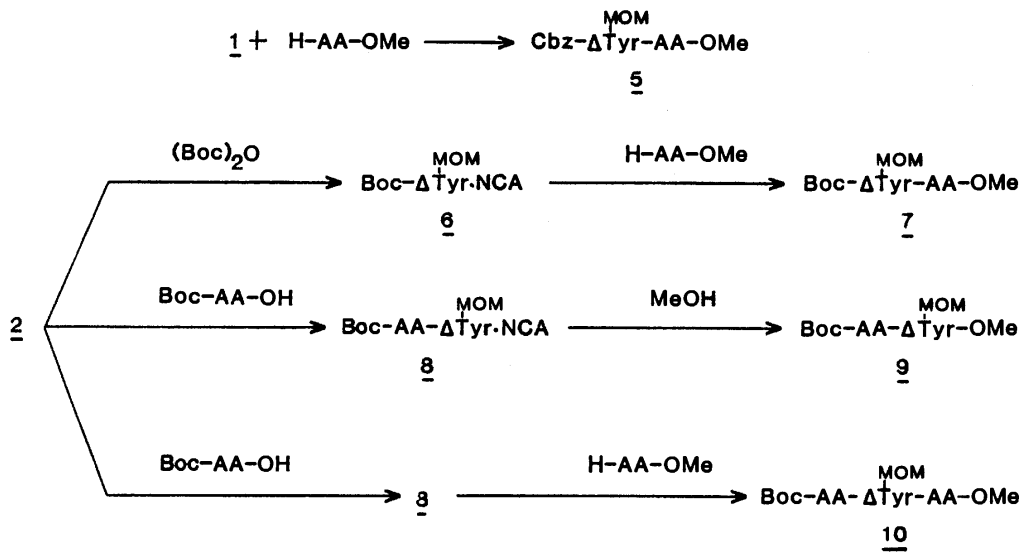
Results and Discussion

Syntheses of Dehydrodi- and tripeptides with ⊿Tyr Residue. We have already reported on the synthesis of (*Z*)-Cbz-(*O*-MOM)dehydrotyrosine [Cbz-⊿Tyr (MOM)-OH] (**1**), derived successively by the condensation of *p*-methoxymethoxy (MOMO) benzaldehyde with *N*-Cbz-2-(diethoxyphosphinyl)glycine methyl ester by the Schmidt method[3)] and the ester hydrolysis of (*Z*)-Cbz-⊿Tyr(MOM)-OMe. Futhermore, the facile conversion of **1** with $SOCl_2$ to (*Z*)-*N*-carboxy-(*O*-MOM)dehydrotyrosine anhydride [⊿Tyr(MOM)·NCA] (**2**) and subsequent deprotection with HCl to ⊿Tyr·NCA (**3**) was also reported[2)] (see Scheme 1).

In addition to the two compounds mentioned above (**2** and **3**), two more starting substrates were synthesized as follows. (*Z*)-*N*-Carboxy-(*O*-Boc)dehydrotyrosine anhydride [⊿Tyr(Boc)·NCA] (**4a**) was purely obtained in 70% yield by the selective acylation of a phenolic hydroxyl group alone of **3** with an equimolar di-*t*-butyl dicarbonate [$((CH_3)_3COCO)_2O$; $(Boc)_2O$] by the usual method.[2)] Moreover, a similar treatment of **3** with more than two moles of $(Boc)_2O$ was carried out to give (*Z*)-*N*-carboxy-*N*-Boc-(*O*-Boc)dehydrotyrosine anhydride [Boc-⊿Tyr(Boc)·NCA] (**4b**) as an unstable



Scheme 1.



Scheme 2.

intermediate, although a pure isolation was unsuccessful. From the above results, in the case of the acylation of **3**, it can be seen that the side-chain phenolic hydroxyl group was more reactive than the ring imino group.

The four (*Z*)-*⊿*Tyr·NCA derivatives (**2**, **3**, **4a**, and **4b**) were subsequently subjected to the syntheses of numerous dehydrodi- and tripeptides by wide variety of combinations of appropriate AA and variously protected *⊿*Tyr residues, as illustrated in Schemes 2 and 3. Three more *N*-acyl-*⊿*Tyr·NCA intermediates were synthesized and then employed in situ to the synthesis of dehydrooligopeptides.

First, the stepwise elongation of **1** with L-*α*-amino acid methyl ester (H-AA-OMe) by using water-soluble [3-(dimethylamino)propyl]ethylcarbodiimide [C_2H_5-N=C=N-$(CH_2)_3$-N$(CH_3)_2$·HCl; WSC] was readily carried out to give Cbz-*⊿*Tyr(MOM)-AA-OMe (**5**) in a 75% yield.

On the other hand, by taking advantage of two highly reactive sites of compound **2**, three sorts of *⊿*^{1},*⊿*^{2}-dehydrotripeptides (**7** and **9**) and *⊿*^{2}-dehydrotripeptides (**10**)[11] containing a *⊿*Tyr(MOM) residue at N, C-termini and at the center could be readily synthesized.[11] In the case of the synthesis of Boc-*⊿*Tyr(MOM)-AA-OMe (**7**), the acylation of **2** with $(Boc)_2O$ was carried out as the first step to form the corresponding intermediate, *N*-Boc-(*O*-MOM)-dehydrotyrosine anhydride [Boc-*⊿*Tyr(MOM)·NCA] (**6**), which was subsequently treated in situ with H-AA-OMe as an *N*-component to give **7** in 56% yield.

Similarly, a one-pot synthesis of *⊿*^{2}-dehydrodipeptides (**9**) containing C-terminal *⊿*Tyr(MOM) residue was also worked up by the following successive reactions. The coupling of **2** with Boc-AA-OH as a *C*-component in the presence of pyridine by the dicyclohexylcarbodiimide (DCC) method and a subsequent reaction of the resulting intermediate Boc-AA-*⊿* Tyr(MOM)·NCA (**8**) with methanol were carried out to give Boc-AA-*⊿*Tyr(MOM)-OMe (**9**) in 71% yield. Consequently, as can be seen by a comparison with the structures of two compounds, **7** and **9**, they are apparently related to each other as a regioisomer.

Furthermore, in an analogous manner (as mentioned above), *⊿*^{2}-dehydrotripeptides (**10**) containing *⊿*Tyr(MOM) residue at the center were also readily synthesized in one-pot by the condensation of **2** with, in turn, Boc-AA-OH and H-AA-OMe. In this case too,

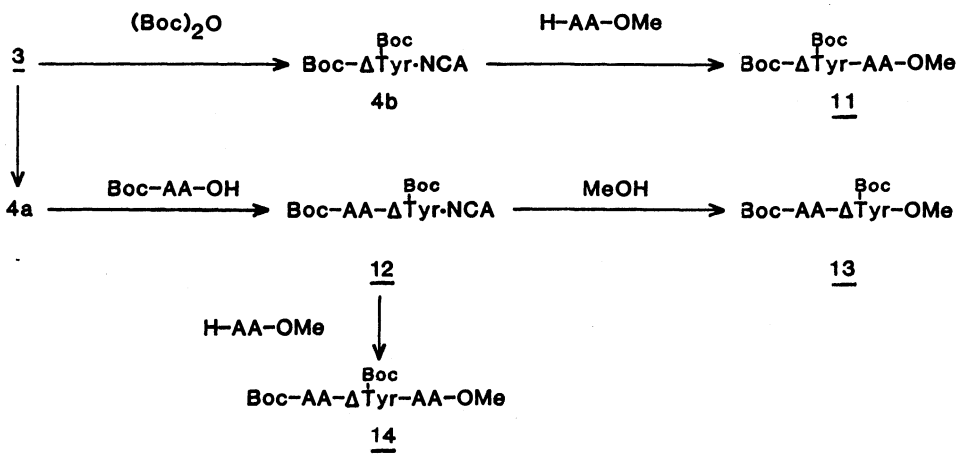

Scheme 3.

after forming the intermediate **8** in the first place, *N*-component subsequently coupled with the resulting **8** to give the expected Boc-AA-⊿Tyr(MOM)-AA-OMe (**10**) in 76% yield. As summarized in Tables 3 and 5, the yields of **7**, **9**, and **10**, thus obtained, were found to attain to 68%.

From the above results, these three synthetic procedures were further ascertained to be appreciably efficient for the synthesis of the diversified and complicating peptides containing polyfunctional α-dehydroamino and/or amino acid residues.

On the other hand, in order to obtain similar dehy-

dropeptides blocked with the same protecting group to the amino and side-chain hydroxyl groups, *N*- and *O*-unsubstituted *N*-carboxydehydrotyrosine anhydride (**3**) was successively acylated with more than two moles of $(Boc)_2O$ and coupled with H-AA-OMe in one-pot to give the desired Δ^1-dehydrodipeptide [Boc-ΔTyr-(Boc)-AA-OMe] (**11**) in 58% yield. In this case too, it is almost certain to initially form Boc-ΔTyr(Boc)·NCA (**4b**) (as mentioned earlier) and then to couple with *N*-component.

In addition, for the purpose of the stepwise elongation of the N- and both N- and C-terminal ΔTyr(Boc) moiety, compound **4a** was subjected to the *N*-acylation with *C*-component, followed by the coupling with *N*-component α-amino acid. In a similar manner as in the case of **2**, the acylation of **4a** with an appropriate Boc-AA-OH took place to yield an intermediate regarded as *N*-carboxy-*N*-Boc-acyl-(*O*-Boc)dehydrotyrosine anhydride [Boc-AA-ΔTyr(Boc)·NCA] (**12**), which was immediately reacted with methanol to give Δ^2-dehydrodipeptide [Boc-AA-ΔTyr(Boc)-OMe] (**13**) in 57% yield. Similarly, according to Scheme 3, **12** was

a) Proton on α-carbon of L-α-amino acid residues.

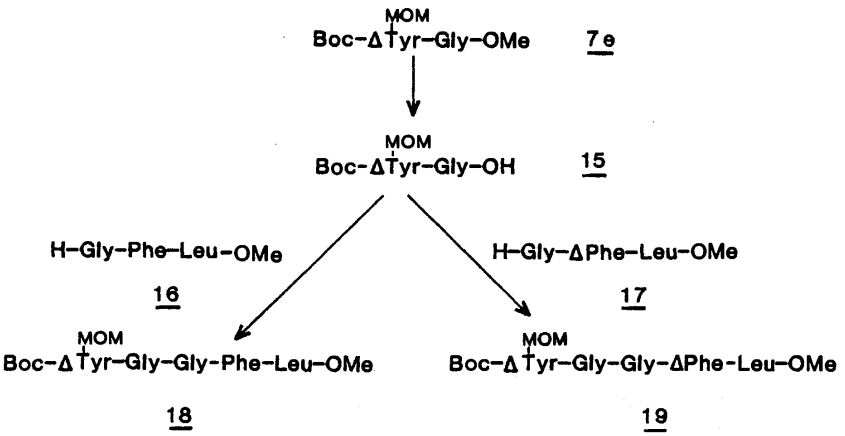
ary amide and carbon-carbon double bond functions appear at 1525—1510 and 1705—1605, and 1650—1620 cm^{-1} regions, respectively. Furthermore, in the ^{1}H NMR spectra, all of the olefin protons of the obtained DHPs shift at the δ 7.40—6.60 region as a singlet. Particularly, based on the chemical shifts of olefin protons, the configurations of the obtained Δ NCA and DHP could be tentatively confirmed to be (Z)-geometry, since the chemical shifts appeared at comparatively higher magnetic fields and the spectral patterns were quite similar to those of DHPs containing (Z)-α-dehydroamino acid (DHA) residues.[5]

From the above results and facts reported previously,[2,12] the selective protection of a hydroxyl group out of two functional groups (OH and NH) of ΔTyr·NCA was found to become feasible. Accordingly, in the case of obtaining various DHPs with a polyfunctional DHA residue as well as DHPs containing a ΔTyr residue protected by different protecting groups, the method developed here must be very effectively utilized. In addition, if α-amino acid and oligopeptide used as both the N- and C-components or segments are variously altered, even in the coupling of compound **2**, which is only one out of ΔTyr·NCAs, the further diversified types of DHP will be afforded. In fact, the various combinations of N- and C-components or moiety protected with the useful N- and O-protecting groups were already carried out to give the further wide variety of DHPs.[13]

Syntheses of Dehydroenkephalins. By utilizing the important N-terminal ΔTyr-Gly moiety, which was derived from Boc-ΔTyr(MOM)·NCA (**6**) and H-Gly-OMe by the ΔNCA method, the syntheses of two kinds of ΔEnk, e.g., Δ^1Enk and $\Delta^{1,4}$Enk, were tried, according to Scheme 4.

First of all, after an ester hydrolysis of the obtained Boc-ΔTyr (MOM)-Gly-OMe (**7e**) with 2 M LiOH, the resulting Boc-ΔTyr(MOM)-Gly-OH (**15**) was then coupled with H-Gly-L-Phe-L-Leu-OMe by the usual DCC method to give the expected Boc-ΔTyr (MOM)-Gly-Gly-Phe-Leu-OMe (**18**) in 45% yield. On the other hand, after preparation of Boc-Gly-(Z)-ΔPhe-L-Leu-OMe, derived by the one-pot reaction of N-carboxy dehydrophenylalanine anhydride (ΔPhe·NCA)[10] with in turn Boc-Gly-OH as an N-component and H-L-Leu-OMe as a C-component, and then conversion to H-Gly-(Z)-ΔPhe-L-Leu-OMe (**17**) by the N-deprotection with 4.5 M HCl, the fragment condensation of **15** with **17** was similarly worked up to give Boc-ΔTyr(MOM)-Gly-Gly-(Z)-ΔPhe-L-Leu-OMe (**19**) in 48% yield, according to Scheme 4.

In the ^{1}H NMR spectra of **18** and **19**, it was found that only the olefin protons of ΔTyr and ΔPhe residues could not be clearly assigned because of the overlap



Scheme 4.

with the signals of aromatic ring and NH protons in the δ 7.34—6.86 region. At least, however, the appearance of a carbon-carbon double bond at about 1630 cm^{-1} in the IR spectra and the satisfactory elemental analyses indicated the formation of **18** and **19**.

Subsequently, in order to deprotect the protecting groups of the N-terminal ⊿Tyr residue, treatment of **18** with 2 M HCl/acetic acid in THF was carried out at room temperature for 1 h. After concentrating the reaction solution under reduced pressure, the obtained crude crystalline residue was gradually changed into a syrup during purification by the usual procedure to give *p*-hydroxyphenylpyruvoylpeptide. Unfortunately, an attempt to isolate the protecting group-free ⊿[1]Enk was unsuccessful. An enthusiastic deprotection of **18** and **19** is now under way.

In conclusion, the one-pot reactions of ⊿Tyr·NCA protected with various combination of *N*- and *O*-protecting groups were performed very smoothly. More interestingly, due to the considerable stability and reactivity of ⊿NCA, it is firmly believed that not only stepwise elongation and fragment condensation but also ring-opening polymerization to poly(α-dehydroamino acid) would be possible and diversify further the field of DHP chemistry.

Experimental

General. Melting points were determined with a Yamato micro melting-point apparatus model (MP-21) and were uncorrected. The IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. The ^1H NMR spectra were measured with a JEOL JMN PS-100 spectrometer in a $CDCl_3$ solution with tetramethylsilane as the internal standard. The specific rotations were measured in a 0.5-dm tube using a JASCO DIP-4 polarimeter (Japan Spectroscopic Co., Ltd.).

⊿Tyr(Boc)·NCA (4a) and Boc-⊿Tyr(Boc)·NCA (4b). A solution of **3** (0.50 g, 2.43 mmol) and $(Boc)_2O$ (0.53 g, 2.43 mmol) in the presence of pyridine (0.2 ml) in THF (2 ml) was stirred at room temperature for 5 h. After removing the solvent under reduced pressure, the residual syrup was crystallized by adding a small amount of hexane. The crude crystals were collected and then recrystallized from benzene to give **4a** as pale-yellow needles. Yield 70%, mp 167—170 °C (decompd). IR ν_{max}^{KBr} (cm^{-1}) 3280 (NH), 1830, 1780, (CO-O-CO), 1665 (C=C); ^1H NMR ($CDCl_3$) δ=11.48 (bs, 1H, NH), 7.40 (dd, 4H, *J*=9.0, 46.0 Hz, C_6H_4), 6.64 (s, 1H, -CH=), 1.48 [s, 9H, $-C(CH_3)_3$]. Found: C, 59.29; H, 5.07; N, 4.64%. Calcd for $C_{15}H_{15}NO_6$: C, 59.01; H, 4.95; N, 4.59%.

In a similar manner, the treatment of **3** with two molar $(Boc)_2O$ was worked up to give **4b**, which was immediately utilized to the next reaction, without isolation.

Cbz-⊿Tyr(MOM)-AA-OMe (5). A solution of an appropriate H-AA-OH·HCl (2.0 mmol) in dry CH_2Cl_2 (10 ml) in the presence of triethylamine (TEA) (0.2 ml, 2.0 mmol) was stirred at −10 °C for 30 min. To the solution, thus prepared, was added **1** (0.6 g, 1.50 mmol) and WSC (0.3 g, 1.56 mmol), and then the resulting solution was further stirred at −10 °C for 1 h. After stirring continuously at room temperature for 8 h, the reaction solution was concentrated under reduced pressure. The residual substance was dissolved in ethyl acetate (30 ml) and the resultant solution was washed successively with water, 10% citric acid, water, saturated $NaHCO_3$ aqueous solution, and then water, and finally dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the crystalline residue, thus obtained, was recrystallized from a mixture of ethyl acetate and hexane to give **5** as colorless needles. See Tables 1 and 2.

Boc-⊿Tyr(MOM)-AA-OMe (7). A solution of **2** (1.25 g, 5.0 mmol) and $(Boc)_2O$ (1.31 g, 6.0 mmol) in dry THF (10 ml) in the presence of pyridine (50 μl) was stirred at room temperature for 8 h. With stirring, to the solution, thus prepared, was added a solution of an appropriate H-AA-OMe·HCl (7.0 mmol) and TEA (0.7 ml, 7.0 mmol) in dry THF (10 ml). To the resulting solution was added *N*-methylmorpholine (NMM) (0.76 ml, 7 mmol) and then stirred continuously at room temperature for 2 h. After removing the solvent under reduced pressure, the residual syrup was dissolved in ethyl acetate (30 ml); the resultant solution was washed successively with chilled 10% citric acid, water, saturated $NaHCO_3$ aqueous solution, and then water, and finally dried over anhydrous Na_2SO_4. The concentration of the solution under reduced pressure gave a residual crude syrup, which was purified on a silica-gel column using a mixture of benzene and acetone (15:1 v/v) as an eluent to give **7** as colorless syrup. See Tables 3 and 4.

Boc-AA-⊿Tyr(MOM)-OMe (9). A solution of an appropriate Boc-AA-OH (6.0 mmol) and DCC (1.24 g, 5.0 mmol) in dry THF (10 ml) was stirred at −10 °C for 20 min; to the solution prepared was added **2** (1.25 g, 5.0 mmol) and pyridine (0.4 g, 5.0 mmol). After stirring at −10 °C for 2 h, the resulting solution was returned slowly to room temperature and then stirred continuously for 12 h. Finally, after treating further with MeOH (15 ml) and stirring for 2 h, to the reaction solution was added NMM (1.1 ml, 10 mmol). After removing THF and MeOH under reduced pressure, the residue was dissolved in ethyl acetate (10 ml); the *N,N'*-dicyclohexylurea separated out was then filtered off. The filtrate was diluted in ethyl acetate (20 ml) and the resultant solution was washed successively with 10% citric acid, saturated $NaHCO_3$ aqueous solution, water and then dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the crude residue was purified on a silica-gel column using a mixture of benzene and acetone (15:1 v/v) as an eluent. The main fraction was concentrated under reduced pressure to give a viscous syrup, which was crystallized with petroleum ether. Recrystallization from a mixture of ethyl acetate and hexane gave **9** as colorless needles. See Tables 3 and 4.

Boc-AA-⊿Tyr(MOM)-AA-OMe (10). To a solution of an appropriate Boc-AA-OH (6.0 mmol) in dry THF (10 ml) was added DCC (1.24 g, 6.0 mmol) at −10 °C and, after stirring for 20 min, further added **2** (1.25 g, 5.0 mmol) and pyridine (0.4 g, 5.0 mmol). After stirring continuously for 2 h, the resultant solution was returned slowly to room temperature and then stirred for 12 h. To the reaction solution was added a solution of another appropriate H-AA-OMe·HCl (7.0 mmol) and TEA (0.7 ml, 7.0 mmol) in THF (10 ml); the resulting solution was then treated with NMM (0.76 ml, 7 mmol). After stirring for 2 h, and then removing the solvent under reduced pressure, the residue was dissolved in chilled ethyl acetate (10 ml) and the *N,N'*-dicyclohexylurea separated out was filtered off. The filtrate was similarly worked up to give a crude syrup, which was purified on a

silica-gel column using a mixture of $CHCl_3$ and acetone (15:1 v/v) to give a viscous syrup. After being crystallized with petroleum ether, the formed crystals were collected and then recrystallized from a mixture of ethyl acetate and hexane to give **10** as colorless needles. See Tables 5 and 6.

Boc-⊿Tyr(Boc)-AA-OMe (11). A solution of **3** (1.0 g, 5.0 mmol) and $(Boc)_2O$ (3.27 g, 15.0 mmol) in THF (10 ml) in the presence of pyridine (5.0 ml) was stirred at room temperature for 8 h. To the resulting solution was added a solution of an appropriate H-AA-OMe·HCl (10.0 mmol) and TEA (1.0 g, 10.0 mmol) in THF (10 ml). After stirring at room temperature for 4 h, as in the case of the synthesis of **7**, the reaction solution was similarly worked up to give **11** as a colorless syrup or crystals. See Tables 7 and 8.

Boc-AA-⊿Tyr(Boc)-OMe (13). A solution of **3** (1.0 g, 5.0 mmol) and $(Boc)_2O$ (1.1 g, 5.0 mmol) in THF (10 ml) in the presence of pyridine (5.0 ml) was stirred until the spot of **3** disappeared on thin-layer chromatography. To the reaction solution, which was chilled to −10 °C, was added successively Boc-AA-OH (5.0 mmol), DCC (5.0 mmol) and pyridine (0.4 g, 5.0 mmol) and then stirred continuously for 1 h. The resulting solution of the intermediate (**12**) was returned to room temperature and stirred continuously for 12 h. Finally, as in the case of the synthesis of **9**, the reaction solution was treated with MeOH (10 ml) and then similarly worked up to give **13** as a colorless syrup or crystals. See Tables 7 and 8.

Boc-AA-⊿Tyr(Boc)-AA-OMe (14). In a similar manner, a solution of the intermediate (**12**) in THF (10 ml) was prepared. Finally, as in the case of the synthesis of **10**, the resulting solution was further treated with H-AA-OMe; then the reaction solution was similarly worked up to give **14** as a colorless syrup or crystals. See Tables 9 and 10.

Boc-⊿Tyr(MOM)-Gly-OH (15). To a solution of **7e** (5.0 g, 12.7 mmol) in THF (20 ml) was added 1 M LiOH (17.8 ml) drop by drop, with stirring, under cooling. After stirring for 1 h, the resulting solution was returned to room temperature and stirred continuously for 2 h. Chilled water (40 ml) was added to the reaction solution; then the aqueous layer was washed twice with diethyl ether (20 ml). The aqueous layer was further chilled and neutralized with chilled 0.5 M HCl and then made acidic to pH 3 with 10% citric acid. The acidic solution was extracted three times with ethyl acetate (30 ml). The combined extracts were washed with a saturated NaCl aqueous solution and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure gave **15** as a colorless syrup. Yield 63%. IR ν_{max}^{KBr} (cm^{-1}) 1662, 1515 (CONH), 1630 (C=C). ^1H NMR (MeOH-d_4) δ=7.42 and 6.90 (d, 4H, J=9.5 Hz, C_6H_4-), 7.08 (s, 1H, -CH=), 5.09 (s, 2H, -O-CH_2-O-), 3.98 (s, 2H, -NH-CH_2-CO-), 3.38 (s, 3H, -CH_2OCH_3), 1.42 [s, 9H, -$C(CH_3)_3$]. Found: C, 56.64; H, 6.45; N, 7.19%. Calcd for $C_{18}H_{24}N_2O_7$: C, 56.83; H, 6.36; N, 7.37%.

HCl·H-Gly-⊿Phe-Leu-OMe (17). A solution of Boc-Gly-⊿Phe-Leu-OMe (0.3 g, 0.76 mmol) in 4.5 M HCl and ethyl acetate (20 ml) was stirred under cooling for 10 min. After removing the solvent under reduced pressure, the crude residue was dissolved in diethyl ether (20 ml) and the resulting solution was again concentrated. After adding a small amount of dry methanol and diethyl ether, the deposited crystals were collected. Yield 97%, mp 93—97 °C (decomp) IR ν_{max}^{KBr} (cm^{-1}) 3448 (NH_2), 1665, 1517 (CONH), 1635 (C=C). ^1H NMR (MeOH-d_4) δ=7.56—7.24 (m, 5H, C_6H_5), 7.09 (s, 1H, -CH=), 3.88 (s, 2H, -NH-CH_2-CO-), 3.72 (s, 3H, -CH_2OCH_3), 1.74 [m, 1H, -$CH(CH_3)_2$], 1.24 [m, 2H, -CH_2CH-$(CH_3)_2$], 0.98 [dd, 6H, J=7.3, 2.8 Hz, -$CH(CH_3)_2$]. $[\alpha]_D^{21}$ +39.3° (c 1.00, in MeOH). Found: C, 56.22; H, 6.90; N, 10.59%. Calcd for $C_{18}H_{26}N_3O_4Cl$: C, 56.32; H, 6.83; N, 10.95%.

Boc-⊿Tyr(MOM)-Gly-Gly-Phe-Leu-OMe (18). To a chilled solution of **15** (1.5 g, 4.0 mmol) in THF (20 ml) was added DCC (0.9 g, 4.4 mmol) and *N*-hydroxysuccinimide (0.5 g, 4.4 mmol). After stirring continuously for 30 min, a solution of **16** (1.7 g, 4.4 mmol) and TEA (0.5 ml, 4.9 mmol) in THF (10 ml) was added to the prepared solution; the combined solution was then further stirred under cooling for 2 h. The reaction solution was returned slowly to the room temperature for 24 h. The deposited *N,N'*-dicyclohexylurea were filtered off and the filtrate was concentrated under reduced pressure. The crude residue, thus obtained, was dissolved in ethyl acetate (70 ml) and the resulting solution was washed successively with 10% citric acid, saturated $NaHCO_3$ aqueous solution, and then saturated NaCl aqueous solution, and finally dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, crude crystalline substance, thus obtained, was recrystallized from a mixture of ethyl acetate and hexane to give **18** as a pale yellow amorphous. Yield 65%, mp 65.5—67.5 °C. IR ν_{max}^{KBr} (cm^{-1}) 1662, 1630 (NHCO), 1630 (C=C). ^1H NMR (DMSO-d_6) δ=7.75 (bs, 1H, NH), 7.32—6.86 (m, 13H, -CH=, C_6H_5, C_6H_4, NH), 6.56 (bs, 1H, NH), 5.13 (s, 2H, -OCH_2O-), 3.94 (d, 2H, -NH-CH_2-CO-), 3.60 (s, 3H, -$COOCH_3$), 3.45 (s, 3H, -OCH_3), 1.42 [s, 9H, -$C(CH_3)_3$)], 0.88 [dd, 6H, J=7.3, 2.8 Hz, -$CH(CH_3)_2$]. $[\alpha]_D^{24}$ −5.11° (c 1.25, in MeOH). Found: C, 60.52; H, 6.93; N, 9.83%. Calcd for $C_{36}H_{49}N_5O_{10}$: C, 60.74; H, 6.94; N, 9.84%.

Boc-⊿Tyr(MOM)-Gly-Gly-⊿Phe-Leu-OMe (19). In a similar manner, the coupling of **15** and **17** was worked up to give colorless syrup, which was purified on a silica-gel column using a mixture of chloroform and acetone (20:1 v/v) as the eluent to give **19** as a colorless syrup. Yield 50%. IR ν_{max}^{KBr} (cm^{-1}) 1665, 1525 (NHCO), 1632 (C=C). ^1H NMR (DMSO-d_6) δ=8.72 (bs, 1H, NH), 8.09 (bs, 1H, NH), 7.86 (bs, 1H, NH), 7.34—6.86 (m, 12H, -CH=, C_6H_4, C_6H_5, NH), 4.13 (d, 2H, J=8.0 Hz, -NH-CH_2-CO-). 4.02 (d, 2H, J=8.0 Hz, -NH-CH_2-CO-), 5.08 (s, 2H, -OCH_2O-), 3.57 (s, 3H, -OCH_3), 3.40 (s, 3H, CH_3O-), 1.28 [s, 9H, -$C(CH_3)_3$], 0.86 [dd, 6H, J=6.3, 2.8 Hz, -$CH(CH_3)_2$]. $[\alpha]_D^{24}$ −10.5° (c 0.9, in MeOH). Found: C, 60.88; H, 6.55; N, 9.86%. Calcd for $C_{36}H_{47}N_5O_{10}$: C, 60.91; H, 6.67; N, 9.87%.

(Received September 28, 1988)

Thermal cycloaddition reactions of 2,3-bis(methoxycarbonyl)-7-oxabicyclo[2.2.1]heptadiene with 2*H*-cyclohepta[*b*]furan-2-ones and 8,8-dicyanoheptafulvene gave [4+2]adducts exclusively. This mode is different from the reported [8+2]adduct formations for 2*H*-cyclohepta[*b*]furan-2-ones with enamines and alkoxyethenes. A consideration of the superjacent and subjacent orbitals effects of the MO calculations gave a better result in favor of [4+2]adduct formation. Thermolysis of cycloadducts gave the methylene derivatives of homobarrelenes.

Recently, we investigated thermal cycloaddition reactions of 2*H*-cyclohepta[*b*]furan-2-ones (**1**) to 2,3-bis(methoxycarbonyl)-7-oxabicyclo[2.2.1]heptadiene (**2**) to give the [4+2]cycloadducts exclusively.[1] This was different from the previously-reported [8+2]cycloadducts formation in the thermal reactions of **1** with enamines[2] and alkoxyethenes.[3] Both reaction modes were explained by molecular orbital (MO) considerations involving not only a frontier molecular orbital approach but also the square of the sum of the products of the coefficients of interacting centers.[1,4] We have proposed that both the [4+2]cycloadducts for **1** and **2** and the [8+2]cycloadducts from **1** and enamines and alkoxyethenes were kinetically-controlled products. However, the above theoretical treatments were not always satisfactory to explain all the experimental results. This was the case for the more complicated molecules; such as substituted **1** and **2**.

Paddon-Row et al. have pointed out[4] the importance of superjacent orbital effects to explain the periselectivity for cycloaddition reactions of nonalternant 6,6-dimethylfulvene and cyclopentadiene, studied by Houk and Luskus.[5] In the case of 2*H*-cyclohepta[*b*]furan-2-ones, nonalternant aromatic compounds, we also found that better results to fit the experiments could be obtained when the calculation was extended to involve both interactions between a superjacent (NLU) and a highest occupied (HO) MOs and a subjacent (NHO) and a lowest unoccupied (LU) MOs. In this paper, we will describe these findings.

Results and Discussion

Cycloadditions of 1 and 2. When 2*H*-cyclohepta[*b*]-furan-2-one (**1a**) amd **2** were heated at 130 °C for 36 h in chlorobenzene, three products (**3a—5a**) were obtained together with 3,4-bis(methoxycarbonyl)furan (**6**). The ^{1}H and ^{13}C NMR spectra of **3a** showed an element of symmetry in a molecule and its structure was determined to be 2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one, a methylenehomobarrelene. Product **4a** was a bis(methoxycarbonyl) derivative of **3a**, a Diels-Alder adduct between **1a** and dimethyl butynedioate. Product **5a** was a [4+2]adduct and its stereochemistry was deduced from the coupling constant of the methine protons. No [8+2]cycloadduct was detected at all. Yields of products are summarized in Table 1.

Next, 3-methoxycarbonyl-2*H*-cyclohepta[*b*]furan-2-one (**1b**)[6] and **2** gave two [4+2]cycloadducts (**5b** and **7b**) and cycloreversed product **3b**. The reactions of **2** and 5-chloro-3-methoxycarbonyl (**1c**),[7] 5-methoxy-3-methoxycarbonyl (**1d**),[7] and 6-isopropyl-3-methoxycarbonyl (**1e**)[8] derivatives afforded similar products as shown in Scheme 1. The structures of these products were determined from comparison with the NMR data of the products from **1a** and **2**. In the case of **1e**, a single product (**5e**) was obtained in 8% yield. This low yield might be attributable to steric hindrance of the bulky isopropyl group at the reaction site. A reaction under 3000 bar afforded [4+2]adducts in improved yields; from **1b** and **2**, two [4+2]adducts (**5b** and **7b**) formed in 70% yield together with **3b** in 12% yield.

Table 1. Cycloaddition Products from **1** and **2**[a]

Substrate	Products (Yield/%)			
1a	**3a** (35)	**4a** (7)	**5a** (26)	—[b]
1b	**3b** (40)	—	**5b** (43)	**7b** (11)
	3b (12)[c]	—	**5b**+**7b** (70)[c]	
1c	**3c** (33)	**4c** (2)	**5c** (14)	**7c** (6)
1d	**3d** (50)	**4d** (3.6)	**5d** (34)	**7d** (12)
1e	—	—	**5e** (8)	—

a) Yields shown indicate amounts isolated based on consumed starting materials. b) Not isolated. c) Under 3000 bar.

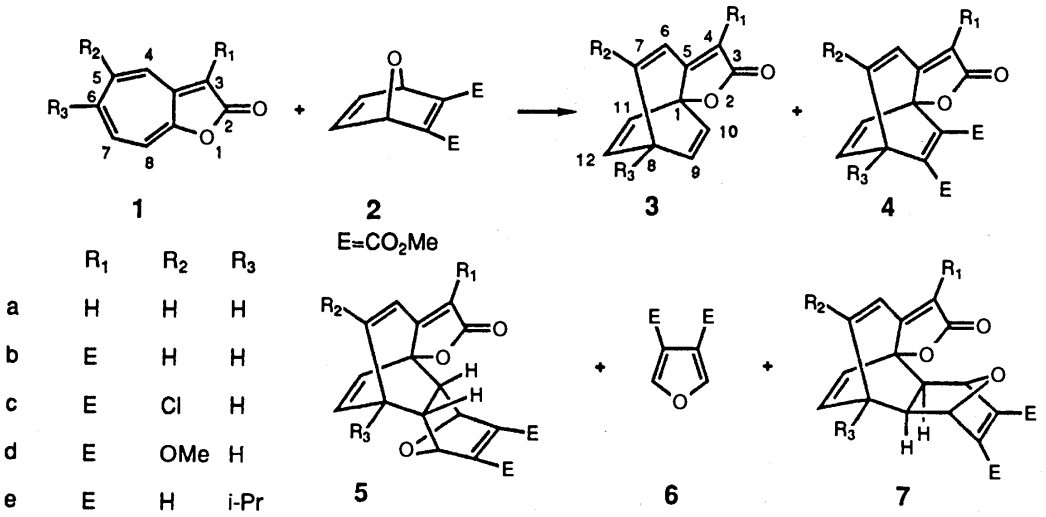
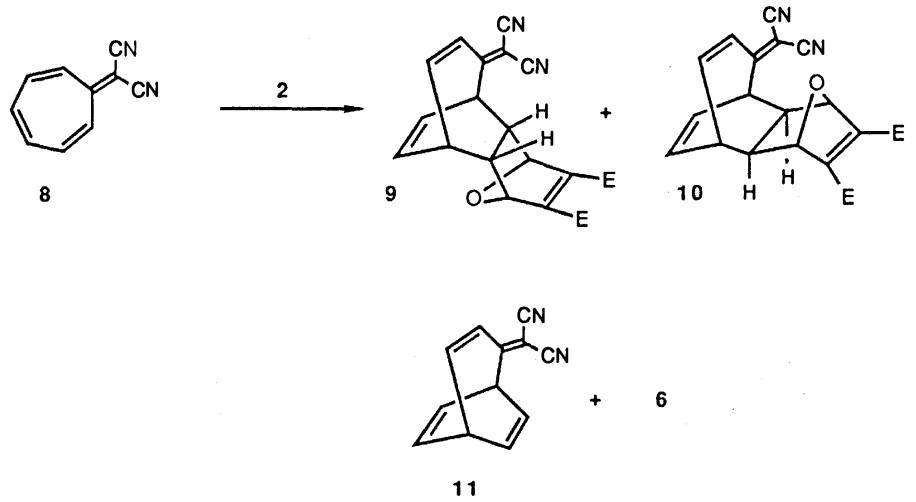


Scheme 1.



Scheme 2.

Similarly, the reaction of **2** and 8,8-dicyanoheptafulvene (**8**) gave [4+2]adducts (**9** and **10**) in 43 and 10% yields along with a cycloreversed 2-(dicyanomethylene)-homobarrelene (**11**). Yields of **9** and **10** increased to 76 and 13%, but that of **11** was 2.5% under 3000 bar. Thus, cycloreversions to **3** and **11** were suppressed under 3000 bar.

Pyrolysis of Adducts. Thermolyses of **5** and **9** in chlorobenzene gave methylenehomobarrelenes as summarized in Table 2. The chemical shifts of C_9 (δ 131.9—133.6) in **4** were high-field shifted by ca. 11—16 ppm than that of C_{10} (δ 145.0—147.8) and as well as the chemical shift of unsubstituted olefinic carbons, C_{11} and C_{12} (δ 131.0—135.4). From these observations, a methoxycarbonyl group at C_{10} took an out-of-plane conformation due to steric interactions with adjacent substituents.

Molecular Orbital Considerations. As mentioned above, no [8+2]adduct was isolated from the reactions of **1** and **2**. The molecular orbitals of **1** and **2** were calculated by the MNDO method together with (dimethylamino)ethene (**A**) and methoxyethene (**B**). From the energy separation between the frontier orbitals, the [8+2]adducts are preferred in the reactions between **2** and **1** (except for **1c**), whereas the [4+2]adducts are favored in the reactions of **1** with **A** and **B**. These are not in accord to the experimental observations.

Namely, other than the reactions of 5-substituted **1c** and **1d**, the exclusive formation of [4+2]adducts from **1**

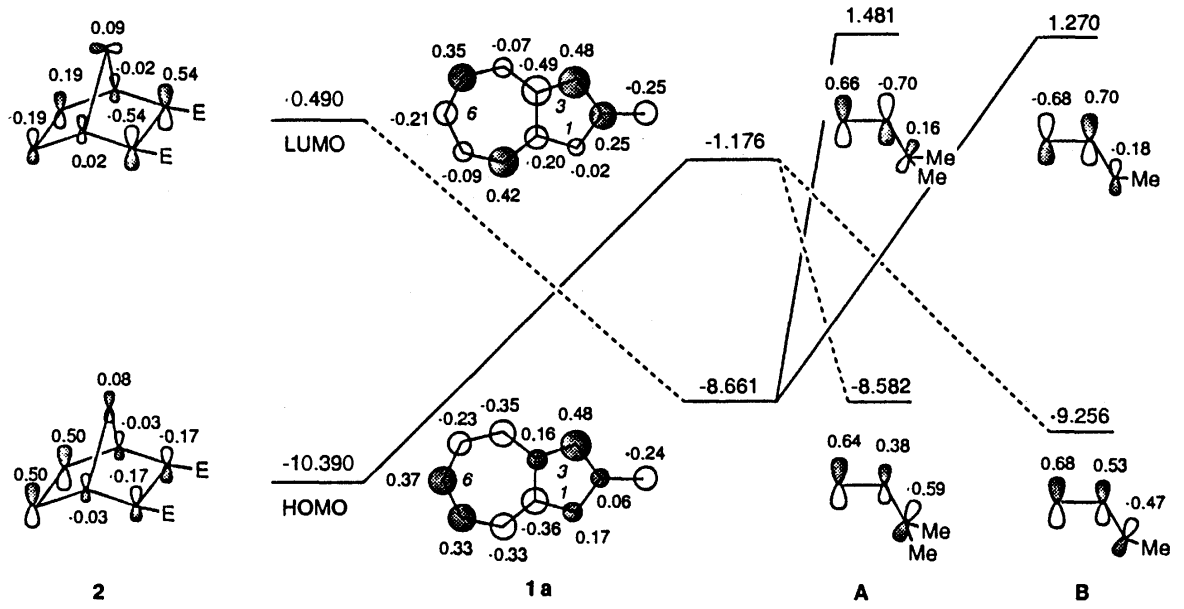

Fig. 1. HOMO-LUMO correlation diagrams of **1a** and olefins

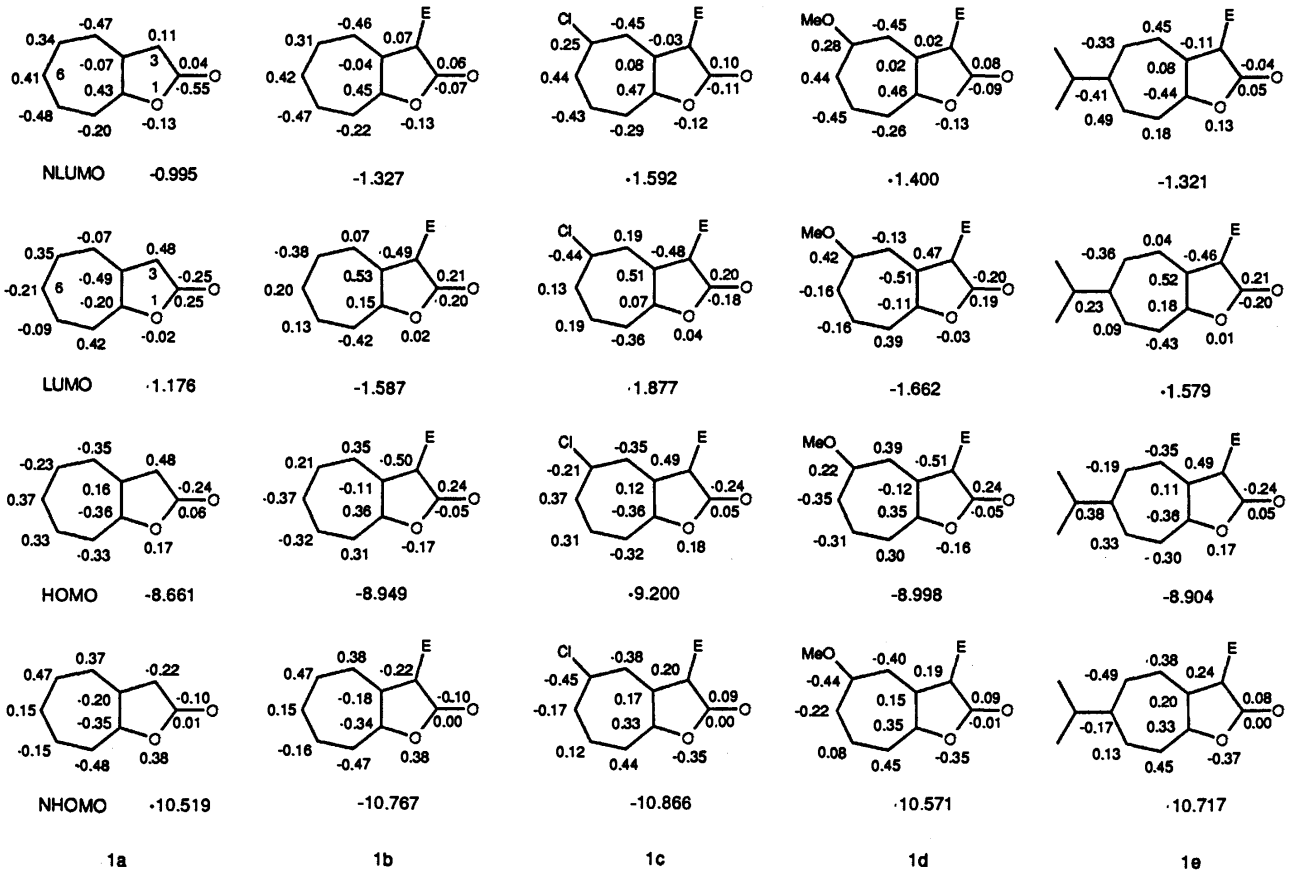

Fig. 2. Coefficients and energy levels of selected molecular orbitals of **1**.

and **2** is consistent with the prediction from the square of the sum of the products of the coefficients of interacting centers:[4] the HOMO(**2**)-LUMO(**1a**) interaction which expected the [4+2]adduct, is more favorable than the [8+2]adduct-forming HOMO(**1a**)-LUMO(**2**) interaction as shown in Fig. 1 and Table 3. In the same time, the antibonding interaction indicated to disfavor a formation of the [8+2]adduct. However, this treatment favored the formation of an [8+2]adduct between 5-substituted **1** and **2**, although it was not

a) See the Ref. 4.

Table 4. Calculation of Stabilization Energy between **1a** and **A** and **B**

	Reaction mode	**A**	**B**
HOMO(**A** or **B**)-LUMO(**1a**)	[4+2]	0.0058	0.0076
LUMO(**A** or **B**)-HOMO(**1a**)	[8+2]	0.0324	0.0340
HOMO(**A** or **B**)-NLUMO(**1a**)	[4+2]	0.0245	0.0314
LUMO(**A** or **B**)-NHOMO(**1a**)	[4+2]	0.0094	0.0100
[4+2]/[8+2]		397/324	490/340

consistent with the experimental results.

In order to provide a consistent explanation of the results, we took the participations of NLUMO and NHOMO of **1** into account since both pairs of LUMO(**1**) and NLUMO(**1**) and HOMO(**1**) and NHOMO(**1**) have the same pseudosymmetries at C_6 and C_{8a}[4] and the coefficients of the NLUMO(**1**) at these atoms are larger than those of LUMO(**1**). As shown in Table 3, the interaction between HOMO(**2**) and NLUMO(**1**) is the largest and it contributes 77—92% towards the total stabilization energy[4] for the [4+2]cycloaddition reaction. Thus, the formation of the [4+2]adduct could be explained.

On the other hand, the results of **1** and enamines and alkoxyethenes were reported to give rather complicated product distributions; the reactions of **1a** and 1-(1-pyrrolidinyl)-1-butene and 3-ethoxycarbonyl-2*H*-cyclohepta[*b*]furan-2-one and 1-morpholino-1-butene gave the [8+2]cycloadducts, 1-ethylazulene, and 1-ethyl-3-ethoxycarbonylazulene in 90 and 88% yields, respectively.[9] No [4+2]adduct formed.

Recently, Nozoe et al. reported the formation of a [8+2]cycloadduct by isolating 1-methoxycarbonylazulene in 74% yield together with an isomeric mixture of three [4+2]adducts in 21% yield, from **1b** and ethoxyethene to reveal two reaction modes.[3] There remained the problem of which cycloadduct is the kinetically-controlled product. From the HOMO-LUMO interactions, the formations of [8+2]adducts were expected, whereas an involvement of NLUMO and NHOMO effects would result in the formation of [4+2]adducts. The calculation of the stabilization energy between **1a** and **A** or **B** is shown in Table 4.

To make these points clear, a further study under high-pressure conditions should be desirable, where a formation of a kinetically-controlled product is expected to be predominant.

Experimental

Elemental analyses were performed by Miss S. Hirashima,

of the Institute of Advanced Material Study, Kyushu University. NMR spectra were measured with JEOL FX 100 Model and GSX 270 H Model spectrometers in $CDCl_3$ solution (unless otherwise specified); chemical shifts are expressed in the unit δ. Mass spectra were measured with a JEOL OlSG-2 spectrometer at 70 eV. IR spectra were taken as KBr disks or as liquid films inserted between NaCl plates using a Jasco IR-A 102 spectrometer. UV spectra were measured with a Hitachi U-3200 spectrophotometer.

Cycloadditions of 1 and 2. General Method. A chlorobenzene solution (1.5 cm^3) of **1** (0.2—1 mmol) and **2** (0.5—1.1 mmol) was heated at 130 °C for 36 h in a sealed ampule, purged with N_2. The mixture was chromatographed on a silica-gel column to give products.

3a: Colorless crystals, 35%; mp 116.5—117.5 °C. ^{1}H NMR δ=3.96 (1H, dtt, J=7.7, 6.6, 1.1 Hz), 5.70 (1H, s), 6.00 (1H, d, J=10.6 Hz), 6.35 (2H, dd, J=7.7, 1.1 Hz), 6.52 (2H, dd, J=7.7, 6.6 Hz), and 6.57 (1H, dd, J=10.6, 7.7 Hz); ^{13}C NMR δ=40.1, 87.8, 111.6, 118.7, 132.1 (2C), 133.0 (2C), 139.8, 158.2, and 173.5; IR 1760, 1620, 1350, 1105, 1025, 905, and 850 cm^{-1}; UV (MeOH) 259.4 (ε 10600) and 297.0 nm (5000); MS m/z (%) 170 (M^+, 10), 116 (62), 115 (base), 89 (29), and 63 (38).

Found: C, 60.91; H, 4.33%. Calcd for $C_{21}H_{18}O_9$: C, 60.87; H, 4.38%.

7b: Colorless crystals, 11%; mp 187—188 °C. ^{1}H NMR δ=2.58 (1H, dd, J=8.8, 5.9 Hz), 3.02 (1H, d, J=8.8 Hz), 3.73 (1H, dddm, J=8.4, 7.0, 5.9 Hz), 3.80 (3H, s), 3.81 (3H, s), 3.89 (3H, s), 4.74 (1H, d, J=1.1 Hz), 4.87 (1H, d, J=1.1 Hz), 6.22 (1H, dd, J=8.4, 0.7 Hz), 6.44 (1H, dd, J=8.4, 7.0 Hz), 6.73 (1H, dd, J=10.6, 8.4 Hz), and 7.41 (1H, d, J=10.6 Hz); ^{13}C NMR δ=38.3, 41.8, 52.1, 52.4, 52.5, 52.6, 79.1, 83.2, 87.4, 113.3, 125.9, 133.1, 135.1, 144.5, 145.4, 146.1, 161.5, 161.8, 162.5, 167.2, and 167.9; IR 1775, 1720, 1620, 1440, 1280, 1210, and 1035 cm^{-1}; UV (MeOH) 243.2 (ε 5900) and 295.8 nm (7600).

Found: C, 60.89; H, 4.40%. Calcd for $C_{21}H_{18}O_9$: C, 60.87; H, 4.38%.

3c: Colorless crystals, 33%; mp 148—149 °C. ^{1}H NMR δ=3.89 (3H, s), 4.26 (1H, tq, J=6.6, 1.5 Hz), 6.48 (2H, dd, J=7.7, 1.5 Hz), 6.72 (2H, dd, J=7.7, 6.6 Hz), and 6.95 (1H, d, J=1.5 Hz); ^{13}C NMR δ=50.5, 52.3, 85.3, 111.6, 115.8, 131.2 (2C), 134.6 (2C), 152.1, 161.5, 162.8, and 168.1; IR 1780, 1710, 1610, 1250, and 1035 cm^{-1}; UV (MeOH) 283.4 (ε 10500) and 321.4 nm (9400); MS m/z (%) 266 (M^++2, 11), 264 (M^+, 34), 229 (base), 197 (61), and 149 (36).

Found: C, 58.80; H, 3.42%. Calcd for $C_{13}H_9O_4Cl$: C, 59.00; H, 3.43%.

4c: Colorless crystals, 2%; mp 155—157 °C. ^{1}H NMR δ=3.83 (3H, s), 3.84 (3H, s), 3.90 (3H, s), 4.82 (1H, ddd, J=7.0, 1.8, 1.5 Hz), 6.51 (1H, dd, J=8.1, 1.5 Hz), 6.82 (1H, dd, J=8.1, 7.0 Hz), and 7.09 (1H, d, J=1.8 Hz); ^{13}C NMR δ=49.7, 52.6, 53.2 (2C), 84.0, 112.8, 117.0, 131.9, 132.8, 133.5, 145.8, 150.6, 160.4, 161.0, 162.2, 163.1, and 166.6; IR 1780, 1730, 1615, 1440, 1275, 1250, 1035, and 1025 cm^{-1}; UV (MeOH) 267.4 (ε 8600) and 322.6 nm (8200); MS m/z (%) 382 (M^++2, 14), 380 (M^+, 42), 349 (29), 323 (35), 321 (base), 292 (47), 289 (45), 277 (33), 207 (33), and 59 (75).

Found: C, 53.92; H, 3.58%. Calcd for $C_{17}H_{13}O_8Cl$: C, 53.63; H, 3.44%.

5c: Colorless crystals, 14%; mp 209—210 °C. ^{1}H NMR δ=2.36 (1H, dd, J=7.7, 1.1 Hz), 2.74 (1H, dd, J=7.7, 1.1 Hz), 3.77 (1H, dm, J=7.7 Hz), 3.81 (3H, s), 3.83 (3H, s), 3.90 (3H, s), 4.97 (1H, d, J=1.1 Hz), 5.47 (1H, d, J=1.1 Hz), 6.15 (1H, dm, J=8.8 Hz), 6.35 (1H, dd, J=8.8, 7.7 Hz), and 7.35 (1H, d, J=1.8 Hz); ^{13}C NMR δ=43.9, 49.5, 50.0, 52.4, 52.5, 52.7, 83.2, 84.8, 84.9, 110.9, 118.9, 129.7, 130.7, 145.0, 145.2, 155.5, 161.5, 162.0, 162.3, 166.7, and 167.2; IR 1775, 1720, 1610, 1438, 1260, and 1220 cm^{-1}; UV (MeOH) 242.6 (ε 8200) and 305.6 nm (13700).

Found: C, 56.29; H, 3.87%. Calcd for $C_{21}H_{17}O_9Cl$: C, 56.20; H, 3.82%.

7c: Colorless crystals, 6%; mp 155—156 °C. ^{1}H NMR δ=2.63 (1H, dd, J=8.8, 6.2 Hz), 3.00 (1H, d, J=8.8 Hz), 3.81 (3H, s), 3.83 (3H, s), 3.90 (3H, s), 3.9 (1H, m), 4.75 (1H, d, J=1.1 Hz), 5.06 (1H, d, J=1.1 Hz), 6.28 (1H, dd J=8.4, 0.7 Hz), 6.50 (1H, dd, J=8.4, 7.3 Hz), and 7.58 (1H, d, J=1.8 Hz); ^{13}C NMR δ=41.8, 48.4, 51.3, 52.4, 52.5, 52.6, 79.2, 82.4, 86.4, 112.6, 123.2, 132.8, 134.3, 145.3, 145.8, 150.2, 161.3, 161.7, 162.4, 165.6, and 167.4; IR 1775, 1720, 1620, 1440, 1335, 1270, 1250, and 1030 cm^{-1}; UV (MeOH) 240.0 (ε 7000) and 312.6

nm (11200).

Found: C, 56.26; H, 3.86%. Calcd for $C_{21}H_{17}O_9Cl$: C, 56.20; H, 3.82%.

3d: Colorless crystals, 50%; mp 136—137 °C. ^{1}H NMR δ=3.78 (3H, s), 3.87 (3H, s), 4.07 (1H, tdt, J=6.6, 2.6, 1.5 Hz), 6.06 (1H, d, J=2.6 Hz), 6.52 (2H, dd, J=7.4, 1.5 Hz), and 6.60 (2H, dd, J=7.4, 6.6 Hz); ^{13}C NMR δ=47.1, 53.1, 56.7, 85.7, 88.6, 106.0, 130.2 (2C), 136.5 (2C), 163.1, 169.1, 169.6, and 172.6; IR 1760, 1710, 1580, 1380, 1360, 1290, 1265, and 1035 cm^{-1}; UV (MeOH) 269.6 (ε 6300) and 344.2 nm (16250): MS m/z (%) 260 (M^+, base), 229 (39), 200 (35), 145 (35), 115 (38), 102 (37), 76 (30), and 65 (31).

Found: C, 64.81; H, 4.65%. Calcd for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65%.

4d: Colorless crystals, 3.6%; mp 186—187 °C. ^{1}H NMR δ=3.80 (6H, s), 3.84 (3H, s), 3.87 (3H, s), 4.65 (1H, ddd, J=7.0, 2.2, 1.5 Hz), 6.19 (1H, d, J=2.2 Hz), 6.55 (1H, dd, J=7.7, 1.5 Hz), and 6.73 (1H, dd, J=7.7, 7.0 Hz); ^{13}C NMR δ=46.5, 52.6, 53.1 (2C), 56.7, 84.3, 89.6, 107.2, 131.0, 131.9, 135.4, 147.8, 162.5, 162.6, 163.5, 166.8, 167.7, and 170.9; IR 1780, 1730, 1690, 1440, 1285, and 1260 cm^{-1}; UV (MeOH) 208.8 (ε 17900), 263.6 (7900), and 348.4 nm (13900): MS m/z (%) 376 (M^+, 42), 317 (37), 288 (35), 285 (43), 203 (35), 119 (34), 93 (36), 76 (36), 59 (base), and 44 (60).

Found: C, 57.58; H, 4.30%. Calcd for $C_{18}H_{16}O_9$: C, 57.45; H, 4.29%.

5d: Colorless crystals, 34%; mp 232—233 °C. ^{1}H NMR δ=2.35 (1H, dd, J=8.1, 1.1 Hz), 2.61 (1H, dd, J=8.1, 1.5 Hz), 3.56 (1H, dm, J=6.6 Hz), 3.80 (3H, s), 3.82 (3H, s), 3.83 (3H, s), 3.88 (3H, s), 4.97 (1H, d, J=1.1 Hz), 5.47 (1H, d, J=1.1 Hz), 6.19 (1H, dt, J=8.8, 1.1 Hz), 6.26 (1H, dd, J=8.8, 6.6 Hz), and 6.50 (1H, d, J=2.2 Hz); ^{13}C NMR δ=43.4, 45.9, 50.2 (2C), 51.9, 52.6, 56.8, 83.2, 85.0, 85.1, 92.0, 105.2, 128.5, 132.5, 145.2, 145.6, 162.1, 162.5, 163.1, 168.5, 172.8, and 176.7; IR 1760, 1715, 1690, 1440, 1270, and 1235 cm^{-1}; UV (MeOH) 215.0 (ε 13500), 240.8 (10100), and 336.0 nm (18000).

Found: C, 59.33; H, 4.57%. Calcd for $C_{22}H_{20}O_{10}$: C, 59.46; H, 4.54%.

7d: Colorless crystals, 12%; mp 233—234 °C. ^{1}H NMR δ=2.59 (1H, dd, J=8.8, 7.0 Hz), 2.95 (1H, d, J=8.8 Hz), 3.65 (1H, tm, J=7.0 Hz), 3.81 (3H, s), 3.82 (3H, s), 3.84 (3H, s), 3.88 (3H, s), 4.78 (1H, d, J=1.1 Hz), 4.91 (1H, d, J=1.1 Hz), 6.33 (1H, dd, J=8.4, 1.5 Hz), 6.39 (1H, dd, J=8.4, 7.0 Hz), and 6.76 (1H, d, J=2.2 Hz); ^{13}C NMR δ=41.6, 44.7, 51.2, 51.8, 52.5 (2C), 56.8, 79.7, 82.3, 86.3, 96.6, 106.9, 131.6, 136.4, 145.2, 146.1, 161.8, 162.5, 162.9, 168.5, 171.3, and 173.4; IR 1760, 1710, 1695, 1440, and 1230 cm^{-1}; UV (MeOH) 219.2 (ε 12400) and 341.6 nm (16200).

Found: C, 59.27; H, 4.55%. Calcd for $C_{22}H_{20}O_{10}$: C, 59.46; H, 4.54%.

5e: Colorless crystals, 8%; mp 212 °C. ^{1}H NMR δ=1.17 (3H, d, J=6.6 Hz), 1.18 (3H, d, J=6.6 Hz), 2.17 (1H, sept, J=6.6 Hz), 2.34 (1H, d, J=8.1 Hz), 2.55 (1H, d, J=8.1 Hz), 3.80 (3H, s), 3.81 (3H, s), 3.89 (3H, s), 5.13 (1H, d, J=1.1 Hz), 5.49 (1H, d, J=1.1 Hz), 6.05 (1H, dd, J=9.2, 1.1 Hz), 6.10 (1H, dd, J=9.2, 1.1 Hz), 6.82 (1H, d, J=11.0 Hz), and 7.22 (1H, d, J=11.0 Hz); ^{13}C NMR δ=16.2, 18.4, 32.4, 47.6, 49.2, 50.5, 52.3, 52.4, 52.6, 80.5, 83.3, 85.8, 110.9, 121.3, 128.3, 136.3, 145.0, 146.0, 151.1, 161.8, 162.2, 162.6, 167.8, and 168.0; IR 1765, 1735, 1710, 1620, 1435, 1275, and 1225 cm^{-1}; UV (MeOH) 245.8 (ε 9800) and 294.0 nm (15600).

Found: C, 62.96; H, 5.32%. Calcd for $C_{24}H_{24}O_9$: C, 63.15; H, 5.30%.

Cycloaddition of 2 and 8. A chlorobenzene solution, (2 cm^3) of **8** (188 mg) and **2** (265 mg) was heated at 130 °C for 20 h in a sealed tube. The mixture was chromatographed on a silica-gel column to give 54 mg (47%) of **6**, 100 mg (43%) of **9**, 23 mg (10%) of **10**, 38.7 mg (42%) of **11**, and unreacted **8** (78.9 mg).

9: Colorless crystals, mp 164—165 °C; ^{1}H NMR δ=2.38 (1H, dm, J=7.7 Hz), 2.65 (1H, dd, J=7.7, 1.1 Hz), 3.51 (1H, ddm, J=8.1, 7.7 Hz), 3.82 (3H, s), 3.83 (3H, s), 4.17 (1H, dm, J=7.0 Hz), 4.93 (1H, d, J=1.1 Hz), 5.10 (1H, d, J=1.1 Hz), 6.09 (1H, dd, J=7.7, 7.0 Hz), 6.46 (1H, t, J=7.7 Hz), 6.52 (1H, dd, J=10.6, 2.2 Hz), and 7.02 (1H, dd, J=10.6, 8.1 Hz); ^{13}C NMR δ=40.0, 44.0, 46.1, 48.2, 52.5, 52.6, 81.1, 85.5, 86.4, 111.7, 112.8, 125.4, 126.3, 136.6, 144.9, 145.6, 152.0, 162.3, 162.7, and 169.4; IR 2250, 1730, 1610, 1440, 1290, 1255, and 1230 cm^{-1}. UV (MeOH) 243.4 (ε 8600) and 302.6 nm (16200).

Found: C, 65.97; H, 4.47; N, 7.47%. Calcd for $C_{20}H_{16}N_2O_5$: C, 65.93; H, 4.43; N, 7.69%.

10: Colorless crystals, mp 183—184 °C; ^{1}H NMR δ=2.63 (1H, dd, J=8.4, 5.8 Hz), 2.78 (1H, dd, J=8.4, 5.5 Hz), 3.64 (1H, td, J=8.0, 5.8 Hz), 3.81 (3H, s), 3.83 (3H, s), 4.27 (1H, dd, J=7.0, 5.5 Hz), 4.82 (2H, s), 6.16 (1H, dd, J=7.3, 7.0 Hz), 6.62 (1H, dd, J=8.0, 7.3 Hz), and 6.7—6.8 (2H, m); ^{13}C NMR δ=38.8, 44.9, 47.3, 48.0, 52.5, 52.6, 81.7, 82.6, 83.2, 111.8, 113.2, 129.2, 129.9, 140.4, 145.3, 146.0, 147.3, 162.4, 162.5, and 169.5; IR 2240, 1725, 1610, 1440, 1290, 1265, and 1230 cm^{-1}; UV (MeOH) 243.4 (ε 7900) and 307.2 nm (12600).

Found: C, 65.76; H, 4.45; N, 7.40%. Calcd for $C_{20}H_{16}N_2O_5$: C, 65.93; H, 4.43; N, 7.69%.

11: Colorless needles, mp 71—73 °C; ^{1}H NMR δ=3.98 (1H, dtm, J=8.4, 6.6 Hz), 4.68 (1H, tdd, J=6.6, 2.2, 1.5 Hz), 6.06 (1H, dd, J=10.6, 2.2 Hz), 6.36 (2H, td, J=6.6, 1.5 Hz), 6.84 (2H, td, J=6.6, 1.5 Hz), and 6.95 (1H, dd, J=10.6, 8.4 Hz); ^{13}C NMR δ=41.8, 46.8, 81.8, 111.6, 113.1, 122.3, 128.3 (2C), 140.2 (2C), 149.2, and 164.1; IR 2245, 1600, 1530, 1355, 1290, 930, and 897 cm^{-1}; UV (MeOH) 287.4 (ε 12700) and 390.6 nm (6200); MS m/z (%) 180 (M^+, 28), 153 (35), 115 (base), 76 (36), 75 (34), 63 (50), 62 (38), 51 (34), 50 (71), and 49 (33).

Found: C, 79.94; H, 4.49; N, 15.57%. Calcd for $C_{12}H_8N_2$: C, 79.98; H, 4.47; N, 15.54%.

Cycloadditions under 3000 bar. a) A chlorobenzene solution (2 cm^3) of **1b** (110 mg) and **2** (115 mg) was heated at 120 °C for 36 h. The mixture was purified to give 7.1 mg (11%) of **3b**, 5.7 mg (12%) of **6**, 78.6 mg (70%) of **5b** and **7b**, and unreacted **1b** (53 mg).

b) A chlorobenzene solution (1.5 cm^3) of **8** (153 mg) and **2** (353 mg) was heated at 120 °C to give 210.5 mg (76%) of **9**, 37 mg (13%) of **10**, 3.4 mg (2.5%) of **11**, and unreacted **8** (36.3 mg).

Thermolysis of 5 and 9. A chlorobenzene solution (1 cm^3) of **5** (40 mg) was heated at 130 °C for 24 h. The mixture was chromatographed to give the products. The results were summarized in Table 2.

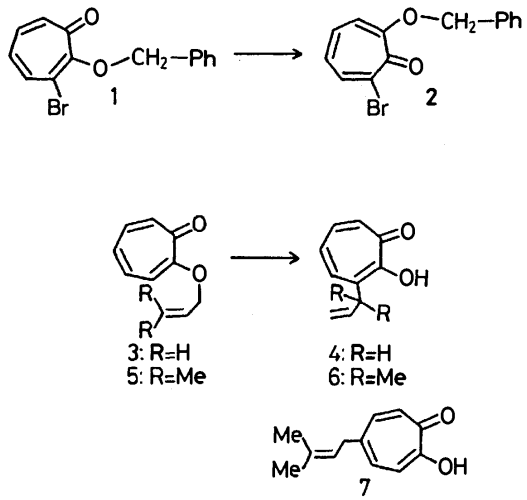
The Effect of Pressure on Sigmatropic Rearrangements of Seven-Membered Conjugated Systems. [3,3] and [1,9] Sigmatropies

Shigeru SUGIYAMA,* Akira MORI,† Nobuo KATO,† and Hitoshi TAKESHITA*,†
Department of Chemical Science and Technology, Faculty of Engineering, The University of Tokushima, Minamijosanjima-cho, Tokushima 770
†Institute of Advanced Material Study, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received September 30, 1988)

The kinetic features of the [1,9] sigmatropy (with 2-benzyloxy-3-bromotropone) and the [3,3] sigmatropy (with 2-allyloxytropone and 2-[(3-methyl-2-butenyl)oxy]tropone) were investigated under various pressures (1 to 1600 bar). The activation volume of [1,9] sigmatropy was of the same order as those of [1,5] sigmatropy of cyclopentadienes. The activation volume of [3,3] sigmatropy of more sterically-hindered substrate was more negative than that of the unhindered one.

Studies of the sigmatropic rearrangement have attracted considerable interest. Its mechanistic aspects and applications to organic syntheses have been investigated continuously.[1] However, although it is recognized in general that the high-pressure technique is a powerful synthetic method, investigations of sigmatropies under high-pressure conditions still remain unexplored. The sigmatropies of troponoids are unique in view of their interesting π-electron arrangement. A tautomerism of 2-acetoxytropones has been known for a long time,[2] and a kinetic analysis for the process by means of ^{13}C NMR spectroscopy was carried out by Masamune et al., [3a] who proposed an ionic mechanism. Recently, we showed[4] that the migration of the acetyl group[3] of 2-acetoxytropones between their C-1 and C-2 is a concerted [1,9] sigmatropy (acetotropy) by the kinetic analysis using temperature-variable ^{13}C NMR spectroscopy. Consequently, the kinetic analysis of various sigmatropic rearrangements under high-pressure conditions should be worthwhile. Herein, we describe, in addition to our preliminary presentation[5] of [1,9] sigmatropy of 2-benzyloxy-3-bromotropone,[6] the effect of pressure on the [3,3] sigmatropy of troponoids. A determination of the activation volume is essential in order to evaluate the synthetic aspect of any pressure effect. Previously, such studies were limited to [1,5] sigmatropy of cyclopentadiene derivatives[7] and 2-alkoxypridine *N*-oxide[8] and [3,3] sigmatropy of benzenoids and acyclic compounds.[9]



Scheme 1.

Results and Discussion

[1,9] Sigmatropy. The thermally-allowed [1,5] sigmatropies are well-known with cyclopentadienes. However, the next higher thermally-allowed electrocyclic systems, [1,9] process, are not so common. The concept of a [1,9] sigmatropy was introduced into troponoid chemistry by Harrison et al. when they observed a thermal rearrangement of 2-benzyloxy-3-bromotropone (**1**) to 7-benzyloxy-2-bromotropone (**2**).[6] Harrison et al. have also carried out a kinetic study of this rearrangement and expressed a view to favor a [1,9] process on the basis of the value of the activation energy (E_a).[6] However, it is known that E_a of sigmatropies varies from 27 to 210 kJ mol^{-1}, depending on the nature of the substrates.[10] Therefore, the conclusion drawn by Harrison deserves further investigation. We decided to examine the sigmatropy by means of a kinetic analysis. The results are summar-

Table 1. The Rate Constants (10^7k/s^{-1}) of the Rearrangement of **1** at Various Temperatures

Solv.	Temperature/°C			
	110	120	130	140

ized in Table 1. The activation parameters obtained at 130 °C are listed in Table 2.

Each activation parameter in both solvents, isopropylbenzene (cumene) and 1-hexanol, showed a similar tendency to those of a typical [1,5] sigmatropy operating within the range of temperature.[10] The activation entropies (ΔS^*) obtained at 130 °C were −47 and −92 J mol^{-1} K^{-1} in cumene and 1-hexanol, respectively. As a general tendency, the stronger the solvation, the more negative ΔS^* is expectable from the pressure effect on this rearrangement. This indicates a weak, but not negligible, contribution of a polarized structure in the transition state. The activation free energy (ΔG^*) remained nearly constant in both solvents as a result of the compensation effect between ΔS^* and the activation enthalpy (ΔH^*).[11] Then, we investigated the high-pressure kinetic analysis of this [1,9] sigmatropy of **1** to **2**.

In Table 3, the rate constants for the rearrangement of **1** to **2** at various pressures at 130 °C are listed. The activation volume (ΔV^*) was evaluated with Eq. 1 by using a linear function of $\ln k$ vs. pressure (P).

$$\Delta V^* = -RT(\partial \ln k/\partial P)_T, \quad (1)$$

The rates were accelerated with pressure; in cumene, the logarithm of the rate constants was linear to the pressure (correlation coefficient r: 0.998), but in 1-hexanol, it showed a curvature (Fig. 1 (A)). If one neglects the difference toward compressibility between the ground and transition states by assuming this rearrangement to be a unimolecular reaction, one reason of this behavior must be the contribution of a somewhat polarized transition state. This contribution may alter the degree of solvation in 1-hexanol under high pressure. Thus, from Eq. 1, ΔV^* were evaluated by a linear function in the case of cumene and a quadratic function in the case of 1-hexanol (tabulated in Table 4). The solvent effect on ΔV^* was very small and the above-mentioned solvation effect on the transition state was very weak. The rate constant at atmospheric pressure in 1-hexanol (dielectric constant ε=13.3 D) was five-times larger than that in cumene (ε=2.4 D). This magnitude of the rate enhancement is just similar to that of the Diels-Alder reaction of isoprene to maleic anhydride,[12] where the rate was about eight times larger in nitromethane (ε=38.6 D) than that in ethyl acetate (ε=6.06 D). These results show that the rearrangement of **1** to **2** is a concerted process, i.e., [1,9] sigmatropy. At the same time, the effect of pressure on [1,9] sigmatropy is similar to that of the other typical sigmatropy.

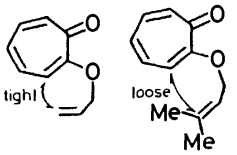
Consequently, from the temperature, pressure, and solvent effects, the present rearrangement is undoubtedly a concerted [1,9] sigmatropy.

[3,3] Sigmatropy. The Claisen rearrangement of tropolone derivatives has been a focus of attention. As early as in 1953, Sebe et al. carried out pioneering work, and reported some fundamental features.[13] However, Kitahara's studies on natural product syntheses, nootkatin and procerin,[14] have revealed a limitation of the process, i.e., the yields of the Claisen products, prenylated products, were only a few %. This was later explained by ourselves, i.e., the proto-Claisen thermolysates of the γ-substituted allyl ethers of tropolones cause another thermally-allowed fragmentation to tropolones and diene via the $[_s6_\pi + _s2_\pi + _s2_\sigma]$ electro-

cyclic reaction.[15] Intramolecular Diels-Alder reactions of the proto-products from the substituted troponyl allyl ethers found by Harrison et al.[16] and Schmid et al.[17] also constitute a limitation of the Claisen rearrangement. Nevertheless, the Claisen rearrangement of troponoids may be competitive with other electrocyclic reactions, and it is interesting from a theoretical point of view.

As a typical [3,3] sigmatropy, Claisen rearrangements of 2-allyloxytropone (**3**) to 3-allyltropolone (**4**) and 2-[(3-methyl-2-butenyl)oxy]tropone (**5**) to thermolysates (**6** and **7**) were carried out. Prior to high-pressure kinetics, authentic samples of thermolysates were prepared and isolated as 2-methoxytropone derivatives, i.e., 3-allyl-2-methoxytropone (**8**), 2-allyl-7-methoxytropone (**9**), 2-methoxy-3-(1,1-dimethyl-2-propenyl)tropone (**10**), 2-methoxy-7-(1,1-dimethyl-2-propenyl)tropone (**11**), and 2-methoxy-5-(3-methyl-2-butenyl)tropone (see Experimental). The rates of reactions under various pressures were measured by high-pressure liquid chromatography (HPLC) of the product mixture after treatment with ethereal diazomethane.

Table 3 shows the pressure effect on Claisen rearrangements of **3** and **5**. At 1 bar, the rate constant of **5** was three-times larger than that of **3**. This is predictable in terms of an electron-releasing effect of the methyl groups of **5**; however, the effect of this electronic character on the solvation term must be very small in this concerted reaction.[18] As shown in Fig. 1 (B), the acceleration with pressure was much larger in the case of **5** than **3**. By using a quadratic function of pressure to express this dependence $\Delta V^{\ddagger}$ was evaluated (listed in Table 4). Evidently, the rearrangement of **5**, being more sterically hindered at the reaction center, was more accelerated with pressure than that of **3**, being less hindered. There have been several discussions about a pressure effect on the steric hindrance to Menshutkin reaction.[19,20] Le Noble and Asano found that, by volume criterion, the transition state of Menshutkin reaction is more product-like as the reaction is more hindered. In other words, more hindered Menshutkin reactions tend to become more accelerated with pressure. This is consistent to a postulation by Hammond.[20] In order to explain the results, one has to consider the difference of the bulkiness of the reactant. That is, in order to cause a rearrangement, a reactant having a bulky substituent must be contracted



3 5

$|\Delta V^{\ddagger}| < |\Delta V^{\ddagger}|$

to a greater extent than that having a non-bulky one. As a result, the $\Delta V^{\ddagger}$ value for the more hindered rearrangement must be more negative (Scheme 2).

The Claisen rearrangement of **5** was much more accelerated with pressure than that of unsubstituted **3**, due to the contribution of two additional methyl groups. If there were more crowded substituents at the reaction center, the Claisen rearrangement might be more pressure-accelerated to give a more negative $\Delta V^{\ddagger}$ value than the ordinary [3,3] sigmatropy ($-18 < \Delta V^{\ddagger} < -7$).[9]

Experimental

Materials. Solvents were carefully purified by dehydration and distillation under N_2 atmosphere. All materials were prepared by the known procedures, and purified by silica-gel column chromatography. Recrystallizations for a solid sample were performed by using the solvents indicated in parentheses. The NMR spectra were measured in $CDCl_3$ solutions, and the chemical shifts were expressed in δ units with the internal standard, Me_4Si. The IR spectra were taken in $CHCl_3$ solutions.

Kinetic Measurements. The apparatus for kinetic runs was the same as used in our previous studies.[21] The reaction temperature was controlled within ±0.5 °C. The progress of the reaction was monitored by high-pressure liquid chromatography [Nippon Waters Model 244 apparatus] by the increase of product formations. In the case of Claisen rearrangements of **3** and **5**, tropolone derivatives were methylated with ethereal CH_2N_2 prior to analysis.

[1,9] Sigmatropy of 1 (Preparative). A cumene solution of **1** (mp 44—45 °C (from benzene-hexane) (lit,[6] 43—44 °C); 254 mg) was heated in a sealed tube at 150 °C for 24 h. The mixture was chromatographed on a silica-gel column to give the desired product:

2: Mp 94—95 °C (from benzene-hexane) (lit,[6] 96—97 °C).

Claisen Rearrangement of 3 (Preparative). Characterization of the Thermolysate (4) as its Methyl Ethers (8 and 9). A toluene solution of **3** (bp 60 °C/0.3 Torr (1 Torr=133.22 Pa)) (177 mg) was refluxed for 8 h. The mixture was then heated in vacuo to remove the solvent and the residue was chromatographed on a silica-gel column with benzene-EtOAc (1 : 1) to give **4** [colorless crystals, mp 42—43 °C (hexane-EtOAc) (lit,[22] 43—44 °C); 49.5 mg; 60%] and the recovered **3** (95.1 mg). The **4** was treated with ethereal diazomethane. Silica-gel column chromatography of the mixture with benzene-EtOAc (5 : 1) afforded methylated derivatives:

8: A pale yellow oil; 15 mg. Found: m/z 176.0836. Calcd for $C_{11}H_{12}O_2$: M, 176.0837; ^{1}H NMR δ=3.44 (2H, dt, J=6.6, 1.5 Hz), 3.91 (3H, s), 5.09 (1H, dtd, J=16.1, 1.5, 1.1 Hz), 5.10 (1H, dtd, J=11.0, 1.5, 1.1 Hz), 5.91 (1H, ddt. J=16.1, 11.0, 6.6 Hz), and 6.8—7.2 (4H, m). ^{13}C NMR δ=38.9, 58.9, 116.7, 129.7, 135.3, 135.4, 137.1, 137.7, 138.6, 163.9, and 181.8. IR ν; 1620, 1580, and 1275 cm^{-1}.

9: Colorless crystals, mp 48—49 °C (benzene-hexane);

35 mg. Found: C, 74.87; H, 6.79%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%. ^{1}H NMR δ=3.52 (2H, d, J=6.6 Hz), 3.93 (3H, s), 5.10 (1H, dm, J=9.9 Hz), 5.15 (1H, dm, J=17.0 Hz), 5.99 (1H, ddt, J=17.0, 9.9, 6.6 Hz), 6.74 (1H, br d, J=9.4 Hz), 6.84 (1H, br t, J=9.4 Hz), 7.01 (1H, br t, J=9.4 Hz), and 7.37 (1H, br d, J=9.4 Hz); ^{13}C NMR δ=39.8, 56.3, 112.1, 117.0, 127.1, 131.0, 135.8 (2C), 147.9, 164.0, and 179.3. IR ν: 1640, 1595, and 1275 cm^{-1}.

Claisen Rearrangement of 5 (Preparative). Characterization of the Thermolysates (6 and 7) as Methyl Ethers (10, 11, and 12). A toluene solution (20 cm^3) of **5**[23] (527 mg) was similarly refluxed for 17 h. The mixture was then heated in vacuo to remove the solvent, and the residue was chromatographed on a silica-gel column with benzene-EtOAc (1 : 1) to give **10** (89.2 mg; 19%), **11** (166.6 mg; 36%), **12** (130.2 mg; 28%), 2-methoxytropone (38.4 mg; 11%), and the recovered **5** (67.1 mg):

10: A pale yellow oil. Found: m/z 204.1148. Calcd for $C_{13}H_{16}O_2$: M, 204.1149. ^{1}H NMR δ=1.47 (6H, s), 3.80 (3H, s), 4.94 (1H, dd, J=17.6, 1.1 Hz), 4.99 (1H, dd, J=10.6, 1.1 Hz), 6.12 (1H, dd, J=17.6, 10.6 Hz), 6.82 (1H, ddd, J=11.7, 7.6, 1.8 Hz), 7.05 (1H, dd, J=12.1, 1.8 Hz), 7.15 (1H, ddd, J=12.1, 7.6, 7.1 Hz), and 7.28 (1H, br d, J=11.7 Hz); ^{13}C NMR δ=28.0 (2C), 43.5, 57.8, 109.6, 128.2, 134.2, 135.3, 136.9, 144.8, 148.5, 165.7, and 182.6. IR ν: 1630, 1605, and 1290 cm^{-1}.

11: Colorless crystals, mp 49—50 °C (benzene-hexane); Found: C, 76.21; H, 7.94%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%. ^{1}H NMR δ=1.49 (6H, s), 3.86 (3H. s), 5.01 (1H, dd, J=10.6, 1.1 Hz), 5.02 (1H, dd, J=17.6, 1.1 Hz), 6.16 (1H, dd, J=17.6, 10.6 Hz), 6.57 (1H, d, J=9.5 Hz), 6.75 (1H, br t, J=9.5 Hz), 6.91 (1H, br t, J=9.5 Hz), and 7.39 (1H, d, J=9.5 Hz). ^{13}C NMR δ=27.1 (2C), 44.1, 56.3, 110.1, 110.8, 125.9, 130.4, 133.5, 147.7, 153.1, 163.1, and 180.9. IR ν: 1625 and 1270 cm^{-1}.

12: A yellow oil, MS m/z, 204 (M^+). ^{1}H NMR δ=1.71 (3H, s), 1.76 (3H, s), 3.25 (2H, d, J=7.3 Hz), 3.92 (3H, s), 5.23 (1H, tm, J=7.3 Hz), 6.71 (1H, d, J=10.3 Hz), 6.92 (1H, br d, J=10.3 Hz), 7.11 (1H, dd, J=12.5, 1.8 Hz), and 7.20 (1H, d, J=12.5 Hz); ^{13}C NMR δ=17.9, 25.8, 37.6, 56.1, 113.1, 121.5, 130.5, 134.6, 136.7, 139.3, 141.9, 163.8, and 180.2. IR ν: 1630, 1570, and 1250 cm^{-1}.

Oxidation of 2,4-Di-*t*-butylphenol with Hydrogen Peroxide Catalyzed by Bis(ethylenediamine)copper(II) Complexes

Keiko KUSHIOKA,* Iwao TANIMOTO, and Kazuhiro MARUYAMA†
Department of Food Science, Faculty of Home Economics, Kyoto Women's University, Higashiyama-ku, Kyoto 605
†Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received October 11, 1988)

2,4-Di-*t*-butylphenol (**1**) was efficiently oxidized with H_2O_2 in methanol in the presence of bis(ethylenediamine)copper(II) (Cu(II)$(en)_2$) complexes. Activity of the Cu(II) complexes was strongly dependent on the structure of the en ligands, as in the cases of the O_2 oxidation of phenol **1**.[1] In the H_2O_2 oxidation of **1**, ens having none of *N*-alkyl substituent were of the most efficient. By addition of H_2O_2, stable Cu(II)$(en)_2$ complexes exhibited a new absorption at 340 nm, which was assigned to Cu(II)-en-H_2O_2 (1 : 2 : 1) complexes. Furthermore, the rapid-scanning spectrophotometry proved that quadruple Cu(II)-en-phenol **1**-H_2O_2 (1 : 1 : 1 : 1) complexes were the key intermediate for the oxidation of **1**. The initial velocity can be summarized in the equation $v=k[H_2O_2]^1[\text{phenol } \mathbf{1}]^1[\text{Cu(II)}(en)_2]^1$. The oxidation mechanism of phenol **1** with H_2O_2 is proposed.

In the previous papers[1,2] reported on the autoxidation of phenols with molecular oxygen catalyzed by bis(*N*-alkylethylenediamine)copper(II) (abbreviated as Cu(II)(*N*-Ren)$_2$ (R=alkyl group) hereafter; the related complexes are also shown by the same type of abbreviation) complexes, we showed that the most active complexes were those derived from sterically overcrowded ens around the nitrogen atoms. This paper deals with the oxidation of 2,4-di-*t*-butylphenol (**1**) by hydrogen peroxide. Oxidation of phenols with hydrogen peroxide in the presence of Cu(II)-amine complexes has been scantly reported with exception of the hydroxylation of phenols.[3] Compared with molecular oxygen, hydrogen peroxide is a stronger oxidant and has a higher coordinating ability to copper(II). We have investigated Cu(II) complexes of a series of ens bearing *N*-alkyl or *C*-alkyl substituents to determine how the structure of en ligands affects the oxidation of phenol **1**. Only en and *C*-alkyl ens having none of *N*-alkyl substituent formed active Cu(II) complexes in this oxidation. Using such complexes, the initial stage of the oxidation was kinetically examined.

Results and Discussion

Phenol **1** was oxidized in methanol with hydrogen peroxide under a set of standard conditions (see Experimental section) except for minor deviations specified, if any. The oxidation of phenol **1** with hydrogen peroxide, as well as that with molecular oxygen,[1,2] afforded only 3,3′,5,5′-tetra-*t*-butyl-2,2′-dihydroxybiphenyl (**2**) and its oxidation product, i.e., 2,4,7,9-tetra-*t*-butyloxepino[2,3-*b*]benzofuran (**3**).

[I] Phenol Oxidation with Hydrogen Peroxide Catalyzed by Cu(II)(en)$_2$ Complexes. The results of the oxidation of phenol **1** with hydrogen peroxide in the presence of **stable** Cu(II)$(en)_2$ complexes are shown in Table 1, together with their stability constants.[4] In Tables 1 and 2, the relative oxidation activities of Cu(II)$(en)_2$ complexes are expressed as the percent yields of biphenol **2** for the first 10 min of oxidation, because the amount of benzofuran **3** produced during this period was negligible.

In the presence of the stable complexes, yields of biphenol **2** exceeded over 20% without exception, proving that hydrogen peroxide acted as a two-electron oxidant. Since oxidation was carried out under the conditions at hydrogen peroxide/phenol **1** (molar ratio) of 0.19, yields of **2** could not exceed over 19% if we would assume that one molecule of hydrogen peroxide oxidized only one molecule of phenol **1**. In

the absence of either copper(II) or en, phenol **1** was hardly oxidized to biphenol **2** under the same conditions (0.5—2.2%).

The copper(II) complexes of a series of *N,N'*-R_2ens were examined similarly (Table 2). All of the complexes were less active in the oxidation reactions. In the oxidation with molecular oxygen,[1] the less stable and tetrahedral copper(II) complexes which had alkyl branching on the carbon attached to nitrogen were the most active. The Cu(II) complexes could undergo facile coordination of phenolate anion and facile electron transfer from phenolate anion to Cu(II). Hydrogen peroxide of the high coordinating ability to Cu(II) complexes would expel diamine ligands or/and phenolate anion coordinated to Cu(II). Actually, addition of hydrogen peroxide to the concentrated methanolic solution of unstable Cu(II)(*N,N'*-(*t*-butyl)$_2$en)$_2$ complex resulted in the formation of a dark brown precipitate. The precipitate was proved to be peroxo-copper complexes with the luminol test (see Experimental section).

Too quick and exclusive replacement of diamine ligands or/and phenolate anion by hydrogen peroxide molecules in the less stable diamine complexes would block the oxidation of phenol **1**. This was confirmed by the reactions using 1:9 mixture of water and methanol as a solvent (Table 2), where yields of biphenol **2** increased by a factor of 3 to 5.[5] In the mixture, the hydrogen bond[6] between water and hydrogen peroxide would reduce concentration of hydrogen peroxide which is able to coordinate to copper complexes. Consequently, the succesive coordination of hydrogen peroxide to copper complexes would be retarded and the oxidation of phenol **1** would be facilitated. Furthermore, increase of concentration of phenol **1** in solution heightened yields of biphenol **2**, owing to impediment to the succesive coordination of hydrogen peroxide (Fig. 1). Those results indicate that the diamine complexes of copper(II) bearing both hydrogen peroxide and phenol **1** are indispensable for the oxidation of **1**.

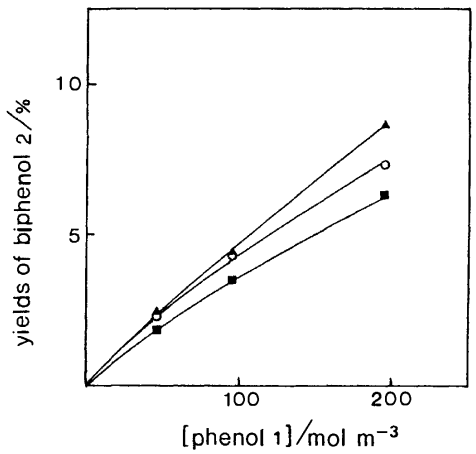

Fig. 1. Effect of phenol **1** concentration in oxidation of **1** in the presence of Cu(II)(*N,N'*-R_2en)$_2$ complexes. R: C_2H_5 ▲; *n*-C_3H_7 ■; *n*-C_4H_9 ○.

[II] The Mechanism of Oxidation of Phenol 1.

(1) Effect of en/Cu(II) Ratio. In methanolic solutions of copper(II) and ens, only 1:1 and 1:2 complexes were detected spectrophotometrically.[1] In the presence of copper(II) chloride and en, yields of biphenol **2** were affected by ratios of en to Cu(II) (Fig. 2). The maximum yield of biphenol **2** was achieved at en/Cu(II) ratio of 2/1. In the reaction at the higher ratio than 2/1, decrease of yields of **2** as well as appearance of an induction period was observed. On the other hand, in the mixtures of *N,N'*-R_2ens and Cu(II) which formed the less stable complexes, the maximum yield of **2** was achieved at the higher ratio than 2/1, but with no induction period. These observations suggest that Cu(II)(en)$_2$ complexes are the active catalysts. Excess en molecules surrounding the stable Cu(II)(en)$_2$ complex could impede the ligand exchange by hydrogen peroxide and/or phenol **1**, while, in the cases of the less stable complexes, presence of excess diamines surrounding Cu(II) may be advantageous for reproducing the active catalytic species.

(2) Spectral Studies. By addition of phenol **1**, a solution of less stable Cu(II)(*N,N'*-R_2en)$_2$ complexes exhibited a broad absorption at the region of 350—600 nm, whereas the spectrum of the stable Cu(II)(en)$_2$ complex was slightly changed by addition of **1** at 370—440 nm. Since in the latter case the absorbance at 410 nm increased with time, gradual coordination of phenol **1** to the stable Cu(II)(en)$_2$ complexes was substantiated. On the other hand, addition of hydrogen peroxide to a solution of the stable Cu(II)(en)$_2$ complexes exhibited absorption maximum at either 340 or

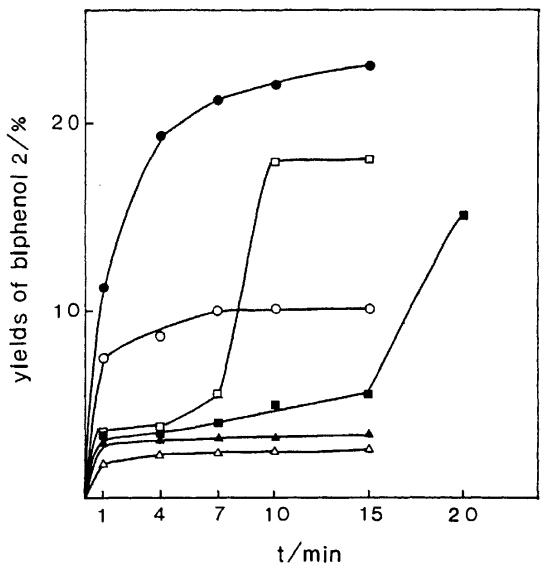

Fig. 2. Effect of en/Cu(II) ratio in oxidation of phenol **1**. en/Cu(II): 0.5 △; 1 ▲; 1.5 ○; 2 ●; 3 □; 4 ■; 2.43×10^{-3} mol of phenol **1**, 6.06×10^{-6} mol of $CuCl_2$ and 4.56×10^{-4} mol of H_2O_2 in 50 mL of methanol.

360—400 nm, which was depending on added amount of hydrogen peroxide. The absorption at 340 nm appeared at the relatively lower molar ratio of hydrogen peroxide in solution. However, examination by rapid-scanning spectrophotometry even at the higher molar ratio of hydrogen peroxide showed absorption (λ_{max} 340 nm) at the initial stage after mixing Cu(II)$(en)_2$ complex with hydrogen peroxide. Keeping the concentration of Cu(II)$(en)_2$ complex in solution at a constant, we added different amount of hydrogen peroxide and followed change of the absorbance at 340 nm by a stopped flow method. Initial increasing rate of the absorption at 340 nm was the first order with respect to initial concentrations of hydrogen peroxide (Fig. 3). Therefore, under our conditions the absorption at 340 nm was attributed to ternary Cu(II)-en-H_2O_2 (1:2:1) complexes, but not to hydroxo- or alkoxo-bridged copper(II) binuclear complexes which showed the characteristic absorption at 350—400 nm.[7] While, the absorption at 360—400 nm observed in the presence of the higher molar ratio of hydrogen peroxide would be formed via a complex showing the absorption at 340 nm. The similar broad absorption at around 360—400 nm was exhibited by addition of hydrogen peroxide to a solution of less stable Cu(II)-(N,N'-R_2en)$_2$ complexes. The absorption probably arise from Cu(II)-ens-H_2O_2 (1:1:2) complexes.

Then, applying rapid-scanning spectrophotometry, we examined appearence of an intermediate after mixing Cu(II)$(en)_2$ complex, phenol **1**, and hydrogen peroxide. By the addition of hydrogen peroxide, a solution of Cu(II)$(en)_2$-phenol **1** exhibited an absorption spectrum having maximum at 370 nm. The same spectrum appeared as well when a mixture of H_2O_2-phenol **1** was added to a solution of Cu(II)$(en)_2$ complex.[8] Thus, the absorption maximum at 370 nm could be attributed to a quadruple Cu(II)-en-H_2O_2-phenol **1** (1:1:1:1) complex. In order to examine the

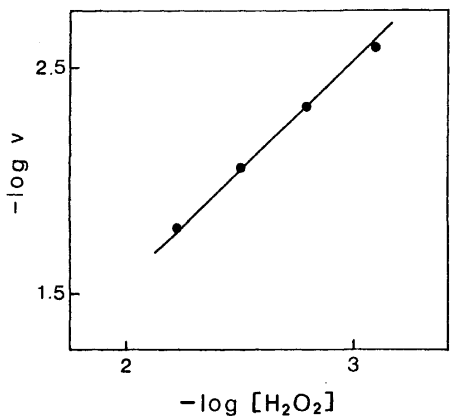

Fig. 3. Dependence of initial rate of the formation of the absorption at 340 nm on hydrogen peroxide concentration. $[CuCl_2]$=0.97 mol m^{-3}, [en]=1.94 mol m^{-3}, $[H_2O_2]$=0.76—6.06 mol m^{-3} in methanol, at 25°C.

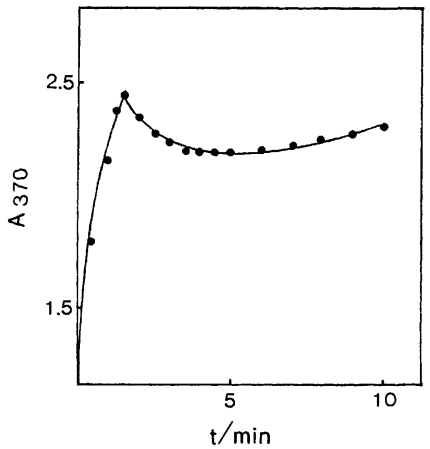

Fig. 4. Absorbance behavior at 370 nm indicating the formation of quadruple complex. 4.85×10^{-5} mol of $CuCl_2$, 9.7×10^{-5} mol of en, 2.43×10^{-3} mol of phenol **1** and 1.21×10^{-3} mol of H_2O_2 in 50 mL of methanol.

Table 3. Oxidation of Phenol **1** with Hydrogen Peroxide

$[H_2O_2]_{initial}$/mol m^{-3}	Biphenol **2**/%[a,b]
0.76	93
1.52	89
3.03	83
6.06	78

a) $[CuCl_2]$=0.121 mol m^{-3}, [en]=0.242 mol m^{-3} and [phenol **1**]=48.5 mol m^{-3}. The oxidation was carried out in methanol at 25°C for 7 min. b) Yields of biphenol **2** were estimated on the basis of hydrogen peroxide added, taking account of the experimental results that hydrogen peroxide acted as a two-electron oxidant (see Text).

formation and decay processes of the quadruple complex, the absorbance at 370 nm was traced (Fig. 4). As shown in Fig. 4, absorbance at 370 nm reached rapidly at a maximum, but falled then, and began to rise again gradually. This phenomenon indicates that besides of the quadruple Cu(II)-en-H_2O_2-phenol **1** complex the other species which has absorption at around 370 nm was accumulating in the solution with time. Actually, Cu(II)-en-biphenol **2** (reaction product)-H_2O_2 complex had absorption at around 370 nm. Thus, although exact trace of the quadruple Cu(II)-en-H_2O_2-phenol **1** complex was not carried out, it might be concluded that the quadruple complex was formed and reasonably stable.

On the other hand, addition of hydrogen peroxide to a solution containing unstable Cu(II)(N,N'-R_2en)$_2$ complexes and phenol **1** exhibited similarly the absorption at about 370 nm, but it disappeared within about 0.1 s. The instability of Cu(II)-N,N'-R_2en-H_2O_2-phenol **1** complexes might be responsible for less activity in the oxidation of **1**.

(3) Kinetic Studies. The kinetics were studied in the presence of the stable Cu(II)$(en)_2$ complex. The initial rate (v) of the reaction ([biphenol **2**]$_{initial}$/min^{-1})

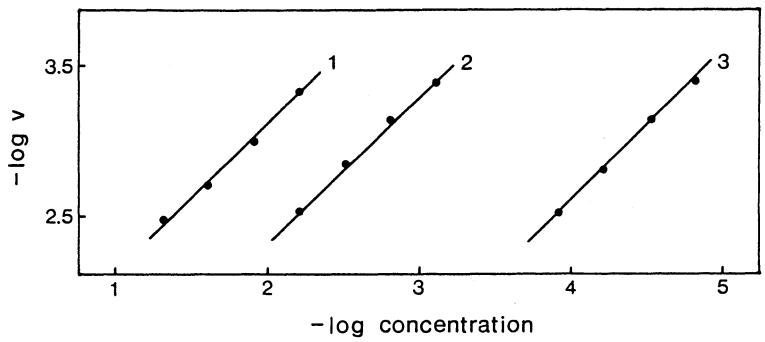

Fig. 5. Kinetic plots.
1: [phenol **1**]=6.06—48.5 mol m^{-3}, 2: [H_2O_2]=0.76—6.06 mol m^{-3}, 3: [Cu(II)-en]=1.52×10^{-2}—1.21×10^{-1} mol m^{-3}. Other conditions were as follows: [phenol **1**]=48.5 mol m^{-3}, [H_2O_2]=6.06 mol m^{-3} and [Cu(II)-en]=0.121 mol m^{-3} in methanol at 25 °C.

was determined. The initial rate increased linearly with concentration of hydrogen peroxide. From plots of log v against log [H_2O_2], the dependence on [H_2O_2] is of the first order. The dependence on [phenol **1**] and [Cu(II)(en)$_2$ complex] are also of the first order, respectively (Fig. 5). From those results, the following empirical rate expression was deduced.

$$v = k[H_2O_2]^1[\text{phenol } \mathbf{1}]^1[\text{Cu(II)(en)}_2 \text{ complex}]^1$$

Consequently, the kinetic results as well as spectral data indicate that under our conditions the oxidation of phenol **1** was not catalyzed by copper(II)-binuclear complexes.

The Cu(II)-en complex catalyzes decomposition of hydrogen peroxide.[9] Therefore, in the kinetic studies of the oxidation, we controlled conditions so that the oxidation of **1** can exclusively proceed (see Experimental section).

(4) Control Experiments. To determine whether free hydroxyl or hydroperoxyl radical which might be generated in our reactions could oxidize phenol **1** to biphenol **2**, first we attempted oxidation of **1** with free hydroxyl radical produced by photodecomposition of hydrogen peroxide.[10] After irradiation of the methanolic solution containing hydrogen peroxide and phenol **1** for 2 h, about 50% of hydrogen peroxide was decomposed. However, phenol **1** was wholly recovered and no oxidation product was detected by high performance liquid chromatography and by thin layer chromatography. Prior to the oxidation of **1**, hydroxyl radical would be quenched by methanol.[11]

Secondly, the decomposition of hydrogen peroxide catalyzed by Cu(II)(en)$_2$ complexes was studied in the absence of phenol **1**. The results are shown in Table 4, together with yields of biphenol **2** obtained in the studies of the oxidation of **1**. The less stable Cu(II)-(*N*,*N*′-R$_2$en)$_2$ complexes decomposed hydrogen peroxide efficiently, but were less active in the oxidation of **1**. In the stable Cu(II)(en)$_2$ complexes, yields of **2** exceeded considerably those expected to be produced by the decomposition products of hydrogen peroxide. While hydrogen peroxide in the presence of various metal ions (including copper(II)) or their complexes has been reported to oxidize 4-substituted phenols to hydroperoxidation products at the 4-position,[12] none of hydroperoxidation products was detected in the present studies.

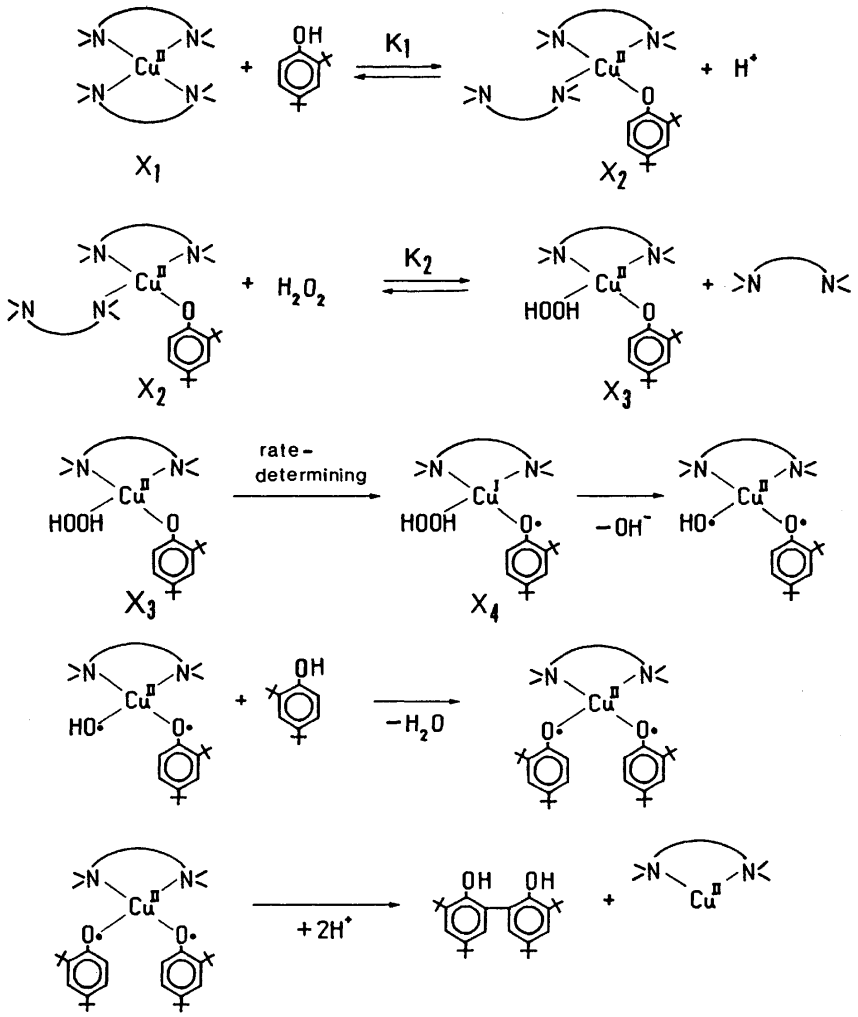
Table 4. Decomposition of Hydrogen Peroxide Catalyzed by Cu(II)(en)$_2$ Complexes. Control Experiments

Diamine	Decomposition[a] H_2O_2/%	
less stable Cu(II)-complex		
$(CH_3NH\text{-}CH_2\rangle_2$	84	[7.7][b]
$(n\text{-}C_3H_7NH\text{-}CH_2\rangle_2$	80	[5.0]
$(n\text{-}C_4H_9NH\text{-}CH_2\rangle_2$	75	[6.4]
stable Cu(II)-complex		
$(dl\text{-}H_2N\text{-}CHCH_3\rangle_2$	33	[60]
$(H_2N\text{-}CH_2\rangle_2$	44	[56]
$(meso\text{-}H_2N\text{-}CHCH_3\rangle_2$	38	[56]

a) The decomposition of hydrogen peroxide was examined in the absence of **1**. The conditions were the same as those used in b), except for **1**. b) The yields of biphenol **2** in the oxidation of **1** under standard conditions.

In conclusion, under our conditions, phenol **1** was not oxidized with decomposition products of hydrogen peroxide, e.g., free hydroxyl or hydroperoxyl radical. Oxidation of **1** was achieved within the coordination sphere of the quadruple Cu(II)-en-H_2O_2-phenol **1** complex.

(5) The Mechanism of Oxidation of Phenol 1. The oxidation of phenol **1** was carried out within the coordination sphere of mononuclear Cu(II)-en-H_2O_2-phenol **1** complex and two molecules of **1** for each molecule of hydrogen peroxide was oxidized to biphenol **2**. The reaction sequence consisting with these results and kinetics as well as the spectral data is given in Scheme 1. Spectroscopic studies demonstrated similarly that under our conditions the quad-



Scheme 1.

ruple complex $\mathbf{X_3}$ was produced via the coordination of **1** to Cu(II)-diamine complex $\mathbf{X_1}$. The formation of the quadruple complex $\mathbf{X_3}$ depended on the molar ratio of hydrogen peroxide to phenol **1**. A large excess of **1** would hinder coordination of hydrogen peroxide to Cu(II)-diamine-phenol **1** complex $\mathbf{X_2}$ and bring about an induction period into the whole sequence of reactions. On the contrary, for excess of hydrogen peroxide, yields of biphenol **2** were lowered with increasing concentration of hydrogen peroxide. Cu(II)-en-H_2O_2 (1 : 1 : 2) complex[9c] which is responsible for the decomposition of hydrogen peroxide would be formed in competition with the quadruple complex $\mathbf{X_3}$.

After forming the quadruple complex $\mathbf{X_3}$, phenolate anion would transfer an electron to hydrogen peroxide through copper.[13] The redox potential of Cu(II) complexes having two nitrogen donors is optimum for reduction of Cu(II).[9c] While, hydrogen peroxide is reduced with the generation of hydroxyl radical. The radical was not quenched by methanol because of the coordination with Cu(II) complex and oxidized another molecule of **1** by the participation of copper-(II). The whole process in which one molecule of hydrogen peroxide oxidized two molecules of **1** is consistent with the experimental results.

In the reaction, the reduction process of hydrogen peroxide of complex $\mathbf{X_4}$ might be rate-determining step, but this could be unlikely judging from redox potentials of both copper(II) complexes[14] and hydrogen peroxide. Then we assumed that complexes $\mathbf{X_1}$, $\mathbf{X_2}$, and $\mathbf{X_3}$ were in fast equilibrium and the process in which phenolate anion of the quadruple complex $\mathbf{X_3}$ transferred an electron to Cu(II) was the rate-determining step. By the assumptions a rate expression is deduced as follows,

$$v = k'[\text{complex } \mathbf{X_3}] \quad (1)$$

$$K_1 = [\text{complex } \mathbf{X_2}][H^+]/[\text{complex } \mathbf{X_1}][\text{phenol } \mathbf{1}]$$
$$K_2 = [\text{complex } \mathbf{X_3}][\text{en}]/[\text{complex } \mathbf{X_2}][H_2O_2]$$
$$K_1K_2 = [\text{complex } \mathbf{X_3}][H^+][\text{en}]/[\text{complex } \mathbf{X_1}][\text{phenol } \mathbf{1}][H_2O_2] \quad (2)$$

from Eqs. 1 and 2

$$v = k'K_1K_2[H_2O_2][\text{phenol } \mathbf{1}][\text{complex } \mathbf{X_1}]/[H^+][\text{en}] \quad (3)$$

Since all complexes in Scheme 1 were catalytic species,

they would be in low concentrations and in steady state. Then, $[H^+]$ and [en] which were mainly subjected to the respective concentrations of complexes $\mathbf{X_1}$ and $\mathbf{X_2}$ would be constant.

$$v = k''[H_2O_2][\text{phenol } \mathbf{1}][\text{complex } \mathbf{X_1}] \quad (4)$$

The rate expression (Eq. 4) consists with the foregoing empirical rate expression.

Experimental

GLC analyses were carried out on a JEOL Model JGC-20K equipped with 3% Apiezone L grease on Celite 545 NAW column. HPLC analyses were performed using methanol as a eluent on a Shimadzu Model LC-3A liquid chromatograph with Zorbax ODS column. Ultraviolet and visible spectra were taken using a Shimadzu UV-300 spectrophotometer. Stopped flow method and rapid scan technique were performed on an Otuka Denshi RA-401 stopped flow system equipped with RA-415 rapid scan system, gas driving device and RA-451 data processor. Temperature of a thermostat used in the kinetic measurement was controlled (±0.15 °C) by using a Komatsu-Yamato Coolnics CTR-220. Spectrophotometric determination of hydrogen peroxide was performed on a Shimadzu Model Double-Beam Spectrophotometer UV-140-02. The photoreactions were carried out on a Eichosha PIL-120, a low-pressure mercury lamp with quartz housing: $\Phi = 7.74\times10^{-5}$ (using a potassium tris(oxalato)ferrate(III) actinometer) in the decomposition reaction of hydrogen peroxide under the conditions used.

Materials. Anhydrous copper(II) chloride was prepared by heating the dihydrate in an oven at 100 °C for 20 h. Hydrogen peroxide (30%) was obtained from Santoku Kagaku Kogyo Co. and concentration was determined by iodometry before use. *dl*- And *meso*-2,3-butanediamine,[15] *N,N'*-dipropyl- and *N,N'*-dibutylethylenediamines (*N,N'*-(propyl)$_2$en and *N,N'*-(butyl)$_2$en)[16] and 3,3',5,5'-tetra-*t*-butyl-2,2'-dihydroxybiphenyl (**2**)[17] were prepared by procedures given in literatures.

Standard Conditions. Oxidation of 2,4-Di-*t*-butylphenol (1). Phenol **1** (2.43×10^{-3} mol) and the en (1.21×10^{-5} mol) were dissolved in methanol, and the volume was made up to 50 mL by adding methanol. Under a nitrogen atmosphere, anhydrous copper(II) chloride (6.06×10^{-6} mol) and hydrogen peroxide (4.56×10^{-4} mol) were added successively to the mixture and the oxidation was conducted at 25 °C for 10 min. The products were only biphenol **2** and its oxidation product, 2,4,7,9-tetra-*t*-butyloxepino[2,3-*b*]benzofuran (**3**).[1] The yields of product **2** were determined by GLC.

The Luminol Test. Addition of hydrogen peroxide (4.85×10^{-3} mol) to the methanolic solution (100 mL) containing anhydrous copper(II) chloride (9.7×10^{-5} mol) and *N,N'*-(*t*-butyl)$_2$en (1.94×10^{-4} mol) resulted in a precipitate, which was separated by centrifugation. The precipitate was thoroughly washed with methanol to remove free hydrogen peroxide and suspended in methanol. The suspension of the precipitate produced luminescence by addition of the luminol reagent.[18]

Effect of en/Cu(II) Ratio. In the presence of Cu(II)-en mixtures of various ratios, phenol **1** was oxidized under standard conditions.

Spectral Studies. Ultraviolet and Visible Absorption Spectra: In various combinations of phenol **1** (4.85×10^{-4} mol), biphenol **2** (2.43×10^{-4} mol), anhydrous copper(II) chloride (9.7×10^{-6} mol), the en (1.94×10^{-5} mol), and hydrogen peroxide (4.85×10^{-4}—7.6×10^{-6} mol), the absorption spectra of a methanolic solution (10 mL) of the mixture were taken using a spectrophotometer.

Rapid Scanning Spectra: Conditions were the same as those used in ultraviolet and visible absorption spectra, and the absorption spectra at 295—485 nm were obtained using a stopped flow system at 25 °C.

Formation Kinetics of the Absorption at 340 nm by Stopped-Flow Method: Concentrations of anhydrous copper(II) chloride (0.97 mol m^{-3}) and en (1.94 mol m^{-3}) were kept constant and concentration of hydrogen peroxide was varied from 0.76 mol m^{-3} to 6.06 mol m^{-3}. The change of the absorbance at 340 nm was followed by a stopped flow system at 25 °C. In every case, the result was accumulated about 10 times.

Absorbance Behavior at 370 nm: Phenol **1** (2.43×10^{-3} mol) and en (9.7×10^{-5} mol) were dissolved in 50 mL of methanol. Under a nitrogen atmosphere, anhydrous copper(II) chloride (4.85×10^{-5} mol) and hydrogen peroxide (1.21×10^{-3} mol) were added successively to the mixture at 25 °C. The sample was taken out of the reaction solution and the absorbance at 370 nm was measured on a spectrophotometer.

Kinetic Measurements. Bis(ethylenediamine)copper(II) complexes catalyzed both the oxidation of phenol **1** with hydrogen peroxide and the decomposition of hydrogen peroxide. For the purpose of carrying out the oxidation of **1** exclusively (Table 3), concentration of hydrogen peroxide was lowered from that under standard conditions by a factor of 2/3. Other conditions were the same as standard. The initial rate of the reaction ($[\text{product } \mathbf{2}]_{\text{initial}}/\text{min}^{-1}$) was determined by GLC.

Control Experiments. Photoreaction: Phenol **1** (1.21×10^{-2} mol) was dissolved in methanol, and the volume was made up to 250 mL by adding methanol. The solution was then placed in an inside-irradiation-type reaction flask equipped with a low-pressure mercury lamp. Under a nitrogen atmosphere, hydrogen peroxide (2.28×10^{-3} mol) was added to the solution and the irradiation was conducted at 30 °C for 2 h. The reaction mixture was analyzed by TLC (HPTLC-Fertigplatten Kieselgel 60 F_{254} Merck/benzene). Phenol **1** and biphenol **2** were determined by HPLC. The rate of decomposition of hydrogen peroxide was determined by iodometry.

Decomposition of Hydrogen Peroxide in the Absence of Phenol 1: Conditions were the same as those used in the oxidation, except for absence of **1**. The samples were taken out of the reaction solution and mixed with titanium(IV) chloride in 6 mol dm^{-3} HCl. The absorbance of titanium-H_2O_2 complex was measured at 450 nm on a spectrophotometer.[19]

Induced Circular Dichroism Spectrum of α-Cyclodextrin Complex with Heptylviologen

Masato KODAKA* and Toshio FUKAYA
National Chemical Laboratory for Industry, Higashi, Tsukuba 305
(Received October 15, 1988)

The rotational strength of α-cyclodextrin (α-CDx) complex with heptylviologen (1,1′-diheptyl-4,4′-bipyridinium dibromide) was calculated by using the Kirkwood-Tinoco expression. The calculation shows that electric transition polarized along the long axis of heptylviologen gives negative induced circular dichroism (ICD) whereas the short-axis polarized transition gives positive ICD, when HV is axially included in α-CDx and the electric transition moment is located out of the cavity of α-CDx (above the narrower rim). From the comparison between the experimental and calculated results, it is concluded that the heptyl chain of heptylviologen is involved in the cavity while the pyridinium part is situated out of the cavity.

Induced circular dichroism (ICD) has been frequently used to determine the orientation of the aromatic molecule included in α-, β-, and γ-CDx's.[1-6] The theoretical calculation undertaken thus far is based on the expression developed by Kirkwood and Tinoco, and the agreement between the calculated and experimental results is fairly good.[1-4]

The calculation presented the general rule that the transition with an electric dipole moment parallel to the axis of CDx gives a positive ICD while the transition with an electric dipole moment perpendicular to the axis of CDx gives a negative ICD.[1-4] Although many experimental data have been analyzed using this rule, we must remember that this rule is applicable only when a chromophore is situated in the cavity of CDx. There has been no calculation dealing with the complex with the chromophore outside the cavity. For example, the complex between α-CDx and heptylviologen (4,4′-diheptyl-1,1′-bipyridinium dibromide; HV) gives negative ICD,[7] although HV seems to be axially included and the electric transition moment is expected to be parallel to the long axis of HV molecule. The observed ICD spectrum cannot be explained by the general rule described above. In the present study, therefore, the calculation is extended to the outside region of CDx.

Theoretical

The theoretical rotational strength of the transition from the ground state (0) to the excited state (a), R_{0a}, was calculated by the same method as that of Harata et al.,[1] using the following Kirkwood-Tinoco expression.[8]

$$R_{0a} = \pi \nu_a \mu_{0a}^2 \sum_j \frac{\nu_{0j}^2(\alpha_{33} - \alpha_{11})_j (\mathrm{GF})_j}{c(\nu_{0j}^2 - \nu_a^2)}$$

$$(\mathrm{GF})_j = \frac{1}{r_j^3}\left[\vec{e}_{0a} \cdot \vec{e}_j - \frac{3(\vec{e}_{0a} \cdot \vec{r}_j)(\vec{e}_j \cdot \vec{r}_j)}{r_j^2}\right]\vec{e}_{0a} \times \vec{e}_j \cdot \vec{r}_j$$

Here $\vec{e}_j$ is the unit vector in the direction of the symmetry axis of the bond j in α-CDx; $\vec{r}_j$ is the vector directed from the center of the chromophore (bipyridinium moiety) to the bond j in α-CDx; ν_{0j} is the frequency of the electric transitions of the bond j in α-CDx; $\vec{e}_{0a}$ is the unit vector in the direction of the electric dipole moment (μ_{0a}) of the transition from the ground state (0) to the excited state (a) in the chromo-

phore, and ν_a is its frequency; α_{33} and α_{11} are bond polarizability at zero frequency parallel and perpendicular, respectively, to the symmetry axis of the bond in α-CDx; c is the velocity of light.

The values of α_{33}, α_{11},[9,10] and ν_{0j}[1] are shown in Table 1. The assignment of the electronic transition of HV was undertaken by the CNDO/S-CI calculation. The electric transition moment was put at the center of the bipyridinium moiety. The geometry of α-CDx was derived from the X-ray data of the α-CDx-potassium acetate complex.[11] The axes of the coordinates were defined as shown in Fig. 1, where the origin of the coordinates was fixed on the plane determined by the six O_4 atoms. All the C_6-O_6 and O-H bonds were neglected owing to the flexibility. Furthermore, the effects of all the C-H bonds were neglected, for they may have isotropic polarizability.[12]

Results and Discussion

As the angle of twist (θ) around the central C-C bond of HV cannot be determined unequivocally, it seems to be appropriate that the CNDO/S-CI calculation is done at each point corresponding to the planar and angular conformations. In the case of biphenyl, the angle θ is about 42° in the gaseous phase,[13,14] while it is planar in the crystalline state.[15] On the other hand, in solution θ is 23°.[16] Taking into account these results about biphenyl, θ of HV is expected to be about 0—45°. And so we have undertaken the MO calculation about the three conformations (θ=0°, 22.5°, and 45°), with the central C-C bond length of HV fixed to 1.48 Å. For the pyridinium rings, all the C-N and C-C bond lengths and all the bond angles were assumed to be similar to those of benzene ring. The other bond lengths and bond angles were estimated from the standard values. In the CI calculations, 60 singly-excited configurations were taken into consideration. In Table 2 are summarized the calculated wavelengths and symmetries of the lower singlet states together with the oscillator strengths. The symmetries were determined on the assumption that HV has D_{2h} conformation for ϕ=0° and D_2 conformations for ϕ=22.5° and 45°. In the wavelength region under consideration, there can be seen three transitions. In these transitions, the $A_g \rightarrow B_{3u}$ (or $A \rightarrow B_3$) transition has the largest intensity, with its moment directed along the long axis of HV. On the other hand, the oscillator strength of the $A_g \rightarrow B_{2u}$ (or $A \rightarrow B_2$) transition is only ca. 40% of that of the $A_g \rightarrow B_{3u}$ (or $A \rightarrow B_3$) one, and the $A_g \rightarrow B_{1g}$ (or $A \rightarrow B_1$) transition is negligible as compared with the $A_g \rightarrow B_{3u}$ (or $A \rightarrow B_3$) transition. Experimentally HV has the absorption at 264 nm (D=38.4 debye^2), while the CNDO/S-CI calculation reproduced reasonable wavelengths and dipole strengths (the $A_g \rightarrow B_{3u}$ or the $A \rightarrow B_3$ transition); λ=266 nm and D=51.0 debye^2 at θ=0°, λ=261 nm and D=48.0 debye^2 at θ=22.5°, λ=250 nm and D=40.0 debye^2 at θ=45°; with the corresponding electric transition moments along the long axis of HV molecule.

In Fig. 2 is shown the dependence of the rotational strength of α-CDx-HV complex on the Z coordinates, with the X and Y coordinates fixed to be 0 Å. The electric transition moment is rotated in the X-Z plane by the angle ϕ as shown in Fig. 1. Inside the cavity of α-CDx, the large positive ICD is given at ϕ=0° (maximun; 36.3×10^{-40} cgs at Z=−0.5 Å) and the negative ICD at ϕ=90° (minimum; -17.7×10^{-40} cgs at Z=−0.6 Å). These results agree qualitatively with those for β-CDx complex obtained by Harata et al.[1] On the other hand, outside the cavity the sign of the ICD value is reversed, especially remarkably on the side of the primary hydroxyl groups (narrower rim) of α-CDx, with minimum at ϕ=0° (-19.6×10^{-40} cgs at

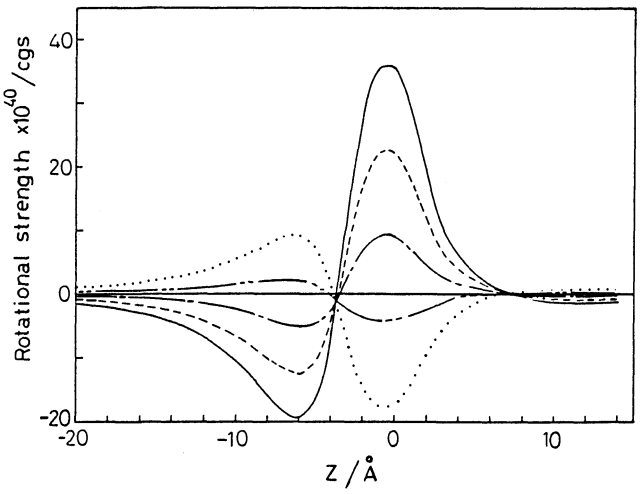

Fig. 2. The dependence of the calculated rotational strengths of α-CDx-HV complex on the Z coordinates (X=Y=0 Å). The directions of the electric transition moment(the angle ϕ) are 0° (——), 30° (----), 45° (-·-·-), 60° (— — —), 90° (·····).

Z=−6.1 Å) and maximum at ϕ=90° (9.2×10^{-40} cgs at Z=−6.4 Å). As shown in the previous report, methylviologen (1,1′-dimethyl-4,4′-bipyridinium dichloride) does not give ICD, while HV with hydrophobic alkyl chains gives negative ICD (R=-5.7×10^{-40} cgs) at 257 nm. It is suggested that in the case of HV the heptyl chain is included in the cavity of α-CDx and the bipyridinium part is placed outside the cavity.[7] This speculation is compatible with the calculated results shown in Fig. 2. Although there is a possibility that the $A_g\rightarrow B_{2u}$ (or $A\rightarrow B_2$) transition with the short-axis polarization may contribute to the positive rotational strength, the value must be about five times smaller than that due to the $A_g\rightarrow B_{3u}$ (or $A\rightarrow B_3$) transition in view of the results shown in Table 2 and Fig. 2. Consequently, the contribution from the $A_g\rightarrow B_{2u}$ (or $A\rightarrow B_2$) transition seems to be negligible.

Figures 3—5 show the rotational strength calculated with moving the position of the electric transition moment of HV in the X-Y plane, concerning the narrower rim region of α-CDx ($Z\leqq-4$ Å). In these figures, the left-hand figures indicate the rotational strength maps for the α-CDx-HV complex at various ϕ values. The maps are drawn on the rectangular region containing the X and Y-axes, the electric transition moment being parallel to the X-Z plane with a given rotation angle ϕ. The right-hand figures in Figs. 3—5 show the approximate negative ICD region (black region). When Z=−4.0 Å and ϕ=0° (Fig. 3 (a)), the negative region(black) is located in the centre of the map while the positive area (white) is far from the centre. As ϕ increases, the negative region shifts to the surroundings (Fig. 3 (b), (c)) and at last the central area becomes positive at ϕ=90° (Fig. 3 (d)). Similar tendencies are found in the case of Z=−6.0 Å and Z=−8.0 Å (Figs. 4 and 5). The rotational strength maps for Z=−6.0 Å and Z=−8.0 Å are relatively simple and resemble each other, whereas those for Z=−4.0 Å is more complicated (Fig. 3). Although the distribution of the positive area varies with the Z and ϕ values, it can be estimated qualitatively from Figs. 3—5 that the long axis of HV is nearly parallel to the axis of α-CDx, probably $0\leqq\phi<$ ca. 30°, and the centre of HV is not so

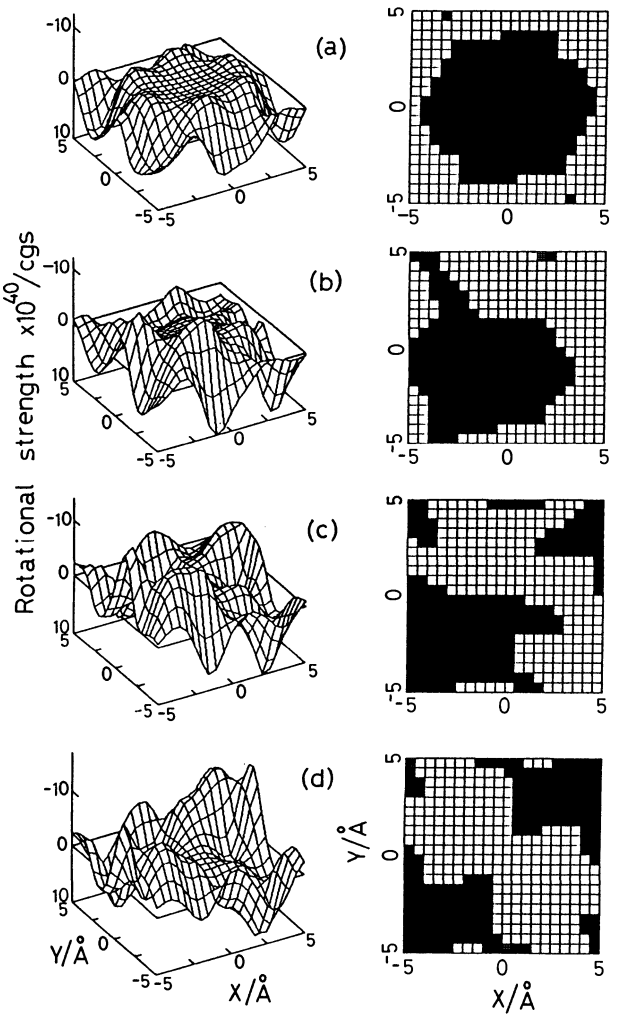

Fig. 3. The rotational strength maps for the α-CDx-HV complex at Z=−4.0 Å. (a) ϕ=0°, (b) ϕ=30°, (c) ϕ=60°, (d) ϕ=90°. The black area of the right-hand figures shows the approximate negative ICD region.

far from the axis of α-CDx, perhaps within 4—5 Å.

From the calculation undertaken in the present study, it can be said qualitatively that when a chromophore is placed outside the cavity of CDx (especially above the narrower rim), the transition with an electric dipole moment nearly parallel to the axis of CDx gives a negative ICD and the transition with perpendicular polarization gives a positive ICD. This rule is quite the reverse of the general rule presented by Harata et al. for the chromophore included in the inner region of β-CDx.[1] The estimated structure of the α-CDx-HV complex is schematically depicted in Fig. 6.

Recently CDx derivatives which bear aromatic groups bound to the primary hydroxyl groups (narrower rim) have been studied by using CD spectra, as models of host-guest phenomena.[17-20] The findings obtained in the present study may be also useful for analyzing such CDx derivatives.

The authors wish to thank Dr. Kazutoshi Tanabe, National Chemical Laboratory for Industry, for his kind supply of the CNDO/S-CI program.

2-Chloro- or 2-methoxytropone reacts with *o*-phenylenediamine to give 2-(*o*-aminoanilino)tropone, which upon heating provides 6*H*-cyclohepta[*b*]quinoxaline (**10a**). Upon acidification, **10a** reversibly gives a green cation, **9a**. **10a** is easily converted, especially under basic conditions, into the oxidative dimer **16a**, which reproduces **9a** by reduction with Zn in acetic acid. The isopropyl derivatives of these compounds are prepared by the same method from 5-isopropyl-2-methoxytropone. The 5-methyl (**21a**) and 5,11-dimethyl derivatives **23** are made by the reaction of 2-chloro- or 2-methoxytropone with *N*-methyl- and *N,N'*-dimethyl-*o*-phenylenediamines. However, the methylation of **21a** with methyl fluorosulfate affords 5,11-dihydro-8,11-dimethyl-6*H*-cyclohepta[*b*]quinoxaline-5,6-sultone. H_2O_2 oxidation of **10a** mainly gives **16a** in addition to a small quantity of 6*H*-cyclohepta[*b*]quinoxalin-6-one. Compound **21a** is stable under basic conditions, but **23** rearranges under alkaline conditions to give, among other unidentified products, *N*-methyl-*N*-[*o*-(methylamino)phenyl]benzamide and 5,10-dihydro-5,10-dimethyl-2-phenazinecarbaldehyde. Reactions of title compounds with alkali and hydrogen peroxide are compared with those of *O*- and *S*-analogues.

One of the authors (T.N.) and his co-workers reported about thirty years ago that reactions of 5-nitroso- and 5-arylazotropolone (**1a,b**) with *o*-phenylenediamine (**2a**) gave quinoxaline derivatives (**3a,b**), which were considered to have quinonoid structures.[3] They subsequently found[4] that the reactions of 2-chloro- and 2-methoxytropone (**4a,b**) with **2a** afforded pale-violet crystals **A**, which, on catalytic reduction, produced **6a** and **7a** almost quantitatively.[4,5] They presumed that **A** was 5*H*-cyclohepta[*b*]quinoxaline (**5a**), which they named "benzo[*b*]tropazine."[4] However, they could not determine the position of the H-atom of **5a,b**, because NMR spectroscopy was not available at that time. Furthermore, they found that the reaction of 3-carboxytropolone (**4c**) with *o*-phenylenediamine (**2a**) and its methyl homologue (**2b**) produced **A** and its methyl derivative **B**, respectively. The former gave **6a** and **7a**, and the latter afforded their respective methyl derivatives (**6b** and **7b**) upon catalytic reduction. They attempted to purify the colored

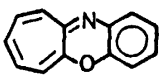
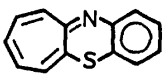
product **A** by using an alumina column chromatography and obtained colorless crystals **C** that were sparingly soluble in the usual organic solvents. They then considered that **C** was pure "benzo[*b*]tropazine" (**5a**).

In 1971, Fukunaga reported[5] that the reaction of ethoxytropylium tetrafluoroborate (**8**) with *o*-phenylenediamine (**2a**) and its dimethyl derivative (**2c**) gave greenish-black crystals **9a,c**, which upon basification produced neutral species **10a,c** that reverted to **9a,c** quantitatively upon acidification.[5] He believed that the structure of **10** was the quinoxaline form, and **9** existed as a resonance-stabilized (aromatic) peripheral 16 π electron system on the evidence of detailed NMR studies. He also recognized that **10** was easily dimerized oxidatively during alumina chromatography and suggested that the colorless product **C** obtained by Nozoe[4] was an oxidative dimer derived from **10a**; however, its structure was not studied.[5]

Recently, we reported in detail on cyclohepta[*b*]-[1,4]benzoxazine (**11**)[6] and its *S*-analogue (**12**);[7] we also reexamined previous studies on "benzo[*b*]tropazine"[4] because before-mentioned Fukunaga's research[5] has remained unpublished. In this report we wish to describe the detailed study on reactions of the reactive troponoids **4a,b,d** with *o*-phenylenediamine (**2a**) and its derivatives (**20a,b**).



11



12

Results and Discussion

We first observed the reaction of **4a** with **2a** in EtOH by using time-dependent HPLC by the same method as in the case of the *S*-analogues.[8] It was found that

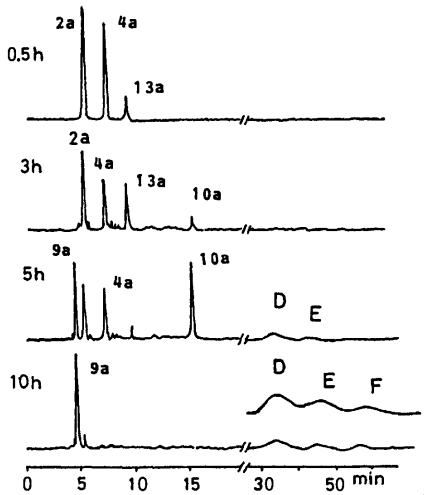


Fig. 1. Time-dependent HPLC chromatograms of the reaction mixture of **4a** with **2a** in EtOH at 80 °C.

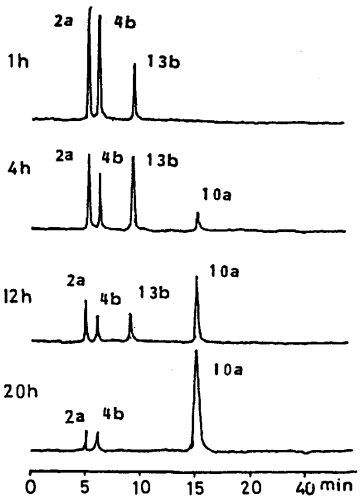

Fig. 2. Time-dependent HPLC chromatograms of the reaction mixture of **4b** with **2a** in EtOH at 80 °C.

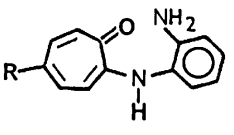
2-(*o*-aminoanilino)tropone (**13a**) formed at an early stage of the reaction was gradually transformed into **10a** and highly polar **9a**. Finally, **13a** and **10a** almost disappeared; in addition to the main peak of polar **9a**, broad peaks with retention time (RT) 32 min (**D**), 44 min (**E**), and 57 min (**F**) appeared (see Fig. 1).

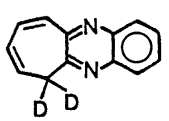
A similar reaction of **4b** with **2a** under nitrogen looked very simple chromatographically, giving **13a** and **10a** in good yields without the formation of **9a** and **D**, **E** (Fig. 2).

Compound **13a**, obtained as yellow needles, mp 183 °C, by the reaction of **4b** with **2a** in a sealed tube at 80 °C, was identified as 2-(*o*-aminoanilino)tropone on the basis of its IR, UV, NMR, and mass spectra, as well as elemental analysis; for assignments of the spectral signals, see the Experimental section. Upon further heating at 120 °C in a sealed tube, **13a** gave the dehydrated product as pale-yellow needles mp 69 °C, *m/z* 194 (M^+). This product was confirmed spectroscopically to exist in the quinoxaline form **10a**;[5] a methylene proton signal appeared at δ 3.59 (NMR), NH absorption was not seen in the IR and NMR spectra, and there was no absorption in the visible region.

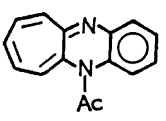
Although the exitence of the tautomeric form **5a** ("benzo[*b*]tropazine") could not be detected spectroscopically, upon treatment of **10a** with MeOH-d_4 and a small amount of triethylamine at 40 °C, the H_2-6 signal gradually disappeared, presumably giving rise to the formation of deuterio compound **14** via "enamine" form **5a**.



13a: R=H
b: R=i-Pr



14



15

When **10a** (RT, 15 min) was heated in acetic anhydride containing a small amount of 1,4-diazabicyclo-[2.2.2]octane (Dabco) under nitrogen, we could observe (in the HPLC diagram) a new peak (RT, 12 min), having UV absorption maxima at 225, 253, and 385 nm and *m/z* 236 (M^+) corresponding to the *N*-acetyl derivative **15**; the exact structure of **15**, however, could not be confirmed because of its instability.

On acidification of both **13a** and **10a** were converted into a dark-green salt **9a**, which showed considerably long-wavelength absorption bands at 564, 616, 670, and 752 nm (log ε 3.01, 2.91, 2.83, and 2.34), in addition to the three intense absorption bands (449, 464, and 491 nm) in the visible region (Fig. 3). The ^{1}H NMR spectrum of **9a** consisted of five 2H signals and a 1H signal (at δ 6.04, t, *J*=9.5 Hz, H-8), indicating a symmetric structure. Neutralizing of **9a** with alkali under nitrogen gave **10a** quantitatively, however, an oxidative dimeric product **16a** was gradually formed by the same treatment under aerobic conditions. Compound **16a** was also formed when **10a** was passed through an alumina column[5] or underwent heating in EtOH (in this case, giving rise to two other products **E** and **F**, presumably oxidative oligomers of **10a** as well.) When **9a** and **10a** were (separately) treated with a base in open air, the former produced **16a** much faster than the latter, suggesting that **16a** was formed by the dimerization of radical **17**, that may be more readily derived from the diazinium form **9a** than from the 6*H*-cyclohepta[*b*]quinoxaline form **10a** (Scheme 1). Compound **16a** showed a UV spectrum similar to that of **10a**. The ^{1}H NMR spectrum of **16a** closely resembled that of **10a**, with the exception of the presence of a methine proton signal at δ 4.59 (instead of the H_2-6 signal of **10a** at δ 3.59), indicating also a symmetric structure. In the mass spectrum there are no fragment peaks between *m/z* 386 (M^+) and *m/z* 193 (M^+−193); we could therefore conclude that **16a** is the dehydro dimer (2H less in mass) of **10a**. Reduction of **16a** with Zn in AcOH was found to reproduce **9a** quantitatively. Heating of **16a** at 220 °C under vacuum gave **10a** and a reddish-brown substance, the latter being presumed a fulvalene derivative **19** on the basis of mass spectrometry [*m/z* 384 (M^+)] and UV spectrum; carbene **18** formed by disproportionation of radical **17** is suggested as the most likely intermediate to give **19** (Scheme 1). From the experimental evidence described so far, we now consider that colorless crystals **C**[4] must have been the dimer **16a**, as speculated by Fukunaga.[5] Further, the soluble, slightly colored substace used for the catalytic reduction[4] to give **6a** and **7a** was in fact pure **10a**, because our experimental results appear to be compatible with the Fukunaga's structures **9a** and **10a**[5] (except for their electronic structure).[9]

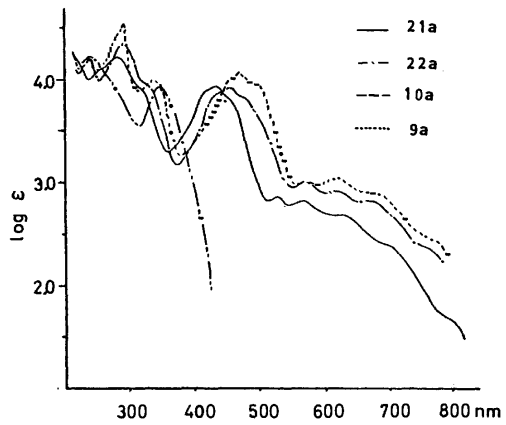


Fig. 3. Electronic spectra of some cyclohepta[*b*]quinoxalines in MeOH.

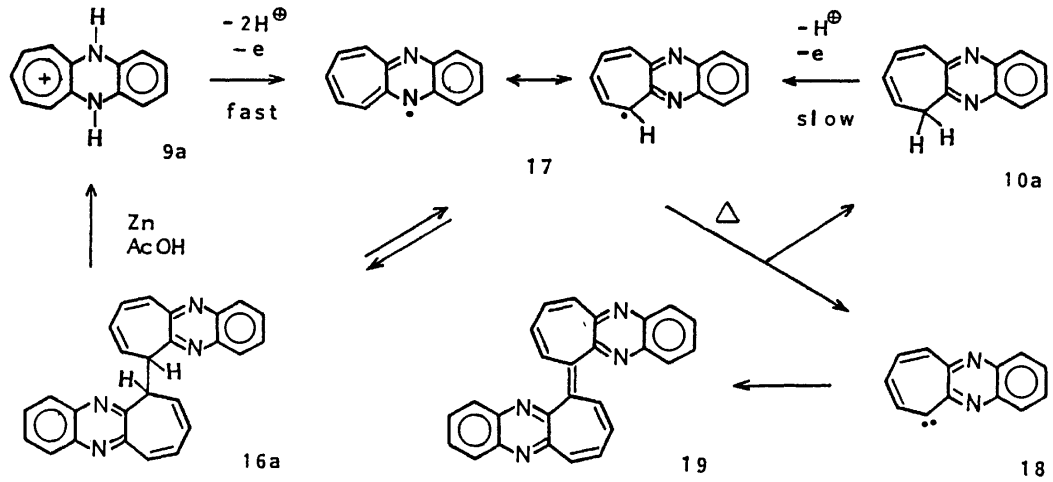
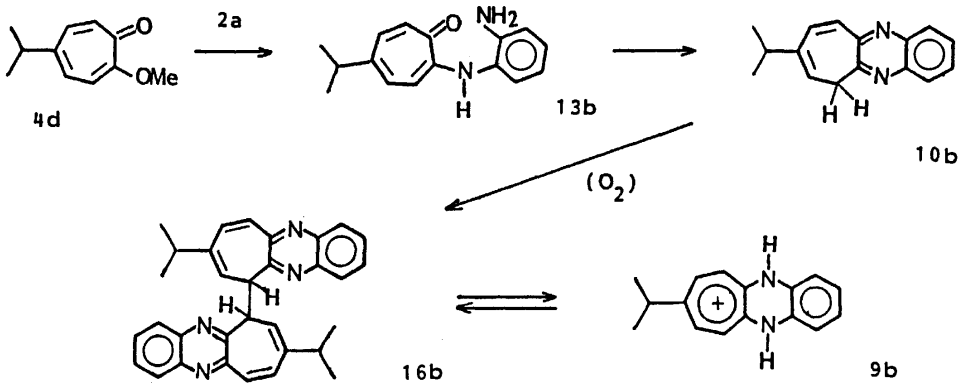
To make sure the characteristics of cyclohepta[*b*]-quinoxaline system, we also studied the isopropyl derivatives (**9b** and **10b**) prepared from 5-isopropyl-2-methoxytropone (**4d**) and **2a**, and we obtained a similar dimer **16b** reversibly from **9b**, as illustrated in Scheme 2.

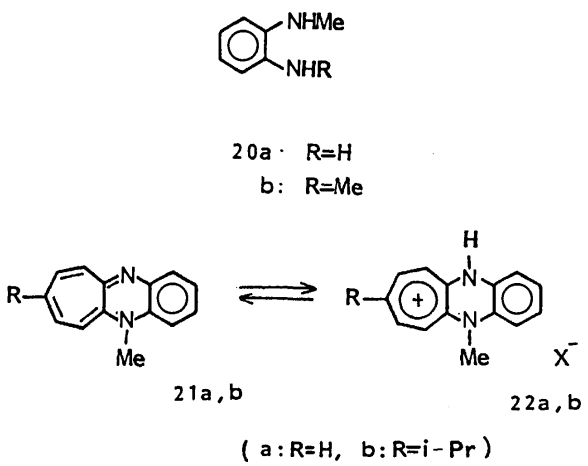
We then tried to synthesize the *N*-methyl derivative **21a** (of **5a**), which can not take the tautomeric, qui-



Scheme 1.



Scheme 2.

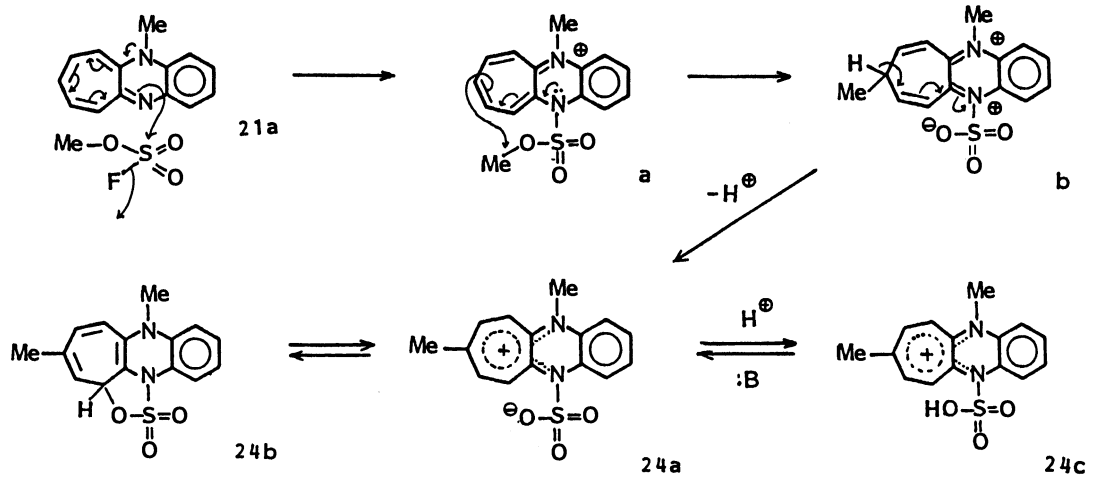


noxalo form, in order to compare its properties with those of the *O*- and *S*-analogues (**11**, **12**). Thus, *N*-methyl-5*H*-cyclohepta[*b*]quinoxaline (**21a**) was obtained as green needles having a low melting point (mp 68 °C), by the reaction of **4b** with *N*-methyl-*o*-phenylenediamine (**20a**). The structure of **21a** was established on the basis of the spectral data. It showed ^{1}H NMR signals at δ 2.67 (*N*-methyl), and at δ 4.47 (H-6) and 6.24 (H-4) due to two peri-protons; these were assigned on the basis of NOE experiment. It is worth noticing that the free *N*-methyl compound **21a** and its protonated cation **22a** have the same deep green color and are similar to **9a** in terms of the UV/VIS and ^{1}H NMR spectra, indicating that these compounds have a similar π-electron system.[9] We also prepared 8-isopropyl compound **21b** and its salt **22b** from methyl ether of γ-thujaplicin (5-isopropyltropolone).

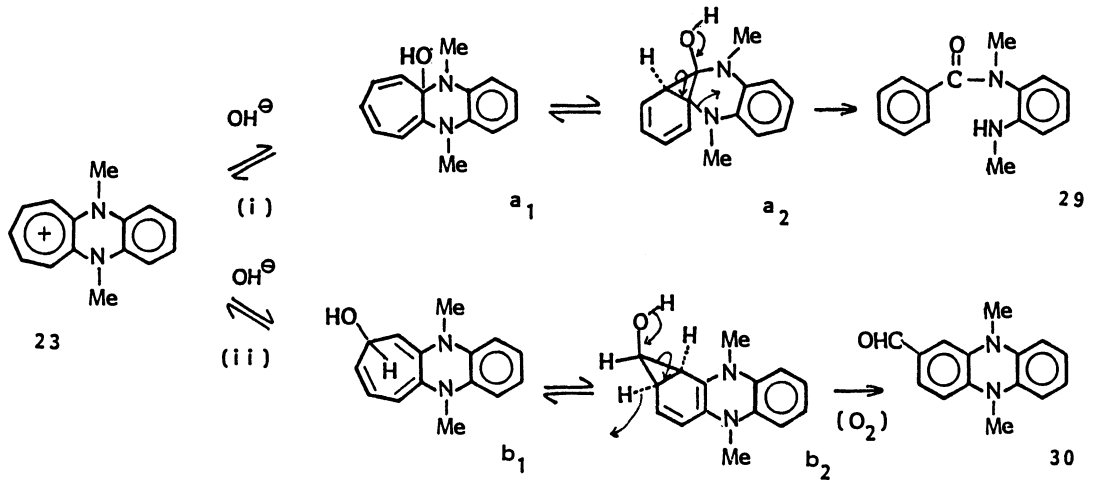
N,N'-Dimethyl cation (**23**) was obtained as dark-greenish needles (chloride and BF_4^- salts) by heating **4a** or **4b** with *N,N'*-dimethyl-*o*-phenylenediamine (**20b**) at 120 °C in the presence of acid.[2] The long-wavelength absorptions at 578, 620, and 732 nm (log ε 3.07, 3.05, and 2.56) of **23** in MeOH are similar to those of **9a** and **22a** (Fig. 3). These bands disappear in alkali and exhibit only UV maxima of an unidentified conjugate base at 230, 250, 280, and 354 nm (they are restored upon acidification). The symmetrical structure of **23** was confirmed by the NMR spectrum, which showed two methyl signals at δ 3.10 (well-resolved), three signals at δ 6.25, 6.57, and 7.24 (ratio 2 : 1 : 2) due to the seven-membered ring protons, and signals of A_2 B_2 type at δ 6.71 and 6.95 due to benzene ring protons.

We then attempted to obtain compound **23** by the treatment of **21a** with "magic methyl," which, however, resulted in the formation of green needles **24**, mp 127—128.5 °C, which had a molecular composition of $C_{15}H_{14}N_2O_3S$ (gaining a methyl and an SO_3 groups) and showed characteristic IR absorptions (KBr) at 1340 and 1160 cm^{-1} (-SO_2-). This product exhibited visible absorption at 616, 676, and 680 nm in MeOH, but in hexane the longest-wavelength absorption was at 434 nm; the absorption maxima in MeOH shifted to slightly longer wavelengths in the presence of acid. ^{1}H NMR signals in benzene-d_6 appeared at δ 1.63 and 3.29 due to two methyl protons and at δ 3.33 due to a methine proton in addition to seven olefinic proton signals, thus showing that **24** would preferably exist in the form of the intramolecular conjugate base form, 5,10-dihydro-8,11-dimethyl-6*H*-cyclohepta[*b*]quinoxaline-5,6-sultone (**24b**) in nonpolar aprotic solvent. However, the H-6, H-1, and Me-8 proton signals of **24** shifted downfield (1 ppm) in CD_3CN from those in benzene-d_6 and the spectral pattern became rather similar to that of **21a**, thus indicating that **24** is more likely to exist in another tautomeric form **24a** predominantly in a polar solvent and in a solid as well. On the other hand, in acidic methanol, the spectrum of **24b** closely resembled those of cyclohepta[*b*]quinoxalinium salts **9a** and **22**, suggesting the cationic form **24c** in acid. It should be noted that methylation with magic methyl takes place at the seven-membered ring of **21a** to give **24**; this differs from the case of methylation of *O*- and *S*-analogues (**11** and **12**) with magic methyl,[8] and also from the result of methylation of **21a** with methyl iodide.[10] Although the mechanism of this unusual reaction has not been clarified yet, one of the possible pathways is shown in Scheme 3.

A comparison is now made between the reactivities of 5*H*-cyclohepta[*b*]quinoxaline (**21** and **23**) and those of *O*- and *S*-analogues (**11** and **12**) and their respective

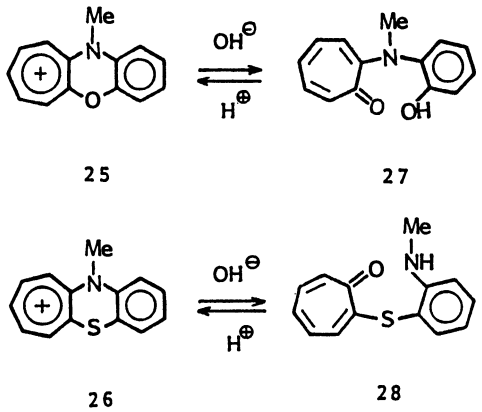


Scheme 3.



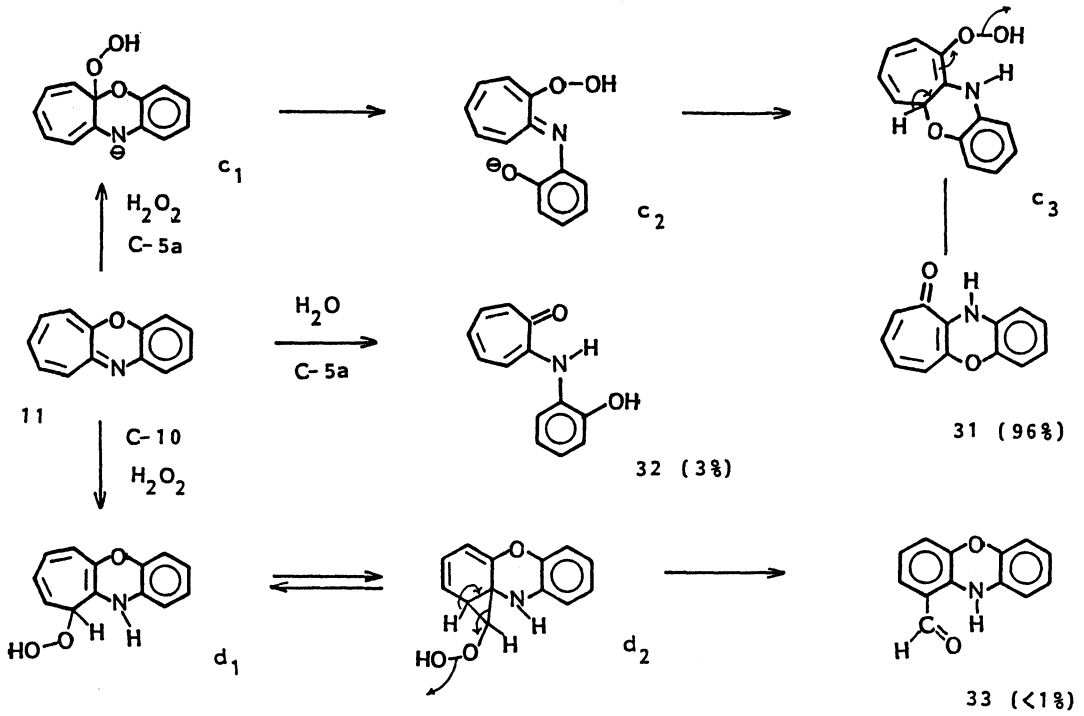
Scheme 4.

N-methylated cations (**25** and **26**). Facile ring opening by alkali and ring closure by acid is one of the characteristics of cyclohepta[*b*][1,4]benzoxazine **11** and its derivatives.[6] In paticular, *N*-methyl derivative **25** is readily saponified to 2-(*N*-methyl-*o*-hydroxyanilino)-tropone **27** (even with water at room temperature), by the attack of hydroxide ion at C-5a. Although *S*-analogue **12** is stable to warm alkali, its *N*-methyl



cation **26** is saponified with cold alkali to give 2-[*o*-(methylamino)phenylthio]tropone **28** by an attack of the hydroxide ion at C-10a.[8]

On the contrary, 5-methyl-5*H*-cyclohepta[*b*]quinoxaline **21a** is quite stable to warm alkali, whereas its *N*,*N*′-dimethyl cation **23a** give a colorless conjugate base by dilute alkali, but is restored to **23a** upon acidification. When a methanolic solution of **23a** containing 5 equiv of sodium hydroxide was allowed to stand overnight at room temperature, various products were formed (accompanied by autoxidation), from which a 6.5% yield of 5,10-dihydro-5,10-dimethyl-2-phenazinecarbaldehyde (**30**)[12] and 11% of benzamide **29** were isolated. Possible pathways for the formation of these compounds are shown in Scheme 4. It is considered that in path (i), intermediate a_1, produced by the attack of a hydroxide anion at C-5 of **23**, gives **29** via norcaradiene a_2 as illustrated in the scheme, whereas in path (ii) intermediate b_1, produced by the attack of a hydroxide anion at C-7, aromatizes to **30** via b_2 by autoxidation. In concentrated methanolic alkali, however, **23** rearranges to benzamide **29** in 89% yield.

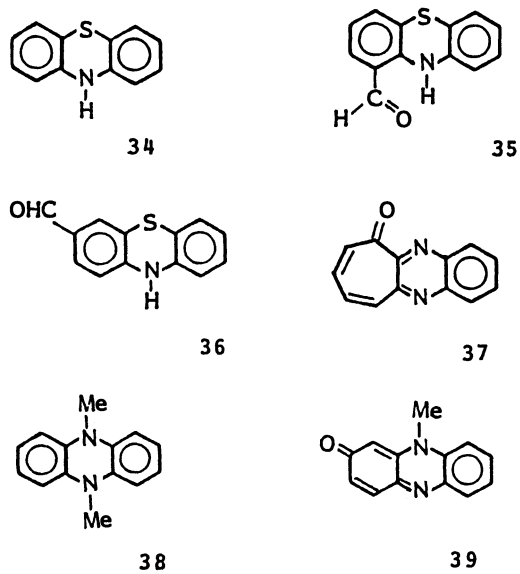


Scheme 5.

We then examined the reaction of **10a** (or **9a**) with hydrogen peroxide for a comparison with the behavior of the H_2O_2 to *O*- and *S*-analogues (**11**,[6] **12**[7,8]). Our previous findings may be summerized as follows: (1) Treatment of *O*-analogue **11** with H_2O_2 in MeOH gave almost exclusively (96%) cyclohepta[*b*][1,4]benzoxazin-10(11*H*)-one (**31**) and 2—3% of the hydrolyzed product **32**, along with a small proportion (<1%) of 1-formyl-10*H*-phenoxazine (**33**); for the reaction pathways, see Scheme 5. (2) The *S*-analogue **12** reacted[8] with H_2O_2 in MeOH slightly more slowly than **11**, producing many kinds of rearranged products, 10*H*-phenothiazine (**34**), its 1- and 3-formyl derivatives (**35**, **36**).

On the other hand, oxidation of **10a** with H_2O_2 in acetic acid gave mainly the dehydro dimer **16a** mentioned above and a small quantity of **E**, **F**, and 6*H*-cyclohepta[*b*]quinoxalin-6-one (**37**).[13] Compound **21a** is stable under basic conditions and also to H_2O_2 in MeOH at room temperature; upon heating at 60 °C, however, it was gradually oxidized to a complex mixture of products. One of them was separated as a reddish oil, which was identified spectroscopically as 10-methyl-2(10*H*)-phenazinone (**39**).[14] It was considered that **39** was formed by the oxidation of 5,10-dihydro-5-methylphenazine (**38**), derived from an oxidative rearrangement of **21a**, because phenothiazines usually form quinone derivatives upon radical oxidation.[15]

It is interesting to note that cyclohepta[*b*][1,4]benzoxazine (**11**), its *S*-analogue **12**, and *N*-analogues **10**, **21** have considerable different chemical properties. These compounds can be regarded as π-excessive heteroaromatics[16] fused with benzene and cycloheptatriene rings. Therefore, the diversity of these reactivities could be explained in terms of the electronegativity and porarizability of the hetero atoms as well as the nature of the attaching reagents. However, detailed studies (including theoretical calculations) on the π-electron system of cyclohepta[*b*]quinoxalines and those *O*- and *S*-analogues in relation to their chemical properties are currently in progress, and the results will be reported in a future paper.[17]



Experimental

Melting points were determined with a Yanagimoto MP-

3S apparatus and are uncorrected. The IR spectra were taken on a Shimadzu IR-400 or IR-450, and the UV spectra were recorded with a Shimadzu UV-202 or a Hitachi 557 spectrometer. The NMR spectra were recorded with JEOL JNM-PS100 (100-MHz) and GX270 (270-MHz) spectrometers using TMS as the internal standard. The mass spectra were taken on Shimadzu LKB9000 and JEOL JMS-01SG mass spectrometers. The HPLC was carried out on Hitachi gel #3011 with MeOH–hexane (9 : 1) as the solvent. The UV spectra in acid and alkali were taken after adding a drop of 3 M HCl or 3 M NaOH (1 M=1 mol dm^{-3}) to the sample solution. TLC analyses were carried out with Merck Kieselgel 60F-254 and Aluminium oxide F-254 plates.

Reaction of 2-Methoxytropone (4b) with *o*-Phenylenediamine (2a). A solution of **4b** (250 mg, 1.84 mmol) and **2a** (240 mg, 2.22 mmol) in EtOH (5 cm^3) was heated in a sealed tube for 6 h at 80 °C and then the solution was set aside at room temperature, depositing crystals after several hours. The precipitates were filtered off, giving **13a** (238 mg, 61%, combined with second crop). Compound **10a** (37 mg, 10%) and unreacted **4b** (56 mg, 22%) were isolated by preparative HPLC.

Heating of an ethanolic solution of **13a** in a sealed tube at 120 °C for 6 h gave a quantitative yield of **10a**.

2-(*o*-Aminophenylamino)tropone (13a): Yellow needles (from EtOH), mp 183—183.5 °C; UV (MeOH) λ_{max} 235, 338, and 401 nm (log ε 4.45, 4.00, and 4.10), (MeOH+HCl) 236, 280, 289, 333, 345, 439, 464, and 490 nm (log ε 4.22, 4.41, 4.52, 3.95, 3.92, 3.92, 4.04, and 3.90); IR (KBr) 3460, 3320 (NH_2), 3240 (NH), and 1620 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=3.75 (2H, br, NH_2), 6.64 (1H, dd, J=10.3 and 1.0 Hz, H-7), 6.75—7.46 (9H, m, ar-H), and 8.33 (1H, br, NH); MS, m/z 212 (M^+).

Anal. ($C_{13}H_{12}N_2O$) C, H, N.

***6H*-Cyclohepta[*b*]quinoxaline (10a):** Pale yellow needles (from $CHCl_3$); mp 68—69 °C; UV (MeOH) λ_{max} 235, 243, and 342 nm (log ε 4.21, 4.21, and 3.94), (MeOH+HCl) 238, 280, 289, 333, 345, 449, 464, and 491 nm (log ε 4.21, 4.34, 4.42, 3.92, 3.90, 3.79, 3.91, and 3.79), (MeOH+NaOH) 231, 247, 270, 349, and 392 nm (log ε 4.27, 4.26, 4.17, 3.94, and 3.48); ^{1}H NMR (CD_3 CN) δ=3.59 (2H, d, J=5.8 Hz, CH_2), 6.08 (1H, dt, J=10.3 and 5.8 Hz, H-7), 6.28 (1H, dd, J=10.3 and 5.3 Hz, H-8), 6.80 (1H, dd, J=11.7 and 5.3 Hz, H-9), 7.71 (2H, m, H-2,3), 7.28 (1H, d, J=11.7 Hz, H-10) and 8.05 (2H, m, H-1,4); MS, m/z 194 (M^+).

Anal. ($C_{13}H_{10}N_2$) C, H, N.

Reaction of 5-Isopropyl-2-methoxytropone (4d) with 2a. Reaction of **4d** (200 mg, 1.12 mmol) with **2a** (145 mg, 1.34 mmol) as described above gave **13b** (153 mg, 54%), **10b** (18 mg, 7%) and unreacted **4d** (54 mg, 27%).

Heating of **13b** (100 mg, 0.39 mmol) as described for **13a** (see above) gave **10b** (73 mg, 79%) and unreacted **13b** (27 mg, 27%).

2-(*o*-Aminoanilino)-5-isopropyltropone (13b): Yellow needles (from EtOH); mp 155—156 °C; UV (MeOH) λ_{max} 236, 341, and 405 nm (MeOH+HCl) 236, 283, 291, 334, 347, 448, 471, and 500 nm; ^{1}H NMR ($CDCl_3$) δ=1.20 (6H, d, J=6.8 Hz, $2CH_3$), 2.79 (1H, sept, J=6.8 Hz, CH), 3.77 (2H, br, NH_2), 6.57 (1H, d, J=10.3 Hz, H-7), 6.78—7.28 (7H, m, ar-H), and 8.14 (1H, br, NH); MS, m/z 254 (M^+).

Anal. ($C_{16}H_{18}N_2O$) C, H, N.

8-Isopropyl-6*H*-cyclohepta[*b*]quinoxaline (10b): Pale yellow oil; UV (MeOH) λ_{max} 213, 247, and 340 nm (MeOH+HCl) 215, 249, 292, 340, and 468 nm ; ^{1}H NMR ($CDCl_3$) δ=1.05 (6H, d, J=6.8 Hz, $2CH_3$), 2.48 (1H, sept, J=6.8 Hz, CH), 3.51 (2H, d, J=6.3 Hz, CH_2), 5.81 (1H, t, J=6.3 Hz, H-7), 7.72 (1H, d, J=12.2 Hz, H-9), 7.71 (2H, m, H-2,3), 7.80 (1H, d, J=12.2 Hz, H-10), and 8.03 (2H, m, H-1,4); MS, m/z 236 (M^+).

Anal. ($C_{16}H_{16}N_2$) C, H, N.

***5H*-Cyclohepta[*b*]quinoxalinium Salts (9a).** A solution of **10a** (100 mg, 0.52 mmol) in EtOH (2 cm^3) was treated with various acids (1 : 2); the mixture was set aside at room temperature, depositing crystals. The precipitates were filtered off, giving **9a** (BF_4^- salt, 121 mg, 85%) as dark green needles. BF_4^- salt: mp 227.2—229 °C; UV (MeOH) λ_{max} 236, 279sh, 289, 331, 445, 449sh, 464, and 481sh (log ε 4.16, 4.37, 4.46, 3.89, 3.84, 3.96, 4.00, and 3.94), (MeOH+NaOH) 231, 246, 347, and 391 (log ε 4.24, 4.22, 3.85, and 3.31); ^{1}H NMR (CD_3CN) δ=5.68 (2H, d, J=11.2 Hz, H-6,10), 6.04 (1H, t, J=9.5 Hz, H-8), 6.14 (2H, m, H-1,4), 6.52 (2H, m, H-2,3), 6.62 (2H, dd, J=11.2 and 9.5 Hz, H-7,9), and 7.95 (2H, br, NH).

Anal. ($C_{13}H_{11}N_2BF_4$) C, H, N.

ClO_4^- salt: mp 227—228.5 °C. CF_3COO^- salt: mp 198—199 °C. Br^- salt: mp 300 °C. Cl^- salt: mp 190—190.5 °C.

8-Isopropyl-5*H*-cyclohepta[*b*]quinoxalinium Salts (9b). Treatment of **10b** (50 mg, 0.21 mmol) with acid (as described above) gave **9b** (BF_4^- salt, 57 mg, 83%) as dark green needles. BF_4^- salt: mp 237—238 °C; UV (MeOH) λ_{max} 236, 283, 291, 338, 347, 446, 470, and 500 nm (log ε 4.18, 4.35, 4.48, 3.91, 3.83, 3.96, 4.04, and 3.87), (MeOH+NaOH) 245 and 341 nm (log ε 4.29 and 3.85); ^{1}H NMR (CD_3CN) δ=1.10 (6H, d, J=6.8 Hz, $2CH_3$), 2.39 (1H, m, J=6.8 Hz, CH), 5.71 (2H, d, J=11.5 Hz, H-6,10), 6.10 (2H, m, H-1,4), 6.48 (2H, m, H-2,3), 6.64 (2H, J=11.5 Hz, H-7,9), and 7.75 (2H, br, NH).

Found: C, 58.97; H, 5.51; N, 8.43%. Calcd for $C_{16}H_{17}N_2BF_4$: C, 59.29; H, 5.29; N, 8.64%.

ClO_4^- salt: mp 289—290 °C.

6,6′-Bi-6*H*-cyclohepta[*b*]quinoxaline (16a): Aqueous $NaHCO_3$ was slowly added to a suspension of **9a** (BF_4^- salt, 100 mg, 0.35 mmol) in EtOH (1 cm^3); the mixture was allowed to stand overnight exposed to air. The precipitates were filtered off and extracted with $CHCl_3$. The extracts were combined with the precipitates and purified by preparative HPLC, giving **16a** (57 mg, 84%, RT 32 min) as colorless plates: mp 193.5—194.5 °C (from $CHCl_3$); UV (MeOH) λ_{max} 215, 233, and 338 nm; ^{1}H NMR (270 MHz in $CDCl_3$) δ=4.59 (2H, br, H-6,6′), 6.20 (2H, d, J=10.2 Hz, H-7,7′), 6.43 (2H, dd, J=10.2 and 5.1 Hz, H-8,8′), 7.02 (1H, dd, J=11.7 and 5.1 Hz, H-9,9′), 7.40 (2H, t, J=8.1 Hz, H-3,3′ or 2,2′), 7.49 (2H, d, J=8.1 Hz, H-4,4′ or 1,1′), 7.53 (2H, t, J=8.1 Hz, H-2,2′ or 3,3′), 7.54 (2H, d, J=11.7 Hz, H-10,10′), and 7.96 (2H, d, J=8.1 Hz, H-1,1′ or 4,4′); MS, m/z 386 (M^+, 7), 294 (58), 193 (100), and 192 (30).

Anal. ($C_{26}H_{18}N_4$) C, H, N.

6,6′-Bicycloheptiden[*b*]quinoxaline (19): Heating of **16a** of 220 °C in vacuo in a sealed tube gave **10a** and **19** (observed by HPLC). **19**: reddish brown needles, mp 300 °C decomp.; MS m/z 384 (M^+, 100), 193 (6), and 191 (23); UV (Hexane-MeOH) λ_{max} 217, 249, 349, and 404 nm.

8,8′-Diisopropyl-6,6′-bi-6*H*-cyclohepta[*b*]quinoxaline (16b). Treatment of **9b** (BF_4^- salt, 50 mg, 0.15 mmol) with alkali (as described above) gave **16b** (27 mg, 74%) as pale yellow needles: mp 134—135 °C; UV (MeOH) λ_{max} 220, 244, and 336 nm; ^{1}H NMR ($CDCl_3$) δ=1.08 (6H, d, J=6.8 Hz, $2CH_3$), 1.13 (6H, d, J=6.8 Hz, $2CH_3$), 2.59 (2H, m, J=6.8 Hz, CH), 4.50 (2H, br, H-6,6′), 5.88 (2H, br, H-7,7′), 7.00 (2H, d,

J=11.7 Hz, H-9,9'), 7.39—7.61 (8H), and 7.91—8.01 (2H); MS, m/z 470 (M^+).

Anal. ($C_{32}H_{30}N_4$) C, H, N.

5-Methyl-5*H*-cyclohepta[*b*]quinoxaline (21a). A solution of **4b** (224 mg, 1.65 mmol) and *N*-methyl-*o*-phenylenediamine (**20a**) (251 mg, 2.06 mmol) in EtOH (2 cm^3) was heated in a sealed tube for 24 h at 120 °C. After removing the solvent, the residue was taken in a small amount of $CHCl_3$ and chromatographed on silica-gel thin-layer plates with acetonitrile as the eluant, giving **21a** (237 mg, 69%) as dark green needles along with unreacted **4b** (16 mg, 7%) : mp 68 °C; UV (MeOH) λ_{max} 229, 274, 324, 429, 458, 525, 568, 630, and 696 nm (log ε 4.09, 4.22, 3.87, 3.98, 3.75, 2.62, 2.61, 2.45, and 2.15), (MeOH+HCl) 237, 288, 334, 430, 451, 485, 565, 616, 670, and 752 nm (log ε 4.17, 4.33, 3.91, 3.79, 3.91, 3.76, 3.01, 2.91, 2.83, and 2.34); ^{1}H NMR (270 MHz in CD_3CN) δ=2.67 (3H, s, CH_3), 4.47 (1H, d, J=9.7 Hz, H-6), 5.22 (1H, dd, J=10.8 and 7.6 Hz, H-8), 5.40 (1H, J=12.3 Hz, H-10), 5.79 (1H, ddd, J=12.3, 7.6, and 1.5 Hz, H-9), 5.84 (1H, ddd, J=10.8, 9.7, and 1.5 Hz, H-7), 6.24 (1H, dd, J=8 and 1.5 Hz, H-4), 6.48 (1H, dd, J=8 and 1.5 Hz, H-6), 6.52 (1H, td, J=8 and 1.5 Hz, H-2), and 6.68 (1H, td, J=8 and 1.5 Hz, H-3), (250 MHz in CF_3COOD) δ=3.02 (3H, s, CH_3), 5.95 (1H, d, J=11 Hz, H-10), 6.08 (1H, d, J=11 Hz, H-10), 6.35 (1H, t, J=9 Hz, H-8), 6.37 (1H, dd, J=7.5 and 1.5 Hz, H-4), 6.51 (1H, dd, J=8 and 1.5 Hz, H-1), 6.78 (1H, td, J=8, 7.5 and 1.5 Hz, H-3), 6.88 (1H, ddd, J=11, 9 and 1.5 Hz, H-9), 6.88 (1H, td, J=8 and 1.5 Hz, H-2) and 7.01 (1H, ddd, J=11, 9, and 1.5 Hz, H-7); MS, m/z 208 (M^+).

Anal. ($C_{14}H_{12}N_2$) C, H, N.

8-Isopropyl-5-methyl-5*H*-cyclohepta[*b*]quinoxaline (21b). The reaction of **4c** and **20a** was conducted in a manner similar to that described above for **21a**, giving **21b** in 51% yield: Dark green oil; mp 200 °C (picrate); UV (MeOH) λ_{max} 228, 260, 282, 324, 432, 525, 568, 628, and 686 nm (log ε 4.19, 4.18, 4.27, 3.29, 3.99, 2.88, 2.81, 2.62, and 2.30), (MeOH+HCl) 237, 299, 332, 428, 446, 488, 564, 616, 672, and 760 nm (log ε 4.24, 4.60, 3.97, 3.88, 4.00, 3.83, 3.01, 2.99, 2.84, and 2.23); ^{1}H NMR (100 MHz in $CDCl_3$) δ=0.98 (6H, d, J=6.6 Hz, $2CH_3$), 2.09 (1H, sept, J=6.6 Hz, CH), 2.70 (3H, s, N-CH_3), 4.41 (1H, d, J=9.8 Hz, H-6), 5.47 (1H, d, J=12.5 Hz, H-9), 5.74 (1H, d, J=9.8 Hz, H-7), 6.01 (1H, d, J=12.5 Hz, H-10), 6.12 (1H, d, J=7.3 Hz, H-4), 6.61 (3H, m, H-1,2,3), (CF_3COOD) δ=1.15 (6H, d, J=7.1 Hz, $2CH_3$), 2.51 (1H, sept, J=7.1 Hz, CH), 2.98 (3H, s, N-CH_3), 5.93 (1H, d, J=12 Hz, H-6), 6.07 (1H, d, J=12 Hz, H-10), 6.30 (1H, d, J=7 Hz, H-4), 6.41 (1H, d, J=7 Hz, H-1), 6.70 (2H, m, H-2,3), 6.88 (1H, d, J= 12 Hz, H-9 or 7) and 6.98 (1H, d, J=12 Hz, H-7 or 9); MS, m/z 250 (M^+).

Anal. ($C_{17}H_{18}N_2$) C, H, N.

5,11-Dimethyl-5*H*-cyclohepta[*b*]quinoxalinium Salts (23). (a) Concd HCl (100 mg) was added to a solution of **4a** (300 mg, 2.14 mmol) and *N,N'*-dimethyl-*o*-phenylenediamine **20b** (436 mg, 3.21 mmol) in EtOH (2 cm^3); the mixture was heated in a sealed tube for 20 h at 120 °C. After cooling, the precipitates were collected, giving **23** (481 mg, 87% with the second crop). (b) The reaction of **4b** (120 mg, 0.88 mmol) with **20b** (180 mg, 1.32 mmol) and 42% HBF_4 as above gave the BF_4^- salt (106 mg, 39%). Cl^- salt: Dark green needles; mp 230 °C (from EtOH); UV (MeOH) λ_{max} 238, 287, 328, 440, 580, 620, and 630 nm. (log ε 4.18, 4.23, 3.84, 3.81, 3.07, 3.05, and 2.56); ^{1}H NMR (270 MHz in CD_3CN) δ=3.10 (6H, s, $2CH_3$), 6.25 (2H, d, J=11 Hz, H-6, 10), 6.57 (1H, t, J=9.5 Hz, H-8), 6.71 (2H, m, H-1, 4), 6.95 (2H, m, H-2, 3), and 7.24 (2H, dd, J=11.3 and 9.5 Hz, H-7,9).

BF_4^- salt: Dark green needles; mp 223 °C

Reaction of 23 with NaOH. (a) Aqueous NaOH (1 g/3 cm^3 of H_2O) was added to a green solution of **23** (150 mg, 0.58 mmol) in MeOH (150 cm^3); the solution turned to colorless. After removing the solvent, the residue was extracted with $CHCl_3$. The combined extracts were concentrated and chromatographed on a silica-gel column with 10 : 1 benzene-MeOH as the eluant, giving **29** (124 mg, 89%). (b) Aqueous NaOH (80 mg/ H_2O, 0.5 cm^3) was added to a solution of **23** (100 mg, 0.39 mmol) in MeOH (100 cm^3) and the solution was set aside overnight at room temperature; it slowly became reddish brown. After removing the solvent, the residue was chromatographed on silica-gel thin-layer plates with 10 : 1 benzene-MeOH as the eluant, giving **30** (5 mg, 6.5%) besides **29** (11%) and many products.

***N*-Methyl-*N*-[*o*-(methylamino)phenyl]benzamide (29):** Colorless needles (from MeOH), mp 140 °C; MS, m/z 240 (M^+); UV (MeOH) λ_{max} 238 and 301 nm (log ε 4.19 and 3.57), (MeOH+HCl) 233, 271, and 278 nm (log ε 4.15, 4.08, and 4.14); IR (KBr) 3360 (NH) and 1630 cm^{-1} (CO); ^{1}H NMR (270 MHz in $CDCl_3$) δ=2.92 (3H, d, J=5.5 Hz, CH_3), 3.29 (3H, s, CH_3), 4.19 (1H, q, J=5.5 Hz, NH), 6.46 (1H, t, J=7.7 Hz), 6.61 (1H, d, J=8.2 Hz), 6.71 (1H, d, J=7.7 Hz), 7.12 (3H, m), 7.20 (1H, d, J=7.1 Hz) and 7.29 (2H, dd, J=7.7 and 7.1 Hz); MS, m/z 240 (M^+, 41), 163 (12), 135 (31), 120 (28), 119 (78), 106 (9), 105 (42), 91 (9), and 77 (100).

(Received October 17, 1988)

The chiral compounds (*R*)- and (*S*)-*N*-(*p*-tolylsulfonyl)benzenesulfonimidamide have been prepared efficiently from *N*-(*p*-tolylsulfonyl)benzenesulfonimidoyl chloride and both enantiomers were transformed into chiral selenium diimide reagents, (*S*)- and (*R*)-*N*,*N*′-bis[*N*-(*p*-tolylsulfonyl)benzenesulfonimidoyl]selenium diimide, respectively, for the asymmetric allylic amination of olefins. Asymmetric allylic amination of methylenecyclohexane with the *S*-configured selenium diimide reagent afforded allylic amide, (1*S*)-*N*-[(*R*)-*N*-(*p*-tolylsulfonyl)benzenesulfonimidoyl]-2-methylenecyclohexylamine as a major diastereomer (42% diastereomeric excess). Similarly, cyclohexene, 1-heptene, and cyclooctene gave chiral allylic amides with 34%, 32%, and 20% diastereomeric excess, respectively. It is apparent that the *S*-configured diimido selenium reagent gives *S*-configured allylic amides, and that the *R*-configured reagent affords *R*-configured allylic amides as the major diastereomers in all of the cases investigated.

Great progress has been made in the area of asymmetric oxygenations of prochiral olefins since the finding of the enantioselective epoxidation of allylic alcohols by Sharpless and Katsuki in 1980.[1] However, the aza analogues of direct asymmetric oxygenations of olefins have not been studied extensively, and only chiral aziridination of the special olefins such as α-methylene-γ-butyrolactone is reported[2] to date as a direct asymmetric nitrogenation of prochiral olefins, although an indirect but excellent method for the synthesis of chiral primary amines through 2-alkyl-1,3,2-dioxaborinanes is developed by Brown et al.[3]

In 1976, we reported a method for the direct allylic amination of olefins and acetylenes by selenium diimide compounds.[4] The probable mechanism for the allylic amination is the aza analogue of the well-established mechanism for the allylic oxygenation of olefins by selenium dioxide.[5] If the substituent on the nitrogen atom in the selenium diimide reagent were chiral, some asymmetric induction would be anticipated in the allylic amination. This report describes the application of this concept to achieve asymmetric allylic amination of olefins. It must be admitted at the outset that this approach to asymmetric allylic amination by means of the chiral substituent on the nitrogen introduced is not likely to be of much practical value, for it involves the stoichiometric use of a resolved chiral reagent. However, the area of asymmetric amination is new enough that the factors which enable one to achieve good enantioselectivities are poorly understood, and there are only a few literatures[6,7] to refer to about it. In this circumstance it seems defensible, even desirable, to engage in studies which involve the stoichiometric use of a chiral agent which is not a commercially available natural product. Of course, the real future for a practical asymmetric allylic amination process lies in the development of highly effective chiral catalysts.

Jones and Cram have reported the synthesis of the chiral *N*-(menthyloxycarbonyl)-*p*-toluenesulfonimidamide (**1**).[8] The amide **1** was prepared following their procedure and transformed into its sodiochloramine derivative **2**, which was found to be effective in the selenium mediated allylic amination of methylenecyclohexane, as shown in Scheme 1. Although the allylic amination product **3** was shown to have a diastereomeric purity of about 48%,[9] it was very difficult to obtain more than a few hundred milligrams of the optically pure amide **1** due to the difficulty of its isolation from the diastereomeric mixture. However, this preliminary result encouraged us to devise a more practical route to other chiral alkylbenzenesulfonimidamides.

Results and Discussion

After several false starts, the exceedingly efficient sequence shown in Scheme 2 for the preparation of chiral *N*-(*p*-tolylsulfonyl)benzenesulfonimidamide [(*R*)-**8** and (*S*)-**8**] was developed. The racemic sulfonimidoyl chloride **6** is readily available from diphenyl disulfide (**4**) by sequential application of two literature procedures.[10] The nitrogen was introduced into sulfonimidamide **7** in the form of (*S*)-α-methylbenzylamine. At this point we had the good fortune to expe-

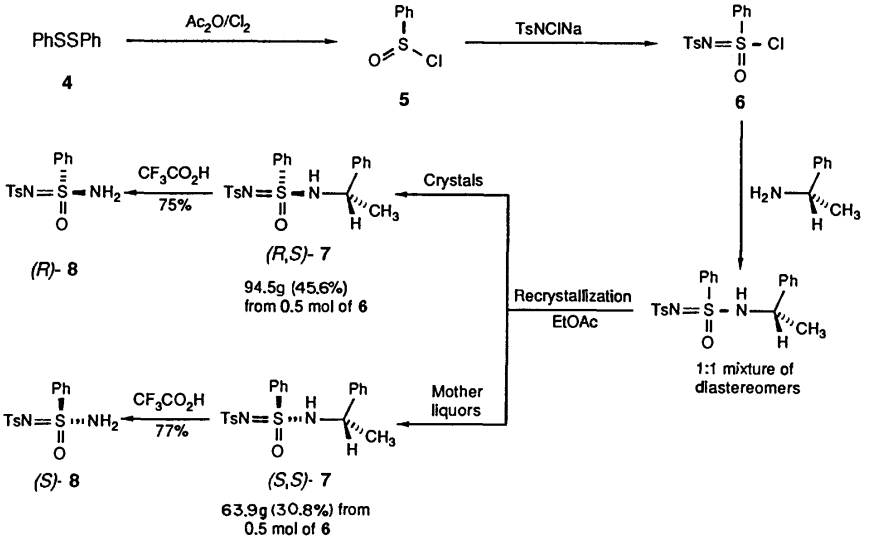

Scheme 2.

rience a completely painless resolution. One of the diastereomeric sulfonimidamides [(*R*,*S*)-**7**] is almost completely insoluble in ethyl acetate. Thus, a single recrystallization from ethyl acetate led to its isolation in 45.6% yield. The other diastereomer (*S*,*S*)-**7** was isolated in 30.8% yield by concentrating the mother liquor and adding diethyl ether to induce its crystallization. Therefore, the total yield of the two diastereomers was 76.4% from the sulfonimidoyl chloride **6**, and it will be noted in Scheme 2 that large amounts of (*R*,*S*)-**7** and (*S*,*S*)-**7** were easily obtained by carrying out a 0.5 mole scale reaction. A single-crystal X-ray analysis of (*S*,*S*)-**7** allowed assignment of the absolute stereochemistry at the chiral sulfur center; it is *S* as shown in Fig. 1.

Numerous unsuccessful attempts were made to cleave the α-methylbenzyl moiety from (*R*,*S*)-**7** and (*S*,*S*)-**7** by hydrogenolysis. Finally, a literature

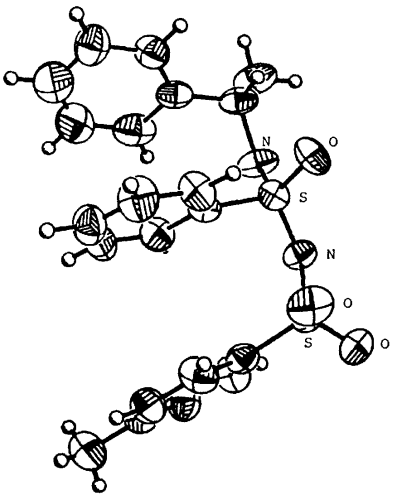

Fig. 1. The perspective drawing of the (*S*,*S*)-**7** molecule.

method[11] involving solvolysis in trifluoroacetic acid was found to be very effective. A priori one might have expected these acidic conditions to either racemize or hydrolyze the desired chiral sulfonimidoyl amides (*R*)-**8** and (*S*)-**8**, but no such difficulties were encountered. We, therefore, now had a good route to the chiral benzenesulfonimidamides (*R*)-**8** and (*S*)-**8**.[12] Sulfonimidamide (*R*)-**8** is readily converted to the corresponding chloramine salt (*S*)-**9**, as shown in Scheme 3. The salt (*S*)-**9** is stable for months at room temperature. The salt (*S*)-**9** is slightly soluble in dry dichloromethane, and when exposed to selenium metal in this solvent it reacts to afford an uncharacterized substance which behaves as if it were the selenium(IV) diimide species (*S*)-**10**.[13] The putative diimide reagent (*S*)-**10** is effective for the allylic amination of olefins.

The probable mechanism for the allylic amination process is that shown in Scheme 4, and it is simply the aza analogue of the rather well-established mechanism for the allylic oxygenation of olefins by selenium dioxide.[5] The key events bearing on the question of chirality transfer from the selenium reagent to the allylic

Table 1. Asymmetric Inductions

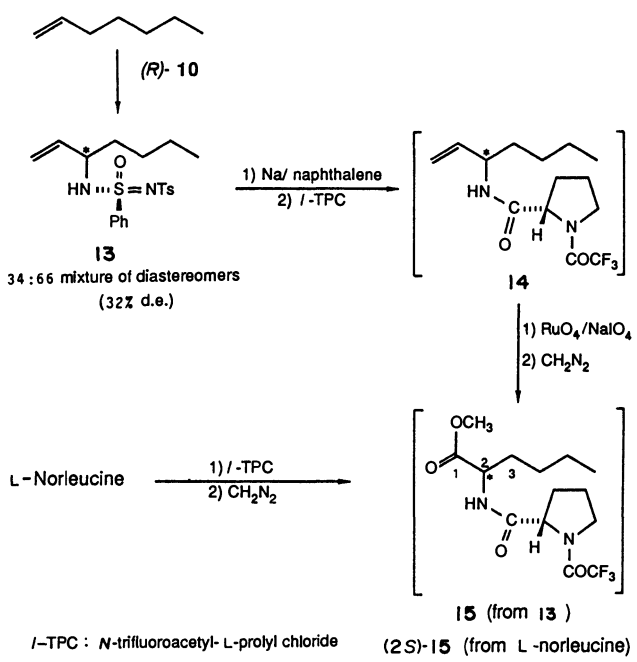
Entry	Olefin	Configuration of R*N=Se=NR* a)	Product	Ratio of diastereomers	Diastereomeric excess	Yield
1		*S*		29 : 71	42% (*S*)	51%
2		*R*		34 : 66	32% (*R*)	25%
3		*R*		33:67	34% (*R*)	29%
4		*R*		4.0 : 6.0	20% (*R*)	30%

a) R*= -S*(=O)(=NTs)-Ph.

amination product are the ene step and the [2,3]sigmatropic step. For an olefin which bears a terminal double bond such as methylenecyclohexane or 1-heptene (Entry 2, Table 1), the ene step would induce a chiral center at the selenium, but leads to an intermediate which has no chirality in the olefinic part of the structure. In this case, therefore, the asymmetric selection could take place in the [2,3]sigmatropic step.[7] For example, the diimide reagent (*S*)-**10** (*S* configuration at sulfur) derived from the optically active sulfonimidamide (*R*)-**8**, reacted with methylenecyclohexane at 0 °C to give the expected allylic amide **11** as the mixture of diastereomers in the ratio of 29 : 71 (42% diastereomeric excess). The ratio was not changed even when the reaction was performed at various temperatures between −40 °C and 25 °C. The diastereomers were distinguished clearly by their ^{1}H NMR spectra and were separated by column chromatography on silica gel to give (*S*,*R*)-**11** as the major isomer and (*R*,*R*)-**11** as the minor isomer. The circular dichroism of the *N*-salicylidene Schiff base of the allylic amine (*S*)-**12**, which was derived from (*S*,*R*)-**11** by naphthalene-sodium reduction,[14] showed positive Cotton effects at 253 and 317nm. Therefore, the newly induced chiral center at carbon in the major diastereomer was assigned the *S*-configuration[15] following the salicylideneamino chirality rule.[16]

An acyclic olefin such as 1-heptene was aminated with the selenium diimide reagent (*R*)-**10** which contains *R*-configured sulfurs, and a somewhat lower diastereomeric excess (32%) was observed for the allylic amination product **13** (Scheme 5).[17] The absolute configuration of the newly induced chiral center in **13** was correlated to the corresponding chiral center in an authentic sample of *N*-(*N*-trifluoroacetyl-L-prolyl)-L-norleucine methyl ester [(2*S*)-**15**] which was derived from commercially available L-norleucine as shown in Scheme 5. The GC retention time of the major diastereomer of **15** which was derived from the diastereomeric mixture **13** was the same as that of (2*S*)-**15** from L-norleucine. Therefore the induced chiral center in the major diastereomer of **13** was proved to be *S*-configured.

For the majority of olefins which do not bear a terminal double bond (e.g. Entries 3 and 4, Table 1), the ene product possesses chirality in the olefinic part of the structure, and in this case the chirality of the final product is determined only by the asymmetric induction in the ene step. An example is shown in Scheme 6



Scheme 5.

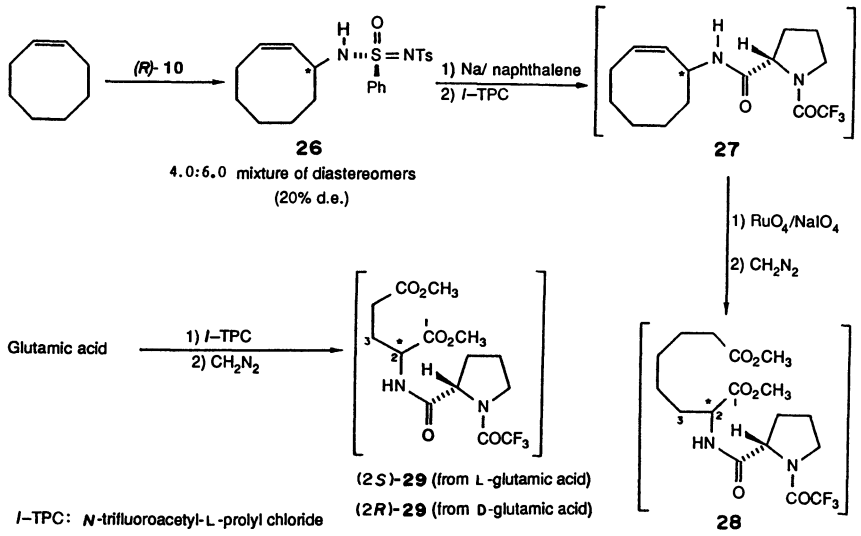
Scheme 7. Preparation of authentic samples.



Scheme 8.

for cyclohexene as the olefin. When the aminating reagent (*R*)-**10** was used, two diastereomers (**16**) were produced in the ratio of 33 : 67 (34% diastereomeric excess). As they are not separable by column chromatography on silica gel, the structure was confirmed by comparison of the diastereomeric mixture with an authentic sample of diastereomeric mixture **16'** which was derived from racemic allylic amine *dl*-**20** as shown in Scheme 7. In order to determine the absolute configuration of the newly induced chiral center in the major diastereomer of **16**, the diastereomeric mixture (**16**) was converted to methyl *N*-(*N*-trifluoroacetyl-L-prolyl)-2-aminoadipate (**18**) as shown in Scheme 6. As the GC retention time of the major diastereomer of **18** was the same as that of an authentic sample of methyl *N*-(*N*-trifluoroacetyl-L-prolyl)-L-2-aminoadipate [(2*S*)-**18**], which was derived from L-2-aminoadipic acid, the induced chiral center in the major diastereomer of **16** must be *S*-configured.

A medium-sized cyclic olefin such as cyclooctene afforded two diastereomers (**26**) upon the asymmetric allylic amination with the diimido selenium reagent (*R*)-**10** (Scheme 8). However, the asymmetric induction (20% diastereomeric excess) was somewhat lower than for the other olefins already described. As shown in Scheme 8, the diastereomeric mixture **26** was converted to **28** in order to assign the absolute configuration of the induced chiral center in the major diastereomer of the allylic amide. The GC analysis of **28** showed two peaks on PEG, and the major diastereomer eluted before the minor one. While diastereomers with *S*-configuration at C-2, such as (2*S*)-**18** (Scheme 6), (2*S*)-**15** (Scheme 5), and (2*S*)-**29** (Scheme 8) have in all cases longer retention times than the corresponding diastereomers with *R*-configuration at C-2 on the same GC column as shown in Table 2.[18] Therefore, as the major diastereomer of **28** has a shorter retention time than the minor one, the *R*-configuration was assigned

Table 2. GC Retention Times of *N*-(*N*-Trifluoroacetyl-L-prolyl) Derivatives of Amino Acid Methyl Ester

Amino acid	D-Enantiomer	L-Enantiomer	Column temp, flow rate[a)]
Norleucine	7.80 min	10.50 min	170 °C, 24 mL min^{-1}
Glutamic acid	18.20 min	22.20 min	180 °C, 45 mL min^{-1}
2-Aminoadipic acid	15.17 min	17.40 min	200 °C, 24 mL min^{-1}

a) 1m 1% PEG-20M-P.

to C-2 in the major diastereomer of **28**, and accordingly the induced chiral center in the major diastereomer of **26** was assigned the same *R*-configuration.

It seems noteworthy that the *R*-configured selenium reagent (*R*)-**10** gives the *R*-configured allylic amides in all four cases examined (Table 1). As can also be seen in Table 1 the asymmetric inductions we have observed are in the unimpressive 20—42% range. We had hoped for better inductions as chiral transfer is known to be excellent for [2,3]sigmatropic processes.[19] There are at present far too many unknown factors to support any speculation about the reasons for the modest inductions we have observed. However, since the relative bulk of the substituents around the chiral sulfurs in the imido selenium reagent could play an important part in determining the geometry of the transition states, the asymmetric inductions might be improved by exploring structural variations in the chiral sulfonimidamide **8** (Scheme 2). Fortunately, the synthetic route to the chiral sulfonimidamides (*R*)-**8** and (*S*)-**8** is straight-forward and should lend itself to the introduction of structural modifications.

Experimental

Melting points were determined on a capillary tube melting point apparatus and are uncorrected. Optical rotations were measured using a Perkin-Elmer 241 polarimeter. Infrared (IR) spectra were recorded on a Jasco A-100 grating infrared spectrometer and proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Jeol FX-90Q spectrometer (90 MHz). Tetramethylsilane (TMS) was used as an internal standard; however, when the solvent was D_2O, the standard was sodium 3-(trimethylsilyl)propionate-d_4 (TSP-d_4); chemical shifts are denoted in ppm downfield from TMS or TSP-d_4 at δ=0. Elemental analyses were performed by Stanford university or Takeda Chemical Industries Ltd., Chemistry Laboratories. Gas chromatographic (GC) analyses were performed on a Hitachi 163 gas chromatograph with a flame ionization detector using glass columns (3 mm i.d.) and nitrogen carrier gas. All the column packings used were purchased from Gasukuro Kogyo Inc. Analytical high-performance liquid chromatography (HPLC) was carried out on a Jasco BIP-1 high-performance liquid chromatograph equipped with a UV detector (adjusted to 260 nm). The CD spectrum was recorded on a Jasco J-20 spectropolarimeter at Takeda Chemical Industries Ltd., Chemistry Laboratories. Analytical thin-layer chromatography was performed on precoated silica-gel glass plates (0.25 mm, Kieselgel 60, F-254, E. Merck) and siica gel (Wakogel C-300, Wako Pure Chemical Industries Ltd.) was used for column chromatography.

(*R*)-*N*-[(*S*)-α-Methylbenzyl]-*N*′-(*p*-tolylsulfonyl)benzenesulfonimidamide [(*R*,*S*)-7] and (*S*)-*N*-[(*S*)-α-Methybenzyl]-*N*′-(*p*-tolylsulfonyl)benzenesulfonimidamide [(*S*,*S*)-7]. To an ice-cooled solution of 165 g (0.5 mol) of *N*-(*p*-tolylsulfonyl)benzenesulfonimidoyl chloride (prepared according to the published procedure[10]) in 1 L of dichloromethane was added a mixture of 66.5 g (0.55 mol) of (*S*)-(−)-α-methylbenzylamine (Aldrich) and 50.4 g (0.6 mol) of sodium hydrogencarbonate in 550 ml of water, and the mixture was stirred at room temperature overnight. After the separation of the organic layer, it was washed with 10% HCl, and water, successively, and concentrated in vacuo to afford crude crystals. Recrystallization from 1.5 L of ethyl acetate gave 94.5 g (45.6%) of (*R*,*S*)-**7** as needles (mp 166.5—168.0 °C), which was diastereomerically pure by ^{1}H NMR. An analytical sample was obtained by recrystallization from ethyl acetate: mp 167.5—168.5 °C; $[\alpha]_D^{23}$ −60.3° (*c* 1.02, acetone); IR (KBr) 3240, 1600, 1450, 1430, 1306, 1265, 1150, 1092, 1055, and 952 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.33 (3H, d, *J*=6.9 Hz, methyl), 2.37 (3H, s, aryl methyl), 4.50 (1H, q, *J*=6.9 Hz, CH-N), 7.0—8.0 (15H, NH and aromatic). Found: C, 60.84; H, 5.32; N, 6.77%. Calcd for $C_{21}H_{22}N_2O_3S_2$: C, 60.85; H, 5.35; N, 6.76%.

The mother liquor was concentrated and 1.2 L of diethyl ether was added to the residue to give 69.8 g of the other diastereomer (*S*,*S*)-**7** as prisms (mp 89.5—91.5 °C, contains approximately 1% of (*R*,*S*)-**7** judging from its ^{1}H NMR spectrum). Concentration of the mother liquor afforded a second crop of 17.2 g of crude crystals, which were dissolved in 75 mL of hot ethyl acetate and 3.29 g of crystals (mp 164—166.5 °C) were precipitated on cooling to room temperature. [These precipitated crystals were further recrystallized from 50 mL of ethyl acetate to give 2.9 g of diastereomerically pure (*R*,*S*)-**7**, mp 167.5—168.5 °C. Therefore, the total yield of (*R*,*S*)-**7** is 97.4 g (47%).] After separating the crystals, the mother liquor was concentrated and 200 mL of diethyl ether was added to the residue to give 13.1 g of (*S*,*S*)-**7** (mp 89.5—91.5 °C, contains approximately 2% of (*R*,*S*)-**7** judging from its ^{1}H NMR spectrum). The combined (*S*,*S*)-**7** (82.9 g) was dissolved in 100 mL of hot ethanol, and addition of hexane (100 mL) afforded 63.9 g (30.8%) of diastereomerically pure (*S*,*S*)-**7**: mp 91.5—92.5 °C; $[\alpha]_D^{23}$ −70.6° (*c* 1.08, acetone); IR (KBr) 3240, 1600, 1450, 1290, 1260, 1150, 1092, 1062, and 967 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.54 (3H, d, *J*=6.9 Hz, methyl), 2.37 (3H, s, aryl methyl), 4.48 (1H, d of q, *J*=6.9 and 6.9 Hz, CH-N), 6.71 (1H, d, *J*=6.9 Hz, NH), 6.9—8.0 (14H, aromatic). Found: C, 60.55; H, 5.47; N, 6.57%. Calcd for $C_{21}H_{22}N_2O_3S_2$: C, 60.85; H, 5.35; N, 6.76%.

X-Ray Diffraction Studies on (*S*)-*N*-[(*S*)-α-Methylbenzyl]-*N*′-(*p*-tolylsulfonyl)benzenesulfonimidamide [(*S*,*S*)]-7].

Compound (*S,S*)-**7** exists as colorless prisms in the space group $P2_12_12_1$, with four molecules in a unit cell having the dimensions: a =11.500±0.003; b=8.254±0.002; c=21.384± 0.005 Å. The calculated density is 1.356 g cm^{-3}. A total of 1626 reflections were measured on an automated four-circle diffractometer, using monochromatic copper radiation. A partial solution was found using the direct method routines of the SHELXTL program library, with the remaining peaks being located through successive difference E maps. The solution was refined by the least squares method to R=0.0755, with anisotropic temperature factors for all atoms except hydrogen. Hydrogen atoms were included with isotropic temperature factors at calculated positions. Supplementary materials (unit cell atomic coordinates, bond lengths, bond angles, anisotropic temperature factors, hydrogen atom coordinates, and nonbonded distances) are deposited as Document No. 8864 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

(*R*)-*N*-(*p*-Tolylsulfonyl)benzenesulfonimidamide [(*R*)-8] and (*S*)-*N*-(*p*-Tolylsulfonyl)benzenesulfonimidamide [(*S*)-8]. To 40 mL of trifluoroacetic acid was added 16.56 g (40 mmol) of (*R,S*)-**7**. After stirring for 40 h at 35 °C, trifluoroacetic acid was removed in vacuo to give crude crystals. Recrystallization of the crystals from 600 mL of ethyl acetate afforded 10.63 g (86%) of (*R*)-**8** ([α]$_D^{23}$ +97.8°), which was further recrystallized from the same solvent to give 9.3 g (75%) of pure (*R*)-**8**, mp 178.5—179.5 °C,[20] [α]$_D^{23}$ +103° (*c* 1.03, acetone). Further recrystallization of this material did not change the rotation: IR (KBr) 3220 (sh), 3170, 3060, 1590, 1558, 1448, 1388, 1290, 1259, 1135, 1042, 930, 800, and 750 cm^{-1}; ^{1}H NMR ($CDCl_3$/DMSO-d_6, ca. 1 : 1) δ=2.36 (3H, s, aryl methyl), 4.39 (2H, broad s, NH), and 7.0—8.0 (9H, aromatic). Found: C, 50.47; H, 4.48; N, 8.93%. Calcd for $C_{13}H_{14}N_2O_3S_2$: C, 50.31; H, 4.55; N, 9.02%.

The other enantiomer (*S*)-**8** (6.3 g, 77%) was obtained from 12.52 g (30 mmol) of (*S,S*)-**7** following the same procedure: mp 178.5—179.5 °C, [α]$_D^{23}$ −103° (*c* 1.03, acetone). The ^{1}H NMR and IR spectra were identical to those of (*R*)-**8**.

Sodium Salt of (*R*)-*N*-Chloro-*N'*-(*p*-tolylsulfonyl)benzenesulfonimidamide [(*R*)-9] and Sodium Salt of (*S*)-*N*-Chloro-*N'*-(*p*-tolylsulfonyl)benzenesulfonimidamide [(*S*)-9]. To an ice-cooled, stirred suspension of 14.23 g (46 mmol) of (*S*)-**8** in 115 mL of methanol was added dropwise 5.21 mL (4.99 g, 46 mmol) of *t*-butyl hypochlorite (Tokyo Kasei Kogyo Co., Ltd.) under a nitrogen atmosphere. After stirring for 15 min, 2.53 g (47 mmol) of sodium methoxide was added while still stirring under ice-bath cooling. The solution was concentrated on a rotary evaporator at 30 °C to a volume of approximately 30 mL, and addition of 300 mL of diethyl ether to the concentrated solution induced crystallization. After standing overnight at room temperature, the crystals were separated and washed with diethyl ether under nitrogen to avoid contact with moisture (if this procedure is done without nitrogen, some of the crystals melt presumably due to the absorption of moisture), and dried at 80 °C in vacuo (ca. 1 mmHg; 1 mmHg≈133.322 Pa) for 1 h, to give 15.62 g (93%) of (*R*)-**9**. Titration of this material with 0.1 M (1 M=1 mol dm^{-3}) sodium thiosulfate showed a purity of 96%, and this anhydrous (*R*)-**9** was stable for months at room temperature if protected from the atmosphere in a well-sealed bottle. An analytical sample of these crystals was obtained by recrystallization from isopropyl alcohol, which afforded fine needles: mp 175.5—176.5 °C (decomp). Found: C, 42.32; H, 3.19; N, 7.58%. Calcd for $C_{13}H_{12}ClN_2NaO_3S_2$: C, 42.57; H, 3.30; N, 7.64%.

The other enantiomer (*S*)-**9** was prepared from (*R*)-**8** in the same manner.

Preparation of Diimido Selenium Reagents (*S*)-10 and (*R*)-10. To a stirred suspension of 3.67 g (10 mmol) of the chloramide salt (*S*)-**9** (dried at 80 °C in vacuo for 1 h) in 20 mL of dry dichloromethane (methanol-free dichloromethane was passed through a column of neutral aluminum oxide, activity grade I, Woelm, and stored over 3A Molecular Sieves) was added 474 mg (6 mmol) of selenium powder (dried at 80 °C in vacuo for 1 h) under a nitrogen atmosphere. The resulting mixture was stirred vigorously at room temperature and almost all the solids in the solution disappeared within 30 min, only a small amount of the excess selenium powder remained. After stirring for an additional 3 h, the reaction mixture was used as reagent (*S*)-**10** for the amination of olefins.

Reagent (*R*)-**10** was similarly prepared from the chloramide salt (*R*)-**9**.

Allylic Amination of Methylenecyclohexane with the Diimido Selenium Reagent (*S*)-10. To reagent (*S*)-**10**, which was prepared from 3.67 g (10 mmol) of chloramide salt (*S*)-**9** and 6 mmol of selenium powder according to the method described above, was added dropwise 768 mg (8 mmol) of methylenecyclohexane at 0 °C (an ice bath) while stirring under a nitrogen atmosphere. After stirring for 24 h in the refrigerator (0 °C), the reaction mixture was allowed to warm to room temperature (15 min), and stirring was continued for 1 h. the reaction mixture was then diluted with 200 mL of 1 : 1 ethyl acetate/diethyl ether and 50 mL of an alkaline aqueous solution consisting of 2 parts 1 M NaOH and 1 part saturated NaCl solution. After stirring for 30 min, the red mixture was filtered through Celite 545 and the organic layer of the filtrate was washed again with 50 mL of the above mentioned alkaline brine solution (2×50 mL), dried (Na_2SO_4) and concentrated to give an oil. The crude product was chromatographed on 60 g of silica gel (dichloromethane/ethyl acetate, 95 : 5 as eluent) to give 1.66 g (51% based on the olefin) of a crystalline diastereomeric mixture of (*S,R*)-**11** and (*R,R*)-**11**, which showed two spots by TLC analysis [hexane/ethyl acetate, 3:2, R_f 0.464 (major) and R_f 0.536 (minor)]. GC analysis (1m 1% PEG-HT on 60/80 mesh Uniport HP, 270 °C, flow rate: 38 mL min^{-1}) of the crystalline diastereomeric mixture showed two peaks at 10.03 min and 12.50 min in a ratio of 29 : 71, respectively. The ratio matched that obtained by comparison of the integrated vinyl proton resonances for each of the diastereomers in the ^{1}H NMR spectrum.

A part of the diastereomeric mixture (0.1 g) was chromatographed on 20 g of silica gel (elution with 10—20% ethyl acetate/hexane) to yield two fractions. Eluting first was the minor diastereomer (*R,R*)-**11**, which was recrystallized from ethyl acetate/hexane to give 21 mg of pure crystals: mp 92—93 °C; [α]$_D^{23}$ + 25.4° (*c* 1.00, acetone); IR (KBr) 3196, 1651, 1599, 1450, 1311, 1255, 1154, 1124, 1090, and 1069 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.1—2.3 (8H, m, methylene), 2.39 (3H, s, aryl methyl), 3.76 (1H, m, CH-N), 4.57 (2H, s, vinyl), 6.40 (1H, d, J=8 Hz, NH), 7.0—8.1 (9H, m, aromatic). Found: C, 59.34; H, 5.91; N, 7.04%. Calcd for $C_{20}H_{24}N_2O_3S_2$: C, 59.38; H, 5.98; N, 6.92%.

Eluting second was the major diastereomer (*S,R*)-**11**, which was recrystallized from ethyl acetate/hexane to afford

39 mg of pure crystals: mp 132—133 °C; $[\alpha]_D^{23}$ +6.9° (*c* 1.01, acetone); IR (KBr) 3246, 1648, 1599, 1450, 1313, 1303, 1252, 1156, 1119, and 1080 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—2.3 (8H, m, methylene), 2.39 (3H, s, aryl methyl), 3.76 (1H, m, CH-N), 4.80 (1H, s, vinyl), 5.04 (1H, s, vinyl), 6.22 (1H, d, *J*=8.0 Hz, NH), 7.0—8.1 (9H, m, aromatic). Found: C, 59.38; H, 5.84; N, 7.05%. Calcd for $C_{20}H_{24}N_2O_3S_2$: C, 59.38; H, 5.98; N, 6.92%.

Determination of the Absolute Configuration of (*S,R*)-11. To a stirred solution of naphthalene-sodium reagent[14] [prepared by stirring a mixture of 11 mg (0.49 mmol) of sodium metal and 66 mg (0.51 mmol) of naphthalene in 1 mL of freshly distilled dry 1,2-dimethoxyethane for 2 h at room temperature under nitrogen] was added 20 mg (0.049 mmol) of (*S,R*)-**11** under nitrogen at room temperature, and stirring was continued for 2 h. After addition of chilled water (3 mL) to the reaction mixture cooled in an ice bath, 1 M HCl was added until the solution became acidic (pH<1), and the resulting mixture was washed twice with 10 mL of diethyl ether. The aqueous layer was separated, made strongly basic (pH>11) with aqueous 30% NaOH and extracted with chloroform (3×5 mL). After drying the combined extracts with sodium sulfate, 0.05 mL of concd HCl was added and the resulting mixture was evaporated to dryness in vacuo to give 4.2 mg of crude crystals, which was recrystallized from 1-propanol/hexane to afford 1.3 mg of (*S*)-**12**. The ^1H NMR spectrum was identical with that of *dl*-2-methylenecyclohexylamine hydrochloride (*dl*-**12**), which was prepared as described below.

For observation of the circular dichroism, the *N*-salicylidene derivative of (*S*)-**12** was prepared in situ according to Smith's procedure.[21] Sodium salicylaldehyde[22] (1.26 mg, 8.74 μmol) and 1.14 mg (7.72 μmol) of (*S*)-**12** were weighed into a 5-mL volumetric flask on a microgram balance. Methanol (3 mL) was added and the mixture was warmed for 15 min with steam, cooled, and made up to 5 mL. This solution was diluted (1 : 10) for observation of the CD maxima: CD (*c* 0.0033, MeOH, 25 °C) $[\theta]_{317}^{peak}$ +7800, $[\theta]_{253}^{peak}$ +16000.[23]

Allylic Amination of Methylenecyclohexane at Various Temperatures. Four test tubes (10 cm, 13 mm i.d.) containing 0.25 mmol of diimido selenium reagent (*R*)-**10** in 2 ml of dichloromethane were kept at −40 °C (Dry Ice-aqueous ethanol bath), −20 °C (Dry Ice-carbon tetrachloride bath), −5 °C (ice-salt bath), and 25 °C, respectively. After an addition of 60 μL (0.5 mmol) of methylenecyclohexane to each of the tubes under nitrogen, they were stirred magnetically for 1 week maintaining their initial temperatures in freezers (−40, −20, or −5 °C) or in the room (25 °C). One drop of water was added to each tube to destroy the reagent and the resulting mixtures were then diluted with 4 mL of diethyl ether and 1 mL of an alkaline aqueous solution consisting of 2 parts 1 M NaOH and 1 part saturated NaCl solution. After stirring for 30 min at room temperature, the reaction mixtures were filtered through Celite 545 and the organic layers of the filtrates were concentrated to give oils. Each crude product was analyzed by GC (1 m 1% PEG-HT on 60/80 mesh Uniport HP, 270 °C, flow rate: 38 mL min^{-1}), and the diastereomeric ratios were determined as 29 : 71 (42% diastereomeric excess) in four cases.

Allylic Amination of Cyclohexene with Diimido Selenium Reagent (*R*)-10. Cyclohexene (493 mg, 6 mmol) was aminated with reagent (*R*)-**10** according to the method and conditions described for allylic amination of methylenecyclohexane with reagent (*S*)-**10**. The crude product (oil) was chromatographed on 60 g of silica gel using 50—60% dichloromethane/hexane to give 686 mg (29%) of a diastereomeric mixture (**16**) as crystals in a ratio of 33:67 (34% diastereomeric excess); mp 160—166 °C; IR (KBr) 3245, 1647, 1599, 1452, 1311, 1303, 1154, 1117, 1090, 1060, and 1050 cm^{-1}. The NMR spectrum was identical with an authentic sample of a 73 : 27 diastereomeric mixture of **16'** (vide infra) with the exception of differing peak intensities in the olefinic proton region. HPLC (4 mm i.d. 250 mm LiChrosorb Si 60, 5 μm, 55 : 1 hexane/isopropyl alcohol, 1 mL min^{-1}) retention times of the major (t_r=17.20 min) and minor (t_r=16.00 min) diastereomers in the mixture were identical with those of the authentic sample of **16'**. The above diastereomeric ratio (33 : 67) was determined by GC analysis of *N*-trifluoroacetyl-L-prolyl derivative **17**, which was derived by reductive cleavage of the diastereomeric mixture **16** and subsequent acylation with *N*-trifluoroacetyl-L-prolyl chloride as shown in Scheme 6 (see the following general method for the determination of diastereomeric ratios).

General Method for the Determination of Diastereomeric Ratios. As diastereomeric mixture **16** was not well-resolved either by analytical GC or by analysis of its NMR spectrum, *N*-trifluoroactyl-L-prolyl chloride was used to derivatize[24] the amine enantiomers which were derived by reductive cleavage of the diastereomeric mixture **16**. Separation of the newly derived diastereomeric mixture **17** was achieved by GC. This method was also applied to diastereomeric mixtures **13** and **26**.

To a 0.01 mmol diastereomeric mixture of asymmetric amination product was added 0.4 mL (0.2 mmol) of naphthalene-sodium reagent[14] at room temperature [the reagent was prepared by stirring a mixture of 115 mg (5 mmol) of sodium metal and 673 mg (5.25 mmol) of naphthalene in 10 mL of freshly distilled dry 1,2-dimethoxyethane for 2 h under a nitrogen atmosphere, and 0.4 mL of the resulting deep green solution was used. The rest was stored at 0 °C in the refrigerator for the next use]. After stirring for 1 h, 1 mL of water was added to the ice-chilled (ca. 0 °C) reaction mixture to quench the reaction and the mixture was acidified with an addition of 3 drops of 6 M HCl to pH<1. The resulting solution was washed with diethyl ether (2×1 mL), made strongly basic (pH>11) with 30% aqueous NaOH (ca. 4 drops), saturated with NaCl, and extracted with diethyl ether (2 mL), and the extract was dried (Na_2SO_4). To the ethereal solution was added 0.1 mL (0.01 mmol) of *N*-trifluoroactyl-L-prolyl chloride solution (Regis, 0.1 M in chloroform, contains 6.2% D-isomer), and the resulting mixture was stirred for 30 min. Fifteen minutes after addition of 1 drop of triethylamine and 1 drop of water, the organic layer was separated, dried (Na_2SO_4), and evaporated. A diastereomeric ratio of the diastereomers in the resulting product was analyzed by GC.

Determination of Absolute Configuration of the Major Diastereomer of 16. To the mixture of 8 mg (0.05 mmol) of L-2-aminoadipic acid (Calbiochem) and 5.5 mg of magnesium oxide (heavy) in 0.2 mL of water was added 0.5 mL (0.05 mmol) of *N*-trifluoroacetyl-L-prolyl chloride solution (Regis, 0.1 M in chloroform, contains 6.2% D-isomer) at 0 °C (ice bath), and the mixture was stirred for 2 h at 0 °C, and then for 4 h at room temperature. After dilution with 2 mL of ethyl acetate, the solid material (MgO) was filtered off

through Celite 545 (water wash, 0.5 mL). To the filtrate was added 6 M HCl until the aqueous layer became acidic (pH<1) with stirring. The organic layer was separated, dried (Na_2SO_4), and treated with excess diazomethane (diethyl ether solution). After stirring for 5 min, the excess diazomethane and solvents were removed in vacuo to afford 9 mg of an oil. Analysis by GC (1 m 1% PEG-20M-P on 80/100 mesh Uniport HP, 200 °C, flow rate: 24 mL min^{-1}) afforded single peak[25] (t_r=17.40 min) due to (2*S*)-**18** (*S*-configuration at the asterisk in Scheme 6). The reaction was repeated with *dl*-2-aminoadipic acid and GC analysis of the product showed a 1.0:1.0 ratio of (2*R*)-**18** (t_r=15.17 min) to (2*S*)-**18** (t_r=17.40 min).

To 1.2 mL of the naphthalene-sodium reagent (see above) was added 12 mg (0.03 mmol) of the diastereomeric mixture **16** (33:67) under a nitrogen atmosphere. After stirring for 1 h, the reaction mixture was cooled to 0 °C (ice bath), quenched by addition of 2 mL of ice-water, and acidified to pH<1 with concd HCl (ca. 3 drops). The resulting mixture was washed with diethyl ether (3×1 mL) to remove naphthalene and other nonbasic substances. The separated aqueous layer was made strongly basic (pH>11) with 30% aqueous NaOH (ca. 6 drops), saturated with NaCl, and extracted into diethyl ether (3×2 mL). The ethereal solution (dried with Na_2SO_4) was treated with 0.3 mL (0.03 mmol) of *N*-trifluoroacetyl-L-prolyl chloride (Regis, 0.1 M in chloroform, contains 6.2% D-isomer) and allowed to stand for 1 h. After addition of 1 drop of triethylamine and 3 drops of water, the reaction mixture was stirred for 30 min, and successively washed with 1 mL of 1 M HCl, 1 mL of 1 M NaOH, and brine (2×2 mL), dried (Na_2SO_4), and concentrated to give amide **17** as an oil. The oil was dissolved in 1 mL of ethyl acetate. To this solution was added RuO_4/$NaIO_4$ reagent [a mixture of 52 mg (0.24 mmol) of $NaIO_4$, 0.3 mg (0.0018 mmol) of $RuO_2 \cdot 2H_2O$, 0.5 mL of CCl_4, and 1 mL of water was stirred until all the $RuO_2 \cdot 2H_2O$ dissolved (ca. 2 min) and the resulting mixture was used as the reagent] to cleave the carbon-carbon double bond and the mixture was stirred vigorously for 3 h. Then isopropyl alcohol (3 drops) was added and the reaction mixture was stirred for 30 min. After acidification of the aqueous layer with 3 M sulfuric acid to pH<1, the organic layer was extracted with 3 mL of ethyl acetate, and dried ($MgSO_4$). The ethyl acetate solution was treated with excess diazomethane (diethyl ether solution). After standing for 5 min, the excess diazomethane and solvent were removed in vacuo to afford 8 mg of a crude oil. Analysis by GC (1 m 1% PEG-20M-P, the same conditions as above) showed a 67:33 ratio of (2*R*)-**18** (t_r=15.17 min) to (2*S*)-**18** (t_r=17.40 min), thus establishing the *R*-configuration at the carbon bearing the nitrogen in the major diastereomer of the amination product **16**.

Allylic Amination of 1-Heptene with Diimido Selenium Reagent (*R*)-10. 1-Heptene (471 mg, 4.8 mmol) was aminated with reagent (*R*)-**10** according to the method and conditions described for the allylic amination of methylenecyclohexane with diimido selenium reagent (*S*)-**10**. The crude product (oil) was chromatographed on 70 g of silica gel using 5—10% EtOAc/hexane to give 488 mg (25%) of the diastereomeric mixture **13** in a ratio of 34:66 (32% diastereomeric excess) as an oil: IR (neat) 3228, 2962, 2938, 2864, 1601, 1451, 1318, 1303, 1290, 1263, 1155, 1114, 1095, 1020, and 929 cm^{-1}. The NMR spectrum was identical with an authentic sample of a 1.0:1.0 diastereomeric mixture of **13′** (vide infra) except for intensities of the peaks in the olefinic proton region. HPLC (4.6 mm i.d. 150 mm Finepak SIL C_{18} S; 3:7 H_2O/MeOH, 1 mL min^{-1}) retention times of the major (t_r=8.35 min) and minor (t_r=9.23 min) diastereomers in the mixture were identical with those of the authentic sample of **13′**. The above diastereomeric ratio (34:66) was determined by GC analysis of the *N*-trifluoroacetyl-L-prolyl derivative **14**, which was derived by reductive cleavage of the diastereomeric mixture **13** and subsequent acylation with *N*-trifluoroacetyl-L-prolyl chloride as shown in Scheme 5 (see general method for the determination of diastereomeric ratios).

Determination of the Absolute Configuration of the Major Diastereomer of 13. L-Norleucine (L-2-aminohexanoic acid, 6 mg) was acylated with *N*-trifluoroacetyl-L-prolyl chloride and the resulting amide was then methylated with diazomethane (Scheme 5) according to the method and conditions described for the determination of absolute configuration of the major diastereomer of **16**. GC analysis (2 m 3% Silicone OV-17 on 80/100 mesh Uniport HP, 180 °C, flow rate: 50 mL min^{-1}) of the crude product revealed a single peak[25] (t_r=39.60 min) attributed to (2*S*)-**15**. The reaction was repeated with *dl*-norleucine and GC analysis of the product showed a 1.0:1.0 ratio of (2*R*)-**15** (t_r=34.60 min) to (2*S*)-**15** (t_r=39.60 min).

The diastereomeric mixture **13** (34:66, 12 mg) was converted to amido ester **15** according to the method and conditions described for the conversion of diastereomeric mixture **16** to amido ester **18**. GC analysis (2 m 3% Silicone OV-17 on 80/100 mesh Uniport HP, 180 °C, flow rate: 50 mL min^{-1}) of the crude product showed a 66:34 ratio of (2*R*)-**15** (t_r=34.60 min) to (2*S*)-**15** (t_r=39.60 min), thus providing the *R*-configuration at the carbon bearing the nitrogen in the major diastereomer of **13**.

Allylic Amination of Cyclooctene with Diimido Selenium Reagent (*R*)-10. Cyclooctene (330 mg, 3 mmol) was aminated with reagent (*R*)-**10** according to the method and conditions described for allylic amination of methylenecyclohexane with reagent (*S*)-**10**. The crude product (oil) was chromatographed on 40 g of silica gel using 5—10% EtOAc/hexane to give 379 mg (30%) of the diastereomeric mixture **26** in a ratio of 4.0:6.0 (20% diastereomeric excess) as crystals: mp 117—127 °C; IR (KBr) 3205, 2920, 2850, 1650, 1599, 1447, 1326, 1302, 1217, 1150, 1113, 1088, 1052, and 1023 cm^{-1}. The NMR spectrum was identical with an authentic sample of a 62:38 diastereomeric mixture of **26′** (vide infra) with the exception of differing peak intensities in the olefinic proton region and the shape of proton signal due to the NH. The NH proton signal appeared at 6.10 ppm as a broad singlet. HPLC (4.6 mm i.d. 150 mm Finepak SIL C_{18} S; 3:7 H_2O/MeOH, 1 mL min^{-1}) retention times of the major (t_r=7.95 min) and minor (t_r=8.41 min) diastereomers in the mixture were identical with those of the authentic sample of **26′**. The above diastereomeric ratio (4.0:6.0) was determined by GC analysis of *N*-trifluoroacetyl-L-prolyl derivative **27**, which was obtained by reductive cleavage of the diastereomeric mixture **26** and subsequent acylation with *N*-trifluoroacetyl-L-prolyl chloride as shown in Scheme 8 (see general method for the determination of diastereomeric ratio).

GC Studies for the Determination of Absolute Configuration of the Major Diastereomer of 26. The diastereomeric mixture **26** (4.0:6.0, 13 mg) was converted to amido ester **28** (Scheme 8) according to the method and conditions de-

scribed for the conversion of diastereomeric mixture **16** to amido ester **18**. GC analysis (1 m 1% PEG-20M-P on 80/100 mesh Uniport HP, 195 °C, flow rate: 45 mL min^{-1}) of the product showed a 4.0:6.0 ratio of the minor (t_r=23.02 min) to the major diastereomer (t_r=28.17 min).

L-Glutamic acid (7 mg) was acylated with *N*-trifluoroacetyl-L-prolyl chloride and the resulting amide was then methylated with diazomethane according to the method and conditions described for the determination of absolute configuration of the major diastereomer of **16**. GC analysis (the same column as above, 180 °C, flow rate: 45 mL min^{-1}) of the product afforded a single peak[25] (t_r=22.20 min) assigned to (2*S*)-**29**. The reaction was repeated with *dl*-glutamic acid and GC analysis of the product showed a 1.0:1.0 ratio of (2*R*)-**29** (t_r=18.20 min) to (2*S*)-**29** (t_r= 22.20 min).

A 1:1 diastereomeric mixture of (2*R*)-**15** and (2*S*)-**15** were analyzed by GC using the same column as above (170 °C, flow rate: 24 mL min^{-1}). Retention times of (2*R*)-**15** and (2*S*)-**15** were 7.80 and 10.50 min, respectively.

***dl*-2-Cyclohexenylamine Hydrochloride (*dl*-20).** To naphthalene-sodium reagent[14] [prepared by stirring the mixture of 276 mg (12 mmol) of sodium metal, 1.62 g (12.6 mmol) of naphthalene and 24 mL of freshly distilled dry 1,2-dimethoxyethane for 2 h under nitrogen] was added 503 mg (2 mmol) of *dl*-*N*-*p*-tolylsulfonyl-2-cyclohexenylamine (**19**).[4] After stirring for 1 h, the reaction was quenched by addition of ice-water (10 mL), acidified with 1 M HCl to pH<1, and the resulting solution was washed with diethyl ether (3×35 mL) to eliminate naphthalene and other nonbasic substances. The aqueous layer was then made strongly basic (pH>11) with 30% NaOH, saturated with NaCl, and extracted with chloroform three times (30, 10, and 10 mL). The combined chloroform extracts were dried by passing through a cone of anhydrous sodium sulfate. After addition of 0.5 mL of concd HCl, the mixture was concentrated and the crystalline residue was washed succesively with 1 mL of hexane and 1 mL of benzene to give 187 mg (70%) of *dl*-**20** as off-white crystals. An analytical sample was obtained by recrystallization from 1-propanol/hexane to afford white crystals, mp 159.5—160.5 °C; IR (KBr) 2910, 2714, 2604, 2516, 2042, 1653, 1600, 1502, 1450, 1400, 729, and 670 cm^{-1}; ^{1}H NMR (D_2O) δ=1.4—2.3 (6H, methylene), 3.87 (1H, m, CH-N), 4.78 (3H, s, $NH_2 \cdot HCl$), 5.62 (1H, m, C=CH-C-N), 6.10 (1H, m, CH=C-C-N). Found: C, 54.01; H, 8.79; N, 10.40%. Calcd for $C_6H_{12}ClN$: C, 53.93; H, 9.05; N, 10.48%.

***N*-(2-Cyclohexenyl)-*N'*-(*p*-tolylsulfonyl)benzenesulfonimidamide (16').** To the stirred mixture of 134 mg (1 mmol) of *dl*-2-cyclohexenylamine hydrochloride (*dl*-**20**), 1 g of ice, 2 mL of dichloromethane, and 330 mg (1 mmol) of *N*-(*p*-tolylsulfonyl)benzenesulfonimidoyl chloride (**6**)[10] was added 1 mL of 17% aqueous sodium hydrogencarbonate solution under ice-bath cooling. The reaction mixture was allowed to warm to room temperature (ca. 1 h) and stirred for an additional 24 h. The reaction mixture was twice extracted with ethyl acetate (10 mL, 5 mL), and the combined extracts were dried (Na_2SO_4). Evaporation of the solvent gave crude product which was then passed through a short plug of silica gel (3 g) using 1:1 EtOAc/hexane as eluent. Polar impurities were thus removed and evaporation of the solvent gave crystals, which were further recrystallized from EtOH/hexane to give 169 mg (43%) of optically inactive diastereomeric mixture **16'** (73:27[26]): mp 147—153 °C; HPLC (4 mm i.d. 250 mm LiChrosorb Si 60, 5 μm, 55:1 hexane/isopropyl alcohol, 1 mL min^{-1}) t_r=17.20 min (major), t_r=16.00 min (minor); IR (KBr) 3245, 1647, 1599, 1452, 1311, 1303, 1154, 1117, 1090, 1060, and 1050 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.2—2.1 (6H, methylene), 2.40 (3H, s, aryl methyl), 3.85 (1H, m, CH-N), 5.45—6.20 (3H, m, two vinyl protons and NH), and 7.10—8.10 (9H, aromatic). Found: C, 58.34; H, 5.86; N, 7.17%. Calcd for $C_{19}H_{22}N_2O_3S_2$: C, 58.44; H, 5.68; N, 7.17%.

***dl*-*N*-*p*-Tolylsulfonyl-2-cyclooctenylamine (23).** A mixture of 729 mg (10.5 mmol) of dry selenium powder (dried in vacuo at 80 °C for 1 h) and 4.55 g (10 mmol) of anhydrous Chloramine-T (commercially available Chloramine-T was dehydrated in vacuo at 80 °C for 1 h) in 35 mL of dry dichloromethane (methanol-free dichloromethane was passed through activated alumina, Woelm neutral alumina activity I and stored over 3A Molecular Sieves) was vigorously stirred (magnetically) for 14 h at room temperature under a nitrogen atmosphere (a white or white-gray slurry was usually produced after stirring for 2 to 4 h). Several minutes after addition of 1.56 mL (1.32 g, 12 mmol) of cyclooctene to the stirred slurry at room temperature, a gentle exothermic reaction was observed and the stirring was continued overnight (for about 14 h). The solvent was then removed in vacuo, and the residue was dissolved in a mixture of 150 mL 1:1 ethyl acetate/diethyl ether and 90 mL of an alkaline aqueous solution consisting of 2 parts 1 M NaOH and 1 part saturated NaCl solution. After stirring for 30 min, the entire reaction mixture was filtered through Celite 545 and the organic layer of the filtrate was washed again with the above mentioned alkaline brine solution (2×50 mL), dried (Na_2SO_4), and concentrated to give crude crystals. The crystals were dissolved in 20 mL of acetone. The acetone solution was refluxed for 2 min with 30 mg of activated charcoal and the mixture was passed through a two layered column (13 mm i.d.) consisting of 1.3 g of Celite 545 (lower layer) and 100 mg of activated charcoal (upper layer). More acetone (30 mL) was used to ensure elution of **23** and the combined eluates were concentrated to give white crystals, which were recrystallized from carbon tetrachloride/hexane (ca. 10 mL:15 mL) to give 2.66 g (84%) of **23**: mp 125.0—125.5 °C; IR (KBr) 3230, 2910, 2845, 1595, 1437, 1300, 1144, 1087, and 1060 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.0—2.2 (10H, methylene), 2.41 (3H, s, aryl methyl), 4.19 (1H, m, CH-N), 4.92 (1H, d, J=6.81 Hz, NH), 5.14 (1H, d of d, J=7.69 and 10.55 Hz, C=CH-C-N), 5.54 (1H, d of t, J=10.55 and 5.54 Hz, CH=C-C-N), 7.1—7.9 (4H, aromatic). Found: C, 64.44; H, 7.66; N, 5.02%. Calcd for $C_{15}H_{21}NO_2S$: C, 64.48; H, 7.58; N, 5.01%.

***dl*-2-Cyclooctenylamine Hydrochloride (*dl*-24).** *dl*-2-Cyclooctenylamine hydrochloride (*dl*-**24**) was prepared from 1 g (3.58 mmol) of **23** according to the method and conditions described for the preparation of *dl*-2-cyclohexenylamine hydrochloride (*dl*-**20**), and the crude crystalline hydrochloride was recrystallized from isopropyl alcohol/hexane to give 407 mg (70%) of *dl*-**24**: mp 268—269 °C (sealed tube under nitrogen); IR (KBr) 2926, 2652, 2576, 2040, 1655, 1609, 1586, 1519, 1457, 1410, 758, and 716 cm^{-1}; ^{1}H NMR (D_2O) δ=1.2—2.4 (10H, methylene), 4.26 (1H, m, CH-N), 4.80 (3H, s, $NH_2 \cdot HCl$), 5.47 (1H, d of d, J=7.91 and 10.54 Hz, C=CH-C-N), 5.96 (1H, m, CH=C-C-N). Found: C, 59.54; H, 10.20; N, 8.62%. Calcd for $C_8H_{16}ClN$: C, 59.43; H; 9.97; N, 8.66%.

***N*-(2-Cyclooctenyl)-*N'*-(*p*-tolylsulfonyl)benzenesulfonimidamide (26').** Compound **26'** was prepared from 162 mg (1 mmol) of *dl*-**24** according to the method and conditions

described for the preparation of *N*-(2-cyclohexenyl)-*N'*-(*p*-tolylsulfonyl)benzenesulfonimidamide (**16'**), and recrystallization from ethanol/hexane gave 307 mg (73%) of diastereomeric mixture **26'** (62:38[26]): mp 123—134 °C; HPLC (4.6 mm i.d. 150 mm Finepak SIL C_{18} S; 3:7 H_2O/MeOH, 1 mL min^{-1}) t_r=7.95 min (major), t_r=8.41 min (minor); IR (KBr) 3205, 2920, 2850, 1650, 1599, 1447, 1326, 1302, 1217, 1150, 1113, 1088, 1052, and 1023 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.0—2.2 (10H, methylene), 2.39 (3H, s, aryl methyl), 4.14 (1H, m, CH-N), 4.8—5.8 (2H, m, CH=CH), 5.98 (0.62H, d, J=6.8 Hz, NH in the major diastereomer), 6.20 (0.38H, d, J=7.3 Hz, NH in the minor diastereomer), 7.1—8.0 (9H, aromatic). Found: C, 60.12; H, 6.23; N, 6.49%. Calcd for $C_{21}H_{26}N_2O_3S_2$: C, 60.26; H, 6.26; N, 6.69%.

***dl*-*N*-*p*-Tolylsulfonyl-1-butyl-2-propenylamine (21).** *dl*-*N*-*p*-Tolylsulfonyl-1-butyl-2-propenylamine (**21**) was prepared by allylic amination of 1-heptene (1.18 g, 12 mmol) according to the method and conditions described for the preparation of *dl*-*N*-*p*-tolylsulfonyl-2-cyclooctenylamine (**23**). The crude product (oil) was chromatographed on 80 g of silica gel using 50—75% benzene/hexane to give 2.08 g (65%) of **21** as an oil. An analytical sample was obtained by Kugelrohr distillation of a portion of this oil (180 °C, 13 Pa): IR (neat) 3280, 2970, 2940, 2860, 1648, 1600, 1500, 1432, 1330, 1163, 1098, 923, and 817 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80 (3H, diffuse t, J=5.9 Hz, methyl), 1.0—1.7 (6H, methylene), 2.41 (3H, s, aryl methyl), 3.72 (1H, m, CH-N), 4.8—5.1 (2H, three peaks, CH=C), 5.18 (1H, d, J=7.0 Hz, NH), 5.55 (1H, m, C=CH-N), 7.1—7.9 (4H, aromatic). Found: C, 62.80; H, 8.13; N, 5.14%. Calcd for $C_{14}H_{21}NO_2S$: C, 62.98; H, 7.92; N, 5.24%.

***dl*-1-Butyl-2-propenylamine Hydrochloride (*dl*-22).** *dl*-1-Butyl-2-propenylamine hydrochloride (*dl*-**22**) was prepared from 1 g (3.74 mmol) of **21** according to the method and conditions described for the preparation of *dl*-2-cyclohexenylamine hydrochloride (*dl*-**20**). the crude crystalline hydrochloride was recrystallized from isopropyl alcohol/hexane to give 243 mg (43%) of *dl*-**22**: mp 118—119 °C; IR (KBr) 2928, 2666, 2548, 2060, 1617, 1504, 1439, 1000, and 960 cm^{-1}; ^1H NMR (D_2O) δ=0.887 (3H, t, J=5.93 Hz, methyl), 1.1—1.9 (6H, methylene), 3.78 (1H, d of t, J=6.81 and 6.81 Hz, CH-N), 4.79 (3H, s, aryl methyl), 5.2—5.5 (2H, m, CH=C), 5.6—6.1 (1H, m, C=CH-C-N). (Received October 24, 1988)

Bakers' yeast reduces esters of 2-alkyl-3-oxobutanoic acid ($CH_3COCHRCO_2R'$; R=methyl, ethyl, propyl, propargyl, and allyl) into the corresponding (*S*)-hydroxy esters with exclusive stereoselectivity, while the configuration at the 2-position of the hydroxy esters is either *S* (anti) or *R* (syn) depending on the structure of the alkoxyl group in the carboalkoxyl moiety of the ester. Oftenly, the stereoselectivity with respect to the 2-position is not satisfactory. In general, the reduction of *t*-butyl esters exerts predominancy in the products, whereas that of 1,1-dimethylpropyl esters exerts the syn predominancy. A marked difference between these two esters in diastereoselectivity is discussed from the view point of plausible conformations of the esters.

Esters of 2-alkyl-3-hydroxybutanoic acids are important chiral building blocks for syntheses of antibiotics and other natural products. There are three major methods in the literatures to prepare the esters with high diastereo- and enantioselectivities. First of all is the aldol condensation of chiral enolates with aldehydes,[1,2] and the second method is α-alkylation of a dianion from a chiral 3-hydroxybutanoate.[3] The latter method is restricted to synthesize the hydroxy ester of anti conformation. These two methods are chemical transformations and require an optically active starting material(s) in order to obtain an optically active product. The third and biological method involves the reduction of achiral 2-alkyl-3-oxobutanoate by means of certain microbes.[4,5] The biological method has some advantages over the chemical methods in that two chiral centers are introduced into the product in one step starting from an achiral compound, and that some microbes such as bakers' yeast (BY) are quite cheap and easily obtainable. However, on the other hand, diastereoselectivity of microbial reduction is not always satisfactory and sometimes both syn and anti products are produced in nearly equal amounts, which means that dehydrogenases

present in the microbe and responsible for the reduction cannot recognize the configuration at the α (or 2)-position of racemic α-substituted β-keto esters (alkyl 3-oxocarboxylates).

It is known that the stereochemistry of the reduction of β-keto esters by BY affords the corresponding (*S*)-hydroxy esters with moderate to high enantioselectivities,[6] and the substitution by an alkyl group at the α-position of the ester increases the selectivity.[7,8] Therefore, if an α-substituted β-keto ester has a structure which exerts a large difference in rate of reduction between its 2*S*- and 2*R*-enantiomeric isomers, one can expect to obtain the product with a high diastereomeric excess (d.e.). There remains another problem, i.e., if the rate of isomerization between the 2*S*- and 2*R*-isomers is not fast enough compared to the rate of reduction, the chemical yield of the product cannot exceed 50% even though the recognition between 2*S*- and 2*R*-isomers with an enzyme is excellent. On the other hand, if racemization at the α-position takes place much faster than the reduction, the starting material remains racemic whole through the reaction period and the product is expected to be highly diastereoselective after 100% completion of the reaction.

We would like to report in this paper that the diastereoselectivity of the reduction of an α-substituted β-keto ester with BY can be controlled by the change in the structure of alkoxyl group: the presence and absence of a methylene group next to the alkoxyl oxygen play a crucial role in determining the syn/anti selectivity, therefore the d.e., of the reduction.

Results

Various esters of 2-methyl- (**1**), 2-ethyl- (**2**), 2-propyl- (**3**), 2-propargyl- (**4**), and 2-allyl-3-oxobutanoates (**5**) were prepared from the corresponding unsubstituted esters by alkylation and subjected to the reducion with BY. The diastereoselectivities of the reduction (syn/anti ratio in the product) were monitored on GLC. The authentic samples for the anti isomers were prepared by the reaction of the dianion of 3-hydroxybutanoates with the corresponding alkyl halides.[3]

The rate of deuterium incorporation at the 2-position of ethyl 2-methyl-3-oxobutanoate (**1b**) in neutral deuterium oxide was measured on a ^{1}H NMR spectrometer. The signal from the methine proton of **1b** (δ_{TMS}: 3.8) was compared with that from the methylene protons in the ethyl group (δ_{TMS}: 4.3). The intensity of the former signal decreased gradually with a half-life of about 1.5 hours, which is at least an order of magnitude faster than the rate of reduction. On the other hand, practically no incorporation of deuterium was observed with 2-methyl-3-hydroxybutanoate (**6b**) under the same reaction conditions.

Results from the reduction of various esters are summarized in Table 1.[9] The diastereomeric composition of 2,2-dimethylpropyl 2-methyl-3-hydroxybutanoate (**6j**) obtained by the reduction with BY was measured in detail, after it was converted into **6a**, and found the ratio of 2*R*, 3*S* : 2*S*, 3*S* : 2*R*, 3*R* : 2*S*, 3*R* to be 96 : 4 : $<$1 : $<$1. Thus, it was confirmed that the contamination of the (3*R*)-isomers is negligible, if any.

Discussion

Since H-D exchange and racemization at the α-position of a β-keto ester pass through the same intermediate (enolate), there remains no doubt that fast incorporation of deuterium in **1b** under neutral conditions reveals that the starting material stays in a racemic mixture with respect to the enantiomorphism at the α-position whole through the reduction by BY, where there are many acid and base catalysts to promote the enolization. That is, all starting materials subjected to the present reduction can, at least theoretically, be converted into the product of desired configuration (kinetic resolution), provided the difference in rate of reduction for two enantiomers is large enough.

Elongation of alkyl chain in alkoxyl group of the β-keto ester did not show remarkable difference in the diastereoselectivity of the reduction for all α-substituents so far studied. This is in contrast to the reduction of β-keto esters unsubstituted at the α-position.[10] In addition, substitution of a methylene group in the alkyl chain by either a heteroatom such as oxygen or sulfur or an aromatic group did not affect the selectivity in recognizable extent as can be seen in Table 1. Thus, the change in the polarity (or hydrophobicity) of the alkoxyl group seems to exert very little effect, if any, on the selectivity. Another interesting trend seen in Table 1 is that α-allyl substituent tends to afford the anti product, whereas others prefer to yield the syn product. The latter trend is the strongest with the α-methyl substituent, the shortest alkyl group. Since the propargyl group belongs to the syn-preferential substituent, it is clear that the anti-orientation with the allyl group is not due to the presence of a π-bonding in this substituent.

A remarkable change in the diastereoselectivity can be seen in anti preference with 2-allyl-3-oxobutanoates (**10**) when the alkoxyl oxygen is bound directly to a tert-carbon such as in *t*-butyl (**10h**) and 1,1-dimethylpropyl (**10i**) esters. The same structure also shifts the selectivity toward the anti direction in 2-methyl-3-hydroxybutanoates (**6**), and the syn/anti ratio becomes the worst in **6h**. Instead, the insertion of a methylene group between the alkoxyl oxygen and a bulky alkyl substituent such as in 2,2-dimethylpropyl (**j**) or cyclohexylmethyl (m) esters shifts the selectivity to syn direction. Consequently, the syn/anti ratio in **6** is improved by the alkoxyl group of this kind, but the value for **10** with these alkoxyl groups becomes worse.

It is interesting to note that one methylene group in the alkoxyl moiety affects the stereochemistry of the reduction. It should be emphasized that the reduction

a) Numbers in parentheses are chemical yields. b) No reaction.

with BY is catalyzed by a variety of catalysts, dehydrogenases, and reductases, in this microbe, and we cannot nominate any one of enzymes as the sole candidate for the catalyst. Zhou and his co-workers reported that there are at least three dehydrogenases in BY to reduce 4-chloro-3-oxobutanoates.[11)] Furuichi and his co-workers found that benzyl 2-methyl-3-oxobutanoate is reduced by a pure enzyme into the corresponding β-hydroxy ester with the syn/anti ratio of 8/1, whereas the reduction of the same ester with a yeast affords the syn/anti ratio to be 2/1[12)] suggesting the contribution of plural enzymes in yeast. Nevertheless, the sum of individual diastereoselectivities of all enzymes involved in the reduction can be attributed to the diastereoselectivity of an "imaginary" enzyme.[13)]

Inspection of molecular structures of the esters with the aid of CPK-models seems to suggest a simple rule; *a principle of the smallest volume*. Figures 1a and 1b show molecular models for (2*R*,3*S*)-**6j** (syn) and (2*S*,3*S*)-**6j** (anti), respectively, where a bulky substituent is represented by an iodine atom. Suppose that the carboxylate oxygen assumes the syn-conformation with respect to the carbonyl oxygen to be reduced and the "hydride" from NAD(P)H attacks the carbonyl group from the front side to give the (3*S*)-hydroxy ester as seen in Fig. 1. Also suppose that the molecule is folded in the pocket of the "imaginary" enzyme so that the alkoxyl oxygen in the ester can assume the syn-conformation in the molecular plane. From Fig. 1, it is recognized that the alkoxyl oxygen in the *syn*-**6j** can assume the full syn-conformation in the molecular plane without being suffered from any strain, whereas

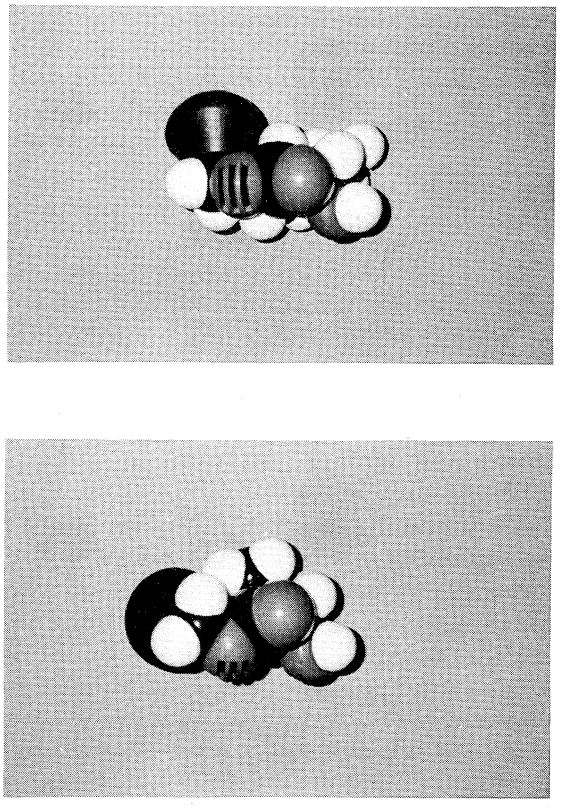

Fig. 1. CPK-models for (a) 2*R*,3*S* (*syn*)- and (b) 2*S*,3*S* (*anti*)-alkyl 2-methyl-3-hydroxybutanoates. The bulky substituent in the alkoxyl group is represented by an iodine model.

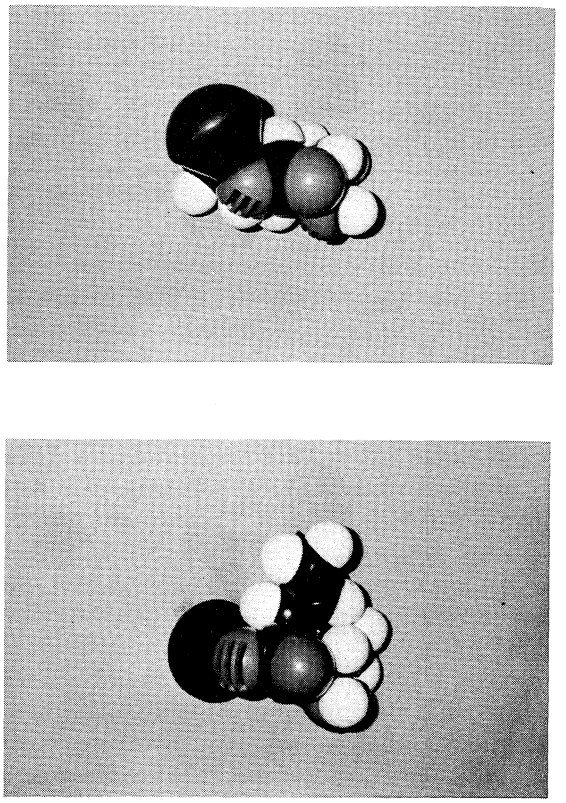

Fig. 2. CPK-models for (a) 2*R*,3*S* (*syn*)- and (b) 2*S*,3*S* (*anti*)-alkyl- 2-allyl-3-hydroxybutanoates. The bulky substituent in the alkoxyl group is represented by an iodine model.

the oxygen in the *anti*-**6j** has to be twisted from the plane to be in the syn-conformation.

Contrary, the alkoxyl oxygen can assume the full syn-conformation in (2*S*,3*S*)-**10h** (anti), as shown in Fig. 2 in which a bulky substituent is again represented by an iodine, but it is largely twisted from the planarity in (2*R*, 3*S*)-**10h** (syn). Thus, the reduction affords satisfactory diastereoselectivity only when the structure of an ester is such that in which the alkoxyl oxygen can assume *a planar syn-conformation* in the product β-hydroxy ester. In other words, the pocket of the "imaginary" enzyme does not have enough room and elasticity to accept a bulky molecule, and the stereoselectivity appears large either in syn or anti direction when the fundamental skeleton of β-keto ester can assume the smallest volume. The presence or absence of a methylene group adjacent to the alkoxyl oxygen is crucial to make the syn or anti conformation more stable than the other, respectively. Since the substituent at the 2-position of **7**, **8**, or **9** is larger than that in **6**, the steric bulk of the alkoxyl group becomes more important in these esters, and the syn/anti predominancy is reversed in **7h**, **8h**, and **9h**. The conformational effect is more important than the hydrophobicity of the alkoxyl group to determine the selectivity. Similar trend in the steric bulk of the alkoxyl group was also observed in the reduction of 2-methyl-3-oxopropanoates.[14] It should be emphasized again that the argument has been done for a pocket of imaginary enzyme composed of a pack of many real enzymes.

In order to confirm the proposed principle, and to prove its versatility, we have to accumulate further results from various esters. However, we believe that the principle at the present stage can suggest the structure of substituents we should try in order to obtain the β-hydroxy ester of certain configuration at least as a working hypothesis.

Experimental

Instruments. ^{1}H NMR spectra were recorded on a Varian VXR-200 spectometer in $CDCl_3$ with tetramethylsilane (TMS) as an interal reference or in D_2O with sodium 3-(trimethylsilyl)-1-propanesulfonate-1,1,2,2-d_4 (DSS) as an internal reference. Gas chromatography was recorded on a Yanaco G-1800 and a G-2800 gas chromatographs. Optical rotations were measured with a Perkin-Elmer 241 polarimeter.

Materials. Organic reagents were purchased from Nacalai Tesque Co., Tokyo Kasei Co., and Aldrich Chemical Co. unless otherwise indicated. Solvents and commercially available starting materials were generally used without additional purification unless otherwise indicated. Pyridine and benzene were refluxed on calcium hydride for 1 day and distilled before the use. Satisfactory results were obtained from elemental analyses of all of the products.

Rate of Enolization. Into 0.5 ml of D_2O containing DSS in an NMR sample tube, 20 mg of ethyl 2-methyl-3-oxobutanoate (**1b**) was added and the solution was immediately subjected to ^1H NMR spectroscopy. The intensity of signal from the methine proton (δ_{DSS}: 3.8) was compared with that from the methylene proton in the ethyl group (δ_{DSS}: 4.3). Initially, the ratio of the intensities of both signals was 1/2, but it decreased to 1/4 after 1.5 h, revealing that the rate of enolization takes place much faster than the reduction.

Preparation of Alkyl 2-Alkyl-3-oxobutanoate. In general, into 200 ml of a benzene solution containing 0.1 mol of an alkyl 3-oxobutanoate and 0.1 mol of 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) was added 0.1 mol of an appropriate alkyl iodide in 100 ml of benzene. The resulted mixture was stirred for 3 h at room temperature and filtered. The filtrate was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residue was distilled to give an alkyl 2-alkyl-3-oxobutanoate. For 1,1-dimethylpropyl esters, the residue was subjected to a column chromatography on silica gel using hexane-ether (100:3) as an eluent. 2-Methyl-3-oxobutanoates, except for **1a**, **1b**, **1h**, and **1i**, were prepared by transesterification with the corresponding ethyl ester (**1b**) according to the literature procedure.[14] Chemical yields (%), boiling points (°C/mmHg[15]), and ^1H NMR spectral data (δ_{TMS} in $CDCl_3$) of the esters are summalized below in this order.

Preparation of Racemic Esters of 3-Hydroxy-2-alkylbutanoate. Sodium borohydride (9.5 mg, 0.25 mmol) was added to a stirred and cooled solution composed of 1 mmol of alkyl 2-alkyl-3-oxobutanoate and 10 ml of tetrahydrofuran (THF) in an ice bath. The resulted solution was stirred at room temperature for 1 h and the THF was removed under reduced pressure, then the residual solution was acidified with dilute aqueous hydrochloric acid. The organic portion was extracted with ether (30 ml), and the ether layer was washed with water, aqueous sodium hydrogencarbonate, and water (10 ml each), respectively. The ethereal solution was dried over anhydrous sodium sulfate, and the solvent was evaporated under reduced pressure. Esters of 3-hydroxy-2-alkylbutanoate were obtained by distillation of the residue with a Kugelrohr apparatus. Chemical yields (%), boiling points (°C/mmHg[15]), and ^{1}H NMR spectral data (δ from TMS in $CDCl_3$) of the esters are summarized below in this order.

6a: 46; 75 (17); 1.17 (syn: s), 1.21 (anti: a) (3H, d, J=6.4 Hz), 1.22 (3H, d, J=6.4 Hz), 2.40—2.67 (2H, m), 3.70 (3H, s), and 4.01—4.28 (1H, m). **6b**: 42; 75 (17); 1.17 (s), 1.21 (a) (3H, d, J=6.3 Hz), 1.17 (3H, d, J=7.0 Hz), 1.26 (3H, t, J=7.2 Hz), 2.35—2.55 (1H, m), 2.59—2.72 (1H, b), 3.79—4.12 (1H, m), and 4.16 (2H, q, J=7.2 Hz). **6c**: 63; (17); 0.92 (3H, t, J=7.2 Hz), 1.16—1.22 (3H, m), 1.17 (3H, d, J=7.2 Hz), 1.28—1.46 (2H, m), 1.55—1.69 (2H, m), 2.36—2.53 (1H, m), 2.59—2.72 (1H, b), 3.79—4.22 (1H, m), and 4.10 (2H, t, J=6.6 Hz). **6d**: 92; 80 (2); 0.88 (3H, t, J=6.6 Hz), 1.16 (s), 1.20 (a) (3H, d, J=6.4 Hz), 1.17 (3H, d, J=6.8 Hz), 1.20—1.40 (6H, m), 1.56—1.68 (2H, m), 2.35—2.56 (1H, m), 2.63 (1H, b), 3.79—4.22 (1H, m), and 4.09 (2H, t, J=6.8 Hz). **6e**: 80; 100 (1.5); 0.87 (3H, t, J=6.5 Hz), 1.15—1.22 (6H, m), 1.15—1.40 (10H, m), 1.57—1.70 (2H, m), 2.37—2.56 (1H, m), 2.55—2.75 (1H, b), 3.81—4.22 (1H, m), and 4.09 (2H, t, J=6.6 Ha). **6g**: 66; 80 (18); 0.96 (6H, d, J=6.8 Hz), 1.17 (s), 1.21 (a) (3H, d, J=6.6 Hz), 1.19 (3H, d, J=7.2 Hz), 1.80 (1H, b), 1.84—2.04 (1H, m), 2.38—2.58 (1H, m), 3.89 (2H, d, J=6.6 Hz), and 3.77—4.21 (1H, m). **6h**: 84; 100 (16); 1.11—1.21 (6H, m), 1.45 (9H, s), 2.25—2.45 (2H, m), 3.75—4.06 (1H, m). **6i**: 68; 100 (20); 0.88 (3H, t, J=7.5 Hz), 1.12—1.21 (6H, m), 1.42 (6H, s), 1.77 (2H, q, J=7.5 Hz), 2.25—2.47 (2H, m), and 3.96—4.21 (1H, m). **6j**: 37; 130 (18); 0.94 (9H. s), 1.18 (s), 1.22 (a) (3H, d, J=6.4 Hz), 1.20 (3H, d, J=7.2 Hz), 2.40—2.60 (1H, m), 2.56—2.77 (1H, b), 3.81 (2H, s), and 3.83—4.12 (1H, m). **6k**: 75; 145 (19); 1.15 (3H, d, J=7.2 Hz), 1.16 (s), 1.20 (a) (3H, d, J=6.1 Hz), 1.50—1.98 (8H, m), 2.26—2.51 (1H, m), 2.55—2.85 (1H, b), 3.78—4.10 (1H, m), and 5.14—5.24 (1H, m). **6l**: 87; 160 (21); 1.15—1.22 (6H, m), 1.25—1.89 (11H, m), 2.34—2.53 (1H, m), 3.79—4.10 (1H, m), and 4.72—4.85 (1H, m). **6m**: 88; 175 (21); 1.17 (s), 1.21 (a) (3H, d, J=6.3 Hz), 1.18 (3H, d, J=7.2 Hz), 0.88—1.79 (11H,

Reduction of Alkyl-3-oxobutanoates with Bakers' Yeast. One mmol of an alkyl 2-alkyl-3-oxobutanoate was added to a suspension of 20 g of bakers' yeast in 25 ml of water and the mixture was stirred at room temperature for 2 days. Then Hyflo-Super-Cell (10 G) was added to the mixture and the resulted suspension was filtered. The organic portion was concentrated under reduced pressure and the residue was subjected to column chromatography on silica gel with an eluent of hexane-ethyl acetate (9 : 1) mixture to give the corresponding hydroxy ester. The diastereomeric ratios and chemical yields are listed in Table 1.

Determination of Syn/Anti Ratio. The syn/anti ratio in the product was determined on GLC (PEG. 1.5 m) with column temperatures: **6a**, 80 °C; **6b**, 90 °C; **6c**, 110 °C; **6d**, 120 °C; **6e**, 150 °C; **6g**, 110 °C; **6h**, 80 °C; **6i**, 120 °C; **6j**, 100 °C; **6k**, 120 °C; **6l**, 130 °C; **6m**, 150 °C; **6n**, 160 °C; **6p**; 130 °C; **6q**, 130 °C; **6r**, 130 °C; **6s**, 130 °C; **6t**, 130 °C.

Determination of Diastereomeric Composition. The reduced product **6j** was converted into the corresponding methyl ester and the ^{1}H NMR spectrum of its MTPA ester[16] was compared with those of the authentic samples prepared by methylation of racemic and (*S*)-methyl 3-hydroxybutanoates.[3]

9) The diastereomeric composition of the product seems to depend on the activity of bakers' yeast employed for the reduction. For example, the ratio preliminary reported for **6e** was 95/5,[5] which turned out to be 92/8 in the present report. In the preliminary experiment which was run 2 years ago, the yeast employed was less active than that employed presently and unable to reduce the substrate completely unless glucose was added at each 6 h. The yeast in the present work reduced **6e** within 1 day without adding extra glucose.

Synthesis and Properties of the Tridecafulvene Derivatives. The Substituent Effect at the 14-Position on the Tropicity of Thirteen-Membered Fulvene System

(Received October 26, 1988)

Dimethylbisdehydrotridecafulvene derivatives bearing various substituents at the exocyclic bond have been synthesized and the inductive effect of substituents upon the tropicity of the thirteen-membered ring is discussed on the basis of the spectral data.

The cyclic cross-conjugated π-electron systems, fulvalene (**1**) and fulvene (**2**), containing small- and medium-rings have been extensively studied.[1] However, there is little study on those containing a monocyclic large-membered ring. It is expected that an examination of the ring current effect of the large-membered ring system can be made more readily than those of the small- and medium-ring ones, since the former has both the olefinic inner and outer protons, as compared with that the latter has only the olefinic outer protons.[2]

3

Recently, we have investigated the cross-conjugated π-electron systems **4**—**9** as well as their 15-, 17-, and 19-membered counterparts,[3] which were derived from the bisdehydroannulenones (**3**).[4] Among these compounds, the diphenyl (**4**)[3a] and the dichloro derivative (**5**)[3b] proved to be atropic, reflecting little cross-conjugation of π-electrons, or of little contribution from dipolar structures (**4a**) and (**5a**), respectively, in the ground state. In contrast, the dinitrile derivative (**6**)[3c] exhibited the ring current effect (paratropicity), owing to polarization of an exocyclic bond. These results and relatively easy preparation of **6** directed us to prepare the various derivatives of tridecafulvene in order to study the inductive effect of substituents upon the tropicity of the thirteen-membered ring.

Results and Discussion

Synthesis. Reduction of **6** with a little excess of diisobutylaluminum hydride (DIBAH)[5] gave only the nitrile aldehyde derivative **11** in 53% yield, along with recovery of a small amount of **6**. A further reduction of **11** with the same reagent resulted in formation of the hydroxy aldehyde derivative **12** (9%) and the hydroxy nitrile derivative **13** (12%), but the diformyl derivative was not obtained in these reductions. Compound **13** was also obtained from **11** by reduction with $NaBH_4$ (75%). Treatment of **13** with phosphorus tribromide gave the bromomethyl nitrile derivative **14** (84%), which was led to the methyl ether derivative **15** (15%) by reaction with NaOMe. The reaction of **11** with MnO_2-NaCN-MeOH, according to the procedure of Corey et al.,[6] afforded the methyl ester derivative (**16**) (42%). Similarly, the reaction of **11** with MnO_2-NaCN-NH_3[7] afforded the amide derivative (**17**) (17%). Oxidation of **11** with Jone's reagent[8] resulted in formation of the annulenone (**10**), arising from the attack of the pinch bond of **11**.

^{1}H NMR and Electronic Spectra. The chemical shifts of the olefinic protons, labeled in the formulas, of the compounds **11**—**17** as well as the closely related compounds **4**—**10**[3a-e,4a] are listed in Table 1. The chemical shift differences between the inner (H^B, $H^{B'}$) and the outer (H^A, $H^{A'}$, H^C, $H^{C'}$) protons, $\Delta\delta=H^i-H^o$ (H^i=inner protons; H^o=outer protons), which would be an experimental measure of the magnitude of ring current of these compounds, are also given in Table 1.

Considering the chemical shift differences ($\Delta\delta$), the following decreasing order of the tropicity of the 13-membered ring of these compounds may be established: **6** (CN, CN)>**10** (annulenone)>**16** (CN,

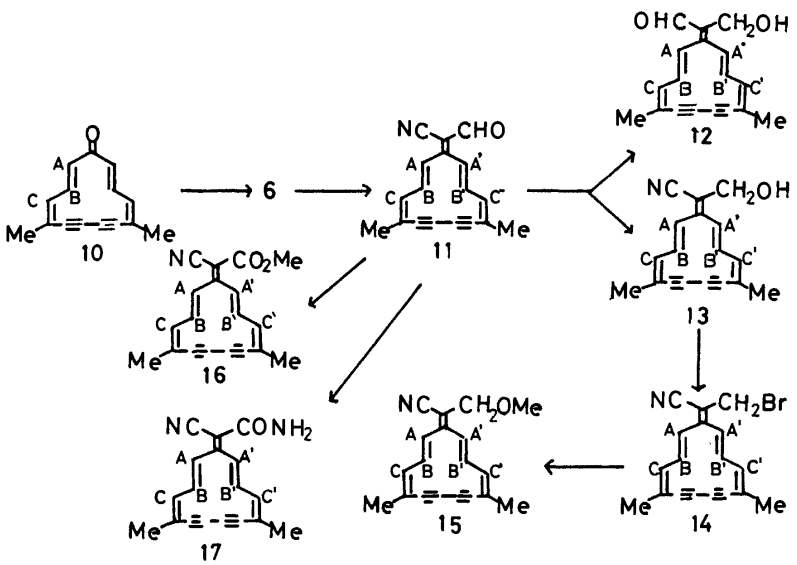
a) a. in THF: λ_{max} (nm) (ε_{max}/1 $mol^{-1}cm^{-1}$); b. in acetonitrile: λ_{max} (nm) (relative extinction coefficients)

CO_2Me)>**17** (CN, $CONH_2$)>**11** (CN, CHO)>**14** (CN, CH_2Br)>**13** (CN, CH_2OH)>**15** (CN, CH_2OMe)>**7** (pentafulvalene)>**8** (dibenzopentafulvalene) >**5** (Cl, Cl)≃**12** (CHO, CH_2OH)≃**4** (Ph, Ph)>**9** (heptafulvalene). Since both the inner H^B and $H^{B'}$ protons suffer a rather large local anisotropy of the diacetylene bond in these compounds,[9] the tropicity of **12** as well as **4** and **5** is quite small, i.e., **4**, **5** (as mentioned above), and **12** are atropic. This result also supports the interpretation that the heptafulvalene (**9**) ($\Delta\delta$: −0.01) is diatropic, as reported previously.[3e] All other tridecafulvene derivatives including the fulvalenes **7** and **8** are paratropic and show the contribution of the dipolar structure such as **6a**.

Among the compounds in which one substituent is nitrile group, the paratropicity decreases in the following order of another substituent: CN (**6**)>COOMe (**16**)>$CONH_2$ (**17**)>CHO (**11**)>CH_2Br (**14**)>CH_2OH (**13**)>CH_2OMe (**15**). This is roughly in accord with a decreasing order of the inductive, electron-withdrawing effect of their substituents, except that of the CHO group.

Since the chemical shifts of H^A, H^B, H^C, and $H^{C'}$ protons are similar in compounds **11** , **16**, and **17**, the deviation of **11** from the order of the electron-withdrawing effect is ascribed to the rather large difference of the chemical shifts of $H^{A'}$ and $H^{B'}$ protons between **11** and **16** (and **17**). Although the higher field shift of $H^{B'}$ proton of **11** as compared with those of **16** and **17**, could not be explained, the higher field shift of $H^{A'}$ proton of **11** might be attributed to a local anisotropic effect of the formyl group at 14-position.

The electronic absorption maxima of compounds **11**—**17**, determined in both tetrahydrofuran (THF) and acetonitrile, are listed in Table 2. It is evident from Table 2 that all the maxima of compounds **11**—**17** show a small hypsochromic shift or do not show any shift on changing the solvent from less polar (THF) to polar (acetonitrile). This solvent effect also supports the interpretation that the polarization, depicted in structure (**6a**), from the large rings to the exocyclic moiety occurs in these systems **11** and **13**—**17**,



as revealed by ^{1}H NMR spectral data.

In conclusion, it was found that the paratropicity of the tridecafulvene system decreases with the decreasing electron-withdrawing order of the inductive effect of substituents at 14-position.

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. IR spectra were measured on a Hitachi 260—50 spectrophotometer as KBr disk; only significant maxima are reported. Electronic spectra were determined on a Hitachi 220A spectrophotometer (sh=shoulder). ^{1}H NMR spectra were measured on a JEOL FX-90Q (90 MHz) and refer to solutions in $CDCl_3$, in δ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. Assignments were assisted by decoupling experiments where necessary. Mass spectra were determined with a JMS D-200 spectrometer at 75 eV using a direct inlet system. Silica gel (Merck) and alumina (Merck, activity II—III) were used for column chromatography and preparative thin-layer chromatography was carried out on 20×20 cm plate (Merck, 0.5 mm thick). Dichloromethane was distilled over calcium hydride before use. Reactions were followed by TLC aluminum sheets precoated with Merck silica gel F_{254}. Organic extracts were dried over anhydrous sodium sulfate prior to solvent removal.

14,14-Dicyano-5,10-dimethyl-6,8-bisdehydrotridecafulvene (6). This compound was prepared with a slight modification of the reported method.[3c] To a stirred solution of dimethylbisdehydro[13]annulenone (**10**)[4a] (500 mg, 2.40 mmol) and malononitrile (286 mg, 4.33 mmol) in dry dichloromethane (27 ml) was added dropwise a solution of titanium tetrachloride (1.1 ml, 10 mmol) in dry dichloromethane (17 ml) during 50 min under ice-bath. Then a solution of pyridine (2.3 ml) in dry dichloromethane (17 ml) was added dropwise during 40 min to the ice-cooled mixture. After stirring for 1 h at room temperature, a solution of titanium tetrachloride (1.1 ml) in dry dichloromethane (17 ml) was added to the ice-cooled mixture. Then a solution of malononitrile (286 mg) in dry dichloromethane (27 ml) was added dropwise during 90 min, and a solution of pyridine (2.3 ml) in dry dichloromethane (17 ml) was added dropwise during 30 min. The mixture was stirred for 1 h at room temperature. Then 7% hydrochloric acid (17 ml) was added and the mixture was stirred for a further 10 min. Then the mixture was separated and the aqueous layer was extracted with dichloromethane. The combined organic layer was washed with aqueous sodium hydrogencarbonate solution and brine, successively, and dried. The residue after solvent removal was chromatographed on silica gel (4.1×10.5 cm). The fractions eluted with 35% benzene in hexane afforded fulvene **6** (356 mg, 58%).

14-Cyano-14-formyl-5,10-dimethyl-6,8-bisdehydrotridecafulvene (11). To a stirred solution of fulvene **6** (150 mg, 0.59 mmol) in dry toluene (105 ml) was added a solution of diisobutylaluminum hydride (1.8 ml, 1.77 mmol) in toluene by a syringe under argon during 10 min at −7 °C, and the solution was stirred for 50 min at the same temperature. Then 5% sulfuric acid (30 ml) was added and the mixture was extracted with benzene. The combined extracts were washed with aqueous sodium hydrogencarbonate solution and brine, successively, and dried. The residual red liquid was chromatographed on silica gel (3.8×10.0 cm). The early fractions eluted with 30—50% benzene in hexane gave the recovered **6** (18 mg). The later fractions eluted with 80% benzene in hexane afforded fulvene **11** (83 mg, 53%). It formed dark brown needles, mp 195—197 °C (decomp), from hexane-benzene; MS m/z 259 (M^+, 50%) and 214 (100); mol wt 259.2; IR 2225, 2160 (C≡N), 2100 (C≡C), 1665 (CHO), 1610 (C=C), and 980 cm^{-1} (trans C=C); UV Table 2; ^{1}H NMR δ=9.89 (s, 1H, CHO), 9.38 (dd, J=16, 10 Hz, 1H, H^B), 8.48 (dd, J=16, 8 Hz, 1H, $H^{B'}$), 6.88 (d, J=16 Hz, 1H, $H^{A'}$), 6.59 (d, J=16 Hz, 1H, H^A), 6.49 (d, J=10 Hz, 1H, H^C), 6.32 (d, J=8 Hz, 1H, $H^{C'}$), 1.82 (s, 3H, Me), and 1.81 (s, 3H, Me).

Found: C, 83.60; H, 5.15; N, 5.41%. Calcd for $C_{18}H_{13}NO$: C, 83.37; H, 5.05; N, 5.40%.

14-Formyl-14-hydroxymethyl-5,10-dimethyl-6,8-bisdehydrotridecafulvene (12) and 14-Cyano-14-hydroxymethyl-5,10-dimethyl-6,8-bisdehydrotridecafulvene (13). To a stirred solution of fulvene **11** (112 mg, 0.43 mmol) in dry toluene (130 ml) was added a solution of diisobutylaluminum hydride (1.0 ml, 0.99 mmol) in toluene by a syringe at −7 °C. After stirring for 1 h at −7 °C, the mixture was poured into 5% sulfuric acid and extracted with benzene. The combined extracts were worked up as for the isolation of **11**. The residue after solvent removal was chromatographed on silica gel (3.4×8.5 cm). The early fractions eluted with 40% benzene in hexane gave recovered **11** (5 mg). The later fractions eluted with 40—70% benzene in dichloromethane gave a mixture of **12** and **13** as a liquid. The liquid was purified by preparative plate chromatography (dichloromethane-acetone (7 : 3) as eluent). The fast moving, first band gave fulvene **13** (14 mg, 12%). It formed red needles, mp 151—152 °C, from hexane-benzene: MS m/z 261 (M^+, 58%) and 189 (100); mol wt 261.7; IR 3400 (OH), 2200, 2160 (C≡N), 2100 (C≡C), and 970 cm^{-1} (trans C=C); UV Table 2; ^{1}H NMR δ=8.27 (dd, J=16.5, 10 Hz, 1H, H^B), 8.09 (dd, J=16.5, 9 Hz, 1H, $H^{B'}$), 6.51 (d, J=10 Hz, 1H, H^C), 6.49 (d, J=16.5 Hz, 1H, H^A), 6.44 (d, J=9 Hz, 1H, $H^{C'}$), 6.31 (d, J=16 Hz, 1H, $H^{A'}$), 4.46 (d, J=5 Hz, 2H, -CH_2-), 1.95 (broad t, J=5 Hz, 1H, -OH, exchangeable with D_2O), 1.83 (s, 3H, Me), and 1.84 (s, 3H, Me).

Found: C, 82.40; H, 5.85; N, 5.29%. Calcd for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36%.

The fast moving, second band gave fulvene **12** (10 mg, 9.0%). It formed red needles, mp 138—139 °C, from hexane-benzene: IR 3400 (OH), 2170 (C≡N), 2100 (C≡C), 1660 (CHO), and 975 cm^{-1} (trans C=C); UV Table 2; ^{1}H NMR δ=10.12 (s, 1H, CHO), 7.90 (dd, J=16, 10 Hz, 1H, H^B), 6.72 (dd, J=16, 7 Hz, 1H, $H^{B'}$), 6.66 (d, J=16 Hz, 2H, H^A and $H^{A'}$), 6.65 (d, J=10 Hz, 1H, H^C), 6.44 (d, J=7 Hz, 1H, $H^{C'}$), 4.52 (s, 2H, -CH_2-), 2.45 (broad s, 1H, -OH, exchangeable with D_2O), 1.87 (s, 3H, Me), and 1.89 (s, 3H, Me).

HRMS: Found: m/z 264.1088. Calcd for $C_{18}H_{16}O_2$: M, 264.1148.

Preparation of 13 from 11 by Reduction with $NaBH_4$. To a stirred solution of fulvene **11** (158 mg, 0.61 mmol) in dry ethanol (170 ml) was added sodium borohydride (26.5 mg, 0.72 mmol) in one portion, and the mixture was stirred for 3 h at room temperature. After cooling under ice-bath, water (30 ml), and then 2 M hydrochloric acid (27 ml) were added, and the mixture was extracted with benzene. After usual work up, the residual liquid was chromatographed on silica gel (3.2×8.3 cm). The fractions eluted with dichloromethane gave fulvene **13** (120 mg, 75%).

14-Bromomethyl-14-cyano-5,10-dimethyl-6,8-bisdehydrotridecafulvene (14). To a stirred solution of fulvene **13** (142 mg, 0.54 mmol) in dry dichloromethane (21 ml) was added dropwise a solution of phosphorus tribromide (214 mg, 0.79 mmol) in dry dichloromethane (11 ml) during 40 min at −6 °C under argon, and the mixture was stirred overnight at room temperature. After refluxing for a further 3 h, the mixture was poured into water and extracted with dichloromethane. The extracts were washed with aqueous sodium hydrogencarbonate solution and brine, successively, and dried. The residual red liquid after solvent removal was passed through a short column of silica gel (3.2×4.6 cm). The fractions eluted with benzene gave fulvene **14** (148 mg, 84%). It formed dark red needles, mp 159—161 °C, from hexane-benzene: MS *m/z* 325 (M^+, 10%), 323 (M+, 10%), and 228 (100); mol wt 323.2; IR 2210, 2175 (C≡N), 2100 (C≡C), 1620, 1600 (C=C), and 980 cm^{-1} (trans C=C); UV Table 2; ^1H NMR δ=8.54 (dd, J=16, 9.5 Hz, 1H, H^B), 8.35 (dd, J=16, 9 Hz, 1H, $H^{B'}$), 6.46 (d, J=16 Hz, 1H, H^A), 6.46 (d, J=9.5 Hz, 1H, H^C), 6.44 (d, J=9 Hz, 1H. $H^{C'}$), 6.29 (d, J=16 Hz, 1H, $H^{A'}$), 4.23 (s, 2H, $-CH_2-$), and 1.81 (s, 6H, Me).

Found: C, 66.43; H, 4.32; N, 4.20%. Calcd for $C_{18}H_{14}BrN$: C, 66.68, H, 4.35; N, 4.32%.

14-Cyano-14-methoxymethyl-5,10-dimethyl-6,8-bisdehydrotridecafulvene (15). A solution of sodium methoxide, prepared from sodium (45 mg, 1.96 mg atm) and dry methanol (200 ml), was added dropwise during 12 h to a stirred solution of fulvene **14** (148 mg, 0.456 mmol) in dry benzene (60 ml) at room temperature and the solution was stirred for 2 h at the same temperature. The precipitates formed were filtered and washed with hexane. The filtrate was poured into water, and the aqueous layer was extracted with benzene. The combined organic layer was washed with brine, and dried. The residue after solvent removal was chromatographed on alumina (3.2×9.4 cm). The fractions eluted with 10—25% benzene in hexane afforded fulvene **15** (19 mg, 15%). It formed orange cubes, mp 95—96 °C, from hexane: MS *m/z* 275 (M^+, 38%) and 228 (100); mol wt 275.3; IR 2200, 2170 (C≡N), 2100 (C≡C), and 970 cm^{-1} (trans C=C); UV Table 2; ^1H NMR δ=8.31 (dd, J=15, 10 Hz, 1H, H^B), 8.13 (dd, J=15, 10 Hz, 1H, $H^{B'}$), 6.61 (d, J=15 Hz, 1H, H^A), 6.54 (d, J=10 Hz, 1H, H^C), 6.43 (d, J=10 Hz, 1H, $H^{C'}$), 6.32 (d, J=15 Hz, 1H, $H^{A'}$), 4.22 (s, 2H, $-OCH_2-$), 3.40 (s, 3H, OMe), 1.83 (s, 3H, Me), and 1.82 (s, 3H, Me).

Found: C, 82.64; H, 6.29; N, 5.06%. Calcd for $C_{19}H_{17}NO$: C, 82.88; H, 6.22; N, 5.09%.

14-Cyano-14-methoxycarbonyl-5,10-dimethyl-6,8-bisdehydrotridecafulvene (16). Manganese dioxide (350 mg), sodium cyanide (75 mg), and acetic acid (27 ml) were added in one portion, respectively, to a stirred solution of fulvene **11** (70 mg, 0.27 mmol) in dry methanol (160 ml), and the mixture was refluxed for 3 h. Then a further quantity of manganese dioxide (210 mg) was added and stirring was continued overnight at room temperature. Then a further quantity of manganese dioxide (350 mg), sodium cyanide (37 mg), acetic acid (10 ml) were added and the mixture was refluxed for further 5 h. After cooling, inorganic materials were filtered and washed with dichloromethane. Then the filtrate was poured into water, and the aqueous layer was extracted with dichloromethane. The combined organic layer was washed with aqueous sodium hydrogencarbonate solution and brine, successively, and dried. The residue after solvent removal was chromatographed on silica gel (3.6×6.0 cm). The fractions eluted with 30—40% benzene in hexane afforded fulvene **16** (33 mg, 42%). It formed dark red needles, mp 147—148 °C, from ether-methanol: MS *m/z* 289 (M^+, 63%) and 214 (100); mol wt 289.3; IR 2200, 2150 (C≡N), 2100 (C≡C), 1710 (CO_2-), and 960 cm^{-1} (trans C=C); UV Table 2; ^1H NMR δ=9.41 (dd, J=16, 10 Hz, 2 H, H^B and $H^{B'}$), 7.11 (d, J=16 Hz, 1H, $H^{A'}$), 6.45 (d, J=16 Hz, H^A), 6.35 (d, J=10 Hz, 1H, H^C or $H^{C'}$), 6.32 (d, J=9 Hz, 1H, H^C or $H^{C'}$), 3.82 (s, 3H, $-CO_2Me$). and 1.74 (s, 6H, Me).

Found: C, 78.58; H, 5.27; N, 4.75%. Calcd for $C_{19}H_{15}NO_2$: C, 78.87; H, 5.23; N, 4.84%.

14-Carbamoyl-14-cyano-5,10-dimethyl-6,8-bisdehydrotridecafulvene (17). To isopropyl alcohol (30 ml) saturated with ammonia at −3 °C, was added powdered sodium cyanide (180 mg, 3.65 mmol) in one portion. After 10 min, fulvene **11** (120 mg, 0.463 mmol) was added in one portion, then manganese dioxide (1.10 g) was added in two equal portions 10 min apart. After stirring for 5 h at −3 °C, the mixture was diluted with dichloromethane (30 ml) and was filtered to remove inorganic materials. The filtrate was poured into water, and the aqueous layer was extracted with dichloromethane. The combined organic layer was washed with aqueous sodium hydrogencarbonate solution and brine, successively, and dried. The residue after solvent removal was chromatographed on alumina (3.2×6.8 cm). The fractions eluted with hexane-dichloromethane (1 : 9) afforded fulvene **17** (22 mg, 17%). It formed brown needles, mp 198 °C (dec), from hexane-benzene: MS *m/z* 274 (M^+, 54%) and 214 (100); mol wt 274.3; IR 3350, 3170 ($-NH_2$), 2200, 2100 (C≡N), 2100 (C≡C), 1660 (C=O), 1600 (C=C), and 980 cm^{-1} (trans C=C); UV Table 2; ^1H NMR δ=9.23 (dd, J=16, 10 Hz, 1H, H^B), 9.19 (dd, J=15.5, 9 Hz, 1H, $H^{B'}$), 7.16 (d, J=16.5 Hz, 1H, $H^{A'}$), 6.42 (d, J=16 Hz, 1H, H^A), 6.38 (d, J=9 Hz, 1H, H^C or $H^{C'}$), 6.34 (d, J=10.5 Hz, 1H, H^C or $H^{C'}$), 6.11 (broad s, 1H, $-NH_2$), 5.61 (broad s, 1H, NH_2), 1.76 (s, 3H, Me), and 1.74 (s, 3H, Me).

Found: C, 78.92; H, 5.48; N, 9.54%. Calcd for $C_{18}H_{14}N_2O$: C, 78.81; H, 5.14; N, 10.21%.

Oxidation of Fulvene 11. A chromium trioxide solution (0.4 ml), prepared from chromium trioxide (13.3 g), sulfuric acid (11.5 ml), and water (50 ml), was added to a stirred solution of fulvene **11** (70 mg, 0.27 mmol) in acetone (50 ml) at room temperature. After stirring for 1 h at the same temperature, a further quantity of the chromium trioxide solution (0.5 ml) was added, and stirring was continued for a further 4 h. Then the mixture was poured into water and extracted with dichloromethane. The extracts were washed with brine, and dried. The residue after solvent removal was chromatographed on silica gel (3.8×3.5 cm). The fractions eluted with 10% dichloromethane in benzene gave annulenone **10** (12 mg, 16%).

This work was partly supported by a Grant-in-Aid (No. 61470023) for Scientific Research from the Ministry of Education, Science and Culture.

Sequential Reactions of Michael Addition and Peterson Condensation of 1-Silylvinyl Ketones with Grignard Reagents: Study of Stereoselectivity

Junji TANAKA, Hiroshi KOBAYASHI, Shuji KANEMASA,* and Otohiko TSUGE*
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received October 26, 1988)

1-Silylvinyl ketones undergo smooth Michael addition with Grignard reagents generating magnesium enolates which are then trapped with benzaldehyde to give *E*- and *Z*-isomers of enones after Peterson condensation. (*E*)-Olefins become major products under a thermodynamic control when the condensation with benzaldehyde is carried out at room temperature in diethyl ether, while *Z*-isomers are more favored as kinetically controlled products at −78 °C in THF. Reaction mechanism is briefly discussed.

Nucleophilic addition of organocopper reagents to α,β-unsaturated carbonyl compounds and subsequent trapping of the intermediate enolates with a variety of electrophiles are now synthetically useful.[1] Applications of this sequence to α,β-unsaturated ketones followed by enolate-trapping with aldehydes lead to β-hydroxy ketones.

Michael addition of organometallics to 3-silyl-3-buten-2-ones[2,3] would offer a convenient and direct route to silyl-substituted metal enolates with a variety of counter cations. Hopefully the intermediate enolates may be utilized, in the same flask, to the Peterson condensation with carbonyl compounds leading to highly substituted enones.

In a previous communication,[4] we have reported the Michael addition-Peterson condensation sequence of methyl 2-(trimethylsilyl)acrylate with organomagnesium and -lithium compounds. As an extension of this program we have investigated the Michael addition-Peterson condensation sequence of 1-silylvinyl ketones with Grignard reagents. The details are presented here.

Results and Discussion

The Michael addition and Peterson condensation sequence of 3-trimethylsilyl-3-buten-2-one (**1**) was simply carried out by the initial treatment of **1** with a Grignard reagent followed by the reaction with benzaldehyde after completion of the Michael addition. No copper catalyst was needed in the Michael addition. For example, methylmagnesium iodide was added to a solution of **1** in diethyl ether at −15 °C, benzaldehyde was introduced after 1 h, and the reaction was continued at the same temperature for additional 1 h. The mixture was quenched with aqueous ammonium chloride to give a 6.7:1 mixture (by GLC) of *E*- and *Z*-isomers of 3-ethyl-4-phenyl-3-buten-2-one (**2a**) in 45% yield based on **1** (Scheme 1 and Entry 1 in Table 1). Both isomers could be separated from each other by column chromatography on silica gel.

Formation of (*E*)-olefins was again preferred in the

reactions of **1** with propyl-, isopropyl-, and phenylmagnesium bromides under the equal conditions, **2b** (*E*:*Z*=5.2:1, Entry 3), **2c** (5:1, Entry 6), and **2e** (6.5:1, Entry 21) being produced. However, *Z*-isomer was predominantly produced (*E*:Z=1:4.7, Entry 20) in the reaction of **1** with *t*-butylmagnesium chloride, which was carried out in tetrahydrofuran (THF).[5] This unusual selectivity will be discussed below.

Stereostructures of (*E*)-**2** and (*Z*)-**2** were based on the chemical shifts of the olefin proton and the acetyl methyl protons. One typical example is shown as follows in the case of **2b**. (*E*)-**2b**: δ=2.44 (MeCO) and 7.46 (4-H). (*Z*)-**2b**: 2.05 (MeCO) and 6.64 (4-H).

The reaction of **1** with isopropylmagnesium bromide and benzaldehyde was performed under a variety of conditions to know factors by which the *E*/*Z* selectivity is influenced. The *E*/*Z* ratios were determined by gas-liquid chromatography (GLC) using (*E*)-4-phenyl-3-buten-2-one as an internal reference.

The *E*/*Z* ratio was found to be dependent upon the reaction temperature as shown in Entries 5—8. Since (*E*)-**2c** was relatively more favored at a higher temperature (Entry 8, *E*:*Z*=5.4:1), (*E*)-**2c** must be a thermodynamically controlled product, and hence (*Z*)-**2c** is a kinetically controlled one. This indicates that either the Michael addition step or the Peterson condensation step is reversible.

Figure 1 shows a possible reaction course for the formation of both isomers of olefin **2c**. The Michael addition between **1** and isopropylmagnesium bromide forms (*E*)- **C** and/or (*Z*)-enolate(s) **D**. As the carbonyl

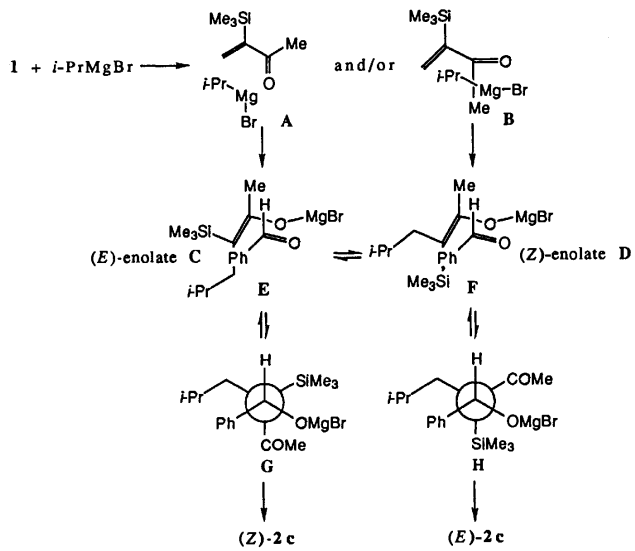

Fig. 1. Stereochemical course of the Michael-Peterson sequence between enone **1** and isopropylmagnesium bromide.

addition of magnesium enolates should be chelation-controlled,[6] the chair transition state **E** involving (*E*)-enolate **C** forms adduct alkoxide **G**; similarly its diastereomeric alkoxide **H** is formed from **F**. Cis-elimination is the far major path in the alkoxide-mediated Peterson condensation.[7] Therefore, (*Z*)-**2c** and (*E*)-**2c** are produced from **G** and **H**, respectively.

A high isomer ratio ($E:Z$=6.8:1, Entry 9) was obtained when the Michael adduct formed at −78 °C was warmed at room temperature for 1 h and the reaction with benzaldehyde was followed at the same temperature, while the stereoselectivity was poor ($E:Z$=2.2:1, Entry 10) when the adduct formed at room temperature was cooled to −78 °C and reacted with benzaldehyde.

It is concluded, on the ground of these results, that the stereostructures of product **2c** do not reflect those of magnesium enolate intermediates **C** and **D**,[8] and that the step of carbonyl addition is reversible. Thus, the thermodynamically controlled olefin, (*E*)-**2c**, was produced as a major product from the mixture of adduct alkoxides **G** and **H** which were equilibrating via **E** and **F**. The thermodynamic preference of (*E*)-**2c** might be due to the higher stabilization of (*Z*)-enolate **D** than **C** by an attractive interaction between the silyl and the alkoxide moieties.

Unlike in diethyl ether, (*Z*)-**2c** was produced as a major isomer in the reaction of **1** with isopropylmagnesium bromide and benzaldehyde in THF where the $E:Z$ ratio was not very much affected by the reaction temperature (Entries 12 and 13). A similar result was observed when THF (25 vol%) was added as an additive in the reaction performed in diethyl ether (Entry 14).

The aforementioned reaction of **1** with *t*-butylmagnesium chloride and benzaldehyde (Entry 20) in THF became a little more selective in favor of (*Z*)-**2c** when carried out at −78 °C ($E:Z$=1:5.8, Entry 19).

Thus the reaction in THF is kinetically controlled. As shown in Fig. 1, the Grignard reagent adds to enone **1** leading to (*E*)-enolate **C** as a kinetic adduct which

gradually isomerizes into (*Z*)-enolate **D**. This isomerization presumably took place also in the reactions carried out in diethyl ether. As soon as the chelation-controlled addition of **C** to benzaldehyde forms the adduct alkoxide **G**, the elimination of silanol takes place quickly to give (*Z*)-**2c**. The elimination reaction is accelerated in THF because THF has a greater solvation ability than diethyl ether and therefore the oxygen-magnesium bond is much more polarized in this solvent.

Addition of hexamethylphosphoric triamide (HMPA) or tin(IV) chloride, either with a catalytic or a comparable amount, lowered the $E:Z$ ratio (Entries 15 to 18). These additives presumably broke down the chelation in the transition state of carbonyl addition.

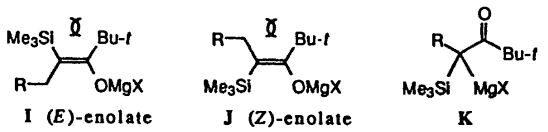
Scheme 2.

The vinylsilane with a bulky acyl substituent, 4,4-dimethyl-2-trimethylsilyl-1-penten-3-one (**3**), was employed to the Michael-Peterson sequence. No Michael addition of **3** proceeded with methylmagnesium iodide at −78 °C, and *t*-butylmagnesium chloride as a bulky Grignard reagent could not react even at −15 °C. The starting enone **3** was recovered in both cases (Entries 1 and 4 in Table 2). Therefore, all the sequences were carried out at room temperature.

Both reactions of **3** with methylmagnesium iodide (Entry 2) and isopropylmagnesium bromide (Entry 3) in diethyl ether gave almost 1 : 1 mixtures of the *E*- and *Z*-isomers of olefins **4**. The $E:Z$ selectivity was poor also in the reaction of **3** with *t*-butylmagnesium chloride in THF (Entry 5, $E:Z$=1 : 3.7).



Two sterically congested magnesium enolates, **I** and **J**, which are expected to form in the Michael additions of **3** with Grignard reagents, seem too unstable to be involved as reacting intermediates. Even if they exist, their thermodynamic stability can not be sufficiently high so as to fully contribute to such an equilibrium as Fig. 1 shows. Therefore the adduct anions formed in the Michael additions of **3** should have reacted with benzaldehyde in a way different from the case of **1**. Probably they were involved in the carbonyl condensations, at least partly, in the form of β-oxo Grignard reagents **K**. This would be the major reason why the $E:Z$ selectivity was so decreased both in the reactions in diethyl ether and THF.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz), a JEOL FX-100 (100 MHz), or a JEOL GSX-270 instrument (270 MHz), and ^{13}C NMR on a JEOL FX-100 (25.05 MHz) or a JEOL GSX-270 spectrometer (67.94 MHz). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra as well as high-resolution mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph (Yanagimoto) with an ionization flame detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Silicone GE, SE-30, 0.25×50000 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Material. 3-Trimethylsilyl-3-buten-2-one (**1**) was prepared according to the reported method using 1-(trimethylsilyl)vinylmagnesium bromide.[2]

General Procedure for the Michael Addition and Peterson Condensation Sequence of 1-Silylvinyl Ketone 1. As a typical procedure, the reaction of **1** with methylmagnesium iodide and benzaldehyde is described. To a solution of freshly

prepared methylmagnesium iodide (1.2 mmol) in diethyl ether (3 ml) was added **1** (0.142 g, 1 mmol in diethyl ether (1 ml)) at −15 °C under dry nitrogen. After stirring for 1 h at this temperature, benzaldehyde (0.127 g, 1.2 mmol in diethyl ether (1 ml)) was added. The mixture was stirred at −15 °C for 1 h and then at 0 °C for 0.5 h. Saturated aqueous ammonium chloride was added and the organic products were collected in diethyl ether (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate (30 : 1 v/v) to give (*Z*)-**2a** (0.01 g, 6%) and then (*E*)-**2a** (0.067 g, 39%).

In all other cases, the *E*- and *Z*-isomers were separated by silica-gel chromatography with hexane-ethyl acetate (30:1 v/v). The results are summarized in Table 1.

3-Ethyl-4-phenyl-3-buten-2-one (2a): (*E*)-**2a**: Colorless oil; IR (neat) 1662, 1490, 1380, 1345, 1228, 1115, 1020, 755, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.11 (3H, t, J=7.0 Hz, Et), 2.45 (3H, s, MeCO), 2.53 (2H, q, J=7.0 Hz, Et), 7.40 (5H, br s, Ph), and 7.47 (1H, s, 4-H); ^{13}C NMR ($CDCl_3$) δ=13.78, 19.63 (each Et), 26.09 (MeCO), 128.22, 128.58, 129.23, 135.81 (each Ph), 139.35 (4-C), 144.11 (3-C), and 200.08 (MeCO); MS m/z (rel intensity, %) 174 (M^+, base peak), 173 (62), 159 (56), 131 (72), 129 (19), 116 (23), 115 (28), 91 (55), 73 (50), and 43 (68). HRMS Found: m/z 174.1033. Calcd for $C_{12}H_{14}O$: M, 174.1044. (*Z*)-**2a**: Pale yellow liquid; IR (neat) 1655, 1430, 1380, 1340, 1220, 1115, 1020, 755, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15 (3H, t, J=7.0 Hz, Et), 2.05 (3H, s, MeCO), 2.3—2.6 (2H, m, Et), 6.66 (1H, s, 4-H), and 7.1—7.5 (5H, m, Ph); MS m/z (rel intensity, %) 174 (M^+, base peak), 173 (66), 159 (74), 131 (93), 129 (25), 128 (18), 116 (31), 115 (49), 102 (24), 91 (85), 77 (36), 51 (25), and 43 (97). HRMS Found: m/z 174.1044. Calcd for $C_{12}H_{14}O$: M, 174.1044.

3-Butyl-4-phenyl-3-buten-2-one (2b): (*E*)-**2b**: Colorless liquid; IR (neat) 1660, 1375, 1350, 1240, 1215, 740, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, *n*-Bu), 1.3—1.5 (4H, m, *n*-Bu), 2.44 (3H, s, MeCO), 2.50 (2H, t, J=7.0 Hz, *n*-Bu), 7.3—7.4 (5H, m, Ph), and 7.46 (1H, s, 4-H); ^{13}C NMR ($CDCl_3$) δ=13.85, 22.98, 26.16, 31.35 (each *n*-Bu), 31.35 (MeCO), 128.53, 129.24, 135.89, (each Ph), 139.38 (4-C), 143.12 (3-C), and 200.27 (MeCO); MS m/z (rel intensity, %) 202 (M^+, 31), 201 (15), 159 (22), 129 (30), 117 (47), 116 (17), 115 (49), 91 (36), 77 (16), and 43 (base peak). HRMS Found: m/z 202.1350. Calcd for $C_{14}H_{18}O$: M, 202.1357. (*Z*)-**2b**: Colorless oil; IR (neat) 1680, 1485, 1345, 1190, 1115, 750, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—1.1 (3H, m, *n*-Bu), 1.1—1.6 (4H, m, *n*-Bu), 2.04 (3H, s, MeCO), 2.2—2.5 (2H, m, *n*-Bu), 6.64 (1H, s, 4-H), and 7.1—7.6 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.88, 22.38, 30.40 (each *n*-Bu), 30.87 (MeCO), 35.20 (*n*-Bu), 127.83, 128.38, 128.46, 130.16 (each Ph), 136.52 (4-C), 145.01 (3-C), and 208.00 (MeCO); MS m/z (rel intensity,%) 202 (M^+, 4), 129 (20), 128 (15), 117 (47), 116 (16), 115 (60), 91 (35), 77 (16), and 43 (base peak). HRMS Found: m/z 202.1361. Calcd for $C_{14}H_{18}O$: M, 202.1357.

3-(2-Methylpropyl)-4-phenyl-3-buten-2-one (2c): (*E*)-**2c**: Colorless oil; IR (neat) 1670, 1470, 1380, 1350, 1225, 1130, 750, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82 (6H, d, J=6.6 Hz, *i*-Bu), 1.6—1.8 (1H, m, *i*-Bu), 2.45 (3H, s, MeCO), 2.48 (2H, d, J=7.3 Hz, *i*-Bu), 7.3—7.4 (4H, m, Ph), and 7.50 (1H, s, 4-H); ^{13}C NMR ($CDCl_3$) δ=22.59, 26.34 (each *i*-Bu), 28.06 (MeCO), 34.47 (*i*-Bu), 128.35, 128.52, 129.25, 136.06 (each Ph), 139.78 (4-C), 142.70 (3-C), and 200.80 (MeCO); MS m/z (rel intensity, %) 202 (M^+, 7), 128 (10), 116 (12), 115 (52), 91 (12), and 43 (base peak). HRMS Found: m/z 202.1350. Calcd for $C_{14}H_{18}O$: M, 202.1357. (*Z*)-**2c**: Colorless oil; IR (neat) 1685, 1460, 1365, 1350, 1200, 1120, 755, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.79 (6H, d, J=6.6 Hz, *i*-Bu), 1.6—1.7 (1H, m, *i*-Bu), 1.86 (3H, s, MeCO), 2.10 (2H, dd, J=7.3 and 1.1 Hz, *i*-Bu), 6.49 (1H, s, 4-H), and 7.0—7.2 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=22.62 (*i*-Bu), 27.30 (MeCO), 31.08, 45.39 (each *i*-Bu), 128.17, 128.67, 128.73 (each Ph), 132.01 (4-C), 136.75 (Ph), 144.27 (3-C), and 208.02 (MeCO); MS m/z (rel intensity, %) 202 (M^+, 24), 159 (17), 117 (21), 116 (19), 115 (35), 91 (16), and 43 (base peak). HRMS Found: m/z 202.1354. Calcd for $C_{14}H_{18}O$: M, 202.1357.

3-(2,2-Dimethylpropyl)-4-phenyl-3-buten-2-one (2d): (*E*)-**2d**: Colorless oil; IR (neat) 1675, 1470, 1360, 1235, 1200, 1160, 755, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.69 (9H, s, *t*-Bu), 2.45 (3H, s, MeCO), 2.66 (2H, s, *t*-BuCH_2), 7.2—7.5 (5H, m, Ph), and 7.50 (1H, s, 4-H); ^{13}C NMR ($CDCl_3$) δ=29.86 (*t*-Bu), 33.23 (MeCO), 36.76 (*t*-Bu), 49.08 (*t*-BuCH_2), 128.45, 128.48, 129.00, 136.76 (each Ph), 139.61 (4-C), 142.43 (3-C), and 201.51 (MeCO); MS m/z (rel intensity, %) 216 (M+, 10), 160 (34), 159 (24), 145 (29), 117 (21), 116 (30), 115 (36), 56 (59), and 42 (base peak). HRMS Found: m/z 216.1510. Calcd for $C_{15}H_{20}O$: M, 216.1513. (*Z*)-**2d**: Pale yellow oil; IR (neat) 1675, 1470, 1360, 1200, 1155, 760, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (9H, s, *t*-Bu), 2.00 (3H, s, MeCO), 2.39 (2H, s, *t*-BuCH_2), 6.74 (1H, br s, 4-H), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=29.60 (*t*-Bu), 30.60 (MeCO), 32.17 (*t*-Bu), 49.07 (*t*-BuCH_2), 127.99, 128.43, 128.47 (each Ph), 135.11 (4-C), 136.70 (Ph), 143.15 (3-C), and 207.19 (MeCO); MS m/z (rel intensity, %) 216 (M^+, 27), 201 (16), 160 (base peak), 159 (48), 145 (42), 117 (30), 116 (78), 115 (30), and 56 (87). HRMS Found: m/z 216.1512. Calcd for $C_{15}H_{20}O$: M, 216.1513.

3-Benzyl-4-phenyl-3-buten-2-one (2e): (*E*)-**2e**: Colorless needles; mp 68—70 °C; IR (KBr) 1665, 1495, 1450, 1350, 1255, 1215, 970, 750, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.43 (3H, s, MeCO), 3.94 (2H, s, PhCH_2), 7.1—7.4 (10H, m, Ph), and 7.74 (1H, s, 4-H); ^{13}C NMR ($CDCl_3$) δ=26.29 (PhCH_2), 32.21 (MeCO), 126.04, 127.96, 128.55, 128.64, 128.94, 129.24, 135.36, 139.49 (each Ph), 139.87 (4-C), 141.22 (3-C), and 199.29 (MeCO); MS m/z (rel intensity, %) 236 (M^+, 35), 192 (25), 133 (20), 121 (69), 115 (62), 105 (43), 94 (27), 91 (49), 77 (28), 75 (24), 73 (40), 65 (35), and 43 (base peak). HRMS Found: m/z 236.1197. Calcd for $C_{17}H_{16}O$: M, 236.1200. (*Z*)-**2e**: Pale yellow oil; IR (neat) 1680, 1495, 1445, 1350, 1245, 1200, 830, 755, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.95 (3H, s, MeCO), 3.81 (2H, d, J=1.4 Hz, PhCH_2), 6.80 (1H, br s, 4-H), and 7.2—7.6 (10H, m, Ph); MS m/z (rel intensity, %) 236 (M^+, base peak), 235 (30), 221 (20), 193 (47), 192 (41), 178 (23), 115 (69), 91 (46), and 43 (36). HRMS Found: m/z 236.1196. Calcd for $C_{17}H_{16}O$: M, 236.1200.

4,4-Dimethyl-2-trimethylsilyl-1-penten-3-one (3): This compound was prepared by an application of the synthetic method of **1**.[2] From 1-bromo-1-(trimethylsilyl)ethene (5.0 g, 28 mmol), magnesium metal (0.83 g), and 2,2-dimethylpropanal (2.4 g, 28 mmol), enone **3** was obtained in 32% yield: Pale yellow liquid; bp 97—99 °C/4790 Pa (bulb-to-bulb); IR (neat) 2970, 1670, 1480, 1365, 1250, 1180, 1050, 1000, 940, 850, 760, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.15 (9H, s, Me_3Si), 1.19 (9H, s, *t*-Bu), 5.67, and 5.84 (each 1H, d, J=2.2 Hz, $=CH_2$); ^{13}C NMR ($CDCl_3$) δ=−1.02 (Me_3Si), 27.39, 44.06 (each *t*-Bu), 126.62 ($=CH_2$), 155.66 (2-C), and 215.57 (CO); MS m/z (rel intensity, %) 184 (M^+, 6), 127 (37), 73 (72), 57 (49), 45 (21), and 43 (base peak).

General Procedure for the Michael Addition and Peterson Condensation Sequence of 1-Silylvinyl Ketone 3. As a typical procedure, the reaction of **3** with methylmagnesium iodide and benzaldehyde is described. To a solution of freshly prepared methylmagnesium iodide (1.2 mmol) in diethyl ether (3 ml) was added **3** (0.168 g, 0.91 mmol in diethyl ether (1 ml)) at −15 °C under dry nitrogen. After stirring for 1 h at this temperature, benzaldehyde (0.127 g, 1.2 mmol in diethyl ether (1 ml)) was added. The mixture was stirred at −15 °C for 1 h. Saturated aqueous ammonium chloride was added and the organic products were collected in diethyl ether (30 ml × 2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate (50 : 1 v/v) to give an inseparable mixture of *E*- and *Z*-isomers of **4a** (0.158 g, 80%, *E* : *Z*=1 : 1 (GLC)).

All results obtained in other cases are listed in Table 2.

2-Ethyl-4,4-dimethyl-1-phenyl-1-penten-3-one (4a): Obtained as an inseparable 1 : 1 mixture of *E*- and *Z*-isomers (GLC). Colorless oil; IR (neat) 1680, 1475, 1460, 1390, 1360, 1170, 1080, 1065, 930, 750, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) *E*-isomer: δ=1.32 (9H, s, *t*-Bu), 1.17 (3H, t, J=7.7 Hz, Et), 2.54 (2H, dq, J=7.7 and 1.8 Hz, Et), 6.82 (1H, s, 1-H), and 7.2—7.4 (10H, m, Ph). *Z*-isomer: δ=0.99 (9H, s, *t*-Bu), 1.03 (3H, t, J=7.7 Hz, Et), 2.34 (2H, dq, J=7.7 and 1.8 Hz, Et), 6.35 (1H, s, 1-H), and 7.2—7.4 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=12.54, 13.43 (each Et), 22,52, 29,21 (each Et), 27.44, 28,29 (each *t*-Bu), 44.19, 44.25 (each *t*-Bu), 127.30, 127.57, 128.32, 128.38, 128.85, 129.72, 130.65, (each Ph), 136.04, 137.23, (each 1-C), 145.34, 144.39 (each 2-C), 212.65, and 218.50 (each CO); MS *m*/*z* (rel intensity, %) 216 (M^+, 9), 159 (base peak), 131 (90), 129 (26), 116 (37), 115 (58), 91 (87), 57 (37), and 41 (43). HRMS Found: *m*/*z* 216.1515. Calcd for $C_{15}H_{20}O$: M, 216.1513.

4,4-Dimethyl-2-(2-methylpropyl)-1-phenyl-1-penten-3-one (4b): Obtained as an inseparable 1 : 1.3 mixture of *E*- and *Z*-isomers (GLC). Colorless oil; IR (neat) 1685, 1480, 1465, 1370, 1095, 985, 755, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) *E*-isomer: δ=0.84 (6H, d, J=6.6 Hz, *i*-Bu), 1.33 (9H, s, *t*-Bu), 2.43 (2H, dd, J=7.3 and 1.1 Hz, *i*-Bu), 6.89 (1H, br s, 1-H), and 7.2—7.4 (10H, m, Ph). *Z*-isomer: δ=0.97 (6H, d, J=6.6 Hz, *i*-Bu), 1.00 (9H, s, *t*-Bu), 2.17 (2H, dd, J=7.3 and 1.1 Hz, *i*-Bu), 6.32 (1H, br s, 1-H), and 7.2—7.4 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) *E*-isomer: δ=22.61, 27.92 (each *i*-Bu), 28.55 (*t*-Bu), 37.68 (*i*-Bu), 44.15 (*t*-Bu), 143.11 (2-C), and 212.84 (CO). *Z*-isomer: δ=22.35, 26.80 (each *i*-Bu), 27.47, 44.28 (each *t*-Bu), 46.12 (*i*-Bu), 142.80 (2-C), and 217.65 (CO). Other signals are overlapped: δ=127.08, 127.32, 127.44, 128.30, 128.38, 128.91, 132.18, 136.22, 137.09; MS *m*/*z* (rel intensity, %) 244 (M^+, 3), 115 (32), 57 (98), 43 (38), and 41 (base peak). HRMS Found: *m*/*z* 244.1823. Calcd for $C_{17}H_{24}O$: M, 244.1826.

4,4-Dimethyl-2-(2,2-dimethylpropyl)-1-phenyl-1-penten-3-one (4c): Obtained as a 1 : 3.7 mixture of *E*- and *Z*-isomers (GLC) from which each isomer was roughly separated by column chromatography on silica gel with hexane-ethyl acetate (50 : 1 v/v). (*E*)-**4c**: Colorless oil; ^1H NMR ($CDCl_3$) δ=0.76, 1.38 (each 9H, s, *t*-Bu), 2.60 (2H, s, *t*-$BuCH_2$), 7.07 (1H, s, 1-H), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=29.45 (*t*-Bu), 29.69, 32.67, 40.03 (each *t*-$BuCH_2$), 44.06 (*t*-Bu), 127.35, 128.35, 128.81, (each Ph), 134.29 (1-C), 136.70 (Ph), 141.88 (2-C), and 212.69 (CO); MS *m*/*z* (rel intensity, %) 258 (M^+, 7), 201 (base peak), 145 (30), 115 (29), 57 (68), and 40 (40). HRMS Found: *m*/*z* 258.1968. Calcd for $C_{18}H_{26}O$: M, 258.1982. (*Z*)-**4c**: Colorless solid; mp 47—49 °C; IR (KBr) 1670, 1450, 1350, 1220, 1110, 980, 745, and 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.99, 1.00 (each 9H, s, *t*-Bu), 2.21 (2H, d, J=1.1 Hz, *t*-$BuCH_2$), 6.36 (1H, br s, 1-H), and 7.2—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=27.76 (*t*-Bu), 29.92, 32.89 (each *t*-$BuCH_2$), 44.22 (*t*-Bu), 49.66 (*t*-$BuCH_2$), 127.31, 128.17, 128.65 (each Ph), 129.93 (1-C), 136.84 (Ph), 141.67 (2-C), and 216.88 (CO); MS *m*/*z* (rel intensity, %) 258 (M^+, 6), 201 (base peak), 145 (24), 115 (25), 57 (60), and 40 (35). HRMS Found: *m*/*z* 258.1988. Calcd for $C_{18}H_{26}O$: M, 258.1982.

Diene-Transmissive Hetero Diels-Alder Reactions of 3-Oxo-1,4-pentadiene Equivalents Leading to Functionalized 2-Chromanones

Eiji WADA,* Shuji KANEMASA,* and Otohiko TSUGE
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received October 26, 1988)

Through hetero Diels-Alder reaction with a vinyl ether and Horner-Emmons olefination, diethyl 2-oxo-3-butenylphosphonate leads to 2-ethoxy-6-(1-alkenyl)-3,4-dihydro-2*H*-pyrans which are further transformed into 2-chromanones via regioselective Diels-Alder reactions with activated acetylenes followed by hydrolysis and oxidation.

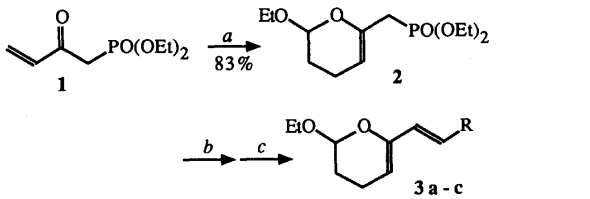
Diene-transmissive Diels-Alder reactions of cross-conjugated trienes offer a direct and stereoselective synthetic route to highly functionalized hydronaphthalene skeletons.[1] The cross type of reactions with activated trienes[2] as well as the reaction sequences with some cross-conjugated triene equivalents[3] has been also developed.

In the preceding article we have opened a new synthetic route of diethyl 2-oxo-3-alkenylphosphonates which can be successfully applied to regioselective Diels-Alder reactions with vinyl ethers to give 4-substituted 2-alkoxy-6-[(diethoxyphosphinyl)methyl]-3,4-dihydro-2*H*-pyrans.[4] As these pyrans have an allylphosphonate functionality, they should be transformed into 1,3-dienes by a Horner-Emmons olefinations.[5] Diels-Alder reactions of the resulting 6-(1-alkenyl)-3,4-dihydro-2*H*-pyrans with acetylenes would become a convenient route to highly functionalized chroman derivatives after dehydrogenation. The present article describes details of the research performed along these lines.

Results and Discussion

The Diels-Alder reaction between diethyl 2-oxo-3-butenylphosphonate (**1**) and ethoxyethene regioselectively leads to 2-ethoxy-6-[(diethoxyphosphinyl)methyl]-3,4-dihydro-2*H*-pyran (**2**) in 83% yield.[4] As Horner-Emmons olefinations of **2** as an allylphosphonate are expected to produce 1,3-dienes,[5] the reaction of **2** with benzaldehyde was examined under various conditions. Deprotonation of **2** readily took place with butyllithium in tetrahydrofuran (THF) and the resulting anion reacted with bezaldehyde at room temperature to give the expected diene **3a** (Scheme 1). Under these conditions, however, the yield of **3a** was poor (34%) and some starting phosphonate **2** was recovered unchanged (37%), indicating the participation of a competitive retro carbonyl addition which has been often observed when the phosphonate anions are not so highly stabilized.[6]

It was found that the elimination reaction was accelerated by hexamethylphosphoric triamide (HMPA),



3a: R = Ph 66%
3b: R = *p*-MeOC$_6$H$_4$ 63%
3c: R = *n*-Pr 54% (recovered **2**: 28%)

a CH_2=CHOEt
b *n*-BuLi in THF-HMPA (5:1 v/v)
c RCHO

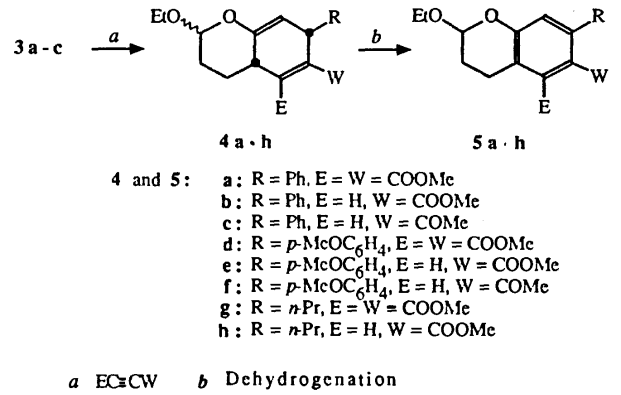
Scheme 1.

but still a temperature higher than 5 °C was needed to complete the elimination. After some efforts, the reaction was optimized as follows: The anion of **2** was generated with butyllithium (1.2 equiv) in THF containing HMPA (THF : HMPA=5 : 1 v/v) at −78 °C and benzaldehyde (1.2 equiv) was added. The reaction temperature was gradually raised to 10 °C and the reaction was continued for 6 h. Thus (*E*)-1,3-diene **3a** was obtained as the sole product in 66% yield.

Similar condensations with *p*-methoxybenzaldehyde and butanal produced (*E*)-6-(1-alkenyl)-2-ethoxy-3,4-dihydro-2*H*-pyrans **3b**, **c** in 63 and 54% yields, respectively (Scheme 1).

Three activated acetylene dienophiles such as dimethyl acetylenedicarboxylate (DMAD), methyl propynoate (MPR), and 3-butyn-2-one (BYO) were employed in the Diels-Alder reactions with these dienes **3a—c**. The Diels-Alder reactions were carried out in benzene in a sealed tube at 90—115 °C, and a catalytic amount of hydroquinone or 2,5-di(*t*-butyl)hydroquinone was used as an inhibitor for the homolytic polymerization of **3**.

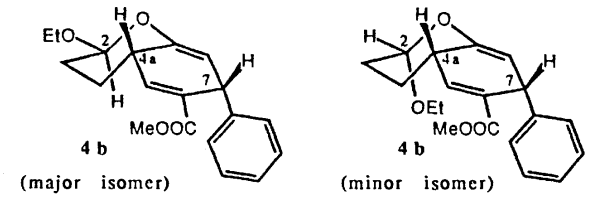
Since the starting 1,3-dienes **3a—c** are 2-alkoxy-substituted *E*-isomers, the cycloadducts **4a—h** must be regiochemically pure and accordingly consist of only two isomers of cycloadducts, 2,4a-cis and 2,4a-trans isomers, on the basis of the high regio control by an



Scheme 2.

oxygen substituent and the stereochemical integrity of Diels-Alder cycloadditions (Scheme 2 and Table 1). Thus the Diels-Alder reactions of 1-aryl-substituted dienes **3a, b** with MPR and BYO afforded a clean mixture of two stereoisomers of regioselective cycloadducts **4a, b**. Only in the reaction of **3c** bearing a 1-alkyl substituent with MPR a trace of regioisomer **5h** (R=*n*-Pr, E=COOMe, W=H) was produced. In one case where the Diels-Alder reaction was carried out at such a high temperature as 155 °C for 60 h, spontaneous dehydrogenation of the cycloadduct **4b** took place.

Assignment of each stereoisomer of Diels-Alder cycloadducts **4** as well as determination of the isomer ratio was not thought so important in this particular sequence directed to 2-chromanones that characterization was made only for limited cases. The stereostructures of 2,4a-cis and 2,4a-trans isomers were determined on the basis of ^{1}H NMR spectra. As for two stereoisomers of **4b**, the major isomer with lower ethoxy methyl protons (δ=1.22) was assigned to be 2,4a-trans and the minor one with higher protons (1.05) 2,4a-cis. The major isomer should have an axial 2-H, and this was confirmed by the coupling constant $J_{2\text{-}3}$ (8.8 and 2.6 Hz).[7,8] An abnormally large 1,4-long-



$J_{2\text{-}3}$ = 8.8 and 2.6 Hz
$J_{4a\text{-}7}$ = 8.1 Hz

range coupling constant was observed between 4a-H and 7-H of the major isomer of **4b** ($J_{4a\text{-}7}$=8.1 Hz). This large coupling is anticipated for the 4a,7-cis structure with two methine hydrogen in a pseudo-axial configuration.[9]

As shown in Table 1, 2,4a-trans isomers were a little more favored than 2,4a-cis isomers, indicating the preference of the sterically less hindered approach of an acetylene dienophile to **3** from the face opposite to the axial 2-ethoxy substituent.[10]

The 1,4-cyclohexadiene rings of the Diels-Alder cycloadducts **4a—h** were readily aromatized by treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) or tetrachloro-1,4-benzoquinone (*p*-chloranil) under reflux in benzene or toluene, respectively, to give 2-ethoxychromans **5a—h** (Scheme 2 and Table 1). As DDQ is stronger dehydrogenating reagent than chloranil, a less amount of DDQ and a lower reaction temperature were enough to complete the dehydrogenation. Existence of an acetyl moiety in **4** resulted in

3c	MPR	105	84	**4h**	72	g)	A	**5h**	80[i]

a) DMAD: dimethyl acetylenedicarboxylate. MPR: methyl propynoate. BYO: 3-butyn-2-one. b) Carried out in a sealed tube in the presece of a catalytic amount of hydroquinone or 2,5-di(*t*-butyl)hydroquinone. c) A: DDQ (2 equiv), reflux in benzene, 24 h. B: *p*-chloranil (5 equiv), reflux in toluene, 48 h. d) Yield of isolated products. e) Ratio of 2,4a-trans : 2,4a-cis isomers (^{1}H NMR). f) Yield in parenthesis from procedure B. g) No ^{1}H NMR taken. h) Contaminated by a trace of **5b** (**4b** : **5b**=12 : 1 mol/mol). i) Contaminated by a trace of *m*-isomer (**5h** : R=*n*-Pr, E=COOMe, W=H).

the low-yield formation of **5c** and **5f**; *p*-chloranil gave better yields of **5e, f** than DDQ in dehydrogenations of *p*-methoxyphenyl-substituted cycloadducts **4e, f**.

The coupling constants between 2-H and 3-Hs of **5a—h** are relatively small ($J_{2\text{-}3}$=2.6 to 2.9 Hz). This indicates that the benzo-fused 2-ethoxy-3,4-dihydro-2*H*-pyran ring exclusively takes one conformation, in a chloroform solution, with the 2-ethoxy substituent axial.

The acetal moiety of 2-ethoxychromans **5a—h** was readily hydrolyzed with 4 M hydrochloric acid (1 M=1 mol dm^{-3}) in THF at room temperature; the products **6a—e** excellently produced were characterized as not 3-(*o*-hydroxyaryl)propanals but as 2-chromanols (Scheme 3) on the basis of the absence of formyl proton in ^{1}H NMR spectra. However, they were smoothly oxidized into 2-chromanones **7a—e** with pyridinium chlorochromate (PCC) in good yields. In most cases, both steps of hydrolysis and oxidation of **5** were performed in a single procedure without trouble. Total yields of 2-chromanones **7** were as good as 68 to 78% based on **5a—h**, not depending upon the isolation procedure of **6** (Table 2).

In conclusion, a new entry to the synthesis of 2-chromanones has been presented here. The method starts with diethyl 2-oxo-3-butenylphosphonate (**1**) through the Diels-Alder reaction with a vinyl ether, the Horner-Emmons olefination, the Diels-Alder reaction with acetylenes, and the PCC oxidation. Through the above sequence of reactions, the phosphonate **1** can be regarded as a synthetic equivalent of 1,4-pentadien-3-ones, a hetero cross-conjugated triene. 7-Substituted 2-chromanones bearing functional groups at 5- and 6-positions were synthesized in this article, and further introduction of several substituents or functional groups would be possible at the 4- and 8-positions of 2-chromanones by a simple extension of the present method.

Table 2. Transformation of 2-Ethoxychromans **5a—h** into 2-Chromanones **7a—h** by a Sequence of Hydrolysis and Pyridinium Chlorochromate Oxidation

a) Obtained by hydrolysis of **5** with 4M-HCl in THF at room temperature for 15 h. b)Obtained by oxidation of **6** with PCC (3 equiv) in dichloromethane at room temperature for 24 h. c) Yield of isolated product based on **5**. d) Yield of isolated product based on **6**. Yield based on **5** in parenthesis e) Crude **6** was used in the subsequent transformation without isolation.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-720 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz), a JEOL FX-100 (100 MHz), or a JEOL GSX-270 instrument (270 MHz), and ^{13}C NMR on a JEOL FX-100 (25.05 MHz) or a JEOL GSX-270 spectrometer (67.94 MHz). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra as well as high-resolution mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph (Yanagimoto) with an ionization flame detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Silicone GE, SE-30, 0.25×50000 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Material. Compound **2**[4] was prepared according to the previously reported method.

General Procedure for the Horner-Emmons Olefination of 2-Ethoxy-6-[(diethoxyphosphinyl)methyl]-3,4-dihydro-2*H*-pyran (2) Leading to 6-(1-Alkenyl)-3,4-dihydro-2*H*-pyrans 3a—c. As a typical example the preparation of **3a** is described as follows: To a solution of **2** (1.7 g, 6.11 mmol) and HMPA (5 ml) in dry THF (25 ml) was added butyllithium (15% in hexane, 4.57 ml, 7.33 mmol) at −78 °C under nitrogen. After 1 h at the same temperature, benzaldehyde (0.777 g, 7.33 mmol) was added and stirring was continued at 10 °C for 6 h. The mixture was poured into saturated aqueous ammonium chloride and extracted with diethyl ether (25 ml×2). The combined extracts were dried over anhydrous magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-diethyl ether (96 : 4 v/v) as an eluent to give **3a** (0.93 g, 66%).

(*E*)-2-Ethoxy-6-(2-phenylethenyl)-3,4-dihydro-2*H*-pyran (3a): Colorless liquid; IR (neat) 1640, 1610, 1490, 1445, 1120, 1030, 955, 750, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.24 (3H, t, J=7.0 Hz, EtO), 1.8—1.9 (2H, m, 3-H), 2.0—2.2, 2.3—2.5 (each 1H, m, 4-H), 3.66, 3.93 (each 1H, dq, J_{gem}=9.9 and J=7.0 Hz, EtO), 5.00 (1H, t, $J_{5\text{-}4}$=4.4 Hz, 5-H), 5.18 (1H, t, $J_{2\text{-}3}$=3.3 Hz, 2-H), 6.44 (1H, d, J=15.8 Hz, 6-CH=), 6.83 (1H, d, J=15.8 Hz, =CHPh), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.25 (EtO), 17.80 (4-C), 26.54 (3-C), 63.81 (EtO), 97.19 (2-C), 104.47 (5-C), 124.33, 125.94, 126.46, 127.28, 128.55, 137.23, 147.77 (6-C); MS *m/z* (rel intensity, %) 230 (M^+, 30), 131 (67), 129 (37), 128 (46), 115 (46), 105 (36), 103 (71), 102 (25), 91 (37), 76 (base peak), 55 (24), and 51 (44). HRMS Found: *m/z* 230.1332. Calcd for $C_{15}H_{18}O_2$: M, 230.1306.

(*E*)-2-Ethoxy-6-[2-(*p*-(methoxyphenyl)ethenyl]-3,4-dihydro-2*H*-pyran (3b): Pure **3b** was obtained in 63% yield by silica-gel column chromatography of the curde product by using hexane-diethyl ether (7 : 1 v/v) as an eluent: Colorless solid (hexane); mp 62—64 °C; IR (KBr) 1640, 1595, 1500, 1440, 1245, 1175, 1110, 1040, 970, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25, (3H, t, J=7.0 Hz, EtO), 1.8—2.0 (2H, m, 3-H), 2.11, 2.33 (each 1H, m, 4-H), 3.67, 3.94 (each 1H, dq, J_{gem}=9.9 and J=7.0 Hz, EtO), 3.80 (3H, s, *p*-MeO), 4.95 (1H, t, $J_{5\text{-}4}$=4.4 Hz, 5-H), 5.17 (1H, t, $J_{2\text{-}3}$=3.3 Hz, 2-H), 6.32 (1H, d, J=16.1 Hz, 6-CH=), 6.77 (1H, d, J=16.1 Hz, =CHPh), 6.85 (2H, dt, J=8.8 and 1.9 Hz, Ar), and 7.34 (2H, dt, J=8.8 and 1.9 Hz, Ar); ^{13}C NMR ($CDCl_3$) δ=15.25 (EtO), 17.83 (4-C), 26.64 (3-C), 55.26 (*p*-MeO), 63.79 (EtO), 97.23 (2-C), 103.35 (5-C), 114.05, 122.36, 125.51, 127.66, 130.06, 147.94 (6-C), and 159.10 (Ar); MS m/z (rel intensity, %) 260 (M^+, 74), 178 (25), 161 (48), 136 (64), 135 (base peak), 92 (21), and 77 (33). Found: C, 74.01; H, 7.79%. Calcd for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74%.

(*E*)-2-Ethoxy-6-(1-pentenyl)-3,4-dihydro-2*H*-pyran (3c): Pure **3c** was obtained in 54% yield by silica-gel column chromatography of the crude product by using hexane-diethyl ether (9 : 1 v/v) as an eluent: Pale yellow liquid; IR (neat) 1660, 1625, 1440, 1370, 1120, 1035, 955, and 920 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.86 (3H, t, J=7.3 Hz, *n*-Pr), 1.10 (3H, t, J=7.0 Hz, EtO), 1.37 (2H, sex, J=7.3 Hz, *n*-Pr), 1.6—1.9 (3H, m, 3- and 4-H), 2.03 (2H, q, J=7.3 Hz, *n*-Pr), 2.30 (1H, m, 4-H), 3.43, 3.88 (each 1H, J_{gem}=9.5 and J=7.0 Hz, EtO), 4.72 (1H, dd, $J_{5\text{-}4}$=5.2 and 3.6 Hz, 5-H), 4.98 (1H, dd, $J_{2\text{-}3}$=3.3 and 2.7 Hz, 2-H), 5.84 (1H, br d, J=15.4 Hz, 6-CH=), and 6.24 (1H, br dt, J=15.4 and 7.3 Hz, =CHPr-*n*); ^{13}C NMR ($CDCl_3$) δ=13.87 (*n*-Pr), 15.45 (EtO), 17.68 (4-C), 22.94 (*n*-Pr), 26.98 (3-C), 34.82 (*n*-Pr), 63.70 (EtO), 97.35 (2-C), 101.12 (5-C), 126.89, 128.23, 148.17 (6-C); MS m/z (rel intensity, %) 196 (M^+, 78), 153 (39), 151 (21), 150 (41), 121 (20), 109 (20), 107 (23), 97 (34), 86 (45), 79 (31), and 73 (base peak). HRMS Found: m/z 196.1470. Calcd for $C_{12}H_{20}O_2$: M, 196.1462.

General Procedure for the Diels-Alder Reaction and Dehydrogenation of 6-(1-Alkenyl)-2-ethoxy-3,4-dihydro-2*H*-pyrans 3a—c Leading to 2-Ethoxychromans 5a—h. As a typical example the reaction of **3a** with methyl propynoate is described as follows: A solution of **3a** (0.105 g, 0.46 mmol), methyl propynoate (0.084 g, 1 mmol), and a catalytic amount of hydroquinone in dry benzene (2 ml) was charged in a sealed tube and heated at 115 °C for 60 h. The benzene was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-diethyl ether (6 : 1 to 4 : 1 v/v) to give **4b** which was contaminated by a trace of **5b** (**4b** : **5b**=12 : 1 mol/mol by ^1H NMR).

The product **4b** consisted of two stereoisomers (2,4a-trans : 2,4a-cis=8 : 3 by ^1H NMR) from which 2,4a-*trans*-**4b** was separated by crystallization. 2,4a-*trans*-**4b**: Colorless prisms (diethyl ether-hexane); mp 131—132 °C; IR (KBr) 1710, 1690, 1430, 1250, 1130, 1040, 960, 830, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, t, J=7.0 Hz, EtO), 1.56 (1H, dq, J_{gem}=$J_{4\text{-}3}$=$J_{4\text{-}4a}$=12.4 and $J_{4\text{-}3}$=8.8 Hz, 4(ax)-H), 1.83 (1H, dddd, J_{gem}=13.6, $J_{3\text{-}4}$=12.4, 4.8, and $J_{3\text{-}2}$=8.8 Hz, 3(ax)-H), 2.03 (1H, m, 3(eq)-H), 2.21 (1H, m, 4(ax)-H), 3.01 (1H, m, 4a-H), 3.53, 3.94 (each 1H, dq, J_{gem}=9.9 and J=7.0 Hz, EtO), 3.56 (3H, s, COOMe), 4.46 (1H, ddd, $J_{7\text{-}4a}$=8.1, $J_{7\text{-}8}$=3.7, and $J_{7\text{-}5}$=1.5 Hz, 7-H), 4.58 (1H, dd, $J_{2\text{-}3}$=8.8 and 2.6 Hz, 2-H), 5.20 (1H, dd, $J_{8\text{-}7}$=3.7 and $J_{8\text{-}4a}$=1.5 Hz, 8-H), 6.85 (1H, dd, $J_{5\text{-}4a}$=3.7 and $J_{5\text{-}7}$=1.5 Hz, 5-H), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.21 (EtO), 28.45 (4-C), 31.16 (3-C), 34.86 (4a-C), 42.68 (7-C), 51.52 (COOMe), 64.58 (EtO), 103.14 (2-C), 109.15 (8-C), 126.46, 128.04, 128.42 (each Ph), 131.10 (6-C), 138.15 (5-C), 143.93 (Ph), 148.61 (8a-C), and 166.73 (COOMe); MS m/z (rel intensity, %) 314 (M^+, 3), 165 (15), 153 (24), 152 (26), 141 (20), 115 (37), 85 (27), and 77 (28). Found: C, 72.40; H, 7.11%. Calcd for $C_{19}H_{22}O_4$: C, 72.59; H, 7.05%.

A solution of **4b** (0.47 g, 1.495 mmol) and DDQ (0.679 g, 2.99 mmol) in dry benzene (25 ml) was heated under reflux for 20 h. The solid precipitated was removed off by filtration through Celite 545 and the filtrate was again filtered through alumina by using ethyl acetate as an eluent. The eluate was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-diethyl ether (5 : 1 v/v) to give **5b** (0.418 g, 90%).

In other cases, Diels-Alder cycloadducts **4a** and **4c—h** were not characterized, but the cis/trans ratio was determined by ^1H NMR spectrum of the unpurified mixture. The ratio between the 3,4a-trans and 3,4a-cis isomers was determined on the basis of the relative integration of the 2-ethoxy methyl protons (in parenthesis): **4b**: 8 : 3 (δ=1.22 and 1.05); **4c**: 9 : 5 (1.20 and 1.08); **4d**: 3 : 1 (1.23 and 1.05); **4e**: 2 : 1 (1.22 and 1.08); **4f**: 1 : 1 (1.20 and 1.11). The reaction conditions and results are summarized in Table 1.

Dimethyl 2-Ethoxy-7-phenylchroman-5,6-dicarboxylate (5a): Colorless viscous oil; IR (neat) 1725, 1600, 1560, 1320, 1270, 1040, 960, 880, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.0 Hz, EtO), 1.91, 2.08 (each 1H, m, 3-H), 2.74 (1H, ddd, J_{gem}=17.3, $J_{4\text{-}3}$=5.5, and 3.3 Hz, 4(eq)-H), 3.03 (1H, ddd, J_{gem}=17.3, $J_{4\text{-}3}$=11.4, and 5.9 Hz, 4(ax)-H), 3.53 (3H, s, 6-COOMe), 3.62, 3.86 (each 1H, dq, J_{gem}=9.9 and 7.0 Hz, EtO), 3.87 (3H, s, 5-COOMe), 5.28 (1H, t, $J_{2\text{-}3}$=2.9 Hz, 2-H), 6.92 (1H, s, 8-H), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.97 (q, EtO), 18.25 (t, 4-C), 25.85 (t, 3-C), 51.83, 52.29 (each q, COOMe), 63.98 (t, EtO), 96.87 (d, 2-C), 120.28 (s), 120.28 (d), 127.41 (d), 128.00 (d), 133.50 (s), 140.05 (s), 140.99 (s), 153.62 (s), 168.01, and 168.48 (each s, COOMe); MS m/z (rel intensity, %) 370 (M^+, 26), 338 (base peak), 281 (25), 279 (27), 249 (24), 185 (21), 165 (24), and 154 (21). HRMS Found: m/z 370.1418. Calcd for $C_{21}H_{22}O_6$: M, 370.1415.

Methyl 2-Ethoxy-7-phenylchroman-6-carboxylate (5b): Colorless prisms (hexane); mp 46—48 °C; IR (KBr) 1700, 1610, 1550, 1480, 1440, 1290, 1155, 960, and 880 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.19 (3H, t, J=7.0 Hz, EtO), 1.95, 2.08 (each 1H, m, 3-H), 2.68 (1H, br ddd, J_{gem}=16.8, $J_{4\text{-}3}$=6.0, and 3.6 Hz, 4(eq)-H), 3.20 (1H, br ddd, J_{gem}=16.8, $J_{4\text{-}3}$=12.1, and 6.2 Hz, 4(ax)-H), 3.56 (3H, s, COOMe), 3.64, 3.88 (each 1H, dq, J_{gem}=9.5 and J=7.0 Hz, EtO), 5.29 (1H, t, $J_{2\text{-}3}$=2.6 Hz, 2-H), 6.80 (1H, s, 8-H), 7.2—7.5 (5H, m, Ph), and 7.65 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=15.03 (EtO), 20.00 (4-C), 26.32 (3-C), 51.48 (COOMe), 63.88 (EtO), 97.28 (2-C), 119.22, 121.50, 122.44, 126.94, 127.71, 128.23, 131.86, 141.39, 142.92, 154.79 (each Ph and Ar), and 168.31 (COOMe); MS m/z (rel intensity, %) 312 (M^+, 28), 266 (23), 74 (30), 59 (66), 57 (28), 45 (51), 43 (51), and 31 (base peak). Found: C, 73.30; H, 6.54%. Calcd for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

6-Acetyl-2-ethoxy-7-phenylchroman (5c): Colorless prisms (hexane); mp 51—53 °C; IR (KBr) 1675, 1600, 1545, 1475, 1275, 1145, 1100, 1045, 955, and 875 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.0 Hz, EtO), 1.96 (1H, m, one of 3-H), 1.96 (3H, s, MeCO), 2.09 (1H, m, the other of 3-H), 2.70 (1H, ddd, J_{gem}=16.2, $J_{4\text{-}3}$=6.0, and 3.6 Hz, 4(eq)-H), 3.03 (1H,

ddd, J_{gem}=16.2, J_{4-3}=12.6, and 5.4 Hz, 4(ax)-H), 3.66, 3.90 (each 1H, dq, J_{gem}=9.5 and J=7.0 Hz, EtO), 5.30 (1H, t, J_{2-3}=2.9 Hz, 2-H), 6.82 (1H, s, 8-H), and 7.2—7.5 (6H, 5-H and Ph); ^{13}C NMR ($CDCl_3$) δ=15.10 (EtO), 20.09 (4-C), 26.42 (3-C), 30.27 (MeCO), 63.96 (EtO), 97.28 (2-C), 118.67, 121.77, 127.70, 128.51, 128.76, 130.23, 133.16, 140.97, 141.15, 154.47 (each Ph and Ar), and 203.10 (MeCO); MS m/z (rel intensity, %) 296 (M^+, 41), 281 (57), 235 (31), 209 (21), 165 (28), 153 (27), 152 (38), and 43 (base peak). Found: C, 77.19; H, 6.85%. Calcd for $C_{19}H_{20}O_4$: C, 77.00; H, 6.80%.

Dimethyl 2-Ethoxy-7-(*p*-methoxyphenyl)chroman-5,6-dicarboxylate (5d): Colorless prisms (hexane); mp 94—95 °C; IR (KBr) 1725, 1600, 1430, 1320, 1265, 1230, 1020, 955, and 830 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.18 (3H, t, J=7.3 Hz, OEt), 1.92, 2.07 (each 1H, m, 3-H), 2.73 (1H, ddd, J_{gem}=17.3, J_{4-3}=5.5, and 3.3 Hz, 4(eq)-H), 3.03 (1H, ddd, J_{gem}=17.3, J_{4-3}=11.4, and 5.9 Hz, 4(ax)-H), 3.58 (3H, s, 6-COOMe), 3.63, 3.83 (each 1H, dq, J_{gem}=9.5 and J=7.3 Hz, OEt), 3.81 (3H, s, 5-COOMe), 3.87 (3H, s, *p*-MeO), 5.27 (1H, t, J_{2-3}=2.6 Hz, 2-H), 6.90 (1H, s, 8-H), 6.90 (2H, dt, J=8.8 and 2.2 Hz, Ar), and 7.22 (2H, dt, J=8.8 and 2.2 Hz, Ar); ^{13}C NMR ($CDCl_3$) δ=15.08 (EtO), 18.39 (4-C), 26.02 (3-C), 52.08, 52.44 (each COOMe), 55.23 (*p*-MeO), 64.00 (EtO), 96.97 (2-C), 113.69, 120.11, 120.38, 124.03, 129.24, 132.47, 133.42, 140.64, 153.65, 159.19 (each Ar), 168.19, and 168.86 (each COOMe); MS m/z (rel intensity, %) 400 (M^+, 32), 368 (43), 58 (35), and 43 (base peak). Found: C, 66.11; H, 6.02%. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%.

Methyl 2-Ethoxy-7-(*p*-methoxyphenyl)chroman-6-carboxylate (5e): Colorless viscous oil; IR (neat) 1725, 1610, 1490, 1280, 1240, 1160, 960, 880, 830, and 730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.19 (3H, t, J=7.0 Hz, EtO), 1.95, 2.08 (each 1H, m, 3-H), 2.68 (1H, ddd, J_{gem}=16.8, J_{4-3}=6.0, and 3.6 Hz, 4(eq)-H), 3.02 (1H, ddd, J_{gem}=16.8, J_{4-3}=12.1, and 6.2 Hz, 4(ax)-H), 3.63 (3H, s, COOMe), 3.65, 3.88 (each 1H, dq, J_{gem}=9.9 and J=7.0 Hz, EtO), 3.83 (3H, s, *p*-MeO), 5.29 (1H, t, J_{2-3}=2.9 Hz, 2-H), 6.87 (1H, s, 8-H), 6.91 (2H, dt, J=8.8 and 2.2 Hz, Ar), 7.21 (2H, dt, J=8.8 and 2.2 Hz, Ar), and 7.62 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=15.10 (EtO), 20.04 (4-C), 26.41 (3-C), 51.65 (COOMe), 55.22 (*p*-MeO), 63.96 (EtO), 97.35 (2-C), 113.33, 119.28, 121.22, 122.50, 129.44, 131.89, 133.76, 142.53, 154.77, 158.83 (each Ar), and 168.65 (COOMe); MS m/z (rel intensity, %) 342 (M^+, 14), 248 (27), 246 (21), 58 (26), 44 (37), and 43 (base peak). HRMS Found: m/z 342.1459. Calcd for $C_{20}H_{22}O_5$: M, 342.1466.

6-Acetyl-2-ethoxy-7-(*p*-methoxyphenyl)chroman (5f): Colorless prisms (hexane); mp 99—101 °C; IR (KBr) 1675, 1600, 1570, 1270, 1230, 1145, 1100, 1045, 870, and 825 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.0 Hz, EtO), 1.97 (3H, s, MeCO), 1.97, 2.07 (each 1H, m, 3-H), 2.68 (1H, ddd, J_{gem}=16.1, J_{4-3}=5.9, and 3.5 Hz, 4(eq)-H), 3.02 (1H, ddd, J_{gem}=16.1, J_{4-3}=12.1, and 6.2 Hz, 4(ax)-H), 3.65, 3.90 (each 1H, dq, J_{gem}=9.5 Hz, and J=7.0 Hz, EtO), 3.84 (3H, s, *p*-MeO), 5.30 (1H, t, J_{2-3}=2.9 Hz, 2-H), 6.80 (1H, s, 8-H), 6.94 (2H, dt, J=8.8 and 2.2 Hz, Ar), 7.24 (2H, dt, J=8.8 and 2.2 Hz, Ar), and 7.36 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=15.12 (EtO), 20.06 (4-C), 26.44 (3-C), 30.32 (MeCO), 55.29 (*p*-MeO), 63.96 (EtO), 97.33 (2-C), 114.01, 118.50, 121.44, 129.87, 130.13, 133.26, 133.29, 140.73, 154.41, 159.43 (each Ar), and 203.52 (MeCO); MS m/z (rel intensity, %) 326 (M^+, base peak), 311 (58), 265 (21), 247 (27), 246 (38), 245 (23), 231 (46), 221 (42), 217 (22), 123 (27), 109 (20), 108 (69), 57 (38), and 56 (20). Found: C, 73.83; H, 6.94%. Calcd for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%.

Dimethyl 2-Ethoxy-7-propylchroman-5,6-dicarboxylate (5g): Colorless liquid; IR (neat) 1725, 1605, 1570, 1440, 1300, 1140, and 1060 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.93 (3H, t, J=7.3 Hz, EtO), 1.18 (3H, t, J=7.0 Hz, *n*-Pr), 1.59 (2H, sex, J=7.3 Hz, *n*-Pr), 1.89, 2.04 (each 1H, m, 3-H), 2.6—2.8 (3H, m, *n*-Pr and 4(eq)-H), 2.95 (1H, ddd, J_{gem}=16.9, J_{4-3}=11.7, and 6.2 Hz, 4(ax)-H), 3.63, 3.81 (each 1H, dq, J_{gem}=9.9 and J=7.0 Hz, EtO), 3.82, 3.86 (each 3H, s, COOMe), 5.24 (1H, t, J_{2-3}=2.9 Hz, 2-H), and 6.78 (1H, s, 8-H); ^{13}C NMR ($CDCl_3$) δ=14.00 (*n*-Pr), 15.09 (EtO), 18.36 (4-C), 24.46 (*n*-Pr), 26.09 (3-C), 35.64 (*n*-Pr), 52.12, 52.31 (each COOMe), 63.99 (EtO), 96.99 (2-C), 119.12, 120.18, 123.54, 133.66, 141.91, 155.93 (each Ar), 168.37 (COOMe), and 168.53 (COOMe); MS m/z (rel intensity, %) 336 (M^+, 28), 304 (base peak), 289 (40), 275 (21), 245 (18), 215 (12), 163 (14), and 43 (12). HRMS Found: m/z 336.1574. Calcd for $C_{18}H_{24}O_6$: M, 336.1571.

Methyl 2-Ethoxy-7-propylchroman-6-carboxylate (5h): This compound is contaminated by a trace of regioisomer **5h** (R=*n*-Pr, E=COOMe, W=H). Colorless viscous oil; IR (neat) 1715, 1610, 1560, 1430, 1270, 1135, 1055, 970, and 870 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97 (3H, t, J=7.3 Hz, *n*-Pr), 1.19 (3H, t, J=7.0 Hz, EtO), 1.60 (2H, sex, J=7.3 Hz, *n*-Pr), 1.92, 2.04 (each 1H, m, 3-H), 2.62 (1H, ddd, J_{gem}=16.2, J_{4-3}=5.5, and 4.1 Hz, 4(eq)-H), 2.8—3.0 (3H, m, 4(ax)-H and *n*-Pr), 3.64, 3.88 (each 1H, dq, J_{gem}=9.5 and J=7.0 Hz, EtO), 3.84 (3H, s, COOMe), 5.26 (1H, t, J_{2-3}=2.9 Hz, 2-H), 6.69 (1H, s, 8-H), and 7.68 (1H, s, 6-H); ^{13}C NMR ($CDCl_3$) δ=14.77 (*n*-Pr), 15.12 (EtO), 20.03 (4-C), 24.69 (*n*-Pr), 26.54 (3-C), 36.40 (*n*-Pr), 51.52 (COOMe), 63.94 (EtO), 97.41 (2-C), 118.99, 119.90, 121.39, 132.64, 145.03, 155.33 (each Ar), and 167.68 (COOMe); MS m/z (rel intensity, %) 278 (M^+, base peak), 247 (22), 233 (29), 232 (52), and 231 (24). HRMS Found: m/z 278.1520. Calcd for $C_{16}H_{22}O_4$: 278.1517.

General Procedure for the Hydrolysis and Oxidation of 2-Ethoxychromans 5a—h Leading to 2-Chromanones 7a—h. As a typical example the sequence of hydrolysis and PCC-oxidation of **5a** is described as follows: A solution of **5a** (0.53 g, 1.43 mmol) in THF (50 ml) containing 4M hydrochloric acid (25 ml) was stirred at room temperature for 15 h. The THF was evaporated in vacuo and the residual solution was extracted with dichloromethane (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (1 : 1 v/v) to give **6a** (0.44 g, 90%).

6a: ^{1}H NMR ($CDCl_3$) δ=1.8—2.1 (2H, m, 3-H), 2.77 (1H, dt, J_{gem}=16.9 Hz, and J_{4-3}=5.5 Hz, 4(eq)-H), 3.01 (1H, ddd, J_{gem}=16.9, J_{4-3}=10.2, and 6.9 Hz, 4(ax)-H), 3.52 (3H, s, 6-COOMe), 3.86 (3H, s, 5-COOMe), 3.93 (1H, d, J=2.7 Hz, OH), 5.57 (1H, q, J_{2-3}=J_{2-OH}=2.7 Hz, 2-H), 6.85 (1H, s, 8-H), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=18.32 (3-C), 26.52 (4-C), 52.12, 52.57 (each COOMe), 92.14 (2-C), 119.89, 120.41, 124.03, 127.54, 128.06, 128.19, 133.49, 140.02, 141.22, 153.73 (each Ar), 168.25, and 168.81 (each COOMe).

A mixture of this compound **6a** (0.065 g, 0.19 mmol) and PCC (0.123 g, 0.57 mmol) in dichloromethane (3 ml) was stirred at room temperature for 24 h. Diethyl ether (10 ml) was added and the ether layer was decanted. This procedure was repeated three times. The combined ether extracts were filtered through a short column packed with silica gel and the silica gel was washed with ethyl acetate. The ether and the ethyl acetate were combined and evaporated in vacuo.

The residue was again chromatographed over silica gel with hexane–diethyl ether (4 : 1 v/v) to give **7a** (0.054 g, 83%).

The eluents used for the final column chromatography are as follows: **7b**: hexane–diethyl ether (4:1 v/v); **7c**, **7d**, **7f**: hexane–ethyl acetate (1 : 1 v/v); **7e**, **7h**: hexane–ethyl acetate (3 : 1 v/v); **7g**: hexane–ethyl acetate (3 : 2 v/v). The results are summarized in Table 2.

Dimethyl 2-Oxo-7-phenylchroman-5,6-dicarboxylate (7a): Colorless needles (dichloromethane–hexane); mp 205—207 °C; IR (KBr) 1780, 1730, 1715, 1600, 1430, 1330, 1275, 1220, 1180, and 1150 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.81 (2H, dd, $J_{3\text{-}4}$=7.7 and 5.9 Hz, 3-H), 3.17 (2H, dd, $J_{4\text{-}3}$=7.7 and 5.9 Hz, 4-H), 3.58 (3H, s, 6-COOMe), 3.90 (3H, s, 5-COOMe), 7.17 (1H, s, 8-H), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=21.57 (3-C), 28.41 (4-C), 52.38, 52.85 (each COOMe), 120.53, 121.22, 128.03, 128.17, 128.49, 128.59, 131.82, 138.81, 141.87, 152.94 (each Ph and Ar), 166.88, 167.08, and 168.10 (each COOMe and 2-C); MS *m/z* (rel intensity, %) 340 (M^+, 8), 339 (27), 309 (44), 308 (78), 281 (40), 280 (base peak), 265 (25), 249 (80), 222 (21), 221 (27), 194 (53), 166 (24), 165 (75), 153 (25), 152 (42), 151 (22), and 139 (34). Found: C, 66.80; H, 4.60%. Calcd for $C_{19}H_{16}O_6$: C, 67.05; H, 4.75%.

Methyl 2-Oxo-7-phenylchroman-6-carboxylate (7b): Colorless prisms (diethyl ether–hexane); mp 144—145 °C; IR (KBr) 1755, 1725, 1270, 1230, 1130, 1080, and 900 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.84 (2H, dd, $J_{3\text{-}4}$=7.6 and 5.5 Hz, 3-H), 3.08 (2H, dd, $J_{4\text{-}3}$=7.6 and 5.5 Hz, 4-H), 3.62 (3H, s, COOMe), 7.04 (1H, s, 8-H), 7.2—7.5 (5H, m, Ph), and 7.73 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=23.33 (3-C), 29.00 (4-C), 51.99 (COOMe), 119.10, 121.45, 126.71, 127.64, 128.13, 130.22, 140.20, 143.68, 153.73 (each Ph and Ar), 167.57 (2-C), and 168.03 (COOMe); MS *m/z* (rel intensity,%) 282 (M^+, base peak), 251 (85), 223 (61), 181 (27), 166 (21), 165 (63), 153 (43), 152 (85), 151 (25), 139 (36), 127 (21), 115 (22), and 77 (21). Found: C, 72.05; H, 4.86%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

6-Acetyl-2-oxo-7-phenylchroman (7c): Colorless prisms (diethyl ether–hexane); mp 134—135 °C; IR (KBr) 1755, 1675, 1610, 1470, 1350, 1275, 1135, 900, 770, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.96 (3H, s, MeCO), 2.85 (2H, dd, $J_{3\text{-}4}$=8.4 and 5.9 Hz, 3-H), 3.09 (2H, dd, $J_{4\text{-}3}$=8.4 and 5.9 Hz, 4-H), 7.06 (1H, s, 8-H), 7.3—7.4 (2H, m, Ph), and 7.4—7.5 (4H, m, 5-H and Ph); ^{13}C NMR ($CDCl_3$) δ=23.35 (3-C), 29.03 (4-C), 30.34 (MeCO), 118.47, 121.77, 128.40, 128.69, 128.87, 136.96, 139.62, 141.64, 153.36 (each Ph and Ar), 167.63 (2-C), and 203.28 (MeCO); MS *m/z* (rel intensity, %) 266 (M^+, 41), 251 (base peak), 223 (22), 209 (28), 165 (52), 153 (45), 152 (50), 139 (22), and 63 (25). Found: C, 76.77; H, 5.20%. Calcd for $C_{17}H_{14}O_3$: C, 76.67; H 5.30%.

Dimethyl 7-(*p*-Methoxyphenyl)-2-oxochroman-5,6-dicarboxylate (7d): Colorless needles (diethyl ether–hexane); mp 164—165 °C; IR (KBr) 1775, 1725, 1710, 1600, 1435, 1335, 1280, 1225, 1185, and 1150 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.80 (2H, dd, $J_{3\text{-}4}$=7.7 and 7.0 Hz, 3-H), 3.14 (2H, dd, $J_{4\text{-}3}$=7.7 and 7.0 Hz, 4-H), 3.62 (3H, s, 6-COOMe), 3.83 (3H, s, 5-COOMe), 3.89 (3H, s, *p*-MeO), 6.92 (2H, br d, J=8.4 Hz, Ar), 7.14 (1H, s, 8-H), and 7.22 (2H, dt, J=8.4 and 1.8 Hz, Ar); ^{13}C NMR ($CDCl_3$) δ=21.59 (3-C), 28.47 (4-C), 52.44, 52.86 (each COOMe), 55.30 (*p*-MeO), 113.99, 120.53, 120.83, 128.56, 129.27, 131.11, 131.66, 141.48, 152.90, 159.65 (each Ar), 166.91, 167.17, and 168.32 (each COOMe and 2-C); MS *m/z* (rel intensity, %) 370 (M^+, base peak), 339 (46), 338 (70), 311 (25), 310 (98), 279 (59), 224 (33), 152 (31), and 139 (27). Found: C, 64.98; H, 4.87%. Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%.

Methyl 7-(*p*-Methoxyphenyl)-2-oxochroman-6-carboxylate (7e): Colorless prisms (cyclohexane); mp 85—87 °C; IR (KBr) 1775, 1720, 1615, 1490, 1250, 1130, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.83 (2H, dd, $J_{3\text{-}4}$=8.1 and 5.8 Hz, 3-H), 3.05 (2H, dd, $J_{4\text{-}3}$=8.1 and 5.8 Hz, 4-H), 3.65 (3H, s, COOMe), 3.84 (3H, s, *p*-MeO), 6.93 (2H, dd, J=8.8 and 2.2 Hz, Ar), 7.02 (1H, s, 8-H), 7.20 (2H, dd, J = 8.8 and 2.2 Hz, Ar), and 7.69 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=23.28 (3-C), 29.01 (4-C), 52.05 (COOMe), 55.26 (*p*-MeO), 113.63, 119.02, 121.05, 126.65, 129.37, 130.15, 132.44, 143.22, 153.67, 159.27 (each Ar), 167.64 (2-C), and 168.26 (COOMe); MS *m/z* (rel intensity, %) 312 (M^+, base peak), 281 (24), 239 (10), and 152 (9). Found: C, 69.03; H, 5.13%. Calcd for $C_{18}H_{16}O_5$: C, 69.22; H, 5.16%.

6-Acetyl-7-(*p*-methoxyphenyl)-2-oxochroman (7f): Colorless prisms (diethyl ether–hexane); mp 118—120 °C; IR (KBr) 1760, 1670, 1605, 1480, 1270, 1250, 1130, 900, and 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.97 (3H, s, MeCO), 2.84 (2H, dd, $J_{3\text{-}4}$= 7.7 and 5.5 Hz, 3-H), 3.07 (2H, dd, $J_{4\text{-}3}$=7.7 and 5.5 Hz, 4-H), 3.86 (3H, s, *p*-MeO), 6.92 (2H, dt, J=8.8 and 2.2 Hz, Ar), 7.04 (1H, s, 8-H), 7.23 (2H, dt, J=8.8 and 2.2 Hz, Ar), and 7.42 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=23.31 (3-C), 29.06 (4-C), 30.32 (MeCO), 55.35 (*p*-MeO), 114.34, 118.28, 121.35, 128.30, 129.87, 131.85, 136.96, 141.25, 153.38, 159.91 (each Ar), 167.73 (2-C), and 203.68 (MeCO); MS *m/z* (rel intensity, %) 296 (M^+, base peak), 295 (20), 281 (76), 239 (32), and 55 (25). Found: C, 72.81; H, 5.47%. Calcd for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%.

Dimethyl 2-Oxo-7-propylchroman-5,6-dicarboxylate (7g): Colorless prisms (hexane); mp 81—83 °C; IR (KBr) 1770, 1720, 1580, 1440, 1310, 1200, 1140, 990, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ = 0.94 (3H, t, J = 7.3 Hz, *n*-Pr), 1.61 (2H, sex, J = 7.3 Hz, *n*-Pr), 2.69 (2H, t, J = 7.3 Hz, *n*-Pr), 2.76 (2H, dd, $J_{3\text{-}4}$=7.7 and 5.5 Hz, 3-H), 3.10 (2H, dd, $J_{4\text{-}3}$=7.7 and 5.5 Hz, 4-H), 3.87, 3.88 (each 3H, s, COOMe), and 7.03 (1H, s, 8-H); ^{13}C NMR ($CDCl_3$) δ = 13.85 (*n*-Pr), 21.51 (3-C), 24.26 (*n*-Pr), 28.51 (4-C), 35.36 (*n*-Pr), 52.50, 52.72 (each COOMe), 120.03, 120.33, 128.38, 131.73, 142.62, 153.13 (each Ar), 167.17, 167.35, and 167.93 (each 2-C and COOMe); MS *m/z* (rel intensity,%) 306 (M+, 5), 279 (25), 274 (31), 217 (43), 201 (21), 167 (27), 149 (55), and 40 (base peak). Found: C, 62.53; H, 5.99%. Calcd for $C_{16}H_{18}O_6$: C, 62.74; H, 5.92%.

Methyl 2-Oxo-7-propylchroman-6-carboxylate (7h): Colorless prisms (hexane); mp 50—51 °C; IR (KBr) 1775, 1700, 1610, 1430, 1400, 1260, 1110, and 895 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (3H, t, J=7.3 Hz, *n*-Pr), 1.61 (2H, sex, J=7.3 Hz, *n*-Pr), 2.80 (2H, dd, $J_{3\text{-}4}$=7.7 and 5.5 Hz, 3-H), 2.92 (2H, dd, J=7.3 Hz, *n*-Pr), 3.01 (2H, dd, $J_{4\text{-}3}$=7.7 and 5.5 Hz, 4-H), 3.89 (3H, s, COOMe), 6.92 (1H, s, 8-H), and 7.77 (1H, s, 5-H); ^{13}C NMR ($CDCl_3$) δ=14.05 (*n*-Pr), 23.23 (3-C), 24.59 (*n*-Pr), 29.14 (4-C), 36.15 (*n*-Pr), 51.96 (COOMe), 118.99, 119.79, 125.43, 130.97, 146.03, 154.19 (each Ar), 167.84 (2-C), and 168.36 (COOMe); MS *m/z* (rel intensity, %) 248 (M^+, 40), 217 (base peak), 201 (48), 91 (24), 57 (66), 56 (32), and 43 (27). Found: C, 67.96; H, 6.57%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

(Received October 31, 1988)

6-Substituted and unsubstituted 6,7-dihydro-7-hydroxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones were predominantly obtained in excellent yield by the reduction of the corresponding 5,7-diones with sodium borohydride in the presence of Mg ion at 0 °C. The highly regioselective production of the 7-hydroxy lactam in preference to the 5-hydroxy isomer was reasonably interpreted in terms of a chelate complex formation between the dione and Mg ion. The regioisomeric assignment was achieved by the transformation of the 7-hydroxy lactam to 2-(hydroxymethyl)-3-pyridinecarboxamides which could be converted to the known azaphthalide, furo[3,4-*b*]-pyridin-5(7*H*)-one. Furthermore, the high chemoselectivity was found to be retained below 0 °C to give the partial reduction product, hydroxy lactam, exclusively.

The partial reduction of 6-substituted 5*H*-pyrrolo-[3,4-*b*]pyridine-5,7(6*H*)-diones (quinolinimides **1**) with sodium borohydride ($NaBH_4$) has been known to produce 6-substituted 6,7-dihydro-7-hydroxy-5*H*-pyrrolo-[3,4-*b*]pyridin-5-ones (**2**) along with the corresponding 5-hydroxy-7-oxo isomers (**3**).[1—3] Recent attention has been directed to these hydroxy lactams as precursors to pharmacologically active compounds[1,2] or to aza analogs of fused heterocyclic systems.[3] The partial $NaBH_4$-reduction of cyclic imides, which involve alicyclics[4] and aromatics,[5] to the corresponding hydroxy lactams has been well investigated. However, in the case of the unsymmetrical imide **1**, the study on the control of the regioselectivity as well as the chemoselectivity of the reduction is scanty. We previously reported[6] that the chemoselectivity of the $NaBH_4$-reduction of *N*-unsubstituted quinolinimide (**1a**) could be thermally controlled; the partial reduction to the corresponding hydroxy lactams **2a** and **3a** was effected at −20 °C. In contrast, the regioselectivity of the reduction was unsatisfactory (**2a** : **3a**=3 : 1). Therefore, we turned our attention to improving the regioselectivity and expanding the scope of this method to the synthesis of *N*-substituted hydroxy lactams. Eventually, we found that the addition of Mg ion lead to the highly regioselective $NaBH_4$-reduction of *N*-substituted and *N*-unsubstituted quinolinimides (**1a—g**) to the corresponding hydroxy lactams **2a—g**. In this paper, we wish to describe the detail of this selective reduction.

Results and Discussion

First of all, the $NaBH_4$-reduction of *N*-unsubstituted quinolinimide (**1a**) to the hydroxy lactam **2a** and **3a** was examined under the various reaction conditions as shown in Table 1. A mixed solvent (MeOH-$CHCl_3$ (1 : 1 (v/v)) was principally employed for the reduction because of the relatively high solubility of the substrate **1a**. Although the reduction also proceeded in MeOH uneventfully, the degree of regioselectivity was diminished (Runs 1 and 2). We could not find any merit at a lowered temperature (−40 °C, Run 3), while at an elevated temperature (0 °C), the over-reduction took place to give 3-(hydroxymethyl)-2-pyridinecarboxamide (**5a**) as a by-product (Run 4). In our further efforts to find the reaction conditions for high degree of regioselectivity, we reasoned that the formation of a chelate complex, in which the 1-nitrogen atom and the oxygen atom of 7-carbonyl group of imide **1** coordinate to

a metal ion, should activate the 7-carbonyl group in preference to the 5-carbonyl group for the reduction. Indeed, when magnesium perchlorate was added into the reduction system, ^1H NMR of the product indicated the predominant formation of 7-hydroxy lactam **2a**. Unfortunately, the hydroxy lactam **2a** could not be separated from the magnesium salt by usual methods because **2a** was less soluble in normal organic solvents such as chloroform. When a polar solvent such as methanol was employed as an eluent for column chromatography, a mixture of the hydroxy lactam and the magnesium salt was obtained. The similar problem also occurred in the case of using magnesium chloride instead of the perchlorate. This trouble could be avoided by "continuous extraction." Thus, the worked-up reaction mixture was continuously extracted with refluxing chloroform for 4 d to give the hydroxy lactam **2a** in an excellent yield (Run 5). Surprisingly, in the presence of Mg salt, the chemoselectivity was completely retained at 0 °C (Run 6). Even at r.t., the hydroxy lactam was obtained in 70% yield along with a minor over-reduction product (Run 7). It deserves emphasis that this result is a striking contrast to the reduction in the absence of Mg ion at r.t., in which the over-reduction products, 2-(hydroxymethyl)-3-pyridinecarboxamide (**4a**) and its regioisomer **5a** was produced exclusively.[6] In a word, Mg ion controlled not only the regioselectivity but also the chemoselectivity.

Encouraged by the success of this selective reduction, we turned to the synthesis of *N*-substituted hydroxy lactams. In order to obtain the best reaction conditions, *N*-methylquinolinimide (**1b**) was reduced under the various reaction conditions as shown in Table 2. The Mg ion was apparently effective for the highly regioselective reduction (Runs 1—4), and the degree of regioselectivity came to a maximum when two equivalents of Mg ion was used (Runs 4 and 5). On the other hand, lowered temperatures (−20 and −40 °C) did not influence the regioselectivity (Runs 6 and 7). This highly regioselective and chemoselective reduction could be also carried out in a synthetic scale (Run 8). The major regioisomer **2b** was readily available in the pure form by the recrystallization of the crude product obtained by the continuous extraction.

Although the minor product **3b** could not be isolated in the pure form, the formation of **3b** was confirmed by the conversion of **3b** to the over-reduction product, 3-(hydroxymethyl)-2-pyridinecarboxamide (**5b**). It should be noted that the present reduction was also successful in EtOH (Run 9) and MeCN (Run 10), since it has been reported that the partial reduction of cyclic imide required MeOH as a solvent[7] or an addition of acid in EtOH.[8] The univalent Li and Ag ions have no essential effect for the regioselectivity (Runs 11 and 12). This fact suggests the formation of a divalent metal ion chelate complex at the initial stage of the reaction (vide infra). Although an alternative divalent ion, Zn^{2+}, was expected the desirable effect as well as Mg^{2+}, the continuous extraction of the reaction mixture gave only low yield of the hydroxy lactam without any other products and recovered substrate (Run 13). Furthermore, we observed a similar unsuccessful result with $Zn(BH_4)_2$. The reasons for the unusual low yields in the presence of Zn ion as well as Ag ion (Run 12) are uncertain. It is likely that in the methanol-involved solvent, Zn or Ag ion accelerates the formation of hemiacetal or acetal of the imide, which inhibits the $NaBH_4$-reduction.[9] But, this possibility is ruled out because (i) we could not observe any products such as acetal before addition of $NaBH_4$ into the solution of the substrate and the metal salt, and (ii) similarly low yield was obtained with dry acetonitrile (Run 15). Hence, it is supposed that another pathway lead to a product which could not be obtained by the continuous extraction.

According to Speckamp and co-workers,[10] the present reduction will proceed through the pathways depicted in Scheme 1. As aforementioned, in the presence of Mg ion, a chelate complex **8** might be formed, and then 7-carbonyl group would be more strongly activated for the attack of a hydride ion in comparison with 5-carbonyl group. As the result, oxide anion **9** will be produced regioselectively. The formation of such a magnesium ion chelate on a pyrrolo[3,4-*b*]-pyridine[3] or furo[3,4-*b*]pyridine[11] ring has been suggested in the case of regioselective addition reactions of magnesium Grignard reagents. However, as far as we know, the present reaction is the first example of Mg ion assisted regioselective reduction on the pyrrolo-[3,4-*b*]pyridine ring. If the oxide anion **9** undergoes ring-cleavage to formyl amide **10**, the over-reduction will readily occur to afford the hydroxymethyl amide **4**. It is easily envisioned, however, that in the presence Mg ion, the oxide anion would be stabilized by the chelation, and the ring-cleavage might become an unfavorable pathway. Ultimately, direct protonation of **9** would afford the hydroxy lactam **2**. Thus, Mg ion precludes the over-reduction to improve the chemoselectivity as mentioned above. In the case of the reduction of *N*-methylquinolinimide (**1b**), the high chemoselectivity was retained at 0 °C even in the absence of Mg ion (Run 1, Table 2). This is not surprising when one considers that the methyl group is an electron-donating group, and the ring-cleavage of *N*-methylated **9** to **10** will be more unfavorable in comparison with *N*-unsubstituted one.

Since we have been able to optimize the reaction conditions, we applied this selective reduction to several *N*-alkylated and *N*-arylated quinolinimides (**1c—g**) in a synthetic scale to demonstrate the general synthetic utility of this method. As listed in Table 3, the

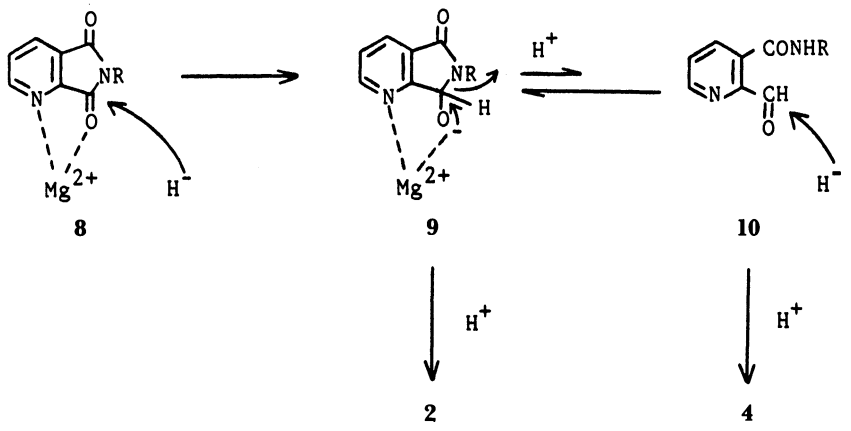

Scheme 1.

reduction was smoothly effected in the presence of Mg ion to produce the corresponding hydroxy lactams **2c—g** in excellent yields with high degree of regioselectivity and chemoselectivity. Consequently, the present method is potentially fruitful for the synthesis of the 7-hydroxy lactam **2** because of excellent yield, high selectivity, simple manipulation, and easy availability of the substrate and reducing reagent.

Finally, we studied the assignment of the regioisomeric structure of **2b—g**. Although Hitchings and Vernon described the regioisomeric assignment of such a hydroxy lactam by ^{1}H NMR,[3] the directly definitive evidence has not been obtained. In our previous study,[6] the regioisomeric assignment of hydroxy lactams **2a** and **3a** has been clearly attained by transformation of **2a** and **3a** to the corresponding (hydroxymethyl)pyridinecarboxamides **4a** and **5a**, which could be converted to the known azaphthalides **6** and its regioisomer **7**, respectively. Because the (hydroxymethyl)pyridinecarboxamides **4** and **5** are key compounds to determine the regioisomeric structures, our initial attention was focused on the preparation of the over-reduction products, *N*-substituted (hydroxymethyl)pyridinecarboxamides **4b—g** and **5b—g** from the corresponding quinolinimide **1b—g** followed by the conversion to **6** and **7**, respectively. When *N*-methylquinolinimide (**1b**) was treated with $NaBH_4$ in MeOH-$CHCl_3$ at r.t. according to previous report,[6] the desired products **4b** and **5b** were produced in very low yield. After examining reaction conditions, the best result was obtained in EtOH at 50 °C for 1.5 h. These conditions could be applied with equal success to other *N*-substituted quinolinimides **1c—g** as shown in Table 4. Table 4 also exhibits that the hydrolysis and cyclization of the (hydroxymethyl)pyridinecarboxamide **4b—g** and **5b—g** smoothly proceeded in hot acidic methanol to give the known azaphthalides **6** and **7**, respectively. Consequently, we could assign the regioisomeric structures of **4** and **5**. Eventually, we carried out the reduction of aforementioned hydroxy lactams **2b—g** with $NaBH_4$ to confirm their regioisomeric structure. As listed in Table 5, the 2-(hydroxymethyl)-3-pyridinecarboxamides (**4b—g**) were obtained in moderate to good yields. From the synthetic point of view, it is noteworthy that the sequential combination of the two steps (**1**→**2**→**4**) amounts to a regioselective synthesis of *N*-substituted 2-(hydroxymethyl)-3-pyridinecarboxamides (**4**), which can be recognized as a precursor to nicotinamide derivatives bearing side chain on 2-position.

In summary, the present partial $NaBH_4$-reduction of quinolinimide **1** in the presence of Mg ion proceeded with high degree of regioselectivity and chemoselectivity. This procedure provides an attractive synthetic route to the 7-hydroxy lactam **2** as a useful synthetic precursor to biologically active compounds, whose isomeric structure can be clearly established by the conversion to the known azaphthalide **6** via (hydroxymethyl)pyridinecarboxamide **4**.

Experimental

Measurements. Melting points were uncorrected. ^{1}H NMR spectra at 90 MHz were recorded with Hitachi R-22. IR spectra were recorded with Hitachi 295 and 260-50. Mass spectra were recorded with Hitachi RMU-6M and M-2000. Elemental analyses were determined with Yanagimoto MT-3.

Materials. Magnesium, zinc, and lithium perchlorate were dried over phosphorus pentachloride for 1 d under reduced pressure at 100 °C. Acetonitrile was dried over calcium hydride and distilled before use.

6-Substituted and Unsubstituted 5*H*-Pyrrolo[3,4-*b*]pyridine-5,7(6*H*)-dione (1a—g) were prepared according to a procedure in the literature.[12]

Partial $NaBH_4$-Reduction of 1. A representative procedure is described with **1a**: Into a solution of **1a** (0.148 g, 1 mmol) and $Mg(ClO_4)_2$ (0.446 g, 2 mmol) in MeOH-$CHCl_3$ (10 ml (1:1 v/v)) cooled at 0 °C under argon was added $NaBH_4$-powder (0.057 g, 1.5 mmol) with stirring. After 30 min, the reaction mixture was acidified with aqueous HCl approximately to pH 2. The resulting mixture was stirred for 10 min and basified with aqueous NaOH approximately to pH 11. After being warmed up to room temperature, the mixture was concentrated in vacuo until the evaporation of water began. This aqueous residue was continuously extracted with refluxing $CHCl_3$ for 4 d. The extract was concentrated in vacuo to give a colorless solid of **2a** (0.146 g, 97%).[6]

1b—g were reduced to **2b**—g with a similar procedure.

***N*-Substituted 2-(Hydroxymethyl)-3-pyridinecarboxamides (4b—g) and 3-(Hydroxymethyl)-2-pyridinecarboxamides (5b—g) by the Reduction of 1b—g with $NaBH_4$.** As a general procedure, into a solution of **1** (10 mmol) in EtOH (100 ml) was added $NaBH_4$-powder (20 mmol) at room temperature. After 15 min, the solution was heated at 50 °C for 1.5 h. The reaction mixture was cooled to room temperature and acidified with aqueous HCl approximately to pH 2. The resulting mixture was stirred for 5 min and basified with aqueous NaOH approximately to pH 9. The evaporation of the solvent in vacuo gave a solid which was extracted with hot ethanol (30 ml×4). The combined extracts were concentrated in vacuo to give the mixture of **4** and **5**. When the crude product was chromatographed (silica gel, MeOH-$CHCl_3$ (1 : 10 v/v)), **5** was obtained from the first fraction. The second fraction gave **4**.

4b: Mp 88—89 °C (from MeCN); ^{1}H NMR ($CDCl_3$) δ= 2.94 (3H, d, J=5 Hz, CH_3), 4.78 (2H, d, J=5 Hz, CH_2O), 5.39 (1H, t, J=5 Hz, OH), 7.23 (1H, dd, J=9 and 5 Hz, H-5), 7.60 (1H, br s, NH), 7.89 (1H, dd, J=9 and 2 Hz, H-4), and 8.50 (1H, dd, J=5 and 2 Hz, H-6); IR (KBr) 1630 (C=O) and 3250 (NH and OH) cm^{-1} ; MS (70 eV) m/z 166 (M^+); Found: C, 57.96; H, 6.06; N, 16.89%. Calcd. for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07, N, 16.86%.

5b: Mp 58—59 °C (from Et_2O); ^{1}H NMR ($CDCl_3$) δ=3.00 (3H, d, J=5 Hz, CH_3), 4.81 (2H, d, J=8 Hz, CH_2O), 5.29 (1H, t, J=8 Hz, OH), 7.34 (1H, dd, J=9 and 5 Hz, H-5), 7.75 (1H, dd, J=9 and 2 Hz, H-4), and 8.45 (2H, dd+br s, J=5 and 2 Hz, H-6 and NH); IR (KBr) 1650 (C=O) and 3230 (NH and OH) cm^{-1}; MS (70 eV) m/z 166 (M^+); Found: C, 57.91; H, 6.07; N, 16.79%. Calcd for $C_8H_{10}H_2O_2$: C, 57.82; H, 6.07, N, 16.86%.

4c: Mp 76—77 °C (from AcOEt); ^{1}H NMR ($CDCl_3$) δ= 1.23 (3H, t, J=7 Hz, CH_3), 3.3—3.6 (2H, m, CH_2), 4.81 (2H, s, CH_2O), 5.25 (1H, br s, OH), 7.24 (2H, dd+br s, J=8 and 5 Hz, H-5 and NH), 7.88 (1H, dd, 8 and 2 Hz, H-4), and 8.50 (1H, dd, J=5 and 2 Hz, H-6); IR (KBr) 1640 (C=O) and 3280 (NH and OH) cm^{-1}; MS (70 eV) m/z 180 (M^+); Found: C, 59.99; H, 6.73; N, 15.53%. Calcd for $C_9H_{12}N_2O_2$: C, 59.99; H, 6.71; N, 15.55%.

5c: Mp 32—34 °C (from Et_2O); ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, t, J=8 Hz, CH_3), 3.4—3.7 (2H, m, CH_2), 4.82 (2H, d, J=8 Hz, CH_2O), 5.32 (1H, t, J=8 Hz, OH), 7.36 (1H, dd, J=8 and 5 Hz, H-5), 7.73 (1H, dd, J=8 and 2 Hz, H-4), and 8.46 (2H, dd+br s, J=5 and 2 Hz, H-6 and NH); IR (KBr) 1660 (C=O) and 3340 (NH and OH) cm^{-1}; MS (70 eV) m/z 180 (M^+); Found: C, 57.90; H, 6.70; N, 15.48%. Calcd for $C_9H_{12}N_2O_2$: C, 59.99; H, 6.71; N, 15.55%.

4d: Mp 86—87 °C (from AcOEt);^{1}H NMR ($CDCl_3$) δ=1.24 (6H, d, J=7 Hz, CH_3×2), 4.0—4.4 (1H, m, CH), 4.74 (2H, d, J=6 Hz, CH_2O), 5.41 (1H, t, J=6 Hz, OH), 7.17 (1H, dd, J=9 and 5 Hz, H-5), 7.35 (1H, br s, NH), 7.83 (1H, dd, J=9 and 2 Hz, H-4), and 8.43 (1H, dd, J=5 and 2 Hz, H-6); IR (KBr) 1650 (C=O) and 3370 (NH and OH) cm^{-1}; MS (70 eV) m/z 194 (M^+); Found: C, 61.92; H, 7.36; N, 14.57%. 4f: Mp 118—120 °C (from AcOEt); ^{1}H NMR ($CDCl_3$) δ= 4.86 (2H, s, CH_2O), 5.39 (1H, br s, OH), 7.0—7.7 (7H, m, H-5+arom+NH), 8.04 (1H, dd, J=8 and 2 Hz, H-4), and 8.48

(1H, dd, J=6 and 2 Hz, H-6); IR (KBr) 1660 (C=O) and 3280 (NH and OH) cm^{-1}; MS (70 eV) m/z 228 (M^+); Found: C, 68.40; H, 5.28; N, 12.20%. Calcd for $C_{13}H_{12}N_2O_2$: C, 68.41; H, 5.30, N, 12.27%.

5f: Mp 108—109 °C (from AcOEt); ^1H NMR ($CDCl_3$) δ= 4.90 (3H, s, CH_2O+OH), 7.1—7.8 (7H, m, H-5,+arom+NH), 7.82 (1H, dd, J=9 and 2 Hz, H-4), and 8.53 (1H, dd, J=9 and 2 Hz, H-6); IR (KBr) 1680 (C=O), 3320 and 3500 (NH and OH) cm^{-1}; MS (70 eV) m/z 228 (M^+); Found: C, 68.30; H, 5.25; N, 12.27%. Calcd for $C_{13}H_{12}N_2O_2$: C, 68.41; H, 5.30, N, 12.27%.

4g: Mp 155—156 °C (from AcOEt); ^1H NMR (DMSO-d_6) δ=2.27 (3H, s, CH_3), 4.75 (2H, d, J=6 Hz, CH_2O), 5.30 (1H, t, J=6 Hz, OH), 7.15 (2H, d, J=8 Hz, arom), 7.42 (1H, dd, J=8 and 5 Hz, H-5), 7.61 (3H, d, J=8 Hz, arom+NH), 7.96 (1H, dd, J=8 and 2 Hz, H-4), and 8.60 (1H, dd, J=5 and 2 Hz, H-6); IR (KBr) 1650 (C=O) and 3280 (NH and OH) cm^{-1}; MS (70 eV) m/z 242 (M^+); Found: C, 69.54; H, 5.78; N, 11.50%. Calcd for $C_{14}H_{14}N_2O_2$: C, 69.41; H, 5.82; N, 11.56%.

5g: Mp 117—118 °C (from AcOEt). ^1H NMR (DMSO-d_6) δ=2.27 (3H, s, CH_3), 4.97 (2H, d, J=6 Hz, CH_2O), 5.34 (1H, t, J=6 Hz, OH), 7.12 (2H, d, J=8 Hz, arom), 7.59 (1H, dd, J=8 and 5 Hz, H-5), 7.70 (3H, d, J=8 Hz, arom+NH), 8.17 (1H, dd, J=8 and 3 Hz, H-4), and 8.53 (1H, dd, J=5 and 3 Hz, H-6); IR (KBr) 1670 (C=O) and 3320 (NH and OH) cm^{-1}; MS eV) m/z 242 (M^+); Found: C, 69.28; H, 5.78;N, 11.61%. Calcd for $C_{14}H_{14}N_2O_2$: C, 69.41; H, 5.82, N, 11.56%.

Starting with **2b**—g, a similar procedure gave **4b**—g, respectively.

Furo[3,4-*b*]pyridin-5(7*H*)-one(6) and Furo[3,4-*b*]pyridin-7(5*H*)-one(7). As a general procedure, a solution of **4** or **5** (1 mmol) in MeOH (5 ml) added HCl (1 mol dm^{-3}, 5 ml) was heated at 80 °C for 2 d. The reaction mixture was neutralized with aqueous NaOH and concentrated in vacuo. After the residue was extracted with $CHCl_3$ (10 ml×5), the combined extracts were washed with water, dried over Na_2SO_4, and concentrated in vacuo to afford spectroscopically pure **6** or **7**.[13]

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 63740271 from the Ministry of Educstion, Science and Culture.

Monosubstituted Tetramethoxynaphthalenes[1)]

Yasuhiro TANOUE, Akira TERADA,* Kazuhiko TORISU, and Hiroshige TANIGUCHI
Department of Chemistry, Kyushu Institute of Technology, Tobata, Kitakyushu, Fukuoka 804
(Received November 7, 1988)

As new intermediates for the syntheses of monosubstituted naphthazarins and anthracyclines, several tetramethoxynaphthalenes having a substituent such as CH_3, COOH, CN, Br, OAc, OH, and OMe groups were prepared from 1,4,5,8-tetramethoxynaphthalene and 2-formyl-1,4,5,8-tetramethoxynaphthalene.

We have already reported that 1,4,5,8-tetramethoxynaphthalene (**1**) could be converted to 2-formyl-1,4,5,8-tetramethoxynaphthalene (**2**) in almost quantitative yield; from this, (±)shikonin was first prepared.[2)] Generally, tetramethoxynaphthalens could be easily demethylated by our methods to give the corresponding naphthazarin compounds[3)] (Scheme 1). The tetramethoxynaphthalene **1** was used as an intermediate in the synthesis of nogalamycin,[4)] which belonged to anthracycline series antibiotics.

These results suggest to us the possibility that these monosubstituted tetramethoxynaphthalenes will become new intermediates for naphthoquinones and anthracyclines. Here, we consider the syntheses of monosubstituted tetramethoxynaphthalenes having CH_3, COOH, CN, Br, OAc, OH, or OMe as the substituent.

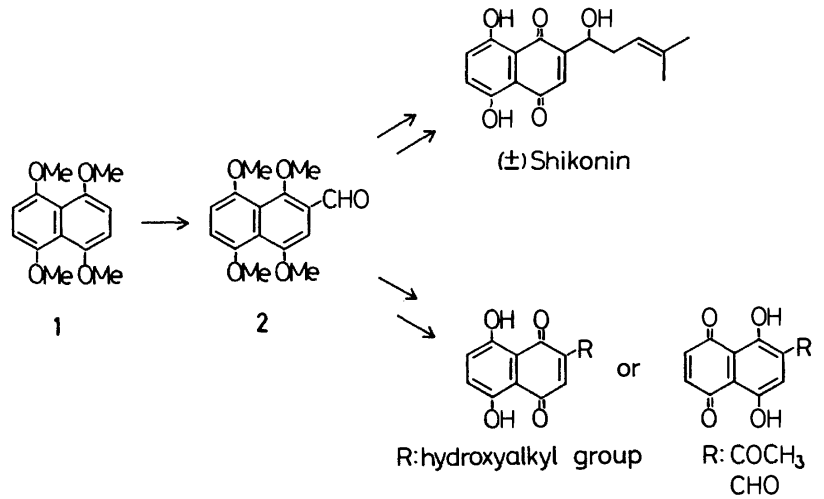
Results and Discussion

Reduction of the aldehyde **2** with $LiAlH_4$ gave 2-hydroxymethyl-1,4,5,8-tetramethoxynaphthalene (**3**),[3)] followed by hydrogenolysis in the presence of palladium carbon, 2-methyl-1,4,5,8-tetramethoxynaphthalene (**4**) resulted in 58% yield.

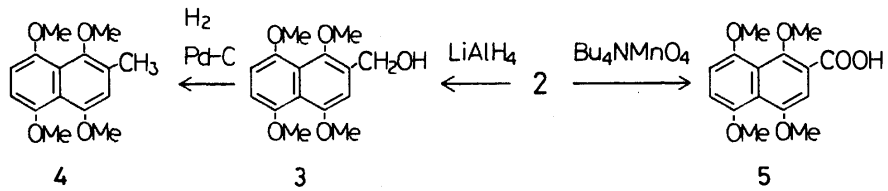
Although the oxidation of **2** with potassium permanganate gave a negative result, tetrabutylammonium permanganate[5)] was tried and our proposed 1,4,5,8-tetramethoxy-2-naphthoic acid (**5**) was obtained in 87% yield.

With chlorosulfonyl isocyanate[6)] in dichloromethane the tetramethoxynaphthalene **1** gave an *N*-chlorosulfonyl amide intermediate; subsequent treatment with DMF afforded 2-cyano-1,4,5,8-tetramethoxynaphthalene (**6**) in 71% yield (Scheme 3).

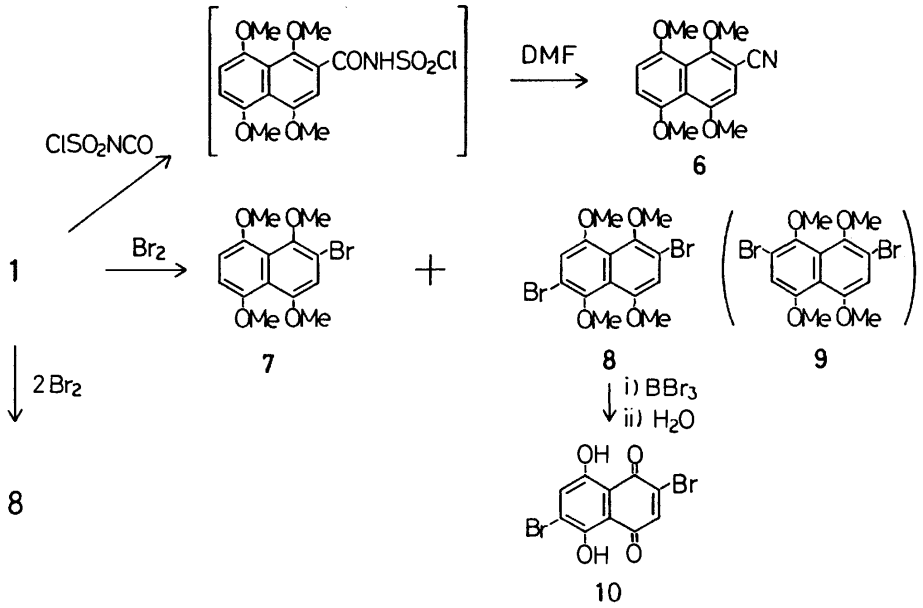
With an equimolar amount of bromine in chloroform, **1** gave 2-bromo-1,4,5,8-tetramethoxynaphthalene (**7**) (44% yield) and 2,6-dibromo-1,4,5,8-tetramethoxynaphthalene (**8**) (17%) at the same time. However, two molar equiv. of bromine wholly afforded the dibromide (**8**); the product yield was 87%. Since the structure of this dibromide was either 2,6-dibromide (**8**) or 2,7-



Scheme 1.



Scheme 2.



Scheme 3.

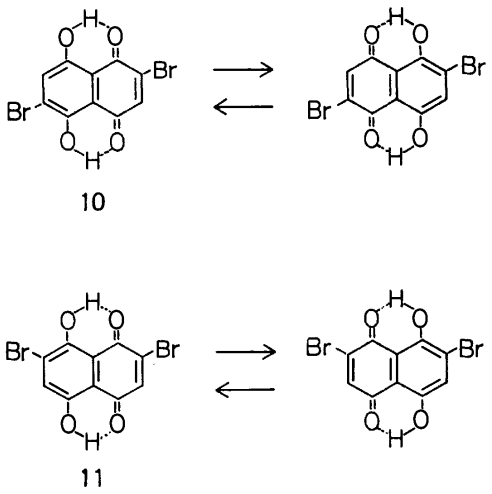


Chart 1.

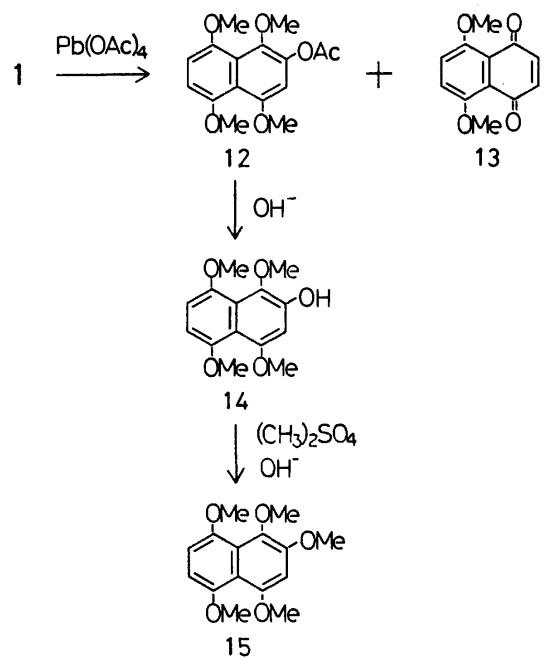
dibromide (**9**), shown in Scheme 3, the dibromide was changed into a dibromonaphthazarin and identified as follows. Both the naphthazarin dibromides, **10** and **11** in Chart 1, are tautomers of each other. The dibromonaphthazarin which we obtained showed a sharp single peak in the ^{1}H NMR at δ 12.56 due to two equivalent hydroxyl groups. Since the naphthazarin was, therefore, **10**, the above dibromide was proved to be **8**. If the naphthazarin product was another **11**, its hydroxyl signal in ^{1}H NMR had to be separated into two peaks as like A in Chart 2.[7]

The treatment of **1** with lead tetraacetate in benzene gave 2-acetoxy-1,4,5,8-tetramethoxynaphthalene (**12**) (40% yield) and 5,8-dimethoxy-1,4-naphthoquinone (**13**) (46%). The structure of **13** was identical with that of the authentic sample[3] already obtained in our laboratory by the oxidative demethylation of **1** with cerium(IV) ammonium nitrate.



Scheme 4.

Alkali hydrolysis of **12** gave 1,4,5,8-tetramethoxy-2-naphthol (**14**) in 91% yield, and methylation with dimethyl sulfate afforded 1,2,4,5,8-pentamethoxynaphthalene (**15**) (Scheme 4).

Experimental

Melting points were determined with a Yanagimoto micromelting point apparatus and were uncorrected. ^{1}H and ^{13}C NMR spectra were taken on a JEOL JNM-60 in $CDCl_3$ using Me_4Si and $CDCl_3$ as internal standards, respectively. Mass spectra and IR spectra were obtained with a JEOL DX-300 spectrometer, and a Hitachi 260-30 spectrometer, respectively. Column chromatography was carried

out on silica gel (Wakogel C-200) or alumina (Sumitomo, KCG-30) eluting with chloroform.

2-Methyl-1,4,5,8-tetramethoxynaphthalene (4). A mixture of 2-hydroxymethyl-1,4,5,8-tetramethoxynaphthalene (**3**)[3] (189 mg, 0.68 mmol) and palladium carbon (200 mg, Pd content 5%) in tetrahydrofuran (5 ml) and ethanol (30 ml) was stirred at 60 °C for 8 h under 50 kg cm^{-2} of hydrogen in an autoclave. After filtration and washing the residue with chloroform, evaporation of the combined filtrate gave a solid which was purified by alumina chromatography to give a sample of **4** (102 mg, 58%). Recrystallization from hexane gave an analytical sample, mp 95.5—96.5 °C. IR (KBr) 1600, 1355, 1260, and 1070 cm^{-1}; ^{1}H NMR δ=2.41 (s, 3H, CH_3), 3.73, 3.89 (each s, 3H, OCH_3), 3.92 (s, 6H, 2×OCH_3), 6.7 (s, 1H, ArH), and 6.78 (s, 2H, 2×ArH); MS, *m/z* 262 (M^+), 247 (M^+-CH_3), 204. Calcd for $C_{15}H_{18}O_4$: C, 68.69; H, 6.92%. Found: C, 68.30; H, 6.58%.

1,4,5,8-Tetramethoxy-2-naphthoic Acid (5). Tetrabutylammonium permanganate[5] (360 mg, 1 mmol) was added to a solution of 2-formyl-1,4,5,8-tetramethoxynaphthalene[2] (**2**) (138 mg, 0.5 mmol) in pyridine (3 ml) and stirred at room temperature for 20 h under a nitrogen atmosphere. The reaction mixture was poured into dil. hydrochloric acid (100 ml) containing sodium hydrogensulfite and extracted with chloroform. The chloroform solution was washed with dil. hydrochloric acid (100 ml ×2), brine (100 ml) and dried over anhydrous sodium sulfate, and concentrated. The crude product was chromatographed on silica gel to give 127 mg (87%) of **5**. Recrystallization from hexane-ethanol (5:1) gave an analytical sample, mp 131—132 °C. IR (KBr) 3100—2500 (broad, OH), 1695, 1670 (each C=O), 1610, 1585, 1265 (C-O), and 1070 cm^{-1}; ^{1}H NMR δ=3.91, 3.94, 3.98, 3.99 (each s, 3H, OCH_3), 6.99 (s, 2H, 2×ArH), 7.46 (s, 1H, ArH), and 11.23 (broad, 1H, COOH); ^{13}C NMR δ=56.70, 56.87, 57.90, 64.41 (each OCH_3), 106.36 (C-3), 108.94 (C-7), 111.85 (C-6), 118.37, 121.17, 123.28, 150.49 (C-5), 150.83 (C-4), 151.46 (C-8), 153.92 (C-1), and 165.81 (COOH); MS, *m/z* 292 (M^+), 277, 259, 247. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H, 5.52%. Found: C, 61.36; H, 5.45%.

2-Cyano-1,4,5,8-tetramethoxynaphthalene (6). A solution of chlorosulfonyl isocyanate (700 mg, 4.4 mmol) in dichloromethane (2 ml) was added to a solution of 1,4,5,8-tetramethoxynaphthalene(**1**)[2] (992 mg, 4 mmol) in dichloromethane (28 ml) and stirred at room temperature for 2 h. *N,N*-Dimethylformamide (800 mg) was added and stirred at room temperature for 3.5 h. The reaction mixture was poured into ice water and extracted with dichloromethane (100 ml×3). The dichloromethane solution was washed with brine (100 ml) and dried over anhydrous sodium sulfate, and concentrated. The residue was purified by silica-gel chromatography to give 778 mg (71%) of **6**. Recrystallization from hexane gave an analytical sample, mp 127—128 °C. IR (KBr) 2225 (CN), 1605, 1390, 1370, 1270, 1080, and 1050 cm^{-1}; ^{1}H NMR δ=3.89, 3.94 (each s, 3H, OCH_3), 3.95 (s, 6H, 2×OCH_3), 6.82 (s, 1H, ArH), and 6.97 (s, 2H, 2×ArH); ^{13}C NMR δ=57.04, 57.15, 58.01, 63.56 (each OCH_3), 104.02 (C-2), 106.71 (C-3), 109.28 (C-7), 112.19 (C-6), 117.11, 122.34, 122.71, 150.72 (C-5), 151.35 (C-8), 153.69 (C-4), 155.46 (C-1); MS, *m/z* 273 (M^+), 258, 243, 215. Calcd for $C_{15}H_{15}O_4N$: C, 65.93; H, 5.53; N, 5.13%. Found: C, 65.85; H, 5.61; N, 5.07%.

2-Bromo-1,4,5,8-tetramethoxynaphthalene (7) and 2,6-Dibromo-1,4,5,8-tetramethoxynaphthalene (8). A solution of bromine (323 mg, 2.02 mmol) in chloroform (5 ml) was added dropwise to a solution of 1,4,5,8-tetramethoxynaphthalene (500 mg, 2.02 mmol) in chloroform (20 ml) at room temperature. The solution was stirred for 2 h, poured into water, and extracted with chloroform. The chloroform solution was washed with aqueous sodium hydrogensulfite, sodium hydrogencarbonate and brine and dried over anhydrous sodium sulfate, and concentrated. The residue was chromatographed on silica gel to give 291 mg (44%) of **7**, 140 mg (17%) of **8** and 14 mg (3%) of the starting material **1**.

7: mp 104—105 °C (from hexane); IR(KBr) 1605, 1580, 1380, 1365, 1310, 1260, 1070, and 1040 cm^{-1}; ^{1}H NMR δ=3.82, 3.88 (each s, 3H, OCH_3), 3.92 (each s, 6H, 2×OCH_3), 6.86 (s, 2H, 2×ArH), and 7.00 (each s, 1H, ArH); MS, *m/z* 328 (M^++2, 99%), 326 (M^+, 100), 313, 311, 232, 217, 204. Calcd for $C_{14}H_{15}O_4Br$: C, 51.40; H, 4.62%. Found: C, 51.27; H, 4.55%.

8: mp 215—216 °C (from methanol); IR (KBr) 1570, 1355, 1310, 1240, 1070, 1030, and 795 cm^{-1}; ^{1}H NMR δ=3.80 (s, 6H, 2×OCH_3), 3.95 (s, 6H, 2×OCH_3), 7.04 (s, 2H, 2×ArH); MS, *m/z* 408 (M^++4, 51%), 406 (M^++2, 100), 404 (M^+, 50), 391, 312, and 310. Calcd for $C_{14}H_{14}O_4Br_2$: C, 41.41; H, 3.47%. Found: C, 41.00; H, 3.46%.

2,6-Dibromo-5,8-dihydroxy-1,4-naphthoquinone (10). To a solution of the tetramethoxydibromide **8** (200 mg, 0.49 mmol) in dichloromethane (15 ml) was added dropwise boron tribromide (500 mg, 1.96 mmol) in dichloromethane (5 ml) at −70 °C. After stirring at −70 °C for 4 h, the solution was allowed to warm to room temperature and to stand overnight. It was then decomposed with dil. hydrochloric acid (100 ml) and extracted with dichloromethane (100 ml×3). The dichloromethane solution was worked up as usual and gave a crude product which was chromatographed on a silica-gel column to give 156 mg (91%) of **10**. Recrystallization from ethanol gave an analytical sample, mp 258—261 °C (decomp). IR (KBr) 1610 (C=O), 1580, 1560, 1420, 1400, 1260, 1180, and 995 cm^{-1}; ^{1}H NMR δ=7.61 (s, 2H, 2×ArH) and 12.56 (s, 2H, 2×OH); MS, *m/z* 350 (M^++4, 51%), 348 (M^++2, 100), 346 (M^+, 52), 304, 302, 269, and 267. Calcd for $C_{10}H_4O_4Br_2$: C, 34.52; H, 1.16%. Found: C, 34.40; H, 1.28%.

2-Acetoxy-1,4,5,8-tetramethoxynaphthalene (12) and 5,8-Dimethoxy-1,4-naphthoquinone (13). Lead tetraacetate (244 mg, 0.55 mmol) was added to a solution of the tetramethoxynaphthalene **1** (124 mg, 0.5 mmol) in benzene (20 ml) and stirred at 60 °C for 1 h. It was then decomposed by the addition of water and extracted with dichloromethane. The usual work-up and chromatography on silica gel gave 62 mg (40%) of **12** and 60 mg (46%) of **13**.

12: mp 85—85.5 °C (from hexane); IR (KBr) 1760 (C=O), 1600, 1365, 1265, 1205, 1090, 1065, 1025, and 990 cm^{-1}; ^{1}H NMR δ=2.37 (s, 3H, $COCH_3$), 3.78, 3.88 (each s, 3H, OCH_3), 3.91 (s, 6H, 2×OCH_3), 6.64 (s, 1H, ArH), and 6.82 (s, 2H, 2×ArH). Calcd for $C_{16}H_{18}O_6$: C, 62.74; H, 5.92%. Found: C, 62.73; H, 5.89%.

13: mp 157—159 °C (lit,[3] mp 160—161 °C). This did not depress the melting point of an authentic sample of **13** on admixture.

1,4,5,8-Tetramethoxy-2-naphthol (14). Aqueous sodium hydroxide (1 M, 6 ml; 1 M=1 mol dm^{-3}) was added to a solution of the ester **12** (343 mg, 1.12 mmol) in methanol (8 ml) under a nitrogen atmosphere and stirred at room temperature for 3 h. The solution was acidified by the addition of 1 M hydrochloric acid (100 ml) and extracted with chloroform. The chloroform solution was concentrated to

give 269 mg (91%) of **14**, mp 149—152 °C. This was unstable and decomposed during usual recrystallization or column chromatography. IR (KBr) 3400 (sharp OH), 1600, 1375, 1260, 1070 cm^{-1}; ^1H NMR δ=3.81, 3.88 (each s, 3H, OCH_3), 3.92 (s, 6H, 2×OCH_3), 5.20 (broad, 1H, OH), 6.69 (s, 2H, 2×ArH), 6.74 (s, 1H, ArH); MS, *m/z* 264 (M^+), 249, 221, 203, and 104. HRMS, Calcd for $C_{14}H_{16}O_5$: M, 264.0997. Found: *m/z* 264.0989.

1,2,4,5,8-Pentamethoxynaphthalene (15). Under a nitrogen atmosphere aqueous sodium hydroxide (1 M, 4 ml) was added to a solution of the naphthol **14** (223 mg, 0.84 mmol) in methanol (20 ml) at room temperature. To this solution was altenately added dropwise dimethyl sulfate (1.2 g, 8.4 mmol) and aqueous sodium hydroxide (1 M, 4 ml) at room temperature. After stirring at 50 °C for 2 h, the solution was concentrated until 10 ml and then extracted with chloroform, dried, and concentrated. The residue was chromatographed on silica-gel column to give 141 mg (60%) of **15**. Recrystallization from hexane afforded an analytical sample, mp 104—105 °C. IR (KBr) 1600, 1390, 1370, 1355, 1265, 1070, 1045, and 805 cm^{-1}; ^1H NMR δ=3.82 (s, 3H, OCH_3), 3.90 (s, 6H, 2×OCH_3), 3.94 (s, 3H, OCH_3), 3.99 (s, 3H, OCH_3), 6.64 (s, 1H, ArH), 6.74 (s, 2H, 2×ArH); MS, *m/z* 274 (M^+), 264, 263, 249, 231, and 124. Calcd for $C_{15}H_{18}O_5$: C, 64.74; H, 6.52%. Found: C, 64.26; H, 6.74%.

Nonacidic and Highly Chemoselective Protection of the Carbonyl Function. 3-Methylbenzothiazolines as a Base- and Acid-Resistant Protected Form for the Carbonyl Groups

Hidenori CHIKASHITA,* Shun-ichiro KOMAZAWA, Nishiki ISHIMOTO, Koji INOUE, and Kazuyoshi ITOH

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564

(Received November 21, 1988)

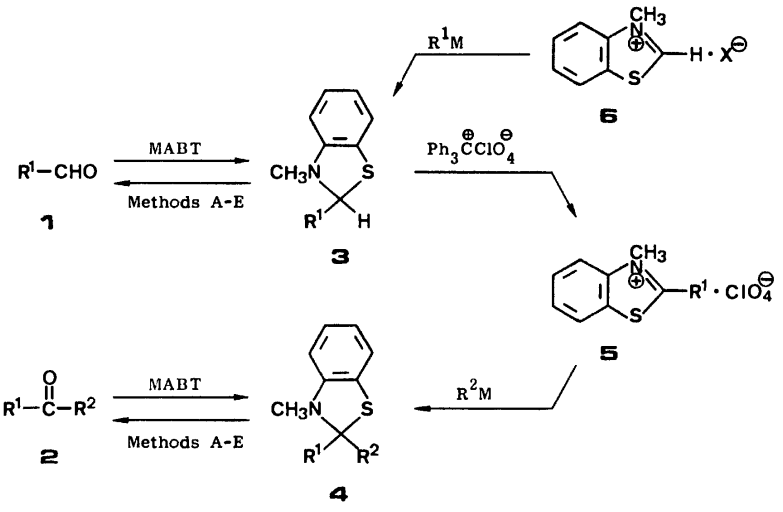
A simple and useful new type of protection method for carbonyl groups by conversion into 3-methylbenzothiazoline derivatives with *o*-(methylamino)benzenethiol was described. With this method, 3-methylbenzothiazolines were conveniently obtained in excellent yields from various aldehydes and ketones. This method allows efficient protection and deprotection under mild and neutral conditions and affords protection of the carbonyl group against both basic and acidic conditions. The difference in reactivity between different carbonyl groups was successfully utilized for the chemoselective benzothiazolination of the formyl group of 4-oxopentanal and also for the chemoselective conversion of 4-androstene-3,17-dione and progesteron into the corresponding benzothiazolines with the nonconjugated keto groups remaining intact. 2-Substituted benzothiazolines derived from aldehydes were efficiently converted into 2,2-disubstituted benzothiazolines via alkylation, with a variety of Grignard or organolithium reagents, of 2-substituted 3-methylbenzothiazolium salts which were readily obtained by the treatment of the former thiazolines with trityl perchlorate in acetonitrile. These salts were also obtained in good yields from aldehydes in one-pot syntheses by the treatment with *o*-(methylamino)benzenethiol in acetonitrile followed by addition of trityl perchlorate. 3-Methylbenzothiazolium iodide was found to be also effective as a formyl cation equivalent and the reactions with Grignard or organolithium reagents produced the corresponding 2-substituted benzothiazolines in good yields. With this reaction, 2-deuterio-3-methylbenzothiazolium iodide was effectively applied as a deuterated formyl cation equivalent for the synthesis of aldehyde-*d*.

The protection of carbonyl groups as acetals is now widely and frequently used as an important synthetic operation during the course of various synthetic projects. Acetalization of carbonyl compounds is generally performed in the presence of various acidic catalysts and the protected form is known to be very stable under various basic conditions while it can be easily deprotected by treating with acid.[1] However, this simplicity is disadvantageous at the same time because acetalized compounds can not be treated with acid except for removing the protection and in addition, acid-sensitive molecules can not be protected and deprotected as acetals. Furthermore, a convenient and at the same time highly chemoselective acetalization method capable of discrimination between aldehydes and ketones has not yet been achieved in spite of its great importance and necessity.[2] On the other hand, thioacetalization is an important and widely used protecting method for carbonyl compounds as well as acetalization. However, this method is also not exempted from some of these disadvantages.

In this paper, we report a new type of convenient and highly chemoselective protection of carbonyl compounds by conversion into 3-methylbenzothiazoline derivatives with *o*-(methylamino)benzenethiol (MABT). This method allows efficient protection and deprotection under mild and neutral conditions and affords protection of carbonyl groups against both basic and acidic conditions. We will also show that the benzothiazoline ring system is very useful as a functional protective group via 3-methylbenzothiazolium salts (**5** and **6**) as an acyl and a formyl cation equivalent (Scheme 1).

Benzothiazolination of Aldehydes and Ketones with MABT. In order to establish optimum conditions, the rates of benzothiazolination for pentanal (**1a**) and 2-pentanone (**2a**) with one equiv of MABT in various solvents at reflux temperatures were followed by GLC. The results are presented in Figs. 1 and 2. Regarding the benzothiazolination of aldehyde **1a**, the reaction proceeded using a protic or an aprotic solvent in excellent yields (>88%) during the 6 h reaction time and the rates did not vary significantly based on type of solvent (Fig. 1). However, ethanol was apparently the most effective and the reaction proceeded almost quantitatively during the 6 h reaction time even in 98% ethanol. On the other hand, the reaction of ketone **2a** with MABT occurred more slowly as compared to **1a** and did not proceed in hexane at all. Although the reaction rates varied considerably based on type of solvent, the rate in alcohols or acetonitrile was sufficiently rapid to be synthetically useful for the protection of ketones (Fig. 2). The different reactivity of **1a** and **2a** is advantageous from a synthetic viewpoint since it enables the selective protection of aldehydes in the presence of ketones. It is noteworthy and very attractive that these reactions were performed under neutral conditions without any additives by a very simple operation which does not require even the removal of the water formed during the reaction.

By this simple method, benzothiazolinations of several aldehydes were successfully performed with the



Scheme 1.

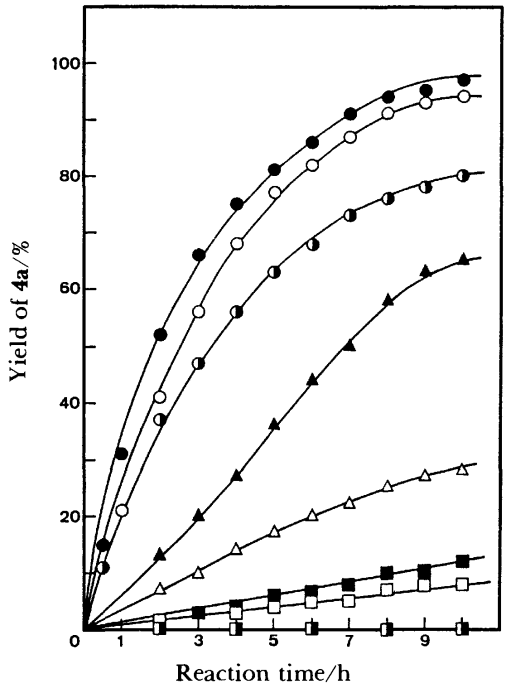

Fig. 2. Benzothiazolination of 2-pentanone (**2a**) with one equiv of MABT in various solvents at reflux temperatures. Symbols are identical with those used in Fig. 1.

results summarized in Table 1. As is seen in Table 1, aliphatic as well as aromatic aldehydes **1a—k** were all cleanly converted to the corresponding 2-substituted benzothiazolines **3a—k** with MABT in ethanol. Unexpectedly, the benzothiazolination of conjugated enal (**1l**) proceeded very slowly under the present conditions to afford **3l** in low yield. Benzothiazolination with MABT in ethanol was also examined with several ketones and the results are listed in Table 2. The linear ketones **2a—e** except for highly hindered ketone, 2,4-dimethyl-3-pentanone (**2f**) which almost did not react, were all cleanly converted to the corresponding 2,2-disubstituted benzothiazolines **4a—e** in almost quantitative yields. In the case of linear conjugated enones **2i** and **2j**, the reaction proceeded very slowly and much of the substrate was recovered unchanged. It is noteworthy that the benzothiazolination of the cyclic ketone **2g** and cyclic enone **2h** proceeded much more rapidly than the linear ketones and enones to afford **4g** and **4h** in quantitative and good yields, respectively. Thus, the order of relative reactivity of ketones in the present benzothiazolination was as

follows: cyclohexanone > linear ketones > 1-cyclohexen-1-one > linear conjugated enones > 2,4-dimethyl-3-pentanone.

Selective Benzothiazolination of Carbonyl Groups in the Presence of a Different Carbonyl Group. In order to examine the selectivity of the present benzothiazolination with MABT, experiments with compounds having two different carbonyl groups were performed (Scheme 2). As seen in the successful conversion of the keto carboxylic acid **7** and the keto ester **8** into the corresponding benzothiazolines **12** and **13** (94 and 92% yields, respectively) with one equiv of MABT in ethanol at reflux temperature, the benzothiazolination of keto groups can be easily performed in the presence of carboxylic acid or similar ester functional group. The benzothiazolination by the same method also exhibited splendid selectivity towards the formyl group. For example, the reaction of keto aldehyde **9** gave **14** as the sole product in 99% yield. The striking chemoselectivity of the present method was also emphasized by the fact that perfect selectivity could be realized in the benzothiazolination of steroid ketones **10** and **11** to **15** and **16** in dichloromethane and ethanol, respectively, with one equiv of MABT at reflux temperatures. After completion of the reactions, the products **15** and **16** were obtained in 93 and 97% yields, respectively and neither starting materials nor any by-products derived from the benzothiazolination at the nonconjugated keto carbonyl group was observed. These excellent chemoselectivities are in sharp contrast to acetalization or thioacetalization of the same steroid ketones.[3]

Hydrolysis and Stabilities of Benzothiazolines. Hydrolysis of benzothiazolines to the parent carbonyl

compounds was examined using two test substances **3g** and **4e**. As shown in Table 3, the hydrolysis could be effectively accomplished under neutral conditions in four ways (Methods A—D) using $AgNO_3$, $HgCl_2$, NBS, and Chloramine T to afford benzaldehyde (**1g**) and acetophenone (**2e**) in excellent yields, although the hydrolysis of **4e** by Method D gave exceptionally low yield of **2e**. Using another method, methylation with $MeOSO_2F$ followed by hydrolysis under mildly basic conditions was also effective to afford the products **1g** and **2e** in excellent yields. Notable in the case of Method A is the fact that such mild conditions did not affect the epimerizable center[4] or the α-hydroxyl group.[5] In addition, the mild nature of Method A is also illustrated in the conversion of 2-(β-hydroxyalkyl)-benzothiazolines **17** and **18** to the corresponding β-hydroxy ketones **19** and **20** (88 and 94% yields, respectively) without any evidence of dehydration (Scheme 3). Further results for the deprotection of benzothiazolines using Method A are given in Tables 1 and 2. All the tested benzothiazolines derived from aldehydes and ketones were cleanly cleaved with no difficulties and produced the corresponding carbonyl compounds in nearly quantitative yields.

Stabilities of the benzothiazolines were checked using **3g** and **4b** as samples. As shown in Table 4, both of these compounds survived the severe conditions

a) Method A: benzothiazoline (4 mmol), $AgNO_3$ (12 mmol), CH_3CN-phosphate buffer (pH 7, 0.05 M)-H_2O (15 : 3 : 5 v/v), r.t. for 40 min (for the aldehyde) or r.t. to 40 °C for 100 min (for the ketone), $(C_2H_5)_3N$ (4 mmol). Method B: benzothiazoline (4 mmol), $HgCl_2$ (6 mmol), CH_3CN-H_2O (4 : 1 v/v), reflux temp, 4 h. Method C: benzothiazoline (4 mmol), NBS (8 mmol), H_2O, r.t., 10 min. Method D: benzothiazoline (4 mmol), Chloramine T (4.8 mmol), C_2H_5OH, r.t., 1 h (for the aldehyde) or 24 h (for the ketone). Method E: benzothiazoline (4 mmol), CH_3OSO_2F (4.8 mmol), CH_2Cl_2, r.t., 18 h (for the aldehyde) or 24 h (for the ketones), and then 5% aq. K_2CO_3-THF (4 : 5 v/v), r.t., 4 h.

commonly required for removal of other protecting groups. The resistability to both basic and acidic conditions is especially attractive and increases the importance of the present protection method.

Conversion of 2-Substituted Benzothiazolines 3 into 2,2-Disubstituted One 4 via Benzothiazolium Salts 5 as Acyl Cation Equivalents. During the course of a study about the reactivity of 2-substituted benzothiazolines **3**, we have found that 3-methylbenzothiazolium perchlorates **5** are readily prepared in excellent yields by the reaction of **3** with trityl perchlorate in acetonitrile with the results summarized in Table 5. As shown in Table 5, these easily handled and stable carbocations were also conveniently obtained in good yields from aldehydes by the one-pot reaction with MABT in acetonitrile followed by the addition of trityl perchlorate. In order to demonstrate the possibility of using these salts as an acyl cation equivalent, we have studied the reaction of **5** with a variety of Grignard or organolithium reagents. The results are summarized in Table 6. The conversion of **5** into 2,2-disubstituted benzothiazolines **4** was most conveniently achieved by the addition of 1.2 equiv of Grignard or organolithium reagent to the suspension of **5** in THF or ether at −78 °C. These reactions generally proceeded quite cleanly and nearly pure products were obtained in excellent yields after a simple workup procedure. Thus, by these methods not only alkyl including tertiary but also aryl, allyl, and alkynyl groups were substituted for the hydrogen at the C-2 position of **3**. The ready availability of benzothiazolium salts **5** from aldehydes and facile convertibility of them into 2,2-

a) Method A: Benzothiazoline (5 mmol) was reacted with trityl perchlorate (5 mmol) in acetonitrile at room temperature. Method B (one-pot reaction): Aldehyde (5 mmol) was reacted with MATP (5 mmol) in refluxing acetonitrile followed by the addition of trityl perchlorate (10 mmol). b)Yield of crude, nearly pure product (in Method A). Yield of pure product after recrystallization (in Method B).

Table 6. Alkylation of 2-Substituted Benzothiazolium Salts **5** into 2,2-Disubstituted Benzothiazolines **4**[a]

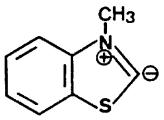
(c) C_6H_5MgBr, THF, -78°C-r.t.; (d) Method A (see Table 3).

Scheme 4.

disubstituted benzothiazolines **4** illustrate the synthetic usefulness of the benzothiazoline ring system as a functional protected form for carbonyl groups.

Preparation of 2-Substituted Benzothiazolines 3 by the Reaction of Grignard or Organolithium Reagents with 3-Methylbenzothiazolium Salt 6. 1,3-Dithienium tetrafluoroborate,[6] 2-chloro-1,3-dithiane,[7] and heteroaromatic cations such as 1,3-benzodithiolylium salts[8] are well-known as promising candidates for heterocyclic formyl cation equivalents. However, the reaction of former two compounds with either Grignard or organolithium reagents does not produce or produces with difficulty the corresponding 1,3-dithianes.[7,9] As another synthetic advantage of the benzothiazoline ring system, we have found that Grignard and organolithium reagents react with 3-methylbenzothiazolium salts **6** to give the expected adducts **3** in good yields (Table 7). The reactions were conveniently achieved by a procedure similar to the alkylation of the salts **5**. When **6** was reacted with butylmagnesium bromide or butyllithium, 2-butyl-3-methylbenzothiazoline (**3a**) was most effectively obtained in 70% yield in the case of the reaction using the iodide **6a**. Butylmagnesium cupurate was also used to alkylate **6a** but the yield of **3a** was not improved. The uppermost limit of yields in these reactions is probably due to formation of the ylide **21**



21

derived from proton abstraction from the salt **6** by organometallic reagents. On the other hand, the reaction of **6a** with aryl, allyl, or alkynyl Grignard reagent went to completion yielding the corresponding 2-substituted benzothiazolines in near quantitative yields. Thus, it appears that the reaction of 3-methylbenzothiazolium iodide (**6a**) as a formyl cation equivalent with Grignard or organolithium reagents is a useful way to produce 2-substituted benzothiazolines **3**.

With the aim of evaluating the synthetic potential of **6a**, we present a useful method for the preparation of aldehydes-*d* according to Scheme 4. 2-Deuterated 3-methylbenzothiazolium iodide (**23**) was conveniently prepared in high yield by methylation of benzothiazole-2-*d* (**22**) with iodomethane, which was readily prepared by the lithiation of commercially available benzothiazole with butyllithium followed by quenching with D_2O.[5] The reaction of **23** with phenylmagnesium bromide and subsequent hydrolysis by method A gave benzaldehyde-*d* in excellent yield with almost complete deuterium incorporation. The easy accessibility of **22**, the high yields of the products and the excellent deuterium incorporation offers promise for a new method of synthesizing aldehydes-*d* from Grignard reagents via carbon-carbon bond formation with the deuterated formyl cation equivalent **23**. The deuterated heteroaromatic cation, 2-deuterio-1,3-benzodithiolylium salt, has already been reported as a deuterated formyl cation equivalent for the synthesis of aldehydes-*d* by Degani et al.[10] However, compared with their original method or the improved one,[11] the present method is advantageous because of its high simplicity.

Conclusion

Benzothiazolination with MABT is a very effective, convenient, and mild (no acidic catalyst is required) method for the protection of aldehydes and ketones. The mildness of benzothiazolination and effective convertibility of benzothiazolines into parent carbonyl compounds under neutral and very mild conditions are suitable for the synthetic operation of acid-sensitive multifunctional molecules. High chemoselectivity of benzothiazolination makes the present method more attractive and should be useful for selective protection of carbonyl groups in the presence of a

different carbonyl group. In addition, the resistability of benzothiazolines to both basic and acidic conditions allows one to use the protected form under these conditions. Furthermore, the functionality of the benzothiazoline ring system via benzothiazolium salts as an acyl or formyl cation equivalent increases the value of benzothiazolines in use as a protected form for carbonyl compounds.

Experimental

Melting points were recorded on a Yanagimoto micro melting-point apparatus and are uncorrected. ^{1}H NMR spectra were measured with a JEOL PMX-60 spectrometer at 60 MHz using tetramethylsilane as an internal reference. IR spectra were recorded on a JASCO A-202 spectrophotometer. Mass spectra were obtained on a JMS-QH100 GC-Mass spectrometer. The yields by quantitative GLC were measured on a Shimadzu Gas Chromatograph GC-6AM equipped with a hydrogen flame ionization detector using glass columns (1.5 m) packed with 2% Silicone OV-7 on Uniport HP (60—80 mesh), by the internal standard method using dodecane as an internal standard. Silica gel (Wakogel C-300) was used for short column chromatography.

Materials. Solvents were purified and dried according to standard procedures. MABT was prepared by the reductive ring opening reaction of commercially available benzothiazole with $LiAlH_4$ according to a slightly modified method of Huning et al.[12] Phosphate buffer (0.05 M, pH 7; 1 M=1 mol dm^{-3}) was prepared by dilution of the 0.1 M solution (0.4 M Na_2HPO_4+0.4 M KH_2PO_4) which was commercially available. Trityl perchlorate was prepared by the method of Dauben et al.[13] Carbonyl compounds and the other reagents were obtained as high-grade commercial products.

Benzothiazolination of Aldehydes and Ketones; General Procedure. MABT (0.70 g, 5 mmol) was added to a solution of aldehyde or ketone (5 mmol) in ethanol (5 ml) and the mixture was refluxed for an appropriate reaction time (monitored with TLC; see Tables 1 and 2). The solvent was removed under reduced pressure to give crude product. Purification of the crude oily products (**3a—f**, **31**, **4a—d**, **4g—j**) and crystalline products (**3g—k**, **4e**) was carried out by short column chromatography or recrystallization from ethanol, respectively, to afford pure samples. Product yields are summarized in Tables 1 and 2.

3a: colorless oil; IR (neat) 2940, 1660, 1580, 1670, 1380, 1280, 1120, 1060, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, 3H), 1.08—2.08 (m, 6H), 2.67 (s, 3H), 4.78 (dd, 1H), and 6.00—7.00 (m, 4H). Calcd for $C_{12}H_{17}NS$: C, 69.51; H, 8.26; N, 6.76%. Found: C, 69.40; H, 8.55; N, 6.28%.

3b: pale yellow oil; IR (neat) 2900, 2850, 1660, 1580, 1480, 1380, 1300, 1110, 1020, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.87 (t, 3H), 1.03—2.07 (br, 16H), 2.70 (s, 3H), 4.80 (t, 1H), and 6.00—6.90 (m, 4H). Calcd for $C_{17}H_{27}NS$: C, 73.59; H, 9.81; N, 5.05%. Found: C, 73.74; H, 9.92; N, 5.35%.

3c: pale yellow oil; IR (neat) 2940, 1660, 1580, 1480, 1380, 1300, 1110, 1020, 730, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 0.50—2.17 (m, 15H), 2.70 (s, 3H), 5.12 (d, 1H), and 6.03—7.27 (m, 4H). Calcd for $C_{15}H_{23}NS$: C, 72.23; H, 9.29; N, 5.62%. Found: C, 72.90; H, 8.91; N, 5.81%.

3d: colorless oil; IR (neat) 2900, 1660, 1580, 1480, 1380, 1300, 1110, 1010, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.67—2.17 (m, 16H), 2.67 (s, 3H), 4.87 (m, 2H), and 6.00—6.90 (m, 4H). Calcd for $C_{17}H_{25}NS$: C, 74.13; H, 9.15; N, 5.08%. Found: C, 73.94; H, 9.22; N, 5.13%.

3e: pale yellow oil; IR (neat) 2950, 1660, 1580, 1480, 1380, 1340, 1300, 1220, 1110, 1020, 1000, and 730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.00 (d, 6H), 2.00 (m, 1H), 2.68 (s, 3H), 5.10 (d, 1H), and 5.84—6.84 (m, 4H). Calcd for $C_{11}H_{15}NS$: C, 68.35; H, 7.82; N, 7.25%. Found: C, 68.33; H, 7.74; N, 7.07%.

3f: colorless oil; IR (neat) 2950, 1570, 1470, 1380, 1350, 1290, 1200, 1120, 1100, 1020, 980, 880, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (s, 9H), 2.90 (s, 3H), 4.42 (s, 1H), and 6.17—6.90 (m, 4H). Calcd for $C_{12}H_{17}NS$: C, 69.51; H, 8.26; N, 6.76%. Found: C, 69.33; H, 8.32; N, 6.58%.

3g: colorless needles; mp 113 °C; IR (KBr) 1580, 1480, 1450, 1340, 1300, 1190, 1110, 1020, 740, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.70 (s, 3H), 5.80 (s, 1H), and 6.10—7.50 (m, 4H). Calcd for $C_{14}H_{13}NS$: C, 73.97; H, 5.76; N, 6.16%. Found: C, 73.66; H, 5.73; N, 5.90%.

3h: colorless needles; mp 78—78.5 °C; IR (KBr) 1570, 1460, 1400, 1320, 1300, 1260, 1180, 1100, 1080, 1010, 860, 830, 780, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.47 (s, 3H), 5.75 (s, 1H), and 6.07—7.40 (m, 8H). Calcd for $C_{14}H_{12}NSCl$: C, 64.24; H, 4.62; N, 5.35%. Found: C, 64.11; H, 4.53; N, 5.22%.

3i: colorless needles; mp 106—106.5 °C; IR (KBr) 1600, 1570, 1510, 1460, 1330, 1280, 1250, 1160, 1100, 1030, 860, 830, 790, and 750 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.52 (s, 3H), 3.70 (s, 3H), 5.80 (s, 1H), and 6.33—7.50 (m, 8H). Calcd for $C_{15}H_{15}NOS$: C, 70.01; H, 5.87; N, 5.44%. Found: C, 69.94; H, 5.92; N, 5.29%.

3j: colorless needles; mp 43—43.5 °C; IR (KBr) 2900, 2850, 1580, 1480, 1370, 1300, 1110, 1020, 880, 740, and 710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.85—2.33 (m, 11H), 3.17 (s, 3H), 4.45 (d, 1H), and 6.84—7.50 (m, 4H). Calcd for $C_{14}H_{19}NS$: C, 72.05; H, 8.21; N, 6.00%. Found: C, 71.48; H, 8.09; N, 5.82%.

3k: colorless needles; mp 89—89.5 °C; IR (KBr) 2900, 1580, 1490, 1430, 1380, 1310, 1220, 1120, 1020, 740, and 670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.17—2.50 (m, 7H), 2.77 (s, 3H), 5.02 (d, 1H), 5.53 (m, 2H), and 6.00—7.00 (m, 4H). Calcd for $C_{14}H_{17}NS$: C, 72.68; H, 7.41; N, 6.05%. Found: C, 72.36; H, 7.38; N, 5.85%.

3l: colorless oil; IR (neat) 1640, 1570, 1470, 1420, 1340, 1300, 1120, 1040, 1020, 960, 740, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.67 (s, 3H), 5.43 (dd, 1H), and 6.00—7.33 (m, 11H). This compound is slightly unstable in air.

4a: colorless oil; IR (neat) 2950, 1580, 1480, 1360, 1300, 1120, 1050, 1020, 740, and 720 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.92 (t, 3H), 1.13—2.07 (m, 4H), 1.52 (s, 3H), 2.60 (s, 3H), and 5.87—6.90 (m, 4H). Calcd for $C_{12}H_{17}NS$: C, 69.51; H, 8.26; N, 6.76%. Found: C, 69.41; H, 8.18; N, 6.63%.

4b: colorless oil; IR (neat) 2950, 1580, 1480, 1360, 1300, 1210, 1120, 1050, 1020, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.67—2.00 (m, 14H), 2.60 (s, 3H), and 5.73—6.83 (m, 4H). Calcd for $C_{14}H_{21}NS$: C, 71.44; H, 8.99; N, 5.95%. Found: C, 71.26; H, 8.89; N, 5.91%.

4c: colorless oil; IR (neat) 2900, 1580, 1480, 1360, 1300, 1220, 1120, 1050, 1020, 900, and 730 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.50—2.00 (m, 22H), 2.53 (s, 3H), and 5.73—6.77 (m, 4H). Calcd for $C_{18}H_{29}NS$: C, 74.17; H, 10.03; N, 4.81%. Found: C, 73.99; H, 10.10; N, 4.81%.

4d: pale yellow oil; IR (neat) 1950, 1580, 1480, 1370, 1300, 1220, 1120, 1020, and 740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (d, 6H), 1.55 (s, 3H), 2.03 (m, 1H), 2.58 (s, 3H), and 5.83—6.83

(m, 4H). Calcd for $C_{12}H_{17}NS$: C, 69.51; H, 8.26; N, 6.76%. Found: C, 69.14; H, 8.11; N, 6.66%.

4e: colorless needles; mp 62—63 °C; IR (KBr) 2900, 1580, 1470, 1440, 1370, 1300, 1110, 1040, 1020, 900, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.97 (s, 3H), 2.55 (s, 3H), and 6.10—7.67 (m, 9H). Calcd for $C_{15}H_{15}NS$: C, 74.65; H, 6.26; N, 5.80%. Found: C, 74.38; H, 6.29; N, 5.61%.

4g: pale yellow needles; mp 34—34.5 °C; IR (neat) 2900, 1680, 1470, 1360, 1300, 1200, 1100, 1040, 1020, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00—2.23 (m, 10H), 2.67 (s, 3H), and 6.00—7.00 (m, 4H). Calcd for $C_{13}H_{17}NS$: C, 71.18; H, 7.81; N, 6.39%. Found: C, 71.26; H, 7.88; N, 6.27%.

4h: colorless oil; IR (neat) 2900, 1580, 1500, 1480, 1420, 1300, 1210, 1160, 1120, 1030, 960, 740, and 680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00—2.13 (m, 6H), 2.60 and 2.73 (each s, 3H), and 6.00—7.33 (m, 6H). Calcd for $C_{13}H_{15}NS$: C, 71.85; H, 6.96; N, 6.44%. Found: C, 71.48; H, 6.88; N, 6.80%.

4i: colorless oil; IR (neat) 2950, 1580, 1470, 1420, 1350, 1300, 1120, 1050, 1020, 960, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.73 (s, 3H), 2.58 (s, 3H), and 6.00—7.37 (m, 11H). This compound is slightly unstable in air.

4j: colorless oil; IR (neat) 1580, 1470, 1420, 1360, 1300, 1220, 1120, 1050, 1020, 990, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.67 (s, 3H) and 6.13—7.87 (m, 16H). Calcd for $C_{22}H_{19}NS$: C, 80.20; H, 5.81; N, 4.25%. Found: C, 80.36; H, 5.72; N, 4.14%.

Benzothiazolination of Keto Carboxylic Acid 7, Keto Ester 8, and Keto Aldehyde 9. Benzothiazolination of these compounds **7—9** was carried out on a 5 mmol scale for 24 h according to standard procedure. Purification of the crude products which did not contain any by-product or regioisomer (monitored by TLC and ^1H NMR) by recrystallization from ethanol or short column chromatography afforded pure products (**12—14**).

12 (1.12 g, 94%): colorless needles; mp 82.5—83.5 °C; IR (KBr) 2900, 1700, 1580, 1480, 1420, 1350, 1300, 1220, 1160, 1110, 1020, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.57 (s, 3H), 2.00—2.50 (m, 4H), 2.62 (s, 3H), 5.97—7.00 (m, 4H), and 11.00 (br, 1H). Calcd for $C_{12}H_{15}NO_2S$: C, 60.73; H, 6.37; N, 5.90%. Found: C, 60.30; H, 6.26; N, 5.75%.

13 (1.22 g, 92%): colorless oil; IR (neat) 2950, 1720, 1580, 1480, 1360, 1300, 1180, 1120, 1020, amd 740 cm^{-1}; ^1H NMR (CCl_4) δ=1.17 (t, 3H), 1.57 (s, 3H), 1.67—2.57 (m, 4H), 2.63 (s, 3H), 3.95 (q, 2H), and 5.90—6.83 (m, 4H). Calcd for $C_{14}H_{19}NO_2S$: C, 63.36; H, 7.22; N, 5.28%. Found: C, 63.18; H, 7.27; N, 5.31%.

14 (1.23 g, 99%): pale yellow oil; IR (neat) 2900, 1720, 1660, 1580, 1480, 1360, 1300, 1120, 1020, 910, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.50—1.83 (m, 11H), 2.70 (s, 3H), 4.76 (br, 1H), and 6.17—7.27 (m, 4H). Calcd for $C_{14}H_{19}NOS$: C, 67.43; H, 7.68; N, 5.62%. Found: C, 67.26; H, 7.29; N, 5.63%.

Benzothiazolination of Steroid Ketones 10 and 11. MABT (0.14 g, 1 mmol) was added to a solution of 4-androstene-3,17-dione (**10**) (0.29 g, 1 mmol) in dichloromethane (1 ml) and the mixture was refluxed for 48 h. After removal of the solvent under reduced pressure, the residual crystalline product which did not contain the other isomers (monitored by TLC, ^1H NMR and IR) was recrystallized from methanol to afford pure **15** as colorless plates (0.38 g, 93%): mp 191—192 °C; IR (KBr) 2950, 2900, 1740, 1590, 1480, 1450, 1400, 1300, 1210, 1120, 1030, 860, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.87 (s, 3H), 1.05 (s, 3H), 1.10—2.45 (m, 19H), 2.62 (s, 3H), 5.47 (bs, 1H), and 6.00—7.00 (m, 4H). Calcd for $C_{26}H_{33}NOS$: C, 76.61; H, 8.16; N, 3.44%. Found: C, 76.98; H, 8.04; N, 3.15%.

Benzothiazolination of progesterone (**11**) was carried out on a 1 mmol scale for 24 h according to standard procedure. Recrystallization of crude product which did not contain the other isomers (monitored by TLC, ^1H NMR, and IR) from ethanol afforded pure **16** as colorless needles (0.42 g, 97%): mp 203—204 °C; IR (KBr) 2950, 2870, 1710, 1580, 1480, 1450, 1360, 1310, 1110, 1030, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.63 (s, 3H), 1.03 (s, 3H), 1.13—2.03 (m, 20H), 2.07 (s, 3H), 2.63 (s, 3H), 5.47 (bs, 1H), and 6.03—7.00 (m, 4H). Calcd for $C_{28}H_{37}NOS$: C, 77.19; H, 8.56; N, 3.21%. Found: C, 76.98; H, 8.58; N, 3.09%.

Benzothiazolination of β-Hydroxy Ketones 19 and 20. Benzothiazolination of **19** and **20** was carried out on a 5 mmol scale for 72 h according to standard procedure. Purification of the crude products by short column chromatography afforded pure **17** and **18**.

17 (0.81 g, 48%): pale yellow oil; IR (neat) 3400, 2900, 2850, 1580, 1470, 1360, 1290, 1160, 1120, 1040, 1020, and 730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—1.83 (m, 24H), 2.60 and 2.65 (ds, 3H), 2.97 (br, 1H), 4.00 (br, 1H), and 5.98—6.93 (m, 4H). Calcd for $C_{20}H_{33}NOS$: C, 71.59; H, 9.91; N, 4.17%. Found: C, 71.83; H, 9.69; N, 4.35%.

18 (0.29 g, 24%): colorless needles after recrystallization from ethanol; mp 83.5—84 °C; IR (KBr) 3350, 2950, 1580, 1470, 1370, 1330, 1300, 1260, 1170, 1100, 940, 790, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (s, 6H), 1.57 (s, 3H), 2.12 (d, 2H), 2.69 (s, 3H), 3.10 (br, 1H), and 6.17—7.14 (m, 4H). Calcd for $C_{13}H_{19}NOS$: C, 65.78; H, 8.07; N, 5.90%. Found: C, 65.49; H, 8.02; N, 5.80%.

Hydrolysis of 3-Methylbenzothiazolines. Method A (General). Silver nitrate (1.02 g, 6 mmol) dissolved in water (10 ml) was added to a stirred solution of benzothiazoline **3** (4 mmol) in acetonitrile (60 ml) and 0.05 M phosphate buffer (pH 7) (12 ml). After 15 min at room temperature, additional silver nitrate (1.02 g, 6 mmol) dissolved in water (10 ml) was added. After another 20 min at room temperature, triethylamine (0.6 ml, 6 mmol) was added to neutralize the released acid (HNO_3) and stirring was continued for 5 min. Saturated aq. NaCl solution was added to the reaction mixture and filtered through Celite. The filtrate was extracted with ether and the extract was filtered through silica gel (Wakogel C-300). Removal of the solvent afforded almost pure aldehyde **1** that was free of MABT. Benzothiazoline **4** was similarly hydrolized, except that stirring was continued for 1 h at 45 °C after the addition of triethylamine, to afford almost pure ketone **2** that was free of MABT. Product yields are summarized in Tables 1 and 2. The compounds **17** and **18** were hydrolyzed by the similar method to benzothiazoline **4** to give the corresponding β-hydroxy ketones **19** (88%) and **20** (94%).

Method B. Mercury(II) chloride (1.63 g, 6 mmol) was added to a solution of benzothiazoline **3g** or **4e** (4 mmol) in 4:1 (v/v) acetonitrile-water (25 ml). The mixture was refluxed for 4 h and then cooled. After filtration to remove the precipitate, the aqueous solution was extracted with dichloromethane. The extract was dried with $MgSO_4$ and concentrated under reduced pressure to afford almost pure aldehyde **1g** (0.39 g, 93%) or ketone **2e** (0.45 g, 94%) as a colorless oil.

Method C. *N*-Bromosuccinimide (1.42 g, 8 mmol) was added to a suspension of benzothiazoline **3g** or **4e** (4 mmol)

in water (40 ml) and the mixture was stirred at room temperature for 10 min. After filtration, the filtrate was extracted with dichloromethane and the extract was dried with $MgSO_4$. Removal of the solvent under reduced pressure afforded almost pure aldehyde **1g** (0.39 g, 93%) or ketone **2e** (0.41 g, 86%).

Method D. Chloramine T (1.35 g, 4.8 mmol) was added to a solution of benzothiazoline **3g** (4 mmol) in ethanol (40 ml) and the mixture was stirred at room temperature for 1 h. After concentration of the mixture under reduced pressure, the residue was diluted with dichloromethane and washed thoroughly with water. The dichloromethane solution was dried with $MgSO_4$ and concentrated to give almost pure aldehyde **1g** (0.36 g, 85%). Benzothiazoline **4e** (0.97 g, 4 mmol) was similarly treated with Chloramine T (1.35 g, 4.8 mmol) for 24 h to give almost pure ketone **2e** (0.10 g, 21%).

Method E. Methyl fluorosulfate (0.55 g, 4.8 mmol) was added to a stirred solution of benzothiazoline **3g** or **4e** (4 mmol) in dichloromethane (16 ml) and stirring was continued at room temperature until no starting material remained (monitored with TLC; 18 h for **3g**, 24 h for **4e**). The excess reagent was quenched with ether (4 ml) for 30 min and the solvent was removed under reduced pressure. The residue was taken up in a mixture of 5% aq. K_2CO_3 solution (8 ml) and THF (10 ml) and the mixture was stirred at room temperature for 4 h. The solution was extracted with ether and the extract was washed with 5% aq. HCl, 5% aq. $NaHCO_3$, and saturated aq. NaCl solutions. It was then dried with $MgSO_4$. Concentration of the organic layer under reduced pressure afforded almost pure aldehyde **1g** (0.39 g, 92%) or ketone **2e** (0.46 g, 96%).

Identification of the carbonyl products obtained in these hydrolysis experiments was performed by spectroscopic (NMR, IR, and MS) methods. These spectral data were in satisfactory agreement with those of the corresponding authentic samples.

Preparation of 3-Methylbenzothiazolium Perchlorates 5; General Procedure. (A) From 3-Methylbenzothiazolines 3: Trityl perchlorate (3.43 g, 10 mmol) was added to a stirred solution of benzothiazoline **3** (10 mmol) in dry acetonitrile (10 ml). The mixture was warmed to 50—60 °C and continuously stirred for 30 min after the mixture became a complete solution. After cooling for 30 min at 0 °C, ether was added to completely precipitate product. The separated precipitate was collected by filtration and washed with dry ether to give crude product which was sufficiently pure to use directly in the next alkylation step. Recrystallization of crude products from methanol afforded pure salts as colorless needles. Product yields are summarized in Table 5.

(B) From Aldehyde 1 (One-Pot Reaction): MABT (1.39 g, 10 mmol) was added to a solution of aldehyde (10 mmol) in acetonitrile (10 ml) and the mixture was refluxed until the starting aldehyde disappeared (monitored with TLC; similar reaction times when compared to the benzothiazolination in ethanol were required). After cooling to room temperature, trityl perchlorate (6.86 g, 20 mmol) was added with stirring and warmed to 50—60 °C. The mixture was stirred for 10 min at the same temperature after the mixture became a complete solution and then stirred for 30 min at 0 °C. Ether was added to precipitate product completely and separated precipitate was collected by filtration and then washed with ether. The crude salt was decolorized in methanol with active charcoal and recrystallized from methanol to give pure **5** as colorless needles. Product yields are summarized in Table 5.

5a: mp 163.5—164.5 °C (decomp); IR (KBr) 2950, 1580, 1520, 1460, 1440, 1340, 1200, 1090, 760, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.97 (t, 3H), 1.17—2.17 (m, 4H), 3.43 (t, 2H), 4.13 (s, 3H), 7.67 (m, 2H), and 8.17 (m, 2H). Calcd for $C_{12}H_{16}NO_4SCl$: C, 47.14; H, 5.27; N, 4.58%. Found: C, 46.83; H, 5.11; N, 4.41%.

5b: mp 84.5—85 °C (decomp); IR (KBr) 2950, 1520, 1460, 1380, 1340, 1200, 1080, 760, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.67—2.17 (m, 14H), 3.87 (m, 1H), 4.33 (m, 3H), 7.83 (m, 2H), and 7.97 (m, 2H). Calcd for $C_{15}H_{22}NO_4SCl$: C, 51.79; H, 6.37; N, 4.03%. Found: C, 51.85; H, 6.31; N, 3.77%.

5c: mp 138.5—139 °C (decomp); IR (KBr) 2950, 1580, 1520, 1460, 1340, 1220, 1080, 820, 760, 720, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.48 (d, 6H), 3.83 (m, 1H), 4.17 (s, 3H), 7.67 (m, 2H), and 8.17 (m, 2H). Calcd for $C_{11}H_{14}NO_4SCl$: C, 45.29; H, 4.84; N, 4.80%. Found: C, 45.09; H, 4.73; N, 4.78%.

5d: mp 213—214 °C (decomp); IR (KBr) 1580, 1540, 1450, 1340, 1250, 1090, 760, 700, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=4.17 (s, 3H), 7.03 (m, 2H), 7.73 (m, 5H), and 8.27 (m, 2H). Calcd for $C_{14}H_{12}NO_4SCl$: C, 51.62; H, 3.71; N, 4.30%. Found: C, 51.43; H, 3.63; N, 4.06%.

5e: mp 216—217 °C (decomp); IR (KBr) 1590, 1480, 1470, 1400, 1240, 1090, 840, 700, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=4.20 (s, 3H), 7.75 (m, 6H), and 8.27 (m, 2H). Calcd for $C_{14}H_{11}NO_4SCl_2$: C, 46.68; H, 3.08; N, 3.89%. Found: C, 46.30; H, 3.42; N, 3.86%.

5f: mp 195—196 °C (decomp); IR (KBr) 1600, 1500, 1460, 1400, 1340, 1310, 1260, 1180, 1080, 830, 770, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=3.88 (s, 3H), 4.20 (s, 3H), 7.18 (m, 2H), 7.77 (m, 4H), and 8.23 (m, 2H). Calcd for $C_{15}H_{14}NO_5SCl$: C, 50.64; H, 3.97; N, 3.94%. Found: C, 50.83; H, 3.89; N, 3.68%.

5g: mp 173—174 °C (decomp); IR (KBr) 2950, 1580, 1520, 1450, 1300, 1200, 1080, 760, 700, and 620 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.00—2.83 (m, 6H), 3.83 (m, 1H), 4.27 (s, 3H), 5.77 (m, 2H), 7.72 (m, 2H), and 8.22 (m, 2H). Calcd for $C_{14}H_{16}NO_4SCl$: C, 50.99; H, 4.89; N, 4.25%. Found: C, 50.86; H, 4.76; N, 3.78%.

Alkylation of Benzothiazolium Salts 5 with Grignard or Organolithium Reagents; General Procedure. A solution of Grignard reagents (prepared from 20% excess of the corresponding bromide or chloride) in dry THF or ether (20 ml) was added dropwise to a stirred and cooled suspension at −78 °C of benzothiazolium salt **5** (4 mmol) in THF or ether (40 ml). The mixture was stirred for 30 min at −78 °C and allowed to warm to room temperature. After being stirred for 1 h at room temperature, the mixture was quenched by the addition of saturated aq. NH_4Cl solution. The aqueous mixture was extracted with ether and the extract was dried with $MgSO_4$. Concentration of the solution under reduced pressure to afford the crude products **4k**, **4n—s**, and **4u**. A 20% excess of butyllithium in hexane or a solution of nonynyllithium or phenylethynyllithium in THF (prepared by lithiation of 20% excess of 1,1-dibromo-1-nonene[14] or phenylacetylene with butyllithium) was similarly used in place of the Grignard reagents, giving **4k—m** and **4t**. Purification was carried out by short column chromatography for compounds **4p**, **4q**, and **4u** and by recrystallization from ethanol for compounds **4o**, **4r**, and **4s**. The other products were almost pure (monitored with TLC) without purification.

Product yields are summarized in Table 6.

4k: pale yellow oil; IR (neat) 2900, 1580, 1480, 1360, 1300, 1260, 1120, 1050, 1020, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—2.00 (m, 18H), 2.73 (s, 3H), and 5.83—6.97 (m, 4H). Calcd for $C_{16}H_{25}NS$: C, 72.95; H, 9.56; N, 5.32%. Found: C, 73.22; H, 9.77; N, 5.10%.

4l: pale yellow oil; IR (neat) 2900, 2850, 2200, 1580, 1470, 1340, 1290, 1120, 1020, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.53—2.30 (m, 24H), 2.93 (s, 3H), and 6.38—7.05 (m, 4H). Calcd for $C_{21}H_{31}NS$: C, 76.54; H, 9.48; N, 4.25%. Found: C, 76.71; H, 9.77; N, 4.11%.

4m: pale yellow oil; IR (neat) 2950, 2850, 2200, 1580, 1470, 1350, 1300, 1260, 1120, 1070, 1020, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.57—2.33 (m, 9H), 2.75 (s, 3H), and 6.05—7.47 (m, 9H). Calcd for $C_{20}H_{21}NS$: C, 78.13; H, 6.88; N, 4.56%. Found: C, 78.17; H, 6.73; N, 4.04%.

4n: pale yellow oil; IR (neat) 2950, 1580, 1480, 1380, 1360, 1300, 1200, 1120, 1050, 1020, and 730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—2.00 (m, 18H), 2.73 (s, 3H), and 5.83—6.97 (m, 4H). Calcd for $C_{16}H_{25}NS$: C, 72.95; H, 9.56; N, 5.32%. Found: C, 72.59; H, 9.58; N, 5.45%.

4o: colorless needles; mp 70.5—71 °C; IR (neat) 2900, 1580, 1480, 1440, 1360, 1300, 1220, 1100, 1040, 1020, 730, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—1.67 (m, 9H), 2.58 (s, 3H), and 6.40—7.60 (m, 9H). Calcd for $C_{18}H_{21}NS$: C, 76.28; H, 7.47; N, 4.94%. Found: C, 76.11; H, 7.49; N, 4.74%.

4p: colorless oil; IR (neat) 2950, 1620, 1580, 1480, 1370, 1300, 1220, 1120, 1020, and 730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—2.00 (m, 24H), 2.60 (s, 3H), and 5.67—6.83 (m, 4H). Calcd for $C_{19}H_{31}NS$: C, 72.95; H, 9.57; N, 5.32%. Found: C, 73.14; H, 9.91; N, 4.81%.

4q: colorless oil; IR (neat) 2950, 1580, 1480, 1360, 1300, 1220, 1120, 1020, and 730 cm^{-1}; ^1H NMR (CCl_4) δ=0.50—2.13 (m, 16H), 2.57 (s, 3H), and 5.67—6.77 (m, 4H). Calcd for $C_{15}H_{23}NS$: C, 72.23; H, 9.29; N, 5.62%. Found: C, 72.37; H, 9.59; N, 5.37%.

4r: colorless needles; mp 140—140.5 °C; IR (KBr) 1570, 1480, 1440, 1340, 1300, 1220, 1150, 1100, 1120, 980, 890, 730, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.55 (s, 3H) and 6.33—7.50 (m, 14H). Calcd for $C_{20}H_{17}NS$: C, 79.17; H, 5.65; N, 4.62%. Found: C, 79.66; H, 5.42; N, 4.35%.

4s: colorless needles; mp 98.5—99 °C; IR (KBr) 3100, 2950, 1580, 1480, 1440, 1370, 1300, 1220, 1180, 1120, 1050, 1020, 770, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.62 (s, 3H), 3.53 (s, 2H), and 6.07—7.67 (m, 14H). Calcd for $C_{21}H_{19}NS$: C, 79.46; H, 6.03; N, 4.41%. Found: C, 78.84; H, 6.04; N, 4.16%.

4t: pale yellow oil; IR (neat) 2950, 1580, 1500, 1420, 1320, 1160, 1040, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—1.83 (m, 9H), 2.53 (s, 3H), 3.68 (s, 3H), and 6.37—7.50 (m, 8H). Calcd for $C_{19}H_{23}NOS$: C, 72.80; H, 7.40; N, 4.47%. Found: C, 72.66; H, 7.62; N, 4.82%.

4u: colorless oil; IR (neat) 2900, 1650, 1580, 1460, 1360, 1300, 1220, 1120, 1020, 960, 920, and 730 cm^{-1}; ^1H NMR (CCl_4) δ=0.67—2.23 (m, 16H), 2.64 (s, 3H), 5.47 (m, 2H), and 5.73—6.83 (m, 4H). Calcd for $C_{18}H_{25}NS$: C, 75.21; H, 8.77; N, 4.87%. Found: C, 75.69; H, 9.08; N, 4.61%.

3-Methylbenzothiazolium Iodide (6a). A solution of benzothiazole (1.1 g, 8 mmol) in DMF (3 ml) and iodomethane (3 ml, 48 mmol) was refluxed for 2 h. The mixture was diluted with ether and cooled in an ice bath to completely precipitate the product. The pale yellow needles obtained were collected by filtration and washed thoroughly with ether. Recrystallization of the crude product from methanol afforded pure **6a** as colorless needles (2.1 g, 95%): mp 217 °C (decomp); IR (KBr) 3000, 1580, 1520, 1450, 1400, 1370, 1110, 1030, 880, 750, and 695 cm^{-1}; ^1H NMR (DMSO-d_6) δ=4.33 (s, 3H), 7.75 (m, 2H), 8.28 (m, 2H), and 10.38 (s, 1H). Calcd for C_8H_8NSI: C, 34.67; H, 2.91; N, 5.05%. Found: C, 34.48; H, 2.83; N, 4.86%.

3-Methylbenzothiazolium Fluorosulfate (6b). Methyl fluorosulfate (3.42 g, 30 mmol) was added to a solution of benzothiazole (1.35 g, 10 mmol) in dichloromethane (10 ml) and the mixture was refluxed for 24 h. After cooling to room temperature and a similar workup as in the preparation of **6a**, recrystallization of crude product from methanol afforded pure **6b** (2.24 g, 90%): mp 107—108 °C (decomp); IR (KBr) 3450, 3050, 1720, 1620, 1580, 1520, 1440, 1400, 1280, 1080, 900, 880, 820, 760, and 580 cm^{-1}; ^1H NMR (DMSO-d_6) δ=4.35 (s, 3H), 7.72 (m, 2H), 8.27 (m, 2H), and 10.38 (s, 1H). Calcd for $C_8H_8NO_3S_2F$: C, 38.55; H, 3.23; N, 5.62%. Found: C, 38.46; H, 3.18; N, 5.61%.

3-Methylbenzothiazolium Methyl Sulfate (6c). Benzothiazole (1.35 g, 10 mmol) was methylated for 72 h with dimethyl sulfate (3.78 g, 30 mmol) in dichloromethane (10 ml) by the same procedure for **6b**. Recrystallization of crude product from methanol afforded pure **6c** (0.42 g, 16%): mp 122—124 °C (decomp); IR (KBr) 3450, 3050, 1610, 1580, 1520, 1440, 1400, 1280, 1250, 1210, 1060, 1020, 900, 760, 720, and 570 cm^{-1}; ^1H NMR (DMSO-d_6) δ=3.32 (s, 3H), 4.33 (s, 3H), 7.72 (m, 2H), 8.25 (m, 2H), and 10.33 (s, 1H). Calcd for $C_9H_{11}NO_4S_2$: C, 41.37; H, 4.24; N, 5.36%. Found: C, 40.92; H, 4.10; N, 5.26%.

3-Methylbenzothiazolium Tetrafluoroborate (6d). Trimethyloxonium tetrafluoroborate (1.63 g, 10 mmol) was added in portions to a solution of benzothiazole (1.35 g, 10 mmol) in dichloromethane (10 ml). After the reaction mixture was refluxed for 20 min, the solvent was removed by evaporation under reduced pressure. The residual sirup was crystallized from acetone-dichloromethane-ether to give the crude product as colorless needles. Recrystallization from acetone-dichloromethane afforded pure **6d** as colorless needles (2.26 g, 95%): mp 118.5—119.5 °C (decomp); IR (KBr) 3050, 1580, 1520, 1440, 1400, 1370, 1320, 1280, 1080, 900, 760, 720, 570, and 520 cm^{-1}; ^1H NMR (DMSO-d_6) δ=4.37 (s, 3H), 7.73 (m, 2H), 8.23 (m, 2H), and 10.33 (s, 1H). Calcd for $C_8H_8NSBF_4$: C, 40.54; H, 3.40; N, 5.91%. Found: C, 40.42; H, 3.19; N, 5.88%.

Alkylation of 3-Methylbenzothiazolium Salts 6. Benzothiazolium salts **6a—d** (4 mmol) were allowed to react with 1.2 equiv of organometallic reagent according to standard procedure for the alkylation of the salt **5**, giving **3a**, **3g**, **3i**, and **3m—o**. In the case of **3a** obtained in the reaction of **6a** with butylmagnesium bromide, purification by short column chromatography was carried out to give pure **3a** as pale yellow oil. The other products were almost pure (monitored with TLC) without purification. Product yields are summarized in Table 7.

3m: pale yellow oil; IR (neat) 3050, 2900, 2850, 1640, 1580, 1480, 1370, 1330, 1300, 1120, 1020, 920, and 740 cm^{-1}; ^1H NMR (CCl_4) δ=2.50 (t, 2H), 2.68 (s, 3H), 4.67—5.17 (m, 3H), 5.50 (m, 1H), and 5.87—6.83 (m, 4H). Calcd for $C_{11}H_{13}NS$: C, 69.06; H, 6.85; N, 7.32%. Found: C, 69.29; H, 6.83; N, 7.38%.

3n: pale yellow oil; IR (neat) 3050, 2800, 1950, 1680, 1580, 1480, 1370, 1330, 1290, 1120, 1020, 1000, 920, and 740 cm^{-1};

^{1}H NMR ($CDCl_3$) δ=1.05 (d, 3H), 2.74 (s, 3H), 5.06 (m, 3H), and 6.21—7.25 (m, 4H). This compound is slightly unstable in air.

3o: pale yellow oil; IR (neat) 2200, 1670, 1580, 1470, 1420, 1350, 1320, 1280, 1100, 1020, 740, and 690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.13 (s, 3H), 6.00—7.50 (m, 9H), and 7.93 (s, 1H). This compound is slightly unstable in air.

Benzothiazole-2-*d* (22). A stirred solution of benzothiazole (6.0 g, 45 mmol) in dry THF (90 ml) under nitrogen was cooled to −78 °C and 20% excess of butyllithium in hexane (1.6 M solution) was added dropwise. 2-Lithiobenzothiazole was immediately formed. This orange-colored anion solution was quickly quenched at −78 °C with D_2O (4.5 ml) after the addition of butyllithium. The mixture was allowed to warm to room temperature and diluted with water. The aqueous mixture was extracted with ether. The ether extract was dried with $MgSO_4$. Removal of the solvent under reduced pressure afforded almost pure **22** as a pale yellow oil (5.85 g, 95%; >98% deuteration by ^{1}H NMR): bp 73 °C/2 mmHg (1 mmHg≈133.322 Pa); ^{1}H NMR (CCl_4) δ=6.50—7.50 (m, 4H).

2-Deuterio-3-methylbenzothiazolium Iodide (23). Benzothiazole-2-*d* (**22**) (4.1 g, 30 mmol) was methylated with iodomethane (11.2 ml, 180 mmol) in DMF (16.8 ml) according to the procedure for the preparation of **6a**. Recrystallization of crude product from methanol afforded pure **23** as colorless needles (7.8 g, 94%): mp 217 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=4.33 (s, 3H), 7.75 (m, 2H), and 8.23 (m, 2H).

3-Methyl-2-phenylbenzothiazoline-2-*d* (24). Benzothiazolium salt **23** (7.23 g, 26 mmol) was alkylated with phenylmagnesium bromide (1.2 eq) in THF according to standard procedure described previously. Recrystallization of the crude product as pale yellow needles from ethanol afforded pure **24** as colorless needles (4.7 g, 80%; >98% deuteration by ^{1}H NMR): mp 113 °C; ^{1}H NMR ($CDCl_3$) δ=2.58 (s, 3H) and 6.17—7.67 (m, 9H).

Benzaldehyde-2-*d*. Benzothiazoline **24** (4.6 g, 20 mmol) was hydrolyzed by Method A to afford almost pure benzaldehyde-*d* as a colorless oil (1.99 g, 94%; >98% deuteration by ^{1}H NMR): bp 72.5 °C/20 mmHg; ^{1}H NMR (CCl_4) δ=7.30—7.87 (m, 5H).

Vanadium Oxides (V_2O_x) Catalysts for Dry-Type and Simultaneous Removal of Sulfur Oxides and Nitrogen Oxides with Ammonia at Low Temperature

Shigeaki KASAOKA,* Eiji SASAOKA, and Hideto IWASAKI
Faculty of Engineering, Okayama University, Okayama 700
(Received August 11, 1988)

In order to develop highly functional catalysts for a dry-type, simultaneous removal of sulfur oxides (SO_x) and nitrogen oxides (NO_x) the catalytic activities of V_2O_x/TiO_2, V_2O_x/TiO_2/AC(activated carbon) and V_2O_x/AC ($4<x<5$) were studied using a fixed bed flow reactor. In this process SO_2 is catalytically oxidized to SO_3 and then fixed on the catalyst as ammonium sulfates by reactions with H_2O and NH_3; NO_x are reduced to N_2 with NH_3 over the same catalyst at low temperature (ca. 130 °C). The sulfates deposited on the catalyst must be periodically removed for regeneration in order to realize repeated use of the catalyst. V_2O_x/TiO_2 was found to be a suitable catalyst for the simultaneous removal and to have an acceptable tolerance for reiterative regeneration. Also, water washing of the used catalyst after a NH_3 pretreatment was found to be preferable for regeneration. The sulfates deposited on the catalyst could be recovered as $(NH_4)_2SO_4$ by this type regeneration. The deposited sulfates were amorphous and could be regarded as being a mixture of NH_4HSO_4 and $(NH_4)_2SO_4$. These sulfates reacted with NO_x to produce N_2.

SO_x and NO_x in the flue gases emitted from stationary sources have been removed by two consecutive processes. NO_x in flue gas are catalytically reduced to N_2 with NH_3 by a dry process at around 350 °C; SO_x are absorbed by a wet process at around 50 °C. These processes are well established, though complicated and not very energy saving-type processes. Furthermore, in wet-type desulfurization, waste water must be cleaned. For both simplification and energy saving, it is desirable to estabish a low-temperature, dry-type process for the removal of SO_x and NO_x.

The authors have already reported a dry-type, simultaneous removing process, in which CuO containing metal oxides (TiO_2, SiO_2, etc.) are used as the catalyst and sorbent. In this case SO_2 is oxidized to SO_3, and then fixed as $CuSO_4$ ($SO_3 \rightarrow CuO$). NO_x are catalytically reduced to N_2 with NH_3 over the $CuSO_4$ formed. This dry-type process gives a high completion rate for the simultaneous removal of SO_x and NO_x at around 350 °C. Furthermore, it was found that CuO containing multi-component metal oxides has sufficient tolerance for reiterative regeneration from $CuSO_4$ to CuO.[1-3]

A new dry-type, simultaneous process using active carbon or coke was proposed[4,5] and studied regarding practical applications.[6-9] In this process SO_2 is oxidized to SO_3 over the catalyst and then fixed on the catalyst:

$$SO_2 + (1/2)O_2 + H_2O = H_2SO_4, \quad (1)$$

and

$$H_2SO_4 + NH_3 = NH_4HSO_4. \quad (2)$$

NO is reduced to N_2 with NH_3 over the same catalyst:

$$NO + (1/4)O_2 + NH_3 = N_2 + (3/2)H_2O. \quad (3)$$

The catalysts are claimed to be highly active for simultaneous removal, even when a lot of the sulfate is fixed on the catalyst surface. Furthermore, the catalyst which lost its activity at last has to be regenerated, because of the deposition of sulfate. That is, the sulfate has to be removed from the used catalyst without loss and deactivation of the catalyst.

The regeneration of the used catalyst can be achieved according to the reactions:

$$H_2SO_4 + (1/2)C = SO_2 + H_2O + (1/2)CO_2, \quad (4)$$

and

$$NH_4HSO_4 + (1/2)C = NH_3 + H_2O + SO_2 + (1/2)CO_2. \quad (5)$$

Therefore, loss of the carbon catalysts during regeneration is unavoidable.

In the present study, vanadium oxides catalysts were studied to develop a dry-type, simultameous removal process; reiterative regeneration by a wet-type method was also studied in order to establish a regeneration method in which the used catalyst could be regenerated without loss and deactivation. Vanadium oxides catalysts have been used as a commercial denitrification catalyst, and are highly active even at low temperature if the preparation is adequate.[10] The sulfation of SO_x with H_2O and NH_3 over the vanadium oxides catalysts were also studied.[11-14] The object of this work is to clarify the performance and the possibility of any practical applications of vanadium oxides catalysts.

Experimental

Materials. Gases (NO, SO_2, NH_3, O_2, N_2, and He) from commercial cylinders were used. NH_3 and H_2O were supplied as aqueous ammonia. All chemicals used for the preparation of catalysts were reagent grade. Before use, AC(activated carbon) was washed with hot water (ca. 100 °C), dried at 110 °C for 25 h and then calcined at 900 °C for 1 h in a stream of N_2.

Catalysts. The support TiO_2(anatase) was prepared by the precipitation method. A 10 wt% $TiCl_4$ aqueous solution was poured instantly into a 7 wt% NH_3 aqueous solution under intensive mixing at room temperature. The precipi-

tate was washed with repeated decantation, filtered, dried at 110 °C for 25 h, calcined at 400 °C for 3 h in the stream of air, crushed, and then sieved to average diameter of 1.0 mm (surface area: 90 $m^2 g^{-1}$, bulk density: 0.83 g cm^{-3}). The AC as a support was crushed and sieved to an average diameter of 1.0 mm (surface area: 1460 m^2 g^{-1}, bulk density: 0.42 g cm^{-3}). TiO_2/AC was prepared by a chemical vapor deposition method. That is, the AC was packed in a glass tube reactor and dried at 150 °C for 1 h in a N_2 stream, cooled down to room temperature, exposed to $TiCl_4$ vapor using a mixed gas of 1% $TiCl_4$ and N_2(100 $cm^3N\,min^{-1}$) for 3 h, and then exposed to a mixed gas of 40% NH_3, 2% H_2O and N_2 (180 $cm^3N\,min^{-1}$) for 3 h. After this procedure, the sample was washed with water, dried at 110 °C for 25 h and calcined at 400 °C for 3 h in a N_2 stream (surface area: 1040 $m^2 g^{-1}$, bulk density: 0.53 g cm^{-3}). The TiO_2 content in the TiO_2/AC was ca. 21 wt%.

Catalysts, V_2O_x/TiO_2, V_2O_x/AC, and V_2O_x/TiO_2/AC, were prepared by an impregnation method. The supports were impregnated in aqueous ammonia of NH_4VO_3 at room temperature for 25 h, dried in a rotary evaporator under evacuation at 40 °C, and then dried at 110 °C for 25 h. The amount of NH_4VO_3 loaded on the support was ca. 5 wt% as V_2O_5. The NH_4VO_3 loaded on the support was changed to an active state V_2O_x ($4<x<5$)[10] by a pretreatment with a mixed gas of 250 ppm NO, 250 ppm NH_3, 5% O_2 and N_2(500 $cm^3N\,min^{-1}$) at 200 °C for 3 h.

Reaction Procedure. The simultaneous removal of SO_x and NO_x was carried out in a fixed bed flow reactor under an atmospheric pressure, in the temperature range 130 to 150 °C (mainly 130 °C). Two glass tube reactors were used. The one (inner dia.: 12 mm) was used for 3 ml of catalyst (SV: 1.0×10^4 h^{-1}) and the another (inner dia.: 20 mm) was used for 12 ml (SV: 2.5×10^{-3} h^{-1}) or 18 ml (1.7×10^3 h^{-1}) of catalyst. Inlet gases were a mixture of 250 ppm SO_2, 250 ppm NO, (0—750) ppm NH_3, 5% O_2, 10% H_2O and N_2, and were fed with the total flow rate of 500 $cm^3N\,min^{-1}$. The concentrations of SO_x and NO_x in inlet and outlet gas were measured by the method of Arsenazo III (JIS K0103) and a chemiluminescence-type NO_x meter (YANACO ECL300), respectively. The concentration of NH_3 was measured by the conventional absorption-titration method.[15] Confirmation of the reduction of NO_x to N_2 with NH_3 was carried out using helium instead of N_2 as a balanced gas. The concentration of N_2 was measured by a gas chromatograph using a column packed with Molecular Sieves 5A (zeolite).

The reactivity of NH_4HSO_4 with NH_3 and the thermal stability of NH_4HSO_4, $(NH_4)_3H(SO_4)_2$ and $(NH_4)_2SO_4$ were measured with a flow-type auto-recording micro-thermobalance. Identifications of the sulfates were carried out by X-ray diffraction (XRD) analysis. The pore volume of the catalyst was measured using a mercury porosimeter (Erba MOD-220).

Results and Discussion

Simultaneous Removal of SO_x and NO_x with V_2O_x/AC, V_2O_x/TiO_2, and V_2O_x/TiO_2/AC. Results on the simultaneous removal of SO_x and NO_x over V_2O_x/AC and V_2O_x/TiO_2 are shown in Fig. 1. A comparison of the catalytic activities of the two catalysts led to the conclusion that V_2O_x/AC is more suitable for SO_x removal than V_2O_x/TiO_2, and that V_2O_x/TiO_2 is more suitable for NO_x removal than V_2O_x/AC.

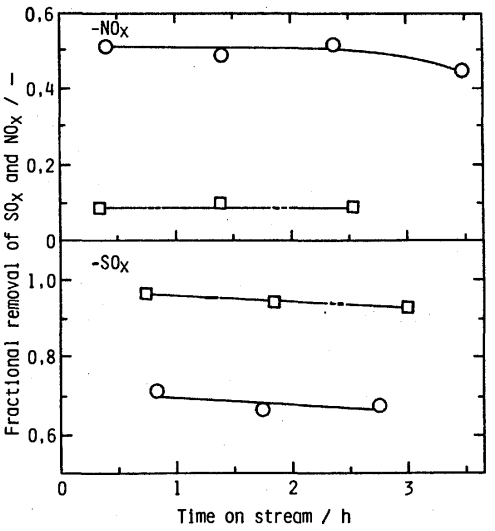

Fig. 1. Simultaneous removal of SO_x and NO_x with V_2O_x/TiO_2 and V_2O_x/AC. Catalysts: virgin, 3.0 ml, reaction conditions: 250 ppm SO_2-250 ppm NO-500 ppm NH_3-5% O_2-10% H_2O-N_2(500 $cm^3N\cdot min^{-1}$, 1.0×10^4 h^{-1}), 403.2 K.

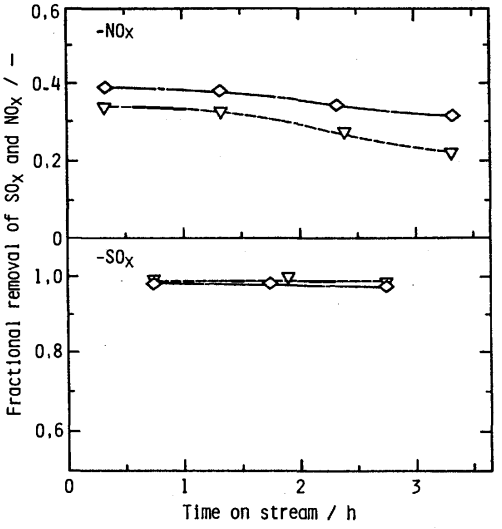

Fig. 2. Simultaneous removal of SO_x and NO_x with V_2O_x/TiO_2/AC and mixture of equi-volume of V_2O_x/TiO_2 and V_2O_x/AC. Catalysts: virgin, 3.0 ml, reaction conditions: 250 ppm SO_2-250 ppm NO-500 ppm NH_3-5% O_2-10% H_2O-N_2(500 $cm^3N\cdot min^{-1}$, 1.0×10^4 h^{-1}) 403.2 K.
▽: V_2O_x/TiO_2/AC, ◇: V_2O_x/TiO_2+V_2O_x/AC.

For the utilization of the characteristics of V_2O_x/AC and V_2O_x/TiO_2, the combination of the two catalysts was studied. That is, the activity of V_2O_x/TiO_2/AC was measured and compared with that of a mixture of the equi-volume of V_2O_x/AC and V_2O_x/TiO_2. These results are shown in Fig. 2. The order of catalytic activities was as follows:

For NO_x removal: $V_2O_x/TiO_2 > (V_2O_x/AC + V_2O_x/TiO_2) > V_2O_x/TiO_2/AC \gg V_2O_x/AC$

For SO_x removal: $V_2O_x/TiO_2/AC$, $(V_2O_x/AC+V_2O_x/TiO_2)$, $V_2O_x/AC>V_2O_x/TiO_2$

Unfortunately, the expected effect with the combination was not found. From the above results, it was found that V_2O_x/TiO_2 is most suitable among the three catalysts for the simultaneous removal of SO_x and NO_x (especially, for the concentration of $NO_x>$ that of SO_x).

Confirmation of the Fixation of SO_x on the Catalyst and the Reduction of NO_x to N_2. The fixation of SO_x on the catalyst was confirmed by the following procedure. The used catalysts (V_2O_x/AC and V_2O_x/TiO_2 used for 3.5 h (Fig. 1)) were washed with water at room temperature, and the amount of ammonium sulfates in the filtrate was measured by Arsenazo III method. The ratios of the amount recovered by the above method to the amount of SO_x removal were from 0.9 to 1.0.

For the comfirmation that NO_x are reduced to N_2 with NH_3, helium was used instead of N_2 as a balance gas. As the results, it was found that almost all of SO_x and NO_x were removed.

Effects of Reaction Temperature and Concentration of NH_3 on the Simultaneous Removal of SO_x and NO_x. The effect of the reaction temperature on the removal of SO_x and NO_x with V_2O_x/TiO_2 is shown in Fig. 3. With the temperature rise, the activity for NO_x removal increased and that for SO_x removal decreased. Although the reason for the decrease of SO_x removal is unknown, it may be possible that the sulfate (such as NH_4HSO_4 (mp 147 °C)) melted and plugged the pores of the catalyst. This plugging probably disturbed the removal of SO_x more than that of NO_x.

The effect of the inlet concentration of NH_3 on the removal of SO_x and NO_x with V_2O_x/TiO_2 is shown in Fig. 4. The fractional removal of NO_x increased with increasing NH_3 concentration, and then reached a constant value above the stoichiometric concentration of NH_3 (calculated from Eq. 3). This means that the dependency of the reduction rate of NO on the concentration of NH_3 is zero order. This result is consistent with the previous results reported.[1,16,17] On the other hand, the fractional removal of SO_x increased with increasing NH_3 concentration. This suggests that NH_3 plays an important role in SO_x removal, and that the rate-determining step of SO_x removal is not the oxidation of SO_2 to SO_3 with O_2.

Stabilities of V_2O_x/TiO_2 and V_2O_x/AC for Regeneration. The experiments on the regeneration of the used catalyst were tried by wet-type methods. In the early stage, the used catalysts were washed with water at room temperature without any pretreatment. In this method part of the V_2O_x on the supports was slightly dissolved with the water. This was due to the acidity of the solution. Therefore, to prevent leaching of V_2O_x from the catalysts, the used catalysts were treated with NH_3 (0.5% NH_3-5% O_2-N_2, 450 cm^3N min^{-1}, 130→100 °C, 0.5 h); that is, the sulfates deposited on the catalyst were neutralized with NH_3. After this treatment, the ammonium salts formed on the catalysts were extracted with water. the ammonium salts taken out from the aqueous solution by drying were identified as $(NH_4)_2SO_4$ by XRD analysis.

The stabilities of V_2O_x/TiO_2 and V_2O_x/AC for reiterative regeneration by the improved regeneration

method are shown in Fig. 5. V_2O_x/AC was found to have good stability, but the activity of V_2O_x/TiO_2 decreased up to the fifth regeneration, and then sustained adequate activity. One of the reasons for the deactivation of V_2O_x/TiO_2 up to fifth regeneration run might be a decrease of the specific surface area; however, the difference of the surface area of the virgin catalyst and that of the seventh regenerated catalyst was small (94→87 m^2g^{-1}). Another reason might be the change of V_2O_x to another vanadium oxide, such as V_2O_5. Therefore, the activities of V_2O_x/TiO_2 and V_2O_5/TiO_2 were compared. TiO_2, which were calcined at 550 °C for 3 h, were used (surface area: 72 m^2g^{-1}, bulk density: 1.1 gcm^{-3}). V_2O_5/TiO_2 was prepared from TiO_2 supported NH_4VO_3 by calcining at 550 °C for 3 h in a stream of air. The activity of V_2O_x/TiO_2 for the simultaneous removal was higher than that of V_2O_5/TiO_2, as shown in Fig. 6. It was indicated that the change of V_2O_x to V_2O_5 might be one of the causes of the deactivation.

Identification of the Sulfates Deposited on the Catalyst. As described previously, SO_x were fixed on a catalyst, though the kinds of sulfates were unknown. Therefore, the identification of deposited sulfates was carried out by XRD analysis; however, no clear X-ray diffraction pattern was found. This indicated that the sulfates were amorphous.

Because of the difficulty of a direct identification of the sulfates by XRD analysis, an indirect identification was tried by the following method. The used catalyst was washed with water; then, the filtrate was dried in a rotary evaporator under evacuation at 40 °C. The sulfates from the filtrate were dried at 110 °C for 25 h, and were then analyzed by XRD. As a result, $(NH_4)_3H(SO_4)_2$(equi-gram-mole mixture of NH_4HSO_4) and $(NH_4)_2SO_4$),[17] and $(NH_4)_2SO_4$ were identified. Since these sulfates might be produced via NH_4HSO_4, the possibility of conversion from NH_4HSO_4 to another sulfate was studied. That is, the reactivity of NH_4HSO_4 with NH_3 under the coexistence of water vapor was studied at 130 °C using a thermobalance. The conversions of the NH_4HSO_4 to $(NH_4)_3H(SO_4)_2$ and $(NH_4)_2SO_4$ were confirmed by thermal gravimetrical and XRD analysis. Furthermore, it was confirmed by a gravimetrical method that the decompositions of NH_4HSO_4, $(NH_4)_3H(SO_4)_2$ and $(NH_4)_2SO_4$ are not detectable by a temperature-programmed method (2 °C min^{-1}) in the temperature range 130 to 150 °C.

From the above results, it was suggested that the sulfates could be regarded as a mixture of NH_4HSO_4 and $(NH_4)_2SO_4$, and that the side reaction of NH_4HSO_4 with NH_3 proceeds according to the following equation:

$$NH_4HSO_4 + NH_3 = (NH_4)_2SO_4. \quad (6)$$

It was also suggested that $(NH_4)_2SO_4$ is the final product from SO_x on the catalyst, if it does not react with SO_x and NO_x.

Reactivities of the Sulfates Deposited on the Catalyst. Shikada et al.[18] already reported that NH_4HSO_4 in a molten salt of $NH_4HSO_4/NaHSO_4$ reacted with NO under the coexistence of V_2O_5. Therefore, the reactivities of the sulfates deposited on the catalyst with NO_x were measured by the following procedure.

For the complete removal of NH_3 remaining on V_2O_x/TiO_2 after the activation step of $NH_4VO_3 \rightarrow V_2O_x$, the sample V_2O_x/TiO_2 was further treated with a mixed gas (250 ppm NO-5% O_2-N_2) at 200 °C. This treatment was stopped when the outlet concentration of NO_x became equal to the concentration in the inlet gas. The treated catalyst was crushed under 100 mesh, mechanically mixed with NH_4HSO_4 or $(NH_4)_2SO_4$ using a mortar, pelletized, crushed, again, and then sieved to an average dieameter of 1.0 mm. The content of the sulfate was ca. 10 wt%. Figure 7 shows the reactivity of the NH_4HSO_4 or $(NH_4)_2SO_4$ loaded on V_2O_x/TiO_2 with NO_x. It was obviously found that $(NH_4)_2SO_4$ and NH_4HSO_4 reacted with NO_x. Furthermore, the reduction of NO_x to N_2 with the sulfates was confirmed by using helium as a balanced gas, and the gas chromatograph, as follows:

$$NO + (1/4)O_2 + NH_4HSO_4 = N_2 + (3/2)H_2O + H_2SO_4, \quad (7)$$

and

$$NO + (1/4)O_2 + (NH_4)_2SO_4 = N_2 + (3/2)H_2O + NH_4HSO_4. \quad (8)$$

On the other hand, small amount of SO_x were removed; the fracional removal of SO_x was almost the same as the value measured without the coexistence of NH_3 (Fig. 4).

The active site of the cataltst for the reactions of Eqs. 7 and 8 will finally be covered by the deposited sulfates. Therefore, any NH_4HSO_4 formed will be converted to $(NH_4)_2SO_4$ with NH_3.

Evaluation of V_2O_x/TiO_2 as a Catalyst for the Simultaneous Removal of SO_x and NO_x. For practical applications, the life of a catalyst and the reaction conditions demanding an almost complete removal of both SO_x and NO_x are important. From these view points, the fractional conversions of SO_x and NO_x were measured for 30 h. The results under the conditions that the inlet concentration of NH_3 was set to be equal to the stoichiometric value in Eqs. 2 and 3 (NO: 250 ppm, SO_2: 250 ppm, $NH_3/(SO_2+NO)$ mole ratio: 1.0) are shown in Fig. 8. At a higher space velocity (1.0×10^4 h^{-1}), both of the conversions of SO_x gradually decreased with the time on stream. From a comparison of the fractional removal of SO_x and NO_x, the SO_x removal proceeded predominantly under this conditions. Since the reason for the decline of the fractional removal of both SO_x and NO_x was considered to be the deposition of the sulfates, the surface area and pore volume of a virgin catalyst and that of a used catalyst were measurd. In this case, NH_4HSO_4 in the used catalyst absorbed water vapor and melt if the catalyst was exposed to the atmosphere at room temperature. Therefore, before the measurements of the surface area and the pore volume, the used catalyst was treated with NH_3, and NH_4HSO_4 was converted to $(NH_4)_2SO_4$ by the same procedure as that of the NH_3 treatment in the regemeration. The surface area of the catalyst decreased ca. 40% after the use (94→54 m^2 g^{-1}) and the pore volume of the catalyst also fell down ca.30% after the use (pore diameter>6 nm : 0.26→0.17 cm^3 g^{-1}). From these results it was confirmed that the reason of the declines of the fractional removal of SO_x and NO_x was the deposition of the sulfates.[11-13] At lower space velocity (2.5×10^3 h^{-1}), NO_x were almost completely removed up to 6 h from the start, but the fractional removal of SO_x fell down gradually up to 12 h. The effect of the space velocity (SV) on the removal of SO_x is not justified, because the conversion of SO_x at the lower SV should be considerably larger than that of the

higher SV. Furthermore, the NO_x removal proceeded predominantly in the early time at the lower SV, being inconsistent with the results obtained at the higher space velocity. It was suggested that these results were due to the insufficiency of the amount of NH_3 supplied. In these experiments, the amount of NH_3 used was just sufficient to form NH_4HSO_4 and to reduce NO_x to N_2; however, $(NH_4)_2SO_4$ was produced in addition to NH_4HSO_4. This formation of $(NH_4)_2SO_4$ caused the insufficiency of the amount of NH_3 for the complete removal of SO_x and NO_x.

Based on the above results, in a following experiment, NH_3 was used in stoichiometric amount (750 ppm NH_3 for 250 ppm SO_2 and 250 ppm NO) according to Eqs. 2 to 6. That is, this amount of NH_3 is just sufficient to form $(NH_4)_2SO_4$ and to reduce NO_x to N_2. SO_x were almost completely removed from start up to 20 h, and the fractional removal of NO_x was kept above 90% for 20 h, as shown in Fig. 9. However, in this case, a considerable amount of NH_3 was detected in the reactor outlet. Furthermore, during the early hours the concentration of NH_3 changed abnormally. It may be considered that the adsorption of NH_3 onto the catalyst occurred, and also that the contributions of the reactions of Eqs. 2 to 6 to the consumption of NH_3 depended on the time on stream. Using the data at the quasi-steady state in Fig. 9 (from 14 to 20 h), the consumption mole ratio of NH_3 to (SO_x +NO_x) was obtained as ca. 1.25. This means that the sulfates produced seem to be a mixture of equi-gram-mole of NH_4HSO_4 and $(NH_4)_2SO_4$. Although, the simultaneous complete removal of SO_x and NO_x was possible under a sufficient amount of NH_3, the practical application of the catalyst claims the almost complete removal of SO_x and NO_x without any leakage of NH_3. Therefore, in the next experiment the inlet mole ratio of NH_3 to (SO_x+NO_x) was decreased from 1.5 to 1.25, and the space velosity was lowered to 1.7×10^3 h^{-1}. In this case, from the start up to 20 h, NO_x were almost completely removed, and SO_x were almost completely removed after 12 h. From these results and the dependency of the removal of SO_x on the concentration of NH_3, it was suggested that the removal rate of SO_x is lower under a smaller amount of NH_3 and, hence, the amount of the catalyst was not sufficient for a complete removal of SO_x.

From the results shown in Fig. 4, it was also suggested that the removal rate of SO_x could be kept higher under a higher mole ratio of NH_3 to SO_x. This claim for the removal of SO_x was satisfied by the application of a catalyst to the NO_x-rich flue gas(concentration of NO_x>that of SO_x). In the next experiment, SO_2, NO, and NH_3 were set to be 100, 250, and 400 ppm, respectively. The almost complete simultaneous removal of SO_x and NO_x without leakage of NH_3 was achieved, except during the early hours, as shown in Fig. 10.

The above-mentioned results might suggest that a just sufficient amount of NH_3 to form a mixture of equi-gram-mole of NH_4HSO_4 and $(NH_4)_2SO_4$, and to reduce NO_x to N_2, had to be used for the complete removal of SO_x and NO_x without leakage of NH_3. However, from previous fundamental studies, it was concluded that the most stable form of the sulfate was $(NH_4)_2SO_4$, and that the mole ratio of NH_4HSO_4 to $(NH_4)_2SO_4$ depended on the time on stream and/or the concentration of NH_3. In any case, it was experimentally clarified that the simultaneous complete removal of SO_x and NO_x in a NO_x-rich gas without leakage of NH_3 was possible.

Conclusion

V_2O_x/TiO_2 was found to be a suitable catalyst for the simultaneous removal of SO_x and NO_x in NO_x-rich flue gas by reactions with NH_3, even at low temperature, such as 130 °C.

V_2O_x/AC was suitable only for the removal of SO_x, and the activity for the removal of SO_x was better than that of the V_2O_x/TiO_2. The water washing of the used catalyst after treatment with NH_3 was found to be a preferable regeneration method for the prevention of the V_2O_x leaching. By this method the SO_x fixed on the catalysts could be recovered as $(NH_4)_2SO_4$. It was found that sulfates deposited on the catalysts are amorphous and can be regarded as being a mixture of NH_4HSO_4 and $(NH_4)_2SO_4$. It was also found that these sulfates reacted with NO_x and did not react with SO_x.

Although, the amount of NH_3 for the complete removal of SO_x and NO_x without leakage of NH_3 for a given flue gas could not be theoretically predicted, it was experimentally confirmed that for the NO_x-rich flue gas, SO_x and NO_x could be completely removed without the leakage of NH_3. For the SO_x-rich flue gas, the use of (V_2O_x/AC+V_2O_x/TiO_2) or V_2O_x/TiO_2 /AC may be suitable. Furthermore, we already found another type catalyst containing Cr_2O_3 for SO_x-rich flue gas.[19] Details of the characteristics of this catalyst will be reported later.

(Received October 8, 1988)

The dielectric solvent effect on the ^{29}Si NMR chemical shifts of some chlorosilanes is calculated by means of the finite perturbation theory within the CNDO/2 framework using the solvaton theory which is employed to estimate specific solute-solvent bonded interactions as a function of the dielectric constant of the medium. The calculated variations are reasonably compared with the gross trend of the observed solvent effects of ^{29}Si chemical shifts. Further, the origin of the dielectric solvent effect is discussed.

Chemical shift in NMR is known to be solvent dependent. ^{13}C NMR chemical shifts in various solvents have been observed and have been well-interpreted theoretically by means of the "solvaton"-MO theory.[1] The polar effects of aprotic solvents on nuclear shielding may be accounted for by means of an imaginary particle called the "solvaton" model.[2-4] This has been successfully employed in the calculation of solvent effects on ^{13}C chemical shifts in a number of molecules.[5-7] According to our best knowledge, there is little systematic calculation by sophisticated methods of solvent effect on ^{29}Si chemical shift considered here.

Therefore, the above approach can be extended to ^{29}Si chemical shifts of some organic compounds containing silicon atom.[8] The purpose of this work is to measure the ^{29}Si NMR chemical shifts of chlorosilanes in various kinds of solvents over a wide range of dielectric constants. Further, we aim to study theoretically dielectric solvent effects on ^{29}Si chemical shifts of chlorosilanes by the finite perturbation theory (FPT)[6] within the CNDO/2 framework.[9] For this, the solvaton model has been employed to study the effect of solvation on the screening of this nucleus in aprotic solvents. It is anticipated that its model may provide a substantial insight into the effects of solute-solvent interactions on the experimentally observed chemical shifts.

Theoretical

For convenience, we describe briefly the "solvaton" theory. In this theory it is assumed that (1) a number of charges (the "solvaton") are induced in the solvent when a solute is infinitely diluted with an aprotic solvent of dielectric constant, ε; and (2) one solvaton is associated with each atomic center of the solute molecule and its charge is equal in magnitude but opposite in sign; and (3) there are no interactions between them. From these assumptions it follows that the strength of the interaction between the solute and the "solvaton" depends on the polar nature of the solvent. The Hamiltonian, H, of the specified molecular system with M electrons and N nuclei consists of the inherent term, H_{inh}, and the solvent interaction term, H_{solv}, and is given as (in atomic units)

$$H = H_{\mathrm{inh}} + H_{\mathrm{solv}}, \tag{1}$$

where

$$H_{\mathrm{inh}} = \sum_{i=1}^{M}\left[-\frac{1}{2}\nabla_i^2 - \sum_{n=1}^{N}\frac{Z_n}{r_{ni}}\right] + \frac{1}{2}\sum_{i}^{M}\sum_{j}^{M}\frac{1}{r_{ij}} + \frac{1}{2}\sum_{k}^{N}\sum_{l}^{N}\frac{Z_k Z_l}{r_{kl}}, \tag{2}$$

$$H_{\mathrm{solv}} = \frac{(\varepsilon-1)}{2\varepsilon}\left[\sum_{i}^{M}\sum_{s}^{N}\frac{Q_s}{r_{si}} - \sum_{k}^{N}\sum_{s}^{N}\frac{Q_s Z_k}{r_{sk}}\right], \tag{3}$$

in which Q_s is the induced "solvaton" charge, r_{si} and r_{sk} are the "solvaton"-electron and "solvaton"-nucleus distances respectively, and Z_i is the nuclear charge. The first term in Eq. 3 is the interaction energy of the electrons and the induced solvent charges while the last term represents the interaction energy between the induced solvent charges (solvaton) and the nuclear core charges. The function of the solvent dielectric constant, $(\varepsilon-1)/2\varepsilon$ determines the degree of solvent-solute interaction. In these calculations, if the AO's and "solvaton" are associated with the same atomic center as the "solvaton"-electron distance r_{si}, the van der Waals radius of the particular atom type is used and if the AO's and "solvaton" are associated with different atomic centers, the "solvaton" is assumed to be centered on the atomic center associated with S and then r_{si} is evaluated. The solvent interaction was incorporated into the FPT-CNDO/2 method proposed by Pople et al.[9,10] As the effective van der Waals radius of silicon atom, 2.00 Å is used.[11] The detail of the calculation is described elsewhere.[1,4]

In this calculation, values used for bond lengths were 2.01, 1.87, 1.48, and 1.09 Å for the Si-Cl, Si-C,

Si-H, and C-H, respectively, and all the ∠C-Si-Cl, ∠Cl-Si-Cl, ∠H-Si-Cl, and ∠Si-C-H bond angles were set at 109.47°.[12] All calculations were carried out by means of a FACOM VP-30 computer at the Computer Center of Kanagawa University, a HITAC M-280H computer of the Tokyo Institute of Technology, and a HITAC S810 computer at the Institute for Molecular Science, Okazaki.

Experimental

All of chlorosilanes, $(CH_3)_3SiCl$, $(CH_3)_2SiCl_2$, $(CH_3)SiCl_3$, $(CH_3)_2HSiCl$, $(CH_3)HSiCl_2$, $HSiCl_3$, and $SiCl_4$ were commercially available spectral-grade products. Solvents used were dried under usual precautions and distilled under an atmosphere of nitrogen: Hexane (ε=1.9), carbon tetrachloride (ε=2.23), chloroform (ε=4.6), tetrahydrofuran (ε=7.39), and acetone (ε=20.7), where the value of the dielectric constant at 20 °C is indicated in parenthesis.[13]

The ^{29}Si NMR spectra were measured by means of a JEOL FX90Q spectrometer operating at 17.75 MHz equipped with a Fourier transform accessory. The measurements were made using the 20% (v/v) solutions of the above-mentioned solvents for chlorosilanes at the probe temperature of 22.4 °C in a 10 mm o.d. NMR tube, and deuterated benzene and tetramethylsilane sealed off in a 5 mm o.d. capillary were used as ^2D lock and an external reference. The observed free-induction decay after a 45° pulse width of 7.0 μs was sampled in 8192 data points and the pulse recycle time was 20 s. The ^{29}Si chemical shift was corrected for bulk magnetic susceptibility.[14] The bulk magnetic susceptibility for a solution, X_{soln}, is given as

$$X_{soln} = \sum_i^n \phi_i X_i, \quad (4)$$

where ϕ_i and X_i are the volume fraction and the bulk magnetic susceptibity of the i-th component molecule in solution, respectively.

Results and Discussion

Observed dielectric solvent effect of NMR chemical shift: The observed ^{29}Si chemical shifts of chlorosilanes in various solvents are plotted as a function of $(\varepsilon-1)/2\varepsilon$ in Fig. 1.

The factor $(\varepsilon-1)/2\varepsilon$ was chosen as abscissa because the chemical shielding is found to be proportional to $(\varepsilon-1)/2\varepsilon$ as described previously.[1] $(CH_3)_2SiCl_2$, $(CH_3)_3SiCl$, $(CH_3)SiCl_3$, $(CH_3)_2HSiCl$, $(CH_3)HSiCl_2$, and $HSiCl_3$ chlorosilanes show linearly downfield shift with increasing $(\varepsilon-1)/2\varepsilon$, but the chemical shift of $SiCl_4$ is almost independent of ε. This indicates that ^{29}Si chemical shift is linearly proportional to $(\varepsilon-1)/2\varepsilon$ as well as in the case of ^{13}C chemical shift. The observed ^{29}Si shifts for chlorosilanes can be fitted approximately by

$$\delta = A\left(\frac{\varepsilon-1}{2\varepsilon}\right) + B. \quad (5)$$

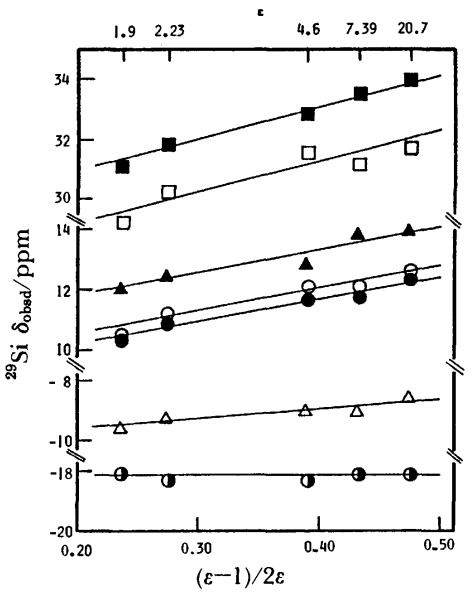

Fig. 1. Dependence on dielectric constant e of the observed ^{29}Si NMR chemical shifts δ in chlorosilanes. The positive sign means downfield shift. The sysmbols used refer to the following compounds: $(CH_3)_2SiCl_2$ (■),$(CH_3)_3SiCl$ (□), $(CH_3)SiCl_3$ (▲), $(CH_3)_2HSiCl$ (○),$(CH_3)HSiCl_2$ (●), $HSiCl_3$ (△), $SiCl_4$ (◑). The straight line was obtained by the linear least-squares fitting.

Table 1. The Variation of the Observed ^{29}Si Chemiccal Shift in Chlorosilanes as in Going from ε=1.9 to 20.7

Compound	Parameter/ppm[b]			
	$\Delta\delta_{obsd}$/ppm[a]	A_{obsd}	B_{obsd}	r[c]
$(CH_3)_3SiCl$	2.3	9.8	27.2	0.93
$(CH_3)_2SiCl_2$	2.8	11.8	28.3	0.99
$(CH_3)SiCl_3$	1.9	7.7	10.2	0.96
$(CH_3)_2HSiCl$	1.9	8.0	8.8	0.97
$(CH_3)HSiCl_2$	1.8	7.8	8.6	0.99
$HSiCl_3$	0.8	3.4	−10.4	0.91
$SiCl_4$	ca. 0	ca. 0	−18.2	0.2

a) $\Delta\delta_{obsd}=\delta_{obsd}(\varepsilon=20.7)-\delta_{obsd}(\varepsilon=1.9)$. A valus of δ_{obsd} corresponds to the linear least-squares fitting. The positive sign means downfild shift. b) The parameters are given by $\delta_{obsd}=A((\varepsilon-1)/2\varepsilon)+B$. c) Correlation coefficient.

The observed data fall approximately on a straight line plot of δ against $(\varepsilon-1)/2\varepsilon$. The magnitude of A provides a measure of the solvent effect on δ, whereas B is the value of δ in an isolated molecule. The parameters A and B can be obtained from the linear least-squares fitting. The variation of the observed ^{29}Si chemical shift ($\Delta\delta_{obsd}$) and the estimated values of parameters A_{obsd} and B_{obsd} for chlorosilanes in going from ε=1.9 to 20.7 are summarized in Table 1.

As seen from Table 1, the ^{29}Si chemical shifts of these compounds give an excellent correlation coefficient except for $SiCl_4$. The value of A_{obsd} for ^{29}Si nucleus is positive except for $SiCl_4$. This means that

the trend of the solvent effect is downfield shift. The observed chemical shift values cover a range from 0 ppm to 2.8 ppm with respect to hexane (ε=1.9).

Calculated dielectric solvent effect: Let us discuss the ^{29}Si chemical shift in chlorosilanes calculated as a function of ε by the CNDO/2 MO method using the "solvaton" theory. The results of the calculation of electron density (d), screening constants (σ^d, σ^P, and $\sigma^T(=\sigma^d+\sigma^P)$), chemical shift difference ($\Delta\sigma_{calcd}$), and correlation parameter (A_{calcd}) as a function of dielectric constant, are presented in Table 2.

Note that the calculated chemical shift (σ) is a nuclear shielding constant and so the negative sign means deshielding. On the other hand, the negative sign of the observed chemical shift (δ) means shielding. Therefore, the relative difference in the calculated chemical shift should be compared with the observed chemical shift. As seen from Table 2, the diamagnetic term, σ^d, moves slightly up-field in going from ε=1.0 to 20.7 for all compounds. This variation is consider-

Table 2. Dependences of the Calculated ^{29}Si Chemical Shifts and Correlation Parameters of Chlorosilanes and Electron Density on the Silicon Atom upon Dielectric Constant

	20.7	3.6371	69.22	−394.23	−325.01	0.90	

a) Dielectric constants are employed (20 °C): Isolated molecule (ε=1.0), hexane (ε=1.9), carbon tetrachloride (ε=2.23), chloroform (ε=4.6), tetrahydrofuran (ε=7.39), and acetone (ε=20.7). b) $\sigma^T=\sigma^d+\sigma^P$. c) Calculated chemical shifts converted to the hexane scale. The positive sign means downfield shift. d) The parameter is given by $\sigma^T=A((\varepsilon-1)/2\varepsilon)+B$.

ably small. On the other hand, the paramagnetic term, σ^P, moves linearly downfield in going from ε=1.0 to 20.7. This means that the solvent effect of the ^{29}Si chemical shift is predominantly governed by the variation of the paramagnetic term.

It would be interesting to compare these calculated value with some observed data. The same relationship (Eq. 5) as the case of the observed data is also found in the calculated data. This agreement implies that there are no specific interactions between chlorosilanes and solvent molecules. This table has two features for the calculated solvent-induced shifts. First, we discuss the solvent-induced ^{29}Si chemical shift variations of $(CH_3)_3SiCl$, $(CH_3)_2SiCl_2$, $(CH_3)SiCl_3$, and $SiCl_4$ series. The magnitude of the calculated solvent-induced shift becomes larger in the order of $SiCl_4$ (A_{calcd}=3.77)< $(CH_3)SiCl_3$ (A_{calcd}=4.73)<$(CH_3)_2SiCl_2$ (A_{calcd}=5.56)< $(CH_3)_3SiCl$ (A_{calcd}=7.03) as ε increases from 1.9 to 20.7. This means that as the number of substituted chlorine atoms is decreased, the value of parameter A_{calcd} is increased. The calculated results reproduce qualitatively the observed trend except for $(CH_3)_2SiCl_2$. Especially, for $SiCl_4$ the calculated chemical shift variation shows the smallest value compared with all the other compounds in going from ε=1.9 to 20.7. This result agrees qualitatively with the trend of the observed one. Therefore, it can be said that this is inactive in various solvent. The above results can be understood from the observed facts that the magnitude of dipole moment μ for these compounds[15] becomes in the order of $SiCl_4$ ($\mu\simeq$0)<$(CH_3)SiCl_3$ (μ=1.87)<$(CH_3)_2SiCl_2$ (μ=1.89)< $(CH_3)_3SiCl$ (μ=2.09) and therefore the magnitude of reaction field becomes in the same order. This means that the reaction field plays an important role in the solvent effect of ^{29}Si chemical shifts. Next, we discuss the solvent-induced ^{29}Si chemical shift variation of $(CH_3)_2HSiCl$, $(CH_3)HSiCl_2$, $HSiCl_3$, and $SiCl_4$ series. The magnitude of parameter A_{obsd} for them become larger in the order of $SiCl_4$<$HSiCl_3$<$(CH_3)HSiCl_2$ <$(CH_3)_2HSiCl$. The calculated results (A_{calcd}) reproduce this result. The calculated results[16] of their dipole moment show that the value of the dipole moment is increased in the order of $SiCl_4$ (μ=0)< $HSiCl_3$ (μ=1.0)<$(CH_3)HSiCl_2$ (μ=1.7)<$(CH_3)_2HSiCl$ (μ=1.8) as the number of substituted chlorine atoms is increased (the experimental data are unknown). Therefore, the above results can be explained reasonably by the same reason as the case of the first compound series.

Finally, we will consider the relationship between the ^{29}Si chemical shift and electron density as a function of the dielectric constant of the medium. In the previous work,[8] it is shown that the ^{29}Si chemical shifts move roughly downfield as an increase of the electron density on the silicon atom. The direction of such a shift is opposite to general consideration[14] that the increase of electron density leads to upfield shift. As seen from Table 2, the electron density on the silicon atom in the molecules considered here increase with an increase of ε. According to general consideration, this leads to upfield shift with an increase in ε. However, this is in disagreement with the observed results. Thus, it is apparent that such arguments must be done by the direct calculation of the ^{29}Si chemical shift as above mentioned.

From the above results, it can be concluded that the general trend found in this work would suggest the potential applicability of the FPT-CNDO/2 calculation with the "solvaton" model in interpreting solvent effects in aprotic polar media which influence ^{29}Si chemical shift.

Inhibiting Effects of Ethanethiol, Dimethyl Sulfide, and Dimethyl Disulfide on the Corrosion of Stainless Steel (405) in Sulfuric Acid

Jalal Mohammed SALEH*,† and Yousif Kadim AL-HAIDARI
Department of Chemistry, College of Science, University of Baghdad, Baghdad, Jadiriya, Republic of Iraq
(Received February 19, 1988)

The corrosion behavior of stainless steel (405) specimen in 5 M H_2SO_4 solution has been investigated potentiostatically at four temperatures in the range 303—323 K. The inhibiting effects of ethanethiol (EtSH), dimethyl sulfide (Me_2S), and dimethyl disulfide (Me_2S_2) have thereafter been tested for four inhibitor concentrations of 0.5, 1, 5, and 10 mmol dm^{-3}. The sulfur compound addition to the H_2SO_4 solution caused a shift, mainly in the cathodic direction, of the corrosion potential, the electrode potential at low current densities as well as of the linear section of the cathodic Tafel line. The protection efficiency of each sulfur compound was determined at various temperatures and inhibitor concentrations. The sulfur compound acted as a corrosion inhibitor in the H_2SO_4 solution through adsorption on the stainless steel surface. The kinetic results, operating through a compensation effect, could well account for the variation of the inhibiting capacities of the various sulfur compounds. The results indicated that inhibition process involved the shift of the stainless steel corrosion to those surface sites which are associated with progressively higher energy of activation. EtSH was the most efficient of the three sulfur compounds for inhibiting the corrosion of the stainless steel in H_2SO_4 solution.

There have been a number of corrosion and corrosion inhibition investigations on various types of stainless steel in the acid media.[1-7] The majority of the previous literature was devoted to the effect of the type of stainless steel on the polarization behavior of this alloy in the corrosion medium, as well as to the ability of organic compounds in general to inhibit the steel corrosion.[8-10]

Organic sulfur compounds have widely been used as inhibitors for the corrosion of various iron alloys.[11-15] The literature in this respect discusses some effects of such inhibitors which could result in the corrosion inhibition, and these involved:

(i) altering the nature of the corrosion product;

(ii) changing the type and the extent of adsorption of the inhibitor on the electrode surface, and;

(iii) rearranging the corrosion current and potential.

There are several other aspects of the corrosion inhibition which are still lacking. Among such aspects are the thermodynamics of the feasibility of inhibition and the kinetics of the corrosion in the presence and absence of the inhibitor in the corrosion medium, and these need careful attention and thorough investigation.

The present research involves the potentiostatic study of the corrosion of a stainless steel specimen (type 405) in 5 M H_2SO_4 (1 M=1 mol dm^{-3}) at four temperatures in the range 303—323 K. The protection efficiencies of three sulfur compounds have been studied at the four experimental temperatures using four concentrations of the inhibitor over the range 0.5 to 10 mmol dm^{-3}. An attempt was made to predict the thermodynamic feasibility of inhibition from the coverages of the stainless steel surface by the adsorbed inhibitor. The effect of the inhibitor on the kinetics of the stainless steel corrosion was also attempted from the rates of corrosion under various experimental conditions.

Experimental

The stainless steel (405) specimen had the following composition as revealed by emission spectroscopic analysis:

element :	Cr	Al	C	Mn	Si	P	S
Wt% :	11.5	0.1	0.08	1.0	1.0	0.04	0.03

Cylinderical working electrodes were made of 8.5 mm thickness and 12.7 mm diameter. The surface of each electrode was carefully polished and then degreased and washed as described earlier.[16] A tight fitting Teflon sleeve was fitted over one end of the stainless steel electrode to expose an apparent surface area of about 1.0 cm^2 of the stainless steel. The surface preparation procedure was shown to give reproducible polarization curves, with an error in corrosion current density of less than 0.1%. The surface area of the electrode was determined by measuring all dimensions to the nearest 0.01 mm and subtracting the area under the Teflon gasket. A two-dimensional measuring microscope (Pye 6147 M) was used for area measurements.

The experimental cell which had a working compartment capacity of 750 cm^3 contained the stainless steel electrode and two platinum auxiliary electrodes and a saturated calomel electrode connected through a Luggin capillary bridge. The cell compartment was provided with a stirror and arrangements for bubbling gases through the cell solution. Before each experiment, the solution was deaerated by bubbling highly pure nitrogen gas for 2 h. The cell solution was prepared from triply distilled water and Analar grade H_2SO_4. Ethanethiol (EtSH), dimethyl sulfide (Me_2S), and dimethyl disulfide (Me_2S_2) were purum grades, obtained from Fluka, with a purity exceeding 99.5%.

The potential-current curves were plotted[16] using 'corrosoript' obtained from Tacussel electronique, which was composed of a potentiostat, an electronic millivoltmeter and

† Saddam University for Engineering and Science, College of Science, Baghdad, Jadiriya, P.O. Box 47077, Iraq.

a chart recorder. The potentiostat had an output voltage of ±10 V, output current of ±500 mA and a response time of 2—3 μs. The recorder enabled the working electrode current to be recorded in either linear or logarithmic coordinates.

Both the cathodic and anodic current-potential curves were obtained with decreasing and increasing polarization and this was repeated several times. The potential scan began initially 1 h after the specimen immersion in the acid solution, beginning at about −1.5 V and proceeded through to 1.0 V versus a saturated calomel electrode. A potentiodynamic potential sweep rate of 15 mV min^{-1} was used recording the current continuously with the change of potential.

Corrosion current densities (i_{corr}) and corrosion potentials (E_{corr}) were calculated from the polarization curves. The linear logarithmic sections of the cathodic and anodic Tafel lines were extrapolated to the point of intersection from which both i_{corr} and E_{corr} were determined.

Results and Discussion

Corrosion Potential (E_{corr}). Table 1 shows the variation of E_{corr} for the stainless steel specimen in 5 M H_2SO_4 solution with temperature and inhibitor concentration. Values of E_{corr} for the stainless steel in the acid solution in the absence of the inhibitor shifted to less negative values with increasing temperature from 303 to 323 K. E_{corr} generally shifted to more negative values with increasing inhibitor concentration in the case of Me_2S and Me_2S_2 at all the experimental temperatures. A similar behavior was observed with EtSH over the concentration range 0.5—1.0 mmol dm^{-3} at 313 and 323 K; at 303 and 308 K the shift of E_{corr} with increasing EtSH concentration was towards less negative values. A similar trend was detected with ethanethiol at 313 and 323 K over the concentration variation from 5 to 10 mmol dm^{-3}.

Tafel Slope. The influence of the inhibitor concentration on the current-potential polarization curve for the stainless steel in the H_2SO_4 solution may be summarized as:

1. The electrode potential at low current densities shifted considerably relative to the values in the absence of the inhibitor. The shift was generally towards more cathodic direction except in the case of EtSH at 303 and 308 K for all inhibitor concentrations and at 313 and 323 K for 5—10 mmol dm^{-3} where the shift was in the anodic direction (Table 1).
2. The linear part of the cathodic Tafel lines shifted parallel with respect to the original line in the absence of the inhibitor. The shift was generally in the cathodic direction (Fig. 1).
3. The Tafel lines generally maintained their linearity and slope at all inhibitor concentrations and temperatures.

The first two effects (1 and 2) indicate that all the three sulfur compounds had significant effects on the hydrogen evolution reaction. The transfer coefficient (β) which was calculated from the Tafel slope had values close to 0.5 (Table 2) in agreement with the generally accepted values of this parameter.[17,18] This suggests that sulfur compound adsorption in the double layer does not change the mechanism of hydrogen evolution reaction despite its effect on the rate. This probably indicates that the sulfur compounds which have been used as inhibitors in the present work act through adsorption on the stainless steel surface.[10,19,20]

a) R_p is expressed in cm^{-2}.

Polarization Resistance. The polarization resistance (R_p) may be taken as a measure of the efficiency of the sulfur compounds to operate as corrosion inhibitors for the stainless steel in the H_2SO_4 solution, where

$$R_p = d(E-E_{corr})/di \quad (1)$$

where E and E_{corr} are in V, i in A cm^{-2}, and R_p in Ω cm^{-2}. For small polarization, values of $(E-E_{corr})$ are proportional to the current density i. Such a relationship was found in the present work to exist for the low cathodic polarization region where $(E-E_{corr})<20$ mV. This is an indication for the fact that some stage in the discharge of hydrogen ions at the electrode should be the rate-determining process. Figure 2 shows the relationship between such small $(E-E_{corr})$ values and the corresponding values of i, for the polarization in the absence and the presence of the inhibitors. Values of R_p have been derived from the slopes of various plots in Fig. 2 and these are presented in Table 2.

Protection Efficiency. The protection efficiency (P) of the sulfur compounds, operating as inhibitors, could be calculated from equation:[15,16,21]

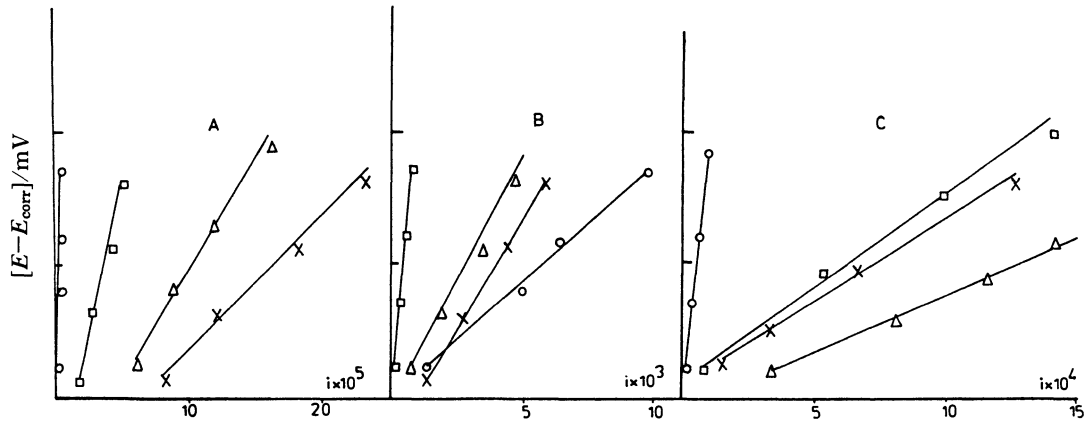

Fig. 2. Values of $(E-E_{corr})$ plotted against the current density (i) for low cathodic polarization of the stainless steel (405) in 5 M H_2SO_4 at 303 K. Symbols ○, ×, △, and □ refer respectively to inhibitor concentrations of zero, 1, 5, and 10 mmol dm^{-3}. Other symbols (A, B, and C) as in Fig. 1.

Table 3. Effect of Inhibitor Concentration (C) at Three Temperatures on the Values of the Protection Efficiency (P) of the Various Inhibitors in the 5 M H_2SO_4 Solution of the Stainless Steel Specimen

C / mmol dm^{-3}	P								
	303 K			313 K			323 K		
	EtSH	Me_2S	Me_2S_2	EtSH	Me_2S	Me_2S_2	EtSH	Me_2S	Me_2S_2
0.5	54.7	23.4	40.2	19.3	4.5	19.0	10.2	8.5	21.1
1.0	97.1	44.3	77.9	40.6	8.0	34.1	22.0	13.6	46.4
5.0	98.8	62.6	82.2	99.3	40.6	54.7	40.7	44.1	70.8
10.0	99.4	88.7	88.9	99.5	79.2	79.1	97.3	73.7	72.4

$$P=100[1-(i_c)_2/(i_c)_1] \quad (2)$$

where $(i_c)_1$ and $(i_c)_2$ are respectively the corrosion current densities (i_{corr}) for the stainless steel in the absence and the presence of the sulfur compound in the acid solution at the same temperatures; $(i_c)_1$ and $(i_c)_2$ are assumed to be proportional respectively to the corrosion rates under similar experimental conditions in the absence and the presence of the inhibitor in the corrosion medium.[22] Values of P that have been calculated, for the three sulfur compounds, from the data of Table 1 are indicated in Table 3.

Values of P generally increased at all the experimental temperatures with increasing concentration of the inhibitor (Table 3). The highest protection efficiency (P_h) of the sulfur compounds was attained at 303 K, as well as at 313 K in the case of EtSH, and corresponded to inhibitor concentration of 10 mmol dm^{-3}. P_h values of the three sulfur compounds could be arranged in the order: EtSH>Me_2S_2>Me_2S. Values of P at 303 K remained relatively high for EtSH even at 1 mmol dm^{-3} and the values of P for this inhibitor at this temperature showed the least dependence on the inhibitor concentration. The least dependencies on the inhibitor concentration were observed with EtSH and Me_2S at 313 and 323 K. At 10 mmol dm^{-3} of either Me_2S and Me_2S_2 in the acid solution, P became higher at 313 K than the values at 323 K in contrast to the behavior at 1 and 5 mmol dm^{-3}. Values of P decreased only slightly in the case of EtSH at 10 mmol dm^{-3}, while the decrease of P for this inhibitor was sharp and substantial at 1 and 5 mmol dm^{-3} beginning at 303 K in the former case and at 313 K at the latter inhibitor concentration. The decrease of P with temperature for Me_2S and Me_2S_2 was gradual at 10 mmol dm^{-3}, but the decrease at the other inhibitor concentrations was rather sharp over the range 303—313 K increasing thereafter on raising the temperature to 323 K (Table 3).

Inhibitor Adsorption. The coverage (θ) of the stainless steel surface by the adsorbed inhibitor was estimated from the current densities at constant potential in the presence (i_2) and absence (i_1) of the inhibitor in the acid solution using the equation:[15,23]

$$\theta=1-(i_2)/(i_1) \quad (3)$$

Table 2 gives the calculated values of θ for the various inhibitors at different experimental temperatures and inhibitor concentrations. At any experimental temperature, θ increased with increasing inhibitor concentration. On the other hand, values of θ, at a given inhibitor concentration, decreased with the rise of the temperature from 303 to 323 K.

The manner in which the values of θ for each inhibitor varied at a constant temperature with the concentration (C) of the inhibitor conformed to Langmuir

adsorption isotherm which may be put as:

$$\frac{C}{\theta} = \frac{1}{b} + C \quad (4)$$

A plot of C/θ values against the corresponding values of C was found to be linear with respect to each inhibitor as seen in Fig. 3. The values of b for each sulfur compound could be estimated from the reciprocal of the intercept of the appropriate plot in Fig. 3. Table 4 gives values of b for the various sulfur compounds which have been utilized as inhibitors for the corrosion of the stainless steel in the H_2SO_4 solution.

The parameter b in Eq. 4 may be defined as:[24,26]

$$b = a \exp(-\Delta H_a/RT) \quad (5)$$

where ΔH_a is the heat of inhibitor adsorption on the stainless steel surface and a is a constant.[24] A plot of $\log b$ versus $1/T$ for each sulfur compound should result in a straight line if a and ΔH_a remained constant over the experimental temperature range as was found with the present results indicated in Fig. 4. Values of ΔH_a for the temperature range 303—323 K have been derived for the various inhibitors from the slopes of the plots in Fig. 4 and these have been listed in Table 4. Values of ΔH_a are shown (Table 4) to be all negative reflecting the exothermic behavior of the inhibitor adsorption on the stainless steel surface. The magnitude of ΔH_a is less negative in the case of Me_2S as compared with the remaining two sulfur compounds. This is an indication for the stronger inhibitor adsorption in the case of EtSH and Me_2S_2 as compared with that of Me_2S. This result well agrees with that presented in Table 3 for the variation of the protection efficiency of the inhibitors with concentration; values of P are shown in Table 3 to be generally higher for EtSH and Me_2S_2 at all inhibitor concentrations than of Me_2S.

The parameter b, given in Eq. 4 represents the equilibrium constant for the adsorption/desorption processes of the inhibitor on the stainless steel surface and could be expressed as;[24]

$$b = \exp(-\Delta G_a/RT) = \exp(\Delta S_a/R)\exp(-\Delta H_a/RT) \quad (6)$$

where ΔG_a, ΔS_a, and ΔH_a are respectively the changes in the free energy, entropy, and enthalpy of the inhibitor adsorption on the stainless steel surface. Values of

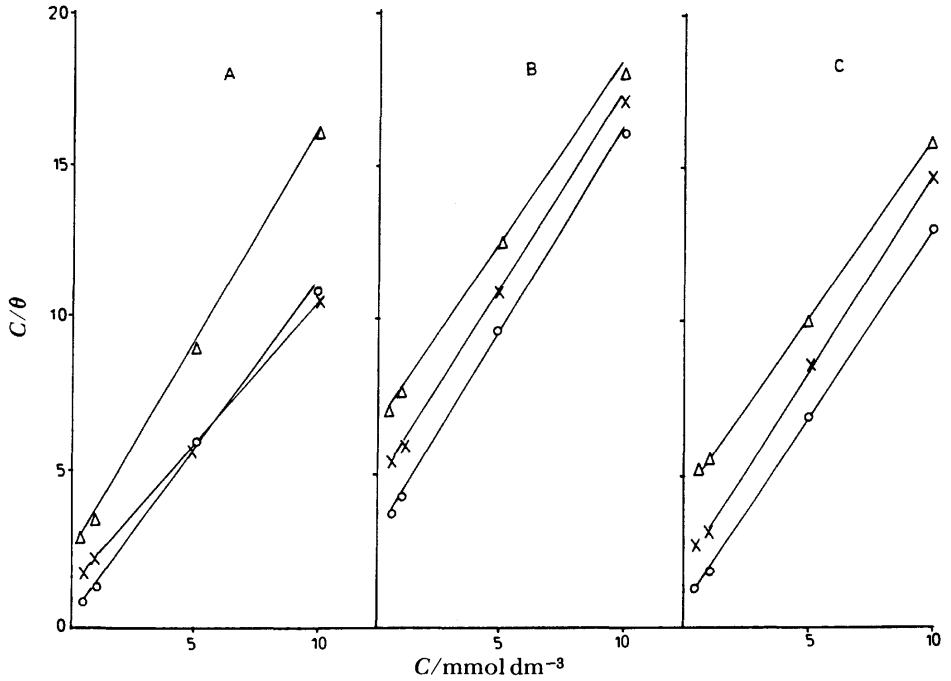

Fig. 3. Langmuir adsorption isotherms plotted as C/θ versus C for the three inhibitors at 303 (○), 313 (×), and 323 K(△).

Table 4. Values of b, ΔG_a (kJ mol^{-1}), ΔH_a (kJ mol^{-1}), and ΔS_a (J K^{-1} mol^{-1}) for the Adsorption of the Inhibitors on the Stainless Steel Specimen at Three Temperatures, in the Range 303—323 K

T	EtSH				Me_2S				Me_2S_2			
K	b	$-\Delta H_a$	$-\Delta G_a$	$-\Delta S_a$	b	$-\Delta H_a$	$-\Delta G_a$	$-\Delta S_a$	b	$-\Delta H_a$	$-\Delta G_a$	$-\Delta S_a$
303	2857		20	184	328		14.6	153	1432		18.3	185

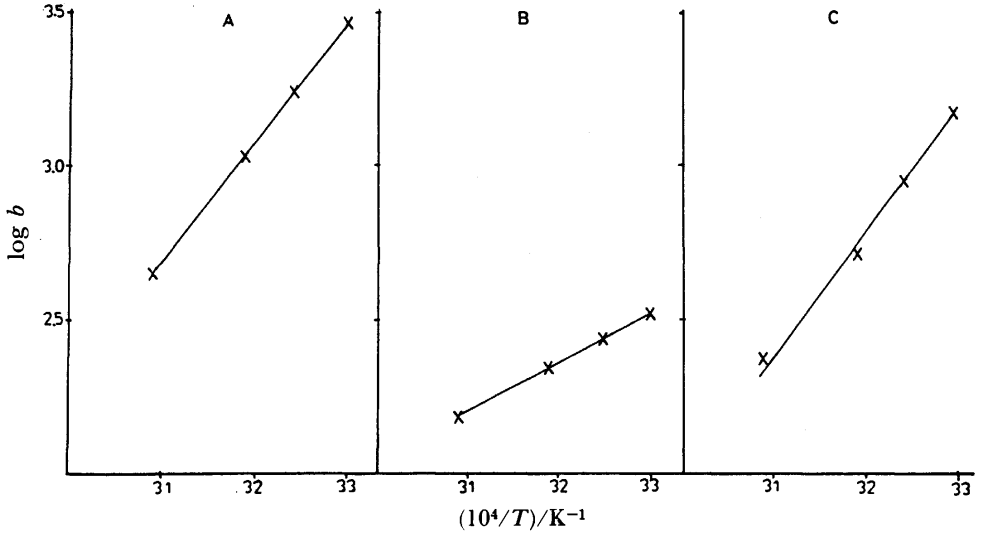

Fig. 4. Values of $\log b$ plotted versus $1/T$ for the three inhibitors in the stainless steel/sulfuric acid system.

ΔH_a have previously been derived from the plots of Fig. 4 which have been presented in Table 4. Using values of b and ΔH_a from Table 4 at each of the four experimental temperatures in the range 303—323 K, it was possible to deduce the corresponding values of ΔG_a and ΔS_a and these have been inserted in Table 4. Values of ΔG_a indicate inhibition of the stainless steel corrosion in the H_2SO_2 solution by the sulfur compounds became less favorable as the temperature increased from 303 to 323 K. This conclusion generally agrees with the results of Table 3 where the values of P were higher at 303 K than at the higher temperatures. The overall changes in ΔG_a and ΔS_a over the temperature range 303—323 K are shown in Table 4 to be almost the same for both EtSH and Me_2S_2 and the values are more negative than for Me_2S. The less negative values of ΔS_a for Me_2S than for EtSH and Me_2S_2 should reflect a far less decrease in the degrees of freedom subsequent to adsorption on the electrode surface in the case of the former inhibitor than of the latter two sulfur compounds. This suggests a weaker adsorbed species as a consequence of Me_2S adsorption on the stainless steel than those resulting throughout adsorption of EtSH or Me_2S_2.

Kinetics of Corrosion. The rate (r) of the stainless steel corrosion in the H_2SO_4 solution increased generally with the rise of the temperature from 303 to 323 K, and the behavior followed Arrhenius equation:

$$r = A \exp(-E/RT) \quad (7)$$

where A and E are respectively the preexponential factor and the energy of activation. Due to the linearity of the Tafel slope segment of the current-potential polarization curve, the value of r in Eq. 7 was taken to be directly proportional to the corrosion current density (i_{corr}) through such relation as:[21]

$$r = 0.13(\theta/d)i_{corr} \quad (8)$$

where θ is the equivalent weight of the metal and d its density. Using the appropriate conversion factor, the values of i_{corr} at each temperature could be converted into rate (i) in units of 'atom cm^{-2} s^{-1}'. Figure 5 shows Arrhenius plots for the blank (absence of inhibitor) and various inhibitor concentrations; values of E and A have been derived from the slopes and intercepts of the plots respectively. Table 5 gives the resulting values of E and $\log A$ for the corrosion of the stainless steel specimen in the acid solution. Both $\log A$ and E increased smoothly with increasing inhibitor concentration.

A linear relationship was found to exist between the experimental values of $\log A$ and the corresponding values of E which could be expressed as:[27]

$$\log A = mE + l \quad (9)$$

where m and l are respectively the slope and the intercept of the plot in Fig. 6. Such a relationship is termed a 'compensation effect' which is frequently found to describe the kinetics of catalytic and a number of tarnishing reactions on metals.[28-31] Equation 9 shows that simultaneous increases or decreases in E and $\log A$ for a particular system tend to compensate from the standpoint of the reaction rate. A number of interpretations have been offered for the phenomenon of the compensation effect in surface reactions,[32-35] among which the effect could be ascribed to the presence of energetically heterogeneous reaction sites on the metal surface; and the corrosion reaction should therefore occur first on surface sites with low energy of activation and spreading thereafter to those sites where E values are progressively higher.

The activation energy (E) of the stainless steel corrosion in the H_2SO_4 solution in the absence of the inhibitor was 69.5 kJ mol^{-1}; the corrosion should thus be confined to surface sites with such energy of activa-

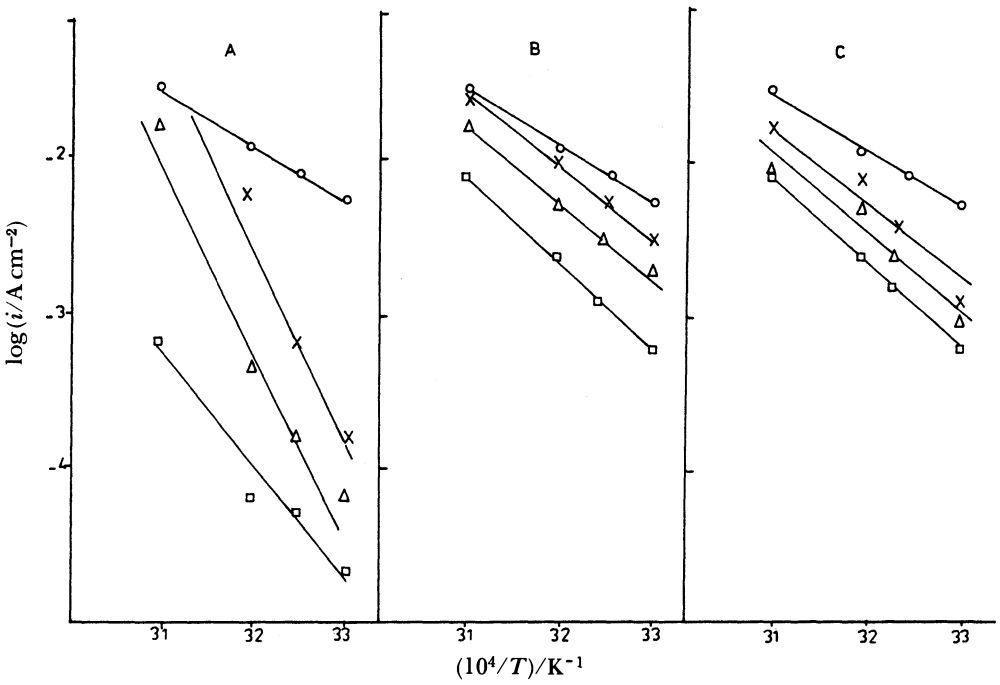

Fig. 5. Arrhenius plots, relating log i_{corr} to $1/T$, for the corrosion of the stainless steel (405) in 5 M H_2SO_4 in the absence and the presence of the inhibitors in the acid. Symbols as in Fig. 2.

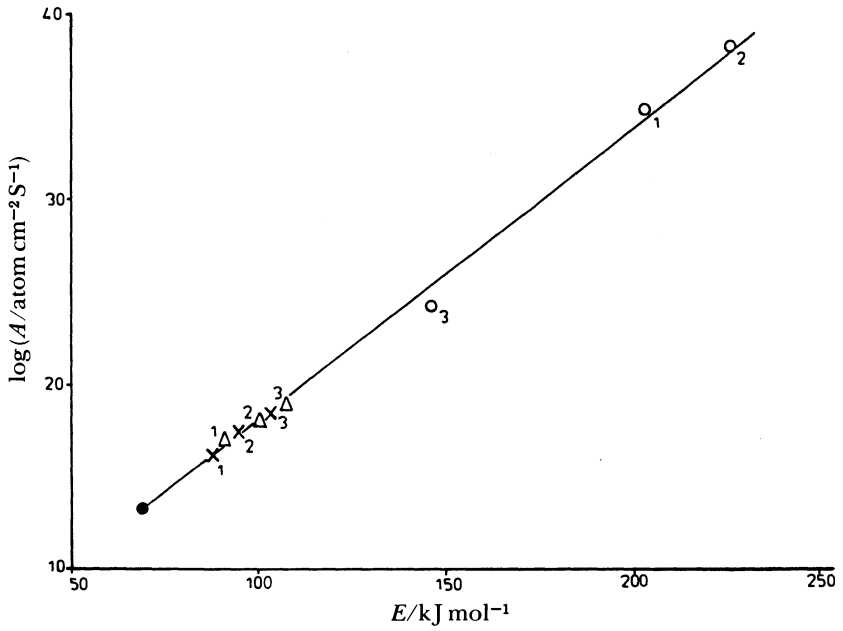

Fig. 6. Variation of the activation energy (E) with the preexponential factor ($\log A$) for the corrosion of the stainless steel (405) in 5 M H_2SO_4. EtSH, O; Me_2S, △; Me_2S_2, ×. Numbers 1, 2, and 3 refer respectively to inhibitor concentrations of 1, 5, and 10 mmol dm^{-3}. ●, corresponds to the value in the absence of the inhibitor.

tion. The presence of the sulfur compound in the acid solution accordingly shifts the corrosion reaction to those sites where E values are greater. The corrosion reaction will further be pushed to surface sites which are characterized with progressively higher values of E as the concentration of the inhibitor in the acid solution became greater.

The results of Fig. 6 and Table 5 reveal the following:

1. For all inhibitor concentrations in the acid, the variation of E values for the three sulfur compounds, followed the sequence:

Table 5. Activation Energies (E) and Preexponential Factors (A/atom cm^{-2} s^{-1}) for the Corrosion of the Stainless Steel Specimen in 5 M H_2SO_4 at Four Inhibitor Concentrations (C)

Inhibitor	C / mmol dm^{-3}	log A	E / kJ mol^{-1}
EtSH	0.0	11.6	69.5
	0.5	32.2	186.5
	1.0	34.7	204.7
	5.0	38.0	227.2
	10.0	24.1	147.0

	0.5	14.8	78.0
	1.0	16.1	87.7
	5.0	16.8	93.6
	10.0	18.2	103.8
Me_2S_2	0.0	11.6	69.5
	0.5	15.4	86.5
	1.0	16.8	91.9
	5.0	17.8	100.5
	10.0	18.7	106.8

$$EtSH > Me_2S_2 > Me_2S$$

This reflects the greatest tendency of the stainless steel for corrosion in the acid solution containing Me_2S as compared with the behavior of the specimen in the presence of EtSH under similar inhibitor concentration and temperature. This conclusion agrees with the protection efficiency results which have been presented in Table 3. The results are also in line with the variation of the ΔG_a values (Table 4) which have been obtained for the inhibitor adsorption on the stainless steel electrode.

2. The dependence of the E and log A values on the inhibitor concentration is seen in Fig. 6 to be far more smaller in the case of Me_2S and Me_2S_2 as compared with that of EtSH.

Molecular Structure Consideration. The tendencies of the sulfur compounds to adsorb on, and hence protect, the stainless steel surface are shown from the kinetic results to decrease from EtSH, through Me_2S_2, to Me_2S. A qualitative explanation of this sequence may be found from the consideration of the electronic structures of these compounds. Each of EtSH and Me_2S has one lone pair of electrons on sulfur while there are two such pairs in Me_2S_2. The lone pairs of electrons on the sulfur atoms are delocalized and hence produce delocalization or resonance energy which stabilizes the sulfur compound.[36] Thus the larger the number of delocalized electrons, the more stable is the charge density on the 'anchoring' atoms (in this case the sulfur) and hence the larger is the strength of adsorption on the metal surface. Comparing Me_2S_2 with Me_2S, one would expect stronger adsorption of the former, and therefore greater inhibition, than of the latter. Furthermore, both Me_2S_2 and Me_2S do not contain hydrogen atoms linked to sulfur as in the case of EtSH. This should produce an additional adsorption tendency for this compound (EtSH) on the electrode surface as compared with the remaining two sulfur compounds.

The organic sulfur compounds which have been dealt with in the present work are classified as toxic substances and can inhibit the catalytic activity of metal surfaces due to the presence of lone pairs of electrons on the sulfur atoms.[37] The poisoning effect results from the formation of strong dative bonds between the toxic molecules and the surface atoms. It has been established that the poisoning effect among a series of alkyl sulfides and disulfides increased by lengthening the chain in these compounds.[38] These facts showed that Me_2S_2 was more toxic than Me_2S and that EtSH behavior was comparable with that of Me_2S_2. This conclusion well agrees with the calculated values of ΔH_a (Table 4) as the heat of adsorption is known to be a good measure of the strength of adsorption on a surface.

Viscosity *B*-Coefficients of Tetraalkylammonium Bromides in 2-Methoxyethanol at 25 °C

Debasis DASGUPTA, Susanta DAS, and Dilip K. HAZRA*
Department of Chemistry, North Bengal University, Darjeeling 734430, India
(Received April 18, 1988)

The relative viscosities of solutions of tetraalkylammonium bromides, R_4NBr, ($R=C_2H_5$ to C_7H_{15}) have been measured in 2-methoxyethanol (ME) at 25 °C. The data have been analyzed in the form of associated electrolytes and the *B*-coefficients have been evaluated. The ionic *B*-values have been determined using the "reference electrolytes" viz. Bu_4NBBu_4 and Bu_4NBPh_4. The results have been discussed on the basis of Einstein's equation and in terms of a transition state treatment.

The potentiality of 2-methoxyethanol (ME) as a solvent for use in nonaqueous batteries and its application in synthesis[1] and electrochemical[2] studies have been widely stressed. These necessitate the study of the transport properties of various ions in this 'quasi-aprotic' medium[3] both conductometrically and viscometrically. The viscometric method is known to give valuable information regarding ion-solvent interactions which are the controlling forces in dilute solutions where ion-ion interactions are absent.[4] The variations of the solvational properties are reflected in the viscosity *B*-coefficients of ions. Although a number of extensive viscometric studies[5,6] have been made in various solvents with different electrolytes, but literature provides no information regarding the viscometric studies of tetraalkylammonium halides in 2-methoxyethanol. This led us to undertake the title investigation and the results are reported in this article.

Experimental

2-Methoxyethanol (G.R.E. Merck) was distilled twice in an all-glass distillation set before use. The properties at 25 °C obtained for the purified sample were 0.96002 g cm^{-3} for the density and 1.5414 cP (1 P=0.1 Pa s) for the viscosity (η_0) and these values are in good agreement with the literature values.[7]

Tetraalkylammonium bromides were of Fluka's purum or puriss grade and purified in the manner as given in the literature[8] and also described by us earlier.[9] The salts were purified by recrystallization and the higher homologues were recrystallized twice to ensure highest purity. The recrystallized salts were dried in vacuum at elevated temperatures for 12 h.

Tetrabutylammonium tetraphenylborate (Bu_4NBPh_4) was prepared by mixing equimolar quantities of $NaBPh_4$ and Bu_4NBr as described in the literature.[10] Tetrabutylammonium tetrabutylborate (Bu_4NBBu_4) (Alfa product) was purified as suggested by Lawrence et al.[11]

The concentration of the salts was generally varied from 0.009 M to 0.05 M (1M=1 mol dm^{-3}) which was prepared by weight dilution of the stock solution (ca. 0.1 M). The conversion of the molality into molarity was done using the density values. The kinetic viscosities were measured at the desired temperature (accuracy ±0.01 °C) using a suspended Ubbelohde-type viscometer. The densities were measured using an Ostwald-Sprengal type pycknometer. The details of the experimental procedure employed have been described previously.[9] The accuracies of the density and viscosity measurements were $\pm 3\times10^{-5}$ g cm^{-3} and 0.01% respectively. The electrical conductivities were measured with a Pye-Unicam conductivity meter (PW 9509) within an accuracy of ±0.1%.

The dielectric constant of ME (ε=16.93) was taken from the literature.[12]

Results and Discussion

The relative viscosities of the electrolytes in solution are generally analyzed by the well-known Jones-Dole equation,[13]

$$(\eta/\eta_0-1)/\sqrt{c}=A+B\sqrt{c}, \quad (1)$$

where η and η_0 are the viscosities of the solution and the solvent respectively and c is the molar concentration.

As these electrolytes have been found to be strongly associated in this solvent from conductivity measurements,[14] so the viscosity data have been analyzed by Eq. 2 as recently done by Feakins et al.[15] instead of Eq. 1,

$$\eta_r=1+A\sqrt{\alpha c}+B_i(\alpha c)+B_p(1-\alpha)c, \quad (2)$$

where, A, B_i, B_p are the characteristic constants and α is the degree of dissociation of the ion pair. The values of ion-pair dissociation constants for the electrolytes were calculated from the conductivity data[14] using the set of equations as described in the literature.[15]

Equation 2 was rearranged to give

$$(\eta_r - 1 - A\sqrt{\alpha c})/\alpha c = B_i + B_p\left(\frac{1-\alpha}{\alpha}\right). \quad (3)$$

The $(\eta_r-1-A\sqrt{\alpha c})/\alpha c$, concentration c, density ρ, and $(1-\alpha)/\alpha$ values of the solutions of different electrolytes at 25 °C are reported in Table 1.

The A-values were calculated theoretically from the physical properties of the solvent and the limiting ionic equivalent conductances[14] using the Falkenhagen and Vernon equation,[16]

$$A_{Theo} = \frac{0.2577\,\Lambda^\circ}{\eta_0(\varepsilon T)^{1/2}\lambda_+^\circ\lambda_-^\circ}\left[1-0.6863\left(\frac{\lambda_+^\circ-\lambda_-^\circ}{\Lambda^\circ}\right)^2\right] \quad (4)$$

Table 1. Density (ρ), Concentration (c), Relative Viscosity (η_r), $(1-\alpha)/\alpha$ and $(\eta_r-1-A\sqrt{\alpha c}\,)/\alpha c$ of Tetraalkylammonium Bromides and the Two Reference Electrolytes viz. Bu_4NBBu_4 and Bu_4NBPh_4 in 2-Methoxyethanol at 25 °C

The A-coefficient values thus obtained have been recorded in Table 2. These A-values have been used for analysis of the data.

The plots of $(\eta_r-1-A\sqrt{\alpha c})/\alpha c$ against $(1-\alpha)/\alpha$ were linear in all cases. The intercept at $(1-\alpha)/\alpha=0$ were taken as the required value of B_i. The B-coefficients (B_i-values) reported in Table 2 for the electrolytes were obtained using the least square method.

Viscosity data have also been analyzed on the basis of the transition state treatment of the relative viscosity of electrolytic solutions as suggested by Feakins et al.[17]

The B-coefficient is expressed by

$$B = \frac{\bar{V}_1^\circ - \bar{V}_2^\circ}{1000} + \frac{\bar{V}_1^\circ}{1000}\left(\frac{\Delta\mu_2^{\circ\neq} - \Delta\mu_1^{\circ\neq}}{RT}\right), \quad (5)$$

where $\bar{V}_1^\circ$ and $\bar{V}_2^\circ$ are the partial molar volumes of the solvent and the solute respectively. $\Delta\mu_2^{\circ\neq}$, the contribution per mole of solute to the free energy of activation for viscous flow of the solution, has been determined from the above relationship. $\Delta\mu_1^{\circ\neq}$, the free energy of activation per mole of the pure solvent, is given by

Table 2. A-Coefficients (Theoretical), B-Coefficients and $\Delta\mu_2^{\circ\neq}$ Values for the Electrolytes in 2-Methoxyethanol at 25 °C

Salt	A	B-Coefficient	$\Delta\mu_2^{\circ\neq}$
	$dm^{3/2}\,mol^{-1/2}$	$dm^3\,mol^{-1}$	$kJ\,mol^{-1}$
Et_4NBr	0.0215	0.231	23.69
Pr_4NBr	0.0244	0.327	28.76
Bu_4NBr	0.0260	0.425	34.09
$(C_5H_{11})_4NBr$	0.0281	0.607	41.76
$(C_6H_{13})_4NBr$	0.0308	0.703	47.01
$(C_7H_{15})_4NBr$	0.0345	1.258	66.26
Bu_4NBBu_4	0.0326	0.609	48.41
Bu_4NBPh_4	0.0201	0.678	50.36

The maximum uncertainty of the B-coefficient is ±0.005. Errors in $\Delta\mu_2^{\circ\neq}$ values are generally ±0.1 or less.

$$\Delta\mu_1^{\circ\neq} = \Delta G_1^{\circ\neq} = RT \ln\left(\frac{\eta_0 \bar{V}_1^{\circ}}{hN}\right), \tag{6}$$

and the value for 2-methoxyethanol at 25°C is 14.18 kJ mol^{-1}. The activation parameters for viscous flow for the electrolytes are given in Table 2.

The viscosity B-coefficients (Table 2) are larger and positive and increase as we go from Et_4NBr to $(C_7H_{15})_4NBr$. This is a common feature in most nonaqueous solvents.[18] The B-coefficients for tetraalkylammonium halides in almost in all dipolar aprotic solvents show a weak temperature dependence[18] whereas those in ME show a strong temperature dependence as observed in water.[18] This may be due to the 'quasi-aprotic' nature of ME. The changes in the $\Delta\mu_2^{\circ\neq}$ follows the same pattern as the B-values.

In order to distinguish the effect each single has in 2-methoxyethanol, the ionic B-values were calculated using Bu_4NBBu_4[18-21] and Bu_4NBPh_4[14,22,23] as reference electrolytes by

$$B_{Bu_4N^+} = B_{Bu_4B^-} = \frac{1}{2} B_{Bu_4NBBu_4} \tag{7}$$

and

$$\frac{B_{Ph_4B^-}}{B_{Bu_4N^+}} = \frac{r^3_{Ph_4B^-}}{r^3_{Bu_4N^+}} = \left(\frac{5.35}{5.00}\right)^3. \tag{8}$$

The average B_{ion}-values of tetraalkylammonium ions are recorded in Table 3. The ionic $\Delta\mu_2^{\circ\neq}$ values have also been recorded in Table 3.

The ionic B-coefficients for the tetraalkylammonium ions have been found to increase continuously from Et_4N^+ to $(C_7H_{15})_4N^+$ in ME. An analysis of B-coefficients can be made on the basis of Einstein's equation,[24]

$$B_{\pm} = 2.5 \times \frac{4}{3}\pi \frac{R_{\pm}^3 N}{1000}, \tag{9}$$

where $R_{\pm}$ is the radius of the ion assumed as a rigid sphere moving in a continuum and 2.5 is the shape factor for a sphere. The number (n_s) of solvent molecules bound to the ion in the primary sphere of solvation can be calculated by combining the Jones-Dole equation with Einstein's[25]

$$B_{\pm} = \frac{2.5}{1000}(V_i + n_s v_s), \tag{10}$$

where V_i represents the bare ion molar volume and is related to the crystallographic radius r_c of the ion, v_s is the solvent molar volume. The values of $R_{\pm}$ and n_s are shown in Table 4. The values may be compared with the corrected Stokes' radii obtained from conductance studies. For cations R_+ values are much less than r_c values, showing that these ions are scarcely solvated in this medium. On the other hand the comparatively high n_s as well as R value for Br^- ion indicate this ion's capacity for interactions in the solvent as already found in other aprotic solvents.[6]

From Table 3 we find that the change in ionic $\Delta\mu_2^{\circ\neq}$ values is much more in case of larger ions than the smaller ones. If the solvent offers no appreciate structure resistance to the coordination of the solvent molecules in the ground state, steric inhibition will now limit the coordination of ions and this will effect the smaller ion more than the larger. With a bond breaking mechanism the effects on $\Delta\mu_2^{\circ\neq}$ will be complex, but the relief of steric hindrance in the transition state would be one factor tending to decrease $\Delta\mu_2^{\circ\neq}$ for the smaller relative to the larger ions. Moreover, $\Delta\mu_2^{\circ\neq}$ for all the ions is positive, thus, the formation of the transition state is less favorable by these ions. $\Delta\mu_2^{\circ\neq}$ for

the Br^- ion is lower than the cations and this suggests that cations interact with ME more strongly than the anion.

A New Method for the Calculation of the Sextet Polynomial of Unbranched Catacondensed Benzenoid Hydrocarbons

Ivan GUTMAN*,† and Sven J. CYVIN
Division of Physical Chemistry, The University of Trondheim, N-7034 Trondheim-NTH, Norway
(Received May 28, 1988)

A method for the calculation of the sextet polynomial of unbranched catacondensed benzenoid molecules is proposed. It requires the multiplication of a small number of 2×2 matrices and is therefore very simple.

The concept of the sextet polynomial was introduced by Hosoya and Yamaguchi[1] in 1975 and was thereafter subject of numerous investigations.[2-19] The theory based on the sextet polynomial and its various chemical applications can be found in the reviews[20,21] and books.[22,23]

The sextet polynomial is defined via the resonant sextet numbers $r(B, k)$. Let B be a benzenoid system. Then $r(B, k)$ is the number of distinct Clar-type formulas for B, in which exactly k hexagons contain a resonant sextet, $k=1,2,\cdots,s$. Here s is the maximal number of aromatic sextets which can be inserted in a Clar-type formula for B, i.e. $r(B, s)\neq 0$, $r(B, s+1)=0$. By definition, $r(B, 0)=1$.

Then the sextet polynomial of B is

$$\sigma(B, x)=\sum_{k=0}^{s} r(B, k)\, x^k. \qquad (1)$$

If B is an unbranched catacondensed benzenoid system, then an acyclic graph G=G(B) can be constructed,[4] such that for all values of k,

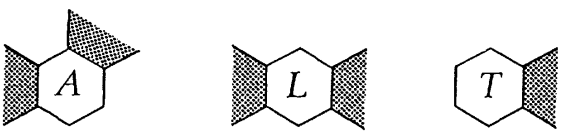
$$r(B, k)=m(G, k) \qquad (2)$$

where $m(G, k)$ is the number of k-matchings of the graph G. When Eq. 2 is substituted back into Eq. 1 we obtain

$$\sigma(B, x)=\sum_{k=0}^{s} m(G, k)\, x^k. \qquad (3)$$

The right-hand side of Eq. 3 is exactly the so-called "Z-counting polynomial" (of the graph G), introduced in 1971 by Hosoya.[24] Therefore in the case of unbranched catacondensed benzenoids, the calculation of the sextet polynomial reduces to the finding of the Z-counting polynomial of the associated graph.

The graph G has the following structure. Suppose that the unbranched catacondensed molecule considered possesses n hexagons of type A (i.e. n kinks). The number of hexagons of type L between the i-th and the $(i+1)$-th A hexagon is t_i, $i=1, 2,\cdots, n-1$. Further, t_0 is the number of L hexagons lying between the terminal (T) hexagon and the first A hexagon.



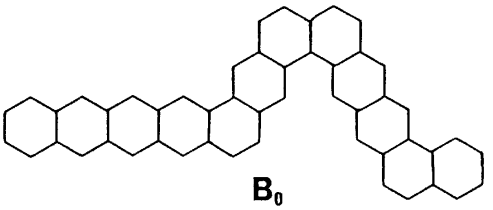
† Permanent address: Faculty of Science, University of Kragujevac, P. O. Box 60, YU-34000 Kragujevac, Yugoslavia.

Similarly, t_n counts the L hexagons between the n-th A hexagon and the other terminal hexagon. With these conventions, the LA-sequence[4] of a general unbranched catacondensed benzenoid system has the form

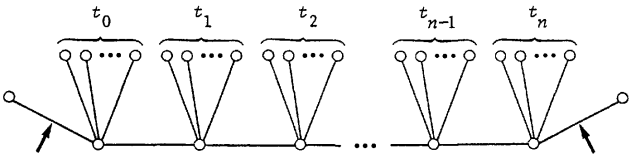
$$TL^{t_0}AL^{t_1}AL^{t_2}A\cdots L^{t_{n-1}}AL^{t_n}T \qquad (4)$$

where LL, LLL, LLLL etc. is abbreviated by L^2, L^3, L^4 etc. Note that t_i may be equal to zero, which simply means that the i-th and the $(i+1)$-th hexagon of the type A are first neighbors.

For example, the below unbranched benzenoid system B_0 has $n=4$ kinks and its LA-sequence is TL^3A-$LAAL^2AT$; hence $t_0=3$, $t_1=1$, $t_2=0$, $t_3=2$, and $t_4=0$.



Now, the graph G in Eqs. 2 and 3 is of the form:[4]

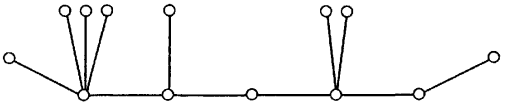


$G = G(t_0, t_1, t_2, \ldots, t_{n-1}, t_n)$

The graphs of the above type are called caterpillars[15,21] or sometimes[19,21] Gutman trees.

One should observe that the caterpillar G has n horizontal edges, each corresponding to a hexagon of type A. This explains why the branching points of G are numbered from 0 to n (and not from 1 to n as, at the first glance, may look more appropriate). Anyway, it should not be forgotten that the main object of the present paper are benzenoid hydrocarbons whereas their LA-sequences and the associated Gutman trees are auxiliary mathematical constructions needed only to deduce our expression for the sextet polynomial.

The caterpillar corresponding to B_0 is $G(B_0)$:



$G(B_0)$

As already mentioned, the Z-counting polynomial of $G(t_0, t_1, t_2 \cdots, t_{n-1}, t_n)$ coincides with the sextet polynomial of an unbranched catacondensed hydrocarbon whose LA-sequence is given by Eq. 4.

The properties of the matching numbers $m(G, k)$, the Z-counting polynomial $Q(G, x)$ and the closely related matching polynomial have been studied in detail.[25] In the present paper we need only two simple relations[24] for $Q(G, x)$.

(i) Let G be an arbitrary graph, e its arbitrary edge, and let e connect the vertices u and v. Then

$$Q(G, x) = Q(G\text{-e}, x) + xQ(G\text{-u-v}, x). \tag{5}$$

(ii) Let G be a graph composed of two components G_1 and G_2. Then

$$Q(G, x) = Q(G_1, x) \cdot Q(G_2, x). \tag{6}$$

The Main Result. The sextet polynomial of an unbranched catacondensed benzenoid system whose LA-sequence is given by Eq. 4 is equal to $U_{11}+U_{12}+U_{21}+U_{22}$ where

$$\begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = M_0 M_1 M_2 \cdots M_{n-1} M_n \begin{pmatrix} 1 & 0 \\ 0 & x \end{pmatrix} \tag{7}$$

and

$$M_i = \begin{pmatrix} 1 + t_i x & 1 \\ x & 0 \end{pmatrix}.$$

For the previous example,

$$\begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = \begin{pmatrix} 1+3x & 1 \\ x & 0 \end{pmatrix}\begin{pmatrix} 1+x & 1 \\ x & 0 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ x & 0 \end{pmatrix}$$
$$\begin{pmatrix} 1+2x & 1 \\ x & 0 \end{pmatrix}\begin{pmatrix} 1 & 1 \\ x & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & x \end{pmatrix}$$

which after simple matrix multiplication gives

$$\begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = \begin{pmatrix} 1+10x+29x^2+21x^3 & x+9x^2+23x^3+15x^4 \\ x+6x^2+7x^3 & x^2+5x^3+5x^4 \end{pmatrix}$$

yielding the sextet polynomial of B_0:

$$\begin{aligned} \sigma(B_0, x) &= (1+10x+29x^2+21x^3)+(x+9x^2+23x^3+15x^4) \\ &\quad +(x+6x^2+7x^3)+(x^2+5x^3+5x^4) \\ &= 1+12x+45x^2+56x^3+20x^4. \end{aligned}$$

Two special cases of Eq. 7 are worth mentioning. If on the left-hand side from the first kink there are no L-type hexagons (i.e. $t_0=0$), then

$$\begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ x & 0 \end{pmatrix} M_1 M_2 \cdots M_n \begin{pmatrix} 1 & x \\ 0 & x \end{pmatrix}.$$

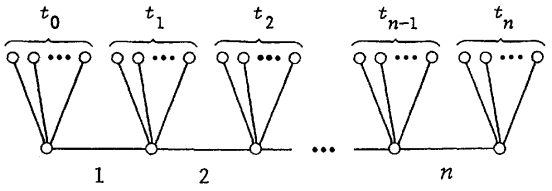
If on the right-hand side from the last kink there are no hexagons of the type L (i.e. $t_n=0$), then

$$\begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = M_0 M_1 \cdots M_{n-1} \begin{pmatrix} 1 & x \\ x & 0 \end{pmatrix}.$$

Verification of Equation 7. We first apply Eqs. 5 and 6 to the two edges of $G(t_0, t_1, t_2, \cdots, t_{n-1}, t_n)$ which on the previous diagram are indicated by arrows. Bearing in mind that for the graph E_p with p vertices but without edges $Q(E_p)\equiv 1$, we straightforwardly obtain:

$$\begin{aligned} &Q[G(t_0, t_1, t_2, \cdots, t_{n-1}, t_n), x] \\ &\quad = Q[F(t_0, t_1, t_2, \cdots, t_{n-1}, t_n), x] \\ &\quad + xQ[F(t_0, t_1, t_2, \cdots, t_{n-1}), x] \\ &\quad + xQ[F(t_1, t_2, \cdots, t_{n-1}, t_n), x] \\ &\quad + x^2 Q[F(t_1, t_2, \cdots, t_{n-1}), x] \end{aligned} \tag{8a}$$

where the caterpillar F is defined as follows:



$F(t_0, t_1, t_2, \ldots, t_{n-1}, t_n)$

It is expedient to use the shorthand notation

$$Q[F(t_0, t_1, t_2, \cdots, t_{n-1}, t_n), x] \equiv (0, n).$$

Then Eq. 8a is simplified as

$$\begin{aligned} &Q[G(t_0, t_1, t_2, \cdots, t_{n-1}, t_n), x] \\ &\quad = (0, n) + x \cdot (0, n-1) + x \cdot (1, n) + x^2 \cdot (1, n-1). \end{aligned} \tag{8b}$$

Another way to deduce the identity Eq. 8 is to apply the inclusion and exclusion principle to the Q polynomial. Let a and b denote the edges of G indicated by arrows. Then the first term on the right-hand side of either Eq. 8a or 8b corresponds to the subgraph of G from which both a and b are excluded. The second term in Eqs. 8a and 8b corresponds to the subgraph of G in which a is included, but b is excluded; the third term corresponds to the subgraph from which a is excluded, but b is included. Finally, the last term in Eqs. 8a and 8b corresponds to the subgraph to which both a and b are included. The authors are indebted to the referee for pointing out this observation.

Applying Eqs. 5 and 6 to the i-th horizontal edge of $F(t_0, t_1, t_2, \cdots, t_{n-1}, t_n)$ we arrive at

$$(0, n) = (0, i)(i+1, n) + x \cdot (0, i-1)(i+2, n)$$

and in a fully analogous manner:

$$\begin{aligned} (0, n-1) &= (0, i)(i+1, n-1) + x \cdot (0, i-1)(i+2, n-1) \\ (1, n) &= (1, i)(i+1, n) + x \cdot (1, i-1)(i+2, n) \\ (1, n-1) &= (1, i)(i+1, n-1) + x \cdot (1, i-1)(i+2, n-1). \end{aligned}$$

These four equations can be written in a matrix form as

$$\begin{pmatrix} (0, n) & (0, n-1) \\ x \cdot (1, n) & x \cdot (1, n-1) \end{pmatrix} =$$
$$\begin{pmatrix} (0, i) & (0, i-1) \\ x \cdot (1, i) & x \cdot (1, i-1) \end{pmatrix} \begin{pmatrix} (i+1, n) & (i+1, n-1) \\ x \cdot (i+2, n) & x \cdot (i+2, n-1) \end{pmatrix}. \tag{9}$$

The above relations hold for $2 \leq i \leq n-3$. They can eas-

ily be extended to apply for all values of i, $i=0, 1, \cdots, n-1$ if one sets $(j,j-1)\equiv 1$ and $(j+1,j-1)\equiv 0$. One should recall that $(j,j)=1+t_j x$.

Setting $i=n-1$ in Eq. 9 we obtain

$$\begin{pmatrix} (0,n) & (0,n-1) \\ x\cdot(1,n) & x\cdot(1,n-1) \end{pmatrix} = \begin{pmatrix} (0,n-1) & (0,n-2) \\ x\cdot(1,n-1) & x\cdot(1,n-2) \end{pmatrix} \begin{pmatrix} 1+t_n x & 1 \\ x & 0 \end{pmatrix}$$

i.e.

$$\begin{pmatrix} (0,n) & (0,n-1) \\ x\cdot(1,n) & x\cdot(1,n-1) \end{pmatrix} = \begin{pmatrix} (0,n-1) & (0,n-2) \\ x\cdot(1,n-1) & x\cdot(1,n-2) \end{pmatrix} M_n$$

from which is immediately seen that

$$\begin{pmatrix} (0,n) & (0,n-1) \\ x\cdot(1,n) & x\cdot(1,n-1) \end{pmatrix} = M_0 M_1 M_2 \cdots M_{n-1} M_n \ .$$

Equation 7 follows now from the fact that

$$\begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = \begin{pmatrix} (0,n) & (0,n-1) \\ x\cdot(1,n) & x\cdot(1,n-1) \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & x \end{pmatrix} .$$

Discussion

Another form in which we can express our main result is

$$\sigma(\mathrm{B}, x) = \begin{pmatrix} 1 \\ 1 \end{pmatrix}^T M_0 M_1 \cdots M_n \begin{pmatrix} 1 \\ x \end{pmatrix} . \qquad (10)$$

For $x=1$ the sextet polynomial reproduces the number of Kekulé structures.[1,3] Therefore Eq. 10 provides an expression for the Kekulé structure count of unbranched catacondensed benzenoid systems, viz.

$$K\{\mathrm{B}\} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}^T L_0 L_1 \cdots L_n \begin{pmatrix} 1 \\ 1 \end{pmatrix} \qquad (11)$$

where

$$L_i = \begin{pmatrix} t_i & +1 & 1 \\ & 1 & 0 \end{pmatrix} .$$

Formulas of this type, but not Eq. 11, are previously known.[26]

We wish to point at a property of the matrix elements U_{ij}, Eq. 7, whose meaning and possible significance are not understood. We have seen that $U_{11}+U_{12}+U_{21}+U_{22}$ is the sextet polynomial. In addition,

$$U_{11}U_{22} - U_{12}U_{21} = (-1)^n x^{n+1}. \qquad (12)$$

The above relation is obtained if one calculates the determinants of the left- and right-hand sides of Eq. 7, taking into account that $\det M_i = -x$. The special case of Eq. 12 for $x=1$ was observed previously.[27]

One of the authors (I. G.) thanks the Royal Norwegian Council for Scientific and Industrial Research for financial support.

Conductometric Determination of Thermodynamics Dissociation Constants of Benzoic and Nitrobenzoic Acid in Methanol-Water Mixtures at 298 K

M. S. K. Niazi
Department of Chemistry, Quaid-I-Azam University, Islamabad, Pakistan
(Received July 4, 1988)

The thermodynamic dissociation constants and the limiting molar conductivities of 2-, 3-, 4-nitrobenzoic and benzoic acids have been determined in water-methanol mixtures at 298 K. The experimental data are analyzed with the Lee and Wheaton conductance equation incorporating modifications. The derived results are compared with the ones in literature, pertaining to analogous media. The findings are interpreted in terms of solute-solvent interactions, intramolecular hydrogen bonding, resonance and inductive effect and the substituent position. The study showed that the dissociation order decreases as 2-nitrobenzoic acid> 3-nitrobenzoic acid≈ 4-nitro benzoic acid> benzoic acid.

Protonation/deprotonation equilibria leading to the study of acid-base equilibria have been under investigation in pure and mixed solvents since many years. The ionization constant of an acid is largely influenced mostly by the structure of the acid but also by the nature of the solvent.[1-4] Potentiometric and spectrophotometric techniques are quite popular for obtaining dissociation constants of acids and bases.[5-7] However, the ionization of acids in methanol-water (MeOH-H_2O) mixtures varies with solvent composition in a manner which is still not completely understood.[8,9] In contranst to potentiometry, the conductimetry provides a simple and accurate method for the determination of dissociation constants of acids without any primary and secondary buffer solutions required for calibration of the platinum electrode.[10-12]

In this paper the conductance behavior of 2-, 3-, 4-nitrobenzoic acids along with benzoic acid (as a model compound) in MeOH-H_2O mixtures at 298 K is examined. The pK_a values (thermodynamic dissociation constants) are derived from conductance data using the Lee and Wheaton conductance equation (in series form) incorporating modifications.[13,14] Finished results are compared with those by other workers pertaining to the same and similar acids in analogous media.

Experimental

Benzoic and nitrobenzoic acids used in the present work were Merck products of ultrahigh purity. They were crystallized twice from ethanol-water mixtures, dried under vacuum over P_2O_5 and stored in a desiccator.

Methanol (Analar BDH) was distilled over sulfanilic acid and the middle fraction was collected for use. The deionized conductivity water (triply distilled) was used as an aqueous medium and for preparation of MeOH-H_2O mixtures (w/w composition). The purity of solvents was checked from their physical parameters such as density, viscosity, and dielectric constant at 298 K.

The conductance measurements were made in the same way as described elsewhere.[15,16] An Orion Research conductivity meter model 101, was used for the purpose. Two platinized platinum electrodes (cell constants: 0.857 and 1.151 cm^{-1}) were used. The temperature of water baths was controlled at 25±0.01 °C. No appreciable variations in conductance were observed in changing frequency range from 80 Hz to 3 kHz. Duplicate measurements for each mixture were made, the results varied within±0.1% only.

Viscosities, densities, and dielectric constants of various mixtures were measured in the same way as described earlier,[17] which have been found in good agreement with the values cited in literature.[18]

Results

Physical properties of MeOH-H_2O mixtures are listed in Table 1. The corresponding values of the molar conductances are given in Table 2 for all the four acids in solvent mixtures of different composition listed therein. The experimental data were analyzed with the Lee and Wheaton conductance equation in its series form.[13,14] The selection of the equation was tentative since it was based on a model warranting the study of the dissociation process and short range interactions closely. The limiting molar conductance (Λ_0) and association constant (K_A) for the process $[H^+ + A^- \overset{K_A}{\rightleftarrows} H^+A^-]$ were deduced from the equations:

$$\Lambda = \gamma[\Lambda_0(1+\Delta X/X)-\Delta\Lambda_{el}] \quad (1)$$

$$K_A = (1-\gamma)/\gamma^2 f^2 c \quad (2)$$

$$-\ln f = bk/2(1+kR),\ b = e^2/DKT \quad (3)$$

for Λ_0 and K_A values which minimize

$$\sigma_\Lambda = \sum_i [\Lambda_i(\text{cal})-\Lambda_i(\text{obs})]^2/n-2 \quad (4)$$

Table 1. Physical Properties of MeOH-H_2O Mixtures at 298 K

% MeOH (w/w)	ρ / g·cm^{-3}	η / cP[a]	D
0	0.9971	0.890	78.65
10	0.9806	1.153	74.23

50	0.9129	1.545	55.17
70	0.8481	1.215	37.88

ρ=density; η=viscosity; D=dielectric constant.
a) 1 cP=10^{-3} Pa s.

The symbols have their usual significance. The study revealed that in the case of carboxylic acids no minimum is observed in a R-σ_A (%) plot. The value of distance parameter R was set equal to $2b$ as suggested by Fuoss.[22] The derived conductance parameters are given in Table 3.

From the K_A values, the respective pK_a (i.e. dissociation constant) values were calculated using the relationship:

$$pK_a = -\log K_d = -\log (1/K_A) \quad (5)$$

Values of pK_a for benzoic and nitrobenzoic acids at 298 K are presented in Table 4. The solvent effect of MeOH on the dissociation of these acids is shown in Fig. 2, where the difference between pK_a^s (the value of pK_a in the fixed solvent-mixture) and pK_a^w (the value of pK_a in water) is plotted as a function x, the mole fraction of MeOH in methanol-water mixtures. observed changes of pK_a^s and standard molar Gibbs free energy of transfer $\Delta_{tr}G^\circ_m$ were calculated from:

$$\Delta_{tr}G^\circ_m = -RT \ln 10\Delta pK_a = 5.707\,[pK_a^s - pK_a^w]\ \text{kJ·mol}^{-1} \quad (6)$$

and are presented in Table 4.

Discussion

The pK_a values of benzoic and 2-, 3-, and 4-nitrobenzoic acids in aqueous medium are in good agreement with those quoted in literature, mainly derived by potentiometric and some other methods.[23] The dissociation study of benzoic and the nitrobenzoic acid in alcohol-water mixtures is available in literature.[1,19–21] The present pK_a values for benzoic acid (in some MeOH-H_2O mixtures) are in good agreement with previous study in Fig. 1. In this figure, the derived results are compared with those by Lahiri et al.[19] for 4-nitrobenzoic acid in MeOH-H_2O mixtures. As is obvious, their pK_a values in 8—60 wt% MeOH-H_2O mixtures are higher than our derived values. This could be attributed to their so called corrections in pH values of acidic solutions in binary solvent mixtures. Also, procedural digression from the normal potentiometric method for determination of pK_a values of carboxylic acids in mixed solvent systems could also be another cause for this effect.[1,4] On similar ground, the present results do not agree with those derived by Dash et al.[21] who undertook potentiometric calibration with reference to aqueous phase. Therefore, a direct comparison with their results could be oversimplification of actual situation.

The solvent effect on the dissociation of these acids is shown in Fig. 2. The plots of pK_a vs. mole fraction x of methanolic contents in MeOH-H_2O mixtures are not linear. A similar behavior of these acids in pK_a vs. $(1/D_s - 1/D_w)$ plots, may also be observed, where D_s and D_w are dielectric constants of mixtures and water, respectively. If only electrostatic interactions among the ions would have been operational these plots should have been linear, detailed by Born.[24] The present investigation thus suggest that in case of nitrobenzoic acids a nonelectrostatic part of the standard free

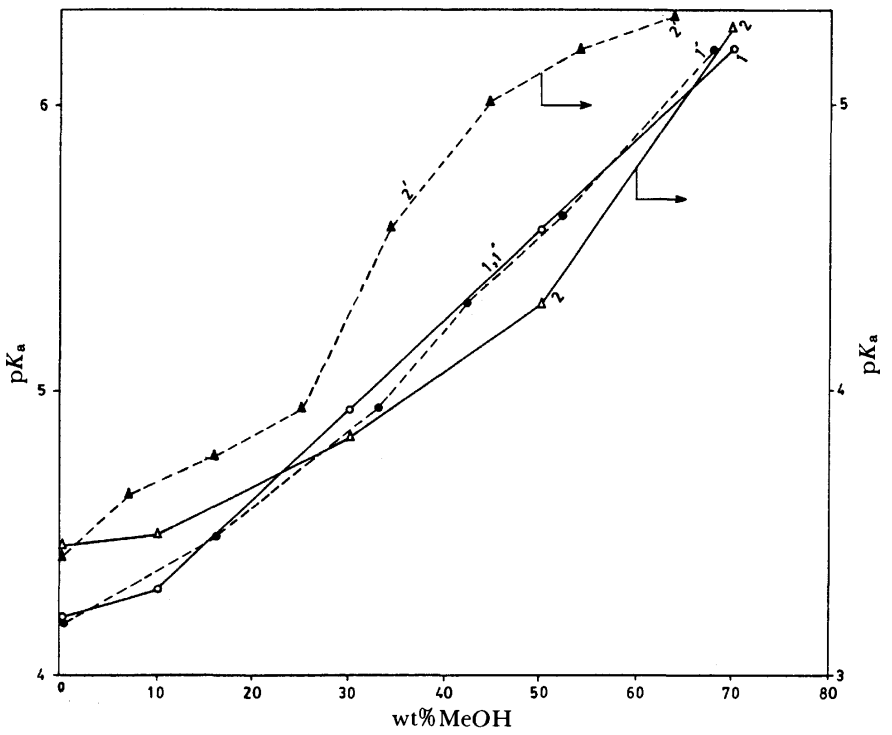

Fig. 1. Dependence of pK_a values of benzoic (○,●) and 4-nitrobenzoic acids (△,▲) on composition of MeOH-H_2O mixtures at 298 K: 1, 2 present work; 1′, 2′ taken from Refs. 26 and 19.

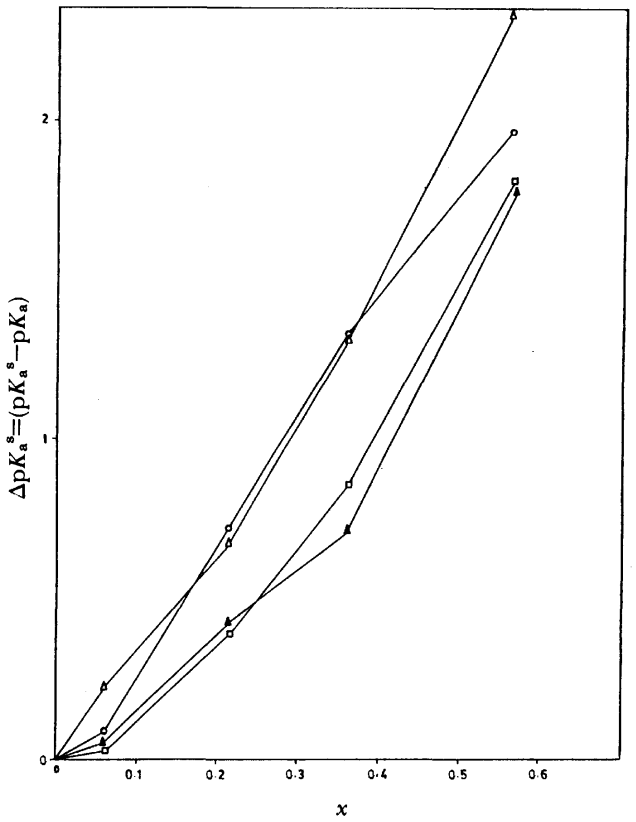

Fig. 2. Effect of changes of solvent composition on the pK_a values of benzoic (○); 2-nitrobenzoic (△); 3-nitrobenzoic (▲); and 4-nitrobenzoic (□) acids in $x\{CH_3OH+(1-x)\ H_2O\}$ at 298 K.

energy of transfer from aqueous to aqueous-methanol mixtures is playing a dominant role. It means that these are specific chemical interactions going on between ions of these acids and the solvent.

The dissociation order in respect of the acids studied in MeOH-H_2O mixtures turns out to be; 2-nitrobenzoic acid > 3-nitrobenzoic acid ≃ 4-nitrobenzoic acid > benzoic acid. This observed difference of acidities among the same isomers of nitrobenzoic acid could be explained on basis of intramolecular hydrogen bonding, inductive and resonance effects of the substituent and its respective position on the benzene ring with respect to carboxyl group.[25]

The normalized Walden products ($\Lambda_0\eta/\Lambda_{0w}\eta_w$) against percentage of methanol in MeOH-H_2O system, decreases as the solvent mixture is enriched in methanol. The changes in the Walden product are not only due to viscosity or dielectric constant variations but also to an altering proton transfer mechanism.[7]

The assistances rendered by the following persons are acknowledged gratefully: M. Zafar Iqbal Khan for conductance measurements, Mahmood Hussain for preparation of typescript, and Dr. M. Jaffar for correcting the manuscript.

(Received August 4, 1988)

Studies on hydrodynamic and electroosmotic permeation of water and aqueous solutions of NaCl, KCl, and $MgCl_2$ across progesterone plug membrane have been carried out to characterize the electrical nature of progesterone interfaces. Electrophoretic mobilities of progesterone particles dispersed in these aqueous solutions have also been measured. Experiments were confined to the range where linear flux/force relationships hold. Membrane parameters have been evaluated with the data obtained and the membrane/solution electrical interface has been explained using electrical double layer model and theory of nonequilibrium thermodynamics. Zeta potentials have been evaluated from electroosmotic and electrophoretic flux data and their dependence on concentration examined.

A variety of transport phenomena is known to take place when a membrane system is subjected to various driving forces such as gradients of electric potential, concentration, and hydrostatic pressure. The phenomenon of mass transmission through natural membranes is very complex[1] having immense physiological and medicinal applications.[2] In view of the complexities of these membranes considerable interest has developed in the study of transport behavior through model membranes.[3] It has been found that these model membranes possess certain dimensional, electrical permeability, and excitability characteristics that closely resemble the behavior of natural membranes.[4] Recently we have made extensive studies on the application of nonequilibrium thermodynamics to the transport phenomenon across testosterone plug membrane[5-7] (model membrane).

This paper is concerned with the study of the transport properties of an isothermal system consisting of a progesterone plug membrane, water, and aqueous solutions of NaCl, KCl, and $MgCl_2$ in the concentration range of 10^{-4} to 10^{-3} mol l^{-1} on the basis of nonequilibrium thermodynamics. Such studies with respect to progesterone interfaces in various types of electrolytic solutions are expected to throw light on various facets of its functions.[8] For this purpose measurements on hydrodynamic permeability, electroosmosis and electrophoresis have been carried out on progesterone/aqueous electrolyte systems and the data so obtained have been analysed in the light of nonequilibrium thermodynamic theories with a view to ascertaining the form of transport equation and evaluating the phenomenological coefficients.

Experimental

(a) Materials: Progesterone obtained from Sigma Chemical Company (Saint Louis, USA) was used as such to prepare the membrane plug. Analytical grade NaCl, KCl, and $MgCl_2$ obtained from BDH, India were used to prepare their aqueous solutions in distilled water (specific conductance of the order 10^{-6} S). Various solutions of $MgCl_2$ were prepared from its stock solution standardized by EDTA titration.

(b) Experimental Cell/Membrane-Plug Assembly and Silver-Silver Chloride Electrodes: A known amount of progesterone powder was mixed with a small amount of araldite which was then cast in the form of a plug, in a Pyrex glass cell having a constriction in the middle by mechanical compression as described elsewhere.[9] The thickness of the membrane was 5.02 mm and the area of the surface was nearly 3.24×10^{-4} m^2. Reversible silver-silver chloride electrodes were prepared by anodic deposition of chloride ions on a silver disc attached with a silver rod, from 0.1 M NaCl solution (1 M=1 mol dm^{-3}) at 0.4 mA cm^{-2}. It was found that anodically formed chloride layer on silver was very thin.

(c) Measurement of Electroosmotic Permeabilities: The experimental cell was filled with the permeants under investigation and left for 24 h for equilibration. The cell was subsequently filled with degassed fresh permeant to ensure that the concentration of experimental solution remained the same as compounded before equilibration. An electronically operated power supply (HIL, India) was used to apply potential gradients upto 50 V employing Ag-AgCl electrodes. The electrodes were adjusted to cover the maximum surface area of the plug from both the sides.

The volumetric flux was measured by following the rate of displacement of solution/air meniscus in a horizontally placed graduated capillary tube of cross sectional area 1.484×10^{-6} m^2. The electroosmotic flux was found to take place from negative to positive electrode.

The hydrodynamic permeability was measured with the same cell as used for electroosmosis. A constant hydrostatic pressure difference was maintained across the membrane by a constant pressure head device and the volume flow was calculated from the movement of solution/air meniscus in the horizontally placed graduated capillary attached to the cell. The difference of the pressure on the two surfaces of the membrane was measured to $\pm$ 0.001 cm with a cathetometer.

It was observed that the flow of solution takes place in the measuring capillary even when pressure difference and potential difference on both sides of the plug membrane is zero. This residual flow arises due to capillary active forces operating at the solution/air interface in the measuring capillary tube. The data given in these measurements have

been corrected for this residual flow.

(d) Conductance of Membrane Equilibrated with Permeants: Conductance of membrane equilibrated with various solutions were measured with a conductivity bridge (Toshniwal, India) at 50 Hz. Conductances of the permeants were measured before and after electroosmosis with the same apparatus.

(e) Measurement of Electrophoretic Velocities: The electrophoretic velocities of progesterone particles dispersed in the aqueous solutions were measured by the method described elsewhere.[10] Corrections were made for the downward movement due to the action of gravitational forces. Movement of the boundary was from anode to cathode. Measurements of electroosmotic permeability and electrophoretic velocities for a particular system were repeated several times. The deviation from the average value was always less than 5% showing that the measurements are fairly reproducible.

All the measurements were carried out in an air thermostat maintained at 25±0.5 °C.

Results and Discussion

According to nonequilibrium thermodynamics, the isothermal volume flux J_v and the electric current I, through a permeant-equilibrated membrane under the simultaneous action of a hydrodynamic pressure difference ΔP and an electric potential difference $\Delta\Phi$, are given by[11,12]

$$J_v = L_{11}\left(\frac{\Delta P}{T}\right) + L_{12}\left(\frac{\Delta\Phi}{T}\right) \quad (1)$$

$$I = L_{21}\left(\frac{\Delta P}{T}\right) + L_{22}\left(\frac{\Delta\Phi}{T}\right) \quad (2)$$

The parameters L_{ij} (i, j=1, 2) are called phenomenological coefficients. We restrict ourselves to the examination of the applicability of Eq. 1 only. This equation predicts a linear relationship between $(J_v)_{\Delta\Phi=0}$ and ΔP with the slope yielding the value of hydrodynamic transport coefficient L_{11}/T. A linear relationship was also observed between the electroosmotic volume flux $(J_v)_{\Delta P=0}$ and $\Delta\Phi$, whose slope yielded the value of L_{12}/T. L_{22}/T, the conductance of membrane equilibrated with permeant was directly noted by conductivity bridge.

Further the classical theory[13] of electrical double layer reveals that for a plug membrane consisting of an array of n parallel capillaries and equivalent pore radius r, the transport coefficients are given by:

$$\frac{L_{11}}{T} = \frac{n\pi r^4}{8\eta l} \quad (3)$$

$$\frac{L_{12}}{T} = \frac{n\varepsilon r^2}{4\eta l}\cdot\zeta_{e.o.} \quad (4)$$

$$\frac{L_{22}}{T} = \frac{n\pi r^2}{l}\cdot\kappa \quad (5)$$

where η is the coefficient of viscosity of the permeating solutions, l is the average length of membrane capillaries, $\zeta_{e.o.}$ is the zeta potential causing electroosmosis and κ is the specific conductance of the permeant. Values of these transport coefficients are recorded in Table 1.

The electroosmotic flow was found to occur towards positive electrode. This behavior may be explained on the basis of the electrical double layer formed at the membrane permeant interface. The oxygen atom of >C=O groups at C-3 and C-20 and electron density around the olefinic bond is collectively responsible for generating overall negative charge at the progesterone molecules present in the membrane matrix. The cations and anions present in the solution are hydrated and move with the same linear velocity as respective ions.[14] Water dipoles present in the permeating solution get preferentially adsorbed at the negatively charged matrix oriented with their positive ends towards the membrane surface and form the inner Helmholtz plane (IHP). The hydrated cations are attracted towards the negative part of water dipoles forming outer Helmholtz plane (OHP). The diffusely dispersed part of the electrical double layer (Fig. 1) has an excess of hydrated chloride ions with the result that electroosmotic transport would occur towards the anode in accordance with our observation.

Electrophoresis. Electrophoretic migration of progesterone particles dispersed in these electrolytic solutions occur towards the cathode. The following linear relationship holds between the electrophoretic velocity $(V_e)_{g=0}$ and applied potential difference $\Delta\Phi$ as found earlier.[5]

$$(V_e)_{g=0} = \frac{L_{12}^*}{T}\cdot\Delta\Phi \quad (6)$$

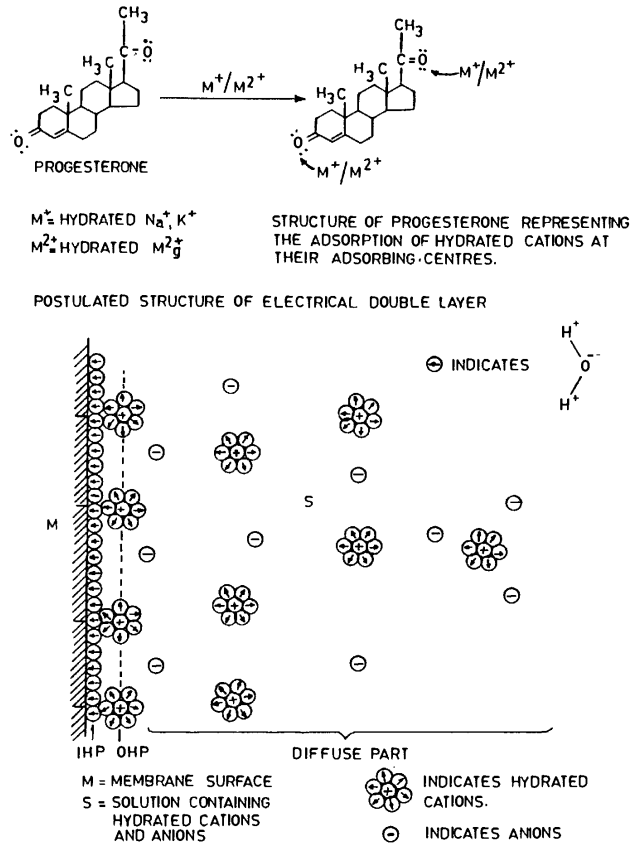

Fig. 1.

where

$$\frac{L_{12}^*}{T} = \frac{\varepsilon \zeta_{e.p.}}{4\pi\eta l'} \tag{7}$$

L_{12}^*/T is the electrophoretic transport coefficient, ε and η are the dielectric constant and viscosity of the solution, respectively. $\zeta_{e.p.}$ is the zeta potential and l' is the distance between the two electrodes of the electrophoretic cell.

The values of L_{12}^*/T obtained from the slope of linear plots of $(V_e)_{g=0}$ vs. $\Delta\Phi$ are recorded in Table 1.

The preferential adsorption of hydrated cations at the surface of progesterone particles cause it to have net positive charge. This facilitates the electrophoretic migration towards cathode.

Membrane Parameters/Characterization of Membrane Structure. The extent of flow and nature of flow through a membrane is determined to a great extent by the characteristics of membrane itself. Hence, certain important parameters which provide an insight into the structural details viz., (i) average pore radii and average number of pores, (ii) zeta potential have been determined using fluid permeation measurements e.g., electroosmosis and hydrodynamic permeation, conductance of the membrane equilibrated with permeants. The average pore radii r and average number of pores n, have been evaluated using the equations[5]

$$r = \left[\frac{8\eta\kappa L_{11}/T}{L_{22}/T}\right]^{1/2} \tag{8}$$

and

$$n = \frac{\frac{L_{22}}{T} \times l}{\pi r^2 \kappa} . \tag{9}$$

The values of these parameters are recorded in Table 2.

Evaluation of Zeta-Potentials: Electrokinetic phenomena are only directly related to the nature of the mobile part of the electric double layer and may, therefore, only be interpreted in terms of potential (zeta) or the charge density at the surface of shear. No direct information is given about the charge density at the surface of the membrane. Zeta potentials have been calculated using the following equations[5]

$$\zeta_{e.o.} = \frac{4\pi\eta\kappa}{\varepsilon\left(\frac{L_{22}}{T}\right)} \times \left(\frac{L_{12}}{T}\right)_{e.o.} \times 9 \times 10^4 \text{ V} \tag{10}$$

and

$$\zeta_{e.p.} = \frac{4\pi\eta l'}{\varepsilon} \times \frac{L_{12}^*}{T} \times 9 \times 10^4 \text{ V} \tag{11}$$

where $\zeta_{e.o.}$ and $\zeta_{e.p.}$ are the zeta potentials calculated using electroosmotic and electrophoretic transport coefficients respectively. There are instances where the above relationships are not applicable due to complicating effects arising on account of double layer polarization.[15]

It is evident from Table 2 that the zeta potentials calculated from electroosmotic and electrophoretic data are not comparable, which observation is consistent with our earlier findings.[5,7]

The discrepancy in the two values of zeta potentials

a) Average pore radii r, average no. of pores n, and zeta potentials $\zeta_{e.o.}$ and $\zeta_{e.p.}$.

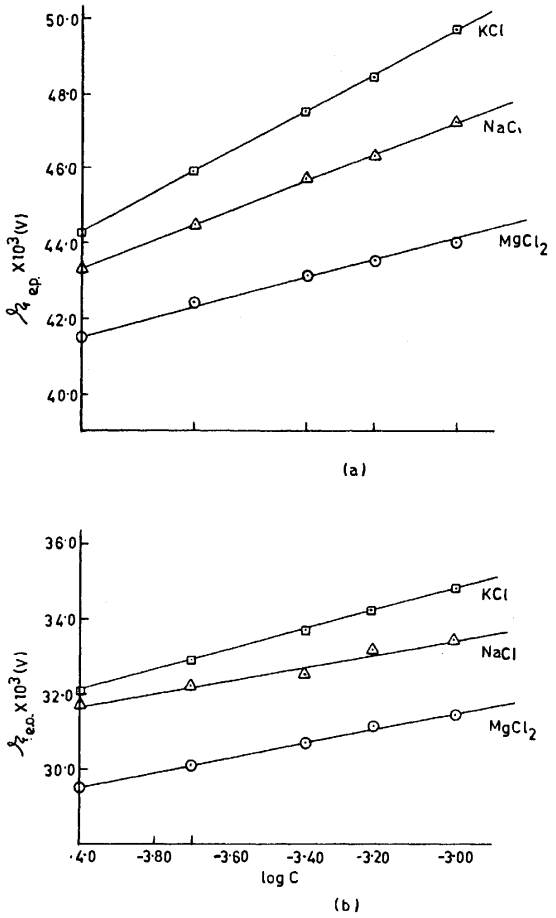

Fig. 2. Dependence of zeta potential (ζ) on log$C$ for progesterone/aq electrolyte solution systems (concn 10^{-3} mol l^{-1}).

is attributable to: i) change in the electrokinetic behavior owing to the decrease in particle size for electrophoretic measurements, ii) change in the hydrodynamic environment in the two cases, and iii) variation of the dielectric constant ε and the viscosity η in the double layer. It is not possible to calculate these quantities directly within the double layer. Therefore, no definite conclusion could be drawn.[16]

Zeta potentials vary nonlinearly with concentration of solutions while its dependence with log C is found to be linear (Fig. 2) and the following equation[5] holds good.

$$\zeta = A + B \log C \quad (20)$$

where A is taken as approximately constant for conditions under which the charge on the membrane surface does not change sign and B is another constant. The existence of positive zeta potentials may be attributed to the firm attachment of cations at the surface of capillary channels of the membrane.

The authors would like to express their thanks to late Prof. S. C. Tripathi, Head, Chemistry Department, Gorakhpur University, Gorakhpur, for providing laboratory facilities. Financial support by CSIR, New Delhi, to one of us (Bali Ram) is thankfully acknowledged.

Molecular and Electronic Structures of Thieno[3,4-*b*]thiophene-2-carboxylic Acid and Acetic Thieno[3,4-*b*]thiophene-2-carboxylic Anhydride. An AM1, MNDO, and CNDO/S Study

Giuseppe BUEMI
Dipartimento di Scienze Chimiche, Università di Catania, Viale A. Doria 6-95125 Catania, Italy
(Received August 8, 1988)

AM1 and MNDO methods have been used for optimizing the molecular geometry of all the possible conformations of thieno[3,4-*b*]thiophene-2-carboxylic acid (**1**), of its methyl ester (**2**) and of acetic thieno[3,4-*b*]thiophene-2-carboxylic anhydride (**3**). Both methods give comparable results for the thieno[3,4-*b*]thiophene framework but rather different bond angles for the substituent group of **3**. In any case, an equilibrium between two (**1**,**2**) or more (**3**) conformations is conceivable. Although the most stable conformations are predicted to be planar, the rotation of the substituent group implies only low energy increase (rotation barriers are calculated to be about 2 kcal mol^{-1}) which allows wide oscillations. The $\pi \rightarrow \pi^*$ electronic transitions do not differ appreciably from those of the parent thieno[3,4-*b*]thiophene molecule and are better accounted for by the conformations having remarkable rotation around the C_7-C_9 bond.

Thieno[3,4-*b*]thiophene-2-carboxylic acid (**1**), its methyl ester (**2**) and acetic thieno[3,4-*b*]thiophene-2-carboxylic anhydride (**3**) are stable derivatives[1] of the unstable thieno[3,4-*b*]thiophene. The geometry and electronic structure of this latter bicyclic compound have been previously studied at MNDO and CNDO/S level.[2] In spite of the increasing of the π system dimension, the UV absorption bands of the parent compound are still present—only slightly affected by substitution—also in the spectra of **1**—**3**, together with a new band of moderate intensity lying on the long wavelengths side (about 340 nm).[1] This band is certainly peculiar of the substituent group and probably involves oxygen(s) lone pairs.

Aim of the present study is the investigation of the electronic structures of the title compounds in order to evidence what changes occur in the electronic transitions as well as in the involved frontier MO's, with respect to those of the thieno[3,4-*b*]thiophene, consequently to the substitution of an H atom with a carboxyl or more extensive group. Moreover, we propose to investigate the role played by the molecular geometry on the electronic spectra.

Since different possible accomodations of the atoms constituting the lateral chain are conceivable, and, therefore, quite a lot of conformations can be originated, a preventive conformational analysis study has been accomplished in order to determine the relative stabilities of these conformations to select the most probable conformers.

Calculation

The geometry optimization, including all the independently variable parameters needed for geometry definition, was carried out by means of AM1 method[3] since it is claimed to evaluate the "core-core" repulsion energy better than other semiempirical methods. Further optimization at MNDO level[4] was carried out too, in order to get geometries of **1**—**3** homogeneous with those previously obtained for the parent thieno[3,4-*b*]thiophene, and, on the same time, to evidence what differences, if any, characterize the molecular structures coming from the two different methods.

All the possible conformations arising from the different possible geometrical arrangements of -COOH, -$COOCH_3$, or -$COOCOCH_3$ groups of **1**—**3** were taken into account in the present study. In a first step full planarity was imposed to the molecules, then the obtained minimum energy structures were again optimized allowing free rotation to the substituent groups in order to check if loss of planarity leads to energy gain. Since MNDO is often not able to give correct geometries when rotation is considered,[5] because of its tendency to underestimation of rotation barrier energies, only AM1 was used in exploring nonplanar conformations. Calculations were performed on a Vax-11-750 computer by using the AMPAC program (in which MINDO/3, MNDO, and AM1 options are included) furnished by Q.C.P.E.[6]

The electronic transitions were evaluated by means of CINDO/SHIFT/UV program[†7] which allows (if wanted) inclusion of 3d atomic orbitals of S atoms. 80 monoexcited configurations were taken into account in the CI procedure. The importance of doubly excited configurations was also tested by means of the CNDUV99 program.[8]

Results and Discussion

Molecular Conformations. The most stable conformers of **1**—**3** are shown in Fig. 1. The relative stabilities resulting from our calculations are given in Table 1, where also the theoretical dipole moments are reported.

† CNDO-SHIFT-UV program furnished by Q. C. P. E was properly modified by us to run on VAX computers and to allow calculations of the excited state dipole moments. At present a version of the same program running on IBM-PC is available too.[7b]

a) Pseudo minimum. P=Planar, NP=Nonplanar.

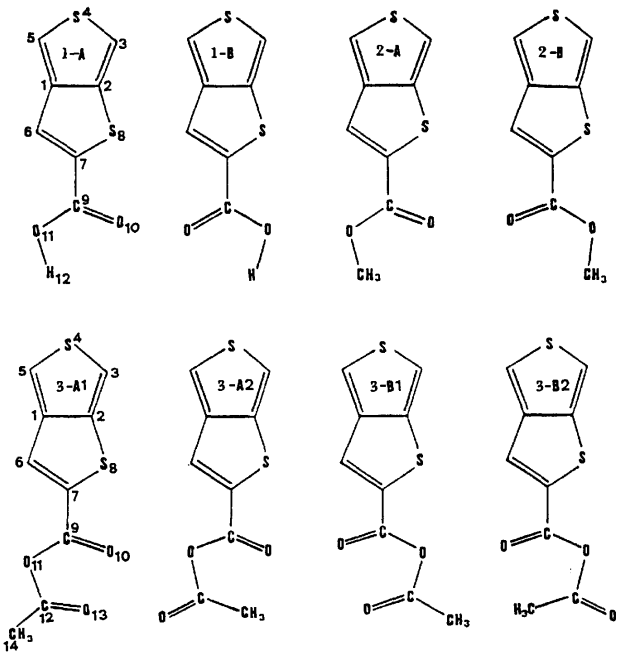

Fig. 1. Numbering system and molecular structure of the most stable conformations of **1**—**3**.

Additionally to the conformations of Fig. 1, we took into account also the less probable structures in which the H, CH_3, or $COCH_3$ groups are oriented towards the bicyclic framework, i.e. having $\omega_{10\text{-}9\text{-}11\text{-}12}=180°$. They will be indicated as **1**-AR, **2**-BR, **2**-AR, and so on. **1**-AR and **1**-BR minimum energy geometries retain their planarity after optimization but are less stable than **1**-A and **1**-B by 5.56 and 4.83 kcal mol^{-1}, respectively. The corresponding planar conformations of **2** and **3**

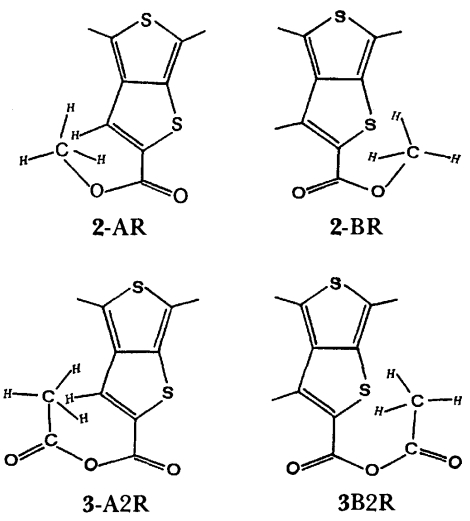

Fig. 2. Pseudo minima found when S_8 or the H bonded to C_6 bisects the bond angle of the methyl out-of-plane H atoms.

(**2**-ARP, **2**-BRP, **3**-A2RP, and **3**-B2RP) reach pseudo minima when the two out of plane H atoms of the CH_3 group are arranged as shown in Fig. 2. In such a situation, owing to the interaction with the H atom bonded to C_6 or with the S_8 electronic cloud, any rotation of the methyl group causes energy increasing which prevents the displacement towards the most stable structures **2**-A, **2**-B, **3**-A2, and **3**-B2 (a similar pseudo minimum was previously noticed in studying the molecular structures of methoxy derivatives of heptalenediones.[9)] Since **2**-ARP, **2**-BRP, **3**-A2RP, and **3**-B2RP forms are by far less stable than **2**-A, **2**-B, **3**-A2, and **3**-B2, no detail about their geometrical parameters is reported here. When the above cited pseudo minima were avoided a different behavior of **2** and **3** was found. In particular, both **2**-AR and **2**-BR converge towards a nonplanar single minimum energy structure (indicated as **2**-RNP in Table 1) in which the CH_3 group is still oriented towards the thieno[3,4-*b*]thiophene framework but has the whole $COOCH_3$ group rotated by about 80° around the C_7-C_9 bond.

Differently from **3**-A2R and **3**-B2R, the conformers **3**-A1R and **3**-B1R show no minimum and after optimization, come back to **3**-A1 and **3**-B1 respectively. **3**-A2 and **3**-B2 are all planar conformations whilst **3**-A1 and **3**-B1 are not, because of repulsion between O_{10} and O_{13} which causes rotation of about 20° around to the C_9-O_{11} and O_{11}-C_{12} bond; however, the energy difference between the planar and nonplanar structures is very low: ≃0.3 kcal mol^{-1}. These results lead to the conclusion that the $OCOCH_3$ group in **3** can widely oscillate. Although null or negligible rotation around the C_7-C_9 bond is predicted for the most probable conformations of **1**—**3** the calculated torsion barriers are not excessively high and the related potential well is rather flattened (in **1** and **2** a rotation of 45° of the substituent group implies an energy increase lower

a) This bond length was not optimized at MNDO level. MNDO geometries refer to all planar conformations (see text).

than 1 kcal mol^{-1}) so that wide oscillations around this bond are also possible. Let we now analyze more carefully the details of AM1 and MNDO geometries of the bicyclic framework and of the substituent groups, reported in Tables 2 and 3, respectively.

A first remark to point out is that, independently of the adopted method, the geometry of the thieno[3,4-*b*]-thiophene framework is practically the same calculated for the parent compound and it does not change significantly on changing the attached group. As it can be seen by comparing the geometrical data of **1**-A, reported in Table 2, the ring bond lengths differ by about 0.01 Å and bond angles by about one degree on passing from AM1 to MNDO or from the substituted to the unsubstituted molecule. These findings are noticed in compounds **2** and **3** too. More important

differences between AM1 and MNDO geometries occur in the -COOR and, mainly, in the $-COOCOCH_3$ framework (see Table 3). In particular, the C_7-C_9 bond length, in all the examined compounds, and the C_{12}-C_{14} bond length in **3** are predicted by AM1 about 0.03 Å shorter than the MNDO ones, whilst $r_{O\text{-}CH_3}$ in **2**-A and **2**-B is calculated by AM1 about 0.02 Å longer than that calculated by MNDO.

In all conformers of A type $\delta_{6\text{-}7\text{-}9}$ is 3—4 degrees larger than in the conformers of B type: being $\delta_{6\text{-}7\text{-}9}$ value practically constant, the substituent group is bent towards the right more than it is in B type conformers. This could be due, at least partially, to a lower repulsion between S_8 and oxygen with respect to that between C_6-H and oxygen owing to a greater interatomic distance in the former case, deriving from the large C_7-S_8 bond length in comparison with C_6=C_7 double bond length. Moreover the MNDO values concerning $\delta_{9\text{-}11\text{-}12}$ are, in general, from six to ten degrees larger than AM1 ones. These large angle differences are to be ascribed to the overestimation of "core-core" repulsion by MNDO with respect to AM1 method. As a consequence, the two methods lead to different final stability order, at least for the most probable conformations. So MNDO predicts structures **1**-B, **2**-B, and **3**-B1 to be the most stable ones, in contrast with AM1, which indicates **1**-A, **2**-A, and **3**-A2 as the most stable conformers. Indeed, apart from the question about which of them is the most stable, the ΔE between structures **1**-A and **1**-B and between **2**-A and **2**-B, both at MNDO and AM1 level, is less than 0.5 kcal mol^{-1}, whilst the ΔE among **3**-A2, **3**-B1, **3**-A1, and **3**-B2, at AM1 level, are less than, or, at the most, equal to 1 kcal mol^{-1}. On this ground an equilibrium between these structures is conceivable.

At present, at best of our knowledge, no experimental support is available in favor of one or another conformation. Unfortunately, the calculated electronic spectra of the above conformers are not sufficiently different from each other. However we note that the calculated dipole moments of the cited conformations are rather unlike one another, therefore an important contribution to the problem could be achieved from their measurement.

Electronic Spectra. As previously pointed out for thieno[3,4-*b*]thiophene,[2] the contribution of 3d orbitals of sulfur atoms to the orbitals involved in the low energy electronic transitions is very low.

The molecular orbitals involved in the electronic transitions responsible of the UV absorption maxima of **1**—**3** are chiefly the two highest occupied (π_1 and π_2) and the two lowest vacant (π_1* and π_2*) together with the *n* ones. In **1** and **2** the n orbital is mainly localized on O_{10}, whilst in **3** we have two n orbitals whose highest coefficients are located mainly on O_{10} and O_{13}, respectively.

Figure 3 shows the coefficient distribution of π_1, π_2, π_1*, and π_2* of **1** and **3** (the coefficient distribution of the frontier MO's of **2** is not reported because it is practically coincident with that of the MO's of **1**). In the same figure also the corresponding MO's of the thieno[3,4-*b*]thiophene are reported for comparison. It appears clearly that the coefficient distribution on the bicyclic framework is practically equal in the parent and in the derivative compounds, although non-negligible coefficients are found also on O_{10} (π_1 and π_2) and on the C_9=O_{10} fragment (π_1* and π_2*). Owing to the fact that these MO's in **3** do not span appreciably the extreme $COCH_3$ framework (which is the most rotated with respect to the molecular plane), the electronic transitions calculated by adopting the minimum energy conformations (nonplanar) or the planar ones, are practically coincident (differences are limited to 1 or 2 nm). Similarly, no appreciable difference exists between the calculated transitions of A and B type structures.

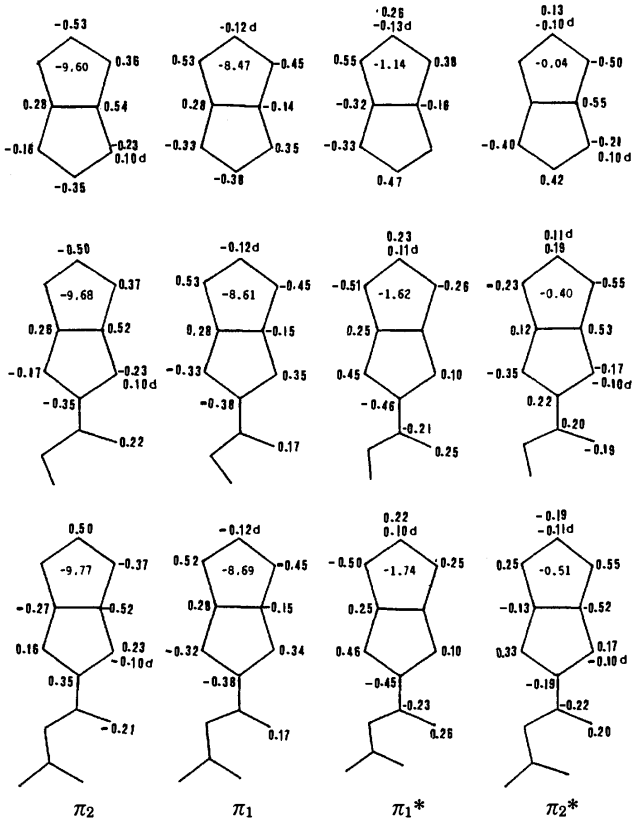

Fig. 3. Coefficient distribution of the two highest occupied (HOMO and NHOMO) and the two lowest unoccupied (LUMO and NLUMO) MO's of thieno[3,4-*b*]thiophene and its derivatives **1** and **3**. The figures inside the rings are the orbital energies (in eV). The n-type orbitals were calculated at −11.32 eV in **1**-A, at −11.23 eV in **2**-A, and at −11.06 and −11.68 eV in **3**-A2.

The charge densities on the atoms of the bicyclic framework mantain the same order noted in the parent compound,[2] so that also in **1**—**3** the C atoms in α position with respect to S are once again the most negatively charged.

Table 4. Electronic Transitions (eV) of **1—3** in Their Minimum Energy Conformation (Geometries from AM1 method).

a) Angle between the transition moment vector and the short molecular axis. b) Ref. 1 (95% ethanol). c) Values in parentheses are those obtained without d orbitals inclusion. d) Values in parentheses refer to the conformation rotated by 90° around C_7-C_9.

The CNDO/S results obtained for the most stable conformers (AM1 geometries) are collected in Table 4, together with those of thieno[3,4-*b*]thiophene, for which the optimized geometry coming from AM1 method was adopted too. Here also the literature experimental absorption maxima are reported. These latter were recorded in 95% EtOH solution. According to Skancke[10] the vapor phase values of thieno[3,4-*b*]-thiophene would be roughly 0.08 eV higher than the solution ones. A similar correction could be accepted also for **1—3**.

By comparing the experimental absorption maxima of thieno[3,4-*b*]thiophene and those of **1—3** we observe two noteworthy features: i) The maxima centered at 297 and 266 nm in the spectrum of the parent compound shift by 4—5 nm towards the blue after substitution; ii) the two maxima recorded at 276 and 257 nm in the thieno[3,4-*b*]thiophene spectrum, where they are equidistant from the band at 266 nm, show to be differently affected by substitution: The former shifts towards the red and is found in the range of 280 nm, the latter remains unchanged in **1—2** and is absent in **3**.

Theory predicts that the lowest energy transition of **1** and **2** and the lowest two transitions of **3** are $n \rightarrow \pi^*$ in nature: they are responsible of the absorption band observed in the range of 3.6 eV.

Owing to the slight changes noted in the frontier orbitals of the title molecules, also the lowest energy $\pi \rightarrow \pi^*$ transitions undergo negligible changes with

a) Total percentage of doubly excited configurations. Values marked with * refer to n→π^* transitions.

respect to those of the parent compound. So the band at 4.2 eV is mainly due to the $\pi_1\rightarrow\pi_1^*$, HOMO→LUMO transition, whilst the two bands recorded at 4.7 and 5.3 eV originate from HOMO→NLUMO and NHOMO→LUMO transitions. The oscillator strength of the transition calculated at 4.6 eV is strongly enhanced by substitution but it becomes gradually weaker as the substituent goes away from planarity.

The two experimental maxima centered at 284 nm and at about 255 nm, corresponding to the maxima at 276 and 257 nm of thieno[3,4-*b*]thiophene, are not supported by calculations: this occurred also in the parent compound, where they lie in a wavelengths range affected by a vibrational progression and were assigned to vibrational modes. Although in **1—3** they are no more equidistant from the band recorded at 266 nm, we think they originate once again from molecular vibrations.

The two lowest virtual orbitals of **1—3** are stabilized by substitution more than the two highest occupied ones, so that the calculated $\pi\rightarrow\pi^*$ transitions involving them are calculated 10—15 nm shifted towards the red with respect to those of thieno[3,4-*b*]thiophene. This result, seems contrasting with the weak blue shift appearing in the experimental findings, even if it is in line with the red shift observed on passing from the spectrum of benzene to that of the benzoic acid.[11] However, the eletronic transition energies of **1—3** shift towards the blue when remarkable rotation around C_7-C_9 is considered (see values in parentheses for **2** in Table 4). This behavior, together with the fact that the rotation barrier of the carboxyl group (calculated by the same method[2]) in the benzoic acid is $\simeq$1 kcal mol^{-1} higher than in **1**, suggest that contributions from conformers highly rotated around C_7-C_9 are important in the electronic structure description of the title compounds.

Calculations carried out by using CNDUV/99 program,[8] in order to test the importance of doubly excited configurations, are reported in Table 5. Apart from an overestimation of the n→π^* transition(s) (a peculiarity of this program), also these last results support the above assignments and conclusions as regards the $\pi\rightarrow\pi^*$ transitions. Double excitations are present in percentages comparable with those noticed in the parent molecule and the highest total value was found for the transitions lying at $\simeq$5—5.4 eV.

Conclusion

The results of the present study indicate that the most stable conformations of **1—3** have the substituent group coplanar to the bicyclic framework. The low energy difference between the most stable conformers (two in **1**, **2**, four in **3**) suggests the possibility of an equilibrium among them; moreover the rather flattened potential well when rotation around C_7-C_9 is considered allows a wide out of plane oscillation of the substituent group.

The frontier molecular orbitals of **1—3** show a coefficient distribution similar to that observed for thieno[3,4-*b*]thiophene with a weak extension on C_9 and O_{10}. The absorption band on the long wavelengths side originates from n→π^* transitions. The two maxima lying in the range of 280 and 250 nm are probably to be assigned to vibrational modes. The slight blue shift (4—5 nm) shown by the lowest energy bands on passing from the parent compound to its derivatives can be accounted for if a remarkably contribution from the conformers with high rotation around the C_7-C_9 bond is assumed.

The Effect of Cadmium Ions on the Polarographic Reduction of Poly[(*p*-methylbenzyl)viologen] Dibromide in Water

Bhim Bali PRASAD
Analytical Division, Chemistry Department, Faculty of Science, Banaras Hindu University, Varanasi-221 005, India
(Received February 25, 1988)

The d.c. polarographic reduction of a redox polyelectrolyte, poly[(*p*-methylbenzyl)viologen] dibromide, in the presence of cadmium sulfate salt demonstrated two well-defined, irreversible diffusion-controlled cathodic waves corresponding to the reduction of protonated form as well as the cadmium complex of the polyelectrolyte in aqueous buffers (pH 2.00—6.00). No wave was observed due to the reduction of the unprotonated form of the polymer in the present instance, however, another ill-defined wave of irreversible nature was emerged at relatively higher negative potential presumably because of the catalytic evolution of hydrogen, at the dropping mercury electrode. An attempt has been made to correlate these results in terms of cadmium ion interaction with the polyelectrolyte during the course of electrode processes.

A comprehensive study on the polarography of the redox polymers, viz., poly[(*p*-methylbenzyl)viologen] dibromides (*o*, *m*, *p*-$PMVBr_2$) has recently been made to understand their reduction mode as well as electron-transfer mechanism involved.[1] The present paper deals with the effect of cadmium ions on the polarographic reduction of poly[(*p*-methylbenzyl)viologen] dibromide (*p*-$PMVBr_2$) in the aqueous solutions of pH 2.00—6.00 range.

Polyelectrolytes have been found to demonstrate a significant impact over their conformational alterations with the addition of simple salts.[2] As a consequence of such salt-induced conformational transition, i.e., the coiling or contraction of cationic polyelectrolyte in interaction with the anions of the added salt in dilute solution and sometimes the possibility of a chemical reaction of polyelectrolyte with the added salt, the reduction behavior of these systems would likely to differ than those of the salt-free polymeric materials. As is evident from the structural formulation of *p*-$PMVBr_2$ [represented by the structure **1**], one of the two nitrogens of the terminal bipyridine is not quaternized and may therefore serve as the proton acceptor allowing the system to exhibit an equilibrium between its protonated and unprotonated form as *p*-$PMVBr_2 + H^+ \rightleftarrows$ *p*-$PMVBr_2H^+$. However, in the presence of Cd^{2+} ions, this uncharged nitrogen of the compound would act as a potential site for the complexation as well. It seems to be feasible that both the protonation and complexation may occur simultaneously and/or compete with each other on the time scale involved for the electroreduction. Thus, a different type of electrode process as compared to that of the polymer alone could be expected, in the presence of cadmium sulfate in this investigation.

Experimental

Materials. Demineralized water, distilled twice from a Pyrex glass still, with specific conductivity ranging between 1×10^{-6} to 2.5×10^{-6} $S\,cm^{-1}$ was used in the preparation of solutions.

The preparation and characterization of the polymer *p*-$PMVBr_2$ (MW=11000) was followed according to the earlier recipes.[1c,3] All other chemicals were of analytical grade.

Methods. All the polarograms were recorded in the usual manner[1c] at room temperature (ca. 25 °C) with the help of Leeds Northrup Type E Electrochemograph using a dropping mercury electrode (DME) and a saturated calomel electrode (SCE) as working and reference electrodes, respectively. First, a known volume (15 ml) of the supporting electrolyte was introduced into the cell and purged with nitrogen gas, and the residual current was obtained. Then, desired amounts of solid depolarizer(s) were added to the solution in the cell; after each addition, the nitrogen gas was allowed to pass through the mixture until the solid completely dissolved and then the final polarogram was run under the blanket of this gas.

The DME used had following characteristics in the open circuit: m=1.90 mg s^{-1} and t=4.3 s (h_{Hg}=35 cm; 0.1 M aqueous KCl, M=mol dm^{-3}). The supporting electrolytes used were a KCl-HCl mixture (pH= 2.00) and citrate buffers (pH=4.40 and 6.00); the ionic strength was maintained at 0.1 M with the addition of requisite amounts of KCl. In each case of these buffers, polarograms were run in two ways: (i) keeping the concentration of *p*-$PMVBr_2$ in the buffer fixed and recording the current-voltage curves with subsequent addition of different known amount of cadmium sulfate, (ii) varying the concentration of polymer by introducing the weighed amount of *p*-$PMVBr_2$ into the buffer containing fixed concentration of cadmium ions.

It must be mentioned that any investigation in an alkaline medium may arise some complications of dequaternization[4] or ylide formation[5] in the system. Therefore all investiga-

tions made in this case had to be confined to only acidic buffers.

The currents and potentials used in the final calculations have been corrected for the residual currents as well as the *iR* drops involved.

Results and Discussion

The representative polarograms of (i) *p*-$PMVBr_2$ with varying amount of Cd^{2+} ions and (ii) Cd^{2+} solution with increasing concentration of *p*-$PMVBr_2$ in a KCl-HCl mixture (pH=2.00) are illustrated in Figs. 1 and 2, respectively. All results obtained with different buffers from analysis of both kinds of polarograms are summarized in Tables 1 and 2.

As is evident from Fig. 1 , two irreversible waves ($E_{1/2}$(I)=−0.520 V and $E_{1/2}$ (II)=−1.00 V vs. SCE) were

obtained for pure *p*-$PMVBr_2$ (concentration: 4.65 mg cm^{-3}; pH=2.00). The cathodic currents for these waves (which are also obtained with other buffers studied; Table 1) have been previously correlated in terms of a protonation equilibrium *p*-$PMVBr_2+H^+ \rightleftarrows$ *p*-$PMVBr_2H^+$.[1c] Keeping in view of the gross effect of pH variation on the wave height which decreases for first wave and increases for the second one with decreasing acidity of the medium, both waves have been attributed to the reduction of protonated and unprotonated form of the polymer, respectively. However, more interesting results are obtained in the presence of $CdSO_4$ which still demonstrated two well-defined waves with their pH-independent half-wave potentials approximately at −0.51 V and −0.75 V vs. SCE, and a third ill-defined wave emerging beyond −1.00 V depending upon the pH of the solution (Table 1). Similar results are also observed with the solution having fixed amounts of Cd^{2+} ions and varying concentration of *p*-$PMVBr_2$ (Fig. 2). In this case, the wave height for wave I increases while the limiting currents of waves II and III are practically constant at a certain pH with the successive increment in the polymer concentration (Table 2). It may be noted that the variation of Cd^{2+} ions concentration only affects the height of second wave which is found to be increasing; others remaining constant as before for a certain solution (Table 1). All three waves are, however, found to be increasing with the height of the mercury pressure.

The appearance of the first wave of the polymer in the presence of cadmium ions seems to be similar in every respect with the wave obtained for the reduction of the protonated form of *p*-$PMVBr_2$ alone.[1c] The wave II, whose wave height remains uneffected by the pH variation, may be assigned to a cadmium-$PMVBr_2$ complex. The negative shift in half-wave potential as compared to that of free Cd^{2+} ions and moreover the gradual decrease in $E_{1/2}$ values of wave II with the increase of *p*-$PMVBr_2$ concentration conforms the existance of a pH-independent complexation process in the solution (Table 2). It is of interest to note that the acidity of the medium is not effective at all in controlling the limiting current for wave II (Tables 1 and 2) since even smallest amount of unprotonated polymer ($PMVBr_2$) at any pH, is found to be sufficient enough to cause complete complexation with Cd^{2+} ions taken in the present instance. The increasing trend of the height of the wave II with the increase of Cd^{2+} ions concentration (Table 1) may reflect the spontaneous complexation process with high molecular weight unprotonated compound ($PMVBr_2$) obtained after the protonation equilibrium. However, a constant limiting current of wave II, irrespective of the variation of polymer concentration (Table 2), interestingly indicates the limiting magnitude of complexation between Cd^{2+} (fixed) and minimum concentration of unprotonated polymeric species available, at any pH.

The rates of electron-transfer processes and hence the limiting currents for the reduction of *p*-$PMVBr_2H^+$ (wave I) and Cd^{2+}-$PMVBr_2$ complex (wave II) are diffusion-controlled as slopes for the plots of $\log i_l$ vs. $\log h_{Hg}$ (Table 2; pH=2.00; [$PMVBr_2$]=3.962 mg cm^{-3}) are found to be close to 0.5 for both waves. However, a slope value of 0.8 in the case of wave III indicates that the electroreduction is not governed by a diffusion process. Further, on substitution of $E_{1/4}$ and $E_{3/4}$ values of waves I and II (Fig. 1, [Cd^{2+}]=0.215 mg cm^{-3}, pH=2.00) in the following relationships of an irreversible (Eq. 1) and a reversible wave (Eq. 2) at 25 °C

$$E_{3/4}-E_{1/4}=-0.0517/\alpha n \quad (1)$$

$$E_{3/4}-E_{1/4}=-0.0564/n \quad (2)$$

the fractional values of αn and n obtained for first and second waves [wave I (αn=0.47, n=0.51); wave II (αn=0.35, n=0.37)] reveal the irreversible nature of the reduction in either case. Moreover, the negative shift in half-wave potentials with the increase of ionic strength (>0.1 M) of the supporting electrolyte in the respective buffer is typically suggestive of the irreversibility of all the three waves appeared in the present case.[6a]

It is interesting to emphasis that wave I is still noticeable even at higher pH (in the presence of Cd^{2+} ions) whose wave height decreases with the pH of the solution conforming the reduction of *p*-$PMVBr_2H^+$ and therefore, one may conclude that the prospect of a protonation equilibrium is not at all hampered by the addition of Cd^{2+} ions. It appears that as and when protonation equilibrium exhibits in the solution, the Cd^{2+} ions subsequently start complexing to a maximum extent as discussed earlier with the unprotonated species (*p*-$PMVBr_2$) of the compound available, irrespective of the pH of the medium concerned. The complete omission of waves owing to the reductions of free unprotonated polymer and Cd^{2+} ions, surplus if any, in the solution after complexation is quite surprising and seems to reflect the nonavailability of the these species in the vicinity of the electrode for the reduction as such. One may speculate the existance of a somesort of interaction or binding between metal ion and ligand (not complexation) which probably restricts the process of reduction of these species individually on the time scale involved. Although D(complex)<D(Cd^{2+}), the relatively large decrease in the magnitude of free cadmium current (Table 2) when complexed with the polymeric material, might also corroborate the fact that all Cd^{2+} ions are not consumed in complexation with the unprotonated polymer; however some of these ions would presumably behave like electroinactive substance as a consequence of their possible interactions with *p*-$PMVBr_2$ and/or the cationic radical species[1c] obtained after the first reduction.

The nature of third wave is rather more interesting. The height of this wave, which is irreversible in

nature, remains practically constant irrespective of the amount of *p*-$PMVBr_2$ added in the solution. The half-wave potentials realised in the case of *p*-$PMVBr_2$ (without Cd^{2+} ions) are pH-independent[1c] whereas the same for wave III, in the present instance, shifts towards more negative potential with the increase of pH of the solution. Furthermore, the height of this wave in the presence of cadmium salt decreases with the pH in contrast to the wave obtained for the polymer alone which increases with increase of the pH of the medium concerned. As is apparent from the above experimental facts, the wave III in the present study, thus, might be considered due to the reduction of some different species other than unprotonated *p*-$PMVBr_2$. Further, this wave does not appear in shape as a polarographic maximum; however, an attempt to suppress the wave by the use of several maximum suppressors (e.g., gelatine, Triton X-100, soap etc.) was failed. On the basis of these observations, the wave III could reasonably be assigned to only a catalytic hydrogen current, appearing in the shape of a wave, before the normal evolution of hydrogen.[6b] It should be mentioned in this connection that Brdička[7] has discovered somewhat similar kind of catalysis and polarographic behavior during an investigation of proteins in the presence of cobalt salts. The interpretation of catalytic wave in the present investigation might be correlated with the first reduction of *p*-$PMVBr_2$. The catalytic effect corresponds to the first reduction product i.e., a cation radical *p*-$PMVBr_2H^{\ddagger}$; from which, under the influence of cadmium, hydrogen is irreversibly reduced at the DME with decreased overvoltage.[8] Thus, the following overall scheme for wave III can be tentatively suggested.

$$p\text{-}PMVBr_2H^{\ddagger} + Cd^{2+} + e^- \rightarrow (p\text{-}PMVBr_2Cd^{2+})^- + 1/2\ H_2$$

The interaction of *p*-$PMVBr_2H^{\ddagger}$ with cadmium ions must be considered as further conditions necessary for the formation of a catalytic wave[7] in the present case. As no catalytic wave was observed in the absence of Cd^{2+} ions in the case of the reduction of *p*-$PMVBr_2$ compound alone[1c] in the similar concentration ranges (cf., Table 2), it seemed reasonable to consider some sort of intercoulombic bond between *p*-$PMVBr_2H^{\ddagger}$ and Cd^{2+} ion on the electrode surface which essentially facilitates the reduction of hydrogen with decreased overvoltage. The cation radical protons consumed in the electrode process are replaced by a reaction with proton of the medium. Normally, the height of the catalytic wave should increase with the concentration of *p*-$PMVBr_2$ (and hence *p*-$PMVBr_2H^{\ddagger}$) and Cd^{2+} ions[8] but it was found to be practically unaltered at a certain pH. This supports the fact that the surface of mercury electrode becomes fully covered, mainly at higher negative potential under the force of electrostatic attraction, by the adsorption of even small amount of high-molecular-weight catalytically-active cationic reduction product [a cation radical *p*-$PMVBr_2H^{\ddagger}$ under the interaction of Cd^{2+} ions in the present instance] which eventually limits the height of the catalytic wave to a constant magnitude.[9] The anticipated decrease in current of this wave at lower acidities is quite interesting which reflects somewhat implicit behavior in context to the adsorption phenomenon as proposed above. However, the remarkable decrease in the catalytic wave height at pH=6.00 might be attributed to the scavenging of the electrode by the hydroxide ions of the medium.[1b] It should be further noted that the possibility of partial adsorption of cationic cluster of *p*-$PMVBr_2H^{\ddagger}$ and Cd^{2+} ion [i.e., *p*-$PMVBr_2H^{\ddagger}$-Cd^{2+}] even in the lower potential range of wave II cannot be fully ignored. This eventually appears to impede the reduction current of wave II to some extent, supporting as one of the possible reasons for the drastic decrease in the magnitude of free cadmium current after complexation (Table 2).

The catalytic wave height was observed to be decreasing with the increase of ionic strength (>0.1 M) by addition of KCl.[8,9] This probably suggests the significant desorption of catalytic active cluster of cation radical reduction product with Cd^{2+} ions [*p*-$PMVBr_2H^{\ddagger}$-Cd^{2+}] from the surface of the mercury electrode by the large amount of KCl added in the solution. The process of adsorption of "cationic cluster" at higher negative potential under the electrostatic influences might be apparently mitigated by the large excess of KCl present in the solution. Furthermore, a higher concentration of KCl may also induce curling or the contraction[2] of the polyelectrolyte envelop around the electrode surface which, in turn, may cause desorption phenomenon. It should be pointed out in this connection that the cadmium salt or supporting electrolyte present in the solution might have also similar impact over the conformation of the polymeric film but not showed up effectively at the DME. On the other hand, the *p*-$PMVBr_2H^{\ddagger}$-Cd^{2+} interaction appears to be instigating the catalytic reduction of hydrogen at ionic strength <0.1 M in the present study.

Polarography of Metal Hydroxamates. Individual and Simultaneous Determination of Tungsten and Molybdenum Using Benzo- and Cinnamohydroxamic Acids

Sabooj Kumar BHOWAL* and Mita BHATTACHARYYA
Department of Chemistry, Jadavpur University, Calcutta 700032, India
(Received May 16, 1988)

Methods for the determination of traces of tungsten have been developed by directly subjecting the organic extracts of its benzo- and cinnamohydroxamic acid complexes to d. c. and derivative pulse polarography. Well defined waves and peaks are obtained in a ternary solvent mixture containing the extract, methanolic lithium chloride and aqueous phase. The methods are highly selective and allow determination of the metal in the ppm range. A procedure has also been developed for the simultaneous determination of tungsten and molybdenum using their benzohydroxamates. Effects of acids and solvents on the system have been studied and the probable mechanism of reduction of the complexes has also been discussed.

Studies on the extraction-polarography of metal hydroxamates directly in the organic phase have led to the development of excellent methods for the determination of traces of molybdenum.[1-3] In this article is reported similar investigations carried out to develop methods of analysis of traces of tungsten and simultaneous determination of tungsten and molybdenum. Investigations carried out with the benzohydroxamic acid (BHA) and cinnamohydroxamic acid (CHA) complexes of tungsten reveal that the complexes after extraction into a mixture of chloroform and isobutyl alcohol or chloroform can directly be subjected to d.c. and derivative pulse polarography (D.P.P.) in a mixture of solvents containing the extract, methanolic lithium chloride and water in a definite ratio. The systems yield well defined waves or peaks which have been utilized for the determination of trace quantities of tungsten. Solvent extraction separation and direct submission of the extract to polarography have resulted in the development of highly selective and quick determination methods which are superior to those known up to date. Furthermore a quick and sensitive method for the simultaneous determination of molybdenum and tungsten, two closely related metals, have also been worked out utilizing the benzohydroxamic complexes of the elements. Highly reproducible results have been obtained with synthetic mixtures of the metals. The probable mechanism of reduction of the complexes have been discussed.

Experimental

Apparatus. A Tacussel PRG 5 Pulse polarograph was used as reported earlier.[1-3] The capillary characteristics were as follows in the different solvent extracts at the mercury height of 45 cm.

Chloroform-isobutyl alcohol extract
m=0.376 mg s^{-1} t=9.78 s.
Chloroform extract
m=0.371 mg s^{-1} t=9.90 s.

All d.c. and D.P.P. were recorded with a controlled drop time of 1 and 3 s respectively, 4 mV s^{-1} recorder speed and 50 mV pulse amplitude.

Reagents and Solutions. Standard tungsten solution was prepared from $Na_2WO_4 \cdot 2H_2O$ (analar grade) and standardized as the oxine complex.[4] Standard molybdenum solution was prepared as described earlier.[1-3]

Benzohydroxamic acid (BHA) and cinnamohydroxamic acid (CHA) were prepared as mentioned earlier.[1,3] 1.0% (w/v) ethanolic solution of BHA and 0.2% (w/v) ethanolic solution of CHA were used for the investigations.

Lithium chloride (analar, Riedel) was used as the supporting electrolyte. Methanol (G.R.S. Merck) was distilled before use. All other metal salts, solvents, acids, and chemicals used were of analytical reagent grade. Twice distilled water was used in all the studies.

Results and Discussion

Procedure for Determination of Tungsten and Simultaneous Determination of Molybdenum and Tungsten with BHA. An aliquot of standard tungsten solution or a mixture of standard molybdenum and tungsten solutions were taken in a 50 ml separatory funnel and diluted to 10 ml with water. After addition of 3 ml of BHA the acidity was adjusted to 1.5 mol dm^{-3} with 6 mol dm^{-3} hydrochloric acid and the mixture was shaken with 3 ml of 1 : 1 chloroform and isobutyl alcohol for one minute. The organic layer was drained into a 50 ml flask and aqueous layer was washed with 3 ml of the same solvent mixture. The washing was mixed with the main extract. To the combined extract was added 7 ml 1% methanolic lithium chloride, 12 ml 0.5 mol dm^{-3} perchloric acid solution and the mixture was made up to volume with methanol. Direct current and D.P.P. were recorded from −500 to −950 mV after deaeration with nitrogen for ten minutes.

Procedure for Determination of Tungsten with Cinnamohydroxamic Acid. A standard aliquot of tungsten solution taken in a 50 ml separatory funnel was diluted to 10 ml with water. The solution was treated with 5 ml of CHA solution. After adjusting acidity to 1.5 mol dm^{-3} with 6 mol dm^{-3} hydrochloric acid the mixture was extracted with 4 ml of chloroform and the organic layer was taken in a 50 ml flask. The

aqueous layer was washed with 2 ml chloroform and the washing was taken with the main extract. The organic layer was made up to volume with 7 ml 1% methanolic lithium chloride, 12 ml 4 mol dm^{-3} perchloric acid and methanol. Direct current and D.P.P. were recorded from −300 to −800 mV after deaeration with nitrogen for ten minutes.

Extraction and Polarographic Behavior of W-BHA and W-CHA Complexes. The colorless complex of tungsten with BHA is found to be sparingly soluble in common extracting solvents like chloroform, benzene, methyl isobutyl ketone, and 3-methyl-1-butanol. However, the complex can be easily extracted into a 1 : 1 mixture of chloroform and isobutyl alcohol from 1.0 to 6.0 mol dm^{-3} hydrochloric acid solutions. The extract when mixed with methanolic lithium chloride and an aqueous phase containing 0.5 mol dm^{-3} perchloric acid in the ratio 3:16:6 furnishes excellent polarograms with d.c. and D.P.P. techniques. The pulse polarogram yields a sharp peak at −800 mV and d.c. polarogram shows a single wave with $E_{1/2}$ value at −780 mV (Fig. 1). Inspite of the fact that tungsten benzohydroxamate produces a single reduction wave like molybdenum,[1] the nature of reduction happens to be quite different. The value of the slope obtained from the log plot of the d.c. wave (50.8 mV) is nearly compatible with a one electron reduction step which is not totally reversible. The transfer coefficient, α, 1.16, being close to unity points towards a quasireversible reduction. The peak half width (123 mV) of the D.P.P. at 50 mV amplitude is, however, indicative of a reversible one electron process. Thus it may be concluded that the d.c. wave and pulse peak indicate the reduction of W(VI) to W(V) species. Like molybdenum, reduction of tungstate ion in aqueous medium observed by other workers[5] show two reduction waves W(VI) to W(V) and W(V) to W(III) where the first wave appears at a potential of zero volt. So in the present case the reduction of tungsten appears to happen in the complexed form as the $E_{1/2}$ of the first wave is shifted to negative direction and that of second one cannot be obtained due to the same reason. The linear relationship of current with square root of mercury height indicates that the reduction is diffusion controlled.

The W-CHA complex is freely soluble in chloroform due to presence of a conjugation in the reagent molecule. The complex is completely extracted into the said solvent from 0.5 to 2.5 mol dm^{-3} hydrochloric acid solution. The organic phase can be mixed with aqueous phase and methanol in the ratio 3 : 6 : 16 to give a homogeneous phase whose D.P.P. produce a sharp peak at −620 mV. $E_{1/2}$ of the d.c. polarogram lies at −625 mV (Fig. 2). The average slope (50.2 mV) obtained from the log plot of the d.c. wave and transfer coefficient, 1.17 suggest the reduction to be a one electron quasireversible one. The peak half width 115 mV is also indicative of the same. That the wave appears due to reduction of complex rather than the uncomplexed oxo ion, WO_2^{2+}, is evidenced by the fact that free tungstate ion under the same conditions does not show any wave or peak. The linear relationship of current with square root of mercury height indicates the reduction is diffusion controlled.

We have previously reported[1] the determination of traces of molybdenum after extraction of its benzohydroxamate in chloroform and subjecting the extract to polarography in a solvent mixture containing chloroform, methanol, and an aqueous phase in a definite ratio. It has now been observed that molybdenum benzohydroxamate can be extracted into a chloroform isobutyl alcohol mixture like that of the tungsten complex. The extract when subjected to polarography in the same solvent mixture as used in the case of tungsten, furnishes well defined peak in D.P.P. with an E_p of −330 mV. Simultaneous determination of

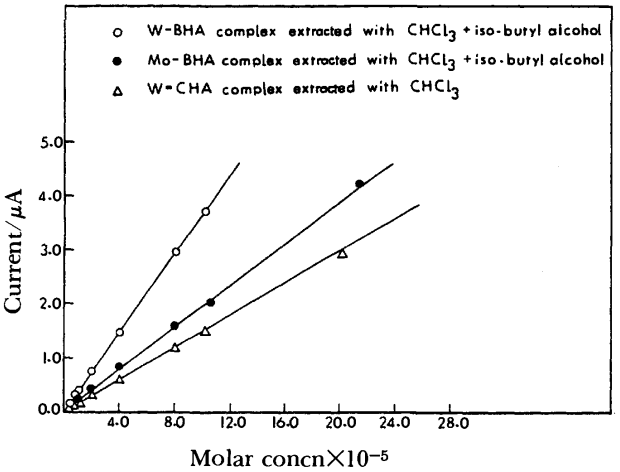

Fig. 5. Current-concentration relationship of benzo- and cinnamohydroxamates of W and Mo (D.P.P.).

trace quantities of the said metals has become possible in a ratio of 1 : 5 and vice versa (Fig. 3). The results are given in Table 1. Attempts have been made to develop a method for the simultaneous determination of molybdenum and tungsten after extraction of their cinnamohydroxamates in chloroform. But the method could not be worked out as the peaks of the two metals happened to be overlapping with each other.

Extracting Solvents, Supporting Electrolyte, Composition of Solvent Mixture and Current-Concentration Relationship. Chloroform-isobutyl alcohol mixture in a ratio of 1 : 1 was found to be the best extractant for the W-BHA complex. A homogeneous solution was obtained by mixing 6 ml of the extract, 7 ml 1% methanolic lithium chloride, 12 ml of aqueous phase and 25 ml of methanol in a total volume of 50 ml. Acids like HCl, H_2SO_4, CH_3COOH, H_3PO_4, and also NH_3 in the aqueous phase did not furnish well defined waves or peaks. Most well defined and reproducible polarograms were produced only when the aqueous phase contained 0.25 to 1.0 mol dm^{-3} $HClO_4$. For the tungsten-CHA complex chloroform alone was found to be the best extractant. A mixture of the chloroform extract, methanolic lithium chloride, and aqueous phase containing 3 mol dm^{-3} to 5 mol dm^{-3} $HClO_4$ in the ratio 3 : 16 : 6 produced the best polarogram in this case. Acids such as HCl, H_2SO_4, H_3PO_4, CH_3COOH were not found suitable as an aqueous phase. Methanolic solution of LiCl was used as the supporting electrolyte in all the cases. For both W-BHA and W-CHA complexes the diffusion current is found to vary linearly with concentration of the metal and the said ranges applicable for d.c. and D.P.P. techniques are shown in Figs. 4 and 5.

Effect of Diverse Ions. The effects of diverse ions and complexing agents are given in Table 2. It is observed W-CHA system can tolerate larger concentration of metals like iron(III) and cerium(IV) and complexing agents like ascorbic acid, tartaric acid, oxalic acid, and fluoride. This behavior may be attributed to the greater stability of the W-CHA complex in comparison to W-BHA complex. However, benzo and cinnamohydroxamates of tungsten cannot be extracted in presence of metals like copper(II), cobalt(II), manganese(II), chromium(III), cadmium(II), mercury(II), titanium(IV), tin(IV). Molybdenum(VI) is found to interfere with determination of tungsten with CHA.

Table 2. Tolerance Limits of Diverse Ions and Complexing Agents
Concentration of W=2.0×10^{-5} mol dm^{-3}

Metal ion or complexing agent	Tolerance ratio of the metal ion or complexing agent to complexes of W with		Remarks
	BHA	CHA	
Fe(III)	10	70	Extracted in presence of ascorbic acid
Pb(II)	100	100	Extracted from 1.5 mol dm^{-3} perchloric acid solution
Ni(II)		2	
Re(VII)	100	100	
Ce(IV)	10	100	Extracted in presence of ascorbic acid
V(V)	10	100	Extracted in presence of ascorbic acid
Zr(IV)	10	50	Extracted in presence of fluoride
U(VI)	50	50	
Mo(VI)	5		
Ascorbic acid	20	500	
Tartaric acid	200	500	
Citric acid	500	500	
Oxalic acid	40	70	
Fluoride	40	100	
EDTA	500	500	

Statistical Errors in the Determination of Tungsten. The relative standard deviation values for the pulse polarographic determination of tungsten with benzo- and cinnamohydroxamic acids have been calculated from a set of ten determinations in each case. The said values are ±6.37% for the W-BHA and ±2.78% for W-CHA complexes.

The authors express their thanks to the authorities of Alexander Von Humboldt-Stiftung, West Germany for the donation of the Pulse Polarograph. One of the authors (M.B.) likes to thank the U.G.C., India, for the award of a research fellowship.

Preparation and Crystal Structure of Diaquabis-(1,8-naphthyridine 1-oxide)cobalt(II) Nitrate

Zhu YIN, Gan XINMIN, Tang NING, and Tan MINYU*
Department of Chemistry, Lanzhou University, Lanzhou, P. R. China
(Received May 21, 1988)

The complex $[Co(napyo)_2(H_2O)_2](NO_3)_2$ was formed by the reaction of cobalt(II) nitrate with 1,8-naphthyridine 1-oxide (napyo) in methanol medium. The complex crystallizes in the monoclinic system, space group $P2_1/n$ with Z=2. Lattice parameters are: a=7.165(2), b=11.797(2), c=11.830(3) Å, β=95.14(3)°, V=995.9(4) Å^3, D_c=1.705 g cm^{-3}, D_o=1.714 g cm^{-3}, λ(Mo $K\alpha$)=0.71069 Å, μ=9.26 cm^{-1}, F(000)=522. The final R=0.036 for 1433 unique observed reflections. Co^{2+} ion is coordinated by two nitrogen atoms and four oxygen atoms to form a distorted octahedron.

Many complexes of aromatic amine *N*-oxide with metal ions have been synthesized and characterized in recent twenty years.[1] However any complexes of 1,8-naphthyridine 1-oxide (napyo), which belongs to the kind of aromatic amine *N*-oxide, with transition metal ions have never been reported. In order to investigate the coordinating power of napyo with transition metal ions we recently synthesized a series of complexes of napyo with 3d metal ions. The present paper reports on the synthesis and crystal and molecular structure of the title compound.

Experimental

Preparation of $[Co(napyo)_2(H_2O)_2](NO_3)_2$. 0.1 mmol $Co(NO_3)_2 \cdot 6H_2O$ and 0.2 mmol napyo[2] were dissolved in 40 ml methanol. Then the solution was placed in a desiccator with $CaCl_2$ at room temperature. After about two weeks pink needle-like crystals of the title compound were obtained. Calcd for $C_{16}H_{16}CoN_6O_{10}$: C, 37.59; H, 3.15; N, 16.44; Co, 11.53%. Found: C, 37.70; H, 3.21; N, 16.13; Co, 11.79%).

Crystal Structure Determination of $[Co(napyo)_2(H_2O)_2](NO_3)_2$. Crystal Data: $C_{16}H_{16}CoN_6O_{10}$, M=511.27, monoclinic, space group $P2_1/n$, a=7.165(2), b=11.797(2), c=11.830(3) Å, β=95.14(3)°, V=995.9 Å^3, Z=2, D_c=1.705 g cm^{-3}, D_o (flotation in CCl_4/CH_2I_2)=1.714 g cm^{-3}, λ(Mo $K\alpha$)=0.71069 Å, μ=9.26 cm^{-1}, F(000)=522.

A crystal of approximate dimension 0.2×0.2×0.3 mm was selected for the data collection on an Enraf-Nonius CAD4 diffractometer with graphite-monochromated Mo $K\alpha$ radiation, $\omega/2\theta$ scan. 25 reflections were used for measuring lattice parameters. 1928 independent reflections were collected in the range of $2° \leqslant 2\theta \leqslant 50°$. 1433 reflections with $I > 3\sigma(I)$ were used in the structure determination and refinement. The intensity data were corrected for LP effect and empirical absorption. The structure was solved by the direct method and Fourier techniques, refined by full-matrix least-squares with anisotropic temperature parameters for all non-hydrogen atoms and isotropic thermal parameters for H atoms. Atomic scattering factors were taken from Ref. 3. All calculations were done by using computer programs from the Enraf-Nonius SDP package.[4] Final R=0.036, R_w=0.038.

Results and Discussion

The final atomic coordinates and equivalent isotropic temperature factors are given in Table 1,[5] selected bond lengths and bond angles in Tables 2 and 3. The equations of the least-squares planes concerned, deviations of atoms and dihedral angles between these planes are given in Table 4. The structure of complex cation $[Co(napyo)_2(H_2O)_2]^{2+}$ and the packing of the molecules in the unit cell are presented in Figs. 1 and 2, respectively. The crystal of the complex consists of discrete $[Co(napyo)_2(H_2O)_2]^{2+}$ cations and nitrate group anions. All the atoms in both napyo rings are fairly coplanar, as shown in Table 4. It can be seen from Fig. 1 that the cobalt atom locates at the inversion center of the complex cation and is bonded to two oxygen atoms and two nitrogen atoms of two different napyo ligands and two oxygen atoms of two water molecules. The six coordinating bonds are nearly equal in length (2.037—2.096 Å) but the three coordinating planes (Table 4) are not strictly vertical with each other. So the coordinated configuration of Co atom is a distorted octahedron.

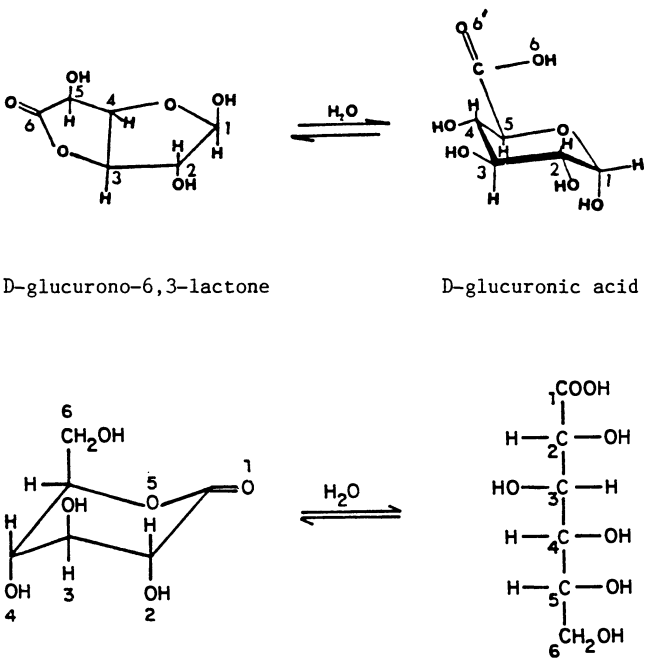
Carbohydrate Complexes with Lead(II) Ion. Interaction of Pb(II) with β-D-Glucurono-6,3-lactone, D-Glucono-1,5-lactone, and Their Acid Anions and the Effects of Metal Ion Binding on the Sugar Hydrolysis

Heidar-Ali TAJMIR-RIAHI
Department of Chemistry, University of Laval, Quebec, G1K 7P4 Canada
(Received April 27, 1988)

The interaction of Pb(II) ion with β-D-glucurono-6,3-lactone, D-glucuronic acid, D-glucono-1,5-lactone, and their acid anions has been investigated in aqueous solution and solid compounds of the type Pb(D-glucurono-6,3-lactone)$(NO_3)_2$, Pb(D-glucuronic acid)$(NO_3)_2$, Pb(II)-D-glucuronate, Pb(D-glucono-1,5-lactone)$(NO_3)_2$, and Pb(II)-D-gluconate have been isolated. These compounds are characterized by means of FT-IR, ^1H and ^{13}C NMR spectroscopy and molar conductivity measurements. Among these Pb-sugar complexes, the crystal structure of the Pb(II)-D-gluconate is known through X-ray diffraction measurements, in which the lead(II) ion is hexa-coordinated, binding to four D-gluconate anions via a carboxylato oxygen and an α-hydroxyl group of the two anions (chelation) and to a carboxylato oxygen atom of the other two sugar anions (unidentately). Spectroscopic evidence suggested that in the Pb-lactone or Pb-acid adducts, the metal ion could be bonded to a lactone or acid molecule through one of the carbonyl oxygen atom and other sugar donor group as well as to two bridging nitrato groups. In the Pb(II)-D-glucuronate, the metal ion could be bonded to four sugar moieties (similar to that of the Pb(II)-D-gluconate) via a carboxylato oxygen atom and other sugar donor group of the two anions and to a carboxylato oxygen atom of the other two acid anions, resulting into a hexa-coordinated lead(II) ion. The β-anomer sugar configuration is predominant in the free D-glucurono-6,3-lactone, D-glucuronic acid, D-glucuronate anion and in these Pb-sugar complexes.

The highly toxic effect of lead on the environmental pollution have been known for some years,[1] and correlations between lead poisoning[2,3] and its carcinogenic action in animals have been established.[4] It has been also demonstrated that the injected lead in rats accumulates in the cell nuclei.[5] In recent years, the stabilizing or destabilizing effects of the Pb(II) ion interaction on the double-helix structure of DNA have been investigated and the mode of Pb-DNA binding has been the subject of several studies.[6-8] Sugar is a part of nucleic acids and lead-sugar interaction could have biological importance. On the other hand, D-glucurono-6,3-lactone and D-glucono-1,5-lactone show biological properties and are readily hydrolyzed to D-glucuronic and D-gluconic acid in aqueous solution (Scheme 1).

In our recent report, it was shown how the silver nitrate complexes with the free β-D-glucurono-6,3-lactone, D-glucuronic acid, and D-glucono-1,5-lactone in aqueous solutions, while the silver acetate facilitates the lactone hydrolysis and the acid ionization.[9-11] Similarly, the alkaline earth metal ions (Mg^{2+} and Ca^{2+}) coordinate with D-glucuronate anion in aqueous solutions, whereas in ethanolic solution, the binding of these metal ions to the free lactone is preferred.[12] In this work, we describe the Pb(II) ion interaction with β-D-glucurono-6,3-lactone, D-glucuronic acid, and D-glucono-1,5-lactone, in aqueous solution and the isolation and characterization of the complexes formed, using FT-IR, ^1H and ^{13}C NMR spectroscopy and molar conductivity measurements, that have not been reported so far. Furthermore, the effects of metal ion binding on the sugar hydrolysis have been discussed here.



D-glucurono-6,3-lactone D-glucuronic acid

D-glucono-1,5-lactone D-gluconic acid

Scheme 1.

Experimental

Materials and Methods. β-D-Glucurono-6,3-lactone, D-glucuronic acid, and D-glucono-1,5-lactone were purchased from Aldrich Chemical Co., and were used as supplied. Other chemicals were reagent grade and were used without further purification.

Synthesis of Pb-Sugar Adducts. The Pb-lactone adducts

Table 1. Analytical Data for Pb-Sugar Complexes

Compound	Calcd(Found)		
	%Pb	%C	%H
Pb(D-glucurono-6,3-lactone)$(NO_3)_2$	40.93	14.25	1.58
	(39.90	13.95	1.70)
Pb(D-glucuronic acid)$(NO_3)_2$	39.43	13.17	1.91
	(38.80	13.55	1.75)
Pb(D-glucuronate)$_2$	34.90	24.44	3.05
	(33.55	23.80	2.90)
Pb(D-glucono-1,5-lactone)$(NO_3)_2$	40.66	14.15	1.97
	(39.70	13.85	2.10)
Pb(D-gluconate)$_2$	34.46	24.20	3.69
	(33.80	23.50	3.85)

were prepared by the addition of $Pb(NO_3)_2$, 1 mmol in H_2O (20 ml) to a solution of the free lactone 1 mmol in H_2O (10 ml). The solution mixtures were left at room temperature for a period of 48 h under slow evaporation and then ethanol-acetone (50/50) was used to bring down the white precipitate (avoid heating the solution, due to rapid lactone hydrolysis and acid ionization). This was filtered off and washed with acetone several times and dried over $CaCl_2$. The Pb-acid adducts were also prepared in a similar fashion, using D-glucuronic acid instead of the lactone and using ethanolic solution to bring down the metal-acid precipitate. The analytical results given in Table 1, showed the composition of the type Pb(D-glucurono-6,3-lactone)$(NO_3)_2$, Pb(D-glucuronic acid)$(NO_3)_2$, and Pb(D-glucono-1,5-lactone)-$(NO_3)_2$. The Pb-lactone adducts are very hygroscopic and should be kept in a desiccator over $CaCl_2$.

Synthesis of Pb-Sugar Salts. The Pb-sugar salts were prepared by the addition of the equimolar amount of the $PbCO_3$ and the lactone or acid in H_2O (50 ml) and the mixtures were heated up till all the lead carbonate was dissolved. After cooling down the solution to room temperature, ethanol was used to precipitate the white Pb-sugar salt. This was filtered off and washed with ethanol several times and dried over $CaCl_2$. The analytical data given in Table 1, showed the composition of Pb(D-gluconate)$_2$ and Pb(D-glucuronate)$_2$. The Pb-sugar salts synthesized here, are very soluble in water, but they are not soluble in common organic solvents.

Physical Measurements. The infrared spectra have been recorded on a NICOLET 5DXB Fourier Transform infrared instrument with DTGS detector. The spectra were taken as KBr pellets with a resolution of 2—4 cm^{-1}. The ^1H NMR spectra were recorded with a Varian XL-200 instrument in D_2O solution containing DSS as reference. The ^{13}C NMR spectra have been recorded on a Bruker WH-80 instrument in D_2O solution containing dioxane as reference. Conductance measurements were carried out at room temperature in aqueous solution (10^{-3} mol dm^{-3}) with a conductivity meter type CDM2e (Radiometer, Copenhagen).

Results and Discussion

FT-IR Spectra. The infrared spectra of the free D-glucurono-6,3-lactone, D-glucuronic acid, and D-glucono-1,5-lactone and their lead complexes have been recorded in the region of 4000—500 cm^{-1} and a comparison has been made with those of the structurally identified D-glucuronate-CaBr·$3H_2O$,[13] Mn(II)-D-gluconate·$2H_2O$[14] and the corresponding Ag-sugar compounds[9-11] and the results of the spectral analysis will be discussed below.

Sugar OH Stretching Vibrations and Lead(II) Binding. The assignments of the infrared vibrational frequencies of the free D-glucurono-6,3-lactone, D-glucuronic acid, and D-glucono-1,5-lactone were reported earlier.[9-12] The free lactone and acid OH stretching vibrations appeared as several strong and broad absorption bands in the region of 3500—3200 cm^{-1} of their spectra[9-12] and exhibited considerable intensity changes and shifting towards lower frequencies, on sugar metalation or acid ionization. The observed spectral changes in this region, are related to the participation of sugar OH group in lead-sugar binding. Similar trends were observed in the IR spectra of the structurally known D-glucuronate-CaBr·$3H_2O$ and Mn(II)-D-gluconate·$2H_2O$, where sugar bindings were found to be via sugar OH groups as well as the carboxylate anion.[13-15]

Lactone Carbonyl Stretching Vibrations and Lead(II) Ion Binding. Drastic spectral changes were observed for each sugar carbonyl stretching vibration, upon lead ion interaction, which will be dealt with separately.

D-Glucurono-6,3-lactone. The carbonyl stretching vibration of the free D-glucurono-6,3-lactone was observed as a strong band at 1758 cm^{-1} and exhibited shifting and splitting at 1760 and 1757 cm^{-1}, in the spectrum of the Pb(D-glucurono-6,3-lactone)$(NO_3)_2$ adduct (Fig. 1). The shifting and splitting of the lactone C=O stretching vibration are related to the direct metal-carbonyl binding. Similar spectral changes were observed for the carbonyl stretching vibration, in the IR spectra of the $AgNO_3$, $AgClO_4$, and alkaline earth metal halide (Mg^{2+} and Ca^{2+}) adducts with D-glucurono-6,3-lactone molecule, where metal sugar binding was concluded to be through the carbonyl oxygen atom.[11,12] The carbonyl stretching vibration of the free D-glucuronic acid was observed at 1709 cm^{-1} and showed shifting and splitting at 1758 and 1730 cm^{-1}, in the spectrum of the Pb(D-glucuronic acid)$(NO_3)_2$ adduct (Fig. 1). The observed changes for the carbonyl group are due to the participation of the acid C=O group in metal ligand bonding, in the Pb(D-glucuronic acid)$(NO_3)_2$ compound. Similar trends were observed in the spectrum of the Ag(D-glucuronic acid)(NO_3) adduct, where metal-acid binding was suggested to be through the acid carbonyl oxygen atom.[11] It should be noted that, one of the components of the C=O stretching vibration at 1758 cm^{-1} in the spectrum of the Pb-acid adduct bears similarity to that of the free lactone (1758 cm^{-1}) or to that of the lactone at 1757 cm^{-1}, in the Pb-lactone adduct (Fig. 1). This can lead to the question of the purity of the Pb-acid compound that might be contaminated with the free lactone or Pb-lactone adduct (since the reaction has been carried out in aqueous solution, where acid $\rightleftarrows$ lactone conver-

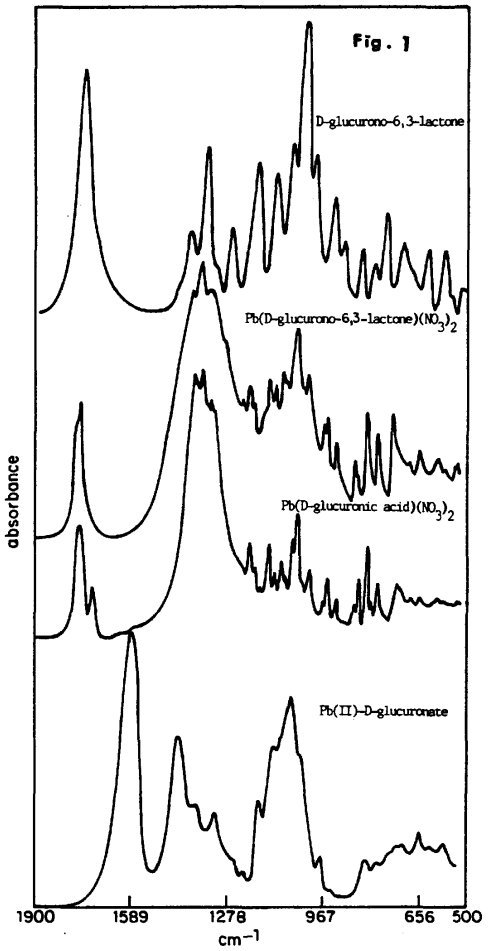


Fig. 1. The FT-IR spectra of D-glucurono-6,3-lactone and its lead(II) complexes in the region of 1900—500 cm^{-1}.

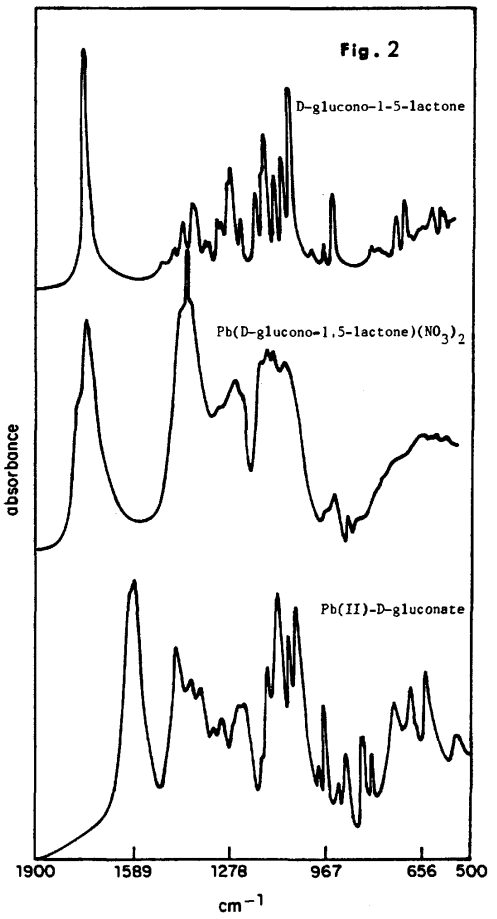

Fig. 2. The FT-IR spectra of D-glucono-1,5-lactone and its lead(II) complexes in the region of 1900—500 cm^{-1}.

sion is readily occurred). Since the separation between the two components of the C=O groups in the Pb-acid ($\Delta\bar{\nu}$=28 cm^{-1}) and Pb-lactone adducts ($\Delta\bar{\nu}$=3 cm^{-1}) are different, therefore, the spectral changes observed for the carbonyl groups are related to two different metal-sugar complexes. On the other hand, even an absorption band is present at about 1758 cm^{-1}, both in the free lactone and the Pb-acid adduct, the one at 1758 cm^{-1} in the free lactone has lost most of its intensity in the spectrum of the Pb-acid adduct (Fig. 1) and this is indicative of the complexed C=O group and it is not related to the free lactone (present in the lead-acid compound). However, the purity of these Pb-sugar adducts are also confirmed from their ^{13}C NMR spectra (see next pages). On comparing the IR spectra of the Pb-sugar adducts with that of the Pb(II)-D-glucuronate (Fig. 1), one can see that the carbonyl stretching vibration of the free acid at 1709 cm^{-1}, shifted towards lower frequencies and split into two components at 1583 and 1420 cm^{-1}, in the spectrum of the lead-D-glucuronate. These two absorption bands are related to the antisymmetric and symmetric OCO^- stretching vibrations.[11,12] The observed spectral changes for the carboxylate group, in the spectrum of the lead-D-glucuronate are due to the ionization and the participation of the sugar OCO^- group in metal-ligand bonding.

D-Glucono-1,5-lactone. The C=O stretching vibration of the free D-glucono-1,5-lactone was observed as a strong band at 1728 cm^{-1} and exhibited shifting and splitting at 1775 and 1741 cm^{-1}, in the spectrum of the Pb(D-glucono-1,5-lactone)$(NO_3)_2$ adduct (Fig. 2). The shifting and splitting of the carbonyl stretching vibration is indicative of the Pb-sugar binding through the lactone carbonyl oxygen atom. Similar changes were observed for the C=O group in the Ag(D-glucono-1,5-lactone) NO_3 adduct, where the silver sugar binding was suggested to be through carbonyl oxygen atom.[9] On the other hand, in the IR spectrum of the Pb(II)-D-gluconate, the carbonyl stretching vibration showed splitting and shifting towards lower frequency (Fig. 2). The two broad and strong bands at 1586 and 1430 cm^{-1} in the spectrum of the lead-gluconate are attributed to the antisymmetric and symmetric OCO^- stretching vibrations.[9] It should be noted that, in the crystal structure of the Pb(II)-D-gluconate,[16] the Pb(II) ion was bonded to four D-gluconate residues through a carboxylato oxygen atom and an OH group (in α-

position) of the two sugar anions (chelation) and to a carboxylato oxygen atom of the other two sugar anions (unidentately). It is worth mentioning that, no Pb-sugar containing bonded D-gluconic acid can be isolated, due to the partial acid ionization and salt formation and this is evident, by the presence of a strong band at about 1600 cm^{-1}, which is related to the antisymmetric sugar OCO^- stretching vibration.[9]

Other sugar absorption bands in the region of 1350—900 cm^{-1} related to the strongly coupled OH, CO, and CH modes,[17,18] exhibited drastic changes, upon Pb(II) interaction (Figs. 1 and 2). The shifting and intensity changes observed in this region for the OH bending and C-O stretching vibrations are related to the participation of the sugar OH and CO groups in metal sugar bindings.

Nitrato Group Vibrational Frequencies and Binding Modes. The strong and broad absorption band at about 1400 cm^{-1} related to the ν_3 of the ionic nitrate in D_{3h} symmetry,[19] exhibited shifting and splitting in the spectra of the Pb(D-glucurono-6,3-lactone)$(NO_3)_2$, Pb(D-glucuronic acid)$(NO_3)_2$, and Pb(D-glucono-1,5-lactone)$(NO_3)_2$ adducts (Figs. 1 and 2). The splitting of the NO_3^- band at 1380 cm^{-1} is indicative of the presence of the nitrato group in lower symmetry and the possible Pb-NO_3 coordination. Similar changes were observed for the nitrato group vibration in the IR spectra of the Ag(D-glucurono-6,3-lactone)NO_3, Ag(D-glucuronic acid)NO_3, and Ag(D-glucono-1,5-lactone)-$NO_3 \cdot H_2O$ adducts,[9-12] where the possibility of the bridging NO_3^- group (sugar-Ag-NO_3-Ag-sugar) and the ionic NO_3^- was proposed. Thus a similar nitrate binding modes (bridging and ionic) could be suggested, in these Pb-sugar adducts. This is also consistent with the molar conductivities observed for the free $Pb(NO_3)_2$ and its sugar adducts, which indicated the presence of both bonded and ionic NO_3^- groups, in aqueous solutions. Other nitrate absorption bands in the region of 1300—7000 cm^{-1} were masked by the strong sugar vibrations (Figs. 1 and 2).

Solution Spectra. In D_2O solution, the IR spectra of the free lactones, acids, and their lead(II) complexes in the region of 1900—1400 cm^{-1}, showed marked similarities with those of the corresponding solid compounds. The C=O stretching vibrations of the free lactones at about 1750 cm^{-1} (D-glucurono-6,3-lactone), 1700 cm^{-1} (D-glucuronic acid), and 1720 cm^{-1} (D-glucono-1,5-lactone) showed splitting and shifting towards higher frequencies, in the spectra of the $Pb(NO_3)_2$-sugar adducts. These changes are consistent with the Pb(II) ion binding to the carbonyl oxygen atoms of the free lactone and acid. On the other hand, in the spectra of the Pb(II)-D-glucuronate and Pb(II)-D-gluconate, the carboxyl stretching vibrations showed splitting and shifting towards lower frequencies, which are characteristic of the acid ionization and salt formation. The observed spectral changes in aqueous solution also indicate the participation of the sugar C=O group in the Pb-lactone and Pb-acid complexation, while in the Pb-sugar salts the OCO^- is mainly involved in metal-sugar bindings.

^{13}C and ^1H NMR Spectra. The ^{13}C NMR spectra of D-glucurono-6,3-lactone, D-glucuronic acid, D-glucono-1,5-lactone, and D-gluconic acid have been reported.[20,21] In this work, in D_2O solution, the ^{13}C NMR chemical shifts (δ/ppm) were observed for D-glucono-1,5-lactone, 175.20 (C-1), 82.24 (C-2), 75.70 (C-3), 72.00 (C-4), 67.95 (C-5), 60.80 (C-6), for the Pb(D-glucono-1,5-lactone)$(NO_3)_2$, 177.50 (C-1), 83.20 (C-2), 73.70 (C-3), 72.20 (C-4), 67.90 (C-5), 60.88 (C-6), for D-gluconic acid, 176.40 (C-1), 73.25 (C-2), 72.30 (C-3), 71.95 (C-4), 71.50 (C-5), 63.50 (C-6), for Pb(II)-D-gluconate, 180.50 (C-1), 75.40 (C-2), 72.99 (C-3), 71.99 (C-4), 71.77 (C-5), 63.40 (C-6), for β-D-glucurono-6,3-lactone, 103.60 (C-1), 74.90 (C-2), 85.60 (C-3), 78.55 (C-4), 70.50 (C-5), 177.50 (C-6), for Pb(D-glucurono-6,3-lactone)$(NO_3)_2$, 103.7 (C-1), 74.95 (C-2), 85.60 (C-3), 78.60 (C-4), 71.20 (C-5), 178.50 (C-6), for β-D-glucuronic acid, 96.90 (C-1), 74.65 (C-2), 76.35 (C-3), 72.45 (C-4), 75.40 (C-5), 173.40 (C-6), for Pb(D-glucuronic acid)$(NO_3)_2$, 96.80 (C-1), 74.70 (C-2), 76.40 (C-3), 73.20 (C-4), 75.50 (C-5), 174.50 (C-6), and for Pb(II)-D-glucuronate, 96.85 (C-1), 74.80 (C-2), 76.40 (C-3), 72.90 (C-4), 73.60 (C-5), and 177.40 (C-6). As it is evident, D-glucono-1,5-lactone and D-gluconate anion bind the Pb(II) ion via O-1, and O-2 (due to the downfield shifts of the C-1 and C-2 chemical shifts for both lactone and acid) and this is consistent with the structural analysis of the Pb(II)-D-gluconate, which showed Pb(II) ion binding through O-1 (carboxylato) and O-2 oxygen atoms.[16] Similarly, the major downfield shifts for the C-6 and C-5 chemical shifts of the β-D-glucurono-6,3-lactone, C-6 and C-4 of the β-D-glucuronic acid would indicate the Pb(II) binding via a carbonyl oxygen atom in concert with O(5)-H (lactone) or O(4)-H (acid) (chelation). Similar binding of the D-glucuronate anion was observed in the crystal structure of D-glucuronate-$CaBr \cdot 3H_2O$, with one of the sugar anion being bonded to Ca(II) ion via a OCO^- oxygen and O(4)-H group.[13]

The ^1H NMR spectra of the free D-glucurono-6,3-lactone and D-glucuronic acid in D_2O solution showed both α- and β-anomer forms with the α-H chemical shift at δ 5.56, and β-H at δ 5.45 for the free lactone and α-H at δ 5.58 and β-H at δ 5.28 for the free acid, with the β-anomer domination for both lactone and acid. In the spectra of the Pb(D-glucurono-6,3-lactone)$(NO_3)_2$ and Pb(D-glucuronic acid)$(NO_3)_2$ and Pb(II)-D-glucuronate, the β-anomer was found. It has been suggested[22] that the binding modes of the α- and β-anomers of D-glucuronic acid are different and in order one can have a better understanding of the binding modes of D-glucuronate or D-gluconate anion, a comparison between the coordination chemistry of the two acids has been made here.

Coordination Chemistry of D-Glucuronic Acid. Among all the metal D-glucuronats compounds

formed, the crystal structures of potassium-D-glucuronate·$2H_2O$,[23] and D-glucuronate-CaBr·$3H_2O$[13] are known through X-ray diffraction measurements. In the potassium salt, the potassium ion is surrounded by the sugar O-1, O-3, O-6, O-6′, and two H_2O molecule, with sugar anion having β-anomer configuration.[23] In the D-glucuronate-CaBr·$3H_2O$, the calcium ion is bonded to three sugar anions, through O-6, O-5 of the first, O-6′, O-4 of the second, and O-1, O-2 of the third sugar anion as well as to two H_2O molecule, with sugar having α-anomer form.[13] As it is evident, the α-anomer complexes via both carboxylate oxygen atoms and in concert with ring O-5 or O(4)-H group (chelation). Recently, on the basis of the ^{13}C NMR spectroscopy,[24] and other techniques,[25] it has been shown how copper and molybdenum ions bind to D-glucuronate anion, in aqueous solution and the solid state. In the presence of the Cu(II) ion of different concentrations and at variable pH's, the binding modes of D-glucuronic acid have been monitored[24] and the flexibility of this sugar moiety towards metal ion coordination has been shown. The main binding sites are the carboxylate oxygen atom (unidentately) or chelation in concert with other sugar OH groups,[25] while molybdenum binding was suggested to be through sugar hydroxyl groups as well as the carboxylate anion.[25] Therefore, the binding of the Pb(II) ion could be through a carboxylate oxygen atom and O-4 (chelation)(in both acid and anion), while lactone binding is possibly through carbonyl O-6 and O(5)-H group.

Coordination Chemistry of D-Gluconic Acid. The crystal structures of the sodium-D-gluconate,[26] potassium-D-gluconate,[27] potassium-D-gluconate·H_2O,[28] ammonium-D-gluconate,[29] manganese-D-gluconate·$2H_2O$,[14] and lead-D-gluconate[16] are known through X-ray diffraction analysis. The Na^+ ion binds to six oxygen atoms belonging to six different D-gluconate anions with the participation of the OCO^- group and other sugar OH groups (except O-3).[26] The K^+ ion in the potassium-D-gluconate is bonded to both carboxylate and OH group oxygen atoms,[27] whereas the potassium-D-gluconate·H_2O contains two different types of crystals, in which one of the potassium ion is bonded to the sugar OH groups and not the carboxylate group,[30] while in the other crystal potassium ion binding is through both sugar OH and OCO^- groups as well as H_2O molecule.[28] In the ammonium-D-gluconate, the NH_4^+ has a strong hydrogen bonding network with all the sugar OH groups, which stabilizes the crystal structure.[29] In the manganese(II)-D-gluconate·$2H_2O$, the Mn(II) ion is coordinated to two sugar anions through a carboxylate oxygen atom and an OH group of each anion as well as to two H_2O, forming hexa-coordinated metal ion.[14] In the Pb(II)-D-gluconate, the Pb(II) ion is bonded to four sugar anions via a carboxylate oxygen atom and O(2)-H group of the two anions and to a OCO- oxygen atom of the other two anions, resulting into a hexa-coordinate Pb(II) ion.[16] Therefore, it seems that the main binding of the D-gluconate anion is through carboxylato oxygen atoms and O(2)-H hydroxyl group (in α-position), forming a five-membered ring with metal cations. This is also true for the Pb(II) ion binding here, which is through a carboxylato oxygen atom and O(2)-H group of each D-gluconate anion, while in the Pb-lactone adduct, the binding could be through the C=O oxygen atom and the O(2)-H hydroxyl group.

Conclusion

On the basis of the spectroscopic (FT-IR, ^1H and ^{13}C NMR) and structural properties of the D-glucurono-6,3-lactone, D-glucuronic acid, and D-glucono-1,5-lactone and their Pb(II) complexes, the following points can be emphasized:

(a) In the Pb(D-glucurono-6,3-lactone)$(NO_3)_2$ adduct, the Pb(II) ion could be coordinated to a lactone molecule via C(6)=O and O(5)-H oxygen atoms as well as to two nitrato groups, while in the Pb(D-glucuronic acid)$(NO_3)_2$, the lead ion is bonded to an acid molecule, through carbonyl O(6′) and O(4)-H as well as to two nitrato groups. In the Pb(II)-D-glucuronate, the metal ion is bonded to carboxylato group (one or both oxygen atom) or a carboxylato oxygen atom and O(4)-H group (chelation) of the two acid anions and to a OCO^- oxygen atom of the other two sugar anions, forming a hexa-coordinated Pb(II) ion (similar to that of the Pb(II)-D-gluconate salt).

(b) In the Pb(D-glucono-1,5-lactone)$(NO_3)_2$, the metal ion would be bonded to a lactone molecule via C(1)=O and O(2)-H oxygen atoms as well as to two nitrato groups. In the Pb(II)-D-gluconate, the lead ion is hexa-coordinated, binding to four sugar anions through a carboxylato oxygen atom and an O(2)-H group of the two anions and to a OCO^- oxygen atom of the other two D-gluconate anions, which is known through X-ray structural determination.[16]

(c) The β-anomer sugar configuration is predominant in the free D-glucurono-6,3-lactone, D-glucuronic acid, and their lead sugar complexes.

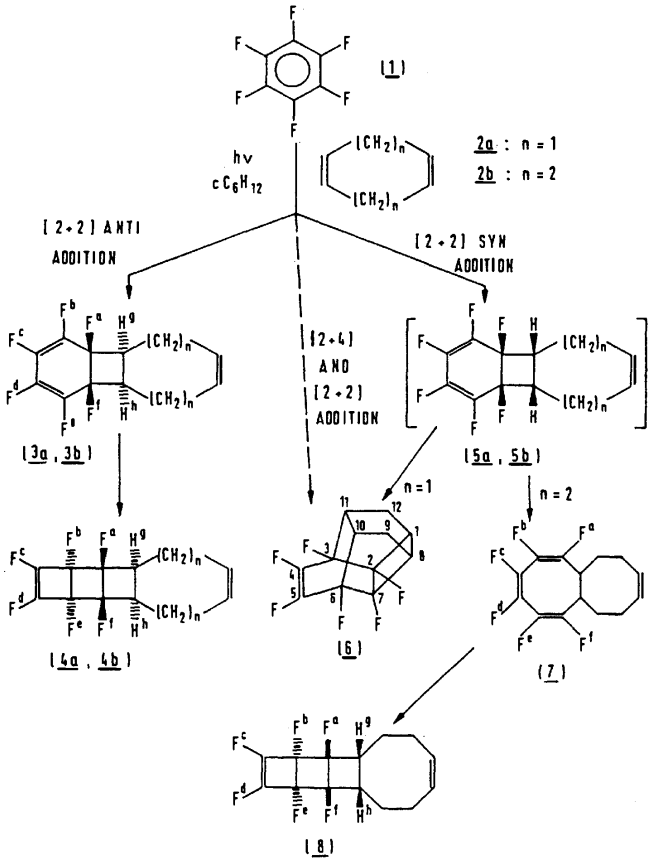
Photocycloadditions of Cyclodienes to Hexafluorobenzene

Boris ŠKET, Nataša ZUPANČIČ, and Marko ZUPAN*
Department of Chemistry and "Jožef Stefan" Institute, E. Kardelj University of Ljubljana, Ljubljana, Yugoslavia
(Received May 18, 1988)

The stereochemistry of photocycloaddition reactions of various cyclodienes to hexafluorobenzene in cyclohexane solution depends on the structure of the cyclodiene and [2+2]cycloadducts are mainly observed. Photoreaction of 1,5-cyclooctadiene with hexafluorobenzene gives nearly equal amounts of syn and anti [2+2]adducts, which are further transformed to tetracyclic systems, contrary to this, the stereochemistry observed by reactions with 1,4-cyclohexadiene depends on the molar ratio of cyclodiene-hexafluorobenzene and 30—54% of syn addition is observed, the syn adduct, however, being further transformed to 2,3,4,5,6,7-hexafluoropentacyclo-[6.4.0.0^{2,7}.0^{3,11}.0^{6,10}]dodec-4-ene. Syn selectivity of [2+2]cycloaddition was enhanced when bicyclic dienes were used and it is interesting that in the case of norbornadiene and benzonorbornadiene only exo attack was observed, and no anti attack occurred in the case of benzonorbornene. The quantum yields of [2+2]photocycloaddition reactions depend on the structure of the cyclodiene and the concentrations of hexafluorobenzene and cyclodiene. The quantum yields for norbornadiene and 1,4-cyclohexadiene are nearly the same, while it is two times higher in a photoreaction with 1,5-cyclooctadiene, when equal amounts of hexafluorobenzene and 1,5-cyclooctadiene were irradiated in cyclohexane at λ=253.7 nm.

Aromatic molecules undergo various photochemical transformations, depending on their structure, the reagents and the reaction conditions which initiated wide ranging investigations in the last twenty years.[1] Photocycloaddition reactions of benzene derivatives with alkenes and dienes resulted in 1,2-, 1,3-, or 1,4-cycloaddition products, the course of the reaction depending on the substituent on the phenyl ring and on the structure of the olefin and diene. The advantage of fluorine as a substituent in investigations of phototransformations of organic molecules have been shown in several studies.[2] We have already demonstrated that hexafluorobenzene readily reacted with various cycloalkenes when irradiation was carried out in cyclohexane solution, however, the structure of the olefin played the major role in the stereochemistry of [2+2]cycloaddition reactions: cyclopentene gave predominantly anti products[3] while with indene stereospecific syn addition was observed.[4] We now report investigations of the effect of the structure of the cyclodienes on photocycloaddition reactions to hexafluorobenzene.



Scheme 1.

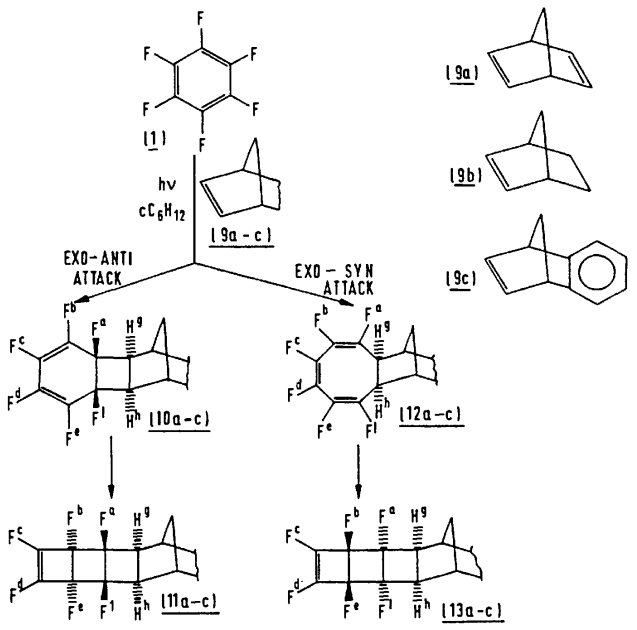
Results and Discussion

Cyclohexane solution of 1,4-cyclohexadiene (1 mmol) and hexafluorobenzene (2 mmol) was irradiated for 1 h at λ=253.7 nm, the solvent evaporated and the crude reaction mixture analyzed by ^{19}F NMR spectroscopy and nine signals, corresponding to three different products in the following relative yields: 61% (**3a**), 16% (**4a**), and 23% (**6**) (Scheme 1), were observed.

Products were separated by preparative TLC and VPC and the structures of the products determined on the basis of their NMR, MS, and X-ray data. The major product **3a** shows in its ^{19}F NMR the following signals at δ=−169.5, −171.75, and −198.0, while ^{1}H NMR spectrum confirms the presence of olefinic protons, CH_2 group and a signal at δ=3 with a coupling constant $^{3}J_{FH}$=7.5 Hz. Mass spectrum confirms the presence of 1:1-adduct, while irradiation of the pure product **3a** gave exclusively product **4a**, which shows the following three signals in its ^{19}F NMR spectrum at δ=−129.0, −190.5, and −204.25, and in its ^{1}H NMR spectrum olefinic protons at δ=5.9, methylenic protons at δ=2.3 and a signal at δ=3.08 with $^{3}J_{FH}$=7.5 Hz. The third product formed (**6**) shows a

quite different ^{19}F NMR spectrum with a signal at $\delta=-167.25$ (corresponding to fluorine atoms on olefinic carbon atom), and two signals at a much higher field: $\delta=-216.75$ and -217.5, corresponding to fluorine atoms bonded to saturated carbon atoms. ^{1}H NMR spectrum also shows only signals at higher fields: $\delta=3.2$ (2H), 2.64 (2H), and 1.8 (4H). However, mass spectrum (m/z 266 (M^+, 24%)) confirms the formation of 1 : 1 adduct, whose structure was finally proven by X-ray analysis.[5] 2,3,4,5,6,7-hexafluoropentacyclo-[6.4.0.$0^{2,7}$.$0^{3,11}$.$0^{6,10}$]dodec-4-ene (**6**) could be formed either by the primary [2+2] syn addition, followed by intramolecular [2+4] or by primary [2+4] addition, followed by [2+2] addition; we were unable to detect the presence of primary formed [2+2] or [2+4] adducts and so the origin of the product **6** formation remains open. However, further studies of the stereochemistry of [2+2]cycloaddition reaction with 1,5-cyclooctadiene (**2b**) where four products were formed (Scheme 1) diminished the possibility of the formation of product **6** via primary [2+4]cycloaddition. The irradiation of cyclohexane solution of 1,5-cyclooctadiene (**2b**) and hexafluorobenzene gave the crude reaction mixture containing four products (**3b**, 41%; **4b**, 9%; **7**, 41%; and **8**, 9%) which were partly separated by preparative TLC. The mixture containing **3b** and **7** was further irradiated for forty hours and the formation of two isomeric tetracyclic products **4b** and **8** was established. On the basis of the spectroscopic data we have found that the formation of the four products corresponds to the exclusively [2+2]cycloaddition process (syn attack 50%). In Scheme 1, the course of photocycloaddition reactions with 1,4-cyclohexadiene and 1,5-cyclooctadiene is presented.

Further, we have studied the stereochemistry of photocycloaddition reactions with norbornadiene (**9a**) and benzonorbornene (**9c**), where there are four possible [2+2] attacks: exo-syn, exo-anti, endo-syn, and endo-anti. As in the case of norbornene (**9b**),[6] only exo-attack was observed with **9a** and **9c**, while the amount of anti attack was diminished from 20% observed with norbornadiene to the exclusive exo-syn attack, occurring in the case of benzonorbornene. The course of cycloaddition reactions is presented in Scheme 2.



Scheme 2.

Table 1. The Effect of Cyclodiene or Cycloalkene Ring Size on the Stereochemistry of the [2+2]-Photocycloaddition[a] to Hexafluorobenzene

Cyclodiene or ycloalkene	exo-syn		exo-anti
	12	**13**	**11**
9a	47	33	20
9b	57	38	5
9c	72	28	—

a) The relative yields were determined by ^{19}F NMR spectroscopy; concentration of C_6F_6 0.111 mol l^{-1}; concentration of cyclodienes or cycloalkenes 0.055 mol l^{-1}; solvent cyclohexane; 35 °C, λ 253.7 nm.

Table 2. ^{19}F NMR Spectroscopic Data for Photoadducts[a]

	Product	δ_F/ppm		
		$F^{c,d}$	$F^{b,e}$	$F^{a,f}$
2a	**4a**	−129	−204.25	−190.5
2b	**4b**	−125.5	−195	−190
	7	−158.5	−155.2	−165.5
	8	−126	−195	−161.25
9a	**11a**	−123.75	−194.23	−180.8
	12a	−161.25	−159	−168
	13a	−125.25	−180	−164.25
9b	**11b**	−123	−193.5	−177.4
	12b	−159.75	−156	−163.5
	13b	−124.5	−179.25	−158.25
9c	**12c**	−158.3	−156.75	−165
	13c	−124.9	−180	−163

The starting cycloalkenes or cyclodienes were as follows: **2a;** 1,4-cyclohexadiene, **2b;** 1,5-cyclooctadiene, **9a;** norbornadiene, **9b;** norbornene, **9c;** benzonorbornene.

a) All signals correspond to 2F.

The structures of the products were determined on the basis of their mass spectra, NMR spectra, and X-ray data. Selected NMR data for photoadducts are presented in Table 2, the exact determination of the stereochemistry of the products was, however, enabled by the fact that the structures of **11a**[7] and **13b**[8] were confirmed by X-ray analysis.

In Scheme 3 various thermal and photochemical transformations of [2+2]adducts formed by irradiation of norbornadiene and hexafluorobenzene are presented. Product **12a** is converted stereospecifically to the pentacyclic system **13a** under photochemical conditions, while heating **12a** to 150 °C resulted in the primary formed anti adduct **10a**, which was further transformed under photochemical conditions to the pentacyclic system **11a**. Heating of the pentacyclic

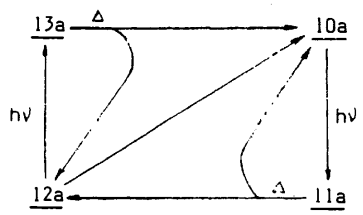
Concentration B: cyclodiene or cycloalkene concentration (mol l^{-1}). c) R; ratio of [2+2]photocycloaddition quantum yield at the given concentration to [2+2]photocycloaddition quantum yield at concentration of both C_6F_6 and cyclodiene or cycloalkene 0.1 mol l^{-1}.



Scheme 3.

products **11a** and **13a** at 150 °C gave mixtures of **10a** and **12a** .

Photocycloaddition reactions of hexafluorobenzene and norbornadiene at λ=350 nm as well as in the presence of benzophenone as sensitizer did not occur, while photoreaction was completely quenched by 1,3-pentadiene and resulted in a complex mixture of the 1,3-pentadiene-hexafluorobenzene adducts.

The effect of the cyclodiene structure on the quantum yield of photocycloaddition reactions to hexafluorobenzene in cyclohexane solutions is presented in Table 3.

It is evident that the photoreactions of norbornadiene and 1,4-cyclohexadiene with hexafluorobenzene are 30% more efficient than the photoreaction of norbornene, while as much as a 1.5-fold increase of efficiency was observed in the case of [2+2]cycloaddition with 1,5-cyclooctadiene. The effect of the molar ratio of cyclodiene and hexafluorobenzene on photocycloaddition and on the efficiency of syn and anti addition is also presented in Table 1. Variations in the amount of reactants did not play significant role on the efficiency of syn/anti addition in the case of norbornadiene and 88% of syn addition was observed, the increase of the amount of cyclodiene diminished the quantum yield, while an increased amount of hexafluorobenzene increased the quantum yield for 46%. A similar absence of the effect of the reactant concentration on stereochemistry was also observed by 1,5-cyclooctadiene, where only 52% syn addition was observed, however, a variation of the reactant concentration increased the quantum yield, i.e., 10% by changing concentration of cyclodiene from 0.1 to 0.5 mol l^{-1}, and 62% by increasing the hexafluorobenzene concentration from 0.1 to 0.5 mol l^{-1}. The change of the concentration of the reactants influenced in the case of 1,4-cyclohexadiene photoreaction both the stereospecificity and the efficiency of the [2+2]cycloaddition. Irradiation of equal amounts of the reactants hexafluorobenzene and 1,4-cyclohexadiene resulted in 44% of syn attack, an increase of cyclodiene concentration increased the syn addition to 54% and the quantum yield for 32%, while an increase in hexafluorobenzene concentration decreased the syn attack to 39% but increased the efficiency of the photoprocess by 62%.

Experimental

Preparative experiments were carried out with a Rayonet Model RPR 100 with RPR 253.7 nm lamps. IR spectra were recorded using a Perkin Elmer 727B spectrometer and ^{1}H and ^{19}F NMR spectra by JEOL JNM-PS-100 spectrometer from $CDCl_3$ or CCl_4 solutions with $(CH_3)_4Si$, or CCl_3F as internal reference. Mass spectra and high resolution measurements were taken on a CEC 21-110 spectrometer. TLC was carried out on Merck PSC Fertigplatten F 254, and GLC on Varian Aerograph, Model 1800.

Materials: Hexafluorobenzene, 1,4-cyclohexadiene, 1,5-cyclooctadiene, norbornadiene, were commercially available and distilled before use, while benzonorbornene was synthesized. Cyclohexane was purified and distilled before use. It had been demonstrated in a separate experiment that the presence of oxygen had no significant effect on product distribution and quantum yields and thus no special attention was paid to air exclusion.

Photocycloaddition Reactions of Hexafluorobenzene with Cyclodienes. 1 mmol of cyclodiene and 2 mmol of hexafluorobenzene were dissolved in 18 ml of cyclohexane, the solution irradiated for various times (1—60 h) at λ=253.7 nm, the solvent evaporated in vacuo, the crude reaction mixture

analyzed by ^{19}F NMR and the products separated by preparative TLC or GLC.

Reaction with 1,4-Cyclohexadiene (2a). After 1 h irradiation, the reaction mixture was separated by preparative TLC (SiO_2, petroleum ether), and 23% of oily product **3a**, 7% of white crystalline product **4a**, mp=56—58 °C, and 10% of white crystalline product **6**, mp=137—139 °C, was obtained.

Spectroscopic Data for 3a: NMR δ_F −169.5 (m, 2F), −171.75 (broad s, 2F), −198 (m, 2F), δ_H 2.2 (m, 4H), 3.0 (m, 2H), 5.8 (m, 2H), $^3J_{FH}$=7.5 Hz; MS: Calcd for $C_{12}H_8F_6$: M, 266.0931. Found: *m/z* 266.0930; *m/z* 266 (M^+, 5%), 212 (20), 186 (30), 169 (20), 133 (35), 109 (25), 93 (20), 80 (80), 79 (95), 54 (55), 51 (60), 39 (100), 30 (40).

Spectroscopic Data for Product 4a: NMR (numbering of fluorine atoms is evident from Scheme 1): $\delta_{F^{c,d}}$ −129.0 (d, 2F), $\delta_{F^{b,e}}$ −204.25 (m, 2F), $\delta_{F^{a,f}}$ −190.5 (m, 2F, $^3J_{FH}$=7.5 Hz); δ_H 2.3 (m, 4H), 3.08 (m, 2H), 5.9 (m, 2H); MS: Calcd for $C_{12}H_8F_6$: M, 266.05301. Found: *m/z* 266.05272; *m/z* 266 (M+, 4%), 169 (31), 133 (43), 109 (37), 80 (100), 79 (98), 77 (43), 54 (63), 39 (64).

Spectroscopic Data for Product 6: NMR δ_F −167.25 (m, 2F), −216.75 (m, 2F), −217.5 (m, 2F); δ_H 1.88 (m, 4H), 2.64 (dm, 2H), 3.2 (m, 2H); MS: Calcd for $C_{12}H_8F_6$: M, 266.0530. Found: *m/z* 266.0530; *m/z* 266 (M^+, 24%), 164 (30), 134 (31), 133 (100), 115 (40), 80 (36), 79 (76).

Reaction with 1,5-Cyclooctadiene (2b). After 1 h irradiation, the reaction mixture was separated by preparative TLC (SiO_2, petroleum ether), and 36% of mixture of **3b** and **7** and 9% of mixture of **4b** and **8** was isolated. All attempts to separate the products were unsuccessful, however, when 80 mg of mixture of **3b** and **7** was dissolved in 5 ml of cyclohexane and irradiated at λ=253.7 nm for 40 h the formation of isomeric tetracyclic products **4b** and **8** was established.

NMR Data for Product 3b: δ_F −150.75 (m, 2F), −157.0 (broad s, 2F), −204 (m, 2F).

NMR Data for Product 7 (numbering of fluorine atoms is evident from Scheme 1): $\delta_{F^{c,d}}$ −158.5 (m, 2F), $\delta_{F^{b,e}}$ −155.2 (m, 2F), $\delta_{F^{a,f}}$ −165.5 (broad s, 2F), mass spectrum of mixture of **3b** and **7**: Calcd for $C_{14}H_{12}F_6$: M, 294.0844. Found: *m/z* 294.0841.

NMR Data for Product 4b (numbering of fluorine atoms is evident from Scheme 1): $\delta_{F^{c,d}}$ −125.5 (m, 2F), $\delta_{F^{b,e}}$ −195.0 (m, 2F), $\delta_{F^{a,f}}$ −190.0 (m, 2F).

NMR Data for Product 8 (numbering of fluorine atoms is evident from Scheme 1): $\delta_{F^{c,d}}$ −126 (m, 2F), $\delta_{F^{b,e}}$ −195 (m, 2F), $\delta_{F^{a,f}}$ −161.25 (m, 2F); MS of mixture of **4b** and **8**: Calcd for $C_{14}H_{12}F_6$: M, 294.0844. Found: *m/z* 294.0844.

Reaction with Norbornadiene (9a). After 3 h irradiation the reaction mixture was separated by preparative TLC (SiO_2, petroleum ether) and 2% of white crystalline product **10a**, mp=83—85 °C, and 9% of white crystalline product **12a**, mp=85—87 °C was isolated.

Spectroscopic Data for Product 10a: NMR δ_F −162.3 (m, 2F), −163.9 (broad s, 2F), −188.62 (m, 2F); δ_H 6.12 (broad s, 2H), 3.36 (broad s, 2H), 2.34 (m, 2H), 1.35 (m, 2H), $^3J_{FH}$=7.5 Hz; MS: Calcd for $C_{13}H_8F_6$: M, 278.0530. Found: *m/z* 278.0535; *m/z* 278 (M^+, 6%), 232 (43), 186 (71), 117 (50), 92 (83), 91 (100).

Spectroscopic Data for Product 12a: NMR (numbering of fluorine atoms is evident from Scheme 2): $\delta_{F^{c,d}}$ −161.25 (broad s, 2F), $\delta_{F^{b,e}}$ −159.0 (m, 2F), $\delta_{F^{a,f}}$ −168.0 (m, 2F); δ_H 6.2 (broad s, 2H), 3.09 (broad s, 2H), 2.7 (m, 2H), 1.5 (m, 2H), $^3J_{FH}$=26 Hz, $^3J_{F^bF^a}$=13 Hz; MS: Calcd for $C_{13}H_8F_6$: M, 278.0530. Found: *m/z* 278.0518; *m/z* 278 (M^+, 9%), 232 (16), 97 (22), 92 (32), 91 (40), 66 (100).

After 60 h irradiation, the reaction mixture was separated by preparative TLC, and 27% of solid **12a** and 29% of mixture of **11a** and **13a** was isolated. Isomeric pentacyclic products **11a** and **13a** were separated by preparative VPC (FFAP 30%, Chrom A AW, T=120 °C) and 7% of white crystalline product **11a**, mp=92—94 °C, and 50% of white crystalline product **13a**, mp =98—100 °C, was isolated.

Spectroscopic Data for Product 11a: NMR (numbering of fluorine atoms is evident from Scheme 2): $\delta_{F^{c,d}}$ −123.75 (d, 2F), $\delta_{F^{b,e}}$ −194.25 (dd, 2F), $\delta_{F^{a,f}}$ −180.75 (dd, 2F); δ_H 6.33 (s, 2H), 3.24 (s, 2H), 2.55 (d, 2H), 1.74 (broad s, 2H), $^3J_{FH}$=7.5 Hz, $^3J_{F^cF^a}$=15 Hz, $^3J_{F^cF^b}$=9 Hz; MS: Calcd for $C_{13}H_8F_6$: M, 278.0530. Found: *m/z* 278.0550; *m/z* 278 (M^+, 10%), 237 (19), 232 (7), 109 (21), 93 (24), 92 (14), 91 (42), 79 (43), 67 (44), 66 (100).

Spectroscopic Data for Product 13a (numbering of fluorine atoms is evident from Scheme 2): $\delta_{F^{c,d}}$ −125.25 (broad s, 2F), $\delta_{F^{b,e}}$ −180 (d, 2F), $\delta_{F^{a,f}}$ −164.25 (d, 2F); δ_H 6.24 (d, 2H), 3.18 (s, 2H), 2.7 (d, 2H), 1.53 (broad s, 2H), $^3J_{FH}$=24 Hz, $^3J_{F^bF^a}$=15 Hz, $^3J_{F^cF^b}$=4.5 Hz; MS: Calcd for $C_{13}H_8F_6$: M, 278.0530. Found: *m/z* 278.0545; *m/z* 278 (M^+, 6%), 237 (5), 232 (18), 97 (20), 92 (25), 91 (44), 79 (20), 67 (14), 66 (100).

0.5 mmol of product **12a** dissolved in 9 ml of cyclohexane, was irradiated at λ=253.7 nm for 60 h, the solvent evaporated in vacuo and the crude reaction mixture, containing only pentacyclic product **13a**, was isolated. 0.5 mmol of product **10a**, dissolved in 9 ml of cyclohexane, was irradiated at λ=253.7 nm for 60 h, the solvent evaporated in vacuo and the reaction mixture, containing only pentacyclic product **11a**, was isolated.

0.5 mmol of pentacyclic product **13a** was heated for 5 min at 150 °C in a sealed glass tube. The crude reaction mixture contained 65% of **10a** and 35% of **12a**. Similar heating of 0.5 mmol of isomeric pentacyclic product **11a** gave a mixture, containing 67% of **10a** and 33% of **12a**.

0.5 mmol of product **12a** was heated for 5 min in a sealed glass tube. The crude reaction mixture contained 30% of the starting material and 70% of **10a**.

After 60 h irradiation of mixture of hexafluorobenzene and norbornadiene at λ=350 nm no products were formed.

Reaction of Benzonorbornene (9c). After 60 h irradiation the reaction mixture was separated by preparative TLC (SiO_2, petroleum ether), 15% of white crystalline product **13c**, mp=132—134 °C and 37% of white crystalline product **12c**, mp=141—143 °C, was isolated.

Determination of Quantum Yields. Quantum yields

were measured by using a trioxalatoferrate(III) actinometer and in each experiment the amount of transmitted light was measured. Quartz cuvettes (12 ml) were filled with 10 ml of a cyclohexane solution of hexafluorobenzene and cyclodiene and thermostated by external cooling and the temperature of the solution measured. The light source was an RPR 253.7 nm lamp without filters. In a separate experiment with filters only 2—3% difference was found. The products were analyzed using ^{19}F NMR spectroscopy with $CF_3C_6H_5$ or octafluoronaphthalene as the internal standard, which was added after solvent evaporation. Irradiation times were chosen so that conversion of hexafluorobenzene did not exceed 5—7% of its initial amount. Each quantum yield determination was repeated at least three times and the average data are presented in Table 3, together with the data on concentrations of reagents, light intensity, and temperatures.

Electronic Spectra of 9,10-Phenanthrenediamine: Effects of Solvents and Acid Concentrations

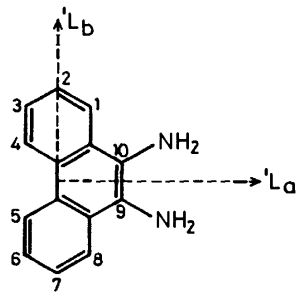
R. MANOHARAN and Sneh K. DOGRA*
Department of Chemistry, Indian Institute of Technology, Kanpur-208 016, India
(Received June 20, 1988)

Dual fluorescence is observed from 9,10-phenanthrenediamine (PDA) in defferent solvents. Normal Stokes shifted fluorescence band is a structured one with vibrational frequency of ca. 750 cm^{-1} and is polarized along the longer axis (^1L_b state). Large Stokes shifted fluorescence is a broad band and is polarized along the shorter axis of phenanthrene (^1L_b state). Fluorescence intensities of both the bands decrease with the increase of polarity and hydrogen-bond formation tendency of the solvents, but the preferential decrease in the fluorescence intensity of latter band system is more than that of the former band system under the above environments. Equilibrium for the prototropic reaction of monocation-free base is not established in the S_1 state within the lifetimes of the conjugate acid-base pair. Proton-induced fluorescence quenching constant for monocation is found to be 2×10^7 $dm^3 mol^{-1} s^{-1}$ and this low value, as compared to that for neutral aromatic amines, is because of the presence of positive charge on the monocation.

In the cata-condensed aromatic hydrocarbons, generally three electronic absorption bands are very prominent.[1,2] The long wavelength band (also known as α or ^1L_b band) is a long axis polarized weak band. Next band of high energy [polar(p) or ^1L_a band] is short axis polarized and is stronger than the α band. The third one is either a mixture of short axis and long axis polarized transitions (^1B_a or ^1B_b) or a single band i.e. β (^1B_b) and it is the most intense band. p-band is more easily susceptible to any change in the geometry of the molecule or to the presence of basic substituent along the short axis. For example α- and p-bands are well separated in benzene but are mixed in case of anthracene. In 1-naphthoic acid,[3] the long wavelength absorption band is of ^1L_a character whereas in naphthalene it is ^1L_b, which is of the lowest singlet energy.

As said earlier, the p-band is more polar and easily succeptible to the changes in the molecule or environments than the α-band. The presence of basic substituent at position-1 of linearly condensed systems will affect the p-band very much because roughly speaking the transition moment vector coincides with dipole moment vector. On the other hand the presence of basic substituent at 2-position affects both the α- and p-bands because dipole moment vector is lying in between the long axis and the short axis. Due to this, the dipole moment vector will have finite value along the short and the long axes of the molecule. However, the long axis polarized band will be affected more than the short axis polarized.

Because of the presence of benzo group along the angular direction, phenanthrene molecule belongs to C_{2v} symmetry point group. Due to this, unlike anthracene, α- and p-bands are well-separated and α-band possesses a nice vibrational structure, with vibrational frequency of 705 cm^{-1}. As can be seen from the structure of the phenanthrene molecule, the presence of basic groups at positions 9 and 10 will affect the p-band more than the α-band. The present study on



Scheme 1.

9,10-phenanthrenediamine (PDA) is in continuation of our earlier studies on the molecules containing similar two functional groups[4-6] to find out (i) how the amino groups affect the various band systems of phenanthrene and (ii) how the various prototropic species formed by the protonation or deprotonation of the amino groups will affect the α- and the p-bands. The conclusions are based on the absorption and fluorescence spectra recorded in different solvents and at various proton concentrations. The pK_a values for the different prototropic reactions have been determined in s_0 and s_1 states and are discussed. Lastly, this study was undertaken because the molecule, 9-phenanthrenamine is studied thoroughly.[7-9]

Experimental

9,10-Phenanthrenediamine (PDA) was obtained from Aldrich Chemical Company and was recrystallized from benzene. Finally, PDA was purified by vacuum sublimation and was stored under nitrogen atmosphere. The purity was checked by noting its sharp melting point, absorption spectrum and getting the similar fluorescence band maxima when excited at different wavelengths. Being very sensitive to air and light, the compound and the stock solutions were kept in amber-colored bottles and in oxygen free nitrogen atmosphere. Spectrograde methanol (BDH), trifluoroacetic acid (TFA, Fluka), analytical grade sulfuric acid, sodium hydroxide, and orthophosphoric acid were used without

further purifiction. Whereas cyclohexane, ether, and acetonitrile were further purified according to the procedure suggested in the literature.[10] Triply distilled water was used for aqueous solutions. pH of the solutions in the range of 3—10 was adjusted by adding appropriate quantities of sodium hydroxide and orthophosphoric acid, since the small quantities or phosphate buffers do not quench the fluorescence of the species and do not alter the pK_a of the prototropic reactions.[11] Hammett's acidity scale[12] for the solutions with pH<1 (prepared by the mixture of H_2SO_4 and water) and Yagil's basicity scale[13] for the solutions with pH>13 (prepared by the mixture of NaOH and water) were used.

The abosrption spectra were recorded on Shimadzu 190UV spectrophotometer, equipped with 135U recorder. The fluorescence measurements were carried out on a recording spectrofluorimeter fabricated in our laboratory of which details are available elsewhere.[14] Both the monochromators were calibrated from time to time with low-pressure mercury lamp. The band width used for excitation purposes is 8 nm. The concentration of the solution was kept at 5×10^{-5} M (1 M=1 moldm^{-3}), containing not more than 5% (v/v) methanol. For titration purposes, the solutions were prepared just before taking the measurements and the solutions were excited using the isosbestic wavelengths. The excitation wavelength used in determining the equilibrium constants for dication-monocation, monocation-free base and free base-monoanion equilibria in S_1 state were 300, 370, and 350 nm. The fluorescence quantum yields were determined from the solutions whose absorbances were less than 0.1. The fluorescence spectra were corrected[15] and quantum yields were calculated using quinine sulfate in 0.05 M H_2SO_4 as a standard.[16] The wavelength used for excitation was 385 nm. The pH of the solutions in the range of 1—13 were measured with Toshniwal's pH meter model CL 44A.

Results

The absorption spectra of PDA in different solvents and at different proton concentrations are depicted in Figs. 1 and 2 respectively. The relevant data are compiled in Table 1. Data of Table 1 clearly indicate that the absorption spectra of PDA can be divided into three band systems above 250 nm. One around 400 nm, the second around 330 nm and the third around 270 nm. The 400 nm band is broad and less structured as compared to the long wavelength band of phenanthrene,[1] whereas the structure is observed in the 274 nm band system and unlike other band systems, the structure of this band is retained in polar as well as hydrogen-bonding solvents. The vibrational frequency observed in the long wavelength band in cyclohexene is nearly equal to 730±30 cm^{-1}. A small red shift is noticed in the long wavelength absorption band in going from cyclohexane to acetonitrile, whereas a blue shift is observed in 400 and 330 nm bands in methanol and water.

With the decrease of pH (ca. 2), the 400 nm band system develops into a very nice vibrational structured absorption band which is red-shifted as compared to neutral one, whereas the other band systems follow a small blue shft. The absorption band systems at 303

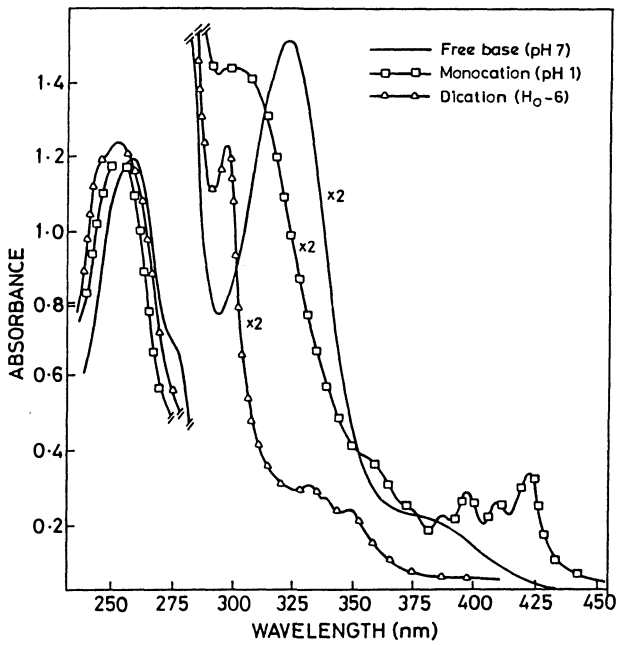

Fig. 2. Absorption spectra of the various prototropic species of PDA at 298 K.

and 252 nm resemble with that of 9-phenanthrenamine.[7] The vibrational frequency observed in the long wavelength band is 740±20 cm^{-1}. This spectrum is assigned to the monocation of PDA formed by the protonation of one of the amino groups. With further increase of proton concentration, all the band systems are blue-shifted and exactly agree with the band systems of phenanthrene,[1] both in the band maxima

and the vibrational frequencies observed in α- and p-bands. This species is thus assigned to dication formed by the protonation of both the amino groups. In the basic region above pH 14, a red shift is observed in the absorption spectrum, indicating the formation of monoanion. This equilibium is not complete, even at H_- 16, the highest basic solution used.

The fluorescence spectra of PDA in different solvents and at various proton concentrations are depicted in Figs. 3 and 4 respectively. The relevant

data are compiled in Table 1. In cyclohexane, only one normal stokes shifted fluorescence band (422 nm) is observed, whereas in other solvents, both the normal Stokes shifted and large Stokes shifted fluorescence (495 nm) bands are noticed. The normal Stokes shifted fluorescence band is nicely structured in all the solvents, with the vibrational frequency of ca. 720±20 cm^{-1}, whereas a large stokes shifted fluorescence emission is a broad band. With the increase in solvent polarity and proton donor capacity of the solvets, the fluorescence band maximum of large Stokes shifted band gets red-shifted, whereas that of normal Stokes shifted band remains unaffected. The fluorescence intensities of both the bands decrease under the above environments, but the relative decrease in the fluorescence intensity of the large Stokes shifted band is more than that of the normal Stokes shifted one. In water as solvent, PDA is nonfluorescent.

The prototropic species formed in the excited singlet state are the same as formed in the ground state. That is a blue-shifted fluorescence band (430 nm) is ovserved at pH 1 and this resembles with that of 9-phenanthrenamine in water as a solvent[9] and thus can be assigned to the monocation. At H_0-6 a large blue shifted structured fluorescence band is observed, agreeing nicely with that of phenanthrene.[17] The species formed thus a dication, obtained by protonating both the amino groups. No other fluorescence bands are observed even on increasing the proton concentration to H_0-10. Free base is nonfluorescent in the pH range of 6—14. Only at H_- 15, a fluorescence band (ca. 410 nm) appears and it reaches maximum intensity at H_- 16.5. This band system agrees with the fluorescence band maximum observed in case of 9-phenanthrenamine[9] at H_- 15. This can be assigned to monoanion.

The pK_a values of the various prototropic reactions are determined spectrophotometrically and are listed in Table 2. The pK_a for the monocation-free base equilibrium is much lower than that observed for similar reactions of other aromatic amines,[18] but agrees with the pK_a value obtained in case of 2,3-naphthaleneamine.[6] Similar is the case for dication-monocation equilibrium. The smaller pK_a value is because of the steric hindrance offerred by the two adjacent amino groups. The ground state pK_a value for the free base-monoanion equilibrium cannot be determined because the formtion of monoanion is not complete even at H_- 16.5, the highly basic solution used. The excited singlet state pK_a values are determined with the fluorimetric titrations (Fig. 5) and the values so obtained are listed in Table 2. Förster cycle method[19] cannot be used for the monocation-free base equilibrium as free base molecule is nonfluorescent in water at 298 K and the absorption spectrum of cation gets some complex structure (see later). Fluo-

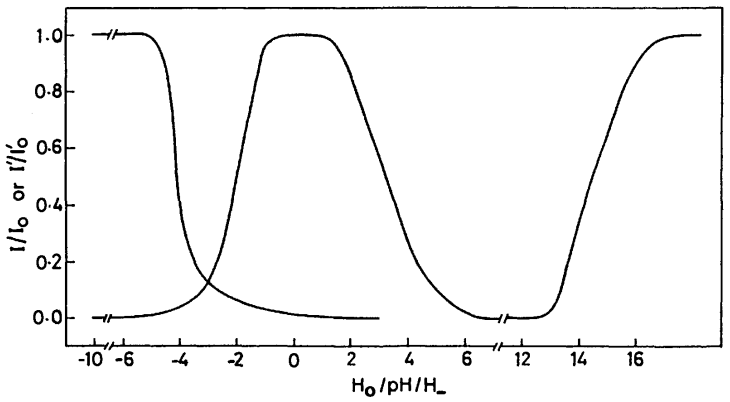

Fig. 5. Plot of relative fluorescence intensities of various prototropic species versus H_0/pH/H_-.

rescence data at 77 K and Förster cycle method do indicate that the ammonium ion becomes stronger acid in S_1 state. On the other hand, fluorimetric titrations have yielded the ground state pK_a for the monocation-free base equilibrium. This indicates that the prototropic equilibrium is not attained in the S_1 state during the short lifetimes of the conjugate acid-base species. Similar results have been observed in some other systems,[4-6,20] although it is anomalous. Similar to the normal behavior of aromatic amines, no correspondence is observed between the decrease in fluorescence intensity of monocation and the increase in the fluorescence intensity of the dication. The pK_a^* values for this reaction has been determined using fluorimetric titrations but from the formation curve of the dication only (Fig. 5) and is listed in Table 2.

As described earlier no correspondence is observed between the decrease and increase in the fluorescence intensity of the monocation and dication of PDA respectively. This has been attributed to the proton-induced fluorescence quenching of monocation.[21-29] This is because there was no quenching effect due to the counterion SO_4^{2-} under the experimental conditions. Applying the similar model as suggested by Shizuka et al.[27] and under conditions that proton concentration is small and thus rate for the backward protonation reaction is small as compared to its lifetime, the final equation reduces to a simple Stern-Volmer equation i.e.

$$I_0/I = 1 + k_q\tau[H^+]$$

where I and I_0 are fluorescence intensities in the presence and absence of quencher, k_q is the proton-induced fluorescence quenching rate constant and τ is the lifetime of the monocation. I_0/I vs. $[H^+]$ has been plotted in Fig. 6 and the slope obtained is 0.02 $dm^3 mol^{-1}$. The natural lifetime τ_{FM} is calculated using Strickler and Berg[30] equation and τ by using $\tau=\tau_{FM}\phi_f$ equation. The value of τ obtained is 1.1 ns and that of k_q is 2×10^7 $dm^3 mol^{-1} s^{-1}$. This value is quite small as compared to that observed for the similar reactions of other aromatic amines.

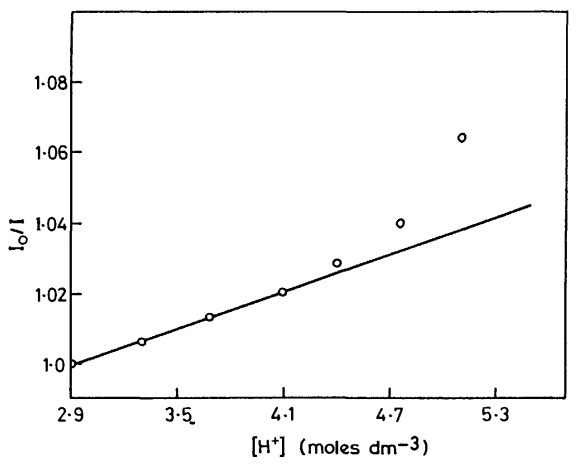

Fig. 6. Stern-Volmer plot for proton-induced fluorescence quenching of the monocation of PDA.

Discussion

Phenanthrene molecule has three band systems, one near 340 nm, highly structured with vibrational frequency 705 cm^{-1} (α-band), the other at 290, moderately structured with vibrational frequency 1320 cm^{-1} (p-band) and the third around 250 nm (β-band). Tsutsumi et al.[31] have clearly indicated with the help of semi-empirical SCF-MO-CI method that the charge migration from the amino group to the phenanthrene ring in the ^1L_a (p-band) occurs much more than in the other states in case of 9-phenanthrenamine. Thus based on these results the two amino groups in phenanthrene will perturb the above transitions but the effect will be more on the p-band than on the α- and β-bands. This is clear from the Scheme 1 shown earlier. Though the perturbation due to the presence of amino groups is more on the p-band, it is believed that the long wavelength band in PAD and its prototropic species is still the α-band. This is based on the following results:

(i) Molecular extinction coefficient of the long wavelength band (1.26×10^3 $dm^3 mol^{-1} cm^{-1}$) is less than that of second band (1.1×10^4 $dm^3 mol^{-1} cm^{-1}$). The former is more close to that of phenanthrene (0.4×10^3 dm^3 $mol^{-1} cm^{-1}$). The increase in the ε_{max} of this band of PDA is due to the interaction of amino groups with the phenanthrene moiety.

(ii) The difference between the two band maxima in phenanthrene is ca. 56 nm. Though the two band systems may get mixed up in PDA but it is highly improbable that the p-band will be of lower energy than that of α-band. It is also clear from the absorption spectrum (Fig. 1) that ca. 400 nm band appears as shoulder to the 333 nm band system.

(iii) Lastly the vibrational frequency observed in the long wavelength band (730 ± 30 cm^{-1}) resembles with that noticed in the absorption spectrum of phenanthrene (705 cm^{-1}).

The loss in the vibrational structure of α- and p-bands is because of the interation of lone pairs of the amino groups with the aromatic ring, which is commonly observed. Further, the loss of vibrational structure with the increase in the polarity and hydrogen-bond-forming tendency of the solvents is due to the interaction of the solvents with PDA. The data of Table 1 indicate that the molecule is acting as a proton acceptor in the ground state.

The blue shift observed in the p- and β-bands of the absorption spectra of PDA with the increase of proton concentration is consistent with the protonation of one of the amino groups, leading to the formation of monocation and protonation of both the amino groups, to the formation of dication. The band maximum in the former resembles with that of 9-

phenanthrenamine[9] and that of latter resembles with phenanthrene molecule.[1] But the behavior of α-band system is different from that of the other two. The absorption band maximum is slightly red-shifted and the band system has very nice structure, with vibrational frequency of 720±20 cm^{-1}. This structure is similar to the α-band system of phenanthrene molecule. The similar behavior is also observed in the α-band of PDA in cyclohexane when different amounts of TFA is added. Though the formation of monocation of PDA is confirmed but it is difficult to explain the appearance of a red-shifted structured absorption spectrum.

From the data of Table 1, we assign the normal Stokes shifted fluorescence band to the transition from ^1L_b. This is because the vibrational frequency observed in the short wavelength emission (ca. 750 cm^{-1}) spectrum agrees with that noticed in the absorption spectrum, indicating that the mirror image symmetry is observed between the long wavelength band of absorption and the short wavelength of fluorescence spectrum. This proves that the excited electronic state involved in the long wavelength absorption band and the short wavelength fluorescence band is the same i.e. ^1L_b. More evidences will be given later on. We assign the long wavelength fluorescence band to ^1L_a transition. This assignment is further based on the following evidences:

(i) The excitation spectra were recorded in two different solvents (ether and acetonitrile) at both the fluorescence band maxima and are shown in Fig. 7. The excitation spectrum recorded at long wavelength band does possess a small peak at 400 nm but the vibrational structure present in the absorption band is absent and the most intense band is around 350 nm, agreeing with the ^1L_a transition of absorption spectrum. On the other hand the excitation spectrum recorded at short wavelength fluorescence band possesses the vibrational structure, with the similar vibrational frequency as noticed in the long wavelength absorption spectrum. This spectrum does not contain the band around 350 nm, arising out of ^1L_a transition. The mixing of the small absorbance due to 400 nm band in the excitation spectra recorded at 500 nm is due to the mixing of these two bands in the absorption spectrum of PDA. (ii) ^1L_a electronic excited state is generally more polar than the ^1L_b electronic state. The presence of electron donating groups in the proper direction makes it further more polar. It has been shown by Tsutsumi et al.[31] that the charge migration from amino group to phenanthrene ring, in case of 9-phenanthrenamine, is much larger in the ^1L_a state than others. Due to this ^1L_a state is stabilized much more as compared to that of ^1L_b in more polar solvents and thus it appears at lower energy than the ^1L_b state. This is further manifested from the effect of solvents on the fluorescence spectrum of PDA, recorded in different solvents. The fluorescence band maximum at 400 nm is hardly affected by the polarity or proton-donor capacity of the solvents, whereas a large red shift is noticed in 500 nm band under the similar environments. (iii) Although the fluorescence intensities of both the fluorescence bands decrease in going from ether to water (molecule is nonfluorescent in water), the ratio of I_{500}/I_{400} decreases very rapidly in the above environments. This could be due to the fact that ^1L_a state is more polar and will have more interactions with the polar and proton donor or aceptor solvents. This will increase the rates of radiationless processes of the polar state. (iv) The more polar nature of ^1L_a state is further confirmed from the results of the fluorescence spectra of PDA recorded in cyclohexane containing TFA. The cyclohexane solution containing TFA upto 2×10^{-2} % (v/v) does produce a blue shift in the ^1L_a band system of absorption spectrum but ^1L_b band system becomes more structured, similar to the results observed in the absorption spectrum of PDA in aqueous solution containing H_2SO_4. But the fluorescence spectrum contains both the band systems and the red shift in the large Stokes shifted fluorescence band

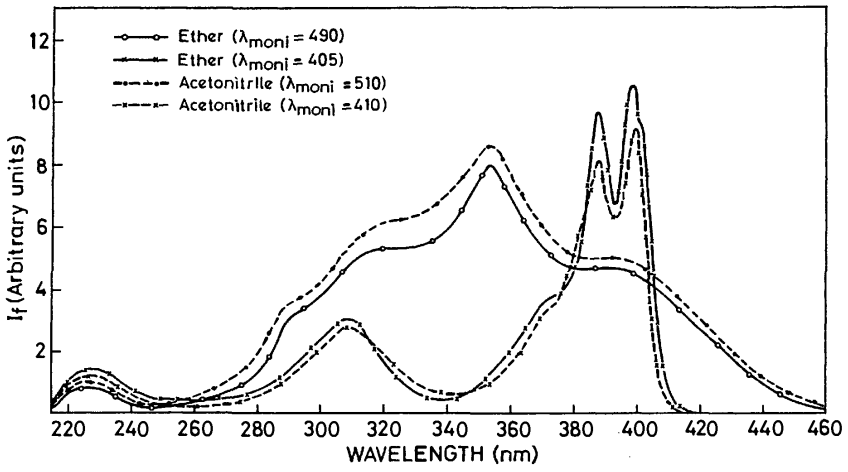

Fig. 7. Excitation spectra (uncorrected) of PDA recorded at 510 and 400 nm.

increases with the increase in the TFA concentration upto 2×10^{-2} % (Table 3). This is because TFA makes the cyclohexane polar and stabilizes the ^1L_a electronic state more than the ^1L_b one. This is further manifested from the fact that fluorescence intensities of both the emission bands decrease with increase of TFA in cyclohexane and PDA is nonfluorescent in cyclohexane containing 0.2% (v/v) TFA. (v) Last possibility that the long wavelength fluorescence belongs to the excimer is ruled out on the ground that the ratio of I_{500}/I_{400} does not change with the increase in the concentration of PDA by thousand fold.

The fluorescence spectra of the various prototropic species of PDA are consistent with the behavior of aromatic amines. The 430 nm fluorescence band of monocation, formed by protonating one of the amino group is originating from the ^1L_a electronic state, because this band maximum, similar to large Stokes shifted fluorescence band of PDA, is solvent dependent i.e. band maximum is red-shifted with the increase in the polarity of the solvent. Further monocation of PDA is similar to 9-phenanthrenamine, where it has been shown that ^1L_a is the lowest excited singlet state.[8] Finally, the structured fluorescence spectrum at H_0-6 is assigned to dication, formed by protonating both the amino groups, as this spectrum resembles with that of phenanthrene. In general, the fluorescence intensity of neutral aromatic amine is quenched by pH 14, without observing fluorescence from the monoanion, formed by the deprotonation of amino group, with few exceptions.[32] In our case, the additional problem is that the free base is also nonfluorescent in pH range 6—14, so it cannot be said with certainity that monoanion is formed in the excited state, but from the results of literature, the formation of this species can be speculated in the excited state. Based on our earlier results on 9-phenanthrenamine,[9] the 410 nm band can be assigned to a dianion formed by the deprotonation of either $-NH^-$ or $-NH_2$ group. This was further based on the similar results observed for 1- and 2-naphthylamine.[33] The results of Choudhury and Chatopadhyay,[34] on 2-naphthylamine and *N,N*-dimethyl-2-naphthylamine have clearly shown that the fluorescence band ovserved at *H*- 15 is due to the species formed by the deprotonation of ring hydrogen rather than from $-NH^-$, as *N,N*-dimethyl-2-naphthylamine has no dissociable proton. Based on these results and the similarity of the fluorescence band observed in PDA, with that of 9-phenanthrenamine it is possible that this species is similar to that formed in case of 2-naphthylamine. Fluorimetric titration curve has indicated that pK_a^* value for the equilibrium between the monoanion and the latter species (may also be monoanion) is 14.5, which actually agrees with the results of 9-phenanthrenamine.[9]

Results of fluorimetric titrations indicate that the prototropic equilibrium between monocation and free base pair is not established in the excited state during the lifetimes of the conjugate acid-base pair. This result is anomalous but similar behavior has been shown by the aromatic systems containing two amino groups,[4-6] 6-indazolamine,[35] and 4-(9-anthryl)-*N,N*-dimethylaniline.[20] This can be attributed to the short lifetimes of the two species. The pK_a^* value for the dication-monocation equilibrium has indicated that the ammonium ion becomes stronger acid on excitation.

Lastly, the small value of k_q observed for the proton-induced fluorescence quenching as compared to that for normal aromatic amines, is due to the presence of positive charge on the monocation.

Conclusion

Following conclusions can be drawn from the above study. (i) Dual fluorescence is observed in all the solvents. Abnormal Stokes shifted fluorescence arises from more polar and short axis polarized state, whereas the normal Stokes shifted, structured fluorescence is assigned to the less polar, long axis polarized state. (ii) The equilibrium between the monocation-free base species is not attained in the S_1 state and is due to the short lifetimes of the conjugate acid-base pair. (iii) Proton-induced fluorescence quenching for the monocation is observed and k_q value is found to be 2×10^7 $dm^3\,mol^{-1}\,s^{-1}$. The small value is due to the presence of positive charge on the monocation.

The authors are thankful to the Department of Science and Technology for the financial support to the project entitled, "Proton Transfer Reactions in the Excited States."

Kinetics of Electron Transfer from Cyclic Ketones to Ni(IV) Periodate Complex in Aqueous Alkaline Medium

Jaffar Ali KHAN, U. CHANDRAIAH, B. Kishore KUMAR, and Sushama KANDLIKAR*
Department of Chemistry, Nizam College, Hyderabad-500 001, India
(Received June 27, 1988)

The kinetics of electron transfer from cyclic ketones (represented by (S)) to Ni(IV) periodate complexes has been studied in aqueous alkaline medium. The kinetics exhibit a pseudo-first-order disappearance of Ni(IV) periodate complexes when the [substrate] is present in excess. The pseudo-first-order rate constants, k_{obs}, were linearly dependent on [S] and the order in [S] were found to be unity. The rate of the reaction increased with the increase in [OH^-], however the rates were retarded with the increase in [periodate]. Salt and solvent effect studies indicate that the reaction is of ion-dipole type. A suitable mechanism involving slow adduct formation between enol and oxidant, and its decomposition in a fast step have been suggested. A rate law consistent with the proposed mechanism has also been derived. The products of oxidation were identified as corresponding decarboxylic acids.

The metal complexes containing nickel in the trivalent[1,2] and tetravalent[3-6] states have recently received considerable attention and significant progress has been made in understanding Ni(III) species. A few reports are also available on the preparation and characterization of Ni(IV) oxime complexes and their reactions with different organic and inorganic substrates.

In the kinetic studies of electron transfer reactions from ascorbate ion[5] and tris(1,10-phenanthroline)-cobalt(II),[6] it is reported that electron transfer at above pH 5 takes place by a two seperate one-electron reductive steps. In some cases electron transfer, such as from ascorbic acid[7] and hexacyanoferrate(II)[8] to tris (dimethylglyoximato)nickelate(IV), is assumed to proceed through a kinetically indistinguishable Ni(III) species. Kinetic studies on oxidation of organic compounds by dihydroxydiperiodatonickelate(IV) were reported earlier from our laboratory.[9-11] However, the present investigation is intended to study the mode of electron transfer from cyclic ketones to Ni(IV) periodate complexes and to suggest a suitable mechanism.

Material and Methods

All the solutions were prepared afresh in twice distilled water. Cyclic ketones viz. cyclopentanone, cyclohexanone, cycloheptanone, and cyclooctanone were of Fluka (puriss) and were used as such. The other chemicals such as KOH, KIO_4, $NaClO_4$, *t*-butyl alcohol were of BDH AnalaR grade.

Preparation of Oxidant. The nickel(IV) periodate complex, $KNiIO_6 \cdot 1/2\,H_2O$, was prepared by the method suggested by Ray[12] and standardized as given earlier.[9]

Kinetic Measurements. The kinetics of the reaction between the diperiodatonickelate(IV) ion and the substrate was followed in the temperature range 293—313 K by monitoring the disappearance of Ni(IV) at 410 nm employing a UV-vis double beam spectrophotometer model 140.02 (Shimadzu Corporation, Japan). A mixture containing requisite quantities of aqueous solution of cyclic ketone and potassium hydroxide and the solution of the Ni(IV) periodate complex were thermally equilibrated at desired temperature (±0.1 °C) separately for about 30 min and the known volume of aqueous solution of the Ni(IV) periodate complex was transferred to alkaline substrate solution. The supporting electrolyte for maintaining ionic strength was sodium perchlorate.

Pseudo-first-order rate constants, k_{obs}, were calculated from linear least square fit from Eq. 1, which was found to be valid well over three half-lives of disappearance of the Ni(IV) periodate complex

$$-\ln (A_t - A_\infty / A_0 - A_\infty) = k_{obs} t \quad (1)$$

where A_t, A_0, and A_∞, respectively, represent the absorbances at time *t*, before commencement of the reaction and at infinite time. Ni(II) periodate, a product of reduction of Ni(IV) periodate, was found to have negligible absorbance at 410 nm.

Results

Products of oxidation of cyclic ketones by the diperiodatonickelate(IV) ion were identified as corresponding dicarboxylic acids as determined by their characteristic tests.[13]

The stoichiometric experiments were conducted at different [OH^-] range viz. 5.0×10^{-2} mol dm^{-3} to 10.0×10^{-2} mol dm^{-3}, [Ni(IV)]=2.0×10^{-4} mol dm^{-3} and $[S]_0=1.0\times10^{-5}$ mol dm^{-3}. Unreacted Ni(IV) was estimated spectrophotometrically at the end of the reaction. It was found that three moles of Ni(IV) reacted with one mole of cyclic ketone. The stoichiometric equation is

$$= O + 3[Ni(OH)_2(H_3IO_6)_2]^{2-} \longrightarrow$$

$$HOOC(CH_2)_4COOH + 3Ni(II) + 6H_3IO_6^{2-} + 3H_2O \quad (2)$$

The kinetic results can be summarized as follows:

i) The rate of the reaction increased linearly with the increase in $[S]_0$. Under the conditions $[S]_0 \gg$ [Ni(IV)] the plot of $\log[(abs)_0/(abs)_t]$ versus time was linear passing through origin, showing first-order dependence on [Ni(IV)]. From the slope of such plots the pseudo-first-order rate constants, k_{obs}, were evalu-

ated (Table 1). The plot of log k_{obs} versus log $[S]_0$ was linear and from the slope of such plots the order in [S] was found to be unity for all the cyclic ketones.

ii) The reactions were conducted at different $[OH^-]$. The rate of the reaction, at fixed $[S]_0$, [Ni(IV)], and [periodate] increased with the increase in $[OH^-]$ (Table 2).

iii) At fixed [Ni(IV)], [ketone], and $[OH^-]$ increase in [periodate] decreased the rate of the reaction. For example, under the conditions $[Ni(IV)]=1.0\times10^{-4}$ mol dm^{-3}, $[S]_0=5.0\times10^{-2}$ mol dm^{-3}, $[OH^-]=1.0\times10^{-2}$ mol dm^{-3}, increase in [periodate] from 1.0×10^{-5} mol dm^{-3} to 1.0×10^{-4} mol dm^{-3} decreased the $10^4\times k_{obs}$ values from 5.76 s^{-1} to 3.19 s^{-1} at 298 K.

iv) Effect of changing dielectric constant of the medium by using aqueous *t*-butyl alcohol as a solvent had negligible effect on the rate of the reaction. For example, under identical conditions as above and at $[periodate]=5.0\times10^{-5}$ mol dm^{-3} decreased negligibly the $10^4\times k_{obs}$ values from 4.35 s^{-1} to 4.16 s^{-1} at 298 K when the percentage of *t*-butyl alcohol was increased from 0—60% (v/v).

v) The rate of the reaction, at fixed $[S]_0$, $[OH^-]$, [Ni(IV)], and [periodate], was not altered by added sodium perchlorate.

vi) The reactions were carried out at different temperatures in the range of 293—313 K. Activation energy of the reaction and other thermodynamic parameters were evaluated (Table 3).

vii) The addition of acrylamide to deaerated reaction mixture did not alter the reaction rates nor there was any polymerization showing the absence of free radicals in the reaction.

viii) The observed order of the oxidation rate was found to be decreased in the order, cyclohexanone > cyclooctanone > cyclopentanone > cycloheptanone. Probably this may be due to enolic content of the above cyclic ketones decreasing in the same order.[14]

Discussion

Mukherjee et al.[15] reported the structre of the water-soluble Ni(IV) periodate complex as $[Ni(OH)_2(HIO)_6)_2]^{6-}$. The electronic spectrum of the water-soluble Ni(IV) periodate complex was reported to have a hump at 410 nm assignable to charge transfer from metal t_{2g} to ligand orbital and a strong band at 210 nm, due to IO_6 octahedron. The electronic spectrum of the complex prepared by us also showed similar spectral characteristics. However, in aqueous alkaline medium and in the pH range employed, the periodate cannot exist as HIO_6^{4-}.

Crouthamel and co-workers[16,17] suggested the following equilibria at different pH ranges

$$H_5IO_6 \overset{K_1}{\rightleftharpoons} H_4IO_6^- + H^+ \quad (3)$$

$$H_4IO_6^- \overset{K_2}{\rightleftharpoons} H_3IO_6^{2-} + H^+ \quad (4)$$

$$H_3IO_6^{2-} \overset{K_3}{\rightleftharpoons} H_2IO_6^{3-} + H^+ \quad (5)$$

The dissociation constants K_1, K_2, and K_3 at 298 K are 2.3×10^{-2}, 4.35×10^{-9}, and 1.05×10^{-15} respectively. Among the above species periodic acid, H_5IO_6 exist in acidic media and $H_4IO_6^-$ near pH 7. Hence in the pH range employed in the present study, the main species can be $H_3IO_6^{2-}$ and $H_2IO_6^{3-}$. The existence of $H_2IO_6^{3-}$ looks improbable owing to very low value of K_3 and

Table 3. Activation Parameters for the Oxidation of Cyclic Ketones with Diperiodatonickelate(IV) Ion in Aqueous Alkaline Medium

Substrate	$10^3\times k''$ / dm^3 mol^{-1} s^{-1}					E_a	$\Delta H^{\#}$	$\Delta G^{\#}$	$-\Delta S^{\#}$

Cyclooctanone	3.96	6.40	10.2	15.9	24.7	69.9	67.4	85.5	60.8

[NI(IV)]=1.0×10^{-4} mol dm^{-3}, [S]=5.0×10^{-2} mol dm^{-3}, $[OH^-]=1.0\times10^{-2}$ mol dm^{-3}, [periodate]=1.0×10^{-4} mol dm^{-3}.

periodate exists in the dimerized form $I_2O_9^{4-}$ only when it is present in higher concentrations. Hence the soluble complex may be represented by the formula $[Ni(OH)_2(H_3IO_6)_2]^{2-}$.

The $[OH^-]$ depenednce of oxidation of cyclic ketones by the Ni(IV) periodate complex indicates the equilibrium between deprotonated reactive species **2** and deprotonated unreactive species **1**:

$$[Ni(OH)_2(H_3IO_6)_2]^{2-} + OH^- \rightleftharpoons [Ni(OH)_2(H_2IO_6)(H_3IO_6)]^{3-} + H_2O \quad (6)$$

The dependence of the rate of oxidation on the periodate complex indicates a dissociative equilibrium in which Ni(IV) moiety loses a periodate ligand from its coordination sphere forming the monoperiodatonickelate (IV) ion (**3**):

$$[Ni(OH)_2(H_2IO_6)(H_3IO_6)]^{3-} \rightleftharpoons [Ni(OH)_2(H_2IO_6)]^- + H_3IO_6^{2-} \quad (7)$$

The formation of species **3** directly from **1** is also possible:

$$[Ni(OH)_2(H_3IO_6)_2]^{2-} + OH^- \rightleftharpoons [Ni(OH)_2(H_2IO_6)]^- + H_3IO_6^{2-} + H_2O \quad (8)$$

A sequence of Eqs. 6 and 7 is preferred as the loss of the periodate ion occurs preferentially from a species having higher negetive charges. Hence deprotonated species **3** is assumed to be an active oxidant species. Such protonated and deprotonated forms in the inner sphere also exist for tris(dimethylglyoximato)nickelate(IV) complex[4] and the periodato and tellurato complexes of copper and the peptide complexes of silver in their trivalent states.[18-20] The assumption that **3** is the reactive species of oxidant is also in conformity with the earlier findings.[21] In the oxidation of the thiocyanate ion by the dihydroxydiperiodatonickelate(IV) complex the charge on the reactive species of oxidant was found to be unit negetive from the observed salt effect.

Oxidation of ketones may proceed by any one of the following stages:

(a) If the rate of oxidation>rate of enolization, the oxidation process can be represented as

$$\text{Ketone} + \text{Oxidant} \longrightarrow \text{Products} \quad (9)$$

with first-order dependence in oxidant.

(b) If the rate of enolization>rate of oxidation and the order in oxidant is unity, the oxidation can be represented as

$$\text{Ketone} + OH^- \rightleftharpoons \text{Enol} \quad (10)$$

$$\text{Enol} + \text{Oxidant} \xrightarrow[\text{slow}]{} \text{Products} \quad (11)$$

(c) If the rate of enolization > rate of oxidation and the order in oxidant is zero, the oxidation can be represented as

$$\text{Ketone} + OH^- \overset{\text{slow}}{\rightleftharpoons} \text{Enol} \quad (12)$$

$$\text{Enol} + \text{Oxidant} \xrightarrow[\text{fast}]{} \text{Products} \quad (13)$$

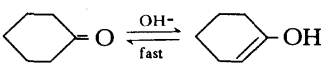
In the present study, the order in [oxidant] was found to be unity as the log (absorbance) versus time plot was perfectly straight line (correlation coefficient, r=0.9992) and the rate of oxidation of cyclic ketones was found to be in the order of ca. 10^{-8}. The rates of enolization of all cyclic ketones determined by iodination method were found to be in the order of ca. 10^{-6} to ca. 10^{-5} which are very much higher than the rate of oxidation of cyclic ketones with the diperiodatonickelate(IV) ion. Hence, it may be concluded that enol may be reacting with oxidant. One of the possibilities of an electron transfer may be due to the reaction between species **3** and enol giving an unstable adduct which decomposes subsequently to given an intermediate and Ni(II) in the fast step. The intermediate may react with two moles of Ni(IV) to give the final products. The other posibility of the electron transfer may be by two seperate one-electron reductive steps, the first step of which produces Ni(III) and enol free radical () which induces polymerization of acrylamide. However, no polymerization was observed by adding acrylamide to deaerated reaction mixture, showing the absence of one-electron reductive step. Hence in the absence of polymerization one could envisage that the adduct of 3-enol is formed in the slow step which dissociates with the electron transfer in the fast step.

A plausible mechanism, based on the above discussions for the electron transfer is shown in Scheme 1.

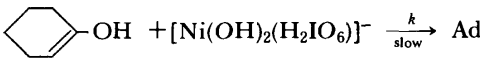
Though an adduct formation is envisaged no evidence could be given for its formation as it must be unstable and because of its low concentration it is difficult to detect it kinetically. A plot of $1/k_{obs}$ versus $1/[S]_0$ was linear yielding a straight line passing almost through origin. The observed stoichiometry

$$[DPN]^{a)} + OH^- \overset{K_1}{\rightleftharpoons} [Ni(OH)_2(H_2IO_6)(H_3IO_6)]^{3-} + H_2O \quad (14)$$

$$[Ni(OH)_2(H_2IO_6)(H_3IO_6)]^{3-} \overset{K_2}{\rightleftharpoons} [Ni(OH)_2(H_2IO_6)]^- + H_3IO_6^{2-} \quad (15)$$



(16)



(17)

$$\text{Adduct} \xrightarrow[\text{fast}]{} \text{Intermediate} + \text{Ni(II)} \quad (18)$$

$$\text{Intermediate} + 2[Ni(OH)_2(H_2IO_6)]^- \xrightarrow[\text{fast}]{} \text{Products} + 2\text{Ni(II)} \quad (19)$$

Scheme 1. a) Diperiodatonickelate(IV) ion, $[(Ni(OH)_2(H_3IO_6)_2]^{2-}$ is represented as [DPN] for simplicity.

i.e., 1 cyclic ketone: 3Ni(IV), salt and solvent effects also reinforce the above mechanism.

The rate of oxidation could be written as

$$\text{rate}=k[\text{enol}][\mathbf{3}]. \quad (20)$$

As enol is consumed in product formation more and more ketone is converted into enol form. As [ketone] is far excess to [oxidant], [ketone] can be taken as equal to [enol]. The concentration of **3** can be calculated by taking into consideration the two equilibria, Eqs. 14 and 15, in terms of $[\text{DPN}]_{\text{total}}$.

$$[\text{DPN}]_t=[\mathbf{1}]+[\mathbf{2}]+[\mathbf{3}] \quad (21)$$

As the disappearance of [DPN] is monitored, the rate of the reaction, Eq. 20 can be written as

$$\text{rate} = -\frac{d[\text{DPN}]}{dt} = \frac{kK_1K_2[\text{DPN}]_t[\text{ketone}][\text{OH}^-]}{K_1K_2[\text{OH}^-]+\{K_1[\text{OH}^-]+1\}[\text{H}_3\text{IO}_6^{2-}]}$$

$$\equiv k_{\text{obs}}[\text{DPN}]_t \quad (22)$$

The above equation envisages a linear plot for $1/k_{\text{obs}}$ versus $1/[\text{OH}^-]$. In fact such a plot was obtained giving further support to the derived rate law. The above rate law also explains all experimental observations, such a first order in [DPN] and [ketone], fractional order in $[\text{OH}^-]$ and inverse fractional order in [periodate].

The equilibrium constants, K_1 and K_2 in Eqs. 14 and 15, were calculated kinetically from a kinetic study of oxidation of benzyl alcohol with diperiodatonickelate(IV) ion.[22] The K_2 values were found to be 4.59×10^{-4}, 3.78×10^{-4}, and 3.39×10^{-4} at 300, 305, and 310 K respectively and K_1 values were found to be 33.1, 43.6, and 52.1 at 300, 305, and 310 K respectively. The K_1 and K_2 values were used to calculate k of the rate law and from this it follows that the concentration of **3** (monoperiodatonickelate(IV) ion, $[\text{Ni(OH)}_2(\text{H}_2\text{IO}_6)]^-$) is around 10^{-7} mol dm^{-3}. Even if whole of the concentration of **3** is undergoing adduct formation with enol, the concentration of adduct of **3**-enol at any given time will not be more than 10^{-7} mol dm^{-3}. This may be the reason for non-detectability of adduct of **3**-enol.

The bimolecular rate constants, k'' obtained by dividing k_{obs} with [S], along with activation parameters are listed in Table 3. An examination of the data shows that the reactions are enthalpy controlled as the reaction with lowest enthalpy ($\Delta H^{\#}$) has highest rate. This is also confirmed from the fact that the plot of $\Delta H^{\#}$ versus $\Delta S^{\#}$ was found to be linear with isokinetic temperature, β=693 K (correlation coefficient, r= 0.9985) which is much higher than experimental temperature range (293—313 K). The consistency in $\Delta G^{\#}$ values indicates the similar mechanism to be operative in the present study.

The authors express their thanks to Professors T. Navneeth Rao and B. Sethuram for ecouragement and useful discussions. One of the authors (JAK) is thankful to Principal, Nizal College, for providing laboratory facilities, and another author (UC) is thankful to CSIR, New Delhi for the award of senior research fellowship.

An Investigation into the Mechanism of Acid-Catalyzed Hydrolysis of *N*-Benzylbenzohydroxamic Acid†

Kallol K. GHOSH* and Shiv G. TANDON
Department of Chemistry, Ravishankar University, Raipur 492 010, India
(Received July 27, 1988)

The catalytic effects of hydrochloric, perchloric, and sulfuric acids on the hydrolysis of *N*-benzylbenzohydroxamic acid (BBHA) have been examined in 10% (v/v) dioxane-water at 55 °C. Plots of the pseudo-first-order rate constants k_ψ against $[H^+]$ show maxima which arise from extensive protonation of the substrate. Analyses of the kinetic data by Bunnett and Bunnett-Olsen criteria, solvent deuterium isotope effects, salt effects and entropies of activation are consistent with a bimolecular mechanism.

As a part of a broad program on the hydrolysis reaction of hydroxamic acids in concentrated mineral acids,[1-6] we have presently undertaken the study of the acid catalyzed hydrolysis of *N*-benzylbenzohydroxamic acid (BBHA). No kinetic study of the hydrolysis of BBHA have previously been reported. BBHA has been found to be a highly selective reagent for the spectrophotometric determination of vanadium(V).[7] However, due to hydrolysis of hydroxamic acids into the parent carboxylic acids and hydroxylamines in concentrated mineral acids severe problems are faced in achieving the desired objectives. Hence, reaction mechanisms and hydrolytic stabilities have been investigated.

In investigating the mechanism we have examined our kinetic data in 10% (v/v) dioxane-water medium, with reference to four different diagnostic criteria; the effect of mineral acid and of added salt, the solvent isotope effect, and the effect of temperature.

Experimental

BBHA was provided by Prof. Usha Tandon of this laboratory and characterized by mp, elemental analysis, UV, IR, NMR, and mass spectral data. The acids used were of analytical reagent quality. Their concentrations were determined by titration with standard alkali. Sodium perchlorate was a recrystallized commercial sample. It was dehydrated at 150 °C. Anhydrous sodium chloride was dried similarly. Dioxane (BDH, AR) was used after purification. Deuterium oxide, D_2O (isotopic purity>99.8%), DCl (isotopic purity> 95%), and D_2SO_4 (isotopic purity>95%) were procured from BARC, Bombay. Iron(III)-chloride solution used in colorimetric procedure was prepared by the standard method.

Kinetic measurements were made by use of the spectrophotometric method reported previously[1] using a SPEKOL set at 520 nm.

Results

Rate Profiles. The observed pseudo-first-order rate constants for the catalytic effect of hydrochloric, perchloric and sulfuric acids are given in Table 1. In order to emphasise the difference in the catalytic efficiencies of the different acids and to illustrate that the rate acidity profiles go through maxima, these data have been plotted in Fig. 1. In sulfuric and hydrochloric acid the dependance of BBHA is characterized by an initial rate increase with the acid concentration, passing through a maximum, followed by a rate decrease with further increasing acid concentration. In the case of perchloric acid, the same trend is observed with a maximum except that the final increase occurs at higher acid concentration. We have previously observed,[1] and commented on, similar maxima in the hydrolysis of *N*-phenylbenzohydroxamic acid (PBHA). Such maxima are attributed to two opposing effects of increasing the acid concentration. On the one hand increased acidity raises the concentration of the reactive conjugate acid form of the substrate, but at the same time reduces the available water needed to complete the hydrolysis. The rate maxima that we observe are superficially similar to those found in acid hydro-

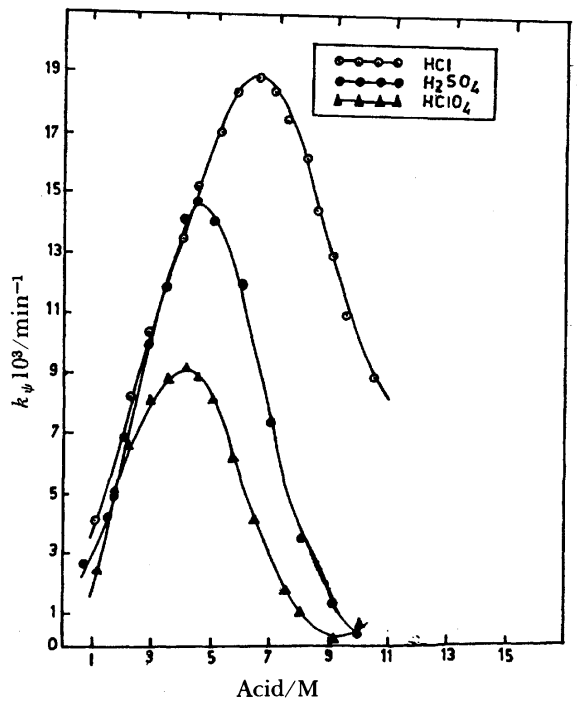

Fig. 1. Rate acidity profiles of pseudo-first-order rate constants for the hydrolysis of BBHA at 55 °C.

lyses of esters,[8] amides,[9] lactams,[10] and hydrazines.[11]

At acid concentrations in the range 0.72 to 4.5 M the catalytic effect (1M=1 mol dm^{-3}) of acids decreases in the order $HCl \approx H_2SO_4 > HClO_4$. At acid concentration above 5.0 M, the catalytic effectiveness of the acids decreases in the sequence $HCl > H_2SO_4 > HClO_4$. Bunton[12] and his co-workers have suggested that such an order is associated with an A-2 mechanism. They attributed this behavior in part to a propensity of perchlorate ion, a large ion of low charge density, to associate preferentially with carbenium ions, actual or partially formed in a transition state. They also consider that transition states with little or no carbenium ion character but with good sites for hydrogen bonding with the medium will be favored in mineral acids having anions of higher charge density (e.g., HSO_4^- or Cl^-). Studies at higher molarities are not possible because of the strong oxidizing and dehydrating properties of H_2SO_4.

The rate of hydrolysis of BBHA is fast as compared to PBHA[1] upto particular acidity region (0.72 to 7.0 M H_2SO_4 and 1.16 to 6.5 M $HClO_4$). It may be due to electron donating nature of $-CH_2$ group attached between C_6H_5 and the nitrogen of the functional group. This may facilitate the protonation of substrate.

Treatment of Rate Data. For all the sets of data in Table 1, we have correlated the data in terms of the acidity function H_0[13] and H_A,[14] activity of water a_{H_2O} and total concentration of hydrogen ion $[H^+]$.

One of the difficulties in the present study in using criteria which utilize acidity function (H_0 and H_A) or activity of water (a_{H_2O}) values is the difference between the temperature and medium at which the hydrolysis of BBHA was studied (55 °C and 10% (v/v) dioxane) and that for which the vast majority of such data is available (25 °C and aqueous medium), and the lack of precise information on the protonation behavior of BBHA. Very few detailed studies of the variation of acidity function with temperature and medium have been reported. We have therefore in the present study used acidity function and water activity at 25 °C for all the acids used. Bunnett and Olsen[15] adopted a similar approach in a study of the acid-catalyzed hydrolysis of *o*-tolunitrile at 133 °C.

The results of Bunnett and Bunnett-Olsen analysis are summarized in Table 3. Most of the correlations

a) The acid concentration range in which the parameters are calculated is inserted in the parentheses.

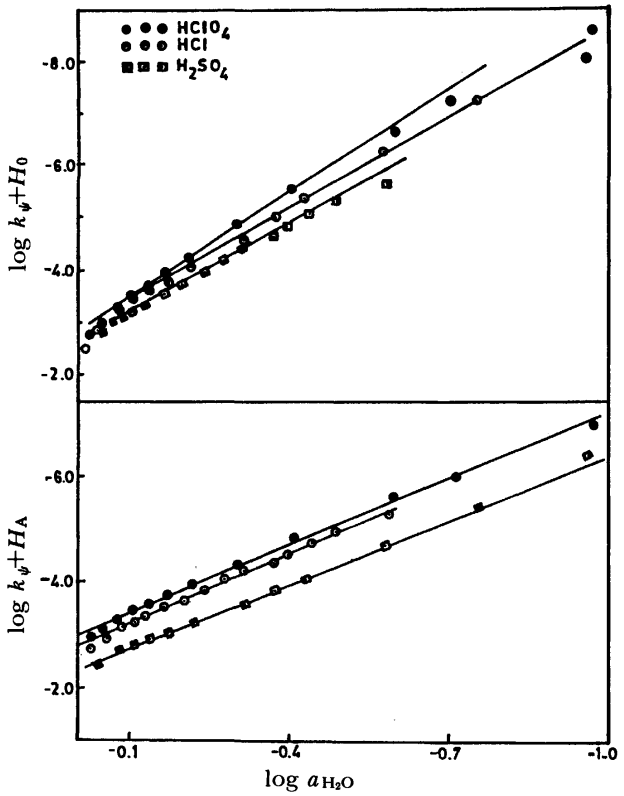

Fig. 2. Bunnett 'w' plots for the hydrolysis of BBHA at 55°C.

are good rather than superb, because of scatter of experimental points. Bunnett[16] plots for the hydrolysis of BBHA (using H_0 and H_A values) are shown in Fig. 2. A good linear correlation is obtained with slopes (w values) in the range 3.9 to 6.4 for all three acids used. Such values of 'w' fall into the range normally associated with water acting as a proton-transfer agent. Plots of ($\log k_\psi - \log [H^+]$) versus $\log a_{H_2O}$ gave Bunnett 'w^*' values of 1.70, 0.92, and 1.12 for hydrochloric, sulfuric, and perchloric acids respectively. Such values are consistent with the mechanistic classification indicated by the Bunnett 'w' values.

Treatment of the data according to Bunnett-Olsen,[17] which does not involve any water-activity data, gave linear plots with slope values ϕ (Table 2). The Bunnett-Olsen plots were far less satisfactory and showed a scattering of points at higher acidities, which could only be resolved into straight lines by omitting certain points and considering limited acid concentration ranges. The 'ϕ' values implies that water plays some additional role in the rate-determining step besides behaving as a nucleophile.

Solvent Isotope Effect. The values obtained for the deuterium kinetic solvent effect, k_D/k_H, for the hydrolysis of BBHA are shown in Table 3. The values for hydrolysis in various concentrations of hydrochloric acid lie in the range 2.1—1.16 which is consistent with specific hydrogen ion catalysis.[18] The values in sulfuric acid are all greater than unity and lie in the range 1.62 to 1.19 approaching less than unity at high concentrations of acid. Thus, the magnitude of the solvent isotope effect at a given acid strength reflects the relative importance of the protonation and the hydrolytic N-acyl bond cleavage steps at that acid strength. These values are also consistent with a reaction involving a preequilibrium at lower acidities followed by a rate-determining nucleophilic attack of D_2O or H_2O.

Salt Effects. Table 4 shows the effect of added sodium chloride and perchlorate on the rate of hydrolysis of BBHA. It is seen that both salts assist the rate of hydrolysis, chlorides doing so more than perchlorates. Bunton et al.[12] have shown that the salt effect of anions of low charge density such as ClO_4^- is slightly negative in A-2 acid-catalyzed ester hydrolysis and anions of high charge density such as Cl^- hinder only slightly or assist the hydrolysis. Thus the data in Table 4 suggest that the substrate is undergoing reaction by an A-2 pathway.

Activation Parameters. The various activation parameters are given in Table 5. The entropy (ΔS^*) and enthalpy (ΔH^*) of activation were calculated from the equation $k=(kT/h)\exp(\Delta S^*/R)\exp(-\Delta H^*/RT)$ by a least-square procedure. These values are fairly typical for A-2 reactions.[19]

Mechanism. On the basis of the above results the plausible mechanism (Scheme 1) appears to involve a rapid protonation equilibrium of BBHA followed by a slow reaction of water with the protonated form, leading to the transition complex and subsequent hydrolysis resulting in the fission of N-acyl bond giving benzoic acid and N-benzylhydroxylamine as the products. At the present time there is no direct evidence as to

Table 4. Salt Effects on the Hydrolysis of BBHA in $HClO_4$ at 55°C

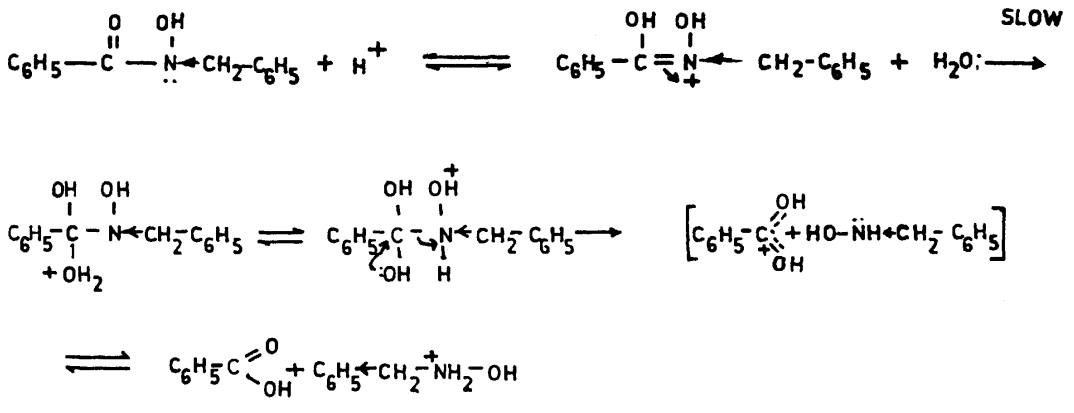

Scheme 1.

whether initial protonation of hydroxamic acid occurs on nitrogen or on oxygen. Protonation studies[20] on *N*-methylhydroxamic acid in concentrated sulfuric acid reveal the presence of both the species. Below 60% (w/w) H_2SO_4 *N*-protonation is preferred and above 60% (w/w) *O*-protonation. Recently, Novak et al.[21] have suggested that for the acid-catalyzed hydrolysis of *N*-hydroxyacetanilides, the protonation of the carbonyl oxygen is favored over the hydroxyl oxygen by ca. 7 orders of magnitude.

A Time-Resolved CIDEP Study of the Laser Photoreduction of Pyruvic Acid by Lactic Acid

Marjory T. CRAW, M. Catherine DEPEW, Frank J. ADRIAN,† and Jeffrey K. S. WAN*
Department of Chemistry, Queen's University, Kingston, Ontario, K7L 3N6 Canada
(Received July 29, 1988)

In addition to the well-known initial phototriplet polarization, unusual Chemically Induced Dynamic Electron Polarization (CIDEP) behavior in solutions of neat pyruvic acid/lactic acid has been attributed to ST_ Radical Pair Mechanism (RPM) polarization in combination with absorptive initial Triplet Mechamism (TM) polarization and ST_0 RPM polarization. Significant ST_ RPM contributions to such carbon centered radicals with small hyperfine splittings have rarely been observer in solution at room temperature.

Pyruvic acid has been utilized quite extensively in this laboratory in studies of free radical reactions with compounds of biological interest including vitamin C, vitamin E, and several quinones.[1-3] The first demonstration of enhanced absorptive triplet mechanism polarization was evidenced in the photoreduction of pyruvic acid;[1] subsequently photolysis of pyruvic acid in glassy ethanol matrices was utilized to demonstrate the concept of spin conservation in energy transfer processes in randomly oriented matrices.[4]

While the pyruvic acid system was an earlier model in our studies to establish the simultaneous contributions of both the initial Triplet Mechanism and the additional ST_0 Radical Pair mechamism in both CIDEP and CIDNP[1] phenomena, the possible operation of the ST- radical pair polarization had eluded our attention until our recent understanding of this mechanism in a more general, but separate chemical system.[5] (The designations ST- and ST_0 refer to polarizations that arise from the interaction or mixing of the singlet and T- or T_0 triplet energy sublevels of the radical pair during the period of separation of the members of the radical pair in which the energies of the two sublevels are nearly degenerate.) In this report, we show the unusual polarization patterns in a series of photoreduction studies of neat pyruvic acid by lactic acid. The complex CIDEP behavior of these systems is due to the substantial and simultaneous contributions of ST- RPM polarization in addition to the expected ST_0 contributions. The significant ST- contribution in the present pyruvic/lactic acid system is mainly due to the very strong molecular interaction between the pair leading to a very high molecular viscosity.

Experimental

Pyruvic acid, lactic acid, and hexafluoro-2-propanol were obtained from Aldrich. Solution viscosities were measured at 25 °C using a falling ball viscosimeter. The CIDEP experiments were conducted using a modified Varian E3 spectrometer without field modulation, as described previously.[6] The solutions were irradiated in situ with a Lambda Physik EMG101-MSC XeCl excimer laser at 308 nm. The path length of the cell used was 0.8 mm in order to reduce any inner filter effects for light absorption.

Results and Discussion

Photolysis of pyruvic acid/lactic acid solutions results in the initial formation of a pair of identical ketyl radicals as shown below.

$$CH_3COCOOH + CH_3CHOHCOOH \longrightarrow 2\,CH_3\dot{C}OHCOOH$$

The time-resolved CIDEP spectrum of a 1:1 v/v mixture of pyruvic acid (PA), and lactic acid (LA) in 50% ethanol is shown in Fig. 1a. There is very good agreement between the experimental spectrum and a spectrum simulated for 40% TM and 60% ST_0 polariza-

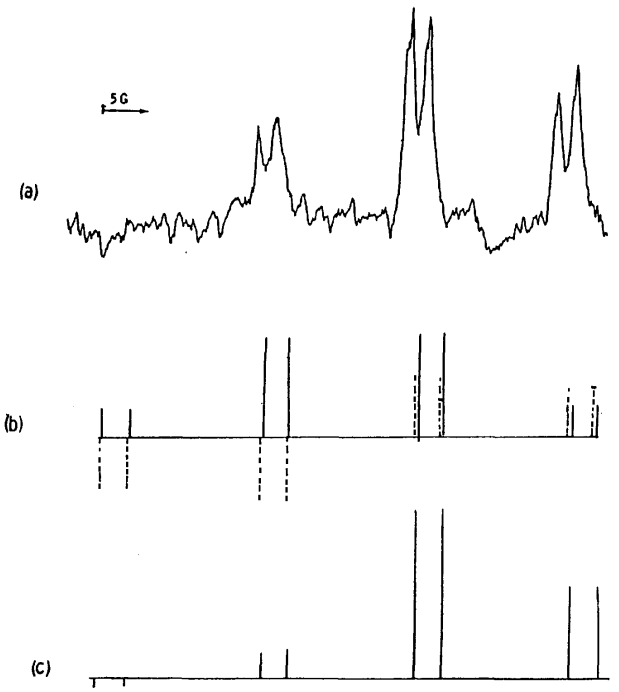

Fig. 1. (a) Time-resolved magnetic resonance spectrum of pyruvate radicals formed following photolysis of a 1:1 v/v PA/LA mixture in 50% ethanol. (b) Expected intensity distribution and phase of TM (——) polarization and ST_0 (----) (right shifted for observation). (c) Simulated CIDEP spectrum for 40% TM and 60% ST_0 radical pair mechanism polarization.

tion (Fig. 1b and 1c).

However, when neat solutions of PA and LA are mixed the resulting solution appears to have a substantially increased viscosity and the relative intensity distribution and phase of the hyperfine lines in the CIDEP spectrum of the ketyl radical changes rather dramatically. Figure 2a—c represents typical spectra observed for neat PA/LA mixtures as a function of relative concentrations of each component, measured at 3 μs after the laser flash. These spectra show that as the pyruvic acid concentration increases the LF/HF ratio also becomes larger and more negative, thus suggesting some additional contribution from ST– mixing.

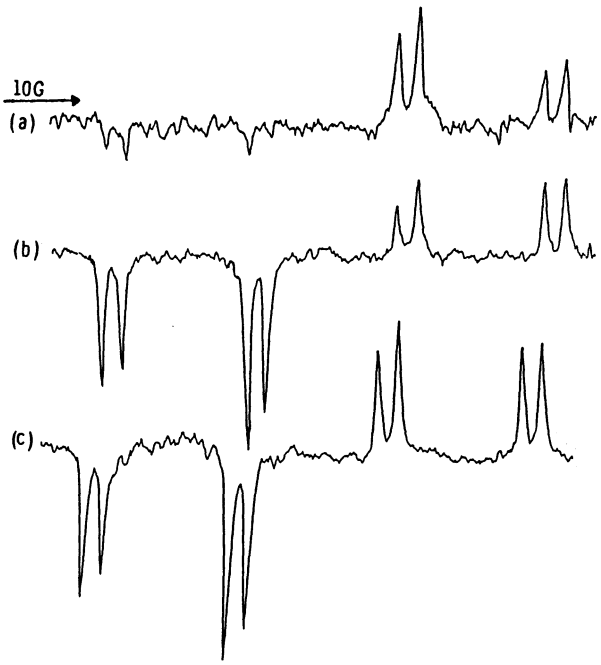

Fig. 2. The time-resolved (3 μs) CIDEP spectra recorded at 25 °C for: (a) 1 : 2 v/v mixture of pyruvic acid/lactic acid, (b) 1 : 1 v/v mixture of pyruvic acid/lactic acid, (c) 2 : 1 v/v mixture of pyruvic acid/lactic acid.

While several examples of a rather large hyperfine induced ST– contributions to polarization spectra have been published,[5,8] the development of "viscosity" induced ST– polarization has not been well-characterized. The CIDEP spectra of 1 : 1 v/v PA/LA at varying temperatures as shown in Fig. 3a—c clearly exhibit a dramatic temperature effect. At 25 °C the relative ratios of the LF/HF lines indicate the presence of an ST– contribution to the observed polarization spectrum. On lowering the temperature the relative intensity of the high field lines diminishes until at −15 °C the phase of these hyperfine lines changes entirely to emission. These observations are consistent with an increase in the ST– contribution to the CIDEP spectrum as the molecular viscosity of the system increases.

Additional insight into the effects of viscosity on this system was obtained by examining the effects of a variety of solvents with a wide range of viscosities from glycerol/water mixtures to nonviscous solvents such as ethanol, hexafluoro-2-propanol, benzene, and formic acid. In neat 1 : 1 v/v mixtures of PA/LA and in solutions containing 50% ethanol or glycerol/water mixtures the viscosity of each solution was measured at 30 °C, ranging from 13 cP (1P=0.1 Pa s) for a solution of 50% ethanol/PA/LA to 73 cP for neat PA/LA system, to 580 cP for a 1 : 1 mixture of PA/LA and glycerol. The time-resolved CIDEP spectra observed

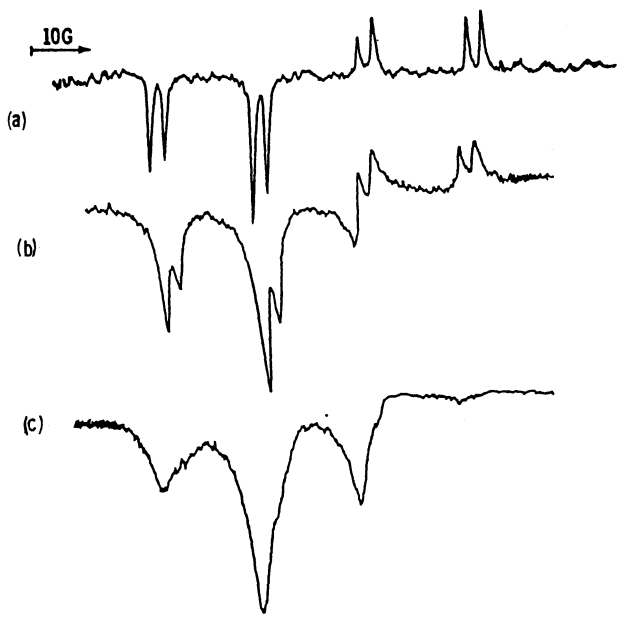

Fig. 3. The CIDEP spectra for a 1 : 1 v/v mixture of pyruvic acid/lactic acid at (a) 25 °C, (b) −2 °C, (c) −15 °C.

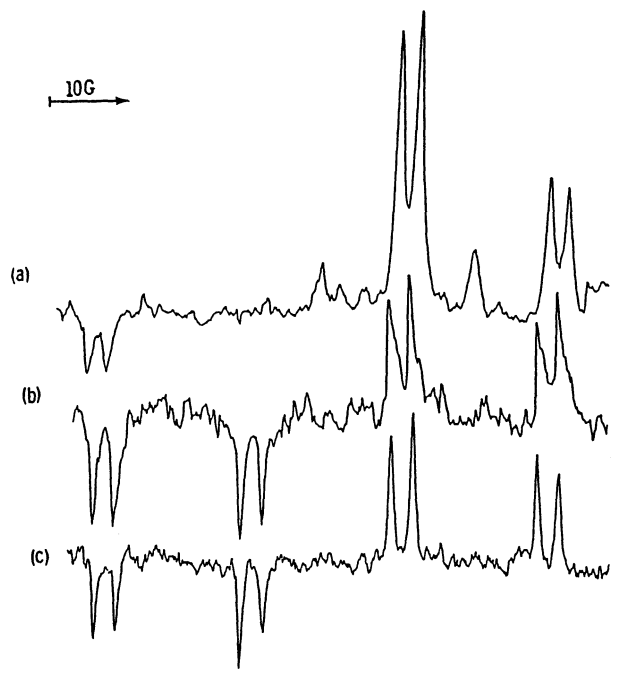

Fig. 4. The time-resolved (3 μs) CIDEP spectra for 1 : 1 PA/LA in 50%. (a) Glycerol, (b) hexafluoroisopropanol, (c) benzene.

for pyruvate radicals under various solvent conditions are shown in Fig. 2a—c. There is no apparent direct correlation between solvent viscosity and the development of ST- polarization for pyruvate radicals, since the most viscous solvent-glycerol-resulted in less ST- contribution than benzene or hexafluoro-2-propanol, or neat PA/LA itself (Fig. 3a).

Pyruvic acid molecules under certain circumstances may dimerize or trimerize, presumably through their carboxyl moieties.[9] This unique property of pyruvic acid may lead to a strong interaction between it and its reduced form, lactic acid. Such a strong molecular interaction may occur both in the ground state and in the radical pair state. Thus ST- mixing may be enhanced when the residence time of an initially formed radical pair in the level crossing region is increased according to[11]

$$\rho_{ST-} = (\pi A^2/4g\,\mu_B{}^H)\,(r_c/2\lambda D) \quad (1)$$

where A is the difference in hyperfine frequencies of the pair and D is the diffusion coefficient. We have used the Smoluchowski equation and the previously published rate constants for the disproportionation of pyruvate radicals in various solvents[7] to calculate D as a function of viscosity,

$$K = 4\pi\sigma\rho DN/1000 \quad (2)$$

where $K=1/2$ the termination rate constant, σ the spin statistical factor for free radical reaction, N is Avogadro's number and ρ the distance of closest approach estimated to be in the region of 6 Å.

The data are presented in Table 1; the assumptions made here suggest that D for pyruvate radicals in $2-4\times10^{-6}$ M pyruvic acid (1 M=1 mol dm^{-3}) in ethanol (viscosity 1.2 cP) is aproximately 10E−5 cm^{2}s^{-1}, not unreasonable for organic radicals in solution.[12] As the viscosity is increased the diffusion of the radicals in a pair would be expected to be very restricted leading to a significant contribution of ST- polarization. While a qualitative analysis suggests that the ST- mechanism becomes more important as the viscosity is increased in a particular solvent, several of the experimentally observed spectra indicate that viscosity arguments alone cannot account for the magnitude of the ST- polarization contributions in defferent solvents. Clearly in solvents such as glycerol and glycerol/water systems the CIDEP spectrum shows contributions from ST_0, TM, and ST- polarizations. However, while the development of ST- polarization for C centered radicals has been observed previously at low temperature[13] and in systems where the solvent viscosity was high,[14] in both cases the ratio of ST-/ST_0 polarization was relatively small.

Table 1. Estimated Diffusion Coefficients for Pyruvate Radicals as a Function of Solvent Viscosity[7]

Solvent	D	Viscosity
	cm^{2}s^{-1}	cP
Ethanol	1.5×10^{-5}	1.2
2-Propanol	7.05×10^{-6}	2.3
1-Butanol	4.23×10^{-6}	3.9
2-Methyl-1-propanol	4.75×10^{-6}	3.9
Benzyl alcohol	4.4×10^{-6}	4.1

As mentioned above pyruvic acid is known to form a polymeric structure, dimer or trimer, in nonpolar solvents.[15] This dimer presumably arises via a hydrogen bonding type of interaction similar to that previously reported for acetic acid.[9] Therefore, it is not surprising that solvent interactions that affect this hydrogen bonding should result in changes in the observed time-resolved spectra. Pyruvic acid has a pK_a of 2.39, while that for lactic acid is 3.83,[16] therefore when ethanol, pK_a=10, is added to a PA/LA acid, it is possible that the concentrations of the protonated forms of the acids are reduced which may limit the extent of such a hydrogen bonding interaction. Comparing the spectra for PA/LA in 50% ethanol with those observed for PA/LA in 50% formic acid and for PA/LA/50% $(CF_3)_2COH$ in which the viscosities of the solutions are similar, a much larger contribution from ST- polarization is found in both of the latter cases. Both $(CF_3)_2CHOH$ have pK_a values in the region of 4—6,[16] therefore in these systems the hydrogen bonding interaction may still be significant, as a result of the acidity of the solvent. This may be further substantiated by the PA/ethyl lactate experiments in which the apparent ST- contribution decreases markedly when the acid functionality of LA is esterified.

When glycerol is used as solvent, the viscosity of the system increases but pK_a for glycerol is $\simeq$14.[16] Therefore the contribution of ST- polarization predicted on the basis of viscosity comparisons may be somewhat lower than expected since in this solvent system the extent of hydrogen bonding and thus the degree of "internal" restricted diffusion may itself be reduced as a result of deprotonation of the acid functionalities. Furthermore, the observed substantial ST- polarization in benzene solutions are consistent with the reduced deffusion expected as a result of the known preference of PA to exist in a polymeric structure in this nonpolar solvent.[15] Also the observed increase in the relative contribution of ST- mixing with increasing concentrations of pyruvic acid is consistent with an increase in the extent of association of pyruvic acid molecules as the concentration relative to LA is increased.

Obviously the complexity of both the physicochemical interactions between the reagants and the solvents in this system and the presence of three contributing polarization mechanisms does not render

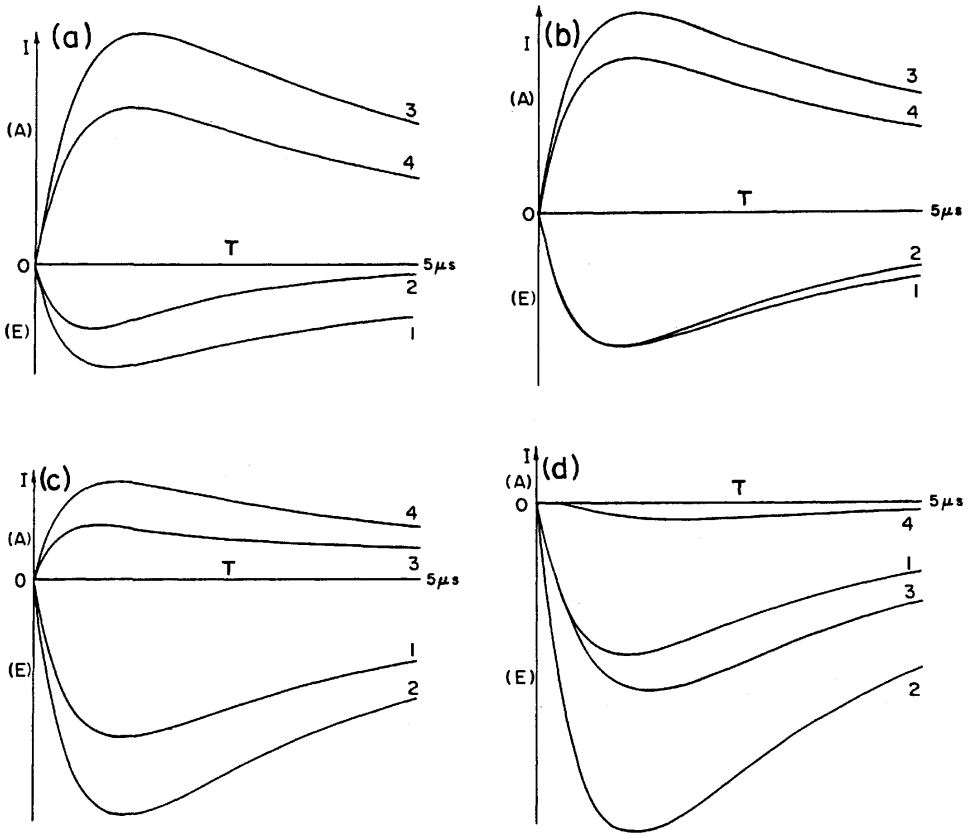

Fig. 5. The calculated line intensities and phases for RPM polarization of pyruvate ketyl radical at various values of D.
(a) $D=10^{-5}$ cm^2s^{-1}, $\rho_{ST_0}=0.033$, $\rho_{ST-}=10^{-4}$, (b) $D=10^{-6}$ cm^2s^{-1}, $\rho_{ST_0}=0.063$, $\rho_{ST-}=10^{-3}$, (c) $D=10^{-7}$ cm^2s^{-1}, $\rho_{ST_0}=0.103$, $\rho_{ST-}=0.01$, (d) $D=10^{-8}$ cm^2s^{-1}, $\rho_{ST_0}=0.151$, $\rho_{ST-}=0.1$.

quantitative examination possible. However an analysis of the variation of the relative hyperfine line intensities and phases with decreasing deffusion between the members of the radical pair which contributes differing relative ST_0 and ST- components to the expected polarization shows some interesting results. Computer simulation of the effects of decreasing D from 10^{-5} to 10^{-8} cm^2s^{-1} is shown in Fig. 5. The relative probabilities of ST_0 to ST- mixing (ρ_{SY_0}/ρ_{ST-}) vary from 330 to 1.5 on going from Fig. 5a to 5d. It is interesting to note the close correlation of line intensity changes with decreasing D value expected in several of the experimental situations; for example, in 50% ethanol the time-resolved spectrum (Fig. 1a) is consistent with the pattern predicted in 5a (with an additional absorptive contribution due to the TM), while in 1 : 2 PA/LA (Fig. 2a) the pattern is quite similar to that shown in 5b. The line intensity changes exhibited in Fig. 3a—c as a result of decreased diffusion due to lowering of the temperature are in good agreement with the changes predicted in Fig. 5c and d.

Finally it is interesting to note the biological role of pyruvic acid and the environment that these molecules exist in in vivo, which can also be studied by CIDEP. We hope to extend this study to other systems in which the possibility of molecular interactions influencing the development of CIDEP may be of importance.

Direct Determination of the Intermolecular Potential for Krypton

Ali BOUSHEHRI* and Jalil Moghadasi ABSARDI
Department of Chemistry, Shiraz University, Shiraz, Iran
(Received September 16, 1988)

In recent years a procedure has been developed for determining potential energy functions directly from measurements of gaseous transport properties, without assuming any particular functional form for the interaction potential. Previous applications of this procedure have required that the potential well depth be known independently. It is shown that this requirement is not necessary, and that the entire potential can be directly obtained with reasonable accuracy from the accurate viscosity data presently avilable. The interaction potential discussed is that for the inert gases.

Many attempts have been made to obtain the forces between molecules, as they are important in determining the physical and chemical properties of matter. Without direct ways of measuring the interaction potential energy function, it has become customary to postulate a parameterized functional form and adjust the parameters for best agreement between the calculated and experimental results. A method for accurately determining the potential energy function for the inert gases by fitting a number of measured quantities has been developed.[1] Here, we reexamine the problem of determining the potential energy function directly from measurements of a single property.

Our method for determining the neutral-neutral interaction potential is based on the method developed by Smith and others[2-6] and recently tested by Boushehri[7,8] in connection with the Extended Law of Corresponding State.[9] Previous applications of this inversion procedure required independent knowledge of the well depth ε. In this work the method used by Boushehri et al.,[10] to determine ε from viscosity data is adapted, so that the value of ε can be obtained from gas viscosities measurements alone. Here we use a unified formulation of viscosity, the ratio η/η_0 of the viscosity η to its value η_0 in the limit of zero temperature. This ratio first rises with increasing temperature to a maximum and then decreases, and the heigth of this maximum can be used to determine the well depth, and a method for its determination using the rate of iteration is described.

Recently a knowledge of the vibrational energy levels has been used to obtain the width of the potential energy well as a function of its depth, and that may be used to determine the shape of the internuclear potential energy function.[11] Lee and his co-workers have been able to obtain potential-energy functions for the inert gases from high-resolution measurements of the differential cross sections.[12] It is unlikely, other than for the simplest molecules, that an accurate potential can be developed from spectroscopic and high-resolution scattering cross section measurements. The method discussed in this paper is an attempt to estimate this quantity purely from viscosity data, which would be considered extremely valuable for substanes where other sources of data are unavailable.

The Kinetic Theory

Our starting point is the well-known equation[13] for the viscosity of an atomic gas

$$\eta = \frac{26.9654(MT)^{1/2} f_\eta^{(3)}}{r_m^2 \Omega^{(2,2)^*}(T^*)} \tag{1}$$

where $T^*=KT/\varepsilon$ and where η is measured in micropoise. The function $f_\eta^{(3)}$, which is nearly unity, and the quantity $\Omega^{(2,2)^*}(T^*)$ are functionals of the potential energy function. It is convenient to write viscosity in a different form. To do this we note that at low temperatures the interactions are dominated by an r^{-6} attractive term. Since $V \simeq C_6\, r^{-6}$, $\Omega^{(2,2)^*}$ takes on the form.[14]

$$\Omega^{(2,2)^*} \rightarrow 1.1943\,(C_6/K_B T)^{1/3}/r_m^2 \tag{2}$$

we can then introduce the viscosity limit η_0 defined by[15]

$$\eta_0 = 22.3903\,(MT)^{1/2}/(C_6/K_B T)^{1/2} \tag{3}$$

and rewrite Eq. 1 as

$$\eta/\eta_0 = 0.85167\, C_6^{1/3}\, \eta/M^{1/2}T^{5/6} \tag{4}$$

where η is in micropoise and C_6 is in atomic units.

We are now in a position to consider Eq. 4 as a unified formulation of the viscosity for all gases. The estimate of well depth is obtained conveniently from the observation of the maximum η/η_0 only.

Inversion Procedure

The experimental collision integral may be used to define the intermolecular potential energy function from which they arise, $V(r)$. A separation distance r_0, for a given temperature, may be defined such that

$$\overline{\Omega}^{(2,2)} = \pi r_0^2 \tag{5}$$

where r_0 represents the collision diameter for hard-sphere molecules which would have the same viscosity as the real molecule and where $\overline{\Omega}^{(2,2)}/\pi r_m^2 = \Omega^{(2,2)^*}$. The potential $V(r_0)$ is given by the relation.

$$V(r_0) = G\, K_B T \tag{6}$$

where G is a temperature dependent function that may be calculated using a model system whose intermolec-

ular potential energy function is known. This process may be repeated to refine the $G(T^*)$ values and hence to obtain an improved $V(r)$ that precisely represent the intermolecular potential energy function. Thus knowing the well depth, the values of viscosity as a function of T can be converted to the potential V as a function of r_0.

In order to obtain a collision integral $\Omega(2,2)$, three successive numerical integrations are needed. Estimation of the triple integral is made by employment of Gatland version of the Computer Program developed by O'Hara and Smith.[16]

To establish the value of the well depth, one may carry out a search procedure. That is, at each stage in the iteration process the values η/η_0 are back calculated from the improved $V(r)$ using an assumed well depth. Several iteration may be used until agreement with the previous iteration is achieved. For findig $V(r)$ directly from measurement of viscosity, one may estimate an initial value of the well depth ε. This estimate value of well depth is obtained conveniently from the observation of the maximum η/η_0, if the maximum η/η_0 is too large, the estimated ε needs to be increased and vice versa, so that a different value of ε is chosen, and the process repeated until agreement with experiment is reached.

In summary, values of collision integral $\Omega(2,2)$ must be obtained from Eq. 1 using highly accurate data. Three interation may be used, if agreement with the previous iteration is not achieved, then a different value of ε is chosen and the process repeated until agreement with experiment is reached. An inital value

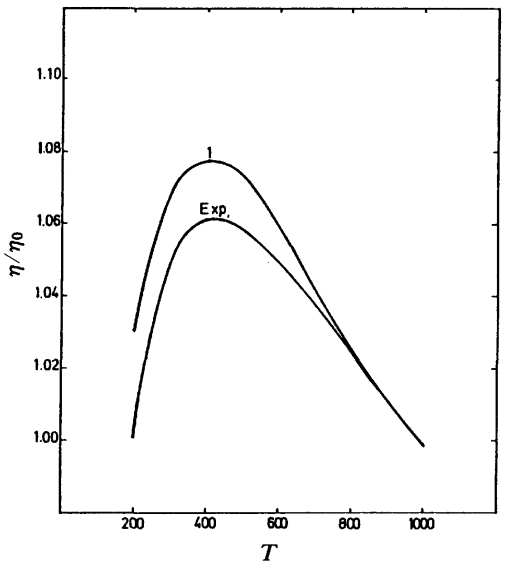

Fig. 1. The ratio η/η_0 as a function of T. Values of η/η_0 in the range $140<T<200$ and $1000<T<2000$ have been omitted for the sake of clarity. The lower curve (Exp.) represents the smoothed viscosity data (Ref. 19). The other curve 1 assuming a well depth $\varepsilon/k=184$. The results in 2nd iteration are nearly identical with those obtained in the first iteration, and are therefore not shown separately.

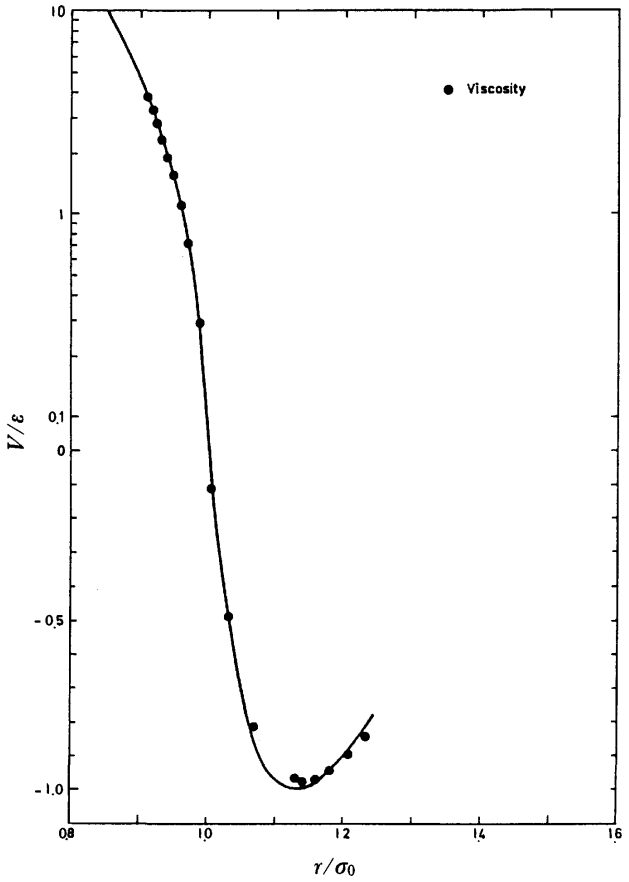

Fig. 2. Reduced pair potential obtained by direct inversion based on the smoothed viscosity data compiled by Smith for krypton (●), $\varepsilon/k=184$ K. Also shown for comparison is a typical curve obtained primarily from thermal scattering data (Kr-Kr, Ref. 18), $\varepsilon/k=198$ K. Note that the scale changes from linear to logrithm at $V/\varepsilon=0.1$.

for the well depth $\varepsilon/k=184$ K is used. The inversion function from Ref. 17 used for an initial estimate of $G(T^*)$. Following the inversion procedure, we obtain calculated values (η/η_0, T) shown as curve 1 in Fig. 1 and compared with the "Smoothed" data shown as Exp. The difference between maximum values, η/η_0 of the two curves is about 1.5%. The (η/η_0, T) values in second iteration are virtually indistinguishable from curve 1 in Fig. 1 and hence is not shown. Thus three steps may be followed in the inversion scheme:

1) Two iteration may be performed to find $V(r)$ for a given ε and a given set of highly accurate data.

2) If the calculated and experimental (η/η_0, T) does not agree within some limit then estimated ε needs to be increased for large value of η/η_0 and vice versa.

3) Return to step 1 and continue until the correct value of ε is obtained.

These three steps should provide a useful technique for the determination of ε values for substances where other source of data are unavailable.

It is of interest to note that the potential obtained for Krypton when plotted in reduced form, using σ and ε/k

determined in this work, is in good agreement with Lee Potential[18] (see Fig. 2).

Conclusion

The present work indicates an application of the concept in Ref. 10 to the smoothed viscosity data. Other than the simplest molecules, it is unlikely to obtain accurate well depth from spectroscopic measurements. The availability of highly accurate viscosity data over a reasonable range of temperature opens up the possibility of obtaining the well depth ε from measure of this single property without the use of additional experimental information or assumption of any mathematical form for the interaction energy function. This method would be considered extremely valuable for substances where other sources of data are unavailable.

We are thankful to Shiraz University Research Council for the support of this work through Grant No. 58-AS-276-256.

4-(2-Quinolylazo)phenol as a Spectrophotometric Reagent for Palladium(II), Osmium(VIII), and Gold(III)

Ishwar SINGH,* Pratap Singh KADYAN, B. S. GARG,† and Sudarsan BARUA†,††
Department of Chemistry, M. D. University, Rohtak 124001, India
†Department of Chemistry, University of Delhi, Delhi 110007, India
(Received May 26, 1988)

Reaction behavior of 4-(2-quinolylazo)phenol (*p*-QAP) is established with three noble metals, i.e. palladium(II), osmium(VIII), and gold(III), under various conditions. Palladium(II) forms a 1:1 greenish violet complex at pH 8—10 (absorption maximum at 580 nm), while osmium(VIII) forms a 1:1 violet compex at pH 8—9.5 (absorption maximum at 550 nm) with the ethanolic solution of *p*-QAP. Color reaction with gold(III) with ethanolic solution of *p*-QAP is instantaneous, but fades away with time. However, a 4:4:2 mixture of water, ethanol, and cyclohexanol stabilizes this color for 45 min. Thus a 1:1 red gold(III) complex formed at pH 8—9.5 absorbs maximum at 550 nm. The Sandell's sensitivities (ng cm^{-2}) of the color reactions are 2.7, 3.9, and 9.8 with palladium(II), osmium(VIII), and gold(III) respectively. Other physicochemical characteristics of the complexes are established. A number of foreign ions tested for their interferences and use of masking agents wherever necessaty it tabulated. Synthetic solutions identical in composition to some palladium(II) and gold(III) alloys are estimated to ascertain the suitability of the reagent.

4-(2-Quinolylazo)phenol (*p*-QAP) was used as an analytical reagent for copper in blood serum[1] and in milk;[2] and for silver[3] and the silver-(*p*-QAP) complex for the indirect determination of iodide.[3] This reagent showed further good analytical potentialities against the micro determination of some other noble metals. Whereas, a very limited number of heterocyclic azo dyes find their uses for the determination of noble metals,[4-19] comparatively this reagent has been found a potential reagent for palladium(II), osmiun(VIII), and gold(III).

Experimental

Apparatus. A Unicam SP 600 spectrophotometer with matched 10-mm glass cells was used for recording the spectra. A Beckman Expandomatic SS-2 pH meter was used for the pH adjustments.

Reagents. *p*-QAP Solution. *p*-QAP was synthesized[1,3] as described earlier, and used as a 1×10^{-3} mol·cm^{-3} solution prepared by dissolving 0.249 g in 1 dm^3 of ethanol. The dark red solid (*p*-QAP) synthesized was quite stable for several months however, *p*-QAP solution more than a week old were discarded, as the older soutions gave slightly less absorbances with metal ions in comparison to freshly prepared solutions.

Palladium(II) Solution. A stock solution of palladium(II) was prepared by dissolving appropriate amount of palladium chloride (Johnson and Mathey, U.K.) in 2 mol·cm^{-3} hydrochloric acid. The solution was standardized gravimetrically with dimethylglyoxime.[20]

Osmium(VIII) Solution. A 1-g ampoule of osmium tetraoxide (Johnson and Mathey, U.K.) was broken beneath the surface of about 100 ml of normal sodium hydroxide solution, contained in a glass-stoppered flask, as described by Ayres and Wells.[21] The orange-red solution was washed into a one litre volumetric flask and made upto volume with doubly distilled water. The solution was standardized iodometrically by the method of Klobbie.[22]

Gold(III) Solution. A stock solution of gold(III) was prepared by dissolving appropriate amount of gold(III) chloride (Johnson and Mathey, U.K.) in doubly distilled water. The solution was 1 mol·dm^{-3} with respect to hydrochloric acid. The solution was standardized iodometrically.[23]

All other reagents were of analytical grade and doubly distilled water was used throughout.

Determination of Palladium(II). To a suitable volume of sample containing 4.7—25.7 μg of palladium(II) add 2 ml of 1×10^{-3} mol·dm^{-3} *p*-QAP solution followed by 1 ml of borate/HCl buffer. Dilute to 10 ml with water and ethanol keeping 50% (v/v) ethanol concentration. Heat on a boiling water bath for 5 min, cool and add ethanol to compensate the loss of volume on heating. Measure the absorbance at 580 nm against a corresponding reagent blank prepared under identical conditions.

Determination of Osmium(VIII). To a suitable volume of sample containing 7.9—32.4 μg of osmium(VIII) add 1 ml of 1 mol·dm^{-3} sodium acetate solution and 2 ml of 1×10^{-3} mol·dm^{-3} *p*-QAP. Raise the volume to 10 ml keeping 50% (v/v) ethanol concentration. Measure the absorbance at 550 nm against a reagent blank and deduce the amount of osmium(VIII) present from the calibration curve.

Determination of Gold(III). To a suitable volume of sample containing 17.4—58.9 μg of gold(III) add 3 ml of 1×10^{-3} mol·dm^{-3} *p*-QAP solution. Add 2 ml of cyclohexanol and 1 ml of aqueous solution 0.05 mol·dm^{-3} $Na_2B_4O_7$. Dilute to 10 ml with water and ethanol, adjusting water, ethanol and cyclohexanol in the ratio 4:4:2(v/v) in the final solution. Measure the absorbance of the solution at 550 nm against a corresponding reagent blank.

Results and Discussion

Among platinum metals, palladium is the easiest to determine and a number of organic reagents are known. Heterocyclic azo dyes are an important class of sensitive reagents for palladium. But very few are known for other noble metals. 4-(2-Quinolylazo)-phenol forms a greenish violet complex with palladium at higher pH's. Full colour development takes place when the mixture is heated on a boiling water bath for about 5 min. Under the appropriate condi-

Sandell's sensitivity ($\mu g \cdot cm^{-2}$)	0.0027	0.0039	0.0098
Molar absorptivity (ε) ($l \cdot mol^{-1} \cdot cm^{-1}$)	3.98×10^4	4.9×10^4	2.0×10^4
Composition(M : L) by job's method	1 : 1	1 : 1	1 : 1

tions found for palladium(II), complexes of zinc, cadmium, mercury, cobalt, and gold decompose and therefore can be tolerated in varying amounts. Platinum metals, except osmium, do not form complexes and thus 50-fold of each are tolerated. A fair amount of EDTA does not interfere and has been used to mask many common metals. On the other hand, *p*-QAP forms violet complex with osmium(VIII) in alkaline medium and no warming is required for the color development. However formation of this complex can be obviated by nitrite and thus palladium can be determined selectively. However palladium(II) interferes in the determination of osmium(VIII).

Preliminary investigations on the colour reaction of gold(III) with ethanolic solution of *p*-QAP showed instantaneous red colour formation at higher pH's. The color, however, fades away with time. To stabilise the colour developed different solvents, singly of their mixtures have been tried and found that a mixture of water, ethanol and cyclohexanol in the ratio 4 : 4 : 2 can be used conveniently since the complex has maximum absorbance and is quite stable for 45 min. The effect of different solvents on the stability of gold(III)-*p*-QAP complex with time has been shown in Fig. 1.

Physicochemical Characteristics. In Fig. 2 are the spectra recorded for the complexes of *p*-QAP with the three metals. The optimum conditions and other physicochemical constants established for the complexes have been given in Table 1.

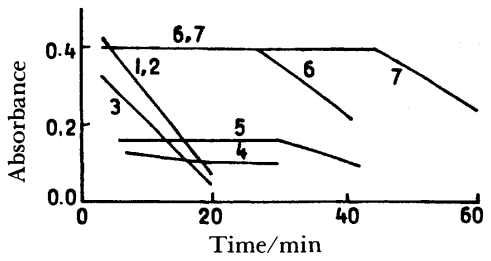

Fig. 1. Effect of different solvents on the stability of Au(III)-(*p*-QAP) complex with time (curves 1 and 2, 50% ethanol and 50% dioxane; 3, 50% DMF; 4, DMF : BuOH : water=5 : 2 : 3; 5, DMF : *c*-$C_6H_{11}OH$: BuOH : water=5 : 1 : 1 : 3; 6, ethanol : *c*-$C_6H_{11}OH$: water=5 : 1 : 4 and 7, ethanol : *c*-$C_6H_{11}OH$: water=4 : 2 : 4).

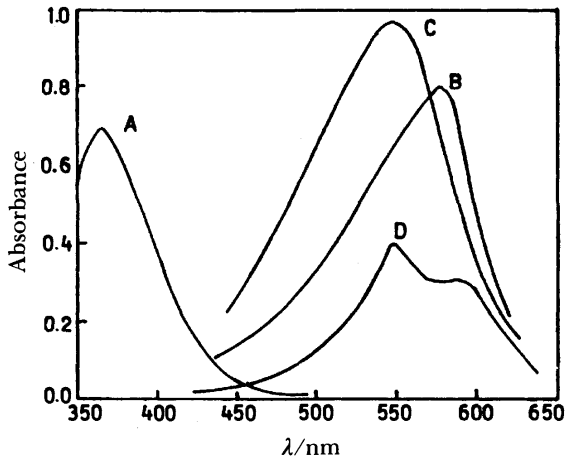

Fig. 2. Absorption spectra of *p*-QAP and its metal complexes at pH 8.0(A) 2.5×10^{-5} mol dm^{-3} *p*-QAP in 50% ethanol (v/v), (B) 2×10^{-5} mol dm^{-3} Pd(II)+1×10^{-4} mol dm^{-3} *p*-QAP[in 50% ethanol (v/v)], (C) 2×10^{-5} mol dm^{-3} Os(VIII)+1×10^{-4} mol dm^{-3} *p*-QAP[in 50% ethanol (v/v)], (D) 2×10^{-5}mol dm^{-3} Au(III)+1×10^{-4} mol dm^{-3} *p*-QAP(in ethanol: water : cyclohexanol=4 : 4 : 2).

Comparison of Sensitivities of the Methods. However many classes of organic spectrophotometric reagents, like oximes, nitroso compounds, hydrazones, reagents containing sulfur as ligand atom, are known for palladium, a number of heterocyclic azo dyes have also been suggested as sensitive reagents for this metal. Sensitivity index[8] 'ϕ' (defined as number of micrograms of an element, present as the absorbing species, in a column of solution of 1 cm^2 cross section giving an absorbance of 0.001 at a specified wavelength) of some important heterocyclic azo dyes are: 1-(2-pyridylazo)-2-naphthol[9] (0.0075 at 678 nm), 4-(2-pyridylazo)resorcinol[10] (0.0057 at 440 nm and 0.012 at 630 nm), 4-(2-thiazolylazo)resorcinol[11] (0.013 at 650 nm), 5-(ethylamino)-2-(2-pyridylazo)-*p*-cresol[12] (0.0039 at 520 nm), 3-(2-thiazolylazo)-2,6-diaminopyridine[13] (0.0077 at 665 nm) and 4-(2-thiazolylazo)-1,3-benzenediamine[14] (0.002 at 585 nm). The present method has the sensitivity index of 0.0027 μg Pd(II)/cm^2 at 580 nm.

A very few heterocyclic azo dyes are known as reagents for gold and osmium. 4-(2-Thiazolylazo)-resorcinol[19] forms a red colored complex with gold-

	(iii) 4.0	0.33 Fe(II)+0.33 Ag(I)	4.0	0.00
White gold	(i) 4.0	0.4 Ni(II)+0.4 Zn(II)	4.02	+0.50
(composition-75—85% Au, 8—10% Ni, 2—9% Zn)	(ii) 4.0	0.4 Ni(II)+0.3 Zn(II)	3.95	−1.25
	(iii) 4.0	0.5 Ni(II)+0.3 Zn(II)	3.96	−1.00

osmium, very less reagents are known. Diphenylcarbazide[30] forms a blue-green complex, absorbing maximum at 560 nm (ϕ, 0.00127). A simple thiourea method[5,6] is popular but is insensitive. Some other known methods have the following sensitivity indices: acenaphthoquinone monoxine[31] (0.0323 at 430 nm), 1-naphthylamine-4,6,8-trisulfonic acid[32] (0.0063 at 573 nm), *o*-aminophenol-*p*-sulfonic acid[33] (0.01 at 440 nm), 3-nitroso-2,6-pyridinediol[34] (0.0079 at 550 nm), and 2-amino-3-pyridinol[35] (0.038 at 600 nm and 0.024 at 540 nm). The sensitivity indices for the present methods are 0.0098 at 550 nm for gold(III) and 0.0039 at 550 nm for osmium(VIII).

Effect of Foreign Ions on the Determination of Palladium(II), Osmium(VIII), and Gold(III). In the determination of the three metal ions [Pd(II)=2.13 $\mu g\,ml^{-1}$, Os(VIII)=1.90 $\mu g\,ml^{-1}$ and Au(III)=3.98 $\mu g\,ml^{-1}$] calcium, magnesium, barium, strontium, aluminium, gallium, indium, antimony(III), manganese(II), lanthanoids upto 100-fold excess and vanadium(V), molybdenum(VI), platinum(IV), rhodium(III), iridium(IV), ruthenium(III) upto 25-fold excess do not interfere. The tolerance limits of other ions which do not cause a deviation of more than ±2% in the absorbance in the determination of the metals are given in Table 2.

Determination of Palladium(II) and Gold(III) in Synthetic Solution of Their Alloys. To ascertain the suitability of the reagent for the determination of palladium(II) and gold(III) in alloys, estimation has been carried out, adopting the appropriate conditions, in synthetic solutions identical in composition to some of their alloys.[36] The results obtained are recorded in Tables 3 and 4 and the percentage recovery obtained suggest that the methods are fairly successful.

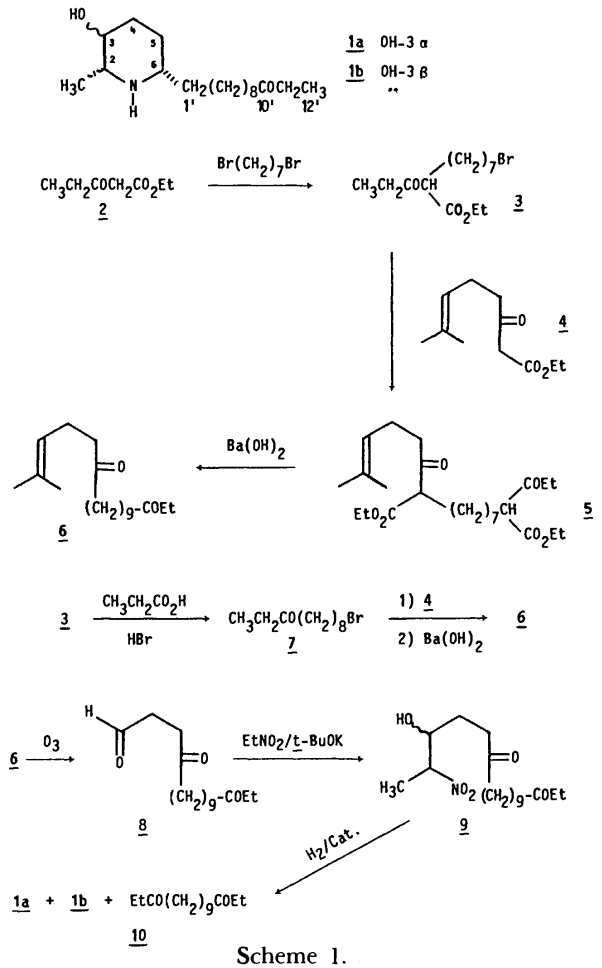
Natural 2,6-Dialkyl-3-piperidinols. 9. Total Synthesis of (±)-Prosafrinine and ^{13}C NMR Studies of Some Analogous Compounds

Michel PATERNE,* Robert DHAL, and Eric BROWN
Laboratoire de Synthèse Organique (U. A. n° 482), Faculté des Sciences,
Route de Laval, BP 535, F-72017 Le Mans, France
(Received June 25, 1988)

1,7-Dibromoheptane was used to alkylate both ketoesters **2** and **4** successively. Hydrolysis and decarboxylation of the resulting intermediate afforded the ethylenic diketone (**6**). Ozonolysis of the double bond of **6** gave the diketonic aldehyde (**8**). Alkaline condensation of nitroethane on the aldehydic carbonyl of the latter, followed by hydrogenation using a Pd-Pt catalyst, afforded 3-*r*-hydroxy-6-*c*-(10-oxododecyl)-2-*c*-methylpiperidine [(±)-prosafrinine] (**1a**) and (±)-3-epiprosafrinine (**1b**). The structures of **1a**, **1b**, and some analogues were confirmed by ^{13}C NMR studies.

The alkaloid prosafrinine (**1a**) was isolated from the leaves of *Prosopis africana*, and its structure was established in 1972.[1] Prosafrinine (**1a**) is a 2,6-dialkyl-3-piperidinol in which the three substituents are cis. We describe here a racemic total synthesis of the alkaloid (**1a**) following a general reaction scheme previously developed in our laboratory for the synthesis of 2,6-dialkyl-3-piperidinols.[2] We have confirmed or established the relative stereochemistry of prosafrinine (**1a**) and some related compounds, more particularly by ^{13}C NMR studies, and by comparison with the data published in a recent paper.[3]



Scheme 1.

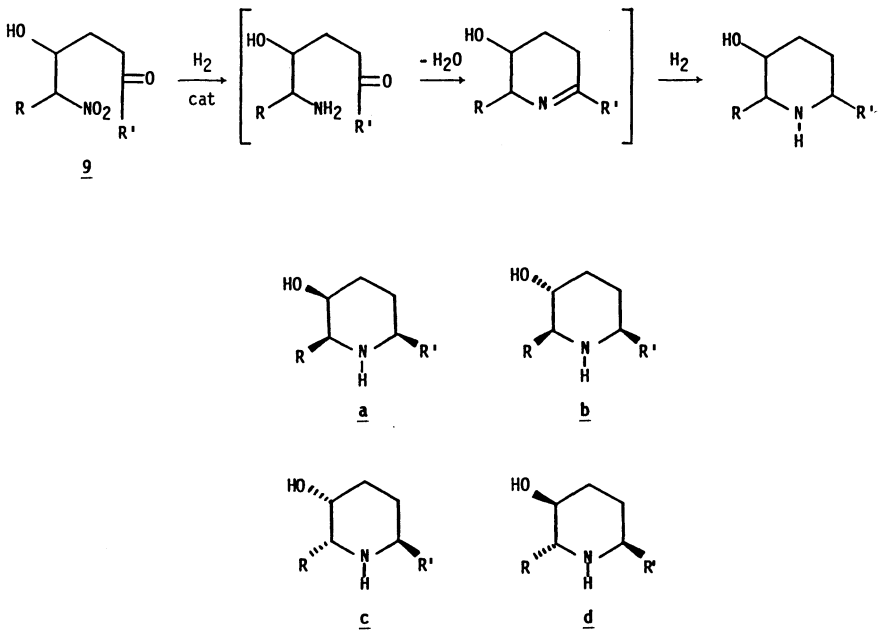
γ,δ-Unsaturated ketones are key-intermediates in our synthetic scheme for 2,6-dialkyl-3-piperidinols. In the present case, we needed to prepare 17-methyl-16-octadecene-3,13-dione (**6**), which contains the carbon atoms at the positions 3 to 6 of the final piperidine ring, as well as the twelve carbon substituent at the position 6 of the same ring. Thus, ethyl 3-oxopentanoate (**2**), prepared from Meldrum's acid,[4] was alkylated with 1,7-dibromoheptane and afforded the monobromo intermediate (**3**) (Scheme 1). Alkylation of the β-keto ester **4**[5] with the bromide **3** gave the diketonic diester **5**, which was next hydrolyzed and decarboxylated in refluxing aqueous barium hydroxide, thus leading to the ethylenic diketone **6** in about 40% yields of purified product, with regards to the starting 1,7-dibromoheptane. Another route to the ethylenic diketone **6** consisted in the decarboxylation of the intermediate **3**, in order to obtain 11-bromo-3-undecanone (**7**) following a known analogous method.[6] Next, the alkylation of the β-keto ester **4** with the bromide **7**, followed by hydrolysis and decarboxylation, afforded the ethylenic diketone **6**. However, this route was found less satisfactory than the former one, which was less toilsome and gave higher yields of **6**.

Ozonolysis of the double bond of **6** in dichloromethane (in the presence of pyridine) at low temperature, followed by reduction of the intermediate ozonide with zinc in acetic acid, afforded the dioxo aldehyde **8** in about 80% yields of purified product. Selective condensation of nitroethane with the aldehydic carbonyl of **8** using potassium *t*-butoxide in a THF/ethanol mixture, gave the β-nitro alcohol **9** as a crystalline mixture of both erythro and threo diastereomers, and in about 80% yields of recrystallized product. The hydrogenation of the mixture of diastereomers **9** was next carried out in ethanol under a pressure of 3 bar, using a mixed catalyst composed of palladium (8%) and platinum (2%) deposited on charcoal. Thin-layer chromatography of the crude reaction product revealed the presence of compounds of high R_f values, together with the piperidinols **1a** and **1b** whose R_f's are very different. By column chromatography on silica

gel, we isolated 3,13-pentadecanedione (**10**) (30%) as well as a mixture of the 3-piperidinols **1a** and **1b** (40—50% yields). The dione **10** probably resulted from a palladium-catalyzed decarbonylation of the γ-keto aldehyde **8** liberated by retrocondensation of the β-nitro alcohols **9**. The above mixture of epimers **1a** and **1b** was easily separated by high-pressure liquid chromatography on an inversed-phase column and using aqueous methanol for the elution. This afforded (±)-prosafrinine (**1a**), mp 69—72 °C and (±)-3-epiprosafrinine (**1b**), mp 76—80 °C, whose structures were confirmed as indicated below.

In principle, four racemic diastereomers could be formed by reduction-cyclization of the mixture of the epimeric β-nitro alcohols **9** (Scheme 2). According to former studies from our laboratory,[7] the catalytic hydrogenation of compounds such as **9** generally yields 2,6-dialkyl-3-piperidinols of types **a** and **b** in which the groups at the positions 2 and 6 are *cis*-diequatorial. In the case of the epimer **a**, the axial hydroxyl can be intramolecularly bound with the lone pair of electrons on the nitrogen atom by hydrogen bonding, which is not possible in the case of the epimer **b** where the hydroxyl is equatorial. Until quite recently, both structures **a** and **b** could be identified essentially by two spectroscopic methods. The infrared spectrum of a dilute carbon tetrachloride solution shows, for the hydroxyl at the position 3, two absorption bands (free and associated OH) for **a** and a single band (free OH) for **b**.[8] On the other hand, the ^{1}H NMR signal of the equatorial carbinolic proton of **a** shows up as a peak whose half-height width is about 6 Hz, whereas the axial carbinolic proton of **b** gives a much flatter peak having a half-height width of about 20 Hz.[9]

Additional information was gained from the examination of the 300 MHz ^{1}H NMR spectra of the isomers **1a** and **1b**. In the case of prosafrinine (**1a**), the H-3 proton shows up as a peak at δ 3.71 whose half-height width is about 5 Hz. This poorly resolved signal having the coupling constants $J_{3\text{-}2,\,4ax,\,4eq}<2$ Hz is characteristic of an equatorial proton, and its selective irradiation allowed the signals at δ 2.99 and 2.76 to be assigned to the H-2 and H-6 protons respectively.



Scheme 2.

Table 1. Characteristic ^{13}C NMR Data of Various 2,6-Dialkyl-3-piperidinols

		δ/ppm			
		C-2	C-3	C-6	C-7
a	**11a** R′=-CH_3	55.80	67.52	52.67	18.48
	12a R′=-$(CH_2)_{12}$-CO-CH_3 (±)-spectaline	57.24	67.90	55.81	18.61
	1a R′=-$(CH_2)_9$-CO-Et (±)-prosafrinine	57.27	67.59	55.92	18.16
b	**11b** R′=-CH_3	58.50	73.61	51.87	18.85
	1b R′=-$(CH_2)_9$-CO-Et (±)-3-epiprosafrinine	58.74	73.72	56.62	19.16

In the case of the epimer (**1b**), the H-3 proton shows up at δ 3.17 as a multiplet whose high coupling constants J_{3-2}=8.8 Hz and J_{3-4}=10.4 Hz are characteristic of trans-diaxal couplings. The selective irradiation of H-3 allowed the signals at δ 2.49, 2.04, and 1.32 to be assigned to the H-2, H-4eq, and H-4ax protons respectively, and made it possible the complete attribution of all the remaining protons of the piperidine ring. However, the H-6 proton at δ 2.52 could not be analyzed because of the overlap with the H-2 signal. The signals and chemical shifts we observed for **1a** and **1b** are in agreement with those reported for (−)-deoxocassine and 3-epideoxocassine, respectively.[3]

The information provided by the infrared and ^1H NMR spectra were confirmed and completed by the study of ^{13}C NMR spectra (see Table 1).

In the case of prosafrinine (**1a**), it can be seen that the C-3 carbon atom, which bears an axial hydroxyl, gives a signal at δ 67.59 whereas in the 3-epimer (**1b**) the same carbon atom (bearing an equatorial hydroxyl) gives a signal at δ 73.72 which corresponds to a difference $\Delta\delta$ =6.13 ppm. This difference has almost the same value in the case of the 2,6-dimethyl-3-piperidinols (**11a** and **11b**) ($\Delta\delta$ =6.09 ppm).[7] It can also be noticed that the C-7 carbon atom of the methyl groups (at the position 2 of the ring) has δ values ranging from 18.16 to 19.16 and which are therefore very close, in all the cases where this methyl group and the substituent at position 6 are cis-diequatorial. These various data confirm the all-cis structure of the epimers of type a.[10]

Experimental

The IR spectra were recorded with a Nicolet 5DX spectrophotometer. The NMR spectra were recorded with Varian EM 390 and Bruker 300 spectrometers for the proton, and Varian FT 80 or Jeol FX 90 Q spectrometers for ^{13}C. NMR spectra were run with samples in $CDCl_3$ solutions. TMS was the internal standard. Chemical shifts are expressed in ppm values (δ scale). Elemental analyses were carried out by the "Centre de Microanalyse du CNRS" (Lyon). Melting points were taken with a Reichert microscope. Thin layer chromatographies (TLC) were carried out using precoated silica gel plates. Preparative column chromatographies were carried out under pressure (1—3 bar) using Merck silica gel (Kieselgel 60). The following abbreviations are used: RP, reduced pressure; RT, room temperature; THF, tetrahydrofuran.

11-Bromo-4-ethoxycarbonyl-3-undecanone (3). To a solution of sodium ethoxide (2.42 g of sodium in 300 ml of anhydrous ethanol) cooled to 0 °C, ethyl 3-oxopentanoate (**2**; 14.4 g) was added dropwise, followed by NaI (100 mg). 1,7-Dibromoheptane (25.8 g) was then added and the mixture was refluxed under stirring for 24 h. The ethanol was removed under RP, the residue was acidified with 0.5 M H_2SO_4 (1 M=1 mol dm^{-3}) and was extracted with ether. The ethereal phase was washed with water until neutral, dried ($MgSO_4$) and evapored under RP. The crude compound (**3**; 29.2 g) was thus obtained in 91% yield, having bp 155—165 °C/0.1 mmHg (1 mmHg≈133.322 Pa). It was used without further purification in the next step; ^1H NMR δ=1.06 (6H, mult., $C\underline{H}_3$-CH_2), 1.33 (12H, -CH_2-), 2.56 (2H, -CH_2-CO), 3.30 (3H, -CH< and -CH_2Br), 4.26 (2H, q, CH_2-O-CO-); IR (film) 1743, 1713, 1186, 1028 cm^{-1}.

4,12-Bis(ethoxycarbonyl)-17-methyl-16-octadecene-3,13-dione (5). To a solution of sodium ethoxide (2.1 g of sodium in 100 ml of anhydrous ethanol) cooled to 0 °C, ethyl 7-methyl-3-oxo-6-octenoate (**4**; 18.01 g)[2] was added, followed by NaI (200 mg). After stirring for 30 min, a solution of crude 11-bromo-4-ethoxycarbonyl-3-undecanone (**3**; 29.2 g) in anhydrous ethanol (150 ml) was added dropwise, and the mixture was refluxed under stirring for 24 h. The ethanol was removed under RP, the residue was acidified with 0.5 M H_2SO_4 and was extracted with ether. The ether phase was washed with water until neutral, dried ($MgSO_4$) and evaporated under RP. The crude compound (**5**; 39.1 g) was thus obtained in 98% yield. It was used without purification in the next step; ^1H NMR δ=1.65 (6H, d, $(CH_3)_2$ C=C), 2.33 (4H, -CH_2-CO-), 3.46 (2H, tertiary CH), 4.20 (4H, q, -CH_2-OCO-), 5.05 (1H, ethylenic proton); IR (film) 1737, 1717, 1180, 1034 cm^{-1}.

17-Methyl-16-octadecene-3,13-dione (6). Crude 4,12-bis-(ethoxycarbonyl)-17-methyl-16-octadecene-3,13-dione (**5**; 39.4 g) was treated with barium hydroxide octahydrate (70 g) in water (1200 ml). After refluxing for 16 h under vigorous stirring, the mixture was cooled down, then acidified with HCl and stirred until complete dissolution of the barium salts. The mixture was then extracted with ether, the organic phase was washed with water, and was dried ($MgSO_4$) and evaporated under RP. The residue was crystallized from pentane, thus giving the purified diketone (**6**; 12.2 g) in 46% yield and as white crystals, mp 71—72 °C (pentane); ^1H NMR δ=1.05 (3H, t, $C\underline{H}_3$-CH_2-), 1.25 (14H, methylenes), 1.65 (6H, d, $(CH_3)_2$C=C-), 2.45 (10H, -CH_2-CO- and $C\underline{H}_2$-CH=C-), 5.0 (1H, ethylenic proton); IR (film) 1716 cm^{-1}; HRMS Found: 294.481; Calcd for $C_{19}H_{34}O_2$: 294.530.

11-Brom-3-undecanone (7). Crude 11-bromo-4-ethoxycarbonyl 3-undecanone (**3**; 14 g) in a mixture of propionic acid (35 ml) and 48% aqueous hydrobromic acid (50 ml) was refluxed for 2.5 h. After cooling, the mixture was added to ice and extracted with toluene. The organic phase was washed with water, dried ($MgSO_4$) and evapored under RP. Crystallization of the residue from pentane afforded the bromide (**7**; 6.5 g) in 60% yield and as white crystals, mp 17—18 °C (pentane); **7** is unstable and should be kept in the refrigerator; ^1H NMR δ=1.0 (3H, t, CH_3-), 1.33 (12H, -CH_2-), 2.30 (4H, -CH_2-CO-), 3.40 (2H, t, -CH_2-Br); IR (film) 1716, 1110, 731 cm^{-1}.

4,14-Dioxohexadecanal (8). Ozone was bubbled through a solution of 17-methyl-16-octadecene-3,13-dione (**6**; 2 g) in dichloromethane (500 ml) at −70 °C until persistence of a blue colour in the ozonolysis reactor. After purging for 5 min, the solution was added to zinc powder (3.4 g), followed by a slow addition of acetic acid (6.8 g) and the resulting mixture was magnetically stirred at RT for 3 h, at which time the peroxide test was found to be negative. The solids were filterd through celite and the filtrate was washed with water. The solution was dried ($MgSO_4$) and evapored under RP and the crystalline residue was chromatographed over silica gel. Elution with 95:5 CH_2Cl_2/ether afforded the dioxo aldehyde (**8**; 1.46 g) in 80% yield, mp 67—69 °C (ether/pentane); ^1H NMR δ=1.03 (2H, t, $C\underline{H}_3$-CH_2), 1.26 (14H, CH_2), 2.43 (8H, CH_2CO), 2.69 (4H, s HCO-$C\underline{H}_2C\underline{H}_2$CO-),

9.95 (1H, s, CHO); ^{13}C NMR δ=211.59 (C-14), 208.67 (C-4), 200.27 (C-1), 42.75 (C-5), 42.40 (C-13), 37.54 (C-2), 35.85 (C-15), 34.70 (C-3), 29.29 (C-7 to C-11), 23.94 (C-6 and C-12), 7.87 (C-16); IR (film) 1712, 1420, 823 cm^{-1}; HRMS Found: 268.2033; Calcd for $C_{16}H_{28}O_3$: 268.2038; Found: C, 71.25; H, 10.29; O, 17.84%. Calcd for $C_{16}H_{28}O_3$: C, 71.60; H, 10.51; O, 17.88%.

16-Hydroxy-17-nitro-3, 13-octadecanedione (9). (Erythro and Threo Isomers). To a solution of potassium *t*-butoxide (0.446 g) in anhydrous ethanol (1 ml) and anhydrous THF (10 ml), a solution of nitroethane (0.343 g) in anhydrous THF (20 ml) was added dropwise. Then a solution of 4,14-dioxohexadecanal (**8**; 0,97 g) in anhydrous THF (20 ml) was added dropwise and the reaction mixture was stirred at RT for 14 h. The potassium salt was destroyed by addition of acetic acid (0.24 g) in THF (5 ml), followed by water (1 ml). The solids were removed by filtration and the solution was dried ($MgSO_4$) and evapored under RP at RT, thus leaving a white crystalline product in quantitative yield. Recrystallization of the latter from ether afforded the mixture of isomers **9** (1 g) in 80% yield, mp 75—76 °C (ether); ^{1}H NMR δ=1.04 (3H, t, C$\underline{H}_3$-CH_2), 1.27 (14H, broad peak, -CH_2-), 1.56 (3H, d, C$\underline{H}_3$-CH-), 2.26 to 2.83 (8H, -CH_2-CO-), 3.0 (1H, -OH), 4.1 (1H, m, -C$\underline{H}$OH), 4.6 (1H, CH-NO_2); IR (film) 3849, 1709, 1559, 1116, 972, 822 cm^{-1}; Found: C, 62.67; H, 9.84; O, 23.35; N, 4.14%. Calcd for $C_{18}H_{33}NO_5$: C, 62.94; H, 9,68; O, 23.29; N, 4.07%.

Hydrogenation of β-Nitro Alcohols (9). (±)-Prosafrnine (1a) and (±)-3-Epiprosafrinine (1b). The hydrogenation was carried out in a Parr apparatus. 16-Hydroxy-17-nitro-3,13-octadecanedione (**9**; 0.73 g) in 95% ethanol (80 ml), and in the presence of a mixed palladium (8%)-platinum (2%) on charcoal catalyst, was hydrogenated under 3 bars at 30 °C for 14 h. After filtration of the catalyst through Celite and evaporation of the solvent under RP, a crude product (0.63 g) was obtained, and whose IR spectrum did not contain a nitro band. TLC over silica gel using 30:9:1 AcOMe/MeOH/15 M aqueous NH_3 as eluent revealed the presence of compounds of high R_f values and two distinct spots at R_f 0.72 and 0.41 corresponding to **1a** and **1b** respectively. The product was chromatographed on a column of silica gel (Merck, 230—400 mesh) using CH_2Cl_2/EtOH/15 M aqueous NH_3 (100:10:1) as eluent, to give a mixture (0.23 g) of (±)-prosafrinine (**1a**) and (±)-3-epiprosafrinine (**1b**) after elimination of less polar head fractions; HRMS of the mixture $[M-C_2H_5]^+$: Found: 268.2287; Calcd: 268.2276; among the head fractions, 3,13-pentadecanedione (**10**) was isolated as a white crystalline solid, mp 78—80 °C (ether), which was characterized as follows; ^{1}H NMR δ=1.06 (6H, t, C$\underline{H}_3$-CH_2), 1.27 (10H, broad peak, -CH_2-), 1.60 (4H, -CH_2CH_2CO-), 2.40 (8H, m, -CH_2-CO-): ^{13}C NMR δ=211.35 (C-3 and C-13), 42.38 (C-4 and C-12), 35.82 (C-2 and C-14), 29.43 and 29.33 (C-6 to C-10), 23.97 (C-5 and C-11), 7.84 (C-1 and C-15): IR (film) 1708, 1701, 1420, 1104, 823 cm^{-1}; HRMS Found: 240.2112; Calcd: 240.2089.

The separation of the mixture of epimers **1a** and **1b** was carried out by high-pressure liquid chromatography on an inversed-phase column (Bondapack Waters C_{18}, 7.8 mm×30 cm, 2 ml min^{-1}) and using MeOH/H_2O (90:10) for the elution. Thus, starting from a solution of the mixture of **1a** and **1b** (250 mg in 1 ml of 90:10 MeOH/H_2O), each 100 µl injection afforded (±)-3-epiprosafrinine (**1b**; 12 mg) and (±)-prosafrinine (**1a**; 9 mg). (±)-3-Epi-prosafrinine (**1b**): mp 76—80 °C (acetone/pentane); ^{1}H NMR (300 MHz) δ=1.05 (3H, t, $J_{12'-11'}$=7.4 Hz, CH_3-12'), 1.18 (1H, m, $J_{5ax-4eq}$=3.6 Hz, $J_{5ax-6ax}\approx$11.5 Hz, $J_{ab}\approx J_{5ax-4ax}$=13.1 Hz, H-5ax), 1.21 (3H, d, J_{7-2}=6.2 Hz, CH_3-7), 1.28 (14H, s, CH_2-1' to 7'), 1.32 (1H, m, $J_{4ax-5eq}$=3.8 Hz, J_{4ax-3}=10.5 Hz, $J_{AB}\approx J_{4ax-5ax}$=13.4 Hz, H-4ax), 1.56 (1H, m, CH_2-8'), 1.75 (1H, dq, $J_{5eq-4eq,\ 4ax,\ 6}\approx$3.0 Hz, J_{AB}=12.5 Hz, H-5eq), 1.81 (2H, large s, OH and NH), 2.04 (1H, dq, $J_{4eq-3,\ 5eq,\ 5ax}\approx$3.5 Hz, J_{AB}=12.0 Hz, H-4eq), 2.39 (2H, t, $J_{9'-8'}$=7.4 Hz, CH_2-9'), 2.42 (2H, q, $J_{11'-12'}$=7.4 Hz, CH_2-11'), 2.49 (1H, m, H-2), 2.52 (1H, m, H-6), 3.17 (1H, ddd, J_{3-4eq}=4.4 Hz, J_{3-2}=8.8 Hz, J_{3-4ax}=10.4 Hz, H-3); ^{13}C NMR δ=212.13 (C-10'), 73.72 (C-3), 58.74 (C-2), 56.62 (C-6), 42.54 (C-9'), 36.64 (C-1'), 35.96 (C-11'), 34.28 (C-4), 31.79 (C-5), 29.85, 29.59, 29.51, 29.37 (C-3' to C-7'), 26.34 (C-2'), 24.07 (C-8'), 19.16 (C-7), 8.01 (C-12'); IR (film) 3261, 3120, 1713, 1113, 1044 cm^{-1}. (±)-Prosafrinine (**1a**): mp 69—72 °C (acetone/pentane); ^{1}H NMR (300 MHz) δ=1.05 (3H, t, $J_{12'-11'}$=7.3 Hz, CH_3-12'), 1.26 (18H, s, CH2-1' to 7'), 1.32 (3H, d, J_{7-2}=6.5 Hz, CH_3-7), 1.56 (m, CH_2-8'), 1.45 to 1.8 (m, H-4ax and CH_2-5), 1.99 (1H, m, H-4eq), 2.39 (2H, t, $J_{9'-8'}$=7.4 Hz, H-9'), 2.42 (2H, q, $J_{11'-12'}$=7.3 Hz, H-11'), 2.76 (1H, m, H-6), 2.99 (1H, q, J_{2-7}=6.3 Hz, H-2), 3.71 (1H, s, H-3), in agreement with the literature;[1,3] ^{13}C NMR δ=211.83 (C-10'), 67.59 (C-3), 57.27 (C-2), 55.92 (C-6), 42.35 (C-9'), 36.34 (C-1'), 35.79 (C-11'), 31.84 (C-4), 29.64, 29.45, 29.32, and 29.11 (C-3' to C-7'), 25.69 (C-5), 25.39 (C-2'), 23.90 (C-8'), 18.16 (C-7), 7.71 (C-12'); IR (film) 3302, 1713, 1107, 1000, 913, 863 cm^{-1}; IR (in dilute CCl_4 solution) 3640 (free OH), 3540 (bound OH) cm^{-1}, $\varepsilon_{ass}/\varepsilon_{free}$: 2.

(Received October 3, 1988)

Iron(III) Schiff base chelates $[Fe_2(PA_2ppd)_2Cl_4]Cl_2$ (**1**), $[Fe_2(PA_2mpd)_2Cl_4]Cl_2$ (**2**), and $[Fe(PA_2opd)Cl_2]Cl$ (**3**), were synthesized, where (PA_2ppd), (PA_2mpd), and (PA_2opd) are the Schiff bases derived from 2-pyridinecarbaldehyde (PA), and *p*-phenylenediamine (ppd), *m*-phenylenediamine (mpd), and *o*-phenylenediamine (opd) respectively. The complexes **1**, **2**, and **3** catalyzed the epoxidation of alkenes with iodosylbenzene as an oxidant providing a chemical model for cytochrome P-450. The binuclear complexes (**1**, **2**) were superior to the mononuclear complex (**3**) as the catalyst for epoxidation of norbornene. Addition of pyridine bases increased the rates, and yields of epoxidation.

The selective addition of oxygen to a hydrocarbon provides a direct means of increasing its commercial potential. But there are only a few preparatively or industrially useful liquid-phase catalytic oxidation processes which do not compromise on the selectivity. In contarst, nature has evolved monooxygenase enzymatic systems, such as cytochrome P-450 which catalyzes oxygenation reactions with utmost selectivity. Hemin forms part of the composition of cytochrome P-450 which are responsible for detoxification of living organisms by hydroxylation of saturated hydrocarbons and epoxidation of alkenes employing molecular oxygen, in their cells.[1]

In the last few years, several chemical models of monooxygenases have been studied. In such systems a metalloporphyrin catalyzes the transfer of an oxygen atom to an alkene, either from a single oxygen donor (e.g. PhIO, $KHSO_5$, NaOCl) or from the combination of molecular oxygen and a reductant (e.g. ascorbic acid, $NaBH_4$).[2-11] Recently, metal complexes other than metalloporphyrins have also been used for catalytic epoxidation of alkenes with iodosylbenzene or alkyl hydroperoxide as an oxygen source.[12-14] However, the systems using iron complexes are limited to porphyrin ligands only.

In the present communication, we report studies on Fe(III) Schiff base chelates as catalysts for epoxidation of alkenes.

Experimental

The elemental analyses were carried out on a Coleman carbon, hydrogen analyzer. The IR spectra were recorded on Shimadzu IR-408 and UV-VIS spectra on Shimadzu UV-240 spectrophotometer. The thermal analyses were performed on Shimadzu DT-30 thermal analyzer. Magnetic moments were determined by Guoy method at room temperature. The conductivity measurements were carried out on Toshniwal conductivity bridge. Gas chromatography analysis were performed on Shimadzu GC 7AG.

Syntheses of Binuclear Complexes. To a solution of 2-pyridinecarbaldehyde (2 mmol), in dry ethanol (50 ml) was added a solution of *p*-phenylenediamine or *m*-phenylenediamine (1 mmol) in dry ethanol (70 ml) and the mixture stirred for 15 min. The Schiff base, thus formed, was added dropwise to a solution of anhydrous $FeCl_3$ (1 mmol) in dry ethanol (100 ml). The mixture was stirred at room temperature for 0.5 h and refluxed on a water bath for 5 h. After cooling to room temperature, the complex was filtered, washed thoroughly with ethanol and dried under vacuum at 100 °C.

Synthesis of Mononuclear Complex. To a solution of 2-pyridinecarbaldehyde (2 mmol) in dry ethanol (20 ml) was added a solution of *o*-phenylenediamine (1 mmol) in dry ethanol (35 ml) and the mixture stirred for 15 min. The mixture was warmed slowly to 45 °C and allowed to cool to room temperature. The Schiff base formed was then added dropwise to a solution of anhydrous $FeCl_3$ in dry ethanol (70 ml) and the mixture refluxed for 5 h. It was then cooled to room temperature, filtered and the filtrate was concentrated to one third. To the above solution was added excess of ether and the precipitated complex was filtered, washed first with ethanol and finally with ether, and dried under vacuum at 100 °C.

Epoxidation of Alkenes. All reactions were carried out in a Schlenk tube under nitrogen atmosphere. To a solution of catalyst (0.012 mmol) in acetonitrile (6 ml) and water (1 ml) were added alkene (2.5 mmol), an appropriate quantity of anisole as an internal standard, and iodosylbenzene (0.5 mmol). The mixture was stirred at ambient temperature for 5.5 h. Aliquots (1 μl) were withdrawn and analyzed by gas chromatography (GC column (3 M), Carbowax 20M, 15% on Chromosorb W, carrier gas nitrogen, flow 30 ml min^{-1}, detector FID, injector temp 240 °C).

Results

The metal complex $[Fe_2(PA_2ppd)_2Cl_4]Cl_2$, $[Fe_2(PA_2mpd)_2Cl_4]Cl_2$, and $[Fe(PA_2opd)Cl_2]Cl$, were characterized by elemental (C, H, N, and metal), spectral (IR and UV-VIS) and thermal analyses, and by conductivity and magnetic moment measurements. The elemental analyses and the magnetic moment data are presented in Table 1. Molecular conductivity was measured in water, methanol, and in a mixture of acetonitrile-water (6 : 1). However, molar conductance of **1** in methanol could not be measured because of its poor solubility. Molar conductance data have been

a) Yields based on iodosylbenzene charged.

presented in Table 2. All the three complexes are soluble in water, but sparingly soluble in acetonitrile, dichloromethane and benzene. However, they are soluble in the acetonitrile-water (6:1) solvent mixture, which was used as a reaction medium for the epoxidation reactions.

The effectiveness of the complexes (**1**—**3**) as catalysts for epoxidation were compared using norbornene as the substrate and iodosylbenzene as an oxidant. The addition of iodosylbenzene to a system containing catalytic amounts of the complex and norbornene in an acetonitrile-water solvent mixture leads to complete reaction within 4 h. The results are given in Table 3. Control experiments showed that norbornene gave extremely low quantity of epoxide in the absence of catalyst. The credibility of anisole as an internal standard was checked by carrying out an oxidation reaction using anisole as the substrate. Anisole did not react under these conditions.

From the catalytic epoxidation of norbornene using the three catalysts, **2** was selected as the catalyst of choice. Oxidation capability of this complex was then screened against various alkenes. The results are presented in Table 4. Effect of various base additives, such as pyridine, 4-picoline, and imidazole has been studied. These results are shown in Fig. 1.

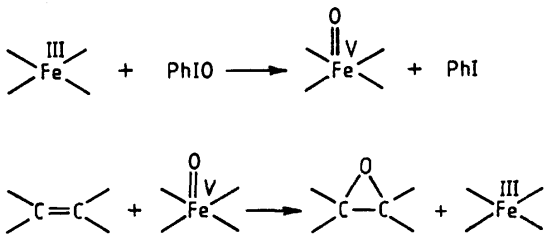
Discussion

The analytical data presents the formula as $C_{36}H_{28}N_8Cl_6Fe_2$ for binuclear complexes and $C_{18}H_{14}N_4Cl_3Fe$ for the mononuclear complex. The structures of the complexes are shown in Fig. 2. Molecular conductivity measurements in water and in methanol show that four chloride ions in the binuclear complexes are inside, and two chlorides are outside the coordination sphere, whereas in the mononuclear complex one chloride is present outside and two inside the coordination sphere. Thermogravimetric analyses from ambient temperature to 800 °C rules out the possibility of any associated water molecules. The magnetic susceptibility measurements at room temperature show that the complexes (**1—3**) are high-spin paramagnetic compounds (4.2—5.13 BM). Infrared spectra of the complexes showed bands at 1615 cm^{-1} corresponding to the coordinated azomethine C=N-stretching, and at 1330 cm^{-1} corresponding to the coordinated C=N-stretching of the pyridyl ring.

Catalytic oxygenation of olefins is taken as evidence for the formation of the highly reactive oxoiron species. In iron porphyrin systems, this species have been identified as the Fe(IV) porphyrin π-radical complex $[FeO(P\cdot)]^+$. However, with one apparent exception no such oxoiron species has been isolated, but several have been spectroscopically detected in situ.[15]

In the present study, where iron Schiff base complexes are involved, the reaction probably proceeds through an oxoiron intermediate as in the porphyrin systems (Scheme 1). But electronic spectra of the complexes (**1—3**) in acetonitrile-water mixture (6 : 1) in the presence of iodosylbenzene did not show any new band for the transient oxoiron species. This may be due to the charge-transfer band masking the dd transition bands. However, it may be suggested that the catalytic reaction occurs via an oxoiron species as shown below (Scheme 1):



Scheme 1.

All the three catalysts were screened against norbornene to compare their oxidation capabilities. From the yields of norbornene oxide formed (Table 3), it is clear that both the binuclear complexes (**1**, **2**) are superior to the mononuclear complex (**3**). Out of the two binuclear complexes, the one with *m*-phenylenediamine Schiff base (**2**), is a better catalyst than the one with *p*-phenylenediamine Schiff base (**1**).

The formation of the oxo-bridged binuclear species Fe^{IV}-O-Fe^{IV} may be the reason for the termination of the catalytic activity. In case of binuclear complexes the formation of oxo-bridged species appear to be less probable than the mononuclear complex because of its bigger molecular size. However, the reasons for the superiority of the binuclear complex having *m*-phenylenediamine Schiff base over the one with *p*-pheneylenediamine Schiff base is not clear at present.

Addition of bases are known to increase the rates of the reaction dramatically without affecting much the overall yields.[16] However, in the present study of the epoxidation of norbornene, addition of various bases such as imidazole, pyridine, and 4-picoline, not only enhanced the rates but showed marked increase in the yields of epoxide. Addition of 4-picoline gave higher yield of epoxide, as compared to that with pyridine. In contrast to this, imidazole was comparatively less effective (Fig. 1).

Conclusion

The metal Schiff base complexes described here catalyze the epoxidation of olefins providing a good chemical model for monooxygenases. Their easy preparation from readily available materials as compared to that of metalloporphyrins makes them attractive catalyst for monooxygenase model studies.

(Received August 11, 1988)

Synopsis. The molecular and crystal structure of the title compound has been determined by the X-ray method. The cation structure consists of well-separated dimeric pairs of the octahedrally coordinated cobalt(III) atom linked by two μ-hydroxo bridges. There are two intramolecular N-H···O hydrogen bonds bridging the two chromophores.

There have been many reports on the preparation and characterization of dicobalt(III) complexes containing two bridging hydroxo ligands.[1] The complexes of this type are fundamental in the study of the polynuclear complexes, and a comparative study of the geometrical isomers of the $(\mu\text{-}OH)_2$ complexes is important in clarifying the factor stabilizing the polynuclear structure. Recently, three isomers of the $[(gly)(en)Co(\mu\text{-}OH)_2Co(gly)(en)]^{2+}$ complex ion were synthesized by one of the present authors.[2] However, there are so many possible isomers (theoretically 20 isomers) in the complex ion that it is necessary to confirm the structure of the synthesized isomers by the X-ray method.

Experimental

$[(en)(gly)Co(\mu\text{-}OH)_2Co(en)(gly)]\cdot 2ClO_4$ was prepared by the method reported previously[2] and then recrystallized from a water-ethanol solution. A wine-red crystal with approximate dimensions of 0.30×0.18×0.15 mm^3 was used for the X-ray measurement. The unit-cell parameters and reflection intensities were measured on a Rigaku AFC-4 automatic four-circle diffractometer with graphite-momochromated Mo $K\alpha$ radiation (λ=0.71073 Å). Independent reflections with the range of $2\theta<55°$ were collected by the 2θ-ω scan technique. The scan width, scan rate, and background counting time at both ends of scan were $\Delta\omega=(1.2+0.35\tan\theta)°$, $4°(2\theta)min^{-1}$, and 4 s respectively. Three standard reflections were measured after every 100 reflections; they showed no decay during the intensity measurement. The Lorentz and polarization effects were corrected, but no corrections for absorption and extinction were applied. 2116 independent reflections with $F_o>3\sigma(F_o)$ were used for the structure analysis. The structure was solved by the direct method (MULTAN 78)[3] and refined by the block-diagonal least-squares procedure (HBLS-V),[4] with anisotropic thermal parameters for nonhydrogen atoms. The function minimized was $\sum w(|F_o|-|F_c|)^2$, where a unit weight was applied throughout the refinement. All the hydrogen atoms were found in the difference Fourier map and included in the refinements with isotropic thermal parameters. The final R-value was 0.051 (R_w=0.056). The final atomic parameters are listed in Table 1.[5] The atomic-scattering factors were taken from International Tables for X-ray Crystallography.[7] The computations were carried out on an IBM-3081 computer at the Information Processing Center of Shimane University.

Crystal data: $C_8H_{26}N_6O_6Co_2\ 2ClO_4\ 2H_2O$, $F.W.$=655.11, Monoclinic, $P2_1/n$, a=15.982(2), b=11.732(2), c=6.086(1) Å, β=94.51(1)°, Z=2, D_x=1.912 Mg m^{-3}, D_m=1.913(3) Mg m^{-3}, μ=1.84 mm^{-1}, $F(0\ 0\ 0)$=672.

Results and Discussion

The crystal structure consists of well-separated dimeric cations, perchlorate ions, and H_2O molecules. The bond distances and angles of the complex are listed in Table 2. A perspective view of the complex cation is shown in Fig. 1. The complex cation has an inversion center at the middle of the dimer. The coordination of Co(III) is roughly octahedral, and the bridging unit, Co-O-Co-O, is strictly planar. The Co-Co and O-O separations in the bridging unit are 2.874 (1) and 2.524 (4) Å respectively. The two independent bridging Co-O bond lengths are essentially the same (1.917 (3) and 1.908 (3) Å). The Co-O-Co and O-Co-O angles are 97.4 (2)° and 82.6 (1)° respectively. The geometry of the Co-O-Co-O bridging unit is similar to that of the Cr-O-Cr-O unit found in $[Cr(gly)_2(OH)_2]$[9] and $[Cr(L\text{-}Pro)_2(OH)_2]$.[10] There are two intramolecular hydrogen bonds formed between the N(2)-H ethylenediamine ligating to one of the two cobalt atoms and the O(1) of glycinate coordinated to the other cobalt atom, whose N(2)···O(1) length is 2.968(5) Å. The hydrogen bonds significantly contribute to stabilizing the dinuclear structure. The ethylenediamine-chelate ring adopts a gauche conformation, where C(3) and C(4) are 0.482(8) and −0.203(8) Å, from the plane of the three remaining atoms (Co, N(2), and N(3)). On the other hand, the glycinate-chelate ring adopts an envelope conformation, where C(1) and C(2) are 0.491(7) and 0.252(7) Å, from the plane of the remaining atoms (Co, N(1), and O(1)). As shown in Fig. 2, the O(2) and N(3) form intermolecular hydrogen bonds with the water molecules, and the lengths of O(2)···O(w) ($-x$, $-y$, $1-z$) and N(3)···O(w) (x, y, z) are 2.918(6) and 3.037(6) Å respectively. The N(2) forms an intermolecular hydrogen bond with the O(7) of the perchlorate ion, and

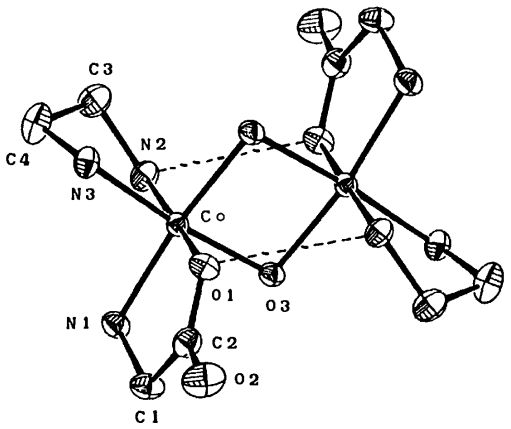

Fig. 1. A perspective view of the $[(gly)(en)Co(\mu\text{-}OH)_2Co(gly)(en)]^{+2}$ drawn by a ORTEP.[8] Thermal ellipsoids are drawn at the 50% probability. Hydrogen bonds are indicated by broken lines.

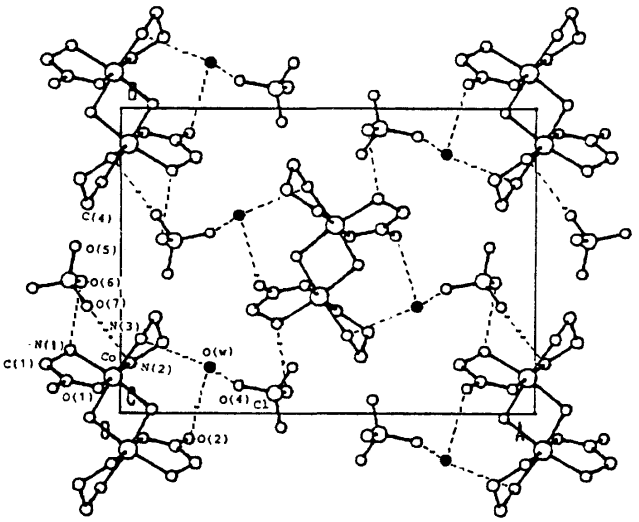

Fig. 2. A crystal structure of the complex along c-axis. Water molecules are drawn in solid circles. Hydrogen bonds are indicated by broken lines.

the length of N(2)···O(7) ($-x$, $1-y$, $-z$) is 2.925(10) Å. The N(1) also forms a hydrogen bond with the O(6), whose N(1)···O(6) ($-x$, $1-y$, $1-z$) length is 3.029(8) Å. The water molecule also forms an intermolecular hydrogen bond with O(4) of the perchlorate ion, O(w)···O(4) ($1/2-x$, $-1/2+y$, $1/2-z$) being 2.958(8) Å.

The authors wish to express their thanks to Professor Yukiteru Katsube of the Crystallographic Research Center, Institute for Protein Research, Osaka University, for the use of the diffractometer.

Intrinsic Reaction Coordinates for the Dissociation and the Isomerization Reactions of Formaldehyde

Seikichi CHO
Department of Chemistry, Faculty of Education, Gunma University, Aramakicho 4-2, Maebashi, Gunma 371
(Received September 9, 1988)

Synopsis. Static and dynamic intrinsic reaction coordinates are defined by using the eigenvectors of the force constant matrix, and the simultaneous eigenvectors of the relative kinetic energy and the force constant matrix, respectively. The theory was applied to the dissociation and the isomerization reactions of the formaldehyde molecule. It is shown that the intrinsic reaction coordinate of the dissociation reaction of formaldehyde left from the normal coordinate of the equilibrium formaldehyde with the second lowest wavenumber, the rocking mode of vibration, while that of the isomerization reaction departed from the scissoring mode having the third lowest wavenumber.

The transition state is usually defined as a stationary point, that is, all the first-order differentials are vanishing, and the force constant matrix has only one negative eigenvalue.[1] A unit vector along the direction of the eigenvector with a negative eigenvalue is called the transition vector by McIver and Stanton.[2] Fukui[3] defined the intrinsic reaction coordinate (IRC) as a curve passing through the initial and the transition points and orthogonal to the energy equipotential contour surface. He also proved that at a stationary point, the IRC merges with one of the eigenvectors of the force constant matrix. From these considerations we might infer that the IRC is alternatively defined as a curve along one of the eigenvectors of the force constant matrix with a negative or a small positive eigenvalue, and all the first order differentials along the eigenvectors other than the IRC are null. This statement can also be applicable to the normal coordinate space,[4] where the eigenvectors of the force constant matrix should be replaced by the simultaneous eigenvectors of the relative kinetic energy and the force constant matrix.[5]

The IRC's in ordinary space and in the normal coordinate space may differ, since the transformation matrix is not unitary, nor orthogonal. The former is *'static'* as it lies on an adiabatic potential surface, while the latter is *'dynamic'* as the normal coordinates are the solutions of the classical equations of motion, despite of vibration or 'infinitely slow' motion.[5] However, actual calculations showed that the two IRC's are unexpectedly simillar to each other. This is partially because at each stage corrections were made so that the first order differentials along eigenvectors other than the IRC were zero. To follow the 'dynamic' IRC has some merit; it gives the vibrational mode of the initial state from which the reaction departs, and also the change of vibration wavenumbers during the course of the reaction.

The IRC's of the formaldehyde molecule were treated by normal coordinate analysis using the STO-3G potential surface. Although the potential surface of the formaldehyde molecule has been extensively investigated with the more extended basis sets,[6] we apted to choose the minimal basis set as a consideration of cost and quality.

Now we briefly review the procedure to determine the IRC. At first a normal coordinate analysis is applied to a transition state and the resulting normal coordinates are normalized, as the normal coordinates are usually not normalized. Choosing the transition vector as the IRC vector, we proceed downwards along the IRC at a constant stepwidth. At the next point we repeat the normal coordinate analysis and again normalize the resulting normal coordinates. From these normalized normal coordinates we choose a new IRC vector by calculating the overlaps between these and the IRC vector at the previous point. If necessary, the correction is made so that the first-order differentials along the normal coordinates other than the IRC vector are zero.[5] Thus the steepest-descent requirement of IRC[7] is automatically satisfied. These procedures are repeated until an equilibrium point is attained, where the first-order differential along the IRC vector is zero.

The program was implemented into HONDO76[8] and the calculations were carried out on the HITAC M-240H computer located at Gunma University.

The vibrational wavenumbers of the equilibrium state calculated on the STO-3G potential surface were in the correct order, although the calculated values were generally larger than the observed ones. The numbering of the normal coordinates is in an increasing order of wavenumber, and that of the eigenvectors of the force constant matrix is also in an increasing order of the magnitude of the eigenvalues. The Q_1

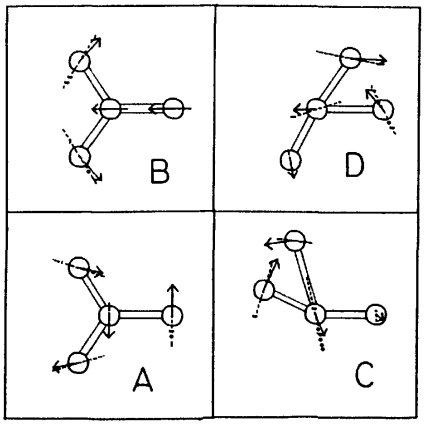

Fig. 1. Normalized normal coordinates and the nearest valleys on the formaldehyde STO-3G potential surface. (A) Q_2 and V_1; (B) Q_3 and V_2 at the equilibrium state; (C) Q_1 and V_1 at the dissociation transition state; (D) Q_1 and V_1 at the isomerization transition state (C_s symmetry).

normal coordinate is an out-of-plane wagging vibration and corresponds to the third eigenvector (V_3) of the force constant matrix, the third 'valley' of the potential energy surface. Q_1 is thus omitted from a candidate of IRC of the dissociation or the isomerization reaction. Q_2 and Q_3 might be chosen as IRC vectors, and are graphically shown in Fig. 1 with the nearest valleys. At this time it is difficult to decide, which normal coordinate, Q_2 or Q_3, lead to the dissociation reaction or the isomerization reaction of the formaldehyde molecule. The dissociation reaction IRC should pass the dissociation transition state,[9] and the isomerization IRC should go through the isomerization transition state.[9]

The transition vectors of the dissociation and the isomerization transition states are also shown in Fig. 1. (Actually using the geometry shown in Fig. 1-D, the formaldehyde molecule on the STO-3G potential surface has two imaginary wavenumbers and may be said to be on a '*hilltop*'. The lowest wavenumber vibration has C_s symmetry while the second one is in an out-of-plane mode. The more elaborate calculations[6] mentioned above gave C_s symmetry for the isomerization transition state of formaldehyde, so we ignored the second imaginary wavenumber vibration and adopted the C_s symmetry transition state.) The mode of the transition vector at the isomerization transition state (Fig. 1,D) is closely related to Q_3 of the equilibrium state (Fig. 1,B), while the correspondence between that of the dissociation transition state (Fig. 1,A) and Q_2 of the equilibrium state (Fig. 1,C) is not clear.

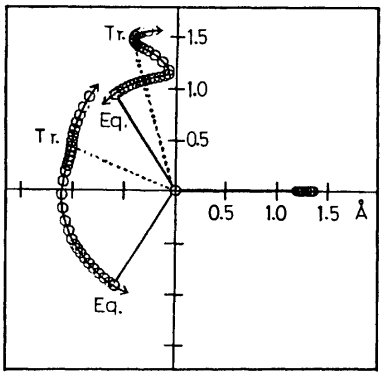

Fig. 2. Dissociation IRC of the formaldehyde on the STO-3G potential surface. The carbon atom is fixed at the origin and the oxygen atom is floating on the abscissa.

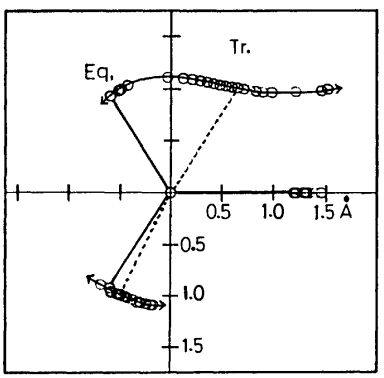

Fig. 3. Isomerization IRC of the formaldehyde on the STO-3G potential surface.

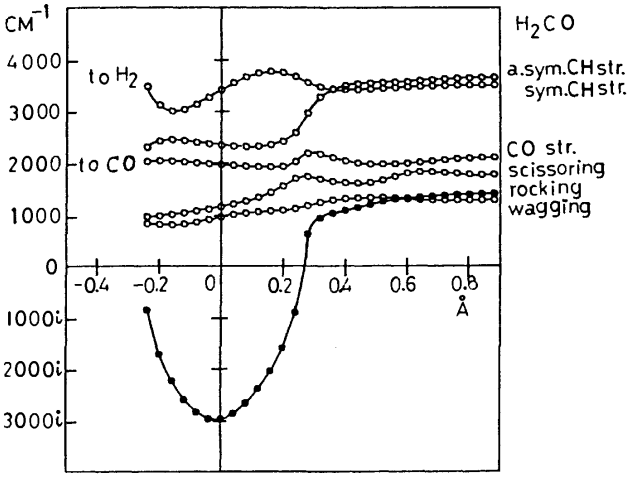

Fig. 4. Variations of vibrational wavenumbers in the course of the dissociation IRC of formaldehyde, calculated on the STO-3G potential surface.

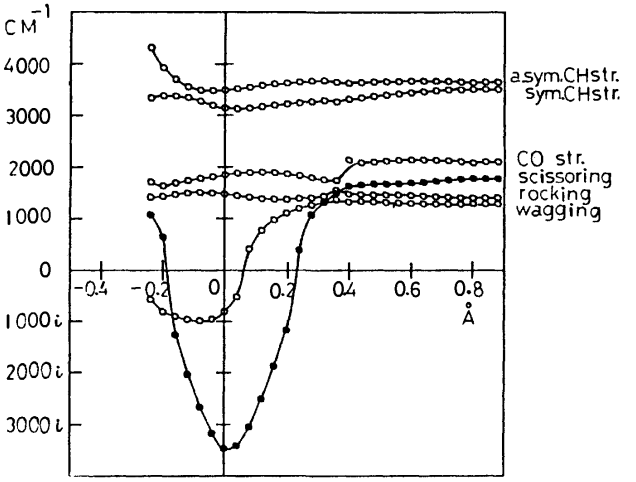

Fig. 5. Variations of vibrational wavenumbers in the course of the isomerization IRC of formaldehyde, calculated on the STO-3G potential surface.

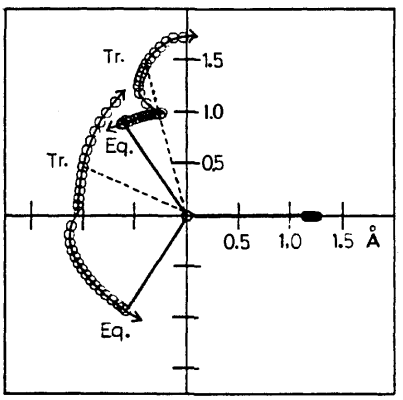

Fig. 6. '*Static*' IRC of the dissociation reaction of formaldehyde, calculated on the STO-3G potential surface.

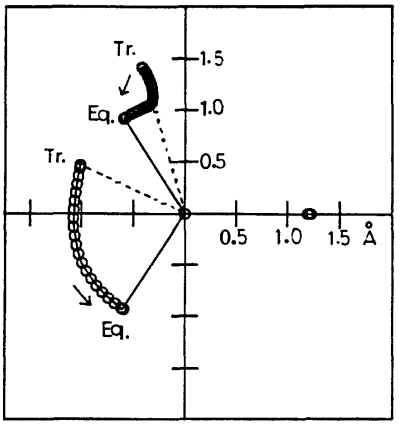

Fig. 7. *'Steepest descent'* IRC of the dissociation reaction of formaldehyde, calculated on the STO-3G potential surface, using the program GAMESS.[10]

The IRC's of the dissociation and the isomerization reactions of the formaldehyde molecule are shown in Figs. 2 and 3. The variations of the wavenumbers during the course of the IRC's are also shown in Figs. 4 and 5. From these figures it can be easily seen that the dissociation IRC and the isomerization IRC tend to the Q_2 (rocking) and the Q_3 (scissoring) mode of the equilibrium formaldehyde molecule, respectively. Finding these, we can follow the IRC's upwards to each transition state by leaving from Q_2 and Q_3, respectively.

The *'static'*, and the *'steepest descent'* IRC's calculated by GAMESS,[10] of the dissociation reaction of formaldehyde are shown in Figs. 6 and 7 for the comparison. Figure 6 resembles to the results by Cerjan and Miller[9] obtained on the adiabatic potential surface. On the other hand, the *'steepest descent'* IRC cannot reverse the direction, the uphill side from the equilibrium to the transition state.

In conclusion, the dissocation IRC of formaldehyde reaches the Q_2 normal coordinate (the rocking mode) at the equilibrium state, and the isomerization IRC leads to the Q_3 normal coordinate (the scissoring mode), respectlvely. The rocking and scissoring vibrations may be said to be 'key vibrations' of the dissociation and the isomerization reactions of equillbrium formaldehyde, in a sense recently described by Fuke et al.[11]

The Amidation of Carboxylic Acid with Amine over Hydrous Zirconium(IV) Oxide

Kyoko TAKAHASHI, Makoto SHIBAGAKI,* Hideyuki KUNO, Hiroshi KAWAKAMI, and Hajime MATSUSHITA
Life Science Research Laboratory, Japan Tobacco, INC., 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227
(Received November 5, 1988)

Synopsis. The reaction of a carboxylic acid or an ester with an amine to give the corresponding amide was carried out efficiently over hydrous zirconium(IV) oxide, whether in the vapor phase or in the liquid phase.

Hydrous zirconium(IV) oxide is a colorless, translucent, amorphous, and hard solid. It is insoluble in organic solvents and stable at room temperature in air. In previous papers,[1-3] we reported that the reduction of aldehydes and ketones with 2-propanol proceeded efficiently over hydrous zirconium(IV) oxide. During our studies to clarify the scope and the limitations of the reaction and to characterize the hydrous zirconium(IV) oxide, it was found that the oxide could also catalyze the amidation of carboxylic acid with amine. A homogeneous catalyst such as phosphoric acid or alkoxide[4] of titanium or zirconium was ordinarily used in the amidation, but the isolation of the products involves tedious work-up procedures. On the other hand, alumina,[5-7] silica gel,[8,9] and silica-alumina have also been reported as heterogeneous catalysts of the amidation, and they had such advantages as the easy isolation of products. In order to compare the catalytic activity, amidations were carried out using hydrous zirconium(IV) oxide and other catalysts.

Experimental

Materials. The hydrous zirconium(IV) oxide was prepared in the manner reported earlier.[1-3] Commercial reagents were used for the amidation without further purification.

Vapor-Phase Reaction Procedure. The catalytic amidation was carried out in a glass-flow reactor (6.5 mm or 7.0 mm in diameter) with a fixed-bed catalyst: flow rate of nitrogen gas=30—60 $cm^3 min^{-1}$, catalyst=2.0 g, reaction temperature=150—200 °C. A mixture of carboxylic acid or ester, amine or aqueous ammonia (28%), and dodecane or tridecane as an internal standard was fed, by means of a microfeeder, into the reactor (5 $cm^3 h^{-1}$). In the case of the reaction with ammonia gas, a benzene solution of carboxylic acid or ester was fed an excess amount of ammonia gas. The products were then analyzed by means of gas chromatography (a capillary column; PEG 20M 30 m).

Liquid-Phase Reaction Procedure. In a 25 cm^3 round-bottomed flask equipped with a reflux condenser were placed the catalyst (2.0 g), a carboxylic acid or ester, an amine, and a hydrocarbon as an internal standard. The contents were heated under a gentle reflux. In the reaction with ammonia, excess ammonia was supplied to the reaction solution of benzene before heating. In some reactions, xylene or toluene was added to the solution in order to raise the reaction temperature. The reaction mixture was col-

lected after 5 hours' reflux, and the products were analyzed by means of gas chromatography. The products was identified by a comparison of their retention times with those of authentic samples.

Results and Discusion

Vapor-Phase Reaction. The results of the vapor-phase amidation of some carboxylic acids or esters with amine, ammonia, and aqueous ammonia over hydrous zirconium(IV) oxide are listed in Table 1. The amidation of acetic acid or ethyl acetate with amine gave a corresponding amide in high yields at 200 °C (Entries 1—4). The amidation of acetic acid with ammonia at 150 °C gave acetamide in a high yield (Entry 5). At 100 °C, the amidation did not proceed (Entry 7). At 200 °C, acetonitrile was mainly obtained by the subsequent dehydration of the product (Entry 8). These results suggest that the selectivity of the reaction is strongly affected by the reaction temperature. The reaction of acrylic acid with ammonia caused undesirable polymerization (Entry 9). The amidation of carboxylic acid with aqueous ammonia at 200 °C gave the corresponding amides (Entries 10—13), though in lower yields.

Liquid-Phase Reaction. The results of the liquid-phase amidation of carboxylic acid or ester with amine or ammonia over hydrous zirconium(IV) oxide are shown in Table 2. The hydrous zirconium(IV) oxide also catalyzed the amidation of carboxylic acid with ammonia in the liquid phase. Since ammonia gas was liberated under the reflux conditions, an additional supply of ammonia during the reaction could improve the yield, as is shown in the case of the amidation of propionic acid (Entry 10).

Table 3. Catalytic Activities of Several Catalysts

Catalyst	Yield/%	
	A	B
Hydrous zirconium(IV) oxide	100	100
Hydrous titanum(IV) oxide	92	63
Hydrous tin(IV) oxide	90	3
Hydrous cerium(IV) oxide	—	39

Hydrous iron(III) oxide	29	8
Hydrous niobium(V) oxide	75	24
Silica gel	87	2
Zeolite, A-4	25	8
Al_2O_3	1	2
ZrO_2	1	2
Al_2O_3-SiO_2	91	2

Catalyst: 2.0 g. A Vapor-phase: 200 °C, N_2; 60 cm^3 min^{-1}, CH_3COOH: n-$C_4H_9NH_2$=1:5, sample feed; 5 cm^3h^{-1}. B Liquid-phase: reflux 5 h, CH_3COOH; 10 mmol, n-$C_4H_9NH_2$; 50 mmol.

Comparison of Catalytic Activity among Several Catalysts. The liquid-phase and vapor-phase amidations of acetic acid with butylamine were carried out by using different heterogeneous catalysts. The results are shown in Table 3. In the case of vapor-phase amidation, hydrous zirconium(IV) oxide, hydrous titanium(IV) oxide, hydrous tin(IV) oxide, silica gel, and silica-alumina worked efficiently. However, only hydrous zirconium(IV) oxide acted as an efficient catalyst for the liquid-phase amidation. It was concluded that the hydrous zirconium(IV) oxide is the most active catalyst in these types of amidations.

Voltammetric Characterization of α- and β-Dodecamolybdophosphates in Aqueous Organic Solutions

Sadayuki HIMENO,* Toshiyuki OSAKAI, and Atsuyoshi SAITO
Department of Chemistry, College of Liberal Arts, Kobe University, Nada-ku, Kobe 657
(Received April 28, 1988)

Synopsis. The electrochemical properties of α- and β-dodecamolybdophosphates were characterized at the glassy carbon (GC) electrode. It was found that the β-isomer was only stable in neat organic solvents. When molybdophosphate was prepared in aqueous organic solutions, a mixture of α- and β-isomers formed.

It has been known that heteropolymolybdates known as Keggin anions exist in α- and β-modifications.[1,2] According to Halasz and Pungor,[3] the β-modification converts spontaneously into the α-modification for silico- and germanomolybdic acids while α-arsenomolybdic acid changes into the β-modification.

As for phosphomolybdic acid, the increase of the absorbance by the presence of water-miscible organic solvents has been accounted for in terms of the formation of the β-form.[4] It has been assumed that both α- and β-forms are stable and no isomerization occurs. Recently Hori and Fujinaga have obtained spectrophotometric evidence that the irreversible change of β-molybdophosphate into the α-form occurs in aqueous organic solvents.[5] However, the solution chemistry of the β-form is still obscure.

Electrochemical measurements have proved to be suitable for distinguishing clearly between both forms of molybdophosphate. The purpose of the present study is to characterize both isomers in aqueous organic solutions.

Experimental

The electrochemical measurements were made with a PAR (Princeton Applied Research) Model 174-A polarographic analyzer and a computer-controlled voltammetry system.[6] The voltammograms were recorded on a Riken Denshi Model D-8CP X-Y recorder. Working electrodes were GC rods of 3 mm diameter (GC-30S, Tokai Carbon) which were mounted in a Teflon tube by means of silicone rubber tubing. A saturated calomel electrode (SCE) was used as a reference and a platinum wire as a counter electrode.

Ultraviolet(UV)-visible spectra were obtained with a Hitachi Model 220-A spectrophotometer equipped with a constant temperature housing for the cell. Electrochemical and spectrophotometric measurements were carried out at 25±0.1 °C.

β-$[(n\text{-}C_4H_9)_4N]_3PMo_{12}O_{40}$ was prepared by the method of Rocchiccioli-Deltcheff et al.[7] Phosphomolybdic acid, $H_3PMo_{12}O_{40}\,xH_2O$ was purchased from E. Merck. This acid is referred to as the stable α-compound. The anhydrous acid obtained by heating at 150 °C was used. For the sake of brevity, Keggin anions, $XMo_{12}O_{40}^{m-}$ will be designated as XMo_{12} in the following, where X=P, Si, Ge, and As. All other reagents were of analytical grade and were used as received.

Results and Discussion

Electrochemistry of α- and β-PMo_{12}. Figure 1(a) shows a cyclic voltammogram of 1.60×10^{-4} M (M= mol dm^{-3}) α-PMo_{12} in 80% (v/v) CH_3CN containing 0.1 M HCl. Reduction waves were observed with peak potentials (E_p's) of +0.25, +0.14, −0.10, and −0.29 V. The anodic peaks occurred at +0.27, +0.16, −0.08, and −0.25 V in the reverse scan.[8-11]

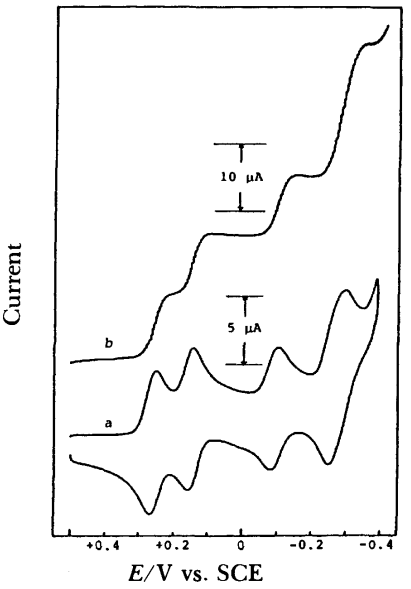

Fig. 1. A cyclic voltammogram (a) and a normal pulse polarogram (b) of 1.60×10^{-4} M α-PMo_{12} in 80% (v/v) CH_3CN containing 0.1 M HCl. Scan rate, (a) 100 mV s^{-1}; (b) 10 mV s^{-1}.

For the reduction of $SiMo_{12}$, $GeMo_{12}$, and $AsMo_{12}$, the polarographic half-wave potentials ($E_{1/2}$'s) of the β-isomers are more positive than those of the corresponding α-isomers.[2] According to Fruchart and Souchay,[12] a four-electron reduction species of β-PMo_{12} showed two oxidation waves with $E_{1/2}$'s of +0.55 and +0.37 V and a reduction wave with an $E_{1/2}$ of −0.07 V in 1 M $HClO_4$, while the oxidized form of α-PMo_{12} showed four reduction waves with $E_{1/2}$'s of +0.36, +0.22, −0.01, and −0.15 V vs. SCE in 1 M $HClO_4$ containing 50% dioxane at a rotating platinum electrode. On the basis of their findings, it has been assumed that β-PMo_{12} is electroreduced at more positive potentials than α-PMo_{12}. However, there have been no previous studies on the voltammetric behavior of the oxidized form of β-PMo_{12}.

Figure 2(a) shows a typical cyclic voltammogram of 1.68×10^{-4} M β-PMo_{12} in 80% (v/v) CH_3CN containing 0.1 M HCl. The peak potentials for the cathodic waves are: +0.35, +0.25, −0.15, and −0.34 V while those for the anodic waves are: +0.38, +0.28, −0.12, and −0.27 V. Each wave is diffusion-controlled. Coulometric analysis showed that the first three waves corresponded to a

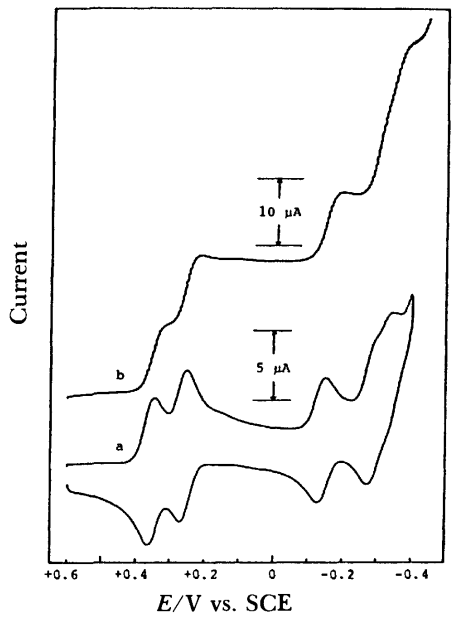

Fig. 2. A cyclic voltammogram (a) and a mormal pulse polarogram (b) of 1.68×10^{-4} M β-PMo_{12} in 80% (v/v) CH_3CN containing 0.1 M HCl. Scan rate, (a) 100 $mV\,s^{-1}$; (b) 10 $mV\,s^{-1}$.

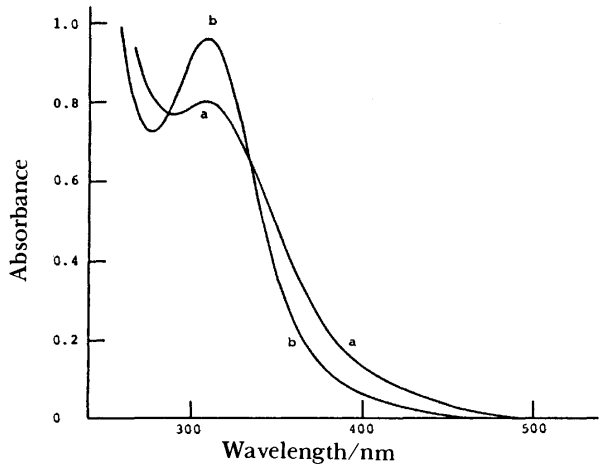

Fig. 3. UV-visible spectra of 4.2×10^{-5} M α- and β-PMo_{12}. (a) β-PMo_{12} in neat CH_3CN; (b) α-PMo_{12} in 70% (v/v) CH_3CN. Path length, 1 cm.

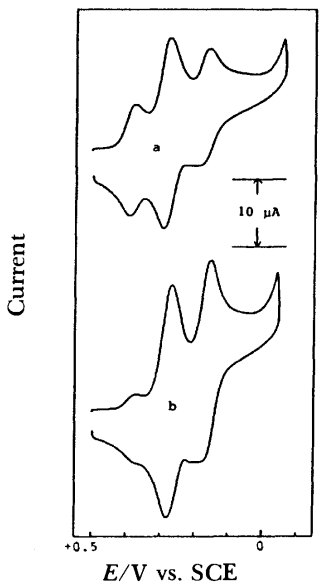

Fig. 4. Cyclic voltammograms of the 10.0 mM Mo(VI)/0.5 M HCl/40% (v/v) CH_3CN/0.5 mM phosphate system. (a) Immediately after the addition of phosphate; (b) 60 min after the addition of phosphate. Scan rate, 100 $mV\,s^{-1}$.

two-electron reduction and the fourth to a four-electron reduction. Curve (a) was obtained immediately after the addition of β-PMo_{12} in the solution. When the solution was allowed to stand, a reduction wave with an E_p of +0.14 V appeared. From a comparison with curve (a) of Fig. 1 it follows that β-PMo_{12} changes gradually into the α-form. It should be noted that the E_p for the 1st wave of α-PMo_{12} is identical with that for the 2nd wave of β-PMo_{12}. Curves (b) in Figs. 1 and 2 show the corresponding normal pulse polarograms of α- and β-PMo_{12} in 80% (v/v) CH_3CN containing 0.1 M HCl. Both polarograms resemble in shape and their limiting current ratios are 1 : 1 : 1 : 2, fitting the 2 : 2 : 2 : 4 electron ratios.

Formation of α- and β-PMo_{12} in Aqueous Organic Solutions. The yellow color of PMo_{12} is enhanced by the presence of water-miscible organic solvents such as acetonitrile and acetone. Since the color enhancement has been used for the spectrophotometric determination of the orthophosphate ion, it seems important to clarify the properties of α- and β-PMo_{12} in aqueous organic solutions. Figure 3(a) shows a UV-visible spectrum of 4.2×10^{-5} M β-PMo_{12} in neat CH_3CN. The spectrum was unchanged under these conditions. In 70% (v/v) CH_3CN solutions, on the other hand, the yellow color faded with time. Simultaneously, the gradual change of the spectrum was observed. Curve (b) is the spectrum of α-PMo_{12} obtained after standing for 3 h; as discussed below, the complete transformation of β-PMo_{12} to α-PMo_{12} was confirmed by the voltammetric measurements. The oxidized form of each isomer shows a common absorption maximum at 308 nm. The molar absorption coefficients of α- and β-PMo_{12} at 420 nm are calculated as 990 and 2120 $cm^{-1}M^{-1}$, respectively. Since UV-visible spectra of α- and β-forms are very similar, it is difficult to identify individual anions when both anions coexist in solution. As shown in Figs. 1 and 2, on the other hand, α- and β-PMo_{12} showed their characteristic reduction waves.

Therefore voltammetric measurements were made to elucidate the formation and conversion reactions of α-and β-PMo_{12} in aqueous organic solutions. Similar experiments were carried out with coulopotentiography.[13] An aliquot of 0.1 M phosphate solution was added to a 20 ml solution consisting of 10 mM Mo(VI)/0.5 M HCl/40% (v/v) CH_3CN, and the cyclic voltammogram was taken immediately after the addition of phosphate. As shown in Fig. 4(a), three reduction waves appeared with E_p's of +0.37, +0.27, and +0.15 V until the final current rise due to the reduction

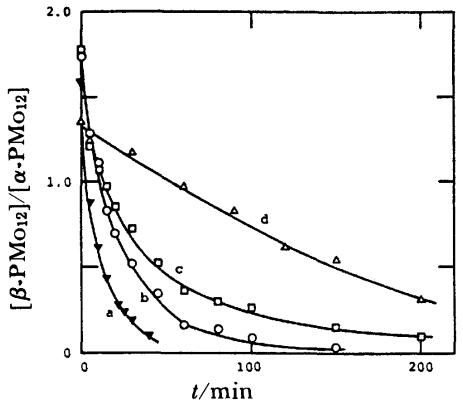

Fig. 5. Dependence of the ratio of [β-PMo_{12}] to [α-PMo_{12}] on time for 50 mM Mo(VI)/0.5 M HCl/0.5 mM phosphate systems containing 40% (v/v) organic solvents; (a) ethanol, (b) acetonitrile, (c) 1,4-dioxane, (d) acetone.

of Mo(VI). The 1st and 2nd waves correspond to the reduction of β-PMo_{12}, and the 2nd and 3rd waves to the reduction of α-PMo_{12}. When the solution was allowed to stand, as shown in curve (b) of Fig. 4, the 1st wave decreased with a simultaneous increase of the 3rd wave, which indicates the spontaneous conversion of β-PMo_{12} to α-PMo_{12}.

Normal pulse polarographic measurements were carried out in order to study the kinetics of the transformation of β-PMo_{12} to α-PMo_{12} in aqueous organic solutions. Figure 5 shows the change of the ratio of [β-PMo_{12}] to [α-PMo_{12}] with time for 50 mM Mo(VI)/0.5 M HCl/0.5 mM phosphate systems containing 40% (v/v) ethanol, acetonitrile, 1,4-dioxane, and acetone. The ratio of [β-PMo_{12}] to [α-PMo_{12}] in solution was determined by measuring the limiting currents of the 1st and 2nd waves.[9] It was found that the transformation rate was the slowest in the acetone-containing solution. Kinetic analysis for the curves showed that the conversion reaction was of the first-order, and the rate constants were calculated as 7.6×10^{-4}, 3.3×10^{-4}, 1.9×10^{-4}, and 0.6×10^{-4} s^{-1} in solutions containing ethanol, acetonitrile, 1,4-dioxane, and acetone, respectively. As the concentrations of organic solvents were increased, the transformation rates became slower. However, the ratio of [β-PMo_{12}] to [α-PMo_{12}] did not exceed 2 in solutions containing the organic solvents examined here. It should be emphasized that a mixture of α- and β-PMo_{12} is always obtained in aqueous organic solvents.

Kinetics of the Thermal Intramolecular Redox Reaction of Pentaamminenitrosylcobalt(III) Chloride in the Solid State

Kikuo MIYOKAWA,*,† Hakaru MASUDA, and Hisanobu WAKITA
Department of Chemistry, Faculty of Science, Fukuoka University, Fukuoka 814-01
(Received August 17, 1988)

Synopsis. The kinetics of the thermal intramolecular redox reaction between NO^- and Co(III) in $[Co(NH_3)_5NO]Cl_2$ has been studied by means of thermogravimetric and thermomagnetic analyses. The reaction is found to follow the first-order equation, with $\Delta H^*=129\pm6$ kJ mol^{-1} and $\Delta S^*=14\pm16$ J mol^{-1} K^{-1}. These results are compared with the kinetics of other nitrosylcobalt(III) and hexaamminecobalt(III) complexes.

It is well-known that the thermal decomposition of cobalt(III) complexes is often accompanied by an intramolecular redox reaction between the Co(III) ion and the ligand.[1] However, the kinetics of the reaction which characterizes the thermal property of Co(III) complexes has not been studied well[2—4] because the complicated decomposition reaction of the ligand oxidized by the Co(III) ion makes it difficult to examine the kinetics by means of a usual technique like thermogravimetry.

Pentaamminenitrosylcobalt(III) chloride has a "bent" NO group and has been depicted formally as having the bonding unit[5] Co(III)-NO^-. This complex decomposes around 350 K to evolve nitrogen monoxide and ammonia, yielding the amminecobalt(II) complex as the solid product.[6] As the decomposition temperature is fairly low for a cobalt(III) complex it seems of interest to compare its kinetic properties with those of other cobalt(III) complexes. Since the diamagnetic nitrosyl complex yields a paramagnetic, high-spin cobalt(II) complex, the kinetics of the intramolecular redox reaction can be effectively followed by measuring the change in the magnetic susceptibility of the sample. We wish to report here the kinetics of the intramolecular redox reactions of $[Co(NH_3)_5NO]Cl_2$ as examined by means of thermomagnetic analysis,[7] which has previously been successfully applied to the kinetic study of low spin $\rightleftarrows$ high spin transformation of bis(*N*-substituted-salicylideneaminato)nickel(II) in the solid state.[8]

Experimental

$[Co(NH_3)_5NO]Cl_2$ was prepared according to the published procedure;[9] it was identified by means of elemental analyses and magnetic-susceptibility measurements. The thermomagnetic analysis was carried out using a thermomagnetic analysis instrument constructed by assembling a Faraday-type magnetobalance, an infrared-lamp furnace, and a temperature-controller.[8,10] The isothermal thermomagnetic curves (hereafter abbreviated as ITM curves) were obtained by plotting the change in the sample weight induced when the magnetic field was applied to the sample against the time, while the sample was kept under isothermal conditions; the sample was usually heated to the desired temperature at a heating rate of 200 K min^{-1}. The strength of the applied magnetic field was regulated to an appropriate constant value of around 0.85 T. The isothermal weight-loss curves (hereafter abbreviated as IWL curves) were recorded on the same instrument when no magnetic field was applied to the sample.

Results and Discussion

The thermogravimetric (heating rate=1 K min^{-1}) and pyrolysis gas-chromatographic analyses have indicated that the thermal decomposition of $[Co(NH_3)_5NO]Cl_2$ proceeds through three stages:[6]

$$[Co(NH_3)_5NO]Cl_2 \xrightarrow{353-413\ K} Co(NH_3)_2Cl_2 + 3NH_3 + NO$$

$$Co(NH_3)_2Cl_2 \xrightarrow{413-427\ K} Co(NH_3)Cl_2 + NH_3$$

$$Co(NH_3)Cl_2 \xrightarrow{>427\ K} CoCl_2 + NH_3$$

As the redox reaction occurs in the first stage of decomposition, the kinetic analysis was carried out in the temperature range of 363—377 K.

The apparent increase in the sample weight at the time t induced by applying the magnetic field, ΔW_t, is given by Eq. 1:

$$\Delta W_t = H_c(\chi_r W_{r,t} + \chi_p W_{p,t}) \quad (1)$$

where χ_r and $W_{r,t}$ denote, respectively, the gram magnetic susceptibility and the weight of $[Co(NH_3)_5NO]Cl_2$ in the sample at the time t; χ_p and $W_{p,t}$ are corresponding values for $Co(NH_3)Cl_2$. The H_c is a constant value determined by the apparatus and the strength of the applied magentic field. The weight change when the reaction has been completed, ΔW_f, is expressed by:

$$\Delta W_f = H_c \chi_p W_{p,f} \quad (2)$$

where $W_{p,f}$ is the final weight of the product. Then the ratio of ΔW_t to ΔW_f is given by:

$$\Delta W_t/\Delta W_f = \chi_r/\chi_p(W_{r,t}/W_{p,f}) + W_{p,t}/W_{p,f} \quad (3)$$

In the present experiments, χ_r/χ_p was virtually zero ($<1\times10^{-3}$), so that the first term on the right-hand side of Eq. 3 can be neglected, and the fraction of $[Co(NH_3)_5NO]Cl_2$-reduced α_{ITM}, which is defined as $W_{p,t}/W_{p,f}$, becomes equal to $\Delta W_t/\Delta W_f$:

$$\alpha_{ITM} = \Delta W_t/\Delta W_f$$

From the IWL curves α_{IWL} is calculated as:

$$\alpha_{IWL} = (W_t - W_i)/(W_i - W_f)$$

where W_i and W_f represent the initial and final weights of the sample respectively and W_t, the weight

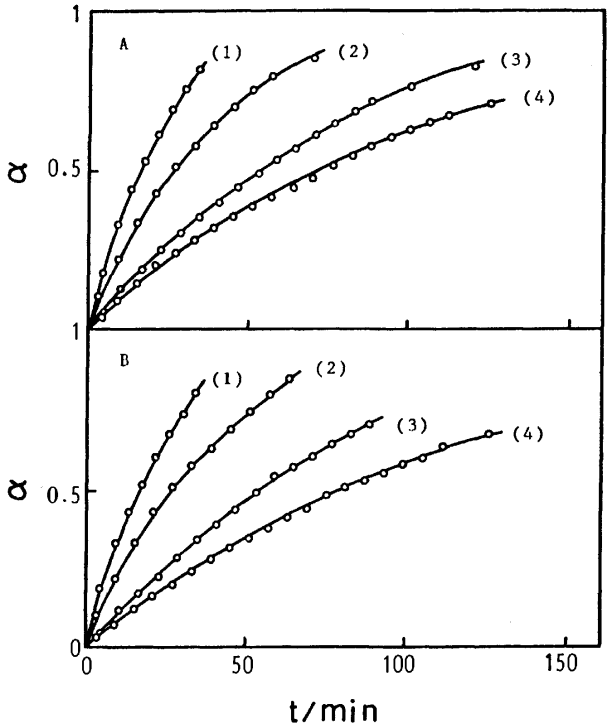

Fig. 1. α vs. t curves calculated from (A) ITM and (B) IWL curves. (1) 362.6 K, (2) 367.4 K, (3) 371.5 K, (4) 377.2 K.

of sample at the time t.

Figure 1 shows α_{ITM} and α_{IWL} versus the t curves thus calculated from the ITM and IWL data. From these curves, it was found that the reactions fit the first-order equation:

$$-\ln(1-\alpha)=kt \quad (k\text{: rate constant})$$

in the range of α=0.05—0.60, with no distinct induction period. The rate constants, k, and its standard deviation, as estimated from the residue of the least-square line for each run, are given in Table 1. The temperature dependence of the rate constants conforms to the Arrehenius rate law; the activation energy (E_a) and the preexponential factor (A) are calculated by the least-square analysis. Then they are converted to the activation enthalpy $\Delta H^{\ddagger}$ and entropy $\Delta S^{\ddagger}$ at 300 K, assuming that the Eyring equation is valid for the solid state reaction:

$$\Delta H^{\ddagger}=E_a-RT$$
$$\Delta S^{\ddagger}=R(\ln A+h/kT-1)$$

Furthermore the assumptive rate constant at 300 K, k_{300}, was evaluated from E_a and A in order to compare quantitatively the reactivities of the complexes. They are listed in Table 1. As Table 1 shows, the rate constants obtained from the ITM and IWL curves agree with each other within the limits of experimental error, indicating no intermediary formation of any cobalt(II) species other than $Co(NH_3)_2Cl_2$ in the first stage of the decomposition reaction.

Although it is practically impossible to draw up a general rule applicable to the kinetics of the redox reaction of Co(III) complexes from the limited number of data now available, some aspects can be pointed out by comparing the present results with the kinetics of other Co(III) complexes thus far reported. The nitrosylcobalt(III) complexes of the CoL^4NO** type dissociate nitrogen monoxide on heating to yield its parent complexes. As Co(salen)NO** and Co(bzacen)NO** have a bent nitrosyl group[11,12] like $[Co(NH_3)_5NO]Cl_2$, the dissociation reaction is considered to be accompanied by an intramolecular redox reaction between the Co(III) ion and the NO^- group. It has been reported that the reaction follows the first-order equation and that the activation paramerters and k_{300} values are nearly invariable, regardless of the nature of the L^4 ligand.[3] As Table 1 shows, in spite of the large difference in the reactivity between $[Co(NH_3)_5NO]Cl_2$ and CoL^4NO (i.e., their k_{300} values differ by more than two orders of magnitude), there is almost no difference in their activation enthalpies. This is somewhat surprising because the reactivity of a compound is usually considered to be determined by the magnitude of its activation enthalpy. As these complexes have nothing in common in their molecular and crystal structures

**L^4 represents the tetradentate Schiff base dianion; N,N'-ethylenebis(1-phenyl-3-oxobutylideneaminate) dianion (bzacen), N,N'-ethylenebis(salicylideneaminate) dianion (salen), and its 5-nitro, 5-chloro, and 5-methyl derivatives.

other than the Co(III)-NO^- moiety, these findings seem to suggest that the enthalpies of activation of these complexes are mainly determined by the energetic feature of the electron-transfer process from the NO^- group to the Co(III) ion and that the reactivity of these complexes is dominated by the activation entropy. In fact, the difference in the ΔS^* values of these complexes exceeds 60 $J\,K^{-1}\,mol^{-1}$.

It is also of interest to compare the activation parameters of $[Co(NH_3)_5NO]Cl_2$ with those of hexaamminecobalt(III) halides, which have the same CoN_6 coordination structure as the nitrosyl complex. Hexaamminecobalt(III) halides undergo a thermal redox reaction between the ligands and the Co(III) ion; the stoichiometry[13] and relatively reliable kinetic parameters have been reported[4] for $[Co(NH_3)_6]Cl_3$ and $[Co(NH_3)_6]I_3$. The cobalt(III) ion of the former complex has been considered to be reduced by the NH_2^- produced by the thermally induced autoionization of the NH_3 ligand,[6] and that of the latter complex, by the iodide anion. As Table 1 shows, whereas the reactivities of these complexes increase in the order of: $[Co(NH_3)_6]Cl_3 < [Co(NH_3)_6]I_3 < [Co(NH_3)_5NO]Cl_2$ the activation enthalpies increase in the order of: $[Co(NH_3)_6]I_3 < [Co(NH_3)_5NO]Cl_2 < [Co(NH_3)_6]Cl_3$. These facts indicate that the activation enthalpy does not solely determine the reactivities of these cobalt(III) complexes, as in the case of the nitrosyl complexes. The order of the activation enthalpy is explainable in terms of the reducing power of the NH_2^-, NO^-, and I^- anions. The standard electrode potential (SEP) of the NO/NO^- couple (0.712 eV) is higher than $SEP(I_2/I^-) = 0.536$ eV.[14] Presently $SEP(NH_2/NH_2^-)$ is not known; however, since those potentials of the $N_2H_5^+/NH_4^+$ (1.275 eV) and NH_3OH/NH_4^+ (1.35 eV) couples with the same change in the oxidation number of nitrogen in the reduction of the amide ion are around 1.3 eV,[14] $SEP(NH_2/NH_2^-)$ may not differ largely from 1.3 eV, which is considerably higher than the SEP's of nitrogen monoxide and iodine. Therefore, as far as the cobalt(III) complexes so far studied are concerned, it can be said that the activation enthalpy of the redox reaction of cobalt(III) complexes is determined mainly by the reducing power of the reductant and that the activation entropy plays an important role in determining the thermal stability of these complexes. It has been reported that, in the thermal redox reactions of Co(salen)(β-diketonato) compleses, the activation entropy dominates the reactivity of these complexes.

A Glassy Carbon Electrode Modified with *N*-(2-Hydroxybenzyl)chitosan for Voltammetric Determinations of Cu^{2+} and Pb^{2+}

Yoshiaki KURAUCHI, Eiichi TSURUMORI, and Kazuya OHGA*

Oita University, Dannoharu, Oita 870-11
(Received November 24, 1988)

Synopsis. A glassy carbon electrode was chemically modified with *N*-(2-hydroxybenzyl)chitosan which could act as an agent to preconcentrate Cu^{2+} and Pb^{2+}. The modified electrode was stable for 30 d and its calibration curves for the voltammetric determination of these ions are linear in the concentration range of $(1—10)\times10^{-7}$ mol dm^{-3}. The usage limitation of this electrode has also been discussed.

High metal-chelating ability is one of the most attractive functions of chitosan which is obtained by deacetylation of chitin, a naturally occurring polysaccharide.[1] The chelating ability arises primarily from the amino group of the 2-amino-2-deoxy-D-glucose (glucosamine) unit and is enhanced by chemical modification of the amino group. For example, the capacity of *N*-(2-hydroxybenzyl)chitosan (HBC) to adsorb Cu^{2+} is 47 times as much as that of chitosan itself.[2]

Recently much attention has been drawn to the voltammetric determination of metal ions using electrodes modified with preconcentrating agents or media. The agents frequently used to preconcentrate transition metal ions are chelating compounds, including 2,9-dimethyl-1,10-phenanthroline[3] and cross-linked polystyrene with bis(carboxymethyl)amino groups.[4] Chitosan and its derivatives with high chelating abilities are therefore anticipated to act as efficient agents for transition metal ions. In this research, we prepared a glassy carbon (GC) electrode modified with HBC and examined its applicability to the determination of trace amounts of Cu^{2+} and Pb^{2+}.

Experimental

Reagents. Chitosan (100% deacetylation) was kindly donated by Katokichi Co., Kagawa, Japan. Commercial salicylaldehyde and dicyclohexylcarbodiimide (DCC) were distilled under reduced pressure just before use. Water was purified by reverse osmosis (Millipore Milli RO15) and deionization. All other chemicals were of reagent grade or better and used without further purification.

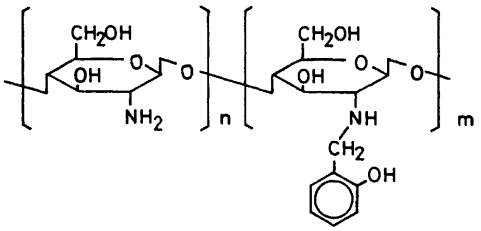
Modification of a GC Electrode. *N*-Salicylidenechitosan was formed from chitosan and salicylaldehyde[5] and reduced with $NaBH_3CN$ to give a HBC gel.[2] The molar quantity of salicylaldehyde used was half that of the glucosamine unit. A GC electrode (Tokai Carbon GC-30S, 6 mm diameter) covered with a Teflon tube was polished with alumina (FUJIMI FM-No. 4, 0.5 μm) and then oxidized with H_2SO_4 according to the procedure reported by Wingard and Gurecka.[6] After being washed with water and dried at 120 °C for 2 h, the oxidized surface was coated with 20 mm^3 of 2% aqueous acetic acid–methanol (7:3) containing 0.08 mg of HBC and was dried again at room temperature for 5 h and further at 120 °C for 12 h. The dried electrode having a thin HBC film was immersed in 20 cm^3 of DMF–acetonitrile (1 : 1) containing 2 g of DCC for 5 h at room temperature. The HBC-modified electrode (HME) thus obtained was washed successively with DMF, 2% aqueous acetic acid, and water and was stored in 0.05 M (1 M=1 mol dm^{-3}) aqueous KNO_3.

Cyclic Voltammetry. After being soaked in 0.05 M aqueous KNO_3 containing a metal ion to be analyzed for a prescribed period, the HME was rinsed briefly with water and then subjected to a cyclic voltammetry in 0.05 M KNO_3 which had previously been deaerated with N_2 and thermostated at (25.0±0.5) °C. The cyclic voltammetry was carried out with a Hokuto Denko HB 104 function generator, a Hokuto Denko HA 301 potentiostat, and a Yokogawa 3086 X-Y recorder. The HME was used as a working electrode, and reference and counter electrodes were Ag/AgCl and Pt, respectively.

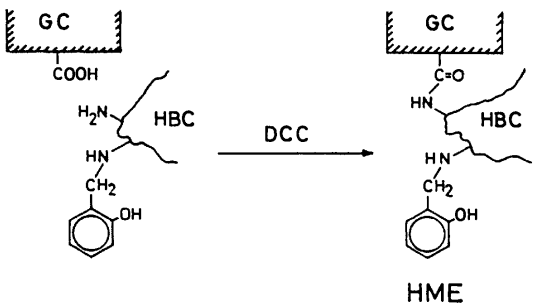
Results and Discussion

The IR spectrum of HBC showed no absorption band at 1640 cm^{-1} which is assigned to the C=N stretching vibration of *N*-salicylidenechitosan, while the band assigned to the aromatic C-H bending vibration (760 cm^{-1}) still remained. These suggest that the reduction reaction took place sufficiently. The presence of the remaining amino groups was confirmed by observation of a band at 1600 cm^{-1}. The treatment with DCC during the modification of the GC electrode with HBC was carried out with the intention of forming amide bonds from the amino groups and the carboxylato groups on the oxidized electrode surface (Fig. 1), and resulted in formation of a thin HBC film adhering firmly to the electrode surface.

Figure 2 shows typical cyclic voltammograms



HBC



HME

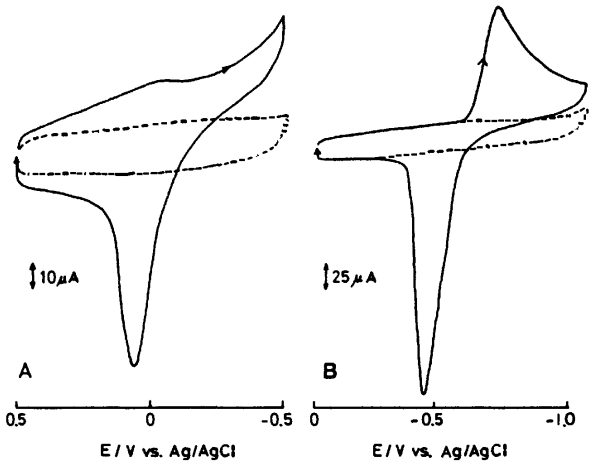

Fig. 2. Cyclic voltammetric *I-E* curves after soaking in 1.0×10^{-5} M Cu^{2+} (A) and 1.0×10^{-5} M Pb^{2+} (B) solutions: scan rate, 100 mVs^{-1}; soaking time, 60 min; electrolyte, 0.05 M KNO_3. Dashed lines represent the curves before soaking.

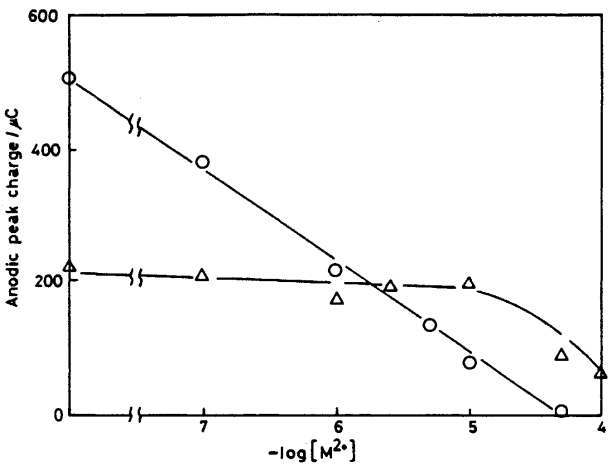

Fig. 3. Anodic-peak-charge changes for 1.0×10^{-5} M Pb^{2+} by the addition of Cu^{2+} (○) and for 1.0×10^{-5} M Cu^{2+} by the addition of Pb^{2+} (△). The left edge of the abscissa implies the absence of the coexisting divalent cation. Other conditions are as in Fig. 2.

obtained with the modified electrode HME which was soaked in 1.0×10^{-5} M Cu^{2+} and Pb^{2+} solutions for 60 min. Large anodic waves were observed at +0.04 V for Cu^{2+} and −0.45 V for Pb^{2+}. The anodic peak charge of Pb^{2+} (273 μC) calculated from the peak area is about twice as large as that of Cu^{2+} (132 μC). At lower metal-ion concentrations, 10^{-7} M, the uptake was slower and hence a longer soaking time was required to obtain such well-defined anodic peaks. The accumulated Cu^{2+} and Pb^{2+} were completely removed by dipping in 0.1 M EDTA for 10 min.

The anodic peak charge of the 1.0×10^{-5} M Pb^{2+} sample was reproducible to ±4% for 10 accumulation/measurement/renewal cycles. The ability of the HME to accumulate Cu^{2+} or Pb^{2+} lowered only slightly with repeated runs. The peak charge of 1.0×10^{-5} M Pb^{2+} was 90% of its initial value even after the cycle was repeated about 100 times for 30 d. In addition, the calibration curves of peak charge vs. concentration for Cu^{2+} and Pb^{2+} were both linear in the concentration range of $(1-10)\times10^{-7}$ M (soaking time, 120 min; correlation coefficient, 0.990 for Cu^{2+} and 0.999 for Pb^{2+}). These results suggest that the HME is available for the voltammetric determination of trace amounts of Cu^{2+} and Pb^{2+}.

On the other hand, when no DCC treatment was applied, the HBC film peeled off after three cycles and the accumulation ability disappeared nearly completely. Further, when chitosan itself was used in place of HBC, the electrode obtained showed a Pb^{2+} peak charge only one fifth of that of the HME, though having a stable film.

In the case of the other metal ions, Cd^{2+}, UO_2^{2+}, Co^{2+}, and Ni^{2+}, no redox waves were observed when the HME was soaked for 60 min in a 1.0×10^{-5} M solution of each metal ion. The selectivity of the HME toward Cu^{2+} agrees with the fact that HBC has a high ability to adsorb Cu^{2+},[2] though the reason why the peak charge of Pb^{2+} is larger than that of Cu^{2+} is not yet clear.

As shown in Fig. 3, the anodic peak charge of Pb^{2+} ($[Pb^{2+}]=1.0\times10^{-5}$) was reduced enormously by the presence of Cu^{2+} and to nearly zero when the Cu^{2+} concentration increased up to 5×10^{-5} M. The peak charge of Cu^{2+}, in contrast, was not so much affected by the addition of Pb^{2+} of concentrations below 1×10^{-5} M ($<[Pb^{2+}]/[Cu^{2+}]=1$). Such a more significant reduction of the Pb^{2+} peak charge may be explained in terms of the weaker coordination ability of hydroxyl and amino groups to Pb^{2+} than to Cu^{2+}.[7] Thus, in the Pb^{2+} determination, it is necessary to previously remove other metal cations which can strongly form complexes with HBC, if present.

The Photochemistry of Steroidal 6-Membered Cyclic α-Nitro Enones[1)]

Hiroshi SUGINOME* and Yoshitaka KUROKAWA
Organic Synthesis Division, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received September 7, 1988)

Synopsis. The products of the photolysis of two steroidal cyclic α-nitro enones, newly synthesized, were compared with those of the cyclic α-nitro ketones and cyclic enones. Direct irradiation of 2α-nitrocholest-4-en-3-one in protic solvents resulted in an unexpected α-cleavage of the carbonyl group and gave 3-alkoxy-2-nitro-2,3-secocholest-4-en-3-one while irradiation of 4α-nitro-5α-cholest-1-en-3-one gave the parent cholest-1-en-3-one which arose from the removal of the nitro group.

In a previous paper,[2)] we have reported the results of the photolysis of several 6-membered cyclic α-nitro ketones in ethanol.

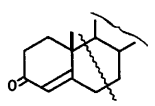
We have found that two versions of the products, the corresponding α-diketones and α-diketone monooximes, can be obtained when 6-membered cyclic α-nitro ketones which exist exclusively or predominantly in their enol forms in protic solvents, are irradiated in ethanol. We have also found that the corresponding α-diketone monooximes are products which do not accompany any corresponding α-diketones when the 6-membered cyclic α-nitro ketones, which exist in their keto forms, are irradiated in ethanol.

In this paper, we wish to report the results of a further investigation in this area: the photolysis of two steroidal cyclic α-nitro enones, 2α-nitrocholest-4-en-3-one (**2**) and 4α-nitro-5α-cholest-1-en-3-one (**6**). The study was carried out to help us to understand more fully the behavior of the excited nitro group in protic solvents.

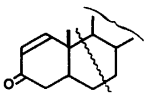
Preparation of α-Nitro Enones 2 and 6. The two steroidal α-nitro enones **2** and **6** chosen for the present investigation were prepared in a standard manner by nitration of the corresponding steroidal α,β-unsaturated ketones **1** and **5** with an alkyl nitrate and a base.[3-5)] The IR spectra of α-nitro enones **2** and **6** exhibited strong bands assignable to the α,β-unsaturated carbonyl and nonconjugated nitro groups. These α-nitro enones therefore exist almost exclusively as their keto form in the Nujol. An ^{1}H NMR spectra of both α-nitro enones also indicated that these α-nitro enones in $CHCl_3$ exist in their keto form.

The UV spectrum of α-nitro enone **2**, on the other hand, exhibited an absorption maximum with a medium intensity at 375 nm (ε; 1620), besides an intense absorption maximum at 244 nm (ε; 13200). The former is attributable to the presence of a small portion of α-nitro enone **2** in its enol form. The UV spectrum of α-nitro ketone **6** in ethanol exhibited a weak absorption maximum at 335 nm attributable to the $\pi \rightarrow \pi^*$ transition of the nitro group of the corresponding enol form[2)] besides a strong absorption maximum at 231 nm due to the $\pi \rightarrow \pi^*$ transition.

It has been reported that in the mass spectra of Δ^4- and Δ^1-androstan-3-ones, the base peaks occur at *m/z* 124 and 122 respectively. Both base peaks arise from a cleavage across ring B as indicated in the formulae **A** and **B**.[6)] On the basis of deuterium labelling studies

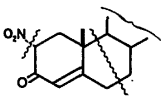


A *m/z* 124

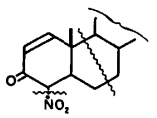


B *m/z* 122

Shapiro and Djerassi have suggested that the mechanism for the production of the base peak at *m/z* 124 involves the migration of hydrogen atoms from C-8 and C-11 of the steroid to the ring A fragment while the formation of the base peak at *m/z* 122 involves the reciprocal migration of hydrogen to the ring **A** fragment. It should be noted that in contrast to the simple enones studied by Shapiro and Djerassi, the mass spectra of both α-nitro enones **2** and **6** exhibited a base peak at *m/z* 121. Both ions seem to be formed as a result of the loss of NO_2 and a cleavage across the ring **B** as indicated in the formulae C and D.

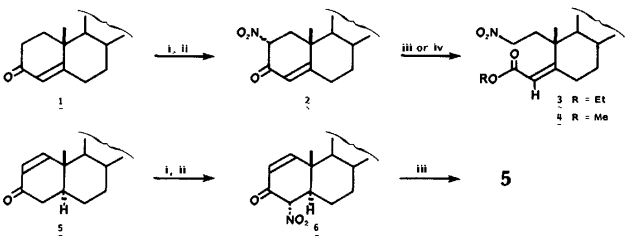


C *m/z* 121



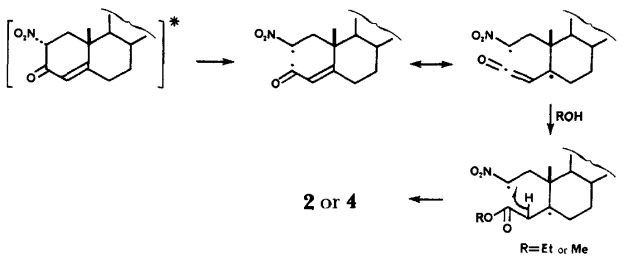
D *m/z* 121

Photochemistry of α-Nitro Enones 2 and 6. Photolysis of α-nitro enone **2** in ethanol with a 450-W high-pressure Hg arc through a Pyrex filter for 6 h gave a product mixture from which a product **3** (25%) was isolated by means of preparative TLC as the only indentifiable product (Scheme 1). The high-resolution mass spectrometry indicated that the photoproduct **3** had the molecular formula $C_{29}H_{49}NO_4$. The UV and IR spectra indicated that the new product was an α,β-unsaturated ester carrying a nitro group (see Experimental). The analysis of ^{1}H NMR spectrum of **3** with the aide of a double resonance study indicated that the structure of product **3** was 3-ethoxy-2-nitro-



i) $CH_3CH_2CH_2ONO_2$-$(CH_3)_3COK$ ii) CH_3COOH iii) EtOH-*hν* iv) MeOH-*hν*

Scheme 1.



Scheme 2.

2,3-secocholest-4-en-3-one (**3**) (See Experimental). The ^{13}C NMR spectrum exhibited five signals at δ 167.0, 165.5, 112.0, 71.5, and 59.6 in the downfield. On the basis of the results revealed by the INEPT technique and by considering the known structure-shift correlations, these signals were assigned respectively to the C=O of the ethoxycarbonyl, the trigonal α-carbon of the α,β-unsaturated ester, the trigonal β-carbon of the α,β-unsaturated ester, the methylene carbon carrying a nitro group, and the methylene carbon of the ethoxycarbonyl group of **3**.

The photolysis of **2** was also undertaken by using methanol as the solvent to give 3-methoxy-2-nitro-2,3-secocholest-4-en-3-one **4** in a 30% yield.

Photolysis of α-nitro enone **6** in ethanol under conditions similar to those described above gave the parent ketone **5** (37%) as the only identifiable product.

Although the photochemistry of nitro compounds has been extensively investigated,[7] the photochemistry of cyclic α-nitro enones has never been reported. The foregoing experiments have shown that the photoreaction of an α,β-unsaturated carbonyl group preceded the photoreaction of the nitro group in 2α-nitrocholest-4-en-3-one (**2**), while the photoreaction of nitro group preceded that of α,β-unsaturated carbonyl group in 4α-nitrocholest-1-en-3-one **6**. The probable pathway which led to the secosteroid **3** is outlined in Scheme 2.

Although the photoreactions of enones[8] have been extensively investigated only a few examples of the photochemical α-fission of α,β-unsaturated carbonyl group have so far been reported.[9] The general process of α,β-unsaturated ketones in hydrogen-donating solvents such as ethanol appears to be a photoreduction.[10] Thus, irradiation of testosterone acetate in ethanol has been reported to give a mixture of products from which only the corresponding saturated ketone have been isolated.[10] It is well-known that the irradiation of steroidal 4-en-3-ones in *t*-butyl alcohol leads to fascinating photorearrangements.[8,10,12,13]

The present α-cleavage of excited steroid-4-en-3-one therefore, is apparently due to the presence of the 2α-nitro group which directs the α-cleavage over other photochemical processes common to the excited α,β-unsaturated carbonyl group.

Experimental

For instruments and general procedure see Ref. 2.

Preparation of 2α-Nitrocholest-4-en-3-one (2). To THF (14 ml) containing potassium *t*-butoxide (0.5 g), cholest-4-en-3-one (1 g, 2.6 mmol) dissolved in THF (22 ml) was added over the course of 30 min at −30 °C. To this solution, propyl nitrate (0.6 g) in THF (5 ml) was added and the solution was stirred for 45 min during which period the temperature of the solution was raised to 0 °C. The solution was neutralized with glacial acetic acid. The solution was then poured into iced water (200 ml) and the aq solution was extracted twice with dichloromethane. The combined organic layers were dried over Na_2SO_4 and worked up in the usual way to give an oily product (1.173 g). This crude product was recrystallized from ethanol to yield yellow crystals (0.637 g, 57%), mp 140—142 °C. (Found: C, 75.44; H, 9.98; N, 3.28%. Calcd for $C_{27}H_{43}NO_3$: C, 75.48; H, 10.09; N, 3.26%): IR (Nujol) 1695 (C=O), 1605 (C=C), and 1544 cm^{-1} (NO_2); ^1H NMR (270 MHz) δ=0.71 (3H, s, 18-H), 1.3 (3H, s, 19-H), 2.06 (1H, dt, J=12.82, 3.3 and 3.3 Hz, 6α-H), 5.31 (1H, dd, J=13.19 and 5.86 Hz, 2β-H), 5.84 (1H, s, 4-H); MS *m/z* (rel intensity) 429 (M^+, 17) 413 [$(M-O)^+$, 12.4], 397 (14), 383 [$(M-NO_2)^+$, 27.5], 316 (20.3), 261 (16.7), 147 (36.7), 135 (40.3), 121 (100), 109 (27.1), 95 (42.3), 81 (33.7), 69 (35.5), 57 (44.2), and 43 (47.2); UV (C_2H_5OH) λ_{max} 375 nm (ε: 1620) and 2.44 (ε: 13240).

Preparation of 4α-Nitro-5α-cholest-1-en-3-one (6). To THF (28 ml) containing potassium *t*-butoxide (1 g), 5α-cholest-1-en-3-one (2 g, 5.21 mmol) dissolved in THF (44 ml) was added over the courses of 30 min at −30 °C. To this solution, propyl nitrate (1.2 g) in THF (10 ml) was added and the solution was stirred for 45 min during which time the temperature of the solution was raised to 0 °C. The solution was neutralized with glacial acetic acid until the pH of the solution became ca. 3. The solution was then poured into water (300 ml) and the aq solution was extracted with dichloromethane. The organic layers were combined and the solution was dried over Na_2SO_4 and worked up in the usual way to give an oily product (2.381 g). The crude product was subjected to column chromatrography (silica gel, 40 g). Elution with benzene gave a crude α-nitro ketone **5** (1.080 g, 48.3%) which was recrystallized from methanol. Mp 149—151 °C. (Found: C, 75.52; H, 9.97; N, 3.14%. Calcd for $C_{27}H_{43}NO_3$; C, 75.48; H, 10.09; N, 3.26%); IR (Nujol) 1694 (C=O), 1616 (C=C), and 1542 cm^{-1} (NO_2); ^1H NMR (270 MHz) δ=0.70 (3H, s, 18-H), 1.12 (3H, s, 19-H), 5.12 (1H, d, J=13.56 Hz, 4β-H), 6.01 (1H, d, J=10.25 Hz, 2-H), and 7.31 (1H, d, J=10.25 Hz, 1-H); MS *m/z* (rel intensity), 429 (M^+, 20.4%), 383 [$(M-NO_2)^+$, 26.7], 229 (31), 173 (15.4), 147 (43.4), 121 (100), 109 (24.5), 95 (35.4), 81 (30), 69 (33.4), 55 (42.2), and 43 (42.9); UV (EtOH) λ_{max} 335 nm (ε: 60).

Photolysis of 2α-Nitrocholest-4-en-3-one (2). The nitro ketone **2** (400 mg, 0.93 mmol) in ethanol (400 ml) was flushed with nitrogen and irradiated for 6 h with a Hanovia 450-W high-pressure Hg arc through a Pyrex filter in an atmosphere of dry nitrogen. The solvent was then removed to give an oily product (455 mg). The product was subjected to preparative TLC with benzene to give product **3** (122 mg, 25.2%). (Found: *m/z* 475.3623; Calcd for $C_{29}H_{49}NO_4$: M, 475.3659); IR (Nujol) 1710 (COOEt), 1626 (C=C), 1548 (NO_2), 1191, 1183, and 1161 cm^{-1} (C-O-C); ^1H NMR (270 MHz) δ=0.70 (3H, s, 18-H), 1.14 (3H, s, 19-H), 1.29 (3H, t, J=7.14 Hz, CH_3-CH_2O), 3.38 (1H, dt, J=14.29, 3.3 and 3.3 Hz, 6α-H), 4.15 (2H, q, J=7.14, CH_3CH_2-O), 4.33 (1H, ddd, J=12.8, 12,8 and 6.2 Hz, 2-H), 4.49 (1H, ddd, J=12.8, 12.8 and 4.8 Hz, 2-H), and 5.67 (1H, s, 4-H); MS *m/z* (rel intensity) 475 (M^+, 3.4), 458 (27.7), 440 (11.2), 430 [$(M-OEt)^+$, 15.8], 402 [$(M-COOEt)^+$, 68.9], 372 (100), 147 (20.8), 133 (22.0), 121 (23.6), 107 (31.6), 95 (20.0), 82 (47.1), 69 (47.7), 55 (65.7), and 43 (74.6). UV(ethanol) λ_{max} 212 nm (ε; 13850).

The photoreaction of **2** (400 mg) in methanol (400 mg) for 8 h under the above conditions gave a product. The product was subjected to preparative TLC (3 : 1 dichloromethane-hexane) to yield a methoxy analogue **4** (180 mg, 47%, based on the converted nitro ketone) and the starting nitro ketone (41

mg). (Found: *m/z* 461.3457: Calcd for $C_{28}H_{47}NO_4$: M, 461.3505); IR (Nujol) 1710 (COOEt), 1630 (C=C), and 1577 cm^{-1} (NO_2); ^1H NMR (270 MHz) δ=0.70 (3H, s, 18-H), 1.14 (3H, s, 19-H), 3.70 (3H, s, OMe), 3.84 (1H, td, J=14.3 and 3.7 Hz, 6α-H), 4.33 (1H, ddd, J=12.8, 11.0 and 6.2 Hz, 2-H), 4.48 (1H, ddd, J=12.8, 11.4 and 4.8 Hz, 2-H), and 5.69 (1H, s, 4-H): ^{13}C NMR δ=56.1 (OMe), 71.5 (CH_2NO_2), 11.6 (the α-carbon of the α,β-unsaturated ester), 165.9 (the β-carbon of the α,β-unsaturated ester), and 167.3 (the C=O of the methoxycarbonyl); MS *m/z* (rel intensity) 461 (M^+, 9.2), 444 (38.9), 430 [$(M-OMe)^+$, 13.3], 426 (15.3), 402 [$(M-COOMe)^+$, 53.6], 386 (33.8), and 372 (100).

Photolysis of 4α-Nitro-5α-cholest-1-en-3-one (6). α-Nitro ketone **6** (300 mg, 0.7 mmol) in ethanol (350 ml) was flushed with nitrogen and irradiated for 3 h with a EIKOSHA 500-W high-pressure mercury arc through a Pyrex filter under an atmosphere of a nitrogen. The removal of the solvent left an oily residue (326 mg) which was subjected to preparative TLC with dichloromethane to yield two fractions. The most mobile fraction (26 mg, 8.7%) was starting nitro ketone. The next mobile fraction (91 mg, 36.8%) was 5α-cholest-1-en-3-one, **4** which was purified by recrystallization from methanol (55 mg), mp 149—151 °C.

Nontemplate Synthesis of Macrocyclic Tetraimine Schiff Bases Incorporating Dithienylmethane Units[1)]

Tyo SONE,* Yoshihiro OHBA, and Ryuji WATANABE
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received October 11, 1988)

Synopsis. Novel 26- and 28-membered macrocyclic tetraimine Schiff bases incorporating four thiophene units as ring constituents were synthesized by a nontemplate method starting from bis(5-formyl-2-thienyl)methane derivatives and aliphatic diamines under high-dilution conditions.

Recently, much attention has been given to the synthesis and characterization of macrocyclic tetraimine Schiff bases and their metal complexes.[2)] In addition to ligands, macrocyclic Schiff bases are potential precursors[3)] of the cyclic tetramines, which are also ligands,[4)] and potential inclusion hosts[5)] for organic molecules. Although several macrocyclic Schiff bases incorporating a heteroaromatic unit as a ring constituent have been reported,[6)] most of them have been derived from 2,6-pyridinedicarbonyl compounds and isolated as metal complexes. In spite of growing interest as mixed donor macrocyclic ligands, macrocyclic Schiff bases incorporating a heteroaromatic unit other than a pyridine nucleus have received less attention. Regarding the thiophene family, for example, it is limited to those[7-9)] derived from 2,5-thiophenedicarbaldehyde, all of which contain two thiophene units as a ring constituent. We investigated the synthesis of a novel-type macrocyclic Schiff bases (**3** and **4**)[5)] which contain four thiophene units, namely two di-2-thienylmethane units substituted at the methylene bridges. The results are reported.

Macrocyclic Schiff bases have generally been synthesized by the condensation of dicarbonyl compounds with diamines by employing a metal template procedure. However, it is rather difficult to isolate metal-free Schiff bases from the metal complex, because of the instability of the macrocycles under demetalation conditions. Only a few examples[3,5,7,9)] for the nontemplate synthesis of macrocyclic Schiff bases have been reported, including those prepared by the [2+2] condensation of 2,5-thiophenedicarbaldehyde with α,ω-alkanediamines[7,9)] under reflux in ethanol.

The 26-membered macrocycles, **3a—d**, which contain four thiophene units, could also be synthesized in high yields in the absence of a template metal by using a high-dilution procedure. Thus, when equimolar amounts of bis(5-formyl-2-thienyl)methane derivatives, **2a—d**, and 1,2-ethanediamine were allowed to react in a highly diluted $CHCl_3$ solution at room temperature, the expected **3a—d** were obtained in 70—86% yields. The 28-membered macrocycle (**4**) was obtained similarly by the condensation of **2a** and 1,3-propanediamine, but in rather low yield (18%). The condensation of **2b** with 1,4-butanediamine or 1,6-hexanediamine for the synthesis of 30- or 34 membered macrocycles gave no macrocyclic imines, but only polymeric materials. These results indicate that 1,2-ethanediamine is the most suitable building block for the construction of the macrocyclic tetraimine Schiff bases derived from bis(5-formyl-2-thienyl)methane derivatives, **2a—d**. The reason why **2** efficiently undergoes the [2+2] condensation with 1,2-ethanediamine, but not with its higher homologs, is not clear at present. The contribution of the facile precipitation of the products in the reaction media as well as the conformation of the starting dicarbonyl compounds were suggested to be the result of efficient [2+2] condensation of 2,5-pyrrole- or 2,5-thiophenedicarbaldehyde with 2-hydroxy-1,3-propanediamine.[9)] However, this is not the case regarding the condensation of **2** with 1,2-ethanediamine; products **3** and **4** are soluble in the reaction media, $CHCl_3$, and are derived from the same dicarbonyl compound, **2**. There must be a favoured mutual positioning between the two end groups of the noncyclic intermediates in the final stage of the ring closure between **2** and 1,2-ethanediamine.

The structures of **3a—d** and **4** were determined by elemental analysis as well as spectral data (MS, IR, ^1H and ^{13}C NMR). The IR spectra display an absorption band in the 1620—1630 cm^{-1} region (C=N stretching band). The ^1H NMR spectra show singlets at δ 8.15—8.18, while ^{13}C NMR singlets at ca. 156 ppm are ascribable to the four equivalent imine protons and imine

carbons, respectively. Any signals due to aldehyde and primary amine were not detected in the IR and NMR spectra.

All of the macrocyclic Schiff bases oblained are, contrary to our expectation, only slightly soluble in most solvents, except $CHCl_3$. Variatons of the alkyl group at the methylene bridges and of amine produced little effect on solubility. This makes it difficult to utilize **3** (or **4**) as inclusion hosts or a precursor for the macrocyclic polyamines.

Experimental

All melting points are uncorrected. The ^1H and ^{13}C NMR spectra were obtained on a Hitachi R-90H (90.0 MHz) and Hitachi R-90H (22.6 MHz) spectrometer, using TMS as an internal reference. The IR and Mass spectra were recorded on Hitachi EPI-S2 and UMU-5MG spectrometers. 2,2-Di(2-thienyl)propane (**1a**) and 2,2-bis(5-formyl-2-thienyl)propane (**2b**) were obtained according to methods described in the literature.[10]

Synthesis of 2,2-Di(2-thienyl)butane (1b). The procedure is a modification of the method used for the synthesis of **1a**.[10] 2-Butanone (48.3 g, 0.67 mol) was added to a mixture of thiophene (84 g, 1 mol) and 72% aqueous H_2SO_4 (126 g) over a period of 30 min at room temperature; the mixture was then stirred at 70—75 °C for 4 h. The cooled mixture was extracted with $CHCl_3$ (300 ml×2) and washed with water and dried over Na_2SO_4. After removing the solvent, the residue was distilled under reduced pressure to give **1b** (41.8 g, 38%). Colorless oil, bp 108—115 °C/3 Torr (1 Torr=133.322 Pa). IR ($CHCl_3$) 2980, 2950, 850, and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, J=7.2 Hz), 1.78 (3H, s), 2.23 (2H, q, J=7.2 Hz), 6.82 (2H, d, J=2.4 Hz), 6.85 (2H, d, J=4.2 Hz), and 7.08 (2H, d,d, J=4.2, 2.4 Hz); MS m/z 222 (M^+, 28%). Anal. ($C_{12}H_{14}S_2$) C, H.

Synthesis of 2,2-Di(2-thienyl)-3-methylbutane (1c). By a similar procedure used for the preparation of **1b**, **1c** was obtained in 19% yield. Yellow oil, bp 137—145 °C/5 Torr. IR ($CHCl_3$) 2970, 2860, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (6H, d, J=5.4 Hz), 1.75 (3H, s), 2.40—2.80 (1H, m), and 6.80—7.20 (3H, m); MS m/z 236 (M^+, 11%). Anal. ($C_{13}H_{16}S_2$) C, H.

Synthesis of Bis(5-formyl-2-thienyl)methane (2a). This compound was not obtained in satisfactory yield by the reported procedure.[11] Another route described below was used. A solution of bis(5-bromo-2-thienyl)methane[12] (6.3 g, 19 mmol) in dry ether (40 ml) was added over a period of 10 min to 15% buthyllithium-hexane solution (19 g) in dry diethyl ether (30 ml) at −40 °C—−50 °C under N_2 atmosphere. Then, *N,N*-dimethylformamide (DMF) (2.8 g, 38 mmol) in dry diethyl ether (20 ml) was added over a period of 5 min; the mixture stirred for 1 h at room temperature. After this solution was added to crushed ice (100 g) the ether layer was washed successively by a 5% HCl aqueous solution, a saturated $NaHCO_3$ solution, and a saturated NaCl solution and then dried over Na_2SO_4. After removing the solvent, the crude product was crystallized with ethanol to give **2a** (1.9 g, 42%). Colorless prisms, mp 95 °C (lit.[11] 95 °C). IR (KBr) 1645 cm^{-1} (CHO); ^1H NMR ($CDCl_3$) δ=4.43 (2H, s), 7.00 (2H, d, J=3.6 Hz), 7.62 (2H, d, J=3.6 Hz), and 9.83 (2H, s, CHO); MS m/z 236 (M^+, 100%).

Synthesis of 2,2-Bis(5-formyl-2-thienyl)butane (2c). To a mixture of **1b** (22.2 g, 0.1 mol) and DMF (9.2 g, 0.13 mol), $POCl_3$ (19.2 g, 0.13 mol) was added under cooling in a water bath with stirring. The mixture was stirred at 80—90 °C for 1 h and then cooled to room temperature. DMF (9.2 g, 0.13 mol) and $POCl_3$ (19.2 g, 0.13 mol) were added to this mixture. After heating at 80 °C for 2 h, the reaction mixture was poured into crushed ice (100 g), neutralized with sodium acetate, and then extracted with $CHCl_3$ (250 ml×2). The $CHCl_3$ layer was washed with water (200 ml×2) and dried over Na_2SO_4. The solvent was removed and the residue was chromatographed on silica gel (Wako C-200, hexane/ethyl acetate=1/1) to give the crude product, which was recrystallized from ethanol gave **2c** (12.2 g, 48%). Yellow powder, mp 63—63.5 °C. IR (KBr) 2975, 2950, 2850, 1655, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, J=6.9 Hz), 1.80 (3H, s), 2.24 (2H, q, J=6.9 Hz), 6.91 (2H, d, J=3.6 Hz), 7.53 (2H, d, J=3.6 Hz), and 9.74 (2H, s, CHO); MS m/z 278 (M^+, 14%). Anal. ($C_{14}H_{14}S_2$) C, H.

Synthesis of 2,2-Bis(5-formyl-2-thienyl)-3-methylbutane (2d). Diformyl compound **2d** was obtained in 55% yield by a similar procedure to that used for the synthesis of **2c**. Pale-yellow powder, mp 88—89.5 °C. IR (KBr) 1660 and 1650 cm^{-1} (CHO); ^1H NMR ($CDCl_3$) δ=0.94 (6H, d, J=6.0 Hz), 1.80 (3H, s), 2.47—2.90 (1H, m), 7.07 (2H, d, J=3.6 Hz), 7.59 (2H, d, J=3.6 Hz), and 9.78 (2H, s, CHO); MS m/z 292 (M^+, 12%). Anal. ($C_{15}H_{16}O_2S_2$) C, H.

Synthesis of 31,32,33,34-Tetrathia-3,6,18,21-tetraazapentacyclo[26.2.1.1^{8,11}.1^{13,16}.1^{23,26}]tetratriaconta-1(30),2,6,8,10,13,15,17,21,23,25,28-dodecaene (3a). A solution of **2a** (0.25 g, 1.0 mmol) in $CHCl_3$ (20 ml) and a solution of 1,2-ethanediamine (0.06 g, 1.0 mmol) in $CHCl_3$ (20 ml) were added simultaneously to the $CHCl_3$ (20 ml) over a period of 1.5 h with stirring at room temperature. After stirring for 30 min, the reaction mixture was filtered in order to remove any insoluble precipitate; the filtrate was then dried over Na_2SO_4 and concentrated. The yellow powder, thus obtained, was washed with ethanol (20 ml×2) giving **3a** (2.2 g, 83%). Colorless powder, mp 158—165 °C (decomp). IR (KBr) 2820, 1620, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.83 (8H, s), 4.20 (4H, s), 6.73 (4H, d, J=3.6 Hz), 7.03 (4H, d, J=3.6 Hz), and 8.15 (4H, s); MS m/z 520 (M^+, 10%). Anal. ($C_{26}H_{24}N_4S_4$) C, H.

Synthesis of 12,12,27,27-Tetramethyl-31,32,33,34-tetrathia-3,6,18,21-tetraazapentacyclo[26.2.1.1^{8,11}.1^{13,16}.1^{23,26}]tetratriaconta-1(30),2,6,8,10,13,15,17,21,23,25,28-dodecaene (3b). (Typical procedure) The solution of 2,2-bis(5-formyl-2-thienyl)propane (2.6 g, 10 mmol) in $CHCl_3$ (50 ml) and 1,2-ethanediamine (0.6 g, 10 mmol) in $CHCl_3$ (100 ml) were added simultaneously to 50 ml of $CHCl_3$ over a period of 15 h with stirring at room temperature; the mixture was stirred for an additional 30 h. After usual work-up, the crude product was obtained as yellow powder, which was recrystallized with $CHCl_3$-hexane to give **3b** (2.4 g, 84%). Pale-yellow powder, mp 233—236 °C (decomp). IR (KBr) 2970, 2930, 2830, 1630, and 800 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.80 (12H, s), 3.79 (8H, s), 6.74 (4H, d, J=3.6 Hz), 6.99 (4H, d, J=3.6 Hz), and 8.18 (4H, s); ^{13}C NMR ($CDCl_3$) δ=32.41, 40.92, 61.07, 123.61, 130.04, 155.83, and 158.09; MS m/z 576 (M^+, 26%). Anal. ($C_{30}H_{32}N_4S_4$) C, H, N.

The cyclic tetraimines, **3c**, **3d**, and **4a**, were synthesized in a similar manner.

12,27-Diethyl-12,27-dimethyl-31,32,33,34-tetrathia-3,6,18,21-tetraazapentacyclo[26.2.1.1^{8,11}.1^{13,16}.1^{23,26}]tetratriaconta-1(30),2,6,8,10,13,15,17,21,23,25,28-dodecaene (3c). Yield 86%. Pale yellow powder, mp 197—200 °C. IR (KBr) 2970, 2930, 2830, 1630, and 790 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.90 (6H, t, J=7.2 Hz), 1.78 (6H, s), 2.22 (4H, q, J=7.2 Hz), 3.80 (8H, s), 6.75 (4H, d, J=3.6 Hz), 7.00 (4H, d, J=3.6 Hz), and 8.15 (4H, s); ^{13}C NMR ($CDCl_3$) δ=9.71, 27.96, 37.11, 44.70, 61.04, 124.06, 129.98, 140.28, 155.86, and 157.33; MS m/z 604 (M^+, 28%). Anal. ($C_{32}H_{36}N_4S_4$) C, H, N.

12,27-Diisopropyl-12,27-dimethyl-31,32,33,34-tetrathia-3,6,18,21-tetraazapentacyclo[26.2.1.1^{8,11}.1^{13,16}.1^{23,26}]tetratriaconta-1(30),2,6,8,10,13,15,17,21,23,25,28-dodecaene (3d). Yield 70%. Pale yellow powder, mp 188—191 °C. IR (KBr) 2980, 2840,

and 1630 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.90 (12H, d, J=6.2 Hz), 1.70 (6H, s), 2.30—2.50 (2H, m), 3.79 (8H, s), 6.87 (4H, d, J=3.6 Hz), 7.03 (4H, d, J=3.6 Hz), and 8.17 (4H, s); ^{13}C NMR ($CDCl_3$) δ=18.42, 22.17, 39.18, 48.11, 61.07, 124.09, 130.01, 139.95, 155.93, and 157.08; MS m/z 632 (M^+, 5%). Anal. ($C_{34}H_{40}N_4S_4$) C, H, N.

13,13,29,29-Tetramethyl-33,34,35,36-tetrathia-3,7,19,23-tetraazapentacyclo[28.2.1.$1^{9,12}$.$1^{14,17}$.$1^{25,28}$]hexatriaconta-1(32), 2,7,9,11,14,16,18,23,25,27,30-dodecaene (4). Yield 14%. Colorless powder, mp 270—275 °C. IR (KBr) 2975, 2840, and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40—2.40 (16H, m), 3.53 (8H, t, J=7.2 Hz), 6.76 (4H, d, J=3.6 Hz), 7.00 (4H, d, J=3.6 Hz), and 8.20 (4H, s); ^{13}C NMR ($CDCl_3$) δ=31.74, 32.38, 40.89, 58.60, 123.54, 129.64, 140.56, 154.46, and 157.94; MS m/z 604 (M^+, 1%). Anal. ($C_{32}H_{36}N_4S_4$) C, H, N.

The authors with to thank Mr. Takayuki Ebisawa and Yasuo Nagai for their assistance with some experiments and Mr. Kazuaki Sato for elemental analyses.

(Received October 24, 1988)

Synopsis. The reaction of acetanilide derivatives with benzyltrimethylammonium dichloroiodate in acetic acid in the presence of $ZnCl_2$ at room temperature or at 70 °C gave iodo-substituted acetanilide derivatives in good yields.

The nuclear iodo-substituted acetanilide derivatives (**2**) have usually been prepared by the *N*-acetylation of iodo-substituted anilines. As an iodinating agent for acetanilide derivatives (**1**) iodine monochloride (ICl) has considerably been used in place of molecular iodine.[2] However, experimental data concerning the direct iodination of **1** have not been appreciably revealed in the literature.

Recent work in this series has shown that benzyltrimethylammonium dichloroiodate (BTMA ICl_2) is an excellent iodinating agent to phenols,[3] aromatic amines,[4] aromatic ethers,[5] and arenes.[6] In this paper we wish to report on the iodination of **1** by the use of BTMA ICl_2 in the presence of $ZnCl_2$.

Results and Discussion

The reaction of **1** with a calculated amount of BTMA ICl_2 and $ZnCl_2$ in acetic acid at room temperature or at 70 °C gave **2** in good yields. The results are summarized in Table 1, and ^1H NMR data and analyt-

ical data of the new **2** are shown in Table 2.

Although BTMA ICl_2 is slightly soluble in acetic acid at room temperature, the addition of $ZnCl_2$ makes this reagent soluble in acetic acid, and the iodination reaction of **1** smoothly proceeds under mild conditions. In this case an equimolar amount of $ZnCl_2$ is required for BTMA ICl_2. Therefore, we assumed the existence of a complex, formed from BTMA ICl_2 with equimolar $ZnCl_2$, as the active species.[6]

We believe that the procedure for the iodination of **1** using BTMA $ICl_2/ZnCl_2$ is an efficient method owing to its ease, mildness of conditions, and good product yields.

As a limitation of this iodinating method, the less reactive **1** such as nitro-, chloro-, and bromoacetanilides gave no product. The reactions of 3-methoxy- (**1l**), 3-ethoxy-(**1o**), 3-hydroxy- (**1q**), and 3-aminoacetanilide (**1r**) with 1-equiv of BTMA $ICl_2/ZnCl_2$ were so vigorous that mixtures of mono, and diiodinated products were obtained, respectively.

Experimental

4-Iodoacetanilide (2a); Typical Procedure: To a solution of acetanilide (**1a**) (0.50 g, 3.70 mmol) in acetic acid (20 ml) was added BTMA ICl_2 (1.42 g, 4.08 mmol) and $ZnCl_2$ (0.7 g, 5.14 mmol). The mixture was stirred for 2 h at room temperature. The yellow color of the solution gradually changed to light brown. The solvent was distilled and a 5% aq solution of $NaHSO_3$ (10 ml) was added to the obtained residue. A 5% aq solution of $NaHCO_3$ was added to the mixture to neutralize; then, the solution was extracted with dichloromethane (40 ml×4). The dichloromethane layer was dried over $MgSO_4$, and passed through a short alumina column. The elute (dichloromethane solution) was concentrated in vacuo to give **2a** as colorless crystals; 0.75 g (77%); mp 186—187 °C (lit,[2] mp 184 °C).

A Facile and Practical Synthesis of 1-Aryl-3,3,3-trifluoropropynes

Tamejiro HIYAMA,* Ken-ichi SATO, and Makoto FUJITA
Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara, Kanagawa 229
(Received October 26, 1988)

Synopsis. A facile and practical method for the synthesis of $ArC{\equiv}CCF_3$ is described which involves (1) conversion of aldehydes ArCHO into $ArCH{=}CClCF_3$ with 1,1,1-trichloro-2,2,2-trifluoroethane, zinc powder, and acetic anhydride in one-pot and (2) dehydrochlorination with sodium *t*-butoxide or sodium amide/*t*-butyl alcohol.

In view of rapidly growing role of organofluorine compounds particularly in material and pharmaceutical science, synthesis of organofluorine compounds is becoming more and more important.[1] Introduction of fluorine and polyfluoroalkyl groups to organic molecule at the late stage of the synthesis often encounters technical and economical problems.[2,3] Use of fluorine-containing building blocks[2] is the alternative approach to the synthesis of organofluorine compounds. Of various trifluoromethyl-substituted building blocks, 1-aryl-3,3,3-trifluoropropynes, which were studied previously with structural interest,[4] have recently been attracting much attention from polymer chemists,[5] organometallic chemists,[6] and synthetic chemists[7] as well as pharmaceutical scientists.[8] Synthetic methods of this type of acetylenes reported so far are classified into four categories: (1) Bromination of trifluoromethylethenes followed by double dehydrobromination,[9] (2) thermal decomposition of triphenylphosphonium trifluoroacetylmethylylides,[8] (3) palladium-mediated coupling reaction of 3,3,3-trifluoropropyne with iodoarenes,[5] and (4) trifluoromethylation of stannylacetylenes.[10] The method (1) is chronologically the first one but suffers restricted application, since we failed to apply the procedure to an acetylene of higher boiling points, e.g. 1-(1-naphthyl)-3,3,3-trifluoropropyne. The second one is suitable only for laboratory-scale synthesis. The third method apparently have practical advantage, but trifluoropropyne should be generated in situ from a relatively expensive precursor.[11] The last one is of no practical use. We report herein a readily accessible two-step entry for the synthesis of 1-aryl-3,3,3-trifluoropropynes.

$$\mathrm{RCHO} + \mathrm{CCl_3CF_3} \longrightarrow \underset{\mathbf{1}}{\mathrm{RCH{=}CClCF_3}} \longrightarrow \underset{\mathbf{2}}{\mathrm{RC{\equiv}CCF_3}}$$

Results and Discussion

Aldehydes RCHO are readily transformed to olefins $RCH{=}CClCF_3$ (**1**) by the one-pot reaction which employs 1,1,1-trichloro-2,2,2-trifluoroethane, zinc powder, and acetic anhydride.[12] Dehydrochlorination of the olefins should give rise to the desired acetylenes $RC{\equiv}CCF_3$ (**2**). We studied various bases to effect the β-elimination. Tertiary amines and lithium amides were totally ineffective. Potassium *t*-butoxide gave fair amount of the acetylenes. Changing the counter ion to sodium or employing a reagent derived from sodium amide and *t*-butyl alcohol was found to be highly effective. Various olefins of $RCH{=}CClCF_3$ were treated with the sodium amide/*t*-butyl alcohol system. Although the olefins which have R = aliphatic or alicylic were either recovered unchanged or decomposed, those having aryl groups gave excellent yields of acetylenes. Results are listed in Table 1.

Table 1. Dehydrochlorination of **1**

Run	Olefin	Product	Yield/%[a]
1			90[b]
2			91[c]
3			51[d]
4			77[c]
5			81[c] 95[f]
6			60[g]

a) Isolated yields after distillation unless otherwise stated. b) The reaction was carried out in 0.78 mmol scale. c) The reaction was carried out in 2 mmol scale. d) The reaction was carried out in 0.46 mmol scale. e) The reaction was carried out in 1 mmol scale. f) The reaction was carried out in 0.01 mol scale. g) Estimated by ^{19}F NMR with 1,3,5-trichloro-2,4,6-trifluorobenzene as an internal standard. This reaction was carried out in 2 mmol scale.

In addition to 3,3,3-trifluoropropynyl-substituted carbocyclic aromatics (Runs 1—5), a furan derivative (Run 6) is now accessible. Our strategy is based on two-carbon elongation of ArCHO by using inexpensive reagents and thus find wide practical application.

Experimental

Boiling points were measured by use of Büchi Kugelrohor or Glass Tube Oven (Shibata) and are given in °C/Torr(1 Torr=133.322 Pa). ^1H NMR spectra (tetramethylsilane as an internal standard) were obtained with a Hitachi R-90H or Varian EM-390 spectrometer and ^{19}F NMR spectra (trichlorofluoromethane as an internal standard) with a Hitachi R-20B spectrometer. IR data were recorded with a JASCO A-202 spectrometer. MS spectra (70 eV) were recorded with a Hitachi RMU-6MC machine. Sodium amide was purchased

from Yoneyama Chem. Ind. and used directly. Benzene and *t*-butyl alcohol were freshly distilled before use over benzophenone ketyl and calcium hydride respectively. The chlorotrifluoromethyl substituted olefins **1** were prepared through a modified procedure of our previous publication.[12]

2-Chloro-3,3,3-trifluoro-1-(1-naphthyl)propene. To a *N,N*-dimethylformamide (DMF) (20 ml) solution of 1-naphthalenecarbaldehyde (3.12 g, 20.0 mmol) were added 1,1,1-trichloro-2,2,2-trifluoroethane (2.84 ml, 24.0 mmol) and zinc powder (1.44 g, 22.0 mmol), and the mixture was stirred at room temperature for 1 h and at 50 °C for 24 h before treatment with acetic anhydride (3 ml) and zinc powder (2.62 g, 40 mmol). The resulting mixture was stirred at 50 °C for 2 h, poured to 10% hydrochloric acid (100 ml) and extracted with diethyl ether (100 ml×3 times). The ethereal extract was washed with sat sodium hydorgencarbonate (50 ml) aq solution and then with sat sodium chloride aq solution (50 ml×twice) and dried over magnesium sulfate. Filtration and concentration followed by distillation in vacuo gave the desired olefin (3.2 g, 62% yield) as a colorless oil. Bp 89 °C (bath temp)/0.3 Torr; ^{1}H NMR ($CDCl_3$) δ=7.3—7.6 (m, 3H), 7.7—7.9 (m, 4.5H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=69.0 (s) for (*Z*)-isomer, 62.2 (s) for (*E*)-isomer, intensity ratio (*Z*):(*E*)=7:1. IR (neat) 3060, 1640, 1285, 1260, 180, 1160, 1140, 960, 800, 770 cm^{-1}; MS *m/z* (rel intensity) 256 (48, M$^+$), 221 (100), 201 (74), 152 (79). Found: C, 60.93; H, 3.34%. Calcd for $C_{13}H_8ClF_3$: C, 60.84; H, 3.14%.

2-Chloro-3,3,3-trifluoro-1-(2-furyl)propene. To furfural (1.66 ml, 20.0 mmol) dissolved in DMF (20 ml) were added 1,1,1-trichloro-2,2,2-trifluoroethane (2.85 ml, 24 mmol) and zinc powder (1.44 g, 22 mmol), and the resulting mixture was stirred at 50 °C for 4 h. Acetic anhydride (3.0 ml, 27 mmol) and zinc powder (2.62 g, 40 mmol) were added to the mixture at 0 °C, and the whole was stirred at 50 °C for 1 h and then at 50 °C for 18 h. After workup as above, the ether solvent was stripped off by atmospheric distillation through 10 cm-Vigreux column. Final distillation afforded the title olefin (2.12 g, 54% yield) as a colorless oil. Bp 60 °C (bath temp)/20 Torr. ^{1}H NMR ($CDCl_3$) δ=6.55 (dd, 1H), 7.13 (dd, 1H), 7.22 (s, 1H) for the (*Z*)-isomer, 6.47 (dd, 1H), 6.69 (d, 1H), 6.94 (s, 1H), 6.49 (d, 1H) for the (*E*)-isomer, (*Z*):(*E*)=6:1. ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=69.0 (s) for (*Z*)-isomer, 63.0 for (*E*)-isomer; IR (neat) 3160, 3070, 2950, 1650, 1480, 1290, 1180, 1140, 1020, 970, 880, 742 cm^{-1}; MS *m/z* (rel intensity) 196 (100, M$^+$), 167 (27), 133 (31), 113 (17), 99 (16), 83 (10), 63 (20). Found: C, 42.77; H, 1.84%. Calcd for $C_7H_4ClF_3O$: C, 42.78; H, 2.05%.

1-(1-Naphthyl)-3,3,3-trifluoropropyne. A Typical Procedure for Dehydrochlorination of 1. A benzene (1 ml) solution of 2-chloro-1-(1-naphthyl)-3,3,3-trifluoropropene (0.20 g, 0.78 mmol) and *t*-butyl alcohol (0.5 ml) was added to sodium amide (0.22 g, 5.2 mmol) suspended in benzene (2 ml), and the mixture was heated to reflux for 5 h. The reaction mixture was poured to 10% hydrochloric acid (10 ml) and extracted with ether (20 ml×3). The combined ethereal extract was washed with aq sodium hydrogencarbonate solution (20 ml×2) and dried over magnesium sulfate. Filtration, concentration under reduced pressure followed by preparative TLC (silica gel, hexane) afforded 1-(1-naphthyl)-3,3,3-trifluoropropyne (0.156 g, 90% yield) and the recovered starting material (3%). The acetylene showed bp 95 °C (bath temp)/0.7 Torr; ^{1}H NMR ($CDCl_3$) δ=7.20—7.90 (m, 6H), 8.10—8.20 (m, 1H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=49.5 (s); IR (neat) 3800, 2250, 1400, 1315, 1260, 1205, 1140, 800, 770 cm^{-1}; MS *m/z* (rel intensity) 220 (100, M$^+$), 201 (48), 170 (28), 150 (10), 85 (14). Found: C, 70.85; H, 3.31%. Calcd for $C_{13}H_7F_3$: C, 70.91; H, 3.20%.

1-(1-Naphthyl)-3,3,3-trifluoropropye. An Alternative Procedure with Sodium *t*-Butoxide. Sodium *t*-butoxide was prepared by heating a mixture of sodium amide (0.29 g, 74 mmol), benzene (2 ml), and *t*-butyl alcohol (0.7 ml) at reflux temperature for 1 h. 2-Chloro-1-(1-naphthyl)-3,3,3-trifluoropropene (0.26 g, 1.0 mmol) dissolved in benzene (1 ml) was added, and the mixture was heated to reflux for 5 h. Workup as above followed by purification by TLC gave the desired acetylene (161 mg, 73% yield) and the starting material (9%).

Other acetylenes in Table 1 were prepared by the typical procedure and showed following physical properties.

1-(3-Phenoxyphenyl)-3,3,3-trifluoropropyne: Bp 140 °C (bath temp)/1.5 Torr; ^{1}H NMR ($CDCl_3$): δ=6.93—7.40 (m); ^{13}C NMR ($CDCl_3$): δ=75.9 (q, $J_{C\text{-}CF_3}$=52.6 Hz), 85.9 (sextet, *J*=6.4 Hz), 114.8 (q, J_{CF_3}=256.9 Hz), 119.5 (d), 119.8 (d), 121.3 (d), 127.2 (d), 121.8 (d), 124.2 (d), 127.0 (d), 130.0 (d), 130.1 (d), 156.1 (s), 157.7 (s); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=50.3 (s); IR (KBr) 3100, 3050, 2260, 1580, 1490, 1325, 1203, 1140, 695, 685 cm^{-1}; MS *m/z* (rel intensity) 262 (100, M$^+$), 165 (42), 94 (5), 77 (56), 51 (39). Found: C, 68.76; H, 3.36%. Calcd for $C_{15}H_8F_3O$: C, 68.97; H, 3.09%.

1-(4-Chlorophenyl)-3,3,3-trifluoropropyne: Bp 60 °C (bath temp)/5 Torr (lit[8] 64 °C/44 Torr); ^{1}H NMR ($CDCl_3$) δ=7.32 (d, 2H), 7.48 (d, 2H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=50.3 (s); IR (neat) 2940, 2870, 2260, 1598, 1495, 1325, 1310, 1130—1180, 1105, 1085, 1015, 870, 830, 750, 530 cm^{-1}; MS *m/z* (rel intensity) 204 (100, M$^+$), 185 (32), 169 (64), 154 (16), 99 (11), 74 (11), 50 (11).

1-(3,4-Methylenedioxyphenyl)-3,3,3-trifluoropropyne: Bp 95 °C (bath temp)/5 Torr; ^{1}H NMR ($CDCl_3$): δ=6.00 (s, 2H), 6.75 (d, 1H), 6.90 (α, 1H), 7.70 (dd, 1H); ^{13}C NMR ($CDCl_3$): δ=74.4 (q, $J_{C\text{-}CF_3}$=52.3 Hz), 86.8 (sextet, $J_{C\text{-}CF_3}$=6.0 Hz), 101.8 (t), 108.8 (d), 111.5 (s), 111.9 (d), 115.0 (q, J_{CF_3}=256.4 Hz), 128.0 (d), 147.7 (s), 150.1 (s); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=49.5 (s); IR (neat) 2920, 2250, 1500, 1440, 1315, 1240, 1180, 1140, 1100, 1040, 930, 860, 810, 610, 540 cm^{-1}; MS *m/z* (rel intensity) 214 (100, M$^+$), 195 (14), 156 (12), 106 (9), 87 (27). Found: C, 56.05; H, 2.56%. Calcd for $C_{10}H_5F_3O_2$: C, 56.09; H, 2.35%.

1-(2-Furyl)-3,3,3-trifluoropropyne: Boiling point of this compound could not be measured as it distilled with low-boiling solvents. Its analytical sample was obtained by preparative GLC. ^{1}H NMR ($CDCl_3$) δ=6.47 (dd, 1H), 6.92 (d, 1H), 7.53 (d, 1H); ^{13}C NMR ($CDCl_3$) δ=80.3 (q, $J_{C\text{-}CF_3}$=53.3 Hz), 111.4 (d), 114.9 (q, J_{CF_3}=257.5 Hz), 120.1 (d), 128.4 (s), 133.4 (q, *J*=1.9 Hz), 146.1 (d); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=51.0 (s); IR (neat) 3150, 2260, 2240, 1300, 1220, 1190, 1150, 1010 cm^{-1}; MS *m/z* (rel intensity) 160 (100, M$^+$), 141 (25), 131 (29), 106 (14), 81 (39), 78 (29), 63 (65). Found: C, 52.30; H, 1.82%. Calcd for $C_7H_3F_3O$: C, 52.52; H, 1.89%.

1-(4-Phenylphenyl)-3,3,3-trifluoropropyne. A Procedure for Gram-Order Synthesis. Sodium amide (2.73 g, 0.07 mol) was added to a benzene (50 ml) solution of 2-chloro-1-(4-phenylphenyl)-3,3,3-trifluoropropene (2.82 g, 0.01 mol) under an argon atmosphere. To the resulting mixture was added *t*-butyl alcohol (6.64 ml, 0.07 mol) at room temperature. The mixture immediately turned to thick under slightly exothermal evolution of ammonia. Benzene (30 ml) was added to facilitate stirring, and the whole was stirred for 2 h before treatment with 10% hydrochloric acid (100 ml). The organic layer was separated, and the aqueous layer was extracted with ether (50 ml×2). The combined organic layer was washed with sat sodium hydrogencarbonate aq solution (50 ml×2) and dried over sodium sulfate. Concentration followed by column chromatography (silica gel, hexane) afforded the title acetylene (2.34 g, 95% yield) as colorless solid. Mp 87 °C; ^{1}H NMR ($CDCl_3$): δ=7.30—7.60 (m); ^{13}C NMR ($CDCl_3$): δ=76.3 (q, $J_{C\text{-}CF_3}$=52.9 Hz), 86.6 (m), 114.0 (q, J_{CF_3}=256.6 Hz), 117.2 (m), 127.1 (d), 127.2 (d), 128.3 (d), 129.0 (d), 132.9(d), 139.6 (s), 143.7 (s); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=49.9 (s); IR (KBr) 3100, 3050, 2270, 2200, 1530, 1490, 1410, 1330, 1220, 1170, 1120—1140, 875, 848, 767, 720, 690 cm^{-1}; MS *m/z* (rel intensity) 246 (100, M$^+$), 227 (10), 196 (5),

176 (7), 123 (5). Found: C, 72.90; H, 3.59%. Calcd for $C_{15}H_9F_3$: C, 73.17; H, 3.68%.

A Synthesis of (+)-Cyclaradine, Carbocyclic Analogue of 9-β-D-Arabinofuranosyladenine

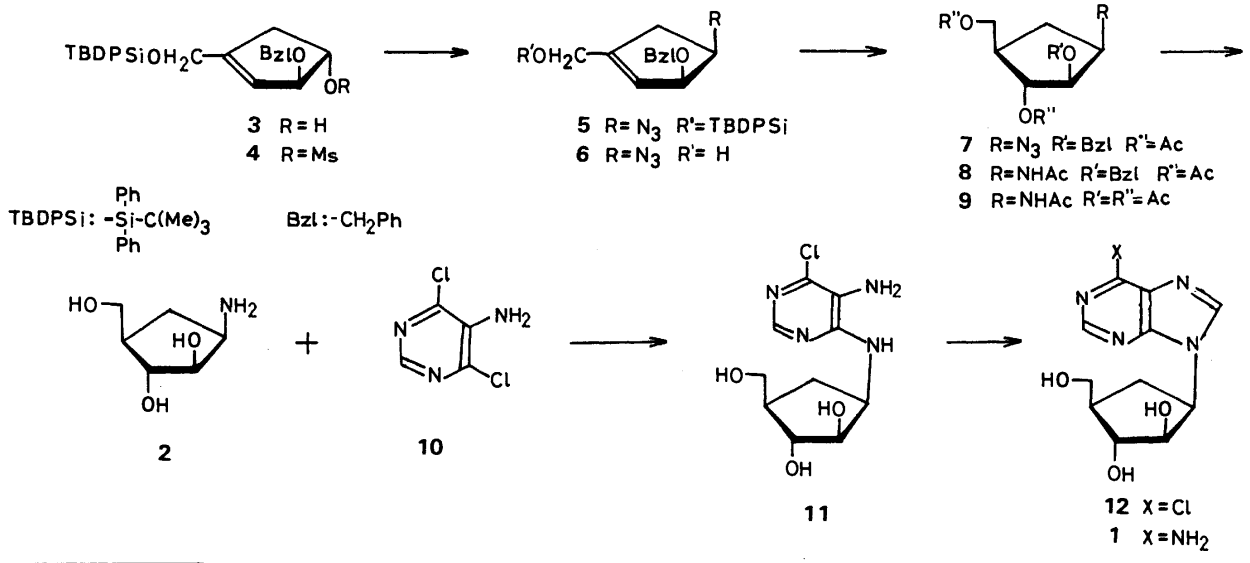
Kin-ichi TADANO,* Hiroshi KIMURA, and Seiichiro OGAWA
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received November 16, 1988)

Synopsis. The title compound, a promising antiviral carbocyclic nucleoside analogue, was synthesized enantiospecifically. The present synthesis involves a coupling reaction of 5-amino-4,6-dichloropyrimidine and (1*R*,2*R*,3*R*,4*R*)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentanamine which was in turn prepared from D-xylose.

Aristeromycin[1] and neplanocin A[2] known as antimicrobial and antitumor agents are representatives of carbocyclic analogue of nucleosides. Sugar moieties of nucleosides are replaced by (hydroxymethyl)cyclopentanepolyol or (hydroxymethyl)-1-cyclopentenepolyol in their structures. The synthesis and biological evaluation of the carbocyclic analogues of nucleosides are current concerns from a pharmacological viewpoint.[3] In 1977, Vince and Daluge reported a synthesis of racemic carbocyclic analogue of arabinosyladenine.[4] This synthetic carbocyclic analogue (**1**) of nucleoside, simply called cyclaradine, arouses much attention owing to its remarkable cytotoxicity against P-388 mouse lymphoid leukemia cells ($LD_{50}=1\times10^{-5}$ M†). Compound **1** was completely resistant to deamination by adenosine deaminase under the conditions in which the antiviral nucleoside 9-β-D-arabinosyladenine was completely deaminated.[4] Furthermore, the racemic **1** inhibits the replication of herpes simplex virus types 1 and 2.[5] This inhibition effect may regard **1** as a candidate for antiherpes agent. We describe herein an enantiospecific synthesis of (+)-cyclaradine (**1**).

Recently, we have reported the synthesis of (3*S*,4*S*)-3-(benzyloxy)-1-[[(*t*-butyldiphenylsilyl)oxy]methyl]-4-hydroxy-1-cyclopentene (**3**) from D-xylose.[6] Our synthesis of **1** commenced with **3**. Mesylation of **3** gave **4** in 96% yield. The mesyloxy group in **4** was displaced by azido group with inversion of configuration at C-4 by treatment with NaN_3 in hot DMF in 81% yield. The silyl protecting group in the resultant azide **5** was then removed with tetrabutylammonium fluoride to give **6** quantitatively. Hydroboration of **6** with borane-THF complex in THF at 0 °C and successive treatment of the product with H_2O_2 in an alkaline solution followed by acetylation provided **7** as a sole product in 79% yield. This highly stereoselective hydroboration with the preferential attack of borane from the less hindered α-side was similar to our previous result obtained by employing the structurally resembling model.[6] Treatment of **7** with H_2S in aqueous pyridine followed by acetylation gave **8** in 98% yield. Debenzylation of **8** according to the Hanessian's procedure[7] followed by acetylation provided the fully acetylated derivative (**9**) of (1*R*,2*R*,3*R*,4*R*)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentanamine (**2**) in 93% yield. Hydrolysis of **9** with aqueous HCl gave **2** in 81% yield after purification by passage through Amberlite CG-120 column.

Coupling of **2** and 5-amino-4,6-dichloropyrimidine (**10**)[8] in boiling 1-butanol in the presence of triethylamine gave a carbocyclic analogue of pyrimidine nucleoside **11**. Cyclization of **11** to a purine derivative **12** was achieved by treatment with triethyl orthoformate in the presence of *p*-toluenesulfonic acid at 60 °C under reduced pressure. Finally, desired **1** was obtained by heating a solution of **12** in saturated methanolic ammonia at 60 °C in an autoclave. The conversion of **2** into **1** was achieved in an overall yield



† 1 M=1 mol dm^{-3}.

of approximately 50% (compounds **11** and **12** were not purified to obtain analytical samples). The synthetic **1** was fully characterized by spectral means.

The IC_{50} of the synthetic **1** for P-388 mouse lymphoid leukemia cells (in vitro) was 4.25 μg ml^{-1}.

Experimental

General procedure was described in the previous paper.[6]

(3*S*,4*S*)-3-(Benzyloxy)-4-[(methylsulfonyl)oxy]-1-[[(*t*-butyldiphenylsilyl)oxy]methyl]-1-cyclopentene (4). A solution of **3** (1.01 g, 2.2 mmol) and methanesulfonyl chloride (0.51 ml, 6.6 mmol) in pyridine (10 ml) was stirred at room temperature for 1 h. The reaction mixture was diluted with CH_2Cl_2 (200 ml) and washed with water (100 ml). The aqueous layer was extracted with CH_2Cl_2 (200 ml×3). The combined organic phases were dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 10) to give **4** (1.13 g, 96%) as a colorless oil: TLC R_f 0.60 (AcOEt/hexane 1 : 3); $[\alpha]_D^{25}$+38.7° (*c* 0.86, $CHCl_3$); IR ν_{max}^{neat} 3090, 2875, 1670, 1185 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.05 (9H, s, Me_3CSi), 2.0—2.2 (2H, m, H-5,5′), 2.94 (3H, s, $MeSO_2O$), 4.16 (2H, br s, $CH_2OTBDPSi$), 4.59 (2H, s, $OC\underline{H}_2C_6H_5$), 4.5—4.8 (1H, m, H-3), 5.13 (1H, dt, *J*=5 and 9 Hz, H-4), 5.69 (1H, br s, H-2), 7.2—8.0 (15H, m, 3×C_6H_5). Found: C, 67.43; H, 6.76%. Calcd for $C_{30}H_{36}O_5SSi$: C, 67.13; H, 6.76%.

(3*S*,4*R*)-4-Azido-3-(benzyloxy)-1-[[(*t*-butyldiphenylsilyl)oxy]methyl]-1-cyclopentene (5). A mixture of **4** (1.12 g, 2.1 mmol) and sodium azide (814 mg, 12.5 mmol) in DMF (60 ml) was heated at 130 °C with stirring for 7 h. The mixture was diluted with AcOEt (400 ml) and washed with water (100 ml×3). The combined aqueous phases were extracted with CH_2Cl_2 (200 ml×3). The combined organic phases were dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 100) to give **5** (822 mg, 81%) as a colorless oil [42.5 mg (4%) of **4** was recovered]: TLC R_f 0.88 (AcOEt/hexane 1 : 10); $[\alpha]_D^{25}$+37.4° (*c* 0.71, $CHCl_3$); IR ν_{max}^{neat} 3075, 2860, 2100, 1590, 1430 cm^{-1}, ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.03 (9H, s, Me_3CSi), 2.49, 2.56 (each 1H, each br s, H-5,5′), 3.85 (1H, dd, *J*=6 and 12 Hz, H-4), 4.22 (2H, br s, $CH_2OTBDPSi$), 4.4—4.7 (1H, m, H-3), 4.65 (2H, d, *J*=4.5 Hz, $OC\underline{H}_2C_6H_5$), 5.82 (1H, br s, H-2), 7.3—7.9 (15H, m, 3×C_6H_5). Found: C, 72.02; H, 6.81; N, 8.61%. Calcd for $C_{29}H_{33}N_3O_2Si$: C, 72.02; H, 6.88; N, 8.69%.

(3*S*,4*R*)-4-Azido-3-(benzyloxy)-1-cyclopentene-1-methanol (6). A solution of **5** (797 mg, 1.65 mmol) in THF (20 ml) was stirred in the presence of tetrabutylammonium fluoride (1 M in THF, 2.5 ml, 2.5 mmol) at room temperature for 30 min. The solution was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 7) to give **6** (401 mg, 99%) as a colorless oil: TLC R_f 0.57 (AcOEt/hexane 1 : 1); $[\alpha]_D^{29}$+43.4° (*c* 0.67, $CHCl_3$); IR ν_{max}^{neat} 3610, 2100, 1420 cm^{-1}. ^{1}H NMR (90 MHz, $CDCl_3$) δ=2.37 (1H, br s, OH), 2.51, 2.57 (each 1H, each br s, H-5,5′), 3.87 (1H, dd, *J*=6 and 12 Hz, H-4), 4.13 (2H, br s, $C\underline{H}_2OH$), 4.49 (1H, br s, H-3), 4.55, 4.74 (each 1H, each d, *J*=12 Hz, $OC\underline{H}_2C_6H_5$), 5.75 (1H, m, H-2), 7.37 (5H, s, $OCH_2C_6\underline{H}_5$).

(1*R*,2*R*,3*R*,4*R*)-2-Acetoxy-1-(acetoxymethyl)-4-azido-3-(benzyloxy)cyclopentane (7). To a solution of **6** (400 mg, 1.6 mmol) in THF (30 ml) was added BH_3-THF (1 M in THF, 13.0 ml, 13.0 mmol) at 0 °C under an argon atmosphere. The mixture was stirred at 0 °C for 2 h, and to it were added water (15 ml), 3 M aqueous NaOH (18 ml), and 35% aqueous H_2O_2 (20 ml) successively. The mixture was then stirred at room temperature for 4 h. To it was added saturated aqueous $NaSO_3$ (20 ml). This was extracted with CH_2Cl_2 (300 ml×4) and AcOEt (300 ml×2). The combined organic phases were dried (Na_2SO_4) and concentrated in vacuo. The residue was acetylated with acetic anhydride (3 ml) in pyridine (3 ml) for 2 h. The mixture was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 14) to give **7** (446 mg, 79%) as a colorless oil: TLC R_f 0.60 (AcOEt/hexane 1 : 3); $[\alpha]_D^{29}$−12.8° (*c* 0.80, $CHCl_3$); IR ν_{max}^{neat} 3020, 2110, 1730, 1450, 1360 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.5—2.5 (3H, m, H-1,5,5′), 2.02 (6H, s, 2×OAc), 3.5—3.9 (2H, m, H-3,4), 4.09 (2H, dd, *J*=4.5 and 6 Hz, CH_2OAc), 4.68 (2H, s, $OC\underline{H}_2C_6H_5$), 4.99 (1H, t, *J*=4.5 Hz, H-2), 7.32 (5H, s, $OCH_2C_6\underline{H}_5$). Found: C, 58.47; H, 5.99; N, 11.81%. Calcd for $C_{17}H_{21}N_3O_5$: C, 58.78; H, 6.09; N, 12.10%.

(1*R*,2*R*,3*R*,4*R*)-1-Acetamido-3-acetoxy-4-(acetoxymethyl)-2-(benzyloxy)cyclopentane (8). To a solution of **7** (440 mg, 1.3 mmol) in a mixture of water and pyridine (1 : 4, 50 ml) was bubbled H_2S at room temperature for 2 h. This solution was stirred more 24 h, and then concentrated in vacuo. The residue was acetylated with acetic anhydride (4 ml) in pyridine (4 ml) for 1 h. The mixture was concentrated in vacuo. The residue was chromatographed on silica gel ($PhCH_3$, then AcOEt/hexane 1 : 1) to give **8** (452 mg, 98%) as a colorless oil: TLC R_f 0.56 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{26}$+41.5° (*c* 1.42, $CHCl_3$); IR ν_{max}^{neat} 3300, 2925, 1730, 1650, 1535, 1360, 1230 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.4-2.5 (3H, m, H-4, 5, 5′), 1.93 (3H, s, $NCOCH_3$), 2.04, 2.06 (each 3H, each s, 2×$OCOCH_3$), 3.71 (1H, d, *J*=5 Hz, H-2), 4.1—4.5 (3H, m, H-1, CH_2OAc), 4.51, 4.81 (each d, each 1H, *J*=12 Hz, $OC\underline{H}_2C_6H_5$), 4.99 (1H, dd, *J*=1 and 3.5 Hz, H-2), 5.90 (1H, d, *J*=8 Hz, NH), 7.3—7.4 (5H, m, $OCH_2C_6\underline{H}_5$); high-resolution mass spectrum, Calcd for $C_{19}H_{25}NO_6$: M, 363.1680, Found: *m/z* 363.1680.

(1*R*,2*R*,3*R*,4*R*)-1-Acetamido-2,3-diacetoxy-4-(acetoxymethyl)cyclopentane (9). A solution of **8** (443 mg, 1.2 mmol) in a mixture of cyclohexene (10ml) and EtOH (6 ml) in the presence of 20% $Pd(OH)_2$ on charcoal (600 mg) was refluxed for 2 h. The catalyst was removed through a Celite pad, and the filtrate was concentrated in vacuo. The residue was acetylated with acetic anhydride (4 ml) in pyridine (4 ml) for 2 h. The reaction mixture was concentrated in vacuo. The residue was chromatographed on silica gel (EtOH/$PhCH_3$ 1 : 20) to give **9** (356 mg, 93%) as colorless needles, mp 125.5—126.5 °C: TLC R_f 0.36 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{31}$+28.8° (*c* 0.86, $CHCl_3$); IR ν_{max}^{neat} 3300, 1745, 1660, 1545, 1440, 1375 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ=1.40—1.48 (1H, m, H-5), 1.99 (3H, s, $NCOCH_3$), 2.07, 2.13 (6H, 3H, each s, 3×$OCOCH_3$), 2.25—2.40 (2H, m, H-4, 5′), 4.07—4.19 (2H, m, CH_2OAc), 4.55—4.63 (1H, m, H-1), 4.92 (1H, dd, *J*=2.4 and 4.9 Hz, H-3), 5.08 (1H, dd, *J*=2.4 and 5.4 Hz, H-2), 5.62 (1H, d, *J*=8.8 Hz, NH); high-resolution mass spectrum, Calcd for $C_{14}H_{22}NO_7$: M+H, 316.1394. Found: *m/z* 316.1387. Found: C, 53.14; H, 6.49; N, 4.47%. Calcd for $C_{14}H_{21}NO_7$: C, 53.33; H, 6.71; N, 4.44%.

(1*R*,2*R*,3*R*,4*R*)-2,3-Dihydroxy-4-(hydroxymethyl)cyclopentanamine (2). A solution of **9** (32 mg, 0.1 mmol) in 2 M aqueous HCl (2 ml) was heated at 70 °C for 2 h, and then concentrated in vacuo. The residue was dissolved in water (2 ml) and the aqueous solution was neutralized by addition of Amberlite IRA-400 (OH^-). The resin was removed, and the filtrate was concentrated in vacuo. The residue in a small amount of water was applied on a column of Amberlite CG-120 (H^+). The column was eluted with 0.1 M aqueous NH_4OH to give **2** (12 mg, 81%) as a colorless oil: TLC R_f 0.43 (MeOH/water 1 : 2); $[\alpha]_D^{22}$−125.8° (*c* 0.56, H_2O); ^{1}H NMR (90 MHz, CD_3OD) δ=1.1—2.4 (4H, m, H-1, 4, 5, 5′), 3.50, 3.56 (2H, each s, $C\underline{H}_2OH$), 3.4—4.0 (2H, m, H-2, 3); ^{13}C NMR (100 MHz, $CD_3\underline{O}D$) δ=33.69, 47.24, 53.55, 64.79, 79.74, 79.86; high-resolution mass spectrum, Calcd for $C_6H_{13}NO_3$: M, 147.0894. Found: *m/z* 147.0886.

9-[(1*R*,2*R*,3*R*,4*R*)-2,3-Dihydroxy-4-(hydroxymethyl)cyclopentyl]adenine, (+)-Cyclaradine (1). Compound **9** (216 mg) was hydrolyzed as described above. After neutralization of the reaction solution with Amberlite IRA-400, the filtrate was concentrated to give **2** (141 mg) which was used without further purification. A mixture of **2** and 5-amino-4,6-dichloropyrimidine (674 mg, 4.1 mmol) in 1-butanol (45 ml) was refluxed for 22 h in the presence of triethylamine (0.96 ml, 6.9 mmol). The reaction mixture was then concentrated in vacuo. The residue was dissolved in water (100 ml), and this was washed with $CHCl_3$ (20 ml×5). The combined organic phases were extracted with water (100 ml×2). The combined aqueous phases were concentrated, and the residual yellow crystals were dissolved in water (3 ml), then this aqueous solution was heated with active carbon. This was filtered, and the filtrate was concentrated in vacuo. The resultant white solids were chromatographed on silica gel (EtOH/$PhCH_3$ 1 : 9) to give 5-amino-4-chloro-6-[[(1*R*,2*R*,3*R*,4*R*)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentyl]amino-pyrimidine (**11**) (140 mg) as white powders: IR ν_{max}^{KBr} 3340, 2920, 1570, 1410 cm^{-1}; ^1H NMR (90 MHz, CD_3OD) δ=1.3—2.6 (3H, m, H-4, 5, 5′ of the cyclopentane ring), 3.59, 3.65 (each 1H, each s, $C\underline{H}_2OH$), 3.7—3.9, 3.9—4.1 (each 1H, each m, H-2, 3 of the cyclopentane ring), 7.74 (1H, s, H-2 of the pyrimidine ring).

A solution of **11** (115 mg) in a mixture of DMF (12 ml) and triethyl orthoformate (0.7 ml) was heated at 60 °C under 13 mmHg[††] in the presence of *p*-TsOH (80 mg). After 1 h, *p*-TsOH (10 mg) was added and the mixture was heated for total 2 h. The reaction mixture was neutralized with Amberlite IRA 400 (OH^-), and the resin was removed. The filtrate was concentrated in vacuo. The residue in a small amount of water was applied on a column of Amberlite CG-120 (H^+). The column was eluted with water to give 6-chloro-9-[(1*R*,2*R*,3*R*,4*R*)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentyl]-purine (**12**) (89 mg) as white powders: IR ν_{max}^{KBr} 3380, 2920, 1595,1560, 1490 cm^{-1}; ^1H NMR (90 MHz, CD_3OD) δ=1.9—2.6 (3H, m, H-4, 5, 5′ of the cyclopentane ring), 3.65, 3.70 (each 1H, each s, $C\underline{H}_2OH$), 3.88 (1H, t, J=3 Hz, H-2 or 3 of the cyclopentane ring), 4.01 (1H, dd, J=3 and 6 Hz, H-3 or 2 of the cyclopentane ring), 5.0—5.3 (1H, m, H-1 of the cyclopentane ring), 8.49, 8.53 (each 1H, each s, H-2 and 8 of purine ring).
