Assuming that HPC molecules adsorb both on the HPC monolayer deposited on the support and on the surface of the support, critical values of m=0.30 or 0.60 can be expected if one or two layers are available respectively. The value of m at the limiting value of the apparent rate constant m_L for H_3PMo/SiO_2-200 in

Table 1. Limiting Activity for the Dehydration of Liquid TBA

HPC[a]	m_L[b] mmol/g-supt	θ_L[c]	$k_L \times 10^3$[d] min^{-1}
H_3PMo	0.55	1.82	5.30
KH_2PMo	0.30	1.01	11.25
K_2HPMo	0.30	1.02	9.15
K_3PMo	0.35	1.20	2.40
Na_3PMo	0.60	1.01	2.00
Cs_3PMo	0.35	1.20	2.25
$(BiO)_3PMo$	0.30	1.22	1.40
H_3PW	0.40	1.79	8.50
K_3PW	0.25	1.15	1.25
$(NH_4)_3PW$	0.25	1.13	1.75

a) The support used is AEROSIL-200 (S=200 $m^2 g^{-1}$). b) m_L means the amount of HPC supported reached at the limiting activity. c) θ_L means the surface coverage given by Eq. 15 at m_L. d) k_L is the limiting activity.

Table 1 agrees well with the latter one. For the other catalysts studied, the values of m_L are in harmony with either critical one.

The number of layers of HPC available for the dehydration of TBA θ_L is, estimated as:

$$\theta_L = m_L/m_1 \quad (15)$$

where m_1 represents the amount of HPC required for the formation of a monolayer on a support. As θ_L=1.82 for H_3PMo/SiO_2-200 is obtained, it is presumed that two layers at the surface of H_3PMo take part in the dehydration of liquid TBA. For the cation-substituted catalyst KH_2PMo/SiO_2-200, on the contrary, the value of θ_L is estimated to be 1.01, implying that only one layer takes part in the catalytic reaction. The difference in the thickness of the pseudo-liquid phase between HPA and its salts may be attributable to the difference in their hydrophilic/hydrophobic properties. Consequently, it is presumed that the dehydration of liquid TBA using the supported HPC proceeds through a pseudo-liquid mechanism.

Effect of Water. Figure 4 shows the plots of the K_W/K_B ratio against the amount of H_3PW and its potassium salts supported on AEROSIL-200. It is apparent that the K_W/K_B ratio decreases with the increase in the number of hydrogen ions substituted n from 1 to 3, this is consistent with the magnitude of the k_1' value. There is no doubt that the anomalously low activity of HPA for the dehydration of TBA compared with those of its salts is attributable to the adsorption of water: the greater the number of hydrogen ions substituted, the more hydrophobic the resulting catalyst is. The cause is the decrease in the affinity of HPC for alcohol. Similar results were also obtained for H_3PMo and its potassium salts (Table 1). It is, therefore, concluded that the hydrophobic/hydrophilic properties of the surface for the supported catalyst are a primary factor affecting their catalytic

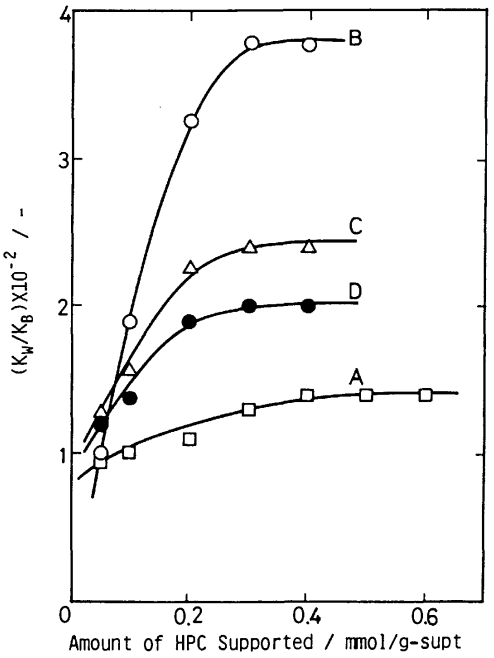

Fig. 4. The plots of K_W/K_B as a function of the amount of $K_nH_{3-n}PW$ supported on AEROSIL-200 m; A: n=0, B: n=1, C: n=2, D: n=3.

activity for the dehydration of liquid TBA.

In Fig. 5, the rate constant k_1 is plotted as a function of the amount of H_3PW and its potassium salts supported on AEROSIL-200. The value of k_1 increases with the HPC loadings until it reaches a maximum at m=0.20; thereafter decreases. At the maximum, θ_L=1, so that the increase in the rate constant at low loadings may be ascribed to the two-dimensional network formation of H_3PW molecules, while the decrease at higher loadings seems due to the stacking effect of HPC molecules on each other. Also, it is presumed that the cluster of HPC in the two-dimensional network works more effectively as a catalyst than does the HPC molecule distributed separately.

Effect of Surface Area of Support. Concerning the surface area of the support, the relative activity of HPC is found to be enhanced as the surface area decreases (Table 2). This may come from the fact that the smaller the surface area is, the easier the two-dimensional network formation of HPC should be.

Comparison of Heterogeneous and Homoeneous Catalysts. The elution of HPA in the heterogeneous system mentioned above has been examined. The kinetics of the dehydration of TBA in the homogeneous systems with the H_3PMo and H_3PW solutions confirms that the reaction proceeds through the same mechanism as does that of the heterogeneous system. H_3PW was found to be more active than H_3PMo, which is the same in the heterogeneous system. A comparison between the heterogeneous and the homogeneous systems indicates that the apparent rate constant of the heterogeneous one is much larger than

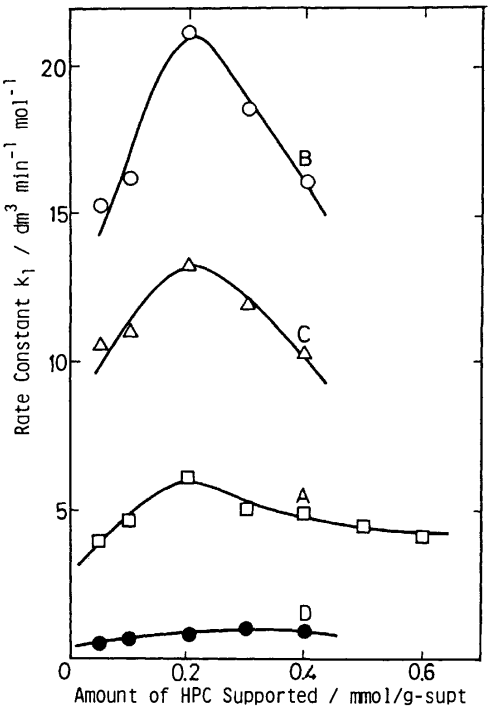

Fig. 5. The plots of rate constant k_1 as a function of the amount of $K_nH_{3-n}PW$ with supported on AEROSIL-200 m; A: n=0, B: n=1, C: n=2, D: n=3.

that of the homogeneous one by a factor of 10. The HPA (6.2, 7.2, and 10.5%) was eluted into the solution in 20 min in the heterogeneous system with H_3PMo, with m=0.20, 0.40, and 0.80 respectively. Hence, under these conditions, the elution of H_3PMo is not considered to affect the activity significantly, especially the initial activity.

Kineties of the Dehydration of Gaseous *t*-Butyl Alcohol. For the dehydration of gaseous TBA, the conversion become constant in 10 min, whatever the catalyst examined. Figure 6 shows plots of the conversion X(gas) as a function of the contact time W/F, in which W denotes the weight of the catalyst (g). There is no doubt that the dehydration of gaseous TBA proceeds through a zero-order reaction.

Assuming the reaction:

$$\text{TBA}\cdot\text{Catalyst} \xrightarrow{k_0} \text{IB} + H_2O + \text{Catalyst} \quad (6')$$

where k_0 is the rate constant for Reaction 6′ per gram of the catalyst (mol g^{-1} h^{-1}), the rate for Reaction 6′ V (mol h^{-1}) is given by:

$$V = k_0\cdot[\text{TBA}\cdot\text{Catalyst}] \quad (16)$$

where [TBA·Catalyst] is the weight of the species TBA·Catalyst (g). If K_B is big enough, and if K_W is small enough to neglect, Eq. 16 should be expressed as:

$$V = k_0\cdot[\text{Catalyst}] = k_0\cdot W \quad (17)$$

where [Catalyst] is the weight of the catalyst (g). By combining Eqs. 2 and 17, the following relation is derived:

$$X(\text{gas}) = k_0\cdot W/F\times 100 \quad (18)$$

The rate constant k_0 was obtained from the slopes given in Fig. 6 at a constant temperature. It is noticeable that the activity of the catalyst was decreased markedly after the feed had been stopped once or when the reaction temperature was raised over 473 K. However, it was re-activated by calcination at 573 K for 3 h. Further investigations of this point are in progress.

Effect of the Amount of HPC Supported for the Gas-Phase Dehydration of *t*-Butyl Alcohol. Figure 7 shows the plot of the rate constant k_0 as a function of the amounts of various HPCs supported on AEROSIL-200. It is obvious that the rate constant k_0 increases with the increase in the amount of HPC supported at the low loadings and is in the order of: $H_3PW \fallingdotseq H_3PMo > KH_2PMo > K_2HPMo > K_3PMo$, in harmony with the increase in the number of hydrogen ions replaced by potassium. For the H_3PMo/SiO_2-200 and H_3PW/SiO_2-200, the values of m_L at the maximum rate constant were 0.25—0.30 (θ_L=0.83—0.99) and 0.20 (θ_L=0.90) respectively. These values are remarkably different from those for the dehydration of liquid TBA, supporting the idea that only the first layer of HPC in contact with reaction gases takes part in the dehydration of gaseous TBA. It is, therefore, concluded that the dehydration proceeds through the outer-surface mechanism.

Table 2. Limiting Activity for the Dehydration of Liquid TBA

Catalyst	m_L[a]	θ_L[b]	$k_L\times10^3$[c]	$k_L/S\times10^5$[d]
	mmol/g-supt		min^{-1}	min^{-1} m^{-2} g
H_3PMo/AEROSIL-OX50[e]	0.15	1.98	3.00	6.00
H_3PMo/AEROSIL-130[f]	0.35	1.78	3.45	2.65
H_3PMo/AEROSIL-200[g]	0.55	1.82	5.30	2.65
H_3PMo/AEROSIL-300[h]	0.75	1.62	7.20	2.40
H_3PMo/AEROSIL-380[i]	1.00	1.74	8.35	2.20

a) m_L means the amount of HPC supported reached at the limiting activity. b) θ_L means the surface coverage given by Eq. 15 at m_L. c) k_L is the limiting activity. d) k_L/S means the relative activity per unit of surface area. d—h) The supports used have the surface areas S of e) 50, f) 130, g) 200, h) 300, and i) 380 m^2 g^{-1}.

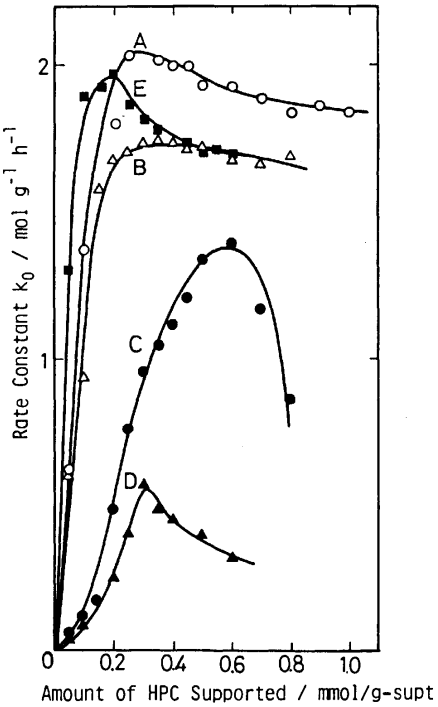

Fig. 7. The plots of the rate constants for the dehydration of gaseous TBA k_0 at 453 K against the amount of HPC supported on AEROSIL-200 m; A: H_3PMo/SiO_2-200, B: KH_2PMo/SiO_2-200, C: K_2HPMo/SiO_2-200, D: K_3PMo/SiO-200, E: H_3PW/SiO_2-200.

At higher loadings of HPC, X-ray diffraction confirmed that they were crystallized. If the diffusion of TBA in the crystal of HPC plays a significantly important rôle in its dehydration rate, the activation energy should depend on the amount of the supported HPC. However, as may be seen in Table 3, the activation energies for the gas-phase dehydration using H_3PMo/SiO_2-200 are independent of the amounts loaded. It is, therefore, presumed that the reaction at the surface is the rate-determining step for the dehydration of gaseous TBA. These results also supported the outer-surface mechanism.

In the dehydration of gaseous TBA using HPA and its potassium salts, the order for the activity with respect to the substitution of hydrogen ions of HPA can reasonable interpreted in terms of the acidity. In the dehydration of liquid TBA, on the contrary, the activity of HPA is not consistent with the order of the acidity. It is conceivable that the extremely low activity of HPA is due to the adsorption of water at the surface of the catalyst.

Concerning the species formed by the replacement of the hydrogen ion by the potassium ion, it has been reported that only one species, $K_3PMo_{12}O_{40}$, is formed, while the $H_3PMo_{12}O_{40}$ species grows epitaxially on its surface.[13] Taking this into consideration, the species with the compositions of K_2HPMo and KH_2PMo are considered to be mixtures of the $H_3PMo_{12}O_{40}$ and $K_3PMo_{12}O_{40}$ species, with K/HPC molar ratios of 2

Table 3. Activation Energy for the Dehydration of Gaseous TBA over HPC Supported on AEROSIL-200

m[a]	Activation energy/kJ mol^{-1}				
mmol/g-supt	H_3PMo[b]	KH_2PMo[b]	K_2HPMo[b]	K_3PMo[b]	H_3PW[b]
0.05	27.2	38.2	39.0	38.2	17.4
0.10	26.6	34.9	35.2	35.8	15.4
0.25	26.8	19.1	20.8	50.7	10.0
0.40	26.2	18.3	18.3	25.7	10.4
0.70	27.0	10.0	17.4	36.6	—
1.00	27.0	—	—	—	—
Free[d]	1.9	—	—	—	—

a) m means the amount of HPC supported on AEROSIL-200. b) The support used is AEROSIL-200 (S=200 m^2 g^{-1}). d) "Free"the support-free H_3PMo-HPA.

and 1 respectively. It can, therefore, be speculated that, at low loadings of HPC, the two species are formed simultaneously on the silica support, while at higher loadings the $H_3PMo_{12}O_{40}$ species is stacked on the $K_3PMo_{12}O_{40}$.

As may be seen from Fig. 7, the values of m_L are 0.30—0.40 (θ_L=1.01—1.34), 0.60 (θ_L=2.04), and 0.30 (θ_L=1.03), for KH_2PMo/SiO_2-200, K_2HPMo/SiO_2-200, and K_3PMo/SiO_2-200 respectively. The dehydration of gaseous TBA with potassium-substituted HPA is thought to proceed through the outer-surface mechanism. If $H_3PMo_{12}O_{40}$ and $K_3PMo_{12}O_{40}$ are distributed homogeneously, the value of θ_L is expected to be approximately unity. Taking the heterogeneous distribution of $H_3PMo_{12}O_{40}$ and $K_3PMo_{12}O_{40}$ (the growth of the $H_3PMo_{12}O_{40}$ species on the surface of the $K_3PMo_{12}O_{40}$ species) into consideration, however, the theoretically estimated values of θ_L are 1.50 and 3.00 for KH_2PMo/SiO_2-200 and K_2HPMo/SiO_2-200 respectively. The experimental results support the latter distribution (Fig. 7).

The activation energies for K_3PMo/SiO_2-200 are about 37 kJ mol^{-1}, regardless of the amount of HPC supported. As may be seen in Table 3, the activation energies for the gas-phase dehydration using partially potassium-substituted HPA decrease with an increase in the amount of HPC supported: at low loading of HPC supported, the activation energy is similar to the value for K_3PMo/SiO_2-200, while at higher loadings of HPC, it is similar to that for H_3PMo/SiO_2-200. It is, therefore, reasonable to speculate that the $H_3PMo_{12}O_{40}$ and $K_3PMo_{12}O_{40}$ species are distributed heterogeneously on the surface of the catalyst.

In conclusion, it is deduced that, for the partially potassium-substituted catalysts, mixtures of $H_3PMo_{12}O_{40}$ and $K_3PMo_{12}O_{40}$ with different mole ratios are formed and that the surfaces of the catalysts are covered with $H_3PMo_{12}O_{40}$ predominantly.

Selective Preparation of 2,3-Epoxypropanamide and Its Facile Conversion to 2,3-Dihydroxypropanamide with Acidic Resins

Shigeru SUGIYAMA,* Shinji ŌHIGASHI, Ryûichi SAWA, and Hiromu HAYASHI
Department of Chemical Science and Technology, Faculty of Engineering, The University of Tokushima, Minamijosanjima, Tokushima 770
(Received April 18, 1989)

In the equimolar reaction of acrylonitrile with hydrogen peroxide to 2,3-epoxypropanamide (glycidamide), the selectivity and the yield of the epoxide were improved by adding aq. NaOH solution continuously at a constant rate. The conventional literature procedure, by controlled pH from 7.0 to 7.5, resulted in an unfavorable decomposition of hydrogen peroxide. 2,3-Epoxypropanamide could be easily converted to 2,3-dihydroxypropanamide (glyceramide) by a catalytic amount of commercially available acidic resins.

In 1961, Payne and his colleague reported the alkaline epoxidation of acrylonitrile (**1**) with hydrogen peroxide (**2**) to 2,3-epoxypropanamide (**3**), which was hydrated to 2,3-dihydroxypropanamide (**4**) with formic acid.[1] The epoxide (**3**) is a useful intermediate for resins, plant protective and preservative agents, and dyes. An aqueous solution of **4** is equivalent to commercial glyceric acid (65—70% in water). Many articles[2] and patents[3,4] related to the preparation and the properties of **3** have been reported. Payne emphasized that the solution pH should be controlled from 7.3 to 7.5 to obtain **3** in high yield.[1] The succeeding patents[4] also supported his conclusion: that the pH was controlled from 7.0 to 7.5, and improved mainly in the concentration of **2** and the removal of the peroxides. However, an excess of **2** to **1** was sometimes mentioned in those reports,[3,4] where the selectivity of **3** based on **2** must be relatively poor. In the conversion of **3** to **4**, formic acid, which is difficult to remove from the reaction solution, was employed as a catalyst, as mentioned in the literature.[1] If hydration might have occurred with acidic resins, the removal of the acid can be very easy.

Herein, we describe in detail the effect of the pH and the continuous supply of an alkaline solution on the epoxidation of **1** with **2**. The conversion of **3** to **4** with various organic acids and acidic ion-exchange resins is also described.

Experimental

Apparatus and Procedure. Epoxidation of Acrylonitrile (1) to 2,3-Epoxypropanamide (3). To a three-neck, flat-bottom flask equipped with a dropping funnel or a micro-tube pump (MP-101, Tokyo Rika Kikai), a condenser and a standard electrode connected to pH meter (M-5 pH meter, Hitachi-Horiba) were charged with a known amount of *acrylonitrile (1) and hydrogen peroxide (2) (0.2 mol respectively, unless otherwise stated)* in water (total volume of the reaction solution, 100 cm^3) at 35 or 45 °C. The solution was magnetically stirred while a known concentration of aq. NaOH was added through a dropping funnel or a micro-tube pump. After a given reaction period, hydrogen peroxide (**2**) and 2,3-epoxypropanamide (**3**) were analyzed by means of iodometric titration for **2**[5] and titration for oxirane oxygen of **3**,[6] respectively. Furthermore, in order to analyze the other organic species, after the treatment of the reaction solution with 5% palladium carbon to decompose the excess peroxide,[1] and after evaporation of the solution at 50 °C in vacuo, the residue was analyzed with NMR in a DMSO-d_6 solution (Hitachi R-24 spectrometer at 60 MHz); chemical shifts are expressed in the unit δ.

Hydration of 2,3-Epoxypropanamide (3) to 2,3-Dihydroxypropanamide (4). An aqueous solution (30 cm^3) of 18.0 mmol of 2,3-epoxypropanamide (**3**) containing 2.37 mmol of formic acid, acetic acid, carboxylated resin (Amberlite IRC-50, 10 mequiv/g, Rohm and Haas Co.), or sulfonated resin (Amberlyst 15, 4.9 mequiv/g, Rohm and Haas Co.) was allowed to warm at 80 °C. Monitoring of the epoxide (**3**) and 2,3-dihydroxypropanamide (**4**) was carried out with the oxirane titration[6] and the glycol cleavage by periodic acid,[7] respectively.

Materials. Preparation of 2,3-Epoxypropanamide (3). After observing the epoxidation behavior of acrylonitrile (**1**) to 2,3-epoxypropanamide (**3**), the reaction mixture was treated overnight with 5% palladium carbon. After removing the catalyst, the mixture was concentrated at 50 °C in vacuo. To the residue, acetone was added and an insoluble hygroscopic salt was removed by filtration. The solvent was evaporated and the residue was distillated under reduced pressure (bp 90 °C/1.8 mmHg, lit of **3**,[1] 72—73 °/0.2 mmHg 1 mmHg≈133.322 Pa). By using dilute alkali (e.g., 0.2 M NaOH) (1 M=1 mol dm^{-3}) in the epoxidation of acrylonitrile (**1**), acrylamide (**5**) was detected in this fraction; however, upon using 6 M NaOH, the amide (**5**) was not detected with NMR (see Results and Discussion).

2,3-Epoxypropanamide (**3**): ^{1}H NMR (DMSO-d_6) δ= 2.65—3.15 (2H, m), 3.39 (1H, dd, J=5, 3 Hz), and 5.7—7.0 (2H, br m). IR (KBr) 3300, 1660, 1320, 895, and 790 cm^{-1}.

Preparation of 2,3-Dihydroxypropanamide (4). Procedure A. After observing of the hydration behavior of 2,3-epoxypropanamide (**3**) to 2,3-dihydroxypropanamide (**4**) (in the case of the acidic resin, the resin was filtered off), the reaction mixture was evaporated in vacuo at 80 °C. The residue was purified by recrystallization from methanol to give pure diol (**4**).

Procedure B from Glyceric Acid. Commercial glyceric acid (Tokyo Kasei Co., 65—70% in water: the purity was checked by acidmetry; 67.1%; 10.02 g, 63.4 mmol) was dissolved in a mixture of benzene and methanol (1/1 by

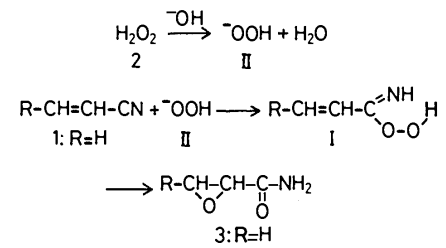
volume). Water was removed by azeotropic distillation. Benzene was also removed by azeotrope with methanol.[8] To this solution, 14% boron trifluoride methanol complex (Wako Co., 96 cm^3, 198 mmol) was added and refluxed for 1 h. The solution was then cooled to room temperature and poly(4-vinylpyridine) (Aldrich, 7.6 mequiv/g: 40.03 g, 304 mequiv) was added to the solution in order to remove the Lewis acid. After the solution was stirred for 15 min, the polymer was filtered off and the filtrate was evaporated. The residue was distillated in vacuo to give methyl glycerate (**6**) (5.77 g, 75.7%). To the methanol solution of **6**, NH_3 gas was bubbled until a spot of **6** in TLC (silica gel 60 GF_{254} (Merck); R_f=0.75 with AcOEt) disappeared. The solution was evaporated in vacuo to give 2,3-dihydroxypropanamide (**4**), almost quantitatively. The diol (**4**) was purified with silica-gel column chromatography (Wakogel C-300 (Wako)) with MeOH-AcOEt (1:1) and recrystallization from methanol.

2,3-Dihydroxypropanamide (4): Mp 85—87 °C (lit,[1] 89—90 °C); Found: C, 34.05; H, 6.58; N, 13.11%. Calcd for $C_3H_7NO_3$: C, 34.29; H, 6.71; N, 13.33%. ^{1}H NMR (CD_3OD) δ=3.68 (2H, m), 4.00 (1H, m). IR (KBr) 3200 and 1640 cm^{-1}.

Methyl Glycerate (6): Bp 92—94 °C/2.1 mmHg (lit,[9] 67—69 °C/0.1 mmHg); Found: C, 40.07; H, 6.85%. Calcd for $C_4H_8O_4$: C, 40.00; H 6.71%. ^{1}H NMR (CD_3OD) δ=3.75 (3H,s), 3.76 (2H, d, J=4 Hz), 4.13 (1H, t, J=4 Hz). IR (KBr) 3400 and 1740 cm^{-1}.

Results and Discussion

Epoxidation of 1 to 3. The Effect of pH. Under a weakly alkaline condition, the reaction of α,β-unsaturated nitrile with hydrogen peroxide forms a peroxycarboximidic acid intermediate (**I**) to give epoxyamide (Scheme 1).[1]



Scheme 1.

In the epoxidation of **1** to **3**, Payne emphasized it was necessary to keep the pH between 7.3 and 7.5 in order to produce **3** in high yield.[1] Indeed, the perhydroxyl anion (**II**) from **2** is generated with alkali.[9] However, an excess of alkali may decompose **2** and polymerize **3**. Thus, the optimum for the yield and selectivity must depend on the concentration of the additive alkaline solution, but not on the pH of the reaction solution.

As shown in Fig. 1, without alkali at 35 °C,[1,10] practically no reaction was observed in the attempted epoxidation. However, according to Payne's procedure, using 1 M NaOH to control the pH from 7.0 to 7.5 at 35 °C,[1] the reaction occurred quickly to give a 38% yield of **3** after 5.2 h, while the selectivity of **3** based on **2** in charge was 45%. In this case, during the initial stage of the reaction, **2** quickly decomposed along with the generation of molecular oxygen. Epoxidation after 2 h was slow due to a lack of **2**. Thus, under this condition, alkali is used both for the generation of **II** from **2** and its decomposition. By controlling pH from 6.0 to 6.5 with 0.5 M NaOH at 35 °C, the consumption of **2** was rather slow and the selectivity of **3** was improved to 63% at 5 h. However, the yield of **3** was scarcely increased (35% at 5 h). These results show that maintaining the pH at an acidic condition can not increase the yield of **3**, while the selectivity can not be improved under a basic condition.

The Effect of Continuous Supply of Aqueous Alkali with Various Concentrations. From the above results, it seemed likely that the yield and the selectivity of **3** might be improved with a continuous addition of an alkaline solution of the appropriate concentration to the reaction solution, instead of the above Payne's procedure. Figure 2 compares the epoxidation behavior for both added 0.2 M and 6 M NaOH at

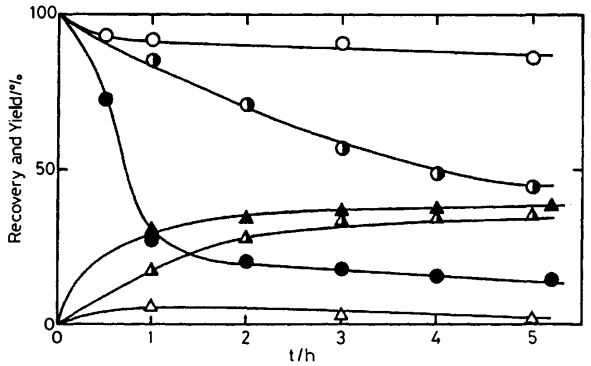


Fig. 1. The effect of pH on the reaction of **1** with **2** at 35 °C.
○: Recovery of **2**. △: Yield of **3**. Open symbols: without alkali. Half-filled symbols: pH at 6.0—6.5. Filled symbols: pH at 7.0—7.5.

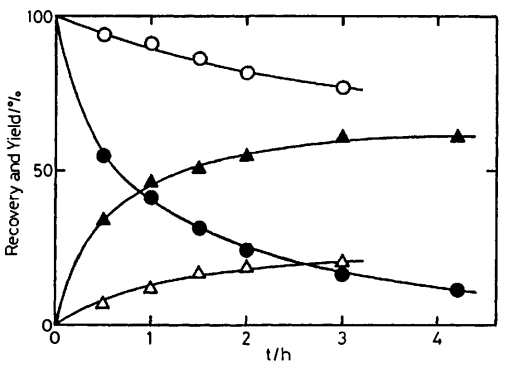

Fig. 2. The effect of concentration of alkali supplying at 1.0 ml h^{-1} on the reaction of **1** with **2** at 45 °C.
○: Recovery of **2**. △: Yield of **3**. Open symbols: addition of 0.2 M NaOH. Filled symbols: addition of 6 M NaOH.

a constant rate of 1.0 ml h^{-1} with a micro-tube pump at 45 °C.[10] In the case of 0.2 M NaOH, the pH was varied between 5.98 and 5.50, and the reaction proceeded very slowly (the yield of **3** was 20% at 3 h), while the selectivity was up to 87% after 3 h. In the case of 6 M NaOH, the pH was varied from 6.34 to 8.51 with the proceeding of the reaction and the yield of **3** increased up to 61% with a relatively poor selectivity of 73% after 3 h. The yield and the selectivity were remarkably improved compared with those of Payne's procedure. During the initial stage, at a reaction time within 1 h, where the concentration of alkali in the reaction solution was low and the pH was less than 6.9, the reaction occurred very quickly with high selectivity. After 1 h, the reaction became slow with lower selectivity and the observed pH was more than 7.0. Therefore, after 1 h, the decomposition of **2** should have occurred prior to epoxidation. Furthermore, in such a strongly alkaline condition (e.g. pH>8), a polymerization of **3** may also be possible (see below).

In Fig. 3, the effects of the concentration of the alkaline solution on the yield of **3**, the conversion of **2**, and the selectivity at 3 h are shown. At a lower concentration (less than 2 M NaOH), the selectivity was relatively good, but the yield was less than 50%. At a higher concentration (more than 3 M NaOH), the yield was better than 50%, but the selectivity was relatively poor. In the present procedure, the yield and the selectivity should depend on both the initial rate of formation of **3** and that of consumption of **2**. As shown in Fig. 4, at a lower concentration (less than 2 M NaOH), the initial rates of formation and consumption overlapped on a single curve to form **3** in high selectivity, while the decrease in the selectivity of **3** was observed at a higher concentration (more than 3 M NaOH) where the rate of consumption of **3** exceeded that of the formation of **2**. The present results show that our improved procedure given above favorably contributes to avoiding the decomposition

of **2** with alkali, and results in increasing both the yield and selectivity of **3**.

The Effect of the Molar Ratio of 1 to 2. According to Payne's procedure,[3] the yield of **3** was affected with a molar ratio of **1** to **2**. This should be related to the decreasing of the selectivity due to the decomposition of **2** with an excess of alkali to maintain the pH. In our procedure, the effect of the alkali must be the most critical factor. We examined the effect of the molar ratio of **1** to **2**. To the solution of a known ratio of **1** and **2** (**1**/**2**=0.1 mol/0.2 mol, 0.2 mol/0.2 mol, or 0.2 mol/0.1 mol, respectively), 0.5 M NaOH was added at 0.9 ml h^{-1}. As shown in Fig. 5, the rate of the forma-

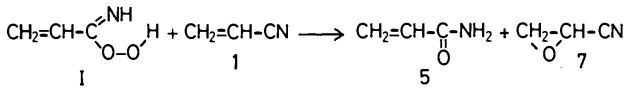
tion of **3** and that of the consumption of **2** are equal in each case. In this case, an excess of alkali did not exist in the reaction mixture and the selective epoxidation to **3** proceeded. It seemed that the rate of formation of **3** and the selectivity were not affected with a molar ratio of **1** and **2** in our procedure.

Formation of 3 via 5. Payne reported that **4** and **5** were given as by-products in the present epoxidation.[1,3] It was apparent that **4** was formed through the hydration of **3**. With our NMR analysis, although the formation of **4** was observed, the reaction mixture had to stand at room temperature for several days. We also detected **5** with NMR in the case of 0.2 M NaOH, where **5** disappeared with time, as shown in Table 1. However, **5** was not detected for a concentration of the alkali higher than 6 M NaOH.

The **5** must be formed by an intermolecular nucleophilic attack of the active intermediate **I** to **1** (Scheme 2).



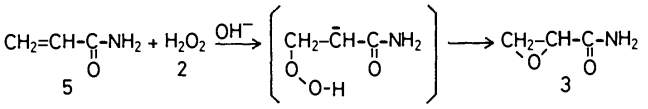
Scheme 2.

2,3-Epoxypropanenitrile (**7**), formed together with **5**, must be reactive to give **3**, successively. The disappearance in 0.2 M NaOH and no formation of **5** in 6 M NaOH could not refer to the oxidation of **5** with **I**. In the oxidation of **5** with **I**, **3** and **5** are formed. Therefore, **5** does not decrease at all with time. Generally,

Table 1. The Behavior of **5** in the Reaction of **1** and **2** with 0.2 M NaOH

t/min	15	45	75	105	150
3/mmol	7	21	23	24	30
5/mmol	8	8	7	3	3

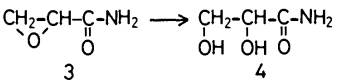
an olefin conjugated with ketons may be oxygenated directly with **2** under the alkaline condition to give an epoxide.[11] In the present case, **5** must be epoxidized directly with **2** to give **3** (Scheme 3).



Scheme 3.

In the reaction with 6 M NaOH, the signals for a polymer of **3** or other organic species scarcely appeared in the NMR spectra.

Hydration of 3 to 4. Payne gave **4** by the hydration of **3** with a catalytic amount of formic acid (1/4 equiv) at 75 °C for 5 h (Scheme 4).



Scheme 4.

A comparison of the hydration at 80 °C with a small amount (ca. 1/10 equiv) of formic acid and acetic acid is shown in Fig. 6.

Obviously, acetic acid was as effective as the stronger acid, formic acid, for the hydration of **3** to afford **4** with the selectivity more than 85%. However, removal of organic acids from the aqueous solution is very difficult to decrease the yield during purification with distillation.[1] By employing acidic resins as a catalyst, the expected product **4** could be separated by simple filtration, and the yield of **4** would be increased. Hydration occurred smoothly on a carboxylated resin (Fig. 6), but it was relatively slow and the selectivity of **4** decreased to less than 74%, presumably due to trapping of the substrate on the resin. In order to increase the yield of **4**, a strongly acidic

sulfonated resin was effectively used (comparable to formic acid, as shown in Fig. 7).

In conclusion, for the preparation of **3** more selectively than the known procedure, a continuous supply of an alkaline solution was a very effective procedure. The hydration of **3** to **4** proceeded smoothly with acidic resins.

The Effect of Alternative Magnetic Field on the Pigment Ejection from Magnetic Anisotropic Gel Beads

Yasuzo SAKAI, Hidefumi TAGUCHI, and Fujio TAKAHASHI*
Department of Applied Chemistry, Faculty of Engineering, Utsunomiya University,
2753 Ishii-machi, Utsunomiya 321
(Received April 20, 1989)

Magnetic anisotropic gel beads (MA gel beads) were prepared by the gelation of a ferrite suspension in a static magnetic field. MA gel beads were found to oscillate in an alternating magnetic field. This oscillation can possibly reduce the thickness of the diffusion layer on the interface between the gel beads and the surrounding solution, so that the substance can be transferred more quickly across the gel-liquid interface. MA gel beads consisted of alginate gel containing ferrite powder and toluidine blue as a pigment. MA gel beads were loaded into a dual glass tube to make a column bed, which was inserted into a coreless coil which produced the alternating magnetic field. The concentration change of the pigment in the effluent from the column was measured during a lapse in time with repeating off and on the input of the alternating magnetic field. The pigment concentration in the effluent upon exposure to the alternating magnetic field increased to twice the maximum value obtained without a magnetic field. The stronger was the static magnetic field at the time of gelation and the alternating magnetic field, the larger was the increase in pigment concentration in the effluent. Also, the higher was the concentration of ferrite in gel beads, the larger was the increase in pigment concentration in the effluent.

There have been many papers concerning the utilization of gel as a carrier for the immobilization of enzymes or microorganisms.[1-3] A gel carrier is generally useful, but not efficient, if a sufficient amount of substrate can not be supplied to immobilized enzymes or microorganisms in the gel. In this case, the diffusion process of a substrate from the liquid bulk to the gel surface and that of the product from the gel to the liquid might produce the rate-determining steps. The mechanical stirring of gel beads reduces the thickness of the diffusion layer on the interface between the gel and the surrounding liquid, and increases the rate of diffusion. However mechanical stirring can possibly to break the gel beads. Although a fluidized bed was utilized, gel beads were so likely to flow out of the column bed that the flow rate of the effluent might not be sufficiently promoted for stirring.[4]

The stirring method was improved by applying a magnetic field.[4-7] Magnetite containing gel beads which exhibit a magnetic isotropic property (MI gel beads) can be moved due to an applied magnetic force. MI gel beads were reported to spin under a revolving magnetic field.[7] However, some aggregation of the beads was unavoidable in the magnetic field.[8] It seemed that the device for magnetic stirring might be a rather sophisticated instruments.[6,7]

We prepared magnetic anisotropic gel beads (MA gel beads), which exhibited a magnetic dipole like that of a magnet. MA gel beads were expected to oscillate owing to the torque, without migration or aggregation to each other in the alternating magnetic field.

This paper presents the results from a fundamental study concerning the magnetic properties of MA gel beads. Concentration measurements of the pigment diffused from inside the gel into the liquid were carried out for surveying the effects of various conditions, such as the strength of an alternating magnetic field, the concentration of ferrite powder in the gel, the size of the gel beads and the strength of the static magnetic field, in which MA gel beads were prepared.

Experimental

MA gel beads were prepared by the following method: A requisite amount of ferrite powder and 0.1 g of sodium alginate were added into 6.5 mmol dm^{-3} toluidine blue in water to make 10 g (whole weight) and mixed homogeneously (mixture A). Also, a solution of 0.1 mol dm^{-3} $CaCl_2$ in 6.5 mmol dm^{-3} toluidine blue was prepared (solution B). Into a dual beaker (inside diameter: 35 mm), 50 cm^3 of solution B were poured and kept at 25 °C. This dual beaker was placed in the center of the gap between the poles of a permanent magnet (diameter of poles: 75 mm, gap: 55—95 mm) and exposed in a magnetic field of various strengths within the range 500—1900 Oersted. Into solution B, 10 g of mixture A were added (drop by drop) by a syringe to make gel beads. These were allowed to leave over a period of 2 h in the static magnetic field. The shape of the MA gel beads became spheroid, the long axes of which were directed parallel to the flux of the static magnetic field. MI gel beads, the shapes of which were almost spherical, were prepared in the same manner, except that the dual beaker was placed far away from magnet.

Figure 1 shows a schematic diagram of the experimental apparatus. The column (inside diameter: 8 mm) was equipped with a water jacket maintained at 25 °C by circulating water. This column was surrounded with an electromagnetic coil which generated an alternating magnetic field owing to a 50-Hz alternating current. The axis of the alternating magnetic flux was set to be parallel with that of column. The column was filled with 4 cm^3 (real volume) of gel beads, producing a bed height of 9 cm^3. A gauze patch was placed at the bottom of column to hold the MA gel beads. Ten mmol dm^{-3} $CaCl_2$ was fed to the column at a flow rate of 17 $cm^3 min^{-1}$. The effluent out of column was fractionated, and each concentration of the pigment in

the effluent was determined by measuring the absorption with a spectrophotometer (Hitachi model 200-20).

In this paper we use cgs·emu as system of units and a permeability constant of, $\mu_0=1$. Therefore, the magnetic strength, H, was obtained by measuring the density of magnetic flux, B, with a Gauss meter (Yokogawa, type 3251), because $H=B$. Subscripts, s and a of H hereafter express the static and alternating magnetic field, respectively. The deviation of H_a in the column was less than 5%.

The movement of MA gel beads was observed by eye and by slow-motion video-tape.

Results and Discussion

MA Gel Beads and MI Gel Beads. Figure 2 shows photographs of the cross sections of MA and MI gel beads. Ferrite powder in MA gel beads was observed to orient along the direction of the magnetic flux. On the other hand, ferrite powder in MI gel beads dispersed without orientation.

MA gel beads were found to stick to the iron plate, having two points of each bead surface on which the magnetic flux was measured to be 10 Oersted or higher. The movement of an MA gel bead in water was observed in the alternating magnetic field. The bead was observed to leap. This motion was examined with slow-motion video-tape, showing MA gel beads which did not follow the 50-Hz field: At a magnetic strength of 200—500 Oersted, the long axes of the MA gel beads were observed to be at right angles to the magnetic flux, and oscillated at an angle of several to 10 and more degrees. They occasionally rotated to the long axis of the MA gel bead. These results suggest that MA gel beads might possess magnetic poles and a magnetic moment like a magnet.

MI gel beads, on the contrary, exhibited neither magnetic attraction to iron plate in a non-magnetic field nor oscillation under an alternating magnetic field.

The Diffusion Rate of Pigment from MA Gel Beads.

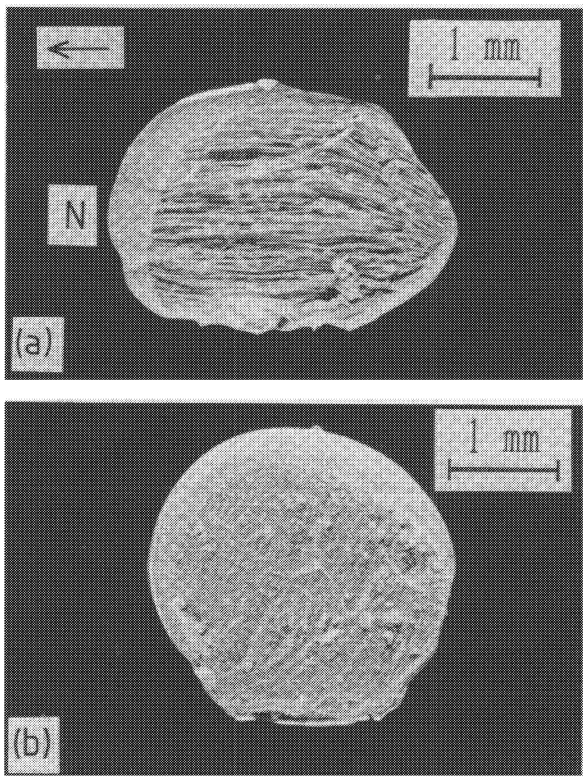

Fig. 2. Photographs on cross sections of an MA gel bead and an MI gel bead. (a): An MA gel bead, which contained 5% ferrite and was prepared in H_s=1600 Oersted. The direction of magnetic flux is shown by an arrow. N and S show north and south as both poles of a bead. (b) An MI gel bead, which contained 5% ferrite and was prepared in H_s<0.5 Oersted.

MA or MI gel beads filling the column were exposed to the alternating magnetic field. The concentration change of toluidine blue as pigment in the effluent was determined. The results are shown in Fig. 3. The concentration of toluidine blue in the effluent gradually decreased with a lapse of time, and increased only when MA gel beads were exposed to the alternating magnetic field. No concentration change of toluidine blue occurred in the case of MI gel beads.

It should be noticed that the surface area of the MA gel beads might not change, since these beads did not transform under a magnetic force in the magnetic field. Meanwhile, the rate of the efflux was kept constant. Therefore, it is reasonable that only the rate change of molecular transfer across the interface between the surface of the gel beads and the liquid bulk may exert to the concentration change of toluidine blue in effluent. The oscillation of MA gel beads may cause a decrease in the thickness of the diffusion layer on the interface between the surface of the gel beads and the liquid bulk, and to increase the concentration of toluidine blue in the effluent.

The Factors Influencing on Efflux of Pigment from MA Gel Beads. The effects of the strength of the

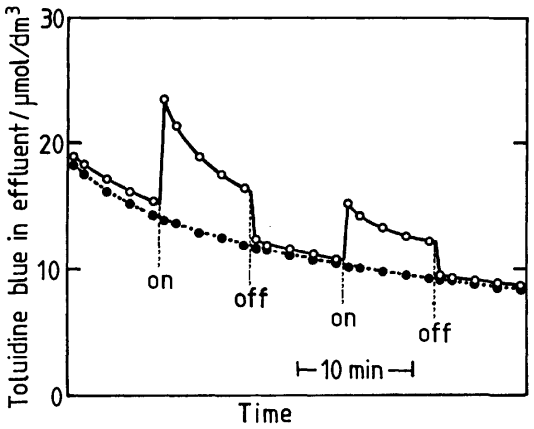

Fig. 3. The concentration change of pigment in effluent by exposing alternating magnetic field off and on. MA gel beads (—○—) prepared in H_s=1600 Oersted and MI gel beads (—●—) prepared in H_s<0.5 Oersted. H_a=600 Oersted. Ferrite concentration in gel beads: 5%. Average diameter of gel beads: 2.7±0.3 mm.

alternating magnetic field (H_a), the concentration of the ferrite powder in the gel, the size of the gel beads and the strength of the static magnetic field (H_s) for producing MA gel beads on the concentration change of the pigment in the effluent were surveyed.

Figures 4, 5, 6, and 7 show the results concerning the concentration change of toluidine blue in the effluent with a time lapse under various conditions. It was found from the inserted figures in Figs. 4—6 that the ΔC_s (the values of subtraction of the toluidine blue concentration before and after exposing magnetic field) are almost proportional to H_a, the size of the gel beads and the concentration of the ferrite powder, respectively. Figure 7 shows that no change appeared below 500 Oersted. It seems that ΔC may be proportional to H_s as a function of the second degree in the region above 500 Oersted in the inserted figure in Fig. 7. These results suggest that the static magnetic field might be the most effective factor concerning the concentration change of the pigment in the effluent.

The magnetic force from both poles in the gap of magnet to ferrite powder inside the gel caused the shape of MA gel beads to be slightly ellipsoidal. This fact was more clearly observed at higher H_s.

The magnetic moment of MA gel beads is produced by the orientation of ferrite powder inside the gel parallel to the direction of the magnetic flux. It seems that the more the NS poles of each ferrite particle of powder are forced to orient parallel to the magnetic flux with elevating H_s, the more the magnetic moment of MA gel beads increases. Also, the magnetic moment may increase with increasing the size of the MA gel beads. The magnetic moment of MA gel beads brings about a torque which is the product of H_a and the magnetic moment of the gel

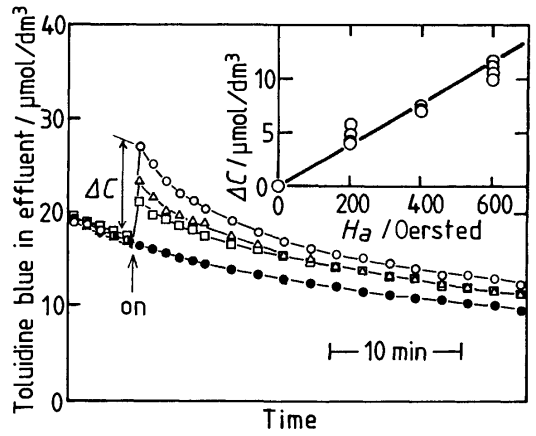

Fig. 4. The relation between ΔC and H_a. H_a=600 (—○—), 400 (—△—), 200 (—□—), and 0 (—●—) Oersted. Other conditions were the same as those in Fig. 3.

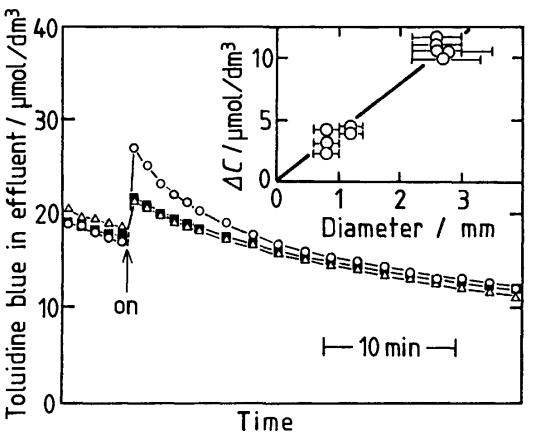

Fig. 5. The relation between ΔC and the size of average diameters of gel beads. Gel beads diameter were 2.6 (—○—), 1.2 (—■—), and 0.8 (—△—) mm. Other conditions were the same as those in Fig. 3.

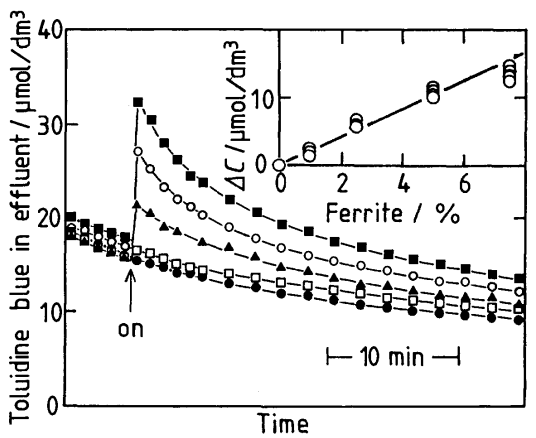

Fig. 6. The relation between ΔC and ferrite concentration in gel. Ferrite concentrations: 7.5 (—■—), 5.0 (—○—), 2.5 (—▲—), 1.0 (—□—), and 0 (—●—) %. Other conditions were the same as those in Fig. 3.

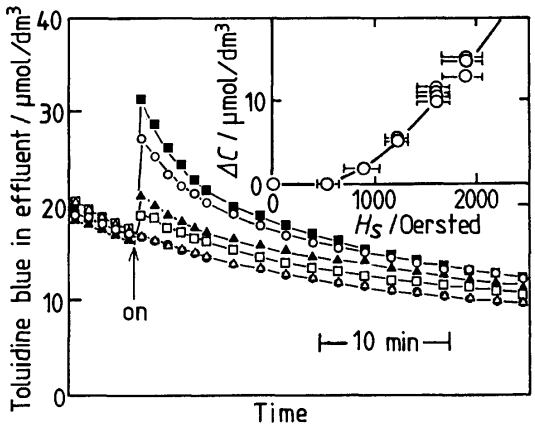

Fig. 7. The relation between ΔC and H_s. H_s=1900 (—■—), 1600 (—○—), 1200 (—▲—), 900 (—□—), 500 (—●—), and 0 (—△—) Oersted. Other conditions were the same as those in Fig. 3.

beads in the magnetic field. MA gel beads oscillate owing to the torque. It is plausible that the diffusion layer on the surface of gel beads reduces the thickness by intensifying the oscillation of MA gel beads. In order to obtain ΔC. H_s has to be pushed up more than 500 Oersted in Fig. 7. This fact indicates the existence of a threshold: The magnitude of the torque must overcome the frictional resistance caused by the thrust of MA gel beads on each other. In this connection, the oscillation can prevent the aggregation of gel beads with each other.

Conclusion

It was demonstrated that MA gel beads prepared in a static magnetic field oscillated due to the torque produced by an alternating magnetic field. The oscillation of MA gel beads promoted the velocity of pigment ejection from the inside gel beads to the liquid bulk, as compared with no alternating magnetic field. This is different from the behavior of MI gel beads in a magnetic field. It is obvious from Figs. 2 and 4—7 that (1) the orientation of magnetite powder in gel in the static magnetic field yields the magnetic moment. (2) the magnitude of the magnetic moment of MA gel beads varies as the concentration of ferrite powder in the gel, the size of MA gel beads and H_s for gelation, and (3) the magnitude of the torque of MA gel beads increases with increasing H_a. We discussed this phenomena in this paper. A theoretical analysis of the relation between the oscillation and the magnetic moment of MA gel beads will be presented in a separate paper.

The J-Like Structures of Azobenzene-Containing Amphiphiles, $C_{10}AzoC_5N^+Br^-$ and $C_8AzoC_5N^+Br^-$

Kenji OKUYAMA,* Chiyo MIZUGUCHI, Guiqing XU, and Masatsugu SHIMOMURA
Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received March 20, 1989)

Totally synthetic azobenzene-containing amphiphiles $C_{10}AzoC_5N^+Br^-$ and $C_8AzoC_5N^+Br^-$ ($C_{31}H_{50}N_3O_3Br$ and $C_{29}H_{46}N_3O_3Br$ respectively) were crystallized from their solutions by the solvent-evaporation method. Both crystals are triclinic, with the space group of $P\bar{1}$ and $Z=2$. The unit cell dimensions of the former crystal are $a=3.233(5)$, $b=0.854(2)$, $c=0.608(1)$ nm, $\alpha=106.96(8)$, $\beta=86.6(1)$, and $\gamma=88.3(1)°$. Those of the latter crystal are $a=3.0098(6)$, $b=0.8553(2)$, $c=0.6084(1)$ nm, $\alpha=72.99(1)$, $\beta=92.57(2)$, and $\gamma=95.64(2)°$. The crystal structure of $C_{10}AzoC_5N^+Br^-$ was solved by the direct method and refined by the block-diagonal least-squares method: $R=0.082$ for 2927 observed reflections ($2\theta<120°$, Cu $K\alpha$, $\lambda=0.15418$ nm). On the other hand, that of $C_8AzoC_5N^+Br^-$ was refined by the full-matrix least-squares method: $R=0.058$ for 2993 reflections ($2\theta<120°$, Cu $K\alpha$). The molecular and crystal structures of these compounds are quite similar to those of the homologous compounds, $C_{12}AzoC_5N^+Br^-$ and $C_6AzoC_5N^+Br^-$. That is, the $C_nAzoC_5N^+Br^-$ molecules incline about 30° to the bilayer surface to pack in a tail-to-tail fashion. The azobenzene chromophore has a pronounced planarity which makes possible the parallel stacking of adjacent phenyl groups.

Totally synthetic azobenzene-containing amphiphiles with a single alkyl chain, $C_nAzoC_mN^+Br^-$ (Fig. 1), show several types of azobenzene chromophore-aggregation states, depending on the number of carbon atoms in the tail part (n) and the spacer part (m).[1] Different aggregation states of the azobenzene chromophores cause different types of orientation of the transition dipole of the long axis of the chromophore, detectable as a bathochromic or a hypsochromic shift of the absorption spectrum. According to a semi-quantitative application of Kasha's molecular exciton theory,[2] the hypsochromic shift is attributable to the parallel (or side-by-side) orientation of the transition dipole (H-aggregate). This aggregation state was confirmed by an X-ray diffraction study of the cast films of $C_8AzoC_{10}N^+Br^-$.[3] On the other hand, the bathochromic shift is derived from the head-to-tail orientation between adjacent transition dipoles (J-aggregate). This type of aggregation was found in the single crystals, casted films, and the aqueous dispersion of $C_nAzoC_5N^+Br^-$ (n=12, 10, 8, and 6). In the cases of n=12 and 6, their crystal structures were determined in detail by the X-ray single crystal structure analyses and bore out the J-aggregation of azobenzene chromophores at the atomic level.[4,5]

In this paper, the crystal structures of the two compounds (n=10, 8) in the family of $C_nAzoC_5N^+Br^-$ will be determined for the further understanding of the stereochemical characteristics of the J-aggregation.

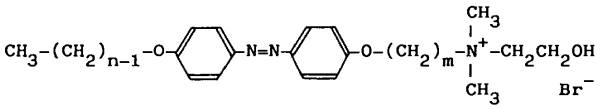

Fig. 1. Chemical formula of azobenzene-containing single chain amphiphiles (abbreviated as $C_nAzoC_5N^+Br^-$).

Experimental and Structure-Determination

Materials. The $C_{10}AzoC_5N^+Br^-$ (15 mg) was dissolved in a boiling solution (18 ml) of water and ethanol (water/ethanol=1/1 by volume ratio). Yellow, plate-like crystals with a thickness of about 0.02 mm were deposited from the solution by the solvent-evaporation method for about a week at room temperature. Single crystals of $C_8AzoC_5N^+Br^-$ were obtained by a similar method using a solution of ethanol and benzene (ethanol/benzene=1/2 by volume ratio).

X-Ray Work. The lattice parameters and diffraction intensities of $C_{10}AzoC_5N^+Br^-$ were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation (λ=0.15418 nm). Those of $C_8AzoC_5N^+Br^-$ were measured on the same type of diffractometer with graphite-monochromatized Cu $K\alpha$ radiation (RASA-5RII). The lattice parameters were refined by the least-squares fit using 31 reflections in the 2θ range of 10—50° for $C_{10}AzoC_5N^+Br^-$ and 25 reflections in the 2θ range of 45—50° for $C_8AzoC_5N^+Br^-$. Crystal data are listed in Table 1. Since the peak profiles of the reflections from the $C_{10}AzoC_5N^+Br^-$ crystal used for data collection were broken into two parts, a considerably wide scan-width was applied. The densities of the crystals were measured by the flotation method in a hexane and tetrachloromethane solution.

Three reference reflections, monitored every 50 reflections, showed no significant intensity-deterioration during the data collection of either sample. Corrections were made for the Lorentz and polarization factors, but not for the absorption and extinction effects. The experimental conditions are summarized in Table 1.

Structure-Determination. The structure of the $C_{10}AzoC_5N^+Br^-$ crystal was solved by the direct method with the MULTAN 78 program,[8] and the atomic parameters were refined by the block-diagonal least-squares method. On the other hand, the direct method with the SAPI 85 program[9] was applied to the structure of the $C_8AzoC_5N^+Br^-$ crystal and the atomic parameters were refined by the full-matrix least-squares method. The quantity minimized in the refinement was $\sum w(|F_o|-|F_c|)^2$, with w=1.0 in the case of $C_{10}AzoC_5N^+Br^-$ and with $w=1/(\sigma^2(F)+(0.01\times F_o)^2)$ in the other case. In the refinement, the reflections with $F_o<3\sigma$ were excluded from the reflection data. After several refinement cycles, the magnitudes of the observed structure factors of ($h00$) reflections were found to be consistently smaller than those of the calculated ones in both crystals. The same phenomenon was observed in the structure analyses of $2C_nN^+2C_1Br^-$ (n=18, 14);[6,7] it is attributable to the absorption effect originating from the very thin plate-like crystal shape and its long lattice constant normal to the plate

surface and from the fairly large absorption coefficient. Therefore, the (h00) reflections with $h<9$ for $C_{10}AzoC_5N^+Br^-$ and those with $h<10$ for $C_8AzoC_5N^+Br^-$ were excluded from the corresponding reflection data set at the final stage of the analyses. The final R values were 0.082 for all the non-hydrogen atoms and for the 46 hydrogen atoms of $C_{10}AzoC_5N^+Br^-$ and 0.058 for all the non-hydrogen atoms and for the 44 hydrogen atoms of $C_8AzoC_5N^+Br^-$. The final atomic parameters for non-hydrogen atoms are given in Tables 2 and 3.[10]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography, Vol. IV.[11] Computations for $C_{10}AzoC_5N^+Br^-$ were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University, and on a HITAC M-280H computer at the Computer Center, University of Tokyo, with the help of the UNICS III program.[12] Those for $C_8AzoC_5N^+Br^-$ were done on an A-70 minicomputer with the aid of the CRYSTAN program in the RASA5R-II system (Rigaku Denki).

Results and Discussion

Molecular Conformation of $C_{10}AzoC_5N^+Br^-$ and $C_8AzoC_5N^+Br^-$. The bond distances and angles are shown in Fig. 2, together with their atomic labelling for non-hydrogen atoms. The numbering system of these atoms is the same as those of homologous compounds analyzed previously.[4,5] The average C-C bond distance and C-C-C bond angle in the alkyl spacer and the tail parts are 0.151(3) nm and 113(1)° for $C_{10}AzoC_5N^+Br^-$, and 0.151(2) nm and 113(1)° for $C_8AzoC_5N^+Br^-$. These values are in good agreement with those reported previously for the long hydrocarbon chains of the amphiphilic compounds.[4-7,13,14]

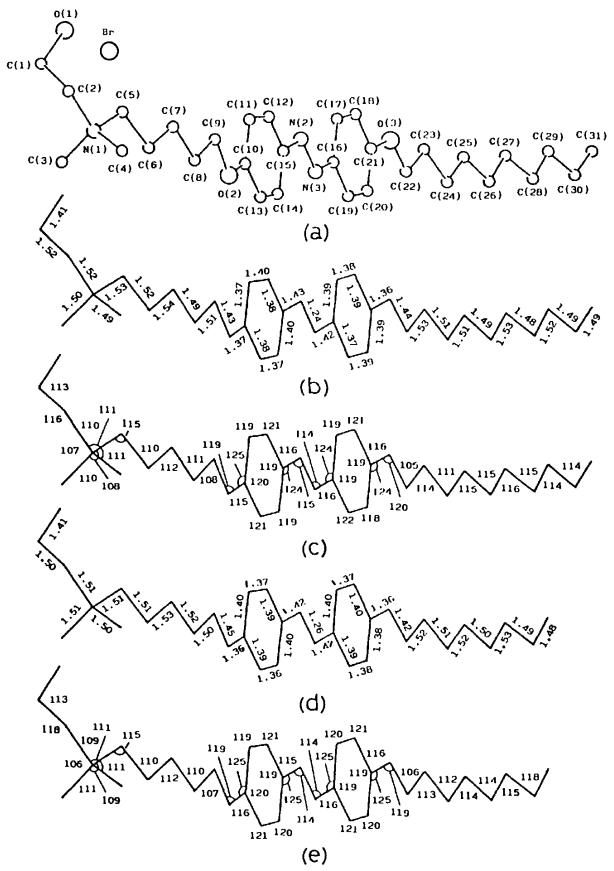

Fig. 2. Atomic labelling (a), bond lengths (1×10/nm) (b), and bond angles (/°) (c) in $C_{10}AzoC_5N^+Br^-$, together with those in $C_8AzoC_5N^+Br^-$ (d) and (e). Maximum estimated standard deviations for bond lengths and angles are 0.003 nm and 1° in $C_{10}AzoC_5N^+Br^-$ and 0.002 nm and 1° in $C_8AzoC_5N^+Br^-$.

The structural similarity of four homologous compounds, $C_nAzoC_5N^+Br^-$ (n=6, 8, 10, 12), clearly appears in the dihedral angles listed in Table 4. The dihedral angles of the four compounds are so similar to each other that the maximum deviation from the average is within 2° in every case. With the exception of the first two, all the dihedral angles have trans conformation. Especially, the planarity of the azobenzene moiety, which depends on the C(12)-C(15)-N(2)-N(3), C(15)-N(2)-N(3)-C(16) and N(2)-N(3)-C(16)-(19) angles, is very remarkable compared with those for other azobenzene-containing compounds, such as *trans*-azobenzene[15] and 4,4′-dimethylazobenzene.[16] The pronounced planarity of the azobenzene moiety must be one of the main features of the J-aggregation state of the $C_nAzoC_5N^+Br^-$ compounds. The alkyl tail part also makes a well-ordered zigzag plane. On the other hand, the zigzag plane in the alkyl spacer part is slightly distorted. This distortion may be ascribed to hydrogen bonds between terminal hydroxyl moieties and bromide anions, to electrostatic interactions between nitrogen cations and bromide anions, and to the existence of

bulky methyl moieties.

Crystal Structure of $C_{10}AzoC_5N^+Br^-$ and $C_8AzoC_5N^+Br^-$. The packing arrangement viewed along the *c*-axis is shown in Fig. 3 ($C_{10}AzoC_5N^+Br^-$) and Fig. 4 ($C_8AzoC_5N^+Br^-$), together with the short interatomic distances between neighbouring chains and those between a bromide anion and the head portion of the amphiphile. The crystal structure of these two compounds can be seen as an alternation of the hydrophobic and hydrophilic layers stacked in the *a*-direction. Here, the hydrophilic and hydrophobic parts correspond to the bilayer surface and the inner part of the bilayer respectively.

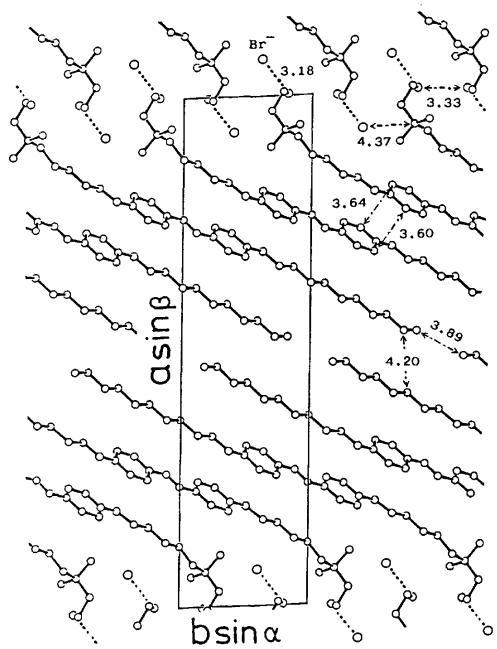

Fig. 3. Packing of $C_{10}AzoC_5N^+Br^-$ projected onto the *c*-plane (ORTEP[17] drawing). Hydrogen bonds between bromide anions and hydroxyl groups are indicated by broken lines. Some short interatomic distances (1×10/nm) are shown.

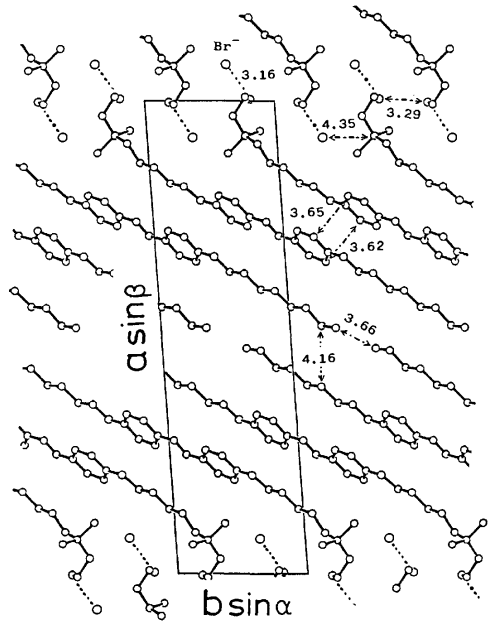

Fig. 4. Packing of $C_8AzoC_5N^+Br^-$ projected onto the *c*-plane.

In the hydrophobic layer, two molecules arranged in a tail-to-tail fashion and related by the inversion symmetry are inclined by about 30° to the layer surface. There is a remarkable tendency for the tail-to-tail distance to decrease along with the number of carbon atoms in the tail part of $C_nAzoC_5N^+Br^-$ compounds. That is, the tail-to-tail distances for n=12, 10, 8 and 6 are 0.391, 0.389, 0.366, and 0.356 nm respectively. This kind of systematic tendency was not found for the intermolecular distances in the other part of the amphiphile, such as the hydrogen-bond distances in the hydrophilic part and interatomic distances between adjacent azobenzene moieties.

In the hydrophilic layer, ammonium cations and bromide anions make a plane parallel to the bilayer surface. Two such planes are contained in one hydrophilic layer. The bromide anion is linked to the hydroxyl group of the adjacent molecule in a different bilayer by a hydrogen bond (0.318 nm in $C_{10}AzoC_5N^+Br^-$ and 0.316 nm in $C_8AzoC_5N^+Br^-$). Through this hydrogen bond, the head groups of amphiphiles in adjacent bilayers interdigitate mutually. In addition to the electrostatic interactions between the cationic ammonium nitrogens and the bromide anions, this interdigitated structure in the hydrophilic layer must contribute to the stabilization of crystals. On the other hand, the hydrophobic alkyl chains and azobenzene moieties are stabilized only by the van der Waals interactions. Therefore, the above tendency for the tail-to-tail distance in the hydrophobic part to decrease is attributable to the increase in the influence of various strong interactions in the hydrophilic part as shortening the tail length in $C_nAzoC_5N^+Br^-$.

The authors wish to express their deep thanks to Professor Yukiteru Katsube at the Crystallographic Research Center, Institute for Protein Research, Osaka University, for the use of the Institute's facilities to analyse one of the specimens.

Polymorphism and Crystal Structure of Chiral Smectogenic 4′-Heptyloxy-4-biphenylyl *p*-[(*S*)-2-Methylbutyl]benzoate

Kayako HORI* and Yuji OHASHI
Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received March 31, 1989)

Two crystal forms **1** and **2** were found for the title compound. DSC measurements showed that the two crystals transform to different mesophases (Sm* I and Sm* J). Crystal data. 4′-Heptyloxy-4-biphenylyl *p*-[(*S*)-2-methylbutyl]benzoate, **1**, M_r=458.61, $C_{31}H_{38}O_3$, monoclinic, $P2_1$, T=298 K, a=15.065(3), b=45.59(2), c=5.636(1) Å, β=95.51(2)°, V=4109(2) Å^3, Z=6, d_x=1.118 Mg m^{-3}, μ=0.475 mm^{-1}, $F(000)$=1488; **2**, triclinic, $P\bar{1}$, a=13.37(2), b=22.96(2), c=10.213(5) Å, α=105.55(5), β=105.22(6), γ=102.31(9)°, V=2775(5) Å^3, Z=4, d_x=1.102 Mg m^{-3}. The crystal structure of **1** has been determined by single crystal X-ray analysis. Final R was 0.109. The crystal has a distinct layer structure similar to that of a smectic liquid crystal. Two of the three crystallographically independent molecules with extended paraffin chains have parallel arrangement, to which the third molecule with a twisted and highly disordered chain is antiparallel. The paraffin chains of the parallel molecules in a layer have close contacts with each other. Such contacts would enhance the intra-layer interaction which causes the transition to Sm* I.

In the preceding papers,[1,2] we discussed the relationships between mesophase behavior and crystal structures for the two series of chiral smectogenic biphenyl esters. The first series crystals (I-*n*), *p*-pentyloxyphenyl and *p*-heptyloxyphenyl 4′-[(*S*)-2-methylbutyl]biphenyl-4-carboxylates (I-5 and I-7, respectively), transform to a Sm*C followed by a cholesteric, while the second ones (II-*n*), *p*-[(*S*)-2-methylbutyl]phenyl 4′-heptyloxybiphenyl-4-carboxylate and 4′-octyloxybiphenyl-4-carboxylate, (II-7 and II-8, respectively), to a Sm*C and then to a Sm A phase. In the former crystals paraffin chains have close contacts between layers,[1] while in the latter whole molecules including paraffin chains contribute to the lateral molecular overlapping within a layer.[2] Different mesophase behavior related to the different phase sequences was successfully interpreted by the intermolecular interaction revealed in the crystal structures.

In contrast to these two series, the third one, 4′-alkoxy-4-biphenylyl *p*-[(*S*)-2-methylbutyl]benzoates (III-*n*), was reported to have phase sequences highly dependent on the chain length.[3] Since the preceding studies revealed that the different mesophase behavior is closely related to the difference in the packings of paraffin chains in the crystals, the crystal structure analyses of the third series were intended to elucidate the relationships between the mesophase behavior and the chain length. In the course of the crystal structure determination of these compounds, two crystal forms were found for III-7.

This paper describes the polymorphism of III-7 and one of the crystal structures.

Experimental

Compound. 4′-Heptyloxy-4-biphenylol was synthesized in an analogous way to that described previously.[4] 4-[(*S*)-2-Methylbutyl]benzoyl chloride was supplied by Dr. Shungo Sugawara. $[\alpha]_D^{20}$=13.8° (cf. $[\alpha]_D^{20}$=13.1° for the free acid[5]). Esterification and purification were done in the same way as described previously.[5]

Transition temperatures were measured using a Seiko SSC570 DSC and an Olympus POM polarizing microscope equipped with a Mettler FP82.

Crystal Structure Analysis. Transparent long parallelepiped or flat plate-like crystals were separately grown from a methanol-chloroform solution. The unit cell dimensions and space groups determined from oscillation and Weissenberg photographs revealed that they are polymorphs (III-7(**1**) and III-7(**2**), respectively). Accurate cell parameters of III-7(**1**) and III-7(**2**) were determined by a least squares fit for 15 and 20 reflections, respectively, within the range, 22°<2θ<45°, measured on a Rigaku AFC-4 diffractometer with Cu$K\alpha$ radiation (λ=1.54184 Å) monochromated by graphite.

Intensity data of III-7(**1**) were collected on the diffractometer using a crystal of 0.2×0.18×0.15 mm up to 2θ=100°. A 2θ-ω scan mode and scan width of ω=(1.0+0.15tanθ)° were applied. Backgrounds were counted for 5 s at both ends of a scan. Three standard reflections were recorded after every 50 reflections. No significant intensity variations were observed. A total of 4286 reflections were collected at the rate of 4°(2θ) min^{-1}, of which 3378 were treated as significant ($|F_o|>3\sigma(|F_o|)$). The data were corrected for Lorentz and polarization factors but not for absorption. For the III-7(**2**) crystal, unfortunately, sufficient intensity data for the structure analysis have not been obtained probably due to poor crystallinity and large thermal motions.

The structure was determined by applying the program MULTAN78[6] and refined by block-matrix least-squares using SHELX76[7] and subsequently HBLS,[8] since the number of parameters exceeded the limit of SHELX76 at later stages. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, where $w=(\sigma(F_o)^2+0.004|F_o|^2)^{-1}$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[9] In the course of the refinement, several additional peaks of 0.37—0.44 e Å^{-3} were found around the terminal moiety of the twisted paraffin chain, where the atoms had remarkably large temperature factors. These peaks were included as disordered atoms in further refinement. All the non-hydrogen atoms with occupation factors above 0.7 were refined anisotropically. Only 19 hydrogen

atoms found in the difference Fourier maps were included in the refinement, because the number of the reflections was limited due to the large thermal effect. Max. Δ/σ and max. $\Delta\rho$ in the final difference map were 0.46 and 0.30 e Å^{-3}, respectively. Final R and R_w were 0.109 and 0.130. The large R value is due to the large thermal motion and the highly disordered chain.

The final coordinates of non-hydrogen atoms are given in Table 1.[10] Computations were carried out on a HITAC M-680H computer at the Computer Center of the University of Tokyo.

Results and Discussion

Polymorphism. In order to find a relationship

a) $B_{eq}=(4/3)\sum_{ij}\beta_{ij}(a_i\cdot a_j)$. b) Isotropic temperature factors. c) Occupation factors are fixed to be 0.7 for C(24A), 0.3 for C(24A′), and 0.5 for (35A) to C(37A′).

Table 2. Enthalpies of Transitions (ΔH/kJ mol^{-1})

Transition	III-7a	III-7b
Crystal-mesophase	16.3±0.7	16.8±0.7
Sm*I-Sm*C	2.4±0.2	2.4±0.2
Sm*C-cholesteric	4.7±0.2	4.6±0.1
Cholesteric-isotropic[a)]	1.1±0.1	1.4±0.2

a) Via a blue phase.

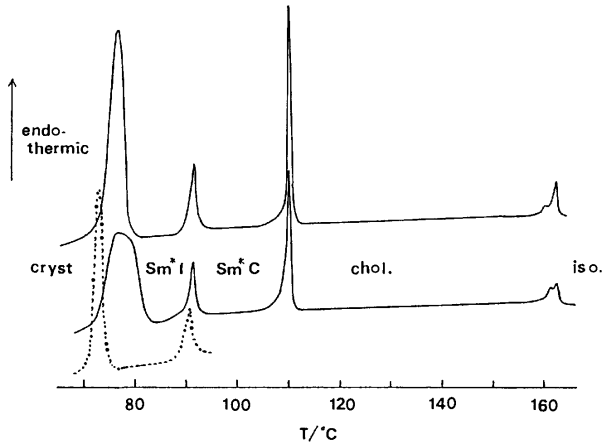

Fig. 1. DSC peaks for the two polymorphs of 4′-heptyloxy-4-biphenylyl *p*-[(*S*)-2-methylbutyl]-benzoate: III-7(**1**) (upper) and III-7(**2**) (lower). A broken line denotes a curve for the solid obtained from a melt. Scan speed was 2° min^{-1}.

between the two polymorphs, DSC measurements were carried out. ΔH values are summarized in Table 2. Transition temperatures of Sm*I-Sm*C and Sm*C-cholesteric were in good agreement with the reported values,[3)] while the cholesteric-isotropic transition temperature was higher (ca.161 °C) than the reported one (154 °C) and a blue phase was observed during the transition.

As shown in Fig. 1, the shapes of the crystal-mesophase transition peaks are remarkably different: a sharp peak for III-7(**1**) and a broad one for III-7(**2**). The former peak is as sharp as the crystal-Sm*C transition peaks of the series I and II and the profile is independent of the heating rate, while the latter has a truncated profile, which is slightly dependent on heating rate. These facts indicate that the former peak corresponds to a single step of transition while the latter is composed of two (or more) steps. Goodby and Leslie reported that the phase sequence of III-7 was crystal-Sm*J-Sm*I-Sm*C-cholesteric-isotropic.[3)] Refering to this, it is interpreted that the sharp peak of III-7(**1**) corresponds to a direct transition to Sm*I, while the broad one of III-7(**2**) to successive transitions, Sm*J-Sm*I-Sm*C, because the Sm*I-Sm*C transition temperature is in good agreement with the reported one. On re-heating, the peak of III-7(**2**) also becomes sharp and ΔH is about 60—70% of the first run, showing that the solid obtained from a melt is much more disordered than the crystalline state obtained from a solution.

Molecular Conformations in the Crystal. All the bond lengths and angles are almost compatible with those found in the mesogens studied previously,[1,2)] as shown in Table 3. All the phenyl rings are planar within the experimental error. Table 4 shows torsion angles. The molecule A has two disordered conformations in the largely twisted chain and the other two molecules B and C have straightly extended paraffin chains. The C(24) atom in the molecule A is also slightly disordered. The molecules B and C have approximately the same structure. Figure 2 shows ORTEP drawings of the molecules A and B with the numbering scheme.

Biphenyl moieties were nearly coplanar in all the molecules. The ester moieties composed of C(10), C(13), C(14), O(1), and O(2) atoms, which are planar within the experimental error, are approximately coplanar with the phenyl rings of C(14)—(19), as is easily expected by considering the conjugation of the double bonds. In the cases of the I and II crystals, they are coplanar with one of the biphenyl rings.

Crystal Packing. Figure 3 shows the crystal structure. In a distinct layer structure parallel to the (010) plane, molecules have two opposite tilt (±45°) alternately from layer to layer.

Molecular arrangement within a layer is quite different from those of the series I and II. The latter two series have antiparallel arrangements of molecular long axes related by a pseudo-inversion (I) or a 2-fold screw axis (II). On the other hand, in the III-7(**1**) crystal the two molecules with the extended paraffin chains have parallel arrangement, to which the third molecule with the twisted chain is antiparallel.

The phenyl rings of adjacent molecules have non-

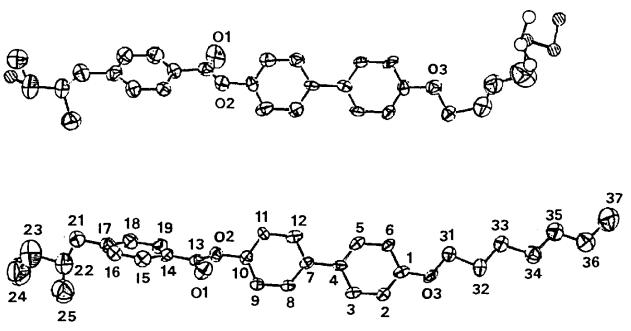

Fig. 2. ORTEP views of the molecules A (upper) and B (lower) in III-7(**1**) with 50% probability thermal ellipsoids. The molecule C has almost the same conformation as the molecule B. The isotropically refined atoms are shown by spheres with an arbitrary diameter. Shadowed atoms indicates the other conformer. All the molecules are numbered in the same way.

parallel contacts as found in the former two series. The angles between the mean planes are 60°, on average. The molecular overlapping within a layer is relatively large from an end to the other, as in the case of the series II crystals, although the tilt angle is larger than that in the series II crystals (30°). On the other hand, the packing of the paraffin chains within a layer is different. In the series II crystals paraffin chains have rather loose contacts, while those of the parallel molecules in the III-7(**1**) crystal form sheets composed of close contacts along the c axis, as shown in Fig. 4. This seems to enhance the molecular interaction within a layer, leading to the transition to Sm*I, an intermediately highly ordered smectic with a pseudo-hexagonal arrangement in a layer.[12)]

Intermolecular interaction due to the close contacts

between the paraffin chains would largely depend on the chain length. This may be responsible for the different phase sequences depending on the chain length in this series.

The authors express their thanks to Dr. Shungo Sugawara of NTT Ibaraki Electrical Communication Laboratories for supplying the chiral acid chloride and to Professor Atsuko Shimada of this University for supporting the DSC measurement. Acidity Enhanced Pillared Clay Catalysts. Modification of Exchangeable Sites on Fluor-tetrasilicic Mica by the Fixed Interlayer Cations

Hiroaki SAKURAI, Kazuo URABE,* and Yusuke IZUMI*
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received April 12, 1989)

By the use of fluor-tetrasilicic mica (TSM) as a starting material, La^{3+}-modified pillared TSM was prepared by calcining La^{3+}-exchanged TSM followed by Al-pillaring. Nonmodified pillared TSM managed only a 0.1% conversion for toluene alkylation with methanol, but the alkylation activity was greatly enhanced by the modification to give more than a 7% conversion, the activity level of which was roughly comparable to that of the conventional pillared montmorillonite. The effect of modification greatly depended on the calcination temperature at the pretreatment of La^{3+}-exchanged TSM prior to a pillaring operation; the optimum calcination temperature was between 300 and 400 °C. Other multivalent cations with large ionic radii, such as Ce^{3+}, Ca^{2+}, and Sr^{2+}, were also useful as modifiers. On the basis of the results of measurements involving X-ray diffraction, cation-exchange capacity and IR spectra of the adsorbed pyridine, it was concluded that a part of the thermally dehydrated La^{3+} ions lost their exchangeability to be fixed on the cation exchange sites of layers, remained between layers even after Al-pillaring, and took charge of the genesis of acidic sites.

Pillared clays, which function as acid catalysts having good thermal stability and a molecular sieve property, are obtained by the intercalation of aluminum hydroxy cluster cations into the region between the silicate sheets of clay minerals.[1-4] Several kinds of polyoxocations other than Al, e.g., Zr, Cr, Ti, and Fe are also available as guest species, and the clays pillared by these guest species have been extensively studied.[5] In these studies, smectite clay minerals are exclusively employed as host clays: namely, montmorillonite,[2,3] hectorite,[6] fluor-hectorite,[6] laponite,[7,8] beidellite,[9-11] and saponite.[12-14] Through the examination of the acid catalysis of various types of clays, we have recently demonstrated the catalytic efficiency-determining factors in Al-pillared clay catalysts.[13] The factors on host clays include particle size, cation-exchange capacity (CEC) and the position of isomorphous substitution.

Fluor-tetrasilicic mica (TSM) is another interesting material clay, since it has a large CEC and a well-arranged layer structure. The sodium form of TSM, which was first synthesized as $Na(Mg_{5/2})^{oct.}(Si_4)^{tet.}O_{10}F_2$ by Kitajima and Daimon,[15] is known to have a free swelling property and a high cation-exchange ability. Morikawa et al.[16] reported an unusual property of TSM: that it possesses no acidic sites, even in the proton-exchanged form. By employing TSM as a starting material we could prepare an Al-pillared TSM (PTSM).[12,14] Due to its large CEC, TSM could be effectively pillared and the PTSM, thus obtained, showed a pore structure similar to that of pillared montmorillonite (PM); unexpectedly, however, it had few acid sites effective for toluene alkylation with methanol. We thus induced that a principal part in acidity genesis in pillared clays is played not by the pillars as guests but by the sheet silicate itself as a host.[14,17] It is therefore promising to modify not the pillars, but the silicate sheets of pillared clay in order to build up more acidic and active clay catalysts.

There have already been some examples of pillared clays modified through cation exchange. Shabtai et al.[18-20] introduced La^{3+} and Ce^{3+}, Vaughan et al.[21] introduced La^{3+} and Suib et al.[22,23] introduced Cr^{3+} and Fe^{3+}, into pillared montmorillonites or pillared bentonites (montmorillonite is a principal clay mineral of "bentonite" rock). However, the modification effects reported by them on activity improvement for some typical acid-catalyzed reactions remained obscure, because each nonmodified pillared montmorillonite used by them already had a substantial activity by itself. We recently found that the acidity of PTSM can be greatly enhanced when the silicate sheets of pillared TSM are modified by La^{3+} ions.[24,25] After native TSM was exchanged with La^{3+} and calcined at 300—400 °C, successive pillaring by aluminum hydroxy cluster cation was carried out in a mixture of acetone and water. The resulting catalyst gave a much higher catalytic activity for the toluene alkylation with methanol than nonmodified pillared TSM.

In this paper we described the preparative conditions of this La^{3+}-modified pillared TSM to give highly active catalysts in detail, and discuss the mechanism of acid-site generation by La^{3+} modification.

Experimental

Material Clay and Pillaring Agent. Samples of synthetic fluor-tetrasilicic mica were supplied from Topy Ind. and refined by means of the conventional sedimentation technique. The refined TSM contained only trace amounts of impurities, such as α-cristobalite. Reportedly, the composition of this clay by chemical analysis is[26] $Na_{1.00}Mg_{2.63}^{oct.}(Si_{3.94}Al_{0.05}Mg_{0.01})^{tet.}O_{10.19}F_{1.81}$. As a reference clay, refined natural montmorillonite (Kunipia F) was supplied by Kunimine Ind.

An aluminum hydroxy cluster cation solution (OH/Al=2.0) was prepared according to a known method.[2] An aqueous 0.5 M NaOH solution (1 M=1 mol dm^{-3}) was slowly added (100 ml h^{-1}) to a 0.2 M $Al(NO_3)_3$ solution at 60 °C, and the mixture was aged for 2 h at the same temperature. The product solution was stored at room temperature.

Catalyst Preparation. The preparative procedure of various types of metal-modified pillared TSM (M^{n+}-PTSM) is illustrated in Fig. 1. First, metal ion-exchanged TSM (M^{n+}-TSM) was prepared using a metal nitrate solution followed by calcination at 200—500 °C for 3 h (procedure of calc.1). Al-pillaring manipulation was then achieved in a mixture of acetone and water according to the method of Yamanaka et al.[27] The calcined M^{n+}-TSM (1.2 g) was dispersed in a mixed solution of acetone and water (50 ml each) and stirred for 30 min; then, 150 ml of the aluminum hydroxy cluster cation solution (vide supra) was added to the dispersion. After stirring for 12 h, the product was filtered, washed repeatedly with deionized water and air-dried overnight at 60 °C. The M^{n+}-PTSM, thus obtained, was calcined in air (procedure of calc.2) and served as a catalyst. Nonmodified pillared TSM (PTSM) and pillared montmorillonite (PM) were prepared according to a previously reported method.[12,14]

Reaction Procedure and Analysis. Toluene alkylation with methanol and 2-propanol dehydration were both carried out using a conventional continuous-flow system under atmospheric pressure. The liquid products collected in an ice trap were analyzed by GLC using a Bentone 34 and DNP column (4 m) for toluene alkylation and a Porapack S column (1 m) for 2-propanol dehydration, respectively.

Characterization. X-Ray diffraction (XRD) analysis was carried out employing an oriented clay film spread on a glass slide. The nitrogen adsorption on the catalyst was measured at 78 K using constant-volume adsorption equipment; the surface area was calculated according to either the B.E.T. or to the Langmuir equation, depending on the type of adsorption isotherm.

Cation-exchange capacities (CEC) of clay samples were determined based on the amount of the Ca^{2+} which was replaced by Na^{+}[28] in a similar way to the conventional CEC determination.[29] Each clay sample (0.3 g) was diluted with quarts sand and packed in a Pyrex column (18 mm diameter). Aqueous $Ca(CH_3COO)_2$ (0.5 M) was added and the clay was saturated with Ca^{2+} ion. The clay was washed with a 90% EtOH solution and again exchanged to the sodium form with 1.71 M aqueous solution of NaCl. The Ca^{2+} ions leached out were determined by chelatometric titration.

IR spectra were recorded on a JASCO IR-810 spectrophotometer at room temperature. Each wafer sample of clay was mounted in a Pyrex-made IR cell and evacuated for 1 h at 300 °C. After cooling, the background spectrum was recorded, and pyridine was adsorbed at 150 °C. The sample was then treated at a given temperature between 150 and 450 °C in vacuo followed by cooling, and the corresponding spectrum was recorded. Finally, water was adsorbed on the sample at 200 °C, and the sample was evacuated at the same temperature, then the spectrum was recorded to examine the transformation of Lewis into Brønsted acid sites.[30]

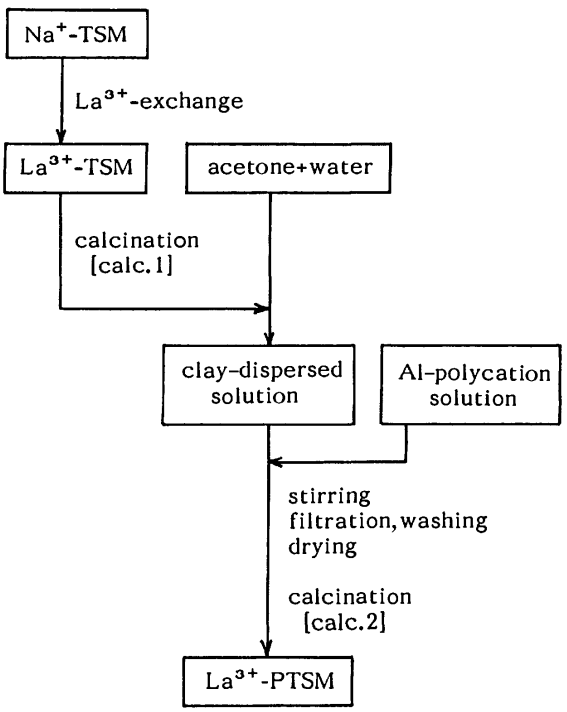

Fig. 1. Preparation procedure of La^{3+}-PTSM.

Results and Discussion

Time Course of Catalytic Activity. The activities for the toluene alkylation with methanol over three kinds of catalysts (La^{3+}-modified pillared TSM (La^{3+}-PTSM), nonmodified pillared TSM (PTSM) and pillared montmorillonite (PM)) are compared in Fig. 2. La^{3+}-PTSM exhibited a high activity by the modification almost comparable to that of the conventional PM, whereas nonmodified PTSM showed only a meager conversion. Owing to carbon deposition, the toluene conversion was rapidly decreased with the

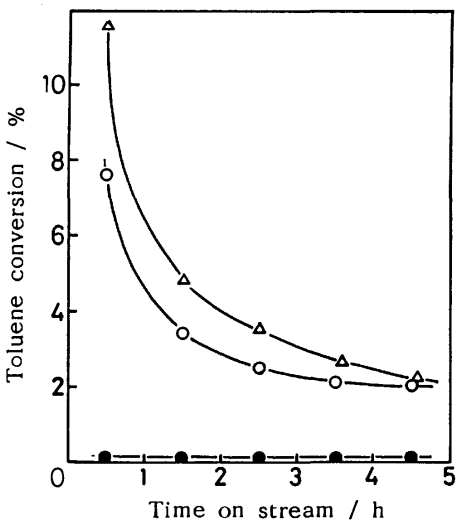

Fig. 2. Time course of catalytic activity for toluene alkylation. Reaction temp 350 °C, W/F=60 g h mol^{-1}, toluene : methanol=2 : 1 (mole ratio), flow rate of N_2 carrier gas 200 ml h^{-1}. (△) PM, (○) La^{3+}-PTSM, (●)PTSM.

time on stream for all catalysts tested. Incidentally, the deactivation rate was somewhat slower for La^{3+}-PTSM than for PM. Taking such deactivation into account, the averaged toluene conversion and xylene selectivity obtained 1 h after the reactant feed was initiated were subsequently taken as standard data to evaluate the catalytic efficiency.

Influence of Modifying Procedure on Catalytic Activity. Table 1 shows the initial conversions of the toluene alkylation by the catalysts obtained through various preparation methods, together with the data of basal spacing and surface area of the catalyst. Over the TSM-based catalysts, xylene was found to be a major product with a selectivity of more than about 80%. The Al-pillared, but nonmodified, catalyst (PTSM; No.1) showed a large surface area (197 $m^2 g^{-1}$) and a basal spacing of 18.4 Å. Considering the layer thickness of the clay itself (9.6 Å), the catalyst has an interlayer spacing (8.8 Å) large enough to accept the reactant organic molecules, though the nonmodified PTSM gave a very low activity. In the case of the La^{3+}-exchanged but nonpillared catalyst (La^{3+}-TSM; No. 2), the interlayer region collapsed (d_{001}=9.7 Å) on heating at 400 °, and the reaction did not proceed. In connection with the La^{3+}-modified and Al-pillared catalyst (La^{3+}-PTSM; Nos. 3—7), the activity varied widely, depending not only on the order of Al-pillaring and La^{3+}-exchange manipulation procedures, but also on the kind of clay-dispersion medium used in Al-pillaring and on the calcination conditions. When La^{3+} was ion-exchanged after Al-pillaring (No.3), the activity improved only slightly (from 0.1% to 0.7% conversion). In this case, La^{3+}-PTSM probably incorporated only a small amount of La^{3+}, because the CEC of once calcined pillared clay is greatly reduced to 10 to 20% of the initial CEC of the parent clay.[10,21] In order to prepare a highly active catalyst, the La^{3+}-exchange procedure prior to the Al-pillaring operation was indispensable. When non-calcined La^{3+}-TSM was pillared, the activity of the resulting La^{3+}-PTSM (No. 4) remained unaltered from that of nonmodified PTSM. On the other hand, when the La^{3+}-TSM was calcined at 400 °C and subsequently pillared in water without acetone (No. 5), the product clay showed a small basal spacing of 9.9 Å, indicating that aluminum hydroxy cluster cations were not intercalated. Thus, only when La^{3+}-TSM was first calcined, followed by Al-pillaring in a mixed medium of acetone and water (No. 6), a very active catalyst was obtained to afford high toluene conversion (3.2%). The best catalyst, which gives a higher toluene conversion (7.6%), was obtained when calc.1 was operated at 300 °C and calc. 2 was omitted (No. 7).

Effect of Calcination Conditions. Since both calc.

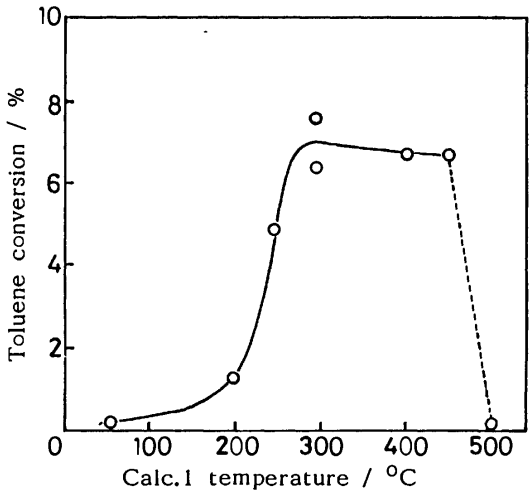

Fig. 3. Effect of the temperature of calc. 1 on toluene aklylation activity of La^{3+}-PTSM. Reaction temp 350 °C, W/F=60 g h mol^{-1}, toluene : methanol=2 : 1 (mole ratio), flow rate of N_2 carrier gas 200 ml h^{-1}.

a) Reaction temp 350 °C, W/F=60 g cat. h mol^{-1} (W=weight of catalyst, F=feed rate of reactants), toluene : methanol=2 : 1 (mole ratio), flow rate of N_2 carrier gas 200 ml h^{-1}, averaged initial activity for 1 h after feeding of reactants. b) A: Al-pillaring only B: La^{3+}-exchange only C: La^{3+}-exchange after pillaring D: Al-pillaring after La^{3+}-exchange. c) Used for Al-pillaring (W: water W+A: mixture of water and acetone). d) Calcined for 3 h. e) Calcined for 4 h. f) Measured after evacuation at 300 °C for 1 h. g) *p*-Isomer fraction among the xylenes produced. h) Dried at 60 °C. i) Pretreated at 350 °C for 1 h under nitrogen gas flow before reaction. j) Langmuir type N_2 adsorption isotherm.

1 and calc. 2 procedures greatly affect the catalytic activity, appropriate calcination conditions were explored. Figure 3 shows the alkylation activities of La^{3+}-PTSM as a function of the temperature of calc. 1. The activity of the catalyst dried at 60 °C as calc. 1 was as low as that of nonmodified PTSM. When the calc. 1 temperature rose to over 200 °C, the activity rapidly increased with a rise in temperature and reached a maximum at 300 °C. The activity was maintained at over 6% conversion until the temperature reached 450 °C, but became almost inactive at 500 °C. This activity loss is due to the unsuccessful formation of a pillared structure of the catalyst (vide infra).

To evaluate the effect of the calc. 2 temperature, 2-propanol dehydration, which proceeds effectively even at a relatively low reaction temperature of 200 °C, was examined. As shown in Fig. 4, 2-propanol conversion rapidly decreased with increasing calcination temperature for both La^{3+}-PTSM and PTSM, but La^{3+}-PTSM exhibited a much higher activity than PTSM at every temperature. La^{3+}-PTSM showed 23% conversion at 300 °C, while PTSM dropped the conversion below 2% at the same temperature. Over either catalyst, the main product was propylene with a selectivity of more than 75%.

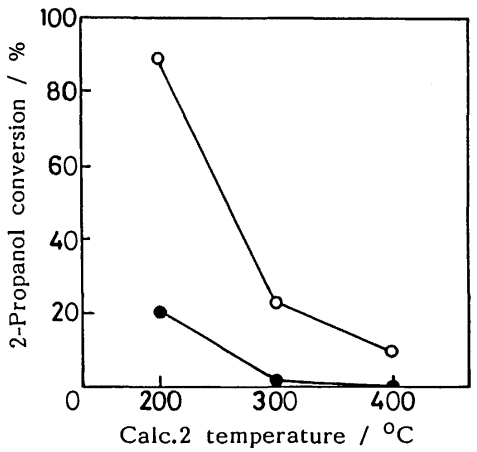

Fig. 4. Effect of the temperature of calc. 2 on 2-propanol dehydration activity. (○) La^{3+}-PTSM and (●) PTSM. Reaction temp 200 °C, W/F=2.1 g h mol^{-1}, flow rate of N_2 carrier gas 600 ml h^{-1}.

Modification by Various Cation Species. The modification of PTSM by various types of cations was performed in the same manner as in the case of La^{3+}-PTSM. As listed in Table 2, the modified pillared catalysts with large basal spacings of more than 17 Å were obtained, except for Al^{3+}-PTSM. These pillared catalysts, whose N_2 adsorption isotherms fitted with the Langmuir equation, showed specific surface areas of more than 160 m^2 g^{-1}. These catalysts have distinct pillared structures in this regard, but displayed different catalytic activities, depending on the modifying cation species used. With respect to monovalent cation Na^+, no differences in terms of both basal spacing and catalytic activity were found between Na^+-PTSM and PTSM (Table 1). With each of the divalent and trivalent cations (Ca^{2+}, Sr^{2+}, Ce^{3+}, and La^{3+}), the catalytic activity was greatly enhanced along with an increase of the *p*-xylene fraction. The highest modification effect was found for La^{3+}-PTSM. On the other hand, Al^{3+}-PTSM showed a "collapsed" basal spacing (9.8 Å) and N_2 adsorption isotherm obeyed the B.E.T. equation. The catalyst, hence, showed only very low activity (not more than 0.1% toluene conversion).

Structure Change of Clay. The structural change of clay in the course of the catalyst preparation process was traced by the use of XRD (Fig. 5). La^{3+}-TSM dried at 60 °C [(a) in Fig. 5(A)] had a double-layer hydrated form (d_{001}=15.8 Å); upon heating to 300 °C, another diffraction peak appeared which corresponds

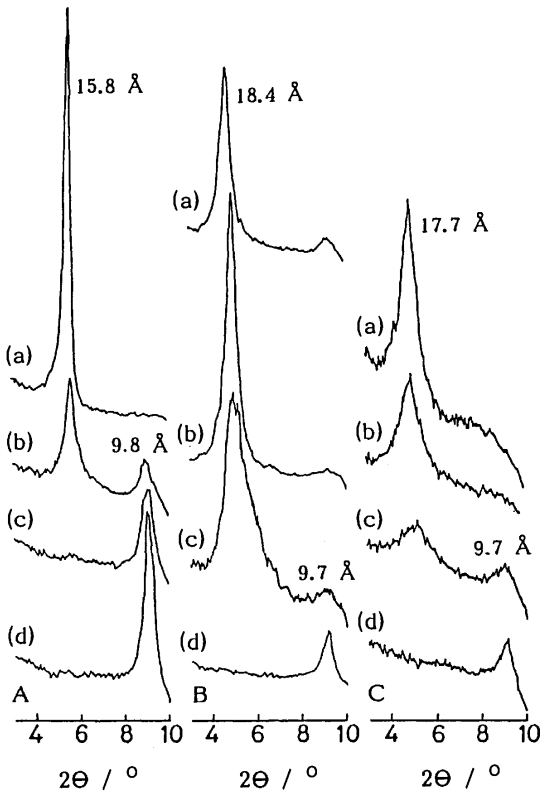

Fig. 5. Change in XRD patterns during the preparation of La^{3+}-PTSM. (A) La^{3+}-TSM after calc. 1, (B) La^{3+}-PTSM after Al-pillaring and drying at 60 °C, (C) after calc. 2 at 400 °C for 4 h. Calcined before Al-pillaring (calc. 1) at 60 °C (a), at 300 °C (b), 400 °C (c), and at 500 °C (d).

to an anhydrous form (d_{001}=9.7 Å) [(b) in Fig. 5(A)]. At 400 °C or above, only this anhydrous form was observed [(c) and (d) in Fig. 5(A)].

Such anhydrous clays could swell no longer in water, and it was impossible to introduce pillars between the layers by the conventional pillaring technique (see Table 1; No. 5). When a mixture of acetone and water was adopted as a clay dispersion medium, the basal spacing of La^{3+}-PTSM expanded to a definite level (17—18 Å) [(a), (b), and (c) in Fig. 5(B)]. When calc.1 was performed at 500 °C, the expansion of basal spacing by pillaring occurred no longer [(d) in Fig. 5(B)]. The low catalytic activity of the La^{3+}-PTSM which underwent heating at 500 °C in calc.1 (vide supra) is ascribed to the lack of an actual pillared structure.

The diffraction peak intensity after calc. 2 at 400 °C also altered, depending upon the calc. 1 temperature. The diffraction peak became weaker with increasing temperature of calc. 1. No collapsed basal spacing after calc. 2 was found, provided the calc.1 temperature remained below 300 °C [(a) and (b) in Fig. 5(C)], indicating a heat-stable pillared structure was obtained.

Thermal Change in CEC of La^{3+}-TSM. Figure 6 shows a change in the CEC of lanthanum-exchanged

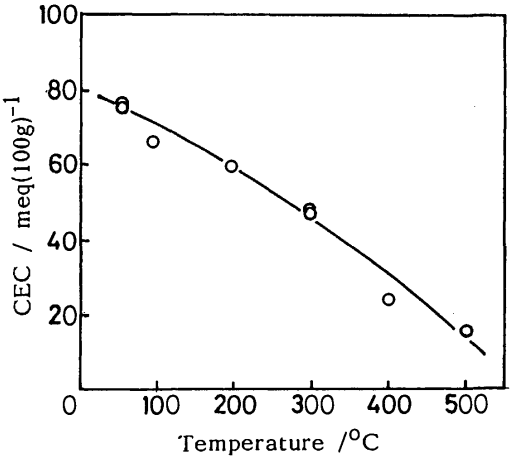

Fig. 6. Cation-exchange capacity of La^{3+}-TSM as a function of temperature of calc. 1.

TSM (La^{3+}-TSM) with the calc.1 temperature. A La^{3+}-TSM sample dried at 60 °C had a CEC of 78 mequiv/100 g-clay. This value is much smaller than the reported CEC of native Na^+-TSM (190 mequiv/100 g)[31] but quite the same as that of Al^{3+}-TSM (78 mequiv/100 g). The discrepancy between the CEC values of Na^+-TSM and Al^{3+}-TSM has been reported to be due to a partial hydrolysis of the Al^{3+} ion.[26] Since the La^{3+} ion[32] is as the easily hydrolyzed as Al^{3+} ion, the small CEC value observed with dried La^{3+}-TSM is not unexpected.

The CEC value of La^{3+}-TSM linearly decreased from 78 to 15 mequiv/100 g with an increase in the temperature of calc.1 from 60 to 500 °C. This means that a part of the La^{3+} ions lost their exchangeability with other metal cations and became fixed between the silicate layers during the course of calcination. In other words, the amount of the fixed La^{3+} must increase with an increase in temperature. Such a reduction of CEC by heating was reported by Mozas et al.[33] in respect of La^{3+}-montmorillonite. Hofmann et al.[34] and Kondo et al.[35-37] also reported that the fixation of exchangeable cations in Ca^{2+}-bentonite occurred upon heating and that the CEC linearly reduced with increasing temperature.

It is well-known that when Li^+-exchanged montmorillonite is heated, small Li^+ ions migrate into the vacant octahedral sites and neutralize the negative charge of montmorillonite, resulting in the reduction of CEC (Hofmann-Klemen effect).[38,39] Since the diameter of La^{3+} (2.34 Å) is larger than that of Li^+ (1.80 Å), such migration of La^{3+} ions into an octahedral vacancy is considered to be unfeasible. Another mechanism must therefore be proposed for the case of La^{3+}-TSM.

Figure 7 shows the oxygen framework of TSM. The oxygen atoms which face an interlayer region (basal oxygens) form a repeated pattern of hexagons, and there is a depression which is called a "hexagonal hole" in the center of this network. When 2:1 type

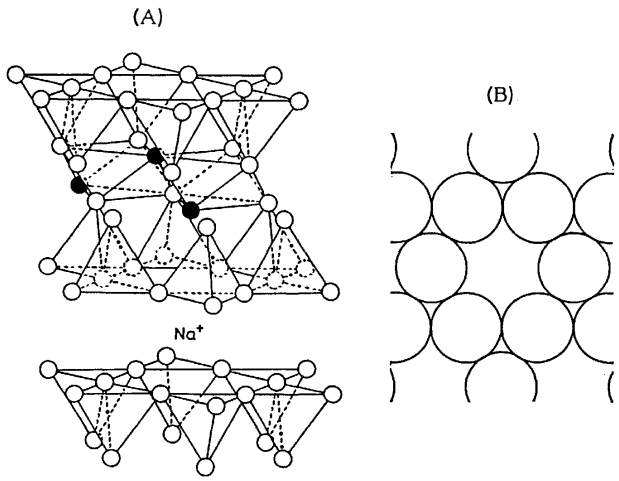

Fig. 7. Structure of fluor-tetrasilicic mica. (A) Layer structure, (○) oxygen, (●) fluorine. Every tetrahedral site is occupied by silicon and octahedral sites are occupied by magnesium or vacancy. (B) Hexagonal network of basal oxygens. "Hexagonal hole" is located in a center.

clay minerals, such as smectites and vermiculites, are heated so as to be converted to anhydrous forms, the interlayer cations are situated more or less within the hexagonal holes.[39] Taking account of the ionic diameter of La^{3+} (2.34 Å) and the fact that the basal spacing of La^{3+}-TSM heated at above 300 °C (9.7 Å) is very close to the layer thickness of TSM (9.6 Å), it seems probable that La ions are almost lodged in the hexagonal holes. The actual form of the fixed La ions in the dehydrated La^{3+}-TSM is not obvious at the present stage. The existence of a species such as $La(OH)^{2+}$, $(La\text{-}O\text{-}La)^{4+}$ or $(La\langle^{O}_{O}\rangle La)^{2+}$ [40-42] has been suggested in the case of La^{3+}-exchanged Y-type zeolite. The bridged species are unlikely to exist in dehydrated La^{3+}-TSM, considering the small size of the hexagonal depression.

Kondo et al. found that the fixation of interlayer cations did occur in Ca^{2+}-bentonite, but not in Na^{+}-bentonite below 500 °C.[35-37] Above this temperature the clay lost its structural OH groups due to thermal dehydroxylation. The ease of the fixation of Ca^{2+} was ascribed to its greater electrostatic force than that of Na^{+} ion acting toward negatively charged surface oxygens.[37] If the La species exists in the form of La^{3+} or $La(OH)^{2+}$, such a nonbridged small-size species is also likely to be easily fixed onto silicate sheets.

Because the La^{3+}-fixed and charge-reduced TSM had a lower swelling ability than the original TSM, the intercalation of large aluminum hydroxy cluster cations into the interlayer spaces became difficult in an aqueous solution, and a pillared clay with an expanded basal spacing was not obtainable. To overcome this situation, the use of a mixture of acetone and water as a clay dispersion medium was effective and indispensable. Such a mixed medium was already reported by Yamanaka and Brindley[27] to be helpful for the Zr-pillaring of charge-reduced montmorillonites which was prepared by applying the Hofmann-Klemen effect described above. The larger dipole moment of the acetone molecule than that of water (water, 1.84×10^{-18} e.s.u.; acetone, 2.71×10^{-18} e.s.u.) must assist in the solvation of the residual exchangeable cations.[43]

Surface Acidity Generated by La-Modification. It has already been ascertained through the temperature-programmed desorption (TPD) of adsorbed NH_3 that the enhancement of the alkylation activity by La^{3+}-modification is attributable to an increased acidity.[25] To examine the characteristics of the acid sites generated by the modification in more detail, the IR spectra of the pyridine adsorbed on both PTSM and La^{3+}-PTSM were analyzed (Fig. 8). After pyridine adsorption at 150 °C followed by evacuation at the same temperature, three apparent absorption peaks of the adsorbed pyridine were observed at 1615, 1490, and 1450 cm^{-1} for La^{3+}-PTSM. The band at 1450 cm^{-1} indicates the presence of coordinatively adsorbed pyridines on the Lewis acid sites and both 1615 and 1490

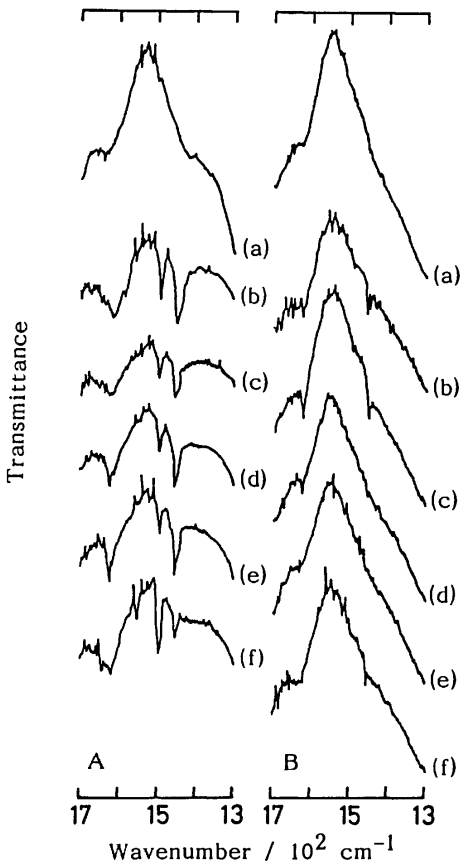

Fig. 8. IR spectra of pyridine adsorbed on La^{3+}-PTSM(A) and PTSM(B). (a) Back ground spectra, (b) after pyridine adsoption followed by evacuation at 150 °C, (c—e) followed by successive evacuation at 250 °C (c), 350 °C (d), and at 450 °C (e), (f) followed by water vapor adsorption and evacuation at 200 °C.

cm^{-1} bands are ascribed to the contribution of the pyridines adsorbed on both the Brønsted acid sites and the Lewis acid sites.[30] The 1490 cm^{-1} band gradually decreased its intensity ratio to the 1450 cm^{-1} band with increasing evacuation temperature up to 450 °C, whereas the intensity of 1450 cm^{-1} band remained nearly constant. This means that La^{3+}-PTSM contains both relatively weak Brønsted acid sites and strong Lewis acid sites. After water adsorption at 200 °C followed by evacuation at the same temperature, the intensity ratio of 1490 cm^{-1} to 1450 cm^{-1} reversed, and a new absorption band appeared at 1550 cm^{-1}. Apparently, some parts of the Lewis acid sites were converted to the Brønsted acid sites by adsorption of water.

For PTSM, the adsorbed pyridine was detected at 1620 and 1455 cm^{-1} after pyridine adsorption followed by evacuation at 150 °C. These bands, however, vanished readily upon evacuation at temperatures higher than 350—450 °C.

These results indicate that the fixed La^{3+} ions which remained between layers after Al-pillaring took charge of the genesis of acidic sites. Probably the fixed La^{3+} ions themselves function as Lewis acid centers; some part of them dissociate water molecules to liberate protons. Multivalent cations, such as La^{3+}, with a high electric field could thus effectively modify PTSM.

Concluding Remarks

Here, we succeeded for the first time in obtaining an acidity-enhanced pillared clay catalyst by making use of a unique phenomenon which occurred over the hexagonal network of a clay tetrahedral array, or the fixation of large interlayer cations, such as La^{3+} ions, onto the hexagonal cavities as cation exchange sites through thermal treatment. Recalling the very weak acidic nature or very low catalytic activity, shown by nonmodified PTSM, we can regard La^{3+}-modified pillared TSM as a well-organized pillared clay which possesses almost all of its acidic sites not on the pillars as guests, but on the walls of silicate sheets as hosts. Studies on the peculiar catalytic performance and microstructure of this modified pillared TSM are in progress through the application to other types of organic reactions and through the analysis by ^{27}Al, ^{29}Si-MAS NMR spectroscopy etc.

The Electronic Spectra of Jet-Cooled Tropolone. Vibrational Assignment for the $\tilde{A}^1B_2$-$\tilde{X}^1A_1$ Transition

Hiroshi Sekiya,* Yusuke Nagashima, and Yukio Nishimura
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Graduate School of Engineering Sciences, Kyushu University, Kasuga-shi, Fukuoka 816
(Received May 22, 1989)

The laser fluorescence excitation spectrum and the single vibronic level fluorescence spectra from the $\tilde{A}^1B_2$ state of tropolone have been measured in a supersonic free jet. Some vibronic bands observed in the region of 270—450 cm^{-1} from the 0_0^0 band have been assigned. A tunneling doublet separation for the ν'_{14} in-plane ring deformation mode has been measured to be 30 cm^{-1}, which is significantly larger than 19 cm^{-1} for that for the zero-point level, suggesting that the average geometry of the ν'_{14} mode deviates significantly from that of the zero-point level.

A tropolone molecule possesses an intramolecular hydrogen bond, and the hydroxyl proton tunnels from one oxygen atom to the other. Spectroscopic studies indicate that tropolone exhibits a double-minimum potential energy function along the proton tunneling coordinate.[1-7] Tunneling doublings have been detected in many vibronic bands in the absorption spectra[1,2,6] and the laser fluorescence excitation spectra.[4,5,7] The separation of tunneling doublings involves information on the interaction between the normal mode and the proton tunneling coordinate. On the other hand, these tunneling doublings make it difficult to assign vibronic bands.

The assignment for the vibronic transitions between the $\tilde{A}^1B_2$ and $\tilde{X}^1A_1$ states has long been a problem. Recently, Alves et al.[6] indicated that some of the complexity in vibrational bands around the 0_0^0 band is due to strong Duschinsky effect[8] involving the two lowest b_1 modes ν_{26} and ν_{25}. Very recently, Redington et al.[7] observed the laser fluorescence excitation spectrum of jet-cooled tropolone, and newly assigned about thirty vibronic bands in the region of 270—450 cm^{-1} from the 0_0^0 band. We have measured single vibronic level fluorescence (SVLF) spectra from about twenty vibronic bands in the $\tilde{A}^1B_2$ state of tropolone in order to confirm the previous assignment, since Redington et al.[7] observed no SVLF spectra. It has been found that previous assignments for vibronic bands involving the ν'_{39} and ν'_{14} modes and $25_0^n26_0^{2n+1}$ (n=1—4) and 26_0^n (n=9—14) progressions are invalid. New assignments have been proposed for some vibronic bands.

Experimental

Experimental apparatus used is essentially the same as that used for the observation of the electronic spectra of 3-isopropyltropolone.[9] Briefly, laser fluorescence excitation spectrum was measured for jet-cooled sample of tropolone in He as a carrier gas. Tropolone was commercially available and used without further purication. The sample was excited by a nitrogen laser pumped dye laser source (Molectron UV22 and DL14P), and total fluorescence was detected with a Hamamatsu R955 photomultiplier and averaged with a boxcar integrator (NF BX-531). SVLF spectra were measured with a 0.75 m monochromator (Spex 1702). The sample was placed in the housing of a pulsed nozzle with an orifice of 0.4 mm diameter and heated to about 70 °C to increase the vapor pressure.

Results and Discussion

In Fig. 1 is shown a typical laser excitation spectrum of tropolone, which is essentially the same as that reported previously.[5,7] The band origin was identified at 27018 cm^{-1}.

Figure 2 shows the SVLF spectrum obtained by the excitation of band ***b*** with $\Delta\nu(\nu-0_0^0)$=293 cm^{-1}, which had been assigned as 39_0^2 by Redington et al.[7] They concluded that the $\Delta\nu$=230.8 cm^{-1} band observed in the absorption spectrum of Alves et al.[6] was $14_0^1 39_1^1$. On the basis of this assignment, $\nu''_{39}(b_1)$ was estimated to be 147 cm^{-1}. However, as is clear from Fig. 2, no $2\nu''_{39}$ band is detected in the SVLF spectrum and dominant bands are combinations of ν''_{25} and ν''_{26}. This suggests that the corresponding upper state involves ν'_{25} and/or ν'_{26}. We have assigned band ***b*** as $25_0^1 26_0^3$ for the reason that $\nu'_{25}+3\nu'_{26}\simeq$289 cm^{-1} is close to 293 cm^{-1}.

Redington et al.[7] had assigned the 295.82 and 326.41 cm^{-1} bands as $39_0^2H_1^1$ and 26_0^{10} respectively. These assignments contradict to the result of SVLF spectra, which are shown in Figs. 3a and 3b. Figure 3a has been obtained by the excitation of band ***c*** at 296 cm^{-1}, which shows a long progression in $\nu''_{14}(a_1)$. This clearly indicates that the corresponding upper state is 14^1. A similar spectrum has been obtained by the excitation of band ***d*** at 326 cm^{-1} as is shown in Fig. 3b, and this band has been assigned to $14_0^1H_1^1$, where H_1^1 designates the high wavenumber tunneling doublet component.[1]

It is worth noting that the separation between 14_0^1 and $14_0^1H_1^1$ (30 cm^{-1}) is much larger than 19 cm^{-1} for the separation between 0_0^0 and H_1^1. Since the tunneling splitting in the zero-point level of the ground state has been estimated to be very small ($\simeq$0.3 cm^{-1})[7] these separations nearly equal to the tunneling doublet splitting in the upper state. The increase in the tunneling splitting for the ν'_{14} mode from that for the

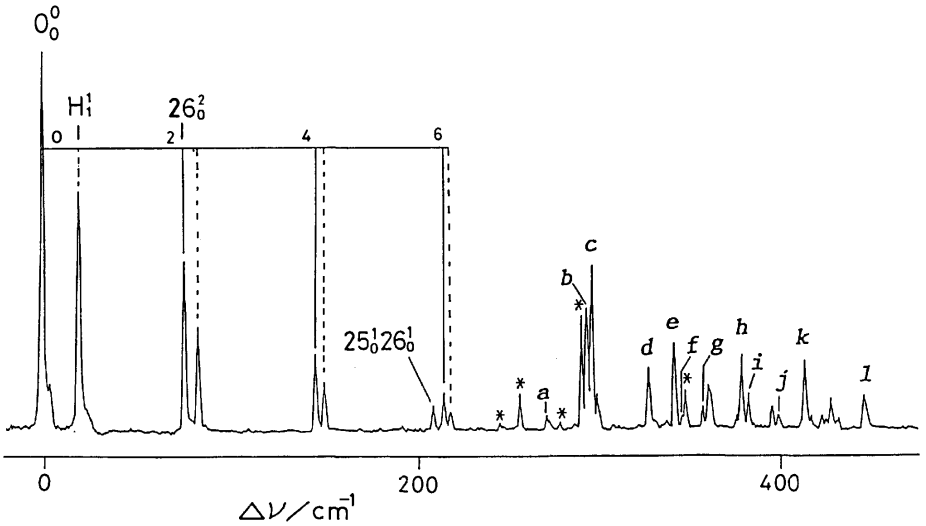

Fig. 1. Laser fluorescence excitation spectrum of tropolone. The stagnation pressure was 0.4 atm. SVLF spectra were measured for bands *a*—*l*. The broken lines indicate high wavenumber tunneling doublet component. The asterisks indicate bands due to the hydrogen-bonded complex between tropolone and water.

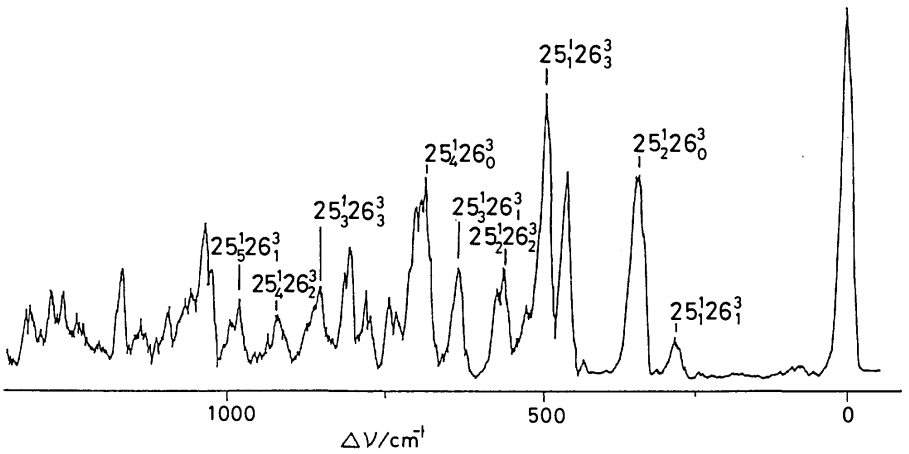

Fig. 2. Part of the SVLF spectrum obtained by the excitation of band *b*.

zero-point level implies that the average geometry of ν'_{14} deviates significantly from that of the zero-point level. From the above result ν'_{14} is considered to be a C-C-O bending in the chelate moiety such that the O···O distance is modulated as suggested by Rossetti et al.[4] rather than a C-C-C bending in the seven-membered ring proposed by Redington and Redington.[3]

The SVLF spectra obtained by the excitation of bands *h* and *i* at 378 and 382 cm^{-1} show one and two quanta of ν''_{14} and various combinations of one and two quanta of ν''_{25} and ν''_{26}, which suggests that the upper state involves both the ν'_{14} and ν'_{26} modes or ν'_{14} and ν'_{25} modes. We have assigned band *h* as $14_0^1 26_0^2$, since the frequency $\nu'_{14}+2\nu'_{26}(\simeq 381\ cm^{-1})$ nearly equals to 378 cm^{-1}. Similarly, band *i* has been assigned as $14_0^1 26_0^2 H_1^1$. These bands had been assigned as 14_0^1 and 26_0^{12}, respectively.[7] A long progression in ν''_{14} was observed in the SVLF spectrum obtained by the excita-

a) From Ref. 7.

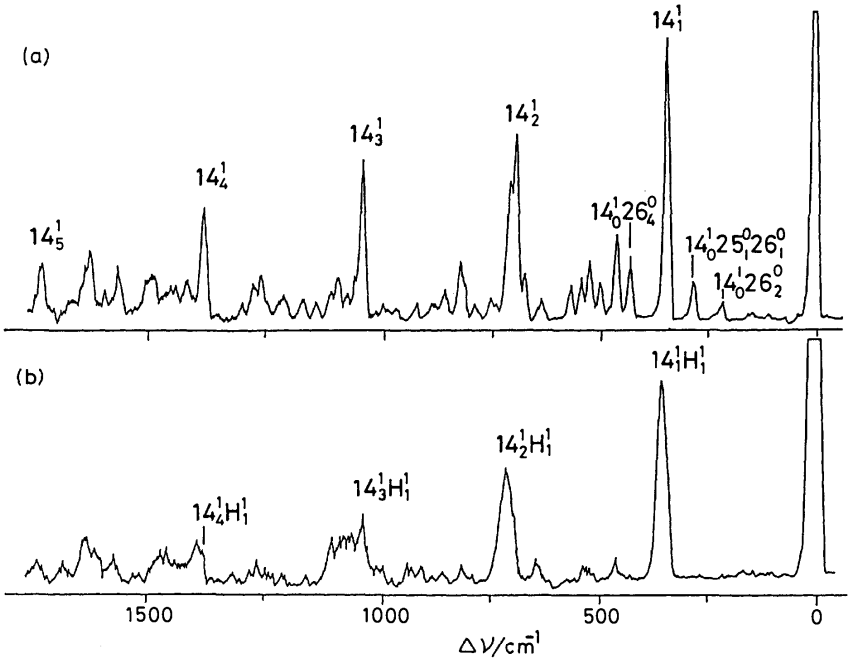

Fig. 3. Part of the SVLF spectra obtained by the excitation of bands *c* (a) and *d* (b).

tion of the $\Delta\nu$=230.8 cm^{-1} band in the absorption spectrum.[6] Since this band is not detected in Fig. 1, the 230.8 cm^{-1} band must be a hot band.

The ν''_{13} fundamental (438 cm^{-1}) has been observed in the SVLF spectra obtained by exciting into bands ***k*** and ***l*** at 415 and 447 cm^{-1}, which suggests that the transitions are from 13^1 and 13^1H^1. Therefore, bands ***k*** and ***l*** should be 13_0^1 and $13_0^1H_1^1$, respectively, which agree with previous assignments.[7]

The 25_0^2 and $25_0^2H_1^1$ bands were identified by Redington et al.[7] at 340.74 and 344.92 cm^{-1}, respectively. The SVLF spectra obtained by the excitation of bands ***e*** and ***f*** at 341 and 345 cm^{-1} show various combinations of one, two, three, and four quanta of ν''_{25} and ν''_{26}. This result is consistent with the previous assignments.[7]

The SVLF spectra obtained by the excitation of bands ***g*** and ***j*** at 355 and 400 cm^{-1} show very low-frequency (65 cm^{-1}) unidentified vibration. Such a low-frequency band was observed in temperature dependent microwave spectrum of tropone.[10] The 65 cm^{-1} vibration would be very low-frequency skeletal wag. The observation of the low-frequency vibration in the ground state suggests that corresponding low-frequency vibration is involved in vibronic bands in the upper state, although bands ***g*** and ***j*** were assigned as 26_0^{11} and $14_0^1H_1^1$, respectively.

In Table 1 are listed the vibronic bands assigned this work together with those assigned by Redington et al.[7] Since the previous assignments of 26_0^{10}, and 26_0^{12}, $25_0^1 26_0^3$ are invalid, the assignments of 26_0^n(n= 9,11,13,14) and $25_0^2 26_0^{n+2}$(n=5,7) are also dubious. Further study is needed to assign these bands.

Entrained Responses of the Current Oscillation of Polymer Gels to Sinusoidal Stimulation

Yoshihito OSADA,* Kayo UMEZAWA, and Aizo YAMAUCHI†
Department of Chemistry, Ibaraki University, Mito 310
†Research Institute for Polymers and Textiles, AIST, MITI, 1-4-4 Higashi Tsukuba 305
(Received June 26, 1989)

The responses of the current oscillation of the water-swollen polymer gels generated by dc current to the sinusoidal stimulation were investigated. The current oscillation was semiquantitatively analyzed by fast Fourier transform and the phase diagram was made up from power spectra. It was found that the entrainment of oscillation occurred in the polymer gels when the frequency of sinusoidal stimulation was closed to that of parent current oscillation. It was also found that the stronger sinusoidal voltage caused the entrainment in wider frequency range.

Recently a variety of spatial- and time-ordered structures (dissipative structure) have been experimentally and theoretically investigated in many nonlinear and nonequilibrium systems. Action potential of nerves occurred by external electrical stimulation is the representative example.[1] In the chemical reaction systems, Belousov-Zhabotinsky reaction whose the reactor concentration changes periodically by means of the autocatalytic process is well-known.[2] More recently, banding pH pattern surrounding the root and the corresponding current pattern was investigated by Toko et al.[3]

The ordered structure is often generated by synchronizing many rhythms consisting the system and this effect is called entrainment. For example, the self-sustained oscillation with a frequency of 145 Hz occurs in the squid giant axon by exchanging seawater for mixture of seawater and 550 mM NaCl solution (1 M=1 mol dm^{-3}). When the external sinusoidal current frequency is closed to 145 Hz, the forced firing frequencies that is the firing frequencies under the sinusoidal current, are entrained to the sinusoidal frequencies.[4] Away from these frequency ranges and in the case of weak sinusoidal current, the amplitude modulation upon the repetitive spikes is only observed. Some chaotic behavior is observed in the forced repetitive spikes when a strong ac is applied.

On the contrary, the artificial oscillating systems consisting of porous polyelectrolyte membranes are the simple artificial model for these oscillative systems observed in biological systems and they were made by Teorell,[5] Kobatake,[6] Seno,[7] Mounier,[8] Shashoua,[9] Katchalsky,[10] and others. For example, Teorell demonstrated that a system consisting of polyelectrolyte membrane, separating two electrolyte solutions of different conductance shows oscillation with a frequency as low as 5×10^{-4} Hz, when a dc flows through the membrane. The oscillatory phenomena was explained as an electroosmotic process causing periodic resistance changes of the membrane. The generation of pulses superimposed on dc was observed by Seno in ion-exchange membranes dipped in an aqueous sodium chloride solution. The phenomenon was associated with the formation of a salt-depletion diffusion layer. Shashoua reported the generation of current oscillations under constant dc electric field in the membranes consisting of polymeric acid-base composite facing each other. In these cases the presence of salt on both sides of the membrane was one of the requirements in order to generate spikes. Katchalsky explained the appearance of these oscillative phenomena as follows: the current flow through the membrane induces salt accumulation in the polymer membranes, which, at a certain concentration, leads to the shrinkage of the membrane and a breakdown region is formed. The excess ions are washed off to reestablish the original state of the membrane.

An electrically activated mechanochemical system made of polyelectrolyte gels was recently reported[11,12] and a variety of electro-mechanical conversion devices were developed.[13-15]

In the course of this study, We found that the repetitive current oscillation occurred in the gel[11,16] when a dc was applied through electrodes and the semiquantitative analyses of the oscillation were made by use of fast Fourier transform (FFT). The Lorentz plot of the current of the gel obtained by plotting each amplitude against the preceding one resulted in a convergent set around a point on the line of slope 1 indicating that the frequency of the repetitive oscillation fluctuates around this peak and any irregular oscillation can be attributed to a quasi-periodic motion. In fact, the Lorentz plot of the gel currents formed a closed line. Different from the membranes described, the oscillation of our gels is not induced neither by change in gradient of the transmembrane concentration of the ions nor by the periodical response of specific chemical reagents like liquids,[17-19] but induced by the amorphous and homogeneously swollen polyelectrolyte gels. The application of constant electric potential, higher than a certain threshold value, is the only requirement for the generation of periodical oscillations.

The purpose of this paper is to report the effects of external sinusoidal voltage upon the current oscillation of the gel. It was found that the entrainment of current oscillation occurs when the frequency of the sinusoidal stimulation become close to that of parent current oscillation and that the stronger sinusoidal voltage caused the entrainment in wider frequency range.

Experimental

Materials. Gel from alginic acid was prepared by immersing a visking tube (diameter 42 mm) containing 1.1% of sodium salt solution of alginic acid in a large amount of 1.0% calcium chloride solution for 2 days. Crosslinked water-swollen gels of poly(methacrylic acid)(PMAA) and poly(2-acrylamido-2-methyl-1-propanesulfonic acid) (PAMPS) were prepared by radical polymerization of 5.0 mol% aqueous solutions of corresponding monomers in the presence of 5×10^{-2} mol% *N,N'*-methylenebis(acrylamide) (MBAA) which was used as a crosslinking agent. In these cases polymerization was carried out at 60 °C under vacuo, and 5×10^{-2} mol% of potassium peroxodisulfate was used as an initiator. The obtained gels were then immersed in water at least for 1 week to remove excess salt. The degree of swelling $DS=(W_s-W_d)/W_d$ was calculated by weighing the weights of dry (W_d) and water-swollen (W_s) gels, respectively.

Method of Measurement. A piece of water-swollen cylindrical polymer gel, 11 mm long and 24 mm in diameter, was placed in a Petri dish containing water of ca 10 mm depth. A pair of platinum wire electrodes 20 mm long and 0.2 mm in diameter were inserted in the gel with a distance of 10 mm and 10 mm in depth. A dc voltage (V_o=5 V) was applied in order to induce the current oscillation through the platinum wire electrodes. A stable current oscillation with a frequency of f_o, was observed after a certain induction period. The sinusoidal voltage, $V_o+V \sin 2\pi f_i xt$ was then applied by the same platinum wire electrodes. In these cases the current supply was delivered to the electrodes from Hokuto 501 potentiometer. The oscillative response of the gel was recorded on a data recorder (Hitachi 561) and the response of the current oscillation to the sinusoidal stimulation (f_i) was analyzed by a personal computer (NEC, model PC 9801 Vm2). The oscillation was simultaneously sampled at intervals 500 ms and in the range of $0.005<f_i<1$ Hz and $0.005<V<2$ V depending on the nature of oscillation and was used for computer analysis.

Measurement of the oscillation was carried out at 25 °C. Water used in these experments had an electric conductivity in the range $1-5\times10^{-7}\ \Omega^{-1}\ cm^{-1}$.

Results and Discussion

Figure 1(A) shows a repetitive curve and its power spectrum of the gel when dc (7 V) was applied to the calcium alginate gel. As reported in the earlier paper[16] the oscillatory current appeared after a certain induction period, and this oscillation occurred undamped for more than several hours and more. There existed a "threshold" value of potential, below which (in this experiment about 3 $V\,cm^{-1}$ or below) practically no oscillation appeared. During the induction period, the undamped oscillations appeared in every crosslinked water-swollen polymeric gel, provided they possess ionized moieties, regardless of strong or weak polyelectrolytes. The power spectrum of this oscillation shows a main peak at the frequency of 0.013 Hz (f_o) with higher harmonics. The magnitude of the main peak was about 9.80% of that of total energy within a range of 0.5 Hz. The maximum amplitude of the current oscillation was about 0.22 mA.

Entrainment by Sinusoidal Voltage. Figure 1 B—D shows the effects of external sinusoidal voltage upon the current oscillations and the power spectra when the ac frequencies (f_i) from 0.005 through 0.03 Hz and amplitude (V) of 2 V were superimposed afterward to the oscillation induced by dc voltage (V_o=5 V). Thus, the electric field by dc+ac does not exceed the value applied by dc. When the ac with the frequency of 0.005 Hz was applied to this oscillating gel, the response of the current oscillation became chaotic as shown in the power spectrum (Fig. 1(B)). The magnitude of this ac was about 0.08 mA and this value was much lower than that induced by dc 5 V. The power spectrum in this case has many peaks but the peak induced by dc (f_o) also remained at 0.013 Hz. The magnitude of f_o is about 0.85% of the total energy and that of frequency of ac (f_i) is about 0.63%. The frequency of the main peak was shifted to 0.15 Hz and magnitude of this peak was about 1.30%.

Figure 1(CI) shows the response of current oscillation and its power spectrum when the ac with a frequency of 0.01 Hz was applied. The power spectrum has a sharp peak at the frequency of 0.01 Hz but there is no peak of f_o this time. The magnitude of this peak is large and comprises about 28.8% of that of total within the range of 0.5 Hz. This suggests the 1:1 entrainment of current oscillation occurred. The response of this current oscillation gradually changed with time. As shown in the spectrum of Fig. 1 (CII); the frequency of main peak changed to that of ac in the course of experiment and after 17 min (1026 s) the entrained frequency changed from 0.01 Hz to 0.02 Hz. This shows that the frequency of the entrained oscillation became twice of that of sinusoidal stimulating oscillation (2 : 1 entrainment).

When the ac of 0.03 Hz was applied to the gel, a complete change of the oscillation was observed as shown in Fig. 1 (D). There is no peak of f_o any more, but only the repetitive oscillation with a frequency of f_i (0.03 Hz) was observed. The magnitude of the peak corresponding to 0.03 Hz was as large as 94% of that of total within a range of 0.5 Hz, clearly showing that the current oscillation induced by dc was completely entrained to the oscillation induced by ac even the magnitude of the latter was much lower. Thus, it was demonstrated that the entrainment of oscillation occurs in the gel when ac with certain frequency is

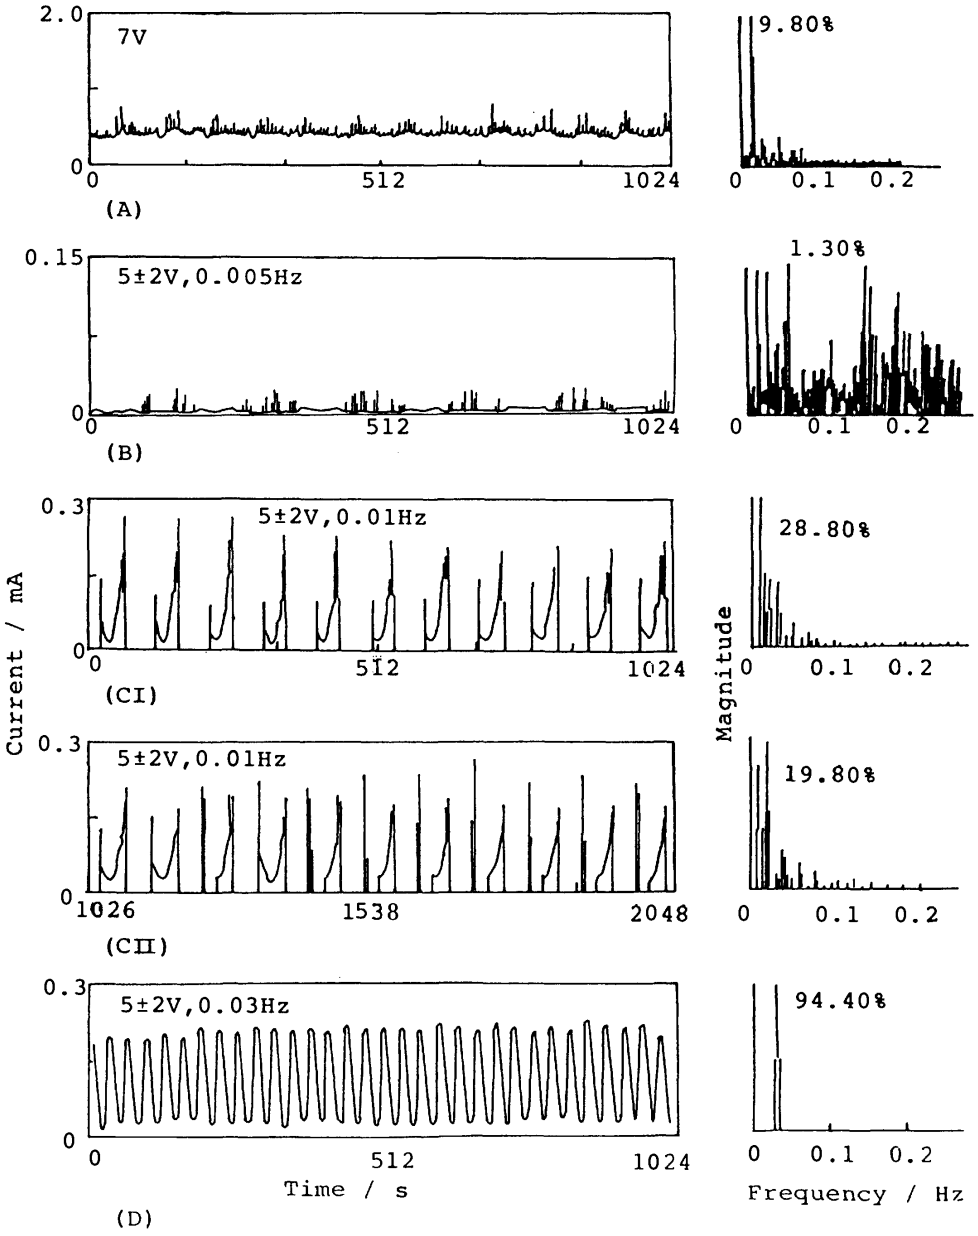

Fig. 1. The effects of frequency of external sinusoidal voltage upon the current oscillation. Gel: calcium alginate, 24 mm in diameter, 11 mm long, DS: 40, electrode distance: 10 mm.

imposed, and the phenomena were observed repeatedly for various polymer gels.

Effect of ac Frequency of Sinusoidal Voltage. The dependence of the magnitude of f_o and f_i on the frequency of f_i for various polymer gels is shown in Fig. 2(A—C). In the case of calcium alginate gel (Fig. 2(A)), magnitude of f_o decreased quickly with increasing ac frequency and the oscillation with a frequency of f_o completely disappeared at the value f_i=0.01. This fact indicates that the entrainment of current oscillation was completed at this frequency, and suggests that there exists the threshold ac frequency in this case in order to cause an entrainment.

The entrainment of the oscillation was also observed in other polyelectrolyte gels regardless of weak (PMAA) or strong (PAMPS) polyelectrolyte. The examples are shown in Fig. 2B and 2C, respectively. The threshold frequency in order to induce an complete entrainment was 0.05 Hz for PMAA gel and the magnitude of the peak at 0.05 Hz was 80.5% as shown in Fig. 2B. As shown in Fig. 2B the magnitude of the oscillation corresponding to f_o decreased

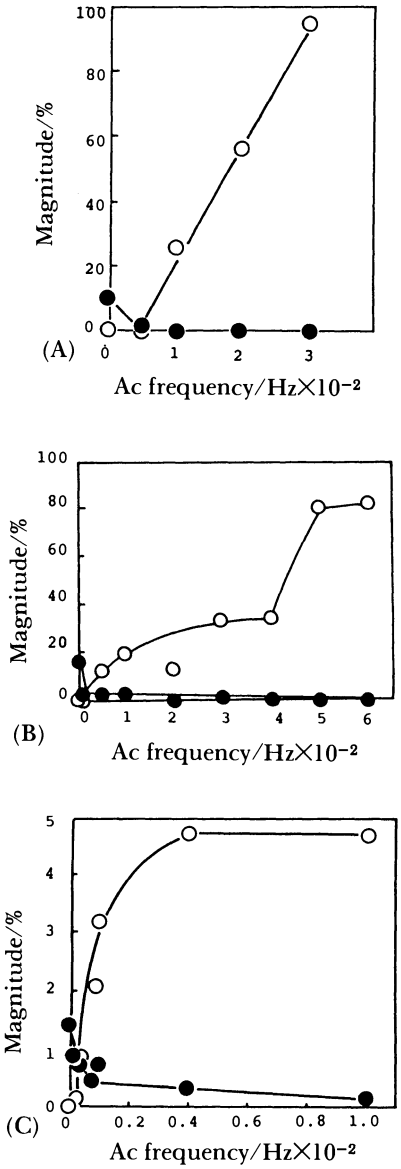

Fig. 2. Dependence of magnitude of f_o(●) and f_i (○) on the frequency of f_i.
Polymer gels: (A) calcium alginate: 26 mm in diameter, 12 mm long, DS: 40, electrode distance: 5 mm, dc: 5 V, ac: 2 V. (B) PMAA: 14 mm in diameter, 10 mm long, dc: 10 V, electrode distance: 7 mm, dc: 5 V, ac: 1 V. (C) PAMPS: 12 mm in diameter, 17 mm long, DS: 50, electrode distance: 7 mm, dc: 5 V, ac: 1 V.

quickly when ac with a frequency (f_i) of 1×10^{-3} Hz was imposed. A gradual decrease of magnitude of f_o was then observed whereas the magnitude of f_i increased rather rapidly. A complete entrainment occurred when f_i was larger than 0.04 Hz. A sudden and steep increase in magnitude of f_i was simultaneously observed.

In the similar manner the magnitude of parent oscillation f_o of PAMPS gel decreased rapidly when ac was imposed (Fig. 2C). However, a complete entrainment was not observed within a range of 1 Hz.

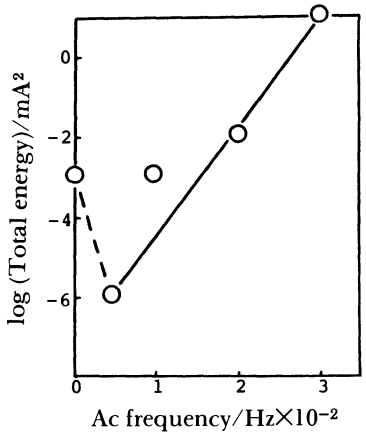

Fig. 3. Dependence of total energy whthin a range from 0 to 0.5 Hz on the frequency of f_i. gel: calcium alginate, 24 mm in diameter, 11 mm long, DS: 40, electrode distance: 10 mm, dc: 5 V, ac: 2 V.

The magnitude of f_i was not large comparing preceding two examples and the value was only 5% or less. Figure 3 shows the dependence of total energy on the ac frequency f_i. Total energy is defined as an integral calculus of the power spectrum within a certain frequency range. It is seen from Fig. 3 that the total energy calculated within 2.5 Hz is extremely low as 10 mA^2 when ac with a frequency of 0.05 Hz was imposed. However, it increased exponentially with increase in ac frequency and the total energy of the oscillation entrained by ac with a frequency of 0.03 Hz, was 10^6 times larger than that entrained by ac 0.005 Hz. We cannot clarify the reason at present, but as reported in the previous paper, PAMPS is a strong polyelectrolyte and exhibits intensive oscillation with many higher harmonics. The different characteristics of entrainment observed in PAMPS gel should be explained with this different nature of the oscillation.

Effect of Amplitude of Sinusoidal Voltage. Complete entrainment could be observed when the frequency of sinusoidal stimulation was kept constant but ac voltage was altered. Figure 4 shows the effects of external sinusoidal voltage upon the current oscillation of calcium alginate gel. Here, the ac frequency (f_i) was kept constant at 0.03 Hz, while amplitude was varied as 0.05, 0.08, 0.13, 0.82, 2.0 V, respectively. Figure 4(A) corresponds to repetitive oscillation curve and its power spectrum of the gel when dc (5 V) was applied. It was found from Fig. 4A that the frequency of the current oscillation induced by dc was about 0.038 Hz and the amplitude of this oscillation was about 0.1 mA.

The current of ac in the gel at 2 V ac was 0.04 mA and this value was less than 50% that of current oscillation induced by dc. Thus, the current oscillation induced by dc is not covered by the ac imposed afterward. When ac voltage (0.03 Hz) as low as 0.05 V

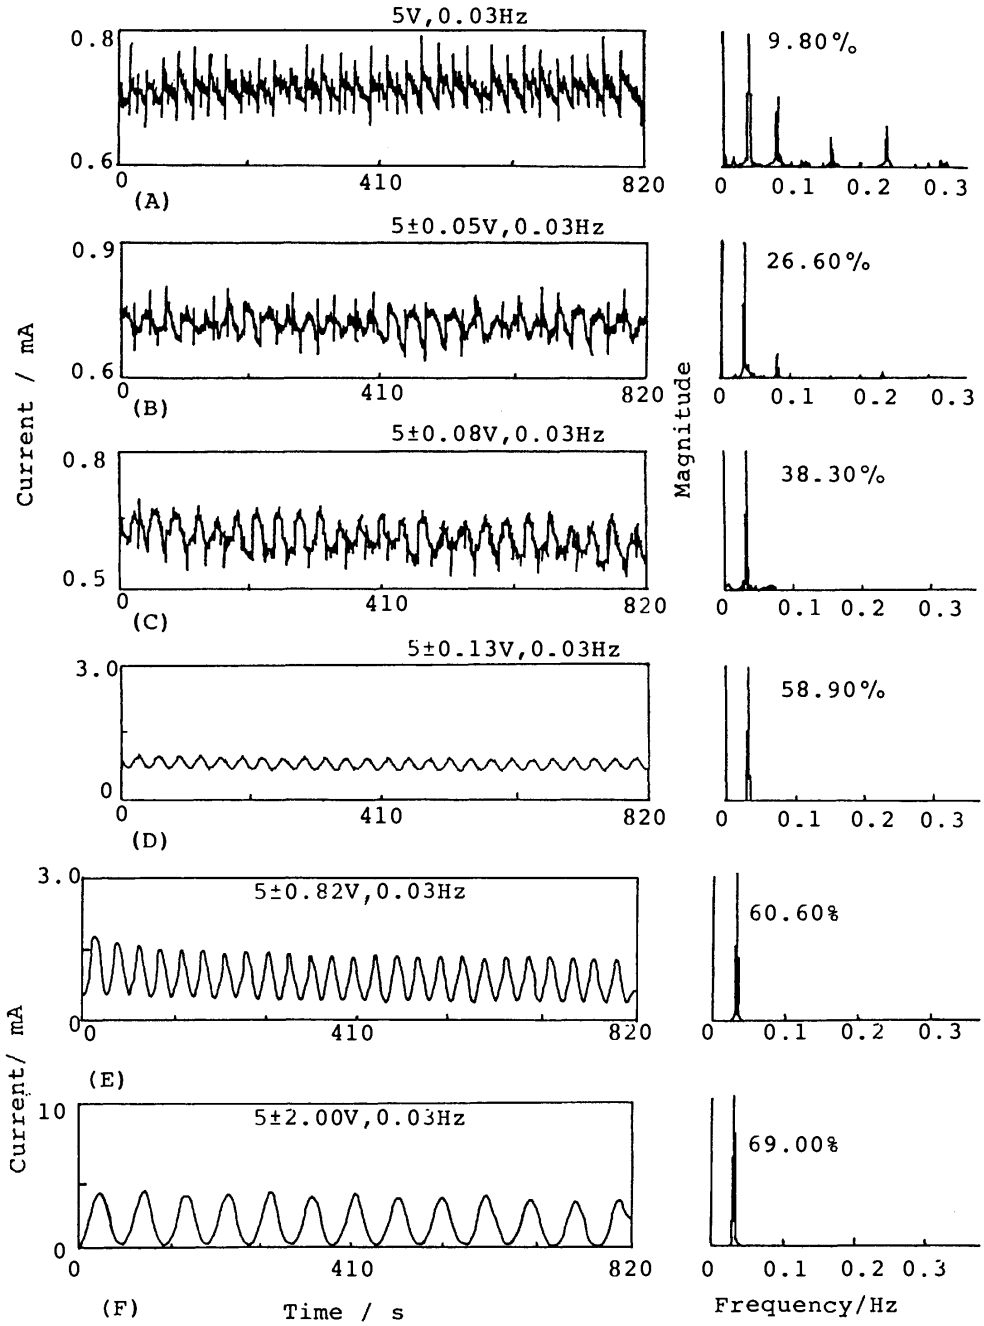

Fig. 4. The effects of amplitude of external sinusoidal voltage upon the current oscillation. Gel: calcium alginate, 26 mm in diameter, 12 mm long, DS: 40, electrode distance: 5 mm.
(A) dc: 5 V, (B) dc: 5 V, ac: 0.05 V, 0.03 Hz, (C) dc: 5 V, ac: 0.08 V, 0.03 Hz. (D) dc: 5 V, ac: 0.13 V, 0.03 Hz, (E) dc: 5 V, ac: 0.82 V, 0.03 Hz, (F) dc: 5 V, ac: 2.00 V, 0.03 Hz. Figures denoted in the power spectra indicate percent magnitude of the main peak of total energy generated within a range from 0 to 2.5 Hz.

or 0.08 V was applied, magnitude of f_o induced by dc decreased from 9.80% to 0.73%. Instead, a new peak corresponding to f_i (0.03 Hz) appeared and this is clearly seen in their power spectra (Fig. 4B and 4C). When the ac amplitude is as high as 0.13 V, the parent oscillation completely disappeared and new ac current having only one peak of f_i was observed (Fig. 4D, 4E, and 4F). Magnitude of this peak is about 58.9%. Further increase in ac voltage up to 0.82 V or 2.0 V (Fig. 4E and 3F) lead to additional increase of magnitude of the oscillation consisting of only one peak of f_i(0.03 Hz). From these results it is seen that the 1 : 1 entrainment of the current oscillation occurs at the amplitude from 0.13 V to 2.0 V and chaotic behavior appears when the ac amplitude is less than 0.13 V. Figure 5 shows the dependences of magnitude of spec-

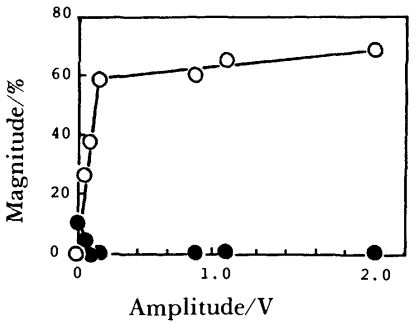

Fig. 5. Dependence of magnitude of f_o and f_i on ac amplitude. gel: calcium alginate, 26 mm in diameter, 12 mm long, DS: 40, electrode distance: 5 mm.

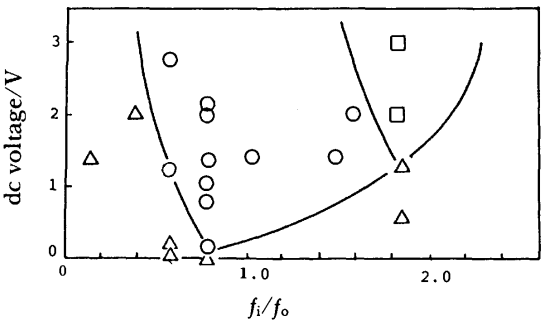

Fig. 6. The phase diagram of the current oscillation under the sinusoidal stimulation. Gel: calcium alginate, 24 mm in diameter, 11 mm long, dc: 40, electrode distance: 10 mm. ○: 1 : 1 entrainment, □: 2 : 1 entrainment, △: chaotic.

tra of f_o and f_i on ac amplitude. The magnitude of the peak at the frequency of 0.038 Hz (f_o) decreased quickly by imposing ac current and disappeared completely at the voltage as low as 0.13 V. Simultaneously, the magnitude of a peak corresponding to 0.03 Hz (f_i) increased until ac voltage becomes 0.13 which then changed almost plateau. It should be noted again that after entrainment only one peak corresponding to 0.03 Hz was seen in the power spectra. Thus, in the similar manner as changed ac frequency (Fig. 2A and 2B), the threshold amplitude of ac was required in order to make an entrainment of current oscillation.

Phase Diagram. The phase diagram of the response of the current oscillation to the sinusoidal stimulation in the case of calcium alginate gel is shown in Fig. 6. When the f_i/f_o is 0.8 or higher, the entrainment of current oscillation was observed in the wide range of dc from 0.1 to 2 V. If the dc voltage is increased, the entraiment occurs in lower f_i/f_o. At higher dc voltage and higher f_i/f_o, a 2 : 1 entrainment preferably occurs. From this figure it is seen that an entrainment of the oscillation induced by dc occurs more easily when the ac frequency was close to that of parent oscillation. It is also seen the stronger sinusoidal voltage cause the entrainment in wider frequency range. Away from these frequency ranges and weak ac amplitude, the chaotic behavior was observed.

Our preliminary hypothesis of the oscillation in the gel is that nonlinear ion transport causes a periodic electrostatic as well as osmotic potential owing to change in charge densities on a local level. One of the experimental evidences is that the pH oscillation occurred in the gel[20] for a prolonged period of time after the electric field was turned off; as reported previously[20] a constant potential was applied to the PAMPS gel for 40 min, thereafter the electrodes were removed, instead a specific micro-pH electrode was inserted. No periodic oscillation or fluctuation of pH appeared for the first 50 min, however, intensive and clear oscillation accompanied with some satellite peaks suddenly appeared.

The obtained results indicate that many ion transport process can be ordered and syncronized by superimposing ac. This fact means that the factors which may cause the nonlinear ion transport have many degree of freedom and are flexible and it is possible to be able to synchronize to external stimulation. To our knowledge, there has been no study on such periodical nature of oscillations in the water-swollen homogeneous gels having no ion gradient and may be of interest in relation to many rhythmic systems and "deterministic chaos".

There has been an increasing interest in the rhythmic systems appeares in the individuals in biology such as oscillation of heart, circadian rhythms, the cellular fussion. Entrainment phenomena observed in the hydrated gel may provide the simplest and suitable model for understanding syncronized rhythmic system in biology.

We are grateful to Dr. Gen Matsumoto (Electrotechnical Laboratory, AIST) for kind advices, useful suggestion to data analysis, and encouragement.

Syntheses, Spectroscopic Properties, Crystal Structures, and Antitumor Activities of the Optically Isomeric Mandelate Chelates, Mandelato(*trans*-1,2-diaminocyclohexane)platinum(II)

T. Ken MIYAMOTO,* Kojiro OKUDE, Kazuyuki MAEDA, Hikaru ICHIDA, Yukiyoshi SASAKI, and Tazuko TASHIRO†

(Received May 10, 1989)

The four optical isomers of mandelato(*trans*-1,2,-diaminocyclohexane)platinum(II) have been prepared. The CD and NMR spectra of these compounds in solution indicate that the mandelate coordinates to platinum(II) to form a five-membered chelate ring. The X-ray crystal structure analyses of a pair of diastereomers, (*R*)-mandelato[(1*R*,2*R*)-1,2-diaminocyclohexane]platinum(II) and (*S*)-mandelato[(1*R*,2*R*)-1,2-diaminocyclohexane]platinum(II), have confirmed that the skeletal configuration of (*R*)- or (*S*)-mandelic acid is retained during the chelation of platinum(II). As a whole, the structural features of both diastereoisomers are analogous to each other. However, slight differences in hydrogen bonding are noticeable in relation to the solubilities. A preliminary animal test against mice leukemia L1210 was carried out using these compounds. The four isomers show different activities. All these facts together support the conclusion that the chiralities of both ammine (carrier) and mandelate (leaving group) influence the antitumor activities of the platinum agents.

Since the discovery of significant antineoplastic activity of *cis*-dichlorodiammineplatinum(II),[1] this complex has been widely used as an anticancer agent. The drug, however, is highly toxic, especially regarding renal damage. Consequently, a vast number of platinum complexes have been prepared in search of less toxic antitumor agents.

In the process of amelioration, 1,2-diaminocyclohexane (dach) was reported as being a potent ligand (carrier ligand) for antitumor platinum complexes.[2-4] Kidani et al. resolved three isomers of dach and found that the platinum(II) complexes of each isomer have different antitumor activities against mice luekemia L1210.[5] The *trans*-dach complexes were more potent than the *cis*-dach complex. The different activities between the *trans*-dach complexes. i.e., (1*R*,2*R*)- and (1*S*,2*S*)-isomeric complexes, were supposed to be derived from chiral recognitions between the active platinum(II) species and their final targets, DNA bases. This point of view leads to one of the most important subjects in drug design: the chirality of the carrier ligand. Further emphasis should be placed on the fact that the anionic ligands (leaving groups) in the platinum complexes also have considerable influence on antitumor activities,[6,7] and have been supposed to play important roles in drug metabolism. Accordingly, special regard will be paid to not only the chiralities of the carrier ligands, but those of the leaving groups.

Recently, Totani et al. have reported the syntheses of a series of (glycolato-*O*,*O'*)platinum(II) complexes.[8] These complexes have a novel chelate ring in which glycolate is bound to platinum(II) with both carboxylato- and alcoholato-oxygens. By using the optically active mandelate(md) as a leaving group instead of glycolate, a chiral point can be brought about in the vicinity of platinum(II).

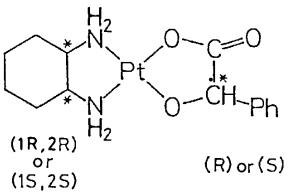

Fig. 1. The proposed structure of [Pt(dach)(md)].

In general, platinum(II) alkoxides are unstable and a limited number of examples are known to date.[9-11] Therefore, alcoholato-platinum(II) bonding stabilized by chelation arouse interest in the study of the structural characteristics. However, even X-ray crystal structure analysis has not so far been applied to the glycolate or mandelate-chelating complexes.

Thus, we have prepared the four optical isomers of platinum(II) complexes with *trans*-dach and md as ligands; i.e., (*R*)- or (*S*)-mandelato[(1*R*,2*R*)- or (1*S*,2*S*)-1,2-diaminocyclohexane]platinum(II) (Fig. 1). Syntheses, X-ray structure analyses and their properties, including the antineoplastic activities, are described here.

Experimental

Materials. From a commercially available mixture of *trans*- and *cis*-diaminocyclohexane an optically pure (1*R*,2*R*)-*trans*- or (1*S*,2*S*)-*trans*-isomer was resolved according to a method described in the literature.[12]

The four nitrate complexes, i.e., dinitrato[(1*R*,2*R*)-1,2-diaminocyclohexane]platinum(II); [Pt(*RR*-dach)$(NO_3)_2$], dinitrato[(1*S*,2*S*)-1,2-diaminocyclohexane]platinum(II); [Pt(*SS*-dach)$(NO_3)_2$], *cis*-dinitratodiammineplatinum(II); [Pt$(NH_3)_2(NO_3)_2$] and *cis*-dinitratodiisopropylamineplatinum(II); [Pt$(ipr)_2(NO_3)_2$], were prepared using a similar method to that of Lippert et al.[13]

The Optical Isomers of Mandelato(*trans*-1,2-diaminocyclohexane)platinum(II): The compound was synthesized

by the modified method from the literature.[8] A 4.61 g (11 mmol) portion of [Pt(*RR*-dach)(NO_3)$_2$] was dissolved in 150 ml of water with heating. The solution was passed through a column packed with the anion exchange resin (Diaion SA10AOH, 160 ml) and a further amount of water was passed through the column. To the combined eluate 1.52 g of (*R*)-mandelic acid (10 mmol) was dissolved. After stirring overnight, the solution was evaporated to dryness. A small amount of water was added and the mixture was stirred at 60 °C. By filtration, a white powder of (*R*)-mandelato[(1*R*,2*R*)-1,2-diaminocyclohexane]platinum(II) monohydrate [Pt(*RR*-dach)(*R*-md)]·H_2O was obtained (3.68 g. 8.0 mmol, 80% yield). A crystal suitable for **X**-ray crystal analysis was obtained by recrystallization from water. In a similar manner, another three optical isomers of mandelato(*trans*-1,2-diaminocyclohexane)platinum(II) were synthesized. Found: [Pt(*RR*-dach)(*R*-md)]·H_2O: C, 35.16; H, 4.65; N, 5.86%; [Pt(*RR*-dach)(*S*-md)]·H_2O: C, 35.37; H, 4.62: N, 5.86%; [Pt(*SS*-dach)(*R*-md)]·H_2O: C, 35.09; H, 4.53; N, 5.81%; [Pt(*SS*-dach)(*S*-md)]·H_2O: C, 35.23; H, 4.62; N, 5.75%. Calcd for $C_{14}H_{22}N_2O_4Pt$: C, 35.22; H, 4.62; N, 5.75%.

(*R*)-Mandelatodiammineplatinum(II) [Pt(NH_3)$_2$(*R*-md)]·1/2H_2O: The complex [Pt(NH_3)$_2$(NO_3)$_2$] (1.05 g, 3.0 mmol) was dissolved in water (150 ml) with heating. The solution was passed through a colunm packed with the anion exchange resin (Dianion SA10AOH, 160 ml) and a further amount of water was passed through the colunm. To the combined eluate 451 mg of (*R*)-mandelic acid (3.0 mmol) was dissolved. After standing overnight the solution was evaporated to ca. 50 ml. The solution turned pale blue after 3 days of standing. After removing the precipitate the solution was cooled to 0 °C overnight. A white crystalline solid containing a small amount of pale blue material was obtained. A blue impurity could not be removed by recrystalization from water. Yield: 23g mg (0.62 mmol, 21%). Found: C, 24.89; H, 3.30; N, 7.21%. Calcd for $C_8H_{13}N_2O_{3.5}Pt$: C, 24.74; H, 3.37; N, 7.21%.

(*S*)-Mandelatodiisopropylamineplatinum(II) [Pt(ipr)$_2$(*S*-md)]: This complex was similarly synthesized as anhydrous salt: Found: C, 36.25; H, 5.25; N, 5.94%. Calcd for $C_{14}H_{24}N_2O_3Pt$: C, 36.28; H, 5.22; N, 6.04%.

Spectroscopy. The CD spectra were recorded with a JASCO-J500A spectrometer. UV-Vis spectra were obtained by the use of a Hitachi 340 spectrometer.

400-MHz ^{1}H NMR spectra were measured for [Pt(*RR*-dach)(*R*-md)] and [Pt(*RR*-dach)(*S*-md)] in D_2O with DSS as an internal standard by the use of a JEOL JNM-GX FT NMR spectrometer. [Pt(*RR*-dach)(*R*-md)]: δ=1.12—1.22 (2H, m, 4- or 5-dach), 1.24—1.33 (2H, m, 4- or 5-dach), 1.55—1.58 (2H, m, 3- or 6-dach), 2.01—2.07 (2H, m, 3- or 6-dach), 2.31—2.35 (2H, m, 1- and 2-dach), 4.931 (1H, s, α-md), 7.39—7.47 (1H, m, *p*-phenyl), 7.44 (2H, d, J=8 Hz, *m*-phenyl), 7.65 (2H, d, J=8 Hz, *o*-phenyl). [Pt(*RR*-dach)(*S*-md)]: δ=1.12—1.21 (2H, m, 4- or 5-dach), 1.22—1.32 (2H, m, 4- or 5-dach), 1.53—1.61 (2H, m, 3- or 6-dach), 2.00—2.05 (2H, m, 3- or 6-dach), 2.20—2.27 (1H, m, 1- or 2-dach), 2.30—2.37 (1H, m, 1- or 2-dach), 4.93 (1H, s, α-md), 7.37—7.49 (1H, m, *p*-phenyl), 7.45 (2H, d, J=7 Hz, *m*-phenyl), 7.72 (2H, d, J=7 Hz, *o*-phenyl).

22.5-MHz ^{13}C NMR spectrum was recorded with a JEOL FX90Q to [Pt(*SS*-dach)(*R*-md)] in DMSO-d_6 with TMS as an internal standard. δ=24.2 (2C, 4- and 5-dach), 31.4 (1C, 3- or 6-dach), 31.9 (1C, 3- or 6-dach), 60.9 (1C, 1- or 2-dach), 61.5 (1C, 1- or 2-dach), 79.7 (1C, α-md), 126.3 (2C, *o*-phenyl), 127.3 (3C, *m*-, and *p*-phenyl), 145.5 (1C, 1-phenyl), 189.4 (1C, C=O).

19.2-MHz ^{195}Pt NMR spectra were measured for [Pt(*RR*-dach)(*R*-md)] (ca. 20 mg cm^{-3}) and [Pt(*RR*-dach)(*S*-md)] (ca. 200 mg cm^{-3}) in DMSO-d_6 with Na_2PtCl_6 in D_2O as an external standerd. (a JEOL FX90Q) [Pt(RR-dach)(S-md)]: δ=−1897. [Pt(*RR*-dach)(*R*-md)]: δ=−1904. A new peak (δ=−2968) had been growing for [Pt(*RR*-dach)(*S*-md)] with time, but no change was observed for [Pt(*RR*-dach)(*R*-md)].

The IR spectra were measured with a Hitachi 260-30. ν(C=O)/cm^{-1} in KBr disk: [Pt(*RR*-dach)(*R*-md)]·H_2O: 1649; [Pt(*RR*-dach)(*S*-md)]·H_2O: 1664; [Pt(NH_3)$_2$(md)]·H_2O: 1622.

Solubility Test. Solubility (mg ml^{-1}) in H_2O (or dmso) at 26 °C: [Pt(*RR*-dach)(*R*-md)]·H_2O: 7.8 (20); [Pt(*RR*-dach)(*S*-md)]·H_2O: 15.3 (>200).

X-Ray Diffraction Measurement and Structure Determination. Among the four optical isomers, a pair of diastereomers, [Pt(*RR*-dach)(*R*-md)]·H_2O and [Pt(*RR*-dach)(*S*-md)]·H_2O, were applied to the **X**-ray crystal structure analysis.

A colorless plate crystal was subjected to an **X**-ray diffraction measurement. The density of the crystal was measured by a flotation method in mixtures of 1,2-dibromoethane and carbon tetrachloride. X-Ray diffraction intensities were collected on a Rigaku AFC-5R goniometer with graphite monochromatized Mo$K\alpha$ (λ=0.71069 Å) radiation (50 kV, 150 mA) at Research Centre for Spectrochemistry, Faculty of Science, The University of Tokyo. The crystal gradually became yellow during exposure to X-rays, but no significant influences was observed regarding the intensities. Data were corrected for both Lorenz and polarization effects. An empirical absorption correction by ψ-scan was applied to both isomers. The positions of the Pt atoms were solved by Mithril,[14] and other atoms were located by successive Fourier and differential syntheses. An absolute configuration was determined by anomalous scattering factors. The enantiomeric structure was rejected because of the larger *R*-factor. H atoms, except crystal water, were located from calculations, but were not refined. Anisotropic thermal parameters were applied for non-hydrogen atoms and isotropic ones for H atoms. The thermal and positional parameters of all non-hydrogen atoms were refined by full-

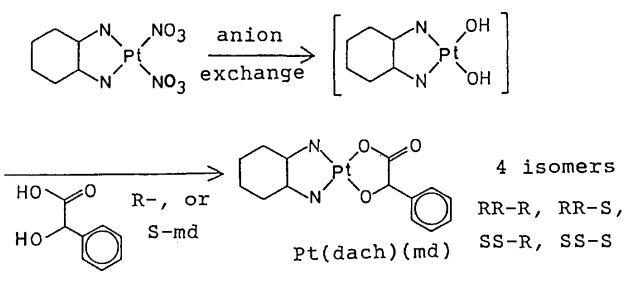
matrix least squares on F with $W=1/\sigma(F_o)$. All calculations were performed with the TEXSAN[15] program with complex scattering factors from International Tables for X-ray Crystallography[16]and were carried out on DEC Micro Vax II at the Research Centre for Spectrochemistry. Crystallographic data and measurement details are listed in Tables 1 and 2, respectively. The complete F_o—F_c data are deposited as Document No. 8893 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Antitumor Assay in vivo. The antitumor activities of the [Pt(dach)(md)] isomers against mice leukemia L1210 were tested. 10^5 cells/mouse were transplanted i.p. into CDF_1 mice (6 mice/group) and samples were administered i.p. on days 1, 5, and 9. From the mean survival times of treated (T) and control (C) mice, T/C values were calculated as indlcators of activity.

Results and Discussion

Syntheses of the Compounds. By the anion exchange of $[Pt(dach)(NO_3)_2]$, dihydroxo species is supposed to be formed in aqueous solution. The dihydroxo complex was neutralized by the addition of the equivalent mandelic acid. The procedure results in the five-membered chelation of platinum(II) (Scheme 1). The neutralization is a relatively slow process: after overnight standing of the reaction mixture at room temperature, an oily product was only obtained; heating of the aqueous solution at 60 °C for several hours gave a crystalline solid. However, at higher temperature (>80 °C), the solution turned red. This coloring indicated a partial decomposition of platinum(II) alkoxide.



Scheme 1. Synthetic procedure to [Pt(dach)(md)]·H_2O.

In the preparation of $[Pt(NH_3)_2(md)]\cdot 1/2H_2O$ without protection to light, the solution turned blue. The addition of excess mandelic acid to this solution precipitated a blue-black solid. The blue product, which showed IR absorption bands due to mandelate and ammine ligands, was assumed a platinum oligomer, such as a "platinum blue"; however, the structure of this compound has not yet been determined. The formation of the oligomeric species by the use of the bidentate ligands seems to be a relatively familiar phenomenon. For example, the well known oligomers of platinum(II) have bidentate bridging ligands such as uracil, pyridone, pyrrolidone, phosphate;[17-19] in our case mandelate. In the preparation of mandelatoplatinum(II) complexes, the oligomer formation is reduced under shading and at higher pH (with use of excess platinum nitrate).

Table 3. The CD and UV Data

Complex	CD λ_{max}/nm($\Delta\varepsilon$)	UV λ_{max}/nm(ε_{max})

Spectroscopic Properties. The CD and UV data are listed in Table 3. The CD spectra of [Pt(*RR*-dach)(*R*-md)] and [Pt(*RR*-dach)(*S*-md)] are inverse to those of their enantiomers, [Pt(*SS*-dach)(*S*-md)] and [Pt(*SS*-dach)(*R*-md)], respectively. On the other hand, the spectra of diastereomers are quite different from each other, indicating a marked influence of the mandelate ligands. The additivity rule due to ligand contributions is generally applied to the CD spectra of coordination compounds. The notable contribution of mandelate is rationalized on the assumption that it is bound to platinum(II) by both carboxylato- and alcholato-oxygens because the chelate configurations have great effects on the CD spectra. If mandelate is linked to the metal via only carboxylato-oxygen, namely in a unidentate fashion, only a vicinal effect could be observed in the CD spectra as a minor contribution. Free mandelic acid has a weak CD at 250 nm or longer wavelength,[20] which is not consistent with the observed strong CD curve. These CD data suggest mandelate chelation in solution.

The CD spectrum of [Pt(dach)(NO_3)$_2$] has two peaks (λ_{max} 330 and 246 nm) assignable to $^1A_{1g}\rightarrow{}^3E_g$ and $^1A_{1g}\rightarrow{}^1E_g$, respectively.[21] Hawkins et al. reported that the octant sign was negative when $^1A_{1g}\rightarrow{}^1E_g$ transition had a positive Cotton effect.[22] In the case of the square planar complexes, the five-membered chelate with λ-gauche conformation has a negative octant sign. The $^1A_{1g}\rightarrow{}^1E_g$ transition of [Pt(*RR*-dach)(NO_3)$_2$] shows a positive Cotton effect and is assumed to have λ-gauche conformation, which is consistent with the (1*R*,2*R*)-configuration of the ligand.

The complex [Pt(NH_3)$_2$(*R*-md)] has four donor atoms (i.e., two nitrogen and two oxygen atoms) in common with [Pt(*RR*-dach)(NO_3)$_2$]. It is therefore expected that the CD spectrum of the former complex may have the $^1A_{1g}\rightarrow{}^1E_g$ transition at similar wavelength as that of the latter complex. A λ_{max} peak at 255 nm, which shows a positive Cotton effect, may be assigned to the $^1A_{1g}\rightarrow{}^1E_g$ transition. In this way we can estimate that the mandelate chelate may have a λ-gauche conformation in aqueous solution. However, this proposal might not be reliable since the mandelate chelate contains a carboxyl group and its symmetry is lower than that of *RR*-dach chelate. In any case, the CD data support the (*R*)-configuration of the mandelate.

The CD spectra of the four isomers, [Pt(dach)(md)] are essentially linear combinations of those of [Pt(dach)(NO_3)$_2$], [Pt(NH_3)$_2$(*R*-md)], and/or [Pt(ipr)$_2$(*S*-md)]. This result suggests again that the configurations of the ligands are retained on the coordination to platlnum(II).

The ^1H NMR spectra were measured for a pair of diastereomers, [Pt(*RR*-dach)(*S*-md)] and [Pt(*RR*-dach)(*R*-md)]. The dach ligand of [Pt(*RR*-dach)(*S*-md)] shows two sets of multiplets due to the methine protons, since these protons become nonequivalent with the coordination of asymmetric mandelate. In the case of [Pt(*RR*-dach)(*R*-md)], such a separation of methine protons is not observed. Both diastereomers also show the mandelate-methine proton as a singlet; unfortunately, though, the coupling with ^{195}Pt, the corroborative evidence,[8] cannot be detected under the influence of too large an HDO signal. Several attempts to reduce the HDO signal (such as a WEFT method, an off-resonance decoupling or the recrystallization from D_2O) have been unsuccessful up to the present. As a whole, the chemical shifts of both diastereomers bear a close resemblance to each other, but only slight differences have been observed on the phenyl proton signals. These differences may be caused by the mandelate conformations.

The ^{13}C NMR spectrum was measured for the soluble isomer, [Pt(*SS*-dach)(*R*-md)] in DMSO-d_6. Since the mandelate ligand is asymmetric, splits of 1,2- and 3,6-dach carbons are observed. On the methine carbons of both dach and mandelate, no satelite peaks have been detected, though the observed signals are somewhat broad.

The ^{195}Pt NMR spectra of both [Pt(*RR*-dach)(*R*-md)] and [Pt(*RR*-dach)(*S*-md)] have a broad peak at ca. −1900 ppm. Usually, the chemical shifts of ^{195}Pt NMR range very widely from compound to compound. The shift differences between the isomers are negligibly small, in due consideration of the concentration difference in solution. The observed shift-values belong to the range characteristic of a type of coordination compound, PtN_2O_2, which consists of the four donor atoms (two nitrogens, two oxygens) and a platinum atom. After 60 days standing in solution, the original compound, [Pt(*RR*-dach)(*S*-

md)], partly changed into another species; a new peak was observed at −2970 ppm. On the other hand, the isomer, [Pt(*RR*-dach)(*R*-md)], did not change at all. The half decay time of the original peak was ca. 25 days. The new species is tentatively assignable to a platinum-dimethyl sulfoxide (DMSO-d_6) complex in which dmso is bound to platinum(II) through an S atom, while mandelate coordinates via only carboxylate-oxygen. A similar reaction between dmso and *cis*-[Pt(NH_3)$_2$$Cl_2$] was reported,[23] but the half decay time of the original peak due to cis-platin is 3 h which is much shorter than that of [Pt(*RR*-dach)(*S*-md)]. From the comparison, it is obvious that the mandelate chelate is relatively stable in solution in spite of the expected instability of platinum alkoxide.

Thus, all CD and NMR results are consistent with the chelate structure of mandelatoplatinum(II) complexes in solution.

The solid state IR spectra of [Pt(*RR*-dach)(*R*-md)]·H_2O and [Pt(*RR*-dach)(*S*-md)]·H_2O are identical to [Pt(*SS*-dach)(*R*-md)]·H_2O, and [Pt(*SS*-dach)(*R*-md)]·H_2O, respectively.

The C=O stretching absorption appears at 1710 cm^{-1} for mandelic acid[24] and at 1582 cm^{-1} for potassium mandelate.[25] The mandelatoplatinum complexes, i.e., the [Pt(dach)(md)]·H_2O isomers and [Pt(NH_3)$_2$-(*R*-md)]·1/2H_2O have the absorption bands between these peaks. As a cosequence of the reduced resonance by coordination, the complexes increase the bond strength of C=O in comparison with that of free mandelate. The spectrum of [Pt(*RR*-dach)(*R*-md)]·H_2O shows the C=O stretching at 1649 cm^{-1} while the band position of [Pt(*RR*-dach)(*S*-md)]·H_2O is 15 cm^{-1} higher. Such a difference between the diastereomers might be caused by the hydrogen-bonding patterns to a carboxyl oxygen.

Structure Description of [Pt(dach)(md)]·H_2O Isomers. The crystal structure of [Pt(*RR*-dach)(*R*-md)]·H_2O is shown in Fig. 2. Two complexes and two water molecules are crystallographically independent.

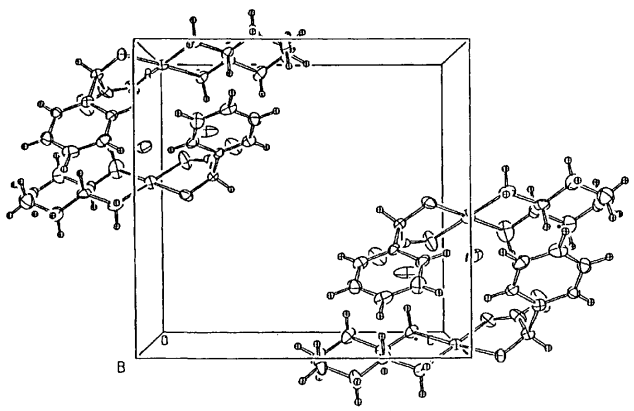

Fig. 2. ORTEP[26] plot of crystal structure of [Pt(*RR*-dach)(*R*-md)]·H_2O. View along b-axis.

These two complexes form a rather discrete cluster; the two independent complexes are related by a pseudo 2-fold axis. Their coordination planes are approximately perpendicular to each other.

The molecular structure of the complex, i.e., crystallographically independent unit of [Pt(*RR*-dach)(*R*-md)]·H_2O, is shown in Fig. 3. The bond lengths and angles are listed in Table 4. Both ligands, namely *RR*-dach and *R*-md, retain their skeletal configurations. The *RR*-dach has a λ-gauche chelate

Thus, the complex, [Pt(*RR*-dach)(*R*-md)]·H_2O is the first example of the bidentate chelate formed by a mandelate ligand. This type of five-membered chelate has been proposed to glycolatoplatinum(II) in solution,[8] but the solid state structure is unknown to date. For the first time the crystal structure has been firmly determined in this work. Historically, the platinum alkoxides are believed to be unstable[29] and few examples have been reported so far.[9-11] In the mandelatoplatinum complex, the metal-alkoxide

a) Intermolecular distances between O and N which are shorter than 3.20Å are listed. b) The atom designator code. The 5-digit number is a composite of three one digit numbers and one two digit number: TA(1st)+TB(2nd)+TC(3rd)+SN(4th and 5th). TA, TB, and TC are the lattice translation along cell edges a, b and c, where digit of 5 indicates the origin cell. The SN is symmetry operation.
Symmetry operators: (1) x,y,z. (2) $-x,1/2+y,-z$.

bond may be stabilized by five-membered chelation. The phenyl group of mandelate rises up to the axial direction to the coordination plane. Such a direction possibly resulted from the crystal packing. Consequently, the *R*-md has δ-gauche conformation in the solid state though λ-gauche conformation is suggested in the aqueous solution by the CD spectra.

The crystal and molecular structures of [Pt(*RR*-dach)(*S*-md)]·H_2O are depicted in Figs. 4 and 5, respectively. The bond lengths and angles are listed in Table 5. The structural feature is analogous to that of [Pt(*RR*-dach)(*R*-md)]·H_2O. Two complexes and two water molecules also have crystallographic independence. The configurations of the ligands are retained in comparison with the corresponding free amine or acid. The *RR*-dach ligand has a λ-gauche conformation. The md ligand is bound to the platinum atom to form a five-membered chelate of λ-gauche conformation. The phenyl group rises up to the axial direction to the coordination plane.

Both isomers have a typical square-planar coordination, except for rather small N-Pt-N and O-Pt-O angles due to the five-membered chelation. As a whole, the structural features of both diastereomers (bond lengths and angles) are very similar.

The hydrogen bonds are listed in Table 6. Between the alcoholates and the water molecules, strong hydrogen bonds are formed. The hydrogen-bonding patterns of both isomers have many similarities to each other, though the hydrogen-bond distributions in a pair of diastereomers are slightly different. Fig. 6 shows that only [Pt(*RR*-dach)(*R*-md)]·H_2O has a hydrogen-bond between carboxylate oxygen and amine nitrogen, directly reflecting the configurations of the two diastereomers. Not only the IR spectra,

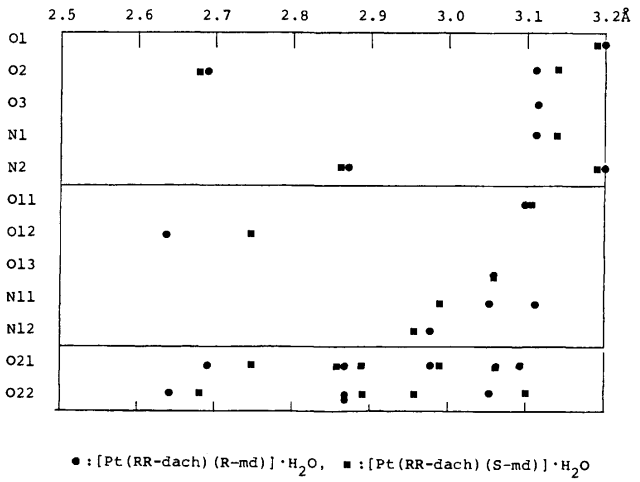

Fig. 6. Hydrogen-bond distributions of two isomers.

but also the solubilities of the diastereomers are practically different from each other. The complex [Pt(*RR*-dach)(*S*-md)]·H_2O is a more soluble isomer in water or dmso (see Experimental). These experimental facts agree well with the above difference in the hydrogen-bond distributions.

Antitumor Activities of [Pt(dach)(md)] Isomers. The results of animal tests against mice luekemia L1210 are listed in Table 7. The complexes show antitumor activities to a certain extent, but not completely. On the other hand, the toxicities are greatly reduced, compared to cis-platin. The four optical isomers exhibit differeences in antitumor activities. Complex [Pt(*RR*-dach)(*R*-md)] is effective over a wide range of dose where its enantiomer, [Pt(*SS*-dach)(*S*-md)], shows no activity. The antitumor activity of [Pt(*RR*-dach)(*S*-md)] is similar to that of [Pt(*SS*-

Table 7. Antitumor Activities against Mice Leukemia L1210

SS-S	Toxic	124	114			

T/C value over 125 was evaluated as antitumor active and indicated with P.

dach)(*R*-md)], but the toxic dose is different.

These results show that the chiralities of not only the carrier ligands, but that the leaving groups influence the antitumor activities of the complexes. It is also likely that the solubilities of the complexes influence the activities.

Synthetic, Spectroscopic and X-Ray Crystallographic Studies of Bivalent Metal Complexes with Amino Acids Having a Thiazolidine Ring. III. The Properties of Bivalent Metal Complexes with Racemic 2-Thiazolidinecarboxylic Acid and the Structure of *trans*-Diaquabis-(2-thiazolidinecarboxylato)zinc(II)

Makoto NAGASE, Yasuhiko YUKAWA,† Yoshie INOMATA,* and Toshio TAKEUCHI
Department of Natural Sciences, Faculty of Science and Technology, Sophia University, 7-1 Kioi-cho, Chiyoda-ku, Tokyo 102
(Received March 4, 1989)

Several complexes with the formula of $ML_2 \cdot 2H_2O$ (HL=racemic 2-thiazolidinecarboxylic acid, S-CH_2-CH_2-NH-CH-COOH, M=Co, Ni, Zn), anhydrous CdL_2 and $CdCl_2(HL)$ were synthesized and characterized by means of their infrared absorption and reflection spectra, magnetic susceptibility, thermal analyses, and powder X-ray patterns. In addition, the crystal structure of $ZnL_2 \cdot 2H_2O$ was also determined. Crystals of this complex are monoclinic, with the space group $P2_1/n$ with a=7.224(1), b=18.246(4), c=5.306(1) Å, and β=104.57(1)° and Z=2. The structure was solved by the heavy atom technique and refined by a block-diagonal least-squares method to a final R value of 0.056 for 1774 unique reflections. The zinc environment consists of two carboxylic oxygen atoms and two thiazolidine nitrogen atoms from two centrosymmetrically related organic ligands in a square-planar arrangement. Two water molecules in the axial positions complete a tetragonal bipyramidal coordination around the metal atom. No sulfur atom is coordinated to the zinc atom. The infrared absorption spectra and the structure of this zinc(II) complex are discussed in comparison with those of zinc(II) complexes with (*S*)-4-thiazolidinecarboxylic acid and racemic 4-thiazolidinecarboxylic acid.

As 4-thiazolidinecarboxylic acid has been reported to induce the restoration of the contact inhibition of tumor cells.[1-3] Tatarowski et al.[4] investigated the NMR and crystallography of zinc(II) complexes with 4-thiazolidinecarboxylic acid and 2-thiazolidinecarboxylic acid. Then we ourselves investigated in detail the coordination behavior of racemic and (*S*)-4-thiazolidinecarboxylic acid toward bivalent metals in the solid state.[5,6] These studies have clearly demonstrated that whether or not the nitrogen atom of the thiazolidine ring coordinates to metal ions depends on the pH of the solution used in the preparation. For complexes which have been prepared in a basic aqueous solution, both a carboxylato oxygen atom and the nitrogen atom bind to metal ions.

In the zinc(II) complex with (*S*)-4-thiazolidinecarboxylic acid prepared at pH<7, the zinc atom is ligated with a carboxylato oxygen atom of a (*S*)-thiazolidinium-4-carboxylate, which has a zwitter ion structure, with two carboxylato oxygen atoms, and with the nitrogen atom of a (*S*)-4-thiazolidinecarboxylate anion and a chlorine atom;[5] in dichlorobis(thiazolidinium-4-carboxylate)zinc(II), the zinc atom seems to be ligated through two chlorine atoms and the carboxylato oxygen atom of the racemic thiazolidinium-4-carboxylate, which has a zwitter ion structure.[6]

In order to discuss the effect of the position of the carboxyl group in thiazolidinecarboxylic acid on the structures of complexes, we have now synthesized it by two methods and characterized bivalent metal complexes with racemic 2-thiazolidinecarboxylic acid. The structure of *trans*-diaquabis(2-thiazolidinecarboxylato)zinc(II) has also been determined. Moreover, we have summarized the coordination behavior of metal complexes with (*S*)-4-thiazolidinecarboxylic and racemic acid as well as with racemic 2-thiazolidinecarboxylic acid.

Experimental

Preparation of Racemic 2-Thiazolidinecarboxylic Acid.[7] An ethanol solution (59.2 g) containing 25% of glyoxylic acid was slowly added to 200 cm^3 of an ethanol solution including 35.5 g (0.31 mol) of cysteamine hydrochloride. This mixed solution was then refluxed for 90 minutes at 80 °C. After the solution had then cooled until room temperature, colorless crystals were precipitated. After these crystals had been separated, they were recrystallized from water and dried in a silica-gel desiccator.

Preparation of Complexes. $CoL_2 \cdot 2H_2O$ was prepared by adding 0.01 mol of fresh cobalt(II) hydroxide to a hot aqueous solution containing 0.02 mol of racemic 2-thiazolidinecarboxylic acid. After the solution had been stirred for an hour in a water bath at 60 °C, the precipitate which formed was filtered, washed with water, and dried in vacuo for six hours at room temperature. $NiL_2 \cdot 2H_2O$, $ZnL_2 \cdot 2H_2O$, and CdL_2 were prepared from the corresponding metal hydroxides by the same procedure as was used for the cobalt(II) complex. The crystal used for the single crystal X-ray analysis was prepared by keeping the saturated aqueous solution for two weeks at room temperature.

$CdCl_2(HL)$ was prepared by adding 0.01 mol of cadmium-

† Present address: Division of Chemistry, General Education Department, Niigata University, 8050 Ikarashi, Ninocho, Niigata 950-21.

(II) chloride to an aqueous solution containing 0.01 mol of this ligand. The mixed solution, after it had been stirred and condensed for an hour at 80 °C, was allowed to stand for two weeks. The crystals thus precipitated were dried in vacuo for six hours at room temperature.

Deuterated complexes were obtained by recrystallization in D_2O.

Physical Measurements. The powder diffuse reflection and infrared absorption spectra, magnetic moments, and thermal analysis were obtained by the methods described in previous papers.[5,6]

Single Crystal X-Ray Analysis. The reflection intensities were collected by the ω-2θ scan technique on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite monochromated Mo$K\alpha$ radiation. 1774 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the refinement. The intensities were corrected for the Lorentz and polarization factors: however, no corrections were made for absorption and extinction because $\mu r(<1)$.

All the calculations were carried out on a HITAC M-680H computer at the Computer Center of the University of Tokyo, using the local version of UNICS.[8] The scattering factors were taken from the tables.[9]

The structure was solved by the heavy-atom method and refined by a block-diagonal least-squares method. The positions of the zinc and oxygen atoms were obtained from a three-dimensional Patterson map, while the positions of all the other non-hydrogen atoms were successively located by Fourier syntheses. The positions of the hydrogen atoms were obtained by means of difference-Fourier syntheses. The weighting scheme was $w=1/[\{\sigma(|F_o|)\}^2+(0.02\times|F_o|)^2]$. In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) was 0.056.

Results and Discussion

The results obtained from the elemental analyses and those of the reflection spectra and magnetic moment calculations are listed in Tables 1 and 2 respectively. These results and the infrared spectra suggest that there are two types of complexes: A and B. The A type is $ML_2\cdot nH_2O$ (M=Co(II), Ni(II), Zn(II), Cd(II), HL=racemic 2-thiazolidinecarboxylic acid n=0, 2). The B type is $CdCl_2$(HL).

The reflection spectra and magnetic moments are similar to those of the corresponding complexes with racemic 4-thiazolidinecarboxylic acid. From these

Table 1. Elemental Analyses of Racemic 2-Thiazolidinecarboxylic Acid (HL) and Its Metal Complexes

Compound	Found (Calcd) /%				
	H	C	N	M	Cl
HL	5.54 (5.30)	35.45 (36.07)	10.52 (10.52)

a) As metal oxide. b) As metal sulfide.

assignments of the reflection spectra, it seems that the cobalt(II) and nickel(II) complexes have an octahedral configuration, as is suggested by reference to the X-ray analyses for diaqua((*S*)-4-thiazolidinecarboxylato)-zinc(II)[4] and diaqua(2-thiazolidinecarboxylato)-zinc(II) to be discussed below and by the reflection spectra of other complexes.[10-12]

Thermal Analysis. The temperature range and the percentage of the mass loss obtained from the TG and DTA curves are summarized in Table 3. The cobalt(II), nickel(II), and zinc(II) complexes release two molecules of water in the first endothermic reaction. Thereafter these complexes change to the corresponding metal oxides in an exothermic reaction.

The cadmium(II)-A complex gives two exothermic reaction steps with a mass loss. In the first step, the cadmium(II)-A complex becomes cadmium sulfide; then this sulfide seems to change to cadmium oxide in the second step.

For the cadmium(II)-B complex, an endothermic peak is observed at about 190 °C. This peak is assigned to the melt of this complex. After that, the exothermic reaction occurs immediately, with a mass loss, and the complex decomposes to cadmium halide. Finally, after several exothermic reactions with a gradual mass loss, no residual is obtained. In these steps, cadmium halide changes into cadmium oxide, which then sublimes. The same behavior is observed for dichloro(4-hydroxy-L-proline)cadmium(II).[13]

Infrared Absorption Spectra. The infrared spectral data are listed in Table 4. The assignments of the observed frequencies have been made by referring to (*S*)-4-thiazolidinecarboxylic acid, racemic 4-thiazolidinecarboxylic acid, and their metal complexes.[5,6] In the zinc(II) complex, the absorption bands are assigned through comparison with its deuterated compound.

Racemic 2-Thiazolidinecarboxylic Acid: Some bands shift to a lower frequency region on deuteration. They are assigned to the NH_2^+ stretching and bending vibrations. The bands at 1610 cm^{-1} and at 1360 cm^{-1} are assigned to the COO^- antisymmetric and symmetric stretching vibrations respectively. Thus, this ligand has a zwitter ion structure.

Complexes: For the zinc(II) complex, some absorption bands which can be observed in the ligand disappear, while new bands which shift to a lower frequency region on deuteration can be observed. These are assigned to the NH stretching and bending vibrations.

The antisymmetric and symmetric stretching vibrations of the carboxyl group shift to higher frequency regions than those of the free ligand. Therefore, in the zinc(II) complex, each zinc atom is coordinated through a carboxylato oxygen atom and a nitrogen atom of the thiazolidine ring. This fact is confirmed by X-ray analysis.

Since, in the A-type complexes, the C-S stretching vibrations are observed in the same region as for the zinc(II) complex, the sulfur atoms do not seem to be associated with coordination.

The spectra of the cadmium(II)-B complex is different from that of the cadmium(II)-A complex. Some absorption bands due to NH_2^+ vibrations are observed in the same region as those of the free ligand. The antisymmetric and symmetric stretching vibrations of the carboxyl group shift to lower and higher frequency regions respectively than those of the free ligand. The frequency separation between the antisymmetric and symmetric stretching vibrations of the carboxyl group (Δ) is smaller than that of the free ligand.

Deacon and Phillips[14] arrived at the following conclusions on the basis of an examination of the infrared absorption spectra of many acetates and trifluoroacetates with known X-ray crystal structures.[15] Unidentate complexes exhibit Δ values much greater than those of ionic complexes. Chelating (bidentate) complexes exhibit Δ values significantly lower than the ionic values. The Δ values for bridging complexes are close to the ionic values. Therefore, in the cadmium(II)-B complex, two oxygen atoms of the carboxyl group seem to be coordinated with the cadmium atom by either bidentate or bridging types. It has been determined by X-ray analysis that dichloro-(4-hydroxy-L-proline)cadmium(II)[13] and dichloro-(L-proline)cadmium(II) hydrate[16] have bridging carboxyl groups and that dichloro(*N*-methylglycine)-cadmium(II)[17] has a bidentate carboxyl group.

Structure of $ZnL_2 \cdot 2H_2O$. The crystal data are

given in Table 5. The final atomic parameters are listed in Table 6.[18] The bond lengths and bond angles are shown in Tables 7 and 8 respectively. A perspective drawing of the complex, together with the numbering scheme of the non-hydrogen atoms, is shown in Fig. 1. The projection of the unit cell along the b axis is shown in Fig. 2. The zinc atom lies on a center of symmetry and is octahedrally trans-coordinated: two nitrogen atoms of two thiazolidine rings, two oxygen atoms of two carboxyl groups, and two oxygen atoms of two water molecules. In diaquabis((*S*)-4-thiazolidinecarboxylato)zinc(II), however, the zinc atom was octahedrally coordinated by two oxygen and two nitrogen atoms of two ligands and two water molecules in the cis position.[4] The bond distance of Zn-O(w) is longer than that of diaquabis(4-thiazolidinecarboxylato)zinc(II), which

(*S*)-4-HL: (*S*)-4-thiazolidinecarboxylic acid. Racemic-4-HL: racemic 4-thiazolidinecarboxylic acid. Racemic-2-HL: racemic 2-thiazolidinecarboxylic acid. a) Bridging atom. b) Attempts to prepare these complexes in our laboratory were unsuccessful.

was determined by Tatarowski et al.,[4] while the bond distances of Zn-O(1) 2.059(3) and Zn-N(3) 2.109(3) Å are shorter than those of that complex (Zn-O, 2.137(8) and 2.172(8) Å; Zn-N, 2.149(12) and 2.134(12) Å).

The bond angle values of O(1)-Zn-N(3)(82.1(1)°) and O(w)-Zn-O(1)(94.3(1)°) are a little larger than those of diaqua(4-thiazolidinecarboxylato)zinc(II) (78.1(4) and 92.4(4)°). The differences between these and Tatarowski's results are due to the different geometry— that is, cis or trans.

Table 9 summarizes the data for metal complexes with (*S*)-4-thiazolidinecarboxylic acid, racemic 4-thiazolidinecarboxylic acid, and racemic 2-thiazolidinecarboxylic acid, which have been prepared in our laboratory, and the atoms coordinated to the metal atoms.

As for all A-type complexes, the nitrogen atom and an oxygen atom coordinate to the metal ion and form a chelate ring; in some B-type complexes, except for the zinc(II) complex with (*S*)-4-thiazolidinecarboxylic acid, an oxygen atom and chlorine atoms coordinate to the zinc atom. Therefore, in A-type complexes there are no effects of the position of the carboxyl groups in thiazolidinecarboxylic acids on the coordination of the complexes.

The authors wish to express their thanks to Professor Akira Ouchi of the University of Tokyo for the X-ray-intensity data. They would also like to thank Dr. F. S. Howell and Mr. H. Yamaguchi of Sophia University for their helpful advice and for correcting this manuscript.

Facial-Meridional Isomerization of Some Tris-(β-diketonato)ruthenium(III) Complexes

Kyohko KOBAYASHI, Yuichi SATSU, Yoshimasa HOSHINO, Shinji ARAI, Kiyoshi HATAKEYAMA, Akira ENDO, Kunio SHIMIZU, and Gen P. SATÔ*
Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102
(Received May 31, 1989)

Nine complexes of type $[Ru^{III}(R\text{-}CO\text{-}CH\text{-}CO\text{-}R')_3]$ were examined; only those with R=$-CF_3$ underwent the facial-meridional isomerization in *N,N*-dimethylformamide (DMF) at the reflux temperature. Qualitative examination of the occurrence of isomerization of the complex with R=$-CF_3$ and R'=$-CH_3$ in various solvents supports the presence of solvent-assisted bond-rupture mechanisms. This complex did not isomerize photochemically in acetonitrile. The isomerization of four complexes with R=$-CF_3$ and R'=$-CH_3$, $-C_2H_5$, $-CH(CH_3)_2$, and $-C(CH_3)_3$ in DMF at 70—100 °C followed the reversible first-order kinetics. The equilibrium constants, which were temperature independent, decreased from 4.27 to 1.74 in the order cited above. The enthalpies of activation, ranging from 66.4 kJ mol^{-1} (R'=$-CH(CH_3)_2$) to 96.0 kJ mol^{-1} (R'=$-CH_3$), depended linearly on the atomic bond populations of the Ru-O bonds calculated by means of a modified extended Hückel method.

The facial-meridional isomerization reactions of tris(unsymmetrical β-diketonato)metal chelates have been studied in a number of cases.[1-8] Tris(β-diketonato)ruthenium(III) complexes are known to behave as "slow" complexes in the isomerization and racemization reactions.[4,5] These reactions are believed to proceed through intramolecular, bond-rupture mechanisms. Recently Hoshino et al.[9] reported that the rearrangement reactions between the three geometrical isomers of acetylacetonatobis(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)ruthenium(III) proceeded through certain types of bond-rupture mechanisms.

The rate of the facial-meridional isomerization reaction is largely enhanced by the presence of a trifluoromethyl group at the β-position of the diketone.[4] It is of interest to see how the substituents of the β-diketonato ligands affect the rate of the isomerization.

This report presents qualitative observations on the facial-meridional isomerization reactions of a series of nine tris(substituted acetylacetonato)ruthenium(III) complexes and quantitative kinetic data for four of them.

Experimental

Preparation of Complexes. The complexes studied here are listed in Table 1 together with the ligand names. They will be cited by the numbers given there. The preparation of **1**, **4**, and **6—9** has been described previously.[10] Each of them, except **6** and **7**, was obtained as a mixture of geometri-

8	$-CF_3$	$-C_4H_3O$	r	4,4,4-Trifluoro-1-(2-furyl)-1,3-butanedionato
9	$-CF_3$	$-C_6H_5$	r	4,4,4-Trifluoro-1-phenyl-1,3-butanedionato

a) Reaction observed when the complex was refluxed in DMF: i, isomerization; n, no isomerization; r, reduction to the Ru^{II} species. b) New compound. c) Only the meridional form was obtained.

cal isomers: the facial and the meridional forms (Fig. 1). The samples of **6** and **7**, however, contained only the meridional forms. The isomeric mixtures of **2**, **3**, and **5** were prepared by means of the "ruthenium blue solution" method.[10] 1,1,1-Trifluoro-2,4-hexanedione and 1,1,1-trifruoro-5-methyl-2,4-hexanedione were prepared according to the method of Reid and Calvin,[11] while 2,4-hexanedione was purchased from Dojindo Laboratories.

Isolation of Isomers. The isomeric mixture of **1**, dissolved in a small volume of benzene, was applied to a column of Merck Kieselgel 60 and developed with a benzene-hexane mixture (volume ratio, 5 : 8). Fractions containing each of the pure isomers were combined, and the solvent was evaporated off. The residue was dissolved in ethanol. Crystals of each isomer were obtained on concentrating the ethanolic solution. The fractions containing incompletely separated isomers were collected and concentrated; the isomers therein were then separated by means of preparative thin-layer chromatography on Merck Kieselgel 60 plate (1 mm thick, 20×20 cm), developing agent being a benzene-hexane mixture (volume ratio, 1 : 1). Separation of the isomers of **2**, **3**, **4**, and **8** was carried out similarly on the silica-gel column with benzene-hexane mixtures (the volume ratios were 1 : 9 for **2** and **3**, 1 : 4 for **4**, and 1 : 1 for **8**). The meridional isomer preceded the facial isomer in every case. In the case of **5**, only partial separation was achieved by means of Kieselgel 60—chloroform preparative thin-layer chromatography: the meridional form was completely separated from the facial isomer, but the latter could not be obtained in pure state. Separation of the isomers of **9** has been described previously.[12] No attempt was made at resolving the optical isomers.

Complexes **2**, **3**, and **5** are new compounds. Their elemental analyses and ^{1}H NMR data are as follows: **2** Found: C, 35.73 (*fac*) and 35.79 (*mer*); H, 2.89 (*fac*) and 2.97% (*mer*). Calcd for $RuC_{18}H_{18}O_6F_9$: C, 35.89; H, 3.01%. **3** Found: C, 39.05 (*fac*) and 38.94 (*mer*); H, 3.70 (*fac*) and 3.65% (*mer*). Calcd for $RuC_{21}H_{24}O_6F_9$: C, 39.14; H, 3.75%. **5** Found (isomeric mixture): C, 48.82; H, 6.21%. Calcd for $RuC_{18}H_{27}O_6$: C, 49.08; H, 6.18%. ^{1}H NMR ($CDCl_3$, room temp): *fac*-**2** δ=−36.1 (3H, s, CH), −4.8 (3H, s, CH_2), −4.3 (3H, s, CH_2), 3.0 (9H, s, CH_3); *mer*-**2** δ=−52.9 (1H, s, CH), −42.9 (1H, s, CH), −26.2 (1H, s, CH), −13.5 (1H, s, CH_2), −12.2 (1H, s, CH_2), −7.7 (1H, s, CH_2), −7.0 (1H, s, CH_2), −2.5 (1H, s, CH_2), −2.0 (1H, s, CH_2), 1.6 (3H, s, CH_3), 1.8 (3H, s, CH_3), 3.2 (3H, s, CH_3); *fac*-**3** δ=−36.4 (3H, s, COCHCO), −2.7 (3H, s, $(CH_3)_2\underline{C}H$), 2.3 (9H, s, CH_3), 3.7 (9H, s, CH_3); *mer*-**3** δ=−51.2 (1H, s, COCHCO), −41.0 (1H, s, COCHCO), −28.4 (1H, s, COCHCO), −7.9 (1H, s, $(CH_3)_2\underline{C}H$), −4.6 (1H, s, $(CH_3)_2\underline{C}H$), −1.8 (1H, s, $(CH_3)_2\underline{C}H$), 0.6 (3H, s, CH_3), 1.0 (3H, s, CH_3), 1.9 (3H, s, CH_3), 2.0 (3H, s, CH_3), 2.4 (3H, s, CH_3), 3.3 (3H, s, CH_3); *fac*-**5** δ=−31.8 (3H, s, CH), −6.4 (9H, s, CH_3CO), −5.3 (3H, s, $CH_3\underline{C}H_2$), −3.3 (3H, s, $CH_3\underline{C}H_2$), 2.6 (9H, s, $\underline{C}H_3CH_2$) (these were obtained from an isomeric mixture by subtracting the peaks of *mer*-**5**); *mer*-**5** δ=−41.7 (1H, s, CH), −31.5 (1H, s, CH), −22.0 (1H, s, CH), −11.4 (3H, s, CH_3CO), −10.0 (1H, s, $CH_3C\underline{H}_2$), −7.9 (1H, s, $CH_3C\underline{H}_2$), −5.6 (3H, s, CH_3CO), −5.0 (1H, s, $CH_3C\underline{H}_2$), −3.7 (1H, s, $CH_3C\underline{H}_2$), −1.1 (3H, s, CH_3CO), −0.3 (1H, s, $CH_3C\underline{H}_2$), 0.7 (1H, s, $CH_3C\underline{H}_2$), 2.3 (3H, s, $C\underline{H}_3CH_2$), 2.5 (3H, s, $C\underline{H}_3CH_2$), 2.6 (3H, s, $C\underline{H}_3CH_2$). Half-wave potentials for one-electron steps in 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$-acetonitrile vs. Ag|0.1 mol dm^{-3} $AgClO_4$-acetonitrile at 25 °C: *mer*-**2**, −0.48 V (Nernstian reduction) and 1.29 V (quasi-reversible oxidation); *mer*-**3**, −0.50 V (Nernstian reduction) and 1.28 V (quasi-reversible oxidation).

Other Chemicals. *N*,*N*-Dimethylformamide (DMF) was spectral reagent grade (Dojindo Laboratories, Dotite Spectrosol). Acetonitrile (AN) was purified as described previously.[13] Benzene and hexane used in chromatography were chromatographic grade solvents (Wako Pure Chemical Industries, Ltd.), and the other chemicals were of reagent grade.

Apparatus. A Shimadzu Seisakusho Ltd. CHN Analyzer CHN-1A was used for the elemental analyses. UV-vis spectra were measured with a Hitachi Model 200-20 spectrophotometer, and ^{1}H NMR spectra with a JEOL JMN GX270. The light sources for photochemical experiments were a 32 W low-pressure mercury lamp (Riko Kagaku Sangyo, UVL-321LA) and a 250 W high-pressure mercury lamp (Ushio Model UI-501C). High-performance liquid chromatography (HPLC) was carried out by means of a Toyo Soda apparatus consisting of a CCPM solvent delivery system, a UV-8000 spectrophotometric monitor, and a TSK gel ODS-80T$_m$ column (4.6 mm i.d.×150 mm, Toyo Soda).

Measurement of Isomerization Rates. A weighed sample (about 0.025 mmol) of each isolated isomer of **1**—**4** was dissolved in 25 cm^3 of DMF. The solution was transferred into a 30 cm^3 flask containing a magnetic stirrer bar. The flask was immersed in an oil bath (thermostated within ±1 °C) placed on a magnetic stirrer, which was at once put in motion. Small aliquots (ca. 5 mm^3 each) were taken out of the solution at suitable time intervals by means of a microsyringe which had been kept at room temperature, and 4 mm^3 of the aliquot was immediately injected into the HPLC system.

The compositions of the mobile phases used are given in Table 2 together with the retention times. The flow rate was 1 cm^3 min^{-1}. The spectrophotometric monitor was operated at the wave length of the π–π* absorption band[14,15] of each pair of the isomers (Table 2).

The product of the HPLC peak height and the half-peak width was proportional to the amount of the isomer injected. The isomeric concentrations in each aliquot were determined by means of the calibration curves that had been drawn for standard series of mixtures prepared gravimetrically from the isolated samples of the isomers. Statistical tests showed that the main source of error of the HPLC determination was the day-to-day variance. The reproducibility was estimated to be within 4%.

The isomerization of **4** in AN solutions was carried out in a similar way. The mixture was refluxed on an oil bath kept at 90 °C. The reaction temperature was practically the

Table 2. Compositions of the Mobile Phases for HPLC, the Operating Wavelengths (λ), and the Retention Times (t_r) of the Isomers

4	AN(0.95)-H_2O	277	5.1	4.5

normal boiling point of the solvent (81.6 °C).

Molecular Orbital Calculation. The calculation was based on a modified variety of the extended Hückel method. Computation was carried out on an NEC ACOS-850 at the Computer Center of Sophia University for the facial isomers of **1**—**5** and two representative meridional isomers (**1** and **4**). The details of the procedure and the results are described elsewhere,[15] and only the atomic bond populations for the Ru-O bonds are presented here.

Results

Qualitative Observations. Isomerization of 1 in Various Solvents: The meridional isomer was dissolved in a deoxygenated solvent to ca. 1 mol m^{-3}. The solution was refluxed for ca. 20 h under an argon atmosphere on an oil bath kept at a temperature 5 °C heigher than the normal boiling point of the solvent; it was then examined for the presence of the facial isomer by means of thin-layer chromatography on Merck Kieselgel 60 (developing solvent, hexane-benzene, 5 : 8 by volume).

The results are presented in Table 3. In the first four solvents, neither the facial isomer nor any other product was detected even when the refluxing was prolonged to more than 30 h. In pyridine, the color changed from red to dark green only by allowing the solution to stand overnight at room temperature, indicating that decomposition and/or ligand exchange took place; no facial isomer was detected in the resultant solution. In the other ten solvents, the isomerization occurred more or less rapidly, and the facial isomer was accompanied by some amounts of one or more by-products, which appeared to be ruthenium species produced by partial ligand exchange.

The isomerization of *mer*-**1** did not occur photochemically. Irradiation of its AN solutions under an argon atmosphere with the high-pressure mercury lamp for 9.5 h or with the low-pressure mercury lamp for 25.5 h at room temperatures yielded a small amount of a decomposition product, but no facial isomer was detected. The irradiation of *mer*-**1** in ethanol with the low-pressure mercury lamp did not bring about the isomerization either; instead, *mer*-**1** was reduced to the corresponding ruthenium(II) species, which was completely reoxidized back to the original meridional isomer by atmospheric oxygen. This result agrees with the observation reported by Gordon et al.[4] that no isomerization accompanied the chemical reduction and reoxidation.

a) From Ref. 19. b) Normal boiling temperature. c) Relative permittivity at 25 °C or at 20 °C (those marked by asterisks). d) Dipole moment; $\mu_D = 3.336\times10^{-30}$ C m. e) +, detected accompanied by by-product(s) after ca. 20 h of refluxing; −, not detected. f) Decomposition and/or ligand exchange.

Isomerization in DMF: The results are indicated in Table 1. Complexes **5** and **6** did not undergo any isomerization in DMF even after being refluxed (ca. 158 °C) for more than 30 h, while **7**, **8**, and **9** were reduced to the corresponding ruthenium(II) species. Complexes **1**, **2**, **3**, and **4** underwent the isomerization when heated in DMF, and their kinetics were studied quantitatively.

Determination of the Rate Constants and Equilibrium Constants. A typical set of isomeric concentration-time curves is shown in Fig. 2. Since preliminary experiments showed that the half-lives of the facial-to-meridional isomerization and its backward reaction

$$\textit{fac}\text{-form} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \textit{mer}\text{-form} \qquad (1)$$

were independent of the initial concentration, they were treated as essentially reversible, first-order reactions. But the isomerization reactions were accompanied by slow decomposition, as is seen from Fig. 2.

It can be readily shown that Eq. 2 holds if the decomposition is irreversible and follows the first-order rate law with respect to the total concentration of the facial and the meridional isomers:

$$-\ln\{(x-x_e)/(x_0-x_e)\} = (k_1+k_{-1})t. \qquad (2)$$

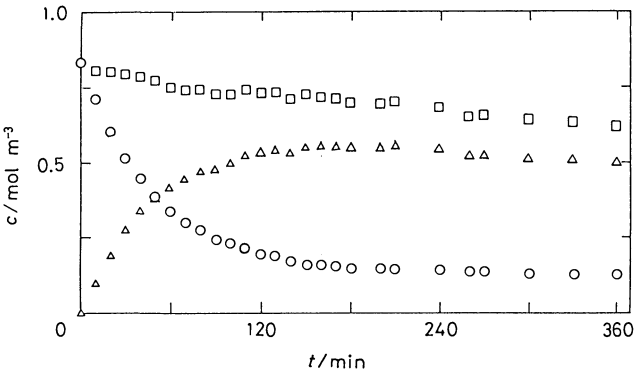

Fig. 2. Concentration-time curves for the reaction of *fac*-**1** in DMF at 90 °C.
○, [*fac*-**1**]; △, [*mer*-**1**]; □, [*fac*-**1**]+[*mer*-**1**].

Here x is the isomeric fraction of the facial isomer at time t as defined by Eq. 3

$$x=[fac]/([fac]+[mer]), \quad (3)$$

where the brackets mean the amount-of-substance concentration at time t of the specified isomer; x_e is its equilibrium value, and x_0 is the initial value of x.

In the present cases, the rates of decomposition were actually proportional to the total concentration of the two isomers with rate constants less than ca. 7% of k_1+k_{-1}.

The present experimental procedure inevitably involved a time lag: it took some time for the temperature of the reaction mixture, T, to reach the bath temperature, T_b. The reaction gradually accelerated during this time lag, and the plot of the left-hand side of Eq. 2 against t became distorted at small times. But beyond a short period (ca. 6 min in the most unfavorable cases), the plot became linear. The values of k_1+k_{-1} were obtained from the slope of the linear portion.

A separate experiment showed that the variation of T followed the Newton's law of heat flow, that is, $dT/dt=a(T_b-T)$ with $a=8.85\times10^{-3}$ s^{-1} for the present experimental arrangement. Digital simulations were carried out on the basis of this value of a and the actual activation energies. Their results reproduced the experimental plots quite well and ascertained that the slope of the linear portion gave exactly the value of k_1+k_{-1}.

The equilibrium constant of reaction (1) is defined by

$$K=[mer]_e/[fac]_e=k_1/k_{-1}=(1-x_e)/x_e. \quad (4)$$

Their values were obtained in the following way, instead of direct measurement of the equilibrium concentrations, in order to avoid possible errors owing to extensive decomposition brought about by prolonged heating and to increase the precision by making use of as many data points as feasible.

Two parallel kinetic runs were carried out: one (run a) was started with a solution of pure facial isomer ($x_0=1$), and the other (run b) with a solution of pure meridional isomer ($x_0=0$). In run a, the fraction of the meridional form at time t_a, $1-x_a$, was determined; in run b, the fraction of the facial form at time t_b, x_b, was determined. Equation 1 shows that

$$1-x_a=(1-x_e)[1-\exp\{-(k_1+k_{-1})t_a\}]$$

and

$$x_b=x_e[1-\exp\{-(k_1+k_{-1})t_b\}],$$

so that

$$(1-x_a)/x_b=f\{(1-x_e)/x_e\}=fK, \quad (5)$$

where

$$f=[1-\exp\{-(k_1+k_{-1})t_a\}]/[1-\exp\{-(k_1+k_{-1})t_b\}].$$

The left-hand side of Eq. 5 would give the K value if t_a could be made exactly equal to t_b. In practice, there was some uncertainty in both t_a and t_b owing to the above-mentioned time lag, and the experimental values of $(1-x_a)/x_b$ at shorter times showed deviating fluctuations. Only the points that gave stable values were used for calculating the mean values of K. The f values of these points were between 0.99 and 1.01 for t_a-t_b up to ±6 min, the largest time lag ever observed.

The equilibrium constants obtained in this way are listed in Table 4. No definite temperature dependence was detectable except for **3**. In the case of **3**, the plot of ln K against T^{-1} was fairly linear, and its linear regression line had a slope which was statistically non-zero at 10% significance level. The slope would give the standard reaction enthalpy value of (3.4±3.2) kJ mol^{-1}. This non-zero slope, however, is very likely to be accidental, in view of the fact that the determinations of the equilibrium constants of this complex (and **2**, too) were difficult owing to relatively poor separation between the chromatographic peaks and the larger extent of the decomposition. It was, therefore, decided that the equilibrium constant was independent of the temperature, and the values for the four temperatures were averaged. In the case of **2**, the value for 373 K was excluded from the average, because its deviation was almost statistically significant at 5% significance level.

The left-hand side of Eq. 2 was calculated with the

	average	1.74±0.10			

a) The uncertainties are 90% confidence limits. b) Not included in the average.

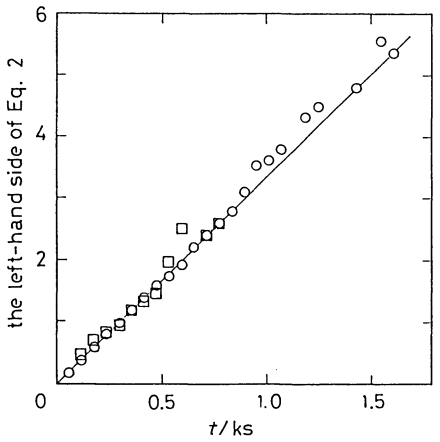

Fig. 3. The left-hand side of Eq. 2 plotted against the reaction time, t, for the reactions of **1** in DMF at 90 °C.
Starting isomer: ○, *fac*-**1**; □, *mer*-**1**.

value of x_e obtained from the K value and plotted against t. The plots were quite linear until the magnitude of the logarithmic term reached ca. 2.5—3 except for the deviations due to the time lag, which were noticeable during the initial period of a few runs with higher bath temperatures. An example is given in Fig. 3 (here the effect of the time lag is barely perceptible). The slopes of the plots were independent of the isomeric form with which the reactions were started. The individual values of k_1 and k_{-1} listed in Table 4 were calculated from the slope and the K value.

Kinetic Parameters. If the equilibrium constant is independent of the temperature, the standard enthalpies of activation of the forward and the backward reactions are the same ($\Delta H^{\neq}$). The $\Delta H^{\neq}$ value and the standard entropies of activation of the forward and backward reactions ($\Delta S_1^{\neq}$ and $\Delta S_{-1}^{\neq}$, respectively) were obtained on the basis of the following equations, by plotting the logarithmic value of $(k_1+k_{-1})/T$ against $1/T$:

$$\ln[\{(k_1+k_{-1})/T\}/\mathrm{s^{-1}\,K^{-1}}]=-\Delta H^{\neq}/RT+A'$$

$$\Delta S_1^{\neq}/R=A'-\ln(k_B h^{-1}/\mathrm{s^{-1}\,K^{-1}})-\ln(1+K^{-1})$$

$$\Delta S_{-1}^{\neq}/R=A'-\ln(k_B\, h^{-1}/\mathrm{s^{-1}\,K^{-1}})+\ln(1+K)$$

Here k_B is the Boltzmann constant and h is the Planck constant.

Table 5. Standard Enthalpies ($\Delta H^{\neq}$) and Entropies ($\Delta S^{\neq}$) of Activation[a]

Comoplex	$\Delta H^{\neq}$/kJ mol^{-1}	$-\Delta S_1^{\neq}/R$[b]	$-\Delta S_{-1}^{\neq}/R$[b]
1	96.0± 3.3	6.1	7.6 ± 1.1
2	85.0± 9.5	9.8	10.8 ± 3.2
3	66.4±14.6	15.5	16.5 ± 4.9
4	81.1± 3.0	10.4	11.0 ± 1.0

a) The uncertainties are 90% confidence limits. b) R is the gas constant, ca. 8.314 J mol^{-1} K^{-1}. Subscripts $_1$ and $_{-1}$ refer to *fac*-to-*mer* and *mer*-to-*fac* reactions, respectively. The uncertainties apply to both $\Delta S^{\neq}$ values.

Table 6. Effect of Electrolytes on (k_1+k^{-1})/ 10^{-5} s^{-1} of the Isomerization of *fac*-**4** in Acetonitrile, at ca. 82 °C

Electrolyte	Concentration/mol dm^{-3} 0.10	0.02	0.01	0
$N(C_2H_5)_4ClO_4$	2.86	2.80	2.78	2.19[a]
$Mg(ClO_4)_2$	2.67	2.66	2.68	
CH_3COOH	3.11	2.92	2.80	

a) The equilibrium constant was 1.83.

The plots were fairly linear. The point for 343 K in the case of **3** appeared to deviate more than the other points did, but the deviation was not statistically significant enough to exclude the point as an outlying one. The values of the kinetic parameters are presented in Table 5.

Effects of Electrolytes. Effects of some electrolytes on the rate of the isomerization of *fac*-**4** were examined by refluxing it in AN instead of DMF, since solubilities of the electrolytes in the latter solvent were insufficient. The reaction temperature was ca. 82 °C. The values of k_1+k_{-1} are listed in Table 6.

Discussion

Effects of Solvents and Electrolytes. The kind of solvent largely influenced the rate of isomerization of *mer*-**1** (Table 3). The isomerization was observed in solvents with higher relative permittivities, except for pyridine, in which the complex was decomposed.

Solvent-assisted bond-rupture mechanisms (e.g., Ref. 2) is compatible with this fact and with the observation that the resultant *fac*-**1** was always accompanied by by-products. An intermediate with a dangling ligand is formed when an Ru-O bond is attacked by solvent molecules. The open end of the dangling ligand may recombine with the central atom either at the original position or at some other position, the latter case leading to the isomerization. The solvent must be a coordinating agent powerful enough to break the Ru-O bond. But it should not be so too much; then the dangling end fails to recombine, and ligand exchange or decomposition predominates, as was the case of the reaction in pyridine, a strong coordinative agent.

The isomerization rate of **1** in AN was not affected by the addition of the free ligand, 1,1,1-trifluoro-2,4-pentanedione, up to 1 mol dm^{-3}; but its addition appeared to reduce the extent of the decomposition. This observation will indicate that the isomerization is a solvent-assisted intramolecular process and the decomposition is ligand-exchange by solvent.

The addition of tetraethylammonium perchlorate and magnesium perchlorate increased the isomerization rate of *fac*-**4** in AN; the addition of acetic acid produced an even larger increase (Table 6). The presence of ions may assist the bond rupture through

the relaxation of the charge separation accompanying the bond rupture. But there seem to be contributions of more specific interaction, since acetic acid is a very weak electrolyte in AN.[16] Their quantitative interpretation is difficult at this stage.

Effects of Substituents. Trifluoromethyl Group: All the complexes for which the facial-meridional isomerization was observed in DMF have trifluoromethyl groups (Table 3). To the authors' knowledge, the ruthenium(III) complexes that so far have been reported to undergo isomeric rearrangement are fluorine substituted β-diketonato complexes, with one exception of tris[(+)-3-acetylcamphorato]ruthenium-(III).[17] Fay et al.[5] reported that no conversion of the optical isomers of tris(acetylacetonato)ruthenium(III) was observed when they were heated in chlorobenzene for 10 h at 165 °C. Complexes **7**, **8**, and **9** would isomerize, were they not reduced when heated in DMF. There is an indication that the equilibrium constants for these three complexes will be almost the same and quite large (see the next subsection). The fact that the facial form of **7** could not be obtained is attributable to experimental difficulty rather than to the absence of isomerization.

The presence of trifluoromethyl group, therefore, appears to be a necessary condition for a β-diketonato ruthenium(III) complex to undergo the facial-meridional isomerization with appreciable rates. The primary reason is that a trifluoromethyl group, being strongly electron-withdrawing, "weakens and lengthens metal-oxygen bonds, thereby facilitating rearrangement."[4] This view is substantiated by a molecular orbital calculation, as will be discussed later.

Equilibrium Constants: Gordon et al.[4] reported that the equilibrium constant of reaction (1) for **1** in 1,1,2,2-tetrachloroethane at 150 °C was 4.9 with $\Delta_rH^\circ=(-4.6\pm2.5)$ kJ mol^{-1} and $\Delta_rS^\circ=(+2.5\pm5.9)$ J mol^{-1} K^{-1}. This equilibrium constant is quite close to the present result in DMF at 70—100 °C (Table 4). On the other hand, Δ_rH° was not detectable in our case. In view of the present experimental errors, a value of $|\Delta_rH^\circ|$ amounting to 2.5 kJ mol^{-1} or more should have been detected.

This discrepancy may be explained in terms of the relative permittivities of the two solvents (Table 3). In each solvent, the major part of the standard affinity of the isomerization will probably be the difference between the solvation Gibbs energies of the facial and the meridional isomers, and these solvation energies will arise mainly from the electrostatic interaction between the polar isomer molecules and the dielectric solvent. By analogy to the ion-dielectric interaction, it is likely that the standard enthalpy of such an interaction will be proportional to $\varepsilon_r^{-1}-T(d\varepsilon_r^{-1}/dT)$. For various common solvents near room temperature, ε_r follows the empirical formula $\varepsilon_r=\varepsilon_r^\circ \exp(-T/\theta)$, where the characteristic temperarue θ usually lies quite near the normal melting point of the solvent (T_{fus}).[18] Then, Δ_rH° will be roughly proportional to the factor $(1-T/T_{fus})/\varepsilon_r$. The value of this factor is −0.18 for the tetrachloroethane (T_{fus}=229.3 K[19]) at 150 °C, and it is −0.03 for DMF (T_{fus}=212.7 K[19]) at 100 °C.

The K values (Table 4) are not very much different from 3, the value expected if the equilibrium is determined solely by the probability. But they show a tendency: K decreases with the increase in the electron donating character of the substituent R′. A fairly straight line is obtained when ln K is plotted against the reversible half-wave potential of the Ru^{III}/Ru^{II} process of the complex (Fig. 4) or against the Hammett constant of R′ (a linear relationship has been established between the reversible half-wave potential and the sum of the Hammett constants of the substituents[13]). This linearity, being based on only four points, cannot be generalized too much. But if its extrapolation is allowed, the K values for complex **7**, **8**, and **9**, whose half-wave potentials were −0.33 V, −0.32 V, and −0.33 V, respectively,[13] will be around 16.

It is difficult to explain this tendency quantitatively. The following is one possibility. Quite likely the entropy of solvation plays a decisive role, since the standard reaction Gibbs energies were essentially entropic. There will be two opposite factors. One is the decrease of entropy caused by the orientation of solvent molecules around the dipolar complex species. This decrease makes the facial form less favorable in terms of entropy, because it always has a larger dipole moment than that of the corresponding meridional form. This effect will play an important role in mildly polar and less structured solvents. The other factor, however, comes into effect in a highly

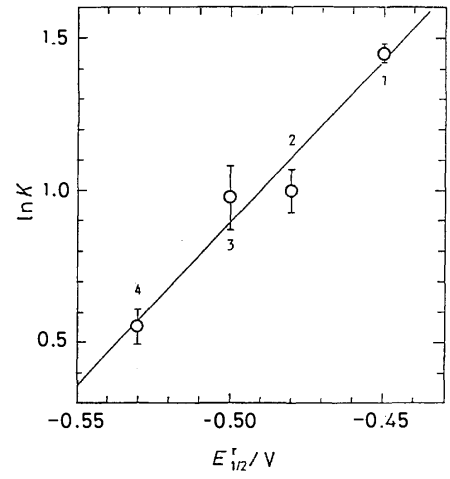

Fig. 4. Correlation between ln K and the revesible half-wave potential of the Ru^{III}/Ru^{II} process in 0.1 mol dm^{-3} $(C_2H_5)_4NClO_4$ in AN at 25 °C vs. Ag|0.1 mol dm^{-3} $AgClO_4$-AN ($E^\circ_{1/2}$).
The error bars represent 90% confidence limits; correlation coefficient=0.9756.

associated or structured solvent like DMF (its entropy of evaporation is 90.0 $J mol^{-1} K^{-1}$ [19]). Then the structure of the solvent will be broken by the presence of strongly dipolar solute molecules and an increase of entropy results, thereby making the facial form more favorable. Even in DMF, the first factor seems to predominate in the case of **1**. But as the substituent R′ becomes more and more strongly electron-donating and bulky, the second factor will overcome the first, and the K value becomes progressively smaller than 3.

Whatever the reason may be, there is an interesting parallelism in the HPLC retention times. With AN-water mixtures of various compositions, the retention time (t_r) of each complex increased with the water content. In a given mixture, the t_r value of *fac*-**1** was smaller than that of *mer*-**1**, indicating that the *fac*-form was more stable in a polar mobile phase. In the cases of **3** and **4**, on the contrary, the order was reversed (Table 2); the *fac*-forms are less stable, in spite of their higher polarity.

Enthalpies of Activation: For the isomerization of **1** in 1,1,2,2-tetrachloroethane at 140.5—174.5 °C,[4] $\Delta H^{\neq}$/kJ mol^{-1} is 138±3.3 (*fac*-to-*mer*) and 118±4.6 (*mer*-to-*fac*). These are a little larger than the present value (Table 5), probably reflecting the smaller dielectric character of the chloroethane. The entropy of activation for the *fac*-to-*mer* reaction, $\Delta S_1^{\neq}/R$=−3.8±1.0, is larger and that for the reverse reaction, $\Delta S_{-1}^{\neq}/R$=−11.5±1.5, is smaller than the corresponding present values.

The enthalpy of activation, showing a minimum at complex **3**, cannot be simply related to the half-wave potential or the Hammett constant, since the latter vary monotonically. But it will be related to the robustness of the Ru-O bonds, if the isomerization proceeds via a solvent-assisted bond-rupture mechanism. One of the measures of bond strength is the atomic bond population,[20] which is believed to be proportional to the bond order. The values obtained by means of a modified extended Hückel method are presented in Table 7. Results of such a calculation

Table 7. Atomic Bond Populations of Ru-O Bonds Calculated by Means of the Modified Extended Hückel MO Method[15]

Ru-O bond[a]	Complex 1	2	3	4	5
fac					
a, c, d	0.244	0.240	0.240	0.241	0.251
b, e, f	0.237	0.234	0.233	0.235	0.250
mer					
a′	0.242			0.239	
b′	0.238			0.236	
c′	0.240			0.238	
d′	0.244			0.241	
e′	0.239			0.238	
f′	0.242			0.238	

a) For the bond designation, see Fig. 1.

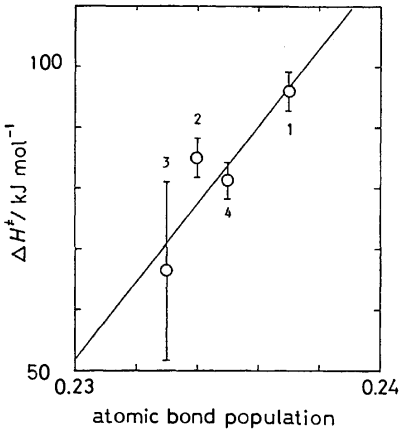

Fig. 5. Correlation between $\Delta H^{\neq}$ and the atomic bond population of the Ru-O bonds b, e, and f. The error bars represent 90% confidence limits; correlation coefficient=0.8985.

are generally not precise. Nevertheless, in these particular instances, where all the compounds are very similar, the values of atomic bond population will correctly reflect the relative robustness of the bond.

The facial isomer has two distinguishable kinds of Ru-O bonds: the atomic bond population of the three Ru-O bonds that are adjacent to the substituents R′ (bonds b, e, and f in Fig. 1) is lower than that of the others in each complex. There is a fairly linear correlation between $\Delta H^{\neq}$ and the atomic bond population of the former Ru-O bonds, as shown in Fig. 5. This may indicate that the isomerization is initiated by the rupture of the least robust Ru-O bond.

The bond rupture mechanisms can be classified according to the idealized geometry of the transition state: trigonal bipyramidal (TBP) or square pyramidal (SP). The rupture of the bonds a′, c′, e′, or f′ is required for the *mer*-to-*fac* conversion to occur through the TBP transition states, whereas the rupture of any bond leads to the *fac*-to-*mer* conversion through both transition states.[2] It is tempting to suggest that the isomerization involved the SP transition states, in view of the result that the least robust bond in the meridional form was the bond b′. Drawing such an inference, however, will be too early because the reaction may involve more than one type of transition state.[2]

The calculated values clearly indicate the weakening effect of trifluoromethyl group.[4] The atomic bond population of *fac*-**5**, 0.250, is very much higher than those of the trifluoromethyl-substituted complexes. If the above linear correlation is extrapolated to this value, $\Delta H^{\neq}$ of **5** will be ca. 180 kJ mol^{-1}. With such a large value of $\Delta H^{\neq}$, k_1+k_{-1} at 100 °C would be of the order of 10^{-15} s^{-1} or less.

The authors are very grateful to Prof. Hiroshi Kobayashi of Kitazato University not only for many valuable suggestions and encouraging discussions,

but also his kindness in providing them with the program of the original Hückel method. They also thank Dr. S. F. Howell, Sophia University, for correcting the manuscript. The elemental analyses were carried out by Mrs. Nakako Tokita and the NMR measurement by Mrs. Hiroko Kin and Mrs. Yukari Suetsugu of the Department of Chemistry, to whom the authors' thanks are due.

Osaka University of Pharmaceutical Sciences, 2-10-65, Kawai, Matsubara-shi, Osaka 580
(Received June 1, 1989)

A sensitive and selective spectrophotometric determination of palladium(II) based on ternary-complex formation with Phloxine and thiamine was established. The apparent molar absorptivity of the proposed method, which does not require an extraction procedure, was 1.02×10^5 dm^3 mol^{-1} cm^{-1} at 565 nm. Only gold(III) in an equimolar ratio of palladium(II) among the metal ion examined interfered. The method was applied to a determination of palladium in palladium carbon and palladium asbestos; the results were in good agreement with those obtained by potassium iodide method, the Michler's thioketone method and ICP-AES. The sensitivity could be further enhanced by about 20 times over that of spectrophotometry and/or fluorimetry by combining it with a membrane filter preconcentration technique. It was suggested that the collection of an aggregate on a membrane filter depends on the molecular size through observing by an scanning electron microscope.

Various determination methods for metal ions based on the ternary-complex formation have been reported[2-4)] for the purpose of enhancing the determination sensitivity, selectivity and so on. Of the ternary-complex system, the ion-association type based on complex formation between a metal ion-organic base cation and the anion of a dyestuff has often used. The organic bases used are limited[3,4)] to such ligands as 1,10-phenanthroline and 2,2′-bipyridyl. Most of these methods are not sufficiently selective and require an extraction step in spite of the high sensitivity.

We have already reported[5-7)] on the determination of organic compounds utilizing a ternary-complex system, {**RML**}, where {**R**}, {**M**}, and {**L**} denote an organic dye, a metal ion and an organic compound, respectively. In previous papers[6,7)] a simple and sensitive determination of {**L**}, such as thiamine and chlorpromazine, was established by using {**RML**} with Eosine, palladium(II) and these {**L**}. In this case only palladium(II) was effective among the various metal ions tested. Thus, it is speculated that a simple, sensitive and selective determination of palladium(II) would be established by selecting suitable {**R**} and/or {**L**}, particularly {**L**}.

We studied the color reactions of palladium(II) based on the formation of a new type of the ternary complex with fluorescein(fl) dyes, palladium(II) and {**L**}; a selective and sensitive determination of palladium(II) was investigated by using Phloxine as {**R**} and thiamine as {**L**}. The proposed method was applied to an assay of palladium in practical samples. In addition, a membrane filter preconcentration technique[8,9)] was also studied for the purpose of enhancing the determination sensitivity. A collection of ternary-complex aggregates on a membrane filter was observed with a scanning electron microscope (SEM).

Experimental

Apparatus. The absorption spectra and absorbance values were measured with a Shimadzu Model 160 recording spectrophotometer using 1.0-cm quartz cells. A Shimadzu Model RF-540 spectrofluorometer with a 1.0-cm quartz cell was used. The pH measurements were made with a Hidachi-Horiba F-7 AD glass electrode pH meter. A Shimadzu Model ICPS-1000V inductively coupled plasma emission spectrometer was used. A Toyo TM 3 membrane filter(made of nitrocellulose, 25 mm diameter, 0.65 μm pore size) and Toyo KGS-25 filter holder were used.

Reagents and Materials. A stock solution (1.0×10^{-2} mol dm^{-3}) and a working solution of palladium(II) were prepared according to a previous report.[7)] All fl derivative solutions were prepared in 1.0×10^{-3} mol dm^{-3} aqueous solutions. 2,4,5,7-Tetrabromo-3′,4′,5′,6′-tetrachloro fl (Phloxine), 2,4,5,7-tetrabromo fl (Eosine), 2,4,5,7-tetraiodo-3′,4′,5′,6′-tetrachloro fl (Rose Bengal), 2,4,5,7-tetraiodo fl (Erythrosine), 4,5-dibromo fl and 4,5-diiodo fl were purchased from Wako Pure Chemical Ind. Ltd., Tokyo Kasei Kogyo Co., Ltd., and Aldrich Chemical Com. Inc., respectively. Fl, 2,4,5,7-tetrachloro fl, 2,7-dichloro fl and 3′,4′,5′,6′-tetrachloro fl were synthesized according to methods described in the literature.[10,11)] A 5.0×10^{-3} mol dm^{-3} thiamine solution was prepared by dissolving thiamine hydrochloride in water. A 1.0% aqueous solution of (2-hydroxypropyl)cellulose (HPC, 6-10 cps) and polyethylene glycol (PEG, 2000) were prepared. A 0.2 mol dm^{-3} sodium acetate-0.2 mol dm^{-3} acetic acid buffer solution was used for pH adjustments. All other reagents and materials were of analytical reagent grade, and deionized water was used.

Standard Procedure for the Spectrophotometry. To a solution containing up to 8 μg of palladium(II) were added 0.3 cm^3 of a 5.0×10^{-3} mol dm^{-3} thiamine solution, 0.5 cm^3 of a 1.0% HPC solution, 3.0 cm^3 of the buffer solution (pH 4.6) and 1.0 cm^3 of a 1.0×10^{-3} mol dm^{-3} Phloxine solution; the solution was diluted to mark with water in a 10-cm^3 volumetric flask. After being kept at room temperature for 20 min, the absorbance of a Phloxine-thiamine-palladium(II) solution (Solution A) was measured at 565 nm against the Phloxine-thiamine (=reagent blank, Solution B) as a reference.

Recommended Procedure for a Membrane Filter Preconcentration. A solution containing up to 0.5 μg of palladium(II) was placed in a 10-cm^3 volumetric flask; to this were added 0.3 cm^3 of a 5.0×10^{-3} mol dm^{-3} thiamine solu-

tion, 0.3 cm^3 of a 1.0 % PEG solution, 3.0 cm^3 of the buffer solution (pH 4.6), and 1.0 cm^3 of a 1.0×10^{-3} mol dm^{-3} Phloxine solution. The mixture was diluted to the mark with water, agitated well, and kept at room temperature for 20 min together with a reagent blank. Both solutions were then filtered through a 0.65-μm pore size membrane filter to collect the aggregates; the filtered substances were then washed with about 20 cm^3 of water. After being dried with a hair-drier, the membrane filter and aggregates were dissolved in 5 cm^3 of dimethyl sulfoxide (DMSO). The absorbance of a DMSO solution containing palladium(II) (Solution A′) was measured at 555 nm against the DMSO solution of a reagent blank (Solution B′). In the case of fluorimetry, the difference in the relative fluoresence intensity between Solutions A′ and B′ at 575 nm emission wavelength with excitation at 520 nm was measured.

Results and Discussion

Choice of Dye {R} and Organic Base {L}. In order to examine the effect of {R} on the color reaction among {R}, {L} and palladium(II), thiamine was selected as {L}. In the absence of a dispersion agent Solution A precipitated gradually; thus, a nonionic surfactant,[9] such as HPC and Methyl Cellulose, was added to Solutions A and B. Of the ten fl derivatives tested, Phloxine, Eosine, Erythrosine, and Rose Bengal were superior to the other {R} in sensitivity. The relationships between the pH change and absorbance by using these four {R} are shown in Fig. 1.

The effect of {L} was examined by combinations of four {R} and various {L} at each optimum pH. Of the various {L} examined (thiamine, papaverine, dibucaine, scopolamine, pilocarpine, pyridoxine, lincomycin, quinine, ergotamine, chlorpromazine, chlorhexidine, acrinol, theophylline, cycloserine, diphenhydramine, sparteine, and spermine), thiamine was the best since it gave the highest sensitivity and stability of the coloration. In addition, compared with the other {R}, thiamine scarcely produced the colored complex with {R}, i.e. the absorbance of Solution B was relatively low. {R} could be arranged in the following order with respect to sensitivity: Phloxine≈Rose Bengal>Erythrosine≈Eosine. Phloxine was superior to Rose Bengal in terms of color contrast between sample and reagent blank solutions, and the purity of reagent. The results are shown in Table 1.

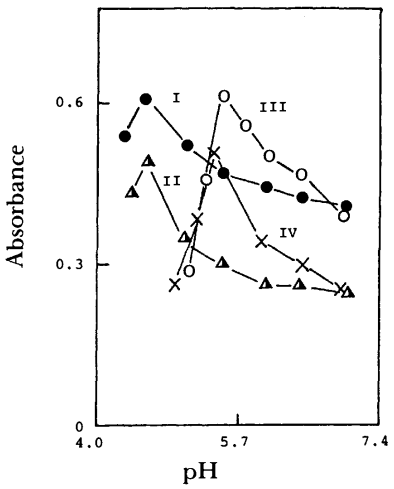

Fig. 1. Effect of pH on the color reaction between palladium(II) and dye-thiamine solution.
Pd(II): 6.0×10^{-6} mol dm^{-3} (4.2 μg/10 cm^3); dye: 1.0×10^{-4} mol dm^{-3}; thiamine: 1.5×10^{-4} mol dm^{-3}; HPC: 0.05%; Reference: Solution B (dye-thiamine solution); dye: I (—●—), Phloxine; II(—▲—), Eosine; III (—○—), Rose Bengal; IV (—×—), Erythrosine.

On the basis of these resutls, Phloxine and thiamine were chosen as {R} and {L}, respectively, for the further experiments.

Optimisation of Conditions. The maximum difference in absorbance between Solutions A and B was at 565 nm. The optimum pH for the color reaction was narrow and was 4.5—4.7. The absorbance of Solution A against Solution B dropped rapidly at both higher and lower pH regions. Hence, 3.0 cm^3 of 0.2 mol dm^{-3} acetate buffer solution (pH 4.6) was used for the pH adjustments. Of various nonionic surfactants tested (HPC, Methyl Cellulose, PEG, poly(*N*-vinylpyrrolidone) and poly(vinyl alcohol)), HPC was the

Table 1. Effect of Organic Bases {L} by Using Four fl Dyes {R}

{L}	{R}, Absorbance at (λ/nm)			
	Phloxine	Eosine	Rose Bengal	Erythrosine
Thiamine	0.610 (565)	0.510 (545)	0.615 (580)	0.502 (560)
Papaverine	0.134[a] (575)	0.153[a] (540)	0.103[a] (565)	0.095[a] (560)
Dibucaine	0.153[a] (575)	0.097[a] (540)	0.102[a] (565)	0.079[a] (560)
Scopolamine	0.089[a] (545)	0.072 (540)	0.096[a] (565)	0.096[a] (535)
Pilocarpine	0.144 (565)	0.079 (540)	0.276 (575)	0.099[a] (535)

Pd(II): 6.0×10^{-6} mol dm^{-3}; {R}: 1.5×10^{-4} mol dm^{-3}; HPC: 0.05%; pH: Phloxine and Eosine—pH 4.5, Rose Bengal and Erythrosine—pH 5.5; Reference: {L}-{R} solution (Solution B).
a) {R-L} complex produced and absorbance of {L}-{R} solution was remarkably high.

best in terms of sensitivity and stability of coloration. A constant absorbance was obtained by the addition of more than 0.1 cm^3 of 1.0% HPC solution to the final volume of 10 cm^3. Since a maximum and almost constant absorbance was obtained upon by the addition of more than 0.2 cm^3 of 5.0×10^{-3} mol dm^{-3} thiamine solution, 0.3 cm^3 was adopted in the final volume of 10 cm^3. Further experiments were carried out with 1.0×10^{-4} mol dm^{-3} Phloxine in the final volume, considering the absorbance of Solution B.

Under standard conditions, the constant absorbance of Solution A at 565 nm against Solution B as a reference was obtained by maintaining it at room temperature for more than 15 min; the absorbance value was almost constant for at least 3 h. Therefore, 20 min of standing time at room temperature was adopted for all measurements.

Calibration Curve. Beer's law held over the range up to 8 μg of palladium(II) in the final volume of 10 cm^3. The apparent molar absorptivity (ε) and the Sandell sensitivity were 1.02×10^5 dm^3 mol^{-1} cm^{-1} and 0.0010 $\mu g\,cm^{-2}$, respectively. This procedure is much more than the methods using potassium iodide[12] (KI, $\varepsilon=1.02\times10^4$) and dithizone[13] ($\varepsilon=3.55\times10^4$), but less sensitive than the methods using Michler's thioketone[14] (MTK, $\varepsilon=3.0\times10^5$) and Rhodamine 6G[15]

Pd(II) taken: 4.2 $\mu g/10\ cm^3$; Phloxine: 1.0×10^{-4} mol dm^{-3}; HPC: 0.05%; pH: 4.6; Reference: Solution B. a) Ion/Pd(II).

(ε=3.0×10^5).

The relative standard deviation (R.S.D.) was 0.84% for ten runs with 4.2 μg of palladium(II).

Interference. Various amounts of foreign metal ions were added to a fixed amount of palladium(II) (4.2 μg). There was no interference under the following conditions: 50- to 100-fold molar ratio of copper(II), cobalt(II), nickel(II), cadmium(II), zinc(II), lead(II), manganese(II), lanthanum(III), chromium(III); 10- to 20-fold molar ratio of titanium(IV), iron(III), mercury(II), scandium(III), rhodium(III), silver(I); equimolar to 2-fold molar ratio of molybdenum(VI), bismuth(III), zirconium(IV), osmium(VIII), iridium(III). Only gold interfered in equimolar ratio of palladium(II). On the other hand, among the anions tested, chloride, sulfate, phosphate, citrate, tartrate, nitrate, and fluoride ions did not interfere in 100- to 250-fold excess over palladium(II). A fairly large error appeared in the presence of some anions belonging to soft bases (sulfide, thiosulfate, nitrite, cyanide, and iodide ions) at a low concentration because of a complex formation between these anions and palladium(II). Interference from gold(III) up to a 2-fold molar ratio of palladium(II) could be overcome by the addition of bromide ion (5.0×10^{-4} mol dm^{-3}) as a masking agent. The interference from iodide, thiosulfate, sulfide, and cyanide ions could be overcome by a preliminary treatment with silver(I), and that from sulfite and nitrite ions with permanganate and hydrogen peroxide. The results are shown in Table 2.

Composition of the Ternary Complex Formed. The palladium(II)-to-thiamine ratio and (palladium/thiamine)-to-Phloxine ratio determined by Job's method of continuous variation were 1:2 and 1:1, respectively. The ternary complex formed may be expressed as $\{Pd^{II}(thiamine)_2\}(Phloxine)$.[7]

Application. The proposed method was applied to the assay of palladium in palladium carbon and palladium asbestos. The palladium in the samples was readily dissolved in aqua regia, the insoluble residue being removed by filtration. The obtained results were in good agreement with those obtained by the KI method, the MTK method and ICP-AES. The recoveries of palladium(II) from each sample were about 98—103%. The results are given in Table 3.

Study for Membrane Filter Preconcentration Technique. A membrane filter preconcentration technique was investigated for the purpose of enhancing the determination sensitivity. Only the use of a surfactant was examined to improve the sensitivity and reproducibility under the same conditions for the standard procedure for spectrophotometry. Only PEG was effective among the various surfactants tested. Several filters of different sorts and pore sizes were examined to collect the ternary-complex aggregates. A nitrocellulose membrane filter was suitable since it readily dissolves in organic solvents. Constant absorbances were obtained over a range of pore size, from 0.2 to 0.65 μm; the absorbances decreased with increasing pore size of the membrane filter. A 0.65 μm pore size was subsequently used because of the higher filtration rate. Of the organic solvents examined, DMSO was the best with respect to the high absorbance and low deviation. The absorption spectra of Solutions A′ and B′ are shown in Fig. 2.

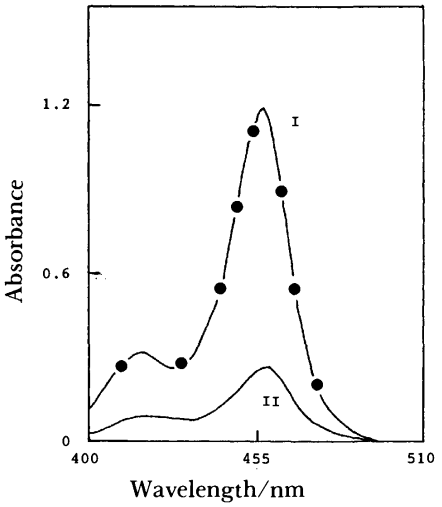

Fig. 2. Absorption spectra of Phloxine-thiamine-palladium(II) DMSO solution (Solution A′) and Phloxine-thiamine DMSO solution (Solution B′) after membrane filter preconcentration technique.
Pd(II): 0.42 μg; Reference: DMSO.

Table 3. Determination of Palladium Carbon (Pd-C) and Palladium Asbestos (Pd-A)

Sample	Pd, Amount/%				Recovery test[a] of proposed method	
	Proposed method	KI method	MTK method	ICP-AES	Recovery[b] /%	R.S.D.[c] /%
5% Pd-C	4.75	4.73	4.76	4.70	101.6	1.00
10% Pd-A	9.60	9.71	9.60	9.80	100.1	0.73
20% Pd-A	19.40	19.31	19.32	19.40	102.8	0.70
30% Pd-A	30.54	30.58	30.32	31.00	98.8	0.86

a) Mean of 5 determinations. b) Palladium taken, 2.1 μg/10 ml. c) Relative Standard Deviation.

This procedure is more than 20 times as sensitive as the method employing aqueous medium. Analytical values of 5% palladium carbon and 20% palladium asbestos in Table 3 were 4.60% and 19.20%, respectively.

Furthermore, since Solutions A′ and B′ emitted fluorescence, fluorimetry could be used. The difference in the relative fluorescence intensity between Solutions A′ and B′ at 575 nm of emission wavelength with excitation at 520 nm was measured.

In general, the formation of a ternary-complex results in a quenching of the fluorescence[3] of the dye used. Nevertheless, the fluorescence intensity of Solution A′ was larger than that of Solution B′. The absorption spectrum and the emission spectrum of an independently prepared Phloxine DMSO solution were almost identical to that of Solutions A′ and B′. It is probable that the ternary-complex aggregate collected on a membrane filter dissociates to form at least two components, $\{Pd^{II}(thiamine)_2\}$ and Phloxine. The latter will give a fluorescence and absorption spectrum in a DMSO solution. The reason why the method with a membrane filter preconcentration technique gives an abnormally highly sensitivity ($\varepsilon > 10^6$) is probably that a few Phloxine molecules associate with the ternary complex and a bulky aggregate forms.

The surface of membrane filters was observed with SEM. In the case of depth-type (networks) membrane filters, a little difference was recognized between the sample (photograph(c)) and the reagent blank (photograph(d)), whereas a large difference was observed between the sample (photograph(a)) and the

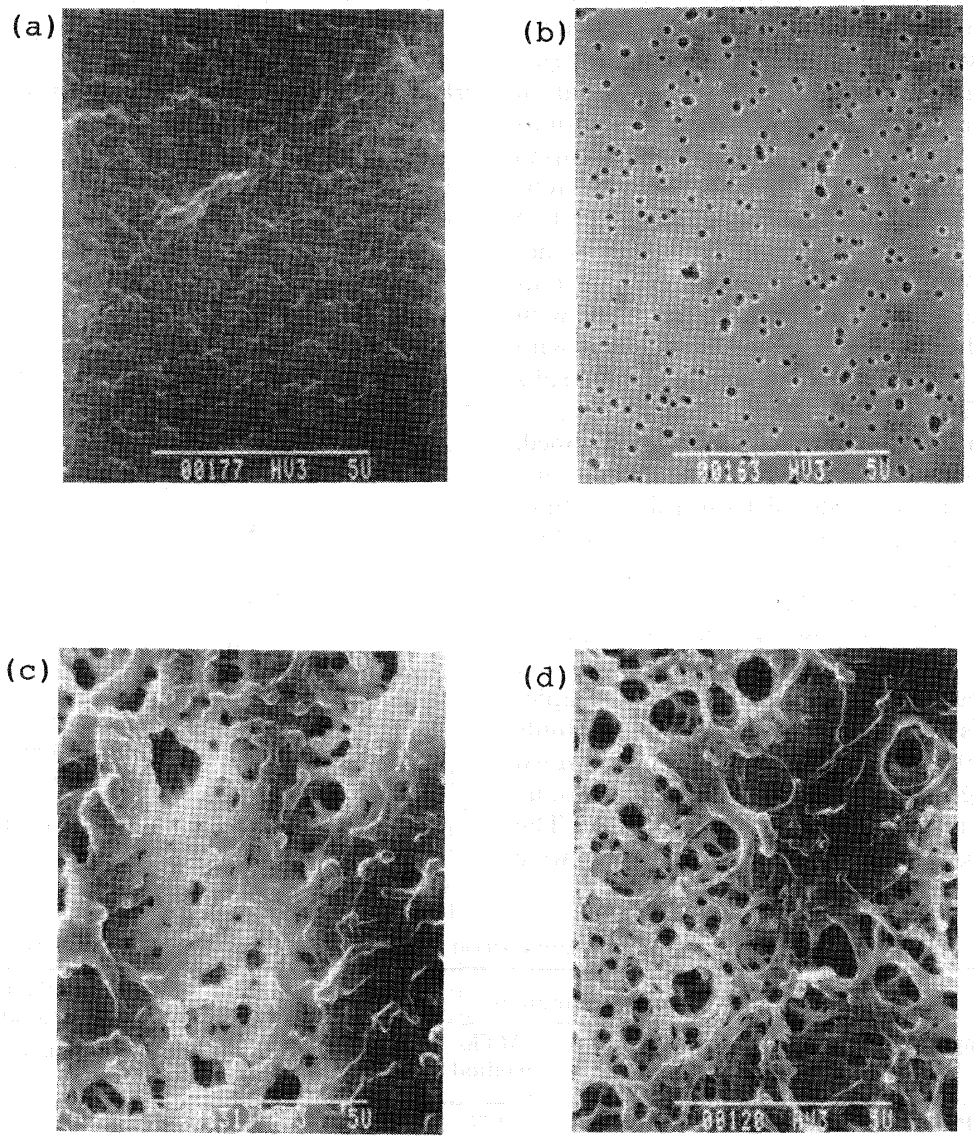

Fig. 3. Scanning electron microscope (SEM) pictures of the aggregates collected on membrane filters.
(a) Sample (Phloxine–thiamine–palladium(II)) on screen-type filter. (b) Reagent blank (Phloxine–thiamine) on screen-type filter. (c) Sample on depth-type filter. (d) Reagent blank on depth-type filter.

reagent blank (photograph(b)) in screen-type (holes) membrane filters. Thus, the collection of aggregate on membrane filters was found to depend not on the adsorptivity but on the molecular size. These photographs are shown in Fig. 3. This point should be studied in greater details.

Conclusion

A simple, sensitive and selective spectrophotometric method of palladium(II) with Phloxine as {**R**} and thiamine as {**L**} was established. The method was applied to the assay of palladium in practical samples, and the analytical results were in good agreement with those obtained by other methods. The sensitivity was enhanced by about 20 times over spectrophotometry and/or fluorimetry (probably by measuring free Phloxine in DMSO) by combining a membrane filter preconcentration technique. It was suggested by observing with SEM that the collection of aggregate on a membrane filter should depend on the molecular size. Though further investigations are necessary for the application of this method to a variety of samples, including the development of the membrane filter preconcentration technique, the proposed method should be useful and convenient for a simple, sensitive determination of palladium(II).

The authors wish to thank Mr. Tsutomu Iwamoto of Osaka University of Pharmaceutical Sciences for SEM photographing of the collection of aggregate on a membrane filter.

Formation of (η-Cyclopentadienyl)(1,2-ethylenedithiolato, 1,2-ethylenediselenolato, and 2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III) Complexes in a One-Pot-Reaction of (η-Cyclopentadienyl)(1,5-cyclooctadiene or dicarbonyl)cobalt(I) with Alkyne and a Mixture of S_8 and Se_8

(Received May 19, 1989)

A one-pot-reaction of (η-cyclopentadienyl)(1,5-cyclooctadiene or dicarbonyl)cobalt(I) with alkyne (diphenylacetylene and phenylacetylene) and a mixture of S_8 and Se_8 gives (η-cyclopentadienyl)(2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III) complex in addition to the corresponding dithiolato and diselenolato complexes. When phenylacetylene was used as an alkyne, a (2-phenyl-2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III) complex was formed preferentially rather than the (1-phenyl-2-selenolatothiolato-*S*,*Se*)cobalt(III) complex. The separation of the diselenolato and selenolatothiolato complexes from the dithiolato complex was successfully done by utilizing the difference in how these complexes form adducts with tributylphosphine. The dithiolato complexes have more negative reversible half-wave potentials (for reduction) than the diselenolato complexes; the selenolatothiolato complexes have intermediate half-wave potentials.

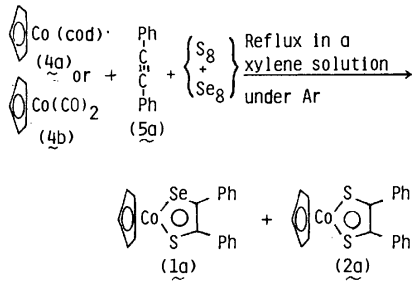
Dithiolatometal complexes have unique electronic structures[1] and show several useful functions,[2] such as catalysts for the synthesis of thiophene derivatives[3] and for isomerization of quadricyclane to norbornadiene.[4] Photocatalysis for hydrogen evolution[5] and quenching of singlet oxygen[6] have been reported, along with electron transport[7] and electric conductivity properties.[8] The interest in the chemistry of chalcogen compounds is now expanding to compounds containing selenium and tellurium.

Owing to the development of a new and facile synthetic method for (η-cyclopentadienyl)(1,2-ethylenedithiolato)cobalt(III) complexes in a one-pot-reaction of [Co(cp)(CO)$_2$] or [Co(cp)(cod)] (cod=1,5-cyclooctadiene) with elemental sulfur and alkynes,[3] dithiolatometal complexes of this type with various substituents can be easily synthesized.

This type of reaction has been applied to the synthesis of diselenolatometal complexes.[9] However, this type of reaction has never been examined by using a mixture of elemental sulphur and elemental selenium. In this paper we report that the one-pot-reactions of η-cyclopentadienylcobalt species with alkyne and a mixture of S_8 and Se_8 give (η-cyclopentadienyl)(2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III), in addition to the corresponding dithiolato and diselenolato complexes.[10] Only three reports have appeared on the synthesis of selenolatothiolatometal complexes.[9,11,12] We also discuss the properties of dithiolato, diselenolato, and selenolatothiolato complexes.

Results and Discussion

Formation of Dithiolato, Diselenolato, and Selenolatothiolato Complexes. When a mixture of (η-cyclopentadienyl)(1,5-cyclooctadiene or dicarbonyl)cobalt(I)([Co(cp)(cod)]: **4a** or [Co(cp)(CO)$_2$]: **4b**), diphenylacetylene, elemental sulfur, and elemental selenium is refluxed in xylene, (η-cyclopentadienyl)-(1,2-diphenyl-1,2-ethylenedithiolato)cobalt(III)(**2a**), (η-cyclopentadienyl)(1,2-diphenyl-1,2-ethylenediselenolato)cobalt(III) (**3a**), and (η-cyclopentadienyl)-(1,2-diphenyl-2-selenolatoethylenethiolato-*S*,*Se*)-cobalt(III) (**1a**) are formed.



These three complexes could not be separated by ordinary chromatographic methods. However, the separation was successfully carried out by the combination of the adduct formation of these complexes with tributylphosphine and chromatography. Complexes **1a** and **3a** form 1 : 1 adducts with tributylphosphine and are separated from **2a** by means of silica-gel chromatography under Ar (**2a** is eluted more easily than the phosphine-adducts of **1a** and **3a**). The complexes **1a** and **3a** can be easily regenerated from the adducts with tributylphosphine by oxidizing the phosphine on exposure to the air.

When we choose the compositions of S_8 and Se_8 such that **3a** is not formed (for example, under the condition of S : Se=1 : 6), the selenolatothiolato complex, **1a**, can be obtained in pure form.

The yields of **1a**, **2a**, and **3a** determined by the ^{1}H NMR spectroscopy, are shown in Table 1, together with the initial ratios of sulfur and selenium.

Table 1. Yields of Selenolatothiolato (**1a**), Dithiolato (**2a**), and Diselenolato (**3a**) Complexes in the Reaction of [Co(cp)(cod)] (cod=1,5-cyclooctadiene) (**4a**), Diphenylacetylene (**5a**), and a Mixture of S_8 and Se_8

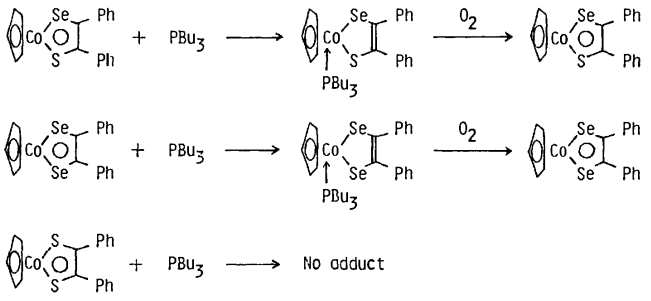
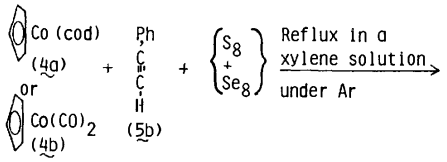
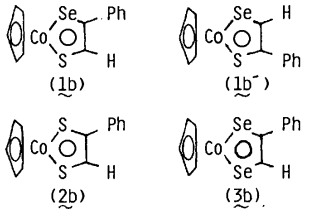
a) Yield=(amount of product/amount of **4a** used) ×100.



When we used phenylacetylene as an alkyne, we obtained (η-cyclopentadienyl)(2-phenyl-2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III) (**1b**) and (η-cyclopentadienyl)(1-phenyl-2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III) (**1b′**) as the complexes containing both S and Se. In this case, the amount of **1b** was greater than that of **1b′**.





The identification of **1b** and **1b′** was done by the synthesis of **1b′** by the reaction of [Co(cp)I_2CO] and 5-phenyl-1,3-thiaselenole-2-thione in ethanol in the presence of sodium ethoxide. 5-Phenyl-1,3-thiaselenole-2-thione was prepared according to the method of Mayer and Müller.[13]

The dependences of the yields of **1b**, **1b′**, **2b**, and **3b** on the initial ratio of S_8 and Se_8 are shown in Table 2.

The addition of sulfur to the [Co(cp)(cod)]-alkyne-Se_8 system causes remarkable decreases in the yields of the diselenolato complexes. But the addition of selenium to the [Co(cp)(cod)]-diphenylacetylene-S_8 system promotes the formation of the dithiolato complex. In the [Co(cp)$(CO)_2$]-phenylacetylene-S_8 system, the addition of selenium lowers the yield of the dithiolato complex, but the inhibiting effect of selenium on the formation of dithiolato complex is much smaller than that of sulfur on the formation of the diselenolato complex in the reaction of [Co(cp)$(CO)_2$], phenylacetylene, and Se_8.

Table 2. Yields of Selenolatothiolato (**1b** and **1b′**), Dithiolato (**2b**), and Diselenolato (**3b**) Complexes in the Reaction of [Co(cp)$(CO)_2$] (**4b**), Phenylacetylene (**5b**), and a Mixture of S_8 and Se_8

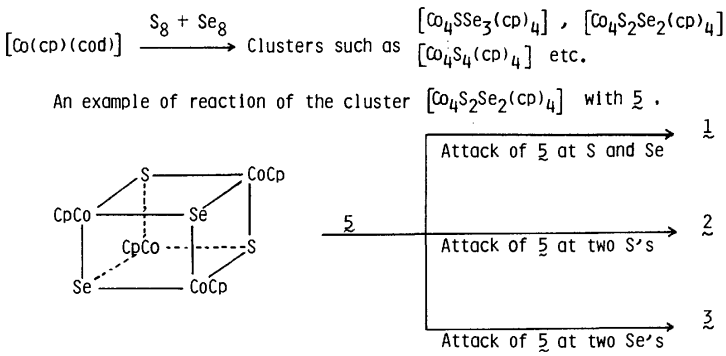
Reaction Mechanism. For the formation of dithiolato, diselenolato, and selenolatothiolato complexes, the intermediacy of "clusters" consisting of η-cyclopentadienylcobalt and chalcogen atoms is presumed. In the absence of alkyne, [Co(cp)(cod)] reacts with a mixture of S_8 and Se_8 (molar ratio of S_8 and Se_8 to **4a** are 1/20 and 1/5 (=4/20), respectively) to give a dark brown solid. The mass spectral analysis of the dark brown solid showed that the solid consists of several S, Se-mixed clusters. A chromatographically separated fraction, which consists of $[Co_4S_2Se_2(cp)_4]$, $[Co_4S_3Se(cp)_4]$, and $[Co_4S_4(cp)_4]$, reacts with **4a** in boiling xylene to afford **1a**, **2a**, and **3a**.

This result indicates that the dithiolato, diselenolato, and selenolatothiolato complexes are formed by the attack of alkyne to the chalcogen atoms of the cluster complexes either in a concerted or in a stepwise process.

One factor in determining the relative amounts of dithiolato, diselenolato, and selenolatothiolato complexes would be the selectivity in the attack of alkyne to the cluster complexes. However, there exists another factor to determine the amounts: the ligand exchange of the primarily formed dichalcogenato complexes. A prolonged heating of a selenolatothiolato complex **1b′** in xylene under reflux (140 °C) brings about the formation of the dithiolato complex



2b. This fact shows the exchange of the chalcogen atoms.

Physical Properties of Dithiolato, Diselenolato, and Selenolatothiolato Complexes. Some important spectroscopic properties as well as the reversible half-wave potentials (for reduction) of the complexes **1**, **2**, and **3** are summarized in Table 3.

The patterns of the electronic spectra of the diselenolatocobalt(III) complexes are similar to those of the dithiolato complexes. Each complex has four absorptions in the UV-vis. region. The absorption maxima of the diselenolatocobalt(III) complexes are situated at wavelengths longer than those of the corresponding dithiolato complexes. The absorption maxima of the selenolatothiolato complexes are located between those of the dithiolato and diselenolato complexes. The weak absorptions around 750—820 and 420—480 nm shift more sensitively dependent on the kinds and number of the chalcogen atoms than the strong absorptions around 600—620 and 290—300 nm.

The reversible half-wave potentials (for reduction) of the diselenolato complexes are higher than those of the corresponding dithiolato complexes: thus the diselenolato complexes are reduced more easily than the dithiolato complexes. The selenolatothiolato complexes have intermediate half-wave potentials between the dithiolato and diselenolato complexes.

The fact that the $E^{r}_{1/2}$ values of the diselenolato complexes are higher than those of the dithiolato complexes suggests that the central cobalt atoms in the diselenolato complexes are charged more positively than those in the dithiolato complexes. There is a contradiction in the values of electronegativities of selenium and sulfur: according to Pauling, the electronegativity of sulfur (2.5) is larger than that of selenium (2.4),[14] while according to Allred-Rochow, the electronegativity of sulfur (2.4) is smaller than that of selenium (2.5).[15] The observed half-wave potentials of diselenolato and dithiolato complexes suggest that the selenium behaves in dichalcogenatometal complexes as a more electronegative element than sulfur does.

The delta value of chemical shifts in ^{1}H NMR spectra for the proton attached to the diselenolene ring in **3b** is larger than that for the proton attached to the dithiolene ring in **2b**. The chemical shifts ascribed to H in selenathiolene rings in **1b** and **1b′** are interme-

diate. A similar tendency has been reported for 1,3-dichalcogenolene-2-thiones and selones (**6**, **7**, and **8**).[16] (Delta-values of ^{1}H NMR in **6** and **7** are 7.17 and 7.92, respectively. Those in **8** are 7.26 and 7.80.) These facts seem to agree with the results of $E^r_{1/2}$: The more positive selenium attracts electrons more strongly than sulfur does.

The chemical shifts of the ^{1}H and ^{13}C NMR in the cyclopentadienyl ring are influenced much less by the chalcogen atoms than those of H in the dichalcogenolene rings. However, an opposite effect of chalcogen is observed: The signals due to ^{1}H and ^{13}C in the cyclopentadienyl ring in diselenolato complexes appear in higher magnetic field than those in the dithiolato complexes.

The chemical shifts of ^{1}H and ^{13}C NMR in the selenolatothiolato complexes are situated between those of the dithiolato complexes and those of the diselenolato complexes.

Adduct Formation with Tributylphosphine. A remarkable difference in chemical properties among dithiolato, diselenolato, and selenolatothiolato complexes with phenyl group as the substituent is the adduct formation with phosphine. Complexes **1a** and **3a** form 1 : 1 adduct with tributylphosphine, while **2a** does not react with tributylphosphine. A similar difference in the reactivities was observed for **1b**, **1b′**, **2b**, and **3b**. In a separate report,[17] we have described that the adduct formation of dithiolatocobalt complexes with phosphines and phosphites is dependent on the (reversible) half-wave potentials of reduction of the dithiolato complexes: The dithiolato complexes, the $E^r_{1/2}$'s of which are higher than -1.13 V, form an adduct with tributylphosphine. The $E^r_{1/2}$ values of the dithiolato, diselenolato, and selenolatothiolato complexes are accidentally distributed across the critical $E^r_{1/2}$ value. This is the reason why we could separate these complexes by the adduct formation with tributylphosphine.

Experimental

Materials. Commercially available diphenylacetylene, elemental sulfur, and elemental selenium were used as purchased. Phenylacetylene was purified by distillation.

Spectroscopy and Elemental Analysis. NMR spectra were recorded on a JEOL GX-270 instrument and mass spectra on a JEOL JMS-D300 instrument. UV-vis. spectra were measured with a Hitachi spectrometer Model 228. Elemental analysis was carried out with a Perkin-Elmer Model 240 C apparatus.

Reaction of η-Cyclopentadienylcobalt(I) Species, Alkyne, and Elemental Chalcogen. A mixture of [Co(cp)(cod)] or [Co(cp)(CO)$_2$] (ca 1.4 mmol), alkyne (ca 1.7 mmol), and a mixture of S_8 and Se_8 in xylene (25 cm^3) was refluxed for 24 h under an atmosphere of Ar.

Separation and Identification of Products. After the evaporation of the solvent under reduced pressure, the residue was extracted with dichloromethane. The extract was concentrated and the product mixture was submitted to the column chromatography (column, silica gel C-300 made by Wako Pure Chemical Co.; eluent, hexane-dichloromethane). The complexes **1**, **2**, and **3** were eluted together.

In order to obtain pure **1a**, the following procedure was followed. The reaction mixture from the reaction under the condition of S : Se=1 : 6 (the conditions under which only a small amount of **3a** was formed) was preliminarily separated by the procedure described above. The composition of the mixture of **1a**, **2a**, and **3a** was determined by means of ^{1}H NMR. Then, to the mixture under Ar was added tributylphosphine, the amount of which was equal to the sum of the amounts of **1a** and **3a**. Then the mixture was submitted to the column chromatography using a column packed with silica gel C-300. After the elution of **2a** with a mixture of dichloromethane and hexane, the column was exposed to the air and **1a** and **3a** were regenerated by the oxidative elimination of tributylphosphine. By the elution with dichloromethane-hexane, **1a** was obtained in analytically pure form. A similar method was applied to the separation of **1b**, **1b′**, **2b**, and **3b**.

(η-Cyclopentadienyl)(1,2-diphenyl-1,2-ethylenedithiolato)cobalt(III) (2a) was identified by reference to the spectra reported by Bönnemann.[18] Blue crystals; mp 235—238 °C; IR (KBr disk) 3098, 764, 743, and 698 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.39 (5H, s, cp) and 7.12—7.26 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=79.62 (cp), 127.1 (Ph), 127.8m (Ph), 129.0 (Ph), 142.0 (Ph), and 168.8 (dithiolene ring); MS (70 eV) *m/z* (rel intensity) 368 (5, M$^+$), 367 (11, M$^+$), 366 (49, M$^+$), 190 (9), 189 (7), 188 (100), 178 (16), 124 (26), and 59 (7). Found: C, 62.51; H, 3.95%.

(η-Cyclopentadienyl)(1,2-diphenyl-1,2-ethylenediselenolato)cobalt(III) (3a): Green crystals; mp 250—255 °C (lit,[9] mp 237 °C); IR (KBr disk) 3095, 762, 727, and 697 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.35 (5H, s, cp) and 7.10—7.23 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=77.97 (cp), 126.84 (Ph), 127.74 (Ph), 129.22 (Ph), 143.83 (Ph), and 169.14 (diselenolene ring); MS (70 eV) *m/z* (rel intensity) 462 (6, M$^+$), 460 (6, M$^+$), 459 (2, M$^+$), 458 (3, M$^+$), 286 (12), 284 (43), 282 (37), 281 (12), 280 (23), 178 (100), 124 (43), and 59 (7).

Found: C, 49.57; H, 3.26%. Calcd for $C_{19}H_{15}CoSe_2$: C, 49.59; H, 3.29%.

(η-Cyclopentadienyl)(1,2-diphenyl-2-selenolatoethylenethiolato-*S*,*Se*)cobalt(III) (1a): Green crystals; mp 234—236 °C; IR (KBr disk) 3098, 763, 734, and 698 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.37 (5H, s, cp) and 7.10—7.25 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=78.80 (cp), 126.84 (Ph), 127.15 (Ph), 127.78 (Ph), 127.85 (Ph), 128.73 (Ph), 129.56 (Ph), 142.57 (Ph), 143.75 (Ph), 165.95 (thiaselenolene ring), and 171.93 (thiaselenolene ring); MS (70 eV) *m/z* (rel intensity) 416 (8, M$^+$), 415 (7, M$^+$), 414 (32, M$^+$), 412 (16, M$^+$), 411 (6, M$^+$), 410 (6, M$^+$), 238 (22), 237 (8), 236 (100), 234 (49), 233 (17), 232 (19), 178 (57), 124 (55), and 59 (11)

Found: C, 54.87; H, 3.89%. Calcd for $C_{19}H_{15}CoSSe$: C, 55.07; H, 3.62%.

(η-Cyclopentadienyl)(phenyl-1,2-ethylenedithiolato)cobalt(III) (2b) was identified by reference to the spectra

reported by Bönnemann.[18] Blue crystals; mp 85—87 °C; IR (KBr disk) 3098, 757, and 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.37 (5H, s, cp), 7.24—7.80 (5H, m, Ph), and 9.00 (1H, s, H in dithiolene ring); ^{13}C NMR ($CDCl_3$) δ=79.28 (cp), 126.47 (Ph), 127.53 (Ph), 128.62 (Ph), 140.14 (Ph), 155.23 (dithiolene ring attached to H), and 172.47 (dithiolene ring attached to Ph); MS (70 eV) *m/z* (rel intensity) 292 (6, M^+), 291 (10, M^+), 290 (64, M^+), 190 (9), 189 (7), 188 (100), 124 (36), 102 (8), 59 (16).

Found: C, 55.09; H, 3.79%. Calcd for $C_{13}H_{11}CoS_2$: C, 53.79; H, 3.79%.

(η-Cyclopentadienyl)(phenyl-1,2-ethylenediselenolato)-cobalt(III) (3b): Blue crystals; mp 116—118 °C; IR (KBr disk) 3096, 763, 740, and 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.35 (5H, s, cp), 7.29—7.71 (5H, m, Ph), and 9.85 (1H, s, diselenolene ring); ^{13}C NMR ($CDCl_3$) δ=77.61 (cp), 126.96 (Ph), 127.28 (Ph), 128.39 (Ph), 150.70 (Ph), 154.23 (diselenolene ring), 174.00 (diselenolene ring); MS (70 eV) *m/z* (rel intensity) 338 (9, M^+), 386 (29, M^+), 384 (26, M^+), 383 (10, M^+), 382 (15, M^+), 380 (6, M^+), 286 (31), 285 (6), 284 (100), 282 (86), 281 (29), 280 (51), 279 (14), 278 (20), 124 (99), 102 (33), and 59 (18).

Found: C, 40.93; H, 2.84%. Calcd for $C_{13}H_{11}CoSe_2$: C, 40.66; H, 2.87%.

(η-Cyclopentadienyl)(2-phenyl-2-selenolatoethylene-thiolato-*S,Se*)cobalt(III) (1b): Violet crystals; mp 86—88 °C; IR (KBr disk) 3098, 755, and 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.36 (5H, s, cp) and 9.15 (1H, s, thiaselenolene ring); ^{13}C NMR ($CDCl_3$) δ=78.50 (cp), 126.49 (Ph), 127.29 (Ph), 128.70 (Ph), 141.88 (Ph), 158.72 (thiaselenolene ring), and 169.74 (thiaselenolene ring); MS (70 eV) *m/z* (rel intensity) 340 (10, M^+), 339 (7, M^+), 338 (43, M^+), 336 (22, M^+), 335 (8, M^+), 334 (8, M^+), 238 (22), 237 (7), 236 (100), 235 (4), 234 (49), 233 (17), 232 (19), 124 (71), 102 (12), and 59 (22).

Found: C, 45.88; H, 3.22%. Calcd for $C_{13}H_{11}CoSSe$: C, 46.32; H, 3.27%.

(η-Cyclopentadienyl)(2-phenyl-2-selenolatoethylene-thiolato-*S,Se*)cobalt(III) (1b′) was identified by the synthesis in the reaction of [Co(cp)I_2CO] with 5-phenyl-1,3-thiaselenole-2-thione. Violet crystals; mp 98—100 °C; IR (KBr disk) 3096, 764, 746, and 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.36 (5H, s, cp), 9.74 (1H, s, H in the dithiolene ring); ^{13}C NMR ($CDCl_3$) δ=78.51 (cp), 127.06 (Ph), 127.56 (Ph), 128.39 (Ph), 140.74 (Ph), 150.62 (CH in the dithiolene ring), and 176.60 (CPh in the dithiolene ring); MS (70 eV) *m/z* (rel intensity) 340 (11, M^+), 339 (7, M^+), 338 (48, M^+), 336 (24, M^+), 335 (9, M^+), 334 (9, M^+), 238 (22), 237 (7), 236 (100), 235 (4), 234 (49), 233 (16), 232 (19), 124 (80), 102 (17), and 59 (29).

Found: C, 45.72; H, 3.09%. Calcd for $C_{13}H_{11}CoSSe$: C, 46.32; H, 3.27%.

Determination of Yields of Products. The fraction containing **1**, **2**, and **3**, which resulted from the column chromatography of the products, was submitted to the measurement of ^1H NMR in a $CDCl_3$ solution. The contents of **1a**, **2a**, and **3a** from the reaction among diphenylacetylene, [Co(cp)$(CO)_2$], S_8, and Se_8 were calculated from the areas of the ^1H NMR peaks ascribed to cp rings (δ=5.37 for **1a**, δ=5.39 for **2a**, and δ=5.35 for **3a**).

The composition of the mixtures from the reaction among phenylacetylene, [Co(cp)$(CO)_2$], S_8, and Se_8 were calculated from the areas of the ^1H NMR peaks ascribed to the protons in the dithiolene ring (δ=9.15 for **1b**, δ=9.74 for **1b′**, δ=9.00 for **2b**, and δ=9.85 for **3b**).

Formation, Separation, and Identification of Cluster Complexes. A mixture consisting of [Co(cp)(cod)] (4.3 mmol), Se_8 (0.54 mmol), and S_8 (0.54 mmol) in xylene (35 cm^3) was heated under reflux (140 °C) under Ar for 24 h. After the evaporation of the solvent under reduced pressure, the residue was extracted with dichloromethane and the dichloromethane-insoluble substances were removed by filtration. The dichloromethane-soluble substances were separated by column chromatography (column, silica gel C-300 made by Wako Pure Chemical Co.; eluent, dichloromethane–diethyl ether). Black solid was eluted with dichloromethane (3)–diethyl ether (1). The mass-spectral measurement showed it to be a mixture of cluster complexes of [$Co_4S_2Se_2(cp)_4$], [$Co_4S_3Se(cp)_4$], and [$Co_4S_4(cp)_4$] (the mass spectra of the mixture (70 eV): *m/z* (rel intensity) 720 (0.42, M^+ of [$Co_4S_2Se_2(cp)_4$]), 718 (0.36, M^+ of [$Co_4S_2Se_2(cp)_4$]), 674 (1.07, M^+ of [$Co_4S_3Se(cp)_4$]), 672 (3.46, M^+ of [$Co_4S_3Se(cp)_4$]) 670 (1.71, M^+ of [$Co_4S_3Se(cp)_4$]), 626 (2.52, M^+ of [Co_4S_4-$(cp)_4$]), 624 (11.87, M^+ of [$Co_4S_4(cp)_4$], 124 (10.09, Co(cp)), and 66 (100, cpH)).

Reaction of a Mixture of Cluster Complexes with Diphenylacetylene. Diphenylacetylene (30 mg) and the mixture of the cluster complexes (30 mg) described above were reacted in xylene (30 cm^3) under Ar at 140 °C for 24 h. After the reaction, the products were separated in the procedure described above. The yields of **1a** and **2a** are 54 mmol and 46 mmol, respectively. The complex **3a** was formed in a trace amount.

Cyclic Voltammetry. All the electrochemical measurements were carried out in acetonitrile solutions containing 0.1 mol dm^{-3} tetraethylammonium perchlorate at 25 °C with a Yanaco Polarographic Analyzer P-1100. A platinum disk electrode (ϕ=2 mm) served as both a stationary working electrode and a rotating electrode. The potential of the working electrode was measured against a silver-silver ion electrode (Ag| 0.1 mol dm^{-3} $AgClO_4$ in acetonitrile).

The authors are grateful to Professor Kunio Shimizu and Mr. Hirobumi Ushijima for the measurement of cyclic voltammogram.

Physicochemical Studies on Solid Solutions of Calcium Phosphorus Arsenic Hydroxyapatites

P. P. MAHAPATRA,* L. M. MAHAPATRA, and Bagmi MISHRA
Post-Graduate Department of Chemistry, Khallikote College, Berhampur, GM: 760001, India
(Received April 20, 1988)

Samples of arsenic hydroxyapatite and its solid solutions with calcium hydroxyapatite are synthesized in aqueous media. The samples are characterized by X-ray, infrared spectra, the assignments of phosphate, arsenate, and hydroxyl bands are recorded. The possibility of anion migration in the apatite lattice is proposed. Presence of water, adsorbed in nature, is indicated in the TGA and DTA analysis of the samples. The solubility product, K_{sp}, of the samples of arsenic hydroxyapatite $Ca_{10}(AsO_4)_6(OH)_2$, and the solid solutions, $Ca_{10}(PO_4)_{6-x}(AsO_4)_x(OH)_2$, ($x$=1 to 5) are determined considering the formation of ion pairs $[CaHAsO_4]^0$, $[CaHPO_4]^0$, $[Ca(H_2AsO_4)]^+$, and $[Ca(H_2PO_4)]^+$ in solution. The instability of the samples in solution is indicated from the experimental $\Delta G^0_{soln.}$ values.

Arsenic has been recognised as a toxic element, which causes poisoning in vivo.[1,2] It is deposited in bones and bony tissues[3,4] due to the possibility of $P^{5+} \rightarrow As^{5+}$ exchange reaction in the calcium hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, CaPHA of bone.[5] When this exchange reaction in calcium hydroxyapatite is complete, it leads to the formation of arsenic hydroxyapatite, $Ca_{10}(AsO_4)_6(OH)_2$, CaAsHA, isomorphous with $Ca_{10}(PO_4)_6(OH)_2$, CaPHA; while incomplete/partial substitution in it, results in the formation of solid solutions of calcium phosphorus arsenic hydroxyapatite, $Ca_{10}(PO_4)_{6-x}(AsO_4)_x(OH)_2$ (where x is the compositional parameters, ranges from 1 to 5). Though arsenic in naturally occurring phosphatic minerals is well-known[6] and formation of CaAsHA by solid state reaction[7] at high temperature and its characterization is well established, similar studies on CaAsHA and its solid solutions with CaPHA are not available. We, therefore, report here the formation of CaAsHA and calcium phosphorus arsenic hydroxyapatite samples, their characterization by X-ray, IR, and electron microscopy. Since the samples are synthesized in aqueous media at 100 °C, they are likely to carry attendent seats of water molecules with them. The nature of water present in the samples and their thermal stabilities are studied by TGA and DTA methods. The solubility of the samples of the solid solutions are investigated in the pH range 4.0 to 8.0 and their solubility products are reported.

Experimental

The chemicals used in the preparations of the samples were either BDH or E. Merck grade and the solutions are prepared in CO_2 free conductivity water. Calcium nitrate diammonium hydrogen phosphate and disodium hydrogen arsenate were used as desired by the stoichiometry for a sample of the general formula, $Ca_{10}(PO_4)_{6-x}(AsO_4)_x(OH)_2$ for an yield of 15 g. The method used for the preparation was reported earlier.[8] The samples after preparation were centrifuged, washed repeatedly with conductivity water until free from the adsorbed ions. Care was taken to exclude the possibility of incorporation of carbonate during preparation. The samples were dried (12 h) at 110 °C to constant weight and analyzed for Ca, P, and As complexometrically.[9] The X-ray diffraction patterns of the samples were recorded by a Debye-Scherrer powder diffraction instrument using Ni filtered Cu $K\alpha$ radiation. The electron microscopic patterns of acetone-washed samples were obtained using Simens Elminskop I by the method of electromagnetic disperson. The IR spectra of the samples, preheated at 800 °C, were recorded on a Perkin Elmer IR grating instrument. The range covered was from 4000—400 cm^{-1}. The thermal analyses of the samples were made on a Derivatograph (Budapest) which recorded simultaneous photographs of TG, DTA, and DTG of the samples. The samples were heated at a rate of 10° min^{-1} upto 1000 °C in a platinum crucible using Al_2O_3 as reference. The activation energy of dehydration of the samples was obtained by using Freeman and Carrol's equation[10] and also from Arrhenius plot obtained from DTA peaks.

The solubility of the samples was investigated at 35 °C under a constant ionic environment[11] of 0.165 mol dm^{-3} $NaNO_3$ by the method of equilibration. The different concentrations of As_2O_5 in doubly distilled water, for studies in pH range 4.0 to 6.0 and sodium hydroxide for pH 7.10 and 8.0 were used. Equilibration was done in air tight polyethylene thermostated flask containing 200 mg of the samples of particle size 200 μm in 50 ml of the desired solvent. Attainment of saturation was followed kinetically by analyzing in solution calcium, arsenic, and phosphorus content complexometrically.[9] The system attained saturation within ten hours of equilibration.

Calculations

The calculations used in the studies of the solubility are as follows. From the pH of the medium of equilibration and total calcium, arsenic, and phosphorus content, the concentrations of free ionic species XO_4^{3-}, HXO_4^{2-}, and $H_2XO_4^-$ were calculated using Eqs. 1 to 3 (where X=As or P).

$$[XO_4^{3-}] = [X]_{total} \Big/ \left[\frac{(H^+)^3}{K_1K_2K_3} + \frac{(H^+)^2}{K_2K_3} + \frac{(H^+)}{K_3 f_{HAsO_4^{3-}}} + \frac{1}{f_{XO_4^{3-}}}\right] \quad (1)$$

$$[HXO_4^{2-}] = [X]_{total} \Big/ \left[\frac{(H^+)^2}{K_1K_2} + \frac{(H^+)}{K_2 f_{H_2XO_4^-}} + \frac{1}{f_{HXO_4^{2-}}}\right] \quad (2)$$

$$[H_2XO_4^-]=[X]_{total}/\left[\frac{(H^+)}{K_1}+\frac{1}{f_{H_2XO_4^-}}\right] \quad (3)$$

Where K_1, K_2, K_3 are the three dissociation constants of orthoarsenic acid;[12,13] $f_{XO_4^{3-}}$, $f_{HXO_2^{2-}}$, $f_{H_2XO_4^-}$ are the activity coefficients of XO_4^{3-}, HXO_4^{2-}, and $H_2XO_4^-$ respectively. The quantity in the parentheses represented activities. Assuming the activity coefficients unity, approximate ionic strength, μ, was obtained using the equation.

$$\mu=\frac{1}{2}\sum C_iZ_i^2$$

The activity coefficients of the above ionic species of arsenic and phosphorus are obtained by the extended Debye equation.

$$\left(\log f_i=\frac{-A\sqrt{\mu}\,Z_i^2}{1+\sqrt{\mu}}+0.3\mu\right)$$

These were subsequently used and a fresh value of μ was calculated.

Following an iterative procedure, constancy in the value of ionic strength is obtained. The ion activity product, synonymous with the solubility product was calculated using the equation:

$$K_{sp}=[Ca]^{10}[AsO_4^{3-}]^x[PO_4^{3-}]^{6-x}\left[\frac{K_W}{(H^+)}\right]^2 f_2^{10}f_1^{2-}f_{AsO_4^{3-}}^{x}f_{PO_4^{3-}}^{6-x}$$

where f_1 and f_2 stand for activity coefficients of the XO_4 (X=P or As) ions, H^+ and Ca^{2+} ions respectively. The solubility products are redetermined after considering the formation of the ion pairs $Ca(H_2AsO_4)^+$, $(CaHAsO_4)^0$, $Ca(H_2PO_4)^+$, $(CaHPO_4)^0$ in solution. The values of association constants used in the calculations are 8.71×10^{-3}, 0.108×10^{-6} for the arsenate[14,15] and 5.88×10^2, 7.49 for phosphate[16] species respectively. The solubility products of the samples after considering the ion pair formation are determined using the equation:

$$K_{sp}=[Ca-T]^{10}Y_2^{10}[PO_4^{3-}]_{IP}^{6-x}[AsO_4^{3-}]_{IP}^{x}Y_{PO_4^{3-}}^{6-x}Y_{AsO_4^{3-}}^{x}\left[\frac{K_W}{(H^+)}\right]^2$$

where T is the total calcium involved in complex formation: $[PO_4]_{IP}$ and $[AsO_4]_{IP}$ refer to the concentration of the respective species after considering the ion pairs; Y_2, $Y_{PO_4^{3-}}$, and $Y_{ASO_4^{3-}}$, are the activity coefficients of Ca^{2+}, PO_4^{3-}, and AsO_4^{3-} species respectively; and (H^+) in the equation refers to the activity of H^+ ion.

The calculations reported here satisfy the following conditions:

(i) Saturation with respect to the samples.

(ii) Congruent dissolution of the samples.

$$\frac{[Ca]}{([As]-[As]_0)+[P]}-\frac{5}{3}=0 \quad \text{for solid solutions, and}$$

$$\frac{[Ca]}{[As]-[As]_0}-\frac{5}{3}=0 \quad \text{for CaAsHA, and}$$

(iii) Electroneutrality, $E_\pm=Z_iC_i=0$.

where $[As]_0$ is the molar concentration of initial arsenic in As_2O_5, as is the total arsenic in the medium after equilibration and $E_\pm$ is the summation, which includes all the ionic species in the medium.

Results and Discussion

The results of chemical analyses of the samples are given in Table 1. Considering a total of six gram atoms of arsenic and phosphorus in a mole of the sample, chemical formulae are proposed from the analytical data. The [Ca]/[As] and [Ca]/([As]+[P]) gram atom ratio varying is found equal to 1.66±0.01 (Theo. 1.667) indicating the formation of apatite samples.

The X-ray powder diffraction pattern of all samples contained broad and diffused lines due to the colloidal dimensions of the crystals. Consequent upon substitution of a bigger AsO_4^{3-} ion in $Ca_{10}(PO_4)_6(OH)_2$ a dilation of the unit cell with an increase in the lattice parameters a and c (Table 1) resulted. These values when plotted against composition of the samples (Fig. 1) fell on a straight line (Vegard's law) indicating that

Table 1. Results of Chemical Analysis, Lattice Constant of Samples of Calcium Arsenic Hydroxyapatite and Its Solid Solution with Calcium Phosphorus Hydroxyapatite

Sample No.	Wt%			Molecular formula	[Ca]/([P]+[As])	Lattice constants (Å)	
	Ca	P	As			a	c
I	38.52	15.46	5.83	$Ca_{10}(PO_4)_{5.19}(AsO_4)_{0.81}(OH)_2$	1.66	9.47 (±0.01)	7.00 (±0.10)
II	36.58	11.13	14.14	$Ca_{10}(PO_4)_{3.93}(AsO_4)_{2.06}(OH)_2$	1.66	9.65 (±0.01)	7.14 (±0.05)

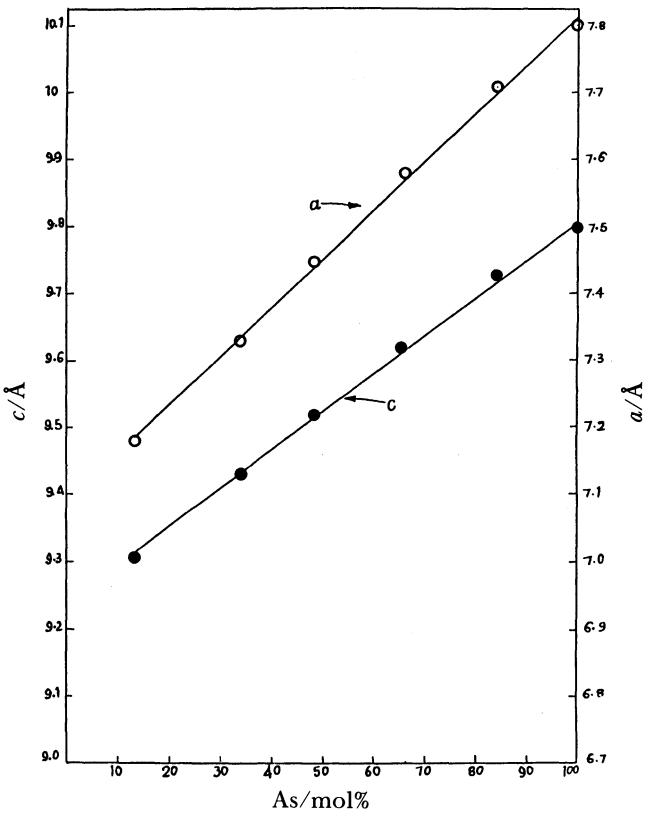

Fig. 1. Dependence of lattice constants a and c on the mole percent arsenic of the samples.

the samples are homogeneous solid solutions.

The electron microscopic patterns of the samples contained distinctly needle shaped crystals characteristic of apatites. The purity of the samples are indicated from the absence of extraneous phases in the microscopic patterns. With increase of AsO_4^{3-} in the samples, the crystals increased in size, the increase along the c-axis, however, is more pronounced than that along the a-axis.

The position in cm^{-1} and the assignments of the IR bands of the samples for x=1 to 5 are given in Table 2. The stretching hydroxyl bands appeared in the spectra of all the samples in the region 3560 to 3539 cm^{-1}. These bands are shifted with respect to the hydroxyl absorption in calcium hydroxide. This is indicated of a hydroxyl lattice interaction[17,18] and strongly suggest that the hydroxyl groups are situated within the three dimensional lattice. In fact, no vibrations at frequency about 3600 cm^{-1}, which are characteristics of hydroxyl group on the surface,[9] have been detected in the spectra.

A decrease of ν_s(OH) with an increase of the proportion of arsenate (AsO_4^{3-}) can be observed in Table 2. In addition, the phosphate vibrations also shifted to lower frequencies. These effects of substitution may be interpreted by considering that the interaction between OH group and the crystal becomes stronger as the arsenate content is increased, besides the effects

	430	430	420	425	420	$\nu_4(AsO_4)$

of binding energies and atomic masses[20] respectively. The nonappreciable variance of the ν_t(OH) indicates that the relative positions of the OH group with respect to the particular plane varies from one sample to another.

In the spectra of the samples, the ν_1 (As-O) mode cannot be detected, because the force constant of As-O and P-O are quite similar (k for P-O and As-O are 5.66 N cm^{-1} and 5.67 N cm^{-1} respectively) so that ν_1(As-O)/ν_1(P-O)=[μ_m(P-O)/μ_m(As-O)]$^{1/2}$, where μ_m is the reduced mass. In apatites, the ν_1(P-O) appears approximately around 950 cm^{-1}. The ν_1(As-O) appears in the IR region around 850 cm^{-1}, where the intense ν_3 mode of AsO_4 appeared. Therefore, the ν_1(As-O)$\approx$850 cm^{-1} is not observed due to the overlapping of ν_3 AsO_4 vibration in all cases.

The ideal symmetry of the tribasic phosphate ion in the free or undistorted state is tetrahedral i.e. it is a member of the T_d point group. In this ideal symmetry condition, absorptions corresponding to ν_3 and ν_4PO_4 mode should be observed. The appearance of ν_1 and ν_2 modes of phosphate in addition to the ν_3 and ν_4 modes in all cases indicate that T_d symmetry of the phosphate has been lowered to Cs site symmetry[21,22] consequent upon the substitution of the arsenate in CaPHA.

In the IR spectra only one ν_s(OH) at about 3560 cm^{-1} and one ν_t(OH) at about 533 cm^{-1} appeared for all the samples. This indicates that three equivalent anions are situated in the normal plane to the hydroxyl rotation axis of each hydroxyl group. If this were not true, then more than one ν_s(OH) and ν_t(OH) should have resulted. Therefore, in order that this should not happen, the two exchanging anions (PO_4^{3-} and AsO_4) belonging to the unit cell of hydroxyapatite are equivalent and exchange their positions through an interplanar anionic migration, so that each anion site in the phosphorus arsenic hydroxyapatite is occupied by an effective anion, whose characteristics are an average of all the anions present in the unit cell.

In the thermographic analyses in all the samples a

uniform loss in weight was observed upto 800 °C. TG curves (Fig. 2) have no distinct horizontals indicating nonappearance of a new stable phase during the thermal treatment. The possibility of decomposition appears unlikely since it has already been established that stoichiometric apatites decompose[23,24] at about 1200 °C. The total loss in weight may, therefore, be due to adsorbed water. The dehydration process in all cases is only of the type, a hydrate + water vapors is a two component system, where the dissociation pressure is a continuous uniform loss of water on dehydration. In each case an endothermic peak between 170—200 °C was detected. The IR peak at 1620 cm^{-1} in all the unheated samples disappeared after thermal treatment, which confirmed the presence of adsorbed water with the sample.[25] The activation energy of over all dehydration process from the TG

curves and DTA curves are given in Table 3. The nonuniformity in the values obtained by both the methods is due to difficulty in fixing the base line in DTA curve.

The results of solubility of the samples obtained at a series of pH are summarized in Tables 4 and 5 together with the calculated quantities $E_{\pm}$, K'_{sp}, and ΔG^{0}. Table 5 shows that $E_{\pm}$ is within the anticipated experimental error, indicating no gross error in the analytical figures, calculations, and model used. It is seen from Table 4 that the samples exhibited a stoichiometric dissolution,[25-28] represented by the reaction:

$$Ca_{10}(PO_4)_{6-x}(AsO_4)_x(OH)_2 \rightarrow 10Ca^{2+} + (6\text{-}x)PO_4^{3-} + xAsO_4^{3-} + 2\ OH^-$$

(where x=1—6). The saturation condition is evidenced by the smooth curves obtained in the plots of calcium concentration, versus pH (Fig. 3) for all samples and a reasonable constancy in K_{sp} for the solid solutions. The solubility product (K'_{sp}) without considering the presence of ionpairs and (K_{sp}) after considering ion pairs are given in Table 5. From the K_{sp} values of each solid solution over the entire pH range, the free energy of the solution ΔG^{0}_{soln} have been calculated and are given in Table 5. The investigations indicate that the solubility of solid solutions decreased with increase of OH^- concentration of the medium of dissolution. This observation is understandable from the considerations of alteration in chemical potential[8] of $Ca(OH)_2$, H_3AsO_4, and H_3PO_4 with increase of pH. The solution with increase in OH^- concentration becomes supersaturated and decrease in solubility is therefore resulted.

From the K_{sp} values of the sample given in Table 5 it can be concluded that the solubility of the samples increased with increase in proportion of arsenate. At the first instance, this could reasonably be due to the higher dissociation constant of H_3AsO_4 than H_3PO_4 at a given temperature. This, however, can be substantiated from the possible alteration of lattice energy of the solid solutions consequent upon the replacement of bigger arsenate (1.18 Å) ion in place of phosphate

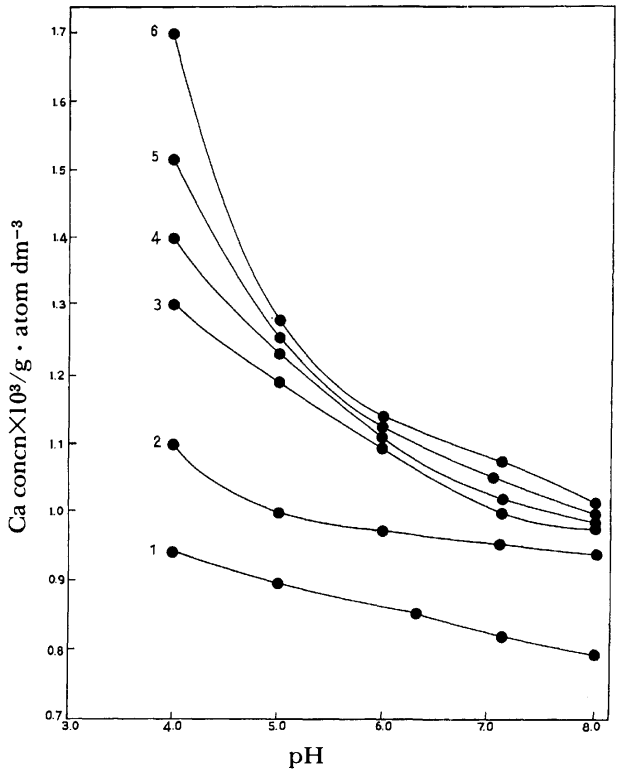

Fig. 3. Solubility equilibria of samples of calcium arsenic phosphorus hydroxyapatite in the pH range 3.0 to 8.0.

(1.10 Å) ion in calcium hydroxyapatite. Thus, the loose packing crystalline structure of the solid solution with decreased lattice energy supports the observed increasing solubility trend of the solid solutions with higher proportion of arsenate ions. The decreasing stabilities of the solid solutions is also evidenced from the experimental ΔG^{0}_{soln} values.

Solvent and Reversed Phase Extraction Chromatographic Separation of Molybdenum and Tungsten with Quaternary Ammonium Salt Reagent, Aliquat 336

Nitya Ranjan DAS* and Putul CHATTOPADHYAY
Nuclear Chemistry Division, Saha Institute of Nuclear Physics,

(Received August 8, 1988)

A quaternary ammonium salt reagent, Aliquat 336 has effectively been used for radioanalytical separations of molybdenum and tungsten through the techniques of solvent extraction and reversed phase extraction chromatography (RPEC). Studies on solvent extraction revealed that quantitative separations of the elements in a mixture can be achieved by extracting tungsten with ca. 10^{-4} mol dm^{-3} solution of Aliquat 336 in cyclohexane from an aqueous solution of 1 mol dm^{-3} H_3PO_4. The efficiency of separation of the elements which form varieties of metal salts of poly- and heteropolyanion species in aqueous solution is very much dependent on the types of acids as well as on the reagent concentration. In RPEC system, both the elements were found to be quantitatively extracted by an Aliquat 336 impregnated column of Kieselguhr from an alkaline solution containing a hydroxy compound like tartaric acid. The extracted species were subsequently separated by eluting molybdenum and tungsten respectively with HCl solutions of 0.05 mol dm^{-3} and 0.1 mol dm^{-3} concentrations. The purity of the separated species at various stages of their separations was verified by means of gamma-ray spectrometry.

The elements, molybdenum and tungsten, due to lanthanoid contraction, form a critical pair of elements having very close chemical properties. In respect of occurrence, metallurgy and properties of metals, the elements are markedly similar. They exist in varieties of oxidation states and their aqueous chemistry is very complex amongst the transitional elements. Since the formations of varieties of metal complexes, especially poly- and heteropolyanion species are most important feature of the chemistry of both molybdenum and tungsten, it was expected that the high molecular weight amines or the quaternary ammonium salts which are very selective for different elements[1-10] under specific experimental conditions would be very effective in anion-exchange separation of the elements from each other. In this respect, a quaternary ammonium salt reagent, Aliquat 336 ($R_3R'NCl$), has been shown to be a versatile extractant in both solvent and reversed-phase extraction chromatographic (RPEC) separations of metals that are capable of existing as complex anionic species in aqueous solutions.[11-20] Several workers[21] have effectively used the extractant in studying the extraction behaviors of both molybdenum and tungsten in different experimental conditions. Recently, Shabana et al.[22] reported the extraction separation of tungsten in radiochemical purity with Aliquat 336 from rhenium in different acid media. Studies on the extraction chromatographic separation of small quantities of Cr(IV), W(VI), and Mo(VI) in Aliquat 336-HCl system was also reported by Stro'nski.[23] Although Aliquat 336 has been used for extraction separation of molybdenum and tungsten in various systems, no systematic studies on their mutual separation through solvent extraction and RPEC have yet been attempted. The present investigation deals with the development of suitable radioanalytical procedures involving both the extraction techniques for clean separation of molybdenum and tungsten in a mixture using Aliquat 336 as liquid anion exchanger.

Experimental

Reagent. Chemical reagents used were of analytical grade. The extractant, Aliquat 336 (trialkylammonium chloride) of molecular wt. 404.17 was supplied by Aldrich Chemical Co., Inc. USA. The radiotracers, ^{99}Mo(67h), ^{185}W (73d), and ^{187}W (24h), were procured from BARC, Trombay, as sodium molybdate and sodium tungstate respectively in sodium hydroxide solution having high specific activity which were diluted as per requirements.

For gamma-spectrometric study, an ND65 8K channel analyzer connected with a High Purity Germanium detector of 30 cm^3 active volume and with resolution of 2.06 keV at 1.33 MeV was used.

Solvent Extraction Procedure. In solvent extraction separation, 20 ml of aqueous feed containing the tracers ^{99}Mo and ^{185}W or ^{187}W ($<10^{-7}$ mol dm^{-3}) in different acid media was equilibrated with equal volume of Aliquat 336 of desired concentration in different diluents together with 3% (v/v) 1-octanol for a certain period. After disengagement of the liquid phases, radioactivities present in both the phases were rediometrically measured and identified whereby tungsten was found to be preferentially or completely extracted by the organic extractant depending upon the experimental conditions.

Reversed-Phase Extraction Chromatographic Procedure (RPEC). The column material, Kieselguhr, used for reversed-phase extraction chromatographic separation was first hydrophobised with dimethyldichlorosilane and then impregnated with Aliquat 336 following the procedure developed earlier.[24] A packed column (3 cm×0.3 cm) of impregnated Kieselguhr was prepared in a stoppered glass tube. A syringe was inserted through a rubber cork fitted at the top of the glass tube. The flow rate of the eluent

percolated in the column through this syringe was regulated throughout the experiment with a peristaltic pump (LKB 2132 Micro Perpex). Before loading of the radiotracer on the column, it was preconditioned by passing a 8 mol dm^{-3} $LiNO_3$-0.01 mol cm^{-3} HNO_3 solution which made the column more effective in the separation of the elements pair.

In RPEC separation system, small amount of tartaric acid was added to the tracer mixture containing molybdenum and tungsten in alkaline medium and was allowed to extract by the impregnated reagent in the column. After complete extraction, the elements were separated by eluting molybdenum first with a 0.05 mol dm^{-3} HCl solution and then tungsten by a 0.1 mol dm^{-3} HCl solution. A flow rate of 10—12 drops per minute was maintained throughout the experiment. Activities present in different fractions of the effluents were verified and measured by GM counters.

Initially, both solvent extraction and RPEC procedures were tried with individual radiotracers, ^{99}Mo and ^{185}W or ^{187}W, under similar experimental conditions. The purity and extent of separation of the radiotracers at different stages of separation procedures were verified radiometrically.

Discussion

Studies on the solvent extraction behavior of molybdenum and tungsten at tracer scales, in various acid media, namely, HCl, HNO_3, H_2SO_4, and H_3PO_4, with Aliquat 336 as extractant revealed that the extractability of tungsten, in general, is always higher than that of molybdenum whatever be the acidity of the media (Table 1). For both the elements, the extents of extractions follow a decreasing trend with increasing acidity of the aqueous solution but interestingly, it has been found that the differences in the distribution ratio values for the elements at different acidities are very much pronounced in case of orthophosphoric acid.

Extraction studies of molybdenum and tungsten with Aliquat 336 in cyclohexane from phosphoric acid solutions at different acidities, as shown in the Fig. 1, indicate that complete extraction of tungsten free from molybdenum can be achieved at ca. 1 mol dm^{-3} H_3PO_4 concentration below of which partial extraction of molybdenum along with tungsten always takes place. However, at phosphoric acid concentration>1 mol dm^{-3}, although the extraction of molybdenum is very insignificant, extraction of tungsten also follows a decreasing trend. Thus the optimal conditions for extraction of tungsten free from molybdenum is to extract tungsten with a reagent solution of 10^{-4} mol dm^{-3} concentration in cyclohexane from an aqueous phosphoric acid solution of ca. 1 mol dm^{-3} concentration.

The extraction of tungsten from orthophosphoric acid medium at different concentration follows almost similarly with that of molybdenum but with higher degree of extraction (Fig. 1). The insignificant extractibility of molybdenum at higher acidity beyond 1 mol dm^{-3} is attributed to the fact that in this region, it exists mostly in the cationic forms, such as

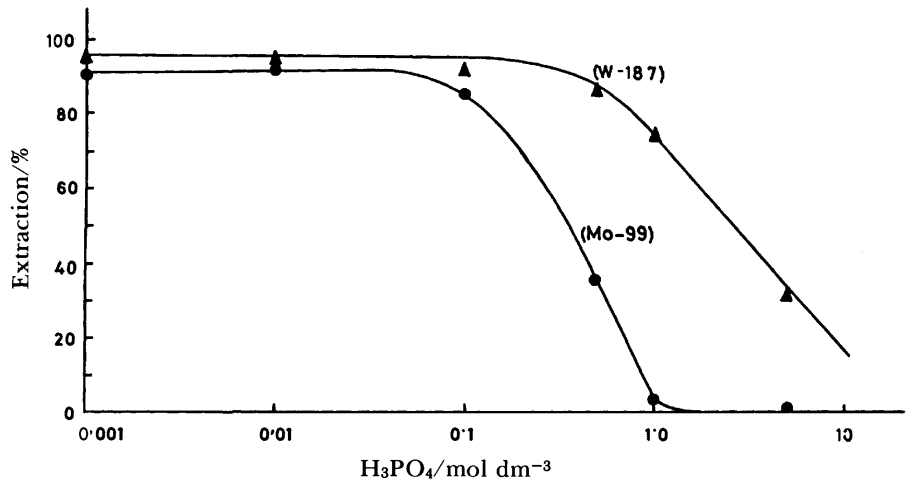

Fig. 1. Extractions of ^{99}Mo and ^{187}W with Aliquat 336 (ca. 10^{-4} mol dm^{-3}) at different concentrations of H_3PO_4.

Table 1. Extraction of Molybdenum and Tungstn from Different Acids at Different Concentrations with 10^{-4} mol dm^{-3} Aliquat 336 in Cyclohexan

$[MoO_2]^{2+}$, $[MoO(OH)_2]^{2+}$, or $Mo_2O(OH)_8 \cdot 2H_2O^{2+}$ [25] and in very strong acid it is present mainly as $[MoO_2]^{2+}$ [26,27] which are not extractable by the anionic extractant, Aliquat 336. But at comparatively lower acidity, the possibility of formation of heteropoly species like $H_3PMo_{12}O_{40}$ [25] increases resulting in higher extraction of molybdenum by the reagent. Higher extraction of molybdenum with a quaternary ammonium salt at lower acidity as observed by us also corroborates to the findings of Akaiwa et al.[28] who reported that at higher acidity the extracted species, $(R_3R'N)_3PMo_{12}O_{40}$ changes to $(R_3R'N)_2HPMo_{12}O_{40}$ resulting in the decrease of extraction of molybdenum by the reagent. Similarly in strong acid solution the extraction of tungsten is low, but with decreasing acidity, the efficiency of extraction increases appreciably probably due to gradual formation of the heteropoly species like $H_3PW_{12}O_{40} \cdot xH_2O$ and ultimately the existence of varieties of polytungstate anions helps in complete extraction of tungsten by the reagent. The large variation in the distribution ratio values for molybdenum and tungsten which form almost similar types of complex species is perhaps due to the fact that the heteropoly anions of tungsten are in general more stable than those of molybdenum[25] and the existence of varieties of paratungsten anions in solution as well.

Studies on the effect of concentration of Aliquat 336 on the extraction of the elements concerned, as shown in Fig. 2, indicate that the distribution ratio values for molybdenum increase with increasing concentration of the extractant starting from ca. 10^{-4} mol dm^{-3} whereas almost complete extraction of tungsten is possible with the reagent at this concentration other parameters remaining same. Thus to avoid the possibility of contamination due to molybdenum, extraction of tungsten with the reagent of higher concentration is not favored.

The effect of diluents on the extraction behavior of the extractant in extracting the elements was studied with different diluents. Diluents like heptane, cyclohexane, carbon tetrachloride, benzene, and toluene having very close dielectric constant values (1.9—2.38)[29] behave similarly as there is no significant change in D values with change of diluents in the extraction systems. But in case of chloroform which has comparatively a higher dielectric constant value of 5.05, some variations in the D values were observed. It has been reported that the dielectric properties of the diluents effects the extraction efficiency of the extractant and the change in the D values as observed in the study was due to different dielectric constant value of chloroform.

In RPEC system, the extractions of both molybdenum and tungsten by the Aliquat 336 impregnated column in simple sodium hydroxide medium were found to be partial. However, presence of small amount of tartaric acid in alkaline medium containing the tracers, helps in complete extraction of the elements by the reagent in the column. The extracted elements are later separated by eluting molybdenum first and then tungsten with hydrochloric acid solution of 0.05 mol dm^{-3} and 0.1 mol dm^{-3} concentrations respectively (Fig. 3).

In alkaline medium, the oxoanions, MoO_4^{2-} and WO_4^{2-}, with hydroxy compound like tartaric acid form anionic complexes which are found to be totally extracted by the impregnated reagent. Under the experimental conditions, the anionic complexes[30,31]

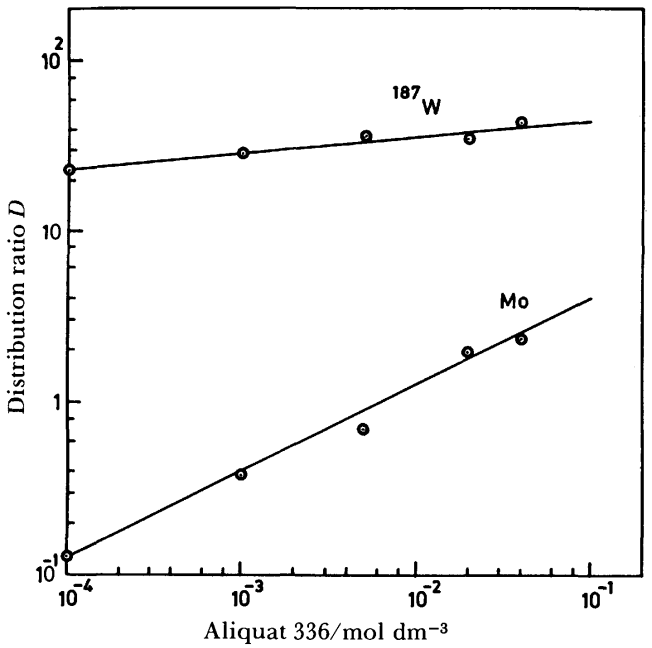

Fig. 2. Extractions of ^{99}Mo and ^{187}W from 1 mol dm^{-3} H_3PO_4 solution with Aliquat 336 solutions of different concentrations.

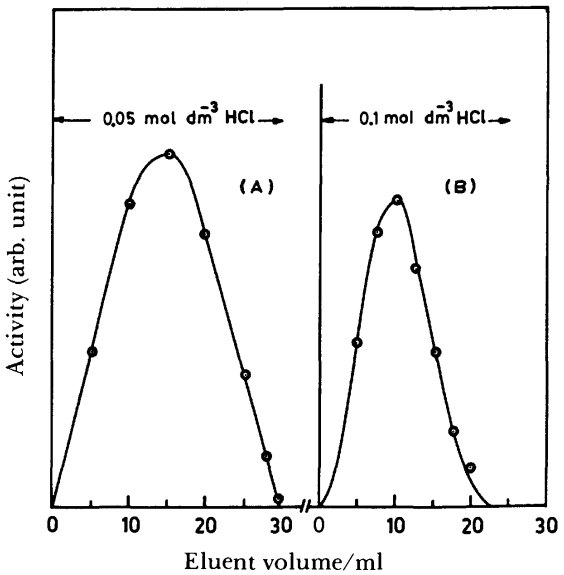

Fig. 3. Elution curves for ^{99}Mo and ^{187}W in RPEC: (A) elution of ^{99}Mo by 0.5 mol dm^{-3} HCl and (B) elution of ^{187}W by 0.1 mol dm^{-3} HCl.

formed by tungsten are comparatively more stable than those of molybdenum and it is expected that tungsten would be bonded more firmly to the reagent than that of molybdenum. Although the nature of anionic species are yet to be ascertained, but the experimental results corroborate the assumptions. For elution of tungsten species which are bonded strongly with the reagent, a solution comparatively of higher acid concentration is required.

Since both the elements in question form varieties of metal anion complexes, more or less of similar types, in different aqueous media, the general reaction responsible for extractions of the elements by the reagent in analogy of our previous investigations,[24,32] may be depicted as:

$$q\mathrm{R_3R'N^+Cl^-_{org}} + \mathrm{MX^{q-}_{aq}} \rightarrow (\mathrm{R_3R'N})_q\mathrm{MX_{org}} + q\mathrm{Cl^-_{aq}}$$

where MX^{q-} is the metal anionic species, $R_3R'N^+Cl^-$ is the quaternary salt having R="capryl" (C_8—C_{10} alkyl) group and R'=methyl group.

For both the techniques, the preliminary measurements of the radioactivities due to the respective isotopes, ^{99}Mo, ^{185}W, or ^{187}W, in different separated media were made by a GM counter. The purity of the separated elements were verified by taking recourse to gamma-ray spectrometry. The presence of molybdenum and tungsten in different phases were characterized by the photopeaks corresponding to the gamma

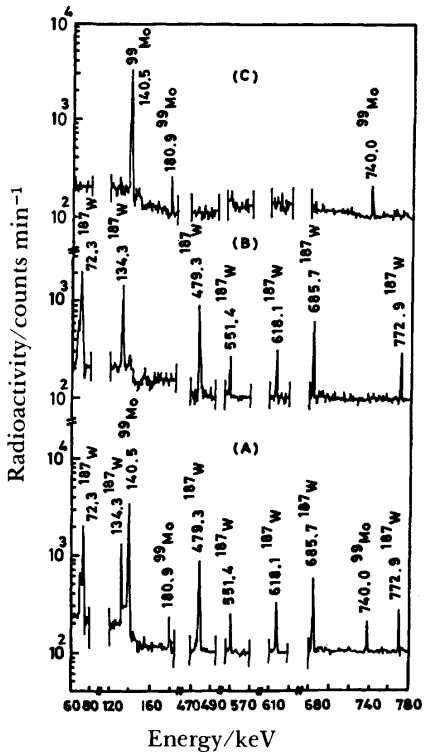

Fig. 4. Gamma-spectra of ^{99}Mo and ^{187}W in solvent extraction system: (A) a mixture of the radiotracers, ^{99}Mo and ^{187}W, (B), organic extractant (ca. 10^{-4} mol dm^{-3} Aliquat 336), and (C) aqueous phase left after extraction of ^{187}W.

energies of 140.5, 180.9, and 740.0 keV due to ^{99}Mo and of 72.3, 134.3, 479.3, 551.4, 618.1, 685.7, and 772.9 keV due to ^{187}W respectively. Typical gamma spectra of a mixture of the radiotracers, ^{99}Mo and ^{187}W and the isotopes in separated phases, as shown in Fig. 4, indicate complete separation of the elements through solvent extraction.

As regards column meterial in RPEC system, Kieselguhr which has been used as inert solid support for the extractant has got the favorable properties of considerable chemical stability, higher absorbing capacity for the extractant and also the resistivity towards any nuclear radiation which is essential in any radiochemical studies.

The extraction profile of the elements under the experimental conditions shows that the methods of solvent extraction and RPEC are almost complementary to each other. The developed procedures are simple and effective in mutual separation of the elements in tracer concentrations. The methods are of considerable importance especially in the field of nuclear technology where the purity of the element is of prime importance.

Prototropic Equilibria in Few β-Hydroxy-Substituted 1-Naphthylamines in the Ground and Excited Singlet States

Ranjit S. SARPAL and Sneh K. DOGRA*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received August 18, 1988)

The longest wavelength transition in the absorption spectra of β-hydroxy-substituted 1-naphthylamines is long axis polarised, whereas the fluorescence occurs from the more polar, short axis polarized state. This is based on the spectral characteristics in different solvents. Five different prototropic species are formed in the ground state and six species are obtained in the S_1 state. The ground state precursor for the formation of zwitterion is the monocation. pK_a values for the different prototropic reactions have been calculated in the ground and excited singlet states.

It is now well-established that the amino and hydroxyl groups[1-5] become stronger acids in their first excited singlet states. The monoanion formed by the deprotonation of amino group is generally nonfluorescent,[6-10] with few exceptions.[11,12] Further the proton-induced fluorescence quenching of the free aromatic amine is generally observed before it is protonated to form the monocation.[13-15] Recently, a few exceptions have been observed, where the lifetimes of the aromatic amines are very short and no fluorescence quenching is noticed by the proton,[16,17] even though the charge-transfer state is of lowest energy, a prime condition for the proton-induced fluorescence quench ing. The latter is a common feature during the first protonation of the aromatic diamines[18-20] and in these cases the fluorimetric titrations give rise to the ground state pK_a values for the first prototropic equilibrium. On the other hand, most of the phenoxide ions are nonfluorescent,[21-24] whereas the naphtholate ions are fluorescent.[25-28] Further, the fluorimetric titrations in the former cases yield the ground state pK_a values and this may be due to the shorter lifetime of the conjugate acid-base pairs. In case of naphthols, stretched sigmoid curves are observed, giving rise to both the ground state and excited state pK_a values.

Molecules containing electron-donating and electron-withdrawing groups have been studied extensively.[5] On the other hand, molecules containing electron-donating groups only, have not been investigated in detail and very few such examples are available in literature.[23,24,29-31]

The present study is on the molecules containing electron-donating groups only (i.e. $-NH_2$ and -OH) and the molecules are 2-hydroxy- (1,2 NA), 6-hydroxy- (1,6 NA), and 7-hydroxy-1-naphthylamines (1,7 NA), i.e. hydroxyl group is at the β-position and the amino group is at the α-position. Literature survey has indicated that the above molecules along with 1,3 NA and similar other molecules have been studied by Ellis and Rogers.[32] These workers have predicted the presence of zwitterion for some aminonaphthols in the excited singlet state in the pH range of ca. 4 to 10. The argument given is that the excited singlet state deprotonation constant of 2-naphthol (2 NOH) is 2.8[28] and it is enough to protonate the amino group ($pK_a \approx 4$) to form the zwitterion. But on the other hand, the excited state protonation constant of 1-naphthylamine (1 AN) is (−1.0)[33] and thus it may not be possible to form the phototautomer in the pH range of ca. 4 to 10 in the S_1 state, especially when the phototautomerism is biprotonic in the case of 1,6 NA and 1,7 NA, as the proton migration depends on the environment. The purpose of this study is to resolve this controversy and to find out why the zwitterion has not been observed for 1,7 NA and 1,2 NA. To supplement the above study, 7-methoxy-1-naphthylamine (1,7 MNA) has been prepared. Solvent effects have been studied and pK_a values of the various prototropic reactions have been determined and discussed.

Materials and Method

1-Amino-2-naphthol hydrochloride and 1,7 NA were procured from Aldrich Chemical Company. 1,6 NA was obtained from ICN Pharmaceuticals. 1,6 NA and 1,7 NA were purified from ethanol by repeated crystallization. Neutral 1,2 NA was prepared by titrating its salt with sodium hydrogencarbonate maintaining the pH≈5. 7-Methoxy-1-naphthylamine (1,7 MNA) was prepared from 1,7 NA by the method suggested by Ellis and Rogers.[32]

The purity of these compounds, purification of the solvents, instruments used, and the procedure used for calculating the various parameters are the same as described in our recent papers.[18-20] Pariser-Parr-Pople (PPP)[34,35] method was employed to calculate the transition energies, ground and excited state charge densities at the various centers of the molecules and their monoanions. The program was obtained from QCPE Indiana University, Bloomington, U.S.A. Different parameters required for calculations were taken from the literature.[36] The one center two electron repulsion integrals were calculated by Pariser approximation.[37] Two center electron repulsion integrals were calculated by the Nishimoto-Mataga method.[38] All the configurations obtained by single-electron excitation from occupied molecular orbitals to unoccupied molecular orbitals were considered in calculating all the configurational interaction. The species were assumed to be planar and the rings are taken as regular hexagon. The data regarding the

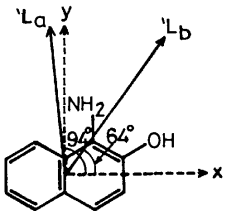
charge densities on nitrogen and oxygen atoms of $-NH_2$ and -OH/OMe groups of aminonaphthols have been listed in Table 1. The relevant data for 1 AN and 2 NOH are also listed in Table 1 for comparison. The directions of the axes are shown below.



Results and Discussion

Effect of Solvents. Figure 1 depicts the fluorescence spectra of these compounds in different solvents and relevant spectral data are compiled in Tables 2 and 3. Data of Table 2 indicate that the molecular extinction coefficient of each band system decreases with the increase in the wavelength. With the increase in the polarity of solvents, a red shift is noticed in each band system, but in methanol and water, the absorption spectra are blue shifted. On the other hand, a continuous red shift is observed in the fluorescence spectra of these molecules under the similar environments. The fluorescence band maxima of 1,6 NA, 1,7 NA, and 1,7 MNA are nearly at the same wavelength, whereas that of 1,2 NA is slightly red shifted. The above data show that molecules behave as proton donor in polar solvents and proton acceptor in methanol and water in the ground state, whereas proton donor in all the solvents in the first singlet state.

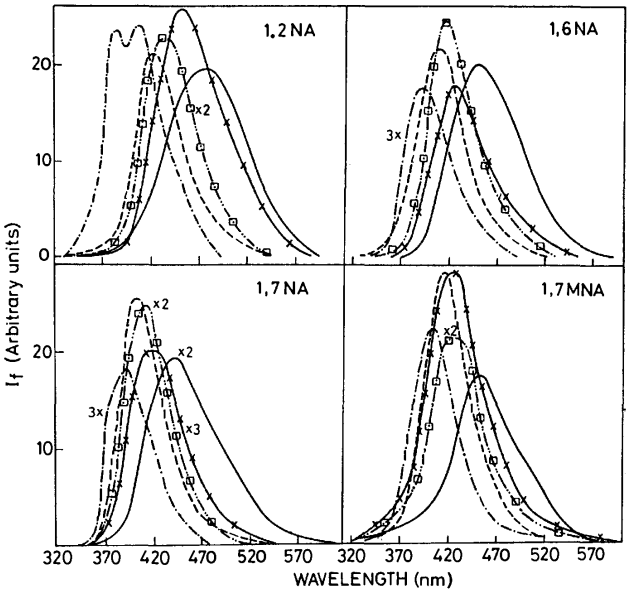


Fig. 1. Fluorescence spectra of 1,2 NA, 1,6 NA, 1,7 NA, 1,7 MNA in different solvents.

a) Monoanion of MNA.

naphthol (2 NOH) is $^1A \rightarrow {}^1L_b$ (335 nm, ethanol).[36] Further, the resonating effect of the amino group on the spectral transitions is more than that of hydroxyl group. The molecules studied in our work contain the amino group along the shorter axis which will perturb ^1L_a state and the hydroxyl group along the longer axis will primarily affect the ^1L_b state. From the data of Table 2, 340 nm band can be assigned to $^1A \rightarrow {}^1L_b$, whereas 315 nm and 300 nm band to $^1A \rightarrow {}^1L_a$ transitions. This is because: (i) the effect of solvents on ca. 340 nm band is less than that observed on ca. 300 nm band, (ii) the molecular extinction coefficient of 340 nm band is less than that of 300 nm, even though the difference is not so large as observed in naphthalene molecule.[39] The increase in the molecular extinction coefficient of 340 nm band could be partly because of the presence of -OH group and partly due to the mixing of the two transitions, (iii) two peaks around 300 nm band are the vibrational bands of $^1A \rightarrow {}^1L_a$ transition. The vibrational frequency of ca. 1580 cm^{-1} further substantiates our point, as the vibrational frequency associated with $^1A \rightarrow {}^1L_b$ transition[39] is ca. 1000 cm^{-1}, (iv) the above results are further manifested from PPP calculations (Table 1). The agreement between the band maxima, predicted by PPP method and experimental results is not bad. The oscillator strength clearly indicate that the long wavelength band is more forbidden than the short wavelength one. The polarization direction of the second transition is always along the shorter axis (y-axis), indicating that it is ^1L_a one. Whereas the polarization direction of the long wavelength band depends upon the position of the -OH group. Though the direction of this transition does not cor-

a) Monoanion of MNA. b) pH 4. c) H_0−4.

respond exactly along the longer axis (x-axis), it lies between the x- and y-axes. This indicates that the long wavelength band is influenced by the short wavelength one. This is also reflected by the molecular extinction coefficient, observed for the long wavelength band.

The fluorescence band maxima of each compound is close to that of 1 AN (445 nm, water)[40,41] than to that of 2 NOH (353 nm).[26] Based on the data of Table 3, we speculate that the reversal of ^1L_a and ^1L_b states takes place and ^1L_a becomes the lowest energy singlet state. This can be explained as follows: (i) ^1L_a state is more polar than ^1L_b and its polarity is further increased by the presence of amino group along the shorter axis. (ii) The energy gap between ^1L_a and ^1L_b states is not very large. (iii) Solvatochromic effect observed in case of these compounds resembles more with that of 1 AN[41] than with 2 NOH.[26] (iv) Though the PPP calculations show that the lowest energy state is ^1L_b, these calculations do not take account of solvent interactions and thus the agreement between the results calculated by PPP method and those obtained by fluorescence spectroscopy will not be good. The near consistency of the fluorescence band maxima in all the compounds indicates that the effect of -OH group on the spectral characteristics is same, so long as it is at the β-position of naphthalene moiety. The larger red shift observed in case of 1,2 NA could be either due to the presence of both the groups on the same ring or due to the presence of intramolecular hydrogen bonding.

Effect of Acid Concentration. 1,2 NA decomposes at pH>5, so its spectral characteristics are studied in the H_0/pH range of −10 to 5, whereas those of 1,6 NA, 1,7 NA, and 1,7 MNA have been investigated in the H_0/pH/H_- range of −10 to 17. The absorption and

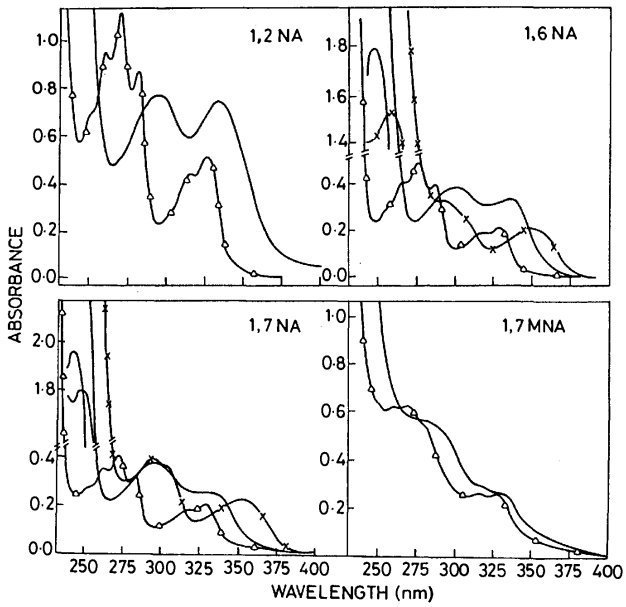

Fig. 2. Absorption spectra of various prototropic species of 1,2 NA, 1,6 NA, 1,7 NA, 1,7 MNA. (——) neutral, (—×—) monoanion, (—△—) monocation.

fluorescence spectra of the various prototropic species are shown in Figs. 2 and 3 respectively. The relevant data have been compiled in Tables 2 and 3. The absorption band maxima of monocation, neutral and monoanion (wherever these exist) of 1,2 NA and 1,7 NA agree with the literature values.[32]

Spectral characteristics accompanying the prototropic dissociation are related to the electron donor properties of the hydroxyl or amino group i.e. dissociation of hydroxyl or amino group will lead to red shift, whereas the protonation reaction will lead to the

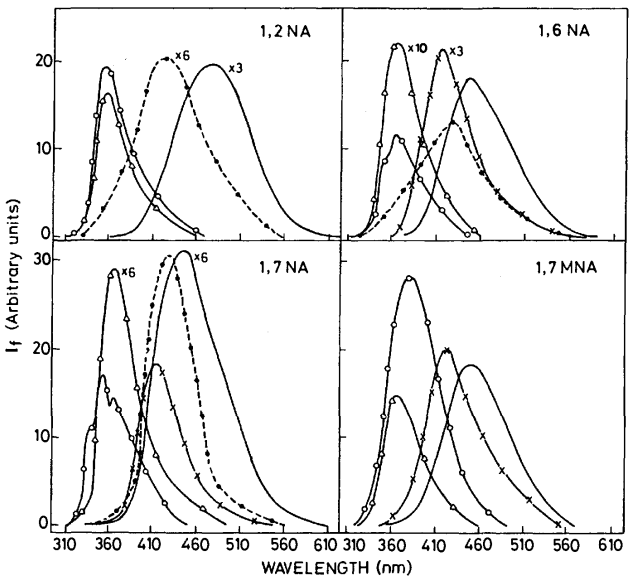

Fig. 3. Fluorescence spectra of various prototropic species of 1,2 NA, 1,6 NA, 1,7 NA, 1,7 MNA. (——) neutral, (—×—) monoanion, (—△—) monocation, (—●—) zwitterion, (—○—) dication.

blue shift in the absorption and fluorescence spectra if $\pi \rightarrow \pi^*$ is the lowest energy transition.

7-Methoxy-1-naphthylamine. Based on above arguments, the molecule exists as a neutral species in the pH/H_- range of 5 to 15. At $H_- > 15$, the species is a monoanion, formed either by the deprotonation of $-NH_2$ group or by one of the C-H bond. Chattopadhyaya and Chowdhury[42] have shown that the absorption spectra of 1 AN and *N,N*-dimethyl-1-naphthylamine are exactly same at $H_- > 15$. The latter compound does not possess the dissociable proton at the amino group. Thus the deprotonation of one of the C-H bond is preferred over the deprotonation of amino group. At pH<4, the species is a monocation. Resemblance of absorption spectrum of this species with that of 2-methoxynaphthalene[15] further confirms this assignment. At $H_0 < -4$, the species is a dication formed by protonating the ring carbon atom of monocation, because protonation of -OH/OMe leads to blue shift.[43-45] Besides this at H_0 −7, the monocation starts decomposing to give a large red shifted absorption spectrum and yellow-colored solution. This is an irreversible reaction and the results obtained are not very accurate in this range of acid concentration.

Prototropic reactions occurring in the S_1 state are exactly same as observed in the S_0 state i.e. dication, $H_0 < -4$; monocation, H_0 −3 to pH 3; neutral, pH 4 to 13 and monoanion, pH>13. The shifts observed in the fluorescence maxima are similar to those observed in the absorption spectra.

The ground state dissociation constant of monocation-free amine was calculated using absorption spectral data and is found to be 3.5. This value agrees with that observed in case of 1 AN. Data of Table 1 also show that the charge density at the nitrogen center of amino group at position 1 is not affected by the presence of methoxyl group at position 7. The equilibrium constants for dication-monocation and free amine-monoanion could not be determined as the formation of dication and monoanion were not complete even at the extreme acid/base conditions.

The pK_a's in the excited singlet state were determined with the help of fluorimetric titrations (Fig. 4). The fluorescence intensities of monoanion and dication were not plotted in Fig. 4 as the intensities for the respective species were quite small. The pK_a* value for the free amine-monoanion equilibrium is thus determined from the decrease in the fluorescence intensity of neutral species, whereas that for dication-monocation is speculated. The spectral data indicate that the C-H bond and amino group become stronger base and acid respectively in the excited singlet state, whereas the fluorimetric titrations have yielded the ground state pK_a values for dication-monocation and monocation-free amine equilibria. The former is consistent with earlier results that the equilibrium for the ring protonation is not established in the S_1 state. The latter result is anomalous in the sense that proton-induced fluorescence quenching is not observed before the amino group is protonated, which is a common feature of this reaction. Recently few exceptions are observed[16,17] and thus it can be concluded that the lifetimes of the conjugate acid-base pair are very short and the prototropic equilibrium is not established in S_1 state. The proton-induced fluorescence quenching of monocation of 1,7 MNA is consistent with earlier results of 2-methoxynaphthalene,[1] with the difference that it is observed at higher acid concentration. This is due to the presence of positive charge on the monocation of 1,7 MNA.

7-Hydroxy-1-naphthylamine. The ground state prototropic species of 1,7 NA, formed in the H_0/pH range −10 to 8 are exactly same as observed for 1,7 MNA, i.e. dication, −10 to −4; monocation, −4 to pH 3; neutral, pH 3 to 8. At pH>8, the species is a

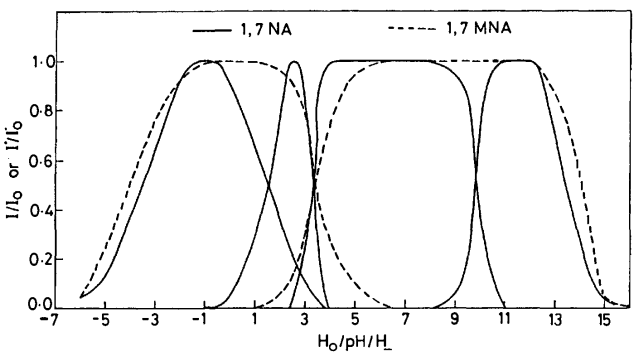

Fig. 4. Fluorimetric titration curves of the various prototropic species of 1,7 NA and 1,7 MNA.

monoanion, formed by deprotonating -OH group. At $H_-<15$, the species is a dianion, obtained by further deprotonating the C-H bond, rather than $-NH_2$ group. This can be explained on the same lines as has been done for the monoanion of 1,7 MNA. The pK_a values for the monocation-free amine and free-amine-monoanion equilibria, determined by using absorption spectral data, are 3.35 and 9.8 respectively. These values are not very different from the protonation constant of 1 AN (3.92) and deprotonation constant of 2 NOH (9.5).[26] As explained for 1,7 MNA, these pK_a's are not affected much by the presence of hydroxyl group or amino group respectively. This is further manifested from the data of Table 1, i.e. formal charge densities at the oxygen atom of -OH group of 1,7 NA and that of 2 NOH are nearly equal. Same is true for the nitrogen atom of amino groups of 1,7 NA and 1 AN.

The prototropic reactions of 1,7 NA occurring in the H_0/pH range of -10 to 0 are the same as observed for 1,7 MNA in S_1 state i.e. dication, -10 to -4; monocation, -4 to pH 0 and proton-induced fluorescence quenching of monocation of 1,7 NA is also observed prior to the formation of dication. This behavior is similar to that of 2 NOH, except that this process is taking place at higher acid concentration and this is due to the presence of positive charge on the 1,7 NA monocation.

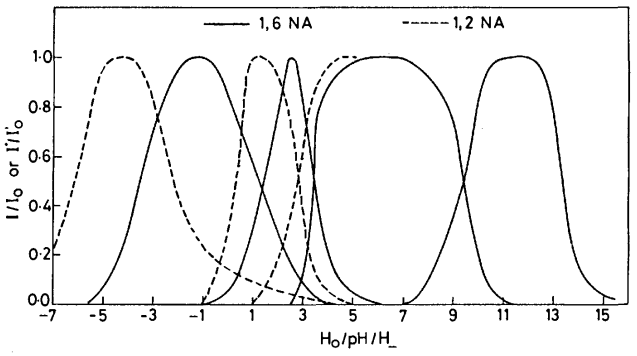

Fig. 5. Fluorimetric titration curves of the various prototropic species of 1,2 NA and 1,6 NA.

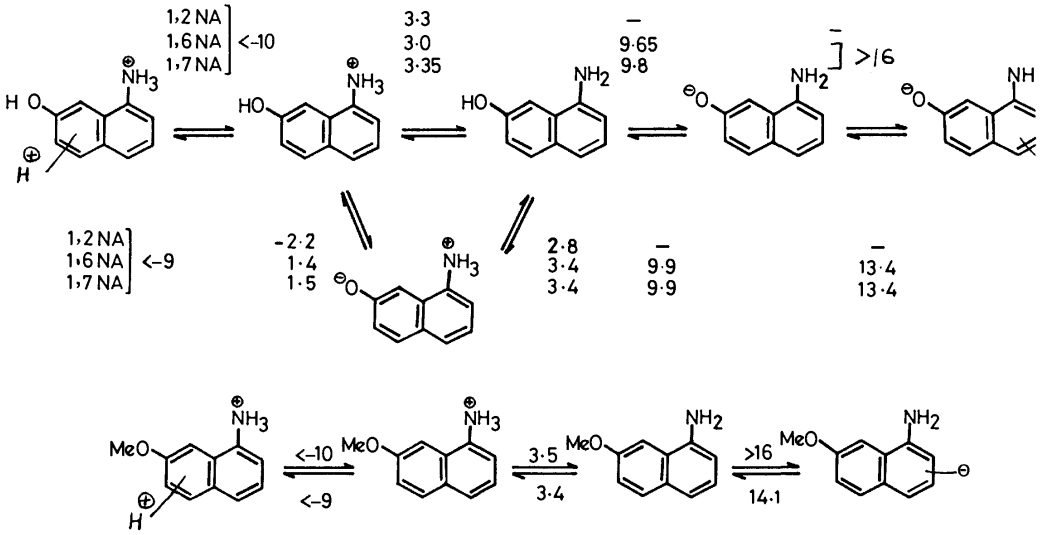
In the H_0/pH range -1 to 4 two fluorescence bands were observed. One at 426 nm and the other at 443 nm. The latter one is assigned to a neutral species because this band maximum nearly resembles that of 1,7 MNA, where there is no dissociable -OH group. The former is assigned to a zwitterion, formed by the deprotonation of the -OH group of monocation in the S_1 state. The monocation is the ground state precursor of zwitterion and the above assignment is based on the following results. (i) The fluorescence excitation spectrum of the zwitterion resembles the absorption spectrum of monocation, rather than the neutral molecule. (ii) Had the neutral molecule been the ground state precursor for the zwitterion, the similar results should have been observed at the earlier pH range and the fluorescence spectrum of this species in the pH range of 4 to 0 would have resembled the neutral molecule in nonpolar solvents and that of 1,7 MNA. (iii) The fluorescence spectrum of zwitterion resembles closely the β-naphtholate ion (418).[27] The fluorimetric titration curves in the pH range 4—0 cannot be drawn accurately, as three species are present simultaneously. Assuming that only two species are present in the given range (this assumption is not bad as the fluorescence intensity of monocation is never more than 10% of the fluorescence intensity of zwitterion, where the zwitterion-free-amine species are present) fluorimetric titration curves are drawn (Fig. 4) and the approximate pK_a value is listed on the arrows of Scheme 1. The value cannot be off by more than 10%.

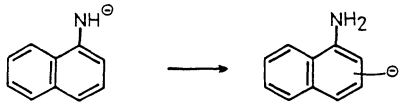
At pH > 9, the 414 nm band is assigned to monoanion formed by the deprotonation of -OH group. The



Scheme 1. Scheme representing the various prototropic reactions in the S_0 and S_1 states.

fluorimetric titration curves have given the ground state pK_a value, indicating that free naphthol-monoanion equilibrium is not established in S_1 state. This result is anomalous from that of 2 NOH,[27] in the sense, that extended sigmoid curve is not observed in case of 1,7 NA. It could be due to the shorter lifetimes of the conjugate acid-base pair.

At the extreme basic conditions H_- 16, 418 nm band is assigned to the dianion, formed either by deprotonating the -OH and $-NH_2$ groups or -OH group and the C-H bond. The latter process is preferred because of the following reasons: (i) The monoanion of 1 AN[12] is nonfluorescent and its pK_a* is 12.2, whereas that of 2 AN[12] is fluorescent [λ_{max}(flu)520] with pK_a* 12.3. At H_- 15, 412 nm fluorescence band of 1 AN is assigned to a kind of monoanion (**2** as shown below) by Choudhury and Chattopadhyay,[42] based on their study of 1 AN and 1-(dimethylamino)naphthalene. In general the deprotonation reaction of $-NH_2$ group in S_1 state starts at pH≈11 and is completed by pH≈14, whereas in case of 1,7 NA, this process occurs



1 **2**

at pH > 14 and the correspondence is observed between the decrease of the fluorescence intensity of monoanion and the increase in that of dianion. (ii) The pK_a* value, determined from Fig. 4, falls in the same region as observed for the ring deprotonation of 1 AN.[12] (iii) Data of Table 1 clearly indicate that the charge density at the nitrogen atom of amino group of monoanion of 1,7 NA is equal to that on the amino group of 1 AN in S_0 state but in S_1 state, the charge density in case of former species is more than that of the latter species. This indicates that the pK_a* for this deprotonation reaction of $-NH_2$ group will increase on excitation as compared to that of 1 AN. (iv) The fluorescence band maximum of dianion of 1,7 NA falls in the same region where the species (**2**) of 1 AN fluorescence.[12] The intensity of 418 nm fluorescence band is weak and pK_a in S_1 state for monoanion-dianion equilibrium is determined from the decrease in the fluorescence intensity of monoanion (Fig. 4).

6-Hydroxy- and 2-Hydroxy-1-naphthylamines. The spectral characteristics of 1,6 NA in H_0/pH/H_- −10 to 16 are exactly similar and the results can be explained in the similar manner, whereas 1,2 NA decomposes at pH > 5.

The Scheme 1 represents the various prototropic reactions occurring in S_0 and S_1 states pK_a* values are depicted on the arrows.

Conclusion

Following conclusions can be drawn from the above study. (i) In absorption spectrum, the long wavelength band is long axis polarized, whereas the fluorescence is observed from ^1L_a state. (ii) The ground state precursor for the formation of zwitterion in the S_1 state is monocation. (iii) At high basic strength, the dianions are formed by the deprotonation of -OH group and one of the C-H bond.

We are thankful to the Department of Science and Technology, New Delhi for the financial support to the project entitled, "Proton Transfer Reactions in the Excited States."

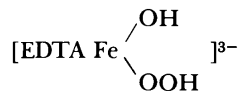
Prebiotic Evolution of Oxidoreductases: $[Fe(III)(CN)_5(L)]^{n-}$ Complexes as Models

KAMALUDDIN,* Nath MALA, and W. Deopujari SUSHAMA
Department of Chemistry, University of Roorkee, Roorkee 247667 (U.P.), India
(Received October 31, 1988)

The transition state, where primary ligands like CN^- partially replaced by biomolecules, has been assumed to be interesting from point of view of chemical evolution of oxidoreductase enzymes. Complexes of type $[Fe(III)(CN)_5(L)]^{n-}$ (where n=2, 3 and L=glycine, imidazole, triglycine, and histidine) are proposed as models for peroxidases and catalases. Detailed kinetic investigations of decomposition of hydrogen peroxide catalyzed by $[Fe(III)(CN)_5(L)]^{n-}$ complexes at 40 °C over a wide pH range 6.0—11.0 are discussed. The decomposition reaction is highly pH dependent. In alkaline media, initially L^- is substituted by ^-OH in $[Fe(III)(CN)_5(L)]$; subsequently HOO^- binds to ^-OH through weak intramolecular hydrogen bonding, formation of peroxo complexes has been proposed to be an active intermediate responsible for accelerating the reaction. Decomposition of hydrogen peroxide catalyzed by $[Fe(III)(CN)_5(L)]^{n-}$ complexes conforms to Michaelis Menten type of kinetics.

Peroxidases and catalases are iron containing metalloporphyrins and these enzymes are widely distributed in plants and animals. A common reaction catalyzed by peroxidases is rapid oxidation of organic substrates coupled with decomposition of hydrogen peroxide. Early kinetic investigations on peroxidase-catalyzed decomposition of hydrogen peroxide were interpreted in terms of formation of free radicals.[1-4] The experimental evidences for the partcipation of hydroxyl radicals were also reported.[5-8] While exploring the mechanism of catalytic activity of peroxidases[9,10] intermediates with higher oxidation state of metal were reported.[11] Credit goes to Kremer and Stein,[12,13] who earlier proposed the active species as $[FeO]^{3+}$ for peroxide system containing Fe^{3+}, and to Jones et al. for Fe^{4+} in iron porphyrin systems.[14] From structural and functional point of view, catalases are related to peroxidases. A characteristic reaction of catalases is the rapid catalysis of hydrogen peroxide decomposition with itself.

In recent years, considerable attention has been given on synthesis of metal complexes possessing enzyme-like activity. Peroxidases and catalases are the most extensively studied enzymes which created a lot of interest in the synthesis of model compounds. Metal ions as such or their complexes have been shown to possess enzyme-like activity. Complexes of copper with amino acids, amides, amines, diammines, di- and tripeptides, biurets, heterocyclic compounds,[16,17] some proteins as well as copper complexes of 2,2′-bipyridyl, bis(2,9-dimethyl-1,10-phenanthroline),[18,19] and imidazole[20] have been found to show very high catalytic activity towards decomposition of hydrogen peroxide. Catalytic activity of few iron complexes was also tested towards decomposition of hydrogen peroxide.[21,22] Francis et al.[23] carried out kinetic investigation in detail on [Fe(III) EDTA]-catalyzed decomposition of hydrogen peroxide and proposed hexa coordinated ion viz.



as an active species on the basis of NMR and spectral studies. However, relevance of these models towards chemical evolutionary steps of peroxidases or catalases is very little as these enzymes neither possess copper in their prosthetic group, nor coordination sites of metals in enzymes occupied by ligands like EDTA. It is therefore important to study catalytic behavior of iron(III) complexes with important prebiotic ligands towards decomposition of hydrogen peroxide from the viewpoint of chemical evolution.

In previous papers kinetics of $[Fe(II)(CN)_5(L)]^{n-}$-catalyzed decomposition of hydrogen peroxide were reported.[24,25] In present manuscript we reported the kinetic studies on decomposition of hydrogen peroxide catalyzed by $[Fe(III)(CN)_5(L)]^{n-}$ (where L=glycine, histidine, imidazole, or triglycine; n=2 or 3) from point of view of chemical evolution of peroxidases.

Materials of Methods

Materials. Glycine (B.D.H.), triglycine (Sigma), histidine (Sisco), imidazole (E. Merck), potassium hexacyanoferrate(III) (B.D.H.), sodium pentacyanonitrosylferrate(III) (B.D.H.), and hydrogen peroxide (B.D.H.) were used as supplied and were of Anal R grade. All other chemicals used were of reagent grade.

Preparation of $[Fe(III)(CN)_5(L)]^{n-}$ (Where L=Glycine, Triglycine, Histidine, and Imidazole). Imidazole pentacyanoferrate(III) was prepared by the method of Walters and Spiro.[26] Similar procedure was also adopted for synthesis of triglycine, glycine, and histidine pentacyanoferrate(III) complexes. Sodium (amine)pentacyanoferrate(II) (1.0 g, 3.0 mmol) was dissolved in 6% hydrogen peroxide containing at least five fold excess ligand with constant stirring. Reaction mixture was then kept in dark 45—60 min to allow the formation of $[Fe(III)(CN)_5(L)]^{n-}$ complexes. A few milligrams of activated charcoal was added to the solution to decompose excess of hydrogen peroxide and removed

by filtration. Potassium iodide (8.0 g, 48.0 mmol) was added to the solution and stirred for another 15 min. The complexes were precipitated by adding ethanol and recrystallized from ethanol-water system.

Infrared spectra of complexes of type $[Fe(III)(CN)_5(L)]^{n-}$ are quite similar to those of corresponding analogs of $[Fe(II)(CN)_5(L)]^{n-}$ complexes implying resemblence in the mode of coordination of ligand to metal ion.[24,25] The cyanide stretching frequencies are very sensitive to the oxidation state of central metal ion and generally shifts towards higher wavenumber in case of cyanoferrate(III) complexes. The cyanide stretching frequencies for (amino acid) pentacyanoferrate(III) complexes were obserbed in the range 2070—2100 cm^{-1}, whereas in hexacyanoferrate(III) complexes C≡N was observed around 2100—2200 cm^{-1} region.[27] The weak bands of δFe-CN and νFe-CN were observed respectively in the range 560—595 cm^{-1} and 400—410 cm^{-1} in all Fe(III) complexes. The ν_{asym} COO^- and ν_{sym} COO^- were observed at $1620—1640_m$ cm^{-1} and at $1410—1440_w$ cm^{-1} respectively. When equivalance of CO bond is removed, particularly in case of -COO^- group, the separation in vibrational frequencies was observed.[28] The shift towards higher wavenumber showed the possibility of participation of COO^- group in coordination to metal ion in $[Fe(III)(CN)_5(L)]^{n-}$ complexes (where L=glycine or triglycine). But little or negligible shift for this band in case of histidine complex indicates that the coordination is through nitrogen of imidazole ring, as in case of $[Fe(III)(CN)_5(im)]^{2-}$.[26] Infrared spectral frequencies of all complexes are tabulated in Table 1.

Electronic spectra of all pentacyanoferrate(III) derivatives showed nearly constant bands at 280—290, 350, and 400—410 nm due to transition involving only CN^- ligand and are in agreement with those observed for $[Fe(III)(CN)_6]^{3-}$ by Gale and McCoffery.[29] However, for sodium pentacyanonitrosylferrate(III), Manoharan and Gray[30] observed three peaks at 200 nm, 394 nm, and 495 nm with shoulder peaks at 238, 264, and 363 nm respectively. The absorption spectra of pentacyanoferrate(III) complexes of glycine, triglycine, and imidazole are compared with $[Fe(III)(CN)_5(NH_3)]^{2-}$ and due to the previously reported $[Fe(III)(CN)_5(im)]^{2-}$ and $[Fe(III)(CN)_5(his)]^{2-}$ complexes.[26,31] The absorption bands in UV region at 280—290 nm have been assigned to the CN^- →Fe-$(III)_{d\pi}$ transitions. The absorption bands in visible region 400—410 nm are due to d-d transitions and can be compared with absorption spectra of many other pentacyanoferrate[32] and cobaltates.[33] The visible absorption spectra bands of triglycine pentacyanoferrate(III) and glycine showed very little shift and similarity with the corresponding analogs of iron(II) complexes implies the possibility of coordination through ammine ligand only. The broad charge transfer absorption band at 470—480 nm observed in both imidazole and histidine pentacyanoferrate(III) complexes due to imidazole→Fe(III) transitions thus indicates that the mode of coordination in histidine complex is also through imidazole ring of histidine. The data of electronic spectra are summarized in Table 2.

Rate Measurements. Decomposition of H_2O_2: Test for catalytic activity of iron(III) complexes for decomposition of hydrogen peroxide was studied by monitoring concentration of H_2O_2 at different time intervals. The reaction was initiated by adding known amount of catalyst (1 ml of 0.005 M; 1M=1 mol dm^{-3}) into hydrogen peroxide solution (25 ml of 0.01—0.1M) previously thermostated at 40 °C. Aliquots (2 ml) of reaction mixture were withdrawn each time and titrated against standard sodium thiosulfate in acid medium. The data for $[H_2O_2]$ at corresponding time did not fit a simple rate equation, therefore the initial rate method was used to determine the order of reaction with respect to hydrogen peroxide and catalyst.

Results and Discussion

Catalytic activities of complexes like $[Fe(III)(CN)_5(L)]^{n-}$ towards decomposition of hydrogen peroxide have been studied over a wide pH range 6.0 to 11.0. It was found that decomposition rate of hydrogen peroxide increased sharply till pH 9.18 and thereafter increased slowly (Fig. 1) indicating the participation of only ^-OH in decomposition reaction. An increase in rate of decomposition with increase in pH displayed the possibility of participation of ^-OH and HO_2^- in reaction mechanism. A value of pH 9.18 was found to be most suitable for carrying out all kinetic studies. In alkaline medium, HO_2^- species

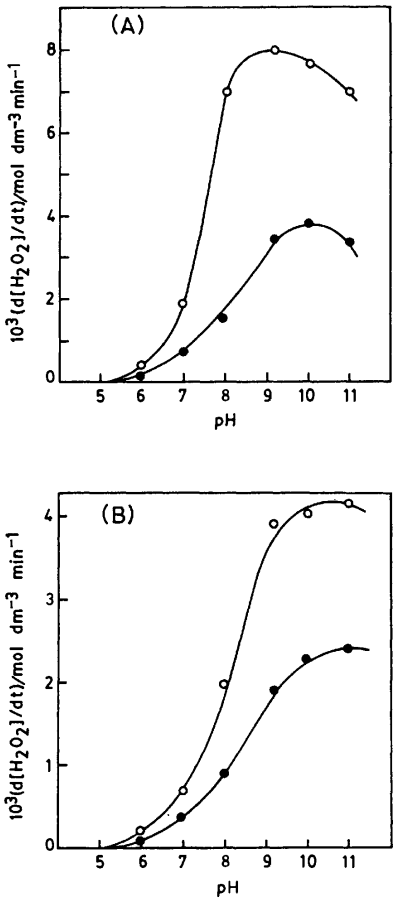

Fig. 1. Hydrogen peroxide decomposition rate as a function of pH. $[H_2O_2]_0=4.5\times10^{-2}$ M; [Catalyst]= 2×10^{-4} M; temp 40±0.1 °C.
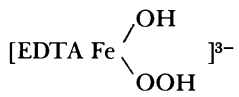
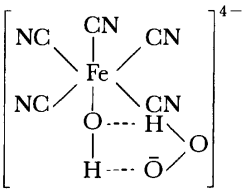
(A) ○=$K_3[Fe(CN)_5(gly)]$, ●=$K_2[Fe(CN)_5(his)]$.
(B) ○=$K_2[Fe(CN)_5(im)]$, ●=$K_3[Fe(CN)_5(trigly)]$.

has been proposed by Francis et al.[23] to be most effective species around pH range 9.0—11.0 which easily could form a complex of type



and decomposition of this intermediate complex makes the rate determining step for $[Fe(III)EDTA]^-$-catalyzed decomposition of hydrogen peroxide. In our experiments probability of formation of hepta-coordinated complex like $[Fe(III)(CN)_5(OH)(OOH)]^{4-}$ can not be considered because of high ligand-field stabilization energy of CN^- groups. However, increase in rate with pH may be due to participation of HOO^- species rather than undissociated hydrogen peroxide molecule. Another possibility of replacement of amino acid molecule by ^-OH can also not be ignored at higher pH. It is therefore thought that initially ^-OH is coordinated to metal by replacing weakly-bonded amino acid ligand and subsequently HO_2^- attached to ^-OH group through weak interactions of hydrogen bonding.



It appears that the function of ^-OH in coordination sphere is simply to facilitate the formation of peroxo complex by weak hydrogen bonding. Sigel[34] compared the catalase like activities of a number of copper(II) chelates and pointed out that the copper polyammine chelate with two free coordination sites show maximum activity while fully coordinated copper(II) complex is inactive. A high catalytic activity was observed for decomposition of H_2O_2 by Mn(II) and Fe(III) chelates of diethylenetriammine when two coordination sites in metal ion were available for inner sphere mechanism as proposed by Wang and Jarinagin.[35,36] In our experiments, the possibility of outer sphere mechanism was completely discarded since $[Fe(III)(CN)_6]^{3-}$ did not show any comparable rate of catalytic activity to $[Fe(III)(CN)_5(L)]^{n-}$ indicating that only inner sphere mechanism for decomposition of hydrogen peroxide is possible. Only one coordination site is available on $[Fe(III)(CN)_5(L)]^{n-}$ complexes for substrate binding that is loosely bonded sixth ligand (L), which can be replaced in presence of substrate, where as in case of hexacyanoferrate(III) CN^- is not easily replaced.

In order to ensure that the catalytic activity observed in decomposition of hydrogen peroxide was only due to (amino acid)pentacyanoferrate(III) derivatives and not because of traces of uncomplexed metal ions, 10% EDTA was added. Addition of EDTA, however, did not change the rate of catalytic activity. Addition of ligands as catalyst was also not effective (Fig. 2).

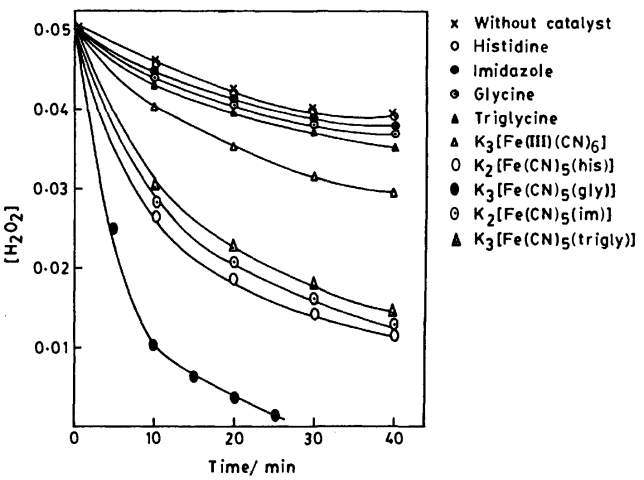


Fig. 2. $[Fe(III)(CN)_5(L)]^{n-}$ catalyzed decomposition of hydrogen peroxide. $[H_2O_2]=5.0\times10^{-2}$ M; [Catalyst]=2×10^{-4} M; pH=9.18; temp=40±0.01 °C.

A tentative mechanism for decomposition of hydrogen peroxide catalyzed by amino acid pentacyanoferrate(III) complexes may be written as follows:

$$H_2O_2 \xrightarrow{K_{H_2O_2}} H^+ + {}^-OOH \quad (1)$$

$$\underset{\mathbf{A}}{[Fe(III)(CN)_5(L)]^{n-}} + {}^-OH \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \underset{\mathbf{B}}{[Fe(III)(CN)_5(OH)]^{3-}} + L^- \quad (2)$$

$$\underset{\mathbf{B}}{[Fe(III)(CN)_5(OH)]^{3-}} + {}^-OOH \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \underset{\mathbf{C}}{[Fe(III)(CN)_5(OH\cdots OOH)]^{4-}} \quad (3)$$

$$[Fe(III)(CN)_5(OH\cdots OOH)]^{4-} \xrightarrow{k_5} \text{Product} \quad (4)$$

The proposed mechanism is somewhat similar to the mechanism proposed by Sigel et al.[18] for decomposition of hydrogen peroxide catalyzed by Cu^{2+} ions and Cu^{2+} complexes of 2,2'-bipyridyl. Applying steady state approximation of **B** and **C** species, the rate of decomposition of hydrogen peroxide may be written as follows:

$$V = \frac{-d[H_2O_2]}{dt} = \frac{k_1 k_5 k_{H_2O_2}[H_2O_2][Fe]_T}{k_1 K_M[H^+] + K_{H_2O_2}[H_2O_2]\left(k_1 + \frac{k_5[H^+]}{k_W}\right)} \quad (5)$$

Also rearranging Eq.5 in Lineweaver-Burk form of equation:

$$\frac{1}{V} = \frac{K_M[H^+]}{k_5 K_{H_2O_2}[H_2O_2][Fe]_T} + \frac{\left(k_1 + \frac{k_5[H^+]}{k_W}\right)}{k_1 k_5 [Fe]_T} \quad (6)$$

where, $K_M = \dfrac{k_4 + k_5}{k_3}$.

Equation 5 clearly indicates that decomposition of hydrogen peroxide follows a first order kinetics with respect to [Catalyst], which is in accord with experimental findings (Fig. 3). The initial rate as function of $[H_2O_2]$ is shown in Fig. 4, where linearity of the curve at lower concentration of H_2O_2 suggests first order dependency at that concentration, whereas at higher concentration the reaction rate becomes constant showing independency on $[H_2O_2]$. The independency of decomposition rate on $[H_2O_2]$ could also be explained from Eq. 5 due to the presence of $[H_2O_2]$ term in the denominator. The most exciting feature of Eq. 5 lies in its nature, being a typical Michaelis-Menten type of kinetics supported by the straight line (Fig. 5), which is obtained on plotting $(d[H_2O_2]/dt)^{-1}$ vs. $[H_2O_2]^{-1}$. Intercept and slope obtained in Fig. 5 should be equal to

$$\frac{k_1 + \frac{k_5[H^+]}{k_W}}{k_1 k_5 [Fe]_T} \quad \text{and} \quad \frac{K_M[H^+]}{k_5 K_{H_2O_2}[Fe]_T}$$

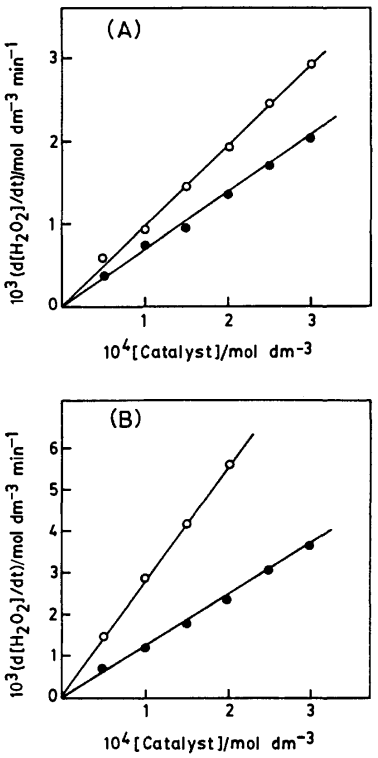

Fig. 3. Hydrogen peroxide decomposition rate as a function of [Catalyst]: $[H_2O_2]_0 = 2.7\times10^{-2}$ M: pH= 9.18; temp=40±0.1 °C.

respectively as warranted by Eq. 6. On comparing the terms with normal Michaelis-Menten curve,

$$\text{Intercept} = \frac{1}{V'_{max}[Fe]_T}$$

$$\text{where, } \frac{1}{V'_{max}} = \frac{k_1 + k_5[H^+]/k_W}{k_1 k_5}$$

$$\text{and slope} = \frac{K'_M}{k_5[Fe]_T}$$

$$\text{where, } K'_M = \frac{K_M[H^+]}{K_{H_2O_2}}.$$

From the intercept and slope, V'_{max} and K'_M and turnover numbers have been calculated and are tabulated in Table 3.

The proposed mechanism for decomposition of hydrogen peroxide catalyzed by cyano complexes of iron(III) and their derivatives is similar to the catalyzed decomposition of hydrogen peroxide in many ways. Peroxidase and catalase are iron-containing enzymes in which iron(III) is strongly bonded to porphyrin ring, the fifth ligand is imidazole and the sixth ligand is loosely bonded water or cyanide ion. It has been assumed that the peroxidase operates by the exchange of the ligand at the sixth position[37] with peroxide. In our proposed model, five CN^- are tightly bonded to iron(III) and decomposition of H_2O_2 proceeds after exchange with loosely bonded sixth ligand which is an amino acid or peptide.

Cyano complexes of transition metal have a special evolutionary significance to the biological systems.[38] Appearance of biomolecules on earth replaced primary ligands and thereby catalytic activity of the metal complexes increased towards biological processes. The effect of transition where primary ligands were replaced by secondary ligands on biological reactions has been considered to be decisive from evolutionary point of view and therefore, efforts were made to trace out the possible evolutionary path for iron-containing oxidoreductase enzymes. $[Fe(II)(CN)_5(L)]^{n-}$[24,25] and $[Fe(III)(CN)_5(L)]^{n-}$ complexes found to be well-suited models for peroxidases and catalases and these complexes showed remarkable increase in catalytic activity towards decomposition of hydrogen peroxide when one of the cyanide ligands is substituted by biomolecules. Catalytic activity or turnover number of amino acid pentacyanoferrate(III) towards decomposition of hydrogen peroxide does not indicate any dramatic change in catalytic rate when compared with their corresponding analogs amino acid pentacyanoferrate(II) complexes.[24,25] Thus it can be safely concluded that perhaps at later stages of evolution of metalloenzymes, oxidation state of metal played vital role in determining catalytic activity of enzymes and not at very early stages of chemical evolution.

The proposed model for evolution of iron-containing enzymes is not contradictory to the one proposed by Calvin.[39] The only difference lies in the fact that in present studies we have considered much more early stages of proenzymes.

Table 3. Kinetic Constants for Decomposition of Hydrogen Peroxide Catalyzed by $[Fe(III)(CN)_5(L)]^{n-}$

Catalyst	V'_{max}[a]	Turnover number[b]	K'_M[c]
	M min^{-1}	min^{-1}	M
$K_3[Fe(III)(CN)_5(gly)]$	0.100	500.0	0.533
$K_3[Fe(III)(CN)_5(trigly)]$	0.011	55.55	0.178
$K_2[Fe(III)(CN)_5(im)]$	0.018	91.00	0.121
$K_2[Fe(III)(CN)_5(his)]$	0.0125	62.50	0.117

Reaction conditions: Catalyst=2.0×10^{-4} mol dm^{-3}, pH=9.18, temp=40.0±1 °C, a) $V'_{max}=k_1k_5/[k_1+k_5[H^+]/k_w]$. b) Turnover number=$V'_{max}/[Fe]_T$. c) $K'_M=K_M[H^+]/K_{H_2O_2}$.

Appendix

$$H_2O_2 \xrightarrow{K_{H_2O_2}} HOO^- + H^+ \quad (1)$$

$$\underset{\mathbf{A}}{[Fe(III)(CN)_5(L)]^{n-}} + {}^-OH \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \underset{\mathbf{B}}{[Fe(III)(CN)_5(OH)]^{n-}} + L^- \quad (2)$$

$$\underset{\mathbf{B}}{[Fe(III)(CN)_5(OH)]^{n-}} + HOO^- \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \underset{\mathbf{C}}{[Fe(III)(CN)_5(OH\cdots OOH)]^{(n+1)-}} \quad (3)$$

$$\underset{\mathbf{C}}{[Fe(III)(CN)_5(OH\cdots OOH)]^{(n+1)-}} \xrightarrow{k_5} \text{Product} \quad (4)$$

$$\text{Reaction rate} = V = \frac{-d[H_2O_2]}{dt} = k_5[\mathbf{C}]. \quad (5)$$

Assuming steady state to [C], we get,

$$k_3[\mathbf{B}][HO_2^-] = k_4[\mathbf{C}] + k_5[\mathbf{C}]$$

$$[\mathbf{C}] = \frac{k_3[\mathbf{B}][HO_2^-]}{k_4 + k_5}. \quad (6)$$

Assuming steady state to [B], we get

$$k_1[\mathbf{A}][{}^-OH] + k_4[\mathbf{C}] = k_2[\mathbf{B}][L^-] + k_3[\mathbf{B}][HO_2^-]$$

but from Eq. 6,

$$[\mathbf{C}](k_4 + k_5) = k_3[\mathbf{B}][HO_2^-]$$

$$k_1[\mathbf{A}][{}^-OH] + k_4[\mathbf{C}] = k_2[\mathbf{B}][L^-] + k_4[\mathbf{C}] + k_5[\mathbf{C}]$$

$$[\mathbf{C}] = \frac{k_1[\mathbf{A}][{}^-OH] - k_2[\mathbf{B}][L^-]}{k_5}. \quad (7)$$

Equating Eqs. 6 and 7, we get

$$\frac{k_3k_5[\mathbf{B}][HO_2^-]}{k_4 + k_5} = k_1[\mathbf{A}][{}^-OH] - k_2[\mathbf{B}][L^-]$$

$$[\mathbf{B}][k_3k_5[HO_2^-] + k_2[L^-](k_4 + k_5)] = k_1(k_4 + k_5)[\mathbf{A}][{}^-OH]$$

$$[\mathbf{B}] = \frac{k_1(k_4+k_5)[\mathbf{A}][{}^-OH]}{k_3k_5[HO_2^-]+k_2[L^-](k_4+k_5)}. \quad (8)$$

Putting [B] from Eq. 8 in Eq. 6, we get

$$[\mathbf{C}] = \frac{k_1k_3[\mathbf{A}][HO_2^-][{}^-OH]}{k_3k_5[HO_2^-]+k_2[L^-](k_4+k_5)}. \quad (9)$$

Putting the value [C] from Eq. 9 in Eq. 5, we get

$$V = \frac{-d[H_2O_2]}{dt} = \frac{k_1k_3k_5[\mathbf{A}][HO_2^-][{}^-OH]}{k_3k_5[HO_2^-] + k_2[L^-](k_4+k_5)} \quad (10)$$

$$\text{or} \quad V = \frac{k_1k_5[\mathbf{A}][HO_2^-][{}^-OH]}{k_5[HO_2^-] + k_2K_M[L^-]}$$

$$\text{where,} \quad K_M = \frac{k_4 + k_5}{k_3}.$$

Also, if $[Fe]_T$ represent the total concentration of iron(III) containing species participating in the reaction, we can write

$$[Fe]_T = [\mathbf{A}] + [\mathbf{B}] + [\mathbf{C}]$$

$$= [\mathbf{A}] + \frac{k_1(k_4+k_5)[\mathbf{A}][{}^-OH]}{k_3k_5[HO_2^-] + k_2[L^-](k_4 + k_5)} + \frac{k_1k_3[\mathbf{A}][HO_2^-][{}^-OH]}{k_3k_5[HO_2^-] + k_2[L^-](k_4 + k_5)}$$

$$[\mathbf{A}] = \frac{[Fe]_T[k_3k_5[HO_2^-] + k_2[L^-](k_4 + k_5)]}{k_3k_5[HO_2^-] + k_2[L^-](k_4 + k_5) + k_1(k_4 + k_5)[{}^-OH] + k_1k_3[HO_2^-][{}^-OH]}.$$

In the denominator of the above equation, assuming $k_2[L^-](k_4+k_5)$ is very small compared to other terms, hence neglected

$$[\mathbf{A}] = \frac{[Fe]_T[k_3k_5[HO_2^-] + k_2[L^-](k_4 + k_5)]}{k_3k_5[HO_2^-] + k_1(k_4+k_5)[{}^-OH] + k_1k_3[HO_2^-][{}^-OH]}.$$

Putting the value of [A] from above equation in Eq. 10, we get

$$V = \frac{k_1k_5[Fe]_T[HO_2^-][{}^-OH]}{k_5[HO_2^-] + k_1K_M[{}^-OH] + k_1[HO_2^-][{}^-OH]}$$

$$= \frac{k_1k_5K_{H_2O_2}[H_2O_2][{}^-OH][Fe]_T}{[H^+]\left[k_5\frac{K_{H_2O_2}[H_2O_2]}{[H^+]} + k_1K_M[{}^-OH] + k_1\frac{K_{H_2O_2}[{}^-OH][H_2O_2]}{[H^+]}\right]}$$

$$= \frac{k_1k_5K_{H_2O_2}[H_2O_2]\,[Fe]_T}{[H^+]\left[k_5\frac{K_{H_2O_2}[H_2O_2]}{[H^+][{}^-OH]} + k_1K_M + k_1\frac{K_{H_2O_2}[H_2O_2]}{[H^+]}\right]}$$

$$= \frac{k_1k_5K_{H_2O_2}[H_2O_2]\,[Fe]_T}{k_5\frac{K_{H_2O_2}}{k_W}[H_2O_2][H^+] + k_1K_M[H^+] + k_1K_{H_2O_2}[H_2O_2]}$$

$$V = \frac{k_1k_5K_{H_2O_2}[H_2O_2][Fe]_T}{k_1K_M[H^+] + K_{H_2O_2}[H_2O_2]\left(k_1 + \frac{k_5}{k_W}[H^+]\right)}.$$

Application of Flory Theory to Mixtures of Molten Tetrahydrates of Calcium and Cadmium Nitrates

Nurul ISLAM* and Girija MAHESHWARI
Department of Chemistry, Aligarh Muslim University, Aligarh 202002, India
(Received November 17, 1988)

The Flory theory has successfully been employed to predict the excess volume, viscosity of mixtures, surface tension, and the ultrasonic velocities of mixtures of molten tetrahydrates of calcium and cadmium nitrates. The agreement in the computed and the experimental values has been good. The excess volume as well as the excess adiabatic compressibility suggest maximum solute-solvent interactions at ca. 0.55 mole fraction of Cd^{2+}.

Even though the Flory theory[1,2] was meant to explain the behavior of nonpolar liquids and their mixtures, it was adequately employed to evaluate[1-5] the reduced and the characteristic thermodynamic parameters of polar liquids as well. These parameters, in turn, were employed to evaluate the excess volume, the excess thermodynamic properties, the viscosity of mixtures, the excess viscosity of mixing, the surface tension,[4,5,9,11-13] and the ultrasonic velocity of low melting salts.

In view of the interdependence/correlation of these properties with the intermolecular interactions, they were employed to highlight the solute-solvent interactions. For this purpose, molten tetrahydrates of calcium and cadmium nitrates as well as their mixtures were chosen.

Experimental

Commercial tetrahydrates of calcium and cadmium nitrates (BDH, E. Mercks) were recrystallized. The water of crystallization was determined by the method of comparison of their measured densities with those of the reported values.[14,15]

The density and viscosity measurements were made using a pycnometer (±0.03%) and a Cannon-Ubbelohde viscometer[16] (± 0.3%) in an ultrathermostat (type u-10) of ±0.01 °C thermal stability. The surface tension was measured with a stalagmometer for the purpose of comparison with the predicted values. The ultrasonic velocity (within ± 0.15%) was measured using an ultrasonic interferometer (NPL patent, Mittal's M 77).

Results and Discussion

The Excess Volume. The reduced and the characteristic thermodynamic variables ($\tilde{V}$, $\tilde{T}$ and V^*, T^*, P^*) of Flory theory[1-3] obtained essentially from the density data are employed for the evaluation of excess/reduced volume, $\tilde{V}^E$ using the relevant relations given elsewhere. The computed values of the excess

a) 1. Experimental values of η. 2. Computed values of η.

volume agree well with those obtained experimentally ($V^E = V - \sum_i x_i V_i$) (Table 1). The minimum value of V^E corresponds to 0.55—0.599 mole fraction of Cd^{2+} at every temperature of measurement within the range, 303.15 to 333.15 K.

The Viscosity of Mixture. The viscosities of binary mixtures have been obtained using the equation,[7-9]

$$\ln \eta_{min} = -\frac{\Delta G_m}{RT} + \frac{1}{\tilde{V}-1} - \sum_i \frac{x_i}{\tilde{V}_i - 1} + \sum_i x_i \ln \eta_i ,$$

in which

$$\Delta G_m = \sum_i x_i P_i^* V_i^* \left[\left(\frac{1}{\tilde{V}_i} + \frac{1}{\tilde{V}} \right) + 3\tilde{T}_i \ln \left(\frac{\tilde{V}_i^{1/3} - 1}{\tilde{V}^{1/3} - 1} \right) \right] + x_1 V_1^* \theta_2 x_{12} V .$$

An examination of Table 2 reveals a reasonably good agreement between the experimental and the computed values of viscosity. The viscosity has been found to decrease with an increase in the mole fraction of Cd^{2+} as well as with temperature.

The Excess Adiabatic Compressibility. The excess adiabatic compressibility $\beta_S^E (= \beta_S - \sum_i x_i \beta_{Si})$ of molten Ca^{2+}-Cd^{2+} mixtures has been found to be negative, which suggests the presence of strong associative interactions between the solvent and the solute molecules. However, β_S^E is not affected significantly with temperature. The value of β_S^E shows variations with composition, as apparent from Fig. 1 in which the presence of minima at 0.554 mole fraction of Cd^{2+} indicates maximum interaction at this composition.

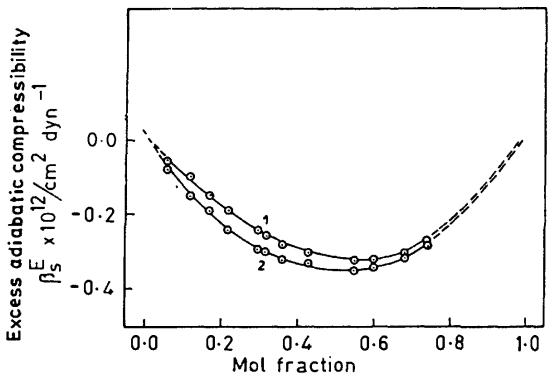

Fig. 1. Plot of excess adiabatic compressibility vs. [solute] for $Ca(NO_3)_2 \cdot 4.31H_2O$-$Cd(NO_3)_2 \cdot 4.34H_2O$ system at 1; 303.15 K and 2; 333.15 K.

It is noteworthy that the excess volume of mixing and the excess adiabatic compressibility factor, both of them suggest the maximum solvent-solute interaction at ca. 0.55 mole fraction of Cd^{2+}.

The Surface Tension. The agreement between the predicted values of surface tension, σ obtainable essentially from the Flory theory[4,5,10,12] with those obtained experimentally has been reasonably good even though σ was measured using the stalagmometer. An examination of Table 3 reveals that unlike the pure $Cd(NO_3)_2 \cdot 4H_2O$ Auerbach relation does not seem to apply to Ca^{2+}-Cd^{2+} system in which Ca^{2+} may appar-

Table 3. Experimental and Computed Values of Surface Tension (σ/dyn cm^{-1}) of Molten $Ca(NO_3)_2 \cdot 4.31\ H_2O$-$Cd(NO_3)_2 \cdot 4.34\ H_2O$ System

a) 1. Experimental U. 2. Computed U using.[18,21] 3. Computed U using.[19,22] 4. Computed U using.[20,23] 5. Computed U using Flory theory.

ently be responsible for offsetting the agreement between the computed and the experimental values. Also, the agreement between the two values is much better at higher temperatures compared to those at lower ones. The σ values of $Ca(NO_3)_2 \cdot 4.3H_2O$ and $Ca(NO_3)_2 \cdot 4.1H_2O$ are, respectively, 1.1% and 0.32% lower when compared with that of $Ca(NO_3)_2 \cdot 4H_2O$.[17] Such a difference seems to have been caused by the difference in the water of hydration which seems to be responsible for decreasing the corresponding cohesive forces.

The Ultrasonic Velocity. The computed values of ultrasonic velocity based on the relation,[11]

$$U = \left\{ \left[(kT^*P^{*2})^{1/3} \left(M\tilde{V}^{-5/3} - \frac{\tilde{V}^{1/3}-1}{\tilde{V}^2} \ln \frac{V^{1/3}-0.5}{V^{1/3}-1} \right) \right] / \rho \times 6.3 \times 10^{-4} \right\}^{2/3}$$

on comparison with the experimental values reveal that the agreement between the two values is better in the case of pure component of Cd^{2+}. Nevertheless, an excellent agreement between the computed values obtained using essentially Nomoto,[18] Van Dael et al.,[19] and Schaaff's collision factor theory[20] and the experimental values of ultrasonic velocities may be seen from Table 4.

The authors wish to express their gratitude to Professor M. S. Ahmad, Chairman of the Department for the necessary facilities and one of them (GM) also thanks the UGC for the Junior Research Fellowship.

Kinetics and Mechanism of Oxidation of Amino Acids by Dichloramine T

B. Thimme Gowda* and P. Jagan Mohana Rao
Department of Post-Graduate Studies and Research in Chemistry, Mangalore University, Mangalagangothri 574 199, Mangalore, India
(Received December 6, 1988)

Kinetics of oxidations of several amino acids (alanine, leucine, aspargine, glutamine, and proline) by *N,N*-dichloro-*p*-toluenesulfonamide (generally known as dichloramine-T) have been studied in 1 : 1 (v/v) water-methanol medium in the presence of perchloric acid. The oxidations of alanine and leucine showed second order kinetics in [oxidant], first order in [amino acid] and inverse fractional order in [H^+] over the entire range of [$HClO_4$](0.0005—0.10 mol dm^{-3}) used. But the kinetics of oxidations of aspargine, glutamine, and proline were [H^+] dependent. The rate dependence in [oxidant] was second and first orders in [H^+] ranges 0.0005—0.005 mol dm^{-3} and 0.005—0.10 mol dm^{-3}, respectively. The kinetics in [amino acid] for these oxidations were also different. Variation in ionic strength of the medium or addition of the reduced product of the oxidant had no or negligible effects on the rates of reactions. Decrease in dielectric constant of the medium by increasing the methanol composition of the solvent decreased the rate in all the cases. Activation parameters have been computed from the Arrhenius plots. Plausible mechanisms consistent with the observed kinetics have been discussed.

Although extensive studies have been reported on the kinetics and mechanisms of oxidation of a variety of substrates by *N*-halosulfonamides like *N*-chloro- and *N*-bromobenzene- or toluenesulfonamides,[1-8] studies by *N,N*-dihalosulfonamides have recently been initiated in our laboratories.[7-9]

As a part of these investigations, we report herein the kinetics of oxidation of several amino acids by *N,N*-dichloro-*p*-toluenesulfonamide in 1 : 1 (v/v) water-methanol medium in the presence of perchloric acid. The amino acids studied are alanine, leucine, aspargine, glutamine, and proline.

Materials and Methods

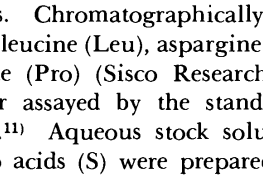
N,N-Dichloro-*p*-toluenesulfonamide, abbreviated as dichloramine-T (DCT) was prepared by the method of Jacob and Nair.[10] The stock solution (ca. 0.05 mol dm^{-3}) of the oxidant in pure methanol was prepared and standardised by iodometric method and preserved in amber colored bottles. Chromatographically pure amino acids: alanine (Ala), leucine (Leu), aspargine (Asn), glutamine (Gln), and proline (Pro) (Sisco Research Laboratories, India) were further assayed by the standard methods reported elsewhere.[11] Aqueous stock solution (0.1 mol dm^{-3}) of the amino acids (S) were prepared in doubly distilled water. Preliminary investigations of the reactions showed that the variations in ionic strength of the medium had no significant effect on the rates of all the oxidations. All other reagents used were of accepted grades of purity.

Kinetic Measurements: Kinetic studies were made in glass stoppered pyrex boiling tubes under pseudo-first-order or pseudo-second-order conditions with [S]≫[DCT]. The reactions were initiated by the quick addition of measured amounts of oxidant solution (0.0005—0.005 mol dm^{-3}), thermostated at a desired temperature, to solutions containing required amounts of amino acid (0.005—0.10 mol dm^{-3}), perchloric acid (0.0005—0.10 mol dm^{-3}), methanol, and water (to maintain 1 : 1 (v/v) water-methanol composition), equilibrated at the same temperature. The progress of the reactions was monitored for two half-lives by iodometric estimation of unreacted oxidant at regular time intervals. The pseudo-first-order or pseudo-second-order rate constants (k_{obs}) were calculated by the graphical methods and the values were reproducible within ±4% error.

Stoichiometry and Product Analysis

The stoichiometries of DCT-amino acid reactions are determined in 1 : 1 (v/v) water-methanol medium in the presence of varying concentrations of perchloric acid (0.0005—0.10 mol dm^{-3}) by equilibrating varying ratios of [DCT]$_0$ to [S]$_0$ at room temperature for different intervals of time. The products were found to be CO_2, ammonia, and the corresponding aldehyde by standard tests.[12,13] *p*-Toluenesulfonamide, the reduced product of DCT, was detected by paper chromatography. The observed stoichiometries may be represented by Eqs. 1 and 2.

$$2RCH(NH_2)COOH + ArSO_2NCl_2 + 2H_2O \longrightarrow 2RCHO + 2CO_2 + 2NH_4^+ + 2Cl^- + ArSO_2NH_2 \quad (1)$$



$$+ ArSO_2NCl_2 + 2H_2O \longrightarrow 2H_2C{=}CHCH_2CHO + 2CO_2 + 2NH_4^+ + 2Cl^- + ArSO_2NH_2 \quad (2)$$

where R=CH_3(Ala), $(CH_3)_2CHCH_2$(Leu), $H_2N(CO)CH_2CH_2$(Gln), $H_2N(CO)CH_2$(Asn).

Results

The kinetics of oxidations of Ala, Leu, Asn, Gln, and Pro by DCT in 1 : 1 (v/v) water-methanol medium were studied under varying conditions: [DCT] (0.0005—0.005 mol dm^{-3}), [S] (0.005—0.10 mol dm^{-3}), and [$HClO_4$] (0.0005—0.10 mol dm^{-3}). The results are shown in Tables 1—4 and Figs. 1—6. The kinetics of oxidations were [H^+] dependent. The order in [oxidant] was two and one in the acid ranges 0.0005—0.005 mol dm^{-3} and 0.005—0.10 mol dm^{-3}, respectively, for the oxidations of Asn, Gln,

and Pro. The dependence in [S] for these oxidations was also different (Table 4). But the oxidations of Ala and Leu showed second-order dependence in [oxidant], first order in [S] and inverse fractional order in [H^+] over the entire range of [$HClO_4$](0.0005—0.10 mol dm^{-3}).

(i) Pseudo-Second-Order Kinetics: At fixed [S]$_0$ and [$HClO_4$], the plots of 1/[DCT] versus time were linear at least for two-half lives (Figs. 1 and 2). The pseudo-second-order rate constants (k_{obs}), computed from the plots, were unaffected by changes in [DCT]$_0$ (Table 1), establishing second-order kinetics in [DCT] for the oxidations of Ala and Leu over the entire acid range studied and for Asn, Gln, and Pro in the acid range 0.0005—0.005 mol dm^{-3}. At constant [DCT]$_0$ and [$HClO_4$], the rates increased with increase in [S]$_0$ (Table 1) and the plots of log k_{obs} versus log[S]$_0$ were linear with varying slopes (Table 4), showing nearly first-order to first-order kinetics in [S]. The rates decreased with increase in [$HClO_4$], at fixed [DCT]$_0$ and [S]$_0$, with inverse fractional order to inverse first-order dependences in [H^+]. Variation in ionic strength of the medium or addition of the reduced product of the oxidant, *p*-toluenesulfonamide (TSA), had negligible effects on the rates of oxidations. But the decrease in dielectric constant of the medium by increasing the methanol composition of the solvent

Table 3. Effect of Varying Dielectric Constant of the Reaction Medium and Addition of the Reaction Product, *p*-Toluenesulfonamide (TSA) on the Rates of Oxidations of Amino Acids by *N,N*-Dichloro-*p*-toluenesulfonamide (DCT) in 1 : 1 (v/v) Water-Methanol Medium

decreased the rates of oxidations for all the amino acids. The plots of log k_{obs} versus % methanol (by volume) were linear with negative slopes (Fig. 6). The rates were measured at different temperatures (293—313 K) and the activation parameters computed from the Arrhenius plots (Table 4).

(ii) Pseudo-First-Order Kinetics: Oxidations of Asn, Gln, and Pro in the acid range $\geq$0.005 mol dm^{-3} showed pseudo-first-order kinetics in [oxidant]. At fixed [DCT]$_0$ and [S]$_0$, the plots of log[DCT] versus time were linear for at least two-half lives (Fig. 3) and the pseudo-first-order rate constants calculated from the plots were insensitive to the variations in [DCT]$_0$, showing first-order kinetics in [DCT]. The rates increased with increase in [S]$_0$ and the plots of log k_{obs} versus log[S]$_0$ were linear with varying slopes, indicating varying kinetic orders in [S] (Table 4). At constant [DCT]$_0$ and [S]$_0$ the rates decreased with increase in [HClO$_4$] with inverse fractional order dependences in [H$^+$] for oxidations of all the amino acids. Variations in ionic strength of the medium or the addition of *p*-toluenesulfonamide had no effect on the rates. Decrease in dielectric constant of the medium by increasing the methanol composition of the solvent decreased the rates even under these conditions (Table 3). The plots of log k_{obs} versus % methanol (by volume) were also linear with negative slopes (Fig. 6). The rates of oxidations were also measured at different temperatures (283—313 K) and activation parameters were computed from the plots of log k_{obs} versus $1/T$ and log (k_{obs}/T) versus $1/T$ (Table 4).

Discussion

(i) Pseudo-Second-Order Kinetics in [DCT]: The kinetics of second order in [DCT], nearly first-order in [S] and inverse fractional order in [H$^+$] observed for the oxidations of Ala, Leu, Asn, Gln, and Pro may be explained by a mechanism shown in Scheme 1.

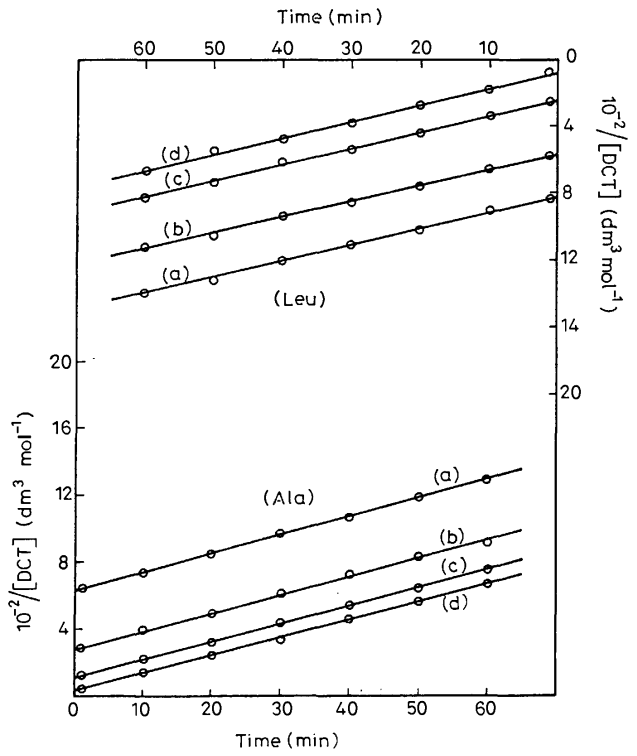

Fig. 1. Plots of 1/[DCT] versus time (Ala and Leu)
$10^2[S]_0$=2.0 mol dm^{-3}, $10^2[HClO_4]$=1.0 mol dm^{-3}, temp 303 K.

$$SH^+ \underset{}{\overset{K_1}{\rightleftharpoons}} S + H^+ \qquad \text{(fast)}$$

$$ArSO_2NCl_2 + S \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{Intermediate} \qquad \text{(fast)}$$
(DCT) (X)

$$ArSO_2NCl_2 + X \xrightarrow{k_3} \text{Products} \qquad \text{(slow)}$$

where SH^+: Protonated amino acid

Scheme 1.

Applying the steady state approximation to the intermediate X, we have

$$[X] = \frac{k_2[ArSO_2NCl_2]_0\,[S]}{k_{-2}+k_3[ArSO_2NCl_2]+k_2[S]} \qquad (3)$$

where $[ArSO_2NCl_2]=[ArSO_2NCl_2]_0-[X]$ and $[S]_0\approx[S]$. Since k_3 is small and $[S]\gg[ArSO_2NCl_2]$, $k_3[ArSO_2NCl_2]$ is negligibly small compared with other terms in the denominator, then Eq. 3 becomes,

$$[X]=\frac{k_2[ArSO_2NCl_2]_0[S]}{k_{-2}+k_2[S]}=\frac{K_2[DCT]_0[S]}{1+K_2[S]} \qquad (4)$$

where $K_2=k_2/k_{-2}$.
The rate of the reaction is then given by Eq. 5

$$-\frac{d[DCT]}{dt} = k_3[DCT]\,[X] = \frac{K_2k_3[DCT]_0[DCT][S]}{1+K_2[S]}. \qquad (5)$$

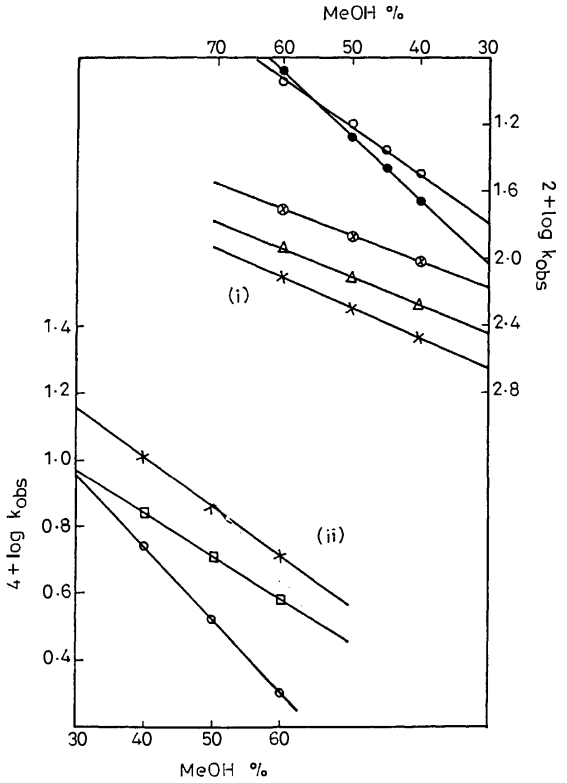

Fig. 6. Plot of log k_{obs} versus % MeOH
(i) Pseudo-second-order rate constants
$10^3[DCT]_0=50[S]_0=10^2[HClO_4]=1.0$ mol dm^{-3}, temp 303 K (Ala and Leu).
$10^3[DCT]_0=20[S]_0=10^3[HClO_4]=1.0$ mol dm^{-3}, temp 293 K (Asn, Gln, and Pro).
● Ala, ○ Leu, △ Asn, × Gln, ○ Pro.
(ii) Pseudo-first-order rate constants
$10^3[DCT]_0=[S]_0=10^2[HClO_4]=1.0$ mol dm^{-3}, temp 303 K.
□ Asn, ×Gln, ○ Pro.

If we now make further assumption that $[DCT]_0\times[DCT]\approx[DCT]^2$ then the rate law (5) becomes

$$-\frac{d[DCT]}{dt} = \frac{K_2k_3[DCT]^2[S]}{1+K_2[S]}, \qquad (6)$$

rearranging Eq. 6, we have Eq. 7

$$-\frac{1}{[DCT]^2}\frac{d[DCT]}{dt} = \frac{K_2k_3[S]}{1+K_2[S]}. \qquad (7)$$

But LHS of Eq. 7 may be written as

$$-\frac{1}{[DCT]^2}\frac{d[DCT]}{dt} = \frac{d\{1/[DCT]\}}{dt} = k_{obs}$$

hence Eq. 7 becomes Eq. 8

$$k_{obs} = \frac{K_2k_3[S]}{1+K_2[S]}. \qquad (8)$$

We also have

$$[S]=K_1[SH^+]/[H^+]. \qquad (9)$$

Therefore Eq. 8 takes the form

$$k_{obs} = \frac{K_1K_2k_3[SH^+]}{[H^+]+K_1K_2[SH^+]} . \quad (10)$$

If K_2 is small, the rate law (8) will take the form

$$k_{obs}=K_2k_3[S]=K_1K_2k_3[SH^+]/[H^+]. \quad (11)$$

The plots of k_{obs} versus [S] (amino acid) gave straight lines passing through the origin with most of the amino acids (Figs. 4 and 5), in conformity with the rate law (11).

The rate laws (Eqs. 10 and 11) explain the observed inverse fractional to nearly inverse first-order in $[H^+]$. The plots of either k_{obs} versus $1/[H^+]$ or $1/k_{obs}$ versus $[H^+]$ were non-linear in most cases (figure not shown).

(ii) Pseudo-First-Order Kinetics in [DCT]: The observed kinetic data (Table 4) for the oxidations of Asn, Gln, and Pro may be accounted for by a mechanism shown in Scheme 2 (modified Scheme 1).

$$SH^+ \overset{K_1}{\rightleftharpoons} S + H^+ \quad \text{(fast)}$$

$$\underset{(DCT)}{ArSO_2NCl_2} + S \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \underset{(Y)}{\text{Intermediate}} \quad \text{(fast)}$$

$$Y + S \xrightarrow{k_5} \text{Products} \quad \text{(slow)}$$

Scheme 2.

Application of the steady state approximation to the intermediate Y, through a procedure similar to the previous one, we have

$$[Y] = \frac{k_4[ArSO_2NCl_2]_0[S]}{k_{-4}+k_5[S]+k_4[S]} \quad (12)$$

or

$$[Y] = \frac{K_4[DCT]_0[S]}{1+K_4[S]} \quad (13)$$

as $k_5[S](k_5$ is very small) in the denominator is negligible compared to other terms and $K_4=k_4/k_{-4}$.

The rate of reaction is then given by Eq. 14

$$-\frac{d[DCT]}{dt} = k_5[Y][S] = \frac{K_4k_5[DCT]_0[S]^2}{1+K_4[S]} \quad (14)$$

or

$$k_{obs} \approx \frac{-1}{[DCT]_0}\frac{d[DCT]}{dt} \approx \frac{K_4k_5[S]^2}{1+K_4[S]} , \quad (15)$$

introducing Eq. 9 into Eq. 15 we have

$$k_{obs} = \frac{K_1^2K_4k_5[SH^+]^2}{[H^+]\{[H^+]+K_1K_4[SH^+]\}} . \quad (16)$$

Thus the rate laws (15) and (16) explain the kinetic data for the oxidations of Asn, Gln, and Pro.

A typical detailed mechanism of oxidation of amino acids is shown in Scheme 3.

Similarly monochlorosulfonamide and HOCl formed further react with amino acids in fast steps to give products.

$$RCH(NH_3^+)COO^- + ArSO_2NHCl + H_2O \xrightarrow[\text{(fast)}]{}$$

$$RCHO + ArSO_2NH_2 + CO_2 + NH_4^+ + Cl^-$$

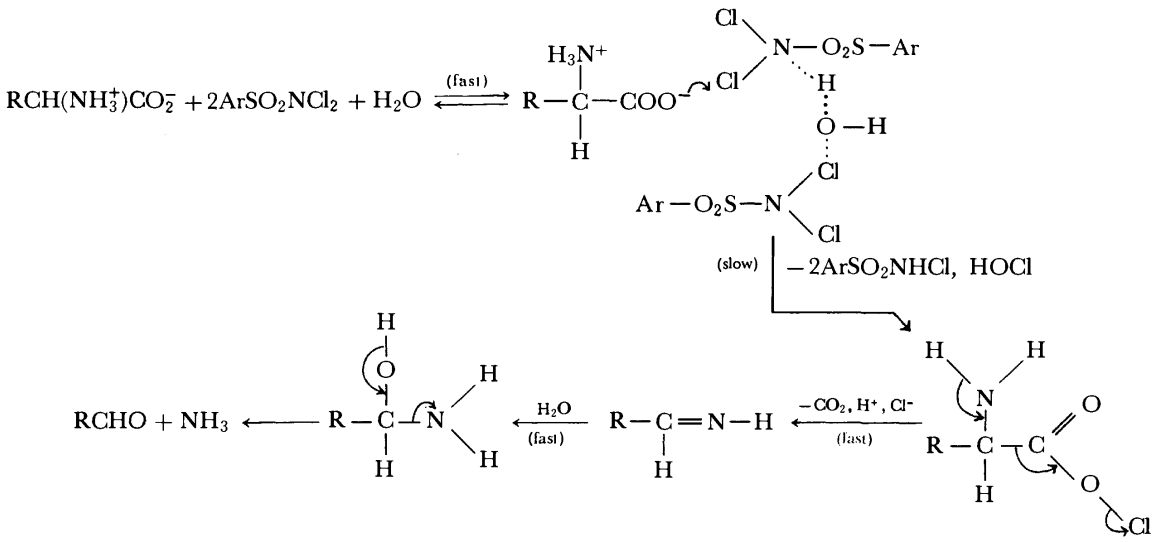

Scheme 3. Where R=CH_3 (Ala), $(CH_3)_2CHCH_2$ (Leu), $H_2N(CO)CH_2$ (Asn), and $H_2N(CO)CH_2CH_2$ (Gln).

$$RCH(NH_3^+)COO^- + HOCl \xrightarrow[(fast)]{} RCHO + CO_2 + NH_4^+ + Cl^-$$

This is supported by investigations with *N*-chloro-*N*-sodio-*p*-toluenesulfonamide (Chloramine-T, $ArSO_2NHCl$) and HOCl under identical conditions (Tables 5 and 6). The rates with these species showed first-order kinetics in [oxidant] and varying orders in [S] and [H^+]. The rates for these oxidations are much higher than those for dichloramine-T oxidations.

Aspargine and glutamine are the amides of acidic amino acids, aspartic and glutamic acids, respectively. Proline is a cyclic amino acid. It is evident from the kinetic data that the kinetic behavior of these amino acids is different from that of simple amino acids (alanine and leucine). The former exhibit different kinetic orders in [DCT] and [S] depending upon [H^+] of the reaction medium, whereas the latter (simple amino acids) show same kinetics over the entire range of [H^+]. This difference in behavior is obvious from the comparison of pK_a values of the amino acids. Asparagine, glutamine, and proline have relatively large values for dissociation constants (Table 7) (smaller pK_a's) and hence are more susceptible to change in [H^+] than the simple amino acids. Hence it is not quite unexpected that they show different kinetic behavior at different [H^+](Table 4).

The observed negligible effect of added reduced product of the oxidant, TSA, and of varying ionic strength of the medium on the rates of oxidations are in agreement with the proposed mechanisms. The latter are also supported by the moderate values of the activation parameters (Table 4).

The observed dielectric effect on the rates of oxida-

Table 7. Ionization Constants and pH Values at the Isoelectric Points of Amino Acids at 25 °C

Amino acid	pK_1	pK_2	pH_i
Alanine	2.34	9.69	6.01
Leucine	2.36	9.60	5.98
Aspargine	2.02	8.80	5.41
Glutamine	2.17	9.13	5.65
Proline	2.00	10.60	6.30

Isoelectric point (or IP): This is the pH at which the maximum number of amino acid molecules are present as zwitter ions, $pH_i=(pK_1+pK_2)/2$.

tions (Table 3), is in conformity with Amis-Jaffee equation for dipolar molecule-dipolar molecule interaction.[14,15]

$$\log k_D = \log k_\infty - \frac{2\mu_1\mu_2}{2.303\, k_B T r^3 D} \quad (17)$$

Where k_D and k_∞ are the rate constants in media of dielectric constant D and ∞, respectively, k_B is the Boltzmann constant, μ_1 and μ_2 are the permanent moments on the dipoles, r is the distance of approach for the dipoles, and T *is* the absolute temperature.

The plots of $\log k_{obs}$ versus $1/D$ were linear (Fig. 6) with negative slopes in accordance with Eq. 17.

Concentrated Mixtures of 1:1 Electrolytes: Densities and Excess Volumes of Aqueous KBr with KCl and NaBr

Anil KUMAR
Department of Sugar Chemistry, Deccan Sugar Institute, Manjari (Bk), Poona 412307, India
(Received December 9, 1988)

Densities of aqueous KCl-KBr and NaBr-KBr mixtures are reported from the ionic strengths 0.5 to 4 mol kg^{-1} of water. The results are analyzed in the light of Pitzer theory of specific interactions. The deviations of experimental quantities from the Young rule (excess volumes) are discussed in terms of interactions between the ions of like charges. The excess volumes showed weak dependence on temperature.

In recent years there has been upsurge in interest in the thermodynamic properties of aqueous concentrated electrolyte mixtures. This upsurge has most probably been caused due to the development of ion-interactions or specific interactions approach of Pitzer,[1,2] which describes various thermodynamic properties like osmotic, activity coefficients, and enthalpies of both pure and mixed electrolyte solutions of high concentrations.[3] However, the understanding of volume properties of concentrated aqueous mixed electrolytes is still very poor, as evidenced by little amount of work in this direction,[4-9] where the studies were carried out in diluted solutions.

The present article describes the densities and apparent molal volumes of mixtures of aqueous KBr with KCl, and with NaBr up to the constant ionic strength of 4 mol kg^{-1} of water. The results are analyzed with the help of Pitzer theory.[1,2] The ion-ion interactions are also discussed in relation to the excess volumes of mixing. Besides detailed study at 298.15 K, the article also discusses the temperature dependence of the excess volumes.

Materials and Methods

KBr, KCl, and NaBr were Baker analyzed and were crystallized twice before preparing solutions on molality basis in deionized water. The concentrations of the solutions were determined by volumetric analysis. The mixtures of different compositions were prepared by mixing appropriate amounts of stock solutions as $y_B=m_B/I$, and remembering that $y_A+y_B=1$. y corresponds to ionic strength fraction, and B refers to KBr. The symbols m and I are molality and ionic strength, respectively.

The experimental density differences, Δd, were measured using a Paar vibrating tube densimeter. The difference between density of solution, d, and of pure water, d_0, is called the density difference, Δd. The densimeter was calibrated using the densities of pure water[10] and of aqueous NaCl solutions.[11] The temperature of thermostat bath was maintained constant to ±0.005 K, and the Δd values were accurate to within 3×10^{-6} g cm^{-3}.

Data Treatment

The Pitzer theory is based on the evaluation of three adjustable parameters from constituent pure electrolytes and then using them in the ionic equations of mixtures. The estimation of ionic property in mixture primarily is based on the cation-anion pair interactions. Subsequently, the corrections arising out of two like charged ion interactions (binary) and three-ion interactions are treated as difference parameters. The volumetric equations of Pitzer as derived from the pressure dependence of the equations applicable to activity coefficients are summarized below. The details of the Pitzer equations are given elsewhere.[12]

Apparent molal volume, ϕ_V, of a single electrolyte is related to its molality, m, as

$$\phi_V = \phi_V^\circ + \nu|Z_M Z_X|\frac{A_V}{2b}\ln(1+bI^{1/2}) + 2\nu_M\nu_X RT[mB_{MX}^V + m^2(\nu_M\nu_X)^{1/2}C_{MX}^V] \quad (1)$$

where

$$B_{MX}^V = \left(\frac{\partial\beta^{(0)}}{\partial P}\right)_T + \left(\frac{\partial\beta^{(1)}}{\partial P}\right)_T (2/\alpha^2 I)[1-(1+\alpha I^{1/2})\exp(-\alpha I^{1/2})] \quad (2)$$

and

$$C_{MX}^V = (\partial C^\phi/\partial P)/2. \quad (3)$$

In these equations $I=1/2\sum_i m_i Z_i^2$, $\nu=\nu_M+\nu_X$, $R=83.1441$ cm^3 bar mol^{-1} K^{-1}, $\alpha=2$ and $b=1.2$, A_V is the Pitzer-Debye-Hückel slope having value of 1.874 cm^3 kg$^{1/2}$ mol$^{-3/2}$ at 298.15 K. ϕ_V° is the partial molal volume of an electrolyte at infinite dilution. $(\partial\beta^{(0)}/\partial P)_T$, $(\partial\beta^{(1)}/\partial P)_T$, and $(\partial C^\phi/\partial P)_T$ are the virial coefficients in the Pitzer equations.

Rogers and Pitzer[13] have suggested that the term $(\partial\beta^{(1)}/\partial P)_T$ could be neglected, as it is not possible to obtain it accurately from volumetric results. Thus, the omission of $(\partial\beta^{(1)}/\partial P)_T$ from Eq. 2 yields into a very simple expression as Eq. 1 with two unknown parameters as $(\partial\beta^{(0)}/\partial P)_T$ and $(\partial C^\phi/\partial P)_T$.

The apparent molal volume of an ion in the mixture, ϕ_{Vi}^* (considering cation-anion pairwise interactions only) is given by

$$\phi_{Vi}^* = \phi_{Vi}^\circ + \frac{Z_i A}{2b}\ln(1+bI^{1/2})RT\sum_j B_{ij}m_j + \frac{RT}{2|Z_i|^{1/2}}\sum_j C_{ij}m_j^2|Z_j|^{1/2} \quad (4)$$

where the summations over j are over ions of opposite charge.

ϕ^*_{Vi} then yields the apparent molal volume of an electrolyte in mixture, ϕ_{VJ}, as

$$\phi_{VJ}=\sum_i \nu_i \phi^*_{Vi} \quad (5)$$

which in turn calculates theoretical mean apparent molal volumes ϕ^*_{Vth} by

$$\phi^*_{Vth}=\sum_J m_J \phi_{VJ}/\sum m_J. \quad (6)$$

Theoretical density, d_{th}, of the mixture is obtained from

$$d_{th}=(1000+\sum_J m_J M_J/(1000/d_0)+\sum_J m_J \phi_{VJ} \quad (7)$$

where M_J is molecular weight of an electrolyte.

The experimental densities, d_{exp}, may be converted to experimental mean apparent molal volumes ϕ^*_{Vexp} by the relationship

$$\phi^*_{Vexp}=\frac{1000(d_0-d_{exp})}{\sum_J m_J d_{exp} d}+\frac{\sum_J m_J M_J}{d_{exp}\sum_J m_J}. \quad (8)$$

Equation 4 does not include the interactions due to the ions of like charge. These interactions i.e. Na^+ and K^+; Cl^--Br^- designated by θ^V_{ik} (i, k are ions with like charges) can be evaluated in the form of difference parameter as:

$$\theta^V_{ik}=(\phi^*_{Vexp}-\phi^*_{Vth})\,(m_i+m_k)/2RT\,m_i\,m_k. \quad (9)$$

It may be noted that Eq. 9 is consistent with Eq. 17 of reference by Pitzer and Kim,[2] who described the mixing therms θ_{ik} for osmotic and activity coefficients of aqueous mixed electrolytes.

An additional term $RT\sum_k \theta^V_{ik} m_k$ may be appended to Eq. 4 in order to obtain ϕ^*_{Vi} with both the cation-anion pair and cation-cation or anion-anion pair interactions as

$$\phi^*_{Vi,corr}=\text{R. H. S. of Eq. 4}+RT\sum_k \theta^V_{ik} m_K. \quad (10)$$

Results and Discussion

Table 1 lists the experimental density differences for both KCl-KBr and NaBr-KBr as a function of y_{KBr} at constant ionic strengths of 0.5, 1, 2, 3, and 4 mol kg^{-1} of water. The values of ϕ^*_{Vexp} can readily be obtained from Eq. 8. The density values for pure constituent electrolytes, i.e. KCl, KBr, and NaBr were in excellent agreement with recent literature.[14-18]

In order to employ the virial coefficients equation of Pitzer, it is essential to obtain the $(\partial\beta^{(0)}/\partial P)_T$, $(\partial\beta^{(1)}/\partial P)_T$, and $(\partial C^\phi/\partial P)_T$ parameters of pure electrolytes from Eqs. 1 to 3. The $(\partial\beta^{(0)}/\partial P)_T$ and $(\partial C^\phi/\partial P)_T$ terms for KCl, KBr, and NaBr were taken from our earlier work[19,20] or calculated from the coefficients cited therein. The values of pure electrolyte parameters are listed in Table 2. The use of these parameters

KBr	33.84	11.45	−14.33	0.01
NaBr	23.52	8.70	−8.70	0.01

in Eqs. 4 to 7 yields the calculated ϕ^*_{Vth} and d_{th} of the mixtures. It is interesting to note that these calculations are manifestation of a simple Young's rule,[21] where the mixture properties are computed from the properties of the individual ions at the same ionic strength. The results of calculations are shown in Table 3 in terms of average deviations of fits, indicating systematic negative deviations for Δd values as demonstrated for example at the highest ionic strength I=4 mol kg^{-1} for both the systems in Fig. 1. In view of these deviations, the interactions between like charged ions were taken into account with the use of Eq. 10, where the θ^V_{ik} values (Table 4) were obtained from Eq. 9. The results of calculations are shown in Table 3. Figure 1 also depicts the results for both the systems at I=4 mol kg^{-1} with the use of θ^V_{ik} terms. An examination of Table 3 indicates a remarkable improvement in the fits, and, also the systematic deviations are removed. In general, the average deviations for KCl-KBr and NaBr-KBr are reduced to 7 and 5 ppm respectively with the use of θ^V_{ik}.

Very recently, Patwardhan and Kumar[22,23] have derived a simple equation from the concept of reduced inoic activity coefficient for estimating densities of concentrated mixed electrolyte solutions. The equation is

$$d=\sum_J(1000\,y_J+m_J M_J)/\sum_J(1000\,y_J+m_J M_J/d^0_J). \quad (11)$$

In this equation, d^0_J is density of constituent Jth electrolyte at the ionic strength of the mixture. Their equation neglects any interactions due to like charged ions and, thus, is again equivalent to Young's rule.[21] The results, hence, listed in Table 3 without the θ^V_{ik} are also applicable to Eq. 11.

The excess volumes of mixing, ΔV_m, for these mixtures can be obtained as

$$\Delta V_m=\phi^*_{V\,exp}\,m_J-\sum_J m_J\,\phi''_{VJ} \quad (12)$$

where ϕ''_{VJ} is apparent molal volume of Jth electrolyte at the ionic strength of mixture. The ΔV_m values can be fitted to the Friedman equation.[24]

$$\Delta V_m=y_B(1-y_B)I^2[v^0+v^1(1-2y_B)] \quad (13)$$

where v^0 and v^1 are the Friedman parameters indicating binary (ik) and ternary (ijk) interactions, respectively. The use of Eq. 13 fitted, the ΔV_m with good accuracy and v^1 values were found negligible. The values of v^0 values as a function of I can conveniently be represented as

$$v^0=15.3\times10^{-2}-15.0\times10^{-3}I\,(\text{for KCl-KBr}) \quad (14)$$

and

$$v^0=4.5\times10^{-2}-4.75\times10^{-3}I\,(\text{for NaBr-KBr}). \quad (15)$$

One should note that data of I=0.5 are not included in the fit, as the error becomes significantly large at lower ionic strengths.

Wood and Smith[25] reported the heats of mixing data up to I=1 for these mixtures, and fitted the data to analogous equation of Friedman in order to obtain RTh_0 and RTh$_1$ as we did to Eq. 13. Negligible RTh_1 values from their study support our negligible v^1 values for both the systems. A study of their data shows that h_0 value is approximately ten times higher in the case of aq. NaBr-KBr than that of aq. KCl-KBr. The present study on volume indicates the relationships inversed by three times. The former effect is

Table 5. Temperature Dependence of v^0 Values for Aqueous KCl-KBr and NaBr-KBr Systems at Low and High Ionic Strengths

I	Temperature	
mol kg^{-1}	278.15 K	318.15 K
	KCl-KBr	
1	0.131	0.144
4	0.084	0.100
	NaBr-KBr	
1	0.036	0..046
4	0.022	0.032

obtained from the temperature dependence of activity coefficients, while the latter from pressure dependence.

Friedman[24,26,27] using Mayer's ionic cluster expansion method estimated the excess properties of mixing of aqueous mixed electrolytes with a common ion. The equations incorporated the primitive model consisting of hard spheres in a continuous dielectric. According to him, the interaction terms RTg_0 and RTh_0 for excess free energy and enthalpy of mixing, respectively, are finite for common ion mixtures even at infinite dilution. The values of intercepts in Eqs. 14 and 15 confirm Friedman's results of calculations for excess volumes of mixing too. One clearly notes the absence of high order limiting law[28] in the symmetric mixtures like these under study. A survey of v_0 values for both the mixtures indicates a slow variation of v_0 with I or total molality. Thus, v_0 values arising out of like-charged ion-interactions are more important than v^1 which is an indication of ternary interaction. This observation is confirmed both by enthalpy of mixing data of Wood and Smith[25] and by the present work on volumes.

The binary mixing term of Pitzer, θ^V_{ik} could be correlated with v^0 term of Friedman using Eqs. 9, 12, and 13 to give

$$\theta^V_{ik}=v^0/2RT. \quad (16)$$

It is natural that θ^V_{ik} will have same ionic strength dependence.

Since the ΔV_m values at 298.15 K showed maxima at $y_B=0.5$, we conducted one experiment each for $I=1$ and 4 mol kg^{-1} for both the systems at 278.15 and 318.15 K in order to obtain temperature dependence of ΔV_m. Table 5 lists the results in terms of v^0, which indicate poor temperature dependence in both the cases. The values of $\partial v^0/\partial T$ for aqueous KCl-KBr and aqueous NaBr-KBr were found to be 3.6×10^{-4} and 2.5×10^{-4}, respectively in the temperature range of 278.15 to 318.15 K. In view of this, we deferred conducting further experimentations at other intermediate ionic strengths and temperatures.

To summarize, the densities of concentrated aqueous mixed electrolytes can be estimated with accuracy with the Pitzer theory of specific interactions, provided both the interactions (cation-anion and cation-cation or anion-anion) are explicitly considered. Ternary interactions are negligible throughout, although they could be significant in many other systems. In near future, we shall present complete description of the symmetric and asymmetric mixtures, for which we are collecting experimental data. Also, the experimental data, for the treatment of which, ternary interaction term is required, will be presented.

Solvent Effect on Hydrogen Bonding Interaction between 5,6,7,8-Tetrahydro-2-naphthol in the Ground and Excited States and Triethylamine

T. K. PAL, G. K. MALLIK, T. GANGULY, and S. B. BANERJEE*
Department of Spectroscopy, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700032, India
(Received December 12, 1988)

In the ground state 5,6,7,8-tetrahydro-2-naphthol (ThOH) forms with triethylamine (TEA) simple hydrogen bond, hydrogen-bonded ion pair or solvent-separated ion pair complex depending on the polarity of solvents. Fluorescence emission of ThOH is quenched by TEA in all solvents. The quenching rate constant k_q is large in weakly polar solvents than in highly polar solvents and there is no evidence of formation of solvent-separated ion pair in latter solvents. It is suggested that restricted electron delocalization in excited ThOH molecule lowers the tendency of deprotonation of the OH group. The likely pathway of energy depletion is through intermediate singlet contact CT exciplex of the type A^-D^+ between ThOH and TEA.

Hydrogen-bonding interactions between an acid A-H and a base B can be of different types depending on the polarity of the solvents in which the systems are studied and may lead to simple hydrogen-bond, hydrogen-bonded ion pair or solvent-separated ion pair complex. The present paper concerns absorption and fluorescence spectra of ThOH, a bicyclic molecule of biological interest specially in hormone biology, measured in solvents of different dielectric constant (ε_0) in the presence of TEA as the hydrogen-bond acceptor. In the ThOH molecule the π-electrons extend over one ring and the other alicyclic like ring of the molecule has a flexible distorted half-chair structure like cyclohexane. In a previous communication[1] some changes in the π-electronic absorption spectrum of ThOH and other similar molecules due to hydrogen-bonding with TEA were described. It was also reported that fluorescence of some bicyclic tetrahydronaphthols and amines is quenched by hydrogen-bonding molecules like TEA.[1-3] Hydrogen-bonding properties of molecules are generally different in the ground and excited states. The absorption and emission spectra of ThOH have been measured in the same set of solvents. One of the main objectives is to elucidate dependence of hydrogen-bonding interaction between ThOH in the ground and excited states and TEA on solvent polarity and the nature of the complexes that might be formed. Possible reaction schemes in the ground and excited states and kinetics of energy depletion have been examined.

Experimental

5,6,7,8-Tetrahydro-2-naphthol (ThOH) (Aldrich, 98% pure) was sublimed under reduced pressure before use. TEA (Fluka, AG) was distilled at atmospheric pressure. Spectroscopic grade solvents hexane, ethanol (EtOH), methanol (MeOH), dichloromethane (DCM), tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), acetonitrile (ACN) supplied by E. Merck, W. Germany were used as received. TEA and all the solvents were tested carefully for any possible interfering emission when excited at 280 nm.

The concentration of ThOH was about 2.25×10^{-4} mol dm^{-3} for both absorption and emission experiments. In ternary mixtures, the concentration of TEA in different solvents varied from 0.1 to 1 mol dm^{-3} for absorption and from 10^{-3} to 0.1 mol dm^{-3} for emission study. The excitation wavelength was 280 nm.

The absorption spectra were recorded with a Shimadzu UV-VIS spectrophotometer model 210A and the emission spectra with a Perkin-Elmer model MPF 44A fluorescence spectrophotometer attached with corrected spectra unit.

Fluorescence decay measurements were made using a time-correlated single photon-counting fluorimeter (model 199, Edinburge Instruments, U. K). The excitation source was a coaxial H_2 flash lamp giving an instrumental response function of about 1.2 ns full width at half-maximum (FWHM) at 30 kHz repetition rate. The excitation and emission wavelengths were 280 nm and 305 nm, respectively. Count versus channel number was recorded separately and fluorescence lifetime was calculated by fitting single exponential function with the experimental data and the computation was done using HCL PC Computer model BUSYBEE PC/XT.

Results and Discussion

Hydrogen-Bonding and Absorption Spectral Changes. The π-electronic absorption spectrum of ThOH in 260—310 nm region has been measured at 300 K in different nonpolar and polar protic and aprotic solvents without and with added amounts of TEA. Figure 1 shows that when TEA is added to the solution of ThOH in hexane (dielectric constant $\varepsilon_0\approx1.89$ at 300 K) the absorption spectrum undergoes a small shift towards the longer wavelength. An isosbestic point is also noted at 290 nm in the absorption spectrum (Fig. 1). TEA does not produce any change in the absorption spectrum of an analogous molecule 6-methoxy-1,2,3,4-tetrahydronaphthalene which is unlikely to have hydrogen-bonding interaction with TEA in hexane. Addition of excess amount of TEA to the tetrahydronaphthol-hexane system does not yield any band on the long wavelength side characteristic of charge transfer or ion pair formation. All this indicates that in hexane medium hydrogen-bonding

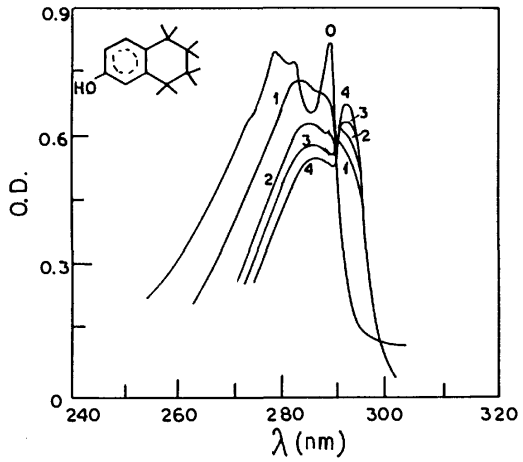

Fig. 1. Ultraviolet absorption curves for ThOH in hexane (2.23×10^{-4} mol dm^{-3}) at 300 K. Concentration (mol dm^{-3}) of TEA: (0) 0; (1) 0.10; (2) 0.67; (3) 0.83; (4) 1.0.

between ThOH and TEA is weak and a simple hydrogen-bonded complex is formed. The simple hydrogen-bonded equilibrium may be expressed as

$$\underset{C_f}{\mathrm{ThOH}}+\underset{C_A}{\mathrm{NR_3}} \overset{K_1}{\rightleftharpoons} \underset{C_b}{\mathrm{ThOH\cdots NR_3}} \qquad (1)$$

where R stands for C_2H_5.

The equilibrium constant K_1 is given by

$$K_1 = C_b/C_fC_A$$

where C_f, C_A, and C_b represent concentrations of free ThOH, TEA, and the hydrogen-bonded species respectively.

When ThOH is dissolved in polar protic solvents EtOH or MeOH or in polar aprotic solvent tetrahydrofuran (THF) the absorption bands of the molecule shift towards the red with respect to the bands observed in hexane solution. When TEA is added to the binary mixture of ThOH-alcohol or ThOH-THF, no further shift is observed. Apparently ThOH becomes engaged in hydrogen-bonding with EtOH, MeOH, or THF and when TEA is added, direct hydrogen-bonding between TEA and ThOH does not take place.

In dichloromethane (DCM) which has a relatively high dielectric constant ($\varepsilon_0 \approx 9.80$ at 300 K) compared to hexane, the tetrahydronaphthol-TEA system yields two absorption maxima at 289 and 325 nm which may be assigned to simple hydrogen-bonded species and hydrogen-bonded ion pair, respectively (Fig. 2, Table 1). This implies establishment of a tautomeric equilibrium between simple hydrogen-bonded complex and the hydrogen-bonded ion pair and the following equilibria may be assumed

$$\mathrm{ThOH}+\mathrm{NR_3} \overset{K_1}{\rightleftharpoons} \mathrm{ThOH\cdots NR_3}$$

$$\underset{C_{HB}}{\mathrm{ThOH\cdots NR_3}} \overset{K_2}{\rightleftharpoons} \underset{C_{HBIP}}{\mathrm{ThO^-\cdots NH^+R_3}} \qquad (2)$$

where K_2 is given by C_{HBIP}/C_{HB}. Here C_{HB} and C_{HBIP} stand for concentration of simple hydrogen-bonded complex and hydrogen-bonded ion pair complex

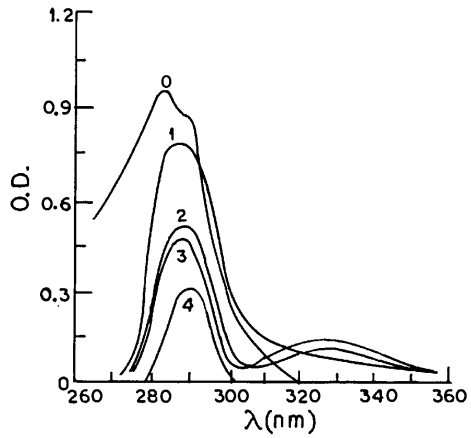

Fig. 2. Ultraviolet absorption curves for ThOH in DCM (2.25×10^{-4} mol dm^{-3}) at 300 K. Concentration (mol dm^{-3}) of TEA: (0) 0; (1) 0.23; (2) 0.67; (3) 0.83; (4) 1.0.

a) Values given at 300 K.

respectively. Baba et al.[3] made similar observation in the case of *p*-nitrophenol-TEA in DCM. The peak at 289 nm in DCM represents absorption by ThOH, hydrogen-bonded with TEA. The corresponding peak due to free molecule before the addition of TEA is at 283 nm (Fig. 2, Table 1). When concentration of TEA is sufficiently high (≈1 mol dm^{-3}) the longer wavelength band at 325 nm assigned to hydrogen-bonded ion pair disappears and only the 289 nm band due to simple hydrogen-bonded species persists (Fig. 2). Therefore, at large concentration of TEA, the tautomeric equilibria shown by Eq. 2 are disturbed. The equilibrium under these conditions is weighted in favor of the simple hydrogen-bonded complex. Evidently when a large amount of TEA, which has a comparatively low dielectric constant (ε_0≈2.24), is present in the mixture containing DCM and TEA, the effective dielectric constant is lowered and the situation tends to be the case of solution of low dielectric constant in which only simple hydrogen-bonded complex is formed.

When TEA is gradually added to solution of ThOH in highly polar aprotic solvents *N*,*N*-dimethylformamide (DMF) (ε_0≈36.7) and acetonitrile (ACN) (ε_0≈37.0), a single broad structureless band (Fig. 3) appears at 340 nm (Table 1) in place of the 325 nm band due to hydrogen-bonded ion pair observed in DCM. At the same time, intensity of the absorption band due to free molecules diminishes (Fig. 3). It is seen from Fig. 3 that naphtholate ion in aqueous solution absorbs near the same wavelength and therefore the 340 nm band may be attributed to absorption by deprotonated naphtholate ion ThO$^-$ in the ground state. The presence of isosbestic point in the spectrum (Fig. 3) indicates a chemical equilibrium which

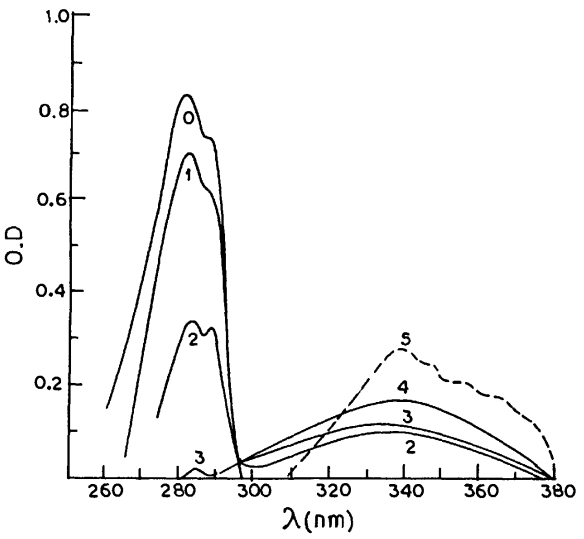

Fig. 3. Ultraviolet absorption curves for ThOH in ACN (2.31×10^{-4} mol dm^{-3}) at 300 K. Concentration (mol dm^{-3}) of TEA: (0) 0; (1) 0.10; (2) 0.67; (3) 0.83; (4) 1.0. Dotted curve (5): spectrum of tetrahydronaphtholate ion (ThO$^-$) in aqueous solution.

may be expressed as

$$\mathrm{ThOH}+\mathrm{NR_3} \overset{K_3}{\rightleftharpoons} \mathrm{ThO^-(solv.)N^+HR_3} \qquad (3)$$

which assumes formation of solvent-separated ion pair by transfer of proton. The ions are separated by one or more solvent molecules and are linked electrostatically.

Hydrogen-Bonding and Fluorescence Spectral Changes. To sum up, absorption measurements demonstrate different types of interaction between ThOH in the ground state and TEA in different solvents depending on the dielectric constants of solvents. It would be interesting to investigate the nature of interaction between excited ThOH and TEA in the same solvents as were employed in absorption study. The fluorescence spectra of ThOH at 300 K are given in Fig. 4(a) and Fig. 4(b). It is seen that in the solvents hexane (ε_0≈1.89 at 300 K), THF (ε_0≈7.58 at 300 K), DCM (ε_0≈9.08 at 300 K), DMF (ε_0≈36.7 at 300 K), and ACN (ε_0≈37.5 at 300 K), fluorescence emission of ThOH is reduced remarkably in the presence of very small amount of TEA (concentration≈ 10^{-3}—10^{-2} mol dm^{-3}), but the shape and position of the bands are unchanged (Figs. 4(a) and (b)).

The absorption spectral changes described above, require comparatively large concentration of TEA (0.1 mol dm^{-3}). So, for very low TEA concentration, ranging from 10^{-3} to 10^{-2} mol dm^{-3}, used in fluorescence measurements, static quenching or innerfilter effect may be neglected and the dynamic quenching rate constant k_q may be determined from simple Stern-Volmer equation

$$f_0/f = 1 + K_{sv}[\mathrm{Q}] \qquad (4)$$

where $K_{sv}=k_q\tau_0$, τ_0 being the fluorescence decay time in absence of TEA. Plots of f_0/f versus [Q] in different solvents are found to be linear and the computed k_q's are given in Table 2. It is seen that the dynamic fluorescence quenching rate constant k_q measured in hexane is larger than the rate constants measured in more polar solvents THF, DMF, and ACN (Table 2). In DCM, k_q is slightly higher than in hexane. In this solvent, external heavy atom perturbation is likely to contribute to deactivation of the excited singlet state of ThOH. In alcoholic solvents, on addition of TEA (Fig. 4(c)), the fluorescence of ThOH is not quenched and this indicates that the nonbonding lone-pair electrons on the nitrogen atom of TEA form hydrogen-bonding of R-OH···N type with alcohols and charge transfer in ThOH-TEA system is retarded. The solvent dependence of quenching constant k_q is not very regular. But it is found to be generally high in solvents of low polarity than in solvents of high polarity (Table 2). This negates existence of solvent-separated ion pair complex in the excited state, similar to the one formed in the ground state, even in highly polar solvent like ACN. Plainly, hydrogen-bonding

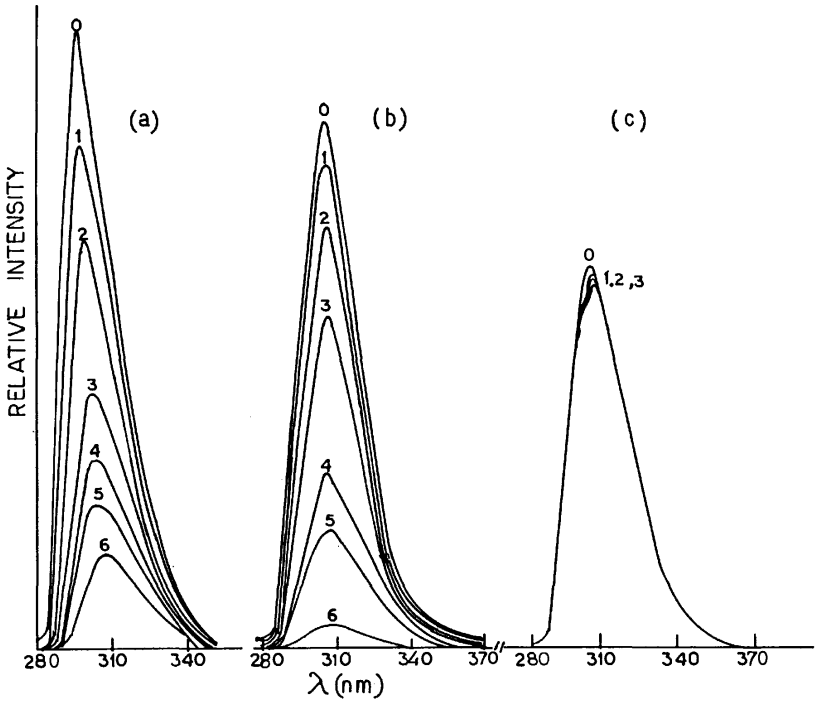

Fig. 4. (a) Fluorescence spectra of ThOH in hexane (2.23×10^{-4} mol dm^{-3}) at 300 K (excitation wavelength: 280 nm). Concentration (mol dm^{-3}) of TEA in (0) 0; (1) 3.17×10^{-3}; (2) 9.51×10^{-3}; (3) 1.90×10^{-2}; (4) 3.17×10^{-2}; (5) 4.76×10^{-2}; (6) 9.52×10^{-2}.
(b) Fluorescence spectra of ThOH in ACN (2.31×10^{-4} mol dm^{-3}) at 300 K (excitation wavelength: 280 nm). Concentration (mol dm^{-3}) of TEA in (0) 0; (1) 1.60×10^{-2}; (2) 3.20×10^{-2}; (3) 6.40×10^{-2}; (4) 1.28×10^{-1}; (5) 1.92×10^{-1}; (6) 9.52×10^{-1}.
(c) Fluorescence spectra of ThOH in EtOH (2.25×10^{-4} mol dm^{-3}) at 300 K (excitation wavelength: 280 nm). Concentration (mol dm^{-3}) of TEA in (0) 0; (1) 1.60×10^{-2}; (2) 6.40×10^{-2}; (3) 1.92×10^{-1}.

Table 2. Bimolecular Fluorescence Quenching Rate Constant (k_q) in Solvents of Varing ε_0 Values for ThOH-TEA System at 300 K

Solvent	ε_0	τ_0/ns	K_{sv}/dm^3 mol^{-1}	k_q/dm^3 mol^{-1} s^{-1}
Hexane	1.89	4.19	69.32	1.65×10^{10}

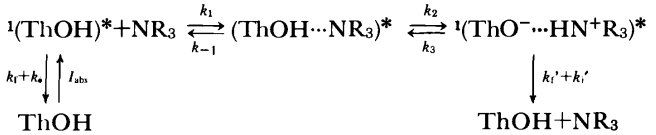
MeOH	32.70		No quenching	
DMF	36.70	6.83	3.18	4.65×10^{8}
ACN	37.00	4.54	9.20	2.02×10^{9}

properties of ThOH are different in the ground and excited states. The deactivation of the excited ThOH molecule may be through formation of hydrogen-bonded ion pair or contact CT exciplex and the equilibrium may be represented by



Scheme 1.

The energy gap between the CT state ^{1}(ThO$^-$···NH$^+$R$_3$)* and the ground state of ThOH may be small enough to favor internal conversion[5] and fast non-radiative decay as pictured in Scheme 1. It is interesting to note that in the ground state, 2-naphthol, in which the π-electrons extend over both the rings, reportedly[6,7] enters into simple hydrogen-bonding with TEA in nonpolar solvents. In polar solvents bonding between TEA and unexcited 2-naphthol is supposed to be hindered[6] due to large solvation of both the acceptor and donor molecules. On the other hand, due to interaction between TEA and excited 2-naphthol in polar solvents, formation of solvent-separated ion pair complex equlibrium state from which fluorescence transition occurred was reported.[6]

Therefore hydrogen-bonding behaviors of 2-naphthol and the bicyclic tetrahydronaphthol are different, particularly in the excited state. This difference in behavior may be attributed to the lessening of electron delocalization due to the saturation of one of the rings of the bicyclic system of ThOH and consequent lowering of the number of π-bonds. The outcome of low electron delocalization is that tendency of deprotonation of OH group of ThOH decreases.

Apparently this restriction of electron delocalization is specially important in the excited state of ThOH because as has been noted above, there is no indication of solvent-separated ion pair formation in polar solvents.

We wish to thank Mrs. Jaya Mukherjee and Dr. S. C. Bera of Physical Chemistry Department, Jadavpur University for the fluorescence lifetime measurments. We acknowledge useful conversation with Dr. S. P. Ghosh of Inorganic Chemistry Department of IACS.

Kinetics and Mechanism of the Reduction of Dodecatungstocobaltate(III) by Iminodiacetate, Nitrilotriacetate, and Ethylenediaminetetraacetate. A Comparative Study of the Reactivity of Different Amine-*N*-carboxylates

Swapan K. SAHA, Prabir BHATTACHARYA, Mahammad ALI, and Pradyot BANERJEE*
Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India
(Received October 19, 1988)

The kinetics of reduction of dodecatungstocobaltate(III) by iminodiacetate (IDA), nitrilotriacetate (NTA), and ethylenediaminetetraacetate (EDTA) have been studied in aqueous solution at 50 °C, 30 °C, and 15 °C respectively. In general, the reactivity of the amine-*N*-carboxylates is in the order EDTA > NTA > IDA. All the anionic species have been found to undergo oxidation via both a spontaneous and an alkali metal ion-catalyzed pathway, while molecular form of the acids are oxidized only via spontaneous pathway. The rate of oxidation is given by a general expression $k_{ox}=k^{\circ}+k[M^+]^n$ where $k_{ox}=k_{obs}/2[L]_T$ ($[L]_T$=total concentration of a particular amine-*N*-carboxylate) and n may have values 1 or 2 depending on the nature of M^+. The terms k° and k account for the rate constants of the spontaneous and catalyzed paths respectively. A general trend $K^+ > Na^+ > Li^+$ for the catalyzed path has been observed for the oxidation of these amine-*N*-carboxylates. Reactivities of different species present in the experimental pH range have been evaluated by carrying out experiment at different pH and using these data in appropriate rate expressions. The reactivities (50 °C) of Hida$^-$ are $k^{\circ}=4.70\times10^{-5}$ dm^3 mol^{-1} s^{-1} and $k_1=3.44\times10^{-4}$ dm^6 mol^{-2} s^{-1} for the spontaneous and Na^+ catalyzed paths respectively. For NTA oxidation (30 °C), rates are k°_{10}(H_3nta)$=1.11\times10^{-3}$ dm^3 mol^{-1} s^{-1}, k°_{11}(H_2nta$^-$, spontaneous)$=7.00\times10^{-3}$ dm^3 mol^{-1} s^{-1}, k_{11}(H_2nta$^-$, Na^+ catalyzed)$=3.50\times10^{-2}$ dm^6 mol^{-2} s^{-1}, k°_{12}(Hnta^{2-}, spontaneous)$=7.20\times10^{-3}$ dm^3 mol^{-1} s^{-1}, k_{12}(Hnta^{2-}, Na^+ catalyzed)$=4.01\times10^{-2}$ dm^6 mol^{-2} s^{-1}. The corresponding reactivities (15 °C) for EDTA oxidation are k°_{20}(H_4edta, spontaneous)$=6.80\times10^{-3}$ dm^3 mol^{-1} s^{-1}, k°_{21}(H_3edta$^-$, spontaneous)$=4.80\times10^{-2}$ dm^3 mol^{-1} s^{-1}, k_{21}(H_3edta$^-$, Na^+catalyzed)$=0.48$ dm^9 mol^{-3} s^{-1}, k°_{22}(H_2edta^{2-}, spontaneous)$=0.21$ dm^3 mol^{-1} s^{-1}, k_{22}(H_2edta^{2-}, Na^+ catalyzed)$=1.70$ dm^6 mol^{-2} s^{-1}, k°_{23}(Hedta^{3-}, spontaneous)$=1.71$ dm^3 mol^{-1} s^{-1}, k_{23}(Hedta^{3-}, Na^+ catalyzed)$=30.00$ dm^6 mol^{-2} s^{-1}. A plausible mechanism considering an outer-sphere association between the complex and reductant has been suggested where the alkali metal ions are assumed to act as a bridge between the reactants.

The fascinating redox property of the cage molecule, dodecatungstocobaltate(III) has been considered by several groups[1-9] in the past. In recent years, we have shown that alkali metal ions play significant role in the electron-transfer reactions between this heteropolyanion and a series of carboxylates e.g., formate,[10] oxalate,[11] malonate,[12] and citrate.[13]

We now report here another family of carboxylates e.g., iminodiacetate, nitrilotriacetate, and ethylenediaminetetraacetate that give promise of a similarly rich redox chemistry. Previous studies on the oxidation reactions of some of the amine-*N*-carboxylates by cerium(IV) have been carried out[14] at high acidity where the unique species present was in the molecular form. We have paid a particular attention to explore the reactivity of the individual amine-*N*-carboxylate species present under varying pH and obtain a possible relationship in the light of their behavior toward cation catalysis phenomenon leading to the redox process.

Experimental

Materials and Reagents. Potassium salts of dodecatungstocobaltate(III), $[CoW_{12}O_{40}]^{5-}$ and dodecatungstocobaltate(II) $[CoW_{12}O_{40}]^{6-}$, hereafter designated as $Co^{III}W$ and $Co^{II}W$ respectively, have been prepared, characterized and standardised in the same way as reported earlier.[2,15] Doubly recrystallized disodium salt of iminodiacetic acid, Na_2ida (Fluka AG), nitrilotriacetic acid, H_3nta (Fluka AG), and disodium salt of ethylenediaminetetraacetic acid, Na_2H_2edta (BDH AnalaR) have been used to prepare stock solutions.[16] Cation variation studies have been performed using doubly recrystallized sodium perchlorate, sodium nitrate, sodium sulfate, potassium nitrate, and lithium perchlorate. The pH adjustment has been done with the respective acids (perchloric, nitric, and sulfuric) and carbonate free alkali solutions (sodium, potassium, or lithium hydroxide). All solutions have been prepared using doubly distilled water.

Kinetic Studies. A Pye-Unicam SP8-150 spectrophotometer, equipped with a thermostated cell compartment has been used to monitor the reactions by observing the decrease in absorbance at the absorption maximum 388 nm of $Co^{III}W$ ($\varepsilon_{max}=1155\pm5$ dm^3 mol^{-1} cm^{-1}).[2] Identical kinetic results have been obtained when experiments are carried out at 625 nm, the absorption maximum of $Co^{II}W$.[2] Dissolved oxygen has not shown any observable kinetic effect. pH measurements are done with a Systronics (model 335, India) digital pH meter. Temperature has been controlled using a Haake F3 thermostat.

Polymerization Studies. The generation of free radicals during the course of reaction has been tested by the polymerization of acrylonitrile.[10-13] In three separate vials solutions of IDA, NTA, and EDTA (ca. 0.1 mol dm^{-3}) are taken, and the pH of these solutions are adjusted to 4.45, 3.50, and 4.50 respectively. These solutions are then degassed with dinitrogen and acrylonitrile (5 ml 20% v/v) is added to each reaction mixture at room temperature. When the degassed solution of the complex (ca. 2×10^{-4} mol dm^{-3}) is added to

these reaction mixtures, a heavy precipitate appears almost immediately for the EDTA containing mixture and after about 5—10 minutes for NTA and IDA containing solutions. No polymerization of the monomer is observed when acrylonitrile is added separately to solutions of the complex and amine-*N*-carboxylates. This suggests that the reaction proceeds via the generation of free radicals in solution.

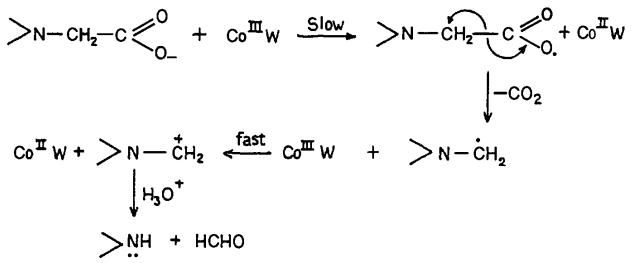
Stoichiometry and Reaction Products. To determine the stoichiometry of the reactions, the amine-*N*-carboxylates have been mixed with a large excess of $Co^{III}W$, and then kept under the reaction conditions, ($(1-5)\times10^{-4}$ mol dm^{-3} $HClO_4$, $[Na^+]=1.0$ mol dm^{-3}) for several days. In the oxidation of iminodiacetic acid, one mole of IDA was consumed per two moles of the $Co^{III}W$ complex after ca. two weeks of the reaction. The organic products which have been identified by paper electrophoresis are glycine and formaldehyde. For NTA oxidation, the same stoichiometry 2:1 is obtained, and the organic products are iminodiacetic acid and formaldehyde. In the case of EDTA oxidation, time dependent stoichiometry is obtained which becomes constant at a complex:reductant ratio of 16:1. Analysis of the products of a 1:1 mixture of complex: EDTA shows the presence of a mixture of ethylenediaminediacetic acid (EDDA), formaldehyde and unreacted EDTA. Carbon dioxide has been detected as one of the oxidation products for all the acids. For EDTA oxidation, following the first decarboxylation, several paths for further oxidation are available. These consecutive and concurrent reactions are expected to yield the observed time dependent stoichiometry. The stoichiometric reactions may therefore be depicted as follows

$$2\,Co^{III}W+HN(CH_2COOH)_2 \longrightarrow 2\,Co^{II}W+\text{other products} \quad (1)$$

$$2\,Co^{III}W+N(CH_2COOH)_3 \longrightarrow 2\,Co^{II}W+\text{other products} \quad (2)$$

$$16\,Co^{III}W+(HOOCCH_2)_2NCH_2CH_2N(CH_2COOH)_2 \longrightarrow 16\,Co^{II}W+\text{other products.} \quad (3)$$

A similar time dependent stoichiometry for EDTA oxidation by Ce(IV) has been observed by Hanna et al.[14] However, the elementary process requires two moles of $Co^{III}W$ per mole of amine-*N*-carboxylate represented by a generalized Scheme 1.



Scheme 1.

Results and Discussions

General Kinetic Features of the Reactions. The kinetics of the oxidation of amine-*N*-polycarboxylates by $Co^{III}W$ has been studied in the pH range 0.05—5.45 at varying alkali metal ion concentrations which have been used as supporting electrolyte. The spectral changes observed during the reactions of $Co^{III}W$ with different carboxylates give a clear isosbestic point near 510 nm in each case. This indicates the absence of appreciable amounts of reaction intermediates. Under pseudo-first-order conditions with excess reductant, the plots of $-\log(A_t-A_\infty)$ vs. time (t), where A_t and A_∞ are the absorbances at times t and infinity respectively, show excellent linearity upto ca. 80—90% of the reactions. Linearity of a plot of k_s vs. $[\text{reductant}]_T$ (where k_s includes the stoiochiometric factor 2 and is defined by $k_s=k_{obs}/2$) holds good at any point in the pH range experimented for the individual amine-*N*-polycarboxylates suggesting a first-order dependence of rate on $[\text{reductant}]_T$. The k_s values for the reduction of $Co^{III}W$ by IDA, NTA, and EDTA are shown in Table 1.

Effect of Specific Ions on Reaction Rates. Reactions between two similarly charged ions are usually found to be catalyzed by a third substance bearing an opposite charge.[17-19] In the reactions of $Co^{III}W$ with the deprotonated forms of the amine-*N*-polycarboxylates, rate acceleration by alkali metal ions have been noticed. Both the change in nature and concentration of supporting electrolytes have considerable effect on the rates. The individual effects of K^+, Na^+, and Li^+ ($=M^+$) on the reaction rate were investigated. In each case, a positive intercept is obtained on the rate axis, and the rate of oxidation is given by the following expression

$$k_{ox}=k^\circ+k[M^+]^n \quad (4)$$

where $k_{ox}=k_s/[L]_T$ ($[L]_T$=total concentration of a particular amine-*N*-polycarboxylate) and n may have values 1 or 2 depending on the nature of M^+. The terms k° and k account for the rate constants of the spontaneous and catalyzed paths respectively. In the cases of IDA, NTA, and EDTA oxidations, a second-order dependence on $[Li^+]$ is obtained. When $[H_3edta]^-$ is the reacting species, the order with respect to $[Na^+]$ is also 2. Dependence on $[K^+]$ is always first-order, and the cation catalytic order[20] is $K^+>Na^+>Li^+$. The kinetic data are presented in Table 2. Equations 5—7 quantitatively describe all of these salt effect results, considering that constant ionic strength was not maintained. The intrinsic effect of ionic strength alone on the reaction was, however, verified by using a mixture of $MClO_4$ (or MNO_3) and M_2SO_4 whereby the total $[M^+]$ was kept constant but ionic strength varied. The results show that the effect of ionic strength on rates for the present system is negligibly small.

To ensure further that the rate enhancement is caused by catalysis and not an ionic strength effect, the rate parameters obtained for $[M^+]$ variation has been subjected to the Bronsted-Bjerrum-Christiansen relationship (Eq. 5) from which $\log k_0'$ defined by Eq. 6[21] has been calculated by using a value of +5 for Z_AZ_B

and a theoretical value[22] of −0.504 for the constant A.

$$\log k_{ox} = \log k_0 + 2AZ_AZ_B \frac{\sqrt{I}}{1+\sqrt{I}} + BI \qquad (5)$$

$$\log k_0' = \log k_{ox} - 2AZ_AZ_B \frac{\sqrt{I}}{1+\sqrt{I}} \qquad (6)$$

Combining these two equations, we get

$$\log k_0' = \log k_0 + BI. \qquad (7)$$

Judging from a simple electrostatic approach, based on the Bronsted-Christiansen-Scatchard equation (Eq. 7),[23] all points should fall on straight line very close together, because the coefficient B should depend mainly on the nature of the ions of opposite signs to that of the reactants.[24] Although this relation has been verified for several reactions, for the present system the plot of $\log k_0'$ vs. I deviates from linearity for each of the cations experimented (Fig. 1). Inter-

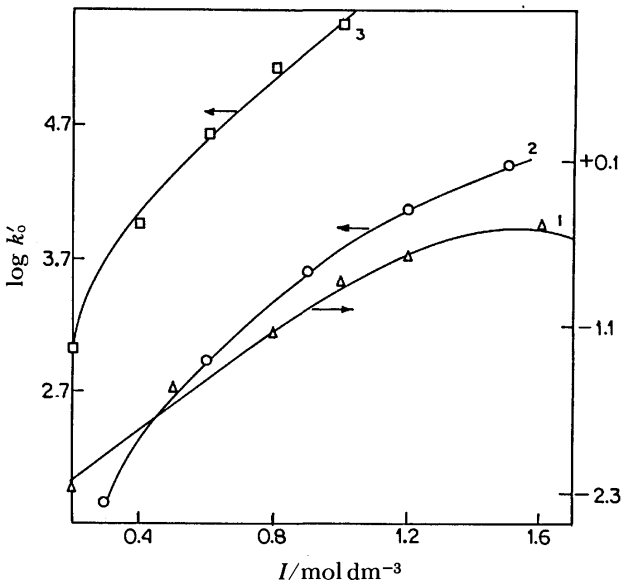

Fig. 1. A plot of $\log k_0'$/vs. I (calculated from $[Na^+]$ variation data for the reactions of $Co^{III}W$ with 1) iminodiacetate at pH 4.45, $[IDA]_T$=0.20 mol dm^{-3} and temperature 50 °C, 2) nitrilotriacetate at pH 3.90, $[NTA]_T$=0.01 mol dm^{-3} and temperature 30 °C, and 3) ethylenediaminetetraacetate at pH 4.50, $[EDTA]_T$=0.003 mol dm^{-3} and temperature 15 °C.

pretation of such deviation obviously requires some specific catalytic intervention by M^+, possibly through a combination of reduction of anion-anion repulsion and facilitation of actual electron transfer through a superexchange type process.[25,26]

The foregoing discussions lead us to believe that the reactions of $Co^{III}W$ with the amine-*N*-polycarboxylates take place in two pathways—a spontaneous and an alkali metal ion catalyzed path. Considering the fact that the heteropolyanion under study is a substitution inert species, the sequence of reactions may be described by assuming an outer-sphere association between the reactants. In general, the mechanism may be depicted as follows

$$Co^{III}W^{5-}+H_nA \rightleftarrows Co^{III}W^{5-},H_nA \xrightarrow{k^\circ} Co^{II}W^{6-}+\text{free readical}_1. \quad (8)$$

The above equation describes the reactions of molecular species of the acids (H_nA). For the anionic forms, the spontaneous path would be the same as in above, and the catalyzed path would incorporate M^+ in the rate-determining step as follows[27]

$$Co^{III}W^{5-}+H_{n-m}A^{m-} \rightleftarrows Co^{III}W^{5-},\ H_{n-m}A^{m-} \xrightarrow{k} Co^{II}W^{6-}+\text{free radical}_2 \quad (9)$$

$$Co^{III}W^{5-}+M^+ +H_{n-m}A^{m-} \rightleftarrows Co^{III}W^{5-}\cdots M^+\cdots H_{n-m}A^{m-} \xrightarrow{k} Co^{II}W^{6-}+\text{free radical}_2. \quad (10)$$

The second order dependence on $[M^+]$ may be explained by incorporating another M^+ in the transition state, i.e., the transition state may be a doubly bridged species of the types

$$MCo^{III}W^{4-} \ldots M^+ \ldots H_{n-m}A^{m-} \quad \text{or} \quad Co^{III}W^{5-}\begin{matrix} M^+ \\ H_{n-m}A^{m-} \\ M^+ \end{matrix}.$$

(A) (B)

A recent vibration spectral study[28] of ionic association has suggested the formation of (B) type of species of mixed aggregates between lithium thiocyanate and lithium halides in nonaqueous solvents.

Reactivities of Different Amine-*N*-polycarboxylate Species. Determination of reactivities of different reacting species present in a reaction mixture is one of the major criteria for the elucidation and interpretation of kinetic data. So an attempt has been made to identify the possible reactants under given conditions and to determine their reactivities. For all the acids and their anions, plots of k_s vs. [reductant]$_T$ where the subscript T denotes the total concentration of any particular amine-*N*-polycarboxylate give straight lines passing through the origin ensuing a first-order dependence of the rate on the reductant concentrations. The rate parameters corresponding to the oxidation of molecular forms of the acids have thus been determined directly from the slope of the plot of k_s vs. [reductant]$_T$ at pH 0.05 for NTA and at pH 0.50 for EDTA. Since the reactions with the anionic amine-*N*-polycarboxylates are catalyzed by alkali metal ions, the rate parameters corresponding to the spontaneous and catalyzed paths have been evaluated by considering the dissociation constants of the acids and identifying the reaction species in solution. For the oxidation of iminodiacetate, though the spontaneous (k°) and catalyzed (k) paths have been evaluated from a plot of $k_{ox}(=k_s/[\text{reductant}])$ vs. $[Na^+]$, the reactivity of the molecular form could not be determined, owing to its extremely slow reaction and poor solubility in water. However, for nitrilotriacetate oxidation, H_3nta is reasonably soluble in aqueous medium and its reactivity (k°_{10}) has been determined by plotting k_s vs. [H_3nta] at pH 0.05. Since the pK_1, pK_2, and pK_3 values of H_3nta are 1.70, 2.40, and 9.67 respectively,[29] rate parameters (k°_{12} and k_{12}) corresponding to the oxidation of $[Hnta]^{2-}$ have been obtained by plotting the values of $k_s/[Hnta^{2-}]$ vs. $[Na^+]$ at pH 3.90±0.02. To determine the reactivity of the monoanionic species (H_2nta^-), a set of experiments have been carried out at pH 1.05±0.02 (where the reacting species are H_3nta and H_2nta^-) varying $[Na^+]$. Utilizing these k_{obs} values, k°_{10} and K_1 (the first acid dissociation constant of H_3nta), the reactivities of the catalyzed (k_{11}) and spontaneous (k°_{11}) paths of $[H_2nta]^-$ have been evaluated from the slope and intercept of the plot of left hand side (LHS) vs. $[Na^+]$ (Fig. 2) in Eq. 11,

$$\frac{k_s(K_1+[H^+])-L_T[H^+]k^\circ_{10}}{K_1L_T} = k^\circ_{11}+k_{11}[Na^+] \quad (11)$$

where L_T denotes the total amount of nitrilotriacetate added. The values of the rate parameters are shown in Table 3.

A similar approach has been followed to evaluate the reactivities of the EDTA. A series of kinetic experiments were carried out at constant $[Co^{III}W]=2\times10^{-4}$ mol dm^{-3}, $[EDTA]_T=(2-3)\times10^{-3}$ mol dm^{-3} but at varying pH and $[Na^+]$. (i) At pH 0.50, kinetic studies have been carried out by varying $[EDTA]_T$ with $[Co^{III}W]=2\times10^{-4}$ mol dm^{-3}. From the slope of k_s vs. $[EDTA]_T$ plot, we can get k°_{20}, the reactivity of H_4edta. (ii) At pH 1.10±0.02 kinetic studies have been carried out by varying $[Na^+]$ at constant $[EDTA]_T=2\times10^{-3}$ mol dm^{-3} and $[Co^{III}W]=2\times10^{-4}$ mol dm^{-3}. It is to be noted here that the acid dissociation constants of H_4edta are given by pK_1'=1.99, pK_2'=2.67, pK_3'=6.16, and pK_4'=10.26 respectively,[30] and at pH 1.10, the species taking part in the reaction are H_4edta (k°_{20}) and $[H_3edta]^-$ (k°_{21} and k_{21}). Utilizing the k_s values at pH 1.10, K_1' and k°_{20}, we can evaluate the values of k°_{21} and k_{21} from the slope and intercept of the plot of LHS vs. $[Na^+]^2$ of Eq. 12

$$\frac{k_s(K_1'+[H^+])-L_T[H^+]k^\circ_{20}}{K_1'L_T} = k^\circ_{21}+k_{21}[Na^+]^2 \quad (12)$$

The evaluated parameters are shown in Table 3. (iii) At pH 4.50 ± 0.02, a set of kinetic experiments has

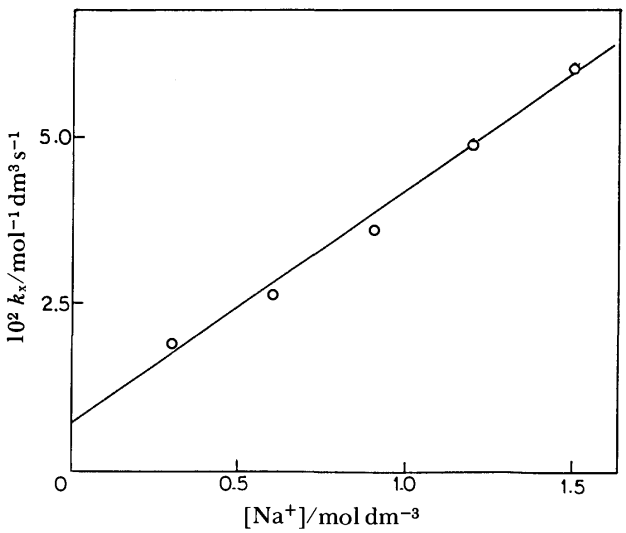

Fig. 2. Representative plot for the evaluation of k°_{11} and k_{11} for H_2nta^- oxidation at pH 1.05±0.02. The ordinate k_x represents the LHS of Eq. 11.

been carried out by varying $[Na^+]$ at a constant $[EDTA]_T$=3×10^{-3} mol dm^{-3} and $[Co^{III}W]$=2×10^{-4} mol dm^{-3}. Considering the second and third acid dissociation constants of H_4edta, the reaction mixture consists of largely $[H_2edta]^{2-}$ species. A plot of k_{ox} vs. $[Na^+]$ gives a straight line from which we can extract a pair of kinetic parameters k°_{22} and k_{22}. We consider these as apparent values since a little amount of $[Hedta]^{3-}$ is also present at this pH. (iv) By varying $[Na^+]$=0.10—0.50 mol dm^{-3}, the rates of the reduction have been followed at $[Co^{III}W]$=2×10^{-4} mol dm^{-3} having $[EDTA]_T$=2×10^{-3} mol dm^{-3} at pH 5.45±0.02. The apparent values of k°_{22} and k_{22} were substituted to the rate equation (Eq.13) to get again a set of apparent k°_{23} and k_{23} values, the uncatalyzed and catalyzed rates for the species $[Hedta]^{3-}$, from a plot of LHS of Eq. 13 vs. $[Na^+]$,

$$\frac{k_s(K_3' + [H^+]) - L_T[H^+](k_{22} + k_{22}[Na^+])}{K_3' L_T} = k^\circ_{23} + k_{23}[Na^+] \quad (13)$$

where L_T denotes the total concentration of EDTA. For the refinement of k°_{22} and k_{22}, the apparent k°_{23} and k_{23} values from Eq. 13 were substituted to the rearranged form Eq. 14 of Eq. 13 but now with the k_s values at pH 4.50.

$$\frac{k_s(K_3' + [H^+]) - K_3' L_T(k^\circ_{23} + k_{23}[Na^+])}{L_T[H^+]} = k^\circ_{22} + k_{22}[Na^+] \quad (14)$$

A new set of k°_{23} and k_{23} can now be generated from Eq. 13 utilizing refined k°_{22} and k_{22} values. The refined parameters obtained by this procedure are listed in Table 3 and the representative plots are shown in Figs. 3(a) and 3(b).

pH-Rate Profiles and the Generalized Rate Equations for NTA and EDTA Oxidations. A general pH variation study has been carried out for both the NTA and EDTA oxidations, and an attempt has been made to match the experimental data with the calculated rate parameters. For this purpose generalized rate expressions have been derived (given by Eqs. 15 and 16) based on the respective reaction schemes (Schemes 2 and 3).

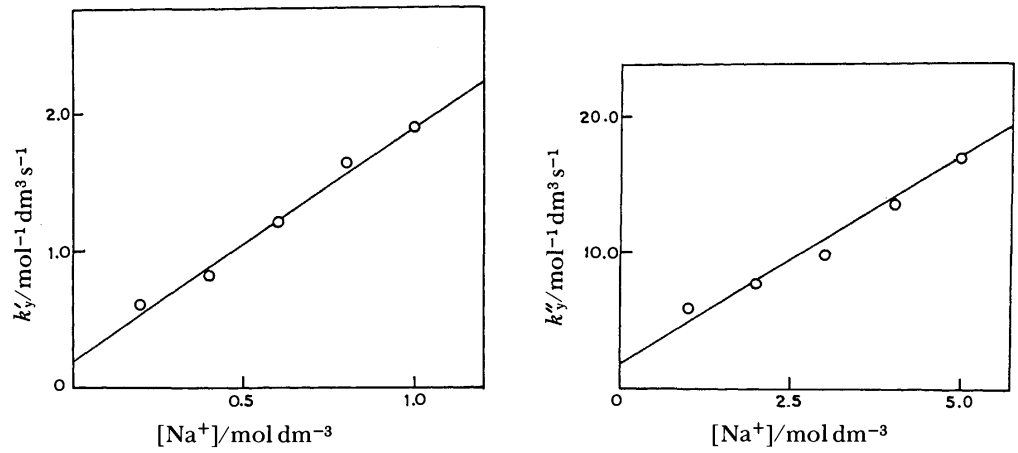

Fig. 3. Representative plots for the evaluation of (a) k°_{22} and k_{22} (refined parameters as presented in Table 3) for H_2edta^{2-} oxidation at pH 4.50±0.02. k'_y represents the LHS of Eq. 14. $$Co^{III}W^{5-} + Na^+ + Hedta^{3-} \xrightarrow{k_{23}} Co^{II}W^{6-} + Na^+$$

Scheme 3.

All the reaction sequences generate respective amine-*N*-polycarboxylate free radicals as stated earlier.

With the help of the various rate parameters included in Table 3, the k_s values at different pH have been calculated. An excellent agreement between the theoretical and experimental values has been obtained (Figs. 4 and 5) and thus the mechanistic formulations are supported strongly.

The pH-rate profile in Fig. 4 for NTA oxidation shows that the rate of reaction increases with increase in pH of the solution at the first phase. It is due to the increase in $[H_2nta^-]$, which has a higher reactivity than H_3nta. Rate saturation starts at pH≈2.80 where $[Hnta]^{2-}$ starts to prevail and no inflexion in the profile is noted below this pH indicating very close reactivities of $[H_2nta]^-$ and $[Hnta]^{2-}$. This is also reflected in the evaluated rate parameters (Table 3). In the case of EDTA, an examination of the pH-rate profile in Fig. 5 reveals that the increase in rate at the first phase is attributable to the increase in $[H_3edta]^-$ reactivity and to a lesser extent by $[H_2edta]^{2-}$ species,

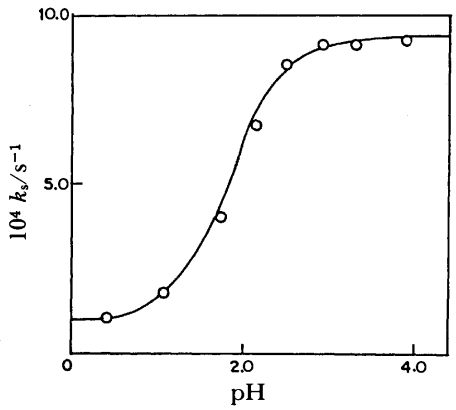

Fig. 4. pH variation results for the reaction of $Co^{III}W$ with nta at $[NTA]_T$=0.02 mol dm^{-3}, $[Na^+]$= 1.00 mol dm^{-3} and temperature=30 °C. Bold line represents the theoretical graph and the experimental values are shown by points O.

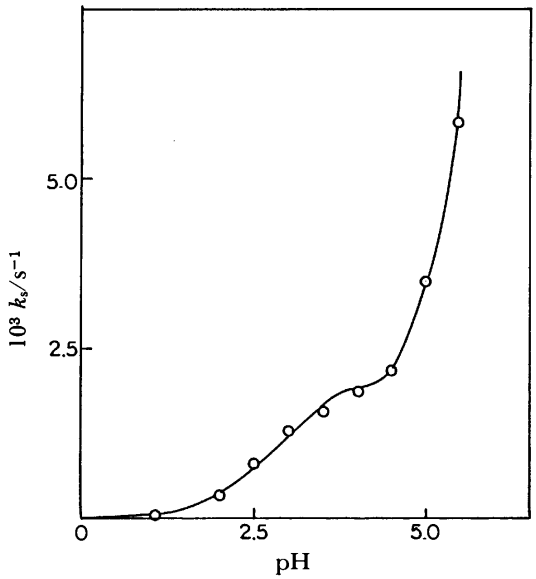

Fig. 5. pH variation results for the reaction of $Co^{III}W$ with edta at $[EDTA]_T=0.002$ mol dm^{-3}, $[Na^+]=0.40$ mol dm^{-3} and temperature=15 °C. The solid line represents the theoretical graph and the experimental values are given by points.

since the pK_1' and pK_2' values are close enough. This trend is followed upto pH≈4.0 where the rate saturation due to both $[H_3edta]^-$ and $[H_2edta]^{2-}$ occurs. This is manifested by a little inflexion in the profile at pH ca. 4.0—4.5. The rate increases sharply beyond pH 4.50, and obviously due to the increased reactivity of $[Hedta]^{3-}$ (Table 3). Since the complex is stable in the pH range 0.0—5.5, kinetic experiments had to be carried out in this range only.

Conclusion

The present study thus provides a systematic approach to the oxidation of amine-*N*-polycarboxylates by $Co^{III}W$. Previous studies on these acids[31-33] have been made in strong acid solutions mainly characterizing a particular species as the reductant. However, in spite of the complications arising out from the overlapping pK values, we could experimentally design and evaluate the different reactivities of various reacting species present in the reaction mixture within our experimental pH range. A comparison of the reactivities of these amine-*N*-polycarboxylates shows a general trend EDTA>NTA>IDA. It has been experimentally recognized that glycine is inert towards $Co^{III}W$. Thus it may be concluded that the increase in number of carboxylate functions for the amino acids increases the reactivities of the molecules i.e., the reducing power. The reactivities of different species for the individual acids have also shown some interesting feature. For EDTA, the trend is $H_4edta<H_3edta^-<H_2edta^{2-}<Hedta^{3-}$. However, for NTA oxidation it is $H_3nta<H_2nta^-\approx Hnta^{2-}$. The above sequences are also true for the catalyzed paths.

The cation catalytic order $K^+>Na^+>Li^+$ obtained in this study is similar to our previous studies[10,11,13] and may be explained by considering the aquated cationic sizes which falls in the order $K^+<Na^+<Li^+$. Thus K^+ will be more effective than Na^+ or Li^+ in bringing the two negatively charged reacting ions together. The absence of catalysis in the oxidation of molecular species is reasonable since the reductant does not carry any charge. But the observation that less effective Li^+ shows a second-order dependence is rather difficult to explain. The greater tendency of the smaller cations to associate with a negatively-charged species[34] is the likely cause for this. Also the second-order dependence on $[Na^+]$ for H_3edta^- in contrast to those observed for H_2edta^{2-} and $Hedta^{3-}$ oxidations seems interesting. Such type of anomaly was encountered in our earlier study in the redox interactions of this heteropolyanion with oxalate.[11] A proper justification of this phenomenon seems difficult because of several factors like size and charge of the reactants, their polarizability as also the size and polarizability of the various cations are associated. An apparent explanation may be put forward by considering the charges of the reactants. As shown in Eqs. 9 and 10, the proposed mechanism involves a cation bridged activated complex where both the complex and the reductant share the alkali metal ion in the transition state. It may be assumed that H_2edta^{2-} and $Hedta^{3-}$ can compete for the Na^+ in the ion pair by virtue of their greater negative charge and utilize it to act as a bridging metal ion in the transition state. Hence the first-order dependence of rate on $[Na^+]$ prevails for these two species. For H_3edta^-, the mononegative charge may not be sufficient to compete for Na^+ in the ion pair. The bridge formation is facilitated by the incorporation of another Na^+ in the ion pair i.e., by reducing the effective charge on the complex, and it results in a second-order dependence on $[Na^+]$.[35]

35) A referee has commented that a higher order dependence on $[Na^+]$ is plausible for electrostatically more favorable species (e.g., H_2edta^{2-} and $Hedta^{3-}$). This is not unlikely, though we could not find such phenomenon even at $[Na^+]\leq 0.50$ mol dm^{-3} with [EDTA]=0.002 mol dm^{-3}. Beyond this $[Na^+]$, experiments could not be carried out by conventional spectrophotometric method owing to rapidity of the reaction.

Synthetic and Spectroscopic Studies of Xanthato-Bridged Heterobimetallic Complexes Containing Diamagnetic and Paramagnetic Metal Ions

Nanhai SINGH,* Nand Kishore SINGH, and Chetna KAW
Chemistry Department, Banaras Hindu University, Varanasi-221005, India
(Received November 8, 1988)

A series of heterobimetallic complexes of the form M[M′(Etxant)$_3$] and M[M′(Etxant)$_3$]$_2$ have been prepared by the reaction of K[M′(Etxant)$_3$] [M′=Ni(II), Cd(II), or Pb(II)] and metal nitrate or sulfate [M=Co(II), Ni(II), Cd(II), Tl(I), Pb(II), or Ag(I), Etxant=ethylxanthate]. These complexes have been characterized by elemental analysis, molecular weight, molar conductance, magnetic susceptibility, (^{1}H, ^{13}C) NMR, electronic, and infrared spectral studies. Magnetic moment and electronic spectral data indicate square planar geometry around Co(II) or Ni(II), except Tl[Ni(Etxant)$_3$] in which Ni(II) is octahedrally coordinated. NMR spectra of M[M′(Etxant)$_3$]$_2$ clearly indicate the presence of two different ethylxanthate moieties, one attached to the diamagnetic Ni(II), Cd(II), or Pb(II) and the other to the paramagnetic Co(II) centre. Electrical conductance values indicate their nonelectrolytic behavior. Interaction of heterobimetallic complexes with different solvent have been studied and solvent characteristics (donor number, dielectric constant, EB (electrovalent) and CB (covalent) parameters) have been related to the structural properties of the complexes. On the basis of these studies, monomeric structure for M[M′(Etxant)$_3$]$_2$ and polymeric structure for M[M′(Etxant)$_3$] have been suggested.

The synthesis and study of heterobimetallic complexes have been the subject of active research over the past few years. The interest in heterobinuclear transition metal complexes has risen sharply in recent years for several reasons.[1-8] The combination of an electron-deficient and an electron-rich metal in a single complex presents the possibility of Lewis acid activation of a substrate molecule bound to the electron rich metal center. This type of cooperative heterobimetallic activation holds potential for applications in catalysis. Heterobinuclear complexes have been used as models for the active sites of many enzyme systems.[9] In addition to enzyme modeling, heteronuclear complexes are of interest in evaluating the factors that contribute to magnetic exchange.[10] Formation of heterobinuclear complexes with bridging ligands as precursor complex is of extreme importance in electron-transfer reaction[11,12] via inner sphere mechanism. Binary and ternary complexes[13,14] of xanthate ion have been extensively studied. Ample work has been done on heterobimetallic complexes of ambidentate ligands, such as SCN^-, $SeCN^-$ etc., involving different donor atoms of these ligands in bridging the two different metal ions. Despite this intensive interest, scarce of work[15,16] has been done on heterobimetallic complexes of dithioligands where two identical sulfur donor atoms are involved in bridging the two different metal ions. We wish to report our investigation on heterobimetallic xanthates of the form M[M′(Etxant)$_3$] and M[M′(Etxant)$_3$]$_2$ containing both univalent and bivalent as well as diamagnetic and paramagnetic metal ions.

Experimental

Material and Methods: All the chemicals used in the preparative work were BDH (AR) or equivalent grades. The solvents were freshly distilled and where necessary dried before use. Potassium ethylxanthate used in the preparative work was prepared by standard literature procedure.[17]

Preparation of the Complexes M[M′(Etxant)$_3$] and M[M′(Etxant)$_3$]$_2$. K[M′(Etxant)$_3$] required for the synthesis of M[M′(Etxant)$_3$] or M[M′(Exant)$_3$]$_2$ [M′=Ni(II), Pb(II), or Cd(II)] was prepared in situ by mixing 25 cm^3 aqueous solution of (2 mmol) potassium ethylxanthate (0.32 g) and (2 mmol) solution/suspension of Ni(Etxant)$_2$ (0.602 g), Cd(Etxant)$_2$ (0.70 g) or Pb(Etxant)$_2$ (0.90 g), in 50 cm^3 acetone/ethanol, following the reported methods.[18,19] M′(Etxant)$_2$ used in the synthesis were prepared by known methods.[13] To the above K[M′(Etxant)$_3$] solution 25 cm^3 (2 mmol/1 mmol) $AgNO_3$ (0.34 g), Tl_2SO_4 (0.50 g), $Pb(NO_3)_2$ (0.33 g), $Co(NO_3)_2 \cdot 6H_2O$ (0.29 g), or $Ni(NO_3)_2 \cdot 6H_2O$ (0.29 g) dissolved in 80:20 water-acetone/water-ethanol (v/v) was gradually added with constant stirring. All the heterobimetallic complexes which precipitated as fine crystalline material were filtered, washed with acetone-water/ethanol-water 50:50 (v/v) mixture and finally with ether, and dried in vacuum. Our attempts to synthesize similar compounds with Cu(II), Fe(II), and Mn(II) were not successful.

Analysis and Physical Measurements: All the complexes were analyzed for their metal contents following standard literature procedures.[20] Sulfur was estimated as barium sulfate. Carbon and hydrogen were determined microanalytically on a Perkin-Elmer 240C model microanalyzer.

The molecular weight of soluble complexes was determined cryoscopically in benzene. The experimental details pertaining to the measurements of electrical conductance, room temperature magnetic susceptibility, recording of electronic and infrared spectra as Nujol mull were the same as described earlier.[16] The absorption spectra of soluble complexes were obtained in $CHCl_3$, THF, DMSO, and pyridine. The infrared spectra were recorded on Perkin-Elmer 783 spectrophotometer. ^{1}H and ^{13}C NMR spectra of the complexes were recorded in $CDCl_3$ while that of potassium ethylxanthate in DMSO-d_6 using TMS as internal reference. The relevant analytical and physicochemical data are give in Tables 1, 2, and 3.

Results and Discussion

The analytical data show the formation of the heterobimetallic xanthates of general formulae M[M′(Etxant)$_3$] or M[M′(Etxant)$_3$]$_2$. The compounds are formed according to the following equations.

[1] M′(Etxant)$_2$+KEtxant ⟶ K[M′(Etxant)$_3$]

[2] K[M′(Etxant)$_2$]+MNO_3/M_2SO_4 ⟶ M[M′(Etxant)$_3$]$_2$+KNO_3/K_2SO_4

[3] $2K[M'(Etxant)_3]+M(NO_3)_2 \longrightarrow M[M'(Etxant)_3]_2+2KNO_3$

M′=Ni(II), Pb(II), Cd(II)

M=Ag(I), Tl(I), Ni(II), Co(II), Pb(II).

All the complexes are insoluble in water and common organic solvents, such as ethanol, methanol, acetone, but M[M′(Etxant)$_3$]$_2$ are considerably soluble in chloroform and benzene. M[M′(Etxant)$_3$] are only moderately soluble in nitrobenzene. Poor solubility of M[M′(Etxant)$_3$] indicates their polymeric nature. Electrical conductance value 1.10—4.95 S cm^2 mol^{-1} in 10^{-3} nitrobenzene solution indicate their nonionic nature.[21] The observed molecular weight for M[M′(Etxant)$_3$]$_2$ is well in the range of their monomeric formulation.

Magnetic and Spectroscopic (Electronic, Infrared, ^{1}H and ^{13}C NMR) Studies: The diamagnetism of Ag[Ni(Etxant)$_3$], Pb[Ni(Etxant)$_3$]$_2$, and Ni[Pb(Etxant)$_3$]$_2$ indicate square planar geometry around Ni(II).

Three bands are observed in the visible spectral region of these compounds in 14800—16000 (ν_1), 20600—21000(ν_2), and 23800—25000 cm^{-1} (ν_3) regions which are well in the range reported for square-planar Ni(II) xanthate.[22] The first two bands in each case may be assigned to $^1A_{1g}\rightarrow{}^1B_{1g}$ and $^1A_{1g}\rightarrow{}^1A_{2g}$ transitions[23] respectively in D_{4h} symmetry around Ni(II). The single electron parameter Δ_1 for these complexes have been calculated following the method of Gray and Ballhausen[24] as modified by Shupack,[25] assuming $F_2=10F_4=800$ cm^{-1} in the equation $\Delta_1=35F_4+\nu_1$. The Δ_1 values thus obtained for the above Ni(II) complexes are almost of the same magnitude as for a number of square-planar Ni(II) complexes of dithioligands[26,27] such as dithiocarbamate, isomaleonitrile dithiolate, and trithiocarbonate.

The magnetic moment of 2.90 BM and the presence of electronic spectral bands at 8700; 14080, 15400 (doublet), and 26300 cm^{-1} suggest octahedral coordination around Ni(II) in Tl[Ni(Etxant)$_3$]. These bands may be assigned to $^3A_{2g}\rightarrow{}^3T_{2g}$, $^3A_{2g}\rightarrow{}^3T_{1g}$, and $^3A_{2g}\rightarrow{}^3T_{1g}$(P) transitions[28] respectively. Splitting in ν_2 band is observed because the D_q/B value is nearly unity which is mainly due to mechanism of spin-orbit coupling where spin-forbidden transition has stolen intensity from spin-allowed transition. The μ_{eff} values (2.88—2.95 BM) for Co[Pb(Etxant)$_3$]$_2$, Co[Cd(Etxant)$_3$]$_2$, and Co[Ni(Etxant)$_3$]$_2$ and electronic spectral bands observed in the region 6000—6500, 10800—11000, 15900—16000, and 20400—20600 cm^{-1} suggest square-planar geometry around Co(II). The magnetic moments are almost temperature independent down to 90 K ruling out any possibility of antiferromagnetic interaction in these complexes. The first and third bands are assigned to $^2A_{1g}\rightarrow{}^2E'_g$ and $^2A_{1g}\rightarrow{}^2E_{2g}$ transitions respectively.[29,30] As suggested by Nishida and Kida,[30] the most characteristic band at ca. 11000 cm^{-1} for square-planar Co(II) complexes may be taken as equal to 15B which gives the value of B=720 cm^{-1}. Appearance of a broad band between 14880—16100 cm^{-1} and an additional band at 24000 cm^{-1} in Co[Ni(Etxant)$_3$]$_2$ similar to other heterobimetallic complexes of Ni(II) in the present series suggests square-planar geometry around Ni(II).

The bands occurring in the infrared spectra of M[M′(Etxant)$_3$] and M[M′(Etxant)$_3$]$_2$ in 1200—1260

cm^{-1} and 1020—1030 cm^{-1} regions are consistently assigned to ν(C-O) and ν(C=S) modes respectively,[13,16,19] which are characteristic of the C_2H_5-O-CS_2^- group. ν(C-O) is observed at a lower frequency (ca. 1170 cm^{-1}) in Tl[Ni(Etxant)$_3$]. This marked negative shift in ν(C-O) is probably due to octahedral geometry around nickel(II) as observed[18] with other octahedral complexes. The occurrence of a single band for ν(C⋯S) and its position indicate uninegative bidentate behavior of xanthate ion[31] in the above complexes.

In all the complexes, the bands occurring below 400 cm^{-1} have been tentatively assigned[18,32] to ν(M-S) modes, the lower one may be due to Ag-S, Tl-S, Pb-S and the higher one due to Co-S or Ni-S stretching modes respectively.

The purity and composition of the complexes have been confirmed by ^{1}H and ^{13}C NMR spectral studies. Proton NMR spectrum of potassium ethylxanthate yields a triplet at δ 1.32 and a quartet at δ 4.33 due to -CH_3 and -OCH_2 protons respectively. The spectra of M[M′(Etxant)$_3$]$_2$ [M=Ni(II), Pb(II); M′=Ni(II), Pb(II), Cd(II)], where both metal centers are diamagnetic show a triplet at δ 1.48—1.57 and a quartet at δ 4.57—4.62 (Fig. 1), in the intensity ratio of 3 : 2 for -CH_3 and -OCH_2 protons respectively. The downfield shifts observed for these protons as compared to the ionic potassium ethylxanthate clearly indicate the deshielding of ethoxyl protons in these complexes. For paramagnetic compounds, Co[Ni(Etxant)$_3$]$_2$, Co[Pb(Etxant)$_3$]$_2$, and Co[Cd(Etxant)$_3$]$_2$, the number of peaks (Fig. 1) for -OCH_2 protons are 5 or 6. The increased number of peaks may be due to the mixing of -OCH_2 protons attached to the paramagnetic Co(II) and the diamagnetic Ni(II), Cd(II), or Pb(II) in the heterobimetallic compounds.

^{13}C NMR spectra of the diamagnetic complexes give two signals at δ 13.8 and 67.1—68.6 for -CH_3 and -CH_2 carbons which are comparable to those reported for $Me_2AuS_2COC_2H_5$[33] in which ethylxanthate group is bidentate. However, the spectra of paramagnetic compounds (Fig. 2) show splitting in the peak appearing at δ ca. 67 due to -OCH_2 carbon indicating the presence of two different types of ethoxylcarbon arising from the influence of the unpaired electron of Co(II). But such splitting is absent in case of diamagnetic compounds.

These observations clearly indicate the presence of two different ethylxanthate moieties, one of which attached to the diamagnetic Ni(II), Pb(II), or Cd(II) and the other to the paramagnetic Co(II) center.

Effect of Solvents on the Complexes: While describing their bonding and structure on the basis of various physicochemical studies, it was considered worthwhile to see the effect of solvents on the complexes. Accordingly, they have been treated with a number of solvent and their electronic spectra studied. The effect of solvents on Co(II) and Ni(II) heterobimetallic complexes have been related to their donor numbers, dielectric constant and CB (covalent) and EB (electrovalent) parameters. The results of absorption maxima given in Table 2 show the following:

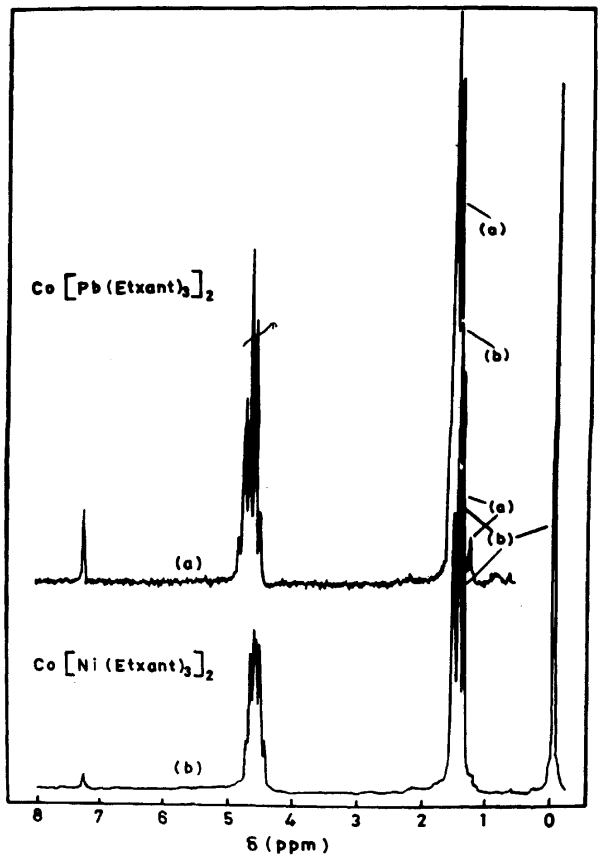

Fig. 1. ^{1}H NMR spectrum in $CDCl_3$.

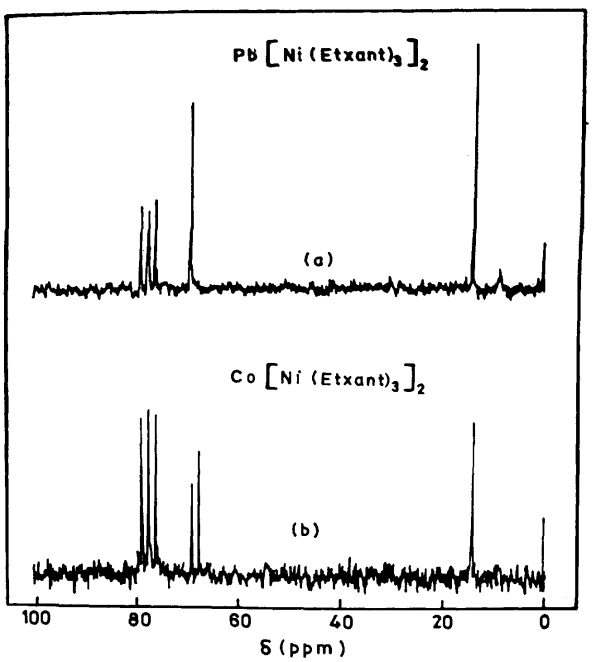

Fig. 2. ^{13}C NMR spectrum in $CDCl_3$.

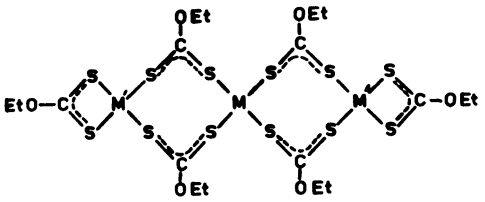
(1) The complexes Pb[Ni(Etxant)$_3$]$_2$, Ni[Pb(Etxant)$_3$]$_2$, and Co[Ni(Etxant)$_3$]$_2$ are fairly soluble in solvents, such as DMSO and pyridine, having donor number (29.8—33.1) and dielectric constant (12.3—45.0) with a change in color due to coordination of the solvent molecules. The positions of their band maxima and molar absorption coefficient at maximum (Table 2) in DMSO and pyridine clearly indicate that these solvents are coordinated to NiS_4 chromophore bringing octahedral stereochemistry around Ni(II). Co[Pb(Etxant)$_3$]$_2$ and Co[Cd(Etxant)$_3$]$_2$ are also highly soluble in the above solvents. The wavenumbers of their absorption maximum are indicative of square planar geometry around Co(II) ruling out any possibility of solvent coordination to Co(II).

(2) All the above complexes are also soluble in THF with donor number (20.0) and dielectric constant (7.3) but, as indicated by their band maxima, it does not coordinate to either Co(II) or Ni(II).

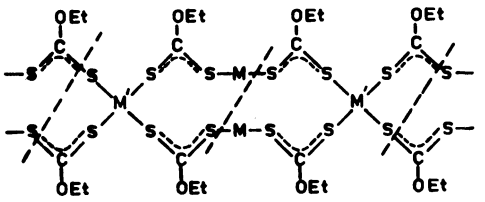
(3) The absorption maxima of the above complexes recorded in nonpolar solvents like chloroform and benzene with donor number (0.1) and dielectric constant (2.3—4.8) indicate their noncoordinating behavior.

(4) Solvents like ethanol, methanol, acetone, acetonitrile, and water having donor number (14.0—20.0) and dielectric constant (20.7—81.7) neither dissolve nor coordinate but on boiling they decompose M[M′(Etxant)$_3$] because of the disruption of -S-C-S- bridge in their polymeric structure.

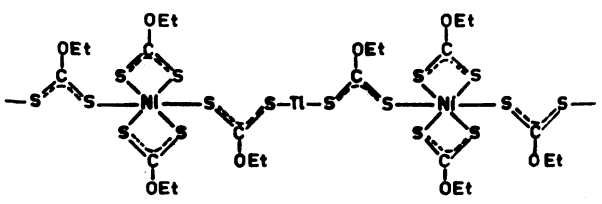
Based on chemical composition and physicochemical studies, dimeric structure (**1**) and polymeric structures (**2** and **3**) are proposed for the complexes subject to final confirmation by single crystal X-ray analysis. The arrangement of xanthate group around Ag(I) is nonlinear possibly due to d-electron contribution to the expected linear sp-hybridization scheme as observed when sulfur is the donor atom.[34,35] Zn(II), Cd(II), and Pb(II) presumably possess their preferential tetrahedral geometry as in the case of simple xanthate complexes.[36]



1. M [M′(Etxant)$_3$]$_2$



2. M[M′(Etxant)$_3$]



3. Tl[Ni(Etxant)$_3$]

Conclusion

On the basis of the foregoing studies, following conclusions are drawn regarding the present series of complexes:

(1) On the basis of the solubility and molecular weight determination, the complexes are categorised in two classes, viz., monomeric M[M′(Etxant)$_3$]$_2$ and polymeric M[M′(Etxant)$_3$].

(2) Borderline metal ions Ni(II), Co(II), Pb(II), when present together in a complex, form monomeric xanthato-bridged complex, M[M′(Etxant)$_3$]$_2$ with soft sulfur donor atoms of the xanthate moiety. However, if one of the metal ions is soft and the other is soft or borderline, e.g. Ni(II), Ag(I); Ni(II), Tl(I); Ag(I), Pb(II); Tl(I), Pb(II), polymeric bridged complexes are formed.

(3) The low-spin planar geometry of Co(II) and Ni(II) are stabilized in their heterobimetallic complexes except in Tl[Ni(Etxant)$_3$].

(4) As observed by absorption maxima and molar absorption coefficient data, solvents like pyridine and DMSO having higher donor number[37] and CB parameter (2.85—6.40)[38] show coordinating ability towards M[Ni(Etxant)$_3$]$_2$ and Ni[Pb(Etxant)$_3$]$_2$.

(5) Infrared spectral studies invariably indicate uninegative bidentate behavior of xanthate group.

(6) NMR data clearly indicate two types of ethylxanthate in the paramagnetic complexes.

The authors thank the Head of the Department of Chemistry for providing the necessary laboratory facilities. One of the authors (C.K.) is also thankful to C. S. I. R. for financial support.

Correlation of ^{13}C Shifts with Substituent Parameters in 3,4-Diphenyl-1,2,5-oxadiazole 2-Oxides Substituted at the Para-Positions of Either or Both Phenyl Rings[1)]

S. N. Balasubrahmanyam,* N. Rajendran, and D. K. Singh
Department of Organic Chemistry, Indian Institute of Science, Bangalore 560012, India
(Received November 16, 1988)

C-1′, C-1″, C-3, and C-4 ^{13}C shifts in 3,4-di(4′-or/and 4″-X)phenyl-1,2,5-oxadiazole 2-oxides (3,4-diarylfurazan 2-oxides; three series: X=NMe_2, OMe, Me, Cl, H, and NO_2) were correlated vs. seven different divided substituent parameter sets. Results have implied that i) the C-3–C-4 bond does not transmit mesomeric effects efficiently; ii) no effects can be specifically attributed to the possibility that the C-3 aryl maintains a higher dihedral angle with respect to the furoxan ring than the C-4 aryl; iii) there appears to be a directionality to the propagation of localized π-polarization due to lesser ability of C=N(O)→O to convey effects compared with C=N(O); and, iv) the furazan *N*-oxide ring, being generally an electron acceptor, transmits substituent effects nonlinearly.

Correlation of ^{13}C shifts with nonresonance and resonance effects of substituents in the two series of furazan 2-oxides, **1** and **2**, was attempted with a view to examine the consequences of known or expected presence in them of the following features:

a) There is delocalization of charge from the *N*-oxide oxygen towards C-3,[2)] a fact made use of in assigning ^{13}C shifts in the two series.[3)]

b) Transmission of polar effects are different in series **1** and **2** (contrast with polar transmission in the disubstituted series **3** could be instructive).

c) In the solution phases of systems **1** and **2**, the 4-substituted phenyl, vicinal to *N*-oxide in the former, maintains, on the average, a higher dihedral angle (θ) with the furazan ring than the similarly substituted phenyl, distant to *N*-oxide, in the latter; a parallel difference may persist between the two 4-substituted phenyls in series **3**.

Assignment of chemical shifts to C-1′, C-1″, C-3, and C-4 in the three series **1**—**3** has been described;[3)] in Table 1 are gathered the shifts of these carbons relative to those of corresponding carbons in 3,4-diphenylfurazan 2-oxide **3e**. The nature of correlation at these four centers in the three series was expected to provide information sufficient for the proposed assessments. The available substitution, however, fell short of the minimal basis requirement[4)] in three respects. A carbonyl acceptor or even a CF_3 group could not be

included because of difficulties encountered during attempted synthesis. The 4″-NMe_2 system **2a**, for the presence of which ^1H NMR evidence was available, was not formed in quantity sufficient for its ^{13}C lines to be discernible in the spectrum of its mixture with the 4′-isomer **1a**; the mixture could not be separated.[3] The line corresponding to C-1′ was obscured by other lines in the ^1H-decoupled ^{13}C spectrum of the 4′-NO_2 system **1f**. Moreover, the range of variation in chemical shift attending change in substitution was quite small at certain centers, giving room to uncertainty in correlative significance corresponding to error in measurement of small chemical shift changes. There was, however, a possibility that effects of these shortcomings could be compensated to an extent if correlation were tested vs. several different divided substituent parameter sets. The expectation was that any overall trends or consistencies seen could provide means to consider apparent correlations as significant. It has turned out that differences among the correlation coefficients are real, even based on small changes in chemical shift.

A standard statistics library routine, which included in its output certain indices of correlation (correlation coefficient r and the F-test of variance[5]), was used for carrying out the two-variable regression analyses. Data on the seven divided substituent parameter sets against which correlations were tested are listed in Table 2. Calculations, initially carried out with C-1′ and C-1″ shifts in series **3** showed good to very good correlation vs. all sets of Table 2 except set 3 (this set, developed[4] for electron-rich centers, could be inappropriate to C-1′ and C-1″ in furazan 2-oxides of type **3** which may be expected to be electron-deficient; see later discussion). Polar and resonance coefficients from the remaining sets were not dissimilar to those

found, with the same sets, for C-1 and C-4, respectively, of para-substituted benzonitriles **4** and monosubstituted benzenes **5** with the same six substituents as in series **3** (cf. C-1′, C-1″ data in Table 3C with data in Table 4AB). Therefore, seeing small changes in coefficients as reflecting real differences in transmission of effects, when the three series **1**, **2**, and **3** are compared, appeared justified. However, in the next correlation, attempted with C-1′ shifts in series **1** without a value for the NO_2 substituted system **1f**, the coefficients were found to diverge from those found for the "complete model series" of benzonitriles, monosubstituted benzenes or series **3** even though the quality of correlation had not deteriorated. Such a result could have flowed from any or all of the following reasons: i) the number of variables was too small and correlation (regression) coefficients are unstable to dropping any of them, especially the extreme ones, pertinent to NO_2 and NMe_2; ii) NO_2 was the only representative of groups that cause a positive shift (deshielding with respect to the H-system) at resonance-intensive centers; iii) numbers pertinent to NO_2 are not good in any of the parameter sets (or somewhat better in some than in others); iv) nonlinear effects underlie changes in the regression coefficients, etc. In a possible partial test, correlations were carried out with the "model series" dropping values pertinent to NO_2 and NMe_2, one at a time. Results gathered in Table 5 show that the wide divergences from coefficients obtained with the "complete set," found when NO_2 values are dropped, are not seen when NMe_2 values are dropped, pointing to the possible importance of nonlinear effects. In any case, these results were taken as strong indication that the same set of extreme substituents (i.e. NMe_2 and NO_2) should be taken if one wished to compare correlation in different series, such as the three series of furazan 2-oxides in the present instance.

A plot of C-1′ shifts in series **1** against C-1″ shifts in series **2** for the four substituents common to the two series (OMe, Me, Cl, and H) was found to be linear (Fig. 1; curve E) and it seemed valid to obtain the unavailable values (C-1′ shift in system **1f** and C-1″ shift in system **2a**) by extrapolation. Correlation parameters obtained by including these shift values form part of the listings in Tables 3A—3C. As regards the remaining centers, C-1′, C-3, and C-4 in series **2**, recalculations were carried out for the comparable centers in series **1** and **3**, omitting the NMe_2 values, and the resulting correlations are listed in Tables 6A—6C. Assessments that follow are predicated on effects perceived on both of these bases:

i) Polar coefficients in series **2** seem significantly higher than in series **1** if centers C-1′, C-1″, C-3, and C-4 of series **2** are compared, in order, with C-1″, C-1′, C-4, and C-3 of series **1**.

ii) Polar coefficients at C-3 and C-4 of series **3** are similar to those at centers corresponding, respectively,

a) Refer to Table 2. b) I: Polar or nonresonance coefficient; R: resonance coefficient; r: coefficient of correlation; F: F-test of variance. c) Correlation includes C-1′ shift in the NO_2 system **1f** obtained by extrapolation. d) Correlation includes C-1″ shift in the NMe_2 system **2a** obtained by extrapolation; correlation at the other centers, C-1′, C-3, and C-4, not including shifts pertinent to the NMe_2 system, are given in Table 6.

in series **1** and **2** i.e. C-3 in series **1** and C-4 in series **2**.

iii) The polar coefficient at C-1″ of series **2** is higher than either at C-1′ of series **1** or at C-1′ or C-1″ of series **3**.

iv) The resonance coefficient at C-1′ of series **1** is higher than at C-1″ of series **2**.

v) Consistent with this is the resonance coefficient at C-1′ being higher than at C-1″ within series **3**.

vi) There appears to be little or no transmission of resonance information along C-3–C-4 in any of the systems.

Resonance Effects. Taking resonance effects first, it is seen that effects comparable to those at β-centers in 4-substituted styrenes[4,11] are not present at C-4 in series **1**, at C-3 in series **2** or at C-3 or C-4 in series **3**. This indicated near total lack of mesomeric communication between C-3 and C-4. Furazan 2-oxides are, presumably, not unlike other 5-membered heteroaromatics in having π-character highly localized[12] between centers 2—3 and 4—5. This proposition as well as that the C-3 and C-4 para-substituted phenyls maintain different θ's was open to test by way of observations on the nature of changes in correlation of ^{15}N shifts in the three series. But constrained resources prevented procurement of enough ^{15}N enriched hydroxylamine hydrochloride to enable preparation[3] of ^{15}N enriched samples of the furazan *N*-oxides in amounts needed to measure required shifts accurately.

X-Ray crystallographic evidence has not decided the question whether the 3-phenyl normally maintains a higher θ than the 4-phenyl in 3,4-diphenylfurazan 2-oxide (**3e**) since it disclosed[12] considerable disorder in the crystalline phase of **3e**: the two phenyls exchange their respective θ's of ca. 59 and 17° in about 16% of the molecules. Clearly, intracrystalline forces play a major role here since it had been reported earlier[13] that the equivalent phenyl groups in 3,4-diphenylfurazan (**6**) are rotated out of coplanarity with the

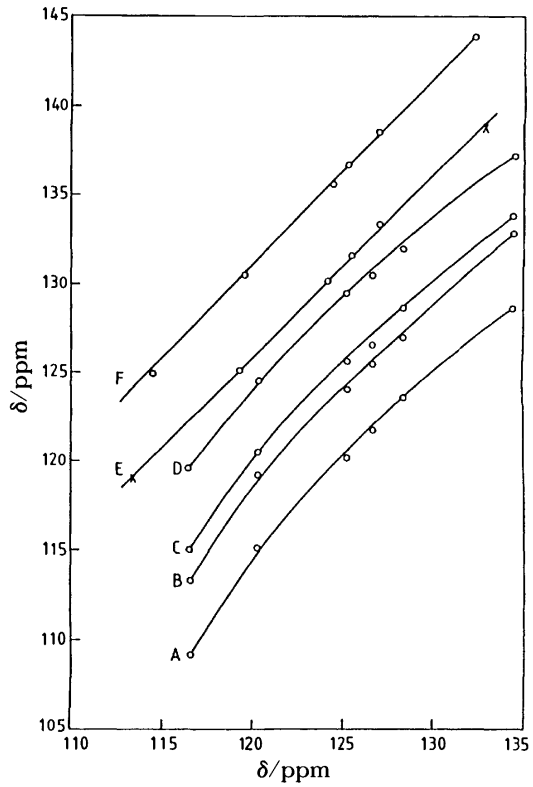

Fig. 1. Plots of ^{13}C shifts of C-1′ in series **1** (A), C-1″ in series **2** (B) and C-1′ and C-1″ in series **3** (C and D, respectively) vs. C-4 shifts in monosubstituted benzenes for the series of substituents NMe_2, OMe, Me, Cl, H, and NO_2. Plots E and F are, respectively, C-1′ shifts in series **1** vs. C-1″ shifts in series **2** and C-1′ shifts vs. C-1″ shifts in series **3**. Points obtained by extrapolation (see text) are indicated by crosses in plot E. For clarity, plots have been displaced along the ordinate as follows: A and B 0, C and D +5, E +10 and F +15 δ (ppm) units while the values on the abscissa apply to all plots.

C-3 aryl would maintain, on the average, a higher θ than C-4 aryl in the solution phases of systems **1**—**3**. Centers C-1′ and C-1″ can then be compared with C-1 centers in 4-substituted α-*t*-butylstyrenes (**7c**) and 4-substituted styrenes (**7a**), respectively. In these styrenes, increase in resonance transmission to C-1 on proceeding from **7a** to **7c** (Table 7) has been attributed to the isolation of the resonance effect at C-1 as θ increases;[11] there is also a small increase in polar transmission to C-1.[11] Resonance transmission to C-1′ in series **1** and **3** is higher than to C-1″ in series **2** and that to C-1′ is higher than to C-1″ in series **3**, both by about the same extent as it is higher at C-1 in **7c** than in **7a**. This can be taken as indicating that the C-3 aryl maintains a higher θ than the C-4 aryl. Higher polar transmission to C-1″ in series **2**, where the substituted phenyl is expected to have *lower* θ than the one in series **1**, is, however, contrary to the situation in the styrenes. This does not detract from the case for higher θ on the part of the C-3 aryl since special circumstances govern polar transmission in furazan 2-oxides, as is hoped to be shown.

It is instructive to compare series **2** with the 2-substituted diazapentadienium (aminopropenimi-

nium) salts **8** for which correlations at C-1 and C-1′ vs. the seven parameter sets are given in Table 8 (^{13}C shifts reported in Ref. 14 were used). The resemblances that both polar and resonance transmissions at C-1′ in series **8** bear to those at C-1″ in series **2** (Table 6B) are striking. Persuasive arguments were advanced[14] as demonstrating that the 4-substituted phenyl stays at right angles to the diazapentadienium plane in series **8**. Resemblances in correlation noted now show that the C-4 aryl should be taken as maintaining a high dihedral angle (ca. 90°) with the furazan oxide ring in series **2**. This contradicts arguments advanced earlier as showing that the C-4 aryl maintains *lower* θ than the one at C-3 in series **1** or **3**. Contradiction is resolved only if it is regarded that effects in series **2** and systems **8** have different bases. The lesser magnitude of the resonance coefficient at C-1″ in series **2** compared with that at C-1′ in series **1** as well as maintenance of a similar difference between C-1″ and C-1′ in series **3** could derive from a difference in onward transmission of mesomeric information. Such a difference could arise due either to the steric effect discussed above or to a directionality in the transmission of effects in furazan 2-oxides in the manner about to be described. In systems **8**, on the other hand, opposing effects could be operative at C-1′: decrease in the resonance coefficient at C-1′, caused by the side chain retaining positive charge, is counteracted by increase due to the mesomeric effect being isolated at the same center. Similarity of the coefficient at C-1′ in series **8** to that at C-1″ in series **2** is, then, only coincidental.

Polar (Nonresonance) Effects. Observations noted under i)—iii), earlier, imply a directionality to the

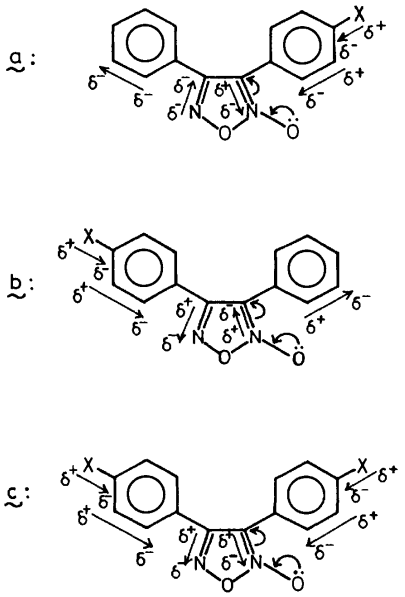

Fig. 2. Structural representations illustrative of conveyance of localized π-polarization (straight arrows) by an electron-repeller substituent X in the furazan 2-oxide series **1** (a), **2** (b), and **3** (c). The resident (mesomeric) delocalization from *N*-oxide oxygen to C-3 (curved arrows) may attenuate the ability of C-3-N-2(O)→O to convey polarization, either way, compared with C-4-N-5(O).

transmission of polar effects. Directionality can appear if the *p*-substituted phenyl maintains different θ's in series **1** and series **2** and induces *extended* π-polarization[4] to different extents at the 4-substituted styrene β-centers', C-4 in series **1** and at C-3 in series **2**. However, such cannot be the case since the sign of polarization at both centers is negative while that of extended polarization is positive[4] (whether extended polarization is active in systems like **1**, **2**, or **3**, involving nitrogen atoms as styrene β-centers, remains to be tested).

It is known that placing a conjugative group at the β-center of a styrene can change the magnitude of the 'reverse' polar effect at the α-center. In 4-substituted chalcones, for example, the effect is a substantial increase in the magnitude of the polar coefficient at C-α (I=−4.0).[4] The effect seen in series **1** and **2** is no way comparable since the value of the polar coefficient at C-3 in series **1** is lower than and that at C-4 in series **2** just about the same as at C-α in 4-substituted styrenes **7** (I=−2.4;[4] cf. relevant entries in Tables 6A and 6B); furazan 2-oxides cannot, therefore, be regarded as β-azastyrenes with a conjugative substituent at the β-atom (nitrogen).

Directionality of the type seen can derive from a difference in the behavior of C-4-N-5(O) and C-3-N-2(O)→O moieties, which constitute the furazan 2-oxide system, in transmitting a second type of polarization viz. *localized* π-polarization:[4] greater polarizability of the former can lead to greater localized effect at C-4 in series **2** or, lesser polarizability of the latter to lesser effect at C-3 in series **1** (see Fig. 2 and Tables 6A and 6B). This consideration is directly applicable to series **3** if the 'right' and 'left' sides of these systems are considered as resembling series **1** and **2**, respectively. However, the effect transmitted onward to C-3 in series **2** is greater than that transmitted onward to C-4 in series **1**. The difference could be only an apparent one since what is conveyed (inefficiently) by C-3-N-2(O)→O in series **2** is an effect that could be larger than that conveyed (efficiently) by C-4-N-5(O) in series **1**. Lesser ability of the C-3-N-2(O)→O moiety to convey localized polarization effects may derive from an intervention by the resident (mesomeric) delocalization from the *N*-oxide oxygen to C-3 (Fig. 2; curved arrows).

Evidence of 'directionality' to the transmission of polar effects is seen in the isomeric phenylfurazan 2-oxides **9a** and **9b** in which the varying substituent is

a) Correlations based on chemical shifts reported[15] for C-1′ in series **9a** and C-1″ in series **9b** for the set: X=NMe_2, NH_2, Me, Ph, SPh, Cl, H, and NO_2. b) This numbering conforms with that in furazan 2-oxides **1**, **2**, or **3**. c) Refer to Table 2. d) See footnote b of Table 3.

directly on the furazan oxide ring[15] (cf. polar coefficients at C-1′ in **9a** with those at C-1″ in **9b**; Table 9).

An interesting further observation is that *'ipso'* centers of the phenyl groups, C-1″ in series **1** and C-1′ in series **2**, exhibit polar coefficients of higher magnitude than centers nearer the sites of substitution, C-4 in series **1** and C-3 in series **2**, to which they are respectively bonded. A reason could be that phenyl groups are more easily polarized (as a whole, by the localized mechanism) than C-3-C-4 bonds in furazan 2-oxide rings, to which only a minor degree of double-bond character can be attributed ("30%" according to Ref. 12).

Nonlinear Effects. Plots of C-1′ shifts in series **1** (Fig. 1; curve A), C-1″ shifts in series **2** (curve B) and C-1′ and C-1″ shifts in series **3** (curves C and D) vs. C-4 shifts in monosubstituted benzenes with the same set of substituents are depicted in Fig. 1 (with shifts referred to TMS=0 ppm). These plots show distinct curvature in comparison with a plot either of C-1′ shifts in series **1** vs. C-1″ shifts in series **2** (curve E) or of C-1′ shifts vs. C-1″ shifts in series **3** (curve F). The gradual transition from higher to lower slope as the substituent changes from electron donor to electron acceptor contrasts with clear bilinearity exhibited by a plot of C-1 shifts in para-substituted nitrobenzenes vs. C-4 shifts in monosubstituted benzenes (Fig. 1 of Ref. 10). The contrast may be taken as evidence that the furazan 2-oxide system responds in nonabrupt manner and only reluctantly to change from electron release to electron withdrawal. The sense of the change indicates that furazan 2-oxide systems are electron accep-

tors. It remained to be tested whether a C-4 substituent is depleted of electron density to a greater extent than one at C-3 on the account that delocalization from *N*-oxide oxygen enhances electron density at C-3 considerably. A symptom of the difference between the two locations is that C-3 shifts are about 40 ppm lower than C-4 shifts in all furazan 2-oxides[3] (Table 1). An effect is also apparently conveyed (σ-inductively?) to C-1′ and C-1″ of the para-substituted phenyls: C-1′ carbons in series **1** are shifted upfield of C-1″ carbons in series **2** about 4 ppm,[3] as seen from Fig. 1 curves A and B (cf. curves C and D pertinent to series **3**).

Tests of nonlinear transmission of effects were possible:

a) The dual substituent parameter-nonlinear resonance (DSP-NLR) treatment[10] offered one possibility and was applied to C-1′ and C-1″ shifts in series **3** for each member of which measured shifts were available for the two centers. The values of the "electron demand parameter", ε, obtained by applying iterative procedure to Eq.1:

$$\Delta\delta = \sigma_I\rho_I + \sigma_R^0\rho_R/(1-\varepsilon\sigma_R^0), \quad (1)$$

were −0.44 and −0.49, respectively. While the negative signs confirmed that both centers are depleted of electron density, the difference in magnitude indicated that the C-3 substituent is less affected than the C-4 substituent, as expected. The electropositivity at C-3 of the furazan 2-oxide system, which can be considered as a net effect, is still within the range set by CF_3 ($\varepsilon=-0.42$) and COMe ($\varepsilon=-0.49$).[10]

b) It was thought possible to obtain independent check on certain of these aspects by comparing the $|B|/|r^*|$ ratio at C-1′ in series **1** and at C-1″ in series **2** with those at corresponding centers in series **3**. The ratio, which has been interpreted[9] as a measure of 'polarization' of a phenyl by such 'π-substituents' as CO_2H, CO_2R, or OH, can be obtained by carrying out regression analysis employing the three-parameter equation[9] (Eq. 2):

$$\Delta\delta = \rho^*\sigma^* + r^*\sigma^r + B \quad (2)$$

where B is a 'free' parameter used in conjunction with set 7. Since at least six values of the dependent variable were required in a three-parameter treatment, C-1′ shift pertinent to system **1f** and C-1″ shift pertinent to system **2a**, both obtained by extrapolation as described earlier, had to be included in the calculations. Results gathered in Table 10, which show greater $|B|/|r^*|$ ratio at C-1″ than at C-1′, allow the interpretation that the furazan 2-oxide system exerts greater influence through C-4 than through C-3. This accords with the following two, not mutually exclusive, possibilities:

i) A para-substituted phenyl at C-4 can exchange mesomeric information with the C-4–N-5 bond of the furazan 2-oxide system more effectively than can a similar group at C-3 with the C-3–N-2 bond because the former can maintain lower θ on the average (cf. earlier comparisons with para-substituted styrenes).

ii) Electron release from the *N*-oxide oxygen towards C-3 attenuates passage of mesomeric information to and from the para-substituted phenyl at C-3, regardless of its conformation with respect to the furazan 2-oxide ring.

A way to disentangle one possibility from the other is not apparent at this time but possibility ii) appears to have greater weightage.

It is noteworthy that the three-parameter treatment also shows higher polar effect at C-1′ (in series **1**) than at C-1″ (in series **2**). This is consistent with the proposition that higher electron density in the phenyl or para-substituted phenyl placed at C-3 makes for greater ease of its polarization through nonresonance mechanisms, a proposition considered earlier in connection with polarization being higher at centers farther from the point of substitution than those nearer.

A Recent Suggestion. Recently, a view has been projected[16] that the concept that resonance effects *complement* polar effects, underlying all efforts hitherto undertaken to separate polar from resonance effects "cleanly", could be seriously flawed. The observation that composite plots of electron-releasing and electron-withdrawing effects vs. any measurable property are bilinear must be seen as resulting from an abrupt major electronic rearrangement within a benzene ring when a π-donor substituent is replaced by a π-acceptor substituent, a rearrangement that must, naturally, affect transmission of polar effects. All hitherto employed dual parameter analyses which do not take into account this deep-seated coupling between polar and resonance effects must be regarded as misdirected. The earlier concept should be replaced by one that sees polar effects as *modified* by resonance.

Without taking a stand on this question, one can take the position that directionality to the conveyance of effects in substituted furazan 2-oxides, originating in the manner just discussed, could be a manifestation of the coupling between polar and resonance effects, since polar transmission seems to be considerably affected by delocalization from the *N*-oxide oxygen towards C-3, really a "resonance" effect. It is neces-

Table 10. Results of the Three-Parameter Correlation (Eq. 2) of C-1′ Shifts in Series **1**, C-1″ Shifts in Series **2** and C-1′ and C-1″ Shifts in Series **3**

Carbon center	ρ^*	r^*	B	r	F	$\lvert B\rvert/\lvert r^*\rvert$
C-1′ in **1**	−2.22	8.92	0.34	0.998	213.3	0.038
C-1″ in **2**	−2.06	8.83	0.84	0.998	184.6	0.095
C-1′ in **3**	−2.10	8.51	0.45	0.999	290.4	0.053
C-1″ in **3**	−2.08	8.06	0.77	0.999	311.6	0.096

sary to point out, however, that the directionality has surfaced in spite of the use of parameter sets developed by authors working in light of the earlier concept.

Oxidation of Indigo Carmine by *N*-Haloarenesulfonamidates: A Kinetic Study

PUTTASWAMY, Dandinasivara Siddalingaiah MAHADEVAPPA,* and Kanchugarakoppal Subbegowda RANGAPPA
Department of Studies in Chemistry, University of Mysore, Manasagangothri, Mysore-570006, India
(Received December 20, 1988)

Kinetics of oxidation of indigo carmine (IC) by sodium *N*-haloarenesulfonamidates (RNXNa, where R=$CH_3C_6H_4SO_2$- or $C_6H_5SO_2$- and X=Cl or Br) chloramine T (CAT), bromamine T (BAT), chloramine B (CAB), and bromamine B (BAB) in alkaline buffer (pH 9—11) has been followed spectrophotometrically at λ_{max}=610 nm. Rate law, $-d[IC]/dt=k[OX]_0[IC]_0[OH^-]^x$ where $x<1$, is obeyed. The reaction products, benzenesulfonamide and toluenesulfonamide retard the rate. Sulfonated anthranilic acid formed was quantitatively determined. Variation of ionic strength or dielectric constant of medium and addition of halide ions have no effect on the reaction. A two pathway mechanism is proposed in which the hypohalous acid (HOX) and the anion of *N*-haloamine RNX^- interact with the substrate in rate limiting steps. The rate increases in the order: BAT>BAB>CAT>CAB, which is attributed to the difference in electrophilicities of halogen cations Br^+ and Cl^+ involved in the oxidation process and the ease with which these species are formed in reactions.

Considerable attention has centered around the chemistry of *N*-haloarenesulfonamidates because of their diverse properties to act as halonium cations, hypohalites and *N*-anions which behave both as bases and nucleophiles. The subject has been reviewed by Campbell and Johnson[1] and more recently by Banerji et al.[2] The prominent members of this class of compounds are chloramine T (p-$CH_3C_6H_4SO_2NClNa\cdot 3H_2O$ or CAT) and chloramine B ($C_6H_5SO_2NClNa\cdot 1.5H_2O$ or CAB) and analytical and kinetic aspects of their reactions have been extensively studied.

Indigo carmine (IC) is employed as a redox indicator in analytical chemistry. The *N*-haloarenesulfonamides have been used for estimating this compound[3] in solution but very few kinetic studies of this indole derivative are reported in literature.[4,5] The present paper is the first report discussing the spectrophotometric kinetics of oxidation of indigo carmine by chloramine T, chloramine B, bromamine T, and bromamine B in alkaline buffer (pH 9—11) with a view to elucidate the mechanism of oxidation of the dye in solution and also to assess the relative rates of oxidation of the substrate by the *N*-haloarenesulfonamidates.

Results

The reaction was first order in $[IC]_0$ as shown by the linear plots of log(absorbance) vs. time under conditions, $[IC]_0 \ll [OX]_0$ ($r>0.9980$; $s\leq 0.03$; Fig. 1). The pseudo-first-order rate constants k' given in Table 1, were found to be independent of $[IC]_0$ confirming the first-order dependence on substrate. The rate increased with increase in $[OX]_0$ and plot of $\log k'$ vs. $\log [OX]_0$ gave a straight line with unit slope ($r>0.9982$; $s\leq 0.01$).

The rate of reaction increased with pH of medium (Table 2). Plots of $\log k'$ vs. pH were linear ($r<0.9859$; $s\leq 0.03$) with fractional slopes. Further, plots of k' vs. $[OH^-]$ were linear with a Y- intercept corresponding to a rate law of the type: rate=$a+b[OH^-]$.

Addition of reaction product, p-toluenesulfonamide (TSA) or benzenesulfonamide (BSA) to reaction mixture retarded the rate (Table 3), in oxidations involving the respective oxidants.

Ionic strength variation (0.2—0.8 mol dm^{-3}) or addition of bromide or chloride ions in the form of NaBr or NaCl (2×10^{-4}—2×10^{-3} mol dm^{-3}) had no effect on reaction. The rate was not significantly altered on varying the dielectric constant of medium by the addition of methanol (5—20% v/v).

The reaction was studied at different temperatures (298—313 K) and from the Arrhenius plots ($r>0.9961$; $s\leq 0.04$) activation parameters were calculated (Table 4).

Discussion

Investigations of Pryde and Soper,[6] Morris et al.,[7] Bishop and Jennings,[8] and Hardy and Johnston[9] on sodium *N*-haloarenesulfonamidates have shown that similar equilibria exist in acid and alkaline solutions. The following equilibria are noted in acid medium:

$$RNX\,Na \rightleftharpoons RNX^- + Na^+ \quad (1)$$

$$RNX^- + H^+ \rightleftharpoons RNXH \quad (2)$$

$$2\,RNXH \rightleftharpoons RNX_2 + RNH_2 \quad (3)$$

$$RNXH + H_2O \rightleftharpoons RNH_2 + HOX \quad (4)$$

$$HOX \rightleftharpoons H^+ + OX^- \quad (5)$$

Here X=Cl or Br and R=*p*-$CH_3C_6H_4SO_2$- or $C_6H_5SO_2$-.

The free acid RNXH and dihaloamine RNX_2 are present in fairly high concentrations in acid medium. The oxidation potential of haloamine-sulfonamide system is pH dependent[10] and decreases with increase in pH of medium. In alkaline solutions, RNX_2 does not exist, and the predominant species are RNX^-, RNXH, HOX, and OX^- ion. Hardy and Johnston[9] have calculated the concentrations of species present in alkaline BAB solutions. At pH<11, concentra-

tion of OX^- ion is small and it does not make a significant contribution to the oxidation of indigo carmine. Hence RNX^-, RNXH, and HOX are the likely oxidizing agents in alkaline solutions of *N*-haloamines.

In the present investigations, there is a first-order dependence of rate each on $[IC]_0$ and $[OX]_0$. A fractional order dependence on $[OH^-]$ is observed. The rate is retarded by the reaction product, sulfonamide (RNH_2), indicating that it is involved in a preequilibrium. Further a plot of k_{obs} vs. $[OH^-]$ is linear ($r>0.9924$; Fig. 2) with an intercept. Hence, a two pathway mechanism shown in Schemes 1 and 2 can be proposed to account for the experimental observations:

$$RNXH + OH^- \underset{}{\overset{K_1}{\rightleftharpoons}} RNX^- + HOX \quad \text{(i) fast}$$

$$HOX + IC \xrightarrow{k_2} Y \quad \text{(ii) slow}$$

$$Y + 3HOX \xrightarrow{k_3} \text{Products} \quad \text{(iii) fast}$$

Scheme 1.

$$RNX^- + IC \xrightarrow{k_4} Y' \quad \text{(i) slow}$$

$$Y' + 3\,RNX^- \xrightarrow{k_5} \text{Products} \quad \text{(ii) fast}$$

Scheme 2.

The combined rate law from Schemes 1 and 2 can be obtained as in Eq. 6:

$$\text{Rate} = \frac{k_2K_1[OX]_0[OH^-][IC]}{[RNH^-]} + k_4[IC][OX]_0 \quad (6)$$

From Eq. 6

$$k_{obs} = k' = \left[\frac{k_2K_1[OH^-]}{[RNH^-]} + k_4\right][OX]_0. \quad (7)$$

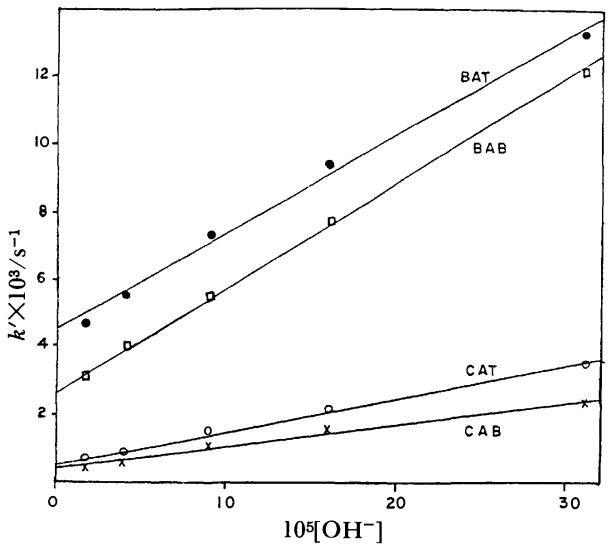

Fig. 2. Plot of k' vs. $[OH^-]$ for the oxidation of IC by *N*-haloamines.
$[OX]_0=5\times10^{-4}$ mol dm^{-3}; $[IC]_0=5\times10^{-5}$ mol dm^{-3}; $\mu=0.5$ mol dm^{-3}; temp: 30 °C.

Table 5. Variation of pH on the Rate of Reaction in Presence of Added Sulfonamide.
$[OX]_0=5\times10^{-4}$ mol dm^{-3}; $[IC]_0-5\times10^{-5}$ mol dm^{-3}; $\mu=0.5$ mol dm^{-3}; $[TSA]_a=[BSA]_a=0.001$ mol dm^{-3}. Temp: 30 °C

pH	$10^3k'/s^{-1}$			
	BAT	BAB	CAT	CAB
9.24	2.78 (3.55)	1.25 (1.85)	0.41 (0.68)	0.35 (0.52)
9.60	3.33 (3.83)	2.02 (2.23)	0.60 (0.74)	0.45 (0.56)
9.94	4.42 (4.41)	3.26 (3.03)	0.90 (0.87)	0.65 (0.64)
10.20	5.28 (5.27)	4.56 (4.23)	1.25 (1.07)	0.82 (0.75)
10.49	7.60 (7.13)	7.50 (6.77)	1.98 (1.49)	1.21 (1.01)

Values in parentheses were calculated from Eq. 7.

To test the validity of Eq. 7 the reaction was studied at different $[OH^-]$ with a constant concentration of added sulfonamide $[RNH_2]_a$ (Table 5). The concentration of RNH^- ion was obtained from the relation,

$$[RNH^-] = \frac{K_s}{K_s + [H^+]}[RNH_2]_a \quad (8)$$

where K_s is the dissociation constant of sulfonamide in aqueous solution (2.88×10^{-11} and 1.55×10^{-11} for TSA and BSA respectively at 30 °C). Plots of k' vs. $[OH^-]$ under these conditions were found to be linear ($r>0.9934$; Fig. 3) and from the slope and intercept, values of k_2K_1 and k_4 are determined:

	BAT	BAB	CAT	CAB
k_4	5.44 (6.68)	2.34 (3.12)	0.76 (1.26)	0.68 (0.98)
k_2K_1	6.42 (4.91)	5.00 (4.05)	2.10 (1.20)	0.69 (0.40)

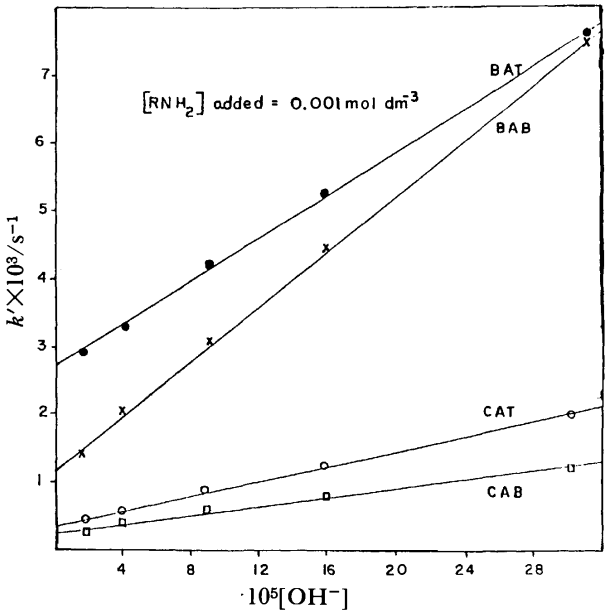

Fig. 3. Plot of k' vs. $[OH^-]$ for the oxidation of IC by *N*-haloamines in presence of added sulfonamide (RNH_2)$_a$.
$[OX]_0=5\times10^{-4}$ mol dm^{-3}; $[IC]_0=5\times10^{-5}$ mol dm^{-3}; $[RNH_2]_a=0.001$ mol dm^{-3}; $\mu=0.5$ mol dm^{-3}; temp: 30 °C.

Values of k_4 and k_2K_1 thus obtained were used to predict the rate constants k' when $[RNH_2]$ was varied in the reaction mixture. The values of k' thus obtained are shown in parenthesis in Table 3. It is seen that there is fair agreement with the experimental values. Further, a plot of k_{obs} vs. $1/[RNH^-]$ (Table 3) at constant $[OH^-]$ and $[OX]_0$ is found to be linear ($r>0.9912$; Fig. 4) and a second set of k_4 and k_2K_1 values could be extracted from these plots, which are shown in parenthesis above. These values of k_4 and k_2K_1 can be employed for predicting the rate constants k' obtained with varying $[OH^-]$ at constant $[RNH_2]=0.001$ mol dm^{-3} (Table 5). The value of k' so obtained are shown in parentheses in Table 5. Thus a fair agreement with the experimental values supports the proposed mechanism for oxidation of IC by the *N*-haloamines.

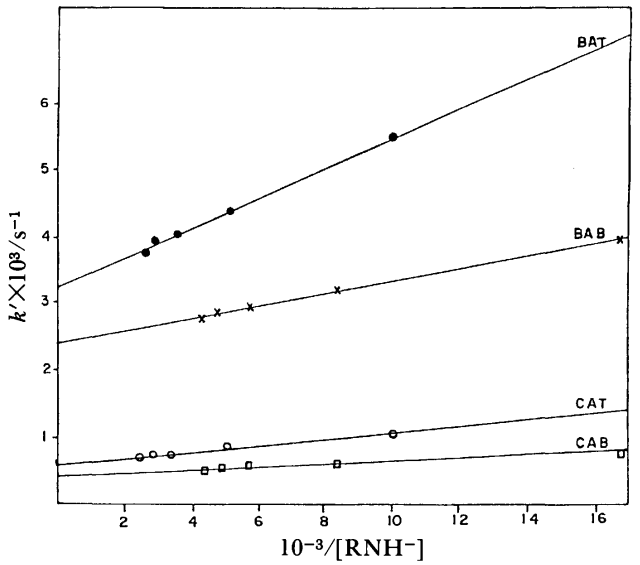

Fig. 4. Plot of k' vs. $1/[RNH^-]$ for the oxidation of IC by *N*-haloamines.
$[OX]_0=5\times10^{-4}$ mol dm^{-3}; $[IC]_0=5\times10^{-5}$ mol dm^{-3}; pH=9.94; $\mu=0.5$ mol dm^{-3}; temp: 30 °C.

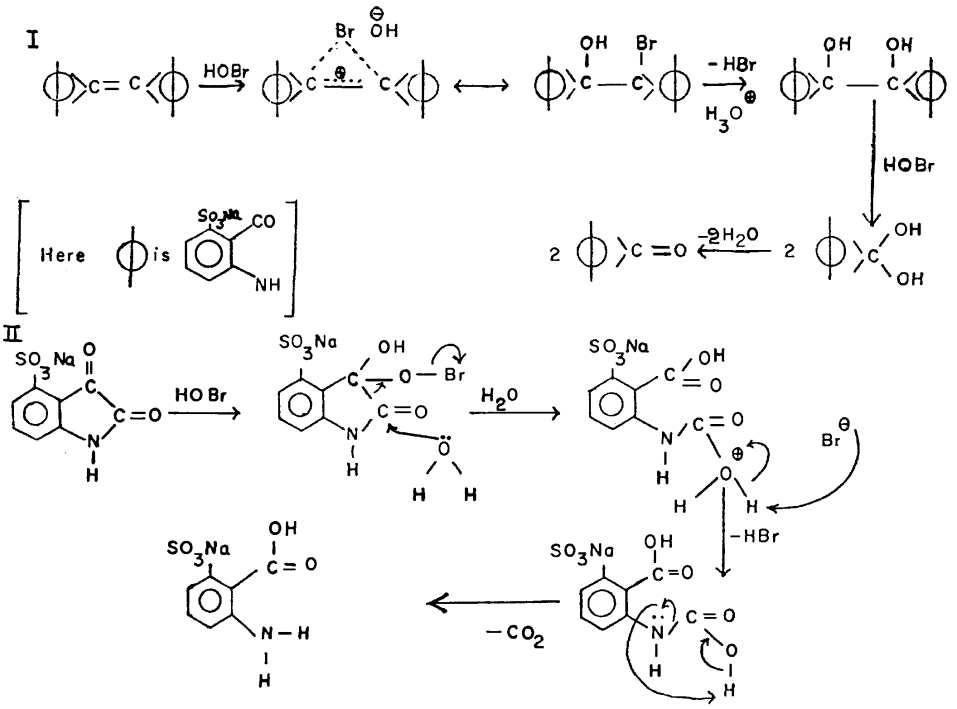
A detailed mechanism showing the electron transfer during the oxidation of indigo carmine by the *N*-haloamines is given in Scheme 3. An electrophilic attack by X^+ species of oxidant forms a halohydrin across the C-C double bond in the substrate which subsequently leads to bond rupture. Isatinsulfonate formed undergoes further oxidation to sulfonated anthranilic acid by HOX. A similar scheme can be written for the oxidation of substrate by the anion RNX^-.

The solvent isotope effect[11] shows that the rate is not very much affected in D_2O medium as OH^- ion is involved in an equilibrium (Scheme 1) and only a part of the reaction proceeds through a pH dependent path.

Variation of dielectric constant (D) of medium does not affect the rate. An explanation can be offered in terms of the Born treatment applied by Laidler[12] for a dipole-dipole reaction.

$$\ln k' = \ln k_0 + \frac{3}{8kT}(2/D-1)\left[\frac{\mu_A^2}{r_A^3} + \frac{\mu_B^2}{r_B^3} - \frac{\mu_\pm^2}{r_\pm^3}\right] \quad (9)$$

Here k_0 is the rate constant in a medium of infinite dielectric constant and μ and r refer to the dipole moment and radii of reactants A and B and the activated complex. It is seen from Eq. 9 that rates should be higher in a medium of lower dielectric constant



Scheme 3.

when $r^3_{\pm} > r^3_A + r^3_B$ indicating that the extent of charge dispersal in the transition state is different. On the other hand, $r^3_{\pm} \approx r^3_A + r^3_B$ implies the absence of dielectric effect of solvent on rate, as was observed in the present investigations.

The rates are found to be higher with BAB and BAT than the chlorine analogues by a factor of 5 (Table 1), and follow the sequence: BAT>BAB>CAT>CAB. This could be attributed, to the difference in electrophilicities of the halogen cations Br^+ and Cl^+ involved in the oxidation process and is related to the ease with which these species can be formed in reactions. A similar behavior has been noted in the oxidation of dialkylsulfides[13] and conjugated alcohols,[14] by the *N*-haloamines.

Experimental

Chloramine T (Merck) was purified by the method of Morris et al.[7]

Chloramine B was prepared[15] by passing chlorine through benzenesulfonamide dissolved in 4 mol dm^{-3} NaOH over a period of 1 h at 70 °C. The mass obtained was filtered, dried, and recrystallized from water.

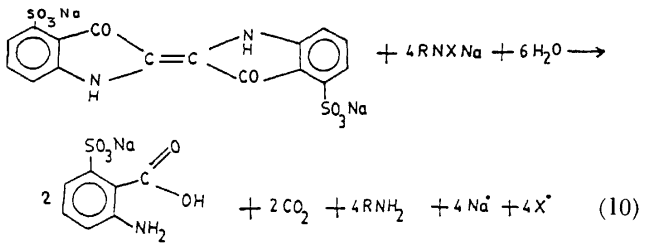
Bromamine T was obtained[16] by the partial debromination of dibromamine T (DBT). To a solution containing ca. 20 g of CAT in 400 ml of water, about 4 ml of liquid bromine were added dropwise from a microburette, with constant stirring at room temperature. The dibromamine separated out was filtered under suction, washed thoroughly with water until all the absorbed bromine was completely eliminated and then vacuum dried for 24 h. About 20 g of DBT was dissolved with stirring in ca. 30 ml of 4 mol dm^{-3} NaOH at room temperature and the resultant aqueous solution was cooled in ice. Pale yellow crystals of BAT formed were filtered under suction, washed quickly with the minimum amount of ice cold water, and dried over P_2O_5.

Bromamine B was prepared[17] by the partial debromination of dibromamine B (DBB) which was obtained as follows: Pure chlorine was bubbled through an aqueous solution of CAB (30 g in 560 ml of water) and liquid bromine (6 ml) was added dropwise from a burette with constant stirring. The yellow precipitate of DBB formed was thoroughly washed with water, filtered under suction and dried in a vacuum desiccator. Dibromamine B (31.5 g) was digested in small lots with constant stirring in 50 ml of 4 mol dm^{-3} NaOH. The mass was cooled in ice, filtered under suction and the product dried over anhydrous calcium chloride.

The purity of all oxidants was checked by iodometric assay of the active halogen and by recording their Fourier transform ^{1}H and ^{13}C NMR spectra. Aqueous solutions of compounds were standardized by the iodometric method and preserved in brown bottles to prevent photochemical deterioration.

Aqueous solutions of indigo carmine (Merck) were prepared. Koch-Light (England) benzenesulfonamide and *p*-toluenesulfonamide were used. All other reagents were of Analar grade. Heavy water (99.2%) employed for solvent isotope studies was supplied by the Bhabha Atomic Research Centre, Trombay, India. The ionic strength of system was kept at a high value with a concentrated solution of sodium perchlorate. Standard buffer systems (borax+NaOH)[18] were used. The pK_s values of sulfonamides were determined by emf methods. Regression analysis of experimental data to get the regression coefficient r and s, the standard deviation of points from the regression line were performed on a TDC-316 computer and EC-72 statistical calculator.

Stoichiometry. Varying ratios of oxidant to indigo carmine in presence of buffer (pH 9.94) were equilibrated at 30 °C for 24 h. The unchanged oxidant in the reaction mixture was determined by iodometric titrations. The analysis showed that one mole of IC reacted with four moles of oxidant. The observed stoichiometry is shown by Eq. 10:



(10)

Here R=*p*-$CH_3C_6H_4SO_2$- for CAT and BAT and $C_6H_5SO_2$- for CAB and BAB; X=Cl or Br.

Product Analysis. *p*-Toluenesulfonamide was detected by paper chromatography. Benzyl alcohol saturated with water was used as the solvent with 0.5% vanillin in 1% HCl solution in ethanol as spray reagent (R_F 0.905). Benzenesulfonamide was identified by TLC using pet. ether-$CHCl_3$-1-butanol (2:2:1 v/v) as the solvent system and iodine as spray reagent (R_f 0.88). The anthranilate was precipitated as its zinc salt.[19] To the reaction mixture calculated volumes of 1 mol dm^{-3} NaOH were added followed by 10 ml of pH 5 buffer and 10 ml of 1% zinc sulfate. The ppt formed was filtered, dried at 105—110 °C and weighed; recovery of $(C_7H_6O_2N)_2$ Zn was 85—90%.

Kinetic Procedure. The kinetic runs were carried out under pseudo-first-order conditions. The course of reaction was followed spectrophotometrically by measuring the absorbance of unreacted indigo carmine at 610 nm using an Elico Model CL 24 spectrophotometer, for three half-lives. Plots of log(absorbance) versus time were linear. The pseudo-first-order rate constants (k') calculated from these plots were reproducible within ±3%.

Ortho Effects in Organic Molecules on Electron Impact. 20. Parallel Oxygen Transfers from Nitro Group to Sulfur and Acetylenic Triple Bond in 3-(*o*-Nitrophenylthio)-1-propynes

D.V. RAMANA* and N. V. S. RAMA KRISHNA
Department of Chemistry, Indian Institute of Technology, Madras 600036, India
(Received January 5, 1989)

Oxygen transfers from nitro group to both the sulfur and acetylenic triple bond are noticed in parallel fragmentation pathways during the electron impact induced decompositions of 3-(*o*-nitrophenylthio)-1-propynes. Single oxygen transfer from nitro group to sulfur leads to abundant ions corresponding to *o*-nitrosobenzenesulfinyl cation and $[M-SO]^{+\cdot}$ while a concerted double oxygen transfer to sulfur followed by ejection of SO_2 from the rearranged molecular ion affords intense quinoline radical cation. Further, a single oxygen transfer to acetylenic triple bond, followed by a simple cleavage produces intense fragments corresponding to *o*-nitrosobenzenethiol radical cation at *m/z* 139 and *o*-nitrosophenylthio cation at *m/z* 138. The proposed fragmentation pathways and ion structures are established through high-resolution data, collision-induced dissociation (CID) mass-analyzed ion kinetic energy (MIKE) spectra, B/E linked scan spectra and chemical substitution.

The nitro group in the ortho position is a powerful interacting function in aromatic compounds during mass spectral decompositions. It is capable of transferring oxygens to the double bond,[1-3] heteroatoms[4,5] and activated carbon[6] in the side chain of aromatic ortho-disubstituted compounds. Recently the ortho interaction of nitro group with acetylenic triple bond is described[7] through an oxygen transfer producing abundant aroyl cations in (*o*-nitrophenyl)phenylacetylenes. Sulfur in the form of a thiocarbonyl[8,9] and a sulfide[10,11] is known to interact with the nitro group by accepting one or more oxygen atoms with the subsequent expulsions of SO and SO_2. It is also shown[12] that the oxygen transfer from the nitro group to the acetylenic triple bond is more predominant than to the sulfur when both were present together in the side chain as in (*o*-nitrophenylthio)phenylacetylenes. In the present study the mass spectral decompositions of 3-(*o*-nitrophenylthio)-1-propynes have been undertaken to assess the relative interacting abilities of sulfur and carbon-carbon triple bond to accept oxygens from ortho nitro group under electron impact conditions when a methylene group is inserted between sulfur and acetylenic moiety (Scheme 1).

Results and Discussion

Evidence for the oxygen transfers from the nitro group to both the sulfur and acetylenic triple bond in parallel pathways is adduced from the mass spectral fragmentations of 3-(*o*-nitrophenylthio)-1-propyne (**1**). The molecular ion rearranges to 'a' after the initial single oxygen transfer from the nitro group to the sulfur (Scheme 2). An α-cleavage with respect to sulfur in 'a' affords 'b' at *m/z* 154 (87). The accurate mass of this fragment, as determined by high-

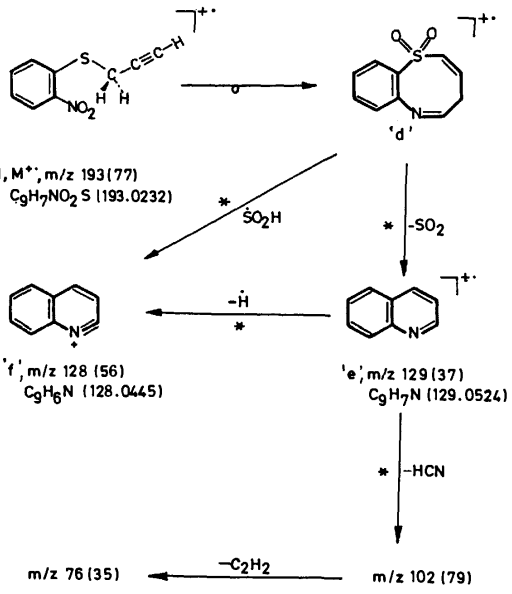
Table 2. B/E Linked Scan Spectra

Parent ion	Daughter ions with relative abundances in parentheses
$M^{+\cdot}$, *m/z* 193 of compound **1**	176(5), 163(5), 154(58), 147(3), 145(100), 139(82), 138(78), 129(65), 128(75), 122(34), 96(20).
c, *m/z* 145 of compound **1**	144(100), 115(60), 106(21).
i, *m/z* 139 of compound **1**	138(32), 120(8), 111(40), 106(50), 95(8), 78(36).
$M^{+\cdot}$, *m/z* 225 of compound **6**	186(30), 170(65), 106(100).
$M^{+\cdot}$, *m/z* 177 of compound **8**	160(50), 131(40), 123(80), 122(100).

resolution technique is 153.9981 (Table 1) which corresponds to an elemental composition of $C_6H_4NO_2S$. Furthermore, examination of the B/E linked scan spectrum of $M^{+\cdot}$ of **1** (Table 2) revealed that the ion 'b' at *m/z* 154 is directly formed from the molecular ion. The ion at *m/z* 154 could also arise by a simple α-cleavage with respect to the sulfur in the molecular ion prior to the oxygen transfer. However, such a cleavage can, in principle, occur in the para-isomer (**2**) as well. But the intensity of the ion at *m/z* 154 in the mass spectrum of para-compound (**2**) is insignificant (Table 3). Therefore an ortho interaction is invoked for the formation of this fragment at *m/z* 154. Further the collision-induced dissociation (CID) mass-analyzed ion kinetic energy (MIKE) spectrum of the ion 'b' at *m/z* 154 from **1** is found to be identical (Fig. 1) with that of the ion at *m/z* 154 derived from bis(*o*-nitrophenyl) disulfide (reference compound). Since the fragment at *m/z* 154 in the reference compound is obtained as a result of a simple cleavage, an *o*-nitrosobenzenesulfinyl cation structure can be assigned to it. By the comparative study of the CID MIKE spectra of (Fig. 1) the ion 'b' from **1** and the fragment at *m/z* 154 from the reference compound an *o*-nitrosobenzenesulfinyl cation structure is proposed for the ion 'b' at *m/z* 154 in **1**.

The other characteristic ion resulting from the single oxygen transfer to sulfur in the mass spectrum of **1** is at *m/z* 145(45). Loss of 'SO from the rearranged molecular ion 'a' produces the $[M-SO]^{+\cdot}$ ion 'c' at *m/z* 145 (Scheme 2). The elemental composition C_7H_7NO (145.0531) for 'c' is in good agreement with the proposed elimination of 'SO' from the molecular ion and its direct formation is supported by the B/E linked scan spectrum of $M^{+\cdot}$ of **1** (Table 2). A 1-nitroso-2-(1,2-propadienyl)benzene radical cation structure is proposed for 'c' at *m/z* 145 in **1**, based upon the accurate mass measurements and secondary fragmentations of 'c'.



Scheme 3.

The most interesting decomposition mode in the mass spectrum of **1** is the expulsion of SO_2 and SO_2H radical in parallel fragmentation pathways from the molecular ion giving rise to intense ions at *m/z* 129(37) and 128(56), respectively (Scheme 3). The transfer of two oxygens from nitro group to sulfur followed by cyclization leading to the rearranged molecular ion 'd' is envisaged as an intermediate for this process. The rearranged molecular ion 'd' on ejection of SO_2 affords the abundant ion 'e' at *m/z* 129(37) (Scheme 3). Further loss of $\dot{H}$ from 'e' gives rise to an ion 'f' at *m/z* 128 (Scheme 3). The formation of 'f' at *m/z* 128 also takes place through a concerted elimination of SO_2H radical from 'd' as evidenced from the B/E linked scan spectrum of $M^{+\cdot}$ of **1** (Table 2). The elemental compositions C_9H_7N (129.0524) and C_9H_6N (128.0445) for 'e' and 'f' obtained by high-resolution technique, support the proposed elimination of SO_2 and $\dot{S}O_2H$ from the molecular ion for the formation of 'e' and 'f', respectively. Based on these facts a quinoline radical cation structure to 'e' and a dehydroquinolinium cation structure to 'f' are postulated (Scheme 3). Evidence for the proposed quinoline radical cation structure for 'e' is obtained from the observation that the CID MIKE spectra of 'e' from **1** and that of the molecular ion of quinoline, taken as a reference compound, at *m/z* 129 are superimposable (Fig. 3).

Another novel ortho interaction noticed in the mass spectrum of **1** is the formation of fragments initiated by the single oxygen migration from the nitro group to the acetylenic triple bond leading to the rearranged molecular ion 'g' (Scheme 4). An α-cleavage with respect to sulfur in 'g' affords 'h' at *m/z* 138(91) while the ion 'i' at *m/z* 139(61) is derived from a similar cleavage with an α-hydrogen migration. An *o*-nitrosophenylthio cation structure to 'h' and an *o*-

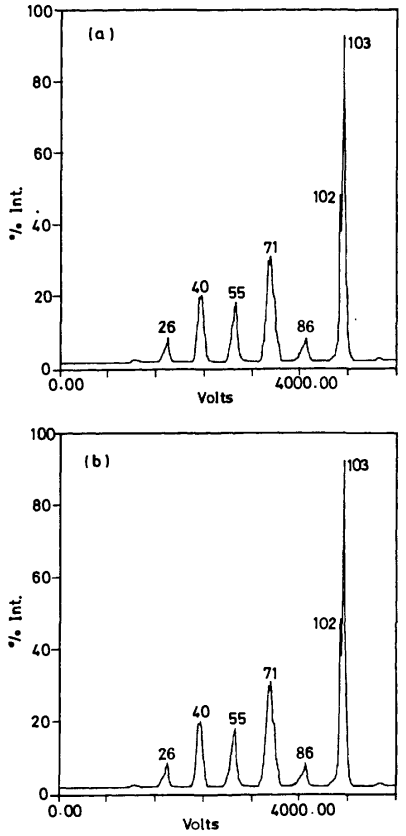


Fig. 2. CID MIKE spectra of ions at (a) *m/z* 129 of compound **1**, (b) $M^{+\cdot}$, *m/z* 129 of quinoline.

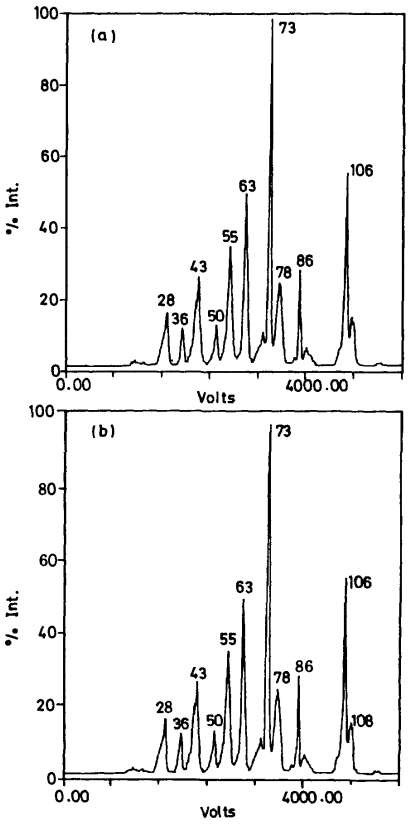

Fig. 3. CID MIKE spectra of ions at (a) *m/z* 138 of compound **1**, (b) *m/z* 138 of bis(*o*-nitrophenyl) disulfide.

nitrosobenzenethiol radical cation structure to 'i' are assigned. The elemental compositions C_6H_4NOS (138.0076) and C_6H_5NOS (139.0149) for 'h' and 'i' respectively, obtained by high-resolution technique agree with the elemental compositions of the structures proposed for the ions 'h' and 'i'. The *o*-nitrosophenylthio cation structure envisaged for 'h' at *m/z* 138 is supported by the fact that the CID MIKE spectrum of 'h' is identical (Fig. 3) with that of the CID MIKE spectrum of the ion *m/z* 138, obtained from bis(*o*-nitrophenyl) disulfide, having *o*-nitrosophenylthio cation structure.[13] The fragmentation pathways described in Scheme 4 are substantiated by B/E linked scan spectra of $M^{+\cdot}$, 'h', and 'i' (Table 2) of compound **1**. All the ions noticed in the mass spectrum of **1** as a result of ortho interaction are also present in the substituted derivative (Compound **3**) with the corresponding shifts in the *m/z* values of the ions (Table 3).

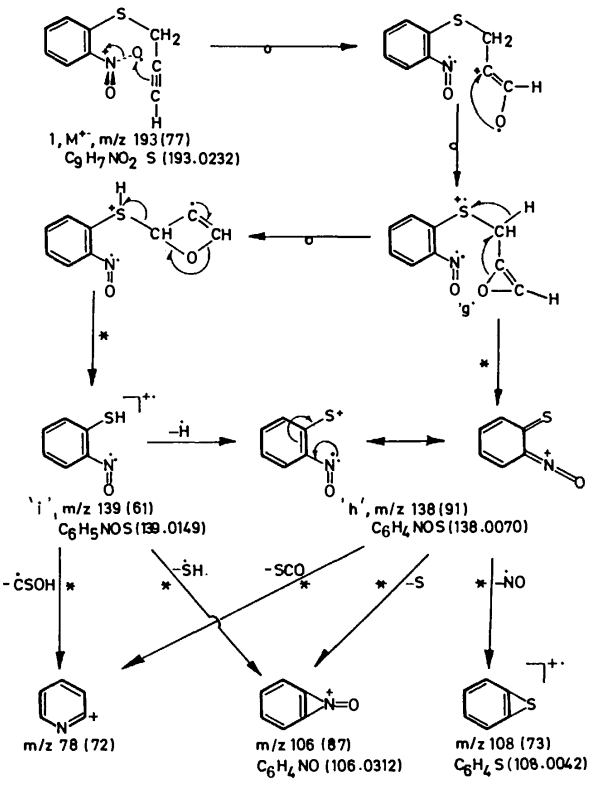
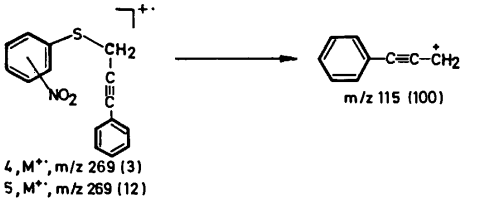
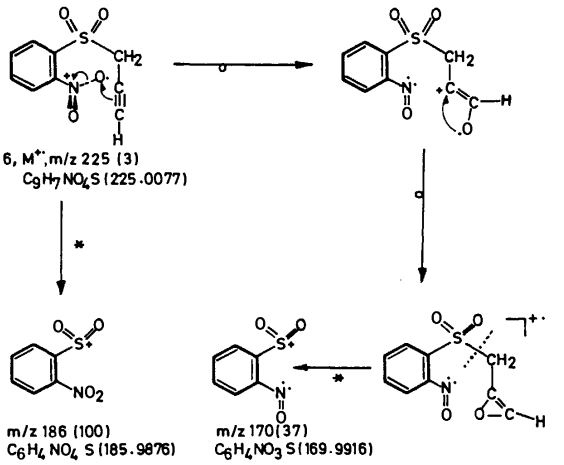


Scheme 4.



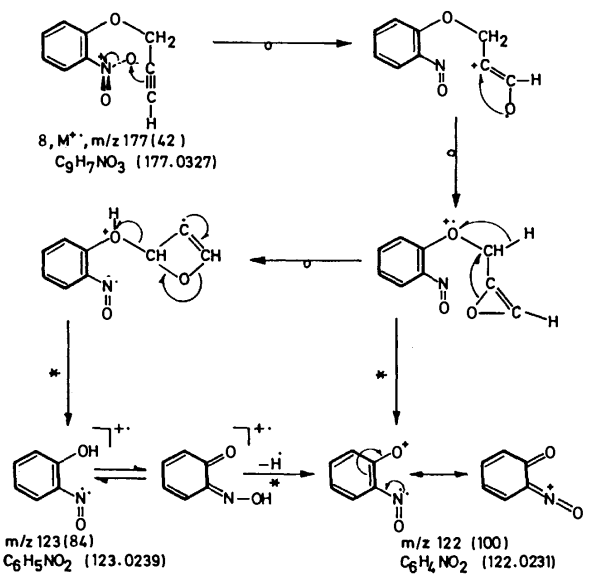
Scheme 5.



Scheme 6.

When this study is extended to 3-(*o*-nitrophenylthio)-1-phenyl-1-propyne (**4**) and its corresponding para-isomer (**5**), the chief fragment ion observed in the mass spectra of these two compounds is due to simple α-cleavage with respect to sulfur producing the stable 3-phenyl-2-propynyl cation at *m/z* 115 (Scheme 5) (Table 3). However no fragment ions corresponding to oxygen transfers from the nitro group either to sulfur or to the acetylenic triple bond are noticed in the ortho-isomer (**4**).

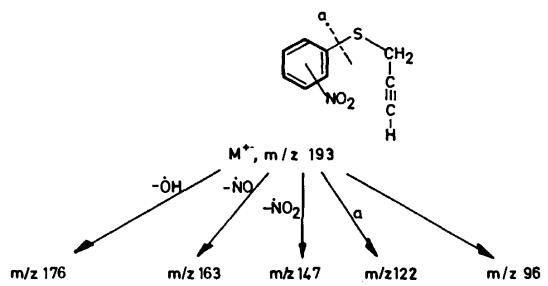
The mass spectrum of 3-(*o*-nitrophenylsulfonyl)-1-propyne (**6**) is also studied in this work to evaluate the feasibility of ortho interaction of nitro group with the side chain containing acetylenic triple bond and a sulfonyl group. The base peak in the mass spectrum of **6** is due to simple α-cleavage with respect to sulfonyl group producing the ion at *m/z* 186(100) (Scheme 6). Another intense ion observed in the mass spectrum of this compound is due to an oxygen transfer from nitro group to acetylenic triple bond followed by simple cleavage affording the ion at *m/z* 170(37) (Scheme 6). The oxygen analogue of compound **1** i.e., 3-(*o*-nitrophenoxy)-1-propyne (**8**), shows in its mass spectrum, the base peak at *m/z* 122(100) corresponding to oxygen migration from nitro group to acetylenic triple bond followed by simple cleavage



Scheme 7.

(Scheme 7). The same migration process leads to another intense ion at m/z 123(84) by an α-hydrogen transfer followed by simple cleavage from the rearranged molecular ion (Scheme 7). The fragmentation pathways described in Schemes 6 and 7 are substantiated by B/E linked scan spectra (Table 2) and accurate mass measurements (Table 1). It can be noticed from this comparative study of sulfur and oxygen compounds that the ortho interactions of nitro group are noticed with both sulfur and acetylenic triple bond as expected in compound **1** while fragments corresponding to the ortho interaction of the nitro group with the triple bond only are noticed in oxygen analogue (Compound **8**). These fragmentations due to the ortho interactions are of either negligible abundance or totally absent in the corresponding para-isomers (**2** and **9**) (Table 3). In the absence of these ortho interactions, the para-isomers (**2** and **9**) show almost similar fragmentation process (Table 3). The other common fragments observed in **1** and **2** are shown in Scheme 8.

It can be inferred from this study that the oxygen transfers from the nitro group to both sulfur and acetylenic triple bond are equally facile even when a methylene group is interjected between sulfur and acetylenic moiety. It can also be noticed that the carbon-carbon triple bond continues to act as a good oxygen acceptor even when placed one carbon atom away from sulfur. Another interesting aspect observed in this study is that while the sulfur is accepting two oxygens from nitro group, the acetylenic function is able to take only one oxygen, perhaps due to the unfavorable transition states required for the transfer of both the oxygens. Further, it can also be observed that if sulfur already possess oxygens as in the case of sulfone **6**, or if the sulfur is replaced by an oxygen as in the case of ether **8**, the oxygen transfer to the acetylenic triple bond is still noticed.



Scheme 8.

Experimental

Compounds **1** to **3** were prepared from the appropriate nitrobenzenethiol and 3-bromo-1-propyne by mechanically stirring for 6 hours in *N,N*-dimethylformamide solvent in the presence of potassium carbonate according to the general procedure reported in the literature.[14] Compounds **4** and **5** were synthesized by the same general procedure using appropriate nitrobenzenethiol and 3-bromo-1-phenyl-1-propyne. The 3-bromo-1-phenyl-1-propyne used in these reactions was prepared from phenylethyne, paraformaldehyde and phosphorus tribromide according to the literature[15] reported procedure. Compounds **6** and **7** were obtained through oxidation of **2** and **4** respectively using hydrogen peroxide in acetic acid at room temperature. Compounds **8** and **9** were prepared from the appropriate nitrophenol and 3-bromo-1-propyne using the same procedure reported for **1** to **3**.

All the compounds studied were recrystallized to constant melting point and their purity was checked by thin-layer chromatography (TLC). The compounds were characterized by nuclear magnetic resonance (^{1}H NMR) and infrared (IR) spectral data. Table 4 gives the yield, melting point (uncorrected), and microanalytical data for the hitherto unreported compounds discussed in this work. The low-resolution mass spectra were taken on a Varian MAT CH-7 and Finnigan MAT 8230 mass spectrometers. The spectra were run at 70 eV or with an emission current of 100 μA. All the compounds were introduced into the mass spectrometer through the direct probe insertion at probe temperatures varying between 30 and 110 °C.

Accurate mass measurements were carried out at a resolution of 7000 (10% valley) with Finnigan MAT 8230 double focussing mass spectrometer using peak-matching technique and PFK was used as reference. The B/E linked scan spectra in the first field free region were investigated with VG micromass 7070-H and Finnigan MAT 8230 mass spec-

a) Solvent used for crystallization is benzene-hexane.

trometers. The collision-induced dissociation (CID) mass-analyzed ion kinetic energy (MIKE) spectra were measured using VG analytical ZAB 2F double focussing mass spectrometer with the following conditions: electron energy 70 eV, electron trap current 200 μA, accelerating voltage 6 kV and ion source temperature 200—300 °C. The ions of interest were focussed magnetically into the 2nd FFR and the MIKE spectrum obtained by scanning the ESA voltage. The collision was achieved by introducing 'He' gas into the collision cell of the 2nd FFR at such a rate that the intensity of the main beam was reduced to 50%.

The authors thank Prof. J. H. Beynon and Mr. Dipankar Ghosh, University College of Swansea, Swansea, UK for providing CID MIKE spectra and RRL, Hyderabad, India for few B/E linked scan spectra. Acknowledgements are due to RSIC, IIT, Madras, for high-resolution data. One of us (NVSRK) thanks CSIR, India for a research fellowship.

Stopped-Flow Kinetic Investigations of One-Electron Transfer Reactions of Phenothiazines and Their Radical Cations in Aqueous Solution

Lakshmanan VENKATASUBRAMANIAN and Pichai MARUTHAMUTHU*
Department of Energy, University of Madras, A. C. College Campus, Madras 600025, India
(Received March 14, 1989)

The kinetics of one-electron oxidation of the protonated forms of phenothiazines namely, chlorpromazine ($CPZH^+$) and promethazine ($PMZH^+$) with the inorganic peroxides, peroxomonosulfate and peroxodisulfate in aqueous medium, were investigated by stopped flow spectrophotometric technique. The reactions of both the phenothiazines obeyed a total second-order kinetics, first-order each with respect to [phenothiazine] and [peroxide]. Both peroxides generated radical cations from the respective phenothiazines by one-electron transfer. The radical cations, $CPZH^{\cdot 2+}$ and $PMZH^{\cdot 2+}$ were found to oxidize ascorbic acid generating the parent compounds, whereas $CPZH^{\cdot 2+}$ alone was able to react with sulfite, thiosulfate and dithionite to regenerate $CPZH^+$. The kinetics of all these reactions were investigated and discussed.

There is currently a considerable interest focussed on the thermal and photoinduced electron-transfer reactions of phenothiazines and their radical cations. The primary interest in this group of compounds

Phenothiazine	H	H
Chlorpromazine	$(CH_2)_3$-N$(CH_3)_2$	Cl
Promethazine	$CH_2CH(CH_3)N(CH_3)_2$	H

stems from two aspects: (i) they undergo reversible one-electron redox reaction and (ii) the possible use of phenothiazines as photoredox sensitizers in solar energy conversion systems.[1-3] Furthermore, the diamine derivative of phenothiazine in conjunction with Fe(II) constitutes one of the most studied systems for photogalvanic effects.[4] Phenothiazine drugs have long been used for treatment of psychiatric diseases.[5-8] The effective use of *N*-alkylphenothiazines in psychiatric therapy is attributed to their redox reactivity. The sensitivity of these compounds towards chemical oxidation is well-known and it has been suggested that free-radical cations derived from them may be important intermediates in their potential biochemical action.[9-11]

In the present study, the kinetics of electron-transfer reactions of the protonated forms of phenothiazines (chlorpromazine, $CPZH^+$ and promethazine $PMZH^+$) with peroxosulfur salts, peroxomonosulfate (PMS) and peroxodisulfate (PDS) and the reactions of phenothiazine radical cations ($CPZH^{\cdot 2+}$ and $PMZH^{\cdot 2+}$) with various reducing agents, sulfite, thiosulfate dithionite, and ascorbic acid have been investigated.

Experimental

Chlorpromazine and promethazine were from Fluka (Switzerland). Peroxomonosulfate (Du Pont de Nemours & Co., USA) in the form of a triple salt $2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$ was used as such. All the other chemicals used were of the research grade available from E. Merck (India). The reaction solutions were prepared with doubly distilled water and were thoroughly deaerated by purified N_2 or Ar. The kinetic experiments were carried out in aqueous medium using stopped-flow technique. The details of the stopped-flow spectrophotometer and the kinetic analysis are given elsewhere.[12] The kinetics of the formation and decay of the radical cations were measured at their respective absorption maxima[13] ($CPZH^{\cdot 2+}$: λ_{max}=510 nm; ε=1.2×10^4 dm^{3}mol^{-1} cm^{-1} and $PMZH^{\cdot 2+}$: λ_{max}=505 nm; ε=9.5×10^3 dm^{3}mol^{-1}cm^{-1}).

Results and Discussion

Because of low solubility of the titled compounds in aqueous medium in neutral and alkaline conditions, the experiments have been limited to solution of pH<7, where the side-chain nitrogen atoms of both the phenothiazines are protonated (pK_a=9.3).[14] Hence the phenothiazines are represented as protonated forms, $CPZH^+$ and $PMZH^+$. The oxidants, peroxomonosulfate and peroxodisulfate were found to oxidize the protonated phenothiazines to their respective radical cations. The radical cations were found to be quite stable for several hours even in the presence of excess concentrations of these oxidants or in the absence of any other reducing agents. The radical cations generated with the stoichiometric amounts of the reactants (phenothiazine : peroxide=1 : 2) were stable for about a week.

All the experiments were carried out under pseudo-first-order conditions, [peroxide]≫[phenothiazine]. The kinetic runs were performed with [PMS] or [PDS]=1.0—5.0×10^{-3} mol dm^{-3} and [$CPZH^+$]=1.0—5.0×10^{-4} mol dm^{-3}; and [PMS]=1.0—5.0×10^{-3} mol dm^{-3}; [PDS]=1.0—5.0×10^{-2} mol dm^{-3}; and [$PMZH^+$]=1.0—5.0×10^{-4} mol dm^{-3}. The plots of log ($A_\infty - A_t$) (where A_∞ is the absorbance at the end of the reaction and A_t is the absorbance at time 't') vs. time for different initial [phenothiazine] were linear with

almost the same slope indicating the first-order dependence of the rate on [phenothiazine]. The pseudo-first-order rate constants for the formation of the radical cation, k_f'/s^{-1} were calculated from the slopes of the above mentioned plots. Variation of the initial [peroxide] at a fixed [phenothiazine] increased the rate and the corresponding plots of k_f' vs. [peroxide] were linear passing through the origin (Figs. 1 and 2) confirming the first-order dependence of the rate on [peroxide]. The overall second-order rate constants for the formation of the radical cation, $k_{2d}/dm^3\,mol^{-1}s^{-1}$ were evaluated from the slopes of the above plots (Table 1). From the observed kinetics the general rate law for the one-electron oxidation of phenothiazines by peroxides may be given as

$$\text{Rate}=\frac{d[CPZH^{\cdot 2+}\text{ or }PMZH^{\cdot 2+}]}{dt}=k_{2f}\,[\text{peroxide}][CPZH^{+}\text{ or }PMZH^{+}]$$

where $k_{2f}/dm^3\,mol^{-1}s^{-1}$ is the overall second-order rate constant for the formation of the radical cation.

Table 1. Rate Constants for the One-Electron Transfer Reactions of the Phenothiazines at pH 4.0 and Temp=25 °C

	Oxidizing agent	$k_{2f}/dm^3\,mol^{-1}\,s^{-1}$
$CPZH^+$	PMS	6.4×10^2
	PDS	2.1×10^2
$PMZH^+$	PMS	10.0
	PDS	3.1

It is known that both peroxomonosulfate and peroxodisulfate are potential electron acceptors and are two-electron oxidants. Even though the reactions are carried out at excess concentrations of these oxidants, the formation of only the radical cations and the absence of further reaction of these radical cations indicate that these peroxo salts undergo stepwise two one-electron reduction process, probably with the formation of $SO_4^{\cdot-}$ and $SO_4^{\cdot-}/\dot{O}H$ as the radical intermediates respectively with $S_2O_8^{2-}$ and HSO_5^-. These radical intermediates react fast with the substrates, again generating the respective radical cation.

The following mechanisms may be proposed for the reactions of the peroxides with phenothiazines.
Peroxomonosulfate:

$$CPZH^+/PMZH^+ + HSO_5^- \xrightarrow{\text{slow}} CPZH^{\cdot 2+}/PMZH^{\cdot 2+} + (\dot{O}H + SO_4^{2-})/(OH^- + SO_4^{\cdot-}) \quad (1)$$

$$CPZH^+/PMZH^+ + \dot{O}H/SO_4^{\cdot-} \xrightarrow{\text{fast}} CPZH^{\cdot 2+}/PMZH^{\cdot 2+} + OH^-/SO_4^{2-} \quad (2)$$

Peroxodisulfate:

$$CPZH^+/PMZH^+ + S_2O_8^{2-} \xrightarrow{\text{slow}} CPZH^{\cdot 2+}/PMZH^{\cdot 2+} + SO_4^{\cdot-} + SO_4^{2-} \quad (3)$$

$$CPZH^+/PMZH^+ + SO_4^{\cdot-} \xrightarrow{\text{fast}} CPZH^{\cdot 2+}/PMZH^{\cdot 2+} + SO_4^{2-} \quad (4)$$

From the magnitude of the second-order rate constants (Table 1) it is observed that peroxomonosulfate is ca. 3 times more reactive than peroxodisulfate, albeit, on thermodynamic grounds, peroxomonosulfate is more powerful than peroxodisulfate (E°_{PMS}=1.84 V[15] and E°_{PDS}=2.01 V[16]). The higher reactivity of

PMS over that of PDS has already been observed for the reactions of halide ions[17] and 2,2′-azinobis-(3-ethylbenzothiazole-6-sulfonate)[18] with these peroxides.

Among the phenothiazines investigated, chlorpromazine is found to be more reactive than promethazine. The rate constants measured for the formation of $CPZH^{\cdot 2+}$ and $PMZH^{\cdot 2+}$ by both the peroxides indicate that chlorpromazine reacts ca. 60—70 times faster than promethazine. This difference in reactivities is probably due to the difference in the redox potentials of the phenothiazines (E_{CPZ}=0.78 V and E_{PMZ}=0.86 V).[19]

Reactions of the Radical Cations. The reactions of the radical cations, $CPZH^{\cdot 2+}$ and $PMZH^{\cdot 2+}$ with reducing agents were performed using freshly prepared radical cations by the oxidation of $CPZH^{+}$ and $PMZH^{+}$ with stoichiometric amount of peroxomonosulfate. The radical cations were found to undergo one-electron reduction with ascorbic acid. The reaction of $CPZH^{\cdot 2+}$ with ascorbic acid was very fast and found to occur within the mixing time of the instrument (2 ms) even at a very low concentrations of the reactants ([ascorbic acid]=1×10^{-5} mol dm^{-3} and [$CPZH^{\cdot 2+}$]=1×10^{-6} mol dm^{-3}) and at low pH≤1. However the reactions of $PMZH^{\cdot 2+}$ with ascorbic acid ([ascorbic acid]=1.0—5.0×10^{-5} mol dm^{-3} and [$PMZH^{\cdot 2+}$]=1.0—5.0×10^{-6} mol dm^{-3}) was found to occur at convenient rates measurable by the stopped-flow technique. By pulse-radiolysis technique, Pelizzetti and coworkers[19] have reported the rate constant, k_2($CPZ^{\cdot 2+}$+ascorbic acid)=1.4×10^{9} dm^3 mol^{-1}s^{-1} at pH 5.9. Even though it is expected that decrease of pH will decrease the reactivity of ascorbic acid (AH_2) due to the acid-base equilibrium,[20]

$$AH_2 \underset{pKa}{\overset{4.25}{\rightleftharpoons}} AH^- + H^+ \qquad (5)$$

it is found that even at pH 1, the reaction between ascorbic acid and $CPZH^{\cdot 2+}$ is immeasurably fast to be monitored by the stopped-flow technique. The kinetic investigation of the reaction of $PMZH^{\cdot 2+}$ with ascorbic acid exhibited an overall second-order reaction, first-order each with respect to [ascorbic acid] and [$PMZH^{\cdot 2+}$]. The linear plots of log (absorbance) vs. time and the almost constant slope for different initial [$PMZH^{\cdot 2+}$] indicate the first-order dependence of the rate on [$PMZH^{\cdot 2+}$]. The pseudo-first-order rate constants for the decay of the radical cation, k_d'/s^{-1} were calculated from the slopes of the above plots. Increase in the [ascorbic acid] increased the rate and the plot of k_d' vs. [ascorbic acid] is a straight line passing through the origin confirming the first-order dependence of the rate on [ascorbic acid]. The slope of the above plot gives the second-order decay rate constant, k_{2d}/dm^{3}mol^{-1}s^{-1}. The rate constants for the reaction of $CPZH^{\cdot 2+}$ with the other reducing agents, SO_3^{2-}, $S_2O_3^{2-}$, and $S_2O_4^{2-}$ were also determined (Fig. 3 and Table 2; [$CPZH^{\cdot 2+}$]=1.0—5.0×10^{-4} mol dm^{-3}; [SO_3^{2-}] or [$S_2O_3^{2-}$]=1.0—5.0×10^{-3} mol dm^{-3} and [$S_2O_4^{2-}$]=1.0—5.0×10^{-4} mol dm^{-3}). There was no detectable reaction between these reducing agents with $PMZH^{\cdot 2+}$.

Fig. 3. Decay of $CPZH^{\cdot 2+}$ or $PMZH^{\cdot 2+}$: k_d' vs. [reducing agent] A: SO_3^{2-}; B: $S_2O_3^{2-}$; C: $S_2O_4^{2-}$; and D: AH_2.

Table 2. Rate Constants for the One-Electron Transfer Reactions of the Phenothiazine Radical Cations at Temp=25 °C

	Reducing agent	pH	k_{2d}/dm^3 mol^{-1} s^{-1}
$PMZH^{\cdot 2+}$	Ascorbic acid	2.2	4.1×10^5
		5.9	1.3×10^{9} [a]
$CPZH^{\cdot 2+}$	Ascorbic acid	1.0	$>10^6$
		5.9	1.4×10^{9} [a]
	SO_3^{2-}/HSO_3^-	6.0	1.2×10^4
	$S_2O_3^{2-}$	6.0	1.9×10^4
	$S_2O_4^{2-}$	6.0	1.2×10^5

a) Data from Ref. 19.

The mechanism of oxidation of ascorbic acid may be given as

$$PMZH^{\cdot 2+} + AH_2/AH^- \xrightarrow{slow} PMZH^+ + (AH^{\cdot} + H^+)/(A^{\cdot -} + H^+) \qquad (6)$$

$$AH^{\cdot}/A^{\cdot -} \xrightarrow{fast} \text{product} \qquad (7)$$

conforming to the rate law,

$$\text{Rate} = \frac{-d[PMZH^{\cdot 2+}]}{dt} = k_{2d}[PMZH^{\cdot 2+}][\text{reducing agent}].$$

From the magnitudes of the second-order rate constants for the above reaction at two different pH, 2.2 and 5.9, the reactivity of AH^- is found to be ca. 10^3 times higher than that of AH_2.

The proposed rate law and the mechanisms for the reactions of $CPZH^{\cdot 2+}$ with sulfite, thiosulfate and dithionite may be given as,

$$\text{Rate} = \frac{-d[CPZH^{\cdot 2+}]}{dt} = k_{2d}[CPZH^{\cdot 2+}][\text{reducing agent}].$$

$$CPZH^{\cdot 2+} + SO_3^{2-}/HSO_3^- \xrightarrow{\text{slow}} CPZH^+ + SO_3^{\cdot -}/SO_3^{\cdot -} + H^+ \quad (8)$$

$$2SO_3^{\cdot -} \xrightarrow{\text{fast}} S_2O_6^{2-} \quad (9)$$

$$CPZH^{\cdot 2+} + S_2O_n^{2-} \xrightarrow{\text{slow}} CPZH^+ + S_2O_n^{\cdot -} \quad (10)$$
$$(n=3 \text{ and } 4)$$

$$2S_2O_n^{\cdot -} \xrightarrow{\text{fast}} S_4O_6^{2-} + (n-3)O_2. \quad (11)$$

From the magnitudes of the second-order rate constants, the reactivity trend of the reducing agents is in the order, ascorbic acid>dithionite>thiosulfate> sulfite.

In conclusion, chlorpromazine and promethazine are oxidized to the stable radical cations, $CPZH^{\cdot 2+}$ and $PMZH^{\cdot 2+}$ by the inorganic peroxides, peroxomonosulfate and peroxodisulfate. Although these two radical cations individually oxidize ascorbic acid to revert back to the parent compounds, only $CPZH^{\cdot 2+}$ was found to react with the other reducing sulfur compounds, sulfite, thiosulfate, and dithionite.

Photoelectric Effect of Metallophthalocyanine Derivatives

Ryo HIROHASHI,* Toyohide TANAKA, Yoshihiro KOSHIJIMA, and Masafumi KAMIYAMA
Department of Image Science and Engineering, Faculty of Engineering, Chiba University, Yayoi-cho 1-33, Chiba-shi 260
(Received December 16, 1988)

Synopsis. The photoelectric effect of copper phthalocyanine derivatives ($CuPcR_4$) in a dispersed system in polycarbonate (PC) has been investigated with a sandwich-typed cell configuration of Au/$CuPcR_4$ in PC/Ag. When the incident irradiation was directed through the Ag electrode, the photocurrent and photovoltage were observed for all $CuPcR_4$ cells. It has been concluded that the photoelectric characteristics are not missed and that the values of the work functions of all $CuPcR_4$ derivatives are between 4.67 and 4.78 eV.

Metallophthalocyanines (MPc) have been shown to be characteristic of the photoconductivity between visible and infrared irradiation. These materials are used in the field of imaging technology as organic photoconductors[1] or as organic solar cells.[2] The thin films of MPc are prepared by vacuum evaporation,[3] ion sputtering,[4] and a dispersed system in a polymer.[5] We have investigated the photoelectric effect of copper phthalocyanine derivatives ($CuPcR_4$) in a dispersed system in polycarbonate. These $CuPcR_4$ were synthesized by sulfonylation of CuPc or by the Wyler method[6] of trimellitic anhydride with urea.

Experimental

Materials (Specimen). The $CuPcR_4$ derivatives used in the present experiments were synthesized by the methods shown in Fig. 1. The structures of $CuPcR_4$ derivatives are shown in Fig. 2. Though the positions of the substituents in $CuPc(CONH_2)_4$ and $CuPc(COCl)_4$ could be determined in the synthetic processes, the positions of $CuPc(SO_2Cl)_4$ obtained by a substitution reaction of CuPc could not confirmed. Purification of these $CuPcR_4$ derivatives by sublimation at about 600 °C was not successful.

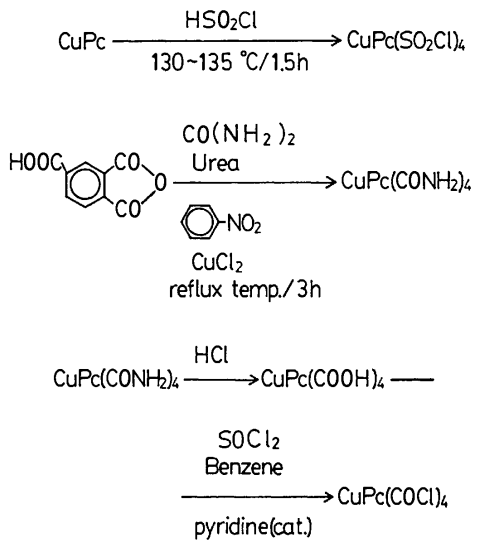

Fig. 1. The synthetic process of CuPc derivatives.

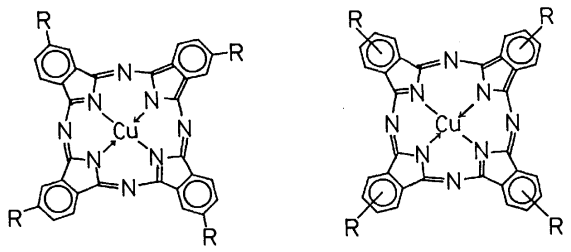

Fig. 2. The molecular structure of CuPc derivatives. The positions of the substituents in $CuPc(COCl)_4$ and $CuPc(CONH_2)_4$ are determined, but $CuPc(SO_2Cl)_4$ is not confirmed.

IR and UV Spectera. The IR spectra from 700 to 800 cm^{-1} of the $CuPcR_4$ derivatives show characteristic absorption at 740 and 790 cm^{-1}; these $CuPcR_4$ derivatives were expected to have a β-type crystalline structure.[7] The IR absorption spectra did not change upon dipping in THF (tetrahydrofuran) for about 24 hours. Since there is no good solvent for these $CuPcR_4$ derivatives, each $CuPcR_4$ derivative was dipped in hot 1-chloronaphthalene for 48 hours. The UV and visible spectral peaks, thus obtained, are shown in Table 1.

Cell Structure. A sandwich-typed cell configuration of Au/$CuPcR_4$ in PC/Ag was used in the experiment; R and PC are substituents and polycarbonate, respectively. The semi-transparent electrode of Au and Ag were coated on the sample by an ion-sputtering method. PC was used as a binder: the $CuPcR_4$ derivatives were blended with PC (weight ratio of 1 to 2) by dispersing for 48 hours with ball-milling by the addition of THF; the resulting product formed into a film by a spin-coating method. The connection between the electrode and lead wire (Ag) was made by the use of an Ag paste (Du Pont).

Measurements. Measurements of the dark current and photocurrent were carried out in a cryostat in vacuum (ca. 10^{-5} Torr; 1 Torr≈133.322 Pa) through the Au or Ag electrode. The apparatus used for the current measurement and spectroscopy were a vibrating reed electrometer (Advantest TR-84M) and a monochromator (Nikon G-250), respectively. Work functions were measured using a low-energy UPS system (Riken Keiki AC-1).

Table 1. Wavelength of Absorption Peaks

	Solution/nm		Dispersed in PC/nm	
CuPc	608	688	650	734
$CuPc(COCl)_4$	628	694	600	710
$CuPc(SO_2Cl)_4$	644	717	605	720
$CuPc(CONH_2)_4$	642	710	632	705

Wavelength of absorption peaks observed on the solution of CuPc derivatives in 1-chloronaphthalene and on the dispersed system in polycarbonate.

Results and Discussion

Dark Current. The applied field dependence of dark current for Au/CuPc$(SO_2Cl)_4$ in PC/Ag cell structure is shown in Fig. 3. The observed non-linearity indicates the presence of a barrier in this device. The highest dark conductivity is obtained in CuPc$(COCl)_4$, followed by CuPc$(SO_2Cl)_4$. The least conductive derivative on the dark state is CuPc-$(CONH_2)_4$. We can note that the dark current is affected by the structure of each molecule.

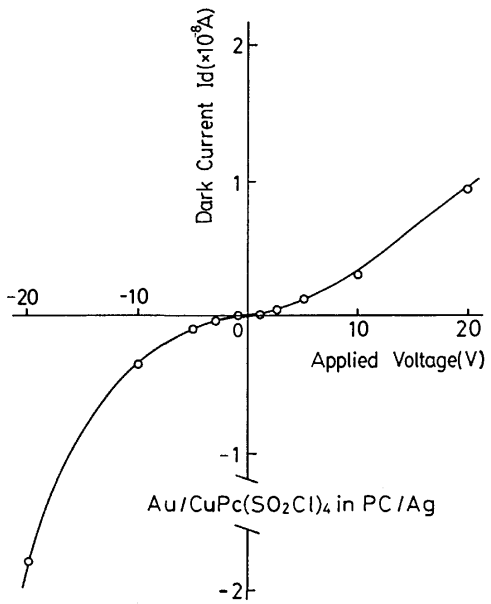

Fig. 3. Applied voltage dependence of dark current for Au/CuPc$(SO_2Cl)_4$ dispersed in PC/Ag cell structure. Applied voltage is measured on the basis of Ag electrode. Thickness of the cell is approximately 10 μm.

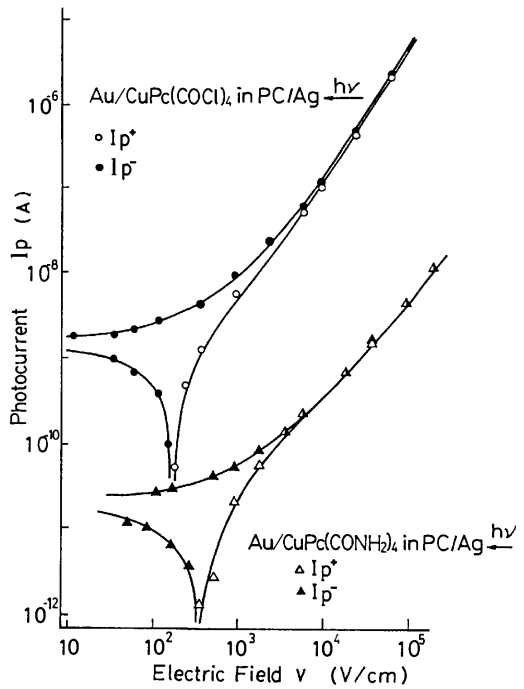

Fig. 4. Applied field dependence of photocurrent for Au/CuPcR$_4$ dispersed in PC/Ag type cells. R is substituent. The signs of I_p^+ and I_p^- represent the polarities of irradiated electrode. The magnitude of photocurrent is the absolute value.

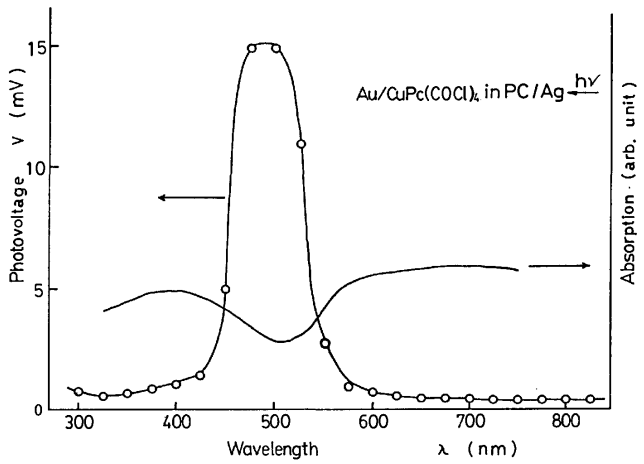

Fig. 5. Action spectrum of photovoltage for Au/CuPc$(COCl)_4$ dispersed in PC/Ag cell, and absorption spectrum of dispersed system (CuPc$(COCl)_4$ in PC. The thickness of the cell is approximately 10 μm. Irradiated electrode is Ag plane.

Photocurrent. The applied field dependences of the photocurrent are shown in Fig. 4. In this figure, the polarity signs of the current were determined by the polarity of the Ag electrode potential. The current and electric field are indicated in absolute value.[8] The photoelectric sensitivity is determined by the ratio of the photocurrent to the dark current (I_p/I_d); these ratios for CuPc$(CONH_2)_4$, CuPc$(SO_2Cl)_4$ and CuPc-$(COCl)_4$ at about 10^3 V cm^{-1} were approximately 14.5, 7.4, and 4.8, respectively. These values may be rather higher than for dispersed systems. The current tends to greatly decrease around 10^2 V cm^{-1} (Fig. 4), indicating that it comes to equilibrium between the applied voltage and photovoltage.

Photovoltage. The photovoltages of CuPc$(CONH_2)_4$, CuPc$(SO_2Cl)_4$, and CuPc$(COCl)_4$ generated by direct irradiation through the Ag electrode with a Xenon lamp, and then followed photocurrent measured by potentiometry, were approximately 200, 110, and 140 mV, respectively. When the Ag electrode is irradiated, the positive polarity of the photovoltage was obtained in all cases. The action spectrum of the photovoltage for Au/CuPc$(COCl)_4$ in PC/Ag cell is shown in Fig. 5. Due to the internal resistance of the voltmeter, the measured photovoltages are smaller than the true values, though the relative forms are not affected. In Fig. 5, the photovoltage peak is obtained in the wavelength region where absorption is the weakest. On the other hand, when the incident irradiation was directed through the Au electrode, a photovoltage was not generated. These result show that the photovoltage is generated not at the Au interface but, rather, only at the Ag interface. Consequently, a Schottky barrier could be formed between the CuPcR$_4$ and Ag interface. The work functions of Au and Ag

are 4.78 and 4.67 eV, and these interfaces form ohmic and Schottky barrier, respectively. Therefore, the values of the work function of the $CuPcR_4$ derivatives are between 4.67 and 4.78 eV.

Interaction of Sodium Dodecyl Sulfate with Pig Serum Low-Density Lipoprotein

Yuki YANO, Toshio TAKAGI,† and Masanobu JANADO*,††

(Received December 20, 1988)

Synopsis. The interaction of sodium dodecyl sulfate (SDS) with the pig serum low-density lipoprotein (LDL) showed a subtle dependence on the SDS concentration. At the SDS concentrations below 0.01%, the binding isotherm conformed to the Langmuir's type, from which the maximum number of the binding site and the intrinsic binding constant were respectively estimated to be 1600 mol mol^{-1} and 6.5×10^3 (mol dm^{-3})$^{-1}$. At the SDS concentrations at or above 0.03%, the LDL structure irreversibly dissociated.

Sodium dodecyl sulfate (SDS), a well-known protein denaturant, has been widely used for various analytical purposes in protein chemistry. The protein denaturation by SDS is believed to involve the hydrophobic binding of SDS and consequent structural unfolding of protein molecules.[1,2] Interaction of SDS with lipoproteins, the micellar complexes of lipid and protein, is expected to be more complex, as both stabilizing and destabilizing effect can be resulted depending on the SDS concentration. The serum lipoproteins in general are quite unstable, readily undergoing irreversible aggregation, particularly after separation, and that often hampers the routine biochemical analyses of the lipoproteins. In this context, elucidation of the SDS-lipoprotein interaction is not only of interest but also profitable in view of possible stabilizing effect of SDS. This communication describes the effects of SDS on the structure of the pig serum low density lipoprotein (LDL) which is known to be closely similar to the human serum LDL in the physicochemical properties.[3]

The pig serum LDL was prepared by ultracentrifugal flotation and, where necessary, separated into two fractions (LDL_1 and LDL_2) by differential flotation.[3] The LDL fractions were exhaustively dialyzed against 0.1 mol dm^{-3} NaCl containing 0.02% EDTA in which most of the measurements were conducted. (For analysis of lithium dodecyl sulfate (LDS)-LDL interaction, 0.1 mol dm^{-3} LiCl was used as the background solution.) The binding data were obtained by the frontal gel chromatography[4] as well as by the equilibrium dialysis at an LDL concentration of 0.1% with the SDS concentration varying from 0.001 to 0.033%. The velocity sedimentation was carried out in a Hitachi model SCP 70H ultracentrifuge equipped with a UV scanner, and gel filtration was performed on a Superose 6 column (1×30 cm, Pharmacia) using an FPLC system (Pharmacia). The SDS-LDL mixtures for the sedimentation and gel filtration experiments were prepared by dializing an appropriate amount of LDL solution (0.1%) against a large volume of SDS solution for 48 hours at 20 °C. Therefore, the SDS concentrations in the mixtures, denoted as [s] in the results, refer to the equilibrium concentrations of free SDS. The distribution curve of the sedimentation coefficient, $g(s)$, was produced from the differential concentration diagram (dc/dx vs. x) according to the equation,[5]

$$g(s)=\frac{1}{c_0}\frac{dc}{dx}\left(\frac{x}{x_m}\right)^2(x\omega^2t),$$

where c_0 is the initial concentration, x the distance from the axis of rotation, x_m the distance to the meniscus, and t and ω the effective centrifugation time and angular velocity, respectively.

Figure 1 shows the binding curve for SDS-LDL in 0.1 mol dm^{-3} NaCl in which the data obtained at two temperatures, 5 ° and 20 °C, were plotted according to the Langmuir's adsorption isotherm in the form,[6]

$$\frac{1}{\theta}=\frac{1}{nk}\cdot\frac{1}{[s]}+\frac{1}{n},$$

where θ is the number of moles of bound SDS per mole of LDL, n the number of the binding site on LDL molecule, K the association constant and [s] the equilibrium concentration of free SDS, respectively. Two prominent features are revealed in Fig. 1: first, at the low concentrations of SDS ([s]<ca. 0.01%) the SDS-LDL binding conforms to the Langmuir's adsorption isotherm giving a linear plot, but it breaks at around [s]=0.01% above which the plot extrapolates to $n=\infty$ and second, the SDS-LDL binding is little affected by temperature. The binding parameters of SDS-LDL at the low SDS concentrations were:

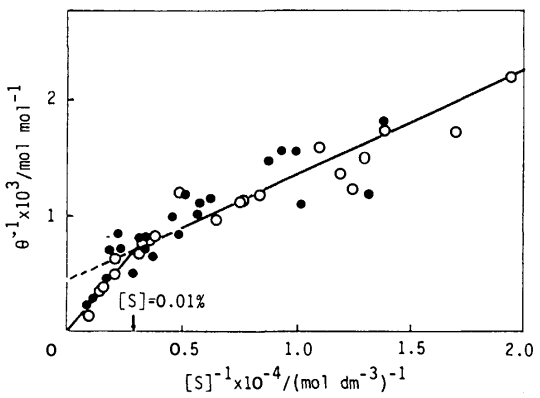

Fig. 1. Binding isotherms for SDS-LDL in 0.1 mol dm^{-3} NaCl at 20 °C (●) and 5 °C (○). θ is the number of moles of bound SDS per mole of LDL and [s] is the equilibrium concentration of free SDS. Concentration of LDL was fixed at 0.1%.

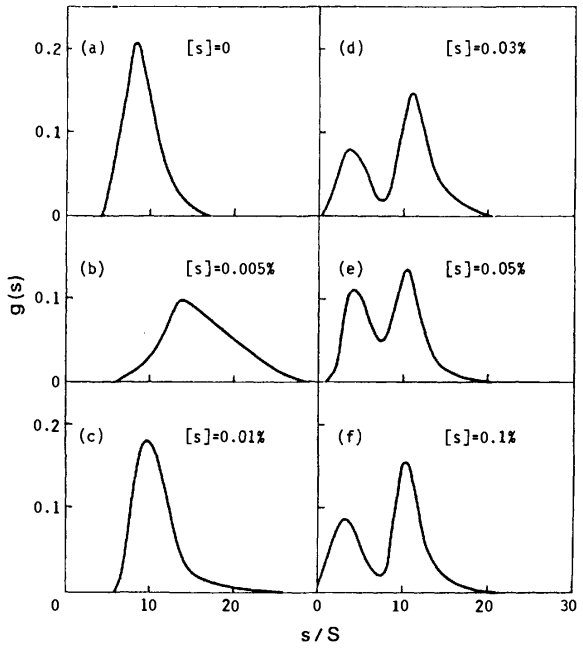

Fig. 2. Effect of SDS concentration on the distribution curve of sedimentation coefficient, $g(s)$, of LDL. [s] refers to the equilibrium concentration of free SDS in the LDL solutions. Concentration of LDL was 0.1%.

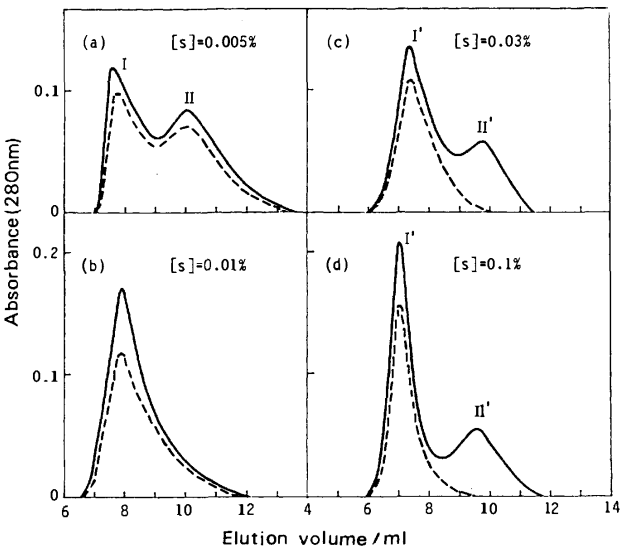

Fig. 3. Effect of SDS concentration on the gel filtration profile of LDL. [s] refers to the equilibrium concentration of free SDS. Gel filtration was performed on a column of Superose 6 (1×30 cm) preequilibrated with the eluent (0.1 mol dm^{-3} NaCl) containing SDS to the concentrations indicated by [s]. The loading concentration of LDL was 0.1%. ——, Absorbance at 280 nm; ----, Lowry's protein.

K=5×10^3 (mol dm^{-3})$^{-1}$ and n=2×10^3 mol mol^{-1}. The binding isotherm for lithium dodecyl sulfate (LDS)-LDL interaction was much similar to that of SDS-LDL interaction yielding n=2×10^3 mol mol^{-1} and K=5×10^3 (mol dm^{-3})$^{-1}$. Figure 2 shows the distribution profiles of the sedimentation coefficient, $g(s)$, of SDS-LDL (0.1%) mixtures with various SDS concentrations. At [s]=0.005% (Fig. 2b), the $g(s)$ curve was notably broad as compared to that at [s]=0 (Fig. 2a), but by increasing [s] to 0.01% it nearly restored the original profile with somewhat increased sedimentation coefficient (Fig. 2c). It is important to note that the broadening and sharpening of the $g(s)$ curves observed at the two concentrations could readily be reversed each other by adjusting [s] by dialysis. Further increases of [s] to above 0.03% caused an irreversible structural dissociation leading to bimodal $g(s)$ curves (Figs. 2d—f).

Figure 3 shows the result of gel filtration obtained for SDS-LDL (0.1%) mixtures with [s] varying from 0.005% to 0.1%. It is to be noted that, due to an LDL-gel interaction, the elution of LDL required the presence of at least 0.005% SDS in the eluent, and hence that the apparent elution volume cannot be directly related to the molecular size. The SDS effect manifested in Figs. 3a and 3b at the low concentrations ([s]<0.01%) was completely reversible, but that observed at the higher concentrations (Figs. 3c and 3d) could not be reversed. The two fractions of Fig. 3a (I and II) both contained protein (the Lowry's protein) and all the lipid components of LDL, i.e., phospholipids, neutral lipids, cholesterol and its ester, and sphingolipids. (The lipid components were identified by thin-layer chromatography after extraction in a chloroform(2)-methanol(1) mixture.) In contrast, as shown in Figs. 3c and 3d, protein was found only in fraction I', although both fractions (I' and II') contained the lipid components.

The present study shows that the mode of the interaction between LDL and SDS depends on the concentration of the latter. At the low SDS concentrations ([s]=0.005—0.01%), the binding isotherm conformed to the Langmuir's type, and the relevant thermodynamic parameters were estimated to be: $\Delta F°$=—5.0 kcal mol^{-1}, $\Delta H°$=0, $\Delta S°$=17 e.u., respectively. The entropic nature of the interaction suggests involvement of the hydrophobic effect. However, even within the narrow range of [s](0.005—0.01%), the state of LDL molecule varies with the SDS concentration: as evident from Fig. 2 (b and c) and Fig. 3 (a and b), at [s]=0.005% LDL reversibly associates to form their oligomers which, upon increasing [s] to 0.01%, dissociates into the monomeric units possessing somewhat greater sedimentation coefficients than the intact LDL. This increment in the sedimentation coefficient may be attributed to the SDS binding. The nature of the reversible association-dissociation of LDL is not clear, but it may be worth to note that a similar behavior was observed for the mixtures of the human serum LDL and dextran sulfate (DS), i.e., aggregation of LDL-DS complexes at low DS/LDL ratios and disaggregation at high DS/LDL ratios.[7,8] The former was attributed to the ionic interactions between LDL-SDS complexes and LDL molecules, and the latter to disruption of the ionic interactions consequent upon an increased binding of DS leading to an increased negative charge density on the LDL molecules. It may tentatively be assumed that a sim-

ilar mechanism operates in the present system.

Upon further increases in [s] to above 0.01%, e.g. 0.03%, the LDL structure appears to irreversibly disintegrate. Breake of the linearity of the binding isotherm at around 0.01% of [s], leading to $n=\infty$ (Fig. 1), may be indicative of a structural dissociation of LDL molecule with subsequent micellar complex formation between SDS and the dissociated LDL fragments. Indeed, this postulate is strongly supported by the sedimentation and gel filtration experiments which revealed that at high SDS concentrations ([s]$\geq$0.03%) LDL irreversibly dissociated into two fragments, an apoprotein containing fraction and a nonprotein fraction (Figs. 2d—2f, 3c, and 3d).

Since there is no additional peak detectable other than the main peak in both sedimentation and gel filtration experiments at [s]=0.01% (Figs. 2c and 2b), one may reasonably conclude that LDL molecules retain their original structures with their hydrophobic surfaces covered by the bound SDS. As expected, SDS of this concentration was found to protect LDL from the disruptive effect of NaSCN,[9] a highly chaotropic salt.

Synopsis. *fac*-(+)$_{546}$-[Cr(L-ala)$_2$(L-leu)]·1.5H$_2$O and *fac*-(−)$_{546}$-[Cr(D-ala)$_2$(L-leu)]·1.5H$_2$O were prepared by the method using an ethanol solution, with [Cr(L-leu)$_2$(NCS)(OH$_2$)](leu=leucinato) with L- or D-alanine used as the starting material respectively. Also, *fac*-[Cr(L- or D-ala)(L-leu)$_2$]·2H$_2$O was obtained from the filtrate, the standing temperatures were 5, 25, 40, and 55 °C. The optical purity of *fac*-(Λ)-[Cr(L- or D-ala)(L-leu)$_2$]·2H$_2$O increases with the rise in the standing temperature. In the case of DL-alanine, [Cr(L-ala)$_2$(L-leu)]·1.5H$_2$O and [Cr(D-ala)(L-leu)$_2$]·2H$_2$O were obtained during heating and from the filtrate respectively. By using this procedure, the possibility of the optical resolution of DL-alanine was shown.

We reported previously that tris(amino acidato)chromium(III) complexes which exhibit very high stereoselectivities were obtained by a solid state reaction[2,3] or by use of an ethanol solution.[3] However, no study has been reported concerning the preparation of chromium(III) mixed amino acidato complexes except for that of Watabe et al.[4] It is interesting to study the stereoselectivity in the case of the chromium(III) complexes involving different kinds of amino acid ligands.

We will report here the preparation of some new (mixed amino acidato) chromium(III) complexes containing L-leucine and L- or D-alanine, using [Cr(L-leu)$_2$(NCS)(OH$_2$)] as the starting material. A very high stereoselectivity was also remarked in the cases of the (mixed amino acidato) chromium(III) complexes.

An optical resolution of DL-alanine based on the different reactivities of [Cr(L-leu)$_2$(NCS)(OH$_2$)] to L- and D-alanine is suggested.

Experimental

a) Preparation of the Starting Material, [Cr(L-leu)$_2$(NCS)(OH$_2$)]·H$_2$O. A solution of Reinecke's salt, NH$_4$[Cr(NH$_3$)$_2$(NCS)$_4$]·H$_2$O (2×10^{-2} mol),[5] and L-leucine (6×10^{-2} mol) in 200 cm^3 of H$_2$O was evaporated to dryness in an evaporating dish on a water bath. The residue was washed with 80 cm^3 of H$_2$O. After air-drying, the solid was dissolved in 200 cm^3 of ethanol. After filtration, the filtrate was added to 400 cm^3 of H$_2$O, causing an immediate precipitation of the purple crystals. These crystals were subsequently dried overnight at 55 °C; yield, 21%. Found: C, 37.91; H, 6.72; N, 10.93%. Calcd for CrC$_{13}$H$_{26}$O$_5$N$_3$S: C, 38.39; H, 6.89; N, 10.34%.

b) Preparation of (Mixed Amino Acidato)Chromium(III) Complexes, [Cr(L- or D-ala)$_2$(L-leu)]·1.5H$_2$O and [Cr(L- or D-ala)(L-leu)$_2$]·2H$_2$O. A solution of [Cr(L-leu)$_2$(NCS)(OH$_2$)]·H$_2$O (406 mg: 1×10^{-3} mol) in 50 cm^{-3} of ethanol was added to L-alanine (89 mg: 1×10^{-3} mol). After the addition of 0.5 cm^3 of butylamine, the mixed solution was refluxed for 5 hours at 75 °C. Pink crystals were deposited during the heating. After immediate filtration and washing with ethanol and methanol, [Cr(L-ala)$_2$(L-leu)]·1.5H$_2$O was obtained.

The filtrate was separated into four portions, which were then placed in sealed flasks. They were kept at 5, 25, 40, and 55 °C respectively. The crystals grown in the flasks were filtered after 10 days. In spite of the difference in the standing temperature, only pink crystals of [Cr(L-ala)(L-leu)$_2$]·2H$_2$O were obtained.

By the same method, in the case of D-alanine [Cr(D-ala)$_2$(L-leu)]·1.5H$_2$O was obtained as a purplish pink powder during the heating. From the filtrate, [Cr(D-ala)(L-leu)$_2$]·2H$_2$O was obtained. With the use of DL-alanine [Cr(L-ala)$_2$(L-leu)]·1.5H$_2$O was obtained during the heating and [Cr(D-ala)(L-leu)$_2$]·2H$_2$O was obtained from the filtrate. The yields and elementary analyses are summarized in Table 1.

Measurements. The VIS-UV spectra were measured with a Hitachi 124 spectrophotometer in DMSO. The CD measurements were made with a JASCO-J-500A spectropolarimeter in DMSO.

Table 1. Analytical Data and Yields of [Cr(ala)$_x$(L-leu)$_{3-x}$](10 Days Standing)

Results and Discussion

The absorption spectral data of the mixed-tris type complexes are listed in Table 2. No splitting of the first band was observed, and the absorption coefficient of the first band is larger than that of the second band. These finding agree well with those of the reported *fac*-tris(amino acidato)chromium(III) complexes,[3] suggesting a *fac*-structure of the present tris type mixed amino acidato complexes.

The CD spectra of (+)$_{546}$-[Cr(L-ala)$_2$(L-leu)] and (−)$_{546}$-[Cr(D-ala)(L-leu)$_2$] in DMSO are shown in Fig. 1, while the numerical data are summarized in Table 2. They are very similar in shape and peak position to those of (+)$_{546}$-and (−)$_{546}$-[Cr(AA)$_3$](AA=amino acidato).[3] Comparing the CD curves of the present complexes with those reported for *Λ*- and *Δ*-[Cr(AA)$_3$], the configuration of the present complexes can be identified as *Λ* for the (+)$_{546}$- and *Δ* for the (−)$_{546}$-isomers.

As is shown in Fig. 1, the Δε values of the major components of the first absorption band of [Cr(L-ala)$_2$(L-leu)] and [Cr(D-ala)(L-leu)$_2$] were +2.38 (505 nm) and −1.81 (495 nm) respectively. We have previously reported that the absolute configuration of [Cr(L-ala)$_3$] was the *Λ*(+) form.[3] On the other hand, the tris complex containing D-alanine, which was prepared according to the literature,[3] is *Δ* form (Δε=−2.41 (495 nm)). Thus, L- and D-alanine favor the *Λ*(+) and the *Δ*(−)-product respectively. From these results, it may be seen that the absolute configuration of the mixed tris-type complexes obtained is dependent on the that of the two alanine molecules coordinated. The reason for this may be the difference in the solubilities of the diastereoisomers, although this is still not clear.

The CD spectra of [Cr(L-ala)(L-leu)$_2$], which was obtained at 5, 25, 40, and 55 °C, are shown in Fig. 2, while the numerical data are summarized in Table 2,

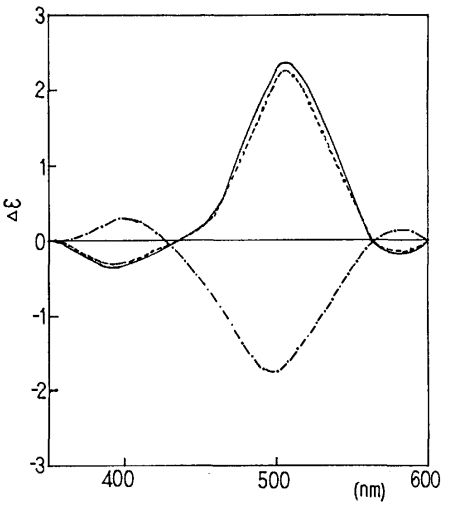

Fig. 1. The CD spectra of *fac*(+)$_{546}$-[Cr(L-ala)$_2$(L-leu)] (——), *fac*(−)$_{546}$-[Cr(D-ala)$_2$(L-leu)] (— · —), and *fac*(+)$_{546}$-[Cr(L-ala)$_2$(L-leu)](Used DL-alanine) (----).

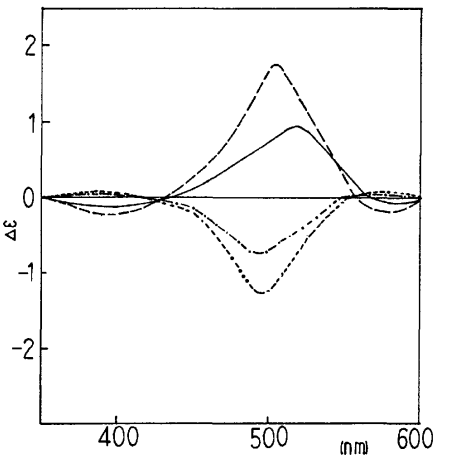

Fig. 2. The CD spectra of [Cr(L-ala)(L-leu)$_2$] obtained at each standing temperature. 55 °C (— —), 40 °C (——), 25 °C (— · —), 5 °C (----).

together with those of [Cr(D-ala)(L-leu)$_2$]. The peak positions and the signs of $\Delta\varepsilon$ of $(-)_{546}$-[Cr(L- or D-ala)(L-leu)$_2$] obtained at 5 °C and of $(+)_{546}$-[Cr(L- or D-ala)(L-leu)$_2$] obtained at 55 °C appear to be similar to those of $(+)_{546}$- and $(-)_{546}$-[Cr(AA)$_3$] respectively. Thus, the configurations of the present complexes can be identified as *Λ* for $(+)_{546}$- and *Δ* for $(-)_{546}$-isomers. On the other hand, the CD data of [Cr(L- or D-ala)(L-leu)$_2$] obtained at 25 °C or 40 °C suggest that the products are mixtures of *Λ*- and *Δ*-isomers. It was found that the ratio of the *Λ*-isomer to the *Δ*-isomer increases with a rise in the standing temperature, irrespective with the difference in the optical isomer of alanine involved.

The preparation of [Cr(L-leu)$_3$] was undertaken according to the present method. The $\Delta\varepsilon$ values of the tris complex obtained at 55 °C and at 5 °C are −0.316 and −0.583 respectively. It may be suggested that the ratio of the *Λ*-isomer to the *Δ*-isomer increases with a rise in the standing temperature. However, the ratio of the increase of the *Λ*-isomer of [Cr(L-leu)$_3$] is smaller than that of [Cr(L-ala)(L-leu)$_2$)]. The solubilities of [Cr(L-leu)$_3$] and [Cr(L-ala)(L-leu)$_2$] obtained at 5 °C and at 55 °C were investigated in an ethanol solution, which was added to KNCS at 5 °C and 55 °C. Nor was [Cr(L-leu)$_3$] dissolved in the solution at each temperature. On the other hand, the $(-)_{546}$-[Cr(L-ala)(L-leu)$_2$] obtained at 5 °C was dissolved at 55 °C, but was not dissolved at 5 °C. The $(+)_{546}$-[Cr(L-ala)(L-leu)$_2$] obtained at 55 °C was slightly dissolved at 55 °C, but was not dissolved at 5 °C. From these results, the stereoselectivity of [Cr(L-ala)(L-leu)$_2$] obtained after standing seems to be brought about by the difference in the solubility of the $(-)_{546}$-isomer, which arises from the difference in the standing temperature.

The characteristic feature of the present method of preparation is that it gives two different types of products.

i) Cr(L- or D-ala)$_2$(L-leu)]. These complexes were obtained during heating, in spite of using the bis-leucinato chromium(III) complexes, [Cr(L-leu)$_2$(NCS)(OH$_2$)], as the starting material.

It should also be noted that the reactions are stereospecific; that is, the $(+)_{546}$- and $(-)_{546}$-isomers were obtained with L- and D-alanine respectively.

ii) [Cr(L- or D-ala)(L-leu)$_2$]. These complexes were obtained from the filtrate. It should be noted that the reactions are also stereospecific and that the optical purity of the product, $(+)_{546}$-[Cr(L- or D-ala)(L-leu)$_2$], increases with a rise in the standing temperature of the filtrate.

The optical resolution of DL-alanine based on the different reactivities of [Cr(L-leu)$_2$(NCS)(OH$_2$)] for L- and D-alanine has been undertaken, the results will be requested in a future report.

The numerical data of the absorption spectra and the CD spectra of the mixed complexes obtained during heating and after standing using DL-alanine are listed in Table 2. The CD curve of the mixed complex obtained during heating is also shown in Fig. 1. A comparison with the CD curves of the mixed complexes obtained using L- and DL-alanine shows that the CD curves and the $\Delta\varepsilon$ values of these complexes are similar to each other. Therefore, in the case of DL-alanine, the mixed complex obtained during heating may be $(+)_{546}$-[Cr(L-ala)$_2$(L-leu)].

In addition, compared with the mixed complexes obtained using D- and DL-alanine, the $\Delta\varepsilon$ values of these complexes obtained after standing are also similar to each other at each temperature. Therefore, in the case of DL-alanine, the mixed complexes which were obtained after standing at each temperature may be [Cr(D-ala)(L-leu)$_2$]. The optical resolution of DL-alanine may be possible through the reaction.

The Magnetic Properties of Dinuclear Copper(II) 2-Fluoroalkanoates

Shuji EMORI* and Hideki KONDO
Department of Chemistry, Faculty of Science and Engineering, Saga University,
Honjo-machi, Saga 840
(Received March 22, 1989)

Synopsis. Copper(II) pentafluoropropionate and heptafluorobutyrate adducts with 1,4-dioxane, tetrahydropyran, and tetrahydrofuran have been prepared and characterized by means of magnetic-susceptibility and IR-spectroscopy measurements. The variation in their magnetic moments is discussed in terms of the acidity of the parent acid and the hyperconjugative effect of the fluoroalkyl group.

Numerous studies have been carried out to ascertain the factors which determine the magnetic properties of dinuclear copper(II) carboxylates, because they are necessary to understand the mechanism of the spin-exchange coupling. For several series of copper(II) carboxylates, a correlation between the strength of spin-exchange coupling and the acidity of the parent carboxylic acid has been recognized;[1-4] this correlation is supported by molecular orbital calculations.[5,6] However, there are also some exceptions, such as the unusually strong couplings observed for dinuclear copper(II) formates[7] and fluoroacetates,[3,4] which have led many investigators to be critical of such a correlation.[8] They have presumed alternative factors, such as the group polarizability of the carboxylate substituents[9] and the steric hindrance between the substituents and the axial donor ligands.[1] However, these alternative factors have soon been found unjustifiable.[3] In order to investigate the general trend of the magnetic properties of fluoroalkanoates, we have prepared the 1,4-dioxane (dox), tetrahydropyran (THP), and tetrahydrofuran (THF) adducts of copper(II) pentafluoropropionate and heptafluorobutyrate. For the sake of comparison, the corresponding adducts of copper(II) fluoroacetate and difluoroacetate have also been prepared.

The compounds were obtained by standard procedures.[1,10] Their effective magnetic moments (Table 1) were evaluated from the room-temperature molar magnetic susceptibilities (χ_M) using this equation: $\mu_{eff}=2.83\ [(\chi_M-\chi_{dia}-N\alpha)T]^{1/2}$. The appropriate diamagnetic corrections (χ_{dia}) were estimated from the Pascal constants,[11] while the temperature-independent paramagnetic contribution ($N\alpha$) was taken as 60×10^{-6} emu mol^{-1} (1 emu$=4\pi\times10^{-6}$ m^3). For the dioxane adducts of copper(II) difluoroacetate and pentafluoropropionate, the temperature dependence of their magnetic susceptibilities was measured in the temperature range of 80—300 K; it can be represented by the Bleaney-Bowers equation,[12] with parameters of $g=2.17$ and $2J=-314$ cm^{-1} for the difluoroacetate and of $g=2.18$ and $2J=-296$ cm^{-1} for the pentafluoropropionate. The IR spectra of the solid compounds show bands characteristic of bridging carboxylate due to unsymmetric and symmetric carboxyl stretching vibrations.[13] The magnetic and IR spectral data indicate that the present compounds have their "dinuclear tetracarboxylate frameworks."

It has been found that the magnetic moments of dinuclear copper(II) alkanoate adducts with unhindered hard donors, except those of fluoroalkanoate adducts, are determined by these factors: the acidities of the bridging carboxylato and axial donor ligands,[14] the steric strain among the substituents,[14] and the hydrogen bonding between the carboxylato oxygen atoms and the neighboring hydrogen donors.[15] For

example, the room-temperature magnetic moments (BM) for the copper(II) salts of a series of monosubstituted acetic acids can be formulated by the following equation:

$$\mu_{eff}=-0.052(pK_a-0.068pK_a'-4.56+C_{HB})+1.32_7, \quad (1)$$

where pK_a and pK_a' are the acidities of the parent acid and of the conjugate acid of the axial donor ligand respectively, and where C_{HB} is a correction term for the hydrogen bonding in the hydrates and ammonium chloride adducts (the value of $C_{HB}=-0.29$ has been estimated).[15] In order to examine a similar correlation for fluoroalkanoates, the room-temperature magnetic moments of the present compounds, together with the literature data for the hydrates and ammonium choride adducts of copper(II) fluoroalkanoates,[3,4,16] are plotted against the $pK_a-0.068\ pK_a'+C_{HB}$ values in Fig. 1. These points consist of a straight line, with the best least-squares fit yielding:

$$\mu_{eff}=-0.052(pK_a-0.068pK_a'-4.56+C_{HB})+1.18_2. \quad (2)$$

Although the magnetic moments of the corresponding quinoline adducts (1.32 and 1.40 BM at 20 °C for the fluoroacetate[17] and trifluoroacetate[18] respectively) show a similar trend, they are excluded from the plots because the axial coordination of quinoline is affected by the steric hindrance.[19] The variation in the singlet-triplet separation values (e.g., $-2J=384$,[10] 314, and 296 cm^{-1} for the dioxane adducts of copper(II) 2-fluoropropionate, difluoroacetate, and pentafluoropropionate respectively) indicates that the smaller magnetic moment is accompanied by the stronger magnetic interaction between copper(II) ions. Similarly, the carboxyl frequencies (cm^{-1}) for the present compounds, in conformity with Eq. 3, show systematic shifts against the acidities of the carboxylato and axial ligands:

$$\tilde{\nu}_{unsym}=1692-14.9(pK_a-0.068\ pK_a'+C_{HB}). \quad (3)$$

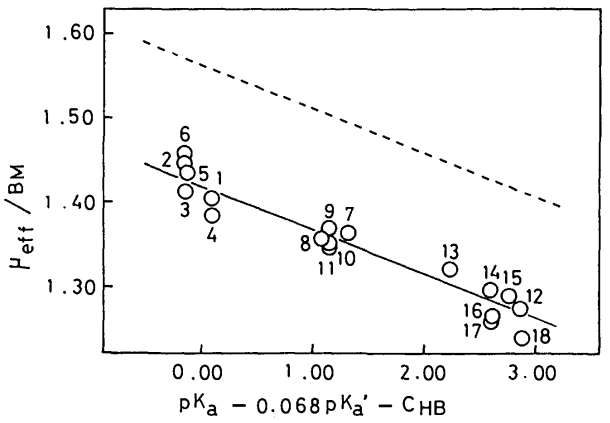

Fig. 1. The magnetic moments at 20 °C plotted against the acidities of the ligands for the copper(II) pentafluoropropionate (**1—3**), hexafluorobutyrate (**4—6**), difluoroacetate (**7—11**), fluoroacetate (**12—17**), and 2-fluoropropionate (**18**) adducts with σ-donor ligands. The broken line represents the linear correlation for copper(II) alkanoates except fluoroalkanoates.

These linear correlations suggest that the influence exerted by the fluoro-substituents is mainly inductive. Nevertheless, the value of the constant term in Eq. 2 (1.18_2 BM) is much smaller than the corresponding values for any other series of alkanoates (e.g., 1.32_7 BM in Eq. 1), indicating the existence of an additional factor affecting their magnetic properties. For the 2-fluoroalkanoates, this effect seems to be independent of the number of fluoro-substituents, for the lines in Fig. 1 are parallel to each other. An inspection of the crystal structures of the copper(II) fluoroacetate[20-22] and trifluoroacetate[8] adducts reveals that they have a fluoro-substituent located closely in the plane of the carboxylato group. This fact seems to indicate that the fluoro-substituent in the plane of the carboxylato group is responsible for this effect.

Previously, we have pointed out that the difference in magnetic moments between copper(II) acetate and copper(II) (substituted acetate)s is attributable to the hyperconjugation of the methyl group of the acetato ligand in addition to the difference in acidities between their parent acids.[14] Similarly, the magnetic moments of fluoroalkanoates must be affected by the hyperconjugation of the fluoroalkyl group.[23] Generally, carboxylic acid may be regarded as a substituted formic acid RCOOH, and the perturbation by a substituent R on the carboxyl group is comprised of changes in both the σ- and π-electron distributions. Since the effect of the change in the σ-electron distribution appears in the acidity change, the residual change in the magnetic moment of dinuclear copper(II) carboxylate may be related to the change in the π-electron distribution:

$$\mu_{eff}=-0.052(pK_a-0.068pK_a'+C_{HB}-3.55)+\Delta\mu_\pi+1.06_9, \quad (4)$$

where $\Delta\mu_\pi$ is a correction term for the perturbation of the π-electron density of the carboxyl group, being obtained as 0.16_8, 0.28_5,[14] 0.30_5,[14] 0.36_3,[14] and 0.35_2[24] BM for the $R=CF_3$, $(CH_3)_3C$, C_2H_5, CH_3, and C_6H_5 substituents respectively. Swain and Lupton have proposed that substituent constants predicting the substituent effects on any kinds of physical properties may be expressed as $fF+rR$,[25] where F and R are field and resonance constants, and where f and r are weight-

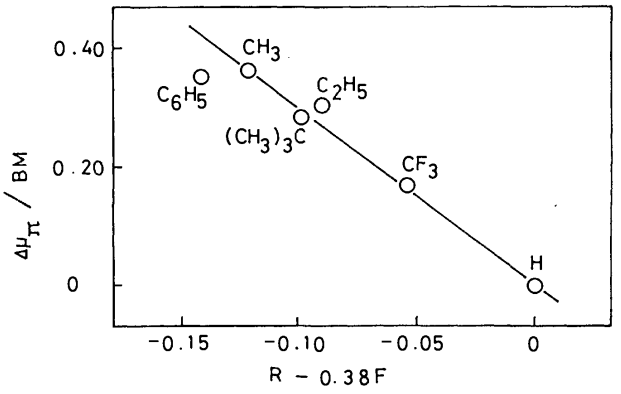

Fig. 2. The correction term for the perturbation on π-electrons in the carboxyl group plotted against the substituent constants $R-0.38F$.

ing factors independent of the particular substituent. The ratio of f to r being chosen as -0.38, the $\Delta\mu_\pi$ values for these substituents are plotted against $R-0.38F$ in Fig. 2. Most data have a linear relation with the slope of -3.0_0 BM, although the plot for the phenyl substituent is a little scattered, perhaps because of the torsion about the C-C bond between the phenyl and carboxyl groups (the dihedral angles are 0.2—27.2°).[26,27] This correlation substantiates the participation of the π-orbitals of the bridging carboxylato in the superexchange pathway. This electron-delocalization mechanism is consistent with the quite large contact shifts observed for the H resonances of copper(II) benzoates[28] and for the ^{13}C resonances of copper(II) butyrate.[29]

(Received April 22, 1989)

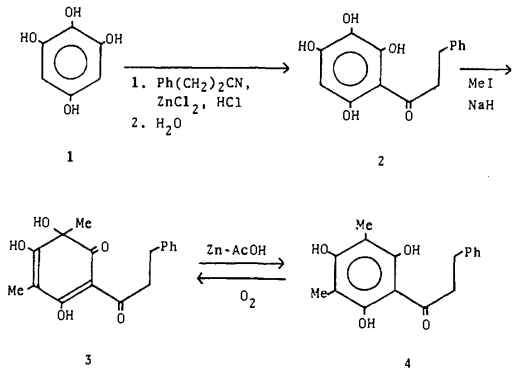
Synopsis. Ceratiolin, a constituent of *Ceratiola ericoides* was synthesized by the methylation of 2′,3′,4′,6′-tetrahydroxydihydrochalcone, prepared by the Hoesch reaction of 1,2,3,5-benzenetetrol with 3-phenylpropionitrile. Furthermore, it was proved that ceratiolin easily forms by the oxidation of 2′,4′,6′-trihydroxy-3′,5′-dimethyldihydrochalcone.

Recently, Fischer et al.[1] isolated a new constituent, ceratiolin, from the water-soluble extracts of the fresh leaves of *Ceratiola ericoides*, one of only three genera in the Empetraceae, and proposed the racemic structure **3** for this new compound from its spectral and CD data.

A novel structure of **3** and its characteristic allelopathic property[1,2] have prompted us to attempt the synthesis of **3**.

In this paper, we wish to report on the convenient synthesis of **3** by the di-*C*-methylation of 2′,3′,4′,6′-tetrahydroxydihydrochalcone (**2**). Dihydrochalcone **2** was obtained from 1,2,3,5-benzenetetrol (**1**)[3] and 3-phenylpropionitrile by the Hoesch reaction in 63% yield. Ceratiolin (**3**) was prepared by the methylation of **2** with methyl iodide in the presence of sodium hydride in dimethyl sulfoxide in 48% yield. The structure of synthetic **3** was identified by a comparison of IR, ^{1}H NMR, and ^{13}C NMR spectra with those of a natural sample.

Furthermore, Fischer et al.[1] reported that ceratiolin biogenetically appears to be an oxidative derivative of dihydrochalcone **4**. This speculation was experimentally proved by the formation of **3** through the oxidation of 2′,4′,6′-trihydroxy-3′,5′-dimethyldihydrochalcone (**4**).



Experimental

All the melting points were uncorrected. The IR and UV spectra were recorded with a Hitachi 100-50 spectrophotometer and Hitachi 215 spectrophotometer, respectively. The ^{1}H NMR and ^{13}C NMR spectra were measured with a Hitachi R-600 spectrometer and a Hitachi R-90H spectrometer, using tetramethylsilane as an internal standard, respectively. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer.

2′,3′,4′,6′-Tetrahydroxydihydrochalcone (2). To a mixture of 1,2,3,5-benzenetetrol (**1**)[3] (10.0 g), 3-phenylpropionitrile (15.0 g), and anhydrous zinc chloride (3.5 g) in dry ether (100 ml), dry hydrogen chloride gas was passed for 3 h under cooling with an ice-salt bath. The reaction mixture was allowed to stand overnight at 0 °C, and the resulting dark-brown precipitate was heated with water (600 ml) on a water bath for 2 h. The hydrolysis product was extracted with ethyl acetate and chromatographed on a column of silica gel using benzene-ethyl acetate-acetic acid (6:1:1) as an eluent to afford **2** (12.1 g, 63%) as yellow crystals. Mp 138—139 °C (recrystallized from chloroform). MS *m/z* 274 (M^+). IR (KBr) ν 3420, 3030, 1640, 1424, 1200, and 718 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=2.85—3.48 (4H, m, H_α and H_β), 5.92 (1H, s, 5′-H), 7.26 (5H, s, Ar-H), 11.29 and 12.13 (each 1H, s, OH). Found: C, 65.55, H, 5.04%, Calcd for $C_{15}H_{14}O_5$: C, 65.69, H, 5.14%.

Ceratiolin (3). Into a mixture of **2** (3.0 g) and sodium hydride (0.4 g) in dry dimethyl sulfoxide (60 ml) was added methyl iodide (4.6 g) under cooling with ice-water; the mixture was stirred for 3 h at room temperature. The reaction mixture was poured into cold dilute hydrochloric acid and extracted with ethyl acetate. The organic layer was worked up in the usual manner and the resulting crude product was chromatographed on a column of silica gel (Wakogel C-200) with carbon tetrachloride-ethyl acetate-acetic acid (6:1:1) to give **3** (1.57 g, 48%) as light yellow crystals. Mp 148—149 °C (from benzene) (lit,[1] mp 148—149 °C). MS *m/z* 302 (M^+). ES λ_{max} (MeOH) 227, 326, and 354 nm (log ε=4.46, 4.48, and 4.52). IR (KBr) ν 3450, 1668, 1639, 1578, 1520, 1468, 1285, 1240, 1072, 1056, 1020, and 700 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.50 (3H, s, Me), 1.85 (3H, s, Me), 2.86—3.31 (4H, m, H_α and H_β), 7.26 (5H, s, Ar-H), 18.86 (1H, s, chelated OH). ^{13}C NMR (CD_3OD) δ=7.0 (q), 28.9 (q), 32.4 (t), 41.8 (t), 75.7 (s), 104.0 (s), 105.8 (s), 127.0 (d), 129.2 (d), 142.3 (s), 174.0 (s), 190.6 (s), 197.8 (s), and 201.6 (s).

The synthetic ceratiolin (**3**) was completely identical with a natural specimen. (Natural ceratiolin, although it has a chiral carbon, is optically inactive[1]).

2′,4′,6′-Trihydroxy-3′,5′-dimethyldihydrochalcone (4). A mixed solution of **3** (0.25 g) and activated zinc dust (0.8 g) in acetic acid (10 ml) was refluxed for 10 h. The reaction mixture was filtered and the filtrate was evaporated in vacuo; the residue was recrystallized from benzene to give **4** (0.7 g, 85%) as yellow crystals. Mp 119—120 °C. MS *m/z* 286 (M^+). IR (KBr) ν 3580, 3450, and 1620 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=2.05 (6H, s), 2.97 and 3.42 (each 2H, m), 7.17 (5H, s), and 10.58 (br. s). Found: C, 71.05, H, 6.23%, Calcd for $C_{17}H_{18}O_4$: C, 71.31, H, 6.34%.

Oxidation of 4 with Air. A mixture of **4** (30 mg) and lead (II) acetate (40 mg) in methanol (0.2 ml) was stirred for 4 h with airing at room temperature. The resulting yellow precipitates were treated with 6 M sulfuric acid (1 M=1 mol dm^{-3}) and extracted with ether. The ether layer was washed with water and dried over anhydrous sodium sulfate and evaporated in vacuo. The residue was chromato-

graphed on a column of silica gel with benzene–ethyl formate–formic acid (15 : 5 : 1) as an eluent to afford pale-yellow crystals (mp 148—149 °C, 9.5 mg, 30%). This compound was completely identical with **3**.

The authors are grateful to Professor N. H. Fischer of Louisiana State University for the identification of our synthetic sample with natural ceratiolin. We also wish to express their thanks Dr. Satoru Kumazawa of the Kureha Chemical Industry Co., Ltd., for the measurement of ^{13}C NMR spectra.

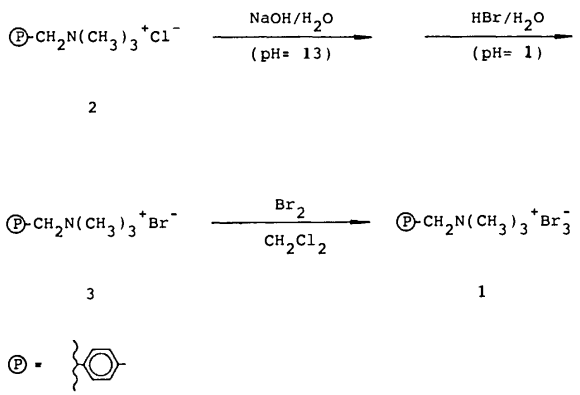
Synopsis. Bromo-substituted phenols were obtained quantitatively by passing a solution of phenols in dichloromethane–methanol through a column packed with styrene polymer-bound benzyltrimethylammonium tribromide.

Subsequent to Merrifield's report of the solid-phase peptide synthesis in 1963,[2] a number of functional polymers have been found, and the development of the regeneratable polymers as support is even now an interesting subject regarding organic synthesis. During the course of our investigation on the bromination of aromatic compounds with benzyltrimethylammonium tribromide (BTMA Br_3),[3] we happen to think of the use of polymer-bound BTMA Br_3 (Ⓟ-BTMA Br_3) (**1**) as a brominating agent.

Cacchi et al. have already reported the α-bromination of ketones by the use of a polymeric brominating agent (Amberlyst A 26-Br_3^- form).[4] However, their bromination method was carried out by mixing ketones with the insoluble polymeric agent in a solvent in the usual way. In this paper we wish to report on a facile bromination of phenols by the use of a column packed with **1**.

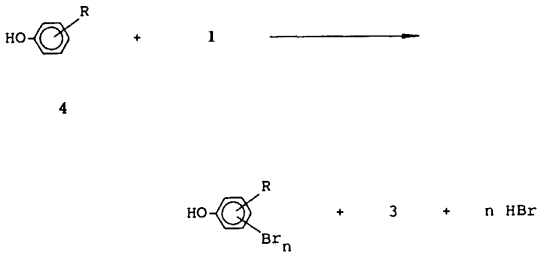
Results and Discussion

Our polymeric agent **1** (orange red) was readily prepared from AGl-X_2 (**2**) (100—200 mesh, chloride form), which was a commercially available (Bio-Rad Laboratories, USA) anion exchange resin containing a quaternary ammonium group, as shown in Scheme 1:



Scheme 1.

Passing a solution of phenols (**4**) in dichloromethane–methanol through a column packed with **1** at room temperature gave bromo-substituted phenols (**5**) in quantitative yields (Scheme 2). As shown in Scheme 2, polymer **1** is transformed into a colorless



Scheme 2.

Ⓟ-BTMA Br^- (**3**) which can be easily regenerated to the original **1** by passing a solution of bromine in dichloromethane through the column. Still, $CaCO_3$ powder was used for the bromination of phenols bearing electron-attracting groups, because $CaCO_3$ should activate these inactive aromatic ring by the formation of the phenolate ion. The results are summarized in Table 1.

We have already prepared **5** by the reaction of **4** with BTMA Br_3, a soluble reagent in dichloromethane–methanol, at room temperature.[5] However, the procedure using **1** thus provides a facile method of obtaining bromo-substituted products from the corresponding aromatic compounds, owing to the ease of the operation and the capability of regeneration of the reagent. We believe that this method using **1** may be satisfactorily applied for the industrial production of bromo-substituted aromatic compounds.

As a limitation of the procedure, the selective bromination of phenols is difficult since this method cannot be carried out stoichiometrically. Furthermore, attempts at the bromination of a more reactive **4**, such as 4-methoxyphenol, 5-methyl-1,3-benzenediol, 1,3,5-benzenetriol, 1-naphthol, and 2-naphthol, were unsuccessful because these substrates underwent oxidation by **1**.

Experimental

Preparation of Styrene Polymer-Bound BTMA Br_3 (1): To a stirred suspension of AGl-X_2 (**2**) (100 g) in water (300

a) Yield of isolated product. b) $CaCO_3$ powder was used. c) This run was done in dichloromethane without methanol.

ml) we added 1-M aqueous sodium hydroxide (1M=1 mol dm^{-3}) at room temperature until the pH of the solution was indicated at about 13. The obtained precipitate was filtered and washed with water until it was neutral; a suspension of the above-mentioned powder in water (300 ml) was made sufficiently acidic (pH=1) with 1-M hydrobromic acid under stirring for 1 h at room temperature. The solid residue was then filtered and washed with water until neutral to give polymer-bound BTMA Br (**3**) as a white polymer; 47.2 g.

A dilute solution of bromine in dichloromethane was slowly added into a stirred suspension of **3** in dichloromethane (300 ml) until the color of bromine in the solution did not fade. The mixture was stirred overnight at room temperature; the obtained solid was filtered, washed with dichloromethane and dried under vacuum at room temperature to give a stable, orange red polymer **1**: yield 61.2 g; mp 210 °C.

2,4,6-Tribromo-3-methylphenol (5c); Typical Procedure: Compound 3-methylphenol (0.54 g, 5 mmol) in dichloromethane (20 ml)–methanol (20 ml) was adsorbed on **1** (50 g) packed in a column. The developing solvent (dichloromethane–methanol (3 : 1)) was passed through the column at a rate of 7 ml/10 min. In this case, the upper part of **1**, which reacted with the substrate, was completely decolorized. The obtained eluate (200 ml) was concentrated and treated with 5% aq solution of $NaHSO_3$ (10 ml); the mixture was then extracted with ether (40 ml×4). The ether solution was dried over $MgSO_4$ and concentrated in vacuo to give **5c** as a colorless crystals; yield 1.70 g (99%); mp 82—83 °C (lit,[8] mp 81 °C).

(Received May 19, 1989)

Synopsis. The reaction of sulfides with a stoichiometric amount of benzyltrimethylammonium tribromide and aqueous sodium hydroxide in dichloromethane at room temperature or in 1,2-dichloroethane under reflux gave the corresponding sulfoxides in good yields.

The usual methods of oxidation of sulfides (**1**) to sulfoxides (**2**) were occasionally found to be unsatisfactory. One of the difficulties is the relative ease of further oxidation of **2** to sulfone. However, the selective oxidation of **1** to **2** can be brought about by several reagents. For example, 30% hydrogen peroxide in acetone,[2] chromic acid in pyridine,[3] manganese dioxide in light petroleum,[3] liquid dinitrogen tetroxide under cooling by alcohol-solid carbon dioxide,[4] some organic hydroperoxides in appropriate solvent in sealed tube,[5] and dimethyl sulfoxide under heating at 160—175 °C[6] have been used. For the same purpose, some halogenating agents such as NBS,[7] the addition complex of 1,4-diazabicyclo[2.2.2]octane with bromine,[8] iodine with potassium iodide,[9] *t*-butyl hypochlorite,[10] and sodium bromite[11] are also used.

In connection with our further investigation on the synthetic utility of quaternary ammonium polyhalides, we have found that benzyltrimethylammonium

a) Products were characterized by comparing ^1H NMR spectra and mp or bp with those of authentic samples or reported data. b) Yield of isolated product. In the cases of run r, v, and y, products **2r**, **2v**, and **2y** were isolated by column chromatography on silica gel. c) Yield was based on its ^1H NMR spectrum.

tribromide (BTMA Br_3) is a useful oxidizing agent. In this paper we wish to report on a selective synthesis of **2** from **1** by the use of BTMA Br_3 in aqueous sodium hydroxide.

Results and Discussion

The reaction of **1** with a calculated amount of BTMA Br_3 and aqueous sodium hydroxide in dichloromethane at room temperature or in 1,2-dichloroethane under reflux gave **2** in good yields. The results are summarized in Table 1, and the reaction scheme can be represented as

$$\underset{\mathbf{1}}{R^1\text{-}S\text{-}R^2} + \text{BTMA } Br_3 + 2\ \text{NaOH} \longrightarrow \underset{\mathbf{2}}{R^1\text{-}S(=O)\text{-}R^2} + \text{BTMA Br} + 2\ \text{NaBr} + H_2O.$$

Aliphatic and aromatic sulfides **1a—z** have readily been oxidized to the corresponding **2a—z.** Our method, using BTMA Br_3, has a merit in that this stable reagent (orange red) can be treated safely and stoichiometrically. Furthermore, the end-point of the reaction can be recognized by decolorization of its initial orange color.

As a limitation of the procedure, attempts at the preparation of an unsaturated **2**, such as allyl phenyl sulfoxide and benzyl styryl sulfoxide, were unsuccessful, since the double bond underwent bromine addition under these conditions.

Experimental

Dihexyl Sulfoxide (2g); Typical Procedure: BTMA Br_3 (4.68 g, 12 mmol) was added to a mixture of dihexyl sulfide (**1g**) (2.02 g, 10 mmol) in dichloromethane (30 ml) and sodium hydroxide (1.1 g, 27.5 mmol) in water (15 ml), and the mixture was stirred at room temperature for 1 h. The orange color of the solution gradually faded and then completely decolorized during the period. To the reaction mixture was added a 20% aq solution of $NaHSO_3$ (10 ml); the organic layer was then separated. The aqueous layer was extracted with dichloromethane (10 ml×2) and the combined solution of dichloromethane was dried over $MgSO_4$ and evaporated in vacuo to give **2g** as colorless crystals; yield 2.14 g (98%); mp 57—58 °C (lit,[12] mp 60 °C).

Generation and Chemical Fate of 2,2,2-Trifluoro-1-phenylsulfonylethyl Carbanion

Kenji UNEYAMA* and Makoto MOMOTA
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Okayama 700
(Received May 6, 1989)

Synopsis. 2,2,2-Trifluoro-1-phenylsulfonylethyl carbanion generated by the action of LDA in THF-HMPA can be methylated and iodinated, where the tetraethylammonium cation plays an essential role for the stabilization of the carbanion.

The development of reactions at the carbon atom bearing trifluoromethyl group is a subject of interest regarding the preparation of biologically active trifluoromethylated organic compounds.[1] Carbanions bearing the trifluoromethyl group are too reactive to be alkylated and mostly undergo defluorination. Thus, both trifluoroethyl phenyl ether[2] and sulfide[2,3] undergo facile defluorination by the action of LDA. Ishikawa demonstrated an alkylation of dimethyl trifluoromethylmalonate in the presence of a large excess of cesium fluoride where the nucleophilic addition of fluoride anion to the difluoromethylenemalonate occurs, consequently, to maintain a moderate concentration of the carbanion.[4] Recently, Fuchigami and Nakagawa showed an efficient alkylation of dimethyl trifluoromethylmalonate by the aid of electrogenerated base.[5] The alkylation of 2,2,2-trifluoroethyl phenyl sulfide and the subsequent desulfurization of the alkylated products would provide us with a promising process for the preparation of the trifluoromethylated compounds. The phenylsulfonyl group stabilizes any carbanion more effectively than the phenylthio group; there would thus still be a chance to trap 2,2,2-trifluoro-1-phenylsulfonylethyl carbanion **1** by an electrophile. The present note describes a method regarding the alkylation conditions in which the tetraethylammonium cation in THF-HMPA plays an essential role.

Results and Discussion

Both the phenylsulfonyl and trifluoromethyl groups activate the methylene proton of **2** so that even weak bases such as triethylamine, sodium hydroxide, and sodium methoxide can abstract a proton from **2**. However, the carbanion **1** is so unstable that it instantaneously undergoes defluorination rather than nucleophilic substitution. At −70 °C, stronger bases are required for this purpose. At first, LDA was employed in a mixed solvent of THF and HMPA. The carbanion can be trapped with methyl iodide, which must be employed in large excess (tenfold). Under these conditions a mixture of mono- and dimethylated sulfones **3** and **4** was obtained. An increase in methyl iodide resulted in the formation of the dimethylated sulfone **4**, even by the use of one equivalent of LDA (Run 1). This result suggests the existence of the dianion of **2** as an intermediate in an LDA-THF-HMPA system.[6] HMPA is a useful cosolvent for the present methylation. Otherwise, no methylation proceeds and defluorination exclusively occurs in THF where the lithium cation tightly associates with the electron lobe of the carbanion **1** and induces an intramolecular defluorination, as suggested.[7] The reaction temperature is also critical. At a higher temperature the total yields of **3** and **4** become lower (Run 3), suggesting that defluorination is faster than methylation under the reaction conditions.

Then, the effect of a base and the counter cation of diisopropylamide was examined so as to realize an exclusive monomethylation. Hard bases, such as butyllithium and ethylmagnesium bromide, failed in methylation (Runs 5 and 6). Lithium hexamethyldisilazide, potassium *t*-butoxide, and sodium methoxide gave a mixture of **3** and **4**. In contrast, replacing the lithium of LDA with tetraethylammonium leads to exclusive monomethylation (Run 10). Fuchigami and Nonaka demonstrated that a pyrrolidone anion with tetraethylammonium promoted the alkylation of

dimethyl trifluoromethylmalonate.[5)] It is well-known that tetraalkylammonium salts affect the electroreductive carbon-carbon bond formation in an aprotic solvent, although the effect has not yet been clearly explained.[8)] The dianion of **2** would abstract a proton from tetraethylammonium leading to the monoanion **1**.

The monomethylation conditions were applied to the other electrophiles (Table 2). Allyl iodide gave the allylated sulfone in a poor yield (12%). Neither ethyl iodide nor benzyl bromide can trap the carbanion **1** under the present reaction conditions. Interestingly, the reaction of **1** with iodine provides the desired iodinated sulfone **6** as crystals in 82% yield, rather than the oxidative dimer of **1**.[9)]

Experimental

Materials and Measurements: All of the solvents were distilled and stored under nitrogen. The ^{1}H NMR spectra were recorded at 500 MHz by using a Varian VXR-500 spectrometer with tetramethylsilane as the internal standard in $CDCl_3$. The IR spectra were recorded on a Hitachi 270-30 spectrometer.

1,1-Dimethyl-2,2,2-trifluoroethyl Phenyl Sulfone (4): To a solution of **2** (112 mg, 0.5 mmol) and methyl iodide (0.4 ml, 5 mmol) in THF (1 ml) and HMPA (0.9 ml) was added dropwise the LDA solution (1.5 mmol), and the mixture was stirred at −70 °C. After 10 min, the reaction mixture was neutralized with saturated NH_4Cl aq and 10% HCl aq, then extracted with ether/hexane (1 : 1). The extract was washed with water, dried over Na_2SO_4, and then evaporated in vacuo. The crude product was chromatographed on silica gel with hexane/AcOEt (10 : 1) as an eluent to yield 87 mg (69%) of **4** as a viscous oil; bp 125—130 °C/399 Pa; IR (neat) 1343, 1145 (SO_2) cm^{-1}; ^{1}H NMR δ=1.54 (s, 6H, CH_3), 7.55—8.00 (m, 5H, Ph). Found: C, 47.46; H, 4.47%. Calcd for $C_{10}H_{11}F_3O_2S$: C, 47.62; H, 4.40%.

1-Methyl-2,2,2-trifluoroethyl Phenyl Sulfone (3): To a suspension of tetraethylammonium chloride (260 mg, 1.6 mmol) in THF (1 ml) was added the LDA solution (1.6 mmol) at −70 °C; the mixture was then stirred at room temperature for 20 min. A supernatant liquid of the suspension was dropped into a solution of **2** (112 mg, 0.5 mmol) and methyl iodide (0.4 ml, 5 mmol) in THF (1 ml)-HMPA (0.9 ml) at −70 °C. After 10 min, the mixture was neutralized with saturated NH_4Cl aq and 10% HCl aq, and then extracted with ether/hexane (1 : 1). The extract was washed with water, dried over Na_2SO_4, and then evaporated in vacuo. The crude product was chromatographed on silica gel with hexane/AcOEt (10 : 1) as an eluent to yield 96 mg (80%) of **3** as a viscous oil; bp 125—130 °C/399 Pa; IR (neat) 1328, 1150 (SO_2) cm^{-1}; ^{1}H NMR δ=1.61 (d, J=7.4 Hz, 3H, CH_3), 3.75 (qq, $J_{H\text{-}H}$=7.4, $J_{H\text{-}F}$=8.5 Hz, 1H, CH), 7.55—8.00 (m, 5H, Ph). Found: C, 45.41; H, 3.69%. Calcd for $C_9H_9F_3O_2S$; C, 45.38; H, 3.81%.

1-Iodo-2,2,2-trifluoroethyl Phenyl Sulfone (6): Yield (82%) as colorless crystals; mp 72—74 °C; IR (Nujol) 1338, 1156 (SO_2) cm^{-1}; ^{1}H NMR δ=5.51 (q, J=7.2 Hz, 1H, CH), 7.45—8.05 (m, 5H, Ph). Found: C, 27.62; H, 1.75%. Calcd for $C_8H_6F_3IO_2S$: C, 27.45; H, 1.73%.

1-Trifluoromethyl-3-butenyl Phenyl Sulfone (5): Yield (12%) as a viscous oil, bp 95—100 °C/133 Pa; IR (neat) 1650 (C=C), 1330, 1150 (SO_2) cm^{-1}; ^{1}H NMR δ=2.62—3.10 (m, 2H, CH_2), 3.63—3.81 (m, 1H, CH). 5.13—5.26 (m, 2H, =CH_2), 5.75—6.00 (m, 1H, =CH), 7.56—8.00 (m, 5H, Ph). Found: C, 49.80; H, 4.11%. Calcd for $C_{11}H_{11}F_3O_2S$; C, 50.00; H, 4.20%.

We are grateful to the CIBA-GEIGY Foundation for the financial support and the SC-NMR laboratory of Okayama University for the 500 MHz-NMR analysis.

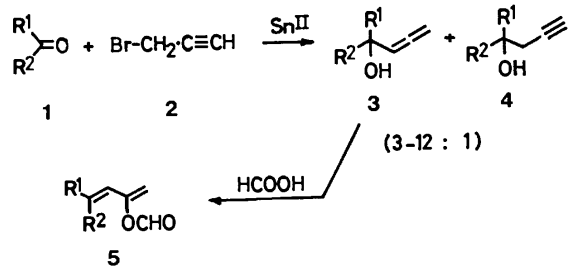
Simple and Efficient Synthesis of α-Allenic Alcohols and Their Novel Conversion into 1-Aryl-3-formyloxy-1,3-butadienes

Masahiko IYODA,* Yoshiaki KANAO, Minoru NISHIZAKI, and Masaji ODA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received May 19, 1989)

Synopsis. Reactions of carbonyl compounds with 3-bromo-1-propyne in the presence of $SnCl_2 \cdot 2H_2O$ and $LiI \cdot 3H_2O$ gave α-allenic alcohols in moderate yields together with small amounts of β-acetylenic alcohols. The α-allenic alcohols can be converted into 1-aryl-3-formyloxy-1,3-butadienes, novel 1,3-butadiene derivatives.

In connection with our interest in the synthetic utility of cumulenic compounds,[1] we required a simple method for the preparation of α-allenic alcohols **3**.[2] Although the reactions of carbonyl compounds with 3-halo-1-propynes are known to give α-allenic alcohols **3**,[3,4] the yields were usually low and large amounts of β-acetylenic alcohols **4** were obtained as a major product of these reactions. We report here a very convenient solution of this problem and the synthesis of 1-aryl-3-formyloxy-1,3-butadienes **5** from the α-allenic alcohols **3**.



1 2 3 4 5

Scheme 1.

The reactions of **1** with 3-iodo-1-propyne in the presence of anhydrous $SnCl_2$ were reported to give α-allenic alcohols **3**, but considerable amounts of β-acetylenic alcohols **4** were also formed [e.g., the reaction of benzaldehyde with 3-iodo-1-propyne in the presence of $SnCl_2$ gave **3** and **4** in the ratio of 48 : 52 in 98% yield].[3a]

As shown in Table 1, the reaction of carbonyl compounds **1** with 3-bromo-1-propyne (**2**) proceeds smoothly under mild conditions to give α-allenic alcohols **3** as a major product. The hydrates of both $SnCl_2$ and LiI are employed for the reaction without removing water. Thus, benzaldehyde and its derivatives (**1a—h**: R^1=aryl and R^2=H) react with **2** in the presence of $SnCl_2 \cdot 2H_2O$ to give α-allenic alcohols **3a—h** in relatively good yields (Entries 1—9). In the case of 4-methoxybenzaldehyde (**1i**), the yield of a mixture of **3i** and **4i** obtained in the reaction reduced to 40%, owing to the instability of the α-allenic alcohol (**3i**) under the reaction conditions. The reactions of phenylacetaldehyde (**1j**) and butyraldehyde (**1k**) with **2** under similar conditions afforded the corresponding α-allenic alcohols **3j** and **3k** also as a major product (Entries 9 and 10). Furthermore, similar treatment of cyclohexanone (**1l**) with **2** gave the α-allenic alcohol **3l** selectively (Entry 11). Therefore, our method provides a simple and convenient way for the preparation of **3**.

Synthesis of 2-formyloxy-1,3-butadiene (**5**: R^1=R^2=H) was reported five decades ago,[5] and Diels-Alder reaction of this compound was discussed experimentally and theoretically as a typical diene.[6] However, the synthetic methodology for access to 2-formyloxy-1,3-butadiene derivatives is still very limited.

We have found that α-allenic alcohols **3** yield 3-formyloxy-1,3-butadienes (**5**) readily by dissolving **3** in formic acid. Thus, a solution of **3** in ether is added to formic acid at room temperature and the mixture is

a) Method A: HCOOH, room temperature, 30 min. Method B: HCOOH, Ac_2O, 0 °C, 1 h.

stirred for 30 min (Method A in Table 2). A side reaction of this conversion is the formation of α,β-unsaturated ketones **6** which may be attributable to the competitive addition of water instead of formic acid to the *sp*-carbon of **3**. Therefore, some modification was carried out for the conversion of **3** into **5**. A solution of **3** in ether is added to a solution of formic acid containing acetic anhydride at 0 °C and the mixture is stirred for 1 h at the same temperature (Method B in Table 2). α-Allenic alcohols **3** having electron-withdrawing groups as substituents of aryl rings gave **5** in satisfactory yields by either Method A or B (Entries 1—6). In the case of *p*-tolyl derivative, however, **5b** was obtained in 27% yield by Method A and the yield was improved to 49% by Method B (Entries 7 and 8). A marked difference in yields of **5** was observed for the case involving 2-naphthyl substituent. Thus, the 2-naphthyl-substituted α-allenic alcohol **3h** was converted into the corresponding butadiene **5h** only in 7% yield using Method A, but this conversion was achieved in 35% yield by Method B (Entries 9 and 10).

In conclusion, the 2- or 3-formyloxy-1,3-butadiene derivatives **5** are now readily available through the acid-catalyzed rearrangement of α-allenic alcohols **3**.

Experimental

General. ^1H and ^{13}C NMR spectra were recorded on a Varian XL-100 or JEOL JNM-PMX60Si and JNM-FX90Q instruments, and are reported in δ from tetramethylsilane. IR spectra were observed on a Hitachi EPI-G3 spectrometer. Mass spectral analysis (MS) were performed on a JEOL JMS-O1SG-2 instrument. Melting points were determined on a Mettler FP-2 apparatus and are uncorrected. Column chromatography was carried out with use of Merck silica gel 60, 70—230 mesh, art 7734, or Merck neutral alumina activity II—III, 70—230 mesh.

General Procedure for Table 1. The Reaction of Carbonyl Compound 1 with 3-Bromo-1-propyne (2). To a solution of $SnCl_2{\cdot}2H_2O$ (677 mg, 3 mmol) and $LiI{\cdot}3H_2O$ (752 mg, 4 mmol) in 1,2-dimethoxyethane (DME) (10 ml) were added successively 3-bromo-1-propyne (**2**) (476 mg, 4 mmol) and a solution of carbonyl compound **1** (2 mmol) in DME (5 ml) at 0 °C under argon atmosphere. After the reaction mixture had been stirred at 0 °C for 2—5 h, water (10 ml) was added. Benzene (30 ml) was then added, and the organic layer separated. The aqueous layer was extracted with ether. The combined organic layers were washed successively with aqueous 5% $Na_2S_2O_3$ and saturated NaCl, and dried over $MgSO_4$. After removal of $MgSO_4$, the solution was filtered through a short column of alumina (ca. 20 g) in order to avoid isomerization of **3** to **6**. The filtrate was evaporated and the residue was chromatographed on silica gel with benzene–ether as eluent to give a mixture of α-allenic alcohol **3** and β-acetylenic alcohol **4**. Separation of **3** and **4** can be carried out by column chromatography on silica gel with hexane–ethyl acetate as eluent. α-Allenic alcohols **3** decompose gradually on standing at room temperature, but can be stored at 0 °C in solution using hexane, benzene or carbon tetrachloride as solvent.

1-Phenyl-2,3-butadien-1-ol (3a),[3a—c] **1,2-heptadien-4-ol (3K),**[7] **and 1-(1,2-propadienyl)cyclohexan-1-ol (3l)**[8] were characterized by comparison of the ^1H NMR, IR, and mass spectra with those of literatures.

Calcd for $C_{14}H_{12}O$: C, 85.68; H, 6.16%.

1-Phenyl-3,4-pentadien-2-ol (3j): Colorless oil, IR (neat) 3350 and 1957 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.97 (br. s, 1H), 2.85 (d, *J*=6.0, 2H), 4.39 (m, 1H), 4.81 (m, 2H), 5.28 (m, 1H), and 7.11—7.42 (m, 5H); MS *m/z* 160 (M^+).

3b—g and **3j** were not satisfied with their elemental analyses because of their instabity.

General Procedure for the Synthesis of 5 (Table 2). Method A. To 99% formic acid (5 ml) was added a solution of **3** (1 mmol) in ether (2 ml) at room temperature. After stirring at room temperature for 30 min, benzene was added and the resulting solution was evaporated in vacuo (the bath temperature was kept below 30 °C). 1-Aryl-3-formyloxy-1,3-butadienes (**5a—c**, **5f**, and **5h**) were obtained after passing a short column of silica gel (20 g, activity V) at 0 °C using benzene-hexane as eluents. 1-Aryl-3-formyloxy-1,3-butadienes thus obtained are rather unstable and decomposes gradually on standing at room temperature.

Method B. To a solution of acetic anhydride (1 ml) in formic acid (5 ml) was added a solution of **3** (1 mmol) in ether (2 ml) at 0 °C. The solution was stirred at the same temperature for 1 h, and benzene was added. The resulting mixture was evaporated in vacuo below 30 °C, and the evaporations with benzene were repeated until most formic acid and acetic anhydride were removed. After passing through a short column of silica gel (20 g, activity V, 0 °C) with benzene-hexane **5** was obtained in yields summarized in Table 2.

1-Phenyl-3-formyloxy-1,3-butadiene (5a): Colorless oil, decomposed by distillation, IR (neat) 1745, 1645, and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.98 (d, *J*=2.0, 1H), 5.12 (d, *J*=2.0, 1H), 6.60 (d, *J*=17.0, 1H), 6.80 (d, *J*=17.0, 1H), 7.26—7.45 (m, 5H), and 8.27 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=105.1 t, 121.8 d, 127.0 d, 128.6 d, 128.7 d, 131.2 d, 135.7 s, 151.8 s, and 159.0 d; MS *m/z* 174 (M^+).

1-(*p*-Tolyl)-3-formyloxy-1,3-butadiene (5b): Colorless oil, IR (neat) 1742, 1642, and 1608 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.35 (s, 3H), 4.96 (d, *J*=2.0, 1H), 5.09 (d, *J*=2.0, 1H), 6.56 (d, *J*=17.5, 1H), 6.78 (d, *J*=17.5, 1H), 7.15 (d, *J*=8.5, 2H), 7.32 (d, *J*=8.5, 2H), 8.27 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=21.2 q, 104.4 t, 120.8 d, 126.9 d, 129.4 d, 131.1 d, 132.9 s, 138.6 s, 152.0 s, and 159.3 d; MS *m/z* 188 (M^+).

1-(4-Chlorophenyl)-3-formyloxy-1,3-butadiene (5c): Colorless needles, mp 35.5—36.5 °C, IR (KBr) 1725, 1640, and 1608 cm^{-1}; ^1H NMR (acetone-d_6) δ=5.08 (d, *J*=2.0, 1H), 5.25 (d, *J*=2.0, 1H), 6.77 (d, *J*=16.0, 1H), 6.98 (d, *J*=16.0, 1H), 7.38 (d, *J*=8.0, 2H), 7.57 (d, *J*=8.0, 2H), and 8.39 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=105.5 t, 122.4 d, 128.1 d, 128.9 d, 129.3 s, 129.6 d, 134.2 s, 151.5 s, and 158.8 d; MS *m/z* 210 and 208 (M^+).

1-(2-Chlorophenyl)-3-formyloxy-1,3-butadiene (5f): Colorless oil, IR (neat) 1745, 1641, and 1608 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.05 (d, *J*=2.0, 1H), 5.17 (d, *J*=2.0, 1H), 6.61 (d, *J*=15.0, 1H), 7.14 (d, *J*=15.0, 1H), 7.16—7.60 (m, 4H), and 8.27 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=106.2 t, 124.3 d, 126.7 d, 126.8 d, 127.0 d, 129.3 d, 129.9 s, 133.8 s, 151.4 s, and 158.9 d; MS *m/z* 210 and 208 (M^+).

1-(2-Naphthyl)-3-formyloxy-1,3-butadiene (5h): Colorless plates, mp 57—58 °C, IR (KBr) 1740, 1643, and 1610 cm^{-1}; ^1H NMR (acetone-d_6) δ=5.08 (d, *J*=2.0, 1H), 5.27 (d, *J*=2.0, 1H), 6.92 (d, *J*=16.0, 1H), 7.10 (d, *J*=16.0, 1H), 7.43—7.97 (m, 7H), and 8.44 (s, 1H); ^{13}C NMR (acetone-d_6) δ=106.3 t, 124.1 d, 124.8 d, 127.7 d, 127.8 d, 128.9 d, 129.0 d, 129.4 d, 129.7 d, 131.9 d, 134.7 s, 134.9 s, 135.0 s, 153.6 s, and 160.8 d; MS *m/z* 224 (M^+).

Elemental analyses of **5a—c**, **5f**, and **5h** were not satisfactory because of their instability.

Aromatic Acetonylation by Using Aryltins with Acetonylium Equivalents under the Palladium Catalysis

Masanori KOSUGI,* Yoshio MIYAJIMA, Hideyuki NAKANISHI, Hiroshi SANO, and Toshihiko MIGITA*
Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376
(Received May 30, 1989)

Synopsis. Palladium-catalyzed reactions of heteroaromatic tins with 2-ethoxyallyl diethyl phosphate and of nitrophenyltins with 2-methoxymethoxyallyl chloride were found to give the coupling products, which can be hydrolyzed to the corresponding acetonylated aromatics in good yields.

Although a number of methods for aromatic acetonylation were reported so far,[1] there is still in need of an efficient method for aromatics having electron-withdrawing groups or heteroaromatics. Previously, we reported that acetonyltributyltin prepared in situ from methoxytributyltin and isopropenyl acetate reacted with aryl bromide under the palladium catalysis to give the arylacetone in good yield.[2] The reaction, however, was hardly applied to the aryl bromides having electron-withdrawing groups, although recent survey brought some improvements.

On the other hand, we report here an alternative method of preparing acetonyl aromatics, that is, the reaction of aryltins with acetonylium equivalent under the palladium catalysis.

$$Bu_3SnAr + CH_3COCH_2^+ \xrightarrow{[Pd]} ArCH_2COCH_3 + Bu_3Sn^+ \quad (1)$$

Acetonyl halide is the most simple reagent for acetonylium synthon, but is not suitable for the present reaction, because it has a carbonyl group which is reactive toward aryltins. Among the other acetonylium equivalents, 2-methoxyallyl bromide[3] which is labile and 2-trimethylsiloxyallyl halide[4] which is also labile in the presence of palladium complexes are not proper for the present reaction. On the basis of the stability of the compounds and the easiness of their preparation, we chose the following compounds; 2-ethoxyallyl diethyl phosphate,[5] 2-ethoxyallyl acetate,[6] and 2-ethoxyallyl carbonate,[7] 2-methoxymethoxyallyl chloride,[8] and 1-chloromethylvinyl diethyl phosphate.[9] These allylic compounds are converted into π-allyl palladium complexes by the palladium catalyst, and then react with aryltin compounds to give the coupled products.[10] Treatment of the products with aqueous acid would give the expected acetonylated products.

$$Bu_3SnAr + CH_2{=}C(OR)CH_2X \xrightarrow{[Pd]} ArCH_2C(OR){=}CH_2 \xrightarrow{H^+} ArCH_2COCH_3 \quad (2)$$

Palladium-catalyzed reactions of the phenyltributyltin with the various acetonylium equivalents gave the results as shown in the following equations.

$$PhSnBu_3 + CH_2{=}C(OEt)CH_2OPO(OEt)_2 \xrightarrow{[Pd]} PhCH_2C(OEt){=}CH_2 \quad 74\% \quad (3)$$

$$PhSnBu_3 + CH_2{=}C(OEt)CH_2OAc \xrightarrow{[Pd]} PhCH_2C(OEt){=}CH_2 \quad 49\% \quad (4)$$

$$PhSnBu_3 + CH_2{=}C(OEt)CH_2OCO_2Me \xrightarrow{[Pd]} PhCH_2C(OEt){=}CH_2 \quad 17\% \quad (5)$$

$$PhSnBu_3 + CH_2{=}C(OMOM)CH_2Cl \xrightarrow{[Pd]} PhCH_2C(OMOM){=}CH_2 \quad 79\% \quad (6)$$

(OMOM = OCH_2OCH_3)

$$PhSnBu_3 + CH_2{=}C(CH_2Cl)OPO(OEt)_2 \xrightarrow{[Pd]} PhCH_2C[OPO(OEt)_2]{=}CH_2 \quad 58\% \quad (7)$$

2-Methoxymethoxyallyl chloride and 2-ethoxyallyl diethyl phosphate gave the products in good yields.

Palladium-catalyzed reactions of 2-ethoxyallyl diethyl phosphate with nitrophenyltributyltins, pyridyltributyltins, and thienyltributyltins which are chosen as representatives of aromatics having electron-withdrawing group and heteroaromatics, are described in Table 1.

As Table 1 shows, although the yields of *p* and *m*-nitrophenylacetone were rather low, good yields for the reaction of heteroaryltins were obtained. As acetonylpyridines were labile, the coupled products were isolated without hydrolysis.

Results of palladium-catalyzed reactions of 2-methoxymethoxyallyl chloride with aryltributyltins were shown in Table 2.

Good yields of the arylacetones were obtained from the reaction with the *m* and *p*-nitrophenyltin, but moderate yields from the thienyltins. And the reaction with the pyridyltins did not give the product. Thus, suitable reagents for acetonylium synthon are differ-

ent with the kind of aromatic tin compounds.

There are a number of methods for the conversion of allyl acetate or phosphate into the corresponding allylstannane.[11] If such a conversion could be attained, the same coupling products could be obtained from the 2-alkoxyallylstannane and aryl halide. Unfortunately, many trials for the preparation of the 2-alkoxyallylstannane failed.

However, palladium-catalyzed reaction of a ternary system composed of bromobenzene, hexabutyldistannane, and 2-methoxymethoxyallyl chloride or 2-ethoxyallyl diethyl phosphate gave the expected product in moderate yields, although the reaction with substituted aryl bromides gave the product in lower yields.

$$PhBr+Bu_3SnSnBu_3+CH_2=C(OMOM)CH_2Cl \xrightarrow{[Pd]} PhCH_2C(OMOM)=CH_2 \quad 69\% \quad (8)$$

$$PhBr+Bu_3SnSnBu_3+CH_2=C(OEt)CH_2OPO(OEt)_2 \xrightarrow{[Pd]} PhCH_2C(OEt)=CH_2 \quad 53\% \quad (9)$$

The reaction seems to proceed through the formation of aryltributyltin prepared in situ by the reaction of aryl bromide with hexabutyldistannane under the palladium catalysis,[12] followed by its reaction with acetonylium equivalent under the reaction conditions.

Experimental

Instruments. JASCO Model A-100 for infrared spectra, Varian Associates Model EM-360 for ^1H NMR spectra, JEOL Model JMS-DX302 for mass spectra, JAI Model LC-08 for liquid chromatography, and Ohkura Model for gas chromatography using 10% Silicone SF96 or SE30 on Celite 545 were used.

Materials. 2-Bromothiophene (bp 65—75 °C/15 mmHg; 1 mmHg=133.322 Pa) was prepared by the bromination of thiophene.[13] 3-Bromothiophene (bp 75—77 °C/46 mmHg) was prepared by the bromination of thiophene giving 2,3,5-tribromothiophene (bp 135 °C/16 mmHg), followed by the treatment with zinc in acetic acid.[14] 2-Ethoxyallyl diethyl phosphate,[5] 2-ethoxyallyl acetate,[6] 2-ethoxyallyl carbonate,[7] 2-methoxymethoxyallyl chloride,[8] and 1-chloromethylvinyl diethyl phosphate[9] were prepared according to the method described in the literatures. Phenyltributyltin was prepared by the reaction of phenylmagnesium bromide with tributyltin chloride [prepared from bis(tributyltin) oxide and hydrochloric acid].[15] *m*-, *p*-Nitrophenyltributyltin were prepared by the reaction of the corresponding aryl bromide with hexabutyldistannane in the presence of palladium complexes.[12] 2-, 3-Pyridyl- and 2-,3-thienyltributyltin were prepared by the reaction of the corresponding pyridyl or thienyl bromide with butyllithium, followed by the reaction with tributyltin chloride.[16] Hexabutyldistannane was prepared by the reaction of the tributyltin hydride [prepared from bis(tributyltin) oxide and poly(methylhydrosiloxane)] in the presence of palladium complexes.[17] Tetrakis(triphenylphosphine)palladium,[18] dichlorobis(triphenylphosphine)palladium,[19] and tris(benzylideneacetone)dipalladium,[20] were prepared by the methods described.

Reaction Procedures. In Eqs. 3 and 4, the mixture of aryltin (1.3 mmol), the acetonylating agent (1.0 mmol), and tetrakis(triphenylphosphine)palladium (1 mol%) in HMPA (1 mL) was heated in a sealed tube at 100 °C for 20 h. The product was analyzed by GLC. In Eq. 5, the reaction was carried out at 120 °C. In Eq. 6, at 120 °C and dichlorobis(triphenylphosphine)palladium in THF were used. In Eq. 7, the reaction was carried out at 120 °C by using tris(dibenzylideneacetone)dipalladium (0.5 mol%) plus triphenylphosphine (2 mol%) in HMPA. In Tables 1 and 2, three times of the scale and dichlorobis(triphenylphosphine)palladium in benzene or toluene were used. The reaction mixture was washed with aqueous potassium fluoride, followed by the extraction of organic layer with ether, then dried over anhydrous magnesium sulfate. The product was isolated by Kugelrohr distillation under reduced pressure. It was acetonylated by the use of column chromatogaraphy on silica gel.

Products. 2-Ethoxyallylbenzene, ^1H NMR (CCl_4) δ=1.30 (t, J=7 Hz, 3H), 3.30 (s, 2H), 3.65 (q, J=7 Hz, 2H), 3.70 (bs, 2H), 7.15 (s, 5H). 1-Benzylvinyl diethyl phosphate, ^1H NMR (CCl_4) δ=1.30 (t, J=7 Hz, 6H), 3.50 (s, 2H), 3.95 (q, J=7 Hz, 2H), 4.16 (q, J=7 Hz, 2H), 4.40 (s, 1H), 4.90 (s, 1H), 7.30 (s, 5H). (2-Methoxymethoxyallyl)benzene, ^1H NMR (CCl_4) δ=3.30 (s, 3H), 3.35 (s, 2H), 4.00 (s, 1H), 4.20 (s, 1H), 4.85 (s, 2H), 7.25 (s, 5H). These compounds were hydrolyzed to give phenylacetone. ^1H NMR (CCl_4) δ=2.05 (s, 3H), 3.65 (s, 2H), 7.35 (s, 5H). Its IR spectra were consistent with that of the authentic sample.[21] 3-(2-Ethoxyallyl)-pyridine, ^1H NMR ($CDCl_3$) δ=1.25 (t, J=7 Hz, 3H), 3.40 (s, 2H), 3.80 (q, J=7 Hz, 2H), 3.90 (bs, 2H), 7.1—8.7 (m, 4H). Exact MS, Found: m/z 163.0952, Calcd for $C_{10}H_{13}NO$: M, 163.0997. 2-(2-Ethoxy-2-propenyl)pyridine, ^1H NMR ($CDCl_3$) δ=1.30 (t, J=7 Hz, 3H), 3.60 (s), 3.80 (q, J=7 Hz) 4.00 (s) 6H, 6.9—8.6 (m, 4H). *p*-Nitroacetonylbenzene, ^1H NMR (CCl_4) δ=2.20 (s, 3H), 3.80 (s, 2H), 7.40, 8.25 (ABq, J=10 Hz, 4H). IR (CCl_4) 1715 (C=O), 1515 and 1345(NO_2) cm^{-1}. Exact MS, Found: m/z 179.0549, Calcd for $C_4H_9NO_3$: M, 179.0582. *m*-Nitroacetonylbenzene, ^1H NMR (CCl_4) δ=2.20 (s,3H), 3.80 (s, 2H), 7.5—8.3 (m, 4H). IR (KBr) 1715 (C=O), 1510 and 1340 (NO_2) cm^{-1}. Exact MS, Found: m/z 179.0526, Calcd for $C_4H_9NO_3$: M, 179.0582. *p*-Cyanoacetonylbenzene, ^1H NMR ($CDCl_3$) δ=2.20 (s, 3H), 3.80 (s, 2H), 7.45, 7.80 (ABq, J=10 Hz, 4H). IR (KBr) 2250(CN), 1718 (C=O) cm^{-1}. Exact MS, Found: m/z 159.0668, Calcd for $C_{10}H_9NO$: M, 159.0684. 2-Acetonylthiophene, ^1H NMR ($CDCl_3$) δ=2.20 (s, 3H), 3.90 (s, 2H), 6.8—7.4 (m, 3H). IR (neat) 1710 (C=O) cm^{-1}. Exact MS, Found: m/z 140.0289, Calcd for C_7H_8OS: M, 140.0296. 3-Acetonylthiophene, ^1H NMR ($CDCl_3$) δ=2.20 (s, 3H), 3.65 (s, 2H), 6.8—7.4 (m, 3H). IR (neat) 1720 (C=O) cm^{-1}, Exact MS, Found: m/z 140.0275, Calcd for C_7H_8OS: M, 140.0296.

The gift of bis(tributyltin) oxide by Hokkoh Kagaku Kogyou Co. Ltd. is gratefully acknowledged. The present work was partially supported by a Grant-in-Aid for Special Project Research No. 61225002 from the Ministry of Education, Science and Culture.

A Convenient Synthesis of Trifluoromethylated Pyrroles and Porphyrins

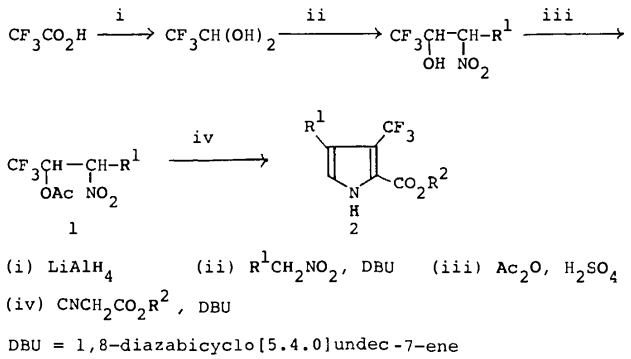
Noboru ONO,* Hisayuki KAWAMURA, and Kazuhiro MARUYAMA*
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received June 9, 1989)

Synopsis. 4-Alkyl-3-trifluoromethyl-2-pyrrolecarboxylic acid esters (**2**) were conveniently prepared by the reaction of trifluoromethylated β-nitro acetates (**1**) with ethyl isocyanoacetate. The pyrroles were converted into the corresponding porphyrins via tetramerization of 2-(hydroxymethyl)pyrroles.

Over past several years organofluorine compounds obtained considerable interest due to the enhanced biological activity.[1] A number of fluorine-containing heterocyclic compounds have been prepared so far. As pyrroles are basic components in various biologically active substances such as porphyrins and related compounds, the preparation of trifluoromethylated pyrroles is very important. Recently, Ogoshi and his co-workers have reported the first synthesis of 3-(trifluoromethyl)pyrroles[2] and their conversion into the corresponding porphyrins.[3] These porphyrins are useful probes for clarifying the structure of enzymes and the interaction between substrates and enzymes by use of ^{19}F NMR spectroscopy.[4] The first method to get trifluoromethylpyrroles is based on the Knorr reaction of ethyl trifluoroacetate,[2] and later the method is modified by the reaction of β-trifluoromethyl α,β-unsaturated ketones with *p*-tolylsulfonylmethyl isocyanide.[5] However, much difficulty still exists in the preparation of trifluoromethylpyrroles. In this paper we wish to report a simple and general method to get 4-alkyl-3-trifluromethyl-2-pyrrolecarboxylic acid exters (**2**), which are good precursors to the corresponding porphyrins. Our method is summarized in Scheme 1.

As shown in Scheme 1, the requisite materials to prepare **2** are all readily available and the procedures are very simple.

Reduction of perfluoroacetic acid with $LiAlH_4$ afforded 2,2,2-trifluoro-1,1-ethanediol (bp 105 °C),[6] which was directly converted into nitro alcohols on treatment with nitroalkanes in the presence of DBU. Thus, the tedious procedure for handling perfluoroacetaldehyde (bp −18 °C) is not required. The nitro alcohols were acetylated with acetic anhydride to give the corresponding β-nitro acetates (**1**) in good yields. The reaction of **1** with ethyl isocyanoacetate or *t*-butyl isocyanoacetate in the presence of DBU (2 equiv) gave 4-alkyl-3-trifluoromethyl-2-pyrrolecarboxylic acid (**2**).[7] The results are summarized in Table 1.



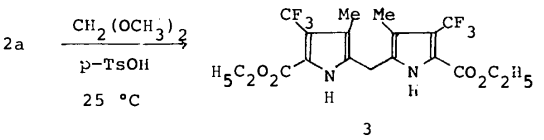
Scheme 1. Preparation of pyrroles (**2**).

Table 1 Preparation of 4-Alkyl-3-trifluoromethyl-2-pyrrolecarboxylic Acid Esters (**2**)

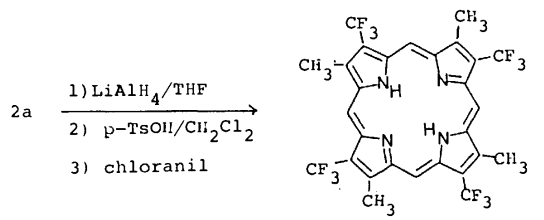
R^1	R^2	**2**, Yield/%
CH_3	C_2H_5	**2a**, 60
CH_3	*t*-C_4H_9	**2b**, 57
C_2H_5	C_2H_5	**2c**, 65
C_2H_5	*t*-C_4H_9	**2d**, 57
$CH_2CH_2CO_2CH_3$	C_2H_5	**2e**, 60

Thus, trifluoromethylated pyrroles are readily prepared starting from CF_3CO_2H and nitroalkanes. Other perfluoroalkylated pyrroles may be also prepared by the similar procedure as shown in Scheme 1 if appropriate perfluoro carboxylic acids are used.

Trifluoromethylpyrroles **2** are less reactive toward electrophiles than the corresponding alkyl derivatives. For example, **2a** reacts with methylal in the presence of *p*-toluenesulfonic acid (*p*-TsOH) to give dipyrromethane **3** in 60% yield. However, it takes about 7 days to complete the reaction, while the corresponding alkyl derivatives react with methylal very quickly under the same conditions.[8]



Pyrroles **2** are ideally functionalized for porphyrin synthesis. For example, pyrrole **2a** was converted into porphyrin **4a** via reduction with $LiAlH_4$ followed by treatment with *p*-TsOH and oxidation with chloranil, where type I porphyrin was formed selectively.[8] Other types of porphyrins are prepared via pyrromethanes such as **3**, which is well documented.[9]



Absorption maxima in electronic spectra and redox potentials of **4a** and Zn complex of **4a** (Zn**4a**) are

Table 2 Absorption Maxima in Electronic Spectra and Redox Potentials of porphyrins

Porphyrins	λ_{max}/nm	Redox potentials[a] E^1/V	E^2/V
4a	407, 504, 539, 580, 635	0.84	1.22
OEP	396, 497, 532, 565, 619	0.60	1.02
Zn**4a**	404, 532, 568	0.78	1.02
ZnOEP	405, 532, 568	0.45	0.79

a) Redox potentials were determined by cyclic voltammetry. Measurements were made on platinum electrode in 0.1 M tetrabutylammonium perchlorate in CH_2Cl_2 at 25 °C. Reversible oxidation was observed, and E^1 and E^2 are the first and second oxidation peak potentials, respectively. Reference is Ag-$AgClO_4$.

compared with those of octaethylporphyrin (OEP) and Zn complex of OEP (ZnOEP). The results are summarized in Table 2. Each absorption maxima of **4a** shows red shift by about 10 nm compared with that of OEP. The redox potentials are dramatically changed by the introduction of the trifluoromethyl group at the β-position. The ring oxidation of **4a** and Zn**4a** occurs at about 200—300 mV higher than for OEP and ZnOEP, respectively.

Experimental

2,2,2-Trifluoro-1,1-ethanediol was prepared according to the procedure of the literature.[6] To a solution of perfluoroacetic acid (0.333 mol) in 300 ml of anhydrous diethyl ether was added slowly a slurry of $LiAlH_4$ (0.19 mol) in 250 ml of anhydrous diethyl ether at −5 °C to 0 °C during 1.5 h. Stirring was continued at −5 °C for 1 h. The reaction mixture was hydrolyzed with 15 ml of water followed by 30 ml of concd H_2SO_4 in 70 ml of water. The ether was decantated, and the solids remaining in the flask were dissolved in 300 ml of water. The aqueous solution was extracted with diethyl ether, and the extracts were combined and dried with anhydrous magnesium sulfate. After the removal of the solvent, the residue was distilled to give 2,2,2-trifluoro-1,1-ethanediol in 70—80% yield, bp 105 °C. This material was used for the next step without further purification.

3-Nitro-1,1,1-trifluoro-2-butanol. A mixture of 2,2,2-trifluoro-1,1-ethanediol (10 g, 0.086 mol), nitroethane (13 g, 0.17 mol), and DBU (2.6 g, 0.12 mol) was stirred at room temperature for 24 h. The resultant solution was poured into 1 M-HCl (100 ml) (1M=1 mol dm^{-3}) and extracted with ethyl acetate. The extracts were washed with water and dried with anhydrous magnesium sulfate. The solvent was removed and the residue was distilled to give the alcohol, 8.7 g (67% yield). Bp 85—87 °C/25 mmHg; 1 mmHg=133.32 Pa. ^{1}H NMR ($CDCl_3$) δ=1.90 (d, 3H), 3.70 (s, 1H), 4.62 (m, 1H), 5.10 (m, 1H). IR (neat) 3400, 1560, 1380, 1260, 1180 cm^{-1}. This compound was acetylated on treatment with acetic anhydride in the presence of H_2SO_4. Yield 90%, bp 57 °C/5 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.75 (d, 3H, J=7 Hz), 2.28 (s, 4H), 4.46—4.84 (m, 1H), 5.85 (m, 1H).

Following nitro alcohols and their acetates were prepared in the same way as described above.

3-Nitro-1,1,1-trifluoro-2-pentanol. Yield 65%, bp 57—58 °C/4 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.02 (t, 3H, J=7 Hz), 2.05 (m, 2H), 3.5 (br s, 1H), 4.45 (m, 1H), 4.75 (m, 1H), IR (neat) 3400, 1560, 1380, 1260, 1180 cm^{-1}. Acetyl Derivative: bp 62 °C/5 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.05 (t, 3H, J=7 Hz), 1.97—2.08 (m, 2H), 2.21 (s, 3H), 4.70—4.83 (m, 1H), 5.75—5.96 (m, 1H).

Methyl 5-Hydroxy-4-nitro-6,6,6-triflurohexanoate. Yield 60%, bp 80 °C/2 mmHg. ^{1}H NMR ($CDCl_3$) δ=2.0—2.2 (m, 4H), 3.4 (br s, 1H), 3.65 (s, 3H), 4.70 (m, 2H), 5.22 (m, 1H). IR (neat) 3400, 1720, 1560, 1380, 1260, 1200 cm^{-1}. Acetyl Derivative: bp 95 °C/2 mmHg.

Preparation of Pyrroles. Ethyl 4-Methyl-3-trifluoromethyl-2-pyrrolecarboxylate (Typical Procedure). To a stirred solution of ethyl isocyanoacetate (2.5 g, 22 mmol) and 2-acetoxy-3-nitro-1,1,1-trifluorobutane (4.0 g, 19 mmol) in tetrahydrofuran (20 ml) was added DBU (5.5 g, 36 mmol) at 0 °C. The resulting mixture was stirred at 25 °C for 12 h. The reaction mixture was poured into water (100 ml) containing 1 M-HCl (10 ml) and extracted with ethyl acetate. The extracts were combined and washed with water. After drying with anhydrous magnesium sulfate and removal of the solvent, the residue was subjected to column chromatography (silica gel/benzene) to give the desired pyrrole (**2a**), 2.5 g (60% yield). Mp 73—75 °C. ^{1}H NMR ($CDCl_3$) δ=1.31 (t, 3H, J=7 Hz), 2.19 (s, 3H), 4.38 (q, 2H, J=7 Hz), 6.65 (d, 1H, J=4 Hz), 9.28 (s, 1H). IR (KBr) 3280, 1670, 1290, 1260, 1140 cm^{-1}. Found: C, 48.97; H, 4.47; N, 6.38; F, 25.60%. Calcd for $C_9H_{10}NO_2F_3$: C, 48.87; H, 4.56; N, 6.33; F, 25.77%.

***t*-Butyl 4-Methyl-3-trifluoromethyl-2-pyrrolecarboxylate (2b).** This pyrrole was prepared by the same procedure as the preparation of **2a**, but *t*-butyl isocyanoacetate was used instead of ethyl isocyanoacetate. Mp 103—105 °C. ^{1}H NMR ($CDCl_3$) δ=1.55 (s, 9H), 2.18 (s, 3H), 6.65 (d, 1H, J=4 Hz), 9.16 (s, 1H). IR (KBr) 3280, 1660, 1290, 1260, 1140 cm^{-1}. Found: C, 53.08; H, 5.60; N, 5.68%. Calcd for $C_{11}H_{14}NO_2F_3$: C, 53.01; H, 5.66; N, 5.62; F, 22.87%. Following pyrroles were prepared by the same procedure.

2c: oil, ^{1}H NMR ($CDCl_3$) δ=1.33 (t, 3H, J=7 Hz), 1.38 (t, 3H, J=7 Hz), 4.32 (q, 2H, J=7 Hz), 6.70 (d, 1H, J=4 Hz), 9.63 (s, 1H). IR (neat) 3300, 1670, 1290, 1260, 1150 cm^{-1}. Found: C, 50.92; H, 5.07; N, 5.67%. Calcd for $C_{12}H_{12}NO_2F_3$: C, 51.06; H, 5.14; N, 5.96%.

2d: mp 93—94 °C. ^{1}H NMR ($CDCl_3$) δ=1.39 (t, 3H, J=7 Hz), 1.59 (s, 9H), 2.63 (q, 2H, J=7 Hz), 6.71 (d, 1H, J=4 Hz), 9.25 (s, 1H). IR (KBr) 3280, 1660, 1290, 1260, 1140 cm^{-1}. Found; C, 54.43; H, 6.07; N, 5.51%. Calcd for $C_{12}H_{16}NO_2F_3$: C, 54.75; H, 6.08; N, 5.31%.

2r: oil ^{1}H NMR ($CDCl_3$) δ=1.32 (t, 3H, J=7 Hz), 2.50—2.72 (m, 4H), 3.72 (s, 3H), 4.26 (q, 2H, J=7 Hz), 6.65 (q, 1H, J=4 Hz), 9.90 (s, 1H). IR (neat) 3300, 1670, 1700, 1290, 1260, 1150 cm^{-1}. Found: C, 49.02; H, 4.72; N, 4.52%. Calcd for $C_{12}H_{14}NO_4F_3$: C, 49.15; H, 4.80; N, 4.78%.

Preparation of Dipyrromethane 3. A mixture of **2a** (0.22 g, 1 mmol), methylal (0.38 g, 5 mmol), and *p*-TsOH (0.1 g) in CH_2Cl_2 (10 ml) was stirred at room temperature for 7 days. The reaction mixture was poured into water, extracted with CH_2Cl_2, and washed with aqueous $NaHCO_3$. The organic layer was dried with anhydrous $MgSO_4$, and the solvent was removed. The residue was subjected to column chromatography (silica gel/CH_2Cl_2) to give **3**, 0.13 g (60% yield). Mp 166—168 °C. ^{1}H NMR ($CDCl_3$) δ=1.31 (t, 3H, J=7 Hz), 2.16 (s, 6H), 3.94 (s, 2H), 4.21 (q, 4H, J=7 Hz), 10.12 (s, 2 H). IR (KBr) 3280, 1680, 1290, 1260, 1140 cm^{-1}. Found: C, 50.15; H, 4.44; N, 6.17%. Calcd for $C_{20}H_{20}N_2O_4F_6$: C, 50.22; H, 4.43; N, 6.16%.

Preparation of Porphyrin 4. To a stirred mixture of $LiAlH_4$ (0.08 g, 2 mmol) in 30 ml of THF was added a solution of **2a** (0.50 g, 2.26 mmol) in 10 ml of THF. The mixture was stirred at 0 °C for 2 h and to the mixture was added 1 ml of ethyl acetate. The reaction mixture was poured into water containing dilute HCl and extracted with CH_2Cl_2. The organic layer was dried with anhydrous $MgSO_4$ and *p*-TsOH (0.1 g) was added to the organic layer

(ca. 100 ml). The resulting solution was stirred at room temperature for 12 h, and then chloranil (0.28 g, 1.1 mmol) was added to the resulting reaction mixture. After stirring at room temperature for 8 h, the reaction mixture was washed with 5%-$NaHCO_3$ and dried with anhydrous Na_2SO_4. The solvent was removed and the residue was subjected to column chromatography (silica gel/$CHCl_3$) to give **4**, 51 mg (14% yield). ^1H NMR ($CDCl_3$) δ=−3.48 (s, 2H, NH), 3.65 (s, 12H, CH_3), 10.40 (s, 4H, meso H). IR (KBr) 1120, 1050 cm^{-1}. Absorption maxima and redox potentials are summarized in Table 2. All these data are in good agreement with those reported by Ogoshi.[3,5]

Synopsis. A variety of lithium enolates derived from esters and ketones could be readily alkylated with 3-methylbenzothiazolium salts to give the novel α-(benzothiazolinyl) esters and ketones, 2-[1-(alkoxycarbonyl)alkyl]-3-methylbenzothiazolines and 3-methyl-2-(2-oxoalkyl)benzothiazolines in good yields, respectively.

1,3-Dithienium tetrafluoroborates,[1] are well-known promising candidates of heterocyclic formyl or acyl cation equivalents. Although, up to now, the introduction of masked formyl and acyl groups at the α-position of carbonyl compounds has been achieved by the reaction of these salts with enol silyl ethers prepared from esters and ketones, a simpler and more direct method with lithium enolates have not been reported yet.[1] We have recently demonstrated that 3-methylbenzothiazolium salts can be used as useful formyl and acyl cation equivalents.[2,3] As an extension of our previous work[2] and as a requirement for the convenient preparation method of α-(benzothiazolinyl) carbonyl compounds in our study of enolate-transfer type aldol reaction,[4] we were interested in examining the direct reaction of lithium enolates with 3-methylbenzothiazolium salts. We now report that lithium enolates **2** and **3** derived from esters and ketones are readily alkylated under mild conditions with 3-methylbenzothiazolium salts **1**, leading to the introduction of the 3-methylbenzothiazoline unit at the α-position of carbonyl compounds.

5 : R^2=alkyl, aryl

The alkylation of ester enolates **2** was carried out by the enolization of esters with lithium diisopropylamide in THF followed by treatment with one equiv of the benzothiazolium salts **1a**—c at −78 °C to room temperature, with the results summarized in Table 1. Under these conditions, 3-methylbenzothiazolium iodide (**1a**), which has a very acidic hydrogen at the 2-position, reacted with a variety of ester enolates **2** without significant abstraction of that hydrogen as a proton[5] to give the corresponding 2-[1-(ethoxycarbonyl)alkyl]benzothiazolines **4a**—**e** in good yields (Entries 1—5). Diastereoselectivity on the reaction of **1a** with the enolates produced from ethyl propionate, ethyl butanoate, and ethyl 3-methylbutanoate was found to be roughly 1 : 1 in each case (Entries 3—5), although the relative stereochemistry of each diastereoisomers has been not clarified. On the other hand, 2-substituted benzothiazolium salts **1b**, c reacted more efficiently with ester enolates to give the corresponding 2,2-disubstituted 3-methylbenzothiazolines in high yields (Entries 6,7).

The alkylation of ketone enolates **3** was similarly and efficiently achieved with benzothiazolium salts **1a**, **b** at 0 °C to room temperature giving the corresponding 2-(2-oxoalkyl)benzothiazolines **5a**—**g** in good

yields. The results are listed in Table 2. In contrast to the case of ester enolates **2**, the diastereoselectivity on the reaction with ketone enolates **3** was very high, as seen in the results of reactions with the enolates produced from propiophenone, butyrophenone, and cyclohexanone (Entries 5—7). As shown in the successful conversion of the kinetic enolate of 2-pentanone to **5d**, the regiocontrolled introduction of a 3-methylbenzothiazoline unit at the α-position of ketones can be conveniently achieved by the present method (Entry 4).

The present study is the first example of the direct alkylation of lithium enolates with heterocyclic formyl and acyl cation equivalents and provides a useful procedure for introduction of masked formyl and acyl groups at the α-position of carbonyl compounds because of ready and diverse availability of benzothiazolium salts[2,3] and high operational conveniency. The alkylation products can be regarded as selectively protected 1,3-dicarbonyl compounds and potentially useful synthetic intermediates because, for example, the 3-methylbenzothiazoline unit could be, after desired synthetic transformation, hydrolyzed to a carbonyl group as shown in the previous work.[2,3] In addition the another unique functionalities of 3-methylbenzothiazoline ring system increases the value of the present alkylation products in organic synthesis.[4,6]

Experimental

Melting points were recorded on a Yanagimoto micro-melting-point apparatus and are uncorrected. ^{1}H NMR spectra were measured with a JEOL PMX-60 spectrometer at 60 MHz using tetramethylsilane as an internal reference. IR spectra were recorded on a JASCO A-202 spectrophotometer. Silica gel (Merck silica gel 60, 230—400 mesh ASTM) was used for medium-pressure liquid chromatography (MPLC).

Materials. 2,3-Dimethylbenzothiazolium iodide (**1c**) was prepared by methylation of commercially available 2-methylbenzothiazole with iodomethane according to the preparation method reported for 3-methylbenzothiazolium iodide (**1a**).[2] 3-Methyl-2-phenylbenzothiazolium fluorosulfate (**1b**) was prepared by the methylation of 2-phenylbenzothiazole with methyl fluorosulfate according to the preparation method reported for 3-methylbenzothiazolium fluorosulfate.[2]

The Reaction of Benzothiazolium Salts 1 with Lithium Enolates 2 from Esters; General Procedure. To a solution of diisopropylamine (1.21 g, 12 mmol) in THF (20 ml), a 1.6 M hexane solution (1M=1 mol dm^{-3}) of *n*-BuLi (6.9 ml, 11 mmol) was slowly added with stirring at −78 °C and the mixture was then stirred at 0 °C for 10 min. To this mixture, a THF (5 ml) solution of ester (10 mmol) was slowly added at −78 °C and the mixture was then stirred for 50 min. Benzothiazolium salts **1** (10 mmol) was added at −78 °C and the mixture was stirred for 1 h at −78 °C and for 2 h at room temperature. The mixture was quenched by the addition of water and the aqueous mixture was extracted with ether. The extract was dried with $MgSO_4$ and concentrated under reduced pressure. The residue was subjected to MPLC to give pure product **4**. The results are summarized in Table 1. The spectral and physical data of the products **4** are as follows:

4a: pale yellow oil; IR (neat) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.16 (t, 3H, *J*=7 Hz), 2.67 (s, 3H), 2.73 (m, 2H), 4.00 (q, 2H, *J*=7 Hz), 5.15 (dd, 1H, *J*=8, 5 Hz), and 6.05—6.87 (m, 4H). Calcd for $C_{12}H_{15}NO_2S$: C, 60.73; H, 6.37; N, 5.90%. Found: C, 60.12; H, 6.46; N, 6.04%.

4b: pale yellow oil; IR (neat) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.13 (s, 3H), 1.17 (s, 3H), 1.20 (t, 3H, *J*=7 Hz), 2.82 (s, 3H), 4.04 (q, 2H, *J*=7 Hz), 5.23 (s, 1H), and 6.25—6.90 (m, 4H). Calcd for $C_{14}H_{19}NO_2S$: C, 63.36; H, 7.22; N, 5.28%. Found: C, 62.86; H, 7.30; N, 5.30%.

4c: pale yellow oil (diastereomeric mixture of 55:45 by ^{1}H NMR analysis); IR (neat) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.17 (d, 3H, *J*=7 Hz), 1.23 (t, 3H, *J*=7 Hz), 2.74 and 2.82 (each s, 4H), 4.06 and 3.94 (each q, 2H, *J*=7 Hz), 5.13 and 5.29 (each d, 1H, *J*=5 Hz), and 6.10—6.93 (m, 4H). Calcd for $C_{13}H_{17}NO_2S$: C, 62.12; H, 6.82; N, 5.57%. Found: C, 61.86; H, 6.96; N, 5.52%.

4d: pale yellow oil (diastereomeric mixture of 50:50 by ^{1}H NMR analysis); IR (neat) 1710 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=0.93 (t, 3H, *J*=7 Hz), 1.20 (t, 3H, *J*=7 Hz), 1.66 (q, 2H, *J*=7 Hz), 2.80 and 2.87 (each s, 4H), 4.05 (m, 2H), 4.97 and 5.08 (each d, 1H, *J*=2, 3 Hz), and 6.23—7.17 (m, 4H). Calcd for $C_{14}H_{19}NO_2S$: C, 63.36; H, 7.22; N, 5.28%. Found: C, 63.31; H, 7.21; N, 5.31%.

4e: pale yellow oil (diastereomeric mixture of 60:40 by ^{1}H NMR analysis); IR (neat) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=0.93 and 0.96 (each d, 6H, *J*=7 Hz), 1.22 (t, 3H, *J*=7 Hz), 2.27 (m, 1H), 2.62 and 2.64 (each d, 1H, *J*=8, 6 Hz), 2.80 and 2.83 (each s, 3H), 3.95 and 4.08 (each q, 2H, *J*=7 Hz), 5.10 and 5.12 (each d, 1H, *J*=8, 6 Hz), and 6.25—7.00 (m, 4H). Calcd for $C_{15}H_{21}NO_2S$: C, 64.48; H, 7.58; N, 5.01%. Found: C, 64.03; H, 7.71; N, 5.06%.

4f: pale yellow oil; IR (neat) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.00 (t, 3H, *J*=7 Hz), 2.53 (s, 3H), 3.27 (s, 2H), 3.84 (q, 2H, *J*=7 Hz), and 6.57—7.50 (m, 9H). Calcd for $C_{18}H_{19}NO_2S$: C, 68.98; H, 6.11; N, 4.47%. Found: C, 69.06; H, 6.09; N, 4.50%.

4g: pale yellow oil; IR (neat) 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.19 (t, 3H, *J*=8 Hz), 1.33 (s, 6H), 1.90 (s, 3H), 2.73 (s, 3H), 3.98 (q, 2H, *J*=8 Hz), and 6.00—6.92 (m, 4H). Calcd for $C_{15}H_{21}NO_2S$: C, 64.48; H, 7.58; N, 5.01%. Found: C, 64.16; H, 7.32; N, 4.91%.

The Reaction of Benzothiazolium Salts 1 with Lithium Enolates 3 from Ketones; General Procedure. A THF (5 ml) solution of ketone (10 mmol) was slowly added to a THF solution of LDA (11 mmol) at −78 °C and the mixture was allowed to gradually warm to room temperature. The mixture was stirred for 3 h and then cooled to 0 °C. Benzothiazolium salt **1** (10 mmol) was added to the mixture and the mixture was stirred for 1 h at 0 °C and for 1 h at room temperature. After a similar work-up to the reaction of ester enolates, the crude product was purified by MPLC to give pure product **5**. The results are summarized in Table 2. The spectral and physical data of the products **5** are as follows:

5a: pale yellow oil; IR (neat) 1680 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=2.43 (s, 3H), 3.10 (m, 2H), 5.10 (dd, 1H, *J*=8, 6 Hz), and 5.76—7.57 (m, 9H). This compound was unstable at room temperature in air.

5b: pale yellow needles; mp 119—120 °C; IR (KBr) 1680 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=2.55 (s, 3H), 3.83 (d, 1H, *J*=16 Hz), 4.33 (d, 1H, *J*=16 Hz), and 6.05—7.83 (m, 14H). Calcd for $C_{22}H_{19}NOS$: C, 76.49; H, 5.54; N, 4.05%. Found: C, 76.42; H, 5.53; N, 3.85%.

5c: pale yellow needles; mp 123—124 °C; IR (KBr) 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=2.10 (s, 3H), 2.55 (s, 3H), 3.21 (d, 1H, *J*=11 Hz), 3.47 (d, 1H, *J*=11 Hz), and 6.21—7.52 (m, 9H). Calcd for $C_{17}H_{17}NOS$: C, 72.05; H, 6.05; N, 4.94%. Found: C, 71.91; H, 5.96; N, 4.83%.

5d: pale yellow needles; mp 66—66.7 °C; IR (KBr) 1700

cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.80 (t, 3H, J=8 Hz), 1.50 (m, 2H), 2.33 (t, 2H, J=6 Hz), 2.50 (s, 3H), 3.28 (d, 1H, J=18 Hz), 3.72 (d, 1H, J=18 Hz), and 6.23—7.70 (m, 9H). Calcd for $C_{19}H_{21}NOS$: C, 73.28; H, 6.80; N, 4.50%. Found: C, 73.09; H, 6.80; N, 4.46%.

5e: pale yellow needles; mp 153—153.5 °C; IR (KBr) 1680 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.53 (d, 3H, J=8 Hz), 2.42 (m, 3H), 4.56 (q, 1H, J=8 Hz), and 6.43—7.33 (m, 14H). Calcd for $C_{23}H_{21}NOS$: C, 76.85; H, 5.89; N, 3.90%. Found: C, 76.75; H, 5.98; N, 3.69%.

5e′: pale yellow needles; mp 120.3—121.5 °C; IR (KBr) 1700 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.05 (d, 3H, J=6 Hz), 2.55 (s, 3H), 3.85 (q, 1H, J=6 Hz), and 6.31—7.40 (m, 14H). Calcd for $C_{23}H_{21}NOS$: C, 76.85; H, 5.89; N, 3.90%. Found: C, 76.41; H, 6.04; N, 4.55%.

A New Method for the Selective Synthesis of Biphenyl by Dehydrogenative Coupling of Benzene

Masahiro NAKADA, Yu AIMIN, Shigenobu KAWAKAMI,
Shingo IWAKI, and Tatsuaki YAMAGUCHI*
Laboratory of Organic Chemistry, Chiba Institute of Technology,
Tsudanuma, Narashino-shi, Chiba 275
(Received March 13, 1989)

Synopsis. A method has been developed for the direct preparation of biphenyl by the thermal dehydrogenative coupling of benzene in the vapor phase on the surface of heater at 1000—1200 °C. Biphenyl was obtained at a high selectivity of more than 94% over the wide range of benzene conversion (3—77%).

Biphenyl was first reported by Fittig, and then identified by Berthelot as the main product obtained by passing benzene vapor through a hot tube.[1] Since then many methods have been developed for the preparation of this compound.[2-4] Biphenyl is now important as the starting material for heating oil, high aromatic solvent, electric insulating oil and other synthetic use in industry. The modern commercial production process of biphenyl is the thermal dehydrogenation of benzene in a hot tube. In this method, however, the higher is the conversion of benzene, the lower is the biphenyl selectivity due to additional coupling of biphenyl to terphenyls and quaterphenyls. Therefore, the conversion is to be kept below 15% to obtain biphenyl in high selectivity (88—92%).[5] Biphenyl is also obtained as a by-product of benzene production by hydrodealkylation of toluene.[6] A further purification of biphenyl is necessary in this process. A novel method to prepare pure biphenyl in high selectivity and yield will be described in this paper. The characteristic feature of the present method is the temperature gradient system of the reactor heated by a heater from inside. In such a system, the thermal diffusion effect is significant, and the product of the higher molecular weight was separated at the cold wall of the reactor. The highly selective synthesis of ethylene from methane by the thermal diffusion reactor has recently been reported by one of the authors.[7]

Experimental

An electric heater was placed inside of a 1 L three-necked separable flask fitted with a reflux condenser. The heater was made of a nickel chromium steel wire of 0.5 mm in diameter and 25 cm in length made in a spiral. The flask containing 50 g of benzene was heated by a heating mantle under nitrogen. After the boiling of benzene was started, the power of the heater inside was turned on, and the vapor of benzene was contacted with the heater. The surface temperature of the heater was monitored by a radiation pyrometer (Minolta IR-120) and controlled. The reaction mixture was sampled periodically and analyzed by a gas chromatograph (Shimadzu GC-9A).

Results and Discussion

Figure 1 shows the dependence of the benzene conversion on the surface temperature of the heater. The reaction started substantially at 1000 °C. The conversion of benzene increased exponentially with the surface temperature, reaching 77% at 1150 °C. At 1200 °C the color of the benzene vapor near the heater turned brown, suggesting a considerable carbonization. In fact fairly large amount of carbonaceous material deposited on the surface of the nickel chromium steel wire under these conditions. The results are summarized in Table 1 with experimental details. The selectivity of biphenyl remained almost the same 94% over a wide range of benzene conversion. Even at the high conversion of benzene 77.5%, the selectivity of biphenyl was 94.0%. This high selectivity of biphenyl at high conversion of benzene is one of the advantages of this new method over the conventional one, in which benzene vapor is passed through a hot tube heated from outside. In the conventional method, the high selectivity of biphenyl of 90% is obtained only when the one path conversion of benzene is below 15%.

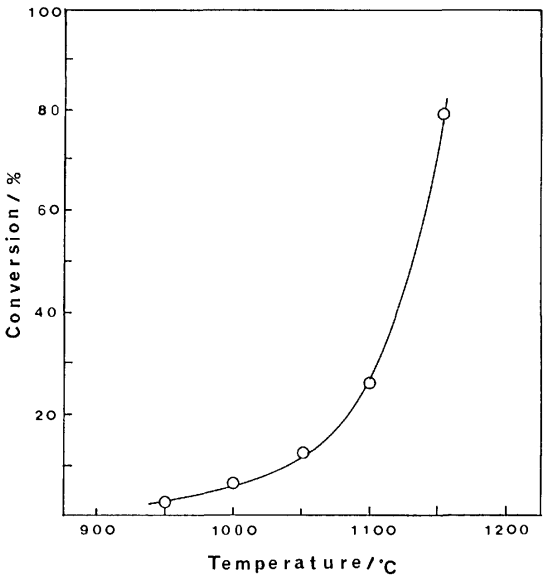

Fig. 1. Dependence of benzene conversion on the surface temperature of the heater (reaction time 6 h).

The phenomenon giving high selectivity of biphenyl may be due to the thermal diffusion effect. The thermal diffusion caused by the temperature gradient between the surface of the heated wire and the cold wall of the reactor effects the produced biphenyl molecule, which is of higher molecular weight than benzene, to leave the heated surface of the heater for the cold wall immediately after its production and

Synopsis. A flow-through transport system was fabricated by using a hollow-fiber impregnated with a 14-crown-4 dinitrophenol solution and was found to allow selective Li^+ transport.

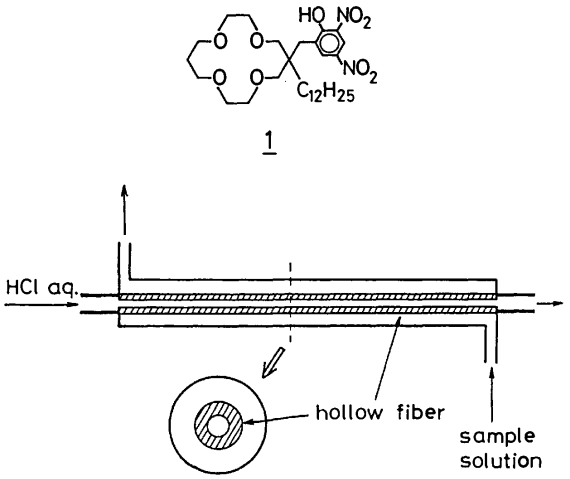
Many attempts to transport alkali metal ions through liquid membranes containing crown ether derivatives as ionophores have been widely made in order to attain an effective separation of a certain metal ion from others. In this kind of liquid membrane system, supported liquid membranes[1-3] containing a crown ether solution using a water-immiscible organic solvent (such as diphenyl ether, *o*-nitrophenyl phenyl ether, and *o*-nitrophenyl octyl ether (NPOE)) may be superior in handling to bulk liquid membranes, and may be employed for industrial applications. In the case of using a hollow-fiber as the support for a liquid membrane,[4] separation of a certain metal ion can be carried out under conditions in which the aqueous solutions of the source and receiving phases flow along either or both sides of the membrane phase. Therefore, such a decrease in the metal ion flux with the ion concentration change in the source phase, as is frequently observed in the conventional membrane transport systems, can be prevented. Since the flux in this flow system is kept constant, a large quantity of the desired cation can be separated from the source phase solution continuously. Alternatively, the transport rate of a certain metal ion may be effectively altered with the ion concentration change in the source phase.

We have synthesized several 14-crown-4 derivatives[5] endowed with a lipophilic chain and a nitrophenol moiety and have employed them as ionophores for proton-driven transport of alkali metal ions using a supported liquid membrane.[2] It was found that Li^+ was transported selectively and enriched in the receiving phase on the proton-driven ion transport. Applications of this Li^+-selective membrane transport system to the corresponding flow-through transport system are useful for effective Li^+ recovery from both spring- and seawater and for the construction of pretreatment systems for selective Li^+ analyses.

In this paper we report on the competitive proton-driven transport of alkali metal ions through a hollow-fiber membrane impregnated with a solution of 14-crown-4 dinitrophenol **1**. The effects of the transport conditions on the ion transportability in this hollow-fiber ion-transport system are also described.

Experimental

Competitive transport of alkali metal ions through a hollow-fiber membrane containing 14-crown-4 dinitrophenol **1**, which was prepared according to a previously used procedure,[5] was conducted by using a flow-through transport system (shown schematically in Fig. 1). The inner tube was a hollow fiber (pore size: 0.1 μm, thickness: 0.27 mm, outer diameter: 1.22 mm, inner diameter: 0.68 mm), which was kindly given by Asahi Chemical Industry Co., Ltd. The outer tube was a glass tube (inner diameter: 4.0 mm), both ends of which were joined to the hollow fiber with an epoxy resin adhesive. The hollow fiber was impregnated with a NPOE solution of 14-crown-4 dinitrophenol. Impregnation was performed by slowly flowing a 4×10^{-2} M (1 M=1 mol dm^{-3}) crown ether NPOE solution through the inside of the hollow-fiber membrane. The exposed area in the outer surface of the hollow-fiber membrane was 2.0 cm^2, unless otherwise specified. Aqueous solutions for the source and receiving phases were flowed countercurrently at the inside and outside phases of the hollow-fiber membrane, respectively, at a constant flow rate by using peristaltic pumps. The flow-through transport system was kept at 25 °C by using a thermostated bath during the transport experiment.



1

Fig. 1. 14-Crown-4 dinitrophenol **1** and schematic diagram of flow-through transport system.

For the proton-driven cation transport, the source (outer) phase contained 1.1×10^{-2} M tetramethylammonium hydroxide (TMAOH) and alkali metal ions, and the receiving (inner) phase did 2.0×10^{-3} M hydrochloric acid. The source phase contained alkali metal chlorides (Li^+, Na^+, K^+, Rb^+, Cs^+) of 1.0×10^{-3} M each for competitive transport. Upon examining the dependence of metal ion (Li^+ and Na^+) concentrations on the Li^+ transportability, the source phase contained Li^+ and Na^+ of appropriate concentrations. In competitive cation transport under conditions in which the temperature was changed from 6 to 45 °C, the source phase of the transport system contained Li^+ and Na^+ of 1.0×10^{-3} M each.

The eluted solution of the receiving phase was collected by a fraction collector every fifteen minutes. The alkali

metal ions in the receiving aqueous phase were determined by flame photometry. Aliquots (1 ml) of the aqueous phase were occasionally taken; then, ten-fold diluted solutions were subjected to ion determination.

Results and Discussion

Competitive Transport of Alkali Metal Ions. Crown ether **1** is endowed with a 14-crown-4 site, which complexes Li^+ selectively, a dinitrophenol moiety as a proton-dissociable anionic site to counterbalance the positive charge of the complexed cation, and a dodecyl group to have the ionophore stay in the membrane phase. This crown ether, the pK_a of which is 4.92 (in 50% dioxane-H_2O), is able to deprotonate under weakly basic conditions and, thereby, to complex Li^+. It was previously shown that effective Li^+-selective transport was attained by using a U-tube equipped with a supported liquid membrane made from a microporous polypropylene film, which was impregnated with a **1**-NPOE solution. That is to say, at the basic interface the dinitrophenol moiety loses a proton; concurrently the crown ether moiety interacts with a lithium ion and forms an electrically-neutral complex. The crown-Li^+ complex diffuses to the acidic interface through the membrane, where it is forced to release the Li^+ by protonation of the anionic site.

The transport profile of alkali metal ions for a flow-through system with a hollow-fiber membrane containing the crown ether NPOE solution is depicted in Fig. 2. It should be noted that cation transport through the membrane is extremely specific to Li^+ and the Li^+ flux appears to level off within 1 h. The other alkali metal ions, even Na^+ which is quite similar to Li^+ in the chemical property, moved through the membrane only at such low transport rates. The Li^+ concentration in the receiving phase was 4.5×10^{-5} M at a flow rate of 0.19 ml min^{-1} (a linear velocity of 52.3 cm min^{-1} in the inner phase of the hollow fiber). The concentration of metal ion in the receiving phase varied inversely as the flow rate of the receiving phase, while the concentration was independent of the flow rate of the source phase. The metal ion transportability was also proportional to the exposed membrane area and, therefore, the length of hollow fiber.

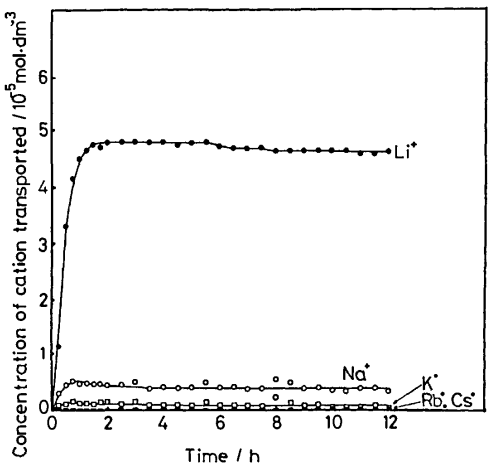


Fig. 2. Competitive proton-driven cation transport of alkali metal ions using flow-through system.

Effects of Transport Conditions. The flux of metal ion transported was directly proportional to the logarithm of the metal ion concentration under conditions in which the Li^+ and Na^+ concentrations in the source phase were varied from 1.0×10^{-5} M to 1.0×10^{-3} M (Fig. 3). The metal ion flux is generally proportional to the cation concentration in the source phase, in the case of a conventional hollow-fiber membrane systems containing ionophores.[6] The difference in the concentration dependence on metal ion flux between this system and conventional hollow-fiber membrane systems has not yet been understood.

The concentration of Na^+ which coexists with Li^+ in the source phase is an important factor governing the Li^+ transportability. Competitive transport of Li^+ and Na^+ through the supported hollow-fiber membrane was carried out by varying the Na^+ concentration in the source phase from 1.0×10^{-3} M to 1.0×10^{-1} M and keeping the Li^+ concentration constant (1.0×10^{-3} M). Increasing the Na^+ concentration enhanced the Na^+ transportability and lowered the Li^+ transportability. It is consequently shown in Table 1 that the selectivity ratio of Li^+ over Na^+ hardly changes.

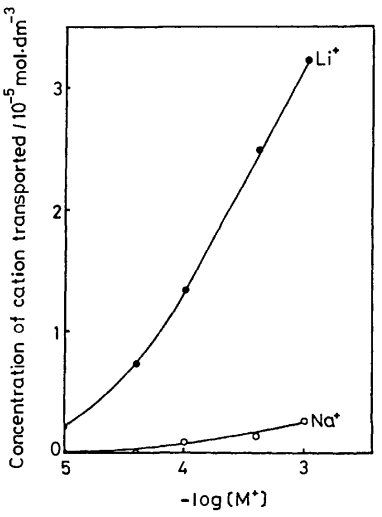

Fig. 3. Effect of cation concentration in source phase on cation transportability.

Table 1. Effect of Na^+ Concentration on Cation Transportability

Cation concentration in source phase (10^{-3}mol dm^{-3})		Concentration of cation transported (10^{-5}mol dm^{-3})		Selectivity ratio
Li^+	Na^+	Li^+	Na^+	Li^+/Na^+
1.0	1.0	3.01	0.10	30
1.0	4.0	2.80	0.32	33
1.0	10.0	2.35	0.83	28
1.0	40.0	1.28	1.98	26
1.0	100.0	0.71	2.62	27

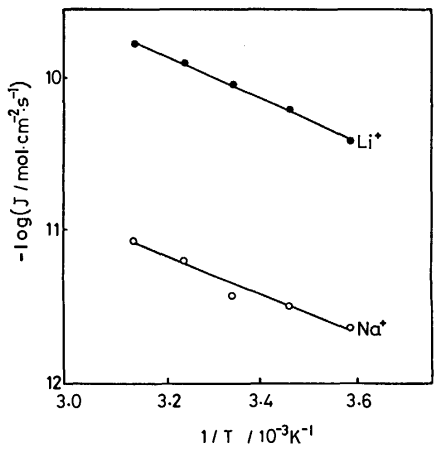

Fig. 4. Arrhenius plots for flux of cation transported.

Permeation coefficients of the metal ions were measured at temperatures ranging from 6 to 45 °C. The Arrhenius plots of Li^+ and Na^+ gave simple straight lines with nearly equal slopes (Fig. 4). If the cation membrane transport were governed only by the cation-crown ether complexation, the transport rates would decrease with a rise in temperature, since the stability of cation-crown ether complexes decreased with temperature.[7,8] It may, therefore, be considered that for a proton-driven cation transport through the hollow-fiber membrane containing **1** the rate-determining step of metal ion transportability is the permeation process of the crown-metal ion complex through the membrane phase.

In conclusion, a hollow-fiber membrane impregnated with a 14-crown-4 dinitrophenol NPOE solution can separate Li^+ efficiently from other alkali metal ions in the flow-through transport system. This supported hollow-fiber membrane was sufficiently stable to permit metal ion transport for 25 h. The present flow-through cation transport system possesses an advantage over a previously-reported batch system in that Li^+ can be separated continuously, although the flow-through system is not superior to the batch system regarding selectivity. Thus, continuity in Li^+ separation seems to allow the present flow-through Li^+ transport system to be applicable to various fields of Li^+ separation and analyses.

We thank Professor Makoto Otomo of Nagoya Institute of Technology for his understanding and support. This work was supported by a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Science and Culture No. 62790216.

Reactivity of $RuCl_3(EPh_3)_2S$ (E=P, As; S=DMSO, DMF, THF, CH_3CHO, CH_3CN, CS_2, $(CH_3)_2CO$) towards 2,4,6-Trichloro-1,3,5,2,4,6-trithiatriazine and Substitution Reactions of $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$(E=P, As; E'=P, As, Sb) with N-Donor Heterocyclic Ligands

Minu GUPTA, Jyoti SETH, and U.C. AGARWALA*
Department of Chemisty, Indian Institute of Technology, Kanpur-208016, India
(Received March 22, 1988)

Synopsis. 2,4,6-Trichloro-1,3,5,2,4,6-trithiatriazine, $N_3S_3Cl_3$, reacts with Ru(III) complexes of the type $RuCl_3(EPH_3)_2S$ to form an intermediate which further reacts with PPh_3, $AsPh_3$, and $SbPh_3$ to form $Ru(NS)Cl_3(EPh_3)_2$ or $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$. Besides, substitution reactions of $Ru(NS)Cl_3(EPh_3)_2$ and $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ with pyridine, γ-picoline, pyrazine, and pyrazole have been carried out. The compounds were characterized by physicochemical methods.

2,4,6-Trichloro-1,3,5,2,4,6-trithiatriazine, $N_3S_3Cl_3$, is air sensitive and unstable in different solvents. It interacts with metal salts or complexes affording various interesting products containing NS^+, N_2S_2, $N_2S_2^{2-}$, $N_3S_2^{3-}$, $NSCl^{2-}$, NSCl, etc. as coligands.[1-7] The use of $N_3S_3Cl_3$ as a synthetic reagent for thionitrosyl complexes depends upon the reaction conditions and no definite suggestion has yet been made in this direction. The problem is, therefore, still in an embryonic state. Since we are interested in the metal thionitrosyl synthesis, we have chosen ligand-exchange reactions as a possible potential route for their synthesis. This communication reports the reactions of $N_3S_3Cl_3$ with ruthenium complexes having coordinated solvent molecules. Substitution reactions of $Ru(NS)Cl_3(EPh_3)_2$ and $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ (E=P, As; E'=P, As, Sb) with N-donor heterocyclic bases and their interconversion reactions with $E''Ph_3$ (E''=P, As, Sb) have also been described.

Experimental

All the chemicals used were of Analar or chemically pure grade. Solvents were dried prior to use by the conventional methods. 2,4,6-Trichloro-1,3,5,2,4,6-trithiatriazine and $RuCl_3(EPh_3)_2S$ (E=P, As; S=DMSO, DMF, THF, CS_2, $(CH_3)_2CO$, CH_3CN, CH_3CHO) were prepared by the literature methods.[8,9]

Reactions. (A) Reactions of $N_3S_3Cl_3$ with $RuCl_3(EPh_3)_2S$ (E=P, As; S=DMSO, DMF, THF, CH_3CN, CH_3CHO, CS, $(CH_3)_2CO$). A typical reaction has been carried out as follows. A saturated mint-green solution of trichlorotrithiatriazine in THF (10 ml) was added with stirring to a solution of $RuCl_3(EPh_3)_2S$ (ca. 0.26 mmol) in 40 ml of dichloromethane. The stirring was continued for an hour. A red colored solution was obtained, 50 ml of methanol was added to it, followed by the addition of EPh_3 (ca. 0.06 mmol) whereupon a brown microcrystalline compound was obtained which was separated, washed with methanol, water, methanol, and finally with ether. It was dried under vacuum (yield, ca. 70%). The analytical data corresponded with the formula given in Table 1.

The same compounds $Ru(NS)Cl_3(EPh_3)_2$ were also obtained, though in low yields, using zinc as reducing agent† in place of the EPh_3.

(B) Reactions of $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$(E=P, As; E'=P, As, Sb) with Heterocyclic Bases L (L=Pyridine, γ-Picoline, Pyrazine, Pyrazole). (i) $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ (ca. 0.14 mmol) in 40 ml of chloroform was refluxed with the heterocyclic base (ca. 0.4 mmol) for a few hours (cf. Table 1) whereby the color of the solution was changed from orange to red-brown. The resulting solution was concentrated to about 10 ml. The addition of petroleum ether (40—60 °C) to the concentrate yielded a compound which was separated. It was recrystallized 2—3 times from benzene/petroleum ether (40—60 °C).

(ii) A solution of $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ (ca. 0.12 mmol), and base (0.7 mmol) in 40 ml of chloroform was refluxed for a few hours. The resulting solution was concentrated to nearly half its volume, followed by the addition of hexane whereby a compound was precipitated. It was separated, thoroughly washed with benzene, ether and recrystallized several times with dichloromethane/hexane.

The reactions described in section B were also carried out in benzene yielding the same compounds.

Measurements. The measurements on the complexes and the analyses were done as reported elsewhere.[10,11] These data matched extremely well with the formula of the complexes given in Table 1.

Results and Discussion

Reactions of $N_3S_3Cl_3$ with $RuCl_3(EPh_3)_2S$ (E=P, As; S=CH_3CHO, DMSO, DMF, THF, CH_3CN) yielded yellowish brown literature known diamagnetic complexes $Ru(NS)Cl_3(EPh_3)_2$[11] freely soluble in halohydrocarbons. Their purity were tested by TLC and by comparing their physical data (mp, mixed mp, X-ray powder pattern, and other spectral data) with those of the authentic sample. Their identical nature with the authentic samples were further confirmed by (1) their IR spectra which displayed the expected band around 1310 cm^{-1} attributable to terminal $(NS)^+$ group besides the characteristic bands of EPh_3 (E=P, As, Sb) and by (2) ^{31}P NMR data[12] (δ 13.3).

X-Ray powder diffraction data of these substituted complexes were carried out and compared with the powder pattern of $Ru(NS)Cl_3(PPh_3)_2$. Both the compounds were found to be isomorphous. $Ru(NS)Cl_3(PPh_3)_2$ was an octahedral complex with two phosphines trans to each other which was confirmed by the X-ray crystal structure of isomorphous osmium analogue.[13] We assumed that the substituted products

† In the reactions of $RuCl_3(EPh_3)_2S$ (S=DMSO, DMF, CS_2) with $N_3S_3Cl_3$, the solution obtained after stirring and zinc reduction yielded $Ru(NS)Cl_3(EPh_3)_2$ as a precipitate in a very low yield and from the filtrate after its concentration, a black material obtained. The black material was not charaterized.

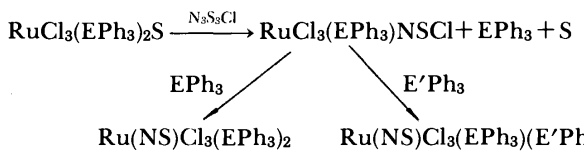
a) Molar ratio of reactant and ligand=1:5. b) Prepared by known literature method.[11] c) Mass spectra (FD) found.

of these completes were also octahedral in nature.

These reactions appeared to be slightly complicated and perhaps undergo through an intermediate formation. All efforts to isolate the intermediate in the pure solid form were unsuccessful. Although the solutions, obtained after the initial $N_3S_3Cl_3$ reactions with ruthenium complexes yielded a precipitate with light petroleum ether but it became oily on purification through precipitation several times from different solvents. Possibly a coordinatively unsaturated Ru(III) complex is initially formed as an intermediate followed by its reduction with the formation of coordinatively saturated complex by linking with the ligand EPh_3 or $E'Ph_3$.



Interconversion reactions of $Ru(NS)Cl_3(EPh_3)_2$ or $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ with $E''Ph_3$ (E=P, As; E'=P, As, Sb; E''=P, As, Sb) led to the formation of $Ru(NS)Cl_3(EPh_3)(E''Ph_3)$, $Ru(NS)Cl_3(E'Ph_3)(E''Ph_3)$, or $Ru(NS)Cl_3(E''Ph_3)_2$ (cf. Table 1). These complexes exhibited similar analytical, spectral (IR, ^{31}P NMR etc.), chemical, and physical properties as those of the literature known complexes synthesized by photochemical process.[11] It suggested that these complexes are the substitution derivatives of $Ru(NS)Cl_3(EPh_3)_2$.

A chemically interesting feature of these interconversion reactions is the fact that the variation in the substitution reaction rates of $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ or $Ru(NS)Cl_3(EPh_3)_2$ with $E''Ph_3$ (E''=P, As, Sb) with respect to leaving ligand is in the order $PPh_3<AsPh_3<SbPh_3$. The reaction of $Ru(NS)Cl_3(PPh_3)_2$ with $AsPh_3$ resulted in the formation of $Ru(NS)Cl_3(AsPh_3)_2$ in 48 hours, on the other hand the reverse process, the formation of $Ru(NS)Cl_3(PPh_3)_2$ from $Ru(NS)Cl_3(AsPh_3)_2$ in presence of PPh_3 takes only two hours. $Ru(NS)Cl_3(AsPh_3)(SbPh_3)$ with $SbPh_3$ did not yield $Ru(NS)Cl_3(SbPh_3)_2$ even after a very long refluxing period. The reason for the variations in rates could be due to the differences in the σ-basic and π-acidic characters of the ligands ($PPh_3>AsPh_3>SbPh_3$). The kinetic and the thermodynamic stability of the complexes were in the order $PPh_3>AsPh_3>SbPh_3$ as reported elsewhere.[14] Owing to the weak σ-basic and π-acidic nature of $AsPh_3$ followed by that of $SbPh_3$, the Ru-As and Ru-Sb bonds should be relatively thermodynamically weaker than Ru-PPh_3 bond. Consequently the substitution rate with respect to leaving group should be $PPh_3<AsPh_3<SbPh_3$.

Substitution reactions of $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ with heterocyclic bases (L) viz. pyridine, γ-picoline, pyrazine, pyrazole led to the formation of $Ru(NS)Cl_3(EPh_3)L$ or $Ru(NS)Cl_3(E'Ph_3)L$. The IR spectra of these complexes exhibited characteristic bands due to vibrational modes of bases besides the bands due to $\nu(NS)^+$ around 1310 cm^{-1} and the characteristic bands of EPh_3. The moderately intense band around 320—290 cm^{-1} was assigned to ν(Ru-Cl).

The substitution reactions of $Ru(NS)Cl_3(EPh_3)(E'Ph_3)$ with bases like 2,2'-bipyridine and 1,10-phenanthroline failed. Inspite the change of solvents and the reaction periods, these reactions led to the formation of a mixture of products. Attempts to separate them were unsuccessful. The presence of different products were confirmed by ^{31}P NMR which displayed a number of bands. Efforts to synthesize bridged compounds with pyrazine were also unsuccessful and only monomers have been obtained.

The substitution of one PPh_3 molecule by heterocyclic base molecule depleted electron density at the ruthenium center through $d\pi$-$d\pi$ back bonding. As a consequence electron density available at ruthenium for $d\pi$-$d\pi$ back bonding towards the remaining PPh_3 molecule is reduced. This results in the reduction of net electron density at phosphorus causing a downfield shift of the ^{31}P NMR band (from δ 13 to δ 25), depending upon the nature of heterocyclic molecule attached to ruthenium. Triphenylphosphine molecules are trans to each other in $Ru(NS)Cl_3(PPh_3)_2$, replacement of one PPh_3 by heterocyclic base will lower the trans effect thereby strengthening the Ru-P bond by sigma bond formation. Thus formation of P→Ru σ bond and weaker Ru→P back bonding will result in the lower electron density at P and will cause the observed downfield shift.

The visible spectra of all the complexes exhibited a rather broad band around 450 nm. Since it is generally believed that (MLCT) transition in ruthenium +2 complexes occur under a broad band around 450—430 nm,[15] a similar band in the electronic spectra of our complexes suggested ruthenium in +2 oxidation state which was also confirmed by magnetic moment (diamagnetic). The electronic spectra of the starting complexes $RuCl_3(EPh_3)_2S$ showed bands in the region 620—350 nm.[16]

In conclusion, all the complexes found to be diamagnetic suggesting ruthenium in +2 oxidation state having (d^6) system.

(Received October 20, 1988)

Synopsis. A new spectrophotometric method for determining rhenium with thiocyanate and organic reagents such as amides, thioamide and hydrazide over 2.0—6.0 mol dm^{-3} H_2SO_4 is described. The molar absorptivity of the complexes in the organic solvents are (2.57—3.01)×10^4 l mol^{-1} cm^{-1} at absorption maximum. Of these, *N*-phenylacetamide (PAA) has been chosen for detailed studies. The detection limit of the method with PAA is 0.03 μg Re cm^{-3}. The effect of kinds of acids, solvents or reagents and of diverse ions is discussed.

Several spectrophotometric methods for the determination of rhenium have been reported.[1-8] Of these, the classical thiocyanate method is one of the most popular method for the spectrophotometric determination of the metal but it suffers from some experimental difficulties.[1] Thiourea[2] and hexamethylphosphoric triamide[3] were proposed to enhance the selectivity of the classical thiocyanate method, however they require a prolonged heating or extraction and involve the interference of some metals. Oximes were employed as sensitive reagents too but they lack selectivity.[4-6] The sulfur containing reagents like 5,6-diphenyl-3-hydroxy-1,2,4-triazine-3(2*H*)-thione[7] and di-2-pyridyl ketone 2-furyl(thiocarbonyl)-hydrazone[8] were reported for the extraction and spectrophotometric determination of the metal and subject to serious interference from the metal ions. The purpose of this work is to develop a selective and sensitive extraction-spectrophotometric method for rhenium-(VII) with a series of commonly available reagents such as *N*-(alkyl or aryl)acetamides, *N*-(2-pyridyl)-thiobenzamide ($C_6H_5CSNHC_5H_4N$), and *N'*-phenylacetohydrazide ($CH_3CONHC_6H_5$) in presence of thiocyanate ion. Of ten compound reported, the simplest one, *N*-phenylacetamide ($CH_3CONHC_6H_5$) was chosen for detailed studies in the present investigation. The method is applicable over wide acidity range, and removes most of interferences of classical thiocyanate method with improved sensitivity.

Experimental

Reagents. A standard solution of rhenium(VII) was prepared by dissolving (0.5 g) accurately weighed potassium perrhenate in double distilled water. Amides, thioamide, and hydrazide were synthesized as described in the literature.[9] Solutions of amides (1.2—2%) in benzene, and solutions of *N*-(1-naphthyl)acetamide, *N*-(2-pyridyl)thiobenzamide, or *N'*-phenylacetohydrazide (2—3.8%) in chloroform were employed for extraction work. All chemicals and reagents used were of analytical grade (E. Merck). In the case of benzene, all solutions employed were presaturated with benzene.

Procedure. A tin(II) chloride solution (2 cm^3) and 5 cm^3 of 10 mol dm^{-3} H_2SO_4 were added to a perrhenate solution (5—90 μg Re) in a 100-cm^3 separatory funnel, the mixture was reacted with 2 cm^3 potassium thiocyanate solution and diluted to 15 cm^3 with distilled water. The metal complex was extracted with 15 cm^3 benzene solution of the organic reagent for 2 min. The absorbance of the complex was measured at λ_{max} against reagent blank. In the case of *N*-(2-pyridyl)thiobenzamide, *N'*-phenylacetohydrozide, or *N*-(1-naphthyl)acetamide the metal complex was extracted with 15 cm^3 chloroform solution of the reagent and washed with 3×2 cm^3 fresh portions of chloroform. All the dried extract was transferred into a 25-cm^3 volumetric flask and diluted with chloroform to the mark. The absorbance of the complex was measured at λ_{max} against reagent blank.

Results and Discussion

Absorption Spectra. Figure 1 shows the absorption spectra of Re(IV)-SCN^--PAA complex and the reagent blank in benzene. All the complexes of Re(IV) with amides and hydrazide exhibit an absorption maximum around 435 nm while with thiobenzamide at 438 nm. As the reagent shows an absorption at the λ_{max} of the complex, the reagent blank was used as a reference for all measurements.

Choice of Solvents. The extraction of Re(IV)-SCN^- with PAA into various solvents like 1-pentanol, isobutyl methyl ketone, ethyl acetate, chloroform, carbon tetrachloride, benzene, and toluene was performed. The complex was quantitatively extracted in these solvents except carbon tetrachloride (the maximum extraction of the complex require a triple extraction) showing the value of molar absorptivity to be in the range of (2.43—2.70)×10^4 dm^3 mol^{-1} cm^{-1} at λ_{max} 430—435 nm. Of these, benzene was used for further experimental work due to the most sensitive

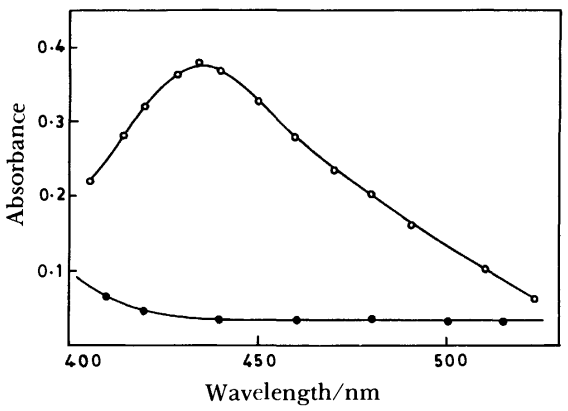

Fig. 1. Absorption spectra of *N*-phenylacetamide (PAA) blank and $[ReO(SCN)_2(PAA)_2]$ in benzene. $[H_2SO_4]$=4 mol dm^{-3}; $[Sn^{2+}]$=0.03 mol dm^{-3}; $[SCN]$=0.26 mol dm^{-3}. (—○—), $[ReO(SCN)_2(PAA)_2]$, $[Re^{7+}]$=1.43×10^{-5} mol dm^{-3}; (—●—) 0.1 mol dm^{-3} PAA in benzene after equilibration.

color reaction in it.

Effect of Acidity. The effect of acids like HCl and H_2SO_4 (10 mol dm^{-3}) on the extraction of Re(IV)-SCN^- with PAA in benzene was studied. With H_2SO_4 in aqueous solution, the rate of extraction was relatively fast and the color intensity of the complex in organic solvent was higher than with HCl. The modified property in hydrochloric acid media is due to further reaction of the thiocyanato or chloro complex species with excess of tin(II) ions.[10] The optimum acidity range was found to be 2.0—6.0 mol dm^{-3} H_2SO_4 with PAA in benzene.

Effect of Reagents and Other Variables. The effect of amount of reagents on the extraction of the metal was examined at 4 mol dm^{-3} H_2SO_4. The reduction of Re(VII) into Re(IV) was made by tin(II) ions and 0.015—0.05 mol dm^{-3} tin(II) ions was adequate for the extraction of the metal. At least 0.15 mol dm^{-3} KSCN and 0.06 mol dm^{-3} PAA (in benzene) were necessary for the maximum color development of the complex in the organic solution, and the addition of more KSCN and PAA up to 0.6 and 0.19 mol dm^{-3}, respectively, caused no adverse effect. The order sequence of addition of reagents was not critical. The variation in volume ratio of the organic to the aqueous phase from 3 : 1 to 3 : 5 did not affect the distribution of the metal. The extract was stable for at least 4 h at room temperature (≈27 °C). The effect of electrolytes i.e. KCl and $(NH_4)_2SO_4$ in extraction of the metal was examined and absorbance of the complex was intact up to 1 mol dm^{-3} KCl or $(NH_4)_2SO_4$.

Stoichiometry of Extraction. The mechanism involved in the reduction of ReO_4^- with tin(II) chloride in the presence of thiocyanate was studied by various workers.[10-12] The formation of $[ReO(SCN)_5]^{2-}$, $[Re(SCN)_6]$, or $[Re(SCN)_6]^-$ has been reported, and the addition of excess Sn^{2+} leads to formation of $[Re(SCN)_6]^{2-}$, exclusively. According to Pavlova[10] the most probable reduced state of rhenium participating in the extraction is Re(IV). In the present investigation, the ratio of variables in the complex was evaluated by plots of logarithm distribution ratio of the metal versus logarithm thiocyanate concentration in the aqueous solution and PAA concentration in the organic solution at equilibrium. Figure 2 shows the slope of these plots to be 1.9 and 2.0, respectively. Since these values are close to 2, the possible reaction mechanism can be written as:

$$ReO^{2+} + n\ SCN^- + n'PAA_o \rightleftarrows [ReO(SCN)_n(PAA)_{n'}]_o$$

For the simplest system, where the metal species in the aqueous phase is ReO^{2+} only and that of the complex is $[Re(SCN)_n(PAA)_{n'}]$ $\log D = \log K + n\log[SCN^-] + n' \log[PAA]_o$.

In present investigation, the value of D (distribution ratio of the metal) was evaluated by spectrophotometric method using the formulae, $D = A/A_{max} - A$. The distribution ratio of PAA in the organic solution is not very high, hence the effective concentration of the amide in the organic phase was determined by following equation.

$$[PAA]_o = \frac{Kd[PAA]_t}{1+Kd}$$

Where, o, Kd, D, K, $[PAA]_o$, $[PAA]_t$, A_{max}, and A represent the organic phase, distribution ratio of the reagent, distribution ratio of the metal, equilibrium or extraction constant, concentration of the reagent in the organic solution at equilibrium, total analytical concentration of the reagent in the organic solvent before equilibrium, maximum absorbance of the complex when the reagent is present in constant excess and absorbance of the complex when the reagent is in equilibrium, respectively.

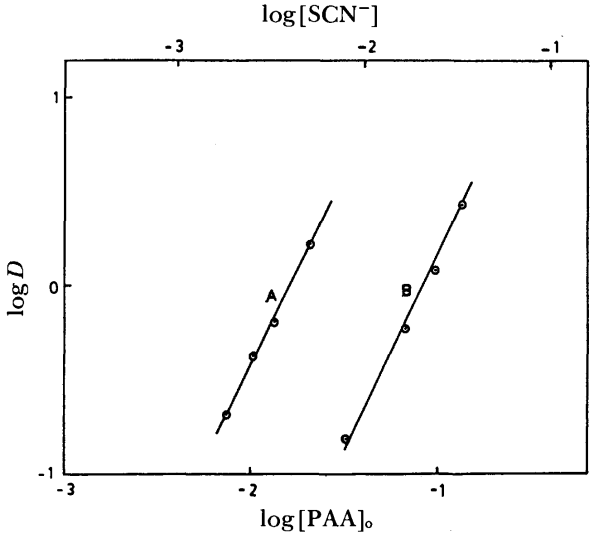

Fig. 2. Determination of the values of the variables in $[ReO(SCN)_n(PAA)_{n'}]$ in benzene. $[H_2SO_4]$=4 mol dm^{-3}; $[Sn^{2+}]$=0.03 mol dm^{-3}; $[Re^{7+}]$=1.43×10^{-5} mol dm^{-3}. (A), log (distribution ratio of the metal) versus $\log[PAA]_o$; $[S\bar{C}N]$=0.26 mol dm^{-3}. (B), log (distribution ratio of the metal) versus log $[S\bar{C}N]$; $[PAA]_o$=0.1 mol dm^{-3}.

Amides, Thioamides, and Hydrazide as Extraction Reagents. In the present investigation, the extraction potentiality of various amides, thioamides, and hydrazide towards Re(IV) in the presence of thiocyanate was examined. In amide series, acetamides derived from aliphatic or aromatic amines (except amines containing electron-withdrawing groups e.g. Cl, OH, etc.) are capable of extracting the metal. Chloroform is an adequate diluent for the extraction of the complex with *N*-(1-naphthyl)acetamide, *N*-(2-pyridyl)thiobenzamide, and *N'*-phenylacetohydrazide. The potentiality of all compounds tested towards Re(IV) are approximately the same, and show the molar absorptivity of (2.57—3.01)×10^4 dm^3 mol^{-1} cm^{-1} at λ_{max} 435—438 nm in the organic solvent. The detection limit of the method is 0.013 μg Re cm^{-3} and it follows Beer's law over 0.5—6.0 μg Re cm^{-3} with PAA in benzene. The relative standard deviation of the method was found to be ±1.4% for 10 measurements each containing 40 μg Re/15 cm^3.

Effect of Diverse Ions. The effect of diverse ions on the determination of 40 μg of Re(VII) was studied with 0.1 mol dm^{-3} PAA in benzene as above. In this method, Nb(V) and Mo(V) seriously interfere in the determination of the metal, and W(VI) is tolerated

only in equal amount. The interference of Mo is removed by prior extraction with 0.1 mol dm^{-3} PAA in benzene from aqueous solution containing 4 mol dm^{-3} H_2SO_4 +0.1 mol dm^{-3} ascorbic acid +0.4 mol dm^{-3} KSCN. The interference of niobium is masked by sodium oxalate (3% solution 3 cm^3). The tolerance limit of various diverse ions (in mg) in the determination of rhenium causing an error less than ±2% is shown in parenthesis as; W (0.04); Pd, Mo (0.1); Cu(0.5); Al, Cr, Co, Zr, F^- (20); U (30); oxalate (40); Zn (75); Cd (100); AsO_4^{3-} (150); tartrate (220); or PO_4^{3-} (250).

We are thankful to Council of Scientific & Industrial Research, New Delhi for partial financial support of this work.

Synopsis. Conjugated esters from (+)-isopinocamphone, with a terpenic skeleton which is easily epimerizable may theoretically exist as four diastereomers (2*R*,4*E*; 2*R*,4*Z*; 2*S*,4*E*; 2*S*,4*Z*). X-Ray analysis shows that the reaction leads to a single isomer, namely an isopinocamphone derivative (2*S*,4*E*).

The study of some conjugated esters obtained from 3-pinanone [(1*R*,2*R*,5*S*)-(+)-isopinocamphone] showed that their stereochemistry is somewhat complicated. Three points had to be defined:

i) configuration around the double bond (*Z* or *E*)

ii) chirality of the conjugated system due to flexibility of the terpenic cycle (right or left-handed helix) and

iii) configuration of the chiral center C-2 (*R* or *S*).

(+)-Isopinocamphone[1] is indeed a terpenic bicyclic ketone in which the α-carbon atom bearing the methyl group epimerizes easily during reactions in basic media. Many authors showed that at room temperature and in presence of sodium alcoholate,[2] (+)-isopinocamphone leads to a mixture of (1*R*,2*R*,5*S*)-(+)-isopinocamphone (75%) and (1*R*,2*S*,5*S*)-(+)-pinocamphone (25%).

On the other hand, Hirata[3] laid the stress upon the difficulties of structural elucidation due to conformational mobility.

This is why, besides studying NMR spectra and circular dichroism (CD) of these compounds, we called, at last, upon X-ray analysis to achieve structure determination of one of these esters.

Results and Discussion

Synthesis of esters has been performed as follows. The formyl ketone[4] was transformed to ester by acylation in pyridine. The ester has the *E* configuration (presence in the ^{1}H NMR spectrum of a lone signal for the ethylenic proton at about δ 8.3). In the *Z* configuration the signal would appear at higher field. In fact, a comparative study of the ^{1}H NMR spectra of two phenylmethylenepinocamphone[5] and nopinone[6] *Z* and *E* showed for the *Z* isomer an ethylenic proton at δ 6.10 and for the *E* isomer at δ 8.3 due to downfield effect of the two double bonds. This result will be confirmed in this paper by X-ray analysis. Thus, the *E* isomer is formed alone in this reaction. The greater stability of the *E* isomer is consistent with i) the less steric hindrance and ii) the less electric interaction between C=O and C-O dipole in this isomer than in the *Z* one.

Synthesis of the (*Z*)-ester (even as a mixture *Z*/*E*) failed although two attempts were performed: photoisomerization of the (*E*) isomer and acylation at low temperature (−70 °C) of the sodium salt of 4-(hydroxymethylene)isopinocamphone. The latter was obtained by reaction with sodium alcoholate. This technique was successful with similar 2- and 3-bornanone derivatives.[7,8]

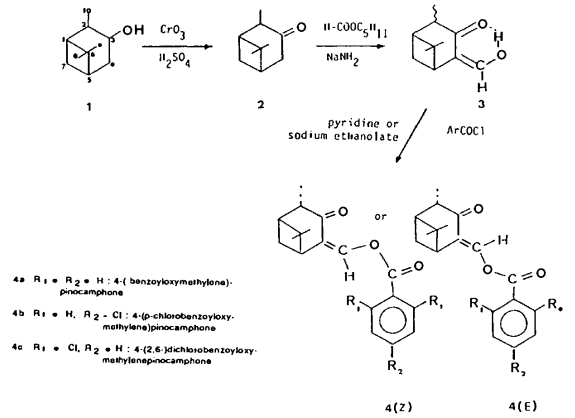
Concerning now the configuration of the C-2 chiral center ^{1}H NMR spectra (300 MHz) of the isolated products give some interesting informations.

The *p*-chlorobenzoate revealed in its spectrum the presence of two doublets with the same coupling constant *J*=6.5 Hz at δ 1.20 and 1.30 in a ratio 89/11. Unlike to the *p*-chloro derivative the benzoate and 2,6-dichlorobenzoate purified under the same conditions show a single doublet at δ 1.20 with *J*=6.50 Hz proving the presence of a lone isomer. It was thus interesting to determine precisely the configuration of one of these pure isomers by X-ray analysis.

X-Ray Analysis. A white crystal with approximate dimensions of 0.2×0.25×0.3 mm was used for the data collection. The intensity was measured using a CAD4-ENRAF-NONIUS[9] four circles diffractometer with graphite monochromated Mo*Kα* radiation (λ=0.71073 Å) by means of the ω-2θ scan technique up to 70° in 2θ (scan speed for the pre-scan 10° min^{-1}) at room temperature.

Crystal Data. $C_{18}H_{20}O_3$ crystallizes in orthorhombic system, space group $P2_12_12_1$ with: *a*=10.425(6), *b*=11.049(7), *c*=13.725(7) Å, *V*=1581(3) Å^3 with *Z*=4, *F*(000)=608, d_{cal}=1.19 g cm^{-3}, μ(Mo *Kα*)=0.7 cm^{-1}.

Among the 3889 reflections measured 1509 inde-



Scheme 1.

pendant reflections with $I>3\sigma(I)$ were used to refine the 190 variable parameters.

The measured intensities were corrected for the Lorentz and polarization factors, no absorption correction was performed according to the small value of the absorption coefficient.

All calculations were performed using a DIGITAL Vax 730 computer, by means of SDP (Structure Determination Package) of ENRAF-NONIUS system. This structure was solved using direct method and refined by full matrix least-squares procedure.

In the last refinement all of the positions and thermal parameters of the nonhydrogen atoms were refined, for the hydrogen atoms their contributions were only introduced but not refined (R=0.055).

The final atomic parameters of the carbon and oxygen atoms are given in Table 1, according with labeling of these atoms shown in Fig. 1.

Analysis shows that the isolated ester obtained from (+)-isopinocamphone is in fact a pinocamphone derivative. Thus, epimerization took place during the reaction. In addition the conjugated system OC-C=C incorporated in the ring is not planar but skewed in the sense of a right-handed helix (torsional angle +11.89°) (Table 2). The skewness in this case is consistent with the sign of the Cotton effect of the $\pi\rightarrow\pi^*$ transition.

However we have to put us in mind of the fact that the CD sign of this transition in conjugated ketones does not reflect always the true chirality of the enone system (many exceptions have been reported[10,11]).

In effect, inspection of Scheme 2 reveals that although the sign of the $\pi\rightarrow\pi^*$ transition in 2-(*p*-chlorobenzylidene) 3-bornanone **6**[12] and 4-(benzoyloxymethylene) 3-pinanone **4** shows the true skewness of the enone system, unfortunately in the case of 3-(*p*-bromobenzylidene) nopinone **5**[13] the CD sign is negative while the conjugated system has a right-handed skewness.

On the other hand, in a similar camphor (bornanone-2) derivative **7**[14] while the enone grouping is planar, the $\pi\rightarrow\pi^*$ transition still has a positive CD.

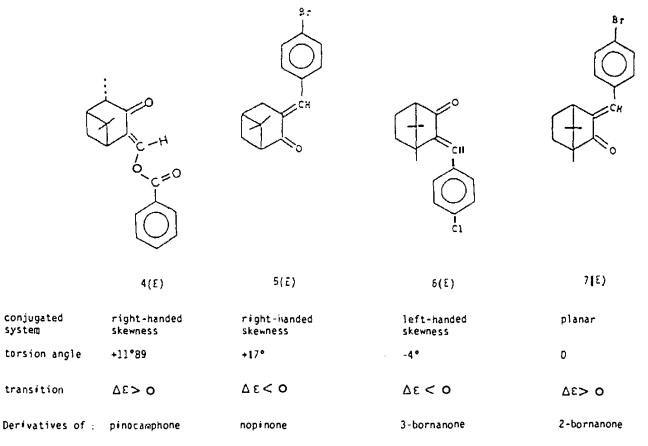

Scheme 2.

These results show undoubtedly that there is no direct correlation between the sign of the CD of the $\pi\rightarrow\pi^*$ transition and the chirality of the conjugated system in enones.

To the best of our knowledge there is yet no satisfactory explanation of these facts.

X-Ray analysis shows also that the aromatic ring is twisted by 10.32° and is no more coplanar with the ester carbonyl group.

At last, the angle between CH_3-10 and the ketone carbonyl group (46°) implies a pseudoequatorial or a pseudoaxial position for this methyl and would explain, in part, the weak values of the CD of the $n\rightarrow\pi^*$ transition.

Experimental

General. Melting points were determined on a oil bath. Values are uncorrected. Rotatory power was measured with a Rudolf type polarimeter and Circular Dichroism with Dichrograph Mark V Jobin-Yvon. IR spectra were recorded on a Perkin-Elmer 1600 FTIR, and NMR spectra on a Bruker AM 300 WB in $CDCl_3$. Shifts are given in parts per million.

The Preparation of (+)-Isopinocamphone (2): (+)-Isopinocamphone [(+)-3-pinanone] was prepared by oxidation with chromium trioxide of (1*R*,2*R*,3*R*,5*S*) (−)-isopinocampheol [mp: 51—53 °C, $[\alpha]_D^{20}$ (*c* 20, ethanol)] by the procedure of Brown et al. (loc. cit.), $[\alpha]_D^{20}=+19°$ (*c* 3, ethanol).

The Preparation of 4-(Hydroxymethylene) Isopinocamphone (3): Formylation of (+)-isopinocamphone has been performed according to the procedure of Bessière-Chrétien et al. (loc. cit.) using sodium amide in the place of sodium ethanolate: yield 75%, $[\alpha]_D^{20}=+52°$ (*c* 3.6, cyclohexane).

The Preparation of Esters of 4-(Benzoyloxymethylene) (4a), 4-(*p*-Chlorobenzoyloxymethylene) (4b), and 4-(2,6-Dichlorobenzoyloxymethylene)pinocamphone (4c). To a stirred solution of **3** (6 g, 0.0209 mol) was added dropwise the acid chloride (6 g, 0.03 mol). A white precipitate is formed. The mixture is kept at room temperature for 12 h, acidified with 100 ml of a 50% hydrochloric acid solution and extracted with ether. The ether solution was washed with a saturated aqueous sodium hydrogencarbonate and water, dried and evaporated. The white residue in recrystallized from cyclohexane: yield 60%.

4a. Mp: 123 °C, $[\alpha]_D^{20}=+112°$, (*c* 3.3, dioxane), IR ($CHCl_3$): C=O ester 1743, C=O terp. 1701, C=C 1629, C-O 1256 and 1149 cm^{-1}; CD (*c* 3.33, dioxane) $\Delta\varepsilon_{333}=+0.85$, (*c* 0.33, dioxane) $\Delta\varepsilon_{270}=+6.1$; ^1H NMR ($CDCl_3$): δ=0.88 (3H, s, C_9H), 1.17 (3H, d, $C_{10}H$, *J*=7.26 Hz), 1.37 (2H, d, C_7H, *J*=10.7 Hz), 1.44 (3H, s, C_8H), 2.01 (1H, m, C_1H, *J*=6.27 and 2.35 Hz), 2.41 (1H, m, C_2H), 2.74 (1H, m, C_7H), 3.25 (1H, t, C_5H, *J*=6.07 Hz), 7.48 (2H, t, *J*=7.8 Hz aromatic protons), 7.62 (1H, dd, *J*=6.19 Hz aromatic protons), 8.07 (2H, m, aromatic protons), 8.37 (1H, s, $C_{11}H$). Found: C, 75.52; H, 7.05; O, 17.43%. Calcd for $C_{18}H_{22}O_3$: C, 75.52; H, 7.69; O, 16.18%.

4b. Mp: 131 °C $[\alpha]_D^{20}=+85.8°$, (*c* 1.3, dioxane), IR ($CHCl_3$): C=O ester 1741, C=O terp. 1701, C=C 1630, C-O 1254 and 1150 cm^{-1}; CD (*c* 1.03, dioxane), $\Delta\varepsilon_{343}=0.52$, (*c* 0.10, dioxane), $\Delta\varepsilon_{266}=5.30$; ^1H NMR ($CDCl_3$): δ=0.88 (3H, s, C_9H), 1.17 (3H, d, $C_{10}H$, *J*=7.2 Hz), 1.37 (2H, d, C_7H, *J*=10.7 Hz), 1.44 (3H, s, C_8H), 2.01 (1H, d, C_1H, *J*=6.22 and 2.39 Hz), 2.63 (1H, m, C_2H), 2.74 (1H, m, C_7H), 3.23 (1H, t, C_5H, *J*=5.90 Hz), 7.47 (2H, t, *J*=7.94 Hz aromatic protons), 8.01 (2H, m, aromatic protons), 8.34 (1H, s, $C_{11}H$). Found: C, 67.11; H, 5.89; O, 14.01; Cl, 12.97%. Calcd for $C_{18}H_{21}O_3Cl$: C, 67.89; H, 6.55; O, 14.97; Cl, 11.07%.

4c. Mp: 108 °C, $[\alpha]_D^{20}=+29°$, (*c* 2.4, dioxane), IR ($CHCl_3$): C=O ester 1763, C=O terp. 1704, C=C 1633, C-O 1249—1154 cm^{-1}; CD (*c* 0.24, dioxane), $\Delta\varepsilon_{345}=+0.42$; (*c* 0.24, dioxane) $\Delta\varepsilon_{258}=+3.90$; ^1H NMR ($CDCl_3$): δ=0.80 (3H, s, C_9H), 1.12 (3H, d, $C_{10}H$, *J*=7.25 Hz), 1.27 (1H, d, C_7H, *J*=10.80 Hz), 1.31 (3H, s, C_8H), 1.93 (1H, m, C_1H, *J*=6.29 and 2.34 Hz), 2.50 (1H, m, C_2H), 2.66 (1H, m, C_7H), 3.25 (1H, t, C_5H, *J*=6.02 Hz), 7.34 (3H, m, aromatic protons), 8.27 (1H, s, $C_{11}H$). Found: C, 61.23; H, 5.12; O, 13.61; Cl, 20.04%. Calcd for $C_{18}H_{20}O_3Cl_2$: C, 61.18; H, 5.13; O, 13.59; Cl, 20.11%.

α-Iodination of Ketones and Enol Acetates with Poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))]

Boris ŠKET,* Pavel ZUPET, Marko ZUPAN, and Darko DOLENC
Department of Chemistry and Jožef Stefan Institute, Edvard Kardelj University of Ljubljana, Yugoslavia
(Received December 19, 1988)

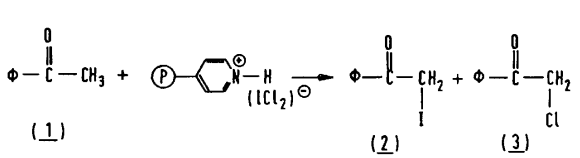
Synopsis. Crosslinked poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))] can be used as a very efficient polymeric reagent for α-iodination of ketones, diketones, and corresponding enol acetates.

Halo ketones represent synthetically useful materials and several general methods for their synthesis have been established.[1] In contrast to the chloro and bromo derivatives, α-iodo ketones received much less attention because of their relative instability. Most of the known methods of preparing α-iodo carbonyl compounds proceed from enol derivatives[2-5] or α-bromo ketone,[6] while for the direct iodination of ketones only a few methods have been described using the copper(II) acetate/iodine[7] or mercury(II) chloride/iodine system.[8] On the other hand, the treatment of alkenes with silver chromate and iodine[9] also led to the formation of α-iodo ketones.

Recently, we have found that crosslinked poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))] can be used as a very efficient polymeric reagent for selective electrophilic iodination of activated benzene and naphthalene derivatives,[10] as well as for iodination of heterocyclic systems[10] where electrophilic substitutions can take place.

We now wish to report that our polymeric reagent can be used for the direct α-iodination of ketones and also for iodination of the corresponding enol acetates.

A 5-hour reaction of 1 mmol of acetophenone with 1 g of polymeric reagent in methanol under reflux led to complete conversion of the starting material. ^{1}H NMR spectrum of the crude reaction mixture showed the signal at δ 4.65 corresponding to the α-chloro derivative[11] (Scheme 1).



Scheme 1.

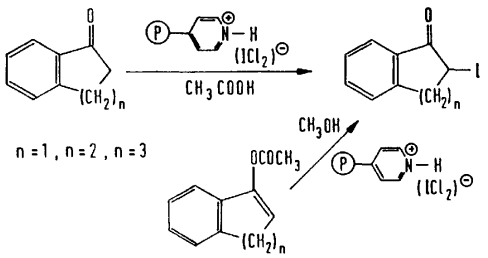
When the reaction was carried out in acetic acid solution at 50 °C, besides α-chloroacetophenone, the α-iodo derivative[11] was also formed (Scheme 1). The use of a lower reaction temperature decreased the conversion of the starting material, but increased the formation of iodinated product.

Table 1. The Effect of the Reaction Conditions on the Course of the Reaction with Acetophenone

Solvent	1 /mmol	Polym. reag. /g	T/°C	Relative yields %1	%2	%3
CH_3OH	1	1	Reflux	—	—	100
CH_3COOH	1	1	50 °C	20	27	53
CH_3COOH	1	1	25 °C	25	56	19
CH_2Cl_2	1	1	25 °C	71	16	13

The results presented in the table suggest the initial formation of the iodinated product, while the degree of further substitution of iodine with chlorine depends on the reaction time.

Further, we studied the iodination of cyclic ketones, and 1-indanone, 1-tetralone, and 6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one were chosen as substrates. A 4.5-hour reaction of 1 mmol of 1-indanone with 1 g of polymeric reagent in acetic acid solution at 50 °C led to complete conversion of the starting ketone. The mass spectrum and ^{1}H NMR of the product (see Experimental) showed that only iodinated product was obtained. On the basis of the spectroscopic data we concluded that 2-iodo-1-indanone was formed (Scheme 2).



Scheme 2.

In order to determine the influence of the ring size of the cycloketone on the reaction pathway with poly[styrene-*co*-(4-vinylpyridinium dichloroiodate-(1−))], we studied the reaction with 1-tetralone and 6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one. The reactions were carried out in methanol at room temperature or at 50 °C, and in both cases complete conversion of the starting material was observed. The product formed in the reaction with 1-tetralone was established to be 2-iodo-1-tetralone[12] by its ^{1}H NMR and mass spectrum. On the basis of the spectroscopic data of the product formed with 6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one we concluded that iodination took place at position six and 6-iodo-6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one was obtained as the only product.

Further, we studied the reaction of two diketones: 5,5-dimethyl-1,3-cyclohexanedione (dimedone) and 1,3-indandione with the polymeric reagent. A 5-hour reaction of 1 mmol of dimedone and 1 g of polymeric reagent at 50 °C in acetic acid solution gave a mixture with two singlet signals in its ^{1}H NMR spectrum at δ=5.16 and 4.50 with 1 : 2 relative ratio of the integrals. The mass spectrum of the crude reac-

tion mixture, besides other fragmentations, also showed signals at m/z=266 and 174. On the basis of the above mentioned spectroscopic data, we determined that 2-chloro and 2-iodo derivatives were formed in the ratio of 1 : 2. We tried to separate the reaction mixture using several types of chromatographic methods, but we were unsuccessful because of the high instability of 2-halo dimedones.

The reaction of 1,3-indandione with the polymeric reagent under the same reaction conditions led to the formation of only the 2-chloro derivative,[13] as determined by ^{1}H NMR spectroscopy and the mass spectrum. When a lower reaction temperature (25 °C) was used, the conversion of the starting diketone decreased, but besides the 2-chloro derivative, the 2-iodo product was also formed, in the ratio of 65 : 35, respectively. From the results we concluded that initially formation of the iodinated product took place, followed by substitution of iodine by chlorine, which depended on the reaction temperature and reaction time.

As in many known methods for the preparation of α-iodo carbonyl compounds enol derivatives are used as substrates, we decided to study the reactions of poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))] with some enol acetates. A 3.5-hour reaction of 1 mmol of 1-phenylethenyl acetate[14] with 0.5 g of polymeric reagent in methanol at 0 °C gave a crude reaction mixture which, besides a singlet signal at δ=2.6 corresponding to acetophenone, showed two singlet signals in its ^{1}H NMR spectrum at δ=4.4 and 4.7. The signal at the lower field corresponded to the chlorinated product, while the signal at δ=4.4 corresponded to iodinated product (iodinated and chlorinated product were in the ratio of 56 : 44). The formation of acetophenone can be explained by the reaction of the enol acetate with the HCl liberated in small quantity during the course of the reaction. The reaction of 1-cyclohexenyl acetate[14] with the polymeric reagent led to complete conversion of the starting material, 2-iodocyclohexanone[15] being formed as the only product. We also studied the reaction of enol acetates of 1-indanone,[16] 1-tetralone,[17] and 6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one.[17] In all cases, α-iodo ketones were formed and the yields of pure products were also satisfactory (Scheme 2).

From the experimental observations we concluded that poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))] can be used as a polymeric reagent for α-iodination of ketones and the corresponding enol acetates.

Experimental

IR spectra were recorded using a Perkin-Elmer 727B instrument, and ^{1}H NMR spectra on a JEOL JNM-PS-100 with Me_4Si as internal reference. Mass spectra were taken on a CEC-21-110 spectrometer. Analytical and preparative TLC were carried out on Merck-PSC-Fertigplatten Kieselgel F 254. Melting points were determined on a Kofler apparatus and are uncorrected.

1-Phenylethenyl acetate,[14] 1-cyclohexenyl acetate,[14] 1*H*-inden-3-yl acetate,[16] 1,2-dihydro-4-naphthyl acetate,[17] and 6,7-dihydro-5*H*-benzocyclohepten-9-yl acetate[17] were prepared by known procedures.

Preparation of Poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))]. a) Thirty-five grams of crosslinked poly(styrene-4-vinylpyridine),[18] containing 42—44% of pyridine rings, was suspended in 150 ml of chloroform, cooled to 0 °C and 50 g of a mixture of HCl-ICl was added. The suspension was stirred at 0 °C for 60 min and at room temperature for a further 30 min. The polymer was filtered off and extracted with chloroform in a Soxhlet apparatus. After drying in vacuo for 24 h, 65 g of polymeric reagent was obtained. Three hours of drying of 1 g of polymer at 100 °C gave 0.93 g of polymeric reagent, containing 30.0% of iodine and 16.6% of chlorine (calculation for poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))] containing 43% of pyridine rings: 29% of iodine and 16.2% of chlorine), which means that the polymeric reagent contained 2.2 mequiv of $(ICl_2)^-$ per gram of resin.

b) Thirty five grams of crosslinked poly(styrene-4-vinylpyridine),[18] containing 42—44% of pyridine rings, was suspended in 150 ml of chloroform, cooled to 0 °C and 30 g of 36% HCl was added. After stirring at 0 °C for 30 minutes, 30 g of ICl was slowly added. The suspension was stirred at 0 °C for another 60 minutes and at room temperature for 30 minutes. The polymer was filtered off, washed with methanol and chloroform, and after drying to constant weight at room temperature 70 g of polymeric reagent was obtained.

General Reaction Procedure: One mmol of substrate was dissolved in the appropriate solvent and a given amount of poly[styrene-*co*-(4-vinylpyridinium dichloroiodate(1−))] was added. The reaction mixture was stirred at a given temperature for a given time, the insoluble beads were filtered off, washed with 10 ml of the reaction solvent, the solvent evaporated in vacuo and the crude reaction mixture analysed by ^{1}H NMR spectroscopy.

Halogenation of Acetophenone: Polymeric reagent: 1 g; solvent: methanol, acetic acid, or CH_2Cl_2, 20 ml. The effect of the solvent and the reaction temperature on the course of the reaction is presented in Table 1. Products were isolated by preparative TLC (SiO_2, CH_2Cl_2 : petroleum ether 1 : 1) and identified on the basis of a comparison of the spectroscopic data with the literature ones.[11]

Iodination of 1-Indanone: Polymeric reagent: 0.5 g; solvent: acetic acid, 20 ml; reaction conditions: 50 °C, 4.5 hours. The crude reaction product was crystallized from ethanol and 193 mg (75%) of 2-iodo-1-indanone were obtained; IR 710, 1260, 1600, 1710 cm^{-1}, ^{1}H NMR (CCl_4) δ=3.45 (1H, dd, $J_{A,B}$=18 Hz, $J_{2,3A}$=3 Hz, H-3A), 3.90 (1H, dd, $J_{A,B}$=18 Hz, $J_{2,3B}$=7.5 Hz, H-3B), 4.92 (1H, dd, $J_{2,3B}$=7.5 Hz, $J_{2,3A}$=3 Hz, H-2), 7.50 (4H, m, aromatic H's), mass spectra m/z (relative intensity): M^+ 258(100), 131(88), 127(23), 103(84), 102(35), 77(61). Found: m/z 257.9550, Calcd for C_9H_7IO: M, 257.9544, mp 68—70 °C (from ethanol).

Iodination of 1-Tetralone: Polymeric reagent: 0.5 g; solvent: methanol, 20 ml; reaction conditions: 25 °C, 5 hours. The crude reaction mixture was crystallized from ethanol and 218 mg (80%) of 2-iodo-1-tetralone[12] were isolated: ^{1}H NMR ($CDCl_3$) δ=2.22 (2H, m, H-4), 3.05 (2H, m, H-3), 5.0 (1H, t, $J_{2,3}$=4.5 Hz, H-2), 7.3 (3H, m, aromatic H's), 8.05 (1H, dd, J=7.5 Hz, 3 Hz, H-8), mass spectra m/z (relative intensity): M^+ 272(77%), 146(17), 145(68), 144(14), 128(17), 127(28), 118(46), 117(86), 116(28), 115(100), 91(40), 90(46), 89(43). Found: m/z 271.9705, Calcd for $C_{10}H_9IO$: M, 271.9700, mp 76—78 °C (lit, 76—77 °C).[12]

Iodination of 6,7,8,9-Tetrahydro-5*H*-benzocyclohepten-5-one: Polymeric reagent: 0.5 g; solvent: methanol, 20 ml: reaction conditions: 50 °C, 5 hours. 257 mg (90%) of oily 6-iodo-6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one were obtained: ^{1}H NMR (CCl_4) δ=2.1 (4H, m, H-3, H-4), 3.06

(2H, t, J=6 Hz H-5), 5.25 (1H, t, $J_{2,3A}=J_{2,3B}$=4.5 Hz), 7.45 (4H, m, aromatic H's), mass spectra m/z (relative intensity): M^+ 286(41%), 160(10), 159(29), 132(13), 131(100), 129(20), 128(11), 127(16), 116(11), 115(17), 104(13), 103(14), 91(14), 89(14), 77(20), 63(15), 51(17). Found: m/z 285.9860, Calcd for $C_{11}H_{11}IO$: M, 285.9856.

Halogenation of 5,5-Dimethyl-1,3-cyclohexanedione: Polymeric reagent: 0.5 g; solvent: acetic acid, 20 ml; reaction conditions: 50 °C, 5 hours. On the basis of ^{1}H NMR and mass spectroscopic data we determined that 2-iodo and 2-chloro-5,5-dimethyl-1,3-cyclohexanedione were formed in the ratio of 2 : 1, and we were unable to separate them.

Halogenation of 1,3-Indandione: Polymeric reagent: 1 g; solvent: acetic acid, 20 ml; reaction conditions: 50 °C, 5 hours. The crude product formed was crystallized from ethanol and 150 mg (83%) of 2-chloro-1,3-indandione (mp 112—114 °C, lit,[13] 112—113 °C) were isolated: ^{1}H NMR ($CDCl_3$) δ=4.8 (1H, s, H-2), 8.05 (4H, m, aromatic H's), mass spectra m/z (relative intensity): M^++2 182(31%), M^+ 180(100), 124(26), 104(38), 89(63), 76(45), 50(33). Found: m/z 179.9980, Calcd for $C_9H_5ClO_2$: M, 179.9978.

Halogenation of 1-Phenylethenyl Acetate: Polymeric reagent: 0.5 g; solvent: methanol, 5 ml; reaction conditions: 0 °C, 3 hours. ^{1}H NMR analysis of the crude reaction mixture revealed that 38% of 2-iodoacetophenone, 30% of 2-chloroacetophenone, and 32% of acetophenone were formed, which were isolated by preparative TLC (SiO_2, petroleum ether 40—70 °C: CH_2Cl_2 1 : 1) and identified on the basis of a comparison of their spectroscopic data with the literature ones.[12]

Iodination of 1-Cyclohexenyl Acetate: Polymeric reagent: 0.7 g; solvent: methanol, 5 ml; reaction conditions: 25 °C, 2.5 hours. After purification of the crude product formed by SiO_2 column chromatography (elution by diethyl ether: hexane 1 : 2), 144 mg (64%) of oily 2-iodocyclohexanone[15] was obtained. The spectroscopic data were in agreement with literature.

Iodination of 1*H*-Inden-3-yl Acetate: Polymeric reagent: 0.75 g; solvent: methanol, 5 ml; reaction conditions: 25 °C, 6 hours. The crude product formed was purified by crystallization from ethanol, and 131 mg (52%) of 2-iodo-1-indanone (mp 65—67 °C) were isolated.

Iodination of 1,2-Dihydro-4-naphthyl Acetate: Polymeric reagent: 0.75 g; solvent: methanol, 5 ml; reaction conditions: 25 °C, 6 hours. The crude product formed was purified by crystallization from ethanol, and 205 mg (75%) of 2-iodo-1-tetralone (mp 77—78 °C, lit,[12] 76—78 °C) were isolated. Spectroscopic data were in agreement with those of the authentic sample.

Iodination of 6,7-Dihydro-5*H*-benzocyclohepten-9-yl Acetate: Polymeric reagent: 0.75 g; solvent: metanol, 5 ml; reaction conditions: 25 °C, 6 hours. The crude product formed was purified by SiO_2 column chromatography, and 226 mg (79%) of 6-iodo-6,7,8,9-tetrahydro-5*H*-benzocyclohepten-5-one were obtained. The spectroscopic data were in agreement with those of the authentic sample.

(Received February 14, 1989)

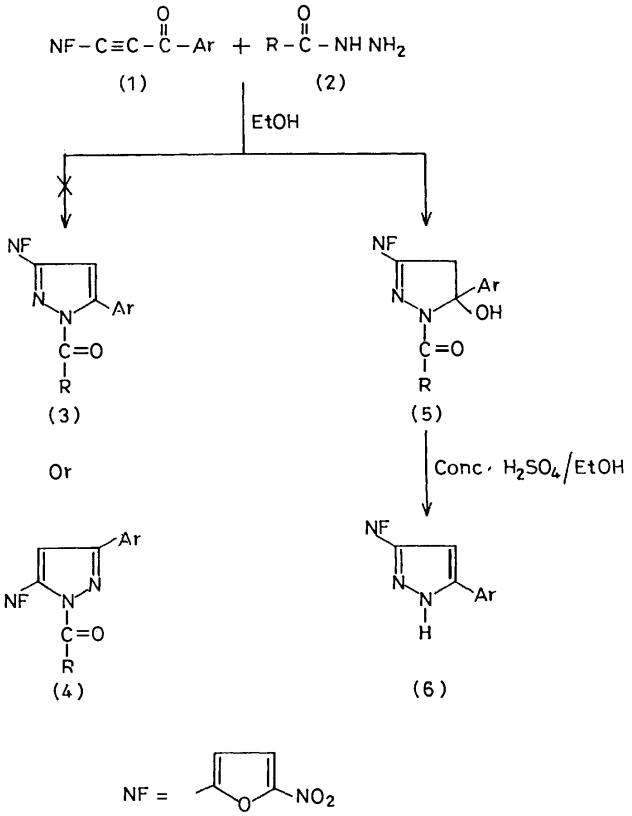
Synopsis. Reaction of 3-(5-nitro-2-furyl)-1-aryl-2-propyn-1-ones (**1**) with aroylhydrazines (**2**) furnished 1-aroyl-3-(5-nitro-2-furyl)-5-aryl-5-hydroxy-2-pyrazolines (**5**) rather than the expected pyrazoles **3** or **4**. On acid-catalyzed hydrolysis these hydroxypyrazolines are converted into the known 3-(5-nitro-2-furyl)-5-aryl-1*H*-pyrazoles (**6**). The structural elucidation of the products was carried out on the basis of analytical and spectral data. The newly synthesized nitrofuran derivatives are screened for their antibacterial properties against Gram-positive and Gram-negative bacteria. Most of them showed significant activity.

A number of pyrazole derivatives are reported to possess varied biological activities such as analgesic, antiinflammatory, antipyretic, amoebicidic, trichomonacidal, antibacterial, antimicrobial, and hypoglycemic.[1] α,β-Acetylenic ketones belong to a class of activated acetylenes.[2] Sasaki and Yoshioka[3] have prepared isoxazoles, pyrazoles, 1-carbamoylpyrazoles, and pyrimidines containing nitrofuran ring by the reaction of nitrofuryl-substituted α,β-acetylenic ketones with hydroxylamine, hydrazine, semicarbazide, and benzamidine respectively.

Prompted by the varied biological activity of pyrazoles and as a part of our general search for chemotherapeutically important nitrofuran derivatives,[4,5] a project aimed at the synthesis of 1-aroyl-3(or 5)-(5-nitro-2-furyl)-5(or 3)-aryl-1*H*-pyrazoles was undertaken employing the condensation of nitrofuryl-substituted α,β-acetylenic ketones with different aroyl- and (aryloxyacetyl)hydrazines. In all such condensations hydroxypyrazolines (**5**) are obtained rather than the expected pyrazoles **3** or **4**. Synthesis, characterization, degradation and biological activities of such hydroxypyrazolines **5** carrying nitrofuryl substituent are reported in this paper.

Results and Discussion

3-(5-Nitro-2-furyl)-1-aryl-2-propyn-1-ones (**1**) obtained by the dehydrobromination of 2,3-dibromo-1-aryl-3-(5-nitro-2-furyl)-2-propen-1-ones were condensed with the aroylhydrazines and (2-naphthyloxyacetyl)-hydrazine. The condensations were carried out using equimolar reactants in refluxing ethanol. In all the cases hydroxypyrazolines (**5**) were obtained as main products in rather good yields. The structures of the condensation products were established by IR, ^{1}H NMR, mass spectra, and elemental analysis. The hydroxypyrazolines have the structure **5** as shown in Scheme 1.



Scheme 1.

The hydroxypyrazoline structure **5** was assigned to these condensation products on the basis of analytical and spectral data and also by conversion of these hydroxypyrazolines **5** into the known pyrazoles **6** by acid hydrolysis. The IR spectra of the most condensation products **5** showed broad bands around 3400 cm^{-1} suggesting the presence of a hydrogen-bonded hydroxyl group. The amide carbonyl absorption was observed around 1650—1690 cm^{-1}. The pyrazoline structure was further confirmed by recording NMR spectra of a few selected compounds. ^{1}H NMR spectrum of the product **5a** showed a doublet of a doublet centred at δ, 8.0 integrating for two protons which is now assigned to the ortho protons of the aroyl moiety. The signals of the other aromatic protons and one β-proton of the nitrofuran ring overlapped with each other and appeared as a multiplet at δ, 7.25—7.65 integrating for nine protons. A sharp doublet (J=4 Hz) integrating for one proton appearing at δ, 7.0 is attributed to furan 3H. The OH signal of the hydroxypyrazoline appeared as a singlet integrating for one proton at δ, 5.3. The signal due to the CH_2 proton at the prochiral carbon atom of the

Compd. No.	Ar	R	Mp/°C	Yield	Mol. formula	Analysis Found (Calcd)		
						C	H	N
5a	Phenyl	Phenyl	168	70	$C_{20}H_{15}N_3O_5$	63.30 (63.66	4.19 3.98	11.01 11.14)
5b	Phenyl	*p*-Chlorophenyl	135	68	$C_{20}H_{14}ClN_3O_5$	58.05 (58.32	3.28 3.41	10.36 10.21)
5c	Phenyl	*o*-Hydroxyphenyl	208	65	$C_{20}H_{15}N_3O_6$	59.84 (61.07	3.75 3.82	10.48 10.69)
5d	Phenyl	2-Naphthyloxymethyl	231	64	$C_{25}H_{19}N_3O_6$	65.19 (65.65	4.02 4.16	9.33 9.19)
5e	*p*-Tolyl	Phenyl	149	69	$C_{21}H_{17}N_3O_5$	64.13 (64.45	3.99 4.35	10.52 10.74)
5f	*p*-Tolyl	*p*-Chlorophenyl	176	68	$C_{21}H_{16}ClN_3O_5$	59.51 (59.22	3.97 3.76	9.66 9.87)
5g	*p*-Tolyl	*o*-Hydroxyphenyl	164	65	$C_{21}H_{17}N_3O_6$	62.00 (61.92	4.26 4.18	10.14 10.32)
5h	*p*-Tolyl	2-Naphthyloxymethyl	124	66	$C_{26}H_{21}N_3O_6$	66.57 (66.24	4.63 4.46	8.83 8.82)
6a	Phenyl	—	216	60	$C_{13}H_9N_3O_3$	61.32 (61.18	3.68 3.53	16.33 16.47)
6b	*p*-Tolyl	—	227	63	$C_{14}H_{11}N_3O_3$	62.30 (62.45	4.25 4.09	15.39 15.61)

pyrazoline moiety appeared as two doublets centred at δ, 3.45 and 3.76 each integrating for one proton with a geminal coupling of 18 Hz. This coupling is observed in the hydroxypyrazoline due to the non-equivalence of the CH_2 protons at position 4 of the pyrazoline ring. The structure **5** is further confirmed by recording mass spectrum of **5a** which showed a molecular ion peak at m/z 377 corresponding to the molecular formula $C_{20}H_{15}N_3O_5$ thus confirming the assigned structure. A M−18 peak is also observed in the mass spectrum which indicates the loss of water molecule from the molecular ion. Two more peaks at m/z 105 and 77 are also observed in the mass spectrum of **5a** which are attributed to $C_6H_5\overset{+}{C}O$ and $\overset{+}{C_6H_5}$ respectively. The mp, yield, and analytical data of hydroxypyrazolines **5** are summarized in Table 1.

The hydroxypyrazoline structure **5** for these condensation products was further established by converting these pyrazolines to the known (nitrofuryl)pyrazoles.[6] The hydroxypyrazolines underwent smooth dehydration and debenzoylation when refluxed with ethanolic sulfuric acid. The pyrazoles thus formed were identified by their melting point and reference to literature[6] (see Table 1). Attempts to synthesize 1-aroyl-3-(5-nitro-2-furyl)-5-aryl-1*H*-pyrazoles by the dehydration of pyrazolines **5** in acetic anhydride were however unsuccessful.

Antibacterial Activity. All the hydroxypyrazolines (**5**) were screened for their antibacterial activity against S. *aureus*, A. *aerogenes*, E. *coli*, and B. *subtilis* by disc diffusion method as described earlier.[7] The results of such studies are given in Table 2.

Most of the compounds showed moderate to good antibacterial activity against all the four microorganisms tested at 5 $\mu g\,ml^{-1}$ dilution. Compound **5e** showed the highest activity among the compounds tested.

Table 2. Antibacterial Activity of Compounds **5a—h**

Experimental

All the melting points are uncorrected. The ^1H NMR spectra in $CDCl_3$ were recorded with a Bruker WH-200 200-MHz NMR spectrometer and the mass spectra with a JEOL JMS D-300 spectrometer. The IR spectra (KBr pellet) were recorded on a Perkin Elmer IR spectrophotometer.

α,β-Acetylenic ketones (**1**) were prepared by the methods reported.[3] Sustituted benzoylhydrazines were prepared from the corresponding carboxylic acids according to literature methods.[8,9]

General Procedure of Synthesizing Hydroxypyrazoline (5a—h). A mixture of appropriate nitrofuryl-substituted α,β-acetylenic ketone (**1**) (10 mmol) and suitably substituted

benzoylhydrazine (**2**) (10 mmol) in absolute ethanol (100 ml) was refluxed on a water bath for 7 h. The solvent was removed under reduced pressure and the residue was triturated with methanol. The residue was collected by filtration, dried and recrystallized from ethanol. Characterization data are given in Table 1.

General Procedure for the Conversion of Pyrazolines (5) into Pyrazoles (6): A solution of hydroxypyrazoline (**5**) (1 mmol) in ethanol (40 ml) was treated with a solution of concentrated sulfuric acid (5 ml) in ethanol (10 ml). The reaction mixture was refluxed for 3 h. The contents were cooled and diluted with water. Yellow precipitate of pyrazoles **6** were collected by filtration and recrystallized from ethanol. Treatment of **5a** as above gave pyrazole (**6a**). Similar treatment of **5g** gave pyrazole **6b**. Characterization data of **6a** and **6b** are also given in Table 1.

We are thankful to RSIC, CDRI, Lucknow for elemental analysis and mass spectra and to CSIR New Delhi for a senior research fellowship to K.V.U. We also thank Dr. K. S. Keshavamurthy, University of Alberta for 200 MHz NMR spectra of some of the samples.

Electronic Conduction in Solid Nitrobenzene Containing Nitrobenzene Anion Radical and Tetrabutylammonium Perchlorate

Kosaku SUGA,* Hirofumi TAKEMURA, and Masamichi FUJIHIRA
Department of Biomolecular Engineering, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received March 30, 1989)

The electric conductivities of frozen nitrobenzene containing various amount of tetrabutylammonium perchlorate and nitrobenzene anion radical were measured. The conductivity increased markedly with the concentration of the nitrobenzene anion radical. The mechanism of the electric conduction of the nitrobenzene is discussed and it is concluded that at low concentration of anion radical the increase of the electric conductivity is due to electronic conduction by a hopping mechanism. The rate constant of electron transfer (hopping) between any nearest neighbored sites is about $10^5\ s^{-1}$ at $-15\ °C$, which is smaller by 2 orders than that in hypothetical liquid nitrobenzene at the same temperature.

The ionic conductivity and the diffusion coefficient of an ionic species in a solution are expected to increase by its fast electron exchange reaction with other species in the solution as suggested by Levich, Dahms, and Ruff and Friedrich.[1-3] In our previous paper,[4] we reported that the contribution of the fast electron exchange reaction of the anthracene anion radical with anthracene to its ionic conductivity was successfully detected in a dimethylformamide solution. However, we could not detect such a contribution to the diffusion coefficient of the nitrobenzene anion radical (NB^-) which was undergoing a fast electron exchange reaction with nitrobenzene (NB) as a solvent.[5] In the latter experiment, it was difficult to detect the smaller contribution of the electron exchange reaction to the total conductivity, since the solution contained large amounts of tetraalkylammonium salts as supporting electrolytes.

In this paper, we report the electric conductivity of solid nitrobenzene containing its anion radical and tetrabutylammonium perchlorate (TBAP), and discuss the contribution of the electron exchange reaction between nitrobenzene and its anion radical to the conductivity of the solid, because in such a solid the contribution of the ion migration may be neglected. Furthermore, we discuss the difference between the rate constants of the electron exchange reactions in solution and in the solid state.

Experimental

Reagents. Commercially obtained nitrobenzene was dried with calcium chloride and distilled under reduced pressure in a nitrogen atmosphere. It was then passed through a column packed with activated alumina. Tetrabutylammonium perchlorate was prepared and purified as described in the previous paper.[6]

Preparation of Sample Solutions. Sample solutions of nitrobenzene containing various amounts of its anion radical and TBAP were prepared by electrolysis in an air-tight glass cell filled with nitrogen as described in the previous paper.[5] The concentration of NB^- in the solution was determined by the electric change consumed during the electrolysis.

Measurements of Electric Conductivity. Figure 1 shows the conductivity cell used for measurements in this experiment. Electrodes were made of two platinum disks of 1 cm diameter, which were fixed 3 mm apart from each other with face to face. The temperatures of the samples in the vicinity of the electrodes were measured with a thermister thermometer inserted into the cell as shown in Fig. 1. The sample solution prepared by the electrolysis was transferred to the conductivity cell under nitrogen atmosphere and the cell was cooled in a Dewar-type thermostat filled with liquid air-ethanol refrigerant. The conductivity or resistivity of the cell containing the sample solid was measured with a Mita-Musen Model 12K impedance bridge. The cell constant was determined by measuring the conductivity of a standard KCl solution.

Results and Discussion

Figure 2 shows the temperature dependence of the conductivities (σ) of solid NB containing 0.1 M

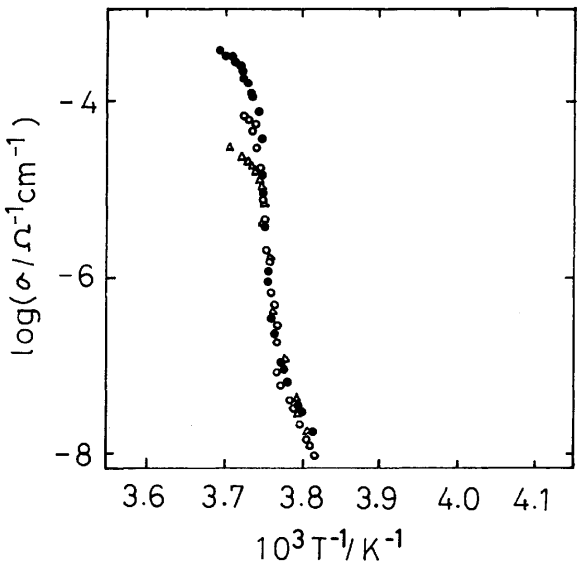

Fig. 2. Temperature dependence of the electric conductivity of NB containing (●) 0.63 M, (○) 0.27 M, (△) 0.10 M TBAP in the absence of NB^-.

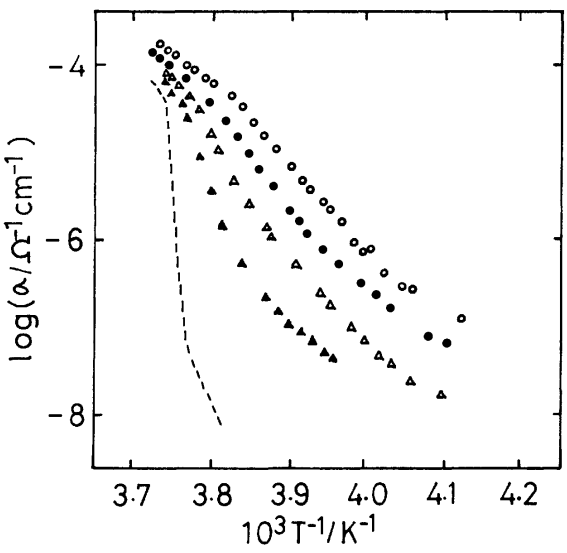

Fig. 3. Temperature dependence of the electric conductivity of NB containing 0.27 M TBAP and (○) 130 mM, (●) 87 mM, (△) 65 mM, and (▲) 43 mM NB^-. Dashed line shows the conductivity at $[NB^-]=0$.

(1 M=1 mol dm^{-3}), 0.27 M and 0.63 M TBAP in the absence of NB^-. In the temperature range used for this experiment, σ decreases rapidly with lowering temperature. Below −6.5 °C the conductivity does not depend on the concentration of TBAP.

Figure 3 shows the temperature dependence of the conductivity of NB cotaining 0.27 M TBAP and various amounts of NB^-. The conductivity increased remarkably with the concentration of NB^- especially at low temperatures. The apparent activation energies for these conductivities determined from the linear part of the curves in this figure are about 170 kJ mol^{-1}. Solid NB samples containing other concentrations of TBAP and various amounts of NB^- showed behavior similar to Fig. 3.

Since the migration of ions is difficult in the solid state, the electric conduction of solid NB containing NB^- may be mainly determined by electronic conduction. In fact, the conductivity of solid NB in the absence of NB^- is much smaller than samples containing NB^-, especially at low temperature.

Electronic conduction in solids is generally classified to two categories, i.e. band conduction and hopping conduction. If the present case is the former, conduction electrons in solid NB are supplied by NB^- and they may be trapped by the electric potential induced by positively charged tetrabutylammonium cations (TBA^+). In other words, the electrons are trapped in the donor levels which are the highest occupied molecular orbitals of NB^- residing in the vicinity of TBA^+. In such a case, the activation energy of σ is mainly determined by the excitation energy of the donor electron to the conduction level. The observed large activation energy of about 170 kJ mol^{-1}, however, can not be explained by a band conduction model, because the excitation energy estimated from the Coulomb interaction energy between NB^- and TBA^+ is not large enough.

If the present case is the latter, the conductivity is represented by the following equation according to Bagley.[7]

$$\sigma = ne^2\delta^2 k_1/k_B T \quad (1)$$

where n, δ, k_1, and k_B denote the number of hopping electrons in unit volume, the jumping distance of hopping electron between two sites, the first-order rate constant of electron hopping and the Boltzmann constant, respectively. Other nomenclature has the usual meaning. This equation has a close relation with the following equation derived by Ruff and Friedrich[3] for the ionic conductivity of ionic species A which is undergoing fast electron exchange with other species B.

$$\lambda_A = \lambda_A^0 + \pi F^2 \delta^2 k_2 c_B/4RT \quad (2)$$

where λ_A, λ_A^0, δ, k_2, and c_B represent the ionic conductivity of A in the presence and absence of B, the electron jumping distance, the second-order rate constant of electron exchange between A and B, and the concentration of B, respectively. The second term of Eq. 2 represents the contribution of the electron exchange to the ionic conductivity of A. The conductivity σ is related to the ionic conductivity λ by the following equation.

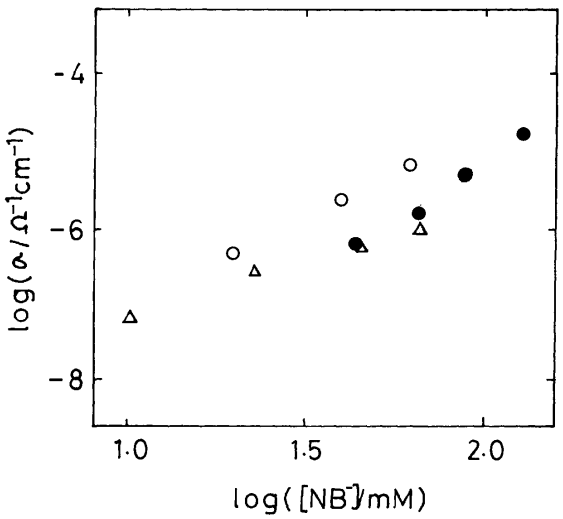

Fig. 4. The electric conductivity, σ vs. the concentration of NB^- plots for NB containing (○) 0.1 M, (●) 0.27 M, and (△) 0.63 M TBAP at −15 °C.

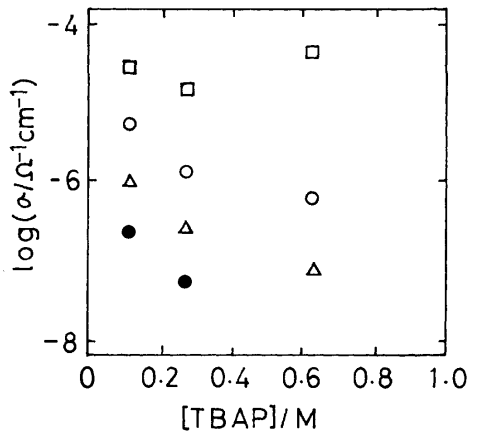

Fig. 5. The electric conductivity, σ vs. the concentration of TBAP plots for NB containing 65 mM NB^- at (□) −10 °C, (○) −15 °C, (△) −20 °C, and (●) −25 °C.

$$\sigma = \sum_i \lambda_i c_i \quad (3)$$

where the summation is taken for all ionic species, i.e. NB^-, TBA^+, and ClO_4^- in this case. Since migration of the ionic species can be neglected in this experiment, we consider only the second term of Eq. 2. In this case, NB^- and NB correspond to A and B, respectively. The following equation, therefore, is derived from Eq. 3.

$$\sigma = \pi F^2 \delta^2 k_2 c_A c_B / 4RT = \pi [NB^-] F^2 \delta^2 k_2 [NB] / 4RT. \quad (4)$$

Considering that $N_A e = F$, $n/N_A = [NB^-]$, $k_2[NB] = k_1$, and $R = N_A k_B$ (N_A: Avogadro's number, F: Faraday's constant), we can obtain Eq. 1 except for the factor $\pi/4$. The difference of this factor is due to the neglect of the electron hopping or jumping directions other than in the direction parallel to the electric field in the derivation of Eq. 1 by Bagley. Coincidence between the Eqs. 1 and 4 shows that hopping conductivity denoted by Eq. 1 is equivalent to the contribution of electron exchange to the ionic conductivity denoted by Eq. 2.

In the case of the hopping conduction, the electron hopping process is the activation process and needs a certain value of activation energy. Such an activation energy is included in the equation which represents the rate constant of electron hopping or electron exchange as follows;

$$\begin{aligned} k_1 &= k_2[NB] = \nu[NB]\exp(-\Delta G^*/RT) \\ &= \nu[NB]\exp(\Delta S^*/R)\exp(-\Delta H^*/RT), \end{aligned} \quad (5)$$

where ν, ΔG^*, ΔS^*, and ΔH^* denote the frequency of electron hopping with zero activation free energy, activation free energy, activation entropy, and activation enthalpy for electron hopping, respectively. Therefore, the fact that the observed conductivity of solid nitrobenzene has a large activation energy does not contradict this hopping mechanism.

If the hopping mechanism can be applied to the solid nitrobenzene in this experiment, Eqs. 1 and 4 show that the conductivity of solid nitrobenzene must be proportional to the number in unit volume or the concentration of NB^-.

Figure 4 shows the plots of $\log(\sigma/\Omega^{-1}\,cm^{-1})$ vs. $\log([NB^-]/mM)$ for NB containing various concentrations of TBAP at −15 °C. It is apparent that the conductivity increases with the concentration of NB^-, although the value of σ at constant $[NB^-]$ and temperature is dependent on the concentration of TBAP as shown in Fig. 5. In these plots, there is fairly good linearity between $\log(\sigma/\Omega^{-1}\,cm^{-1})$ and $\log([NB^-]/mM)$ when the concentration of TBAP is constant. The slope of the plots is about 1 at low concentration of NB^-, while it increases to about 3 at high concentration of NB^-. Although the reason for this is not obvious at the present stage, the conductivity is almost proportional to $[NB^-]$ at low concentration of NB^-. In this concentration range, the rate constant of electron hopping therefore can be determined, if appropriate jumping distance is assumed. If the jumping distance δ is assumed to be 10 Å, the rate constant $k_1 = k_2[NB]$ is estimated to be about $10^5\ s^{-1}$ at −15 °C. The corresponding rate constant in solution is estimated to be about $10^7\ s^{-1}$ at the same temperature by an extrapolation.[5] Such a large difference between the values of k_1 in the solid and in solution can be attributed to the freezing of the molecular motion (orientational and vibrational) in solid NB needed for the formation of activation states of an electron transfer reaction.[8] In particular, near the freezing point of NB at which the measurements were

performed in this experiment, the sudden freezing of molecular motion with the decrease of the temperature may occur.

In the quantum mechanical treatment of electron transfer reactions,[8c] the first-order rate constant for electron transfer at fixed distance is given by the following equation,

$$k_1 = (2\pi/\hbar)H_{AB}^2(FC) \quad (6)$$

where H_{AB} is the matrix element describing the electronic coupling between the electronic states of reactants and products, and the quantity (FC) is the 'Franck-Condon' factor, which is a sum of products of overlap integrals of the vibrational and solvational wave functions of the reactants with those of the products, suitably weighted by Boltzmann factors for the vibrational and solvational energy levels of reactants. With freezing of the sample solution, the orientational vibration of NB^- and NB molecules may be frozen easily and the frequencies of these vibrations may increase remarkably. Consequently, the separation of these vibrational levels increases considerably, the contribution of these vibrations to the value of (FC) can be expected to decrease greatly.

Therefore, the larger activation energy observed in solid NB compared with that observed in solution (about 35 kJ mol^{-1})[5] can also be attributed to the apparent decrease in the value of (FC) as a result of such sudden freezing of molecular motion with the decrease of the temperature.

Mesomorphic Properties of Dialkyl *N,N'*-[1,4-Phenylenebis(methylidyne)]-bis[4-aminobenzoates]

Yoshio MATSUNAGA* and Hiroyuki MATSUZAKI
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 26, 1989)

The mesomorphic behavior of fourteen dialkyl *N,N'*-[1,4-phenylenebis(methylidyne)]bis[4-aminobenzoates] has been examined by optical microscopy and differential scanning calorimetry in order to make a comparison with the behavior of *N,N'*-[1,4-phenylenebis(methylidyne)]bis[4-alkylanilines] and to study the effects of branching of the ester alkyl groups. Among the results obtained, the following may be particularly important: (1) the unbranched alkyl ester is generally less polymesomorphic than the corresponding alkyl compound, (2) mesophase(s) is completely eliminated by the 1-methylation, and (3) the 3-methylbutyl, 3-methylpentyl, and 4-methylpentyl esters are more polymesomorphic than the unbranched alkyl esters.

The mesomorphic properties of organic compounds are highly sensitive to changes in chemical structure; therefore, a systematic study of closely related compounds is desirable in order to elucidate the relationship between the structural parameters and the thermal stabilities of various mesophases. This paper presents our work on dialkyl *N,N'*-[1,4-phenylenebis(methylidyne)]bis[4-aminobenzoates] which have the general structure given below (**1**) and are closely related to that of *N,N'*-[1,4-phenylenebis(methylidyne)]-bis[4-alkylaniline] (**2**), well-known for their smectic polymorphism.[1,2] For example, the propyl compound exhibits the smectic H, G, C, and A phases as well as the nematic phase, and the hexyl compound exhibits the smectic G, F, C, and A phases as well as the nematic phase.[2] Therefore, we may be able to find various types of the mesophase in the compounds to be studied. Indeed, Arora et al. have shown that the dibutyl ester exhibits smectic C and A phases as well as the nematic phase.[3] Secondly, we were interested in extending our work on the effects of the branching of the ester alkyl chain on the mesomorphic properties to diesters in which the effects may be more appreciable than in the monoester. The bis(2-methylbutyl) ester has been known to show only the nematic phase, through the work of Coates et al.[4]

Experimental

Materials. Alkyl *p*-aminobenzoates were obtained by reactions between *p*-nitrobenzoyl chloride and alcohols, followed by reduction with iron powder and dilute hydrochloric acid, as described by Adams et al., or with zinc dust in 75% aqueous ethanol.[5,6] The Schiff's bases were prepared by condensing terephthalaldehyde with the alkyl *p*-aminobenzoates in boiling ethanol or benzene, employing a small amount of acetic acid as a catalyst.

Measurements. Microscopic observations and calorimetric measurements were made as described in our previous paper.[7] Phase diagrams were determined by the calorimetric curves for binary mixtures in order to identify the smectic phases.

Results and Discussion

The transition temperatures and enthalpy changes are listed in Table 1 for the fourteen esters examined in this work. Here, K, S, N, and I stand for crystalline, smectic, nematic, and isotropic liquid phases, respectively. The seven unbranched alkyl esters are given in section a in this table.

The methyl and ethyl esters are purely nematogenic. Because of the thermal decomposition near the clearing point the enthalpy change in the former ester could not be measured. Both their melting and clearing points are much higher than those of the corresponding alkyl compounds, respectively. The appearance of the smectic H phase in the temperature range from 126 to 150 °C reported by Neubert and Maurer was not supported by Wiegeleben et al.

The propyl ester is transformed into an isotropic liquid at a temperature almost the same as that of the propyl compound (260 °C by Neubert and Maurer and 255 °C by Wiegeleben et al.). The temperature range of the smectic A phase is a little wider than that of the corresponding alkyl compound (26 to 30 °C). The three other smectic phases given by the propyl compound, H, G, and C, are not detectable in this ester.

Thus, the clearing point of the ester is reduced as the

ester alkyl group becomes longer and a profound alternation of the transition temperature is exhibited by higher homologous members. The transformation of the butyl ester from the nematic phase to an isotropic liquid occurs at a lower temperature than the corresponding alkyl compound; namely, 209 versus 235 °C.[1,2] Similarly, the smectic A and C properties are decreased compared with those in the alkyl compound. The difference in their thermal stabilities is in the following order: $S_C > N > S_A$. Therefore, a large depression of the smectic A phase in the hexyl and heptyl esters may explain the absence of nematic properties in these two members. It must be noted that all of the mesophases appearing below the smectic C in the alkyl compounds are eliminated by the change of the terminal substituent from the alkyl to the alkoxycarbonyl group.

Turning now to the branched alkyl esters, the thermal properties are given in section b in Table 1. According to the systematic studies by Gray and Harrison, all of the branched chain esters have lower liquid crystal stabilities than the unbranched chain esters.[8] Especially, the branching methyl group occupying the 1 position greatly reduces the thermal stability and, as the methyl group is moved towards the end of the chain, the transition temperature rises again. In addition to the information given in table, the esters carrying the following alkyl groups were studied: isopropyl, *t*-butyl, 1-methylbutyl, 1,2-dimethylpropyl, 1-methylbutyl, and 1-methylpentyl. No mesophase was found for these esters, indicating that the liquid crystalline behavior in the present series dramatically suffers as the result of a branching methyl substituent on the 1 position in the alkyl chain.

The nonmesomorphic behavior of the neopentyl ester in the present series is in sharp contrast with the observation made for the corresponding ester in the 4-(4-phenylbenzylideneamino)benzoate series.[7] In the latter, the N-I transition temperature of the propyl ester remains at 133 °C by the introduction of a methyl group at the 2 position and is depressed only by 8 °C by the second methyl group. This remarkable discrepancy strongly supports our previous view that the effects of the branching of the alkyl chain on mesomorphic properties greatly vary with the features of the molecular structure.

The N-I transition temperature of the 2-methylpropyl ester is lower by 17 °C than that of the unbranched propyl ester. The smectic A phase observed for the latter compound is lost by the

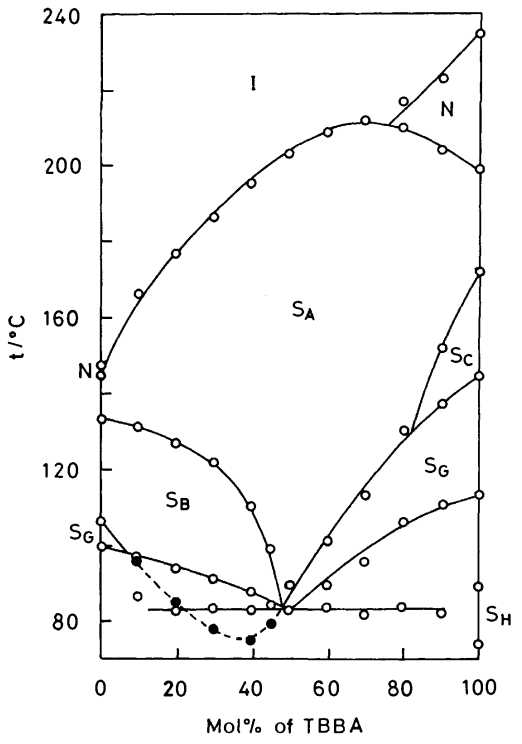

Fig. 1. Phase diagram of the binary system consisting of compound **1** with R=3-methylpentyl and TBBA (compound **2** with R=butyl). The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

introduction of a methyl group at the 2 position.

When the branching methyl group is located at the 2 or 3 position in the butyl ester, the change in the transition temperature is rather unusual. Contrary to what is generally known,[8-11] the 2-methylbutyl ester gives an N–I transition temperature higher by 13 °C than the 3-methylbutyl ester. The latter compound exhibits smectic A and C phases, both of which are characteristic of the butyl ester. While the smectic A behavior is depressed by as much as 32 °C, the smectic C behavior is a little bit promoted by the branching methyl group.

The branching at the 2 or 3 position of the pentyl ester presents very interesting features. The N–I transition temperature of the 2-methylpentyl ester is higher by 28 °C than that of the 3-methylpentyl ester. Although the former ester exhibits only the nematic phase, the latter gives polymesomorphic changes. It must be pointed out that the smectic B phase shown by the 3-methylpentyl ester is not observable for the unbranched pentyl ester. In order to supplement the identification made by the microscopic observation, a phase diagram of the binary system with the butyl compound (TBBA) was prepared.[12] This reference compound is known to exhibit the smectic H, G, C, and A phases and the nematic phase.[2] As is shown in Fig. 1, the eutectic point is found at 50 mol% and 83 °C. Since the smectic A phase is stabilized by mixing, only parts of the N–I transition temperature curve are observable. Nevertheless, it is easily seen that the temperature varies monotonously with the composition. The thermal stabilities of the other smectic phases of TBBA, especially those of the smectic C and H phases, are drastically reduced by the addition of the ester. The intermediate smectic phase in the ester is clearly different from any smectic phase given by the reference compound and was identified to be of the smectic B type by a microscopic observation of the texture. This assignment is in accordance with one of the possible sequences of appearance for three smectic phases.[13] On the other hand, the low-temperature smectic phase is apparently miscible with the smectic G phase of TBBA, even though the smectic B–smectic G transition temperature curve shows a deep minimum.

By a shift of the methyl group from the 3 position to the 4 position, the nematic phase is stabilized by 23 °C and the smectic A phase by 15 °C. The above-mentioned effects of the branching methyl group on the N–I transition temperature of the pentyl ester indicates that the temperature changes alternately in the present series as the branching methyl group moves from the odd to even position in the chain. One may recognize such an alternation, even in the N–I transition temperatures of the methyl-substituted pentyl 4-(4-cyanobenzylideneamino)cinnamates reported by Gray and Harrison;[8] however, it was not detectable in our earlier series of alkyl 4-(4-alkoxybenzylideneamino)benzoates.[10] Thus, the magnitude may markedly depend on the features of the molecular structure. Because of the presence of two alkyl groups, the alternation in the present series may be so large that one cannot miss it. However, monoesters exhibiting similar changes will be provided by the forthcoming papers. The present ester exhibits the smectic C phase, which is not known for the unbranched pentyl ester.

Finally, we add that the 2-methylhexyl ester is purely nematogenic, while the unbranched hexyl ester is purely smectogenic. The appearance of the nematic phase by a partial destruction of the smectic A phase by a branching methyl group has been amply demonstrated in the present author's previous studies.[7,10,11]

Adsorption of Poly(methyl methacrylate) on Silica Surfaces Having Various Silanol Densities

Kazutoshi KOBAYASHI,* Kazuo ARAKI, and Yoshio IMAMURA
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 2, 1989)

The adsorption of poly(methyl methacrylate) (PMMA) on silica surfaces having various silanol densities was studied by ESR and IR spectroscopies. Three silica samples, Nipsil HD, Aerosil 300, and Aerosil R812, which have 8, 2.2, and 0.54 nm^{-2} silanol densities, respectively, were used as the adsorbents. The amount of adsorption, A, the surface coverage, θ, and the fraction of train segments in the polymer, p, were determined. The values of the segment fractions anchoring through the hydrogen bond in all train segments of the adsorbed polymer, f_{HB}, were also estimated. When PMMA adsorbed on Nipsil HD, the polymer adsorbed predominantly by the formation of hydrogen bonds; on the other hand, when PMMA adsorbed on Aerosil 300, the polymer adsorbed through the hydrogen bond in the part of 30—40%. When PMMA adsorbed onto Nipsil HD, the value of p_{ESR} obtained by the ESR method was almost the same as the p_{IR} obtained by the IR method. When PMMA adsorbed onto Aerosil 300, the value of p_{ESR} was 0.47, twice the value of p_{IR}(0.24).

The adsorption of macromolecules is quite different in many respects from that of small molecules. The difference between them arises from the obvious differences in the size and the resultant flexibility of molecures. Among the molecular models proposed for characterizing polymer molecules adsorbed from solution onto a solid surface, the "loop-train-tail" model would be most general and successful. In order to discuss the conformation of an adsorbed polymer molecule, it is very important to estimate the fraction of train segments in the polymer, p. Usually, IR,[1,2] NMR,[3-5] and ESR[6-8] methods are utilized to estimate the value of p.

Fortana and Thomas first developed a technique for a quantitative estimation of the segment fraction attached to the surface sites through the hydrogen bond using IR spectroscopy.[1] They obtained values of p from 0.3 to 0.4 for the adsorbed poly(alkyl methacrylate) on silica in organic solvents. Robb and Smith first employed the ESR method for studies of the adsorption of poly(*N*-vinylpyrrolidone) onto silica, mainly from aqueous solution.[6] They obtained values of p from 0.6 to 0.9. Sakai et al. studies the conformation of adsorbed poly(methyl methacrylate) (PMMA) by the ESR method using three-component spectrum analysis.[7] They discussed the molecular weight dependence upon the polymer adsorption,[8] and also made a direct comparison of the ESR and IR methods using an identical solution-adsorbent system (PMMA-carbon tetrachloride-silica).[9] Based on their experimental results, they pointed out a disagreement in the obtained p values: the ESR method gave much greater values of p than did the IR method. In the present study one of our purposes was to pursue the cause of this disagreement. It was reported that when PMMA adsorbed on a silica surface, the polymer would mainly adsorb by the formation of a hydrogen bond between a carbonyl group of methyl methacrylate and a silanol group of the surface site.[10] Since the IR method evaluates only the segments adsorbed through a hydrogen bond between the carbonyl group and the silanol group, if the segments in PMMA adsorbed except for the hydrogen bond, the value of p would be understimated. In this paper we report on whether the adsorption of PMMA onto a silica adsorbent is caused exclusively by the formation of hydrogen bonds or not. We studied the amount of adsorption (A), the segment fraction of train (p), and the surface coverage (θ), using three kinds of silica surfaces having various silanol densities.

Experimental

Materials. The experimental procedures were basically the same as those described previously.[7,8] Spin-labeled PMMA was prepared by an anionic copolymerization of methyl methacrylate with 4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxyl in toluene at 0 °C using a phenylmagnesium bromide catalyst. The polymer was repeatedly fractionated in an acetone-water mixture to give narrow molecular weight distributions. The number-average molecular weight and the $\bar{M}_w/\bar{M}_n$ ratio of the PMMA sample were determined by GPC, calibrated with a standard polystyrene. They were 1.5×10^5 and 1.6, respectively. The spin-concentration of PMMA was approximately one spin per 400 monomer units. Details of the hyperfine coupling- and g-tensor values of the PMMA sample were published in a previous paper.[7]

Three silica-based adsorbents were used (Table 1). Nipsil HD (Nippon Silica Industrial) is a silica of surface area 263 $m^2 g^{-1}$, as determined by N_2 adsorption; it contains a relatively high level of silanol groups, 8 per nm^2. Aerosil 300 (Degussa) is a silica of surface area 303 $m^2 g^{-1}$ with a lower content of silanol groups, 2.2 per nm^2. A sample of surface-

Table 1. Characterization of Silica Sample

Sample name	Specified surface area/$m^2 g^{-1}$	SiOH/nm^2
Nipsil HD	263	8
Aerosil 300	303	2.2
Aerosil R812	245	0.54

modified silica, Aerosil R812 (Degussa), was prepared by treating Aerosil 300 with trimethylchlorosilane; this treatment converts most of the silanols to trimethylsilyl groups. It was reported that the differences of the particle sizes and the specific surface coverage in the used samples do not influence the amount of adsorption, A, and the train segment in polymer, p.[8]

Carbon tetrachloride and benzene used in this work were spectrometric grade.

Techniques of Measurements. The adsorption isotherms of PMMA on the various silica surfaces at 25 °C were measured by ESR spectroscopy, as described previously.[7] Solutions (10 ml) of various polymer concentrations were shaken vigorously with a solid adsorbent (0.1 g) in order to disperse the solid, then tumbled slowly over 24 h to ensure that equilibrium had been reached. The suspensions were then centrifuged and the ESR spectra of the supernatant solution and the adsorbed polymer were recorded. All ESR spectra were recorded with a JEOL JES FE-3X spectrometer.

The surface coverage (fraction of surface silanol groups occupied), θ_{IR}, was determined by the method of Kawaguchi et al., using infrared spectroscopy.[2] The differential IR spectra between the supernatant polymer solution and the silica on which PMMA was adsorbed show two characteristic bands: a band located at 3730 cm^{-1} due to the free silanol groups and another band located at 3420 cm^{-1} due to an interaction between the silanol groups and the carbonyl groups of the adsorbed PMMA. If we know the molar extinction coefficients (L mol^{-1} cm^{-1}) at 3730 and 3420 cm^{-1}, both the number of free silanol groups (S_{3730}) and the number of occupied silanol groups (S_{3420}) can be determined, and the surface coverage, θ_{IR}, can be calculated from the equation

$$\theta_{IR} = S_{3420}/(S_{3420} + S_{3730}). \quad (1)$$

All IR spectra were recorded with JASCO FT-IR 7000 spectrometer. In the case of Aerosil R812, we could not decide on the surface coverage, θ_{IR}, since the absortion of the silanol group was broad and did not shift before and after adsorption. Therefore, instead of θ_{IR}, we determined the surface coverage, θ_{As} (amount of adsorption/amount of maximum adsorption), of Aerosil R812 by using the same procedure as in a previous paper, from data regarding the amount of adsorption.[8]

Analyses of the ESR spectra of the adsorbed polymers were performed using the same procedure described in a previous paper.[7] The ESR line shape observed from the adsorption system was simulated by the summation of three model spectra: a triplet line with a narrowed width showing high mobility, an intermediately broadened line showing a restricted segment motion, and a powder pattern showing rigid immobilization. The spectrum was normalized by the singal intensity obtained from a second integration of the first-derivative spectrum. The amplitude of each model spectrum was determined by a least-squares method on the multiple regression to fit the summation of the three spectra with the observed spectrum. The model spectra were selected to make the correlation coefficient close to unity between the observed spectrum and the summation of the three model spectra. In the three-component analysis, close curve fitting was found in every case.

Results and Discussion

The adsorption isotherms for labeled PMMA from carbon tetrachloride and benzene onto the three kinds of adsorbents are shown in Fig. 1, indicating that the solvent has a strong influence on the affinity of the polymer for the surface. Here, Nipsil HD showed no indication of saturation over the concentration observed. In a benzene solution, relatively small amounts of polymer were required to saturate the surface. In a carbon tetrachloride solution, the adsorption of PMMA was more favored. The difference in the adsorption of PMMA adsorbed from carbon tetrachloride and benzene would be caused by the fact that carbon tetrachloride is a poorer solvent than benzene for PMMA and that benzene has a stronger affinity for a silica surface than does carbon tetrachloride. In both solvents, the adsorption of PMMA decreased with a decrease in the silanol density of the surface (Fig. 1). In the cases of Aerosil 300 and Nipsil HD, the adsorption of PMMA were of a high-affinity type and increased steeply under low equilibrium concentration.

Typical plots of the values of θ_{IR} and θ_{As} against the equilibrium concentration for the PMMA adsorbed on various silica surfaces from carbon tetrachloride solution are displayed in Fig. 2. The values of θ_{IR} increased steeply at a low concentration and reached a

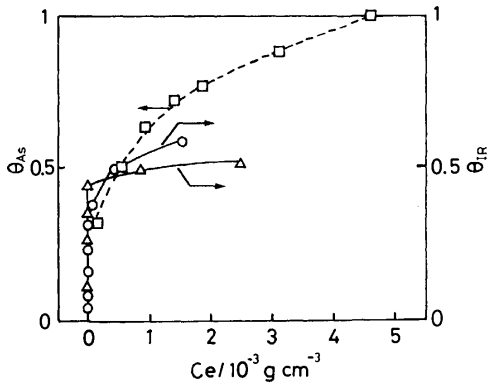

Fig. 2. Plots of the values of θ_{IR} and θ_{AS} against the equilibrium concentration for adsorbed PMMA from CCl_4. O: Nipsil HD, △: Aerosil 300, □: Aerosil R812.

constant value. The values of θ_{As} gradually increased and reached naturally to unity.

When the affinity of the polymer for the surface is relatively weak, the adsorbed polymer molecules are likely to be held rather loosely and have an abundance of loops and tails. When the affinity of the polymer for the surface is strong, the adsorbed chains are held more strongly on the surface. The resulting motionally restricted conformations tend to be relatively flat and to have an abundance of trains. Such conformational differences are apparent in the ESR spectra of the adsorbed labeled PMMA. The spectra of the PMMA adsorbed on the three kinds of silica surfaces from a carbon tetrachloride solution are illustrated in Fig. 3. The ESR spectra of PMMA adsorbed on Nipsil HD and Aerosil 300 are virtually identical and are composites of broad and motionally-nallowed lines, indicating that some of the segments at the surface are located in loops or tails which are relatively free and more mobile. The ESR spectra of PMMA adsorbed on the Aerosil R812 have motionally-nallowed lines, suggesting a loopy conformation.

When PMMA molecules are adsorbed onto an Aerosil 300 silica surface, the segment fractions of train, short loop, and long loop segments against the surface coverage, θ_{IR}, can plotted as in Fig. 4, which shows a decrease in the number of train segments and an increase in the number of long loop segments with an increase in θ_{IR}. At relatively low θ_{IR}, most of the segments were highly localized near the surface. As a result, the adsorbed polymer was flattened and formed a thin adsorbed layer. All of the theoretical treatments predict that a flexible chain polymer molecule would be strongly attracted by a solid surface and would have an appreciably flat structure with a large fraction of train segments, in the case of a high level of the adsorption energy between the segments and the surface. The revealed structures roughly agree with the theoretical predictions.

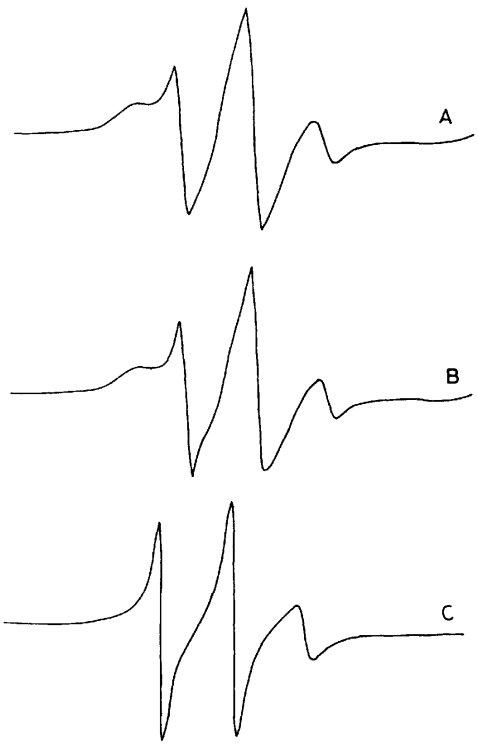

Fig. 3. ESR spectra of the adsorbed PMMA adsorbed on the three silica surfaces. A: Nipsil HD, B: Aerosil 300, C: Aerosil R812.

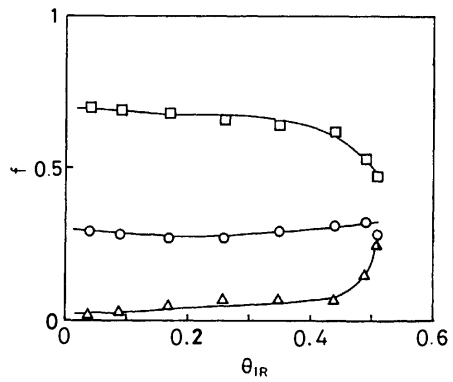

Fig. 4. Plots of the segment fractions, f, of train, short loop, and long loop against the surface coverage, θ_{IR}, for OMMA adsorbed onto the Aerosil 300 silica surface. □: train, O: short loop, ▲: long loop.

The segment fractions of train, short loop, and long loop at the maximum surface coverage are listed in Table 2. In both solvents the fraction of train segments decreased and that of long loop segments increased with a decrease in the silanol densities of the surface. On the three kinds of silica surfaces in benzene, the fraction of train segments is smaller and the fraction of long loop segments is larger than those in carbon tetrachloride. The obtained results in both solvents (Table 2) indicate that when PMMA adsorbs onto Nipsil HD and Aerosil 300, the polymer would

Table 2. Segment Fractions of Adsorbed Polymer

Solvent	Adsorbent	Train	Short loop	Long loop
CCl_4	Nipsil HD	0.50	0.30	0.20
	Aerosil 300	0.47	0.28	0.25
	Aerosil R812	0.12	0.16	0.72
C_6H_6	Nipsil HD	0.48	0.28	0.24
	Aerosil 300	0.41	0.20	0.39
	Aerosil R812	0.11	0.09	0.80

Table 3. Fraction of Hydrogen Bond

Solvent	Adsorbent	A_{train} / $\times 10^{-4}$ g m^{-2}	A'_{train} / $\times 10^{-4}$ g m^{-2}	f_{HB}
CCl_4	Nipsil HD	8.5	7.7	0.91
	Aerosil 300	5.5	1.9	0.34
	Aerosil R812	6.8	—	—
C_6H_6	Nipsil HD	7.3	6.8	0.93
	Aerosil 300	3.6	1.5	0.40
	Aerosil R812	2.0	—	—

have flat conformations; however adsorption onto Aerosil R812 would have a loopy conformation.

The values of the segment fractions anchoring through the hydrogen bond in all train segments of the adsorbed polymer, f_{HB}, are listed in Table 3.

In the table A_{train}(g m^{-2}) indicates the weight of a train segment in terms of the amount of adsorption, and is given by

$$A_{train} = A_s \times p, \tag{2}$$

where A_s is the amount of saturated adsorption. A'_{train}(g m^{-2}) also indicates the weight of segment anchoring through the hydrogen bond in a train segment of a polymer, and is given by

$$A'_{train} = N_{SiOH} \times \theta_{IR} \times M, \tag{3}$$

where N_{SiOH} is the mumber of silanol per unit area and M is the molecular weight of the methyl methacrylate monomer. Consequently, f_{HB} is denoted A'_{train}/A_{train} and is used for the notation of the segment fraction anchoring through the hydrogen bond in all train segments of the adsorbed polymer. As can be seen from the table, when PMMA is adsorbed on Nipsil HD, the polymer adsorbs predominantly by the formation of hydrogen bonds; however, when PMMA is adsorbed on Aerosil 300, the polymer adsorbs through hydrogen bonds in a ratio of 30—40%. The value of f_{HB} of the PMMA adsorbed on Aerosil 300 is similar to the result of Sakai and Imamura,[9] who made a direct comparison of the ESR method with the IR method using an identical solution-solvent system (PMMA-carbon tetrachloride-silica).

When PMMA is adsorbed onto Nipsil HD, f_{HB} is nearly equal to 1. It is then expected that the values of

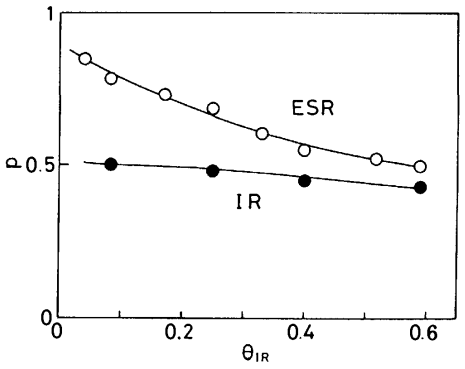

Fig. 5. Plots of the values of p_{ESR} and p_{IR} against the surface coverage, θ_{IR}, for PMMA adsorbed onto Nipsil HD. ○: p_{ESR}, ●: p_{IR}.

p_{ESR} and p_{IR}, obtained by ESR and IR methods, respectively, at the maximum surface coverage, θ_{IR}, are identical. The values of p_{ESR} and p_{IR} in the adsorption onto Nipsil HD, are plotted against the surface coverage, θ_{IR}, in Fig. 5. The values of p_{ESR} and p_{IR} decreased moderately with an increase in θ_{IR}. At a maximum surface coverage, θ_{IR}=0.58, the value of p_{ESR} is almost the same as p_{IR}. This fact is consistent with the result given in Table 3. At a relatively low θ_{IR}, some of the train segments in the polymer adsorb through the hydrogen bond; and the remaining train segments adsorb except for the hydrogen bond. At the maximum surface coverage, most of the train segments in the polymer adsorb through the hydrogen bonds.

When PMMA is adsorbed onto Aerosil 300, f_{HB} is 0.3—0.4; it is expected that the values of p_{ESR} are a much higher level than those of p_{IR}. The values of p_{ESR} and p_{IR} for the PMMA adsorbed onto Aerosil 300 are plotted against the surface coverage, θ_{IR}, in Fig. 6. The values of p_{ESR} and p_{IR} were moderately decreased

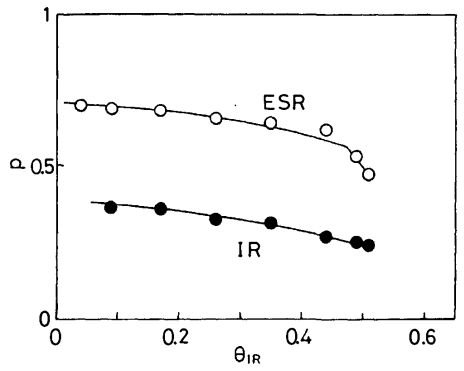

Fig. 6. Plots of the values of p_{ESR} and p_{IR} against the surface coverage, θ_{IR}, for PMMA adsorbed onto Aerosil 300. ○: p_{ESR}, ●: p_{IR}.

with an increase of θ_{IR}. At the maximum surface coverage, $\theta_{IR}=0.51$, the value of p_{ESR} was 0.47. It was twice as the value of p_{IR}, 0.24. This fact is consistent with the result given in Table 3. From the results of Figs. 5 and 6, when Nipsil HD, which has a relatively high level of silanol groups (8 per nm^2) was used as the adsorbent, the value of p_{ESR} was identical with the value of p_{IR}. When Aerosil 300, which has a lower content of the silanol group, 2.2 per nm^2, was used as the adsorbent, the results from the ESR method exhibit a much higher level than those of the IR method.

One possible explanation for the large differences in Figs. 5 and 6, is as follows: some of the train segments in the polymer interact with the silanol groups, while the remaining train segments interact with "non-hydroxylic sites"[11] on the silica surface. The IR method is used to evaluate only the train segments adsorbed through hydrogen bonds between carbonyl groups and silanol groups, whereas the ESR method is used to evaluate the train segments adsorbed through any mechanism. On Nipsil HD, train segments in the adsorbed polymer mainly adsorbed by the formation of hydrogen bonds between carbonyl groups of methyl methacrylate and silanol groups of the surface site; thus, the results obtained from the ESR and IR methods are identical. Since on Aerosil 300, train segments in the adsorbed polymer are anchored with or without hydrogen bonds, the results obtained from the ESR method exhibited a much higher level than those of the IR method.

Thermodynamic Properties of Solution of Nonspherical Molecules Determined from Gas-Liquid Chromatography and Calculated by the Scaled Particle Theory Using the Kihara Potential[1)]

Hideaki FUJIWARA,* Ikuji OHTAKU, Rieko MIYAGI, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565
(Received May 6, 1989)

The free energies, enthalpies, and entropies of solution have been determined for nonspherical molecules by gas-liquid chromatography and the data are discussed on the basis of a simple theory of solution, the scaled particle treatment. The solutes used are normal alkanes from pentane to decane and the solvents used are 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclohepten-5-one (DDCO), 9-heptadecanone (HPDN), and squalane. Some basic equations are derived for the nonspherical molecules by regarding the alkane solutes, HPDN and squalane as spherocylinders and DDCO as a disk and by incorporating the Kihara potential in estimating the nonspherical interactions. The enthalpies and entropies observed can be reproduced fairly well by assigning appropriate values of the sizes and potential constants for the solutes as well as for the solvents. However, these two properties tend to cancel each other in yielding the free energies, and the free energies are not reproduced so well as the enthalpies and entropies separately are. The presence of long alkyl chains in HPDN and squalane needs be allowed for better prediction of the entropies and, especially, the free energies. The present method of calculation is also applied to a spherical solute of tetramethyltin in the solvents of HPDN and DDCO with reasonable results. In this way, a relatively simple treatment of the scaled particle theory and the Kihara potential is shown to be fruitful in discussing the thermodynamic properties of solution for nonspherical molecules.

Thermodynamic properties of solution such as the changes in free energy, enthalpy, and entropy accompanying dissolution of a solute from gas phase to liquid phase are key parameters in the studies of partition coefficients and solubilities.[2)] In dealing with these properties, the scaled particle theory has disclosed an important role of cavity formation when transferring a solute from gas to liquid.[3)] Pierotti has shown successful calculations of the solubility properties of gases by applying the scaled particle theory to obtain the cavity term and by combining the Lennard-Jones potential to obtain the solute-solvent interaction terms.[3a)] A merit of the scaled particle treatment is its simplicity with moderate fitness to the experimental results. However, Abraham and Nasehzadeh[4)] reported that a version of the scaled particle treatment yields reasonable values of the free energy of solution ΔG_s^0 for nonpolar solutes in nonaqueous solvents but not for those in water, and that it yields also reasonable values of the entropy of solution ΔS_s^0 for nonpolar solutes in water but not for those in nonaqueous solvents. Hitherto, the scaled particle theory has been developed and applied almost always by assuming both solute and solvent as spheres. The effects of nonspherical shape have also been discussed and found nontrivial by several investigators with regard to the virial coefficients, the excess volumes, the Gibbs free energies and the equations of state.[5a-c)] The scaled particle treatment is also utilized in the perturbation study of solubilities of some simple gases.[5d)]

Recently, the authors have reported that the entropies of solution of several alkanes in nonaqueous solvents measured by the gas-liquid chromatography are interpreted by the scaled particle theory extended to nonspherical molecules.[6)] In the present study we further extend such a treatment to include the enthalpy of solution by using the Kihara potential in estimating the interaction term, and thermodynamic properties of solution are examined with regard to the free energies, enthalpies, and entropies.

Experimental

Gas-Liquid Chromatogaphic Experiments. The gas-liquid chromatographic measurements were made on a Yanagimoto G-1880 gas chromatograph with a TCD cell. A Pyrex glass column with i.d. 3.4 mm and length 2 m was used after a treatment with dichlorodimethylsilane. The solutes used were normal alkanes from pentane to decane. The stationary phases used were 10,11-dihydro-5*H*-dibenzo-[*a*,*d*]cyclohepten-5-one (DDCO), 9-heptadecanone (HPDN), and squalane (2,6,10,15,19,23-hexamethyltetracosane) which were coated on 60/80 mesh Chromosorb W DMCS to an amount of 25 wt%. The column temperature was set at five temperatures between 50 °C and 90 °C for the two solvents, DDCO and HPDN, and between 66 °C and 140 °C for squalane, and monitored with a copper-constantan thermocouple. The retention time was measured 5 times at each temperature and averaged. Such measurements were repeated 3 times for the solvent DDCO and 2 times for that HPDN. The solvent coated lost its quantity slightly during the measurement of retention time. This weight loss was less than 1% and was taken into account in the data treatment.

Materials. The solvents HPDN and DDCO from commercial sources were distilled under reduced pressure. The coating was achieved by using distilled dichloromethane as a diluent. The solutes, normal alkanes from pentane to decane, tetramethyltin, and squalane, all from commercial sources, were used without further purification.

Results

The enthalpies, entropies and free energies of solution were measured by gas-liquid chromatography, which is reported to produce reliable values[7] comparable to a calorimetric method.[8] The solvents DDCO, squalane and HPDN were selected as stationary phases suitable for the GLC measurements. The standard states are selected as 1 atm in gas phase and 1 mole fraction in liquid phase, and so the relationships used for the determination of the thermodynamic properties are:[7,9]

$$V_g^0 = [(t_r - t_a)jF/w](273.15/T) \quad (1)$$

$$K = (W_M/273.15R)V_g^0 \quad (2)$$

$$\ln K = -\Delta H_s^0/RT + \Delta S_s^0/R. \quad (3)$$

In these equations, the meanings of symbols are: V_g^0= specific retention volume, K=partition coefficient, t_r=retention time of sample, t_a=retention time of a reference (air), j=correction factor for the pressure, F=flow rate of the carrier gas (He), w=weight of solvent in the column, T=absolute temperature, W_M=molecular weight of solvent, and R=the gas constant. From the measurement of retention times, V_g^0 is obtained (Eq. 1), which is converted to K through Eq. 2. And then, the plots of ln K vs. $1/T$ afford the values of ΔH_s^0 and ΔS_s^0 (Eq. 3). The plots of ln K vs. $1/T$ are linear successfully as indicated by the correlation coefficients larger than 0.999. The observed thermodynamic properties of solution are listed

a) The units of ΔG_s^0, ΔH_s^0, and $T\Delta S_s^0$, are all in kJ mol^{-1}. ΔG_s^0 and $T\Delta S_s^0$ are calculated at 298.15 K. Molecular parameters of the solvent used are: a=1.88 Å, l=28.98 Å, and $U_{0,B}/k$=4285 K. When a and $U_{0,B}$ are changed as : a=2.08 Å and $U_{0,B}/k$=4744 K, the values of ΔH_s^0 change to −29.1, −31.9, −34.7, −37.2, −39.9, and −42.5 from pentane to decane, and those of $-T\Delta S_s^0$ change to 16.2, 16.7, 17.1, 17.5, 17.9, and 18.3 from pentane to decane, respectively. b) In parentheses listed are the values estimated from: $\Delta G_s^0=\Delta H_s^0-T(1.49\Delta S_s^0)$ (see text). c) In parentheses listed are the entropies corrected (see text).

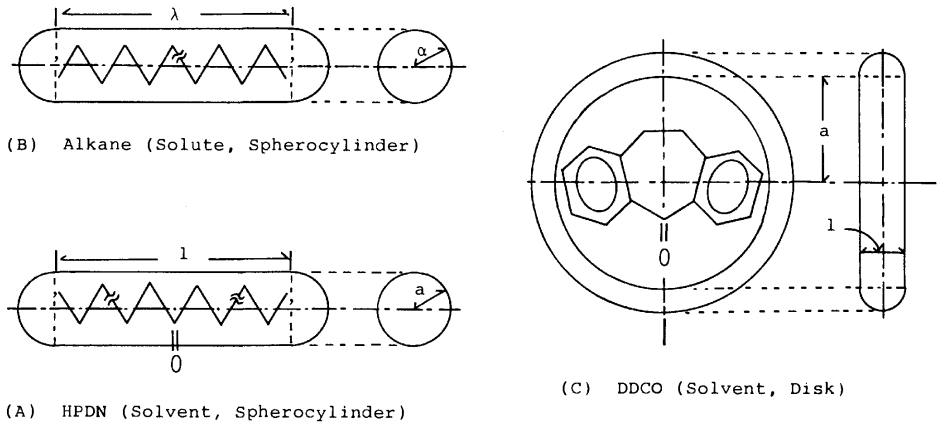

Fig. 1. The nonspherical models of the solute and solvent. The designation of a and l in DDCO needs be corrected as above in the Figure of Ref. 6a.

in Tables 1 to 3. All of these values change linearly with the number of carbons in the alkane solutes. Experimental values of ΔH_s^0 and $T\Delta S_s^0$ are both negative and their absolute values increases with the number of carbons in normal alkanes, and hence they are in a compensation relation. ΔG_s^0 decreases with the carbon number, indicating a relative importance of the enthalpy term.

Discussion

The entropy of solution ΔS_s^0 of nonspherical molecules can be better interpreted by a scaled particle treatment with reasonable molecular sizes when and only when nonspherical shapes are taken into account in the calculation, as already reported in the preliminary report.[6] However, when such a treatment is applied to obtain the cavity term of the enthalpy of solution, positive values are obtained, indicating a necessity of a solute-solvent interaction term to make the enthalpies negative. The authors adopted here the Kihara potential[10] to estimate the interaction term for nonspherical molecules, and derived equations of the thermodynamic properties of solution for spherocylinder and disk shaped molecules (see Appendix).

The solvents HPDN and squalane and the solutes alkanes are approximated as spherocylinders, and the solvent DDCO is approximated as a disk (Fig. 1). The entropy of solution is interpreted reasonably by such models of solute and solvent as discussed in the preliminary report.[6] To calculate the enthalpy of solution ΔH_s^0, the potential constants and the molecular sizes are needed for the normal alkanes as well as for the solvents. The molecular sizes have been determined so as to reproduce the entropy of solution ΔS_s^0 (Table 1 in Ref. 6a) with reasonable precision, and the potential constants are available for several normal alkanes[10a,11] from the data of virial coefficients. The potential constants for nonane and decane are currently unavailable but can be obtained by the extraporation of the data for other normal alkanes. The potential constants of the two solvents are determined by a trial and error method so that they minimize the square sum of the difference between the observed and calculated enthalpies of solution (Fig. 2). Standard deviations between the experimental and recalculated enthalpies are relatively small, supporting a usefulness of the simple model used here. Thermodynamic properties of solution obtained in the experiment and in the calculation are summarized in Tables 1 to 3 for the DDCO, HPDN, and squalane solvents, respective-

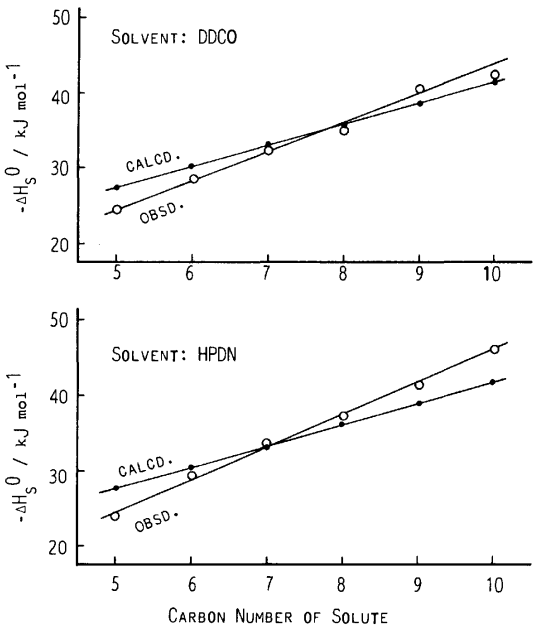

Fig. 2. Comparison of the enthalpies calculated and observed for the normal alkanes in HPDN (lower plots) and DDCO (upper plots). Potential constants of the solvents are $U_{0,B}/k$=3669 K (HPDN) and $U_{0,B}/k$=4080 K (DDCO).

Table 4. Thermodynamic Properties of Solution of Tetramethyltin Dissolved in the Solvents of DDCO and HPDN[a]

Solvent	Experimental			Calculated				
	ΔG_s^0	$-\Delta H_s^0$	$-T\Delta S_s^0$	$\Delta G_s^{0b)}$	$-\Delta H_s^0$	$-T\Delta S_s^{0c)}$	α	$U_{0,B}/k$
DDCO	1.1±0.1	28.1±0.1	29.2±0.14	10.5	17.8	28.3	3.07 Å	400 K
				0.2	28.1	28.3	3.07 Å	495 K
				10.4	18.6	29.0	3.18 Å	400 K
				0.9	28.1	29.0	3.18 Å	482 K
HPDN	−3.9±0.1	30.8±0.1	26.9±0.1	0.02(5.4)	20.7	20.7(26.1)	3.07 Å	400 K
				−7.4(−2.0)	28.1	20.7(26.1)	3.07 Å	481 K
				0.5(5.0)	21.6	21.1(26.6)	3.18 Å	400 K
				−7.0(−1.5)	28.1	21.1(26.6)	3.18 Å	467 K

a) All values are given in the unit of kJ mol^{-1} and at 298.15 K. b, c) See footnotes b and c in Table 2. The same factor of 1.26 is used here.

ly. The enthalpies and entropies of solution calculated fit well with the experimental ones in DDCO (Table 1). However, these two parameters tend to cancel each other in yielding the free energy as already described in the Results section. The errors in estimating the free energies, therefore, become relatively large after such cancellation. Quite a similar trend is seen in the system of HPDN (Table 2). In this case deviations in the entropies are relatively large between the experiment and the calculation. This may be related to some extent to the presence of long alkyl chain. To investigate further an effect of long alkyl chain, squalane is tested as a stationary phase (Table 3). Squalane molecule is regarded to be in a stretched zigzag conformation and approximated by a spherocylinder, for which the length l is estimated to be 28.98 Å, i.e., 23×1.26 Å, and the radius a is set equal to 1.88 Å (the compactness factor y=0.38). This radius is tested with a little larger values, considering several methyl group branches from the normal alkane chain. A relatively good fit is obtained when a is smaller than 2.08 Å (Table 3). The calculated values of ΔS_s^0 become smaller by ca. 7% and larger by ca. 40% when a is changed from 2.08 Å (y=0.46) to 1.88 Å (y=0.38) and 2.28 Å (y=0.56), respectively. Therefore, the entropies of solution observed for the normal alkanes in squalane are said to be reproduced by the calculation to an extent of about 65—70%. This percentage certainly drops from the value of 80% observed in the HPDN solvent having a shorter length of chain. That is, the reproducibility of the entropy of solution decreases much more by the presence of longer alkyl chain in the solvent molecule. This is probably because the flexibility of the long alkyl chain is not taken into account in the present model. An improvement of the model by incorporating this molecular flexibility is not a simple task. But when the correction is assumed to be proportional to the entropies calculated by neglecting the flexibility, the correction factor is determinable so that the corrected entropies fit better with the experimental ones for all of the alkane solutes treated here. Such corrections are included in Tables 2 and 3 (see footnotes b and c). The enthalpies observed in squalane are best fitted by setting $U_{0,B}/k$=4744 K (S.D.=2.4 kJ mol^{-1}) and $U_{0,B}/k$=4285 K (S.D.=2.0 kJ mol^{-1}) when a is set to 2.08 Å and 1.88 Å, respectively. These values of U_0 are higher than that for octane (1150) reflecting the increased molar volume.

To investigate further the applicability of our model, tetramethyltin is tested as a sphere solute (Table 4). The GLC experiment was done once and the errors were estimated from the linear plot of ln K vs. $1/T$. The spherical molecule of tetramethyltin can be included in a spherocylindrical model with vanishing length (λ=0). Note that we have assumed a line with a definite length for the core of spherocylinder, and hence the Kihara function becomes equivalent to the Lennard-Jones one in case of spheres.[12] The standard values of the molecular radius and the potential constant are known to be σ (diameter)=6.13 Å and ε/k=400 K.[4] Several model calculations are compared with the experimental results in Table 4. In the DDCO system ΔH_s^0 and ΔS_s^0 are reproduced best by a calculation using the parameters for DDCO above obtained and the values of α=3.18 Å and $U_{0,B}/k$=482 K for tetramethyltin. The latter value is slightly larger than the average of reported values, 400 K.[4] However, the potential constant reported is relatively large in nonpolar solvents,[13] and hence the value reached in the present study may be accepted as reasonable. In the HPDN system about 80% of ΔS_s^0 is reproduced by the calculation (Table 4). This percentage is the same with that observed[6] for the normal alkane solutes in the same solvent. ΔH_s^0 is seen to be reproduced well by the potential constant quite similar to the above DDCO system.

Conclusion

The main purpose of this study is to examine if thermodynamic properties of solution determined by the GLC method, which has been accepted to yield reliable values of these properties, are reproduced well

by relatively simple modifications of the scaled particle theory and the Kihara potential when nonspherical shapes of molecules are taken into account. The entropies of solution observed are explained almost fully by the cavity term derived from the scaled particle theory, indicating negligible contribution from the interaction term. In the HPDN solvent, however, a flexibility in its long alkyl chain seems to affect the entropies, and some correction factor is necessary for the improved reproducibility of the entropies and free energies of solution.

The enthalpies of solution observed are well reproduced by the calculation when reasonable values are assigned to the potential constants of the solvents. The calculation indicates that the interaction term is dominant for the enthalpies, whereas the cavity term contributes positively (unstably) to the total energy. For the precise estimation of the free energies of solution, much precise estimation of the enthalpy and entropy terms is needed since these two parameters tend to cancel each other in yielding the free energy.

In conclusion, the scaled particle theory is evidenced to be applicable in calculating the thermodynamic properties of solution for nonspherical molecules when nonspherical shapes are taken into account and nonspherical interactions are included through the Kihara potential in the calculation.

Appendix

Equations of the Thermodynamic Properties of Solution for Nonspherical Molecules Derived Basing on the Scaled Particle Theory Incorporated with the Kihara Potential. The free energy of solution ΔG_s^0 is divided into three terms of a cavity formation, solute-solvent interactions, and a correction for the standard states in gas and liquid phases:[3b]

$$\Delta G_s^0 = G_{cav} + G_{int} + RT \ln (RT/V_1) \quad (4)$$

where V_1 means the solvent molar volume and the gas constant R is expressed as 0.08206 atm·l(K·mol)$^{-1}$. Similarly, the enthalpy ΔH_s^0 and entropy ΔS_s^0 of solution are divided as follows:[3,4]

$$\Delta H_s^0 = H_{cav} + H_{int} + \alpha_p RT^2 - RT \quad (5)$$

$$\Delta S_s^0 = S_{cav} + S_{int} + \alpha_p RT - R - R \ln (RT/V_1) \quad (6)$$

G_{cav} in Eq. 4 includes terms of PV work and surface energy. The PV work is expressed as $W=P<V_{A+B}>$, where V_{A+B} is the volume excluded by the center of molecule B surrounding a solute A and $<>$ means a statistical average for the relative orientation of the two molecules. A following equation is reached for $<V_{A+B}>$,[10] where S is the surface area and M is

$$<V_{A+B}> = V_A + V_B + (S_A M_B + S_B M_A)/4\pi \quad (7)$$

the measure which is defined as the mean curvature integrated over the whole surface of the convex molecule.[10] The three fundamental values V, S, and M are derived for a few convex bodies and listed in Table 5. On the other hand, the surface energy is expressed by a differential equation $dW=\gamma dS$, where γ is the surface tension. Here the surface tension is considered to be dependent on the curvature of a surface,

$$\gamma/\gamma_0 = 1 - 2\delta_0 C = 1 - \delta_0(1/R_1 + 1/R_2) \quad (8)$$

where γ_0 is the surface tension for a flat plane and δ_0 the distance corresponding to the plane interface, and where C is the curvature which is equal to $1/R_1+1/R_2$, R_1, and R_2 being the principal radii of curvature.[14]

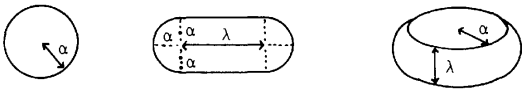
The free energy term of solute-solvent interactions is obtained as follows. To take into account nonspherical shape of molecules we adopted the Kihara potential[10] for intermolecular interactions.[15] The Kihara potential assumes a core in each molecule and energy of interaction is expressed as a function of the closest distance ρ between the cores of the two interacting molecules:

$$U(\sigma) = U_0[(\sigma_0/\sigma)^{12} - 2(\sigma_0/\sigma)^6] \quad (9)$$

Here, σ_0 and $-U_0$ are the closest core distance and energy, respectively, under the most stable interaction. In the present study we assume for simplicity that a core possesses a vanishing thickness and a molecule is made up of a surface located at a constant distance ρ_0 from the core (Fig. 3). Equation 9 is also adopted here for the potential, where $\sigma_0=\rho_{0,A}+\rho_{0,B}$, $\sigma=\sigma_0+\rho$, and $U_0=(U_{0,A}\cdot U_{0,B})^{1/2}$ are assumed between the interacting molecules of A and B. Therefore, the most stable interaction is reached when surfaces of the two molecules come into contact ($\rho=0$), ρ being the closest distance between the surfaces of the two molecules (Fig. 3). The interaction energy E_{int} is approximated to be equal to the free energy of interaction and is expressed as follows:

Table 5. The Three Fundamental Measures V, S, and M of Convex Bodies

	Sphere	Spherocylinder	Disk
V	$4\pi\alpha^3/3$	$\pi(4\alpha^3/3+\alpha^2\lambda)$	$\pi(\alpha^2\lambda+\alpha\lambda^2/4+\lambda^3/6)$
S	$4\pi\alpha^2$	$2\pi(2\alpha^2+\alpha\lambda)$	$\pi(2\alpha^2+\pi\alpha\lambda+\lambda^2)$
M	$4\pi\alpha$	$\pi(4\alpha+\lambda)$	$\pi(\pi\alpha+2\lambda)$



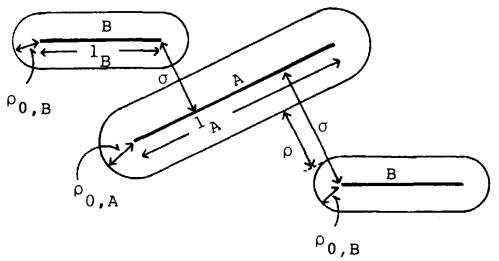


Fig. 3. A model for the Kihara potential of the interacting spherocylindrical molecules of solute (A) and solvent (B). —: Core of the molecule. See text for further details.

$$G_{inl} \simeq E_{int} = <N\int_{vol} U(\sigma)\cdot dg\cdot d\tau> \quad (10)$$

where N means the Avogadro Number, dg is the number density d multiplied by the radial distribution function g, and $d\tau$ is the volume element equal to $S_{A+B+\rho}\cdot d\rho$, $S_{A+B+\rho}$ being the surface area when solute A is surrounded by solvent B separated by a distance of ρ. The symbol "vol" means the integration over the whole system, but the region with positive interaction energies is excluded in practice.[3b] When $g=1$ is assumed over the region of integration, Eq. 10 turns out to be Eq. 11 since ρ is independent of the mutual orientation of the two interacting molecules.

$$G_{int} \simeq E_{int} = Nd\int_{vol} U(\sigma)<S_{A+B+\rho}>d\rho \quad (11)$$

The statistically averaged surface area $<S_{A+B+\rho}>$ is substituted as follows by using Eq. 7 for $<V_{A+B+\rho}>$:

$$\begin{aligned}<S_{A+B+\rho}> &= d<V_{A+B+\rho}>/d\rho \\ &= S_A + S_B + M_A M_B/2\pi + 2(M_A+M_B)\rho + 4\pi\rho^2. \quad (12)\end{aligned}$$

When dg is independent of temperature, $G_{int}=H_{int}$ and $S_{int}=0$ hold, and hence,

$$\begin{aligned}G_{inl} = H_{inl} &= Nd\int_{2^{-1/6}-1}^{\infty} U_0[\{\sigma_0/(\sigma_0+\rho)\}^{12} - 2\{\sigma_0/(\sigma_0+\rho)\}^6]\cdot \\ &\quad \{S_A + S_B + M_A M_B/2\pi + 2(M_A+M_B)\rho + 4\pi\rho^2\}d\rho \\ &= -NdU_0[17(\rho_{0,A}+\rho_{0,B})\{S_A + S_B + M_A M_B/2\pi\}/55 + \\ &\quad 2(\rho_{0,A}+\rho_{0,B})^2(M_A+M_B)/11 + 128\pi(\rho_{0,A}+\rho_{0,B})^3/495 \quad (13)\end{aligned}$$

As described above, ΔG_s^0, ΔH_s^0, and ΔS_s^0 are calculated when molecular shapes and sizes of solute (A) and solvent (B) are known as well as the potential constants $U_{0,A}$ and $U_{0,B}$ and the surface tension of solvent γ_0. Usually the surface tension appears only implicitly in the scaled particle treatment. That is, the form of G_{cav} is determined by considering its dependency on the size parameters of solute.[3a,5c] This process follows to that reported for a spherocylindrical solute in a spherocylindrical solvent.[5c] Equations of the thermodynamic properties related to the cavity formation are listed below which are reached in the present study for a few systems of nonspherical solute in nonspherical solvent. A more advanced theory of solutions, Percus-Yevick theory, predicts that a correction term is necessary in the intuitive Pierotti's expressions when intermolecular interactions are taken into account.[16-18] Such a correction term is now studied to apply to the nonspherical cases together with the terms of induced and dipolar interactions.

i) Spherocylindrical solute in spherocylindrical solvent:

$$\begin{aligned}G_{cav} &= RT\{-\ln(1-y) + \pi d(2a^2+al)(2\alpha+\lambda/2)/(1-y) + \\ &\quad \pi d(4a+l)(\alpha^2+\alpha\lambda/2)/(1-y) + [\pi d(2a^2+al)/ \\ &\quad (1-y)]^2(2\alpha^2+\alpha\lambda)\} + NP\pi(\alpha^2\lambda + 4\alpha^3/3)\end{aligned}$$

$$\begin{aligned}H_{cav} &= \{y + \pi d(2a^2+al)(2\alpha+\lambda/2)/(1-y) + \pi d(4a+l)\cdot \\ &\quad (\alpha^2+\alpha\lambda/2)/(1-y) + [\pi d(2a^2+al)/(1-y)]^2\cdot \\ &\quad (\alpha^2+\alpha\lambda/2)\}\alpha_p RT^2/(1-y) + NP\pi(\alpha^2\lambda + 4\alpha^3/3)\end{aligned}$$

$$\begin{aligned}S_{cav} &= R\{\ln(1-y) + y\alpha_p T/(1-y) + \pi d(2a^2+al)(2\alpha+\lambda/2)\cdot \\ &\quad [\alpha_p T/(1-y) - 1]/(1-y) + \pi d(4a+l)(\alpha^2+\alpha\lambda/2)\cdot \\ &\quad [\alpha_p T/(1-y) - 1]/(1-y) + [\pi d(2a^2+al)/(1-y)]^2\cdot \\ &\quad (2\alpha^2+\alpha\lambda)[2\alpha_p T/(1-y) - 1]\} \\ &\quad y = \pi a^2(4a/3 + l)d\end{aligned}$$

ii) Spherocylindrical solute in disk-like solvent:

$$\begin{aligned}G_{cav} &= RT\{-\ln(1-y) + \pi d(2a^2+\pi al+l^2)(\alpha+\lambda/4)/(1-y) \\ &\quad + \pi d(\pi a + 2l)(\alpha^2+\alpha\lambda/2)/(1-y) + [\pi d(2a^2+\pi al \\ &\quad + l^2)/(1-y)]^2(\alpha^2/2 + \alpha\lambda/4)\} + NP\pi(\alpha^2\lambda + 4\alpha^3/3)\end{aligned}$$

$$\begin{aligned}H_{cav} &= \{y + \pi d(2a^2+\pi al+l^2)(\alpha+\lambda/4)/(1-y) + \pi d(\pi a \\ &\quad + 2l)(\alpha^2+\alpha\lambda/2)/(1-y) + [\pi d(2a^2+\pi al+l^2)/ \\ &\quad (1-y)]^2(\alpha^2+\alpha\lambda/2)\}\alpha_p RT^2/(1-y) + \\ &\quad NP\pi(\alpha^2\lambda + 4\alpha^3/3)\end{aligned}$$

$$\begin{aligned}S_{cav} &= R\{\ln(1-y) + y\alpha_p T/(1-y) + \pi d(2a^2+\pi al+l^2)\cdot \\ &\quad (\alpha+\lambda/4)[\alpha_p T/(1-y) - 1]/(1-y) + \pi d(\pi a + 2l)\cdot \\ &\quad (\alpha^2+\alpha\lambda/2)[\alpha_p T/(1-y) - 1]/(1-y) + [\pi d(2a^2 + \\ &\quad \pi al + l^2)/(1-y)]^2(\alpha^2/2 + \alpha\lambda/4)[2\alpha_p T/(1-y) - 1]\} \\ &\quad y = \pi(a^2 l + \pi al^2/4 + l^3/6)d\end{aligned}$$

iii) Disk-like solute in disk-like solvent:

$$\begin{aligned}G_{cav} &= RT\{-\ln(1-y) + \pi d(2a^2+\pi al+l^2)(\pi\alpha/4+\lambda/2)/ \\ &\quad (1-y) + \pi d(\pi a + 2l)(\alpha^2/2 + \pi\alpha\lambda/4 + \lambda^2/4)/(1-y) \\ &\quad + [\pi d(a^2 + \pi al/2 + l^2/2)/(1-y)]^2(\pi^2\alpha^2/8 + \pi\alpha\lambda/2 \\ &\quad + \lambda^2/2)\} + NP\pi(\alpha^2\lambda + \alpha\lambda^2/4 + \lambda^3/6)\end{aligned}$$

$$\begin{aligned}H_{cav} &= \{y + \pi d(2a^2+\pi al+l^2)(\pi\alpha/4+\lambda/2)/(1-y) + \pi d(\pi a \\ &\quad + 2l)(\alpha^2/2 + \pi\alpha\lambda/4 + \lambda^2/4)/(1-y) + [\pi d(a^2 + \pi al/2 \\ &\quad + l^2/2)/(1-y)]^2(\pi^2\alpha^2/4 + \pi\alpha\lambda + \lambda^2)\}\alpha_p RT^2/(1-y) \\ &\quad + NP\pi(\alpha^2\lambda + \alpha\lambda^2/4 + \lambda^3/6)\end{aligned}$$

$$\begin{aligned}S_{cav} &= R\{\ln(1-y) + y\alpha_p T/(1-y) + \pi d(a^2 + \pi al/2 + l^2/2)\cdot \\ &\quad (\pi\alpha/2+\lambda)[\alpha_p T/(1-y) - 1]/(1-y) + \pi d(\pi a/2 + l)\cdot \\ &\quad (\alpha^2 + \pi\alpha\lambda/2 + \lambda^2/2)[\alpha_p T/(1-y) - 1]/(1-y) + \\ &\quad [\pi d(a^2 + \pi al/2 + l^2/2)/(1-y)]^2(\pi^2\alpha^2/8 + \pi\alpha\lambda/ \\ &\quad 2 + \lambda^2/2)[2\alpha_p T/(1-y) - 1]\} \\ &\quad y = \pi(a^2 l + \pi al^2/4 + l^3/6)d\end{aligned}$$

Hongo, Bunkyo-ku, Tokyo 113
(Received May 11, 1989)

The photocatalytic reaction of kraft lignin at titanium dioxide photocatalyst was investigated. Kraft lignin was completely decomposed into carbon dioxide and water through dehydrodimers of phenol derivatives constituting kraft lignin, methanol and organic acids such as oxalic and formic acids. Aromatic compounds such as vanillin could not be recovered due to their tendency to dehydrodimerization and the strong oxidizing power of the photo-generated holes by the action of which the dehydrodimers were completely decomposed into carbon dioxide and water. The production of methane, ethane, and ethylene was much smaller than that in the decomposition with hydroxyl radicals in homogeneous solution.

The photo-generated holes at semiconductor powders suspended in solution generally have strong oxidizing power. For example, irradiated titanium dioxide can catalytically decompose substances, which cannot be completely decomposed by activated sludge processes, into inorganic substances like carbon dioxide and water entirely.[1-10]

Lignin and its degradation products cannot be completely decomposed by such sludge processes[11,12] and are the source of chemical oxygen demand (COD) of waste water from pulp and paper mills.[11] Even though the COD value of the discharged water is less than the value regulated by Japanese law,[11] the remaining lignin and its degradation products give an unfavorable impression of the discharged water owing to their brown color.[11] In case the activated sludge process is repeated, the brown color will become lighter. However, this process is expensive so that an inexpensive alternative method is desirable.

Strong oxidants were required for the decomposition of lignin and its degradation products.[12-14] It was reported that hydroxyl radicals produced by the reaction of hydrogen peroxide with UV light or ferric ions (Fenton's reagent) can decompose kraft lignin into carbon dioxide and hydrocarbon gases such as methane and ethane.[13] The decomposition by semiconductor photocatalysts is another possibility due to their strong oxidizing power of the generated holes. This paper describes the catalytic photodecomposition of kraft lignin on TiO_2 photocatalyst.

While kraft lignin can be decomposed into inorganic substances, formation of many useful intermediates such as vanillin and vanillic acid can be expected as are recovered in the electrochemical oxidation of lignin.[15-17] Therefore, in addition to the measurement of the COD value and the absorbance of the irradiated solution, we also identified and determined in detail possible intermediates.

Experimental

The aqueous test solution was 0.02 wt% in kraft lignin (alkali lignin derived from softwoods, Tokyo Kasei Kogyo). Rutile type TiO_2 powder (Furuuchi Chemical, 99.9%, 300 mesh) was used as photocatalyst. This powder showed comparatively high photocatalytic activity for the decomposition of kraft lignin among commercially available TiO_2 powders.[18]

For the examination of the changes of COD, the color of solution and the products in the solution, irradiation was carried out in open system, that is, 0.500 g of TiO_2 powder and 20 cm^3 of air-saturated test solution were placed in a 50 cm^3 beaker and stirred magnetically under the irradiation of a 500 W high-pressure mercury lamp. The solutions were cooled with ice to prevent evaporation of the products. After irradiation for a predetermined time, the photocatalyst was centrifugated off and the filtrate was analyzed. Absorption spectra were measured using a spectrophotometer, and the COD values were calculated according to the JIS K0102 method. The degradation products were identified and determined by high-performance liquid chromatography (HPLC), gas chromatography (GC) and chemical analysis. The experimental conditions of HPLC and GC were as follows. For HPLC, packing material was ODS-silica (Hitachi Kasei, 3056); the column was 4 mm I.D.×150 mm long; the eluent, aqueous acetonitrile solution (15 v/v%) of 0.05% phosphoric acid; the flow rate of eluent, 1.0 $cm^3\ min^{-1}$; the detector, UV (254 nm). For GC, the packing materials, PEG 20M (Shimarite F) and Unisole F-200; the column, 3.2 mm I.D.×2 m long (glass tube); the carrier gas, nitrogen; the detector, FID.

For the determination of the gaseous products irradiation was carried out in a closed system containing 70 cm^3 of the test solution and 1.5 g of TiO_2 powder under oxygen atmosphere. The gaseous products were identified and determined by a GC equipped with a column of active carbon packing and FID detector.

Results and Discussion

Changes of the Properties of the Test Solution with Reaction Time. The optical absorption spectrum of the test solution under nitrogen atmosphere did not change after irradiation for 8 h as shown by the curve b in Fig. 1. On the contrary, in the presence of dissolved oxygen, the brown color of the test solution became lighter with irradiation and disappeared after 8 h as

shown by the curves c and d in Fig. 1. From this result, oxygen was necessary to scavenge the photo-generated electrons. The curve a in Fig. 2 shows the change of the absorbance at 280 nm as a function of irradiation time. This absorption originated predominantly from benzenoid compounds. Therefore, the curve a shows that they decreases almost linearly with irradiation time and disappears after 7 h.

The COD value, shown as the curve b in Fig. 2, also decreases with reaction time. After 7 h of irradiation, COD becomes almost zero suggesting that organic compounds are no more present in the solution. The irradiation time dependence of pH is also given in Fig. 2 (curve c). The pH of the test solution, initially slightly basic, is lowered with the decomposition of kraft lignin. It reaches the lowest value after 4 h and then increases again to neutral. Carbonic acid was identified by the production of CO_2 upon addition of hydrochloric acid to the white precipitate, obtained by adding barium chloride to the filtrate. Oxalic acids was also identified by chemical analysis. The accumulation of oxalic acids, which is stronger than carbonic, will make the solution acidic and its perfect decomposition to carbonic acid will increase the pH of the test solution.

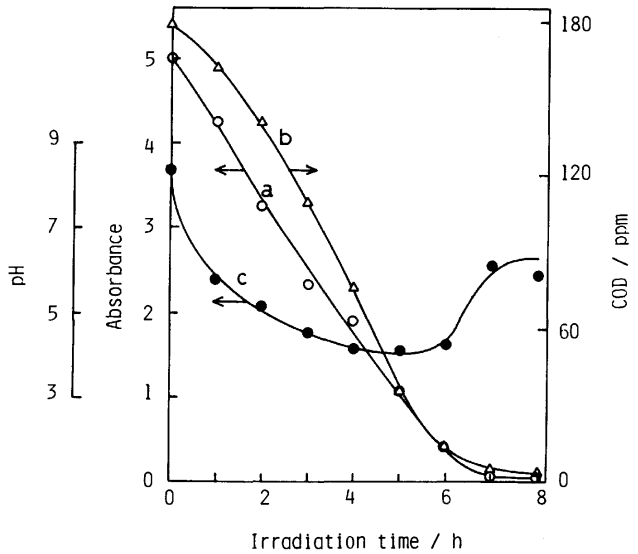

Fig. 2. Changes of the absorbance at 280 nm (a), COD (b), and pH (c) with irradiation time.

Products. Dehydrodimers: Prior to the determination of the degradation products, the separation performance of HPLC was confirmed. Under the conditions used, a number of phenol derivatives, which were expected as the degradation products from kraft lignin, were separated satisfactorily. Their retention times (t_R) were longer than two minutes. The larger the number of hydroxyl or carboxyl group in molecule, the shorter the retention time.

Figure 3 shows the HPLC chromatograms of the test solution before and after 3 h of photocatalytic reaction. Seven peaks are observed in the chromatogram of the starting solution (chromatogram a). Five peaks with retention times longer than 2 minutes were assigned to derivatives of phenol, such as catechol (t_R=4.0 min) and vanillin (t_R=6.7 min), by comparison with the retention time of the authentic compounds. As the degradation of kraft lignin proceeds, the heights of

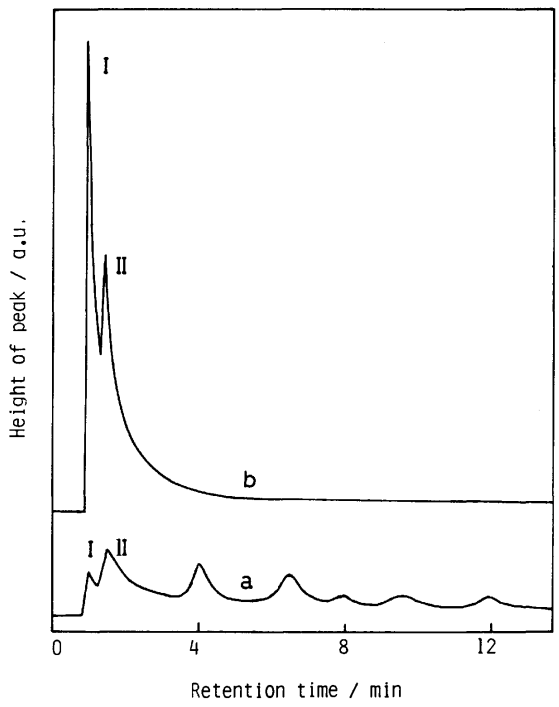

Fig. 3. HPLC chromatograms of the solution of kraft lignin. a: before irradiation, b: after 3 h of irradiation.

peaks longer than 2 minutes decrease, and after 3 h of irradiation they disappear as shown by the chromatogram b in Fig. 3. However, up to 4 h of irradiation two peaks denoted by I (t_R=1.0 min) and II (t_R=1.5 min) increased and then decreased with irradiation time as shown in Fig. 4. The substances corresponding to peaks I and II were thought to be dehydrodimers of the phenol derivatives constituting kraft lignin from following experimental results.

(i) Kraft lignin may be degraded by successive breaking from the terminal of the polymer, almost all of which are phenolic compounds. They are known to be dehydro-dimerized by electrochemical oxidation.[19-21] Therefore, the phenol derivatives liberated from lignin polymer may be also dimerized by the TiO_2 photocatalyzed oxidation.

For the lack of authentic smaples, dehydrodimers of some phenol derivatives were prepared by electrochemical oxidation and their retention times were measured. Protocatechuic acid (3,4-dihydroxybenzoic acid) gave two oxidation products, possibly dehydrodimers, which had the same retention times as peaks I and II. Vanillic acid (4-hydroxy-3-methoxybenzoic acid) gave one prodcut which had the same retention time as peak I and demethoxylated, hydroxylated vanillic acid, that is, protocatechuic acid. The difference in the number of the dehydrodimers produced from above two compounds is attributed the different structure of these compounds. That is, the dimerization of phenol derivatives takes place at the *o*- and *p*-positions to hydroxyl group,[19] so the formation of two types and one type of dimer was expected from protocatechuic and vanillic acid, respectively.

(ii) The t_R (1.5 min) of oxalic acid is identical with that of peak II. However, its peak height was only one half of that of peak II on the chromatogram a in Fig. 3, so that, oxalic acid was not the main product corresponding to peak II.

There is no peak which originates from kraft lignin itself in the chromatogram a in Fig. 3. Alkali lignin becomes insoluble in the acidic eluent, and the insoluble polymers cannot pass through the layer of packing material in the column. This is supported by the observation that a brown substance remained on the top of packing material.

In addition to the dehydrodimers of phenol derivatives, methanol, ethanol, formaldehyde, and oxalic acid were detected as intermediates in solution.

Methanol and Ethanol: The curve a in Fig. 5 shows the relation between the concentration of methanol and the irradiation time. Methanol is produced immediately after irradiation. Its concentration reaches a maximum value after one hour, remains at this value for 2 h and then decreases. Methanol may be formed from methoxy groups. This is confirmed by a catalytic photo-oxidation of vanillic acid and the identification of methanol in the reaction products.

The formation of ethanol was observed after 4 to 4.5 h of irradiation, as shown by the curve b in Fig. 5. This period was thought to be corresponding to the stage of the rapid decomposition of accumulated dimers as shown in Fig. 4.

Formaldehyde: Formaldehyde cannot be distinguished by the colorimetric method from acetaldehyde.[22] However, the production of methanol is larger than that of ethanol as shown in Fig. 5, so that the aldehyde formed is considered mostly to be formaldehyde. The concentration of formaldehyde changes with irradiation time as shown in the curve c of Fig. 5. Formaldehyde is started to be produced immediately after methanol formation. The maximum concentration of formaldehyde is observed when the concentration of methanol has considerably decreased.

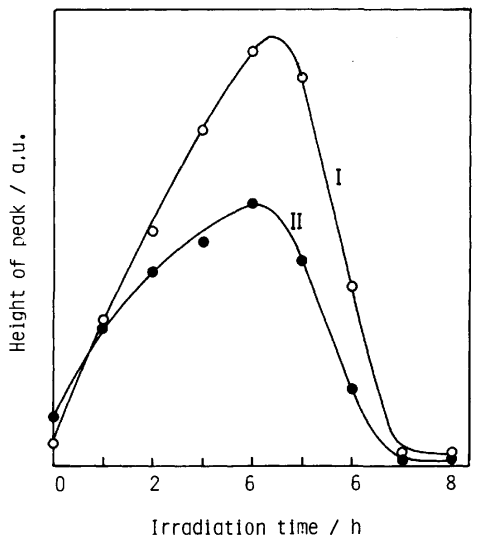

Fig. 4. Changes of the peak heights I and II of HPLC chromatograms as a function of irradiation time.

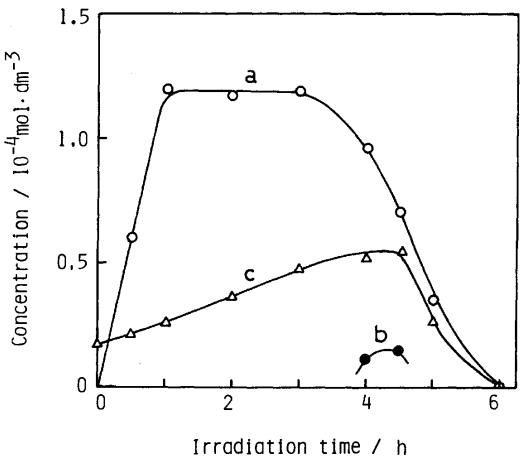

Fig. 5. Changes of the concentration of intermediates with irradiation time. a: methanol, b: ethanol, c: formaldehyde.

Formic Acid: Formic acid was not detected by GC. However, the production of methanol, formaldehyde, and CO_2 suggests the formation of formic acid.

Oxalic Acid: Oxalic acid was detected by glycolic acid formation method[23] and indole method.[24] It might be produced by the decomposition of benzene ring since it was produced by the photocatalytic decomposition of muconic acid (2,4-hexadiendioic acid),[18] the intermediate of benzene ring decomposition.

Gaseous Products: Trace amounts of methane and ethylene were detected. Both yields are about one molecule per twenty thousands of constituents of kraft lignin and are very small compared to those in the decomposition of kraft lignin by hydroxyl radicals.[13]

Decomposition of Kraft Lignin on the TiO_2 Photocatalyst. It was reported that hydroxyl radical, produced by the reaction of hydroxyl group on the photocatalyst surface or water molecule with photo-generated hole, take part in the photocatalytic reactions.[25] However, in the reaction under investigation, the participation of hydroxyl radical is thought to be small for the following reasons.

(i) The photocatalytic oxidation of benzene, phenol, and catechol proceeds by photo-generated holes.[10]

(ii) Large amount of methane, ethane, and ethylene are produced from the decomposition of lignin by Fenton's reagent which produces hydroxyl radicals,[13] whereas very small amounts of these compounds are formed by the TiO_2 catalyzed photoreaction.

(iii) Aromatic phenol compounds are not dimerized by hydroxyl radicals[26,27] whereas they are dimerized by TiO_2 photocatalyst.

So, the photocatalytic decomposition of kraft lignin on TiO_2 proceeds most likely via photo-generated holes.

Conclusion

Following conclusions were obtained.

(1) Kraft lignin is decomposed into inorganic compounds such as carbon dioxide and water by the action of the photo-generated holes.

(2) Aromatic compounds such as vanillin can not be recovered because they are predominantly dehydrodimerized and then decomposed by TiO_2 photocatalyst.

(3) The production of gaseous hydrocarbon products such as methane and ethane is less than that obtained in the decomposition by hydroxyl radicals in homogeneous solution.

The authors thank Dr. Takeo Yamabe, former Professor of Kanagawa University, for his helpful advice in the HPLC analysis, Kazunobu Ishikawa (Tokushu Uchusen Kogyo) for valuable contributions to the experiments and Professor Horst Kisch of Universität Erlangen-Nürnberg for valuable discussions.

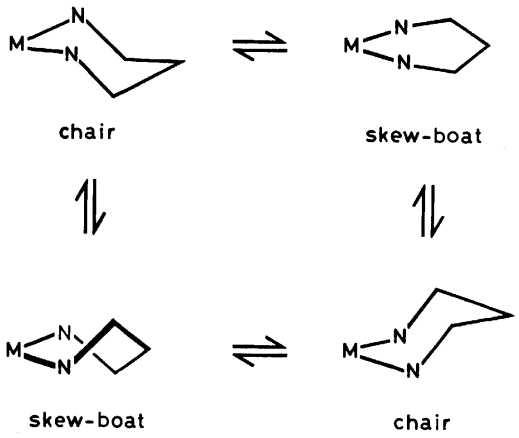
The Conformational Interconversion of 1,3-Diamine Chelate: Tetracyano(1,3-propanediamine)ferrate(III)

Yoshitaka KURODA, Masafumi GOTO,* and Tomoya SAKAI
Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467
(Received February 22, 1989)

The activation parameters for the chair-to-chair interconversion of the six-membered chelate ring of $[Fe^{III}(CN)_4(1,3\text{-propanediamine})]^-$ have been determined from a line-shape analysis of the ^1H NMR spectra of the paramagnetic complex by taking advantage of the large differences in the chemical shift: $\Delta H^{\neq}=32.2\pm4.6$ kJ mol^{-1}, $\Delta S^{\neq}=31.2\pm28.6$ J mol^{-1} K^{-1}, and $\Delta G^{\neq}_{298}=22.9\pm3.9$ kJ mol^{-1}. The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values are larger by 7.5 kJ mol^{-1} and 31 J mol^{-1} K^{-1} than those of the corresponding 1,2-ethanediamine chelate, $[Fe^{III}(CN)_4(1,2\text{-ethanediamine})]^-$, respectively. The kinetic data supported the transition state with a half-boat conformation.

Five- and six-membered chelate rings are formed by the coordination of multidentate ligands to transition metal ions.[1,2] Five-membered chelates are known to take either δ or λ *gauche* conformations, while for six-membered ones, chair, skew-boat, and boat forms are possible.[1-4] These chelate rings rapidly change their conformations among such conformers at the ambient temperature.[2-8]

The stereochemistry of the chelate ring of 1,3-propanediamine has been the subject of many studies.[1-4] The most populated conformers are both chair forms, but the interconversion between them has been considered to occur through skew-boat forms as intermediates.[1-4]



The determination of the rate constant for the conformational interconversion would be desirable for understanding the stereochemistry of metal complexes. We have developed a method of determining the rate constants for paramagnetic compounds by means of NMR spectroscopy; an application to the five-membered chelate ring has been reported in a previous paper.[6]

There have been few reports on the dynamics of the conformational change of six-membered chelate rings except for $[Mo^0(CO)_4(tmtn)]$ (tmtn=*N,N,N',N'*-tetramethyl-1,3-propanediamine), the activation free energy of which has been estimated as $\Delta G^{\neq}_{178}<34$ kJ mol^{-1} for the chair-to-chair interconversion, based on the broadening of $^{13}CH_3$ NMR line-shape at 178 K.[9] Tetracyano(1,3-diamine)ferrate(III) complexes show well-resolved and strongly orientation-dependent ^1H and ^{13}C NMR spectra.[4] These characteristics are suitable for line-shape analysis. We have now applied the method to the chair-to-chair interconversion of the six-membered chelate ring of tetracyano(1,3-propanediamine)ferrate(III).

Experimental

Materials. Tetracyano(1,3-diamine)ferrate(III) complexes, $H[Fe^{III}(CN)_4(tn)]\cdot2H_2O\cdot(CH_3)_2CHOH$ and $H[Fe^{III}(CN)_4(meso\text{-ptn})]\cdot2H_2O\cdot3/4(C_2H_5OH)$ (tn=1,3-propanediamine and *meso*-ptn=(2*R*,4*S*)-2,4-pentanediamine), were prepared as has been reported previously.[4]

NMR Measurements. The measurements were carried out as has been reported previously[6] with a JEOL FX-100 spectrometer at 183—323 K. The positive chemical shifts indicate downfield shifts from sodium 3-(trimethylsilyl)-propionate-2,2,3,3-d_4 (TSP).

Calculation of the Line-Width and the Interconversion Rate Constant. The line-width and the interconversion rate were calculated by using two least-squares programs, SALS[10] and MULTI,[11] on the NEAC ACOS 850 apparatus of the computing center of this university.

Results

Variable-Temperature ^1H NMR Spectra. The 100-MHz ^1H NMR spectra of $[Fe^{III}(CN)_4(tn)]^-$ (tn=1,3-propanediamine) at 8 different temperatures are reproduced in Fig. 1. The temperature range was limited to 183—323 K by the boiling and freezing points of the solvent (CD_3OD containing 0.25% DCl).[6] Two resonances with an area ratio of 2:1 were observed between 183 and 323 K. The upfield signal showed a small temperature dependence, while the downfield signal showed a significant downfield shift, with the decrease in the temperature. These spectra show that the predominant species are the chair forms, which rapidly interconvert on the NMR time scale.

The 100-MHz ^1H NMR spectra of $[Fe^{III}(CN)_4(meso\text{-ptn})]^-$ (*meso*-ptn=(2*R*,4*S*)-2,4-pentanediamine) at 8 different temperatures are reproduced in Fig. 2. Apart from the signals of the solvent impurities (H_2O and

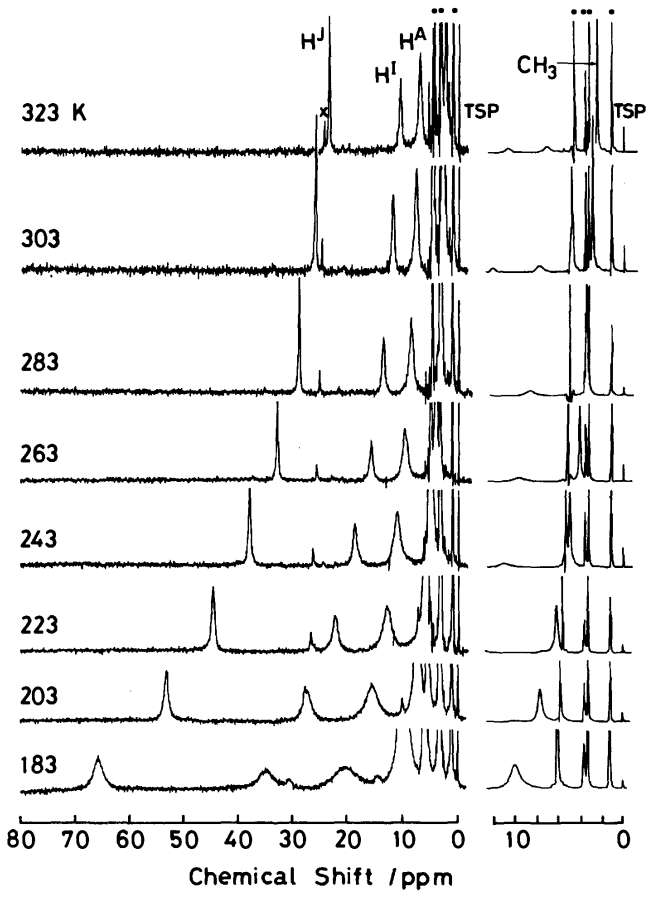

Fig. 2. Temperature-dependent ^{1}H NMR spectra of $[Fe^{III}(CN)_4(meso\text{-ptn})]^-$ in CD_3OD containing 0.25% DCl. A dot (●) indicates signals of the solvent impurities (H_2O and CH_3OH) and ethanol included in the sample. The x-shaped mark denotes a noise which appeared at the central frequency of the irradiation pulses.

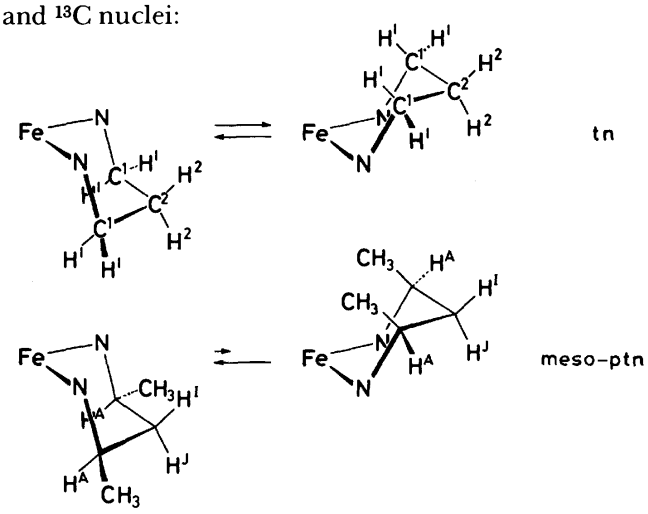
CH_3OH) and ethanol included in the sample, four paramagnetically shifted resonances were observed. These resonances moved downfield with the decrease in the temperature. The x mark in Fig. 2 denotes a noise which appeared at the central frequency of the irradiation pulses. These spectral changes show that the conformational interconversion can be regarded as occurring between the two chair forms which are shown below, along with the numbering for the ^{1}H and ^{13}C nuclei:



The signal assignments for these complexes have been described in a previous paper.[4] The large difference in chamical shift between the H^I and H^J of the *meso*-ptn chelate shows that the conformation is fixed to the chair form with two equatorial methyl groups.[4] The alteration of the tn chelate between the two chair forms is supported by the observation that the chemical shift of H^2 was almost the same as the mean of the H^I and H^J shifts of the *meso*-ptn chelate.

The plots of the chemical shift vs. T^{-1} showed that the dependence of each ^{1}H shift of the tn and *meso*-ptn complexes on the temperature was not represented by a straight line but by a concave line. This non-Curie law behavior is caused by the participation of both the Fermi contact and pseudocontact mechanisms for this class of complexes. Although the separation of the H^1 or H^2 signal into two peaks, corresponding to the axial and equatorial protons in a frozen conformation, could not be attained even at 183 K, the broadening of these signals, e.g., the half-line-width at the half-height of 236 Hz at 183 K relative to 20 Hz at 303 K for

the H^2 signal, were large enough to obtain the rate constant of the interconversion by means of line-shape analysis. The decrease in the temperature made all signals of the *meso*-ptn chelate broad according to the reduction in the spin-relaxation times. However, the further signal broadening for the tn chelate is caused by an additional factor, i.e., the exchange of resonance sites between the two chair forms.

The rate of the conformational interconversion can be calculated if we can estimate the chemical shifts and line-widths intrinsic to a fixed chair conformer of the tn chelate. In this work, the calculation of the rate for the tn chelate was carried out on the assumption that the H^I and H^J values of the *meso*-ptn chelate are magnetically equivalent to the axial (H^{ax}) and equatorial (H^{eq}) H^2 values of the tn chelate fixed in a chair conformation.

The "one-way" rate constants for the interconversion, k, were calculated from the line-shapes of the H^2 peaks at 183—213 K using the Gutowsky-McCall-Slichter equation[12] according to the method reported previously.[6] The intrisic chemical shifts (ν_{ax} and ν_{eq}) and transverse relaxation times (T_{2ax} and T_{2eq}) expected for the tn chelate fixed in a chair conformation at each temperature were estimated from Eqs. 2 and 5 of Ref. 6, which represent the difference in chemical shift between H^I and H^J (Δ) and the half-line-widths at their half-height (W). The k values at 183, 193, 203, and 213 K were obtained as follows: 1.0×10^5, 4.0×10^5, 8.2×10^5, and 2.5×10^6 s^{-1}. If we assume errors as much as 10% for both Δ and W, the ranges of k were estimated to be $(0.68—1.5)\times10^5$, $(2.0—6.5)\times10^5$, $(0.32—1.6)\times10^6$, and $(1.2—5.7)\times10^6$ s^{-1} at 183, 193, 203, and 213 K respectively. The k values above 213 K could not be determined with sufficient accuracy, since the extent of line-broadening was not large enough.

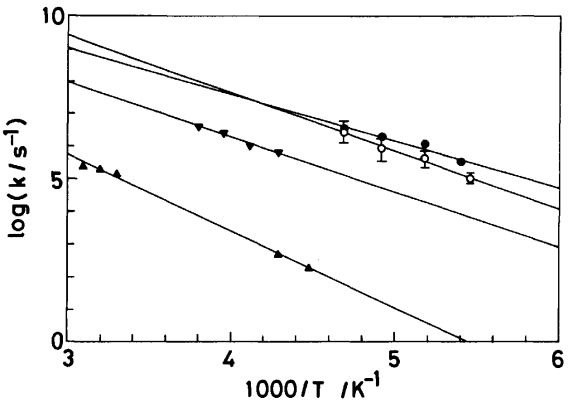


Fig. 3. Arrhenius plots for the conformational interconversion of the chelate ring of $[Fe^{III}(CN)_4(diamine)]^-$ in CD_3OD-DCl: diamine=tn (○), en (●), *meso*-bn (▼), and *cis*-chxn (▲). The I-shaped marks indicate the maximum and minimum of the inversion rate constants.

The activation parameters were calculated from the Eyring equation:[13]

$$k = \kappa(k_B T/h)[\exp(-\Delta H^{\neq}/RT)][\exp(\Delta S^{\neq}/R)]$$

where k_B is the Boltzmann constant and κ is the transmission coefficient, which was set as unity. The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values were obtained by a least-squares linear regression analysis of $-R\ln(kh/k_BT)$ on T^{-1}: they are summarized in Table 1, along with those obtained for the 1,2-diamine chelates.[6] The Arrhenius plots are shown in Fig. 3.

The errors in the activation parameters are primarily derived from the estimated values of the intrinsic ν_{ax}, ν_{eq}, T_{2ax}, and T_{2eq}. The experimental errors in the temperature (±1 K) and the chemical shift were much smaller than the estimated errors.

Discussion

There are three types of conformations of six-membered chelate rings: chair, skew-boat, and boat.[2,3] The chair form is the most stable conformation, as has been confirmed by X-ray diffraction analysis,[1] NMR spectroscopy,[7,8] and force-field calculation.[14—16] The conformation of the six-membered chelate ring of $[Fe^{III}(CN)_4(meso\text{-ptn})]^-$ is fixed in a chair form, with two equatorial methyl groups at 183—323 K, as has been described in the preceding section. The time-averaged H^2 shift of $[Fe^{III}(CN)_4(tn)]^-$ was nearly equal to the mean of the H^I and H^J shifts of the *meso*-ptn chelate between 183 and 323 K. Therefore, the six-membered chelate ring of the tn complex rapidly alternates between two chair forms, and the population of skew-boat conformers is small in contrast to the chelate ring formed by (2*R*,4*R*)-2,4-pentanediamine,[4] which showed a population of skew-boat and chair conformers of 80:20.[4]

In a previous paper,[6] we have reported that the five-membered chelate rings of tetracyano(1,2-diamine)-

a) Ref. 6.

ferrate(III) (1,2-diamine=1,2-ethanediamine (en), (2*R*,3*S*)-2,3-butanediamine (*meso*-bn), and *cis*-(1*R*,2*S*)-1,2-cyclohexanediamine (*cis*-chxn)) alternate between δ and λ conformers through an envelope structure as the transition state. Their activation parameters are collected in Table 1. Figure 3 and Table 1 show that the rate of the interconversion of the tn chelate is slower than that of the en chelate below 240 K, but at 298 K the former becomes faster than those of the en as well as *meso*-bn and *cis*-chxn chelates. This difference between the 1,2- and 1,3-diamine chelates is attributable to: (1) the $\Delta H^{\neq}$ of the tn chelate, which is larger by 7.5 kJ mol^{-1} than that of the en chelate,[6] and (2) the positive $\Delta S^{\neq}$ value of the tn chelate, in contrast to a zero or small negative $\Delta S^{\neq}$ value for the 1,2-diamine chelates.[6] The transition state for the tn chelate is, hence, more endothermic than that for the en chelate.

Gollogly and Hawkins have reported the results of energy-minimization calculations for octahedral transition metal-1,3-diamine complexes with a metal-nitrogen bond length of 200 pm.[14] The minimum energy pathway between two chair forms involves a transition state with a conformation where one C^1 is out of the coordination plane, while the other C^1 and C^2 lie on the plane. This pathway has the skew-boat conformation as an intermediate, and the $\Delta H^{\neq}$ value for this pathway is ca. 32 kJ mol^{-1}. A $\Delta H^{\neq}$ value larger than 42 kJ mol^{-1} has been obtained for two other pathways which pass successively through a symmetrical boat conformation and a transition state with the N-C^1-C^2-C^1-N or C^1-N-M-N-C^1 fragment coplanar.[9]

The $\Delta H^{\neq}$ value for the tn chelate was obtained as 32.2 kJ mol^{-1}; this value is in close agreement with the value estimated by Gollogly and Hawkins.[14] The tn chelate is, therefore, expected to change its conformation through the pathway predicted by Gollogly and Hawkins.[14]

According to the force-field calculation by Gollogly et al.,[14,17] the N-C-C angle of the five-membered chelate is larger by 3° in the envelope structure than in the *gauche* form. In the half-boat structure of the six-membered chelate, the angles of M-N-C^1 and N-C^1-C^2 have been reported to be 125.7 and 119.5° respectively, i.e., an increase of more than 7.5° compared with the chair form.[14] The increment in $\Delta H^{\neq}$ observed for the six-membered chelate is attributable to the increase in such angle and torsional strains.

The activation free energy for [$Mo^0(CO)_4$(tmtn)] has been estimated as $\Delta G^{\neq}_{178} < 34$ kJ mol^{-1} from the linewidth of the $^{13}CH_3$ signal at 178 K.[9] The $\Delta G^{\neq}_{178}$ for the tn chelate is evaluated as 26.6 kJ mol^{-1} from the data in Table 1, so that the increment in $\Delta H^{\neq}$ due to the four methyl groups of the tmtn is estimated to be less than 7.4 kJ mol^{-1}, which is almost half of the 14.7 kJ mol^{-1} [6] observed between [$Fe^{III}(CN)_4$(en)]$^-$ and [$Cr^0(CO)_4$(tmen)] (tmen=*N*,*N*,*N*′,*N*′-tetramethyl-1,2-ethanediamine). The difference between 1,2- and 1,3-diamine chelates can be explained by the repulsive interaction of the *N*-methyl groups if tmtn and tmen take half-boat and envelope conformations as transition states respectively. Since the distances between the *N*-methyl groups and the adjacent CH's for both tmtn and tmen are shorter in the transition state than in the ground state, the transition state can be expected to have a larger repulsion energy than the ground state. This difference causes the increase in $\Delta H^{\neq}$ for both diamine chelates. On the other hand, the repulsions between the *N*-methyl groups and other ligands and between the two pseudoaxial *N*-methyl groups are expected to be larger in the ground state than in the transition state in the case of tmtn, but the opposite situation is expected for tmen. Consequently, the $\Delta H^{\neq}$ for 1,2-diamine chelate increases further, but the increase of $\Delta H^{\neq}$ for 1,3-diamine chelate is reduced.

The $\Delta H^{\neq}$ value for the chair-to-chair interconversion of cyclohexane have been reported as 43.1—48.1 kJ mol^{-1}.[18-20] The $\Delta H^{\neq}$ value for the six-membered chelate ring of the tn complex is smaller by 11—16 kJ mol^{-1} than that for cyclohexane, though the former has nonbonded interactions between the ring protons and the apical ligands which are absent in the latter.

Cyclohexane is believed to have a half-chair conformation in the transition state of the conformational interconversion.[21] Wiberg and Boyd,[22] in reporting the results of their force-field calculation for cyclohexane, say that the half-chair conformation is higher in energy by 2.5 kJ mol^{-1} than the half-boat form. This difference has been attributed to the torsional and angle strains arising from the difference in the number of carbon atoms coplanar in the transition state.[22,23]

X-Ray diffraction analysis for [$Co(tn)_3$]$Cl_3 \cdot H_2O$ has revealed a chair conformation of the tn chelate with the following angles: Co-N-C^1, 122.0°; N-C^1-C^2, 112.4°; C^1-C^2-C^1, 113.6°.[24] The transition state for the six-membered chelate, which is expected to have a structure with the N-Fe-N-C^1-C^2 fragment coplanar, corresponds to the half-boat form of cyclohexane. The six-membered chelate ring will be flattened more easily than cyclohexane with the C-C-C angle of 109.5°, since the angles in the former are closer to the angle of ca. 120° required for the transition state. This feature seems to reduce the $\Delta H^{\neq}$ value for the six-membered chelate by ca. 10 kJ mol^{-1} relative to that for cyclohexane.

Formation of Hydrotalcite-Acrylate Intercalation Compounds and Their Heat-Treated Products

Masahito TANAKA, In Yong PARK, Kazuyuki KURODA, and Chuzo KATO*
Department of Applied Chemistry, Waseda University, Ohkubo-3, Shinjuku-ku, Tokyo 169
(Received March 29, 1989)

Hydrotalcite-like compounds (HT), layered double hydroxides with a few kinds of interlayer anions (X=CO_3^{2-}, Cl^-, and NO_3^-) were allowed to react with acrylate anions in order to prepare a novel inorganic-organic interstratified layered material by anion exchange. When HT-CO_3 was used the anion exchange reaction did not occur. When HT-NO_3 was employed the reaction proceeded to form a HT-acrylate intercalation compound. The formation of the intercalation compound from HT-Cl was observed only under a reaction condition using a concentrated acrylate solution. When the intercalation compound was heated at 80 °C with the addition of an initiator, the interlayer acrylate anions were polymerized to form a HT-polyacrylate intercalation compound.

Hydrotalcite-like compounds (abbreviated HT) are layered double hydroxides, expressed as $[Mg_{1-x}Al_x(OH)_2]^{x+}[A_{x/n}^{n-}\cdot mH_2O]^{x-}$, where A^{n-} is an exchangeable anion, and $0.2 \leqq x \leqq 0.33$.[1,2] A part of Mg in the brucite layer $[Mg(OH)_2]$ is replaced with Al, and the positively charged layers are compensated with interlayer anions. The metals in the layers are not limited to Mg and Al, since many divalent and trivalent metals are employed to form different types of layered double hydroxides.[3] Interlayer anions and water occupy the interlayer space. Since these interlayer anions are exchangeable, hydrotalcite-like compounds have been investigated from the viewpoint of an inorganic anion exchanger. Regarding the selectivity of the interlayer inorganic anions, the high selectivity of anions with higher valency and smaller size has been reported.[4]

In general, HT does not exhibit a swelling property. The layer charge density is also relatively higher than those of intercalating layered oxide materials, such as smectite clay. Accordingly, there have been only several reports on exchange with organic anions in HT. Dicarboxylic acids (Zn^{2+}-Al^{3+} hydroxide),[5] D,L-histidines (Mg^{2+}-Al^{3+}),[6] acetic acid (Ni^{2+}-Fe^{3+} (Co^{3+})),[7] and alkyl sulfates (Zn^{2+}-Cr^{3+}),[8] (Mg^{2+}-Al^{3+})[9] have been investigated so far.

In the present study, as a course of our study on the intercalation chemistry of hydrotalcite, the acrylate anion was selected as the guest anion and the possibility of an anion exchange was examined, since the acrylate anion is small in size and polymerizable. Thus, the interlayer polymerization of acrylate anions by thermal treatment was also investigated.

Experimental

Materials. The HT used in this study was a CO_3-exchanged type (Kyowaad 500 manufactured by Kyowa Chemical Industry Co.). The ratio of aluminum in the total metals (x=Al/(Mg+Al)) was 0.25. The XRD, IR, and thermoanalytical data coincided with the previous results.[4]

The Cl- and NO_3-exchanged types were prepared by the following procedure. HT-CO_3 (5 g) and sodium chloride (ca. 20 g) were mixed with decarbonated water to make a suspension (200 ml) by stirring. The suspension was stirred under a nitrogen flow and 2 M hydrochloric acid (1 M= 1 mol dm^{-3}) was added into the reaction mixture and the pH was maintained at 4.2—4.5 for 10 min. The mixture was centrifuged and washed with decarbonated water twice. The end of the washing was checked by ion chromatography. The ion-exchanged product was dried under reduced pressure at room temperature. The XRD, IR, and thermal analyses of the products showed the same results as the previous data of the HT-Cl.[4] HT-NO_3[10] was prepared with sodium nitrate and 2 M nitric acid instead of sodium chloride and hydrochloric acid, respectively. The other procedure was the same as that for the preparation of HT-Cl.

The ion exchange capacities of both HT-Cl and HT-NO_3 were ca. 270 mequiv/100 g HT, which was ca. 90% of the calculated values based on the chemical formulae of the fully exchanged HT-Cl and HT-NO_3. This finding suggested that a part of interlayer carbonate anions was not exchanged with Cl^- or NO_3^-. Commercially available acrylic acid (Tokyo Kasei Co.) was used without further purification.

Ion Exchange with Acrylate Anions. The amount of acrylate anions used in the anion exchange was calculated on the basis of the anion exchange capacity of hydrotalcite. The amounts were 3, 5, 7, 10, 20, and 50 times the anion exchange capacity when HT-NO_3 was used. The amounts of 5, 10, and 50 times the capacity were selected for experiments with HT-CO_3 and HT-Cl. A given amount of acrylic acid was dissolved in water and the pH of the solution was adjusted to be 7 with a NaOH aq. solution to form acrylate anions; the total volume of the final solution was 400 ml. Thus, the concentrations of acrylate anions were varied from 0.10 to 1.69 mol dm^{-3} for HT-NO_3, and from 0.17 to 1.69 mol dm^{-3} for HT-CO_3 and HT-Cl. When HT-Cl was employed, an exchange reaction using a highly concentrated acrylate solution (6.75 mol dm^{-3}, the total volume was 100 ml, the amount of acrylate anions was 50-times the ion exchange capacity of HT, pH 7) was also performed.

HT (5 g each) was added into these solutions and the reaction mixtures were stirred for 1 week at room temperature. When a shorter reaction time, e.g. 5 days, was attempted, the unreacted HT partly remained. After centrifugation, the products were washed with decarbonated water. The completion of the washing was checked by CHN analyses of the products. After a few repetitions of washing,

the carbon contents reached a constant value. After washing, the products were dried under reduced pressure at room temperature and analyzed. All of the anion-exchange experiments were performed under a nitrogen atmosphere.

Polymerization. The HT-acrylate intercalation compounds were heat-treated at 80 °C for 1 day after the addition of potassium peroxodisulfate (an initiator for polymerization) into the undried products followed by homogeneous mixing.

Analyses. X-Ray powder diffraction patterns were obtained with a Rigaku Rad-IB diffractometer using Ni-filtered Cu $K\alpha$ radiation. IR analyses were performed with a Perkin-Elmer FT-IR 1640 using a KBr disk technique. DTA curves were recorded on a Shimadzu DT-20 thermal analyzer at a heating rate of 10 °C min^{-1} under an air atmosphere. TG curves were recorded on a Shimadzu DT-40 apparatus.

Results and Discussion

Hydrotalcite-Acrylate Intercalation Compound. The formation of intercalation compounds was primarily judged by the variation in the X-ray diffraction patterns. The ratio of the intercalation compound to unreacted HT was roughly estimated by the peak intensities of their (003) diffraction lines. When HT-NO_3 was used as the starting material, the reaction with acrylate solutions of lower concentrations yielded the intercalation compound at a very low ratio with a large amount of unreacted HT. With the increase in the concentration, the formation of the intercalation compound became pronounced. The intercalation compound obtained from the highest concentration formed a single phase and the reproducibility was highest. Therefore, the compound obtained from the acrylate solution (1.69 M) was employed for the following analyses.

Figure 1 shows the X-ray powder diffraction patterns of the reaction products obtained from HT-NO_3. In the profile of the HT-acrylate reaction product (Fig. 1(b)), the diffraction peak due to (003), which corresponded to the basal spacing, shifted to a lower 2θ angle at 6.4° (d=13.8 Å). Correspondingly, the peaks due to (006) and (009) shifted to lower angles in a similar manner.

The IR spectra of HT-NO_3, sodium acrylate, and the reaction product are shown in Fig. 2. In the spectrum of the HT-acrylate reaction product (Fig. 2(c)), the absorption peak due to nitrate anions at 1380 cm^{-1} (ν_3) almost disappeared, whereas peaks due to acrylate anions at 1640 cm^{-1} ($\nu_{C=C}$), 1560 cm^{-1} (ν_{asCOO^-}), and 1450 cm^{-1} (ν_{sCOO^-})[11,12] appeared. A slight deformation in the peak profile at 1360 cm^{-1} (δ_{C-H}) can be explained by considering that the small peak due to carbonate anions ($\nu_{CO_3^{2-}}$) overlapped. As described in Experimental, carbonate anions partly remained in the original HT-NO_3. However,

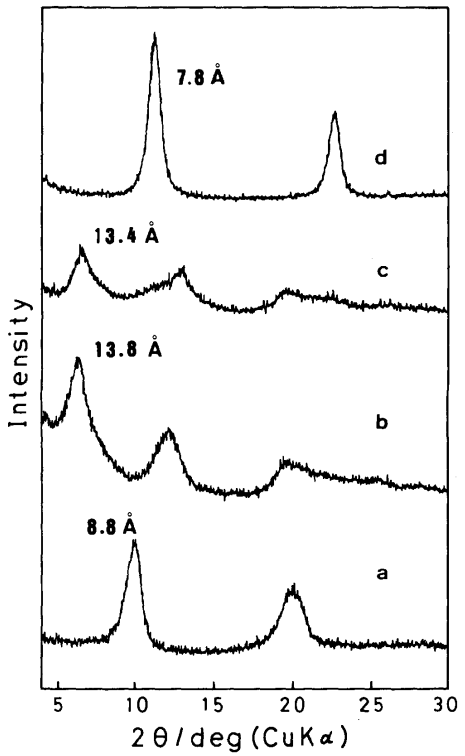

Fig. 1. X-Ray powder diffraction patterns of a) HT-NO_3, b) HT-acrylate intercalation compound, c) HT-polyacrylate intercalation compound, and d) CO_3 re-exchanged HT.

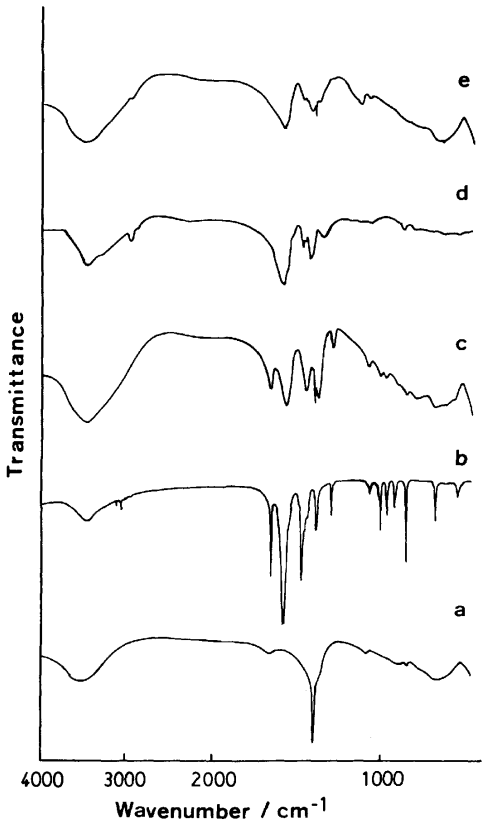

Fig. 2. Infrared spectra of a) HT-NO_3, b) sodium acrylate, c) HT-acrylate intercalation compound, d) sodium polyacrylate, and e) HT-polyacrylate intercalation compound.

carbonate anions must have been partly intercalated during the procedure of ion exchange or washing, since these anions have the highest selectivity in HT.[4]

Part of the product was re-exchanged with carbonate anions by being immersed in a sodium carbonate aqueous solution (2 M) for one day. The XRD result of the re-exchanged product is shown in Fig. 1(d). The peaks shifted to higher angles and showed the characteristic pattern of HT-CO_3. The IR spectrum of the product also showed the presence of carbonate anions along with a disappearance of acrylate anions. From these results, it can be concluded that the reaction can be treated as an interlayer anion exchange and that the double hydroxide layer was retained.

The Mg and Al contents (Mg/Al=0.74/0.26) analyzed by ICP, carbon contents (8.8%) determined by CHN analysis, and the amount of the interlayer water ($0.33H_2O$) calculated from the thermogravimetric curve led to the following chemical formula of the HT-acrylate intercalation compound: $[Mg_{0.74}Al_{0.26}(OH)_2](Ac)_{0.18}(CO_3)_{0.04}\cdot 0.33H_2O$, where Ac represents the acrylate anion. The amounts of acrylate anions and CO_3^{2-} could not be determined separately by TG curves because their weight losses overlapped each other. Therefore, the amounts was deduced from the relationship among the anion exchange capacity, total carbon contents, and the charges of acrylates and carbonates.

When HT-CO_3 was employed as the starting material, the XRD results did not show any variation in their profiles, indicating no reactions. Since the basal spacing of HT is dependent on the size of unhydrated interlayer anions,[4] the increase in the basal spacing should have been detected if acrylate anions were intercalated. The IR results also showed no absorption peaks due to acrylate anions. From these findings, an anion exchange did not take place in a system using HT-CO_3.

When HT-Cl was used, the HT-acrylate intercalation compound was partly obtained only in the case when a highly concentrated acrylate solution was used. The basal spacing of the intercalation compound showed the same value of 13.8 Å. Based on the intensities of (003) diffraction lines of HT-acrylate and HT-Cl, the ratio of the HT-acrylate to the unreacted HT-Cl was roughly estimated to be 3 : 1. In all other cases, however, the intercalation compounds could not be prepared. Therefore, the reactivity of HT-Cl was much lower than that of HT-NO_3.

From these results, the kind of interlayer anions in the starting materials greatly affected the formation of HT-acrylate intercalation compounds. The reason why only HT-NO_3 has a high intercalating ability may be explained by the following two points: the difference in selectivity (or stability) of the interlayer anions and the difference in the interlayer spacings. Regarding the former factor, it has been known[4] that the selectivity decreases in the order

$$CO_3^{2-} \gg Cl^- > NO_3^-.$$

With regard to the latter point, the interlayer distances of both HT-Cl and HT-CO_3 are ca. 3 Å, while that of HT-NO_3 is ca. 4 Å. On the other hand, the thickness of the acrylate anion, which takes a planar geometry, is 2.8 Å. If acrylate anions are intercalated in a flat arrangement during the initial stage of intercalation, it is preferable to use HT-NO_3 due to its larger interlayer thickness. Consequently, it is supposed that acrylate anions can be intercalated more easily. For both of these reasons, HT-NO_3 was most successful for the inclusion of acrylate anions.

Hydrotalcite-Polyacrylate Intercalation Compound. Figure 1(c) shows the XRD data of the polymerized product. The IR spectrum of the product is shown in Fig. 2(e). In the XRD data, the d_{003} value became slightly smaller (d=13.4 Å) than that for a monomer-intercalated substance. Although the peak intensities were weakened, the layer structure was retained. The IR spectrum showed the main characteristic bands due to polyacrylate anions.[13,14] In particular, the absorption peak arising from $\nu_{C=C}$ at 1640 cm^{-1} disappeared and the total profile was similar to that of sodium

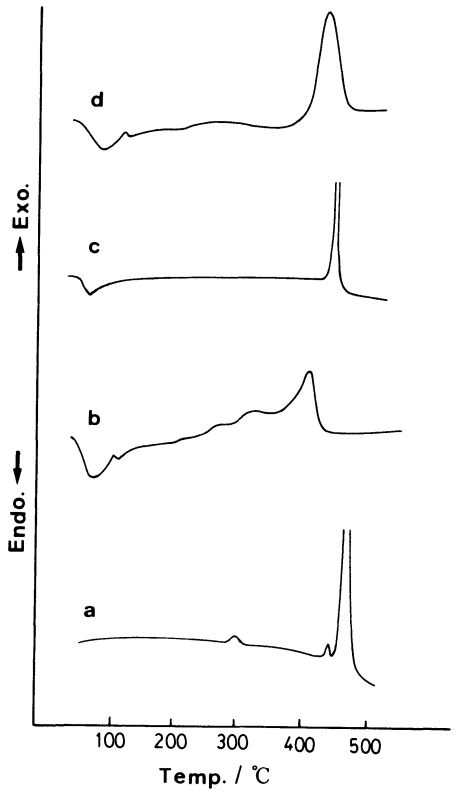

Fig. 3. DTA curves of a) sodium acrylate, b) HT-acrylate intercalation compound, c) sodium polyacrylate, and d) HT-polyacrylate intercalation compound.

polyacrylate, indicating a polymerization of acrylate anions in the interlayer space.

The DTA curves of the intercalation compounds before and after polymerization, sodium acrylate, and sodium polyacrylate are shown in Fig. 3. The DTA curve of sodium acrylate showed exothermic peaks due to polymerization at 280—290 °C and oxidative decomposition starting at 430—440 °C.[15] The reason why decomposition occurred at a comparatively higher temperature may be attributed to the formation of a thermally stable polymer with three-dimensionality which was prepared by bulk polymerization. The DTA curve of sodium polyacrylate did not show an exothermic peak due to polymerization but, rather, exhibited a similar sharp exothermic peak due to its oxidative decomposition.

The complex DTA curve was observed in the HT-acrylate intercalation compound. The several exothermic peaks overlapped and the first started at 250 °C. The XRD data of the heat-treated product at 250 °C for 1 h showed a decrease in the basal spacing to ca. 9 Å. The IR spectrum of the heat-treated product also showed a drastic decrease in the absorption peaks due to acrylate anions. Therefore, the oxidative decomposition of the HT-acrylate intercalation compound proceeded at much lower temperatures than that of the polymerized intercalation compound.

The DTA curve of the HT-polyacrylate intercalation compound was similar to that of sodium polyacrylate. The XRD result of the heat-treated product of the intercalation compound at 250 °C showed the retention of the same basal spacing as the HT-polyacrylate intercalation compound. The IR spectrum of the heat-treated product also showed absorption peaks due to polyacrylate anions. Thus, the difference in the thermal behavior of the intercalation compounds before and after polymerization was confirmed.

From these results we can conclude that acrylate anions were polymerized in the interlayer region of hydrotalcite. The difference in the thermal behavior between HT-acrylate and HT-polyacrylate intercalation compounds was observed, which was attributed to the formation of interlayer polymers.

Interfacial Adsorption of Iron(II)-4,7-Diphenyl-1,10-phenanthroline Complex in Ion-Association Extraction Systems

Hitoshi WATARAI* and Yoko SHIBUYA
Department of Chemistry, Faculty of Education, Akita University, Akita 010
(Received April 6, 1989)

The interfacial adsorptivity of an iron(II)-4,7-diphenyl-1,10-phenanthroline (DPP) complex in chloroform/aqueous salt solution systems was investigated by means of a high-speed stirring method and interfacial tension measurements. The interfacial spectra observed in the stirred system suggested that the adsorbed species at the interface is the tris-DPP complex. A minor effect of the anion concentration on the adsorptivity suggested that the tris-complex adsorbed as an ion-pair in a 0.1 M anion concentration. The interfacial adsorption of the ion-pair under stirring was analyzed by the Langmuir isotherm. The adsorptivity increased, depending on the counter ions, in the order $ClO_4^- < CCl_3COO^- \simeq Br^- < Cl^- < SO_4^{2-}$, i.e. the order of increasing hydration energies of these anions.

Interfacial phenomena in solvent extraction processes have recently become an attractive subject in both fields of fundamental solvent extraction chemistry[1] and practical solvent extraction technology.[2]

Many studies have been reported concerning the solvent extraction mechanisms of ion-association extraction equilibria. The reactions in the ion-association extraction systems are usually thought to occur in two bulk phases, and the influence of the interface which exists between two liquid phases is completely ignored. Therefore, the extraction constants in the ion-association extraction equilibria are usually represented by using the ion-pair formation constants in bulk phases and the distribution constant of the ion-pair.

In our recent studies, some observations suggested a significant role of the interface in ion-association extraction processes. For example, methyl or phenyl derivatives of 1,10-phenanthroline adsorbed at the interface of chloroform/aqueous dilute hydrochloric acid, more abundantly at lower pH.[3] A tris(1,10-phenanthroline)iron(II) complex, which did not adsorb at the air/water interface,[4] showed the characteristic interfacial adsorptivity, depending on the kinds of organic solvents.[5] The distribution equilibrium of 4,7-diphenyl-1,10-phenanthroline under stirring was affected by the addition of zinc(II) or copper(II) ion, probably because of the interfacial adsorption of a metal complex of the ligand.[6] These findings required extensive investigations concerning the interfacial adsorption of the metal complexes, including 1,10-phenanthroline or its derivatives, in order to clarify the role of the interface in the ion-association extraction mechanism.

In the present study the interfacial adsorptivity of an iron(II) complex with 4,7-diphenyl-1,10-phenanthroline (abbreviated as DPP or L) was investigated in both static and highly agitated chloroform/aqueous electrolyte solution systems. Here, the adsorption isotherm and the effect of counter anions on the adsorptivity are discussed.

Experimental

Chemicals. DPP, Wako G. R., was used as purchased. A stock solution of iron(II) was prepared by dissolving recrystallized iron(II) chloride in dilute hydrochloric acid with hydroxylamine hydrochloride or iron(II) sulfate in dilute sulfuric acid with ascorbic acid. A solution of iron(II)-DPP complex in chloroform was prepared by a batch extraction method in a glass-stoppered centrifuge tube or by extraction in a high-speed stirring apparatus in advance. Sodium salts of perchlorate, bromide, trichloroacetate, chloride, and sulfate (all G. R. grade reagents) were used for the preparation of the aqueous electrolyte solutions. Chloroform (Wako G. R.) was washed three times with water prior to use. Water was purified by means of a Millipore Milli-QII system. Other chemicals used in the present study were of analytical reagent grade.

Interfacial Tension. Interfacial tensions, γ, were measured by means of a drop-volume method at 25±0.1 °C. The apparatus used in this study was the same as described previously.[5] The liquid-liquid systems used for the measurements were prepared by shaking 10 ml of 3×10^{-6}—3×10^{-3} M DPP (1 M=1 mol dm^{-3}) in chloroform and 10 ml of 1×10^{-3} M or 5×10^{-3} M Fe^{2+} in 0.1 M aqueous salt solution for 30—60 min in order to attain extraction equilibrium. The concentrations of $[Fe(DPP)_3]^{2+}$ in the organic phase were determined photometrically. The volume of a detached aqueous drop from a glass capillary was measured with precision to 0.1 μl by the use of Gilmont digital micrometer-syringe. The interfacial tension was calculated by the equation reported by Lando and Oakley.[7] The densities of the aqueous phases required for the calculations of γ were determined in the present study by using a pycnometer.

Stirring Experiment. Interfacial adsorption under stirring was observed at 25±0.1 °C by means of a high-speed stirring apparatus (described in detail elsewhere[3]). Fifty ml of iron(II)-DPP complex in chloroform and an equal volume of aqueous solution containing iron(II) ($<10^{-3}$ M) and 0.1 M sodium salt, which attained extraction equilibrium, was agitated by stirring at a stirring rate of 4700 rpm. The stirring caused a reversible decrease in the organic phase absorbance. From the decrement of the absorbance at the wavelength where the ion-pair showed a maximum absorbance, the interfacial amount of the complex was calculated. The effect of pH on the interfacial amount is not significant

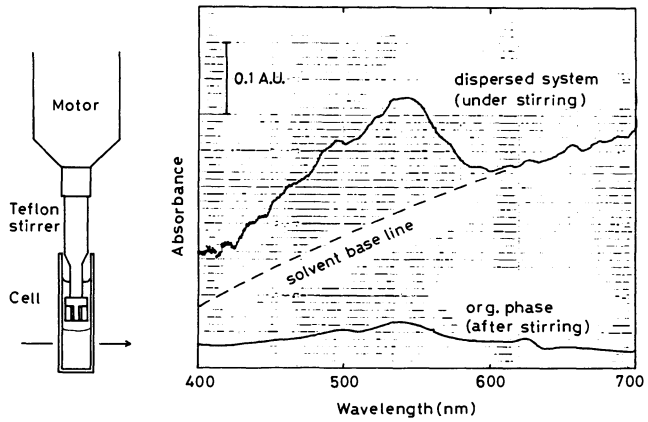

Fig. 1. Left; method for the measurements of interfacial spectra under stirring. Right; an example of the interfacial spectra, $[Fe^{2+}]_{init}=1.0\times10^{-3}$ M, $[DPP]_{o,init}=3.0\times10^{-3}$ M, and $[Na_2SO_4]=0.05$ M, 3500 rpm.

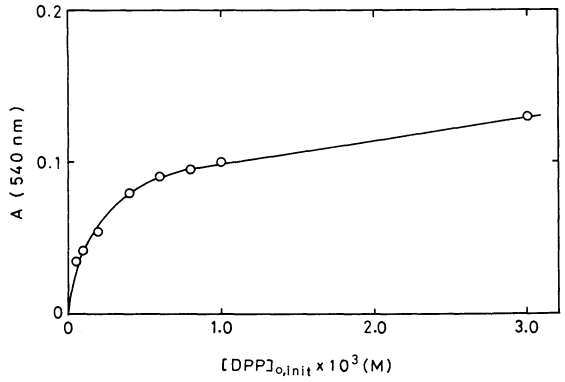

Fig. 2. Effect of DPP concentration on the interfacial spectra; $[Fe^{2+}]_{init}=1.0\times10^{-3}$ M, $[Na_2SO_4]=0.05$ M, 3500 rpm.

over a pH range of 3.5—5.5.

Spectral Measurement. Direct measurements of the absorption spectra of the interfacially adsorbed species were attempted by using the method shown in Fig. 1. In a 1 cm optical cell mounted in a cell compartment of a Jasco Uvidec 430 spectrophotometer, a 1.5 ml chloroform solution of DPP was stirred with an equal volume of aqueous solution of iron(II) and sodium sulfate or sodium chloride by a small Teflon stirrer at the rate of 3500 rpm. The spectra of the dispersed system was recorded while maintaining stirring. The spectra of the solvent blank under stirring and that of the organic phase after stirring were also measured.

Extraction Experiment. The extractability of the ion-pair was observed in four-anion systems by a batch method. Five ml of DPP in chloroform and an equal volume of an aqueous phase containing iron(II) and 0.1 M sodium salt was shaken by a mechanical shaker for 30 min in a thermostated room at 25±1 °C. After centrifugation, the concentration of the ion-pair in the organic phase was determined photometrically. The distribution ratio of iron(II) was obtained under various concentrations of iron(II) and DPP.

Results and Discussion

Interfacial Spectra of the Stirred System. When 6.0×10^{-5}—3.0×10^{-3} M DPP in chloroform was stirred with 1.0×10^{-3} M iron(II) in a 0.05 M sodium sulfate solution, there was no appreciable extraction of the red iron(II) complex in the organic phase after stirring; nor was there an appreciable amount of it formed in the aqueous phase. However, only during stirring of the two-phase system did a reddish color appear on the dispersed mixture. A typical example of the absorption spectrum of the dispersed mixture of a $CHCl_3$/Na_2SO_4 solution system is shown in Fig. 1. The net absorbance of the spectrum under stirring is obviously larger than that after stirring. Since there was no colored species in the bulk aqueous phase, the spectrum observed under stirring was attributable to an interfacial species, which was produced only at the interface. From the shape of the spectrum (maximum at 540 nm), the interfacial species was assigned to the tris-DPP complex, $[Fe(DPP)_3]^{2+}$. The net absorbance at 540 nm under stirring was increased with DPP concentration, as shown in Fig. 2. The plots showed a saturation curve which suggested that the observation was characteristically an interfacial phenomena. In a chloride system, a stirred mixture of 2.0×10^{-4} M DPP in chloroform and 1.0×10^{-3} M iron(II) in a 0.1 M NaCl solution at 3500 rpm gave 0.190 as the difference between absorbances at 537 nm and 600 nm, while the organic phase after stirring gave 0.325 as the corresponding absorbance difference; the aqueous phase showed no color. If there is no formation of the complex at the interface during stirring, the absorbance difference under stirring is equal to half of the absorbance difference of the organic phase after stirring. The experimental result (that 0.190 is larger than 0.325/2=0.1625) strongly suggested the contribution of an extra formation of $[Fe(DPP)_3]^{2+}$ at the interface.

Interfacial Adsorption Isotherm. A typical example of the effect of stirring on the extraction equilibria is shown in Fig. 3 for the cases of trichloroacetate systems. The initiation of stirring of a two-phase system which had already attained an extraction equilibrium caused a decrease in the organic phase absorbance of the ion-pair $[Fe(DPP)_3]X_2$ (X denotes an anion) until it reached a new equilibrium under stirring. When the stirring was stopped, the absorbance was restored to that before stirring, as shown in Fig. 3.

From the absorbance before or after stirring (A) and that under stirring (A'), the absorbance decrement ($\Delta A=A-A'$) was calculated. The values of ΔA depended on the ion-pair concentration in the organic phase as well as on the anion concentration in the aqueous phase. The ion-pair concentration dependence is shown as plots of ΔA against A' for a four-

anion systems in Fig. 4. The value of ΔA was largest in a chloride system and smallest in a perchlorate system, when compared at a given A'. If the observed stirring effects were responsible for the interfacial adsorption of the iron(II)-DPP complex, the interfacial tension in those systems must also be changed with the concentration of the ion-pair in the organic phase. The interfacial tension of the chloroform/aqueous phase system was indeed lowered with an increase in the concentration of the ion-pair in organic phase, depending on the anions (Fig. 5). The order of the lowering in the interfacial tension was found from Fig. 5 to be perchlorate<bromide<trichloroacetate< chloride, which can be understood as the order in the effect of anions on the adsorptivity of the ion-pair. It must be noticed, however, that the interfacial tension lowering in a trichloroacetate system includes the contribution of the adsorption of the anion, itself.

The above results suggest an interfacial adsorption of the complex; thus, the results of stirring were analyzed as follows. The mass balance equation of the tris-complex, FeL_3^{2+} under stirring is represented by

$$[FeL_3^{2+}]_{o,init}V_o = [FeL_3^{2+}]_oV_o + [FeL_3^{2+}]_iA_i, \quad (1)$$

where subscripts o, i, and init refer to the organic phase, interface, and initial concentration, respectively. V_o refers to the volume of the organic phase (l) and A_i to the total interfacial area (cm^2). The interfacial concentration was assumed to obey the Langmuir isotherm,

$$[FeL_3^{2+}]_i = \frac{aK'[FeL_3^{2+}]_o}{a + K'[FeL_3^{2+}]_o} \quad (2)$$

where a refers to the saturated interfacial concentration (mol cm^{-2}) and K' to the adsorption constant (l cm^{-2}) defined by $K'=[FeL_3^{2+}]_i/[FeL_3^{2+}]_o$ at infinitly diluted concentration of FeL_3^{2+}. From Eqs. 1 and 2, the relation between ΔA and A' can be derived as

$$\frac{1}{\Delta A} = \left(\frac{1}{a} + \frac{\varepsilon}{K'A'}\right)\frac{V_o}{\varepsilon A_i}, \quad (3)$$

where ε is the molar absorptivity of the ion-pair in the organic phase. Based on Eq. 3, $1/\Delta A$ was plotted against $1/A'$ for the four-anion systems (Fig. 6). The

linear relations in Fig. 6 strongly support the interfacial adsorption mechanism for the stirring effect. From the slopes and the intercepts of the plots in this figure, parameters aA_i and $K'A_i$ were obtained (Table 1).

Effect of Anions on the Interfacial Adsorption. The saturated interfacial amount of the complex, aA_i (Table 1), shows an order of 10^{-7} mol irrespective of the anions, while the values of $K'A_i$ obviously depend on the anions: largest in chloride ion and smallest in perchlorate ion. The results of the interfacial spectra and the stirring effect showed that the effect of the anions on the adsorptivity increased in the order $ClO_4^-<CCl_3COO^-\simeq Br^-<Cl^-<SO_4^{2-}$, essencially corresponding to the same order in the hydration energies of the anions.[8] This order was reversed concerning the effect of anions on the conditional extraction constants, K_{ex}*, of the ion-pair, as listed in Table 1. Similar results were reported in the interfacial adsorption of tridodecylmethylammonium and trioctylmethylammonium salts in *o*-xylene/2 M aqueous acid systems, in which the adsorptivity increased in the order $ClO_4^-<CH_3COO^-<NO_3^-<Cl^-$.[9] As opposed to this, the interfacial adsorptivity of tetrabutylammonium halides increased in the order $Cl^-<Br^-<I^-$.[10] From these results, it can be concluded that when the cation which adsorbs at the interface is highly hydrophobic and the interfacial adsorption takes place from the organic phase side, as in the present case of $[Fe(DPP)_3]^{2+}$, the cation is more adsorbable when a counter anion is more hydrophilic and less extractable. On the other hand, when the cation which adsorbs is soluble in water and its interfacial adsorption occurs from the aqueous phase side, as in the case of tetrabutylammonium ion, interfacial adsorption is more favorable in a less hydrophilic and more extractable anion system.

It is important to know whether $[Fe(DPP)_3]^{2+}$ exists at the interface as an ion-pair or a free cation. Figure 7 shows the effect of the concentrations of ClO_4^- and Cl^- on both ΔA and A. In the ClO_4^- system, the ion-pair concentration in the organic phase (shown by A) was not affected by the anion concentration, while the interfacial amount (shown by ΔA) slightly decreased with an increase in the ClO_4^- concentration. In the Cl^- system, although the ion-pair concentration

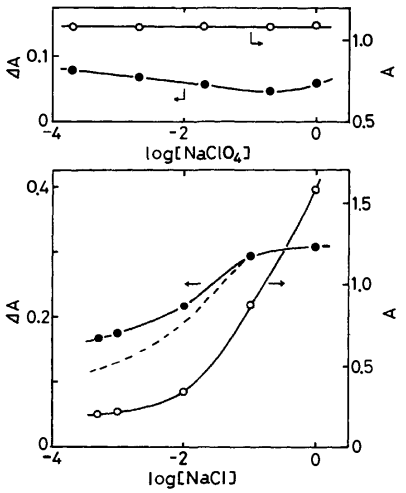

Fig. 7. Effect of the salt concentrations on ΔA and A; upper figure, $[Fe(DPP)_3X_2]_{o,init}=3.0\times10^{-5}$ M, lower figure, $[Fe^{2+}]_{init}=1.0\times10^{-3}$ M, $[DPP]_{o,init}=3.3\times10^{-4}$ M. Dotted line shows hypothetical ΔA when A is the plotted one in [NaCl]=0.1 M.

steeply increased with an increase in the Cl^- concentration, the interfacial amount gradually increased with an increase of the Cl^- concentration and became almost constant around $[Cl^-]=0.1$ M.

A comparison between the change in ΔA observed by varying the NaCl concentration and that observed by varying the $[Fe(DPP)_3]^{2+}$ concentration at [NaCl]= 0.1 M under the same values of A (Fig. 7) indicated that the values of ΔA slightly increased at lower concentrations of Cl^- than 0.1 M. From these results it is supposed that the effect of the anion concentration on the adsorbed amount is not ascribable to an ion-pair formation at the interface but, rather, to the extraction equilibrium between bulk phases. Hence, the interfacial species in 0.1 M anion concentrations is probably the ion-pair.

In conclusion, interfacial adsorption in the ion-association extraction equilibria of a tris-DPP iron(II) complex was clarified and the extent of the contribution was found to be more remarkable in systems of a more dilute complex concentration (as shown by the observation of Langmuir isotherm) and in less extractable anions. These results strongly suggest that the extraction reaction in this system takes place at the

interface, opposite to the usual assumption that the extraction mechanism comprises ion-pair formation in the aqueous phase and a distribution of the ion-pair between two-phases. The role of the interface in the extraction mechanism will be further clarified by kinetic studies which are now in progress.

The authors thank Miss Naoko Sasaki for measurements of the interfacial spectra. This study was supported by a Grant-in-Aid for General Scientific Research from the Ministry of Education, Science and Culture (No. 6140034).

Chromatographic Separation of Rare Earth Pairs by a Chelating Resin Having Bis(carboxymethyl)amino Groups

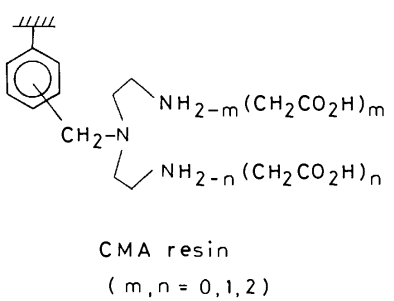
Masatoshi KANESATO,* Toshiro YOKOYAMA, and Toshishige M. SUZUKI
Government Industrial Research Institute, Tohoku, 4-2-1, Nigatake, Miyagino-ku, Sendai 983
(Received April 6, 1989)

Adsorption properties of rare earth elements toward a cross-linked polystyrene resin having bis(carboxymethyl)amino groups (CMA) have been studied. The selectivity sequence of the resin for a series of rare earth metals was in good accordance with that of the corresponding stability constants of diethylenetriamine-*N,N,N',N'',N''*-pentaacetic acid (DTPA) complexes. The chromatographic separation of La(III)/Pr(III), Nd(III)/Sm(III), and Y(III)/Gd(III) has been carried out by use of the present resin. The chromatographic conditions were empirically evaluated in terms of resolution (R_s), with varying column length, pH of the eluent, the flow rate and the column temperature.

Ion exchange chromatography has significantly contributed to the separation of rare earth elements.[1-4] In the conventional separation process, a cation-exchange resin and an aqueous solution of chelating reagent are employed as a stationary phase and a selective mobile phase, respectively.

Complexane-type reagents such as ethylenediamine-*N,N,N',N'*-tetraacetic acid (EDTA),[1] *N'*-(2-hydroxyethyl)ethylenediamine-*N,N,N'*-triacetic acid (HEDTA)[5,6] and DTPA[7] are widely used as the selective reagent in a mobile phase due to their high separation factors for adjacent rare earths. However the solubilities for their protonated forms and the rare earth complexes are sometimes remarkably low. Therefore undesirable precipitation tends to take place during the column operations.[8,9] On the contrary, when we use a highly selective resin as a stationary phase, a simple buffer solution can be used as an eluent in place of valuable chelating reagents. In addition, the difficulty of extracting the rare earths as simple salts from the stable chelate compounds will be eliminated.

It has already been pointed out that selective resins including chelating resins[10,11] and reagent-impregnated resins[12] are effective for the separation of rare earth elements in the chromatographic systems. Takeda et al.,[11] demonstrated the chromatographic separation of several pairs of rare earths using polystyrene resins having functional groups structurally similar to EDTA and DTPA. Prior to experimentation, they have optimized the chromatographic conditions by computer simulation based on newly introduced thermodynamic parameters.



CMA resin
(m, n = 0, 1, 2)

Fig. 1. Cross-linked polystyrene resin having bis(carboxymethyl)amino groups.

We have developed the cross-linked polystyrene beads (macroreticular type) in which diethylenetriamine is linked uniquely through the secondary nitrogen.[13] Upon carboxymethylation of the aminated resin, we have obtained the chelating resin having bis(carboxymethyl)amino moieties (Fig. 1).[13,14] In this paper we have examined the adsorption selectivity of the CMA resin for a series of rare earth metals by measuring the distribution coefficient. The separation efficiency of the present resin has been evaluated by the separation factor derived from the distribution coefficients of the respective metal pairs. The mutual separation of several pairs of metals has also been carried out chromatographically under the optimum experimental conditions.

Experimental

Materials. A rare earth chloride solution was prepared by dissolving the corresponding oxide (99.9%, Japan Yttrium Co., Ltd.) in analytical grade hydrochloric acid. Other reagents were of analytical grade and were used without further purification. Chloromethylated polystyrene beads (Cl, 17.1%, 60—100 mesh) were kindly donated by Mitsubishi Chemical Co., Ltd. The resin matrix was a macroreticular (MR) type styrene-10%-divinylbenzene copolymer with the surface area and mean pore diameter, 7.3 $m^2 g^{-1}$ and 720 Å, respectively.

Preparation of the Chelating Resin. The CMA resin was prepared by *N*-carboxymethylation of the dien-resin[13] in which diethylenetriamine (dien) is linked to the polystyrene resin uniquely through the imino nitrogen. Nitrogen analysis indicated that the CMA resin contains 1.65 mmol of the functional group per gram resin.[14]

Determination of the Adsorption Capacity. A batchwise technique was employed to determine the equilibrium adsorption capacity (amount of metal ion sorbed on one gram of dry resin) with the metal ion always being in excess over the ligand content. Typically, 500 mg of the dry resin (H^+ form) was added to 100 cm^3 of metal ion solution (0.025 mol dm^{-3}) of various pH. After shaking 2 days at 25 °C the equilibrium pH and the amount of metal ion remaining in the solution were determined. The capacity of

the resin was calculated by the change in the metal concentration observed. The resin beads were packed in a glass column and washed thoroughly with water. The sorbed metal ion was liberated from the resin beads by elution with 20 cm^3 of 2 mol dm^{-3} hydrochloric acid and the metal ion in the eluent was analyzed. In most cases, a satisfactory material balance was observed between the metal ion liberated from the resin and that which remained in the solution.

Distribution Coefficients. The equilibrium distribution coefficient of the metal ion was determined under a batchwise procedure. A 500 mg batch of dry resin was immersed in 100 cm^3 of metal ion solution (0.001 mol dm^{-3}). The pH was adjusted with acetate buffer in the pH range 3.0—5.0, with hydrochloric acid below 3.0. After shaking 7 days at 25 °C, the equilibrium pH and the amount of metal ion remained in the solution were determined. The results are expressed as the distribution coefficient, K_d=amount of metal sorbed in one gram of the resin/amount of metal remaining in 1 cm^3 of the solution.

Column Separation of Metal Ion Mixture. A typical procedure is as follows; the resin beads were swollen with water and poured onto a glass column (ϕ 10 mm). An aqueous solution containing two kinds of rare earths of equal molar concentration was prepared. The pH of the solution was adjusted to 3.0 with 1 mol dm^{-3} glycine buffer. The metal ion solution was supplied to the column at a constant flow rate (0.25—1.00 cm^3 min^{-1}), and the sorbed metal ions were then eluted with a buffer solution (1 mol dm^{-3} glycine) of the pH ranging 0.8—2.0. The effluent was fractionated into 10 cm^3 portions and the amount of metal ion was determined.

Metal Analysis. The metal ion concentration was determined by a SEIKO ICP-atomic emission spectrometer, model SPS-1200A.

Results and Discussion

Equilibrium Adsorption Capacity. The capacity-pH profiles for La(III), Pr(III), and Sm(III) are given in Fig. 2. A similar trend was observed for other rare earth metals. The adsorption capacity apparently depends on the pH of the solution due to the competing protonation and complexation reactions of the functional group. The maximum capacity is approximately 1.4 mmol g^{-1} at pH higher than 4.9 irrespective of the metal ions examined. This value is close to the estimated ligand content (1.65 mmol g^{-1}). Hence the functional group in the CMA resin appeared to form 1:1 complexes with these metal ions in a similar manner to those of the EDTA complexes. The adsorbed metal ions can be quantitatively released from the resin on treatment with 2 mol dm^{-3} hydrochloric acid for regeneration.

Distribution Coefficients. Distribution coefficients of the CMA resin for several rare earth metal ions were examined as a function of pH and the results are given in Fig. 3. The reaction of the CMA resin with a metal ions can be expressed as follows;

$$M^{n+} + RH_m \overset{K}{\rightleftharpoons} RH_{m-n}M + nH^+ \quad (1)$$

where R and M denote the resin group and the metal, respectively. The equilibrium constant of the above reaction should be given by

$$K = \frac{[RH_{m-n}M][H^+]^n}{[M^{n+}][RH_m]} \quad (2)$$

The distribution coefficient (K_d) of the metal ion between the resin phase and the aqueous phase is defined by

$$K_d = \frac{[RH_{m-n}M]}{[M^{n+}]} \quad (3)$$

From Eqs. 2 and 3, the following relationship can be obtained.

$$\log K_d = \log K + \log [RH_m] + n\mathrm{pH} \quad (4)$$

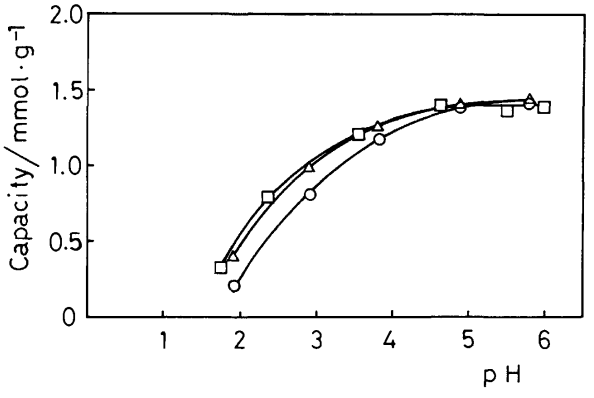


Fig. 2. Equilibrium adsorption capacity of the CMA resin for La(○), Pr(△), and Sm(□) as a function of pH (25 °C).

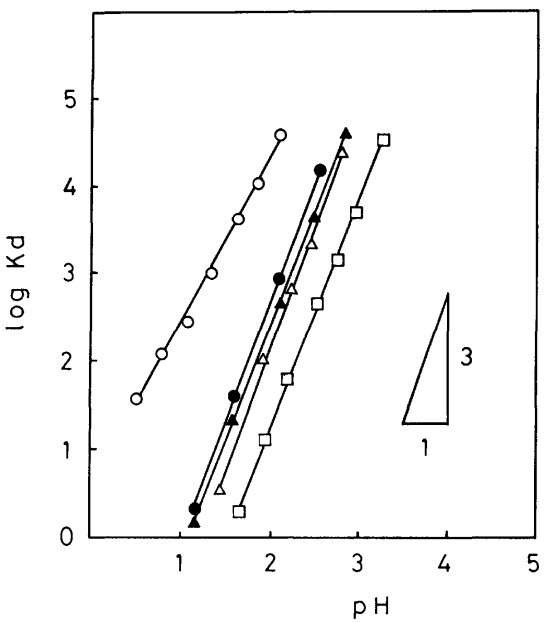

Fig. 3. log K_d of the CMA resin for several rare earth metal ions as a function of pH (25 °C). Sc(○), Y(△), La(□), Eu(●), and Yb(▲).

Equation 4 predicts that the plot of log K_d against pH gives a straight line of slope n under the condition where the amount of functional group is much larger than that of the metal ion. The slopes of the linear plots for the fourteen rare earth elements except Sc(III) were in the range from 2.7 to 3.0, which indicates that the adsorption of a rare earth metal ion is accompanied by the release of three protons. The slope for the Sc(III), 2.0, was smaller than that for other rare earth elements. In this case, some reaction mechanism other than those expressed in Eq. 1 may be involved.

Figure 4 shows the log K_d values at pH 1.6 for fifteen rare earth elements. The distribution coefficient apparently increased with decreasing ionic radius for the light rare earths (La—Sm), reached a maximum and then gradually decreased toward the heavy rare earths. Scandium, having the smallest ionic radius showed the highest affinity to the resin whereas yttrium occurred in the light rare earths. These trends are in good accordance with the stability constant sequence of the corresponding DTPA complexes where the gradual decrease in stability constant takes place for the heavy rare earths.[15] Therefore the selectivity of the resin can be attributed to the nature of a functional group which is structurally similar to DTPA.

Column Separation. The selectivity profile of the CMA resin (Fig. 4) suggests the possibility for mutual separation of light rare earths as well as Y from Sm—Dy. The separation efficiency of a metal ion pair is evaluated by the separation factor expressed by the ratio of distribution coefficients of individual metal ions 1 and 2.

$$S = K_{d1}/K_{d2} \quad (5)$$

In the present study, we chose the following pairs of rare earth metals, La(III)/Pr(III), Nd(III)/Sm(III), and Y(III)/Gd(III) for the chromatographic separation. The separation factors of the above three metal pairs calculated from the K_d values at pH 1.6 are 7.9, 2.3, and 3.0, respectively. Among them, the Nd/Sm pair seems to be most difficult to separate. The chromatographic separation was empirically characterized in terms of the resolution (R_s) of the species 1 and 2.

$$R_s = 2(t_{R2} - t_{R1})/(w_1 + w_2) \quad (6)$$

where t_{R1} and t_{R2} denote the retention time of the species 1 and 2, and w_1 and w_2 denote the band widths of 1 and 2, respectively.

Figure 5 shows the effect of pH of the eluent on the R_s for the separation of the three pairs of metal ions. It is said that the pH of the eluent is an important factor which affects the chromatographic separation.[16,17] The variation in R_s values with pH was not remarkable in the given pH range studied. When the pH is too low, the separation was unfavorable due to the small difference in the retention time, whereas the elution at higher pH lead to a significant band broadening. Therefore the most favorable pH for the separation of La(III)/Pr(III), Nd(III)/Sm(III), and Y(III)/Gd(III) were around 1.6, 1.2, and 1.2, respectively. In the present study we used 1 mol dm^{-3} glycine buffer as an eluent to keep the pH constant.

The effect of column length was examined for the separation of La(III)/Pr(III) (Fig. 5). Better resolution was attained with an increased column length, and a

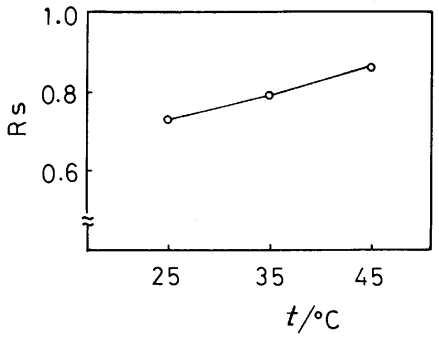

Fig. 7. Effect of the column temperature on the R_s for the separation of La/Pr. Column size: ϕ 1.0×27 cm. The pH of the eluent: pH 1.6. Flow rate: 0.25 cm^3 min^{-1}.

reduced flow rate (Fig. 6). An apparent improvement has also been attained by raising the column temperature from 25 to 45 °C (Fig. 7). The effect of temperature on the chromatographic separation may be attributed to two reasons. One is the increase of the separation factor. We have observed the increase of the retention times for La(III) and Pr(III) with increasing of the column temperature; the t_R values at 45 °C were about 1.20 and 1.24 times those at 25 °C for La(III) and Pr(III), respectively, leading to a better resolution. The second reason is the increase of the number of theoretical plates (N),[18] the N values of Pr(III) evaluated from the chromatograms were 61, 65, and 68 at 25, 35, and 45 °C, respectively. In the present study, all the column operations were carried out below 45 °C for practical reasons.

Figure 8 shows the chromatogram of the La(III)/Pr(III) pair at the optimized column condition. The degree of overlap of two peaks is less than 5% and the R_s value was found to be 0.86. Generally a separation is said to be "good" when R_s is >1.[19] For the separation of rare earth on a small scale, there are some reports in which R_s becomes larger than 1.[20,21] Considering the amount of metal ion in such as 1.2 mmol, the value 0.86 may be fairly good (Fig. 8).

It is interesting to consider a scale-up of these systems for productive purpose. Traditional ion-exchange systems where a chelating reagent is contained in the mobile phase essentially involve a restriction of solubility of the eluent. For example, the concentration of EDTA solution commonly used as an eluent is restricted due to the only moderate solubilities of the protonated EDTA or metal-EDTA com-

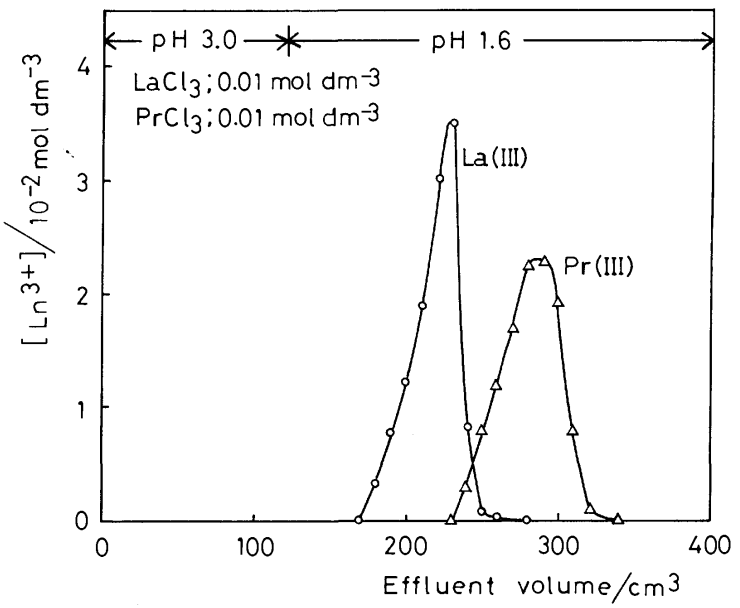

Fig. 8. Separation of La/Pr with the CMA resin. Column size: ϕ 1.0×27 cm. The pH of the eluent: pH 1.6. Flow rate: 0.25 cm^3 min^{-1}. Column temperature: 45 °C. Amount of the each metal ion: 1.2 mmol.

pounds. However, a chelating reagent is not always necessary in the present system, and hence the trouble due to precipitation during column operation can be eliminated. Figures 9, 10, and 11 show the separation chromatograms of the three pairs of metals. The amount of each metal ion is 10 mmol in all cases. The degree of overlapping of the two peaks for the separation of La(III)/Pr(III), Y(III)/Gd(III), and Nd(III)/Sm(III) were 1.1, 2.7, and 19.6%, respectively. In Fig. 9, about 95% of the loaded La(III) was collected in the fractions from 400 to 590 cm^3 of the eluate with the contamination by Pr(III) being less than 0.01%. In this experiment, the band ratio of ion-exchange zone to the metal loaded zone in the column is approximately 3 to 4 (0.75). Thus, highly purified La(III) was obtained in a reasonable yield in spite of the low band ratio. The maximum concentrations in the fractionated eluates are 8.5×10^{-2}, 4.8×10^{-2}, 9.4×10^{-2}, 5.2×10^{-2}, 8.0×10^{-2}, and 4.3×10^{-2} mol dm^{-3} for La(III), Pr(III), Y(III), Gd(III), Nd(III), and Sm(III), respectively.

A favorable separation has been realized under appreciably high loading using the CMA resin as the column stationary phase. In addition this system has advantages over the traditional ion-exchange systems where the chelating reagents are essentially required as the mobile phase. Thus, elution with only a buffer

Synthetic Inorganic Ion-Exchange Materials. LI. Synthesis, Characterization, and Thermal Decomposition of Cubic Ammonium Molybdate

Abdul Jabbar KHAN, Masamichi TSUJI, and Mitsuo ABE*
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology,
2-12-1 Ookayama, Meguro-ku, Tokyo 152
(Received April 27, 1989)

A crystalline cubic ammonium molybdate (CAM) was synthesized by the reaction of hexaammonium heptamolybdate and HNO_3 at 60 °C. The X-ray diffraction pattern showed a body-centered cubic structure with crystal lattice of 12.94±0.005 Å. Ammonia free molybdic acid was not obtained even at high acid concentration. CAM contains both exchangeable and structural ammonium ions. On the basis of chemical and thermal analyses and amount of exchangeable H^+, the empirical formula of the H^+ form of CAM referred to $[H_{0.68}(NH_4)_2]O_{1.34}\cdot 14.16MoO_3\cdot 6.92H_2O$. CAM was found to be stable at relatively high acid concentration and temperature, and was suitable for column operations by grading to the desired mesh size.

The oxides and hydrous oxides of molybdenum have been known since 1826.[1] This field got a real interest after Carpenie.[2] Preparation and structure of various molybdenum oxides, hydrates or ammonium molybdates have been studied by different authors. According to Jander et al.[3] the polycondensation of tri, hexa, 12, and 24 molybdates takes place at low pH. A significant number of authors have investigated the polymerization reaction through different analytical means.[2,4-14] A general review for normal ($M_2Mo_3O_{12}$), poly ($M_2Mo_nO_{3n+3}$), and basic ($n<3$) molybdates has been reported by Gleitzer.[15] Ma[16] and Kiss et al.[17] have reported the formation of different Mo(VI) oxide hydrates with ill-defined composition, through the thermal decomposition of ammonium heptamolybdate tetrahydrate. According to Tytko et al.[18] the aqueous chemistry of polymolybdates is very complex. The acid concentration controls the protonation to mono and dibasic species of MoO_4^{2-} present in basic solutions.

Hydrous Mo(VI) oxide or isopolymolybdates have been the subject of research of a significant number of workers. Even though Abe[19] has reported some ion-exchange behavior of $MoO_3\cdot nH_2O$, further investigations were still required to study the optimum conditions or rate of reaction for the synthesis of such compounds. In addition the formation of a product with definite composition by the reaction of hexaammonium heptamolybdate and nitric acid has not been known with certainty. Moreover the definite ion exchange behavior of these materials has not been reported prior to our study.

The present investigations were therefore carried out to describe the systematic synthesis, characterization, thermal decomposition, and some ion-exchange properties of crystalline cubic ammonium molybdate (CAM) as an ion exchanger.

Experimental

Synthesis of CAM. The optimum conditions and reagent specifications for the synthesis of the final product were set up through consideration of starting material and its concentration, $[H^+]/[Mo(VI)]$ mole ratios, aging time and temperature. The apparent rate of reaction for the product formation was determined for a series of samples with different mole ratios. The yields (%) of different products were calculated from the change in molybdenum concentration in the supernatant solutions with respect to the aging time. The Mo concentration was determined by Inductively Coupled Plasma (ICP) spectrometer, model SPS-7000, Seiko Instruments Inc. (Japan). The final synthesis of CAM was carried out as follows.

A 0.2 M (M=mol dm^{-3}) (as Mo-concn) solution of hexaammonium heptamolybdate was added slowly to an equal volume of 0.2 M HNO_3 solution with constant stirring. The mixed solution was kept at 60 °C for three days and then cooled at room temperature. A yellow product was filtered under suction and washed with deionized water till pH>2 and dried in air at room temperature.

H-CAM. CAM (100—200 mesh) was conditioned with 0.5 M HNO_3 in a column till no ammonium ion was detected in effluent, followed by washing with deionized water till pH>2 and was dried in air. The product was again sieved and rewashed to remove the adherent tiny particles. H-CAM thus obtained was finally dried in air and then over silica gel.

A-CAM. The NH_4^+ form of CAM was obtained by successive batch equilibration of H-CAM with 0.1 M NH_4NO_3 solution.

Chemical Composition. The chemical composition of H-CAM was determined by the chemical and thermal analyses. A known quantity (0.1 g) of the sample was dissolved in an adequate volume of 0.1 M NaOH solution. The total ammonia was then determined by Nessler's method spectrophotometrically at 400 nm using a double beam spectrophotometer, model UV-150-02, Shimadzu Co. (Japan). The total molybdenum content of H-CAM was determined gravimetrically by lead(II) acetate precipitation following the Japan Industrial Standards method No. K-8905.

Thermal Analysis. The Rigaku Denki Thermoflex, model 8001, was employed for thermogravimetry (TG) and differential thermal analysis (DTA) at a heating rate of 10 °C min^{-1} using α-Al_2O_3 as a reference material. The ammonia evolved during the thermal decomposition of H-CAM in N_2 gas atmosphere and collected in 0.05 M H_2SO_4

was also determined spectrophotometrically by Nessler's method.

X-Ray Diffraction, IR Spectra, and Electron Microscopy. X-Ray diffractions were carried out with JEOL JDX-7E X-ray diffractometer, Rigaku Denki Co. (Japan), model CN-5320 A-1/CN-2155 D-5 and Philips Automated powder diffractometer model PW-1700, using Ni-filtered Cu $K\alpha$ radiations. The crystal structure was deduced by SANDMAN computer programs.[20-22] The IR spectra were measured by KBr disk method on a JASCO IR spectrometer, model DS-701 G. The JEOL scanning microscope, model JSM-T220, was incorporated for the study of crystal morphology and growth.

Reagents. Hexaammonium heptamolybdate tetrahydrate (Wako Pure Chemical Ind., Ltd. Japan) was used without further purifications. All other reagents used were also of analytical grade.

Results and Discussion

Synthesis. No precipitation was observed even at reasonably long keeping of the mixed solutions at room temperature. Fast precipitation at elevated temperatures (>80 °C) resulted in the reduction of the apparent crystal size. In order to decide the optimum conditions for synthesis, the rate of reaction was studied at different mole ratios of $[H^+]/[Mo(VI)]$ at 60 °C. The prereaction specification of the reactants is given in Table 1 along with yields of the samples in percent. The time dependence of yield in Fig. 1 is shown for the samples A—E. The crystal formation was slower with an increase in the $[H^+]/[Mo(VI)]$ mole ratio greater than unity. Yield of the products decreased with the increase in acid concentration (samples C—E or Q—S), whereas at very low acid concentration (sample A) it resulted in a composite product formation which required maximum aging time at 60 °C. Hence the acid concentration affected both the yield and the composition of CAM.

Table 1. The Specification of Reactants and Yield (%) of Products

Sample	Concn in mixed soln		Mole ratio	Yield
	[Mo(VI)]/M	$[H^+]$/M	$[H^+]/[Mo(VI)]$	%
A	0.11	0.055	0.5	46
B	0.11	0.11	1.0	99
C	0.11	0.55	5.0	86
D	0.11	0.88	8.0	51
E	0.11	1.10	10.0	51
N	0.06	0.03	0.5	0
P	0.06	0.06	1.0	98
Q	0.06	0.30	5.0	88
R	0.06	0.48	8.0	76
S	0.06	0.60	10.0	60

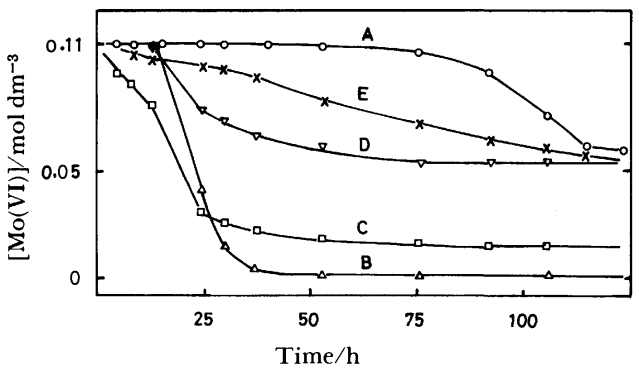

Fig. 1. Change in the concentration of Mo(VI) at different mole ratios of $H^+/Mo(VI)$. Aging temp: 60 ±0.5 °C; initial [Mo(VI)]: 0.11 mol dm^{-3}; mole ratio: 0.5(A), 1.0(B), 5.0(C), 8.0(D), and 10.0(E).

The maximum yield was observed at the mole ratio of 1.0 upto aging time of 72 h irrespective of the HNO_3 concentration. A similar trend was also observed for those of samples P—S. Sample B, due to maximum yield and reasonable rate of formation, was considered for the bulk preparation and subjected to further investigations. In the case of lower concentration of HNO_3, no product was observed in sample N upto the same aging time as for sample A.

Scanning Electron Microscopy (SEM) and X-Ray Diffraction. The SEM photograph of the crystals (Fig. 2) showed the hexagonal crystal shape of CAM arising from the wall of the beaker like cluster of flowers and the crystals were quite large (100—200 μm) in size. Almost the same X-ray diffraction patterns were observed for all samples (B—E or P—S) studied (Fig. 3), except sample A which showed a mixture of CAM and unknown materials in the JCPDS files. The crystal system of the samples was indexed to the body centered cubic structure of space group I43m (Td^3) with a lattice constant (a_0) of 12.94±0.005 Å (Table 2). The H-CAM and A-CAM also showed the same a_0 value within the experimental error.

Thermal Analyses. The TG and DTA curves of CAM and A-CAM (Fig. 4) indicated a broad endothermic peak around 150—160 °C due to loss of H_2O, a small exothermic peak at around 300 °C due to loss of exchangeable NH_4^+ and a strong exothermic peak at around 430 °C due to loss of structural ammonia and water. The small exothermic peak at around 300 °C vanished in the DTA curve of H-CAM (Fig. 5) due to absence of exchangeable NH_4^+. However, a distinct rise in the DTA curve at around 310 °C ending in a sharp exothermic peak at around 430 °C indicates the existence of structural ammonia with different bonding strength. The fractions of ammonia evolved during thermal decomposition of H-CAM was collected with respect to each rise in heating temperature and analyzed (Fig. 6). The evolution profile was in accordance with the weight loss vs. temperature shown by the TG curve (Fig. 5). However the collected ammonia was 33.1% of the total ammonia (1.54%) in H-CAM. Obviously a considerable amount of NO_x was formed due to the oxidation of NH_3, even though the N_2 gas atmosphere was incorporated. It can be estimated that the evolved ammonia at 310—430 °C is

98.7% of the total ammonia, if the evolved ammonia at around 100 °C did not oxidized to NO_x. The powder X-ray diffraction patterns of H-CAM heated upto 300 °C (Fig. 7) showed no change in crystal structure. A little change was indicated upto 400 °C and a mixed X-ray diffraction of H-CAM and orthorhombic MoO_3 was observed. The observed lattice constant was found to be 12.976±0.005 Å. A complete crystal transformation to orthorhombic MoO_3[23] was observed at 660 °C. The little change in structure upto

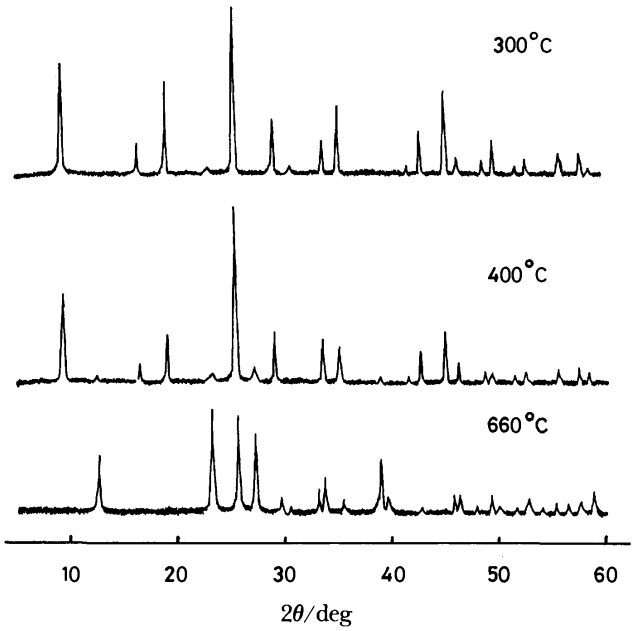

Fig. 7. The X-ray diffraction patterns of the heated samples.

400 °C also supports the evolution of a fraction of structural ammonia and water.

IR Spectroscopy. The IR spectrum of H-CAM (Fig. 8) shows a broad absorption band at 3400 cm^{-1} indicating the ν HOH stretching vibration for water. The absorption at 1600 cm^{-1} is the deformation vibration δ HOH.[24] The absorption bands around 3120 and 1400 cm^{-1} indicate the presence of NH_4^+ [25] as ν_3 and ν_4 stretching vibrations respectively.[28] Since no difference in the IR spectra of CAM and H-CAM was observed in this absorption region, the bands cannot be differentiated as for exchangeable and structural ammonia. The

Table 3. The Exchange Capacity of H-CAM for NH_4^+

	NH_4^+ uptaken (mequiv g^{-1})	H^+ released (mequiv g^{-1})
1st. Equilibration	0.25_2	0.25_7
2nd. Equilibration	0.03_5	0.05_7
sum	0.28_7	0.31_4

shoulders at 2900 and 1430 cm^{-1} can be assigned to the deformation mode of vibration of NH_4^+. The absorption at 2900 cm^{-1} indicates the combination band of ν_2 and ν_4.[26] The absorption peaks at 3120 and 1400 cm^{-1} diminished at 400 °C and vanished in the IR spectra of heated samples after the exothermic peak at 430 °C. These results supported the scheme of thermal decomposition mentioned above. The strong absorption between 900—1000 cm^{-1} shows the Mo-O stretching vibrations.[27] The weak absorption at 800—900 cm^{-1} in H-CAM can be explained as O-Mo-O stretching vibrations containing ν(O-O) peroxo O_2 vibrations. These absorption bands split into three when oxygen quantity is greater,[28] which can be observed in the IR-spectra of the samples heated at 400 and 660 °C, where H-CAM change to MoO_3 at 660 °C. According to Nakamura et al.[29] the absorption between 500—600 cm^{-1} are due to the M-O-M stretching vibrations. These are the resultant of $\nu(O_2)$ and $\nu_{a,s}$(Mo) complexed together. The absorptions between 200—400 cm^{-1} in H-CAM indicate the Mo-Mo stretching vibrations[30] which become stronger in the heated samples.

Ion-Exchange Capacity for NH_4^+. The NH_4^+/H^+ ion-exchange reaction on H-CAM was carried out by batch experiment using 0.1 M NH_4NO_3 solution. A 1.0 g of exchanger was equilibrated by two successive addition with each 10 cm^3 of the above solution (Table 3). The amount of liberated H^+ from H-CAM was

equivalent to NH_4^+ uptake in the first equilibration. However slightly higher $[H^+]$ was observed in the supernatant solution than the amount of NH_4^+ uptaken by H-CAM due to the hydrolysis in the 2nd equilibration. The ion-exchange capacity for NH_4^+ was found to be 0.31 mequiv g^{-1} of H-CAM.

The acidification of hexaammonium heptamolybdate (aqueous solution) did not result into ammonia free molybdic acid even with 7.5 M HNO_3 or HCl solutions. The positive test for ammonia contents in commercially available so-called molybdic acids proves the authenticity of our observations, though the quantity of ammonia varies from product to product depending on the maker. As a matter of fact even a small content of NH_4^+ cannot be ignored from the ion exchange point of study and the empirical composition of the material. Therefore the products reported by different authors[11,25,31-34] as $MoO_3 \cdot H_2O$ or H_2MoO_4 prepared from aqueous solutions of ammonium heptamolybdate seem to be misleading.

The chemical formulae of H-CAM and A-CAM deduced from the chemical and thermal analysis and ion-exchange capacity, can be represented as $[H_{0.68}(NH_4)_2]O_{1.34} \cdot 14.16MoO_3 \cdot 6.92H_2O$ and $[(NH_4)_{0.68}(NH_4)_2]O_{1.34} \cdot 14.16MoO_3 \cdot 5.26H_2O$ respectively. The empirical formula of the CAM is $[(NH_4)_{0.78}(NH_4)_2]O_{1.39} \cdot 14.16MoO_3 \cdot 6.08H_2O$. The presence of 0.10% higher exchangeable NH_4^+ in CAM than that of A-CAM was due to the greater ammonia concentration in the mother liquor (supernatant solution). The amount of ammonia (1.54%) in H-CAM is independent of the preparation method and cannot be removed by washing even with 1 M HNO_3 solution. The results indicated that the amount of water in H-CAM varies slightly. However, the amount of ammonia evolved upto 100 °C (Fig. 6) was only 0.0226% of total ammonia and the weight loss at around 310 to 450 °C was due to evolution of structural ammonia and water. Kiss et al.[17] have reported the possible presence of $[Mo_{14}O_{43}]^{2-}$ polyanions by heating the ammonium heptamolybdate hydrate at 260 °C called as New Phase-1 $(NH_4)_2O \cdot 14MoO_3 \cdot 3.3H_2O$. They assumed the composition of the precipitate obtained from aqueous solutions to be the same as new phase-1. However for lack of information about the exchangeable NH_4^+ and NO_x formation during thermal decomposition, the calculated composition of their reported material seems to be deceptive.

The thermal decomposition reaction of H-CAM can be written as follows,

$$[H_{0.68}(NH_4)_2]O_{1.34} \cdot 14.16MoO_3 \cdot 6.92H_2O \quad \text{(H-CAM)}$$
$$\xrightarrow{100-300\,^\circ C} [H_{0.68}(NH_4)_2]O_{1.34} \cdot 14.16MoO_3 + 6.92H_2O(\uparrow)$$
$$\xrightarrow{300-450\,^\circ C} 14.16MoO_3 + 2NH_3(\uparrow) + 1.34H_2O(\uparrow).$$

Conclusion

Crystalline cubic ammonium molybdate (CAM) can be prepared by the reaction of HNO_3 and hexaammonium heptamolybdate under controlled temperature conditions and reagents specifications. The chemical and thermal analyses and the amount of exchangeable H^+ indicated the composition of H-CAM as $[H_{0.68}(NH_4)_2]O_{1.34} \cdot 14.16MoO_3 \cdot 6.92H_2O$. The CAM is suitable for grading to a desired mesh size to be used for column chromatography. A reversible exchange NH_4^+/H^+ reaction would find a new application field as an ion exchanger and a catalyst.

Metal Complexes of Peptides. IV. Cobalt(III) Complexes with β-Alanyl-L-histidine (Carnosine) Functioning as a Quadridentate Ligand

Tomoharu AMA,* Hiroshi KAWAGUCHI, Masato UCHIJIMA, Norio KOINE,† and Takaji YASUI

(Received May 11, 1989)

Three cobalt(III) complexes containing β-alanyl-L-histidine (or carnosine: H_2car), $[Co(car)(L)]^+$ (L=en) and $[Co(car)(L)]^-$ (L=ox^{2-} or CO_3^{2-}), were newly prepared and characterized on the basis of their ^{13}C NMR, UV and visible absorption, and circular dichroism spectra. In these complexes, the carnosine coordinates to a cobalt(III) ion as a quadridentate ligand in a meridional form with respect to the peptide chain. In the pH range of 0—6, these complexes exhibited the visible absorption spectral changes with pH. These changes are attributed to the protonation on the oxygen in β-alanyl moiety of the coordinating carnosine and the pK_a values of $[Co(car)(en)]^+$ and $[Co(car)(ox)]^-$ were estimated as ca. 1.5. The spectral behaviors of the present complexes were compared with that of $[Co(Hcar)(en)(OH_2)]^{2+}$, in which the carnosine functions as a terdentate ligand.

Some studies on the cobalt(III) complexes containing peptides have been reported.[1-16] However, there are few studies on the cobalt(III) complexes of β-alanyl-L-histidine (or carnosine: H_2car), in spite that the complexes are important compounds in a biological sense. Only one coordination mode is reported for the carnosine-cobalt(III) complex,[1] in which the carnosine functions as a terdentate with the uncoordinated amino group. However, it is expected that the carnosine also functions as a quadridentate in a cobalt(III) complex, as found in a chromium(III) complex by Murdoch et al.[17] This expection led us to the experiments to prepare some cobalt(III) complexes containing a quadridentate carnosine under different synthetic conditions from those reported for the terdentate carnosine complex.[1] In the present paper, we will describe the preparation of new carnosine-cobalt(III) complexes and discuss their structures and properties on the basis of the ^{13}C NMR, UV and visible absorption, and CD spectral data.

Experimental

Preparation of Complexes. [Co(car)(en)]Cl (Complex 1): Carnosine (0.1 g) was dissolved in 40 cm^3 of water, and the pH of the solution was adjusted to 9.0 with 1 mol dm^{-3} KOH. To this solution, $K[Co(en)(CO_3)_2]\cdot H_2O$ (1.3 g)[18] was added with stirring. After stirring at 70 °C for 16 h, the solution was cooled to room temperature and then filtered. The filtrate was charged on an SP-Sephadex column (K^+ form) and flushed with water to remove a violet-brown band which was elutable with water, and then developed with 0.2 mol dm^{-3} KCl. A red orange band appeared on the development, a violet-brown band remaining on the top of the column. The red orange band was transferred to another SP-Sephadex column and then repeatedly developed with 0.2 mol dm^{-3} KCl using a micropump. After the red orange band separated into pink and orange bands, an eluant from the orange band was collected and concentrated to small volume with a vacuum evaporator. To the concentrated solution, a large amount of methanol was added in order to make deposit KCl, and then the solution was filtered. The filtrate was evaporated under reduced pressure to a few milliliters, again. The concentrated solution was loaded on a Sephadex G-10 column to eliminate KCl and eluted with water. The eluate from the orange band was concentrated to a small volume. A crude complex was obtained by adding methanol to the concentrate. It was recrystallized from water by addition of methanol (Complex 1; yield: 100 mg). Found: C, 31.44; H, 5.58; N, 20.21%. Calcd for $[Co(car)(en)]Cl\cdot 2H_2O$= $C_{11}H_{24}N_6O_5ClCo$: C, 31.93; H, 5.85; N, 20.31%.

Na[Co(car)(ox)] (Complex 2): Carnosine (0.5 g) was dissolved in 40 cm^3 of water. After the pH of the solution was adjusted to 8.5 with 2 mol dm^{-3} KOH, $K_3[Co(ox)_3]\cdot 3H_2O$ (0.96 g)[19] was added to the solution with constant stirring. The temperature of the solution was kept 40 °C for 10 h. The solution was cooled to room temperature, and then insoluble materials were filtered off. The filtrate was charged on a QAE-Sephadex column (Cl^- form, 4 cm×50 cm). After a violet-brown band elutable with water was eluted out with 1 dm^3 of water, the adsorbed band was developed with 0.1 mol dm^{-3} KCl. A violet band was appeared on the development, a green band remaining on the top of the column. The eluate from the violet band was concentrated to a few milliliters by using a vacuum evaporator and then KCl which deposited was filtered off. To the filtrate, methanol was added to deposit excess of KCl. The solution was filtered and a crude complex (K[Co(car)(ox)]) was precipitated by addition of acetone to the filtrate. The solution obtained by dissolving the crude complex in a small amount of water was treated with an SP-Sephadex column (Na^+ form; eluent: water) to convert the potassium salt to the sodium salt. After the eluate was concentrated, ethanol, saturated with $NaClO_4$, was added to the concentrated solution. A crude complex of Na[Co(car)(ox)] thus deposited was recrystallized from water by addition of ethanol containing $NaClO_4$ (Complex **2**; yeild: 350 mg). Found: C, 23.28; H, 3.22; N, 9.96%. Calcd for $Na[Co(car)(ox)]\cdot NaClO_4\cdot 3H_2O$=$C_{11}H_{18}N_4ClNa_2O_{14}Co$: C, 23.15; H, 3.18; N, 9.82%.

K[Co(car)(CO_3)] (Complex 3): Carnosine (0.5 g) was dissolved in 40 cm^3 of water and $Na_3[Co(CO_3)_3]\cdot 3H_2O$ (0.8 g)[20] was added to the solution. The solution was stirred at 45—50 °C for 24 h. After being cooled to room temperature, the solution was filtered and the filtrate was charged on a QAE-Sephadex (Cl^- form) column. The column was swept with 1 dm^3 of water to remove the violet-brown band which was

elutable with water. The adsorbed band was developed with 0.1 mol dm^{-3} KCl. A violet band appeared on the development, a brown band remaining on the top of the column. The eluate from the violet band was concentrated to a few milliliters by using a vacuum evaporator and then methanol was added to the concentrated solution. White precipitates (KCl) were filtered off. The filtrate was again evaporated almost to dryness and then the residue was dissolved in a few milliliters of water. The solution was treated with a Sephadex G-10 column in order to remove KCl. The crude complex, which was obtained from the violet eluate by addition of ethanol, were recrystallized from water by addition of ethanol (Complex **3**; yield: 250 mg). Found: C, 31.35; H, 4.23; N, 12.85%. Calcd for $K[Co(car)(CO_3)]\cdot 0.5C_2H_5OH\cdot 2H_2O=C_{11}H_{17}N_4O_{7.5}KCo$: C, 31.21; H, 4.05; N, 13.25%.

$[Co(Hcar)(en)(OH_2)]Cl_2\cdot H_2O$ (Complex 4): This complex was prepared by the method described in a previous paper.[1]

Absorption Spectral Changes with pH. In Lower pH Region: 5 cm^3 of the solution containing complex **1** (0.2004 g, 4.8×10^{-4} mol dm^{-3}) in 50 cm^3 of water was placed in a measuring flask (10 cm^3), and then a prescribed volume of 2 mol dm^{-3} HCl solution was added to it. The volume of the acidic solution was adjusted to 10 cm^3 with water. By the same procedure, seven solutions with different pH's (0.1—6.0) were prepared. Absorption spectrum and pH of the each solution were recorded at room temperature. In the same manner as above, the absorption spectral changes with pH's were examined for Complexes **2** and **4**.

In Higher pH Region: The spectral changes in the range of pH 5—10 were examined by the method similar to that described above, except for using 1 mol dm^{-3} NaOH instead of 2 mol dm^{-3} HCl.

Measurements. The absorption and CD spectra were measured by a HITACHI 557 spectrophotometer and a JASCO J-22 spectropolarimeter, respectively. The ^{13}C NMR spectra were recorded on a HITACHI R-90H spectrometer. The chemical shifts in ^{13}C NMR were measured relative to internal dioxane (δ=67.40).

Results and Discussion

^{13}C NMR Spectra. The ^{13}C NMR measurements at various pH provide useful information on the coordination modes of ligand. Figure 1 shows the ^{13}C NMR shift patterns of carnosine and its complexes, together with those of the related complexes. The numbering of all carbons in carnosine and their signal assignments adopted those described in the report of Viola et al.[21] (Fig. 1).

As Fig. 1 shows, the ^{13}C chemical shifts of the free carnosine vary with pH of the solution. The C_5 resonance peak of free carnosine in a pH 5 solution locates at more down-field than that in a 1 M DCl solution. This down-field shift arises from deprotonation on the carboxyl group. The C_7 and C_9 peaks of free carnosine at pH 9 shift to more down-field than those at pH 5, and the C_1 and C_2 peaks of free carnosine at pH 12 shift to more down-field than those at pH 9. The down-field shifts for the former and

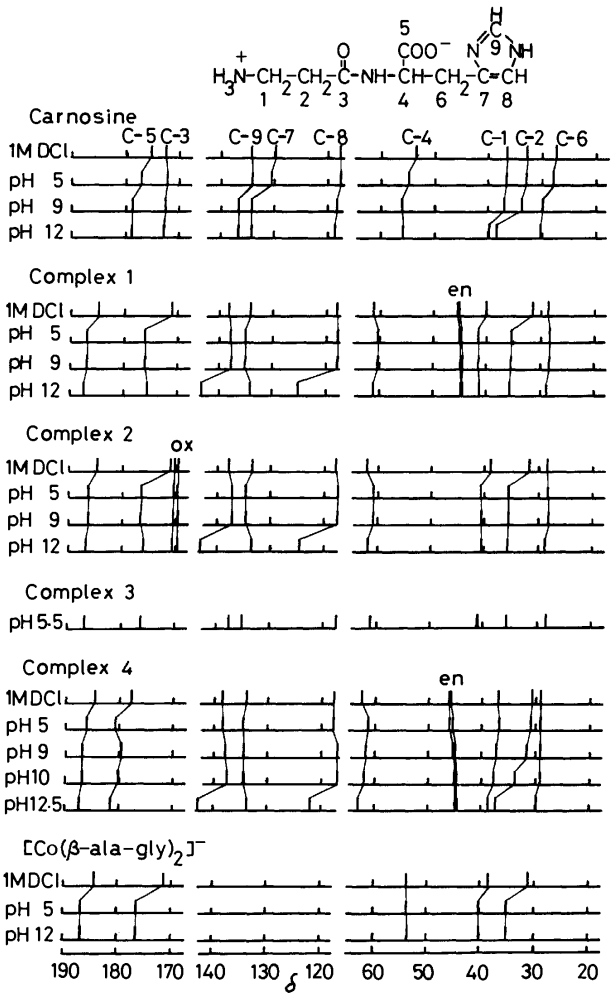

Fig. 1. ^{13}C NMR spectral patterns of carnosine and cobalt(III) complexes at various pH.

latter are related to deprotonations on the imidazole NH and on the amino groups, respectively.

The C_5 resonance peaks of the present complexes at pH 5—7 are observed in more down-field region than that of free carnosine at pH 5. These down-field shifts results from the coordination of the carboxyl groups to cobalt(III). Such down-field shifts due to the coordination of the carboxyl groups to cobalt(III) are also well recognized for the amino acidato and aliphatic acidato complexes.[22]

The ^{13}C chemical shifts of the carnosine-carbons in the present Complexes **1**, **2**, and **3** coincide well with each other for their neutral solutions, suggesting that the coordination mode of carnosine is the same in these complexes. In addition, the ^{13}C chemical shifts of the C_1, C_2, C_3, and C_5 carbons in Complexes **1**, **2**, and **3** are almost equal to those of the corresponding carbons of the terdentate β-ala-gly in $[Co(\beta\text{-ala-gly})_2]^-$. These results suggest that the coordination mode of carnosine in the present complexes is similar to that of β-ala-gly in $[Co(\beta\text{-ala-gly})_2]^-$ with respect to the peptide chain. The C_7 and C_9 resonance peaks of

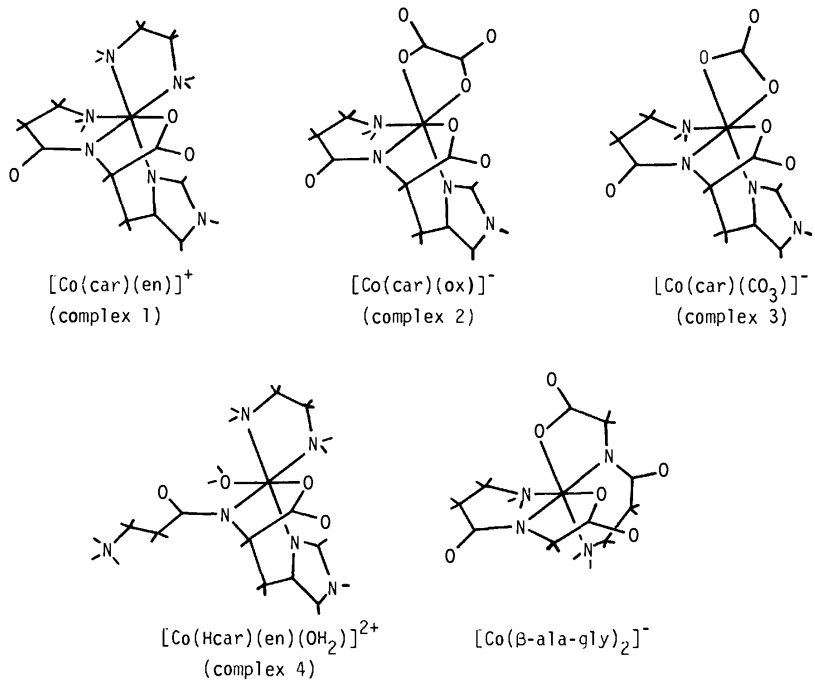

Fig. 2. Structures of the cobalt(III) complexes containing carnosine.

Complexes **1**, **2**, and **3** at pH 5 (or 5.5) are observed at more down-field than those of free carnosine at pH 5. These down-field shifts show that the coordination of imidazole moiety to cobalt(III) occurs. Consequently, the structures shown in Fig. 2 are proposed for Complexes **1**, **2**, and **3**. In these complexes, the marked up-field shifts of C_3 and C_2 at low pH (1 M DCl) are attributed to protonation on the oxygen in β-alanyl moiety of the coordinating carnosine,[23] and the down-field shifts of C_8 and C_9 at high pH (pH 12) are attributed to deprotonation of NH on the coordinating imidazole moiety.

Absorption and Circular Dichroism Spectra. The absorption and CD spectra of the newly prepared carnosine complexes are shown in Fig. 3, together with those of Complex **4** reported in our previous study.[1] The absorption spectral behaviors of complexes **2** and **3** resemble to each other, indicating that these complexes have the same chromophore of the *fac*-$[Co(N)_3(O)_3]$ type[24] and the same coordination mode of carnosine, that is, carnosine coordinate to Co(III) as quadridentate with carboxyl O, amino N, amide N, and imidazole N. The replacement of oxalato in Complex **2** with ethylenediamine gives Complex **1**, whose first absorption band shifts to higher energy side than that of Complex **2**. Moreover, the first absorption band of Complex **1** has characteristics of the $[Co(N)_5(O)]$ type chromophore.[24] These results based on the absorption spectra coincide with the assignment based on the ^{13}C NMR mentioned in the previous section.

While the band splitting in the first absorption band of Complex **1**, **2**, or **3** is not obvious, that of Complex **4** is obvious. This spectral pattern of Complex **4** is characteristic to the *trans*(*O*)-$[Co(N)_4(O)_2]$ type chromophore.[24] This result is consistent with the structure

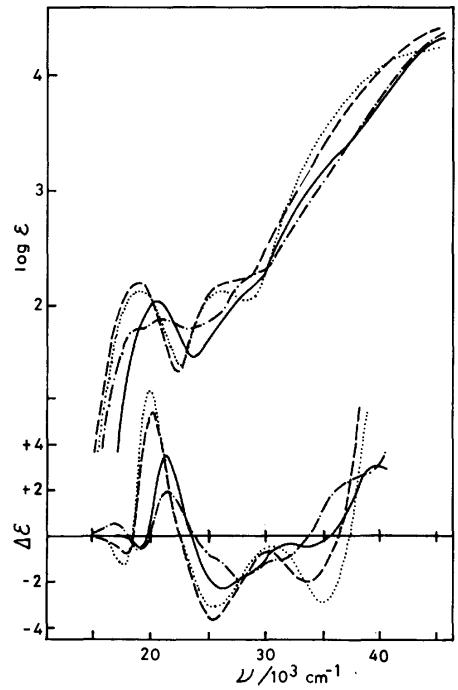

Fig. 3. Absorption and CD spectra of the complexes. $[Co(car)(en)]^+$ (Complex **1**) (——), $[Co(car)(ox)]^-$ (Complex **2**) (———), $[Co(car)(CO_3)]^-$ (Complex **3**) (·····), and $[Co(Hcar)(en)(OH_2)]^{2+}$ (Complex **4**) (—·—·—). (The ε and $\Delta\varepsilon$ values are given in $mol^{-1}\,dm^3\,cm^{-1}$).

determined by means of X-ray crystal analysis.[1]

The CD behaviors of Complexes **2** and **3** quite resemble each other. Both the complexes show two CD peaks with opposite signs in the first absorption band region (a weak (−) sign at lower energy side and an intense peak with (+) sign at higher energy side) and a (−) CD peak in the second band region. Similar spectral pattern also appears in Complex **1**. This similarlity in CD pattern suggests that these complexes have the same absolute configuration (Fig. 2). The CD pattern of Complex **4**, however, is different from those of Complexes **1**, **2**, and **3**, that is, three CD peaks ((+), (−), and (+) signs from lower energy side) appear in the first absorption band region. Such difference in CD patterns is attributed to difference in the coordination modes of carnosine.

Spectral Change with pH. The absorption spectral changes with pH were observed for the present complexes. Figure 4(A) shows the spectral change of Complex **1** in the range of pH 0.53—5.84. The isosbestic points appear at 463 and 426 nm. These spectral changes result from the protonation on the oxygen in the β-alanyl moiety of the coordinating carnosine.[23] The pK_a value estimated from the spectral change is 1.46. Analogous spectral change in an acidic solution (pH range: 1.12—6.19) was also observed for Complex **2**, with four isosbestic points at 523, 448, 335, and 350 nm. The pK_a value was estimated as 1.78. These pK_a values (1.46 and 1.78) are larger than 0.75 for [Co(mida)(L-ala-gly)]$^-$ (mida=*N*-methyl iminodiacetato), but smaller than 2.56 for [Co(mida)(β-ala-gly)]$^-$.[3]

The spectral change of Complex **4** in the range of pH 0.13—5.12 provided three isosbestic points at 565, 389, and 366 nm. The pK_a value estimated is 0.51 and smaller than those of Complexes **1** and **2**. This small value results from that the coordination mode of carnosine in Complex **4** (terdentate with uncoordinated amino moiety) is different from that in Complex **1** or **2** (quadridentate). The X-ray crystal data of Complex **4** imply that hydrogen bond is present between β-alanyl O$^-$ in carnosine and coordinating H_2O. This hydrogen bond makes it difficult for another proton to attach to β-alanyl O$^-$, and lowers the pK_a value of Complex **4**. In addition, the hydrogen bond makes the amino group on the β-alanine moiety keep away from the cobalt center and stabilizes the unique structure containing cis-peptide bond[25] (C_2 and C_4 carbons are in cis position with respect to C_3–N bond) (Figs. 1 and 2).

Complex **4** shows marked absorption spectral change in the range of pH 5.27—9.10, as shown in Fig. 5 (the spectral curve at pH 10.03 coincides with that at pH 9.10 in the range 600—320 nm). However, ^{13}C chemical shifts of Complex **4** at pH 9 are nearly equal to those at pH 5. These results indicate that no deprotonation occurs on the carnosine ligand at pH 9.10 (that is, no deprotonation occurs on either amino or imino group at this pH) but deprotonation occurs on coordinating H_2O to give a hydroxo complex. The pK_a value estimated from the spectral changes is 7.87.

In Complex **4** the absorption spectral curve at pH 9.10 coincides with that at pH 10.03 in the range 600—320 nm, as mentioned above. However, the ^{13}C resonance peaks of the β-alanine moiety in carnosine at pH 9 shift to more down-field than those at pH 10.

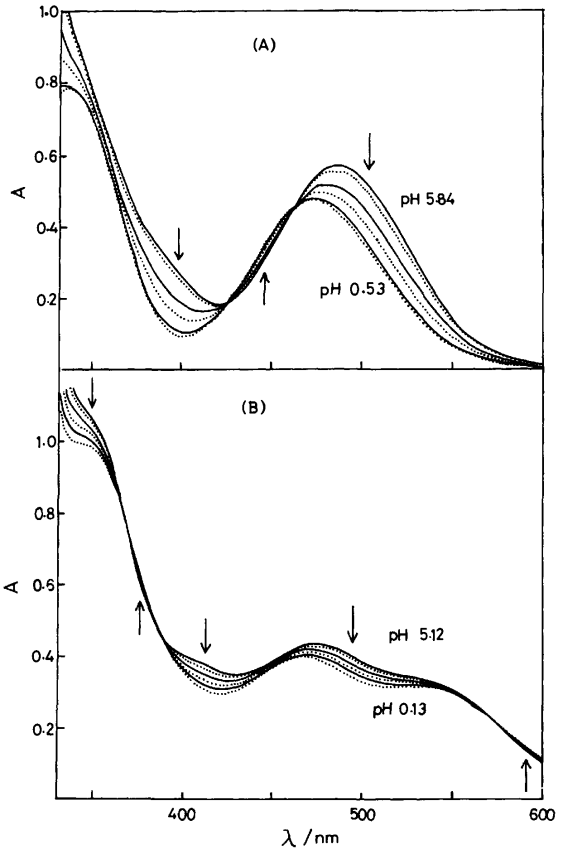

Fig. 4. Absorption spectral changes of the complexes with pH in acidic region. (A) Complex **1** (pH=5.84, 2.29, 1.60, 1.27, 0.79, and 0.53). (B) Complex **4** (pH=5.12, 0.78, 0.55, 0.40, 0.30, and 0.13).

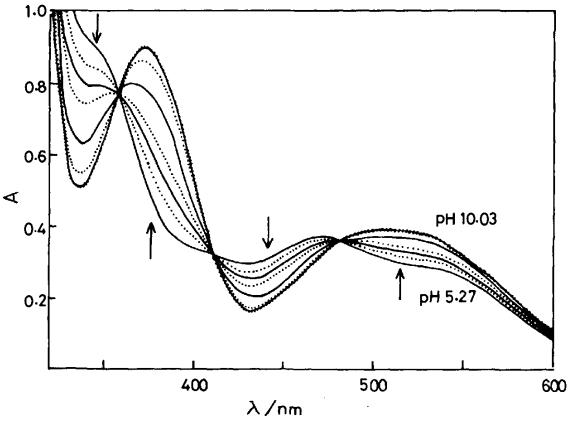

Fig. 5. Absorption spectral change of Complex **4** with pH in basic region. (pH=5.27, 7.20, 7.56, 7.87, 8.35, 8.99, 9.10, and 10.03).

This down-field shift is attributed to the deprotonation on $-NH_3^+$ of the β-alanyl moiety. The C_7 and C_9 resonance peaks of Complex **4** at pH 12.5 locate at more down-field than those at pH 10. The down-field shifts are attributed to the deprotonation of NH in the imidazole moiety. It is noteworthy that the basic solution of Complex **4** (containing carnosine as terdentate with uncoordinated $-NH_3^+$ moiety) does not produce easily Complex **1** (containing carnosine as quadridentate); replacement of the coordinating hydroxy ligand by the uncoordinating amino group does not occur easily. This results from that the cis-peptide bond in Complex **4** is stabilized by the hydrogen bond described above and that the structural conversion from cis- to trans-peptide is not easy at room temperature.

Tetrakis[3-(diethylamino)propyl]- and Tetrakis[3-(diethylmethylammonio)-propyl]phthalocyanines: The First Amphiphilic Phthalocyanines

Nagao KOBAYASHI,* Fumihiro OJIMA, Tetsuo OSA,* Steve VIGH,† and Clifford C. LEZNOFF*,†
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
†Department of Chemistry, York University, 4700 Keele Street, North York, Ontario, Canada M3J 1P3
(Received June 23, 1989)

The first amphiphilic cobalt (**III**) and copper phthalocyanines (**V**) have been prepared and are characterized by UV-absorption and magnetic circular dichroism (MCD) spectra in water and organic solvents and in their mixtures. These phthalocyanines exist as dimers in water and as monomers in some organic solvents. Monomer-dimer equilibrium was affected by solvent polarity (or hydrophobicity); with lower cosolvent polarity favoring formation of monomers. Cyclic voltammetry suggests that **III** adsorbed onto glassy carbon (GC) from an aqueous or acetonitrile (AN) solution in monomeric, irrespective of its state in solution. The $Co^{II/I}$ redox potential of **III** shifts anodically by adsorption onto GC, and this shift is larger when adsorbed from an AN solution than from an aqueous solution. Electroreduction of oxygen occurs at more positive potential at **III**-adsorbed GC in plain solution than at bare GC in **III**-dissolved solution.

Phthalocyanines (Pcs) are a remarkably versatile and robust class of compounds.[1] However, the solubility of the unsubstituted parent molecules is notoriously low, so that the introduction of bulky or long alkyl chains is generally required to increase their solubility in organic solvents.[2] Phthalocyanines containing sulfonyl,[3] carboxyl,[4] and amino groups[5] are, on the other band, water soluble. Phthalocyanines which dissolve in water at all pH values have not been reported to date, although a brief report on compound **I** and its zinc derivatives for use in photodynamic therapy of cancer appeared recently.[6] In view of such considerations, we report here the first example of amphiphilic phthalocyanines, i.e. the cobalt **III** and copper **V** complexes of **I**. These dissolve not only in water at all pH values, but also in many of the common organic solvents such as chloroform, acetone, alcohols, and benzenes. As will be shown below, they are compounds which can bridge the chemistry of phthalocyanines in water and organic solvents.

Experimental

Measurements. Matheson high-purity argon or high-purity nitrogen has passed through concentrated sulfuric acid (H_2SO_4) and preheated copper filings was used to maintain inert atmosphere conditions. Oxygen was purified by passage through concentrated H_2SO_4. Infrared spectra were recorded on a Pye Unicam SP 1000 infrared spectophotometer using KBr discs. Fast-atom-bombardment (FAB) spectra were obtained with a Kratos MS-50 tripic analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and an Ion Tech atom gun. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Absorption spectra were collected on a Hewlett Packard HP8451A Diode Array spectrophotometer or on a Shimadzu UV-250 spectrophotometer. In the experiments in the mixed solvent system, the following procedures were adopted in order to minimize concentration differences among each of the samples. Initially, a concentrated phthalocyanine solution was prepared in acetonitrile. From this solution, a fixed small amount was transferred into a 1 cm cuvette using a microsyringe, and the solvent evaporated. To this cuvette was added 3 cm^3 of a mixed solvent of desired composition ratio, and the spectra were recorded. MCD spectra were run on a Jasco J-500 spectropolarimeter equipped with a Jasco electromagnet to produce longitudinal magnetic fields up to 1.1 T. Each measurement was made with both parallel and antiparallel fields.

Cyclic voltammetric (CV) sweeps were generated by an NF circuit design block FG-100 AD function generator in conjunction with a potentiostat which was built by methods recorded in the literature.[7] A glassy carbon (GC) (area 0.070 cm^2), a saturated calomel electrode (SCE), and a platinum foil were used, respectively, as a working electrode, a reference electrode, and a counter electrode. The GC was polished on one side to a bright surface with fine emery paper and alumina powder (final polish with 0.05 μm particle size, Buehler) immediately prior to use.

Materials. *o*-Dichlorobenzene (DCB) (Aldrich, Gold Label), acetonitrile (AN) (Wako, spectrograde), dioxane, 2-butoxyethanol, and 2-propanol (Nakarai, Guaranteed reagents) were used as supplied. Measurements at pH 1 or 7 were performed in 0.05 M H_2SO_4 or 0.1 M phosphate buffer (1 M=1 mol dm^{-3}), respectively. The GC electrode was purchased from Tokai Carbon Ltd.

2,9,16,23-Tetrakis[3-(diethylamino)propyl]phthalocyaninatocobalt(II), (II). To a solution of 108 mg (0.11 mmol) of **I**[6] in 10 ml toluene/2-methoxyethanol (1:1 v/v), was added 150 mg (1.15 mmol) of anhydrous cobalt dichloride. The solution was stirred at 120 °C (reflux) under argon for 20 h. The crude reaction mixture was applied directly to a short (10 cm×1 cm) basic alumina column (act 3) and eluted with toluene/2-methoxyethanol (3:1 v/v). Evaporation of the solvent gave **II** as a dark blue shining solid, 110 mg (96.5% yield); mp >300 °C. IR (KBr) 2980, 2800, 1610, 1520, 1340, 1100, 750 cm^{-1}. MS, *m/z* 1025 (M^++1, 75), 1024 (M^+, 57), 995(18), 968(15), 924(20). Analysis was performed on the quaternized methyl iodide salt (**III**).

2,9,16,23-Tetrakis[3-(diethylmethylammonio)propyl]-phthalocyaninatocobalt(II) Tetraiodide, (III). To a solution of 75 mg (0.073 mmol) of **II** in 10 ml toluene was added 0.5 ml (8 mmol) of methyl iodide. This solution was stirred for 20 h at room temperature. The observed blue precipitate

was filtered and washed with ether. The yield of the blue powdery solid (**III**) was 94.3 mg (81% yield). Found: C, 48.20; H, 5.39; N, 10.85; Co, 3.60%. Calcd for $C_{64}H_{88}N_{12}CoI_4$: C, 48.28; H, 5.57; N, 10.56; Co, 3.70%. Mp >300 °C. IR (KBr) 2960, 1610, 1520, 1460, 1330, 1100, 820, and 760 cm^{-1}.

2,9,16,23-Tetrakis[3-(diethylamino)propyl]phthalocyaninatocopper(II), (IV). To a solution of 76 mg (0.07 mmol) of **I**[3] in 10 ml of a toluene/2-methoxyethanol (1:1 v/v) mixture was added 150 mg (0.83 mmol) of anhydrous copper(II) acetate. The solution was stirred at 120 °C reflux under an argon atmosphere for 20 h. The crude reaction mixture was applied directly to a short basic alumina (Act 3) column (10×1 cm) and eluted with toluene/2-methoxyethanol (3:1 v/v). Evaporation of the solvent gave **IV** as a dark blue shining solid; 78 mg (96% yield). Mp >300 °C. IR (KBr) 2980, 2800, 1610, 1520, 1330, 1100, 830, and 750 cm^{-1}. MS, *m/z* 1030(10), 1029(M^++1, 15), 1028(M^+, 8), and 927(5). Analysis was performed on the quaternized methyl iodide salt (**V**).

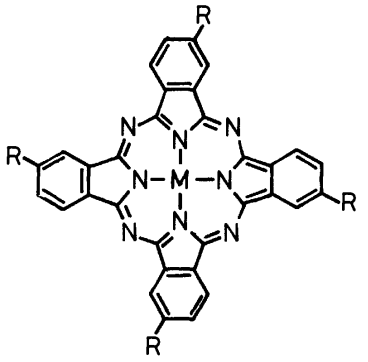
2,9,16,23-Tetrakis[3-(diethylmethylammonio)propyl]-phthalocyaninatocopper(II) Tetraiodide, (V). To a solution of 35 mg (0.034 mmol) of **IV** in 10 ml of toluene was added 0.5 ml (8 mmol) of methyl iodide. This solution was stirred for 20 h at room temperature. The observed blue precipitate was filtered and washed with ether. The yield of blue powdery solid (**V**), after drying, was 40 mg (74% yield). Found: C, 47.80; H, 5.50; N, 10.94; Cu, 3.66%. Calcd for $C_{64}H_{88}N_{12}CuI_4$: C, 48.14; H, 5.55; N, 10.53; Cu, 3.98%. Mp >300 °C. IR (KBr) 2960, 1610, 1450, 1410, 1330, 1170, 1090, and 750 cm^{-1}.

UV data of **II**—**V** in several solvents are summarized in Table 1.

Results and Discussion

Experiments were designed to illustrate the amphiphilic properties of the compounds.

(i) UV-Absorption and MCD Spectroscopy. Figures 1 and 2 show absorption and MCD spectra of **III** and **V**, respectively, in water, AN and in their mixtures. Their absorption spectra in AN are characteristic of monomeric phthalocyanines.[7] When trace amounts of water were admixed, the spectra changed only in the region higher in energy than 270 nm probably as a result of coordination of water molecule to cobalt or copper. When the water content in the solvent exceeded 50% in each case, the whole spectrum started to change as shown by arrows with sets of isosbestic



(**I**) R=$(Et)_2N(CH_2)_3$-, M=H_2
(**II**) R=$(Et)_2N(CH_2)_3$-, M=Co
(**III**) R=$(Et)_2\overset{\oplus}{N}Me(CH_2)_3$-$\overset{\ominus}{I}$, M=Co
(**IV**) R=$(Et)_2N(CH_2)_3$-, M=Cu
(**V**) R=$(Et)_2\overset{\oplus}{N}Me(CH_2)_3$-$\overset{\ominus}{I}$, M=Cu

Table 1. Absorption Spectra of Phthalocyanines (Pcs) (**II**—**V**) in Some Solvents

Pc	Solvent	λ(max)/nm (ε in log)			
II	DCB[a]	672(5.16)	650(4.63)	610(4.48)	332(4.76)
		292(4.47)			
III	H_2O[b]	670(4.77)	626(4.82)	320(4.82)	292(4.88)
		226(5.14)			
	AN[c]	660(5.26)	598(4.61)	326(4.98)	287(4.86)
		244(5.10)			
IV	DCB[a]	682(5.14)	658(4.60)	650(4.52)	616(4.53)
		346(4.70)	292(4.18)		
V	H_2O[b]	670(4.57)	630(4.75)	334(4.73)	225(5.01)
	AN[c]	670(5.24)	607(4.39)	338(4.84)	245(4.89)

a) DCB; *o*-dichlorobenzene. b) Data in water were collected at 4.665×10^{-6} M for **III** and 5.216×10^{-6} M for **V**. c) AN; acetonitrile.

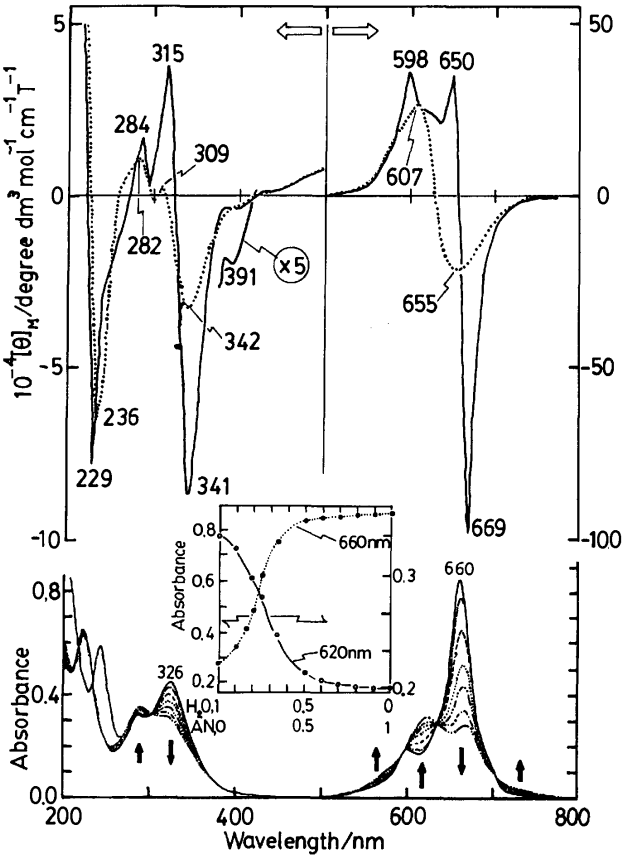


Fig. 1. Absorption (bottom) and MCD (top) spectra of **III** in acetonitrile (solid line), water (dotted line) and in their mixtures. Concentration=4.665×10^{-6} M. Cell path length=10 mm. Magnetic field=1.09 T. The inset shows the absorbance at 660 and 620 nm in acetonitrile-water mixtures.

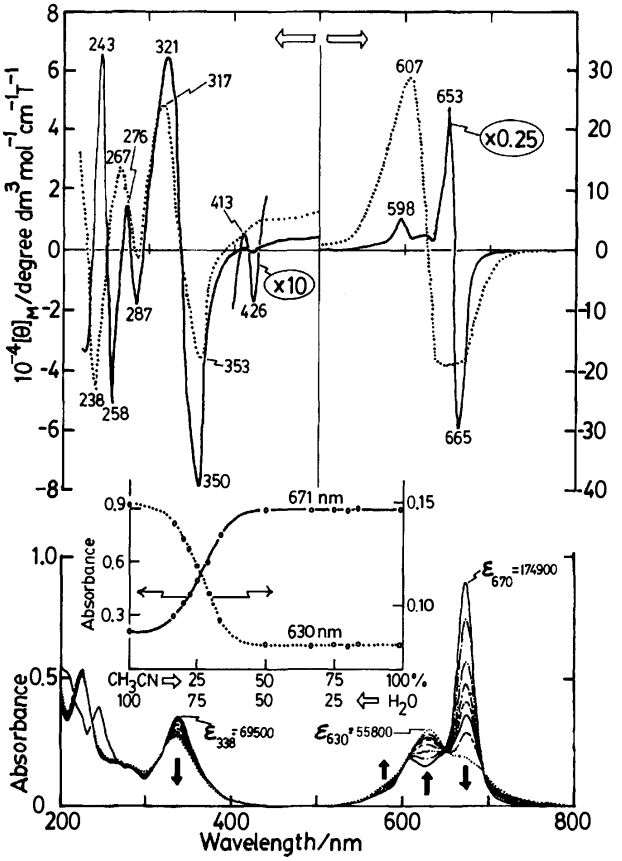

Fig. 2. Absorption (bottom) and MCD spectra (top) of **V** in acetonitrile (solid line), water (dotted line) and in their mixtures. Concentration=5.146×10^{-6} M. Cell path length=10 mm. Magnetic field=1.09 T. The inset shows the absorbance at 671 and 630 nm in acetonitrile-water mixtures.

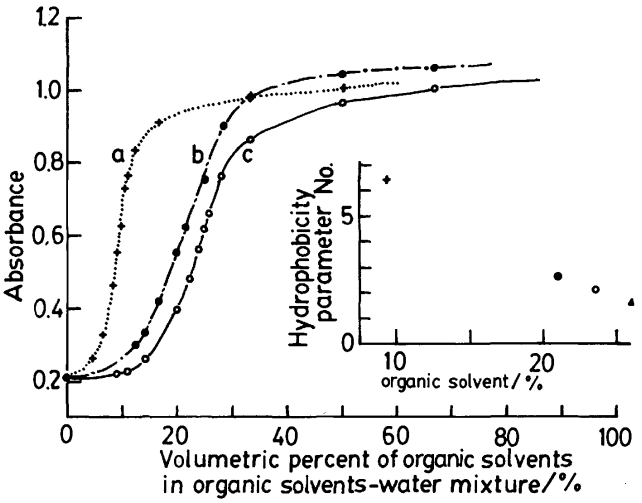

Fig. 3. Absorbance of the Q band of **V** in (a) 2-butoxyethanol-water, (b) dioxane-water, and (c) 2-propanol-water mixtures. Concentration=5.216×10^{-6} M. The inset shows the relationship between the hydrophobicity parameter and the organic solvent percent in organic solvent-water mixtures where 50% of the monomers have formed dimers. These data were obtained from lines a—c and the inset in Fig. 2.

points, and finally in pure water the spectra shown by the dotted lines were recorded. Although shapes of the spectra in pure water can be classified into those of aggregated phthalocyanines,[7] these are thought to be the spectra of dimeric species, since clear isosbestic points at several positions were observed in each case. The blue shift of the Soret and Q bands observed accompanying the change of solvent from AN to water suggests that the phthalocyanine dimers in water are in a card-pack arrangement.[7-9] This type of aggregation has been formed for tetrasulfonated phthalocyanine in water.[9] It is conceivable that, by the increase of polarity of solvent, the more hydrophobic phthalocyanine moieties approach each other (thereby forming dimers). As can be seen from the inflection points of the two curves in the inset, 50% of the monomeric phthalocyanines have dimerized when the AN:water ratio attains 23:77 (v/v) for **III** or 26.5:73.5 (v/v) for **V**.[10] In order to obtain further information on the state of **III** and **V** in water, the ESR spectrum of **V** was recorded in water. A 3.0×10^{-4} M solution gave an ESR singal at g=2.056 at 77 K, but little hyperfine structure which is observed clearly in monomeric species[7,11] appeared. Thus, **III** and **V** may exist as somewhat cofacial but slipped and/or staggered type dimers in water.

The MCD spectra of **III** and **V** in both water and AN are typical of phthalocyanines, in that Faraday *A*-terms appeared corresponding to the main absorption maxima.[12] However, though hardly detectable in the absorption spectra, a small but explicit Faraday *A*-term which indicates another degenerate excited state was discerned in the spectrum in AN at around 375—400 nm for **III** and 410—430 nm for **V**. The presence of this *A* term was only recently discovered for the first time for ZnPc[13] by MCD spectroscopy and assigned as a transition to the B state. So far the band at around 300—360 nm has generally been considered to be the B band.[14] However, if we follow the so-called "Four-Orbital Model" by Gouterman,[14,15] the band at 671, ca. 387, and 338 nm of **III** and 659, 420, 341, 282, and 250 nm of **V** in AN can be assigned as transitions to Q, B, N, L, and C states, respectively, in this order.[16] The possibility of a charge-transfer (CT) transition may not be ruled out completely; however, this possibility appears to be small, because an iron phthalocyanine[17] also reveals Faraday *A*-term type MCD signals in the same wavelength region (395—430[17] nm), irrespective of the different central metals. Especially, in the case of copper phthalocyanines, the CT band is not expected theoretically except in the near infrared region.[18]

The monomer-dimer transformatins of **V** were studied further in various organic-water solvent mixtures (Fig. 3). Three organic solvents which mix

with water in a wide ratio and have a range of hydrophobicity were selected. These were 2-propanol, dioxane, and 2-butoxyethanol, and have polarity parameters of 2.2, 2.6, and 6.4, respectively[19] (the larger the value, the higher the hydrophobicity). From this figure and the inset, it is found that the higher the hydrophobicity of the organic solvents used, the smaller the organic solvent:water ratio which is required for monomer to dimer transformation. Thus, the hydrophobicity (or polarity) of the solvent does affect the monomer-dimer equilibrium.

(ii) Electrochemistry of III in the Presence or Absence of Oxygen in Water. Cobalt phthalocyanines and porphyrins have been employed as catalysts for the electroreduction of oxygen in systems where the catalysts were homogeneously dissolved[20] in solution or adsorbed[21] onto working electrodes. Although there appears to be a general agreement that mononuclear cobalt complexes promote the O_2 reduction process by two electrons to give H_2O_2, almost no comparison has been made on the catalytic behavior between catalyst-dissolved and -adsorbed systems. The change of solvent on adsorption may also affect catalytic activity, but adsorption of catalysts onto electrodes has always been carried out in a single solvent. No study on the effect of varying the solvent has been reported previously. Since **III** is an amphiphilic cobalt phthalocyanine, we can perform O_2 electroreduction experiments under various conditions and can compare the results mutually.

The adsorption of **III** onto a GC electrode was examined from both 10^{-4} M AN and 10^{-4} M 0.1 M phosphate buffer (pH 7.0) solutions. The electrode was dipped in these solutions for a fixed time, taken out and dried in air, and transferred to a blank solution of 0.05 M H_2SO_4 or 0.1 M phosphate buffer (pH 7.0). The adsorption was saturated within ca. 30 s both in AN and aqueous solutions. Cyclic voltammograms at this prepared electrode are shown in Fig. 4 as curves a and a′ (pH 7, under nitrogen). Clear $Co^{II/I}$ redox couples whose peak currents have a linear relationship with the sweep rate (line b and b′) appeared at ca. −0.3 V vs. SCE, and the amount of the adsorbed catalyst, as deduced from the charge under the area (0.085 μC, i.e. 1.2 μC cm^{-2}) is approximately the same in both cases. The redox couple at the modified GC prepared in aqueous solution appears at a slightly (ca. 30 mV) negative potential than that prepared in AN. The relatively symmetrical redox patterns suggest the absence of significant interaction among the adsorbed species,[22] and imply that although **III** exists as a dimer in water (Fig. 1), the dimer structure may not be retained when it is immobilized onto GC by adsorption.

Figure 4, curves c and c′ are cyclic voltammetric curves at these modified electrodes in the presence of oxygen. Oxygen is reduced catalytically[23] at a much more positive potential than the $Co^{II/I}$ redox couple in curve a or a′, but there is no difference in the peak height between the two types of modified electrodes even over a sweep range of 20 to 200 mV s^{-1}. The peak height was linearly proportional to the square root of the sweep rate (lines d and d′), confirming a diffusion limited process, and to O_2 concentration (line e and e′). The difference in the potentials of O_2 reduction peaks of the two electrodes increases to ca. 50 mV compared with 30 mV for the $Co^{II/I}$ redox couple (curves a and a′). Oxygen reduction at the modified electrode in AN occurs at more anodic potentials than that at the electrode prepared in water. Thus the electrode modified in AN may be slightly better from the standpoint of the O_2 reduction potential.

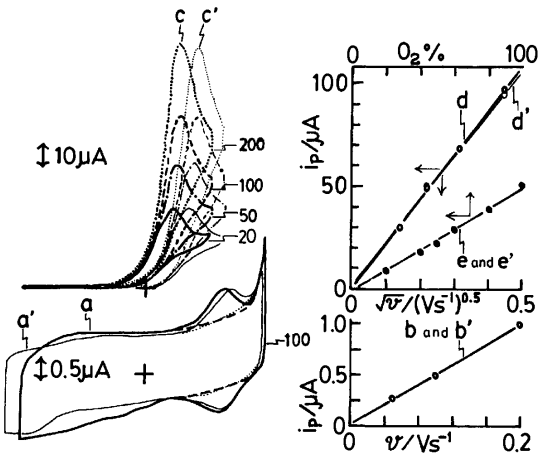

Fig. 4. Cyclic voltammograms at **III**-adsorbed GC electrodes (area, 0.070 cm^2) in water of pH 7.0. Adsorption was carried out either in 10^{-4} M acetonitrile solutions (bolder curves and lines, denoted by alphabet without prime) or in 10^{-4} M aqueous solutions (finer curves and lines denoted by alphabet with prime) for 10 min. Numbers on curves indicate scan rate in mV s^{-1}. Curve a and a′, responses in deaerated solution, and curves c and c′, in O_2-saturated solution. Line b and b′ indicates relationship between peak currents in curve a or a′ (ca. −0.31 or ca. −0.33 V) and scan rate. Lines d and d′ show relationship between peak currents in curves c or c′ and the square root of scan rate, and line e and e′ demonstrates catalytic O_2 reduction peak current vs. O_2 concentration relationship obtained at a sweep rate of 50 mV s^{-1}.

Potentials for the $Co^{II/I}$ couple and O_2 reduction peak at the modified electrodes at pH 1 are summarized together with the data at pH 7 in Table 2. As for other cobalt phthalocyanine systems,[24] the $Co^{II/I}$ redox potentials of **III** at pH 1 lie at much more anodic potentials than at pH 7, but the O_2 reduction potentials at pH 1 do not greatly shift from those at pH 7 and are equal to $Co^{II/I}$ redox potentials of **III** at pH 1. Since the $Co^{II/I}$ and O_2 potentials are similar for the catalyst-adsorbed system at pH 1, the O_2 reduction process can be explained by an electrochemical (EC)

Table 2. Some Potentials at Modified- or Bare Glassy Carbon Electrode

	Electrode with adsorbed **III** from 10^{-4} M AN solution		Electrode with adsorbed **III** from 10^{-4} M 0.1 M phosphate buffer		**III**-dissolved system	
	pH 1	pH 7	pH 1	pH 7	pH 1	pH 7
$Co^{II/I}$potential/V[a]	−0.12	−0.31	−0.15	−0.33	−0.43	−0.38
O_2 reduction Potential/V	−0.12	−0.12	−0.15	−0.17	−0.17	−0.22

a) Defined as (cathodic peak potential+anodic peak potential)/2.

catalytic regeneration mechanism (Eqs. 1 and 2).

$$Co^{II}Pc + e \longrightarrow Co^{I}Pc \quad E' \tag{1}$$

$$Co^{I}Pc + 0.5O_2 + H^+ \longrightarrow Co^{II}Pc + 0.5H_2O_2 \tag{2}$$

where Pc stands for the phthalocyaninato dianion. The mechanism at the catalyst-adsorbed system at pH 7, on the other band, may be different, since the potential difference between the $Co^{II/I}$ redox couple and O_2 reduction is very large (ca. 200 mV[25]). A reaction mechanism such as a CE (chemical step followed by electron transfer) mechanism (Eqs. 3 and 4) might be considered.[24b]

$$Co^{II}Pc + O_2 \longrightarrow Co^{II}PcO_2 \tag{3}$$

$$Co^{II}PcO_2 + 2e + 2H^+ \longrightarrow Co^{II}Pc + H_2O_2 \tag{4}$$

Some responses in the catalyst-dissolved system in aqueous solution at pH 1 are displayed in Fig. 5. In deaerated solutions, the bare GC electrode detected aggregated[22] electroactive species (curves a and b). When O_2 was admitted, the amount of catalytic O_2 reduction current (curve c), which is proportional to the square root of scan rate (curve d), is approximately the same as that in the catalyst-adsorbed systems, and its potential is much more positive than the $Co^{II/I}$ redox couple. Results at the catalyst-dissolved system at pH 7 are similar to those at pH 1 (Table 2). Since the potential difference between the $Co^{II/I}$ redox couple and O_2 reduction is large, it appears difficult to expalin the mechanism as an EC process which has frequently been adopted for O_2 reduction in catalyst-dissolved systems in the past.[20,26] The reduction mechanisms may be affected by pH value, by the kind of solvents used for adsorption of catalysts and so on. However, we can extract at least the following information based on the data in Table 2 and the above mentioned experimental observations. i) The O_2 reduction potential at GC electrode modified in AN is slightly (20—50 mV) more positive than that prepared in water. ii) The $Co^{II/I}$ redox couple shifts anodically by adsorption onto electrodes, by about 300 mV at pH 1 and 50—70 mV at pH 7. iii) O_2 reduction occurs at more positive potential in the catalyst-adsorbed system than in the catalyst-dissolved system by ca. 20—100 mV. iv) Both monomeric and aggregated forms of the catalyst have catalytic activity toward O_2 electroreduction.

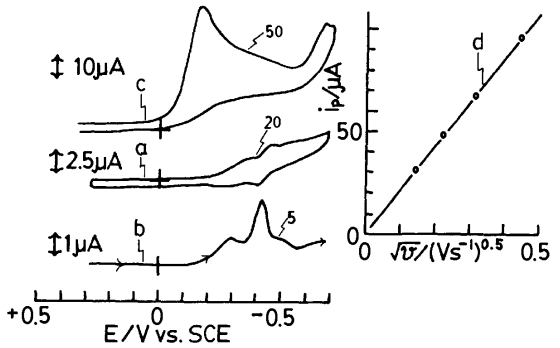

Fig. 5. Cyclic- and differential pulse voltammetric responses at bare GC electrodes in 0.05 M H_2SO_4 solution containing 0.5 mM of **III**. Curves a and b, in deaerated solution, and curve c in O_2-saturated solution. Line d shows the relationship between peak currents in curve c and the square root of the scan rate. Numbers on curves indicate scan rate in mV s^{-1}.

In trying to elucidate reasons for the above observations, and especially iii), we attempted scanning electron microscopy and surface enhanced Raman scattering spectroscopy. However, the amount of adsorbed catalyst was too small for the former spectroscopy and the GC surface was too dark for the latter spectroscopy.

In conclusion, although we cannot yet give a rationale for all the newly observed phenomena, the preparation of amphiphilic phthalocyanines has enabled us to connect and compare phthalocyanine chemistry in organic solvents and in water, which has not previously been possible. Thus, monomer-dimer transformation of phthalocyanines in water-organic solvent mixtures was found to depend on the polarity of organic solvents used. And, although no clear rationale could be given, electroreduction of oxygen at modified electrode was found to be affected not only by the pH value of solution but also by the solvents used for adsorption of catalysts.

We thank Dr. W. A. Nevin for critically reading this manuscript.

Preparation and Spectroscopic Characteristics of Geometrical Isomers of Bis[1,2-bis(dimethylphosphino)ethane]cobalt(III) Complexes with Thiolate Ligands

Takumi KONNO,* Zhi-Ping BAI, Ken-ichi OKAMOTO, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received June 5, 1989)

The thiolato cobalt(III) complexes, $[Co(SR)_2(dmpe)_2]^+$, where R denotes CH_3, C_2H_5, or $CH_2C_6H_5$ and dmpe denotes 1,2-bis(dimethylphosphino)ethane, were newly prepared from *trans*-$[CoCl_2(dmpe)_2]^+$ and monothiolate ligands. The cis and trans isomers were formed for R=CH_3 and $CH_2C_6H_5$, while only the trans isomer was formed for R=C_2H_5. These isomers were assigned on the basis of the ^1H NMR (500 MHz) and absorption spectra in comparison with those of the newly prepared $[Co(SCH_2CH_2S)(dmpe)_2]^+$ complex. The trans isomer showed the sulfur-to-cobalt charge-transfer band at lower energy than that of the cis isomer.

Cobalt(III) complexes with two or three thiolato donor atoms prefer to take the cis(*S*) geometry,[1-3] and no trans isomer has been obtained for $[Co(SR)_2(amine)_4]^+$ (R=CH_3, C_2H_5, $CH_2C_6H_5$, and C_6H_5).[4] On the other hand, chelating diphosphine ligands, such as dmpe (1,2-bis(dimethylphosphino)ethane) and depe (1,2-bis(diethylphosphino)ethane), tend to favor the formation of *trans*-$[CoX_2(diphosphine)_2]^+$ (X=Cl, Br, and I).[5-8] This trend reveals that the trans(*S*) geometry is possibly formed in the $[Co(SR)_2(diphosphine)_2]$-type complex. The present work is concerned with the preparation of $[Co(SR)_2(dmpe)_2]^+$ (R=CH_3, C_2H_5, and $CH_2C_6H_5$), and the trans(*S*) isomers are presented. The isomers obtained were characterized on the basis of the ^1H NMR (500 MHz) and absorption spectra in comparison with those of the newly prepared $[Co(SCH_2CH_2S)(dmpe)_2]^+$. This is the first example of cobalt(III) complexes containing both diphosphine and monothiolate ligands.

Experimental

A) Preparation of Complexes. (1) The starting complex, *trans*-$[CoCl_2(dmpe)_2]ClO_4$, was prepared by the method of Ohishi et al.[6] Found: C, 26.91; H, 6.13%. Calcd for $[CoCl_2(dmpe)_2]ClO_4 \cdot 0.5H_2O = C_{12}H_{33}O_{4.5}Cl_3P_4Co$: C, 26.76; H, 6.18%.

(2) *cis*- and *trans*-$[Co(SCH_3)_2(dmpe)_2]X$ (X=PF_6 and $B(C_6H_5)_4$). To a solution containing 0.1 g of *trans*-$[CoCl_2(dmpe)_2]ClO_4 \cdot 0.5H_2O$ (0.19 mmol) in 20 cm^3 of degassed methanol was added 0.06 g of $NaSCH_3$ (0.86 mmol) in 1 cm^3 of methanol. The mixture was stirred at 50 °C for 30 min under a nitrogen atmosphere, whereupon the solution became deep brown. To this was added 1 g of $NaPF_6$ in 10 cm^3 of water and the solution was allowed to stand in a refrigerator overnight. The resulting brown crystals of *trans*-$[Co(SCH_3)_2(dmpe)_2]PF_6$ (**A-1**) were collected by filtration. The filtrate was kept in a freezer overnight and the resulting **A-1** precipitate was again filtered off. To this filtrate was added 0.1 g of $NaB(C_6H_5)_4$ in 2 cm^3 of methanol. After the mixture was allowed to stand in a refrigerator for 1 h, the resulting greenish-brown precipitate of *cis*-$[Co(SCH_3)_2(dmpe)_2]B(C_6H_5)_4$ (**A-2**) was collected by filtration. The **A-2** isomer was recrystallized from acetone by adding a small amount of $NaB(C_6H_5)_4$ in methanol. **A-1** isomer: Yield: 0.05 g, 45%. Found: C, 28.17; H, 6.47%. Calcd for $[Co(SCH_3)_2(dmpe)_2]PF_6 = C_{14}H_{38}F_6P_5S_2Co$: C, 28.10; H, 6.40%. **A-2** isomer: Yield: 0.03 g, 20%. Found: C, 59.04; H, 7.66%. Calcd for $[Co(SCH_3)_2(dmpe)_2]B(C_6H_5)_4$: C, 59.07; H, 7.57%.

The trans (**A-1**) and cis (**A-2**) isomers of $[Co(SCH_3)_2(dmpe)_2]^+$ were also formed in nearly the same ratio as that observed above, using $[Co(CO_3)(dmpe)_2]ClO_4 \cdot 2.5H_2O \cdot NaClO_4$[9] as the starting complex instead of *trans*-$[CoCl_2(dmpe)_2]ClO_4 \cdot 0.5H_2O$.

(3) *trans*-$[Co(SC_2H_5)_2(dmpe)_2]PF_6$. This complex (**B-1**) was prepared by a method similar to that described above for *trans*-$[Co(SCH_3)_2(dmpe)_2]PF_6$ (**A-1**), using 0.06 cm^3 of neat HSC_2H_5 (0.81 mmol) and 0.3 cm^3 of 1 mol dm^{-3} NaOH (0.30 mmol) instead of $NaSCH_3$. No significant formation of the cis isomer was noticed in this reaction or in a reaction where $[Co(CO_3)(dmpe)_2]ClO_4 \cdot 2.5H_2O \cdot NaClO_4$ was used as the starting complex instead of *trans*-$[CoCl_2(dmpe)_2]ClO_4 \cdot 0.5H_2O$. Yield: 0.04 g, 34%. Found: C, 30.55; H, 6.68%. Calcd for $[Co(SC_2H_5)_2(dmpe)_2]PF_6 = C_{16}H_{42}F_6P_5S_2Co$: C, 30.68; H, 6.76%.

(4) *cis*- and *trans*-$[Co(SCH_2C_6H_5)_2(dmpe)_2]X$ (**X**=ClO_4 and $B(C_6H_5)_4$). The two isomers, trans (**C-1**) and cis (**C-2**), of $[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$ were prepared and separated by a method similar to that described above for $[Co(SCH_3)_2(dmpe)_2]^+$, using 0.1 cm^3 of neat $HSCH_2C_6H_5$ (0.85 mmol) and 0.3 cm^3 of 1 mol dm^{-3} NaOH (0.30 mmol) instead of $NaSCH_3$. The trans (**C-1**) isomer was obtained as the perchlorate salt using a small amount of a saturated $NaClO_4$ solution instead of $NaPF_6$. It was found from the absorption and ^1H NMR (500 MHz) spectral measurements that the tetraphenylborate salt is the cis (**C-2**) isomer containing a small amount of the trans (**C-1**) isomer. **C-1** isomer: Yield: 0.045 g, 34%. Found: C, 44.12; H, 6.72%. Calcd for $[Co(SCH_2C_6H_5)_2(dmpe)_2]ClO_4 = C_{26}H_{46}O_4P_4S_2ClCo$: C, 44.29; H, 6.58%. $B(C_6H_5)_4$ salt: Yield: 0.03 g, 17%. Found: C, 63.98; H, 7.06%. Calcd for $[Co(SCH_2C_6H_5)_2(dmpe)_2]B(C_6H_5)_4 \cdot H_2O = C_{50}H_{64}BP_4S_2Co \cdot H_2O$: C, 63.83; H, 7.07%.

(5) $[Co(SCH_2CH_2S)(dmpe)_2]PF_6$. This complex was prepared by a method similar to that described for $[Co(SCH_3)_2(dmpe)_2]PF_6$, using 0.05 cm^3 of neat $HSCH_2CH_2SH$ (0.60 mmol) and 0.3 cm^3 of 1 mol dm^{-3} NaOH (0.30 mmol) instead of $NaSCH_3$. The reaction was conducted at room temperature for 30 min. Yield: 0.04 g, 35%. Found: C, 28.60; H, 6.02%. Calcd for $[Co(SCH_2CH_2S)(dmpe)_2]PF_6 = C_{14}H_{36}F_6P_5S_2Co$: C, 28.20; H, 6.08%.

B) Measurements. The electronic absorption spectra were recorded in CH_3CN with JASCO UVIDEC-505 and UVIDEC-610 spectrophotometers at ambient temperatures. The 500 MHz ^1H NMR spectra were recorded with a BRUKER-AM-500 NMR spectrometer in CD_3CN at the probe temperature. Tetramethylsilane (TMS) was used at the internal reference.

Results and Discussion

Two geometrical isomers, cis and trans, are possible for $[Co(SR)_2(dmpe)_2]^+$ (R=CH_3, C_2H_5, and $CH_2C_6H_5$), while only one isomer having the cis(*S*) configuration is possible for $[Co(SCH_2CH_2S)(dmpe)_2]^+$ (Fig. 1). In the 500 MHz ^1H NMR spectrum (Fig. 2), $[Co(SCH_2CH_2S)(dmpe)_2]^+$ exhibits characteristic P-methyl signals in the region of δ 1.4—1.6 (from TMS). That is, four sets of signals due to the eight P-CH_3 groups in the complex are observed (Fig. 2a), reflecting the C_2 symmetry of the complex. A quite similar ^1H NMR spectral pattern is observed for the **A-2** isomer of $[Co(SCH_3)_2(dmpe)_2]^+$, though two signals due to the two S-CH_3 groups appear (δ 1.589 and 1.594) besides four sets of signals due to the eight P-CH_3 groups in the region of δ 1.4—1.6 (Fig. 2b). On the other hand, the **A-1** isomer of $[Co(SCH_3)_2(dmpe)_2]^+$ shows one set of P-methyl signals which appears as a quintet at δ 1.629 (J=2.2 Hz) and one singlet S-methyl signal at δ 1.304 (Fig. 2c). The starting *trans*-$[CoCl_2(dmpe)_2]^+$ complex also gave one set of quintet P-methyl signals at δ 1.572 (J=2.4 Hz). These ^1H NMR spectral behavior indicate that the **A-1** and **A-2** isomers are *trans*- and *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$, respectively. The ^1H NMR spectral behavior of the **B-1** isomer of $[Co(SC_2H_5)_2(dmpe)_2]^+$ and the **C-1** isomer of $[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$ are similar to that of *trans*-$[Co(SCH_3)_2(dmpe)_2]^+$ (**A-1**), showing one set of quintet signals due to the eight P-CH_3 groups in the complex (δ 1.623 (J=2.2 Hz) for **B-1** and δ 1.718 (J=2.1 Hz) for **C-1**). Furthermore, the **B-1** isomer shows one set of triplet signals (δ 1.061, J=7.3 Hz) and one set of quartet signals (δ 1.718, J=7.3 Hz) due to the two SC_2H_5 groups, and the **C-1** isomer shows one singlet signal due to the two S-CH_2- groups at δ 2.931. Accordingly, the **B-1** and **C-1** isomers can be assigned to the trans(*S*) configuration. In the ^1H NMR spectrum of the tetraphenylborate salt of $[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$, four sets of P-methyl signals are observed (centered at δ 1.486, 1.566, 1.629, and 1.775) as in the case of *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$ (**A-2**), in addition to one set of quintet P-methyl signals which corresponds to the signals arising from *trans*-$[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$ (**C-1**). The ^1H NMR spectrum suggests that the tetraphenylborate salt is the cis isomer containing a small amount of the trans one. This is supported by the fact that absorption spectral behavior of this salt agrees with that of *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$ (Fig. 3).

As shown in Fig. 3 and Table 1, the absorption spectrum of *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$ is quite similar to that of $[Co(SCH_2CH_2S)(dmpe)_2]^+$ in the whole

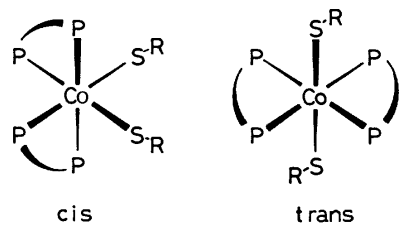

Fig. 1. Two geometrical isomers of $[Co(SR)_2(dmpe)_2]^+$.

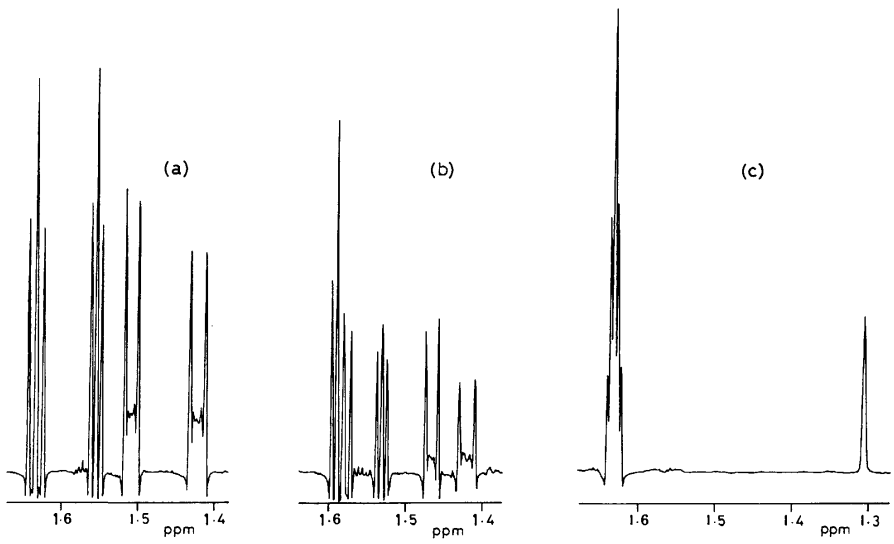

Fig. 2. ^1H NMR (500 MHz) spectra of $[Co(SCH_2CH_2S)(dmpe)_2]^+$ (a), *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$ (b), and *trans*-$[Co(SCH_3)_2(dmpe)_2]^+$ (c) in CD_3CN (TMS reference).

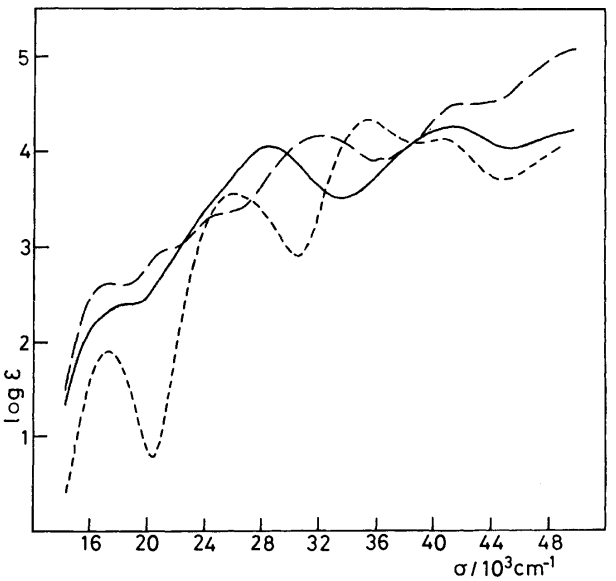

Fig. 4. Absorption spectra of *trans*-$[Co(SCH_3)_2(dmpe)_2]^+$ (——), *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$ (———), and *trans*-$[CoCl_2(dmpe)_2]^+$ (-----) in CH_3CN.

region, though the absorption components of the former complex shift to a somewhat lower energy than those of the latter. On the other hand, the absorption spectral behavior of *trans*-$[Co(SCH_3)_2(dmpe)_2]^+$ differs significantly from those of $[Co(SCH_2CH_2S)(dmpe)_2]^+$ and *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$, especially in the near-UV region (Fig. 4). Namely, the trans SCH_3 isomer exhibits an intense absorption band at 28.53×10^3 cm^{-1}, while the cis SCH_3 isomer exhibits a broad intense band at 32.15×10^3 cm^{-1}. The corresponding broad intense band of $[Co(SCH_2CH_2S)(dmpe)_2]^+$ appears at 33.17×10^3 cm^{-1} (Fig. 3). Quite similar intense absorption bands, which have been assigned to the S-to-Co charge-transfer (SCCT) bands, were observed for the trans(*S*) and cis(*S*) isomers of [Co(quadridentate-SNNS)(diamine)]$^+$:[10] a sharp band at ca. 30×10^3 cm^{-1} for the trans(*S*) isomer and a broad band at ca. 34×10^3 cm^{-1} for the cis(*S*) isomer. For the present $[Co(thiolato)_2(diphosphine)_2]^+$-type complexes, it may be considered that the coordinated diphosphine ligand contributes to the absorption spectral behavior in this region. As shown in Fig. 4, however, *trans*-$[CoCl_2(dmpe)_2]^+$ exhibits an intense band at 35.46×10^3 cm^{-1}, which has been assigned as arising from the P-to-Co charge-transfer (PCCT) transition.[8] Taking this fact into consideration, it is probable that the intense bands for the present isomers are due to the SCCT transition rather than to the PCCT transition. In order to confirm the absorption spectral behavior of the trans and cis isomers, $[Co(SC_2H_5)_2(dmpe)_2]^+$ and $[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$ were also newly prepared. The absorption spectra of the trans SC_2H_5 and $SCH_2C_6H_5$ isomers coincide well with that of *trans*-$[Co(SCH_3)_2(dmpe)_2]^+$ over the whole region (Fig. 5 and Table 1), showing the SCCT band at ca. 28.5×10^3 cm^{-1}. The tetraphenylborate salt of $[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$, which is the cis isomer containing a small amount of the trans one (vide supra), gives a broad SCCT band at ca. 32×10^3 cm^{-1} (Fig. 3), as in the case of *cis*-$[Co(SCH_3)_2(dmpe)_2]^+$. Thus, it is also valid for the present dmpe complexes that the cis(*S*)- and trans(*S*)-type isomers are discriminated on the basis of the relative position of the SCCT bands.[10-13] The cis and trans isomers of $[Co(SCH_3)_2(dmpe)_2]^+$ also show noticeable absorption spectral difference in the visible region (Fig. 4 and Table 1). It has been reported that the cis(*S*) and trans(*S*) isomers of [Co(quadridentate-SNNS)(diamine)]$^+$ can be assigned by the splitting pattern of the first d-d absorption bands.[10] However, it is difficult for the

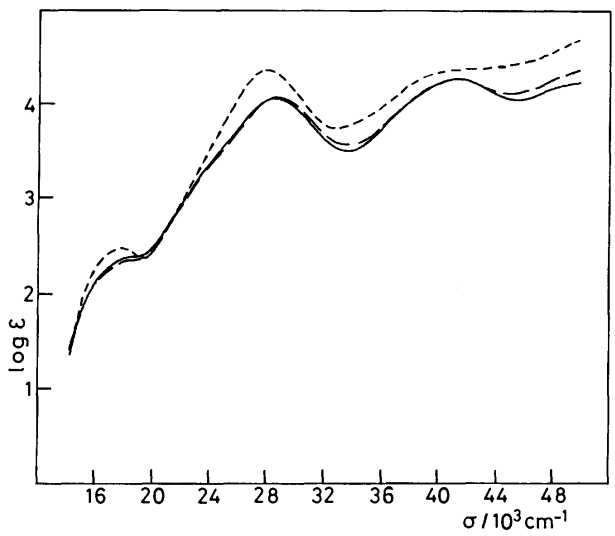

Fig. 5. Absorption spectra of *trans*-$[Co(SCH_3)_2(dmpe)_2]^+$ (——), *trans*-$[Co(SC_2H_5)_2(dmpe)_2]^+$ (— — —), and *trans*-$[Co(SCH_2C_6H_5)_2(dmpe)_2]^+$ (-----) in CH_3CN.

present dmpe complexes to assign the two isomers on the basis of the absorption spectral difference in the visible region.

In this study, a direct treatment of *trans*-$[CoCl_2(dmpe)_2]^+$ with monothiolate ligands produced the $[Co(SR)_2(dmpe)_2]^+$ (R=CH_3, C_2H_5, and $CH_2C_6H_5$) complexes. The trans isomer was formed for all three complexes, while the cis isomer was formed for two complexes (R=CH_3 and $CH_2C_6H_5$). Furthermore, each of the two cis isomers was formed in small amount compared with the corresponding trans isomer. A quite similar preparative result was also obtained by a method in which $[Co(CO_3)(dmpe)_2]^+$ was used as the starting complex instead of *trans*-$[CoCl_2(dmpe)_2]^+$. These results are in contrast to the cis(*S*) selective formation as found in [Co(L-cysteinato-*N*,*S*)$_3$]$^{3-}$,[1,2] [Co(D-penicillaminato-*N*,*O*,*S*)$_2$]$^-$,[3] and $[Co(SR)_2(amine)_4]^+$ (R=CH_3, C_2H_5, $CH_2C_6H_5$, and C_6H_5),[4] and indicate that the trans(*S*) geometry is dominant for $[Co(SR)_2(dmpe)_2]^+$ complexes. Namely, the dmpe ligand functions dominantly in forming *trans*-$[Co(SR)_2(dmpe)_2]^+$. It has been reported that the *cis*-$[CoX_2(dmpe)_2]^+$ (X=Cl, Br, and I) complexes isomerized to the trans isomer and the isomerization reaction was accelerated by ultraviolet light.[8] In contrast to *cis*-$[CoX_2(dmpe)_2]^+$, the present cis and trans isomers of $[Co(SR)_2(dmpe)_2]^+$ in solution are fairly stable in the dark; the intensities of their SCCT bands in CH_3CN or CH_3CN–H_2O (4:1) decreased slightly with time at room temperature (ca. 1.5% in 60 min). No isomerization occurred for the present isomers, even when the solution was exposed to ultraviolet light, though decomposition was promoted. These facts suggest that the cis(*S*) preference of the thiolate ligand prevents the isomerization to the trans(*S*) isomer.

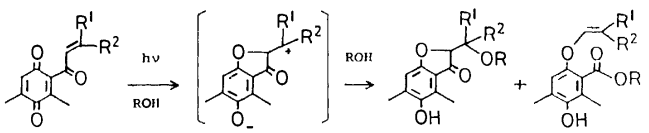
Photoinduced Intramolecular Cyclization Reaction of 3-Substituted 2-Alkenoyl-1,4-benzoquinones

Hidetoshi IWAMOTO
Department of Chemistry, Faculty of Science, Shimane University, Nishikawatsu-cho, Matsue 690
(Received January 20, 1989)

Irradiation of 3-alkoxy-2-alkenoyl-1,4-benzoquinones in solution gave tricyclic compounds (5*H*-pyrano-[4,3,2-*de*][1,3]benzodioxin derivatives) and 3-alkylthio-2-alkenoyl-1,4-benzoquinones gave similar products (5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin derivatives). Each reaction initiates via γ-hydrogen abstraction by photoexcited quinone to produce diradical intermediates which intramolecularly cyclize to give the products.

Such isoprenoid 1,4-quinones as plastoquinone, ubiquinone, and menaquinone have been well known to play important roles in nature,[1] e.g. in processes such as electron transport and oxidative phosphorylation. The photochemical reactions of related quinone compounds, therefore, have been extensively investigated under several conditions.[2] For example, irradiation of isoprenoid 1,4-quinones under aerobic conditions gives trioxane and hydroperoxide, but that of the quinones under anaerobic conditions gives dihydrobenzofuran, chromene, or dimer.[2] Chlorobiumquinone,[3] which is an alkenoyl-1,4-quinone with both an olefinic double bond and a carbonyl group in the side chain, was isolated from a natural source. An investigation of the photochemical reactions of 2-alkenoyl-1,4-benzoquinones **1** is, therefore, of interest from both biological and photochemical points of view.



1 **2** **3** **4** (1)

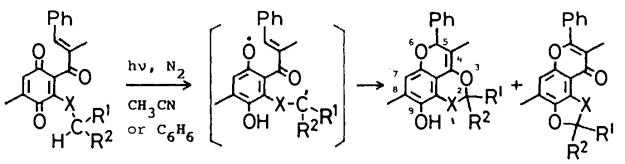
It has been reported that irradiation of alkenoyl quinones **1** in benzene under aerobic conditions affords relatively stable cyclic peroxides.[4] Recently, we reported the photochemical reaction of **1** in alcohols under anaerobic conditions to give two isomeric adducts (**3** and **4**)[5] via a zwitterionic intermediate **2** (Eq. 1). Afterwards, we preliminarily reported that 2-alkenoyl-3-alkoxy-1,4-benzoquinones (**5G**) reacted photochemically to give intramolecular cyclization products, 5*H*-pyrano[4,3,2-*de*][1,3]benzodioxin derivatives (**7G**),[6] via γ-hydrogen abstraction (Eq. 2). The photoinduced γ-hydrogen abstraction of alkoxyquinones[7] or the intramolecular cyclization reaction of 2-alkenyl-3-alkoxy-1,4-quinone,[8] and the intermolecular photochemical reaction of alkoxyquinones with olefins[9] have been extensively investigated so far.

In this paper, we describe the photochemical reaction of alkoxybenzoquinones **5G** and 2-alkenoyl-3-alkylthio-1,4-benzoquinones (**5S**) which are noticeably different from that of other alkoxyquinones; the quinones **5G** gave intramolecularly cyclized products **7G**, and **5S** gave similar cyclization products, 5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin derivatives (**7S**), in high yields together with minor products, 9*H*-[1,3]oxathiolo[4,5-*f*][1]-benzopyran-9-one derivatives (**8S**)[10] (Eq. 2).

Results and Discussion

Photochemical Reaction of 5G in Acetonitrile. When a solution of 3-methoxy-5-methyl-2-(α-methylcinnamoyl)-1,4-benzoquinone (**5Ga**) in acetonitrile (0.01 mol dm^{-3}) was irradiated with light at wavelengths longer than 410 nm under a nitrogen atmosphere for 3 h, an intramolecularly cyclized product, 4,8-dimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]benzodioxin-9-ol (**7Ga**), was obtained as the major product in 50% yield. The structure of **7Ga** was elucidated by its spectral data and chemical transformation, as reported in a previous paper.[6] Similarly, other alkoxyquinones **5Gb—f** reacted under the same conditions to give **7Gb—f** in reasonable yields. All of the products **7Gb—f**, except **7Gd**, were mixtures of diastereoisomers. In the case of **7Gb**, the diastereoisomers were separated by TLC into each isomer after acetylation.

On the other hand, in the cases of the reaction of **5Gd** and **5Ge**, other minor products, **8Gd** and **8Ge**,[11] were respectively obtained, even though in low yields. The results are summarized in Table 1. The relative



5G (X=O) **6G** **7G** **8G**
5S (X=S) **6S** **7S** **8S**

a: $R^1=R^2=H$; b: $R^1=H$, $R^2=Me$; c: $R^1=H$, $R^2=Et$; d: $R^1=R^2=Me$; e: $R^1=Me$, $R^2=Et$; f: $R^1=H$, $R^2=Ph$ (2)

Table 1. Photochemical Reaction of 5[a]

Quinone	Substituents		Yields of products/%[b]	
	R^1	R^2	**7**	**8**
5Ga	H	H	50[c]	0
5Gb	H	Me	75	0
5Gc	H	Et	81	0

5Ge	Me	Et	72	8
5Gf	H	Ph	81	0
5Sb	H	Me	75	15
5Sc	H	Et	70	17
5Sd	Me	Me	80	7
5Se	Me	Et	89	7
5Sf	H	Ph	66	24
5Sg	$XCHR^1R^2$=SBu^t		0[d]	0[d]

a) Acetonitrile was used for **5G** and benzene was used for **5S**. b) Isolated yields based on the quinone used. Hydroquinones of **5S** were obtained as another minor products. The recovered quinones were mostly under 10 per cent for **5G** and were nothing for **5S**. c) **5Ga** was recovered in a 31% yield. d) **5Sg** was almost recovered.

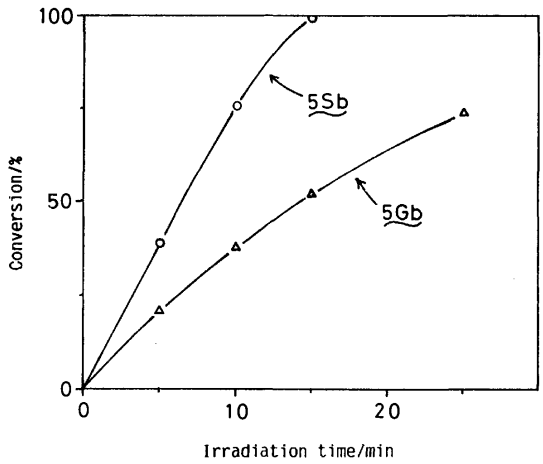

Fig. 1. Comparison of the photoreactivity of **5Gb** and **5Sb**. These reactions were carried out in $CDCl_3$ (ca. 0.026 mol dm^{-3}) and the conversion of quinones was determined by the use of ^{1}H NMR spectrometer.

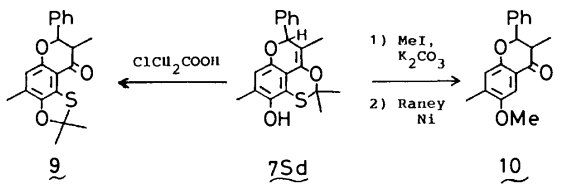
reactivity of **5Ga**, **b**, and **d** having methoxyl, ethoxyl, and isopropoxyl groups increases in this order by 1:2:3.[6]

From these results, as depicted in Eq. 2, the reaction could proceed through γ-hydrogen abstraction by excited quinone carbonyl. Probably the resulting diradical **6G** intramolecularly attacks the carbonyl oxygen in the alkenoyl side chain, and finally cyclizes to give **7G**. This sort of bicyclo-cyclization reaction initiated by γ-hydrogen abstraction is quite novel.

Photochemical Reaction of 5S in Benzene. Irradiation of 3-isopropylthio-5-methyl-2-(α-methylcinnamoyl)-1,4-benzoquinone (**5Sd**) in benzene for 1.5 h under the same conditions as described in the reaction of **5G** gave two cyclization products, 2,2,4,8-tetramethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin-9-ol (**7Sd**, 80%) and 2,2,4,8-tetramethyl-7-phenyl-9*H*-[1,3]oxathiolo[4,5-*f*][1]benzopyran-9-one (**8Sd**, 7%).[10] The structure of **7Sd** was elucidated by its spectral data. The ^{1}H NMR data of **7Sd** showed similar signal patterns to that of **7Gd**; for instance, **7Sd** showed four singlet peaks at δ 1.60, 1.64, 1.78, and 2.10 due to four methyl groups, three singlet peaks at δ 4.52, 5.57, and 6.24 due to hydroxyl, methine, and aromatic protons, and one singlet peak at δ 7.27 due to a phenyl group. The structure of **7Sd** was further confirmed by chemical derivations with chloroacetic acid to 2,2,4,8-tetramethyl-7-phenyl-7,8-dihydro[1,3]-oxathiolo[4,5-*f*][1]benzopyran-9-one (**9**, 63%) and by



9 **7Sd** **10** (3)

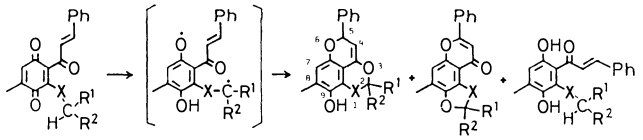
the oxidation of **7Sd** with chloranil to give a stable product **8Sd**.[10] Moreover, the desulfurization[12] of methylated **7Sd** with Raney nickel gave 6-methoxy-3,7-dimethyl-2-phenyl-4-chromanone (**10**, 42%) (Eq. 3).

Similarly, other alkylthioquinones **5Sd—f** reacted to afford **7Sb—f** in good yields together with minor products **8Sd—f** (Table 1). Product **8S** was independently prepared from **7S** by oxidation with chloranil or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).[10]

Thus, the photochemical reaction of alkylthioquinones **5S** in benzene solution was similar to that of alkoxyquinones **5G**. However, the photochemical reaction of **5Sb** was more effective than that of **5Gb**, as shown in Fig. 1.

Irradiation of 3-*t*-butylthio-5-methyl-2-(α-methylcinnamoyl)-1,4-benzoquinone (**5Sg**) for 3 h under the same conditions, however, gave no products and most of **5Sg** was recovered. Therefore, the present reaction proceeds via γ-hydrogen abstraction from the alkylthio group. As expected, the quantum yield of the disappearance of isopropylthioquinone (**5Sd**, Φ=0.50) is larger than that of ethylthioquinone (**5Sb**, Φ=0.30).

Photochemical Reaction of 11G and 11S. Irradiation of an acetonitrile solution of 2-cinnamoyl-3-methoxy-5-methyl-1,4-benzoquinone (**11Ga**), which has no α-methyl group in the alkenoyl side chain, afforded a mixture of 8-methyl-5-phenyl-5*H*-pyrano-[4,3,2-*de*][1,3]benzodioxin-9-ol (**13Ga**, 24%) and 2-cinnamoyl-3-methoxy-5-methylhydroquinone (**15Ga**, 7%) (Eq. 4). The products were separated by column chromatography after acetylation. The structure of each acetate was determined on the basis of spectral data (see Experimental). Other alkoxyquinones, **11Gb** and **11Gd**, similarly reacted to give a mixture of the corresponding **13G** and **15G**. In the case of the reaction of **11Gd** another minor product **14Gd** was obtained.



11G (X=O) 12G 13G 14G 15G

11S (X=S) 12S 13S 14S 15S

a: $R^1=R^2=H$; b: $R^1=H$, $R^2=Me$; d: $R^1=R^2=Me$ (4)

Irradiation of a benzene solution of 2-cinnamoyl-3-ethylthio-5-methyl-1,4-benzoquinone (**11Sb**) for 3 h gave a mixture of 2,8-dimethyl-5-phenyl-5*H*-pyrano-[4,3,2-*de*][3,1]benzoxathiin-9-ol (**13Sb**, 31%), 2,4-dimethyl-7-phenyl-9*H*-[1,3]oxathiolo[4,5-*f*][1]benzo-pyran-9-one (**14Sb**, 29%), and hydroquinone (**15Sb**, 12%). After separation by column chromatography their structures were determined on the basis of spectral data. Another quinone **11Sd** similarly reacted to give a mixture of **13Sd**, **14Sd**, and **15Sd**. The yields of the products are summarized in Table 2.

Effect of α-Methyl Group in the Alkenoyl Side Chain. As shown in Tables 1 and 2, the yields of **13** are appreciably less than those of **7**. Thus, the presence of the α-methyl group in the alkenoyl side chain is favorable for a higher yield of **7**. The structural change of alkyl groups in the alkoxyl or alkylthio groups in **11** only slightly affects the yield of product **13**. Therefore, the differences of the yields between **7** and **13** could be ascribed to the presence or absence of the α-methyl group in the alkenoyl side chain. These results may be explained on the basis of the equilibrium of intermediates **17** and **18** or **20** and **21**, as shown in Scheme 1. The ratio of **17**/**18** could be larger than that of **20**/**21** because of a steric hindrance of the methyl group derived from the alkenoyl side chain. This is one reason why the amount of product **7** is greater than that of **13**.

Table 2. Photochemical Reaction of **11**

Quinone	Substituents		Yields of products/%[a]		
	R^1	R^2	**13**	**14**	**15**
11Ga	H	H	24	0	7
11Gb	H	Me	30	0	16
11Gd	Me	Me	28	10	18
11Sb	H	Me	31	29	12
11Sd	Me	Me	58	19	9

a) Isolated yields based on the quinone used. The starting quinones **11Ga**, **b**, and **d** were recovered in 40, 37, and 15% yields, respectively, and **11S** was not recovered.

On the other hand, the hydrogen at the 5-position of products **7** and **13** should be highly activated, since its hydrogen is situated in the benzylic, allylic, and alkoxyl α-position. Actually, product **13** was easily oxidized by quinone **11** to give **14**.[10,13] Contrary to the expectation, the hydrogen at the 5-position of **7S** is resistant[14] to oxidation owing to the bigger steric hindrance from the surrounding methyl group. As a result, product **7** is moderately more stable than **13**.

Photochemical Reaction of 5 in Alcohols. Upon

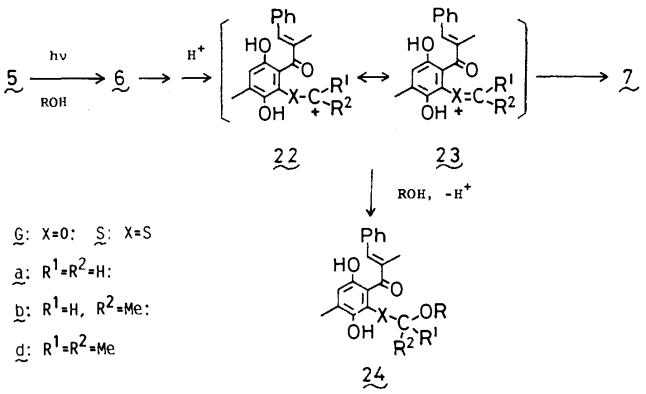
9	**5Sd**	Me	Me	MeOH	80	5	0	5

a) Isolated yields based on the quinone used. The other alcohol adducts (type **3** and **4**) and minor unidentified products were obtained. b) **5H** is the hydroquinone of **5**.

irradiation in a methanol solution, the quinones **5** reacted competitively to give cyclization products **7** and/or alcohol adducts (type **3** and **4**, see Eq. 1).[5] As shown in Table 3, all the quinones **5** gave cyclization products **7**. Especially, **5Gd** and **5Sd**, having an isopropoxy or isopropylthio group at the 3-position, gave cyclization products **7Gd** and **7Sd** in high yields (Runs 4 and 9). Thus, the γ-hydrogen abstraction was more preferential than the adduct formation with alcohol.[5]

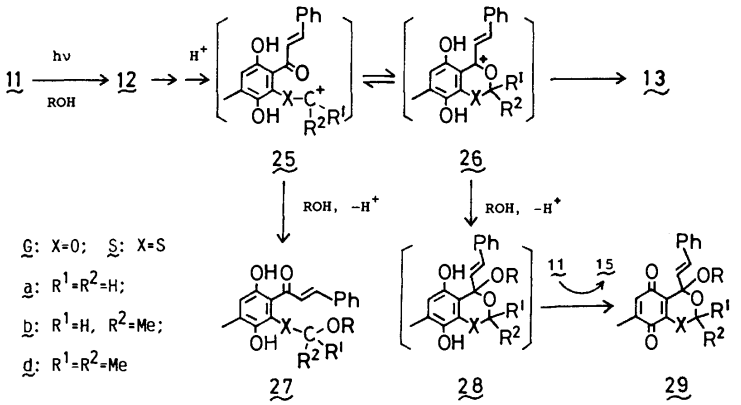
On the other hand, ethylthioquinone **5Sb** (Run 5) gave another type of methanol adduct **24SbM** (50%, R=Me). The adduct **24SbM** can be afforded by the addition of methanol to the cationic intermediate **22Sb**, which probably forms by an intramolecular electron transfer of **6Sb** followed by a protonation and is stabilized by conjugation with a lone-pair electron of the adjacent sulfur atom, as indicated in **23Sb** (Scheme 2). However, isopropylthioquinone **5Sd** (Run 9) gave no methanol adduct **24SdM**, though the cyclization product **7Sd** was obtained in high yield. This can be explained by a steric hindrance for the addition of methanol to the tertiary cation of intermediate **22Sd** (R^1=R^2=Me). The presence of such a steric hindrance can also be supported by the fact that the formation of the alcohol adduct **24Sb** decreased in turn from methanol to ethyl, isopropyl, and *t*-butyl alcohols (Runs 5—8) and the formation of the cyclization product **7Sb** was increased in this order.



Scheme 2.

In the case of ethoxyquinone **5Gb**, only a small amount of **24Gb** was isolated. It may be suggested that the intermediate **22Gb** is less reactive with alcohols than **22Sb**. On the other hand, since the reaction of **5Gb** in isopropyl alcohol (Run 3) gave **7Gb** in high yield, the absence of the adduct **24Gd** in the reaction of the isopropoxyquinone **5Gd** (Run 4) must also be ascribed to the same reason applied for the case of isopropylthioquinone **5Sd**.

Photochemical Reaction of 11 in Alcohols. The reaction of a methanol solution of **11S**, which has no α-methyl group in the alkenoyl side chain (Table 4, Runs 14 and 15), showed a similar tendency to that of **5S**: The quinones **11S** gave cyclization products **13S**



Scheme 3.

Table 4. Photochemical Reaction of **11** in Alcohols

Run	Quinone	Substituents		Solvent	Yields of products/%[a]			
		R^1	R^2		**13**	**27**	**29**	**15**
10	**11Ga**	H	H	MeOH	0	0	16	30
11				*i*-PrOH	9	0	6	16
12	**11Gb**	H	Me	MeOH	0	0	18	32
13	**11Gd**	Me	Me	MeOH	0	0	15	35
14	**11Sb**	H	Me	MeOH	22	22	0	23
15	**11Sd**	Me	Me	MeOH	84	0	0	6

a) Isolated yields based on the quinone used. The other alcohol adducts (type **3** and **4**), **14S**, and other minor products were obtained.

and/or methanol adducts (type **3** and **4**); especially **11Sd**, having an isopropylthio group, afforded **13Sd** in high yield. The ethylthioquinone **11Sb** also gave another methanol adduct **27SbM** (22%, R=Me).

In contrast, the irradiation of alkoxyquinones **11G** in methanol (Table 4, Runs 10, 12, and 13) gave no cyclization product **13G**; however, another methanol adduct **29GM** (R=Me) was obtained in considerable yield. Moreover, no other methanol adduct **27G** was formed.

The structure of **29G** was confirmed by its spectral data and by chemical derivations with zinc-acetic anhydride (see Experimental). As shown in Scheme 4, the adduct **29G** can be formed by the addition of an alcohol to cationic intermediate **26G**, followed by oxidation with the starting quinone **11G**. The reaction of **11Ga** in isopropyl alcohol (Run 11) gave not only the adduct **29GaP** (R=*i*-Pr) but also cyclization product **13Ga**, because the addition of an isopropyl alcohol to **26G** becomes difficult for the steric hindrance.

As described above, the product distribution of **11G** in methanol differed from that of **11S** (Table 4). These differences obviously reflect the relative stability of the cationic intermediates, **25G** and **25S**. Thus, the reaction in alcohols proceeds by an ionic process.

In conclusion, upon the irradiation of alkenoylquinones in acetonitrile or benzene, **5** and **11** readily afforded tricyclic compounds **7** and **13**, respectively. The reaction was initiated by the abstraction of γ-hydrogen; the resulting diradical intramolecularly cyclizes the involved alkenoyl side chain to give **7** or **13**. The presence of an α-methyl group in the alkenoyl side chain affects the yield as well as the stability of product **7**. Upon irradiation in alcohol, the reaction probably proceeds through an ionic process via the cationic intermediates to give the products.

Experimental

The instruments and procedures were as previously reported.[5] 3-Alkoxy-5-methyl-2-(α-methylcinnamoyl)-1,4-benzoquinones (**5G**) were prepared by a modified method of

Table 5. Yields and Physical Data of **5** and **11**

a) Reaction conditions: Benzene was used as solvent. b) Reaction conditions: 50 °C. c) $CDCl_3$ was employed for NMR solvent.

Farina and Valderrama[15] from 5-methyl-2-(α-methylcinnamoyl)-1,4-benzoquinone in the following manner. A mixture of 1 mmol of quinone, 1 mmol of $Cu(AcO)_2 \cdot H_2O$,[16] and 50 cm^3 of an alcohol (or added benzene for dissolving) was stirred at 40 °C in the dark overnight under an oxygen atmosphere. After removing the solvent, the residue was purified by column chromatography with benzene as the eluent. All of the obtained quinones **5G** were recrystallized from hexane containing a small amount of benzene to give yellow prisms. 3-Alkoxy-2-cinnamoyl-5-methyl-1,4-benzoquinones (**11G**) were also prepared in the same manner as for **5G** from 2-cinnamoyl-5-methyl-1,4-benzoquinone with the use of 5 mmol of AgOAc instead of $Cu(AcO)_2 \cdot H_2O$. Yields and physical data of **5G** and **11G** are summarized in Table 5.

2-Alkenoyl-3-alkylthio-1,4-benzoquinones, **5S** and **11S**, were also prepared in a similar manner, as follows. A mixture of 2-alkenoyl-1,4-benzoquinone (1 mmol) and thiol (2—10 mmol) in benzene (25 cm^3) was stirred at room temperature overnight under a nitrogen atmosphere. The obtained 2-alkenoyl-3-alkylthiohydroquinone was purified by column chromatography and oxidized with cerium(IV) ammonium nitrate (CAN, 2.5 equiv) at 5 °C for 5 min. The reaction mixture was worked up as usual. All of the resulting quinones were recrystallized from hexane containing a small amount of benzene as orange or reddish orange prisms. The yields and physical properties of quinones **5S** and **11S** are summarized in Table 5.

Photochemical Reaction of 5Ga—f. A solution of **5G** in acetonitrile (30 cm^3, 0.01 mol dm^{-3}) was irradiated with a 300-W halogen lamp through a yellow glass filter (Toshiba L-42; <410 nm cut off) under a nitrogen atmosphere for 3 h. After the solvent was removed under reduced pressure, the resulting oil was chromatographed on a column with benzene as the eluent. The first very pale-yellow eluate was **7G**, the second yellow eluate recovered was **5G**. The third was a mixture of unidentified products. In the cases of **5Gd** and **5Ge**, minor products **8Gd** and **8Ge** were obtained from the third eluate. The yields of the products are summarized in Table 1. Since products **7G** were not stable in air, IR and ^1H NMR data of **7G** are described for acetates which were prepared by the acetylation with acetic anhydride and pyridine. All of products **7G**, except **7Ga** and **d**, were a mixture of diastereoisomers. Only in the case of **7Gb**, could the diastereoisomers be separated into each isomer after acetylation by both recrystallization (from hexane containing small amounts of benzene) and TLC (benzene as developing solvent, Merk, Art. 5715).

9-Acetoxy-4,8-dimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]-benzodioxin (acetate of **7Ga**): colorless prisms, mp 121—122.5 °C; IR ($CHCl_3$) 1760, 1705 (w), and 1195 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50 (3H, s), 2.02 (3H, s), 2.26 (3H, s), 5.26 (1H, ABq, *J*=5 Hz), 5.31 (1H, ABq, *J*=5 Hz), 5.74 (1H, s), 6.17 (1H, s), 7.32 (5H, s). Found: C, 71.18; H, 5.64%. Calcd for $C_{20}H_{18}O_5$: C, 71.00; H, 5.36%.

9-Acetoxy-2,4,8-trimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*]-[1,3]benzodioxin (acetate of **7Gb**) (a mixture of diastereoisomers; ca. 3:1). Major diastereoisomer: oil; IR (CCl_4) 1770, 1705 (w), 1400, 1195 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.50 (3H, s), 1.64 (3H, d, *J*=5.1 Hz), 2.07 (3H, s), 2.32 (3H, s), 5.34 (1H, q, *J*=5.1 Hz), 5.83 (1H, s), 6.21 (1H, s), 7.3—7.45 (5H, m). Minor diastereoisomer: colorless prisms; mp 150—152 °C; IR (CCl_4) 1770, 1700 (w), 1400, 1195 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.55 (3H, s), 1.65 (3H, d, *J*=5.1 Hz), 2.05 (3H, s), 2.31 (3H, s), 5.25 (1H, q, *J*=5.1 Hz), 5.76 (1H, s), 6.19 (1H, s), 7.33 (5H, s). Found: C, 71.42; H, 5.69%. Calcd for $C_{21}H_{20}O_5$: C, 71.58; H, 5.72%.

9-Acetoxy-2-ethyl-4,8-dimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]benzodioxin (acetate of **7Gc**) (a mixture of diastereoisomers; 1:1): oil; IR (CCl_4) 1765 and 1190 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.08 (3H, t, *J*=7.6 Hz), 1.49 and 1.55 (3H, each s), 1.9—2.25 (2H, m), 2.05 and 2.06 (3H, each s), 2.30 (3H, s), 5.03 and 5.12 (1H, each d, *J*=5.3 Hz), 5.75 and 5.83 (1H, each s), 6.18 and 6.20 (1H, each s), 7.3—7.5 (5H, m). Found: *m/z* 366.1444. Calcd for $C_{22}H_{22}O_5$: M, 366.1465.

9-Acetoxy-2,2,4,8-tetramethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]benzodioxin (acetate of **7Gd**): colorless prisms, mp 154—155 °C; IR (CCl_4) 1765, 1645, 1190 cm^{-1}; ^1H NMR (CCl_4) δ=1.50, 1.56, and 1.60 (9H, each s), 2.01 (3H, s), 2.25 (3H, s), 5.73 (1H, s), 6.11 (1H, s), 7.32 (5H, s). Found: C, 72.04; H, 5.98%. Calcd for $C_{22}H_{22}O_5$: C, 72.11; H, 6.05%.

9-Acetoxy-2-ethyl-2,4,8-trimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]benzodioxin (acetate of **7Ge**) (a mixture of diastereoisomers; 1:1): oil; IR (CCl_4) 1770, 1645, 1190 cm^{-1}; ^1H NMR (CCl_4) δ=0.98 and 1.01 (3H, each t, *J*=7 Hz), 1.49 and 1.52 (6H, each s), 1.65—2.05 (2H, m, *J*=7 Hz), 2.00 (3H, s), 2.18 (3H, s), 5.70 (1H, s), 6.08 (1H, s), 7.30 (5H, s). Found: *m/z* 380.1623. Calcd for $C_{23}H_{24}O_5$: M, 380.1623.

9-Acetoxy-4,8-dimethyl-2,5-diphenyl-5*H*-pyrano[4,3,2-*de*]-[1,3]benzodioxin (acetate of **7Gf**) (a mixture of diastereoisomers; 2:1): oil; IR (CCl_4) 1760, 1700 (w), 1365, 1190 cm^{-1}; ^1H NMR (CCl_4) δ=1.50 and 1.57 (3H, each s), 2.06 (3H, s), 2.20 (3H, s), 5.70 and 5.81 (1H, each s), 6.10 (1H, s), 6.16 and 6.20 (1H, each s), 7.2—7.7 (10H, m). Found: *m/z* 414.1472. Calcd for $C_{26}H_{22}O_5$: M, 414.1466.

2,2,4,8-Tetramethyl-7-phenyl-9*H*-[1,3]dioxolo[5,4-*f*][1]-benzopyran-9-one (**8Gd**): colorless solid, mp 172—174 °C; IR (CCl_4) 1640, 1460 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.79 (6H, s), 2.08 (3H, s), 2.28 (3H, s), 6.70 (1H, s), 7.4—7.65 (5H, m). Found: C, 74.66; H, 5.80%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

2-Ethyl-2,4,8-trimethyl-7-phenyl-9*H*-[1,3]dioxolo[5,4-*f*][1]-benzopyran-9-one (**8Ge**): oil; IR (CCl_4) 1635, 1460 cm^{-1}; ^1H NMR (CCl_4) δ=1.07 (3H, t, *J*=7 Hz), 1.70 (3H, s), 2.02 (3H, s), 2.03 (2H, q, *J*=7 Hz), 2.26 (3H, s), 6.61 (1H, s), 7.4—7.7 (5H, m).

Photochemical Reaction of 5Sb—f. A benzene solution of **5S** was irradiated for 1.5 h under the same conditions as for **5G**. After removing the solvent in vacuo, the residue was chromatographed on a column with benzene as the eluent. The first pale-yellow eluate was **7S** and the second yellow eluate was **8S**. The starting quinone **5S** was not recovered. Since products **7S** were unstable, they were methylated with methyl iodide and potassium carbonate in dry acetone in the usual way. In addition, unstable products **7S** were converted to stable **8S** by oxidation[10] and their elemental analyses were measured unless otherwise noted. The yields of products **7S** and **8S** are tabulated in Table 1. IR and ^1H NMR data of **7S** are described for methyl ether, and those of other **8S** were referred to in a preceding paper.[10]

9-Methoxy-2,4,8-trimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*]-[3,1]benzoxathiin (methyl ether of **7Sb**) (a mixture of diastereoisomers; 5:1): oil; IR (CCl_4) 1680 (w), 1470, and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.49 and 1.62 (3H, each s), 1.71 and 1.73 (3H, each, d, *J*=6 Hz), 2.11 and 2.14 (3H, each

s), 3.66 (3H, s), 4.90—5.25 (1H, m, J=6 Hz), 5.51 and 5.64 (1H, each s), 6.17 and 6.22 (1H, each s), 7.15—7.4 (5H, m). Found: m/z 340.1149. Calcd for $C_{20}H_{20}O_3S$: M, 340.1132.

2-Ethyl-9-methoxy-4,8-dimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin (methyl ether of **7Sc**) (a mixture of diastereoisomers; 3:1): oil; IR (CCl_4) 1675 (w), 1470, 1200 cm^{-1}; ^1H NMR (CCl_4): δ=1.15 (3H, t, J=7 Hz), 1.52 and 1.63 (3H, each s), 1.85—2.3 (2H, m), 2.12 and 2.16 (3H, each s), 3.69 (3H, s), 4.90 and 5.01 (1H, each t, J=6 Hz), 5.58 and 5.70 (1H, each s), 6.23 and 6.28 (1H, each s), 7.37 (5H, s).

9-Methoxy-2,2,4,8-tetramethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin (methyl ether of **7Sd**): oil; IR (CCl_4) 1670 (w), 1470, 1210 cm^{-1}; ^1H NMR (CCl_4) δ=1.56, 1.65, and 1.74 (9H, each s), 2.10 (3H, s), 3.60 (3H, s), 5.57 (1H, s), 6.14 (1H, s), 7.22 (5H, s). Found: m/z 354.1285. Calcd for $C_{21}H_{22}O_3S$: M, 354.1289.

2-Ethyl-9-methoxy-2,4,8-trimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin (methyl ether of **7Se**) (a mixture of diastereoisomers; 1:1): oil; IR (CCl_4) 1670 (w), 1450, 1395 cm^{-1}; ^1H NMR δ=1.03 and 1.10 (3H, each t, J=7 Hz), 1.58, 1.60, and 1.68 (6H, each s), 1.8—2.4 (2H, m), 2.13 (3H, s), 3.66 (3H, s), 5.65 (1H, s), 6.22 (1H, s), 7.30 (5H, s).

9-Methoxy-4,8-dimethyl-2,5-diphenyl-5*H*-pyrano[4,3,2-*de*]-[3,1]benzoxathiin (methyl ether of **7Sf**) (a mixture of diastereoisomers; 7:3): oil; IR (CCl_4) 1675 (w), 1470, 1400, 1210 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.55 and 1.68 (3H, each s), 2.16 and 2.20 (3H, each s), 3.76 (3H, s), 5.73 and 5.86 (1H, each s), 6.08 and 6.18 (1H, each s), 6.40 and 6.47 (1H, each s), 7.3—7.8 (10H, m).

2,2,4,8-Tetramethyl-7-phenyl-9*H*-[1,3]oxathiolo[4,5-*f*][1]-benzopyran-9-one (**8Sf**): orange prisms, mp 154—156 °C; IR ($CHCl_3$) 1620, 1430 cm^{-1}; ^1H NMR (CCl_4) δ=2.04 (3H, s), 2.32 (3H, s), 6.88 (1H, s), 7.07 (1H, s), 7.30—7.75 (10H, m). Found: C, 74.60; H, 4.77%. Calcd for $C_{24}H_{18}O_3S$: C, 74.59; H, 4.70%.

Photochemical Reaction of 11Ga—d. The procedures were same as described above for **5G**. The first yellow eluate was a mixture of cyclization product **13G** and hydroquinone **15G**. The yields of **13G** and **15G** were determined by ^1H NMR spectra and the isolation of those was carried out after acetylation in the usual manner. The second orange eluate was recovered **11G** and the third was a mixture of unidentified decomposition products. In the case of **11Gd**, minor product **14Gd** was contained in the third eluate. The yields of the products are summarized in Table 2. The structure of **15G** was identified by oxidation to **11G**.

9-Acetoxy-8-methyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]-benzodioxin (acetate of **13Ga**): yellow oil; IR (CCl_4) 1765, 1190 cm^{-1}; ^1H NMR (CCl_4) δ=2.08 (3H, s), 2.24 (3H, s), 4.84 (1H, d, J=3.5 Hz), 5.28 (2H, s), 6.00 (1H, d, J=3.5 Hz), 6.21 (1H, s), 7.2—7.4 (5H, m). Found: m/z 324.1020. Calcd for $C_{19}H_{16}O_5$: M, 324.0996.

9-Acetoxy-2,8-dimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][1,3]-benzodioxin (acetate of **13Gb**) (a mixture of diastereoisomers; 1:1): yellow oil; IR (CCl_4) 1765, 1190 cm^{-1}; ^1H NMR (CCl_4) δ=1.56 (3H, d, J=5 Hz), 2.01 and 2.04 (3H, each s), 2.20 and 2.25 (3H, each s), 4.72 and 4.78 (1H, each d, J=3 Hz), 5.18 (1H, q, J=5 Hz), 5.85—6.05 (1H, m), 6.14 and 6.18 (1H, each s), 7.1—7.5 (5H, m). Found: m/z 338.1161. Calcd for $C_{20}H_{18}O_5$: M, 338.1153.

9-Acetoxy-2,2,8-trimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*]-[1,3]benzodioxin (acetate of **13Gd**): yellow oil; IR (CCl_4) 1765, 1200 cm^{-1}; ^1H NMR (CCl_4) δ=1.55 (6H, s), 2.02 (3H, s), 2.18 (3H, s), 4.74 (1H, s, J=3 Hz), 5.95 (1H, d, J=3 Hz), 6.10 (1H, s), 7.1—7.4 (5H, m). Found: m/z 352.1293. Calcd for $C_{21}H_{20}O_5$: M, 352.1308.

2,2,4-Trimethyl-7-phenyl-9*H*-[1,3]dioxolo[5,4-*f*][1]benzopyran-9-one (**14Gd**): pale yellow prisms, mp 168—170 °C; IR (CCl_4) 1650, 1450 cm^{-1}; ^1H NMR (CCl_4) δ=1.74 (6H, s), 2.24 (3H, s), 6.40 (1H, s), 6.65 (1H, s), 7.3—7.5 (3H, m), 7.7—7.9 (2H, m). Found: m/z 308.1019. Calcd for $C_{19}H_{16}O_4$: M, 308.1047.

Photochemical Reaction of 11Sb and d. The procedures were the same as described above for **5S**, except the reaction time was 3 h. The first yellow eluate was a mixture of **13S** and **15S**; their yields were determined by ^1H NMR spectra; separation was achieved after methylation in the usual manner. The second yellow eluate was **14S** and the third was a mixture of unknown decomposition products. Products **13S** were more unstable than **7S**; therefore, elemental analyses of **13S** were achieved with **14S** after oxidation with chloranil. The results are summarized in Table 2. The IR and ^1H NMR data of **13S** are shown for the methyl ether.

9-Methoxy-2,8-dimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*][3,1]-benzoxathiin (methyl ether of **13Sb**) (a mixture of diastereoisomers; 1:1): oil; IR (CCl_4) 1660 (w), 1470, 1215 cm^{-1}; ^1H NMR (CCl_4) δ=1.65 and 1.67 (3H, each d, J=6 Hz), 2.10 and 2.14 (3H, each s), 3.60 and 3.62 (3H, each s), 4.8—5.1 (2H, m), 5.7—5.9 (1H, m), 6.20 and 6.29 (1H, each s), 7.1—7.4 (5H, m).

9-Methoxy-2,2,8-trimethyl-5-phenyl-5*H*-pyrano[4,3,2-*de*]-[3,1]benzoxathiin (methyl ether of **13Sd**): oil; IR (CCl_4) 1655 (w), 1470, 1210 cm^{-1}; ^1H NMR (CCl_4) δ=1.71 (6H, s), 2.18 (3H, s), 3.68 (3H, s), 5.09 (1H, d, J=4 Hz), 5.97 (1H, d, J=4 Hz), 6.37 (1H, s), 7.25—7.5 (5H, m).

2,4-Dimethyl-7-phenyl-9*H*-[3,1]oxathiolo[4,5-*f*][1]benzopyran-9-one (**14Sb**): yellow needles, mp 175—177 °C; IR ($CHCl_3$) 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.77 (3H, d, J=6 Hz), 2.28 (3H, s), 6.21 (1H, q, J=6 Hz), 6.65 (1H, s), 6.94 (1H, s), 7.35—7.6 (3H, m), 7.7—7.95 (2H, m). Found: C, 69.46; H, 4.64%. Calcd for $C_{18}H_{14}O_3S$: C, 69.66; H, 4.55%.

2,2,4-Trimethyl-7-phenyl-9*H*-[3,1]oxathiolo[4,5-*f*][1]benzopyran-9-one (**14Sd**): yellow needles, mp 144—146 °C; IR (CCl_4) 1630 cm^{-1}; ^1H NMR (CCl_4) δ=1.85 (6H, s), 2.28 (3H, s), 6.60 (1H, s), 6.94 (1H, s), 7.4—7.6 (3H, m), 7.8—8.0 (2H, m). Found: C, 70.46; H, 5.01%. Calcd for $C_{19}H_{16}O_3S$: C, 70.35; H, 4.97%.

Photochemical Reaction of 5 in Alcohols. The procedures were the same as described above for **5G**, except regarding alcohol. In the reaction of **5Ga** in methanol, the first yellow eluate was a minor unidentified product; the second pale-yellow eluate was **7Ga** (43%); the third was a mixture of type **3** adduct (18%), type **4** adduct (7%), and **15Ga** (10%) which were separated by TLC with benzene as developing solvent after acetylation; and the fourth was a mixture of chromone derivative (3%) and chromamone derivative (8%) which were separated by TLC with chloroform as the developing solvent.

5-Acetoxy-4-methoxy-2-(α-methoxybenzyl)-2,6-dimethylbenzofuran-3(2*H*)-one (acetate of type **3** adduct) (a mixture of diastereoisomers; 3:1): oil; IR (CCl_4) 1770, 1715, 1625, 1195 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.14 and 1.59 (3H, each s), 2.09, 2.19, 2.22, and 2.31 (6H, each s), 3.06 and 3.29 (3H, each s), 3.87 and 4.12 (3H, each s), 4.40 (1H, s), 6.65 and 6.71

(1H, each s), 7.1—7.5 (5H, m).

Methyl 3-acetoxy-2-methoxy-4-methyl-6-(α-methylstyryloxy)-benzoate (acetate of type **4** adduct) (a mixture of cis-trans isomers; 2:1): oil; IR (CCl_4) 1770, 1735, 1190 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.95, 2.08, 2.14, and 2.31 (6H, each s), 3.82 and 3.85 (6H, each s), 5.80 and 5.96 (1H, each s), 6.57 and 6.70 (1H, each s), 7.1—7.6 (5H, m).

6-Hydroxy-5-methoxy-2,7-dimethyl-3-phenyl-4*H*-1-benzopyran-4-one: solid; IR ($CHCl_3$) 3500, 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.22 (3H, s), 2.38 (3H, s), 3.94 (3H, s), 6.09 (1H, s), 7.02 (1H, s), 7.2—7.5 (5H, m).

6-Hydroxy-2,5-dimethoxy-2,7-dimethyl-3-phenyl-4-chromanone (a mixture of diastereoisomers; 1:1): oil; IR ($CHCl_3$) 3525, 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.36 and 1.39 (3H, each s), 2.26 and 2.30 (3H, each s), 3.18 and 3.22 (3H, each s), 3.75 and 3.84 (3H, each s), 3.65 and 4.03 (1H, each s), 5.76 (1H, bs), 6.60 and 6.67 (1H, each s), 7.22 and 7.31 (5H, each s).

Upon the reaction of **5Gb** and **d** in alcohols, the first yellow eluate was a minor unidentified product, the second pale yellow eluate was **7G**, the third was a mixture of hydroquinone containing the type **3** and **4** adducts, and the fourth was unknown products. In the case of **5Gb** the alcohol adduct **24GbM** (5%, R=Me) was isolated from the fourth eluate, even though in low yield. Since type **3** and **4** adducts yielded only a few per cent, most of them were not separated. The results are summarized in Table 3.

5-Acetoxy-4-ethoxy-2-(α-methoxybenzyl)-2,6-dimethylbenzofuran-3(2*H*)-one (acetate of type **3** adduct): oil; IR (CCl_4) 1770, 1715, 1625, 1195 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.14 (3H, s) 1.37 (3H, t, *J*=7.1 Hz), 2.22 (3H, s), 2.34 (3H, s), 3.07 (3H, s), 4.03 (2H, dq-like, *J*=7.1 and 2.4 Hz), 4.41 (1H, s), 6.66 (1H, s), 7.35—7.55 (5H, m).

3-(1-Methoxyethoxy)-5-methyl-2-(α-methylcinnamoyl)-hydroquinone diacetate (diacetate of **24GbM**): oil; IR (CCl_4) 1770, 1625, 1365, 1185 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.30 (3H, d, *J*=5.4 Hz), 2.14, 2.19, 2.22, and 2.34 (12H, each s), 3.28 (3H, s), 5.04 (1H, q, *J*=5.4 Hz), 6.85 (1H, s), 7.2—7.45 (6H, m).

Upon the reaction of **5S** in methanol, the first eluate was **7S**, the second was a minor unidentified prodcut, the third was **8S**, and fourth was a mixture of hydroquinone and **24S** which were separated as acetates after acetylation. However, in the case of **5Sd**, adducts **24Sd** were not isolated. The yields are summarized in Table 3.

Methyl 2-ethylthio-3-methoxy-4-methyl-6-(styryloxy)benzoate (methyl ether of type **4** adduct): oil; IR (CCl_4) 1740 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.18 (3H, t, *J*=7.3 Hz), 2.30 (3H, s), 2.92 (2H, q, *J*=7.3 Hz), 3.84 (3H, s), 3.93 (3H, s), 6.32 (1H, d, *J*=12.4 Hz), 6.88 (1H, s), 7.03 (1H, d, *J*=12.4 Hz), 7.25—7.40 (5H, m).

3-(1-Methoxyethylthio)-5-methyl-2-(α-methylcinnamoyl)-hydroquinone diacetate (diacetate of **24SbM**: R=Me): colorless prisms, mp 96—97 °C; IR (CCl_4) 1770, 1655, 1365, and 1180 cm^{-1}; ^1H NMR (CCl_4) δ=1.39 (3H, d, *J*=6 Hz), 2.08, 2.15, 2.22, and 2.29 (12H, each s), 3.25 (3H, s), 4.68 (1H, q, *J*=6 Hz), 6.92 (1H, s), 7.01 (1H, s), 7.28 (5H, s). Found: C, 65.37; H, 6.00%. Calcd for $C_{24}H_{26}O_6S$: C, 65.14; H, 5.92%.

3-(1-Ethoxyethylthio)-5-methyl-2-(α-methylcinnamoyl)-hydroquinone diacetate (diacetate of **24SbE**: R=Et): colorless prisms, mp 97—99 °C; IR (CCl_4) 1775, 1660, 1370, and 1180 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=11.4 (3H, t, *J*=7.1 Hz), 1.47 (3H, d, *J*=6.1 Hz), 2.14 (3H, s), 2.21 (3H, d, *J*=1.2 Hz), 2.24 (3H, d, *J*=0.5 Hz), 2.34 (3H, s), 3.30—3.45 (1H, m), 3.65—3.80 (1H, m), 4.89 (1H, q, *J*=6.1 Hz), 7.07 (1H, q, *J*=1.2 Hz), 7.09 (1H, q, *J*=0.5 Hz), 7.3—7.4 (5H, m).

3-(1-Isopropoxyethylthio)-5-methyl-2-(α-methylcinnamoyl)-hydroquinone (**24SbP**: R=*i*-Pr): oil; ^1H NMR (270 MHz, $CDCl_3$) δ=1.11 and 1.14 (6H, each d, *J*=6.1 Hz), 1.34 (1H, d, *J*=6.3 Hz), 2.24 (3H, s), 2.30 (3H, s), 3.79 (1H, m, *J*=6.1 Hz), 4.74 (1H, q, *J*=6.3 Hz), 6.66 (1H, bs), 6.81 (1H, s), 6.93 (1H, s), 7.30—7.45 (5H, m), 7.69 (1H, s).

Photochemical Reaction of 11 in Alcohols. The procedures were the same as described above for **5** in alcohol. Upon the reaction of **11G** in methanol, the first yellow eluate was a minor unidentified product, the second was **15G**, the third was **29GM** (R=Me), and the fourth was a mixture of methanol adducts (type **3** and **4**) and the starting quinone. Upon the reaction of **11Ga** in isopropyl alcohol, a mixture of **13Ga**, **29GaP** (R=*i*-Pr), and alcohol adducts (type **3** and **4**) was obtained from the third yellow eluate. The yields of the products were determined by ^1H NMR spectra and the isolation of those was carried out in the usual way after acetylation. The yields of the major products are summarized in Table 4.

4-Methoxy-7-methyl-4-styryl-4*H*-1,3-benzodioxin-5,8-dione (**29GaM**): oil; IR (CCl_4) 1680, 1660, 1610 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=2.03 (3H, d, *J*=1.5 Hz), 3.34 (3H, s), 5.41 (1H, d, *J*=5.4 Hz), 5.50 (1H, d, *J*=5.4 Hz), 6.48 (1H, q, *J*=1.5 Hz), 6.71 (1H, d, *J*=16.1 Hz), 7.00 (1H, d, *J*=16.1 Hz), 72.5—7.40 (3H, m), 7.40—7.45 (2H, m); ^{13}C NMR (67.8 MHz, $CDCl_3$) δ=15.2 (q), 49.7 (q), 85.8 (t), 95.6 (s), 121.0 (s), 124.9 (d), 127.1 (d), 128.5 (d), 128.7 (d), 134.0 (d), 134.3 (d), 135.8 (s), 142.6 (s), 151.9 (s), 181.5 (s), 183.9 (s). Found: *m/z* 312.1009. Calcd for $C_{18}H_{16}O_5$: M, 312.0996.

4-Isopropoxy-7-methyl-4-styryl-4*H*-1,3-benzodioxin-5,8-dione (**29GaP**): oil; ^1H NMR (270 MHz, $CDCl_3$) δ=1.18 and 1.26 (6H, each d, *J*=6.1 Hz), 2.01 (3H, d, *J*=1.5 Hz), 4.23 (1H, m, *J*=6.1 Hz), 5.48 and 5.51 (2H, ABq, *J*=5.4 Hz), 6.45 (1H, q, *J*=1.5 Hz), 6.81 (1H, d, *J*=16.1 Hz), 7.01 (1H, d, *J*=16.1 Hz), 7.25—7.45 (5H, m).

4-Methoxy-2,7-dimethyl-4-styryl-4*H*-1,3-benzodioxin-5,8-dione (**29GbM**): oil; IR (CCl_4) 1680, 1660, 1610 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.75 (3H, d, *J*=5.4 Hz), 2.02 (3H, d, *J*=1.5 Hz), 3.32 (3H, s), 5.52 (1H, q, *J*=5.4 Hz), 6.47 (1H, q, *J*=1.5 Hz), 6.71 (1H, d, *J*=16.1 Hz), 6.97 (1H, d, *J*=16.1 Hz), 7.25—7.45 (5H, m). Found: *m/z* 326.1151. Calcd for $C_{19}H_{18}O_5$: M, 326.1153.

4-Methoxy-2,2,7-trimethyl-4-styryl-4*H*-1,3-benzodioxin-5,8-dione (**29GdM**): oil; ^1H NMR (270 MHz, $CDCl_3$) δ=1.73 (3H, s), 1.81 (3H, s), 2.01 (3H, d, *J*=1.5 Hz), 3.35 (3H, s), 6.47 (1H, q, *J*=1.5 Hz), 6.62 (1H, d, *J*=16.1 Hz), 6.87 (1H, d, *J*=16.1 Hz), 7.25—7.45 (5H, m).

Upon the reaction of **11S** in methanol, the first eluate was type **4** adduct, the second was **13S**, the third was **15S**, and the fourth was a mixture of **14S** and **27S**. However, in the case of **11Sd**, the adducts **27Sd** was not isolated. The yields are summarized in Table 4.

2-Cinnamoyl-3-(1-methoxyethylthio)-5-methylhydroquinone diacetate (diacetate of **27SbM**: R=Me): colorless prisms, mp 127—129 °C; IR (CCl_4) 1770, 1650, 1175 cm^{-1}; ^1H NMR (CCl_4) δ=1.39 (3H, d, *J*=6 Hz), 2.09 (3H, s), 2.24 (3H, s), 2.32 (3H, s), 3.24 (3H, s), 4.67 (1H, q, *J*=6 Hz), 6.80 (1H, d, *J*=16 Hz), 7.02 (1H, s), 7.10 (1H, d, *J*=16 Hz), 7.15—7.6 (5H, m). Found: *m/z* 428.1280. Calcd for $C_{23}H_{24}O_6S$: M, 428.1291.

Reaction of 7Sd in the Presence of Chloroacetic Acid. A benzene solution (5 cm^3) of **7Sd** (0.15 mmol) and chloroacetic acid (ca. 0.5 mmol) in a sealed test tube was stirred at 40 °C for 2 days in the dark. The mixture was chromatographed on silica gel with benzene as the eluent. 2,2,4,8-Tetramethyl-7-phenyl-7,8-dihydro-9*H*-[1,3]oxathiolo[4,5-*f*][1]benzopyran-9-one (**9**, 63%) was obtained from the first yellow eluate. **9** (a mixture of diastereoisomers, ca. 9:2): yellow oil; IR (CCl_4) 2980, 1680, 1620, 1420 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=0.98 and 1.00 (3H, each d, J=7.3 and 6.8 Hz), 1.83 (6H, s), 2.20 and 2.23 (3H, each s), 2.80 and 2.96 (1H, each dq, J=7.3 and 2.7 Hz and 12.2 and 6.8 Hz), 4.95 and 5.49 (1H, each d, J=12.2 and 2.7 Hz), 6.46 and 6.58 (1H, each s), 7.40 and 7.42 (5H, each s). Found: *m/z* 340.1112. Calcd for $C_{20}H_{20}O_3S$: M, 340.1132.

Desulfurization of Methylated 7Sd by Raney Nickel. A solution of methylated **7Sd** (0.22 mmol) in 95% ethanol (3 cm^3) was refluxed for 2 h with Raney nickel (ca. 0.5 g). The mixture was filtered, evaporated in vacuo, and the residue was chromatographed on silica gel with benzene as the eluent. 6-Methoxy-3,7-dimethyl-2-phenyl-4-chromanone (**10**, 42%) was obtained as major product from the second eluate. **10**: oil; IR (CCl_4) 1690, 1620, 1470, 1420, 1215 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=0.98 (3H, d, J=7.3 Hz), 2.27 (3H, s), 2.77 (1H, dq, J=7.3 and 2.9 Hz), 3.85 (3H, s), 5.52 (1H, d, J=2.9 Hz), 6.92 (1H, s), 7.28 (1H, s), 7.35—7.5 (5H, m). Found: *m/z* 282.1243. Calcd for $C_{18}H_{18}O_3$: M, 282.1254.

Reductive Acetylation of 29GaM with Zinc-Acetic Anhydride. A mixture of **29GaM** (20 mg) and zinc dust (200 mg) in acetic anhydride (2 cm^3) containing two drops of pyridine was stirred at room temperature for 2 h. After removing the zinc, the reaction mixture was worked up in a similar manner to the usual acetylation. The residue was chromatographed on TLC with chloroform as the developing solvent. The first-moved band gave 5,8-diacetoxy-4-methoxy-7-methyl-4-styryl-4*H*-1,3-benzodioxin (diacetate of **28GaM**): 50%; colorless oil; IR (CCl_4) 1770, 1180 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=2.17 (3H, d, J=0.5 Hz), 2.27 (3H, s), 2.34 (3H, s), 3.29 (3H, s), 5.26 and 5.29 (2H, ABq, J=5.6 Hz), 6.54 (1H, d, J=15.9 Hz), 6.60 (1H, bd, J=0.5 Hz), 6.87 (1H, d, J=15.9 Hz), 7.25—7.45 (5H, m). Found: *m/z* 398.1395. Calcd for $C_{22}H_{22}O_7$: M, 398.1365.

Quantum Yield Measurement. The quantum yield for consumed quinone **5Sd** was measured by potassium trioxalatoferrate(III) actinometry. A benzene solution of **5Sd** (0.5 mmol dm^{-3}) and a potassium trioxalatoferrate(III) solution (0.15 mol dm^{-3}) were employed. Conversion of the quinone (5—10%) was detected by UV spectrometer and the quantum yield of the disappearance of **5Sd** (Φ=0.50) was calculated in the usual way. The quantum yield of the disappearance of **5Sb** (Φ=0.30) was determined by a comparison with that of **5Sd**.

I am grateful to Professor Kazuhiro Maruyama of Kyoto University for helpful discussions. I also would like to thank Professor Akio Takuwa and Honorary Professor Osamu Soga of Shimane University for helpful advice.

Binding of Modified Guanine Nucleotides to Ribonuclease T_1 as Studied by Absorption Spectroscopy. 8-Aminoguanosine 2′-Phosphate, 8-Methylaminoguanosine 2′-Phosphate, and 8-Dimethylaminoguanosine 2′-Phosphate

Hiroshi YOSHIDA,* Masazumi SUGIYAMA, and Yoshio SHIBAGAKI

(Received May 6, 1989)

The title nucleotides have been synthesized and their binding to ribonuclease T_1 studied by means of absorption spectroscopy. Measurements were made at pH 5.5 and 4.1, where a major portion of the base moiety of the nucleotides was in a neutral form and a cationic form protonated at N7, respectively. At both pH's, difference absorption spectra were induced upon binding of the nucleotides to the enzyme. A comparison of the difference spectra with that for guanosine 2′-phosphate has led to the conclusion that perturbation in the bound nucleotide is the principal cause for the difference spectra. The difference spectra at pH 5.5 and 4.1 were similar, suggesting that the protonation at N7 of the nucleotides can be ruled out as the cause for the difference spectra. The dissociation constants at pH 5.5 and 4.1 of the enzyme–8-aminoguanosine 2′-phosphate complex were of the same magnitude, indicating that both the neutral and the protonated forms bind tightly to the enzyme. However, the cationic form of 8-methylamino- or 8-dimethylaminoguanosine 2′-phosphate has been shown to interact with the enzyme much more loosely than the neutral form.

Ribonuclease (RNase) T_1 is an endoribonuclease that specifically cleaves single-stranded RNA at the 3′ end of guanine nucleotides via 2′:3′-cyclic phosphate intermediates. Specific recognition of the guanine nucleotide is, therefore, a key step in its action mechanism. It can bind monomer guanine nucleotides, among which guanosine 2′-phosphate (**1**) shows the highest affinity.[1] The binding is detected in a number of ways. Absorption spectroscopy is a simple and sensitive method for detection. A difference absorption spectrum is induced upon the binding of a guanine nucleotide to RNase T_1: the spectrum of the RNase T_1–nucleotide complex is not equal to the sum of the component spectra measured separately.[2]

Interpretation of this phenomenon has been controversial. Oshima and Imahori,[3] followed by others,[4,5] have pointed out a gross similarity between the difference spectrum and the acid-induced spectral change of the guanine nucleotide. This led them to propose the hypothesis that the guanine ligand is protonated on N7 upon binding to the enzyme and that this protonation is the cause for the difference spectrum. However, Yoshida and Kanae argued against this hypothesis on the grounds of a spectroscopic study using 8-bromoguanosine 2′-phosphate (**2**).[6] With nucleotide **2**, the acid-induced spectral change was dissimilar to the difference spectrum. However, a possibility can be envisaged that the protonation site of **2** might be different from N7 due to the introduction of a strongly electron-withdrawing group at C8.

In the present study, we have synthesized 8-aminoguanosine 2′-phosphate (**3**), 8-methylaminoguanosine 2′-phosphate (**4**), and 8-dimethylaminoguanosine 2′-phosphate (**5**) and studied their interactions with RNase T_1. The introduction of an electron-donating group at C8 of the guanine base increases the pK_a considerably, thereby allowing a study of the binding properties of a guanine nucleotide protonated at N7. This provides a direct verification of the protonation hypothesis.

Experimental

RNase T_1. This enzyme was purified as described by Kanaya and Uchida[7] and was determined spectrophotometrically using a molar absorbance of 21200 $M^{-1}\,cm^{-1}$ (1 M=1 mol dm^{-3}).[8]

Chemical Syntheses. Nucleotides **3**, **4**, and **5** were synthesized from **2** by the application of published methods for the syntheses of similar, but not identical, compounds shown in parentheses: **3** according to Holmes and Robins (8-aminoguanosine),[9] **4** according to Long et al. (8-methylaminoguanosine)[10] and **5** according to Miller et al. (8-dimethylaminoguanosine 3′:5′-cyclic phosphate).[11] Nucleotide **2** was synthesized essentially according to Yuki and Yoshida.[12] In each synthesis, some modifications were made to the original method in order to improve the performance. Therefore, the whole synthetic procedures will be described. However, the products were identified only on the grounds of the absorption spectra, since the synthetic reactions were the same as the original ones. Generally, the absorption spectra of our products were in good agreement with the reported spectra of the corresponding compounds. The purity of the products was checked by HPLC, which was carried out under the following conditions: chromatograph, Tosoh HLC-803 A; column, TSKgel IEX-540 K 4 mm (i.d.) ×300 mm; eluent, 0.25 or 0.5 M KH_2PO_4; flow rate, 1.0 $cm^3\,min^{-1}$; detection, absorbance at 260 nm. Special attention was paid so that each product was free from its 3′-isomer, a possible by-product of phosphoryl transfer. The nucleotides were determined through quantitation of phosphorus, which was carried out by the method of Fiske and Subbarow.[13]

8-Bromoguanosine 2′-Phosphate (2). To guanosine 2′-

(3′)-phosphate (free acid, 813 mg, 2.23 mmol) dissolved in 4 cm^3 of *N*,*N*-dimethylformamide, was added 0.15 cm^3 of Br_2 in 1 cm^3 of the solvent. The reaction mixture was left standing at room temperature for 15 min, then added dropwise into 6 cm^3 of ice-cold water under stirring. The solution was adjusted to pH ca. 7 with concd aq. ammonia, then poured into 120 cm^3 of ice-cold acetone. The resulting precipitate was collected by centrifugation, washed twice with acetone and once with ether, and dried in vacuo (yield 933 mg). The crude product was purified on a column of DE 52 (HCO_3^- form, 1.8×70 cm) in three portions. One third of the product was dissolved in 10 cm^3 of water and loaded on the column equilibrated with 0.18 M NH_4HCO_3. The column was developed by a linear gradient of 0.18—0.35 M NH_4HCO_3 over 1 dm^3. Nucleotide **2** and its 3′-isomer were separated and recovered by lyophilization: total yield, **2** (1.17 mmol, 57%), the 3′-isomer (0.69 mmol, 34%). Retention time (t_R) in HPLC with 0.5 M KH_2PO_4 as the solvent, **2** (6.0 min), the 3′-isomer (7.25 min).

8-Aminoguanosine 2′-Phosphate (3). Nucleotide **2** (21.4 μmol) was dissolved in 0.5 cm^3 of water containing 6 mm^3 of hydrazine monohydrate. The solution was heated at 95 °C for 26 h in a sealed glass tube, cooled to room temperature, and diluted with 10 cm^3 of water. After being adjusted to pH ca. 7, the solution was loaded on a column of DE 52 (formate form, 1.6×35 cm). After unadsorbed material was washed off with water, the column was developed by a linear gradient of 0—0.1 M formic acid over 0.6 dm^3. The product **3** (7.1 μmol, 33%) was separated from a small amount of the 3′-isomer (1.0 μmol, 5%) and recovered by lyophilization: t_R (0.25 M KH_2PO_4), 4.2 min (the 3′-isomer, 5.0 min); UV (10 mM HCl), 250 (ε 16700), 288 (10600); (H_2O), 255 (16300), 291 (9600); (10 mM NaOH), 258 (14600), ca. 280 (sh, 11800).

8-Methylaminoguanosine 2′-Phosphate (4). Nucleotide **2** (23.2 μmol) was suspended in 0.3 cm^3 of 40 wt% methylamine in methanol; the suspension was heated at 95 °C for 39 h in a sealed glass tube. The work up and the chromatography as described for **3** afforded **4** (15.2 μmol, 66%): t_R (0.25 M KH_2PO_4), 4.1 min; UV (10 mM HCl), 252 (ε 17500), 289 (10200); (H_2O), 259 (16500), 295 (9200); (10 mM NaOH), 261 (15000), ca. 280 (sh, 12550). Only a small amount (<1 μmol) of the 3′-isomer was detected in the chromatography: t_R, 4.9 min.

8-Dimethylaminoguanosine 2′-Phosphate (5). Nucleotide **2** (156 μmol) was suspended in a mixture of anhydrous dimethylamine (2.2 cm^3) and methanol (10 cm^3). The suspension was heated at 120 °C for 5 h in a steel bomb, then evaporated. The residue was dissolved in 10 cm^3 of water and loaded on a column of DE 52 (HCO_3^- form, 1.8×50 cm) equilibrated with 0.05 M NH_4HCO_3. The product **5** (84.6 μmol, 54%) was eluted from the column by a linear gradient of 0.05—0.35 M NH_4HCO_3 over 1 dm^3 and recovered by lyophylization: t_R (0.5 M KH_2PO_4), 4.8 min; UV (10 mM HCl), 264 (ε 17500), ca. 290 (sh, 11100); (H_2O), 262 (16500), ca. 290 (sh, 8700); (10 mM NaOH), 269 (15100).

Measurement of Difference Spectra. This was carried out as described previously[6] in a solvent, 10 mM sodium acetate buffer (pH 5.5 or 4.1) containing 0.1 M NaCl, with a Hitachi 220 A spectrophotometer equipped with a tandem cell holder thermostatted at 25 °C. A typical experiment was run with 2.0 cm^3 of 39.0 μM RNase T_1 and 2.0 cm^3 of 38.2 μM **3** giving rise to a difference absorbance of 0.128 at a maximum wavelength (λ_{max}) of 308 nm in an optical path of 2.0 cm.

Determination of the Dissociation Constant K_d and the Maximum Difference Molar Absorbance $\Delta\varepsilon(\lambda_{max})$ for a RNase T_1–Nucleotide Complex. This was carried out as described previously.[6] A typical run was as follows. To 2.5 cm^3 of 12.2 μM RNase T_1, was added 8.11 mM **3** in 0.2 mm^3 portions up to a total of 13 mm^3. After each addition, the absorbances at 263 nm (a crossover point of the difference spectrum) and 308 nm (λ_{max}) were measured. The data, thus obtained, were processed to give the K_d and $\Delta\varepsilon(\lambda_{max})$.

Results and Discussion

Spectrophotometric Titration of the 8-Substituted Guanine Nucleotides. Guanosine undergoes spectral changes with pH, showing acid dissociation constants (pK_a) of 2.3 and 9.4. Miles et al. have established that the lower dissociation constant (pK_{a1}) corresponds to protonation at N7 and that the higher one (pK_{a2}) corresponds to deprotonation from N1-H. The pK_a's of **3**, **4**, and **5** were examined by spectrophotometric titration. As shown in Table 1, the introduction of an electron-donating group at C8 increased the pK_{a1} considerably and also the pK_{a2} to a lesser extent. These changes are as expected from the protonation and deprotonation sites described above. Therefore, the base moiety of these nucleotides is supposed to be in a cationic form protonated at N7 in a sufficiently acidic solution.

Interaction of the 8-Substituted Guanine Nucleotides with RNase T_1. The difference absorption spectrum induced upon binding of the parent nucleotide **1** to RNase T_1 at pH 5.5 has been shown to have one major trough at 245 nm and one major peak at 290 nm.[2-5] In addition, it has a minor peak at ca. 260 nm and a minor trough at ca. 270 nm in-between. Sato and Egami examined the difference absorbance at 290 nm as a function of pH and found that it remained nearly constant between pH 4 and 5.5, falling off on both acidic and alkaline sides.[2] This suggests that RNase T_1 binds the ligand equally well in a pH range 4—5.5. We studied the binding of **1** to RNase T_1 at pH 4.1 in detail and found that the entire difference spectrum was unchanged from that at pH 5.5. Moreover, the K_d was determined to be 4.0 μM, in good agreement with that (4.6 μM) at pH 5.5. Since the ionization state of the guanine base is the same at pH 5.5 and 4.1, these results indicate that the nucleotide binding property of the enzyme remains the same at these pH's. Having confirmed this fact, we studied the interaction of **3**, **4**, and **5** with RNase T_1 at these pH's.

Table 1. Acid Dissociation Constants of the 8-Substituted Guanine Nucleotides

Nucleotide	pK_{a1}	pK_{a2}
3	4.9	10.4
4	5.0	10.6
5	3.8	10.2

At pH 4.1, these nucleotides are expected to be mainly in the form protonated at N7, due to the elevated pK_{a1}. Therefore, the effect of protonation on the difference spectrum or the binding can be assessed directly.

The base moiety of **3** was calculated from its pK_{a1} to be 80% in the neutral form at pH 5.5 and 86% in the cationic form at pH 4.1. A change in absorption spectrum takes place with the change of ionization state (see UV characteristics shown in the Experimental section). A blue-shift is the main feature accompanying protonation. In spite of this spectral change, the difference spectra induced upon binding of **3** to RNase T_1 were quite similar at pH 5.5 and 4.1 (Fig. 1A). At pH 5.5, two distinct peaks were observed at 270 and 308 nm and two troughs at 248 and 286 nm. At pH 4.1, a slight blue-shift was seen for the shorter wavelength trough and peak. Compared to the difference spectrum for the parent nucleotide **1**, a large red-shift by 18 nm of the longer wavelength peak is noteworthy. This red-shift corresponds almost exactly to the red-shift between 275 and 290 nm of the longer wavelength absorption bands of **1** and **3**, respectively. This suggests that a perturbation of the nucleotide and not a protein chromophore(s) is the principal cause for the difference spectrum. Clearly, the perturbation cannot be protonation of the ligand, since even the protonated nucleotide causes a similar difference spectrum. It should also be noted that the spectral change accompanying the protonation and the difference spectrum are dissimilar. A blue-shift is the characteristic for the former, whereas the latter can be regarded as being due to a red-shift of the absorption bands of the nucleotide.

The K_d for **3** was slightly lower than that for **1** at both pH 5.5 and 4.1 (Table 2). Especially noteworthy is the low K_d, thus the tight binding at pH 4.1, which means that **3** protonated at N7 can bind tightly to the enzyme. This precludes a binding mechanism in which N7 plays an important role as a hydrogen acceptor. The X-ray analysis of the RNase T_1-**1** complex has indicated the probable hydrogen bonds to N7.[14,15] A ^1H NMR study has also proposed hydrogen bond interaction between N7 of the guanine base and a histidine residue in the active site of the enzyme.[16] However, in the tertiary structure determined by the X-ray analysis, the distance between N7 and any of the suggested hydrogen donors is large (>3 Å). Moreover, an ^{15}N NMR study showed no sign of the participation of N7 in the binding.[17] In accordance with these latter observations, our result presents evidence for the dispensability of the hydrogen bond to N7 in the formation of the enzyme-nucleotide complex. In fact,

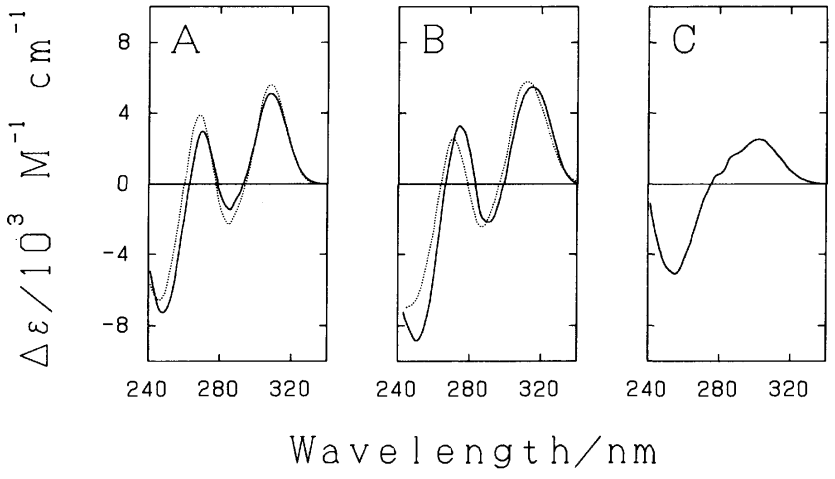

Fig. 1. Difference spectra induced upon binding of the 8-substituted nucleotides to RNase T_1. A: **3**, B: **4**, C: **5**. —: at pH 5.5, ·····: at pH 4.1.

Table 2. Dissociation Constants and Related Parameters for RNase T_1-8-Substituted Guanine Nucleotide Complexes

Nucleotide	pH 5.5			pH 4.1

a) Not determined.

Seela et al. have shown that RNase T_1 is able to hydrolyze poly(7-deazaguanylic acid) lacking N7.[18]

The base moiety of **4** is 72% in the neutral form at pH 5.5 and 91% in the cationic form at pH 4.1. As for the difference spectra shown in Fig. 1B, qualitatively the same argument holds as that described for **3**. The major differences are a larger red-shift of the longer wavelength peak to 315 nm and a shift observed between the spectra at pH 5.5 and 4.1 over the entire wavelength region. In spite of the qualitative similarity, an important quantitative difference emerged: the K_d was much higher at pH 4.1 than at pH 5.5 (Table 2). This shows that nucleotide **4** protonated at N7 binds to the enzyme much more loosely than its neutral form. At pH 5.5, the observed K_d is substantially higher for **4** than for **3**. It should be kept in mind, however, that 28% of **4** is still in the cationic form with a large K_d at pH 5.5. The intrinsic K_d for the neutral form of **4** is, therefore, estimated to be much lower than 26 μM actually observed and to be at a level similar to that for **3**. Accordingly, we conclude that the neutral form of **4** binds to the enzyme tightly, whereas the protonated form binds loosely. This is in contrast to the situation for **3**, whereby both forms interact with the enzyme equally well. We have no explanation for this discrepancy at present. However, it is possible that concomitant occurrence of protonation at N7 and a bulky substituent at C8 may seriously hinder the nucleotide from binding to the enzyme.

Nucleotide **5** is almost entirely (98%) in the neutral form at pH 5.5, but only 33% in the cationic form even at pH 4.1. General properties, e.g. absorption spectrum or pK_a, of **5** cannot be simply extrapolated from those of **3** and **4**. Likewise, the difference spectrum induced upon binding of **5** to RNase T_1 at pH 5.5 (Fig. 1C) differed considerably from those for **3** and **4**. The spectrum has only one trough at 255 nm and one peak at 302 nm, both of relatively small magnitude. At pH 5.5, the K_d is several times higher than that for the parent nucleotide **1** (Table 2), but is equivalent to that for the 3′-isomer of **1** (21.3 μM, our own measurement). Accordingly, nucleotide **5** can be regarded to bind to the enzyme still tightly in spite of the bulky dimethylamino group introduced at C8. This shows the considerable freedom of space in the vicinity of C8 of the bound guanine base. Nucleotide **5** can only adopt a syn conformation about the glycosyl bond rotation, because of the bulky substituent at C8.[19] Relatively tight binding of **5** is in accord with the X-ray structure in which the nucleotide bound at the active site of RNase T_1 assumes a syn conformation.[14,15] At pH 4.1, we were unable to determine the K_d for **5** because of the small magnitude of the difference spectrum. However, the attenuation of the difference spectrum suggests that the protonated form of **5** interacts with the enzyme very weakly, like the protonated form of **4**.

In conclusion, the present study shows that a perturbation of the nucleotide base is the main cause for the difference spectrum induced upon its binding to RNase T_1. The contribution of a protein chromophore(s) may be small, if any. Protonation at N7, which used to be assumed to cause the difference spectrum, should be ruled out. It is also clear that the protonation per se does not interfere a nucleotide from binding to the enzyme. This argues against the participation of N7 in the specific binding as a hydrogen acceptor.

Preparation and Properties of Tetrathia[*n*](1,1′)ferrocenophanes with $Pd(BF_4)_2$. The Metal-Metal Interaction Controlled by the Size of the Thiamacrocycles

Masaru SATO* and Sadatoshi AKABORI†

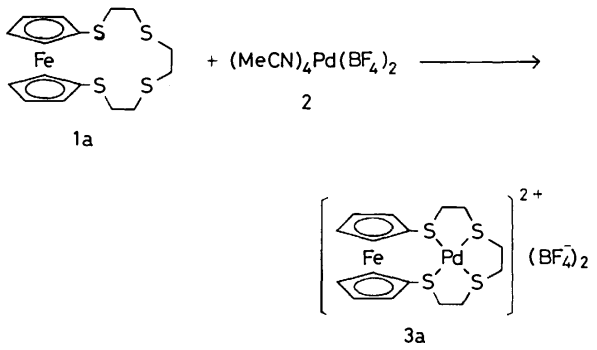
(Received May 25, 1989)

1,4,7,10-Tetrathia[10]-, 1,4,8,11-tetrathia[11]-, 1,5,8,12-tetrathia[12]-, and 1,5,9,13-tetrathia[13](1,1′)ferrocenophanes reacted with $(CH_3CN)_4Pd(BF_4)_2$ to give the corresponding 1/1 complexes in good yield. The ^1H NMR spectra of the Pd(II) complexes were not rigid at room temperature, except for the complex of 1,4,7,10-tetrathia[10](1,1′)ferrocenophane. The ^1H and ^{13}C NMR spectra at low temperature showed that the Pd(II) complex of 1,5,9,13-tetrathia[13]ferrocenophane was a single compound, while the other three complexes were a mixture of two isomers. In the electronic spectra of the above series, the low-energy band shifted to the long-wavelength region and increased its absorbance according to the decrease in the size of the thiamacrocycle.

Recently, numerous studies have been reported about heterobimetallic complexes.[1,2] Such complexes have potential applications in homogeneous catalysis. The presence of another metal in close proximity to the catalytically active metal may offer the possibility of a modification of the catalytic activity. Alternatively, interactions between the two proximate metal centers may lead to unique reactivity. Organometallic ligands are the beneficial starting material for preparing heterobimetallic complexes. We previously reported the syntheses of polythia[*n*]ferrocenophanes[3] as such an organometallic ligand, and some their complexes with transition metals.[4-6] In this paper[7] we describe the synthesis and properties of complexes of tetrathia[*n*](1,1′)ferrocenophanes with $Pd(BF_4)_2$, which is known to have a superior catalytic activity.[8]

A solution of 1,4,7,10-tetrathia[10](1,1′)ferrocenophane (**1a**)[4] in acetonitrile was treated with a solution of $(CH_3CN)_4Pd(BF_4)_2$ (**2**), which was prepared from $(CH_3CN)_2PdCl_2$ and 2 equivalent of $AgBF_2$ in acetone,[9] followed by dilution with anhydrous diethyl ether, gave a 1/1 complex (**3a**) as dark-green needles in



74% yield. In a similar manner, 1,4,8,11-tetrathia[11]- (**1b**), 1,5,8,12-tetrathia[12]- (**1c**), and 1,5,9,13-tetrathia[13](1,1′)ferrocenophanes (**1d**) gave the corresponding 1/1 complexes, **3b**, **3c**, and **3d**, in good yield, respectively. Complex **3b**, alone, contained one equivalent of acetonitrile in the crystal, as shown by elemental analysis. In the IR spectra of these complexes the out-of-plane bending vibration, which was the most diagnostic probe of the oxidation state of ferrocene,[10] was observed at 824, 826, 818, and 818 cm^{-1} for **3a**, **3b**, **3c**, and **3d**, respectively. The frequencies are a little higher than those of the corresponding free ligands **1a—1d**, but considerably lower than those of ferricenium cations (e.g. 846 cm^{-1} in the ferricenium cation of **1d**). These results suggests that the iron atom of a ferrocenyl moiety is somewhat perturbed by the proximate location of the Pd(II) atom. Particularly, in the complexes **3a** and **3b**, there seems to be a significant interaction between two metal atoms. In this connection, the out-of-plane bending vibration in (triphenylphosphine)(1,1′-ferrocenedithiolato-*S*,*S*′,*Fe*)-palladium(II) (**4**), which is confirmed by X-ray analysis to contain a dative Fe-Pd bond,[11] was observed at 830 and 838 cm^{-1}. In the $Pd(BF_4)_2$ complexes of trithia[*n*](1,1′)ferrocenophanes (*n*=7 and 9), this band also appeared at 830 and 844 cm^{-1}, respectively.[7] The differences of the frequencies between the Pd(II) complexes (**3a—3d**) and the corresponding free ligands (**1a—1d**) were 24, 16, 2, and 6 cm^{-1}, respectively. The magnitude of the shifting from the free ligand to the corresponding Pd(II) complex can be assumed to reflect the strength of an interaction between the Pd(II) atom and the Fe atom of a ferrocene nucleus in these complexes, since the coordinating strength of the sulfur atom to the Pd(II) atom seems to be almost the same through the series of the complexes **3a—3d**. Therefore, it will be expected that the largest interaction acts in complex **3a** in a series of complexes, **3a—3d**.

In the ^1H NMR spectrum (CD_3CN, 400 MHz) of **3d**, all signals were broadened at room temperature, indicating the presence of a certain dynamic process.

Table 1. ^{1}H NMR Spectral Data of the Complexes **3a—3d** in the Region of the Cp-Ring Proton Signals (400 MHz, CD_3CN)[a]

Compound	Temp	Isomer	Chemical shifts (δ)[b]
3a	R.T.	Major	5.61 (quasi s, 2H), 5.28 (quasi s, 2H), 4.82 (quasi s, 2H), 4.52 (quasi s, 2H)
		Minor	5.91 (broad s, 2H), 5.61 (quasi s, 4H), 5.82 (quasi s, 2H)
3b	−30 °C	Major	5.67 (quin, 2H), 5.54 (quin, 2H), 4.73 (sex, 2H), 4.27 (sex, 2H)

a) This is assigned to be the bridge-head carbon of a ferrocenyl Cp-rings by using the DEPT measurement. b) This signal (which is probably the bridge-head carbon signal) could not be detected.

The static spectrum was obtained at −30 °C, in which the cyclopentadienyl (Cp) ring protons appeared as three pseudosinglests at δ 5.20 (4H), 4.75 (2H), and 4.52 (2H) (The ^{1}H NMR spectral data was summarized in Table 1). The ^{13}C NMR spectrum of **3d** at low temperature similarly showed the presence of a single conformer. That is, the Cp-ring carbons of a ferrocene moiety produced signals at δ 79.77, 77.53, 75.86, 75.17, and 73.12 (The ^{13}C NMR spectral data was summarized in Table 2). The unsymmetric pattern of the ferrocenyl ring observed in the ^{1}H and ^{13}C NMR spectra of **3d** seems to reflect the stepped conformation[12] in which the Fe, Pd(II), and two sulfur atoms connected to the Cp rings are not coplanar, since **3d** has been proved by X-ray analysis to have such a stepped conformation.[13] The metal complexes of ferrocene derivatives containing heteroatoms in the 1,1′-positions can be regarded as an analog of [3](1,1′)ferrocenophanes which involves a bridge reversal process. The bridge reversal energy observed in 1,2,3-trichalcogeno[3](1,1′)ferrocenophanes is ca. 80 kJ mol^{-1}, in solution.[14,15] The proton signals of the Cp-rings of **3d** at δ 4.75 and 4.52 broadened upon warming and coallesced at 42 °C. At 80 °C the Cp-ring protons appeared at δ 5.22 and 4.66 as almost sharp signals, although signals of the methylene protons were still somewhat broad. A similar marked temperature dependence in the ^{1}H and ^{13}C NMR spectra was observed in the $PdCl_2$ complexes of 1,1′-bis(isobutylthio)ferrocenes (**5**),[16] and two independent dynamic processes, sulfur inversion and bridge reversal, were suggested to be involved.[17] In the complex **3d**, the sulfur inversion process seems to be impossible because the four sulfur atoms in the thiamacrocycle coordinate to the Pd(II) atom and, consequently, the methylene groups on the sulfur atoms at the 1,1′-positions are always forced to be in the same direction as that of the Pd(II) atom. Thus, the remarkable dynamic behavior observed in **3d** is probably due to a flipping of the thiamacrocycle moiety coordinated by the Pd(II) atom in which the Pd(II) atom flips from one side of the plane containing the iron atom and two sulfur atoms at the 1,1′-positions to the other. This phenomenon is considered to result from a concurrent occurance of bridge reversal with S-inversion on the sulfur atoms at the 1,1′-positions. From the coalescence temperature (42 °C), $\Delta G^{\ddagger}$=63.2 kJ mol^{-1} was calculated. This value is comparable with that in the complexes of 1,1′-bis(isobutylthio)ferrocene with palladium halides (**5**).[17] This supports the above elucidation, since it was reported that the bridge reversal was fast and the S-inversion was slow in PdX_2 complexes of 1,1′-bis(alkylthio)ferrocenes.[17] The rate

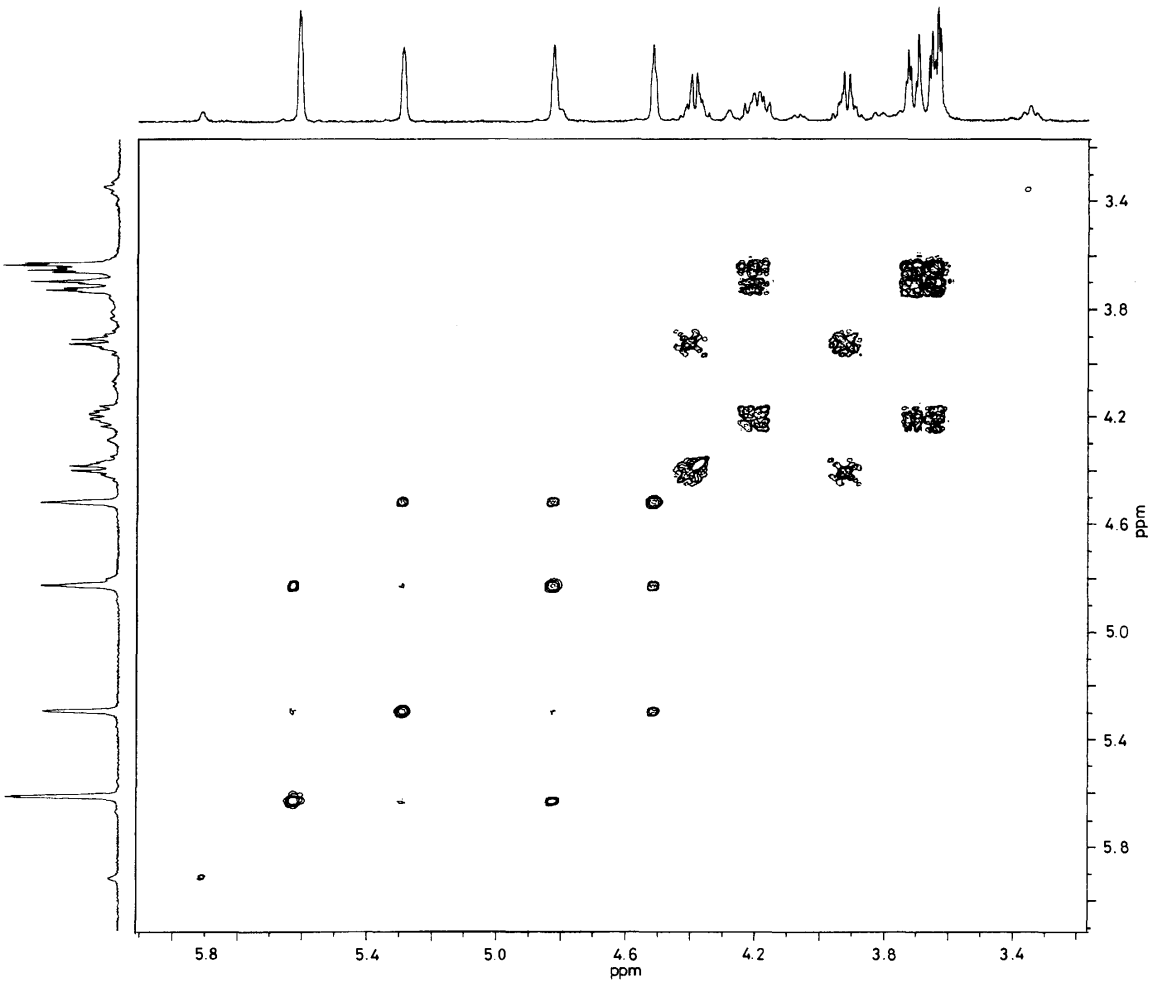

Fig. 1. The H,H-COSY spectrum of the complex **3a**.

of the flipping is, therefore, supposed to be controlled by the rate of S-inversion. The chemical shift of the α- and β-protons of the Cp rings in the ^{1}H NMR spectrum of **3d** is fairly similar to that of **5**.[16] In the latter, the large low-field shift of the α-protons was suggested to be due to a magnetic anisotropy or an inductive effect of the metal halide.[16] A similarity between the complexes **3d** and **5** is also seen in the chemical shift of the ferrocenyl ring carbons in the ^{13}C NMR spectra.

On the other hand, the ^{1}H NMR spectrum of **3a** was static, even at room temperature; moreover, it showed the presence of two isomers in the complex. The isomer ratio of two isomers is established from the integration ratio of the Cp ring proton signals to be about 6:1. In the ^{1}H NMR spectrum of **3a**, the major isomer showed signals of the Cp-ring protons at δ 5.62, 5.29, 4.82, and 4.51. The assignment of these signals to the α- and β-protons of the Cp-rings was successfully performed by the 2D H,H-COSY measurement (Fig. 1). The signals at δ 4.82 and 4.51 correlated intensively with each other and further with the signals at δ 5.62 and 5.29, respectively. This is a clear evidence that the signals at 4.82 and 4.51 can be assigned to the β-protons of the ferrocenyl ring. The remaining signals at 5.62 and 5.29 correspond to the α-protons of the ferrocenyl ring. Thus, the H,H-COSY technique is a more superior method for the assignment of the ferrocenyl ring protons than the *D*-labeling method,[18] if the ring protons are in unsymmetrical circumstances. Here, in order to make a brief explanation, we have tentatively labeled the protons which resonated at δ 5.61, 4.82, 4.52, and 5.28 as H(α), H(β), H(β'), and H(α') atoms, respectively, on the basis of the H,H-COSY experiment. Interestingly, the chemical shifts of the H(α) and H(β) atoms are in a lower field than those of the H(α') and H(β') atoms, especially the signals of the H(α) atom being at a considerably low field (δ 5.61). The difference of the chemical shifts between the H(α) and H(α') atoms ($\Delta\delta$ 0.33 ppm) is fairly large compared with that in **3d**. This is in good agreement with the adoption of the stepped conformation in **3a**. At the same time, the low-field shift of the H(α) signal seems likely to be explained by the anisotropy of the

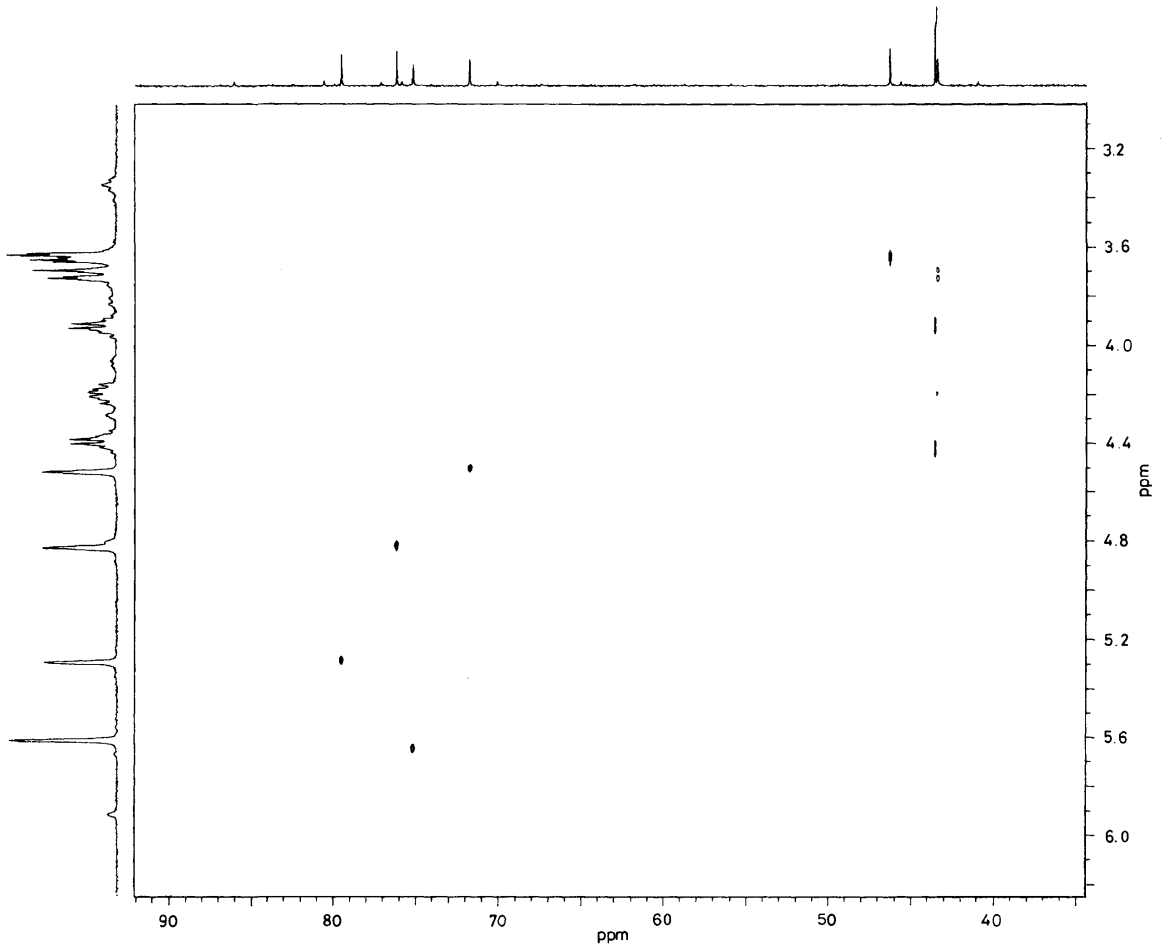

Fig. 2. The C,H-COSY spectrum of the complex **3a**.

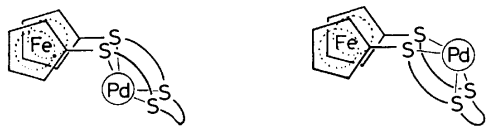
lone pair of the sulfur atom connected to the Cp-rings, since the lone pair of the sulfur atom is placed nearly parallel to the H(α) atom on the basis of the molecular model of **3a**. The assignment of the ferrocenyl ring carbons in the major isomer of **3a** was accomplished by the C,H-COSY experiment (Fig. 2). The carbon signals at δ 79.51 and 75.16 correlated to the α-proton signals at δ 5.28 and 5.61, respectively. The carbon signals at δ 76.17 and 71.74 showed good correlation to the β-proton signals at δ 4.82 and 4.52, respectively. Using the labelling described above, the carbon signals at δ 75.16, 76.17, 71.74, and 79.51 were assigned to the C(α), C(β), C(α'), and C(β') atoms, respectively. It is interseting that the lowest field signal in the ^{13}C NMR spectrum of the major isomer of **3a** is the signal of the C(α') atom, while the signals of the H(α) atom appear at lowest field in the ^{1}H NMR spectrum. This may suggest that a certain interaction due to the metal atom incorporated in the thiamacrocycle exerts an influence on the ferrocenyl ring carbons.

The ^{1}H NMR spectra of **3b** and **3c** were broadened at room temperature, similarly to that of **3d**. The static spectrum of **3b** was obtained at 0 °C, and showed the presence of two isomers, as can be seen in the case of complex **3a** (Table 1). The ratio of the major to minor isomers was estimated from the integration ratio of the signals at δ 4.27 and 4.39 to be ca. 2.2 for **3b**. The averaging process of the proton signals in **3b** on warming was very complex because of the presence of two isomers; **3b** gave no completely averaged spectra, even on warming at 80 °C. The dynamic behavior of the ^{1}H NMR spectrum dependent on the temperature was further complicated for complex **3c**. Two pseudo singlets for the Cp-ring protons of **3c** were observed at δ 5.14 and 4.65 at 80 °C. However, even on cooling at −40 °C (limiting low temperature for acetonitrile) no static spectrum was obtained, although the ^{13}C NMR spectrum of **3c** at −40 °C gave a definite spectrum only for the major isomer (Table 2). Judging from the temperature affording the static spectrum and the spectrum at 80 °C, the flipping motion of the thiamacrocycle moiety coordinating the Pd(II) atom increases in the following order: **3a**<**3b**<**3d**$\lesssim$**3c**, the order being in accord with the increase of the ring size in the thiamacrocycle. It is worthy to note that this order is also consistent with that of the decrease of the Fe(II)–Pd(II) interaction obtained from the IR study. Therefore, we feel justified in assuming that the

interaction between the iron atom of the ferrocene moiety and the Pd(II) atom incorporated in the thiamacrocycle may lock the flipping motion of the thiamacrocycle moiety towards the ferrocenyl part in the complexes **3a—3d**. The chemical shift of the bridge-head carbon of ferrocenyl rings of the series **3a—3d** was shifted down-field from δ 75.17 in **3d** to δ 86.05 in **3a** according to the decrease in the size of the thiamacrocycle, although the other ring carbons were little changed. This seems unlikely to be due to a conjugate interaction between the sulfur lone pair and the π-orbital of the ferrocenyl rings, since there was observed no significant difference in the chemical shift between a flexible molecule at 80 °C (δ 75.56) and a fixed molecule at −30 °C (δ 75.17) in **3d**. This down-field shift (described above) probably stems from the change in the coordination mode of a Pd(II) atom to the thiamacrocycle part (vide infra).

It was proven by X-ray analysis[13] that complex **3d** had a stepped conformation and that the Pd(II) atom was located in the center of a square planar consisting of four sulfur atoms of the thiamacrocycle moiety. This is consistent with the ^{1}H and ^{13}C NMR spectra of complex **3d** in solution at −30 °C. On the other hand, the NMR data of complexes **3a—3c** showed the presence of two isomers at low temperature. We suppose that the Pd(II) atom in the complexes can not fit sufficiently in the center of the cavity of the thiamacrocycle moiety, because of the small size of the cavity, contrary to complex **3d**. Consequently, the Pd(II) atoms in the complexes **3a—3c** deviate up or down from the plane of the thiamacrocycle moiety, resulting in two isomers. Although the structure of the major and minor isomers is not decided from the ^{1}H and ^{13}C NMR spectral data, a consideration of the steric hindrance between the Pd(II) atom coordinated to the sulfur atoms in the thiamacrocycle and the α-protons of the ferrocene ring leads to the assignment of the major isomers to a configuration that the Pd(II) atom is deviated to the outer side of the plane of the thiamacrocycle away from the ferrocene moiety (**3B**).



3A 3B

In the minor isomers of **3a—3c**, the decrease of the size of the thiamacrocycle increases the steric hindrance (described above), and at the same time increases the deviation of the Pd(II) atom from the plane consisting of the four sulfur atoms in the thiamacrocycle moiety. The latter change may shrink somewhat the distance between the Pd(II) atom and the iron atom of the ferrocene moiety, and may increase an interaction between both metals (**3A**). This suggestion appears to be supported by the behavior of the electronic spectra.

The electronic spectrum of **3d** showed broad and weak absorption at 572 nm (ε 113), as well as intensive absorptions at 330 sh (15700) and 296 nm (ε 17000). The free ligand **1d** showed an absorption maximum at 443 nm (ε 190), while the $Pd(BF_4)_2$ complex with the open-chain tetrakis(thioether), 2,6,10,14-tetrathiapentadecane, which is considered to have a square-planar coordination, showed no absorption above 370 nm.[9] Furthermore, the Pd(II) complex of 7,16-dimethyl-1,4,10,13-tetrathia-7,16-diazacyclooctadecane, which contains square-planar configuration of the four thioether donor atoms, also showed an absorption only at 373 nm (ε 2175) in the region above 300 nm,[19,20] although weak absorption at 620 nm (ε 55) was observed in bis(1,4,7-trithiacyclononane)palladium(II) tetrafluoroborate, which was confirmed by X-ray analysis to contain a weak interaction between the Pd(II) atom and the apical thioether donor atom.[21,22] We suppose, therefore, that the absorption band at 572 nm observed in complex **3d** may be concerned with an interaction between the iron atom of the ferrocene nucleus and the Pd(II) atom incorporated into the thiamacrocycle moiety. The absorption at 572 nm showed a bathochromic shift and an increase in absorbance according to the decreasing size of the thiamacrocycle in the series **3a—3d**: **3d**, 572 (ε 113) <**3c**, 604 (376) <**3b**, 612 (245) <**3a**, 670 (499). As mentioned above, the distance between the Pd(II) atom incorporated in the thiamacrocycle moiety and the iron atom of the ferrocene ring decrease potentially according to the size of the thiamacrocycle through series **3a—3d**. The observed bathochromic shift, therefore, may be due to an increasing Fe-Pd interaction in the complexes. However, we cannot rule out the possibility that the shift stems from an increasing deviation of the Pd(II) atom from the thiamacrocycle plane because the hole size is insufficient for a good fit.

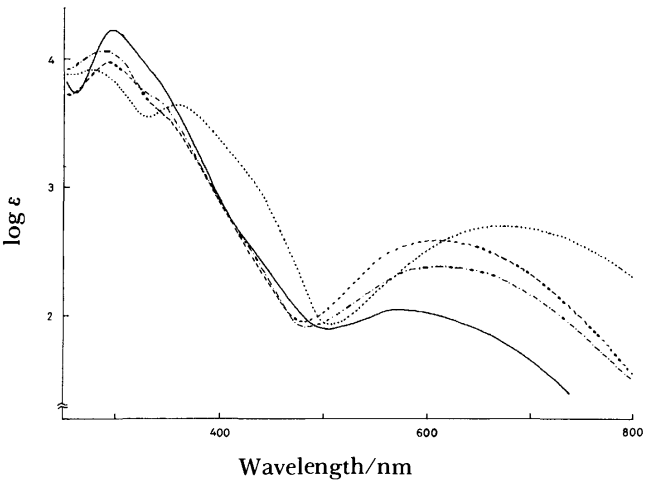


Fig. 3. The electronic spectra of the complex **3a** (·····), **3b** (—·—·), **3c** (----), and **3d** (—).

Finally, we reported the preparation of the $Pd(BF_4)_2$ complexes of 1,5,9-trithia[9]- and 1,4,7-trithia[7](1,1′)-ferrocenophanes.[7,23] In these complexes, a bonding interaction between the Fe atom of the ferrocene nucleus and the Pd(II) atom incorporated into the thiamacrocycle is confirmed by the spectroscopic data. The complexes are rigid, even at high temperature, in contrast with complexes **3b—3d** and showed a greater frequency of out-of-plane bending than that of complexes **3a—3d**. The rigidness of the molecule and the high out-of-plane bending vibration are considered to stem from the presence of the Fe–Pd dative bond in these complexes. From a comparison with these results, it is clear that these is no bonding interaction but, rather, a certain (probably charge-transfer type of) interaction in the present complexes of the tetrathia[*n*](1,1′)ferrocenophanes; the interaction is controlled by the size of the thiamacrocycle moiety.

Experimental

The IR spectra were taken on a Hitachi 270—50 Infrared Spectrometer. The ^1H and ^{13}C NMR spectra were measured on a Bruker AM400 Spectrometer, TMS being chosen as the standard material. The electronic spectra were taken on a Shimadzu UV2100 Spectrometer.

Tetrathia[*n*]ferrocenophanes were prepared as described in a previous paper.[3] Dichlorobis(acetonitrile)palladium-(II) was prepared according to a method from the literature.[9]

(1,4,7,10-Tetrathia[10]ferrocenophane)palladium(II) Tetrafluoroborate (3a). General Procedure. Dichlorobis(acetonitrile)palladium(II) (26 mg, 0.1 mmol) was added to a solution of silver tetrafluoroborate (40 mg, 0.2 mmol) in acetone (5 cm^3). The solution was refluxed for 1 h. The resulting precipitates (AgCl) were filtered off and the filtrate was evaporated under reduced pressure. To a solution of the residue in acetonitrile (2 cm^3) was added a solution of 1,4,7,10-tetrathia[*n*]ferrocenophane (**1a**) (40 mg, 0.1 mmol) in acetonitrile (5 cm^3). The resulting green solution was diluted with anhyd diethyl ether (16 cm^3). The solution was kept overnight in refrigerator. Filtration gave dark green plates, mp ca. 180 °C (decomp). Found: C, 28.71; H, 3.11%. Calcd for $C_{16}H_{20}B_2F_8S_4FePd$: C, 28.41; H, 2.98%.

(1,4,8,11-Tetrathia[11]ferrocenophane)palladium(II) Tetrafluoroborate (3b). Blue black crystals, mp ca. 115 °C (decomp). Found: C, 31.30; H, 3.50; N, 1.95%. Calcd for $C_{17}H_{22}B_2F_8S_4FePd \cdot CH_3CN$: C, 31.20; H, 3.44; N, 1.95%.

Synthesis and Spectroscopic Investigation of Directly Conjugated Polyyne Porphyrins

Kazuhiro MARUYAMA* and Shigeki KAWABATA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received May 29, 1989)

A series of conjugated polyyne porphyrin, in which porphyrin macrocycle is directly connected with one end of diarylpolyyne through aromatic ring, has been prepared and their spectroscopic behaviors were investigated. Diarylpolyynes consisting of aryl group and conjugated triple bond system have rigid and linear structure, and the two chromophores are held at a fixed geometry and a determined distance. The UV-vis absorption spectra of these compounds showed strong conjugative interaction, showing broadening of their spectra and slightly red shifted porphyrin Soret bands with increasing the number of acetylenic bond. From their fluorescence excitation spectra energy transfer efficiencies from polyyne moiety to porphyrin moiety were estimated. The energy transfer efficiencies were almost unity regardless of their substituted position, geometry, and orientation.

In the primary process of natural green plant photosynthesis, energy and/or electron donor and acceptor are held at appropriate distance, geometry and orientation and highly effective energy transfer together with charge separation is achieved in these systems. The X-ray analysis of a bacterial photosynthetic reaction center from Rhodopseudomonas viridis[1] clarified an excellent geometrical arrangement of related pigments. Distance, geometry, and orientation have been recognized more importantly to control the efficiency of energy and electron transfer process. In addition, the environment such as polypeptide, residue of amino acid, π-conjugated system, and long-chain hydrocarbon surrounding the prosthetic molecules has a crucial role for electron transport system as the intervening medium. In order to elucidate the meanings of each factor definitely, it is necessary to construct the model systems of rigidly fixed structure, geometry and orientation. In recent years numerous model systems have been investigated by many investigators in different laboratories.[2-15]

We have synthesized a series of directly conjugated polyyne porphyrins, in which porphyrin macrocycle is directly connected with one end of diarylpolyyne through meso-aromatic ring and investigated the interaction between porphyrin and π-conjugated triple bond system. Since diarylpolyynes have rigid and linear structure, two chromophores are held at a fixed geometry. Changing the substituted position of polyyne, three types of polyyne porphyrin have been synthesized. Increasing the number of conjugated triple bond, distance between both ends of diarylpolyyne can be altered systematically.

Gust et al.[7] had already prepared a variety of carotenoporphyrin and investigated the interaction between porphyrin and carotenoid polyenes, which have typical conjugated double bond system. They revealed that the geometry and distance between them much affected the efficiency of energy transfer. Especially, close proximity is the most important factor of efficient energy transfer.

In our case, energy transfer from polyyne to porphyrin had been also observed. However, the efficiency of energy transfer is almost unity regardless of their substituted position, geometry, and orientation. Strong interaction between polyyne and porphyrin through direct conjugation have been observed with electronic absorption spectra. The excitation energy absorbed by polyyne was efficiently transferred to porphyrin and then porphyrin fluoresced. On the other hand, in the polyyne porphyrin systems in which the two chromophores were connected through ester linkage indirectly, energy transfer efficiency was dependent upon substituted position.

In this report, we will describe detailed synthetic methods of a series of polyyne porphyrins together with characterization of synthesized compounds, and strong interaction through conjugation is discussed.

Results and Discussion

Synthesis. The synthetic route of diarylpolyynes is shown in Scheme 1. Ortho (a series), meta (b series), and para (c series) methoxymethoxymethylbenzaldehydes **1** were used as starting materials, respectively. Most of synthetic method of diarylpolyynes were based on a method reported by Armitage et al.[16] and Akiyama et al.,[17] but in some cases their methods were suitably modified.[18,19] Yields in almost all the reactions were satisfactorily high in each series. Methoxymethyl group was a good protective group of the hydroxyl group under these conditions. In these manners, each series of diarylbutadiynes ($\mathbf{Y}_2$), diarylhexatriynes ($\mathbf{Y}_3$), and diaryloctatetraynes ($\mathbf{Y}_4$) were obtained and recrystallized from ethanol. These compounds were characterized by ^{1}H NMR, IR (Table 1), and mass spectroscopy. Diarylhexatriynes and diaryloctatetraynes are heat- and light-sensitive. They gradually polymerize to give insoluble blue and green colored compounds, respectively.

These synthetic diarylpolyynes ($\mathbf{Y}_n$) were converted into polyyne porphyrins ($\mathbf{P}_n$) according to the reaction Scheme 2. Deprotection by acid hydrolysis and oxi-

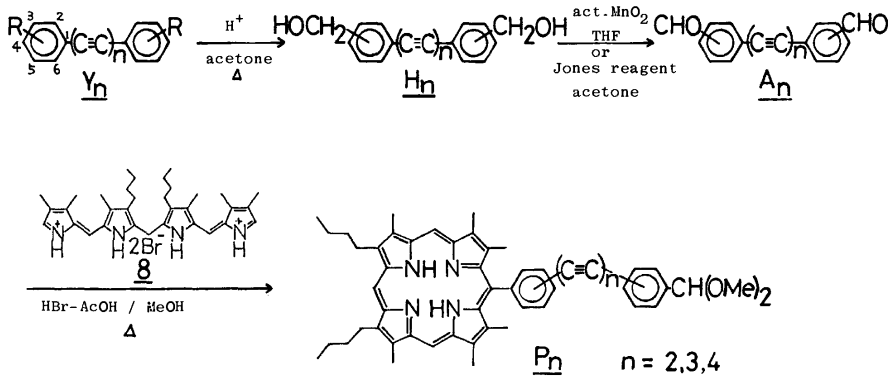

Scheme 2. Synthesis of directly conjugated polyyne porphyrins.

dation with active MnO_2,[20] in some cases with Jones reagent,[21] gave diarylpolyyne dicarbaldehydes ($\mathbf{A}_n$) in satisfactory yields. Melting points, yields, and other spectral data are shown in Table 1. In the dark diarylpolyynes are relatively stable under acidic conditions. The desired conformationally restricted polyyne porphyrins conjugated directly ($\mathbf{P}_n$) could be synthesized by the acid-catalyzed condensation reaction[22] of the corresponding ac-biladiene (**8**)[23] and diarylpolyyne dicarbaldehydes ($\mathbf{A}_n$) in reasonable yields (Table 2). The yields of ortho-substituted polyyne porphyrins were slightly low because of the steric hindrance. Double condensation products of both ends, polyyne porphyrin dimers,[24] could not be produced under these conditions. All these synthesized polyyne porphyrins were recrystallized from dichloromethane-methanol.

Characterization. The structures of directly conjugated polyyne porphyrins are shown in Fig. 1 and melting points, IR, ^{1}H NMR spectral data are shown in Tables 2 and 3. By applying fast-atom-bombardment mass spectrometry to these polyyne porphyrins only characteristic peaks corresponding to the expected $M^+ + nH$ (n=0—4) ions were observed. One end of diarylpolyyne was directly connected with the meso position of porphyrin macrocycle and at the other end aldehyde group was converted into dimethyl acetal group. This dimethyl acetal group was held at fixed geometry toward porphyrin ring, because diarylpolyynes had rigid and linear structure. Especially, in ortho-substituted series its methyl and methine proton were held just on the porphyrin plane and showed upfield shift ($\Delta\delta$=1.2—1.5 ppm) in the ^{1}H NMR spectrum due to the ring current. This upfield shift increases with decreasing the number of acetylenic bond. In para-substituted series dimethyl acetal group

a) Weak, not determined.

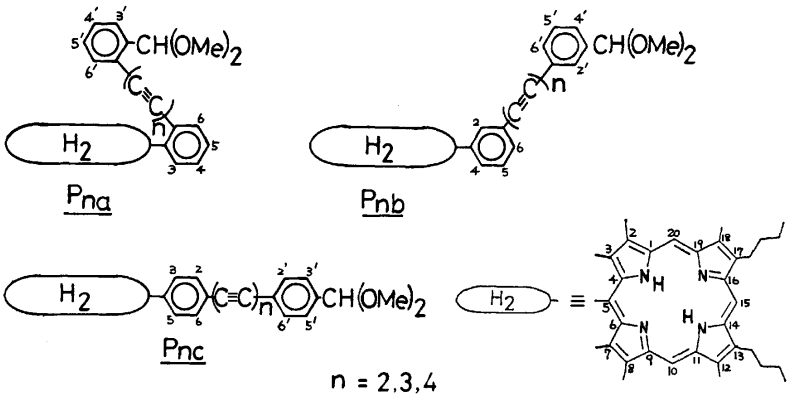

Fig. 1. Directly conjugated polyyne porphyrins.

was so far apart from porphyrin ring that these protons were observed in the lowest field. In the IR spectra a remarkable intensification of the absorption due to $\nu_{C\equiv C}$ with an increase in the number of acetylenic bond was also observed just as in the case of diarylpolyyne.[17] Significant difference, however, was not observed in each substituted series and the number of acetylenic bond. Relatively high melting points and low solubility in organic solvents are similar in ortho- and para-substituted series. Particularly, melting points are low in meta-substituted series.

Absorption and Fluorescence Spectra. The absorption spectra of diarylpolyynes ($\mathbf{Y}_{2c}$—$\mathbf{Y}_{4c}$) and the spectral data of diarylpolyynes ($\mathbf{Y}_n$) are shown in Fig. 2 and Table 4. Diarylpolyynes have vibrational fine structure in their absorption spectra and the novel linear relation between the longest wavelength maxima (λ_{max}) and the number of the acetylenic bond (n) has been found.[25] These synthetic methoxymethoxymethyl-substituted diarylpolyynes have the similar relationship to diphenylpolyyne.[16,25] Absorption maxima and the relationship of each series have not

$$\mathbf{Y}_{na}: \lambda_{max} = 266.0 + 34.0 \times n$$
$$\mathbf{Y}_{nb}: \lambda_{max} = 262.1 + 34.3 \times n$$
$$\mathbf{Y}_{nc}: \lambda_{max} = 266.8 + 33.8 \times n \text{ [26]}$$
$$\text{cf. diphenylpolyyne}: \lambda_{max} = 263.0 + 33.0 \times n \text{ [16,25]}$$

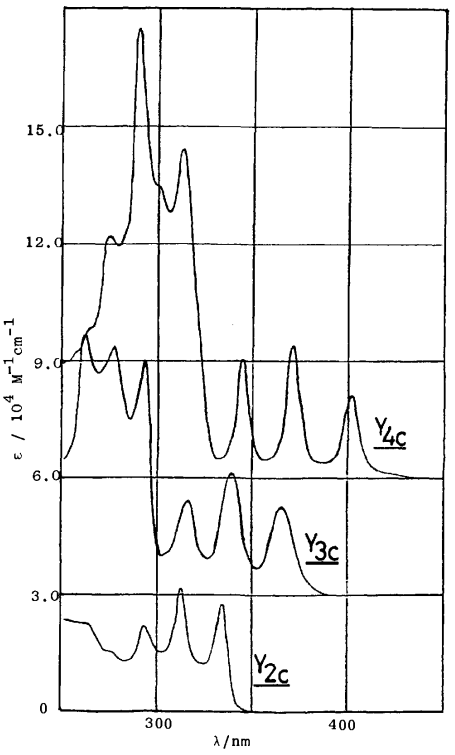

Fig. 2. UV-vis absorption spectra of diarylpolyynes in CH_2Cl_2 solution. Each curve, except for the lowest one, has been displaced upward by 3.0×10^4 ε unit increment from one immediately below it.

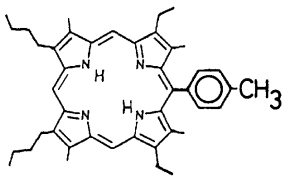
marked difference. Substitution upon aromatic ring by alkyl group showed little perturbation for the electronic state of diphenylpolyyne. In meta-substituted series (b series), however, slightly blue shift relative to other series was observed.

The absorption curves and electronic spectral data of polyyne porphyrins are shown in Figs. 3 and 4 and Table 5. The absorption spectra in the region above 450 nm were similar to those of reference porphyrin (**9**). Therefore, direct conjugation with polyyne have



9

little effect upon porphyrin S_1 state. The absorption maxima (λ_{max}) of porphyrin Soret band are slightly red shifted with increasing the number of conjugated acetylenic bond. Especially in para-substituted series (c series) this tendency is remarkable. On the other hand, significant broadening of the vibrational fine structure of diarylpolyyne was observed. Conjugated large porphyrin macrocycle on one end and unsymmetric structure are presumably responsible for these broadening. The absorption maxima were also red shifted. In ortho-substituted series (a series), however, the extinction coefficient of polyyne was greater relative to other series and the vibrational fine structure was somewhat distinguishable. Similar trend was recognized in the case of indirect conjugated compound. Consequently, it is apparent that not only direct conjugation through bond but also close proximity of each component through space have influenced the electronic absorption spectra.

These synthetic directly conjugated polyyne porphyrin have usual fluorescence emission spectra compared to reference porphyrin **9**. Fluorescence emission maxima and total emission intensity were not significantly perturbed by direct conjugation of polyyne. On one hand, it was found that diarylpolyyne could not quench at all the fluorescence of porphyrins in solution. From Table 6 relative emission intensities (I_b/I_a) are different in each series, respectively. Difference in substituted position was presumed to alter the overlap of 0–0 and 0–1 band.

Energy Transfer. Figure 5 shows the uncorrected fluorescence excitation spectra of directly conjugated polyyne porphyrins ($\mathbf{P_4}$). Assuming that the difference between the absorption spectra of polyyne porphyrin and those of reference porphyrin **9** was the excitation energy absorbed by polyyne, energy transfer efficiency from polyyne to porphyrin could be evaluated from the difference between absorption spectra and fluorescence excitation spectra. These values are shown in

Table 4. UV Vis Spectral Data of Diarylpolyynes

Table 7. Although a little error originating from correction of the fluorescence excitation spectra could not be excluded, energy transfer efficiencies were estimated to be almost unity. Substituted position, distance, and orientation did not affect energy transfer efficiency. Considering the facts that energy transfer had not been observed in a mixed dichloromethane solution of diarylpolyyne and porphyrin and that diarylpolyyne did not fluoresce, this energy transfer mechanism might be intramolecular singlet-singlet energy transfer or internal conversion from polyyne to porphyrin S_1 state through direct conjugation.

For comparison, indirectly conjugated polyyne porphyrins with ester linkage were synthesized (Fig.

6). The UV-vis absorption spectra and the fluorescence excitation spectra of **11a** and **11c** are shown in Figs. 7 and 8. The absorption spectra of indirectly conjugated polyyne porphyrins are approximately identical to the sum of those of the two components, indicating absence of interaction between them. Energy transfer efficiencies from polyyne moiety to porphyrin moiety calculated similarly as described above are shown in Table 8. Characteristic in these porphyrins is that distance and orientation play a crucial role in energy transfer process. That is, close proximity of the concerned chromophores is quite important for the effective energy transfer. In the mixture of each component, however, energy transfer was not observed and energy transfer efficiency was concentration-independent. Therefore, in this case

intramolecular singlet–singlet energy transfer had occurred.

Recently, Kobayashi et al. investigated the absorption spectra of diphenylpolyyne in detail.[27] Excited state of diphenylpolyyne has charge-transfer character, from polyyne to aromatic ring or the opposite direction. Two perpendicular π-conjugated systems interact significantly. As in our case one aromatic ring was directly conjugated with large porphyrin macrocycle system, charge-transfer character was presumed to be eminent. In unsymmetric long linear π-conjugated system, vectorial charge-transfer character might play a role of molecular wire from one end to the other.

Experimental

All melting points were measured with a Yanagimoto micro melting point apparatus and uncorrected. The ^{1}H NMR spectra were recorded on 400 MHz JEOL JNM-GX-400 and 100 MHz JEOL-PS-100 instruments, with tetramethylsilane as an internal reference. Infrared spectra were measured with a JASCO IRA-1 spectrometer. Mass spectra were recorded with a JEOL DX-300 spectrometer. UV-vis spectra were measured with Shimadzu UV-3000 and UV-160 spectrometer. Fluorescence spectra were taken on a Shimadzu RF-502A spectrofluorometer. Dichloromethane was freshly distilled and passed through alumina column. The elemental analysis were performed at the Microanalysis Center of Kyoto University.

Preparation of the Polyyne Porphyrins. Melting points, ^{1}H NMR spectral data in $CDCl_3$ solution, and IR spectral data are given in Tables 1—3. Measurement of mass spectra gave satisfactory values. Synthetic methods of nine kinds of compounds (H_{2a-4c}, A_{2a-4c}, P_{2a-4c}) were similar.

Synthesis of Diarylpolyynediols (H_{2a-4c}). To a solution of the corresponding diarylpolyyne (Y_n) (3 mmol) in 30 ml of acetone was added a 12 ml of 6 mol dm^{-3} HCl solution, and resulting solution was refluxed for 2—4 h under nitrogen in the dark. After cooling, the mixture was extracted with tetrahydrofuran–ether, washed with aqueous $NaHCO_3$ solution, and dried over Na_2SO_4. After evaporation and recrystallization from tetrahydrofuran–hexane, corresponding diols were obtained.

Synthesis of Diarylpolyyne Dicarbaldehydes (A_{2a-4c}).
Method A. To a solution of the corresponding diarylpolyynediol (H_n) (1 mmol) in 30—60 ml of tetrahydrofuran was added a 3.0 g of active MnO_2,[20] and resulting solution was stirred overnight at room temperature in the dark. Manganese oxide was filtered off, and the residue obtained from the filtrate by evaporation of the solvent was purified by chromatography over silica gel, using benzene as an eluent with gradual addition of $CHCl_3$.

Method B (Jones Oxidation).[21] One mmol of diarylpolyynediol (H_n) were dissolved in acetone (150—200 ml). To an ice-cooled solution 2 mol dm^{-3} Jones reagent was added dropwise until an orange tint persisted in the reaction

mixture. Then, isopropyl alcohol was added dropwise to destroy excess Jones reagent, as indicated by the reappearance of a deep green color. After removal of the solvent in vacuo and aqueous treatment, the mixture was extracted with tetrahydrofuran-ether and dried over Na_2SO_4. The solvent was evaporated and the solid was purified by chromatography as described above.

Synthesis of Directly Conjugated Polyyne Porphyrins (P_{2a-4c}). A quarter mmol of diarylpolyyne dicarbaldehyde (A_n) and 0.25 mmol of ac-biladiene (**8**) were dissolved in 40 ml of dry methanol with stirring. Anhydrous 25% HBr-acetic acid solution was added and the mixture was refluxed for 2—5 d under nitrogen in the dark. After cooling, the mixture was poured into water and extracted with $CHCl_3$, and dried over Na_2SO_4. After evaporation, the residue was purified by flash-column chromatography, with an eluent CH_2Cl_2. The second fraction was collected and evaporated in vacuo. Recrystallization from CH_2Cl_2-MeOH gave the desired corresponding polyyne porphyrin conjugated directly.

Synthesis of Indirectly Conjugated Polyyne Porphyrin (11a). 28 mg of porphyrin monoacid **10a** was dissolved in 5 ml of CH_2Cl_2. To this solution 0.1 ml of oxalyl dichloride was added, and the mixture was stirred for 8 h at room temperature in the dark. The excess oxalyl dichloride and CH_2Cl_2 were removed in vacuo quickly, then residue, porphyrin acid chloride, was dissolved in dry CH_2Cl_2 (5 ml) again under N_2. This was added to a solution of diarylpolyynediol (H_{4c}) (12.4 mg) and triethylamine (0.01 ml) in 3 ml of THF, and stirred overnight at room temperature in the dark. The reaction mixture was poured into water, then extracted with $CHCl_3$, washed with aqueous $NaHCO_3$ solution, and dried over Na_2SO_4. The solvent was evaporated and the residue was purified with column chromatography on silica gel, using $CHCl_3$ as an eluent. The second colored fraction gave **11a**: ^{1}H NMR ($CDCl_3$) δ=−3.28 (2H, s, NH), 1.17 (6H, t, ^{n}Bu-Me), 1.79—1.85 (4H, m, ^{n}Bu), 2.30—2.40 (4H, m, ^{n}Bu), 2.32 (6H, s, 3,7-Me), 3.44 (6H, s, 2,8-Me), 3.66 (6H, s, 12,18-Me), 4.03—4.13 (4H, m, ^{n}Bu), 4.54 (2H, d, polyyne close phenyl), 4.71 (2H, s, C$\underline{H}_2$OH), 4.83 (2H, d, polyyne close phenyl), 7.35 (2H, d, polyyne far phenyl), 7.58 (2H, d, polyyne far phenyl), 7.81—7.91 (2H, m, meso-phenyl), 7.99 (1H, d, meso-phenyl), 8.35 (1H, d, meso-phenyl), 9.99 (1H, s, H15), and 10.09 (2H, s, H10,20).

Synthesis of Indirectly Conjugated Polyyne Porphyrin (11c). This was synthesized by the same method as described for the synthesis **11a**: ^{1}H NMR ($CDCl_3$) δ=−3.33 (1H, s, NH), −3.20 (1H, s, NH), 1.12 (6H, t, ^{n}Bu-Me), 1.71—1.81 (4H, m, ^{n}Bu), 2.23—2.31 (4H, m, ^{n}Bu), 2.41 (6H, s, 3,7-Me), 3.51 (6H, s, 2,8-Me), 3.62 (6H, s, 12,18-Me), 4.03 (4H, t, ^{n}Bu), 4.70 (2H, s, C$\underline{H}_2$OH), 7.33 (2H, d, polyyne far phenyl), 7.53 (2H, d, polyyne far phenyl), 7.59 (2H, d, polyyne close phenyl), 7.65 (2H, d, polyyne close phenyl), 8.17 (2H, d, meso-phenyl), 8.44 (2H, d, meso-phenyl), 9.93 (1H, s, H15), and 10.15 (2H, s, H10,20).

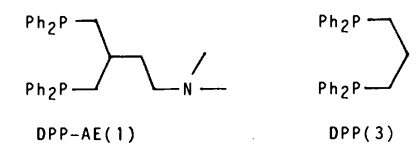
Effects of Solvent and Temperature on the 1,4-Asymmetric Induction in the Diastereoselective Hydrogenation of Dehydrodipeptides

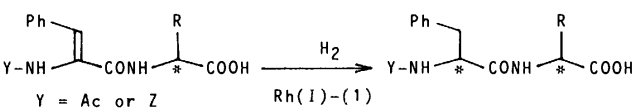
Satoru IKEDA,* Takamichi YAMAGISHI,* Motowo YAMAGUCHI, and Mitsuhiko HIDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received June 6, 1989)

A study of the effets of solvent and temperature on the stereoselectivity of asymmetric hydrogenation of dehydrodipeptides has been made with Rh(I)-(DPP-AE) catalyst, in which an electrostatic interaction is possible between the dimethylamino group of the ligand and the carboxyl group of the substrate. The highest stereoselectivity was attained in the MeOH-water solvent, while aprotic solvents such as DMF and THF gave comparatively low selectivity and reactivity. With increasing the temperature from −40 °C to 80 °C in alcoholic solvent, the stereoselectivity increased to reach a maximum at 20—40 °C, then decreased. The effects of solvent and temperature on the stereoselectivity were discussed.

The asymmetric hydrogenation of olefinic compounds with Rh(I)-diphoshine catalysts has been widely studied and high enantio- or diastereoselectivity was obtained, especially in the case of the hydrogenation of α-dehydroamino acid derivatives.[1] The stereocontrol in these systems is caused by a large steric repulsion between substrate and chiral ligand coordinated to rhodium.[2] On the other hand, enzymes efficiently use attractive forces such as electrostatic interaction, hydrogen bonding, and van der Waals interaction in addition to simple steric repulsion in their highly stereoselective reactions.[3] Incorporation of such attractive interactions to a catalytic system will enhance stereoselectivity in the asymmetric reactions.

Previously, we have reported the application of Rh(I)–achiral diphosphine [2-[2-(dimethylamino)ethyl]-1,3-propanediyl]bis[diphenylphosphine] (DPP-AE(**1**)) system to the hydrogenation of dehydrodipeptides, where the dimethylamino group of the ligand was expected to interact electrostatically with carboxyl group of the substrate (Scheme 1).[4] The detailed examination showed that the presence of both amino group of the ligand and free carboxyl group of the substrate is essential for high stereoselectivity. The Rh(I)-**1** system showed highly selective 1,4-asymmetric induction for the hydrogenation of *N*-acetyl or *N*-benzyloxycarbonyl dehydrodipeptides. For example, the diastereomeric excess was 94% for the hydrogenation of Ac-ΔPhe-(*S*)-Phe-OH, and 92% for Z-ΔPhe-(*S*)-Val-OH, with the selectivity of (*S*,*S*). In the asymmetric reactions, solvent and/or temperature largely affects the stereoselectivity and the reactivity.[5] In this paper we describe the effects of solvent and temperature on the hydrogenation of dehydrodipeptides using this Rh(I)-DPP-AE system, to confirm the contribution of the electrostatic interaction and to establish the optimum conditions for obtaining high stereoselectivity.





Scheme 1.

Results and Discussion

Solvent Effect. The Rh(I)-DPP-AE catalyst system achieved a high stereoselective 1,4-asymmetric induction and afforded a predominant diastereomer with a (*S*,*S*)- or (*R*,*R*)-configuration corresponding to that of the chiral center in the substrate. The hydrogenation of *N*-acetyldehydrophenylalanylamino acids (Ac-ΔPhe-AA-OH (**2**); where AA is a chiral amino acid residue) gave higher stereoselectivities with an increase in polarity of alcoholic solvents (MeOH>EtOH>*i*-PrOH).[4] Therefore addition of water to methanol was expected to raise the stereoselectivity for the hydrogenation of dehydrodipeptides. As was expected, the selectivity of the reaction of **2a** or **2c** increased with an addition of proper amount of water to methanol, although the degree of increase was a little (96% diastereomeric excess for **2a** and 91% d.e. for **2c**) (Table 1). An excessive addition of water, however, lowered both the reactivity and stereoselectivity. Substrate **2a** having a highly hydrophobic amino acid residue afforded 71% d.e. in the 1:1 methanol-water. On the other hand, **2b** gave 77% d.e. even in the 19:1

Table 1. Asymmetric Hydrogenation of Dehydrodipeptides with Rh(I)-DPP-AE System in Aqueous Methanol Solution

Solvent system	%d.e.[a] (time/h)		
	Dehydrodipeptide		
	2a	**2b**	**2c**
$MeOH/H_2O$			
10:0	94(0.5)	88(0.8)	87(1.5)
19:1		77(2)	
9:1		72(12)	91(1)
8:2		—(12)[b]	82(18)
7:3	96(0.5)		—(36)[c]
1:1	71(48)[d]		

The reaction was carried out at 20 °C under atmospheric hydrogen pressure. Dehydrodipeptide : **1** : Rh= 50 : 1.1 : 1. The conversion is 100% unless otherwise noted. The configuration of the predominant product was (*S,S*) for **2a** and **2b**, (*R,R*) for **2c**. a) Diastereomeric excess. b) Conversion was ca. 10%. c) Conversion was 55%. d) Conversion 88%.

methanol-water solution and the reaction was too slow in 8:2 methanol-water solution to determine the diastereoselectivity. Addition of excess water would prevent the electrostatic interaction between substrate and ligand, and also decrease the solubility of the substrates and hydrogen gas in the solvent.

The stereoselectivity and reactivity of **2b** and **2c** in aprotic solvents were rather lower than those in protic solvents (Table 2). The reaction of **2b** required 12 hours in DMF to complete and 20 hours in THF, while the reaction completed within 1 hour in methanol. These results indicated clearly that protic and polar solvent is necessary to obtain good selectivity and reactivity by this Rh(I)-DPP-AE catalyst system for dehydrodipeptides, although large increase of solvent polarity by addition of excess water would lower the selectivity because of the reduction of electrostatic interaction. This solvent effect is in contrast to the hydrogenation of acetamidocinnamic acid with Rh(I)-(*R*)-PheNOP system, which gave high selectivities in DMF or THF and the lowest in MeOH.[5b] On the other hand, the Rh(I)-BPPFA ((*S*)-1-[(*R*)-1,2-bis(diphenylphosphino)ferrocenyl]-*N,N*-dimethylethylamine) having a dimethylamino moiety showed a similar solvent dependence in the hydrogenation of acetamidocinnamic acid derivatives to that of the present Rh(I)-DPP-AE system: Rh(I)-BPPFA gave high selectivity in aqueous methanol rather than in methanol.[5c]

The high stereoselectivity in polar and protic solvents suggests that both proton-donating and proton-accepting characters of solvent affect the selectivity. A proton donor can convert amino group to ammonium cation and a proton acceptor can convert the carboxyl group to carboxylate anion. These ionizations are more feasible in polar solvents such as alcohol or mixture of alcohol-water than in less polar

Table 2. Asymmetric Hydrogenation of Dehydrodipeptides with Rh(I)-DPP-AE in Aprotic Solvents

Dehydrodipeptide	Solvent	Time/h	%d.e.
2b	THF	20	74 (*S,S*)
	DMF	12	65
	MeOH	0.8	88
	THF/H_2O[a]	12	78
2c	THF	3 days	68 (*R,R*)
	EtOH/THF[b]	0.5	86
	EtOH	4	78

The reaction was carried out under atmospheric hydrogen pressure at 20 °C for alcoholic solvents, at 25 °C for others. Dehydrodipeptide : **1** : Rh=50 : 1.1 : 1. Conversion was 100% in all cases. a) The THF : H_2O= 9 : 1. b) The EtOH : THF=9 : 1.

solvents. Here alcohols and water act as proton donor as well as proton acceptor, while THF acts only as proton acceptor. The hydrogenation of **2c** in EtOH-THF and **2b** in THF-H_2O afforded higher diastereoselectivity than in EtOH or THF respectively. These were ascribed to the better combination of proton-donating and proton-accepting solvents. It was concluded that the polarity and the proportion of the proton donor and proton acceptor characters of the solvents are important to affect the ionization of the amino and the carboxyl groups and the electrostatic interaction between them. In the present systems, MeOH-H_2O mixed solvent is the best.

We reported that addition of triethylamine to Rh(I)-DPP-AE system lowered the stereoselectivity.[4] The hydrogenation of **2a** with Rh(I)-DPP-AE in MeOH gave 94%d.e. and addition of amine in 10 molar ratio to the rhodium diminished the selectivity to 66% d.e. On the basis of the above consideration, the influence of addition of amine on selectivity was examined over the amine/Rh ratios from 0 to 50 at 20 °C (Fig. 1), since amine is supposed to be a good proton acceptor to favor the ionization of carboxyl group and to prevent the protonation of dimethylamino group. In the case of Rh(I)-DPP (**3**) system without the electrostatic interaction between ligand and substrate, a maximum selectivity was observed at the amine ratio of 10 to rhodium, and addition of 50 fold amine to rhodium reduced the diastereomeric excess to 22%. The increasing in the diastereoselectivity may be explained as an enhancement of the steric recognition of the substrate by catalyst through the axial coordination of the carboxylate unit formed by addition of amine. It was reported that addition of a small amount of amine increased the stereoselectivity in the hydrogenation of acetamidocinnamic acid or itaconic acid with the Rh(I)-diphosphine catalyst.[6] The Rh(I)-DPP-AE system showed a different behavior from the Rh(I)-DPP catalyst system. Increasing the amount of amine up to 10 molar to the rhodium caused the decrease of the stereoselectivity from 94% to about 60% d.e. By further addition of amine, however,

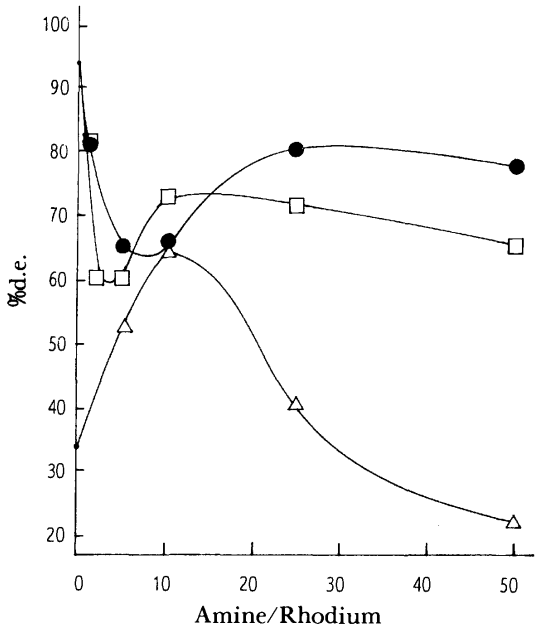

Fig. 1. The influence of amine on stereoselectivity of the hydrogenation of **2b** ●: DPP-AE–triethylamine, □: DPP-AE–*N*-methylmorpholine, △: DPP–triethylamine.

the selectivity turned to increase to reach a maximum (80% d.e. for triethylamine, 72% d.e. for *N*-methylmorpholine) at about 25 molar amine to the rhodium. The initial fall of selectivity was explained by the obstruction of the efficient electrostatic interaction between ligand (**1**) and substrate (**2a**) by the addition of amine. The formed triethylammonium cation will interact with carboxylate anion of the substrate in competition with the ammonium cation unit in the ligand, and suppress the interaction between ligand and substrate. The presence of relatively large amount of amine afforded a high stereoselectivity (80% d.e.), probably by the efficient axial coordination of the carboxylate anion of the substrate, but could not substitute the role of the amino group in DPP-AE catalyst which gave 94% d.e.

Temperature Effect. Generally, the stereoselectivity decreased simply with the elevation of the temperature for the hydrogenation of acetamidocinnamic acid derivatives using Rh(I) catalysts.[5a-d] The reversed trends were reported for some catalytic systems using DIPAMP (1,2-bis[(*o*-methoxyphenyl)phenylphosphino]-ethane) or DIOXOP (4-diphenylphosphino-2-diphenylphosphinomethyl-1,3-dioxolane).[6b,7] We examined the temperature effect of the Rh(I)–DPP-AE system on the hydrogenation of **2b** in MeOH, EtOH, and *i*-PrOH, in the temperature range from −40 °C to 80 °C (Fig. 2). Each plot of the selectivities against temperature showed a curve with a maximum. The optimal temperature shifted to the lower temperature with an increase in the polarity of solvent. EtOH and MeOH gave the maximum around ambient temperature, while *i*-PrOH shifted the maximum to higher temperature. The Arrhenius plot of the (*S,S*)/(*R,S*) ratio apparently showed the presence of at least two predominant active species. Assuming those two species we estimated the difference of activation enthalpies ($\Delta\Delta H^{\neq}$) and entropies ($\Delta\Delta S^{\neq}$) of the reaction in EtOH. The one catalyst species seems to operate at lower temperatures between −40 °C and 20 °C, and has the activation parameters, 16 kJ mol^{-1} of $\Delta\Delta H^{\neq}$ and 74 J deg^{-1} mol^{-1} of $\Delta\Delta S^{\neq}$. The another species seems to operate at higher temperatures between 20 °C and 80 °C, and has −3.9 kJ mol^{-1} of $\Delta\Delta H^{\neq}$ and 8.1 J deg^{-1} mol^{-1} of $\Delta\Delta S^{\neq}$. These activation parameters suggest that the enthalpy term of the former catalyst species selects (*R,S*) isomer, while its entropy term selects (*S,S*) isomer. On the other hand both enthalpy and entropy terms of the latter species select (*S,S*) isomer. The contribution of the entropy term to the stereocontrol of this Rh(I)–DPP-AE catalytic system at lower temperatures is large compared with that of chiral Rh(I) catalyst systems.[8] This fact suggests that the mode of coordination of substrate to catalyst affects largely the control of stereoselectivity. The electrostatic interaction provides an additional recognition point of substrate by catalyst and this interaction plays an important role to determine the mode of coordination at least in the lower temperature range and cause a large contribution of the entropy term to the stereocontrol. This temperature effect is rather similar to the temperature dependence of the heterogeneous systems, hydrogenolytic transamination between α-keto ester and chiral amine with $Pd(OH)_2$ on carbon.[5f] Temperature effects in EtOH were also examined for the hydrogenation of **2b** with DPP and of **2d** (methyl ester of **2b**) with DPP-AE (Fig. 3). Both systems have a similar steric circumstance to that of DPP-AE–**2b** system, but the electrostatic interaction cannot operate in these systems. Both showed stereoselectivities of about 50% d.e. between −40 °C

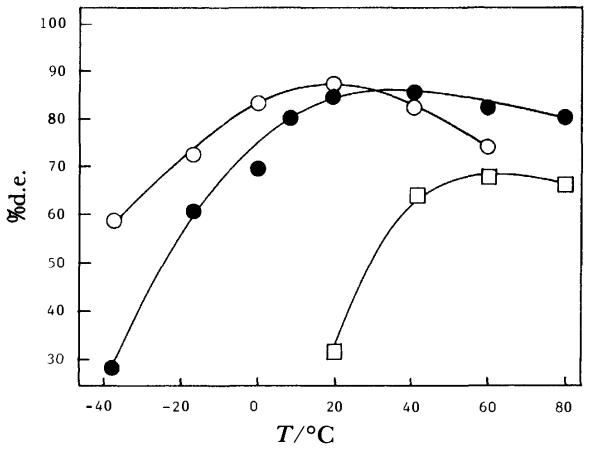

Fig. 2. The temperature dependence of the hydrogenation of **2b** with Rh(I)–DPP-AE system ○: MeOH; ●: EtOH, □: *i*-PrOH.

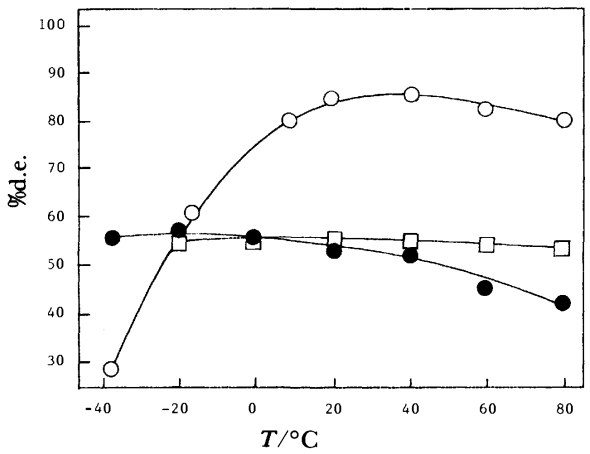

Fig. 3. The temperature dependence of the asymmetric induction in MeOH ○: DPP-AE-**2b**, □: DPP-AE-**2d**,●: DPP-**2b**.

and 80 °C. The $\Delta\Delta S^{\neq}$ was 0.85 J deg^{-1} mol^{-1} (−20 to 80 °C) for DPP-**2b** system, and 13 J deg^{-1} mol^{-1} (−20 to 20 °C), 7.4 J deg^{-1} mol^{-1} (20 to 80 °C) for DPP-AE-**2d** system. The absolute values of $\Delta\Delta S^{\neq}$ of these systems were smaller than that of DPP-AE-**2b** systems. At lower temperature the diastereoselectivity of these two systems are higher than that of DPP-AE system. This suggests that the electrostatic interaction works to increase (*R*,*S*) selectivity by lowering the temperature, although the predominant diastereomer is still (*S*,*S*).

We observed that the Rh(I)-DPP-AE (**1**) system gives the optimum conditions at ambient temperature in MeOH or MeOH-water mixed solvents in which the efficient electrostatic interaction is possible between ligand and substrate for hydrogenation of dehydrodipeptides. This catalytic system achieves highly stereoselective 1,4-asymmetric induction more than 90% d.e. regardless of the chiral amino acid residue in the dehydrodipeptides. Thus this method is useful for synthesis of chiral linear dipeptides.[9]

Experimental

Instrument. ^{1}H NMR spectra were recorded on a Hitachi R-24 or JEOL FX-90Q spectrometer in $CDCl_3$ using tetramethylsilane as an internal standard.

Chemicals and Solvents. DPP-AE (**1**) was prepared in four steps starting from diethyl malonate and 2-chloro-*N*,*N*-dimethylethylamine.[5] DPP (**3**) was prepared from 1,3-dichloropropane and lithium diphenylphosphide. Dehydrodipeptides (**2a**—**2c**) were prepared from the azlactone of acetamidocinnamic acid[10] and corresponding chiral amino acid according to the method by Bergmann et al.[11] Dehydrodipeptide ester (**2d**) was obtained by the reaction of **2b** with MeOH-HCl. Alcohols were dried by refluxing over magnesium (MeOH and EtOH) or sodium (*i*-PrOH) and distilled under nitrogen. Tetrahydrofuran, triethylamine and *N*-methylmorpholine were dried over sodium and distilled, and DMF was dried over Molecular Sieves 4A and distilled. All solvents and amines were stored under nitrogen. NMR shift reagent, Eu(fod)$_3$, was used as purchased. $[Rh(nbd)_2]^+BF_4^-$ (nbd=norbornadiene) was used as the rhodium precursor.

Method of Hydrogenation. All hydrogenations were carried out under atmospheric hydrogen pressure. The catalyst was prepared in situ from the ligand and rhodium precursor. To this catalyst solution in a reaction vessel was added the substrate, and the mixture was stirred for 1 hour under nitrogen. The reaction vessel was immersed in a temperature-regulated bath and hydrogen was introduced. The reaction was monitored by the absorption of H_2 using a gas burette for the reaction above 0 °C. In the case of the reaction under −20 °C, the stopcock of the vessel was closed after introduction of hydrogen and stirring was continued for 1 to 3 days. After the reaction, the catalyst was removed with cation-exchange resin, Dowex 50, and the product was converted to its methyl ester in MeOH-HCl.

Determination of Diastereomeric Excess. ^{1}H NMR spectra of the methyl ester were measured in the presence of Eu(fod)$_3$. Two singlets of diastereotopic methyl protons in the methyl ester shifted in different degrees and the diastereomeric excess was determined based on the area of each signal.

Synthesis of 1,5-Bifunctionalized Optically Active 3-Pentanol as a Reversible Chiral Building Block. Asymmetric Reduction of 4-(1,3-Dithian-2-yl)-3-oxobutanoates with Fermenting Bakers' Yeast

Hidenori CHIKASHITA,* Kazuhiko OHKAWA, and Kazuyoshi ITOH
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564
(Received June 12, 1989)

Bakers' yeast reduction of a homologous series of 4-(1,3-dithian-2-yl)-3-oxobutanoates to the corresponding chiral 4-(1,3-dithian-2-yl)-3-hydroxybutanoates was investigated. A shift in enantiomeric excess, stereochemistry, and chemical yield of the reduction product was observed as the size of the ester alkoxyl group was changed. The kind of bakers' yeast (raw or dry) and reaction conditions also affected the optical purity and chemical yield of the product. These studies showed that the reduction of methyl 4-(1,3-dithian-2-yl)-3-oxobutanoate with the raw yeast in the absence of additives was most efficient, giving methyl (*S*)-4-(1,3-dithian-2-yl)-3-hydroxybutanoate with 77% ee in 37% yield.

The synthetic utility of microorganisms and enzymes as organic reagents has recently been demonstrated by their numerous applications to the synthesis of valuable chiral building blocks of high optical purity.[1] Among these bioorganic transformations, the synthesis of optically active and symmetrically functionalized secondary alcohol such as 1,5-bifunctionalized 3-pentanol, symbolized as **1**, is of importance and has received significant attention in recent years.[2,3] Recent studies in this field have made it possible to obtain this type of bifunctional chiral alcohol with varying degree of enantiomeric selectivity.[2,3] We considered, however, that (*S*)- or (*R*)-4-(1,3-dithian-2-yl)-3-hydroxybutanoate **3** could be an excellent candidate as such type of chiral building block for the synthesis of a variety of natural products (e.g., polyoxygenated compounds) because not only for its ease of functional convertibility but its utility as two configurational antipodes (reversible) by synthetic chemical distinguishing between the potentially equivalent two (dithianyl and ester) functional groups. We now wish to report the synthesis of a novel 1,5-bifunctional 3-pentanol **3** as a reversible chiral building block by employing the asymmetric reduction of 4-(1,3-dithian-2-yl)-3-oxobutanoates **2** with fermenting bakers' yeast (*Saccharomyces Cerevisiae*).

Results and Discussion

Methyl and ethyl esters **2a,b** were prepared by alkylation of dienol silyl ethers **4a,b** of the corresponding 3-oxobutanoates with 1,3-dithienium tetrafluoroborate. Octyl ester **2c** was obtained by the ester-exchange reaction of **2a** with 1-octanol in the presence of *p*-toluenesulfonic acid (*p*-TsOH). Potassium carboxylate **2d** was prepared by the hydrolysis of **2a** in ethanol with 1 M KOH (1 M=1 mol dm^{-3}) and used directly for the subsequent yeast reduction. The reduction of a homologous series of 1,3-dithianyl-3-oxobutanoates **2a—d** with raw bakers' yeast under standard conditions provided the corresponding β-hydroxy esters **3a—c** together with optically pure (*S*)-1-(1,3-dithian-2-yl)-2-propanol (**5**). The latter compound was produced by the yeast reduction of the initially formed decarboxylation product **6**.[4] The results are summarized in Table 1. Optical purity of the β-hydroxy esters obtained was determined by 400 MHz ^1H NMR analyses of the respective (+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid ((+)-MTPA) ester derivatives **7a—c** and the (+)-MTPA esters of the respective racemic form as references obtained by the reduction of **2a,c** with $Zn(BH_4)_2$ and of **2b** with $NaBH_4$.[5]

excess and stereochemistry of the product **3** were observed as a function of the size of the ester alkoxyl group transformed. Methyl and ethyl esters **2a,b** were reduced by bakers' yeast to (*S*)-**3a,b** preferentially in 74% and 50% ee, respectively (Entries 1,2). On the other hand, the yeast reduction of potassium salt **2d** also gave (*S*)-**3a** after work-up with diazomethane with the highest optical purity (86% ee), but the chemical yield was too low to be synthetically useful (Entry 4). However, the reduction of octyl ester **2c** preferentially formed (*R*)-**3c** in 14% ee (Entry 3). Recently, Zhou et al. have closely examined the Prelog rule, which has been used to predict the stereochemistry of yeast reductions of acyclic ketones, on the yeast reduction of 4-chloro-3-oxobutanoates.[6] They showed that the esters having a very small alkoxyl group and a very large one were reduced to the (*S*)- and (*R*)-isomer, respectively, and the ee-value consecutively dropped as the size of the ester alkoxyl group draw near to medium. Our results on stereoselectivity and trend toward the ee-value shift are explicable based on the Prelog rule in analogy to the results of Zhou et al. However, the enantiomeric excess in the reduction of methyl ester **2a** was higher than that (ca. 65% ee) of methyl 4-chloro-3-oxopropanoate while the reduction of octyl ester **2c** showed lower stereoselectivity than that (ca. 97% ee) of octyl 4-chloro-3-oxopropanoate. Since the stereochemical course and enantioselectivity of the bakers' yeast reduction of β-keto esters should be mainly determined by the relative balance in steric bulk derived from the carbonyl substituents, the aforementioned fact is most likely due to the relative bulkiness of the dithianyl moiety when compared with the chloromethyl moiety (i.e., the relatively small difference in size between the dithianyl and ester moieties in **2**).

The absolute configuration of the hydroxy esters obtained in the present bakers' yeast reduction was determined by transforming **3a** into known lactone **11** as follows. Hydrolysis of the dithioacetal group of compound **8** obtained by the silylation of the β-hydroxy ester **3a** with *t*-butyldiphenylsilyl chloride (TBDPS-Cl) and imidazole in DMF provided the aldehyde **9**. The aldehyde **9** was reduced to **10** with $Zn(BH_4)_2$ in ether and the subsequent lactonization of **10** with *p*-TsOH in benzene gave the 3-hydroxyvalerolactone derivative **11**, $[\alpha]_D^{24}$ +7.0° (*c* 0.26, $CHCl_3$). Since the specific rotation of (*R*)-**11** with 80% ee is previously reported in the literature to be $[\alpha]_D$ +9.2° (*c* 7.7, $CHCl_3$),[3] the absolute configuration of the major isomer of **3a** was thus established to be *S*. The absolute configurations of **3b** and **3c** were determined by a similar comparison of $[\alpha]_D$ after respective conversion into the corresponding methyl ester by the ester-exchange reaction with *p*-TsOH in benzene.

11

It is indicated from recent results appeared in the literature that the optical purity of the yeast reduction of β-keto esters depends on substrate concentration, the kind of commercially available forms of bakers' yeast (raw cake or dried granules), and the concentration of sugars.[7] Thus, we evaluated these effects on the reduction of **2a**, with an aim of possible improvement in the chemical yield and optical purity of **3a**. The results are summarized in Table 2. When dry yeast was used in place of raw yeast under the standard conditions, the enantiomeric excess dropped from 74% to 61% (Entry 4). However, considerable improvement in both chemical yield and optical purity could be achieved by the reduction using raw yeast without sugar, giving **3a** in 37% yield with 77% ee (Entry 2). The reduction without additives under low substrate concentration did not further influence the ee-value of **3a** in spite of the significant improvement in decarboxylation of **2a** (Entry 3). Accordingly, the

useful chiral building block, methyl (*S*)-4-(1,3-dithian-2-yl)-3-hydroxybutanoates **3a**, is now available in 37% chemical yield and in 77% optical purity.

Experimental

Melting points were recorded on a Yanagimoto micro melting point apparatus and are uncorrected. Optical rotations were determined with a Union Digital PM-101 polarimeter. IR spectra were obtained on a Perkin Elmer Model 1660 FT-IR spectrophotometer. ^{1}H NMR spectra were measured with a JEOL JNM-GX400 spectrometer at 400 MHz with tetramethylsilane as an internal reference. Silica gel (Merck silica gel 60, 230—400 mesh ASTM) was used for medium-pressure liquid chromatography (MPLC). Analytical and preparative TLC were carried out on Merck precoated silica gel plates (Merck silica gel 60 F_{254}).

Materials. Raw bakers' yeast (Oriental Yeast Co.) and Dry granular yeast (Oriental Yeast Co.) were commercially available. 1,3-Bis(trimethylsiloxy)-1-methoxy-1,3-butadiene (**4a**) and 1,3-bis(trimethylsiloxy)-1-ethoxy-1,3-butadiene (**4b**) were prepared according to reported methods.[8] 1,3-Dithienium tetrafluoroborate was prepared according to the method of Corey et al.[9] Zinc borohydride was prepared from sodium borohydride and zinc chloride as a 0.3 M ethereal solution.[10] The other reagents were supplied as high grade commercial products and used without further purification.

Methyl 4-(1,3-Dithian-2-yl)-3-oxobutanoate (2a). A solution of 1,3-dithienium tetrafluoroborate (9.02 g, 44 mmol) in dry nitromethane (93 ml) was cooled to −40 °C under nitrogen and a solution of dienol silyl ether **4a** (26 g, 100 mmol) in dry dichloromethane (93 ml) was then added dropwise. After stirring for 30 min at −40 °C, the mixture was allowed to slowly warm to room temperature and the stirring was continued for 19 h under nitrogen. 2 M HCl (20 ml) was added to the mixture and the solution was stirred for 30 min. The aqueous mixture was extracted with ether and the extract was washed with saturated aqueous $NaHCO_3$ solution and water. The organic layer was dried with $MgSO_4$ and concentrated under reduced pressure to give crude crystalline product. Recrystallization from methanol afforded pure **2a** as colorless needles (8.06 g, 78%); mp 70—70.2 °C; IR (KBr) 2976, 2956, 2904, 1737, 1714, 1434, 1416, 1404, 1356, 1321, 1275, 1247, 1196, 1172, 1132, 1116, 1085, 1046, 1016, 1000, 966, 910, and 576 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.88 (m, 1H), 2.11 (m, 1H), 2.88 (m, 4H), 2.98 (d, 2H, J=6.8 Hz), 3.51 (s, 2H), 3.75 (s, 3H), and 4.49 (t, 1H, J=6.8 Hz). Calcd for $C_9H_{14}O_3S_2$: C, 46.13; H, 6.02%. Found: C, 46.75; H, 5.92%.

Ethyl 4-(1,3-Dithian-2-yl)-3-oxobutanoate (2b). Dienol silyl ether **4b** (11.5 g, 41.9 mmol) was reacted with 1,3-dithienium tetrafluoroborate (4.15 g, 20.2 mmol) by a method similar to the preparation of **2a**. Recrystallization of the crude product from ethanol afforded pure **2b** as colorless needles (3.22 g, 64%); mp 71.6—72 °C; IR (KBr) 2978, 1724, 1470, 1438, 1411, 1358, 1316, 1279, 1189, 1171, 1131, 1115, 1085, 1029, 1004, 947, 931, 908, 872, 809, 669, 654, 632, and 575 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.29 (t, 3H, J=7.1 Hz), 1.88 (m, 1H), 2.11 (m, 1H), 2.88 (m, 4H), 2.98 (d, 2H, J=6.8 Hz), 3.49 (s, 2H), 4.21 (q, 2H, J=7.1 Hz), and 4.50 (t, 1H, J=6.8 Hz). Calcd for $C_{10}H_{16}O_3S_2$: C, 48.36; H, 6.49%. Found: C, 48.44; H, 6.51%.

Octyl 4-(1,3-Dithian-2-yl)-3-oxobutanoate (2c). A mixture of **2a** (3.81 g, 16.2 mmol), 1-octanol (30 ml), and *p*-TsOH monohydrate (310 mg, 1.62 mmol) in benzene (60 ml) was refluxed for 20 h. The mixture was cooled to room temperature and washed with saturated aqueous $NaHCO_3$ solution and water and then dried with $MgSO_4$. After evaporation of benzene under reduced pressure, most of remained 1-octanol was removed by vacuum distillation. MPLC purification (benzene-ethyl acetate 25:1 v/v) of the residue gave pure **2c** as a colorless heavy oil (4.15 g, 77%); IR (KBr) 2931, 1744, 1716, 1474, 1456, 1438, 1408, 1394, 1357, 1319, 1271, 1189, 1175, 1132, 1116, 1085, 1045, 1025, 991, 966, 913, 812, 722, 633, and 577 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, 3H, J=7.1 Hz), 1.28 (br, 10H), 1.71 (m, 2H), 1.95 (m, 1H), 2.06 (m, 1H), 2.78 (ddd, 2H, J=14.2, 9.8, 2.9 Hz), 2.94 (ddd, 2H, J=14.2, 6.8, 2.9 Hz), 3.36 (d, 2H, J=7.8 Hz), 3.69 (s, 2H), 3.76 (t, 2H, J=6.4 Hz), and 4.32 (t, 1H, J=7.8 Hz). Calcd for $C_{16}H_{28}O_3S_2$: C, 57.79; H, 8.49%. Found: C, 57.89; H, 8.44%.

Bakers' Yeast Reduction of 4-(1,3-Dithian-2-yl)-3-oxobutanoates; Representative Method. Raw bakers' yeast (112 g) was dispersed in a solution of sucrose (22.9 g), $Na_4P_2O_7$ (11.2 g), and $MgSO_4$ (250 mg) in distilled water (335 ml), and the mixture was then stirred for 30 min at 25 °C. To the fermenting mixture was added the β-keto ester **2** (25.6 mmol) and stirred at the same temperature for 7 days (an additional bakers' yeast (56 g), sucrose (11.5 g), $Na_4P_2O_7$ (5.6 g), $MgSO_4$ (125 mg), and distilled water (167 ml) were supplied every day). Ethyl acetate (634 ml) was added to the reaction mixture and the mixture was stirred for 16 h. After filtration through a Celite pad, the filtrate was extracted with ethyl acetate and the extract was dried with $MgSO_4$. The solvent was removed by evaporation under reduced pressure and the residue was diluted with dichloromethane. The solution was filtered through a silica-gel pad (Wakogel

C-300) and evaporated under reduced pressure. Purification of the residue by MPLC (**3a**, hexane-ethyl acetate 5:3 v/v; **3b** and **3c**, benzene-ethyl acetate 10:1 v/v) gave pure β-hydroxy ester **3** as a colorless oil. Spectroscopic and analytical data of the reduction products **3** are as follows:

3a: $[\alpha]_D^{25}$ +1.0° (*c* 1.56, $CHCl_3$) (74% ee); IR (neat) 3460, 2949, 2902, 2850, 1729, 1437, 1372, 1277, 1197, 1075, 1046, 1020, 910, 872, 849, 774, 715, and 665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.79—2.00 (m, 3H), 2.13 (m, 1H), 2.47 (dd, 1H, *J*=16.6, 8.4 Hz), 2.54 (dd, 1H, *J*=16.6, 3.7 Hz), 2.87 (m, 4H), 3.14 (d, 1H, *J*=3.9 Hz), 3.72 (s, 3H), 4.29 (dd, 1H, *J*=9.6, 4.6 Hz), and 4.35 (m, 1H). Calcd for $C_9H_{16}O_3S_2$: C, 45.74; H, 6.82%. Found: C, 45.63; H, 6.89%.

3b: $[\alpha]_D^{33}$ +2.6° (*c* 2.83, $CHCl_3$) (50% ee); IR (neat) 3418, 2903, 1732, 1464, 1424, 1374, 1277, 1186, 1074, 1023, 943, 909, 874, 848, 773, and 665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28 (t, 3H, *J*=7.1 Hz), 1.79—2.00 (m, 3H), 2.13 (m, 1H), 2.45 (dd, 1H, *J*=16.6, 8.5 Hz), 2.52 (dd, 1H, *J*=16.6, 3.7 Hz), 2.88 (m, 4H), 3.21 (d, 1H, *J*=3.9 Hz), 4.18 (q, 2H, *J*=7.1 Hz), 4.30 (dd, 1H, *J*=9.8, 4.6 Hz), and 4.34 (m, 1H). Calcd for $C_{10}H_{18}O_3S_2$: C, 47.97; H, 7.25%. Found: C, 47.95; H, 7.36%.

3c: $[\alpha]_D^{22}$ +0.19° (*c* 2.11, $CHCl_3$) (14% ee); IR (neat) 3452, 2926, 2854, 1729, 1466, 1423, 1345, 1276, 1247, 1182, 1073, 1018, 910, 872, 853, 774, 723, and 666 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (t, 3H, *J*=7.1 Hz), 1.28 (br, 10H), 1.63 (m, 2H), 1.79—2.00 (m, 3H), 2.13 (m, 1H), 2.45 (dd, 1H, *J*=16.6, 8.5 Hz), 2.53 (dd, 1H, *J*=16.6, 3.7 Hz), 2.89 (m, 4H), 3.18 (d, 1H, *J*=4.2 Hz), 4.11 (t, 2H, *J*=6.8 Hz), 4.30 (dd, 1H, *J*=9.8, 4.6 Hz), and 4.34 (m, 1H). Calcd for $C_{16}H_{30}O_3S_2$: C, 57.45; H, 9.04%. Found: C, 57.28; H, 8.97%.

Methyl (*S*)-3-(*t*-Butyldiphenylsiloxy)-4-(1,3-dithian-2-yl)-butanoate (8). To a stirred solution of **3a** (1.01 g, 4.2 mmol) in dry DMF (4.6 ml) was added TBDPS-Cl (1.70 g, 6.2 mmol) and imidazole (0.85 g, 12.4 mmol) at room temperature. After stirring for 2 h at room temperature, the solvent was removed in vacuo. The residue was extracted with ethyl acetate (30 ml) and 5% aqueous oxalic acid solution (8 ml×3). The organic layer was then successively washed with 5% aqueous oxalic acid solution (15 ml), saturated aqueous $NaHCO_3$ solution (15 ml), and water (15 ml). The solution was dried with $MgSO_4$ and evaporated under reduced pressure to give almost TLC-pure product. MPLC purification (benzene-ethyl acetate 25:1 v/v) of the crude product afforded pure **8** as a colorless oil (2.02 g, 99%); $[\alpha]_D^{24}$ −6.9° (*c* 2.28, $CHCl_3$); IR (neat) 3070, 3048, 3014, 2998, 2931, 2896, 2856, 1738, 1472, 1462, 1427, 1390, 1362, 1276, 1197, 1157, 1111, 998, 940, 858, 822, 741, 704, and 610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.05 (s, 9H), 1.78 (m, 1H), 1.97 (m, 3H), 2.50 (dd, 2H, *J*=6.0, 2.2 Hz), 2.67 (m, 4H), 3.52 (s, 3H), 3.94 (dd, 1H, *J*=8.4, 6.1 Hz), 4.43 (m, 1H), 7.40 (m, 6H), and 7.69 (m, 4H).

Methyl (*R*)-3-(*t*-Butyldiphenylsiloxy)-5-oxopentanoate (9). To a solution of **8** (1.01 g, 2.13 mmol) in acetonitrile (11 ml) and water (0.38 ml) was added iodomethane (1.59 g, 11.2 mmol) and K_2CO_3 (196 mg, 1.41 mmol). The mixture was refluxed for 3 h and the solvent was then removed by evaporation under reduced pressure. The residue was extracted with dichloromethane and the extract was dried with $MgSO_4$. The residue obtained by evaporation of the solvent under reduced pressure was purified by MPLC (hexane-ethyl acetate 4:1 v/v) to give pure **9** as a pale yellow oil (231 mg, 28%); $[\alpha]_D^{19}$ −1.7° (*c* 2.56, $CHCl_3$); IR (neat) 3073, 2932, 2859, 1742, 1714, 1473, 1428, 1363, 1308, 1160, 1112, 786, 702, 668, 612, 518, and 512 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.03 (s, 9H), 2.62 (m, 4H), 3.57 (s, 3H), 4.62 (m, 1H), 7.42 (m, 6H), 7.66 (m, 4H), and 9.62 (t, 1H, *J*=2.2 Hz).

Methyl (*R*)-3-(*t*-Butyldiphenylsiloxy)-5-hydroxypentanoate (10). To an ethereal solution of $Zn(BH_4)_2$ (0.3 M, 6.9 ml) cooled to 0 °C was added dropwise a solution of **9** (310 mg, 0.84 mmol) in dry ether (7 ml) with stirring under nitrogen and stirring was then continued for 2 h at 0 °C. After the addition of water (6 ml), the aqueous mixture was filtered and extracted with ether. The organic layer was dried with $MgSO_4$ and concentrated under reduced pressure to give crude product. MPLC purification (benzene-ethyl acetate 4:1 v/v) afforded pure **10** as a colorless oil (160 mg, 49%); $[\alpha]_D^{23}$ −1.7° (*c* 0.92, $CHCl_3$); IR (neat) 2959, 2931, 2858, 1738, 1472, 1428, 1391, 1362, 1309, 1261, 1221, 1164, 1112, 1084, 1027, 1008, 998, 927, 823, 703, and 613 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.05 (s, 9H), 1.66 (brs, 1H), 1.76 (m, 2H), 2.54 (d, 2H, *J*=6.3 Hz), 3.53 (s, 3H), 3.63 (m, 2H), 4.37 (m, 1H), 7.40 (m, 6H), and 7.69 (m, 4H).

(*R*)-3-(*t*-Butyldiphenylsiloxy)-5-pentanolide (11). A mixture of **8** (144 mg, 0.37 mmol) and *p*-TsOH monohydrate (7 mg, 0.037 mmol) in benzene (3.4 ml) was refluxed for 1 h. After cooling to room temperature, saturated aqueous $NaHCO_3$ solution (10 ml) was added to the mixture and the aqueous mixture was then extracted with benzene. The organic layer was dried with $MgSO_4$ and concentrated under reduced pressure to give crude product. MPLC purification (benzene-ethyl acetate 4:1 v/v) afforded pure **11** as a colorless oil (57 mg, 44%): $[\alpha]_D^{24}$ +7.0° (*c* 0.26, $CHCl_3$) (lit,[3] $[\alpha]_D$ +9.2° (*c* 7.69, $CHCl_3$)); IR (neat) 3461, 3071, 3049, 2932, 2856, 1731, 1589, 1567, 1472, 1427, 1391, 1361, 1261, 1223, 1161, 1114, 928, 864, 822, 742, 701, and 610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (s, 9H), 1.84 (m, 2H), 2.58 (d, 2H, *J*=4.9 Hz), 4.22 (m, 2H), 4.62 (ddd, 1H, *J*=11.4, 8.8, 4.2 Hz), 7.42 (m, 6H), and 7.63 (m, 4H).

H. C. thanks the Ministry of Education, Japan, for financial support by a Grant-in-Aid for the Scientific Research (No. 63750820).

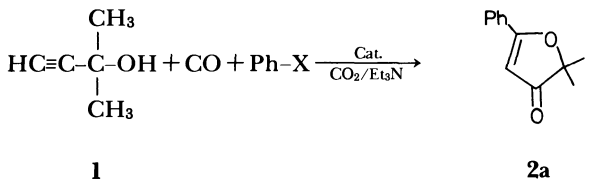
Preparation of 3(2*H*)-Furanones from 2-Propynyl Alcohol, CO, and Phenyl Halides under CO_2 Atmosphere Catalyzed by Transition Metal Complexes

Yoshio INOUE,* Kunihiro OHUCHI, I-Fang YEN, and Shin IMAIZUMI
Department of Engineering Science, Faculty of Engineering, Tohoku University, Aramaki, Aoba-ku, Sendai 980
(Received May 27, 1989)

The novel synthetic method for 2,2-dimethyl-5-phenyl-3(2*H*)-furanone (bullatenone) from 2-methyl-3-butyn-2-ol, CO, and phenyl halides in the presence of a catalytic amount of transition metal complexes under the influence of CO_2 has been described. It was revealed that there was the intermediate formation of an acetylenic ketone from the acetylenic alcohol, CO, and the phenyl halide followed by the formation of a cyclic carbonate from the acetylenic ketone and CO_2 which underwent the decarboxylative transformation into the 3(2*H*)-furanone quantitatively.

In recent years, considerable interest has been paid for the fixation of carbon dioxide (CO_2) from the points of the recycle of carbon resources and the environment.[1)]

During the course of our studies directed at the effective utilization of CO_2, we have explored that 2-methyl-3-butyn-2-ol (**1**) reacts with carbon monoxide (CO) and phenyl halides in the presence of a catalytic amount of transition metal complexes to afford 2,2-dimethyl-5-phenyl-3(2*H*)-furanone (**2a**) under the influence of CO_2.[2)]



1 **2a**

The product **2a** is called bullatenone, which occurs in the essential oil of Myrtus bullata, a shrub endemic to New Zealand.[3)] The 3(2*H*)-furanone ring is contained in many naturally occurring compounds characterized by important biological activity as antitumor agents (eremantholides, geiparvarin) or aroma constituents.[4)]

It appears that the straightforward production of the furanone from the starting materials is difficult. Furthermore the role of CO_2 on this reaction is not distinct, partly because it does not enter into the stoichiometry. In this paper we describe the elucidation of the reaction pathway as well as the scope of this new method for the synthesis of 3(2*H*)-furanones.

Results and Discussion

Various Group 8, 9, and 10 transition metal–triphenylphosphine complexes were active as the catalyst for the formation of the furanone **2a** from the acetylenic alcohol **1**, CO, and iodobenzene in triethylamine under the influence of CO_2 as shown in Table 1. Yields, in general, were moderate to reasonable except in the case of [$RhCl(PPh_3)_3$], where the yield was only modest. In the present reaction triethylamine functions as a base as well as a solvent. The employment of Na_2CO_3 or K_2CO_3 as the base resulted in the marked decrease in the yield. The effect of CO_2 was significant since the yield of **2a** dropped considerably and oily products came out when the reaction was performed under CO atmosphere.

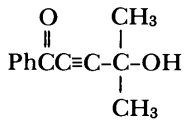
Table 1. Effect of Catalyst on the Synthesis of **2a**[a)]

Catalyst	Solvent	Base	Yield of **2a**[b)]/%
$FeCl_2(PPh_3)_2$	NEt_3	—	62 (21)
$CoCl_2(PPh_3)_2$	NEt_3	—	61 (29)
$CoCl_2(PPh_3)_2$	CH_3CN	K_2CO_3	15
$NiCl_2(PPh_3)_2$	NEt_3	—	57 (36)
$RuCl_2(PPh_3)_3$	NEt_3	—	52 (19)
$RhCl(PPh_3)_3$	NEt_3	—	18 (3)
$PdCl_2(PPh_3)_2$	NEt_3	—	48 (38)
$PdCl_2(PPh_3)_2$	DMF	Na_2CO_3	18
$PdCl_2(PPh_3)_2$	CH_3CN	K_2CO_3	20
$PdCl_2(PPh_3)_2$	CH_3CN	Li_2CO_3	Trace
$PdCl_2(PPh_3)_2$	CH_3CN	Et_3N	69
$Pd(PPh_3)_3$	NEt_3	—	79 (26)
$Pd(PPh_3)_3$	Toluene	Na_2CO_3	0
$Pd(PPh_3)_4$	NEt_3	—	45 (40)
$Pd(PPh_3)_4$	CH_3CN	K_2CO_3	8
$PtCl_2(PPh_3)_2$	NEt_3	—	45 (23)
$Pt(PPh_3)_4$	NEt_3	—	64 (35)

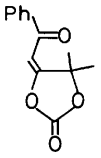
a) **1** 10 mmol, PhI 10 mmol, CO 10 atm, CO_2 10 atm, catalyst 0.2 mmol, solvent 10 cm^3, base 15 mmol; 100 °C, 8 h. b) GLC yield. The figures in the parentheses represent the yields of the reactions performed under CO atmosphere.

In order to elucidate the reaction pathway as well as the role of CO_2, the reaction was performed at 100 °C under CO atmosphere using [$PdCl_2(PPh_3)_2$] as the catalyst. With a shorter reaction time rather than the standard 8 h reaction, an acetylenic ketone, 4-hydroxy-4-methyl-1-phenyl-2-pentyn-1-one (**3**) was formed as the major product. As shown in Fig. 1, the acetylenic ketone **3** occurred at the early stage and decreased gradually, while the furanone **2a** was generated slowly and almost linearly. The acetylenic ketone appears to be an intermediate for the furanone formation. Apparently, however, not all the acetylenic ketone **3** produced was converted into **2a**. This observation is

consistent with the production of the oily substance (vide supra).



3

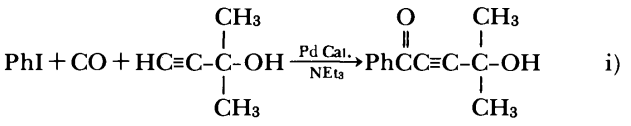


4

On the other hand (*E*)-4-benzoylmethylene-5,5-dimethyl-1,3-dioxolan-2-one (**4**) was produced at the early stage of the reaction in the presence of both CO and CO_2 with $[PdCl_2(PPh_3)_2]$ as the catalyst (Fig. 2). The formation of the acetylenic ketone **3** was not observed in this case. It seems interesting that both CO and CO_2 are incorporated in one molecule. The cyclic carbonate **4** decreased fairly rapidly with efficient formation of the furanone **2a** under the reaction conditions. Consequently the carbonate **4** seems to be another intermediate. This was confirmed actually as follows. The carbonate **4** was subjected to the thermal degradation at 100 °C for 1 h in the presence of 2 molar % of $[Pd(PPh_3)_4]$ under either CO or CO_2 atmosphere. This process led to 73 and 75% conversion of **4** into the furanone **2a**, respectively. The degradation of **4** at 150 °C for 20 min led to the complete conversion into the furanone **2a** after the quantitative evolution of CO_2.

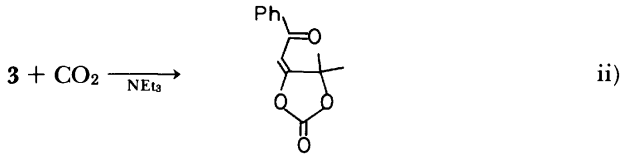
The relationship between **3** and **4** must be elucidated in the next place. This was made clear by reacting **3** with CO_2 at 70 °C for 1 h in triethylamine in the absence of the catalyst. This procedure gave **4** in 68% isolated yield. The cyclization proceeded even in benzene at the sacrifice of the yield (100 °C, 8 h; 21%).

Thus the following pathway is established for the palladium system.



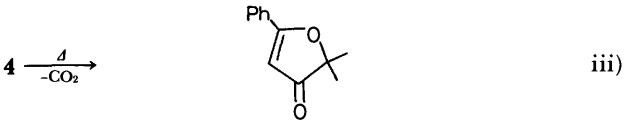
i)

1 3



ii)

4



iii)

2a

The initial step i) is the formation of the acetylenic ketone **3** from iodobenzene, CO, and 2-methyl-3-butyn-2-ol (**1**). This type of the reaction has been documentated by Tanaka et al.[5] The reaction has been recognized to involve the oxidative addition of a phenyl halide to a low valent metal complex followed by the insertion of CO into the resulting metal-aryl bond to give the aroyl intermediate which is in turn cloven by the attack of an acetylenic molecule to afford the acetylenic ketone. The subsequent step ii) is the triethylamine-assisted intramolecular cycloaddition of the monocarbonate ($PhC(O)C{\equiv}CC(CH_3)_2OC(O)OH$) generated intermediarily from the acetylenic ketone **3** and CO_2 giving the cyclic carbonate **4**.[6] Addition of oxygen-containing nucleophiles to aryl ethynyl ketones has been demonstrated to proceed in a syn fashion.[7] The present cyclization reaction corresponds to the intramolecular version predicting the (*E*)-stereochemistry around the double bond in **4**. The final step iii) was the decarboxylative conversion of **4** into the furanone **2a**. The (*E*)-stereochemistry permits the ready conversion.

There is an apprehension that different pathways might be accomodated in the distinct systems. It seems difficult to elucidate the reaction pathway of every catalytically active system because of the diversity of

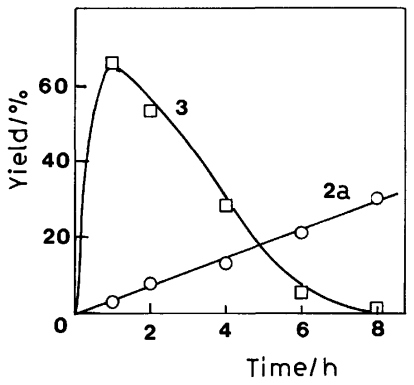


Fig. 1. Reaction of **1** with PhI under CO atmosphere with a $[PdCl_2(PPh_3)_2]$ catalyst.

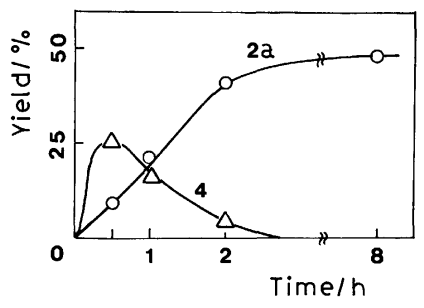

Fig. 2. Reaction of **1** with PhI under CO and CO_2 atmosphere with a $[PdCl_2(PPh_3)_2]$ catalyst.

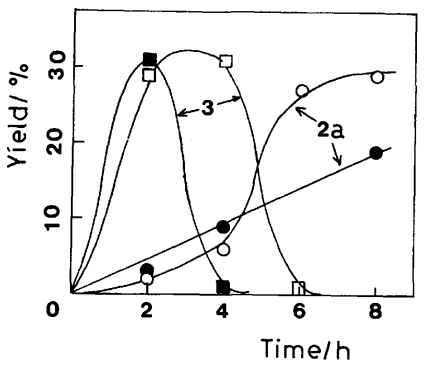

Fig. 3. Reaction of **1** with PhI under CO atmosphere with a $[CoCl_2(PPh_3)_2]$ (□ and ○) or a $[RuCl_2(PPh_3)_3]$ (■ and ●) catalyst.

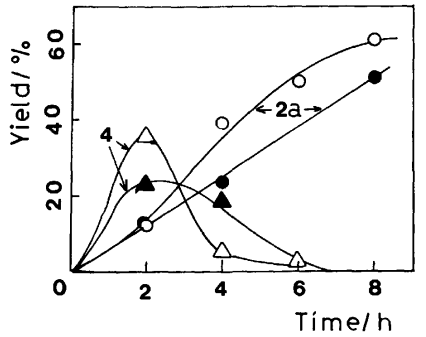

Fig. 4. Reaction of **1** with PhI under CO and CO_2 atmosphere with a $[CoCl_2(PPh_3)_2]$ (△ and ○) or a $[RuCl_2(PPh_3)_3]$ (▲ and ●) catalyst.

metal catalysts. We selected $[RuCl_2(PPh_3)_3]$ and $[CoCl_2(PPh_3)_2]$ as the representative of the Group 8 and 9 metal triad, respectively. The results are shown in Figs. 3 and 4. The same intermediates as the palladium system, **3** and **4**, as well as the similar trends of the reactions were observed. Thus it is evident that the same mechanism is operative at least in these systems, too.

The 3(2*H*)-furanone **2a** occurred even under the atmosphere of CO (Table 1). On careful examination of the products obtained from the reactions performed under CO atmosphere, we found that the cyclic carbonate **4**, albeit in a very small amount, was present in the reaction mixture (by IR; 1855, 1830 cm^{-1}). This indicates the presence of CO_2 in the system. One possible origin is the CO_2 in the air which might be dissolved in triethylamine used as the solvent. To confirm this, the triethylamine distilled under N_2 was subjected to the reaction. However the scope was almost the same under the standard reaction conditions with a $[PdCl_2(PPh_3)_2]$ catalyst. Another one is the water-gas shift reaction, which is known to be catalyzed by transition metal complexes.[8]

$$CO + H_2O \rightleftharpoons CO_2 + H_2$$
$$(\text{or } CO + H_2O + MX_2 \longrightarrow CO_2 + 2HX + M)$$

Table 2. Synthesis of 3(2*H*)-Furanone **2** from Organic Halide (R-X), CO, and **1**[a]

R	X	Yield of **2**[b]/%
C_6H_5-	Br	**2a** (35)
C_6H_5-	I	**2a** (48)

p-ClC_6H_4-	Br	**2c** 68
(*E*)-PhCH=CH-	Br	**2d** 41
1-Naphthyl	Br	**2e** 45
CH_2=$CHCH_2$-	OAc	**2f** 9[c]

a) **1** 10 mmol, organic halide 10 mmol, CO 10 atm, CO_2 10 atm, $[PdCl_2(PPh_3)_2]$ 0.2 mmol, NEt_3 10 cm^3; 100 °C, 8 h. b) Isolated yield. The figures in the parentheses represent the GLC yield. c) The product was the 1-propenyl derivative.

Consequently eventual water may cause the generation of a trace amount of CO_2. Since the CO_2 produced in this way would work catalytically, a considerable amount of the furanone **2a** could be produced via the steps i), ii), and iii). Thus the reaction under CO atmosphere (10 atm) at 100 °C for 8 h with $[PdCl_2(PPh_3)_2]$ as the catalyst afforded **2a** in 30% yield when care was taken to reduce the eventual water from the chemicals employed by adding appropriate desiccants. With a $[CoCl_2(PPh_3)_2]$ catalyst, the yield of **2a** decreased to 8% with concomitant formation of **3** in 38% yield, supporting the above conjecture.

In order to expand the initial scope of our investigation, several aryl and alkenyl halides were submitted to the reaction. The substrates listed in Table 2 afforded the corresponding furanones in moderate yields with $[PdCl_2(PPh_3)_2]$ as the catalyst. In addition to aryl halides, allyl acetate took part in the reaction yielding the 1-propenyl derivative in a modest yield. *o*-$IC_6H_4NO_2$, *o*-$BrC_6H_4CH_3$, *p*-BrC_6H_4Br, *p*-BrC_6H_4OH, *p*-BrC_6H_4CHO, 2-bromopyridine, and cinnamyl acetate did not afford the corresponding furanones although several of them were consumed. The major difficulty of these compounds in producing the furanone seems to lie in the step i), i.e., acetylenic ketone formation.[5] However further study on the effects of substituents has not been undertaken.

All attempts to utilize 2-propynyl alcohol or 3-butyn-2-ol in place of 2-methyl-3-butyn-2-ol (**1**), for the elaboration of the 3(2*H*)-furanones not disubstituted in the 2-position proved fruitless unfortunately. In conclusion, the present reaction offers a new and facile method for the synthesis of certain simple 3(2*H*)-furanones, e.g., bullatenone. The main feature is the employment of easily available starting materials.

Experimental

Melting points are uncorrected. ^1H and ^{13}C NMR spectra were recorded in chloroform-*d* with JEOL FX-60Q spectrometer with tetramethylsilane as an internal standard. IR and MS spectra were recorded on a JASCO A-3 and JEOL

JMS D-300 spectrometer, respectively. Gas and liquid chromatography was performed on a Hitachi 263-30 gas chromatograph.

Materials. CO and CO_2 gases were used without further purification. Organic halides, 2-propynyl alcohols, and solvents were used as received. In certain cases, $MgSO_4$ (for iodobenzene and **1**) and KOH (for triethylamine) were used as desiccants. Transition metal complexes were synthesized according to the standard methods.

Synthesis of the Furanone 2. The synthesis of 2,2-dimethyl-5-phenyl-3(2*H*)-furanone (**2a**) is typical. Into a 50 cm^3 stainless steel autoclave, 2-methyl-3-butyn-2-ol (**1**; 10 mmol), iodobenzene (10 mmol), triethylamine (10 cm^3), and $[PdCl_2(PPh_3)_2]$ (0.2 mmol) were charged. Then the air in the autoclave was evacuated by a water aspirator. After CO (10 atm) and CO_2 (10 atm) were introduced, the mixture was agitated at 100 °C for 8 h. GLC analysis (DEGS, 2 m, 190 °C) showed the formation of **2a** in 48% yield. Kugelrohr distillation (150 °C/2 mmHg) followed by recrystallization from hexane gave an analytical sample; (1 mmHg=133.322 Pa). Mp 66.5—67.5 °C (lit,[3] 67.5—68.5 °C). The IR,[9] ^1H NMR,[9] ^{13}C NMR,[10] and mass[11] spectra were consistent with those reported in the literatures. Found: C, 76.33; H, 6.44%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

2,2-Dimethyl-5-(*p*-tolyl)-3(2*H*)-furanone (2b): Prepared from *p*-iodotoluene and isolated by Kugelrohr distillation (125—135 °C/0.2 mmHg). Recrystallization from hexane gave an analytical sample. Mp 65.2—66.4 °C. Found: C, 77.49; H, 7.05%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%. IR ($CDCl_3$) 1690, 1595, 1180 cm^{-1}. ^1H NMR δ=1.47 (s, 6H), 2.40 (s, 3H), 5.87 (s, 1H), 7.20 (d, J=8 Hz, 2H), 7.70 (d, J=8 Hz, 2H).

5-(*p*-Chlorophenyl)-2,2-dimethyl-3(2*H*)-furanone (2c): Prepared from *p*-bromochlorobenzene and isolated by sublimation under reduced pressure (140—150 °C/1 mmHg). Recrystallization from toluene gave an analytical sample. Mp 218 °C. Found: C, 64.32; H, 5.09; Cl, 16.13%. Calcd for $C_{12}H_{11}ClO_2$: C, 64.73; H, 4.94; Cl, 15.94%. IR (KBr) 1680, 1600, 1325, 1100, 765 cm^{-1}. ^1H NMR δ=1.50 (s, 6H), 5.96 (s, 1H), 7.40 (d, J=9.6 Hz, 2H), 7.75 (d, J=9.6 Hz, 2H).

(*E*)-2,2-Dimethyl-5-styryl-3(2*H*)-furanone (2d): Prepared from β-bromostyrene and isolated by Kugelrohr distillation (130—150 °C/3 mmHg) followed by column chromatography on silica gel (chloroform). Mp 75.0—76.1 °C. Found: C, 78.92; H, 6.78%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%. IR (KBr) 1690, 1630, 1580, 1560, 1380, 1185, 995, 760, 700 cm^{-1}. ^1H NMR δ=1.24 (s, 6H), 5.56 (s, 1H), 6.80 (d, J=16.8 Hz, 1H), 7.20—7.70 (m, 6H).

2,2-Dimethyl-5-(1-naphthyl)-3(2*H*)-furanone (2e): Prepared from 1-bromonaphthalene and isolated by column chromatography on silica gel (chloroform). Mp 130.1—131.3 °C. Found: C, 80.75; H, 5.60%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%. IR (KBr) 1690, 1570, 1180, 810, 780 cm^{-1}. ^1H NMR δ=1.58 (s, 6H), 5.97 (s, 1H), 7.40—8.40 (m, 7H).

(*E*)-2,2-Dimethyl-5-(1-propenyl)-3(2*H*)-furanone (2f): Prepared from allyl acetate and isolated by column chromatography on silica gel (chloroform). Liquid. Bp 75—85 °C/0.3 mmHg. IR (neat) 1700, 1650, 1390, 1185, 980, 760 cm^{-1}. ^1H NMR δ=1.40 (s, 6H), 1.97 (d, J=7 Hz, 3H), 5.40 (s, 1H), 6.23 (d, J=16 Hz, 1H), 6.83 (dp, J=16 Hz, 7 Hz, 1H).

The Reaction in the Absence of CO_2. The reaction was performed in the absence of CO_2 according to the standard procedure for, for example, 0.5 h with $[PdCl_2(PPh_3)_2]$ as the catalyst. GLC analysis (DEGS, 2 m, 190 °C) showed the formation of 4-hydroxy-4-methyl-1-phenyl-2-pentyn-1-one (**3**) in 66% yield together with the furanone **2a** in 3% yield. The acetylenic ketone **3** was isolated by distillation under reduced pressure. Bp 135—137 °C/2 mmHg. IR (neat) 3400, 2200, 1640, 1270, 1175, 960, 700 cm^{-1}. ^1H NMR δ=1.64 (s, 6H), 2.90 (s, 1H), 7.20—7.60 (m, 3H), 8.00—8.15 (m, 2H).

Short Time Reaction in the Presence of CO and CO_2. When the reaction was discontinued in short time, (*E*)-4-benzoylmethylene-5,5-dimethyl-1,3-dioxolan-2-one (**4**) was obtained together with the furanone **2a** as shown in Fig. 2. The cyclic carbonate **4** was isolated by column chromatography on silica gel eluting with chloroform. This compound was converted completely into the furanone **2a** during the GLC measurement (DEGS, 190 °C). Mp 106—107 °C. IR (KBr) 1855, 1830, 1675, 1620, 1270, 1150, 995 cm^{-1}. ^1H NMR δ=1.87 (s, 6H), 6.80 (s, 1H), 7.20—8.00 (m, 5H). ^{13}C NMR δ=24.0, 88.8, 99.6, 128.0, 128.7, 133.3, 138.0, 149.8, 167.1, 188.1. The reactions in the presence or absence of CO_2 with the other catalysts, for example $[CoCl_2(PPh_3)_2]$ and $[RuCl_2(PPh_3)_3]$, were performed in the similar manner as above.

Synthesis of the Cyclic Carbonate 4 from the Acetylenic Ketone 3 and CO_2. **3** (5 mmol) and triethylamine (5 cm^3) were placed in an autoclave. After the introduction of CO_2 (10 atm), the autoclave was heated at 70 °C for 1 h. Column chromatography of the reaction mixture on silica gel (hexane/ethyl acetate=5) gave the cyclic carbonate **4** in 68% yield. On the other hand the reaction of **3** (5 mmol) with CO_2 (10 atm) in benzene (5 cm^3) at 100 °C for 8 h gave **4** in 21% yield.

Decarboxylative Conversion of the Cyclic Carbonate 4 into the Furanone 2a. Into an autoclave, **4** (105 mg, 0.45 mmol), $[Pd(PPh_3)_4]$ (2 molar%), and trietylamine (5 cm^3) were placed. After CO (10 atm) was introduced, the autoclave was heated at 100 °C for 1 h. This procedure gave the furanone **2a** in 73% yield. The degradation of **4** under CO_2 atmosphere (10 atm) led to the formation of **2a** in 75% yield under the similar conditions. The degradation at 150 °C was performed as follows. Into a 50 cm^3 round bottomed flask connected with a gas buret, **4** (218 mg, 0.938 mmol) was placed and heated at about 150 °C for 20 min in an oil bath. The CO_2 gas evolved was 122.1 cm^3 at 22 °C (0.91 mmol, 97%) and the residue weighed was 172 mg (0.936 mmol, 100%). IR analysis confirmed the complete conversion of **4** into the furanone **2a**.

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received June 22, 1989)

Hydrolysis of 2,6-diacetoxybicyclo[3.3.1]nonane (**5**) using lipase from Candida *cylindracea* gave (+)-(1*S*,2*R*,5*S*,6*R*)-6-acetoxybicyclo[3.3.1]nonan-2-ol (**4**) with 81% e.e. and (−)-(1*R*,2*S*,5*R*,6*S*)-**5** with 95% e.e., and pig liver esterase-catalyzed hydrolysis of 2,6-diacetoxy-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (**9**) afforded (−)-(1*S*,2*R*,5*S*,6*R*)-3,3,7,7-tetramethylbicyclo[3.3.1]nonane-2,6-diol (**7**) with 96% e.e. and (+)-(1*R*,2*S*,5*R*,6*S*)-**9** with 86% e.e. By lithium aluminum hydride reduction, (+)-**4** and (−)-**5** were converted to (+)-bicyclo[3.3.1]nonane-2,6-diol (**3**) and (−)-**3** with high optical purity, respectively, and (+)-**7** was obtained from (+)-**9**. Using these optically active diols **3** and **7** as a chiral subunit, optically active crown ethers and podands were prepared and their enantiomer recognition behavior was evaluated by the enantiomer differential transport of (±)-1,2-diphenylethylamine and methyl ester of (±)-phenylglycin hydrochloride through bulk liquid membrane.

Since Cram reported the syntheses of a variety of optically active crown ethers incorporating [1,1′-binaphthalene]-2,2′-diol with C_2-symmetry as a chiral subunit,[2)] various kind of C_2-diols have been incorporated into crown ethers as a chiral subunit.[3)] Recently, we have also reported the syntheses and chiral recognition behaviors of the chiral crown ethers having C_2-5,6,11,12-tetrahydro-6,12-methanodibenzo[*a*,*e*]cyclooctene-5,11-diol[4)] and C_2-7,8,15,16-tetrahydro-7,15-methanodinaphtho[1,2-*a*:1′,2′-*e*]cyclooctene-8,16-diol[5)] as a chiral subunit. These diols possess the bicyclo[3.3.1]nonane-2,6-diol moiety as a common structural feature. These recent results prompted us to examine the chiral recognition properties of crown ethers having the bicyclo[3.3.1]nonane derivatives containing no aromatic moiety as a chiral subunit, and we chose bicyclo[3.3.1]nonane-2,6-diol (**3**) and 3,3,7,7-tetramethylbicyclo[3.3.1]nonane-2,6-diol (**7**) as a chiral building block.

Utilization of enzymes in organic synthesis to prepare chiral compounds of synthetic value is well documented.[6)] Especially, hydrolytic enzymes useful for the preparation of optically active alcohols are attractive in this regard because they operate without requiring expensive coenzymes. We have also investigated the enantioselective reaction mediated by enzyme.[7)] Our continuing interest on biocatalysts in organic synthesis led us to resolve the C_2-diols, the chiral building block, by enzyme-catalyzed kinetic resolution. In this paper we wish to report pig liver esterase (PLE)- and lipase from Candida *cylindracea* (CCL)-catalyzed enantiomerically selective hydrolyses of racemic 2,6-diacetoxybicyclo[3.3.1]nonane (**5**) and 2,6-diacetoxy-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (**9**), and to report syntheses and chiral recognition behavior of crown ethers incorporating bicyclo[3.3.1]nonane-2,6-diol (**3**) and 3,3,7,7-tetramethylbicyclo[3.3.1]nonane-2,6-diol (**7**) as a chiral subunit.

Results and Discussion

Bicyclo[3.3.1]nonane-2,6-diol (**3**) is a chiral molecule of C_2-symmetry, and an introduction of methyl groups, an additional steric barrier, into this skeleton provides 3,3,7,7-tetramethylbicyclo[3.3.1]nonane-2,6-diol (**7**) which has also C_2-symmetry.

Treatment of **1** with excess of methyl iodide and potassium *t*-butoxide in *t*-butyl alcohol gave **2** in 70% yield. Reduction of **2** with lithium aluminum hydride yielded a 95:5 mixture of diastereomers, recrystallization of which from hexane–ether provided **7**, and the minor isomer was not isolated. Treatment of **7** with acetic anhydride and pyridine gave **9**. The C_2-endo,endo-configuration of **9** was unambiguously confirmed by its ^{1}H NMR spectrum which exhibited two singlet signals at δ=0.99 and 1.04 due to the exo- and endo-methyl groups, a singlet signal at δ=2.05 due to the $-OCOCH_3$ protons, and a doublet signal at δ=4.78 (J=6.4 Hz) due to the protons on the carbon bearing the hydroxyl group.

Enzyme-Catalyzed Hydrolyses of Diacetates. PLE- and CCL-catalyzed hydrolysis of **5** and **9** were performed in 0.1 M (1 M=1 mol dm^{-3}) phosphate buffer solution at pH 8.0 and pH 7.4, respectively. In every cases, the reaction processes were monitored by GLC and the reactions were terminated at, or closs to, 50%-of-hydrolysis point. The product was extracted with chloroform and purified by column chromatography. The results are summarized in Table 1.

In the case of hydrolysis of (±)-**5**, CCL-catalyzed hydrolysis gave (+)-**4** and (−)-**5** with 81% and 95% e.e., respectively. By lithium aluminum hydride reduction, (+)-**4** and (−)-**5** were converted into (+)-**3** and (−)-**3**, respectively. Since **3** is a crystalline solid, its optical purity was further enriched by recrystallization from

Table 1. Enantioselective Hydrolysis of Racemic Substrates

Entry	Substrate	Enzyme	Time/h	Product (% yield)	e.e./%
1	(±)-**5**	PLE	5.5	(+)-(1*S*,2*R*,5*S*,6*R*)-**4** (47)	30

ethyl acetate and the both enantiomers of **3** with >98% e.e. were obtained. On the basis of the absolute configuration of (+)-(1*S*,2*R*,5*S*,6*R*)-**3**,[8] the chemical correlations described above revealed unambiguously the absolute configurations of the acetates **4** and **5** as illustrated in their structural formulas. The maximum rotation of (−)-**3** ($[\alpha]_{D\,max.}$ −59.8°) permitted to calculate the e.e. values of acetates **4** and **5**. PLE-catalyzed hydrolysis of (±)-**5** proceeded smoothly to give (+)-**4** and (−)-**5**, but the enantiomer selectivity of this hydrolysis is poor.

It has been described that **3** was resolved via diastereomeric camphanic acid ester,[8] but the chemical method is rather troublesome. The CCL-catalyzed kinetic resolution of **3** was more facile than the chemical method, and provided both enantiomers with high optical purity.

PLE-catalyzed hydrolysis of (±)-**9** gave (−)-**7** with 96% e.e. and (+)-**9** with 86% e.e. The latter was transformed to (+)-**7** by lithium aluminum hydride reduction. CCL-catalyzed hydrolysis of (±)-**9** gave (−)-**8** and (+)-**9** together with a small amount of (−)-**7**, but their optical purities were too low to be synthetically useful as a chiral building block. Reduction of (−)-**8** with lithium aluminum hydride gave (−)-**7**. The determination of absolute configurations of **2** and **7** was straightforward. Treatment of (+)-(1*S*,5*S*)-**1**[8] with methyl iodide gave (+)-(1*R*,5*R*)-**2**, which was converted into (+)-**7**. The chemical correlation assigned the 1*R*,2*S*,5*R*,6*S*-configuration to (+)-**7**. The optically active diol (−)-**7**, prepared by PLE-catalyzed hydrolysis, was converted into the optically active benzoate **10** whose e.e. value was determined to be 96% by HPLC-analysis. On the basis of the e.e. value of **7**, those of the acetates **8** and **9** were confirmed. As described above, PLE-catalyzed hydrolysis of **9** provided a facile method for the preparation of the optically active both enantiomers of **7**.

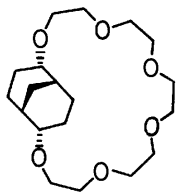
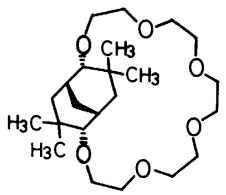
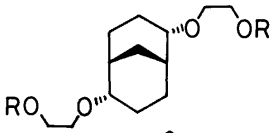
Preparation of Crown Ethers and Podands. Next our task was the preparation of crown ethers and podands using these optically active diols **3** and **7** as a chiral subunit. One of the ethylene glycol units of 18-crown-6 was replaced by the chiral diols (−)-**3** and (+)-**7** to give the crown ethers (−)-**11** and (+)-**12**,



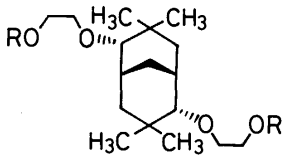
(−)-11



(+)-12

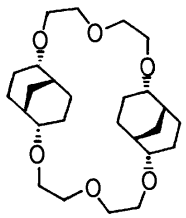


13 R =
(−)-14 R = H
(−)-15 R = Ms
(−)-16 R = Ts
(−)-17 R = $CH_2CH_2OCH_3$

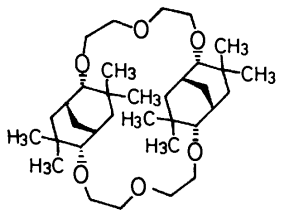


18 R = CH_2OCH_3
(+)-19 R = H
(+)-20 R = Ms
(+)-21 R = $CH_2CH_2OCH_3$

respectively. High dilution condensation of (−)-**3** with pentaethylene glycol bis(*p*-toluenesulfonate) in the presence of sodium hydride in refluxing tetrahydrofuran (THF) provided the crown ether (−)-**11** in 24% yield after chromatography and, similarly, (+)-**12** was prepared from (+)-**7** in 19% yield. The preparation of the crown ethers (−)-**22** and (+)-**23** having two chiral subunits was carried out stepwise. Treatment of (−)-**3** with the *p*-toluenesulfonate of 2-(2-tetrahydropyranyloxy)ethanol and sodium hydride in dimethyl sulfoxide (DMSO) at 40 °C gave **13**, whose protective group was removed with hydrochloric acid and methanol to yield (−)-**14** in 62% yield for two steps. The

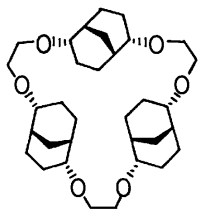


(-)-22

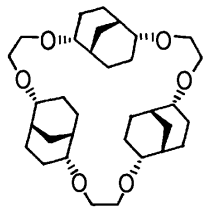


(+)-23

diol (−)-**14** was condensed with (−)-**15**, prepared from (−)-**14** and methanesulfonyl chloride, in the presence of sodium hydride in DMSO at 40 °C to give (−)-**22** in 14% yield. Treatment of (+)-**7** with the *p*-toluenesulfonate of 2-(methoxymethoxy)ethanol and sodium hydride gave **18**, which was transformed to (+)-**19** on treatment with hydrochloric acid and methanol. High dilution condensation of (+)-**19** with (+)-**20**, prepared from (+)-**19**, and sodium hydride in DMSO gave (+)-**23** in 14% yield.

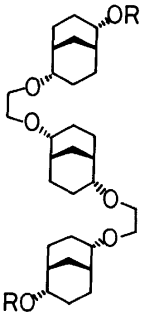


24

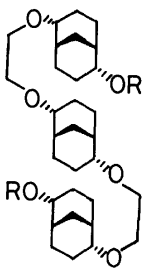


25

Next we attempted to prepare two diastereomeric crown ethers having three chiral subunits.[9] One of them is the crown ether, (*S,S*),(*R,R*),(*S,S*)-isomer **24**, which contains two (2*S*,6*S*)-subunits and a (2*R*,6*R*)-subunit, and the another crown ether, (*R,R*),(*R,R*),(*R,R*)-isomer **25**, contains three chiral subunits, all of which have the same configuration. The key feature of our strategy for construction of these crown ethers **24** and **25** was the preparation of the open-chain polyethers **27** and **30** with the (*S,S*),(*R,R*),(*S,S*) and the (*R,R*),(*R,R*),(*R,R*)-configuration, respectively. The diols (−)-**3** and (+)-**3** were converted into (−)-**6** and (+)-**6**, respectively, with benzyl bromide and sodium hydride in DMSO. Condensation of (+)-**16**, prepared from (+)-**14**, with 2 equiv of (−)-**6** in the presence of sodium hydride in DMSO at 40 °C yielded (−)-**26** with the (*S,S*),(*R,R*),(*S,S*)-configuration in 43% yield. Debenzylation of (−)-**26** with lithium aluminum hydride in THF gave (−)-**27** in 84% yeild, and treatment of (−)-**27** with methyl iodide and sodium hydride yielded (−)-**28** having the methoxyl groups as a terminal group in 76% yield. The another polyether (+)-**29** having three (2*R*,6*R*)-subunits was prepared in 33% yield by condensation of (+)-(2*R*,6*R*)-**16** with 2 equiv of (+)-(2*R*,6*R*)-**6**. Hydrogenolytic debenzylation of (+)-**29** with 10% Pd on carbon and *p*-toluenesulfonic acid under 1 atm of hydrogen gave (+)-**30** in 91% yield, which was also transformed to (+)-**31**. The final step



(-)-26 R = CH_2Ph
(-)-27 R = H
(-)-28 R = CH_3



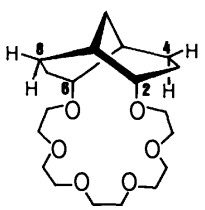
(+)-29 R = CH_2Ph
(+)-30 R = H
(+)-31 R = CH_3

of our strategy was ring closure of the open-chain polyethers (−)-**27** and (+)-**30** by condensation with ethylene glycol bis(methanesulfonate) and sodium hydride. Unfortunately, all attempts to prepare **24** and **25** were failed.

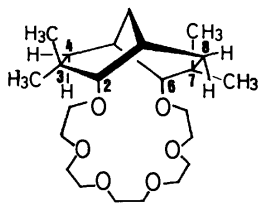
Our final synthetic task was the preparation of the chiral dipodands **17** and **21**. Reaction of (−)-**3** with the *p*-toluenesulfonate of 2-(2-methoxyethoxy)ethanol and sodium hydride in DMSO gave (−)-**17** in 78% yield, and, analogously, (+)-**21** was prepared from (+)-**7** in 90% yield.

Enantiomer Recognition Behavior of Crown Ethers and Podands. The enantiomer recognition behavior of these crown ethers and podands was evaluated by the enantiomer differential transport of (±)-1,2-diphenylethylamine and methyl ester of (±)-phenylglycin hydrochloride through bulk liquid membrane containing the optically active host molecules.[10] The results are given in Table 2.

A few conspicuous features are worth noting. The chiralities of the twisted carbon skeletons of (−)-(1*R*,2*S*,5*R*,6*S*)-subunit **3** and (+)-(1*R*,2*S*,5*R*,6*S*)-subunit **7** are opposite to each other as illustrated in the structures **32** and **33**. However, both (−)-**10** with the



32



33

(1*R*,2*S*,5*R*,6*S*)-subunit **3** and (+)-**11** with the (1*R*,2*S*,5*R*,6*S*)-subunit **7** transferred preferentially (*S*)-1,2-diphenylethylamine and methyl ester of (*R*)-phenylglycin. The reverse of the selectivity by introduction of the methyl groups into the chiral subunit are rationalized by assuming that, in the case of (−)-**10**, two endo-hydrogen atoms at C-4 and C-8 of the subunit act as a 'chiral steric barrier' and, in the case of (+)-**12**, two endo-methyl groups at C-3 and C-7 are more bulky

Table 2. Differential Transport of Enantiomeric Molecules through Bulk Liquid Membrane Containing Chiral Crown Ethers and Chiral Open-Chain Polyethers

a) a: (±)-1,2-Diphenylethylamine hydrochloride b: Methyl ester of (±)-phenylglycin hydrochloride. b) After 10 days, a significant transport of the guest molecule was not observed.

steric barrier than the endo-hydrogen atoms at C-4 and C-8 as illustrated in **32** and **33**. Introduction of the second chiral subunit into (−)-**11** and (+)-**12** produced little change in the enantiomer selectivity. The results appear to suggest that the cavities of (−)-**22** and (+)-**23**, 24-crown-6 analogue, are so large that the both chiral barriers hardly participate simultaneously in interacting on the guest molecule located in the cavity.

Recently, we examined the enantiomer recognition behavior of the chiral dipodands, and reported that, among the dipodands examined, the dipodand having the 1,4,7-trioxaoctyl groups as a side chain showed the highest enantiomer selectivity and the value was nearly equal to that of crown ether.[11] The enantiomer selectivities of dipodands (−)-**17** and (+)-**21**, both of which have two 1,4,7-trioxaoctyl groups as a side chain, were also comparable to these of crown ethers (−)-**11** and (+)-**12**. The open-chain polyethers (−)-**26** and (−)-**28** with the alternate configuration showed higher enantiomer selectivity toward 1,2-diphenylethylamine than the polyethers (+)-**29** and (+)-**31** having three subunits of the same configuration.

As described above, the parent compound, bicyclo[3.3.1]nonane-2,6-diol itself is certainly effective as a chiral subunit of a crown ether, but the enantiomer selectivity of the crown ether having this subunit is lower than those of the crown ethers containing bicyclo[3.3.1]nonane-2,6-diol derivatives with aromatic moieties as an additional bulky steric barrier.

Experimental

All melting and boiling points are uncorrected. Infrared spectral data were taken on a Hitachi 260-10 spectrophotometer, and ^{1}H NMR spectra were obtained from a JNM-MH-100. Chemical shifts are reported in parts per million (δ) down field from tetramethylsilane. Optical rotations were measured with a JASCO DIP-140 automatic polarimeter. Mass spectra were taken with a JEOL-DX-303 HF spectrometer. Elemental analyses were determined on a Yanagimoto CHN-Coder, Type II.

3,3,7,7-Tetramethylbicyclo[3.3.1]nonane-2,6-dione (2). A solution of **1**[8] (1.71 g, 11.2 mmol) was added to a solution of potassium *t*-butoxide (19.0 g, 0.170 mol) in absolute 2-methyl-2-propanol (200 mL) and then the mixture was stirred for 1.5 h at room temperature. After methyl iodide (19.2 g, 0.135 mol) was dropwise added to the reaction mixture, the resulting mixture was stirred for 1.5 h at room temperature and for an additional 14 h at reflux. The solid precipitated was removed by filtration and the filtrate was concentrated in vacuo. The residue was acidified with 5% hydrochloric acid and extracted with chloroform. The extract was washed with saturated aqueous solution of sodium hydrogencarbonate and water and dried ($MgSO_4$). After the solvent was removed in vacuo, the residue was chromatographed on alumina (hexane/benzene 2/1 v/v eluent) to give **2** (1.63 g, 70% yield) as a solid, recrystallization of which from hexane provided the sample for the analysis, mp 43—45 °C; IR (KBr) 1715, 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.05 (6H, s), 1.20 (6H, s), 2.01 (4H, d, J=5.2 Hz), 2.30 (2H, t, J=2.0 Hz), 2.77 (2H, m). Found: C, 74.71; H, 9.70%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

3,3,7,7-Tetramethylbicyclo[3.3.1]nonane-2,6-diol (7). A solution of **2** (1.16 g, 5.57 mmol) in dry ether (100 mL) was slowly added to a suspension of lithium aluminum hydride (600 mg, 15.8 mmol) in dry ether (100 mL) and then the mixture was heated for 13 h at reflux. After the reaction mixture was cooled in an ice bath, 10% hydrochloric acid was

added to the mixture and the resulting mixture was stirred for 1 h. The inorganic solid was removed by filtration and the solid was continuously extracted using Soxhlet-extraction apparatus. The ethereal solutions were combined and concentrated to give a solid, which was a 95:5 mixture of diastereomers (1.09 g). Recrystallization of the mixture from hexane–ether provided **7** (930 mg, 79% yield), mp 117.5—119 °C; IR (KBr) 3390, 1045 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.05 (6H, s), 1.10 (6H, s), 1.70 (2H, s), 3.65 (2H, d, J=6.4 Hz), 1.2—2.5 (8H, m). Found: C, 73.35; H, 11.10%. Calcd for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%.

2,6-Diacetoxy-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (9). To a solution of **7** (15.0 g, 70.7 mmol) in dry pyridine (150 mL) was slowly added acetic anhydride (100 g, 0.980 mol) with ice cooling and then the mixture was stirred for 48 h at room temperature. After the reaction mixture was poured onto ice, the mixture was acidified with hydrochloric acid and extracted with ether. The extract was washed with saturated aqueous solution of sodium hydrogencarbonate and water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on alumina (hexane/benzene 4/1 v/v) to give an oily product, which was distilled to provide **9** (18.5 g, 88% yield); bp 160—165 °C (8 mmHg) (1 mmHg=133.322 Pa); IR (neat film) 1740, 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.99 (6H, s), 1.04 (6H, s), 2.05 (6H, s), 4.78 (2H, d, J=7.0 Hz), 1.4—2.1 (8H, m). Found: C, 68.55; H, 9.46%. Calcd for $C_{17}H_{28}O_4$: C, 68.89; H, 9.52%.

PLE-Catalyzed Hydrolysis of 2,6-Diacetoxybicyclo[3.3.1]nonane (5). To a solution of (±)-**5** (250 mg, 1.04 mmol) in 0.1 M phospate buffer (400 mL, pH 8.0) was added PLE (Boehringer Mannheim Gmbh Co. 104698 100 Units/mg) (460 μL), and the mixture was stirred for 5.5 h at 30 °C. The mixture was extracted with chloroform and the extract was washed with water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on silica gel. The fractions eluted with chloroform gave (−)-**5** (108 mg, 43% yield) as an oil and the subsequent fractions eluted with the same solvent gave (+)-**4** (97 mg, 47% yield) as an oil.

(+)-**4**; $[\alpha]_D^{23}$ +16.6° (*c* 0.802, $CHCl_3$).

(−)-**5**; $[\alpha]_D^{24}$ −23.0° (*c* 1.24, $CHCl_3$).

CCL-Catalyzed Hydrolysis of 2,6-Diacetoxybicyclo[3.3.1]nonane (5). To a solution of (±)-**5** (500 mg, 2.08 mmol) in 0.1 M phosphate buffer (600 mL, pH 7.4) was added Lipase VII (CCL, Sigma 600—700 Units/mg) (500 mg) and the mixture was stirred for 24 h at 30 °C. The mixture was extracted with chloroform and the extract was washed with water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on silica gel. The fractions eluted with benzene–ether (8/2 v/v) gave (−)-**5** (230 mg, 46%) as an oil and the subsequent fractions eluted with the same solvent gave (+)-**4** (148 mg, 36% yield) as an oil.

(+)-**4**; $[\alpha]_D^{23}$ +45.2° (*c* 1.04, $CHCl_3$); IR (neat film) 3400, 1715, 1240 cm^{-1}.

(−)-**5**; $[\alpha]_D^{24}$ −70.7° (*c* 1.05, $CHCl_3$).

PLE-Catalyzed Hydrolysis of 2,6-Diacetoxy-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (9). By using the same procedure described for the hydrolysis of (±)-**5**, (±)-**9** (500 mg, 1.69 mmol) was hydrolyzed with PLE (300 μL) in 0.1 M phosphate buffer (300 mL, pH 8.0). The chromatography on alumina gave (+)-**9** (230 mg, 46% yield) as an oil and (−)-**7** (155 mg, 43% yield) as a solid.

(−)-**7**; $[\alpha]_D^{24}$ −87.5° (*c* 1.26, $CHCl_3$); mp 144—145 °C.

(+)-**9**; $[\alpha]_D^{25}$ +97.0° (*c* 1.05, $CHCl_3$).

CCL-Catalyzed Hydrolysis of 2,6-Diacetoxy-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (9). By using the same procedure described for the hydrolysis of (±)-**5**, (±)-**9** (250 mg, 0.843 mmol) was hydrolyzed with CCL (750 mg) in 0.1 M phosphate buffer (380 mL, pH 7.4). The chromatography on alumina gave (+)-**9** (100 mg, 40% yield) as an oil, (−)-**8** (86 mg, 40% yield) as a solid, and (−)-**7** (9 mg, 5% yield) as a solid.

(−)-**7**; $[\alpha]_D^{20}$ −60.7° (*c* 0.450, $CHCl_3$).

(−)-**8**; $[\alpha]_D^{22}$ −47.7° (*c* 1.01, $CHCl_3$); IR (KBr) 3450, 1710, 1260 cm^{-1}.

(+)-**9**; $[\alpha]_D^{20}$ +59.3° (*c* 1.91, $CHCl_3$).

(−)-(1*R*,2*S*,5*R*,6*S*)-Bicyclo[3.3.1]nonane-2,6-diol (3). To a suspension of lithium aluminum hydride (1.76 g, 46.4 mol) in dry ether (100 mL) was dropwise added a solution of (−)-**5**; $[\alpha]_D$ −70.7° (2.23 g, 9.28 mmol) in dry ether (100 mL) and then the mixture was heated for 10 h at reflux. To the reaction mixture was added a small amount of ethyl acetate and 10% hydrochloric acid with ice cooling, and the resulting mixture was stirred for 1 h at room temperature. The inorganic solid was filtered off and the solid was continuously extracted with ether using Soxhlet extraction apparatus. The etheral solutions were combined and dried ($MgSO_4$). Removal of the solvent gave **3** (1.15 g, 79% yield); $[\alpha]_D^{24}$ −56.8° (*c* 1.17, ethanol), which was recrystallized from ethyl acetate to yield the specimene; $[\alpha]_D^{25}$ −59.4° (*c* 1.02, ethanol); mp 214.5—215 °C. Found: C, 68.98; H, 10.29%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

(+)-(1*S*,2*R*,5*S*,6*R*)-Bicyclo[3.3.1]nonane-2,6-diol (3). By using the same procedure described above, (+)-**4**; $[\alpha]_D$ +45.2° (1.61 g, 8.13 mmol) was converted into **3** (1.08 g, 85% yield); $[\alpha]_D^{25}$ +48.5° (*c* 0.773, ethanol), which was recrystallized from ethyl acetate to yield the specimen; mp 214—215 °C; $[\alpha]_D^{26}$ +59.0° (*c* 0.770, ethanol). Found: C, 69.01; H, 10.28%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

Oxidation of (−)-(1*R*,2*S*,5*R*,6*S*)-Bicyclo[3.3.1]nonane-2,6-diol (3). An excess of Jones' reagent[12] was added to a chilled solution of (−)-**3**; $[\alpha]_D$ −56.4° (*c* 0.378, EtOH) (312 mg, 2.00 mmol), prepared according to Gerlach's procedure,[8] in acetone (8 mL). After stirring for 2 h with ice cooling, sodium bisulfite was added to the reaction mixture. Usual workup followed by chromatography on silica gel (ether) gave (−)-**1**; $[\alpha]_D^{25}$ −206.8° (*c* 1.01, 1,4-dioxane) (94.3% e.e.) (lit,[8] $[\alpha]_{D\,max.}$ −219.2°) (200 mg, 65% yield) as a white solid.

(+)-(1*R*,2*S*,5*R*,6*S*)-3,3,7,7-Tetramethylbicyclo[3.3.1]nonane-2,6-diol (7). By using the same procedure described for the reduction of (−)-**5**, (+)-**9**; $[\alpha]_D$ +97.0° (900 mg, 3.04 mmol) was converted into (+)-**7**; $[\alpha]_D^{25}$ +79.1° (*c* 0.953, $CHCl_3$) (610 mg, 95% yield), which was recrystallized from ether–hexane to provide the specimen; mp 143—144 °C; $[\alpha]_D^{25}$ +91.4° (*c* 1.11, $CHCl_3$). Its spectral data agreed with those of (±)-**7**.

(+)-(1*R*,5*R*)-3,3,7,7-Tetramethylbicyclo[3.3.1]nonane-2,6-dione (2). By using the same procedure described for the preparation of (±)-**2**, (+)-**1**;[8] $[\alpha]_D$ +187.0° (1.71 g, 11.2 mmol) was converted into (+)-**2** (1.25 g, 53% yield); mp 36—38 °C, $[\alpha]_D^{20}$ +100.4° (*c* 0.980, $CHCl_3$). The IR and ^1H NMR spectra are identical with those of (±)-**2**.

Lithium Aluminum Hydride Reduction of (+)-(1*R*,5*R*)-3,3,7,7-Tetramethylbicyclo[3.3.1]nonane-2,6-dione (2). By

using the same procedure described for the preparation of (±)-**7**, (+)-**2**; $[\alpha]_D$ +100.4° (1.16 g, 5.57 mmol) was converted into (+)-**7** (610 mg, 52% yield); mp 141—143 °C, $[\alpha]_D^{24}$ +70.7° (*c* 0.950, $CHCl_3$). The IR and ^1H NMR spectra are identical with those of (±)-**7**.

2,6-Bis(3,5-dichlorobenzoyloxy)-3,3,7,7-tetramethylbicyclo-[3.3.1]nonane (10). To a solution of (±)-**7** (18 mg, 0.085 mmol) in pyridine (2 mL) was added 3,5-dichlorobenzoyl chloride (540 mg, 2.58 mmol) with ice cooling and then the mixture was stirred overnight at room temperature. After addition of ice water to the reaction mixture, the mixture was acidified with 10% hydrochloric acid and then extracted with ether. The extract was washed with saturated aqueous solution of sodium hydrogencarbonate and water and dried ($MgSO_4$). After removal of the solvent, the oily residue was purified by a preparative thin layer chromatography (silica gel, benzene/ether 1/1 v/v) to yield **10** (34 mg, 72% yield) as a white solid; IR (KBr) 1720, 1580, 1270, 810, 780 cm^{-1}. Found: C, 57.76; H, 5.02; Cl, 25.29%. Calcd for $C_{27}H_{28}O_4Cl_4$: C, 58.08; H, 5.06; Cl, 25.40%.

By the same procedure descrived above, (−)-**7**; $[\alpha]_D$ −87.5° was converted into the optically active benzoate, whose e.e. value was determined to be 96% by HPLC-analysis. HPLC-analysis was carried out on Simadzu LC-6A using a chiral column (250×4.6 mm) packed with cellulose tris(3,5-dimethylphenylcarbamate) on silica gel[13] (hexane/2-propanol, 99/1 0.4 mL min^{-1}).

(−)-(1*R*,4*S*,21*S*,24*R*)-5,8,11,14,17,20-Hexaoxatricyclo[19.4.0.0^{4,24}]pentaicosane (11). A suspension of sodium hydride (177 mg, 7.38 mmol) in dry tetrahydrofuran (THF) (80 mL) was gently refluxed and to the boiling mixture a solution of (−)-**3** (327 mg, 2.10 mmol) and pentaethylene glycol bis(*p*-toluenesulfonate) (1.14 g, 2.10 mmol) in dry THF (200 mL) was added dropwise over a period of 12 h in nitrogen atmosphere. The mixture was heated for an additional 50 h at reflux. After the mixture was cooled in an ice bath, a small amount of water was added to the chilled mixture. The solvent was removed in vacuo and the residue was extracted with dichloromethane. The extract was washed with dilute hydrochloric acid, saturated aqueous solution of sodium hydrogencarbonate, and water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on alumina (benzene/chloroform 1/1 v/v) to give **11** (180 mg, 24% yield) as a colorless oil; $[\alpha]_D^{20}$ −33.1° (*c* 0.730, $CHCl_3$); IR (neat film) 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.3—2.2 (12H, m), 3.5—3.8 (20H, m), 4.0—4.2 (2H, m); MS *m/z* 358 (M^+). Found: C, 63.11; H, 9.49%. Calcd for $C_{19}H_{34}O_6$: C, 63.66; H, 9.56%.

(+)-(1*R*,4*S*,21*S*,24*R*)-3,3,22,22-Tetramethyl-5,8,11,14,17,20-hexaoxatricyclo[19.4.0.0^{4,24}]pentaicosane (12). By using the same procedure described above, reaction of (+)-**7** (425 mg, 2.00 mmol) with pentaethylene glycol bis(*p*-toluenesulfonate) (1.08 g, 2.00 mmol) and sodium hydride (168 mg, 7.00 mmol) in dry THF. The crude product was chromatographed on alumina (benzene/chloroform 1/1 v/v) to give **12** (386 mg, 19% yield) as a colorless oil.

12; $[\alpha]_D^{22}$ +53.2° (*c* 0.470, $CHCl_3$); IR (neat film) 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (6H, s), 1.03 (6H, s), 1.67 (6H, s), 1.2—2.3 (8H, m), 3.14 (2H, d, *J*=6.6 Hz), 3.5—3.8 (20H, m); MS *m/z* 414 (M^+). Found: C, 63.86; H, 10.05%. Cacld for $C_{23}H_{42}O_6$: C, 66.63; H, 10.21%.

(−)-(1*R*,2*S*,5*R*,6*S*)-2,6-Bis(2-hydroxyethoxy)bicyclo[3.3.1]-nonane (14). To a suspension of sodium hydride (888 mg, 37.0 mmol) in dry dimethyl sulfoxide (DMSO) (30 mL) was added a solution of (−)-**3** (1.45 g, 9.28 mmol) in dry DMSO (30 mL) and then the mixture was heated at 35 °C for 6 h under nitrogen atmosphere. A solution of the *p*-toluenesulfonate of 2-(2-tetrahydropyranyloxy)ethanol (11.2 g, 37.3 mmol) in dry DMSO (50 mL) was added to the reaction mixture and the resulting mixture was stirred for 15 h at 35 °C. After an ice water (100 mL) was added to the reaction mixture, it was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on silica gel (hexane/ether 1/1 v/v) to give **13** as a pale yellow oil, which was dissolved in methanol (50 mL). Three drops of hydrochloric acid was added to the solution and the resulting mixture was stirred for 12 h at room temperature. After sodium carbonate (1.00 g) was added to the reaction mixture, the mixture was stirred for 30 min. The solid was removed by filtration and the filtrate was concentrated in vacuo to give an oily residue, which was extracted with chloroform. The extract was washed with water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on silica gel (ether/methanol 96/4 v/v) to yield **14** (1.40 g, 62% yield) as a white solid; $[\alpha]_D^{23}$ −60.1° (*c* 1.03, $CHCl_3$); IR (neat film) 3420, 1100, 1090, 1060 cm^{-1}. Found: C, 63.32; H, 9.71%. Calcd for $C_{13}H_{24}O_4$: C, 63.90; H, 9.90%.

(−)-(1*R*,2*S*,5*R*,6*S*)-2,6-Bis(2-mesyloxyethoxy)bicyclo[3.3.1]-nonane (15). To a mixture of (−)-**14** (1.60 g, 6.55 mmol), triethylamine (6.63 g, 65.5 mmol) and dichloromethane (30 mL) was slowly added a solution of methanesulfonyl chloride (6.00 g, 52.4 mmol) in dichloromethane (20 mL) with ice cooling. After being stirred for 2 h at 0 °C and for an additional 1 h at room temperature, the mixture was poured onto ice and extracted with dichloromethane. The extract was washed with dilute hydrochloric acid, saturated aqueous solution of sodium hydrogencarbonate, and water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on silica gel (hexane/ether 1/9 v/v) to give **15** (2.22 g, 85% yield) as a pale yellow oil, which was used for the next reaction without further purification.

(−)-(1*R*,4*S*,12*S*,15*R*,17*R*,20*S*,28*S*,31*R*)-5,8,11,21,24,27-Hexaoxapentacyclo[26.4.0.0^{4,31}.0^{12,17}.0^{15,20}]dotriacontane (22). To a mixture of sodium hydride (216 mg, 9.00 mmol), potassium tetrafluoroborate (100 mg, 0.794 mmol), and dry DMSO (150 mL) was slowly added a mixture of (−)-**14** (550 mg, 2.25 mmol) and (−)-**15** (901 mg, 2.25 mmol) in dry DMSO (15 mL) over a period of 10 h at 40 °C, and then the resulting mixture was heated for an additional 60 h at this temperature under nitrogen atmosphere. After a small amount of ice water was added to the reaction mixture, the solvent was removed in vacuo and the residue was extracted with ether. The extract was washed with water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on silica gel (hexane/ether 4/6 v/v) to yield **22** (140 mg, 14% yield) as a white solid; mp 56—58 °C; $[\alpha]_D^{25}$ −20.0° (*c* 1.01, $CHCl_3$); IR (KBr) 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08—2.40 (24H, m), 3.16—3.76 (20H, m); MS *m/z* 452 (M^+). Found: C, 68.44; H, 9.81%. Calcd for $C_{26}H_{44}O_6$: C, 68.99; H, 9.80%.

(+)-(1*R*,2*S*,5*R*,6*S*)-2,6-Bis(2-hydroxyethoxy)-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (19). By the similar procedure described for the preparation of **14**, reaction of (+)-**7** (2.07 g,

9.75 mmol) with the *p*-toluenesulfonate of 2-(methoxymethoxy)ethanol (14.0 g, 53.8 mmol) and sodium hydride (1.17 g, 48.8 mmol) in dry DMSO was carried out. The crude product was chromatographed on silica gel (hexane/ether 1/1 v/v) to give **18** (3.3 g) as an oil. Treatment of **18** (3.3 g) with methanol and hydrochloric acid followed by chromatography on silica gel gave **19** (2.21 g, 76% overall yield) as a colorless oil; $[\alpha]_D^{25}$ +99.4° (*c* 1.19, $CHCl_3$); IR (neat film) 3350, 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (6H, s), 1.06 (6H, s), 1.2—1.9 (6H, m), 2.15 (2H, s), 2.30 (2H, br s), 3.18 (2H, d, *J*=9.0 Hz), 3.28—3.76 (8H, m). Found: C, 67.35; H, 10.70%. Calcd for $C_{17}H_{32}O_4$: C, 67.96; H, 10.74%.

(+)-(1*R*,2*S*,5*R*,6*S*)-2,6-Bis(2-mesyloxyethoxy)-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (20). By using the same procedure described for the preparation of **14**, (+)-**19** (800 mg, 2.66 mmol) was reacted with methanesulfonyl chloride (2.44 g, 21.3 mmol) and triethylamine (2.69 g, 26.6 mmol) in dichloromethane. The crude product was chromatographed on silica gel (hexane/ether 3/7 v/v) to yield **20** (1.19 g, 98% yield), which was recrystallized from hexane to give the specimen; mp 46—47 °C; $[\alpha]_D^{24}$ +71.0° (*c* 1.00, $CHCl_3$); IR (KBr) 3025, 1350, 1180 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93 (6H, s), 1.07 (6H, s), 1.1—1.9 (8H, m), 2.32 (2H, br s), 3.03 (6H, s), 3.18 (2H, d, *J*=9.0 Hz), 3.66 (2H, m), 4.32 (4H, t, *J*=5.2 Hz). Found: C, 49.65; H, 7.73; S, 13.88%. Calcd for $C_{19}H_{36}O_8S_2$: C, 50.00; H, 7.95; S, 14.05%.

(+)-(1*R*,4*S*,12*S*,15*R*,17*R*,20*S*,28*S*,31*R*)-3,3,13,13,19,19,29,29-Octamethyl-5,8,11,21,24,27-hexaoxapentacyclo[26.4.0.0^{4,31}.0^{12,17}.0^{15,20}]dotriacontane (23). By using the same procedure described for the preparation of **22**, condensation of (+)-**19** (550 mg, 1.83 mmol) with (+)-**20** (835 mg, 1.83 mmol) and sodium hydride (180 mg, 7.50 mmol) in the presence of potassium tetrafluoroborate (100 mg, 0.794 mmol) was carried out in dry DMSO. The product was chromatographed on silica gel (hexane/ether 1/1 v/v) to give **23** (140 mg, 14% yield) as a colorless oil; $[\alpha]_D^{25}$ +104.4° (*c* 1.15, $CHCl_3$); IR (neat film) 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (12H, s), 1.05 (12H, s), 1.1—2.0 (12H, m), 2.28 (4H, br s), 3.14 (4H, d, *J*=9.0 Hz), 3.28—3.80 (16H, m); MS *m/z* 564 (M^+). Found: C, 67.20; H, 10.13%. Calcd for $C_{34}H_{60}O_6$: C, 72.30; H, 10.71%.

(−)-(1*R*,2*S*,5*R*,6*S*)-6-Benzyloxybicyclo[3.3.1]nonan-2-ol (6). To a suspension of sodium hydride (413 mg, 17.2 mmol) in dry DMSO (30 mL) was added a solution of (−)-**3** (1.90 g, 12.1 mmol) in dry DMSO (20 mL) and then the mixture was heated at 35 °C for 6 h. To the reaction mixture was added a solution of benzyl bromide (2.50 g, 14.6 mmol) in dry DMSO (30 mL) and the resulting mixture was stirred for 15 h at room temperature. After an ice water (50 mL) was added to the reaction mixture, the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on silica gel (benzene/ether 1/1 v/v) to give **6** (1.21 g, 41% yield) as a solid; mp 59—61 °C; $[\alpha]_D^{25}$ −60.1° (*c* 1.02, $CHCl_3$); IR (KBr) 3090, 3060, 3020, 740, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.2 (13H, m), 3.4—3.9 (2H, m), 4.47 (1H, d, *J*=10.8 Hz), 4.55 (1H, d, *J*=10.8 Hz), 7.2—7.4 (5H, m). Found: C, 77.55; H, 8.97%. Calcd for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00%.

(+)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis(2-tosyloxyethoxy)bicyclo[3.3.1]nonane (16). To a solution of (+)-**14**; $[\alpha]_D$ +59.1° (1.05 g, 4.30 mmol), prepared from (+)-**3** by the same procedure described for the preparation of (−)-**14**, in pyridine (30 mL) was added *p*-toluenesulfonyl chloride (3.28 g, 17.2 mmol) with ice cooling and then the mixture was stirred for 2 h at the same temperature. After the reaction mixture was poured onto ice, the resulting mixture was acidified with hydrochloric acid and extracted with benzene. The extract was washed with diluted hydrochloric acid, saturated aqueous solution of sodium hydrogencarbonate, and water, and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on silica gel (benzene/ether 9/1 v/v) to give **16** (1.58 g, 67% yield) as an oil; $[\alpha]_D^{26}$ +28.9° (*c* 0.950, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.0—2.0 (12H, m), 2.44 (6H, s), 3.36 (2H, m), 3.58 (4H, t, *J*=4.8 Hz), 4.14 (4H, t, *J*=4.8 Hz), 7.29 (4H, d, *J*=8.0 Hz), 7.76 (4H, d, *J*=8.0 Hz). Found: C, 58.21; H, 6.50; S, 11.56%. Calcd for $C_{27}H_{36}O_8S_2$: C, 58.68; H, 6.57; S, 11.60%.

(−)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis{2-[(1*R*,2*S*,5*R*,6*S*)-6-benzyloxybicyclo[3.3.1]non-2-yloxy]ethoxy}bicyclo[3.3.1]nonane (26). To a suspension of sodium hydride (156 mg, 6.50 mmol) in dry DMSO (40 mL) was added a solution of (−)-**6** (1.00 g, 4.06 mmol) in dry DMSO (30 mL) and then the mixture was heated at 30 °C for 6 h. After the mixture was cooled in an ice bath, a solution of (+)-**16** (895 mg, 1.62 mmol) in dry DMSO (40 mL) was added to the chilled mixture. The resulting mixture was heated at 35 °C for 40 h under nitrogen atmosphere. The reaction mixture was poured into ice water and extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on silica gel (benzene/ether 9/1 v/v) to yield (−)-**26** (488 mg, 43% yield); mp 119—120 °C; $[\alpha]_D^{25}$ −30.3° (*c* 1.01 $CHCl_3$); IR (KBr) 3060, 3030, 1110, 740, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.2 (36H, m), 3.3—3.7 (14H, m), 4.47 (2H, d, *J*=10.8 Hz), 4.55 (2H, d, *J*=10.8 Hz), 7.2—7.4 (10H, m). Found: C, 76.88; H, 9.10%. Calcd for $C_{45}H_{64}O_6$: C, 77.10; H, 9.20%.

(−)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis{2-[(1*R*,2*S*,5*R*,6*S*)-6-hydroxybicyclo[3.3.1]non-2-yloxy]ethoxy}bicyclo[3.3.1]nonane (27). To a solution of (−)-**26** (400 mg, 0.571 mmol) in dry THF (100 mL) was added lithium aluminum hydride (1.75 g, 46.1 mmol) in a small portions and then the resulting mixture was heated for 14 h at reflux. After water (10 mL) was added to the reaction mixture with ice cooling, the mixture was stirred for 2 h. The inorganic solid was removed by filtration and the solid was continuously extracted with ether using Soxhlet extraction apparatus. The organic solutions were combined, washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on silica gel (ether) to yield **27** (250 mg, 84% yield) as a solid; mp 67.5—69 °C; $[\alpha]_D^{26}$ −10.8° (*c* 1.49, $CHCl_3$); IR (KBr) 3360, 2920, 2850, 1100 cm^{-1}. Found: C, 70.15; H, 9.85%. Calcd for $C_{31}H_{52}O_6$: C, 71.50; H, 10.07%.

(−)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis{2-[(1*R*,2*S*,5*R*,6*S*)-6-methoxybicyclo[3.3.1]non-2-yloxy]ethoxy}bicyclo[3.3.1]nonane (28). To a suspension of sodium hydride (55 mg, 2.3 mmol) in dry DMSO (20 mL) was added a solution of (−)-**27** (150 mg, 0.288 mmol) in dry DMSO (40 mL) and the mixture was heated at 35 °C for 4 h. After the mixture was cooled in an ice bath, a solution of methyl iodide (500 mg, 3.52 mmol) in dry DMSO (30 mL) was added to the chilled mixture. The resulting mixture was heated at 35 °C for 14 h and poured into ice water. The mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed

on silica gel (benzene/ether 8/2 v/v) to yield (−)-**28** (120 mg, 76% yield); mp 71—73 °C; $[\alpha]_D^{20}$ −21.5° (*c* 1.08, $CHCl_3$); IR (KBr) 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.1 (36H, m), 3.32 (6H, s), 3.2—3.7 (14H, m); MS *m/z* 548 (M^+).

(+)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis{2-[(1*S*,2*R*,5*S*,6*R*)-6-benzyloxybicyclo[3.3.1]non-2-yloxy]ethoxy}bicyclo[3.3.1]nonane (29). By using the same procedure described for the preparation of **26**, (+)-**29** (260 mg, 33% yield) was prepared by condensation of (+)-**6**; $[\alpha]_D$ +59.7° (700 mg, 2.84 mmol), prepared from (+)-**3**, with (+)-**16** (620 mg, 1.12 mmol) and sodium hydride (108 mg, 4.50 mmol). (+)-**29**; a colorless oil; $[\alpha]_D^{20}$ +78.7° (*c* 0.995, $CHCl_3$); IR (neat film) 1100, 740, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.2 (36H, m), 3.4—3.7 (12H, m), 4.46 (2H, d, *J*=10.8 Hz), 4.54 (2H, d, *J*=10.8 Hz), 7.2—7.4 (10H, m). Found: C, 76.80; H, 9.20%. Calcd for $C_{45}H_{64}O_6$: C, 77.10; H, 9.20%.

(+)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis{2-[(1*S*,2*R*,5*S*,6*R*)-6-hydroxybicyclo[3.3.1]non-2-yloxy]ethoxy}bicyclo[3.3.1]nonane (30). A mixture of (+)-**29** (115 mg, 0.164 mmol), *p*-toluenesulfonic acid monohydrate (10 mg), 10% Pd on carbon (100 mg), and 1,4-dioxane (20 mL) was shaken at 1 atm of hydrogen at room temperature. After hydrogen uptake had ceased, the catalyst was removed by filtration. To the filtrate was added sodium carbonate (200 mg), and the resulting mixture was stirred for 1 h. The solid was removed by filtration and the filtrate was concentrated in vacuo. The residue was extracted with chloroform and the extract was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The resulting oil was chromatographed on silica gel (ether) to give (+)-**30** (78 mg, 91% yield) as a colorless oil; $[\alpha]_D^{20}$ +60.6° (*c* 0.929, $CHCl_3$); IR (neat film) 3370, 1100 cm^{-1}; MS *m/z* 520 (M^+).

(+)-(1*S*,2*R*,5*S*,6*R*)-2,6-Bis{2-[(1*S*,2*R*,5*S*,6*R*)-6-methoxybicyclo[3.3.1]non-2-yloxy]ethoxy}bicyclo[3.3.1]nonane (31). By using the same procedure described for the preparation of **28**, (+)-**31** (68 mg, 86% yield) was prepared from (+)-**30** (75 mg, 0.14 mmol) with sodium hydride (28 mg, 1.2 mmol) and methyl iodide (250 mg, 1.78 mmol).

(+)-**31**; a colorless oil; $[\alpha]_D^{22}$ +70.3° (*c* 0.968, $CHCl_3$); IR (neat film) 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.1 (36H, m), 3.32 (6H, s), 2.9—3.6 (14H, m); MS *m/z* 548 (M^+).

(−)-(1*R*,2*S*,5*R*,6*S*)-2,6-Bis(1,4,7-trioxaoctyl)bicyclo[3.3.1]nonane (17). To a suspension of sodium hydride (93 mg, 3.9 mmol) in dry DMSO (30 mL) was added a solution of (−)-**3** (100 mg, 0.640 mmol) in dry DMSO (20 mL), and then the resulting mixture was heated at 35 °C for 6 h. After the mixture was cooled in an ice bath, a solution of the *p*-toluenesulfonate of 2-(2-methoxyethoxy)ethanol (1.06 g, 3.87 mmol) in dry DMSO (30 mL) was added to the chilled mixture. After being heated at 35 °C for 15 h, the reaction mixture was poured into ice water and extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated in vacuo. The residual oil was chromatographed on silica gel (benzene/ether 1/1 v/v) to yield **17** (180 mg, 78% yield) as a colorless oil; $[\alpha]_D^{22}$ −56.7° (*c* 0.905, $CHCl_3$); IR (neat film) 1140, 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.1 (12H, m), 3.36 (6H, s), 3.4—3.7 (18H, m); MS *m/z* 360 (M^+).

(+)-(1*R*,2*S*,5*R*,6*S*)-2,6-Bis(1,4,7-trioxaoctyl)-3,3,7,7-tetramethylbicyclo[3.3.1]nonane (21). By using the same procedure described for the preparation of **17**, (+)-**21** (440 mg, 90% yield) as an oil was prepared from (+)-**7** (250 mg, 1.17 mmol) and the *p*-toluenesulfonate of 2-(2-methoxyethoxy)ethanol (1.94 g, 7.13 mmol); $[\alpha]_D^{20}$ +84.4° (*c* 0.950, $CHCl_3$); IR (neat film) 1140, 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (6H, s), 1.04 (6H, s), 1.1—1.9 (6H, m), 2.26 (2H, br s), 3.13 (2H, d, *J*=9.0 Hz), 3.36 (6H, s), 3.4—3.7 (16H, m); MS *m/z* 416 (M^+).

Enantiomer Differential Transport. Enantiomer differential transport was carried out in an apparatus which consisted of an outer cylindrical glass vessel (24.5 mm inner diameter) and a central glass tube (15.5 mm inner diameter). The chloroform solution of the optically active host molecule (5.0×10^{-3} M) separated the inner aqueous phase (0.1 M hydrochloric acid) and the outer aqueous phase (0.08 M hydrochloric acid) containing $LiPF_6$ (0.4 M) and the racemic guest molecule (8.0×10^{-2} M). The chloroform layer was gently stirred at a constant speed (60 rpm) at 20—25 °C. Transport was monitored by ultraviolet spectrum and enantiomer excess of the guest molecule transported was monitored by circular dichroism.

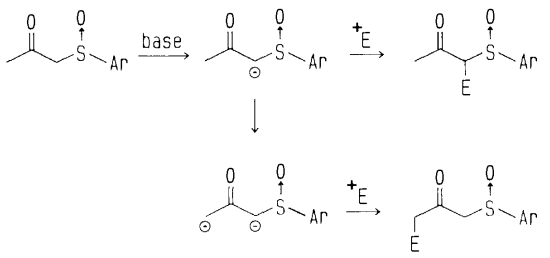
A Practical Optical Resolution of (Arylsulfinyl)acetones and Its Application to the Synthesis of 2-(Arylsulfinyl)cycloalkanones

Katsuyuki OGURA,* Michio ISHIDA,† Hiroshi TOMORI, and Makoto FUJITA
Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, 1-33 Yayoicho, Chiba 260
†Graduate School of Science and Technology, Chiba University, 1-33 Yayoicho, Chiba 260
(Received July 1, 1989)

Racemic (arylsulfinyl)acetones (**1**) were efficiently resolved by formation of their oxazolidine derivatives with (*R*)- or (*S*)-2-amino-2-phenylethanol followed by chromatography on Florisil-MgO and the subsequent hydrolysis to give (*S*)- or (*R*)-**1**, respectively. Further, derivation of **1** to optically active 2-(*p*-tolylsulfinyl)-cyclohexanone and 2-(*p*-tolylsulfinyl)-4-cycloheptenone is described.

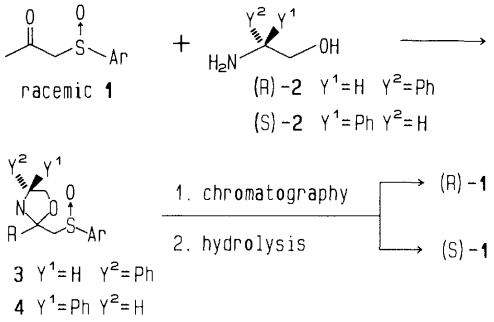
Optically active α-(arylsulfinyl) ketones have proved to be one of the most valuable chiral building blocks for asymmetric syntheses of alcohols,[1] α-hydroxy aldehydes,[2] β-hydroxy ketones,[3] epoxides,[4] γ-substituted γ-lactones,[5] and 4-aryl-3-(*p*-methoxyphenylsulfonyl)-1,4-dihydropyridines,[6] and 3-substituted cycloalkanones.[7] In spite of their potential utilities, these asymmetric syntheses seem to be limited in practical use, mainly due to a multistep preparation of the optically active α-(arylsulfinyl) ketones: Acylation of (*R*)-(methyl *p*-tolyl sulfoxide), obtainable from the reaction of methylmagnesium iodide with *l*-menthyl *p*-toluenesulfinate, has been employed frequently.[1a-d,8] Alternatively, the direct reaction of *l*-menthyl *p*-toluenesulfinate with the enolate ion of a ketone was also reported.[9] Since *l*-menthyl *p*-toluenesulfinate must be synthesized by the reaction of *p*-toluenesulfinyl chloride and *l*-menthyl alcohol followed by repeating recrystallization and epimerization,[10] both of these methods are too tedious to be practical.

For preparing many kinds of optically active α-(arylsulfinyl) ketones, our attention was paid to the utilization of chiral (arylsulfinyl)acetones (**1**) as a versatile intermediate, because the monoanion and dianion of racemic **1** were known to react with various electrophiles to afford a variety of α-(arylsulfinyl) ketones.[11]



Scheme 1.

Here we wish to disclose a practical method for optical resolution of (arylsulfinyl)acetones (**1**), which is achieved by easy formation of an oxazolidine (**3** or **4**) from **1** and (*R*)- or (*S*)-2-amino-2-phenylethanol (**2**), followed by column chromatography on Florisil-MgO. In order to demonstrate the usefulness of



Scheme 2.

optically active **1a**, we further investigated the reaction conditions for deriving **1a** into (R_S)-(*p*-tolylsulfinyl)-cyclohexanone and (S_S)-2-(*p*-tolylsulfinyl)-4-cycloheptenone, the result of which is also described in the present article.

Results and Discussion

Optical Resolution of (Arylsulfinyl)acetones. At first, we found that racemic (*p*-tolylsulfinyl)acetone (**1a**) afforded an oxazolidine derivative (**3a**) by simply stirring **1a** and (*R*)-**2** in ethanol or dichloromethane at room temperature. Thus, an ethanolic solution (3 ml) of racemic (*p*-tolylsulfinyl)acetone (**1a**) (1.0 mmol) and (*R*)-**2** (1.1 mmol) was stirred for 24 h at room temperature. After removal of the solvent under a reduced pressure, the ^{1}H NMR analysis of the residue showed quantitative formation of an oxazolidine (**3a**), which consisted of four diastereomers in the ratio of ca. 2:2:1:1.[12] Without any purification, the crude oxazolidine (**3a**) was subjected to column chromatography (φ 18 mm×290 mm) using benzene–ethyl acetate (9:1) as an eluent. As an adsorbent, we chose 70-fold excess (to **3a** in weight) of Florisil-MgO (70:30, 82:18, and 100:0),[13] prepared by mechanical mixing and subsequent calcination at 200 °C for 2 h. Since **3a** underwent partial hydrolysis during elution, all of the fractions contained **1a** along with **3a**. It was shown by the HPLC analysis that the earlier fractions consisted mainly of **1a** and, as the chromatography proceeded, the content of **3a** increased. The mixture of **1a** and **3a**

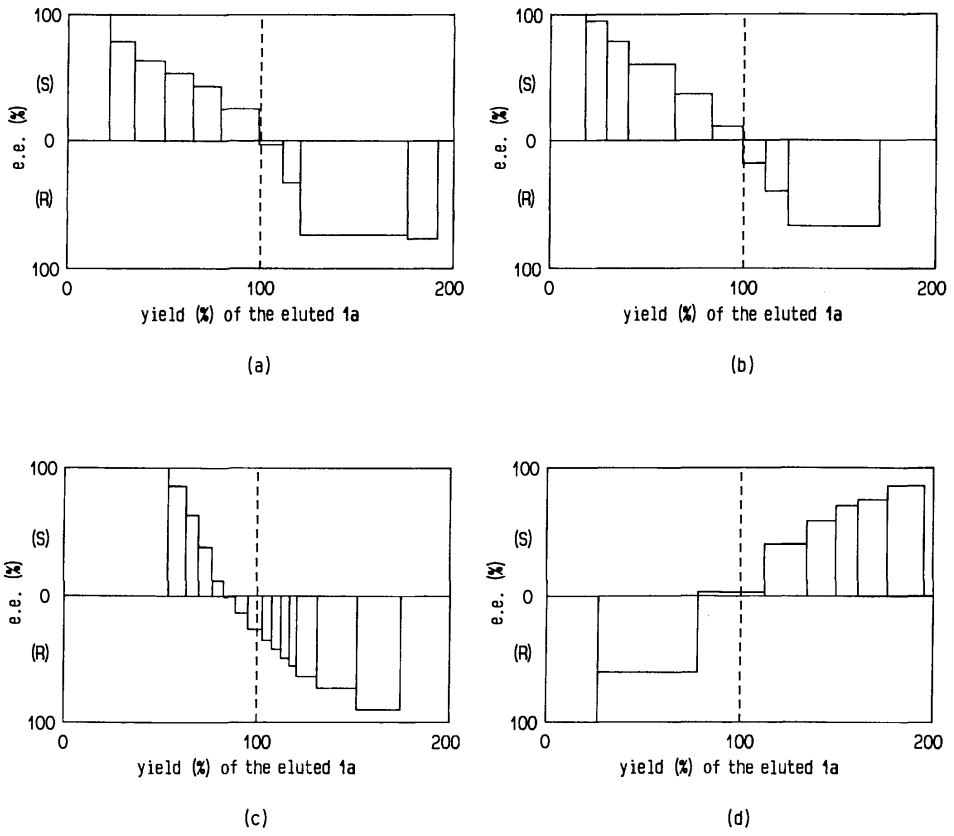


Fig. 1. Chromatography of the oxazolidines: (a) **3a** on Florisil; (b) **3a** on Florisil–MgO (82:18); (c) **3a** on Florisil–MgO (70:30); (d) the oxazolidine derived from **1a** and (*S*)-2-amino-3-methyl-1-butanol on Florisil–MgO (70:30).

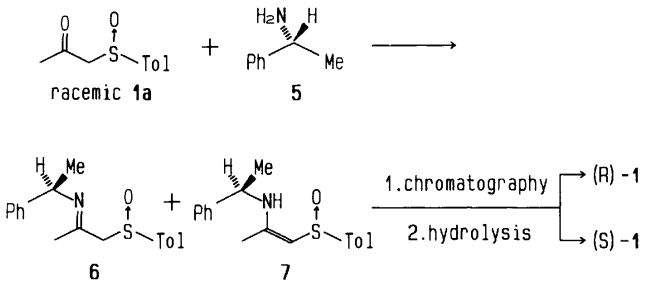
in each fraction was treated with silica gel to hydrolyze the involved **3a** to **1a**. This procedure made it possible to isolate **1a** as a sole product. The enantiomeric excess (e.e.) of **1a** of each fraction was determined by HPLC using a column with a chiral stationary phase (Daisel Chiral-cell OB). The results are summarized in Fig. 1, where the ordinate exhibits the e.e. value and the abscissa does integration of the yield of **1a** in each fraction, based on its one enantiomer. Hereafter, the yields of (*R*)- and (*S*)-**1** based on a half of the amount of the used racemic **1** are utilized. Among the adsorbents examined herein, a 70:30 mixture of Florisil and MgO gave the best result: All the fractions containing (*S*)-**1a** with >99% e.e. were combined and concentrated. The yield of (*S*)-**1a** with >99% e.e. amounted to 54%. A parallel experiment using (*S*)-**2** instead of (*R*)-**2** gave (*R*)-**1a** with >99% e.e. in a comparable yield. The present technique can be suitably applied to a large-scale resolution of **1a**. Thus, the oxazolidine (**4a**), produced from **1a** (10 mmol) and (*S*)-**2** (12 mmol), was eluted through the column (ϕ 45 mm×300 mm) packed with 250 g of Florisil–MgO (70:30) by the use of benzene–ethyl acetate (6:1) as an eluent. Hydrolysis of the fractions containing **1a** with a high enantiomeric excess gave (*R*)-**1a** of >99% e.e. in 48% yield together with (*R*)-**1a** (11% yield) of 98% e.e. It should be noted that the column could be regenerated for reuse by washing with methanol and then with benzene.

The separation mechanism of the present system seems to be quite different from that of the usual chromatography. During elution, the oxazolidine (**3a** or **4a**) is partially hydrolyzed to form **1a**, which is less polar than the oxazolidine and, consequently, is more preferably eluted. Therefore, preferential elution of (*S*)-**1a** on chromatography of **3a** derived from (*R*)-**2** might suggest that the (S_s)-isomers of **3a** is more susceptive to hydrolysis than the (R_s)-isomers.

(*R*)-2-Amino-1-butanol and (*S*)-2-amino-3-methyl-1-butanol also reacted with **1a** to produce the corresponding oxazolidines, but the subsequent chromatography on Florisil–MgO (70:30) resulted in less effective resolution: when (*S*)-2-amino-3-methyl-1-butanol was utilized almost optically pure (*R*)-**1a** (>99% e.e.) was obtained in 27% yield. In the case of (*R*)-2-amino-1-butanol, **1a** was not isolated in an optically pure form. Further, we utilized (*R*)-1-phenylethylamine (**5**) instead of **2**. In the reaction of **5** with **1a**, formation of an imine (**6**) and an enamine (**7**) was observed by the ^{1}H NMR analysis of a crude product. Chromatography of the crude product on Florisil–MgO (70:30) using benzene–ethyl acetate



Scheme 3.

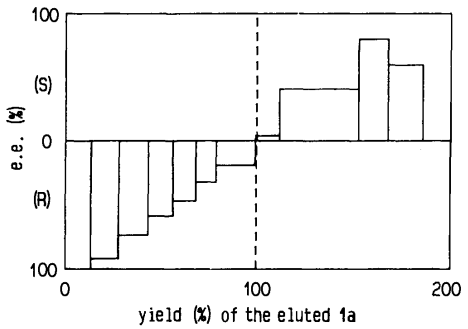


Fig. 2. Chromatography of a mixture of **6** and **7** on Florisil-MgO (70:30).

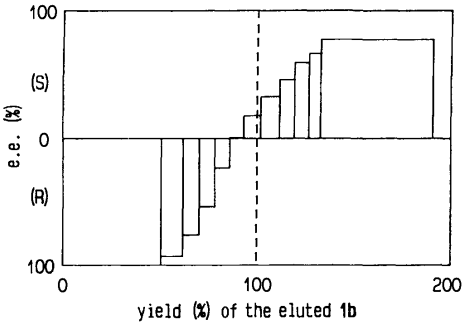

Fig. 3. Chromatography of **4b** on Florisil-MgO (70:30).

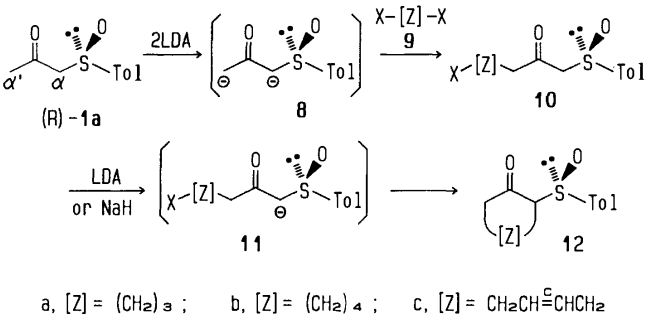

Scheme 4.

(9:1) gave **1a** with >99% e.e. in 13% yield.

In conclusion, chromatography of the oxazolidine (**3a** or **4a**) on Florisil-MgO (70:30) has proved to be most efficient for the optical resolution of **1a**. Recently, (*R*)-(*p*-methoxyphenylsulfinyl)acetone (**1b**) was found to be a good precursor of (*S*)-4-(*m*-chlorophenyl)-3-(*p*-methoxyphenylsulfonyl)-1,4-dihydropyridine, a potent cardiovascular drug.[6] We applied the present technique to an optical resolution of racemic (*p*-methoxyphenylsulfinyl)acetone (**1b**). Like **1a**, **1b** reacted with (*S*)-**2** to quantitatively form the corresponding oxazolidine (**4b**), which was subjected to column chromatography on Florisil-MgO (70:30) using benzene-ethyl acetate (9:1). At the initial stage, we obtained pure (*R*)-**1b** with >99% e.e. in 51% yield (Fig. 3): mp 75.5—77.0 °C (lit,[6] mp 56—58 °C); $[\alpha]_D^{21}$ +231° (*c* 0.75, MeOH) (lit,[6] $[\alpha]_D$ +168°).

Derivation of (*R*$_s$)-2-(*p*-Tolylsulfinyl)cycloalkanones from 1a. Since optically active **1a** are now in hand, their conversion into useful chiral compounds are particularly of interest. As well-known, successive treatment of racemic α-(phenylsulfinyl) ketones with sodium hydride and butyllithium gives the corresponding dianion, which reacts with various electrophiles to give α′-substituted products.[1f,11,14] By applying this chemistry of α-(phenylsulfinyl) ketones to the optically active **1**, we investigated a short-step synthesis of (*R*$_s$)-2-(*p*-tolylsulfinyl)cycloalkanones, which are novel precursors of optically active cyclic compounds, as outlined in Scheme 4. This route may be complementary to the conventional way leading to chiral 2-(*p*-tolylsulfinyl)cycloalkanones which are prepared by the reaction of *l*-menthyl *p*-toluenesulfinate with the enolate of a cycloalkanone.[9]

By the use of racemic **1a**, we first tested the possibility of the reaction paths depicted in Scheme 4. Treatment of **1a** with lithium diisopropylamide (LDA) (2.2 mol equiv) in tetrahydrofuran (THF) at −78 °C to room temperature generated the corresponding dianion (**8**).[15] After addition of excess amount (3 mol equiv) of 1,ω-dihaloalkane (**9**), the resulting mixture was stirred for 10—30 min to give an α′-substituted product (**10**). Reaction of the dianion (**8**) with **9a** (X=Br), **9a** (X=I), and **9b** (X=I) gave the corresponding **10** in 41%, 49%, and 60% yields, respectively. In contrast, treatment of the dianion (**8**) with 1,2-diiodoethane (**9**, X=I) did not give the corresponding **10**, but 1-iodo-3-(*p*-tolylsulfinyl)propanone (54% yield). Next, intramolecular cyclization of **10** to **12** was examined. LDA (1.1 mol equiv) was added to a 0.04 M# THF solution of **10** at −78 °C, and the resulting mixture was stirred at −15 °C to room temperature. In the case of **10a** (X=I), a smooth cyclization took place at −15 °C for 20 h to give **12a** in 51% yield. The reaction of **10a** (X=Br) was so slow that **12a** was produced in 27% yield even after stirring at room temperature for 10 h. However, cyclization of **10b** (X=I) did not form the expected **12b**, but a de-

1 M=1 mol dm^{-3}.

hydroiodinated product, 1-(*p*-tolylsulfinyl)-6-hepten-2-one. Consequently, the synthetic path depicted in Scheme 4 was shown to be suitable to the preparation of **12a**. Starting from (*R*)-**1a**, we obtained (R_s)-**12a** as a 64:36 mixture of two diastereomers: $[\alpha]_D$ +215° (*c* 0.80, $CHCl_3$).[16]

Further, we found that optically active 2-(*p*-tolylsulfinyl)-4-cycloheptenone (**12c**), which seems to be a good synthetic precursor of optically active cycloheptanone derivatives, was synthesized according to the reaction path of Scheme 4: Treatment of the dianion (**8**), generated from (*S*)-**1a**, with *cis*-1,4-dichloro-2-butene (**9c**) in THF at −78 °C for 30 min gave 7-chloro-1-(*p*-tolylsulfinyl)-5-hepten-2-one (**10c**) in 72% yield. Sodium hydride (2 equiv) was added to a THF solution of the thus-obtained **10c** under ice-cooling, and the reaction mixture was stirred at room temperature for 2 h. By the usual workup and subsequent chromatography on silica gel, (S_s)-**12c** was obtained in 74% yield as a 52:48 mixture of two diastereomers.

Thus, (*R*)- or (*S*)-**1a** was shown to provide a new and novel method for preparing optically active 2-(*p*-tolylsulfinyl)cyclohexanone (**12a**) and 2-(*p*-tolylsulfinyl)-4-cycloheptenone (**12c**).

Experimental

Melting points were determined on a hot-stage microscope apparatus (Yanagimoto) and are uncorrected. ^{1}H NMR spectra were obtained on Hitachi R-600 (60 MHz), JEOL JNM-GSX 270 (270 MHz), and JEOL JNM-GSX 500 (500 MHz) spectrometers. Infrared spectra were determined with a JASCO A-200 spectrometer. Optical rotations were measured on a JASCO polarimeter. The adsorbent for chromatography of the oxazolidines (**3** or **4**) was prepared by mechanically mixing Florisil (Wako; 100—200 mesh) and MgO (Merck Art. 5866) followed by being dried in a microwave oven (30 min) and then in an oven (200 °C/2 h). (*R*)-**2** and (*S*)-**2** were prepared by reduction of (*R*)-phenylglycine (Tokyo Kasei) and (*S*)-phenylglycine (Aldrich), respectively, with lithium aluminium hydride in THF and purified by recrystallization from dichloromethane-hexane. Their enantiomeric excesses were determined to be 100% by measuring ^{1}H NMR of their diacetyl derivatives, which were obtained by acetylation with acetic anhydride and pyridine, in the presence of Eu(hfc)$_3$ (0.4 mol equiv).

Preparation of (Arylsulfinyl)acetone (1). The starting materials, racemic **1a** and **1b**, were obtained by oxidation of the corresponding (arylthio)acetone with sodium periodate in ethanol-water (1:1). **1a**: colorless crystals; mp 44.5—45.5 °C (from hexane-diethyl ether) (lit,[17] mp 44—47 °C). **1b**: colorless crystals; mp 69.5—71.0 °C (from hexane-diethyl ether); ^{1}H NMR ($CDCl_3$) δ=2.23 (3H, s), 3.78 (1H, d, *J*=13.5 Hz), 3.87 (1H, d, *J*=13.5 Hz), 3.86 (3H, s), 7.04 (2H, d, *J*=8.9 Hz), and 7.59 (2H, d, *J*=8.9 Hz); IR (KBr) 1711, 1032, and 1020 (sh) cm^{-1}. Calcd for $C_{10}H_{12}O_3S$: C, 56.60; H, 5.70%. Found: C, 56.65; H, 5.69%.

Optical Resolution of 1. A Typical Procedure. A solution of **1a** (196 mg, 1.0 mmol) and (*R*)-**2** (151 mg, 1.1 mmol) in absolute ethanol (2 ml) was stirred at room temperature for 15 h under an atmosphere of nitrogen. After evaporation, the residue was chromatographed through a column (φ 17.5 mm×290 mm) packed with a 70:30 mixture (70 fold excess in weight) of Florisil (16.1 g) and MgO (6.9 g). A 9:1 mixture of benzene and ethyl acetate was eluted and 80-ml fractions were collected. Finally, ethyl acetate was eluted to completely recover **1a** and **3a**. Each fraction was evaporated in vacuo and the residue was subjected to short-path column chromatography on silica gel using benzene-ethyl acetate (1:1) as an eluent. The result was summarized in Table 1 and Fig. 1c. The fractions 23, 24, and 25 involved the oxazolidine (**3a**), which was hydrolyzed by treatment with silica gel in dichloromethane. The enantiomeric excess (e.e.) was analyzed by HPLC with a chiral stationary phase (Daisel Chiral-cell OB) using 2-propanol-hexane (1:2) as an eluent (flow rate: 0.7 ml min^{-1}). Under these conditions, the retention times of (*S*)-**1a** and (*R*)-**1a** were about 13 min and 17 min, respectively. The obtained (*S*)-**1a** and (*R*)-**1a** were identified by comparison of their physical properties (IR and ^{1}H NMR) with those of racemic **1a**. Specific optical rotations of (*S*)-**1a** and (*R*)-**1a** were $[\alpha]_D^{22}$ −269° (*c* 1.00, acetone) and $[\alpha]_D^{22}$ +269° (*c* 1, acetone) (lit,[18] $[\alpha]_D$ +255.0° (*c* 1.00, acetone)).

Table 1. Chromatography of **3a** on Florisil-MgO (70:30)

Fraction	Eluent[a]	Vol/ml	**1a**/mg	E.e./%
1—11	A	80×11	52.8	100 (*S*)
12	A	80	9.1	86 (*S*)
13	A	80	6.4	63 (*S*)
14	A	80	7.0	38 (*S*)
15	A	80	5.6	12 (*S*)

a) A: PhH-AcOEt (9:1); B: AcOEt.

Except for the use of (*S*)-2-amino-3-methyl-1-butanol (1.1 mmol) and (*R*)-1-phenylethylamine (1.1 mmol) instead of **2** (1.1 mmol), the same procedure was repeated and the results were depicted in Figs. 1d and 2. It was shown by ^{1}H NMR analysis that reaction of **1a** with (*R*)-1-phenylethylamine in ethanol gave a mixture which consisted of **6** and **7** in the ratio of ca. 1:1. The signals at δ=3.6—3.9 which consisted mainly of an AB quartet at 3.67 and 3.76 (*J*=13.0 Hz) and a singlet at δ=3.80 were assigned to those of **6** (mainly two isomers). The olefinic protons of **7** (two isomers) appeared at δ=4.83 (s) and 4.95 (s) in a relative intensity of 7:5.

In a similar manner, (*p*-methoxyphenylsulfinyl)acetone (**1b**) was resolved and the result is depicted in Fig. 3. The (*R*)- and (*S*)-**1b** were identified by comparison of their physical properties (IR and ^{1}H NMR) with those of racemic **1b**. Pure (*R*)-**1b** (>99.5% e.e. by HPLC): colorless crystals;

mp 75.5—77.0 °C (diethyl ether-hexane) (lit,[6] mp 56—58 °C); $[\alpha]_D^{21}$ +231° (*c* 0.75, MeOH) (lit,[6] $[\alpha]_D$ +168° (MeOH); no comment on its e.e.).

Reaction of the Dianion (8) with 1,3-Dibromopropane (9a, X=Br). (a) Dianion Formation Using 2 Equiv of LDA: To a solution of **1a** (589 mg, 3.00 mmol) in THF (20 ml), was added a THF solution of LDA, prepared by the action of butyllithium (6.60 mmol/4.26 ml of hexane) and diisopropylamine (1.2 ml, 8.6 mmol) in THF (10 ml), at −78 °C under an atmosphere of nitrogen. The resulting mixture was stirred at the same temperature for 30 min and then at room temperature for 1 h. After the mixture was again cooled to −78 °C, **9a** (X=Br) (0.94 ml, 9.0 mmol) was added and the reaction mixture was stirred at the same temperature for 30 min. The mixture was poured into a saturated aqueous solution (20 ml) of ammonium chloride, followed by extraction with diisopropyl ether (IPE) (20 ml×3). The combined extracts were dried ($MgSO_4$), evaporated, and subjected to column chromatography on silica gel using benzene-ethyl acetate (4:1) as an eluent to give **10a** (X=Br) (390 mg: 41% yield) along with the unchanged **1a** (186 mg). **10a** (X=Br): colorless crystals; mp 107—108 °C (from diethyl ether-hexane); ^{1}H NMR ($CDCl_3$) δ=1.60—1.73 (2H, m), 1.73—1.87 (2H, m), 2.42 (3H, s), 2.50 (1H, dt, *J*=18.5 and 6.9 Hz), 2.55 (1H, dt, *J*=18.5 and 6.6 Hz), 3.36 (2H, t, *J*=6.6 Hz), 3.75 (1H, d, *J*=13.2 Hz), 3.81 (1H, d, *J*=13.2 Hz), 7.34 (2H, d, *J*=7.9 Hz), and 7.52 (2H, d, *J*=7.9 Hz); IR (KBr) 1705 and 1035 cm^{-1}. Calcd for $C_{13}H_{17}BrO_2S$: C, 49.21; H, 5.40%. Found: C, 49.27; H, 5.38%.

(b) Dianion Formation Using NaH and Butyllithium: To a solution of **1a** (498 mg, 2.54 mmol) in THF (20 ml) and hexamethylphosphoric triamide (2 ml), was added NaH (60% dispersion in an oil) (156 mg, 3.90 mmol) under ice-cooling under N_2 atmosphere, and then the resulting mixture was stirred at room temperature for 1 h. After the mixture was cooled to −78 °C, a 1.55 M hexane solution (1.97 ml) of butyllithium (3.05 mmol) was added and the mixture was stirred at room temperature for 1 h. After **9a** (X=Br) (0.94 ml, 9.0 mmol) was added at −78 °C, the reaction mixture was stirred at the same temperature for 1 h. The workup similar to that described in (a) and column chromatography on silica gel gave **10a** (X=Br) (322 mg: 40% yield) along with the unchanged **1a** (63 mg).

In the manner analogous to that described in (a), the reaction of **1a** (316 mg, 1.61 mmol) with **9a** (X=I) (0.56 ml, 4.8 mmol) afforded **10a** (X=I) (246 mg: 42% yield) together with **1a** (105 mg). **10a** (X=I): colorless crystals; mp 101—106 °C (from diethyl ether-hexane); ^{1}H NMR ($CDCl_3$) δ=1.59—1.69 (2H, m), 1.69—1.82 (2H, m), 2.43 (3H, s), 2.49 (1H, dt, *J*=18.5 and 6.9 Hz), 2.51 (1H, dt, *J*=18.5 and 6.9 Hz), 3.13 (2H, t, *J*=6.6 Hz), 3.75 (1H, d, *J*=13.2 Hz), 3.81 (1H, d, *J*=13.2 Hz), 7.35 (2H, d, *J*=7.9 Hz), and 7.53 (2H, d, *J*=7.9 Hz); IR (KBr) 1710 and 1035 cm^{-1}. Calcd for $C_{13}H_{17}IO_2S$: C, 42.86; H, 4.70%. Found: C, 42.89; H, 4.72%.

Similarly, **9b** (X=I) reacted with **1a** to give the corresponding **10b** (X=I) in 60% yield: colorless crystals; mp 73.5—75.0 °C (from diethyl ether-hexane); ^{1}H NMR ($CDCl_3$) δ=1.28—1.42 (2H, m), 1.49—1.63 (2H, m), 1.73—1.85 (2H, m), 2.43 (3H, s), 2.48 (1H, dt, *J*=18.5 and 7.3 Hz), 2.52 (1H, dt, *J*=18.5 and 7.3 Hz), 3.16 (2H, t, *J*=6.9 Hz), 3.75 (1H, d, *J*=13.2 Hz), 3.83 (1H, d, *J*=13.2 Hz), 7.35 (2H, d, *J*=7.9 Hz), and 7.53 (2H, d, *J*=7.9 Hz); IR (KBr) 1705 and 1030 cm^{-1}. Calcd for $C_{14}H_{19}IO_2S$: C, 44.45; H, 5.06%. Found: C, 44.63; H, 5.06%.

Reaction of the Dianion (8) with 1,2-Diiodoethane (9, X=I). To a THF solution (5 ml) of the dianion (**8**) prepared from **1a** (500 mg, 2.55 mmol) and LDA (2.2 equiv), was added a solution of **9** (X=I) (2.22 g, 7.88 mmol) in THF (5 ml) at −78 °C, and the reaction mixture was stirred at the same temperature for 5 min. The mixture was poured into a saturated aqueous solution (20 ml) of ammonium chloride, followed by extraction with IPE (20 ml×1) and dichloromethane (10 ml×4). The combined extracts were washed with 5% aqueous solution of $Na_2S_2O_3$, dried ($MgSO_4$), evaporated, and subjected to column chromatography on silica gel using benzene-ethyl acetate (6:1) as an eluent to give a colorless oil (477 mg) which was too unstable to be completely identified. Its ^{1}H NMR spectrum exhibited the signals which were in accordance with those of 1-iodo-3-(*p*-tolylsulfinyl)-2-propanone: ^{1}H NMR ($CDCl_3$) δ=2.45 (3H, s), 4.00 (1H, d, *J*=13.5 Hz), 4.03 (1H, d, *J*=13.5 Hz), 4.17 (2H, s), 7.39 (2H, d, *J*=9.0 Hz), and 7.55 (2H, d, *J*=9.0 Hz).

Intramolecular Cyclization of 10a (X=I). A Typical Procedure. A THF solution (10 ml) of LDA, prepared from butyllithium (1.26 mmol/0.81 ml of hexane) and diisopropylamine (0.23 ml), was dropwise added to a solution of **10a** (379 mg, 1.04 mmol) in THF (20 ml) at −78 °C under N_2 atmosphere over 5 min. After being stirred at the same temperature for 30 min and then at −15 °C for 20 h, the mixture was poured into a saturated aqueous solution (20 ml) of ammonium chloride, followed by extraction with IPE (15 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated. The oily residue was separated by column chromatography on silica gel using benzene-ethyl acetate (4:1) as an eluent to give **12a** (125 mg: 15% yield) which was shown by HPLC analysis to consist of two diastereomers in the ratio of 6:4. **12a**: colorless crystals; mp 105—115 °C: ^{1}H NMR ($CDCl_3$) δ=1.20—2.10 (6H, broad m), 2.30—2.80 (2H, m), 2.42 (3H, s), 3.00—3.70 (1H, m), 7.30 (2H, d, *J*=9.0 Hz), and 7.51 (2H, d, *J*=9.0 Hz); IR (KBr) 1710 and 1035 cm^{-1}. Calcd for $C_{13}H_{16}O_2S$: C, 66.07; H, 6.82%. Found: C, 66.25; H, 6.83%.

This compound was identified with the product derived from oxidation of 2-(*p*-tolylthio)cyclohexanone[19] with *m*-chloroperbenzoic acid in dichloromethane by comparison of their IR and ^{1}H NMR spectra.

In a similar manner, (R_s)-**12a** was prepared by the cyclization of (R_s)-**10a**: colorless crystals which was shown by HPLC to consist of two diastereomers (64:36); mp 110—118 °C; $[\alpha]_D^{22}$ +215° (*c* 0.80, $CHCl_3$).[16]

Synthesis of (S_s)-12c. To a solution of (*S*)-**1a** (234 mg, 1.19 mmol) in THF (5 ml), was added a THF solution of LDA, prepared by the action of butyllithium (2.86 mmol/1.92 ml of hexane) and diisopropylamine (0.48 ml) in THF (3 ml), at −78 °C under an atmosphere of nitrogen. The resulting mixture was stirred at the same temperature for 30 min and then at room temperature for 1 h. After the mixture was again cooled to −78 °C, **9c** (X=Cl) (464 mg, 2.38 mmol) was added and the reaction mixture was stirred at the same temperature for 30 min. The mixure was poured into a saturated aqueous solution (5 ml) of ammonium chloride, followed by extraction with IPE (5 ml×3). The combined extracts were dried ($MgSO_4$), evaporated, and subjected to column chromatography on silica gel using

benzene-ethyl acetate (1:1) as an eluent to give (*S*)-**10c** (**X**=Cl) (246 mg: 72% yield): colorless crystals; mp 59.5—60.5 °C (from diethyl ether-hexane); $[\alpha]_D^{22}$ −181° (*c* 1.00, $CHCl_3$). The IR and ^1H NMR of this compound was in complete accordance with those of racemic **10c**: colorless crystals; mp 65—66 °C (from diethyl ether-hexane); ^1H NMR ($CDCl_3$) δ=2.10—2.90 (4H, m), 2.42 (3H, s), 4.08 (2H, d, *J*=6.0 Hz), 5.35—5.85 (2H, broad s), 7.35 (2H, d, *J*=8.4 Hz), and 7.57 (2H, d, *J*=8.4 Hz); IR (KBr) 1705 and 1025 cm^{-1}. Calcd for $C_{14}H_{17}O_2ClS$: C, 59.04; H, 6.01%. Found: C, 59.24; H, 6.00%.

To a DMF solution (2 ml) of (*S*)-**10c** (87 mg, 0.31 mmol), was added NaH (60% dispersion in an oil, 15 mg, 0.37 mmol) under ice-cooling, and then the resulting mixture was stirred at room temperature for 2 h. The mixture was poured into a saturated aqueous solution (3 ml) of ammonium chloride and extracted with IPE (5 ml×3). The combined extracts were dried ($MgSO_4$), evaporated, and subjected to column chromatography on silica gel using hexane-ethyl acetate (1:1) as an eluent to give (S_s)-**12c** (56 mg: 74% yield) which was shown by HPLC analysis to consist of two diastereomers in the ratio of 52:48. An analytical sample (its diastereomeric ratio: 72:28) of (S_s)-**12c** was obtained by recrystallization from diethyl ether: colorless crystals; mp 95.5—100.5 °C; $[\alpha]_D^{20}$ −246° (*c* 0.75, $CHCl_3$). The IR and ^1H NMR of this compound was identical to those of racemic **11c**: mp 95—96 °C: ^1H NMR ($CDCl_3$) δ=2.10—3.20 (6H, m), 2.49 (3H, s), 3.72 (1H, dd, *J*=4.8 and 11.4 Hz), 5.28 (2H, broad s), 7.38 (2H, d, *J*=8.4 Hz), and 7.58 (2H, d, *J*=8.4 Hz); IR (KBr) 1705 and 1025 cm^{-1}. Calcd for $C_{14}H_{16}O_2S$: C, 67.71; H, 6.49%. Found: C, 67.74; H, 6.57%.

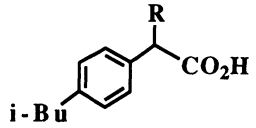
A Convenient Reductive Removal of Benzylic Hydroxyl and Trimethylsilyloxyl Groups with Me_3SiCl-NaI-MeCN Reagent

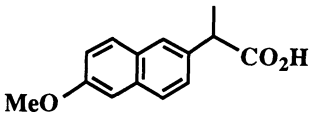
Takashi SAKAI,* Kazuyoshi MIYATA, Sadao TSUBOI, Akira TAKEDA, Masanori UTAKA,* and Sigeru TORII
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700
(Received February 2, 1989)

Secondary and tertiary hydroxyl groups at benzylic positions were reductively removed by treatment with 6 equivalents of Me_3SiCl-NaI-MeCN reagent in hexane at room temperature. A benzylic trimethylsilyloxyl group was also eliminated by the addition of 2 equivalents of water to the reaction system. The reduction was applied to the syntheses of precursors of such anti-inflammatory agents as ibuprofen, butibufen, naproxen, and related compounds, as well as (±)-*ar*-turmerone, an odorous sesquiterpene.

Recently, attention has been devoted to α-arylalkanoic acids and their derivatives because of their usefulness as nonsteroidal anti-inflammatory agents.[1] For example, ibuprofen (**1a**),[2] butibufen (**1b**),[3] and naproxen (**2**)[4] have been extensively utilized for medical purposes and various synthetic methods for the α-arylalkanoic acid skeleton have been developed.

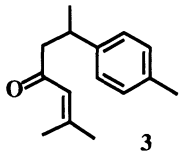


1a R=Me
1b R=Et



2

One of the straightforward approaches to them relies upon the reductive removal of such benzylic functional groups as $-OP(=O)(OEt)_2$,[2a] -OAc,[2b] $-SO_2Ph$,[2c] -OH,[3] and -SMe.[4] Therein, a convenient reduction method is still sought. It is of interest that a Me_3SiCl-NaI-MeCN reagent has been used for a variety of organic transformations.[5,6] For example, aliphatic alcohols are converted into the corresponding iodides[6,7] and α-ketols are reduced to ketones.[8] We describe here a new potential use of the reagent, in which a benzylic hydroxyl group can be reductively removed.[9] Moreover, a reduction of the benzylic trimethylsiloxyl group was also achieved by the addition of water to the system. The advantages of the present method include the reagent availability and procedural simplicity using mild conditions compared with the reported methods.[10] The synthetic utility of the method has been demonstrated by the syntheses of the precursors of racemic **1a**, **b** and **2** as well as (±)-*ar*-turmerone (**3**),[11a,b] a constituent of the essential oil from Curcuma Longa Linn.[11c]



3

Results and Discussion

The reduction of secondary or tertiary benzylic alcohols **4b—p** with the Me_3SiCl-NaI-MeCN reagent gave products **5b—p** in good yields (Scheme 1). The results are summarized in Table 1. Optimun yields were obtained when the reaction was carried out with 6 equivalents of the reagent in hexane at room temperature. A decrease in the reagent ratio to three equivalents against **4a** resulted in a lower yield of **5b** and the partial recovery of **4b**. The obtained products were essentially pure after a simple workup, although cyanohydrins **4j** and **4k** decomposed partially to the corresponding ketones through a reverse cyanohydrin reaction under weakly acidic conditions. The reaction for menthyl ester **4m** required heating and gave a mixture of ester **5m** and its acid.

Furthermore, δ-hydroxy β-keto ester **6** gave β-keto ester **7** in 62% yield and diol **8** was deoxygenated regioselectively, giving alcohol **9** (39% yield) and iodide **10** (7% yield) (Scheme 2). Other functional groups such as aryl, carbonyl, cyano, carboxyl, alkoxycarbonyl, and the β-keto ester moiety were scarcely affected.[12]

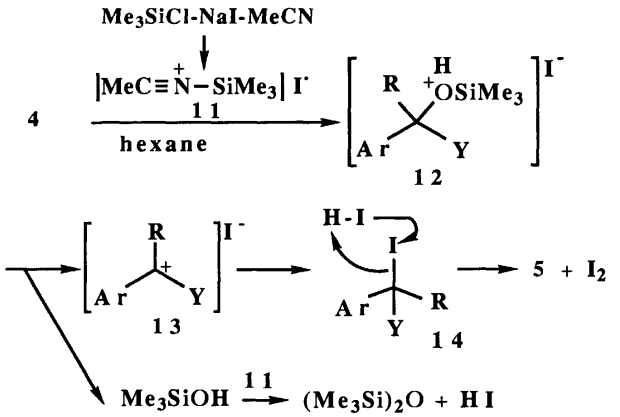
a) Six equivalents of the reagent were used at room temperature for 24 h unless otherwise stated. b) All compounds listed are known. c) Isolated yield by distillation for **5b**—i or preparative TLC for **5j**—p. d) Commercially available. e) Benzyl iodide was obtained (94%). See Refs. 6 and 7. f) Three equivalents of reducing agent. Alcohol **4b** was recovered (12%). g) Acetophenone was produced (60%). h) *p*-Isobutylphenyl methyl ketone was recovered (12%). i) Reaction for 96 h. j) Diastereomeric excess of 22% (^{1}H NMR). k) Reaction for 3 days under reflux. The corresponding carboxylic acid was produced (21%). l) Racemic mixture. m) Enantiomeric excess of 70% (^{1}H NMR, Eu(hfc)$_3$).



Scheme 3.

Scheme 3 illustrates a possible mechanism for the present reduction, which involves the conversion of the initially formed oxonium ion **12** to intermediate iodide **14**[6] and a subsequent reduction with an in situ generated HI, as discussed previously.[13] The proton for the reduction would, therefore, come from the original hydroxyl group. Optically active alcohols **4m** and **4n** gave racemic products **5m** and **5n**, respectively. Consequently, the present reaction seems to proceed through benzylic cation **13**. The difficulty in the formation of a primary carbonium ion from **4a** would result in the isolation of benzyl iodide.[7]

The above method leaves room for refinement in the case of cyanohydrins **4j** and **4k**. Both their yields and the product selectivity were improved by the use of

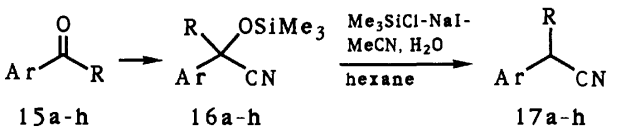
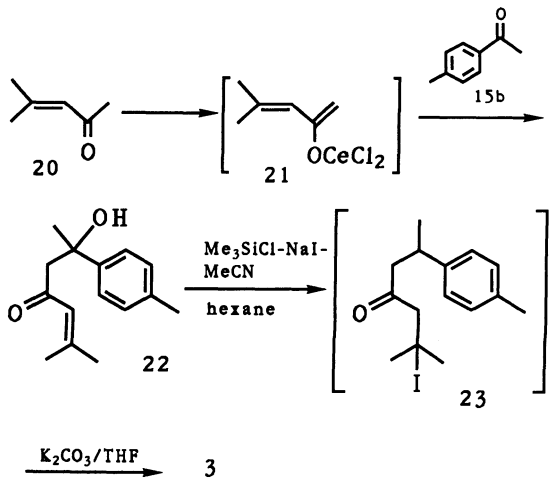


Scheme 4.

α-(trimethylsilyloxy) nitriles **16a** and **16c** (Scheme 4 and Table 2), which gave **5j** and **5k** exclusively. In these cases, the addition of 2 equivalents of water is required as a proton source. Fortunately, nitriles **16** are conveniently prepared from ketones **15**.[14] Reduction using a variety of nitriles, **16b** and **16d**—h,



Scheme 5.

afforded **17b** and **17d—h** in acceptable yields, respectively. Nitriles **5k**, **17d**, and **17g** are known to be converted into **1a**, **b** and **2** by alkaline hydrolysis;[3a,10c] other nitriles are also important precursors for anti-inflammatory compounds.

By using this method, a deuterated benzylic compound was conveniently prepared. Thus, the reaction of **16b** in the presence of 2 equivalents of D_2O yielded 2-deuterio-2-*p*-tolylpropiononitrile (**18**) in 56% yield. This result supports the mechanism shown in Scheme 3.

In the case of α-(trimethylsilyloxy) nitriles, decreasing the amount of the reagent made the reaction rather complex. For example, the reaction of **16b** with 3 equivalents of the reagent and 2 equivalents of water in hexane gave a mixture of nitrile **17b** (33% yield), ketone **15b** (26% yield), and 2-*p*-tolylpropanamide (**19**) (26% yield). The reduction may be retarded under the conditions and accompanied by an acidic hydrolysis of the nitrile group or a reverse cyanohydrin reaction.

Finally, the present reaction was applied to an efficient synsthesis of (±)-**3**[11] from mesityl oxide (**20**) and *p*-methylacetophenone (**15b**), as communicated previously[9] (Scheme 5). Cerium enolate **21**[15] was allowed to react with **15b** to give aldol **22** in 54% yield. The reduction of **22** gave a 1:2 mixture of iodide **23** and **3** which, without isolation, was treated with K_2CO_3 in THF to afford **3** in 82% yield from **22**. This method offers one possible straightforward approaches to the synthesis of (±)-**3**.[9,11]

Experimental

General. IR spectra were taken on a JASCO A 102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a JEOL-PMX 60 SI spectrometer. Chemical shifts are reported in value (ppm) down field from Me_4Si and *J* values are given in hertz. Preparative TLC was performed on silica gel (E. Merck, Kiesel gel 60 PF_{254}). Elemental analyses were performed by Eiichiro Amano of this laboratory using a Yanagimoto MT-3 CHN recorder.

Alcohols 4a—p. Compounds **4a—c** and **4h** are commercially available; the others were prepared according to the various methods reported.[16]

Ketones 15a—h. Compounds **15a**, **15b**, and **15h** are commercially available and **15c—g** were prepared by acylation of substituted benzene derivatives ($AlCl_3$, dichloromethane).[17]

General Procedure for Deoxygenation of Benzylic Alcohols 4a—p. To a stirred mixture of Me_3SiCl (1.54 ml, 12 mmol), NaI (1.8 g, 12 mmol), and acetonitrile (0.61 ml, 12 mmol), was added a solution of benzylic alcohol **4a—p** (2 mmol) in hexane (2 ml) at room temperature. The mixture slowly turned dark purple due to liberated iodine. After being stirred for 24 h at room temperature, the reaction was quenched by the addition of water. The organic layer was separated and the aqueous layer was extracted with ether. The combined organic layer was washed with aqueous $Na_2S_2O_3$ and brine, dried over $MgSO_4$, and then concentrated under vacuum. Distillation or preparative TLC (Table 1) of the residual oil gave clean products **5a—p**,[18] whose structures were identified by using IR and ^1H NMR spectra.

Ethyl 3-Oxo-5-phenylpentanoate (7). Crude product from **6**[19] (236 mg, 1 mmol) was purified by preparative TLC (hexane–acetone, 3:1) to give **7**[20] (136 mg, 62% yield): R_f 0.41—0.53; IR (neat) 1745, 1715 cm^{-1}; ^1H NMR (CCl_4) δ=1.20 (3H, t, *J*=7 Hz), 2.83 (4H, m), 3.23 (2H, s), 4.06 (2H, q, *J*=7 Hz), 7.10 (5H, m), 12.15 (trace, br s).

4-Phenyl-2-butanol (9)[21] and 3-Iodo-1-phenylbutane (10).[22] A crude product from diol **8**[23] (166 mg, 1 mmol) was separated by preparative TLC (hexane–acetone, 3:1) to give **9** (R_f 0.24—0.34, 58 mg, 39% yied) and **10** (R_f 0.78—0.90, 23 mg, 7% yield).

General Procedure for the Preparation of α-(Trimethylsilyloxy) Nitriles 16a—h. These reactions were carried out by a modification of Rasmussen's method.[14a] To a stirred suspension of NaCN (735 mg, 15 mmol), Me_3SiCl (1.02 ml, 8 mmol), and ZnI_2 (50 mg) in acetonitrile (2 ml) was added alkyl aryl ketone **15a—h** (5 mmol) at room temperature. The mixture was heated under gentle reflux for 48 h and then made basic by the addition of aqueous $NaHCO_3$; the organic layer was extracted with ether. It was then washed with brine, dried ($MgSO_4$) and concentrated under reduced pressure. The residue was purified by vacuum distillation to give **16a—h** (5 mmol) at room temperature. The mixture was heated under gentle reflux for 48 h and then made basic by the addition of aqueous $NaHCO_3$; the organic layer was extracted with ether. It was then washed with brine, dried ($MgSO_4$) and concentrated under reduced pressure. The residue was purified by vacuum distillation to give **16a—h**. Compound **16a**[14] was identified by a comparison of the spectral data with those reported. Those of **16b—h** are shown below.

2-*p*-Tolyl-2-(trimethylsilyloxy)propiononitrile (16b):[24] bp 140—152 °C (9 mmHg, 1 mmHg=133.322 Pa); IR (neat) 2225 cm^{-1}; ^1H NMR (CCl_4) δ=0.13 (9H, s), 1.76 (3H, s), 2.31 (3H, s), 7.06 (2H, d, *J*=8 Hz), and 7.32 (2H, d, *J*=8 Hz).

2-(*p*-Isobutylphenyl)-2-(trimethylsilyloxy)propiononitrile (16c): bp 115—130 °C (0.2 mmHg); IR (neat) 2230 cm^{-1}; ^1H NMR (CCl_4) δ=0.14 (9H, s), 0.89 (6H, d, *J*=6 Hz), 1.08 (3H, s), 1.5—2.6 (1H, m), 2.46 (2H, d, *J*=8 Hz), 7.05 (2H, d, *J*=9 Hz), and 7.37 (2H, d, *J*=9 Hz). Found: C, 69.71; H, 8.82; N, 5.12%. Calcd for $C_{16}H_{25}NOSi$: C, 69.82; H, 9.09; N, 5.09%.

2-(*p*-Isobutylphenyl)-2-(trimethylsilyloxy)butyronitrile

(**16d**): bp 110—130 °C (0.2 mmHg); IR (neat) 2240 cm^{-1}; ^1H NMR (CCl_4) δ=0.10 (9H, s), 0.89 (6H, d, J=6 Hz), 0.96 (3H, t, J=7 Hz), 1.5—2.2 (3H, m), 2.46 (2H, d, J=7 Hz), 7.03 (2H, d, J=8 Hz), and 7.30 (2H, d, J=8 Hz). Found: C, 70.66; H, 9.37; N, 4.64%. Calcd for $C_{17}H_{27}NOSi$: C, 70.59; H, 9.34; N, 4.84%.

2-(*p*-Isobutylphenyl)-3-methyl-2-(trimethylsilyloxy)butyronitrile (16e): bp 140—155 °C (0.3 mmHg); IR (neat) 2250 cm^{-1}; ^1H NMR (CCl_4) δ=0.14 (9H, s), 0.80—0.36 (12H, m), 1.45—2.35 (2H, m), 2.52 (2H, d, J=7 Hz), and 7.24 (4H, m). Found: C, 71.53; H, 9.59; N, 4.76%. Calcd for $C_{18}H_{29}NOSi$: C, 71.29; H, 9.57; N, 4.62%.

2-(*p*-*t*-Butylphenyl)-3-methyl-2-(trimethylsilyloxy)butyronitrile (16f): bp 105—120 °C (0.3 mmHg); IR (neat) 2350 cm^{-1}; ^1H NMR (CCl_4) δ=0.14 (9H, s), 0.87 (3H, d, J=7 Hz), 1.11 (3H, d, J=7 Hz), 1.38 (9H, s), 1.4—2.7 (2H, m), and 7.35 (4H, s). Found: C, 71.42; H, 9.31; N, 4.50%. Calcd for $C_{18}H_{29}NOSi$: C, 71.29; H, 9.57; N, 4.62%.

2-(6-Methoxy-2-naphthyl)-2-(trimethylsilyloxy)propiononitrile (16g): bp 145—155 °C (0.18 mmHg); IR (neat) 2229 cm^{-1}; ^1H NMR (CCl_4) δ=0.15 (9H, s), 1.85 (3H, s), 3.80 (3H, s), and 7.0—8.0 (5H, m). Found: C, 68.47; H, 6.84; N, 4.55%. Calcd for $C_{12}H_{21}NO_2Si$: C, 68.23; H, 7.02; N, 4.68%.

2-(2-Thienyl)-2-(trimethylsilyloxy)propiononitrile (16h): bp 143—157 °C (15 mmHg); IR (neat) 3125, 3100, 3000, 2250 cm^{-1}; ^1H NMR (CCl_4) δ=0.16 (9H, s), 1.91 (3H, s), 6.78 (1H, m), and 7.16 (2H, m). Found: C, 53.14; H, 6.44; N, 6.13%. Calcd for $C_{10}H_{15}NOSSi$: C, 53.33; H, 6.67; N, 6.22%.

General Procedure for the Reductive Removal of α-Trimethylsilyloxyl Group of 16a—h. Nitriles **16a—h** (0.5 mmol) were added to a mixture of Me_3SiCl (0.38 ml, 3 mmol), NaI (450 mg, 3 mmol), acetonitrile (0.19 ml, 3 mmol), and hexane (1 ml). After the addition of water (18 mg, 1 mmol), the mixture was stirred for 24 h at room temperature. The usual workup, followed by purification with preparative TLC on silica gel (hexane-acetone, 3:1) gave α-aryl nitriles **17a—h**. IR and ^1H NMR data of **17g** were identical with those reported.[25b,c] Those of others, which are not given in the literature, are shown below.

2-*p*-Tolylpropiononitrile (17b):[25a] R_f 0.48—0.60; IR (neat) 2250 cm^{-1}; ^1H NMR (CCl_4) δ=1.53 (3H, d, J=7 Hz), 2.31 (3H, s), 3.64 (1H, q, J=7 Hz), and 7.11 (4H, m).

2-(*p*-Isobutylphenyl)butyronitrile (17d):[25b] R_f 0.61—0.72; IR (neat) 2240 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (6H, d, J=6 Hz), 1.05 (3H, t, J=7 Hz), 1.5—2.3 (3H, m), 2.46 (2H, d, J=7 Hz), 3.61 (1H, t, J=6 Hz), and 7.10 (4H, m).

2-(*p*-Isobutylphenyl)-3-methylbutyronitrile (17e):[25c] R_f 0.56—0.81; IR (neat) 2250 cm^{-1}; ^1H NMR (CCl_4) δ=0.85—1.28 (12H, m), 1.3—2.7 (2H, m), 2.45 (2H, d, J=7 Hz), 3.54 (1H, d, J=6 Hz), and 7.09 (4H, m).

2-(*p*-*t*-Butylphenyl)-3-methylbutyronitrile (17f):[25d] R_f 0.44—0.60 (hexane-acetone, 5:1); IR (neat) 2250 cm^{-1}; ^1H NMR (CCl_4) δ=0.99 (3H, d, J=7 Hz), 1.03 (3H, d, J=7 Hz), 1.29 (9H, s), 2.10 (1H, m), 3.05 (1H, d, J=6 Hz), and 7.26 (4H, m).

2-(2-Thienyl)propionitrile (17h):[25f] R_f 0.41—0.49; IR (neat) 3130, 3020, 2960, 2260 cm^{-1}; ^1H NMR (CCl_4) δ=1.69 (3H, d, J=7 Hz), 4.09 (1H, q, J=7 Hz), 6.3—7.4 (3H, m).

2-Deuterio-2-*p*-tolylpropiononitrile (18). Nitrile **16b** (233 mg, 1 mmol) was added to a mixture of 6 equivalents of a Me_3SiCl-NaI-MeCN reagent in 1 ml of hexane, and then D_2O (99.6%, 36 mg, 2 mmol) was introduced. The mixture was treated in the usual way, giving **18** (81 mg, 55% yield): IR (neat) 2250 cm^{-1}; ^1H NMR (CCl_4) δ=1.52 (3H, m), 2.29 (3H, s), 3.26 (0.27H, q, J=7 Hz), 7.09 (4H, m); ^{13}C NMR ($CDCl_3$) δ=21.0 (q), 21.3 (q), 30.5 (t from C-D), 30.8 (d, C-H, trace), 121.7 (s), 126.5 (d), 129.7 (d), 134.1 (s), 137.8 (s). The ^1H NMR data indicates the deuterated ratio is 91%.

Reaction of 16b with 3 Equivalents of the Reducing Agent. Crude product from **16b** (233 mg, 1 mmol) was separated by preparative TLC (hexane-acetone 3:1) to give nitrile **17b** (R_f 0.42—0.73, 48 mg, 33% yield), amide **19** (R_f 0.03—0.16, 42 mg, 26% yield), and ketone **15b** (R_f 0.22—0.42, 15.5 mg, 11% yield). Compound **19**: IR (KBr) 3350, 3200, 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.34 (3H, d, J=7 Hz), 2.26 (3H, s), 3.37 (1H, q, J=7 Hz), 5.80 (1H, br s), 6.97 (4H, m). Found: C, 73.41; H, 7.84; N, 8.64%. Calcd for $C_{10}H_{13}ON$: C, 73.62; H, 7.98; N, 8.59%.

6-Hydroxy-2-methyl-6-*p*-tolyl-2-hepten-4-one (22).[26] To a cooled (−78 °C) solution of LDA (4.4 mmol) [diisopropylamine (0.62 ml, 4.4 mmol) and 1.59 mol dm^{-3} BuLi hexane solution (2.75 ml, 4.4 mmol)] in THF (4 ml) in an acetone-Dry Ice bath, was added dropwise a solution of mesityl oxide (392 mg, 4 mmol) in THF (1 ml). After sitrring for 1 h at −78 °C, a suspension of $CeCl_3$ (1.16 g, 4.7 mmol) in THF (5 ml) was slowly added. The mixture was stirred for 1 h to form a cerium enolate anion. A solution of *p*-methylacetophenone (**15b**) (536 mg, 4 mmol) in THF (1 ml) was then added dropwise through a syringe. Stirring was continued for an additional 3 h at −78 °C. The resulting mixture was poured into water and acidified with 10% HCl. The organic layer was extracted with ether, dried over $MgSO_4$, and then concentrated under reduced pressure. The residue was subjected to vacuum distillation to give **22** (505 mg) as a clean oil: 54% yield; bp 140—150 °C (5 mmHg); IR (neat) 3475, 1675, 1610 cm^{-1}; ^1H NMR (CCl_4) δ=1.37 (3H, s), 1.80 (3H, s), 2.00 (3H, s), 2.24 (3H, s), 2.72 (1H, s), 2.81 (1H, s), 4.41 (1H, brs), 5.81 (1H, m), 6.94 (2H, d, J=8 Hz), and 7.21 (2H, d, J=8 Hz).

(±)-*ar*-Turmerone (3).[11] Compound **22** (101 mg, 0.43 mmol) was treated with Me_3SiCl (0.39 ml, 3 mmol), NaI (450 mg, 3 mmol), acetonitrile (0.15 ml, 3 mmol) in hexane (1 ml) in the usual manner and 116 mg of oily product was obtained. ^1H NMR analysis showed that it was a 1:2 mixture of 2-iodo-2-methyl-6-*p*-tolyl-4-heptanone (**23**)[27] and **3**, which was then stirred with K_2CO_3 (36 mg, 0.26 mmol) in THF (2 ml) for 20 h at room temperature. After the addition of water, the organic layer was extracted with ether, washed with aqueous $Na_2S_2O_3$ and brine, dried over $MgSO_4$, and then concentrated. The residual oil was subjected to vacuum distillation to give **3** (76 mg): 82% yield from **22**; bp 150—160 °C (7 mmHg); IR (neat) 1685, 1620, 1515, 819 cm^{-1}; ^1H NMR (CCl_4) δ=1.31 (3H, d, J=7 Hz), 1.81 (3H, s), 2.05 (3H, s), 2.22 (3H, s), 2.54 (2H, m), 3.15 (1H, m), 5.85 (1H, m), and 6.94 (4H, s). The spectral data are consistent with those reported.[11]

We are grateful to the SC-NMR Laboratory of Okayama University for 500 MHz ^1H NMR and 125 MHz ^{13}C NMR experiments concerning compound **18** using a Varian VXR-500 instrument.

Photochemical Hydrogen Abstraction Reactions of 9,10-Dihydro-9,10-*o*-benzenoanthracene-1,4-dione Derivatives with Xanthene: Intramolecular Charge Transfer Quenching

Nobuya KITAGUCHI†

Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606

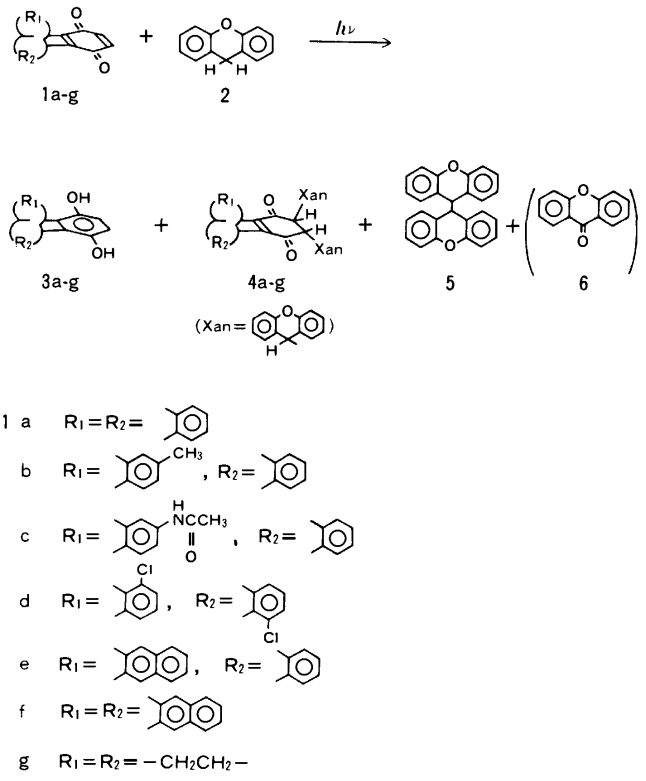
(Received April 19, 1989)

Intramolecular charge transfer interaction in triptycene system was investigated. 9,10-Dihydro-9,10-*o*-benzenoanthracene-1,4-dione (triptycenequinone) and its analogs were readily photoreduced with xanthene to give the corresponding hydroquinones and the adducts with two xanthenyl radicals. The chemically induced dynamic nuclear polarization examination and the corresponding thermal reaction proved the adducts to be originated from free radical coupling of xanthenyl radicals and quinones. The quantum yield for disappearance of the quinones depended upon both the substituents and solvents. Kinetic analysis by applying Stern–Volmer plot, using anthracene as a quencher, revealed that the quantum yield of intersystem crossing and the lifetime of the triplet state decreased with increasing electron-donating power of the aromatic rings in triptycenequinones. These solvent and substituent effects suggest that intramolecular charge transfer quenching of both the singlet and the triplet excited states of quinones by neighboring aromatic rings occurs in the triptycenequinone system. Such intramolecular charge transfer interaction would lower the rate constants of hydrogen abstraction reaction from xanthene via the triplet states of triptycenequinone derivatives.

Transannular π–π interaction among neighboring benzene rings in triptycene system is one of the problems of increasing interest in organic chemistry.[1–8] It will be fascinating to investigate a change of such intramolecular interaction caused by introducing benzoquinone moiety into the triptycene system. 9,10-Dihydro-9,10-*o*-benzenoanthracene-1,4-dinoe (triptycenequinone) (**1a**) has one benzoquinone moiety and two benzene rings. Murata has observed the charge transfer (CT) transition for symmetry-forbidden CT interaction in unsubstituted and methyl- or methoxy-substituted triptycenequinones.[6,7] The present author has reported the substituent and solvent effects on the electronic spectra of triptycenequinones **1a—f**.[8] Triptycenequinones show characteristic absorption maxima as a result of intramolecular charge transfer. The substituents on the benzene rings strongly affect the CT bands. Strong electron-donating substituents induce shifts of the absorption maxima to long wavelengths. Calculations by the extended Hückel theory reveal that the charge of aromatic ring is somewhat delocalized to the benzoquinone moiety in the course of HOMO-LUMO excitation.[8] These findings clearly show that intramolecular CT interaction does exist in the singlet excited state of the triptycenequinone system.

On the other hand, benzoquinone derivatives are easily photoreduced with hydrogen donors such as xanthene (**2**) to the corresponding hydroquinones by hydrogen abstraction reactions.[9–14] Some quinones gave 2,3-di(9-xanthenyl)-2,3-dihydro-1,4-naphthoquinone derivatives.[11]

In this paper, the effect of the substituents on the hydrogen abstraction reaction of triptycenequinones with xanthene will be reported to reveal the efficiency of the intramolecular CT quenching of the singlet and triplet excited states of triptycenequinones.



Results and Discussion

Product Analysis. In the photoreactions of tripty-

† Present address: Bio-Science Laboratory, Life Science Research Laboratories, Asahi Chemical Industry Co., Ltd., 2-1 Samejima, Fuji city, Shizuoka 416.

Table 1. Product Yields[a] in Photoinduced Reductions of Triptycenequinones with Xanthene (**2**)

Solvent	Quinone	Hydroquinone **3**	Adduct **4**
		Yield/%	Yield/%

a) Yields of isolated products based on the consumed quinones. b) Not detected.

cenequinones **1a**—**f** and 5,6,7,8-tetrahydro-5,8-ethano-1,4-naphthoquinone (**1g**) with xanthene (**2**), all quinones were reduced to the corresponding hydroquinones in high yields. A degassed C_6H_6 solution of **1a** and **2** (molar ratio was 1:2) was irradiated to give the hydroquinone **3a**, the adduct **4a** and 9,9′-bixanthenyl (**5**). The results of various quinones in three solvents are summarized in Table 1. When acetone was used as a solvent, the solution was irradiated at longer wavelengths than 340 nm. In acetonitrile, xanthone (**6**) was also isolated. Triptycensquinones other than those summarized in Table 1 were similarly photoreduced to give only the corresponding hydroquinones.

The structures of the adducts **4** were determined by mass, ^{1}H NMR, UV, and IR spectra. Further, 7.4×10^{-5} mol of the adduct **4a** was oxidized with $KBrO_3$ in acetic acid to give triptycenequinone (**1a**) (6.1×10^{-5} mol) and xanthone (**6**) (1.0×10^{-4} mol). This result confirms that **4a** consists of **1a** and xanthenyl moieties in the ratio of 1:2. Since the ^{1}H NMR spectrum of **4e** shows multiplet-like two doublets at δ=4.16, two xanthenyl groups may be in trans.

Formation of **4a** can be explained in terms of attack of two 9-xanthenyl radicals on **1a** in the ground state. In a thermal coupling experiment, **1a** and 9-xanthenyl radical generated by thermal reaction of **2** and di-*t*-butyl peroxyoxalate gave the adduct **4a** and bixanthenyl (**5**).

$$\mathbf{1a} + \mathbf{2} + (t\text{-BuOOC}\overset{\overset{\displaystyle O}{\|}}{}\!)_2 \xrightarrow[\text{benzene}]{\Delta,\ N_2} \mathbf{4a} + \mathbf{5}$$

On the contrary, the irradiation of **1a** and **5** in benzene gave no adduct **4a** but gave xanthone (**6**) and hydroquinone **3a**.

Chemically Induced Dynamic Nuclear Polarization (CIDNP) Examination of Photoinduced Hydrogen Abstraction Reaction of 1a with 2. In the photoreaction of **1a** with **2**, enhanced ^{1}H NMR signals were observed, although the signals were not so intense compared with those of 1,4-benzoquinone[10,12] or 1,4-naphthoquinone.[10,11] Figures 1 and 2 show the

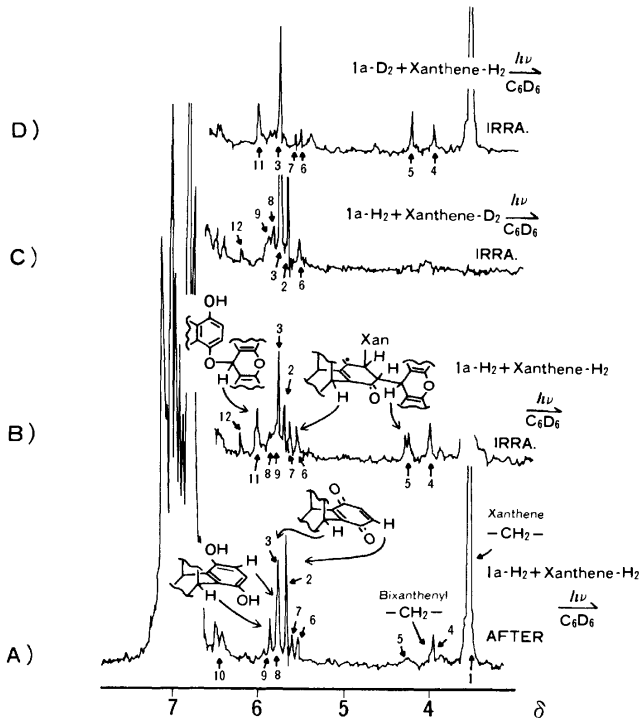

Fig. 1. ^{1}H NMR spectra observed in the photochemical reaction of **1a** with **2** at room temperature (solvent; C_6D_6). A) After irradiation. B) During irradiation. C) During irradiation with xanthene-9,9-d_2 instead of **2**. D) During irradiation with triptycenequinone-2,3-d_2 instead of **1a**.

^{1}H NMR signals observed in the reactions of **1a** with **2** and of **1g** with **2** for comparison. Signal No. 1 was due to the methylene protons of **2**, signals Nos. 2 and 3 due to **1a**, signals Nos. 4 and 10 due to **5**, and signals Nos. 8 and 9 due to the hydroquinone **3a**. By comparison of the spectra given in Fig. 1 A—D, signals Nos. 5, 7, and 11 can be assigned to the methylene protons of xanthenyl groups and signal No. 6 to the bridgehead protons of a triptycenequinone moiety. Signal No. 12 may be due to an unstable intermediate in the reaction of **1a** and the corresponding hydroquinone **3a**, because the similar absorption signal was observed during irradiation of a solution of these two compounds.

The chemical shifts of signals Nos. 5 and 6 were compatible with those of the adduct **4a**. Since these enhanced signals Nos. 5. and 6 were hardly observed at 6 °C and clearly observed at 78 °C (Fig. 2), they may be due to escape products from the solvent-caged initial radical pair. Application of "Kaptein's simple rule",[15] as well as the results of the thermal coupling reaction described in the previous section, also confirms that the precursor of **4a** is a free radical pair (Scheme 1).

In the photoreduction of naphthoquinone derivatives with **2**,[11] the CIDNP examination and the analysis of the structures of isolated products reveal that the quinones give 1:1 adducts, 2-(9-xanthenyl)-

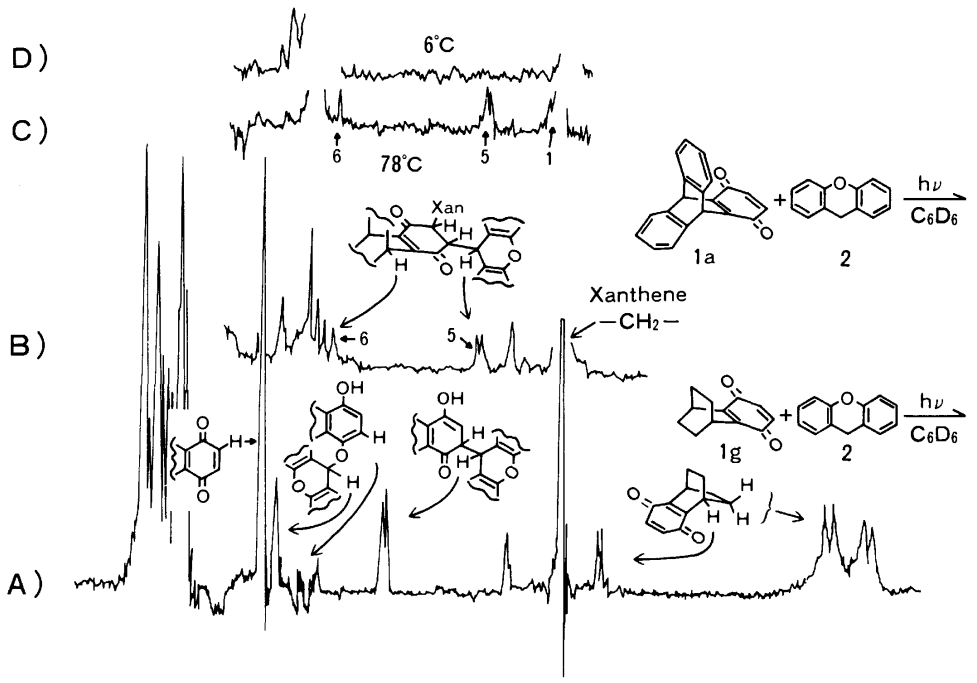

Fig. 2. ^{1}H NMR spectra observed in the photochemical reaction of quinones **1g** or **1a** with **2** during irradiation (solvent; C_6D_6). A) Non-aromatic quinone **1g** was irradiated at room temperature. B—D) Triptycenequinone **1a** was irradiated: B) at room temperature, C) at 78°C, D) at 6°C.

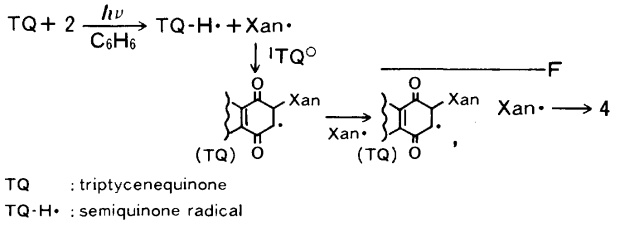

Scheme 1.

2,3-dihydro-1,4-naphthoquinones, as well as 1:2 adducts. In the present study, the non-aromatic derivative **1g** gave CIDNP signals of 1:1 coupling products as shown in Fig. 2. Although triptycenequinone (**1a**) also gave a CIDNP signal which may be assigned to a proton of a 1:1 adduct (Fig. 1B), such 1:1 adduct was not isolated in any photoreactions of triptycenequinone derivatives. Phenoxy type 1:1 adducts may be unstable because of susceptibility to oxidation and steric hindrance between a xanthenyl group and benzene rings of triptycenequinones.

Quantum Yields for Disappearance of Triptycenequinones ($\Phi_{disap.}$). The data of $\Phi_{disap.}$ in the reactions with **2** are summarized in Table 2. The details of the measurement method are described in the experimental section. Electron-donating substituents on benzene ring clearly suppressed the $\Phi_{disap.}$ values in each solvent (**1d**>**1a**>**1b**). Further, the $\Phi_{disap.}$ values of triptycenequinones having electron-donating groups, **1b**, **e**, and **f**, were much smaller in the reactions in polar solvents (acetonitrile and acetone) than in a non-polar solvent (benzene). As previously reported,[8] change of the reduced charge (population change) in the course of HOMO-LUMO excitation, calculated by the extended Hückel theory, can be adopted as a parameter of electron-donating ability. The $\Phi_{disap.}$ values are plotted against the population change of

Table 2. Quantum Yields for Disappearance of Quinones in the Photoreductions with Xanthene (**2**)[a]

benzoquinone moiety ($\sum Q\Delta_{L-H}$) in Fig. 3. The $\Phi_{disap.}$ values obtained in benzene gently decrease with increasing population change $\sum Q\Delta_{L-H}$, while those in more polar solvents, acetonitrile and acetone, steeply decrease to go down to about 0.1 at $\sum Q\Delta_{L-H}$ value of 0.4—0.5. This population-change dependency of $\Phi_{disap.}$ values suggests that CT quenching occurs in the triplet excited state of triptycenequinones.

The $\Phi_{disap.}$ values of **1e** in various solvents clearly showed a decisive effect of solvent polarity. Figure 4 shows that the $\Phi_{disap.}$ values decrease with increasing solvent polarity; Dimroth's E_T values.[16,17] The reason why Kosower's Z-values were not adopted was described previously.[8]

These substituent and solvent effects on the $\Phi_{disap.}$ values suggest that the lowest excited states of triptycenequinones, especially the quinones having electron-donating substituents, may have a strong CT character in polar solvents.

Exceptionally, the $\Phi_{disap.}$ values of **1c** were exceedingly low compared with others (Table 2). Although

the Hammett σ^+ constant of acetylamino group (−0.25) is almost identical with that of methyl group (−0.26),[21] the $\Phi_{disap.}$ values of **1c** in both benzene and acetonitrile were less than one-tenth of those of **1b**. This can be explained in terms of quenching of the excited state of quinones by intra- and/or intermolecular electron transfer from lone pair electrons of the nitrogen atom of amino group to carbonyl groups.[18-20] This conception was confirmed by the intermolecular quenching experiment of the photoreduction of **1a** with **2** using acetanilide or acetotoluidide as a quencher. Acetanilide and acetotoluidide strongly decreased the $\Phi_{disap.}$ value of **1a** as shown in Table 3. More effective intramolecular quenching by 3,4-dimethylaniline moiety could suppress the $\Phi_{disap.}$ value of **1c** to about one-tenth of that of intermolecularly-quenched **1a**. A similar substituent effect is observed in the photoreduction of substituted fluorenone.[20] In that case, acetylamino group gives much higher quenching efficiency than ethoxy group (σ^+=−0.78).

Quenching of the Photoreductions of Triptycenequinones. Photoreductions of triptycenequinones with **2** were quenched by anthracene (the energy of the excited singlet state E_S=319.7 kJ mol^{-1}, the energy of the excited triplet state E_T=176.0 in a non-polar solvent), *trans*-stilbene (E_S=394.7, E_T=209.5 in a non-polar solvent), pyrene (E_S=322.2 in a non-polar solvent, E_T=201.5 in a polar solvent)[21], and oxygen. Because quinones were excited with the 450 nm monochromatic light (265.6 kJ mol^{-1}) in the present experiments of quantum yield determination, the quenchers described above could quench the triplet, not singlet, excited states of the quinones. Further, in general, hydrogen abstraction reactions have been considered to occur via the n-π^* triplet excited states.[22] Therefore, the present photoreduction reactions also can be considered to proceed through the n-π^* triplet excited states.

The triplet energy of triptycenequinone was assumed to be similar to the value of 2,3-dimethyl-1,4-benzoquinone (216.2 kJ mol^{-1}).[23] In the following experiments on kinetics, anthracene was used as a suitable quencher because of its E_S and E_T values. Pyrene and *trans*-stilbene were not suitable because

pyrene formed a CT complex with **1a** in the ground state, and the quenching efficiency of *trans*-stilbene was fairly small.

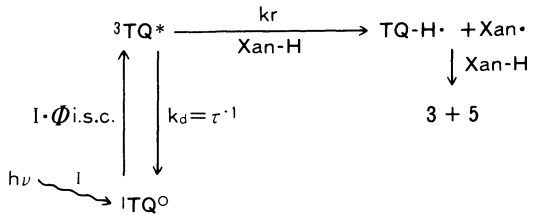
The reaction scheme for the hydrogen abstraction reactions of triptycenquinones can be drawn as described in Scheme 2.

From the thermal coupling experiment and the CIDNP examination described in the previous sections, the excited states of quinones might not directly participate in the formation of the adducts **4**, and the amount of **4** may be negligibly small in the initial step of the reaction. Therefore, formation of the adducts can be excluded from the following kinetic analysis. Based on Scheme 2, a straight line is expected in the Stern–Volmer plot of $\Phi_{disap.}^{-1}$ vs. $[\mathbf{2}]^{-1}$ from the following equation:

$$\Phi_{disap.}^{-1} = \Phi_{i.s.c.}^{-1} + k_d \times \Phi_{i.s.c.}^{-1} \times k_r^{-1} \times [\mathbf{2}]^{-1} \quad (1)$$

where $\Phi_{i.s.c.}$ is the quantum yield of intersystem crossing, k_r is the rate constant of the reaction between the triplet excited triptycenequinones (^{3}TQ*) and **2**, and k_d is the decay rate constant of ^{3}TQ*, that is, the reciprocal of the lifetime τ of ^{3}TQ*.

As another pathway to the hydroquinones **3**, the disproportionation of the semiquinone radicals (TQ–H·) could also be included in the reaction scheme. Based on the scheme containing disproportionation pathway, the intercept in the plot of $\Phi_{disap.}^{-1}$ vs. $[\mathbf{2}]^{-1}$ ($2/\Phi_{i.s.c.}$) cannot be less than two. However, the intercept was found to be less than two in many cases in the present study, suggesting that the contribution of the disproportionation of TQ–H· can be estimated to be small. In such cases, the hydroquinones **3** may be produced mainly by hydrogen abstraction reaction of TQ–H· from **2**.



Scheme 2.

In the presence of a quencher (Q) of ^{3}TQ*, Eq. 1 is modified as follows:

$$\Phi_{disap.}^{-1} = \Phi_{i.s.c.}^{-1} + k_d \times \Phi_{i.s.c.}^{-1} \times k_r^{-1} \times [\mathbf{2}]^{-1} + k_q \times \Phi_{i.s.c.}^{-1} \times k_r^{-1} \times [\mathbf{2}]^{-1} \times [Q] \quad (2)$$

where k_q is the quenching rate constant and [Q] is the concentration of the quencher. Based on Eq. 2, a straight line is expected in the Stern–Volmer plot of $\Phi_{disap.}^{-1}$ vs. [Q] at a constant concentration of [**2**].

Stern–Volmer Plots. Benzene (Dimroth's E_T value is 34.5) and acetonitrile (46.0) were adopted as a nonpolar and a polar solvent, respectively. Since the quenching reactions proceed nearly in the diffusion-control, the following rate constants of the quenching reactions were adopted, k_q=5.0×10^9 dm^3 mol^{-1} s^{-1} in benzene and 1.0×10^{10} dm^3 mol^{-1} s^{-1} in acetonitrile.[19,24] All quinones investigated (**1a**, **b**, **d**, **e**, and **g**) gave straight lines in the plots of $\Phi_{disap.}^{-1}$ vs. $[\mathbf{2}]^{-1}$ in both solvents. Since the $\Phi_{disap.}$ values did not depend on the concentration of triptycenequinones (data not shown), intermolecular interaction of triptycenequinones can be neglected at least in the concentrations adopted in these experiments.

The kinetic parameters obtained by Stern–Volmer plots are summarized in Table 4. The $\Phi_{i.s.c.}$ values of the investigated quinones were mostly similar to each other in benzene, but they greatly changed in acetonitrile. The $\Phi_{i.s.c.}$ and τ values obtained in acetonitrile decreased in the order of electron-donating power of the aromatic rings except for the τ value of **1g**. The k_r values of substituted triptycenequinones **1a**, **b**, and **d** in both solvents decreased in the same order as the $\Phi_{i.s.c.}$ and τ values in acetonitrile. These results can be explained by intramolecular CT quenching, that is, by increase of the CT characters of the lowest excited

Table 4. Kinetic Parameters of the Triplet State of Triptycenequinones in the Reactions with Xanthene (**2**)

Solvent	Quinone	$\Phi_{i.s.c.}$	τ / 10^{-7} s	k_r / 10^8 mol^{-1} dm^3 s^{-1}
C_6H_6	**1d**	0.72	5.4	8.0
	1a	0.70	4.2	1.1
	1b	0.74	4.8	0.48
	1e	0.58	11	2.1
	1g[a]	0.83	0.4	4.8
CH_3CN	**1d**	0.67	>20	33
	1a	0.49	16	6.9
	1b	0.16	3.6	5.7
	1e	0.09	1.1	26
	1g	0.7	0.8	17

a) Because **1g** formed CT complex with C_6H_6, **2**, and **5**, the kinetic parameters of **1g** were not so accurate as those of other quinones.

singlet (^{S1}TQ) and triplet (^{T1}TQ) states of the quinones.

As previously reported,[8] increase of electron-donating power of the neighboring aromatic rings enlarges the CT character of ^{S1}TQ, especially in polar solvents. This substituent effect on the $\Phi_{i.s.c.}$ values in acetonitrile (Table 4) can be explained by increase of the CT character, therefore, decrease of the n-π^* character, of ^{S1}TQ. Similarly to the singlet state, the CT character of ^{T1}TQ may increase in the order of electron-donating power of the substituents in **1a**, **b**, and **d**, resulting in decrease of the n-π^* character of ^{T1}TQ to give the low k_r values. Further, the k_r values of the respective quinones were larger in acetonitrile than in benzene. This solvent dependency of the k_r values suggests great contribution of a polar transition state in the reaction with **2**, that is, the exciplex of the triplet excited quinone and **2**. The electron-donating substituents could enlarge electron density in the benzoquinone moiety, resulting in suppression of the formation of the exciplex with the electron-rich hydrogen donor **2**. The large k_r values of **1e** suggest that a naphthalene ring may accelerate such exciplex formation.

The small τ values of the lowest excited triplet state of the quinones having electron-donating substituents, determined by Stern-Volmer plot analysis, can be explained by assuming that the lifetimes of the CT triplet states of triptycenequinones are shorter than those of the n-π^* triplet states, whereas the lifetimes of the CT triplet states of substituted benzophenones, determined by phosphorescence measurement, are longer than those of the n-π^* triplet states.[25]

In benzene, the $\Phi_{i.s.c.}$ and τ values of substituted triptycenequinones (**1a**, **b**, and **d**) were almost identical (Table 4). Since CT levels are higher and n-π^* excited levels are lower in non-polar solvents than in polar solvents, the CT characters of ^{S1}TQ and ^{T1}TQ may decrease in benzene. As a result, the $\Phi_{i.s.c.}$ and τ values would not be affected by the electron-donating power of aromatic rings. The τ value of **1e** with a naphthalene ring, was about twice and that of **1g**, without an aromatic ring, was about one-tenth of those of other triptycenequinones in benzene (Table 4). Therefore, the τ values in benzene seem to depend on somewhat the number of neighboring π electrons (**1e**>**1a**=**1b**=**1d**>**1g**). This can be explained in terms of increasing π-π^* character of ^{T1}TQ. That is, since increase of neighboring π electrons may cause increase of the π-π^* character of ^{T1}TQ and the lifetime of the π-π^* triplet state is reported to be much longer than that of the n-π^* triplet state,[26,27] the τ values of **1e** would be larger and that of **1g** would be smaller than others.

In the case of non-aromatic derivative **1g**, since the lowest excited singlet and triplet states may be n-π^* both in benzene and in acetonitrile, the $\Phi_{i.s.c.}$ and τ values of **1g** showed weaker solvent dependency than those of other quinones.

The CT quenching described above is hard to explain in terms of the energy transfer from the neighboring π-electron systems to benzoquinone moiety, because the triplet energy of the neighboring aromatic ring (benzene, E_T=353.2 kJ mol^{-1}; naphthalene, 255.2)[21] may be too high to quench the triplet excited triptycenequinones (E_T of **1a** is assumed to be about 216.2 kJ mol^{-1} as described in the previous section, and was estimated to be about 200 kJ mol^{-1} by the comparison of the quenching rate constant of **1a** with those of E_T-known compounds, using *trans*-stilbene as a quencher, data not shown).

In conclusion, intramolecular CT quenching may occur both in the singlet and triplet excited states of the triptycenequinone system. Such intramolecular CT interaction may also suppress the exciplex formation between triptycenequinones and an electron-rich hydrogen donor **2**.

Experimental

Apparatus for Measurements. Electronic spectra were taken with a Shimadzu UV-200 spectrometer. ^{1}H NMR and CIDNP spectra were taken with a JEOL PS-100 MHz spectrometer in suitable solvents using TMS as an internal standard. IR spectra were recorded on a JASCO IR-G spectrometer using a KBr disc.

Quinones. **1a—g** were synthesized according to the previous report.[8] **Deuterated Compounds.** 2,3-d_2-Derivative of **1a** was synthesized by Diels-Alder reaction of 1,4-benzoquinone-2,3,5,6-d_4 with anthracene and subsequent oxidation in the same manner as described previously.[8] Xanthene-9,9-d_2 was obtained by the reduction of xanthone (**6**) with $LiAlD_4$.

Photoreductions of the Quinones with 2 on a Large Scale. Deaeration of a reaction solution was undertaken by means of pump-freeze-thaw cycles using a vacuum line covered with black sheets. A degassed solution in a usual glass tube was irradiated with a 300 W high pressure Hg-arc lamp through a water layer 5 cm thick at room temperature, with or without suitable filters. The products, except precipitated hydroquinones, were isolated by column chromatography or by preparative thin-layer chromatography on silica gel. The structure of the hydroquinones were identified after acetylation by comparison of their spectra and melting points with the authentic diacetates. The structure of 9,9'-bixanthenyl was determined by comparison of its spectra and melting point with the authentic sample. Physical properties of the adduct **4a** were as follows. ^{1}H NMR ($CDCl_3$): δ=3.06 (d, J=4 Hz, 2H), 4,21 (d, J=4 Hz, 2H), 5.46 (brs and m like d, 4H), 5.82 (m like d, 2H), 6.5—7.5 (m, 20H). IR (KBr): ν_{CO}=1663 cm^{-1}, $\nu_{C=C-O-C}$=1607, 1578, 1480, 1460, 1240. UV(ethyl acetate): λ_{max}=437 nm (sh, ε=300), 408 (sh, 660), 389 (sh, 920), 341 (1670), 274 (sh, 6800), 265 (sh, 7100). MS m/z=647 (M^+), 646, 466 (M−**X**an), 465, 464, 463, 285 (M−2Xan), 284, 182 (**X**an+1). Molecular weight measured by vapor pressure method; 638±26 (calcd. 646.8). Found: C, 85.21; H, 4.82%. Calcd for $C_{46}H_{30}O_4$: C, 85.43; H, 4.68%. Physical properties of the adduct **4e** were as follows. Mp >195 °C (decomp), 268 °C (melt). ^{1}H NMR ($CDCl_3$):

δ=3.04 (d, J=4 Hz, 2H), 4.13 (d, J=4 Hz, 1H), 4.17 (d, J=4 Hz, 2H), 4.52—4.80 (m, 2H), 5.26—5.50 (m, 2H), 5.45 (s, 2H), 5.65—5.89 (m, 2H), 6.2—7.8 (m, 1H). IR (KBr): ν_{CO}=1660 cm^{-1}, $\nu_{C=C-O-C}$=1605, 1575, 1477, 1458, 1245. MS m/z=515 (M−Xan), 334 (M−2Xan), 181 (Xan). Found: C, 85.91; H, 4.50%. Calcd for $C_{50}H_{32}O_4$: C, 86.19; H, 4.63%.

Quantum Yield Measurement. The $\Phi_{disap.}$ values were measured directly by means of iron(III) oxalate actinometry or indirectly with a merry-go-round as relative quantum yields to a standard solution. A reaction solution in a glass ample was degassed by means of pump-freeze-thaw cycles as described in the previous paragraph and was irradiated at room temperature with the 450 nm monochromatic light (using a 300 W high pressure Hg lamp with one Toshiba KL-45 and two VY-42 filters). A glass ample equipped with a 4 ml cuvette for irradiation and electronic spectra measurements was used in absolute $\Phi_{disap.}$ measurements. The disappearance of quinones was monitored with their visible absorption at more than three points of wavelength. High pressure liquid chromatography (column, μ-porasil Waters; eluent, CH_2Cl_2) was adopted in the case of **1g**.

Stern-Volmer Plot. In the absence of anthracene, the concentration of **2** ([**2**]) was set at several points from 1×10^{-2} to 2×10^{-1} mol dm^{-3} and that of the quinones ([quinone]) were 4×10^{-2} (**1a** in benzene), 3×10^{-3} (**1a** in acetonitrile), 5×10^{-3} (**1b** in both solvents), 3×10^{-3} (**1d** in both solvents), 3×10^{-3} (**1e** in both solvents), 3×10^{-2} mol dm^{-3} (**1g** in both solvents).

In quenching experiments, the concentration of anthracene was set at several suitable points from 0 to 2×10^{-2} mol dm^{-3}. [**2**] was 2×10^{-2} (**1d** in acetonitrile), 5×10^{-2} (**1g** in both solvents), 6.7×10^{-2} mol dm^{-3} (other cases). [Quinone]'s were almost the same as in the anthracene-free experiments.

In all experiments, good straight lines were obtained in the plots of $\Phi_{disap.}$ vs. $[\mathbf{2}]^{-1}$ or vs. [quencher].

The author wishes to express his grateful thanks to Professor Kazuhiro Maruyama for his guidance and invaluable discussions in this work. The author is grateful to Dr. Yasuo Kubo for his helpful suggestions. Thanks are also due to Dr. Tetsuo Otsuki, Dr. Yoshinori Naruta, and Dr. Tatsuhisa Kato for fruitful discussion.

(Received April 21, 1989)

A variety of benzylated 1-OH derivatives, having an acetyl or an allyl group, of D-glucose, D-galactose, D-mannose, D-xylose, L-arabinose, L-fucose, and L-rhamnose, were synthesized from the corresponding protected 2-methoxyethyl glycosides through a brief treatment with $TiCl_4$ in dichloromethane and a subsequent hydrolysis of the intermediary 1-Cl derivatives on a silica-gel column.

Benzyl derivatives of aldose, whose reducing OH group is unprotected, are useful as a precursor of activated glycosyl donors in glycoside synthesis.[1] Under certain conditions,[2] such 1-OH derivatives can perform cross-condensation with alcohols as acceptors to give the corresponding glycosides. Several kinds of protecting groups for the reducing OH group have been proposed for the synthesis of 1-OH derivatives.[3] This report describes the 2-methoxyethyl (ME) group as a novel protecting group for the reducing OH group of aldose (Figs. 1 and 2).

Regeneration of the Reducing OH Group of the Protected 2-Methoxyethyl Glycosides. The isolation of a significant amount (22%) of the 1-OH derivative **4** in a study of rapid (4 s at room temp) anomerization of 2-benzyloxyethyl 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranoside with $TiCl_4$ in CH_2Cl_2 indicated that such a reaction could be useful in preparing **4** and similar compounds.[4] Later, a facile conversion of the glucoside **3** into the chloride **5** was observed upon its treatment with $TlCl_4$ in CH_2Cl_2 for 5 min at room temp.[5] The reaction mixture containing **5**, thus obtained, was adsorbed on a silica-gel column and eluted afterwards to give the hydrolyzate **4**.[5] The treatment of **3** with a slightly reduced amount (0.7 equiv) of $TiCl_4$ for 5 min at room temp was best for removing the ME group; **4** was obtained in a 66% yield. A longer reaction time and a larger quantity of the reagent diminished the yield of **4**, due to a concurrent formation of debenzylation products. A similar treatment of the α-anomer **8** with 1,2-cis disposition also afforded **4**, but required more reagent (1.0 equiv) to remove the ME group; thus the yield of **4** was low (41%). This procedure was then applied to the other 1,2-trans aldoside derivatives, **35**, **72**, **103**, **127**, **154**, and **181**, to produce the corresponding 1-OH derivatives, **36**, **73**, **104**, **128**, **155**, and **182**, in moderate yields.

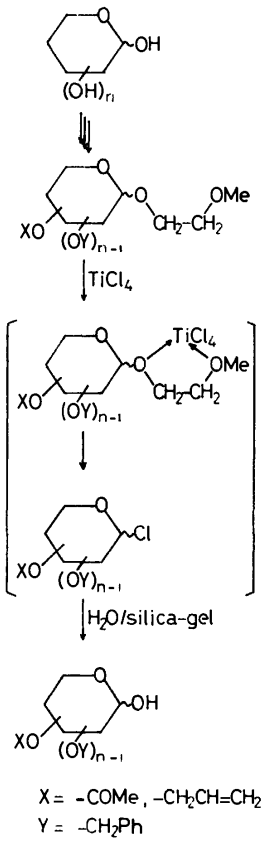

Fig. 1. General scheme.

The benzylated ME glycosides having one acetyl group, **10**, **16**, **23**, **28**, **38**, **49**, **59**, **66**, **75**, **80**, **81**, **98**, **106**, **119**, **129**, **141**, **145**, **156**, **168**, **172**, **183**, **191**, and **200**, and those having one allyl group, **13**, **18**, **25**, **30**, **41**, **51**, **61**, **68**, **78**, **84**, **95**, **100**, **109**, **112**, **121**, **132**, **143**, **147**, **159**, **170**, **174**, **186**, **193**, and **197**, were also converted into the corresponding 1-OH derivatives. The syntheses of the particular 1-OH derivatives, 3-*O*-acetyl-2,4-di-*O*-benzyl-D-xylopyranose[6] and 3-*O*-acetyl-2,4-di-*O*-benzyl-6-deoxy-D-glucopyranose,[7] have been reported before. They may be useful synthones for a linear portion of various oligosaccharides.

Preparation of Protected 2-Methoxyethyl Glycosides. The starting acetylated ME glycoside **33**, the precursor of **35** and **43**, was conveniently prepared from D-galactose (**32**) via a through-process of acetobromination with AcBr in AcOH[8] and a subsequent condensation with 2-methoxyethanol (MEOH) over Ag_2CO_3; the furanoside **34** was separated during chromatography. The fucoside acetate **152** was similarly synthesized from L-fucose (**151**) but L-arabinose (**123**) formed the furanoside **125** seriously;

the pyranoside **124** was eventually synthesized from the acetate **126**[9] via a convenient bromination using AcBr and H_2O in $CHCl_3$.[10] Methanolysis of the acetates **33**, **124**, and **152** afforded the starting ME glycosides, **43**, **134**, and **161**, respectively. The mannoside **71**, on the other hand, was prepared by a direct condensation of D-mannose (**70**) and MEOH in the presence of $MeSO_3H$. The rhamnoside **179** was similarly obtained.

The 2-acetate **10** prepared from the acetate **9** via a rearrangement of a benzylated orthoester[11] was converted into the 2-*O*-allyl ether **13** through deacetylation and allylation. Such a process was used for obtaining the other 2-acetates, **38**, **75**, **106**, **129**, **156**, and **183**, and the corresponding 2-*O*-allyl ethers, **41**, **78**, **109**, **132**, **159**, and **186**. In the case of **151** and **178**, peracetylation prior to the bromination as in the cases of the hexoses could be omitted, both were directly

transformed into the 2-acetates, **156** and **183**, respectively.

Kinetic benzylation of the diol **20**[7] mainly gave the 4-OH compound **21**, the precursor **23** and **25**. A similar method was appled to the diols, **57** and **91**, obtained from the acetals, **53** and **86**, for preparing the 4-OH derivatives, **48** and **92**, which were then changed into the corresponding acetates, **59** and **81**, and the allyl ehers, **61** and **95**.

The 6-OH compound **22** obtained through conventional tritylation of the glucoside **7**[12] was derived into the acetate **28** and the allyl ether **30**. A similar process was applied to **43** and **71** to synthesize the other 6-OH

compounds **58** and **93**, and their derivatives, **66**, **68**, **98**, and **100**.

The diol **46** obtained through isopropylidenation of **43** was selectively benzylated with $PhCH_2Cl$ and KOH in 1,2-dimethoxyethane (DME) to furnish the 3-OH derivative **47**, the precursor of **49** and **51**. Such mild benzylation was useful in the monobenzylation of the diols, **138**, **165**, and **202**, which were derived from the corresponding acetals, **136**, **163**, and **195**, to give **139**, **166**, and **190**, respectively. A similar reaction using allyl bromide instead of $PhCH_2Cl$ worked well in the synthesis of the monoallyl ethers, **63**, **149**, **176**, and **203**, from the correspoinding diols, **46**, **138**, **165**, and **202**. This kinetic allylation was usefully applied to the acetals, **53** and **86**, to synthesize the monoallyl ethers, **54** and **88**, the precursors of **51** and **84**, respectively. The kinetic benzylation using $PhCH_2Cl$ and LiOH[13] for the diols, **138** and **165**, mainly afforded the 4-OH derivatives, **140** and **167**, respectively.

A controlled reaction of the acetate **2** with $PhCH_2Cl$ in the presence of a limited amount of NaOH mainly gave the 3-OH compound **15** (ca. 40%), the precursor of **16** and **18**. A similar reaction of the acetate **33**, but using DME as diluent, afforded the 2-OH derivative **40** (ca. 25%) as the main product. A kinetic benzylation of **71** with $PhCH_2Cl$ and KOH, followed by acetylation and chromatography, mainly furnished the 3-acetate **80** (35%), whereas the use of LiOH instead of KOH brought forth a preferential formation of the 4-acetate **81** (25%).[11]

Tritylation[14] of the xyloside **114** mainly gave the 4-*O*-trityl ether **115** (25%), the precursor of the 4-OH compound **118**, whereas the rhamnoside **179** formed the 3-*O*-substituted glycoside **188** (51%), the precursor of the 3-OH derivative **190**.

The 4-*O*-acetyl derivative **200** was prepared throgh deallylation and reacetylation of the 4-*O*-allyl ether **197**, which was readily obtained from the acetal **195**. The acetals, **136** and **163**, provided alternative routes to the 2-*O*-allyl derivatives, **132** and **159**, respectively.

All the structures of the derivatives of the ME glycosides are to be evident, since the ^1H NMR spectra of the monoacetates were consistently assigned; every proton on the carbon bearing OAc group definitely deshielded (Tables 1 and 2).

Thus, the ME group is considered to be an alternative choice for the protection of the hemiacetal OH group of aldose.[3] In the preparation of various derivarives of the ME glycosides, several kinetic substitutions of the polyols[15] (Fig. 3) were usefully carried out. The ME glycoside derivatives in which one OH group remains unprotected might be of use as

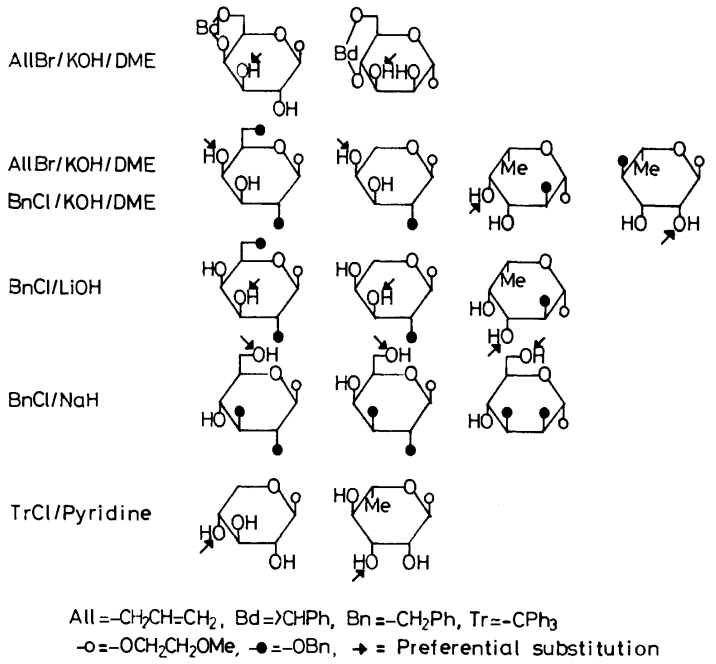

Fig. 3. Kinetic substitution of polyols.

acceptors in oligosaccharide synthesis.

Experimental

The ^{1}H NMR spectra were measured with a Varian VXR-300 spectrometer. The optical rotations were measured at room temp (20—25 °C). The other items were described previously.[16]

The aldoses used were the products of Wako Pure Chemicals Industries, Ltd., whereas the hexose acetates, **9**, **37**, and **74**, were available from Kyowa Pure Chemicals Industries, Ltd.

Synthesis of 1-OH Derivatives. To a stirring solution of a well-dried, protected 2-methoxyethyl aldoside (0.1—2 mmol) in dry CH_2Cl_2 (10 ml mmol^{-1} of substrate) was added $TiCl_4$ (0.7 equiv) at room temp to give a colored (pale yellow to reddish brown) solution. After 5 min, iced H_2O and then toluene were added to the solution. The organic layer was washed well with H_2O and dried over Na_2SO_4 briefly. After evaporation, the residue was adsorbed on a column of silica gel (40 g/g of substrate). After standing overnight, the column was eluted with toluene–2-butanone (TB) system (gradient) to give the corresponding 1-OH derivative. Compounds **4**[17] (66% from **3** and 41% from **8** (1.0 equiv of $TiCl_4$)), **11**[10] (77%), **29**[18] (76%), **36**[17] (74%), **73**[17] (66%), **85**[11] (70%), **96**[11] (67%), and **113**[6] (70%) were identified with the respective compounds prepared before.

2-*O*-Allyl-3,4,6-tri-*O*-benzyl-D-glucopyranose (**14**). 70%, mp 136—137 °C (from diisopropyl ether (IPE)), $[\alpha]_D$ +25° (*c* 0.4, $CHCl_3$) (lit,[19] mp 137—139 °C, $[\alpha]_D$ +25.7° ($CHCl_3$)) (Found: C, 73.37; H, 7.00%).

3-*O*-Acetyl-2,4,6-tri-*O*-benzyl-D-glucopyranose (**17**). 60%, mp 124—126 °C (from IPE), $[\alpha]_D$ +42° (*c* 1.4, $CHCl_3$)

Anal. ($C_{23}H_{28}O_5$) C, H.

4-*O*-Acetyl-2,3-di-*O*-benzyl-L-rhamnopyranose (**201**). 85% $[\alpha]_D$ −13° (*c* 0.9, $CHCl_3$).

Anal. ($C_{22}H_{26}O_6$) C, H.

Formation of the Chloride 5. To a stirring solution of **3** (46 mg) in CH_2Cl_2 (0.77 ml) was added $TiCl_4$ (8.5 µl, 1.0 equiv) at room temp. After 5 min, iced H_2O and toluene were successively added and the organic layer was washed well with H_2O. After a brief treatmetnt with Na_2SO_4, the solution was concentrated up to give a sirup (43 mg) whose ^1H NMR spectrum measured in $CDCl_3$ showed a characteristic doublet of **5** at δ=6.09 ($J_{1,2}$=4 Hz, H-1). TLC indicated that the mixture contained **5** as the dominant product and slower-moving partially debenzylated products.

Synthesis of 2-Methoxyethyl Glycosides and Their Derivatives.

2-Methoxyethyl α-D-glucopyranoside (**6**). A mixture of **1** (200 mg), MEOH (2 ml), and $MeSO_3H$ (200 µl) was heated at 100 °C for 6 h. After neutralizaton with $NaHCO_3$ (0.40 g) and concentration, chromatography with $CHCl_3$-MeOH (CM) system (gradient) gave, after the elution of **7** (14 mg, 5%), **6** (217 mg, 82%), $[\alpha]_D$ +108° (*c* 1.2, H_2O)(lit,[31] $[\alpha]_D$ +94° (H_2O), ^1H NMR (D_2O) δ=3.30 (s, OMe), 3.43 (dd, $J_{1,2}$=4 Hz, $J_{2,3}$=10 Hz, H-2), 4.82 (d, H-1) (Found: C, 45.20; H, 7.82%).

2-Methoxyethyl α-D-Mannopyranoside (**71**). A similar reaction of **70** (10 g) and MEOH (100 ml) containing $MeSO_3H$ (3.0 ml) for 2 h at 100 °C, followed by processing and chromatography (CM system), gave **71** (10.8 g, 82%), $[\alpha]_D$ +29° (*c* 1.4, H_2O), ^1H NMR (D_2O) δ=3.31 (s, OMe), 3.88 (dd, 1H, $J_{1,2}$=1.5 Hz, $J_{2,3}$=3.5 Hz, H-2), 4.80 (d, H-1).

Found: C, 44.76; H, 7.56%. Calcd for $C_9H_{18}O_7$: C, 45.37; H, 7.62%.

2-Methoxyethyl α- and β-L-Rhamnopyranosides (**179** and **180**). A reaction of **178** (monohydrate, 10 g) with MEOH (40 ml) in the presence of H_2SO_4 (0.1 ml) for 3.5 h at 80 °C, followoed by processing and chromatography (CM system), afforded **180** (1.5 g, 12%), $[\alpha]_D$ +29° (*c* 0.3, H_2O), ^1H NMR (D_2O) δ=1.23 (d, $J_{5,6}$=6 Hz, H-6), 3.31 (s, OMe), 3.89 (dd, $J_{2,3}$=3 Hz, $J_{3,4}$=8 Hz, H-3), 3.93 (d, $J_{1,2}$=0 Hz, H-2), 4.58 (s, H-1), and then **179** (7.6 g, 62%), $[\alpha]_D$ −28° (*c* 1.2, H_2O), ^1H NMR (D_2O) δ=1.21 (d, $J_{5,6}$=6.5 Hz, H-6), 3.31 (S, OMe), 3.35 (t, $J_{3,4}$=$J_{4,5}$=10 Hz, H-4), 3.69 (dd, $J_{2,3}$=3.5 Hz, H-3), 3.88 (dd, $J_{1,2}$=1.5 Hz, H-2), 4.72 (d, H-1).

Anal. ($C_9H_{18}O_6$) **179**, C, H. **180**, C, H.

2-Methoxyethyl 2,3,4,6-Tetra-*O*-acetyl-β-D-galactopyranoside (**33**) and 2,3,5,6-Tetra-*O*-acetyl-β-D-galactofuranoside (**34**). To a cold mixture of AcBr (17 ml) and AcOH (11 ml) was added **32** (3.0 g); the suspension was then stirred at 25 °C for 1.5 h. After evaporation and co-evaporation with toluene, the residue was dissolved in cold MEOH (18 ml) and powdery Ag_2CO_3 (7.5 g) was added to the stirring solution. The suspension was stirred in the dark at room temp overnight. After filtration and concentration, the residue was chromatographed (TB system) to afford **34** (0.41 g, 6%), $[\alpha]_D$ −31° (*c* 3.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=2.03, 2.05, 2.07, 2.10 (4s, OAc), 3.35 (s, OMe), 4.18 (dd, $J_{5,6b}$=7 Hz, $J_{6a,6b}$=12 Hz, H-6b), 4.25 (dd, $J_{3,4}$=6 Hz, $J_{4,5}$=3.5 Hz, H-4), 4.32 (dd, $J_{5,6a}$=4.5 Hz, H-6a), 4.97 ($J_{2,3}$=2 Hz, H-3), 5.05 (d, $J_{1,2}$=1 Hz, H-1), 5.07 (dd, H-2), 5.34 (m, H-5), and then **33** (3.61 g, 53%), $[\alpha]_D$ −13° (*c* 4.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.97, 2.04, 2.05, 2.14 (4s, OAc), 3.35 (s, OMe), 4.55 (d, $J_{1,2}$=8 Hz, H-1), 5.01 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=3.5 Hz, H-3), 5.21 (dd, H-2), 5.37 (dd, $J_{4,5}$=1 Hz, H-4).

Found: **33**, C, 50.12; H, 6.52%. **34**, C, 49.75; H, 6.38%. Calcd for $C_{17}H_{26}O_{11}$: C, 50.24; H, 6.45%.

2-Methoxyethyl 2,3,4-Tri-*O*-acetyl-β-L-fucopyranoside (**152**) and 2,3,5-Tri-*O*-acetyl-β-L-fucofuranoside (**153**). To chilled AcBr (4 ml) was added **151** (1 g) and the mixture was stirred for 1 h at 25 °C. After evaporation and co-evaporation with toluene, the bromide was then treated with MEOH (5.5 ml) and Ag_2CO_3 (2.7 g). Processing and chromatography (TB system) furnished **153** (0.20 g, 9%), $[\alpha]_D$ +21° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.30 (d, $J_{5,6}$=6.5 Hz, H-6), 2.07, 2.08, 2.09 (3s, OAc), 3.38 (s, OMe), 4.11 (dd, $J_{3,4}$=6.5 Hz, $J_{4,5}$=4 Hz, H-4), 4.99 (dd, $J_{2,3}$=2 Hz, H-3), 5.07 (d, $J_{1,2}$=1 Hz, H-1), 5.09 (dd, H-2), 5.14 (m, H-5), and then **152** (1.59 g, 75%), $[\alpha]_D$ −12° (*c* 2.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.20 (d, $J_{5,6}$=6.5 Hz, H-6), 1.96, 2.04, 2.15 (3s, OAc), 3.34 (s, OMe), 3.79 (m, $J_{4,5}$=1 Hz, H-5), 4.51 (d, $J_{1,2}$=8 Hz, H-1), 5.00 (dd, $J_{2,3}$=11.5

Hz, $J_{3,4}$=4 Hz, H-3), 5.18 (dd, H-2), 5.21 (dd, H-4).

Anal. ($C_{15}H_{24}O_9$) **152**, C, H. **153**, C. H.

2-Methoxyethyl 2,3,4-Tri-*O*-acetyl-α-L-arabinopyranoside (**124**). To a stirring solution of **126**[9] (0.49 g) in $CHCl_3$ (1.5 ml) was added AcBr (0.61 ml) and then H_2O (0.12 ml) at 0 °C. The mixture was stirred for 0.5 h at room temp. After evaporation and co-evaporation with toluene, the bromide was treated with MEOH (1.5 ml) containing Ag_2CO_3 (0.70 g) overnight, followed by chromatoraphy (TB system) to yield **124** (0.40 g, 78%), $[\alpha]_D$ −21° (*c* 2.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=2.01, 2.04, 2.09 (3s, OAc), 3.34 (s, OMe), 3.61 (dd, $J_{4,5b}$=2 Hz, $J_{5a,5b}$=13.5 Hz, H-5b), 4.01 (dd, $J_{4,5a}$=4 Hz, H-5a), 4.48 (d, $J_{1,2}$=7 Hz, H-1), 5.02 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=4 Hz, H-3), 5.18 (dd, H-2), 5.23 (t, H-4).

Anal. ($C_{14}H_{22}O_9$) C, H.

Attempt to prepare **124** directly from **123** (1.0 g) through the procedure described for **152** provided 2-methoxyethyl 2,3,5-tri-*O*-acetyl-α-L-arabinofuranoside (**125**) (0.74 g, 33%), $[\alpha]_D$ −41° (*c* 4.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=2.07 (s, 9H, OAc), 3.36 (s, OMe), 4.19 (dd, $J_{4,5b}$=5.5 Hz, $J_{5a,5b}$=10.5 Hz, H-5b), 4.24 (m, $J_{3,4}$=5 Hz, $J_{4,5a}$=2.5 Hz, H-4), 4.40 (dd, H-5a), 4.95 (dd, $J_{2,3}$=1.5 Hz, H-3), 5.06 (d, $J_{1,2}$=0 Hz H-1), 5.11 (d, H-2) (Found: C, 49.97; H, 6.66%) and then **124** (0.79 g, 35%).

2-Methoxyethyl β-D-galactopyranoside (**43**) and β-D-galactofuranoside (**44**). A filtrate obtained after removing the silver salts described for **33**, starting from **32** (3.0 g), was concentrated and redissolved in MeOH (40 ml). The solution was treated with dil NaOMe (7%, 4 ml) overnight. After neutralizatin with AcOH, evaporation and chromatography (CM system) delivered **44** (0.80 g, 12%), $[\alpha]_D$ −41° (*c* 1.4, H_2O), ^1H NMR (D_2O) δ=3.32 (s, OMe), 4.94 (d, $J_{1,2}$=2 Hz, H-1), and then **43** (3.83 g, 58%), $[\alpha]_D$ +4° (*c* 2.1, H_2O) (lit,[32] $[\alpha]_D$ +8.4° (H_2O)), ^1H NMR (D_2O) δ=3.30 (s, OMe), 3.35 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.43 (dd, $J_{1,2}$=8 Hz, H-1), 3.82 (d, $J_{4,5}$=0 Hz, H-4), 4.32 (d, H-1).

Found: **43**, C, 42.16; H, 7.55%. **44**, C, 42.19; H, 7.44%. Calcd for $C_9H_{18}O_7 \cdot H_2O$: C, 42.18; H, 7.87%.

2-Methoxyethyl β-L-Fucopyranoside (**161**) and β-L-Fucofuranoside (**162**). A similar deacetylation of a reaction mixture obtained from **151** (5 g) as described for **152**, followed by chromatography (CM system), produced **162** (0.63 g, 9%), $[\alpha]_D$ +63° (*c* 1.0, H_2O), ^1H NMR (D_2O) δ=1.17 (d, $J_{5,6}$=6.5 Hz, H-6), 3.31 (s, OMe), 4.00 (dd, $J_{1,2}$=1.5 Hz, $J_{2,3}$=3 Hz, H-2), 4.93 (d, H-1), and then **161** (5.64 g, 83%), $[\alpha]_D$ +1.2° (*c* 2.2, H_2O), ^1H NMR (D_2O) δ=1.18 (d, $J_{5,6}$=6.5 Hz, H-6), 3.32 (s, OMe), 3.41 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=10.5 Hz, H-2), 3.56 (dd, $J_{3,4}$=4 Hz, H-3), 4.31 (d, H-1).

Anal. ($C_9H_{18}O_6$) **161**, C, H. **162**, C, H.

2-Methoxyethyl α-L-Arabinopyranoside (**134**). Similarly, a reaction mixture obtained from **126** (1.0 g), followed by chromatography (CM system), gave forth **134** (0.57 g, 87%), $[\alpha]_D$ −8° (*c* 3.8, H_2O), ^1H NMR (D_2O) δ=3.32 (s, OMe), 3.48 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=10 Hz, H-2), 3.84 (dd, $J_{4,5eq}$=2 Hz, $J_{5eq,5ax}$=12 Hz, H-5eq), 4.28 (d, H-1).

Anal. ($C_8H_{16}O_6$) C, H.

An attempt to obtain **134** directly from **123** (12 g) via acetobromination with AcBr (48 ml), 2-methoxyethylation with MEOH (72 ml) and Ag_2CO_2 (36 g), and deacetylation followed by chromatography (CM system), afforded 2-methoxyethyl α-L-arabinofuranoside (**135**) (5.96 g, 36%), $[\alpha]_D$ −39° (*c* 1.2, H_2O), ^1H NMR (D_2O) δ=3.31 (s, OMe), 3.86 (dd, $J_{2,3}$=4 Hz, $J_{3,4}$=6.5 Hz, H-3), 4.02 (dd, $J_{1,2}$=1.5 Hz, H-2), 4.95 (d, H-1) (Found: C, 46.20; H 7.82%), and then **134** (6.4 g, 38%).

2-Methoxyethyl β-D-Xylopyranoside (**114**). Deacetylation of **102**[6] (1.00 g) with dil NaOMe (0.6%), followed by chromatography (CM system), furnished **114** (0.55 g, 88%), $[\alpha]_D$ −45° (*c* 1.8, H_2O) (lit,[33] $[\alpha]_D$ −50.4° (MeOH)), ^1H NMR (D_2O) δ=3.20 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9 Hz, H-2), 3.23 (dd, $J_{4,5ax}$=9.5 Hz, $J_{5eq,5ax}$=12 Hz, H-5ax), 3.31 (s, OMe), 3.36 (t, $J_{3,4}$=9 Hz, H-3), 3.54 (m, $J_{4,5eq}$=5 Hz, H-4), 3.88 (dd, H-5eq), 4.14 (d, H-1)(Found: C, 45.65; H, 7.86%).

2-Methoxyethyl 2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranoside (**8**). A mixture of **6** (77 mg), powdered KOH (0.51 g, 7 equiv of OH) and $PhCH_2Cl$ (2.0 ml) was stirred for 2 h at 120 °C, followed by usual processing and chromatography with hexane-ethyl acetate (HE) system (gradient), to yield **8** (170 mg, 88%), $[\alpha]_D$ +23° (*c* 2.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 4.82 (d, $J_{1,2}$=4 Hz, H-1).

Anal. ($C_{37}H_{42}O_7$) C, H.

Similar benzylations of **71** and **179** furnished **72** (86%) and **181** (70%), respectively.

2-Methoxyethyl 2,3,4,6-Tetra-*O*-benzyl-α-D-mannopyranoside (**72**). $[\alpha]_D$ +25° (*c* 1.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.34 (s, OMe), 3.89 (dd, $J_{1,2}$=2 Hz, $J_{2,3}$=2.5 Hz, H-2), 3.94 (dd, $J_{3,4}$=9.5 Hz, H-3), 4.00 (t, $J_{4,5}$=9.5 Hz, H-4), 4.94 (d, H-1).

Anal. ($C_{37}H_{42}O_7$) C, H.

2-Methoxyethyl 2,3,4-Tri-*O*-benzyl-α-L-rhamnopyranoside (**181**). $[\alpha]_D$ −30° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.35 (d, $J_{5,6}$=6 Hz, H-6), 3.35 (s, OMe), 3.99 (s, $J_{1,2}$=$J_{2,3}$=0 Hz, H-2), 4.82 (s, H-1).

Found: C, 72.81; H, 7.36%. Calcd for $C_{30}H_{36}O_6$: C, 73.15; H, 7.37%.

2-Methoxyethyl 2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranoside (**3**). A mixture of **2**[12] (100 mg), crushed KOH (386 mg, 7 equiv OAc), and $PhCH_2Cl$ (1.5 ml) was stirred for 2 h at 120 °C, followed by processing and chromatogrphy (HE system), to yield **3** (86 mg, 58%), mp 68—70 °C, $[\alpha]_D$ +7° (*c* 1.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.42 (s, OMe), 4.49 (d, $J_{1,2}$=7.5 Hz, H-1).

Anal. ($C_{37}H_{42}O_7$) C, H.

Similar reactions of **33**, **102**,[6] **124**, and **152**, afforded **35** (41%), **103** (78%), **127** (82%), and **154** (80%), respectively.

2-Methoxyethyl 2,3,4,6-Tetra-*O*-benzyl-β-D-galactopyranoside (**35**). $[\alpha]_D$ −6° (*c* 1.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.52 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.84 (dd, $J_{1,2}$=8 Hz, H-2), 3.89 (d, $J_{4,5}$=0 Hz, H-4), 4.40 (d, H-1).

Found: C, 73.67; H, 7.05%. Calcd for $C_{37}H_{42}O_7$: C, 74.22; H, 7.07%.

2-Methoxyethyl 2,3,4-Tri-*O*-benzyl-β-D-xylopyranoside (**103**). $[\alpha]_D$ +10° (*c* 1.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.21 (dd, $J_{4,5ax}$=10 Hz, $J_{5aq,5ax}$=11.5 Hz, H-5ax), 3.39 (s, OMe), 3.41 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9.5 Hz, H-2), 3.58 (t, $J_{3,4}$=9.5 Hz, H-3), 3.94 (dd, $J_{4,5eq}$=4.5 Hz, H-5eq), 4.39 (d, H-1).

Found: C, 72.38; H, 4.39%. Calcd for $C_{29}H_{34}O_6$: C, 72.78; H, 7.16%.

2-Methoxyethyl 2,3,4-Tri-*O*-benzyl-α-L-arabinopyranoside (**127**). $[\alpha]_D$ +6° (*c* 1.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.27 (dd, $J_{4,5ax}$=1.5 Hz, $J_{5eq,5ax}$=13 Hz, H-5ax), 3.39 (s, OMe), 3.52 (dd, $J_{2,3}$=9 Hz, $J_{3,4}$=4 Hz, H-3), 3.84 (dd, $J_{1,2}$=7.5 Hz, H-2), 4.04 (dd, $J_{4,5eq}$=3 Hz, H-5eq), 4.37 (d, H-1).

Anal. ($C_{29}H_{34}O_6$) C, H.

2-Methoxyetheyl 2,3,4-Tri-*O*-benzyl-β-L-fucopyranoside (**154**). $[\alpha]_D$ +7° (*c* 1.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.19 (d,

$J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 3.46 (m, $J_{4,5}$=1 Hz, H-5), 3.52 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=2.5 Hz, H-3), 3.83 (dd, $J_{1,2}$=7.5 Hz, H-2), 4.38 (d, H-1).

Found: C, 72.57; H, 7.36%. Cacld for $C_{30}H_{36}O_6$: C, 73.15; H, 7.37%.

2-Methoxyethyl 3,4-*O*-Isopropylidene-α-L-arabinopyranoside (**136**). To a stirring solution of **134** (2.70 g) in acetone containing 2,2-dimethoxypropane[34] (DMP, 2.5 ml) was added H_2SO_4 (10 μl) at room temp. After 6 h, the solution was treated with $NaHCO_3$ (0.35 g), concentrated, and chromatographed (TB system) to yield **136** (1.80 g, 56%), $[\alpha]_D$ +40° (*c* 2.2, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.34, 1.52 (2s, CMe_2), 3.37 (s, OMe), 3.63 (t, $J_{1,2}=J_{2,3}$=7.5 Hz, H-2), 4.06 (dd, $J_{3,4}$=6 Hz, H-3), 4.21 (d, H-1).

Found: C, 52.61; H, 8.19%. Calcd for $C_{11}H_{20}O_6$: C, 53.21; H, 8.12%.

Similar reactions of **161** and **179** afforded **163** (92%) and **195** (84%), respectively.

2-Methoxyethyl 3,4-*O*-Isopropylidene-β-L-fucopyranoside (**163**). $[\alpha]_D$ −30° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.35, 1.52 (2s, CMe_2), 1.41 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe) 3.55 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=7 Hz, H-2), 3.86 (m, $J_{4,5}$=2 Hz, H-5), 3.99 (dd, $J_{3,4}$=5 Hz, H-4), 4.04 (dd, H-3), 4.19 (d, H-1).

Found: C, 54.52; H, 8.41%. Calcd for $C_{12}H_{22}O_6$: C, 54.95; H, 8.45%.

2-Methoxyethyl 2,3-*O*-Isopropylidene-α-L-rhamnopyranoside (**195**). $[\alpha]_D$ −29° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.34, 1.51 (2s, CMe_2), 1.29 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 4.11 (t, $J_{2,3}=J_{3,4}$=6 Hz, H-3), 4.19 (d, $J_{1,2}$=0 Hz, H-2), 4.98 (s, H-1).

Anal. ($C_{12}H_{22}O_6$) C, H.

2-Methoxyethyl 3,4-*O*-Isopropylidene-β-D-galactopyranoside (**45**). To a stirring mixture of **43** (1.87 g), acetone (50 ml), DMP (7 ml) and *N*,*N*-dimethylformamide[35] (4 ml) was added H_2SO_4 (80 μl) at room temp; the mixture was then stirred for 4 h at a reflux temperature. After processing, chromatography (CM system) afforded **45** (1.21 g, 55%), $[\alpha]_D$ −16° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.33, 1.50 (2s, CMe_2), 3.38 (s, OMe), 3.56 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=7 Hz, H-2), 3.82 (dd, $J_{5,6b}$=4 Hz, $J_{6a,6b}$=11 Hz, H-6b), 3.86 (m, $J_{4,5}$=2 Hz, $J_{5,6a}$=6 Hz, H-5), 3.96 (dd, H-6a), 4.08 (dd, $J_{3,4}$=6 Hz, H-3), 4.14 (dd, H-4), 4.22 (d, H-1).

Found: C, 51.42; H, 8.06%. Calcd for $C_{12}H_{22}O_7$: C, 51.79; H, 7.97%.

2-Methoxyethyl 4,6-*O*-Benzylidene-β-D-galactopyranoside (**53**). A mixture of **43** (1.06 g), benzaldehyde (7 ml), and $ZnCl_2$ (0.3 g) was stirred overnight, followed by the usual processing and chromatography (CM system), to furnish **53** (1.03 g, 71%), mp 139—140 °C (from IPE), $[\alpha]_D$ −18° (*c* 0.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 3.43 (m, $J_{4,5}$=1 Hz, $J_{5,6eq}$=1.5 Hz, $J_{5,6ax}$=2 Hz, H-5), 3.78 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=10 Hz, H-2), 4.04 (dd, $J_{6eq,6ax}$=12.5 Hz, H-6ax), 4.16 (dd, $J_{3,4}$=4 Hz, H-4), 4.29 (dd, H-6eq), 4.32 (d, H-1), 5.52 (s, benzylidene).

Found: C, 59.51; H, 6.74%. Calcd for $C_{16}H_{21}O_7$: C, 59.07; H, 6.51%.

2-Methoxyethyl 4,6-*O*-Benzylidene-α-D-mannopyranoside (**86**). A solution of **71** (643 mg) in *N*,*N*-dimethylformamide (13 ml) containing benzaldehyde dimethyl acetal (0.53 ml) was treated with pyridinium tosylate[36] (13 mg) for 6.5 h at 80 °C. Processing and chromatography (CM system) provided **86** (314 mg, 36%), mp 93—95 °C, $[\alpha]_D$ +51° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.56 (s, OMe), 4.86 (d, $J_{1,2}$=1 Hz, H-1), 5.58 (s, benzylidene).

Found: C, 58.67; H, 6.77%. Calcd for $C_{16}HO_7$: C, 59.07; H, 6.51%.

After the elution of **86**, another acetal (46 mg, 5%) was obtained. That was acetylated with Ac_2O and pyridine, followed by chromatography (TB system), to yield 2-methoxyethyl 4,6-di-*O*-acetyl-2,3-*O*-benzylidene-α-D-mannopyranoside (**87**), mp 52—53 °C, $[\alpha]_D$ −28° (*c* 0.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=2.06, 2.09 (2s, OAc), 3.40 (s, OMe), 3.97 (m, $J_{4,5}$=10.5 Hz, $J_{5,6a}$=5.5 Hz, $J_{5,6b}$=2.5 Hz, H-5), 4.10 (dd, $J_{6a,6b}$=12 Hz, H-6b), 4.24 (dd, H-6a), 4.31 (dd, $J_{1,2}$=1 Hz, $J_{2,3}$=6.5 Hz, H-2), 4.42 (dd, $J_{3,4}$=7 Hz, H-3), 5.12 (dd, H-4), 5.23 (d, H-1), 5.90 (s, benzylidene) (Found: C, 58.60; H, 6.42%).

2-Methoxyethyl 6-*O*-Trityl-β-D-glucopyranoside (**27**). A mixture of **7**[12] (2.40 g), trityl chloride (7.72 g), and pyridine 12 ml) was stirred at 70 °C overnight. The processed mixture was chromatoraphed (CM system) to give forth **27** (2.53 g, 53%), mp 72—73°C (from IPE), $[\alpha]_D$ −32° (*c* 3.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.35 (s, OMe), 4.02 (m, $J_{4,5}$=11 Hz, $J_{5,6}$=3 and 5 Hz, H-5), 4.31 (d, $J_{1,2}$=8 Hz, H-1),

Anal. ($C_{28}H_{32}O_7$) C, H.

Similar tritylations of **43** and **71** afforded (**65**) (50%) and **97** (61%).

2-Methoxyethyl 6-*O*-Trityl-β-D-galactopyranoside (**65**). $[\alpha]_D$ −29° (*c* 3.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.32 (s, OMe), 3.65 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=10 Hz, H-2), 4.23 (d, H-1).

Anal. ($C_{28}H_{32}O_7$), C, H.

2-Methoxyethyl 6-*O*-Trityl-α-D-mannopyranoside (**97**). Mp 65—67 °C, $[\alpha]_D$ +11° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.94 (dd, $J_{1,2}$=1.5 Hz, $J_{2,3}$=3.5 Hz, H-2), 4.85 (d, H-1).

Found: C, 69.39; H, 6.55%. Calcd for $C_{28}H_{32}O_7$: C, 69.98; H, 6.71%.

2-Methoxyethyl 4-*O*-Trityl-β-D-xylopyranoside (**115**). A mixture of **114** (631 mg), trityl chloride (1.27 g), and pyridine (3 ml) was stirred at 70 °C overnight, followed by processing and chromatography (TB system), to give a mixture of the monotrityl ethers (301 mg) and then **115** (338 mg, 25%), mp 43—45 °C (from hexane containing IPE), $[\alpha]_D$ −58° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.32 (s, OMe), 4.66 (d, $J_{1,2}$=4 Hz, H-1).

Anal. ($C_{27}H_{30}O_6$) C, H.

The whole mixture (301 mg) of the faster-moving monotrityl ethers was acetylated with Ac_2O and pyridine, followed by chromatography (TB system), to yield 2-methoxyethyl 3,4-di-*O*-acetyl-2-*O*-trityl-β-D-xylopyranoside (**116**) (77 mg, 5% from **115**), $[\alpha]_D$ −5° (*c* 0.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.78, 2.11 (2s, OAc), 3.26 (s, OMe), 3.45 (dd, $J_{1,2}$=4.5 Hz, $J_{2,3}$=6.5 Hz, H-2), 3.45 (dd, $J_{4,5b}$=6.5 Hz, $J_{5a,5b}$=12.5 Hz, H-5b), 3.95 (dd, $J_{4,5a}$=4.5 Hz), 4.02 (d, H-1), 4.67 (dd, $J_{3,4}$=6.5 Hz, H-4), 5.25 (t, H-3) (Found: C, 69.62; H, 6.26%), and then 2-methoxyethyl-2,4-di-*O*-acetyl-3-*O*-trityl-β-D-xylopyranoside (**117**) (142 mg, 9%), mp 147—148 °C (from IPE), $[\alpha]_D$ −28° (*c* 1.2, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.63, 1.78 (2s, OAc), 3.14 (dd, $J_{4,5b}$=6.5 Hz, $J_{5a,5b}$=12 Hz, H-5b), 3.37 (s, OMe), 4.15 (dd, $J_{4,5a}$=4 Hz, H-5a), 4.34 (dd, $J_{1,2}$=5 Hz, H-1), 4.57 (dd, $J_{3,4}$=6.5 Hz, H-4), 4.87 (dd, $J_{2,3}$=7 Hz, H-2) (Found: C, 70.17; H, 6.42%).

2-Methoxyethyl 3-*O*-Trityl-α-L-rhamnopyranoside (**188**). A similar tritylation of **179** (0.88 g) with trityl chloride (2.2 g)

in pyridine (2.6 ml), followed by chromatography (TB system), produced **188** (0.93 g, 51%), mp 45—47 °C (from hexane containing IPE), $[\alpha]_D$ −48° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.26 (d, $J_{5,6}$=6.5 Hz, H-6), 3.31 (s, OMe), 3.07 (dd, $J_{1,2}$=2 Hz, $J_{2,3}$=3 Hz, H-2), 3.79 (dd, $J_{3,4}$=9 Hz, H-3), 4.57 (d, H-1).

Found: C, 72.87; H, 6.83%. Calcd for $C_{28}H_{32}O_6$: C, 72.39; H, 6.94%.

After the elution of **188**, there appeared another trityl ether (0.18 g, 10%), which was acetylated with Ac_2O and pyridine to furnish, after chromatography (TB system), 2-methoxyethyl 2,3-di-*O*-acetyl-4-*O*-trityl-α-L-rhamnopyranoside (**189**), $[\alpha]_D$ −84° (*c* 0.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.08 (d, $J_{5,6}$=6 Hz, H-6), 1.18, 1.88 (2s, OAc), 3.18 (t, $J_{3,4}=J_{4,5}$=10 Hz, H-4), 3.43 (s, OMe), 4.07 (m, H-5), 4.59 (d, $J_{1,2}$=2 Hz, H-1), 5.22 (dd, $J_{2,3}$=3.5 Hz, H-2), 5.28 (dd, H-3) (Found: C, 70.13; H, 6.74%).

2-Methoxyethyl 2,6-Di-*O*-benzyl-β-D-galactopyranoside (**46**). Amixture of **45** (1.20 g), crushed KOH (3.4 g), and $PhCH_2Cl$ (14 ml) was stirred for 2 h at 120 °C, cooled, and then diluted with toluene. After washing with H_2O thoroughly, the organic layer was concentrated under reduced pressure at 95 °C to give an oily product, which was successively heated in aq AcOH (80%, 20 ml) at 95 °C for 1 h. Concentration and chromatography (TB system) provided **46** (1.36 g, 75%), $[\alpha]_D$ +9° (*c* 3.5, $CHCl_3$), ^1H NMR ($CDCl_3$), δ=3.38 (s, OMe), 3.52 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9.5 Hz, H-2), 3.60 (dd, $J_{3,4}$=3 Hz, $J_{4,5}$=1 Hz, H-4), 3.99 (dd, H-3), 4.42 (d, H-1).

Anal. ($C_{23}H_{30}O_7$) C, H.

Compounds **53** and **86** were similarly transformed into **57** (84%) and **91** (87%), respectively.

2-Methoxyethyl 2,3-Di-*O*-benzyl-β-D-galactopyranoside (**57**). $[\alpha]_D$ −0.4° (*c* 2.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.45 (dd, $J_{4,5}$=0 Hz, $J_{5,6a}$=6 Hz, $J_{5,6b}$=5 Hz, H-5), 3.50 (dd, $J_{3,4}$=9 Hz, $J_{3,4}$=3.5 Hz, H-3), 3.68 (dd, $J_{1,2}$=8 Hz, H-2), 3.77 (dd, $J_{6a,6b}$=11.5 Hz, H-6b), 3.94 (dd, H-6a), 3.99 (d, H-4), 4.42 (d, H-1).

Anal. ($C_{23}H_{30}O_7$) C, H.

2-Methoxyethyl 2,3-Di-*O*-benzyl-α-D-mannopyranoside (**91**). $[\alpha]_D$ +22° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 3.74 (dd, $J_{2,3}$=3 Hz, $J_{3,4}$=9.5 Hz, H-3), 3.87 (dd, $J_{1,2}$=1.5 Hz, H-2), 4.04 (t, $J_{4,5}$=9.5 Hz, H-4), 4.90 (d, H-1).

Anal. ($C_{23}H_{30}O_7$) C, H.

2-Methoxyethyl 2-*O*-Benzyl-α-L-arabinopyranoside (**138**). Benzylation of **136** (1.59 g) with $PhCH_2Cl$ (10 ml) and KOH (2.5 g) at 120 °C for 2 H and subsequent processing and chromatography (HE system) afforded a sirup. That was treated with trifluoroacetic acid (TFA, 6 ml) in $CHCl_3$ (20 ml) containing MeOH (20 ml) for 2.5 h at room temp. After quick concentration with an efficient pump at 25 °C and co-evaporation with toluene, chromatography (TB system) afforded **138** (0.86 g, 58%), mp 47—48 °C, $[\alpha]_D$ −13° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 4.60 (d, $J_{1,2}$=4.5 Hz, H-1).

Anal. ($C_{15}H_{22}O_6$) C, H.

Compounds **163** and **195** were similarly converted into **165** (71%) and **202** (88%), respectively.

2-Methoxyethyl 2-*O*-Benzyl-β-L-fucopyranoside (**165**). $[\alpha]_D$ −18° (*c* 1.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.33 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 3.46 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9.5 Hz, H-2), 4.38 (d, H-1).

Anal. ($C_{16}H_{24}O_6$) C, H.

2-Methoxyethyl 4-*O*-Benzyl-α-L-rhamnopyranoside (**202**). $[\alpha]_D$ −53° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.34 (d, $J_{5,6}$=6.5 Hz, H-6), 3.34 (t, $J_{3,4}=J_{4,5}$=9.5 H, H-4), 3.36 (s, OMe), 3.94 (dd, $J_{2,3}$=3.5 Hz, H-3), 3.98 (dd, $J_{1,2}$=1.5 Hz, H-2), 4.80 (d, H-1).

Anal. ($C_{16}H_{24}O_6$) C, H.

2-Methoxyethyl 3-*O*-Allyl-2-*O*-benzyl-β-D-galactopyranoside (**56**). Benzylation of **54** (380 mg) with $PhCH_2Cl$ (1.6 ml) and KOH (0.41 g) took place for 2 h at 120 °C, followed by a subsequent hydrolysis of the product mixture, processed as described for **46**, with aq AcOH (80%, 15 ml) for 1 h at 95 °C. Chromatography (TB system) gave **56** (295 mg, 77%), $[\alpha]_D$ −0.5° (*c* 3.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 3.40 (dd, $J_{2,3}$=9 Hz, $J_{3,4}$=4 Hz, H-3), 3.45 (m, $J_{4,5}$=1 Hz, $J_{5,6a}$= 7 Hz, $J_{5,6b}$=5 Hz, H-5), 3.60 (dd, $J_{1,2}$=7.5 Hz, H-2), 3.79 (dd, $J_{6a,6b}$=11.5 Hz, H-6b), 3.90 (dd, H-6a), 4.40 (d, H-1).

Found: C, 61.55; H, 7.73%. Calcd for $C_{19}H_{28}O_7$: C, 61.94; H, 7.66%.

2-Methoxyethyl 3-*O*-Allyl-2-*O*-benzyl-α-D-mannopyranoside (**90**). A similar process for **88** (332 mg) afforded **90** (271 mg, 81%), $[\alpha]_D$ +18° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 4.90 (d, $J_{1,2}$=1.5 Hz, H-1).

Found: C, 61.38; H, 7.66%. Calcd for $C_{19}H_{28}O_7$: C, 61.94; H, 7.66%.

2-Methoxyethyl 2,3,4-Tri-*O*-benzyl-β-D-glucopyranoside (**22**). A mixture of **27** (2.3 g), $PhCH_2Cl$ (23 ml), and KOH (5.6 g) was stirred for 2 h at 120 °C, processed as described for **46**, and then hydrolyzed with aq AcOH (80%, 40 ml) for 1 h at 95 °C to deliver, after chromatography (TB system), **22** (1.1 g, 45%), mp 63—65 °C (from hexane containing IPE), $[\alpha]_D$ −3° (*c* 5.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.41 (s, OMe), 3.49 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9 Hz, H-2), 4.51 (d, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

A similar process was applied to **65** and **97** to produce **58** (69%) and **93** (46%), respectively.

2-Methoxyethyl 2,3,4-Tri-*O*-benzyl-β-D-galactopyranoside (**58**). Mp 58—59 °C, $[\alpha]_D$ −22° (*c* 1.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.54 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=3 Hz, H-3). 3.86 (dd, $J_{1,2}$=8 Hz, H-2), 4.42 (d, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

2-Methoxyethyl 2,3,4-Tri-*O*-benzyl-α-D-mannopyranoside (**93**). $[\alpha]_D$ +27° (*c* 1.2, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.35 (s, OMe), 3.89 (dd, $J_{1,2}$=2 Hz, $J_{2,3}$=3 Hz, H-2), 3.99 (t, $J_{3,4}=J_{4,5}$= 9.5 Hz, H-4), 4.88 (d, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

2-Methoxyethyl 2,3-Di-*O*-benzyl-β-D-xylopyranoside (**118**). Compound **115** (102 mg) was benzylated with $PhCH_2Cl$ (1.4 ml) and KOH (0.36 g) for 2 h at 120 °C. After processing, as described for **46**, the residue was treated with TFA (0.12 ml) in $CHCl_3$ (2 ml) containing MeOH (2 ml) for 1 h at room temp. After removing the volatile substances, as described for **138**, chromatogrphy (TB system) gave **118** (46 mg, 52%), mp 63—64 °C (from hexane), $[\alpha]_D$ −29° (*c* 0.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.26 (dd, $J_{4,5ax}$=9 Hz, $J_{5eq,5ax}$=11 Hz, H-5ax), 3.38 (s, OMe), 3.45 (dd, $J_{1.2}$=7 Hz, $J_{2,3}$=5 Hz, H-2), 4.00 (dd, $J_{4,5eq}$=4.5 Hz, H-5eq), 4.48 (d, H-1).

Anal. ($C_{22}H_{28}O_6$) C, H.

2-Methoxyethyl 2,4-Di-*O*-benzyl-α-L-rhamnopyranoside (**190**). Compound **188** (510 mg) was converted similarly into **190** (242 mg, 55%), $[\alpha]_D$ −21° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.33 (d, $J_{5,6}$=6.5 Hz, H-6), 3.32 (t, $J_{3,4}=J_{4,5}$=9.5 Hz, H-4), 3.36 (s, OMe), 3.96 (m. H-5), 3.79 (dd, $J_{1,2}$=1.5 Hz,

$J_{2,3}$=4 Hz, H-2), 4.86 (d, H-1).

Found: C, 68.10; H, 7.47%. Calcd for $C_{23}H_{30}O_6$: C, 68.64; H, 7.51%.

2-Methoxyethyl 2-*O*-Allyl-α-L-arabinopyranoside (**137**). A mixture of **136** (147 mg), allyl bromide (1.7 ml), and NaH (60%, 0.17 g, 7 equiv of OH) was stirred for 2 h at a reflux temperature. The mixture was cooled, diluted with toluene and treated carefully with H_2O to destroy NaH. The organic layer was washed well with H_2O, concentrated, and then treated with TFA (1 ml) in $CHCl_3$ (3 ml) containing MeOH (3 ml) for 5 h at room temp. After removing the excess reagents, as described for **138**, chromatography (TB system) furnished **137** (91 mg, 62%), $[\alpha]_D$ −32° (*c* 0.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 4.59 (d, $J_{1,2}$=4.5 Hz, H-1).

Found: C, 52.65; H, 7.85%. Calcd for $C_{11}H_{20}O_6$: C, 53.21; H, 8.12%.

Compounds **163** and **195** were similarly transformed into **164** (49%) and **196** (85%), respectively.

2-Methoxyethyl 2-*O*-Allyl-β-L-fucopyranoside (**164**). Mp 52—54 °C, (from hexane containing IPE), $[\alpha]_D$ −57° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.33 (d, $J_{5,6}$=6.5 Hz, H-6), 3.36 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=2.5 Hz, H-3), 3.37 (dd, $J_{1,2}$=7.5 Hz, H-2), 3.38 (s, OMe), 3.61 (m, $J_{4,5}$=1 Hz, H-5), 4.32 (d, H-1).

Anal. ($C_{12}H_{22}O_6$) C, H.

2-Methoxyethyl 4-*O*-Allyl-α-L-rhamnopyranoside (**196**). $[\alpha]_D$ −64° (*c*, 0.7. $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.31 (d, $J_{5,6}$=6.5 Hz, H-6), 3.23 (t, $J_{3,4}$=$_{4,5}$=9.5 Hz, H-4), 3.37 (s, OMe), 3.67 (m, H-5), 3.89 (dd, $J_{2,3}$=4 Hz, H-3), 3.98 (dd, *J*=1.5 Hz, H-2), 4.79 (d, H-1).

Anal. ($C_{12}H_{22}O_6$) C, H.

2-Methoxyethyl 2-*O*-Acetyl-3,4,6-tri-*O*-benzyl-β-D-glucopyranoside (**10**). To a solution of **9** (1.00 g) in $CHCl_3$ (3.0 ml) containing AcBr (1.00 ml) was added H_2O (0.20 ml) at 0 °C; the mixture was then stirred for 1.5 h at 20 °C. After concentration and co-evaporation with toluene at 30 °C in vacuo, the residue was dissolved in chilled $MeNO_2$ (2.4 ml) and 2,6-dimethylpyridine (0.98 ml) and then MEOH (0.61 ml) were added into the solution under stirring. After standing overnight, the solution was diluted with toluene and washed with aq $NaHCO_3$ (5%) thoroughly. The organic layer was concentrated and then stirred in $PhCH_2Cl$ (20 ml) containing KOH (10 g) for 2 h at 120 °C. The mixture was cooled, diluted with toluene and cold H_2O, and then washed well with H_2O. The concentration and subsequent chromatogrphy on alumina (Woelm, 02084), developed with hexane, IPE, and then 2-butanone, afforded an oily benzylated orthoester. That was then treated with $BF_3 \cdot Et_2O$ (12 μl) in CH_2Cl_2 (15 ml) for 5 min at room temp. Processing and chromatography (HE system) gave **10** (0.68 g, 48%), $[\alpha]_D$ +0.8° (*c* 1.0, $CHCl_3$).

Anal. ($C_{32}H_{38}O_8$) C, H.

The acetates **37**, **74**, **105**, and **126** were similarly converted into the 2-acetates **38** (44%), **75** (49%), **106** (50%), and **129** (43%), respectively.

2-Methoxyethyl 2-*O*-Acetyl-3,4,6-tri-*O*-benzyl-β-D-galactopyranoside (**38**). $[\alpha]_D$ +2° (*c* 6.5, $CHCl_3$).

Anal. ($C_{32}H_{38}O_8$) C, H.

2-Methoxyethyl 2-*O*-Acetyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**75**). $[\alpha]_D$ +27° (*c* 3.8, $CHCl_3$).

Anal. ($C_{32}H_{38}O_8$) C, H.

2-Methoxyethyl 2-*O*-Acetyl-3,4-di-*O*-benzyl-β-D-xylopyranoside (**106**). $[\alpha]_D$ −13° (*c* 5.6, $CHCl_3$).

Anal. ($C_{24}H_{30}O_7$) C, H.

2-Methoxyethyl 2-*O*-Acetyl-3,4-di-*O*-benzyl-α-L-arabinopyranoside (**129**). Mp 60—62 °C (from hexane), $[\alpha]_D$ −9° (*c* 0.9, $CHCl_3$).

Anal. ($C_{24}H_{30}O_7$) C, H.

2-Methoxyethyl 2-*O*-Acetyl-3,4-di-*O*-benzyl-β-L-fucopyranoside (**156**). A mixture of **151** (572 mg) and AcBr (2.9 ml) was stirred for 1 h at 25 °C. After quick concentration and co-evaporation with toluene at 30 °C in vacuo, the residue was dissolved in chilled $MeNO_2$ (3 ml) and the treated with 2,6-dimethylpyridine (2.4 ml) and MEOH (1.5 ml) at room temp overnight. Subsequent processing, benzylation, and rearrangement were carried out as described for **10** to give **156** (383 mg, 25%), mp 84—85 °C (from hexane), $[\alpha]_D$ +1° (*c* 1.1, $CHCl_3$).

Anal. ($C_{25}H_{32}O_7$) C, H.

2-Methoxyethyl 2-*O*-Acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranoside (**183**). Similarly, **178** (monohydrate, 572 mg) was converted into **183** (645.8 mg, 46%), $[\alpha]_D$ −17° (*c* 5.2, $CHCl_3$).

Anal. ($C_{25}H_{32}O_7$) C, H.

2-Methoxyethyl 3-*O*-Allyl-2,4,6-tri-*O*-benzyl-β-D-galactopyranoside (**51**). Benzylation of **56** (172 mg) with $PhCH_2Cl$ (1.5 ml) and KOH (0.37 g) for 2 h at 120 °C and chromatography (HE system) delivered **51** (208 mg, 81%), $[\alpha]_D$ −14° (*c* 2.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.40 (s, OMe), 3.46 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.82 (dd, $J_{1,2}$=8 Hz, H-2), 3.90 (d, $J_{4,5}$=0 Hz, H-4), 4.43 (d, H-1), 5.98 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

The diols **90**, **137**, **164**, and **196** were similarly converted into **84** (78%), **132** (75%), **159** (74%), and **197** (83%), respectively.

2-Methoxyethyl 3-*O*-Allyl-2,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**84**). $[\alpha]_D$ +31° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.33 (s, OMe), 4.91 (d, $J_{1,2}$=1.5 Hz, H-1), 5.95 (m, allyl).

Found: C, 71.82; H, 7.33%. Calcd for $C_{33}H_{40}O_7$: C, 72.24; H, 7.35%.

2-Methoxyethyl 2-*O*-Allyl-3,4-di-*O*-benzyl-α-L-arabinopyranoside (**132**). $[\alpha]_D$ −1.2° (*c* 1.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.25 (dd, $J_{4,5ax}$=1.5 Hz, $J_{5eq,5ax}$=13 Hz, H-5ax), 3.38 (s, OMe), 3.46 (dd, $J_{2,3}$=9 Hz, $J_{3,4}$=3.5 Hz, H-3), 3.70 (dd, $J_{1,2}$=7.5 Hz, H-2), 4.01 (dd, $J_{4,5eq}$=3 Hz, H-5eq), 4.30 (d, H-1), 5.97 (m, allyl).

Anal. ($C_{25}H_{32}O_6$) C, H.

2-Methoxyethyl 2-*O*-Allyl-3,4-di-*O*-benzyl-β-L-fucopyranoside (**159**). $[\alpha]_D$ +24° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.15 (d, $J_{5,6}$=6.5 Hz, H-6), 3.37 (s, OMe), 3.43 (m, $J_{4,5}$=1.5 Hz, H-5), 3.45 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3.5 Hz, H-3), 3.52 (dd, H-4), 3.68 (dd, $J_{1,2}$=7.5 Hz, H-1), 4.29 (d, H-1), 5.99 (m, allyl).

Anal. ($C_{26}H_{34}O_6$) C, H.

2-Methoxyethyl 4-*O*-Allyl-2,3-di-*O*-benzyl-α-L-rhamnopyranoside (**197**). $[\alpha]_D$ −44° (*c* 1.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.32 (d, 6.5 Hz, H-6), 3.34 (s, OMe), 3.66 (m, $J_{5,6}$=10 Hz, H-5), 4.79 (d, $J_{1,2}$=1.5 Hz, H-1), 5.94 (m, allyl).

Anal. ($C_{26}H_{34}O_6$) C, H.

2-Methoxyethyl 4-*O*-Allyl-2,3,6-tri-*O*-benzyl-α-D-galactopyranoside (**61**). The monohydroxy compound **63** (163 mg) was stirred in $PhCH_2Cl$ (1.0 ml) containing NaH (60%, 100 mg, 7 equiv) for 2 h at 120 °C. Processing and chromatography (HE system) furnished **61** (148 mg, 76%), $[\alpha]_D$ −2.5° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.47 (dd, $J_{2,3}$=10.5 Hz, $J_{3,4}$=3 Hz, H-3), 3.73 (dd, $J_{1,2}$=7.5 Hz, H-1), 3.81

(d, $J_{4,5}$=0 Hz, H-4), 4.39 (d, H-1), 5.90 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

Similar benzylations of **149**, **176**, and **203** afforded **147** (79%), **174** (93%), and **186** (85%).

2-Methoxyethyl 4-*O*-Allyl-2,3-di-*O*-benzyl-α-L-arabinopyranoside (**147**). $[\alpha]_D$ +0.8° (*c* 0.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.29 (dd, $J_{4,5ax}$=1.5 Hz, $J_{5eq,5ax}$=13 Hz, H-5ax), 3.38 (s, OMe), 3.51 (dd, $J_{2,3}$=9 Hz, $J_{3,4}$=4 Hz, H-3), 3.77 (dd, $J_{1,2}$=7 Hz, H-2), 4.16 (d, H-1), 5.95 (m, allyl).

Found: C, 70.29; H, 7.02%. Calcd for $C_{25}H_{32}O_6$: C, 70.07; H, 7.53%.

2-Methoxyethyl 4-*O*-Allyl-2,3-di-*O*-benzyl-α-L-fucopyranoside (**174**). $[\alpha]_D$ +1.4° (*c* 0.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.28 (d, $J_{5,6}$=6.5 Hz, H-6), 3.37 (dd, OMe), 3.75 (dd, $J_{1,2}$=7.4 Hz, $J_{2,3}$=9 Hz, H-2), 4.36 (d, H-1), 5.95 (m, allyl).

Anal. ($C_{26}H_{34}O_6$) C, H.

2-Methoxyethyl 2-*O*-Allyl-3,4-di-*O*-benzyl-α-L-rhamnopyranoside (**186**). $[\alpha]_D$ −42° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.32 (d, $J_{5,6}$=6 Hz, H-6), 3.36 (s, OMe), 3.83 (dd, $J_{1,2}$= 1.5 Hz, $J_{2,3}$=3 Hz, H-2), 3.87 (dd, $J_{3,4}$=9.5 Hz, H-3), 4.80 (d, H-1), 5.94 (m, allyl).

Found: C, 70.25; H, 7.67%. Calcd for $C_{23}H_{34}O_6$: C, 70.56; H, 7.74%.

2-Methoxyethyl 2,4,6-Tri-*O*-benzyl-β-D-glucopyranoside (**15**). To a stirring solution of **2**[12] (2.03 g) in $PhCH_2Cl$ (40 ml) was added crushed NaOH (1.7 g) and the mixture was vigorously stirred for 2.5 h at 100 °C. Processing and chromatography (TB system) gave **3** (0.15 g, 5%) and **15** (1.00 g, 39%), $[\alpha]_D$ +6° (*c* 3.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.31 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=9 Hz, H-2), 3.39 (s, OMe), 4.44 (d, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

Further elution gave **21** (0.18 mg, 7%) and **12** (0.20 g, 8%).

2-Methoxyethyl 3,4,6-Tri-*O*-benzyl-β-D-galactopyranoside (**40**). A reaction of **33** (180 mg) with $PhCH_2Cl$ (1.8 ml) and crushed KOH (220 mg) in DME (1.8 ml) was conducted under stirring for 2.5 h at 85 °C. The processed mixture of products was chromatographed (TB system) to deliver **35** (34 mg, 13%), **47** (38 mg, 17%), **48** (29 mg, 13%), and then **40** (61 mg, 27%), $[\alpha]_D$ −9° (*c* 3.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.46 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.90 (d, $J_{4,5}$=0 Hz, H-4), 4.00 (dd, $J_{1,2}$=8 Hz, H-2), 4.30 (d, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

2-Methoxyethyl 3-*O*-Acetyl-2,4,6-tri-*O*-benzyl- and 4-*O*-Acetyl-2,3,6-tri-*O*-benzyl-α-D-mannopyranosides (**80** and **81**). A mixture of **71** (0.98 g), $PhCH_2Cl$ (19 ml), and crushed KOH (1.08 g) was stirred efficiently for 4 h at 110 °C. Processing and chromatography (TB system) afforded **72** (0.18 g, 7%) and then a mixture of **83** and **92**, which was acetylated with Ac_2O (5 ml) and pyridine (1 ml). After concentration and co-evaporation with toluene, the residue was chromatographed (TB system) to deliver **81** (0.46 g, 20%), $[\alpha]_D$ +19° (*c* 2.6, $CHCl_3$) and then **80** (0.80 g, 35%), $[\alpha]_D$ +11° (*c* 1.4, $CHCl_3$).

Anal. ($C_{32}H_{38}O_8$) **80**, C, H. **81**, C, H.

When benzylation of **71** (2.0 g) was carried out using $PhCH_2Cl$ (40 ml) and LiOH (2.7 g) for 6.5 h at 130 °C, followed by the sequential process described above, to give **81** (1.21 g, 26%), **80** (0.10 g, 2%) were obtained.

2-Methoxyethyl 2,3,6-Tri-*O*-benzyl-β-D-glucopyranoside (**21**). Benzylation of **20**[7] (2.47 g) with $PhCH_2Cl$ (25 ml) and NaH (60%, 0.30 g, 1.3 equiv) under stirring for 1 h at 100 °C and chromatography (TB system) furnished **3** (0.23 g, 7%) and **21** (1.99 g, 66%), $[\alpha]_D$ −18° (*c* 2.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (s, OMe), 4.47 (d, $J_{1,2}$=7.5 Hz, H-1).

Found: C, 70.34; H, 7.23%. Calcd for $C_{30}H_{34}O_7$: C, 70.84; H, 7.13%.

Further elution gave **22** (0.54 g, 18%).

The diols **57** and **91** were similarly benzylated to afford **48** (77%) and **58** (5%), and **92** (61%) and **93** (7%), respectively.

2-Methxyethyl 2,3,6-Tri-*O*-benzyl-β-D-galactopyranoside (**48**). $[\alpha]_D$ −4° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.50 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=4 Hz, H-3), 3.56 (m, $J_{4,5}$=1 Hz, $J_{5,6a}$=$J_{5,6b}$=5.5 Hz, H-5), 3.67 (dd, $J_{1,2}$=7.5 Hz, H-2), 3.72 (dd, $J_{6a,6b}$=10 Hz, H-6b), 3.80 (dd, H-6a), 4.02 (dd, H-4), 4.41 (d, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

2-Methoxyethyl 2,3,6-Tri-*O*-benzyl-α-D-mannopyranoside (**92**). $[\alpha]_D$ +1.3° (*c* 1.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 3.89 (dd, $J_{1,2}$=2 Hz, $J_{2,3}$=3.5 Hz, H-2), 4.07 (t, $J_{3,4}$=$J_{4,5}$= 10 Hz, H-4), 4.96 (d, H-1).

Found: C, 70.32; H, 7.20%. Calcd for $C_{30}H_{36}O_7$: C, 70.84; H, 7.17%.

2-Methoxyethyl 2,3-Di-*O*-benzyl-α-L-arabinopyranoside (**140**). Benzylation of the diol **138** (150 mg) with $PhCH_2Cl$ (3 ml) and LiOH (60 mg, 5 equiv) for 2 h at 130 °C and chromatography (TB system) delivered **127** (45 mg, 19%), **139** (9 mg, 5%), and then **140** (56 mg, 29%), $[\alpha]_D$ +6° (*c* 1.0) ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.43 (dd, $J_{4,5ax}$=1.5 Hz, $J_{5eq,5ax}$=13 Hz, H-5ax), 3.54 (dd, $J_{2,3}$=8.5 Hz, $J_{3,4}$=4 Hz, H-3), 3.67 (dd, $J_{1,2}$=7 Hz, H-1), 3.92 (m, $J_{4,5eq}$=3.5 Hz, H-4), 4.00 (dd, H-5eq), 4.37 (d, H-1).

Anal. ($C_{22}H_{28}O_6$) C, H.

The diols **46** (7 equiv of LiOH, 7 h) and **165** (7 equiv of LiOH, 7 h) similarly yielded **47** (20%, the faster-moving) and **48** (32%, the slower-moving), as well as **166** (14%, the faster-moving) and **167** (32%, the slower-moving), respectively.

2-Methoxyethy 2,3-Di-*O*-benzyl-β-L-fucopyranoside (**167**). $[\alpha]_D$ −3° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.34 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 3.49 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=2.5 Hz, H-3), 3.52 (m, $J_{4,5}$=1 Hz, H-5), 3.62 (dd, $J_{1,2}$=7.5 Hz, H-2), 4.37 (d, H-1).

Anal. ($C_{23}H_{30}O_6$) C, H.

2-Methoxyethyl 2,4,6-Tri-*O*-benzyl-β-D-galactopyranoside (**47**). A mixture of **46** (188 mg), $PhCH_2Cl$ (1.5 ml), KOH (53 mg, 2.1 equiv), and DME (1.5 ml) was stirred for 1.5 h at 70 °C, followed by processing and chromatography (TB system), to give **35** (42 mg, 16%) and then **47** (131 mg, 57%), $[\alpha]_D$ −1° (*c*1.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.61 (dd, $J_{1,2}$=7 Hz, $J_{2,3}$=9.5 Hz, H-2), 3.67 (dd, $J_{3,4}$=3 Hz, H-3), 3.87 (d, $J_{4,5}$=0 Hz, H-4), 4.41 (d, H-1).

Found: C, 70.42; H, 7.08%. Calcd for $C_{30}H_{36}O_7$: C, 70.84; H, 7.13%.

Further elution gave **48** (42 mg, 8%).

The diols **138**, **165**, and **202** were similarly benzylated to give **139** (50%) and **140** (22%), and **166** (65%) and **167** (16%), and **190**, (73%, the faster-moving) and **185** (9%, the slower-moving), respectively.

2-Methoxyethyl 2,4-Di-*O*-benzyl-α-L-arabinopyranoside (**139**). Mp 65—66 °C, $[\alpha]_D$ −10° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.47 (dd, $J_{4,5b}$=3 Hz, $J_{5a,5b}$=11 Hz, H-5b), 3.63 (dd, $J_{1,2}$=4.5 Hz, $J_{2,3}$=2 Hz, H-2), 3.80 (m, $J_{3,4}$=3 Hz, $J_{4,5a}$=6 Hz, H-4), 3.97 (dd, H-5a), 4.55 (d, H-1).

Anal. ($C_{22}H_{28}O_6$) C, H.

2-Methoxyethyl 2,4-Di-*O*-benzyl-β-L-fucopyranoside (**166**). $[\alpha]_D$ −12° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.24 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 4.37 (d, $J_{1,2}$=7.5 Hz, H-1).

Anal. ($C_{23}H_{30}O_6$) C, H.

2-Methoxyethyl 3-*O*-Allyl-2,4,6-tri-*O*-benzyl- and 2-*O*-Allyl-3,4,6-tri-*O*-benzyl-β-D-galactopyranosides (**53** and **55**). A mixture of **53** (1.00 g), allyl bromide (9 ml), KOH (0.28 g, 1.6 equiv), and DME (9 ml) was stirred for 1.5 h at 70 °C. Processing and chromatography (TB system) gave the diallyl ether (0.25 g, 20%) and then **55** (0.25 g, 22%), $[\alpha]_D$ −8° (*c* 4.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.40 (m, $J_{4,5}$=$J_{5,6a}$=1.5 Hz, $J_{5,6b}$=2 Hz, H-5), 3.51 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=9.5 Hz, H-2), 3.67 (dd, $J_{3,4}$=4 Hz, H-3), 4.04 (dd, $J_{6a,6b}$=12.5 Hz, H-6b), 4.19 (dd, H-4), 4.29 (dd, H-6a), 4.38 (d, H-1), 5.53 (s, benzylidene).

Further elution afforded **54** (0.52 g, 46%), mp 147—149 °C (from IPE), $[\alpha]_D$ +38° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (s, OMe), 3.48 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=4 Hz, H-3), 3.99 (dd, $J_{1,2}$=8 Hz, H-2), 4.07 (dd, $J_{5,6b}$=2 Hz, $J_{6a,6b}$=12 Hz, H-6b), 4.22 (dd, $J_{5,6a}$=1.5 Hz, H-6a), 4.39 (d, H-1), 5.53 (s, benzylidene).

Found: **54**, C, 61.92; H, 7.07%. **55**, C, 61.93; H, 7.18%. Calcd for $C_{19}H_{25}O_7$: C, 62.45; H, 6.90%.

The diols **46** (3 equiv of KOH, 1 h), **86** (3 equiv of KOH, 2 h), **138** (1.7 equiv of KOH, 45 min), **165** (2 equiv of KOH, 45 min), and **202** (3 equiv of KOH, 1.5 h) were similarly allylated to yield **63** (50%, the faster-moving) and **64** (9%, the slower-moving), **88** (40%, the slower-moving) and **89** (11%, the faster-moving), **149** (56%, the faster-moving) and **150** (21%, the slower-moving), **176** (66%, the faster-moving) and **177** (26%, the slower-moving), as well as **203** (51%, the faster-moving) and **204** (29%, the solwer-moving), respectively.

2-Methoxyethyl 4- and 3-*O*-Allyl-2,6-di-*O*-benzyl-β-D-galactopyranosides (**63** and **64**). **63**, $[\alpha]_D$ −4° (*c* 1.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.53 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9.5 Hz, H-2), 4.38 (d, H-1), 5.88 (m, allyl). **64**, $[\alpha]_D$ +7° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.40 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=3.5 Hz, H-3), 3.60 (dd, $J_{1,2}$=8 Hz, H-2), 4.40 (d, H-1), 5.93 (m, allyl).

Anal. ($C_{26}H_{34}O_6$) **63**, C, H. **64**, C, H.

2-Methoxyethyl 3- and 2-*O*-Allyl-4,6-*O*-benzylidene-α-D-mannopyranosides (**88** and **89**). **88**, $[\alpha]_D$ +40° (*c* 0.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (s, OMe), 4.13 (dd, $J_{1,2}$=1.5 Hz, $J_{2,3}$=4 Hz, H-2), 4.20 (t, $J_{3,4}$=$J_{4,5}$=9 Hz, H-4), 4.93 (d, H-1), 5.59 (m, allyl). **89**, $[\alpha]_D$ +23° (*c* 0.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.40 (s, OMe), 4.92 (d, $J_{1,2}$=1.5 Hz, H-1), 5.57 (s, benzylidene).

Found: **88**, C, 62.42; H, 7.17%. **89**, C, 62.49; H, 7.32%. Calcd for $C_{19}H_{25}O_7$: C, 62.45; H, 6.90%.

2-Methoxyethyl 4- and 3-*O*-Allyl-2-*O*-benzyl-α-L-arabinopyranosides (**149** and **150**). **149**, $[\alpha]_D$ −7° (*c* 0.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 3.48 ($J_{4,5b}$=3 Hz, $J_{5a,5b}$=12 Hz, H-5b), 2.61 (dd, $J_{1,2}$=5 Hz, $J_{2,3}$=7 Hz, H-2), 3.73 (dd, $J_{3,4}$=3 Hz, $J_{4,5a}$=6 Hz, H-4), 3.86 (dd, H-3), 3.95 (dd, H-5a), 4.54 (d, H-1), **150**, $[\alpha]_D$ +15° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.38 (s, OMe), 3.60 (dd, $J_{1,2}$=7 Hz, $J_{2,3}$=9 Hz, H-2), 4.35 (d, H-1), 5.92 (m, allyl).

Anal. ($C_{18}H_{26}O_6$) **149**, C, H. **150**, C, H.

2-Methoxyethyl 4- and 3-*O*-Allyl-2-*O*-benzyl-β-L-fucopyranosides (**176** and **177**). **176**, $[\alpha]_D$ −13° (*c* 0.6, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.30 (d, $J_{5,6}$=6.5 Hz, H-6), 3.37 (s, OMe), 3.55 (m, $J_{4,5}$=1 Hz, H-5), 4.36 (d, $J_{1,2}$=7.5 Hz, H-1), 5.93 (m, allyl). **177**, $[\alpha]_D$ −1.4° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.35 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 3.40 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=4 Hz, H-3), 3.54 (m, $J_{4,5}$=1 Hz, H-5), 3.55 (dd, $J_{1,2}$=7.5 Hz, H-2), 3.76 (dd, H-4), 4.37 (d, H-1), 5.93 (m, allyl).

2-Methoxyethyl 2,4,6-Tri-*O*-benzyl-α-D-mannopyranoside (**83**). $[\alpha]_D$ +16° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.35 (s, OMe), 4.99 (d, $J_{1,2}$=1.5 Hz, H-1).

Anal. ($C_{30}H_{36}O_7$) C, H.

2-Methoxyethyl 3,4-Di-*O*-benzyl-β-D-xylopyranoside (**108**). $[\alpha]_D$ −27° (*c* 2.2, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.28 (dd, $J_{4,5ax}$=9 Hz, $J_{5eq,5ax}$=12 Hz, H-5ax), 3.39 (s, OMe), 3.98 (dd, $J_{4,5eq}$=4.5 Hz, H-5eq), 4.33 (d, $J_{1,2}$=8 Hz, H-1).

Anal. ($C_{22}H_{28}O_6$) C, H.

2-Methoxyethyl 3,4-Di-*O*-benzyl-α-L-arabinopyranoside (**131**). $[\alpha]_D$ +23° (*c* 0.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.29 (d, $J_{4,5ax}$=0 Hz, $J_{5eq,5ax}$=13 Hz, H-5ax), 3.39 (s, OMe), 3.41 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.69 (dd, $J_{4,5eq}$=2.5 Hz, H-4), 4.00 (dd, $J_{1,2}$=7.5 Hz, H-2), 4.07 (dd, H-5eq), 4.22 (d, H-1).

Anal. ($C_{22}H_{28}O_6$) C, H.

2-Methoxyethyl 3,4-Di-*O*-benzyl-β-L-fucopyranoside (**158**). $[\alpha]_D$ +13° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.21 (d, $J_{5,6}$=6.5 Hz, H-6), 3.38 (s, OMe), 3.45 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.50 (m, $J_{4,5}$=1.5 Hz, H-5), 3.98 (dd, $J_{1,2}$=7.5 Hz, H-1), 4.26 (d, H-1).

Found: C, 68.25; H, 7.50%. Calcd for $C_{23}H_{30}O_6$: C, 68.64; H, 7.15%.

2-Methoxyethyl 3,4-Di-*O*-benzyl-α-L-rhamnopyranoside (**185**). $[\alpha]_D$ −31° (*c* 1.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.33 (d, $J_{5,6}$=6 Hz, H-6), 3.38 (s, OMe), 3.47 (t, $J_{3,4}=J_{4,5}$=10 Hz, H-4), 3.89 (dd, $J_{2,3}$=4 Hz, H-3), 4.12 (dd, $J_{1,2}$=1.5 Hz, H-2), 4.86 (d, H-1).

Anal. ($C_{23}H_{30}O_6$) C, H.

2-Methoxyethyl 2,3-Di-*O*-benzyl-α-L-rhamnopyranoside (**199**). The allyl ether **197** (417 mg) was deallylated through the published method,[21] followed by chromatography (TB system), to produce **199** (202 mg, 53%), $[\alpha]_D$ −2° (*c* 1.1, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.32 (d, $J_{5,6}$=6 Hz, H-6), 3.37 (s, OMe), 3.88 (dd, $J_{1,2}$=1.5 Hz, $J_{2,3}$=2.5 Hz, H-2), 4 87 (d, H-1).

Anal. ($C_{23}H_{30}O_6$) C, H.

The monohydroxy alcohols **12**, **15**, **21**, **22**, **40**, **47**, **48**, **58**, **77**, **83**, **92**, **93**, **108**, **111**,[6] **118**, **131**, **139**, **140**, **158**, **166**, **167**, **185**, and **190** were allylated by refluxing in neat allyl bromide containing excess NaH, followed by chromatographical purification (HE system), to furnished the corresponding allyl ethers **13**, **18**, **25**, **30**, **41**, **51**, **61**, **68**, **78**, **84**, **95**, **100**, **109**, **112**, **121**, **132**, **143**, **147**, **159**, **170**, **174**, **186**, and **193**.

2-Methoxyethyl 2-*O*-Allyl-3,4,6-tri-*O*-benzyl-β-D-glucopyranoside (**13**). $[\alpha]_D$ −13° (*c* 2.9, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.33 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=9 Hz, H-2), 3.37 (s, OMe), 3.53 (t, $J_{3,4}=J_{4,5}$=9 Hz, H-4), 3.59 (t, H-3), 4.35 (d, H-1), 5.94 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 3-*O*-Allyl-2,4,6-tri-*O*-benzyl-β-D-glucopyranoside (**18**). Mp 58—59 °C (from hexane), $[\alpha]_D$ +7.3° (*c* 0.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (s, OMe), 4.40 (d, $J_{1,2}$=7.5 Hz, H-1), 5.96 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 4-*O*-Allyl-2,3,6-tri-*O*-benzyl-β-D-glucopyranoside (**25**). Mp 118—119 °C (from IPE), $[\alpha]_D$ +20° (*c* 2.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (s, OMe), 3.44 (dd, $J_{1,2}$=8 Hz, $J_{2,3}$=9 Hz, H-2), 4.44 (d, H-1), 5.82 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 6-*O*-Allyl-2,3,4-tri-*O*-benzyl-β-D-glucopyranoside (**30**). Mp 59—60 °C (from hexane), $[\alpha]_D$ +2° (*c* 0.3, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (s, OMe), 3.46 (m, $J_{4,5}$=9 Hz, $J_{5,6}$=2 and 5 Hz, H-5), 3.49 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9 Hz, H-2), 3.59 (t, $J_{3,4}$=9 Hz, H-3), 3.68 (t, H-3), 4.45 (d, H-1).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 2-*O*-Allyl-3,4,6-tri-*O*-benzyl-β-D-galactopyranoside (**41**). $[\alpha]_D$ −22° (*c* 1.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.46 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.70 (dd, $J_{1,2}$=7.5 Hz, H-2), 3.86 (d, $J_{4,5}$=0 Hz, H-4), 4.33 (d, H-1), 5.91 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 6-*O*-Allyl-2,3,4-tri-*O*-benzyl-β-D-galactopyranoside (**68**). $[\alpha]_D$ −1° (*c* 3.5, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.37 (s, OMe), 3.84 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=10 Hz, H-2), 4.41 (d, H-1), 5.89 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 2-*O*-Allyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**78**). $[\alpha]_D$ +38° (*c* 3.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.36 (s, OMe), 3.85 (dd, $J_{1,2}$=2 Hz, $J_{2,3}$=1.5 Hz, H-2), 4.92 (d, H-1), 5.94 (m, allyl).

Anal. ($C_{33}H_{40}O_7$) C, H.

2-Methoxyethyl 4-*O*-Allyl-2,3,6-tri-*O*-benzyl-α-D-mannopyranoside (**95**). $[\alpha]_D$ +31° (*c* 1.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.34 (s, OMe), 4.92 (d, $J_{1,2}$=1.5 Hz, H-1), 5.84 (m, allyl).

Found: C, 71.60; H, 7.47%. Calcd for $C_{33}H_{40}O_7$: C, 72.24; H, 7.45%.

2-Methoxyethyl 6-*O*-Allyl-2,3,4-tri-*O*-benzyl-α-D-mannopyranoside (**100**). $[\alpha]_D$ +27° (*c* 2.2, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.34 (s, OMe), 3.88 (dd, $J_{1,2}$=2 Hz, $J_{2,3}$=3 Hz, H-2), 4.92 (d, H-1), 5.93 (m, allyl).

Found: C, 71.84; H, 7.41%. Calcd for $C_{33}H_{40}O_7$: C, 72.24; H, 7.35%.

2-Methoxyethyl 2-*O*-Allyl-3,4-di-*O*-benzyl-β-D-xylopyranoside (**109**). $[\alpha]_D$ −18° (*c* 2.0, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.18 (dd, $J_{4,5ax}$=10 Hz, $J_{5eq,5ax}$=11.5 Hz, H-5ax), 3.27 ($J_{1,2}$= 7.5 Hz, $J_{2,3}$=9 Hz, H-2), 3.38 (s, OMe), 3.51 (t, $J_{3,4}$=9 Hz, H-3), 3.91 (dd, $J_{4,5eq}$=5 Hz, H-5eq), 4.31 (d, H-1), 5.95 (m, allyl).

Anal. ($C_{25}H_{32}O_6$) C, H.

2-Methoxyethel 3-*O*-Allyl-2,4-di-*O*-benzyl-β-D-xylopyranoside (**112**). $[\alpha]_D$ −4 ° (*c* 1.5, $CHDCl_3$), ^1H NMR ($CDCl_3$) δ=3.17 (dd, $J_{4,5ax}$=10 Hz, $J_{5eq,5ax}$=11.5 Hz, H-5ax), 3.33 (dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=9 Hz, H-2), 3.38 (s, OMe), 3.43 (t, $J_{3,4}$=9 Hz, H-3), 3.55 (m, $J_{4,5eq}$=5 Hz, H-4), 3.90 (dd, H-5eq), 4.34 (d, H-1), 5.97 (m, allyl).

Anal. ($C_{25}H_{32}O_6$). C, H.

2-Methoxyethyl 4-*O*-Allyl-2,3-di-*O*-benzyl-β-D-xylopyranoside (**121**). $[\alpha]_D$ +2° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.18

(dd, $J_{4,5ax}$=10 Hz, $J_{5eq,5ax}$=11.5 Hz, H-5ax), 3.39 (s, OMe), 4.38 (d, $J_{1,2}$=8 Hz, H-1), 5.89 (m, allyl).

Anal. ($C_{25}H_{32}O_6$) C, H.

2-Methoxyethyl 3-*O*-Allyl-2,4-di-*O*-benzyl-α-L-arabinopyranoside (**143**). $[\alpha]_D$ +11° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=3.39 (dd, $J_{4,5ax}$=1.5 Hz, $J_{5eq,5ax}$=13 Hz, H-5ax), 3.48 (s, OMe), 3.53 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=4 Hz, H-3), 3.87 (dd, $J_{1,2}$=7 Hz, H-2), 4.13 (dd, $J_{4,5eq}$=3 Hz, H-5eq), 4.46 (d, H-1), 6.01 (m, allyl).

Found: C, 69.58; H, 7.49%. Calcd for $C_{25}H_{32}O_6$: C, 70.07; 7.53%.

2-Methoxyethyl 3-*O*-Allyl-2,4-di-*O*-benzyl-β-L-fucopyranoside (**170**). $[\alpha]_D$ +15° (*c* 0.8, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.18 (d, $J_{5,6}$=6.5 Hz, H-6), 3.37 (s, OMe), 3.41 (dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.45 (m, $J_{4,5}$=1 Hz, H-5), 3.54 (dd, H-4), 3.75 (dd, $J_{1,2}$=7.5 Hz, H-2), 4.35 (d, H-1), 5.95 (m, allyl).

Found: C, 70.25; H, 7.85%. Calcd for $C_{26}H_{34}O_6$: C, 70.56; H, 7.74%.

2-Methoxyethyl 3-*O*-Allyl-2,4-di-*O*-benzyl-α-L-rhamnopyranoside (**193**). $[\alpha]_D$ −44° (*c* 0.4, $CHCl_3$), ^1H NMR ($CDCl_3$) δ=1.32 (d, $J_{5,6}$=6 Hz, H-6), 3.34 (s, OMe), 3.57 (t, $J_{3,4}$=$J_{4,5}$=10 Hz, H-4), 3.68 (m, H-5), 3.76 (dd, $J_{2,3}$=3.5 Hz, H-3), 3.82 (dd, $J_{1,2}$=2 Hz, H-2), 4.79 (d, H-1), 5.95 (m, allyl).

Found: C, 70.24; H, 7.67%. Calcd for $C_{25}H_{34}O_6$: C, 70.56; H, 7.74%.

Reactions of Alkylarenes, Benzyl Alcohols, Sulfides, and Phosphine with Manganese(III) Acetate-Chloride Ions

Yasuo FUTAMI, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received May 16, 1989)

The reactions of methoxytoluenes and methylnaphthalenes with a manganese(III) acetate-Cl^- complex gave the corresponding aldehydes in 8 to 54% yields. In a similar reaction aromatic compounds having a methylene group were oxidized to the corresponding acetates and ketones. The primary and secondary benzyl alcohols gave aldehydes and ketones, respectively, in good yields. Sulfides and phosphine were oxidized to give oxides by the complex. The reaction of alkylarenes with lower ionization potentials can be explained in terms of an electron-transfer mechanism involving the manganese(III) acetate-Cl^- complex.

Several papers have been published concerning the complex formation and the reaction of manganese(III) acetate in the presence of chloride ions. The reaction of olefins with the complex yielded mainly addition products,[1,2] while α,β-unsaturated carboxylic acids gave addition and chlorine-substituted products accompanied by decarboxylation.[3] α,β-Unsaturated carboxylates also gave addition and chlorine-substituted products.[4] In a previous paper[5] we reported that the reaction of aryl ketones with manganese(III) acetate–lithium chloride gave α-chlorinated ketones in good yields. In the reaction of toluenes with manganese(III) acetate the addition of an equimolar portion of potassium bromide led to an appreciable rate enhancement and gave increased yields of benzyl acetates and benzaldehydes[6] instead of methyl-substituted benzyl acetates, which were the main products in the reaction of manganese(III) acetate alone. However, the reactions were examined only from the mechanistic point of view. This prompted us to investigate the reactions of aromatic compounds having methyl and methylene groups, benzyl alcohols, sulfides and phosphorus compounds with the manganese(III) acetate-Cl^- complex in order to improve the yields of aldehydes, ketones, and oxides. We have examined the reactions of methoxy-substituted toluenes, methylnaphthalenes, diarylmethanes, xanthene, anthrone, methyl phenylacetates, fluorene, benzyl alcohols, diphenyl sulfide, dibenzothiophene, and triphenylphosphine. These compounds were chosen because they may provide a variety of products which reflect the nature of the reaction and that the products can be easily characterized by spectroscopy. The reaction were carried out under various reaction conditions by changing the molar ratio of the substrate, manganese(III) acetate and chloride ions. The effects of changing the source of the chloride ions, and of additives were also examined.

Results

Methoxy-Substituted Toluenes and Methylnaphthalenes. When 4-methoxytoluene (**1a**) was oxidized with the manganese(III) acetate-Cl^- complex in AcOH in a molar ratio of **1a**:Mn(III):LiCl of 1:4:5 at 100 °C, it gave a mixture of 4-methoxybenzyl acetate (**2a**) and 4-methoxybenzaldehyde (**3a**). The reaction

a) Substrate: Mn(III): Cl^-. b) Yields are based on the substrate added. c) Ac_2O (20 cm^3) was added. d) Water (1 cm^3) was added. e) Isolated as a 2,4-DNP.

was conducted at various molar ratios of **1a**:Mn(III): LiCl until all Mn(III) was consumed, and the best yield for **3a** was attained when the molar was 1:4:10 (Table 1, Entry 2). When Ac_2O was added to the reaction medium, the yield of **3a** decreased (Entry 6). The addition of water did not cause any significant change in the yield (Entry 7). It was found that changing the Cl^- source affects the yield of the products in the reaction of **1a** (Entries 8—12). All other salts lowered the yield of **3a**, but increased that of **2a**. In a similar reaction with the manganese(III) acetate-Cl^- complex 3,4-dimethoxytoluene (**1b**) and 2,3,4-trimethoxytoluene (**1c**) gave the corresponding aldehydes (**3b** and **3c**) in poor yields (Entries 13 and 14). In the reaction of **1b** 2-chloro-4,5-dimethoxytoluene (**5**) was obtained in minor quantity. The reaction of 1-methyl- (**1d**) and 2-methylnaphthalene (**1e**) yielded the corresponding (acetoxymethyl)naphthalenes (**2d** and **2e**) and naphthalenecarbaldehydes (**3d** and **3e**).

Methylene Group Flanked by One or Two Aryl Groups. The reaction of xanthene (**6a**), anthrone (**6b**), and bis(4-methoxyphenyl)methane (**6d**) gave the corresponding carbonyl compounds (**9a**, **9b**, and **9d**) in moderate yields (Entries 17, 18, and 20) together with some other products (**7d** and **10**). Diphenylmethane (**6c**) and fluorene (**6g**) did not give ketonic products, but yielded acetates, **8c** and **8g**, respectively (Entries 19 and 21). Acenaphthene (**6h**) gave 1-acetoxyacenaphthene (**8h**), 1,2-dichloroacenaphthene (**12**), and 1,8-naphthalenedicarboxylic anhydride (**13**). The configuration of the chlorine atoms in **12** is determined as a trans, since the melting point and the IR and ^1H NMR spectrum of **12** were identical with those reported.[7]

Benzyl Alcohols. The reaction of 4-methoxybenzyl alcohol (**4a**) with the complex gave a mixture of **2a** and **3a**, the latter being predominant. 3,4-Dimethoxybenzyl alcohol (**4b**) yielded 3,4-dimethoxybenzaldehyde (**3b**) exclusively (Entry 25). Diphenylmethanol (**7c**) yielded a mixture of an acetate (**8c**) and benzophenone (**9c**). The presence of an electron-donating group, such as a methoxyl group in the aromatic ring, slightly increased the yield of the ketone, as shown in the reaction of (4-methoxyphenyl)phenylmethanol (**7f**) (Entry 28). The reaction of **7f** with manganese(III) acetate alone gave **8f** and **9f** in poor yields (Entry 29). The reaction of 1-(4-methoxyphenyl)ethanol (**7j**) yielded an acetate (**8j**) and 4′-methoxyacetophenone (**9j**), the latter being the major product (Entry 31). Similarly, 1-(4-chlorophenyl)ethanol (**7k**) gave an acetate (**8k**), 4′-chloroacetophenone (**9k**), and 2,4′-dichloroacetophenone (**14**). 1-(2-Naphthyl)ethanol (**7e**) yielded an acetate (**8e**) and 2-acetylnaphthalene (**9e**). The chlorination of acetophenones with the Mn(III)-Cl^- complex has already been reported to give α-chlorinated

a) Substrate: Mn(III): LiCl. b) Yields are based on the substrate added.

acetophenones.[5]

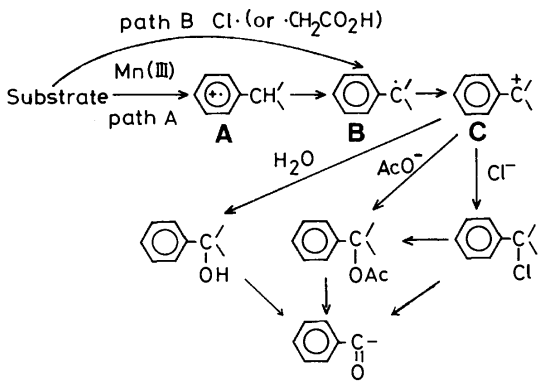
Sulfides and Triphenylphosphine. The reaction of diphenyl sulfide (**17a**) with the complex yielded diphenyl sulfoxide (**19a**) in good yield (Entry 34). The reaction of **17a** with manganese(III) acetate in the absence of Cl^- ions gave an acetate (**18**) in 28% yield and a large amount of **16a** was recovered unchanged (Entry 35). Dibenzothiophene (**17b**) afforded dibenzothiophene oxide (**19b**) in 21% yield (Entry 36). The reaction of triphenylphosphine (**20**) gave triphenylphosphine oxide (**21**) in excellent yield (Entry 37).

Discussion

The oxidation of alkylarenes with manganese(III) acetate afforded aldehydes in minor quantities.[8] The addition of alkali halides as catalysts has been reported to improve the yields of carbonyl compounds.[9] However, these reactions were carried out primarily for mechanistic studies using a large excess of the substrate. By contrast, we used a large amount of the manganese(III) acetate–Cl^- complex compared with those in the previous studies.[6,9] Methoxy-substituted toluenes and methylnaphthalenes gave the corresponding aldehydes in 8 to 54% yields, which are better than those reported. When the acetoxymethyl derivative is stable towards Mn(III)-Cl^-, the yields of the aldehydes are not sufficiently high. The oxidation of benzyl alcohols, on the other hand, gave better yields of the aldehydes.

The oxidation of methylene compounds (**6a—d,g**) with the complex gave ketonic compounds in good yields, except for diphenylmethane (**6c**) and fluorene (**6g**). Secondary benzyl alcohols (**7c**, **7f**, and **7g**) also gave the corresponding ketones (**9c**, **9f**, and **9g**). However, the reaction of 1-arylethanols (**7k** and **7l**) gave α-chlorinated ketones (**14** and **15**) along with an aryl methyl ketone (**9k**) and acetates (**8k** and **8l**) and seems to have a less synthetic value.

Gilmore and Mellor[10] have proposed that the potassium bromide-catalyzed oxidation of toluenes using manganese(III) acetate proceeds via radical intermediates. The reaction of norbornene with manganese(III) acetate–$CaCl_2$ gave no rearranged products, suggesting that the radical process is conceivable.[2] However, it is known that the reaction of manganese(III) acetate with aromatic compounds having relatively lower ionization potentials readily takes place via an electron-transfer process.[8] It was found that the reaction of manganese(III) acetate–Cl^- gave a better yield of the aldehyde in the absence of Ac_2O, which normally facilitates a free-radical process; the addition of water has no appreciable effect on the product distribution. We also found that the presence of electron-donating groups in the aromatic rings changes the product distribution in favor of ketonic compounds, as can be seen in the cases of **6a** and **6d**; also, methyl (4-methoxyphenyl)acetate (**6i**) yielded α-acetoxy ester (**8i**) and methyl (4-methoxyphenyl)-glyoxylate (**9i**), while ethyl phenylacetate, which may have a higher ionization potential than **6i**, was totally unreactive.[4] These facts suggest that the reaction of aromatic substrates of lower ionization potentials may proceed via an electron-transfer mechanism (path A in Scheme 1), although the mechanism need not to be operating in all reactions. The benzyl radical (B), once formed, is further oxidized to the benzyl cation (C), as shown in Scheme 1. The benzyl cation (C) is then combined with a chloride ion, acetate ion, and water molecule to give chloro derivatives, acetates, and alcohols, respectively. The substitution of the benzylic chlorine by an acetate ion should be very fast to give the acetate. Although it has been reported that methyl-substituted benzyl acetate is less reactive towards



Scheme 1.

manganese(III) acetate than methoxytoluene,[8] the acetates in the reactions can still be oxidized in a similar process to give carbonyl componds. In harmony with the above-mentioned mechanism, 4-methoxybenzyl chloride was readily converted to 4-methoxybenzyl acetate (**2a**, 77%) through a treatment with manganese(II) acetate in AcOH at 100 °C for 50 min; in turn, **2a** was converted to **3a** (45%) by oxidation with the manganese(III) acetate-Cl^- complex at 100 °C in 9 h. A direct oxidation of the benzyl alcohols to the carbonyl compounds is indicated by its faster reaction time (0.8 h at 100 °C) than methyl and methylenes. The route from benzyl chloride to the carbonyl compounds could not be ruled out.

Conclusion

Aldehydes and ketones have been obtained in minor quantities in the reaction of alkylarenes with manganese(III) acetate. We found that when a large excess of the manganese(III) acetate-Cl^- complex is used, the aldehydes and ketones become the major product. Moreover, the primary and secondary benzyl alcohols give the corresponding carbonyl compounds in excellent yields. Sulfoxide and phosphine oxide are also prepared by the reaction of the complex. These reactions can be useful in organic syntheses.

Experimental

Measurements. All of the ^1H NMR spectra (60 MHz) were taken with a Hitachi Perkin-Elmer R-24 and a JMN PMX-60SI NMR spectrometer with tetramethylsilane as the internal standard. The IR spectra were measured in chloroform solutions on a JASCO A-102 IR spectrometer. The mass spectra were obtained on a JMS-O1SG-2 instrument. The melting points were determined with a Yanagimoto micromelting point apparatus and were not corrected.

Materials. Methoxytoluenes (**1a—c**), xanthene (**6a**), diphenylmethanes (**6c** and **6d**), fluorene (**6g**) were obtained from the corresponding aldehydes and ketones by Wolff-Kischner reduction.[11] Methylnaphthalenes (**1d** and **1e**), anthrone (**6b**), acenaphthene (**6h**), and triphenylphosphine (**20**) were commercially available from Wako Pure Chemical Industories. Diphenyl sulfide (**17a**) and dibenzothiophene (**17b**) were purchased from Tokyo Kasei Co., Ltd. Methyl (4-methoxyphenyl)acetate (**6i**) was prepared from the acid by esterification. Primary and secondary alcohols (**4a**, **4b**, **7c**, **7e—g**, and **7j—k**) were prepared by the sodium borohydride reduction[12] of the corresponding aldehydes and ketones.

Reactions of Manganese(III) Acetate in the Presence of Chloride Ions. The typical procedure for the oxidation of manganese(III) acetate in the presence of chloride ions is as follows. To a heated solution of manganese(III) acetate, $[Mn_3O(OAc)_6(OAc)(HOAc)]\cdot 5H_2O$,[13] (3—4 milliequivalents for Mn(III)) and Cl^- (10 mmol) in AcOH a substrate (1 mmol) was added. The mixture was then heated under reflux until the dark-brown color turned opaque white. The reaction mixture was diluted with water (60 cm^3) and then extracted with benzene (30 cm^3) twice. The combined benzene solution was washed with aqueous sodium hydrogencarbonate solution and then evaporated in vacuo. The resulting products were purified on TLC with either benzene or chloroform as the eluting solvent, and recrystallized or distilled. The yields are summarized in Tables 1 and 2. The structures of the products were determined by means of IR, ^1H NMR, and mass spectra. Known compounds were also identified by comparisons of their melting points with those reported in the literature and with authentic samples.

4-Methoxybenzyl Acetate (2a) from 4-Methoxybenzyl Chloride. A mixture of 4-methoxybenzyl chloride (1 mmol), manganese(II) acetate tetrahydrate (8 mmol), and lithium chloride (10 mmol) in acetic acid (25 cm^3) was heated at 100 °C for 50 min. After working up in a manner similar to that for the above, 4-methoxybenzyl acetate (**2a**) was obtained in 77% yield.

Oxidation of 4-Methoxybenzyl Acetate (2a) with Manganese(III)-Cl^-. A mixture of 4-methoxybenzyl acetate (**2a**) (1 mmol), manganese(III) acetate (2 mmol), lithium chloride (10 mmol) in acetic acid (25 cm^3) was heated at 100 °C for 9 h. After working up in a manner similar to that mentioned above, the resulting mixture was chromatographed on TLC with chloroform as the eluting solvent to give 4-methoxybenzaldehyde (**3a**) (45%) and *p*-anisic acid (5%) with 4% recovery of **2a**.

We wish to thank Professor Hitoshi Takeshita and Associate Professor Akira Mori of the Research Institute of Industorial Science, Kyushu University for their kind arrangement for measuring mass spectra.

The β-Sheet Structure-Stabilizing Potential of Twenty Kinds of Amino Acid Residues in Protected Peptides[1)]

Mitsuaki NARITA* and Yoshihisa KOJIMA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received June 14, 1989)

A host-guest approach was devised to investigate the β-sheet structure-stabilizing potential of the 20 common amino acid residues in protected peptides where functional groups in side chains were protected by suitable groups commonly used in peptide synthesis. The potential was evaluated using solvent-titration curves for the disruption of the β-sheet structure of cross-linked polystyrene resin-bound host-guest hexa- and octapeptides in CH_2Cl_2 by HFIP. The β-sheet structure of host-guest hexapeptides, Boc-Val-Ile-X_2-Val-Ile-$NHCH_2$-resins, in which X stands for guest amino acid residues, was disrupted in CH_2Cl_2 by adding increasing amounts of HFIP; the disrupted behaviors were strongly dependent on the nature of guest amino acid residues. A scale for the β-sheet structure-stabilizing potential of the 20 kinds of amino acid residues in CH_2Cl_2 could be derived at 0.25 M of HFIP concentration as follows: Ile, Val ≫ Asn > His(Tos) or His, Gln, Cys(Bzl), Tyr(Bzl) > Phe, Gly, Lys(Z), Arg(Tos), Leu > Thr(Bzl), Ala, Met(O), Glu(OBzl), Trp(CHO) ≫ Ser(Bzl), Asp(OBzl) ≫ Pro. To confirm the scale, their β-sheet structure-stabilizing potential was further examined using host-guest octapeptides, Boc-X_2-Val-Ile-X_2-Val-Ile-$NHCH_2$-resins. The disrupted behaviors of the octapeptides having Gly, Ala, and Thr(Bzl) residues as guests were remarkably different from those of the corresponding hexapeptides; the β-sheet structure-stabilizing potential of the Gly, Ala, and Thr(Bzl) residues became significantly high with an increase in their ratios to host residues. The potential of the Gly, Ala, and Thr(Bzl) residues appears to reflect the ratios of guest amino acid residues to hosts, the repeated sequence, and/or neighbor interactions in the sequence. The significance of the present study in the design of synthetic routes for peptides and proteins is briefly discussed.

One of the most serious obstacles in peptide and protein syntheses is the insolubility of protected peptides in organic solvents, which causes difficulty in successive reactions. In previous papers[2,3)] we proposed a predictive method for the solubility of protected peptides in the highly polar solvents commonly used in peptide synthesis and showed its usefulness for the design of synthetic routes for peptides and proteins. In the method we assumed that the insolubility of protected peptides was caused by a β-sheet aggregation consisting of peptide segments, i.e., sequence units separated by tertiary peptide bonds,[2,4)] as long as or larger than an octa- or nonapeptide sequence and that the β-sheet structure-forming potential of peptide segments was estimated using their average coil conformation $\langle P_c \rangle$ values when a peptide segment is smaller than the critical chain length for the development of a stable helix in the solid state. In the solubility prediction for protected peptides,[2)] the $\langle P_c \rangle$ value was practically not used for a peptide segment but was used for a whole peptide; the adequacy of the above assumption was widely confirmed by the application of the solubility prediction method to various kinds of oligopeptides.[2-8)] Here, the $\langle P_c \rangle$ value of a protected peptide is defined as an arithmetic average of coil conformational parameters, P_c, of the amino acid residues composing the protected peptide. As mentioned in a previous paper,[9)] $\langle P_c \rangle$ values of protected peptides must reflect their β-sheet structure-forming potential because the P_c parameters were determined on the basis of three-dimensional structures of 29 kinds of native globular proteins[2)] and must reflect the nature of the 20 kinds of amino acid residues in native globular proteins. However, it should be emphasized that the P_c parameters are not for the 20 kinds of amino acid residues in protected peptides but for those in native globular proteins. Thus, for the solubility prediction of protected peptides in organic solvents, it is essentially important to evaluate the P_c parameters for the 20 kinds of amino acid residues in protected peptides in organic solvents. Especially, the P_c parameters for amino acid residues having functional groups in side chains should be determined for side chains-protected amino acid residues.

For the solubility prediction of protected peptides, it is also important to evaluate their helix-forming potential when they are at a sufficient peptide chain length for the development of a stable helix in the solid state, since their β-sheet → helix conformational transformation results in a remarkable solubility improvement.[6,10)] In previous papers[9,11,12)] we showed that the average helix and β-sheet conformation values, $\langle P_\alpha \rangle$ and $\langle P_\beta \rangle$, of protected peptides are useful for estimating their potential for the β-sheet → helix transformation with an increasing peptide chain length or with an application of strong shear stress. Again, $\langle P_\alpha \rangle$ and $\langle P_\beta \rangle$ values of protected peptides are defined as arithmetic averages of the helix and β-sheet conformational parameters (P_α and P_β) of the amino acid residues composing them, respectively, which are determined by Chou and Fasman on the basis of three-dimensional structures of 15 kinds of native globular proteins.[13)] It should again be

emphasized that, for the solubility prediction of protected peptides, it is essentially important to evaluate the conformational parameters (P_α and P_β) for the 20 kinds of amino acid residues in protected peptides where functional groups in side chains are protected by suitable groups commonly used in peptide synthesis.

In a recent study[9,14,15] we found that a β-sheet structure of a variety of resin-bound peptides was easily disrupted by adding increasing amounts of HFIP and that the stability of the β-sheet structure was strongly dependent on the amino acid composition of protected peptides. The result suggests that the investigation into the disruption of the β-sheet structure of resin-bound host-guest peptides by HFIP makes it possible to evaluate the β-sheet structure-stabilizing potential of guest amino acid residues in protected peptides. A host-guest approach was introduced by Mutter and coworkers[16] to explore the relationship between the sequence and the secondary structure of protected peptides; it was shown to be useful for the evaluation of the conformational preference of guest amino acid residues in host-guest peptides. Thus, in the present study, the cross-linked polystyrene resin-bound host-guest peptides are designed to be suitable for the evaluation of the β-sheet structure-stabilizing potential of the 20 kinds of guest amino acid residues in protected peptides in CH_2Cl_2. The designed host-guest peptides have a sequence of Boc-Val-Ile-X_2-Val-Ile-$NHCH_2$-resin and Boc-X_2-Val-Ile-X_2-Val-Ile-$NHCH_2$-resin, in which X stands for guest amino acid residues as follows: Ala, Arg(Tos), Asn, Asp(OBzl), Cys(Bzl), Gln, Glu(OBzl), Gly, His(Tos) or His, Ile, Leu, Lys(Z), Met(O), Phe, Ser(Bzl), Thr(Bzl), Trp(CHO), Tyr(Bzl), and Val.

Experimental

Materials. Copoly(styrene-1% divinylbenzene) beads of 200—400 mesh, Bio-Beads S-Xl, were purchased from Bio-Rad Laboratories. The aminomethylation was carried out according to a method described in the literature.[17] The aminomethyl content was 66 μmol g^{-1} of resin. The synthesis of the host-guest peptide resins was performed in CH_2Cl_2 substantially according to the general procedures described previously.[12] For the assembly of host-guest peptides, Boc-Val-Ile-OH and Boc-X-OH were used as carboxyl components and the coupling reactions were carried out using DCC and HOBt as coupling reagents.[18] After a double coupling reaction, the completion of the reaction was checked by a ninhydrin test. When the test was positive, a small amount of HFIP (5 vol% to CH_2Cl_2) was added and the reaction was continued an additional day. When the test was still positive, a triple coupling reaction was performed to force the coupling reaction to completion. A termination reaction using pyridine and acetic anhydride was not performed. Acid hydrolyses of host-guest peptide resins were carried out with propionic acid /12 M HCl (2/1 v/v) (1 M=1 mol dm^{-3}) at 115 °C for 10 days.[19] The amino acid ratios except for Ser, Thr, and Trp residues of acid hydrolysates were in agreement with the calculated values. Acid hydrolyses host-guest peptide resins having Ser(Bzl), Thr(Bzl), and Trp(CHO) residues as guests were examined with propionic acid/3 M TosOH (2/1 v/v) at 115 °C for 10 days;[20] however, they did not proceed sufficiently.

IR Absorption Spectra Measurements. The IR absorption spectra of resin-bound peptides were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer. IR measurements in the swollen state were performed by holding the samples between potassium bromide windows after resin-bound peptides were swollen in CH_2Cl_2 containing a variety of molar concentrations of HFIP.

Results

The host-guest hexa- and octapeptides were prepared by a general procedure[12] and the addition of HFIP in a coupling reaction in CH_2Cl_2 was significantly effective for its completion. The IR absorption spectra of the resin-bound host-guest hexa- and octapeptides swollen in CH_2Cl_2 alone showed strong bands around 3280 cm^{-1} in the amide A region and around 1630 cm^{-1}

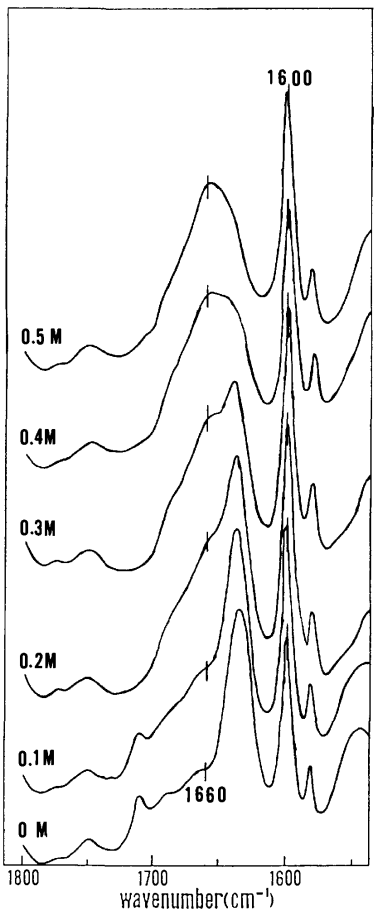

Fig. 1. IR absorption spectra of a resin-bound host-guest hexapeptide (X=Phe) in CH_2Cl_2 containing a variety of molar concentrations of HFIP. The numerals in Fig. 1 indicate molar concentrations of HFIP.

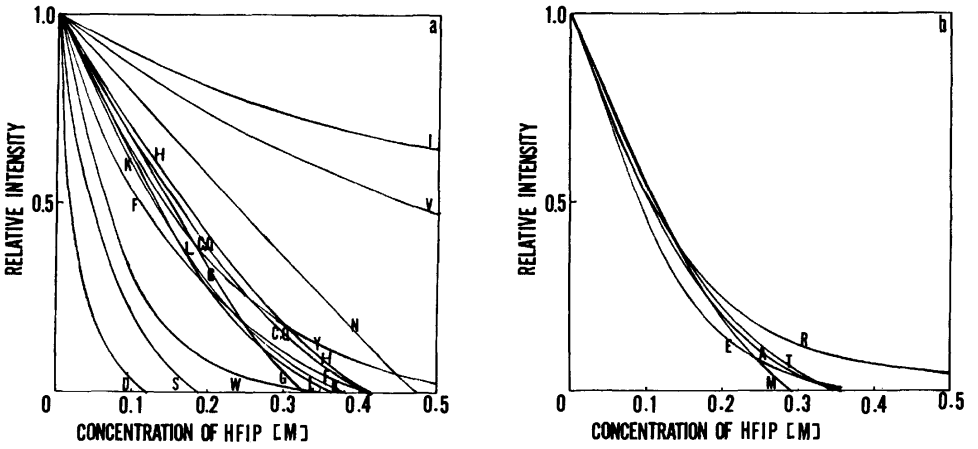

Fig. 2. The solvent-titration curves of resin-bound hexapeptides in CH_2Cl_2 using HFIP as a titrating solvent. A guest amino acid residue for each titration curve is shown in Fig. 2 using a one-letter symbol.[23] a: I=Ile, V=Val, N=Asn, H=His(Tos) or His, C=Cys(Bzl), Q=Gln, Y=Tyr(Bzl), F=Phe, K=Lys(Z), L=Leu, G=Gly, W=Trp(CHO), S=Ser(Bzl), and D=Asp(OBzl) and b: R=Arg(Tos), T=Thr(Bzl), A=Ala, M=Met(O), and E=Glu(OBzl).

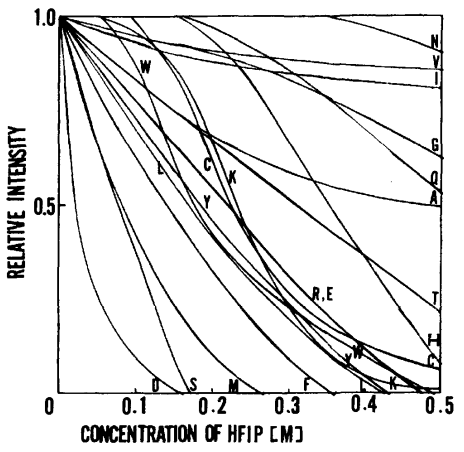

Fig. 3. The solvent-titration curves of resin-bound octapeptides in CH_2Cl_2 using HFIP as a titrating solvent. A guest amino acid residue for each titration curve is shown in Fig. 3 using a one-letter symbol.[23]

in the amide I region, assigned to a β-sheet structure,[12,21] and were accompanied with a weak band around 1660 cm^{-1} (Fig. 1, 0 M), probably assigned to an unordered structure. The disruption of the β-sheet structure by HFIP was investigated using a solvent titration method.[22] It was monitored by a successive decrease in the intensity of the band around 1630 cm^{-1}, together with a successive addition of HFIP. Figure 1 shows the typical IR absorption spectra of resin-bound host-guest hexapeptide (X=Phe) in CH_2Cl_2 containing a variety of molar concentrations of HFIP. The solvent-titration curves of the resin-bound host-guest hexa- and octapeptides in CH_2Cl_2 using HFIP as a titrating solvent are depicted in Figs. 2 and 3, respectively. The relative intensities of the bands around 1630 cm^{-1} shown in Figs. 2 and 3 were obtained using the band at 1603 cm^{-1} due to the aromatic ring of a polystyrene resin support as a standard and were normalized to be 1.0 for each relative intensity in CH_2Cl_2 alone. The relative intensities before the normalization reflected the difference in the intensities of 1660 cm^{-1}-band of host-guest peptide resins and dereased together with an increase in the intensities of the 1660 cm^{-1}-band, indicating the β-sheet structure-forming potential of guest amino acid residues in the resin-bound host-guest peptides. As shown in Figs. 2 and 3, a successive addition of HFIP induced a dramatic decrease in the strong band around 1630 cm^{-1} and an increase in the broad band around 1660 cm^{-1}, indicating that the β-sheet aggregation of the resin-bound hexa- and octapeptides was easily disrupted by increasing the amounts of HFIP.

Discussion

For the evaluation of the β-sheet structure-stabilizing potential of guest amino acid residues in resin-bound host-guest peptides, the completion of a coupling reaction is indispensable at each peptide chain elongation, and the addition of HFIP in a coupling reaction was significantly effective for the quantitative reaction due to the strong β-sheet structure-disrupting potential of HFIP. For the assembly of host-guest peptides, DCC and HOBt were used as coupling reagents. Thus, it is uncertain for the His(Tos) residue to be incorporated in host-guest peptides as a His(Tos) or a His residue since the protecting Tos group for the His residue may be removed by HOBt under the reaction condition.[24] Host-guest peptide resins must also be designed to be

suitable for the evaluation of the β-sheet structure-stabilizing potential of guest amino acid residues. C^{β}-Branched Ile and Val residues are expected to stabilize the β-sheet structure of peptides,[9,13] and the sequence of Ile–X_2–Val resists helix formation due to the repulsion between Ile and Val residues in a helix.[11,14] Thus, host-guest peptides having the sequences of –Val–Ile–X_2–Val–Ile– and –X_2–Val–Ile–X_2–Val–Ile– are suitable for an evaluation of the β-sheet structure-stabilizing potential of guest amino acid residues. In fact, as shown in Fig. 2, the β-sheet structure-disrupted behaviors of resin-bound hexapeptides by HFIP were strongly dependent on the nature of guest amino acid residues. The scale for the β-sheet structure-stabilizing potential of the 20 kinds of guest amino acid residues in hexapeptides can be derived at 0.25 M of the HFIP concentration as follows:

Ile, Val≫Asn>His(Tos) or His, Gln, Cys(Bzl), Tyr(Bzl)>Phe, Gly, Lys(Z), Arg(Tos), Leu>Thr(Bzl), Ala, Met(O), Glu(OBzl), Trp(CHO)≫Ser(Bzl), Asp(OBzl)≫Pro.

The conformational behavior of peptide resins having Pro residues as guests is expected to be different from that of any other one due to the absence of an N–H bond in the Pro residue in peptides;[2,4,15,25] it is obvious that a Pro residue has the lowest β-sheet structure-stabilizing potential in the 20 kinds of amino acid residues. A scale for the β-sheet structure-stabilizing potential of the 20 kinds of guest amino acid residues in octapeptides (Fig. 3) can also be derived at 0.25 M of the HFIP concentration as follows:

Asn, Gln, Val, Ile, Gly, His(Tos) or His≫Ala, Thr(Bzl)≫Glu(OBzl), Arg(Tos), Lys(Z), Cys(Bzl), Tyr(Bzl), Trp(CHO), Leu, Phe≫Met(O), Ser(Bzl), Asp(OBzl)≫Pro.

The disrupted behaviors of the octapeptides having Gly, Ala, and Thr(Bzl) residues as guests are remarkably different from those of the corresponding hexapeptides, and the β-sheet structure-stabilizing potential of the Gly, Ala, and Thr(Bzl) residues becomes significantly high with an increase in their ratios to host residues. The potential appears to reflect the ratios of guest amino acid residues to hosts, the repeated sequence, and/or neighbor interactions in the sequence strongly. The Asn, Gln, and His(Tos) residues in octapeptides also have the same tendency that they stabilize the β-sheet structure of octapeptides.

Here, it is interesting to compare the scale for the β-sheet structure-stabilizing potential of guest amino acid residues in the hexapeptides with the β-sheet structure conformational parameters, P_{β}, obtained by Chou and Fasman,[13] although the media supporting peptide conformations are different from each other (the former, CH_2Cl_2 and the latter, water). The order of the P_{β} parameters is as follows: Met (1.67), Val (1.65), Ile (1.60)≫Cys (1.30), Tyr (1.29), Phe (1.28)>Gln (1.23), Leu (1.22), Thr (1.20), Trp (1.19)≫Ala (0.97), Arg (0.90)>Gly (0.81), Asp (0.80)>Lys (0.74), Ser (0.72), His (0.71), Asn (0.65), Pro (0.62)≫Glu (0.26). For Met(O), Trp(CHO), Arg(Tos), Gly, Lys(Z), His(Tos), Asn, and Glu(OBzl) residues, the former is remarkably different from the latter. Especially, Met(O), Trp(CHO), Arg(Tos), Lys(Z), and Glu(OBzl) residues strongly reflect the influence of their protecting groups and/or media supporting conformations on their β-sheet structure-stabilizing potential. The side-chain protection of Arg, Lys, and Glu residues stabilizes the β-sheet structure of host-guest peptides, while that of Met and Trp residues destabilizes it. Considering the easy disruption of the β-sheet structure of Boc–Val–Gly–Phe–Gly–Leu–Ile–Leu_2–OBzl[26] and Boc–(Val–Gly–Phe–Gly–Leu–Ile–Leu_2)$_n$–Ala–$NHCH_2$–resin (n=1, 2, and 3)[14] by HFIP, the Gly residue in the host-guest hexapeptide appears to reflect the influence of the sequence. It may have a much less stabilizing potential. For Val, Ile, Cys(Bzl), Tyr(Bzl), Phe, Gln, Leu, Thr(Bzl), Ala, Asp(OBzl), and Ser(Bzl) residues, the former is in fair accordance with the latter. As discussed in a previous paper,[9] the P_{β} parameters are assumed to reflect the nature for the β-sheet structure-stabilizing potential of the 20 kinds of corded amino acid residues in native globular proteins. On the other hand, the relative intensities of the 1630 cm^{-1}-band to the 1603 cm^{-1}-band of the host-guest hexapeptides in CH_2Cl_2 alone (data not shown) are assumed to reflect the β-sheet structure-forming potential of the 20 kinds of guest amino acid residues in protected peptides in CH_2Cl_2. A scale for the β-sheet structure-forming potential in the hexapeptides in CH_2Cl_2 alone can be derived: Arg(Tos)>Lys(Z)>Cys(Bzl)>Ile, Val, Leu>Ala, Met(O), Trp(CHO)>Glu(OBzl), Thr(Bzl)>Gly, His(Tos) or His, Phe, Tyr(Bzl)>Gln, Asn>Asp(OBzl), Ser(Bzl). Clearly, the β-sheet structure-forming potential is different from the β-sheet structure-stabilizing potential, and the forming potential of Arg(Tos), Lys(Z), and Cys(Bzl) residues is larger than that of Ile and Val residues.

For the design of synthetic routes for peptides and proteins, an estimation of the β-sheet structure-disrupted behaviors of protected peptides in organic solvents is essentially important since the insolubility of protected peptides due to the β-sheet aggregation causes difficulty in successive reactions. The present study shows that the β-sheet structure-disrupted behaviors of protected peptides are strongly dependent on the nature of amino acid residues composing protected peptides. In previous papers[9,14,15,26] we also demonstrated that the β-sheet structure-disruption by organic solvents is strongly dependent on their electron-acceptor numbers (AN) and electron-donor numbers (DN) and that solvents having large AN or DN values have high potential for the β-sheet structure-disruption. Thus, the scale for the β-sheet

structure-stabilizing potential of the 20 kinds of amino acid residues as well as the β-sheet structure-disrupting potential of solvents is useful for an estimation of the β-sheet structure-disrupted behaviors of protected peptides in organic solvents.

Peptide Segment Separation by Tertiary Peptide Bonds.[1] Synthesis and Conformational Analysis of Cross-Linked Polystyrene Resin-Bound Human Proinsulin C-Peptide Fragments

Mitsuaki NARITA,* Hiroshi UMEYAMA, and Toshihiko YOSHIDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received June 5, 1989)

In order to clarify the role of tertiary peptide bonds in the conformational development of protected peptides in organic solvents, cross-linked polystyrene resin-bound human proinsulin C-peptide fragments were prepared by a fragment condensation method. For the purpose of clarifying the role of tertiary peptide bonds, it is indispensable to force coupling reactions to completion; the addition of HFIP in coupling reactions in CH_2Cl_2 was significantly effective for their completion when they did not proceed smoothly. The conformational behavior of resin-bound human proinsulin C-peptide fragments in CH_2Cl_2 was successively investigated using IR absorption spectroscopy. Two Pro residues forming tertiary peptide bonds played the role of stopping the development of helix and β-sheet structures in peptides, and the structure of N- and C-termini- and side-chain-protected human proinsulin C-peptide could be regarded as being assembled with peptide segment structures separated by the two Pro residues. When a peptide segment had a high helix-forming potential, a Pro residue in an N-terminal part of the peptide segment promoted its helix formation. β-Sheet structures formed by peptide segments in CH_2Cl_2 were easily disrupted by a strong electron-acceptor solvent of HFIP, suggesting that the β-sheet structure disruption of resin-bound peptides is important in achieving efficient coupling reactions.

In peptide and protein syntheses, sufficient solvation of a peptide chain is indispensable to achieve a coupling reaction quantitatively. As one means to accomplish sufficient solvation, we proposed "peptide segment separation by tertiary peptide bonds."[2] In fact, a tertiary peptide bond at a central position of peptide chains (Fig. 1) helps the sufficient solvation and remarkably improves peptide solubility. On the X–Pro and X–(Z)Y bonds in Fig. 1, X and Y are arbitrary amino acid residues and Z designates a suitable protecting group for the X–Y peptide bond,

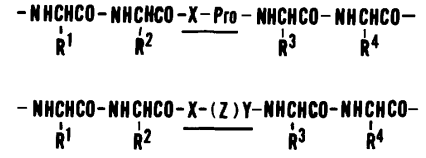

Fig. 1. Insertion of tertiary peptide bonds [X–Pro and X–(Z)Y] into central positions of peptide chains. An explanatory note for X, Y, and Z, see in the text.

which can be removed under certain conditions. Sufficient solvation and solubility improvements have been exactly attributed to the separation and disturbance of a β-sheet structure by rotation, due to a steric hindrance, of the tertiary peptide bond plane.

Here, it is significant to clarify the role of Pro and (Z)Y residues in the conformational development of protected peptides in organic solvents since the conformation of a peptide chain is closely related to sufficient solvation.[3–5] Although the prediction of conformations of protected peptides in organic solvents has been difficult so far, it is important in order to design synthetic routes for peptides and proteins without insolubility problems.[3] A Pro residue is well-recognized as being a strong helix and β-sheet breaker and plays the role in stopping the development of helix and β-sheet structures in native globular proteins.[6,7] Thus, tertiary peptide bonds formed by Pro and (Z)Y residues in protected peptides play the role of separating a peptide structure into various peptide segment structures. Namely, a peptide struc-

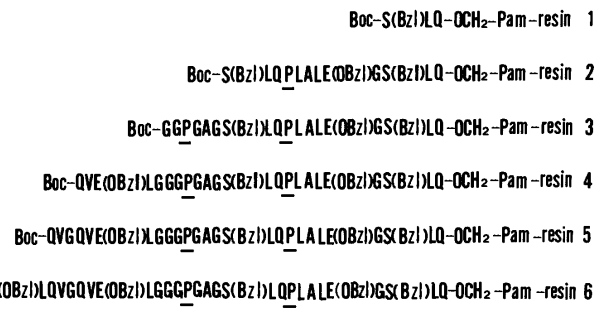

Fig. 2. Resin-bound human proinsulin C-peptide fragments **1**—**6** used in this study.

ture is regarded as being assembled with some of peptide segment structures separated by Pro and (Z)Y residues. We called the role "peptide segment separation by tertiary peptide bonds."[2]

In this study, we prepared resin-bound human proinsulin C-peptide fragments (Fig. 2) and examined their IR absorption spectroscopies in CH_2Cl_2 in order to demonstrate the role of Pro residues in the conformational development of protected peptides in CH_2Cl_2. In connection with efficient coupling reactions in solid-phase peptide synthesis by a fragment condensation procedure, we also investigated the disruption of the β-sheet structure of resin-bound human proinsulin C-peptide fragments in CH_2Cl_2 by the addition of a strong electron-acceptor solvent of HFIP.

Experimental

Materials. Copoly(styrene-1% divinylbenzene) beads of 200—400 mesh, Bio-Beads S-X1, were purchased from Bio-Rad Laboratories. The aminomethylation was carried out according to the method described previously.[8] Human proinsulin C-peptide fragments, Boc-Ser(Bzl)-Leu-Gln-Pro-Leu-Ala-Leu-Glu(OBzl)-Gly-OH, Boc-Gly-Gly-Pro-Gly-Ala-Gly-OH, Boc-Gln-Val-Glu(OBzl)-Leu-Gly-OH, Boc-Gln-Val-Gly-OH, and Boc-Glu(OBzl)-Ala-Glu(OBzl)-Asp(OBzl)-Leu-OH, were prepared before.[9] Boc-Ser(Bzl)-Leu-Gln-*p*-(oxymethyl)phenylacetic acid was obtained by hydrolysis of its trityl ester in a mixture of acetic acid, water, and methanol (5:1:4). The assembly of the peptide fragments was performed in CH_2Cl_2, substantially, according to the general procedures described previously.[10] The coupling reactions were carried out for 1 day using 3 equiv of carboxyl components, DCC, and HOBt, respectively. In the cycle for the peptide chain elongation, no termination reaction using pyridine and acetic anhydride was performed. Each coupling step was tested for completion by a ninhydrin test. When a test was positive after a double coupling reaction, a small amount of HFIP (2 vol% to CH_2Cl_2) was added, and the reaction was continued until the test became negative. Acid hydrolyses of the resin-bound peptides were performed with propionic acid/3 M (1 M=1 mol dm^{-3}) *p*-toluenesulfonic acid[11] (2/1, v/v) at 115 °C for 3 days. Amino acid analyses of the acid hydrolysates showed that the mole ratios of the component amino acid were close to the calculated values (Table 1).

IR Measurements. The IR absorption spectra of resin-bound peptides were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer. IR measurements in the swollen state were performed by holding the samples between potassium bromide windows after resin-bound peptides were swollen in CH_2Cl_2 or in CH_2Cl_2 containing HFIP at 0.1 M.

Results

Syntheses of Cross-Linked Polystyrene Resin-Bound Human Proinsulin C-Peptide. The copoly(styrene-1% divinylbenzene) resin support (Bio-Beads S-X1), used as a starting resin bead, has commonly been used for solid-phase peptide synthesis and the aminomethylated form is expected to have a uniform distribution of aminomethyl groups, based on the reaction mechanism of aminomethylation.[8] The aminomethyl content (76 μmol g^{-1} of resin) was selected in order to obtain rational information regarding the conformational development of peptide chains in the conventional solid-phase method.[12] The carboxyl component peptides were easily soluble in CH_2Cl_2 and were successively coupled with the aminomethylated polystyrene resin in CH_2Cl_2 using DCC and HOBt as coupling reagents.[13] In the preparation of resin-bound peptides **1**—**3**, coulping reactions proceeded smoothly without the addition of HFIP. On the other hand, in the preparation of peptides **4**—**6**, coupling reactions did not proceed smoothly, even at a double coupling reaction, and a ninhydrin test was positive at this stage. The addition of HFIP at this stage[14] was marvelously effective in forcing coupling reactions to completion and a ninhydrin test became negative while the reaction was continued for 24 h.

Conformations of Resin-Bound Human Proinsulin C-Peptide Fragments in CH_2Cl_2. The IR absorption spectra of resin-bound peptides **1**—**6** swollen in CH_2Cl_2 are presented in Fig. 3 in the most significant spectral regions for conformational assignments (3500—3100 cm^{-1}, amide A; 1800—1600 cm^{-1}, amide I). The results indicate the following: (1) resin-bound tripeptide **1** exhibits an unordered structure, characterized by appearance of medium and strong bands at 3425 and 1675 cm^{-1};[10,15] (2) resin-bound dodeca- and octadecapeptides **2** and **3** seem to form a helical structure, assigned by the appearance of medium and strong bands around 3310 and 1660 cm^{-1}, respectively,[10,15] accompanied by a small amount of a β-sheet structure, asigned by the appearance of a weak shoulder band at 1628 cm^{-1};[10,15] and (3) resin-bound tricosa-, hexacosa-, and hentriacontapeptides **4**, **5**, and

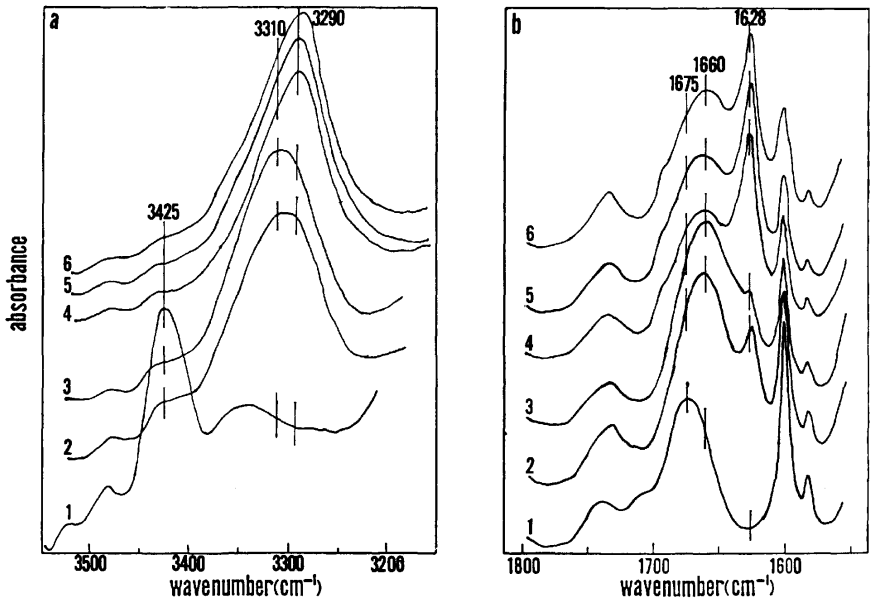

Fig. 3. IR absorption spectra (a) in the amide A and (b) in the amide I regions of resin-bound peptides **1**—**6** swollen in CH_2Cl_2. The absorption band at 1603 cm^{-1} is due to aromatic rings of the polystyrene support.

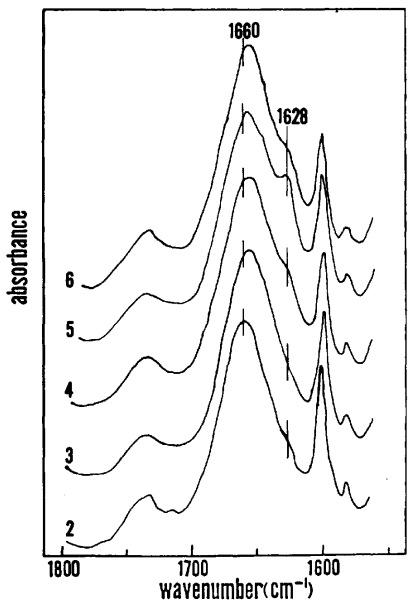

Fig. 4. IR absorption spectra in the amide I region of resin-bound peptides **2**—**6** swollen in CH_2Cl_2 containing HFIP at 0.1 M.

6 appear to have both helical and β-sheet structures, characterized by appearance of bands at 3310, 3290, 1660, and 1628 cm^{-1}, respectively.

In order to elucidate the role of HFIP in efficient coupling reactions in the solid-phase synthesis of human proinsulin C-peptide, conformational analysis of resin-bound peptides **2**—**6** in CH_2Cl_2 containing HFIP at 0.1 M was also performed using IR absorption spectroscopies (Fig. 4). The results showed that the β-sheet structure of resin-bound peptides **2**—**6** was sufficiently disrupted by a strong electron-acceptor solvent of HFIP, even at a low concentration of HFIP.

Discussion

The synthetic results of cross-linked polystyrene resin-bound human proinsulin C-peptide fragments clearly indicated that the addition of HFIP effectively forced coupling reactions in CH_2Cl_2 to completion due to the strong β-sheet structure-disrupting potential of HFIP.[16] Although solid-phase peptide synthesis using a fragment condensation procedure has been expected to be valuable for the synthesis of large peptides and proteins,[17] heterogeneous reaction conditions cause the formation of deletion and truncated sequences, and a drastic decrease in the coupling yields has been a serious obstacle.[18] In previous papers[19] we pointed out that the onset of a β-sheet aggregation by hydrogen bonding among pendant peptide chains brought about an additional cross-linking of the polymer network and that the coupling efficiencies of carboxyl component peptides with pendant peptides were remarkably decreased due to a restriction of their permeability into pendant peptides. The synthetic result, conformational analysis, and β-sheet-structure-disrupted behavior of resin-bound human proinsulin C-peptide fragments clearly indicate that the disruption of their β-sheet structures by the addition of HFIP is effective for the completion of coupling reactions in solid-phase peptide synthesis by a fragment condensation procedure and overcomes the serious obstacle of the drastic decrease in coupling yields.

Conformational analysis of resin-bound peptide **1**—**6** in CH_2Cl_2 also indicates that the concept of "the

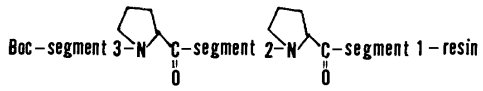

Fig. 5. The separation of human proinsulin C-peptide into three peptide segments by two Pro residues.

peptide segment separation by tertiary peptide bonds" is useful for estimating the conformational development of protected peptides in organic solvents, which is important for designing synthetic routes for peptides and proteins.[3] For example, the conformational behavior of peptides **4**—**6** suggests that the conformations of peptides **4**—**6** can be regarded as being assembled with three peptide segments separated by the two Pro residues (Fig. 5). With respect to conformations of peptides **4**—**6**, most parts of segment 1 and a part of segment 2, namely, Ser(Bzl)-Leu-Gln, are estimated to form a relatively stable helix, and N-terminal segments 3 of peptides **4**—**6** appear to form a relatively stable β-sheet structure although the conformation of segment 2 is not clear. These estimations were actually confirmed by conformational analyses of peptides **2** and **3**. The conformational behavior of resin-bound peptide **2** resembled that of Boc-Ser(Bzl)-Leu-Gln-Pro-Leu-Ala-Leu-Glu(OBzl)-Gly-OPac, which has a helical structure in CH_2Cl_2.[20] In the conformational development of peptide **2**, the Pro residue of resin-bound peptide **2** effectively suppresses the β-sheet formation of the octapeptide segment, Leu-Ala-Leu-Glu(OBzl)-Gly-Ser(Bzl)-Leu-Gln, due to the restriction of the backbone dihedral angles ϕ and ψ of a Pro residue,[4,5,21] and promotes its helix formation due to both the restriction of the backbone dihedral angles ϕ and ψ of a Pro residue[4,5] and the high helix-forming potential of peptide **2**.[20,22] For a prediction of the conformations of protected peptides in organic solvents, we have tentatively used the average helix, β-sheet, and coil conformation values, $<P_\alpha>$, $<P_\beta>$, and $<P_c>$,[3,20,23] which are determined by their amino acid compositions,[6] and demonstrated their validity. Practically, the $<P_\alpha>$ and $<P_\beta>$ values of segment 1 of peptides **2** are 1.06 and 0.92, respectively,[22] indicating the relatively high helix-forming potential of segment 1. The IR absorption spectrum of peptide **3** also shows little contribution of a β-sheet structure, indicating that the Pro residue of Boc-Gly-Gly-Pro-Gly-Ala-Gly- in resin-bound peptide **3** influentially distrurbs the onset of a β-sheet structure by the rotation of the tertiary peptide bond plane (Gly-Pro). A chain elongation of peptide **3** to peptide **4** appears to induce the onset of a β-sheet structure at the N-terminal segment 3 of peptide **4** and a further chain elongation of peptide **4** to peptide **5** seems to develop the β-sheet structure at N-terminal segment 3.[24] On the other hand, the β-sheet structure content of peptide **6** is lower than that of peptide **5**, probably due to the fact that peptide **6** is close to the critical chain length for a stable helix formation in CH_2Cl_2.

Due to the function that a Pro residue stops the development of helix and β-sheet structures in a peptide, conformational development at N-terminal segments 3 of peptides **4**—**6** in CH_2Cl_2 containing HFIP appears to occur regardless of segments 1 and 2. In the mixture, HFIP probably promotes a helical folding and/or a sufficient solvation of each peptide segment, depending on its conformational preference. The conformational development of protected peptides in organic solvents is strongly dependent on the nature of the organic solvents, especially their electron-donating and -accepting properties.[16] Thus, the disruption of the β-sheet structure of resin-bound peptides **2**—**6** by HFIP and by strong electron-donor solvents[22] suggests that the concept of "peptide segment separation by tertiary peptide bonds" is useful for estimating the conformational development of protected peptides in organic solvents having strong electron-donating and -accepting properties.

The Easy Disruption of the β-Sheet Structure of Resin-Bound Human Proinsulin C-Peptide Fragments by Strong Electron-Donor Solvents[1)]

Mitsuaki NARITA,* Hiroshi UMEYAMA, and Toshihiko YOSHIDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received June 5, 1989)

The β-sheet structure disruption of cross-linked polystyrene resin-bound human proinsulin C-peptide fragments containing Pro residues at suitable intervals was investigated by a solvent titration method in CH_2Cl_2, mainly using TFE and HMPA as titrating solvents. The easy disruption of the β-sheet structure of resin-bound peptides in CH_2Cl_2 by TFE and HMPA strongly suggested that the concept of "the peptide segment separation by tertiary peptide bonds" was useful for estimating the β-sheet-structure-disrupted behavior and that the β-sheet structure of the protected peptides having high $<P_c>$ values could easily be disrupted in a medium electron-acceptor solvent of CH_2Cl_2 by the addition of a strong electron-donor solvent of HMPA in spite of the electron donor-acceptor interaction between solvents. The present results indicate that effective solvents for solid-phase peptide synthesis by a fragment condensation procedure should be searched by taking the average helix, β-sheet, and coil conformation values, $<P_\alpha>$, $<P_\beta>$, and $<P_c>$, of peptide segments into consideration.

The β-sheet aggregation of protected peptides bound to a cross-linked polystyrene resin in the swollen state is one of the serious obstacles in solid-phase peptide synthesis because it reduces the efficient coupling reactions of the carboxyl component peptides with the pendant amino component peptides due to the restriction of the permeability of carboxyl components into pendant peptides.[2,3)] Thus, an investigation into the β-sheet structure disruption of resin-bound peptides is indispensable to achieve efficient coupling reactions. In previous studies[4,5)] we demonstrated that the β-sheet structure of resin-bound peptides as large as or larger than an octapeptide was disrupted in CH_2Cl_2 only by the addition of a strong electron-acceptor solvent of HFIP and that the disruption was strongly dependent on the electron-donating and -accepting properties[6,7)] of added solvents, peptide chain length, and average helix, β-sheet, and coil conformation values, $<P_\alpha>$, $<P_\beta>$, and $<P_c>$, of peptides. These values are determined on the basis of the three-dimensional structures of native proteins which were resolved by X-ray crystallography;[8,9)] they should be corrected for an estimation of the conformational behavior of protected peptides in organic solvents. Nevertheless, they were useful for the purpose of the estimation of the conformation.[4)] Practically, the β-sheet structure disruption of peptides having a $<P_c>$ value larger than 0.85 and/or a high potential for the β-sheet → helix transformation proceeded smoothly upon adding increasing amounts of HFIP; that of peptides having a low potential for the randomness as well as for the β-sheet → helix transformation did not.

Moreover, we found that the β-sheet structure disruption of cross-linked polystyrene resin-bound peptides was more difficult than that of peptides to be free from a macromolecular protecting group due to the concentrating efficacy of a cross-linked resin.[5)] As a result, the β-sheet structure of resin-bound peptides, which were as large as or larger than an octapeptide and had a $<P_c>$ value lower than 0.90, could not be disrupted by strong electron-acceptor solvents except for HFIP and by strong electron-donor solvents. This result was quite different from that of the corresponding peptides, which were free from a macromolecular protecting group.[7)]

Recently, we also found that the β-sheet structure of resin-bound human proinsulin C-peptide fragments which contained Pro residues at suitable intervals was easily disrupted by the addition of only a slight amount of HFIP, resulting in efficient coupling reactions in solid-phase peptide synthesis by a fragment condensation procedure.[10)] Thus, the investigation into solvents having a high potential for the β-sheet structure disruption of resin-bound peptides is of practical significance for solid-phase peptide synthe-

sis. In the present paper, we report that the β-sheet structure of resin-bound human proinsulin C-peptide segments having $<P_c>$ values larger than 0.98 is marvelously disrupted in CH_2Cl_2, even by the addition of strong electron-donor solvents such as HMPA and DMSO. We also show that the concept of "the peptide segment separation by tertiary peptide bonds"[11] is useful for estimating the β-sheet-structure-disrupted behavior. Resin-bound peptides **1**—**5** used in this study are shown in Fig. 1, where amino acid residues are represented by one-letter symbols.[12]

Experimental

Resin-bound peptides **1**—**5** were prepared in a previous study.[10] The IR absorption spectra of resin-bound peptides **1**—**5** were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer. IR measurements in the swollen state were performed by holding the samples between potassium bromide windows after resin-bound peptides were swollen in CH_2Cl_2 containing TFE, HMPA, DMSO, or MeOH at various concentrations.

Results

The β-sheet structure disruption of cross-linked polystyrene resin-bound peptides **1**—**5** in CH_2Cl_2 was investigated by a solvent-titration method.[13] It was monitored by following a successive decrease in the intensity of the amide I band around 1630 cm^{-1} due to the β-sheet structure together with the successive addition of a titrating solvent. As a representative example, the IR absorption spectra of the resin-bound peptide **4** in CH_2Cl_2 containing TFE or HMPA over a wide range of concentration are presented in Fig. 2. Figures 3 and 4 illustrate the solvent-titration curves of resin-bound peptides **1**—**5** using TFE and HMPA as titrating solvents, respectively. The relative intensities in Figs. 3 and 4 as well as Fig. 5 were obtained using the band at 1603 cm^{-1} due to the aromatic ring of the resin support as a standard and were normalized to 1.0 for each relative intensity in the absence of a titrating solvent. The results indicate that the β-sheet structure of resin-bound peptides **1**—**5** swollen in CH_2Cl_2 is easily disrupted by adding increasing amounts of TFE and HMPA and that the β-sheet structure disruption

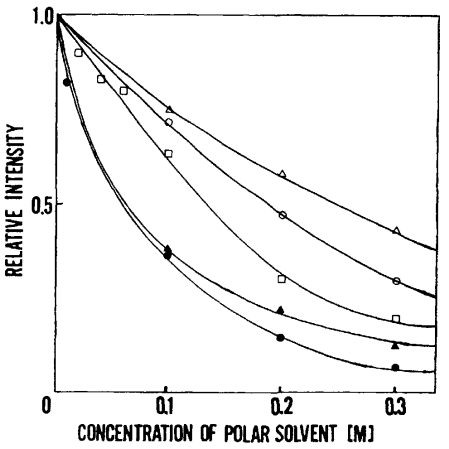

Fig. 3. The solvent-titration curves of resin-bound peptides **1**—**5** in CH_2Cl_2 using TFE as a titrating solvent. Peptide **1**, —▲—; peptide **2**, —●—; peptide **3**, —□—; peptide **4**, —△—; and peptide **5**, —○—.

of peptide **4** is the most difficult in peptides **1**—**5**. In order to elucidate the relationship between the β-sheet structure disruption of peptide **4** and electron-donating and -accepting properties of titrating solvents, the solvent-titration curves of peptide **4** in a medium electron-acceptor solvent of CH_2Cl_2 using strong electron-acceptor solvents of HFIP, TFE, and MeOH and strong electron-donor solvents of HMPA and DMSO as titrating solvents (Fig. 5) were obtained. The solvent-titration curve of peptide **4** in a medium electron-donor solvent of THF using HMPA as a titrating solvent is also shown in Fig. 5.

Discussion

Resin-bound peptides **1**—**5** contain Pro residues at suitable intervals, and Pro residues in peptides generally play a role in stopping the development of helix and β-sheet structures. Thus, the structures of resin-bound peptides **1**—**5** could be regarded as being assembled with peptide segment structures separated by Pro residues;[10] we called the role "peptide segment separation by tertiary peptide bonds."[11] In the swollen state in CH_2Cl_2, in fact, most parts of segment 1 (PLALEGSLQ) and a part of segment 2 (PGAGSLQ), namely, Ser(Bzl)-Leu-Gln, were estimated to form a relatively stable helix and N-terminal segment 3 appeared to form a relatively stable β-sheet structure, although the conformation of segment 2 was not clear.[10] Namely, the β-sheet structure of resin-bound peptides **1**—**5** can be regarded as being constructed by peptide segments having short peptide chain lengths. Thus, the β-sheet structure of resin-bound peptides **1**—**5** swollen in CH_2Cl_2 was expected to be disrupted by the addition of a variety of titrating solvents. Practically, it was easily disrupted by a strong electron-acceptor solvent of TFE and a strong electron-donor solvent of HMPA (Figs. 3 and 4), being in marked contrast with that of resin-bound peptides reported previously.[4,5] Especially, the disruption is clearly independent of the chain length of whole peptides, indicating that, for the evaluation of the β-sheet structure disruption of resin-bound peptides containing Pro residues, we should take account of the chain length of peptide segments instead of whole peptides. This is in harmony with the concept that "peptide segment separation by tertiary peptide bonds" is effective for estimating the conformational development of protected peptides in organic solvents.[10]

Resin-bound dodecapeptide **1** has a relatively stable helix in CH_2Cl_2 and is accompanied by a small amount of a β-sheet structure,[10] which is easily disrupted by TFE and HMPA. The disrupted behavior can be regarded as corresponding with that of segment 1. Resin-bound octadecapeptide **2** is assem-

Table 1. The Average Conformational Values, $\langle P_\alpha \rangle$, $\langle P_\beta \rangle$, and $\langle P_c \rangle$ of Peptide Segments

Peptide segment[a]	Number of segment	$\langle P_\alpha \rangle$	$\langle P_\beta \rangle$	$\langle P_c \rangle$
PLALEGSLQ	1	1.06	0.92	0.82
PGAGSLQ	2	0.89	0.86	1.16
QVELGGG	3	0.94	0.96	1.07

EAEDLQVGQVELGGG	3	1.07	0.91	0.98

a) Amino acid residues are represented by one-letter symbols.[12]

bled with segments 1 and 2 and its β-sheet structure is also easily disrupted by TFE and HMPA, since segment 2 has a high $<P_c>$ value (1.16). Especially, the easy disruption of resin-bound peptides **3—5** in CH_2Cl_2 by TFE and HMPA is marvelous and appears to be attributed to the high $<P_c>$ values of segments 3, suggesting that, for the evaluation of the β-sheet structure disruption of resin-bound peptides containing Pro residues, it is pertinent to use the $<P_\alpha>$, $<P_\beta>$, and $<P_c>$ values of peptide segments instead of whole peptides. The $<P_\alpha>$, $<P_\beta>$, and $<P_c>$ values of peptide segments are determined by their amino acid compositions,[8,9] and are summarized in Table 1. The easiness of the β-sheet structure disruption of peptides **3—5** by TFE and HMPA is in the following order: **3**>**5**>**4**. The most easy disruption of the β-sheet sturcture of peptide **3** is explained by both the short chain length and high $<P_c>$ value (1.07) of its segment 3. Segment 3 of peptide **5** also has a high $<P_c>$ value (0.98), and its chain length is close to the critical size for a stable helix formation of cross-linked polystyrene resin-bound peptides in CH_2Cl_2.[14] Furthermore, its $<P_\alpha>$ value (1.07) is larger than its $<P_\beta>$ value (0.91). The easy disruption of the β-sheet structure of segment 3 of peptide **5** is in good agreement with the observation that the β-sheet structure disruption of peptides having a $<P_c>$ value larger than 0.85 and having a high potential for the β-sheet → helix transformation proceeded smoothly upon adding increasing amounts of HFIP.[4] In addition, the easy disruption of the β-sheet structure of peptide **4** in CH_2Cl_2 by TFE, MeOH, HMPA, and DMSO (Fig. 5) clearly indicates that the consideration of $<P_c>$ values of peptide segments is important for a search for effective solvents to be used in solid-phase peptide synthesis.

In a study of the β-sheet structure-disruption of Boc-Val-Gly-Phe-Gly-Leu-Ile-Leu-Leu-Ala-NH-resin in a mixture of a strong electron-donor solvent of HMPA and a medium electron-acceptor solvent of CH_2Cl_2,[5] the electron donor-acceptor interaction between solvents occurred predominantly and the β-sheet structure disruption did not proceed. Thus, the result that the β-sheet structure of resin-bound peptide **4** in CH_2Cl_2 is disrupted by the addition of HMPA and DMSO strongly suggests that the β-sheet structure of resin-bound peptides having high $<P_c>$ values could be disrupted in CH_2Cl_2 even by a strong electron-donor solvent in spite of the electron donor-acceptor interaction between solvents. Contrary to CH_2Cl_2, THF is a medium electron-donor solvent and a weak electron-acceptor solvent.[6] Thus, the electron donor-acceptor interaction between HMPA and THF becomes negligible, and HMPA in THF shows a high potential for the β-sheet structure disruption of resin-bound peptide **4** (Fig. 5). As reported previously,[7] the potential of hydrogen-donor and -acceptor solvents for the β-sheet structure disruption of resin-bound peptide **4** was in the good relationship with their electron-acceptor and -donor numbers (AN and DN), respectively (Fig. 5). The AN values of HFIP, TFE, and MeOH are 88, 59, and 41.3, and the DN values of HMPA and DMSO, 38.8 and 29.8, respectively.[6,7] As AN and DN of titrating solvents are larger, their β-sheet-structure-disrupting potential becomes higher.

In conclusion, the β-sheet-structure-disrupted behavior of resin-bound peptides **1—5** suggests that concept of "peptide segment separation by tertiary peptide bonds" is useful for estimating their β-sheet-structure-disrupted behavior. In solid-phase peptide synthesis by a fragment condensation procedure, the β-sheet structure disruption in CH_2Cl_2 by the addition of HMPA and DMSO is more favorable than that of HFIP and TFE because the latter is nucleophilic and consumes a carboxyl component peptide in a coupling reaction.[15] Thus, the easy disruption of resin-bound peptides **1—5** in CH_2Cl_2 by HMPA is of practical significance for solid-phase peptide synthesis, indicating that effective solvents for solid-phase peptide synthesis should be searched by taking the $<P_\alpha>$, $<P_\beta>$, and $<P_c>$ values of the peptide segments into consideration.

This work has been supported by a Grant-in-Aid from the Asahi Glass Foundation for Industrial Technology.

Lipid-Coating on Polyamide Microcapsules Having Long Alkyl Chains and the Characterization of the Lipid-Coated Surface

Kenji KONO, Shunsaku KIMURA, and Yukio IMANISHI*
Department of Polymer Chemistry, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto 606
(Received June 12, 1989)

Polyamide microcapsules with diameters in the range of 1—5 μm were prepared by interfacial polycondensation between terephthaloyl dichloride and a mixture of L-lysine and piperazine. The carboxyl groups of L-lysine residues involved in the polyamide microcapsules were reacted with alkylamine by using water-soluble carbodiimide as a coupling reagent. The alkylated polyamide microcapsules were incubated with liposome to have the surface of the polyamide microcapsules coated with lipid bilayer membrane. The amount of lipid assemblies adsorbed on the polyamide microcapsules with octyl chains increased up to 1.5 times as much as that on the polyamide microcapsules without octyl chains. The synthetic glycopeptides were introduced to the lipid membrane adsorbed on the surface of the polyamide microcapsules. Interactions of the glycopeptides with the lipid membrane on the polyamide microcapsules and of the glycopeptides in the lipid membrane on the polyamide microcapsules with lectin were investigated.

Liposome has been used as a model membrane in biophysical investigations of cell membrane. Furthermore, liposome can be a biocompatible carrier in drug-delivery systems.[1] However, the vesicular structure of liposome is not very stable and is easily breakable due to osmotic pressure or interactions with plasma proteins in vivo.

Generally, cell membrane is stabilized by skeletal proteins, such as microfilaments, spectrin and actin.[2] Polyamide microcapsules coated with lipid bilayer membrane should mimic the structure of cell membrane lined with proteins. Lipid-coating on capsules having diameters in the range of 1—3 mm has been already reported by Rosenthal and Chang[3] and Okahata et al.[4] It has been also shown that the large polyamide capsule membranes were modified by synthetic glycolipids and the permeation was regulated by lectin addition.[5] They incubated the prepared polyamide microcapsules with a lipid solution in alkane, and transferred them to water. However, this method of lipid-coating is not successfully applied to microcapsules having diameters in the range of 1—5 μm, because the small microcapsules suspended in alkane can not be transferred easily to water due to the low specific gravity. Since microcapsules having diameters in the range of 1—5 μm are a suitable model of the cell and a useful carrier in the drug-delivery system, we tried to synthesize small microcapsules coated with lipid membrane. In combination with biologically active peptides which are associated with lipid bilayer membrane, the lipid-coated microcapsules are expected to act as functional microcapsules.

In the previous report,[6] we have shown that small microcapsules can be coated with lipid bilayer membrane when they were incubated with liposome. However, the surface of poly(terephthaloylpiperazine) microcapsules was not completely coated with lipid bilayer membrane.

In the present investigation, polyamide microcapsules were surface-grafted with long alkyl chains and subjected to lipid-coating. The alkylated polyamide microcapsules are expected to be easily covered with lipid membrane due to the hydrophobic nature of the modified surface.

Experimental

Preparation of Polyamide Microcapsules (Uncoated/Unmodified Polyamide Microcapsules). Polyamide microcapsules were prepared in principally the same method as that reported by Muramatsu and Kondo.[7] An aqueous solution (5 ml) of piperazine (0.13 M; 1 M=1 mol dm^{-3}), L-lysine HCl (0.2 M), and Na_2CO_3 (0.47 M) was added to a $CHCl_3$/cyclohexane (1/3, v/v) solution (100 ml) containing sorbitan trioleate (5 vol%) at 0 °C, and the mixture was stirred for 10 min. To the water-in-oil (W/O) emulsion a $CHCl_3$/cyclohexane (1/3, v/v) solution (100 ml) of terephthaloyl dichloride (12.5 mM) containing sorbitan trioleate (5 vol%) was added, and the mixture was allowed to react for 30 min. The microcapsules prepared were washed succeedingly with cyclohexane (three times), an aqueous solution containing poly(oxyethylene) sorbitan monolaurate (5 vol%), and water. The molecular structure of polyamide is shown in Fig. 1.

Reaction of Polyamide Microcapsules with Alkylamine. An aqueous solution of octylamine or decylamine (0.5 M) was adjusted to pH 4.75 with HCl, and added to a dispersion of the uncoated/unmodified polyamide microcapsules. Condensation reaction of carboxyl groups of microcapsules with alkylamine was carried out by using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide as a coupling reagent. After standing at room temperature for 12 h, the dispersion was washed several times with water until washing solution became neutral. Although free alkylamines might be adsorbed on polyamide microcapsules, they should be desorbed at the following treatment with the excess amount

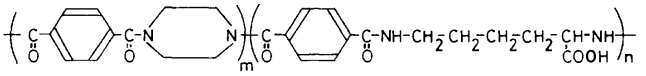

Fig. 1. Chemical structure of uncoated/unmodified polyamide microcapsules.

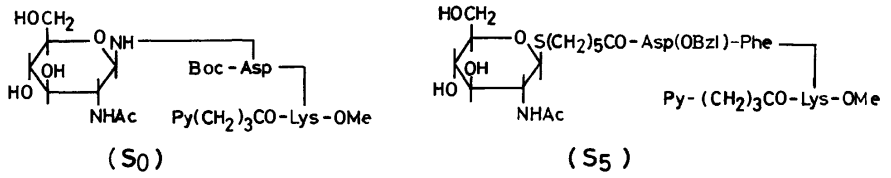

Fig. 2. Structure of synthetic glycopeptides.

of liposome.

Lipid-Coating on Microcapsules. Small unilamellar vesicles (SUV) composed of dimyristoylphosphatidylcholine (DMPC) were prepared by the sonication method. The prepared uncoated/unmodified polyamide microcapsules were incubated with DMPC SUV at 24 °C for 24 h. The dispersion was washed seven times with buffer (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES); 10 mM, NaCl; 0.1 M, pH 7.4) to remove SUV not in use for coating. Other types of microcapsules were also prepared according to the similar procedures.

Synthetic Glycopeptides. The molecular structure of synthesized glycopeptides is shown in Fig. 2. These glycopeptides carry a 1-pyrenyl group in the hydrophobic peptide moiety. The synthetic procedure has been reported previously.[8]

Wheat germ agglutinin (WGA) and lipids were purchased from Sigma. The available agents of the highest grade were used.

Measurements. ζ-Potential of the microcapsules was measured in an aqueous solution buffered with Na_2CO_3/$NaHCO_3$ (pH 10.2, ionic strength 1.8×10^{-4}) using Lazer Zee Meter Model 501 (Ten Kem Inc., New York). The concentration of lipid was determined by colorimetric method using phospholipase D (Diacolor PL, Toyobo, Japan).

The effect of lectin addition on the distribution of glycopeptides in membrane was examined by measuring monomer and excimer emissions of 1-pyrenyl group introduced to the peptide moiety.

Aggregation of polyamide microcapsules upon the addition of lectin was detected by measuring the absorbance at 800 nm.

Fluorescence was measured on an MPF-4 fluorescence spectrophotometer (Hitachi, Japan). 1-Pyrenyl group in the glycopeptides was excited at 345 nm, and monomer and excimer emissions were monitored at 378 and 480 nm, respectively. Absorption spectra were measured on an UVIDEC-1 spectrophotometer (JASCO, Japan).

Results and Discussion

Characterization of the Polyamide Microcapsules. Polyamide microcapsules were prepared by the interfacial polycondensation of terephthaloyl dichloride with L-lysine and piperazine. The size distribution of polyamide microcapsules was examined with a photomicroscope (Fig. 3). The most popular diameter was found to be in the range of 1—2 μm.

The presence of L-lysine as the component of the polyamide microcapsules was confirmed by the existence of free carboxyl groups of L-lysine in microcapsules. That is, ζ-potential of the polyamide microcapsules prepared in the presence of L-lysine was evidently lower than that of poly(terephthaloylpiperazine) microcapsules (Table 1).

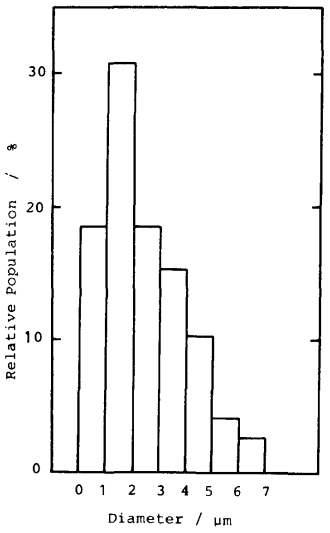

Fig. 3. Size distribution of uncoated/unmodified polyamide microcapsules determined with optical microscope.

Table 1. Zeta-Potential of Polyamide Microcapsules Containing Different Diamine Components

Diamine	Zeta-potential/mV
Piperazine	−20.9±1.6
L-Lysine/piperazine (0.20/0.13 mol/mol)	−42.1±2.0

Potentiometric titration of the polyamide microcapsules revealed that the diamine component of polyamide is composed of 70% of piperazine and 30% of L-lysine units. These values were calculated on the basis of the determination of negative charges on the surface of polyamide microcapsules, in which the contribution from the terminal carboxyl groups was ignored, because it was reported that the interfacial polycondensation of terephthaloyl dichloride and diamines gave polyamides with average molecular weight of about 20000.[9]

The polyamide microcapsules were reacted with

alkylamine to make the surface more hydrophobic. The hydrophobic surface should be favorable for lipid-coating. It was estimated that more than 80% of carboxyl groups of L-lysine units reacted with alkylamine, which was deduced from the titration of the reaction product of poly(terephthaloyllysine) with alkylamine under the same conditions.

Lipid-Coating. The polyamide microcapsules were incubated with DMPC liposome, and washed several times with buffer. It has been reported that lipid molecules not in use for coating are completely removed after seven times of washing, and that the lipid molecules adsorbed on the polyamide microcapsules take a bilayer structure, which was confirmed by the observation of phase transition of membrane by differential scanning calorimetry and measurement of membrane fluidity.[6] The amount of lipid molecules adsorbed on the polyamide microcapsules was determined and is summarized in Table 2. It is clearly shown that the adsorption of lipid molecules on microcapsules is enhanced by the modification of the polyamide microcapsules with alkylamine. The amount of lipid molecules adsorbed on the polyamide microcapsules grafted with octyl chains is 1.5-fold of that on unmodified polyamide microcapsules. Assuming 1.37 g cm^{-3} for the density of polyamide membrane,[10] 13.3 nm for the thickness of polyamide membrane,[10] and 70 $Å^2$ for the area occupied by a DMPC molecule,[11] this amount corresponds to 2.4 bilayers of lipid assemblies. On the other hand, 1.6 bilayers of lipid assemblies were formed on the surface of poly(terephthaloylpiperazine) microcapsules.[6]

Interaction of Glycopeptides with the Polypeptide Microcapsules. The synthetic glycopeptides consist of a hydrophilic glucosamine moiety and a hydrophobic peptide chain. These glycopeptides were shown to be distributed to lipid membrane with the peptide chain buried in the hydrophobic region of lipid membrane.[8] Since the pyrenyl group is connected to the peptide moiety, the interaction of glycopeptides with lipid membrane can be monitored by the fluorescence behavior of the pyrenyl group.

For example, the extent of the distribution of S_0 to lipid membrane can be determined by measuring the quenching rate of pyrenyl fluorescence with acrylamide, because the pyrenyl group is shielded from the aqueous phase upon incorporation into the lipid membrane. S_0 was incubated with various kinds of polyamide microcapsules and the rate of quenching by acrylamide was measured (Table 3). The fluorescence intensity from S_0 was reduced to different extents with the addition of acrylamide in all cases. The fraction of unquenchable S_0 increased in the order of uncoated/unmodified polyamide microcapsules<DMPC-coated/unmodified polyamide microcapsules<DMPC-coated/decyl-grafted polyamide microcapsules<DMPC-coated/octyl-grafted polyamide microcapsules. This order coincides with that of the amount of lipid molecules adsorbed on microcapsules. Therefore, it can be concluded that most of S_0 molecules adsorbed were incorporated into the lipid bilayer membrane formed on the surface of polyamide microcapsules.

The ratio of excimer emission and monomer emission intensities (I_D/I_M) represents the extent of the distribution of glycopeptides in the lipid membrane. Figure 4 shows the dependence of I_D/I_M of S_0 on the temperature in the presence of various kinds of

Table 2. The Amount of Lipid Molecules Adsorbed on Polyamide Microcapsules

Polyamide microcapsule	DMPC adsorbed onto 1 mg microcapsule
Unmodified	280 μg
Octyl-grafted	415 μg
Decyl-grafted	382 μg

Table 3. Quenching of Fluorescence of S_0 Distributed to the Surface of Various Kinds of Polyamide Microcapsules

Polyamide microcapsule	Rate of quenching (%)
Uncoated/unmodified	52.5
DMPC-coated/unmodified	29.9
DMPC-coated/octyl-grafted	22.6
DMPC-coated/decyl-grafted	26.5

[microcapsules]=0.64 mg ml^{-1}. [S_0]=2.2 μM. [acrylamide]=50 mM.

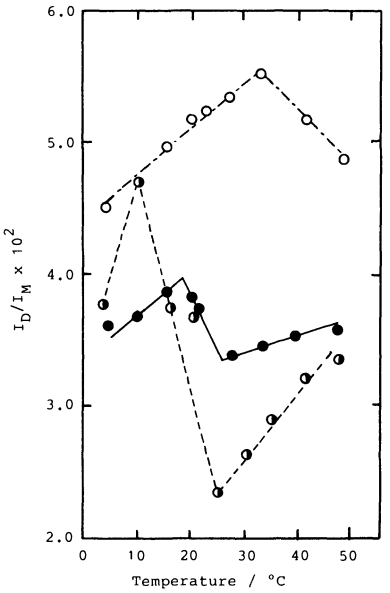

Fig. 4. The temperature dependence of I_D/I_M of S_0 in the presence of uncoated/unmodified polyamide microcapsules (○), DMPC-coated/octyl-grafted polyamide microcapsules (●), and DMPC SUV ([DMPC]= 0.44 mg ml^{-1}) (○). [S_0]=4.3 μM, [microcapsules]= 1.1 mg ml^{-1}.

polyamide microcapsules or DMPC SUV. I_D/I_M of S_0 in the presence of DMPC SUV decreased linearly with descending temperature with a break in the region of the phase-transition temperature of the DMPC bilayer membrane. The monotonous decrease of I_D/I_M should be ascribed to the different temperature dependence of the quantum yields of the excimer and the monomer emission. On the other hand, the abrupt increase of I_D/I_M occurring in the region between 24 and 10 °C can be ascribed to the increasing local concentration of S_0 in the DMPC bilayer membrane due to the phase separation below the phase transition temperature. It is well-known that the phase separation of lipid membrane produces domains of pure lipid molecules in a gel state as well as domains containing high concentrations of solute.[8]

The temperature dependence of I_D/I_M of S_0 in the presence of uncoated/unmodified polyamide microcapsules showed the break at 33 °C. The reason for this phenomenon is two fold. Increasing adsorption of the S_0 to the uncoated/unmodified polyamide microcapsules with descending temperature leads to increasing I_D/I_M in the region of higher temperatures, whilst I_D/I_M by nature decreases with descending temperature as it does in the region of lower temperatures.

In the presence of DMPC-coated/octyl-grafted polyamide microcapsules, the abrupt increase of I_D/I_M of S_0 with descending temperature was observed in the region of the phase transition temperature, indicating that S_0 should be distributed to lipid assemblies, which take the structure of lipid bilayer membrane on the polyamide microcapsules. Although the change observed in the presence of DMPC-coated/octyl-grafted polyamide microcapsules was less marked than that in the presence of DMPC SUV, the former change was more significant than that observed in the presence of DMPC-coated poly(terephthaloylpiperazine) microcapsules.[6] Therefore, the surface of polyamide microcapsules uncoated with lipid membrane can be reduced considerably by grafting octyl groups into microcapsules, resulted in the increase of the amount of lipid assemblies coated on microcapsules.

Interactions of Lectin with Glycopeptides on the Polyamide Microcapsules. The glycopeptide S_5 was used for the investigation on the interaction of lectin and the glycopeptide on the polyamide microcapsules. It has been reported that S_5 in lipid bilayer membrane interacts with lectin without being pulled out of the membrane.[8] WGA is known to possess four binding sites with a high affinity to *N*-acetylglucosamine and to crosslink two glycoproteins embedded in membrane.[12] Interaction of WGA with S_5 on the polyamide microcapsules was investigated by measuring the effect of the lectin addition on I_D/I_M ratio (Fig. 5). I_D/I_M of S_5 increased with the addition of WGA. The relative increase of I_D/I_M was the largest in the presence of DMPC-coated/octyl-grafted polyamide microcapsules, and the second largest in the presence of DMPC liposome. The increase of I_D/I_M with the addition of WGA was not remarkable in the presence of uncoated/unmodified polyamide microcapsules. The interaction of WGA with S_5 on the surface of uncoated/unmodified polyamide microcapsules should have been suppressed by negative charges on the surface of the microcapsules, because the crosslinking of S_5 with the addition of WGA occurred to a higher extent in the presence of uncoated poly(terephthaloylpiperazine) microcapsules.

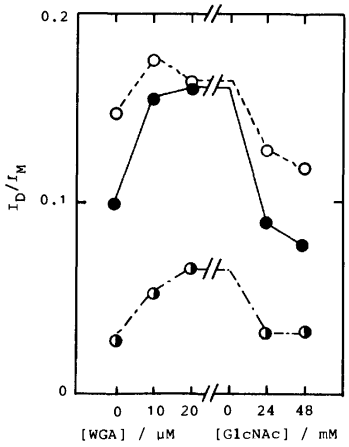

Fig. 5. The change of I_D/I_M of S_5 with the addition of WGA and the dissociation of crosslinked S_5 with the addition of GlcNAc in the presence of uncoated/unmodified polyamide microcapsules (○), DMPC-coated/octyl-grafted polyamide microcapsules (●), and DMPC SUV ([DMPC]=0.44 mg ml^{-1}) (◑). [S_5]=4.5 μM, [microcapsules]=1.1 mg ml^{-1}.

The crosslinking of S_5 molecules by WGA is facilitated on the surface of DMPC-coated/octyl-grafted polyamide microcapsules. The larger change of I_D/I_M in the presence of DMPC-coated/octyl-grafted polyamide microcapsules than that in the presence of DMPC SUV is ascribed to the high local concentration of S_5 on the surface of the polyamide microcapsules. That is, although 2.4 bilayers of lipid membrane are accumulated on DMPC-coated/octyl-grafted polyamide microcapsules, S_5 molecules can not be distributed to the inner bilayers due to the inability of S_5 to permeate through the hydrophobic core of lipid bilayer membrane. Therefore, the concentration of S_5 molecules dispersed in the lipid assembly is higher on the surface of the polyamide microcapsules than that in DMPC SUV for the same total amount of lipid molecules. This explanation is consistent with the higher value of I_D/I_M of S_5 in the presence of DMPC-coated/octyl-grafted polyamide microcapsules than that in the presence of DMPC SUV without the addition of WGA.

The crosslinking of S_5 by WGA was shown to be reversible on the surface of DMPC-coated/octyl-

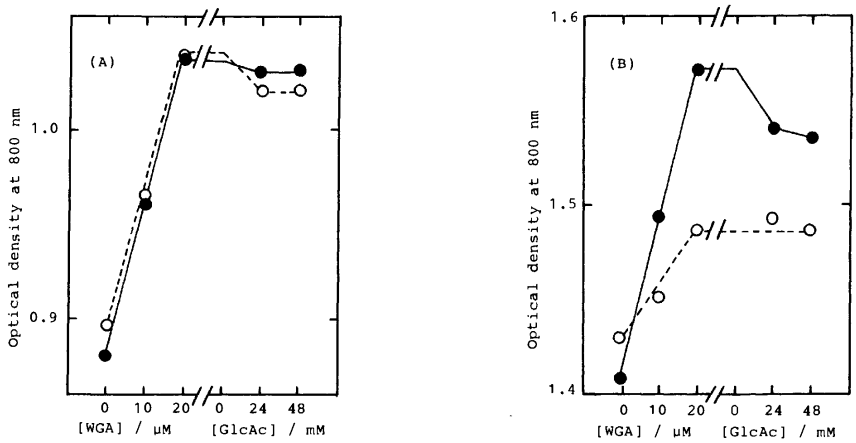

Fig. 6. Aggregation of microcapsules with the addition of WGA and dissociation of the aggregates with the addition of GlCNAc. [microcapsules]=0.64 mg ml^{-1}. [S_5]=0 M (○) and [S_5]=4.5 μM (●). In the presence of (A); uncoated/unmodified microcapsules, and (B), DMPC coated/octyl-grafted polyamide microcapsules.

grafted polyamide microcapsules, since the addition of inhibitor, *N*-acetylglucosamine, restored the original value of I_D/I_M in the absence of WGA.

As shown in Fig. 6A, aggregation of microcapsules was also observed with the addition of WGA, which might have been brought about by crosslinking of microcapsules by WGA. The absorbance of the suspension of uncoated/unmodified polyamide microcapsules increased with the addition of WGA either in the presence or in the absence of S_5. The aggregation of polyamide microcapsules was not dissociated by the addition of *N*-acetylglucose. Therefore, the aggregation should be nonspecific one between WGA and the surfaces of polyamide microcapsules. This type of aggregation was suppressed by coating the microcapsules with lipid membrane, as shown in Fig. 6B. The aggregation of DMPC-coated/octyl-grafted polyamide microcapsules by WGA should occur in the uncoated part of the polyamide microcapsules. The aggregation was enhanced in the presence of S_5 and suppressed partly by the addition of *N*-acetylglucose. Therefore, a part of the aggregation was caused by the specific interaction of WGA with S_5 in lipid membrane on the polyamide microcapsules.

To conclude, it was shown that the surface of polyamide microcapsules having diameters of 1—5 μm can be coated with lipid assemblies, and the efficiency of the lipid coating increased by the introduction of alkyl chains to the surface. The lipid assemblies adsorbed on polyamide microcapsules take the structure of lipid bilayer membrane, and mimics the cellular surface, in which glycopeptides interact with lectin. Therefore, lipid-coated microcapsules provide lipid bilayer membrane stabilized by polyamide microcapsules, and can be utilized as functional microcapsules by modification with biologically active peptides. However, polyamide surface can not be completely covered with lipid membrane. This imperfectness causes some problems in analyzing interactions of glycopeptides in the lipid membrane on the polyamide microcapsules. In addition, the encapsulation of small molecules into the obtained lipid-coated microcapsules will not be possible, which becomes a problem for utilization of microcapsules to the drug-delivery system. Three possibilities are considered for perfect covering the surface with lipid membrane. The first is to introduce more L-lysine residues as a basic component and increase the amount of alkyl chains grafted to the polyamide microcapsules. However, increasing content of L-lysine residues decreases the mechanical strength of the polyamide microcapsules. The second is to use longer alkyl chains to modify the surface. However, the alkylation reaction is very difficult because of the low solubility of long chain alkylamine in water. The third is to use amphiphilic polypeptides to increase the affinity of the polyamide microcapsules to lipid membrane. The last possibility is under investigation.

The Synthesis of Some Dimethylpyranocoumarins and Isopropenyldihydrofuranocoumarins

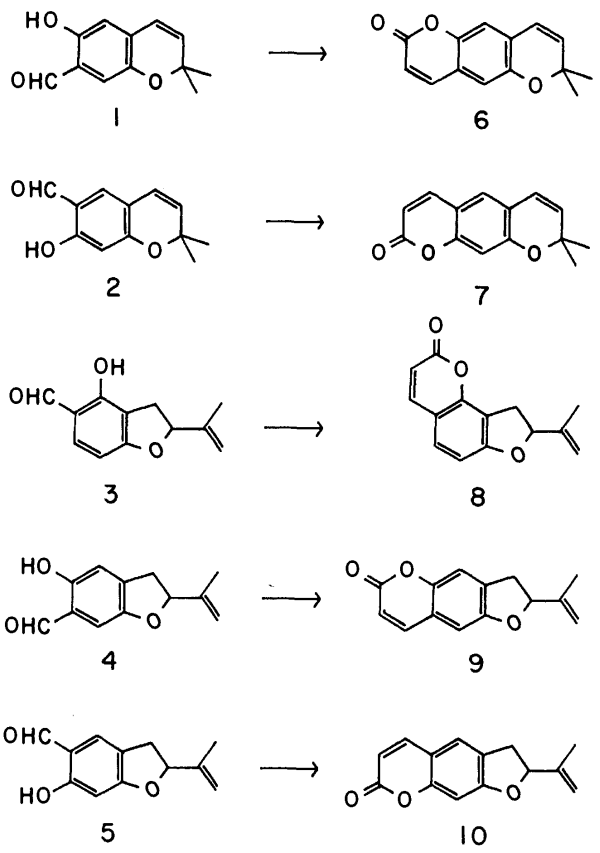
Seiji YAMAGUCHI,* Ryozo MIYAKAWA, Shinobu YONEZAWA, and Yoshiyuki KAWASE*
Department of Chemistry Faculty of Science, Toyama University,
Gofuku 3190, Toyama 930
(Received June 14, 1989)

Two pyranocoumarins, 7,7-dimethyl-2(7*H*)-benzo[1,2-*b*:4,5-*b'*]dipyranone and 8,8-dimethyl-2(8*H*)-benzo[1,2-*b*:5,4-*b'*]dipyranone, and three dihydrofuranocoumarins, 2-isopropenyl-1,2-dihydro-8-furo[1,2-*f*][1]benzopyranone, 2-isopropenyl-2,3-dihydro-6-furo[1,2-*e*][1]benzopyranone, and 2-isopropenyl-2,3-dihydro-7-furo[2,1-*e*][1]benzopyranone, were synthesized by an effective pyrone-ring formation in corresponding *o*-hydroxybenzaldehyde derivatives. And, 2-[1-(hydroxymethyl)vinyl]-1,2-dihydro-8-furo[1,2-*f*][1]benzopyranone was also synthesized selenium dioxide oxidation.

Natural xanthyletin[1] is a dimethylpyranocoumarin, and natural ammirin,[2] isoangenomalin,[3] angenomalin,[4] masquin,[5] and majurin[6] are isopropenyldihydrofuranocoumarins. In plants, these tricyclic *O*-heteroaromatic compounds may be prepared by prenylations of 7-hydroxycoumarin followed by cyclizations. We have studied the syntheses of 2,2-dimethyl-2*H*-chromenes and 2-isopropenyl-2,3-dihydrobenzofurans. In this paper we describe a new approach to dimethylpyranocoumarins and isopropenyldihydrofuranocoumarins by a pyrone-ring formation in some *o*-hydroxybenzaldehyde derivatives having 2*H*-chromene and dihydrobenzofuran structures.

We have already reported the acylation of 2,2-dimethyl-2*H*-chromenes[7] and 2-isopropenyl-2,3-dihydrobenzofurans,[8] and have obtained some methoxyl aldehydes by their formylations. Two *o*-hydroxybenzaldehyde derivatives having chromene structures, 6-hydroxy-2,2-dimethyl-2*H*-chromen-7-carbaldehyde (**1**) and 7-hydroxy-2,2-dimethyl-2*H*-chromen-6-carbaldehyde (**2**), were prepared from the corresponding methoxy derivatives by demethylation with magnesium iodide etherate. Two *o*-hydroxybenzaldehydes having dihydrobenzofuran structures, 5-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran-6-carbaldehyde (**4**) and 6-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran-5-carbaldehyde (**5**), were also prepared by demethylation of the corresponding methoxy derivatives. However, a similar preparation of 4-hydroxy-2-isopropenyl-2,3-dihydrobenzofuran-5-carbaldehyde (**3**) was not so effective, since in the cyclization of *m*-methoxyphenol with 1,4-dibromo-2-methyl-2-butene, the 4-methoxy derivative was the minor and the 6-methoxy derivative the major; the formylation of the minor 4-methoxy derivative, furthermore, gave a mixture of 5- and 7-formylated products. Thus, **3** was prepared in another procedure. A cyclization of 1,3-cyclohexanedione with 1,4-dibromo-2-methyl-2-butene gave 2-isopropenyl-2,3,6,7-tetrahydro-4(5*H*)-benzofuranone (**11**) in 41% yield. The structure of **11** was confirmed by dehydrogenation to 2-isopropenyl-2,3-dihydro-4-benzofuranol (**12**). The methyl ether of **12** was identical with the sample prepared in cyclization of *m*-methoxyphenol with 1,4-dibromo-2-methyl-2-butene.[8] Condensation of **11** with ethyl formate gave 5-hydroxymethylene-2-isopropenyl-2,3,6,7-tetrahydro-4-(5*H*)-benzofuranone (**13**) in 35% yield, which was easily converted by dehydrogenation with DDQ to the desired *o*-hydroxybenzaldehyde **3** in 87% yield. This isopropenyldihydrobenzofuran **3** showed an ABX signal pattern typical in 2-isopropenyl-2,3-dihydrobenzofurans.

Some methods for pyrone-ring formation in *o*-hydroxybenzaldehydes were reported, but they were not so effective. We tried some new pyrone-ring



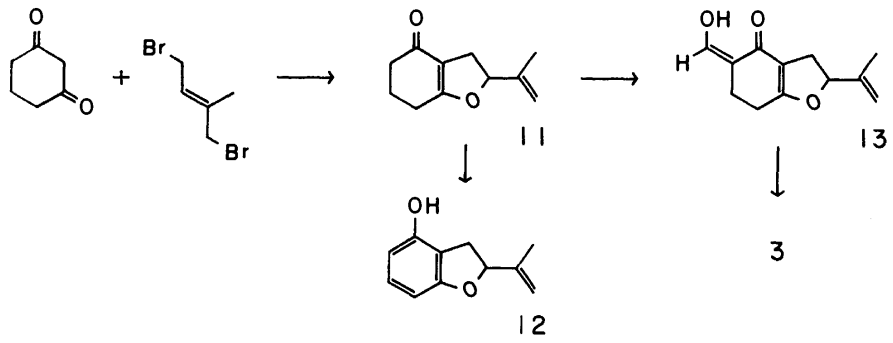


Table 1. The Yields, Some Physical Data, and Elemental Analyses of Dimethylpyranocoumarins and Isopropenyldihydrofurocoumarins

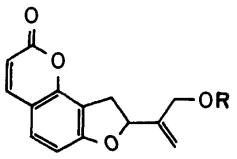
Compound	Yield %	Mp θ_m/°C	IR cm^{-1}	MS (M$^+$)	Elemental analysis[a] C(%)	H(%)
6	64	157—158	1700	228	73.51	5.46
7	49	133—134.5	1720	228	73.46	5.26
8	46	111—113	1735	228	73.96	5.23
9	63	157—158	1710	228	73.45	5.31
10	18[10]	98—98.5	1720	228	73.68	5.30

a) Calcd data for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

Table 2a. NMR Data of Dimethylpyranocoumarins (δ/ppm, J/Hz)

Compound	Me	Olefinic in pyran	Olefinic in pyrone	Aromatic
6	1.4(s)	5.8(d) 6.35(d) J=10	6.3(d) 7.5(d) J=10	6.8(s) 6.9(s)
7	1.4(s)	5.7(d) 6.3(d) J=10	6.2(d) 7.5(d) J=10	6.7(s) 7.0(s)

formation in 2-hydroxy-4-methoxybenzaldehyde, and the corresponding coumarin was obtained in the following three cases: a) heating with acetyl chloride in the presence of DBU at 110—140 °C for 2 h (10%), b) refluxing with *N,N*-dimethylacetamide dimethylacetal in xylene for 30 m (10%), c) refluxing *N,N*-dimethylacetamide dimethylacetal in ether for 6 h (22%). Thus, by pyrone-ring formations with *N,N*-dimethylacetamide dimethylacetal in refluxing ether for 6 h, two chromene derivatives **1,2** were effectively converted to the corresponding pyranocoumarins, 7,7-dimethyl-2(7*H*)-benzo[1,2-*b*:4,5-*b'*]dipyranone (**6**) and 8,8-dimethyl-2(8*H*)-benzo[1,2-*b*:5,4-*b'*]dipyranone (**7**) in 64% and 49% yield. They showed carbonyl absorption at 1700 cm^{-1} (**6**), 1720 cm^{-1} (**7**) in their IR spectra, and new olefinic protons of pyrone-ring at δ 5.8 and 7.5 (**6**), δ 5.7 and 7.5 (**7**) in the ^{1}H NMR spectra. Similar pyrone-ring formations of three dihydrobenzofurans (**3**, **4**, **5**) gave the corresponding furocoumarins, 2-isopropenyl-1,2-dihydro-8-furo[1,2-*f*][1]benzopyranone (**8**), 2-isopropenyl-2,3-dihydro-8-furo[1,2-*e*][1]benzopyranone (**9**), and 2-isopropenyl-2,3-dihydro-7-furo[2,1-*e*][1]benzopyranone (**10**) in 46, 63, and 18%.[9] These furocoumarins showed a carbonyl absorption at 1735 cm^{-1} (**8**), 1710 cm^{-1} (**9**), 1720 cm^{-1} (**10**), and showed the olefinic protons of pyrone-ring at δ 6.2 and 7.6 (**8**), δ 6.3 and 7.6 (**9**), δ 6.2 and 7.6 (**10**). The spectral data of pyrano coumarin **7** were identical with the reported data of natural xanthyletin.[1] Furocoumarins **8**, **10** were also identical with natural majurin,[6] angenomalin,[4] masquin,[5] ammirin,[2] and isoangenomalin,[3] in their spectral data.



14 a) R = Ac
b) R = H

Another furocoumarin having an oxidized isopropenyl graup (**14b**) was also reported as natural sachalinin[10] and discophoridin.[11] We converted **8** to **14b** by oxidation with selenium dioxide. The oxidation of **8** with selenium dioxide in refluxing acetic anhydride for 7 h gave an acetate, 2-[1-(acetoxymethyl)vinyl]-1,2-dihydro-8-furo[1,2-*f*][1]benzopyranone (**14a**), in 18% yield. This acetate **14a**,

Table 2b. NMR Data of Isopropenyldihydrofurocoumarins

showed a new acetoxyl methyl signal at δ 2.0 and a new methylene signal at δ 4.7 in the ^{1}H NMR spectrum. This acetate was easily converted to 2-[1-(hydroxymethyl)vinyl]-1,2-dihydro-8-furo[1,2-*f*][1]benzopyranone (**14b**) in 70% yield by refluxing with 20% potassium hydroxide ethanolic solution for 1 h. This alcohol **14b** showed a hydroxyl absorption at 3400 cm^{-1}, and showed a methylene signal at δ 4.3. The spectral data were identical with those of natural discophoridin.[11]

Experimental

The melting and boiling points were uncorrected (in boiling points: 1 mmHg=133.322 Pa). The IR spectra were measured on a Hitachi 260-50 spectrometer in a liquid film or a KBr disk, and the UV spectra were taken on a Hitachi 220A spectrophotometer in an ethanolic solution. The ^{1}H NMR spectra were recorded on a JEOL PMX-60Si or FX-90Q NMR spectrometer, and the mass spectra were recorded on a JEOL JMS-OISG-2 mass spectrometer.

Preparation of 1 and 2. By a procedure reported in the demethylation of dihydrobenzofurans,[8] 6-hydroxy-2,2-dimethyl-2*H*-chromen-7-carbaldehyde (**1**) and 7-hydroxy-2,2-dimethyl-2*H*-chromen-6-carbaldehyde (**2**) were prepared from the corresponding methoxyl derivatives[7] in 79 and 70% yield. **1**; mp 96.5—98 °C (from hexane). IR (KBr) 1650 cm^{-1}. ^{1}H NMR (CCl_4) δ=1.4 (6H, s), 5.9 (1H, d, J=10 Hz), 6.4 (1H, d, J=10 Hz), 6.6 (1H, s), 7.0 (1H, s), 10.0 (1H, s), 10.8 (1H, s). Found: C, 70.68; H, 5.91%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. MS *m/z* 204 (M^+). **2**; mp 97.5—98.5 °C (from hexane). IR (KBr) 1630 cm^{-1}. ^{1}H NMR (CCl_4) δ=1.4 (6H, s), 5.5 (1H, d, J=10 Hz), 6.2 (1H, d, J=10 Hz), 6.2 (1H, s), 7.0 (1H, s), 9.6 (1H, s), 12.9 (1H, s). Found: C, 70.49; H, 5.87%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. MS *m/z* 204 (M^+).

Cyclization of 1,3-Cyclohexanedione with 1,4-Dibromo-2-methyl-2-butene. To a solution of 1,3-cyclohexanedione (20.0 g, 179 mmol) and 1,4-dibromo-2-methyl-2-butene (40.3 g, 177 mmol) in dry acetone (250 ml) was added anhydrous potassium carbonate (74.0 g); the mixture was stirred for 8 h under refluxing. After removing the acetone, the mixture was diluted with water and extracted with ether. The ether layer was washed with 5% sodium hydroxide solution and saturated sodium chloride solution, and dried over anhydrous sodium sulfate. After removing the ether, the residue was distilled under reduced pressure. The fractions boiling at 144—156 °C/17 mmHg were re-distilled to give 2-isopropenyl-2,3,6,7-tetrahydro-4(5*H*)-benzofuranone (**11**) as fractions boiling at 145—157 °C 16 mmHg (12.8 g, 41%). **11**; IR (neat) 1630 cm^{-1}. ^{1}H NMR (CCl_4) δ=1.8 (3H, s), 2.0—3.2 (8H, m), 4.9 (1H, broad s), 5.0 (1H, broad s), 5.2 (1H, broad t, J=10 Hz). Found: C, 73.97; H, 7.78%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%. MS *m/z* 178 (M^+), 163, 150.

Dehydrogenation of 11 to 12. To a solution of **11** (379 mg, 2.13 mmol) in toluene (20 ml) was added 2,3-dichloro-5,6-dicycano-1,4-benzoquinone (DDQ) (490 mg, 2.16 mmol); the mixture was refluxed for 15 h. After removing of the precipitates by filtration, the filtrate was diluted with benzene and then extracted with 5% sodium hydroxide solution. The alkaline solution was acidified with 10% hydrochloric acid and re-extracted with benzene. The benzene layer was washed with saturated sodium chloride

solution and dried over anhydrous sodium sulfate. After removing the solvent, the residue was purified on a silica-gel column with benzene eluents to give 2-isopropenyl-2,3-dihydro-4-benzofuranol (**12**)(132 mg, 35%); bp 190—210 °C/15 mmHg (bath temp). IR (neat) 3450 cm^{-1}. ^{1}H NMR (CCl_4) 1.8 (3H, s), 3.0 (1H, dd, J=16 and 8 Hz), 3.2 (1H, dd, J=16 and 9 Hz), 4.9 (1H, broad s), 5.0 (1H, broad s), 5.1 (1H, dd, J=9 and 8 Hz), 5.4 (1H, broad s), 6.2 (1H, d, J=8 Hz), 6.3 (1H, d, J=8 Hz), 6.9 (1H, t, J=8 Hz). MS m/z 176 (M^+), 161. This phenol **12** was labile for its probable partial autooxidation. In the IR spectra, its methyl ether was identical with the sample prepared from *m*-methexyphenol.[8]

Condensation of 11 with Ethyl Formate. To a suspension of sodium hydride (0.43 g, 18 mmol) in dry benzene (50 ml) was added ethyl formate (5.32 g, 71.8 mmol), carefully. Then, 2-isopropenyl-2,3,6,7-tetrahydro-4(5*H*)-benzofuranone (**11**) (3.19 g, 17.0 mmol) was added under refluxing, and the mixture was refluxed for 2 h. After cooling, the mixture was treated with 5% sodium hydroxide solution. The alkaline aqueous layer collected was washed with benzene and acidified with 10% hydrochloric acid, and then re-extracted with ether. The ether layer was washed with a saturated sodium chloride solution and dried over anhydrous sodium sulfate. After removing the ether, the residue was distilled to give 5-hydroxymethylene-2-isopropenyl-2,3,6,7-tetrahydro-4(5*H*)-benzofuranone (**13**) (1.29 g, 35%); bp 140—200 °C/23 mmHg. IR (neat) 1635 cm^{-1}. ^{1}H NMR (CCl_4) δ=1.8 (3H, s), 2.5 (4H, broad s), 2.7 (1H, dd, J=16 and 8 Hz), 2.9 (1H, dd, J=16 and 9 Hz), 4.8 (1H, broad s), 5.0 (1H, broad s), 5.2 (1H, dd, J=9 and 8 Hz), 7.0 (1H, broad s). UV (EtOH) 271 (log ε 4.66), 315 nm (sh). MS m/z 206 (M^+), 191, 178, 163. Found: C, 69.96; H, 6.65%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%.

Dehydrogenation of 13 to 3. By a procedure described above in dehydrogenation of **11** to **12**, **13** (3.01 g, 14.6 mmol) was dehydrogenated with DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone) (3.31 g, 14.6 mmol) to give a crude phenol, which was purified with a silica-gel column with hexane-ethyl aceteate (1:1) eluents. 4-Hydroxy-2-isopropenyl-2,3-dihydrobenzofuran-5-carbaldehyde (**3**) (2.59 g, 87%); bp 170—180 °C/20 mmHg (bath temp.). IR (neat) 1645 cm^{-1}. ^{1}H NMR (CCl_4) δ=1.8 (3H, s), 3.0 (1H, dd, J=16 and 8 Hz), 3.3 (1H, dd, J=16 and 9 Hz), 4.9 (1H, broad s), 5.1 (1H, broad s), 5.3 (1H, dd, J=9 and 8 Hz), 6.4 (1H, d, J=9 Hz), 7.3 (1H, d, J=9 Hz), 9.7 (1H, s), 11.5 (1H, s). UV (EtOH) 235 (log ε 3.89), 242 (sh), 291 nm (4.25). MS m/z 204 (M^+), 189. Found: C, 70.81; H, 5.99%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. The methyl ether derived from **3** by methylation with dimethyl sulfate was identical with the sample from formylation of 2-isopropenyl-4-methoxy-2,3-dihydrobenzofuran.[8]

A New Pyrone-Ring Formation to Coumarin Derivatives. To a solution of *o*-hydroxybenzaldehyde derivatives **1—5** (ca. 5 mmol) in dry ether (20 ml) was added *N*,*N*-dimethylacetamide dimethylacetal (ca. 10 mmol); and the mixture was refluxed for 6 h under stirring. After cooling, the mixture was treated with 10% hydrochloric acid. The ether layer was collected, and the aqueous layer was extracted with chloroform. The organic layer was washed with a saturated sodium hydrogencarbonate solution and dried over anhydrous sodium sulfate. After removing the solvents, the two residues from ether and chloroform layers were combined and purified on a short silica-gel column. Pyronocoumarins **6** and **7** were obtained as the fractions eluted with chloroform and recrystallized from benzene. Dihydrofurocoumarins **8**, **9**, **10** were obtained as the fractions eluted with hexane-ethyl acetate (9:1) and recrystallized from cyclohexane. The yields and the spectral data are summarized in Tables 1, 2, and 3.

Oxidation of 8 to 14a with Selenium Dioxide. To a solution of **8** (0.48 g, 2.1mmol) in acetic anhydride (50 ml) was added selenium dioxide (0.25 g, 2.3 mmol); the mixture was refluxed for 7 h with stirring. After cooling, selenium compounds formed were filtered off, and the excess acetic anhydride was removed under reduced pressure. The residue was diluted with chloroform. The chloroform solution was washed with a saturated sodium hydrogencarbonate solution and a saturated sodium chloride solution, and then dried over anhydrous sodium sulfate. After removing the solvent, the residue was purified on a short silical-gel column. The fractions eluted with hexane-ethyl acetate (8:2) were collected and recrystallized from hexane-ether to give 2-[1-(acetoxymethyl)vinyl]-1,2-dihydro-8-furo[1,2-*f*][1]-benzopyranone (**14a**) (0.10 g, 18%); mp 77.5—78.5 °C. IR (KBr) 1720 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.0 (3H, s), 3.2 (1H, dd, J=16 and 8 Hz), 3.6 (1H, dd, J=16 and 10 Hz), 4.7 (2H, broad s), 5.3 (1H, broad s), 5.4 (1H, broad s), 5.5 (1H, dd, J=10 and 8 Hz), 6.2 (1H, d, J=10 Hz), 6.7 (1H, d, J=8 Hz), 7.4 (1H, d, J=8 Hz), 7.7 (1H, d, J=10 Hz). Found: C, 67.01; H, 4.80%. Calcd for $C_{16}H_{14}O_5$: C, 67.12; H, 4.93%. MS m/z 286 (M^+), 226, 186. As the fractions eluted with hexane-ethyl acetate (95:5), **8** was recovered in 20%.

Hydrolysis of 14a to 14b. To a solution of **14a** (0.32 g, 1.1 mmol) in ethanol (10 ml) was added 20% potassium hydroxide aqueous solution (15 ml); the mixture was refluxed for 1 h with stirring. After cooling, the mixture was diluted with water and extracted with chloroform. The chloroform layer was washed with a saturated sodium chloride solution and dried over anhydrous sodium sulfate. After removing the chloroform, the residue was crystallized from ethanol to give 2-[1-(hydroxymethyl)vinyl]-1,2-dihy-

dro-8-furo[1,2-*f*][1]benzopyranone (**14b**) (0.19 g, 70%); mp 102—103 °C. IR (KBr) 3400, 1720 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.3 (1H, broad s), 3.3 (1H, dd, J=16 and 8 Hz), 3.5 (1H, dd, J=16 and 10 Hz), 4.3 (2H, broad s), 5.3 (2H, broad s), 5.5 (1H, dd, J=10 and 8 Hz), 6.2 (1H, d, J=9 Hz), 6.7 (1H, d, J=9 Hz), 7.2 (1H, d, J=9 Hz), 7.8 (1H, d, J=9 Hz). Found: C, 68.96; H, 5.04%. Calcd for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%. MS m/z 248 (M^+), 213, 186.

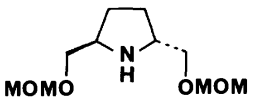
(Received July 11, 1989)

The reduction of α-keto amides derived from (2*R*,5*R*)-*trans*-2,5-bis(methoxymethoxymethyl)pyrrolidine [(*R*)-BMOMP, **1**] with $LiBEt_3H$ or $KBEt_3H$ proceeded with high diastereoselectivity (up to 99% ds) to afford the corresponding α-hydroxy amides in good yields. The additive effect of crown ethers or metallic salts on the stereoselectivity was also examined.

Optically active α-hydroxy acid derivatives are versatile building blocks for the synthesis of natural products[1] and many methods have so far been reported for their preparation.[2] Among them, the diastereoselective reduction of chiral α-keto acid derivatives which bear an appropriate chiral auxiliary, is a conventional approach.[3] However the utility of the reaction has been restricted mainly by its insufficient optical yield. In the course of our investigation on asymmetric reactions using *trans*-2,5-disubstituted pyrrolidine possessed of C_2-axis of symmetry as a chiral auxiliary,[4] we have communicated highly diastereoselective reduction of α-keto amides derived



1 (R)-BMOMP

from **1** as illustrated in Scheme 1.[5] The full details of the study is described here.

Results and Discussion

α-Keto amides (**2a** and **2b**) were prepared from (*R*)-BMOMP by *N*-acylation with mixed pivalic benzoylformic or pyruvic anhydride in the presence of 4-dimethylaminopyridine in good yields. Then, the compounds (**2a** and **2b**) were submitted to reduction by metal borohydrides or DIBAL, or to hydrogenation (H_2/Pd-C), where the preferential formation of (*R*)-hydroxy amides (**3a** and **3b**) was observed except for one case. The diastereoselectivity of the reactions was determined by ^1H NMR and/or GLC analysis. The results obtained are summarized in Table 1. Reduction of **2a** (R=Ph) with ordinary metal borohydrides proceeded with moderate diastereoselectivity in a range of 62—77% diastereoselectivity (ds) (Entries 1—3). Reduction with zinc borohydride or DIBAL exhibited very poor diastereoselectivity (Entries 4 and 7), although the former reagent is known to exhibit high erythro-selectivity on the reduction of β-keto esters[6] and amides.[7] The slightly better selectivity was observed in the reduction with tetrabutylammonium borohydride having low ability of chelation (Entry 5). The catalytic hydrogenation also showed a moderate level of selectivity (Entry 6).

We next examined the reduction of **2a** with the bulky trialkylhydroborates which were expected to discern the diastereomerically different environment more effectively and, as expected, it was found that the diastereoselectivity was markedly enhanced up to 96—99% ds, when $LiBEt_3H$ was used in THF or ether at −78 °C (Entries 8 and 9).

On the other hand, the diastereoselectivity in the reduction of pyruvamide (**2b**, R=Me) with borohydrides was generally not so good as that of **2a** (Entries 13—15 and 17),[8] and zinc borohydride reduction of the same substrate showed the opposite sense of diastereoselection (Entry 16). These results suggested that, although α-keto amides (**2a** and **2b**) existed in the form of *s*-trans conformer (**A**) rather than *s*-cis conformer as discussed later (Scheme 2), the relative proportion of **A**

a) All reactions were carried out at −78°C using α-keto amide (**2b**) as a substrate.

and **B** was affected by steric bulkiness of α-alkyl group (R) and strongly by the oxygenophilicity of metal ions, and that, especially in the latter case, the equilibrium leaned to **B** due to the chelation of two carbonyl groups to the oxygenophilic zinc ion. Therefore, use of $KBEt_3H$ or $KB(OPr^i)_3H$ bearing less oxygenophilic potassium ion was considered to improve the selectivity and actually higher selectivities (88% and 87% ds) were observed with these reagents (Entries 19 and 20).

In the further attempt to improve the stereoselectivity in the reduction of **2b**, we next examined the additive effect of crown ethers which is expected to capture metal ions and to disturb chelate formation. The results are summarized in Table 2. In the reduction with $LiBEt_3H$, addition of a proper size of 12-crown-4 or kryptofix-221 enhanced the selectivity from 82% ds to 87% ds (Entries 2 and 6). Although the combination of 18-crown-6 and $KBEt_3H$ gave no effect on selectivity, that with $KB(OPr^i)_3H$ further improved the selectivity from 84% ds to 90% ds (Entry 11).

Recently Soai et al. reported that diastereoselectivity in the reduction of benzylformamide derived from (*S*)-proline methyl ester, with $LiBH_4$ was improved up to 93.5% ds by addition of LiBr in the reaction mixture, while reduction of the corresponding isobutylformamide proceeded with diminished stereoselectivity of 79% ds even in the presence of LiBr.[3d] Aiming at the further promotion of the stereoselectivity in the re-

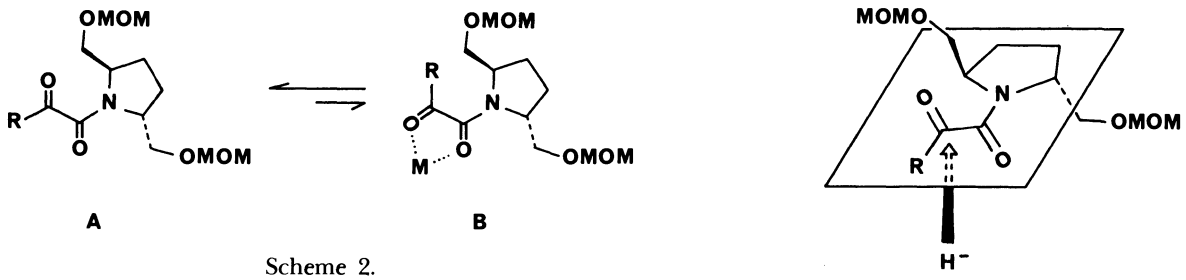

Scheme 2.

duction of **2b**, we also examined the additive effect of the salt. As shown in Table 3, addition of lithium salts increased the selectivity (Entries 2, 4, 5, and 7—9), whereas that of the metal salt such as Mg^{2+} or Zn^{2+}, decrease substantially (Entries 10—12). The optimal result (95% ds) was obtained in the reduction with $KBEt_3H$ in the presence of 2 equiv LiBr (Entry 7).

The hydroxy amide (**3b**) thus obtained was hydrolyzed by refluxing in 1 mol dm^{-3} HCl to give (*R*)-lactic acid without racemization. In the case of **3a** obtained in 99% ds, however, the partial epimerization was observed during hydrolysis, giving (*R*)-mandelic acid of 92% ee.[9]

The exact steric course of the reduction is not clear at present, but preferential formation of (*R*)-α-hydroxy amides and a CPK-model examination suggest as follows. α-Keto amide exists in the equilibrium of two plane conformers (**A** and **B**)[3b] as shown in Scheme 2. The *s*-cis conformer (**B**) is considered to be destabilized by the dipole repulsion of two carbonyl groups and the steric repulsion between α-alkyl group (R) and the amine moiety, and the α-keto amide having a bulky amine component like BMOMP takes *s*-trans conformer preferentially. Another advantage of the use of BMOMP is that the conformational divergence due to the rotation of the bond between the amide carbonyl carbon and nitrogen atoms need not be considered here because of its C_2-symmetry and the planarity of the amide structure. Thus the attack of a hydride anion would occur preferentially from the less hindered side (*si*-face) of α-carbonyl carbon of the predominating *s*-trans conformer to afford the (*R*)-hydroxy amide, as shown in Fig. 1. This seems to hold even for the Pd-catalyzed reduction (Table 1, Entry 6) though *s*-cis conformation has been suggested to catalytic hydrogenation of α-keto amides bearing amine components which are not bulkier than the present pyrrolidine auxiliary.[10]

In summary, we found that highly diastereoselective reduction of α-keto amide could be achieved by using sterically bulky BMOMP as a chiral auxiliary, which weighted the conformational equilibrium of α-keto amide in favor of the *s*-trans conformer, and that addition of crown ethers or lithium salts in the reaction mixture was effective for the further enhancement of the stereoselectivity to a certain extent.

Experimental

Melting points are uncorrected. IR spectra were determined on a Shimadzu IR-435 spectrophotometer and UV spectra on a Shimadzu UV-260 spectrophotometer. ^1H NMR spectra were recorded at 90 MHz with a Hitachi R-90H spectrometer. All NMR spectra were taken in $CDCl_3$ solution with TMS as an internal standard. Optical rotations were determined on a Yanagimoto OR-50 polarimeter. GLC analysis was carried out with a Shimadzu GC-7A chromatograph.

Reactions were carried out under an atmosphere of

nitrogen unless otherwise stated. Tetrahydrofuran (THF) and ether were freshly distilled from sodium benzophenone ketyl before use. Dichloromethane was distilled from calcium hydride. Thin-layer chromatography (TLC) was carried out on Merck glass plates precoated with silica gel 60F-254 (0.25 mm) and column chromatography was performed by using Merck 230—400 mesh silica gel.

(2*R*,5*R*)-*N*-Benzoylcarbonyl-*trans*-2,5-bis(methoxymethoxymethyl)pyrrolidine (2a). Pivaloyl chloride (0.34 ml, 2.78 mmol) was added to a solution of benzoylformic acid (430 mg, 2.78 mmol) and triethylamine (0.39 ml, 2.78 mmol) in dichloromethane (2 ml) at 0 °C and the mixture was stirred for 2 h. (*R*)-BMOMP (152 mg, 0.694 mmol) in dichloromethane (0.5 ml) and 4-dimethylaminopyridine (85.2 mg, 0.694 mmol) were added to the mixture and stirred over night. The reaction mixture was diluted with ether and filtered through Celite. The filtrate was washed with a saturated aqueous $NaHCO_3$ solution and brine successively, and dried over $MgSO_4$. The residue was chromatographed on silica gel (hexane–acetone, 5:1) to give the colorless viscous oil (**2a**, 238 mg, 98%): $[\alpha]_D^{25}$ +165° (*c* 1.07, MeOH); UV (EtOH) 254 nm (ε 54640); IR (neat) 2950, 1678, 1630, 1600, 1428, 1240, 1150, 1110, and 1040 cm^{-1}; ^1H NMR δ=1.53—2.49 (4H, m), 3.04 (3H, s), 3.21—3.32 (2H, m), 3.39 (3H, s), 3.72—3.87 (2H, m), 4.00, 4.15 (2H, ABq, *J*=6.3 Hz), 4.21—4.53 (2H, m), 4.67 (2H, s), 7.30—7.60 (3H, m), 7.95—8.12 (2H, dd, *J*=8.6, 2.0 Hz); Found: C, 61.25; H, 7.40; N, 3.80%. Calcd for $C_{18}H_{25}NO_6$: C, 61.53; H, 7.17; N, 3.99%.

(2*R*,5*R*)-*N*-Acetylcarbonyl-*trans*-2,5-bis(methoxymethoxymethyl)pyrrolidine (2b). Compound **2b** was prepared in a similar manner to that described for **2a**. Yield 77%; $[\alpha]_D^{25}$ +79.7° (*c* 3.314, MeOH); UV (EtOH) 238 nm (ε 2846); IR (neat) 2900, 1710, 1628, 1430, 1210, 1150, 1110, and 1040 cm^{-1}; ^1H NMR δ=1.80—2.24 (4H, m), 2.36 (3H, s), 3.06—3.52 (2H, m), 3.28 (3H, s), 3.33 (3H, s), 3.53—3.81 (2H, m), 4.30 (1H, m), 4.45—4.89 (1H, m), 4.51 (2H, s), 4.58 (2H, s); Found: C, 53.70; H, 8.29; N, 4.54%. Calcd for $C_{13}H_{23}NO_6$: C, 53.97; H, 8.01; N, 4.84%.

General Procedure for Reduction of α-Keto Amide. (2*R*,5*R*)-*N*-[(2*R*)-2-Hydroxy-2-phenylacetyl]-*trans*-2,5-bis-(methoxymethoxymethyl)pyrrolidine (**3a**). A THF solution of $LiBEt_3H$ (1 mol dm^{-3}, 0.23 ml, 0.23 mmol) was added to a solution of the α-keto amide (**2a**, 80 mg, 0.228 mmol) in THF (4.5 ml) at −78 °C. After stirring for 1 h at the same temperature, the reaction mixture was quenched with 5% aqueous H_3PO_4 solution and diluted with ethyl acetate. The organic layer was washed with saturated $NaHCO_3$ solution and brine successively, and dried over $MgSO_4$. An aliquot of the solution was analyzed by GLC (1.5% silicone OV-17 on Chromosorb G, 3 mm×5 m, 210 °C) to give the diastereomeric tatio of 99:1 (34 and 36 min). The solution was concentrated and submitted to preparative TLC on silica gel with hexane–ethyl acetate (1:4) to give the α-hydroxy amide (**3a**) as a colorless oil (74.3 mg, 92%); $[\alpha]_D^{26}$ +5.4° (*c* 1.49, MeOH); IR (neat) 3400, 2900, 1635, 1440, 1370, 1145, 1105, 1030 cm^{-1}; ^1H NMR δ=1.30 (1H, s), 1.56—2.30 (4H, m), 3.28 (3H, s), 3.39 (3H, s), 3.42—3.94 (4H, m), 4.05—4.65 (2H, m), 4.47 (2H, s), 4.63 (2H, s), 5.16 (1H, s), 7.32 (5H, s). 2*S* epimer had the similar spectrum except for δ 5.38 instead of 5.16. Found: C, 60.93; H, 7.92; N, 3.88%. Calcd for $C_{18}H_{27}NO_6$: C, 61.17; H, 7.70; N, 3.96%.

(2*R*,5*R*)-*N*-[(2*R*)-2-Hydroxypropanoyl]-*trans*-2,5-bis(methoxymethoxymethyl)pyrrolidine (3b). A THF solution of $KBEt_3H$ (1 mol dm^{-3}, 0.31 ml, 0.31 mmol) was added to a solution of (**2b**, 90 mg, 0.31 mmol) and lithium bromide (54 mg, 0.62 mmol) in THF (3 ml) at −78 °C and stirred for 1 h. The mixture was quenched with 5% H_3PO_4 solution, diluted with $CHCl_3$–EtOH (3:1), washed with saturated $NaHCO_3$ solution and brine, and dried over $MgSO_4$. Concentration of the solvent and preparative TLC (hexane–ethyl acetate) afforded **3b** (75 mg, 83%) as a colorless oil. GLC analysis showed that the diastereomeric ratio was 95:5 (17 and 19 min, 180 °C). $[\alpha]_D^{25}$ +25.5° (*c* 1.88, MeOH); IR (neat) 3400, 2900, 1635, 1480, 1150, 1110, and 1040 cm^{-1}; ^1H NMR δ=1.31 (3H, d, *J*=6.6 Hz), 1.57 (1H, s), 1.70—2.28 (4H, m), 3.33 (6H, s), 3.38—3.70 (4H, m), 3.95 (1H, m), 4.25 (1H, m), 4.40—4.70 (1H, m), 4.57 (4H, s); Found: C, 53.35; H, 8.93; N, 4.72%. Calcd for $C_{13}H_{25}NO_6$: C, 53.59; H, 8.65; N, 4.81%.

Hydrolysis of (+)-3a to (*R*)-(−)-Mandelic Acid. The amide (**3a**, 37.2 mg, 0.105 mmol) was refluxed in 1 mol dm^{-3} HCl (0.422 ml) for 2 h. The mixture was neutralized with saturated aqueous $NaHCO_3$, washed with dichloromethane, and then adjusted to pH 1 with 2 mol dm^{-3} HCl. The aqueous solution was saturated with sodium chloride, extracted with ethyl acetate, and dried over $MgSO_4$. Evaporation of the solvent gave (−)-mandelic acid (12.8 mg, 80%); $[\alpha]_D^{26}$ −146° (*c* 0.555, H_2O); [lit,[11] $[\alpha]_D$ +158° (H_2O)]. Esterification with diazomethane afforded (−)-methyl mandelate, $[\alpha]_D^{26}$ −167° (*c* 0.48, benzene) [lit,[2d] $[\alpha]_D$ −181.9° (*c* 0.69, benzene)].

Hydrolysis of (+)-3b to (*R*)-(−)-Lactic Acid. A similar treatment of (+)-**3b** (90% de) as described above afforded (*R*)-(−)-lactic acid; $[\alpha]_D^{26}$ −2.0° (*c* 0.76, water). [lit,[12] $[\alpha]_D$ −2.3±0.5° (*c* 3, water)]; lithium salt; $[\alpha]_D^{26}$ +12.7° (*c* 0.315, water). [lit,[13] $[\alpha]_D^{22}$ −14.0° (*c* 3, water)].

Substituted Bisphenols as Antioxidants for Autoxidation of Tetralin

Fukiko YAMADA,* Tomihiro NISHIYAMA, Masahiro YAMAMOTO, and Kazunori TANAKA
Department of Applied Chemistry, Faculty of Engineering, Kansai University,
Yamatecho, Suita, Osaka 564
(Received March 16, 1989)

The antioxidative activities of nineteen compounds of seven series of alkylidene- and benzylidenebisphenols were evaluated by means of an oxygen-absorption method at 60 °C for tetralin. The electrochemical oxidation potentials determined using linear-sweep voltammetry and the ^{13}C NMR chemical shifts (δ) of these compounds were obtained. These data were associated with the antioxidative activities. In particular, the activities exhibited by the induction period (min) were found to closely correlate with the ^{13}C chemical shifts of the ipso-carbon of the OH substituent (corr. coeff.=0.991). Very good activities have been observed with a series of 2,2′-alkylidene- and benzylidenebis(4,6-dimethylphenol) derivatives.

In recent studies of benzylphenol derivatives as antioxidants,[1,2] we found that the introduction of a benzyl group to the para- and/or ortho-positions of the hydroxyl group on the benzene ring improved the antioxidative activities of phenols and that these activities increased with a decrease in the ^{13}C NMR chemical shifts (δ) of the ipso-carbon of the OH substituent. Subsequently, on the basis of these facts, we proposed the idea of obtaining a superior antioxidant in each series.[3] Namely, the introduction of a substituent would contribute to providing an upfield shift of the ipso-carbon of the OH substituent, resulting in a superior antioxidant. In our previous paper[2] a series of 4-methoxy-2-benzylphenols was reported as being very good antioxidants. By applying the above-mentioned idea, it was found that 2,2′-ethylidenebis(4-methoxyphenol) has a very good antioxidative activity, superior to those of a series of 4-methoxy-2-benzylphenols.[2,3] Consequently, the present work was directed toward the preparation of several series of substituted bisphenols as antioxidants.

In the present study, the antioxidative activities of nineteen compounds were evaluated by means of an oxgen-absorption method and are discussed in connection with their ^{13}C NMR chemical shifts and electrochemical oxidation data.

Experimental

Measurements. All melting points were uncorrected. ^{13}C NMR spectra were recorded on a Hitachi R-90H FT spectrometer at 22.66 MHz with complete proton decoupling. The spectra were observed as a 1 mmol cm^{-3} solution in $(CD_3)_2CO$. Chemical shifts were referred to internal TMS. GLC analyses were carried out on a Yanagimoto gas chromatograph (model GCG-G 1800-T) using a 1.50-m column packed with Silicone SE-30 (10% wt). Liquid chromatography was carried out on a Shimadzu model LC-6A using Shim-pack CLC-ODS column.

Antioxidants. The bisphenol derivatives studied in this work were as follows; 2,2′-ethylidenebis(4,5-dimethylphenol) (**1**), 2,2′-propylidenebis(4,5-dimethylphenol) (**2**), 2,2′-ethylidenebis(4,6-dimethylphenol) (**3**), 2,2′-propylidenebis(4,6-dimethylphenol) (**4**), 2,2′-isobutylidenebis(4,6-dimethylphenol) (**5**), 2,2′-benzylidenebis(4,6-dimethylphenol) (**6**), 4,4′-ethylidenebis(2,5-dimethylphenol) (**7**), 4,4′-propylidenebis(2,5-dimethylphenol) (**8**), 4,4′-benzylidenebis(2,5-dimethylphenol) (**9**), 4,4′-ethylidenebis(2,6-dimethylphenol) (**10**), 4,4′-propylidenebis(2,6-dimethylphenol) (**11**), 4,4′-benzylidenebis-(2,6-dimethylphenol) (**12**), 4,4′-ethylidenebis(2-isopropyl-5-methylphenol) (**13**), 4,4′-propylidenebis(2-isopropyl-5-methylphenol) (**14**), 4,4′-ethylidenebis(2-*t*-butyl-5-methylphenol) (**15**), 4,4′-propylidenebis(2-*t*-butyl-5-methylphenol) (**16**), 4,4′-isobutylidenebis(2-*t*-butyl-5-methylphenol) (**17**), 4,4′-benzylidenebis(2-*t*-butyl-5-methylphenol) (**18**), and 4,4′-methylenebisphenol (**19**).

Compounds **1**—**18** were prepared by a condensation of the corresponding phenol and aldehyde, respectively, in nitromethane using concd HCl as the catalyst for the desired time at a suitable temperature.[4] The general method for the preparation is as follows. To a well-stirred solution of phenol (0.1—0.2 mol) and aldehyde (0.09—0.18 mol) in nitromethane (50 ml), concd HCl (0.06—0.12 mol) was added dropwise. The reaction mixture was kept at a constant temperature. The progress of the reaction was followed by means of GLC analysis. After being stirred for a suitable length of time, the reaction mixture was cooled, and dichloromethane was added. The mixture was washed with cold water until freed from acidity. The extract was evaporated to give the crystalline product. The product was recrystallized from the hexane–dichloromethane (2:1). The product purified was characterized by chemical shifts in the ^{13}C NMR spectrum. The reaction conditions, results, and the physical properties of the products are summerized in Table 1.

Compoud **19** was commercially available and was purified by recrystallization; mp 157.5—157.8 °C.

Determination of Antioxidative Activity. Measurements of oxygen-absorption rates were performed with an isobaric gas-absorption apparatus under a closed-flow system (2.0± 0.1 L oxygen/h) provided with an electrolyser using 50 cm^3 of tetralin containing an antioxidant (0.001 mol dm^{-3}) and azobis(isobutyronitrile) as the initiator (0.01 mol dm^{-3}). The oxidation temperature was kept at 60±0.1 °C and oxygen absorption was periodically measured in a constant-pressure closed system. Satisfactory and reproducible data were obtained.

The induction period (IP) and the oxidation rates both

during and after the induction period were determined in the usual way.[2,5]

Tetralin was purified by shaking with concd sulfuric acid, dried with sodium, and distilled under an inert atmosphere.

Electrochemical Determination. Linear-sweep voltammograms were recorded for each compound (0.001 mol dm^{-3}) in acetonitrile with $LiClO_4$ (0.1 mol dm^{-3}) as a supporting electrolyte. The counter and working electrodes were made of platinum and the working electrode potential was referred to Ag/AgCl. Potential sweeps were generated by a Hokuto Deko HB-107A function generator in connection with a potentionstat Hokuto Denko HA-104. All the measurements at the scan rate of 200 mV s^{-1} were carried out at 25±0.1 °C using a constant-temperature bath under a nitrogen atmosphere. The acetonitrile was of optically pure grade and was free from water.

Results and Discussion

The ^{13}C NMR Chemical Shifts of Compounds 1—19. The ^{13}C signals in **1—19** were easily assigned using the known chemical shift rules on the parameters[6,7] and the results are given in Table 2. At first glance these shifts are thought to be dependent in the structures of the phenol nuclei with R_{1-3} substituents and various R substituents.

The δ value of C-1 carbon in compound **19** exhibits the lowest downfield shift in comparison with those of the compounds listed in the table. On the contrary, in compounds **3—6**, the C-1 values exhibit higher upfield shifts due to both substituent and steric effects produced by, ortho-, para-methyl, and R substituents.

In our previous study on benzylphenols,[6] it was found that the methylene carbons show signal shifts mainly due to the mesomeric effect of the OH substituent, and that in the case of ortho-substituted benzyl compounds, the methylene carbon signals exhibit upfield due to both mesomeric and steric effects. In this work, C-7 carbons correspond to the methylene carbons of benzylphenols[6] and the δ values of C-7 are influenced by the effects mentioned above. Furthermore, these shifts are greatly affected by each substituent R in the order methyl, ethyl, isopropyl, and phenyl.

Activities of Antioxidants. Data regarding the activities of compounds, **1—19** along with commercially available antioxidants, BHT and BHA, denoted by the induction period (IP), the stoichiometric factor (n), the rates of the oxygen absorption, and the oxidation potential (E_p) are listed in Table 3.

The autoxidation of tetralin at 60 °C was initiated by azobis(isobutyronitrile) (AIBN) and the inhibition by phenol derivatives can be described by the following chain-reaction schemes:[2,9,10]

Initiation:

$$\text{AIBN; RH} \xrightarrow{O_2} RO_2\cdot \quad (1)$$

Propagation:

$$RO_2\cdot + RH \xrightarrow{k_p} ROOH + R\cdot \quad (2)$$

$$R\cdot + O_2 \longrightarrow RO_2\cdot \quad (3)$$

Termination:

$$2RO_2\cdot \xrightarrow{k_t} \text{non-radical products} \quad (4)$$

$$RO_2\cdot + ArOH \xrightarrow{k_{inh}} ROOH + ArO\cdot \quad (5)$$

$$(n-1)RO_2\cdot + ArO\cdot \longrightarrow \text{non-radical products,} \quad (6)$$

where RH denotes tetralin in this work and $RO_2\cdot$ is the peroxyl radical. In the presence of an antioxidant, ArOH, the oxidation chains become shortened, termination 4 is suppressed, and reactions 5 and 6 occur instead of 4. Consequently, the induction period and the rates of inhibited and uninhibited oxidations can be represented by Eqs. 7, 8, and 9, respectively:

$$IP = n[ArOH]/R_i, \quad (7)$$

$$-d[O_2]/dt = k_pR_i[RH]/nk_{inh}[ArOH], \quad (8)$$

and

$$-d[O_2]/dt = k_p(R_i/2k_t)^{1/2}[RH], \quad (9)$$

where R_i is the rate of the chain initiation.

From the above equations, the characterizations of the antioxidative activities can be expressed by three

Table 3. Activities of Antioxidants along with the Oxidation Potentials for Compounds **1—19**

a) The stoichiometries were determined at 60 °C by the induction period method.[5,8] b) The rates of oxygen absorption; (I) for an inhibited autoxidation during IP and (II) for an uninhibited oxidation after IP.

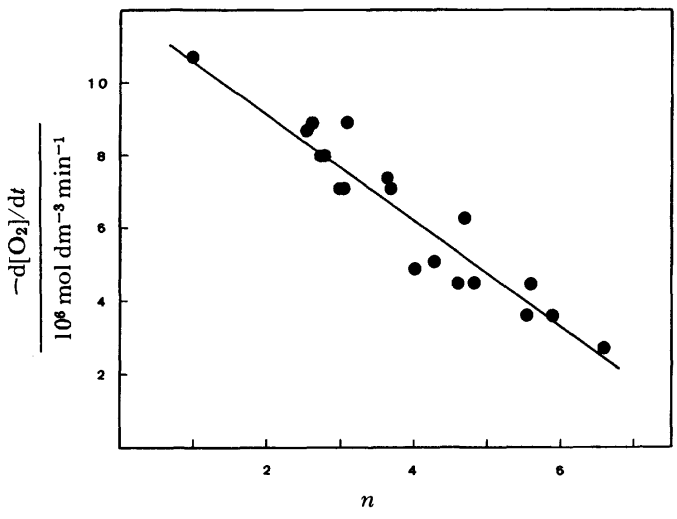

Fig. 1. Plot of n vs. the rate of oxygen absorption.

values: IP, n, and k_{inh}. However, the value of k_{inh} is difficult to obtain experimentally. Consequently, instead of this value the rate of oxygen absorption in Eq. 8 was used.

As can be seen from Table 3, the values are thought to be dependent on the structures of the phenol nuclei with various substitutents at different positions. The IP values increased in the order **3**—**6** (4,6-dimethylphenol)>**10**—**12** (2,6-dimethylphenol)>**1** and **2** (4,5-dimethylphenol)>**13** and **14** (2-isopropyl-5-methylphenol)>**7**—**9** (2,5-dimethylphenol)≧ **15**—**18** (2-*t*-butyl-5-methylphenol)>**19** (phenol). In each series, the compounds with the α-methyl or α-ethyl substituent possessed a longer IP than that of the α-phenyl substituent. Compounds **3**—**6** exhibit a much longer IP and, thus, higher stoichiometric factors, 5.5—6.6 in comparison with those of other compounds.

For oxygen absorption during IP (see (I) in Table 3), relatively lower rates were found in compounds **3**—**5**, while higher rates were observed for **7**—**9** and **17**—**19**. In particular, BHT exhibited the highest rate. According to Eq. 8, the rate varies inversely as the product of n and k_{inh}. In the range around 1 to 6 of n, the data showed an approximately linear relationship, as can be seen in Fig. 1. From this relation, it is thought that the k_{inh} values of compounds **1**—**18** are nearly equal. On the other hand, the rates after IP (see (II) in Table 3) are quite complicated. When all ArOH are consumed by reactions 5 and 6 (up to IP), the rate of autoxidation obeys Eq. 9 and is nearly equal to that of the control test. All of the observed rates are not close to 8.6, but are much lower. This means that the retardation ability persists, even after IP is over, due to some products of the antioxidant.

Correlations of Antioxidative Activities with ^{13}C NMR Chemical Shifts. In order to understand the factors and mechanisms govering the antioxidative activities of compounds **1**—**19**, several attempts were made to plot their IP values and the rates of oxygen absorption against the ipso-carbon chemical shifts of the OH substituets (C-1 shifts in Table 2). The data used in this attempt are listed in Tables 2 and 3.

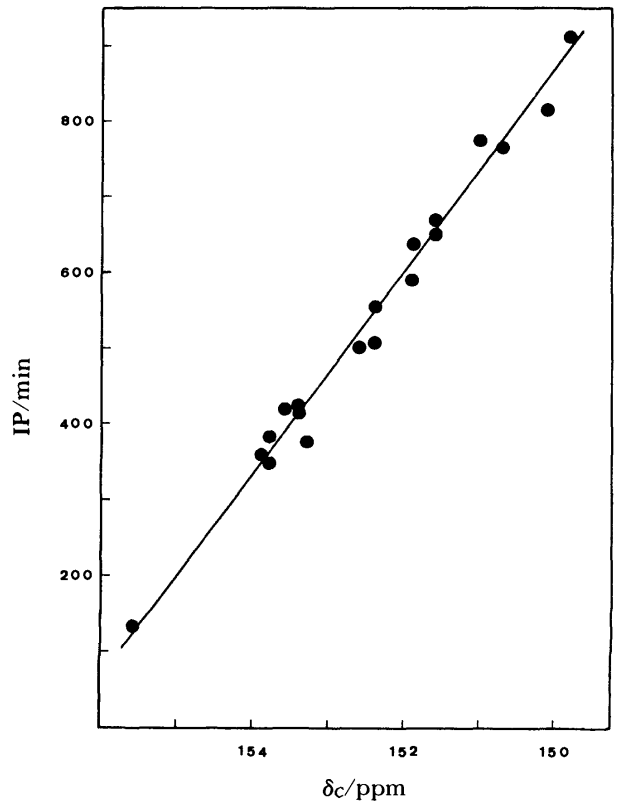

Fig. 2. Plot of IP vs. ^{13}C chemical shift of the ipso-carbon of OH, r=0.991.

Figure 2 shows the relation between the IP values and the ipso-carbon chemical shifts of the OH substituents. The plotted points fall on a straight line. This fact indicates that the IP values increase with a decrease in the chemical shifts, and that the electron density on ipso-carbon of the OH substituent governs the antioxidative activities. In a previous paper[11] we proved that, on the basis of the ^{13}C chemical shifts of *p*-substituted benzylbenzenes, electron transmission through the system by a resonance interaction is the most important factor for the α-carbon. It is, therefore, thought that electron transmission through the ipso-carbon to the oxygen atom in phenols depends mostly upon the resonance contribution. Consequently, the total π-electron density of the oxygen atom may be increased by increasing the electron density of the ipso-carbon atom. This will necessarily decrease the electronegativity of the oxygen atom and make the Coulomb integral of the σ orbital on the oxygen more positive.[12] In the inhibition processes, reactions 5 and 6, the reactivities of phenolic hydrogen and phenoxyl radical are the controlling factors. The reactivity of phenolic hydrogen for an attack of a peroxyl radical, electrophilic radical, is greatly elevated by an increased

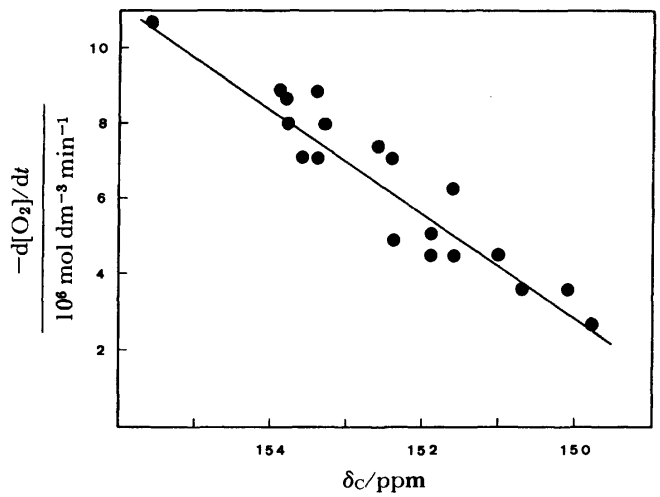

Fig. 3. Plot of the rate of oxygen absorption vs. ^{13}C chemical shift of the ipso-carbon of OH.

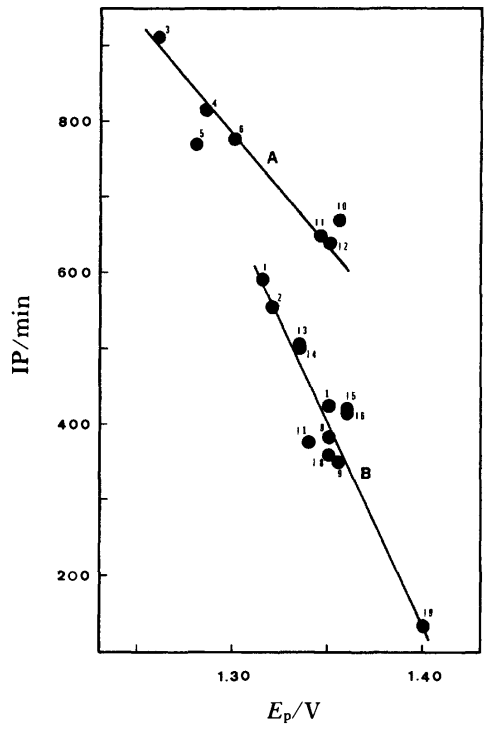

Fig. 4. Plot of IP vs. E_p.

π-electron density on the oxygen. The reactivity of the phenoxyl radical produced can be elevated by the increased π-electron density.

From the reasons mentioned above, the ipso-carbon chemical shifts of the OH substituents may be considered as being reliable and objective indications of the reactivities in the inhibition processes.

Figure 3 also shows a linear relation between the rates of oxygen absorption during IP and the ipso-carbon chemical shifts of the OH substituents. The rates increase with increasing chemical shifts. This indicates that the activity of the antioxidant, which can be expressed by both n and k_{inh} values, is greatly elevated by an increased π-electron density on the phenolic oxygen, as was mentioned above.

Correlations of Antioxidatiove Activities with Oxidation Potentials. As can be seen in Fig. 4, the IP values show two linear relationships, A and B, with the E_p values. Compounds having points plotted on line A have great steric effects on the OH substituent. The other compounds having points plotted on line B have a somewhat weak steric effect (see the structures and ^{13}C NMR data in Table 2). When the oxidation of a molecule is carried out at some potential, the reaction involves an initial electron loss, followed by proton migration. The simplicity of these transfers can be seen by the lower E_p values. In a previous paper[2] we proved that the ease of one-electron and one-proton transfers is greatly increased by an increased electron density at the ipso-carbon of the OH substituent, on the basis of the ^{13}C NMR chemical shifts.

In compounds **7** (on line B) and **10** (on line A), their E_p values are nearly equal (see also Table 3), while the IP values and the ^{13}C chemical shifts (Table 2) of the ipso-carbons of the OH substituents show considerable differences. In ^{13}C NMR data, the steric compression shift due to the substituent can be easily detected. For example, the OH substituent of 4-(α-methylbenzyl)phenol[2] or compound **19** is not sterically crowded. Consequently, their ipso-carbons of the OH substituents exhibit the shifts at δ 156.2[2] and 155.6 (Table 2), respectively. Compound **7**, having one methyl substituent at the ortho-position of the OH substituent, exhibits a shift at δ 153.4, while compound **10**, having two methyl substituents at both ortho-positions of the OH substituent, exhibits a shift at δ 151.6. This shift is 1.8 ppm upfield from that in **7**. Thus, compounds having sterically hindered phenol moieties, such as **3—6** and **10—12**, show very good antioxidative activities.

These facts indicate that in these compounds the electrochemical oxidation in solution and the inhibition reaction for autoxidation under an oxygen atmosphere proceed by a similar mechanism. However, there are some differences in the reaction mechanisms between the initial steps of both oxidations. Consequently, the contribution of the steric effect to the OH substituent appeared to be an important factor.

The present work was supported by a Grant-in-Aid for Scientific Research No. 62550619 from the Ministry of Education, Science and Culture.

The Discharge Characteristics of FeOCl in an Aprotic Organic Solvent

Zen-ichiro TAKEHARA,* Kiyoshi KANAMURA, Nobuyuki IMANISHI, and Chen ZHEN
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University,
Yoshida Hommachi, Sakyo-ku, Kyoto 606
(Received March 1, 1989)

The discharge reaction of FeOCl was investigated and the discharge products were identified by XRD and EPMA. Lithium and solvent co-intercalate into FeOCl during the early stage of the discharge, in the low lithium concentration range in the FeOCl solid matrix (Li_xFeOCl, $x<0.6$). Such compounds are stable. However, at higher concentrations of lithium, FeOCl co-intercalated by lithium and solvent gradually decompose to yield α-Fe and other compounds. The results show that three electrons are consumed during the discharge. On the other hand, the discharge curve of FeOCl in propylene carbonate containing 1.0 M $LiBF_4$ indicates only a single charge transfer step. Therefore, the reaction mechanism of FeOCl can be explained by the intercalation of lithium in FeOCl followed by the decomposition of the intercalation compound formed between FeOCl, lithium and the solvent. The structure of FeOCl intercalated by lithium changes during the course of immersion in various solvents. This fact indicates that the solvent can easily intercalate into FeOCl and deintercalate from FeOCl. Such a behavior may arise from a weakening of the interaction between FeOCl layers after lithium intercalation, since the intercalation of lithium into FeOCl influences the chemical bonds in FeOCl. As a result, the interaction between FeOCl layers becomes weaker. Therefore, the intercalation and deintercalation of the solvent can easily take place. The stability of the FeOCl structure after cathodic reduction does not depend only on the concentration of lithium in FeOCl, but also on the kind of solvent.

Layered compounds have been investigated and used as a cathode material for lithium batteries, since lithium ions can be intercalated into their van der Waals gap. The transition metal dichalcogenides, e.g. TiS_2 and MoS_2, are representatives of the most popular layered compounds. On the other hand, some of the transition metal halogenide oxides are also classified as layered compounds. Particularly, iron chloride oxide (FeOCl) has been investigated by some workers in order to be utilized as a cathode material for lithium secondary batteries.[1-3]

In this study, the intercalation of lithium into FeOCl was investigated. The stability of the FeOCl host matrix intercalated with lithium and its structural changes during the course of lithium intercalation are discussed in order to understand the discharge reaction mechanism of FeOCl when in contact with a propylene carbonate electrolyte.

Experimental

FeOCl was prepared by heating on an α-Fe_2O_3 and $FeCl_3$ mixture in a 3:4 mole ratio in sealed and evacuated Pyrex glass tube at 350 °C in an electric furnace for 3 days according to the method of Kikkawa et al.[4] The reaction products were washed fully for 1 day with water to remove excess $FeCl_3$ and washed again with acetone and then dried. The products, thus prepared, were identified by a comparison of the X-ray diffraction (XRD) results of Lind.[5] In this study the prepared FeOCl had the same structure as Lind's with respect to the XRD measurement. Cathode composites were prepared by compressing a mixture of FeOCl, a conducting material (acetylene black), and a binding agent (PTFE) in a weight ratio of 80:15:5. The apparent surface area was 0.785 cm^2. These electrodes were discharged at a constant current in propylene carbonate (PC) containing 1.0 M $LiBF_4$ (1 M=1 mol dm^{-3}). Lithium metal was used as both the reference electrode and the counter electrode. PC was distilled under vacuum. $LiBF_4$ was also dried at 150 °C under vacuum for 2 days. The structural changes of the host matrix along with the discharge process were traced by the XRD method. The samples for X-ray analysis were wrapped with a thin poly(vinylidene dichloride) film in order to avoid any reaction with oxygen and water from the air. Oxygen and water cannot permeate through the thin film during X-ray analysis. The measurement was conducted from $2\theta=70°$ to $2\theta=4°$ at a scan rate of 1° min^{-1}. The iron and chlorine contents of the active materials were analyzed by Electron Probe Micro Analysis (EPMA). All procedures, except for XRD and EPMA, were performed under an argon atmosphere at room temperature.

Results and Discussion

Figure 1 shows the discharge curves of FeOCl at two different current densities in PC containing 1.0 M $LiBF_4$. The discharge curve of FeOCl is different from that of TiS_2. In the case of lithium intercalation into

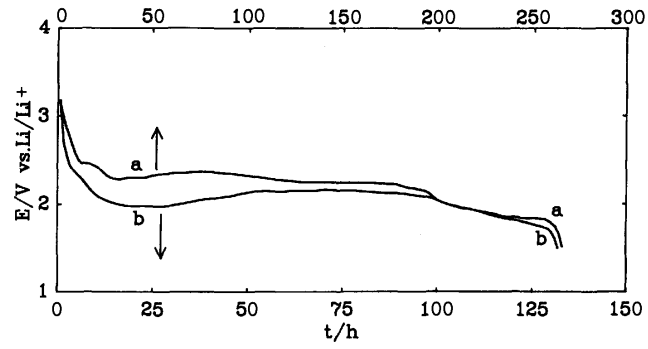

Fig. 1. The discharge curves of FeOCl in PC containing 1.0 M $LiBF_4$ at a constant current of 0.15 mA (a) and 0.3 mA (b).

TiS_2, the S-shaped discharge curve shows a typical simple intercalation of lithium into the host matrix, which takes place during the discharge.[1] For FeOCl, however, the profile of the electrode potential goes through a minimum during the initial period of discharge and then reaches to a potential plateau of about 2 V vs. Li/Li^+. Finally, the electrode potential sharply decreases to more cathodic potentials of about 1.5 V vs. Li/Li^+. Apparently, the discharge reaction may proceed via a single-step charge-transfer reaction.

When lithium intercalates into an interlayer of FeOCl, one electron reaction occurs during the discharge in aprotic solvents containing a lithium salt. Such a reaction can be written as

$$FeOCl + xLi^+ + xe^- \rightarrow Li_xFeOCl\ (0<x<1). \quad (1)$$

The valence of the iron in FeOCl decreases from three to two during the intercalation of lithium. Therefore, the theoretical capacity can be calculated to be 10 mA h from the weight of FeOCl included in the composite of the cathode material (weight of FeOCl=40 mg). The theoretical discharge duration is also calculated to be 33.4 hours (discharge current=0.3 mA). If the discharge was terminated at 1.9 V vs. Li/Li^+, the observed capacity was 30 mA h, which was about three times that of 10 mA h. This means that another reaction takes place in the course of the reduction of FeOCl. The observed capacity corresponds to that expected from the conversion of the iron valence from three to zero.

In order to confirm such a discharge reaction, X-ray diffraction analyses of the discharge products were performed. The X-ray diffraction patterns of FeOCl discharged in PC containing 1.0 M $LiBF_4$ are summarized in Fig. 2. All of the XRD results shown in Fig. 2 were for the stable structures after one week had passed. Figure 2 (a) shows the X-ray diffraction patterns of FeOCl before the discharge. The main peak at $2\theta=11.2°$ corresponds to the van der Waals gap of FeOCl. Figure 3 shows the structure of FeOCl.[5,6] It has a b-axis preferred orientation with an interlayer distance of 7.9 Å. From these patterns, it can be seen that the structure of FeOCl changes during a discharge. During the early stages of a discharge ($Li_{0.2}FeOCl$), its structure is quite different from that before the discharge. However, regarding this point, it must be noted that the stabilization of the structure requires a certain time after intercalation. As shown in Fig. 4, the structure of $Li_{0.2}FeOCl$ changed with the immersion time in PC. From the patterns it can be seen that the structural change was complete after two days. The new peaks in Figs. 2 (b) and (c) correspond to an expanded gap, for which the distance between FeOCl layers is 10.5 Å. Such a large interlayer distance cannot be explained by the intercalation of lithium

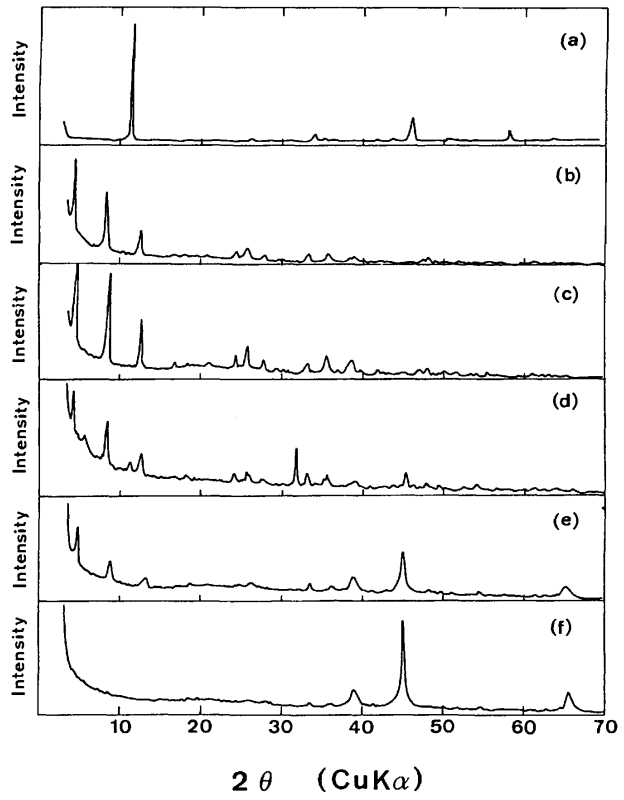

Fig. 2. X-Ray diffraction patterns of FeOCl before and after discharge. Discharge current=0.3 mA. (a) FeOCl, (b) $Li_{0.2}FeOCl$, (c) $Li_{0.6}FeOCl$, (d) LiFeOCl, (e) Li_2FeOCl, (f) Li_3FeOCl, where x in Li_xFeOCl corresponds to the mole ratio of lithium to iron. All the samples had been immersed in PC for one week after discharge.

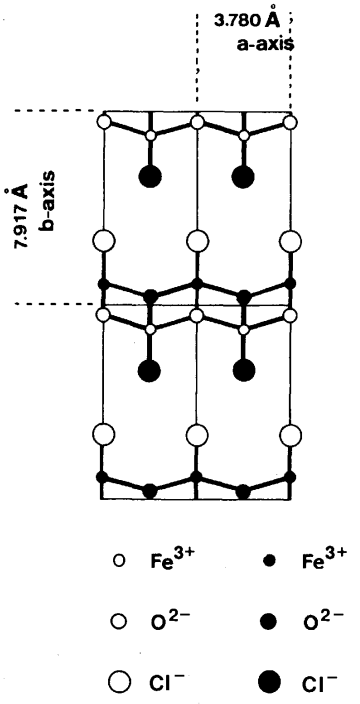

Fig. 3. Schematic illustration of the structure of FeOCl.

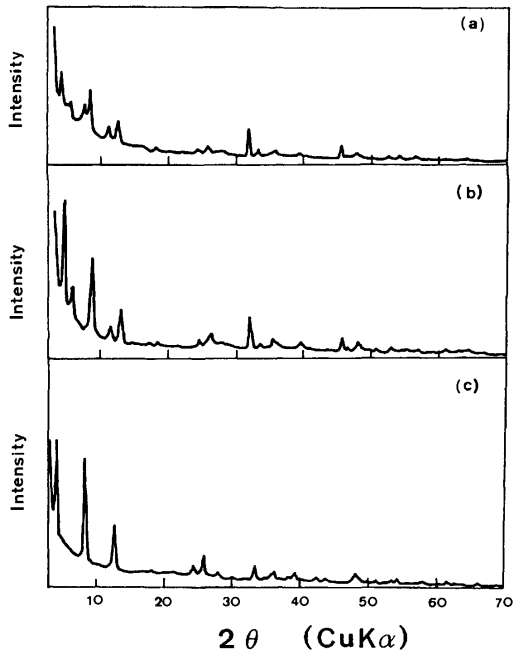

Fig. 4. X-Ray diffraction patterns of $Li_{0.2}FeOCl$ after immersion in PC for one hour (a), seven hours (b), and two days (c).

alone, since lithium is smaller than 1 Å. The large interlayer expansion results from the intercalation of lithium and the solvent. The molecular size of PC is about 5 Å. If PC intercalates into the FeOCl interlayer, the interlayer distance between Fe atoms could expand from 7.9 to 10.5 Å.

The X-ray diffraction pattern of $Li_{0.6}FeOCl$ showed the same peaks as $Li_{0.2}FeOCl$ (Fig. 2), indicating the formation of FeOCl intercalated by lithium and solvent. After sitting for two weeks, such a structure remained unchanged. These results indicate that the intercalation compound of FeOCl with lithium and the solvent is formed during a discharge and is stable in the region from $x=0$ to $x=0.6$, where x corresponds to the ratio of lithium to iron.

Figure 5 shows XRD patterns of $Li_{0.6}FeOCl$ which were discharged in PC and then immersed in various solvents. These XRD patterns were similar, except in the case of acetonitrile (ACN) and dimethoxyethane (DME). From the XRD patterns, no structural change could be observed. However, the peaks slightly shifted to a lower or higher angle. After the immersion in tetrahydrofuran (THF) or dimethylformamide (DMF), the three peaks shifted toward a higher angle. On the other hand, they shifted toward a lower angle after immersion in dimethylsulfoxide (DMSO) or γ-butyrolactone (γ-BL). In this way, the structural change of FeOCl intercalated by lithium was caused by immersion in various solvents. This fact indicates that an exchange of the solvent in the interlayer of FeOCl takes place between PC and the bulk solution, such as

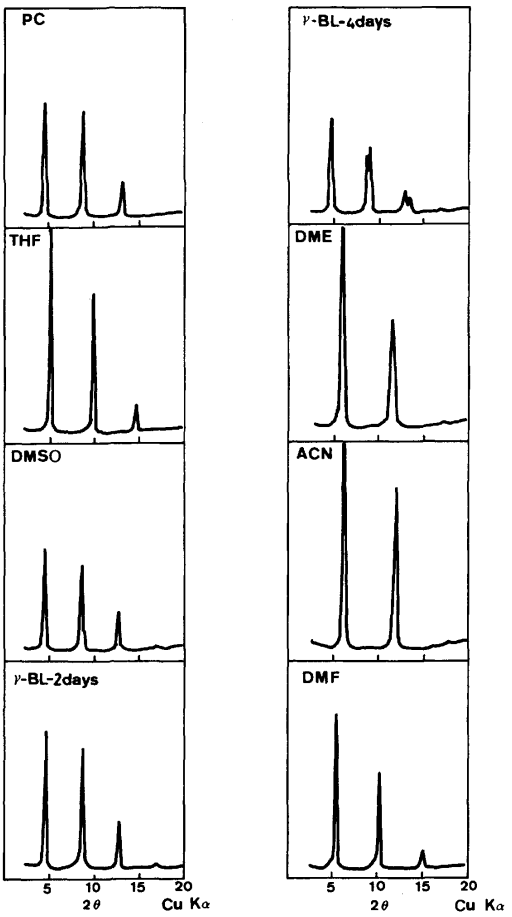

Fig. 5. X-Ray diffraction patterns of $Li_{0.6}FeOCl$ after the immersion in THF, DMSO, γ-BL, DMF, DME, ACN, and PC for two days and γ-BL for four days.

THF, DMSO, γ-BL, and DMF. However, XRD patterns after the immersion in ACN or DME indicated a structural change of $Li_{0.6}FeOCl$. Such a phenomenon can be understood by the strength of the interaction between solvent and FeOCl host matrix. The weak interaction between FeOCl layers may also be the main cause of the solvent exchange. The weak interaction between FeOCl interlayers results in the poor stability of Li intercalated FeOCl.

However, Li_xFeOCl ($x<0.6$) had to be treated carefully, because the stability of these compounds sharply decreased with increased drying time. X-Ray diffraction patterns of Li_xFeOCl ($x<0.6$) changed with the drying time under vacuum, as showed in Fig. 6. When Li_xFeOCl samples were removed from the experimental cell and then kept in an argon dry box for one or two weeks, the structure of the discharged FeOCl changed to an amorphous-like type. It seemed that the solvent being intercalated into the FeOCl deintercalated from the FeOCl interlayer while drying. On the other hand, Li_xFeOCl samples, which were kept in solvent for one or two weeks, were very stable and their X-ray peak positions did not change. From these results, it can be seen that the stability of

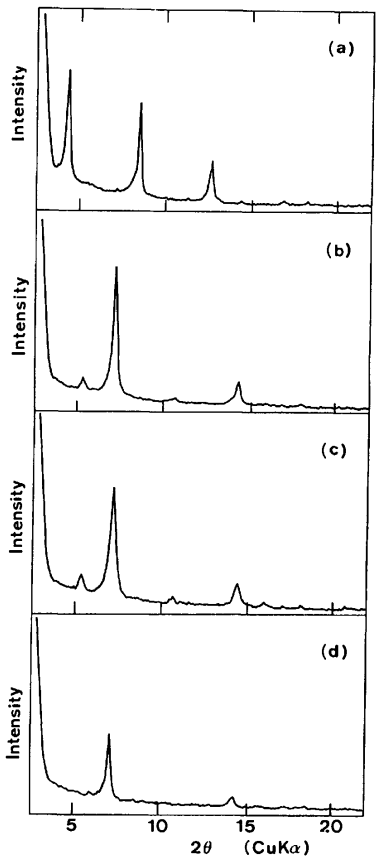

Fig. 6. The structural change of $Li_{0.2}FeOCl$ during drying under vacuum at 80°C for 0 min (a), 25 min (b), 45 min (c), and 65 min (d).

Li_xFeOCl is dependent upon the solvent intercalated into the FeOCl interlayer.

On the contrary, X-ray diffraction patterns of Li_xFeOCl ($x>1$) were very different from those of Li_xFeOCl ($x<0.6$), as shown in Figs. 2 (b), (c), (d), (e), and (f). The main peaks at $2\theta=12.62°$, 8.42°, and 4.24°, decrease when more lithium is inserted into the FeOCl. Moreover, some new peaks appear at $2\theta=45°$ and 66°, and increase with the lithium content. These new peaks in Fig. 2 (f) correspond to those of α-Fe. This tendency increases when more lithium is added. In Li_3FeOCl, X-ray peaks at the lower-angle region disappeared and new peaks increased in intensity and sharpness. Thus, FeOCl was reduced to α-Fe through the intermediate product. Apparently, three electrons are consumed during the discharge reaction of FeOCl. The electron number expected from the results of the X-ray diffraction method was in agreement with that expected from the observed discharge capacity. However, the decomposition of the intercalation compound of FeOCl is a very complex process. The X-ray diffraction pattern of Li_2FeOCl shows that other compounds besides α-Fe are formed during the decomposition. These compounds could not be identified by the XRD method.

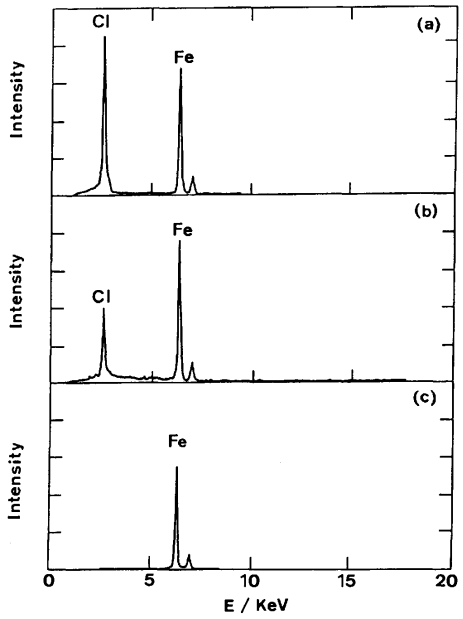

Fig. 7. EPMA results for FeOCl (a), Li_3FeOCl (b), and Li_3FeOCl washed by PC (c).

Elementary analyses of the discharge products of FeOCl were performed by using EPMA. Figure 7 shows the results. Before the discharge, the intensities of the iron and chloride peaks were almost the same, as shown Fig. 7(a). On the other hand, after the three-electron discharge of FeOCl, the chloride peak decreased to about one half that of iron, as shown in Fig. 7 (b). This result indicates that chloride was lost from the FeOCl structure during reduction. This sample was fully washed with PC and again analyzed for chloride. The result is shown in Fig. 7(c). The chloride peak became even smaller, and it was proved that chloride existed as a soluble species (LiCl). Part of the chloride ion remains in the cathode composite as LiCl, since the solubility of LiCl in PC is not very high.

The overall reaction of FeOCl can be assumed to be

$$FeOCl + 3Li^+ + 3e^- \rightarrow \alpha\text{-}Fe + LiCl + Li_2O. \quad (2)$$

However, Li_2O and LiCl were not detected by the XRD method.

Thus, the kinetics of the discharge reaction of FeOCl in an aprotic solvent are not simple. To summarize, as the discharge proceeds, lithium and solvent intercalate into the FeOCl interlayer. As a result, $Li_x(PC)FeOCl$ ($x<0.6$) is formed, which is a stable product in PC. With the proceeding of the discharge reaction, $Li_x(PC)FeOCl$ ($x>0.6$) decomposes to yield α-Fe as the discharge product.

The intercalation compound of FeOCl with lithium was stable in the region of low lithium concentrtion. However, with increasing lithium concentration,

FeOCl decomposes and α-Fe is formed. Such a decomposition permits a three-electron reaction of FeOCl. As a result, the capacity of FeOCl in primary cells is attractive. On the other hand, FeOCl cannot be utilized as the cathode material of a secondary lithium cell, because such a displacement reaction is not reversible. However, if this decomposition reaction could be somehow interrupted, it has the possibility of being utilized in a secondary battery. Further, it is seen that one possible way might be to insert another solvent into the FeOCl gap leading to a stable structure.

Analysis of Isotropic ^1H and ^{13}C NMR Shifts of Low-Spin Fe^{III} Complexes: Tetracyano(1,2-ethanediamine)ferrate(III) and Tetracyano(*N,N'*-dimethyl-1,2-ethanediamine)ferrate(III)

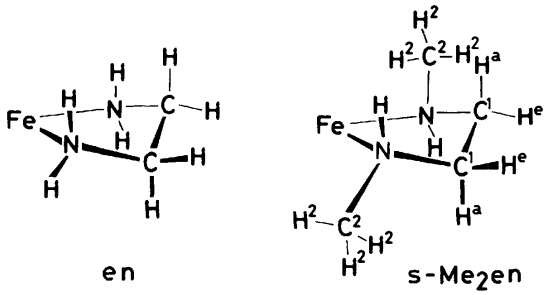
Yoshitaka KURODA,* Masafumi GOTO, and Tomoya SAKAI
Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467
(Received March 31, 1989)

^1H NMR spectra of low-spin d^5 complexes, $[Fe^{III}(CN)_4(en)]^-$ and $[Fe^{III}(CN)_4(s\text{-}Me_2en)]^-$ (en=1,2-ethanediamine, *s*-Me_2en=*N,N'*-dimethyl-1,2-ethanediamine), were measured at 185—323 K. These complexes showed a non-Curie behavior. The spin states of the complexes were determined by an analysis of the *g* values from the ESR spectrum of a polycrystalline sample of $[Fe^{III}(CN)_4(en)]^-$ measured at liquid-helium temperatures. The isotropic shifts for the ^1H and ^{13}C nuclei, δ^{iso}, were separated into Fermi contact shifts, δ^{con}, and dipolar shifts, δ^{dip} and the strong dependence of δ^{iso} on the location of ligand nuclei was found to be due to the different δ^{con} as well as δ^{dip}. A combination of information concerning ESR and NMR enabled the assignment of the *g* values obtained from a polycrystalline sample, i.e. $g_{xx}=3.15$, $g_{yy}=1.99$, and $g_{zz}=0.82$, and determination of spin-orbit coupling constant, $\zeta=160\ cm^{-1}$.

Numerous studies have appeared which applied NMR to investigate the stereochemistry and spin states of paramagnetic complexes, e.g. porphyrins[1] and heme proteins.[2-4] Most of the studies have, however, dealt with the NMR of unsaturated ligands, and little work has been done with saturated compounds coordinated to paramagnetic transition metal ions to investigate the correlations between the NMR shift and stereochemistry.[5]

Tetracyano(1,2-diamine)ferrates, $[Fe(CN)_4(1,2\text{-diamine})]^-$ and $[Fe(CN)_4(1,2\text{-diamine})]^{2-}$, are low-spin complexes with 1,2-diamine as a saturated compound. In a previous paper, we reported that the isotropic ^1H and ^{13}C NMR shifts, δ^{iso}, of the Fe^{III} complexes are strongly dependent on the location of the ligand nuclei and do not follow the Curie law.[6,7]

We have chosen $[Fe^{III}(CN)_4(en)]^-$ and $[Fe^{III}(CN)_4(s\text{-}Me_2en)]^-$ (en=1,2-ethanediamine and *s*-Me_2en=*N,N'*-dimethyl-1,2-ethanediamine) since the five-membered chelate ring formed by en is the simplest one among this class of complexes, and that formed by *s*-Me_2en is practically fixed in either the δ or λ conformation, at least below 323 K.[7] In this paper δ^{iso} for the ^1H and ^{13}C nuclei of the en and *s*-Me_2en complexes[6] were separated into Fermi contact shifts, δ^{con}, and dipolar shifts, δ^{dip}, by using the equations of Kurland and McGarvey.[8,9] Analysis of the ESR spectra of $[Fe^{III}(CN)_4(en)]^-$ at liquid-helium temperatures afforded the information necessary for the separation of δ^{iso} and the clarification of the non-Curie behavior. The distribution of unpaired spin over the chelates is discussed on the basis of the Fermi constants and spin populations in s orbitals for CH, NH, and C nuclei. The present treatment of δ^{iso} is a useful method for assigning the *g* values obtained from ESR measurements of polycrystalline samples, and determining the spin-orbit coupling constant.



Experimental

Materials. Sodium tetracyano(diamine)ferrate(III) and ferrate(II) (diamine=1,2-ethanediamine (en)[10] and *N,N'*-dimethyl-1,2-ethanediamine (*s*-Me_2en)[11]) and potassium tetracyano(1,2-ethanediamine)cobaltate(III)[12] were prepared as reported previously.

ESR Measurement. The ESR sample was prepared as follows: $Na[Fe^{III}(CN)_4(en)]\cdot 3H_2O$ (0.0010 g) and $K[Co^{III}(CN)_4(en)]\cdot H_2O$ (0.101 g) were dissolved in a solution (precooled at 0 °C) of acetic acid (0.25 cm^3), water (0.25 cm^3), methanol (1.0 cm^3), and ethanol (1.0 cm^3). Ether was added to this solution until it became turbid; the resulting mixture was allowed to stand at −15 °C overnight. Yellow crystals of the Co^{III} complex doped with the Fe^{III} complex were collected on a filter, washed with ether, and dried in vacuo. The obtained crystals were pulverized with an agate mortar and a pestle, placed in an ESR sample tube of 4 mm outer diameter, and sealed in vacuo. The sample was kept at −15 °C while being protected from light until the measurement.

ESR spectra on the polycrystalline sample were recorded with a Varian E-112 spectrometer at X-band frequency at liquid-helium temperatures. The magnetic field was calibrated with 2,2-diphenyl-1-picrylhydrazine (DPPH).

NMR Measurement. ^1H NMR spectra of $[Fe^{III}(CN)_4(diamine)]^-$ in CD_3OD (containing 0.25% DCl) were recorded on a JEOL FX-100 spectrometer at 323—185 K using a sample tube 5 mm in diameter. The concentrations of the complexes were ca. 0.05 mol dm^{-3} in order to prevent the deposition of the complexes below 273 K. Spectra with S/N ratios of ca. 20/1 were obtained by collecting 20—40 transients. Probe temperature were controlled with a JNM-VT-3C temperature-control apparatus and determined based

on the chemical shift difference between the methyl and hydroxyl protons of methanol.[13]

The ^1H and ^{13}C NMR spectra (NH and CH) of $[Fe^{III}(CN)_4(diamine)]^-$ were recorded on a JEOL FX-100 spectrometer at 300 K using a sample tube of 5 mm in diameter and 40—50 mg of the complexes dissolved in pD 2.0 DCl-D_2O (0.3 cm^3). The ^1H and ^{13}C NMR spectra of $[Fe^{II}(CN)_4(diamine)]^{2-}$ were measured in a manner similar to that described above, except that D_2O was used as the solvent.

Sodium 3-(trimethylsilyl)propionate-2,2,3,3-d_4 (TSP; 0.00 ppm) and 1,4-dioxane (67.44 ppm) were used as internal standards for ^1H and ^{13}C NMR measurements, respectively. Positive chemical shifts indicate downfield shifts.

Theoretical

We set the coordinate axes as shown in Fig. 1 for convenience, where the x axis coincides with the twofold axis of C_2 symmetry, and the other two axes are perpendicular to the twofold axis and are involved in the two symmetry planes defined by the donor atoms.

We assume that (1) the delocalization of 3d electrons into ligand orbitals is represented by the "orbital reduction factor",[14,15] k, and (2) there is no mixing of t_{2g} and e_g states. These assumptions lead to sixfold-degenerate t_{2g}^5 spin states in the field of O_h symmetry. The t_{2g}^5 configuration can be treated as being one electron hole in a closed t_{2g}^6 shell (one-hole notation).[15-18]

One-hole notation simplifies the expressions of the six states as follows:

$$|d_{xz}^{\pm}\rangle \equiv -(1/\sqrt{2})(|1^{\pm}\rangle - |-1^{\pm}\rangle),$$
$$|d_{yz}^{\pm}\rangle \equiv (i/\sqrt{2})(|1^{\pm}\rangle + |-1^{\pm}\rangle),$$

and

$$|d_{x^2-y^2}^{\pm}\rangle \equiv (1/\sqrt{2})(|2^{\pm}\rangle + |-2^{\pm}\rangle),$$

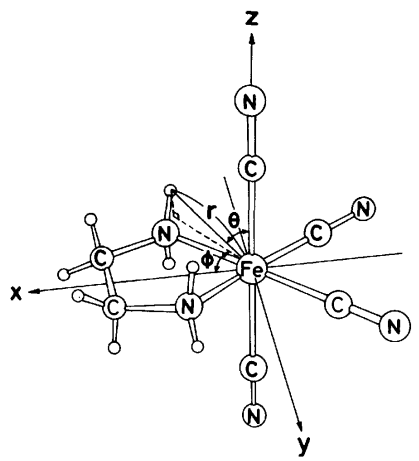


Fig. 1. Schematic representation of the coordinate system for analyzing magnetic resonances of $[Fe^{III}(CN)_4(diamine)]^-$.

where, for example, $|1^+\rangle$ represents a +1/2 spin state with a magnetic quantum number of +1.

ESR. The degeneracy of the t_{2g}^5 configuration is released to generate three Kramers doublets (Eq. 1) by perturbation arising from crystal-field distortions and spin-orbit coupling:

$$|\psi_i^{\pm}\rangle = \pm A_i|d_{xz}^{\mp}\rangle - iB_i|d_{yz}^{\mp}\rangle + C_i|d_{x^2-y^2}^{\pm}\rangle \quad (1)$$
$$i = 1, 2, \text{ and } 3,$$

where i=1 represents the ground doublet.

According to the methods reported by Bohan[19] and Taylor,[20] the eigenvalues of the Kramers doublets, E_i, and the axial and rhombic distortions of the crystal field, U and R, are expressed as follows:

$$E_i/\zeta = -(A_i+B_i+C_i)(1/A_i+1/B_i+1/C_i)/6+1/2, \quad (2)$$
$$U/\zeta = -(A_1+B_1+C_1)(1/A_1+1/B_1-2/C_1)/4, \quad (3)$$

and

$$R/\zeta = -(A_1+B_1+C_1)(1/A_1-1/B_1)/2, \quad (4)$$

where ζ (>0) is the spin-orbit coupling constant.

The principal g values are related to the coefficients of the ground Kramers doublet by the following expressions:[21]

$$g_{xx} = 2(-A_1^2 + B_1^2 + C_1^2 + 2kB_1C_1),$$
$$g_{yy} = 2(A_1^2 - B_1^2 + C_1^2 + 2kA_1C_1), \quad (5)$$

and

$$g_{zz} = -2(A_1^2 + B_1^2 - C_1^2 + 2kA_1B_1),$$

where $A_1^2+B_1^2+C_1^2=1$. For k=1, the coefficients are expressed in terms of the principal g values:

$$A_1 = (g_{yy} - g_{zz})/\sqrt{8(g_{xx} + g_{yy} - g_{zz})},$$
$$B_1 = (g_{xx} - g_{zz})/\sqrt{8(g_{xx} + g_{yy} - g_{zz})}, \quad (6)$$

and

$$C_1 = (g_{xx} + g_{yy})/\sqrt{8(g_{xx} + g_{yy} - g_{zz})},$$

where $g_{xx}+g_{yy}-g_{zz}$ must be positive because Eq. 5 shows

$$g_{xx} + g_{yy} - g_{zz} = 2(A_1 + B_1 + C_1)^2 > 0. \quad (7)$$

The coefficients and eigenvalues for the excited Kramers doublets are obtained by diagonalizing the following perturbation matrix with the U/ζ and R/ζ values calculated from Eqs. 3 and 4:

$$\begin{array}{c} \begin{matrix} |d_{xz}^{\mp}\rangle & -i|d_{yz}^{\mp}\rangle & |d_{x^2-y^2}^{\pm}\rangle \end{matrix} \\ \begin{pmatrix} -U/(3\zeta)-R/(2\zeta) & -1/2 & -1/2 \\ -1/2 & -U/(3\zeta)+R/(2\zeta) & -1/2 \\ -1/2 & -1/2 & (2U)/(3\zeta) \end{pmatrix} \end{array}$$

NMR. The tetracyano(diamine)ferrate(III) com-

plexes are paramagnetic (low-spin),[22] and the corresponding Fe^{II} complexes are diamagnetic.[6] We define isotropic shift, δ^{iso}, for the Fe^{III} complexes as the difference in chemical shift between the Fe^{III}, $\delta_{Fe^{III}}$, and Fe^{II} complexes, $\delta_{Fe^{II}}$: $\delta^{iso}=\delta_{Fe^{III}}-\delta_{Fe^{II}}$. δ^{iso} is composed of three parts,[8,9,23]

$$\delta^{iso} = \delta^{con} + \delta_L^{dip} + \delta_M^{dip}, \quad (8)$$

where δ^{con} is a Fermi contact shift, δ_L^{dip} is a ligand-centered dipolar shift, and δ_M^{dip} is a metal-centered dipolar shift. For ^1H nuclei δ_L^{dip} term is expected to be negligible.

The expressions for δ_M^{dip} and δ^{con} reported by Kurland and McGarvey[8,9] can be rewritten with the symbols used in Eqs. 1 and 2 as follows:

$$\delta_M^{dip}=(10^6/24\pi)[(2\chi_{zz}-\chi_{yy}-\chi_{xx})G_A+3(\chi_{xx}-\chi_{yy})G_B], \quad (9)$$
$$G_A = (3\cos^2\theta - 1)/r^3,\ G_B = \sin^2\theta\cos 2\phi/r^3, \quad (10)$$

$$\chi_{qq}=\mu_0\beta^2[k_BT\sum_{i=1}^{3}\exp(-E_i/k_BT)]^{-1}[\sum_{i=1}^{3}\exp(-E_i/k_BT)\cdot <\mu_q>_{ii}^2-2k_BT\sum_{i=1}^{2}\sum_{j=i+1}^{3}Q_{ij}<\mu_q>_{ij}^2], \quad (11)$$

$$Q_{ij}=[\exp(-E_i/k_BT)-\exp(-E_j/k_BT)][E_i-E_j]^{-1}, \quad (12)$$

$$\delta^{con}=10^6a_N\beta[6k_BT\gamma\hbar\sum_{i=1}^{3}\exp(-E_i/k_BT)]^{-1}\sum_{q=x,y,z}[\sum_{i=1}^{3}\exp(-E_i/k_BT)<\mu_q>_{ii}<s_q>_{ii}-2k_BT\sum_{i=1}^{2}\sum_{j=i+1}^{3}Q_{ij}<\mu_q>_{ij}<s_q>_{ij}], \quad (13)$$

where δ_M^{dip} and δ^{con} are in the unit of ppm, and their positive values indicate downfield shifts. G_A and G_B are geometric factors, and the distance r and angles θ and ϕ are defined as shown in Fig. 1. χ_{qq} ($q=x, y$, and z) is the principal axis component of the susceptibility tensor. μ_0, β, k_B, T, a_N, γ, and $\hbar$ are magnetic permeability of vacuum, the Bohr magneton, the Boltzmann constant, absolute temperature, Fermi contact coupling constant, magnetogyric ratio, and the Planck constant. $<\mu_q>_{ij}$ and $<s_q>_{ij}$ ($q=x, y, z$ and $i, j=1, 2, 3$) are defined as follows:

$$<\mu_x>_{ij} \equiv -A_iA_j + B_iB_j + C_iC_j + k(B_iC_j + B_jC_i),$$
$$<\mu_y>_{ij} \equiv A_iA_j - B_iB_j + C_iC_j + k(C_iA_j + C_jA_i),$$
$$<\mu_z>_{ij} \equiv A_iA_j + B_iB_j - C_iC_j + k(A_iB_j + A_jB_i),$$
$$<s_x>_{ij} \equiv -A_iA_j + B_iB_j + C_iC_j,$$
$$<s_y>_{ij} \equiv A_iA_j - B_iB_j + C_iC_j,$$

and

$$<s_z>_{ij} \equiv A_iA_j + B_iB_j - C_iC_j.$$

Since the three Kramers doublets belong to a single 1/2 spin state, Fermi coupling constants for them, a_N, are represented by a single value in Eq. 13, according to the theory of Kurland and McGarvey.[8,9]

Results and Discussion

Temperature Dependence of ^1H NMR Spectra. It is well-known that the 1,2-diamine coordinated to a metal ion takes λ and δ gauche conformations.[24] The λ and δ forms of the en chelate are enantiomeric and identical in energy and, hence, a conformational

a) Positive values indicate downfield shifts. b) Isotropic shift is defined as the difference in chemical shift between the Fe^{III} and Fe^{II} complexes. The chemical shifts for $C^1\underline{H}_2$ and $^{13}\underline{C}H_2$ of $[Fe^{II}(CN)_4(1,2\text{-ethanediamine})]^{2-}$ at 300 K were 2.50 and 45.2 ppm, respectively (Ref. 6). c) The chemical shift for $N\underline{H}_2$ of the Fe^{II} 1,2-ethanediamine complex is expected to be a few ppm, although it was not be measured owing to a rapid H-D exchange. The chemical shift observed for the Fe^{III} complex was hence regarded as isotropic shift. d) Ref. 6. e) The value is the sum of δ^{con} and δ_L^{dip}.

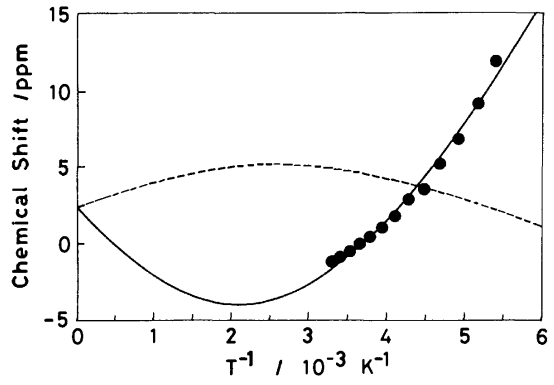

Fig. 2. Temperature dependence of ^1H NMR shift of the methylene protons of $[Fe^{III}(CN)_4(1,2\text{-ethanediamine})]^-$. The observed chemical shift (solid circle) is a time-averaged shift of the axial and equatorial protons due to a rapid conformational interconversion of the chelate between λ and δ gauche forms. Positive values indicate downfield shifts. The solid line shows the best-fitted curve of temperature dependence, and the broken line represents the results obtained from improper assignments of g values. The value at $T^{-1}=0$ represents the chemical shift observed for the diamagnetic Fe^{II} complex, $[Fe^{II}(CN)_4(1,2\text{-ethanediamine})]^{2-}$.

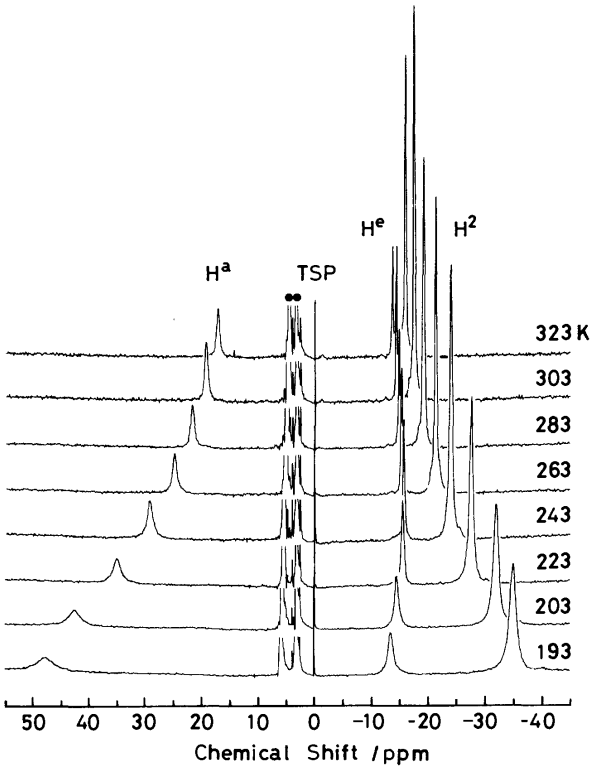

Fig. 3. ^1H NMR spectra of $[Fe^{III}(CN)_4(N,N'\text{-dimethyl-1,2-ethanediamine})]^-$ in CD_3OD containing 0.25% DCl at 323—193 K. A dot (●) indicates a solvent signal.

interconversion between them rapidly occurs on the NMR time scale near room temperature.[6,7] The CH_2 signal of the Fe^{III} complex broadened with a decrease

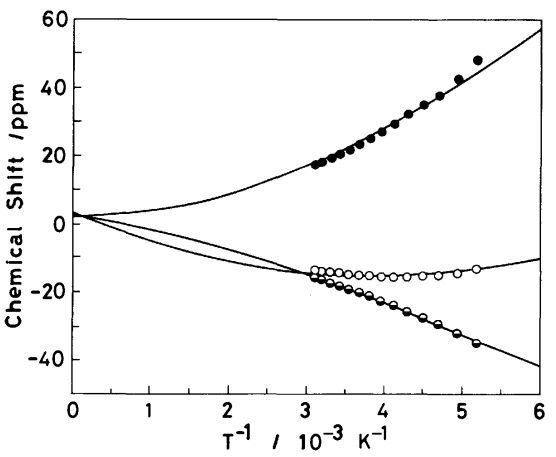

Fig. 4. Temperature dependence of ^1H NMR shifts of $[Fe^{III}(CN)_4(N,N'\text{-dimethyl-1,2-ethanediamine})]^-$. The solid lines are the curves best-fitted to the observed temperature dependence: H^a (●), H^e (○), and H^2 (◒). The values at $T^{-1}=0$ represent the chemical shifts observed for the diamagnetic Fe^{II} complex, $[Fe^{II}(CN)_4(N,N'\text{-dimethyl-1,2-ethanediamine})]^{2-}$.

in temperature, but did not split into two peaks corresponding to the axial and equatorial methylene protons, even at 185 K.[7] The downfield shift of the time-averaged signal accelerated with a decrease in temperature. The observed chemical shifts at 185—303 K are summarized in Table 1 and plotted in Fig. 2.

We reported in a previous paper[6] that a geometric isomerism exists for the Fe^{III} s-Me_2en complex, i.e., racemic and meso forms with respect to the N-methyl groups, and that the isolated complex was a racemic isomer. The five-membered chelate ring of s-Me_2en can be treated as fixed in either a δ or λ gauche conformation; in fact, the axial and equatorial protons (H^a and H^e) appeared as separated peaks at 20.45 and −14.59 ppm, even at room temperature, respectively. The NMR spectra of the racemic isomer measured at 193—323 K are reproduced in Fig. 3. The observed chemical shifts are summarized in Table 2 and plotted in Fig. 4. The decrease in temperature broadened all signals and moved H^a and H^2 signals toward downfield and upfield, respectively. The temperature dependence of H^e is unique: the direction of the variation of the chemical shift reversed at around 243 K. Figures 2 and 4 clearly show the non-Curie behavior of the Fe^{III} complexes.

Chemical Shifts of Amino Protons and Carbon Atoms. Resonances of NH of both the Fe^{III} en and s-Me_2en complexes were observed at 145 ppm at 300 K as a broad peak with a width of 290 and 380 Hz, respectively. The NH signals of the corresponding Fe^{II} complexes could not be observed due to a rapid H-D exchange between the amino protons and the solvent. The ^{13}C shifts of the Fe^{III} and Fe^{II} complexes reported previously[6] are collected together in Tables 1 and 2.

a) Positive values indicate downfield shifts. b) Isotropic shift is defined as the difference in chemical shift between the Fe^{III} and Fe^{II} complexes. The chemical shifts for H^a, H^e, H^2, C^1, and C^2 of $[Fe^{II}(CN)_4(N,N'$-dimethyl-1,2-ethanediamine$)]^{2-}$ at 300 K were 2.12, 2.78, 2.52, 54.2, and 41.8 ppm, respectively (Ref. 6). c) The chemical shift for NH of the Fe^{II} complex is expected to be a few ppm, although it was not be measured owing to a rapid H–D exchange. The chemical shift observed for the Fe^{III} complex was hence regarded as isotropic shift. d) Ref. 6. e) The value is the sum of δ^{con} and δ_L^{dip}.

ESR Spectrum of $[Fe^{III}(CN)_4(en)]^-$. The general expression of δ^{iso} given by Kurland and McGarvey[8,9] suggests that the eigenvalues and eigenfunctions of the excited as well as the ground Kramers doublets associated with the $^2T_{2g}$ term should be determined in order to analyze δ^{iso} which does not obey the Curie law. Since the required quantities are obtained from the analysis of g values, we measured the ESR spectrum of $[Fe^{III}(CN)_4(en)]^-$ shown in Fig. 5 at liquid-helium temperatures, using a polycrystalline sample diluted

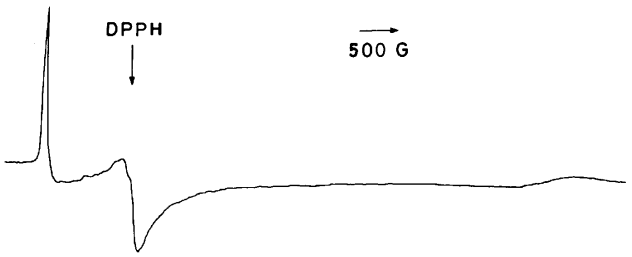

Fig. 5. ESR spectrum of $[Fe^{III}(CN)_4$(1,2-ethanediamine)$]^-$ measured at liquid-helium temperatures. The Fe^{III} complex was magnetically diluted to ca. 1/100 with $K[Co^{III}(CN)_4$(1,2-ethanediamine)].

magnetically to ca. 1/100 with the isostructural Co^{III} complex, $[Co^{III}(CN)_4(en)]^-$. The g values obtained after a correction of the magnetic field with DPPH were 3.15, 1.99, and 0.82.

The following expression of the product $g_{xx}g_{yy}g_{zz}$ is obtained from Eq. 5 with $k=1$:

$$g_{xx}g_{yy}g_{zz} = -8[(A_1 + B_1)^2 - C_1^2][(B_1 + C_1)^2 - A_1^2]\cdot [(C_1 + A_1)^2 - B_1^2].$$

For a complex with a crystal field largly distorted from O_h symmetry, the product is positive. A negative product is obtained for a complex close to O_h symmetry. Since the tetracyano en complex has two kinds of ligands (CN^- and en), which are different in crystal-field strength,[25-27] the complex is expected to have a largely distorted crystal field. The product was, hence, assumed to be positive in an analysis of the g values. To justify this assumption, we measured the Mössbauer spectra of $[Fe^{III}(CN)_4(en)]^-$ at 95—260 K. The temperature dependence of the quadrupole splitting supported $g_{xx}g_{yy}g_{zz}>0$.[28]

The following six sets satisfy Eq. 7 and give a norm close to unity, 0.961: (g_{xx}, g_{yy}, g_{zz})=(3.15, 1.99, 0.82), (1.99, 3.15, 0.82), (3.15, −0.82, −1.99), (−0.82, 3.15, −1.99), (1.99, −0.82, −3.15), and (−0.82, 1.99, −3.15). With the first set, the coefficients for the ground Kramers doublet were calculated from Eq. 6: A_1= 0.2030, B_1=0.4043, and C_1=0.8918. These values were corrected to 0.2108, 0.4141, and 0.8855 by Eq. 5 with k=0.905, respectively. Using the corrected values, we obtained U/ζ=−1.849 and R/ζ=−1.758 from Eqs. 3 and 4. Substitution of the U/ζ and R/ζ values into the perturbation matrix followed by diagonalization gave the following eigenvalues and coefficients for the lowest three Kramers doublets:

Set 1

A_1 = 0.2108, B_1 = 0.4141, C_1 = 0.8855, E_1/ζ = −1.5862,
A_2 = 0.1382, B_2 = 0.8841, C_2 = −0.4464, E_2/ζ = −0.0882,

and

A_3 = −0.9677, B_3 = 0.2165, C_3 = 0.1292, E_3/ζ = 1.6744.

The remaining five g-value sets give the same values of E_i/ζ; the coefficients for each set were obtained by rotating the values of Set 1. For example, Set 2 was obtained from the second set of g values:

Set 2

A_1 = 0.4141, B_1 = 0.2108, C_1 = 0.8855, E_1/ζ = −1.5862,
A_2 = 0.8841, B_2 = 0.1382, C_2 = −0.4464, E_2/ζ = −0.0882,

and

A_3 = 0.2165, B_3 = −0.9677, C_3 = 0.1292, E_3/ζ = 1.6744.

Estimation of Geometric Factors. The geometric factors for the present diamine chelates were calculated from Eq. 10, based on the assumption that the present Fe^{III} complexes have the same configuration of diamine chelate as the Co^{III} complex, *trans*-$[Co^{III}Cl_2(en)_2]Cl\cdot(H_5O_2)^+Cl^-$, the crystal structure of which was analyzed with neutron diffraction by Rozire and Williams.[29] The coordinates of the axial amino protons and the equatorial methyl groups of the Fe^{III} *s*-Me$_2$en complex were estimated, based on an assumption that these nuclei locate at the vertices of tetrahedron with bond lengths of C-H=1.09, N-H= 1.02, and C-N=1.48 Å.

The following values of G_A and G_B were obtained: for the en chelate; H, −1.554, 1.883; N<u>H</u>, −4.355, −1.832; C, −4.275, 3.884×10^{28} m^{-3}, where the former four values are the means of G_A and G_B values for the axial and equatorial protons, and for the *s*-Me$_2$en chelate; H^a, −1.270, 2.346; H^e, −1.838, 1.419; H^2, −0.9783, −1.864; N<u>H</u>, −3.813, −0.9187; C^1, −4.275, 3.884; C^2, −2.735, −2.441×10^{28} m^{-3}. The methyl protons of the *s*-Me$_2$en chelate was assumed to rotate freely.

Analysis of Isotropic Shifts. The observed values of δ^{iso} listed in Tables 1 and 2 were obtained by using the ^1H and ^{13}C chemical shifts for the diamagnetic Fe^{II} complexes, $[Fe^{II}(CN)_4(en)]^{2-}$ and $[Fe^{II}(CN)_4$(*s*-Me$_2$-en)$]^{2-}$, reported previously.[6] Since the chemical shifts for N<u>H</u> of the Fe^{III} complexes were very large, i.e. 145 ppm, and N<u>H</u> shifts of the corresponding Fe^{II} complexes are expected to be at most a few ppm, δ^{iso} of the N<u>H</u>'s was taken as 145 ppm.

The least-squares fitting of Eqs. 8—13 to the δ^{iso} values for C<u>H</u>$_2$ of the en complex yielded ζ=160 cm^{-1} and a_N=−0.69 MHz when Set 1 was used as eigenvalues and eigenvectors. The δ^{iso}, δ_M^{dip}, and δ^{con} estimated by this fitting are shown in the fifth-seventh columns of Table 1. The calculated shifts are compared with the observed shifts in Fig. 2. Set 1 gave the better fit (solid curve), but other sets, e.g. Set 2 gave unsatisfactory results (broken curve). The g values were therefore assigned as follows: g_{xx}=3.15, g_{yy}=1.99, and g_{zz}=0.82.

δ_M^{dip} values for other ^1H and ^{13}C nuclei of the en complex were calculated from Eqs. 9—12 by using Set

1 and ζ=160 cm^{-1}. The difference between the δ_M^{dip} and the observed δ^{iso} values corresponds to δ^{con} for ^{1}H nuclei and $\delta^{con}+\delta_L^{dip}$ for ^{13}C nuclei. These values are collected together in Table 1.

The Fe^{III} *s*-Me$_2$en complex offers an opportunity to investigate the δ^{iso} for H^a and H^e independently, since the complex has a fixed conformation in which both *N*-methyl groups take pseudoequatorial positions (eq-form).[30] The procedure mentioned above was applied to this complex, using Set 1 and ζ=160 cm^{-1}. The calculated results are summarized in Table 2, and the comparison of the observed and calculated shifts is shown in Fig. 4.

The magnitude of the ζ value is considered to be appropriate to the low-spin Fe^{III} complexes for the following reasons. (1) μ_{eff}=2.32 BM[31] at 303 K estimated from ζ=160 cm^{-1} is in good agreement with those observed for a series of tetracyano(1,2-diamine)-ferrate(III) complexes: (*R*)-1,2-propanediamine, 2.3; (1*R*,2*R*)-1,2-cyclopentanediamine, 2.4; (1*R*,2*R*)-1,2-cyclohexanediamine, 2.4 BM.[22] (2) Merrithew et al.[32] employed the spin-orbit coupling constant of ζ=150 cm^{-1} in their Mössbauer study of H[Fe^{III}(CN)$_4$(bpy)] and [Fe^{III}(CN)$_2$(bpy)$_2$]ClO$_4$. (3) We have obtained ζ=150—230 cm^{-1} from the temperature dependence of Mössbauer quadrupole splitting of [Fe^{III}(CN)$_4$(en)]$^-$ at 95—260 K.[28]

Since the application of ζ=160 cm^{-1} to the *s*-Me$_2$en complex gave good agreement between the observed and calculated shifts, as shown in Fig. 4, the variation of ζ is small in this class of Fe^{III} complexes. The combination of Set 1 and ζ=160 cm^{-1} leads to (1) the largest population of the electron hole in $d_{x^2-y^2}$ and (2) the first and the second excited states which are higher in energy by 2.9 and 6.2 kJ mol^{-1} than the ground state, respectively.

Dipolar Shift and Fermi Contact Shift. The δ_M^{dip} for the present Fe^{III} complexes calculated from Set 1 and Eq. 9 (Tables 1 and 2) is zero on the elliptical cone which intersects the *xz* and *yz* planes at 47.3 and 68.9°, respectively. The nuclei inside and outside the cone have negative and positive δ_M^{dip}, respectively. Since the methyl protons of the *s*-Me$_2$en chelate locate inside the cone and the other atoms are outside, δ_M^{dip} is negative for the former and positive for other atoms. The δ_M^{dip} for the methyl carbon is almost zero because this atom exists near the cone.

Subtracting δ_M^{dip} from δ^{iso} gave δ^{con} for each ^{1}H nucleus (Tables 1 and 2). The δ^{con} for H^a is near zero, i.e. $\delta^{iso}\simeq\delta_M^{dip}$. But H^e has large negative δ^{con}, i.e. upfield shift of 30—50 ppm at 193—323 K. H^a and H^e have different δ^{con} values, although they are bound to the same carbon atom.

The δ_M^{dip} for H^e is positive and considerably small in magnitude compared with the negative δ^{con} for H^e. The magnitude of the δ^{iso} for H^e is, hence, reduced and its variation with temperature is small. The characteristics of δ^{iso} for the tetracyanoferrate(III) complexes, e.g. the different sign of δ^{iso} for H^a and H^e and the peculiar temperature dependence of δ^{iso} for H^e, are the results of the different contribution of δ_M^{dip} and δ^{con} for these protons.

The δ_M^{dip} and δ^{con} for H^2 are both upfield shifts, and the δ^{con} of −12.7—−21.1 ppm at 193—323 K is close to the mean of δ^{con}'s for H^a and H^e, i.e. −15.2—−25.3 ppm. This fact suggests that the unpaired spin is transferred to the freely rotating H^2 in a way similar to H^a and H^e.

The large δ^{iso} observed for N<u>H</u> was ascribed to large δ^{con}, ca. 135 ppm, which is larger than at least 4 times that for C<u>H</u>.

For ^{13}C nuclei, δ^{iso} was separated into δ_M^{dip} and $\delta^{con}+\delta_L^{dip}$ (Tables 1 and 2). The carbon atoms constituting the five-membered chelate rings have $\delta^{con}+\delta_L^{dip}$ of 170—210 ppm, and its contribution to the δ^{iso} is over 80%. Since δ_L^{dip} for ^{13}C nucleus is not zero,[8,23] an estimation of δ^{con} for the ^{13}C nucleus requires an elimination of the δ_L^{dip} contribution. A calculation of δ_L^{dip}, however, requires many approximations, as shown in the treatment of ^{13}C NMR shift for [Fe^{III}-(CN)$_6$]$^{3-}$ by Kurland and McGarvey;[8,23] hence, the separation of δ^{con} and δ_L^{dip} may be a problem to settle in future.

Fermi Contact Coupling Constant and Spin Population. The a_N values obtained from the fitting calculation are listed in Table 3. The population of the unpaired spin in the 1s orbital of hydrogen, Q_{1s}, and that in the 2s orbital of carbon, Q_{2s}, were calculated from the a_N by the relations $Q_{1s}=a_N/1420$ and $Q_{2s}=a_N/3110$, where 1420 and 3110 MHz are the Fermi constants calculated for ^{1}H· and ^{13}C· radicals, respectively.[33] The estimated values of Q_{1s} and Q_{2s} are listed in Table 3.

The a_N value for H^e, −1.11 MHz, is similar in magnitude to those for ^{1}H nuclei of unsaturated ligands in low-spin Fe^{III} complexes: −1.08 MHz for ^{1}H nuclei at the position 6 and 6′ of 2,2′-bipyridyl in [Fe^{III}(bpy)$_3$]$^{3+}$, and −1.03 MHz for ^{1}H nuclei at the

Table 3. Fermi Contact Coupling Constants (a_N) and Spin Populations Estimated for [Fe^{III}(CN)$_4$(1,2-ethanediamine)]$^-$ and [Fe^{III}(CN)$_4$(*N*,*N*′-dimethyl-1,2-ethanediamine)]$^-$

Diamine	Nucleus	a_N/MHz	Spin population
en	N<u>H</u>	4.63	0.0033
	H	−0.69	−0.0005
	C	1.42	0.0005
s-Me$_2$en	N<u>H</u>	4.50	0.0032
	H^a	0.01	0.0000
	H^e	−1.11	−0.0008
	H^2	−0.46	−0.0003
	C^1	1.74	0.0006
	C^2	0.98	0.0003

position 2 and 9 of 1,10-phenanthroline in $[Fe^{III}(phen)_3]^{3+}$.[34] The fact that the latter two values are the largest among the a_N values observed for ^1H nuclei within these complexes suggests that σ bonds are not lower in facility of spin propagation than π bonds. The a_N values for ^{13}C nuclei are 1.4—1.7 MHz, though it should be noted that these values were obtained by assuming $\delta_L^{dip}=0$.

Spin population (Table 3) is a better scale for a comparison of the heteronuclear NMR shifts than a_N, since the latter depends on the magnetogyric ratio. The positive spins on NH and C and the negative spins on CH suggest the propagation of spin by polarization effect which results in an alteration in the sign of the spin population with each σ bond.

The transfer of unpaired spin from the Fe^{III} ion to the diamine ligands is considered to occur mainly between the 3d orbitals and the sp^3 hybridized orbitals of the nitrogen atoms by a polarization mechanism.[35] Most of the unpaired spin resides in the $3d_{x^2-y^2}$ orbital, as Set 1 shows; thus, this feature of electronic configuration is expected to result in the predominant population of the unpaired spin near the planes of the chelate rings. The large difference between H^a and H^e can be explained by this anisotropic population.

This work was supported partly by the Joint Studies Program (1980—1981) of the Institute for Molecular Science. We wish to express thanks to Dr. Toshiaki Enoki of Tokyo Institute of Technology for assisting in the measurement of the ESR spectrum. We are grateful to Professor Mitsuo Sato of Teikyo University and Dr. Tetsuo Asaji of Nagoya University for valuable discussions.

(Received May 11, 1989)

The hydrogenation of isoquinoline (**1**) to isomeric decahydroisoquinoline (**4**) via 1,2,3,4-tetrahydroisoquinoline (**2**) or 5,6,7,8-tetrahydroisoquinoline (**3**) was kinetically studied over supported ruthenium catalysts under 50—100 atm hydrogen pressure at 135—170 °C. The results showed that the reaction proceeds mainly via **2** over ruthenium on carbon, and via **2** and **3** competitively over ruthenium on alumina. Such reaction features are explained from the view points of their adsorption and the activation of the molecules on the catalysts based on quantum chemical indices. The acidic nature of alumina support exhibited a preference of nitrogen lone-pair defining the adsorption of substrates, and consequently influencing on the reaction route. The proposed approach distinguished the present catalyst from Raney nickel examined in a previous paper. The noble and base metals may interact differently with the substrate, although both metals are classified as "soft".

In a previous paper,[1] we reported the selective preparation of some useful hydroisoquinolines using several commercial catalysts. Raney nickel (R-Ni) promoted the following consecutive reactions: **1**→**2**→**3**→**4** (cis) →**4** (trans).[2] On the other hand, a preliminary examination of a ruthenium catalyst suggested that **1** was rapidly hydrogenated to the cis- and trans-isomers of **4** via **2** and **3** simultaneously. The isomeric mixture of **4** is a starting material to perfluoro (*N*-methyldecahydroisoquinoline), an oxygen carrier for medical use.[3] Therefore, it is practically important to clarify the kinetics and mechanism of hydrogenation of **1** over ruthenium catalysts to control the product selectivity.

In the present work, the hydrogenation of **1** was studied kinetically in detail using ruthenium on carbon (Ru/C) and on alumina (Ru/Al_2O_3). Such a study may allow discussion on the reaction pathways for the hydrogenation of **1**, and on the adsorption and activation of substrates over ruthenium catalysts, both of which are expected to be entirely different from those over R-Ni. The structural factors of the substrates which influence strongly on their adsorption and activation are discussed by a semiempirical molecular orbital calculation.

Experimental

Materials. Isoquinoline was used after purification of commercial grade material produced from coal tar. Two tetrahydrogenated isomers were separated from the hydrogenated isoquinoline. Both procedures were described in the previous papers.[1,2] No sulfur-containing contaminant was found in all substrates. Ru/C was purchased from Nippon Engelhard Ltd. in dry state. Ru/Al_2O_3 was purchased from Nikki Chemical Co. in wet state (water content is about 50 wt%) and used without drying. Their ruthenium contents were 5 wt% on the dry base.

Hydrogenation Procedure and Analytical Method. 100 g of a starting material was hydrogenated over ruthenium catalyst in a 200 ml-autoclave with stirring at a constant pressure and temperature. The reaction conditions for three starting substrates (**1**, **2**, and **3**) were as follows; temperature range: 135—170 °C, hydrogen pressure range: 50—100 atm, amount of Ru/C or Ru/Al_2O_3 catalysts: 4 wt% in dry state per substrate (see Table 2 for the detailed conditions). The reaction mixture was sampled at appropriate times, and was diluted to 5 ml with methanol. After filtering off the catalyst, the product was analyzed by gas chromatography as described previously.[2] **4** contained two isomers, of which cis/trans ratio ranged from 2 to 4. The compounds other than **1**—**4** were less than 5% in all of the reactions.

Quantum Chemical Calculation. Quantum chemical indices of isoquinoline and its derivatives were obtained by the MNDO-MO[4] calculation using a CRAY X-MP/216 computer.[5] The geometries of all of the molecules were energetically optimized with the flat configuration of aromatic rings.

Results

Kinetic Modeling. Some kinetic models were tested, and the network shown in Fig. 1 and the following Langmuir-Hinshelwood type rate equations[2,6-8] were found to fit with our experimental data. This network contains the isomerization of **2** to **3**, but neither

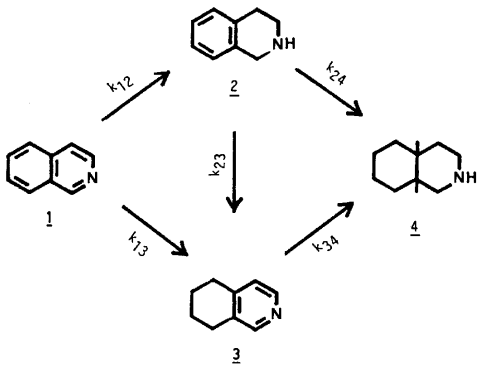

Fig. 1. Simplified reaction network for kinetic analysis.

dehydrogenation nor cis/trans isomerization of **4** was included, because relatively higher hydrogen pressures, lower temperatures, and shorter reaction times were employed in this work.

$$\frac{dC_1}{dt} = \frac{-m(k_{12}+k_{13})K_1C_1}{1+K_1C_1+K_2C_2+K_3C_3+K_4C_4} , \quad (1)$$

$$\frac{dC_2}{dt} = \frac{m[k_{12}K_1C_1-(k_{23}+k_{24})K_2C_2]}{1+K_1C_1+K_2C_2+K_3C_3+K_4C_4} , \quad (2)$$

$$\frac{dC_3}{dt} = \frac{m[k_{13}K_1C_1+k_{23}K_2C_2-k_{34}K_3C_3]}{1+K_1C_1+K_2C_2+K_3C_3+K_4C_4} , \quad (3)$$

and

$$\frac{dC_4}{dt} = \frac{m[k_{24}K_2C_2+k_{34}K_3C_3]}{1+K_1C_1+K_2C_2+K_3C_3+K_4C_4} , \quad (4)$$

where C_i is the concentration of species i (the initial value of isoquinoline, $C_1(t=0)$, was 8.52 mol dm^{-3} under STP conditions), t is the reaction time (h), m is the concentration of catalyst (g dm^{-3}), k_{ij} is the apparent rate constant of reaction $i \rightarrow j$ (the constant is a function of hydrogen pressure), and K_i is the equilibrium adsorption constant of species i. In contrast to the case of the R-Ni catalyst,[2] absolute values of K_i were calculated in this study, because unity in the denominator of Eqs. 1—4 was not neglected on the ruthenium catalysts.

Equilibrium Adsorption Constants and Rate Constants. K_i and k_{ij} in the above equations were determined by a curve fitting procedure. It was assumed that each value of K_i is constant under the present expreimental conditions when the same catalyst is used. The theoretical product distributions were calculated by a numerical analysis containing the Runge-Kutta-Gill routine. The values of K_i and k_{ij} were determined with the degree of agreement between experimental product distributions and the respective theoretical values. First, K_3, K_4, and k_{34} were determined by the Eqs. 3 and 4 and the data obtained from the experiment in which **3** was employed as the starting material. Secondly, K_2, k_{23}, and k_{24}, were determined with the above values of K_3, K_4, and k_{34}, the Eqs. 2—4 and the data obtained from the experiment in which **2** was employed as the starting material. Thirdly, K_1, k_{12}, and k_{13} were determined in a similar manner to the above. Figures 2—7 show some example of the product distributions on the hydrogenation of **1**, **2**, and **3** over Ru/C or Ru/Al_2O_3. The calculated values (solid lines) are in good agreement with the experimental data (dots). Their presisions of simulation were about ±5%. It is noticed during the

Table 1. Equilibrium Adsorption Constants

Catalyst	K_1	K_2	K_3	K_4
	$dm^3\ mol^{-1}$			
Ru/C	35.0	2.3	7.0	0.12
Ru/Al_2O_3	70.0	4.7	14.1	1.8

Table 1 summarizes the values of K_i. The precision of constants K_i was about ±50%. The relative values of K_i/K_1 over the ruthenium catalysts are different from that over R-Ni reported previously.[2] The respective relative values except for K_4/K_1 were much the same over Ru/C and Ru/Al_2O_3.

Table 2 summarizes the values of k_{ij}. The precision of the constants was about ±20%. The value of k_{13} over Ru/Al_2O_3 is much larger than that over Ru/C. Roughly linear relations of the constants against hydrogen pressure were observed at 150 °C over Ru/C as shown in the table.

The effects of temperature on rate constants of all steps over Ru/C under 100 atm of hydrogen pressure are shown in Fig. 8. The apparent activation energy of

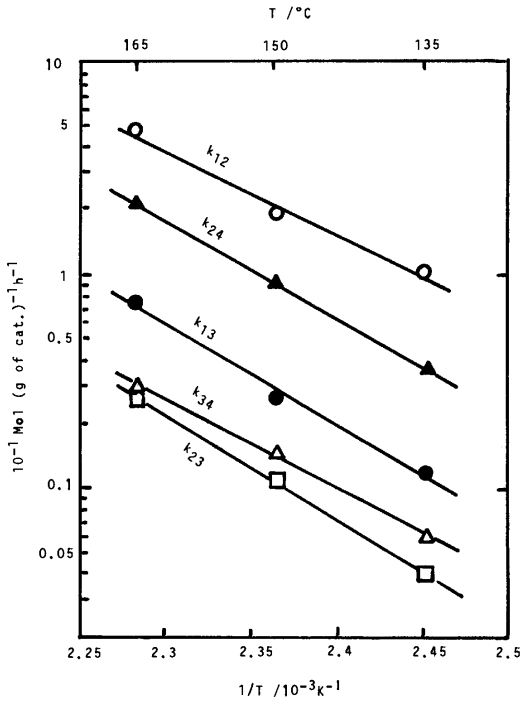

Fig. 8. Arrhenius plot for hydrogenation of isoquinoline over Ru/C under 100 atm H_2 pressure.

step **2**→**4** over Ru/C was calculated to be 20±4 kcal mol^{-1} from the gradients of lines in the figure. It is recognized that the barrier of step **2**→**4** over Ru/C is lower than over R-Ni(about 60 kcal mol^{-1}).[2]

Dominant Reaction Routes. As the result of above analyses, the dominant routes in hydrogenation of **1** to **4** were determined as illustrated in Fig. 9. The reaction proceeds mainly via **2** over Ru/C, and competitively via **2** and **3** over Ru/Al_2O_3. The isomerization of **2** to **3** is very minor and the hydrogenation of **2** to **4** proceeds readily on both ruthenium catalysts in contrast to R-Ni catalyst. The rates of each step except **1**→**2** over Ru/Al_2O_3 are larger than those over Ru/C.

Quantum Chemical Calculation. Table 3 summarizes quantum chemical indices of isoquinoline and its tetrahydrogenated derivatives. Some notable conclusions are as follows: The calculations appear to reproduce the thermodynamic stability of substrates and products. The total energy and energy levels of frontier orbitals indicate that **1** is stabilized by hydrogenation, and that **2** is more stable than **3**. The electronegativity of N-atom localizes more π-electrons in pyridine ring than benzene ring of **1**. The degree of localization is decreased by the hydrogenation of pyridine or benzene ring of **1**. A similar trend of localization is also noted for π-bond orders.

Discussion

The kinetic anlysis of the present study revealed that ruthenium catalysts have some contrast features is the catalytic hydrogenation of isoquinoline to those of R-Ni in the previous studies.[1,2] The catalytic reactions on ruthenium catalysts proceeded in two consecutive routes of **1**→**2**→**4** and **1**→**3**→**4**. The selectivity between the two routes depends upon the supports, carbon or alumina.

Products of **2** and **3** were not further hydrogenated into **4** before almost all of **1** disappeared on the Ru catalysts, while the product retardation indicating stronger adsorption of **2** was observed on R-Ni as previously reported.[2] Such reaction features of the ruthenium catalyst reflect on the equilibrium adsorption constants shown in Table 1. Strong adsorption of **1**, moderate one of **2** and **3** and very weak one of **4** are clearly indicated in the table. In spite of slightly stronger adsorption of **3**, **2** competes with **3** for the active sites for further hydrogenation to **4**, probably due to different concentrations of active sites which reflect on the selectivity.

Such a trend of adsorption strength is completely different from that on R-Ni, which is appreciably related to the pK_a values of the substrates.[1] Although nitrogen heterocyclic compounds such a pyridine and isoquinoline have been widely believed to be vertically adsorbed at their nitrogen lone pair onto the metal surfaces[9,10] as postulated on R-Ni,[2] the aromatic π-electrons can also contribute to the adsorption on metals such as ruthenium which is classified as a "soft" metal.[11] Such π-coordination[12,13] appears to play a major role in defining the trend of adsorption strength on the present noble catalysts.

The equilibrium adsorption constants over the present catalysts will be relevant in first approximation to their number of π-electrons. It is obvious that adsorption of **4** is very weak due to the absence of π-electron. The minor difference betweeen **2** and **3** of the same π-electron number may be ascribed to slightly more localization of π-electron on the nitrogen atom of the substrate **3** according to the quantum chemical calculation. It has been pointed out that the back donation from the metal to the substrate contributes strongly to the adsorption of unsaturated substrate.[14] The energy level of LUMO can be an index for the degree of the back-donation. Substrates **1**, **3**, and **2** show a rising order of energy level of their LUMO as shown in Table 3, corresponding again to the order of their adsorption constants.

Such an adsorption through π-electrons in the aromatic ring defines the adsorption form of **1** to be flat to the surface. The heterocyclic ring which is more reactive as discussed later is preferentially hydrogenated to produce **2**. However, some chance of hydrogenation of benzene ring may also exist to produce **3** especially when the hydrogenation of heterocyclic ring is hindered by some reason. The latter hydrogentation is very difficult on R-Ni, where the substrate seems to be adsorbed vertically at its nitrogen atom in the direction of lone-pair.[2]

The rate constant of the hydrogenation on Ru/C decreased in the order of $k_{12}>k_{24}>k_{34}$. The reactivity of the substrate appears to be related primarily to the π-bond order, which reflects the degree of unsaturation. The highest unsaturation leads to the highest reactivity to hydrogen. The highest value of π-bond order in the substrate **1** is 0.79 and the value is higher than those of **2** and **3**. The energy level of electron donating HOMO may also contribute to the reactivity in such a reaction, the order of substrates **1**, **2**, and **3** corresponds to their reactivity order.

The rate constants k_{12} and k_{13} define the intramolecular selectivity within the substrate **1**. The π-bond

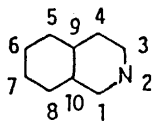
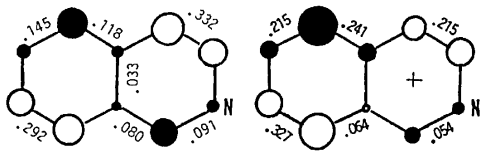
a) The sum of electron energy and core repulsion energy. b) The numbering is as follows;



order in HOMO is largest between atoms 3 and 4, probably contributing to the larger reactivity of its pyridine ring, although the largest π-bond orders (total) in the benzene and pyridine rings of substrate **1** are similar. According to the correlations described above, the hydrogenation reaction may be initiated by the addition of hydrogen radical to one of the unsaturated bonds in pyridine ring of **1** over Ru/C, successive hydrogenation being rapid to complete saturation of the ring.

According to the kinetic analyses, the isomerization step of **2**→**3** was very slow in comparison with the rates of major hydrogenation reactions on the ruthenium catalysts. The substrate **2** of which adsorption was not so strong on ruthenium may not find a time to isomerize before its rapid hydrogenation into **4**.

Catalyst supports for ruthenium play some interesting roles in defining the selectivity in the present catalyic hydrogenation even if Ru behaves as a soft metal on both supports. First point is that Ru/Al_2O_3 produced comparable amounts of **2** and **3**, while Ru/C gave **2** preferentially. The presence of Brønsted acids



(a) Isoquinoline (b) Isoquinolinium cation

Fig. 10. π-Bond orders in HOMO calculated by MNDO method. (a) Isoquinoline, (b) isoquinolinium cation.

was reported to exclude the hydrogenation of heterocyclic ring of **1**.[15,16] The protonation modifies significantly the reactivity indices of isoquinoline as shown in Fig. 10. The modified regioselectivity against hydrogenation may be explained by the π-bond orders in HOMO of the protonated substrate of **1**. A significant increase of the π-bond order between atoms 7 and 8 and decrease of that between atoms 3 and 4 may cause the change of hydrogenation preference from pyridine to benzene ring. It is therefore

considered that acidity of the catalyst decreases the selectivity of **2** and increases that of **3**, although the contribution of Brønsted acid on the alumina support is not definite and the protonated isoquinoline is a critical model. Much larger equilibrium adsorption constant of highly basic **4** (pK_a=11.0) on Ru/Al_2O_3 than that on Ru/C may also reflect acidic natures of the former support, while the constants for other substrates on the former catalyst were only twice larger than those on the latter catalyst.

The second point is concerned with the rate constants of reactions **2**→**3**, **2**→**4**, and **3**→**4**, which were almost twice larger on the Ru/Al_2O_3 than on Ru/C, while the summed rate constants of **1**→**2** and **1**→**3** reactions were identical. However, the differences on rate constants are not discussed in detail.

The dispersion of ruthenium on the supports will be another important factor affecting the catalytic activity, but it is beyond the scope of the present study.

Predictions of the Features of the Potential Energy Surfaces from the Diatomic Constants: A Series of Collinear Abstraction Reactions, H+HX (X=F, Cl, Br, I)

Noboru TANAKA
Hachinohe Institute of Technology, Hachinohe 031
(Received May 22, 1989)

A new method, to predict the feature of potential energy surface (PES) from the diatomic constants of reactants molecules, is presented. The PES is calculated by using our proposed semi-empirical method (MT method). Based on MT method, a graphical method is introduced to investigate the relations between the features of the PES and the diatomic constants. Using these relations as guideline, the features of the PES for a series of linear abstraction reactions, H + HX = HH + X with X=F, Cl, Br, and I, are deduced in a simple manner. The PES thus deduced are in good agreement with available experimental and theoretical information.

The knowledge of topological features of potential energy surfaces (PES), such as potential barrier height and location, reaction-path curvature, etc. is of fundamental importance for the theoretical understanding of chemical reaction processes. In recent years, there have been remarkable advances in quantum mechanical computations of PESs by ab initio methods. However, ab initio computations of this kind are complicated, and the results defy simple, intuitive interpretation. In spite of the capability of modern computers, such calculations require a great deal of computer time, and can be carried out only for rather simple systems. For these reasons, methods for semi-empirical estimation of PESs are of considerble value. The early ingenious semi-empirical method of Ering and Polanyi,[1] as later modified by Sato,[2] is widely known as the LEPS method. In the LEPS method, which starts with a quantum mechanical energy expression based on valence bond theory (London's expression),[3] a PES is constructed from diatomic Morse and anti-Morse potential functions, each of which involves three diatomic constants, i.e., the dissociation energy D, range parameter α, and equilibrium internuclear distance R_e. Besides of its simplicity one of the advantages of the LEPS method is that the PES of a three- or four-atomic system can be immediately correlated with the diatomic constants mentioned above. However, this advantage results from the neglect of all overlap and multiple-exchange terms in London's expression. In the past thirty years, other semi-empirical methods have been put forward by various authors: among them, the PK,[4] DIM,[5] and GDIM[6-8] methods are widely known.

In previous papers,[9,10] the present author proposed a new semi-empirical method, herein referred to as the MT method. In the MT method, all overlap and multiple-exchange terms, which were neglected in the London's energy expression, are evaluated; moreover, the connection between the computed PES and the diatomic constants is easily found. In other papers,[11,12] the author, on the basis of this conection, discussed how the PES of a system consisting of three or four hydrogen atoms changes when the hydrogen atoms are replaced by heteroatoms X. In the present paper, which is a sequel of these papers, a graphical method is employed to examine the connection between the PES of the linear H-H-H system and of the linear H-H-H system. The Morse function for the diatomic molecule H-X has D, α, and R_e values which are different from those of H-H. The effects of varying these constants on the features of the PES is closely examined. In addition, by using these results as a guideline, the special cases when X is a halogen atom are considered; the purpose is to deduce the features of the PES for a series of linear abstraction reactions, H+HX=HH+X with X=F, Cl, Br, and I, in a simple manner. Finally, the PES thus deduced are examined by comparing them with available experimental and theoretical information, and the utility of the method is demonstrated.

Theoretical

Remarks on the MT Method: In 1964 Porter and Karplus (PK)[4] proposed a new analytic semi-empirical method for calculating the ground state PES of the H_3 system. They tried to improve the LEPS method by including overlap and multiple-exchange terms in the energy expression and showed a practical way of computing these terms. The present author's MT method differs from the PK method in the evaluation of the multiple-exchange terms; furthermore, the MT method has been generalized to n-electron, n-atom systems in the following respects.

Based on the nonionic valence bond theory,[13] the potential energy E of an n-electron, n-atom system is given by roots of the secular equation:

$$|\boldsymbol{H} - \boldsymbol{M}E| = 0 \tag{1}$$

where $\boldsymbol{H}$ and $\boldsymbol{M}$ are a Hamiltonian matrix and a function of the overlap integrals, respectively. The matrix $\boldsymbol{H}$ can be expressed in terms of multiple-exchange integrals (Λ_p) which are defined as

$$\Lambda_p = \langle \Omega | H | \mathbf{p}\Omega \rangle, \tag{2}$$

where Ω is Hartree product of the atomic orbitals, and P is the permutation operator of electrons.

The multiple-exchange integrals have been classified into three types; one is a transposition type A_p^1; another is a cycle type A_p^2; and the other is a mixed type A_p^3 of A_p^1 and A_p^2.[10] By using the Mulliken approximation,[14] we have shown that first two types A_p^1 and A_p^2 are reduced to diatomic exchange α_i, Coulomb Q_i, and overlap S_i integrals as follows:

$$A_p^1 \simeq (\Pi S_i^2)[Q + \Sigma(\alpha_i/S_i^2 - Q_i)], \tag{3}$$

$$A_p^2 \simeq (\Pi S_i)[Q + \Sigma(\alpha_i/S_i^2 - Q_i)/2] \tag{4}$$

where $Q=nE_H+\sum_{i=1}^{3n-6} Q_i$, E_H is the energy of an atom. Moreover, the last mixed type A_p^3 was proved to be expressed in terms of A_p^1 and the A_p^2 as

$$A_p^3 = (\Pi S_i^2)(\Pi S_j)[A_p^1/(\Pi S_i^2) + \Sigma(A_p^2/(\Pi S_j) - mQ] \tag{5}$$

where m was the number of the cycle.

As a result, all integrals included in Eq. 1 are reduced to "diatomic components" α_i, Q_i, and S_i. Since the "diatomic components" are a properties of the reactant molecule, the method can be applied to many reaction systems by exchanging the value of "diatomic components". This is the most important characteristic of the MT method, because in other semi-empirical methods the multiple-exchange integrals have been evaluated empirically in more complicated ways[4,15] specific to each system, or simply neglected.[1-3]

The analytical expressions for the "diatomic components" α_i, Q_i, and S_i are well-known. The first two diatomic components, α_i and Q_i are expressed in terms of the Morse and anti-Morse functions as

$$\alpha_i = [({}^1E_i - {}^3E_i) + S_i^2({}^1E_i + {}^3E_i)]/2, \tag{6}$$

$$Q_i = [({}^1E_i + {}^3E_i) + S_i^2({}^1E_I - {}^3E_i)]/2, \tag{7}$$

$${}^1E_i(R_i) = D\{\exp[-2\alpha(R_i - R_e)] - 2\exp[-\alpha(R_i - R_e)]\}, \tag{8}$$

$${}^3E_i(R_i) = \eta\{\exp[-2\beta(R_i - R_e)] + 2\exp[-\beta(R_i - R_e)]\}, \tag{9}$$

where ${}^1E$ and ${}^3E$ are the Morse and anti-Morse functions for the diatomic molecule in the singlet and triplet states, respectively; and η and β are adjustable parameters in ${}^3E_i$, and they may calculated by ab initio methods. The analytical expression for the last "diatomic component" S_i is known to be[4]

$$S_i = (1 + R_i\zeta + R_i^2\zeta^2/3)\exp(-R_i\zeta) \tag{10}$$

where ζ is the orbital exponent of the atomic orbital, and its variation with the interatomic distance R_i can be approximately expressed as

$$\zeta = 1.0 + \kappa\exp(-\lambda R_i). \tag{11}$$

Whereas Porter and Karplus[4] determined the values of the parameters κ and λ in Eq. 11 by using the numerical result of Wang's variational calculation[16] of the hydrogen molecule, the present author proposes that these parameters be used as adjustable parameters as explained below.

It should be noted that the evaluations of potential energy surfaces by the MT method are reduced to calculations of "diatomic components" α_i, Q_i, and S_i, so that they are expressed in analytical functions as in Eqs. 6, 7, and 10. Therefore, potential energy E in Eq. 1 is expressed generally as a function of internuclear distances R as follows:

$$E = F(\chi_i, \tau; R) \tag{12}$$

where χ_i and τ are abbreviation for the diatomic constants of the i-th pair and for the adjustable parameters (η, β, κ, λ), respectively. Equation 12 shows that the PES can be calculated by determining the diatomic constants χ_i of the reactant molecules and adjustable paramethers τ.

Construction of the Standard and Reference PES: To see the effects of heteroatom substitution on a PES mentioned in introduction, we proceed as follows. The PES of the linear H-H-H system is computed by using MT method, and used a standard PES. In the computation, the H-H Morse and anti-Morse functions for the atomic pairs, H_a-H_b, H_b-H_c, and H_a-H_c, are used, where H_a and H_c stands for the end hydrogen atoms and H_b stands for the central one. For the H_2 Morse function, Eq. 8, the following values of the diatomic constants are used:

$$D = 0.1744 \text{ hartree}, \alpha = 1.05 \text{ bohr}^{-1}, R_e = 1.40 \text{ bohr}. \tag{13}$$

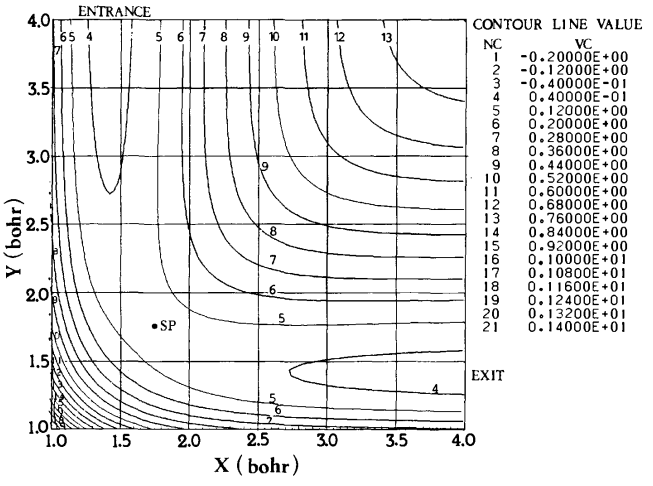

Fig. 1. The standard linear H_3 contour map. The contour intervals are 1/25 of the H_2 dissociation energy. The number and value of each contour line are denoted by NC and VC, respectively.

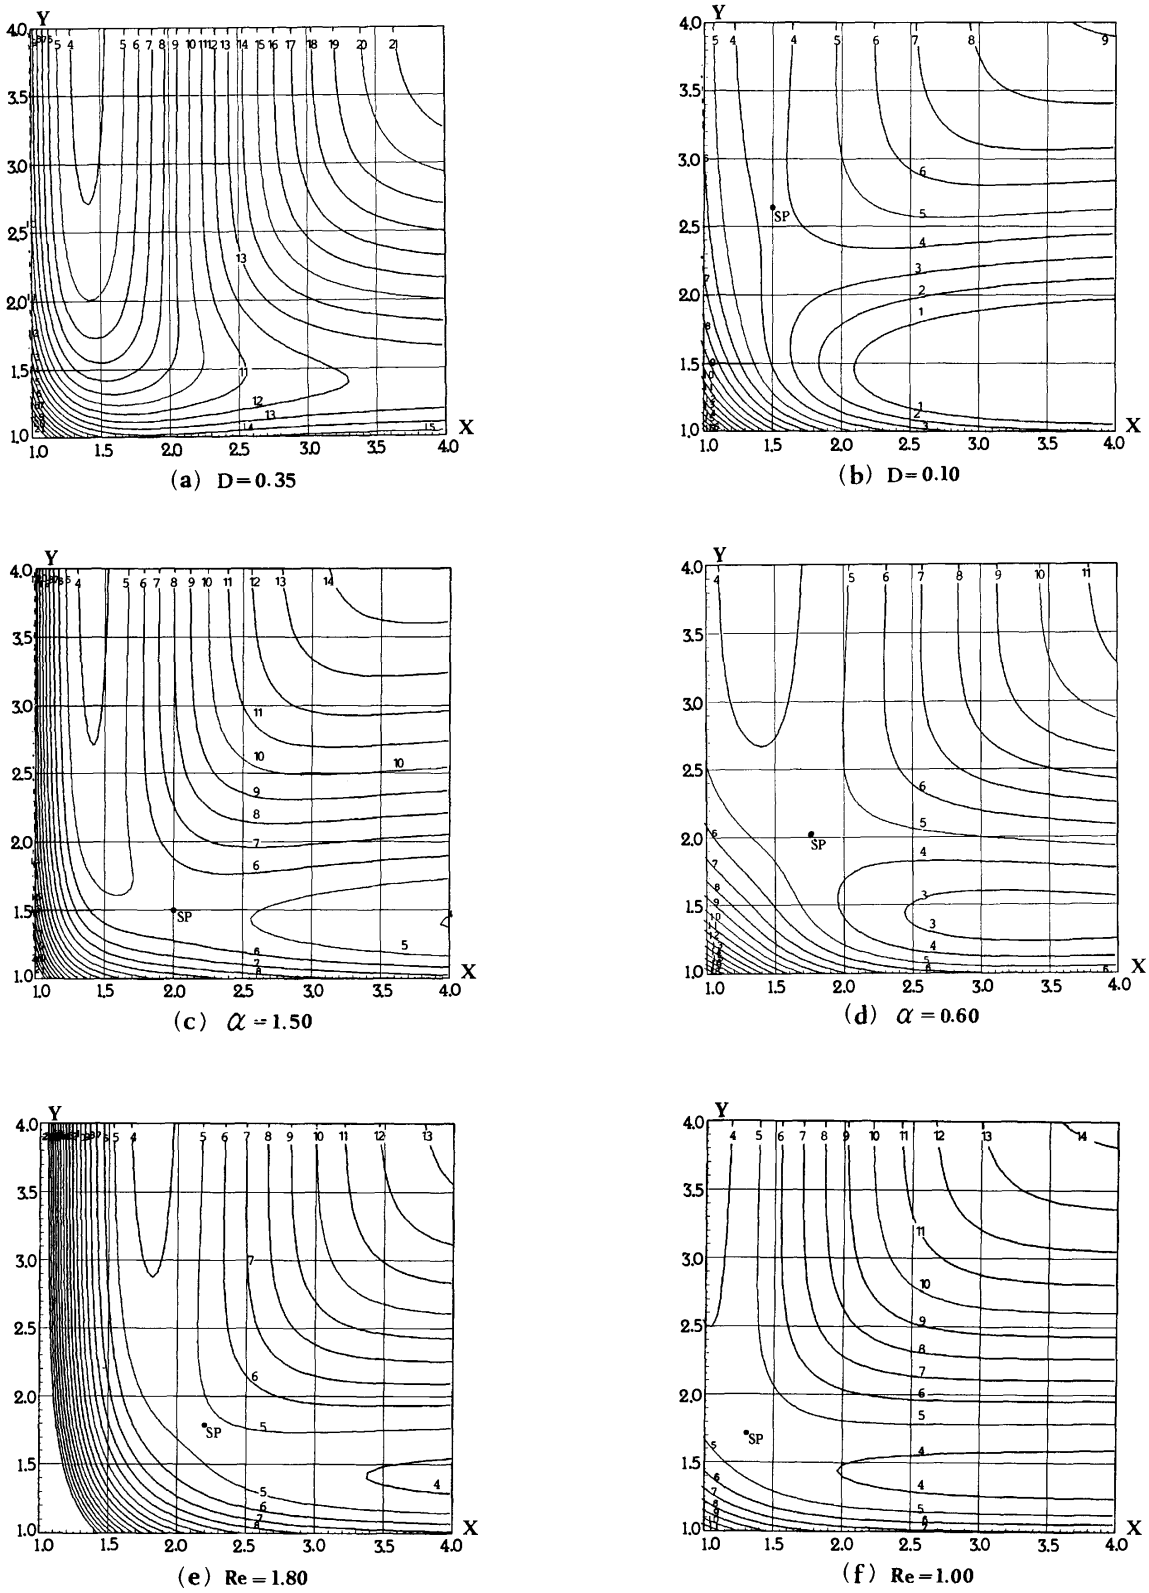

Fig. 2. The contour maps for the linear HHX system with different values of D, α, R_e (see text). The contour intervals are 1/25 of the H_2 dissociation energy. The X-axis and Y-axis show the internuclear distance of H-X and H-H, respectively.

For the H_2 anti-Morse function Eq. 9, the values,

$$\eta = 0.0729 \text{ hertree}, \beta = 1.036 \text{ bohr}^{-1} \quad (14)$$

are employed. The numerical values in Eqs. 13 and 14 have been determined by the results of the precise ab initio calculation for the hydrogen molecule by Kolos and coworkers.[17] For the two adjustable parameters occurring in Eq. 11, the values

$$\kappa = 3.20, \text{ and } \lambda = 1.202 \text{ bohr}^{-1} \quad (15)$$

are chosen to fit the computed H_3 PES at the saddle point and in its vicinity, to the result of Liu's precise ab initio calculation of the H_3 system.[18] All these parameters are given these standard values throughout the following.

The PES so obtained for H_3 is shown in Fig. 1, where the X- and Y-axes represent the H_b-H_c and H_a-H_b distances, respectively. This PES agrees fairly well with the Truhlar-Horowitz PES for linear H_3,[19] which is based on Siegbahn and Liu's precise ab initio calculations[18,20] of the H_3 system.

Now suppose that the end atom H_c is replaced by a heteroatomic X. The PES for this linear H-H-X system is calculated in the same way as the H-H-H PES, except that the H-H Morse functions for H_a-H_c and H_b-H_c in the H-H-H calculation are replaced by the H-X Morse functions, whose D, α, and R_e values are different from those in Eq. 13. To get an idea of how the PES changes by varying these diatomic constants in Eq. 13, six reference contour maps are computed by varying the three constants individually. The results are shown in Figs. 2(a)—(f), where the X- and Y-axes represents the H_b-X and H_a-H_b distances, respectively. The caption of Fig. 2(a), D=0.350 implies that the diatomic constants for H-X are taken to be the same as those for H-H given in Eq. 13, except that D=0.350 hartree is used; also it is assumed that the four parameters in Eqs. 14 and 15 remain unchanged. Captions of similar meaning are attached to Figs. 2(b)—(f). The use of these reference contour maps is described in the next section.

Results and Discussion

Diatomic Constants and the PES of the H-H-X System: Consider the cross section of the PES of the linear H-H-X system by a plane S which is perpendicular to the (X, Y)-plane and parallel to the X-axis. Obviously the cross section continuously approaches the potential curve of the diatomic molecule H-X as the distance between the plane S and the X-axis increases. Owing to this continuity, the features of the entrance valley of the H-H-X PES are immediately deduced from the features of the H-X potential curve.

Interesting points to be noticed as regards Figs. 2(a)—(d) are as follows. We observe in Figs. 2(a) and 2(c) that making D or α greater than the standard values (D=0.1744 or α=1.05) shifts the location of the saddle point to the exit valley side ("late barrier"), and makes the reaction-path curvature larger (a sharper bend of reaction path). Similarly, Figs. 2(b) and 2(d) indicates that making D or α smaller than the standard value shifts the saddle point to the entrance valley side ("early barrier"), and makes the reaction-path curvature smaller.

More quantitative information derived from similar calculations is shown in Tables 1—3 and Figs. 3—7. The trend found in Figs. 2(a) and 2(b) is more evident in Table 1, which indicates how the barrier height E_a, the saddle point location (X_a, Y_a), and the bond extensions ΔR_{HX} and ΔR_{HH} at the saddle point (BESP), change as D is varied. Here ΔR_{HX} and ΔR_{HH} are given by

$$\Delta R_{HX} = X_a - R_e, \Delta R_{HH} = Y_a - R_e,$$

where R_e is taken to be 1.40 bohr (the standard value of R_e). The energy defect ΔE of the abstraction reaction is defined as the energy difference,

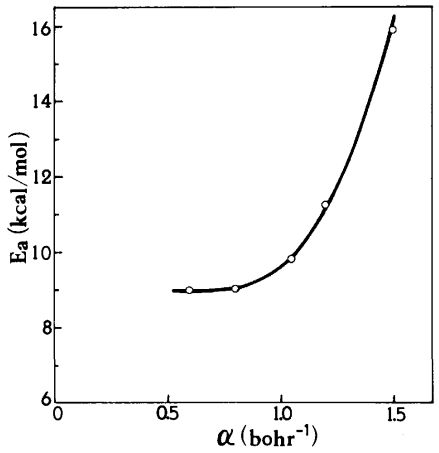

Fig. 6. The relation between range parameter α and barrier height E_a for the linear HHX system.

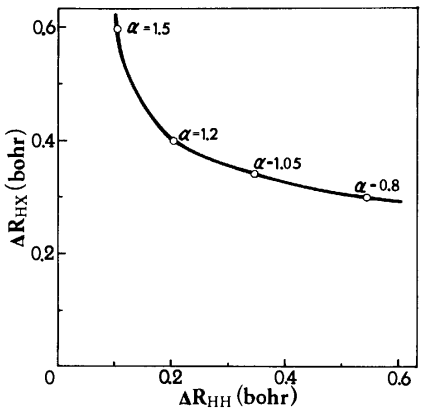

Fig. 7. The relation between the range parameter α and the BESP ΔR_{HX}, ΔR_{HH} for the linear HHX system.

$$\Delta E = E(\text{product}) - E(\text{reactant}). \quad (16)$$

By examining the energy expression of the PK or MT method, it is readily found that

$$E(\text{product}) = -D(\text{H-H}),\ E(\text{reactant}) = -D(\text{H-X}), \quad (17)$$

i.e., ΔE is equal to the difference of the diatomic dissociation energies, D(H-X)−D(H-H). The values of ΔE computed from this relation is also included in Table 1. Table 2 is a table similar to Table 1 but corresponds to Figs. 2(c) and 2(d), and Table 3 corresponds to Figs. 2(e) and 2(f). Also these interesting relations between two sets of quantities presented in Tables 1 and 2 are displayed graphically in Figs. 3—7. For example, Table 2 and Figs. 6 and 7 indicate how the height and location of the barrier change as the range parameter α is varied, provided that the values of the rest of the parameters in Eqs. 13—15 remain the same. In the next section, these relations are used to deduce the features of the PES for a series of linear abstraction reactions, H+HX=

HH+X with X=F, Cl, Br, and I.

PES of the Abstraction Reactions H+HX with X=F, Cl, Br, and I: So far the heteroatom X has not been specified. In this section, we turn to the special case in which X is a halogen atom. This case is of particular interest in relation to the abstraction reaction H+HX=HH+X (X=F, Cl, Br, and I), which are prototypical gaseous elementary reactions and have been the subject of numerous experimental and theoretical investigations.

To proceed in line with the considerations in the preceding section, we need the diatomic constants of the H-X molecules. They are tabulated in Table 4, where theoretical values from ab initio calculations together with some experimental values are given; the former values agree with the latter ones considerably well. We mainly confine our attention to the effect of chaging D(H-X) in the following. Thus, by using the D vs. E_a and the D vs. BESP curves in Figs. 3 and 5 together with the values of D in Table 4, the E_a and BESP for the H-H-X PES are estimated, and the result is tabulated in Table 5, which also includes the values of energy defect ΔE computed by using the relations Eqs. 16 and 17 together with the experimental D values in Table 4.

In recent years, a good knowledge of the PES of the H-H-X systems (X=F, Cl, Br, and I), i.e., those of the abstraction reactions, H+HX=HH+X, has been obtained from ab initio theoretical calculations. Table 6 lists theoretical values relating to the H-H-X PES, calculated by Dunning[21,22] together with experimental values of E_a and ΔE for these abstraction reactions. Comparing Table 5 with Table 6, we find the simple calculations of the present paper lead to results in surprisingly good agreement with those from ab initio calculations. Finally Figs. 8 and 9 are plots similar to Figs. 3 and 5, but are based on the numerical values in Table 6. Again we observe that Figs. 3 and 5 resulting from the present calculation bear a very close resemblance, qualitative and quantitative, to Figs. 8 and 9 obtained from Dunning's ab initio calculation.

Since the early work of Evans and Polanyi,[25] the energetics of the reactions has been discussed by several authors.[26-30] The central point of the arguments may be understood in terms of the relations between the exoergicity and the schematic one-dimensional potential profile of the reaction. Let us start with the case X=I; as pointed out above the molecule HI has the smallest D value in Table 4, i.e., the energy of its bond being broken is smallest. Since D(H-X)<D(H-H), in this case, the reactant valley is shallower than the product valley, and hence $\Delta E<0$ (Table 5); in other words, the abstraction reaction H+HI is exothermic. In this connection the following propensity rules has often been argued: In the case of X=I, where the

reactant valley is shallow, the reaction has an "early" potential barrier[31] and the barrier height E_a is rather small, but on going from X=I to X=Br, Cl, and F or, in other words, as the depth of the reactant valley D(H-X) increases, the barrier shifts to the direction of the product valley (shifts towards a "late" position) and the barrier height increases. Although these rules have been suggested by Mok and Polanyi[28] (based on the LEPS and BEBO[26] method), they have been corroborated by Dunning's ab initio calculation (Figs. 8 and 9), and also by the present calculation (Figs. 2, 3, and 5).

Finally, the problem or whether a reaction has an early or late barrier is interesting in connection with reaction dynamics. It has been deduced from molecular dynamics studies that vibrational (translational) energy excitation is effective for enhancing the rate of a reaction having a late (early) barrier.[32] It is interesting to note that the reverse reactions of the above abstraction reaction, i.e., X+HH=HX+H have been found to be enhanced by vibrational excitation when X=Cl, Br, or I, and furthermore the degree of the enhancement has been found to be in the order of Cl<Br<I.[33] This fact is in agreement with the calculated values of BESP given in Tables 5 and 6. (Remember that the PES of the reverse reactions are obtained from those of the abstraction reactions by interchanging the entrance and exit valleys.)

Conclusion

In the present paper, by using a simple semi-empirical method devised by the present author and called the MT method, the PES for the linear H-H-H and H-H-X systems (the standard and reference PES) have been obtained. Referring to these PES, PES and energetics of the abstration reactions, H+HX=HH+X with X=F, Cl, Br, and I, have been discussed. Conclusions arrived at are in good agreement with those from ab initio quantum mechanical calculations. Although the treatment of the present paper is limited to the linear H-H-X system, the applicability of the MT method is wider as shown in previous paper by the author. Therefore, there are possibilities of extending the method of the present paper to treatment of, for example, systems of X-Y-Z type, or systems consisting of four or more atoms. This problem will be discussed in a forthcoming paper.

The author would like to thank Professor Yuusaku Ikegami of Tohoku University for many helpful discussions and for support regarding the present article. The author also wishes to thank Professor Takasi Nakamura of Hokkaido University for reading and improving the manuscript.

Dielectric Relaxation and Intermolecular Association for Various Secondary and Tertiary Alcohols

Toshiomi SHINOMIYA†
School of Pharmaceutical Sciences, Kitasato University,
Shirokane, Minato-ku, Tokyo 108
(Received May 24, 1989)

The dielectric constants and losses of 2-alkanol (n=4—8), 2-methyl-2-alkanol (n=3—7), six isomeric methylheptanols, and five isomeric nonanols have been measured at the frequencies from 1.35 to 4500 MHz at 15, 25, and 35 °C. The absorption has been resolved into two or three different Debye-like dispersion regions. The first, low-frequency, dispersion region could not be observed for more sterically hindered alcohols, such as several tertiary alcohols. For each alcohol, four concentrations of a linear hydrogen-bonded chain polymer (C_1), a chain dimer and trimer (C_2), a free monomer (C_3), and a nonpolar cyclic polymer (C_R) were evaluated by applying a modified Kirkwood-Fröhlich equation to each dispersion region. The equilibrium between C_1 and C_3 can be considered for more polar alcohols and that between C_R and C_3 for more sterically hindered alcohols. The mechanism of the relaxation process is discussed in terms of observations of the magnitude and relaxation time for the first region. The free energy of activation increases with increasing alkyl chain length, being about 20—23 for the first region, 16—18 for the second region, and 9—12 kJ mol^{-1} for the third region.

The coexistence of two or three dielectric dispersion regions has been found through wide-range measurements of complex dielectric constants for liquid alcohols.[1-4] In a previous paper,[5] we also reported three dispersion regions for pure 1-decanol at 15—40 °C and for cyclohexane and heptane solutions of 1-decanol at 25 °C. We assigned the three dispersion regions to a linear hydrogen-bonded chain polymer, a chain dimer and trimer, and a free monomer. However, no theory can satisfactorily interpret the coexistence of the two or three dispersion regions. The Kirkwood-Fröhlich equation,[6,7] developed on the basis of a single relaxation process, cannot explain a correlation factor that is large or the existence of a nonpolar cyclic polymer which does not contribute to the dispersion. Therefore, we have proposed a modified Kirkwood-Fröhlich equation[8] which could be applied to each dispersion region. These four concentrations, inclusive of a nonpolar cyclic polymer, were evaluated by means of the modified equation and were shown for 1-decanol as a function of temperature and dilution, respectively.[5]

In secondary and tertiary alcohols, dielectric studies have indicated a complex and interesting nature corresponding to a geometric variety of molecules. Dannhauser[4] measured the temperature dependence of the dielectric dispersions for eight isomeric $C_8H_{17}OH$ at low temperatures. A Cole-Cole plot for 3-methyl-3-heptanol shows a small, broad dispersion at 208—189 K. Moriamez et al.[9] also obtained a Cole-Cole plot for 3-ethyl-3-pentanol at room temperature. The small, broad dispersions for tertiary alcohols have been explained by the existence of a ring dimer. The measurement and analysis of the absorption become more difficult at room temperature. There have been almost no reports on detailed analyses of the two or three dispersion regions.

† Present address: 207-52, Shirahata kami-cyo, Kanagawa-ku, Yokohama 221.

We have presently extended the investigation by measuring the dielectric dispersion of various secondary and tertiary alcohols. For these alcohols at room temperature it is interesting to investigate the fact that the dielectric absorption is dependent on the steric interrelation between the hydroxyl group and the terminal methyl and alkyl groups. It was also the purpose of the present work to confirm whether each of the four concentrations, obtained by means of a modified equation, indicates a reasonable behavior or not. The mechanism of the relaxation process is discussed.

Experimental

Purification of Materials. Commercial alcohols were fractionally distilled under reduced pressure at a very high reflux ratio. About 80% of the middle fraction was distilled again by the same method. Two distillation systems were used, as described in a previous paper.[8] The middle portion was dried and finally distilled in a grease-free apparatus under reduced pressure before use.

Apparatus. The dielectric constants and losses were measured by making use of the following three types of apparatus over the frequency range of 1.35—4500 MHz.

In the low-frequency range, a Boonton Radio RX meter (Type 250A) was used for measurements at frequencies of 1.35, 6.3, 17, 30, and 45 MHz. An adaptor (GR 900-QNP) and a T-type adaptor (which is joined to an inductor) were placed between a cell and a terminal of the RX meter's bridge. In the middle-frequency range, measurements at frequencies 60, 80, 100, 150, 200, 250, 300, 400, and 480 MHz were made with a Hewlett-Packard VHF Bridge which comprised a VHF Signal Generator (Model 608C), a VHF Detector (Model 417A), a VHF Bridge (Model 803A), an SWR meter (415E), and a frequency counter. In the high-frequency range, a General Radio Precision Slotted Line (Type 900-LB) was used for measurements at frequencies of 600, 750, 1000, 1400, 2000, 3000, and 4500 MHz. The signal sources were a Modulating Power Supply (Type 1264-B) and a VHF Oscillator (Type 1362), a Modulating Power Supply (Type 1264-B) and a Lockable Oscillator (Type 1218-BV), and a HP Signal Generator (Type 8616A).

In the low- and high-frequency ranges, two dielectric cells were carefully made of a GR Precision Inner-Conductor Rod, an Outer-Conductor Tube, and a GR 900-BT connector. The temperature of the cell was kept constant within ±0.1 °C of the specified values by the circulation of water from a thermostat through a jacket around the cell. The frequencies of the RX meter and VHF Bridge were controlled to be within ±0.01% of the specified values.

The refractive indices were measured by making use of a Pulflich refractometer. The densities and viscosities were measured with a density meter of about 10 cm^3 in volume and with an Ostwald viscometer, respectively.

Results and Discussion

The Cole–Cole plots show that the first dispersion region can be best described by a Debye-like semicircular arc, though it is evident that the experimental data cannot be satisfactorily fitted in the high-frequency region of the absorption. By assuming that the absorption was the sum of several overlapping Debye-like dispersion regions, the data were resolved into two or three different dispersion regions. The limiting high-frequency dielectric constant, ε_3, of the third region contains experimental errors because of a lack of the higher-frequency data of the third region. ε_3, therefore, was assumed to be an average value in all measurements, evaluated using $(\varepsilon_3-1)/(\varepsilon_3+2)=(n_D^2-1)(1+0.19)/(n_D^2+2)$. n_D is the refractive index. The dielectric parameters of two or three dispersion regions were calculated using a least-squares method, as described in a previous paper,[8] and were given for 2-methyl-2-alkanols and isomeric methylheptanols in Table 1, together with the refractive indices, densities, and viscosities. The dielectric parameters were abbreviated for 2-alkanols and isomeric nonanols, since those for the first region were described in a previous paper.[8] We believe that the first dispersion region can be attributed to a linear hydrogen-bonded chain polymer ($n \geqq 4$), the second region to a chain dimer and trimer ($n=2$ and 3), and the third region to a free

monomer (n=1), as described before.[5] The Kirkwood correlation factors were evaluated according to the Kirkwood equation:[6,8,10] g_1=2.38 for the first region, g_2=2.03 as an average value for the second region, and g_3=unity for the third region. Four concentrations, a linear chain polymer (C_1), a chain dimer and trimer (C_2), a free monomer (C_3), and a nonpolar cyclic polymer (C_R), were calculated by means of a modified Kirkwood-Fröhlich equation[8] by making use of these g_i factors and the experimental values of ε_{i-1} and ε_i for the i-th dispersion.

For five 2-alkanols at 25 °C, the Cole-Cole plots are shown in Fig. 1 and the percentages of C_1, C_2, C_3, and C_R against the gross stoichiometric concentration C_0, $C_i \times 100/C_0$, are shown in Fig. 2. The absorption could be resolved into three dispersion regions, except for 2-butanol, as shown by the solid lines in Fig. 1. The magnitude, $\varepsilon_0-\varepsilon_1$, of the first region decreases from 13.44 for 2-butanol to 4.69 for 2-octanol with increasing alkyl chain length. Figure 2 shows that the percentage of C_1 decreases from 71% for 2-butanol to 50% for 2-octanol because of a steric hindrance of the long alkyl group. C_1 decreases linearly with the magnitude. C_2 increases slightly with increasing alkyl chain length, although C_3 decreases, and the sum of C_2 and C_3 almost does not change. Therefore, C_R increases inversely as C_1. The magnitudes of the first region for these 2-alkanols are less than those of normal alcohols[8] having the same number of carbon

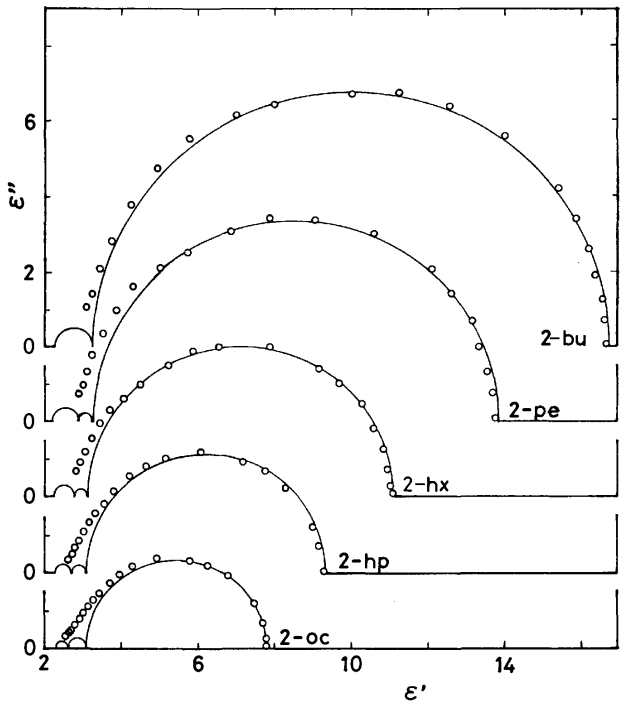

Fig. 1. Cole-Cole plots for 2-alkanol (n=4—8) at 25 °C, together with calculated behavior for the two or three dispersion regions. Butanol, pentanol, hexanol, heptanol, and octanol are abbreviated to bu, pe, hx, hp, and oc, respectively.

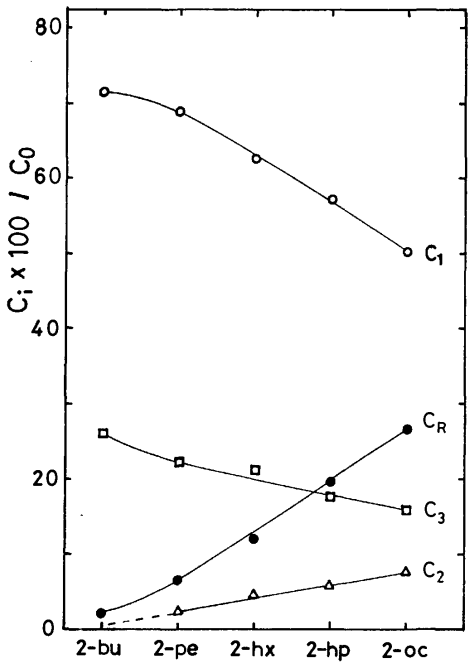

Fig. 2. Percentages of the C_{1-R} at 25 °C as a function of 2-alkanol (n=4—8). Dotted line shows an estimated value.

atoms. It is considered that the formation of a linear hydrogen-bonded chain becomes difficult because of the steric hindrance of the long alkyl group and the terminal methyl group. Figure 2 shows that a linear chain polymer is mainly in equilibrium with a free monomer for 2-butanol and with a nonpolar cyclic polymer for 2-octanol.

For five 2-methyl-2-alkanols at 25 °C, the Cole-Cole plots and the percentages of C_{1-R} are shown in Figs. 3 and 4. The absorption could not be resolved into three dispersion regions for 2-methyl-2-pentanol, 2-methyl-2-hexanol, and 2-methyl-2-heptanol. The magnitude of the first region decreases extremely from 9.39 for 2-methyl-2-propanol to 2.23 for 2-methyl-2-butanol. The percentage of C_1 also decreases from 55 to 15%, as shown in Fig. 4. It is considered for 2-methyl-2-pentanol that the first region comprises both first and second regions, although it could not be resolved into two regions. Separation between the first and second regions becomes difficult, since the magnitude of the first region approaches that of the second one. Moreover, the relaxation frequencies of the Cole-Cole plots in Fig. 3 and an extrapolation (shown as a dotted line) of the C_1 curve in Fig. 4 indicate that the first region vanishes into nothing for 2-methyl-2-hexanol and 2-methyl-2-heptanol. A comparison between Figs. 1 and 3 shows that the tertiary alcohols are more hindered species for intermolecular association. Association into a linear chain polymer becomes unfavorable because of the steric hindrance of the terminal methyl groups. The percentages of C_1, for example, are 69% for 1-octanol, 50% for 2-octanol, and

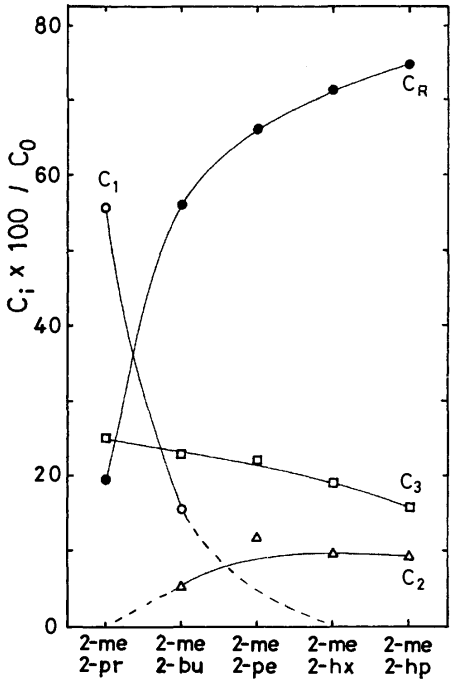

Fig. 4. Percentages of the C_{1-R} at 25 °C as a function of 2-methyl-2-alkanol (n=3—7). Dotted line shows an estimated value.

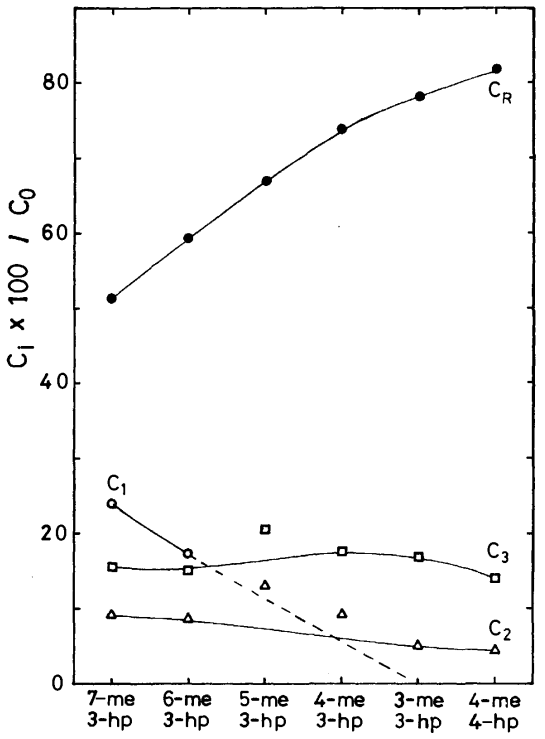

Fig. 6. Percentages of the C_{1-R} at 25 °C as a function of isomeric methylheptanols. Dotted line shows an estimated value.

0% for 2-methyl-2-heptanol at 25 °C. C_1 vanishes into nothing and C_R increases to 74% of the gross concentration for 2-methyl-2-heptanol. Figure 4 shows the equilibrium between a linear chain polymer and a free monomer for 2-methyl-2-propanol and that between a nonpolar cyclic polymer and a free monomer for 2-methyl-2-heptanol.

For six isomeric methylheptanols shown in Figs. 5

and 6 at 25 °C, the absorption could be resolved into three regions for 7-methyl-3-heptanol and 6-methyl-3-heptanol. However, it could not be resolved into three regions for 5-methyl-3-heptanol and 4-methyl-3-heptanol. For both alcohols there was no distinction between the first and second regions. As shown in Fig. 6, therefore, the percentages of C_2 and C_3 become slightly large because of the existence of a small first region. The first region becomes small in magnitude. This indicates that the formation of a linear chain polymer becomes difficult and a nonpolar cyclic polymer is formed as the methyl group approaches the hydroxyl group fixed on the third carbon atom in a molecule. The first region could not be observed in the tertiary alcohols of 2-methyl-2-heptanol (shown in Figs. 3 and 4), 3-methyl-3-heptanol, and 4-methyl-4-heptanol (shown in Figs. 5 and 6). The magnitude of the second region also decreases as both the hydroxyl and the methyl groups approach the center of a molecule. The percentage of C_R is favorable and becomes 74% of the gross concentration for 2-methyl-2-heptanol, 78% for 3-methyl-3-heptanol, and 82% for 4-methyl-4-heptanol. The large value for C_R is one remarkable feature of tertiary alcohols. Figure 6 shows that a nonpolar cyclic polymer is in equilibrium with a linear chain polymer for 7-methyl-3-heptanol and with a free monomer for 3-methyl-3-heptanol.

For five isomeric nonanols at 25 °C, the absorption could be resolved into three dispersion regions, as shown in Figs. 7 and 8. C_1 is large and, accordingly, C_R is small for normal alcohols from propyl through decyl.[8] C_1 decreases rapidly and C_R increases inversely with C_1 as the hydroxyl group approaches the center of a molecule. When the hydroxyl group approaches the center of a molecule (such as 5-nonanol), the formation of a linear chain polymer is hindered by the alkyl groups at both sides of the hydroxyl group. Figure 8 shows that a free monomer is in equilibrium with a linear chain polymer for 1-nonanol and with a nonpolar cyclic polymer for 5-nonanol.

The magnitude of the first region is in proportion to C_1 and becomes small for more hindered alcohols. Both the magnitude and C_1 decrease as the temperature increases.[5] As pure normal alcohol is diluted with a nonpolar solvent[5,11,12] and as the hydroxyl group is more sterically hindered, both the magnitude and C_1 also decrease. Therefore, any decrease in C_1 indicates that the length of a hydrogen-bonded chain shortens, namely, that the number of hydroxyl groups decreases in this polymer. The separation between the first and second regions becomes difficult as the length of a hydrogen-bonded chain approaches that of a chain dimer and trimer. The first region at last vanishes into nothing for the more hindered species (such as several tertiary alcohols), since a long linear chain polymer cannot exist. The hydrogen bond in a long chain polymer is broken by the repulsion between the terminal methyl and the alkyl groups for these more hindered alcohols, although a chain dimer and trimer can be formed. A nonpolar cyclic polymer is stably formed and becomes a preferred species for these alcohols. The second region is due to the chain dimer and trimer and is always small in magnitude. It may, therefore, be considered to be formed as an intermediate.

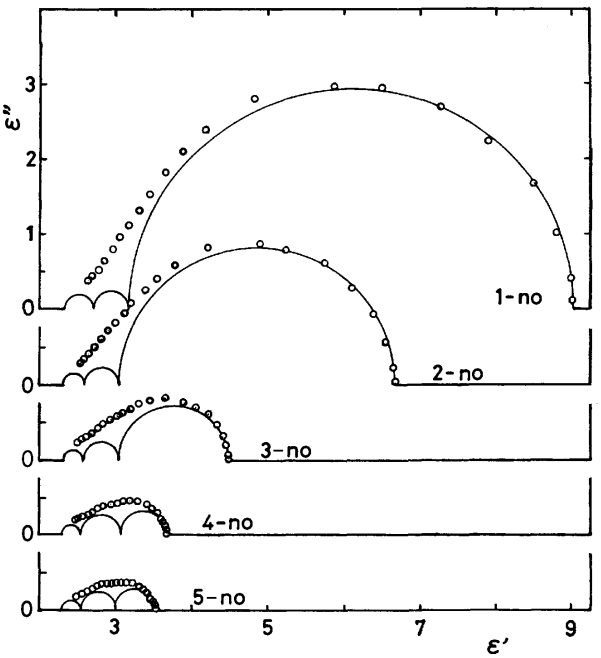

Fig. 7. Cole-Cole plots for isomeric nonanols at 25 °C, together with calculated behavior. Nonanol is abbreviated to no.

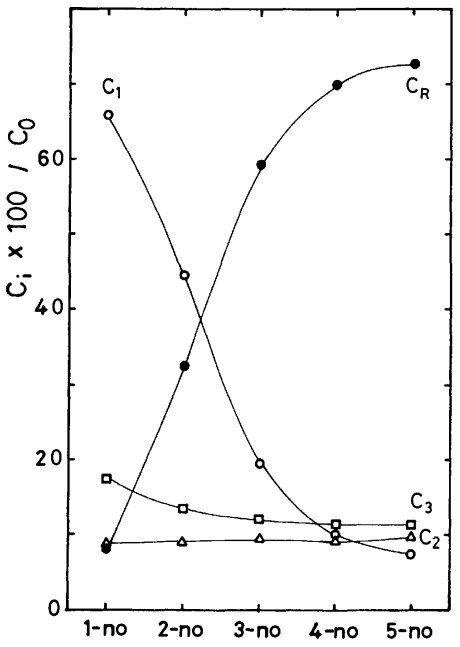

Fig. 8. Percentages of the C_{1-R} at 25 °C as a function of isomeric nonanols.

For the first region of some normal and secondary alcohols (n=3—10),[2,8] the relaxation time (τ_1) becomes long and C_1 decreases with increasing alkyl chain length in a molecule. τ_1 also becomes long with increasing viscosity of the liquid. τ_1 depends on both the alkyl chain length and the viscosity of the liquid. As pointed out by Smyth et al.,[2,13] therefore, it is considered that overall rotation of a molecule is closely associated with the relaxation process. In this work, τ_1 shortens and C_1 decreases for isomeric methylheptanols (in which the alkyl chain length and the viscosity are approximately equal) as the methyl group approaches a hydroxyl group fixed on the third carbon atom in a molecule. For the isomeric nonanols (in which the alkyl chain length and the viscosity also are approximately equal) τ_1 shortens and C_1 also decreases as the hydroxyl group approaches the center of a molecule. These observations show that τ_1 has an immediate association with C_1, namely, that τ_1 becomes shorter with decreasing length of a linear hydrogen-bonded chain. Therefore, τ_1 is considered to be dependent on the alkyl chain length in a molecule, the viscosity of the liquid, and the length of a linear hydrogen-bonded chain. The mechanism of the relaxation process may be envisioned from these relationships, as follows. After one hydrogen bond of a chain-end molecule is broken, the overall rotation of the molecule (which now becomes free) occurs; then, the overall rotation of the next molecule (which is now at the chain end) occurs successively by breaking one hydrogen bond between the molecule and a neighboring molecule. All molecules in this hydrogen-bonded chain are turned over successively. The time of the overall rotation for one molecule depends on the alkyl chain length and the viscosity of the liquid. The magnitude of the dispersion is determined by the concentration of the hydroxyl group in the linear chain polymer. The orientated molecules are rearranged so as to form a linear chain polymer by new hydrogen bondings.

The thermodynamic parameters, the free energy of activation ΔF, the heat of activation ΔH, and the entropy of activation ΔS, were calculated by applying the Eyring's equation[14] to the temperature dependences of the two or three relaxation times τ_{1-3} and the viscosity η. The ΔH and ΔS were calculated from the values at the proper temperatures of 15, 25, and 35 °C in cases where the same dispersion region could not be obtained at all the temperatures investigated. ΔF was obtained at 25 °C. ΔH and ΔS increase with increasing alkyl chain length and also increase for more sterically hindered species. Figure 9 shows that ΔF also increases with increasing alkyl chain length. For isomeric methylheptanols, as shown in Fig. 10, $\Delta F_{\tau 1}$ decreases and approaches $\Delta F_{\tau 2}$ as the methyl group approaches the hydroxyl group. $\Delta F_{\tau 1}$ vanishes into nothing in the vicinity of 3-methyl-3-heptanol, as shown by a dotted line. If the magnitude of the first region would be large for more hindered methylheptanols, the curve of $\Delta F_{\tau 1}$ would be parallel to that of $\Delta F_{\tau 2}$. It is necessary to consider that the thermodynamic parameters should be calculated in terms of the temperature dependence of the same dispersion region for the more hindered alcohols.

Dielectric Behavior and Intermolecular Association for Octanol Isomers. Existence and Transformation of a Nonpolar Cyclic Polymer

Toshiomi SHINOMIYA†
School of Pharmaceutical Sciences, Kitasato University,
Shirokane, Minato-ku, Tokyo 108
(Received May 24, 1989)

The equilibrium dielectric constants of ten isomeric $C_8H_{17}OH$ and binary mixtures of 1-butanol in four isomeric $C_8H_{17}OH$ have been measured at temperatures from 135 to −55 °C. These isomeric $C_8H_{17}OH$ can be grouped roughly into three types, namely, more polar, intermediate, and more sterically hindered alcohols. The dielectric behavior of each of the three types can be explained by equilibrium among a linear hydrogen-bonded chain polymer (**CHAIN**), a free monomer inclusive of a chain dimer and trimer (**MONOMER**), and a nonpolar cyclic polymer (**RING**). As the temperature decreases, **MONOMER** transforms into **CHAIN** for more polar alcohols. Two transformations, **MONOMER** into **RING** at high temperatures and **RING** into **CHAIN** at low temperatures, occur for intermediate alcohols. **MONOMER** transforms into **RING** and **CHAIN** can not be observed for more hindered alcohols. However, a transformation of **RING** into **CHAIN** can be observed by adding 1-butanol to the more hindered alcohols. **CHAIN** is most stable. When formation of **CHAIN** becomes difficult, **RING** can be formed. The transformation is dependent on temperature, molecular geometry, and the amount of 1-butanol in the mixture.

In general, the equilibrium dielectric constants for many compounds increase monotonically with decreasing temperature. However, it is well-known that the dielectric constant for a carboxylic acid decreases conversely with decreasing temperature because of the formation of a nonpolar cyclic dimer. For liquid alcohols, temperature dependence of the dielectric constant indicates a complex and interesting behavior. Dielectric studies have indicated the formation of various hydrogen-bonded species by intermolecular association in pure alcohols and dilute solutions of alcohols. Smyth and Stoops[1] measured the equilibrium dielectric constants for various isomeric $C_8H_{17}OH$ and explained the dielectric complex behavior by molecular orientation. Dannhauser[2] measured the interesting dielectric behavior for 8 isomeric $C_8H_{17}OH$. He analyzed the behavior by the Kirkwood-Fröhlich equation[3,4] and introduced a molecular model which consists of monomers in equilibrium with nonpolar ring dimers and with chain polymers. For various secondary and tertiary alcohols at 15, 25, and 35 °C, we obtained four concentrations, **CHAIN** (C_1), a chain dimer and trimer (C_2), a free monomer (C_3), and **RING** (C_R), by means of a modified Kirkwood-Fröhlich equation.[5,6] An extrapolation of these concentrations to the high- and low-temperature portions was used to explain the complex dielectric behavior for the temperature dependence of the dielectric constant.

The existence of **RING** has been postulated for more sterically hindered alcohols. It is evident that the variable and complex dielectric behavior is attributed to the existence of **RING**. However, there has been little experimental evidence for the existence of **RING** in order not to contribute to the dielectric constant. Therefore, we measured binary mixtures of 1-butanol in some isomeric $C_8H_{17}OH$ to investigate the existence of **RING** and the transformation of **RING** into **CHAIN**.

Experimental

Purification of Materials. Commercial alcohols were fractionally distilled twice, as described in a previous paper.[6]

Apparatus. The equilibrium dielectric constants were measured by making use of a ratio-arm transformer bridge (Ando Electric Co. Type TR-10) at the frequency range of 3—1000 kHz. The cell is a three terminal guarded electrode arrangement of gold-plated brass with Teflon insulation. The cell was made by reference to those reported by Hassion and Cole[7] and Dannhauser and Bahe.[8] The capacitance of the cell is 5.05 pF. The temperature control was maintained within ±0.5 °C.

Results and Discussion

Temperature Dependence of Equilibrium Dielectric Constants (ε_0). Our data shown in Fig. 1 are qualitatively similar to those of eight isomeric $C_8H_{17}OH$ measured by Dannhauser.[2] These isomers have approximately the same dipole moment and the same molecular volume, though the relative positions of the hydroxyl and methyl groups are different. Figure 1, however, shows a variety and complexity of dielectric behavior for these isomeric $C_8H_{17}OH$. This variety and complexity can be attributed to a difference of the hydrogen-bonded species formed by intermolecular association. If it is assumed that all alcohol molecules exist as free monomers, the ε_0 can be calculated from the Kirkwood-Fröhlich equation.[3,4] The behavior of the ε_0 is shown in Fig. 1 as a dotted

† Present address: 207-52, Shirahata kami-cyo, Kanagawa-ku, Yokohama 221.

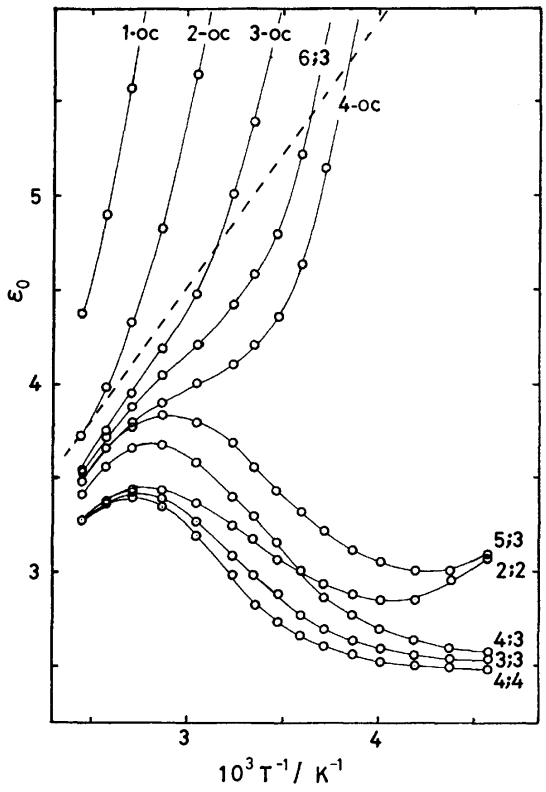

Fig. 1. Equilibrium dielectric constants as a function of reciprocal absolute temperature for ten isomeric $C_8H_{17}OH$. Octanol, 6-methyl-3-heptanol, and 4-methyl-4-heptanol are abbreviated to oc, 6;3, and 4;4, respectively. Dotted line shows a calculated dielectric constant, when all molecules exist as free monomers.

line. In this equation, the limiting high-frequency dielectric constant ($\varepsilon_\infty=\varepsilon_3$) for the third region was evaluated by using $(\varepsilon_\infty-1)/(\varepsilon_\infty+2)=(n_D^2-1)(1+0.19)/(n_D^2+2)$, as described before.[9]

For the isomeric $C_8H_{17}OH$, the behavior of ε_0 can be grouped roughly into three types and explained by estimation of the relative concentrations of the C_{1-R}. A chain dimer and trimer could not be distinguished from a free monomer by the temperature dependence of ε_0. Therefore, **MONOMER** described hereunder includes the existence of a chain dimer and trimer.

The dielectric behavior of the first type is typical of more polar alcohols, such as 1-octanol shown in Fig. 1. The ε_0 is larger than that of the dotted line even at high temperatures and increases linearly with decreasing temperature. This observation indicates that **CHAIN** can be formed at the high temperatures. We established that for 1-octanol at 25 °C the percentages of the C_1, C_3, and C_R are 69, 26, and 5% of the gross concentration, respectively. The C_1 increases and the C_3 decreases because of the transformation of **MONOMER** into **CHAIN**, as the temperature decreases. The ε_0-$1/T$ curve can be explained by an equilibrium between **MONOMER** and **CHAIN**.

The second type consists of intermediate alcohols, such as 4-octanol and 5-methyl-3-heptanol. The ε_0 is smaller than that of the dotted line at high temperatures. Therefore, **RING** can be formed at the high temperatures. For 5-methyl-3-heptanol at 15 °C, the percentages of the C_1, C_3, and C_R are 8, 16, and 76%, respectively. The C_3 decreases and the C_R increases, as the temperature decreases. The C_1 could not be obtained at 25 and 35 °C, since they are small values. The ε_0-$1/T$ curve for 5-methyl-3-heptanol indicates a complex and interesting curve. The ε_0 at first increases with decreasing temperature and becomes a maximum at about 75 °C ($1/T=2.87\times10^{-3}$ K^{-1}) and then decreases conversely with decreasing temperature. Additionally, the ε_0 becomes a minimum at about −40 °C ($1/T=4.29\times10^{-3}$K^{-1}), and increases again with decreases temperature. Therefore, it is necessary to consider the coexistence of **MONOMER**, **RING**, and **CHAIN**, especially, inclusive of two transformations of **MONOMER** into **RING** at high temperatures and of **RING** into **CHAIN** at low temperatures.

The behavior of the third type is typical of more sterically hindered alcohols, such as 3-methyl-3-heptanol and 4-methyl-4-heptanol. The ε_0's for these tertiary alcohols are nearly equal at 135 °C ($1/T=2.45\times10^{-3}$ K^{-1}) and are smaller than that of the dotted line at high temperatures. The ε_0-$1/T$ curve has a maximum at about 80 °C ($1/T=2.83\times10^{-3}$ K^{-1}). The maximum for the tertiary alcohols appears at higher temperature than that for the secondary alcohols, because of the ease of the transformation of **MONOMER** into **RING**. For 3-methyl-3-heptanol at 25 °C, the percentages of the C_1, C_3, and C_R are 0, 22, and 78%, respectively. **CHAIN** can not exist at temperatures between 135 and −55 °C. The C_3 decreases and the C_R increases, as the temperature decreases. The third type shows the equilibrium between **MONOMER** and **RING**.

Binary Mixtures of 1-Butanol in Some Isomeric $C_8H_{17}OH$. When 1-butanol is added to the three types of isomeric $C_8H_{17}OH$, the ε_0-$1/T$ curve for the mixtures differs from that of the pure octanol.

The ε_0-$1/T$ curves for mixtures of 1-butanol in 1-octanol are shown in Fig. 2, together with the dotted line. The ε_0 of pure 1-octanol increases linearly with decreasing temperature, since **CHAIN** can be formed even at high temperatures. The ε_0-$1/T$ curve for the mixture increases in parallel over the temperatures from 135 °C to a freezing point or −55 °C, as 1-butanol is added to 1-octanol. It can be considered that the **CHAIN** formed is composed of both 1-butanol and 1-octanol molecules because the ε_0 increases approximately in proportion to the 1-butanol concentration. Therefore, the first dispersion can be explained by a single relaxation process for binary mixtures of normal alcohols.[10,11]

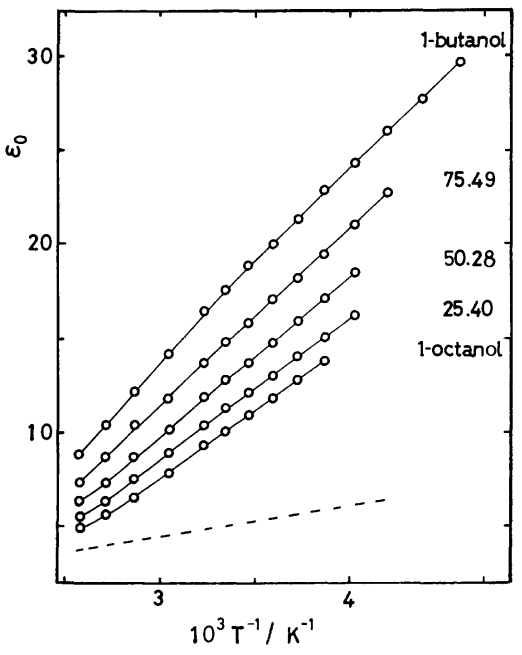

Fig. 2. Equilibrium dielectric constants as a function of reciprocal absolute temperature for the mixtures of 1-butanol in 1-octanol. Number is mol% of 1-butanol.

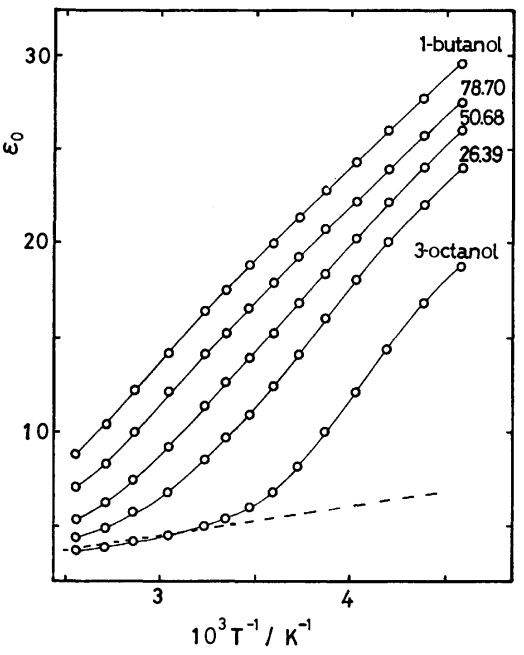

Fig. 3. Equilibrium dielectric constants as a function of reciprocal absolute temperature for the mixtures of 1-butanol in 3-octanol. Number is mol% of 1-butanol.

The ε_0–$1/T$ curves for mixtures of 1-butanol in 3-octanol are shown in Fig. 3. The ε_0 of pure 3-octanol at high temperatures is smaller than that of the dotted line and increases gradually as shown by the dotted line with decreasing temperature. For pure 3-octanol at 25 °C ($1/T$=3.35×10^{-3} K^{-1}), the percentages of the C_R, C_3, and C_1 are 51, 25, and 24%, respectively. The C_R and C_3 decrease and the C_1 increases, as the temperature decreases. Figure 3 shows that **MONOMER** and **RING** coexist at high temperatures and that the transformation of **MONOMER** and **RING** into **CHAIN** occurs, since the ε_0 of pure 3-octanol increases suddenly at about 25 °C. It favors the formation of **CHAIN** at temperatures below about 25 °C. As 1-butanol is added to 3-octanol, the transformation occurs at higher temperatures, namely, at about 25 °C for pure 3-octanol, at about 70 °C ($1/T$=2.91×10^{-3} K^{-1}) for 26 mol% mixture of 1-butanol, and at about 110 °C ($1/T$=2.61×10^{-3} K^{-1}) for 50 mol% mixture of 1-butanol.

The ε_0–$1/T$ curves are shown in Fig. 4 for mixtures of 1-butanol in 4-methyl-4-heptanol and in Fig. 5 for solutions of 1-butanol in heptane in order to emphasize the difference of the dielectric behavior between 4-methyl-4-heptanol and heptane. The ε_0–$1/T$ curve for pure 4-methyl-4-heptanol is similar to that for pure heptane which is a nonpolar solvent. The ε_0 is slightly larger than that of heptane because of the existence of **MONOMER** having a dipole moment. As described above, **CHAIN** can not be formed for pure 4-methyl-4-heptanol over the temperatures from 135 to −55 °C. For 26 mol% mixture of 1-butanol in 4-methyl-4-heptanol, however, the ε_0 at high temperatures increases as indicated by the dotted line with decreasing temperature. It becomes smaller than that of the dotted line over the temperature range of 72—−29 °C and then increases suddenly at about −29 °C ($1/T$=4.10×10^{-3} K^{-1}), although ε_0 of the 25 mol% solution of 1-butanol in heptane hardly changes over the temperature range. This observation can be explained by two transformations of **MONOMER** into **RING** at high temperatures and **MONOMER** and **RING** into **CHAIN** at low temperatures. In a 50 mol% mixture of 1-butanol in 4-methyl-4-heptanol, the transformation of **MONOMER** into **CHAIN** occurs at higher temperatures. The ε_0 of 4-methyl-4-heptanol mixtures is larger than that of heptane solution at the same concentration of 1-butanol and at the same temperature. This difference of ε_0 indicates that the transformation of **RING** into **CHAIN** occurs by the addition of 1-butanol.

At a fixed temperature of −55 °C ($1/T$=4.58×10^{-3} K^{-1}), the ε_0 of the binary mixtures are plotted in Fig. 6 against mol% of 1-butanol. Since the ε_0 of pure 3-octanol is 18.68 at this temperature, almost every molecule exists as **CHAIN** in both pure 3-octanol and mixtures of 1-butanol in 3-octanol. It is noticeable that the ε_0 of the mixtures is larger than that of pure normal alcohols at the same concentration of the hydroxyl group. Figure 6 also shows that the ε_0 is 2.48 for pure 4-methyl-4-heptanol and 2.00 for pure heptane. The difference, 2.48—2.00, suggests the

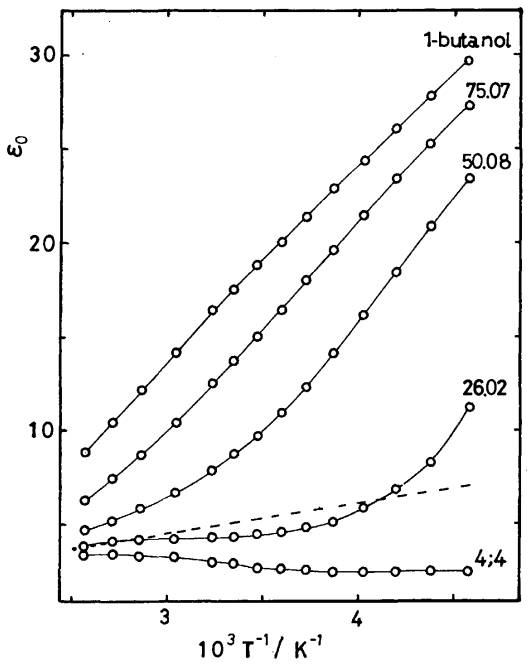

Fig. 4. Equilibrium dielectric constants as a function of reciprocal absolute temperature for the mixtures of 1-butanol in 4-methyl-4-heptanol (4;4). Number is mol% of 1-butanol.

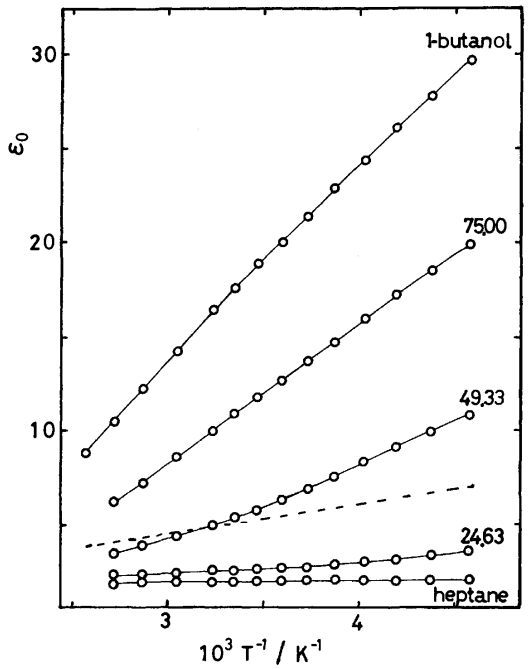

Fig. 5. Equilibrium dielectric constants as a function of reciprocal absolute temperature for the solutions of 1-butanol in heptane. Number is mol% of 1-butanol.

existence of **MONOMER** in pure 4-methyl-4-heptanol. As 1-butanol is added to 4-methyl-4-heptanol, ε_0 increases suddenly at about 30 mol% mixture of 1-butanol. The ε_0 of 50 mol% mixture becomes 23.3

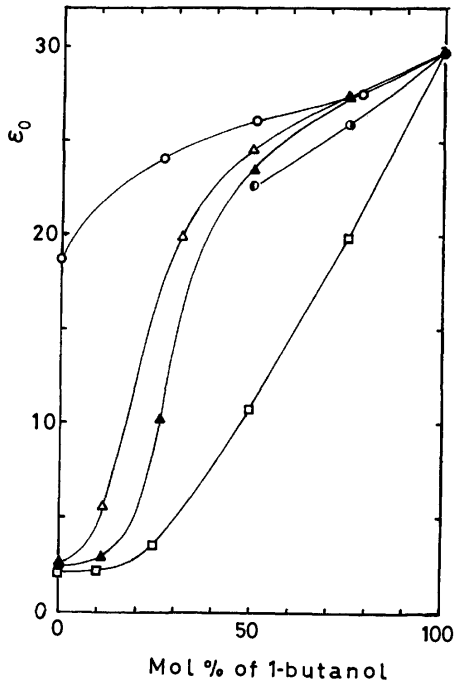

Fig. 6. Equilibrium dielectric constants as a function of mol% of 1-butanol at −55 °C. ○: 1-butanol-3-octanol, △: 1-butanol-4-methyl-3-heptanol, □: 1-butanol-heptane, ▲: 1-butanol-4-methyl-4-heptanol, ◑: pure 1-pentanol, ◐: pure 1-hexanol.

and is larger than 22.5 of pure 1-hexanol having the same concentration of the hydroxyl group, although the ε_0 is 10.9 for 50 mol% solution of 1-butanol in heptane. Therefore, almost every molecule in the 50 mol% mixture is considered to be **CHAIN**, being the same as that in pure normal alcohol. The variation of ε_0, shown in Fig. 6, provides experimental evidence of the existence of **RING**. The mechanism of the transformation of **RING** into **CHAIN** can be envisioned by addition of 1-butanol to some isomeric $C_8H_{17}OH$. For the mixtures of 1-butanol in 4-methyl-4-heptanol at this temperature, for example, **CHAIN** can hardly exist for the 20 mol% mixture which consists of four molecules of 4-methyl-4-heptanol to one of 1-butanol. **CHAIN** can be formed suddenly for 25 and 33 mol% mixtures which are in the molecular ratios of 3:1 and 2:1, respectively. It may be considered that a ring trimer and a ring dimer transform into a chain tetramer and a chain trimer inclusive of one molecule of 1-butanol, respectively. A chain pentamer can not exist because of the repulsion of two alkyl groups of 4-methyl-4-heptanol in both sides of the linear hydrogen-bonded chain. The chain tetramer and chain trimer formed may associate into a chain octamer and chain $3n$-mer, respectively.

Physicochemical Properties of Eicosane-1,20-bis(trimethylammonium) Dibromide in Aqueous Solution

Masaaki YASUDA, Kenji IKEDA, Kunio ESUMI,* and Kenjiro MEGURO
Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 27, 1989)

The physicochemical properties of a cationic α,ω-type(bolaform) surfactant, eicosane-1,20-bis(trimethylammonium) dibromide ($C_{20}Me_6$), were investigated by means of surface tension, electrical conductivity, density, dye solubilization, fluorescence, and light scattering. The results obtained for $C_{20}Me_6$ were compared with those for decyltrimethylammonium bromide ($C_{10}Me_3$). The surface tension measurement suggests that $C_{20}Me_6$ has a folded, "wicket-like" conformation at the air-water interface. The cmc of $C_{20}Me_6$ was smaller than that of $C_{10}Me_3$. The apparent ionization degree of $C_{20}Me_6$ was larger, and the polarity of the micellar Stern layer was higher than that of $C_{10}Me_3$. It was found that the $C_{20}Me_6$ micelle has an aggregation number of about 19, a hydrodynamic radius of 16 Å, and a partial molar volume of 480.49×10^{-3} dm^3 mol^{-1}, suggesting that the micelle is nearly spherical; thus, the main alkyl chain is almost stretched, and the outermost region of the micelle is loose.

The α,ω-type surfactant is different from a "conventional" surfactant since the former has headgroups at each end of the long alkyl chain. This feature can impose a significant constraint on the orientation and the packing of surfactant monomers within a micelle, because both ends of each α,ω-type surfactant monomer must be located on the micellar surface.

There have been several studies of the properties of α,ω-type surfactants in aqueous solution.[1-15] Menger and Wrenn[1] reported that micelles are formed for C_mMe_6 ($m>12$), and concluded that dodecane-1,12-bis(trimethylammonium) dibromide ($C_{12}Me_6$) takes a folded, "wicket-like", conformation at an air-water interface. Johnson et al.[2] confirmed that C_mMe_6 do not form ordinary micelles for $m<10$, indicating that there is considerable bending of the $(CH_2)_m$ chains in aqueous solution and air-water interfaces from measurements of the apparent molar volumes for $m=6$ and 10. In contrast, Zana et al.[4-6,9] found no evidence of conventional micellization for $C_{12}Me_6$ from density, electrical conductivity, and emf measurements, whereas $C_{16}Me_6$ and $C_{22}Me_6$ form micelles. The chemical relaxation studies indicated that $C_{22}Me_6$ monomers diffuse rapidly among the bulk and micellar pseudophases, with a rate similar to that of the conventional surfactant, dodecyltrimethylammonium bromide ($C_{12}Me_3$). Mckenzie et al.[8] estimated the hydrodynamic radii and the ionization degree of $C_{22}Me_6$ using static and dynamic light scattering; they concluded that $C_{22}Me_6$ forms micelles which are similar to those of $C_{12}Me_3$.

On the other hand, Meguro et al.[10-13] have studied the solution properties of anionic α,ω-type surfactants, and concluded that these surfactants also form small and loose aggregates.

The conformational properties of eicosane-1,20-bis(triethylammonium) dibromide ($C_{20}Et_6$) have been investigated by NMR and time-resolved fluorecence quenching.[14-16] It has been concluded that the sufractant chains of $C_{20}Et_6$ adopt a predominantly stretched conformation in micelles. However, the physicochemical properties of α,ω-type surfactants are not fully understood. Still, it is worthwhile studying the properties in the aqueous solution of an α,ω-type surfactant from a comparison of the corresponding conventional surfactants.

In this work we focused the attention on a comparison between the physicochemical property of a cationic α,ω-type surfactant, eicosane-1,20-bis(trimethylammonium) dibromide ($C_{20}Me_6$), and that of a conventional surfactant, decyltrimethylammonium bromide ($C_{10}Me_3$), which has the same head group and an alkyl chain half as long. The comparison was carried out by measuring the surface tension, electrical conductivity, static and dynamic light scattering, steady-state fluorescence quenching, density, and probe solubilization.

Experimental

Materials. The α,ω-type surfactant, $C_{20}Me_6$, was synthesized as follows: 1,20-dibromoeicosane was prepared by the dimerization of 11-bromoundecanoic acid with Kolbe's electrolysis in methanol. A white precipitate was filtered and recrystallized from methanol. The obtained dibromide was converted to $C_{20}Me_6$ according to the procedure.[1] After removing ethanol and trimethylamine, $C_{20}Me_6$ was recrystallized four times from acetone–ethanol mixtures and dried under vacuum for 48 hours. The purity of the product was confirmed to be above 99% by isotachophoresis, elemental analysis, and ^{1}H NMR.

Pyrene was recrystallized four times from ethanol. Orange-OT and Yellow-OB were recrystallized four times from ethanol. Pyrene-3-carbaldehyde and benzoylacetone were used as received. *N*-Hexadecylpyridinium chloride was recrystallized three times from ethanol. Decyltrimethylammonium bromide, $C_{10}Me_3$, was recrystallized three times from acetone. The water used was purified by passing it through a purification system, Milli-Q Reagent Grade Water System, until the specific conductivity of water was below

0.1 μS cm^{-1}.

Measurements. Surface-tension measurements were carried out for various concentrations of $C_{20}Me_6$ in aqueous solutions by using a Wilhelmy-type surface tensiometer (Shimadzu St-1) at 25 °C. The establishment of equilibrium was checked by repeated measurements at 5-minute intervals. The electrical conductivity of $C_{20}Me_6$ solutions was measured by means of an electrical-conductivity meter (Toa Denpa Co. Model CM-30ET) at 25±0.1 °C.

Information about micellar aggregation numbers was obtained by static light-scattering measurements. The scattered intensities were measured at 90° using a light-scattering photometer (DLS-700 (Otsuka electronics Co.)) with an argon laser at 488 nm (13 mW). The average molecular weight of micelles was determined by using the Debye relation. The refractive index increment was measured by a differential refractometer (RM-102 (Otsuka electronics Co.)) at 488 nm. The solutions were previously filtered through a 0.2 μm disposable membrane filter.

The steady-state fluorescence quenching method of Turro and Yekta[17] was carried out by using pyrene as a fluorescence probe and *N*-hexadecylpyridinium chloride as a quencher. In this experiment it was assumed that the probe and the quencher do not migrate from micelle to micelle within the lifetime of pyrene:[18]

$$\ln (I_0/I) = C_q/[\text{micelle}], \quad (1)$$

where C_q is the concentration of the quencher; I_0 and I are the fluorescence intensities in the absence and presence of the quencher. The micellar aggregation number is calculated from

$$N = (C - \text{cmc})/[\text{micelle}]. \quad (2)$$

Dynamic light-scattering measurements were carried out using a sub-micron particle analyzer (4700C (Malvern Co.)) with an argon laser of 488 nm, 5W (Spectra-Physics Co.). The scattering angle was varied from 40 to 140° for a sample with a concentration of 3.0×10^{-2} mol kg^{-1}, and the mean micellar diffusion coefficients for various concentrations were measured at 40°.

The density measurements were carried out by using a ANTON PAAR Model DMA 60 at 25±0.01 °C. The accuracy was ±10^{-5} g dm^{-3}. The apparent molar volume, ϕ, is given by[19]

$$\phi = \frac{M}{d} - \frac{1000(d - d_0)}{m \cdot d \cdot d_0}, \quad (3)$$

where M, m, d, and d_0 are the molar weight of the surfactant, the molality, the density of solution, and the density of water, respectively. The partial molar volume V is related to ϕ by

$$V = \phi + m\left(\frac{\partial \phi}{\partial m}\right)_{T,P,n_0}, \quad (4)$$

where T, P, and n_0 are the temperature, pressure, and mole number of water, respectively. The calculated V is plotted versus the micellized surfactant concentration. The partial molar volume of the micellar species was obtained by extrapolating the plot to the cmc. A similar approach was made for the concentration below the cmc.

The fluorescence spectra of the respective samples were measured by using a fluorescence spectrophotometer (Hitachi 650-10S). The excitation and emission slits were set at 7.5 and 1.0 nm, and the excitation wavelengths of pyrene and pyrene-3-carbaldehyde (PyCHO) were 335 and 356 nm, respectively. The emission spectra were measured in the range 360—520 nm for pyrene and 380—520 nm for PyCHO.

The ultraviolet spectra measurements were carried out using a Hitachi 220A UV spectrophotometer. The concentration of benzoylacetone (BZA) was 1.0×10^{-5} mol dm^{-3}. The absorbances from ketonic- and enolic-form of BZA were measured at 245 and 310 nm.

The procedure of solubilizing power measurements was carried out as follows: after the addition of excess amounts of water-insoluble dyes into the surfactant solution, these mixtures were shaken for 48 hours at 25±0.1 °C. Then, the solutions were centrifuged at 5000 rpm for 10 minutes, and the supernatant liquids obtained were diluted with ethanol. The optical density was measured at the maximal absorption band, and the concentrations of dyes were determined from a calibration of the absorbance versus the dye concentration.

Results and Discussion

Cmc. The cmc values of $C_{20}Me_6$ were found to be 7.5×10^{-3} mol kg^{-1} and 8.2×10^{-3} mol kg^{-1} from surface tension and electrical conductivity measurements, respectively. These cmc values were smaller than that of $C_{10}Me_3$ (6.8×10^{-2} mol dm^{-3}).[20]

Conformation of $C_{20}Me_6$ at Liquid-Air Interface. From the surface-tension values of $C_{20}Me_6$ as a function of the logarithm of the surfactant concentration, the occupying area per molecule at the air-water interface was found to be 78.9 Å^2 using Gibbs adsorption equation:

$$\Gamma = \frac{-1}{nRT} \cdot \left(\frac{\partial \gamma}{\partial \ln C}\right)_T. \quad (5)$$

The value of n was taken as 3 since $C_{20}Me_6$ is regarded as being a 2:1 electrolyte. γ is the surface tension mN m^{-1} and $(\partial\gamma/\partial \ln C)_T$ denotes the maximum slope of γ-log$C$ plots.

$$A = \frac{10^{16}}{N_A \Gamma}, \quad (6)$$

where A is the occupying area per molecule in square angstroms and N_A is Avogadro's number. The value of 78.9 Å^2 for $C_{20}Me_6$ was about twice that of the intrinstic surface area of the trimethylammonium head group (37.9 Å^2)[21] suggesting that $C_{20}Me_6$ has a folded, "wicket-like" conformation at an air-water interface.[1,12]

Ionization Degree. Figure 1 shows the variation of the specific conductivity, κ, with the surfactant concentration. The apparent degree of micelle ionization, α_{ap}, was obtained[9] as the ratio of the slope of these plots above and below the cmc. The α_{ap} value

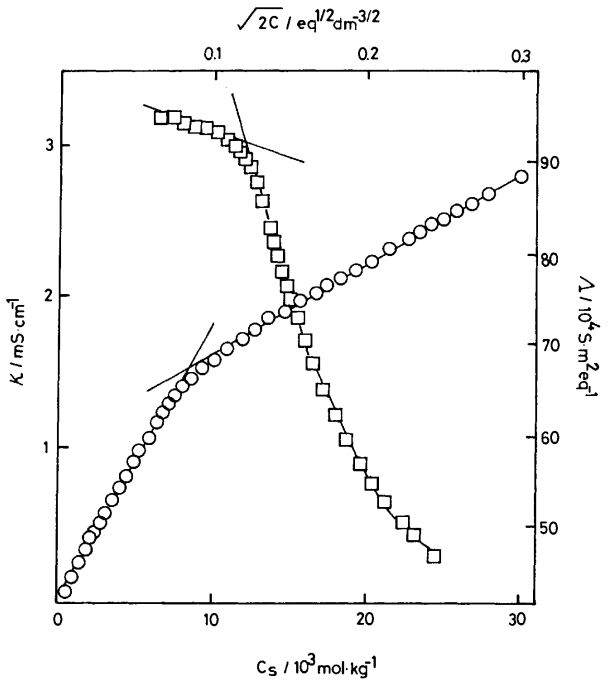

Fig. 1. Variation of specific and equivalent conductivities of $C_{20}Me_6$ with concentration in aqueous solution.

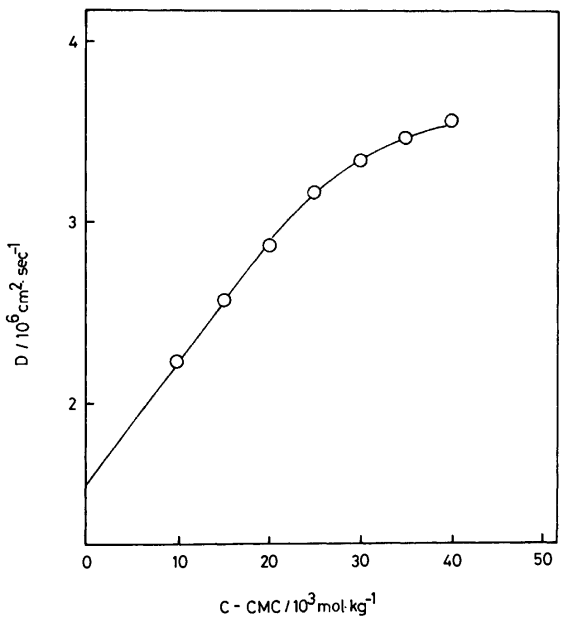

Fig. 2. Mean micellar diffusion coefficients of $C_{20}Me_6$ vs. C—cmc.

of $C_{20}Me_6$ was found to be 0.33, which is somewhat larger than that $C_{10}Me_3$. This α_{ap} value means that the minority of the fixation of the counterion is onto the micelle surface. This high value of $C_{20}Me_6$ indicates that the repulsion force between the two positive charges on trimethylammonium head for $C_{20}Me_6$ is larger than that for $C_{10}Me_3$.

Aggregation Number. From the intercept of the Debye plots at a scattering angle of 90°, the aggregation number of $C_{20}Me_6$ was found to be 18. Similarly, from a good linear relationship between $\ln(I_0/I)$ and C_q, the aggregation number of 19 was obtained by calculating the slope of this plot at the surfactant concentration 3.0×10^{-2} mol kg^{-1}. Thus, the aggregation number of $C_{20}Me_6$ obtained by static light scattering is in good agreement with that obtained by the steady-state fluorescence method. These values are nearly the half that of the aggregation number of $C_{10}Me_3$ (39—41).[22] In other words, the number of head groups per $C_{20}Me_6$ micelle is approximately the same for that of $C_{10}Me_3$ since $C_{20}Me_6$ has two head groups.

Micellar Shape. The shape of $C_{20}Me_6$ was examined by dynamic light scattering.[23,24] The initial slope, Γ, of the decay curve of the field correlation function is defined by the cumulant expansion, and the relationship between Γ and the diffusion coefficient D is generally given by

$$\frac{\Gamma}{q^2} = D_0 + \left(\frac{L^2}{12}\right)\theta f_1(q) + (D_3 - D_1)\left[f_2(q) - \frac{1}{3}\right] + \sum_m D_m a_m(q) \quad (7)$$

The first, second, third, and $\sum$ terms of right side of Eq. 7 are due to contributions of the average translational diffusion, the rotational diffusion, the anisotropy of the translational diffusion, and the motion of bending, respectively. Since the values of Γ/q^2 for each scattering angle are almost constant, terms including q are negligible. Accordingly, the constancy of Γ/q^2 profiles is only derived from the isotropy in the translational diffusion. Thus, this result supports the formation of the spherical micelles for $C_{20}Me_6$ in aqueous solution. The mean micellar diffusion coefficients (D) of $C_{20}Me_6$ are plotted against the surfactant concentration, i.e., C—cmc in Fig. 2. The D value increased with C—cmc due to significant net intermicellar repulsions. This behavior was analyzed according to the following equation:[25,26]

$$D = D_0(1 + KC), \quad (8)$$

where D_0 is the diffusion coefficient in limit of infinite dilution, i.e., extrapolated to the cmc. The radius of the $C_{20}Me_6$ micelle was estimated by using the D_0 value (1.55×10^{-6} cm^2 s^{-1}) and by the Stokes-Einstein equation,

$$D_0 = \frac{kT}{6\pi\eta R_H} \quad (9)$$

where k is Boltzmann's constant, T the absolute temperature, and η the viscosity of the solvent. The hydrodynamic radius value (R_H) of $C_{20}Me_6$ (16 Å) is smaller than that of $C_{10}Me_3$ calculated from reported results.[26] The D versus C—cmc plot for $C_{20}Me_6$ has a

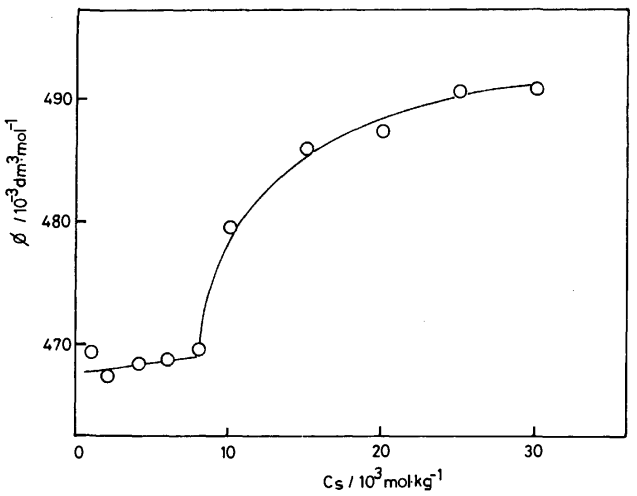

Fig. 3. Apparent molal volume of $C_{20}Me_6$ aqueous solution vs. molality of $C_{20}Me_6$.

larger slope than that for $C_{12}Me_3$.[26] This is attributed to the largeness of the ionization degree for $C_{20}Me_6$.

The partial molar volume derived from the density measurement was used to confirm the conformation of the $C_{20}Me_6$ micelle.[19] The apparent molar volumes, ϕ, are plotted against the molality in Fig. 3. This plot has a clear break, indicating the formation of the micelle of $C_{20}Me_6$. The partial molar volumes below and above the cmc were obtained with the values of 463.91 and 480.49×10^{-3} mol^{-1}, respectively.

In order to estimate the difference in micelles between α,ω-type and conventional surfactants, the surface areas occupied per head group at micelle surface(s) were calculated by some models. For this calculation, the micelle is assumed to be spherical. The superscript of "bola" means α,ω-type surfactants. Three kinds of surface areas are considered for $Br^-(C_{m''}H_{2m''+1})_3N(CH_2)_mN(C_{m''}H_{2m''+1})_3Br^-$:[21,27]

(1) s_0: s_0 is obtained by assuming a micelle radius which is equal to the length of a stretched alkyl chain, plus the length of the head group Δ, corresponding to the charged nitrogen atom and alkyl groups substituting the nitrogen atom:

$$s_0^{bola} = 4\pi[(l_H^{bola} + 2\Delta)/2]^2/2n_0. \quad (10)$$

Here, l_H^{bola} is only due to the methylene $(-CH_2-)_m$ group,

$$l_H^{bola} = 1.265m,[28,29] \quad (11)$$

and

$$\Delta = 0.42m'' + 2.1.[21,27] \quad (12)$$

Equation 12 was obtained by assuming a charged nitrogen atom at the center of a regular tetrahedron having as apexes the three carbon atoms of terminal methyl groups of the three head group alkyl chains.

Table 1. Calculated and Experimental Surface Areas per Head Group

	$C_{20}Me_6$	$C_{10}Me_3$
s_o /Å²	76.1	52.2
s_i /Å²	37.8	37.8
s_H /Å²	84.5	82.7
s_{exp}/Å²	78.0	81.3

(2) s_i: the intrinsic surface area of the head group (s_i) is taken as being that of a circular domain having a radius equal to that of a circle determined by the same three carbon atoms of the terminal methyl groups and corrected for the void space in the packing of these circular domains in a hexagonal lattice,

$$s_1 = 3.46(1.205m'' + 2.1).[2\,21] \quad (13)$$

(3) s_H: s_H is obtained assuming that a micelle radius is equal to the radius of a hydrophobic (oil drop-like) core, plus a length of the head group,[21]

$$s_H^{bola} = 4\pi(r_H + \Delta)^2/2n_0. \quad (14)$$

Zana et al.[4-6] and Broadwater et al.[3] estimated the volume occupied per (CH_2) unit of bolaform alkyl chain for C_mMe_6 (m=6, 10, 16) from density measurements. The value of 15.6×10^{-3} dm^3 mol^{-1} (25.9 Å³) per (CH_2) is adequate for a dispersed monomeric state. The volume per (CH_2) unit in the state of oil drop-like hydrocarbon should be estimated:

$$V^{bola} = 26.9m.[28,29] \quad (15)$$

The radius of the hydrophobic core, r_H, is obtained by $r_H=(3nV^{bola}/4\pi)^{1/3}$ where n is the experimental aggregation number. The calculated values of s_0, s_i, and s_H, are listed in Table 1. In Table 1 the surface areas derived from the partial molar volume, s_{exp}, are also listed. Here, the effect of counter ions on the calculated values of s_0, s_i, and s_H is not taken into consideration. The s_{exp} values for both conventional and α,ω-type surfactants were fairly greater than that of s_i, indicating that the aggregations of both $C_{10}Me_3$ and $C_{20}Me_6$ are controlled by the packing of the surfactant main alkyl chain, not by the head group packing at the micelle surface. For $C_{10}Me_3$, the s_{exp}[30] is comparable to s_H which is derived from an assumption that the moiety of the main alkyl chain is like an oil drop. Accordingly, this result supports the idea that the hydrophobic alkyl chain of $C_{10}Me_3$ takes on an oil drop-like state in the micelle. In contrast with $C_{10}Me_3$, the s_{exp} value of $C_{20}Me_6$ is comparable to that of s_0 rather than s_H. Regarding s_0 it is assumed that the main alkyl chain is stretched, and has a all-trans conformation. It is thereby suggested that the state of the hydrophobic moiety of $C_{20}Me_6$ in the micelles is as follows: the aggregation behavior of

$C_{20}Me_6$ is attributed to the packing of the main alkyl chain. It is likely that the main alkyl chains of $C_{20}Me_6$ do not exist in an oil drop-like moiety, but take on an entangled, predominantly stretched conformation in the micelles.

Polarity of the Micelle. The polarity of the micelle interior was evaluated by the solubilization of two kinds of aromatic compounds, such as pyrene and pyrene-3-carbaldehyde. The intensity ratio of the first emission peak to the third one, i.e., I_1/I_3 of pyrene, is known to be sensitive to the local polarity.[31,32] This value increases upon going from nonpolar to polar solvents. Thus, pyrene can be used as an indicator of the local polarity at the solubilization site in the micelles. In low concentrations, the I_1/I_3 value was over 1.8, indicating that the pyrene monomer is located in water. At around 8.0×10^{-3} mol kg^{-1}, corresponding to the cmc, the I_1/I_3 changed down to about 1.50. This change is attributed to the solubilization of pyrene into the micelles. Since the I_1/I_3 value for $C_{10}Me_3$ is found to be 1.42 at a surfactant concentration (0.2 mol dm^{-3}), it is considered that the pyrene exists in somewhat more polar region in comparison with the conventional surfactant. Therefore, these experimental results suggest either that the interior of the $C_{20}Me_6$ micelles is polar and loose, or that the pyrene in the $C_{20}Me_6$ micelles resides at a more external site than that in the micelles of the conventional surfactant.

The fluorescence of the pyrene-3-carbaldehyde monomer strongly depends on the solvent polarity as well as pyrene.[33] The fluorescence maximum significantly shifts to the region of lower wavelength with increasing solvent polarity, showing a linear relationship with the dielectric constant for a solvent >10.

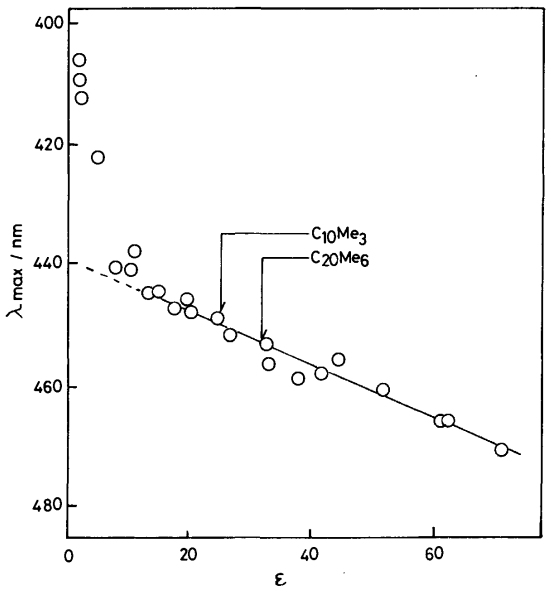

Fig. 4. Relationship between fluorescence maximum of PyCHO and solvent dielectric constant.

Owing to the effect of the solvation in the region of the aldehyde group, PyCHO is considered to be solubilized in the micellar Stern layer.[33] The dielectric constants which denote the polarity are found to be 31.3 for $C_{20}Me_6$ and 25.4 for $C_{10}Me_3$ (Fig. 4). This result indicates that the polarity in the region of the Stern layer of $C_{20}Me_6$ micelles is higher than that of $C_{10}Me_3$

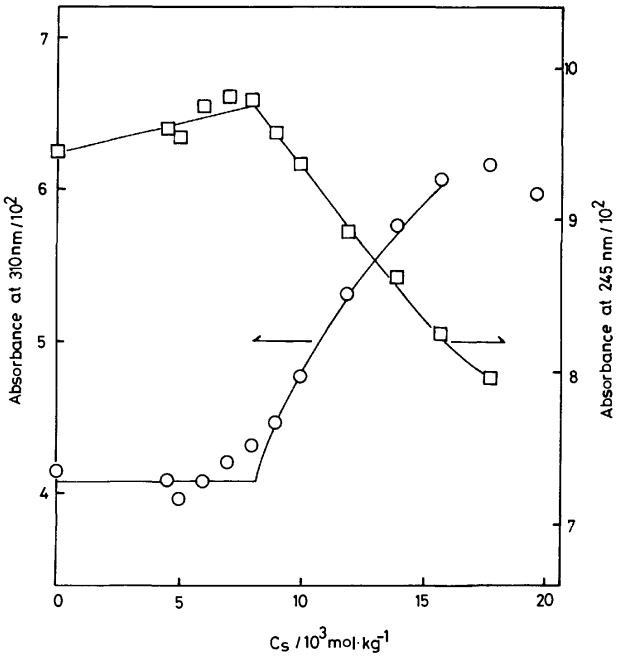

Fig. 5. Change in absorbances of BZA as a function of $C_{20}Me_6$ concentration.

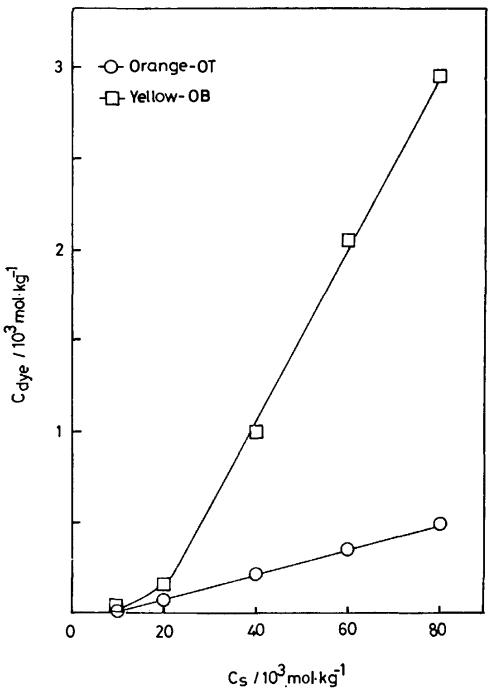

Fig. 6. Molality of Orange-OT solubilized in $C_{20}Me_6$ aqueous solution vs. $C_{20}Me_6$ concentration.

to some degree.

Solubilization of Dyes. It is known[34] that BZA exists in the enolic form in nonpolar media, whereas in the ketonic form in polar media. The change from the ketonic to the enolic form occurs when the polarity of the probe environment decreases. In Fig. 5, the absorbances of the ketonic form decrease, but the absorbances of the enolic form increase above the cmc. The distribution coefficient (α/n) between bulk and micelles is obtained by the following equation:[35]

$$\frac{1}{(C - \mathrm{cmc})} = \frac{(\varepsilon_m - \varepsilon_w)}{(\varepsilon - \varepsilon_w)} \cdot (\alpha/n) - (\alpha/n), \qquad (16)$$

where ε, ε_w, and ε_m are the molar extinction coefficient in the solution, water, and micellar media, respectively. The α/n value obtained was 80, which was somewhat lower than that of $C_{12}Me_3$, dodecyltrimethylammonium bromide (α/n=90).[35]

The molality of Orange-OT solubilized in $C_{20}Me_6$ solutions versus the surfactant concentration is plotted in Fig. 6. Above the cmc, the concentrations of Orange-OT and Yellow-OB increased linearly as the surfactant concentration increased. The solubilizing power (i.e., the number of moles of the solubilized dye per mole of micellized surfactant) was obtained from the slope of the plot. The solubilizing powers were 6.9×10^{-3} and 5.6×10^{-2} moles dye per mole surfactant for Orange-OT and Yellow-OB, respectively. These values of $C_{20}Me_6$ are nearly half that of $C_{10}Me_3$. If the solubilizing power is expressed in moles of solubilized dye per mole of head group, the values of $C_{20}Me_6$ are almost one quarter of those of $C_{10}Me_3$. Further, it has been found that hydrophobic molecules are not easily solubilized into the micelles of $C_{20}Me_6$ in comparison with the corresponding conventional surfactant, $C_{10}Me_3$. Thus, the significant low capacity of the solubilizing power in $C_{20}Me_6$ micelles can be understood on the basis of the conformation of the surfactant chains. The almost stretched conformation of the alkyl chains makes it difficult for hydrophobic compounds to be incorporated into the hydrophobic core of the micelles owing to the inability for the micelles to swell.

Conclusion

The physicochemical properties of $C_{20}Me_6$ in aqueous solution have been studied by measuring the surface tension, electrical conductivity, density, dye solubilization, fluorescence, and light scattering. Further, the properties of $C_{20}Me_6$ are compared with $C_{10}Me_3$.

At the air–water interface, $C_{20}Me_6$ has a folded, "wicket-like" conformation, whereas the micelle is nearly spherical and the main alkyl chain is almost stretched. The apparent ionization degree and the polarity of the micellar Stern layer of $C_{20}Me_6$ are larger than those of $C_{10}Me_3$.

Preparation of Poly(phenylene sulfide)s: Polymerization of Aromatic Disulfides with Lewis Acids

Kimihisa YAMAMOTO, Shu YOSHIDA, Hiroyuki NISHIDE, and Eishun TSUCHIDA*
Department of Polymer Chemistry, Waseda University, Tokyo 169
(Received July 7, 1989)

Poly(*p*-phenylene sulfide) is prepared through the polymerization of diphenyl disulfide with various Lewis acids, such as $AlCl_3$ and $SbCl_5$. Thiophenol also yield poly(*p*-phenylene sulfide) through its oxidation to diphenyl disulfide in the presence of an oxidizing agent or electrolysis during polymerization. Alkyl-substituted diphenyl disulfides are polymerized with a Lewis acid to efficiently yield alkyl-substituted poly(*p*-phenylene sulfide)s such as poly(2-methyl-, 2,6-dimethyl-, and 2,6-diethylphenylene sulfide)s, with high molecular weight and solubility in common solvents.

Poly(*p*-phenylene sulfide)(PPS) has been increasingly used owing to its excellent chemical, thermal, and mechanical properties.[1-6] A commercially important preparation procedure of PPS involves the polycondensation of 1,4-dichlorobenzene and sodium sulfide in a polar solvent, such as *N*-methylpyrrolidone, at high temperature and pressure.[7-9] Much effort has been consumed in the modification of the synthetic routs for PPS. It has been reported that PPS can also be prepared by the polycondensation of metal *p*-halobenzenethiolate at ca. 350 °C.[10-15] High-temperature conditions are required to increase the reactivity of the monomer in the formation of high-molecular PPS. However, the polycondensation of alkyl-substituted monomers does not provide PPSs with high molecular weight, even at high temperatures. Few papers have reported on the preparation of substituted poly(phenylene sulfide)s.[16,17]

We have reported that diphenyl disulfide as a monomer reacts with Lewis acid to cleave its S-S bond and is easily polymerized to a linear PPS at room temperature and atmospheric pressure.[18-20] In this study, alkyl-substituted diphenyl disulfides were applied for this polymerization in order to prepare the corresponding poly(alkylsubstituted phenylene sulfide)s with high molecular weight. The polymerization behavior of the diphenyl disulfides with Lewis acids and the structure of the formed polymers are described.

Experimental

Materials. Diphenyl disulfide was purified by two recrystallization processes from ethanol-water and dried in vacuo for 1 day at 30 °C, producing a white needles: mp 59 °C. Thiophenol was distilled twice under reduced pressure and stored under nitrogen atmosphere. Bis(2-methylphenyl) disulfide, bis(2-methoxyphenyl) disulfide, bis(2,6-dichlorophenyl) disulfide, bis(4-methylphenyl) disulfide, di(2-naphthyl) disulfide, and dibenzyl disulfide were prepared through the oxidation of the corresponding thiophenols with I_2 in alkaline methanol and used through recrystalized twice before use. Bis(2,6-dimethylphenyl) disulfide and bis(2,6-diethylphenyl) disulfide were prepared by a Leuckart reaction from 2,6-dimethylaniline and 2,6-diethylaniline, as the starting material, respectively.[21] Bis(2,6-dimethoxyphenyl) disulfide was obtained by the oxidation of 2,6-dimethoxythiophenol prepared through the reported method from *m*-dimethoxybenzene.[22] The prepared diphenyl disulfides were recrystallized with analytical purity. Bis(2,6-dimethylphenyl) disulfide: ^{13}C NMR ($CDCl_3$), δ=21 (methyl C); 128, 129, 131, 143 (phenyl C). ^1H NMR ($CDCl_3$), δ=2.2 (methyl 6H); 7.0 (phenyl 3H). IR (KBr, cm^{-1}) 2900, 2960, 3040 (ν_{C-H}); 1460 ($\nu_{C=C}$); 760 (δ_{C-H}). Bis(2,6-diethylphenyl) disulfide: ^{13}C NMR ($CDCl_3$) δ=15, 28 (ethyl C); 126, 130, 134, 150 (phenyl C). ^1H NMR ($CDCl_3$) δ=1.1, 2.8 (ethyl 10H); 7.1 (phenyl 3H). IR (KBr, cm^{-1}), 2960, 3050 (ν_{C-H}); 1460 ($\nu_{C=C}$); 750 (δ_{C-H}). Bis(2-methyl-6-chlorophenyl) disulfide: ^{13}C NMR ($CDCl_3$), δ=22 (methyl C); 128.7, 128.7, 130.3, 134.3, 140.7, 145.2 (phenyl C). IR (KBr, cm^{-1}) 2926, 2962 (ν_{C-H}); 1400, 1500 ($\nu_{C=C}$); 745, 860 (δ_{C-H}). 2,6-Dimethoxythiophenol: white needle-like solid, ^{13}C NMR ($CDCl_3$) δ=57 (methoxy C); 125, 131, 133, 162 (phenyl C). ^1H NMR ($CDCl_3$) δ=6.8 (phenyl 3H); 3.9 (methoxyl 6H); 3.7 (mercapto H). IR (KBr, cm^{-1}) 2960, 3040 (ν_{C-H}); 2592 (ν_{S-H}); 1460 ($\nu_{C=C}$); 740 (δ_{C-H}).

Guaranteed reagents of Lewis acids and oxidizing agents were used without further purification and under a dry nitrogen atmosphere. Dichloromethane, 1,1,2,2-tetrachloroethane, nitromethane, and nitrobenzene as the polymerization solvents were purified by distillation in the usual manner.

Measurements. ^1H NMR and ^{13}C NMR spectra were measured of a 90-MHz JEOL FX-100. IR spectroscopy was carried out on a JAS IR-810 model spectrometer. Mass spectra were measured on a JMS-DX300 model spectrometer at an ionization energy of 20 eV.[23] Melting points were determined on the stage of a microscope at a heating rate of 2 °C min^{-1}. DSC measurements were carried out on a SEIKO thermal analyzed model SSC/500 with a heating rate of 20 °C min^{-1}. The molecular weight of the benzene-soluble part of PPS was measured by vapor pressure osmometry.

Polymerization Method. The typical experiment can be described as follows: 0.1 mol l^{-1} of diphenyl disulfide was dissolved in 50 ml of nitromethane and was poured into 50 ml of nitromethane containing Lewis acid kept at 20 °C under nitrogen atmosphere for 20 h. The reaction mixture color changed to deep black from yellow. After the polymerization, the reaction mixture was poured into 500 ml of methanol with 5% hydrogen chloride to precipitate a polymeric material. The polymer was purified according to the previously reported procedure.[18-20] The purified polymer

was not mixed with Lewis acid metal of more than 200 ppm according to an analysis by inductively coupled plasma emission spectroscopy. Polymerization of thiophenol (0.2 mol l^{-1}) was similarly carried out in the coexistence of an oxidizing agent (0.1 mol l^{-1}).

Electrolysis. A pair of platinum plates (2×5 cm) was placed in the cell with a 1 cm spacing as the working and auxiliary electrodes. The reference electrode was Ag/AgCl. A nitromethane solution of thiophenol (0.1 mol l^{-1}) contained Lewis acid and was kept at 20 °C under a nitrogen atmosphere. The preparative electrolysis was carried out under a controlled potential at 1.5 V with a NIKKO KEISOKU NPGS-301 potentiogarvanostat. The electrolysis was turned off at 5 F mol^{-1}.

Spectroscopic Data of the Formed Polymers. Poly(*p*-phenylene sulfide): Calcd for (C_6H_4S): C, 66.67; H, 3.7; S, 29.63%. Found: C, 66.51; H, 3.81; S, 29.44%. Poly(2,6-dimethoxyphenylene sulfide): Calcd for ($C_8H_8SO_2$): C, 54.14; H, 4.76%. Found: C, 55.23; H, 4.86%. IR (KBr, cm^{-1}) 2870 (ν_{C-H}); 1370, 1470, 1600 ($\nu_{C=C}$); 1180 (ν_{C-O-C}); 820 (δ_{C-H}); 480, 1040, 1210, 1280.

Poly(2-methyl-6-chlorophenylene sulfide): Calcd for (C_7H_5SCl): C, 53.67; H, 3.19%. Found: C, 53.25; H, 3.21%. IR (KBr, cm^{-1}) 2870 (ν_{C-H}); 1440, 1560, 1580 ($\nu_{C=C}$); 820, 860 (δ_{C-H}); 720, 740, 780, 1000, 1100, 1180, 1380. ^{13}C NMR ($CDCl_3$), δ=22.0 (methyl C); 122.8, 128.3, 129.2, 130.4, 137.3, 145.7 (phenyl C).

Poly(thiomethylene phenylene): Calcd for (C_7H_6S): C, 68.85; H, 4.92; S, 26.23%. Found: C, 67.81; H, 5.10; S, 25.98%. IR (KBr, cm^{-1}) 3100 (ν_{C-H}); 1410, 1440, 1450, 1500, 1600 ($\nu_{C=C}$); 810 (δ_{C-H}); 465, 700, 760, 900, 1020, 1080, 1260, 1350.

Poly(naphthylene sulfide): Calcd for ($C_{10}H_6S$): C, 75.95; H, 3.80; S, 20.25%. Found: C, 76.12; H, 3.51: S, 19.34%. IR (KBr, cm^{-1}) 1500, 1550, 1580, 1620 ($\nu_{C=C}$); 820, 870 (δ_{C-H}); 480, 540, 740, 780, 960, 1080, 1120, 1260, 1320, 1350.

Isolation of Thianthrene. The reaction mixture was poured into methanol. The methanol solution was evaporated to dryness after the precipitate was separated out. The product was extracted with chloroform from the residue. The thianthrene formation was confirmed by gass cromatography and ^{13}C NMR spectroscopy. ^{13}C NMR ($CDCl_3$), δ=127.4, 128.6, 135.5. IR (KBr, cm^{-1}) 3050 (ν_{C-H}); 1430, 1550 ($\nu_{C=C}$); 760 (δ_{C-H}); 460, 660, 1250, 1100. MS (*m/z*) 108, 139, 171, 184, 216.

^{13}C NMR Spectrum of the Reaction Mixture. The ^{13}C NMR spectra of disulfides with $SbCl_5$ were measured at −30 °C in double compartment cell probes of which internal and standard sample was CD_3OD/tetramethylsilane. ^{13}C NMR (CH_2Cl_2, phenyl carbon); the reaction mixture of diphenyl disulfide: δ=127.4, 132.8, 135.9, 136.4. Diphenyl disulfide: δ=128.4, 128.8, 130. 9, 138.1. The reaction mixture of bis(2-methylphenyl) disulfide: δ=129.2, 131.4, 131.7, 132.3, 132.9, 140.7. Bis(2-methylphenyl) disulfide: δ=127.9, 128.4, 128.5, 132.0, 136.3, 132.0. The reaction mixture of bis(2,6-dimethylphenyl) disulfide: δ=131.1, 131.4, 134.3, 145.8. Bis(2,6-dimethylphenyl) disulfide: δ=129.6, 131.0, 135.9, 144.9.

Results and Discussion

Polymerization of Diphenyl Disulfides. Diphenyl disulfide was allowed to react with aluminum trichloride at room temperature in nitromethane. The

polymer was formed as a white powder having an empirical formula C_6H_4S and was soluble in hot *N*-methylpyrrolidone. The spectroscopic data agreed with that of a commercially available product. Polymerization of bis(2-methylphenyl) disulfide with $AlCl_3$ gave a polymer whose IR spectrum and other spectroscopic data agreed with the prepared poly(2-methyl-1,4-phenylene sulfide) by the polycondensation of sodium 4-bromo-2-methylbenzenethiolate.

The absorption bands at 820 and 880 cm^{-1} were attributed to the adjacent 2H of the C–H out-of-plane vibration and to the isolated 1H, respectively, which supports the 1,4-conjugated thiophenylene. Bis(2,6-dimethylphenyl) disulfide was also polymerized to give the polymer. The formed polymer also showed absorption bands at 860 and 820 cm^{-1}, which supported the belief that the polymer does not only contain the 1,4-conjugated thiophenylene structure, but 1,3-conjugated as well (Fig. 1). Bis(2,6-diethylphenyl) disulfide was also polymerized to form a polymer with a molecular weight of 4×10^4—1×10^3. The elemental analysis data of the formed polymer agreed with the calculated values for poly(2,6-diethylphenylene sulfide). The IR spectrum of the polymer supported the structure of poly(2,6-diethylphenylene sulfide). The complete polymerization of bis(2,6-diethylphenyl) disulfide was also indicated by a decrease in the absorption band at 760 cm^{-1} attributed of an adjacent 3H C–H out-of-plane vibration on the monomer. NMR spectra also supported the idea that the formed polymer dose not combine through a thiomethylene moiety but, through a thiophenylene moiety (Fig. 2).

These polymers were quite soluble in chloroform, benzene, *N*-methylpyrrolidone, *N*,*N*-dimethylformamide. The substituent groups on the phenylene ring of PPS greatly increased the solubility of PPS and expanded its application potential. The melting points of polymers were much higher than those of polymers prepared by the conventional polycondensation (Table 1). The substituent alkyl groups drastically increased the solubility of the polymer providing the polymer with a high molecular weight.

Various diphenyl disulfide derivatives such as dibenzyl disulfide, bis(2-methoxyphenyl) disulfide, and di(2-naphthyl) disulfide were also polymerized with aluminum chloride to yield the corresponding

PPS derivatives in high yield (Table 2). Alkylsubsituted PPSs were also efficiently produced by polymerization. Thus, the polymerization route of diphenyl disulfides with Lewis acid is a convenient procedure for the preparation of PPS and poly(aromatic sulfide)s. However, *p*-substituted and bis(2,6-dichlorophenyl) disulfide were not allowed to give the corresponding polymers. Electron-withdrawing substituents and the positions of substituents influenced the polymerization.

Polymerization Mchanism. In previous papers[18,20] we concluded that the sulfonium cation is the active species for the polymerization of diphenyl disulfide, based on ^{13}C NMR and the isolation of the sulfonium cation as a salt. The ^{13}C NMR spectrum of the reaction mixture of bis(2-methylphenyl) disulfide and bis(2,6-dimethylphenyl) disulfide at −30 °C shows signals which were not assigned to the corresponding disulfides and the other sulfides (Experimental section). In this experiment the phenylbis(phenylthio)sulfonium cation was formed with the Lewis acid.

Figure 3 shows polymerization curves for the diphenyl disulfides. The melting point which corresponds to the molecular weight of the polymer, increased after the polymer yield became constant. The formed polymer or oligomer re-reacted with Lewis acid to form PPS. This means that the polymerization proceeds in a stepwise fashion to yield PPS. It is considered that the cation electrophilically reacts with diphenyl disulfide to form the trimer. The polymerization mechanism of diphenyl disulfide is illustrated in Eq. 1. Poly(methyl-substituted phenylene sulfide)s were rapidly formed on the polymerization in comparison with PPS because of the electron-donating substituents. The results also supported the cationic mechanism.

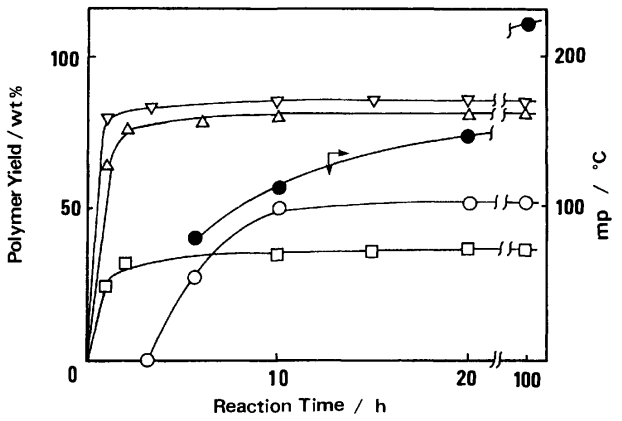

Fig. 3. Polymerization curves of bis(2-methylphenyl) disulfide (□), bis(2,6-dimethylphenyl) disulfide (△), bis(2,6-diethylphenyl) disulfide (▽), and diphenyl disulfide (○); melting point of the formed polymer from diphenyl disulfide (●).

Polymerization with Various Lewis Acids. Polymerization proceeded with various Lewis acids such as $SbCl_5$, $MoCl_5$, and $TiCl_4$, although the PPS yield and/or molecular weight were influenced by Lewis acid and the solvent species (Table 3).

The PPS yield remained at about 50% for the polymerization of diphenyl disulfide, and decreased with an increase in the temperature (Fig. 4). Gaseous mass spectroscopy of the reaction mixture indicated the formation of thianthrene. Thianthrene was isolated and confirmed by the results of NMR and IR spectroscopy (Experimental section). Thianthrene was formed as a by-product during polymerization. In contrast, the polymerization of bis(2,6-substituted phenyl) disulfides gave their polymers with relatively high yield in comparison with those of bis(mono- and unsubstituted phenyl) disulfides (Fig. 4). 2,6-Dialkyl-substituents does not only increased the solubility of the formed polymer, but also strongly suppressed the formation of thianthrene by the side reaction, and gave a polymer with high molecular weight and high yield. These results suggested that the temperature influenced the reaction of diphenyl disulfide with $AlCl_3$. That is, the high temperature resulted in the forma-

tion of thianthrene, the result of which was corresponded to the previously reported polymerization.[24-28]

The optimum concentration of $SbCl_5$, $MoCl_5$, and $FeCl_3$ is two times equimolar of diphenyl disulfide in this polymerization. In contrast, $AlCl_3$, $TiCl_4$, and $BF_3 \cdot O(C_2H_5)_2$ required more than ten times equimolar of the monomer for an efficient formation of PPS (Fig. 5). These results support the difference in the initiation mechanism of the polymerization or initiation efficiency, which was based on the difference of the oxidation ability between $AlCl_3$ and $SbCl_5$.[29,30] The melting point of the polymer increased during polymerization with $AlCl_3$ in nitromethane after the polymer yield became constant. This means that the polymerization proceeds in a stepwise manner to grow the polymer. It is considered that an increase in the molecular weight of the polymer caused by an increase in the polymer solubility on the basis of the formation of a polymer complex with $AlCl_3$ in the presence of excess $AlCl_3$.[31]

Polymerization of Thiophenol. It is well-known that thiophenol is quantitatively oxidized to diphenyl disulfide with oxidizing agents.[32,33] The polymerization of thiophenol as a starting material was carried out in the coexistence of an oxidizing agent and $AlCl_3$ to also give PPS (Table 4). This suggests that thiophenol is preferentially oxidized to diphenyl disulfide and polymerized with $AlCl_3$ without any retardation by oxidizing agents. Electrolysis was applied to the oxidation process on the polymerization instead of oxidizing agents. PPS was also precipitated in the electrolysis cell and on the electrode.

Potential Distribution in a Fluidized Bed Electrode

Tülay Eskikaya
Chemistry Department, Istanbul Technical University, Maslak 80626, Istanbul, Turkey
(Received January 23, 1989)

A study is described on the measurements of potential distribution in the bed and electrolyte of a hydrogen peroxide depolarized fluidized bed electrode consisting of 10 grams of silver coated glass beads in a cell of cyclindrical geometry. The results of potential profiles show that the electrode potentials both in static and fluidized beds were uniform throughout most of the bed. In the latter case, however, the degree of deactivation in the top of the bed is less than for a static bed, which explains current from fluidized bed. The variation of the charge-transfer coefficient along the bed, which is of great importance from the point of the performance of a fluidized bed electrode, is also determined.

In order to understand the functioning of a fluidized bed electrode, the potential distribution in the bed and electrolyte is of great importance. Some work has been done on this line before.[1-8] A direct measurement of electrode potentials was suggested by Backhurst,[1] by means of a pseudo-particle. Hiddleston and Douglas[2,3] recorded bead potentials with respect to the feeder by using a similar probe to that suggested by Backhurst. Mason,[4,5] on the other hand, recorded the frequency of the collisions on the free beads with the pseudo-bead per unit time and the variation in probe potentials as a result of the collisions. A mathematical model for the charge transfer in fluidized bed electrodes was developed by Goodridge et al.[6] Huh[7] also measured the particle and electrolyte potentials and overvoltages in fluidized bed electrodes of two different types. Rojo et al.[8] developed a capacitor model to determine the electric change in fluidized beds on the basis of voltage measurements between a probe and a metallic distributor. Many new contributions by the others, however, are still continuing on the same subject.

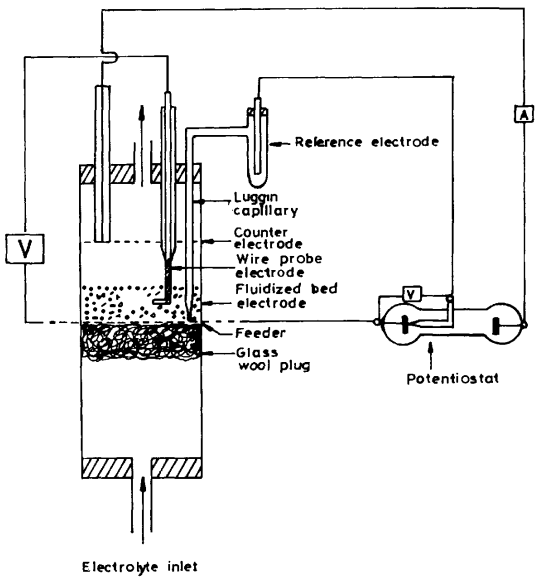

Fig. 1. Experimental cell and potentiostat.

Experimental

Fluidized Bed Material and Catalyst. Potential distribution measurements in the solution and in the bed were studied for a hydrogen peroxide depolarized fluidized bed electrode. The concentrations of the reactant and the electrolyte used during the measurements were 4.1×10^{-2} mol dm^{-3} hydrogen peroxide and 5.0 mol dm^{-3} KOH, respectively.

The body of fluidized beds consisted of "Ballotini" glass beads (mean diameter 600 μm, diameter range 520—690 μm) coated with silver from a solution containing it in the form of ammonia complex and to reduce ammonia complex glucose was used.[9,10] The silver layer acted as both a conducting surface and catalyst. The final mean density of the beads 3.0 g cm^{-3} and the geometric area 33 $cm^2\,g^{-1}$.

Apparatus. The experimental cell system which was used with a potentiostat power supply is shown in Fig. 1. It consisted of two lengths of 2.54 cm dia., Perspex tube joined with an expanded silver coated nickel mesh (strand size 0.00127×0.00127 cm; 772 appertures per cm; mesh 9.8 LWM ×17.7 SWM per cm; free area 60%) stretched between the two sections. A glass wool plug beneath the mesh smoothed the electrolyte flow through the bed. The mesh acted as bed support and electrical contactor to the beads. A nickel mesh counter electrode was situated above the bed. A mercury-mercurly(II) oxide reference electrode was connected to a Luggin capillary, the tip of which was adjacent to the feeder, thus, the feeder potential was controlled.

Other equipments used included an Amel potentiostat capable of giving 10 A at 50 V and a Solartron high impedance voltmeter having a voltage input ranging from ±0.1995 V to 1995 V for measurements of the bed and solution potentials with secondary probes. A Pye cathetometer (accuracy ±0.005 mm) was used to measure bed heights.

Solutions were made up from Analar grade reagents using once-distilled water.

Experimental Procedure. The weight of the bed was 10 g, giving a mean static bed height of 1.16 cm. Fluidizations are quoted as a percentage increase in bed height over the static bed height.

(a) Potential Distribution in the Electrolyte. Potential distribution in the solution within the bed was measured by means of a Luggin capillary which was connected to a mercury-mercury(II) oxide reference electrode. The Luggin capillary was traversed up and down through the bed and at various Luggin capillary positions, solution potentials, ϕ_s,

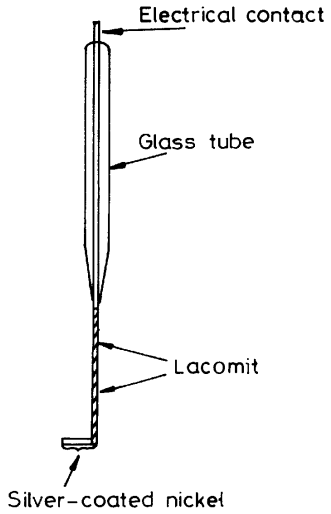

Fig. 2. Wire probe design.

were measured against the feeder.

(b) Potential Distribution in the Bed. For the potential distribution measurements in the bed two different types of probes namely, bead and wire probes were used. The bead probes were prepared by attaching a bead of bed material (600 μm dia. silver plated glass bead) to a nickel wire (0.39 mm dia.) by means of a silver impregnated epoxy resin adhesive (J.M.C. Thermosetting silver cement FSP 49). The wire was insulated from the bed by coating with "Lacomit" varnish. This type of probe was found to be unsatisfactory. A simpler method was adopted, therefore, in which a nickel wire was sealed into a glass road leaving the top end free as electrical contact and the other end of this wire probe, which was bended through 90° providing a horizontal section, acted as pseudo-bead[1,4] (Fig. 2). This pseudo-bead could be made of any area by coating the wire with Lacomit and leaving the correct amount of bare wire projecting. Any oxide film on nickel wire probe was removed by immersing it in dilute hydrochloric acid and then nickel wire was coated with silver in the same way as the plating of the beads. By coupling a Solatron high-impedance voltmeter between the probe and the feeder, it is possible to measure the bead potentials, ϕ_m, which are the potentials detected by the pseudo-bead probe electrode against the feeder electrode.

In order to find the optimum area of the pseudo-bead which would provide the actual potential of beads, potential distribution measurements in the bed were recorded with four different size of wire probes, namely "tip, small, medium and large" having surface areas of silver activated part of 0.477 mm², 1.528 mm², 3.820 mm², and 12.990 mm², respectively.

Results

In Fig. 3 distribution of the solution potential was plotted against x/l, where x is the probe position in the bed relative to the feeder and l is the bed height for 15.0—15.9% fluidized bed at three different applied potentials. As can be seen from the figure the reaction at the feeder surface is insignificant, $\frac{d\phi_s}{dx}=0$ at $x=0$,

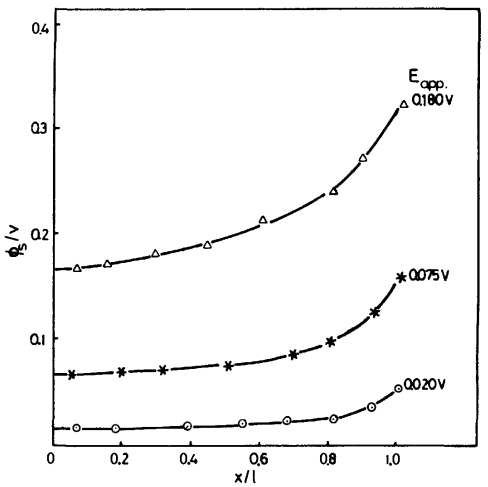

Fig. 4. Potential distribution in solution for the static bed at three different applied potentials.

(where ϕ_s is the solution potential and $x=0$ corresponds to the base of the bed) which satisfies the boundary condition of the following equation developed by Goodridge et al.[6]

$$-\frac{d}{dx}\left(K_s\frac{d\phi_s}{dx}\right)=A_pF(\phi) \quad (1)$$

where A_p is the superficial geometric area of the beads per unit volume of bed in the fluidized state, K_s is the effective specific conductance of the electrolyte in the fluidized bed and $F(\phi)$ is the dependency of current density on, ϕ, electrode potential which is the potential throughout the bed against the feeder.

Figure 4 shows the potential distribution in the solution for the static bed.

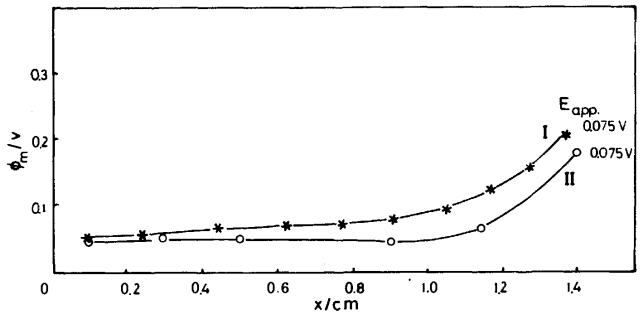

Fig. 5. Potential distribution in a 15% fluidized bed at an applied potential of 0.075 V, large (I) and tip (II) probes.

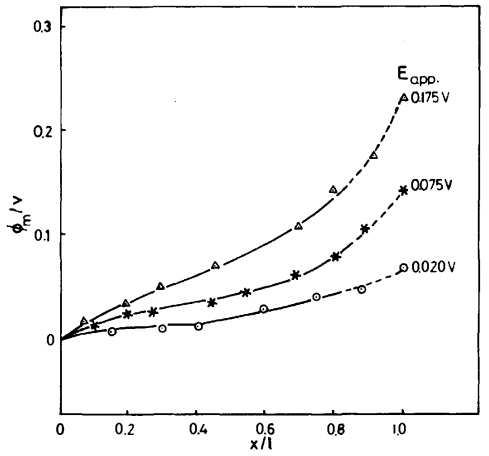

Fig. 6. Potential distribution in a 15% fluidized bed at three different applied potentials, small wire probe.

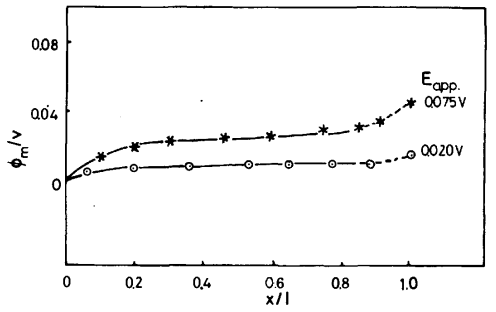

Fig. 7. Potential distribution in the static bed at two different applied potentials, small wire probe.

The potential distribution measurements in the bed taken only with the small and medium probes were quite the same. Figure 5 shows the results for large probes (Curve I) and tip probes (Curve II) for a 15% fluidized bed.

Results of the potential measurements in the bed with four different size of wire probes have shown that the surface area of an adequate probe should not be less than that of the beads, but it should be larger to some extent (the maximum and minimum surface area of the bead used in the experiments were 1.50 mm^2 and 0.85 mm^2 and the active surface area of the small and medium probes were 1.528 mm^2 and 3.82 mm^2, respectively). Since the surface area of the small probe was nearly the same as the beads and the reproducibility of the results recorded with this probe was better than a bead probe, the small probe was used throughout the potential distribution measurements in the bed.

The results recorded by the large probe can be explained by the great influence of the solution on the probe. This probe had an active area of 12.99 mm^2 and the length of the activated part of the probe was 1.35 cm which was more than the half diameter of the bed. There was not enough bead collisions with the probe and its potential was greatly governed by the potential of the solution.

With the tip probes, however, there was a few bed contact with the probe and it was nearly at its rest potential. The deviations observed at the top of the bed was again due to the effect of solution on the probes.

Figure 6 shows the potential distribution of the fluidized beds at three different applied potentials (E_{app}=0.020 V, 0.075 V, and 0.175 V). The dotted line in the figure shows the deviation of the potential at the top of the bed due to the effect of the solution potential on the probe. This could be explained by the assumption that there was not sufficient bead contact on the probe and also 3—4 rows of the beads at the top of the bed were probably not in good contact with the rest of the bed. Comparing the slope of this part of the curve with that of corresponding solution potential curve suggests a 60% solution potential effect on the probe measurement.

Figure 7 shows the potential distribution in the static bed. As can be seen from the figure, after a drop in the potential near to the feeder, the potential distribution in the static bed appeared almost constant through the bed except the slight deviation at the top.

In the operation of a fluidized bed electrode the variation of charge-transfer coefficient (K_m) along the bed has great importance on its performance. In order to observe the general tendency of the variation of charge-transfer coefficient in the fluidized bed, the values of K_m at various points of the bed were calculated using the following equations.[6]

$$I_s = -K_s A\left(\frac{d\phi_s}{dx}\right) \tag{2}$$

$$I_m = -K_m A\left(\frac{d\phi_m}{dx}\right) \tag{3}$$

where I_s is the current flow through the electrolyte, ϕ_s is the solution potential, I_m is the current flow in the bed and A is the area of current flow perpendicular to the direction of flow which is equivalent to the area of the feeder, i.e. 5.06 cm^2.

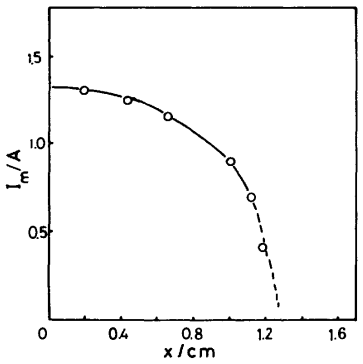

Fig. 8. Variation of current flow along 15% fluidized bed at an applied potential of 0.075 V.

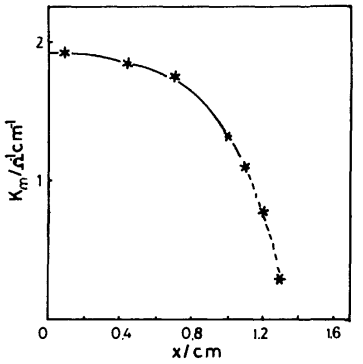

Fig. 9. Variation of charge-transfer coefficient along 15% fluidized bed at an applied potential of 0.075 V.

The current flow through the electrolyte, I_s, was calculated through Eq. 2. The values of $\frac{d\phi_s}{dx}$ were determined from the point slopes of Fig. 3. The effective conductivity of the electrolyte, K_s, which was determined from the Bruggeman relationship, quoted by Goodridge[6] as

$$K_s = \rho \cdot \varepsilon^{3/2} \quad (4)$$

where ε is the bed voidage and ρ is the specific conductivity of the electrolyte. ρ is taken as 0.53 ohm^{-1} cm^{-1} for 5.0 mol dm^{-3} KOH.[11] This equation provides the value of K_s as 0.2247 ohm^{-1} cm^{-1}.

The values of I_s were substracted from the total current values and the values of the current flow in the bed, I_m, were obtained for various points of the bed. The current flow in the bed ceases at the bed boundary so all the current is supported by the solution and at the top of the bed the current flow through the electrolyte should be equal to the total current of the bed. Figure 8 shows the results for a 15% fluidized bed at an applied potential of 0.075 V.

Similary $\frac{d\phi_m}{dx}$ values at various points of the bed can be found from the potential distribution in the bed and since the values of I_m are known, K_m can be obtained from Eq. 3.

Figure 9 shows the variation of charge-transfer coefficient along the bed. The tendency of the curve corresponding to the top of the bed was again represented with a dotted line because of the possibility of the incorrect values of I_m and K_m due to the deviation in the ϕ_m vs. x curve in this region of the bed.

In Fig. 10 the electrode potentials, ϕ, which is $\phi_m - \phi_s$, of a 15% fluidized bed was plotted against x/l at a feeder potential of 0.075 V. From the figure it is shown that the electrode potential is uniform throughout the bed except at the top.

Figure 11 shows the electrode potential for the static bed at the feeder potential of 0.075 V.

Discussion

In porous and similar electrodes the physical properties of the electrode material and its porosity may determine the conductivity of electrode. In a fluidized bed electrode, however, the conductivity is not only a function of bed material. For fluidized beds, Goodridge et al.[6] have introduced the concept of the charge-transfer coefficient, K_m, which is not only dependent on the physical properties of bed material but also electrode reaction and hydrodynamic conditions in the bed. The value of K_m and its variation in the bed are of great importance from the point of the performance of a fluidized bed electrode.
