ized spectra of $[Cu(daco)_2](ClO_4)_2 \cdot 2H_2O$, and deduced with some assumptions that the d-orbital energy order is $b_{1g} \gg b_{2g} > e_g > a_{1g}$ under D_{4h} symmetry.[16] According to their Gaussian resolution of the spectra, the visible band of this perchlorate salt is composed of three components; $^2B_{1g} \rightarrow {}^2B_{2g}$ at 18.2×10^3 cm^{-1}, $^2B_{1g} \rightarrow {}^2E_g$ at 20.8×10^3 cm^{-1}, and $^2B_{1g} \rightarrow {}^2A_{1g}$ at 23.1×10^3 cm^{-1}. Polarization experiments were not performed in this study, but it seems that the Gaussian fitting would become more arbitrary; it requires four components, since at least the crystal structure at room temperature has shown that the effective ligand field symmetry in $[Cu(daco)_2](NO_3)_2$ is no higher than D_{2h}. However, we can still apply the fundamental scheme obtained for the perchlorate analogue that strong σ interaction of the daco ligand raises the energy of $d_{x^2-y^2}$ orbital up high, while the rest of d-orbitals are lying low and relatively close to each other. It is notable in Fig. 3 that, regardless of possible spectral resolution, even the lowest energy transition component with significant intensity should appear at the energy no lower than ca. 20×10^3 cm^{-1} for the room temperature spectrum. This suggests that the σ-interaction of the ligand is stronger in the nitrate salt than in the perchlorate salt. This could well be due to the ligand-nitrate hydrogen bonds enhancing rigidity of the planar coordination geometry and also basicity of the donor nitrogen atoms.

On the other hand, the spectrum recorded at 97 °C indicates at least that some of the d-d transition components have shifted towards lower energy. This can be interpreted as a result of weakening of the ligand field and/or a change in its symmetry; not only is the energy of $d_{x^2-y^2}$ orbital lowered but also the relative spacings among the rest of d-orbitals must have changed, as suggested by the spectral breadth.

A piece of evidence for correlation of the hydrogen bonding to the thermochromic phase transition was obtained from infrared measurements. Comparison of the IR spectra of $[Cu(daco)_2](NO_3)_2$ at 24 °C and at 96 °C, shown in Fig. 4, reveals that most drastic change occurs in the absorption peaks assignable to ν_{NH} stretching mode, which should be sensitive to the nature of the hydrogen bond. Intensification of the peak at 3200 cm^{-1} upon heating can be viewed as release of the intensity of this mode which has been supressed in the low-temperature phase. However, the shift in its energy is minimal, suggesting that the "average" hydrogen bond strength is not much changed in the two phases. Another noticeable intensification upon heating occurs to a peak at 1460 cm^{-1}, which may be assigned to δ_{NH} deformation. Stretching absorption of the NO_3^- ion is too intense to assess a change with temperature on this side of the hydrogen bond. It is noted, however, that a small peak at 1747 cm^{-1}, which can be a combination band of NO_3^- modes, shows no detectable change in shape.

If this complex nitrate is ground together with KBr, resulting powder mixture is colored violet and the IR spectrum of this KBr disk is identical to that of $[Cu(daco)_2]Br_2 \cdot H_2O$,[17] with a characteristic sharp peak at 1649 cm^{-1}, indicating that NO_3^- can be easily relaced by Br^-. It is likely that one of the bromide ions is coordinated to copper in the violet bromide salt,[17] and this inclines one to assume a similar anion coordination in the high-temperature violet form of nitrate salt which is apparently similar in color. However, an EPR evidence has shown that the two violet species are different in terms of the ligand field strength and symmetry. Figure 5 compares the powder EPR spectra of low- and high-temparature forms of $[Cu(daco)_2](NO_3)_2$ and $[Cu(daco)_2]Br_2 \cdot H_2O$. The g-values for the former are $g_{//}=2.142$ and $g_{\perp}=2.033$, which are practically constant from room temperature up to the transition temperature (orange form, Fig. 5a) and change to $g_{//}=2.122$ and $g_{\perp}=2.046$ (violet form, Fig. 5b). Those for the bromide salt, on the other hand, are $g_{//}=2.169$ and $g_{\perp}=2.031$ (Fig. 5c). Thus the thermochromic transition of the nitrate salt is associated with decreases in the $g_{//}$ value and in the anisotropy of the g-values at the elevated temperatures. This behavior is opposite to what would be expected if the anion coordinates axially to the metal center upon heating.[18] What then would be the cause for the color change of the nitrate salt?

On the Mechanism of Thermochromism. The thermochromic phase transition of $[Cu(daco)_2](NO_3)_2$ occurs endothermically at 85.5 °C (at a heating rate of 5 K min^{-1}, $\Delta H=7.61$ kJ mol^{-1}). Solid-state thermochromism has been observed among other metal complexes of daco ligand,[4,5] but in these cases (e.g., $Co(daco)_2I_2 \cdot EtOH$[5] and $Cu(daco)_2X_2 \cdot H_2O$ (X=Br, Cl)[17]) the observed color changes involve dehydration

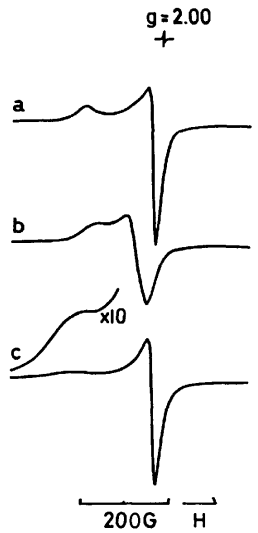

Fig. 5. Powder EPR spectra for (a) orange form and (b) violet form of $[Cu(daco)_2](NO_3)_2$, and (c) $Cu(daco)_2]Br_2 \cdot H_2O$ (violet). Spectra were recorded at the apparent cavity temperatures of 99.7 °C for (a) and (c) and of 120 °C for (b).

or desolvation at relatively high temperatures. On the other hand, there exists a broader class of materials containing *N,N*-diethylethylenediamine (deen) which exhibit thermochromic phase transition, and among them $[Cu(deen)_2](ClO_4)_2$ has been most extensively investigated. Bloomquist and Willett has reviewed[2] the work on this compound including crystal structure determination for both low- and high-temperature forms.[12] A short summary will be given below to facilitate comparison between $[Cu(daco)_2](NO_3)_2$ and $[Cu(deen)_2](ClO_4)_2$ that follows.

This compound is red at room temperature, and changes to deep blue-purple at T_{th}=43 °C (ΔH= 8.91 kJ mol^{-1}) returning to red upon cooling. Mechanistic interpretation for this behavior based on EPR and IR spectroscopies ascribed it to axial interaction of the perchlorate ion, since the evidences suggested an increase in the in-plane ligand field at lower temperatures. However, X-ray crystallographic analyses revealed that the perchlorate ions are isolated from the Cu(II) coordination sphere in both phases; the closest Cu···O distance is 3.65(1) Å and 4.16(2) Å in the low- and high-temperature form, respectively. It was thus concluded that the thermochromic change in $[Cu(deen)_2](ClO_4)_2$ must be due to a sudden change of the in-plane ligand field strength caused by conformational changes in the $Cu(en)_2$ ring system.[12] Bloomquist and Willett noticed that each perchlorate ion is involved in two N-H···O hydrogen bonds with chelate cations (here also) at room temperature and stated further that, "as the temperature is raised, a point is reached at which the thermal motion energy sufficiently weakens the hydrogen bonding network to allow the two Cu-diamine ring systems to begin rapid conformational interconversion." A puzzling part of the results of the above crystallographic study is that the Cu-N bond lengths hardly differ between the two phases, raising a question as to why the change in the in-plane ligand field strength is not reflected in these parameters. This, however, was explained in terms of the ligand disorder, dynamic in nature, preventing optimal Cu-N overlap in the high-temperature blue modification.

Returning to the present case of $[Cu(daco)_2](NO_3)_2$, it is not possible to fully delineate the thermochromic mechanism at the present stage without a complete set of structural evidences. However, the data available at present seem to indicate that this picture of "dynamic" disorder will apply to the case of $[Cu(daco)_2](NO_3)_2$ just as well or even better. It should be emphasized that the visible absorption spectral change accompanying the phase transition of $[Cu(daco)_2](NO_3)_2$ is not a simple shift of a certain d-d transition. It has been conveniently and perhaps reasonably assumed for $[Cu(deen)_2](ClO_4)_2$ that the visible absorption can be ascribed to the d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ transition with the effective ligand field symmetry D_{4h} and that this band shifts up and down according to the variation in the in-plane ligand field. However, the discontinuous absorption spectral change with temperature for $[Cu(daco)_2](NO_3)_2$ appears to involve a rather drastic change in d-orbital energy scheme. The very broad and flat shape of the visible absorption band for the high-temperature form implies that mixing among the d-orbitals has become extensive. The infrared spectral change also suggests that the hydrogen bond strength in a static sense does not change on heating. Thus a simple picture of weakening of the in-plane ligand field due to thermal motion of the ligand and/or to weakening of the ligand/anion hydrogen bonds is not sufficient to explain the thermochromic transition in $[Cu(daco)_2](NO_3)_2$.

Therefore, we would like to point out the possibility that the anions play an active role as a source of disorder in the thermochromic transition of this complex, as suggested in the case of $[Cu(deen)_2](ClO_4)_2$.[2] It can be easily imagined that the thermal motion of the anions would create dynamical fluctuation in the hydrogen bond strength, with protons shifting back and forth, and in the electron density on the ligand nitrogen atoms. It is recalled that the perchlorate group in $[Cu(deen)_2](ClO_4)_2$ (blue) showed anisotropic temperature factors no smaller than those of the ligand.[12] In the case of $[Cu(daco)_2](NO_3)_2$, extensive librational movements of the nitrate ions within the macrocycle-like chelate ring would also induce some distortion in the planar coordination geometry.

Thus the thermochromism of $[Cu(daco)_2](NO_3)_2$ seems to have much part of its origin in the anion/ligand hydrogen bond system. Little attention has been paid to the ability of the anions in metal complexes to form hydrogen bonds to the ligands, and to influence the mode and strength of their coordination, while a number of cationic chelates with ligands which are bulky enough to preclude coordination of the anions to the metal center are known. It certainly deserves more studies to exploit this type of interaction, in order to generate novel physical properties of coordination compounds in solid state.

This work was partially supported by a Grant-in-Aid for Scientific Research from Ministry of Education, Science and Culture (No. 59430009). The authors thank the Computer Center, Institute for Molecular Science (IMS), Okazaki National Institutes for the use of HITAC M-680H. We also thank Dr. Takenaka and Prof. Yoshio Sasada of Tokyo Institute of Technology for the drawing program DCMS82 used in the preparation of Figs. 1 and 2. Assistance of Prof. Tadaoki Mitani of IMS in the single crystal optical measurements is greatly appreciated.

Orientation of Isomeric Phthalic Acids on Alumina and Magnesia Surface Observed by Inelastic Electron Tunneling Spectroscopy

Morihide HIGO,* Sinichi MIZUTARU,† and Satsuo KAMATA
Faculty of Engineering, Kagoshima University, Korimoto, Kagoshima 890
(Received November 4, 1988)

The vibrational spectra of phthalic, isophthalic, and terephthalic acid adsorbed onto alumina and magnesia surfaces from the gas phase have been measured by inelastic electron tunneling spectroscopy. The analysis of the tunneling spectra shows that phthalic and isophthalic acid react with the surface OH groups on Al_2O_3 and MgO to give the adsorbed dicarboxylate ions on both surfaces. Phthalic acid is adsorbed with its benzene ring perpendicular to the surfaces, while isophthalic acid is adsorbed parallel to the surfaces. However, terephthalic acid is adsorbed predominantly as the monocarboxylate ion almost perpendicular to the alumina surface, while it is adsorbed as the dicarboxylate ion parallel to the magnesia surface. These results suggest the different properties of the surface OH groups on Al_2O_3 and MgO. There are more than one type of OH group on the alumina surface and they interact with each other through hydrogen bonding. The magnesia surface has an isolated and a hydrogen-bonding OH group. The OH groups on MgO are more basic than those on Al_2O_3, and thus have higher reactivity. The different properties and basicity of the OH groups cause the different orientation and reactivity of the adsorbed terephthalic acid on the alumina and magnesia surfaces.

Recently there has been an increased interest in a new technique for investigating a metal surface and adsorbed species on it. Inelastic electron tunneling spectroscopy (IETS) is a relatively new and a unique technique using the phenomena of electron tunneling through a metal-oxide-metal tunneling junction at cryogenic temperatures. It reveals the vibrational spectrum of the oxide surface and the adsorbed species on it. The high sensitivity and wide spectral range inherent in IETS enable us to analyze the surface and the adsorbed species in detail.[1]

Alumina has been widely used as the oxide of the tunneling junction for its chemical, physical, and electric stability, in addition to its ease of formation.[1-3] Few IETS studies, however, have utilized magnesia.[4-14] The surfaces of alumina and magnesia have been studied by infrared spectroscopy,[15-17] and their surface models have been proposed.[18-20] These oxides are used as catalysts or catalyst supports in chemical engineering. Alumina is an amphoteric oxide and magnesia is a basic one; thus, these oxides have interesting and sometimes different catalytic properties. However, their surface states and their chemical interaction with adsorbed species are not well understood.[21,22] Thus, the measurement and analysis of the tunneling spectra of Al_2O_3 and MgO and the adsorbed species on both surfaces are important and interesting.

The isomeric phthalic acids have two carboxyl groups bonded to a single benzene ring. The important information on their structures and orientations on oxide surfaces can be obtained by examining the characteristic C=O group. Oxley et al.[23] measured the tunneling spectra of the isomeric phthalic acids on Al_2O_3. They reported that these acids are adsorbed as the dicarboxylate ions. In our previous papers,[24,25] however, we have shown that phthalic and isophthalic acid are adsorbed as the dicarboxylate ions, while terephthalic acid is adsorbed predominantly as the monocarboxylate ion onto Al_2O_3. Lewis and Field[26] also measured the tunneling spectra of these acids on Al_2O_3, however, they reported that these acids are adsorbed as the monocarboxylate ions. The geometry of the isomeric phthalic acids on colloidal silver particles was studied by surface-enhanced Raman spectroscopy.[27] Adsorption of terephthalic acid and terephthalic-d_4 acid onto alumina surfaces has been investigated by external reflection infrared spectroscopy.[28]

In this study, the tunneling spectra of the isomeric phthalic acids adsorbed onto Al_2O_3 and MgO from the gas phase have been obtained. The analysis and comparison of these spectra and the tunneling spectra of isomeric phthalic acids adsorbed onto Al_2O_3 from alcohol solutions clarify the discrepancy of the previous results. These results also give important information on the properties of both surfaces and the chemical interaction with the adsorbed species. The properties of the alumina and magnesia surfaces, and the orientation and reactivity of the isomeric phthalic acids on both surfaces are discussed.

Experimental

The junctions were prepared in a bell jar of a vacuum evaporator evacuated with a liquid nitrogen-trapped 4-inch diffusion pump (ANELVA CDP-600A). The pressure in the bell jar was measured with an ionization gauge (DAIA VACUUM IT-10P) or a Pirani gauge (DAIA VACUUM PT-9P). The base pressure was 6×10^{-7} Torr (1 Torr=133.322 Pa).

Aluminium (Mituwa Chemicals, 99.999%) or magnesium (Rare Metallic Co., 99.99%) was evaporated from a resistively heated molybdenum boat onto a clean glass slide (13×37×1 mm) to form three strips (1 mm wide) at a pressure of 10^{-6} Torr. Magnesium was evaporated from a molybdenum boat with a cover which has a slit in order to prevent the

† Present address: Toshiba Electronic Device Engineering Co., 72, Horikawa-chou, Saiwai-ku, Kawasaki 210.

dispersion of the chips from the boat. The surfaces of the strips were oxidized in an oxygen-DC glow discharge (400—800 V, 75 mTorr, 5 mA, 15—30 s) in the bell jar. For the undoped alumina and magnesia junctions, the longer oxidation time of 1.5—2 and 8—10 min was used, respectively.

The sample molecules were adsorbed onto the oxide surfaces from the gas phase (60—320 mTorr, 60 min) by evaporating the acid from a molybdenum boat at 80—100 °C in the bell jar. Phthalic, isophthalic, and terephthalic acid (Kanto Chemicals, >99.5%) and *p*-acetylbenzoic acid (Aldrich Chemicals, 99.4%) were used without further purification.

The junctions (1×1 mm area) were completed with an evaporated Pb (Wako Chemicals, 99.999%) cross strip (1 mm wide). These operations were done in a class 10000 clean room (Airtech Japan AER-233C).

The tunneling spectrum was obtained by measuring the second derivative of the tunneling current through the junction at liquid-helium temperature (4.2 K). The circuit was of the bridge type developed by Adler and Jackson. The details have been described before.[24,25] A 500 Hz AC modulation signal (2—3 mV_{pp}) and a slowly varying DC voltage were applied to the junction. The aluminium or magnesium electrode was negatively biased with respect to the Pb electrode. The second harmonic signal through a notch filter (NF Electronic Instruments 2BE) and a bandpass filter (NF 3BP) was detected with a lock-in amplifier (NF LI-574A).

The performance of the apparatus and procedures were tested by measuring the tunneling spectrum of benzoic acid on Al_2O_3.[25] The peak positions of the spectrum were corrected by −1 meV (−8 cm^{-1}) owing to the energy gap of the superconducting Pb electrode.[1,29] The resolution was estimated to be 2.5 meV (20 cm^{-1}) by measuring the narrowest peak width in the spectrum. The accuracy of the peak position is estimated to be ±0.5 meV (± 4 cm^{-1}).

Results

Tunneling Spectra of Alumina and Magnesia. The tunneling spectra of the undoped Al-Al_2O_3-Pb and Mg-MgO-Pb junction are shown in Fig. 1. The peak positions and features of the spectra agree well with those previously reported.[1-6,11,25] The peaks at 300 and 930 cm^{-1} of the tunneling spectrum of the alumina junction are assigned to the aluminium phonon and the vibrational mode of the aluminium oxide, respectively. The broad peak at 3610 cm^{-1} is assigned to the stretching mode of the surface OH groups. The broadness and asymmetric tailing toward lower frequencies are typical features of hydrogen-bonding hydroxyl groups. The very weak peak at about 2900 cm^{-1} is due to the CH stretching mode of a hydrocarbon contamination; however, the weakness of this peak indicates that the amount of contamination is negligible.

The peaks at 430 and 640 cm^{-1} of the tunneling spectrum of the magnesia junction are due to the vibrational modes of MgO. The peak at 260 cm^{-1} arises from the magnesium phonon mode. The strong peak at 3650 cm^{-1} and the shoulder at 3590 cm^{-1} are caused by the stretching vibrations of the surface OH groups. These peaks indicate that there are two types of OH groups on the magnesia surface: An isolated OH and a hydrogen-bonding OH group. These peaks of the spectra of magnesia junctions vary in intensity from sample to sample. There is no peak near 2900 cm^{-1}, and these junctions show no organic contamination. Magnesia junctions doped from water or alcohols gave very noisy tunneling spectra. This instability of the spectrum is probably caused by a change of the surface state of the junction due to the dissolution of the magnesia surface.

Tunneling Spectra of Isomeric Phthalic Acids. The tunneling spectra of phthalic, isophthalic, and terephthalic acid doped onto the alumina and magnesia surfaces from the gas phase are shown in Figs. 2—4, respectively. Their peak assignments are shown in

a) Doped from ethanol solution in Ref. 25.

modes of the COO^- group, β_s designates the scissoring, β_{as} denotes the rocking and γ_s the wagging mode. The Wilson number for the normal vibration of the benzene ring is shown in parenthesis.

The peak positions of the tunneling spectra doped from the gas phase and ethanol solution agree well with each other within the measurement accuracy. This agreement shows that our apparatus and procedures are suitable for the accurate measurement of tunneling spectra. It also shows that there is no contribution from the solvent to our previous tunneling spectra.

When phthalic acid is adsorbed onto the Al_2O_3 and MgO surfaces, the peak intensities of the surface OH groups decrease, and the weak and broad peaks remain in both spectra. In contrast, the clear and characteristic peaks of the adsorbed phthalic acid appear. The relative intensities of the peaks in both spectra on Al_2O_3 and MgO are similar except for those of βCC(6b) and γCC(4). This similarity suggests the same molecular structure and orientation of the adsorbed phthalic acid on both surfaces. The tunneling spectrum of phthalic acid on MgO has no νC=O peak, while that on Al_2O_3 has a very weak peak at 1697 cm^{-1}. The tunneling spectra on both surfaces have strong and broad ν_s, medium γ_s and strong β_{as} peaks of the COO^- groups. The peak position of the ν_sCOO^- mode on MgO shifts from that of the mode on Al_2O_3 about 20 cm^{-1} toward lower frequencies. The peak of the $\nu_{as}COO^-$ mode appears as a shoulder on the very strong peak at 1588 cm^{-1} in the spectrum on MgO. These results show that phthalic acid reacts with the surface OH groups on both surfaces by loosing the protons of the COOH groups and is adsorbed as the benzenedicarboxylate ion onto the surface cations (Lewis-acid sites). The peak shift of the ν_sCOO^- mode may relate to the difference in the interaction between the COO^- groups and the surface cations as suggested by Walmsley et al.[6)]

The tunneling spectra of isophthalic acid on Al_2O_3 and MgO have strong and broad ν_s, medium β_s and strong β_{as} peaks of the COO^- groups. The peak position of the ν_sCOO^- mode on MgO also shifts 10 cm^{-1} toward lower frequencies. The peak of the $\nu_{as}COO^-$ mode appears as a shoulder on the strong peak at 1591 cm^{-1} in the spectrum on MgO. The surface OH groups remain on the MgO surface. These results show that isophthalic acid is also adsorbed onto both surfaces as the dicarboxylate ion. The remainder of the surface OH groups on MgO may relate to the orientaion and the surface coverage of the adsorbed isophthalic acid as discussed later.

The tunneling spectrum of terephthalic acid on Al_2O_3 doped from the gas phase has a medium νC=O peak in addition to the νCOO^- peaks. The spectrum is identical with that doped from the ethanol solution,[25)] and it is concluded that terephthalic acid doped from the gas phase is also predominantly adsorbed onto Al_2O_3 as the monocarboxylate ion. On the other hand, the spectrum on MgO has the COO^- peaks with no νC=O peak and it shows that terephthalic acid is adsorbed onto the magnesia surface as the dicarboxylate ion. Because terephthalic acid is adsorbed as the dicarboxylate ion, its benzene ring must be parallel to the surface. The surface OH groups remain as in the case of isophthalic acid. The peak position of the ν_sCOO^- mode on MgO also has a shift of 16 cm^{-1} toward lower frequencies. The features and the relative peak intensities of both spectra on Al_2O_3 and MgO are independent of the doping conditions of the gas pressure: 60—240 mTorr, and the exposure: 10—60 min.

Comparison of Tunneling Spectra of Isomeric Phthalic Acids. The tunneling spectra of the isomeric phthalic acids adsorbed onto Al_2O_3 have previously been measured by Oxley et al.[23)] They concluded that these acids are adsorbed as the dicarboxylate ions onto Al_2O_3. A comparison of their spectra showed that most of the peak positions and the features of their spectra of phthalic and isophthalic acid agreed with those of our spectra. However, their spectrum of terephthalic acid has no νC=O peak, and disagreed with ours. We examined the experimental conditions in detail and found that the peak intensity and the features of the spectrum of

terephthalic acid strongly depend on the solvent used. The spectrum of terephthalic acid doped from a solution of methanol, ethanol, or 1-propanol onto Al_2O_3 has the νC=O peak. However, it has a very weak νC=O peak in the case of an aqueous solution. The weakness of the νC=O peak indicates that terephthalic acid is adsorbed onto Al_2O_3 predominantly as the dicarboxylate ion. The spectra of phthalic and isophthalic acid have no such solvent dependence.[25]

The reason of this discrepancy between our spectrum of terephtalic acid and that measured by Oxley et al. is not clear. However, it seemed to us that the amount of the terephthalic acid adsorbed onto the alumina surface was so small that the νC=O peak disappeared in their spectrum. We concluded that the tunneling spectrum of terephthalic acid doped from the gas phase onto Al_2O_3 also has the νC=O peak, and that terephthalic acid is adsorbed predominantly as the monocarboxylate ion as in the case of the alcohol solutions.[25]

Lewis and Field[26] have also reported the tunneling spectra of the isomeric phthalic acids on Al_2O_3 doped from an ethanol solution. They concluded that these acids are adsorbed as the monocarboxylate ions. We compared the peak positions in their tunneling spectra with those in ours and found that all the peak positions in their spectra have shifts of 15—225 cm^{-1} to higher frequencies. This comparison of the peak positions in the tunneling spectra of terephthalic acid on Al_2O_3 is shown in Table 4. Their assignments for the peaks are completely different from ours. For example, they assigned the strong peak at 1638 cm^{-1} to the νC=O peak, which corresponds to the νCC (8b) peak at 1598 cm^{-1} in our spectrum. No assignment was given to the weak peak at 1735 cm^{-1}, which corresponds to the νC=O peak in our assignment. These peak shifts in their tunneling spectra may be caused by parasitic resistances in the tunneling junctions as indicated by Oxley et al.[23] A comparison between the spectra of terephthalic and *p*-acetylbenzoic acid adsorbed onto Al_2O_3 and MgO clearly shows the presence of the νC=O peak in the tunneling spectrum of the adsorbed terephthalic acid on Al_2O_3 and the absence of the νC=O peak in that on MgO as is shown in Fig. 5.

Discussion

Surface Structure of Alumina and Magnesia. Knözinger and Ratnasamy[20] have proposed the surface models of the ideal planes of γ- and η-Al_2O_3. Though the oxygen lattice is more densely packed in γ-Al_2O_3 than in η-Al_2O_3, both aluminas have defect spinel lattices and the local ionic configurations of the Al^{3+} cations are identical. The preferentially exposed faces are considered to be the (110)- and (111)-faces of γ- and η-Al_2O_3, respectively. Because the net charge

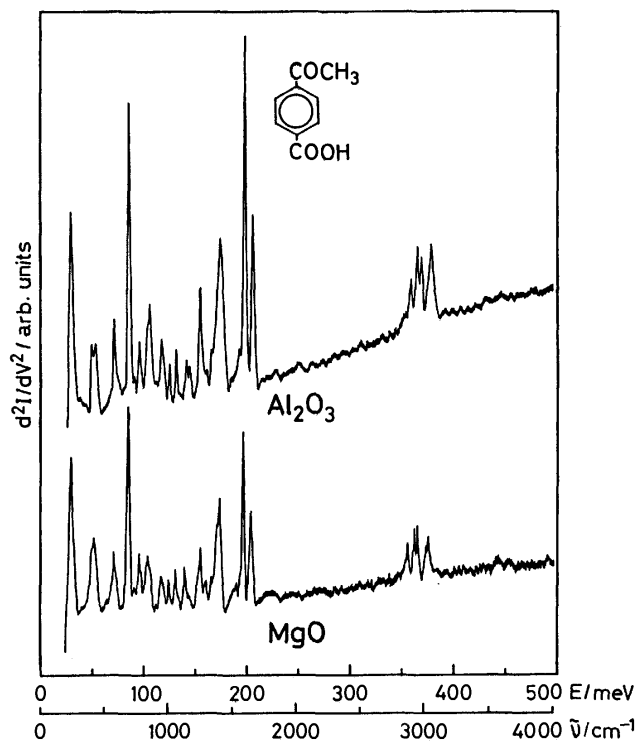

Fig. 5. Tunneling spectra of *p*-acetylbenzoic acid on Al_2O_3 and MgO doped from the gas phase.

in a stable ionic structure should be equal or nearly equal to zero, OH anions are favorable to terminate these faces. From a consideration of the configuration of the aluminium cations and the OH anions, and the coordination numbers of the OH anions, they have shown that there are five types of OH groups on the (111)-face and three types of OH groups on the (110)-face.

The surface OH groups on these faces have different net charge and relate to their different acidity and basicity. The protonic acidity of the OH groups decreases as the net charge on them becomes more negative, while their basicity increases at the same time. The infrared spectra of alumina surfaces have five bands in frequency range 3700—3800 cm^{-1}. They have assigned the band of highest frequency (3800 cm^{-1}) to the most negative OH group with the highest basicity, while the band of lowest frequency (3700 cm^{-1}) is attributed to the most positive OH group with the lowest basicity. The remaining three bands are assigned with decreasing frequency to the corresponding configurations with increasingly positive net charge. Hydrogen bonding between adjacent OH groups perturbs the acidity and basicity, and thus the frequencies of the OH groups to some extent at high OH densities.

The tunneling spectrum of the alumina surface shows the νOH mode in the frequency range 3500—3700 cm^{-1}. The frequency is shifted downward by about 100 cm^{-1}. This shift is due to the image dipole effect of the top lead electrode.[1,29] Using several top metal electrodes and an image dipole theory, Kirtley and Hansma[29] have shown that the νOH mode of hydroxide ions on Al_2O_3 has a shift of approximately 15 meV (120 cm^{-1}), however, the shifts of the vibrational modes of the adsorbed benzoate ion are less than 0.5 meV (4 cm^{-1}). Judging from the broadness and asymmetric tailing toward lower frequencies, there seems to be more than one type of surface OH group on the alumina surface. These appear to interact with each other through hydrogen bonding. The surface model proposed by Knözinger and Ratnasamy[20] is useful to explain the surface structure of the tunneling junction of Al_2O_3.

Magnesia has the structure of NaCl and the external surface of its crystal is predominantly the (100)-face. It has a more ionic character than Al_2O_3 because the electronegativity difference is larger between Mg and O than between Al and O. According to the hydration characteristics and the infrared spectra, Anderson et al.[16] proposed a simple model for the chemisorption of H_2O on this face; the (100)-face consists of a collection of an isolated OH group coordinated on a surface magnesium cation and a second set of OH group formed by the remaining protons and adjacent O^{2-} ions. The second type of OH group interacts with their neighbors through hydrogen bonding. A sharp band at 3752 cm^{-1} has been assigned to the νOH mode of the first OH group, whereas a broad band at 3610 cm^{-1} has been attributed to the second group.[16]

The tunneling spectrum of MgO also shows a strong and sharp peak at 3650 cm^{-1} and a broad peak at 3590 cm^{-1}, these correspond to the isolated and hydrogen-bonding OH group suggested by Anderson et al.[16] The peak positions are shifted downward due to the effect of the top Pb electrode as in the case of the OH groups on Al_2O_3. It is expected that the isolated OH group has higher reactivity and basicity because it is isolated and has the more negative net charge.

Orientation of Adsorbed Isomeric Phthalic Acids. The vibrational spectra of the adsorbed isomeric phthalic acids on metal surfaces have been measured by surface-enhanced Raman spectroscopy (SERS),[27] external reflection infrared spectroscopy (RAIR),[28] and IETS.[25] Moskovits and Suh[27] used SERS to investigate the surface geometry of the adsorbed isomeric phthalic acids on colloidal silver particles from aqueous solutions. The SERS spectra of the isomeric phthalic acids had peaks of the COO^- groups but no C=O group and showed that these acids are adsorbed as the dicarboxylate ions onto the surfaces. However, the spectral features of phthalic acid were quite different from those of the others. They attributed this difference to different surface-bonding geometry, and concluded that phthalic acid is adsorbed with its benzene ring perpendicular to the surface, while isophthalic and terephthalic acid are adsorbed parallel to the surface.

Boerio et al.[28] investigated the adsorption of terephthalic acid and terephthalic-d_4 acid onto aluminium mirrors from dilute solutions in ethanol by RAIR. The spectra of both terephthalic acids showed a strong and characteristic νC=O band of the undissociating COOH group near 1700 cm^{-1} in addition to the bands of the COO^- groups. Because the ν_s and ν_{as} mode of the COO^- groups were observed, they have concluded that terephthalic acids are adsorbed as the monocarboxylate ions with a vertical conformation in which the benzene rings are perpendicular to the surface but the twofold symmetry axes are inclined at least several degrees from the normal to the surface.

The adsorption and orientation of isomeric phthalic acids on Al_2O_3 from alcohol solutions have been studied in our previous paper using IETS.[25] It was found that these acids are adsorbed onto the alumina surface with their own molecular structures and orientations at saturation coverage; phthalic and isophthalic acid are adsorbed as the dicarboxylate ions with their benzene rings almost perpendicular and parallel to the surface, respectively. Terephthalic acid is adsorbed as the monocarboxylate ion almost perpendicular to the surface. Hydrogen bonding through the COOH groups of the adsorbed hydrogen terephthalate ions was observed.

Ogawa et al.[30] have reported the selective monomethyl esterification of dicarboxylic acids adsorbed onto Al_2O_3. Terephthalic and isophthalic acid adsorbed onto Al_2O_3 reacted with diazomethane to give predominantly the monomethyl esters, however, the reaction of phthalic acid was unsuccessful. They have suggested that terephthalic and isophthalic acid are adsorbed onto Al_2O_3 as the monocarboxylate ions, and the unreacting COOH groups are preferentially esterified. The lack of reactivity of phthalic acid was explained by the close proximity of the two COOH groups and the forced orientation of the second COOH group.

Though reactivity is not necessarily a measure of surface orientation of adsorbed species, the orientations and molecular structures of phthalic and terephthalic acid on Al_2O_3 suggested by Ogawa et al.[30] are identical with those observed by IETS. It seems that isophthalic acid which is only weakly bonded to the surface as the monocarboxylate ion may react to give predominantly the monoester. These results indicate that IETS is useful to investigate the surface reactions on an alumina catalyst, and also show that the orientation of the adsorbed species plays an important role to determine the reactivity and selectivity of the surface reaction.

pKa_2	5.41	4.60	4.46

Fig. 6. Schematic representation of the adsorbed isomeric phthalic acids on Al_2O_3 and MgO. Their dissociation constants in water are also shown.

The similarity of the spectral features of the tunneling spectra of phthalic and isophthalic acid adsorbed onto Al_2O_3 and MgO from the gas phase indicates that these acids are adsorbed in the same molecular structure and orientation onto both surfaces. Thus, it can be concluded that phthalic acid is adsorbed as the dicarboxylate ion with its benzene ring perpendicular to the alumina and magnesia surface, while isophthalic acid is adsorbed as the dicarboxylate ion parallel to the alumina and magnesia surface. However, the tunneling spectra of terephthalic acid adsorbed onto Al_2O_3 and MgO show different molecular structure and orientation on both surfaces. It is adsorbed as the monocarboxylate ion onto Al_2O_3; however, it is adsorbed as the dicarboxylate ion onto MgO. A schematic representation of the isomeric phthalic acids adsorbed onto alumina and magnesia surfaces is shown in Fig. 6. Also shown are their dissociation constants in water.

Judging from the dissociation constants of the isomeric phthalic acids, one would expect that phthalic acid is adsorbed predominantly as the monocarboxylate ion because the difference between the two dissociation constants is largest. However the tunneling spectra show that both phthalic and isophthalic acid are adsorbed as the dicarboxylate ions onto Al_2O_3 and MgO. It is clear that the structures and the orientations of these acids on the surfaces are not explained by their dissociation constants. In the case of phthalic and isophthalic acid, when they are adsorbed at one of the COOH groups, the other COOH group seems to be very close to the surface. Thus, the COOH group dissociates more easily than would be expected from their second dissociation constants. According to the molecular models, phthalic acid is adsorbed with its benzene ring almost perpendicular to both surfaces, while isophthalic acid is parallel to the surfaces. The molecular structures and the orientations are identical to those observed on silver colloidal surface by SERS.[27]

The difference in the molecular structure and orientation of the adsorbed terephthalic acid on Al_2O_3 and MgO seems to be caused by the different structures and reactivity of the surface OH groups on both surfaces. The surface OH groups on Al_2O_3 interact with each other through hydrogen bonding. This hydrogen bonding seems to some extent to prevent the reaction between the COOH groups and the surface OH groups. On the other hand, MgO has the isolated OH group on the surface. The OH groups on MgO are expected to have higher reactivity than the OH groups on Al_2O_3. When terephthalic acid is adsorbed onto MgO, both COOH groups easily dissociate to give the dicarboxylate ion with its benzene ring parallel to the surface because of the high reactivity and basicity of the surface OH groups. The remainder of the OH groups on the magnesia surface may relate to the surface coverage; the coverage of the surface by the adsorbed terephthalate ion may make some surface OH groups inactive because of the hindrance of the benzene ring. On the other hand, it seems that the undissociating COOH group of the adsorbed hydrogen terephthalate ion can not interact with the surface OH groups on Al_2O_3 because of the

medium reactivity and the hydrogen bonding of the surface OH groups. Thus, the adsorbed terephthalic acid on Al_2O_3 remains as the monocarboxylate ion with its benzene ring almost perpendicular to the surface at saturation coverage. The hydrogen bonding through the undissociating COOH groups of the adsorbed hydrogen terephthalate ions seems to make them stable on the alumina surface.

Concluding Remarks

IETS is a useful analytical tool for investigating the alumina and magnesia surfaces and the adsorbed species on them. It reveals the different orientations of terephthalic acid adsorbed onto Al_2O_3 and MgO. This difference is caused by the different surface properties of both oxides.

The authors wish to thank Professors Kerry Wayne Hipps and Ursula Mazur of Washington State University for their critical reading of the manuscript and for the valuable comments. The present study was partially supported by a Reseach Aid of the Inoue Foundation for Science No.025.

Studies of the Hydrous Silicon(IV)-Titanium(IV) Oxide Ion Exchanger. I. A Method of Synthesis and Some Properties

Hiromichi YAMAZAKI, Yasuhito KANNO, and Yasushi INOUE*
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received December 1, 1988)

Hydrous silicon(IV)-titanium(IV) oxide ion exchanger was prepared by using $TiCl_4$ and Na_2SiO_3 solutions. From a detailed examination of the dependency of the compositions and the acid-base properties of the products on the conditions for precipitation, a reproducible synthetic procedure was established. The exchangers with 37 to 67 mol% of titanium to metallic elements possess much larger ion-exchange capacities and are more stable to highly alkaline solutions than simple mixtures of hydrous silicon(IV) oxide and hydrous titanium(IV) oxide. The dependency of the ion-exchange capacity on the composition can be explained by the difference in the structure of the matrix as evidenced from the thermal analysis, X-ray diffraction, and infrared absorption studies.

Hydrous metal oxides are a group of promising materials for use in the processing of radioactive liquid wastes. This is on account of their unique ion-exchange selectivity produced by the metallic elements forming the materials.[1] However, amorphous hydrous metal oxides are liable to lose their ion-exchange capacity at high temperatures and their use is limited at elevated temperatures. On the other hand, it is conceivable that thermally stable hydrous metal oxides possessing various ion-exchange characteristics may be synthesized by combining more than two kinds of metallic elements.

Kaneko et al. investigated a silica-titania mixed oxide gel,[2,3] but did not clarify the relation between the ion-exchange properties of this material and those of simple hydrous metal oxides. In the investigation of this group of ion-exchange materials, it is indispensable to examine the synthetic conditions for establishing a reproducible method because of the difficulty in reproducible synthesis due to thermodynamical metastability of the materials.

The present paper deals with an investigation undertaken to establish the best conditions for the synthesis of hydrous silicon(IV)-titanium(IV) oxide ion exchanger, laying emphasis on the dependence of ion-exchange properties on the composition of the materials.

Experimental

Reagents and Apparatus. Sodium metasilicate and titanium(IV) chloride were of reagent grade supplied by Wako Pure Chemical Industries, Ltd., and their purities were checked before use. Hydrofluoric acid was obtained from Hirota Kagaku Kogyo Kaisha, Ltd. The other chemicals were of the highest purity grade supplied by Wako Pure Chemical Industries, Ltd.

Thermal analysis was undertaken using a Shimadzu micro thermal analyzer, Model DT-20B, connected to a thermal balance, Model TGC-20H, for thermogravimetric analysis (TGA), and a high-temperature sample holder, Model MDH-20B, for differential thermal analysis (DTA). The reference material for DTA was α-alumina. The measurement was performed in air at a heating rate of 10 °C min^{-1}. The infrared (IR) absorption spectra were measured with a Hitachi infrared spectrometer, Model 2650-50, using the KBr disk method. The specific surface areas of the samples were determined by the BET method (N_2 adsorption at −196 °C) using a Yanagimoto Surface Area Measuring Apparatus, Model GSA-10. Atomic absorption measurements were made with a Nippon Jarrell-Ash atomic-absorption and flame-emission spectrophotometer, Model AA-782. Spectrophotometric analysis was carried out with a Hitachi Model 557 double wavelength spectrophotometer with a 1 cm-glass cell. X-Ray diffraction patterns were obtained by means of Shimadzu X-ray diffraction unit, Model XD-3A, using Ni-filtered Cu $K\alpha$-radiation.

Synthesis of Ion Exchangers. The starting solution of $TiCl_4$ was prepared by dissolving a desired amount of unhydrated titanium(IV) chloride in distilled water, followed by dilution to a desired volume with either HCl solution or distilled water. The starting solution of Na_2SiO_3 was obtained by dissolving a desired amount of $Na_2SiO_3 \cdot 9H_2O$ in 1M NaOH solution (1 M=1 mol dm^{-3}), followed by dilution to a desired volume with either distilled water or NaOH solution. Hydrous silicon(IV)-titanium(IV) oxide was precipitated at various pH and different concentrations of metal ions by mixing an equal volume of the $TiCl_4$ and the Na_2SiO_3 solutions. After being separated from the mother liquor by decantation and filtration through Toyo No.1 filter paper under suction, the precipitate was uniformly dispersed into distilled water and filtered again after being sedimented. The precipitate was then dried at 70 °C or at room temperature. The product was immersed in distilled water to break it down into fine particles, which were subsequently dried at room temperature. The particles were then ground in a porcelain mortar and sieved to obtain required particle sizes (63 to 210 μm). Hydrous silicon(IV) oxide was precipitated by mixing an equal volume of 0.50 M Na_2SiO_3 solution in 1.0 M NaOH and 1.85 M HCl solution. Hydrous titanium(IV) oxide was precipitated at pH 7 by adding 0.98 M NaOH solution into 0.95 M $TiCl_4$ solution. These precipitates were washed in the same manner described above, until no Cl^- was detected in the filtrate, and then dried at room temperature.

Conditioning. The exchanger of a desired particle size was washed with distilled water to remove any adherent powder. The slurry was poured into a glass tube with glass-wool plugging for column support, and 0.05 M HCl was passed through the column until the pH of the effluent

approached that of the influent. The column was then washed with distilled water until no Cl^- was detected in the effluent and its pH became constant (pH=5.5). The exchangers, thus prepared, were air-dried at room temperature and stored in a desiccator containing a saturated NH_4Cl solution (relative humidity; 79% at 25 °C).

Total Analysis of the Exchanger. A sample of 0.2 g was ignited at 850 °C, and the water content was calculated from the weight loss. The validity of the procedure had been confirmed thermogravimetrically. The oxide thus formed was dissolved in 1 cm^3 of concentrated H_2SO_4 and 2 cm^3 of 46% HF solutions. This solution was gently heated in order to vaporize SiF_4 and HF, followed by dilution to 50 cm^3 with 9 M H_2SO_4 solution. Titanium was assayed by a complexiметric titration: back titration using PAN(1-(2-pyridylazo)-2-naphthol) as an indicator. The amount of TiO_2 thus determined was subtracted from the mass of the calcined exchanger to obtain the amount of SiO_2.

Ion-Exchange Capacity. The ion-exchange capacity for Na^+ was measured as follows. The exchanger (0.10 g) in the H^+ form was immersed in 15 cm^3 of various solutions, prepared by the desired combinations of 0.10 M NaCl and 0.10 M NaOH solutions, for 7 d at room temperature with intermittent shaking. This was followed by pH measurements and by determination of the sodium ions. The sodium ions were converted to an equivalent amount of sodium chloride and indirectly determined by titrating the chloride ions (the Fajans' method). The amount of the ions taken up by the exchanger was evaluated from the difference between the initial and the final concentrations of the ions in the solutions.

Results and Discussion

(I) Synthesis of Hydrous Silicon(IV)-Titanium(IV) Oxides. In order to establish a reproducible synthetic method, the composition and the acid-base property of hydrous silicon(IV)-titanium(IV) oxides (hereafter called the composite exchanger) were studied as a function of the conditions for precipitation, as mentioned below.

(a) Effect of pH at Precipitation. As the solubility of Si^{4+} largely depends on the pH of the solution, in contrast to Ti^{4+} which is precipitated nearly quantitatively from solutions of pH higher than 1, the yield of silicon was examined as a function of pH. The hydrous metal oxides were precipitated at various pH by mixing 0.25 M $TiCl_4$ solution in HCl and 0.25 M Na_2SiO_3 solution in NaOH. Here, the concentrations of HCl and NaOH were adjusted to give the desired pH. After the precipitate had been completely sedimentated, the concentration of SiO_3^{2-} in the supernatant solution was determined spectrophotometrically, using 10% ammonium molybdate as a coloring reagent.[4] As seen in Fig. 1, the concentration of SiO_3^{2-} in the supernatant increases sharply on both sides of pH 7 to 9. Therefore, the pH at precipitation was controlled to be 7.6±0.3 in the subsequent experiments.

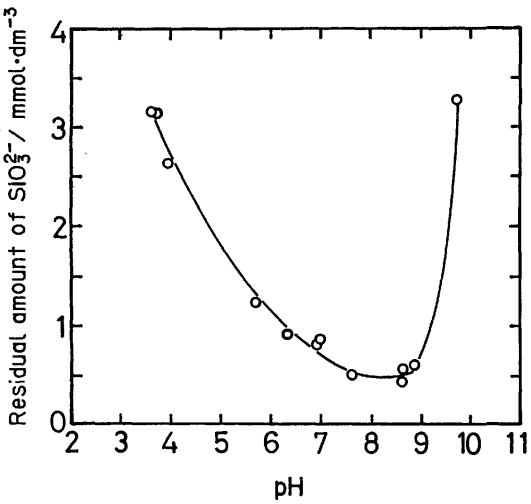

Fig. 1. Dependence of SiO_3^{2-} concentration in supernatant solution on pH at precipitation.

(b) Effect of the Methods of Mixing the Solutions. The ion-exchange capacity and physical strength were studied on the composite exchangers, which were prepared by the following three methods;

Method I: the Na_2SiO_3 solution was added to the $TiCl_4$ solution,

Method II: the $TiCl_4$ solution was added to the Na_2SiO_3 solution,

Method III: the $TiCl_4$ and the Na_2SiO_3 solutions were simultaneously poured into a beaker with vigorous stirring.

For each method, the rate of addition of the solutions was from 5 to 3000 $cm^3\,min^{-1}$. After aging for 2 d, the precipitate was washed in a manner described in the experimental section, and then dried at 70 °C for 50 h. Irrespective of the addition rates, the composite exchangers prepared by methods I and II were glassy or chalky opaque particles large enough to be used for

Table 1. Effect of Addition Rates of Na_2SiO_3 Solution into $TiCl_4$ Solution on Ion-Exchange Capacity and Composition (Method II)

Addition rate	Ti-mol%		Water content	Ion-exchange capacity for Na^+ ions at pH 13
	mol TiO_2	×100	mol H_2O	
$cm^3\,min^{-1}$	mol(SiO_2+TiO_2)		mol(SiO_2+TiO_2)	mmol g^{-1}
3000	50±1		2.19±0.01	3.54±0.06
67	50±1		2.13±0.01	3.62±0.06
16	50±1		1.96±0.01	3.70±0.06
6	50±1		2.03±0.01	3.68±0.06

column operation. In method III, the physical strength of the particles was weak, except with the addition rate of 3000 $cm^3 min^{-1}$. As the precipitate could not be completely washed without suffering from peptization, it was washed only once to avoid wasteful loss. Table 1 shows the effect of the addition rate of the solution in method II on the ion-exchange capacity and the composition of the composite exchangers. The water content increased slightly with the addition rate, but the titanium content (titanium content refers to mol% of Ti/(Si+Ti)) and the ion-exchange capacity were not significantly affected by this factor.

(c) Effect of Concentrations of the Solutions. The hydrous metal oxides were precipitated by mixing the $TiCl_4$ solution and the Na_2SiO_3 solution in 1.0 M NaOH with varying concentration. The addition rates of the solutions were 5 $cm^3 min^{-1}$ for methods I and II, and 3000 $cm^3 min^{-1}$ for method III. Figure 2 shows the Na^+-uptake curves of the materials, indicating that the difference in the ion-exchange capacities is 0.4 mmol g^{-1} (less than 5% of the total exchange capacity) at the largest. Thus, the acid-base properties of the exchangers are not significantly affected by the method of mixing, nor by the concentration of the solutions.

(d) Effect of Titanium Content. The exchange capacities for Na^+ at pH 13 were measured as a function of the titanium content in the exchangers which were precipitated by methods I and III under the best conditions of a constant total concentration of metal

a) Exchangers were prepared in a large amount by the recommended procedure.

ions (0.5 M). These conditions were realized by using desired combinations of 0.5 M $TiCl_4$ solutions in HCl and 0.5 M Na_2SiO_3 solutions in NaOH, where the concentrations of HCl and NaOH were suitably adjusted for providing pH 7.6 at precipitation. The gels thus prepared by method I were dried at 70 °C, while those by method III were dried at room temperature. As is shown in Table 2, the composite exchangers thus prepared have nearly the same titanium content as the solution mixed. The composite exchangers contained appreciably less water than the hydrous titanium(IV) oxide, but much more than the hydrous silicon(IV) oxide.

Figure 3 shows the ion-exchange capacities of the composite exchangers. For comparison, the exchange capacities were measured for simple mixtures of the hydrous silicon(IV) oxide and the hydrous titanium(IV) oxide (the mixed exchanger), as is shown in the same figure (dotted line). The measurement for the mixed exchangers was made at pH 12.2 instead of pH 13 because the dissolution of a part of the hydrous silicon(IV) oxide in the mixed exchangers limited the applicable maximum pH. The line shows that the ion-exchange capacities of the mixed exchangers are the algebraical sums of those of the component simple hydrous oxides. Based on this observation, we can estimate the hypothetical capacities at pH 13 of the mixed exchangers (a chain line). This figure indicates that the exchangers with 37 to 67 mol% titanium have nearly the same ion-exchange capacities, much larger than the mixed exchangers. The exchanger with 90 mol% titanium has a much smaller capacity than the mixed exchanger of the similar titanium content. This figure also indicates that the exchange capacities were not affected by the method of mixing the solutions or the drying temperature.

Figure 4 shows uptake curves for Na^+ of the exchangers with various titanium contents, along with those of the simple hydrous metal oxides. The decrease of the capacities of the exchanger with 10 mol% titanium in pH regions beyond 11.5, similar to the hydrous silicon(IV) oxide, is ascribed to the partial dissolution of the exchanger. This phenomenon is not observed in the other exchangers, which suggests the stabilization of the matrix in highly alkaline solution in spite of the large silicon content. The minimum pH at which sodium ions were adsorbed was significantly lower for the exchangers with 10 to 76 mol% titanium than for the simple hydrous oxides. These findings suggest the formation of a compound, basically different in properties from the hydrous silicon(IV) oxide and the hydrous titanium(IV) oxide.

(e) Effect of Drying Temperature. If no excessive decrease in the capacity occurs, heating is preferable for rapid drying of the hydrous oxide gel. From this standpoint, the acid-base property and the water content were compared between the exchangers dried at 70 °C (Nos. 8—11 in Table 2) and those at room temperature (Nos. 16—18 in Table 2). Although the water content is smaller in the materials dried at 70 °C than in those at room temperature, little difference in the Na^+ uptake curves was observed between them, when it was normalized to the number of moles of Na^+ taken up per mole of metals composing the materials. Hence, drying at 70 °C does not affect the acid-base property of the exchanger.

Recommended Procedure. The composite ex-

Exchangers; ■: No. 1, ▲: No. 4, ● : No. 7, Δ: No. 12, □: No. 15, O: No. 19, ◑: No. 21, ——: No. 23, ------: No. 24. The numbers are the same as those in Table 2.

changers with 37 to 67 mol% titanium possess ion-exchange capacity larger than those with other compositions. In this study, the exchanger with 50 mol% titanium was selected as the best choice for easy control of the composition. Method I was chosen because it produced particles hard and large enough to be used for column operation. The concentrations of $TiCl_4$ and Na_2SiO_3 solutions were 0.5 M, which was as high as practicable to prepare a large amount of the exchanger in one batch. The recommended procedure is as follows: In 2 dm^3 of 0.5 M $TiCl_4$ solution, 2 dm^3 of 0.5 M Na_2SiO_3 solution in 1.0 M NaOH are added at a rate of 16 cm^3/min with vigorous stirring, followed by adjusting pH to 7.6±0.3 by adding a small amount of concentrated HCl or NaOH solutions. After aging for 2 d, the precipitate thus formed is separated from the mother liquor by filtration under suction, and is then uniformly dispersed into 5 dm^3 of water. The precipitate is filtered again after being completely sedimentated, and is dried at 70 °C for 50 h. The resulting product is ground to a desired particle size, and is then converted to the H^+ form by the procedure described in the experimental section. As a result of four independent syntheses, the uptake curves and the compositions agreed well with each other, except for a little larger fluctuation of water content which is susceptible to the environmental conditions (Table 2). The synthetic procedure, therefore, is considered to be highly reproducible. The yield, calculated on the basis of the metallic element used, exceeded 99 percent.

(II) Structural Analysis of the Exchangers. In order to obtain structural information, (a) specific surface area, (b) infrared spectra, (c) thermal analytical curves, and (d) X-ray diffraction patterns were measured on the samples with various titanium content and the simple hydrous metal oxides. Their compositions are shown in Table 2.

(a) Specific Surface Area. Figure 5 shows the specific surface areas of the samples. It is nearly the same as that of the hydrous silicon oxide up to 57 mol% titanium content and decreased with titanium content; reaching to about one-half of the hydrous silicon oxide in the hydrous titanium oxide. As the ion-exchange capacity (Fig. 3) does not increase in keeping with the specific surface area, the uptake of Na^+ in the exchangers cannot be explained by the sorption only on the internal surface of the materials. The change in the ion-exchange capacities with the composition of the exchanger may be ascribed to the variation in the number of exchange sites in the whole sample.

(b) IR Spectra. Figure 6 shows IR spectra of the composite exchangers, along with the simple hydrous metal oxides. The asymmetric absorption band near 3400 cm^{-1} is attributable to the sum of the contributions from water and hydroxyl groups bonding to the metal in the materials; the former at the lower-, and the latter at the higher-wavenumber sides. The absorption band near 1630 cm^{-1} is due to the bending mode of water and the absorption in the wavenumber region below 1500 cm^{-1}, to the metal-oxygen bond in the matrix. The absorption peak due to the hydroxyl groups is larger for the exchanger with 57 mol% titanium than for the others. This result is compatible with the change in the ion-exchange capacities with the composition (Fig. 3), as the hydroxyl groups

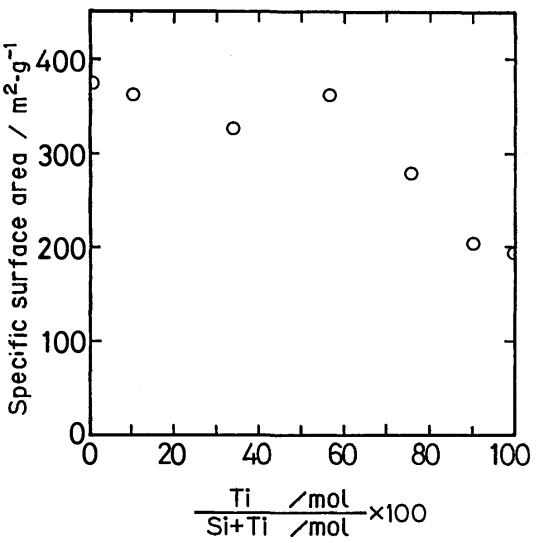

Fig. 5. Dependence of surface area of the exchangers on titanium content.

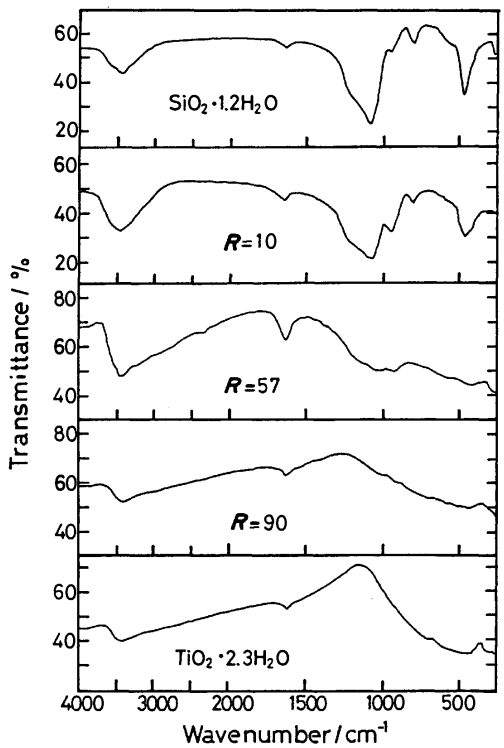

Fig. 6. IR spectra of the exchangers. *R* refers to mol% of Ti/(Si+Ti).

function as ion-exchange sites. In the wavenumber region below 1500 cm^{-1}, the exchangers with 10 and 90 mol% titanium, respectively, showed absorption spectra similar to hydrous silicon oxide and hydrous titanium oxide, while the spectrum of the exchanger with 57 mol% titanium differed from that of the simple hydrous metal oxides.

(c) Thermal Analysis. The TGA and the DTA curves were measured on the same samples as were used in the IR spectrum measurements. In the DTA curves, the large endothermic peak appearing in the range below 250 °C is due to loss of water. A combination of peaks at 90 °C and 125 °C indicates that the exchangers have at least two kinds of water having different binding energies. Figure 7 shows the percentile weight loss at various temperatures. As the fraction of water lost below 100 °C was smaller for the composite exchangers than for the simple hydrous metal oxides, the ratio of water of high binding energy to total is larger in the former than in the latter oxides. As had been discussed previously,[5-7] the water of lower binding energy is zeolitic or adherent, while the water of higher binding energy is present as either hydroxyl groups or water bound thereto. Accordingly, the large amount of bound water accounts for a large ion-exchange capacity of the exchanger with 57 mol% titanium, being compatible with the IR observations. The water lost during drying at 70 °C is mainly zeolitic or adherent and irrelevant to the ion-exchange capacity.

(d) X-Ray Analysis. Figure 8 shows X-ray diffraction patterns of the exchangers with various titanium contents. All exchangers have poor crystallinity. The broad peak at low angle, characteristic of the hydrous silicon oxide, shifts to higher angle and broadens further with the increase of titanium content up to 67 mol%. An increase in titanium content from 67 to 76 mol% results in a sudden change in the matrix; the X-ray diffraction pattern of the exchanger with 76 mol% titanium closely resembles that of the anatase form of the titanium oxide, as compared with the diffuse pattern of the composite exchanger with 67 mol% titanium. The peaks sharpen with titanium content, becoming most clear for the exchanger with 90 mol% titanium, indicating an enhanced crystallization of the matrix. The exchangers with 37 to 67 mol% titanium are amorphous because of the diffuse diffraction patterns.

From the observations described above, the change in the ion-exchange capacity with titanium content can be summarized as follows. The matrices of the exchangers with 37 to 67 mol% titanium are amorphous and contained a large number of hydroxyl groups compared to the exchangers with other compositions, so that these amorphous compounds have large ion-exchange capacity. While the exchanger with 10 mol% titanium possesses much more ion-exchange sites of higher acidity than those of the

hydrous silicon(IV) oxide, it is unstable to highly alkaline solutions because of the similarity in the structure to the hydrous silicon(IV) oxide. The smaller ion-exchange capacity of the exchanger with 90 mol% titanium than the hydrous titanium(IV) oxide is attributable to better crystallinity of the former than the latter.

This research was supported in part by a grant from Tohoku Radiological Science Center.

(Received December 2, 1988)

Superconductive films composed of $Ba_2YCu_3O_{7-\delta}$ were prepared by fume pyrolysis with a temperature programmed electric furnace. Fumes generated from an aqueous solution of Ba, Y, and Cu nitrates with an aid of supersonicant were introduced into the furnace with flowing O_2. Fine particles consisting of Ba, Y, and Cu ions were formed in the furnace and deposited on the surface of a YSZ substrate placed at the top of the furnace. Films thus prepared and annealed at 1273 K showed superconductive properties below 90 K and zero resistivity was observed at 80 K with 100 μA of the current.

Since the announcements of possible high-T_c superconductive oxides[1] and subsequent studies on relating systems,[2-5] numerous works on the structures and the electronic properties of these compounds have been reported.[6-8] Several problems for practical use have been pointed out and among them the developments of the techniques to prepare materials with high-J_c have been strongly desired to be achieved promptly. Since the J_c values have been suggested to depend on the size of powder particles, evenly sized fine particles are prefered to be employed as starting materials. One of the useful methods to produce fine oxide particles is fume pyrolysis with a supersonic nebulizer,[9] and Tohge et al.[10] have adopted this method for the preparation of superconductive bulk materials. The improvement in J_c values was not mentioned in the paper. Studies on the development of superconductive thin films have been of current interest, since high-J_c materials have been expected to be readily achieved with thin films. Films prepared by an epitaxial growth of $Ba_2YCu_3O_{7-\delta}$ on a $SrTiO_3$ substrate or those produced by an ion cluster beame (ICB) method using a MgO substrate have been reported to exhibit a J_c value of higher than 10^6 A cm^{-2} at 77 K.[11] Spray pyrolysis is also a useful method for superconductive films,[12] though sufficiently high-J_c values have not yet been reported.

In the present work, superconductive films were prepared by fume pyrolysis techniques aided by supersonicant with an aqueous solution of Ba, Y, and Cu nitrates. Fumes generated were brought into an electric furnace with flowing oxygen and turned out to be fine oxide or nitrate particles, which accumulated on the surface of a ceramic substrate (Yttrium Stabilized Zirconia, YSZ), placed at the top of furnace. The direct deposition of fine particles on the substrate is a feature of this work and is quite different from the spray pyrolysis, where fumy droplets are spreaded over a hot substrate and, subsequently, small particles are generated. Films mainly composed of a superconductive phase, $Ba_2YCu_3O_{7-\delta}$, were prepared with annealing the accumulated particles at 1273 K in oxygen atmosphere. The superconductive properties of films were discussed with the surface morphorogies of films observed by a scanning electron microscope (SEM).

Experimental

Apparatus. In Fig. 1 is shown the apparatus employed for fume pyrolysis. The apparatus mainly consists of two parts; in part A fumes are generated by a supersonicant mounted at the bottom of a vessel, including an aqueous solution of Y, Ba, and Cu nitrates with a molar ratio of 1 : 2 : 3; the concentration of metal ions was 0.02 mol L^{-1}. The frequency of the supersonicant employed was always 1.5 MHz. The part B is an electric furnace, equipped with 3 heaters located at the top, middle, and bottom of the furnace, respectively. These 3 heaters are independently controlled to give an appropriate temperature distribution in the furnace. At the radial center of the furnace is placed a reaction tube, made of quartz, directly connected with the part A. The fumes generated were introduced into the tube with flowing O_2, the flow rate being 3 L min^{-1}. A YSZ plate (2×7×0.3 mm) was placed at the top of the tube and fine oxide and/or nitrate particles formed in the furnace deposited on the surface of YSZ to be a thin film. In this experiment the temperature was controlled to be 1073 K at any parts of the tube during fume pyrolysis for 2 h. The films thus produced were annealed at 1273 K for 5, 10, 15, and 30 min, respectively, in flowing oxygen and then cooled to 673 K with the rate of 150 K h^{-1} and then to 473 K with the rate of 120 K h^{-1}, still in O_2 atmosphere.

Resistivity Measurements. The electrical resistivity of films was measured by a four-probe DC method with the current of 100 μA in the temperature range of 300—50 K. The resistivity was calculated by measuring the voltage generated between the middle 2 points on the sample film. The film thickness was estimated to be 5 μm in average by an electron probe microanalyzer (EPMA, JEOL Superprobe 733). The sample film was attached on a holder made of metallic copper and was placed in a cryostat available at liquid He temperature. The film temperatures were monitored by an Au(Fe)-Ag thermocouple.

Magnetization Measurements. Magnetization of the sample film was measured by SQUID equipment (Susceptometer 900, SHE Co.,) with an external magnetic field of 100 Öe; the sample films are placed in parallel with the magnetic field. During the measurement the sample film was vibrated with a frequency rate of 500 mm min^{-1}.

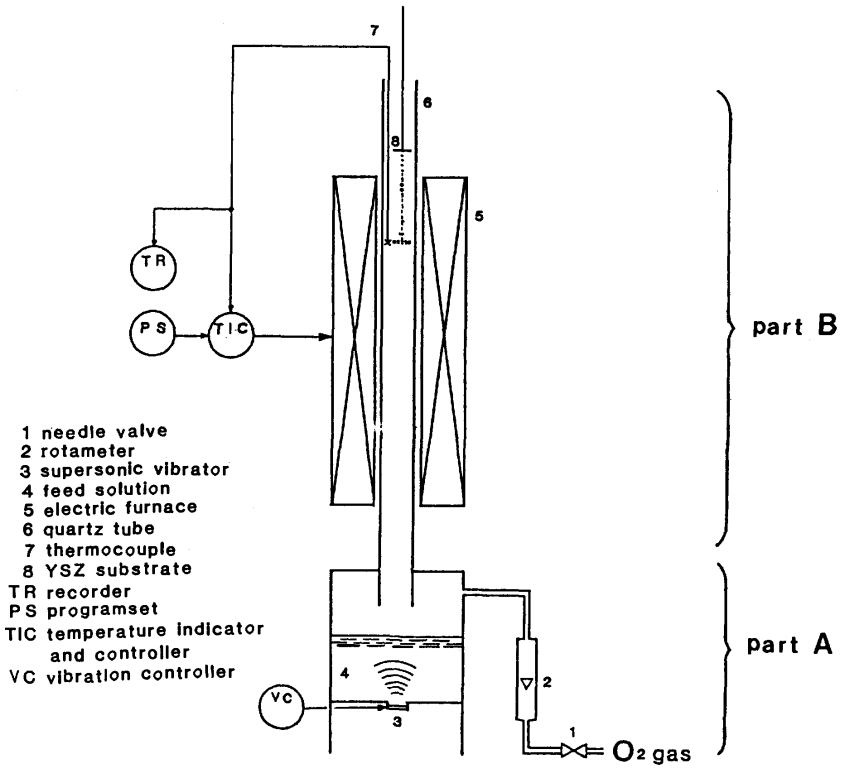

Fig. 1. Apparatus for fume pyrolysis.

Temperature dependencies of magnetization for the films, treated at 1273 K for 5, 10, 15, and 30 min in flowing O_2, respectively, were measured and the volume fractions of superconductive phases in the films were estimated.

X-Ray Diffraction Measurements. The sample film was subjected to X-ray diffraction (XRD) analysis. Since the conventional diffractometer showed peaks due to YSZ substrate as well as those due to $Ba_2YCu_3O_{7-\delta}$, a reflection X-ray diffractometer (Rigaku Denki Co., Rotaflex) was used at 50 kV with a filament current of 40 mA and carbon filter for Cu $K\alpha$ radiation. An incident X-ray angle to the sample film was settled at 0.5 degree from the horizontal plane.

SEM and EPMA Measurements. The surface structures and metal ions distributions on the sample films were observed by EPMA, operated at an accelerating voltage of 15 kV with an energy dispersive detector. The depth profiles of metal ions were also monitored by EPMA with samples mounted in polyethylene supports. All the samples submitted to EPMA measurements were covered with carbon films to prevent the charge-up phenomenon.

TEM Measurements. Particles accumulated on YSZ substrate during fume pyrolysis were removed and suspended in ethanol with the aid of a supersonicant to be submitted to a transmission electron microscope (TEM, Hitachi H-800), operated at an accelerating voltage of 200 kV with a magnification of 10^5. Thus, the size and shape of the fine particles were observed and the compositions of particles were also analyzed by an element analyzer (EMAX, Horiba Co.), equipped with an energy dispersive detector.

Results

Resistivity Measurements. In Fig. 2 are shown the changes in the resistivity of the superconductive films,

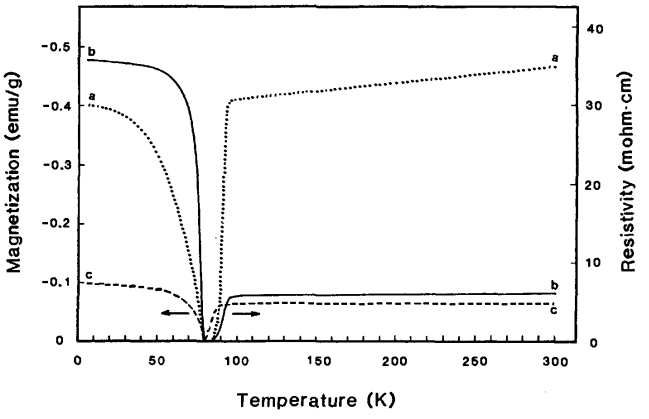

Fig. 2. Temperature dependences of resistivity and magnetization of $Ba_2YCu_3O_{7-\delta}$ films annealed at 1273 K for 5 (a), 10 (b) and 30 min (c).

treated at 1273 K for 5, 10, and 30 min in O_2 atmosphere, with temperatures varied from 50 to 300 K. The film employed was 5 μm in thickness in average. Resistivities with 100 μA of the current were almost constant (3 mohm cm) at temperatures higher than 90 K and decreased to zero at 80 K. The resistivity curves were well-reproducible for samples formed under the similar conditions; T_c=90 K, $T_{c(zero)}$=80 K, ΔT=10 K.

Magnetization Measurements. In Fig. 2 are also shown the temperature dependencies of magnetization for the films treated at 1273 K for 5, 10, and 30 min, respectively. From the saturation magnetizations

thus obtained, the volume fractions of superconducting phases formed in the films were estimated (see Fig. 3).

XRD Measurements. The reflection XRD patterns of the films annealed at 1273 K for 10 and 30 min are given in Figs. 4c and d, indicating the significant crystal growth along with c-axis of $Ba_2YCu_3O_{7-\delta}$ during the oxygen treatment at 1273 K. On the otherhand, the diffraction patterns due to $Ba(NO_3)_2$ were observed for the unannealed film (see Fig. 4a), though the decomposition temperature of $Ba(NO_3)_2$ is described at 871 K.[13] For comparison, X-ray diffraction patterns of the films annealed at 1223 K for 2 h are shown in Fig. 4b. From the slight changes in the diffraction angles of superconductive phases, changes in the lattice constants with annealing time were calculated and listed in Table 1. Oxygen contents in the superconductive unit cell were estimated from the difference between a and b-axial lengths, according to the previous paper[14] and are also given in Table 1.

SEM and EPMA Measurements. Typical SEM photographs showing the changes in surface morphorogies of the films are given in Figs. 5a to 5e with magnification of ×1600, where 5a represents the surface of the unannealed film and 5b to 5e show the surfaces of films annealed at 1273 K for 5, 10, 15, and 30 min, respectively. A SEM photograph of the films annealed at 1223 K for 2 h is shown in Fig. 5f to be compared with those of the films annealed at 1273 K. The depth profiles of Y, Ba, and Cu ions in the film annealed at 1273 K for 10 min are demonstrated in Fig. 6 and X-ray images of Y, Ba, and Cu ions on the films annealed at 1273 K for 30 min are given in Fig. 7.

TEM Photograph. In Fig. 8 are shown the TEM photographs of fine particles deposited on the substrate, particles unannealed. Particles deposited on

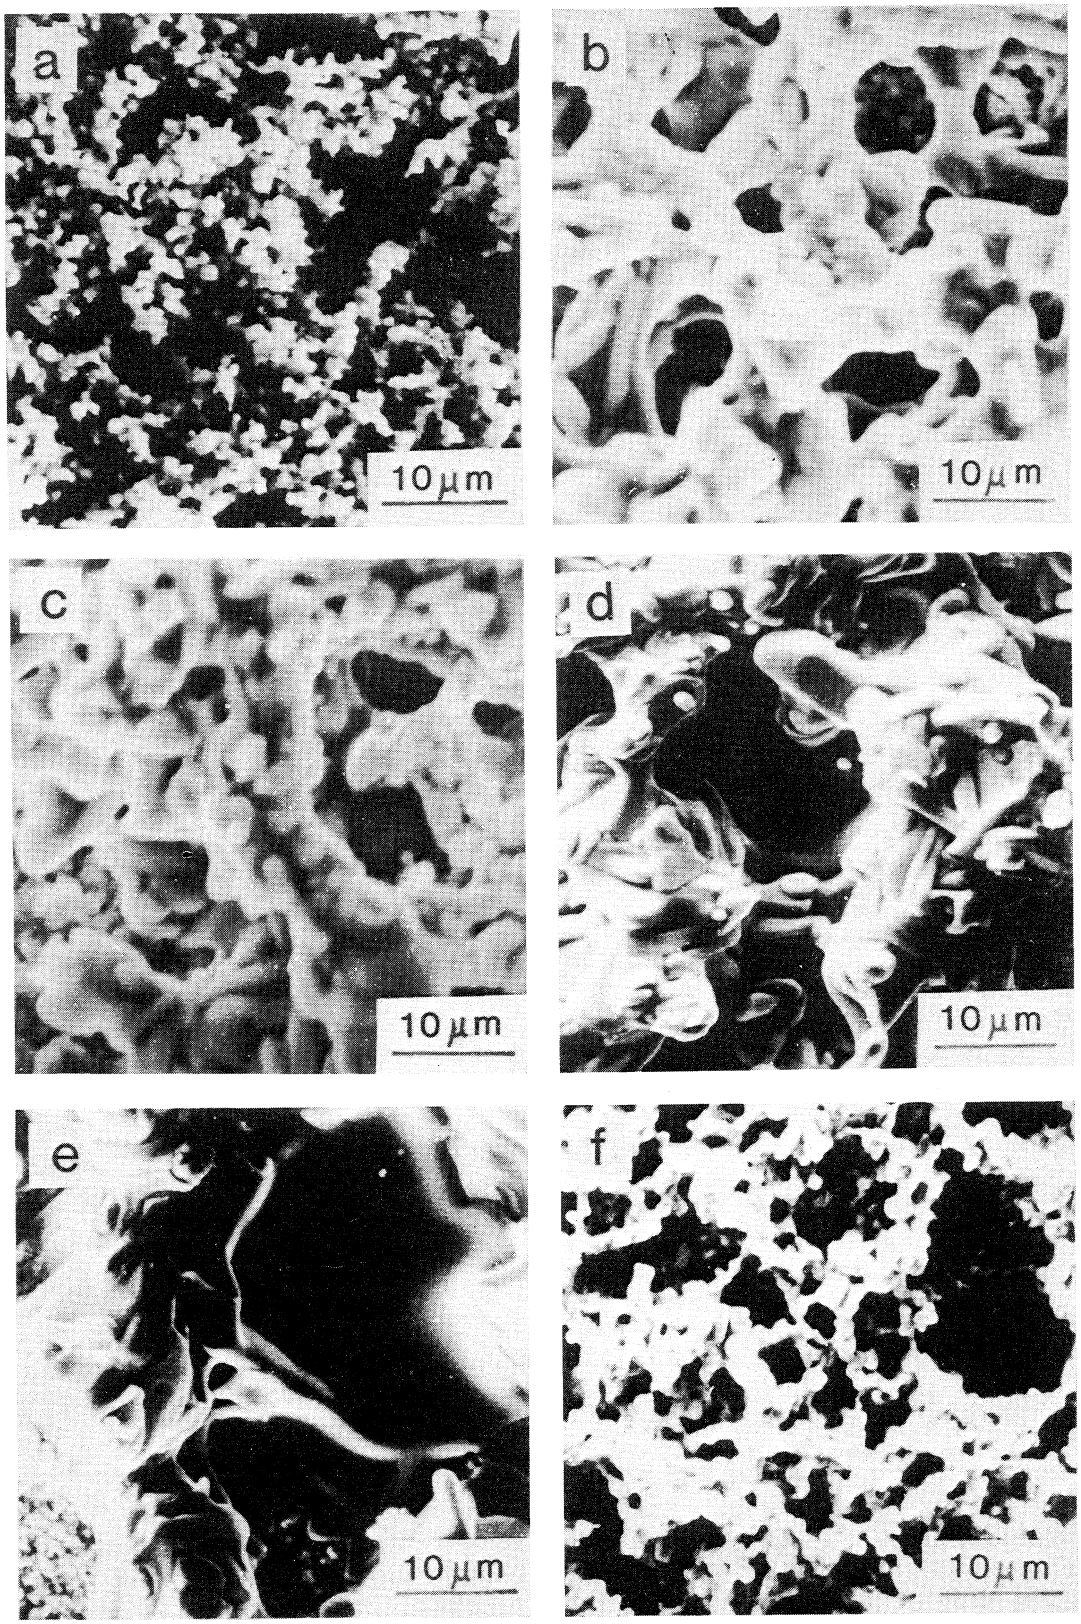

Fig. 5. SEM photographs with the magnification of ×1600; the unannealed films (a), and the films annealed at 1273 K for 5 min (b), 10 min (c), 15 min (d), and 30 min (e) and the films annealed at 1223 K for 2 h (f).

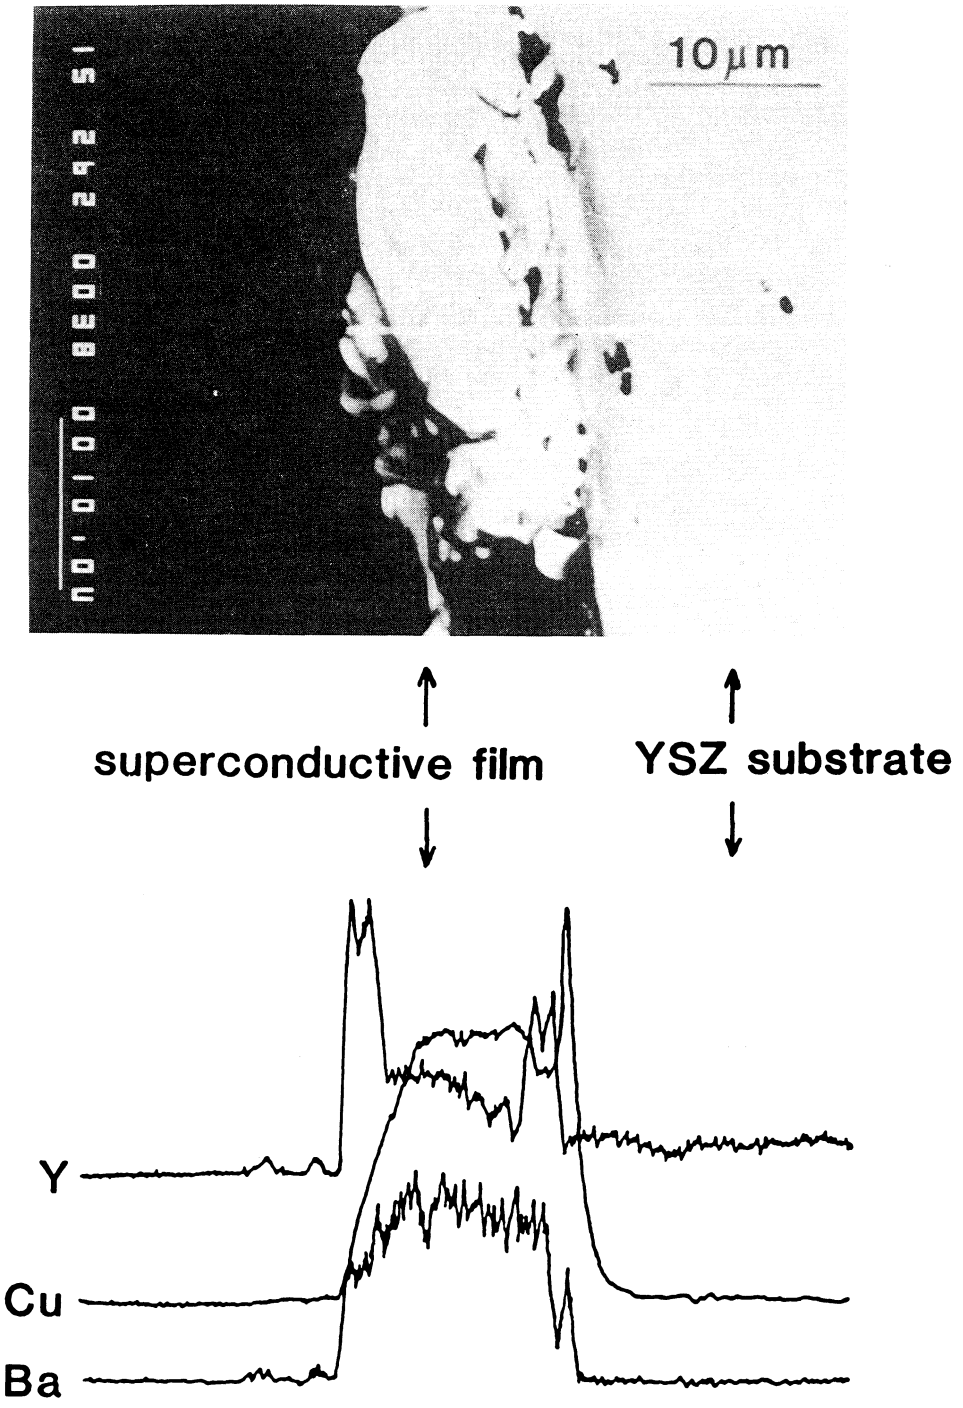

Fig. 6. Depth profilms of Y, Ba and Cu in the films annealed at 1273 K for 15 min, measured by EPMA.

the substrate seem to be spheres with the diameter of 0.5 μm, almost evenly. The composition analysis of particles is also depicted in Fig. 8, suggesting the particle consists of Y, Ba, and Cu ions though Cu ions were rather enriched in the particle than were expected to be 1/2/3 for Y/Ba/Cu.

Discussion

Particles Depositing on YSZ. Fume pyrolysis techniques with an aid of supersonication[15] have been used for the preparation of oxide particles and the particle size will be controlled by the size of droplets in fumes. A droplet size can be estimated by the following equation;[16]

$$d = 0.34\left(\frac{8\pi\gamma}{\rho f^2}\right)^{1/3} \quad (1)$$

where d is the average size of droplets, f means the

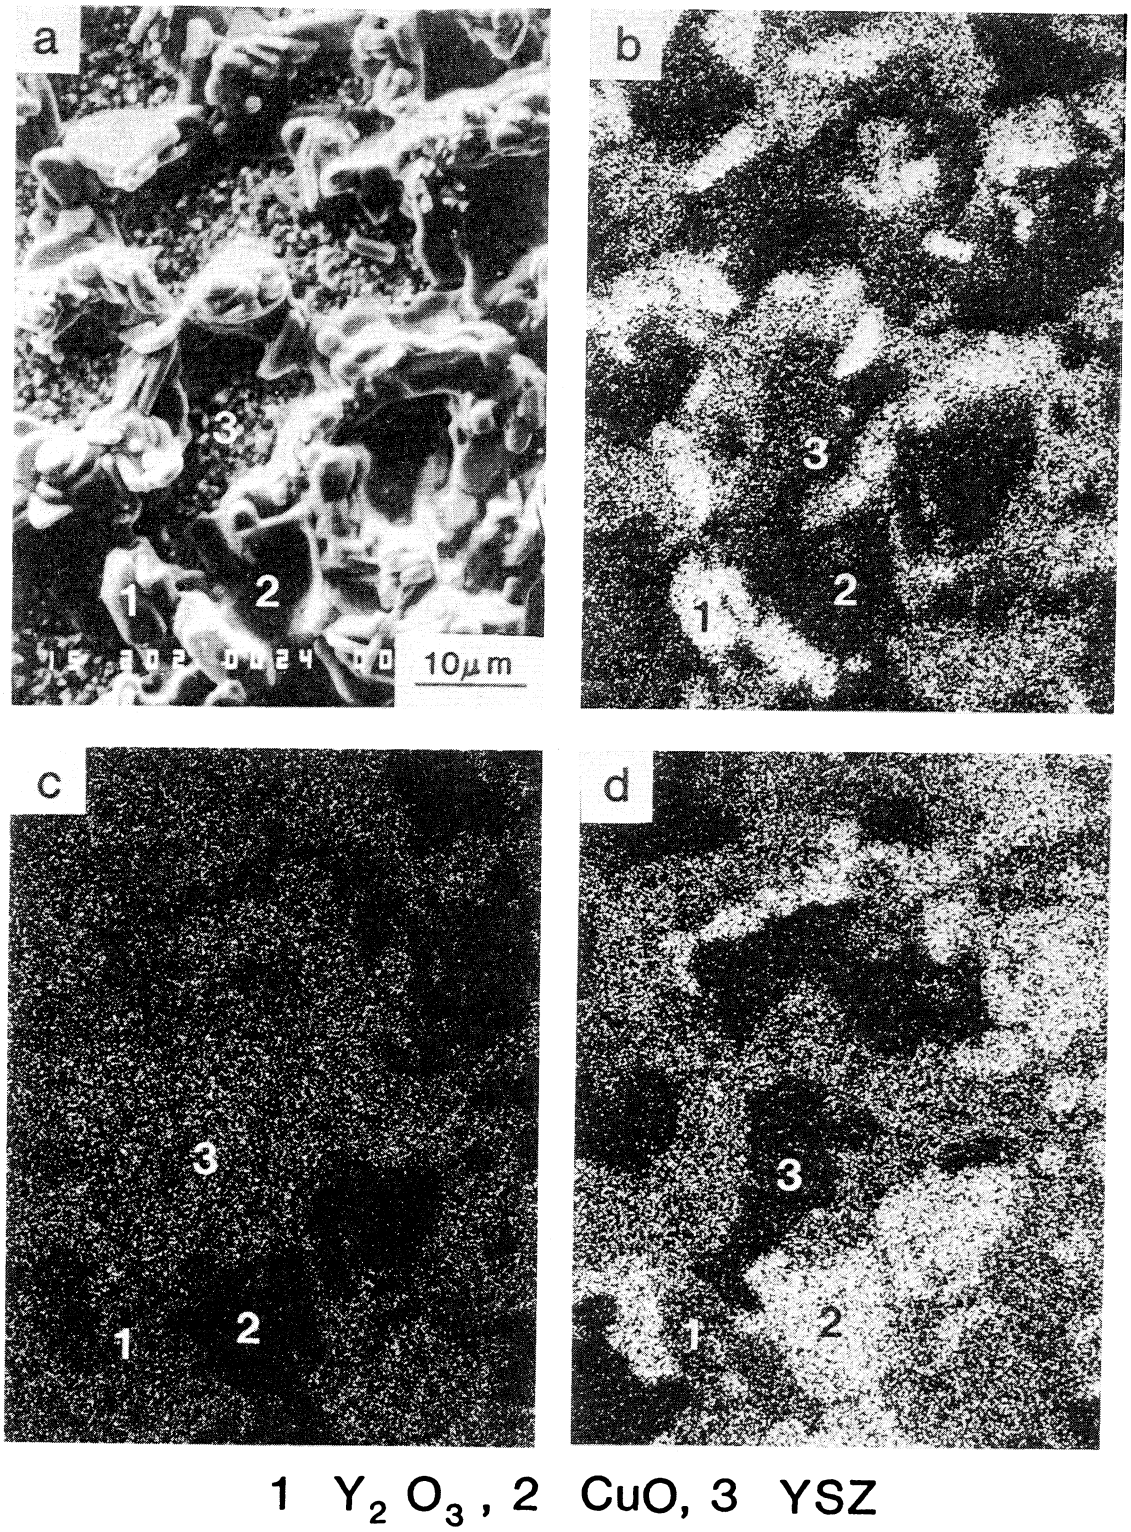

Fig. 7. SEM photograph (a) and X-ray image of Y (b), Ba (c), and Cu (d) in the films annealed at 1273 K for 30 min, measured by EPMA with a magnification of ×1600.

frequency of supersonication (1.5 MHz) and γ and ρ are the surface tension and density of droplets, respectively. In this work, metal nitrates employed are so diluted with water that the surface tension and density of droplets might be approximately the same as those of water. Thus, the average size of droplets in fumes was calculated ca. 3.2 μm and the size of particles formed during pyrolysis was estimated to be ca. 0.41 μm, since the concentration of metal ions in a droplet is 0.02 mol L^{-1}; more than 99 wt% of a droplet is water, volatilized during pyrolysis. As can be seen in Fig. 8 the size of particles depositing on the substrate is ca.

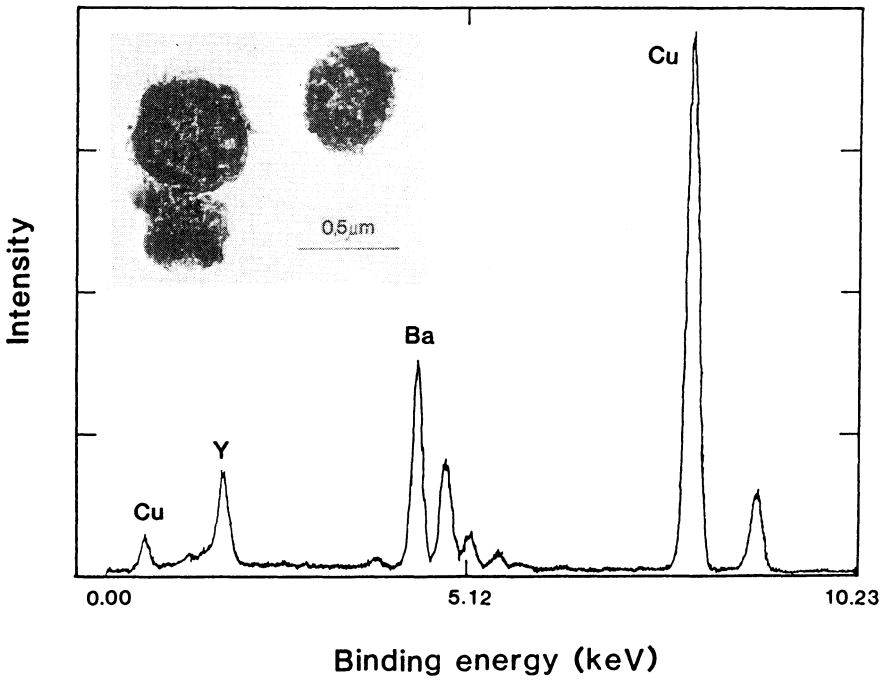

Fig. 8. TEM photograph and composition analysis of the particles depositing on the substrate during fume pyrolysis.

0.5 μm, in good accordance with the estimated size of 0.41 μm, suggesting that a droplet in fumes turned out a particle during pyrolysis. A particle, hence a droplet, was proved to be composed of Y, Ba, and Cu ions although an excess amount of Cu ions was observed (see Fig. 8). In Fig. 4a is shown an XRD spectrum of the particles depositing on the substrate and almost all of the peaks are assigned to $Ba(NO_3)_2$. By annealing the particles at 1223 K for 2 h, the peaks attributed to $Ba(NO_3)_2$ disappeared and those due to $Ba_2YCu_3O_{7-\delta}$ were observed (see Fig. 4b).

SEM Observation and Superconductivity of the Annealed Films. SEM observations of the unannealed films are given in Fig. 5a, where the films are proved to consist of spherical particles sized ca. 0.5 μm. Sintering of the particles are demonstrated in Figs. 5b to 5e, when the films were annealed at 1273 K for 5, 10, 15, and 30 min in flowing O_2. From Figs. 5d and 5e, it will be found that $Ba_2YCu_3O_{7-\delta}$ seems to be sintered by a prolonged annealing at 1273 K. The XRD spectrum of the sintered films is given in Fig. 4d, suggesting the crystalline growth of $Ba_2YCu_3O_{7-\delta}$ with the heat treatments in O_2 atmosphere at 1273 K. Although the photographs given in Figs. 5a to 5e emphasize uneven structures of the films, zero resistivities and Meissner effects were clearly confirmed at 80 K for the annealed films (see Fig. 2). A SEM photograph of the films annealed at 1223 K for 2 h showed unsintered particles mainly composed of $Ba_2YCu_3O_{7-\delta}$ (see Figs. 4b and 5f). The resistivities of this film were proved to decrease gradually below 90 K but did not reach zero even at 50 K with a small current of 10 μA.

Volume Fractions of Superconductive Phases. The saturation magnetiaztions and, consequently, the volume fractions of the superconductive phases in the annealed films strongly depend upon, the annealing time at 1273 K, as shown in Figs. 2 and 3. Thus, the volume fraction as high as 45% was achieved for the films annealed at 1273 K for 10 min but with a prolonged annealing the superconductive phases seem to decompose. In Fig. 7 are shown the X-ray images of Y, Ba, and Cu ions on the films treated at 1273 K for 15 min in O_2 atmosphere, indicating the deposition of copper oxides by the decomposition of superconductive phases. Copper oxides thus yielded were spreaded and covered over YSZ substrate, evidenced by disappearance of diffraction peaks due to YSZ of the films treated at 1273 K for 30 min (see Fig. 4d). As can be seen in Table 1, nevertheless the prolonged annealing the axial lengths of unit cell did not change so much. The difference between a and b-axial length became so small, however, when films were annealed at 1273 K for 30 min, resulting in the decrease of oxygen content in a superconducive unit cell (see Table 1).

The current used in the resistivity measurements was 100 μA and the average thickness of films annealed at 1273 K for 10 min was ca. 5 μm, as is shown in Fig. 6. Accordingly, the J_c value was estimated to be in the order of 10^2 A cm^{-2}. Unfortunately, high-J_c values in the order of 10^6 A cm^{-2} could not be achieved with the present films, probably because of uneven structures of films. Thus, one of the most important

factors to improve J_c value must lie in the homogeneous structures of films. The films with homogeneous structures will depend on the size of particles depositing on the substrate during pyrolysis. To prepare smaller particles, supersonicant with a high frequency should be used, as suggested by the Eq. 1.

Conclusion

1) A feature of fume pyrolysis is a direct accumulation of fine particles over substrate surface and was first applied here to the preparation of superconductive films.

2) With annealing the films at 1273 K, they exhibited superconductive properties below 90 K, but with a prolonged annealing the superconductive phases decomposed, probably, to the respective oxides. Thus, the relationship between annealing time at 1273 K and the volume fraction of superconductive phases in films were revealed.

3) Because of uneven structure of the films, high-J_c could not be achieved in this work. However, it was suggested that films with a homogeneous structure might be posible when fine sized droplets are employed for a fume pyrolysis. Such droplets can be generated by a supersonicant with higher frequency.

The authors express their thanks to Dr. Keizou Masuda at Toray Co. for supplying the YSZ substrates. Thanks are also to Professor Masatoshi Satoh at Institute for Molecular Science for measurements of magnetization at liquid He temperature.

Variable-Temperature and Variable-Pressure Nitrogen-14 NMR Studies on the Exchange Reaction of Different Nitriles at the Nickel(II) Ion

Masao Ishii, Shigenobu Funahashi,* Koji Ishihara,† and Motoharu Tanaka
Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464-01
(Received December 5, 1988)

The activation parameters for the exchange reaction of several nitriles at the nickel(II) ion have been determined for the nickel(II) trifluoromethanesulfonate solutions by means of the ^{14}N NMR line broadening method at various temperatures and pressures up to 220 MPa. Values of activation enthalpy ($\Delta H^{\ddagger}$/kJ mol^{-1}), activation entropy ($\Delta S^{\ddagger}$/J mol^{-1} K^{-1}), and activation volume at zero pressure ($\Delta V_0^{\ddagger}$/cm^3 mol^{-1}) for the exchange of various nitriles are respectively as follows: 41.4±0.5, −30±2, and +12.0±0.4 in acetonitrile; 42.0 ±0.4, −25±2, and +13.7±0.5 in propionitrile; 43.3±0.7, −23±2, and +13.1±0.5 in butyronitrile; 43.3±0.5, −19±2, and +12.4±0.6 in isobutyronitrile; 47.1±1.2, −10±4, and +14.4±0.4 in valeronitrile; 51.6±1.9, +4±6, and +13.1±0.6 in benzonitrile. The activation volume varies little in spite of the large variation of the molar volume of nitriles. The activation energy (E_Q/kJ mol^{-1}) and the activation volume at zero pressure ($\Delta V_q^{\ddagger}$/cm^3 mol^{-1}) for the reorientation of nitrile molecules around the axis perpendicular to the C≡N bond were also determined to be respectively as follows: 7.4±0.1 and +8.3±0.4 for acetonitrile; 8.1±0.1 and +9.5±0.2 for propionitrile; 9.2±0.1 and +9.7±0.3 for butyronitrile; 9.1±0.1 and +11.3±0.2 for isobutyronitrile; 10.7±0.2 and +11.9±0.2 for valeronitrile; 12.5±0.2, and +13.5±0.2 for benzonitrile. Both E_Q and $\Delta V_q^{\ddagger}$ increase with increasing bulkiness of the substituent to the cyano group.

The volume of activation $\Delta V^{\ddagger}$ is one of the useful parameters for elucidating the reaction mechanisms.[1-4] The discussion of the reaction mechanism on the basis of $\Delta V^{\ddagger}$, however, is sometimes still ambiguous, since the effect of the bulkiness of reactants including solvent on the activation volume has not been thoroughly understood.

For the limiting associative (A) mechanism and the limiting dissociative (D) mechanism in the solvent exchange at metal ions, one would expect that the absolute value of the limiting activation volume $|\Delta V^{\ddagger}_{\mathrm{lim}}|$[3,4] is roughly equal to the molar volume of the solvent V°. Interchange mechanisms (Ia, I, and Id) will give smaller $|\Delta V^{\ddagger}|$ values. Therefore, not only $\Delta V^{\ddagger}_{\mathrm{lim}}$ but also $\Delta V^{\ddagger}$ for Ia and Id mechanisms would be anticipated to vary with the molar volume of solvent even for the same mechanism.

This work has been designed to elucidate the effect of the molar volume of solvent upon the value of $\Delta V^{\ddagger}$ for the solvent-exchange reaction. We report $\Delta V^{\ddagger}$ for the exchange of various nitriles at the nickel(II) ion. The utilized nitriles include acetonitrile, propionitrile, butyronitrile, isobutyronitrile, valeronitrile, and benzonitrile. We propose a model for the solvent-exchange reaction based on the volume of activation. In addition, we discuss some microscopic properties of the liquid nitriles obtained from the temperature and pressure dependence of the ^{14}N transverse relaxation time of the neat nitriles.

Experimental

Solvents. Reagent grade acetonitrile (Wako Pure Chemical Industries Co.), propionitrile (Wako), butyronitrile (Tokyo Chemical Industry Co.), isobutyronitrile (Tokyo Chemical), valeronitrile (Tokyo Chemical) were distilled twice after refluxing for 1 h in the presence of P_2O_5 (<2g dm^{-3}). Benzonitrile (Wako) was dried over P_2O_5 for 12 h and distilled twice under reduced pressure.

$[Ni(H_2O)_6](CF_3SO_3)_2$. Trifluoromethanesulfonic acid (50 g, Wako) was added dropwise to basic nickel(II) carbonate (20 g, $NiCO_3 \cdot 2Ni(OH)_2 \cdot 4H_2O$, Wako) suspended in 50 cm^3 water. The resulting mixture was heated to complete the reaction and to concentrate the solution. Finally, the green salt yielded by cooling the solution was recrystallized from water and dried under vacuum at room temperature. Found: C, 5.20; H, 2.63%. Calcd for $[Ni(H_2O)_6](CF_3SO_3)_2$: C, 5.17; H, 2.60%.

Sample Preparation. Nitrile solutions of nickel(II) trifluoromethanesulfonate were prepared by dissolving the hydrated nickel(II) trifluoromethanesulfonate (ca. 4 g) in respective nitriles (ca. 60 cm^3) and removing the water under reflux for about 5 h in the modified Soxhlet extractor with Molecular Sieves 4A in the thimble.[5,6] The reflux was repeated two or three times with freshly activated molecular sieves. The nickel(II) concentration of each stock solution was determined by EDTA titration with TAMSMB (2-(2-thiazolylazo)-4-methyl-5-(sulfomethylamino)benzoic acid) as an indicator.[7] The content of water in sample solutions as determined by the Karl-Fischer titration was less than 5×10^{-3} mol kg^{-1} that corresponded to at most less than 0.05 mol/mol of Ni^{2+}.

The dilution of the stock solution and the transfer of the sample solution into an NMR tube were carried out under dry nitrogen gas in a dry box. The sample solutions for variable-temperature NMR measurement were degassed and sealed on a standard vacuum line. The nickel(II) concentrations of the NMR sample solutions were ranged over 2×10^{-2}—2×10^{-1} mol kg^{-1}.

Variable-Temperature ^{14}N NMR Measurement. ^{14}N NMR measurements were performed at various temperatures on a JEOL JNM-GX270 FT-NMR spectrometer operating at 19.51 MHz. The pulse width was 31 μs (90°) and

† Present address: Department of Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku, Tokyo 160.

pulse repetition time was typically 0.15 s. The number of scans was varied between 300 and 30000 depending on the line width. An 8 mm o.d. NMR sample tube was inserted into a 10 mm o.d. NMR tube containing a lock solvent (CD_3OD or D_2O) and nitromethane as a chemical shift standard. The temperature was measured by a substitution technique using a thermistor (D111-1031 or D641, Takara Thermistor Co.). About 15 to 30 min were required for the temperature equilibration of the sample solution and the temperature stability was ±0.2 K.

Variable-Pressure ^{14}N NMR Measurement. For variable-pressure NMR experiments, a multinuclear NMR probe designed for a wide-bore superconducting magnet (6.34 Tesla) of a JEOL JNM-GX270 FT-NMR spectrometer has been newly constructed. The pressure vessel consisting of four separable parts is illustrated in Fig. 1A. The pressure pipe (1) is made of nonmagnetic titanium alloy, around which spiral is cut. A Dewar vessel (e) covers it to insulate the heat. The thermostating gas is flowed along the spiral in order to adjust the temperature in the pressure vessel. An adapter (2) made of titanium alloy is attached to facilitate insertion and withdrawal of the sample tube. Four leading wires for a saddle-shaped coil and a copper-constantan thermocouple are introduced into the electrical terminal (3). The pressure seal at this part is achieved with the cone-type seal using small copper cones covered with Daiflon (poly(chlorotrifluoroethylene), Daikin-Kogyo Co.) for insulation, and at other parts the pressure sealing is accomplished with standard cone-type seals and O-ring seals. The internal housing (4) made of titanium alloy is the guide for the sample tube and also reduces the volume of pressure-transmitting liquid filled in the pressure vessel. The pressure vessel is connected through the flexible tube (a) to a pressure-generating system[8] consisting of a high-pressure generating pump (KBP56, Hikarikouatsu) and Heise Bourdon gauges. The pressure-transmitting liquid used in this work was Daifloil #1 (poly(chlorotrifluoroethylene), Daikin-Kogyo Co.).

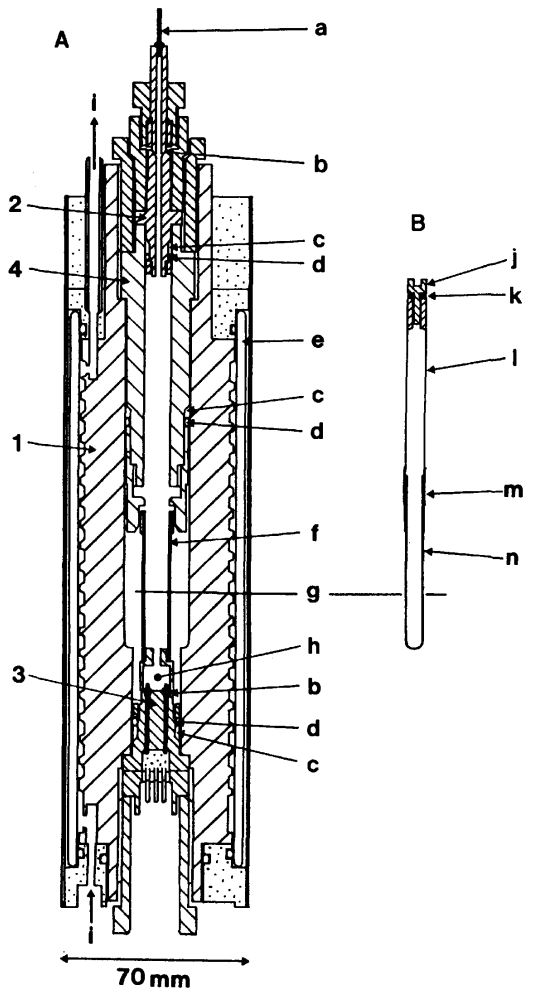

Fig. 1. High-pressure vessel and NMR sample tube for high-pressure NMR experiments.
(A) High-pressure vessel. 1, pressure pipe (titanium alloy); 2, adapter (titanium alloy); 3, electrical terminal; 4, internal housing (titanium alloy); a, flexible tube (SUS316); b, cone-type seal; c, backup ring (Teflon); d, O-ring (Viton); e, Dewar vessel; f, bobbin (glass); g, r.f. coil center; h, copper-constantan thermocouple; i, thermostating gas flow. (B) Sample tube. j, screw (Teflon); k, O-ring (silicone); l, flexible Teflon cap; m, contractive Teflon tube; n, 7 mm o.d. glass tube.

The sample tube, illustrated in Fig. 1B, is filled with the sample solution. It consists of a 7 mm o.d. glass tube and a flexible Teflon cap, both of which are connected with a contractive Teflon tube. At the top a silicone O-ring and Teflon screw are attached.

Before carrying out the high-pressure experiment, the temperature of the sample was measured by a substitution technique using a thermistor, and monitored with a thermocouple introduced into the pressure vessel during the high-pressure experiments. About 5 h were required for the complete temperature equilibration and the temperature stability over several hours was ±0.2 K.

Results and Discussion

Structure of Solvated Ni(II) Ion in Nitrile. The crystal structure of $[Ni(CH_3CN)_6](SbF_6)_2$[9] and $[Ni(CD_3CN)_6](SbF_6)_2$[10] has been determined by the X-ray diffraction method; the nickel(II) ion is octahedrally coordinated by six acetonitrile molecules with the Ni-N-C angle of 175°. The electronic absorption spectra of $Ni(BF_6)_2$,[11] $Ni(MF_6)_2$ (M=Sb, Bi),[10] and $Ni(ClO_4)_2$[6] in acetonitrile are characteristic of an octahedrally coordinated Ni^{2+} ion. The solvation number of 6 for nickel(II) ion in acetonitrile has also been confirmed by means of ^1H NMR.[12,13]

In Fig. 2 are shown the electronic absorption spectra of solutions of $Ni(CF_3SO_3)_2$ in various nitriles which were recorded on a UV-265FW spectrophotometer (Shimadzu) and a U-3400 spectrophotometer (Hitachi). The spectrum of acetonitrile solution is very similar to those reported,[6,10,11] and the spectra of the other nitrile solutions are also characteristic of the octahedrally coordinated Ni^{2+} ion, although the slight band shift is observed. Therefore, we can safely state that Ni^{2+} ion is octahedrally coordinated by the nitrile molecules in all solutions investigated.

Transverse Relaxation Time of ^{14}N in Neat Nitrile. Transverse relaxation time T_2 of nitrogen-14 in neat

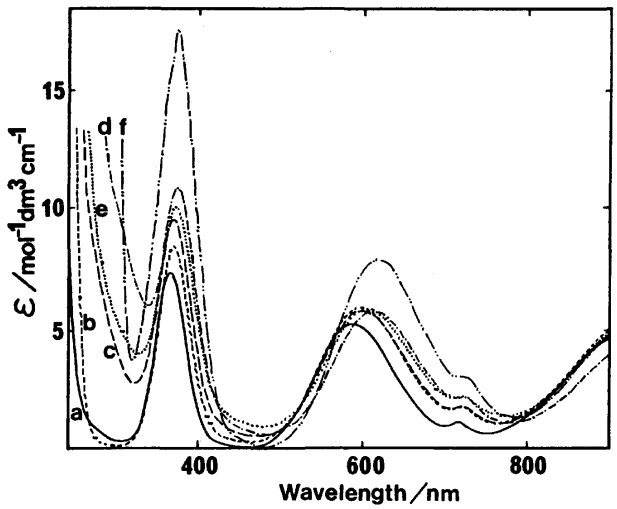

Fig. 2. Electronic absorption spectra of $Ni(CF_3SO_3)_2$ nitrile solutions. a (———), acetonitrile solution; b (·····), propionitrile solution; c (— — —), butyronitrile solution; d (— · —), isobutyronitrile solution; e (·····), valeronitrile solution; f (—··—), benzonitrile solution.
The values of ε are somewhat ambiguous, since the concentrations of the solution in the unit of mol kg^{-1} are transformed into the unit of mol dm^{-3} using the density of the neat solvent.

nitrile is evaluated from the half-height width of the ^{14}N NMR spectrum ($T_2=(\pi\Delta\nu)^{-1}$). Since reorientation of acetonitrile molecules around the axis perpendicular to the C≡N bond in the liquid state is very rapid, ^{14}N ($I=1$) transverse relaxation rate (T_2^{-1}) of acetonitrile is equal to the longitudinal relaxation rate (T_1^{-1}),[14] and these are expressed as follows:

$$T_1^{-1}=T_2^{-1}=\frac{3}{2}\pi^2\chi^2\left(1+\frac{1}{3}\xi^2\right)\tau_q \qquad (1)$$

where χ/Hz is the quadrupole coupling constant ($\chi=e^2Qq/h$), τ_q/s is the correlation time characterizing the reorientation about the axis perpendicular to the C≡N bond and ξ is the asymmetry parameter. This equation is valid for the ^{14}N nuclear relaxation in all the studied nitriles. The temperature and pressure dependence of the relaxation time may be attributable to the variation of τ_q.[14,15]

The temperature dependences of T_2 for ^{14}N of nitriles are shown in Fig. 3. The data were conventionally analyzed by using Eq. 2:

$$\ln T_2=\ln T_2^{298.2}-E_Q(1/T-1/298.2)/R \qquad (2)$$

where $T_2^{298.2}$ and E_Q refer to T_2 at 298.2 K and the activation energy for the reorientation, respectively. The values of $T_2^{298.2}$ and E_Q for acetonitrile are in good agreement with the literature values.[6,14,16] The obtained parameters are listed in Table 1.

By using Eq. 1, we can estimate values of the rate constant (τ_q^{-1}) of the reorientation for some nitriles of which the values of χ and ξ are available; values of τ_q^{-1}

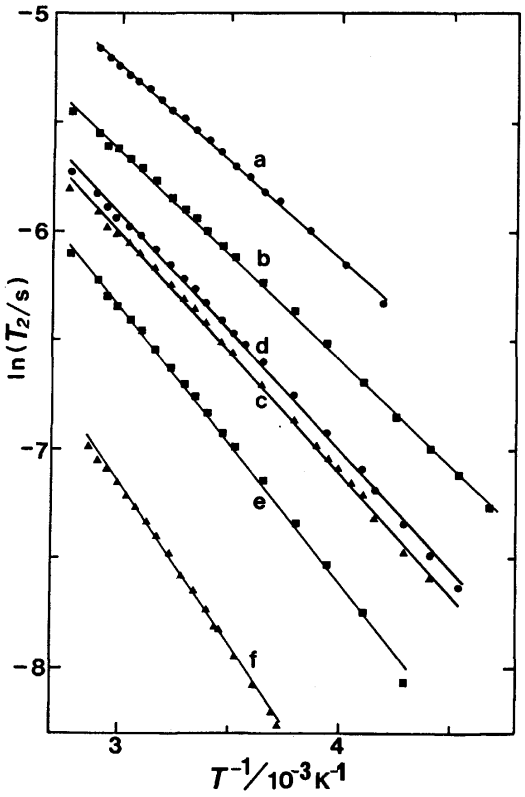

Fig. 3. Temperature dependences of T_2/s for ^{14}N of nitriles. a, acetonitrile; b, propionitrile; c, butyronitrile; d, isobutyronitrile; e, valeronitrile; f, benzonitrile.

Table 1. Transverse Relaxation Time of ^{14}N and Activation Parameters for Reorientation of Nitrile[a]

Solvent	$T_2^{298.2}$	E_Q	$\Delta V_q^{\neq}$		$10^2\Delta\beta_q^{\neq}$	$V^{ob)}$
	s	kJ mol^{-1}	cm^3 mol^{-1}		cm^3 mol^{-1} MPa^{-1}	cm^3 mol^{-1}
Acetonitrile	3.88×10^{-3}	7.4±0.1	+8.3±0.4	(332 K)	+2.0±0.4	52.9
Propionitrile	2.56×10^{-3}	8.1±0.1	+9.5±0.2	(330 K)	+2.0±0.2	70.9
Butyronitrile	1.66×10^{-3}	9.2±0.1	+9.7±0.3	(329 K)	+1.5±0.3	87.9
Isobutyronitrile	1.82×10^{-3}	9.1±0.1	+11.3±0.2	(328 K)	+2.2±0.2	90.3
Valeronitrile	1.12×10^{-3}	10.7±0.2	+11.9±0.2	(329 K)	+2.4±0.2	104.6
Benzonitrile	4.59×10^{-4}	12.5±0.2	+13.5±0.2	(332 K)	+2.0±0.2	103.1

a) Errors quoted are standard deviations. b) Molar volume at 298.2 K. Calculated using the data taken from J. A. Riddick, W. B. Bunger, and T. K. Sakano, "Organic Solvents," 4th ed, Wiley-Interscience, New York (1986).

at 298.2 K and corresponding $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are 8.0×10^{11} s^{-1}, 5.0±0.1 kJ mol^{-1}, and −0.3±0.4 J mol^{-1} K^{-1} (χ=3.738 MHz, $\xi=0.46\times10^{-2}$)[17] for acetonitrile, 5.4×10^{11} s^{-1}, 5.8±0.1 kJ mol^{-1}, and −1.0±0.4 J mol^{-1} K^{-1} (χ=3.776 MHz, $\xi=2.08\times10^{-2}$)[17] for propionitrile, and 1.0×10^{11} s^{-1}, 9.9±0.2 kJ mol^{-1}, and −1.0±0.6 J mol^{-1} K^{-1} (χ=3.885 MHz, $\xi=10.73\times10^{-2}$)[18] for benzonitrile. It is to be noted that the reorientation of these nitriles is characterized by very small entropy values. Since χ values in different nitriles change no more than a few percent and the contribution of $\xi^2/3$ is negligibe,[14] the difference of τ_q is considered to be exclusively responsible for the difference of T_2. Therefore the rate of reorientation is in the order: acetonitrile > propionitrile > isobutyronitrile≈butyronitrile > valeronitrile > benzonitrile.

Plots of $\ln T_2$ vs. pressure are shown in Fig. 4. Since all plots are slightly curved, the data were analyzed according to the quadratic equation:

$$\ln T_2 = \ln T_2^0 - \Delta V_q^{\ddagger} P/RT + \Delta\beta_q^{\ddagger} P^2/2RT \quad (3)$$

where $\Delta V_q^{\ddagger}$ is the activation volume for the reorientation by rotation about the axis perpendicular to the C≡N bond at zero pressure and $\Delta\beta_q^{\ddagger}$ is the compressibility coefficient of activation. The parameters obtained are listed in Table 1 together with the molar volume of the solvent V°. The value of $\Delta V_q^{\ddagger}$ for acetonitrile (+8.3±0.4 cm^3 mol^{-1}) is in excellent agreement with that (+8.5±1.4 cm^3 mol^{-1}) obtained by Bull and Jonas[15] and the agreement is fair with the value (+6.4±0.2 cm^3 mol^{-1}) obtained by Swaddle et al.[6] There is a trend that $\Delta V_q^{\ddagger}$ increase slightly with the increase of V°. In conclusion, correlation time, activation energy, and activation volume for reorientation increase with increasing bulkiness of substituent to the cyano group.

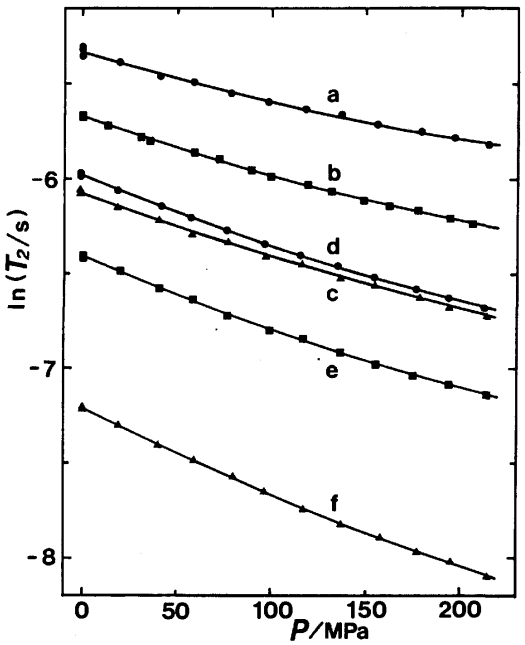

Fig. 4. Pressure dependences of T_2/s for ^{14}N of nitriles. a, acetonitrile; b, propionitrile; c, butyronitrile; d, isobutyronitrile; e, valeronitrile; f, benzonitrile.

Solvent Exchange at the Nickel(II) Ion in Nitrile. The rate for rapid solvent exchange between the bulk and the coordination site of a paramagnetic metal ion can be derived from the transverse relaxation rate of the bulk solvent nuclei.[19-21] The nitrile ^{14}N line broadening, $(T_{2P}P_M)^{-1}$, caused by the interaction with the nickel(II) ion can be expressed as Eq. 4:

$$(T_{2P}P_M)^{-1} = \pi(\Delta\nu_{obsd} - \Delta\nu_{solv})P_M^{-1} \quad (4)$$

where P_M is the ratio of the number of nitrile molecules bound to nickel(II) to that in the bulk, $\Delta\nu_{obsd}$ and $\Delta\nu_{solv}$ are the full widths at half-height of the ^{14}N NMR signal for the bulk nitrile of the nickel(II) nitrile solution and of the neat nitrile, respectively. For $P_M \ll 1$, $(T_{2P}P_M)^{-1}$ is given by the modified Swift-Connick equation (Eq. 5):[19-21]

$$\frac{1}{T_{2P}P_M} = \frac{1}{\tau_M}\frac{T_{2M}^{-2} + (T_{2M}\tau_M)^{-1} + \Delta\omega_M^2}{(T_{2M}^{-1} + \tau_M^{-1})^2 + \Delta\omega_M^2} + \frac{1}{T_{2O}} \quad (5)$$

in which symbols have their usual meaning.[22] We measured the NMR spectra of sample solutions with two or three different concentrations of nickel(II) trifluoromethanesulfonate at various temperatures. The observed line widths ($\Delta\nu_{obsd} - \Delta\nu_{solv}$) are excellently proportional to the P_M value. The temperature dependences of $(T_{2P}P_M)^{-1}$ for the nitrile solutions of $Ni(CF_3SO_3)_2$ are shown in Fig. 5. Since $\Delta\omega_M^2 \gg \tau_M^{-2}$, T_{2M}^{-2} over the temperature range of our experiment, Eq. 5 is simplified to Eq. 6:

$$(T_{2P}P_M)^{-1} = \tau_M^{-1} + T_{2O}^{-1} \quad (6)$$

where τ_M^{-1} is equivalent to the rate constant k_{ex} for the solvent-exchange reaction ($k_{ex} = k_B T/h \exp(-\Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R)$) and T_{2O}^{-1} ($= C_O/T \exp(E_O/RT)$) is the relaxation term due to the interaction in the outer sphere of the nickel(II) ion. We analyzed the data according to Eq. 6 by a least-squares fitting and obtained the kinetic parameters listed in Table 2.

The variable-pressure ^{14}N NMR experiments have been performed at about 330 K where the outer-sphere contribution T_{2O}^{-1} is negligible so that $(T_{2P}P_M)^{-1}$ is exclusively ascribed to the solvent-exchange contribution τ_M^{-1}. The pressure dependences of $k_{ex(p)}$ ($=\tau_M^{-1} = (T_{2P}P_M)^{-1}$ at a given temperature) are presented in Fig. 6. $k_{ex(p)}$ can be expressed as Eq. 7:

$$\ln k_{ex(p)} = \ln k_{ex(0)} - \Delta V_0^{\ddagger} P/RT + \Delta\beta^{\ddagger} P^2/2RT \quad (7)$$

where $k_{ex(0)}$ is the rate constant at zero pressure, $\Delta V_0^{\ddagger}$ is the volume of activation at zero pressure, and $\Delta\beta^{\ddagger}$ is the compressibility coefficient of activation. The kinetic parameters are evaluated by a least-squares fitting of the data to Eq. 7 and are listed in Table 2. The $\Delta V_0^{\ddagger}$ value for the reaction in acetonitrile is in good agreement with that obtained by Merbach et

al. (+11.3±1.0 cm^3 mol^{-1}).[23)]

In spite of the large variation of V° of the nitriles (53—105 cm^3 mol^{-1}), little change is observed in the activation volumes for the solvent exchange at nickel(II) (12.0—14.4 cm^3 mol^{-1}): the molar volume of solvent itself has little influence upon $\Delta V^{\ddagger}$ for the exchange reaction of nitriles.

In order to consider the activation volume for the solvent exchange at a metal ion, we now define the inner sphere of the solvated metal ion as the sphere into which the solvent molecules in the bulk can not penetrate at the initial state (see Fig. 7). The activation volume for the solvent exchange is thought to be the difference between the volume V_d that the leaving solvent loses in the inner sphere and the volume V_a that the entering solvent gets in the inner sphere at the transition state, as illustrated in Fig. 7. According to the molecular model constructed with van der Waals's radii of atoms, the nitrile molecules in the bulk can penetrate into the gaps among the bound nitriles without any steric hindrance regardless of the bulkiness of the substituent: the inner sphere does not include the substituent to cyano group and its size does not depend on the bulkiness of the nitrile. In fact the $\Delta V^{\ddagger}$ value is positive and varies little from solvent to solvent. Therefore both V_a and V_d are

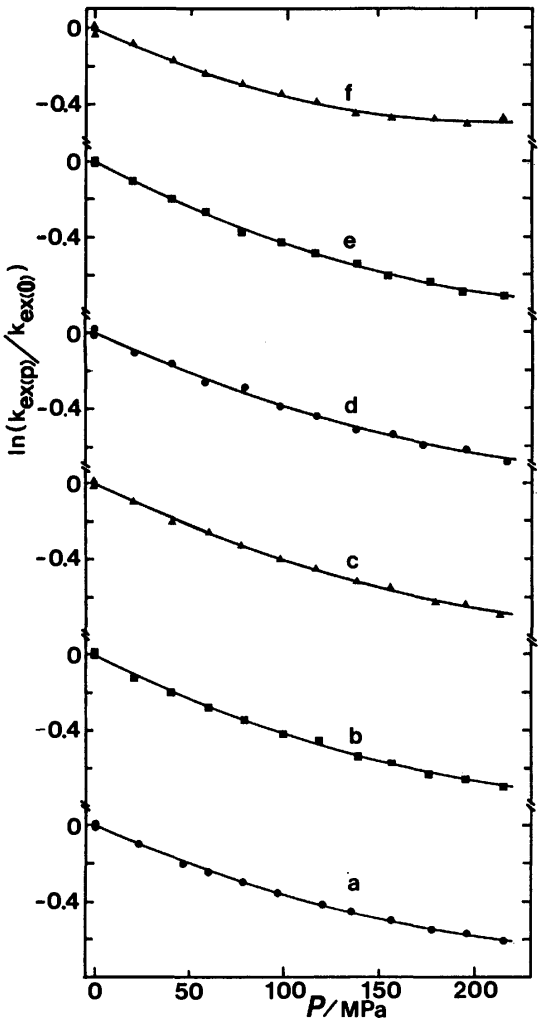

Fig. 6. Pressure dependences of $k_{ex(p)}/k_{ex(0)}$ for solvent exchange at Ni^{2+} in nitriles.
a, acetonitrile solution (P_M=1.76×10^{-2}); b, propionitrile solution (P_M=2.07×10^{-2}); c, butyronitrile solution (P_M=2.39×10^{-2}); d, isobutyronitrile solution (P_M=2.02×10^{-2}); e, valeronitrile solution (P_M=3.02×10^{-2}); f, benzonitrile solution (P_M=4.05×10^{-2}).

expected to be almost the same for all the studied nitriles. After all, the mechanism of the nitrile exchange at the nickel(II) ion is of the similar dissociative character for different nitriles of different bulkiness.

There is no parallel relation between $\Delta S^{\ddagger}$ and $\Delta V_0^{\ddagger}$ in the present systems (Table 2). The activation volume reflects the difference in nuclear positions between reactants and transition state, while the alternative concept of activation entropy seems to reflect the difference in both nuclear positions and energy.[24] Thus the solvent-solvent interaction may contribute considerably to values of $\Delta S^{\ddagger}$.[25] In the present system, acetonitrile liquid is highly structured due to strong dipole-dipole interactions, and the coordination sphere of the central nickel(II) ion has a definite octahedral structure. There should be the less ordered secondary sphere between the coordination sphere and the bulk solvent (B region according to the Frank-Wen model).[26] Therefore the leaving acetonitrile molecule in the activation process may strongly interact with the solvent molecules in the secondary sphere, and then the entropy of activation should become largely negative. Thus we anticipate a trend that the solvent interaction in the transition state should become smaller, and accordingly $\Delta S^{\ddagger}$ values may become larger with increasing size of solvent molecules. We notice such a trend for values of $\Delta S^{\ddagger}$ in Table 2. In conclusion, the sign of $\Delta V^{\ddagger}$ is useful for diagnosing the mechanism, whereas the interpretation of $\Delta S^{\ddagger}$ in terms of mechanism is likely to be complicated by the solvent-solvent interactions.

This work was supported by a Grant-in-Aid for Scientific Research (No. 62470041) from the Ministry of Education, Science and Culture. We thank Professor Jiri Jonas (University of Illinois) for his useful advice and Mr. Sadao Kanbe (JEOL) for his technical assistance on the construction of our high-pressure NMR probe.

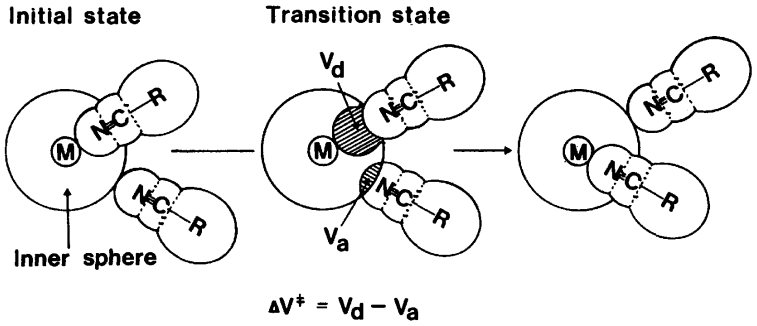

Fig. 7. Illustration for solvent exchange at a metal ion. The non-exchanging solvent molecules are omitted for simplicity; V_d, the volume that the leaving solvent molecule loses from the inner sphere in the activation process; V_a, the volume that the entering solvent molecule gets in the inner sphere in the activation process. The activation volume $\Delta V^{\ddagger}$ is represented as $\Delta V^{\ddagger}=V_d-V_a$.

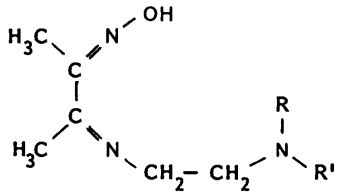
Synthesis and Properties of Copper(II) Perchlorate Complexes with Imino Oximes

Songping WAN, Wasuke MORI, Shoichiro YAMADA, and Shun-Ichi MURAHASHI*
Faculty of Engineering Science and College of General Education, Osaka University, Toyonaka 560
(Received December 23, 1988)

Three types of imino oxime copper(II) complexes were obtained by the reactions of copper(II) perchlorate with imino oximes (3-[2-[(alkylamino)ethyl]imino]-2-butanone oximes or 3-[2-[(dialkylamino)ethyl]imino]-2-butanone oximes, abbreviated as Hdox-enRR′). One type contains the dinuclear complexes $[Cu_2(dox\text{-}enRR')_2]^{2+}$ and uncoordinated perchlorate anions. The magnetic susceptibilities measured over the temperature range 77—320 K indicate that there exists a strong antiferromagnetic spin coupling interaction through the N-O bridge in these complexes. The magnetic behavior can be explained by using the Bleaney-Bowers equation. Complexes of the second type probably contain a square-tetranuclear complex. The copper(II) ions assume a penta-coordinated configuration with perchlorate anion coordinated at the axial coordination site. It is assumed that the dinuclear and mononuclear magnetic units coexist in the complexes of the third type. The plot of the magnetic susceptibilities versus temperature is linear in the two temperature ranges ($T>250$ K, <100 K).

Previous reports on the metal complexes with imino oximes **1** have shown a variety of structural and magnetic properties, which depend upon the substituents R and R′, metal ions and counter anions.[1-5] For example, the reactions of



1a Hdox-enR(R′ = H, R = alkyl)
1b Hdox-enR$_2$(R′ = R = alkyl)
1

nickel(II) salts with imino oximes **1** gave two types of complexes, namely hexa-coordinated octahedral and tetra-coordinated planar nickel(II) complexes. Significant effects of the counter anions[1] are also found in these studies. We have extended similar studies to copper(II) complexes. In the copper(II) thiocyanato complexes, imino oximes **1** are coordinated to copper (II) ion as a bridging quadridentate ligand, and the thiocyanate anion is coordinated through nitrogen atom to form a group of penta-coordinated dinuclear copper(II) complexes.[4] In copper(II) halide complexes with imino oximes, the main skeleton of complexes is similar to that of the copper(II) thiocyanato complexes, in which imino oximes act as a bridging quadridentate ligand. However, halide anions are not coordinated, in contrast to the thiocyanato complexes, showing their weaker coordination ability than that of thiocyanate anion.[5] Although some copper(II) perchlorate complexes with this ligand which were concluded to have a penta-coordinated dinuclear structure have been reported previously,[6] there remain important problems about related complexes with ligands having different steric conditions. In the present work more detailed examination has been carried out on copper(II) perchlorate complexes with a series of imino oximes. The study has shown that tetranuclear complexes and complexes consisting of mononuclear and dinuclear magnetic units, in addition to simple dinuclear one, occur in these copper(II) perchlorate complexes. Reported here are the results of our work on the polynuclear copper(II) perchlorate complexes with imino oximes.

Experimental

Materials. Biacetyl monoxime, *N*-alkylethylenediamine, *N*,*N*-dialkylethylenediamine, and copper(II) perchlorate hexahydrate were commercially available and used as received.

Synthesis. Cu(Hdox-enMe)(ClO$_4$)$_2$ (R′ = H, R = Me; 4a). A mixture of biacetyl monoxime (1.01 g, 0.01 mol) and *N*-methylethylenediamine (0.74 g, 0.01 mol) in 2-propanol (20 cm^3) was heated at 70 °C for 2 h. The resulting solution was added to a suspension of copper(II) perchlorate (3.70 g, 0.010 mol) in ethanol (30 cm^3) at 50 °C and stirred for 2 h. Filtration and subsequent washing with ethanol gave green powder of complex (2.52 g) in 56% yield. Mp: 217 °C. Found: C, 22.85; H, 4.07; N, 9.19%. Calcd for $C_7H_{15}N_3OCu(ClO_4)_2 \cdot 1/2PrOH$: C, 22.70; H, 4.26; N, 9.34%.

Cu(Hdox-enPr)(ClO$_4$)$_2$ (R′=H, R=Pr; 4b). A mixture of biacetyl monoxime (1.01 g, 0.010 mol) and *N*-propylethylenediamine (1.02 g, 0.01 mol) in ethanol(30 cm^3) was heated at 60 °C for 1.5 h. The resulting solution was added to a solution of copper(II) perchlorate (3.70 g, 0.01 mol) in 2-propanol (20 cm^3) at room temperature, and the mixture was stirred for several hours. Slow evaporation of the reaction mixture at room temperature gave green powder of complex (1.18 g) in 24% yield. Mp>300 °C. Found: C, 26.74; H, 5.13; N, 8.92%. Calcd for $C_7H_{15}N_3OCu(ClO_4)_2 \cdot EtOH$: C, 26.75; H, 5.10; N, 8.51%.

Cu(dox-enRR′)ClO$_4$ (R′=H, R=Ph, 2a; R′=R=Pr^i, 2b). These complexes were prepared by a similar method to that for Cu(dox-enPr)ClO$_4$ (**4b**), except that *N*-phenylethylenediamine (1.36 g, 0.01 mol) or *N*,*N*-diisopropylethylenediamine (1.44 g, 0.01 mol) was used in place of *N*-

propylethylenediamine. Dark-green crystalline complexes **2a** (2.83 g) and **2b** (1.40 g) were obtained in 72% yield and 36% yield respectively. Mp: **2a**, 254 °C and **2b**, 229 °C (all accompanied by explosion). Found: C, 38.08; H, 4.25; N, 10.85%. Calcd for $C_{12}H_{16}N_3OCuClO_4 \cdot 1/4EtOH$ (**2a**): C, 38.16; H, 4.48; N, 10.68%. Found: C, 37.08; H, 6.15; N, 10.64%. Calcd for $C_{12}H_{24}N_3OCuClO_4$ (**2b**): C, 37.02; H, 6.21; N, 10.79%.

Cu(dox-enMe)ClO$_4$ (R′=H, R=Me; 3a). This complex was prepared by a similar method to that for Cu(dox-enPr)ClO$_4$ (**4b**), except that *N*-methylethylenediamine (0.74 g, 0.01 mol) was used in place of *N*-propylethylenediamine. Complex **3a** (0.76 g) as dark green crystals was obtained in 23% yield. Mp: 225 °C. Found: C, 26.89; H, 4.57; N, 12.58%. Calcd for $C_8H_{16}N_3OCuClO_4 \cdot 1/4EtOH$: C, 27.24; H, 4.72; N, 12.71%.

Cu(dox-enEt)ClO$_4$ (R′=H, R=Et; 3b). This complex was prepared by a method similar to that for complex Cu(dox-enMe)ClO$_4$, except that *N*-ethylethylenediamine was used instead of *N*-propylethylenediamine. Filtration and recrystallization with ethanol gave dark-green crystals of complex **3b** (1.90 g) in 57% yield. Mp: 240 °C. Found: C, 28.93; H, 4.76; N, 12.78% Calcd for $C_8H_{16}N_3OCuClO_4$: C, 28.83; H, 4.84; N, 12.61%.

Measurements. Electronic absorption spectra were measured at room temperature with a Shimadzu MPS 5000 spectrophotometer. Infrared absorption spectra were recorded as Nujol mulls on a Perkin-Elmer 938G infrared spectrophotometer. Room temperature magnetic moments were determined by the Gouy method using H_2O as a susceptibility standard, and magnetic susceptibilities at temperatures 4 K to 320 K were measured by the Faraday method in a manner as described previously.[11] Pascal's constants were used to estimate the diamagnetic corrections for imino oximes, ClO_4, and Cu.[12]

Results and Discussion

Synthesis of the Copper(II) Perchlorate Complexes with Imino Oximes. In the present work, two types of copper(II) complexes were obtained, depending upon the nature of R and R′, by reactions of copper (II) perchlorate with one equivalent of imino oximes (Hdox-enRR′, **1**). From their magnetic properties, as discussed later in more detail, these complexes can be classified into the following three groups:

i) Cu(dox-enRR′)ClO$_4$ (**2**; R′=H, R=Ph; R′=R=Pr^i)
ii) Cu(dox-enR)ClO$_4$ (**3**; R=Me, Et)
iii) Cu(Hdox-enR)(ClO$_4$)$_2$ (**4**; R=Me, Pr)

Characterization of the Copper(II) Perchlorate Complexes 2. In these complexes **2**, the copper(II) ion is assumed to have a quadri-coordinated square-planar geometry, similar to that in copper(II) halide complexes.[5] The composition determined by the elemental analysis indicates that the imino oximes lose a proton on coordination to the copper(II) ion.

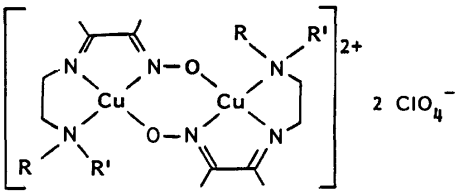
Infrared spectra of the complexes **2** exhibit no vibrations in 3140—3253 cm^{-1}, showing that the deprotonated imino oxime monoanions are coordinated to the copper(II) ion, in agreement with the assumption that the complexes **2** are copper(II) complexes. Moreover,

Table 1. The Main Data for Copper(II) Perchlorate Complexes of Imino Oximes

Complex	R	R′	μ/BM	d-d/10^{3}cm^{-1}	$\nu_{C=N}$/cm^{-1}
2a	Ph	H	0.51	17.0	1654
2b	Pr^i	Pr^i	0.68	16.8	1642
3a	Me	H	1.62	16.1	1637
3b	Et	H	1.62	15.2	1636
4a	Me	H	1.43	15.9	1642
4b	Pr	H	1.34	15.7	1641

the bands due to imino oxime C=N (Table 1) are shifted from the vibration of the free ligand at 1623—1630 cm^{-1}, indicating that the nitrogen atom of imino oxime C=N is bound to the copper(II) ion. The perchlorate anion is not bound to the copper(II) ion, since an unsplit band due to the perchlorate anion appears at about 1080 cm^{-1}.

Electronic absorption spectra of the copper(II) complexes **2** show one broad band in the visible region (Table 1), where d-d bands of square planar copper(II) complexes are expected to occur.[13,14] Since the magnetic moments of these copper(II) complexes at room temperature are subnormal, the spin-coupling interaction between copper(II) ions is presumed to be present. In the light of previous studies on the corresponding copper(II) halide complexes,[5] a similar dinuclear structure [Cu$_2$(dox-enRR′)$_2$]$^{2+}$ (shown in **2**) may also be proposed for the copper(II) perchlorate complexes **2** in the present work. This is supported by the finding in the present work that d-d bands, like those of copper(II) halide complexes,[5] are shifted to higher energy region, as compared with those of thiocyanato copper(II)



2a, R′=H, R=Ph
2b, R′=Pr^i
[Cu$_2$(dox-enRR′)$_2$]$^{2+}$
2

complexes.[4] It is well known that the d-d bands of the square-planar copper(II) complex undergo a bathochromic shift when the fifth ligand is bound to the planar copper(II) ion.[13,14]

Consistent with the assumption about the dinuclear structure, the temperature dependence of the magnetic susceptibilities of copper(II) perchlorate complexes shows that there exists a spin-coupling interaction between two copper(II) ions of dinuclear complexes. Magnetic susceptibilities of complexes **2** measured over the temperature range 77—320 K, which are shown in Fig. 1, indicate the presence of a

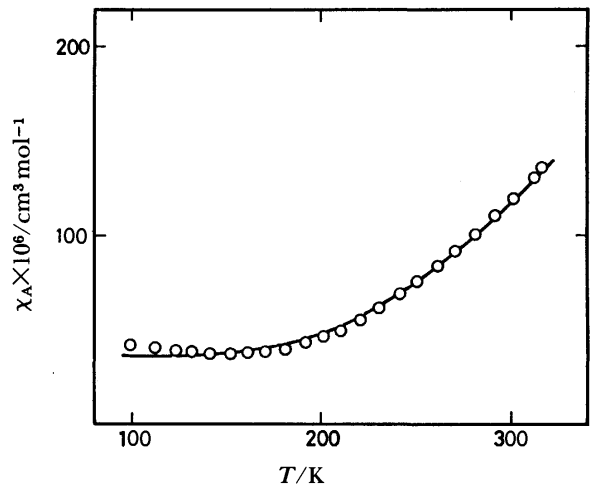


Fig. 1. Temperature dependence of the magnetic susceptibilities for Cu(dox-enPh)ClO_4 (**2a**). The solid line was calculated from Eq. 1 with g=2.29, $2J/k$=−1300 K, $N\alpha$=35×10^{-6} cm^3 mol^{-1}.

strong spin-coupling interaction between copper(II) ions in these dinuclear complexes, in the same way as in copper(II) thiocyanato and copper(II) halide complexes. The magnetic behaviors can be explained using the Bleaney-Bowers equation (Eq. 1)

$$\chi_A = \frac{Ng^2\beta^2}{kT}\frac{1}{3+\exp(-2J/kT)} + N\alpha \quad (1)$$

The symbols in Eq. 1 have their usual meanings. Figure 1 exhibits good agreement between the experimental and calculated values. The exchange parameters for the copper(II) perchlorate complexes **2** are given in Table 2. The values of $-2J$ of the copper(II) perchlorate complexes **2**, just like the copper(II) halide complexes, are greater than those of the thiocyanato copper(II) complexes. This result implies that the spin-coupling interaction between two copper(II) ions is stronger in the perchlorate complexes than that in the thiocyanato complexes, and may be considered to arise from the apical bonding of the thiocyanate anion to the copper(II) ion in the latter. Thus all the findings combined are consistent with the assumption that the complexes **2** adopts a dinuclear structure $[Cu_2(dox\text{-}enRR')_2]^{2+}$ and that there exists a strong antiferromagnetic interaction between two copper(II) ions through two bridging N-O groups.

Table 2. Magnetic Susceptibilities at Room Temperature and Magnetic Parameters of Copper(II) Perchlorate Complexes of Imion Oximes

Complex	χ_g / cm^3 g^{-1}	g	$-2Jk^{-1}$ / K	$N\alpha\times10^6$ / cm^3 mol^{-1}
2a	0.18	2.29	1300	35
2b	−0.09	2.33	1300	50
3a	3.05	2.00	128	60
3b	2.84	2.17	180	60
4a	1.55	2.10	960	60
4b	1.14	2.00	860	60

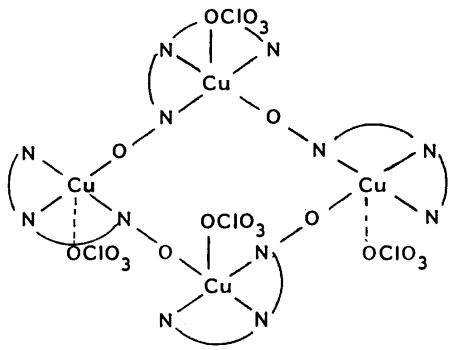
Characterization of Copper(II) Perchlorate Complexes 3. The composition of the elemental analysis shows the same empirical formula as that of complexes **2** though, the magnetic moments (1.62 BM) at room temperature are much higher than those of complexes **2**, indicating that the structure of complexes **3** is significantly different from that of complexes **2**. Similar to complexes **2**, infrared spectra of complexes **3** show that deprotonated imino oximate monoanion is coordinated to the copper(II) ion. A perchlorate anion is coordinated to copper(II) ion (Table 1), which is different from complexes **2**. The d-d bands of complexes **3** (Table 1) appear at a lower wavenumber than those of the copper(II) halides complexes. Therefore, it is likely that copper(II) ion in complexes **3** may be penta-coordinated, in a similar way to copper(II) thiocyanato complexes.

Although the subnormal magnetic moments of complexes **3** indicate the presence of antiferromagnetic spin-interaction, their variable temperature magnetic susceptibilities do not obey the Bleaney-Bowers equation for the dinuclear model. Investigation of variable temperature magnetic susceptibilities shows that complexes **3** have a tetranuclear structure, in which there exist an antiferromagnetic interactions. Over the temperature range 4—300 K, the best fit curve of susceptibilities versus temperature shows a clear peak at about 100 K (Fig. 2). The magnetic behaviors can be explained using Eq. 2 for the square-tetranuclear structure:[15]

$$\chi_A = \frac{Ng^2\beta^2}{2kT}\frac{2+5\exp(-2x)+\exp(2x)}{7+5\exp(-2x)+3\exp(2x)+\exp(4x)} + N\alpha \quad (2)$$

$$(x=-J/kT)$$

where g, J, and $N\alpha$ are g factor, exchange integral, and T. I. P. respectively. The exchange parameters for the copper(II) perchlorate complexes **3** are given in



3a, R′=H, R=Me
3b, R′=H, R=Et
$[Cu_4(dox\text{-}enR)_4(ClO_4)_4]$
3

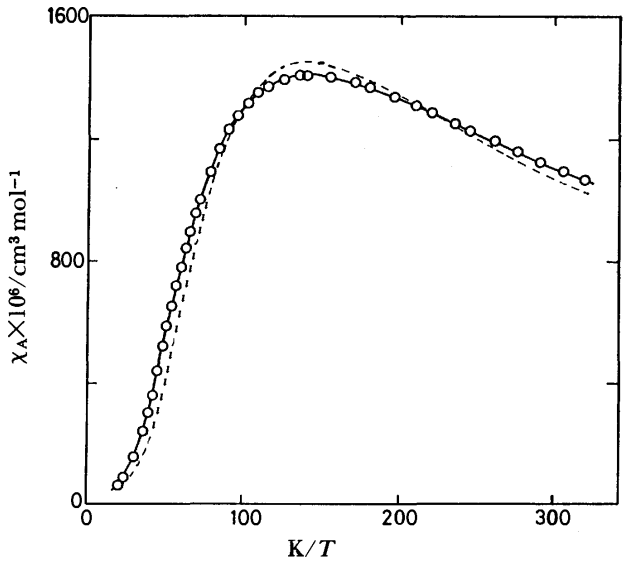


Fig. 2. Temperature dependence of the magnetic susceptibilities for Cu(dox-enEt)ClO_4 (**3b**). The solid line was calculated from Eq. 2 with g=2.17, $2J/k$=−180 K, $N\alpha$=60×10^{-6} cm^3 mol^{-1}. The broken line shows the best fit curve for dinuclear structure with g=2.04, $2J/k$=−255 K, $N\alpha$=60×10^{-6} cm^3 mol^{-1}.

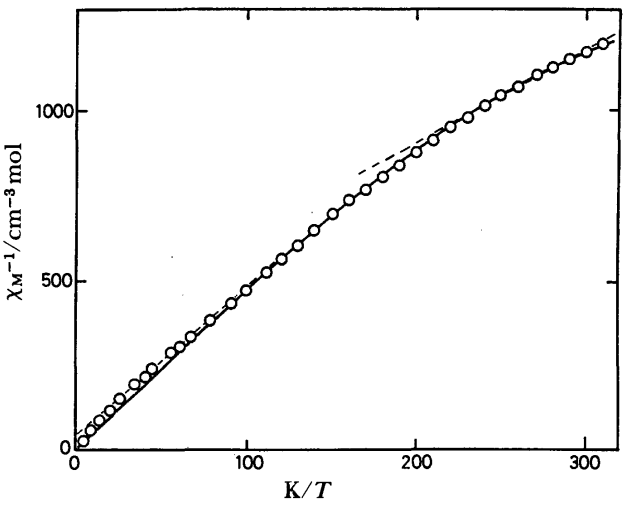

Fig. 3. Reciprocal susceptibility vs. temperature for Cu(Hdox-enMe)$(ClO_4)_2$ (**4a**). The solid line shows the theoretical susceptibilities calculated from Eq. 4 with g=2.10, $2J/k$=−960 K, $N\alpha$=60×10^{-6} cm^3 mol^{-1}. The broken lines show the Curie-Weiss law.

Table 2. Figure 2 exhibits good agreement between the experimental and calculated values, giving support to the assumption that complexes **3** consist of tetranuclear units.[16] One of most possible structures is shown in **3**.

Characterization of Copper(II) Perchlorate Complexes 4. The elemental analysis leads to the empirical formula Cu(Hdox-enR)$(ClO_4)_2$, which is significantly different from those of the complexes **2** and **3**. This formulation, requires that molecules of the imino oximes are coordinated to copper(II) ion in complexes **4**. Infrared spectra show that perchlorate anion, as in complexes **3**, is coordinated to the copper(II) ion. The d-d bands (Table 1) indicate that the coordination geometry around copper(II) ion is pentacoordinated. The magnetic moment calculated per copper(II) ion (1.34—1.43 BM) is smaller than the spin-only value, showing the presence of spin-coupling interaction between copper(II) ion in these complexes **4**. Magnetic susceptibilities were measured over the temperature range 4—300 K. The plot of reciprocal susceptibility versus temperature is linear in two temperature ranges, namely, T<100 K and T>250 K (Fig.3). The data fit to the Curie-Weiss law (Eq.3) with C_h=0.313 emu K mol^{-1} and θ_h=−140 K, C_l=0.226 emu K mol^{-1} and θ_l=−10 K for complex **4a**, and C_h=0.302 emu K mol^{-1} and θ_h=−100 K, C_l=0.185 emu K mol^{-1} and θ_l=−10 K for complex **4b**, where C_h and θ_h are Curie and Weiss constant of the high temperature range, and C_l and θ_l are Curie and Weiss constant of the low temperature range.

$$\chi^{-1}=C^{-1}(T-\theta) \quad (3)$$

It is thus clear that there exists a strong antiferromagnetic interaction between copper(II) ions in these complexes **4**. The ratio C_h/C_l (1.6 for **4a** and 1.4 for **4b**) suggests centered-triangular tetranuclear unit or coexistence of dinuclear and mononuclear magnetic units (1:1 ratio) in complexes **4**. The magnetic susceptibility for the model of coexisting dinuclear and mononuclear copper(II) complexes in 1:1 ratio can be formulated as Eq. 4:

$$\chi_A=\frac{1}{2}\frac{Ng^2\beta^2}{kT}\frac{1}{3+\exp(-2J/kT)}+\frac{1}{2}\frac{Ng^2\beta^2}{4kT}+N\alpha \quad (4)$$

This equation reproduces the observed susceptibilities well with $2J/k$=−960 K, g=2.10 and $N\alpha$=60×10^{-6} cm^3 mol^{-1} for complex **4a** (Fig.3), and $2J/k$=−860 K, g=2.00 and $N\alpha$=60×10^{-6} cm^3 mol^{-1} for complex **4b**. The agreement between calculated and observed susceptibility for the centered-triangular tetranuclear model is much poorer than for the model of coexisting dinuclear and mononuclear units. Therefore, the latter models more likely for complexes **4**. It may be possible that there exists an antiferromagnetic spin interaction between two copper(II) ions in the tetranuclear clusters, but the third and fourth copper(II) ions in the cluster are not involved in spin-coupling with the other copper(II) ions.** Although the precise structure can be determined by the single crystal X-ray study, attempts to grow crystals of the complexes suitable for X-ray studies have not so far been successful.

As discussed above, the present work has revealed

** A referee has questioned whether there would be bridging groups in the proposed formula. It is true that the alcoholato oxygen atom most frequently occurs as a bridge. However, it may also be possible that the alcoholic hydroxyl group functions as a bridge.

that various skeletal structures have been found in copper(II) perchlorate complexes with imino oximes, the result which shows that the structure of copper(II) complexes is quite versatile. It is noteworthy that according to the nature of ligand and the steric condition, copper(II) ion forms various complexes with a different coordination number and a different structure. In consequence of the Jahn-Teller effect, copper(II) complexes show various structures which rarely occur in the corresponding nickel(II) complexes.

(Received December 24, 1988)

A microbiosensing device fabricated by assembling an enzyme-embodied microelectrode with a counter electrode and a reference electrode was applied to the real time determination of trace droplet of glucose sample. The microdevice demonstrated unique properties such as real time response, independence of sample volume, unnecessity of sample mixing by the rendezvous of microfabricated biosensing device with pulse voltammetry. A linear relationship between sensor output and glucose concentration was obtained in the concentration range from 10^{-3} to 10^{-1} mol L^{-1}. The sensing device responded to every glucose sample of different concentration in 2 ms, and the coefficient of variation for 10 mM glucose determination was within 5%.

Microfabrication is one of the common trends in science and technology of our age, since microfabricated sensors will play indispensable roles for the construction of very small sophisticated instrument as well as the microinstrumentation of analytical tools.[1] Being small has many advantages in electrochemical analysis of trace substances of biological importance with biosensors. In the early step of biosensor research many enzyme-immobilized membranes have been attached to Clark-type oxygen electrodes.[2-6] In recent years further application of enzyme electrodes has been extended by the microfabrication of electrode-based biosensors, since multifuctional biosensors can be developed by taking advantages of silicon technology.[7-9] Recent photolithographic techniques for deposition and patterning of thin noble metal films (50—300 nm) have been developed for the purposes of fabrication of planar integrated circuits.[10] These techniques are also promising for the preparation of microtransducer for miniaturized biosensors. However, new favorable techniques for immobilizing enzyme onto microtransducers are strongly required for the fabrication of microenzyme electrodes, which sizes are in the μm range, because the conventional enzyme immobilization techniques are not necessarily compatible with miniaturized transducers as long as enzymes are employed in polymer matrix-supported forms.

In previous papers we have reported fundamental properties of microenzyme electrodes with diameters in the range from 10 to 200 μm prepared by incorporating enzyme molecules onto a platinized surface of microplatinum electrode.[11,12] It was the platinization technique that enabled the microfabrication of the biosensor. It is a well-known fact that platinized platinum, porous microparticles of platinum, possesses very large surface area and high catalytic activities for electrolytic processes. By employing a microelectrode as a base electrode for platinization and simultaneous enzyme immobilization, a microenzyme sensor can be easily fabricated.[13] Enzyme molecules are stably retained in the porous platinum particles.[14] In other words, the platinum particles play the dual roles of transducer of enzyme electrode and matrix for enzyme immobilization.

The fabricated microbiosensors for glucose demonstrates high performances such as low detection limit of 5×10^{-7} mol L^{-1}, wide dynamic range from 5×10^{-7} to 2×10^{-2} mol L^{-1}, rabid response of 3 s, satisfactory coefficient of variation [2%], and time stability of over one month.[14,15]

Here we described a unique microbiosensing device for the real time determination of droplet glucose sample. As the operation mode of the microdevice is a voltammetry driven by the application of pulsed potential, stationary trace glucose sample can be determined in 2 ms.

Experimental

A microplatinum wire having a diameter from 10 to 200 μm, a platinum wire (200 μm diameter), and a silver wire (500 μm diameter) were sealed in a Teflon casing (2.5-mm inner diameter) with polyester resin, ground, and polished to leave exposed a circular surface. Electrodes were polished with Imperial™ wrapping films of alumina powders of different particle sizes. At the final stage of polishing 0.1 μm Al_2O_3 was used as the finish and only the microplatinum electrode for enzyme immobilization was cycled between −0.25 and +1.28 V vs. a silver-silver chloride electrode (reference electrode) in 0.5 M H_2SO_4 (1 M=1 mol dm^{-3}) prior to platinization with a conventional three electrode system. The silver electrode was anodized in 1 M NaCl solution for the preparation of a silver-silver chloride electrode. The microplatinum electrode was platinized in a mixed solution of hexachloroplatinate and lead acetate by following the procedure described previously.[14] After the platinization high purity glucose oxidase (EC 1.1.3.4) (from A. *niger*, 120 units/mg) was embodied with the porous surface of microplatinum electrode, following which crosslinking of the enzyme molecules with glutaraldehyde was performed.[14] Figure 1 shows a schematic illustration of

electrochemical microfabrication techniques. The measuring principle of the microbiosensing device thus prepared is schematically shown in Fig. 2.

A stock buffer solution of pH 6.8 was prepared from phosphate salts (50 mM) and NaCl (50 mM) as working electrolyte.

Experimental assays of droplet glucose sample were carried out with a potentiostat in a three-electrode configuation with the Ag/AgCl reference electrode of the microbiosensing device. The potentiostat was operated in on-off potential application mode. A potential of +0.6 V vs. Ag/AgCl was applied to the enzyme-embodied working electrode. The resulting amperometric signals were recorded by using an x-y-t recorder or a memory scope (MOS static RAM=4×12 bit×4096 word). The response time of the x-y-t recorder was 200 ms. In the later case each recorded datum was stored in a floppy disk, and then recorded on an x-y-t recorder. A schematic diagram of the microbiosensing principle is shown in Fig. 3. Glucose determination was performed by addition of aliquot of glucose stock solution. Potential was applied at 10 s aftter the addition of a droplet glucose sample.

Results and Discussion

Typical Responses of Microbiosensing Device. The effectiveness of the microbiosensing device, pulse voltammetry combination was evaluated in glucose sample by loading aliquot of standard glucose sample (10 mM). Every glucose sample (10 μL) was dropped on the three-electrode biosensing device, and a potential of +0.6 V was applied at 10 s after sample loading. Figure 4 shows typical data recorded on the x-y-t recorder. Also shown is the response curve of a blank

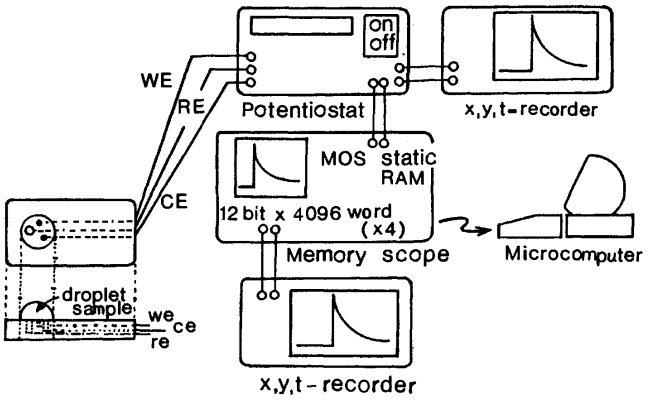

Fig. 3. Schematic diagram of the sensing principle of microbiosensing device.
After the addition of a droplet glucose sample on the three-electrode biosensing device, a potential of +0.6 V is applied to the microdevice and the resulting transient response is recorded on an x-y-t recorder or on a memory scope.

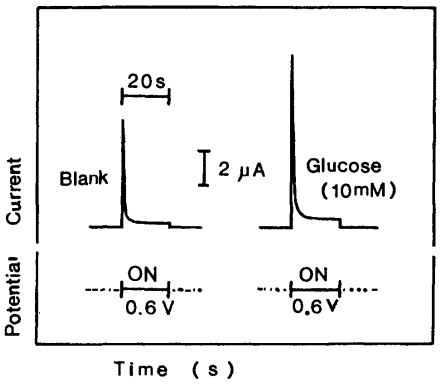

Fig. 4. Typical responses of microbiosensing device.
The responses of the biosensing device to a blank sample (the phosphate-buffered NaCl solution) and a 10 mM glucose sample (in the same buffered solution) were recorded on an x-y-t recorder whose response time is 200 ms.

sample (the phosphate-buffered NaCl solution). After the initial sharp peak, gradually decaying curve was observed. As the response time of the x-y-t recorder is 200 ms, the initial peak seems to the sums of capacitive and faradaic currents. The difference between the peak height of glucose sample and that of blank sample was plotted to the concentration of glucose sample, whose result gave a linear relationship between the peak height current and the glucose concentration in the range from 1 mM to 20 mM against a double logarithmic expression. The calibration curve was a straight line with slope equaled to ca. one-third. Since the slope of the curve seemed worth remarking, we applied a platinized microplatinum electrode to the pulse voltammetric determination of hydrogen peroxide, whose result gave a linear relation against a double logarithmic expression, with a slope of +1, between the initial peak height and the H_2O_2 concentration in the range of 1—100 mM hydrogen peroxide. These results explain the distinction between the enzyme-embodied and the platinized (non-enzyme) electrodes.

The above results make it apparent that in order to measure faradaic current a sufficient recording instrument of fast electrodic process will significantly separate faradaic current from capacitive one.

A sufficiently equipped memory scope was employed to investigate the transient response of the microdevice in further detail. In chronoamperometry current as a function of time is not the response of the microbiosensing devise described in this report but that of the recording system, as long as the x-y-t recorder whose response time is 200 ms is taken. Figure 5 shows a detailed response of the microbiosensing device to 10 mM droplet glucose sample (10 μL). In addition to a blank sample, we employed a fructose sample of the same volume and concentration to know the specificity of the microdevice. All three samples demonstrated similar responses in the rapid decay of initial peak, however, considerable difference among three samples was observed after the decay of charging current. The potential application initiated an instantaneous current as a result of the oxidation of hydrogen peroxide. The resulting current decreases as the electrodic reaction proceeds. In the faradaic process, therefore, the charge passed across the electrode interface is related to the amount of material that has been converted, and the generated current is related to the instantaneous rate at which the oxidation of hydrogen peroxide produced by the immobilized glucose oxidase occurs. In general monitored response to the potential excitation signal for a solution containing supporting electrolyte only is the background response (capacitive current) which should decay rapidly when the electrode has been charged to the applied potential. However, the response to a blank sample shows the faradaic current even after the decay of capacitive current. It should be noted that when platinum electrode is used as a transducer electrode, faradaic current is observed due to the formation of surface oxide of platinum.[16,17] After the anodic polarization the faradaic current for the surface oxide formation decreases significantly.[18] With respect to the response curve of the sensing device in Fig. 5, the difference in the transient response between a glucose sample and a blank sample can be a reasonable sensor signal of the pulse voltammetric biosensing device. As the behavior of the device to a fructose sample was almost similar to that to a blank sample, the microdevice was regarded to have specificity to glucose.

Relation between Transient Response and Glucose Concentration. As the greater difference in the tran-

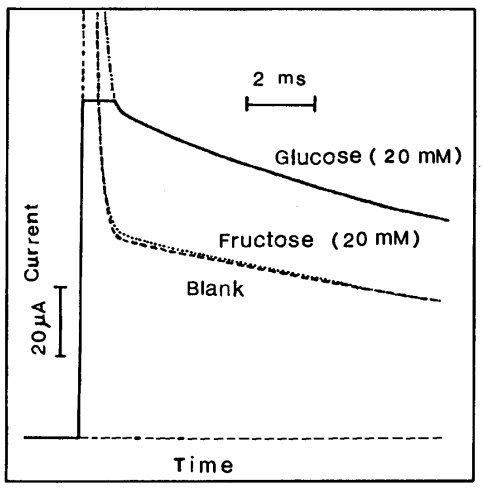

Fig. 5. Transient responses of microbiosensing device.
The responses of the microdevice were obtained by applying a potential of 0.6 V after a glucose sample (20 mM), a fructose sample and a blank sample were separately loaded on the device surface.

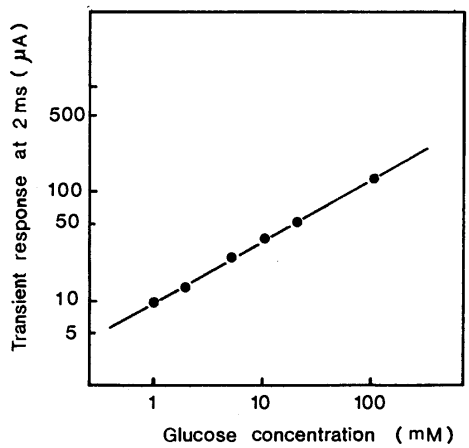

Fig. 6. Calibration curve for real time determination of glucose.
The difference in transient response at 2 ms between glucose sample and blank sample is plotted to the glucose concentration.

sient current between a glucose sample and a fructose sample was observed at 2 ms after the application of +0.6 V to the three-electrode device, the relation between the difference in sensor output and glucose concentration was investigated. Figure 6 shows a linear calibration curve for real time determination of glucose in the range from 1 mM to 100 mM. We have also here a linear relation with a slope of one-third. So far we can not find a resonable explanation for the slope of the calibration curve. In the case of glucose determination in a batch system[14] and a flow system[15] where samples are in hydrodynamic state, we have obtained a linear calibration with a slope of +1. In the determination with the present pulse voltammetric device, droplet samples are in hydrostatic conditions where the flux of hydrogen peroxide to the microelectrode is diffusion control. It is noteworthy that the enzyme reaction is also diffusion-controlled process in the stationary solution. A microplatinized electrode was applied for the pulse-voltammetric determination of hydrogen peroxide in a similar manner, and the resulting calibration curve showed a linear relationship with a slope of +1 in the concentration range from 1 mM to 100 mM hydrogen peroxide, as shown in Fig. 7. A complicated mass transfer process in the enzyme-embodied electrode is reflected on this experimental fact. With this in mind one can easily understand that the transient response seemed to reflect the non-steady state of the enzyme reaction as well as the electrodic reaction. The reasonable explanation for this intriguing phenomenon still remains to be studied in further detail.

Relation between Sensor Output and Sample Volume. The responses of the microbiosensing device to 10 mM glucose sample of different sample volume were obtained to know the relation between sensor output and sample volume. Almost identical responses were observed in this series of measurements where sample volume was varied from 1 to 20 μL. When the sample volume was less than 1 μL, the three-electrode microbiosensing device was not covered with the sample droplet. On the other band, the sample droplet more than 20 μL spilt from the device surface. Table 1 shows the relation between sensor output and sample volume. It should be noted that the sensing principle is independent of sample volume, which is one of the advantages for the microinstrumentation in clinical situations, because the pulse voltammetric device does not require any attached stirring machines.

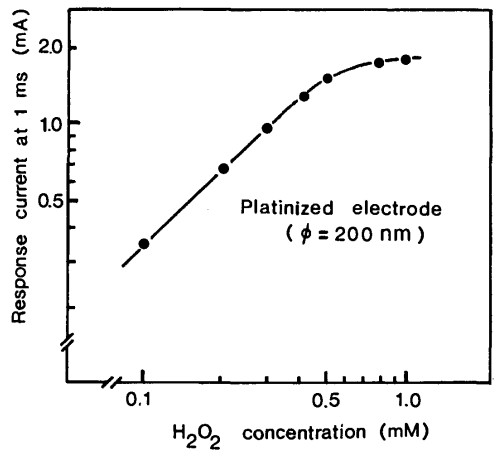

Fig. 7. Relation between transient response and hydrogen peroxide concentration.
The difference in transient responce at 1 ms between hydrogen peroxide sample and blank sample is plotted to the H_2O_2 concentration. The electrode employed here was a platinized microelectrode.

Table 1. Relation between Sensor Output and Sample Volume

Volume (μL)	1	2	5	10	15	20
Sensor output (μA)	29	30	31	31	30	30

The sensor output taken here is the difference in transient response at 1 ms between droplet glucose sample and droplet blank sample.

As the conventional voltammetry such as pulse voltammetry is independent of solution volume being tested, the results in Table 1 are consistent with typical data obtained by pulse voltammetric techniques. It is also worth noting that almost all the measurements with chemical sensors are also independent of sample volume. To our knowledge, however, this is the first experimental demonstration that biosensors are applicable to hydrostatic samples without paying attention to the volume of the sample being tested. Although the present work is in the early stage of experimentation, we examined the accuracy of the pulse voltammetric biosensing device by using 10 mM glucose sample (10 μL). The resulting coefficient of variation was calculated to be +4.4% (N=10).

Conclusion

The microbiosensing device demonstrated several performance characteristics such as real time determination, unnecessity of stirring equipment, and unnecessity of sampling tool. These advantages will allow several design criteria for microinstrumentation of clinical analyzers. The performance characteristics of the platinized platinum microelectrode-based biosensors in batch system, flow system, and pulse voltammetric measurements are summarized in the table.

By combining three microelectrodes into a single sensing unit, we have succeeded in fabricating a miniaturized biosensing device. Therefore, very small amount of sample can be applied to the microdevice, even if the droplet sample volume is a few μL. The microsensing device described here has

a couple of advantages over the dry chemistry-based clinical test papers. Microinstrumentation can be easily performed, because the device does not require additional equipments for the sampling of exact sample and for the stirring of sample solution. Furthermore, the microbiosensing device can be repeatedly used because of the stable, intact immobilization of enzyme molecules in the porous platinized electrode matrix. In addition to these advantages, another most important performance characteristic is that every sample can be determined instantaneously by taking advantage of pulse voltammetric technique. Finally, while we have focused on the fabrication of microbiosensing device which can be operated in the real time determination of analytes, the principle described here will also be a useful means of the microinstrumentation of portable-type biosensors for the daily surveillance of diabetic patients, especially of diabetic blind patients.

(Received January 20, 1989)

The advantages of miniaturized enzyme electrode have been applied to flow injection analysis for the development of a rapid and selective method for the continuous determination of glucose. By assembling a micro-enzyme electrode having a diameter of 10 μm for an amperometric flow-through detector, at least 600 glucose samples can be determined in one hour. And micro-enzyme electrodes are satisfactorily stable for over 4 weeks even after 1000 glucose injections.

Miniaturization is one of the common trends in science and technology of our age. As far as chemistry is concerned, miniaturization is closely related to the microinstrurmentation of analytical tools. As Haugen et al. pointed out in a recent journal,[1] microfabricated sensors will play indispensable roles for the construction of very small sophisticated instruments.

A great number of approaches for microfabrication of chemical sensors are currently under way, particularly in the areas of field effect transistor (FET)-based chemical sensors, metal oxide gas sensors, and biosensors. Since Janata et al. reported the first micro-enzyme electrodes based on FET,[2] a number of groups have been taking microfabrication techniques such as semiconductor technology and photolithography for fabricating micro-enzyme electrodes. Despite enormous efforts of many groups the FET-based micro-enzyme electrodes of practical use have not been realized yet, because this potentiometric method lacks fast response, high sensitivity, and wide dynamic range.

Over several years, microelectrodes having diameters less than 20 μm have been introduced as the in vivo chemical sensors of neurotransmitter.[3-5] Because of their nonselective voltammetric principle, microelectrodes of high selectivity have been earnestly desired to be developed.

Obviously selective membrane layers such as enzyme membranes exhibit for the target substances affinities by taking advantages of specificity and selectivity to enzymes' substrates.

In our previous papers we have successfuly fabricated amperometric micro-enzyme electrodes having diameters from 10 μm to 500 μm by the embodiment of enzyme molecules with platinized microelectrode.[6,7] We have taken two approaches for the construction of micro-enzyme electrodes. One of them is to incorporate enzyme molecules to an platinized microelectrode,[8] and the other is to make enzyme molecules adsorb electrochemically on the surface of an electrochemically growing platinized electrode matrix.[9]

Here we describe an effectiveness of the smallness of enzyme (glucose oxidase, GO) electrodes whose diameters from 10 μm 500 μm by applying them to amperometric detectors of flow injection analysis (FIA) of glucose. In addition to the fundamental characteristics of micro-enzyme electrodes as high-performance detectors for FIA, the authors would like to mention the importance of anodic polarization of the platinized electrodes for the improvement of the selectivity of the enzyme electrodes. The benefits of miniaturization of enzyme-electrodes are also discussed in this paper with respect to the microinstrumentation of FIA.

Experimental

Reagents and Materials. Hexachloroplatinic acid and lead(II) acetate were the products of Wako Chem. Co. (Osaka). Glucose was obtained from Nakarai Chem. Co. (Kyoto), and glucose oxidase (EC 1.1.3.4, 110 u/mg) was the product of Toyobo (Osaka). Bovine serum albumin (Grade V) and glutaraldehyde (50% water solution) were purchased from Tokyo Kasei (Tokyo). All the other reagents were of analytical grade; their solutions were prepared with glass-distilled water.

Platinum wires having diameters from 10 μm to 500 μm were manufactured by Sanwa Metal Co. (Tokyo). Imperial™ wrapping films of alumina powders of different particle sizes from 0.1 μm to 30 μm were obtained from Sumitomo 3M Co. (Tokyo).

Apparatus. The flow-through cell used for a transducer electrode in the FIA system is shown in Fig. 1. The working electrode (WE) was a platinized platinum whose diameter is from 10 μm to 500 μm, the reference electrode (RE) was an Ag/AgCl electrode, and the auxiliary electrode (AE) was a stainless steel upper cell for a thin-layer transducer cell for LCEC (BAS, West Lafayette, IN). Every microelectrode was fixed in an acrylic block bottom cell with a polyester resin. The reference electrode was positioned downstream from the biosensing cell. Potential application and the generated current observation were carried out by a Potentiostat/Galvanostat (Model

† Present address: Department of Bioengineering, Tokyo Institute of Technology, O-okayama 2-12-1, Meguro-ku, Tokyo 152.

2090 with Low Noise of TOHO Technical Research, (Tokyo). The output current was recorded with an X-t recorder (Model R-302V of RIKADENKI, Tokyo). A double plumger pump (Model NF-EX-2 of NIHON SEIMITSU KAGAKU Co., Tokyo) was employed with a pulse damper (NIHON SEIMITSU KAGAKU Co.). A 5 μL sample loop was used for all experiments. The length of the connective tube (inner diameter=200 μm) from the injection valve to the detector was 50 cm. The flow rate of the pump was controlled at 0.8 mL min^{-1}. The electrode potential of micro-enzyme electrode was 0.6 V, and all the electrode potentials are reported vs. an Ag/AgCl reference electrode. All the experiments were carried out at room temperature (23 °C).

Preparation of Micro-Enzyme Electrode in an Electrode-Assembled Transducer Cell. A microplatinum electrode (diameter=10 μm—500 μm) in an acrylic block bottom cell for the thin-layer transducer cell concerned was platinized with a conventional three-electrode system using a platinum wire electrode (diameter=1 mm, l=10 mm) and an Ag/AgCl reference electrode. Electrolytic reduction of hexachloroplatinate (33 mg mL^{-1}) was carried out in the presence of lead acetate (0.6 mg mL^{-1}) at a potential of −0.08 V for 5 min. After the reductive deposition of platinum particles, the platinized electrode was thoroughly rinsed in 0.1M phosphate buffer (pH 6.8). Incorporation of GO molecules in the platinized electrode was carried out by immersing the electrode in an enzyme solution for 10 min before assembling the three electrode detector cell. The solution contained 50 mg of GO in one mL of 0.1 M phosphate buffer (pH 6.8). The electrode was then kept in a bovine serum albumin (20 mg) in 1 mL of 0.1 M phosphate buffer of pH 6.8 for 10 min. The albumin-incorporated platinized microelectrode was treated with a 2% glutaraldehyde solution buffered with 0.1 M phosphate of pH 6.8 for 10 min for the preparation of thin-layer albumin film over the porous electrode surface, following which thorough washing of the electrode was performed overnight. A gasket having a thickness of 100 μm was employed between the upper stainless steel cell and the enzyme electrode-embedded acrylic bottom cell as shown in Fig. 1. Also is shown a schematic diagram of instrumentation.

Anodic polarization of the micro-enzyme electrode was performed before enzyme incorporation by applying +1.2 V to the electrode for 10 min in 0.1 M phosphate buffer (pH 6.8).

Results

Responses of Enzyme-Electrode to the Repeated Injection of Glucose Sample. A glucose sample (10 mM, 5 μl) was repeatedly injected to the transducer assembly. Figure 2 illustrates the typical responses of the detector system. Every response reached a peak within 2 or 3 s and decayed to the baseline within a few seconds. Each peak was highly reproducible, and gave ca. 200 nA maximum peak to 10 mM glucose sample. The micro-enzyme electrode having a diameter of 100 μm demonstrated responses neither to blank samples (0.1 M phosphate buffer of pH 6.80 nor to fructose and galactose samples after the anodic polarization of the platinized transducer electrode at 1.2 V for 10 min. Without anodic polarization the platinized electrodes as well as the enzyme-embodied platinized electrodes demonstrated responses not only to glucose but to galactose, fructose, and maltose. Before anodic polarization, the relative responses of the enzyme electrode were 7.7%, 6.2%, and 3.8% for galactose, fructose, and maltose, respectively, when the responses were normalized to that of glucose. After the anodic treat-

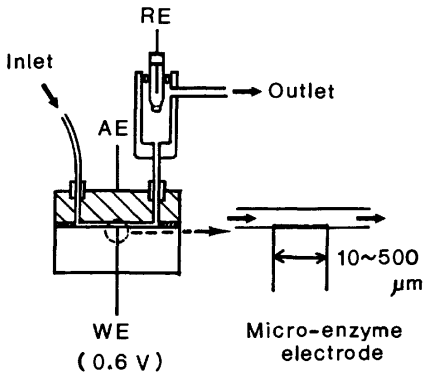

Fig. 1. Schematic diagram of instrumentation for FIA with micro-enzyme electrode.
The upper stainless steel cell is employed as an auxiliary electrode. The micro-enzyme electrode (WE) is embedded with a polyester resin in an acrylic bottom cell. The potential of the enzyme electrode is controlled at 0.6 V vs. Ag/AgCl reference electrode.

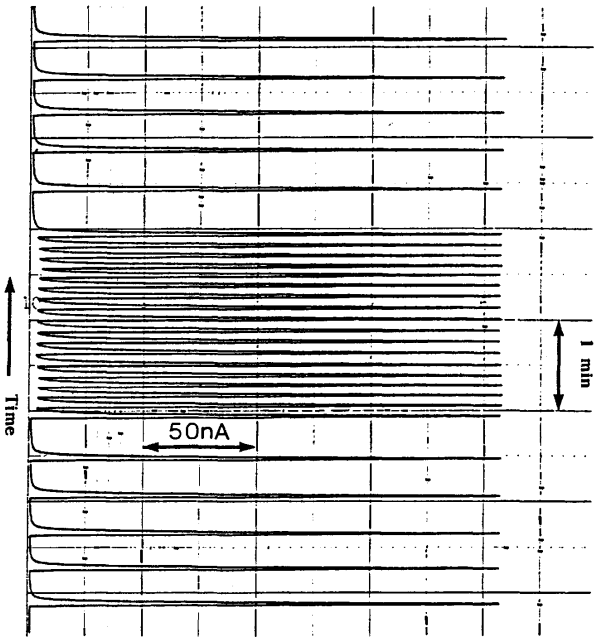

Fig. 2. Typical responses of micro-enzyme sensor system.
A micro-enzyme electrode having a diameter of 100 μm was used at a flow rate of 0.8 mL min^{-1}. Glucose (10 mM) samples were repeatedly injected. The flow-through detector showed no responses to fructose and galactose after anodic polarization.

ment the platinized enzyme electrodes showed no responses to these carbohydrates, and the enzyme electrodes demonstrated selective response to glucose. On the other hand, the anodically polarized platinized electrodes showed no responses to any carbohydrates. However, gradual polarization was observed at 0.6 V when the enzyme electrode was kept at the potential for a few hours. After the gradual oxide formation on the electrode surface at the potential, the enzyme electrode demonstrated selective response to glucose. Since a double plumger pump with a pulse damper was employed, the baseline slightly showed typical behavior of peristaltic wave.

The Relation between the Glucose Concentration and the Peak Current. A series of glucose samples whose concentrations varied from 200 μM to 20 mM were injected to the thin-layer transducer cell consisted of a 100 μm micro-enzyme electrode. Figure 3 shows the responses for the repeated injections. All the responses showed sharp peaks, reaching the peak heights in 2 or 3 s, and returned to the steady state current (residual current) in 7 or 8 s. Every glucose sample was injected 3 times, and all of the resulting three peak heights were almost same. The micro-enzyme electrode demonstrated little response to the injection of blank samples (0.1 M phosphate mobile buffer of pH 6.2). Figure 4 shows a linear relationship between the glucose concentration injected and the peak height in the glucose concentration range from 50 μM to 20 mM. As was already reported,[6,7] the micro-enzyme electrode showed high sensitivity (lowest detection limit: 0.5 μM), and wide dynamic range (0.5 μM—20 mM) in a batch system measurement, however, in this flow type measurement the detection limit still remained to be 50 μM range because of the sample dilution in the tube from the injection value to the transducer cell and of the poor signal to noise ratio due to a peristaltic wave caused by the double plunger pump. The improvement of the sensitivity seems to be easily attained by the employment of a nonperistaltic pump, by which mass transfer process from the mobile phase to the electrode is kept constant.

Figure 5 shows the relationship between the flow rate of the system and the peak height for a glucose sample of 10 mM. In the hydrodynamic voltammetry the transducer output is a function of the thickness of diffusion layer. As far as the electrochemistry between an electrode and an analyte is diffusion-controlled process, a greater response is anticipated at

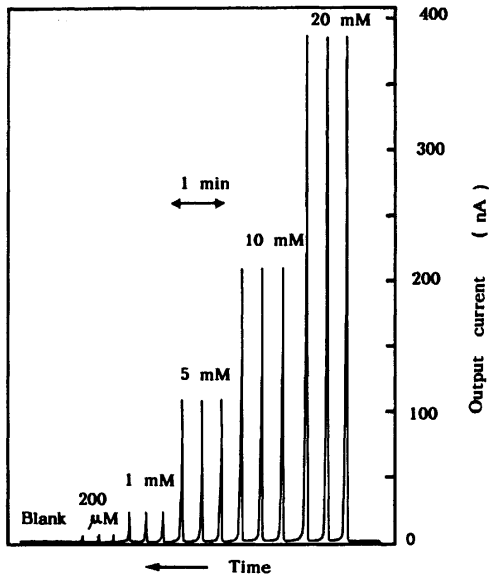

Fig. 3. Responses of micro-enzyme detector system to a series of glucose samples.
A series of glucose samples were injected to a detector system composed of a 100 μm micro-enzyme electrode at a flow rate of 0.8 mL min^{-1}.

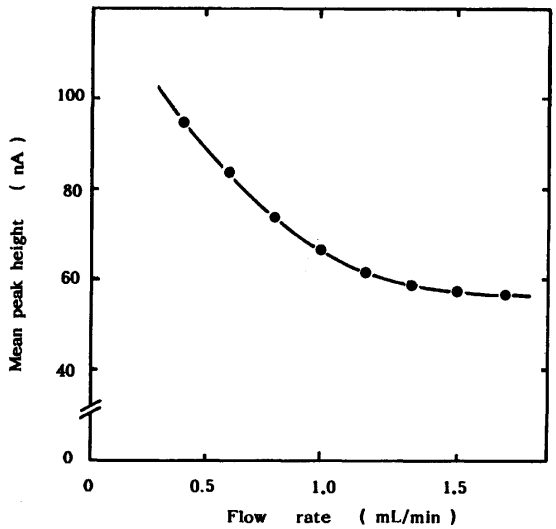

Fig. 5. Relationship between flow rate and peak height.
Micro-emyme electrode having a diameter of 50 μm and glucose sample of 10 mM was employed.

a higher flow rate.[11,12] In the case of highly porous transducer bioelectrode such as the platinized enzyme electrode being concerned, however, there are mainly three processes for the generation of sensor output: mass transfer process, enzyme reaction, and electrochemical reaction (charge transfer process). The mass transfer process in a porous electrode can be divided into two processes, i.e., mass transfer from mobile bulk solution to the apparent surface of electrode by convective flow and that within the crevasses of platinized microparticles. Both the enzyme reaction of glucose oxidase and the electrochemical oxidation of the produced hydrogen peroxide seem to be high enough to generate sensor output, since apparent K_m value (ca. 50 mM) for the enzyme electrode was much greater than the analyte concentration (10 mM), and the applied potential (0.6 V) was higher than the oxidation potential (ca. 0.45 V) of hydrogen peroxide, respectively. Therefore, it would be the mass transfer within the porous particles mainly by diffusion that determines the relation in Fig. 5.

Relation of the Micro-Enzyme Electrode Diameter to the Processing Speed. A variety of enzyme electrodes whose diameters were from 10 μm to 3 mm were prepared to study the relationship between the size of enzyme-microelectrodes and the measuring performance of the detecting system. An enzyme electrode having a diameter of 3000 μm was here employed as a reference to know the effect of miniaturization of enzyme electrode. The flow rate for this experimentation was 0.8 mL min^{-1}. Figure 6 shows the relationship of enzyme electrode diameter and the time required for the measurement of every glucose sample (10 mM). The solid line shows the time when each sample peak returns completely to the baseline, and the dotted one shows the time in which every sample peak has no interaction with each other in the continuous injections of glucose sample. One can easily understand that the smaller the enzyme electrode is employed, the faster measurement is carried out. Figure 6 shows one of the most beneficial characteristics of the microfabricated enzyme electrodes, because smaller electrodes are in shorter contact time with the injected samples.

Table 1 lists the relation of sensor diameter to coefficient of variation. Also listed are the mean sensor response of the respective electrode and the number of injection. Although the mean sensor response was related to the size of micro-enzyme electrode, the enzyme-electrode size was not reflected on the coefficient of variation as long as the enzyme-electrode diameter was in this range. On the other hand, in the case of a macro-enzyme electrode having a diameter of 3000 μm, the coefficient of variation was 1.1% for N=10.

Table 1. Coefficients of Variations of a Series of Micro-Enzyme Sensor Systems

Diameter	Mean sensor response	CV	N
μm	nA	%	
10	13.0	0.61	20
50	75.5	0.59	20
100	205	0.73	20
200	260	0.40	20
500	610	0.61	20

Precision and Reproducibility of the Micro-Enzyme Electrode for FIA of Glucose. A micro-enzyme electrode having a diameter of 100 μm was assembled in a transducer assembly for the repeated injections of 10 mM glucose. The flow rate for this time stability checking in FIA of glucose was 0.8 mL min^{-1}. The micro-enzyme electrode embedded in an acrylic bottom cell was kept in a refrigerator (4 °C) when the electrode was not used. One hundred glucose samples were injected every three days in order to evaluate precision and reproducibility. On the first and fourth days, however, fifty glucose samples were repeatedly injected. Table 2 lists the accuracy of the micro-enzyme electrode. The precision and reproducibility are here expressed as coefficient of variation (CV,%) and relative activity (%) of the micro-enzyme electrode. It is noted that the microfabricated enzyme electrodes demonstrated satisfactory precision in the FIA of glucose.

In another series of experimentations six hundred samples were injected to the flow-through enzyme electrode having a diameter of 100 μm at room temperature, and the coefficient of variation was then calculated. The mean response to 10 mM glucose sample was 252 nA at a flow rate of 0.8 mL min^{-1}. The CV was 1.9 (%) for the six hundred sample injections. One can easily notice the discrepancy that the CV for N=600 is larger than that for N=100 as listed in Table 2. Although all the experimentations were carried out at a room temperature of 23±2 °C, subtle change of the room temperature in one hour seemed to have affected the output of the flow-through enzyme electrodes. We are convinced that the CV for a great number of sample injections can be improved to be

Table 2. Precision and Reproducibility of Micro-Enzyme Sensor in FIA

Time	Relative activity	CV	N
day	%	%	
0	100	1.00	50
4	99	0.73	50
7	100	1.30	100
9	103	0.62	100
12	105	0.51	100
15	100	0.74	100
18	100	1.30	100
21	95	1.10	100
24	99	1.30	100
27	101	0.83	100
30	100	0.75	100

much smaller if the system is strictly thermostated. In the one hundred injections in ca. 10 min the subtle influence of the temperature change seemed to be negligible.

Discussion

The rapid responses of the enzyme (GO)-incorporated platinized microelectrodes can be explained by the properties of the porous platinum surface where sufficient amount of the enzyme molecules (GO) can be embodied with the highly porous platinum, and electrolytic oxidation of hydrogen peroxide proceeds smoothly on the highly catalytic surface of platinized electrode. The asymmetric shape of the response of every electrode can also be interpreted by the porous structure where a part of glucose sample can be retained within the micropores for a relatively long time, although the sample solution was throughly washed away by the mobile buffer.

The surface conditions of the platinized electrodes, both bare platinized electrodes and enzyme (GO)-embodied electrodes, play very important roles in the selective detection of glucose. The improvement of the enzyme electrode selectivity may be elucidated by the surface oxide formation at an anodic potential of ca. 1.2 V. The surface oxide formation of platinum has been uniquely utilized by Johnson et al.[13-15] for the amperometric detection of electroinactive species. In the present study, the hydrogen peroxide to be detected at the electrode seems to promote the surface oxide formation, because the enzyme-incorporated microelectrodes gradually became irresponsive to other sacccharides than glucose after several glucose injections even without anodic polarization at a potential of 0.6 V for 10 min.

One of the benefits of hydrodynamic voltammetry is the impressive detection limit,[16] however, in the FIA of glucose described here we have not succeeded in the sensitive determination of the analyte, which may have been caused mainly by the low signal-to-noise ratio due to the peristaltic wave, as long as a double plumger pump is adopted. Current and future developments are certain to improve detection limits.

A couple of literatures concerning thin-layer electrochemical cells have recently confirmed that the electrode output current depends on the solution velocity to the one-third power. The major reason why the micro-enzyme transducer cell does not obey this theoretical and experimental evidence would be the porous electrode matrix structure where diffusion-controlled as well as convection-controlled mass transfers contribute the output current. From the relationship between the output peak current and the flow rate, it may be stated that there are a few complicated processes until the peak current is generated. In the flow-through electrode like the enzyme electrode being considered, the diffusion process within the crevasses of porous matrix seems to be a rate-determining process, because the output current decreased when the flow rate increased.

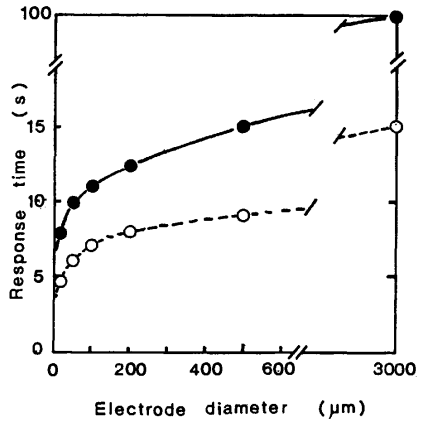

Fig. 6. Relation of micro-enzyme electrode diameter to response time.
The response times in single injection and repeated injections are represented by a solid and dotted lines, respectively.

The most remarkable benefit of miniaturization is the high processing speed of the microfabricated channel electrodes. The evidence is clear in Fig. 6. Another advantage may be the development of microinstrumentation by combining the microsensors with a micropump fabricated by silicon technology.[17]

The satisfactory precision and reproducibility of the FIA electrodes reflect the intact immobilization of enzyme (GO) molecules. Although the GO-entrapped electrode was treated in a glutaraldehyde solution for the preparation of a thin film of albumin, the enzyme molecules within the electrode matrix seemed to be kept as intact as possible.

Coating with anion membrane such as Nafion™ can be a promising approach to make the amperometric enzyme electrode irresponsive to concomitant oxidizable substances such as uricate and ascorbate,[18] however, usage of two electrodes, an enzyme-deactivated electrode and an enzyme-embodied electrode is a general strategy in practical situations, because by measuring the difference between two electrodes the FIA analyzer for glucose would be unaffected by those undesired ingredients. This approach is now under progress.

An X-Ray Diffraction Study on the Structure of Solvated Cadmium(II) Ion and Tetrathiocyanatocadmate(II) Complex in *N,N*-Dimethylformamide

Kazuhiko OZUTSUMI,§ Toshiyuki TAKAMUKU, Shin-ichi ISHIGURO,* and Hitoshi OHTAKI†
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho 4259, Midori-ku, Yokohama 227
†Coordination Chemistry Laboratories, Institute for Molecular Science, Myodaiji, Okazaki 444
(Received December 27, 1988)

The structure of solvated cadmium(II) ion and the tetrathiocyanatocadmate(II) complex in *N,N*-dimethylformamide (DMF) has been determined by means of X-ray diffraction at 25 °C. The radial distribution curve for a cadmium(II) perchlorate DMF solution is well explained in terms of the presence of the octahedral $[Cd(dmf)_6]^{2+}$ complex with the Cd-O bond length of 229.6(4) pm, which is practically the same as that within $[Cd(dmso)_6]^{2+}$ in DMSO and $[Cd(H_2O)_6]^{2+}$ in H_2O. It is also found that the tetrathiocyanatocadmate(II) complex has a tetrahedral structure, $[Cd(NCS)_3(SCN)]^{2-}$, with three Cd-N and one Cd-S bonds, the distances being 223(2) and 257(2) pm, respectively. The coordination structure of the complex in DMF is different from that found in aqueous solution, $[Cd(NCS)_2(SCN)_2]^{2-}$.

Thiocyanate ion binds to metal ions through either the nitrogen or sulfur atom depending on the nature of metal ions. According to the X-ray, Raman, and NMR studies, relatively hard zinc(II) and soft mercury(II) ions form $[Zn(NCS)_4]^{2-}$ and $[Hg(SCN)_4]^{2-}$ in aqueous solution, respectiveiy.[1] Similar coordination geometry has also been reported for the tetrathiocyanato complexes of zinc(II) and mercury(II) ions in dimethyl sulfoxide (DMSO).[2] On the other hand, cadmium(II) ion, which has intermediate hard and soft characters between zinc(II) and mercury(II) ions, forms $[Cd(NCS)_2(SCN)_2]^{2-}$ with coordinating two nitrogen and two sulfur atoms of thiocyanate ions in aqueous solution.[1] It is suggested from Raman spectroscopic and thermodynamic data that the coordination of other thiocyanato complexes of cadmium(II) ion ($[Cd(SCN)_n]^{(2-n)+}$, $n=1-3$) changes with the number of ligand ions, $[Cd(NCS)]^+$, $[Cd(NCS)(SCN)]$ and $[Cd(NCS)_2(SCN)]^-$, in aqueous solution.[3]

The complex formation between cadmium(II) and thiocyanate ions occurs extensively in *N,N*-dimethylformamide (DMF), and a different coordination mode of thiocyanate ions in the complexes in DMF from that in water has been suggested.[4] However, no direct structural information on the thiocyanato complexes has so far been given in DMF. Therefore, in this work we aimed at determining the structure of the tetrathiocyanatocadmate(II) complex in DMF by the X-ray diffraction method. In aqueous and DMSO solutions cadmium(II) ion is octahedrally coordinated with relevant solvent molecules through oxygen atoms.[5,6] Since the corresponding structure of cadmium(II) DMF solvate has been revealed neither in solution nor in the solid state, we also determined the solvation structure of cadmium(II) ion in DMF.

§ Present address: Department of Chemistry, The University of Tsukuba, Tsukuba, Ibaraki 305.

Experimental

Preparation of Sample Solutions. All chemicals used were of reagent grade. *Cadmium(II) perchlorate DMF solvate* was prepared by dissolving cadmium(II) perchlorate hydrate crystals in DMF and recrystallized three times from DMF and finally from acetone. Crystals thus obtained were dried at room temperature in a vacuum oven for several days. The analysis of the cadmium(II) perchlorate DMF solvate by EDTA titration showed the composition of $Cd(ClO_4)_2(dmf)_6$. *Cadmium(II) thiocyanate* was obtained by mixing stoichiometric amounts of aqueous cadmium(II) perchlorate and ammonium thiocyanate solutions. Crystals thus obtained were washed by suspending them in hot water and finally dried at 80 °C under atmospheric pressure. *Ammonium thiocyanate* was used without further purification and dried at room temperature in vacuum. *N,N*-Dimethylformamide was purified by the same method as described elsewhere.[4,7]

X-Ray diffraction measurements were performed for three test solutions A, B, and C (Table 1). Solution A was prepared by dissolving cadmium(II) perchlorate DMF solvate crystals in DMF. Solutions B and C were prepared by dissolving suitable amounts of cadmium(II) and ammonium thiocyanates in DMF so as to involve the tetrathiocyanatocadmate(II) complex as the main species in the solutions. Concentrations of cadmium(II) and thiocyanate ions in the sample solutions were determined by EDTA

Table 1. The Composition (mol dm^{-3}), Stoichiometric Volumes V, and Densities ρ of the Sample Solutions

	A	B	C
Cd^{2+}	0.9738	0.9854	0.9433
SCN^-	—	5.009	5.996
NH_4^+	—	3.038	4.110
ClO_4^-	1.948	—	—
DMF	12.28	9.624	8.872
ρ/g cm^{-3}	1.201	1.160	1.160
$V/10^9$ pm^3	1.705	1.685	1.760
C_{SCN}/C_{Cd}	—	5.083	6.356

titration and by gravimetry as AgSCN, respectively. Densities of the solutions were determined pycnometrically.

X-Ray Diffraction Measurements. X-Ray diffraction data were obtained on a JEOL θ-θ type diffractometer and an Mo tube (λ=71.07 pm) was used as the X-ray source. The observed range of scattering angle 2θ was from 2° to 140° and the data were recorded at least twice over the whole angle range. Corrections for absorption, polarization, and multiple scatterings of X-rays to the observed intensities were made by a usual manner as described elsewhere.[8]

The reduced intensities $i(s)$ are given as

$$i(s)=K\cdot I(s)-\sum_j n_j\cdot f_j^2(s), \qquad (1)$$

were K represents a normalization factor of the observed intensities $I(s)$ to the absolute unit, n_j the number of atom j in a stoichiometric volume and $f_j(s)$ the atomic scattering factors of atom j corrected for anomalous dispersion. The reduced intensities multiplied by s ($=4\pi\ \lambda^{-1}\ \sin\theta$) for the sample solutions are depicted in Fig. 1. The $s\cdot i(s)$ values are converted into the radial distribution function $D(r)$ as

$$D(r)=4\pi r^2\rho_o+\frac{2r}{\pi}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(rs)ds. \qquad (2)$$

ρ_o ($=\{\sum n_j\cdot f_j(0)\}^2/V$) stands for the average scattering density in a stoichiometric volume V per cadmium atom of the sample solution and s_{max} the maximum s-value available in the measurement ($s_{max}=16.6\times10^{-2}$ pm^{-1}). The modification function $M(s)$ has the form of $[\sum n_j\cdot f_j^2(0)/\sum n_j\cdot f_j^2(s)]\cdot\exp(-ks^2)$, the damping factor k being chosen as 100 pm^2 in the present case. The radical distribution curves in the form of $D(r)-4\pi r^2\rho_o$ for the test solutions are shown in Fig. 2.

A least-squares refinement for determining the structure parameters was carried out by comparing the observed and theoretical reduced intensities so as to minimize the error-square sum U,

$$U=\sum_{s_{min}}^{s_{max}} s^2\{i(s)_{obsd}-i(s)_{calcd}\}^2. \qquad (3)$$

The theoretical intensities $i(s)_{calcd}$ resulting from the interatomic interactions in the solutions are calculated as

$$i(s)_{calcd}=\sum_{p}\sum_{\substack{q\\ p\neq q}} n_{pq}f_p(s)f_q(s)\frac{\sin(r_{pq}s)}{r_{pq}s}\exp(-b_{pq}s^2), \qquad (4)$$

where r_{pq}, b_{pq}, and n_{pq} stand for the distance, the temperature factor, and the frequency factor of the atom-pair p-q, respectively.

All calculations were performed by using programs KURVLR[9] and NLPLSQ.[10]

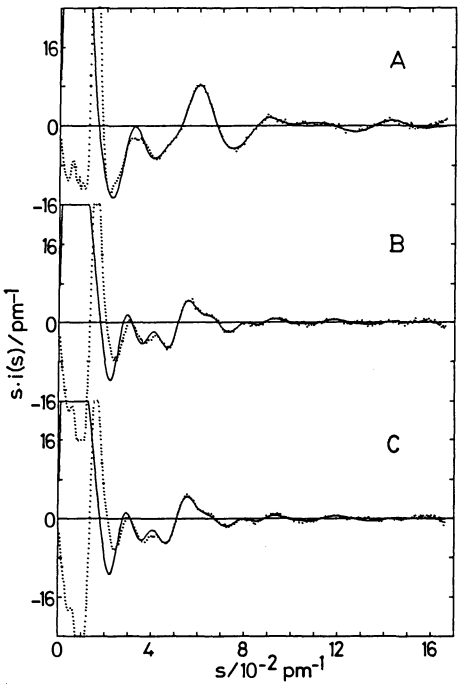

Fig. 1. The reduced intensities multiplied by s for solutions A, B, and C. The observed $s\cdot i(s)$ values are drawn by the dotted lines and calculated ones by the solid lines.

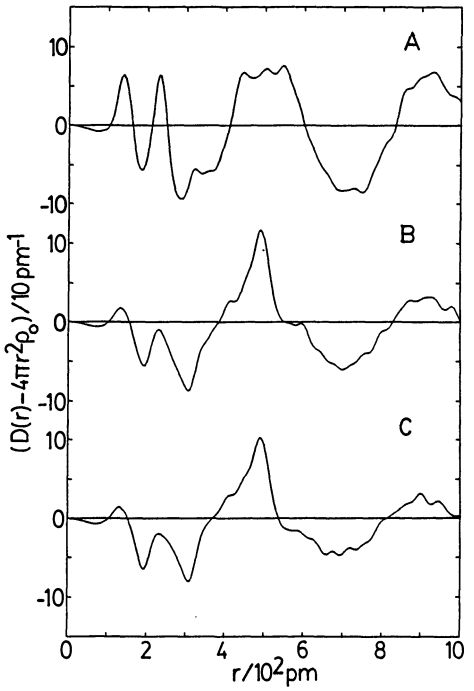

Fig. 2. The radial distribution curves in the form of $D(r)$-$4\pi r^2\rho_o$ for solutions A, B, and C.

Results and Discussion

Structure of Solvated Cadmium(II) Ion. Figure 3 shows the ($D(r)-4\pi r^2\rho_o$) curve of solution A. In the curve six peaks are observed at 140, 230, 320, 440, 500, and 550 pm. The last two peaks are originated from long distant intermolecular interactions which are not analyzed in the present study. The first peak at 140 pm is ascribable to the C-H, C-N, and C=O bonds within DMF molecules and the Cl-O bonds within perchlorate ions. The second peak at 230 pm is expected to be due to the Cd-O(dmf) bond similar to the Cd-O(H_2O) and Cd-O(dmso) bonds within the $[Cd(H_2O)_6]^{2+}$ and $[Cd(dmso)_6]^{2+}$ complexes, respectively.[5,6] The nonbonding C···C, C···O, and N···O interactions within DMF molecules and the O···O contacts within perchlorate ions also contribute to the

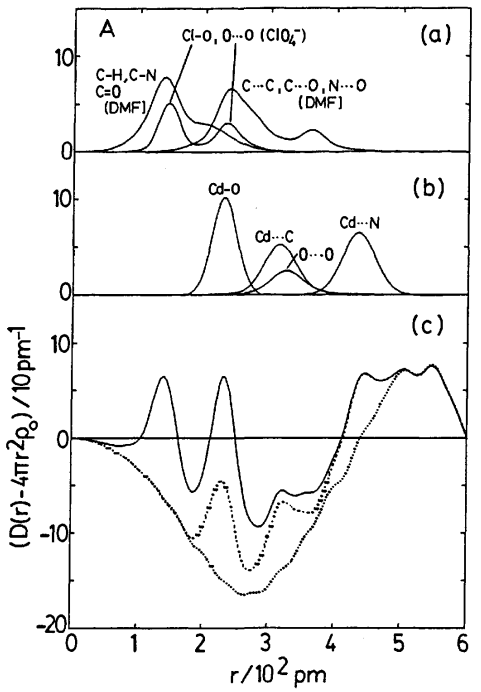

Fig. 3. The $(D(r)-4\pi r^2\rho_0)$ curve for solution A. (a) The theoretical peak shapes for intramolecular interactions within DMF molecule and perchlorate ion. (b) The peak shapes calculated for the Cd-O, Cd···C, O···O, and Cd···N interactions within the $[Cd(dmf)_6]^{2+}$ ion. (c) The chain and dotted lines represent the residual curves after subtraction of the theoretical peaks in (a) and (b), respectively, from the original one (solid line).

peak. The third and fourth peaks at 320 and 440 pm may be attributed to the nonbonding Cd···C(dmf) and Cd···N(dmf) interactions, respectively, the corresponding peaks having also been observed for the solvated copper(II) ion in DMF.[11]

In order to evaluate the structure parameters of the solvated cadmium(II) ion in DMF, the theoretical peak shapes due to the intramolecular interactions within DMF and perchlorate (Fig. 3a) are subtracted from the observed radial distribution function. The parameter values are taken from the literature.[12,13] The residual curve thus obtained (chain line in Fig. 3c) shows a large peak at 230 pm, which is ascribed to the Cd-O bonds within the solvated cadmium(II) ion. The area under the peak corresponds to six Cd-O bonds. Thus the solvated cadmium(II) ion in DMF is concluded to have an octahedral structure. Subtraction of the peaks due to the Cd-O, Cd···C, Cd···N, and O···O interactions based on the octahedral $[Cd(dmf)_6]^{2+}$ structure leads to a smooth background curve (dotted line) with no distinct peak over the range $r<450$ pm.

The least-squares method was applied to the high-angle region of $s\cdot i(s)$ values ($s>4\times10^{-2}$ pm^{-1}) to refine the structure parameters of the $[Cd(dmf)_6]^{2+}$, where the intramolecular interactions within DMF molecule, perchlorate and $[Cd(dmf)_6]^{2+}$ ions mainly contribute to the intensity values. In the course of the refinement, the structure parameters for DMF molecule and perchlorate ion were fixed at the literature values,[12,13] and the interatomic distances and the corresponding temperature factors arising from atom-pairs based on the $[Cd(dmf)_6]^{2+}$ structure were optimized. The interligand O···O distance was calculated from the Cd-O distance. The results thus obtained are summarized in Table 2, together with the structure parameters for the $[Cd(H_2O)_6]^{2+}$ and $[Cd(dmso)_6]^{2+}$ complexes. The Cd-O bond distance within the $[Cd(dmf)_6]^{2+}$ finally determined is 229.6(4) pm, and the Cd···C distance is 315(1) pm. The Cd-O-C bond angle is thus calculated to be 123°.

The structure parameters of the octahedrally solvated cadmium(II) ion in DMF, DMSO, and water in Table 2 show that the Cd-O distance within the solvated ion is not largely different within the limit of experimental uncertainties. However, the observed Cd-O bond length seems to be lengthened in the order Cd-O(H_2O)>Cd-O(dmf)>Cd-O(dmso), i.e., the decreasing order of the solvent donicity DMSO>DMF>water.[14]

Structure of $[Cd(SCN)_4]^{2-}$. According to the formation constants of cadmium(II)-thiocyanato complexes in DMF,[4] the tetrathiocyanatocadmate(II) complex is present as the main species in solutions B and C. The radial distribution curves of solutions B and C depicted in Fig. 2 were analyzed by the similar procedure to that employed for solution A. In the following discussion we describe only the result for solution C because the same conclusion was obtained for solution B. The peaks owing to the C-H, C-N, and C=O bonds within DMF molecule, the C-S and C≡N bonds within thiocyanate ion and the N-H bonds within ammonium ion appear around 100 pm, and those of the nonbonding C···C, C···O, and N···O interactions within DMF molecule and N···S interactions within thiocyanate ion give a composite peak at 200—300

Table 2. Structure Parameters for the Solvated Cadmium(II) Ion in DMF, DMSO, and Water

Interaction	Parameter	DMF	DMSO[a]	Water[b]

(b) The peak shapes for the intramolecular interactions within the $[Cd(NCS)_3(SCN)]^{2-}$ complex. (c) The chain and dotted lines represent the residual curves after subtracting the theoretical peaks in (a) and (b), respectively, from the original one (solid line).

pm. Subtraction of these peaks leads to the residual curve shown by the chain line in Fig. 4c. The peaks in the curve may mainly be ascribed to the intramolecular interactions within the tetrathiocyanatocadmate(II) complex.

The peak at 200—270 pm is doublet and thus consists of at least two kinds of interactions, probably the Cd-N and Cd-S bonds within the tetrathiocyanatocadmate(II) complex. The hump around 340 pm may be due to the intramolecular Cd···C, Cd···N, N···N, and N···S interactions within the complex. The large peak at about 500 pm is mainly due to the nonbonding Cd···S interaction between cadmium(II) ion and sulfur atom of N-bonding thiocyanate ion which has been seen also in aqueous solution.[1]

In the course of the analysis of the tetrathiocyanatocadmate(II) in DMF, we assumed as a first approximation that the distances of atom-pairs within the complex are the same as those in aqueous solution,[1] and the coordination numbers of cadmium(II) ion with nitrogen and sulfur atoms are searched by analyzing the areas under the doublet peak, the hump and the large and sharp peak at about 500 pm. The best result was obtained when we assumed the coordination numbers of three and one for the Cd-N and Cd-S bonds, respectively (Fig. 4b and c). No solvent molecule coordinates to cadmium(II) ion. Thus, we concluded that the tetrathiocyanatocadmate(II) complex has a four-coordinated tetrahedral structure, $[Cd(NCS)_3(SCN)]^{2-}$.

The structure parameters for the tetrahedral $[Cd(NCS)_3(SCN)]^{2-}$ complex in DMF were finally optimized by the least-squares method using the $s\cdot i(s)$ data in the high-angle region ($s>4\times10^{-2}$ pm^{-1}) at the fixed coordination structure. The interligand N···N and N···S distances are calculated from the Cd-N and Cd-S bond lengths and the tetrahedral structure. Since the contribution of the nonbonding Cd···C and Cd···N interactions arising from the S-bonding thiocyanate ion with cadmium(II) ion to the overall intensity is rather small, the distances are calculated from the Cd-S bond length and the Cd-S-C and Cd-S-N bond angles found in aqueous solution (106°)[1] and no significant error could be introduced by this treatment. The parameter values thus refined are given in Table 3, together with those obtained in aqueous solution.[1]

The Cd-N and Cd-S bond distances are finally determined to be 223(2) and 257(2) pm, respectively.

The tetrathiocyanatocadmate(II) complex has the

different coordination structures of $[Cd(NCS)_3(SCN)]^{2-}$ and $[Cd(NCS)_2(SCN)_2]^{2-}$ in DMF and water, respectively. The difference may be ascribed to different solvation tendency of thiocyanate ion in the two solvents. As discussed in a previous paper,[4] thiocyanate ion is strongly solvated at the hydrogen bonding N-site in water, but much weakly at the S-site. Solvation of the thiocyanate ion is much weaker in aprotic DMF with a smaller acceptor number than water, and the solvation at the N-site may be especially weakened and consequently solvation at the S-site may become even relatively stronger than that at the N-site.[15] Therefore, the formation of the Cd-N bond may become more favorable in DMF than in water and the $[Cd(NCS)_3(SCN)]^{2-}$ structure may be formed in the DMF solutions. The coordination geometry of $[Cd(NCS)_3(SCN)]^{2-}$ may be favorable rather than that of $[Cd(NCS)_2(SCN)_2]^{2-}$ in DMF in the respect of solvation of the complex itself, because the former complex exposes more S atoms of ligating SCN^- ions into the bulk DMF solvent, which may be able to better solvate than the N atoms[15] in the ligand.

The work has been financially supported by the Grant-in-Aid for Scientific Research No. 63612005 (Macromolecular Complexes) from the Ministry of Education, Science and Culture. Computer calculations were carried out at the computer center of the Institute for Molecular Science in Okazaki.

Oxidation of Lipids. XVI. Inhibition of Autoxidation of Methyl Linoleate by Diarylamines

Mareyuki TAKAHASHI, Jyunichi TSUCHIYA, and Etsuo NIKI*
Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113
(Received September 21, 1988)

The inhibition of oxidation of methyl linoleate in homogeneous solution and in aqueous dispersions by diarylamines has been studied. Diphenylamines with electron-donating substituents exhibited antioxidant activities, while those having electron-withdrawing substituents such as niflumic acid and flufenamic acid did not suppress the oxidation appreciably. When both 4,4′-dimethoxydiphenylamine and α-tocopherol were present as antioxidants, only α-tocopherol was consumed at first and when α-tocopherol was almost completely depleted, 4,4′-dimethoxydiphenylamine began to be consumed to give nitroxide radical, which further acted as antioxidant.

Oxygen is a double-edged sword: various useful and important chemicals are synthesized from the oxidations of organic compounds by molecular oxygen, but at the same time, oxygen is responsible for oxidative degradation and deterioration of plastics, rubber, oils, foods and even biological membranes and tissues.[1,2] Various kinds of both natural and synthetic antioxidants have been explored and used to protect biological, chemical, and industrial molecules from the oxygen toxicity.[3] Especially, phenols and amines have been used extensively as antioxidants.[4] The inhibition of oxidation by secondary amines has been studied by several groups.[4] Amines scavenge the chain-carrying peroxyl radicals to interrupt the chain propagation reaction giving N-centered aminyl radicals, which may dimerize, disproportionate, react with a second peroxyl radical on nitrogen to give a nitroxide or on carbon to give quinonoid products.[4-10] The diaryl nitroxides may react not only with carbon radical but also with peroxyl radicals to give quinone imine *N*-oxides.[11] Diaryl nitroxides react also with hydroperoxides. Thus, the amines are transformed by several competing reactions into various products which may also act as antioxidants. The relative importance of the above competing reactions depends on the reaction conditions and variables and hence the mechanism for antioxidant action by amines and stoichiometry also depends on the conditions.

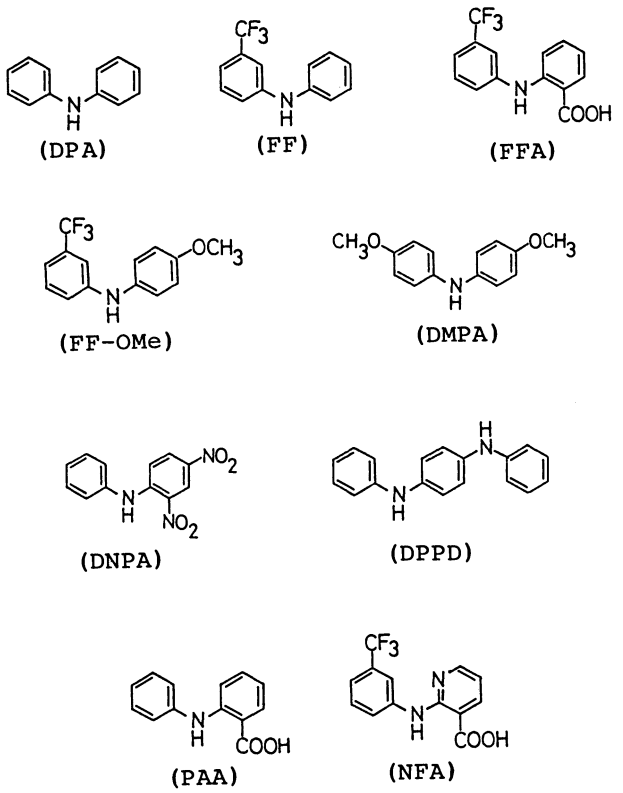

Fig. 1. Diarylamines used in this study and their abbreviations.

We have recently found that disodium 4-chloro-2,2′-iminodibenzoate and disodium 4-chloro-3′,6′-dimethyl-2,2′-iminodibenzoate, the water-soluble derivatives of diphenylamine, function as chain-breaking antioxidants in the oxidations of methyl linoleate micelles and phosphatidylcholine liposomes, oxidative hemolysis of red blood cells and in free radical-mediated damage of biological tissues.[12] The objective of the present work is to study the inhibition of oxidation of methyl linoleate by several types of lipophilic diarylamines. Figure 1 shows the diarylamines used in this study.

Experimental

Commercial methyl linoleate was purified by silica-gel column before use. 2,2′-Azobis(2,4-dimethylvaleronitrile) (AMVN) and 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) were obtained from Wako Pure Chemical Ind. and used as lipid-soluble and water-soluble radical initiators respectively. Di-*t*-butyl diperoxyoxalate (DBPO), used as a *t*-butoxyl radical source, was prepared and purified as described in the literatures.[13,14] Commercial diarylamines, galvinoxyl and 2,2-diphenyl-1-picrylhydrazyl (DPPH) were used as received. RRR-α-tocopherol was kindly supplied by Eisai Co., Ltd.

Methyl linoleate micelles were prepared as reported previously[15] by mixing methyl linoleate and aqueous solution of 10 mM Triton X-100 vigorously with Vortex mixer for 2 minutes. The oxidation was carried out at 37 °C under air. The rate of oxygen uptake was followed with either a

pressure transducer or an oxygen electrode.[15] The rates of consumption of α-tocopherol and diarylamines were followed with a high-performance liquid chromatography. Electron spin resonance (ESR) spectra were recorded on a X-band JEOL FE1X spectrometer.

Results and Discussion

Inhibition of Oxidation of Methyl Linoleate by Diarylamines. The oxidation of methyl linoleate by molecular oxygen induced by a radical initiator proceeds by a free radical chain mechanism and gives four isomeric, conjugated diene hydroperoxides quantitatively as primary products.[16-19] Therefore, the rate of oxidation can be measured quantitatively by following the rate of either oxygen uptake or conjugated diene hydroperoxides formation.[19] In the presence of AMVN but absence of diarylamine, the oxidation proceeded without induction period and a constant rate of oxygen uptake was observed. As observed previously,[15] α-tocopherol (vitamin E) suppressed the oxidation markedly and after some inhibition period, the oxidation proceeded at the similar rate as that without α-tocopherol. α-Tocopherol was consumed linearly with time and when it was depleted the inhibition period was over. Similarly, DPPD, DPA, FF-OMe, and DMPA suppressed the oxidation, but FF, FFA, PAA, DNPA, and NFA did not suppress the oxidation. The pertinent results are summarized in Table 1. It can be seen that electron-donating substituent such as methoxy group on the aromatic ring promotes the antioxidant activity of diarylamine while electron-withdrawing substituent such as trifluoromethyl and nitro group reduces its antioxidant activity. Table 1 shows that DMPA, DPPD, and α-tocopherol act as strong antioxidants and suppress the oxidation markedly, while FF-OMe and DPA function less efficiently and reduce the rate of oxidation (R_{inh}/R_p) to one half to one fourth. Niflumic acid (NFA)[20] and flufenamic acid (FFA)[21] known as anti-inflammatoires had little antioxidant activities.

a) Induction period. b) Rate of oxidation during the induction period. c) Rate of oxidation without antioxidant or after induction period.

Figure 2 shows the plot of inhibition period as a function of [IH]/[AMVN], where IH is an antioxidant such as diarylamine and α-tocopherol. As observed previously, the inhibition period was proportional to the antioxidant concentration and inversely proportional to the rate of chain intiation.[15,22-27]

Figure 3 shows the rates of disappearance of α-tocopherol and FF-OMe during the oxidation of methyl linoleate in benzene in the presence of both antioxidants. Interestingly, α-tocopherol was consumed first, while FF-OMe remained constant at first and it began to be consumed after substantially all of α-tocopherol disappeared. Fast oxidation took place when both antioxidants were depleted.

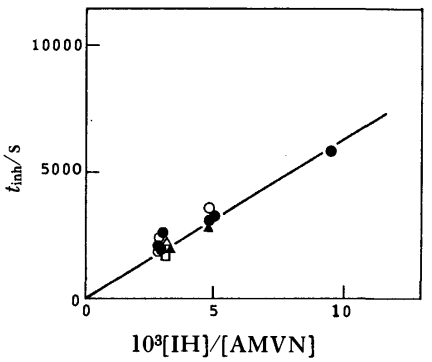

Fig. 2. Plot of inhibition period as a function of [IH]/[AMVN] in the oxidation of methyl linoleate in benzene at 37 °C initiated with AMVN and inhibited by α-tocopherol and diarylamines.
□: α-Tocopherol, ○: DPA, ●: FF-OMe, ▲: DMPA, △: DPPD.

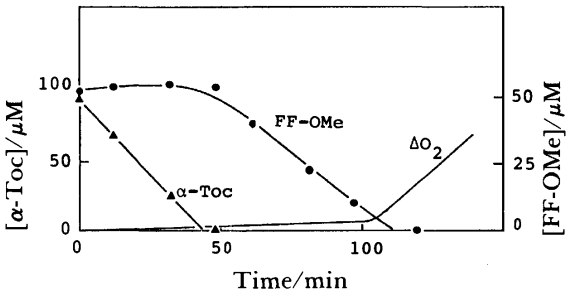

Fig. 3. Rates of disappearance of α-tocopherol and FF-OMe during the oxidation of 151 mM methyl linoleate in benzene initiated with 16.1 mM AMVN at 37 °C under air in the presence of both antioxidants. [α-TOC]=100 μM, [FF-OMe]=50 μM.

Inhibition of Oxidation of Methyl Linoleate Micelles. The oxidation of methyl linoleate micelles in Triton X-100 aqueous dispersions proceeds similarly and gives conjugated diene hydroperoxides quantitatively.[15] AAPH dissolved in water produces free radicals in the aqueous phase and they attack methyl linoleate and induce free radical chain oxidation. Table 2 shows some pertinent results of the oxidation of methyl linoleate micelles induced by AAPH in the presence of diarylamines or α-tocopherol. DPA, DPPD, DMPA, and α-tocopherol inhibited the oxidation, but FFA and PAA did not. As shown in Fig. 4, the inhibition period was again proportional to the antioxidant concentration and inversely proportional to the rate of chain initiation.

Figure 5 shows the rates of consumption of antioxidants during the oxidations of methyl linoleate micelles in aqueous dispersions inhibited by both α-tocopherol and DMPA. As observed in the homogeneous solution, α-tocopherol was consumed first and after all of α-tocopherol disappeared, DMPA was consumed. When both antioxidants were depleted, a fast oxidation proceeded.

ESR Spectra of Radicals Derived from Diarylamines. Figure 6 shows the ESR spectra observed in the oxidations of methyl linoleate in benzene and in aqueous dispersions inhibited with DMPA. Figure 7 shows the relative amount of radicals observed in the oxidation of methyl linoleate micelles initiated with AAPH and inhibited by both α-tocopherol and DMPA. The ESR spectrum of α-tocopheroxyl radi-

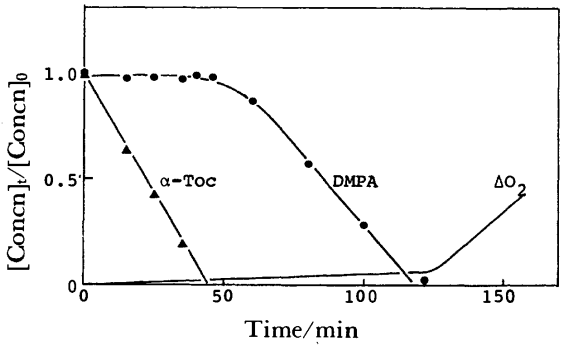

Fig. 5. Rates of disappearance of α-tocopherol and DMPA during the oxidation of 116 mM methyl linoleate micelles in aqueous dispersions initiated with 21.5 mM AAPH and inhibited by 50 μM α-tocopherol and 50 μM DMPA at 37 °C.

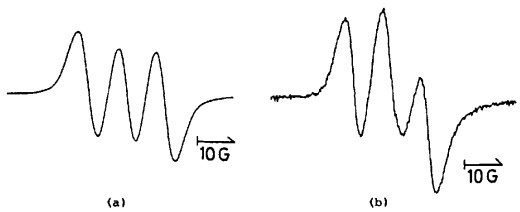

Fig. 6. ESR spectra observed (a) in the oxidation of 151 mM methyl linoleate in benzene at 37 °C under air initiated with 72 mM AMVN in the presence of 204 μM DMPA and (b) in the oxidation of 302 mM methyl linoleate micelles in 10 mM Triton X-100 aqueous dispersions at 37 °C under air initiated with 92.3 mM AAPH in the presence of 600 μM DMPA.

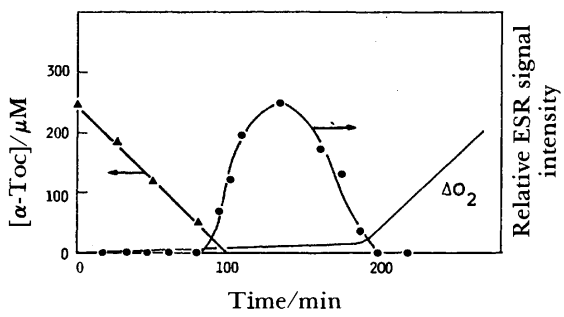

Fig. 7. Relative amount of radical observed during the oxidation of 302 mM methyl linoleate micelles in aqueous dispersions initiated with 92.3 mM AAPH and inhibited by both 204 μM DMPA and 244 μM α-tocopherol at 37 °C under air.

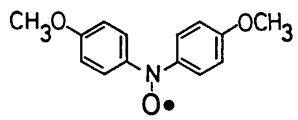
cal (phenoxyl radical from α-tocopherol) is well characterized,[28] but the ESR signal for α-tocopheroxyl radical was not observed, probably because it reacted rapidly with peroxyl radical to give a stable adduct.[29] As Fig. 7 shows, little ESR signal was observed at the initial stage, when only α-tocopherol was consumed. After α-tocopherol was depleted and when DMPA began to be consumed, ESR signal intensity increased and after passing a maximum it decreased. When most of ESR signal disappeared, the rapid oxidation took place.

These results suggest that DMPA scavenges peroxyl radical to give intermediate radical which gives ESR signal and then reacts with another radical to give a stable product. The identification or assignment of the ESR signal observed is difficult at present. It has been reported that 4,4′-dimethoxydiphenylaminyl radical and its *N*-oxyl radical have coupling constants of $a^N=0.849$ mT and $a^N=1.006$ mT, respectively.[30] Since the coupling constant for the radicals observed in this study was 1.0 mT, the radicals shown in Fig. 6 may be ascribed to *N*-oxyl radical **1**.



1

DPA, FFA, and PAA do not react with galvinoxyl nor with DPPH, suggesting that the diarylaminyl radicals derived therefrom are less stable than galvinoxyl and DPPH. However, when these amines were dissolved in benzene containing DBPO, ESR signals were observed and the solution was colored to brown. Figure 8 shows the ESR spectra observed for DPA, FFA, and PAA, respectively.

$$(CH_3)_3COOC(=O)C(=O)OC(CH_3)_3 \rightarrow 2(CH_3)_3CO^{\cdot}+2CO_2 \quad (1)$$

$$(CH_3)_3CO^{\cdot}+Ar_2NH \rightarrow (CH_3)_3COH+Ar_2N^{\cdot} \quad (2)$$

$$(CH_3)_3CO^{\cdot} \rightarrow (CH_3)_2C=O+CH_3^{\cdot} \quad (3)$$

$$CH_3^{\cdot}+O_2 \rightarrow CH_3O_2^{\cdot} \quad (4)$$

$$CH_3O_2^{\cdot}+Ar_2N^{\cdot} \rightarrow CH_3O^{\cdot}+Ar_2NO^{\cdot} \quad (5)$$

When these amines were dissolved in benzene containing both DBPO and *t*-butyl hydroperoxide, the same ESR spectra were observed and the solution became brown similarly. This system generates *t*-butylperoxyl radical[31] and the *N*-oxyl radical must be formed by a sequence of reactions 1, 6, 7, and 8.

$$(CH_3)_3CO^{\cdot}+(CH_3)_3COOH \rightarrow (CH_3)_3COH+(CH_3)_3COO^{\cdot} \quad (6)$$

$$(CH_3)_3COO^{\cdot}+Ar_2NH \rightarrow (CH_3)_3COOH+Ar_2N^{\cdot} \quad (7)$$

$$(CH_3)_3COO^{\cdot}+Ar_2N^{\cdot} \rightarrow (CH_3)_3CO^{\cdot}+Ar_2NO^{\cdot} \quad (8)$$

The ESR spectrum shown in Fig. 8(a) obtained for DPA is the same as that of diphenyl nitroxide radical reported by Mukai et al.[32] Furthermore, the same ESR spectrum was observed as that of Fig. 8(a) when phenylazotriphenylmethane was decomposed thermally under vacuum in benzene containing nitrosobenzene, oxygen was added, and then evacuated again: $a^N=0.990$ mT, $a^H_{o,p}=0.184$ mT, $a^H_m=0.078$ mT.

Thus the results of the present study and those reported in the literature suggest that diarylamines such as DPA, FF-OMe, and DMPA suppress the oxidation mainly by the following sequence:

$$LO_2^{\cdot}+Ar_2NH \rightarrow LOOH+Ar_2N^{\cdot} \quad (9)$$

$$LO_2^{\cdot}+Ar_2N^{\cdot} \rightarrow LO^{\cdot}+Ar_2NO^{\cdot} \quad (10)$$

(or ketone + hydroxylamine)

$$L\cdot(LO_2^{\cdot})+Ar_2NO^{\cdot} \rightarrow \text{stable product} \quad (11)$$

On the other hand, *N*,*N*′-dipheyl-1,4-phenylenediamine (DPPD) behaves differently. DPPD donates hydrogen atom to a peroxyl radical and the resulting aminyl radical must donate one more hydrogen atom to another peroxyl radical to give benzoquinone diimines without generating nitroxide radical.

$$LO_2^{\cdot}+Ph\text{-}NH\text{-}Ph\text{-}NH\text{-}Ph \rightarrow LOOH+Ph\text{-}\dot{N}\text{-}Ph\text{-}NH\text{-}Ph \quad (12)$$

$$LO_2^{\cdot}+Ph\text{-}\dot{N}\text{-}Ph\text{-}NH\text{-}Ph \rightarrow LOOH+Ph\text{-}N{=}\langle\bigcirc\rangle{=}N\text{-}Ph \quad (13)$$

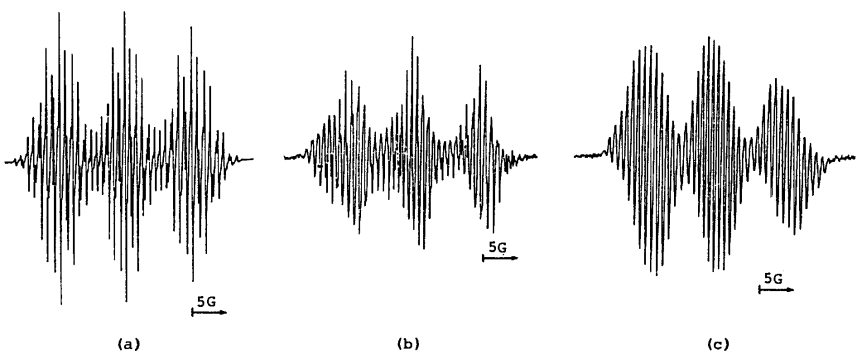


Fig. 8. ESR spectra observed when diarylamines were dissolved in benzene containing DBPO under vacuum at room temperature.
(a) DPA; (b) FFA; (c) PAA.

Under these conditions, each molecule of diarylamines scavenges two molecules of radicals and, as shown in Figs. 2 and 4, they produce similar inhibition period as α-tocopherol which also scavneges two molecules of peroxyl radicals.[22]

Oxidation of Lipids. XVII. Crossover Effect of Tocopherols in the Spontaneous Oxidation of Methyl Linoleate†

Mareyuki TAKAHASHI, Yasuyuki YOSHIKAWA, and Etsuo NIKI*
Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113
(Received September 21, 1988)

Tocopherols suppressed the spontaneous, thermal oxidation of methyl linoleate and produced a clear induction period. During the induction period, small amounts of *cis,trans*-hydroperoxides were formed but the formation of *trans,trans*-hydroperoxides was almost completely inhibited. Tocopherols were consumed and when they were depleted, the induction period was over and a fast oxidation proceeded to give more *trans,trans*-hydroperoxides than *cis,trans*-hydroperoxides. However, tocopherols, especially α-tocopherol, acted as prooxidants when their concentrations were extraordinarily high and the rate of initial radical formation was low. The reducing agent such as ascorbic acid diminished the prooxidant action of α-tocopherol. This prooxidant effect of tocopherols was ascribed to the spontaneous formation of tocopheroxyl radical followed by the hydrogen atom abstraction by the tocopheroxyl radical from the hydroperoxide to give a peroxyl radical.

Lipids are readily oxidized by molecular oxygen. There is an increasing number of evidence that shows the deleterious effects of the oxidation of lipids and its products in foods and in biological systems, and, accordingly, the inhibition of the oxidation of lipids has received much attention recently.[1-11] The aerobic organisms are protected against such oxygen toxicity by an array of defense systems: the preventive antioxidants such as glutathione peroxidase and catalase suppress or reduce the formation of active free radicals by decomposing without generation of free radicals lipid hydroperoxides and/or hydrogen peroxide which are precursors to free radicals, while the chain-breaking antioxidants such as vitamin E and vitamin C scavenge the radicals and interrupt the chain propagation. On the other hand, various kinds of natural and synthetic antioxidants are added to the edible oils and fats to suppress their oxidations. Tocopherols (vitamin E) are known as natural, potent chain-breaking antioxidants. In fact, it has been shown that tocopherols, especially α-tocopherol, scavenge the peroxyl radicals faster than any synthetic, phenolic antioxidants such as 2,6-di-*t*-butyl-4-methylphenol (BHT).[7-11] On the other hand, however, it has been also observed that α-tocopherol can act as a prooxidant under certain conditions.[12-23] For example, Olcott and Einset[13] found that the addition of α-tocopherol into the stabilized oil induced the oxidation during the induction period. Cillard and Cillard[15-17,19,20,22,23] have also observed that tocopherols can act as prooxidants depending on the conditions. More recently, Terao and Matsushita[21] reported the similar effect of α-tocopherol in the oxidation of methyl linoleate. A prooxidant effect of α-tocopherol quinone has been also reported.[24] The detailed mechanism for such a "crossover effect" of α-tocopherol is not well understood. In the course of our study on the oxidation of lipids and its inhibition, we have studied in the present work the prooxidant effect of tocopherols in the spontaneous oxidation of methyl linoleate. Methyl linoleate was chosen as a substrate since the mechanism of its oxidation is well established to give quantitatively four isomeric conjugated diene hydroperoxides, 13-hydroperoxy-9-*cis*,11-*trans*-, 13-hydroperoxy-9-*trans*,11-*trans*-, 9-hydroperoxy-10-*trans*,12-*cis*-, and 9-hydroperoxy-10-*trans*,12-*trans*-octadecadienoic acid methyl esters.[25-29] Thus, it is possible to follow the oxidation quantitatively by measuring either the oxygen uptake, substrate disappearance, hydroperoxide formation or conjugated diene formation.[29] This study confirms some of the previous observations, adds some new data and render a conclusion on the crossover effect of tocopherols.

Experimental

Natural *R,R,R*-α-, *R,R,R*-β-, *R,R,R*-γ-, and *R,R,R*-δ-tocopherols were kindly supplied by Eisai Co., Ltd. Commercial ascorbic acid and its esters were used as received. Methyl linoleate purchased from Daigo Chemical Co. was purified by a silica-gel column before use. *t*-Butyl hydroperoxide kindly supplied by Nippon Oil and Fats Co. was distilled under reduced pressure, 42 °C/24 Torr (1Torr=133.322 Pa). Commercial 2,2-diphenyl-1-picrylhydrazyl (DPPH) was used as received.

Methyl linoleate and additives were dissolved in methyl decanoate and placed in the dark or under laboratory light at room temperature or at 37 °C in air. Sample size was 5 ml. Aliquots of the sample were taken out at regular intervals and analyzed as follows.

The methyl linoleate hydroperoxides were analyzed as their corresponding alcohol, after reduction of the product solution with triphenylphosphine, by high-pressure liquid chromatography (HPLC) using a silica-gel column and hexane/isopropyl alcohol/acetic acid (1000:10:1, v/v/v) as the eluent. The rate of consumption of tocopherols was followed by HPLC with a Finepak SIL 18 column. Methanol was delivered as an eluent at 1 ml min^{-1} and the eluent was monitored at 290 nm. ESR spectrum was

† This work was presented at the 24th General Meeting of the Japan Oil Chemists' Society, October, 1985, Osaka.

recorded on X-band JEOL FE1X spectrometer at room temperature.

Results

Tocopherols are active radical scavengers and efficiently suppress the oxidations of methyl linoleate initiated by a radical initiator.[7,11,29-31] Tocopherols are consumed by the reactions with peroxyl radicals and, when they are depleted, a fast oxidation proceeds.[30] It was found that polyunsaturated fatty acids such as linoleic acid and its esters were oxidized spontaneously even in the absence of any radical initiator. Figure 1 shows the results of spontaneous oxidation of methyl linoleate at room temperature under normal laboratory light in air in the absence and presence of α-tocopherol. In the absence of α-tocopherol, methyl linoleate was slowly oxidized without any noticeable induction period and the conjugated diene hydroperoxides accumulated with time. When 0.25 mM (1 M=1 mol dm^{-3}) of α-tocopherol was added, the oxidation was suppressed and little accumulation of hydroperoxides was observed in about 10 days. α-Tocopherol decreased at roughly constant rate and it was depleted in 14 days. The hydroperoxides were gradually formed as α-tocopherol disappeared. Figure 1 also shows the effect of initial amount of methyl linoleate hydroperoxide. As the initial concentration of methyl linoleate hydroperoxide was increased, the rate of consumption of α-tocopherol increased and the duration of induction period was shortened. In every case, fast oxidation proceeded when α-tocopherol disappeared.

Other tocopherols also suppressed the spontaneous oxidation of methyl linoleate similarly. When α-, β-, γ-, and δ-tocopherols were added simultaneously into methyl linoleate and the solution was stood at room temperature in air under laboratory light, tocopherols were consumed as shown in Fig. 2. As observed previously[30] in the oxidation of methyl linoleate initiated with a radical initiator, α-tocopherol was consumed first, β- and γ-tocopherols decreased after most of α-tocopherol disappeared, and finally δ-tocopherol was consumed. These results may be ascribed partly to the different reactivities of tocopherols (α>β>γ>δ) toward peroxyl radials[7,11,32] and also to the interactions between tocopheroxyl radical (oxyl radical from tocopherol) and tocopherol.[30] For example, α-tocopherol reacts with β-, γ-, and δ-

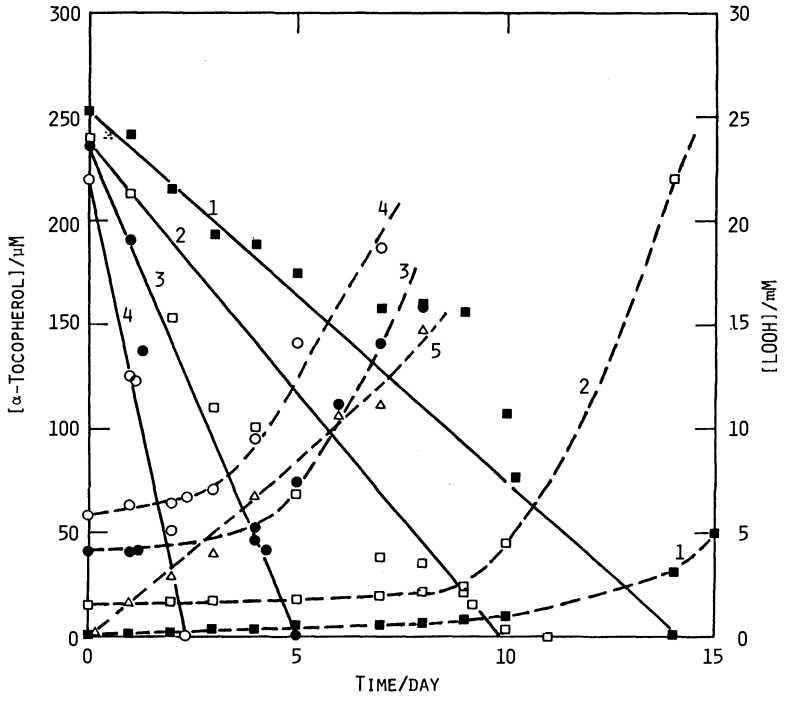

Fig. 1. Rate of accumulation of hydroperoxides (------) and α-tocopherol disappearance (———) in the spontaneous oxidation of methyl linoleate at room temperature under laboratory light.

tocopheroxyl radicals to give α-tocopheroxyl radical and corresponding tocopherols. Mukai has also observed that the reactivities toward phenoxyl radical decreased in the order of α->β-=γ->δ- tocopherols.[33]

Figure 3 shows the distribution of *cis,trans*- and *trans,trans*-hydroperoxides formed in the spontaneous oxidation of methyl linoleate in air under laboratory light in the presence of α-tocopherol. As described above, α-tocopherol suppressed the oxidation and when it was consumed completely, the oxidation proceeded rapidly. Interestingly, when α-tocopherol was present, only *cis,trans*-hydroperoxides were formed and little *trans,trans*-hydroperoxides were observed, whereas more *trans,trans*-hydroperoxides were formed

than *cis,trans*-ones after α-tocopherol was depleted.

Thus, α-tocopherol generally acts as an antioxidant and suppresses the spontaneous oxidation of methyl linoleate as well as the oxidation initiated with a radical initiator. However, when the rate of oxidation is quite slow or when the concentration of tocopherol is extraordinarily high, it may act as a prooxidant. When methyl linoleate was stood in air under laboratory light in the presence of 0.296, 2.43, and 18.3 mM α-tocopherol, the rate of hydroperoxide formation increased with increasing concentration of α-tocopherol (data not shown).

When methyl linoleate was stood at 37 °C in the dark, it was oxidized much slower than that stood under laboratory light. Under these conditions, α-tocopherol had a prooxidant effect even at relatively low concentrations. Figures 4 and 5 show the results observed when methyl linoleate was stood in the dark. The addition of tocopherols increased the initial rate of hydroperoxide accumulation with increasing α-tocopherol concentration (Fig. 4) and α-tocopherol had more profound effect than β- and γ-tocopherols (Fig. 5).

Discussion

α-Tocopherol acts as an antioxidant by scavenging chain-carrying peroxyl radical and breaking a chain propagation sequence. In fact, it is known that α-tocopherol scavenges peroxyl radicals much faster than the synthetic, hindered phenols often used commercially as antioxidants.[7,34,35] α-Tocopherol also suppresses the formation of *trans,trans*-hydroperoxide from methyl linoleate. The oxidation of methyl linoleate proceeds by a scheme shown in Fig. 6.[26,27] When the concentrations and/or activities of hydrogen donors are high, the peroxyl radical **1** rapidly abstracts a hydrogen atom to give *cis,trans*-hydroperoxide **2**, while the peroxyl radical **1** has more chance to release oxygen and yield the peroxyl radical **3** which eventually gives *trans,trans*-hydroperoxide **4** when the concentrations of active hydrogens are low. Thus, α-tocopherol acts as a strong hydrogen donor and gives *cis,trans*-hydroperoxide exclusively.[26,27,36-38]

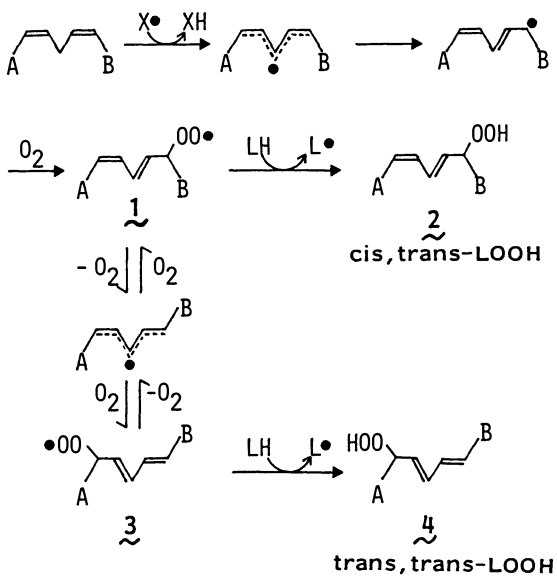

Fig. 6. Scheme for the oxidation of methyl linoleate.
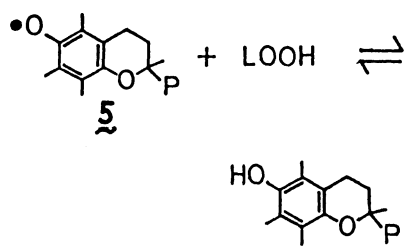
A, B: $CH_3(CH_2)_4$-, $CH_3OC(O)(CH_2)_7$-.

However, as reported previously by other investigators[12-23] and as observed in this study, α-tocopherol can act as a prooxidant under certain circumstances, for example, when the rate of chain initiation is quite low and when the concentration of α-tocopherol is quite high. The prooxidant effect of α-tocopherol must stem from the hydrogen atom abstraction from hydroperoxide by α-tocopheroxyl radicals **5** (reaction 1),



(1)

where P is a phytyl side chain, $C_{16}H_{33}$. This reaction may proceed rapidly. In fact, as shown in Fig. 7, when *t*-butyl hydroperoxide was added to the benzene solution containing α-tocopheroxyl radical, tocopheroxyl radical disappeared quite rapidly. The rate constants for the hydrogen atom abstraction from

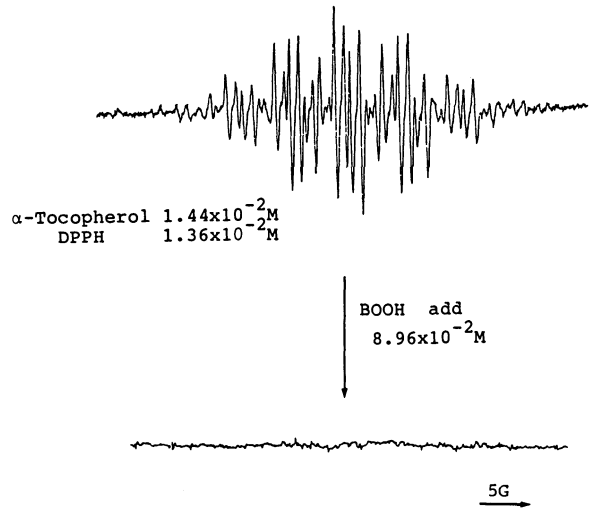


Fig. 7. ESR spectra observed when *t*-butyl hydroperoxide was added to the benzene solution containing α-tocopheroxyl radical.
A: ESR spectrum observed when 14.4 mM α-tocopherol was reacted with 13.6 mM DPPH in benzene. The spectrum was taken under vacuum. B: ESR spectrum observed under vacuum when 89.6 mM *t*-butyl hydroperoxide was added into the solution A.

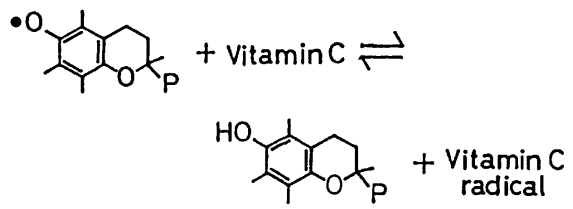
hydroperoxide by phenoxyl radicals have been reported.[39-41] Mukai et al.[42] reported quite recently the rate constant for the hydrogen atom abstraction from *t*-butyl hydroperoxide by 5,7-diisopropyl-6-chromanoxyl radical as 0.365 $M^{-1}s^{-1}$ at 25 °C. Considering the steric effect involved in the hydrogen atom transfer from hydroperoxide to a phenoxyl radical,[39,43,44] the hydrogen atom abstraction from lipid hydroperoxide by α-tocopheroxyl radical must be larger than that. The peroxyl radical formed in the reaction 1 must attack lipid and induce the chain oxidation. The direct attack of α-tocopheroxyl radical on the methyl linoleate can not be ruled out, although it must be much less favorable than the reaction 1.

As reported previously,[30,32,33] the stabilities of tocopheroxyl radicals decrease in the order of $\alpha>\beta=\gamma>\delta$, suggesting that α-tocopheroxyl radical is formed most easily among the four tocopheroxyl radicals. This must explain why α-tocopherol has the most profound prooxidant activity among the four tocopherols. Terao and Matsushita[21] found that BHT did not act as prooxidant for methyl linoleate. This must be because the phenoxyl radical derived from BHT is much less resonance-stabilized[32] and the spontaneous formation of the phenoxyl radical from BHT is quite slow.

In consistent with the above assumption, the prooxidant effect of α-tocopherol was diminished by a reducing agent such as ascorbic acid and its esters. As observed previously by Terao,[21] little prooxidant effect of α-tocopherol was observed in the presence of ascorbic acid esters such as 6-ascorbyl palmitate. Ascorbic acid added to the methyl linoleate as an ethanol solution also had a similar effect. It has been previously observed by pulse radiolysis[45] and ESR[46] studies that α-tocopheroxyl radical is reduced by ascorbic acid to regenerate α-tocopherol. Packer, Slater and Willson[45] obtained a value of 1.55×10^6 $M^{-1}s^{-1}$ as rate constant for the reaction 2. Mukai et al.[47] has recently obtained a rate constant of 549 $M^{-1}s^{-1}$ for the interaction between ascorbic acid and 5,7-diisopropyltocopheroxyl radical.

The crossover effect of α-tocopherol depends on the relative importance of the first step and the following competing reactions 2 and 3, which is determined by the ratio of the concentration of lipid peroxyl radical to that of lipid hydroperoxide. When this ratio is high as in the oxidations initiated with an added initiator, under light, or at high temperature, α-tocopherol functions as an antioxidant, while it acts as a prooxidant when this ratio is low. The higher the α-tocopherol concentration, the more α-tocopheroxyl radical must be formed spontaneously. Furthermore, α-tocopherol must give its radical most easily than any other tocopherols and synthetic phenols.

The prooxidant effect of vitamin E in vivo has not been reported. This may be because the concentration of vitamin E is usually low and/or because the vitamin E radical is reduced readily by, for example, vitamin C in biological systems.



In conclusion, α-tocopherol functions in general as a chain-breaking antioxidant, but it may also act as a prooxidant under certain conditions, for example, when its concentration is quite high or when the rate of oxidation (that is, the rate of chain initiation) is very low. It may be said that the antioxidant, like oxygen molecule, is also a double-edged sword.

(Received September 24, 1988)

Substituted (*RS,SR*)-1-phenylethyl phenyl sulfoxides (threo) ($XC_6H_4S(O)CH(CH_3)C_6H_4Y$) and some substituted (*RR,SS*)-sulfoxides (erythro) were prepared and kinetic investigation for the thermal decomposition was carried out at 80.0, 90.0, and 100.0 °C in dioxane. Hammett plots for *threo*-$XC_6H_4S(O)CH(CH_3)C_6H_5$ gave positive ρ-values (ρ_X=0.60—0.64 at three temperatures), while those for *threo*- and *erythro*-$C_6H_5S(O)CH(CH_3)C_6H_4Y$ showed V-shape lines with bottoms at the *m*-OCH_3 substituent though the effects of the substituents are small. Meanwhile, large kinetic isotope effects for *threo*- and *erythro*-$C_6H_5S(O)CH(CD_3)C_6H_4Y$ (Y=H, *p*-OMe, *m*-Cl) (k_H/k_D=4—6) were observed at all temperatures. The activation energies were in the range of 104—121 kJ mol^{-1} for all sulfoxides, while the activation entropies were relatively large (7—−37 J K^{-1} mol^{-1}) and were correlated with Hammett σ-values to give small negative trend. Reactions of all erythro-isomers examined were 2—3 times faster than those of the corresponding threo-isomers. From these results, it is suggested that the pyrolysis of 1-arylethyl aryl sulfoxides proceeds via a concerted mechanism in which the transition state is variable from an E1-like to a conjugated one. In the latter transition state, conjugation of the phenyl group bearing the electron-withdrawing substituent with the developing π-bond electron acidifies the β-proton.

Thermolysis of sulfoxides bearing at least one β-hydrogen atom has been shown to proceed via an intramolecular cis elimination[1] affording olefins[2-8] and sulfenic acids which are dimerized to thiosulfinic S-esters or can be trapped by activated olefins.[9-16] Cram et al.[1] prposed a radical mechanism based on the observation of loss of stereospecificity for the pyrolysis of 1,2-diphenyl-1-propyl phenyl sulfoxides at high temperatures. However, no evidence suggesting the radical mechanism has been reported ever since. Though the Ei-reaction of sulfoxides is generally regarded as a concerted process, some kinetic investigations using aryl propyl sulfoxides[17] or aryl *t*-butyl sulfoxides[8] reveal that electron-withdrawing substituents on the phenyl ring accelerate the reaction suggesting the polarization of the carbon-sulfur bond and development of partially negative charge on the sulfinyl group in the transition state. From these results, development of partially positive charge on the α-carbon atom, i.e., E1-like mechanism, has been assumed. However, we recently proposed a carbanion-like mechanism for the pyrolysis of 2-phenylethyl phenyl sulfoxide which showed positive trends for Hammett substituent effects on both phenyl groups (ρ_X=0.76 for $XC_6H_4S(O)CH_2CH_2Ph$, ρ_Y=0.32 for $PhS(O)CH_2CH_2C_6H_4Y$). These results reveal that partial charge on the α-carbon atom in the transition state cannot be determined without an examination of the substituent effect on the α-position.

Meanwhile, Oae et al. reported the mechanistic investigation of Ei-reaction of sulfilimines which have isoelectronic structure to the sulfoxides. They suggested cis-concerted E1-like mechanism.[18-21]

In order to clarify the transition state of the Ei-reaction of sulfoxides and to compare with that of sulfilimines, kinetic investigation of the thermolysis of substituted *threo*- and *erythro*-1-phenylethyl phenyl sulfoxides was carried out.

Results

Preparation of Substituted 1-Phenylethyl Phenyl Sulfoxides and Their Diastereoisomer. The substituted *threo*- and *erythro*-1-phenylethyl phenyl sulfoxides were prepared from the corresponding sulfides by oxidation with hydrogen peroxide in acetic acid. The mixture of threo- and erythro-isomers obtained were separated by fractional crystallization and repeated column chromatography. The *threo*- and *erythro*-sulfoxides obtained were tentatively assigned as follows. ^1H NMR chemical shifts of methine protons of the sulfoxides were plotted against Hammett σ-values as shown in Fig. 1.

Apparently, two series of methine signals were observed. The higher field one could be assigned as that of threo isomer by comparing with that of 1-phenylethyl phenyl and 1-phenylethyl *p*-tolyl sulfoxides whose absolute configurations[22,23] are known. A similar series of ^1H NMR methine signals of 1-phenylethyl (*p*-substituted phenyl) sulfoxides and their lanthanoid-induced shifts, solvent effects, and assignments of their absolute configurations were reported.[24,25]

Upon heating the sulfoxides in carbon tetrachloride at 100 °C for 15—20 min, formation of the substituted styrenes were observed by NMR and liquid chromatography. If the reaction should be accompanied by a possible threo-erythro isomerization due to a pyramidal inversion[30] on sulfur atom or a homolytic cleavage like in the racemization of benzyl *p*-tolyl sulfoxide at 135—165 °C,[31] the kinetic behavior should be complicated. But the NMR spectra showed no contamination of the threo-erythro isomerization, also sug-

gesting that the radical mechanism is unlikely.

Kinetics. The reaction was followed by measuring the decreasing peak area of the sulfoxide in liquid chromatography using diphenyl ether, diphenyl sulfide or methyl phenyl sulfide as an internal standard. The process of the reactions was found to follow good first-order kinetics and the rate constants had no dependence on initial concentration of the sulfoxides. The results obtained are listed in Table 1 and Hammett substituent effects are compiled in Table 2.

Effects of X-substituents for the threo-isomer gave positive ρ-values suggesting that departure of leaving group is important in the transition state. However, both the electron-withdrawing and -releasing Y-substituents were found to accelerate the reaction to give concave curves in which a series of substituents from the *p*-OCH_3 to *m*-OCH_3 groups gave negative ρ-values, while the *m*-OCH_3 to *p*-NO_2 groups afforded

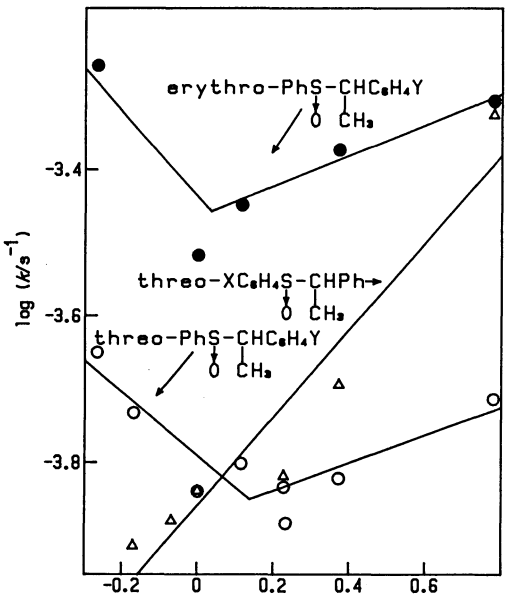

Fig. 2. Hammett plots for the rates of pyrolysis of *threo*- and *erythro*-1-arylethyl aryl sulfoxides at 90.0 °C in dioxane.

positive ρ-values for both the threo- and erythro-isomers as the example at 90.0 °C shown in Fig. 2. Though some Hammett correlations are not very good and the reflecting point is not clear, all of the correlations for different temperatures and different isomers have the same tendencies. The bottoms of the Hammett plots for Y-substituent effects for the threo-isomers seem to be deviated to a positive side at all temperatures unlike the erythro-isomers whose bottom positions are not clear due to only a few measured points. The Hammett plots for the threo- and the erythro-isomers gave the separated parallel lines suggesting that the present assignments of the isomers are valid, especially for 1-(*p*-nitrophenyl)ethyl phenyl sulfoxides ^{1}H NMR methine signals of which cannot be distinguished the isomers.

Large kinetic isotope effects using β,β,β-d_3 sulfoxides were observed as shown in Table 3 for both the *erythro*- and the *threo*-sulfoxides bearing both the electron-withdrawing and -releasing Y-substituents (*p*-OCH_3, *p*-CH_3, H, *m*-Cl), suggesting an involvement of a proton transfer from the β-carbon to the oxygen and no radical cleavage of the C-S bond in the transition state, since the free radical mechanism involving the rate-determining C-S bond cleavage is not in accord with the large kinetic isotope effect. These results reveal that both the C-S bond cleavage and the proton transfer are important in the transition state namely the reaction proceeds via a concerted process.

Activation parameters were calculated for all the sulfoxides (Table 1). The activation entropies are all in the range of 7 to −37 J K^{-1} mol^{-1}. These values are of positively deviated compared to those for primary alkyl aryl sulfoxides (phenyl propyl sulfoxide −63 J K^{-1} mol^{-1},[17] 2-phenylethyl phenyl sulfoxide −45 J K^{-1} mol^{-1}.[26] The activation entropies correlate with the Hammett σ-values giving a negative correlation for Y-substituents as shown in Fig. 3, though the correlation for X-substituents is not clear. Namely, the activation entropy for the reaction of the sulfoxide having more electron-withdrawing Y-substituent is more negative.

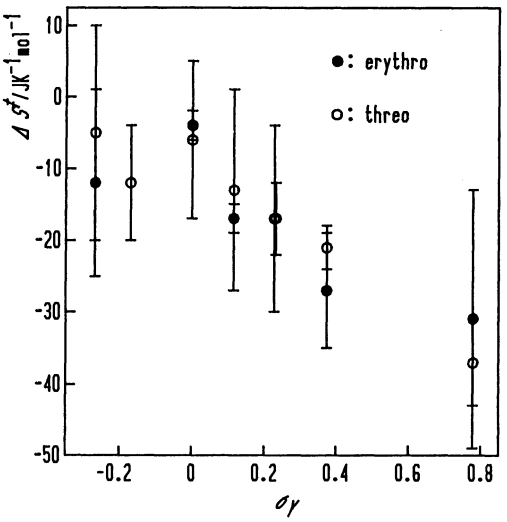

Fig. 3. Dependence of activation entropies on Hammett σ-values for the pyrolysis of *threo*- and *erythro*-1-arylethyl phenyl sulfoxides.

Table 4. Solvent Effect on Pyrolysis of *threo*-1-Phenylethyl Phenyl Sulfoxide at 90.0 °C

Solvent	Dielectric constant	Rate constant $k\times10^5$ / s^{-1}	Relative rates
Dioxane	2.21	14.5 ±0.4	1
DMSO	48.9	7.48±0.09	0.52
Acetonitrile	37.5	5.59±0.25	0.39
Ethanol	24.3	2.31±0.09	0.16

Pyrolysis of the sulfoxide in other solvents was carried out as shown in Table 4. The pyrolysis was not much affected by the solvent change, the rates of pyrolysis are not correlated to the dielectric constants, and the relative rates are very similar to those for the pyrolysis of 2-phenylethyl phenyl sulfoxide[26] and sulfilimines[19] suggesting that the transition state of the reaction is not ionic but concerted one like other sulfoxides and sulfilimines. Namely, the more solvation in the starting state by a dipole-dipole interaction between sulfoxides and dipolar aprotic solvents or by a hydrogen bonding to the sulfoxide oxygen than in the transition state causes the reduction of the reaction rate as described in the previous paper.[26]

Discussion

Though Ei-reaction of sulfoxides are generally recognized as a concerted process, a balance of extent of the C-S bond cleavage and the proton migration from the β-carbon to the oxygen causes the deviation to an E1-like or a carbanion-like mechanism in the five-membered cyclic transition state. Namely, in the E1-like mechanism the departure of leaving group progresses more than the proton abstraction developing a partially positive charge at the α-carbon while in the carbanion-like mechanism the reverse relation develops a partially negative charge at the β-carbon in the transition state.

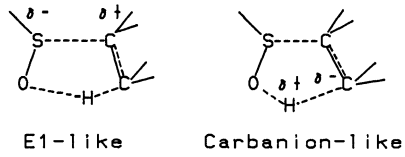

Fig. 4. E1-like and carbanion-like cyclic transition states.

However, unlike E2-reactions the development of charge at the α- or β-carbon should be small, because the stretching of the C-S bond can lead to an enhancement of both the basicity of the oxygen atom and the acidity of the β-proton which would facilitate the proton transfer resulting a neutralization of the positive charge at the α-carbon atom, similarly the progress of the proton transfer would promote the C-S bond cleavage neutralizing the negative charge at the β-carbon. In fact, relative yields of 1-butene to the 2-butene are nearly equal to those on the statistical basis of the numbers of the β-hydrogens in the pyrolysis of ethyl *s*-butyl and propyl *s*-butyl sulfoxides,[4] suggesting that the orientation of elimination has no tendency of Saytzeff or Hofmann rule. Nevertheless, examinations of a Hammett substituent effect have shown to some extent the development of the partial charge in the transition state of the pyrolysis of sulfoxides.[8,17,26] In many variations of Hammett σ-values, use of the usual σ-values for the correlations is considered to be enough to examine such small charge distributions in the concerted transition state, and has been done in these literatures.

Hammett Substituent Effect. The positive Hammett ρ-values for X-substituents appears to be consistent with an E1-like mechanism. Various examples of ρ-values for the pyrolysis of other alkyl aryl sulfoxides and sulfilimines are compiled in Table 5. The effects of X-substituents generally show a positive trend for both sulfoxides and sulfilimines except for 2-cyanoethyl phenyl sulfoxide.[26] However, the pyrolysis proceeding via a carbanion-like mechanism for 2-cyanoethyl phenyl and aryl 2-phenylethyl sulfoxides shows negative or small positive ρ-values. The posi-

Table 5. Representative Hammett ρ-Values of Pyrolysis of Sulfoxides and Sulfilimines

tive trend for the pyrolysis of aryl 2-phenylethyl sulfoxides via even a carbanion-like mechanism is attributed to the substituent effect on the *S*-phenyl group being more susceptible to C-S bond cleavage than proton abstraction.[26] Therefore, from the examination of only the substituent effect on the *S*-phenyl group the mechanism can not be clarified. The substituent effect on the α-phenyl group showed negative Hammett ρ-values from the *p*-OCH_3 group to the *m*-OCH_3 group suggesting apparently development of partially positive charge on the α-position in the transition state, i.e., an E1-like mechanism. However, the ρ-values turned from negative to positive from the *m*-OCH_3 group to the *p*-NO_2 group to give V-shaped Hammett plots. A similar Hammett substituent effect is known in the nucleophilic substitution at substituted benzyl chlorides by trimethylamine which is interpreted in a change of the transition state from S_N1-like to S_N2-like.[29] The present results can also be explained in the same way. Namely, the transition state of the elimination presumably varies from E1-like in the case of the sulfoxides bearing electron-releasing Y-substituents into a conjugated system as shown in Fig. 5 in the case of electron-withdrawing groups.

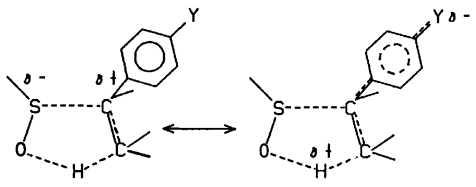

Fig. 5. Conjugated transition state of the pyrolysis of 1-(electron-withdrawing group-substituted phenyl)-ethyl phenyl sulfoxides.

The conjugation with electron-withdrawing groups is advantageous for the elimination, because it acidifies the β-proton effectively, assists the C-H bond cleavage, and stabilizes the transition state. Meanwhile, the conjugation with electron-releasing substituents interferes the development of C-C π-bond formation, instead, stabilizes the partially positive charge at the α-carbon, assisting the extension of the C-S bond to increase the basicity of the sulfoxide oxygen which also accelerates the elimination. Figure 2 shows that the position of 1-phenylethyl phenyl sulfoxide is on the negative line suggesting that the transition state of its Ei is El-like.

Activation Parameters. Activation parameters for pyrolysis of sulfoxides are usually in the range of 106—125 kJ mol^{-1} for activation enthalpies and −71—+30 J K^{-1} mol^{-1} for activation entropies.[1,4,8,17,26] The activation entropy of the slowest type of such simple sulfoxides as phenyl propyl is large negative (−63 J K^{-1} mol^{-1})[17] suggesting that the transition state is more rigid than the starting state due mainly to a cyclization. However, the present system shows a nearly zero activation entropy which is presumably a result of a relatively large contribution of the extension of the C-S bond in the cyclic transition state compared to the small contribution of the progress of the proton transfer according to the following reason. The contribution of extent of the proton transfer to the activation entropy is probably small, because the contribution of looseness of the C-H bond is canceled by that of development of the O-H bond formation. Therefore the increase of the activation entropy to the positive direction in the present system is mainly based on the contribution of the looseness of the C-S bond in the transition state. In the case of the pyrolysis via a carbanion-type transition state such as that of 2-phenylethyl phenyl sulfoxide, the C-S bond is not so loose as compared with the progress of the proton transfer resulting a relatively large negative activation entropy.[26] Therefore, the positively deviated activation entropy for the present system is consistent with the El-like mechanism. The fact that the plot of activation entropies for Y-substituents vs. Hammett σ-values gave the negative trend is probably due to the increase of an El-like character by electron-releasing substituents.

Isotope Effect. Kinetic isotope effects for the Ei-reaction of β-deuterated sulfoxides, sulfilimines, and tertiary amine oxides are usually small (k_H/k_D=2—3.5)[19,20,27] due to the cyclic transition state. However, the present system shows relatively large kinetic isotope effects. Meanwhile, Kwart et al. reported a usual magnitude of kinetic isotope effect for the thermolysis of heptyl-2-*d* phenyl sulfoxide (k_H/k_D=2.3—3.1)[27,28] and a relatively large effect for *t*-butyl-d_9 ethyl sulfoxide (k_H/k_D=3.3—6).[11] They examined a temperature dependence of k_H/k_D to result that the activation energy difference and the frequency factor ratio between hydrogen and deuterium for the cis-elimination of heptyl phenyl sulfoxide ($E_{a_D}-E_{a_H}$=4.81 kJ mol^{-1} A_H/A_D=0.76)[27] are in the range of zero-point energy controlled isotope effect ($E_{a_D}-E_{a_H}<5.9$ kJ mol^{-1}, $0.6<A_H/A_D<1.4$),[28] but those for *t*-butyl ethyl sulfoxide ($E_{a_D}-E_{a_H}$=13 kJ mol^{-1}, A_H/A_D=0.07) are out of that range suggesting the incursion of hydrogen tunneling.[11] The temperature dependences of the isotope effects for the present system were examined as shown in Table 3. Though it is difficult to discuss about the involvement of the tunnel effect from the data for only one sample because of unavoidable large errors in the differences of the activation parameters measured in the narrow temperature range, in total view of data for all samples, the parameter differences do not seem to be deviated so much from the range of the zero-point energy differences. Though the ratios of the frequency factors are scattered, the values do not fit to tunneling since smaller values ($0<A_H/A_D \ll 1$) can be expected for the tunnel effect.[28] Assuming the isotope effect to be controlled by a zero point energy, the large kinetic isotope effects for the present system (the

isotope effects are larger than that for heptyl phenyl sulfoxide[27] even though the values are extrapolated to the same temperatures) should be explained by a change of the structure of the transition state. In general, a maximum magnitude of the hydrogen-deuterium isotope effect controlled by a zero-point energy is known to be ca. 8 for linear hydrogen transfer reactions.[28] Therefore, small isotope effects for Ei reactions have been attributed to their non-linearity. The relatively large activation entropies for the present system are the result of the C-S bond loosened transition state which allows the linear hydrogen transfer to show the large isotope effect.

The substituent effect on the magnitude of the isotope effects is also interesting. There might be two geometric factors in the transition state to affect the isotope effect. One is the linearity of the hydrogen transfer as described above. The C-S bond in the transition state might be more loosened for the sulfoxide having more electron-releasing Y-substituent as discussed in the activation parameters section expecting the more linear hydrogen transfer and larger isotope effect. The other factor is a symmetry of the hydrogen transfer which shows a maximum primary isotope effect. In view of that the hydrogen transfer is performed by a low basic sulfoxide oxygen, the position of the hydrogen atom in the transition state is considered to be nearer to the starting state. In this situation, the more acidic β-proton the sulfoxide has, the more symmetric hydrogen transfer can be expected. Contrary to the former factor, the more electron-withdrawing Y-substituent will show the larger isotope effect. The present results show that the latter effect could be more important than the former in the substituent effect on the kinetic isotope effects.

Reactivity of Isomers. The ratios of pyrolytic rates of threo-erythro-isomers (k_{er}/k_{th}) are listed in Table 6. The pyrolysis of erythro-isomers is 2—3 times faster than that of threo-isomers for all substituents and at all three temperatures.

In 1982, Kobayashi et al.[25] reported that there is some attractive interaction between *S*-phenyl and α-phenyl group (CH-π interaction) in the conformation of both *threo*- and *erythro*-1-phenylethyl aryl sulfoxides, and the most stable conformers are as shown in Fig. 6 for the threo- and the erythro-isomers, respectively. The most stable conformer of the erythro-isomer in the starting state is advantageous for the Ei-reaction compared to that of the threo-isomer since the sulfoxide oxygen and the methyl group is close. Assuming the phenyl-phenyl attractive interaction still remained in the transition state for the erythro-isomer, the activation free energy for the threo-isomer would be larger than that for the erythro-isomer because of an unavoidable breaking of the interaction for the threo-isomer. Thus the pyrolysis results in the faster elimination for the erythro-isomers. Inspection of the data in the Table 6 reveals that there are similar tendencies between k_{er}/k_{th} and σ-values of Y-substituents at all temperatures, though

a) Corrected with number of β-hydrogens.

the data are scattered. The tendencies that both the electron-withdrawing and -releasing substituents enlarge the ratios (k_{er}/k_{th}) are similar to those for log k vs. σ. Though the reason for this observation is not clear, it might be explained by the stronger CH-π interaction for the more polar sulfoxides.

Effect of the α-Phenyl Group on the Rate of the Pyrolysis. The pyrolysis of *threo*- and *erythro*-1-phenylethyl phenyl sulfoxides was found to be 264 and 508 times faster than that of ethyl phenyl sulfoxide at 100 °C in dioxane. The effects of the phenyl substituent on the α- and β-positions of ethyl phenyl sulfoxide and sulfilimine are compared in Table 7. Introduction of a phenyl group at the α-position results in much more acceleration than that at the β-position suggesting that the C-S bond cleavage is more important than the proton transfer in the transition state of pyrolysis for both sulfoxides and sulfilimines.

Conclusion

From these results the following conclusion can be obtained. The large β-hydrogen kinetic isotope effect rules out a radical pair mechanism and an ionic mechanism is also ruled out because of the small solvent effect and the relatively small Hammett substituent effects. The reaction mechanism is thus considered to be a concerted process through a five-membered cyclic transition state. The large activation entropies reveal a C-S bond loosened transition state to make possible to more linear proton transfer and to give the large hydrogen kinetic isotope effect compared to primary alkyl sulfoxides. The V-shaped Hammett plot for the rates and the negative trend for the substituent effect for the activation entropies on the 1-phenyl group indicate that the transition state changes as follows. Electron-releasing substituents on the 1-phenyl group change the transition state to a C-S bond loosened E1-like type, while electron-withdrawing ones change that to C-S bond not so stretched conjugated type in which the acidity of the β-proton is increased. These results suggest that the transition state is on a broad potential energy surface. The higher reactivity of erythro-isomers than threo-isomers can be attributed to a 1-phenyl-*S*-phenyl attractive interaction (CH-π interaction)[25] of the sulfoxide in both the ground and the transition states. The larger enhancement by a 1-phenyl group on the rate of pyrolysis of ethyl phenyl sulfoxide than that by a 2-phenyl group suggests that the Ei-reaction of sulfoxides essentially tend to take an E1-like transition state.

Experimental

General. All melting points were uncorrected. IR spectra were taken on a JASCO IRA-1 spectrometer. NMR spectra were recorded with a Hitachi R-24B spectrometer (60 MHz) using TMS as an internal standard.

Preparation of 1-Arylethyl Aryl Sulfoxides. All sulfoxides were prepared by oxidation of the corresponding 1-arylethyl aryl sulfides with hydrogen peroxide in acetic acid at room temperature. Most of the threo-isomers were obtained by repeated recrystallization from ether, ether-hexane, or methanol except for 1-phenylethyl phenyl, 1-(*m*-methoxyphenyl)ethyl phenyl, and 1-(*m*-chlorophenyl)ethyl phenyl sulfoxides, instead the erythro-isomers of which were isolated by recrystallization. The threo-isomers of the latter three sulfoxides and other erythro-isomers were obtained by repeated silica-gel column chromatography using chloroform or ether-hexane (3 : 1) as an eluent. The sulfoxides thus obtained have the following physical properties.

$XC_6H_4S(O)CH(CH_3)C_6H_4Y$: X,Y, Threo or Erythro: H, *p*-MeO, Threo: Mp 92 °C (from ether-hexane); IR (KBr) 1051 cm^{-1} (S-O); ^{1}H NMR (CCl_4) δ=1.52 (3H, d, J=7 Hz, CH_3), 3.59 (1H, q, J=7 Hz, CH), 3.73 (3H, s, OCH_3), 6.5—7.1 (4H, AB, J=9 Hz, Ar), 7.1—7.5 (5H, s-like, Ph). Preparation of 1-(Substituted phenyl)ethyl-2,2,2-d_3 Phenyl Sulfoxides. To a stirred solution of methyl-d_3-magnesium iodide (0.06 mol) in dry ether (20 ml) was added dropwise substituted benzaldehyde (0.05 mol) in dry ether (20 ml). After usual work-up process, α-methyl-d_3-benzyl alcohol obtained was converted to the corresponding chloride which was then allowed to react with sodium benzenethiolate to give the corresponding sulfide-β,β,β-d_3 in ca. 85% yield. The obtained sulfide was oxidized with 35% H_2O_2 in acetic acid to afford the sulfoxide in ca. 67% yield.

Kinetics. Pyrolysis of the sulfoxides was carried out at 80.0±0.1 °C, 90.0±0.1 °C, and 100.0±0.1 °C in sealed capillary tubes, which contain 50 μl of 2.7 mmol dm^{-3} dioxane solution of each sulfoxide and 32 mmol dm^{-3} diphenyl ether or 5.4 mmol dm^{-3} diphenyl sulfide as an internal standard depending on the retention time of olefin formed in liquid chromatography. A sealed tube was taken out at several time intervals and was cooled in an ice bath to stop the reaction. The decreasing sulfoxide was followed by means of JASCO FAMILIC-100N liquid chromatograph with UV monitor UVIDEC 100II at 256 nm using TAKEDA RIKEN-TR-2217 Automatic Integrator. The rate of the reaction was found to fit nicely with a first-order rate equation and the rate constant was calculated by a least-squares method.

The authors are grateful to Professor Shigeru Oae of Okayama University of Science, and Professor Naomichi Furukawa, the University of Tsukuba, for their helpful discussions. We also would like to thank Dr. Motohiro Nishio, Meiji Seika Kaisha, for his helpful suggestions to assign threo- and erythro-isomers and their favorable conformations of 1-phenylethyl aryl sulfoxides.

Synthesis of a Protected Sperm Whale Myoglobin-(77—96)-Eicosapeptide and Circular Dichroism Spectra of the Related Peptides

Chikao HASHIMOTO* and Ichiro MURAMATSU†
Department of Chemistry, The Jikei University School of Medicine, 8-3-1, Kokuryo-Cho, Chofu-Shi, Tokyo 182
†Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Tokyo 171
(Recevied October 1, 1988)

A protected sperm whale myoglobin-(77—96)-eicosapeptide (**23**) was synthesized by a solution method. The protected peptide **23** could be effectively purified by silica-gel column chromatography with 1-butanol-acetic acid-water as the eluate. The CD spectra of protected fragment peptides were measured in a solution of 2,2,2-trifluoroethanol. A protected sperm whale myoglobin-(85—96)-dodecapeptide and **23** showed CD profiles characteristic of a helical structure.

Myoglobin is a globular heme protein which plays a role in the storage of oxygen in the cells of muscle. The myoglobin molecule of higher animals is composed of a globin chain containing 153 amino acid residues (mol wt 17000) and a protoheme. A higher-order structure of sperm whale myoglobin was elucidated by means of an X-ray analysis by Kendrew et al.[1] The E and F regions of sperm whale myoglobin include distal (E7) and proximal (F8) histidine residues which coordinate a heme iron atom, and are important sites for producing physiological functions. It is of interest to synthesize a peptide of the E-EF-F region and to investigate the structure and functional properties of the peptide in comparison with those of myoglobin. However, few studies have been carried out on the synthesis of those regions of the myoglobin. In the past Eckstein and Bayer[2] tried to synthesize the sperm whale myoglobin-(81—94)-peptide using two methods involving fragment condensation: between positions 81—82 and 83—94, and between positions 81—88 and 89—94. However, they could not obtain the desired peptide.

As an initial approach regarding the subject mentioned above, we synthesized a protected sperm whale myoglobin-(77—96)-eicosapeptide (**23**). Peptide **23** consists of EF and F segments of the myoglobin and includes the important proximal histidine residue. The synthesis of **23** carried out by a solution method which makes it possible to obtain some protected intermediate peptides of various size. Various problems in the synthesis are described in "Results and Discussion". The CD spectra of **23** and the fragment peptides were measured in order to investigate whether those protected peptides can form a helical structure. The helical property deduced from the CD spectra of each peptide was correlated with the secondary structure, shown by X-ray analysis,[1] of the corresponding part of myoglobin.

Results and Discussion

The protected eicosapeptide **23** was built up from four fragment peptides by the route illustrated in Fig. 6. These four fragment peptides were prepared by a stepwise elongation method, according to the routes showed in Figs. 1—5.

Peptide in Positions 91—96. Figure 1 illustrates the synthesis of fragment (**5**), Boc-Gln-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl.[3] Boc-His(Boc)-Ala-Thr-Lys(Z)-OBzl (**3**) was constructed stepwise with Boc-Thr-OH, Boc-Ala-OH, and Boc-His(Boc)-OH using H-Lys(Z)-OBzl as starting material by a mixed anhydride (MA) method.[4] Boc-Thr-Lys(Z)-OBzl (**1**) was purified by chromatography on a silica-gel column with CH_2Cl_2-MeOH systems as eluates. Compound **3** was contaminated with a small amount of impurities, but used for the following coupling without further purification. After the treatment of **3** with trifluoroacetic acid (TFA), the tetrapeptide ester was condensed with Boc-Ser(Bzl)-OH using EDC[5] in the presence of HOBt[6] to give Boc-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl (**4**). The pentapeptide ester derived from **4** was coupled with Boc-Gln-ONp by an active ester method.[7] Product **5** was purified into a chromatographyically homogeneous form by gel filtration on Sephadex LH-20.[8]

Peptide in Positions 85—90. Figure 2 shows the synthesis of fragment (**11**), Boc-Glu(OBzl)-Leu-

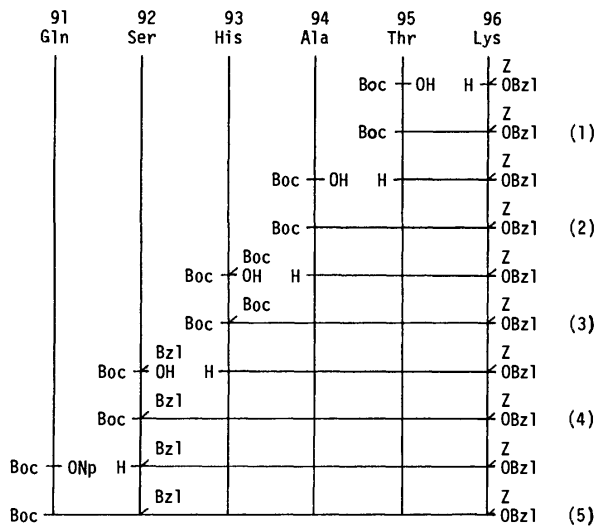

Fig. 1. Synthetic scheme of positions 91—96.

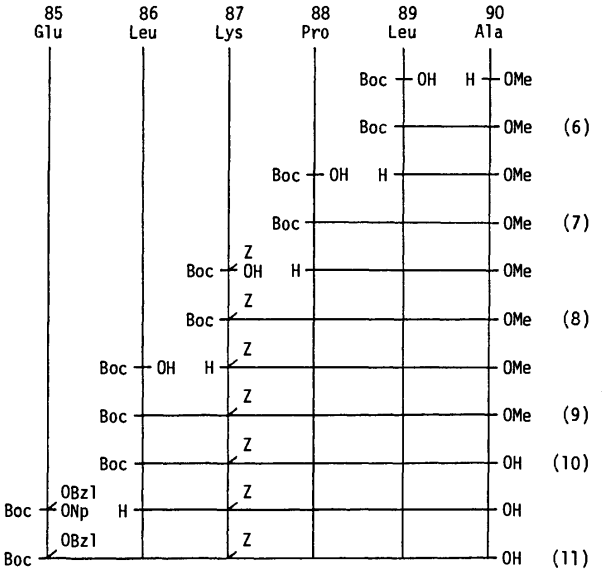

Fig. 2. Synthetic scheme of positions 85—90.

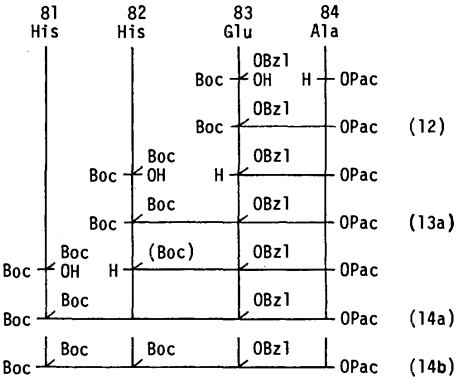

Fig. 3. Synthetic scheme of positions 81—84.

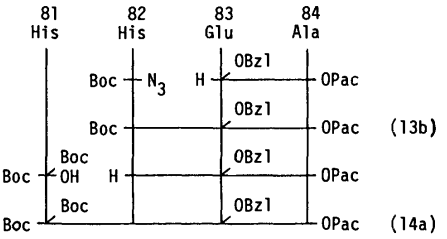

Fig. 4. Alternative synthetic scheme of positions 81—84.

Lys(Z)-Pro-Leu-Ala-OH. In the synthesis of Boc-Leu-Lys(Z)-Pro-Leu-Ala-OMe (**9**), the starting material, H-Ala-OMe, was elongated stepwise with Boc-Leu-OH, Boc-Pro-OH, Boc-Lys(Z)-OH, and Boc-Leu-OH by means of the MA or EDC-HOBt method. Compound **9** was purified by the use of a Sephadex LH-20 column. The methyl ester **9** was hydrolyzed to give Boc-Leu-Lys(Z)-Pro-Leu-Ala-OH (**10**). After removing the N-terminal protecting group of **10**, the resulting partially protected pentapeptide, TFA·H-Leu-Lys(Z)-Pro-Leu-Ala-OH, was neutralized and, then, coupled with Boc-Glu(OBzl)-ONp by an active ester method to afford **11**. Fragment **11** was purified by gel filtration.

Peptide in Positions 81—84. Figures 3 and 4 illustrate the routes employed in the preparation of fragment (**14a**), Boc-His(Boc)-His-Glu(OBzl)-Ala-Opac. The coupling of H-Ala-Opac with Boc-Glu(OBzl)-OH proceeded in yields 43—56% by the MA method, and in an yield of 74% by the EDC-HOBt procedure. Compound **12** was treated with TFA and the dipeptide ester was condensed with Boc-His(Boc)-OH by the MA method to give Boc-His(Boc)-Glu(OBzl)-Ala-Opac (**13a**). After the treatment of **13a** by TFA for 70—340 min at room temperature, the product showed two spots on TLC. The treatment of **13a** with 4 M† HCl/dioxane for 3 h at room temperature also gave a similar result. The two components seemed to be peptides in which, respectively, one and two Boc groups were removed with an acid-treatment. Therefore, the mixture containing the two components was coupled without purification with Boc-His(Boc)-OH by the EDC-HOBt method to yield **14a**. The crude product, including two components (A and B), was chromatographed on a silica-gel column and the two components were separately isolated. Component A was identified as Boc-His(Boc)-His(Boc)-Glu(OBzl)-Ala-Opac (**14b**), and component B as the desired compound **14a** by elemental and FAB mass analyses. Fragment **14a** was also synthesized by another route, illustrated in Fig. 4. The Boc-His-N_3 derived from corresponding hydrazide was coupled with the H-Glu(OBzl)-Ala-Opac to prepare Boc-His-Glu(OBzl)-Ala-Opac (**13b**) by the Honzl and Rudinger method.[9] After the deprotection of **13b** with TFA, the tripeptide ester was condensed with Boc-His(Boc)-OH by the MA method to yield **14a**. Analytical data regarding component B agreed with that of **14a** synthesized by the route shown in Fig. 4.

Peptide in Positions 77—80. Figure 5 outlines the synthesis of fragment (**18**), Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-OH. The starting material, H-Gly-OEt, was succesively elongated by Boc-Lys(Z)-OH with the MA method to produce fragment (**17**), Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-OEt. Product **17** was converted to the corresponding acid **18** by saponification. The synthesis of **18** proceeded smoothly and requires no additional comments.

Peptide in Positions 77—84. The removal of the Boc group of **14a** was carried out smoothly by treating with TFA under the usual conditions. The resulting peptide gave a single spot on TLC and was confirmed to be 3TFA·H-His-His-Glu(OBzl)-Ala-Opac (**19**) by elemental analysis. The tetrapeptide ester **19** was coupled with **18** in the presence of HOBt by EDC to yield protected octapeptide **20**. The product **20** was reduced over zinc powder in acetic acid[10] to afford fragment (**21**), Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-His-

† 1 M=1 mol dm^{-3}.

His-Glu(OBzl)-Ala-OH.

Peptide in Positions 85—96. Several methods were investigated for the synthesis of fragments (positions 85—96 or 87—96). Acyl components, Boc-Glu(OBu^t)-Leu-Lys(Z)-Pro-Leu-Ala-N_3 and Boc-Lys(Z)-Pro-Leu-Ala-N_3, respectively, were condensed with an amino component, H-Gln-Ser-His-Ala-Thr-Lys(Z)-OH. The yields of both couplings were very low. Also, the coupling of the former azide with an amino component, H-Gln-Ser-His-Ala-Thr-Lys(Z)-OBzl, did not give a satisfactory result. The low yield in these coupling reactions seems to be attributed to a conversion of the N-terminal residue to pyroglutamyl, since the glutamine residue of a free hexapeptide, H-Gln-Ser-His-Ala-Thr-Lys-OH, easily changed to the pyroglutamyl residue. This reaction was catalyzed by the imidazole ring of the neighboring histidine residue.[11] Therefore, the hydroxyl group of serine was protected by a benzyl group, as one carrying a steric hindrance in order to suppress the effect of the imidazole ring. Also, the coupling method was changed to the EDC-HOBt procedure, a more reactive compared to the azide method. As illustrated in Fig. 6, fragment **5** was treated with TFA and the corresponding hexapeptide ester was coupled with **11** by the EDC-HOBt procedure to prepare fragment (**22**), Boc-Glu(OBzl)-Leu-Lys(Z)-Pro-Leu-Ala-Gln-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl. The yield was 86% and was extremely high compared with those of the three methods described above. The improvement in the yield may be attributed to the use not only of **5**, but also of the reactive EDC-HOBt procedure. Namely, the slower condensation should cause the formation of a greater amount of pyroglutamic acid residue from the N-terminal glutamine residue of the hexapeptide, H-Gln-Ser-His-Ala-Thr-Lys(Z)-[OH or OBzl].

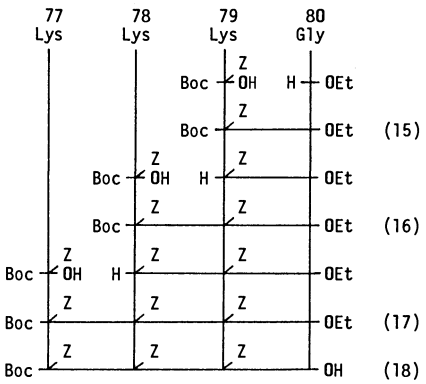

Fig. 5. Synthetic scheme of positions 77—80.

Peptide in Positions 77—96. After removing the Boc group of **22**, the dodecapeptide ester was coupled with **21** in the presence of HOBt by EDC to afford fragment (**23**), Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-His-His-Glu(OBzl)-Ala-Glu(OBzl)-Leu-Lys(Z)-Pro-Leu-Ala-Gln-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl. After the purification of **23** by gel filtration, it still contained small amounts of impurities. A part of **23** was further purified by a silica-gel column with 1-butanol-acetic acid-water solvent system as the eluate. The recovery of pure **23** was 24%. The cause of the low recovery is most likely based on adsorption on the silica gel.

As mentioned above, the improvement in fragment condensation between **5** and **11** has enabled the syn-

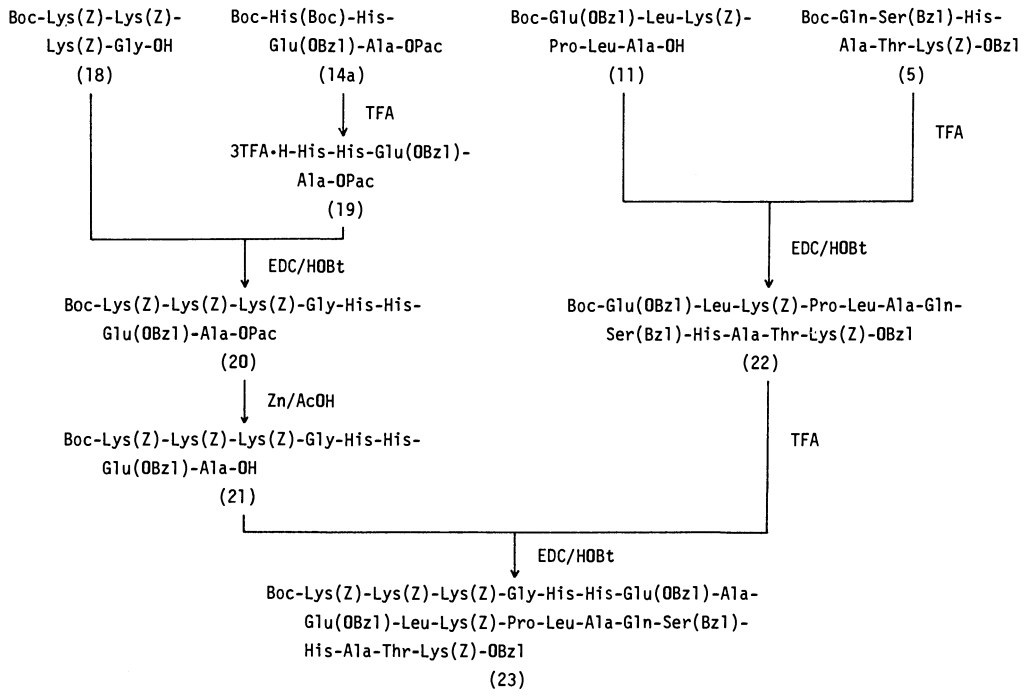

Fig. 6. Synthetic scheme of positions 77—96.

thesis of the protected eicosapeptide **23**; it will further be helpful in the syntheses of longer peptides. Also, it has been found that a solvent system, 1-butanol-acetic acid-water, well dissolves protected peptides and, accordingly, it is very useful in silica-gel chromatography of protected long peptides.

The purity of all the protected compounds was confirmed by TLC, amino acid analysis of acid hydrolyzate and elemental analysis.

Circular Dichroism Spectra. The CD spectra of protected fragment peptides were recorded in the region of approximately 190 to 270 nm. In the CD measurement the protected fragment peptides and sperm whale myoglobin were dissolved in TFE and in 60% TFE, respectively. The CD data were reported as mean residue ellipticity, $[\theta]$, which were expressed in degree square centimeter per decimole. For calculations of helical contents, the value of $[\theta]_{222}$ for completely helical structure was taken as −32000.[12)] The theoretical helicity of a fragment peptide is expressed by the proportion of amino acid residues participating in the helical structure in the known three-dimensional structure of sperm whale myoglobin to the total residues in the fragment peptide. In order to compare the helicity of fragment peptides of different size, the relative helical contents of the fragment peptides were expressed by the helical ratio,[13)] which is the ratio of the observed helical content vs. that expected from the position of the fragment peptide in sperm whale myoglobin. In the amino acid sequence of sperm whale myoglobin-(77—96)-peptide, -Lys-Lys-Lys-Gly-His-His-Glu-Ala-Glu-Leu-Lys-Pro-Leu-Ala-Gln-Ser-His-Ala-Thr-Lys-, the underlined amino acid residues take part in the helical structure according to the result of X-ray analysis.

Figure 7 illustrates the CD spectra of four protected fragment peptides in TFE. The spectrum of **11** shows a shoulder at 228 nm and a negative band at 200 nm. The spectra of **20** and **21** exhibits a negative band near 230 nm and a positive band near 210 nm. Fragments **11**, **20**, and **21** do not exhibit the distinguishing CD profiles for a helical structure. The parts corresponding to fragments **20** and **21** scarcely contributed to the helical structure in the sperm whale

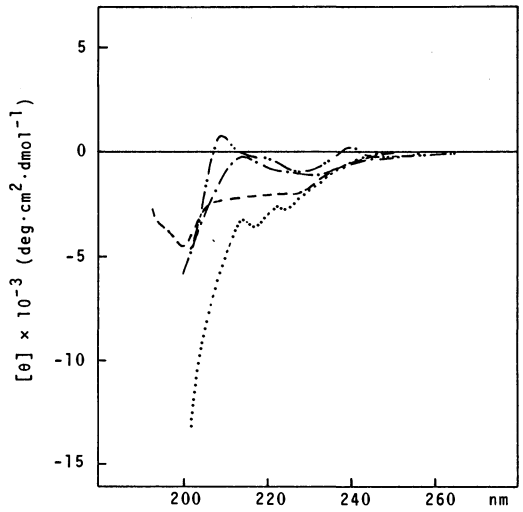

Fig. 7. CD spectra of **5** (·····), **11** (———), **20** (—·—), and **21** (—··—) in TFE.

myoglobin; it is therefore expected that those two peptides do not take a helical structure. Fragment **11** includes a part of the F helical region, though its spectrum did not suggest the exsistence of a helical structure. Fragment **5** also contains a fraction of the F helical region. The spectrum of **5** revealed negative bands at 226 and 217 nm, and suggested the presence of a helical structure, in spite of the small peptide. The helicity of **5** was calculated as 8.4% on the basis of the assumption that its $[\theta]_{222}$ value (−2700) depends only on the helical structure. The theoretical helicity was calculated according to the method stated above. That is, the part corresponding to fragment **5**, within the sperm whale myoglobin, has 4 residues in the helical structure out of 6 residues (theoretical helicity; 67%). Fragment **5**, containing part of a helical segment, is apt to form a helical structure compared with **20** and **21**, including a large portion of a nonhelical segment. However, fragment **11**, containing a helical segment, did not show the presence of a helical structure.

Figure 8 exhibits the CD spectra of two fragments, **22** and **23**, in TFE and sperm whale myoglobin in 60% TFE. The spectra of **22** and **23** showed negative bands at 220 and 205 nm, a cross overpoint at 200 nm and a positive band near 195 nm, and are very similar to that of the myoglobin. These two fragments exhibited conspicuous helical CD profiles. The values of $[\theta]_{222}$ of **22** and **23** were −10400 and −12000, respectively, and the helicity of the two fragments were calculated as being 33% (theoretical helicity; 75%) and 38% (theoretical helicity; 50%), respectively, from those data. It is well-known that TFE used as a solvent stabilizes a helical structure of peptide or protein.

Figure 9 shows the CD spectra of **23** in TFE and TFE containing water. The values of $[\theta]_{222}$ of **23** in TFE, 80% TFE-water, and 60% TFE-water were −12000 (helicity; 38%), −10200 (helicity; 32%), and

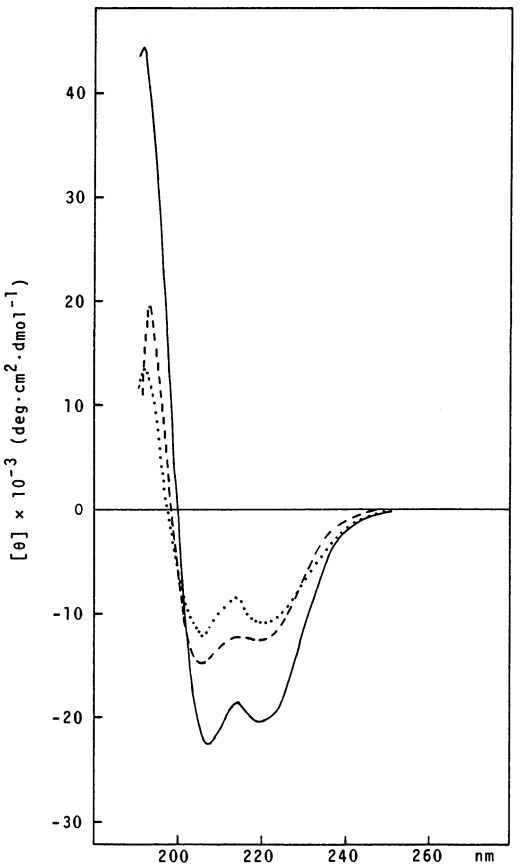

Fig. 8. CD spectra of **22** (·····) and **23** (———) in TFE, and myoglobin (———) in 60% TFE-water.

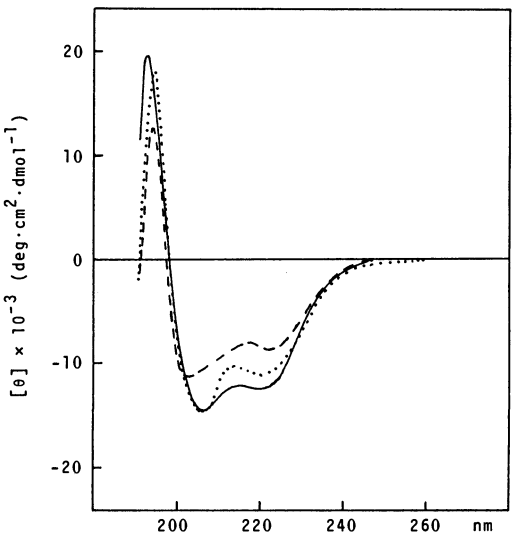

Fig. 9. CD spectra of **23** in TFE (———), 80% TFE-water (·····), and 60% TFE-water (———).

−8300 (helicity; 26%), respectively. The increment of water content diminished the helical content. These results revealed that the helical structure of **22** and **23** are stabilized in TFE solution. Those two fragments possess hydrophobic protecting groups on the side chains of amino acid residues. The helicities

of protecting-group-free peptides derived from **22** and **23** were very small in aqueous solution, and were rather smaller than those of the protected peptides, even in 60% TFE.[14]

In peptides **22** and **23**, the protection of some residues by hydrophobic groups seems to enhance the helical property of these peptides. The disappearance of the ionic property of the side chains of some residues by protection may also affect the helicity. Fragment **23** was formed by the addition of **21**, including almost nonhelical region to **22**. In spite of the addition of an almost nonhelical segment, the helical content of **23** was somewhat larger than that of **22**. This result implied that the helical structure is stabilized by the interaction among amino acid residues remote in the primary sequence. The helical ratios of **5**, **22**, and **23** were 0.13, 0.44, and 0.76, respectively. The ratios increased with the elongation of the peptide chain. The increase of the helical ratios also suggested the importance of the interaction among remote amino acid residues.

In conclusion, the CD study revealed that fragment peptides **5**, **22**, and **23** have helical structures, even though to various extents. The structures of those compounds seem to be stabilized by the effect of TFE and the hydrophobic interaction among hydrophobic protecting groups and side chains arranged spatially near to each other. This result also suggests that the hydrophobic interaction may be an important factor for the formation of a helical structure in myoglobin. Values of the helical ratio suggest that peptides **22**, and particularly **23**, probably possess a structure similar to the corresponding parts of myoglobin. The suggestion of the existence of a helical structure in peptides **22** and **23** is significant as a prerequisite of the formation of a complex between synthesized peptides and a protoheme in a similar way to that in myoglobin.

Experimental

Melting points were measured by the capillary method and are given as uncorrected values. Optical rotations were determined with a DIP-140 type (Jasco) polarimeter. Amino acid analyses were performed on a JLC-6AS automatic analyzer (JEOL) after acid hydrolysis with 6 M HCl in a sealed tube at 110 °C for 20—21 h. The theoretical values of amino acid ratios are shown in parentheses after each results.

In synthetic procedures, the imidazole functional group of histidine was temporarily protected by the Boc group on the occasion of incorporation of a histidine residue into a peptide chain. The functional groups of side chains, other than the hydroxyl group of threonine, were protected. The N^{α}- and N^{im}-Boc protecting groups were removed by TFA in the presence of anisole, or TFA at room temperature for 45—180 min. After evaporation of the solvents, the residue was triturated with diethyl ether to give a product. The removal of Boc groups of compounds **1**, **2**, **3**, **6**, **7**, **8**, **12**, **13b**, and **15** were carried out by a method similar to this method. Compounds **1**, **2**, **3**, **6**, **7**, **9**, **13a**, **14a** in Fig. 4, **15**, and **16** were synthesized by the MA method, compounds **4**, **8**, and **12** by the EDC-HOBt method and compound **13b** by the azide method. After couplings, the organic layers were washed successively with water, 5% citric acid, water, 5% sodium hydrogencarbonate, and water, and then dried over anhydrous sodium sulfate except when noted otherwise. Compound **18** was prepared from **17** by saponification. The evaporation of solvents was carried out under reduced pressure. Unless stated otherwise, residues and crystals were dried over NaOH pellets and P_2O_5 in vacuo at room temperature. Silica gel 60 (Merck and Co.) was used in column chromatography if not mentioned otherwise.

Thin-layer chromatography was performed on TLC plates silica gel 60 F_{254} and HPTLC plates silica gel 60 F_{254} with a concentration zone, (Merck and Co.), using the following solvent systems (volume ratios): R_f^1, chloroform-methanol (95 : 5); R_f^2, chloroform-methanol (9 : 1); R_f^3, chloroform-methanol (2 : 1); R_f^4, chloroform-methanol (1 : 1); R_f^5, chloroform-ethyl acetate (1 : 1); R_f^6, chloroform-methanol-acetic acid (95 : 5 : 5); R_f^7, chloroform-methanol-acetic acid (9 : 1 : 1); R_f^8, 1-butanol-acetic acid-water (3 : 1 : 1); R_f^9, 1-butanol-acetic acid-water (4 : 1 : 1); R_f^{10}, 1-butanol-pyridine-acetic acid-water (4 : 1 : 1 : 2), R_f^{11}, 1-butanol-pyridine-acetic acid-water (16 : 10 : 3 : 12).

Analytical data of compounds **1**, **2**, **3**, **4**, **6**, **7**, **8**, **9**, **12**, **13a**, **13b**, **14a** in Fig. 4, **15**, **16**, and **18** are given in Table 1.

CD measurements were performed using a J-500 spectropolarimeter with a DP-500N Data Processor. The temperature was kept constant at 24 °C. Cells with light paths of 0.1 and 0.5 mm were used. Measurements of fragment peptides and myoglobin were carried out in solutions at concentrations of 5×10^{-4} M and 5×10^{-5} M, respectively. Sperm whale myoglobin was purchased from Sigma and used without further purification.

Boc-Gln-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl (5). Compound **4** (6.410 g) was treated with TFA (25 ml) and anisole (1.45 ml) in the usual manner and yielded a solid. Boc-Gln-ONp (2.952 g) was dissolved in DMF (10 ml); to this solution was added a solution containing the above-mentioned solid and Et_3N (1.86 ml) in DMF (25 ml). The mixture was stirred for 4.5 d at room temperature and then concentrated. The product was dissolved in MeOH (80 ml), and the solution was applied to a Sephadex LH-20 column (3.6×139 cm). The product was eluted with DMF. Fractions of 10 g each were collected. Fractions 53—77 were combined and the solvent was evaporated. The residue was recrystallized from methanol-diethyl ether; 5.816 g (80%), mp 181—183 °C, $[\alpha]_D^{24}$ −13.3° (*c* 1.0, DMF), R_f^2 0.10, R_f^9 0.69. Amino acid ratios in acid hydrolyzate: Thr 0.95 (1), Ser 0.89 (1), Glu 1.07 (1), Ala 1.01 (1), His 1.04 (1), Lys 1.03 (1), NH_3 1.28 (1). Found: C, 57.12; H, 6.53; N, 12.14%. Calcd for $C_{54}H_{72}O_{14}N_{10}\cdot3H_2O$: C, 56.93; H, 6.90; N, 12.29%.

Boc-Leu-Lys(Z)-Pro-Leu-Ala-OH (10). To an ice-chilled solution of **9** (13.587 g) in methanol (15 ml) was added 1.98 M NaOH (9.57 ml). The mixture was stirred for 170 min at room temperature; then, 1 M HCl (18.95 ml) was added to this solution in an ice-bath. After evaporation of the methanol, the residual solution was dissolved in 1-butanol (ca. 150 ml) saturated with water, and the organic layer was washed with water (10 ml×3). After removing the solvent, the product was recrystallized from ethyl acetate-diethyl ether; 12.300 g (92%), mp 105—114 °C, $[\alpha]_D^{24}$

$-77.2°$ (c 1.0, MeOH), R_f^6 0.44, R_f^7 0.81. Amino acid ratios in acid hydrolyzate: Pro 0.97 (1), Ala 0.98 (1), Leu 2.03 (2), Lys 1.02 (1). Found: C, 56.54; H, 7.80; N, 10.07%. Calcd for $C_{39}H_{62}O_{10}N_6 \cdot 3H_2O$: C, 56.51; H, 8.27; N, 10.14%.

Boc-Glu(OBzl)-Leu-Lys(Z)-Pro-Leu-Ala-OH (11). Compound **10** (3.100 g) was treated with TFA (20 ml)–anisole (0.87 ml) to give a solid. The solution of Boc-Glu(OBzl)-ONp (2.847 g) in DMF (10 ml) was mixed with the solution of the above-mentioned solid and Et_3N (1.11 ml) in DMF (20 ml). The mixture was stirred for 69 h at room temperature and then condensed. The residue was dissolved in 1-butanol saturated with water and the 1-butanol layer was washed with 5% citric acid (30 ml×1) and water (10 ml×1). After removing the solvent, the product was dissolved in DMF (ca. 20 ml) and the solution was applied to a Sephadex LH-20 column (2.7×140.5 cm) employing the same solvent as the eluate. Fractions of 10 g each were collected. Fractions 30—38, including the desired peptide, were combined and the solvent was removed. After the residue was extracted with ethyl acetate (200 ml), the organic layer was further washed in the same manner mentioned above and concentrated. Fractions 39—46, containing impurity, were combined and concentrated. After the addition of ethanol to the residue, the resulting precipitate was removed by filtration. An additional crop was obtained from the filtrate by rechromatography on the same column. The combined product was crystallized from diethyl ether; 3.433 g (86%), mp 92—96 °C, $[\alpha]_D^{24}$ $-74.6°$ (c 1.0, MeOH), R_f^6 0.45, R_f^7 0.84, R_f^9 0.87. Amino acid ratios in acid hydrolyzate: Glu 1.05 (1), Pro 1.02 (1), Ala 0.93 (1), Leu 2.04 (2), Lys 0.97 (1). Found: C, 60.94; H, 7.72; N, 9.69%. Calcd for $C_{51}H_{75}O_{13}N_7 \cdot 1/2H_2O$: C, 61.06; H, 7.64; N, 9.77%.

Boc-His(Boc)-His-Glu(OBzl)-Ala-Opac (14a) in Fig. 3. Compound **13a** (3.914 g) was treated with TFA (22 ml) in the presence of anisole (2.23 ml). The solid obtained by the usual method showed two spots (R_f^{10} 0.73, 0.79) on TLC in an approximately equal proportions. The crude product was employed for the following coupling without purification. To an ice-cooled solution of Boc-His(Boc)-OH (2.185 g) in DMF (9.0 ml) were added HOBt (1.246 g), EDC·HCl (1.297 g), and the ice-chilled solution of the above solid and Et_3N (1.42 ml) in DMF (23 ml). The mixture was stirred for 44.5 h in an ice-bath and then at room temperature. After evaporation of the solvent the residue was extracted with ethyl acetate (200 ml), and the organic layer was washed using the usual procedure. The residue obtained after removing the solvent showed two spots on TLC (components A and B). This crude residue was dissolved in chloroform (30 ml) and the solution was subjected to a silica-gel column (2.2×35.0 cm) which was eluted with chloroform–methanol solvent systems. The fractions containing component A, Boc-His(Boc)-His-(Boc)-Glu(OBzl)-Ala-Opac (**14b**), were combined and the solvent was evaporated. The residue was triturated with diethyl ether; 1.305 g, mp 90—91 °C, $[\alpha]_D^{24}$ $-22.0°$ (c 1.0, MeOH), R_f^1 0.47 (trace 0.26, 0.36), R_f^2 0.79 (trace 0.36, 0.66). Amino acid ratios in acid hydrolyzate: Glu 1.06 (1), Ala 1.01 (1), His 1.94 (2). Found: C, 59.80; H, 6.47; N, 11.15%. Calcd for $C_{50}H_{64}O_{14}N_8$: C, 59.99; H, 6.44; N, 11.19%. FAB mass: m/z 1001 (MH^+, $C_{50}H_{65}O_{14}N_8$). Component B, corresponding to the desired peptide, **14a**, was isolated from other fractions in the same chromatography described above; 0.965 g (21%), mp 86—87.5 °C, $[\alpha]_D^{24}$ $-30.0°$ (c 1.0, MeOH), R_f^1 0.11 (trace 0.36), R_f^2 0.40 (trace 0.79). Amino acid ratios in acid hydrolyzate: Glu 1.04 (1), Ala 1.00 (1), His 1.96 (2). Found: C, 58.80; H, 6.40; N, 11.97%. Calcd for $C_{45}H_{56}O_{12}N_8 \cdot H_2O$: C, 58.81; H, 6.36; N, 12.19%. FAB mass: m/z 901 (MH^+, $C_{45}H_{57}O_{12}N_8$).

Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-OEt (17). Compound **16** (24.047 g) was treated with TFA (30 ml)–anisole (3.59 ml), in the usual method, to give a solid. Boc-Lys(Z)-OH prepared from its dicyclohexylammonium salt (22.297 g) was dissolved in DMF (50 ml) and the solution was cooled below -20 °C. NMM (4.37 ml) and ECC (3.81 ml) were added to this solution with stirring. The mixture was stirred for 5 min at -14—-16 °C, and then cooled below -20 °C. To the mixture was added the ice-cooled solution of the above solid and Et_3N (4.60 ml) in DMF (50 ml). The mixture was stirred for 20.5 h in an ice-bath and then at room temperature. After the solvent was evaporated, the residue was extracted with ethyl acetate (300 ml). The solution was washed with water (300 ml×1). The precipitation brought about by the washing was dissolved by warming. The solution was dried and concentrated. The residue was recrystallized from methanol–chloroform–diethyl ether and chloroform–diethyl ether; 25.670 g (78%). For the purpose of analysis, a part of the product (0.320 g) was further purified by a silica-gel column (1.7×35.2 cm) with chloroform–methanol solvent systems as eluates. The obtained product was recrystallized from chloroform–methanol; 0.297 g (93%), mp 148.5—151.5 °C, $[\alpha]_D^{24}$ $-14.3°$ (c 1.0, DMF), R_f^1 0.51, R_f^2 0.78. Amino acid ratios in acid hydrolyzate: Gly 1.00 (1), Lys 3.01 (3). Found: C, 61.26; H, 7.29; N, 9.80%. Calcd for $C_{51}H_{71}O_{13}N_7 \cdot 1/2H_2O$: C, 61.31; H, 7.26; N, 9.81%.

Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-His-His-Glu(OBzl)-Ala-Opac (20). Compound **14a** (1.367 g) was treated with TFA (15 ml) and anisole (0.659 ml), in the usual way, to yield a solid (**19**), 3TFA·H-His-His-Glu(OBzl)-Ala-OPac; R_f^9 0.13, R_f^{10} 0.55, R_f^{11} 0.57. Found: C, 46.40; H, 4.01; N, 10.71%. Calcd for $C_{41}H_{43}O_{14}N_8F_9 \cdot H_2O$: C, 46.42; H, 4.28; N, 10.56%. The ice-chilled solution of **18** (1.824 g) in DMF (4.5 ml) was mixed with HOBt (0.384 g), EDC·HCl (0.436 g), and an ice-cooled solution of **19** and Et_3N (0.633 ml) in DMF (7.0 ml). The mixture was stirred for 18.5 h in an ice-bath and then at room temperature. The residue yielded, after removing the solvent, was dissolved in 1-butanol saturated with water. The organic layer was washed in the routine manner. After the solution was concentrated, the residue was recrystallized from methanol; 2.195 g (88%), mp 170 °C (decomp), $[\alpha]_D^{24}$ $-18.8°$ (c 1.0, DMF), R_f^4 0.90, R_f^9 0.60. Amino acid ratios in acid hydrolyzate: Glu 1.08 (1), Gly 0.98 (1), Ala 0.97 (1), His 1.96 (2), Lys 3.00 (3). Found: C, 60.61; H, 6.57; N, 12.54%. Calcd for $C_{84}H_{105}O_{20}N_{15} \cdot H_2O$: C, 60.67; H, 6.49; N, 12.63%.

Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-His-His-Glu(OBzl)-Ala-OH (21). Compound **20** (6.239 g) was dissolved in acetic acid (27 ml). Zinc powder (8.00 g) was added to this solution. The mixture was stirred for 4.5 h at 40 °C. After removing the catalyst, the filtrate was evaporated and the residue was triturated with water. The precipitates were collected and recrystallized from methanol–ethyl acetate; 4.861 g (84%), mp 176 °C (decomp), $[\alpha]_D^{24}$ $-15.3°$ (c 1.0, DMF), R_f^9 0.53 (trace 0.44). Amino acid ratios in acid hydrolyzate: Glu 1.03 (1), Gly 1.01 (1), Ala 0.98 (1), His 1.98 (2), Lys 3.00 (3). Found: C, 59.04; H, 6.69; N, 13.52%. Calcd for $C_{76}H_{99}O_{19}N_{15} \cdot H_2O$: C, 59.09; H, 6.59; N, 13.60%.

Boc-Glu(OBzl)-Leu-Lys(Z)-Pro-Leu-Ala-Gln-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl (22). Compound **5** (4.070 g) was treated with TFA (40 ml)–anisole (0.815 ml) in the usual manner to produce a solid. To an ice-cooled solution of **11** (4.847 g) in DMF (12.5 ml) were added HOBt (0.988 g), EDC·HCl (1.028 g) and the ice-chilled solution of the above solid and Et_3N (1.04 ml) in DMF (17.5 ml). The mixture was stirred for 72 h in an ice-bath and then at room temperature. The solvent was evaporated, the residue was dissolved in 1-butanol (ca. 150 ml) saturated with water and the organic layer was washed in the usual method. After concentration in vacuo, the crude product was dissolved in DMF (10 ml) and the solution was subjected to a Sephadex LH-60 column (2.2×143.8 cm) using the same solvent as the eluate. Fractions of 10 g each were collected. Fractions 28—53 were combined and the solvent was evaporated. The residue was recrystallized from methanol; 6.300 g (86%), mp 192 °C (decomp), $[\alpha]_D^{24}$ −31.8° (*c* 1.0, DMF), R_f^4 0.99 (HPTLC), R_f^9 0.75 (HPTLC). Amino acid ratios in acid hydrolyzate: Thr 0.84 (1), Ser 0.79 (1), Glu 2.11 (2), Pro 1.16 (1), Ala 1.91 (2), Leu 2.31 (2), His 0.91 (1), Lys 1.98 (2), NH_3 1.07 (1). Found: C, 60.19; H, 7.31; N, 11.71%. Calcd for $C_{100}H_{137}O_{24}N_{17}\cdot 2H_2O$: C, 60.14; H, 7.12; N, 11.92%.

Boc-Lys(Z)-Lys(Z)-Lys(Z)-Gly-His-His-Glu(OBzl)-Ala-Glu(OBzl)-Leu-Lys(Z)-Pro-Leu-Ala-Gln-Ser(Bzl)-His-Ala-Thr-Lys(Z)-OBzl (23). Compound **22** (3.000 g) was treated with TFA-CH_2Cl_2 (1:1) (40 ml) containing anisole (0.498 ml) in the usual procedure to afford a solid. Compound **21** (2.803 g) was dissolved in DMF (12 ml) and the solution was cooled in an ice-bath. The solution was mixed with HOBt (0.372 g), EDC·HCl (0.387 g), and the ice-cooled solution of the above solid and Et_3N (0.475 ml) in DMF (19 ml). The mixture was stirred for 65 h in an ice-bath and then at room temperature. The solvent was evaporated and the residue was dissolved in 1-butanol saturated with water. The 1-butanol layer was washed using the routine method. After removing the solvent, the product was dissolved in DMF (20 ml), and the solution was applied to a column (2.2×140 cm) of Sephadex LH-60 using the same solvent as the eluate. Fractions of 10 g each were collected. Fractions 26—42 were combined and the solvent was evaporated. The residue was repeatedly chromatographed on the same column, and recrystallized from methanol. However, the product still contained minor impurities; 2.856 g (55%). For the sake of further purification for analysis, the product (0.500 g) was dissolved in 1-butanol–acetic acid–water (4:1:1) (2.0 ml) and applied to a column (1.5×38.5 cm) of silica gel (Silica gel 100; Merck and Co.), which had been equilibrated with the same solvent system. It was eluted with the same solvent. Fractions of 5.0 g each were collected. Fractions 17—29 were combined and the solvent was removed. The recrystallization of the residue from methanol afforded a pure product; 0.122 g (24%), mp 198 °C (decomp), $[\alpha]_D^{24}$ −15.9° (*c* 1.0, DMF), R_f^3 0.83, R_f^8 0.67, R_f^9 0.60. Amino acid ratios in acid hydrolyzate: Thr 0.91 (1), Ser 0.87 (1), Glu 3.04 (3), Pro 1.19 (1), Gly 1.00 (1), Ala 2.95 (3), Leu 2.03 (2), His 2.99 (3), Lys 5.01 (5), NH_3 1.19 (1). Found: C, 59.55; H, 6.81; N, 12.93%. Calcd for $C_{171}H_{226}O_{40}N_{32}\cdot 4H_2O$: C, 59.67; H, 6.85; N, 13.02%.

The authors wish to thank Professor Machiko Tozawa, Associate Professor Tomoyoshi Takahashi and emeritus Professor Tsunetaka Kushimoto of The Jikei University School of Medicine, Professor Shosuke Sofuku of Rikkyo University for continuing interest and encouragement, and Associate Professor Sukekatsu Nozaki of Josai University for many discussions. They also thank the members of the Radiochemical Laboratory of Rikkyo University for CD measurements, the Research Laboratory of Toyo Jozo Co. Ltd. for elemental and FAB mass analyses.

The Preparation of Poly(3-methoxy-2,5-thiophenediyl) with Iron(III) Chloride and Its Properties

Susumu TANAKA* and Kyoji KAERIYAMA
Research Institute for Polymers and Textiles, 1-1-4, Higashi, Tsukuba, Ibaraki 305
(Received October 18, 1988)

Soluble and conductive poly(3-methoxy-2,5-thiophenediyl) was obtained by the chemical oxidation of 3-methoxythiophene with iron(III) chloride. The resulting polymer was found to be in a doped state, since it contained 0.1—0.2 counterions ($FeCl_4^-$ and Cl^-) per monomeric unit. This means that the oxidation is a convenient method for preparing conductive polymers in one step. We also obtained a poly-MOT solution and film in a state doped to a great extent, showing no π-π^* transition band and a high stability in air. An undoped polymer film was prepared by the electrochemical reduction of the doped film. The undoped film had a π-π^* transition band at 2.3 eV, indicating that the effective conjugation length of the polymer could be assumed to be the same as that of the poly(3-methoxythiophene) prepared electrochemically.

Electrochemical polymerization has been found to be an advantageous method for preparing conductive polyheterocycles, such as polythiophene[1] and polypyrrole,[2] since it permits polymers to be obtained on the surface of an electrode as films. In electrochemical polymerization, film thickness is proportional to the amount of charge flowed. However, film conductivity has been found to decrease extremely when the thickness becomes great.[3] Heterocyclic conductive polymers can be prepared not only by the electrochemical means, but also by the chemical method using transition metal salts.[4] By this method, the polymers are obtained as powdery products, but the amounts of polymers obtained increase in proportion to the feed of the starting materials.

We have previously prepared poly(3-methoxythiophene)(poly-MOT) electrochemically and found it to be soluble in organic solvents.[5] The doped state of poly-MOT was stable in air. In this paper, we wish to report on the preparation of poly-MOT with iron (III) chloride and its properties. The polymer obtained is soluble in organic solvents and in a doped state, as in the case of the electrochemically prepared one. This is a convenient method for preparing conductive polymers in one step.

Experimental

Materials. MOT[6] was prepared as reported previously. It was then distilled in vacuo: bp 62 °C (30 mmHg; 1 mmHg≈133.322 Pa) (lit,[6] bp 80—82 °C (65 mmHg)). Iron(III) chloride was used without any further purification. Chloroform was washed five times with about half its volume of water, dried with anhydrous calcium chloride, and distilled over calcium hydride under argon; bp 62 °C. Methanol was distilled and dried with Zeolite; bp 65—66 °C. Benzene was dried with anhydrous calcium chloride and distilled over calcium hydride; bp 80.0—80.5 °C. Nitromethane and acetonitrile were purified as reported previously.[3]

Polymerization. The typical polymerization procedures were as follows. In a three-necked flask equipped with a stirrer, a condenser, and an argon inlet, chloroform and iron(III) chloride were placed. Prior to polymerization, argon was bubbled, and bubbling was continued up to the end of the polymerization. The resulting yellowish green suspension was stirred at 30 °C, and MOT was added. A rapid color change into dark red took place. When benzene was used as the solvent, the brown suspension was changed into a dark red one by the addition of MOT. After stirring for 2 h, the reaction mixture was poured into methanol to remove the unreacted iron(III) chloride and iron(II) chloride. The precipitate was collected on a filter, washed with methanol, and dried in vacuo.

Reprecipitated poly-MOT was obtained by adding 100 ml of benzene to a solution of 0.1 g of poly-MOT in 20 ml of dimethyl sulfoxide (DMSO).

An undoped polymer was prepared by the electrochemical reduction of the doped film cast on an indium-tin oxide glass (ITO).

A cast film was obtained from a solution of 20 mg of the polymer in 4 ml of DMSO. About 20 mg of the solution was cast on ITO (1 cm×1 cm=1 cm^2) and dried in vacuo at 120 °C for 1 h.

Electrochemical Doping. A cast film on ITO was used as a working electrode. The counter electrode was a platinum plate or wire. A reference electrode consisting of Ag/Ag^+ was connected to the cell by means of a salt bridge. Acetonitrile was used as the solvent, and $NaClO_4$ (0.1 mol l^{-1}) as the electrolyte. The electrochemical data were obtained using a Hokuto Denko HA-501 potentiostat/galvanostat and an HB-104 function generator.

Measurements. The electrical conductivity was measured on pressed pellets by Van der Pauw's four probe method. Fourier transform IR and VIS-near IR spectra were recorded on a Perkin-Elmer Model 1720 spectrometer and a Hitachi U-3400 spectrometer respectively. The spectral change and cyclic voltammograms were measured according to the method described in a previous paper.[5]

Results and Discussion

Polymerization. The results of the polymerization of MOT are summarized in Table 1. Among the four kinds of solvents shown in Table 1, iron(III) chloride is soluble in nitromethane and methanol, while it is almost insoluble in benzene and chloroform. Considering the color change described in the Experimental section, iron(III) chloride is slightly soluble in benzene and chloroform, and polymerization should

8	$CHCl_3$	0.2	60	109.5[c)]	3.1

a) The concentration of MOT was 0.1 mol l^{-1}. b) The feed of MOT was 100 mg. c) Partly soluble in DMSO. Elemental analyses of poly-MOT obtained in Exp. No. 3: Before reprecipitation: C, 39.94; H, 2.82; S, 20.54; Fe, 5.76; Cl, 17.06. After reprecipitation: C, 44.21; H, 3.49; S, 20.61; Fe, 4.40; Cl, 10.97.

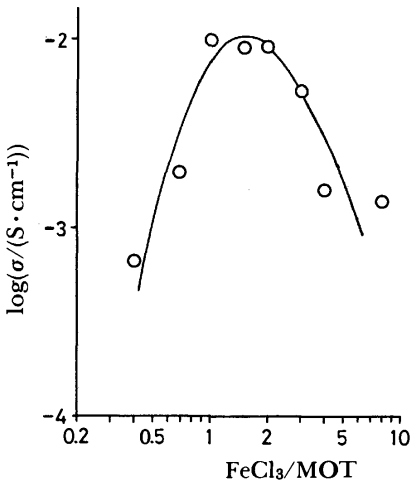

Fig. 1. Effect of the molar ratio of iron(III) chloride to MOT on conductivity of poly-MOT.

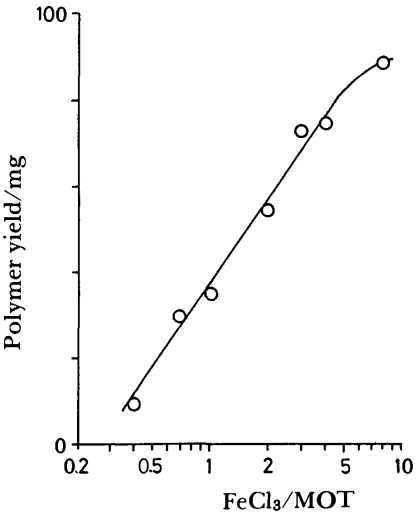

Fig. 2. Effect of the molar ratio of iron(III) chloride to MOT on polymer yield.

occur in a solution of iron(III) chloride. In Exps. Nos. 1—3, a black powdery product was obtained. The highest conductivity was obtained when chloroform was used as the solvent. In the case of methanol, no polymer was obtained as a precipitate from the solution nor by adding benzene or chloroform to the solution. In Exps. Nos. 3 and 5—8, the conductivity of the pressed pellet and polymer yield increased with the increase in the polymerization temperature. However, the polymer obtained above 45 °C was partly soluble in DMSO, although that obtained below 30 °C was soluble in DMSO. Figure 1 shows the effect of the molar ratio of iron(III) chloride to MOT on the conductivity of poly-MOT when MOT was polymerized at 30 °C in chloroform. The conductivity was highest when the ratio was in the range of 1—2. Figure 2 shows the effect of the ratio on the polymer yield when polymerization was done at 30 °C in chloroform. The yield increased with the increase in the ratio.

The above results show that a conductive and soluble product is obtained in a high yield when MOT is polymerized at 30 °C in chloroform with a molar ratio of 2. Thereafter, the polymerization was carried out under these conditions except otherwise mentioned. Elemental analyses showed the resulting poly-MOT to contain 0.16 and 0.11 counterions ($FeCl_4^-$ and Cl^-) per monomeric unit respectively, judging from the ratios of iron to sulfur and of chlorine to iron. However, reprecipitated poly-MOT contained 0.12 counterions ($FeCl_4^-$), indicating that reprecitipation brought about the removal of Cl^-. As to a polythiophene and its derivatives prepared by this method, they have been obtained in the undoped state. The reaction of thiophene with iron(III) perchlorate gave an insulating polymer.[7)] Using iron(III) chloride, soluble polythiophene derivatives were prepared from alkylthiophene monomers ($n\geqq4$), but the polymers were in an undoped state.[8)] Only a small number of papers on a one-step synthesis of doped polythiophenes have been published. Inoue et al. reported that the reaction of 2,2′-bithiophene with copper(II) perchlorate yielded doped polythiophene in one step.[9)] 2,2′-Bithiophene was polymerized more easily than thiophene, since the oxidation potentials of the former and the latter were 1.26 and 1.65 V vs. SCE respectively.[10)] MOT was also polymerized easily because of its low oxidation potential.[11)] The oxidation potential of polythiophene was lower by 0.55 V than that of the thiophene monomer. Therefore, the polymerization of thiophene should be followed by the oxidation of polythiophene in view of the thermodynamic data, but in fact polythiophene was obtained in an undoped state. We have to consider, therefore, that the reaction was not simply controlled thermodynamically.

IR Spectra. Figure 3 shows the Fourier transform IR spectra of doped and undoped poly-MOT. Both

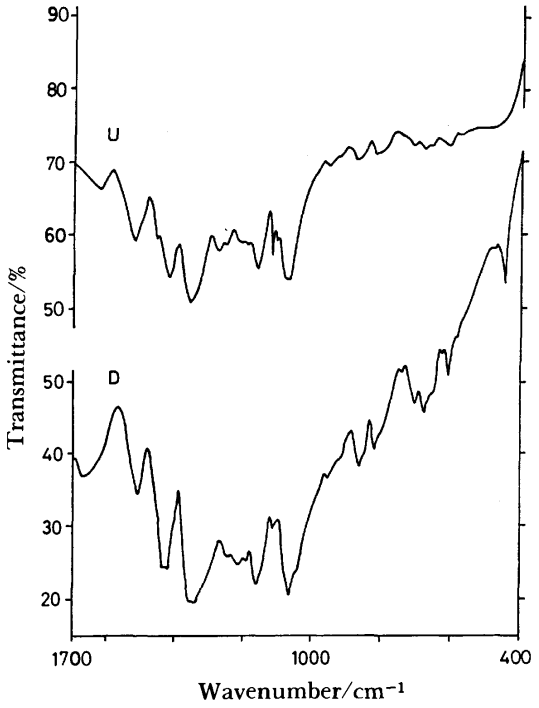

Fig. 3. IR spectra of poly-MOT.
U: an undoped polymer, D: a $FeCl_4^-$ doped polymer.

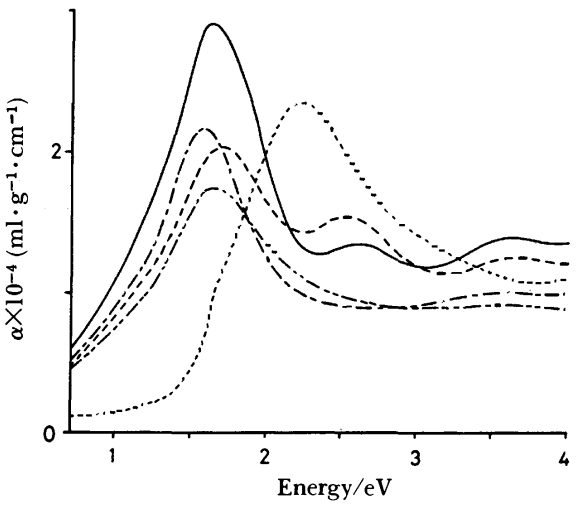

Fig. 4. VIS-near IR spectra of poly-MOT in DMSO.
———: Just after preparation, ----: After 4 days in air, — — —: Just after preparation (reprecipitated), ——·——: After 4 days in air (reprecipitated), ·····: an undoped polymer solution (reprecipitated).

polymers had two peaks, at 820 and 1260 cm^{-1}, assigned to the C-H deformation vibration of the 2,3,5-trisubstituted thiophene ring[12] and the C-O-C stretching vibration of the methoxyl group respectively. Neither had a peak at 795 cm^{-1} assignable to the C-H deformation vibration of the 2,5-disubstituted thiophene ring. Therefore, the structure of poly-MOT was consistent with that of poly(3-methoxy-2,5-thiophenediyl). In the 3000—3100 cm^{-1} frequency range,[12] no peak could be observed. We have previously reported the IR spectra of doped and undoped poly-MOT prepared electrochemically.[5] There was no difference between the spectra of the two undoped poly-MOT. As to the spectra of the two doped poly-MOT, some differences were observed; electrochemically prepared poly-MOT had two bands at 560 and 845 cm^{-1}, possibly due to the supporting electrolyte (Bu_4NPF_6), since the electrolyte had these peaks. The peaks at 445, 610, 870, and 1425—1440 cm^{-1} were observed only in the present poly-MOT.

VIS-Near IR Spectra. As has been mentioned above, poly-MOT was soluble in DMSO. Other polar solvents, such as 1-methyl-2-pyrrolidinone (NMP) and propylene carbonate (PC), were found to dissolve poly-MOT. Figure 4 shows the VIS-near IR spectra of poly-MOT in DMSO. The solid line had three absorption bands, at 1.6, 2.6, and 3.6 eV. The absorbance at 3.6 eV decreased in a broken line, suggesting that the band at 3.6 eV was not due to a π-π^* transition, since the doped state of poly-MOT should gradually change to the undoped state in air.[5] On the contrary, the band at 2.6 eV was considered to be due to a π-π^* transition, judging from the increase in the absorbance at 2.6 eV of the broken line.

To confirm the above estimation, the reprecipitation of poly-MOT was carried out. The spectra of reprecipitated poly-MOT are presented in the same figure. The spectrum of an undoped poly-MOT solution had only one band, at 2.2 eV, assigned to a π-π^* transition. The spectrum of a doped poly-MOT solution had two bands, at 1.6 and 3.6 eV. No band was observed around 2.2 eV, indicating that the reprecipitation brought about the removal of the poly-MOT containing undoped sites.

In the case of the poly-MOT prepared electrochemically, the spectrum of a doped polymer solution had a small π-π^* transition band at 2.3 eV in addition to the two bands at 1.0 and 1.5 eV,[5] suggesting that a slight undoping occurred in this case. These three characteristic bands were also observed in a doped poly-MOT film cast on ITO. On the other hand, the spectrum of the present poly-MOT film had only one band, at 1.6 eV, and no band was exhibited around 2.2 eV (Fig. 5). Thus, we obtained a poly-MOT solution and film in a state doped to a great extent. These results indicate that the doped state of the present poly-MOT was more stable in air than that of the electrochemical one.

As for the two bands at 1.6 and 3.6 eV shown in Fig. 4, further discussion will be given below.

The change in the VIS-near IR spectra during the doping of the film of poly-MOT is shown in Fig. 5. Cast films on the ITO anode were electrochemically doped at different voltages, and in situ spectra were recorded. At −0.7 V, the film had two bands, at 2.3 and 3.4 eV. The doping level became higher as the applied voltage was increased. At 0.3 V, a band at 1.9 eV was observed. When the voltage decreased to −0.7

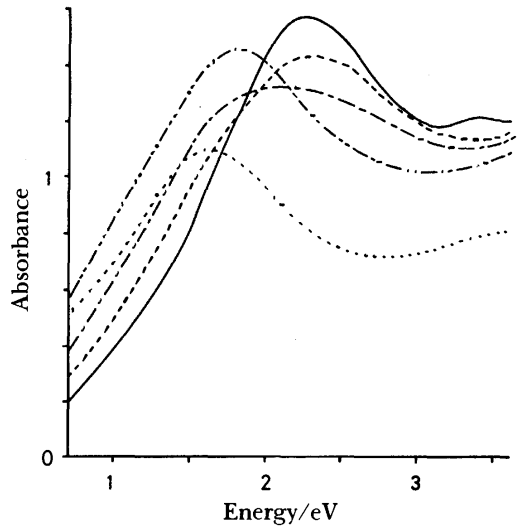

Fig. 5. VIS-near IR spectrum of reprecipitated poly-MOT film cast on ITO (------) and spectral change during electrochemical doping of poly-MOT. Electrolyte: $NaClO_4$ (0.1 mol l^{-1}). Applied voltage: ——: −0.7V; ----: −0.3V; — - —: −0.1V; —·—: 0.3V.

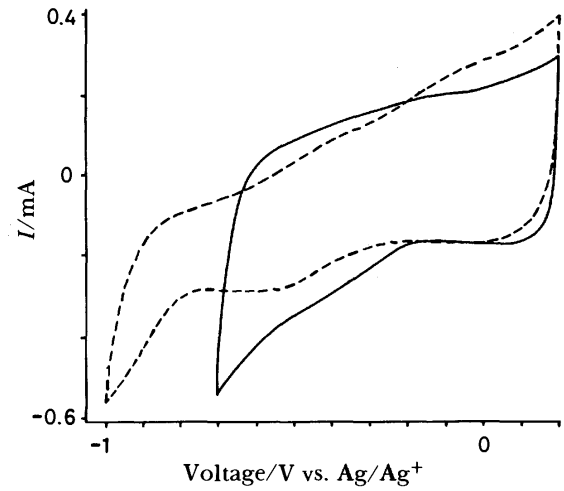

Fig. 6. Cyclic voltammograms of poly-MOT. In every case, current was calculated under the conditions that 1 mg of the polymer was deposited on ITO (1×1=1 cm^2). Electrolyte: $NaClO_4$ (0.1 mol l^{-1}). Sweep rate: 2 mV s^{-1}.

V again, the film had only one band, at 2.3 eV, and the band at 3.4 eV disappeared completely. These results indicate that the band at 2.3 eV is to be assigned to a π-π^* transition, while the band at 3.4 eV might be caused by a contamination. The low-molecular-weight part of poly-MOT should be more soluble than the other part. Moreover, the solubility of undoped poly-MOT was higher than that of doped poly-MOT. Accordingly, at the lower applied voltage, acetonitrile might dissolve the low-molecular-weight part. The band at 1.9 eV observed in the doped film could be attributed to Würster-type radical cations produced by the oxidation of poly-MOT, as has been discussed in the previously reported paper.[5]

Concerning the change in the VIS-near IR spectra of the reprecipitated poly-MOT film, as a whole it was the same as that presented in Fig. 5, including that the band at 3.4 eV, observed initially at −0.7 V, disappeared on the second sweep. The undoped film had a band at 2.3 eV, and the doped one, one at 1.55 eV. The effective conjugation length of the undoped poly-MOT was assumed to be the same as that of the poly-MOT prepared electrochemically, since the latter showed a π-π^* transition band at 2.3 eV.[5]

Cyclic Voltammetry. Figure 6 shows the cyclic voltammograms of cast films of poly-MOT with $NaClO_4$. On the sweep ranging from −0.7 V to 0.2 V, an anodic shoulder was observed at −0.2 V and a cathodic shoulder at −0.5 V, as is shown by the solid line. The film was blue above the oxidation potential and red-purple below the reduction potential. On another sweep ranging from −1.0 V to 0.2 V, the anodic shoulder could be observed more clearly than before, as is shown by the broken line. However, in this case, the anodic and cathodic currents decreased gradually when the sweep was carried out repeatedly, suggesting that poly-MOT deteriorates at applied voltages lower than −0.7 V. Electrochemically prepared poly-MOT presented an anodic peak and a cathodic peak quite clearly at −0.20—−0.18 V and at −0.50—−0.48 V respectively. The present polymer had the anodic and cathodic shoulders in the same regions, but no clear peak was observed. The same results were found in the cyclic voltammograms of the cast films of reprecipitated poly-MOT. The ambiguity of the oxidation and reduction peaks should be mainly explainable by the finding that the background current was about 10 times as high as that in poly-MOT prepared electrochemically.[5]

On the Reaction of *N*-Vinyliminophosphoranes. 9.[1] The Synthesis and Reaction of *N*-(1,3,5-Cycloheptatrienyl)iminophosphoranes to Provide a Novel Route to 1-Azaazulenes

Yukio Iino, Eijiro Hara, and Makoto Nitta*
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 169
(Received November 5, 1988)

The first syntheses of *N*-(2,4,6-cycloheptatrienyl)iminophosphoranes (**3a, b**) and their thermal conversion to *N*-(1,3,5-cycloheptatrienyl)iminophosphoranes (**5a,b**) have been studied. The kinetic study of the 1,5-hydrogen migration of **3a,b** to *N*-(1,3,6-cycloheptatrienyl)iminophosphoranes (**4a,b**) has also been investigated. The reaction of **5b** with α-bromoacetophenone derivatives has provided a novel route to the 1-azaazulene ring system, albeit in low yields.

The reaction of a tertiary phosphine with an organic azide to produce an iminophosphorane after nitrogen evolution is known as the Staudinger reaction.[2] Many intermolecular[3] and intramolecular[4] Wittig-type (aza-Wittig) reactions with carbonyl compounds to construct a carbon-nitrogen double bond have been reported. However, the synthetic versatility of iminophosphoranes has still not been fully explored compared with that of methylenephosphoranes.[5] This fact can be ascribed in part to the poor variation of the substituent on the nitrogen atom of iminophosphoranes. Previously, we demonstrated the simple preparation of novel *N*-(1-phenylvinyl)iminophosphorane,[6] *N*-vinyliminotriphenylphosphorane,[7] and *N*-(1-butylvinyl)iminotriphenylphosphorane[7] by the Staudinger reaction of the corresponding organic azides with tertiary phosphines. *N*-Vinyliminophosphoranes were found to react with α-bromo ketones, α,β-unsaturated ketones, and tropone derivatives in an enamine alkylation process followed by an aza-Wittig reaction to provide a convenient route to phenyl-substituted pyrroles,[8,9] pyridines,[7,9] and 1-azaazulenes.[6,10] However, the potential value of *N*-vinyliminophosphoranes bearing cycloalkene on the nitrogen atom remains unexplored. We describe here the preparation of novel *N*-(1,3,5-cycloheptatrienyl)iminophosphoranes (**5a, b**) and their reactions with α-bromoacetophenone derivatives to give 2-aryl-1-azaazulene derivatives.

Results and Discussion

The reaction of 7-azido-1,3,5-cycloheptatriene (**1**)[11] with triphenylphosphine (**2a**) and tributylphosphine (**2b**) in dry benzene at room temperature afforded *N*-(2,4,6-cycloheptatrienyl)iminotriphenylphosphorane (**3a**) and *N*-(2,4,6-cycloheptatrienyl)iminotributylphosphorane (**2b**), respectively. Compound **3a** is a crystalline compound, which could be easily purified by recrystallization. On the other hand, compound **3b** is not stable on silica gel and it could not be purified. Thus, oily **3b** was used for further reactions. However, the structures of **3a** and **3b** were easily deduced on the basis of spectral data. The ^{13}C NMR

	(9.0)	(12.4)		117.43	113.39		(20.0)	22.48, 12.26	

a) The numerical values in parentheses denote the coupling constants with ^{31}P. b) Downfield relative to external 85% H_3PO_4 standard. c) Each of the chemical shifts for C3—C6 are not assigned distinctly. d) Butyl groups appear as multiplets because of its coupling with ^{31}P.

and ^{31}P NMR spectral data are summarized in Table 1.

In general, the cycloheptatrienes undergo sequential 1,5-hydrogen migration and the equilibrium shifts to the side of the most stable isomer bearing a substituent at C1, although the formation of other isomers has been detected. Therefore, the thermal reaction of **3a, b** is probably a useful method for the attempted preparation of *N*-(1,3,5-cycloheptatrienyl)iminophosphoranes **5a, b**. When **3a** was heated in toluene under reflux, isomer **4a** was formed at first. Progress of the reaction could be followed by ^{1}H NMR spectroscopy. After prolonged heating, only the desired product **5a** was obtained in 89% yield after recrystallization. Similarly, compound **3b** was isomerized in benzene under reflux for 7 h to give **5b** in good yield. The ^{1}H NMR spectra of **5a, b** exhibited a typical pattern of the 1-substituted cycloheptatriene. The ^{13}C NMR and ^{31}P NMR spectral data, which are summarized in Table 1, and other spectral data are in good accordance with the proposed structures, **5a, b**.

Scheme 2.

A kinetic study of the rearrangement (**3a**→**4a** and **3b**→**4b**) was carried out at temperatures ranging from 68.0 °C to 99.0 °C and from 60.3 °C to 79.5 °C, respectively, to establish the mechanistic aspects. Further rearrangement of **4a, b** to **5a, b** was not observed during the kinetic studies of the early stage of the reactions. A plot of the logarithm of the concentration of unchanged **3a, b** against the reaction time was linear. The rate constants, thus obtained, are shown in Table 2. Arrhenius plots of the data for **3a** and **3b** (Table 2) provided straight lines, from which the kinetic parameters were calculated. These parameters as well as those of the thermal 1,5-hydrogen shift of 7-substituted cycloheptatrienes **6a—c** to 3-substituted cycloheptatrienes **7a—c** are summarized in Table 3.

Table 2. The First-Order Rate Constants k of **3a** and **3b**

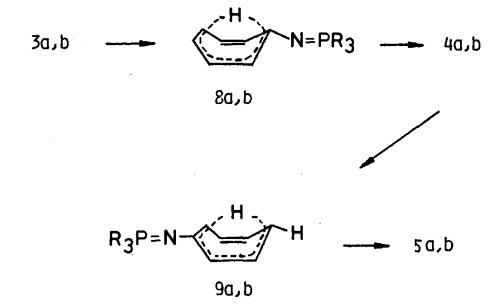
	Temp/ °C	$10^5 \times k/s^{-1}$		Temp/ °C	$10^5 \times k/s^{-1}$
3a	68.0	1.04	**3b**	60.3	0.96
	79.5	3.60		68.0	3.04
	86.5	9.25		76.0	6.04
	99.0	27.56		79.5	8.83

Table 3. The Kinetic Parameters of 1,5-Hydrogen Shift of 7-Substituted Cycloheptatrienes

Compound	E_a/kcal mol^{-1}	log A	$\Delta S^{\neq}$/cal mol^{-1}deg^{-1}
3a	26.6	12.1	−5.0[a]
3b	26.3	12.3	−6.1[a]
6a	33.25±0.19	12.6±0.2	−4.9[b]
6b	26.407	10.04	−15.0[c]
6c	27.6	10.8	−11.7[d]

a) At 80 °C. b) Ref. 12. c) Ref. 13. d) Ref. 14.

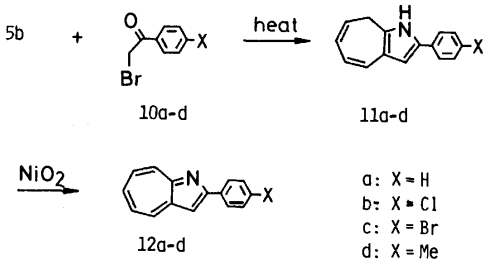
The preexponential factors obtained, $10^{12.1}$ and $10^{12.3}$ for **3a** and **3b**, respectively, correspond to the negative entropy of activation, i.e., −5.0 and −6.1 eu (at 80 °C). These values are intermediate between that of **6a**[12] and those of **6b, c**.[13,14] These facts clearly suggest that the 1,5-hydrogen shift of **3a, b** is sigmatropic in character and proceeds via a rigid transition state such as **8**. The activation energies for **3a** and **3b**



Scheme 3.

are similar to those of **6b**[13] and **6c**.[14] Thus, the steric or electronic effect of the phosphoranylideneamino group seems also to accelerate the 1,5-hydrogen shift in **3a, b**. Compounds **4a, b** further undergo a 1,5-hydrogen shift via a transition state **9**; the equilibrium are almost shifted to the side of the most stable isomers, **5a, b**.

The thermal reaction of **5a** with α-bromoacetophenone (**10a**) in benzene in the presence of triethylamine under reflux afforded no isolable products. However, compound **5b** reacted with **10a** to afford 1,8-dihydrocyclohepta[*b*]pyrrole (**11a**)[6,10] in 28% yield. Compound **11a** is not very stable, and it was dehydrogenated by NiO_2[15] in benzene to afford 2-phenyl-1-azaazulene (**12a**) in 44% yield. When a series of annelation reactions giving **11a** and the subsequent dehydrogenation by NiO_2 was carried out without rigorous purification of **11a**, compound **12a** was also obtained in 12% yield (Table 4, entry 1) (see Experimental). Similarly, reactions of **5b** with **10b—d** were carried out



10a-d 11a-d

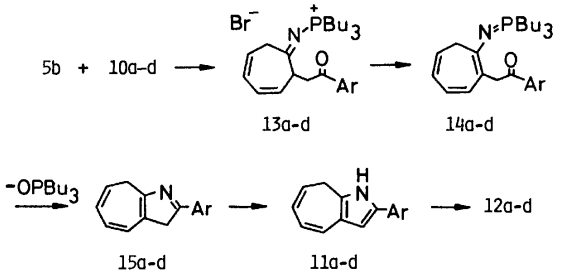
4	**10d**	15	15	**12d**	11

a) All the reactions were carried out in benzene under refluxing. b) Reactions were carried out at room temperature.



Scheme 5.

in dry benzene under reflux to give plausible intermediates **11b—d**, which were subsequently dehydrogenated by NiO_2 to give the 2-aryl-1-azaazulene derivatives **12b—d**. The detailed reaction conditions and the yields of the products are summarized in Table 4. Product **12a**[16] is a known compound, and the other 1-azaazulenes **12b—d** were characterized on the basis of spectral data.

The plausible reaction pathways for the formation of 1-azaazulenes **12a—d** are summarized in Scheme 5. By analogy with the reaction of *N*-vinyliminophosphorane[8,9] with α-bromoketones, the initial step is the formation of a C-C bond between **5b** and **10a—d** to give intermediates **13a—d**, which undergo hydrogen migration to give **14a—d**. The intramolecular aza-Wittig reaction followed by hydrogen migration constructing the pyrrole ring gives **11a—d**. The oxidation of **11a—d** with NiO_2 results in the formation of 1-azaazulenes **12a—d**.

Thus, the desired *N*-(1,3,5-cycloheptatrienyl)iminophosphoranes **5a, b** were easily prepared, and were reacted with α-bromoacetophenones to give arylsubstituted 1-azaazulenes albeit in low yields. Further synthetic applications of the iminophosphoranes are in progress.

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The ^1H NMR and ^{13}C NMR spectra were recorded on Hitachi R-24 and Hitachi R-90H spectrometers, and the chemical shifts are given in ppm (δ) relative to the internal $SiMe_4$ standard. The ^{31}P NMR spectra were recorded on a Hitachi R-90H spectrometer and the chemical shifts are given in ppm (δ) relative to the external 85%-H_3PO_4 standard. Mass spectral and high-resolution mass spectral studies were conducted using Shimadzu GCMS-QP1000 and JEOL DX-300 spectrometers. All the melting points were measured on a Büch apparatus and are uncorrected.

Preparation of *N*-(2,4,6-Cycloheptatrienyl)iminophosphoranes 3a, b. A solution of tropylium tetrafluoroborate (5 g, 28 mmol) and sodium azide (10 g, 154 mmol) in water (50 cm^3) was stirred for 5 min at room temperature. The reaction mixture was extracted with benzene and the benzene extract was dried over $MgSO_4$ and then concentrated to 50 cm^3. To this solution of 7-azidocycloheptatriene (**1**)[11] thus obtained was added to triphenylphosphine (**2a**) (6.5 g, 25 mmol) or tributylphosphine (**2b**) (5 g, 25 mmol) at room temperature and stirred for 2 h or 5 h. After the benzene was evaporated, the resulting residue was crystallized from benzene-hexane to give yellow crystals of **3a** (3.1 g, 89%): mp 109—110 °C (from benzene-hexane); ^1H NMR ($CDCl_3$) δ=3.00 (1H, dm, *J*=19.5 Hz), 5.50 (2H, dd, *J*=4.6, 9.2 Hz), 5.80—6.10 (2H, m), 6.52 (2H, t, *J*=2.6 Hz), 7.30—7.85 (15H, m); IR ($CHCl_3$) 3004, 1591, 1485, 1441, 1393, 1304, 1180, 1105, 908, 697 cm^{-1}; MS, *m/z* (rel intensity) 367 (M^+, 16), 261 (100). Found: C, 81.99; H, 6.19; N, 3.60%. Calcd for $C_{25}H_{22}NP$: C, 81.72; H, 6.04; N, 3.81%. In the case of **3b**, the benzene was evaporated in vacuo and the resulting oily residue was used for further reaction, because of its instability to heat and chromatography on silica gel. For **3b**: ^1H NMR ($CDCl_3$) δ=0.75—1.15 (9H, m), 1.15—1.85 (18H, m), 2.55 (1H, dm, *J*=20.5 Hz), 5.25 (2H, dd, *J*=8.5, 4.5 Hz), 5.70—6.15 (2H, m), 6.54 (2H, t, *J*=3.0 Hz); IR ($CHCl_3$) 2955, 2929, 2866, 1468, 1391, 1305, 1184, 1094 cm^{-1}. HRMS Found: *m/z* 307.2431. Calcd for $C_{19}H_{34}NP$: M, 307.2429.

Thermal Isomerization of 3a,b to *N*-(1,3,5-Cycloheptatrienyl)-iminophosphoranes 5a,b. (A) A solution of **3a** (3.5 g, 9.5 mmol) in toluene (10 cm^3) was heated under reflux for 7 h. After the toluene was evaporated in vacuo, the resulting residue was crystallized from hexane to give yellow crystals of **5a** (3.1 g, 89%): mp 131—132 °C (from EtOH); ^1H NMR ($CDCl_3$) δ=2.65 (2H, dd, *J*=7.8, 1.0 Hz), 4.90—5.40 (2H, m), 5.83—6.30 (3H, m), 7.30—7.91 (15H, m); IR ($CHCl_3$) 2995, 1574, 1496, 1441, 1328, 1174, 1107, 1026 cm^{-1}; MS, *m/z* (rel intensity) 367 (M^+, 75), 366 (100). Found: C, 81.83; H, 6.22; N, 3.60%. Calcd for $C_{25}H_{22}NP$: C, 81.72; H, 6.04; N, 3.81%.

(B) A solution of **3b** in benzene, which was prepared as described above, was heated under reflux for 7 h. After the benzene was evaporated, the resulting residue was distilled under reduced pressure to give **5b** (6.15 g, 81% based on tropylium cation used). For **5b**: bp 137 °C/11 Pa. ^1H NMR (CCl_4) δ=0.75—1.20 (9H, m), 1.20—2.10 (18H, m), 2.23 (2H, dd, *J*=7.2, 1.6 Hz), 4.80—5.15 (2H, m), 5.55—6.40 (3H, m); IR ($CHCl_3$) 2964, 2934, 2871, 1567, 1486, 1441, 1333, 1204, 1026 cm^{-1}. HRMS Found: *m/z* 307.2413. Calcd for $C_{19}H_{34}NP$: M, 307.2429.

Reaction Rate of 1,5-Hydrogen Migration of 3a, b to 4a, b. The solution of **3a** (0.5 mol dm^{-3}) in CCl_2CCl_2 was placed in six reaction tubes (5 mm in outer diameter and 30 mm long), which were fitted in the neck of a 500 cm^3 flask with six necks and a reflux condenser, which contained a suitable solvent. Six tubes were heated at the same time by vapor of boiling solvent such as dioxane (99.0 °C), trichloroethylene

(86.5 °C), benzene (79.5 °C), or hexane (68 °C). During heating, each tube was periodically withdrawn from the flask and cooled quickly with ice bath to quench the reaction. The ^{1}H NMR spectrum was measured by a Hitachi R-24 spectrometer. The concentration ratios of the isomerized product, **4a** and **3a**, were calculated from the proton area of the signal ascribed to the 7H-proton of cycloheptatriene of the corresponding compounds.

The solution of **3b** (3.0 mol dm^{-3}) in CCl_2CCl_2 with 1/6 molar equivalent amounts of anisole was placed in six reaction tubes, which were fitted in the same apparatus described above. Six tubes were heated at the same time by vapor of boiling solvent such as *i*-PrOH (79.5 °C), CCl_4 (76.0 °C), hexane (68 °C), or $CHCl_3$ (60.3 °C). The ^{1}H NMR spectrum was measured, and the concentration ratios of the remaining **3b** was determined by the proton area of the signals ascribed to the 7H-proton of **3b** and the methyl proton of anisole used as the internal standard. From this concentration ratio, the product ratio of **4b** was calculated.

The Reaction of *N*-(1,3,5-Cycloheptatrienyl)iminotributylphosphorane (5b) with α-Bromoacetophenone (10a). A solution of the iminophosphorane (**5b**) (307 mg, 1 mmol), α-bromoacetophenone (**10a**) (199 mg, 1 mmol), and triethylamine (202 mg, 2 mmol) in benzene (5 cm^3) was heated under reflux for 22 h. After the reaction was completed, the reaction mixture was chromatographed on Florisil. The fractions eluted with benzene afforded 1,8-dihydro-2-phenylcyclohepta[*b*]pyrrole (**11a**) (58 mg, 28 %), which was identified by comparison of the spectral data of the authentic specimen.[6]

General Procedure for the Reaction of *N*-(1,3,5- Cycloheptatrienyl)iminotributylphosphorane (5b) with α-Bromoacetophenones (10a—d) and Subsequent Dehydrogenation. A solution of the iminophosphorane (**5b**) (307 mg, 1 mmol), α-bromoacetophenone (**10**) (1 mmol), and triethylamine (202 mg, 2 mmol) in benzene (5 cm^3) was heated under reflux for a period indicated in Table 4. After the reaction was completed, the reaction mixture was chromatographed on Florisil. The fractions eluted with benzene was concentrated to 20 cm^3. To this solution was added NiO_2 (910 mg, 10 mmol); and the mixture was then stirred for 10—15 h at room temperature. After the reaction mixture was filtered through Celite to remove insoluble materials, the filtrate was concentrated and the resulting residue was purified by TLC on Silica gel using hexane-ethyl acetate (1/1) to give 1-azaazulene derivatives (**12**) in the yields indicated in Table 4. 2-Phenyl-1-azaazulene (**12a**): mp 148—149.5 °C (from EtOH) (lit, 157—159 °C); ^{1}H NMR ($CDCl_3$) δ=7.22—7.72 (7H, m), 8.19—8.48 (3H, m), 8.48—8.74 (1H, m); IR ($CHCl_3$) 2906, 2857, 1586, 1466, 1445, 1412, 1030 cm^{-1}; *m/z* (rel intensity) 205 (M^+, 100); UV (EtOH, log ε) 205 (4.33), 237 (4.20), 287 (4.59), 310 (4.45), 355 (4.09), 372 (4.04), 497 (3.44), 529 (3.16) nm; (EtOH-TFA, log ε) 260 (4.30), 282 (4.33), 306 (4.57), 340 (3.90), 446 (4.06) nm. 2-(4-Chrolophenyl)-1-azaazulene (**12b**): mp 165—165.9 °C (from EtOH); ^{1}H NMR ($CDCl_3$) δ=7.24—7.78 (6H, m), 8.06—8.82 (4H, m); IR ($CHCl_3$) 2985, 2955, 1602, 1464, 1437, 1413, 1087, 1012 cm^{-1}; MS, *m/z* (rel intensity) 242 (M^++1, 5), 241 (M^+, 28), 240 (M^++1, 18), 239 (M^+, 100); UV (EtOH, log ε) 205 (4.26), 237 (4.18), 287 (4.50), 312 (4.41), 356 (4.09), 372 (4.06), 496 (3.45), 527 (3.25) nm; (EtOH-TFA, log ε) 263 (4.26), 280 (4.23), 310 (4.49), 345 (3.93), 446 (4.03) nm. The Selective Claisen and Dieckmann Ester Condensations Promoted by Dichlorobis(trifluoromethanesulfonato)titanium(IV)

Yoo Tanabe
Takatsuki Research Laboratory, Sumitomo Chemical Co., Ltd., Takatsuki, Osaka 569
(Received November 7, 1988)

Inter and intramolecular condensations (the Claisen and the Dieckmann condensations) between ester functions have been performed by the combined use of dichlorobis(trifluoromethanesulfonato)titanium(IV) (= dichlorobis(triflato)titanium(IV)) and tertiary amine under mild reaction conditions. These results led to the development of the selective (crossed) Claisen and Dieckmann ester condensation between methoxymethyl ester and methyl ester, in that, dichlorobis(triflato)titanium(IV) contribute to control the direction of the reaction.

The Claisen and the Dieckmann ester condensations are the most fundamental and useful carbon-carbon bond forming reactions in organic synthesis.[1] However, the utility of these reactions have been limited by the several problems. Basic labile functional groups could be hardly introduced in the substrates employed, because these reactions are conventionally carried out in basic media. And, it is more of critical that it has been difficult in controlling the direction of the reaction, namely when the condensation is carried out between two different esters, each of which possesses α-hydrogen, a mixture of all four products is generally obtained.[2] To evade the problem, esters lacking α-hydrogen such as benzoates, carbonates, and oxalates are commonly employed as acylating agents.

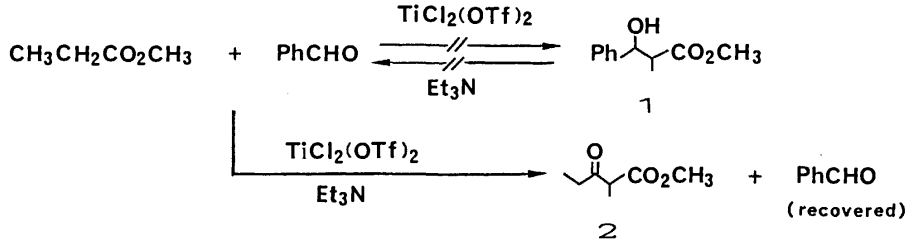
In the preceding communications,[3] we have reported the Claisen and the Dieckmann ester condensation between alkyl esters and the crossed type of the ester condensation between methoxymethyl ester and methyl ester could be performed under mild reaction conditions by using dichlorobis(trifluoromethanesulfonato)titanium(IV)[4] (=dichlorobis(triflato)titanium(IV)). In this paper, the author describe the results of the studies on them in detail.

Results and Discussion

The characteristic properties of the metal triflates (trifluoromethanesulfonates) system had led to the development of significant carbon-carbon bond forming reactions in organic synthesis.[5] In particular, dialkylboryl triflates and tin(II) triflates mediated synthetic processes enjoyed highly regio-, stereo-controlled aldol type[5a-f] and the Michael type[5g,h] reactions. In connection with the progress, we paid our attention to the utilization of titanium(IV) triflates species, which were known in inorganic chemistry.[4,6] Among the four feasible titanium(IV) spesies, we chose the most stable and accessible dichlorobis(trifluoromethanesulfonato)titanium(IV) (=dichlorobis(triflato)titanium(IV)).[7]

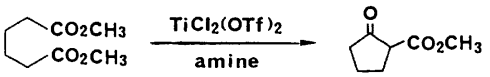
Firstly, we studied the ability of dichlorobis(triflato)-titanium(IV) ($TiCl_2(OTf)_2$) to generate the enolate from ester, because tin(II) triflate or dialkylbolyl triflate fail to promote the reaction perhaps due to the low acidity of α-proton of ester. The addition reaction of methyl propionate with benzaldehyde in the presence of $TiCl_2(OTf)_2$ and triethylamine (molar ratio of ester : aldehyde : $TiCl_2(OTf)_2$: Et_3N=1.0 : 1.1 : 1.1 : 1.1) was found to give not even a trace amount of the β-hydroxy ester **1**, but unexpectedly methyl 2-methyl-3-oxovalerate (**2**) as a main product in 36% yield. Meanwhile, treatment of the β-hydroxy ester **1** with $TiCl_2(OTf)_2$ and triethylamine under the same conditions did not take place the retro-aldol reaction and the ester **1** was recoverd quantitatively. The cross-over experiment showed that the aldol-type reaction did not occured at all in this system (Scheme 1).

Based on these results, the different type of Claisen ester condensation under nonbasic media were studied. To optimize the conditions, intramolecular cyclization (the Dieckmann condensation) of dimethyl adipate was examined. Among several solvents screened, dichloromethane gave the best result in yield (Table 1). Tertiary amines such as triethylamine or *N,N*-diisopropylethylamine was found to give good results. As molar ratio, the combined use of 1.5 equivalent of $TiCl_2(OTf)_2$ and 2.2 equivalent of triethylamine gave



Scheme 1.

Table 1. Effect of the Solvent on the Dieckmann Condensation of Dimethyl Adipate[a]



Solvent	Yield of 2-methoxycarbonyl-1-cyclopentanone/%	Recovery of dimethyl adipate/%
Toluene	32	55
Tetrahydrofuran[b]	0	—
Ether	17	75
Dichloromethane	55	42
1,2-Dichloroethane	35	55

a) The reaction was carried out at 0 °C for 2 h employing triethylamine as base. Molar ratio of dimethyl adipate: $TiCl_2(OTf)_2$: Et_3N=1.0 : 1.1 : 1.5. b) Tetrahydrofuran was polymerized in this condition.

Table 2. Effect of Bases and Molar Ratio on the Dieckmann Condensation of Dimethyl Adipate[a]

9	Triethylamine	(2.2)	1.5	71
10	Triethylamine	(3.3)	1.1	38
11	Triethylamine	(3.3)	1.5	48
12	Triethylamine[c]	(2.2)	1.5	80

a) The reaction was carried out at 0 °C for 2 h employing dimethyl adipate as substrate. b) Isolated yield. c) In the presence of Molecular Sieves 4A.

the best yield (Table 2). The tendency of these conditions is similar to those of other metal (tin(II) and boryl) triflates systems. A somewhat excess of $TiCl_2(OTf)_2$ was required to complete the reaction perhaps owing to compensate the reagent decomposed by an equimolar amount of methanol produced during the condensation. The addition of Molecular Sieves 4A to catch the methanol slightly effected the yield.

Analogous types of titanium complexes such as dichlorobis(fluorosulfonato)titanium(IV) ($TiCl_2(SO_3F)_2$),[8] titanium(IV) chloride ($TiCl_4$), and bis(η-cyclopentadienyl)bis(trifluoromethanesulfonato)titanium(IV) ($TiCp_2(OTf)_2$)[9] were also applied to expect the same reaction. However, their titanium(IV) reagents failed to proceed the condensation reaction, probably because $TiCl_2(SO_3F)_2$ could be hardly soluble in dichloromethane during the reaction and $TiCl_4$, $TiCp_2(OTf)_2$ are less reactive compared with $TiCl_2(OTf)_2$ as Lewis acid.

Methyl 5-(chloroformyl)valerate was examined as substrate to compare the reactivity with dimethyl adipate, but no reaction occured at all under the same conditions. The results suggest that the capture of the methoxyl group by $TiCl_2(OTf)_2$ correlates the driving force of the reaction.

Several examples of the condensation under the optimum conditions were depicted in Table 3. α-unsubstituted esters could be subjected to self ester condensation (Entries 1—3), whereas no desired compound was obtained in the case of α-alkyl-substituted ester such as methyl isobutyrate (Entry 5). The result reflected on the regioselective cyclization of diethyl 2-methyladipate to afford only 2-ethoxycarbonyl-5-methylcyclopentanone (Entry 6). Benzoylation, formylation, and oxalylation were similarly performed employing third fold excess of the corresponding acylating reactants (Entries 7—11).

A plausible mechanism is illustrated in Scheme 2. Small amount of the enolate of an ester in the system, which is successively generated from the ester on equilibrium, immediatly transformed into more stable titanium salt of the enol of the corresponding β-keto ester. The resultant titanium salt of the β-keto ester is quenched by water to give the product. This speculation could be supported by the following facts; (1) the aldol-type reaction did not proceeded under this condition, (2) also in the usual Claisen condensation α-alkyl-substituted ester required more harsh basic conditions.[1a]

In due consideration of the dichlorobis(triflato)titanium(IV) promoted Claisen ester condensation, we studied the direct and the crossed (regiocontrolled) type-Claisen ester condensation which was hitherto enable to be realized under commonly known basic conditions.[10,11] To answer the problem, we planned regioselective enolate formation of one of the two different ester functions. In the hope that titanium(IV) species exhibit the strong chelating ability toward oxygen or sulfur atom adjacent to ester functions, methoxymethyl ester **13**, methylthiomethyl ester **14**, and 2-methoxyethyl ester **15** were examined to produce the enolate predominantly against methyl ester through intramolecular (the Dieckmann) condensa-

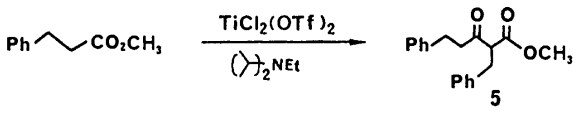
a) The reaction was carried out in dichloromethane and the molar ratio of $TiCl_2(OTf)_2$: **13**=1.3 : 1.0. 2-Methoxycarbonyl-1-cyclopentanone was produced with only a trace amount in every conditions.

Table 5. Self Condensation of Methyl 3-Phenylpropionate[a)]



Entry	Conditions	Yield of 5/%
1	0 °C—r.t., 10 h	37
2	0 °C, 3h	15
3	−23 °C, 3h	trace

a) The reaction was carried out in CH_2Cl_2 and the molar ratio of $TiCl_2(OTf)_2$: diisopropylethylamine : methyl 3-phenylpropionate=1.3 : 3.0 : 2.0.

(ethoxymethyl)ethyl methyl adipate (**21**) were attempted, but more fruitful results were not obtaied both in yield and with selectivity (Scheme 4). The use of *N,N*-diisopropylethylamine (the Hünig base) or *N*-ethylpiperidine at −23 °C gave the best results in yield and with selectivity as shown in Table 4.

Before the investigation of intermolecular condensation, the temperature to control the undesirable self condensation of methyl esters was fixed using methyl 3-phenylpropionate as a substrate , and −23 °C was found sufficient to the purpose (Table 5). Intermolecular condensations between a variety of methyl esters and methoxymethyl esters were examined under the optimum conditions found for the intramolecular reactions (Table 6). As controlled experiments, commonly employed bases such as potassium hydride (Entry 4) and sodium methoxide (Entry 5) were examined in the same reaction,[13)] however, the condensation products were obtained in poor yield with low selectivity.

It is notable that the present method could be successfully applied to esters containing base-sensitive functional groups such as α, β-unsaturated, α-chloro, and β-siloxy esters as substrates giving the β-keto esters without the loss of their functionalities (Entries 1, 2, 9, and 10).

In summary, the present method provides the first example of the crossed type-Claisen ester condensation between two different esters (methyl ester and methoxymethyl ester) under mild acidic conditions, and that the resulting methoxymethyl esters of β-keto acids could have wider applicability in organic syntheses.

Experimental

All the melting points and the boiling points are uncorrected. The IR spectra were determined on a Hitachi Model 260-30 spectrometer. The ^1H NMR spectra were recorded with a Hitachi R-24B and a JEOL FX-90Q spectrometers with tetramethylsilane as an internal standard. The ^{19}F NMR spectra were recorded with a Hitachi R-20B spectrometer. MS and HRMS spectra were obtained with a Hitachi GC/MS M-80 instrument. Purification of products was performed by distillation or column chromatography on silica gel (Wakogel C-200 or Merck, Art. 7734), preparative TLC on silica gel (Wakogel B-5F or Merck Art. 11798).

Preparation of Dichlorobis(trifluoromethanesulfonato)-titanium(IV) (=Dichlorobis(triflato)titanium(IV)). A modified procedure of the reported method[4a)] for large scale preparation: To a stirred solution of trifluoromethanesulfonic acid (35.6 g, 0.237 mol) was added titanium(IV) chloride (5.0 g, 0.026 mol) at −50 °C with stirring under an argon atmosphere. The reaction mixture was allowed to warm to room temperature during 3 h with stirring (HCl gas was evolved). Then, sulfuryl chloride (25 ml) was

a) The reaction was carried out in CH_2Cl_2 at −23 °C for 3 h and at 0 °C for 1 h and the molar ratio of methyl ester : methoxymethyl ester : $TiCl_2(OTf)_2$: amine=1 : 1 : 1.3 : 3.0. b) C; *N,N*-diisopropylethylamine. c) D; *N*-ethylpiperidine. d) Potassium hydride or sodium methoxide was used as a promoter in place of $TiCl_2(OTf)_2$ and amine.

added and filtered the liquid portion under an inert atmosphere. The resultant yellow powder was washed with another sulfuryl chloride (25 ml× 2) and dried up with vacumn to give 9.6 g (89%) of $TiCl_2(OTf)_2$ as powdered yellow crystals; ^{19}F NMR (hexamethylphosphoric triamide) ϕ=77.5 (6F, s, trichlorofluoromethane as an external standard). The quality was checked by the comparison with hexafluorobenzene as an internal standard.

Preparation of Methyl 3-Hydroxy-2-methyl-3-phenylpropionate (1). To a stirred solution of diisopropylamine (1.11 g, 11 mmol) in THF (20 ml) was added 6.9 ml of BuLi in hexane (1.60 M; 1 M=1 mol dm^{-3}) at 0 °C under an nitrogen atmosphere. After 15 min, the resultant mixture was cooled to −78 °C, and methyl propionate (0.88 g, 10 mmol) in THF (5 ml) was added dropwise, followed by stirring at the same temperature for 30 min. Then, benzaldehyde (1.17 g, 11 mmol) in THF (5 ml) was added dropwise and stirred for 1 h at −78 °C. The reaction mixture was poured onto 1 M HCl aq (20 ml) and extracted with ether (20 ml×2). The combined extracts were washed with water and brine and dried ($MgSO_4$). Removal of the solvent under reduced pressure and distilled gave 1.33 g (66%) of **1**: bp 125 °C (oven temp)/0.60 mmHg (1mmHg=133.3Pa), (lit,[14] 100—103 °C/0.50 mmHg); IR (neat) 3300, 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90, 1.05 (total 3H, d, d, J=7.0, 6.0 Hz), 2.40—2.90 (1H, m), 3.45, 3.53 (total 3H, s, s), 4.55, 5.85 (total 1H, d, d, J= 9.0, 5.0 Hz). 6.80—7.25 (5H, m).

Intramolecular Condensation of Dimethyl Adipate: A Typical Procedure. To a stirred suspension of $TiCl_2(OTf)_2$ (415 mg, 0.99 mmol) and Molecular Sieves 4A (1.0 g) in dichloromethane (2.0 ml) was added dimethyl adipate (116 mg, 0.66 mmol) in dichloromethane (0.5 ml) at 0 °C under an argon atmosphere. Then, triethylamine (220 mg, 2.18 mmol) in dichloromethane (1 ml) was added dropwise to the mixture. After being stirred at room temperature for 2 h, the reaction was quenched with phosphate buffer (pH 7.0). The organic phase was separated by Celite filtration and washed with water and dried (Na_2SO_4). Removal of the solvent under reduced pressure and purified with column chromatography using hexane–ethyl acetate (5 : 1) gave 81 mg (80%) of 2-(methoxycarbonyl)cyclopentanone. IR (neat) 1720, 1750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.60—2.50 (6H, m), 3.00—3.50 (1H, m), 3.75 (3H, s,).

2-(Methoxycarbonyl)cyclohexanone[16] (6): IR (neat) 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50—2.60 (8H, m), 3.10—3.50 (1H, m), 3.75 (3H, 2).

2-Ethoxycarbonyl-5-methylcyclopentanone[17] (7): IR (neat) 1720, 1750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85—1.30 (6H, m), 1.50—2.40 (5H, m), 2.95—3.40 (1H, m), 4.00 (2H, q, J=7.0 Hz).

Intermolecular Ester Condensation. A similar procedure of intramolecular condensation of dimethyl adipate except the following conditions; (1) the mixture of the substrates and acylating reagents were added spontaneously to the suspension of $TiCl_2(OTf)_2$, (2) the temperature and the reaction time were shown in Table 3.

Methyl 2-Methyl-3-oxovalerate[15] (3): IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3H, t, J=7.0 Hz), 1.25 (3H, d, J=7.0 Hz), 2.45 (2H, q, J=7.0 HZ), 3.55 (1H, q, J=7.0 Hz), 3.80 (3H, s).

Ethyl 2-Methyl-3-oxovalerate[16] (4): IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3H, J=7.0 Hz), 1.15—1.50 (6H, m), 2.45 (2H, q, J=7.0 Hz), 3.55 (1H, q, J=7.0 Hz), 4.25 (2H, q, J=7.0 Hz).

Methyl 2-Benzyl-5-phenyl-3-oxovalerate (5): IR (neat) 1715, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.55—2.75 (4H, m), 3.00 (2H, d, J=8.0 Hz), 3.45 (3H, s), 3.60 (1H, t, J= 8.0 Hz), 6.80—7.10 (10H, m); HRMS, Found: m/z 296.1427. Calcd for $C_{19}H_{20}O_3$:M, 296.1414.

Methyl 2-Benzyl-3-oxo-3-phenylpropionate (8): IR (neat) 1690, 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.15 (2H, d, J=7.0 Hz), 3.45 (3H, s), 4.40 (1H, t, J=7.0 Hz), 6.80—7.80 (10 H, m); HRMS, Found: m/z 268.1096. Calcd for $C_{17}H_{16}O_3$: M, 268.1100.

Methyl 2-Formyl-3-phenylpropionate (9): IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.90—3.35 (2H, m), 3.45—3.55 (0.3 H, m; methylene), 3.55 (3H, s), 6.80—7.20 (5.7H, m), 9.50 (0.3H, d, J=2.0 Hz; aldehyde), 11.30 (0.7H, d, J=12.0 Hz; enol); HRMS, Found: m/z 191.9951. Calcd for $C_{11}H_{12}O_3$: M, 191.9942.

Methyl 2-Benzyl-3,4-dioxobutyrate (10): IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.90—3.35 (2H, m), 3.40—3.55 (1H, m), 3.55 (3H, s), 6.80—7.20 (5H, m), 10.05 (1H, s); HRMS, Found: m/z 220.0720. Calcd for $C_{12}H_{12}O_4$: M, 220.0735.

2-Benzoyl-γ-butyrolactone (11): Mp 54—56 °C, (lit,[18] 57 °C); IR (Nujol) 1680, 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10—3.10 (2H, m), 4.10—4.60 (3H, m), 7.10—8.10 (5H, m).

2-Formyl-γ-butyrolactone (12): Mp 72 °C, (lit,[19] 72.5—73.5 °C); IR (neat) 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20—3.20 (2H, m), 4.20—4.55 (2H, m), 6.80 (1H, d, J=12.0 Hz), 11.50 (1H, d, J=12.0 Hz).

Methoxymethyl Methyl Adipate (13): To a stirred solution of methyl hydrogen adipate (3.20 g, 20 mmol) and triethylamine (2.45 g, 24 mmol) in *N,N*-dimethylformamide (50 ml) chloromethyl methyl ether (1.93 g, 24 mmol) was added at 0 °C. After being stirred at room temperature for 10 h, the reaction mixture was quenched with water and extracted with ether (50 ml×2). The combined extracts were washed with water and brine, dried (Na_2SO_4), and condensed under reduced pressure. The crude product was distilled to give 3.30 g (81 %) of **13**. Bp 145 °C (oven temp)/0.07 mmHg; IR (neat) 1740, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50—1.85 (4H, m), 2.05—2.50 (4H, m), 3.35 (3H, s), 3.55 (3H, s), 5.10 (2H, s); HRMS, Found: m/z 204.1016. Calcd for $C_9H_{16}O_5$: M, 204.0999.

Methylthiomethyl Methyl Adipate (14): By a similar procedure of preparation of **13**, the reaction of methyl hydrogen adipate (3.20 g, 20 mmol) and chloromethyl methyl sulfide (2.12 g, 22 mmol) gave 3.74 g (85%) of **14**. Bp 180 °C (oven temp)/0.1 mmHg; IR (neat) 1740, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.45—1.85 (4H, m), 2.00 (3H, s), 2.10—2.55 (4H, m), 3.55 (3H, s), 4.95 (2H, s); HRMS, Found: m/z 220.0786. Calcd for $C_9H_{16}O_4S$: M, 220.0771.

2-Methoxylethyl Methyl Adipate (15): By a similar procedure of preparation of **13**, the reaction of methyl hydrogen adipate (3.20 g, 20 mmol) and iodoethyl methyl ether (4.09 g, 22 mmol) gave 3.83 g (88%) of **15**. Bp 150 °C (oven temp)/0.1 mmHg; IR (neat) 1720, 1120 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.45—1.90 (4H, m), 2.05—2.55 (4H, m), 3.35 (3H, s), 3.50—3.70 (2H, m), 3.55 (3H, s), 4.20—4.40 (2H, m); HRMS, Found: m/z 218.1141. Calcd for $C_{10}H_{18}O_5$: M, 218.1156.

The Selective Intramolecular Dieckmann Condensation: A Typical Procedure. To a stirred suspension of $TiCl_2$-

$(OTf)_2$ (417 mg, 1.00 mmol) in dichloromethane (2.0 ml) was added *N,N*-diisopropylethylamine (297 mg, 2.3 mmol) in dichloromethane (1 ml) at −23 °C under an argon atmosphere. Then methoxymethyl methyl adipate **13** (157 mg, 0.77 mmol) in dichloromethane (1.0 ml) was added dropwise to the mixture. After being stirred at −23 °C for 1 h, the reaction was quenched with phosphate buffer (pH 7.0). The organic phase was separated by Celite filtration and washed with water and dried (Na_2SO_4). Removal of the solvent under reduced pressure and purified with thin layer chromatography using hexane-ethyl acetate (3 : 1) gave 110 mg (83%) of methoxymethyl 2-oxocyclopentanecarboxylate **16**, and 4.7 mg (3%) of **13** which was recovered. IR (neat) 1750, 1720, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.90—2.50 (6H, m), 2.90—3.30 (1H, m), 3.35 (3H, s), 5.15 (2H, s); HRMS, Found: *m/z* 172.0731. Calcd for $C_8H_{12}O_4$: M, 172.0735.

Methylthiomethyl 2-Oxocyclopentanecarboxylate (17): IR (neat) 1750, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.80—2.50 (6H, m), 2.05 (3H, s), 2.90—3.30 (1H, m), 5.00 (2H, s); HRMS, Found: *m/z* 188.0880. Calcd for $C_8H_{12}O_3S$: M, 188.0892.

2-Methoxyethyl 2-Oxocyclopentanecarboxylate (18): IR (neat) 1750, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.90—2.55 (6H, m), 2.90—3.30 (1H, m), 3.55 (3H, s), 3.55—3.70 (2H, m), 4.20—4.45 (2H, m); HRMS, Found: *m/z* 186.0899. Calcd for $C_9H_{14}O_4$: M, 186.0892,

Isopropoxymethyl Methyl Adipate (19): By a similar procedure of preparation of **13**, the reaction of methyl hydrogen adipate (3.20 g, 20 mmol) and chloromethyl isopropyl ether (2.60 g, 24 mmol) gave 3.85 g (83%) of **19**. IR (neat) 1740, 1130 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15 (6H, d, *J*=7.0 Hz), 1.30—1.80 (4H, m), 2.00—2.40 (4H, m), 3.55 (3H, s), 3.60 (1H, m), 5.10 (2H, s); HRMS, Found: *m/z* 232.1332. Calcd for $C_{11}H_{20}O_5$: M, 232.1312,

Benzyloxymethyl Methyl Adipate (20): By a similar procedure of preparation of **13**, the reaction of methyl hydrogen adipate (3.20 g, 20 mmol) and chloromethyl benzyl ether (3.75 g, 24 mmol) gave 4.60 g (83%) of **20**. Bp 155—159 °C/0.3 mmHg; IR (neat) 1740, 1130 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30—1.70 (4H, m), 2.00—2.30 (4H, m), 3.50 (3H, s), 4.50 (2H, s), 5.15 (2H, s), 7.00—7.20 (5H, m); HRMS, Found: *m/z* 280.1330. Calcd for $C_{15}H_{20}O_5$: M, 280.1312.

1-Ethoxyethyl Methyl Adipate (21): To a stirred solution of methyl hydrogen adipate (3.20 g, 20 mmol) and a catalytic amount of *p*-toluenesulfonic acid (ca. 20 mg) in ether (40 ml) was added ethyl vinyl ether (1.59 g, 22 mmol) at room temperature. After 1 h the reaction mixture was quenched with saturated $NaHCO_3$ aq and extracted with ether (50 ml). The extract was washed with water and brine, dried (Na_2SO_4), and condensed under reduced pressure. The crude product was distilled to give 3.11 g (67%) of **21**. Bp 180 °C (oven temp)/0.15 mmHg; IR (neat) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (3H, t, *J*=7.0 Hz), 1.30 (3H, d, *J*=7.0 Hz), 1.30—1.65 (4H, m), 2.00—2.45 (4H, m), 3.20—3.60 (2H, m), 3.50 (3H, s), 5.75 (1H, q, *J*=7.0 Hz); HRMS, Found: *m/z* 232.1318. Calcd for $C_{11}H_{20}O_5$: M, 232.1312.

Isopropoxymethyl 2-Oxocyclopentanecarboxylate (22): IR (neat) 1740, 1715, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50 (6H, d, *J*=7.0 Hz), 1.90—2.50 (6H, m), 2.90— 3.30 (1H, m), 3.70—4.10 (1H, m), 5.20 (2H, s); HRMS, Found: *m/z* 200.1052. Calcd for $C_{10}H_{16}O_4$: M, 200.1049.

Benzyloxymethyl 2-Oxocyclopentanecarboxylate (23): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.80—2.50 (6H, m), 2.80—3.20 (1H, m), 4.50 (2H, s), 5.25 (2H, s), 7.10—7.30 (5H, m); HRMS, Found: *m/z* 248.1044. Calcd for $C_{14}H_{16}O_4$: M, 248.1049.

Preparation of Methoxymethyl Esters: By a similar procedure of the preparation of **13**.

Methoxymethyl Butyrate: IR (neat) 1730 cm^{-1}; ^1H NMR δ=0.80 (3H, t, *J*=7.0 Hz), 1.10—1.80 (2H, m), 1.90—2.30 (2H, m), 3.30 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 132.0777. Calcd for $C_6H_{12}O_3$: M, 132.0786.

Methoxymethyl Valerate: IR (neat) 1730 cm^{-1}; ^1H NMR δ=0.80 (3H, t, *J*=7.0 Hz), 1.00—2.35 (6H, m), 3.30 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 146.0955. Calcd for $C_7H_{14}O_3$: M, 146.0943.

Methoxymethyl 4-Bromovalerate: Bp 135 °C (oven temp)/19 mmHg; IR (neat) 1730 cm^{-1}; ^1H NMR δ=1.90—2.70 (4H, m), 3.30 (3H, s), 3.50 (2H, t, *J*=7.0 Hz), 5.10 (2H, s); HRMS, Found: *m/z* 209.9881. Calcd for $C_7H_{14}BrO_3$: M, 209.9891.

Methoxymethyl 2-Chloroacetate: Bp 135 °C (oven temp)/19 mmHg. IR (neat) 1730 cm^{-1}; ^1H NMR δ=3.55 (3H, s), 4.00 (2H, s), 5.25 (3H, s); HRMS, Found: *m/z* 138.0088. Calcd for $C_4H_7ClO_3$: M, 138.0084.

Methoxymethyl 3-(*t*-Butyldimethylsiloxy)propionate: IR (neat) 1715, 1140 cm^{-1}; ^1H NMR δ=0.15 (6H, s), 0.80 (9H, s), 2.55 (2H, t, *J*=7.0 Hz), 3.60 (2H, t, *J*=7.0 Hz), 3.30 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 248.1441. Calcd for $C_{11}H_{24}O_4Si$: M, 248.1444.

The Selective Intermolecular Condensation between Methoxymethyl Ester and Methyl Ester: A similar method of the intramolecular condensation except the point that the mixture of methoxymethyl ester and methyl ester was added.

Methoxymethyl 2-Ethyl-3-oxo-5-phenyl-4-pentenoate (24): IR (neat) 1715, 1140 cm^{-1}; ^1H NMR δ=0.75 (3H, t, *J*=7.0 Hz), 1.35—2.00 (2H, m), 3.55 (3H, s), 3.70 (1H, t, *J*=7.0 Hz), 5.15 (2H, s), 6.75 (1H, d, *J*=16 Hz), 6.90—7.60 (5H, m); HRMS, Found: *m/z* 262.1222. Calcd for $C_{15}H_{18}O_4$: M, 262.1206.

Methoxymethyl 2-Ethyl-3-oxohexanoate (25): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR δ=0.60—1.00 (3H, t, *J*=7.0 Hz), 1.05—2.00 (2H, m), 3.15 (1H, t, *J*=7.0 Hz), 3.55 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 188.1057. Calcd for $C_9H_{16}O_4$: M, 188.1049.

Methoxymethyl 2-Ethyl-3-oxo-5-phenylvalerate (26): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR δ=0.75 (3H, t, *J*=7.0 Hz), 1.35—2.00 (2H, m), 2.70 (4H, brs), 3.15 (1H, t, *J*=7.0 Hz), 3.55 (3H, s), 5.10 (2H, s), 6.90—7.30 (5H, m); HRMS, Found: *m/z* 264.1348. Calcd for $C_{15}H_{20}O_4$: M, 264.1363.

Methoxymethyl 3-Oxo-2-propylvalerate (27): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR δ=0.60—1.05 (5H, m), 1.10—1.90 (5H, m), 2.05—2.50 (2H, m), 3.15 (1H, t, *J*= 7.0 Hz), 3.55 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 202.1994. Calcd for $C_{10}H_{18}O_4$: M, 202.1205.

Methoxymethyl 3-Oxo-2-propylheptanoate (28): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR δ=0.60—1.90 (14H, m), 2.05—2.55 (2H, m), 3.15 (1H, t, *J*=7.0 Hz), 3.55 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 230.1496. Calcd for $C_{12}H_{22}O_4$: M, 230.1519.

Methoxymethyl 2-Ethyl-4-methyl-3-oxohexanoate (29): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR δ=0.60—1.90 (14H, m), 2.05—2.55 (2H, m), 3.15 (1H, t, *J*=7.0 Hz), 3.55 (3H, s), 5.10 (2H, s); HRMS, Found: *m/z* 230.1505. Calcd for $C_{12}H_{22}O_4$: M, 230.1519.

Methoxymethyl 2-(2-Bromoethyl)-3-oxo-5-phenylvalerate (30): IR (neat) 1720, 1140 cm^{-1}; ^1H NMR δ=2.10—2.40

(2H, m), 2.70 (4H, brs), 3.15 (1H, t, J=7.0 Hz), 3.55 (3H, s), 3.60—3.85 (2H, m), 5.10 (2H, s), 6.90—7.30 (5H, m); HRMS, Found: m/z 343.0483. Calcd for $C_{15}H_{19}O_4Br$: M, 343.0468.

Methoxymethyl 6-Bromo-2-(2-bromoethyl)-3-oxohexanoate (31): IR (neat) 1720, 1140 cm^{-1}; ^{1}H NMR δ=1.90—3.90 (11H, m), 3.55 (3H, s), 5.10 (2H, s); HRMS, Found: m/z 358.9508. Calcd for $C_{10}H_{16}O_4Br_2$: M, 358.9494.

Methoxymethyl 2-Chloro-3-oxo-5-phenylvalerate (32): IR (neat) 1720, 1140 cm^{-1}; ^{1}H NMR δ=2.70 (4H, brs), 3.55 (3H, s), 4.80 (1H, s), 5.15 (2H, s), 6.90—7.30 (5H, m); HRMS, Found: m/z 270.0675. Calcd for $C_{13}H_{15}O_4Cl$: M, 270.0660.

Methoxymethyl 2,4-Dichloro-3-oxobutyrate (33): IR (neat) 1720, 1140 cm^{-1}; ^{1}H NMR δ=3.55 (3H, s), 4.30 (2H, s), 4.80 (1H, s), 5.15 (2H, s); HRMS, Found: m/z 213.9813. Calcd for $C_6H_8O_4Cl$: M, 213.9801.

Methoxymethyl 2-(*t*-Butyldimethylsiloxy)-3-oxo-5-phenylvalerate (34): IR (neat) 1720, 1140 cm^{-1}; ^{1}H NMR δ=0.15 (6H, s), 0.80 (9H, s), 2.70 (4H, brs), 3.55 (1H, m), 3.20—3.90 (2H, m), 3.55 (3H, s), 5.10 (2H, s), 6.90—7.30 (5H, m); HRMS, Found: m/z 364.2055. Calcd for $C_{20}H_{32}O_4Si$: M, 364.2071.

The author wish to express his thanks to Professor Teruaki Mukaiyama of Science University of Tokyo for his helpful discussions throughout this work.

Bloomfield, *Org. React.*, **15**, 1 (1967) (the Dieckmann condensation).

2) One feasible solution to these complexities could be found in the reaction between ketene silyl acetals and acid chlorides which afford the desired β-keto esters. For example, see: M. W. Rathke and D. F. Sullivan, *Tetrahedron Lett.*, **1973**, 1297. This method, however, requiers preceding preparation of ketene silyl acetals, and in addition, it is difficult to conduct the reaction in the case of intramolecular (the Dieckmann) condensation.

3) Preliminary work of these reactions has been reported as communications: Y. Tanabe and T. Mukaiyama, *Chem. Lett.*, **1984**, 1867; Y. Tanabe and T. Mukaiyama, *ibid.*, **1986**, 1813.

Reactions of Sodium Salts of Tosylhydrazones of 2- and 3-Thiophenecarbaldehydes, 1-Methyl-2-pyrrolecarbaldehyde, and Furfural with Acrylonitrile

Katsuhiro SAITO,* Tatsuji SATO, Hiraku ISHIHARA, and Kensuke TAKAHASHI
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received November 11, 1988)

Reactions of the sodium salts of tosylhydrazones of several heteroaromatic aldehydes with an equimolar amount of acrylonitrile afforded the corresponding cyclopropane derivatives as the major products accompanied by small amounts of pyrazole derivatives. On the other hand, reactions using ten-molar equivalents of acrylonitrile gave pyrazole derivatives as major products.

Much effort has been devoted to the investigation of the reactivities of tosylhydrazones which generate carbenes via diazo compounds. It is known that the reactivities of the diazo compounds or the carbenes are influenced by conjugation with unsaturated moieties.[1] Many papers have been published on the chemistry of tosylhydrazones conjugated with olefinic, aromatic, or carbonyl moieties, while detailed reports on the chemistry of tosylhydrazones conjugated with heterocyclic moieties have been relatively few.[2]

Previously, Shechter reported that the carbenes generated from the tosylhydrazones of furfural or thiophenecarbaldehyde inserted into the C-H bonds of alkanes or rearranged into unstable acetylene derivatives.[3] Maas[4] has documented the addition reactions of olefins with carbenes conjugated with furan, thiophene, or pyridine moieties to give cyclopropanes. The authors have investigated the reactivities of tosylhydrazones conjugated with heterocyclic moieties and reported 1,3 N-C migration of the tosyl group or nucleophilic and stereospecific additions of the carbenes generated from the tosylhydrazones.[5] As one part of our these studies, we investigated the reactions of tosylhydrazones conjugated with thiophene, pyrrole, and furan moieties with acrylonitrile. Here, the results are discussed.

Results and Discussion

The reaction of sodium salt of 2-thiophenecarbaldehyde tosylhydrazone (**1a**) with an equimolar amount of acrylonitrile (**2**) was carried out in anhydrous diglyme at 120 °C for 20 min. A thin-layer chromatographic separation and purification of the reaction mixture afforded a 1 : 1 mixture of *cis*-**3a** and *trans*-cyclopropane **4a** derivatives and a pyrazoline derivative **5a** in 65.0 and 9.1% yields, respectively. A similar reaction, but using ten-molar equivalents of **2**, afforded a pyrazoline derivative **6a** and a pyrazole derivative **7a** in 45.1 and 6.1% yields, respectively. A

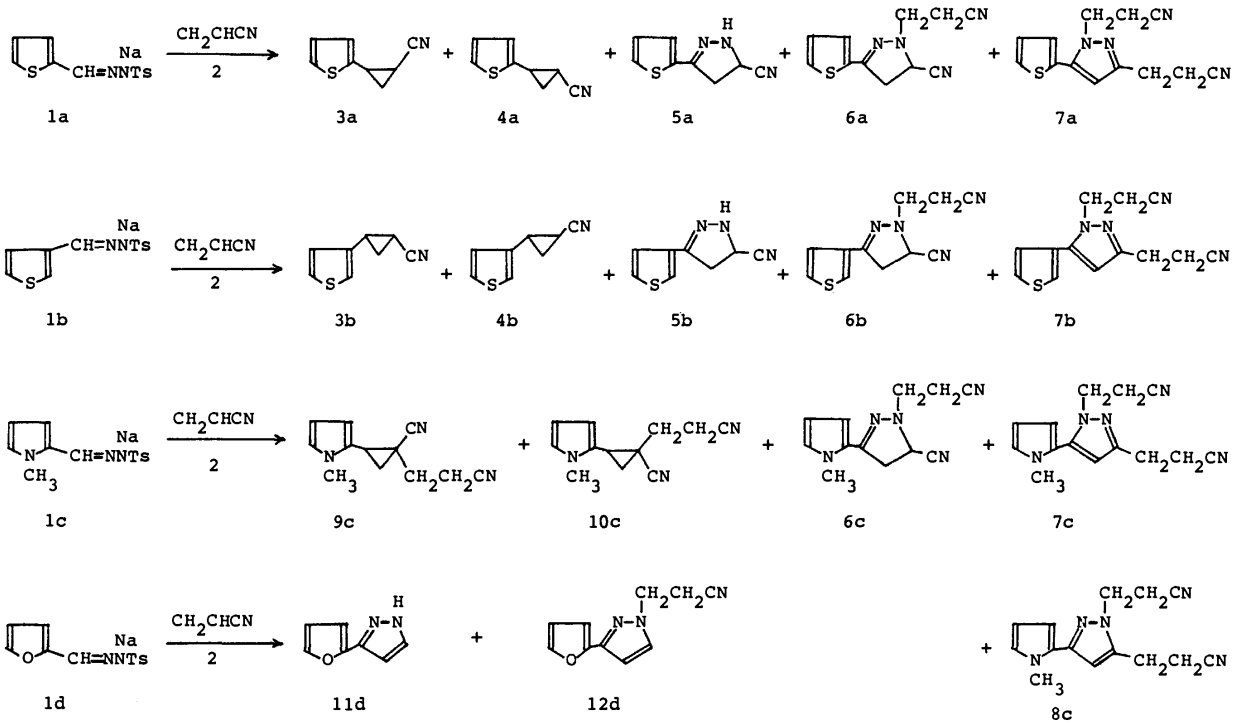

Fig. 1.

reaction with sodium salt of 3-thiophenecarbaldehyde tosylhydrazone (**1b**) gave almost the same result as mentioned above; a reaction of **1b** with an equimolar amount of **2** afforded a 1 : 1 mixture of cyclopropanes, **3b** and **4b**, and a pyrazoline derivative **5b** in 67.3 and 19.7% yields, respectively. A reaction of **1b** with ten-molar equivalents of **2** gave a pyrazoline derivative **6b** and a pyrazole derivative **7b** in 50.1 and 8.9% yields, respectively.

The same type of reaction using sodium salt of 1-methyl-2-pyrrolecarbaldehyde tosylhydrazone (**1c**) with an equimolar amount of **2** afforded no isolatable product. However, the employment of a large excess amount of acrylonitrile gave a better result, as follows. A reaction of **1c** with ten-molar equivalents of **2** yielded a cyclopropane derivative **9c**, a pyrazoline derivative **6c**, and pyrazole derivatives, **7c** and **8c**, in 6.5, 5.6, 3.1, and 4.9% yields, respectively. A reaction with twenty-molar equivalents of **2** promoted the product yields to give **9c**, **10c**, **6c**, **7c**, and **8c** in 18.8, 6.6, 18.6, 4.0, and 3.9% yields, respectively.

No cyclopropane derivatives were detected in the reaction of sodium salt of furfural tosylhydrazone (**1d**). A reaction of **1d** with an equimolar amount of **2** afforded pyrazole derivatives, **11d** and **12d**, each in 1.1% yield; these yields were improved by using ten-molar equivalents of **2** to 2.2 and 11.1%, respectively.

The structures of the products were deduced on the basis of their spectral properties and a comparison of the NMR spectra with those of the analogous compounds.[6] The absorption maxima in the UV spectra of **5a**, **b** and **6a**, **b** (ca. 290 nm), which appear at longer wavelengths than those of **3a**, **b** and **4a**, **b** (238 nm) or thiophene (231 nm), show that these pyrazoline derivatives have double bonds conjugated with the heterocyclic moieties.

The structures of **7c** and **8c** were deduced by measurements of the nuclear overhauser effect in their NMR spectra, as follws. Irradiation of the methylene protons of the *N*-substituted cyanoethyl group of **7c** caused a 10% growth of the signal of the 3-position proton of the pyrrole ring, though the peak of the other cyanoethyl group showed no change, as shown in Fig. 2. On the other hand, a corresponding irradiation of **8c** resulted in a 15% enhancement of the peak of the other cyanoethyl moiety but did not effect on the ring protons. The structures of **7a** and **7b** were assigned on the basis of a comparison of their ^{1}H NMR and ^{13}C NMR spectra with those of **7c** and **8c**.

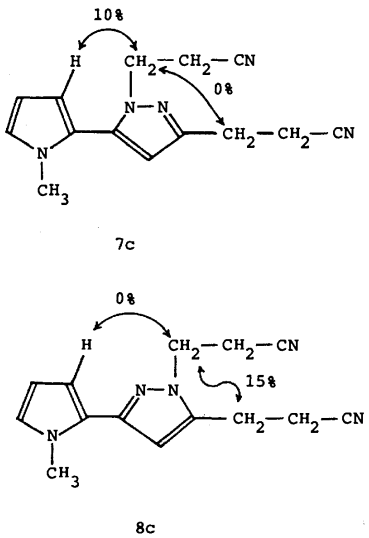

Fig. 2.

The stereochemistries of **9c** and **10c** are not clear, but considering the steric size of cyanoethyl and cyano groups, the major product **9c** is thought to have a pyrrole group and a cyanoethyl group as a trans-configuration, as shown in the figure.

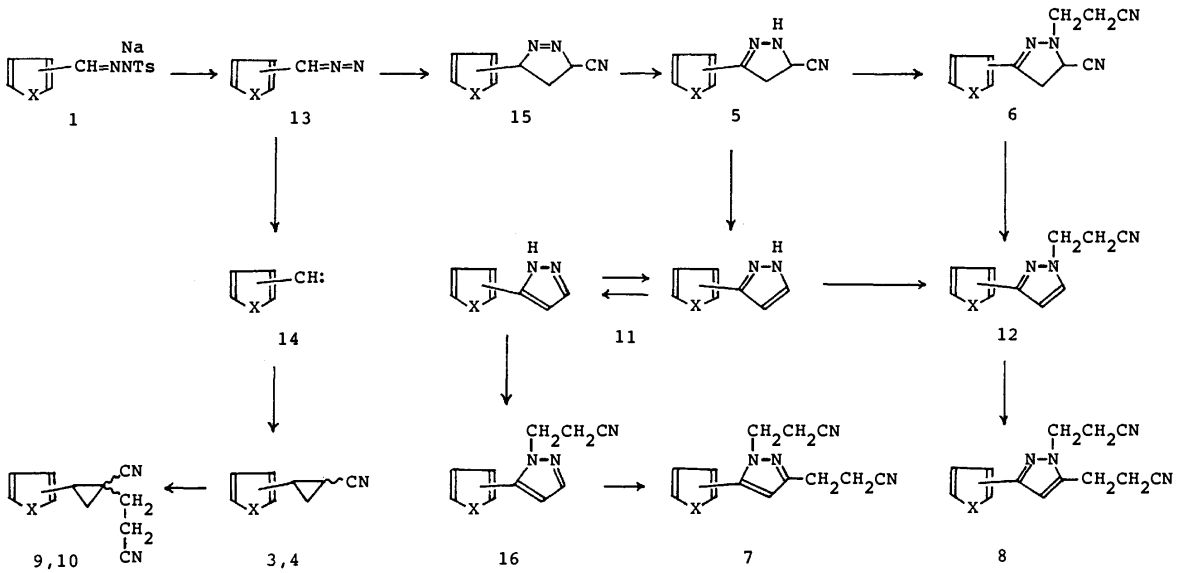

Fig. 3.

The reaction is considered to proceed as follows.[7] The thermolysis of **1** generates the diazo compound **13**, which further decomposes to carbene **14**, and adds to **2** to give **3** and **4**.[8] The cyclopropane derivatives, **9** and **10**, are considered to be formed through reactions of **3** and **4** with **2**. A 1,3-dipolar addition of **13** to **2** gives **5** via an intermediate **15**. An aromatization of **5**, leaving hydrogen cyanide, forms **11**. A nucleophilic attack of **5** to **2** can give **6**, which then aromatizes to **12** leaving hydrogen cyanide. The pyrazole derivatives **7** and **8** are considered to be derived through **11** and **12**, respectively.

There is a possibility of the formation of cyclopropane derivatives (**3**, **4**) from **15** via a loss of nitrogen. In order to examine this possibility, a reaction of **1b** with ten-molar equivalents of **2** was carried out in a five-fold diluted concentration. The products were a 38.0% yield of **6b** and a 21.3% yield of **7b**; no cyclopropane derivatives were detected at all. This fact shows that the cyclopropane derivatives were formed via a reaction of carbene **14** but not via **15**.

In the presence of an excess amount of acrylonitrile, the diazo compound **13** reacts with acrylonitrile to give pyrazoline- or pyrazole-type products. If there is no such excess amount of acrylonitrile, **13** further decomposes to the carbene to give cyclopropane-type products.

It has been reported that in a reaction of **1** with stilbene, dimethyl fumarate, dimethyl maleate, or styrene derivatives, neither pyrazoline nor pyrazole derivatives were detected; only cyclopropane derivatives were afforded.[5] The difference between the above-mentioned result and the present result can be considered to be attributable to the high reactivity of acrylonitrile to diazo compounds.

The product yields of the reaction of **1d** were poor. One of the reasons for this phenomenon is considered to be the liability of the furyl ring to ring opening. Shechter reported that the ring in carbene **14d** can very easily be opened and rearranged to a very unstable acetylene derivative.[3] In the present reaction, **1d** is thought to generate the unreactive diazo compound **13d**, which then forms carbene; it then decomposes to resinous materials via an unstable acetylene derivative.

Experimental

Melting points were recorded on a Yanagimoto Micro Melting Point Apparatus and are uncorrected. NMR spectra were measured with a Varian XL 200 or a Hitachi R-20B spectrometer with tetramethylsilane as an internal standard. UV and IR spectra were measured with Hitachi 220A and JASCO A-102 spectrometers, respectively. Mass spectra were measured with a Hitachi M-52 or a JMS-DX300 spectrometer. Wako gel B5F was used for thin-layer chromatography. Diglyme was distilled from calcium hydride and stored on Molecular Sieves 3A 1/16.

Reaction of 1a with an Equimolar Amount of 2. A typical reaction procedure: To a solution of **1a** (2.80 g, 10 mmol) in anhydrous diglyme (30 ml) was added sodium hydride (50% in mineral oil, 0.72 g, 15 mmol). After the evolution of hydrogen gas had ceased **2** (0.53 g, 10 mmol) was added. The mixture was then heated at 120 °C for 20 min to evolve a nitrogen gas (170 ml, 76%). The reaction mixture was poured into water and extracted with diethyl ether. The ether was washed with water and brine and dried over anhydrous sodium sulfate. The solvent was removed on a rotary evaporator and the residue was subjected to thin-layer chromatography on silica gel by using chloroform as a developing solvent to give an oily mixture of **3a** and **4a** (970 mg, 65.0%, R_f=0.70) and crystals **5a** (169 mg, 9.1%, R_f=0.24).

3a or 4a: Found: *m/z* 149.0279. Calcd for C_8H_7NS: M, 149.0299. MS *m/z* (rel intensity): 149 (M^+, 100) and 121 (40). IR (oil): 2240 cm^{-1}. UV (EtOH): 238 nm (log ε, 3.78). ^1H NMR ($CDCl_3$) δ=1.38 (m, 1H), 1.53 (m, 2H), 2.72 (m, 1H), 6.84 (m, 1H), 6.91 (m, 1H), and 7.12 (m, 1H).

4a or 3a: Found: *m/z* 149.0311. Calcd for C_8H_7NS: M, 149.0299. MS *m/z* (rel intensity): 149 (M^+, 100) and 121 (48). IR (oil): 2240 cm^{-1}. UV (EtOH): 238 nm (log ε, 3.78). ^1H NMR ($CDCl_3$) δ=1.42 (m, 2H), 1.70 (m, 1H), 2.52 (m, 1H), 6.93 (m, 2H), and 7.18 (m, 1H).

UV (EtOH): 291 nm (log ε, 3.99). ^1H NMR ($CDCl_3$) δ=2.71 (t, 2H, *J*=7 Hz), 3.03 (dd, 1H, *J*=18 and 12Hz), 3.36 (m, 3H), 5.00 (dd, 1H, *J*=12 and 11 Hz), 7.02 (m, 1H), 7.24 (m, 1H), and 7.37 (m, 1H).

7a: Found: *m/z* 256.0774. Calcd for $C_{13}H_{12}N_4S$: M, 256.0728. MS *m/z* (rel intensity): 256 (M^+, 100), 215 (69), and 202 (47). IR (oil): 2243 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.91 (m, 6H), 4.35 (t, 2H, *J*=7 Hz), 6.24 (s, 1H), 7.36 (m, 1H), and 7.43 (m, 2H). ^{13}C NMR ($CDCl_3$) δ=17.0, 18.7, 24.4, 44.7, 106.7, 116.9, 119.4, 127.6, 127.9, 128.1, 129.6, 138.0, and 149.4.

Reaction of 1b with an Equimolar Amount of 2. A mixture of **1b** (2.80 g, 10 mmol), sodium hydride (50%, 0.72 g, 15 mmol), and **2** (0.53 g, 10 mmol) in diglyme (30 ml) was heated at 120 °C for 20 min to evolve nitrogen gas (98 ml, 44%). The usual work up using chloroform as a developing solvent gave a mixture of **3b** and **4b** (1004 mg, 67.3%, R_f=0.65) and an oil **5b** (349 mg, 19.7%, R_f=0.30).

Mixture of 3b and 4b: Found: *m/z* 149.0312. Calcd for C_8H_7NS: M, 149.0299. MS *m/z* (rel intensity): 149 (M^+, 100) and 121 (45). IR (oil): 2240 cm^{-1}. UV (EtOH): 238 nm (log ε, 3.72). ^1H NMR ($CDCl_3$) δ=1.2—1.8 (m, 3H), 2.3—2.8 (m, 1H), and 6.7—7.4 (m, 3H).

5b: Found: *m/z* 177.0348. Calcd for C_8H_7NS: M, 177.0335. MS *m/z* (rel intensity): 177 (M^+, 1), 148 (100), and 122 (46). IR (oil): 2230 cm^{-1}. UV (EtOH): 282 nm (log ε, 3.85). ^1H NMR ($CDCl_3$) δ=2.90 (dd, 1H, *J*=18 and 10 Hz), 3.31 (dd, 1H, *J*=18 and 12 Hz), 5.16 (dd, 1H, *J*=18 and 10 Hz), 6.63 (s, 1H), 7.04 (m, 1H), and 7.32 (m, 2H).

Reaction of 1b with Ten-Molar Equivalents of 2. A mixture of **1b** (2.52 g, 9 mmol), sodium hydride (50%, 0.65 g, 14 mmol), and **2** (4.78 g, 90 mmol) in diglyme (30 ml) was heated at 130 °C for 20 min to evolve nitrogen gas (90 ml, 45%). The reaction mixture was treated as usual by using chloroform–diethyl ether 8 : 2 as a developing solvent to give crystals **6b** (2070 mg, 50.1%, R_f=0.70) and an oil **7b** (202 mg, 8.9%, R_f=0.33).

6b: Mp 108—109 °C. Found: *m/z* 230.0625. Calcd for $C_{11}H_{10}N_4S$: M, 230.0626. MS *m/z* (rel intensity): 230 (M^+, 74), 189 (100), 163 (21). IR (KBr): 2250 and 2230 cm^{-1}. UV (EtOH): 291 nm (log ε, 4.05). ^1H NMR ($CDCl_3$) δ=2.65 (m, 2H), 2.97 (dd, 1H, *J*=18 and 13 Hz), 3.30 (m, 3H), 4.87 (dd, 1H, *J*=13 and 11 Hz), 7.16 (m, 1H), and 7.42 (m, 2H).

7b: Found: *m/z* 256.0763. Calcd for $C_{13}H_{12}N_4S$: M, 256.0782. MS *m/z* (rel intensity): 256 (M^+, 93), 215 (83), and 202 (100). IR (oil): 2240 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.74 (t, 2H, *J*=7 Hz), 2.95 (m, 4H), 4.34 (t, 2H, *J*=6 Hz), 6.22 (s, 1H), 7.19 (m, 1H), and 7.45 (m, 2H). ^{13}C NMR ($CDCl_3$) δ=17.0, 18.7, 24.4, 44.6, 105.6, 117.1, 119.4, 124.9, 127.0, 127.8, 129.7, 140.4, and 149.4.

Reaction of 1c with Ten-Molar Equivalents of 2. A mixture of **1c** (2.77 g, 10 mmol), sodium hydride (50%, 0.66 g, 14 mmol), and **2** (5.31 g, 10 mmol) in diglyme (50 ml) was heated at 95 °C for 25 min to evolve nitrogen gas (180 ml, 80%). The usual work up using benzene–diethyl ether 7 : 3 as a developing solvent gave oils **9c** (130 mg, 6.5%, R_f=0.45), **6c** (126 mg, 5.6%, R_f=0.36), **7c** (78 mg, 3.1%, R_f=0.60), and **8c** (125 mg, 4.9%, R_f=0.55).

6c: Found: *m/z* 227.1178. Calcd for $C_{12}H_{13}N_5$: M, 227.1170. MS *m/z* (rel intensity): 227 (M^+, 19), 226 (100), 158 (90), and 145 (48). IR (oil): 2250 and 2220 cm^{-1}. UV (EtOH): 290 nm (log ε, 3.96). ^1H NMR ($CDCl_3$) δ=2.62 (ddd, 1H, *J*=17, 6, and 6 Hz), 2.71 (ddd, 1H, *J*=17, 8, and 6 Hz), 3.01 (dd, 1H, *J*=17 and 14 Hz), 3.27 (ddd, 1H, *J*=13, 6, and 6 Hz), 3.28 (dd, 1H, *J*=17 and 12 Hz), 3.35 (ddd, 1H, *J*=13, 8, and 6 Hz), 3.63 (s, 3H), 4.79 (dd, 1H, *J*=14 and 12 Hz), 6.08 (dd, 1H, *J*=4 and 3 Hz), 6.16 (dd, 1H, *J*=4 and 2 Hz), and 6.66 (dd, 1H, *J*=3 and 2 Hz).

7c: Found: *m/z* 253.1348. Calcd for $C_{14}H_{15}N_5$: M, 253.1327. MS *m/z* (rel intensity): 253 (M^+, 100), 213 (53), 200 (49), and 173 (26). IR (oil): 2265 cm^{-1}. UV (EtOH): 253 nm (log ε, 3.96). ^1H NMR ($CDCl_3$) δ=2.73 (t, 2H, *J*=7 Hz), 2.85 (t, 2H, *J*=7 Hz), 2.99 (t, 2H, *J*=7 Hz), 3.54 (s, 3H), 4.29 (t, 2H, *J*=7 Hz), 6.19 (s, 1H), 6.21 (dd, 1H, *J*=4 and 3 Hz), 6.25 (dd, 1H, *J*=4 and 2 Hz), and 6.69 (dd, 1H, *J*=3 and 2 Hz). ^{13}C NMR ($CDCl_3$) δ=17.0, 18.8, 24.4, 34.5, 44.3, 106.6, 108.1, 111.4, 117.1, 119.5, 120.7, 124.5, 136.5, and 149.2.

8c: Found: *m/z* 253.1355. Calcd for $C_{14}H_{15}N_5$: M, 253.1326. MS *m/z* (rel intensity): 253 (M^+, 21), 252 (100), 212 (55), 200 (52), and 173 (33). IR (oil): 2265 and 2210 cm^{-1}. UV (EtOH): 271 nm (log ε, 4.12). ^1H NMR ($CDCl_3$) δ=2.58 (t, 2H, *J*=7 Hz), 2.83 (t, 2H, *J*=6 Hz), 2.86 (t, 2H, *J*=7 Hz), 3.83 (s, 3H), 4.13 (t, 2H, *J*=6 Hz), 6.10 (dd, 1H, *J*=4 and 3 Hz), 6.21 (s, 1H), 6.36 (dd, 1H, *J*=4 and 3 Hz), and 6.62 (dd, 1H, *J*=3 and 2 Hz). ^{13}C NMR ($CDCl_3$) δ=16.9, 18.8, 21.2, 36.3, 44.0, 103.4, 107.6, 108.8, 117.7, 118.8, 124.4, 126.3, 140.0, and 145.8.

9c: Found: *m/z* 199.1084. Calcd for $C_{12}H_{13}N_3$: M, 199.1108. MS *m/z* (rel intensity): 199 (M^+, 19), 198 (35), and 158 (100). IR (oil): 2240 and 2220 cm^{-1}. UV (EtOH): 225 nm (log ε, 4.01). ^1H NMR ($CDCl_3$) δ=1.43 (dd, 1H, *J*=9 and 6 Hz), 1.71 (dd, 1H, *J*=7 and 6 Hz), 1.82 (dd, 1H, *J*=15 and 7 Hz), 2.05 (dd, 1H, *J*=15 and 7 Hz), 2.21 (dd, 1H, *J*=4 and 3 Hz), 6.04 (dd, 1H, *J*=4 and 2 Hz), and 6.64 (dd, *J*=3 and 2 Hz).

Reaction of 1c with Twenty-Molar Equivalents of 2. A mixture of **1c** (2.77 g, 10 mmol), sodium hydride (50%, 0.66 g, 14 mmol), and **2** (10.62 g, 200 mmol) in diglyme (50 ml) was heated at 100 °C for 10 min to evolve nitrogen gas (195 ml, 87%). The same treatment as above gave oils **9c** (374 mg, 18.8%), **10c** (131 mg, 6.6%), **6c** (423 mg, 18.6%), **7c** (101 mg, 4.0%), and **8c** (98 mg, 3.9%).

10c: Found: *m/z* 199.1094. Calcd for $C_{12}H_{13}N_3$: M, 199.1108. MS *m/z* (rel intensity): 199 (M^+, 23), 159 (100), and 145 (31). IR (oil): 2230 cm^{-1}. UV (EtOH): 227 nm (log ε, 3.84). ^1H NMR ($CDCl_3$) δ=1.38 (m, 2H), 1.79 (m, 2H), 2.43 (m, 2H), 2.62 (dd, 1H, *J*=10 and 7 Hz), 3.62 (s, 3H), 5.83 (dd, 1H, *J*=4 and 3 Hz), 6.01 (dd, 1H, *J*=4 and 2 Hz), and 6.63 (dd, 1H, *J*=3 and 2 Hz).

Reaction of 1d with an Equimolar Amount of 2. A mixture of **1d** (7.89 g, 30 mmol), sodium hydride (50%, 2.16 g, 45 mmol), and **2** (1.59 g, 30 mmol) in diglyme (70 ml) was heated at 90 °C for 20 min to evolve nitrogen gas (600 ml, 89%). The usual work up using benzene–diethyl ether 1 : 1 as a developing solvent gave oils **11d** (45 mg, 1.1%, R_f=0.38) and **12d** (61 mg, 1.1%, R_f=0.25).

11d: Found: *m/z* 134.0467. Calcd for $C_7H_6N_2O$: M, 134.0480. MS *m/z* (rel intensity): 134 (M^+, 100), 115 (25), and 105 (53). IR (oil): 3140 cm^{-1}. UV (EtOH): 262 nm (log ε, 4.08). ^1H NMR ($CDCl_3$) δ=6.46 (dd, 1H, *J*=3 and 2 Hz), 6.54 (d, 1H, *J*=2 Hz), 6.65 (dd, 1H, *J*=3 and 1 Hz), 7.26 (s, 1H), 7.45 (dd, 1H, *J*=2 and 1 Hz), and 7.62 (d, 1H, *J*=2 Hz).

12d: Found: *m/z* 184.0740. Calcd for $C_{10}H_9N_3O$: M, 187.0746. MS *m/z* (rel intensity): 187 (M^+, 79), 147 (100), and 119 (26). IR (oil): 2240 cm^{-1}. UV (EtOH): 266 nm (log ε, 4.58). ^1H NMR ($CDCl_3$) δ=2.98 (t, 2H, *J*=7 Hz), 4.41 (t, 2H, *J*=7 Hz), 6.47 (dd, 1H, *J*=3 and 2 Hz), 6.50 (d, 1H, *J*=2 Hz), 6.66 (dd, 1H, *J*=3 and 1 Hz), 7.46 (dd, 1H, *J*=2 and 1 Hz), and 7.50 (d, 1H, *J*=2 Hz).

Reaction of 1d with Ten-Molar Equivalents of 2. A mixture of **1d** (2.64 g, 10 mmol), sodium hydride (50%, 0.66 g, 14 mmol), and **2** (5.31 g, 100 mmol) in diglyme (30 ml) was heated from 90 °C to 160 °C in a period of 50 min. No nitrogen gas was evolved. The usual work up using benzene–diethyl ether 1 : 9 as a developing solvent gave oils **11d** (29 mg, 2.2%, R_f=0.55) and **12d** (208 mg, 11.1%, R_f=0.46).

Reaction of 1a with Ten-Molar Equivalents of 2 in Diluted Conditions. A mixture of **1a** (2.80 g, 10 mmol), sodium hydride (50%, 0.72 g, 15 mmol), and 2 (5.3 g, 100 mmol) in diglyme (150 ml) was heated at 140 °C for 25 min to evolve nitrogen gas (70 ml, 31%). The reaction mixture was chromatographed on silica gel to give **6a** (873 mg, 38.0%, benzene–diethyl ether 8 : 2) and **7a** (545 mg, 21.3%, benzene–diethyl ether 1 : 1).

(Received November 14, 1988)

The investigation of the reactions of urea and its methyl derivatives with formaldehyde elucidated the formation pathway of 3,5-bis(methoxymethyl)perhydro-1,3,5-oxadiazin-4-one. 1) The addition of formaldehyde to urea became increasingly difficult according to the increase of the number of added formaldehyde molecules, probably because of the steric hindrance of the hydroxymethyl groups. 2) 3,5-Bis(methoxymethyl)perhydro-1,3,5-oxadiazin-4-one was concluded to be derived from urea via tris(hydroxymethyl)urea and 3-(hydroxymethyl)perhydro-1,3,5-oxadiazin-4-one but not via tetrakis(hydroxymethyl)urea or perhydro-1,3,5-oxadiazin-4-one.

Urea-formaldehyde resins have been commercially available as important adhesives in the wood industry because of their low cost. However, previous works on their chemical structure and reaction mechanisms are not necessarily adequate. The maximal number of formaldehyde molecules added to urea has been considered to be 4, because the formation of 3,5-bis(methoxymethyl)perhydro-1,3,5-oxadiazin-4-one (U-2Mcyc2F) has been reported.[1] Although there are several reports[1-4] on the preparations of tris- and tetrakis- substituted products from urea and formaldehyde, the basic problem of the formation pathway of U-2Mcyc2F remained uncertain. Until now, two different pathways for the formation of U-2Mcyc2F have been proposed. Kadowaki[1] proposed that U-2Mcyc2F was produced from urea and formaldehyde via tetrakis(hydroxymethyl)urea (U-4F). Alternatively, Takahashi[4] proposed the formation pathway via perhydro-1,3,5-oxadiazin-4-one (Ucyc2F). These proposals have remained hypothetical partly because of the uncertain confirmation of U-4F.

Ito[2] analyzed the reaction products from urea and a large excess of formaldehyde in the presence of a strong base at 50 °C by two-dimensional paper chromatography. He considered one of the spots to be U-4F. However, Tomita and Hirose[3] assigned it to U-2Mcyc2F by its ^{1}H NMR spectrum and published a negative report on the production of U-4F.

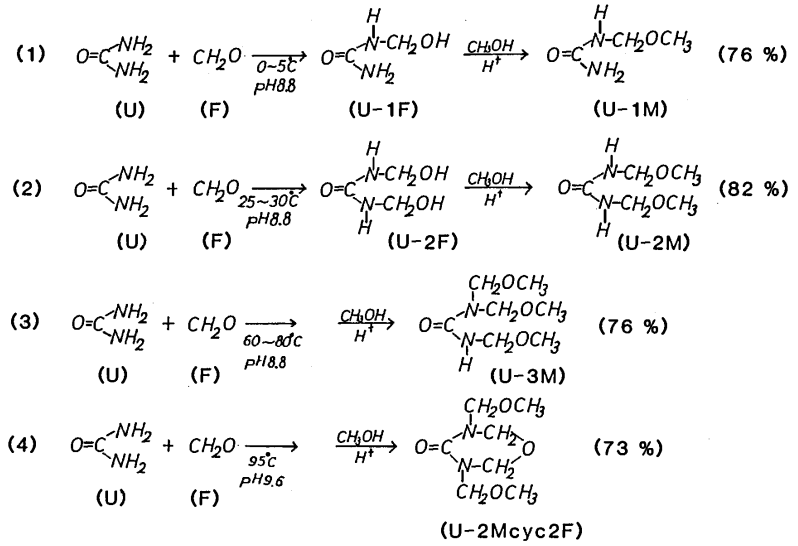
In order to obtain a clue for the elucidation of the formation pathway of U-2Mcyc2F, urea or its methyl derivatives were allowed to react with formaldehyde under various conditions. In our present report, we wish to propose a new formation pathway for U-2Mcyc2F.

Results snd Discussion

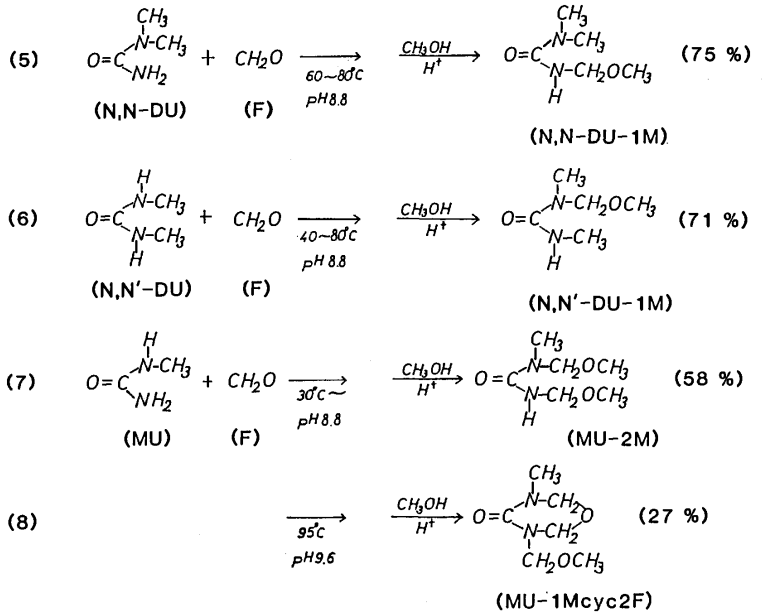
Several reports[5-8] on the selective preparation of mono- and bis(hydroxymethyl)urea (U-1F and U-2F) have been published. They suggested that the number of added formaldehyde molecules could be controlled by the feed ratio of urea/formaldehyde and the reaction temperature. U-1F and U-2F have been reported to be easily isolated from the reaction solution. However, tris(hydroxymethyl)urea (U-3F) and U-4F were difficult to isolate, probably because of their lability to heat, acids or bases. In order to isolate these products, all the hydroxymethylated products were converted to their methyl ethers under the optimal conditions described in the Experimental section. The methylation conditions used were such that the amount of HCl was 50—100 times greater than in the conventional method and the reaction temperature was lowered from 64—65 °C of the conventional method to 0—5 °C. Under these conditions, the condensation and acid hydrolysis of the hydroxymethylated products did not occur and the hydroxymethylated products were stoichiometrically converted to their methyl ethers.

The optimal preparation conditions of mono-, bis-, tris-, and tetrakis-substituted products from urea and formaldehyde are shown in Scheme 1 together with their reaction equations and their highest yields. Although Zigeuner[9] reported the production of the asym-type of U-2F as well as that of the sym-type, the amount of U-2F obtained was speculated not to contain the former from its ^{1}H NMR spectrum. The optimal temperatures were raised from 0—5 °C to 25—30, 60—80, and 95 °C with the increase of the number of added formaldehyde molecules, respectively. Furthermore, the preparation of tris(methoxymethyl)-urea (U-3M) or U-2Mcyc2F necessitated the large excess of formaldehyde in addition to high temperatures. In order to examine the production of tetrakis-(methoxymethyl)urea (U-4M), the products from urea and formaldehyde under appropriate reaction conditions between the optimal conditions for U-3M and U-2Mcyc2F were analyzed by gas-liquid chromatography, but no other products than U-3M and U-2Mcyc2F were detected.

These results suggest that the addition of formaldehyde to urea becomes increasingly difficult according to the increase of the number of added formaldehyde molecules. This is probably due to steric hindrance



Scheme 1.



Scheme 2.

by the hydroxymethyl groups. This speculation is supported by the fact that sym-U-2F is prepared more easily than asym-U-2F by a factor of about ten.[3] U-2Mcyc2F is speculated to be produced via another pathway than those proposed by Kadowaki[1] and Takahashi[4] because neither U-4M nor Ucyc2F was detected. From these facts, the formation pathway of U-2Mcyc2F is proposed as follows:

$$\text{Urea} \rightarrow \text{U-3F} \rightarrow \text{U-1Fcyc2F} \rightarrow \text{U-2Mcyc2F}$$

Under such strong alkaline conditions that the binding of the dimethylene ether may be formed.[10-11] The oxadiazine ring may feasibly be formed from the two hydroxymethyl groups in sym-position of U-3F and this ring formation may be a rate-limiting step in the formation of U-2Mcyc2F. This speculation is supported by the results of the reaction of methyl derivatives of urea with formaldehyde.

The optimal preparation conditions for methoxymethylated products from methylurea (MU), 1,1-dimethylurea (*N,N*-DU), and 1,3-dimethylurea (*N,N'*-DU) with formaldehyde are shown in Scheme 2 together with their reaction equations and their highest yields. By comparison of the optimal temperatures for the highest yields of **MU** → **MU-2M**, *N,N*-DU → *N,N*-DU-1**M**, and *N,N'*-DU → *N,N'*-DU-1**M** with those for urea → U-3**M**, it is seen that the nitrogen atoms in methyl derivatives of urea are equally or more easily attacked by $CH_2(OH)_2$ than those in urea itself because of the electron-donating nature of the

methyl group. Its electron-donating nature is partly compensated by its bulkiness. Although the optimal conditions of MU → MU-1Mcyc2F were closely identical with those of urea → U-2Mcyc2F, the yield of MU-1Mcyc2F was lower than that of U-2Mcyc2F. This may be explained by the probability of the formation of an oxadiazine ring.

Even in the reaction of *N,N*-DU or *N,N'*-DU with a large excess of formaldehyde at high temperatures under strong alkaline conditions, no 1,1-dimethyl-3,3-bis(methoxymethyl)urea or 1,3-dimethyl-1,3-bis(methoxymethyl)urea could be obtained. These results can be understood if two methyl groups and one hydroxymethyl group of 1,1-dimethyl-1-hydroxymethylurea or 1,3-dimethyl-1-hydroxymethylurea interfere with the further addition of formaldehyde and if they cannot form an oxadiazine ring. As an oxadiazine ring can be formed from two hydroxymethyl groups of 1-methyl-1,3-bis(hydroxymethyl)urea (MU-2F), MU-1Mcyc2F can be derived from MU-2F via 3-methylperhydro-1,3,5-oxadiazin-4-one.

Experimental

Preparation of Tris(methoxymethyl)urea (U-3M). Twelve grams of urea and 88.7 g of formalin were mixed and the pH of the mixture was maintained at 8.8 by the successive addition of a 0.1 M (1 M=1 mol dm^{-3}) NaOH solution. While the solution was stirred for 30 min, its temperature was kept at 65 °C. The reaction mixture was then evaporated to dryness under reduced pressure below 40 °C. The desiccated products were dissolved in 400 ml of MeOH. Keeping the temperature of the solution below −15 °C in a Dry Ice-MeOH bath, 5 ml of concd HCl was added dropwise to the solution. The solution was stirred for 10 min at 0—5 °C. After neutralization with 6 M NaOH solution and evaporation of MeOH, the methoxymethylated products were extracted with EtOH, then with dichloromethane, finally with diethyl ether. The solvent was distilled off. The resulting viscous solution was distilled at 1 Torr (1 Torr=133.322 Pa), and a distillate of 128—131 °C containing U-3M was collected (yield : 76%). Found; C, 43.66; H, 8.45; N, 14.49%: Calcd for $C_7H_{16}N_2O_4$; C, 43.75; H, 8.33; N, 14.58%: ^{1}H NMR(DMSO-d_6): δ=7.34 (1H, t, J=6 Hz, -NH-), 4.69 (4H, s,-CH_2-), 4.49 (2H, d, J=6 Hz, -CH_2-), 3.21 (6H,s,-CH_3), and 3.17 (3H, s, -CH_3): ^{13}C NMR (DMSO-d_6): δ=162.43 (O=C<), 82.25, 77.70 (-CH_2-), and 59.98, 59.85 (-CH_3): MS(FD): m/z =192(M^+).

The by-products were U-2M and condensation polymers. With rise in the hydroxymethylation temperature above 65 °C, a decrease of U-2M and an increase of condensation polymers resulted and a trace amount of U-2Mcyc2F was produced.

Preparation of U-2Mcyc2F. U-2Mcyc2F was prepared by the virtually identical procedure described in the preparation of U-3M except for a reaction temperature of 95 °C with the pH of the reaction solution of 9.6. The resulting viscous solution was placed on an alumina column. U-2Mcyc2F was eluted with a hexane-dichloromethane (7:3) mixture (yield: 73%). Found; C, 44.14; H, 7.45; N, 14.60%: Calcd for $C_7H_{14}N_2O_4$; C, 44.21; H, 7.37; N, 14.74%: ^{1}H NMR($CDCl_3$): δ=4.93 (4H, s, -CH_2-), 4.79 (4H, s, -CH_2-) and 3.34 (6H, s, -CH_3): ^{13}C NMR($CDCl_3$): δ=152.25 (O=C<), 76.67, 74.34 (-CH_2-) and 54.24 (-CH_3): MS (FD): m/z= 190(M^+).

All of the remainder other than U-2Mcyc2F in the distillate was elucidated to be U-3M by gas-liquid chromatography on a column of PEG-20M (ϕ 3 mm×2 m) at 190 °C. However, its content was as low as 10%.

Without the successive addition of a 0.1 M NaOH solution, the pH of the reaction solution fell from 9.6 to 7.0—7.2 and the yield of U-2Mcyc2F decreased into 16% and those of U-3M and condensation polymers increased.

Preparation of 1,1-Dimethyl-3-methoxymethylurea (*N,N*-DU-1M). The pH of the reaction mixture of 17.6 g of 1,1-dimethylurea (*N,N*-DU) and 40.3 g of formalin was adjusted to 8.8. The solution was stirred for 30 min at 70 °C. The procedures of methoxymethylation and extraction were the same as described above. The resulting viscous solution was permitted to stand for at least 2—3 days. The deposited crystals were recrystallized from EtOH as white rod-like crystals (yield: 75%). Mp 54.0—55.0 °C: Found; C, 45.32; H, 9.14; N, 21.15%; Calcd for $C_5H_{12}N_2O_2$; C, 45.45; H, 9.09: N, 21.21%: ^{1}H NMR (DMSO-d_6): δ=7.26 (1H,t, J=6Hz, -NH-), 4.49 (2H, d, J=6Hz, -CH_2-), 3.15 (3H, s, -OCH_3), and 2.81 (6H, s, -CH_3): ^{13}C NMR (DMSO-d_6): δ=157.41 (O=C<), 72.49 (-CH_2-), 54.10 (-OCH_3), and 35.54 (-CH_3): MS (FD): m/z=132(M^+).

Preparation of 1,3-Dimethyl-1-methoxymethylurea (*N,N'*-DU-1M). A mixture of 17.6 g of 1,3-dimethylurea (*N,N'*-DU) and 40.3 g of formalin was stirred at 50 °C for 30 min while the pH of the solution was kept at 8.8. The methoxymethylation and extraction procedures were the same as descrived above. A distillate of 95—99 °C at 1 Torr was collected (yield: 71%). Found; C, 45.31; H, 9.14; N, 21.14%: Calcd for $C_5H_{12}N_2O_2$; C, 45.45; H, 9.09; N, 21.21%: ^{1}H NMR (DMSO-d_6): δ=6.43 (1H, m, -NH-), 4.60 (2H, s, -CH_2-), 3.14 (3H, s, -OCH_3), 2.82 (3H, s, -CH_3), and 2.58 (3H, d, J=4Hz, -CH_3), ^{13}C NMR (DMSO-d_6): δ=158.18 (O=C<), 79.15 (-CH_2-), 54.15 (-OCH_3), 33.10 (-CH_3), and 26.84 (-CH_3): MS (FD): m/z=132 (M^+).

Preparation of 1-Methyl-1,3-bis(methoxymethyl)urea (MU-2M). The mixture of 14.8 g of methylurea (MU) and 40.3 g of formalin (F/MU=5) was stirred at 50 °C for 30 min while the pH of the mixture was kept at 8.8. The methoxymethylation and extraction procedures were the same as described above. A distillate of 137—142 °C at 1 Torr was collected (yield: 58%). Found; C, 44.34; H, 8.75; N, 17.14%: Calcd for $C_6H_{14}N_2O_3$; C, 44.44; H, 8.64; N, 17.28%: ^{1}H NMR (DMSO-d_6): δ=6.36 (1H, m, -NH-), 4.63 (4H, s, -CH_2-), 3.20 (6H, s, -OCH_3), and 2.63 (3H, d, J=4Hz, -CH_3): ^{13}C NMR (DMSO -d_6): δ=157.45 (O=C<), 77.94 (-CH_2-), 54.37 (-OCH_3), and 26.85 (-CH_3): MS(FD): m/z=162 (M^+).

The optimal temperature in the preparation of MU-2M was above 30 °C, and over a broad range of temperature the major product from MU and formaldehyde was MU-2M.

Preparation of 3-Methyl-5-methoxymethyl-perhydro-1,3,5-oxadiazin-4-one (MU-1Mcyc2F) The mixture of 7.4 g of MU and 80.6 g of formalin (F/MU =10) was stirred at 95 °C for 30 min while the pH of the solution was kept at 9.6. The methoxymethylation and extraction procedures were the same as described above. The resulting viscous solution was placed on an alumina column and MU-1Mcyc2F was eluted with a hexane-dichloromethane (7:3) mixture

(yield: 27%). Found; C, 44.87; H, 7.61; N, 17.41%: Calcd for $C_6H_{12}N_2O_3$; C, 45.00; H 7.50; N, 17.50%: ^{1}H NMR (DMSO-d_6): δ=4.87, 4.78, 4.63 (2H, s, -CH_2-), 3.17 (3H, s, -OCH_3) and 2.74 (3H, s, -CH_3): ^{13}C NMR (DMSO-d_6): δ=153.09 (O=C<), 79.18, 77.56, 75.31 (-CH_2-), 54.62(-OCH_3), and 30.07 (-CH_3): MS(FD): m/z=160(M^+).

Molecular Structures of Diarylcyclobutanes Associated with Reactivities in Ring-Cleavage Reactions: Implications of Conformationally Controlled Through-Bond Coupling

(Received November 17, 1988)

Molecular structures of diarylcyclobutanes (**1**—**6**) have been determined by single-crystal X-ray analyses. Although the distances and angles of the cyclobutane rings are relatively normal, the torsional angles between the aryl ring and the plane involving the ipso carbon and the aryl-substituted carbons of cyclobutane ring are close to 90° in cases of **1**—**4**, but very small (2.3—11.3 °) in cases of **5** and **6**; conformations of the aryl substituents are highly restricted by the rigid tricyclic structure or by nonbonding interactions between the vicinal substituents in the cis configuration. Restricted conformations are closely related to the different reactivities of the cyclobutane in photochemical, thermal, and radiation-induced ring-splitting reactions. The structure-reactivity relationships are discussed in terms of the conformation-controlled π-σ orbital interactions associated with the capabilities of the π electron systems in through-bond coupling.

The chemistry of cyclobutanes has been of stereochemical significance as a suitable probe for the exploration of both steric and electronic effects on chemical reactivities and as a prototype for theoretical investigations of chemical reaction courses. It can be expected that the chemical behavior of cyclobutanes is remarkably susceptible to a variety of steric and electronic perturbations, since the cyclobutane rings are relatively rigid with small conformational mobilities,[1] and since the molecular-orbital of the ring σ framework shows a small, but significant, π-bonding character.[2] Indeed, we found that aryl-substituted cyclobutanes reveal remarkable structure dependences in photochemical,[3-7] radiation-induced,[8] and thermal[9] ring-splitting reactions as well as in electrochemical oxidation potentials.[3] For instance, the head-to-head transoid cyclobutane dimer of indene (**1**) and related diarylcyclobutanes of "head-to-head" structure are efficiently split into the corresponding olefins by the redox photosensitization that proceeds by way of the π complex with the cation radical of aromatic hydrocarbons (Fig. 1). By contrast, no redox-photosensitized ring splitting occurs at all for the head-to-tail transoid dimer of indene (**2**), other "head-to-tail" diarylcyclobutanes, and monoarylcyclobutanes. Similarly, the head-to-head cisoid dimers of 1,3-dimethylthymine and 1,3-dimethyluracil are efficiently monomerized by redox photosensitization, while the head-to-tail isomers are not at all.[10]

These observations have been interpreted as the consequences of the structure-controlled capabilities of the two π or n electron systems in electronic coupling through the ring σ orbitals, since the "head-to-head" structures are requisite for efficient through-bond coupling. Through-bond coupling has been investigated from theoretical[11] and spectroscopic[12] points of view and has been suggested to play important roles in the photochemical and thermal reactions of some rigid polycyclic compounds with separated π chromophores which are perpendicular to each other.[13] It is, however, predicted that if through-bond coupling is essential in chemistry of diarylcyclobutanes,

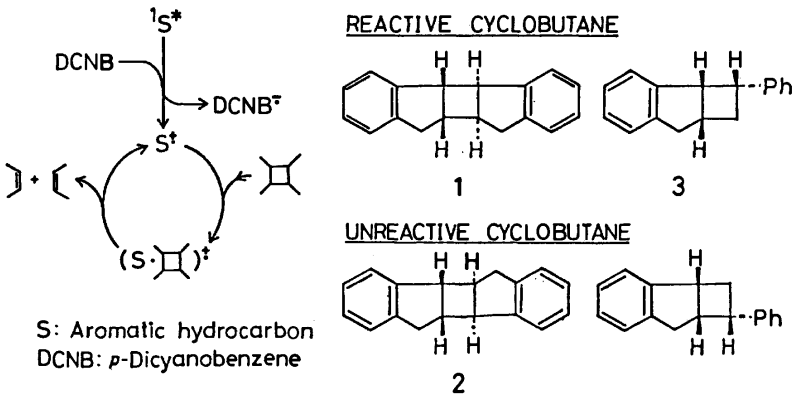

Fig. 1. Redox-photosensitized splitting of the cyclobutane ring; typical "head-to-head" diarylcyclobutanes which are reactive and typical "head-to-tail isomers which are unreactive

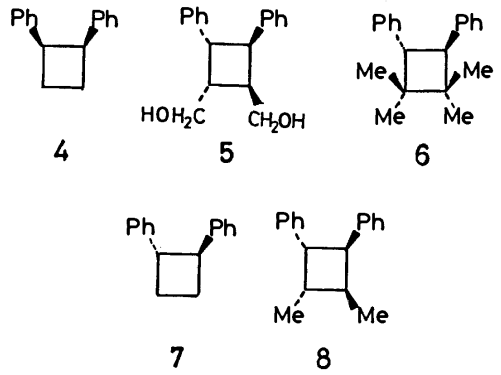
conformations of the aryl substituents should control the stereochemical reaction courses. However, little has been known on what relationships exist between the conformational effects on the chemical reactivities and stereochemical requirements for through-bond coupling. Another important expectation is that through-bond coupling would bring about an unusual elongation of a cyclobutane-ring σ bond to activate the "head-to-head" cyclobutanes[14,15] or may stabilize transition states of the ring-splitting reactions by extended electronic conjugation over relevant orbital arrays. From the above-mentioned points of view, we have performed X-ray crystallographic analyses of diarylcyclobutanes **1—6** in order to determine the exact molecular structure. In this paper we wish to report on the results and to discuss the implications of molecular structures in the through-bond coupling associated with the reactivities of the cyclobutanes.



Experimental

Materials. The preparation of the cyclobutanes was carried out according to reported methods; *cis-transoid-cis*-cyclobuta[1,2-*a*;4,3-*a'*]diindene (**1**),[16] *cis-transoid-cis*-cyclobuta[1,2-*a*;3,4-*a'*]diindene (**2**),[3] *endo*-2-phenyl-2,2a,7,7a-tetrahydro-1*H*-cyclobut[*a*]indene (**3**),[3] *cis*-1,2-diphenylcyclobutane (**4**),[17] *r*-1,*t*-2-bis(hydroxymethyl)-*t*-3, *c*-4-diphenylcyclobutane (**5**),[5] 1,1,2,2-tetramethyl-*trans*-1,2-diphenylcyclobutane (**6**),[18] *trans*-1,2-diphenylcyclobutane (**7**),[17] and *r*-1,*t*-2-dimethyl-*t*-3,*c*-4-diphenylcyclobutane (**8**).[5] Single crystals for X-ray analyses were obtained by recrystallization from methanol for **1—5** and from hexane for **6**. On the other hand, all attempts failed in obtaining single crystals of **7** and **8**; these cyclobutanes remained oily at room temperature.

Single-Crystal X-Ray Analysis. Crystal structure analyses were carried out on an Enraf Nonius automated four-circle X-ray diffractometer (CAD 4) using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). Intensity data were collected by ω-2θ scan upto 50° for **1**, **4**, and **6**, 60° for **2**, 54° for **3**, and 56° for **5** in 2θ. The crystallographic data are shown in Table 1.

Structure Determination. All of the calculations were carried out on a DEC PDP 11/34 system using a SDP and SDP-Plus programs. The structures were solved by the direct method (MULTAN 82) and refined by a full-matrix least-squares method.

In the last cycle of the refinement with anisotropic temperature factors for nonhydrogen atoms, all of the parameter shifts were less than one-third of the corresponding standard deviations. After the refinement hydrogen atoms were located in positions calculated for a C–H bond length = 0.950 Å. Tables of the observed and calculated structure factors, anisotropic temperature factors, and bond distances and angles have been deposited to the Chemical Society of Japan (Document No. 8874).

^{1}H NMR spectra were taken on a JEOL JNM-PS-100 spectrometer for a $CDCl_3$ solution using tetramethylsilane as the internal standard.

Results and Discussion

Molecular Structures. Table 2 lists the final atomic parameters. The crystal packing diagrams and computer-generated molecular structures of **1—6** are shown in Figs. 2 and 3, respectively. For the present investigation, the essential structure parameters are the bond distances and angles of the cyclobutane ring,

a) See Fig. 4.

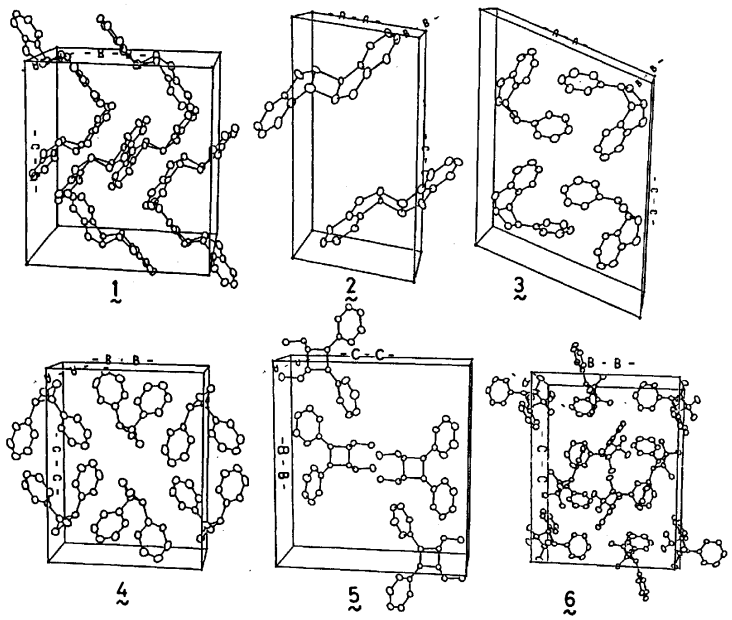

Fig. 2. Crystal-packing diagrams of **1**—**6**.

dihedral angles (ϕ) between the $C_AC_BC_D$ and $C_BC_CC_D$ planes of the cyclobuatne rings, and torsional angles (θ) between the planar ring of the aryl substituent and the plane involving ipso carbon of the aryl group and the C_A-C_B bond. Figure 4 shows the relevant angles, together with notation of the cyclobutane-ring carbon atoms, which are used in further discussion for convenience. These data are shown in Table 3.

The bond distances of the cyclobutane ring of **1**—**3** are slightly longer than the normal distances of monocyclic cyclobutanes (1.52—1.56 Å),[1] perhaps due to the fused tricyclic or bicyclic structure. However, it is important to note that the C_A-C_B bond of **1** and **3** is not unusually longer than the cyclobutane-ring bonds of head-to-tail cyclobutane **2**. The C_B-C_C and C_C-C_D bonds of **4** are relatively short, suggesting a slight distortion of the cyclobutane ring which might arise from steric repulsion between the vicinal phenyl

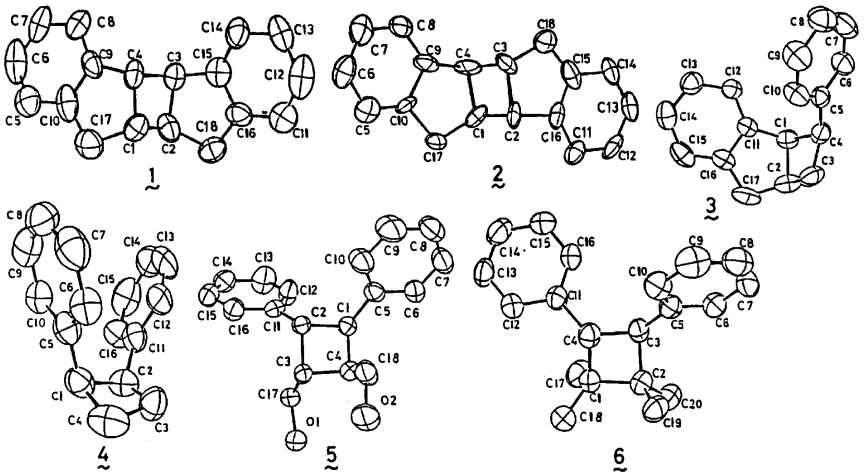

Fig. 3. ORTEP drawing of molecular structures of **1**—**6**.

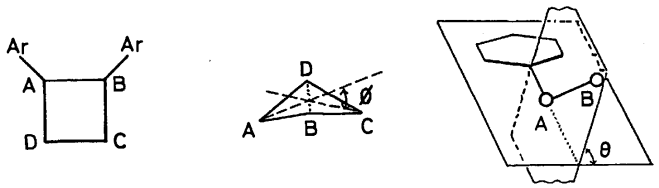

Fig. 4. Notation of each carbon atom of the cyclobutane ring, dihedral angle (ϕ), and torsional angle (θ).

groups in the cis configuration, as shown by the molecular structure in Fig. 1 as well as by molecular models. Similarly, the long C_C-C_D distance of **6** can be attributed to nonbonding interactions between the methyl substituents at C_C and C_D. However, it should be noted that the C_A-C_B distances of **4**—**6** fall within the normal values. The cyclobutane rings of **1**—**6** commonly take puckering forms, in which the $C_AC_BC_D$ and $C_BC_CC_D$ planes meet at the C_B-C_D line with normal dihedral angles (3—30°).[1] The bond angles of the cyclobutane rings are also normal, very close to 90°. It is, therefore, appropriate to conclude that these cyclobutanes are not unusually distorted but, rather, relatively normal.

Of particular related significance regarding through-bond coupling is that the θ values are close to 90° in the cases of **1**, **3**, and **4** but very small (2.3—11.3°) in the cases of **5** and **6**. The solid-state conformations of the aryl substituents should be virtually preserved in solution as well, since the rotational motions of the aryl rings are almost frozen by the rigid tricyclic structures of **1** and **2**, and are largely restricted by nonbonding interactions between the phenyl ring and the vicinal cis substituents in **3**—**6**. This is strongly supported by comparisons of the C_A-H chemical shifts in ^{1}H NMR using **1** as a reference compound with an almost fixed conformation. The resonance of C_A-H of **1** appears at δ 3.50, being considerably higher in field than that of **3** (the methine proton of the indan moiety, δ 3.98) and also than that of **4** (PhC-H, δ 3.92). This is clearly due to shielding of C_A-H by the opposite aryl ring at C_B facing to this proton, while the cis configuration of the two aryl substituents of **3** and **4** prohibits such magnetic anisotropic effects on $C_A(C_B)$-H. The aromatic resonances of **3** and **4** are spread over a wider range of field, δ 6.03—7.8 for **3** and δ 6.61—7.3 for **4** compared with those of **1** (δ 6.8—7.3) and **5**—**8** (δ 6.8—7.4), thus indicating that the aryl rings of **3** and **4** take face-to-face conformations, i.e., $\theta \approx 90°$. On the other hand, the C_A-H resonance of **5** (δ 4.22) is much lower in field than that of **1**, irrespective of similar configurational situations and even lower than that of **4**. This is in line with the solid-state conformation of **6** in Fig. 3, since $C_A(C_B)$-H should be deshielded by the phenyl ring at $C_B(C_A)$. In the case of **6**, however, the deshielding effects of the phenyl ring should be counterbalanced by the shielding effects of the methyl group at $C_D(C_C)$ facing to $C_A(C_B)$-H, whereas one of the geminal ring facing to this group. As a result, **6** reveals a C_A-H(C_B-H) resonance at δ 3.55 and two methyl signals at δ 0.80 and 1.13.

Structure-Dependent Orbital Interactions Associated with Through-Bond Coupling. Figure 5 shows qualitative molecular-orbital diagrams of 1,2-diphenylcyclobutane with $\theta = 90°$ using Salem's σ orbital of cyclobutane[2a] and combinations of the π orbitals of benzene and toluene as the basis-set orbitals, which are symmetric or antisymmetric with respect to two-fold rotation or reflection. As shown in Fig. 6, the π orbitals of "head-to-head" diarylcyclobutanes may interact with the C_A-C_B σ orbitals or with the C_A-C_D and C_B-C_C σ orbitals, depending on the conformations of aryl substituents. The rigid tricyclic structure of **1** or the cis configurations of the vicinal aryl substituents of **3** and **4** almost freeze the conformations of the aryl groups favorable to maximum orbital overlapping of the π orbitals with the C_A-C_B σ orbitals, as demonstrated by the observed

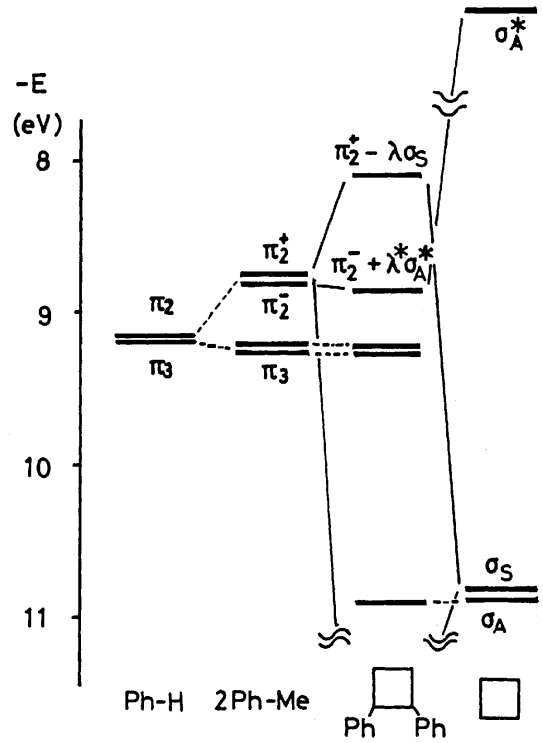

Fig. 5. Schematic molecular-orbital diagrams of 1,2-diphenylcyclobutane with θ=90°; the energy levels of the isolated π and σ orbitals are those of benzene, toluene, and parent cyclobutane, whereas that of $\pi_2^+ - \lambda\sigma_S$ is estimated from the reported ionization potential of *trans*-1,2-diphenylcyclobutane.

torsional angles (θ) being very close to 90°. In the cases of these cyclobutanes (group (i)), the symmetric π_2 combination (π_2^+) can interact with symmetric σ_S to give the highest-occupied molecular orbital (HOMO), $\pi_2^+ - \lambda\sigma_S$, whereas the antisymmetric combination (π_2^-) may interact with σ_A^* to give a bonding MO, $\pi_2^- + \lambda^*\sigma_A^*$.[11,12]

On the other hand, the θ values of **5** and **6** (group (ii)) are very small (2.3—11.3°) because of steric repulsion between the phenyl groups and the vicinal methyl or hydroxymethyl substituents in the cis configuration, demonstrating that the π orbitals can not overlap with the orthogonal C_A-C_B σ orbitals but can do so favorably with the C_A-C_D and C_B-C_C σ orbitals. Such restricted conformations should allow only π_2^--σ_A and π_2^+-σ_S^* interactions, which are certainly ineffective to through-bond coupling. Similarly, the orbital interactions of head-to-tail cyclobutane **2** are ineffective regarding through-bond coupling.

Probably, **7** falls in group (i), since the phenyl substituents can take conformations of $\theta \approx 90°$ without steric repulsion. In this regard, it should be noted that the chemical shift of C_A-H (C_B-H) of **7** (δ 3.50) in the ^{1}H NMR spectrum is the same as that of **1**, but higher in field than that of **4**. This suggests that the phenyl rings of **7** assume stable conformations similar to the structure of **1**. On the other hand, **8** belongs to group (ii), as indicated by the C_A-H (C_B-H) chemical shift (δ 4.10) which is very similar to that of **5** (δ 4.22), but lower in field than that of **1**.

Since the reported ionization potential of **7** (8.2 eV)[19] is considerably lower than those of alkylbenzenes (8.7—8.8 eV),[20,21] through-bond coupling substantially occurs in group (i) cyclobutanes, i.e., $\lambda > 0$. Furthermore, the group (i) cyclobutanes show oxidation waves in cyclic voltammetry at considerably lower potentials than the others; the observed half-peak oxidation potentials ($E_{p/2}^{ox}$ vs. Ag/$AgNO_3$ in CH_3CN) are 1.32 V for **1**, 1.29 V for **4**, and 1.33 V for **7** compared with 1.49 V for **2**, with 1.53 V for **6**, and with 1.63 V for **8**.[3,5] Although all the cyclobutanes reveal irreversible waves in cyclic voltammetry, the irreversible oxidation potentials would be linearly correlated with the energy levels of the HOMO's of the cyclobutanes, as demonstrated for the oxidation potentials of

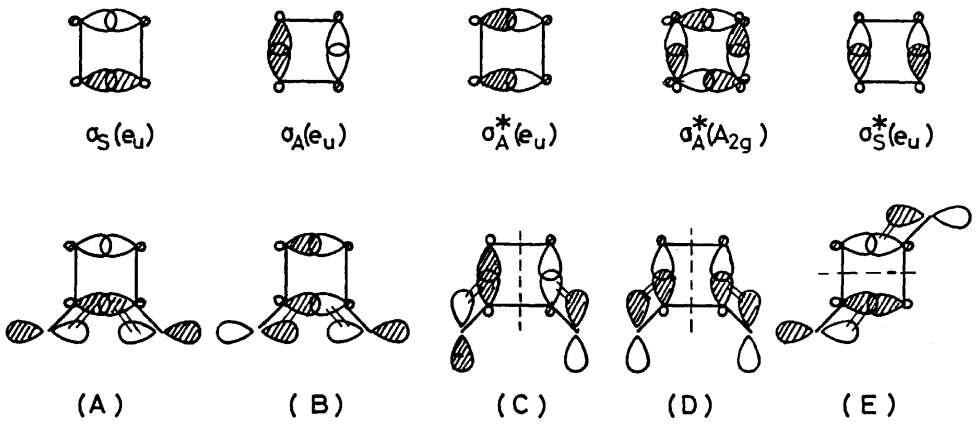

Fig. 6. Top: Salem's σ and σ^* orbitals of cyclobutane. Bottom: (A) π_2^+-σ_S and (B) π_2^--σ_A^* interactions in "head-to-head" cyclobutanes with $\theta \approx 90°$; (C) π_2^--σ_A and (D) π_2^+-σ_S^* interactions in "head-to-head" cyclobutanes with $\theta \approx 0°$ which are ineffective to through-bond coupling; (E) π-σ interactions in "head-to-tail" cyclobutane **2** which are ineffective to through-bond coupling.

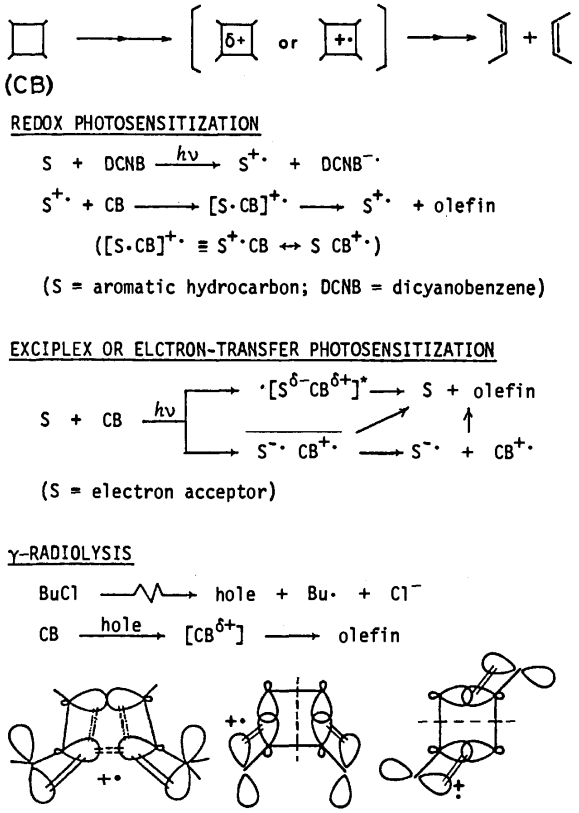
homoleptic alkylmetals and various organic compounds.[22] It might, thereforee, be reasonable to conclude that the π_2 orbitals can significantly couple through interactions with σ_S for the group (i) cyclobutanes while through-bond coupling of π_2 is negligible or inefficient in the other cases, as predicted.

In cases of the group (i) cyclobutanes, the π orbitals may again couple through π_2^--σ_A^* interactions to result in a mixing of the σ^* character in a bonding MO which should bring about a specific elongation of the C_A-C_B bond.[13,14] However, the C_A-C_B bond is normal in the case of **4** or not particularly longer in the cases of **1** and **3** than the other bonds nor than the cyclobutane-ring bonds of **2**. This indicates that π_2^--σ_A^* interactions are not important below room temperature, i.e., $\lambda^* \approx 0$. This is again true for the group (ii) cyclobutanes, as demonstrated by the observed cyclobutane-ring distances. Presumably, the energy levels of σ^*'s are too high for appreciable π-σ^* interactions to occur without any vibrational activation of the relevant σ bond. However, such orbital interactions should play important roles in the transition states of the thermal ring-splitting reactions where σ bonds are vibrationally perturbed (vide infra).

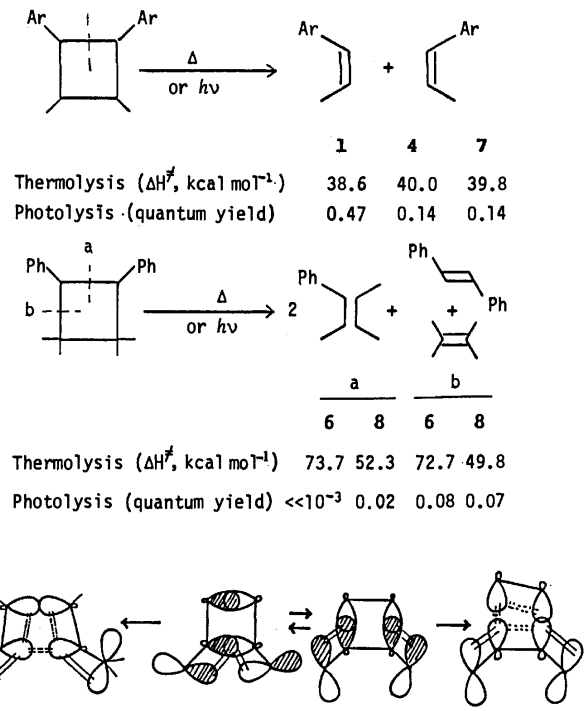
Implications of Through-Bond Coupling in Bond-Cleavage Reactions. The selective C_A-C_B bond cleavage of the group (i) cyclobutanes is effected by redox photosensitization,[3] by exciplex[5] or electron-transfer[6] photosensitization with electron acceptors, and by γ-radiolysis in butyl chloride,[8] giving the corresponding olefins in most cases, as shown in Scheme 1. By contrast, no chemical change of the other cyclobutanes occurs at all by these reactions. The different chemical behavior of the diarylcyclobutanes is certainly in parallel with capabilities of the π-electron systems in coupling through the cyclobutane-ring σ framework.

A key chemical event in the reactions shown in Scheme 1 is the population of a positive charge on the cyclobutanes by charge resonance with a cation radical species and by charge-transfer interactions with or electron transfer to an excited-state electron acceptor. The positive charge population on the group (i) cyclobutanes should be delocalized over the π_2-σ_S-π_2 orbital array, thus leading to decreases in both the C_A-C_B bonding character and the C_A-C_D (C_B-C_C) antibonding character of σ_S, resulting in both a weakening of the C_A-C_B bond and a shortening of the C_A-C_D and C_B-C_C bonds.[23] This is the driving force for the selective bond cleavage of the group (i) cyclobutanes. In the cases of the other cyclobutanes, however, the positive charge should be mostly localized on the isolated-π_2 orbital to cause only minor or slight perturbation of the cyclobutane-ring σ framework, since through-bond coupling is much weaker or disallowed to occur. This is clearly ineffective to bond-cleavage reactions.

Thermal ring-splitting reactions of the "head-to-head" cyclobutanes reveal interesting features in regiochemistry as well as in reactivities, depending on the stable conformations associated with different orbital interactions (Scheme 2).[9] Exclusive or dominant C_A-C_B cleavage occurs upon heating **1**, **4**, or **7** to give



Scheme 1.



Scheme 2.

indene or styrene with activation enthalpies of ca. 40 kcal mol^{-1},[9,24] while **6** and **8** undergo nonselective cleavages of both the C_A-C_B and C_A-C_D bonds with higher activation enthalpies (50—74 kcal mol^{-1}).[9] These observations can be interpreted in terms of conformation-controlled π-σ^* interactions.

Although π-σ^* interactions are negligeble below room temperature, extensive vibrations at elevated temperatures bring about a skeletal distortion of the cyclobutane ring, which should perturb the σ^* levels to allow π-σ^* interactions. Since mixing of the σ_A^* character by π_2^--σ_A^* interactions is inherently more efficient than that of the σ_S^* character by π_2^+-σ_S^* interactions, the activation barriers for the C_A-C_B cleavage should be lower than those for the C_A-C_D (C_B-C_C) cleavage unless the relevant orbital interactions are sterically inhibited. Consequently, the C_A-C_B bond is selectively cleaved in cases of group (i) cyclobutanes where π_2^--σ_A^* interactions are coformationally allowed. On the other hand, nonbonding interactions between the phenyl and the methyl substituents in **6** and **8** inhibit the phenyl rings from taking conformations for π_2^--σ_A^* interactions, thus imposing additional rotational barriers for the C_A-C_B cleavage. This might be the reason why the thermal reactions of **6** and **8** nonselectively occur with higher activation barriers.

The above arguments imply that the effects of through-bond coupling are not static but, rather, dynamic in nature in the control of stereochemical reaction courses in the ring splitting of the diarylcyclobutanes. This is more explicitly shown in photochemistry. The absorption and fluorescence spectra of the cyclobutanes are essentialy identical with those of indan or toluene, independently of the different conformations of the aryl groups,[7] thus demonstrating that the spectroscopic ground and excited singlet states of the cyclobutanes are the same as those of the isolated π chromophores with slight electronic perturbation. Nevertheless, both regioselectivities and efficiencies in the photolytic ring-cleavage reactions are apparently controlled by different orbital interactions, depending on the restricted stable conformations,[7,25] through π^*-σ^* interactions should be taken into consideration when considering the photochemistry.

Conclusion

Among the molecular-structure parameters of the "head-to-head" diarylcyclobutanes which have been determined by X-ray crystallographic analyses, torsional angles (θ) between the aryl ring and the ipso C-C_A-C_B plane are directly related to the different reactivities of the group (i) and group (ii) cyclobutanes in various types of ring-splitting reactions. With $\theta \approx 90°$, through-bond coupling can occur by π-σ_S interactions to give the HOMO and by π-σ_A^* interactions which result in the mixing of the σ_A^* character in a bonding MO. On the other hand, restricted conformations of the aryl groups with $\theta \approx 0°$ allow only π-σ_A and π-σ_S^* interactions which are ineffective to through-bond coupling. The efficient regioselective cleavage of the C_A-C_B bond of the group (i) cyclobutanes can, thus, be interpreted in terms of the delocalization of a positive charge over the π-$C_A(\sigma)$-$C_B(\sigma)$-π orbital array upon partial or complete removal of an electron, in terms of stabilization of the transition state of thermal reaction due to mixing of σ_A^* character at elevated temperature, and in terms of π^*-σ_A^* interactions in direct photolysis. Such effects of through-bond coupling might not be effective regarding the bond-cleavage reactions of group (ii) cyclobutanes. The through-bond coupling concept might provide a general rationale for interpreting the steric control of chemical reaction courses in the cleavage of a C-C bond with vicinal π or n substituents.

Thermal Ring-Splitting Reactions of Diarylcyclobutanes: Significance of Steric Effects on Orbital Interactions in Transition States and Biradical Intermediates

(Received November 17, 1988)

Regiochemistry and reactivities in the thermal ring-splitting reactions of diarylcyclobutanes (**1**—**5**) have been studied and shown to depend on the stable conformations and rotational mobilities of the aryl substituents. The reactions of **1** and **2** result in a regiospecific symmetric cleavage to give indene or styrene along with significant isomerization of **2** to **3**. In the cases of **3**—**5** both the symmetric and unsymmetric cleavages competitively occur with decreasing symmetric-to-unsymmetric ratios with an increase in methyl substitution. The olefin products from **4** are mixtures of *cis*- and *trans*-2-butene, *cis*- and *trans*-β-methylstyrene, and *trans*-stilbene. Thermochemical analyses combined with product analyses indicate that the symmetric cleavage of **1** and the unsymmetric cleavage of **3** proceed with a concerted mechanism, whereas 1,4-biradicals are involved in the other reactions. Structure-reactivity relationships of the present reactions are discussed in terms of mixing of the σ* character in a bonding MO by specific π-σ* interactions, depending on the conformational situations of the aryl groups and in terms of the steric effects which destabilize 1,4-biradicals as well as transition states of the biradical fragmentation to the olefins.

Ring-splitting reactions of cyclobutanes have beeen providing an excelent diagnosis method for exploring the steric and electronic factors controlling chemical reaction courses.[1-3] Theories predict that concerted $[_\sigma 2_s + _\sigma 2_s]$ cycloreversions are forbidden in the ground state.[4] A considerable body of stereochemical and thermochemical evidence indeed supports mechanisms involving 1,4-biradicals in thermal ring-splitting and stereomutation reactions of cyclobutanes with no particular π substituents such as parent cyclobutane,[5,6] alkylcyclobutanes,[7] divinylcyclobutane,[8] and other substituted cyclobutanes,[9] as shown by molecular-orbital considerations.[10,11]

On the other hand, much less has been investigated concerning mechanistic details of thermal reactions of cyclobutanes with large π substituents. It can be presumed that the chemical behavior must be remarkably susceptible to steric and electronic effects of such π substituents, since the cyclobutane rings are small in size and conformationally rigid[12] and since the π-bonding character contributes to the ring σ framework.[13] Since vibrational motions of a C-C bond with a large substituent are very slow, the rate-determining step for the ring cleavage of such cyclobutanes may be not scisson of a C-C bond but rotation or other motions.

It was reported that thermolyses of substituted tetrahydrocyclobuta[*a*]naphthalenes[14] and [4.4.2]propelladienes[15] result in regiospecific ring cleavages to give aromatized products and olefin fragments with high stereoretention. Although the high stereoselectivities would be attributable to steric inhibition of bond rotaion in 1,4-biradicals, an attractive alternative is the participation of a concerted mechanism that would occur as the consequence of extended π conjugation in transition states. This was suggested for thermal reactions of phenylated oxetanes[16] and *cis*-3,6-diphenyl-1,2-diazacyclohexene.[17] Of another stereochemical interest in bond cleavages of π-substituted cyclobutanes are regioselectivities, which would reflect the relative stabilities of different biradicals or which would be controlled by interactions of the π orbitals with each of the σ orbitals of the cyclobutane ring along the reaction coordinate.[1,18]

From the above points of view, we have investigated thermal ring-splitting reactions of diarylcyclobutane (**1**—**5**). It can be expected that the stereochemical features and reactivities of the reactions are controlled by complex combinations of steric and electronic effects of the aryl substituents. We report here mechanistic details concerning the ring-splitting reactions and the significance of steric control of orbital interactions in the stereochemical reaction courses.

Experimental

The cyclobutanes were prepared according to methods described in the literature; *cis-transoid-cis*-cyclobuta[1,2-*a*; 4,3-*a'*]diindene (**1**),[19] *cis*-1,2-diphenylcyclobutane (**2**),[20] *trans*-1,2-diphenylcyclobutane (**3**),[20] *r*-1, *t*-2-dimethyl-*t*-3, *c*-4-diphenylcyclobutane (**4**),[18b] and 1,1,2,2-tetramethyl-*trans*-3,4-diphenylcyclobutane (**5**).[21] Purification was carried out by repeated recrystallization from methanol for **1** and **2** or from hexane for **5**, whereas **3** and **4** were distilled in vacuo. Diphenyl ether was used after vacuum distillation.

Aliquot portions (2 cm^3) of a diphenyl ether solution of **1—5** (0.02 mol dm^{-3}) were introduced into Pyrex tubes (8 mm i.d.), thoroughly degassed by three freeze-pump-thaw cycles under $<10^{-3}$ Torr, and then heated in a Shimadzu GC-6AM electric furnace that had been preheated at given temperatures (±<1 °C). The reactions were followed by vapor-phase chromatography on a Shimadzu GC-8A machine using a 3-m column of 5% OV-17 on Chromosorb W AW-DMCS.

Results

Thermal reactions of **1—5** were performed by heating a degassed diphenyl ether solution (0.02 mol dm^{-3}) at 160—360 °C. The products were exclusively the corresponding olefins, except for the case of **2** where the isomerization to **3** significantly occurred, as shown in Scheme 1. In the cases of **1** and **2**, the ring cleavage is regiospecific in the symmetric (*a*) direction, whereas **3—5** are cleaved in both the symmetric (*a*) and the unsymmetric (*b*) directions in *a*:*b* ratios decreasing with an increase in methyl substitution. Although the formation of ethylene, 2-butene, and 2,3-dimethyl-2-butene was confirmed, their yields were not determined because of analytical difficulties. However the yields of the other products accounted for the conversions of the cyclobutanes within experimental errors (≤5%). It was confirmed that no isomerization of **3** to **2** occurs at all. Similarly, the stereomutation of **4** should be negligible, if any, since no product other than the olefins was detected at all by vapor-phase chromatography (VPC), and since the combined yields of β-methylstyrene and stilbene virtually equaled the amounts of **4** consumed. Although the stilbene formed from **3—5** was only the trans isomer, **4** gave a mixture of *cis*- and *trans*-2-butene in a ca. 35 : 65 ratio independently of temperature and mixtures of *cis*- and *trans*-β-methylstyrene in ratios increasing with an increase in the temperature from 15 : 85 at 280 °C to 27 : 73 at 320 °C. It was confirmed that each isomer of either stilbene or β-methylstyrene is not isomerized at ≤360 °C.

The total rate constants (k_t) for the thermal reactions at various temperature were determined from linear plots of $\ln(C/C_0)$ vs. the reaction time in seconds; C_0 and C represent the concentrations of each cyclobutane before thermolysis and at a given reaction time, respectively. Although k_t equals the rate constant (k_a) for the symmetric cleavage of **1**, each rate constant (k_a, k_b, or k_i) for the symmetric or the unsymmetric cleavage of **2—5** or for the isomerization of **2** to **3** at a given temperature was obtained from k_t multiplied by the molar proportion of the relevant product, styrene product/(styrene product+2×stilbene or 2×**3**), 2×stilbene/(styrene product+2×stilbene), or 2×**3**/(styrene+2×**3**). Table 1 summarizes the calculated rate constants at various temperatures. Figure 1 shows Arrhenius plots of ln k_a, ln k_b, and ln k_i vs. T^{-1} from which the activation enthalpies ($\Delta H_a^{\neq}$, $\Delta H_b^{\neq}$, and $\Delta H_i^{\neq}$) and the frequency factors (A_a, A_b, and A_i) were obtained, as listed in Table 2. In the case of **5**, the unusually high activation barriers and frequency factors appear to involve large experimental errors, because of the very slow reaction occurring even at very high temperatures. Nevertheless, the observed values should indicate that the thermochemical parameters are much larger than those of the other cyclobutanes, thus being of mechanistic significance. Figure 2 shows a plot of ln (cis-trans ratio) vs. T^{-1} for the β-methylstyrene formation from **4**, which gives an activation enthalpy difference of 44.3 kJ mol^{-1}

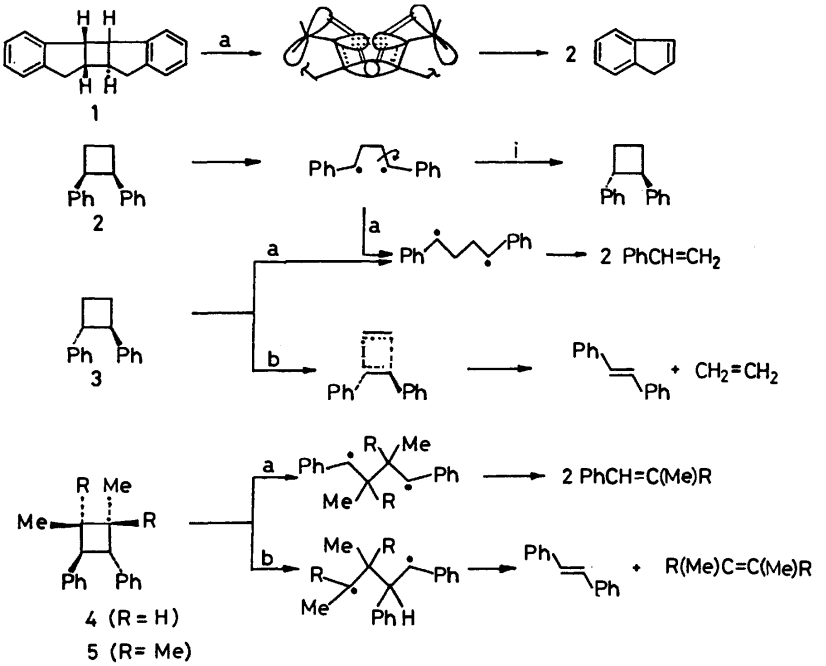
and log (A_{cis}/A_{trans}) of 3.4.

Discussion

Mechanisms. The significant isomerization of **2** to **3** and the losses of stereointegrity in the olefin formation from **4** strongly suggest the intervention of 1,4-biradicals in these reactions. The activation barriers for the symmetric cleavage of **1**—**3** are lower by 94—96 kJ mol^{-1} than that of parent cyclobutane.[6] The differences are similar to the energy gained by the benzylic stabilization of 1,4-butanediyl, 2×54 kJ mol^{-1}. Similarly, $\Delta H_b^{\neq}$ of **4** is a value which is expected for a biradical mechanism for unsymmetric cleavage. Furthermore, the frequency factor for the symmetric cleavage of **3** is very similar to those for the isomerization of *trans*-1,2-divinylcyclobutane which proceeds by way of 1,4-biradicals.[8] The high activation barriers and the large frequency factors for the symmetric cleavage of **4** and, in particular, for both the symmetric and the unsymmetric cleavages of **5** are not accommodated with a concerted mechanism, but with considerable structure changes from the relatively rigid cyclobutanes to very loose transition states.

It is of mechanistic significance to note that log A_a of **1** is unusually low for such a two-bond splitting reaction by way of a discrete 1,4-biradical from a very rigid molecule. Since the transition state should be very tight, as shown by the negative entropy change, the symmetric cleavage of **1** appears to proceed by a concerted or concerted-like mechanism. The rigid tricyclic structure is certainly favorable for efficient orbital overlap between the C-C bonds being broken with minimum molecular motions. By the same token, the unsymmetric cleavage of **3** should be concerted since $\Delta S_b^{\neq}$ at 300 K is −16.2 e.u., still more negative than the entropy change for the concerted Cope rearrangement of *cis*-1,2-divinylcyclobutane to 1,5-cyclooctadiene.[8] Futhermore, $\Delta H_b^{\neq}$ of **3** is much smaller than that of **4** and even smaller than a calculated enthalpy difference (≈163 kJ mol^{-1}) between **3**



Scheme 2.

and 1,2-diphenyl-1,4-butanediyl.[2,23] Effective vibrational motions are probably not inhibited by any steric interactions in **3**, thus realizing the simultaneous cleavage of the C1-C4 and C2-C3 bonds. Scheme 2 summarizes the mechanisms for the thermal reactions of **1**—**5**.

Stereoelectronic Effects on Regioselectivities and Reactivities. The present thermal reactions can not be interpreted in terms of simple steric and electronic effects, e.g., steric assistance of bond breaking by nonbonding interactions between the substituents or benzylic stabilization of 1,4-biradicals. For instance, $\Delta H_a^{\neq}$ of **4** is higher than $\Delta H_b^{\neq}$, even though the 1,4-biradical intermediate for the symmetric cleavage is evidently more stable than that for the unsymmetric one. Another interesting observation is that $\Delta H_a^{\neq}$ of **2** is almost identical with that of **3** irrespective of large steric repulsion between the cis phenyl groups expected for **2**. It appears that both the regioselectivities and the reactivities are controlled by restricted conformations and torsional mobilities of the aryl substituents associated with specific orbital interactions, as demonstrated for photochemical reactions of the cyclobutanes.[1,18]

Figure 3 shows different stable conformations of the aryl substituents, case (i) and case (ii), with respect to each of the ring C-C bonds; the arylated carbon atoms

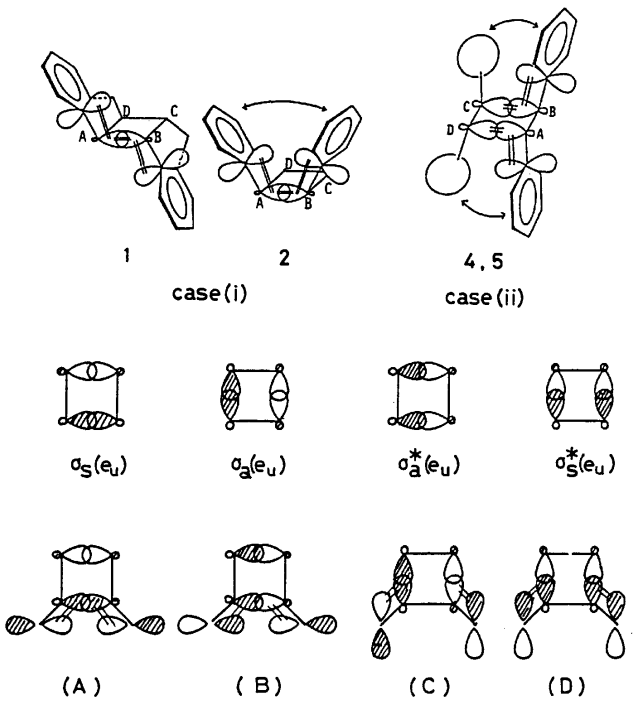


Fig. 3. Top: Different situations for stable rotameric conformations of the aryl rings, case (i) for **1** and **2** and case (ii) for **4** and **5**, associated with specific orbital interactions. Middle: Salem's σ and σ^* orbitals relevant for interactions with the π combinations. Bottom: (A) π_s-σ_s and (B) π_a-σ_a^* interactions occurring in case (i) and (C) π_a-σ_a and (D) π_s-σ_s^* interactions in case (ii)

are abbreviated as C_A and C_B and the others as C_C and C_D for convenience. In order to elucidate implications of orbital interactions in the present reactions, we consider conformation-controlled interactions of Salem's σ and σ^* orbitals of the cyclobutane ring[24] with combinations of the π orbitals, $\pi_s=\pi_A+\pi_B$ and $\pi_a=\pi_A-\pi_B$; subscript s or a denotes the symmetric or antisymmetric character with respect to two-fold rotation or reflection. In case (i), π_s-σ_s (A in Fig. 3) and π_a-σ_a^* (B) interactions can occur to give the highest occupied MO, $\pi_s-\lambda_1\sigma_s$ and a lower bonding MO, $\pi_a+\lambda_1^*\sigma_a^*$, respectively.[25] Similarly, π_a-σ_a (C) and π_s-σ_s^* (D) interactions may occur in case (ii) to give the bonding MO's, $\pi_a-\lambda_2\sigma_a$ and $\pi_s+\lambda_2^*\sigma_s^*$. The π-σ^* interactions should result in mixing of the σ_a^* or σ_s^* character to bring about a weakening of the relevant C-C bonds of the cyclobutane ring, while such bond-weakening effects can not be expected for the π-σ interactions. It is, therefore, reasonable to presume that the π_a-σ_a^* and π_s-σ_s^* interactions are responsible for the symmetric and the unsymmetric cleavages respectively.

It was reported that significant mixing of σ^* character in a bonding MO occurs by through-bond coupling between two π orbitals separated by a C-C bond to bring about unusual elongation of this bond.[26,27] Although the cyclobutane-ring C-C bonds of **1**, **2**, and **5** are not particularly long in common,[28] extensive vibrational and puckering motions of the cyclobutane ring might perturb the σ^* orbitals to allow significant π-σ^* interactions. It should be noted that the π_a-σ_a^* interactions are inherently more effective to through-bond coupling between π_A and π_B than the π_s-σ_s^* interactions. It can, therefore, be predicted that the symmetric cleavage selectively occurs unless there is particular steric inhibition in the orbital interactions. On the other hand, the unsymmetric cleavage may compete with the symmetric one in cases where π_a-σ_a^* interactions are sterically inhibited. This prediction is in good accord with the observed regioselectivities in the reactions of **1**—**5**.

On the basis of these arguments, the reason why $\Delta H_a^{\neq}$ of **3** is almost identical with that of more congested **2** can be easily interpreted by assuming that π_a-σ_a^* interactions are essential in the transition state of the symmetric cleavage of **2** and **3**. Furthermore, the lower-frequency factor for the symmetric cleavage of **3** than that of **2** indicates that a net loss of the rotational motions of the phenyl groups is required for the π_a-σ_a^* interactions in the transition state of **3**, while the orbital interactions are realized with least rotational motions in the case of **2**. Similarly, the thermochemical parameters reveal that the unsymmetric cleavage of **4** proceeds without either significant steric hindrance or large structure changes, being accommodated with the process from stable case (ii) conformations to the π_s-σ_s^* transition state. On the other hand, the relatively large values of $\Delta H_a^{\neq}$ and $\log A_a$ for

the symmetric cleavage of **4** are attributable to steric inhibition of case (i) conformations required for the π_a-σ_a* in transition state. In the case of **5**, the very high activation barriers and the unusually large frequency factors are certainly accommodated with very loose transition states, thus suggesting that the rate-determining step is no longer the orbital interactions but, perhaps, bond breaking of 1,4-biradicals.

Steric Effects on Reactivities of 1,4-Biradicals. Activation enthalpies for cyclization and fragmentation of 1,4-biradicals are usually ca. 30 kJ mol^{-1} in the absence of particular steric inhibition.[2] The cyclization of 1,4-diphenylbutanediyl must suffer a remarkable steric hindrance by the phenyl substituents at the radical centers to require a high activation barrier. Calculations according to the additivity of bond and group properties[2,23] allow us to estimate the heat of formation of **3** or 1,4-diphenylbutanediyl (**3**-BR$_a$) which is 245.8 kJ mol^{-1} or 353.6 kJ mol^{-1} each. The activation enthalpy for the cyclization of **3**-BR$_a$ is, therefore, calculated from the estimated values of the heat of formation and $\Delta H_a^{\neq}$ to be ca. 58 kJ mol^{-1}, a relatively large value in accord with the prediction of remarkable steric hindrance. Moreover, the relatively low value of log A_i of **2** is comparable to that for the isomerization of *cis*-1,2-diphenylcyclopropane.[22] Consequently, the significant isomerization of **2** to **3** is not attributable to the cyclization of a thermally equilibrated 1,4-biradical but, rather, to torsion about PhC-C of a non-streched 1,4-biradical followed by efficient bonding with least motion. On the other hand, the biradical fragmentation of **2** or **3** to styrene appears to proceed with a lower activation barrier since an orbital overlap between each of the radical centers and the C$_C$-C$_D$ bond is easily achieved without steric inhibition.

In the cases of **4** and **5**, however, steric hindrance should be significant for both the ring closure and the fragmentation of 1,4-biradicals because of the substitution of the methyl or the phenyl group at each carbon, as shown in Fig. 4. Extensive gauche interactions in the biradical (**4**-BR$_a$) for the symmetric cleavage of **4** certainly destabilize the biradical to contribute, at least in part, to the high value of $\Delta H_a^{\neq}$, while such steric interactions are less in **4**-BR$_b$, the biradical for the unsymmetric cleavage. Provided that the biradical fragmentation requires orbital overlap between each of the radical centers and the C-C bond being broken,[2,29] the transition state for the *cis*-β-methylstyrene from **4**-BR$_a$ should require much greater vibrational motions than that for the trans-olefin formation. This is in line with the observed difference in either the activation enthalpy or the frequency factor for the formation of *cis*- and *trans*-β-methylstyrene. The rotation of the massive PhCH group is perhaps rate determining. On the other hand, the temperature-independent cis-trans ratio in the 2-butene formation from **4** implies that the rate-determining step is the initial cleavage of C$_A$-C$_D$ (C$_B$-C$_C$) of the cyclobutane ring, since the rotation of the light MeCH group of **4**-BR$_b$ should be very rapid.

In particular, the biradicals of **5** (**5**-BR$_a$ and **5**-BR$_b$) are clearly very crowded and perhaps destabilized by large nonbonding interactions between the substituents.[30] The radical centers of **5**-BR$_a$ suffer large steric repulsion with the bulky substituents at quarter-

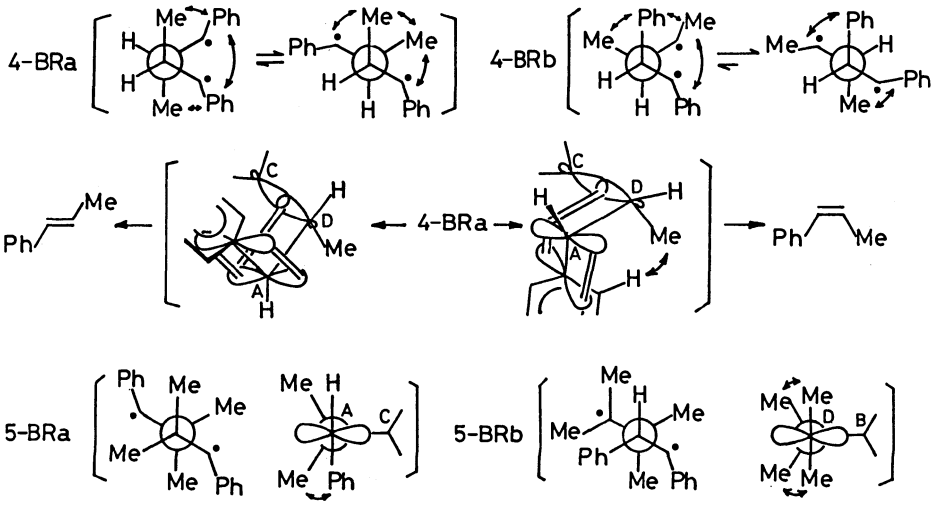

Fig. 4. Top: Newman projection formulas of **4**-BR$_a$ and **4**-BR$_b$ showing that the former is sterically more crowded than the latter. Middle: Perspective illustration of hypothetical transition states for the biradical fragmentation of **4**-BR$_a$ to *cis*- and *trans*-β-methylstyrene. Bottom: Newman projection formulas of **5**-BR$_a$ and **5**-BR$_b$ showing that either of the biradicals is sterically very crowded and that the radical centers are sterically hindered either in taking a planar conformation or in overlapping between the p orbitals and the C-C σ orbitals being broken.

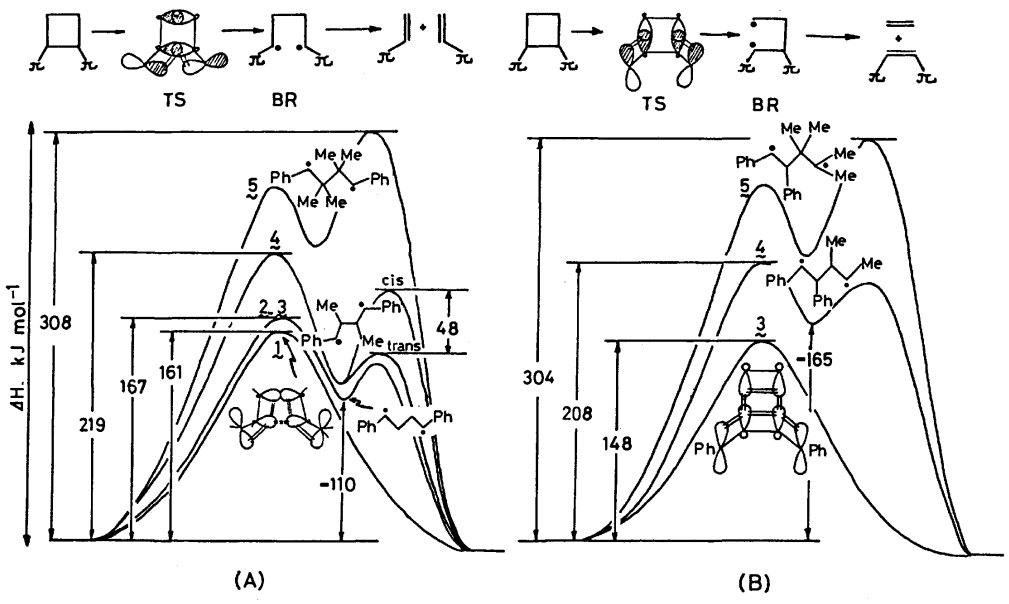

Fig. 5. Schematic potential surface diagrams for (A) the symmetric cleavage of **1**—**5** and (B) the unsymmetric cleavage of **3**—**5**. The numerals are enthalpy differences in kJ mol^{-1}.

nary carbon to inhibit the phenyl rings from taking the coplaner conformations required for benzylic stabilization. Similarly, large nonbonding interactions might destabilize **5**-BR$_b$ by a possible distortion of the Me_2C radical center from a planar conformation. More importantly, such large nonbonding interactions again impede the maximum overlap between the p orbitals of the radical centers and the C-C σ orbitals being broken. Such large steric effects on the destabilization of biradicals as well as on the biradical fragmentation should contribute to the very high values of $\Delta H_a^{\neq}$ and $\Delta H_b^{\neq}$. It is therefore suggested that the biradical fragmentation is rate determining in either the symmetric or the unsymmetric cleavage of **5**. Since the frequency factors are unusually large, extensive vibrational and rocking motions of C-Me are probably important in relieving large steric hindrance in the transition state.

Conclusion

Figure 5 shows schematic potential surface diagrams for the thermal reactions of the diarylcyclobutanes as a summary. The symmetric cleavage of **1** and the unsymmetric cleavage of **3** proceed by a concerted or concerted-like mechanism because of the small steric perturbation in realizing a "pericyclic" transition state, whereas 1,4-biradicals are involved in the other reactions. The net regiochemistry and the reactivities are controlled by both stable conformations and rotational mobilities of the aryl substituents associated with the π_a-σ_a* and π_s-σ_s* interactions occurring by thermal activation. Since the σ_a* character is more efficiently mixed in a bonding MO by through-bond coupling than the σ_s* character, the specific or selective symmetric cleavage of **1**—**3** should arise from the π_a-σ_a* interactions which are allowed without steric inhibition. In the cases of **4** and **5**, where the π_s-σ_s* interactions are sterically favorable, unsymmetric cleavage can occur competitively with the symmetric type. In conclusion, the steric-controlled orbital interactions are essential in the transition states of both the symmetric and the unsymmetric cleavage of the diarylcyclobutanes. For the reaction of **5**, however, the rate-determining step is the biradical fragmentation since nonbonding interactions are very large to destabilize both the biradicals and the transition states of the biradical fragmentation.

Photochemical Reactions of Aromatic Compounds. XLVI.[1] Stereochemical Reaction Courses in the Photolytic Ring-Cleavage Reactions of Diarylcyclobutanes: Implications of Conformation-Controlled Orbital Interactions in the Excited-State Chemistry

Chyongjin PAC,* Kazuyoshi GO-AN, and Shozo YANAGIDA
Department of Chemical Process Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received November 14, 1988)

The photolyses of *cis-transoid-cis*-cyclobutadiindene (**1**), *cis*-2-phenylcyclobut[*a*]indene (**2**), *cis*-1,2-diphenylcyclobutane (**3**), the trans isomer (**4**), and its dimethyl (**5**) and tetramethyl (**6**) derivatives have been investigated to explore stereoelectronic factors controlling the excited-state reaction courses for the ring cleavages. The symmetric ring cleavage occurs regiospecifically in the cases of **1**—**3** and with 98% specificity in the case of **4**. The photolysis of **5** results in both the symmetric and the asymmetric cleavages in a ca. 1 : 3 ratio accompanied by substantial losses of stereointegrity in the olefin formation, and the regiospecific asymmetric cleavage occurs in the case of sterically more congested **6**. The ring-cleavage efficiencies systematically decrease in the order **1**>**2**>**3**>**4**>**5**>**6** and reveal negative temperature dependences, particularly in the cases of **1**, **5**, and **6**. The features of the reactions are in parallel with stable conformations and conformational mobilities of the aryl groups associated with different π-σ orbital interactions, while the spectroscopic properties of the cyclobutanes are essentially identical with those of benzene chromophores with little electronic perturbation. The photolytic ring-cleavage reactions are discussed in terms of crossing from the localized $^1\pi,\pi^*$ state to a σ^* hypersurface, in which conformation-controlled orbital interactions play important roles. The final products are formed via a pericyclic minimum which might be biradicaloid in nature.

Splitting of the cyclobutane rings has been providing an excellent probe for mechanistic and stereochemical studies[2-4] as well as a typical prototype for theoretical understanding of chemical reaction courses[5,6] because of simplicity of the net chemistry. Theories predict that [2+2] cycloreversions of cyclobutanes with stereoretention are forbidden in the ground state but are allowed in the σ,σ^* state of the ring framework.[5,6] Extensive thermochemical and stereochemical data of thermal ring-splitting reactions of parent cyclobutane and alkyl derivatives are indeed accomodated with stepwise mechanisms involving 1,4-biradicals.[3,4] By contrast, little has been known on mechanistic and stereochemical aspects in the photochemistry of simple cyclobutanes bearing no particular chromophore, since no suitable methods are available to achieve the selective population of the ring σ,σ^* state.[7]

Photochemical studies have therefore been carried out with chromophore-substituted cyclobutanes capable of being photoexcited by usual light sources. It was found that a few π-chromophore substituted cyclobutanes undergo the photolytic cycloreversions with complete stereoretention[8] or with only a minor loss of stereointegrity.[9,10] Another interesting observation of stereochemical significance is that the photolysis of π-substituted cyclobutanes results in the regiospecific or regioselective cleavage of a ring C-C bond in cases where a π chromophore and a substituent vicinally attach to each end of this bond in the *cis configuration*. This is called "cis effect".[11]

A crucial question should emerge as to why the photo-excitation of a π substituent can effect the specific or selective cleavage of the ring σ framework that should proceed by way of a reaction hypersurface correlating with the ring σ,σ^* state. Presumably, energy migration might occur from the photoexcited π substituent to a specific C-C bond of the cyclobutane ring to bring about a surface crossing to the σ,σ^* reaction hypersurface. However, there have been presented no convincing experimental data to explicate possible mechanisms and stereoelectronic requirements for such a surface crossing. Another important question is whether or not the photolytic ring cleavage of π-substituted cyclobutanes generally occurs with stereoretention. Systematic studies are certainly required to explore controlling factors in stereochemical reaction courses of photolytic ring-cleavage reactions of π-substituted cyclobutanes. The present paper deals with stereochemical and mechanistic details of the photolytic ring-cleavage reactions of diarylcyclobutanes **1**—**6**. We have found that the cyclobutanes reveal unique dependences of both the fluorescence bahavior and the reaction features on either stable conformations of the aryl substituents or temperature.

Results

Spectroscopic Properties. Table 1 lists the absorption and fluorescence spectra in cyclohexane and the fluorescence quantum yields and lifetimes in acetonitrile at 20 °C together with the relevant quantities of toluene and indane used as reference compounds. The fluorescence spectra of **1**—**4** were taken by means of a photon-counting method, since the

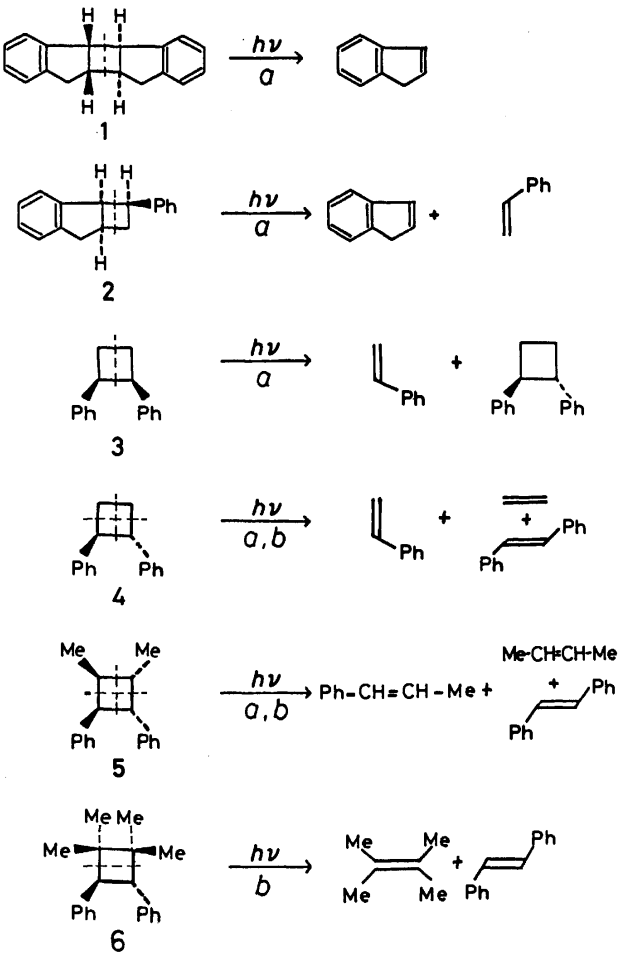
a) Measured for degassed acetonitrile solution. b) In EPA (5:5:2 diethyl ether-isopentane-ethanol mixture) glasses. The lifetimes of **1**, **3**, and **4** in EPA glasses at 77 K are 10 ns, 9 ns, and 9 ns, respectively, but are presumed to be < 1 ns at ≥ -20 °C; see text.

fluorescence efficiencies are very low and since usual measurements resulted in substantial contamination of the fluorescence from indene or styrene formed by the photolysis during the measurements. The absorption and fluorescence spectra of the cyclobutanes are essentially identical with those of indane or toluene, while the fluorescence quantum yields largely vary from $<10^{-2}$ for **1**—**3** to 0.14 for **6**, a value identical with that of toluene.

The fluorescence lifetimes were measured by means of single photon counting after deconvolution. In the cases of **1**—**4**, however, we obtained no reliable lifetime data at room temperature and even at −20 °C, probably because of very low emission efficiencies and very short lifetimes. At 77 K, the lifetimes could be determined to be 9—10 ns but are substantially shorter than those of **5**, **6**, and toluene (35 ns) at this temperature. Table 2 shows the fluorescence lifetimes of **5**, **6**, and cumene at various temperatures, which commonly decrease with the increase of temperature from −20 °C.

Photolysis. Irradiation of deaerated acetonitrile or cyclohexane solution of **1**—**6** at 254 nm gave exclusively the olefins formed by the symmetric (*a*) and/or



Scheme 1.

the asymmetric (*b*) ring cleavages (Scheme 1); the isomerization of **3** to **4** occurred in a low efficiency. Material balances were well over 95% at <5% conversions and no other product was detected at all. Table 3 lists the reaction quantum yields (ϕ_a and ϕ_b) and the $a:b$ ratios at 20 °C. It was found that the reaction efficiencies vary with reaction temperature from 2 °C to 70 °C, particularly in the cases of **1**, **5**, and **6**, as shown in Table 4. The $a:b$ ratios in the photolysis

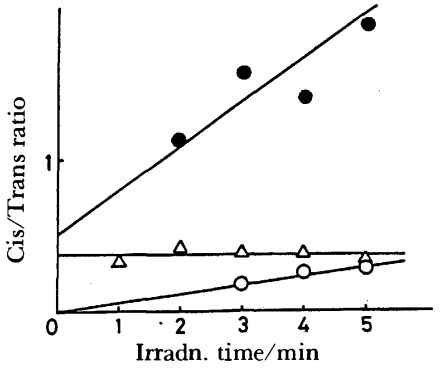

Fig. 1. Plots of cis-trans ratio vs. irradiation time for the formation of 1-phenylpropene (—●—), stilbene (—○—), and 2-butene (—△—) in the photolysis of **5** in acetonitrile at 20 °C; irradiation at 254 nm; [**5**]=0.01 M.

of **5** increase with an increase of temperature to reach 1:1 at 70 °C. In the case of **4**, the asymmetric cleavage is too minor to allow reliable determination of temperature-dependent $a:b$ ratios.

The olefin products from the photolysis of **5** are mixtures of the cis and trans isomers. The cis/trans ratios were determined at various irradiation times under keeping conversions below 3%. As shown in Fig. 1, the isomer ratios in formation of stilbene and 1-phenylpropene increase with irradiation time, probably due to secondary photoisomerization of the primary products. The values obtained by extrapolation of the plots to zero irradiation time should give the primary cis:trans ratios which are 0:100 in the stilbene formation and ca. 2:1 in the 1-phenylpropene formation. On the other hand, 2-butene was formed in a ca. 2:5 cis-trans ratio independently of irradiation time. Similarly *trans*-stilbene was confirmed to be the primary photoproduct from **6**.

Discussion

Mechanism. The isomerization of **3** to **4** and the loss of stereointegrity in the olefin formation from **5** strongly suggest that the photolytic reactions of **3** and **5** proceed by way of a state or an intermediate susceptible to bond rotation. The acetone-photosensitized reaction of **3** gives styrene and **4** in respective quantum yields of 0.15 and 0.04[12] and the styrene: **4** ratio in the thermal reaction of **3** is 2.3:1 at 300 K.[13] Calculations using these values and the data in Table 3 indicate that the participation of either the triplet state of **3** or thermally equilibrated 1,4-diphenylbutane-1,4-diyl should be very minor, 15% or less the total reaction at best, provided that all the formation of **4** would arise only from triplet **3** or from the 1,4-biradical. Similarly, the involvement of a 1,4-biradical in the photolysis of **5** should be negligible since the cis:trans ratio in the 1-phenylpropene by the thermal reaction of **5** is 1:9 at 550 K and is calculated to be ca. 0:100 at 300 K.[13] Furthermore, it was reported that either *trans*-2-heptene or dimethyl maleate does not affect the photolytic reaction of **3**.[12b] We also confirmed that air saturation of solution exerts no effect on the photoreactions of **1**—**4** at all and slightly quenches those of **5** and **6**, probably due to oxygen quenching of the excited singlet state of the cyclobutanes.

The above arguments suggest that the photolytic ring-cleavage reactions of the cyclobutanes are not concerted but involve a reactive state responsible for the product formation, presumably a biradicaloid pericyclic minimum,[6] which should be different from either the triplet state of the cyclobutanes or discrete 1,4-biradicals; this state is denoted as "X" for convenience. Since the absorption and fluorescence spectra of the cyclobutanes are essentially identical with those of alkylbenzenes, the spectroscopic excited state is the $^1\pi,\pi^*$ state of the aryl substituent in which little electronic perturbation by the cyclobutane ring occurs. The basic mechanistic pathways of the photoreactions are shown in Eqs. 1—6 where Eq. 3 involves temperature-independent photophysical processes (e.g., internal conversion and intersystem crossing) and an activated nonradiative process. The reaction quan-

tum yield (ϕ_r) is represented by Eq. 7 where α is the partition coefficient for the product formation from X.

$$M \xrightarrow{h\nu} {}^1M^*({}^1\pi,\pi^*) \quad (1)$$

$${}^1M^* \xrightarrow{k_F} M + h\nu_F \quad (2)$$

$${}^1M^* \xrightarrow{k_d} M \quad (3)$$

$${}^1M^* \xrightarrow{k_r} X \quad (4)$$

$$X \xrightarrow{\alpha} \text{product} \quad (5)$$

$$X \xrightarrow{1-\alpha} M \quad (6)$$

$$\phi_r = \alpha k_r/(k_F + k_d + k_r) = \alpha k_r \tau_s \quad (7)$$

Analysis of Temperature Dependence. It is known that fluorescence lifetimes of benzene and alkylbenzenes decrease with an increase of temperature as the consequence arising from the involvement of an activated pathway in the nonradiative decay.[14] This pathway is attributed to a surface crossing from the excited singlet state to an isomer surface, from which the starting ground-state arene is mostly regenerated along with very inefficient formation of an isomer such as fulvene. At any rate this mechanism should be responsible for the temperature dependence of fluorescence lifetimes of **5** and **6** since k_r appears to be smaller by an order of magnitude than τ_s^{-1}, as calculated by Eq. 7. The temperature dependence can therefore be analyzed by the use of Eq. 8 in which k_d^0 represents the rate constant for overall temperature-independent photophysical processes.

$$1/\tau_s = k_d^0 + A_d \exp(-\Delta H_d^{\neq}/RT) \quad (8)$$

Figure 2 shows best-fit plots of $\log(\tau_s^{-1} - k_d^0)$ vs. $1/T$ for cumene, **5**, and **6**, from which A_d and $\Delta H_d^{\neq}$ are

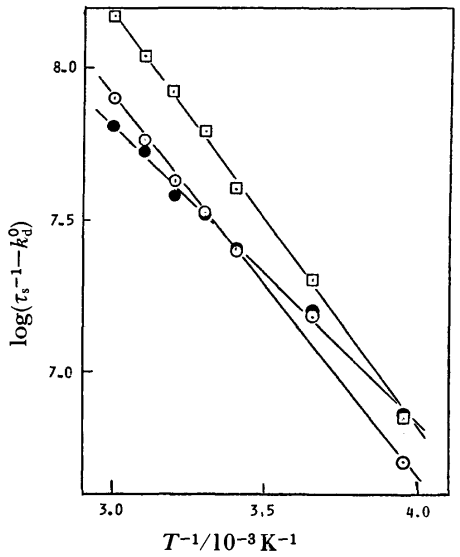

Fig. 2. Best-fit plots of $\log(\tau_s^{-1} - k_d^0)$ vs. T^{-1} for **5** (—●—), **6** (—○—), and cumene (—□—); data are from Table 2.

obtained. Table 5 lists the values of k_d^0, A_d, and $\Delta H_d^{\neq}$ together with the reported quantities for the cis-trans-cis and all-trans isomers of tetraphenylcyclobutane[15] for comparison. These values fall in those reported for benzene and toluene.[14] It is therefore evident that the spectroscopic excited singlet state of **5** and **6** is just the ${}^1\pi,\pi^*$ state of an isolated phenyl substituent not only in the electronic properties but also in the dynamic decay pathways, Eqs. 2 and 3. This appears to be again true for **1**—**4**, since the electronic spectra reveal no perturbation of the ${}^1\pi,\pi^*$ state of the aryl substituent; the very low emission efficiencies should be due to large k_r.

Analysis of the temperature dependences of quantum yield might provide a clue to explore the dynamic reaction pathways from the ${}^1\pi,\pi^*$ state. It can be presumed that no activated pathways participate after the decay from X to the ground-state surface, since a 1,4-biradical minimum is unlikely to be involved in the ring-cleavage reactions as already mentioned. Calculations according to Eq. 7 using the observed lifetimes and quantum yields give the αk_r values at 2—70 °C for **5** and **6**; the lifetimes at 70 °C were estimated from the plots in Fig. 2. Plots of $\log(\alpha k_r)$ vs. $1/T$ give positive slopes for the asymmetric clevage of **5** and for the ring cleavage of **6** at ≥50 °C, whereas the symmet-

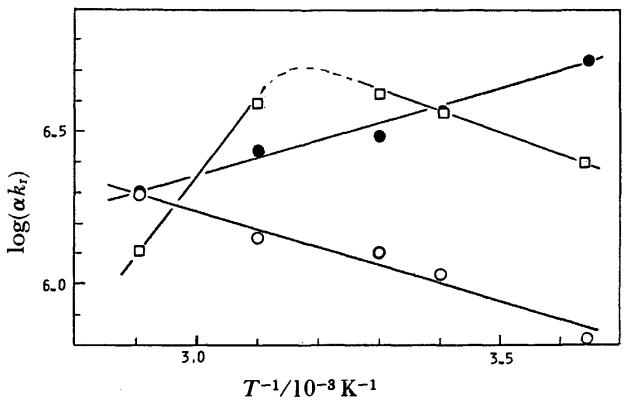

Fig. 3. Plots of $\log(\alpha k_r)$ vs. T^{-1} for the symmetric (—○—) and asymmetric (—●—) cleavages of **5** and for the asymmetric cleavage of **6** (—□—); data are from Tables 2 and 4.

ric cleavage of **5** and the ring cleavage of **6** at lower temperatures reveal plots of usual negative slopes, as shown in Fig. 3.

The negative temperature dependences might arise from α or from k_r as the consequence of increasing regeneration of the starting cyclobutane with the increase of temperature through an activated pathway along the excited-state potential surface. We can assume two possibilities, i.e., (1) thermal regeneration of $^1M^*$ from another intermediate state "Y" involved prior to X in the mechanistic sequence and (2) pseudo equilibrium between an early pericyclic minimum X_1 and another more stable one X_2 which decay to the starting cyclobutane and to the olefin products respectively. In the latter case, X_1 is thermally repopulated from X_2 in which losses of stereo-integrity should occur. It can therefore be presumed that the isomerization of **5** might increasingly occur with the increase of temperature. In order to confirm possible formation of an isomer of **5** (e.g., *r*-1,*c*-2-dimethyl-*c*-3,*t*-4-diphenylcyclobutane), we extensively carried out VPC analyses using different columns for photolysates of **5** irradiated at 60 °C and ^1H NMR analyses for cyclobutane fractions obtained by column chromatography of the photolysates. However, no indication was obtained for the formation of any isomer of **5**.

Accordingly, we choose the former mechanism to analyze the observed temperature dependences under the assumption that α is independent of temperature, though there is no direct evidence to discard the other mechanism. On the basis of this assumption, Eq. 4 is replaced by Eqs. 9 and 10, and k_r is represented by Eq. 11. The positive slopes of the plots in Fig. 3 imply that $k_{-r}>k_c$, thus giving lower limits of the difference between the enthalpy change of Eq. 9

$$^1M^* \underset{k_{-r}}{\overset{k_r'}{\rightleftarrows}} Y \qquad (9)$$

$$Y \xrightarrow{k_c} X \qquad (10)$$

$$k_r = k_r'[k_c/(k_{-r}+k_c)] = k_c[k_r'/(k_{-r}+k_c)] \qquad (11)$$

and the activation enthalpy of Eq. 10, $(\Delta H_{-r}^{\neq} - \Delta H_r^{\neq}) - \Delta H_c^{\neq}$, which are 3±1 kcal mol^{-1} (1 kcal=4.184 kJ) for the asymmetric cleavage of **5** and roughly 10—12 kcal mol^{-1} for the ring cleavage of **6**. On the other hand, the plots of negative slope in Fig. 3 indicate that $(\Delta H_{-r}^{\neq} - \Delta H_r^{\neq}) \gg \Delta H_c^{\neq}$ or $\Delta H_c^{\neq}=0$, giving $\Delta H_r^{\neq}$ and the preexponential factor A_r for the symmetric cleavage of **5** and lower limits of $\Delta H_r^{\neq}$ and A_r for the ring cleavage of **6**, which are listed in Table 6 together with the relevant values reported for the photolysis of tetraphenylcyclobutane.[15]

In the cases of **1—4**, it is reasonable to presume that $k_r \geq 5\times10^8$ s$^{-1} \gg (k_F+k_d)$. In this regard, it should be noted that the fluorescence lifetimes of **1**, **3**, and **4** are 9—10 ns at 77 K, still much shorter than those of **5** and **6** which are similar to that of toluene. Moreover, we confirmed that irradiation of **1—4** in EPA glasses at 77 K gives the corresponding olefins[11] while little photolytic ring cleavage of **5** and **6** occurs under similar conditions. It is therefore implied that $\Delta H_r^{\neq}<3$ kcal mol^{-1} and $A_r>10^{11}$ s^{-1} for the symmetric cleavage of **1—4**. Since $k_r \gg k_d$, the negative temperature dependence of ϕ_r in the photolysis of **1** can be analyzed according to Eq. 12. A best-fit plot of $\log[(\alpha-\phi_r)/\phi_r]$ vs. $1/T$ obtains by assuming α=0.55 as shown in Fig. 4, thus giving the value of $(\Delta H_{-r}^{\neq} - \Delta H_c^{\neq})$ which is 7±1 kcal mol^{-1}.

Stereochemical Reaction Courses Associated with π-σ Orbital Interactions. We previously reported that through-bond coupling between vicinal π electron systems across the cyclobutane-ring σ framework plays essential roles in ring-splitting reactions of diarylcyclobutanes by redox photosensitization,[16] by exciplex photosensitization,[17] by electron-transfer photosensitization,[18] and by γ radiolysis.[19] Although an essential mechanistic event in those reactions is commonly the population of a positive charge by the complete or partial removal of an electron, it can be presumed that the regiochemistry and reactivities in the present photolytic reactions of the cyclobutanes are controlled by different π-σ orbital interactions.

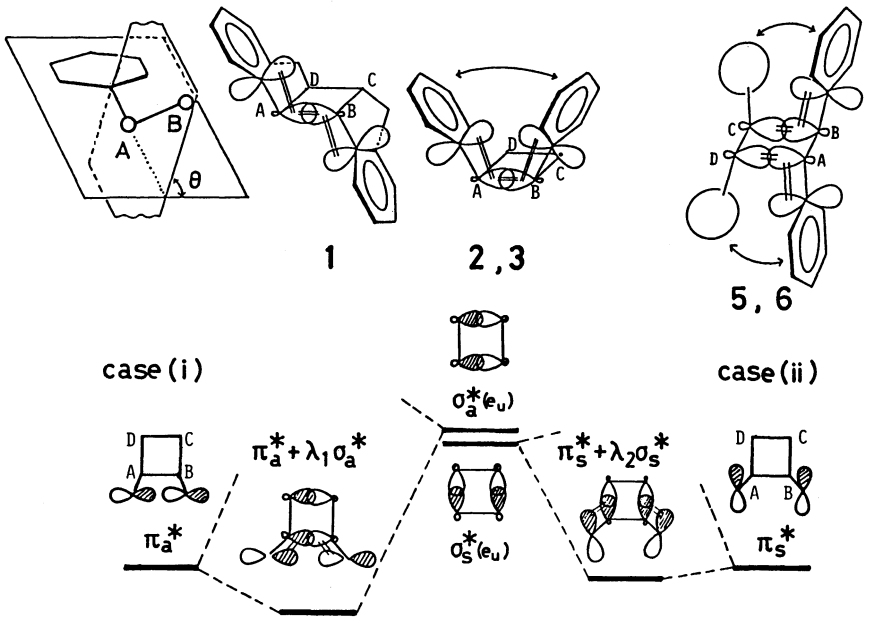

Fig. 5. Top: Stable conformations of the aryl substituents associated with favorable orbital interactions; $\theta \approx 90°$ for case (i) and $\theta \approx 0°$ for case (ii). Bottom: Schematic representation of π_a^*-σ_a^* and π_s^*-σ_s^* interactions.

Figure 5 shows different conformational situations of the aryl ring for π-σ orbital interactions (case (i) and case (ii)) together with the notation of the carbon atoms of the cyclobutane ring.

In case (i) where torsional angles (θ) between the aryl ring and the ipso C-C_A-C_B plane are ca.90°, the π orbitals can maximally overlap with the C_A-C_B σ orbitals. Such conformational situations are indeed realized in **1** by the rigid tricyclic structure as well as in **2** and **3** by steric repulsion between the bulky vicinal aryl substituents in the cis configuration, as demonstrated by the X-ray crystallographic analysis[20] as well as by molecular models. It is evident that conformational rigidity decreases in the order of **1**>**2**>**3**. In case (ii) where $\theta \approx 0°$, the π orbitals can not overlap with the orthogonal C_A-C_B σ orbitals but favorably with the C_A-C_D and C_B-C_C σ orbitals. The X-ray crystallographic analysis of **6** and *r*-1,*t*-2-bis(hydroxymethyl)-*t*-3,*c*-4-diphenylcyclobutane, an analogue of **5**, demonstrates that $\theta \leq 11.3°$ due to nonbonding interactions between the cis substituents.[20] It is therefore evident that conformations of **5** and **6** fall in case (ii) though **5** is more mobile than the very rigid cyclobutane, **6**. On the other hand **4** can take either case (i) or case (ii) conformations. These conformational situations of the cyclobutanes associated with orbital interactions are well in parallel with the observed regiochemistry in the photolytic ring-cleavage reactions. However, effects of orbital interactions on the present photochemistry should be dynamic in nature since the spectroscopic properties of the cyclobutanes are essentially identical with those of alkylbenzenes with little electronic perturbation. It can be presumed that π-σ orbital interactions play important roles in the mechanistic sequence, $^1M^* \rightarrow Y \rightarrow X$.

For qualitative considerations on roles of orbital interactions in the stereochemical reaction courses, we use Salem's σ_s^* and σ_a^* orbitals of cyclobutane[21] and the π^* combinations, $\pi_s^* \equiv (\pi_A^*, \pi_B) + (\pi_A, \pi_B^*)$ and $\pi_a^* \equiv (\pi_A^*, \pi_B) - (\pi_A, \pi_B^*)$; subscript s or a represents the symmetric or antisymmetric character with respect to two-fold rotation or reflection. Orbital interactions can occur between π_a^* and σ_a^* or between π_s^* and σ_s^* to give a half-filled molecular orbital, $\pi_a^*+\lambda_1\sigma_a^*$ or $\pi_s^*+\lambda_2\sigma_s^*$ each,[22] as shown in Fig. 5. It should be however noted that the π_a^*-σ_a^* interactions lead to through-bond coupling between the vicinal π electron systems without large molecular distortions to stabilize $\pi_a^*+\lambda_1\sigma_a^*$, i.e., $\lambda_1 > 0$. In other words the π_a^*-σ_a^* interactions can efficiently occur along the reaction coordinate to bring about delocalization of the photoexcitation of $^1M^*$ over the π_A-σ_A-σ_B-π_B orbital array involved in through-bond coupling, thus facilitating the crossing from $^1M^*$ to a σ,σ^* reaction hypersurface for the symmetric cleavage. On the other hand the π_s^*-σ_s^* interactions are ineffective to through-bond coupling because of little overlap between the C_A-C_D and the C_B-C_C σ orbitals in σ_s^*, i.e., $\lambda_2 \approx 0$ without large structure changes. It can therefore be predicted that the crossing from $^1M^*$ to a reaction hypersurface for the asymmetric cleavage is slow, since energy migration from the photoexcited aryl group to the cyclobutane-ring σ framework through the $^*\pi_s$-σ_s^* interactions should be inefficient.

The above molecular-orbital arguments provide a

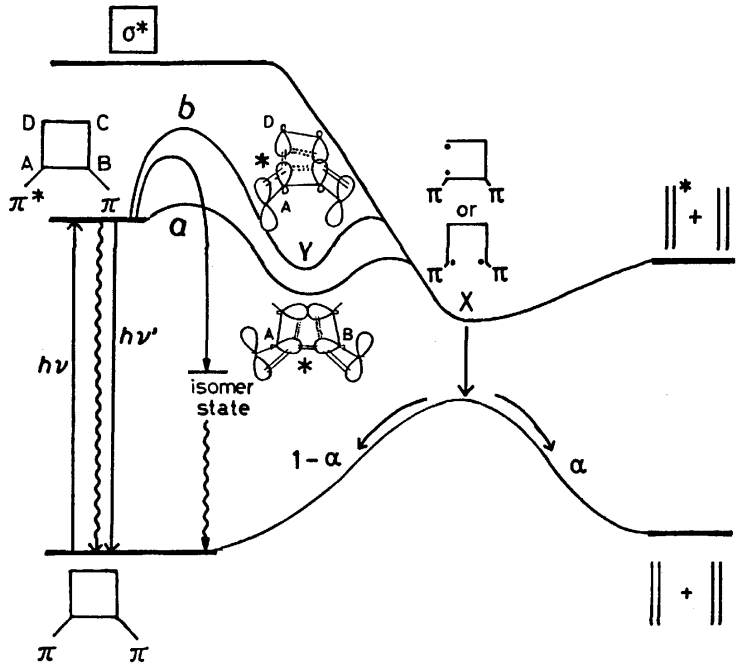

Fig. 6. Schematic reaction surfaces for the photolytic ring cleavages of diarylcyclobutanes in *a* and *b* directions involving the sequential pathways $^1M^*$ (localized $^1\pi,\pi^*$ state)→Y(π^*-σ^* state)→σ,σ^* reaction hypersurface→X(biradicaloid state)→product.

rational to interpret the conformation-controlled regiochemistry and the different reactivities of the symmetric and asymmetric cleavages. In the cases of **1**—**3** where only the π_a^*-σ_a^* interactions are conformationally allowed, the low activation barriers and the large A_r values for the $^1M^*$→Y process suggest that the σ_a^* character should be significantly mixed in the transition state without large structure changes. On the other hand, the slow ring cleavage of **6** in *b* direction suggests that mixing of the σ_s^* character should be inefficient even though only the π_s^*-σ_s^* interactions are conformationally allowed. Since $\Delta H_r^{\neq}>3$ kcal mol^{-1} and $A_r \ll 10^{11}$ s^{-1} for **6**, significant mixing of the σ_s^* character would require highly restricted molecular motions in the transition state of the $^1M^*$→Y process, e.g., elongation of the C_A-C_D and C_B-C_C bonds and concurrent shortening of the C_A-C_B bond with keeping $\theta \approx 0°$. In the cases of **4** and **5**, therefore, more effective mixing of the σ_a^* character may allow the regioselective cleavage of **4** in *a* direction irrespective of mobile conformations and may counterbalance the conformational disadvantage of the π_a^*-σ_a^* interactions in **5**. The low A_r value for the symmetric cleavage of **5** indeed demonstrates that vibrational and rotational motions are extremely restricted in the transition state. Although details of Y still remain unknown, stabilization by the π_a^*-σ_a^* or π_s^*-σ_s^* orbital interactions might be important in Y where structures of the cyclobutanes would be different from those in $^1M^*$. In this regard it should be noted that $\Delta H_r^{\neq}<\Delta H_c^{\neq}$ for **1** and **6** but $\Delta H_r^{\neq} \approx \Delta H_c^{\neq}$ for **3** and **4**. Presumably the rigid structures of **1** and **6** might freeze maximum orbital overlaps to stabilize Y to substantial degrees. On the other hand conformational mobilities of **3** and **4** would be unfavorable for stabilization of Y since the orbital interactions can slip out with small molecular motions, e.g., rotational and rocking motions of the phenyl rings and puckering motions of the cyclobutane ring. At any rate significant mixing of the σ_a^* or σ_s^* character in Y is certainly favorable for the crossing from Y to a σ,σ^* reaction hypersurface for a molecule to reach a biradicaloid pericyclic minimum X,[6] in which the C_A-C_B or the C_A-C_D (or C_B-C_C) bond is elongated enough for substantial bond rotation to occur.

Conclusion

Figure 6 shows schematic reaction surfaces for the photolytic ring cleavages of **1**—**6** as a summary. The mechanism involves the sequential pathways, $^1M^*$ (localized $^1\pi,\pi^*$ state) → Y (π_a^*-σ_a^* or π_s^*-σ_s^* state) → σ,σ^* reaction hypersurface → X (biradicaloid state) → product. The net regiochemistry is determined in the $^1M^*$ → Y process depending on conformations of the aryl substituents associated with the orbital interactions. Since the σ_a^* character is effectively mixed by through-bond interaction without large structure changes, the $^1M^*$→Y→X processes can efficiently occur in cases where the π_a^*-σ_a^* interactions are con-

formationally allowed. On the other hand, the asymmetric cleavage is inherently slow as the consequence of inefficient mixing of the σ_s* character. In other words the specific or selective asymmetric ring cleavage can occur only in cases where the aryl rings are sterically inhibited to take case (i) conformations. In short the "cis effect" should be the consequence arising from steric control of the different orbital interactions.

The present investigation may provide a general concept for the understanding of both regioselectivities and reactivities in photolytic bond-cleavage reactions of various π-substituted cyclobutanes[11,23-25] and, perhaps, of diarylethane-type compounds. Synthetic implications of the present investigation may be given by elegant preparation of bullvalene,[26] pentalene derivatives,[27] cyclobutadiene,[28] and azetidinone[29] from photolyses of rigid polycyclic cyclobutanes with π chromophores, since the regiochemistry is that expected from specific orbital interactions imposed by the rigid structures.

Experimental

Ultraviolet absorption spectra were recorded on a Hitachi 220-A UV spectrophotometer and fluorescence measurements were performed on a Hitachi 850 spectrofluorometer after correction for the spectral response of the instrument. Fluorescence lifetimes were determined on a Horiba NAES-1100 time-resolved spectrofluorometer. Vapor-phase chromatographic analyses were performed on a Shimadzu GC-7A gas chromatograph using a 2-m column of 10% PEG 20M on Shimalite NAW-101, a 3-m column of 2% OV 17 on Chromosorb W AW-DMCS, and a 5-m column of 25% ODPN on Shimalite NAW-101.

Materials. Spectrograde cyclohexane (Wako Pure Chemicals) was used after distillation. Reagent-grade acetonitrile was refluxed over P_2O_5 and then distilled. This procedure was repeated three times, and then the acetonitrile was distilled from CaH_2 prior to use. The cyclobutanes were prepared according to the literature methods; *cis-transoid-cis*-cyclobuta[1,2-*a*;4,3-*a'*]diindene (**1**),[30] *endo*-2-phenyl-2,2a,7,7a-tetrahydro-1*H*-cyclobut[*a*]indene (**2**),[16] *cis*-1,2-diphenylcyclobutane (**3**),[31] *trans*-1,2-diphenylcyclobutane (**4**),[31] *r*-1,*t*-2-dimethyl-*t*-3,*c*-4-diphenylcyclobutane (**5**),[17] and 1,1,2,2-tetramethyl-*trans*-3,4-diphenylcyclobutane (**6**).[32] Purification was achieved by repeated recrystallization from methanol for **1**, **2**, and **3** or from hexane for **6**, whereas **4** and **5** were distilled in vacuo. Vapor-phase chromatographic analyses of the purified cyclobutanes revealed that **4** includes the cis isomer in ca. 5% whereas the other cyclobutanes are virtually pure (> 99%).

Photolysis. A cyclohexane or acetonitrile solution of **1**—**6** (0.01 mol dm^{-3}) in a quartz cuvette was flushed with a gentle stream of Ar, placed in a temperature-regulated water bath, and then irradiated with an Eikosha POL-100 low-pressure mercury arc lamp through a Toshiba UV-D 25 glass filter which cuts off the 185-nm emission from the light source. The progress of the photoreaction was followed by vapor-phase chromatography. A potassium trioxalatoferrate(III) actinometer was used for the determination of quantum yields. It was confirmed that the observed quantum yields for the photoreactions of **1** and **5** are almost constant within experimental errors (± 5%) independently of concentration from 5×10^{-3} to 5×10^{-2} mol dm^{-3}.

This work was partly supported by Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture (Nos. 61113001 and 62113001). We thank to Professors Kensuke Shima and Masahide Yasuda of Miyazaki University for helpful discussions on structure-reactivity relationships in the ring-cleavage reactions of the cyclobutanes.

Nonstabilized Azomethine Ylides Generated by Decarboxylative Condensation of α-Amino Acids. Structural Variation, Reactivity, and Stereoselectivity

Shuji KANEMASA,* Kazushige SAKAMOTO, and Otohiko TSUGE*
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received December 2, 1988)

A variety of aldehydes, containing enolizable aldehydes other than acetaldehyde can be used in the generation method of nonstabilized azomethine ylides by decarboxylative condensation of α-amino acids. Reactivity of the nonstabilized ylides was examined in intermolecular and intramolecular cycloadditions with olefins; stereoselectivity of the intramolecular cycloaddition using nonstabilized ylides was compared with that of ester-stabilized ylides.

Condensation of α-amino esters or related derivatives with carbonyl compounds[1-4] and decarboxylative condensation of α-amino acids[2,4-11] offer a direct and general generation method for carbonyl-stabilized and nonstabilized azomethine ylides, respectively. These two methods can be termed "a deprotonation route" and "a decarboxylation route" for the generation of azomethine ylide 1,3-dipoles.[12]

It was observed in the previous work that two competitive deprotonations took place from the iminium intermediates **A** when an enolizable aldehyde was used in the deprotonation route.[3] One was deprotonation at the α-position (path a in Fig. 1) leading to azomethine ylides **B** and the other at the β′-position leading to enamines **C** (path b). The condensation of ethyl (methylamino)acetate (R=Me) with acetaldehyde exclusively led to enamine **C** (R″=H), and with propanal the **B** : **C** ratio (R″=Me) was 73 : 27.[3]

In the decarboxylation route, the iminium carboxylate betaines **D** must undergo a rapid cyclization into 5-oxazolidinone intermediates, which then lose carbon dioxide to generate nonstabilized azomethine ylides **E**.[2,11] It is therefore expected that a side reaction forming enamine intermediates would be effectively suppressed. However, only limited examples are known for the use of enolizable aldehydes in the decarboxylation route.[5,7,10] In most preceding cases, only aromatic aldehydes and formaldehyde were employed.

Ester-stabilized azomethine ylides, generated from

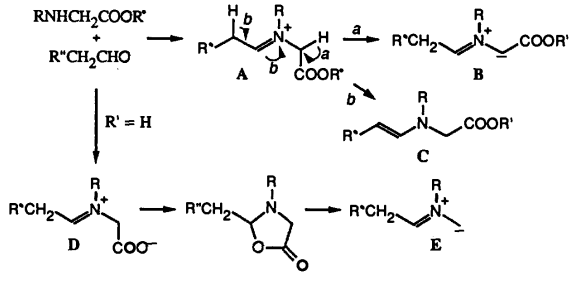

Fig. 1. Generation of azomethine ylides by the deprotonation route and the decarboxylation route.

the deprotonation route, have been well studied in terms of ylide structure, reactivity of ylide, and regio- and stereoselectivity of their cycloaddition.[3] However such chemical properties of nonstabilized azomethine ylides, generated by the decarboxylation route, remain unsolved. In most cases, nonstabilized ylides were applied to the reaction with highly activated dipolarophiles such as maleimides and showed a satisfactory reactivity.[5,6,9-11] It is very exceptional that *C*-unsubstituted ylides and its *C*-phenyl derivative reacted with less reactive olefins.[9] In intramolecular versions, however, nonstabilized ylides can be successfully trapped even with nonactivated olefin dipolarophiles.[2,5-7]

In the present article, several aldehydes are used in the decarboxylation route of azomethine ylide generation to see the scope and limitation of this method, and the reactivity of the resulting nonstabilized ylides both in inter- and intramolecular cycloadditions. Stereochemical selectivity is also briefly discussed.

Results and Discussion

Three *N*-substituted aminoacetic acids, (methylamino)- (**1a**) (benzylamino)- (**1b**), and (*p*-methoxybenzylamino)acetic acid (**1c**), were employed in the decarboxylation route. The benzyl and *p*-methoxybenzyl *N*-protecting groups were selected because they would be readily removed, after cycloaddition by hydrogenation and quinone oxidation, respectively. These α-amino acids were heated with a variety of aldehydes under reflux in toluene and the resulting ylides were trapped with *N*-(*p*-tolyl)maleimide, a highly reactive dipolarophile (Scheme 1 and Table 1).

Though the condensation reaction of (methylamino)acetic acid **1a** with benzaldehyde was previously reported,[9] the result is again listed in Table 1 in order to compare it with other results. Use of crotonaldehyde and paraformaldehyde in the condensation with **1b** and **1c**, respectively, gave no difficulty to generate the corresponding azomethine ylides **F** (R′=MeCH=CH(*E*) and H), while the yield of cycloadduct **2c** from the α,β-unsaturated aldehyde was

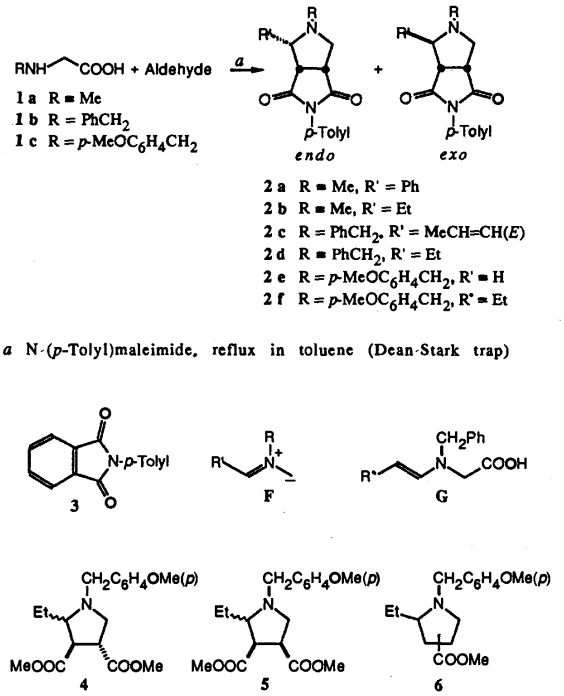

Scheme 1.

rather low.

The reaction of α-amino acid **1b** with acetaldehyde, the simplest enolizable aldehyde, under similar conditions resulted in the exclusive formation of enamine intermediate **G** (R″=H), which then underwent further condensation with another molecule of acetaldehyde to generate (1-propenyl)-substituted azomethine ylide **F** (R′=MeCH=CH(*E*)) or dienamine **G** (R″=CH_2=CH). The ylide **F** reacted with *N*-(*p*-tolyl)-maleimide to give cycloadduct **2c** (54%) while the diene **G** underwent a Diels-Alder reaction with the maleimide to afford phthalimide **3** (18%) after deamination and aromatization. A similar Diels-Alder reaction leading to the dihydro derivative of **3** was previously observed in the deprotonation route using acetaldehyde and ethyl (methylamino)acetate.[3]

In contrast with the above disappointing result, a promising feature of the decarboxylation route was unveiled in the reaction of **1a**—**c** with propanal, the second simplest enolizable aldehyde. The only products **2b**, **d**, **f** obtained in better than 80% yields were the cycloadducts of ethyl-substituted azomethine ylide **F** (R′=Et), no enamine intermediate being even detected. This indicates that any alkyl groups except methyl may be directly introduced from aldehyde to nonstabilized azomethine ylides, and this must be a very important synthetic advantage of the decarboxylation route over the deprotonation route.

The maleimide cycloadducts **2a**—**f** were all mixtures of endo (or 3a,4-cis) and exo (or 3a,4-trans) isomers, however they could be separated from each other by column chromatography over silica gel.

The stereostructures of **2a**—**f** were determined mainly on the basis of ^{1}H NMR spectra. A stereostructural inspection using molecular models indicates that the substituent at 4-position of both 3a,4-cis and 3a,4-trans isomers of **2** would occupy an equatorial position so that $J_{6\text{-}6a}$ (trans) of the 3a,4-cis isomers becomes zero. It was found that, in addition, difference of the chemical shifts between two nonequivalent hydrogens of *N*-benzyl and *N*-(*p*-methoxybenzyl) moieties was much smaller in the 3a,4-trans isomers (0.28—0.34 ppm) than that in the cis isomers (0.94—0.99 ppm).

Since only a little is known on the reactivity of azomethine ylides bearing an alkyl moiety as the only *C*-substituent,[7,9] ethyl-substituted ylide **F** (R=*p*-$MeOC_6H_4$, R′=Et) was allowed to react with several olefin dipolarophiles (Scheme 1 and Table 1). With highly activated dipolarophiles such as *N*-(*p*-tolyl)-maleimide and dimethyl fumarate, satisfactory yields of cycloadducts **2d** (74%, 41:33) and **4** (80%, 52:48 (by GLC)) were obtained under mild reaction conditions. However, this ylide **F** showed only a poor reactivity toward dimethyl maleate and methyl acrylate; low yields of cycloadduct **5** (28%, 20:8) and **6** (39%, more than three isomers) resulted, respectively. Although

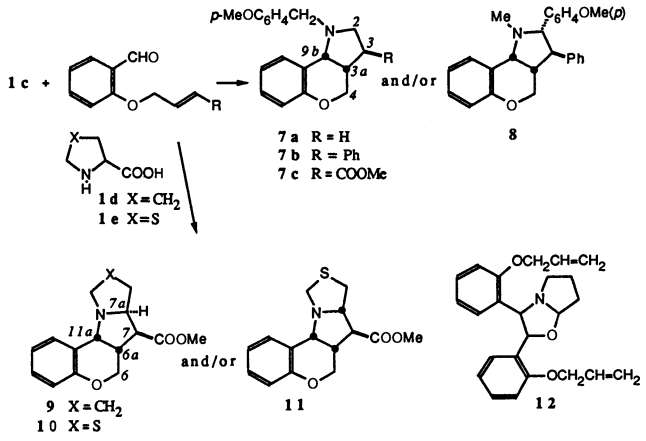

Scheme 2.

the structure of each isomer was not specified, both regio- and stereoselectivity were very poor in the latter case.

Thus, the reactivity of nonstabilized azomethine ylides and the stereoselectivity of their cycloaddition were not sufficient enough for the decarboxylation route to be utilized effectively in organic synthesis. Therefore, application of these ylides to intramolecular cycloaddition reaction was investigated next.

Three benzaldehydes having an internal olefin dipolarophile were selected as partners of (*p*-methoxybenzylamino)acetic acid (**1c**). It was not surprsing that the ester-activated olefin showed a high reactivity toward an internal nonstabilized ylide to give cycloadduct **7c** in a regio- and stereoselective manner (Scheme 2 and Table 2). Both nonsubstituted and phenyl-substituted olefins were also sufficiently reactive to produce the cis-fused cycloadducts, **7a**, **b** and **8**.[5-7]

2-Pyrrolidine- (**1d**) and 4-thiazolidinecarboxylic acid (**1e**) similarly reacted with methyl (*E*)-4-(2-formylphenoxy)-2-butenoate to produce the cis-fused cycloadducts **9**—**11** in satisfactory yields. However, a nonactivated internal olefin failed to trap the nonstabilized ylide,[5] an aldehyde cycloadduct **12** being obtained instead as a single stereoisomer.

Stereostructures of cycloadducts **7**—**11** were determined on the basis of coupling constants and the rule of stereospecificity of 1,3-dipolar cycloaddition.[12,13] Especially two medium couplings $J_{3a\text{-}4}$ (5.1 and 8.4 Hz for **7c**) and a medium coupling of $J_{3a\text{-}9b}$ (6.0 for **7c**) of **7**—**8** were informative. The 6a,11a-cis structures of **9**—**11** and the 6a,7a-cis structure of **11** were assigned on the basis of $J_{6a\text{-}6}$ (3.7 and 4.8 Hz for **9**) and a magnetic shielding of 10-Hs (δ=3.76 and 3.99 for **11**; 4.27 and 4.46 for **10**) by the fused benzene ring, respectively.

Cycloadduct **8** corresponds to the product of ylide **I**. The initially generated ylide **H** presumably isomerized into the more stabilized ylide **I** by a 1,3-proton migration (Fig. 2). This indicates that nonstabilized azomethine ylides may behave as bases and may abstract a proton from acidic molecules around if no reactive dipolarophile exists.

Although the intramolecular trap of 1,3-dipole with an (*E*)-olefin dipolarophile is not known so far, the exclusive formation of cis-fused cycloadducts **7a**—**c** must have resulted from the sterically least crowded transition state **J**. Similar selectivity was previously observed in the intramolecular cycloadditions using a terminal olefin.[4-7]

Products **9** and **10** are the cis-fused cycloadducts of

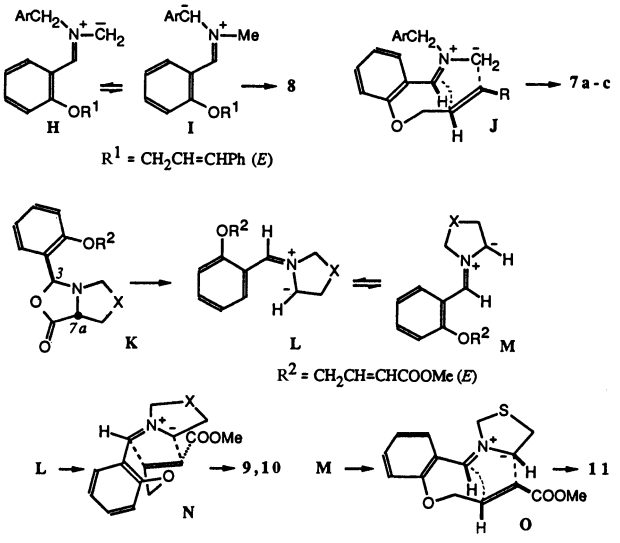

Fig. 2. Stereoselectivity of intramolecular cycloaddition of the nonstabilized azomethine ylides generated by the decarboxylation route.

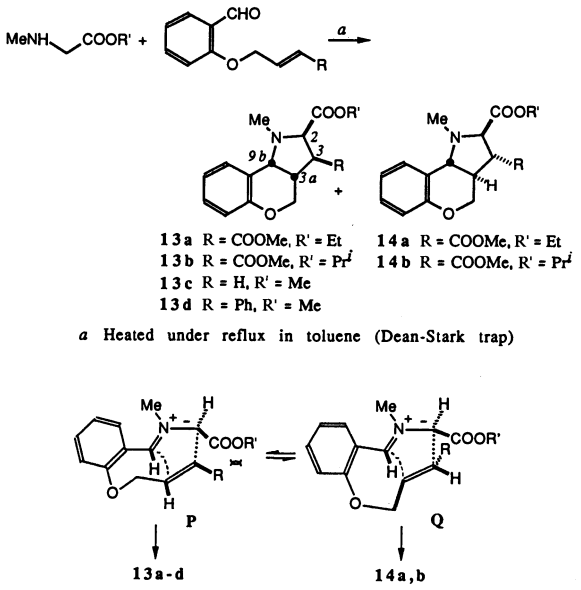
anti ylides **L** (X=CH_2 and S). Exclusive involvement of **L** (X=CH_2) in the reaction of **1d** was conceivable because of the expected stereospecific extrusion of carbon dioxide from the most favorable 3,7a-trans bicyclic lactone intermediate **K** (X=CH_2).[11] However, there should be a significant steric repulsion between the ester moiety and the five-membered heterocycle in its approach **N** (X=CH_2).

If internal trap of anti ylide **L** is sluggish, **L** equilibrates with syn ylide **M**, which then undergoes a cycloaddition via **O**. The formation of **11**, as a side product, in the reaction of **1e** is the case.[10,11]

Intramolecular cycloadditions of ester-stabilized azomethine ylides were next investigated in order to compare their reactivity and stereoselectivity with those of nonstabilized azomethine ylides. Thus, reaction of ethyl (methylamino)acetate with three benzaldehydes above employed were carried out under similar conditions (Scheme 3). The reactions with unsubstituted and phenyl-substituted internal olefins gave the cis-fused cycloadducts as single isomers, **13c** and **13d**, respectively, of anti forms of ester-stabilized azomethine ylides (Table 3).[4,6]

On the other hand, the reaction with a more reactive ester-activated internal olefin furnished two isomeric cyloadducts **13a** and **14a** in comparable yields.



13a R = COOMe, R' = Et
13b R = COOMe, R' = Pr^i
13c R = H, R' = Me
13d R = Ph, R' = Me

14a R = COOMe, R' = Et
14b R = COOMe, R' = Pr^i

a Heated under reflux in toluene (Dean-Stark trap)

Scheme 3.

One product **13a** (42%) is cis fused cycloadduct of anti ylide and the other **14a** (44%) trans-fused isomer of anti ylide. A similar result was obtained from the reaction of isopropyl (methylamino)acetate.

These isomeric cycloadducts **13** and **14** were separated from each other by column chromatography over silica gel. The stereostructures of **13a—d** were determined on the basis of two small coupling constants of $J_{3a\text{-}4}$, a magnetic shielding of 2-COOMe by the adjacent phenyl for **13d**, and medium couplings of $J_{2\text{-}3}$ for **13a,b**, and **13d**.

According to a molecular model inspection, 3a-H of isomeric cycloadducts **14a,b** is located antiperiplanar to 3-H, one of 4-Hs, and 9b-H. The observed large couplings among these hydrogens accord with the model structure. A medium coupling of $J_{2\text{-}3}$ confirmed the 2,3-trans stereochemistry.

It was already reported that ester-stabilized azomethine ylides bearing an *N*-substituent participated in cycloadditions in anti forms.[3] In an approach depicted in **P** which leads to the cis-fused cycloadducts **13a—d**, the ester moiety COOR′ derived from α-amino acids and the olefin substituent R close to each other. This approach **P** becomes sterically more favored if R is either small (R=H) or can interact attractively (R=Ph) with the ester moiety. When a steric repulsion exists between COOR′ and R (R=COOMe), the other ring fusion via **Q** competes with **P**.

Formation of trans-fused [5.6] ring systems by intramolecular cycloadditions is quite rare.[14] The competitive participation of such energetically disfavored approach **Q** may be due to a tight structure of the anti forms of ester-stabilized azomethine ylides. This makes a striking contrast with the ready isomerization of nonstabilized ylides, which was shown above in the isomerization example of **N** into **O**.

Thus, it is concluded that (1) the decarboxylation route offers a general preparation method for nonstabilized azomethine ylides, (2) nonstabilized ylides can be effectively trapped intermolecularly by highly activated olefin dipolarophiles such as maleimides and fumarates, (3) nonstabilized ylides can be trapped by nonactivated and phenyl-substituted internal olefins and ester-activated olefins, (4) cis-fused cycloadducts are exclusively produced in intramolecular reaction, (5) the isomerization of nonstabilized ylides can be sufficiently suppressed by the intramolecular cycload-

Table 3. Intramolecular Cycloadditions of Azomethine Ylides Generated by the Deprotonation Route

ditions using an ester-activated olefin dipolarophile.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL GSX-270 (270 MHz for ^{1}H and 67.94 MHz for ^{13}C) and a JEOL FX-100 instrument (100 MHz for ^{1}H and 25.05 MHz, for ^{13}C). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra and high resolution mass spectra (HRMS) were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Wakogel C-200, C-300 (Wako), and Silica gel 60 (Merck) were employed for preparative column chromatography. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silica gel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph (Yanagimoto) with an ionization flame detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Silicone GE, SE-30, 0.25×50000 mm).

Materials. (Methylamino)acetic acid (**1a**) is commercially available. (Benzylamino)acetic acid (**1b**) and (*p*-methoxybenzylamino)acetic acid (**1c**) were prepared through the condensation of ethyl aminoacetate and aldehydes followed by a reduction with sodium borohydride:[15] The ethyl esters of **1b** and **1c** were first purified by silica-gel chromatography (ethyl acetate-ethanol= 4 : 1 v/v as an eluent) and then hydrolyzed with sodium hydroxide (half an equivalent of the ester used) in aqueous ethanol (75%) at room temperature for 1 h. After 1 M hydrochloric acid (1 M=1 mol dm^{-3}) was added to pH 7, the mixture was evaporated in vacuo and the residue was dried on calcium chloride under vacuum. The resulting α-amino acids **1b** and **1c** containing sodium chloride were used without separation. (3a*R**, 6a*S**)-5-Methyl-4-phenyl-2-(*p*-tolyl)perhydropyrrolo[3,4-*c*]pyrrole-1,3-dione (**2a**)[9] was previously reported.

General Procedure for the Condensations of α-Amino Acids 1a—c with Aldehydes and Trap of the Resulting Azomethine Ylides. A mixture of **1** (2 mmol as a mixture with sodium chloride), an aldehyde (paraformaldehyde and propanal: 5 mmol; crotonaldehyde: 1.5 mmol), and an olefin (1 mmol) was heated under reflux in dry toluene (10—20 ml) with continuous removal of water with the aid of a Dean-Stark trap. Only in the reaction with methyl acrylate, a mixture of **1** (1 mmol), propanal (5 mmol), and methyl acrylate (5 mmol) was employed. After the reaction was complete (checked by TLC), all volatile materials were evaporated in vacuo. The residue was extracted with boiling chloroform (20 ml×2). The chloroform was evaporated and the residue was chromatographed over silica gel by using hexane-ethyl acetate (10 : 1 v/v for **2b**,c; 4 : 1 for **2e**, f; 3 : 1 for **2d**) to give **2a—f** and **3—6**. The reaction conditions and results are summarized in Table 1.

(3a*R,6a*S**)-4-Ethyl-5-methyl-2-(*p*-tolyl)perhydropyrrolo-[3,4-*a*]pyrrole-1,3-dione (2b): 3a,4-*cis*-2b:** Colorless solid; mp 79—81 °C; IR (KBr) 1775, 1700, 1390, and 1200 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.14 (3H, t, J=7.0 Hz, Et), 2.4—2.8 (2H, m, Et), 2.21 (1H, m, 4-H), 2.26, 2.37 (each 3H, s, NMe and *p*-Me), 2.40 (1H, dd, J_{gem}=9.5 and J_{6-6a}=7.7 Hz, one of 6-H), 3.22 (1H, dd, J_{3a-4}=8.0 and J_{3a-6a}=7.7 Hz, 3a-H), 3.35 (1H, t, J_{6a-3a}=J_{6a-6}=7.7 Hz, 6a-H), 3.48 (1H, d, J_{gem}=9.5 Hz, the other of 6-H), and 7.1—7.3 (4H, m, Ar); MS *m/z* (rel intensity, %) 272 (M^+, 8), 244 (16), 243 (base peak), and 82 (51). Found: C, 70.57; H, 7.40; N, 10.29%. Calcd for $C_{16}H_{20}N_2O_2$: C, 70.72; H, 7.47; N, 10.19%. **3a,4-*trans*-2b**: Colorless solid; mp 84—86 °C; IR (KBr) 1780, 1705, 1385, and 1190 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.05 (3H, t, J=7.5 Hz, Et), 1.48 (1H, ddq, J_{gem}=15.7, J= 7.5, and 7.5 Hz, one of Et), 1.84 (1H, ddq, J_{gem}=15.7, J=7.5, and 3.2 Hz, the other of Et), 2.34, 2.38 (each 3H, s, NMe and *p*-Me), 2.6—2.7 (2H, m, 3a- and 4-H), 3.15 (1H, dd, J_{gem}=8.6 and J_{6-6a}=5.4 Hz, one of 6-H), 3.38 (1H, t, J_{gem}=J_{6-6a}=8.6 Hz, the other of 6-H), 3.44 (1H, dt, J_{6a-6}=J_{6a-3a}=8.6 and J_{6a-6}=5.4 Hz, 6a-H), 7.15 and 7.27 (each 2H, d, J=8.4 Hz, Ar); MS *m/z* (rel intensity, %) 272 (M^+, 7), 243 (base peak), 82 (46), and 57 (59). Found: C, 70.61; H, 7.45; N, 10.38%. Calcd for $C_{16}H_{20}N_2O_2$: C, 70.57; N, 7.40; H, 10.29%.

(3a*R,6a*S**)-5-Benzyl-4-[(*E*)-1-propenyl]-2-(*p*-tolyl)perhydropyrrolo[3,4-*a*]pyrrole-1,3-dione (2c): 3a,4-*cis*-2c:** Pale yellow liquid; IR (neat) 1780 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.78 (3H, d, J=6.5 Hz, MeCH=CH), 2.38 (3H, s, *p*-Me), 3.03 (1H, d, J_{gem}=13.9 Hz, one of $PhCH_2$), 3.13 (1H, dd, J_{gem}=9.2 and J_{6-6a}=8.0 Hz, one of 6-H), 3.22 (1H, dd, J_{3a-6a}=8.0 and J_{3a-4}=7.3Hz, 3a-H), 3.33 (1H, t, J_{6a-3a}=J_{6a-6}=8.0 Hz, 6a-H), 3.42 (1H, d, J_{gem}=9.2 Hz, the other of 6-H), 4.02 (1H, J_{gem}=13.9 Hz, the other of $PhCH_2$), 5.41 (1H, m, =CH), 5.85 (1H, dq, J=15.4 and 6.5 Hz, =CH), and 7.0—7.4 (9H, m, Ph and Ar); MS *m/z* (rel intensity, %) 360 (M^+, 4), 91 (45), 86 (50), 84 (68), 59 (22), and 49 (base peak). HRMS Found: *m/z* 360.1839. Calcd for $C_{23}H_{24}N_2O_2$: M, 360.1838. **3a,4-*trans*-2c:** Pale yellow liquid; IR (neat) 1770 and 1715 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.76 (3H, dd, J=6.3 and 1.5 Hz, MeCH=CH), 2.38 (3H, s, *p*-Me), 3.01 (1H, dd, J_{gem}=9.7 and J_{6-6a}=3.9 Hz, one of 6-H), 3.16 (1H, dd, J_{gem}=9.7 and J_{6-6a}=8.3 Hz, the other of 6-H), 3.3—3.9 (3H, m, 3a-, 4-, and 6a-H), 3.48 (1H, J_{gem}=13.5 Hz, one of $PhCH_2$), 3.76 (1H, J_{gem}=13.5 Hz, the other of $PhCH_2$), 5.5—5.9, 6.0—6.4 (each 1H, CH=CH), and 7.1—7.4 (9H, m, Ph and Ar); MS *m/z* (rel intensity, %) 360 (M^+, 5), 239 (28), 210 (29), 108 (28), 107 (25), 106 (31), 105 (20), 91 (base peak), 86 (45), 84 (72), 79 (38), and 77 (32). HRMS Found: *m/z* 360.1837. Calcd for $C_{23}H_{24}N_2O_2$: M, 360.1836.

(3a*R,6a*S**)-5-Benzyl-4-ethyl-2-(*p*-tolyl)perhydropyrrolo-[3,4-*a*]pyrrole-1,3-dione (2d): 3a,4-*cis*-2d:** Colorless needles (hexane); mp 98—99 °C; IR (KBr) 1700, 1385, and 1190 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.16 (3H, t, J=7.2 Hz, Et), 1.4—2.1 (2H, m, Et), 2.34 (1H, dd, J_{gem}=9.6 and J_{6-6a}=7.5 Hz, one of 6-H), 2.38 (3H, s, *p*-Me), 2.56 (1H, ddd, J_{4-Et}=9.8, 3.2, and J_{4-3a}=7.4 Hz, 4-H), 3.12 (1 H, d, J_{gem}=13.5 Hz, one of $PhCH_2$), 3.19 (1H, dd, J_{3a-6a}=8.0 and J_{3a-4}=7.4 Hz, 3a-H), 3.38 (1H, d, J_{gem}=9.6 Hz, the other of 6-H), 3.39 (1H, dd, J_{6a-3a}=8.0 and J_{6a-6}=7.5 Hz, 6a-H), 4.08 (1H, d, J_{gem}=13.5 Hz, the other of $PhCH_2$), and 7.0—7.4 (9H, m, Ph and Ar); ^{13}C NMR ($CDCl_3$) δ=10.70, 21.17 (each Et), 21.79 (*p*-Me), 42.95 (6a-C), 46.71 (3a-C), 56.24 (6-C), 68.98 (4-C), 126.30, 127.11, 128.30, 129.56, 138.51, 138.80 (each Ph and Ar), 176.00, and 178.45 (each CON); MS *m/z* 348 (M^+, 7), 320 (23), 319 (95), and 91 (base peak). Found: C, 75.93; H, 6.93; N, 8.09%. Calcd for $C_{22}H_{24}N_2O_2$: C, 75.84; H, 6.94; H, 8.04%. **3a,4-*trans*-2d:** Pale yellow prisms (hexane); mp 112—113 °C;

IR (KBr) 1770, 1700, 1370, and 1170 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (3H, t, J=7.2 Hz, Et), 1.3—2.0 (2H, m, Et), 2.38 (3H, s, *p*-Me), 2.84 (1H, dd, J_{gem}=9.7 and $J_{6\text{-}6a}$=4.0 Hz, one of 6-H), 3.0—3.5 (4H, m, 3a-, 4-, 6a-H, and the other of 6-H), 3.50, 3.86 (each 1H, d, J_{gem}=13.3 Hz, $PhCH_2$), and 7.0—7.4 (9H, m, Ph and Ar); ^{13}C NMR ($CDCl_3$) δ=9.69 (q, Et), 21.14 (t, Et), 43.94 (d, 6a-C), 49.19 (d, 3a-C), 53.95 (t, 6-C), 55.28 (t, $PhCH_2$), 67.33 (d, 4-C), 126.22, 127.18, 128.28, 128.39, 129.77 (each d, Ar), 138.40, 138.54 (each s, Ar), 177.79, and 178.12 (each s, CON); MS *m/z* (rel intensity, %) 348 (M^+, 4), 319 (85), and 91 (base peak). Found: C, 75.81; H, 6.92; N, 8.01%. Calcd for $C_{22}H_{24}N_2O_2$: C, 75.84; H, 6.94; H, 8.04%.

(3a*R,6a*S**)-5-(*p*-Methoxybenzyl)-2-(*p*-tolyl)perhydropyrrolo[3,4-*a*]pyrrole-1,3-dione (2e):** Colorless prisms (benzene-hexane); mp 139—140 °C; IR (KBr) 1770, 1695, 1505, 1380, 1240, and 1185 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.39 (3H, s, *p*-Me), 2.44, 2.45 (each 1H, dd, J_{gem}=9.9 and J=6.2 Hz, one of 4-H and one of 6-H), 3.29, 3.33 (each 1H, t, $J_{3a\text{-}6a}$=6.2 and J=6.2 Hz, 3a- and 6a-H), 3.38 (2H, d, J_{gem}=9.9 Hz, the other of 4-H and the other of 6-H), 3.56 (2H, s, $ArCH_2$), 3.79 (3H, *p*-OMe), and 6.8—7.3 (8H, m, Ar); MS *m/z* (rel intensity, %) 350 (M^+, 16), 122 (22), and 121 (base peak). Dimethyl (3*R,4*R**)-2-Ethyl-1-(*p*-methoxybenzyl)-3,4-pyrrolidinedicarboxylate (4):** Obtained as an inseparable mixture of two stereoisomers (48:51 by GLC). Pale yellow liquid; IR (neat) 1730, 1615, 1510, 1440, and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 and 0.95 (each 1/2×3H, t, J=7.3 Hz, Et), 1.2—1.8 (2H, m, Et), 2.4—3.9 (5H, m, 2-, 3-, 4-, and 5-H), 3.14, 3.88 (each 1/2×2H, d, J_{gem}=13.2 Hz, $PhCH_2$), 3.36, 3.86 (each 1/2×2H, d, J_{gem}=12.8 Hz, $PhCH_2$), 3.66, 3.67, 3.71, 3.72 (each 1/2×3H, s, COOMe), 3.79, 3.80 (each 1/2×3H, s, *p*-MeO), and 6.8—7.3 (4H, m, Ar); MS *m/z* (rel intensity, %) 335 (M^+, 9), 306 (31), and 121 (base peak). Found: C, 64.47; H, 7.51; N, 4.18%. Calcd for $C_{18}H_{25}NO_5$: C, 64.62; H, 7.62; N, 4.10%.

Dimethyl (3*R,4*S**)-2-Ethyl-1-(*p*-methoxybenzyl)-3,4-pyrrolidinedicarboxylate (5):** Two stereoisomers were obtained in 20 and 8% yields, but the stereostructures could not be determined. The major isomer: Pale yellow liquid; IR (neat) 1730, 1610, 1430, and 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (3H, t, J=7.5 Hz, Et), 1.4—1.9 (2H, m, Et), 2.5—3.2 (5H, m, 2-, 3-, 4-, and 5-H), 3.24 (1H, d, J_{gem}=12.5 Hz, one of $ArCH_2$), 3.60, 3.64 (each 3H, s, COOMe), 3.76 (3H, s, *p*-MeO), 3.93 (1H, d, J_{gem}=12.5 Hz, the other of $ArCH_2$), and 6.7—7.4 (4H, m, Ar); MS *m/z* (rel intensity, %) 335 (M^+, 4), 121 (base peak), 78 (21), and 77 (45). HRMS Found: *m/z* 335.1728. Calcd for $C_{18}H_{25}NO_5$: M, 335.1731. The minor isomer: Pale yellow liquid; IR (neat) 1730, 1610, 1510, 1430, and 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3H, t, J=7.0 Hz, Et), 1.1—2.0 (2H, m, Et), 2.6—3.5 (5H, m, 2-, 3- 4-, and 5-H), 3.36 (1H, d, J_{gem}=13.5 Hz, one of $ArCH_2$), 3.60, 3.68 (each 3H, s, COOMe), 3.77 (3H, s, *p*-MeO), 3.95 (1H, d, J_{gem}=13.5 Hz, the other of $ArCH_2$), and 6.7—7.3 (4H, m, Ar); MS *m/z* (rel intensity, %) 335 (M^+, 8), 138 (67), 137 (36), 121 (base peak), 109 (42), and 77 (26). HRMS Found: *m/z* 335.1729. Calcd for $C_{18}H_{25}NO_5$: M, 335.1731.

Methyl 2-Ethyl-1-(*p*-methoxybenzyl)-3(or 4)-pyrrolidinecarboxylate (6): An inseparable mixture of more than three isomers was obtained as colorless liquid. Only ^1H NMR and mass spectra were taken. ^1H NMR ($CDCl_3$) δ=0.9—1.0 (3H, m, Et), 1.3—2.0 (2H, m, Et), 2.2—3.0 (6H, m, 2-, 3-, 4-, and 5-H), 3.1—3.2 (1H, m, one of $ArCH_2$), 3.65, 3.68, 3.69 (3H, each s, COOMe), 3.79, 3.81 (3H, each s, *p*-MeO), 3.9—4.1 (1H, m, the other of $ArCH_2$), and 6.8—7.3 (4H, m, Ar); MS *m/z* (rel intensity, %) 277 (M^+, 6), 248 (24), and 121 (base peak).

General Procedure for the Reactions of α-Amino Acids 1c—e with *o*-(2-Alkenyloxy)benzaldehydes. A mixture of **1c** (2 mmol as a mixture with sodium chloride) or **1d, e** (1.2 mmol) and an aldehyde (1 mmol) was heated under reflux in dry toluene or xylene (15 ml) with continuous removal of water with the aid of a Dean-Stark trap. After the completion of reaction (checked by TLC), the solvent was removed. The residue was washed with boiling chloroform (20 ml×2). The chloroform was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (15:1 v/v for **7b**; 10:1 for **7a**; 6:1 for **7c**; 3:1 for **9—12**) to give **7a—3c**, **8**, and **9—12**. The reaction conditions and results are summarized in Table 2.

(3a*R,9b*S**)-1-(*p*-Methoxybenzyl)-1,2,3,3a,4,9b-hexahydro-[1]benzopyrano[4,3-*b*]pyrrole (7a):** Pale yellow liquid; IR (neat) 1610, 1580, 1460, and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.37, 2.01 (each 1H, m, 3-H), 2.15 (1H, br q, J_{gem}=9.7 and $J_{2\text{-}3}$=9.7 Hz, one of 2-H), 2.42 (1H, m, 3a-H), 2.84 (1H, dt, J_{gem}=9.7, $J_{2\text{-}3}$=9.7, and 2.7 Hz, the other of 2-H), 3.15 (1H, d, J_{gem}=12.1 Hz, $ArCH_2$), 3.22 (1H, d, $J_{9b\text{-}3a}$=5.5 H, 9b-H), 3.77 (3H, s, *p*-MeO), 4.01 (1H, dd, J_{gem}=10.0 and $J_{4\text{-}3a}$=5.5 Hz, one of 4-H), 4.07 (1H, dd, J_{gem}=10.0 and $J_{4\text{-}3a}$=9.9 Hz, the other of 4-H), 4.32 (1H, d, J_{gem}=12.1 Hz, $ArCH_2$), and 6.8—7.3 (8H, m, Ar); MS *m/z* (rel intensity, %) 295 (M^+, 24), 174 (22), 131 (17), 122 (14), and 121 (base peak). General Procedure for the Reactions of α-Amino Esters with *o*-(2-Alkenyloxy)benzaldehydes. A mixture of the hydrochloride of an ester of (methylamino)acetic acid (1.5—2 mmol), an aldehyde (1 mmol), and triethylamine (1.5—2 mmol) was heated under reflux in dry toluene (10 ml) with continuous removal of water with the aid of a Dean-Stark trap. The solvent was removed in vacuo and the residue was chromatographed over silica gel by using hexane-ethyl acetate (7 : 1 v/v for **13c, d**; 4 : 1 for **13a, b** and **14a, b**) to give **13a—d** and **14a, b**. The reaction conditions and results are summarized in Table 2.

Ethyl (2*R,3*S**,3a*S**,9b*R**)-3-Methoxycarbonyl-1-methyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*b*]pyrrole-2-car-**

boxylate (13a): Pale yellow liquid; IR (neat) 1730, 1600, 1580, 1450, and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (3H, t, J=7.5 Hz, Et), 2.40 (3H, s, NMe), 3.38 (1H, dddd, J_{3a-9b}=9.2, J_{3a-3}=9.1, J_{3a-4}=3.7, and 1.3 Hz, 3a-H), 3.47 (1H, dd, J_{3-3a}=9.1 and J_{3-2}=7.0 Hz, 3-H), 3.71 (3H, s, COOMe), 3.87 (1H, dd, J_{gem}=11.4 and J_{4-3a}=3.7 Hz, one of 4-H), 4.01 (1H, d, J_{2-3}=7.0 Hz, 2-H), 4.03 (1H, d, J_{9b-3a}=9.2 Hz, 9b-H), 4.19 (1H, dd, J_{gem}=11.4 and J_{4-3a}=1.3 Hz, the other of 4-H), 4.20 (2H, q, J=7.5 Hz, COOEt), and 6.9—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=14.43 (Et), 35.58 (NMe), 41.71 (3a-C), 47.70 (3-C), 51.94 (COOMe), 59.84 (2-C), 60.47 (COOEt), 67.66 (9b-C), 69.76 (4-C), 118.02, 121.44, 125.18, 128.62, 129.87, 157.24 (each Ar), 170.98, and 171.77 (COOMe and COOEt); MS m/z (rel intensity, %) 319 (M^+, 6), 246 (base peak), 186 (23), and 131 (21). HRMS Found: m/z 319.1340. Calcd for $C_{17}H_{21}NO_5$: M, 319.1418.

Isopropyl (2*R,3*S**,3a*S**,9b*R**)-3-Methoxycarbonyl-1-methyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*b*]pyrrole-2-carboxylate (13b):** Colorless liquid; IR (neat) 1730, 1610, 1580, and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28, 1.29 (each d, J=6.3 Hz, *i*-Pr), 2.40 (3H, s, NMe), 3.40 (1H, dddd, J_{3a-3}=9.2, J_{3a-9b}=8.8, J_{3a-4}=3.5, and 2.2 Hz, 3a-H), 3.47 (1H, dd, J_{3-3a}=9.2 and J_{3-2}=6.6 Hz, 3-H), 3.71 (3H, s, COOMe), 3.88 (1H, dd, J_{gem}=11.5 and J_{4-3a}=3.5 Hz, one of 4-H), 3.98 (1H, d, J_{2-3}=6.6 Hz, 2-H), 4.00 (1H, d, J_{9b-3a}=8.8 Hz, 9b-H), 4.20 (1H, dd, J_{gem}=11.5 and J_{4-3a}=2.2 Hz, the other of 4-H), 5.10 (1H, m, *i*-Pr), and 6.8—7.4 (4H, m, Ar); MS m/z (rel intensity, %) 333 (M^+, 7), 246 (base peak), 186 (27), 131 (28), 85 (27), and 83 (43). HRMS Found: m/z 333.1575. Calcd for $C_{18}H_{23}NO_5$: M, 333.1575.

Methyl (2*R,3a*S**,9b*R**)-1-Methyl-1,2,3,3a,4,9b-hexahydro-[1]benzopyrano[4,3-*b*]pyrrole-2-carboxylate (13c):** Pale yellow liquid; IR (neat) 1730, 1610, 1590, 1490, and 1200 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.96 (1H, ddd, J_{gem}=13.5, J_{3-2}=8.1, and J_{3-3a}=3.9 Hz, one of 3-H), 2.18 (1H, ddd, J_{gem}=13.5, J_{3-3a}=8.1, and J_{3-2}=3.3 Hz, the other of 3-H), 2.45 (3H, s, NMe), 2.64 (1H, m, 3a-H), 3.72 (3H, s, COOMe), 3.74 (1H, dd, J_{2-3}=8.1 and 3.3 Hz, 2-H), 3.88 (1H, dd, J_{gem}=11.0 and J_{4-3a}=8.4 Hz, one of 4-H), 3.96 (1H, dd, J_{gem}=11.0 and J_{4-3a}=4.7 Hz, the other of 4-H), 3.97 (1H, d, J_{9b-3a}=7.0 Hz, 9b-H), and 6.9—7.2 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=30.40 (3-C), 35.02 (3a-C), 35.54 (NMe), 51.29 (COOMe), 58.72 (2-C), 64.00 (9b-C), 68.10 (4-C), 117.20, 120.21, 121.94, 128.63, 131.30, 155.75 (Ar), and 174.31 (COOMe); MS m/z (rel intensity, %) 274 (M^+, 8), 189 (12), 188 (base peak), and 131 (20). HRMS Found: m/z 247.1209. Calcd for $C_{14}H_{17}NO_3$: M, 247.1207.

Methyl (2*R,3*R**,3a*S**,9b*R**)-1-Methyl-3-phenyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*b*]pyrrole-2-carboxylate (13d):** Colorless prisms (diethyl ether-hexane); mp 148 °C; IR (KBr) 1710, 1580, 1440, and 1160 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.51 (3H, s, NMe), 3.37 (3H, s, COOMe), 3.38 (1H, dddd, J_{3a-3}=9.9, J_{3a-9b}=9.5, J_{3a-4}=3.6, and 2.2 Hz, 3a-H), 3.86 (1H, dd, J_{gem}=11.4 and J_{4-3}=3.6 Hz, one of 4-H), 3.93 (1H, dd, J_{3-3a}=9.9 and J_{3-2}=7.7 Hz, 3-H), 3.96 (1H, dd, J_{gem}=11.4 and J_{4-3a}=2.2 Hz, the other of 4-H), 4.00 (1H, d, J_{2-3}=7.7 Hz, 2-H), 4.40 (1H, d, J_{9b-3a}=9.5 Hz, 9b-H), and 6.9—7.4 (9H, m, Ph and Ar); ^{13}C NMR ($CDCl_3$) δ=35.98 (NMe), 43.48 (3a-C), 48.58 (3-C), 50.67 (COOMe), 60.11 (9b-C), 68.39 (4-C), 72.37 (2-C), 117.99, 121.42, 125.91, 127.41, 128.39, 128.46, 128.55, 129.77, 137.17, 156.80 (each Ph and Ar), and 172.22 (COOMe); MS m/z (rel intensity, %) 323 (M^+, 3), 265 (20), 264 (base peak), and 132 (11). Found: C, 74.22; H, 6.56; N, 4.45%. Calcd for $C_{20}H_{21}NO_3$: C, 74.29; H, 6.55; N, 4.33%.

Ethyl (2*R,3*R**,3a*R**,9b*R**)-3-Methoxycarbonyl-1-methyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*b*]pyrrole-2-carboxylate (14a):** Pale yellow liquid; IR (neat) 1730, 1610, 1490, 1460, and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.31 (3H, t, J=7.0 Hz, Et), 2.54 (3H, s, NMe), 2.66 (1H, dq, J_{3a-3}=J_{3a-9b}=11.0, J_{3a-4}=11.0, and 4.4 Hz, 3a-H), 3.13 (1H, dd, J_{3-3a}=11.0 and J_{3-2}=6.0 Hz, 3-H), 3.74 (3H, s, COOMe), 3.98 (1H, d, J_{9b-3a}=11.0 Hz, 9b-H), 4.15 (1H, d, J_{2-3}=6.0 Hz, 2-H), 4.18 (1H, dd, J_{gem}=10.3 and J_{4-3a}=11.0 Hz, one of 4-H), 4.24 (2H, q, J=7.0 Hz, COOEt), 4.64 (1H, J_{gem}=10.3 and J_{4-3a}=4.4 Hz, the other of 4-H), and 6.8—7.4 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=14.23 (Et), 38.51 (NMe), 41.45 (3a-C), 48.98 (3-C), 52.50 (COOMe), 61.37 (COOEt), 64.58 (2-C), 69.77 (4-C), 71.70 (9b-C), 116.58, 120.23, 123.29, 125.83, 128.23, 154.12 (each Ar), 172.62, and 172.41 (COOMe and COOEt); MS m/z (rel intensity, %) 319 (M^+, 10), 246 (base peak), and 135 (28). HRMS Found: m/z 319.1418. Calcd for $C_{17}H_{21}NO_5$: M, 319.1418.

Isopropyl (2*R,3*R**,3a*R**,9b*R**)-3-Methoxycarbonyl-1-methyl-1,2,3,3a,4,9b-hexahydro[1]benzopyrano[4,3-*b*]-pyrrole-2-carloxylate (14b):** Pale yellow liquid; IR (neat) 1730, 1610, 1490, and 1220 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28, 1.31 (each 3H, d, J=6.2 Hz, *i*-Pr), 2.56 (3H, s, NMe), 2.66 (1H, dq, J_{3a-2}=J_{3a-9b}=11.4, J_{3a-4}=11.4, and 4.4 Hz, 3a-H), 3.07 (1H, dd, J_{3-3a}=11.4 and J_{3-2}=6.0 Hz, 3-H), 3.75 (3H, s, COOMe), 3.99 (1H, d, J_{9b-3a}=11.4 Hz, 9b-H), 4.12 (1H, d, J_{2-3}=6.0 Hz, 2-H), 4.19 (1H, dd, J_{gem}=9.9 and J_{4-3a}=11.4 Hz, one of 4-H), 4.64 (1H, dd, J_{gem}=9.9 and J_{4-3a}=4.4 Hz, the other of 4-H), 5.08 (1H, m, *i*-Pr), and 6.8—7.4 (4H, m, Ar); MS m/z (rel intenity, %) 333 (M^+, 9), 290 (40), 246 (base peak), 214 (20), 187 (22), 186 (54), 161 (20), 131 (42), and 115 (24). HRMS Found: m/z 333.1573. Calcd for $C_{18}H_{23}NO_5$: M, 333.1575.

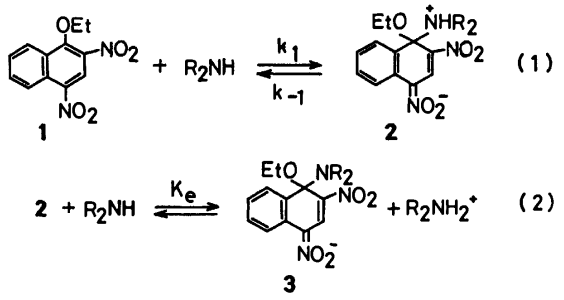
Stopped-Flow Kinetics of Reactions of 1-Ethoxy-2,4-dinitronaphthalene with Pyrrolidine and Piperidine in Dimethyl Sulfoxide Solution[1)]

Hajime FUJINUMA, Masaru HOSOKAWA, Tohru SUZUKI, Mitsuo SATO, and Shizen SEKIGUCHI*
Department of Synthetic Chemistry, Gunma University, Ten-jin cho, Kiryu, Gunma 376
(Received December 3, 1988)

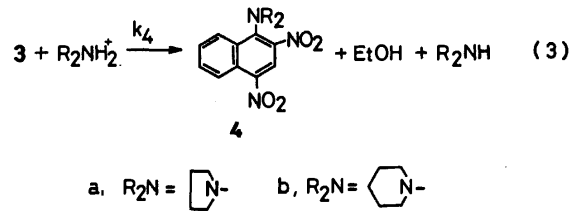
The reaction of 1-ethoxy-2,4-dinitronaphthalene (**1**) with pyrrolidine or piperidine in dimethyl sulfoxide occured in two stages (Stages I and II). In the stage I, a σ-adduct forms at such a rate as is measured by a stopped-flow technique, and in the stage II it decays at a slower and spectrophotometrically measurable rate. The pyrrolidine system is more reactive than the piperidine system in the stages I and II, with the former reactivity in the stage II being ca. 11000 times higher than the latter. This huge difference was found by NMR evidence to stem from the structure of transition state in the stage II. Further, the activation parameters were determined, which corresponded to such difference in reactivity very well.

Previously we carried out the kinetics of the reaction of 1-ethoxy-2,4-dinitronaphthalene (**1**) with pyrrolidine or piperidine in dimethyl sulfoxide (DMSO) and determined the reaction sequence (Scheme 1).[2)] The

Stage I



Stage II



Scheme 1.

reaction occurs in two distinct stages (Stages I and II), in which the stage I is relatively fast and the stage II is slow. As the k_4 stage is rate-determining as shown in Table 5 and general acid catalyzed,[2)] the present reaction can be considered to proceed via the SB-GA (special base [R_2NH]-general acid [$R_2NH_2^+$] catalysis) mechanism.[3,4)] Several aromatic nucleophilic substitution reactions (S_NAr) via the SB-GA mechanism have been observed[5-8)] since Orvik and Bunnett[9)] confirmed the SB-GA mechanism in the reaction of **1** with butylamine and *t*-butylamine in DMSO. In this paper we determined the activation parameters of the reaction in Scheme 1 and reconsidered such huge difference in the k_4 step between the pyrrolidine and piperidine systems [k_4(pyrrolidine)/k_4(piperidine)= ca. 11000], using ^{1}H NMR evidence.

Results

General Features. Upon addition of excess piperidine to a DMSO solution of in the presence of piperidinium chloride, the solution instantly turned red, indicating the formation of a σ adduct, which corresponded to the first spectral change from curve a, attributable to **1**, to curve b, attributable to **3b** (Fig. 1).[2,9-11)] The second spectral change of curve b → c → d → e was much slower, in which curve e was attributable to **4b** (NR_2=$C_5H_{10}N$).

Therefore, the reaction consists of the I and II stages: the stage I is the fast formation of **3** (Eqs. 1 and 2) and the stage II is the relatively slow decomposition of **3**, giving **4**.

Stage I Kinetics. Let us rewrite Scheme 1 in a fashion more useful for the derivation of rate equations as Scheme 2. Under the conditions studied, the reaction occurs rapidly to establish the equilibrium between **1** and **3** (Fig. 1 and Eqs. 4 and 5).

$$1 + R_2NH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2, \qquad (4)$$

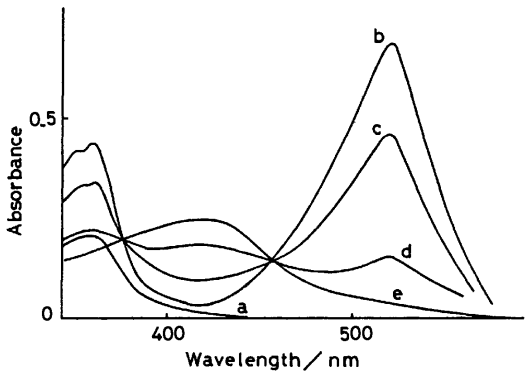


Fig. 1. Time-dependent absorption spectra relevant to the reaction of 1-ethoxy-2,4-dinitronaphthalene (**1**, 2.87×10^{-5}M) with piperidine (1.01 M) in the presence of piperidinium chloride (8.08×10^{-2}) in DMSO at 25 °C: a **1** before addition of piperidine; b, c, d, and e immediately, 60, 240, and 1200 min, respectively, after addition of piperidine.

$$2 + R_2NH \overset{K_e}{\rightleftharpoons} 3 + R_2\overset{+}{N}H_2, \quad (5)$$

$$3 + R_2\overset{+}{N}H_2 \overset{k_4}{\rightleftharpoons} 4 + C_2H_5OH + R_2NH, \quad (6)$$

Scheme 2.

Accordingly the pseudo-first-order rate constant (k_ψ) for attainment of the equilibrium is the sum of those for the foward and reverse reactions, and Eq. 7 holds (see the reference[12] about its derivation).

$$k_\psi = k_1[R_2NH] + \frac{k_{-1}[R_2\overset{+}{N}H_2]}{K_e[R_2NH]} \quad (7)$$

Multiplying each side by [R_2NH],

$$k_\psi[R_2NH] = k_1[R_2NH]^2 + \frac{k_{-1}}{k_e}[R_2\overset{+}{N}H_2]. \quad (8)$$

This kinetic measurements on the stage I were shown in Tables 1 and 2, and a linear plot of $k_\psi[R_2NH]$ against $[R_2NH]^2$, at constant piperidinium chloride concentration, is compatible with Eq. 8 (Fig. 2). From the slope and intercept, k_1 and k_{-1}/K_e can be obtained. The similar relationship was obtained for the pyrrolidine system too (not shown).

As a result, one can evaluate the equilibrium constant, K_i, for the overall stage I by using k_1 and k_{-1}/K_e [$K_i = k_1/(k_{-1}/K_e)$].

The best K_i value, however, was determined as follows: the K_i value derived from the stage I kinetics was put into the rate equation for the stage II (Eq. 9) as an initial value and its best value was evaluated by using a nonlinear least squares method (refer to the next paragraph about the detailed procedure). From the best K_i value and the k_1 values, obtained accurately from the slope in a plot of $k_\psi[R_2NH]$ vs. $[R_2NH]^2$, k_{-1}/K_e was recalculated. These values are summarized in Table 5 together with the activation and thermodynamic parameters obtained from the temperature-dependence of these constants. The calculated k_ψ values, obtained by using these k_1 and k_{-1}/K_e, are in good agreement with the observed k_ψ values (Table 1 and 2).

a) $[\mathbf{1}]_0$ ca. 5.0×10^{-5} M; $[C_5H_{10}\overset{+}{N}H_2Cl^-]_0$ 8.00×10^{-2} M; measurement at 522 nm; all k_{obsd} are average of duplicate runs, differing by <2%. b) Calculated by substituting the k_4 and K_i values in Table 5 into Eq. 9.

chloride concentrations (Tables 3 and 4), and involves K_i, mentioned in the preceding paragraph.

The best K_i and k_4 values were determined as follows: first, the K_i values, derived from the stage I kinetics, were used to calculate k_4, that is, for pyrrolidine K_i=1.32, 0.53, and 0.35, and for piperidine 0.77, 0.33_8 and 0.35 M^{-1} (M=mol dm^{-3}, and so forth) at 35, 45, and 50 °C, respectively; second, by substituting these K_i values and the experimental values ([R_2NH], k_{obsd}, and [R_2NH_2Cl]) of the top line at each temperature in Tables 3 and 4 into Eq. 9, the following k_4 values were calculated, that is, for pyrrolidine 33.4, 69.6, and 94.6, and for piperidine 4.07×10^{-3}, 11.1×10^{-3}, and 18.1×10^{-3} $M^{-1}s^{-1}$ at 35, 45, and 50 °C, respectively; third, by substituting these K_i and k_4 values into Eq. 9 as initial values and using a nonlinear least squares method (Gauss-Newton method), the best K_i and k_4 values were obtained, which are listed in Table 5. The k_{-1}/K_e values in Table 5 were calculated, therefore, by using these K_i values and the k_1 ones (obtained in the stage I kinetics).

Agreement between observed and calculated k_{obsd}, derived by substituting the K_i and k_4 values into Eq. 9, was found to be fairly good (Tables 3 and 4).

Equation 9 is converted to Eq. 10 by rearranging and taking logarithms. To check the validity of Eq. 10, we plotted the quantity on the left side against that on the right side of Eq. 10 by using the pyrrolidine or piperidine concentrations, and the K_i and k_4 values in Table 5 (Fig. 3). The slopes are 1.99 ± 0.02,

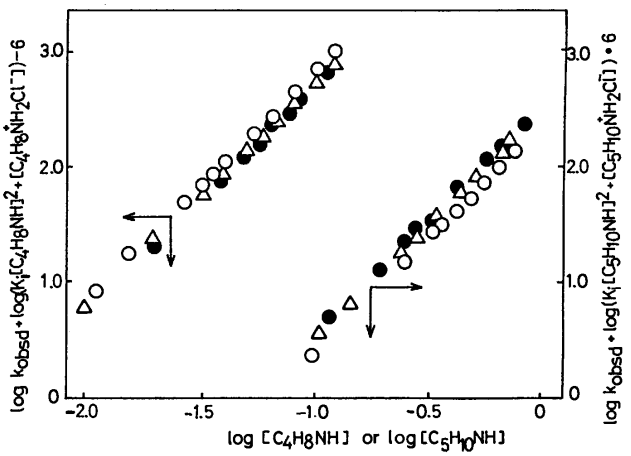

Fig. 3. Relationships between $\log k_{obsd}+\log(K_i[C_4H_8NH]^2+[C_4H_8\overset{+}{N}H_2Cl^-])-6$ and $\log[C_4H_8NH]$, and between $\log k_{obsd}+\log(K_i[C_5H_{10}NH]+[C_5H_{10}\overset{+}{N}H_2Cl^-])+6$ and $\log[C_5H_{10}NH]$ (Stage II).

Table 5. Summary of Rate Constants, Equilibrium Coefficients, Activation and Thermodynamic Parameters

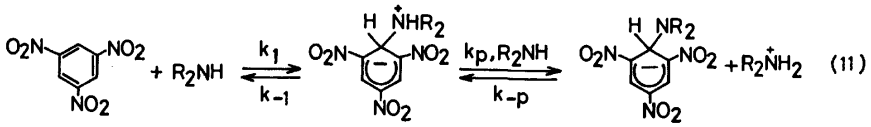
a) Units of $\Delta H^{\ddagger}$, ΔH^0, $\Delta G^{\ddagger}$, and ΔG^0(25 °C) are $kcal_{th}$ dm^{-3};units of $\Delta S^{\ddagger}$ and ΔS^0 (25 °C) are cal_{th} K^{-1} dm^{-3}. b) Cited from the Ref. 2. These values are almost the same as those in the present reaction, differing by <3.0%.



Scheme 2.

1.96±0.01, and 2.00±0.01 for pyrrolidine, and 2.00±0.01, 2.01±0.01, and 2.00±0.01 for piperidine at 35, 45, and 50 °C, indicating the validity of Eq. 10.

$$\log k_{obsd} + \log (K_1[R_2NH]^2 + [R_2\overset{+}{N}H_2]) = \log k_4K_i + 2\log[R_2NH] + \log[R_2\overset{+}{N}H_2] \quad (10)$$

Discussion

Stage I. Rate and Equilibrium Constants. The pyrrolidine system is a little more reactive than the piperidine one at the k_1 step, depending on $\Delta H^{\neq}$ rather than on $\Delta S^{\neq}$ (Table 5). Further, much more difference is seen between the $\Delta S^{\neq}$ values than between the $\Delta H^{\neq}$ ones, although difference between the $\Delta G^{\neq}$ values is much less, which could arise from the steric or stereoelectronic origin, as discussed in the later paragraph, by considering similar properties for these two amines, such as their pK_a values.[2,15] For the nucleophilic attack of pyrrolidine on **1**, electron delocalization would be considered to be somewhat larger between the unshared electron on the nitrogen atom of pyrrolidinyl group and the naphthalene moiety (**1**) than that for piperidine,[2] which would increase, to a larger extent, the repulsion between α-methylene group of the pyrrolidinyl ring and 2-nitro group of **1** (refer to later discussion).

The pyrrolidine/piperidine reactivity ratios at the step are 2.7, 2.3, 2.0, and 1.9 at 25, 35, 45, and 50 °C, respectively, which are close to the corresponding ratios in K_i, overall stage I equilibrium constant: 2.2, 2.1, 1.8, and 1.9 at 25, 35, 45, and 50 °C, respectively. These results naturally stems from the similar k_{-1}/K_e values for the two amine systems. The present kinetics can not tell whether these values (k_{-1}/K_e) arise from each almost same k_{-1} and K_e values or from appropriate balance of their different ones for the two amines (see the next paragraph).

Proton Transfer in K_e Step. The results in Tables 1—4 are fairly consistent with the reaction sequence in Scheme 1. It is well-known, however, that whether the K_e step is a fast mobile equilibrium or a proton transfer is sophisticated or controvertial.[3,4,10,11] A relatively slow proton-transfer reaction has been found in the reactions of methyl 4-methoxy-3,5-dinitrobenzoate with pyrrolidine[5] or butylamine[6] in DMSO, of 1-ethoxy-2,4,6-trinitrobenzene with butylamine,[7] and of 1-phenoxy-2,4-dinitro- and 1-phenoxy-6-methyl-2,4-dinitrobenzene with pyrrolidine and piperidine in 60% dioxane-40% water,[8] from which it is evident that in the case of secondary amines a proton transfer is relatively slow on account of steric effects.

In addition, Bernasconi et al.[13] and Crampton and Greenhalgh[14] determined the rate and equilibrium constants for the reactions of 1,3,5-trinitrobenzene (**5**) with pyrrolidine and piperidine in 30% DMSO-70% water[13] (hereafter abbreviated to DMSO-water) or in DMSO[14] (Scheme 2). From these results k_p and k_{-p} are as follows: k_1 ($M^{-1}\,s^{-1}$), k_{-1} ($M^{-1}\,s^{-1}$), k_p ($M^{-1}\,s^{-1}$), k_{-p}, ($M^{-1}\,s^{-1}$), K_p and K (M^{-1}, overall equilibrium constant) are 9.00×10^3, 6.2×10^5, 1.7×10^7, 5.1×10^4, 3.3×10^2, and 4.7 for the pyrrolidine system and 4.10×10^3, 1.0×10^6, 1.6×10^7, 3.9×10^4, 4.1×10^2, and 1.2 for the piperidine system at 20 °C in 30% DMSO-70% water, whereas 7.5×10^5, 1.0×10^5, 1.5×10^6, 3.0×10^3, 500, and 3.5×10^3 for the pyrrolidine system and $>2\times10^5$, $>1.44\times10^4$, 1.4×10^5, 2.8×10^2, 500, and 2.14×10^3 for the piperidine system at 25 °C in DMSO.

As a result, k_{-1}/K_p, corresponding to k_{-1}/K_e in the present reaction, is calculated to be 1.9×10^3 and $2.4\times10^3\ s^{-1}$ in DMSO-water, and 2×10^2 and $>2.9\times10^{-1}\ s^{-1}$ in DMSO for pyrrolidine and piperidine respectively, in which $(k_{-1}/K_p)_{pyr}/(k_{-1}/K_p)_{pip}$ is 0.8 in DMSO-water and ca. 6.8 in DMSO. The one thing to be commented at this point is that the K_p values in DMSO are presumed ones (see the reference[14] for the details), and therefore a little uncertain. By considering these results, our ratio, mentioned just above, is 1.2, which can be believed to be similar to their values,[13,14] although their magnitudes are reversed or different, probably depending on solvent compositions and structures of substrates.

In addition, we assumed that K_e step is an equilibrium. In some reactions,[5,7,8,13,14] however, rate-limiting or partly rate-limiting proton transfer has been advocated, which can be estimated from the effect of added bases, such as DABCO (1,4-diazabicyclo-[2.2.2]octane), on k_ψ. In the preliminary experiment, we found that in the presence of **1** (2.46×10^{-5} M) and pyrrolidine (2.15×10^{-2} M) k_ψ changed from 10.3±0.5 to 12.5±0.3 s^{-1} at [DABCO]=1.90×10^{-2} to 1.90×10^{-1} M (10-fold change), whereas in the presence of **1** (2.46×10^{-5} M) and piperidine (3.95×10^{-1} M) k_ψ changed from 3.13±0.61 to 3.62±0.116 s^{-1} at [DABCO]=1.40×10^{-2} to 1.76×10^{-1} M (ca. 17-fold change). An increase in k_ψ is 21% for the former and 15.6% for the latter, which is much less than those found already.[5,7,8,13,14] These results indicates that pK_a of **2** is less than that of **6** partly due to an electron-withdrawing character of the ethoxyl group. It would be reasonable, therefore, that the K_e step is

treated as an equilibrium.

Huge Difference in Reactivities of Stage II. It was already described that pyrrolidinium or piperidinium ion catalyzes the explusion of ethoxide ion from **3** (general acid catalysis).[2] Huge difference in k_4 at 25 °C corresponds to $\Delta\Delta G^{\ddagger}$ of 5.6 kcal mol^{-1} (1 cal_{th}=4.184 J) (Table 5). In view of the similarity of the two amines in the stage I behavior and their pK_a [11.27 (H_2O)[15] and 11.42% (30% DMSO-70% water)[13] for pyrrolidine; 11.22 (H_2O)[15] and 11.42 (30% DMSO-70% water)[13] for piperidine] this huge difference is very surprising. We concluded by examination of Dreiding models that some steric, stereoelectronic or conformational effect concerning the carbon-bound amino moiety in the transition state for the k_4 step is the source of this huge stage II reactivity difference [about detailed discussion, refer to the reference[2]].

We have recnetly found the NMR evidence supporting the discussion described just above (Fig. 4).

Interestingly the signal pattern of aromatic protons of 1-dimethylamino-2,4-dinitronaphthalene (**4c**), in which the singlet at δ 8.81 and the multiplets centered at ca. δ 8.68 and ca. δ 7.88 are attributed to H^3, $H^{5,8}$, $H^{6,7}$ respectively, was found to be similar to those of 1-diethylamino- (**4d**), 1-(*N*-methylbutylamino)- (**4e**), and **4b** (about numbering of protons see Fig. 5A). The pattern (Fig. 4C) was obtained in 64 days after piperidine (3 equivalents) were added into a DMSO-d_6 solution of **4b** (NR_2; piperidino). The downfield shift of H^3 singlet of **4b** from δ 8.63 to 9.30 is characteristic for its conversion to an adduct.[10] The signal pattern of **4a** is similar, if anything, to 1,1-dipiperidino-substituted 2,4-dinitronaphthalene anionic σ complex, in which the NR_2 (piperidino) group is substituted in place of the ethoxyl group in **3**, that is, two piperidino groups are attached to C_1. These results show that in the case of **4a** such conjugation as **4** (Fig. 5A) is larger than in the case of **4b** and **4c—d**, suggesting comparatively small steric interaction between α-methylene group of the pyrrolidinyl ring and 2-nitro group. This implies that when the ethoxyl group is expelled from **3** (k_4 step), the pyrrolidinyl ring can more easily keep its plane coplanar to the naphthalene moiety at a certain angle and that its unshared electron pair can assume a configuration antiperiplanar to the rupturing C-O bond with respect to the C_1-N (piperidino nitrogen) bond in the transition state (Fig. 5B). Although in this transition state the pyrrolidinyl ring is drawn as a plane, the conformation with C_2 symmetry is greatly preferred for substituted pyrrolidines.[17] Backside assistance of this electron pair to expulsion of the ethoxyl group would cause a huge increase in reactivity at the k_4 step for the pyrrolidine system.[16]

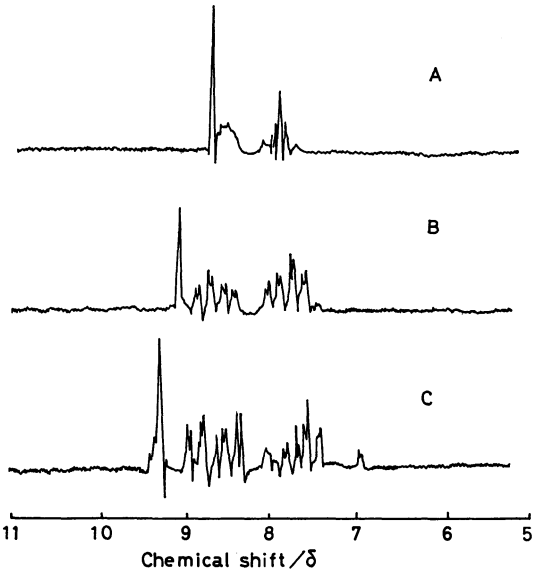


Fig. 4. ^{1}H NMR spectra for 1-dimethylamino- (**4c**, A), 1-pyrrolidino-2,4-dinitronaphthalene (**4a**, B), and 1,1-dipiperidino-substituted 2,4-dinitronaphthalene anionic a complex (C) in DMSO-d_6.

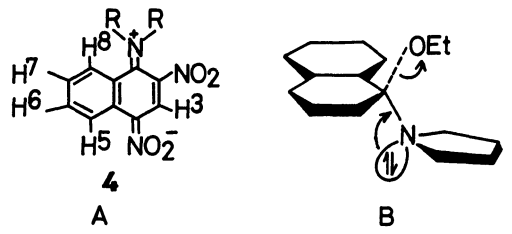

Fig. 5. Canonical structure of 1-(disubstituted amino)-2,4-dinitronaphthalene (A), and transition state at the k_4 step for the pyrrolidine system, in which 2- and 4-nitro groups are omitted for simplicity (B).

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer and UV-VIS absorption spectra on a Hitachi Model 200-10 spectrophotometer. All the melting points were uncorrected.

Materials. Dimethyl sulfoxide, pyrrolidine, piperidine, diethylamine, *N*-methylbutylamine were purified as previously described.[2] Commerical dimethylamine was used without further purification. Pyrrolidinium and piperidinium chloride, and 1-ethoxy-2,4-dinitronaphthalene (**1**) were prepared as previously described.[2]

1-(Disubstituted amino)-2,4-dinitronaphthalene (**4a—e**) were prepared from 1-chloro-2,4-dinitronaphthalenes and corresponding amine as previously described.[18] The yield was higher than 80% and the elemental analysis was within (calculated value ±0.3%) in each case. The physical properties were shown in the following except for **4b**.[18] All mp, λ, ε, and δ were in DMSO.

(1-Pyrrolidinyl)-2,4-dinitronaphthalene (4a): Mp 201.5—202 °C; λ_{438} (ε 2.1×10^4); ^{1}H NMR δ=1.93 [4H, m, NC_4H_8 (2β-CH_2)] and 3.73 [4H, t, NC_4H_8 (2α-CH_2)].

1-Dimethylamino-2,4-dinitronaphthalene (4c): Mp 87—87.5 °C; λ_{419} (ε 8.8×10^3); ^{1}H NMR δ=3.07 [6H, s, $N(CH_3)_2$], 7.87 (2H, m, $H^{6,7}$), 8.67 (1H, s, H^3), and 8.53 (2H, m, $H^{5,8}$).

1-Dimethylamino-2,4-dinitronaphthalene (4d): Mp 87.5—88.5 °C; λ_{430} (ε 1.5×10^4); ^{1}H NMR δ=1.13 [6H, t, $N(CH_2CH_3)_2$], 3.40 [(4H, q, $N(CH_2CH_3)_2$], 7.93 (2H, m, $H^{6,7}$), 8.67 (1H, s, H^3), and 8.53 (2H, m, $H^{5,8}$).

1-(*N*-Methylbutylamino)-2,4-dinitronaphthalene (4e): Mp 66—67 °C; λ_{425} (ε 7.4×10^3); ^{1}H NMR δ=0.80 [3H, t, $N(CH_2)_3CH_3$], 1.50 [4H, m, $N(CH_2)_3CH_3$ (β- and γ-CH_2)], 3.09 (3H, s, NCH_3), 3.21 [2H, t, $N(CH_2)_3CH_3$ (α-CH_2)], 7.95 (2H, M, $H^{6,7}$), 8.53 (2H, m, $H^{5,8}$), and 8.73 (1H, s, H^3).

Rate Measurement. As regards the kinetics of formation of σ adduct (**3**) (Stage I), an increase in the absorbance at 522 nm, due to **3** was followed in order to estimate the apparent first-order rate constant (k_ψ) with a thermostatted stopped-flow spectrophotometer (Otsuka Denshi Co.).[2] In order to estimate k_{obsd} (Stage II) a decrease in the absorbance at 522 nm was followed with a thermostatted Hitachi Model 200-10 spectrophotometer.[2]

Design of the Synthetic Route for Helical Peptides.[1] Synthesis and Solubility of Model Peptides Having a Helical Structure

Mitsuaki NARITA,* Yoshihisa KOJIMA, and Shizuko ISOKAWA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received December 6, 1988)

Fragment condensations between amino- and carboxyl-components of hydrophobic decapeptides, which have a β-sheet structure in the solid state and are insoluble in DMF, NMP, and DMSO, were examined in a mixture of CH_2Cl_2 and TFE (4/1, v/v) using various coupling reagents. By the use of DCC and HOBt as coupling reagents, the reaction proceeded smoothly in moderate yield to give eicosapeptides. These have a stable helical structure in the solid state and are easily soluble in a variety of organic solvents. The hydrophobic eicosapeptides obtained were subjected to a successive coupling reaction in CH_2Cl_2 alone to give helical tetracontapeptides in high yield, which also have high solubility in various organic solvents of low polarity. The solubility of hydrophobic helical peptides presents a solubility feature of helical peptides which are obtained as peptide intermediates in protein synthesis. The synthetic strategy for helical peptides and proteins is discussed in connection with the solubility prediction method.

One of the most serious obstacles in peptide and protein syntheses is the insolubility of protected peptides in organic solvents, which causes difficulty regarding successive reactions. In previous papers[2,3] we proposed the solubility prediction method for protected peptides and showed its usefulness for the design of synthetic routes for peptides and proteins. In this method, peptides which were to be made an object of the prediction were as long as or larger than an octapeptide. Solvents to be done were such as DMF, DMA, NMP, DMSO, and HMPA, which are commonly used for peptide and protein synthesis. Furthermore, the prediction method was practically based on the following four assumptions: (1) a tertiary peptide bond, such as an X-Pro, separates a peptide to peptide segments with respect to the peptide structure (peptide segment separation); (2) the insolubility of protected peptides is caused by a β-sheet aggregation consisting of peptide segments as long as or larger than an octa- or nonapeptide sequence; (3) peptides having helical and/or coiled structures have high solubility in organic solvents; and (4) the potential of peptide segments for a β-sheet formation is estimated using their average coil conformation $\langle P_c \rangle$ values when a peptide is smaller than the critical chain length for the development of a stable helix in the solid state.

In a solubility prediction for protected peptides,[2] the average coil conformation $\langle P_c \rangle$ value was practically applied to a whole peptide instead of a peptide segment, and the adequacy of the above assumptions was widely supported by the application of the solubility prediction method to various kinds of oligopeptides.[4-10] Especially, the potential of protected peptides for β-sheet formation was relevantly estimated using their $\langle P_c \rangle$ values rather than their average β-sheet conformation $\langle P_\beta \rangle$ values when they were smaller than the critical chain length for the development of a stable helix in the solid state. In agreement with the estimation, octa- to tetradecapeptides having a high potential for a helix formation actually had a β-sheet structure in the solid state and were insoluble in DMF, DMA, NMP, DMSO, and HMPA. On the other hand, eicosapeptides having a high potential for helix formation were assumed to be larger than the critical size for the development of a stable helix in the solid state,[11] and were expected to be easily soluble in various organic solvents. Therefore, it is quite important how peptide intermediates larger than the critical chain length for the development of a stable helix in the solid state are prepared.

We recently found that a mixture of CH_2Cl_2 and a strong electron-acceptor solvent such as HFIP, TFE, or phenol have a high solubilizing potential for protected octa- to tetradecapeptides to be insoluble in DMF, DMA, NMP, DMSO, and HMPA.[12,13] This fact suggests that their fragment condensation in a mixture of CH_2Cl_2 and TFE is excellent for the preparation of peptide intermediates larger than the critical chain length for the development of a stable helix in the solid state. In the present study we practically examined fragment condensation between amino and carboxyl components of hydrophobic decapeptides in a mixture of CH_2Cl_2 and TFE (4/1, v/v) using various coupling reagents and demonstrated the usefulness of the mixture for fragment condensation. Here, we also discuss the solubility of helical peptides in organic solvents, and a synthetic strategy for helical peptides and proteins is proposed.

Results

Fragment Condensations between Amino and Carboxyl Components of Decapeptides. Two hydrophobic decapeptides (Boc-$Leu_2Ala_2Leu_6$-OBzl, **1** and Boc-$Leu_2Phe_2Leu_6$-OBzl, **2**) were prepared by the usual method, as shown in Scheme 1, and were used for the present study. Since they are smaller than the

critical chain length for the development of a stable helix in the solid state, they actually have a β-sheet structure in the solid state and are insoluble in DMF, NMP, and DMSO. Due to their insolubility in a mixture of MeOH and AcOH, the removal of their Bzl group was performed by hydrogenolysis in a mixture of HFIP and AcOH using Pd/C as a catalyst to give carboxyl components **1b** and **2b**. The liberation of their amino groups was carried out by treatment with TFA/anisole (9/1, v/v), followed by treatment with NMM to give amino components **1a** and **2a**. These products were used as amino and carboxyl components of decapeptides in order to prepare three eicosapeptides, **3—5**, as shown in Scheme 1. The amino and carboxyl components of decapeptides were also insoluble in DMF, NMP, and DMSO. Their fragment condensation in these solvents was difficult. On the other hand, they were readily soluble in a mixture of CH_2Cl_2 and TFE (4/1, v/v) and their fragment condensation proceeded smoothly in moderate yield using DCC and HOBt as coupling reagents. As a coupling reagent in the reaction of **2a** with **1b**, DCC was superior to EEDQ, DEPC, and DPPA, and the combination of DCC and HOBt gave the highest yield (Table 1).

Fragment Condensations between Amino and Carboxyl Components of Eicosapeptides. Eicosapeptides **3—5** were easily soluble in a variety of organic solvents, and the liberation of their amino groups was readily performed using the same method as described for the decapeptides to give amino components **3a—5a**. The removal of the Bzl group from the eicosapeptide **3** was also readily performed by hydrogenolysis in a mixture of MeOH and AcOH using Pd/C as a catalyst to give the carboxyl component **3b**. Successive fragment condensation between amino and carboxyl components of eicosapeptides were smoothly carried out in CH_2Cl_2 alone using DCC and HOBt as coupling reagents to produce the corresponding tetracontapeptides **6—8** in high yield (Scheme 1).

Table 1. Results of Fragment Condensation between Amino and Carboxyl Components of Decapeptides

Amino component	Carboxyl component (equivalent)	Coupling reagent (equivalent)	Product	Yield %

Conformations and Solubility Properties of the Peptides 1—8. The IR absorption spectra of decapeptides **1** and **2** in the solid state showed strong bands at 3280 cm^{-1} in the amide A region and at 1630 cm^{-1} in the amide I region, indicating a β-sheet structure in the solid state.[14] On the other hand, those of eicosapeptides **3**—**5** and tetracontapeptides **6**—**8** in the solid state showed strong bands at 3330—3320 cm^{-1} in the amide A region and at 1660—1650 cm^{-1} in the amide I region, indicating a helical structure in the solid state.[14]

Table 2 shows the solubility properties of peptides **1**—**8** in a variety of organic solvents. As expected from their conformations, decapeptides **1** and **2**, having a β-sheet structure, were practically insoluble in various organic solvents, while eicosapeptides **3**—**5** and tetracontapeptides **6**—**8**, having a stable helix, were easily soluble in various organic solvents. As reported for octa- to tetradecapeptides having a β-sheet structure in the solid state,[12,13] decapeptides **1** and **2** were also easily soluble in mixtures of CH_2Cl_2 and TFE and of CH_2Cl_2 and HFIP since TFE and HFIP have a high potential for a β-sheet structure disruption due to their strong electron-accepting property. In fact, the IR absorption spectra of the amino and carboxyl components of decapeptides **1a** and **1b** in a mixture of CH_2Cl_2 and TFE showed a sharp, strong band around 1660 cm^{-1} in the amide I region, suggesting a large contribution of a helical or unordered structure and to be free from a β-sheet structure in the solution. Those of the amino and carboxyl components of eicosapeptides **3a** and **3b** in CH_2Cl_2 alone showed bands around 3320 cm^{-1} in the amide A region and around 1655 cm^{-1} in the amide I region, indicating that they have a stable helical structure in CH_2Cl_2.

Discussion

It was shown that the synthetic strategy used for the preparation of helical eicosa- and tetracontapeptides overcame the obstacle of the insolubility of peptide intermediates having a high potential for helix formation. A mixture of CH_2Cl_2 and TFE has a high solubilizing potential for decapeptides to be insoluble in highly polar solvents which are commonly used in peptide and protein syntheses. Fragment condensations between amino- and carboxyl-components of hydrophobic decapeptides in the mixture could be smoothly carried out using DCC and HOBt as coupling reagents. Although the yield was not so high due to the high nucleophilicity of TFE, as exhibited in peptide bond formation in TFE and HFIP,[15] the result indicates that the mixture was excellent for a coupling reaction between deca- to tetradecapeptides having a high potential for a helix formation. As expected from the solubility prediction method,[2] the eicosapeptides obtained were easily soluble in a variety of organic solvents (listed in Table 2). As a result, fragment condensation between eicosapeptides could be readily performed in CH_2Cl_2 alone to give the corresponding tetracontapeptides in high yield, indicating that peptides having a stable helical structure in the solid state can be coupled in CH_2Cl_2 to achieve further peptide chain elongation without any difficulty. Concerning the critical chain length of protected peptides for the development of a stable helix in the solid state, the solubility and conformational behavior of eicosapeptides **3**—**5** indicate that it is sufficient at an eicosapeptide level when protected peptides have a high potential for the formation of a helical structure.

Here, it becomes important to know how to estimate the helix-forming potential of protected peptides. In previous papers[16-18] we showed that the potential can be pertinently estimated using their average helix conformation $\langle P_\alpha \rangle$ values. In fact, $\langle P_\alpha \rangle$ and $\langle P_\beta \rangle$ values of protected peptides were useful for estimating their potential for the β-sheet $\rightarrow$ helix transformation with an increase in the peptide chain length or on the application of strong shear stress.

Both values were also useful for estimating the potential of protected peptides for a β-sheet structure-disruption by the adding of strong electron-acceptor solvents. The $\langle P_\alpha \rangle$ and $\langle P_\beta \rangle$ values of the decapeptide **1** are obtained by taking conformational parameters of P_α and P_β to be 1.36 and 1.17, respectively, and those of decapeptide **2** to be 1.30 and 1.23, respectively. Therefore, the amino and carboxyl components of decapeptides **1** and **2** are estimated to have high potentials for a helix formation and for a β-sheet-structure disruption by strong electron-acceptor solvents. In fact, the β-sheet structure of decapeptides **1a** and **1b** was disrupted in a mixture of CH_2Cl_2 and TFE, and fragment condensation between amino and carboxyl components of decapeptides proceeded smoothly in the mixture using DCC and HOBt as coupling reagents to give helical eicosapeptides in moderate yield. Although the $\langle P_\alpha \rangle$ and $\langle P_\beta \rangle$ values of protected peptides are useful for estimating their helix-forming potential, we should make an effort to establish how to estimate a helix-forming potential of protected peptides exactly, since the conformational behaviors of protected peptides must reflect the individuality of amino acid residues in protected peptides.[17]

With respect to the conformation and solubility of protected peptides, the results of the peptide solubility (shown in Table 2) strongly indicate the adequacy of the assumption in the solubility prediction method. The solubility behavior of the β-sheet-forming decapeptides was the same as that discussed before.[12,13] Furthermore, the solubility behavior of the helix-forming eicosapeptides was similar to that of Aib-containing oligoleucines,[8] which have a stable helix in the smaller peptide size due to a helix-promoting potential of Aib. Actually, hydrophobic eicosapeptides **3—5** were easily soluble in a variety of organic solvents. On the other hand, hydrophobic tetracontapeptides **6—8** were less soluble in highly polar solvents and easily soluble only in solvents of low polarity. Namely, the eicosapeptides were more easily soluble in DMF, NMP, EtOH, and MeOH than the tetracontapeptides. This can clearly be attributed to a large contribution of polar N- and C-termini of a helix to solvation of the eicosapeptides. The high solubilizing potential of HMPA for the hydrophobic tetracontapeptides may be due to the richness of hydrocarbon moieties in HMPA. For the same reason, the solubilizing potential of NMP is higher than that of DMF.

The solubility data of hydrophobic helical peptides illustrate a solubility feature of helical peptides which are obtained as peptide intermediates in protein synthesis. Especially, the solubility of the hydrophobic tetracontapeptides indicates that the solubility depends on the side chain moieties of the helix and that interactions between intermolecular side chain moieties are not strong, even at a tetracontapeptide level. The helical peptides obtained as peptide intermediates in protein synthesis contain various kinds of amino acid residues. Thus, they are probably easily soluble in a variety of organic solvents. The results in the present study strongly suggest that the synthetic strategy for helical peptides **3—8** is applicable to the synthesis of proteins which consist of a few long helical structures. *E. coli* acidic ribosomal protein L12[19] is presumed to be an example.

Experimental

General. Uncorrected capillary melting points will be reported. The optical rotations were taken in a 1 cm-path length cell on a JASCO model ORD/UV-5 optical rotatory dispersion recorder. The amino acid compositions of acid hydrolysates were determined with a Shimadzu HPLC LC-3A all amino acid analysis system. The acid hydrolyses of the peptides were carried out with propionic acid/12 M† HCl (2/1, v/v) for 2 days at 115 °C in evacuated sealed tubes. The IR spectra in the solid state were measured on KBr disks using a JASCO DS 403 G IR spectrophotometer. It was observed that shear stress on peptides examined here scarcely affected the IR spectra. The IR spectra in solution were recorded with a JEOL JIR-100 FTIR spectrophotometer by employing 0.1 mm path length cells with potassium bromide windows.

Preparation of Boc-Leu$_2$Ala$_2$Leu$_6$-OBzl 1 and Boc-Leu$_2$Phe$_2$Leu$_6$-OBzl 2. Boc-Leu$_2$Ala$_2$-OBzl, Boc-Leu$_2$-Phe$_2$-OBzl, and Boc-Leu$_3$-OBzl were prepared by the usual stepwise elongation under the conditions previously described.[4] The Bzl group of these peptides was removed by the usual hydrogenolysis using Pd/C as a catalyst to obtain Boc-Leu$_2$Ala$_2$-OH, Boc-Leu$_2$Phe$_2$-OH, and Boc-Leu$_3$-OH, respectively. Boc-Leu$_6$-OBzl was obtained by fragment condensation of H-Leu$_3$-OBzl (obtained from Boc-Leu$_3$-OBzl by treatment with 3 M HCl/AcOEt, followed by treatment with NMM) with Boc-Leu$_3$-OH in CH_2Cl_2 using DCC and HOBt as coupling reagents.

Boc-Leu$_6$-OBzl 15 g (16.9 mmol) was treated with TFA/anisole (4/1, v/v) (30 ml) at 0 °C for 2 h. Then, the mixture was concentrated in vacuo. The addition of a small portion of hexane to the mixture and its removal were repeated several times. DMF (65 ml) was added to the residue, and the mixture was poured into water (400 ml). The resulting precipitate was filtered, washed with water, and dried. Yield of TFA·H-Leu$_6$-OBzl was 14 g (91%). To NMP (200 ml) solution of TFA·H-Leu$_6$-OBzl, NMM (5 equiv) was added and the mixture was stirred for 10 min at room temperature. Then, the mixture was poured into water (700 ml), and the precipitate was filtered, washed with water, and dried. Yield of H-Leu$_6$-OBzl was 13 g (97%).

To the ice-chilled NMP (50 ml) solution of H-Leu$_6$-OBzl 4 g obtained above, Boc-Leu$_2$Ala$_2$-OH (1.5 equiv) and HOBt (1.5 equiv), was added DCC (1.5 equiv) and the mixture was stirred at 0 °C for 3 h and then at room temperature overnight. The mixture was poured into water and the precipitate was filtered, washed successively with 5% $NaHCO_3$ and water, and dried. The crude product was treated twice with refluxing methanol. Yield of **1**; 4.9 g (76%). mp 273.5—274.5 °C, $[\alpha]_D^{20}=-170°$ (c=1, in CH_2Cl_2-

† 1 M=1 mol dm^{-3}.

TFE(4/1, v/v)). Found: C, 62.18; H, 9.20; N, 11.02%. Calcd for $C_{66}H_{114}O_{13}N_{10}\cdot H_2O$: C, 62.24; H, 9.18; N, 11.00%. Amino acid analysis; Ala 2.00; Leu 8.13.

The peptide **2** was obtained by the same procedure as described above using Boc-Leu$_2$Phe$_2$-OH in place of Boc-Leu$_2$Ala$_2$-OH. Yield of **2**: 82%. mp>300 °C, $[\alpha]_D^{20}=-70°$ (c=1, in CH_2Cl_2-TFE(4/1, v/v)). Found: C, 65.70; H, 8.73; N, 9.86%. Calcd for $C_{78}H_{122}O_{13}N_{10}\cdot H_2O$: C, 65.70; H, 8.77; N, 9.82%. Amino acid analysis: Leu, 7.63; Phe, 2.00.

Preparation of H-Leu$_2$Ala$_2$Leu$_6$-OBzl 1a and H-Leu$_2$-Phe$_2$Leu$_6$-OBzl 2a. The peptide **1a** and **2a** were obtained from **1** and **2**, respectively, by their treatment with TFA/anisole (4/1, v/v) as described for preparation of H-Leu$_6$-OBzl. Yield of **1a**: 94%. Yield of **2a**: 94%.

Preparation of Boc-Leu$_2$Ala$_2$Leu$_6$-OH 1b and Boc-Leu$_2$Phe$_2$Leu$_6$-OH 2b. To the HFIP (5 ml) solution of **1** (1.5 g, 1.2 mmol) was added 10% Pd/C 0.15 g with acetic acid 3 ml and the mixture was stirred under hydrogen at atmospheric pressure for 3 days. After removing Pd/C by filtration and washing with a small amount of a mixture of HFIP and CH_2Cl_2, the joined filtrate and washings were poured into water (100 ml). The resulting precipitate was filtered, washed with water, and dried. Yield of **1b**: 1.35 g (97%). The peptide **2b** was prepared from **2** by the same procedure. Yield of **2b**: 99%.

Fragment Condensation between Amino and Carboxyl Components of Decapeptides. To the ice-chilled solution of an amino component decapeptide (**1a** or **2a**) 100 mg, a carboxyl component decapeptide (**1b** or **2b**) (3 equiv), and an additive (HOBt, HOSu, or HONB) (3 equiv) in CH_2Cl_2-TFE (4/1, v/v) (5 ml) was added DCC (3 equiv) with CH_2Cl_2-TFE (4/1, v/v) (5 ml). The mixture was stirred at 0 °C for 3 h and then at room temperature for 45 h. After removing *N,N*-dicyclohexylurea by filtration, the filtrate was concentrated in vacuo, and water (25 ml) was added to the residue. The resulting precipitate was filtered, washed successively with water, 10% citric acid, water, 5 % $NaHCO_3$, and water, and dried. The crude product was treated with refluxing dichloromethane (15 ml). After allowing the mixture to stand and cool to room temperature, the resulting precipitate was filtered off, and the filtrate was concentrated. The residue was treated with refluxing ethyl acetate (20 ml) in the same manner, and the product was obtained as a residue. A coupling reaction using EEDQ, DEPC, or DPPA was carried out essentially in the same manner as described above. Yields of the peptides **3**—**6** are listed in Table 1. Peptide **3**: mp>300 °C, $[\alpha]_D^{20}=-80°$ (c=1, in CH_2Cl_2). Found: C, 62.06; H, 9.02; N, 12.13%. Calcd for $C_{120}H_{212}O_{23}N_{20}\cdot H_2O$: C, 62.10; H, 9.29; N, 12.07%. Amino acid analysis: Ala, 4.00; Leu 15.70. Peptide **4**: mp>300 °C, $[\alpha]_D^{20}=0°$ (c=1, in CH_2Cl_2). Found: C, 62.89; H, 8.98; N, 11.30%. Calcd for $C_{132}H_{220}O_{23}N_{20}\cdot 3H_2O$: C, 63.18; H, 9.08; N, 11.16%. Amino acid analysis: Ala, 2.19; Leu 15.98; Phe, 2.00. Peptide **5**: mp>300 °C, $[\alpha]_D^{20}=0°$ (c=1, in CH_2Cl_2). Found: C, 64.37; H, 9.08; N, 11.30%. Calcd for $C_{132}H_{220}O_{23}N_{20}$: C, 64.10; H, 9.05; N, 11.33%. Amino acid analysis: Ala, 1.86; Leu, 16.01; Phe, 2.00.

Fragment Condensations between Amino and Carboxyl Components of Eicosapeptides. H-(Leu$_2$Ala$_2$Leu$_6$)$_2$-OBzl, H-Leu$_2$Phe$_2$Leu$_8$Ala$_2$Leu$_6$-OBzl, and H-Leu$_2$Ala$_2$Leu$_8$Phe$_2$-Leu$_6$-OBzl were prepared by the same procedure used for preparation of **1a** and **2a**, from the peptides **3**—**5** in 86, 80, and 89% yield, respectively. Boc-(Leu$_2$Ala$_2$Leu$_6$)$_2$-OH was also prepared from **3** by the usual hydrogenolysis in MeOH-AcOH in 93% yield.

To an ice-chilled solution of an amino component peptide 120 mg, Boc-(Leu$_2$Ala$_2$Leu$_6$)$_2$-OH (1.2 equiv), and HOBt (1.2 equiv) in CH_2Cl_2 (5 ml), was added DCC (1.2 equiv) with CH_2Cl_2 (3 ml), and the mixture was stirred at 0 °C for 3 h, and then at room temperature overnight. After the addition of a small amount of CH_2Cl_2, the mixture was filtered and the filtrate was concentrated in vacuo. The residue was washed successively with water, 10% citric acid, water, 5% $NaHCO_3$, and water, and dried. The crude product was treated with refluxing MeOH (20 ml). After standing, the mixture cooled to room temperature and the precipitate was filtered and recrystallized with ethyl acetate. Yields of the peptides **6**—**8** were 48, 60, and 54%, respectively. Peptide **6**: mp>300 °C, $[\alpha]_D^{20}=-40°$ (c=1, in CH_2Cl_2). Found: C, 61.07; H, 9.14; N, 12.02%. Calcd for $C_{228}H_{408}O_{43}N_{40}\cdot 5H_2O$: C, 61.02; H, 9.39; N, 12.48%. Amino acid analysis: Ala, 8.19; Leu, 32.00. Peptide **7**: mp>300 °C, $[\alpha]_D^{20}=0°$ (c=1, in CH_2Cl_2). Found: C, 62.41; H, 8.97; N, 11.71%. Stereochemistry of a Chiral Germyl Radical in the Reaction of Carbon Tetrachloride

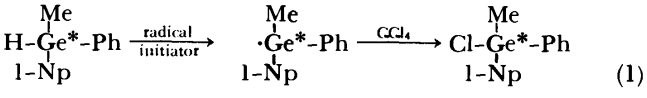
Kunio MOCHIDA,* Takato YAMAUCHI, and Hideki SAKURAI†
Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
†Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Sendai 980
(Received December 13, 1988)

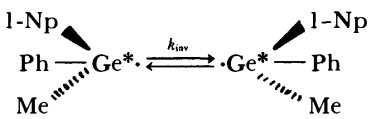
A chiral germyl radical produced from an optically active hydrogermane, 1-NpPhMeGe*H, abstracted a chlorine atom from CCl_4 to give the corresponding chlorogermane with retention of configuration. Progressive dilution of CCl_4 with cyclohexane demonstrated that the chiral germyl radical could also undergo inversion. A mechanism in which inversion of the chiral germyl radical competed with chlorine abstraction was proposed and the relative rate of chlorine abstraction to inversion (k_{Cl}/k_{inv}) of the chiral germyl radical was found to be (0.52±0.13) $mol^{-1}dm^3$ at 80 °C. The rate constant for the chlorine abstraction (k_{Cl}) by germyl radicals with CCl_4 was determined to be $(6.6\pm1.0)\times10^8$ $s^{-1}mol^{-1}dm^3$ by laser-photolysis experiments. By using this rate constant, the k_{inv} value for the chiral germyl radical was estimated to be ca. 2×10^9 s^{-1}.

In a former paper, we have reported that 1-naphthylphenylmethylgermyl radical, 1-NpPhMeGe*, produced from an optically active 1-NpPhMeGe*H undergoes chlorine abstraction mostly with retention of configuration.[1] Thus, the chiral germyl radical exists in a pyramidal form which is in harmony with ESR parameters[2-6] and IR data[7-10] of germyl radicals, and retains asymmetry for the abstraction of a chlorine atom with CCl_4.

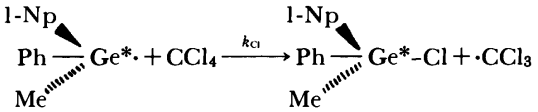


(1)

The inversion process of this germyl radical must be slow in comparison with the chlorine abstraction from CCl_4 since the germyl radical undergoes retention.



(2)



(3)

$$k_{inv} < k_{Cl}[CCl_4]$$

However, racemic or partially racemized products may be obtained from the chiral germyl radical, if product-forming chlorine abstraction is slow enough for the inversion process.

In this paper, we report the benzoyl peroxide (BPO)-catalyzed and uncatalyzed chlorination of optically active 1-NpPhMeGe*H with CCl_4 and the capacity of the chiral germyl radical produced from the optically active hydrogermane in the reaction (1) to invert under conditions of progressively greater dilution of CCl_4 with cyclohexane. Laser-photolysis studies of the photochemical primary processes of hydrogermanes are also described. A mechanism that induces inversion of the chiral germyl radical competes with chlorine abstraction is discussed, and the k_{inv} value for the chiral germyl radical is estimated by using the rate constant for chlorine abstraction, k_{Cl} obtained by laser-photolysis experiments.

Results and Discussion

BPO-Catalyzed Chlorination of an Optically Active Hydrogermane, (+)-1-NpPhMeGe*H. The reaction of (+)-1-NpPhMeGe*H (≡(+)-R_3Ge^*H), $[\alpha]_{589}$ +27.0± 0.9° (*c* 4.3, cyclohexane),[11] with CCl_4 diluted cyclohexane at various concentrations was carried out in sealed and degassed tubes using BPO as an initiator at 80 °C The optically active hydrogermane, (+)-R_3Ge^*H, afforded the corresponding chlorogermane quantitatively in all reactions. The products, obtained after evaporation of CCl_4 and cyclohexane followed by recrystallization from pentane, was identified by comparing IR and NMR spectra, and retention time on GLC (SE30 5% l m) with those of the racemic R_3Ge^*Cl compound. The results are summarized in Table 1. The (+)-R_3Ge^*H and (−)-R_3Ge^*Cl have the same stereochemical configuration, since optical rotation correlated with the configuration of the optically active hydrogermane, R_3Ge^*H, and the optically active chlorogermane, R_3Ge^*Cl.[12] Therefore, it can be concluded that the free-radical chlorination of the optically active hydrogermane, (+)-R_3Ge^*H, with CCl_4 without dilution should proceed with retention of configuration.

$$(+)\text{-}R_3Ge^*H \xrightarrow[\text{BPO, 80 °C}]{CCl_4} (-)\text{-}R_3Ge^*Cl \xrightarrow{LiAlH_4} (-)\text{-}R_3Ge^*H \quad (4)$$

$[\alpha]_{589}$+27.0± 0.9° $[\alpha]_{589}$−4.6±1.1° $[\alpha]_{589}$−17.8±1.2°

The optical purity of the product (−)-R_3Ge^*Cl, $[\alpha]_{589}$ −4.6±1.1° (*c* 3.9, cyclohexane)[12], was about 73%. Furthermore, (−)-R_3Ge^*Cl was converted to (−)-R_3Ge^*H, $[\alpha]_{589}$−17.8±1.2°, again by reduction with lithium aluminum hydride. Thus, the rate of abstraction of a chlorine atom from CCl_4 with the chiral germyl radical is fast in the reaction of the

Table 1. Effects of Cyclohexane Dilution on the Stereospecificity of Reaction of (+)-R_3Ge^*H with CCl_4 at 80 °C

Run	Reactant[a]			Reaction time/h	Product, R_3Ge^*Cl	
	(+)-R_3Ge^*H (mmol)	CCl_4 (mmol·dm^{-3})	BPO (mmol)		Yield/%[b]	$[\alpha]_{589}$
1	1.12	10.4	0.08	5	100	−4.6±1.1
2	1.21	8.17	0.06	5	100	−3.4±0.4
3	1.10	6.06	0.04	5	99	−2.0±0.5
4	1.08	0.90	0.04	5	95	0

a) A value of $[\alpha]_{589}$ of the (+)-R_3Ge^*H is $[\alpha]_{589}$+27.0±0.9°. b) Isolated yield.

optically active R_3Ge^*H with CCl_4. However, the optical purity of the product (−)-R_3Ge^*Cl was decreased as CCl_4 was diluted with cyclohexane as shown in Table 1. Thus, the rate of chlorine abstraction competes with the rate of inversion under conditions of dilution of CCl_4 with cyclohexane.

Optically active hydrosilanes[13,14] and hydrostannane[15] also react stereoselectively with CCl_4 to give the corresponding chlorides, respectively, with retention of configuration.

Uncatalyzed Chlorination of an Optically Active Hydrogermane, (+)-1-NpPhMeGe*H. The reaction of (+)-R_3Ge^*H, $[\alpha]_{589}$+27.0±0.9° (*c* 4.3, cyclohexane), with CCl_4 was carried out without any catalyst in a sealed and degassed tube at 80 °C for 5 h. The product, $[\alpha]_{589}$+11.9±1.0°, (*c* 4.3, cyclohexane), obtained after evaporation of CCl_4, contained unreacted hydrogermane. The conversion of the hydrogermane to the chlorogermane was determined to be 40% by GLC by an internal standard method. The (+)-R_3Ge^*H and (−)-R_3Ge^*Cl have the opposite optical rotation in spite of the same configuration.[12] The value of $[\alpha]_{589}$ of the product, a mixture of (+)-R_3Ge^*H and (−)-R_3Ge^*Cl, by accounting for the concentration of the unreacted optically active hydrogermane is estimated to be +20°, if all the chlorogermane racemizes completely. A test of the optical stability of the R_3Ge^*Cl will be discussed in the next section. From the observed $[\alpha]_{589}$ of the product, the value of the optical rotation of (−)-R_3Ge^*Cl produced in this uncatalyzed chlorination is estimated to be about −6.0°. Therefore, uncatalyzed chlorination of the optically active hydrogermane proceeded mostly with retention of configuration. Since the free-radical mechanism for uncatalyzed chlorination of hydrogermanes with CCl_4 has been established,[16] this result is consistent with that for BPO-catalyzed chlorination of the optically active hydrogermane.

A Test of the Optical Stability of a Chlorogermane, (+)-1-NpPhMeGe*Cl. The optical stability of (+)-R_3Ge^*Cl was investigated in CCl_4, cyclohexane, and $CHCl_3$ under the reaction conditions.

The optically active chlorogermane, (+)-R_3Ge^*Cl, $[\alpha]_{589}$+6.0±1.0° (*c* 4.3, cyclohexane), was heated in CCl_4 in a sealed and degassed tube at 80 °C for 5 h. The value of $[\alpha]_{589}$ of the optically active chlorogermane, (+)-R_3Ge^*Cl, recovered after evaporation of CCl_4 followed by recrystallization from pentane, was +6.0±1.0°. Therefore, no change in the optical purity was observed. Similarly, the optically active chlorogermane, (+)-R_3Ge^*Cl, was heated in both cyclohexane and $CHCl_3$ at 80 °C for 5 h. The optical purity of the chloride, (+)-R_3Ge^*Cl, was also unchanged within experimental error. Thus, the optically active chlorogermane, R_3Ge^*Cl, is configurationally stable in CCl_4, cyclohexane, and $CHCl_3$ under the reaction conditions.

Laser-Photolysis Study of a Hydrogermane, 1-NpPhMeGeH. Laser-photolysis (ca. 0.1 mol·dm^{-3}) in a mixture of benzene and di-*t*-butyl peroxide (DTBP) was carried out at 28.5±2 °C.[17] The laser-photolysis apparatus and measuring system were similar to those published elsewhere.[18] As expected, the rise of the absorption due to the germyl radical was observed in R_3GeH solution. As an example, the time dependence of the probe light intensity, $I(t)$, observed in the R_3GeH solution at 400 nm is shown by curve (a) in Fig. 1. This curve shows the initial rise and the following slow decay of $R_3Ge\cdot$. The time-resolved absorption spectrum corresponding to the rise of $R_3Ge\cdot$ was also measured. The spectrum observed at 50 and 150 ns after excitation of the R_3GeH solution is shown in Fig. 2. As shown in Fig. 2, the transient spectrum observed with the solution of R_3GeH has a peak at 390 nm.

As is shown by curve (a) in Fig. 1, the decay of $R_3Ge\cdot$ was found to be slow. In the presence of CCl_4, how-

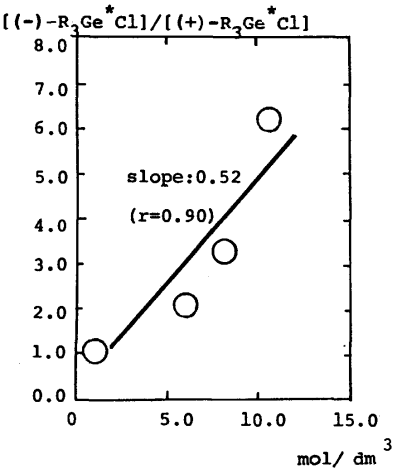

Fig. 3. Correlation between the product ratio and concentrations of CCl_4.

ever, the decay became fast. $R_3Ge\cdot$ was observed to decay with first-order kinetics in the presence of CCl_4, and the rate constant of chlorine abstraction (k_{Cl}) was obtained to be $(6.6\pm1.0)\times10^8$ s^{-1} mol^{-1} dm^3. The k_{Cl} value in a mixture of cyclohexane-DTBP was not changed within experimental error. Recently, Ingold and co-workers have also obtained a similar k_{Cl} value of $Bu_3Ge\cdot$ with CCl_4 using DTBP and an N_2 laser.[19]

Stereochemistry of a Chiral Germyl Radical in the Reaction with CCl_4. The chiral germyl radical produced from an optically active hydrogermane, (+)-R_3Ge^*H, abstracts a chlorine atom from CCl_4 to give the (−)-R_3Ge^*Cl predominantly with retention of configuration. However, the optical purity of the product, (−)R_3Ge^*Cl, decreased as the CCl_4 is diluted with cyclohexane. Since (−)-R_3Ge^*Cl is configurationally stable under these conditions, optically active chlorogermane was produced. Thus, the loss of optical activity in the product must be due to the fact that the rate of abstraction of a chlorine atom from CCl_4 diluted with cyclohexane may be comparable to the rate of inversion of the germyl radical.

Net stereochemistry of the chiral germyl radical with CCl_4 depends on relative rates of chlorine abstraction (k_{Cl}) and inversion (k_{inv}) as shown in the following scheme.

$$\begin{array}{ccccc} (+)\text{-}R_3Ge^*H & \rightarrow & (+)\text{-}R_3Ge^*\cdot & \underset{k_{inv}}{\rightleftharpoons} & (-)\text{-}R_3Ge^*\cdot \\ & & \downarrow{\scriptstyle k_{Cl}}\ CCl_4 & & \downarrow{\scriptstyle k_{Cl}}\ CCl_4 \\ & & (-)\text{-}R_3Ge^*Cl & & (+)\text{-}R_3Ge^*Cl \end{array} \quad \leftarrow (-)\text{-}R_3Ge^*H$$

From this scheme using the relevant rate constants shown above, the product ratio can be expressed by the formula

$$\frac{d[(-)\text{-}R_3Ge^*Cl]}{d[(+)\text{-}R_3Ge^*Cl]} = \frac{[(+)\text{-}R_3Ge^*\cdot]}{[(-)\text{-}R_3Ge^*\cdot]} \quad (5)$$

where [(+)-$R_3Ge^*\cdot$] and [(−)-$R_3Ge^*\cdot$] are the concentrations of each chiral germyl radical, respectively. The product ratio from (+)-R_3Ge^*H can be derived as following by assuming the steady state concentration of (−)-$R_3Ge^*\cdot$ radical.

$$d[(-)\text{-}R_3Ge^*\cdot]/dt = k_{inv}[(+)\text{-}R_3Ge^*\cdot] - k_{inv}[(-)\text{-}R_3Ge^*\cdot] - k_{Cl}[(-)\text{-}R_3Ge^*\cdot][CCl_4] = 0 \quad (6)$$

Combination of Eqs. 5 and 6 yields

$$[(-)\text{-}R_3Ge^*Cl]/[(+)\text{-}R_3Ge^*Cl] = 1 + (k_{Cl}/k_{inv})\times[CCl_4]. \quad (7)$$

Thus, the product ratio depends on the concentration of CCl_4.[20,21]

The relationship between the product ratio and concentrations of CCl_4 are shown in Fig. 3. The k_{Cl}/k_{inv} value was calculated to be (0.52±0.13) mol dm^3.

Taking the k_{Cl} value at 28.5 °C into consideration, it may be assumed that the k_{Cl} value at 80 °C for $R_3Ge^*\cdot$ is less than 1×10^9 s^{-1} mol^{-1} dm^3. Thus the k_{inv} value for $R_3Ge^*\cdot$ at 80 °C may be less than 2×10^9 s^{-1}. If we assume that inversion at the germanium center has a normal pre-exponential factor (i.e., ca. $10^{13.3}$ s^{-1}), it is possible to estimate the activation barrier for the inversion process as ca. 5.7 kcal·mol^{-1}. This value is almost the same as that of the silyl radical inversions previously reported.[22]

In conclusion, the rate of inversion of the chiral germyl radical is comparable to that of chlorine abstraction from CCl_4 and the remarkable configurational stability of the chiral germyl radical in the reaction resulted partly from the rapid chlorine abstraction.

Experimental

Polarimetric analyses of optically active organogermanium compounds were carried out on a Hitachi EPU-2A photoelectric Spectrometer. Laser-photolysis experiments were performed on degassed solutions using a Molectron UV-24 N_2 laser (337 nm, pulse width 10 ns) as an exciting light source.

Materials. Optically active 1-naphthylphenylmethylger-

mane, R_3Ge^*H, and 1-naphthylphenylmethylchlorogermane, R_3Ge^*Cl, were prepared according to the literature.[11,16] (+)-R_3Ge^*H, $[\alpha]_{589}$+27.0±0.9°, mp 74—75 °C; (−)-R_3Ge^*H, $[\alpha]_{589}$−26.6±0.9°, mp 74—75 °C. (+)-R_3Ge^*Cl, $[\alpha]_{589}$+6.0±1.0°, mp 67—69 °C.

Reaction of (+)-R_3Ge^*H with CCl_4 at Various Concentrations. A representative example is described. In a small Pyrex tube were placed 0.36 g (1.21 mmol) of (+)-R_3Ge^*H, $[\alpha]_{589}$+27.0±0.9°, 2.51 g (16.3 mmol) of CCl_4, and 0.02 g (0.06 mmol) of BPO. The reaction mixture was diluted with cyclohexane to 4.0 dm^3. The Pyrex tube was degassed, sealed and immersed in an oil bath kept at 80 °C for 5 h. After completion of the reaction, volatile materials were removed. The chlorogermane, $[\alpha]_{589}$−3.4±0.4°, was purified by recrystallization from pentane. The chlorogermane was identified by comparing IR and NMR spectra and the retention time on GLC (SE30 5% 1 m) with those of an authentic sample.

A Test of Optical Stability of (+)-R_3Ge^*Cl under the Reaction Conditions. In a small Pyrex tube were placed 0.40 g (1.22 mmol) of (+)-R_3Ge^*Cl, $[\alpha]_{589}$+6.0±1.0°, and 4.0 dm^3 of CCl_4. The tube was degassed, sealed and immersed in an oil bath kept at 80 °C for 5 h. After removal of CCl_4, the chlorogermane, $[\alpha]_{589}$=6.0±1.0° was recovered and purified by recrystallization from pentane.

The authors wish to thank Dr. Hisaharu Hayashi of the Institute of Physical and Chemical Research for measuring the laser-photolysis of the hydrogermanes. We also thank Professor Tadashi Suehiro of Gakushuin University for providing the Hitachi EPU-2A photoelectric Spectrometer and the Varian FT-80A NMR Spectrometer.

A New Method for Determination of Disulfide Pairing in Peptides†

Yuji HIDAKA and Yasutsugu SHIMONISHI*
Institute for Protein Research, Osaka University, Yamada-oka 3-2, Suita, Osaka 565
(Received December 21, 1988)

A new method was developed for determination of disulfide pairings in peptides. This method consisted in the synthesis of peptides with deuteriocysteine residues at given positions and the analysis of deuteriocystine generated in the acid hydrolyzates of the synthetic peptides by fast atom bombardment mass spectrometry. The availability of this method was confirmed by its application for determining the positions of disulfide linkages in a heat-stable enterotoxin of enterotoxigenic *Escherichia coli*.

Many biologically interesting peptides contain several Cys residues joined intramolecularly through disulfide bonds.[1-3] The roles of these disulfide linkages in the biological effects of these peptides are not yet clear, but these linkages are known to be important for stabilizing the native conformations of the peptides essential for expression of their biological activity.[4] The mismatching of disulfide pairs during construction of the spatial structure may change the native conformations of peptides and result in marked reduction or loss of their biological activities. Therefore, information on the disulfide pairing in peptides is very useful for understanding of the bioactive conformations of peptides, the mechanisms of a peptide-to-peptide or peptide-to-protein interaction, etc.

In general, the disulfide pairing of cystine residues in peptides is determined by isolation and sequencing of peptides containing cystine, which are generated by either partial acid or enzymatic hydrolysis of the original peptides.[1] Recently a method was reported for measurement of the molecular weights of peptides containing cystine, by direct analysis of the enzymatic digest of peptides by FAB mass spectrometry, resulting in determination of disulfide pairing in the original peptides.[5] These methods are useful for determination of disulfide pairing in peptides that contain Cys residues at interspersed positions in the peptide chain and that release peptides containing cystine with one disulfide linkage, but they are not suitable for peptides in which Cys residues are located in vicinal positions in the peptide chain and from which peptides containing cystines with multiple-disulfide linkages are generated by hydrolysis, because of the difficulty in cleaving peptide bonds between vicinal Cys residues. Another method to determine disulfide pairing in peptides is synthesis of peptides with disulfide linkages at given positions using selectively removable protecting groups at Cys residues and then comparison of the synthetic peptides with the natural one.[6,7] However, this method is very tedious and time-consuming, because peptides with all possible disulfide pairings must be synthesized for comparison with the natural peptide. Furthermore disulfide exchange reaction may occur under the experimental conditions used.

In this paper, we report a new method for determining disulfide pairing in a peptide by synthesizing a peptide with the same sequence as that of the natural peptide but with deuterio-Cys residues and then analyzing hydrolyzates of the peptide by FAB mass spec-

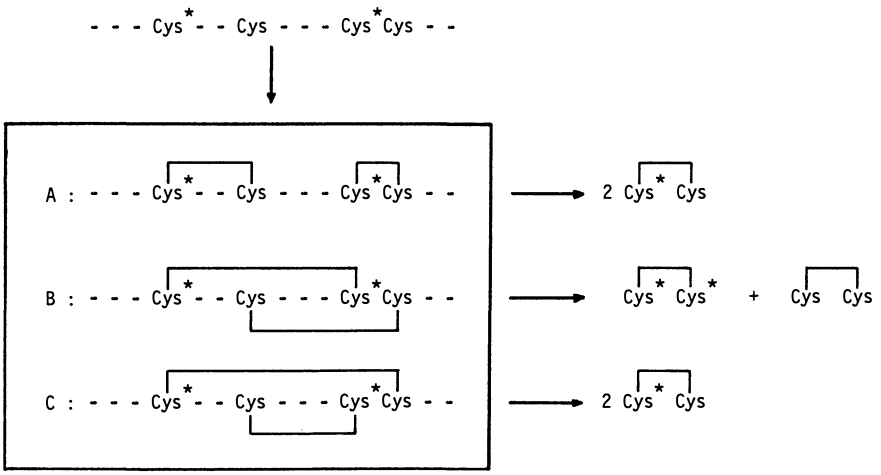

Fig. 1. Strategy for determination of disulfide pairings in a peptide.

† We dedicate this paper to Professor Haruaki Yajima on the occation of his retirerment from Kyoto University.

trometry. The application of this method to confirm the positions of disulfide bonds that were previously determined by chemical synthesis[7] in a heat-stable enterotoxin produced by enterotoxigenic *Escherichia coli*[8] is also described.

Method

The strategy of the present method is as follows: A protected peptide with deuterio-Cys residues (denoted as Cys* in this paper) at given positions is first synthesized by a solid-phase or solution method, and after removal of the protecting groups, the resulting peptide is oxidized to form intramolecular disulfide linkages between Cys residues, as shown in Fig. 1. The oxidized peptide is then purified by HPLC to isolate the fraction with the same retention time on HPLC as that of its corresponding natural or standard peptide, which has one of the possible disulfide pairings shown in Fig. 1. The purified peptide is then hydrolyzed to constituent amino acids including cystine in acidic medium. If no disulfide-exchange reaction occurs during this hydrolysis, the hydrolyzate contains one kind of cystine (Cys*,Cys) from peptide A or C and two kinds of cystines ((Cys)$_2$ and (Cys*)$_2$) from peptide B. In the case of deuterio-Cys (Cys*) in which two hydrogens are replaced by two deuteriums, the three kinds of cystines should have the theoretical mass spectra shown in Fig. 2. The hydrolyzate from peptide B, consisting of two kinds of cystines ((Cys)$_2$ and (Cys*)$_2$) should show the mass spectrum of a mixture of equal amounts of these two cystines, whereas the hydrolyzates of peptides A or C should

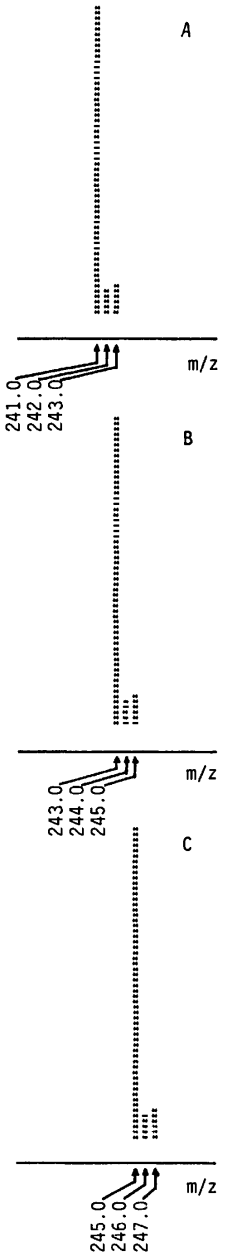

Fig. 2. Theoretical molecular ion distribution of A) (Cys)$_2$, B) (Cys*, Cys), and C) (Cys*)$_2$ (two hydrogens are replaced by two deuteriums in Cys*).

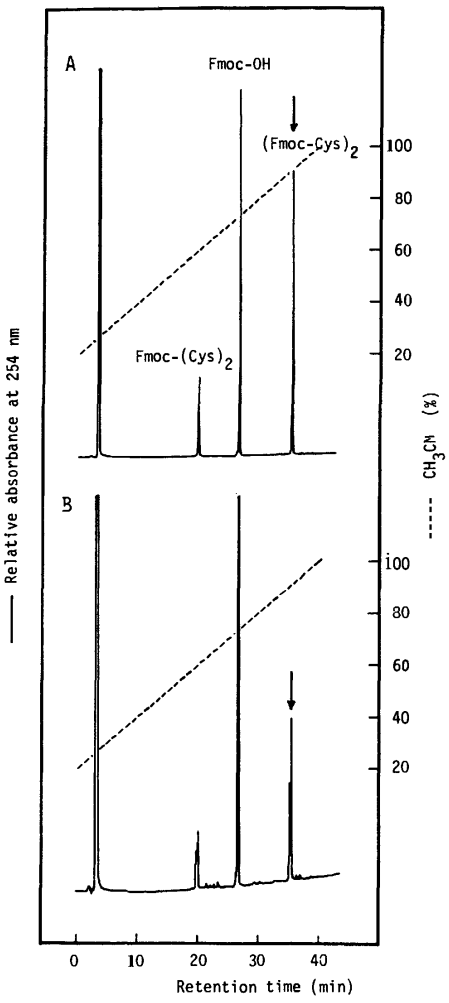

Fig. 3. HPLC profiles of the reaction products of cystine with Fmoc-Cl on a reversed-phase column (Cosmosil C_{18}) with a linear gradient of CH_3CN in 0.05% TFA with increase of 2% min^{-1} at 30 °C: A) without previous treatment and B) after treatment with 5.7 M HCl at 110 °C for 24 h.

exhibit mass spectra consisting of Cys and Cys*. Thus, if the mass spectrum of the hydrolyzate can be measured with similar accuracy to that of the theoretical mass spectrum, the types of cystine present in the hydrolyzate, and so the disulfide pairing in a peptide can be determined. This method has the characteristics that only one kind of the protecting group is used for cysteine residues and disulfide linkages are formed simultaneously after removal of the protecting group but not stepwisely, whereas intermediates with fewer numbers of disulfide linkages than those of peptides should be purified and identified in the method for determination of disulfide pairings using selectively removable protecting groups.[6,7] This theoretical treatment can be extended to complex peptides containing more cystine residues than those in Fig. 1.

Results and Discussion

Detection of Cystine by Fast Atom Bombardment (FAB) Mass Spectrometry: For this strategy, we tried to find suitable conditions for analysis of cystine in hydrolyzates of peptides by FAB mass spectrometry. First we examined a mixture of amino acids including cystine instead of an acid hydrolyzate of a peptide by FAB mass spectrometry, because we considered that direct analysis of an acid hydrolyzate of a peptide was simple and time-saving. However, we could not detect signal of cystine with a satisfactory signal to noise ratio by mass spectrometry, because the signal intensity of cystine was much smaller than those of other amino acids.[9] Consistent with these findings, the hydrophobicity indices of amino acids[10] suggest that ionization of cystine is difficult in an amino acid mixture including amino acids with hydrophobic side chains. Therefore, we tried to compensate for the hydrophilic character of cystine by adding a substituent with a hydrophobic character to it. For this we treated the amino acid mixture with Fmoc-Cl, and then examined it by FAB mass spectrometry. However, we could not detect the signal of the reaction product of cystine in the FAB mass spectrum due to the intense noise signals derived from the excess reagents. Then, we tried to isolate the reaction product of cystine ((Fmoc-Cys)$_2$) from the reaction mixture and examined it alone by FAB mass spectrometry. Fmoc-amino acids are known to be easily

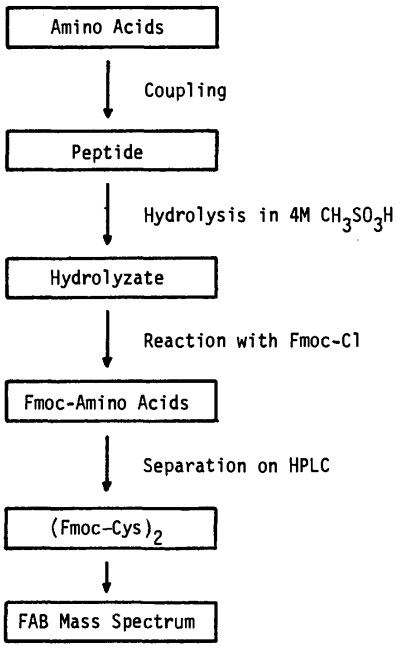

Fig. 6. Flow sheet for detection of cystine in a peptide.

separated by HPLC with a mixture of organic solvents and phosphate buffer as a mobile phase.[11] However, as solvent containing an inorganic salt is not suitable for mass measurement of amino acids and peptides,[12] we used volatile CH_3CN containing 0.05% aq TFA instead of the above mixture as a mobile phase for separation of $(Fmoc-Cys)_2$ from other Fmoc-amino acids by HPLC, as shown in Fig. 3. We found that the $(Fmoc-Cys)_2$ separated in this way could easily be detected in the FAB mass spectrum, as shown in Fig. 4A. These results indicated that cystine could be detected by FAB mass spectrometry of an acid hydrolyzate of a peptide that had been treated by the procedures as shown in Fig. 6.

Conditions for Reaction of Cystine with Fmoc-Cl: As shown in Fig. 4A, $(Fmoc-Cys)_2$ could easily be detected by FAB mass spectrometry. Then we examined the conditions for generating $(Fmoc-Cys)_2$ from cystine in satisfactory yield as a model of the reaction of the hydrolyzate of a peptide with Fmoc-Cl. The reaction was not completed at pH 6.8, but proceeded well at pH 7.8 in 1% aqueous ammonium hydrogen carbonate and $(Fmoc-Cys)_2$ was obtained mainly, as shown in Fig. 3A.

Differentiation of Cystine and Deuteriocystine by Mass Spectrometry: To determine whether cystine could be distinguished from deuteriocystine by mass spectrometry, we examined $(Fmoc-Cys)_2$ and its deuterio derivative ($(Fmoc-Cys^*)_2$), synthesized by the procedure described above, and their mixture by FAB mass spectrometry. In this experiment, we used 3,3,3′,3′-tetradeuteriocystine (denoted as cystine*), which was synthesized as a mixture of the (*S,S*)-, (*R,R*)-, and (*R,S*)-isomers by the procedure described below, as a deuteriocystine. Figures 4A—4C show the FAB mass spectra of $(Fmoc-Cys)_2$, $(Fmoc-Cys^*)_2$, and their mixture. Their mass distributions were very similar to the theoretical molecular ion distributions of these compounds (data not shown), indicating that cystine* can be distinguished from cystine and implying that (Fmoc-Cys, Fmoc-Cys*), which consists of half-cystine and half-deuteriocystine, gives signals between the mass values of Fmoc derivatives of cystine and cystine* and so can easily be distinguished from these cystines.

Conditions for Acid Hydrolysis of Peptides: Another important premise for the present approach was to find conditions for hydrolysis of a peptide without accompanying disproportionation of disulfide linkages. If a marked disulfide-exchange reaction takes place in this hydrolysis, determination of disulfide pairing in a peptide is impossible. For examination of this possibility, we used a model system in which cystine, cystine*, and their mixture were each treated under the usual conditions for acid hydrolysis of a peptide and allowed to react with Fmoc-Cl as described above. Cystine or cystine* treated with 5.7 M† HCl, 4 M CH_3SO_3H, or 4 M TFA at 110 °C for 24 h gave the same HPLC profile as that shown in Fig. 3B, in which the two peak fractions, indicated by arrows, contained $(Fmoc-Cys)_2$ and $(Fmoc-Cys^*)_2$, respectively, while the reaction product of cystine with Fmoc-Cl gave a single peak without prior acid treatment (Fig. 3A). The reason why after this treatment $(Fmoc-Cys)_2$ gave two peak fractions will be discussed later. These two peak fractions were isolated together and examined by FAB mass spectrometry. The reaction products from cystine and cystine* exhibited mass spectra with signals of monoisotope masses at m/z=685 and 689, respectively, with signals of isotope masses that were identical with those of cystine and cystine* without acid treatment, as shown in Figs. 4A and 4B, respectively.

On the other hand, when a mixture of equimolar amounts of cystine and cystine* was treated directly with Fmoc-Cl without previous acid treatment, it gave the mass spectrum shown in Fig. 5A, which was slightly different from that seen in Fig. 4C: the peak height of the ion signal at m/z=687 was slightly increased. The mass value of this ion signal was 2 amu more than that of $(Fmoc-Cys)_2$ (m/z=685) and 2 amu less than that of $(Fmoc-Cys^*)_2$ (m/z=689). This finding suggested that this ion signal was derived from (Fmoc-Cys, Fmoc-Cys*), which was formed by rearrangement of disulfide linkages of cystine and cystine* during the reaction with Fmoc-Cl and consisted of half-cystine and half-cystine*. The degree of this disulfide-exchange reaction was calculated by subtraction of the peak height of the isotope

† 1 M=1 mol dm^{-3}.

mass of (Fmoc-Cys)$_2$ at m/z=687 from the observed peak height at this mass value, as shown in Table 1.

When a mixture of equimolar amounts of cystine and cystine* was treated in 5.7 M HCl, 4 M CH_3SO_3H or 4 M TFA at 110 °C for 24 h and then with Fmoc-Cl, it showed the FAB mass spectra depicted in Figs. 5B—5D, respectively. The mass spectrum (Fig. 5B) of the mixture of cystine and cystine* treated with 5.7 M HCl differed from that seen in Fig. 5A in showing decreased intensities of the ion signals at m/z=685 and 689 and increased intensity of the ion signal at m/z=687. As most of the ion signal at m/z=687 was considered to be due to Fmoc-half-cystine and Fmoc-half-cystine* as described above, treatment of cystine with 5.7 M HCl was concluded to cause considerable rearrangement of its disulfide linkages. The degree of this disulfide-exchange reaction was estimated to be about 60% by a similar calculation to that described above (Table 1). On the contrary, treatment of the mixture of cystine and cystine* with 4 M CH_3SO_3H or 4 M TFA gave the similar mass spectra (Figs. 5C and 5D, respectively) to that without acid treatment seen in Fig. 5A. The amounts of the disulfide-exchange reaction during these treatments were estimated to be as shown in Table 1, suggesting that the disulfide pairings of cystine residues in a peptide were rearranged slightly, but not significantly, during treatment with 4 M CH_3SO_3H or 4 M TFA. The recoveries of amino acids from the hydrolyzate of a peptide with 4M CH_3SO_3H were excellent, but rather low with 4 M TFA (data not shown), indicating that the hydrolysis of a peptide with 4 M CH_3SO_3H is better than that with 4 M TFA. These results show that cystine can be recovered with slight disulfide disproportionation by hydrolysis of a peptide with 4 M CH_3SO_3H at 110 °C for 24 h, a treatment that is generally used for peptide hydrolysis.[13]

Racemization of Cystine in Acid Hydrolysis: When cystine was kept under the conditions for acid hydrolysis of a peptide and then treated with Fmoc-Cl, the reaction product gave two peak fractions, which were eluted very close to each other on HPLC, as shown in Fig. 3B, while a mixture of cystine with Fmoc-Cl gave only one peak fraction, as shown in Fig. 3A. Coelution of the reaction product (Fmoc-Cys)$_2$ in Fig. 3A with these two peak fractions indicated that the second of these two peak fractions was that of (Fmoc-Cys)$_2$. Moreover, these two peak fractions had the same molecular weight as that of (Fmoc- Cys)$_2$, as shown in Figs. 7A and 7B. These results suggested that cystine was partially racemized under the conditions for acid hydrolysis of a peptide, and that the first of these two peaks was that of the meso-isomer of cystine and that the second was that of the D- and L-isomers. This was confirmed by keeping cystine under the same conditions as those described above but in 5.7 M DCl in D_2O and then treating it with 1 M HCl to remove deuterium attached to amino and carboxyl groups. The resulting cystine gave a similar HPLC profile to that in Fig. 3B, but its mass spectrum showed increments of ion signals at mass values by 1 and 2 amu more than that of cystine at m/z=685, as shown in Fig. 7C. This finding indicates that cystine was deuterated at its α,α'-positions during incubation in acidic conditions; that is, cystine was racemized by replacement of protons on its 2,2′-carbons by deuterium from D_2O under the conditions for acid hydrolysis of a peptide. The degree of racemization was calculated to be about 40% from the mass distributions as shown in Figs. 7A and 7C.

Preparation of a Derivative of 3,3-Dideuteriocysteine for Peptide Synthesis: As described above, the protons on the 2,2′-carbons of cystine are replaced

Table 1. Interchange Reaction of the Disulfide Linkage in Cystine under Various Conditions for Acid Hydrolysis of Peptides

Acid	Reaction with Fmoc-Cl	Disulfide-exchange reaction (%)
–	+	4.8
5.7 M HCl	+	62.4
4 M CH_3SO_3H	+	14.0
4 M TFA	+	9.8

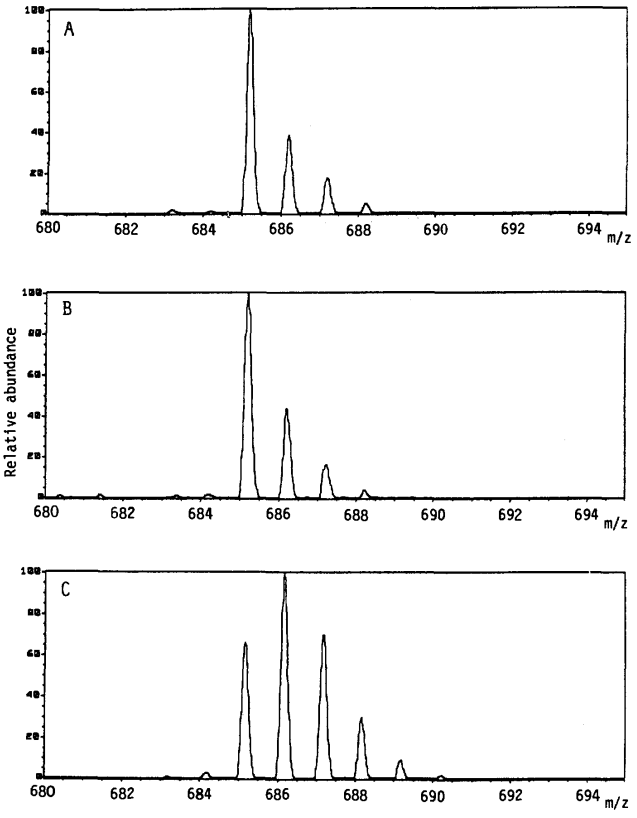

Fig. 7. FAB mass spectra: A) and B) peak fractions indicated by arrows in Figs. 3A and 3B, respectively, and C) (Fmoc-Cys)$_2$ prepared by treatment of cystine with 5.7 M DCl in D_2O at 110 °C for 24 h and with Fmoc-Cl.

by protons derived from a solvent during acid treatment, indicating that a deuteriocysteine with a deuterium substitution on its 2-carbon is not suitable for peptide synthesis by the present method. Moreover, with increase in the mass difference between cystine and deuteriocystine, differentiation of their mass spectra becomes easier. Therefore, we synthesized a cysteine derivative in which two deuteriums were incorporated at the 3,3-positions. The synthesis and use in a peptide of this compound have been reported,[14,15] but we synthesized a 3,3-dideuteriocysteine derivative, *N*-Boc-*S*-(4-methylbenzyl)-3,3-dideuterio-DL-cysteine by the scheme shown in Fig. 8, because this is a rapid and simple procedure for synthesis of this cysteine derivative. Moreover, as separation of the L-isomer from the synthetic racemic compound did not seem necessary, we used the DL-cysteine derivative for peptide synthesis, as described below.

Use of the Method to Establish the Disulfide Pairings in a Heat-Stable Enterotoxin: A heat-stable enterotoxin produced by a porcine strain of enterotoxigenic *Escherichia coli* has the amino acid sequence shown in Fig. 9.[8] The positions of the three intramolecular disulfide pairings were recently determined by chemical synthesis of the enterotoxin using selectively removable protecting groups on Cys residues.[7] To confirm the validity of the present method, we used this method to establish the positions of the disulfide linkages of the enterotoxin and compared them with those determined previously. Thus, we synthesized protected peptides with the sequence from position 5 to 17 of the enterotoxin with Cys* at two positions, which had been determined to be linked or not to be linked in the enterotoxin previously;[7] that is 5 and 10 or 6 and 14 or 5 and 14 or 9 and 17. These peptides were synthesized by a solid-phase method, oxidized by air to form intramolecular disulfide linkages after removal of the protecting groups, and purified by HPLC. The HPLC profile of the synthetic peptide with two Cys* at positions 6 and 14 is

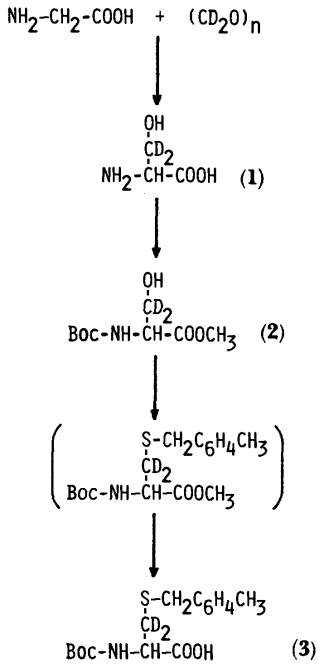

Fig. 8. Scheme for synthesis of *N*-Boc-*S*-(4-methylbenzyl)-3,3-dideuterio-DL-cysteine.

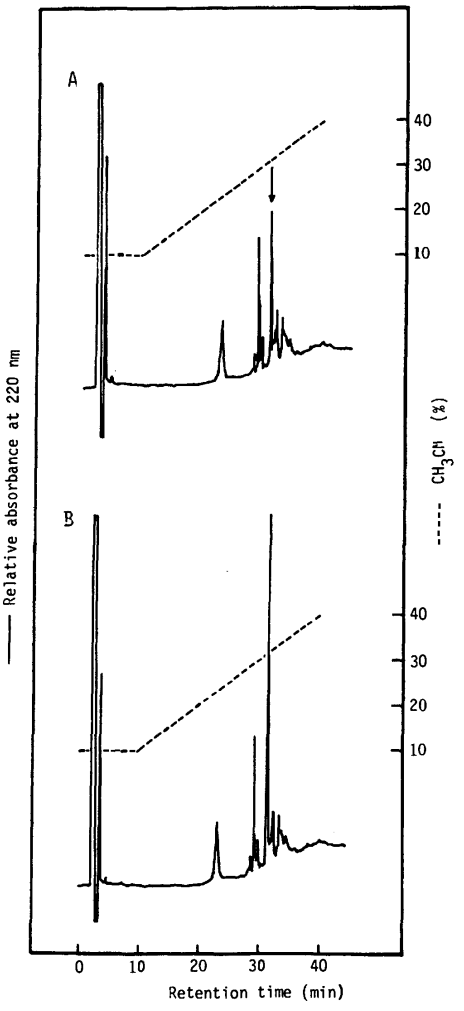

Fig. 10. HPLC profiles of A) a crude synthetic heat-stable enterotoxin with the sequence from position 5 to 17 shown in Fig. 9 and with two Cys* at positions 6 and 14 and B) a mixture of A) and a standard peptide.[16c]

1 5 10 15 18
Asn-Thr-Phe-Tyr-Cys-Cys-Glu-Leu-Cys-Cys-Asn-Pro-Ala-Cys-Ala-Gly-Cys-Tyr

Fig. 9. Amino acid sequence of a heat-stable enterotoxin (ST_P) produced by a porcine strain of enterotoxigenic *Escherichia coli*.[8]

shown in Fig. 10. The peak fraction, which had the same retention time as that of the standard peptide shown by an arrow, was isolated. The purified peptide had almost the same biological activity as that of the standard peptide. Analytical data of synthetic peptides are summarized in Table 2. The peptide with Cys* at positions 6 and 14 was hydrolyzed under the conditions described above and treated with Fmoc-Cl, and the (Fmoc-Cys)$_2$ fractions were isolated by HPLC and analyzed by FAB mass spectrometry. The mass spectrum (Fig. 11A) was similar to the theoretical mass spectrum of a mixture of (Fmoc-Cys)$_2$ and (Fmoc-Cys*)$_2$ (w/w, 2/1), as shown in Fig. 11C. The mass spectra from peptides with Cys* at positions 5 and 10, and 9 and 17 were also quite similar to that in Fig. 11A. However, the spectrum of the peptide with Cys* at positions 5 and 14 was quite different from the theoretical spectrum in Fig. 11C, but almost the same as the theoretical mass spectrum of a mixture of (Fmoc-Cys)$_2$ and (Fmoc-Cys, Fmoc-Cys*) (w/w, 1/2), as shown in Figs. 11B and 11D, respectively. These results indicated that the disulfide pairings of the enterotoxin were present between positions 5 and 10, 6 and 14, and 9 and 17, but not between positions 5 and 14. These findings were compatible with the positions of the disulfide linkages of the enterotoxin determined previously.[7] Thus it was demonstrated that this method is applicable for determination of disulfide pairings in peptides.

Table 2. Amino Acid Compositions,[a] Mass Values,[b] and Yields of Synthetic Peptides

	Cys*$_{5,10}$	Cys*$_{6,14}$	Cys*$_{9,17}$	Cys*$_{5,14}$	Theoretical value

Yield (%)	6.0	7.5	6.9	6.9	

a) Values were calculated as mol/mol of Ala. b) $[M+H]^+$, mass value of quasi-molecular ion.

In summary, we developed a new method for determining disulfide pairings in peptides. This method involves the following procedures: i) synthesis of a peptide with the same sequence as that of the native or a standard peptide and with deuterio-Cys residues at given positions, ii) hydrolysis of the peptide in 4 M CH_3SO_3H at 110 °C for 24 h, and reaction of the hydrolyzate with Fmoc-Cl, and iii) HPLC separation and FAB mass analysis of the (Fmoc-Cys)$_2$ fraction including deuteriocystine. The method was applied to confirm the positions of the three intramolecular disulfide linkages in a heat-stable enterotoxin.

Experimental

The general and analytical methods used were as described previously.[7,16] All chemicals used for synthetic experiments were of reagent grade, while those used for analysis were of guaranteed grade. All amino acids except glycine and deuteriocysteine were of the L-configuration and Boc-amino acid derivatives were purchased from the Peptide Institute Inc. (Minoh, Osaka) unless otherwise mentioned. A reversed-phase column (Cosmosil C_{18}, 4×250 mm) was obtained from Nacalai Tesque Inc. (Kyoto). ^1H NMR spectra were recorded with a JEOL JNM-GX-400 spectrometer. Mass spectra were taken with an FAB mode on a JEOL HX-100 mass spectrometer. The abbreviations used in this paper are those recommended by the IUPAC-IUB [*J. Biol. Chem.*, **261**, 1 (1986)]. Additional abbreviations are: FAB, fast atom bombardment; Fmoc, 9-fluorenylmethoxycarbonyl; Fmoc-Cl, 9-fluorenylmethyl chloroformate; HPLC, high-performance liquid chromatography;

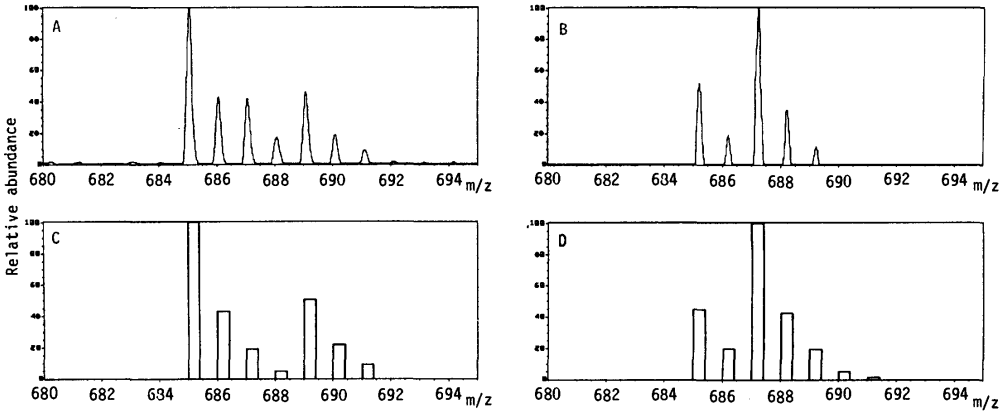

Fig. 11. A) and B), FAB mass spectra of (Fmoc-Cys,)$_2$ fractions isolated from hydrolyzates of heat-stable enterotoxin peptides with the sequence from position 5 to 17 and with two Cys* at positions 6 and 14 and 5 and 14, respectively. C) and D), theoretical molecular ion distributions of mixtures of (Fmoc-Cys)$_2$ and (Fmoc-Cys*)$_2$ (2/1) and (Fmoc-Cys)$_2$ and (Fmoc-Cys, Fmoc-Cys*) (1/2), respectively.

TFA, trifluoroacetic acid; amu, atomic mass unit.

3,3-Dideuterio-DL-serine (1). The title compound was synthesized from glycine (540 mg, 7.2 mmol) in 1 M Na_2CO_3 (30 ml), 0.2 M $CuSO_4$ (0.36 ml), and paraformaldehyde-d_2 (1.73 g, 36 mmol) by the procedure described in Ref. 17 with some modifications. Yield, 235 mg (31% based on the amount of glycine); MS m/z=108.0 (theoretical for $[M+H]^+$ 108.1); ^1H NMR (D_2O), δ=3.82 (1H, s, CH); Found: C, 33.52; H+D, 6.69; N, 13.00%. Calcd for $C_3H_5D_2NO_3$: C, 33.64; H+D, 6.59; N, 13.08%.

Boc-3,3-dideuterio-DL-Ser-OMe (2). Compound **1** (107 mg, 1 mmol) was dissolved in a mixture of dioxane and water (3 ml, v/v: 2/1), and mixed with Boc_2O (262 mg, 1.2 mmol) and triethylamine (140 μl, 1 mmol) under cooling in an ice-water bath. The mixture was stirred for 3 h at room temperature and then concentrated to a syrup under reduced pressure. The syrup was redissolved in MeOH (3 ml), treated with diazomethane, and concentrated to an oily residue under reduced pressure. The residue was dissolved in AcOEt, and washed with 0.2 M HCl, 5% aq $NaHCO_3$, and water. The washed solution was dried over Na_2SO_4 and concentrated to a syrup; 210 mg (95%); MS, m/z=222.0 (theoretical for $[M+H]^+$, 222.1); ^1H NMR ($CDCl_3$), δ=1.46 (9H, s, $(CH_3)_3C$), 3.79 (3H, s, OCH_3), 4.37 (1H, d, CH), 5.52 (1H, d, NH); Found: C, 48.38; H+D, 7.90; N, 6.17%. Calcd for $C_9H_{15}D_2O_5N$: C, 48.86; H+D, 7.74; N, 6.33%.

N-Boc-3,3-dideuterio-DL-Cys(MBzl)-OH (3). Compound **2** (800 mg, 3.6 mmol) was treated with 1.2 equiv each of Ph_3P, 4-methylphenylmethanethiol, and diethyl azodicarboxylate in dry toluene (18 ml) by the method described in Ref. 18. The reaction product was applied to a silica-gel column with ether as an eluent to remove the resulting Ph_3P=O. The eluate was concentrated to a solid under reduced pressure, redissolved in MeOH (36 ml), and saponified by mixing it with 1 M NaOH (4.3 ml). The solution was concentrated to dryness under reduced pressure, and the residue was dissolved in water (100 ml), adjusted to pH 2.0 by adding 1 M HCl, and extracted with AcOEt. The extract was washed with water, dried over anhydrous Na_2SO_4, and concentrated to a residue under reduced pressure. The residue was purified by chromatography on a silica-gel column with a mixture of $CHCl_3$, MeOH, and AcOH (v/v/v, 100/3/1) as eluent; Yield, 775 mg (66% based on the amount of compound **2**); mp 135 °C; MS, m/z=328.0 (theoretical for $[M+H]^+$ 328.1); ^1H NMR (DMSO-d_6/$CDCl_3$, v/v, 1/1), δ=1.46 (9H, s, $(CH_3)_3C$), 2.32 (3H, s, Ar-CH_3), 3.71 (2H, s, Ar-CH_2), 4.36 (1H, d, CH), 5.93 (1H, d, NH), 7.10—7.20 (4H, d,d, ArH); Found: C, 58.36; H+D, 7.20; N, 4.29; S, 9.59%. Calcd for $C_{16}H_{21}D_2O_4NS$: C, 58.69; H+D, 7.08; N, 4.28; S, 9.79%.

Synthesis of Peptides. Peptides were synthesized manually by the solid-phase method.[19,20] Briefly, Boc-Cys (MBzl)- or Boc-Cys* (MBzl)-polystyrene (2% divinylbenzene) (0.2—0.3 mmol of amino acid per 1 g of resin) was used as starting material. The γ-carboxyl group of glutamic acid was protected by Bzl. All couplings were carried out with 5-fold excess of Boc-amino acid and DCC except that of Boc-Cys*(MBzl)-OH (3 equiv). Boc-Asn-OH was coupled repeatedly twice with 2 equiv of 1-hydroxybenzotriazole. After coupling all the amino acid derivatives, peptides were liberated from the resin by treatment with anisole in anhydrous hydrogen fluoride at 0 °C for 1 h, extracted with 10% formic acid in an ice-water bath, and washed three times with hexane. The extract was diluted with water to a final peptide concentration of 5×10^{-5} M. The solution was adjusted to pH 8.0 and stood at room temperature until no free mercapto groups were detectable. The crude peptides were purified by high-performance liquid chromatography, as described below.

High-Performance Liquid Chromatography (HPLC). The synthetic peptide was purified on a reversed-phase column using a high-performance liquid chromatography system consisting of a Waters M600 multisolvent delivery system (Milford, MA) and Hitachi 655A variable wavelength UV monitor and D-2000 chromatointegrator (Tokyo). The peptide was eluted with a linear gradient of CH_3CN in 0.05% TFA or 0.01 M ammonium acetate (pH 5.7) with increase of 1% min^{-1} at a flow rate of 1 ml min^{-1}. Fractions of the eluate were monitored for absorbance at 220 nm.

Hydrolysis of Peptides. Amino acids or peptides were hydrolyzed at 110 °C for 24 h in a Waters pico-TAG™ workstation by either one of the following three methods: 1) The sample amino acid or peptide (ca. 2 nmol) was put into a vial and mixed with 5.7 M HCl (200 μl). 2) The sample (ca. 2 nmol) was put into a vial containing 4 M CH_3SO_3H (20 μl). 3) The sample (ca. 2 nmol) was put into a small test tube containing 4 M TFA (200 μl) and sealed in vacuo.

Reaction of Hydrolyzates of Peptides with Fmoc-Cl. The sample (ca. 50 nmol) was dissolved in 1% ammonium hydrogencarbonate (100 μl) at pH 7.8 and treated with 16 mM Fmoc-Cl in acetone (100 μl) at room temperature for 30 min. The solution was washed three times with hexane, insoluble materials were filtered off, and the filtrate was subjected to HPLC.

Amino Acid and Fast Atom Bombardment (FAB) Mass Spectrometric Analyses. The amino acid compositions of synthetic peptides were examined by amino acid analysis, and the molecular weights of synthetic peptides and deuteriocystine derivative were measured by FAB mass spectrometry, as described in Refs. 20 and 21, respectively.

This work was supported in part by a Grant-in-Aid from the Ministry of Education, Science and Culture (Scientific Research Grant No. 62470022). We deeply thank Drs. Tadao Harada and Hiroshi Ozaki of the Institute for Protein Research, Osaka University for helpful discussions. We are also indebted to Prof. Akira Tai (Basic Research Laboratory, Himeji Institute of Technology) for facilitating use of an NMR spectroscopy instrument, to Mrs. Aiko Kobatake for elemental analysis, and to Mrs. Aiko Kobatake and Miss Yumiko Kuhara for preparation of the manuscript.

Synthesis of Nonadeca- and Octadecaribonucleotides Using the Solid-Phase Phosphotriester with Tetrahydropyranyl Groups as the 2′-Hydroxyl-Protecting Group

Ichiro HIRAO, Masahide ISHIKAWA, Hiroyuki HORI, Kimitsuna WATANABE,† and Kin-ichiro MIURA*
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113
(Received December 27, 1988)

Nonadeca- and octadecaribonucleotides corresponding to the D-loop of $tRNA^{Phe}$ from yeast and the leader sequence of phage f1 coat protein mRNA were synthesized by the activated phosphotriester method. Coupling yield in the synthesis of oligoribonucleotides depended on the extent of nucleosides loaded on controlled pore glass beads (CPG). *N*-Acyl-5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranyl derivatives were used as fully protected ribonucleotide monomer units. The 18mer and 19mer corresponding to the D-loop did not serve as substrates for tRNA (guanosine-2′-)methyltransferase from *T. thermophilus*, but inhibited methylation of the 5′-half fragment of $tRNA^{Phe}$. This indicates that both fragments possess some affinity with the enzyme.

The synthesis of long-chain oligoribonucleotides up to about the icosamer (20mer) has recently been achieved by the solid phase approach: 19mer[1] was synthesized by the chlorophosphite method, 15mer,[2] 11mer,[3] 43mer,[4] 19mer,[5] and 13mer,[6] 77mer[7] by the phosphoramidite method, 21mer[8] and 24mer[9] by the H-phosphonate method, 13mer[10] by the triester method and 9mer[11] and 8mer[12] by the phosphoro-*p*-anisidate method. However, the phosphotriester approach though easy to conduct, is attended by various problems such as the long time required for the coupling reaction, its low yield and the occurrence of side reactions on the uracil and guanine moieties.[13] The synthesis of long-chain oligoribonucleotides (about 20mer) by the phosphotriester solid-phase method has not been reported so far.

The starting materials, 5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranyl-*N*-acylribonucleosides[14] were prepared from 3′,5′-*O*-(tetraisopropyldisiloxane-1,3-diyl) derivatives[15] on a large scale. We previously reported the selective deprotection of the 5′-*O*-dimethoxytrityl group of oligoribonucleotides by treatment with 1% dichloroacetic acid in dichloromethane at room temperature without removal of the 2′-*O*-tetrahydropyranyl (THP) group,[16] followed by the synthesis of undecaribonucleotides (11mers)[17] on a polystyrene support using 2-chlorophenyl-*O*,*O*-bis(1-benzotriazolyl) phosphate, initially reported by van Boom et al.[18] Recently, Kierzek et al. have reported the synthesis of oligoribonucleotides by the phosphoramidite approach, using our method in combination with the THP group.[19]

However, we were unable to synthesize nonadecaribonucleotides (19mers) by this method, possibly since long-chain oligoribonucleotides were easily adsorbed on the polystyrene resin, used for the solid support, during the synthesis. We thus attempted the solid-phase synthesis using controlled pore glass (CPG), a well-known support for nucleic acids synthesis,[20] instead of a polystyrene resin. When the coupling reaction was carried out on the long-chain ω-aminoalkyl CPG resin using acetonitrile as the solvent, with a loading amount less than 20 $\mu mol\,g^{-1}$ the average coupling yields exceeded 95% during a 15 min reaction period.

In the present study, the simple solid-phase synthesis of nonadeca- and octadecaribonucleotides corresponding to the D-loop of yeast $tRNA^{Phe}$ and the leader sequence of phage f1 coat protein mRNA were carried out by the phosphotriester approach.

Results and Discussion

For preparation of guanosine or adenosine bound to the CPG resin, 5′-*O*-dimethoxytrityl-N^2-isobutyryl-2′-*O*-tetrahydropyranylguanosine **1a** or N^6-benzoyl-5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranyladenosine **1b** was succinylated at the 3′-hydroxyl group, followed by its activation with 1-hydroxybenzotriazole and dicyclohexylcarbodiimide (DCC) applying the same procedure as that for preparing, the 2′-*O*-deoxyribonucleoside resin.[21] The activated ester of guanosine derivative was subsequently allowed to react with various CPG resins such as 3-aminopropyl (AP)-, aminoaryl (AA)-, and long-chain aminoalkyl (LCA)-CPG. Unreacted amino groups on the CPG resin were capped with a mixture of 5% acetic anhydride, 3.5% 4-dimethylaminopyridine, and 5% 2,6-lutidine in dry tetrahydrofuran or pyridine.

We first tested the effects of solvents on the condensation reaction of a AA-CPG resin covering a guanosine derivative with 3′-*O*[(1-benzotriazolyloxy)(2-chlorophenoxy)phosphinyl]-5′-*O*-dimethoxytrityl-N^2-isobutyryl-2′-*O*-tetrahydropyranylguanosine **3a**: When 1,4-dioxane, benzene, dichloromethane, or acetonitrile were used as the solvents for promoting the condensation reaction on the polystyrene resin. 1,4-Dioxane was found to be effective solvent. While in case of the CPG resin, a reaction conducted in acetonitrile, provided the highest coupling yield (data not shown).

The condensation reaction was thus carried out in

† Present address: Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Yokohama 227.

acetonitrile on three different CPG resins (AA, AP, and LCA) each having a guanosine derivative. To obtain the 5′-free hydroxyl group, the CPG resins were first treated with 1% dichloroacetic acid in CH_2Cl_2 for 1.5 min. N^4-Anisoyl-5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranylcytidine **1c** (1.1 mole equiv) was phosphorylated with *O*,*O*-bis(benzotriazolyl)-phosphate **2** (1.0 mole equiv) according to the procedure reported by van Boom.[18] The condensation reaction was conducted with a ZEON Genet manual DNA synthesizer (NIPPON ZEON Co., Ltd.). The resulting N^4-anisoyl-3′-*O*-[(1-benzotriazolyloxy)(2-chlorophenoxy)phosphinyl]-5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranylcytidine **3c** and a base catalyst were added to the CPG resin in the reaction vessel. The condensation yields were estimated on the basis of the colorimetric determination of the released dimethoxytrityl cation (Scheme 1 and Table 1).

The LCA-CPG resin (Table 1, Entries 3 and 6) was found to give a dimer in satisfactory yield and lessen the reaction time (15 min). The AA-CPG resin with the highest content of the guanosine derivative provided only a low yield of 50—70% (Table 1, Entries 2 and 5). Next, clarification was made of the relationship between coupling yield and amount of nucleoside loaded on the CPG resin. Coupling efficiency

was assessed using activated cytidine 3′-phosphotriester unit **3c** (0.27 M††, 0.27 ml) and LCA-CPG resins bound to the protected adenosin derivative at various loading amounts, [Weight of the LCA-CPG resin (g)=0.66 (μmol)/loading amount ($\mu mol\,g^{-1}$)], with 1-methylimidazole (0.027 ml) at 30 °C for 10 min. In Fig. 1, the coupling yield has increased with decrease in the amount of nucleoside loaded on the resin. This is possible due to steric hindrance of a nucleoside present on the CPG resin. Therefore the LCA-CPG resin derivatized with a 5′-*O*-dimethoxytrityl ribonucleoside, at a loading amount less than 20 $\mu mol\,g^{-1}$ used.

On the basis of the results obtained above, the 19mer including the D-stem and loop of yeast $tRNA^{Phe}$ and the 18mer lacking the 5′-terminal uridine in the 19mer were synthesized. Two dihydrouridine residues in the D-loop were replaced with uridine in both the 18mer and 19mer (RNA 1 and 2 in Table 2). Synthesis was made also of the sequence of the phage f1 coat protein mRNA (18mer) as well as the AUG initiation codon (RNA 3 in Table 2) and several 18mers in each of which two guanosine residues in the Shine-Dalgarno sequence[22] were replaced by different nucleosides (RNA 4—6 in Table 2).

As protected ribonucleoside monomers, N^2-isobutyrylguanosine **1a**, N^6-benzoyladenosine **1b**, N^4-anisoylcytidine **1c**, and uridine **1d**, each protected at both the 5′- and 2′-hydroxyl groups with the 4,4′-dimethoxytrityl and tetrahydropyranyl groups, respectively[14] were used. These protected ribonucleosides **1** (0.088 mmol/coupling reaction) were converted to *O*-benzotriazolyl phosphate derivatives **3** by treatment with *O*,*O*-bis(benzotriazolyl) 2-chlorophenyl phosphate **2**[18] (0.08 mmol/coupling reaction). In order to perform the reaction of **2** with **1**, a slight excess of **2** was used. By TLC-analysis of the reaction mixture, the resulting **3** was detected along with small amounts of 3′,3′-dinucleotide and remaining **1**. The trityl group of **1a** was removed by treatment with 1-hydroxybenzotriazole in acetonitrile for few hours. Following preparation of the activated ribonucleotide units as the key intermediates **3**, a small amount of pyridine was added to neutralize the resulting slightly acidic species 1-hydroxybenzotriazole and excess pyridine was evapolated off. However, this treatment caused considerable decomposition resulted from hydrolysis of **3** catalyzed by a trace amount of pyridine still remaining. Thus, for the synthesis of long-chain oligoribonucleotides, fresh ribonucleotide units **3** must be prepared within five hours.

Guanosine-bound-LCA-CPG (20—50 mg, 0.3—0.8 μmol) was detritylated by 1% dichloroacetic acid in dichloromethane at 30 °C. To the LCA-CPG resin in the reaction vessel were added **3** in acetonitrile (0.250 ml) and 1-methylimidazole (0.025 ml). The condensation was carried out for 15 min at 30 °C. Fully protected oligoribonucleotides were prepared in the same way. One cycle of the synthesis required 25 min for a coupling yield more than 90% (see Scheme 1 and Table 2). The synthesis cycle is shown in Table 3.

†† 1 M=1 mol dm^{-3}.

Following their synthesis, deprotection of the fully protected oligoribonucleotides was carried out according to the general procedure (see experimental section). 5′-*O*-DMTr-2′-*O*-THP oligomers were purified first by Sep-Pak C-18 (Waters) and then by high-performance liquid chromatography (HPLC) with a reversed-phase C-18 column (M&S Co.) (Fig 2). The eluted oligomers were treated with 0.01 M HCl (pH 2.0) to remove the 2′-*O*-tetrahydropyranyl and 5′-*O*-dimethoxytrityl groups. These crude oligomers were purified by HPLC at 55 °C or room temperature (Fig. 3), and the fractions corresponding to the main peak were collected. The HPLC profiles of the purified oligomers are shown in Fig. 3.

The purity of the oligomers was assessed by electrophoresis on a 20% polyacrylamide gel containing 7M urea, and when a single band could not be detected, purification was conducted again by polyacrylamide gel electrophoresis (Fig. 4). Yields of pure fragments are shown in Table 2. One reason for the low yields is that each fragment was partially lost through the purification process used for increasing the purity.

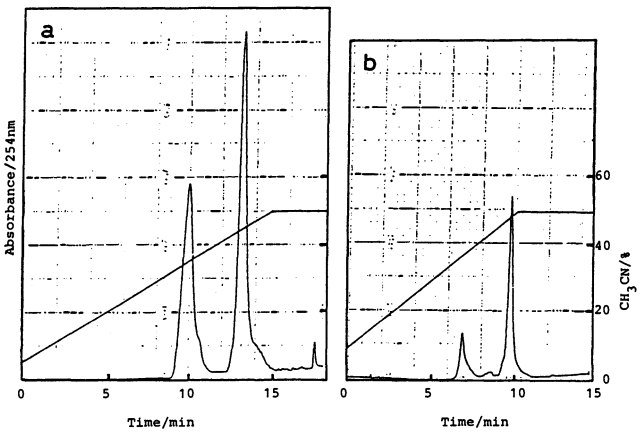

Fig. 2. Separation of 5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranyl r-18mer (RNA 3) (a) and r-19mer (RNA 1) (b) by reversed-phase C-18 HPLC.

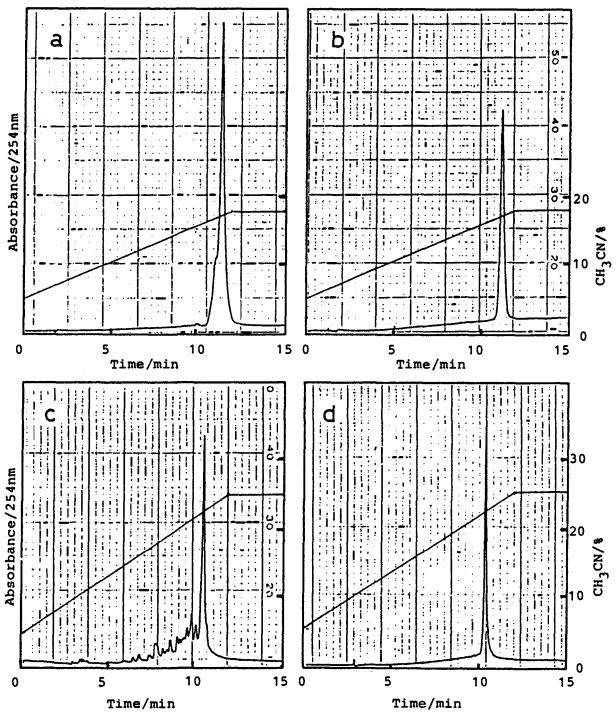

Fig. 3. Reversed-phase HPLC profiles for purification and analysis; the crude product mixture containing r-18mer (RNA 3) (a) and r-19mer (RNA 1) (c), and the elution profiles of the main peaks of RNA 3 (b) and RNA 2 (d).

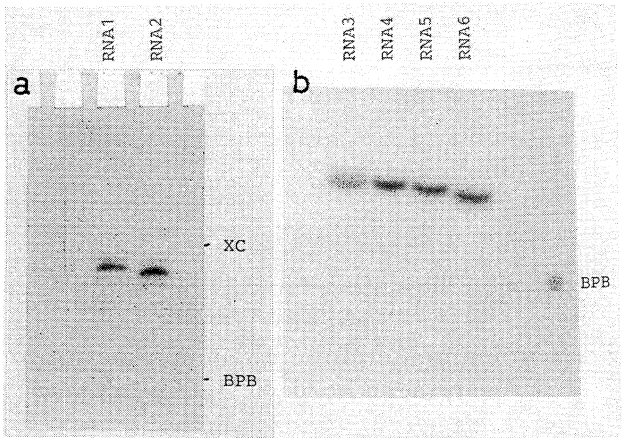

Fig. 4. 20% Polyacrylamide-7 M urea gel electrophoresis of RNA 1 and RNA 2, followed by dying with 0.02% Methylene Blue (a); ^{32}P-labeled RNA 3—6 (b).

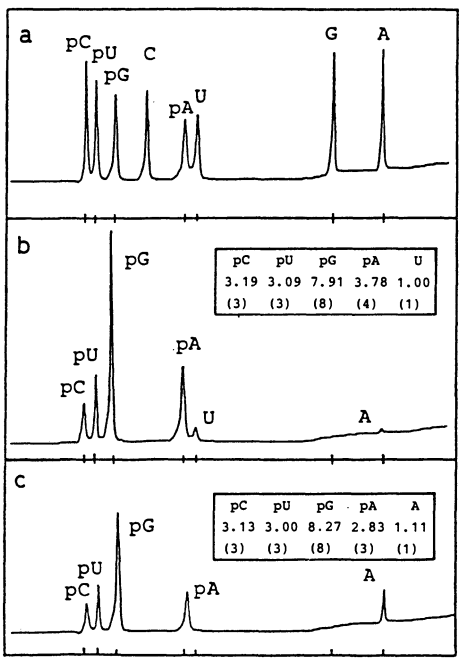

Fig. 5. Reversed-phase HPLC profiles for composition analysis of RNA 1 (b) and RNA 2 (c) both digested with nuclease P1, and authentic ribonucleosides and ribonucleotides (a). The insets show the ratios of their nucleoside and nucleotide compositions, as determined from peak area.

Base compositions were determined by enzymatic digestion using nuclease P1 (Fig. 5). It was observed that the initial digestion product, adenosine 5′-phosphate, underwent simultaneous hydrolysis to adenosine with nuclease P1 but only to a slight degree. The base sequences of the synthesized oligomers were confirmed by partial enzymatic degradation of the 5′-end-labeled oligomers in polyacrylamide gel electrophoresis (Fig. 6).

A convenient method has been presented above for the synthesis of oligoribonucleotides. Compared with the phosphoramidite or H-phosphonate method, our synthetic cycle (see Table 3) is simple owing to elimination of an oxidation step. Side reactions due to the use of 1-hydroxybenzotriazole have been reported,[23] but no other products was detected in the purified oligomers. However, the by-products shown in Figs. 3a and 3c may possibly resulted from base modification or release of the tetrahydropyranyl group; the latter was not observed in our previous paper on the synthesis of the 11mer.[17]

The synthesized 18mer and 19mer corresponding to the D-loop of yeast $tRNA^{Phe}$ (Table 2, RNA 1 and RNA 2) were examined for their ability to be methylated with tRNA (guanosine-2′)-methyltransferase (Gm-methylase) isolated from an extreme thermophile, *Thermus thermophilus* HB 27.[24-26] It has been already elucidated that the D-loop-and-stem structure of tRNA is a minimal prerequisite for recognition with Gm-methylase (Matsumoto et al., unpublished), and that s^4U8 of *E. coli* $tRNA^{fMet}$ is involved in the recognition with Gm-methylase.[27] Therefore, regarding on the substrate ability for Gm-methylase, comparison of the 18mer (RNA 2) having no 5′-terminal U corresponding to U8 of tRNA, with the 19mer (RNA 1) having the U, would be useful to confirm importance of the U residue.

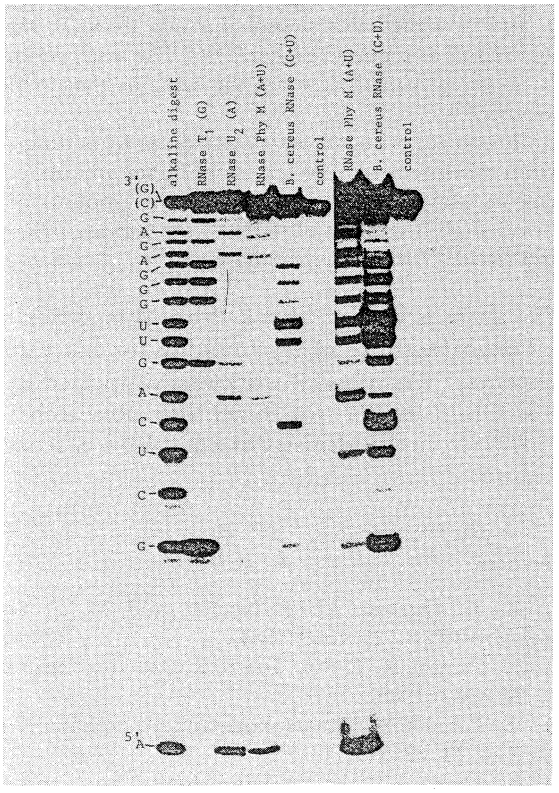

Fig. 6. Autoradiogram of electrophoresis on a 23% polyacrylamide gel containing 7 M urea for RNA sequencing. The 5′-end-^{32}P-labeled RNA 1 was partially digested with ribonucleases according to the method of Donis-Keller.[30]

Table 4. Inhibitory Effect of the Synthetic 18mer and 19mer to the Methylation of the 5′-Half Fragment of $tRNA^{Phe}$ with Gm-methylase (a) and of $tRNA^{fMet}$ with m^1-methylase (b)

	Conditions	Methylation activity/%
(a)	5′-Half fragment	100
	Plus 18mer	31±3
	Plus 19mer	43±5
(b)	$tRNA^{fMet}$	100
	Plus 18mer	95
	Plus 19mer	97

19mer, 18mer, 5′-half fragment and $tRNA^{fMet}$; 0.05 OD_{260} unit.

However, the result was negative, showing that neither 19mer nor 18mer was methylated with the enzyme, instead both fragments inhibited to a great extent methylation of the 5′-half fragment of yeast $tRNA^{Phe}$ which is known as a good substrate for the enzyme (Matsumoto et al., unpublished) as shown in Table 4. A possibility that the inhibition was caused by an impurity which may have been contaminated in the fragment preparations was avoided by the fact that both fragments did not inhibit the methylation of *E. coli* $tRNA^{fMet}$ with tRNA(1-methyladenosine)-methyltransferase (m^1A-methylase)[27] (Table 4). Therefore, it is concluded that the minimal fragment for the substrate with Gm-methylase is longer than the 19mer (RNA 1) synthesized here and it has to take a special tertiary structure which may be supported by other parts in a complete tRNA molecule. The 18mer corresponding to the leader sequence of phage f1 coat protein mRNA is now being examined for its binding efficiency to ribosomes.

Experimental

Reagents and solvents were purified and dried according to the procedure reported by van Boom et al.[8] 1-Hydroxybenzotriazole was purchased from DOJINDO and coevaporated with pyridine just before use.

HPLC was conducted by the Gilson gradient chromatography system with a C-18 column (M&S Co.) for reversed-phase HPLC and the elution buffer was a mixture of CH_3CN and 0.1 M triethylammonium acetate (pH 7.0).

RNase P1 was purchased from Seikagaku Kogyo (a product of Yamasa Co.), RNase U_2 from Sankyo Co., and

RNase T1, RNase Phy M and *B. cereus* RNase, from Pharmacia Co.

Preparation of Fully Protected Nucleosides: The 5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranyl derivatives of N^2-isobutyrylguanosine **1a**, benzoyladenosine **1b**, N^4-anisoylcytidine **1c**, and uridine **1d** were prepared from 3′,5′-*O*-(tetraisopropyldisiloxane-1,3-diyl) derivatives according to the methods described previously.[14]

The starting material, N^2-isobutyryl-3′,5′-*O*-(tetraisopropyldisiloxane-1,3-diyl)guanosine **1a**, was synthesized as follows. To a solution of guanosine (14.2 g, 50 mmol) in an anhydrous mixture of *N*,*N*-dimethylformamide (250 ml) and pyridine (100 ml) was added 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane (18 ml). The mixture was stirred overnight at room temperature, followed by the addition of trimethylchlorosilane[28] (25 ml) and stirring for 1 h. Isobutyric anhydride (45 ml) was then added and stirring was continued for another 3 h at room temperature. The mixture thus obtained was hydrolyzed with water (60 ml) for 15 min at 0 °C, followed by treatment with aqueous ammonia (65 ml) for 15 min at 0 °C. It was concentrated under reduced pressure and the resulting residual oil was dissolved in CH_2Cl_2 (500 ml). The CH_2Cl_2 layer was followed by washing with 1 M sodium hydrogencarbonate, drying with magnesium sulfate and concentrating under reduced pressure. The residue was dissolved in a small amount of CH_2Cl_2 and precipitated into a rapidly stirred mixture of hexane (750 ml) and ethyl acetate (250 ml). The precipitate was crystallized from ethyl acetate, to give **1a** (18.4 g, 60% yield from guanosine).

Preparation of CPG Resins Carrying Nucleosides: Nucleoside-containing CPG resins were prepared according to the literatures.[21] The condensation reaction of fully protected nucleoside 3′-succinate with the CPG resin was carried out at 37 °C for 10—20 min.

Preparation of *N*-Acyl-3′-*O*-[(1-benzotriazolyloxy)(2-chlorophenoxy)phosphinyl]-5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranylnucleoside (3): The method of van Boom[18] was applied as follows with slight modification.

To dried *N*-acyl-5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranylnucleoside **1a**, **1b**, **1c**, or **1d** (0.088 mmol/one coupling reaction) was added a 0.2 M solution (0.4 ml) of **2** in dioxane followed by stirring at room temperature for 30 min. The solution was then evaporated, the residue dissolved in pyridine (0.1 ml) and evaporation was continued to dryness. The residue thus obtained was dissolved in acetonitrile (0.3 ml) which was used within 5 h following the synthesis of oligoribonucleotides.

Synthesis of Oligonucleotides: The fully protected nucleoside derived LCA-CPG resin (50 mg, 0.76 μmol) was introduced into a reaction vessel of the ZEON Genet DNA manual synthesizer (NIPPON ZEON Co.). The cycle for synthesis is shown in Table 3. At the time of the condensation reaction, a solution (0.4 ml) of **3** and 1-methylimidazole (0.04 ml) was added followed by shaking at 30 °C for 15 min.

Following completion of the above cycle, the resin was treated with 0.5 M 2-pyridinecarbaldehyde oxime-tetramethylguanidinium in a mixture of pyridine and water (9 : 1 v/v) (0.2 ml) at 37 °C for 24 h, filtered and then washed with a mixture of pyridine and water (9 : 1 v/v) (1 ml×3). The filtrate was evaporated, and the residue was applied on a Sep Pak C18 (Waters Associates) after treatment with concd aqueous ammonia (55 °C, 1 h) and washed successively with 10 ml of 0.1 M triethylammonium hydrogencarbonate (TEAB) and 20 ml of 15% acetonitrile in 0.1 M TEAB. The 5′-*O*-dimethoxytrityl-2′-*O*-tetrahydropyranyl oligoribonucleotide was finally eluted with 10 ml of 35% acetonitrile in 0.1 M TEAB and then this oligomer was applied on a reversed-phase C18 column (M&S Pack C18, M&S Co.). Elution was conducted with a linear gradient from 5% or 9.5% CH_3CN in 0.1 M triethylammonium acetate (TEAA, pH 7.0) to 50% CH_3CN in 0.1 M TEAA (Fig. 2). The desired product fraction was pooled and evaporated to dryness. The residue was treated with 0.01 M HCl (pH 2.0, 5 ml) at room temperature for 48 h. The solution was neutralized with dil. aqueous ammonia, washed with ethyl acetate (10 ml×5), and evaporated.

Crude oligomers were purified by a reversed-phase C-18 column. Elution was performed with a linear gradient of 5%—25% CH_3CN in 0.1 M TEAA (Fig. 3). Slightly crude oligomers were purified by 20% polyacrylamide gel electrophoresis in the usual manner.[29]

Enzyme Digestion and Nucleotide Sequencing: The above oligomers (0.1 A_{260} units) were treated with Nuclease P1 (1 μg) in 0.1 M ammonium acetate (pH 5.3) at 37 °C for 20 min. The mixtures thus produced were analyzed by HPLC on a C-18 column (elution buffer: CH_3CN-50 mM $NH_4H_2PO_4$, pH 5.2) (Fig 5).

The labeled oligomers were partially digested with RNases or alkali and sequenced by the 20—23% polyacrylamid-7M urea gel electrophoresis developed by Donis-Keller[30] for distinguishing G, A, A+U, and C+U from each other.

Preparation of Methyltransferases and the Enzyme Assay: Gm- and m^1A-methylases were purified from *T. thermophilus* HB 27 as reported earlier.[24,25] The assay conditions for Gm- or m^1A-methylase are the same as those reported previously.[25]

Inhibition experiments were carried out by adding to the reaction mixture several to ten times larger amounts of the fragments (the 18mer or 19mer) than the amounts of substrates (5′-half fragments of $tRNA^{Phe}$ for Gm-methylase and *E. coli* $tRNA^{fMet}$ for m^1A-methylase).

The authors wish to thank Prof. Mitsuo Sekine of the Tokyo Institute of Technology for his valuable comments. The present work was supported in part by a Grant-in-Aid for Scientific Research (No. 62750777) from the Ministry of Education, Science and Culture.

(Received December 28, 1988)

6-*O*-α-D-Glucopyranosyl-α-cyclodextrin (G_1-α-CD)–*p*-nitrophenol (pNP) inclusion complex has been characterized by high resolution ^1H and ^{13}C NMR. From ^1H NMR measurements it is concluded that G_1-α-CD forms a 1:1 inclusion complex with pNP at both pD 7 and 10, and the dissociation constants for their complexation are quite similar to those for α-CD–pNP complexation, suggesting that G_1-α-CD and α-CD have a similar ability of complexation with pNP. The geometry of G_1-α-CD–pNP complex was found to be similar to that of α-CD–pNP complex. Analysis on the NMR spectral parameters of G_1-α-CD have revealed that the asymmetric nature of G_1-α-CD molecule is enhanced by complexation with pNP.

6-*O*-α-D-Glucopyranosyl-α-cyclodextrin (G_1-α-CD), is a branched α-cyclodextrin (α-CD), produced by limited action of *Bacillus macerans* cyclodextrin glucanotransferase on waxy corn starch.[1,2] It can be isolated and purified from the other sugar by-products using procedures of Kobayashi et al.[1,2] As shown in Fig. 1, G_1-α-CD has one branching glucopyranosyl residue attached to one of glucopyranosyl residues constituting α-CD through (1→6)-α-glucosidic linkage and due to this branch G_1-α-CD is more water-soluble and more resistant to enzymic degradation than the parent α-CD.[3] It is well-documented that CDs trap various substances as guests in their cavities to form inclusion complexes in solution and because of this property CD has received a considerable attention from a variety of field.[4-6] Although it is expected that G_1-α-CD forms inclusion complexes with guest molecules in solution in a manner similar to α-CD, neither the interaction between G_1-α-CD and guest molecule nor the structure of its inclusion complexes has been characterized in detail.

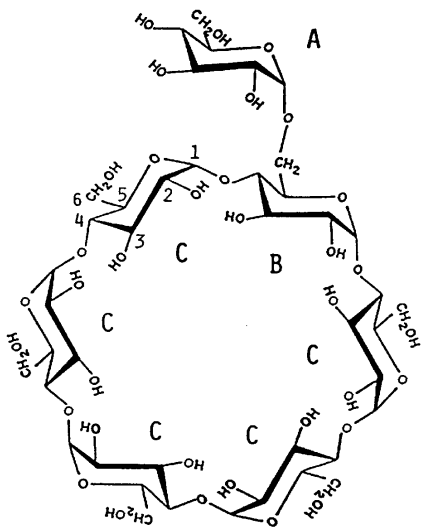

Fig. 1. The structure of G_1-α-CD. The glucopyranose residues are divided into three different groups, **A**—**C**, on the basis of ^1H NMR spectrum.

NMR spectroscopy is one of the most useful techniques for studying CD inclusion complexes in solution because of its sensitivity.[7,8] The interaction of guest molecule with CD is clearly reflected in changes on various NMR spectral parameters.[9,10] Although ^1H NMR spectra of CD derivatives exhibit severely overlapped resonances in the narrow chemical shift range of about δ 3 to 4 from Me_4Si, combined use of various modern two-dimensional NMR spectroscopic techniques can be quite effectively utilized to obtain unambiguous resonance assignments which is essential for detailed structural analysis on CD complexes by NMR.

We report herein the results of 500 MHz ^1H and 125 MHz ^{13}C NMR study of the interaction between G_1-α-CD and *p*-nitrophenol (pNP) in aqueous solution which not only reveal that pNP is indeed inserted into the cavity of G_1-α-CD in a manner similar to α-CD, but also indicate that a considerable conformational change is induced on both the macrocyclic ring structure and constituents of G_1-α-CD upon complexation with pNP.

Results and Discussion

Interpretation of the ^1H Spectra. The 500 MHz ^1H NMR spectra of G_1-α-CD and the mixture of G_1-α-CD and pNP in D_2O at pD 7.0 and 30 °C are illustrated in traces A and B of Fig. 2, respectively. G_1-α-CD exhibits severely overlapped ^1H spectrum in the chemical shift region δ 3.4 to 4.0 and two-dimensional NMR techniques were utilized to assign all the resonances in the spectra of G_1-α-CD.[11] In trace A there are three sets of independent spin net-work systems arising from three different types of glucopyranose residues, which can be assigned to **A**—**C** units illustrated in Fig. 1, respectively. Due to the presence of the C_6 symmetry axis on α-CD molecule in solution, only single set of NMR signal pattern corresponding to a gluco-

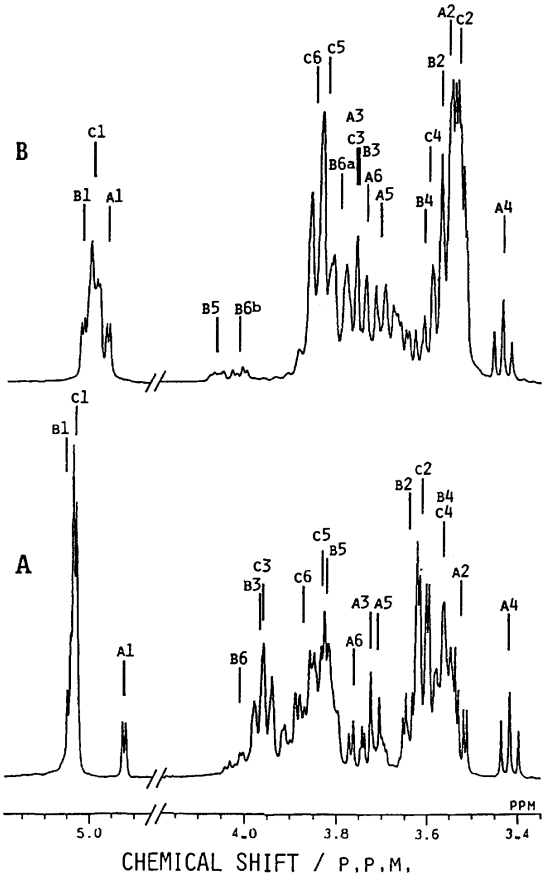

Fig. 2. 500 MHz ^{1}H NMR spectra of (A) 0.04 M G_1-α-CD, (B) 0.04 M G_1-α-CD mixed with 0.08 M pNP, in D_2O at pD 7 and 30 °C. The signals around δ 5 arise from the anomeric protons of the host.

pyranose constituent is observed.[9] Such symmetric property of α-CD is conserved even in the complexed state with pNP owing to the fast averaging of the spatial orientation of pNP with respect to α-CD, although the chemical shifts of α-CD resonances are influenced by the addition of pNP.

On the other hand, in G_1-α-CD the symmetry-breaking constituent, **A** unit, perturbs the C_6 symmetric property of the macrocyclic ring consists of **B** and **C** units, resulting in shifting the resonances of **B** unit relative to those of **C** units, but only single set of NMR signal pattern corresponding to a glucopyranose constituent is observed from **C** units. The observed ^{1}H shifts of the signals of **C** units agree very closely with those of the corresponding resonances of α-CD, suggesting that the substitution of **A** unit perturbs the electronic structure only of **B** unit and all **C** units exist in α-CD-like state.

The complexation of α-CD with pNP in solution leads to a perturbation of NMR spectra of α-CD[9,12] and the ^{1}H resonances of G_1-α-CD are also similarly and even more dramatically perturbed by addition of two-molar excess of pNP as shown in Fig. 2B. The combined use of various 2D NMR techniques (DQF COSY, C-H COSY,[11] HOHAHA,[13] ROESY[14]) makes possible to assign those resonances and their assignment are given with the spectrum in Fig. 2B. Although the resonances arising from **C** units degenerate in only single set of NMR signal pattern, that degeneracy is partially removed by the addition of pNP and the proton resonances, especially H(1) resonance, of **C** unit are split into several peaks.[10]

The resonances of the H(5), H(6a), and H(6b) protons of **B** unit overlap with other proton resonances in Fig. 2A and the individual observation of the spectral patterns of these three proton resonances is difficult. But the H(5) and one of the H(6) resonances are clearly resolved around δ 4.1 in Fig. 2B and the spectral analysis by simulation of these resonances has been carried out to obtain their coupling constants (see below).

Inclusion Complexation between G_1-α-CD and pNP. The induced chemical shift changes of the H(1) and H(3) proton resonances of **C** unit due to the pNP addition are plotted against the molar ratio of pNP to G_1-α-CD in Fig. 3, together with those of α-CD for comparison. Since the H(3) and H(5) protons are located inside the cavity, their resonances are most likely to be influenced by the guest trapped in the cavity. A large upfield shift of H(3) resonance due to the ring-current effect of pNP provides one of the most direct evidence to indicate that pNP is included into the cavity of α-CD,[12] whereas H(1) resonance is slight-

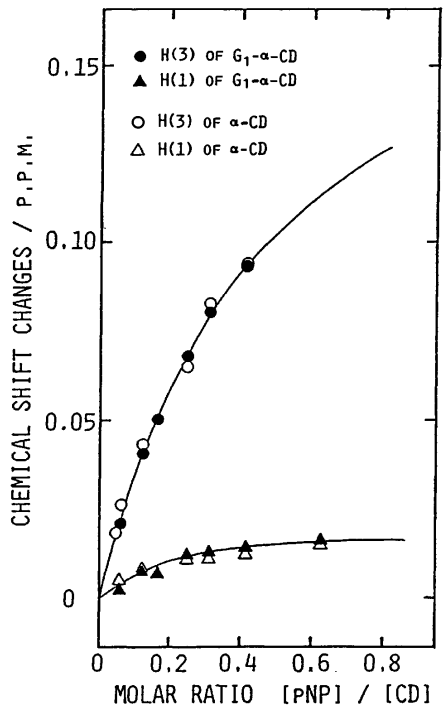

Fig. 3. Effects of *p*-nitrophenol (pNP) on the ^{1}H NMR spectra of G_1-α-CD and α-CD at pD 7 and 30 °C. The pNP-induced changes in chemical shifts of H(1) and H(3) protons of both CDs are plotted relative to the molar ratio [pNP]/[CD]. (▲, ●) G_1-α-CD system; (△, ○) α-CD system.

ly affected and their chemical shift changes are correlated with the conformational changes of the (1→4)-α-linkage and the glucopyranose ring.[10] When pNP was added to G_1-α-CD, H(3) resonances of **C** units as well as **B** unit shift toward upfield considerably due to the ring current effect of aromatic moiety of pNP and the patterns of the chemical shift changes are similar in both G_1-α-CD and α-CD systems, confirming that pNP is inserted into the cavity of G_1-α-CD as in the case of α-CD. The ^{1}H NMR resonances of pNP in free and complexed states can not be observed separately due to a fast exchange process of pNP between the two states and therefore, only single set of pNP resonances, as time-averaged signals, is observed with G_1-α-CD as in the case of α-CD (result not shown).

The chemical shift changes of ortho and meta proton resonances of pNP in aqueous solution of pD 7 are plotted against the molar ratio of G_1-α-CD to pNP and α-CD to pNP in Fig. 4. Downfield shifts are induced for both resonances by G_1-α-CD as well as by α-CD and the meta-proton resonance shifts more significantly in both host-guest systems. The curve indicates a predominant 1 : 1 complexation and the dissociation constant (K_d) of the inclusion complex can be calculated using the chemical shift changes of the meta-proton resonance induced by the host by applying a modified Benesi-Hildebrand equation.[15] Similar procedures were carried out on G_1-α-CD and α-CD-pNP complexes at 30 °C and pD 7 or 10, and the same trend in proton chemical shift changes was also observed in alkaline solution. From these shifts, the

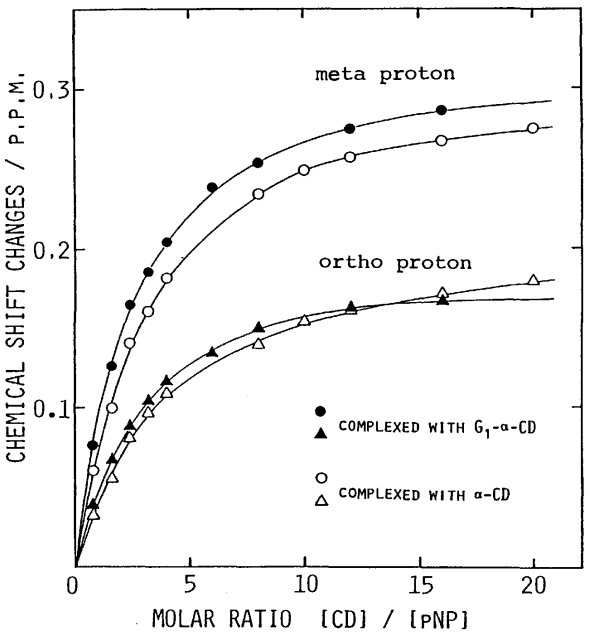

Fig. 4. Effects of G_1-α-CD and α-CD on the ^{1}H NMR spectra of *p*-nitrophenol (pNP) at pD 7 and 30 °C. The CD-induced shifts are plotted as a function of the molar ratio [CD]/[pNP], and [pNP] is constant (2.5 mM).

Table 1. Observed Changes in the Chemical Shift of the ^{1}H Resonances of G_1-α-CD and α-CD Induced by Complexation with pNP

Unit	Chemical shift[a] δ/ppm					
	H(1)	H(2)	H(3)	H(4)	H(5)	H(6)
G_1-α-CD						
A	0.04	0.02	0.03	0.02	0.02	−0.01[b]
B	−0.02	−0.05	−0.22[b]	0.04	0.24[b]	0.00, 0.19[b]
C	−0.03[b]	−0.08[b]	−0.20	0.00	−0.01	−0.03[b]
α-CD	−0.04	−0.07	−0.25	0.00	0.01	−0.04,−0.01

a) Obtained for the solution ([pNP]/[CD]=0.08 M/0.04 M) at pD 7; positive values indicate the downfield shifts. b) Rough estimates due to low resolution of resonances or peak splittings.

K_d values for complexation were estimated to be 4.6×10^{-3}M†† (G_1-α-CD-pNP) and 6.0×10^{-3}M (α-CD-pNP) at pD 7, and 5.1×10^{-4}M (G_1-α-CD-pNP) and 6.1×10^{-4}M (α-CD-pNP) at pD 10. Considering the pK_a value for pNP, the stability of the CD-pNP inclusion complex seems to depend on the ionization state of pNP, and pNP^- ion appears to be more stable than neutral pNP inside the cavity of CD.[16] The K_d values for G_1-α-CD-pNP complex at pD 7 and 10 are markedly close to those of α-CD-pNP complex at corresponding pD values, suggesting that G_1-α-CD and α-CD have a similar ability for complexation with pNP and pNP^-.

Host-Guest Geometry in G_1-α-CD-pNP Inclusion Complex. The orientation of pNP molecule insertion with respect to the cavity of CD can be deduced from the chemical shift changes induced on the resonances of pNP.[17] ^{1}H NMR NOE studies clearly indicated that pNP was preferentially inserted into the α-CD cavity from the 2,3-hydroxyl side with the nitro group first and the respective large and small downfield shifts of the meta- and ortho-proton resonances, respectively, are indicative of inclusion with this orientation.[18,19] The same trend of the chemical shift changes of pNP proton resonances was observed in both G_1-α-CD- and α-CD-pNP complexes, clearly suggesting similar insertion of pNP into the G_1-α-CD cavity as has been suggested for the α-CD-pNP complex. The observed chemical shift differences for the proton resonances of G_1-α-CD between free and complexed states (traces A and B in Fig. 2, respectively) are listed in Table 1, together with the corresponding data of α-CD-pNP complex. The resonances arising from **C** unit of G_1-α-CD are influenced by the addition of pNP like the corresponding resonances of α-CD, and it is consistent with the identical orientation of the pNP insertion in both complexes.

The insertion depth of the guest aromatic molecule into the cavity is determined by using the Johnson-Bovey theory from the chemical shift changes induced by the ring-current effect on the resonances of the H(3)

†† 1 M=1 mol dm^{-3}.

and H(5) protons. The Johnson-Bovey curves for the α-CD-pNP inclusion complex have been reported.[16] Insertion depth is defined as the distance between the center of the benzene ring of pNP and the plane comprised of six H(3) protons and the positive sign representative of the center of the benzene ring lying on the H(5) proton side with respect to the plane of H (3) protons. The depth was found to be 0.8±0.1 Å for α-CD-pNP complex. Assuming the close similarlity of the structural nature of the cavity between both hosts in complexed state, in the case of G_1-α-CD-pNP complex at pD 7 the induced shift changes of the H(3) and H(5) protons of **C** unit, δ −0.22 and −0.01 respectively, suggest that the depth is 0.7±0.2 Å. From these values, the depth of the pNP insertion into the G_1-α-CD cavity is almost the same with that into the α-CD cavity.

Conformation of G_1-α-CD in Complexed State with pNP. The degeneracy of proton resonances of **C** units is removed by complexation with pNP. As already discussed, since the H(1) protons are oriented outside of the cavity, their chemical shift changes may not be explained based on the aromatic ring current effect of pNP. The dispersion of their chemical shift values would be interpreted in terms of small differences in the conformation around the glucosidic bond among the (1→4)-α-linkages of G_1-α-CD in the complexed state with pNP because the magnetic anisotropy effect arising from the lone-pair electrons of the glucosidic oxygen is known to account for the chemical shift of the anomeric proton resonance in glucose derivatives.[20] Conformational changes are presumed to be induced to the different extent among the (1→4)-α-linkages of the macrocyclic ring, and more apparent indications of these conformational changes can be observed on ^{13}C NMR spectra (see below). In addition, the analysis of the vicinal coupling constant, J_{12}, revealed that the structural changes of the glucopyranose C_1 chair conformation of **B** and **C** units appear to be induced by the complexation to the different extent.[10]

It is interesting to investigate where the branch residue is located relative to the macrocyclic ring. The useful information on this location can be obtained from the analysis on the population of the rotamers around C(5)-C(6) bond of **B** unit. Although the spectral parameters for the H(5) and H(6) protons of **B** unit were not easily obtained in the spectrum of G_1-α-CD because of severe overlapping of resonances, two of those proton resonances are resolved in the spectrum of the complexed state with pNP. ^1H vicinal coupling constants, i.e. $^3J_{56a}$ and $^3J_{56b}$, in the spin-network of the glucopyranose residue provide the fractional rotamer populations about the C(5)-C(6) bond[21] and were accurately determined using the LAOCN spin simulation program[22] for **B** unit in the complexed state G_1-α-CD. The obtained spectral parameters are listed in Table 2. The three staggered rotamers, gg, gt, and tg (Fig.5) are considered around the C(5)-C(6) bond of **B** unilt.[23] The

Table 2. ^1H NMR Data for **B** Unit Included in G_1-α-CD Complexed with pNP

Chemical shift δ/ppm	Coupling constant $^3J_{HH}$/Hz	Rotamer population[b]/%
H(5) 4.06		P_{gg} 66 (63)
	J_{56a} 1.8	
H(6a) 3.82[a]		P_{gt} 32 (1)
	J_{56b} 4.6	
H(6b) 4.01[a]		P_{tg} 2 (35)

a) Assignment of H(6a) and H(6b) are interchangeable. The other assignment gives different rotamer populations which are designated in parentheses. b) Calculated with the following equations.[21] $1.7P_{gg}+1.9P_{gt}+11.1P_{tg}=J_{56a}$, $1.5P_{gg}+11.1P_{gt}+2.1P_{tg}=J_{56b}$, $P_{gg}+P_{gt}+P_{tg}=1$.

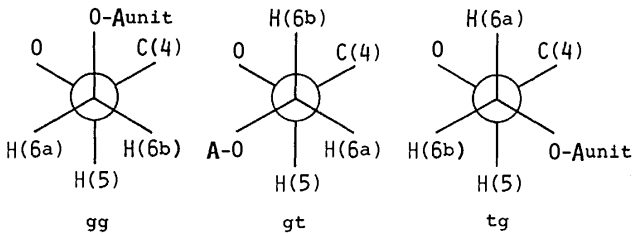

Fig. 5. Stable conformations gg, gt, and tg around C(5)-CH_2O-**A** unit group in **B** unit of G_1-α-CD.

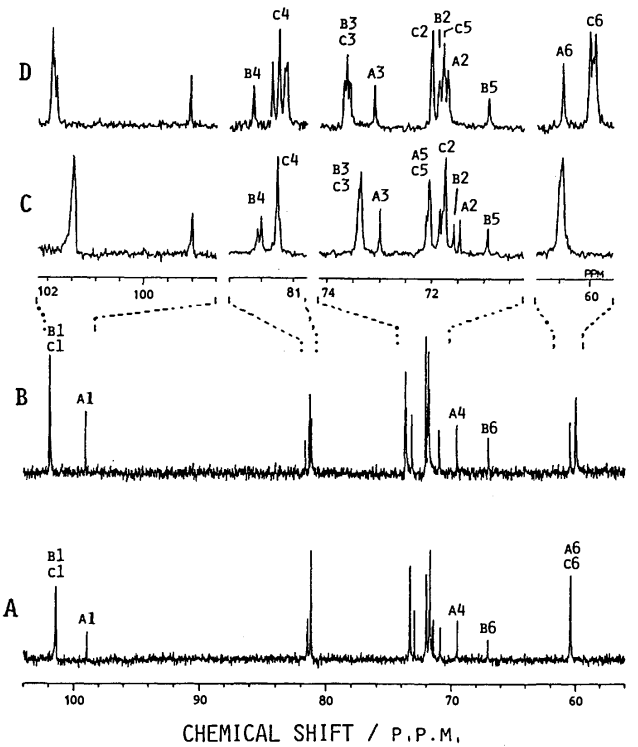

Fig. 6. 125 MHz ^{13}C NMR spectra of (A), (C) 0.04 M G_1-α-CD; (B), (D) 0.04 M G_1-α-CD mixed with 0.08 M pNP, in D_2O at pD 7 and 30 °C.

observed J_{56a} and J_{56b} are expressed with the rotamer populations p_{gg}, p_{gt}, and p_{tg} of the three rotamers by employing the equations in Ref. 21. The assignments of H(6a) and H(6b) are interchangeable, so two alternatives are obtained. In D-glucopyranose units, tg rotamer was very disfavored due to the 1,3-syn repulsion between OR(4) and OR(6).[21] Therefore the data listed in Table 2 represents the most probable rotamer populations for **B** unit. The caluculation indicated predominance of gg rotamer for the **B** unit (p_{gg}=66, p_{gt}=32, and p_{tg}=2), suggesting that the branch residue, **A** unit, is oriented away from the cavity of G_1-α-CD.

Interpretation of the ^{13}C Spectra. The 125 MHz ^{13}C NMR spectra of G_1-α-CD and its complex with two molar excess of pNP in D_2O at pD 7.0 and 30 °C are illustrated in traces A and B of Fig. 6, respectively. From the assignment of the ^1H resonances, the ^{13}C resonances can be assigned using ^1H-^{13}C COSY spectra.[10] The ^{13}C COSY contour plot of G_1-α-CD complexed with pNP, together with ^1H and ^{13}C NMR spectra, are shown in Fig. 7.

In agreement with the results of ^1H NMR, only single set of NMR signal pattern arising from **C** units is observed on ^{13}C NMR spectrum of G_1-α-CD (Fig. 6C), and the observed ^{13}C shifts of the resonances of **C** units are close to those of the corresponding resonances of α-CD (with the differences less than ±0.09 ppm).

Although C_6 symmetric property of α-CD is conserved in the complexed state as described above with the ^1H data, in the case of G_1-α-CD complexed with pNP most of ^{13}C resonances of **C** units are split into several peaks in addition to the shifts of their peaks (Fig. 6D). This indicates that the degeneracy of ^{13}C resonances from **C** units is removed by complexation with pNP, similar to their ^1H resonances, and the splitting of the C(1) and C(4) resonances of **C** units would be interpreted in terms of small differences in the electronic structure of their glucopyranose ring and the conformation of the glucosidic bond among the (1→4)-α-linkages of G_1-α-CD in the complexed state with pNP. It is partly because ^{13}C NMR chemical shifts of the anomeric and aglycone carbon atoms can be correlated with one of the glycoside tortion angles,[23] and partly because conformational distor-

Table 3. Observed Changes in the Chemical Shift of the ^{13}C Resonances of G_1-α-CD and α-CD Induced by Complexation with pNP

a) Obtained for the solution ([pNP]/[CD]=0.08M/0.04 M) at pD 7: positive values indicate the downfield shift. b) Not detected.

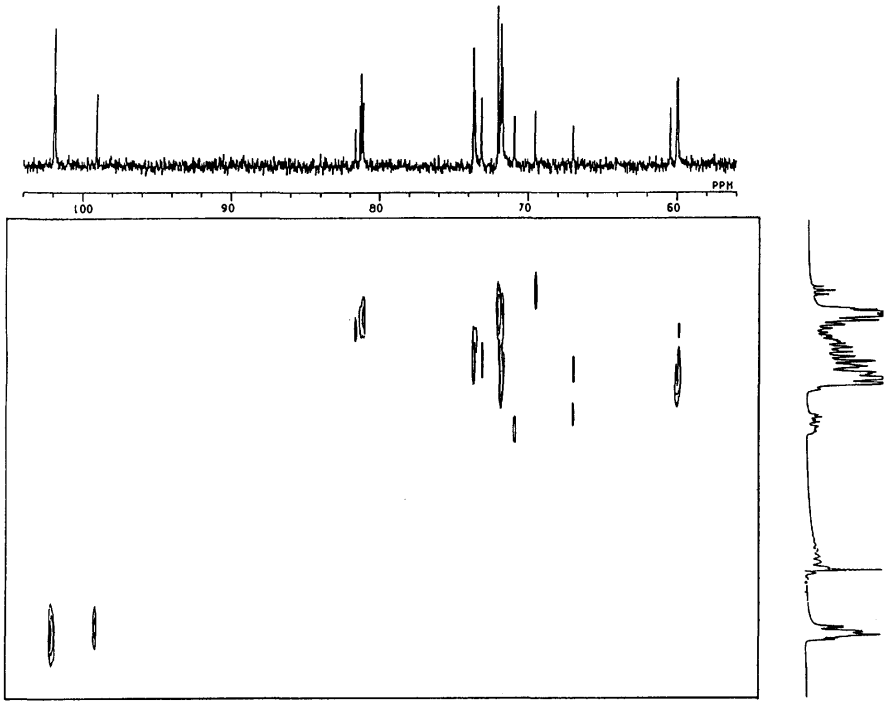

Fig. 7. ^1H-^{13}C COSY spectrum of G_1-α-CD complexed with pNP in D_2O at pD 7 and 30 °C. The ^1H and ^{13}C NMR spectra are attached along F_1 and F_2 axes, respectively.

tion of glucopyranose ring of **C** unit may occur. Due to the lack of C_6 symmetry on G_1-α-CD molecular structure, such conformational changes are not necessarily induced to the same extent among the (1→4)-α-glucosidic linkages of the macrocyclic ring. It is not possible at present to characterize the extent of conformational change of the individual (1→4)-α-linkages. The measurements of long-range C-H J resolved NMR spectra would provide the value of heteronuclear spin-spin coupling constants, $^3J_{COCH}$, which can be interpreted quantitatively in terms of dihedral angles, ϕ, ψ, of the individual(1→4)-α-linkages of G_1-α-CD.[24]

The observed ^{13}C chemical shift differences obtained from the spectra in Fig. 6 are listed in Table 3 with the related data for α-CD. The values for the resonances of **C** unit in G_1-α-CD complex are similar to those of the corresponding resonances of α-CD complex (with differences less than ±0.15 ppm), suggesting that the overall electronic structures are similar between both hosts in complexed state, but the conformational distortions might be induced to the different extent in each (1→4)-α-linkage and each **C** unit as was indicated by the analysis based on the ^1H coupling constant J_{12}. The smaller perturbation induced on the ^{13}C resonances of **A** unit than those of **C** units by the pNP addition indicates that no significant interaction between the branch residue, **A** unit, and pNP inserted into the cavity. This result consistents with those obtained from the analysis on the fractional rotamer populations which lead the conclusion that **A** unit is oriented away from the cavity of G_1-α-CD in complexed state. Although the C(1)-C(3) carbon resonances of **B** unit exhibit almost the same pattern of chemical-shift changes with those of the corresponding resonances of α-CD (with differences less than 0.04 ppm) , those of the resonances of the C(4), C(5), and C(6) carbons are different from those of α-CD (with differences 0.20 to 0.41 ppm). The latter carbons are located nearer the branch residue and the glucopyranose ring conformation of **B** unit is considered to be influenced by the movement of **A** unit. It might be assumed that the difference in the chemical shift changes between **B** unit and others was correlated with some changes of the orientation of **A** unit relative to the macrocyclic ring of G_1-α-CD, and further characterization of this difference and the conformational change is needed.

Experimental

Apparatus and Procedures. The ^1H spectra were recorded at 30 °C on either a JEOL GX-500 (500MHz) or a GX-270 (270 MHz) spectrometers, operating in the quadrature mode. The ^{13}C spectra (125 MHz) and 2D NMR specra were recorded at 30 °C on a GX-500 spectrometer. ^1H and ^{13}C chemical shifts δ are given in parts per million (ppm) downfield from that of Me_4Si with an accuracy of about 0.005 and 0.01 ppm, respectively.

The ^1H-^{13}C COSY spectrum was recorded using the pulse sequence [PD-90° (^1H)-t_1/2-180°(^{13}C)-t_1/2-D_1-90°(^1H, ^{13}C)-D_2-t_2 (with ^1H decoupling)].[25] The delay times D_1 and D_2 were set to 3.4 and 1.7 ms, respectively. A total of 128 transients was accumulated per t_1 value with a pulse delay of 1 s. The initial data matrix was 2K(^{13}C-10000 Hz)×128(^1H-3000 Hz) in the ω_2 and ω_1 dimensions, respectively, and was expanded to the final matrix size 2K×512 by zero filling. The data matrix was apodised with sine bell function and absolute value mode spectrum is presented. DQF-COSY spectra were recorded using the standard procedures.[11]

Spectrum simulations were run on an NEC PC-9801VM personal computer using a LAOCN spin-simulation program.[22]

Materials. G_1-α-CD was prepared using the procedures of Kobayashi et al.[1,2] α-CD was a generous gift from Nihon Shokuhin Kako Co., Ltd. pNP was commercial materials and was purified by high-vacuum sublimation. D_2O with isotopic purity of 99.7% was purchased from Merck Co.

^1H NMR Determination of Dissociation Constants for the Inclusion Complexes. The 270 MHz ^1H NMR spectra were recorded on a GX-270 spectrometer at 30 °C. The change in chemical shift of the pNP aromatic proton resonances was measured as a function of host to guest molar ratio. The pNP and its ionized state, p-nitrophenolate (pNP^-), were prepared in D_2O solution at pD 7.0 and 10.0, respectively. The concentrations of pNP and pNP^- were held constant at 2.5 mM each, and the concentrations of α-CD and G_1-α-CD were varied between 2—50 mM. The data were treated according to a modified Benesi-Hildebrand equation,[15] and linear least-squares analysis were performed on all data.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 62430019).

No Electron-Donating Substituent Effect on the Singlet Excited State Formation from the 5-(5-Aryl-2-pyrazinylamino)-1,2,4-trioxanes in Dimethyl Sulfoxide Triggered by Potassium *t*-Butoxide

Katsunori TERANISHI and Toshio GOTO*
Laboratory of Organic Chemistry, Faculty of Agriculture, Nagoya University, Chikusa, Nagoya 464
(Received January 11, 1989)

5-(5-Phenyl-2-pyrazinylamino)-1,2,4-trioxane derivatives having a substituent on the 4 position of the phenyl group gave chemiluminescence in dimethyl sulfoxide by addition of potassium *t*-butoxide. No electron-donating substituent effect was observed on the yield of singlet excited state formation. This may be explained by the negative charge formed on the nitrogen atom next to the transient dioxetane moiety, which may produce singlet excited-state molecule by the intramolecular CIEEL mechanism.

Simple, isolable dioxetanes such as tetramethyl-1,2-dioxetane are relatively stable at room temperature and afford predominantly triplet excited-state molecules on thermolysis,[1] whereas singlet excited products were efficiently produced in the case of bioluminescent systems such as firefly and *Cypridina*[2] (Scheme 1). In the latter cases, the transient 1,2-dioxetane intermediate produced must be extremely unstable[3] so as in the case of efficiently chemiluminescent compounds. The high efficiency of singlet excited state production and the instability of the intermediate dioxetanes in bioluminescence and efficient chemiluminescence may come from the conjugation of an electron-donating (easily oxidizable) and highly fluorescent chromophore with the excited-state carbonyl group to be formed.[4]

Koo et al.[5] explained these effects in terms of the chemically initiated intramolecular electron-exchange luminescence (intramolecular CIEEL) mechanism. In the firefly case, for example (Scheme 2), electron transfer from the easily oxidizable phenoxide anion to the highly energized dioxetanone moiety to cause a heterolytic O-O bond fission followed by rapid decarboxylation with electron exchange generates an excited state product (emitter). Thus, the phenoxide anion formation would accelerate strongly the dioxetane decomposition[6] and singlet state formation.

This is further supported by the observation of Schaap and Gagnon[7] in chemiluminescence of some dioxetanes. Dioxetane **7b** having a *p*-hydroxyphenyl substituent is fairly stable at room temperature in *o*-xylene (tau 1/2 at 25 °C, 57 h), but addition of *t*-BuOK/18-crown-6 dramatically accelerates the rate of decomposition (4.4×10^6 times) of **7b** with produc-

tion of singlet excited molecules ca. 160 times more than that formed from the neutral molecules. An amino group also has a strongly electron-donating ability and hence is expected to have the effect similar to $-O^-$.[4,8-10]

Coelenterazine (*Oplophorus* luciferin) (**8**)[2] which is a luminescent chromophore of a photoprotein, aequorin, has a *p*-hydroxyphenyl substituent on the 3,7-dihydroimidazo[1,2-*a*]pyrazin-3-one chromophore, which is transformed to a dioxetane intermediate during bioluminescent oxidation (see Scheme 1). Shimomura et al.[11] previously suggested that the phenolic hydroxyl group must be dissociated in the photoprotein. It might indicate that the phenoxide anion, as in the firefly luciferin case, contributes to the quantum yield of singlet excited state formation, but very recently Shimomura et al.[12] also suggested that such an anion formation in aequorin would not be important. To see whether this dissociation of the phenolic hydroxyl group is necessary or not to produce a high-quantum-yield luminescence similar to the case of firefly bioluminescence, we have examined the trioxane **9e** in comparison with those having other substituents, since such the trioxanes **9** have been found to give strong chemiluminescence with base[13,14] and are regarded as a luminescent system similar to coelenterazine (**8**) and *Cypridina* luciferin (**1**) (Scheme 3).[15]

As shown in Table 1, the *p*-hydroxyphenyl-substituted trioxane **9e** gave a slightly higher chemiluminescence quantum yield than the phenyl or methoxyphenyl trioxane, **9a** or **9c**, but quantum yield of singlet excited-state molecules was rather decreased since the fluorescence quantum yield of the product **10e** was better than that of others. In this case the phenolic hydroxyl group was dissociated to form phenoxide anion, which has almost no effect on the formation of the singlet excited molecule. 4-Dimethylaminophenyl and 3-indolyl derivatives, **9f** and **9g**, behave

similarly. The difference in the behavior between the Schaap's compound **7** and the present case may be explained as follows. In the present case, cyclization of the intermediate hydroperoxide anion forms the dioxetane having a negative charge on the nitrogen atom next to the dioxetane moiety. The negative charge donates enough electrons to the dioxetane moiety to produce singlet excited state molecule **10** so

(10f) R=CHO X=NMe_2
(11e) R=H X=OH
(11f) R=H X=NMe_2

that no other electron-donating moiety would be necessary. On the other hand, firefly luciferin (**4**) and the Schaap's compound **7a** without a phenoxide anion on the molecule have insufficient electrton-donating ability to the intermediate dioxetane moiety so that only triplet state produces predominantly. Thus, ionization of the phenolic hydroxyl group in the firefly luciferin (**4**) and **7b** dramatically changes the yield of singlet excited state molecules, whereas no such a change is observed in the present case. This explanation may also be extended to the luminescence of *Cypridina* luciferin (**1**), since the initially produced excited molecule was proven to be anion of the oxyluciferin (**3**).[16]

Experimental

All melting points were measured on a Mitamura Riken mp aparatus and uncorrected. ^{1}H NMR spectra were recorded on a JNM-FX200 spectrometer. Chemical shifts are given in ppm from internal TMS and coupling constants in Hz. IR spectra were taken on a JASCO IR-700 infrared spectrometer. UV spectra were obtained on a Hitachi 228 spectrometer. Mass spectra were measured on a JEOL JMS-DX300 instrument. Chemiluminescence and fluorescence spectra were recorded on an Otsuka Electronics MCPD-110A and JASCO FP-770 spectrometers, respectively. Dimethyl sulfoxide was distilled from calcium hydride under reduced pressure. The other solvents were of reagent grade.

5-(4-Dimethylaminophenyl)-3-benzyl-2-aminopyrazine (11f): To a solution of *p*-dimethylaminophenylglyoxal oxime[17] (3.0 g) and 2-amino-3-phenylpropionitrile (3.0 g) in pyridine (50 ml) was added $TiCl_4$ (2.0 ml) dropwise under argon at 0 °C. After being allowed to stand for 10 min, the mixture was heated at 50 °C for 30 min. To this reaction mixture was added slowly 10% aq $NaHCO_3$ at 0 °C to neutralize it and the resulting mixture was filtered through Celite bed. The filtrate was diluted with water and extracted three times with ethyl acetate. The organic layer was washed with water and sat. NaCl solution, dried over anhydrous Na_2SO_4, and evaporated to dryness. The residue was crystallized from ethyl acetate to give the *N*-oxide of **11f** (2.8 g). The *N*-oxide was dissolved in MeOH (100 ml) and CH_2Cl_2 (20 ml) and reduced with Raney Ni (W2) at 50 °C under hydrogen atmosphere for 5 h with stirring, and the mixture was filtered. The filtrate was concentrated to a small volume and diluted with diethyl ether to give the aminopyrazine **11f** (2.5 g, 52%); slightly brownish needles (from methanol), mp 175—176 °C; IR (KBr) cm^{-1} 3478, 3294, 3134, 1610, 1463; UV (MeOH) λ_{max}/nm (ε) 304 (24800), 366 (10500); MS *m/z* 304 (M^+); ^{1}H NMR ($CDCl_3$) δ (*J*) 3.00 (6H, s), 4.30 (2H, s), 4.40 (2H, br. s), 6.80 (2H, d, 9.0), 7.30 (5H, s), 7.84 (2H, d, 9.0), 8.30 (1H, s). Calcd for $C_{19}H_{20}N_4$: C, 74.97; H, 6.62; N, 18.41%. Found: C, 75.00; H, 6.70; N, 18.63%.

5-[5-(4-Dimethylaminophenyl)-3-benzyl-2-pyrazinylamino]-3-isopropyl-6,6-dimethyl-1,2,4-trioxane (9f): A solution of the aminopyrazine **11f** (400 mg) and isobutyraldehyde (5.0 ml) in hexane (10 ml) was heated at 90 °C for 3 h and then stirred at 20 °C for 3 days with a $CaCl_2$ tube. The mixture was poured in 5% aq $NaHCO_3$ and extracted twice with ethyl acetate. The organic layer was dried over anhydrous Na_2SO_4 and evaporated. The residue was chromatographed on a silica-gel column with ethyl acetate–hexane (1 : 20) to give a mixture of two diastereomers of **9f** (350 mg, 58%), which was crystallized from hexane. Recrystallizations of the mixture from hexane gave a main isomer of **9f** as slightly brownish needles, mp 129—130 °C; IR (KBr) cm^{-1} 1611, 1499; UV (MeOH) λ_{max}/nm (ε) 306 (23900), 362 (12700); MS *m/z* 462 (M^+); ^{1}H NMR ($CDCl_3$) δ (*J*) 0.80 (3H, s), 0.90 (3H, d, 7), 0.91 (3H, s, 7), 1.12 (3H, s) 1.79 (1H, m), 3.00 (6H, s), 4.13 (1H, d, 16), 4.30 (1H, d, 16), 4.42 (1H, br. d, 10), 5.12 (1H, d, 5.0), 5.58 (1H, d, 10), 6.84 (2H, br. d, 9.0), 7.25 (5H, m), 7.86 (2H, d, 9.0), 8.40 (1H, s). Calcd for $C_{27}N_{34}O_3N_4$: C, 70.10; H, 7.41; N, 12.11%. Found: C, 70.23; H, 7.46; N, 12.39%.

5-[5-(4-Hydroxyphenyl)-3-benzyl-2-pyrazinylamino]-3-isopropyl-6,6-dimethyl-1,2,4-trioxane (9e): The trioxane **9e** was prepared from the aminopyrazine **11e**[18] (170 mg), isobutyraldehyde (5.0 ml) and hexane (20 ml) according to the procedure described in the preparation of **9f**. After chromatography was obtained **9e** (180 mg, 70%) as a 4 : 1 mixture of diastereomers; slightly yellowish amorphous solid (from ether–hexane); mp 65—67 °C; IR (KBr) cm^{-1} 3430, 1498; UV (MeOH) λ_{max}/ nm (ε) 280 (22200), 346 (10500); MS *m/z* 435 (M^+). Calcd for $C_{25}N_{29}O_4N_3$: C, 68.94; N, 6.71; N, 9.65%. Found: C, 68.89; N, 6.84; N, 9.58%. ^{1}H NMR ($CDCl_3$) δ (*J*): **major isomer** (20 °C) 0.80 (3H, s), 0.90 (6H, d, 6.8), 1.12 (3H, s), 1.75 (1H, m), 4.14 (1H, d, 16), 4.30 (1H, d, 16), 4.50 (1H, d, 10), 5.12 (1H, d, 4.5), 5.58 (1H, d, 10), 5.80 (1H, br. s), 6.90 (2H, d, 8.7), 7.20—7.40 (5H, m), 7.80 (2H, d, 8.7), 8.38 (1H, s); **minor isomer** (60 °C) : 0.77 (3H, d, 7), 0.78 (3H, d, 7), 0.90 (3H, s),1.60 (3H, s) 1.7 (1H, m), 4.14 (1H, d, 15), 4.29 (1H, d, 15), 4.40, (1H, d, 5.0) 5.42 (1H, d, 9.0), 5.58 (1H, d, 9.0), 6.90 (2H, d, 9.0), 7.4 (5H, m), 7.86 (2H, d, 9.0), 8.41 (1H, s).

5-(4-Dimethylaminophenyl)-3-benzyl-2-(formylamino)-pyrazine (10f): To a solution of the aminopyrazine **11f** (50 mg) in pyridine (0.8 ml) was added acetic formic anhydride (0.2 ml) dropwise at 0 °C. After being stirred further 2 h, the mixture was evaporated to dryness to give the amide **10f**

(45 mg) as yellow needles from methanol; mp 200—202 °C; IR (KBr) 1681 cm^{-1}; UV (MeOH) λ_{max}/nm (ε) 328 (996), 370 (11400); MS m/z 332 (M^+); ^1H NMR ($CDCl_3$-CD_3OD, 80 °C) δ (*J*) 3.00 (6H, s), 4.24 (2H, s), 6.80 (2H, d, 9.5), 7.25 (5H, s), 7.87 (2H, d, 9.5), 8.50 (1H, s), 9.04 (1H, br.s). Calcd for $C_{20}N_{20}ON_4$: C, 72.27; N, 6.07; N, 16.86%. Found: C, 72.23; N, 6.05; N, 17.03%.

5-(4-Hydroxyphenyl)-3-benzyl-2-formylaminopyrazine (10e): To a solution of the aminopyrazine **11e** (50 mg) in pyridine (0.8 ml) was added acetic formic anhydride (0.2 ml) at 0 °C. After being stirred further 2 h, the reaction mixture was evaporated to dryness and the residue purified by silica gel TLC to give **10e** (20 mg, 36%) as colorless needles from methanol; mp 208—210 °C; IR (KBr) cm^{-1} 3368, 1674; UV (MeOH) λ_{max}/nm (ε) 277 (18000), 294 (15800), 341 (15600); MS m/z 305 (M^+); ^1H NMR ($CDCl_3$-acetone-d_6) δ (*J*) 4.30 (2H, s), 6.96 (2H, d, 8.0), 7.28 (5H, s), 7.88 (2H, d, 8.0), 8.20 (1H, br.d, disappeared with D_2O), 8.30 (1H, s, diappeared with D_2O), 8.52 (1H, s), 9.3 (1H, br.s). Calcd for $C_{18}N_{15}O_2N_3$: C, 70.80; H, 4.95; N, 13.76%. Found: C, 70.83; H, 4.95; N, 13.95%.

Chemiluminescence and Fluorescence Measurements. To a solution of a trioxane (concn 1×10^{-5} mol l^{-1}) in dimethyl sulfoxide (2 ml) was added a solution of *t*-BuOK (0.25 mol l^{-1}) in *t*-BuOH (0.1 ml) at 25 °C. The resulting light emission was recorded with a luminometer. Quantum yields of chemiluminescence and fluorescence were determined as described previously.[4]

Synthesis of *S*-Methyl 2-Hydroxyalkanethioates, 2-Hydroxyalkanoic Acids and Related Compounds via the Addition Reaction of Tris(methylthio)methanide Ion to Alkanals

Kazuhiko ORITO,* Yoshikatsu SEKI, Hiroshi SUGINOME, and Tsukasa IWADARE†
Department of Chemical Process Engineering, Hokkaido University, Sapporo 060
†Research Laboratory, Sakura Finetechnical Co., Ltd., 3-1-8, Hikawadai, Nerima-ku, Tokyo 176
(Received January 11, 1989)

In connection with the studies on biological activities on myrmicacin and related compounds, the synthetic method for 2-hydroxyalkanoic acids and the corresponding 1,2-diols was studied. The addition reaction of tris(methylthio)methyllithium to the aldehydes (propanal—dodecanal) gave the corresponding 1,1,1-tris-(methylthio)-2-alkanols **1a—j**. Treatment of **1** with mercury(II) chloride-mercury(II) oxide in water-acetone afforded *S*-methyl 2-hydroxyalkanethioates **2a—j**, and in methanol methyl 2-hydroxyalkanoates **3c—j** were obtained. Reduction of the thioates **2** with lithium aluminium hydride gave 1,2-diols **4c—j** and saponification produced the corresponding 2-hydroxyalkanoic acids **5c—j**.

Myrmicacin was isolated from the secretion of South American leaf-cutting ants, *Atta sexdens*, and identified as (*R*)-(−)-3-hydroxydecanoic acid by Schildeknecht and Koob in 1971.[1] It is understood that this substance prevents germination of collected seeds and intruding spores, as a herbicide, in the ant's nest. Recent studies revealed that it had a reversible inhibitory effect on pollen growth.[2-6] The activity of myrmic acids[7] on cleavage of fertilized sea urchin eggs,[8,9] HeLa cells,[10] human erythrocytes,[11] and propagation of pathogenic bacteria in silk worm, *larvae*[12] has been reported. A close relationship between intensity of inhibitory activity and degree of lipophilicity of myrmicacin analogues has recently been found.[13,14] Strong inhibitory activity of 2-hydroxyalkanoic acids on pollen germination has also been observed.[15]

In view of the above-stated facts, it seemed of significance for further study on biological activity of myrmicacin and related compounds to establish the synthetic method of 2-hydroxyalkanoic acids[16a,17] as well as 1,2-diols[16b,17] with a common starting material and to obtain their physical properties and spectral data. Thus the present study was undertaken.

Results and Discussion

To a solution of tris(methylthio)methanide ion, generated by interaction of tris(methylthio)methane with butyllithium at −78 °C,[18-20] was slowly added the tetrahydrofuran solution of the appropriate aldehydes (C_3—C_{12}). By warming the mixture to room temperature, the corresponding tris(methylthio)methyl adducts (**1a—j**) were obtained in good yields, as shown in Table 1. Preliminary attempts to prepare the straight-chain 2-hydroxyalkanoic acids **5** were made by treating the adducts **1** with mercury(II) chloride or mercury(II) oxide in aqueous solution, according to the procedure described by Seebach.[18] In each case the main product was not the 2-hydroxyalkanoic acid but the *S*-methyl 2-hydroxyalkanethioates **2**.[19a] When stirred in a suspension with mercury(II) chloride-mercury(II) oxide[20] (2.5 : 1.0 mol) in water-acetone (1 : 5) at room temperature for 2 h, the adducts **1** were efficiently converted to the thioates **2** in the yields ranging in 75—95%, as summarized together with boiling and melting points of the analytical samples in Table 2.[21] When heated to reflux for 1 h, the thioates **2** were obtained also in good yield. Longer heating did not give much effect on further hydrolysis (desulfurization) to the acids. Boron trifluoride etherate-mercury(II) oxide[19] worked well and gave **2** in the yields comparable to those given for the aforementioned reactions in the presence of mercury(II) chloride-mercury(II) oxide. Similarly, when the adducts **1** were refluxed with mercury(II) chloride-mercury(II) oxide (2.5 : 1.0 mol) in methanol for 2 h, the ready formation of the methyl esters **3** took place. However, the esters with lower molecular weights were isolated in the lesser yields due to their water-soluble character (Table 3). Treatment of the *S*-methyl thioates **2** with excess

lithium aluminium hydride in boiling tetrahydrofuran gave the 1,2-diols **4** in essentially quantitative yields (Table 4). Saponification of the thioates **2** in the usual manner furnished the corresponding crystalline 2-hydroxyalkanoic acids **5** in good yields as well (Table 5).

Experimental

Melting points were determined on a Laboratory Devices MEL-TEMP, and are uncorrected. Boiling points are uncorrected. IR spectra were recorded using the neat samples, unless otherwise stated, on a Hitachi-Perkin Elmer Model 125 spectrophotometer. ^1H NMR spectra were run in $CDCl_3$ solutions with Me_4Si as an internal reference at ambient temperature and resistered on a 90 MHz Hitachi R-22 spectrometer.

General Procedure for the Addition Reaction of Tris(methylthio)methyllithium to Aldehydes. A stirred solution of tris(methylthio)methane (4.62 g, 0.03 mol)[20] in dry THF (50 ml) under an atmosphere of nitrogen was cooled at −78 °C, *n*-BuLi (0.029 mol, 18.5 ml) of 10 w/v% hexane solution was dropwise added at such a rate that the temperature did not rise more than −15 °C (10 min or more). An additional stirring at −78 °C for 15 min gave a white suspension, probably, due to partly precipitated lithium salt of tris(methylthio)methane. A solution of the freshly distilled appropriate aldehyde (0.025 mol) in dry THF (20 ml) was gradually added in the course of 20 min and the mixture was kept stirring at −78 °C for further 1 h. The cooling bath was removed and the mixture was allowed to warm to room temperature (1 h). To this, saturated NH_4Cl solution (20 ml) was added, and the mixture was shaken. The aqueous layer was extracted with ether (20 ml×2). The combined organic layers were washed with saturated brine (20 ml) and dried over anhydrous Na_2SO_4. Evaporation of the solvent left an oil, which was distilled in vacuo to give the pure alcohol.

1,1,1-Tris(methylthio)-2-butanol (1a). 4.0 g. IR 3460 cm^{-1}; ^1H NMR δ=1.03 (3H, br. t, J=7.0 Hz, CH_3), 1.75 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.74 (1H, d, J=4.0 Hz, OH),[22] 3.62 (1H, ddd, J=9.5, 4.0, 3.0 Hz, C<u>H</u>OH[23]→dd,

J=9.5, 3.0 Hz). Found: C, 39.61; H, 7.50; S, 45.29%. Calcd for $C_7H_{16}OS_3$: C, 39.59; H, 7.59; S, 45.29%.

1,1,1-Tris(methylthio)-2-pentanol (1b). 4.3 g. IR 3470 cm^{-1}; ^1H NMR δ=0.92 (3H, br. t, J=7.0 Hz, CH_3),1.1—1.9 (4H, m, 2×CH_2) 2.19 (9H, s, 3×SCH_3), 2.74 (1H, d, J=4.0 Hz, OH),[22] 3.72 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 3.0 Hz). Found: C, 42.22; H, 7.90; S, 42.59%. Calcd for $C_8H_{18}OS_3$: C, 42.44; H, 8.01; S, 42.48%.

1,1,1-Tris(methylthio)-2-hexanol (1c). 5.3 g. IR 3430 cm^{-1}; ^1H NMR δ=0.87 (3H, br. t, J=7.0 Hz, CH_3), 1.20 (4H, m, 2×CH_2), 1.71 (2H, m, CH_2), 2.19 (9H, s, 3×SCH_3), 2.72 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 44.69; H, 8.27; S, 39.83%. Calcd for $C_9H_{20}OS_3$: C, 44.69; H, 8.38; S, 40.00%.

1,1,1-Tris(methylthio)-2-heptanol (1d). 5.65 g. IR 3450 cm^{-1}; ^1H NMR δ=0.87 (3H, br. t, J=7.0 Hz, CH_3), 1.32(6H, m, 3×CH_2), 1.71 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.75 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 47.11; H, 8.65; S, 37.61%. Calcd for $C_{10}H_{22}OS_3$: C, 47.20; H, 8.71; S, 37.80%.

1,1,1-Tris(methylthio)-2-octanol (1e). 6.1 g. IR 3470 cm^{-1}; ^1H NMR δ=0.85 (3H, br. t, J=6.0 Hz, CH_3), 1.29 (8H, m, 4×CH_2), 1.71 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.74 (1H, d, J=4.0 Hz, OH),[22] 3.70 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 49.14; H, 9.01; S, 35.66%. Calcd for $C_{11}H_{24}OS_3$: C, 49.21; H, 9.01; S, 35.82%.

1,1,1-Tris(methylthio)-2-nonanol (1f). 6.3 g. IR 3450 cm^{-1}; ^1H NMR δ=0.84 (3H, br. t, J=6.0 Hz, CH_3), 1.28 (10H, m, 5×CH_2), 1.72 (2H, m,CH_2), 2.17 (9H, s, 3×SCH_3), 2.73 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 51.02; H, 9.13; S, 34.16%. Calcd for $C_{12}H_{26}OS_3$: C, 51.02; H, 9.28; S, 34.04%.

1,1,1-Tris(methylthio)-2-decanol (1g). 6.5 g. IR 3460 cm^{-1}; ^1H NMR δ=0.85 (3H, br. t, J=6.0 Hz, CH_3), 1.28 (12H, m, 6×CH_2), 1.72 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.73 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 52.54; H, 9.46; S, 32.57%. Calcd for $C_{13}H_{28}OS_3$: C, 52.65; H, 9.52; S, 32.43%.

1,1,1-Tris(methylthio)-2-undecanol (1h). 6.8 g. IR 3460 cm^{-1}; ^1H NMR δ=0.84 (3H, br. t, J=6.0 Hz, CH_3), 1.25 (14H, m, 7×CH_2), 1.72 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.73 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.0, 2.0 Hz). Found: C, 54.10; H, 9.76; S, 30.96%. Calcd for $C_{14}H_{30}OS_3$: C, 54.14; H, 9.74; S, 30.97%.

1,1,1-Tris(methylthio)-2-dodecanol (1i). 7.1 g. IR 3450 cm^{-1}; ^1H NMR δ=0.84 (3H, br. t, J=6.0 Hz, CH_3), 1.24 (16H, m, 8×CH_2), 1.71 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.73 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 55.76; H, 9.96; S, 29.81%. Calcd for $C_{15}H_{34}OS_3$: C, 55.50; H, 9.96; S, 29.63%.

1,1,1-Tris(methylthio)-2-tridecanol (1j). 8.05 g. IR 3470 cm^{-1}; ^1H NMR δ=0.84 (3H, br. t, J=6.0 Hz, CH_3), 1.24 (18H, m, 9×CH_2), 1.71 (2H, m, CH_2), 2.18 (9H, s, 3×SCH_3), 2.73 (1H, d, J=4.0 Hz, OH),[22] 3.71 (1H, m, C<u>H</u>OH[23]→dd, J=8.5, 2.5 Hz). Found: C, 56.73; H, 10.15; S, 28.48%. Calcd for $C_{16}H_{34}OS_3$: C, 56.75; H, 10.15; S, 28.40%.

General Procedure for Preparation of *S*-Methyl 2-Hydroxyalkanethioates (2). A mixture of each orthothiocarboxylic acid trimethyl ester (**1**, 1 mmol), $HgCl_2$ (5 mmol), and HgO (red, 2 mmol) in a solution of H_2O–acetone (1 : 5, 30 ml) was refluxed with stirring for 2 h. Precipitates were filtered, and acetone was evaporated at room temperature. The residue was dissolved in CH_2Cl_2, washed with saturated NH_4Cl solution (2 ml), and dried over anhydrous Na_2SO_4. Evaporation of the solvent gave the crude product, which was distilled in vacuo to afford the pure *S*-methyl 2-hydroxyalkanethioate **2**. Analytical samples of **2g—j** were prepared on crystallization from petroleum ether.

***S*-Methyl 2-Hydroxybutanethioate (2a).** 150 mg. IR 3400, 1660 cm^{-1}; ^1H NMR δ=1.00 (3H, br. t, J=7.5 Hz, CH_3), 1.82 (2H, m, CH_2), 2.23 (3H, s, SCH_3), 3.05 (1H, d, J=6.0 Hz, OH),[22] 4.28 (1H, m, C<u>H</u>OH[23]→dd, J=8.0, 4.5 Hz). Found: C, 44.69; H, 7.57; S, 23.67%. Calcd for $C_5H_{10}O_2S$: C, 44.75; H, 7.51; S, 23.89%.

***S*-Methyl 2-Hydroxypentanethioate (2b).** 186 mg. IR 3400, 1660 cm^{-1}; ^1H NMR δ=0.97 (3H, br. t, J=7.0 Hz, CH_3), 1.53 (2H, m, CH_2), 1.71 (2H, m, CH_2), 2.35 (3H, s, SCH_3), 3.01 (1H, d, J=6.0 Hz, OH),[22] 4.33 (1H, m, C<u>H</u>OH[23]→dd, J=6.0, 4.0 Hz). Found: C, 48.76; H, 8.22; S, 21.44%. Calcd for $C_6H_{12}O_2S$: C, 48.62; H, 8.16; S, 21.62%.

***S*-Methyl 2-Hydroxyhexanethioate (2c).** 275 mg. IR 3400, 1660 cm^{-1}; ^1H NMR δ=0.92 (3H, br. t, J=7.0 Hz, CH_3), 1.43 (4H, m, 2×CH_2), 1.78 (2H, s,CH_2), 2.33 (3H, s, SCH_3), 3.09 (1H, d, J=5.5 Hz, OH),[22] 4.33 (1H, m, C<u>H</u>OH[23]→dd, J=7.0, 4.0 Hz). Found: C, 51.79; H, 8.68; S, 19.83%. Calcd for $C_7H_{14}O_2S$: C, 51.83; H, 8.99; S, 19.76%.

***S*-Methyl 2-Hydroxyheptanethioate (2d).** 306 mg. IR 3400, 1660 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=6.0 Hz, CH_3), 1.33 (6H, m, 3×CH_2), 1.78 (2H, m, CH_2), 2.33 (3H, s, SCH_3), 3.01 (1H, d, J=7.0 Hz, OH),[22] 4.33 (1H, m, C<u>H</u>OH[23]→dd, J=8.0, 4.5 Hz). Found: C, 54.49; H, 9.17; S, 18.16%. Calcd for $C_8H_{16}O_2S$: C, 54.51; H, 9.15; S, 18.19%.

***S*-Methyl 2-Hydroxyoctanethioate (2e).** 338 mg. IR 3400, 1660 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=6.0 Hz, CH_3), 1.33 (8H, m, 4×CH_2), 1.75 (2H, m, CH_2), 2.33 (3H, s, SCH_3), 3.02 (1H, d, J=5.0 Hz, OH),[22] 4.33 (1H, m, C<u>H</u>OH[23]→dd, J=8.0, 4.5 Hz). Found: C, 56.85; H, 9.66; S, 16.73%. Calcd for $C_9H_{18}O_2S$: C, 56.80; H, 9.53; S, 16.85%.

***S*-Methyl 2-Hydroxynonanethioate (2f).** 339 mg. ***S*-Methyl 2-Hydroxyundecanethioate (2h).** 376 mg. IR (Nujol) 3470, 1665 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=6.0 Hz, CH_3), 1.26 (14H, m, 7×CH_2), 1.75 (2H, m, CH_2) , 2.34 (3H, s, SCH_3), 2.92 (1H, br. s, OH), 4.32 (1H, dd, J=7.5, 4.0 Hz, CHOH). Found: C, 61.93; H, 10.32; S, 13.77%. Calcd for $C_{12}H_{24}O_2S$: C, 62.02; H, 10.42; S, 13.80%.

***S*-Methyl 2-Hydroxydodecanethioate (2i).** 408 mg. IR (Nujol) 3470, 1665 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.25 (16H, m, 8×CH_2), 1.75 (2H, m, CH_2) , 2.32 (3H, s, SCH_3), 2.65 (1H, br. s, OH), 4.32 (1H, d, J=6.5, 4.0 Hz, C<u>H</u>OH). Found: C, 63.28; H, 10.52; S, 12.99%. Calcd for $C_{13}H_{26}O_2S$: C, 63.37; H, 10.63; S, 13.01%.

***S*-Methyl 2-Hydroxytridecanethioate (2j).** 430 mg. IR (Nujol) 3470, 1665 cm^{-1}; ^1H NMR δ=0.90 (3H, br. t, J=6.0 Hz, CH_3), 1.24 (18H, m, 9×CH_2), 1.75 (2H, m, CH_2) , 2.32 (3H, s, SCH_3), 2.65 (1H, br. s, OH), 4.32 (1H, dd, J=6.5, 4.0

Hz, CHOH). Found: C, 64.46; H, 10.69; S, 12.38%. Calcd for $C_{14}H_{28}O_2S$: C, 64.57; H, 10.84; S, 12.31%.

General Procedure for Preparation of Methyl Esters 3 from 1. A mixture of **1** (2 mmol), $HgCl_2$ (5 mmol), and HgO (red, 2 mmol) in a solution of 99% MeOH (20 ml) was refluxed for 1 h, and worked up in the same manner as noted for **2**. The crude oily product was distilled in vacuo.

Methyl 2-Hydroxyhexanoate (3c). 171 mg. IR 3450, 1730 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=7 Hz, CH_3), 1.40 (4H, m, 2×CH_2), 1.71 (2H, m, CH_2), 2.90 (1H, d, J=6.0 Hz, OH),[22] 3.82 (3H, s, OCH_3), 4.26 (1H, m, CHOH[23]→dd, J=6.5, 4.5 Hz). Found: C, 57.52; H, 9.53%. Calcd for $C_7H_{14}O_3$: C, 57.51; H, 9.65%.

Methyl 2-Hydroxyheptanoate (3d). 181 mg. IR 3460, 1730 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=7.0 Hz, CH_3), 1.34 (6H, m, 3×CH_2), 1.71 (2H, m, CH_2), 3.04 (1H, d, J=6.0 Hz, OH), 3.82 (3H, s, OCH_3),[22] 4.21 (1H, m, CHOH[23]→dd, J=6.5, 6.0 Hz). Found: C, 60.03; H, 10.16%. Calcd for $C_8H_{16}O_3$: C, 59.98; H, 10.07%.

Methyl 2-Hydroxyoctanoate (3e). 234 mg. IR 3450, 1732 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=7.5 Hz, CH_3), 1.33 (8H, m, 4×CH_2), 1.71 (2H, m, CH_2), 2.94 (1H, d, J=5.5 Hz, OH),[22] 3.83 (3H, s, OCH_3), 4.25 (1H, m, CHOH[23]→dd, J=6.6, 6.0 Hz). Found: C, 61.90; H, 10.32%. Calcd for $C_8H_{16}O_3$: C, 62.04; H, 10.41%.

Methyl 2-Hydroxnonanoate (3f). 282 mg. IR 3450, 1735 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.32 (10H, m, 5×CH_2), 1.72 (2H, m, CH_2), 2.98 (1H, d, J=5.5 Hz, OH),[22] 3.82 (3H, s, OCH_3), 4.25 (1H, m, CHOH[23]→dd, J=6.6, 6.0 Hz). Found: C, 63.70; H, 10.75%. Calcd for $C_9H_{18}O_3$: C, 63.79; H, 10.71%.

Methyl 2-Hydroxydecanoate (3g). 302 mg. IR 3460, 1730 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.30 (12H, m, 6×CH_2), 1.73 (2H, m, CH_2), 2.94 (1H, d, J=5.5 Hz, OH),[22] 3.85 (3H, s, OCH_3), 4.25 (1H, m, CHOH[23]→dd, J=6.5, 5.5 Hz). Found: C, 65.42; H, 10.87%. Calcd for $C_{10}H_{20}O_3$: C, 65.31; H, 10.96%.

Methyl 2-Hydroxyundecanoate (3h). 337 mg. IR 3460, 1735 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.27 (14H, m, 7×CH_2), 1.73 (2H, m, CH_2), 2.97 (1H, br. s, OH), 3.85 (3H, s, OCH_3), 4.25 (1H, br. t, J=6.5 Hz, CHOH). Found: C, 66.69; H, 11.30%. Calcd for $C_{11}H_{22}O_3$: C, 66.63; H, 11.18%.

Methyl 2-Hydroxydodecanoate (3i). 355 mg. IR 3440, 1720 cm^{-1}; ^1H NMR δ=0.87 (3H, br. t, J=6.5 Hz, CH_3), 1.27 (16H, m, 8×CH_2), 1.73 (2H, m, CH_2), 2.84 (1H, br. d, J=5.5 Hz, OH),[22] 3.85 (3H, s, OCH_3), 4.23 (1H, m, CHOH[23]→dd, J=6.0, 5.5 Hz). Found: C, 67.88; H, 11.50%. Calcd for $C_{12}H_{24}O_3$: C, 67.78; H, 11.38%.

Methyl 2-Hydroxytridecanoate (3j). 391 mg. IR 3450, 1722 cm^{-1}; ^1H NMR δ=0.87 (3H, br. t, J=6.0 Hz, CH_3), 1.25 (18H, m, 9×CH_2), 1.73 (2H, m, CH_2), 2.87 (1H, d, J=6.5 Hz, OH),[22] 3.83 (3H, s, OCH_3), 4.23 (1H, m, CHOH[23]→dd, J=6.0, 5.5 Hz). Found: C, 68.77; H, 11.46%. Calcd for $C_{14}H_{28}O_3$: C, 68.81; H, 11.55%.

Preparation of 1,2-Alkanediols (4) by $LiAlH_4$ Reduction of *S*-Methyl 2-Hydroxyalkanethioates (2). A stirred suspension of the appropriate thioate (**2**, 2 mmol) and $LiAlH_4$ (8 mmol, 300 mg) in dry ether (20 ml) was heated. After refluxing for 3 h, the mixture was cooled and water (about 2 ml) was added. The resulting white precipitates were filtered through a thin pad of powdered anhydrous $MgSO_4$. The filtrate and ether washings were combined, and evaporated to leave the crude diol, which was distilled under reduced pressure or crystallized from petroleum ether.

1,2-Hexanediol (4c). 213 mg. IR 3350 cm^{-1}; ^1H NMR δ=0.92 (3H, br. t, J=6.0 Hz, CH_3), 1.39 (6H, m, 3×CH_2), 2.46 (2H, s, 2×OH), 3.28—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 60.87; H, 11.99%. Calcd for $C_6H_{14}O_2$: C, 60.98; H, 11.98%.

1,2-Heptanediol (4d). 238 mg. IR 3350 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=6.0 Hz, CH_3), 1.35 (8H, m, 4×CH_2), 2.48 (2H, s, 2×OH), 3.25—3.80 (3H, m, CHOHCH$_2$OH). Found: C, 63.41; H, 12.23%. Calcd for $C_7H_{16}O_2$: C, 63.59; H, 12.20%.

1,2-Octanediol (4e). 266 mg. IR (Nujol) 3350 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.30 (8H, m, 4×CH_2), 1.38 (2H, m, CH_2), 2.01 (2H, s, 2×OH), 3.28—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 65.67; H, 12.43%. Calcd for $C_8H_{18}O_2$: C, 65.71; H, 12.41%.

1,2-Nonanediol (4f). 266 mg. IR (Nujol) 3300, 3230 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.29 (10H, m, 5×CH_2), 1.39 (2H, m, CH_2), 2.00 (2H, s, 2×OH), 3.30—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 67.62; H, 12.53%. Calcd for $C_9H_{20}O_2$: C, 67.45; H, 12.58%.

1,2-Decanediol (4g). 288 mg. IR (Nujol) 3310, 3220 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.27 (12H, m, 6×CH_2), 1.38 (2H, m, CH_2), 1.93 (2H, s, 2×OH), 3.25—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 67.62; H, 12.53%. Calcd for $C_{10}H_{22}O_2$: C, 68.91; H, 12.72%.

1,2-Undecanediol (4h). 331 mg. IR (Nujol) 3310, 3220 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.27 (14H, m, 7×CH_2), 1.38 (2H, m, CH_2), 1.93 (2H, s, 2×OH), 3.25—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 70.22; H, 12.93%. Calcd for $C_{11}H_{24}O_2$: C, 70.16; H, 12.85%.

1,2-Dodecanediol (4i). 354 mg. IR (Nujol) 3310, 3220 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.26 (16H, m, 8×CH_2), 1.38 (2H, m, CH_2), 2.14 (2H, br.s, 2×OH), 3.25—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 71.31; H, 13.11%. Calcd for $C_{12}H_{26}O_2$: C, 71.23; H, 12.95%.

1,2-Tridecanediol (4j). 388 mg. IR (Nujol) 3310, 3210 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.26 (18H, m, 9×CH_2), 1.39 (2H, m, CH_2), 1.86 (2H, br s, 2×OH), 3.25—3.85 (3H, m, CHOHCH$_2$OH). Found: C, 72.89; H, 12.42%. Calcd for $C_{13}H_{26}O_2$: C, 72.84; H, 12.23%.

Preparation of 2-Hydroxyalkanoic Acids (5). A solution of the appropriate thioate (**2**, 2 mmol) in 90% MeOH (10 ml) containing 5% NaOH was refluxed for 1 h. MeOH was removed under reduced pressure. To the redidue water (10 ml) was added and the resulting solution was extracted with ether (10 ml). Water layer was acidified with diluted HCl and extracted with CH_2Cl_2 (10 ml×2). The CH_2Cl_2 extracts were dried over anhydrous Na_2SO_4, and evaporated to leave a solid. Recrystallization from petroleum ether gave the pure 2-hydroxyalkanoic acid.

2-Hydroxyhexanoic Acid (5c). 238 mg. IR (Nujol) 3600—2300, 3440, 3390, 1710 cm^{-1}; ($CHCl_3$) 3600—2400, 1715 cm^{-1}; ^1H NMR δ=0.92 (3H, br. t, J=6.0 Hz, CH_3), 1.43 (4H, m, 2×CH_2), 1.78 (2H, m, CH_2), 4.28 (1H, dd, J=5.5, 4.4 Hz, CHOH), 4.65 (2H, br. s, OH and COOH). Found: C, 54.46; H, 9.07%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%.

2-Hydroxyheptanoic Acid (5d). 254 mg. IR (Nujol) 3600—2300, 3440, 3390, 1710 cm^{-1}; ($CHCl_3$) 3600—2400, 1715 cm^{-1}; ^1H NMR δ=0.90 (3H, br. t, J=6.5 Hz, CH_3), 1.34 (6H, m, 3×CH_2), 1.72 (2H, m, CH_2), 4.28 (1H, dd, J=5.5, 4.5 Hz, CHOH), 5.82 (2H, br. s, OH and COOH). Found: C,

57.44; H, 9.51%. Calcd for $C_7H_{14}O_3$: C, 57.51; H, 9.65%.

2-Hydroxyoctanoic Acid (5e). 272 mg. IR (Nujol) 3600—2300, 3430, 3380, 1705 cm^{-1}; ($CHCl_3$) 3600—2400, 1715 cm^{-1}; ^1H NMR δ=0.89 (3H, br. t, J=6.0 Hz, CH_3), 1.33 (8H, m, 4×CH_2), 1.78 (2H, m, CH_2), 4.28 (1H, dd, J=5.5, 5.0 Hz, CHOH), 5.58 (2H, br. s, OH and COOH). Found: C, 59.91; H, 10.02%. Calcd for $C_8H_{16}O_3$: C, 59.98; H, 10.07%.

2-Hydroxynonanoic Acid (5f). 303 mg. IR (Nujol) 3600—2300, 3430, 3380, 1705 cm^{-1}; ($CHCl_3$) 3600—2400, 1715 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.30 (10H, m, 5×CH_2), 1.78 (2H, m, CH_2), 4.28 (1H, dd, J=6.5, 5.0 Hz, CHOH), 5.76 (2H, br. s, OH and COOH). Found: C, 61.91; H, 10.62%. Calcd for $C_9H_{18}O_3$: C, 62.04; H, 10.41%.

2-Hydroxydecanoic Acid (5g). 331 mg. IR (Nujol) 3600—2300, 3450, 1740 cm^{-1}; ($CHCl_3$) 3600—2400, 3510, 1715 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.28 (12H, m, 6×CH_2), 1.78 (2H, m, CH_2), 4.28 (1H, dd, J=6.5, 5.0 Hz, CHOH), 6.19 (2H, br. s, OH and COOH). Found: C, 63.72; H, 10.76%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

2-Hydroxyundecanoic Acid (5h). 350 mg. IR (Nujol) 3600—2300, 3550, 1690 cm^{-1}; ($CHCl_3$) 3600—2400, 3510, 1715 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.27 (14H, m, 7×CH_2), 1.78 (2H, m, CH_2), 4.27 (1H, dd, J=6.5, 4.5 Hz, CHOH), 5.52 (2H, br. s, OH and COOH). Found: C, 65.20; H, 10.99%. Calcd for $C_{11}H_{22}O_3$: C, 65.31; H, 10.96%.

2-Hydroxydodecanoic Acid (5i). 389 mg. IR (Nujol) 3600—2400, 3540, 1745, 1690 cm^{-1}; ($CHCl_3$) 3600—2400, 3510, 1715 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.5 Hz, CH_3), 1.26 (16H, m, 8×CH_2), 1.78 (2H, m, CH_2), 4.27 (1H, dd, J=6.5, 5.0 Hz, CHOH), 4.57 (2H, br. s, OH and COOH). Found: C, 66.44; H, 11.23%. Calcd for $C_{12}H_{24}O_3$: C, 66.63; H, 11.18%.

2-Hydroxytridecanoic Acid (5j). 491 mg. IR (Nujol) 3600—2400, 3540, 1745, 1690; ($CHCl_3$) 3600—2400, 3510, 1715 cm^{-1}; ^1H NMR δ=0.88 (3H, br. t, J=6.0 Hz, CH_3), 1.26 (18H, m, 9×CH_2), 1.78 (2H, m, CH_2), 4.27 (1H, dd, J=6.5, 5.5 Hz, CHOH), 4.47 (2H, br. s, OH and COOH). Found: C, 67.72; H, 11.31%. Calcd for $C_{13}H_{26}O_3$: C, 67.78; H, 11.38%.

Uranyl Ion as a Highly Effective Catalyst for Internucleotide Bond Formation

Hiroaki SAWAI,* Kensei KURODA, and Takashi HOJO
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received January 12, 1989)

Uranyl ion catalyzes the polymerization of adenosine-5′-phosphorimidazolide very efficiently in aqueous solution. Up to 95% of the input adenosine-5′-phosphorimidazolide is converted to oligoadenylates from dimer to hexadecamer when 1 mM of UO_2^{2+} is used as a catalyst. The oligomeric products are predominantly 2′-5′ linked. The chain length and the regioselectivity of the resulting oligoadenylates varies greatly with the concentration of the UO_2^{2+} ion catalyst and the pH of the reaction medium. A high total yield of oligouridylates up to dodecamer is also obtained by UO_2^{2+} ion catalyst with high 2′-5′regioselectivity. The oligonucleotide formation is mediated by UO_2^{2+}-nucleotide complex.

An efficient procedure for the nonenzymatic synthesis of oligonucleotides from an activated nucleotide in aqueous solution has been interesting subjects of prebiotic chemistry[1,2] and biomimetic chemistry of nucleic acid biosynthesis,[3] and may provide a new synthetic methodology for the oligonucleotides. Nucleoside-5′-phosphorimidazolide is an activated nucleotide and hydrolyzes to nucleoside-5′-phosphate in the absence of a template or a catalyst. Previously we reported that metal ions such as Pb^{2+} and Zn^{2+}catalyze the oligomerization of nucleoside-5′-phosphorimidazolide to yield short oligonucleotides even in the absence of a template.[3] Pb^{2+} ion has been the most active catalyst. Most of the resulting oligomers are 2′-5′ internucleotide linked. The Pb^{2+}-ion catalyzed oligomerization was applied to the convenient synthesis of 2′-5′ linked oligonucleotides.[5] The mechanistic role of the metal ion catalyst on the oligonucleotide formation is unclear. However, we tentatively believe that the metal ion could organize the nucleoside-5′-phosphorimidazolide by coordination so as to promote internucleotide bond formation. The metal ion may also enhance the nucleophilicity of a OH group of the nucleotide. We have explored other efficient metal ion catalysts which can possibly play such roles, and found that uranyl ion is a highly effective catalyst for the oligonucleotide formation. Here we wish to report the uranyl ion-catalyzed oligonucleotide formation under various reaction conditions.

Experimental

Materials. Adenosine-5′-monophosphate and uridine-5′-monophosphate were purchased from Seikagaku Kogyo. *N*-Ethylmorpholine, from Tokyo Kasei was distilled before use. Imidazole, from Tokyo Kasei, was recrystallized from benzene. Uranyl nitrate was from Yoneyama Chemicals. Reagent grade triethylamine, triphenylphosphine, di-2-pyridyl disulfide, and lead nitrate were obtained commercially. Nuclease P1 (N.P1) was from Yamasa and venom phosphodiesterese (VPDase) from Worthington. Adenosine-5′-phosphorimidazolide was prepared from adenosine-5′-monophosphate and imidazole using triphenylphosphine and di-2-pyridyl disulfide as a condensing agent as described previously.[5a,6] Uridine-5′-phosphorimidazolide (ImpU) was prepared from uridine-5′-monophosphate and imidazole by a similar procedure.[5b]

Standard Procedure for the Polymerization of ImpA. Reactions were carried out in an Eppendorf tube. The reaction mixture was prepared on an ice bath by the addition of compounds in the following order; buffer solution, ImpA solution and finally uranyl nitrate solution. Samples of the mixture were agitated vigorously and kept at 20 °C for various periods of times. A typical reaction mixture (200 μl) contained ImpA (50 mM) and a catalytic amount of uranyl nitrate (10 μM—12.5 mM) in *N*-ethylmorpholine-HNO_3 buffer (0.2 M, pH 7.3) or imidazole-HNO_3 buffer (0.2 M^+, pH 6.0—8.0). When the reaction was carried out at pH 5.5 and 8.9, the pH of the reaction mixture was adjusted to the appropriate value with 0.1 M HCl or 0.1 M NaOH. The reactions were stopped by adding of 20 μl of 0.25 M EDTA solution. Samples were analyzed by high performance liquid chromatography (HPLC).

High-Performance Liquid Chromatograhpy on RPC-5. HPLC was taken with a Hitachi 638 apparatus with a stainless steel column (4 mm×25 cm) packed with RPC-5 material. The RPC-5 was prepared from Adogen 464 and granular polychlorotrifluoroethylene (2—10 μm) by a modification of the method described by Pearson et al.[7] The elution was carried out with a linear gradient of $NaClO_4$ solution (0—0.05 M) buffered with 2.5 mM Tris-acetate (pH 7.5) and 0.1 mM EDTA in 60 min at a flow rate of 1.0 ml min^{-1}. The eluate was monitored by UV absorption at 260 nm. Linkage isomers of oligoadenylates and oligouridylates with 2′-5′ and 3′-5′ internucleotide bonds were separated very well by HPLC on the RPC-5 column. Yields were calculated from peak integrals of the oligonucleotides on the HPLC chromatogram, after allowing for the hyperchromicity of each oligonucleotide. The hyperchromicity of the oligonucleotides up to the octamer was estimated by the ratio of UV absorption at 260 nm after and before alkaline hydrolysis as described previously.[5] We made no estimate of the hyperchromicity of the long oligonucleotides with chain length more than eight, using instead the value of the octamer for the calculation of the yield.

Characterization of Oligonucleotides. Identification of the resulting oligonucleotides was carried out by comparing the HPLC chromatogram with that of the authentic sample and by sequential enzyme and alkaline digestions. Authentic oligonucleotides up to the pentamer were

† 1 M=1 mol dm^{-3}.

obtained as described previously.[5a] When no authentic sample was available, oligonucleotides were identified by degradation with enzymes, alkaline or acidic medium.

The enzyme nuclease P1(N. P1) degrades 3′-5′ internucleotide linkage and is inactive to the 2′-5′ linkage. Thus digestion of the oligonucleotides with N. P1 distinguishes between 2′-5′ and 3′-5′ linked products. After treatment of a total sample with Chelex-100 to remove uranyl ion, digestion of the resulting oligonucleotides with N. P1 gave a series of fully 2′-5′ linked oligonucleotides. Digestion with N. P1 was performed at 37 °C for 2.5 h in a mixture (50 μl) containing the oligonucleotide (0.1—1.0 ODU), 0.03 M Veronal-acetate buffer (pH 5.75) and an enzyme solution (5 μg in 50 μl).

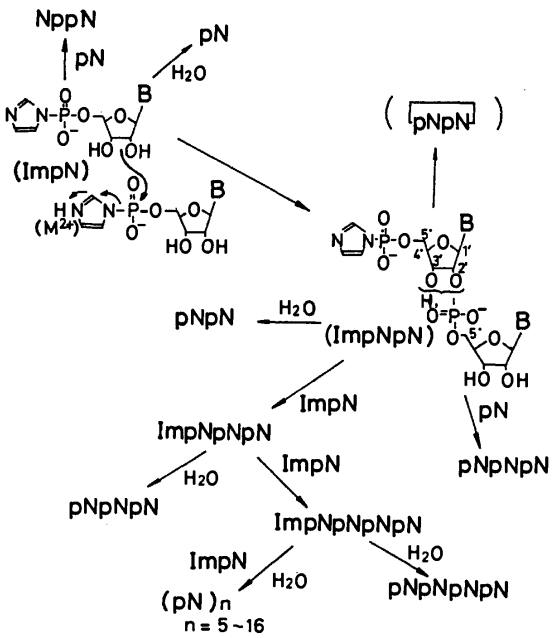
Venom phosphodiesterase (VPDase) degrades both 3′-5′ and 2′-5′ internucleotide linkage to give nucleoside-5′-monophosphate. It also cleaves a pyrophosphate bond. Degradation with VPDase was carried out at 37 °C for 2.5 h in a mixture (50 μl) containing the substrate (0.1—0.3 ODU), 0.01 M Tris-acetate (pH 8.8) 0.01 M $MgCl_2$ and enzyme solution (0.02 unit).

Alkaline hydrolysis of the oligonucleotides was carried out at room temperature for 1 d in a 0.5 M NaOH solution. The hydrolysis of a $(pA)_n$ oligomer containing both 2′-5′ and 3′-5′ linkage yielded on equivalent each of pAp and A and n-2 equivalent of Ap. The ratio of the resulting mononucleotides was determined by HPLC, which permits one to estimate the chain length. The HPLC of the mononucleotides was performed on a modified RPC-5 column with a linear gradient elution of $NaClO_4$ solution (0—0.01 M) buffered with 2.5 mM Tris-acetate (pH 7.5) and 0.1 mM EDTA in 15 min at flow rate of 1.0 ml min^{-1}.

Oligonucleotide-5′-phosphorimidazolide ($Im(pA)_n$, $Im(pU)_n$; n=2, 3, 4) was identified by conversion of the phosphorimidazolide with 1 M acetate buffer (pH 4.5) to the corresponding oligonucleotide-5′-monophosphate by acidic hydrolysis for 1 d. The compounds ImpA2′p5′A and Imp A2′p5′A2′p5′A were further confirmed by comparing the HPLC chromatogram with those of the authentic samples which were prepared from pA2′p5′A and pA2′p5′A2′p5′A in a way similar to that of ImpA.[5a]

Results and Discussion

ImpA was gradually hydrolyzed to pA in neutral aqueous solution in the absence of a template or metal ion catalyst. Addition of a catalytic amount of uranyl nitrate enhanced the polymerization of ImpA greatly and gave a good yield of long, predominantly 2′-5′ linked oligomers. A HPLC elution profile of the reaction mixture, in which 1 mM of uranyl ion ([ImpA]/[UO_2^{2+}]=50) was used as a catalyst, is shown in Fig. 1. The formation of the simple hydrolyzed product, pA was less than 1%. Oligoadenylates from dimer to hexadecamer were obtained in more than 95% total yield. Digestion of the total reaction mixture with nuclease P1 resulted in the disappearance of the



Scheme 1. Reaction scheme of the oligonucleotide formation.

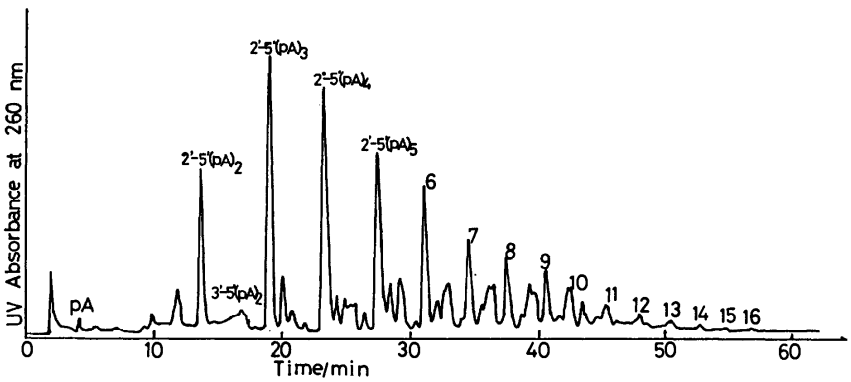


Fig. 1. HPLC elution profile of the products from the uranyl-ion catalyzed polymerization of ImpA. The reaction was run at 20 °C and pH 7.3 for 1 d. 50 mM of ImpA and 1 mM of uranyl nitrate were used for the reaction. The position of the fully 2′-5′ linked oligoadenylates from dimer to hexadecamer are indicated.

subsidary peaks, leaving only the series of main peaks, which indicates that the products are all 2′-5′ linked oligoadenylates. The subsidiary peaks to the right of the main peaks are oligomers of the same chain length containing one or more 3′-5′ linkages. The regioselectivity of the 2′-5′ internucleotide linkage decreased as the chain length of the oligomer increased. Thus the ratio of the fully 2′-5′ linked oligoadenylates was 98% in the case of dimer, and fell to 60% in the case of octamer. The yields of all 2′-5′ linked dimer, trimer, tetramer, pentamer, hexamer, heptamer and octamer were 5.6%, 13.9%, 11.9%, 10.4%, 6.9%, 4.1%, and 3.9%, respectively.

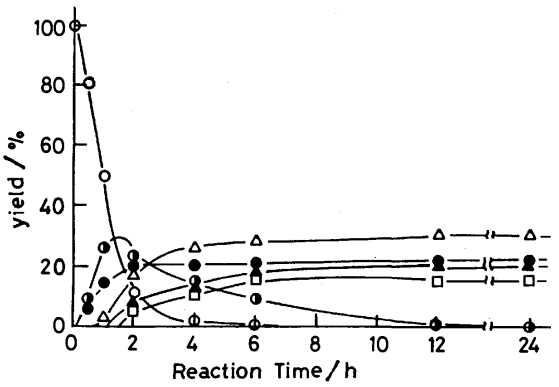

Fig. 2. Time course of the oligoadenylates formation ImpA. Reaction conditions: ImpA, 50 mM; $UO_2(NO_3)_2$, 1 mM; 20 °C; pH 7.3 ImpA, (○); $Im(pA)_2$+$Im(pA)_3$, (◑); $(pA)_2$+$(pA)_3$, (●); $(pA)_4$+$(pA)_5$, (△); $(pA)_6$—$(pA)_8$, (▲); $(pA)_9$, (□).

Figure 2 represents the time course of the polymerization of ImpA. Phosphorimidazolides of di- and triadenylate ($Im((pA)_n$, n=2, 3) formed initially in appreciable amounts, then gradually decreased. The chain length of the oligoadenylates increased with reaction time. The polymerization of ImpA in the presence of 1 mM of $UO_2(NO_3)_2$ catalyst at room temperature was almost complete in 8 h. The time course of the reaction indicates that this oligoadenylate formation proceeds stepwisely as shown in the Scheme 1.

Table 1 shows the effect of the concentration of the uranyl ion catalyst on the oligoadenylate formation. The catalyst concentration had large effect on the chain length and the internucleotide linkage of the resulting oligoadenylate. High catalyst concentration ($UO_2(NO_3)_2$=12.5 mM; [ImpA]/[UO_2^{2+}]=4) gave preferentially short-chained oligomers from dimer to pentamer in addition to small amounts of long oligomers over heptamer. The yields of long-chained oligomers increased as the catalyst concentration decreased and reached a maximum at 1 mM of $UO_2(NO_3)_2$, and fell off substantially at lower concentrations. The highest yield of total oligoadenylates was

obtained with 1—0.25 mM of $UO_2(NO_3)_2$. The proportion of the yield of the fully 2′-5′ linked oligoadenylate to that of the total oligomers with the same chain length are shown in the parenthesis in Table 1. The 2′-5′ regioselectivity of the oligoadenylates was almost the same when 12.5 mM—0.25 mM of uranyl ion was used as a catalyst. Hydrolysis of phosphorimidazolide competes with the internucleotide bond formation and decreases the chain length of the oligoadenylate at lower catalyst concentrations. Thus the yield of short-chained oligoadenylates reached a maximum at 0.25—0.05 mM of the uranyl ion catalyst. 0.05 mM of the uranyl ion gave the 2′-5′ diadenylate in 46.2% yield. The 2′-5′ linked trimer and tetramer were formed in significant yields at 0.1—0.25 mM of uranyl ion catalyst. The catalytic effect of $UO_2(NO_3)_2$ was still significant at concentrations as low as 0.01 mM, though a significant degree of hydrolysis of ImpA took place. Concentration of the catalyst below 0.1 mM decreased the 2′-5′ regioselectivity. The lower the concentration, the lower the proportion of the 2′-5′ linkage of the resulting oligoadenylates. Thus 0.01 mM of the uranyl ion gave 2′-5′ and 3′-5′ linked dimers in 25.4% and 11.0% yield, respectively.

We carried out the polymerization at 0 °C in the presence of 1 mM of uranyl nitrate. The low temperature suppressed the hydrolysis of the phosporimidazolide bond more strongly than the internucleotide bond formation. Therefore, completion of the reaction required long reaction time at 0 °C. On the other hand the yield of long-chained oligoadenylates increased at 0 °C, and oligoadenylates up to octadecamer were obtained at 0 °C for 1 day.

Table 2 presents the effect of pH of the medium on the oligoadenylate formation. The reaction was carried out in the presence of 1 mM $UO_2(NO_3)_2$ catalyst in imidazole buffer between pH 6.0 and 8.0. Replacement of *N*-ethylmorpholine buffer with imidazole buffer at pH 7.3 did not change the total yield of the oligoadenylate, but effected a small decrease in long-chained oligoadenylates. Imidazole coordinates to the UO_2^{2+} ion, which might suppress the UO_2^{2+}-ion catalyzed internucleotide bond formation to some extent. The reactions were also conducted at pH 5.5 and 8.9. At pH 5.5 and 6.0, only small amounts of dimer and trimer were formed with low 2′-5′ regioselectivity. Instead, P^1,P^2-diadenosine 5′-pyrophosphate formed in addition to the hydrolysis of ImpA to pA. The oligoadenylate formation was markedly enhanced at pH 6.5 and increased with the higher of pH of the medium. Optimum pH for the polymerization to obtain 2′-5′ linked oligoadenylates was around pH 7.5. When the reaction was carried out at pH 8.9, both the rate of hydrolysis of phosphorimidazolide and the internucleotide bond formation slowed down, resulting in the low yield of oligoadenylates after 1 day.

In a similar way, the UO_2^{2+} ion catalyzes the oligomerization of ImpU, giving oligouridylates from dimer to dodecamer in high total yields, as shown in Table 3. The resulting oligouridylates contained mainly 2′-5′ internucleotide linkage. Cyclic dimer and trimer were obtained in substantial amounts in addition to the linear oligomer.

The effective catalytic activity of the UO_2^{2+} ion for the internucleotide bond formation is surprising. Without a template or an enzyme, no long-chained oligonucleotide has been obtained in aqueous solution. The UO_2^{2+} ion catalyzes the oligonucleotide-bond formation far more effectively than the Pb^{2+} ion

Reactions were run at 20 °C in 0.2 M imidazole-HNO_3 buffer (pH 7.5). ImpU (50 mM) was used in the reaction. a) Ratio of the fully 2′-5′ linked oligomer is shown below the yield data of each oligouridylate in the parenthesis. b) Oligouridylates with chain length eight to twelve are included.

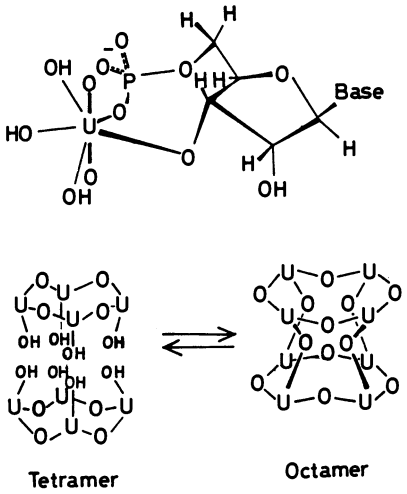

Fig. 3. Structure of the uranyl complex of 5′-nucleotide proposed by Kainosho et al.

which has been considered the most efficient catalysis.[4] High concentration of Pb^{2+} ion is required for its catalytic activity. 0.1 mM of Pb^{2+} ion has a negligible effect on the oligoadenylate formation. 12.5 mM of Pb^{2+} ion catalyst gives oligoadenylates up to hexamer.[4]

Our results do not permit us to draw any conclusions about the reaction mechanism. However the oligoadenylate formation is probably mediated by a uranyl complex of ImpA. The structure of the UO_2^{2+}-ImpA complex remains unclear, but probably is similar to that of the uranyl complex of pA. Two unique structures for the UO_2^{2+}-pA complex have been proposed from NMR studies.[8,9] In an early study, Feldman et al. proposed a dimeric structure in which 2′- and 3′-hydroxyl groups of ribose ring coordinate to the uranyl ion with removal of protons.[8] The 3′-oxo group coordinates to both uranyl ions working as a bridging ligand. Later Kainosho et al. reported a revised structure from the study of 500 MHz NMR and C-13 NMR of the complex from [N^{15}]pA.[9] They claimed that the uranyl complex of nucleoside-5′-monophosphate is composed of several oligomeric species with hydroxo or oxo bridges. Each species has a common structural unit as shown in Fig. 3. The primary coordination sites are phosphate and 3′-hydroxyl group with a removal of a proton.

We tentatively postulate that the uranyl complex of ImpA could form a polymeric structure similar to that claimed for the UO_2^{2+}-pA complex.[9] The activation of 2′-OH of the ribose moiety in the complex by hydrogen bond with 3′-oxo group may be responsible for the efficient 2′-5′ internucleotide bond formation. The formation of polymeric UO^{2+} complex of ImpA could be favorable for the long oligoadenylates formation, since ImpA could line up on uranyl ions in the polymeric complex. The polymeric uranyl ion probably works as a kind of a template. The detailed discussion of the mechanistic roles of UO^{2+} ion for the oligonucleotide formation needs further study of the uranyl complex of ImpA and other nucleotides.

The uranyl ion-catalyzed oligoadenylate synthesis from ImpA has a potent synthetic utility. Since the isolation of 2′-5′ linked triadenylate (2-5A) from interferon-treated cells and the discovery of its strong biological activity,[10] 2—5A and its analogues have been synthesized by a number of groups.[11] Recently, Torrence et al. reported that 2′-5′ linked hexadenylate inhibits DNA topoisomerase reaction.[2] They suggested that 2′-5′ linked oligoadenylates of sufficient chain length may be involved in mediating the interferon-induced translational regulation by an inhibition of DNA topoisomerase. The oligoadenylate synthesis with UO^{2+} ion catalysts seems to provide the most efficient and convenient method for making the 2′-5′ linked oligoadenylates with desired chain length. Any chain length of the oligomer from dimer to decamer can be obtained by changing the catalyst concentration or pH of the medium.

Finally we mention the significance of this reaction in the context of prebiotic chemistry. Egami has suggested that the metal ion which is abundant in seawater was incorporated into protoenzymes, which have evolved to contemporary metalloenzymes.[13] The abundant metal ions in seawater are generally

essential for life. The UO^{2+} ion is more abundant in seawater than the Co^{2+} ion which is essential for many living organisms.[13] No long-chained oligonucleotide has been obtained in the model reactions of prebiotic synthesis without a template. The UO^{2+} might have worked as a catalyst for oligonucleotide formation in the stage of chemical evolution, though its function disappeared during the later evolution.

Ring-Opening Fluorination and Ring-Expansion Fluorination of Cyclopropanemethanols with Amine/Metal Fluoride/ Poly(hydrogen fluoride)-Pyridine Complex

Shigekazu KANEMOTO, Makoto SHIMIZU,* and Hirosuke YOSHIOKA*
The Institute of Physical and Chemical Research (RIKEN), Wako, Saitama 351-01
(Received January 20, 1989)

Treatment of cyclopropanemethanols with pyridinium poly(hydrogen fluoride) in the presence of diisopropylamine and KHF_2 gave selectively homoallylic fluorides or fluorocyclobutanes according to the mode of substitution of the starting cyclopropanemethanols. Cyclopropanemethanols with no substitution at 1-position of the cyclopropane ring gave homoallylic fluorides in a stereoselective manner. While, 1-methylcyclopropanemethanol gave the fluorocyclobutane in high stereoselectivity. Fluorocyclobutanes containing hydroxymethyl group were also prepared from 2-(1-methylcyclopropyl)oxiranes. The amine and the metal fluoride were necessary as additives for the best results. Influencing factors involving solvents and temperature for the reactions are also described.

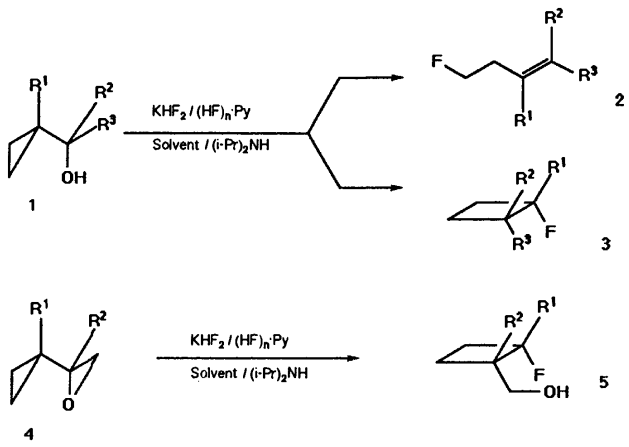
Organic synthons containing a single fluorine atom have been increasingly attracting attentions of chemists in agricultural, and pharmaceutical research areas because of their unique chemical and biological characters useful for the molecular design works.[1] For example, certain monofluorinated steroids[2] are selectively metabolized by insects to generate highly toxic fluoroacetic acid revealing potentiality as new insecticide. Some amino acids containing a fluoromethyl group have been known to be potent suicide inhibitors to enzymatic decarboxylation.[3]

There are two approaches to synthesize monofluorinated compounds. The first is an introduction of a fluorine atom onto a molecule by fluorination of alcohols or halides, and even hydrides. DAST,[4] HFP-DA,[5] quaternary ammonium fluorides,[6] or specifically modified metal fluorides[7] with crown ethers,[8] are recently developed for the nucleophilic fluorination, and F_2,[9] CF_3OF,[10] XeF_2,[11] or other modified hypofluorite reagents are for direct fluorination. The second is to make use of fluorinated building blocks or their equivalents.[12]

Among them, homoallylic fluorides are the most versatile intermediates for synthesis of a variety of monofluorinated bioactive compounds. However, there has been no pertinent method for selective fluorination leading to homoallylic fluorides. Attempts to prepare homoallylic fluorides by nucleophilic substitution of corresponding alcohols or their derivatives often results in troublesome contaminations of by-products. Particularly, fluorination of tertiary hydroxyl groups is hardly successful. For example, fluorination of 4-phenyl-3-buten-1-ol with a common fluorinating reagent such as DAST, gave only dehydrated ethers and dienes.

Thence, we attempted to use cyclopropanemethanols as better precursors to homoallylic fluorides, since a cyclopropylmethyl cation generated from a cyclopropanemethanol or its derivative with pyridinium poly(hydrogen fluoride) will be possibly rearranged to a homoallylic cation, that is promptly quenched with a fluoride anion. Here we wish to report a selective preparation of homoallylic fluorides by the ring-opening fluorination of cyclopropanemethanol derivatives. In addition, selective synthesis of monofluorocyclobutanes containing a *tertiary* fluorine atom is also described for 1-substituted cyclopropanemethanols and corresponding epoxides.[13]

Synthesis of Homoallylic Fluorides Using Modified Pyridinium Poly(hydrogen fluoride) by Ring-Opening Fluorination. Ring opening halogenation of cyclopropanemethanols with aqueous hydrogen bromide or hydrogen chloride has been known as Julia rearrangement, that gives the corresponding homoallylic bromides or chlorides.[14] However, application of this method for fluorination of cyclopropanemethanols with aqueous hydrogen fluoride was not successful at all. Nucleophilicity of water is much stronger than that of fluoride anion, and this gave rise to only homoallylic alcohols and ethers due to self-condensation. In order to make the reaction media anhydrous, we employed the Olah's reagent[15] as fluoride anion source. Olah's reagent, or pyridinium poly(hydrogen fluoride): $(HF)_n \cdot Py$ is widely used, known to be the most useful for halo- or hydro-



Scheme 1.

fluorination of olefins as well as fluorination of alcohols. However, the attempted fluorination of cyclopropanemethanols with the reagent afforded a homoallylic fluoride in poor yield with major contamination of homoallylic alcohols, ethers, and other by-products. It was obvious that poly(hydrogen fluoride) behaved majorly as acid catalyst for ring opening and self-condensation, and not as a reagent for nucleophilic fluorination. This result indicated that it was necessary to activate the fluoride anion more than ever. In order to control the acidity of the system and to activate fluoride anion, we tried certain additives with co-solvents. Various aromatic and aliphatic amines were employed as co-solvent together with inorganic fluorides, NaF, KF, KHF_2, CsF, and quaternary ammonium fluorides for additives. A number of combinations of an amine with a fluoride salt were screened for better result and selectivity using α-phenylcyclopropanemethanol (**6**) as a model substrate. The role of these additives may be explained as follows. These amines diminish the degree of aggregation of poly(hydrogen fluoride), and activate the fluoride anion as nucleophile giving "ammonium fluoride" type reaction species which is more reactive than fluoride anion in Olah's reagent. Second, fluoride salts increase the concentration of fluoride anion and its nucleophilicity. Among them, a combination of diisopropylamine with KHF_2 dried up in a microwave oven gave the best result. Dried KHF_2 has an additional advantage to behave as dehydrant and to avoid the attack of water which was generated from dehydration of an alcohol moiety. The choice of solvents is also essentially important. For example, ethereal solvents such as diethyl ether, or tetrahydrofuran, which are commonly used with $(HF)_n \cdot Py$, were not applicable at all for this reaction. These solvents behaved as nucleophile giving complex products.[16] Only chloroalkanes and chlorobenzene gave acceptable results. Their stability together with lipophilicity and polarity appears to be critical for the reaction. A variety of substituted cyclopropanemethanols were treated in this reaction system, and the results are summarized in Tables 1 and 2. We employed the procedure to add the $(HF)_n \cdot Py$ into a mixture of substrate, KHF_2, and diisopropylamine in dichloromethane or chlorobenzene at 0 °C. Addition of a solution of substrate into a reagent mixture always decreased the yields of the products. In the presence of a certain functional group(s) such as phenyl, vinyl, and alkynyl group which stabilize α-carbocation, the reaction generally proceeds in good yield and selectivity. On the other hand, an α,α-dialkyl-substituted substrate gave the homoallylic fluoride in poor yield (Run 4, Table 1), and majorly yielded diene products. Attack of a fluoride anion generally occurred at the more substituted carbon atom (Runs 1 and 6, Table 2). In the case of the substrate (**28**), only a ring opened and condensed product was obtained under the standard reaction conditions. Among the condi-

Table 1. Formation of Primary Homoallylic Fluorides with Modified Hydrogen Fluoride

tions tried, the best result was obtained in an inverse addition mode. Dropwise addition of a THF solution of the substrate into the mixture of KHF_2, and $(HF)_n \cdot Py$ in THF with $(i\text{-}Pr)_2NH$ gave the desired fluoride (**29**) in 71% yield.

Stereochemistry of the resultant olefin was highly dependent on the steric factor of the substituent at the α-carbon, and a more bulky group is always at trans position to the 2-fluoroethyl group in the resultant olefin. The tertiary ethers (**22**, **24**), could not stand the reaction conditions. Elimination to yield the corresponding olefin was predominant. On the other hand, ester moiety was not affected (Run, 5, Table 2).

These homoallylic fluorides have wide applicability as substrate to the synthesis of monofluorinated analogues of known bioactive compounds as prototype. For example, fluorinated fenvalerate (**31**) was first prepared from α-methyl-α-phenylcyclopropanemethanol (**30**) in good overall yield, and juvenile hormone mimic (**32**) and anti-juvenile hormone mimic (**33**) have been also prepared in a few steps. These compounds showed similar activities as those of the prototypes.[17]

Synthesis of Fluorocyclobutanes Using 1-Substituted Cyclopropanemethanol Derivertives by Ring-Expansion Fluorination. In the course of experiments dealing with ring opening fluorination, we wish to expand it to a synthesis of fluorocyclobutanes. A cyclopropylmethyl cation can be smoothly rearranged to a homoallylic cation with release of ring strain. When a cyclopropane ring has a substituent at 1-position, generation of tertiary cyclobutyl cation by ring expantion would be preferred to rearrangement to primary homoallylic cation, although cyclobutane still has certain ring strain.[18] Then a fluoride anion would immediately attack the cyclobutyl cation to form fluorocyclobutane. Based on the hypothesis, we examined the reaction of 1-methyl-α-phenylcyclopropanemethanol (**34**) with $(i\text{-}Pr)_2NH\text{-}KHF_2\text{-}(HF)_n \cdot Py$ complex in dichloromethane at 0 °C, and it gave fluorocyclobutane in moderate yield. Ring expantion fluorination of α,1-dimethyl-α-phenylcyclopropanemethanol (**36**) gave selectively 1-fluoro-1,2-dimethyl-*trans*-2-phenylcyclobutane (**37**) in 75% yield, but the similar treatment without $(i\text{-}Pr)_2NH$ and/or KHF_2

failed to give the fluorocyclobutane.

Usually poly- and perfluorocyclobutanes are synthesized via thermal,[19] photochemical,[20] or Michael type[21] [2+2] cycloaddition of polyfluoroolefins, which do not appear to be applicable to the synthesis of monofluorocyclobutanes.[22] Besides, regio- and stereochemistry would not be controlled during the cycloaddition if monofluoroolefins were available at all.

This ring expansion reaction was also sensitively affected by solvent for reaction, and we found dichloromethane or chlorobenzene to be the best solvents. The reaction temperature is also crucial to the yield of the fluorocyclobutane. For example, the substrate (**34**) gave the fluorinated cyclobutane (**35**) in 77% yield at −20 °C, whereas the yield decreased to 40% at 0 °C.

The stereoselectivity in fluorine introduction to the cyclobutane ring is highly dependent on the substituent "R^1" on the cyclopropane ring. The substrates containing methyl group for R^1 generally gave the cyclobutanes in high stereoselectivity. Fluorine was introduced in "trans" orientation to the bulkier group at the α-position of the cyclobutane in over 95% stereoselectivity (determined by HPLC, Runs 1, 2, and 3, Table 3). However, the substrates with phenyl group as R^1 gave the trans-products in the lower stereoselectivities (Runs 4 and 5). This may be explained in terms of the fixed geometry of the initially formed carbocation (**46**) due to the steric conflict between the endo hydrogen atoms and R^2, and this results in the observed high stereoselectivity (Fig. 2). When R^1 and R^2 are phenyl groups (Runs 4 and 5), each conformation (**46a**, **46b**) is equally possible and this may cause the formation of cis and trans fluorides. Another possible explanation of the low stereoselectivities observed for formation of **41** and **43** seems to be due to the cyclobutyl cation (**47**) stabilized by an extra phenyl group. The resultant plane sp^2 carbon would reduce the selectivity.[23]

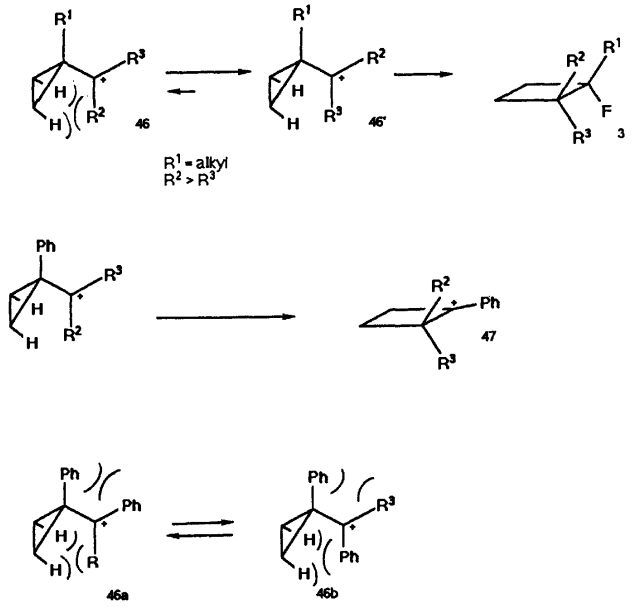

Fig. 2.

Initial formation of the carbocation is supported by the following result. Chiral (*R*)-(+)-1-methyl-α-phenylcyclopropanemethanol (**34**) as prepared from (*R*)-(+)-mandelic acid in three steps, gave the racemic fluorocyclobutane (**35**) losing perfectly its optical integrity.

The reaction pathway is controlled in accordance with the substituent R^1 on the cyclopropane and R^2 at the α-position of the hydroxyl group. No ring rearrangement occurred when substrates having an electron withdrawing group such as acyl or cyano group as R^1 on the cyclopropane ring were applied. These groups appear to prevent the formation of the rearranged carbocation.[24] As for R^2, in sharp contrast to the alkyl or phenyl substituents, the substrates containing the α-acetylenic or olefinic functions were converted exclusively to the corresponding homoallylic fluorides (Run 6, Table 3). The distinct control on the selection of these alternative pathways can be attributed to an electronic effect of acetylenic or olefinic group in the substituent R^2.

Parallel Ring Rearrangement of 2-(1-Substituted cyclopropyl)oxirane to Hydroxymethyl-Substituted Fluorocyclobutanes. It was necessary to seek a group of new substrates in order to provide fluorocyclobutanes whose substituent is variously functionalized for

further transformation. Cyclopropyloxirane was expected to generate fluorocyclobutanes containing hydroxymethyl group at the adjacent position of the fluorinated carbon atom upon the ring-expansion fluorination. Moreover, this parallel three-membered ring system, a cyclopropane connected with oxirane ring, has certain advantages over cyclopropanemethanols. That is, the substrate has highly strained ring system and appear to be more favored to form carbocation. Moreover, on the contrary to the cyclopropanemethanol substrates, oxiranes do not generate water that is adverse to the reaction media under the current fluorination conditions.

Under similar reaction conditions as before, the cyclopropyloxirane (**48**) was transformed stereoselectively into the fluorocyclobutane (**49**) in 83% yield (Table 4). The product has a "trans" configuration with respect to the fluorine and the phenyl groups. As it is similar to the case of the cyclopropanemethanols, the stereoselectivity decreased with the 1-phenylcyclopropyl counterpart (**50**) resulting in nearly a 1 : 1 stereoisomeric mixture (**51**) in moderate yields. Interestingly, the 2-(ethoxycarbonyl)oxirane (**52**) gave the geometrically pure fluorocyclobutane (**53**) in 60% yield (see Table 4). We assume that the oxirane (**52**) can easily take the conformation necessary for the anti-displacement of the C_1-C_2 bond of the cyclopropane when attacked by fluoride anion. In contrast, the stereoisomer (**54**) gave an isomeric mixture of fluorocyclobutane (**55**) in poor yield. Main product was an α-hydroxy-γ-lactone via intramolecular ring formation. The influencing factor over the reaction course may be ascribed for the conformation of the ethoxycarbonyl group in **54**, where the generated cyclobutyl cation and the ethoxycarbonyl group were situated closely. As result, intramolecular attack of oxygen occurred much faser than intermolecular attack of fluoride anion. These cyclobutanes containing a hydroxymethyl group may serve as useful intermediates for further functionalization. Using this ring-expansion fluorination method, we synthesized (±)-2-fluorograndisol (**57**) from the sulfonate (**56**).[25]

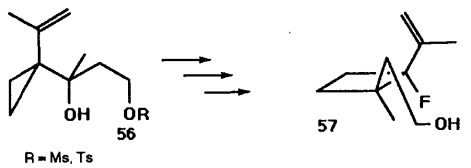

Fig. 3.

In conclusion, homoallyl fluorides or fluorocyclobutanes with multiple substituents or functional groups, which are difficult to provide by any other methods, were selectively synthesized by the current new methods we have developed. Its wide applicability is expected in the selective synthesis of functionalized homoallylic fluorides as well as fluorocyclobutanes.

Experimental

Infrared spectra of neat liquid film samples (unless otherwise noted) were determined on a Shimadzu infrared spectrophotometer IR-430, mass spectra on a Hitachi RMU-6M. and exact mass on a Hitachi M-80. ^{1}H NMR spectra were recorded on a JEOL FX-90Q or EX-90 spectrometer using TMS as an internal standard. ^{19}F NMR spectra were recorded on a JEOL EX-90 or Hitachi R-24F spectrometer using $CFCl_3$ as an internal standard. Multiplicity is designated as s, singlet; d, doublet; t, triplet; q, quartet; m, mutiplet. Preparative TLC plates were prepared with Merck Kiesel Gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-300).

Preparation of Poly(hydrogen fluoride)-Pyridine Complex: The $(HF)_n \cdot Py$ was prepared from anhydrous hydrogen fluoride and pyridine according to the reported procedure.[15] All the reactions were carried out in polyethylene test tube as the reaction vessel and $(HF)_n \cdot Py$ was added through a polyethylene syringe.

General Procedure for the Ring-Opening Fluorination of Cyclopropanemethanol Derivertives with (i-Pr)$_2$NH-KHF$_2$-(HF)$_n \cdot$ Py Complex: Preparation of 4-fluoro-1-phenyl-1-butene (**7**) was representative. 25 ml polyethylene test tube fitted with magnetic stirring bar inside was connected to a nitrogen line. To a suspension of KHF_2 (0.08 g, 1.0 mmol, dried in a microwave oven) in chlorobenzene (1.0 ml) was added a solution of α-phenylcyclopropanemethanol (0.15 g, 1.0 mmol) in 1.0 ml of chlorobenzene and diisopropylamine (0.6 ml), and the whole was stirred for 5 min at 25 °C. The reaction mixture was cooled with ice-water bath and $(HF)_n \cdot Py$ (2.0 ml) was added slowly to the reaction mixture. After stirring at 0 °C for 5 min, the reaction mixture was diluted with ether (5.0 ml) and aqueous KF solution (5.0 ml). The whole was poured into water (10 ml). The water layer was extracted with ether (3×30 ml) and the combined organic layers were washed with saturated aqueous sodium hydrogencarbonate and brine successively, and dried over sodium sulfate. Concentration and purification on preparative TLC (hexane) gave the title compound, 4-fluoro-1-phenyl-1-butene (**7**) (0.11 g, 76%). Methyl (*Z*)-7-Fluoro-4-methyl-4-hepten-2-ynoate (27) (Major Isomer): IR (neat) 2940, 2210, 1715, 1700, 1430, 1250, 1020, and 745 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.9—2.1 (m, 3H), 1.70 (ddt, 2H, J=25.60, 6.50, 7.20 Hz), 3.82 (s, 3H), 4.48 (dt, 2H, J=47.10, 6.50 Hz), 6.06 (tq, 1H, J=7.20, 1.40 Hz); ^{19}F NMR ($CDCl_3$) δ=−218.8; MS m/z (rel intensity in %) 79 (77), 91 (68), 109 (72), 139 (100), 149 (12), 170 (M^+, 26). Found: C, 63.67; H, 7.10%. Calcd for $C_9H_{11}O_2F$: C, 63.52; H, 6.51%.

Methyl (*E*)-7-Fluoro-4-methyl-4-hepten-2-ynoate (27) (Minor Isomer): IR (neat) 2970, 2220, 1710, 1435, 1260, 1010, and 745 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.8—1.9 (m, 3H), 1.54 (ddt, 2H, J=24.50, 6.50, 6.50 Hz), 3.79 (s, 3H), 4.46 (dt, 2H, J=46.80, 6.50 Hz), 6.19 (tq, 1H, J=6.50, 1.80 Hz); ^{19}F NMR ($CDCl_3$) δ=−218.4; MS m/z (rel intensity in %) 69 (100), 91 (84), 109 (58), 139 (94), 149 (39), 170 (M^+, 3). Found: C, 63.36; H, 6.53%. Calcd for $C_9H_{11}O_2F$: C, 63.52; H, 6.51%.

1-Fluoro-1-phenyl-3-octene (29): 25 ml polyethylene test tube, fitted with magnetic stirring bar inside was connected to a nitrogen line. $(HF)_n$·Py (1.0 ml), KHF_2 (0.12 g, 1.5 mmol), and diisopropylamine (0.3 ml) were mixed in THF (1.0 ml) and the mixture was stirred for 30 min at 0 °C. A solution of α-butyl-2-phenylcyclopropanemethanol (**28**) (0.10 g, 0.5 mmol) in THF (1.0 ml) was slowly added to the reaction mixture at 0 °C and the whole mixture was stirred for additional 1 h at 25 °C. After the consumption of the substrate (monitored with TLC), the reaction mixture was diluted with ether (5.0 ml) and aqueous potassium fluoride solution (5.0 ml). Extraction, and concentration gave an oil, which was purified by column chromatography to give 1-fluoro-1-phenyl-3-octene (**29**) (0.07 g, 73%). IR (neat) 3000, 2940, 2900, 2830, 1490, 1445, and 965 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.86 (t, 3H, J=6.10 Hz), 1.0—1.4 (m, 6H), 1.8—2.1 (m, 2H), 2.55 (ddd, 2H, J=26.90, 6.84, 6.84 Hz), 5.38 (dt, 1H, J=43.90, 6.50 Hz), 5.44 (dt, 2H, J=4.30, 6.50 Hz), 7.2—7.4 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−171.1; MS, m/z 91 (15), 109 (100), 129 (25), 143 (11), 186 (7), 206 (M^+, 7); exact mass spectrum m/z 206.1462. Calcd for $C_{14}H_{19}F$: M, 206.1466.

5-(4-Fluorobutyloxy)-2-phenyl-2-pentene:[16] 25 ml polyethylene test tube fitted with magnetic stirring bar inside was connected to a nitrogen line. To a suspension of KHF_2 (0.12 g, 1.5 mmol dried with microwave oven) in THF (0.5 ml) was added 1-cyclopropyl-1-phenylethanol (0.08 g, 0.5 mmol) in 0.5 ml of THF and the suspension was stirred for 10 min at 25 °C. $(HF)_n$·Py was added slowly to the suspension at 0 °C and the whole was stirred for 1 h at that temperature. The reaction mixture was diluted with ether (5.0 ml) and aqueous potassium fluoride (5.0 ml) and the entire mixture was poured into ice water. The organic layer was separated and the water layer was extracted with ethyl acetate (3×30 ml) then the combined organic layers were washed with aqueous sodium hydrogencarbonate and brine successively. The organic layer was dried over sodium sulfate and concentrated. Purification of the crude oil gave the title compound as colorless oil (0.07 g, 65%). IR (neat) 2950, 2870, 1595, 1480, 1445, 1360, 1110, 755, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.5—1.9 (m, 4H), 2.0—2.1 (m, 3H), 2.48 (dt, 2H, J=6.84, 6.84 Hz), 3.49 (t, 2H, J=4.68 Hz), 3.51 (t, 2H, J=6.84 Hz), 4.46 (dt, 2H, J=47.50, 5.94 Hz), 5.77 (tq, 1H, J=6.84, 1.81 Hz), 7.1—7.4 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−218.7; MS m/z (rel intensity in %) 55(46),

74(27), 91(13), 118(70), 131(100), 146(20), 236(M^+, 5); exact mass spectrum m/z 236.1585. Calcd for $C_{15}H_{21}OF$: M, 236.1577.

General Procedure for the Ring-Expansion Fluorination of 1-Substituted Cyclopropanemethanol Derivatives with (i-Pr)$_2$NH-KHF$_2$-(HF)$_n$·Py-Complex: Preparation of 1-fluoro-1,2-dimethyl-t-2-phenylcyclobutane (**37**) was representative. 25 ml polyethylene test tube fitted with magnetic stirring bar inside was connected to a nitrogen line. To a suspension of KHF_2 (0.12 g, 1.5 mmol dried in microwave oven) in dichloromethane (0.5 ml) was added α,1-dimethyl-α-phenylcyclopropanemethanol (**36**) (0.09 g, 0.5 mmol) in 0.5 ml of dichloromethane and diisopropylamine (0.3 ml), and the suspension was stirred for 10 min at 25 °C. The suspension was cooled to −20 °C and (HF)$_n$·Py (1.0 ml) was slowly added into the mixture with cooling. The reaction completed within 5 min and the mixture was diluted with ether (5.0 ml) and aqueous potassium fluoride solution (5.0 ml). The water layer was extracted with ether (3×30 ml), and the combined organic layers were washed with aqueous sodium hydrogencarbonate and brine successively. Drying and concentration followed by chromatographic purification gave the r-1-fluoro-1,2-dimethyl-t-2-phenylcyclobutane (**37**) (0.06 g, 62%). IR (neat) 3000, 1495, 1445, 1380, 1260, and 705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.12 (d, 3H, J=22.70 Hz), 1.51 (d, 3H, J=2.20 Hz), 1.5—2.8 (m, 4H), 7.0—7.5 (m, 5H), ^{19}F NMR ($CDCl_3$) δ=−136.9; MS m/z (rel intensity in %) 78 (8), 103 (11), 117 (22), 118 (100), 150 (6), 178 (M^+, 1). Found: C, 80.72; H, 8.55%. Calcd for $C_{12}H_{15}F$: C, 80.86; H, 8.48%.

1-Fluoro-1-methyl-t-2-phenylcyclobutane (35): IR (neat) 3000, 1605, 1495, 1380, 1255, 1115, 920, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (d, 3H, J=22.30 Hz), 1.0—2.6 (m, 4H), 3.80 (dt, 1H, J=20.90, 10.40 Hz), 7.0—7.4 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−116.7; MS m/z (rel intensity in %) 78 (4), 104 (100), 136 (7), 164 (M^+, 2).

2-Butyl-1-fluoro-1-methyl-t-2-phenylcyclobutane (39): IR (neat) 2950, 2850, 1605, 1450, 1380, 1175, and 705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.79 (t, 3H, J=7.90 Hz), 0.7—1.4 (m, 6H), 1.09 (d, 3H, J=21.60 Hz), 1.6—2.8 (m, 4H), 7.0—7.5 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−138.7; MS m/z (rel intensity in %) 58 (57), 77 (18), 83 (22), 91 (19), 118 (100), 160 (10), 220 (M^+, 2). Found: C, 81.56; H, 9.63. Calcd for $C_{15}H_{21}F$: C, 81.77; H, 9.61%.

1-Fluoro-1,c-2-diphenylcyclobutane (41) (Major Isomer): IR ($CHCl_3$) 3050, 2970, 1605, 1500, 1450, 890, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.0—3.0 (m, 4H), 3.6—4.2 (m, 1H), 7.1—7.6 (m, 10H); ^{19}F NMR ($CDCl_3$) δ=−163.7; MS m/z (rel intensity in %) 78 (11), 91 (9), 104 (100), 122(12), 226 (M^+, 3).

1-Fluoro-1,t-2-diphenylcyclobutane (41) (Minor Isomer): IR ($CHCl_3$) 3050, 2970, 1600, 1495, 1445, 1070, 750, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.8—2.9 (m, 4H), 4.16 (ddd, 1H, 20.90, 9.00, 9.40 Hz), 6.7—7.3 (m, 10H); ^{19}F NMR ($CDCl_3$) δ=−118.2; MS m/z (rel intensity in %) 58 (73), 83 (25), 91 (15), 104 (100), 122 (13), 226 (M^+, 3).

1-Fluoro-2-methyl-1,t-2-diphenylcyclobutane (43) (Major Isomer): IR (neat) 2980, 1600, 1495, 1445, 760, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.70 (d, 3H, J=3.60 Hz), 2.0—3.2 (m, 4H), 6.8—7.5 (m, 10H); ^{19}F NMR ($CDCl_3$) δ=−144.8; MS m/z (rel intensity in %) 78 (7), 117 (36), 118 (100), 204 (13), 205 (7), 220 (4), 240 (M^+, 2). Found: C, 85.29; H, 7.11%. Calcd for $C_{17}H_{17}F$: C, 84.96; H, 7.13%.

1-Fluoro-2-methyl-1,c-2-diphenylcyclobutane (43) (Minor Isomer): IR ($CHCl_3$) 2990, 1605, 1495, 1445, 770, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.22 (s, 3H), 2.6—3.2 (m, 4H), 7.1—7.6 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−149.1; MS m/z (rel intensity in %) 78 (9), 117 (29), 118 (100), 205 (8), 220 (40), 40 (M^+, 1). Found: C, 84.86; H, 7.15%. Calcd for $C_{17}H_{17}F$: C, 84.96; H, 7.13%.

1-Fluoro-c-2-hydroxymethyl-1-methyl-2-phenylcyclobutane (49): IR (neat) 3630, 3450, 3000, 2890, 1605, 1495, 1380, 1030, 880, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20 (dd, 3H, J=23.60, 1.20 Hz), 1.2—2.8 (m, 5H), 3.97 (d, 2H, J=5.70 Hz), 7.0—7.4 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−138.6; MS m/z (rel intensity in %) 55 (100), 69 (56), 95 (31), 105 (27), 129(15), 193(M^+−1, 6). Found: C, 74.03; H, 7.87%. Calcd for $C_{12}H_{15}OF$: C, 74.20; H, 7.78%.

1-Fluoro-c-2-hydroxymethyl-1-phenylcyclobutane (51) (Major Isomer): IR (neat) 3640, 3400, 2980, 1500, 1450, 1300, 1025, 760, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.74 (s, 3H), 1.2—3.0 (m, 4H), 3.60 (bs, 1H), 3.67 (d, 1H, J=11.60 Hz), 4.03 (d, 1H, J=11.60 Hz), 7.2—7.5 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−144.8; MS m/z (rel intensity in %) 83(27), 91(20), 105(22), 115(29), 122(100), 129(41), 193 (M^+−1, 2). Found: C, 73.91; H, 7.90%. Calcd for $C_{12}H_{15}OF$: C, 74.20; H, 7.78%.

1-Fluoro-t-2-hydroxymethyl-2-methyl-1-phenylcyclobutane (51) (Minor Isomer): IR (neat) 3600, 3400, 2980, 2500, 1500, 1450, 1030, 1005, 765, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.38 (d, 3H, J=3.10 Hz), 1.40 (bs, 1H), 1.6—3.0 (m, 4H), 3.24 (bs, 2H), 7.2—7.5 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−143.7; MS m/z (rel intensity in %) 55 (100), 83 (53), 115 (37), 122 (41), 129 (40), 144 (18), 193 (M^+−1, 4). Found: C, 73.84; H, 7.86%. Calcd for $C_{12}H_{15}OF$: C, 74.20; H, 7.78%.

Ethyl (2R*)-2-(2-Fluoro-2-methyl-1-phenylcyclobutyl)-2-hydroxyacetate (53): IR (neat) 3570, 3000, 1730, 1605, 1495, 1450, and 705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.11 (t, 3H, J=7.20 Hz), 3.72 (d, 3H, J=20.60 Hz), 1.8—2.2 (m, 2H), 2.4—2.8 (m, 2H), 3.00 (dd, 1H, J=5.40, 4.30 Hz), 4.01 (q, J=7.20 Hz), 4.93 (d, 1H, J=5.40 Hz), 7.1—7.4 (m, 5H); ^{19}F NMR ($CDCl_3$) δ=−132.8; MS m/z (rel intensity in %) 105 (34), 133 (100), 160 (31), 189 (35), 203 (26), 246 (M^+−20, 29). Found: C, 67.87; H, 7.23. Calcd for $C_{15}H_{19}O_2F$: C, 67.65; H, 7.19%.

Ethyl (2S*)-2-(2-Fluoro-2-methyl-1-phenylcyclobutyl)-2-hydroxyacetate (55) (Inseparable Isomeric Mixture.): IR (neat) 3570, 3000, 1725, 1600, 1490, 1450, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.84 (t, 3H, J=7.00 Hz), 1.32 (d, 3H, J=25.1 Hz), 1.8—2.3 (m, 2H), 2.4—2.8 (m, 2H), 2.9—3.0 (m, 1H), 3.6—3.9 (m, 2H), 4.7—4.8 (m, 1H), 7.0—7.5 (m, 5H), ^{19}F NMR ($CDCl_3$) δ=−135.7 and −132.8; MS m/z (rel intensity in %) 70 (34), 105 (100), 129 (71), 132 (47), 133 (47), 143 (52), 151 (44), 186 (77), 189 (73), 246 (M^+−20, 15).

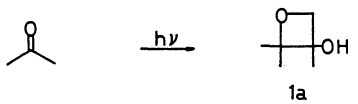
Photolysis of Alcohols and Alkanones in Acetone Solutions. Photochemical [2+2]Cycloaddition Reaction between Acetone and Aliphatic Enols

Nobujiro SHIMIZU,* Toru MIYAHARA, Masaaki MISHIMA, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812
(Received January 20, 1989)

Transient enols including those of acetaldehyde, acetone, cyclopentanone, 3-pentanone, 2,4-dimethyl-3-pentanone, 2-butanone, and 2-methyl-3-pentanone were trapped photochemically with acetone via a [2+2]cycloaddition and isolated as corresponding 3-oxetanols in reasonable yields in the photolysis of six different secondary alcohols and two alkanones, 3-octanone and hexanal, in acetone solutions. The trapping experiments indicated the photodehydrogenation of unsymmetrical alcohols, 2-butanol and 2-methyl-3-pentanol, in acetone to be highly regioselective in preference for the formation of the less alkylated enol.

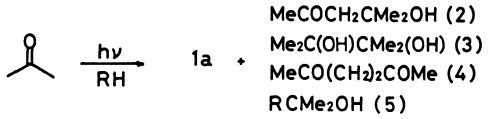
The chemistry of simple enols has received wide attention in recent years from structural and mechanistic interests.[1-4] A number of short-lived enols[1-3,5] have been prepared and characterized directly by spectral analyses including microwave,[6] IR,[7] and NMR.[2,8,9] CIDNP technique is particularly useful for identification of transient enol species which may often be involved in photochemical processes.[10,11] This method, however, does not always provide quantitative information on the formation of such species. In this connection, trapping experiments seem important. Although there have been extensive studies on ketonization of enols via protonation and halogenation,[3,12,13] works on reactions other than ketonization are surprisingly few. Cycloaddition reaction is especially attractive for chemical proof of transient enols. There have been reported several [2+4]-type cycloaddition reactions for some dienols such as photo enols of *o*-alkylated phenyl ketones,[14,15] however, successful trapping of simple enols like vinyl alcohol via a cycloaddition reaction is rare. An interesting observation, in this connection, is the formation of a small amount of 2,2,3-trimethyl-3-oxetanol (**1a**) in the photolysis of acetone in the liquid phase reported by Kagan et al.[16] Although mechanism for the formation of **1a** has not been established yet, a photocycloaddition between acetone and its enol would probably be involved.[17] Accordingly, an excited molecule of acetone seems to be a good candidate for a trapping agent for enol intermediates which are formed in photochemical reactions. We report here our results on the photolysis of eight different alcohols and two alkanones carried out in acetone solutions and show photochemical trapping of various enols with acetone.



1a

Results and Discussion

Photocycloaddition of Acetone with Acetone Enol. We first examined the photolysis of acetone in the liquid phase in the presence of a hydrogen-donating substrate with a view to understanding the mechanism for the formation of the oxetane **1a**. Table 1 shows the results of irradiation of acetone (100 cm^3) with or without a hydrogen-donating substrate (RH, 35 mmol) including cyclohexane, 2-propanol, 3-pentanol, 2-trimethylsiloxypropane, and triethylsilane under the same photolysis conditions (0—5 °C, 2 h under argon) using a 100 W low-pressure mercury lamp. In agreement with the earlier observation,[16] these photolysis reactions gave a mixture of **1a** and several other major compounds including 4-hydroxy-4-methyl-2-pentanone (**2**), pinacol (**3**), 2,5-hexanedione (**4**), and a coupling product **5** between acetone and RH as a low-boiling



liquid distilling under vacuum. Obviously, **1a** is formed much more efficiently in the photolysis of acetone in the presence of a hydrogen donor than in the photolysis of pure acetone. For example, the yield of **1a** increased by a factor of more than nine when acetone was irradiated with 2-propanol instead of acetone alone. Cyclohexane shows a similar effect, although less pronounced. It is worth stating that the photolysis of acetone in cyclohexane has been reported to give a coupling product **5a** (R=cyclohexyl) but not **1a**.[18] The presence of a good hydrogen donor greatly favored the formation of **2** and **3** as well. In contrast, it little affected or in some cases reduced significantly the formation of 2,5-hexanedione. It is also informative that the irradiation of acetone containing 2-propanol and trace *p*-toluenesulfonic acid gave pinacol but not **1a** at all. Although **1a** readily rearranges to 4-hydroxy-3,3-dimethyl-2-butanone under acidic conditions,[19] we could not find the rearranged product either. Thus, the presence of trace acid completely prohibits the formation of **1a**. All these findings are consistent with a mechanism for the formation of **1a** outlined in Scheme 1. An excited molecule

Table 1. Effects of a Hydrogen-Donating Substrate (RH) on the Liquid-Phase Photolysis of Acetone[a)]

Substrate (RH)	Low-boiling fraction/g[b)]	Products/mmol[c)]					
		1a	**2**	**3**	**4**	**5**	Others
None	0.094	0.41	0.19	0.08	0.18		
Cyclohexane	0.584	1.89	0.86	0.59	0.20	1.13	
2-Propanol	1.02	3.71	1.98	2.59	0.25		
2-Propanol/*p*-TsOH	0.303	d)	d)	2.58	d)

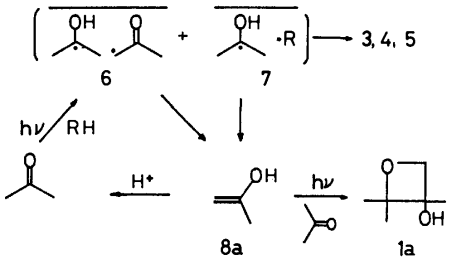
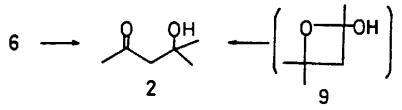
Triethylsilane	3.75	3.80	0.85	3.39	d)		f)
3-Pentanol	4.52[g)]	9.66	3.45	3.60	d)	4.38	h)

a) All the photolysis reactions were carried out under the same irradiation conditions (0—5 °C, 2 h) using a 100 W low-pressure mercury lamp by taking 35 mmol of a substrate (RH) and 100 cm^3 of acetone. b) Amount of low-boiling liquid distilling below 70 °C at 0.5 Torr after fractionation of crude photolysate. c) Determined by GLC using appropriate internal standards. d) Could not be observed. e) 2,2,3-Trimethyl-3-trimethylsiloxyoxetane (**10**) was also formed. f) 2-Triethylsiloxypropane, 3-triethylsiloxy-2,2,3-trimethyloxetane, pinacol mono(triethylsilyl) ether, and triethylsilanol (**14**—**17**) were also formed. g) Irradiation for 4 h. h) 3-Ethyl-2,2,4-trimethyl-3-oxetanol (**1b**) and 3-ethyl-2-methyl-2,3-pentanediol (**20b**) were also formed.



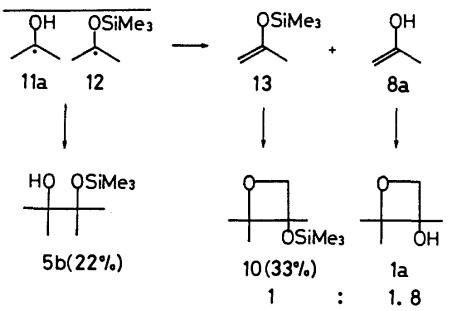
Scheme 1.

of acetone abstracts a hydrogen from solvent acetone or from a hydrogen donor RH yielding radical pairs **6** and **7** which can terminate to **3**—**5** via coupling reactions or to acetone enol **8a** via disproportionation.[20)] The enol thus generated can be trapped with another excited molecule of acetone as **1a** prior to complete ketonization. Under acidic conditions, the ketonization must be so rapid that **8a** cannot be trapped as oxetane. Table 1 clearly indicates that a hydrogen abstraction process leading to **6** which accounts for the formation of **4** does not contribute appreciably to the formation of **8a**, **2**, and **3** when a better hydrogen donor than acetone like 2-propanol is present. The product **2** may be formed directly from **6** or from **8a** via 2,4,4-trimethyl-2-oxetanol (**9**) which is a regioisomer of **1a**.[16,17)] The former is not the major route because



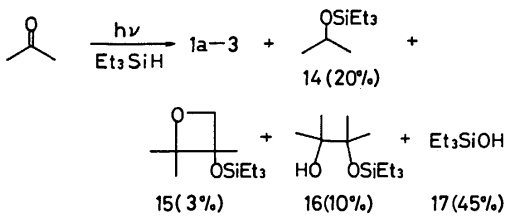
such the pathway should yield **2** in proportion to the formation of **4** against the observation. Both fairly constant **2**/**1a** ratios irrespective of photolysis conditions and the fact that **2** as well as **1a** were not formed at all under acidic conditions are more in accord with the latter pathway.

The photolysis of acetone with 2-trimethylsiloxypropane gave pinacol mono(trimethylsilyl) ether **5b** and 2,2,3-trimethyl-3-trimethylsiloxyoxetane (**10**) in 22 and 33% yields based on the substrate added besides **1a**—**4**. The formation of these products is consistent with the intervention of a pair of radicals, 1-hydroxy-1-methylethyl radical (**11a**) and 1-trimethylsiloxy-1-methylethyl radical (**12**), which terminates to **5b** or disproportionates affording a mixture of **8a** and its trimethylsilyl ether **13**. Noteworthy is the fact that **1a** was formed predominantly over **10** (**1a**/**10**=1.8) in



this photolysis reaction. Although the disproportionation step would give **8a** and **13** in comparable amounts, **8a** must remain in a very low concentration throughout the irradiation because of its short lifetime,[21)] while the concentration of **13** must accumulate during the irradiation. The preferential formation of **1a** therefore suggests that an enol can be trapped efficiently as oxetane as soon as it is generated.

In the case of triethylsilane as a hydrogen donor, four major products, 2-triethylsiloxypropane (**14**), 3-triethylsiloxy-2,2,3-trimethyloxetane (**15**), pinacol mono(triethylsilyl) ether (**16**), and triethylsilanol (**17**) were obtained in 26, 10, 3, and 45% yields, respectively, besides **1**—**3**. Probably, the reaction involves the formation of 1-triethylsiloxy-1-methylethyl radical which accounts for the formation of **14**—**16**.[22)]



Mechanism for the formation of **17** is not clear.

Photocycloaddition of Acetone with Other Aliphatic Enols. Table 1 includes the result of the photolysis of acetone in the presence of 3-pentanol. From the discussion above mentioned, it is expected that irradiation of acetone in the presence of an alcohol (**18b—h**) may lead to formation of an enol (**8b—h**) derived from the alcohol added, hence a new 3-oxetanol (**1b—h**) according to Scheme 2, where Fd and Fc are fractions of enol formation from a hydroxyalkyl radical **11** and oxetane formation from the enol thus generated respectively. Indeed, 3-ethyl-2,2,4-trimethyl-3-oxetanol (**1b**) was obtained as a mixture of two stereoisomers (E/Z=1) in 24% yield on the basis of the consumed 3-pentanol together with 3-pentanone (**19b**, 18%) and 3-ethyl-2-methyl-2,3-pentanediol (**20b**, 25%) besides **1a—3**. Structure of **1b** was deduced from its spectral data (IR, NMR, and MS) and from its chemical property that either stereoisomer of **1b** gave 5-hydroxy-4,4-dimethyl-3-hexanone (**22b**) on treating with boron trifluoride etherate.[19,23] Provided **1b**, **19b**, and **20b** are the sole products from 3-pentanol and all **19b** is formed from an enol **8b**,[20] it follows from the result that a 63% fraction of 1-hydroxy-1-ethylpropyl

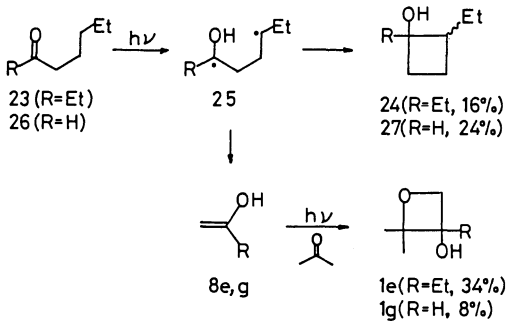
a) All the phtolysis reactions were carried out under argon at 0—5 °C for 4 h with a 100 W low-pressure mercury lamp by taking 100 cm³ of acetone and 35 mmol of a substrate RH. b) Determined by GLC. c) Based on the consumed substrate. d) (**1**+**19**)/(**1**+**19**+**20**+**21**). e) **1**/(**1**+**19**). f) Not determined. g) Based on the substrate added. h) As a mixture of two stereoisomers. i) At −70 °C for 2 h. j) 2-Methyl-3-butanone was also formded. k) Could not be detected. l) 1,2-Diethylcyclobutanol (16%) was also obtained. m) 2-Ethylcyclobutanol (24%) and 2-hydroxy-2-methyl-3-octanone (8%) were formed as well.

radical (**11b**) gave the enol **8b** and that a 57% fraction of **8b** was subsequently trapped as oxetane prior to complete ketonization to 3-pentanone. The results of the photolysis of eight different alcohols **18a—h** and two alkanones, 3-octanone (**23**) and hexanal (**26**), in acetone solutions are summarized in Table 2. Several interesting features are worth noting. First of all, a variety of ketone enols including a cyclic (**8d**) and acyclic ones with one (**8a** and **8e**), two (**8b** and **8f**), and three alkyl substituents (**8c**) were successfully trapped and isolated as corresponding oxetanes **1a—f** in the photolysis of secondary alcohols **18a—f** in fairly good yields, in most cases about 20% of the reacted alcohol. Fd and Fc values suggest that the radicals **11b—f** terminate preferentially via disproportionation to the enols and that the subsequent trapping with acetone proceeds with similar efficiencies about 50% irrespective of structure of enols except for **8d**. Since the photodehydrogenation of alcohols **18b—f** in acetone involves the formation of **8a** hence **1a** as a common side reaction, ratios of oxetanes **1b—f**/**1a**, which are listed in the last column in Table 2, also represent approximate relative efficiencies for the formation of the oxetane from each enol. The fairly constant ratios except for **1d** again suggest that the trapping efficiency does not vary appreciably with the structure of enols.

Norrish II reaction of alkanones is another effective way to generate enols,[24] and it is interesting to see whether photolysis of alkanones in an acetone solution leads to formation of expected 3-oxetanols. Irradiation of 3-octanone (**23**) in acetone gave indeed 3-ethyl-2,2-dimethyl-3-oxetanol (**1e**) in 34% yield together with 1,2-diethylcyclobutanol (**24**) in 16% yield. The formation of **24** and **1e** hence its precursory enol **8e** is



consistent with a conventional scheme for the photolysis of alkanones via an intermediate biradical **25**, although it is not clear whether excitation of 3-octanone is direct or sensitized by acetone under the present photolysis conditions. Photolysis of hexanal (**26**) in acetone was more complicated than that of 3-octanone but an expected vinyl alcohol could be isolated as the corresponding oxetanol **1g** in 8% yield along with several other products including 2-ethylcyclobutanol (**27**, 24%) and 2-hydroxy-2-methyl-3-octanone (**28**, 8%). In the photocycloaddition reactions between acetone and enols **8b—g**, regioisomeric 2-oxetanols like **9** might be formed but we could identify neither such compounds nor their decomposition products, presumably because of small amounts of their formation.

Photodehydrogenation of unsymmetrical alcohols such as 2-butanol (**18e**) and 2-methyl-3-pentanol (**18f**) is expected to produce a mixture of two regioisomeric enols **8** and **8′** which is more highly alkylated, hence thermodynamically more favorable than **8**. Indeed, the formation of **8e** and **8e′** has been confirmed by CIDNP experiments in the photochemical decomposition of *t*-butyl hydroperoxide in 2-butanol.[11] In the present experiments, however, only one of the regioisomers, i.e., the less highly alkylated isomer **8**, could be identified as oxetane in the photolyses of both alcohols **18e** and **18f**. For example, irradiation of **18e** in acetone gave **1e** in 15% yield or in 43% yield when the photolysis was carried out at −70 °C but not an isomeric oxetane **1e′** in detectable amounts. Since, as mentioned earlier, excited acetone would trap **8** and **8′** with similar trapping efficiencies, the above results strongly suggest that the formation of enols from unsymmetrical radicals **11e** and **11f** is highly regioselective in preference for the formation of **8e** and **8f** to their regioisomers **8e′** and **8f′**. Probably, in a disproportionation step, β-hydrogen abstraction from **11e** or **11f** by a partner radical **11a** would predominantly occur at the sterically less hindered site to yield a thermodynamically less favorable enol **8** as the major component in contrast to expectation from acid-catalyzed enolization of ketones.

Oxetanes **1b** and **1f** were obtained as two stereoisomeric mixtures in the ratios 1 : 1 and 4 : 1, respectively. These results appear interesting in relation to the stereochemical structure of the enols **8b** and **8f**; however, the stereochemistry of these oxetanes does not seem to provide meaningful information on the geometry of the enols in view of the fact that the

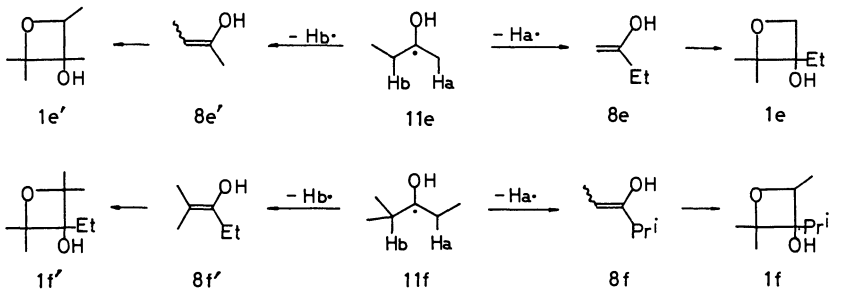


photo-oxetane formation between acetone and electron rich alkenes such as vinyl ethers is a nonstereospecific process.[25]

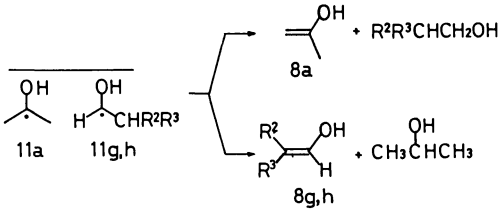
Temperature significantly affected the formation of oxetane and coupling products. Thus, irradiation of **18e** in acetone at 0—5 °C gave **1e**, **20e**, and **21e** in 15, 11, and 4% yields, while at −70 °C, in 43, 5, and 1% yields, respectively. A marked increase in the yield of the oxetane probably arises from retardation of the rate of ketonization of **8e** and partly from an increase in the fraction of disproportionation from **11e**.

Finally, in contrast to the photolysis of secondary alcohols, we could not detect the formation of aldehyde enols **8g** and **8h** as corresponding oxetanols in



the photolysis of two primary alcohols, ethanol (**18g**) and isobutyl alcohol (**18h**), although CIDNP experiments indicate the formation of these enols under similar conditions.[26] In both cases, there were obtained considerable amounts of coupling products but not expected oxetanols **1g** and **1h** in detectable amounts. There seems to be no reason for that excited acetone traps aldehyde enols much less effectively than it does ketone enols. Indeed, vinyl alcohol could be trapped as **1g** in the photolysis of hexanal in acetone. It is therefore conceivable that aldehyde enols are formed in very low concentrations in the photolysis of primary alcohols in acetone solutions. Presumably, disproportionation of a pair of radicals such as **11a** and **11g** would preferentially occur in such a way that **11g** abstracts a hydrogen from **11a** affording acetone enol rather than it loses a β-hydrogen yielding vinyl alcohol, since **11g** is sterically less hindered and probably more reactive than its partner radical **11a**.

The present results indicate that aliphatic enols generated by photodehydrogenation of alcohols and by Norrish II reaction of alkanones can be isolated as corresponding 3-oxetanols when these photolysis reactions are carried out in acetone solutions, providing a rare example of [2+2]cycloadditions of simple enols.

Experimental

IR spectra were recorded on a Hitachi R-215 spectrophotometer. NMR spectra were recorded in carbon tetrachloride on a Hitachi R-20B spectrometer. Mass spectra were taken with a Hitachi M-60 mass spectrometer or an ion cyclotron resonance (ICR) mass spectrometer.[27] GLC were performed with a Hitachi 163 gas chromatograph equipped with glass columns (6 mm×1.5, 2.0, and 3 m) packed with 10% Silicone oil SE-30 on Chamelite CS (SE-30), 25% silicon oil DC-550 on Chamelite CS (SIDC), 25% Apiezon grease L on Chromosorb W (AGL), 15% Carbowax 20M on Chamelite CS (CW), or 10% diethylene glycol succinate polyester on Chamelite CS (DGS). Acetone was purified by refluxing with potassium permanganate followed by fractionation.

2,2,3-Trimethyl-3-(trimethylsiloxy)oxetane (10). A solution of 2-(trimethylsiloxy)propene (4.61 g) in acetone (100 cm³) was irradiated with a 100 W low-pressure mercury lamp under argon for 2 h, during which period 56% starting material was consumed. Fractionation of crude photolysate gave **10** as a colorless oil (1.68 g, 55%): bp 66—68 °C (22 Torr; 1 Torr=133.3 Pa); IR (neat) 1255, 1025, and 845 cm⁻¹; ^{1}H NMR δ=0.09 (9H, s), 1.18 (3H, s), 1.30 (3H, s), 1.43 (3H, s), 3.94 (1H, d, J=6.0 Hz), and 4.32 (1H, d, J=6.0 Hz). Found: C, 57.25; H, 10.70%. Calcd for $C_9H_{20}O_2Si$: C, 57.40; C, 10.71%. A foregoing fraction, bp 35—58 °C (28 Torr) contained another component which was shown to be 4-hydroxy-4-methyl-2-pentanone (**2**). GLC analysis (SE-30, 100 °C) of the crude photolysate indicated the formation of **10** and **2** in the ratio 86:14. **10** gave quantitatively 2,2,3-trimethyl-3-oxetanol (**1a**) on treatment with methanol.

Photolysis of Acetone in the Presence of a Hydrogen-Donating Substrate. General Procedure. Acetone (100 cm³) was directly irradiated under argon with or without a hydrogen donating substrate (35 mmol) using a 100 W low-pressure mercury lamp (Eikosha Halos PIH-100) in a 200 cm³ photolysis vessel which was immersed in an ice bath. After irradiation, acetone was first removed by distillation under reduced pressure (ca. 120 Torr) and resulting oil was fractionated under vacuum from 6 to 0.5 Torr. Each fraction was analyzed directly by GLC using an appropriate internal standard. In most cases, products were isolated by GLC and characterized from their spectral data.

Photolysis of Acetone. Irradiation of acetone (100 cm³) for 2 h gave 0.094 g of an oil, bp 42—58 °C (6 Torr), besides high-boiling material (0.212 g) after fractionation of photolysate. The former oil was shown to be a mixture of 2,2,3-trimethyl-3-oxetanol (**1a**), 4-hydroxy-4-methyl-2-pentanone (**2**), pinacol (**3**), and 2,5-hexanedione (**4**) in the ratio 51:23:9:17 in agreement with the earlier observation.[16]

Photolysis of Acetone with 2-Propanol (18a). Irradiation of acetone (100 cm³) containing 2-propanol (2.19 g, 35.5 mmol) for 2 h gave a mixture of **1a—4** in the ratio 42:23:31:3 [1.016 g, bp 48—58 °C (6 Torr)] besides 0.246 g of a high boiling material.

Photolysis of Acetone with 2-Propanol in the Presence of p-Toluenesulfonic Acid. A solution of 2-propanol (2.14 g), p-toluenesulfonic acid (99 mg), and acetone (100 cm³) was irradiated for 2 h. Most acetone was removed by distillation at 110 Torr. Residue was dissolved in ether, washed with aq. $NaHCO_3$, and dried. Solvent was removed to give a solid (303 mg) which was shown to be almost pure pinacol hydrate.

Photolysis of Acetone with Cyclohexane. Irradiation of an acetone solution of cyclohexane (2.99 g) for 2 h gave 0.583 g of an oil, bp 49—53 °C (6 Torr), besides 0.381 g of a high-boiling material. The former oil consisted of **1a—4** and another major component which was shown to be 2-cyclohexyl-2-propanol (**5a**) by comparison with an authentic sample: IR 3400 cm⁻¹; ^{1}H NMR δ=1.08 (6H, s), 0.9—2.0 (11H, m). GLC analysis of the crude photolysate indicated the formation of **1a—4** and **5a** in the ratio 40:18:13:4:24.

Photolysis of Acetone with 2-Trimethylsiloxypropane. Irradiation of an acetone solution of 2-trimethylsiloxypropane (4.73 g) for 2 h led to 16% consumption of 2-trimethylsiloxypropane to give 1.361 g of an oil distilling below 49 °C at 2 Torr besides 0.136 g of a high-boiling material. GLC analysis (2 m, SE-30, 80 °C) indicated the former oil to be a mixture of **1a—4** and two other major components (t_R=10.7 and 11.4 min), which were isolated by GLC and assigned to 2,3-dimethyl-3-(trimethylsiloxy)-2-butanol (**5b**) and **10**, respectively. **5b**: ^{1}H NMR δ=0.13 (9H, s), 1.08 (6H, s), 1.21 (s, 6H). On treatment with methanol **5b** cleanly gave pinacol. GLC analysis indicated the formation of **5b** and **10** in 22 and 33% yield, respectively on the basis of 2-trimethylsiloxypropane consumed. The relative yields of **1a—4**, **5b**, and **10** were 36 : 19 : 11 : 1 : 13 : 20.

Photolysis of Acetone with Triethylsilane. An acetone solution of triethylsilane (2.35 g) was irradiated for 2 h. Distillation of photolysate gave two fractions, I (2.22 g) distilling below 90 °C at 17 Torr and II (1.51 g), bp 123—135 °C (3 Torr). The fraction I contained **1a—3** and two other components. They were identified as triethylisopropoxysilane (**14**) and triethylsilanol (**17**) by comparison with authentic specimens. The fraction II consisted of two major components and they were assigned to 3-triethylsiloxy-2,2,3-trimethyloxetane (**15**) and 2,3-dimethyl-3-triethylsiloxy-2-butanol (**16**) from their spectral data. **15**: ^{1}H NMR δ=0.4—1.1 (15H, m), 1.18 (3H, s), 1.32 (3H, s), 1.42 (3H, s), 3.95 (1H, d, J=6.0 Hz), 4.29 (1H, d, J=6.0 Hz). On treatment with methanol **15** cleanly gave **1a**. **16**: IR 3430, 1020, and 740 cm^{-1}; ^{1}H NMR δ=0.45—1.1 (15H, m), 1.09 (6H, s), 1.22 (6H, s), 1.97 (1H, s, disappeared on adding D_2O). GLC analysis indicated the formation of **14**, **15**, **16**, and **17** in 26, 3, 10, and 45% yields, respectively. The relative yields for **1a—3**, **14**, **15**, **16**, and **17** were 15 : 3 : 14 : 21 : 2 : 8 : 36, respectively.

Photolysis of Acetone with 3-Pentanol (18b). Irradiation of 3-pentanol (3.10 g) in acetone (100 cm^3) for 2 h resulted in 46% consumption of 3-pentanol to give an oil (3.18 g) distilling below 60 °C at 2 Torr besides a high-boiling residue (0.51 g). The distilled oil was shown to be a mixture of three major components besides **1a—3**, unchanged **18b**, and 3-pentanone (**19b**). They were assigned to (*E*)- and (*Z*)-stereoisomers of 3-ethyl-2,2,4-trimethyl-3-oxetanol (**1b**) and 3-ethyl-2-methyl-2,3-pentanediol (**20b**) from their spectral data. (*E*)-**1b** (tentative stereochemical assignment): MS (ICR) m/z 145 (M^+ +1); IR 3420, 1150, 1055, 1010, and 905 cm^{-1}; ^{1}H NMR δ=0.84 (3H, t, J=7.2 Hz), 1.19 (3H, d, J=6.6 Hz), 1.24 (3H, s), 1.28 (3H, s), 1.65 (2H, q, J=7.2 Hz), 1.85 (1H, s, OH), and 4.30 (1H, q, J=6.6 Hz). On treatment with boron trifluoride etherate in dichloromethane (−15 °C, 30 min), this compound was smoothly converted into a single product which was shown to be 5-hydroxy-4,4-dimethyl-3-hexanone (**22b**): IR 3460 and 1700 cm^{-1}; ^{1}H NMR δ=0.99 (3H, t, J=7.2 Hz), 1.03 (3H, d, J=6.6 Hz), 1.10 (6H, s), 2.46 (2H, q, J=7.2 Hz), 2.32 (1H, OH), 3.80 (1H, q, J=6.6 Hz). Found: C, 66.50; H, 11.25%. Calcd for $C_8H_{16}O_2$: C, 66.68; H, 11.18%. (*Z*)-**1b** (tentative stereochemical assignment): MS (ICR) m/z 145 (M^+ +1); IR 3450, 1060, and 1015 cm^{-1}; ^{1}H NMR δ=0.89 (3H, t, J=7.2 Hz), 1.18 (3H, d, J=6.6 Hz), 1.20 (3H, s), 1.30 (3H, s), 1.69 (2H, q, J=7.2 Hz), and 4.35 (1H, q, J=6.6 Hz). On treatment with boron trifluoride etherate, this isomer also gave **22b** as a single product. An attempt at isolation of **1b** by GLC (3m, DGS) at 130 °C resulted in collection of **22b**. **20b**: IR 3450, 1380, 1125, and 950 cm^{-1}; ^{1}H NMR δ=0.77—1.5 (10H, m), 1.16 (s, 6H), and 1.63 (2H, s, disappeared on adding D_2O). GLC analysis of crude photolysate indicated the formation of **1a—3**, **1b**, **19b**, and **20b** in the ratio 34 : 12 : 13 : 15 : 11 : 15. The yield of the last three products were shown to be 24 (*E*/*Z*=1.0), 25, and 18%, respectively, based on 3-pentanol reacted.

Photolysis of Acetone with 2,4-Dimethyl-3-pentanol (18c). Irradiation of a solution of **18c** (4.14 g) in acetone (100 cm^3) for 4 h resulted in 40% consumption of **18c** to give two fractions, I [2.524 g, bp 25—46 °C (6 Torr)] and II [2.364 g, bp 52—64 °C (1 Torr)], besides a high-boiling residue (0.378 g) after fractionation of photolysate. The fraction I contained mainly **1a—3** (in the ratio 61 : 24 : 15), unchanged **18c**, and 2,4-dimethyl-3-pentanone (**19c**). The fraction II contained two major components and three minor ones besides small amounts of **1a—3**. The former two were shown to be 3-isopropyl-2,2,4,4-tetramethyl-3-oxetanol (**1c**) and 3-isopropyl-2,4-dimethyl-2,3-pentanediol (**20c**) by their spectral data. **1c**: mp 99—100 °C; MS (ICR) m/z 173 (M^+ +1); IR (Nujol) 3440, 1020 cm^{-1}; ^{1}H NMR δ=0.82 (6H, d, J=6.0 Hz), 1.20 (6H, s), 1.37 (6H, s), 1.60 (1H, s, OH), and 1.88—2.63 (m, 1H). **20c**: IR 3420 cm^{-1}; ^{1}H NMR δ=1.05 (12H, d, J=6.0 Hz), 1.27 (6H, s), 1.8—2.4 (2H, m), and 1.80 (2H, broad s, disappeared on adding D_2O). One of the three minor components in II was assigned to 3,4-diisopropyl-2,5-dimethyl-3,4-hexanediol (**21c**) from its spectral properties: IR 3470 cm^{-1}; ^{1}H NMR δ=0.93 (24H, d, J=6.6 Hz), 1.7—2.3 (2H, m), and 2.0 (2H, broad s, OH). The rest two components were not identified yet. GLC analysis (1.5 m, AGL, 130 °C) of crude photolysate indicated the formation of **19c**, **1c**, **20c**, and **21c** in 23, 18, 14, and 4% yields, respectively.

Photolysis of Acetone with Cyclopentanol (18d). Irradiation of a solution of cyclopentanol (3.10 g) in acetone for 4 h resulted in 34% consumption of the alcohol to yield two liquid fractions, I (1.23 g, distilling below 48 °C at 1 Torr) and II [0.36 g, bp 63—70 °C (0.5 Torr)], besides a high-boiling residue (1.09 g) after fractionation of crude photolysate. The fraction I contained mainly **1a—3**, cyclopentanol, and cyclopentanone (**19d**). The fraction II contained mainly two components. They were isolated by GLC and assigned to 1-hydroxy-7,7-dimethyl-6-oxabicyclo[3.2.0]heptane (**1d**) and 1-(2-hydroxyprop-2-yl)cyclopentanol (**20d**). **1d**: MS (ICR) m/z 143 (M^+ +1); IR 3430 cm^{-1}; ^{1}H NMR δ=1.17 (3H, s), 1.38 (3H, s), 1.5—2.1 (m, 6H), 2.36 (1H, disappeared on adding D_2O), and 4.62 (1H, d, J=2.5 Hz). **20d**: IR 3500 cm^{-1}; ^{1}H NMR δ=1.19 (6H, s), 1.47—1.87 (8H, m), and 2.35 (2H, disappeared on adding D_2O). GLC analysis (1.5 m, AGL, 130 °C) of crude photolysate indicated the formation of **1a—4**, **19d**, **1d**, and **20d** in the ratio 31 : 12 : 14 : 3 : 21 : 6 : 13. The yields of the last three components were 20, 5.2, and 12%, respectively, based on the consumed **18d**.

Photolysis of Acetone with 2-Butanol (18e). Irradiation of a solution of 2-butanol (2.71 g) in acetone for 4 h resulted in 37% consumption of 2-butanol to give two liquid fractions, I (1.1 g, distilling below 62 °C at 6 Torr) and II [0.89 g, bp 80—88 °C (2 Torr)], besides a high-boiling residue (0.3 g). I contained mainly **1a—4** (in the ratio 48 : 20 : 23 : 9). GLC analysis (2 m, SE-30, 130 °C) showed II to be a mixture of three major components (t_R 4.7, 5.1, and 7.8 min). They were assigned to 3-ethyl-2,2-dimethyl-3-oxetanol (**1e**), 2,3-dimethyl-2,3-pentanediol (**20e**), and 3,4-dimethyl-3,4-

hexanediol (**21e**) from their spectral data. **1e**: MS (ICR) *m/z* 131 (M+1); IR 3420 cm^{-1}; ^1H NMR δ=0.90 (3H, t, J=6.0 Hz), 1.26 (3H, s), 1.33 (3H, s), 1.44—1.91 (2H, m), and 4.16 (2H, almost s). On treatment with boron trifluoride etherate, **1e** was converted into 1-hydroxy-2,2-dimethyl-3-pentanone (**22e**): ^1H NMR δ=1.00 (3H, t, J=7.2 Hz), 1.11 (6H, s), 1.81 (1H, disappeared on addition of D_2O), and 3.43 (2H, s). The NMR spectrum was in agreement with that reported.[28] **22e** was also obtained when **1e** was passed through a 3 m DGS column at 130 °C. **20e**: IR 3430 cm^{-1}; ^1H NMR δ=0.92 (3H, t, J=6.6 Hz), 1.07 (3H, s), 1.15 (6H, s), 1.43 (2H, q, J=6.6 Hz), and 1.65 (2H, OH). The IR spectrum was superimposable with that reported.[29] The NMR spectrum of **21e** [δ=0.91 (6H, complicated), 1.06 (6H, s), 1.8 (2H, OH)] was in agreement with that reported.[30] GLC analysis of crude photolysate indicated the formation of **1a—4**, **1e**, **20e**, and **21e** in the ratio 36:15:17:14:8:3. The yields of the last three components were 15, 11, and 4%, respectively, based on 2-butanol reacted.

Photolysis of Acetone with 2-Butanol at Low Temperature. Irradiation of 2-butanol (2.71 g) in acetone (100 cm^3) at Dry Ice temperature for 2 h resulted in 14% consumption of 2-butanol to give 1.18 g of an oil distilling below 57 °C at 3 Torr. GLC analysis indicated the oil to be a mixture of **1a—4**, **1e**, **20e**, and **21e** in the ratio 38:16:4:10:26:3:1. The yields of the last three components were 43, 5, and 1%, respectively, on the basis of 2-butanol consumed.

Photolysis of Acetone with 2-Methyl-3-pentanol (18f). Irradiation of 2-methyl-3-pentanol (3.63 g) in acetone for 4 h resulted in 42% consumption of the alcohol to give two liquid fractions, I (3.13 g, distilling below 48 °C at 2 Torr) and II [1.0 g, bp 55—70 °C (1.5 Torr)]. Fraction I contained mainly **1a—3**, unchanged **18f**, and 2-methyl-3-pentanone (**19f**). GLC analysis (1.5 m, SIDC, 130 °C) indicated the fraction II to be a mixture of two major components (t_R 15.2 and 28 min) together with two minor ones (t_R 17.2 and 18.8 min) besides small amounts of **1a—3**. The major two products were shown to be 3-isopropyl-2,2,4-trimethyl-3-oxetanol (**1f**) and 3-ethyl-2,4-dimethyl-2,3-pentanediol (**20f**). **1f**: MS (ICR) *m/z* 159 (M^++1); IR 3430 cm^{-1}; ^1H NMR δ=0.76 (3H, d, J=7.2), 0.80 (3H, d, J=7.2 Hz), 1.15 (3H, d, J=6.0 Hz), 1.21 (3H, s), 1.35 (3H, s), 1.97 (1H, disappeared on addition of D_2O), 1.9—2.4 (1H, m), and 4.40 (1H, q, J=6.0 Hz). **20f**: IR 3440 cm^{-1}. ^1H NMR δ=0.93 (3H, d, J=6.6 Hz), 0.99 (3H, d, J=7.2 Hz), 0.8—1.0 (3H), 1.21 (6H, s), 1.4—2.1 (2H, m), and 2.2 (2H, disappeared on addition of D_2O). One of the two minor products was assigned to a stereoisomer of **1f** from the following spectral data: IR 3430 cm^{-1}; ^1H NMR δ=0.82 (3H, d, J=6.6 Hz), 0.85 (3H, d, J=6.6 Hz), 1.16 (3H, d, J=7.2 Hz), 1.22 (3H, s), 1.36 (3H, s), 1.9—2.4 (1H, m), and 4.24 (1H, q, J=7.2 Hz). The rest one components was not identified yet. GLC analysis indicated the formation of **1a—3**, **19f**, **1f** (4:1 mixture of stereoisomers), and **20f** in the ratio 39:17:11:12:13:11. The yields of the last three products were 19, 21, and 17%, respectively, on the basis of 2-methyl-3-pentanol consumed.

Photolysis of Acetone with Ethanol (18g). Irradiation of ethanol (1.67 g) in acetone for 4 h gave 2.134 g of an oil distilling below 63 °C at 2 Torr besides a high-boiling residue (0.323 g). GLC analysis (1.5 m, SIDC, 100 °C) indicated the oil to be a mixture of two major products (t_R 3.6 and 6.0 min) besides **1a—3**. They were shown to be 3-hydroxy-3-methyl-2-butanone and 2-methyl-2,3-butanediol (**20g**) by comparison with the authentic specimens. **20g**: IR 3420 cm^{-1}; ^1H NMR δ=1.13 (6H, s), 1.14 (3H, d, J=7.2 Hz), 3.50 (1H, q, J=7.2 Hz), and 3.61 (2H, disappeared on addition of D_2O). GLC analysis showed the formation of **1a—3**, 3-hydroxy-3-methyl-2-butanone, and **20g** in the ratio 38:17:18:5:22.

Photolysis of Acetone with Isobutyl Alcohol (18h). Irradiation of isobutyl alcohol (2.70 g) in acetone for 4 h resulted in 40% consumption of the alcohol to give 1.85 g of an oil distilling below 53 °C at 2 Torr besides a high-boiling residue (0.467 g). GLC analysis (2 m, SE-30, 80 °C) indicated the oil to be a mixture of two major components (t_R 10.6 and 26 min) besides **1a—4**. They were assigned to 2,4-dimethyl-2,3-pentanediol (**20h**) and 2,5-dimethyl-3,4-hexanediol (**21h**, mostly as meso form) from their spectral data which were in agreement with those reported.[29] GLC analysis indicated the formation of **1a—4**, **20h**, and **21h** in the ratio 32:14:13:7:27:8. The yields of the last two products were 28 and 8%, respectively, based on isobutyl alcohol consumed.

Photolysis of Acetone with 3-Octanone (23). Irradiation of 3-octanone (4.66 g) in acetone (100 cm^3) for 4 h resulted in 42% consumption of 3-octanone to give, after fractionation of crude photolysate, two liquid fractions, I (4.04 g, distilling below 33 °C at 0.5 Torr) and II [0.67 g, bp 42—64 °C (0.5 Torr)], besides a high-boiling residue (1.09 g). Fraction I contained mainly **1a** and **2** other than **23**. Fraction II contained two major components which were assigned to **1e** and 1,2-diethylcyclobutanol (**24**) from their spectral properties. **24**: MS *m/z* 129 (M^++1); IR 3430 cm^{-1}; ^1H NMR δ=0.87 (6H, complicated), 1.2—2.07 (9H, m), 1.17 (1H, disappeared on adding D_2O). GLC analysis (2 m, SE-30, 80 °C) indicated the formation of **1a**, **2**, **1e**, and **24** in the ratio 46:19:24:11. The yields of the last two products were 34 and 16%, respectively, on the basis of 3-octanone consumed.

Photolysis of Acetone with Hexanal (26). Irradiation of hexanal (3.64 g) in acetone (100 cm^3) for 4 h resulted in 96% consumption of hexanal to give, after fractionation of photolysate, two liquid fractions, I (1.54 g distilling below 30 °C at 0.5 Torr) and II [0.80 g, bp 54—67 °C (0.5 Torr)], besides a high-boiling residue (0.26 g). GLC analysis (1.5 m, SIDC, 70 °C) indicated the fraction I to contain three major components (t_R 27.6, 32.8, and 40.4 min) other than **1a** and **2** (t_R 44.4 and 35.2 min, respectively). They were characterized as (*E*)- and (*Z*)-stereoisomers of 2-ethylcyclobutanol (**27**) and 2,2-dimethyl-3-oxetanol (**1g**) from their spectral properties. (*E*)-**27** (tentative stereochemical assignment): IR 3350 and 1105 cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=6.6 Hz), 1.08—2.27 (7H, m), 2.07 (1H, disappeared on adding D_2O), and 3.69 (1H, m). (*Z*)-**27** (tentative stereochemical assignment): IR 3330 and 1120 cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=6.6 Hz), 1.06—2.6 (7H, m), 1.54 (1H, disappeared on adding D_2O), and 4.27 (1H, m). These NMR spectra were in agreement with those reported.[31] **1g**: MS *m/z* 103 (M^++1), 72, and 59; IR 3400, 1150, 1120, 1045, 975, 955, and 825 cm^{-1}; ^1H NMR δ=1.29 (3H, s), 1.32 (3H, s), 4.0—4.62 (3H, m). Fraction II contained two major components. One of them was assigned to 2-hydroxy-2-methyl-3-octanone (**28**): IR 3450 and 1715 cm^{-1}; ^1H NMR δ=0.91 (3H, t, J=6.5 Hz), 1.29 (6H, s), 1.07—1.64 (6H, m), 2.46 (2H, t, J=6.6 Hz), and 3.4 (1H, OH). GLC analysis indicated the formation of **1a**, **2**, **27** (2:1 stereoisomeric mixture), **1g**, and **28** in the ratio 14:6:48:16:16. The yields of the last three products were 24, 8,

and 8%, respectively, on the basis of hexanal consumed.

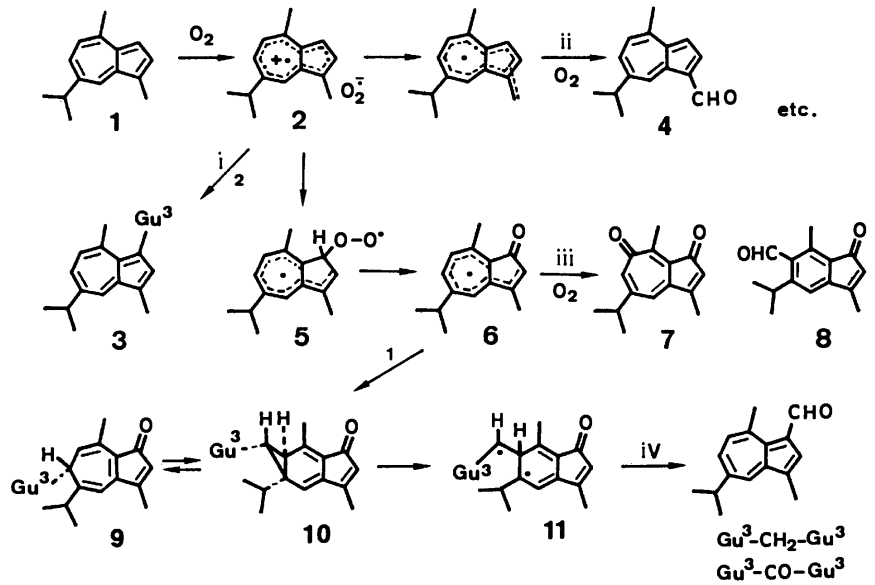
(Received January 27, 1989)

Oxidation of guaiazulene (**1**) with peracetic acid in hexane at 25 °C afforded as high as an 80% yield of the title biguaiazulenedione (**12**), which upon heating at 60 °C under nitrogen gave the title 1-azulenone (**13**) quantitatively. Oxidation of **12** and **13** was studied under various conditions, and these compounds were shown to be highly important key intermediates for a large number of the complex products obtained by autoxidation of **1**.

For the past several years we have undertaken a systematic investigation on autoxidation of various azulenic hydrocarbons and isolated a wide variety of interesting products, whose structures were mostly elucidated.[2-11)] These products can be classified mainly into four groups according to their structural type: i) oxidative coupling products (dimers and trimers), ii) side-chain oxidation products, iii) nucleus-oxidation products (azulenequinones, indenones, naphthalenoids, and benzenoids), and iv) one- carbon-transfer products (formylazulenes, diazulenylmethanes, and ketones). Compounds coupled with substrate azulenes have also been obtained as the secondary products.

In particular, autoxidation of guaiazulene (**1**), which possesses a high, redox potential (E_{pa} 0.71 V vs. SCE),[12)] has been intensively studied under various conditions as a model compound for investigation of oxidation of azulenic hydrocarbons, and a preliminary view on the possible pathways for the extremely complex, competitive reactions has been proposed;[5,11)] see Scheme 1 for intermediates and products **2**—**11** as well as paths i—iv corresponding to the classified structural type mentioned above. We now wish to report herein our study on the reaction of **1** with peracetic acid in hexane, which enabled us to efficiently isolate unique compounds that are considered to be highly important in view of further clarification of complex mechanisms of oxidation of azulenic hydrocarbons.



Scheme 1. Autoxidation of guaiazulene (**1**):[5,11)] Gu^3=3-guaiazulenyl.

† Present address: Guangzhou Institute of Chemistry, Academica Sinica, P.O.Box 122, Guangzhou, China.

Results and Discussion

It was briefly reported[10] that treatment of **1** with equimolar peracetic acid in acetic acid at 15 °C for 3 min gave [5,6′-biguaiazulene]-3,3′(5*H*,6′*H*)-dione (**12**, 18% isolated yield) together with **9**[4,11] (20%), **10**[4,11] (10%), and other minor products. However, we have now found out that when the same reaction was carried out in hexane using an excess of 30% peracetic acid at 25 °C for 1 h, **12** was exclusively produced on the evidence of TLC and HPLC; see the reaction conditions summarized in Table 1. Addition of saturated aq sodium carbonate to the reactant afforded **12** as a precipitate in an 80% isolated yield; see the Experimental section for additional spectroscopic data (FAB-MS and ^{13}C NMR) obtained presently to confirm the asymmetrically coupled dimeric structure. The rest of the products isolated from the hexane filtrate and purified by chromatography were **4**,[2,5] **7**,[2,5] **8**,[2,5] **9**, **10**, and 5-isopropylidene-3,8-dimethyl-1(5*H*)-azulenone (**13**), besides a polar resinous substance that remained unidentified (Scheme 2). The yields of these isolated products are summarized in Table 2. Among these products, **13** was newly obtained here in an extremely low yield, but it was prepared efficiently from **12** (see below).

Table 1. Reaction Conditions of Peroxy Acid Oxidation of **1** in Hexane

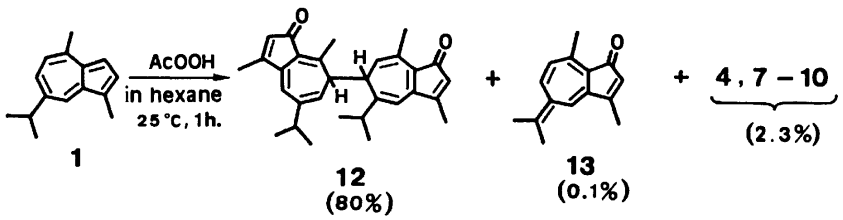
Expt	Temp/ °C	Time/ h	Mole equiv of peracid[a]	Recovered **1**/%
I	25	1	1	70
II	25	1	3	42
III	25	1	6	13

a) Mol equiv of 30% peracetic acid in 40 parts of hexane.

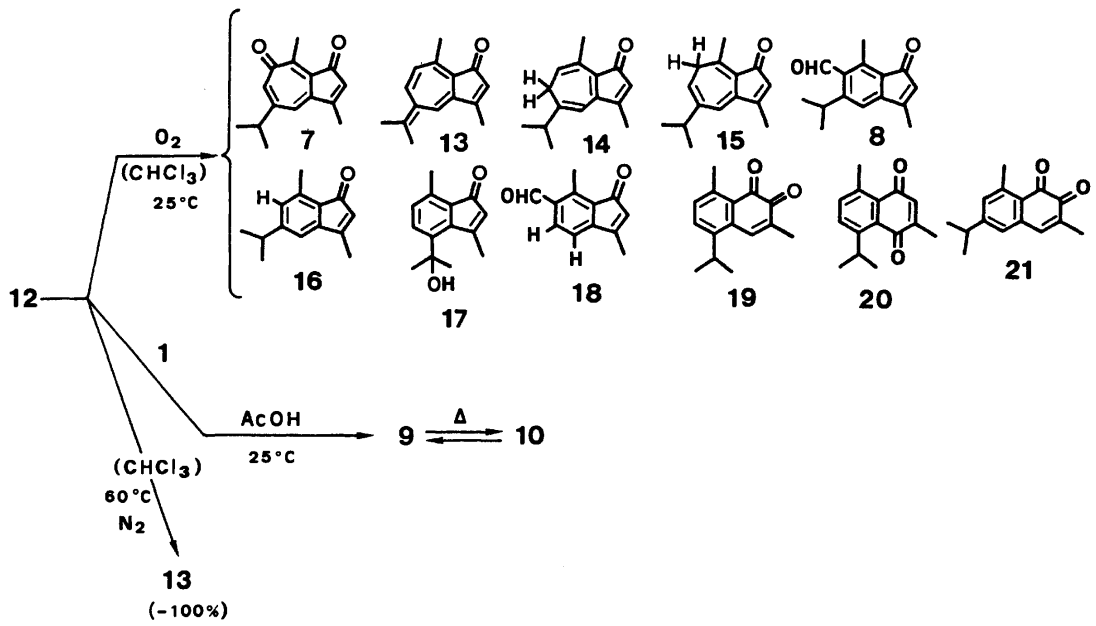
Table 2. Isolated Yield[a]/% of the Oxidation Products from **1**

Product	Expt (reaction conditions)[b]		
	I	II	III
4	0.7	0.2	0.2
7	0.3	0.2	0.1
8	0.7	0.5	0.2
9	1.3	1.6	0.5
10	0.7	0.2	1.3
12	70.5	70.2	80.1
13	0.3	0.2	0.1
RS[c]	20.1	23.3	15.2

a) The yield of each product is based on the consumed **1**. b) Expts I—III correspond to those in Table 1. c) Polar resinous substance.



Scheme 2. Oxidation of **1** with peracetic acid.



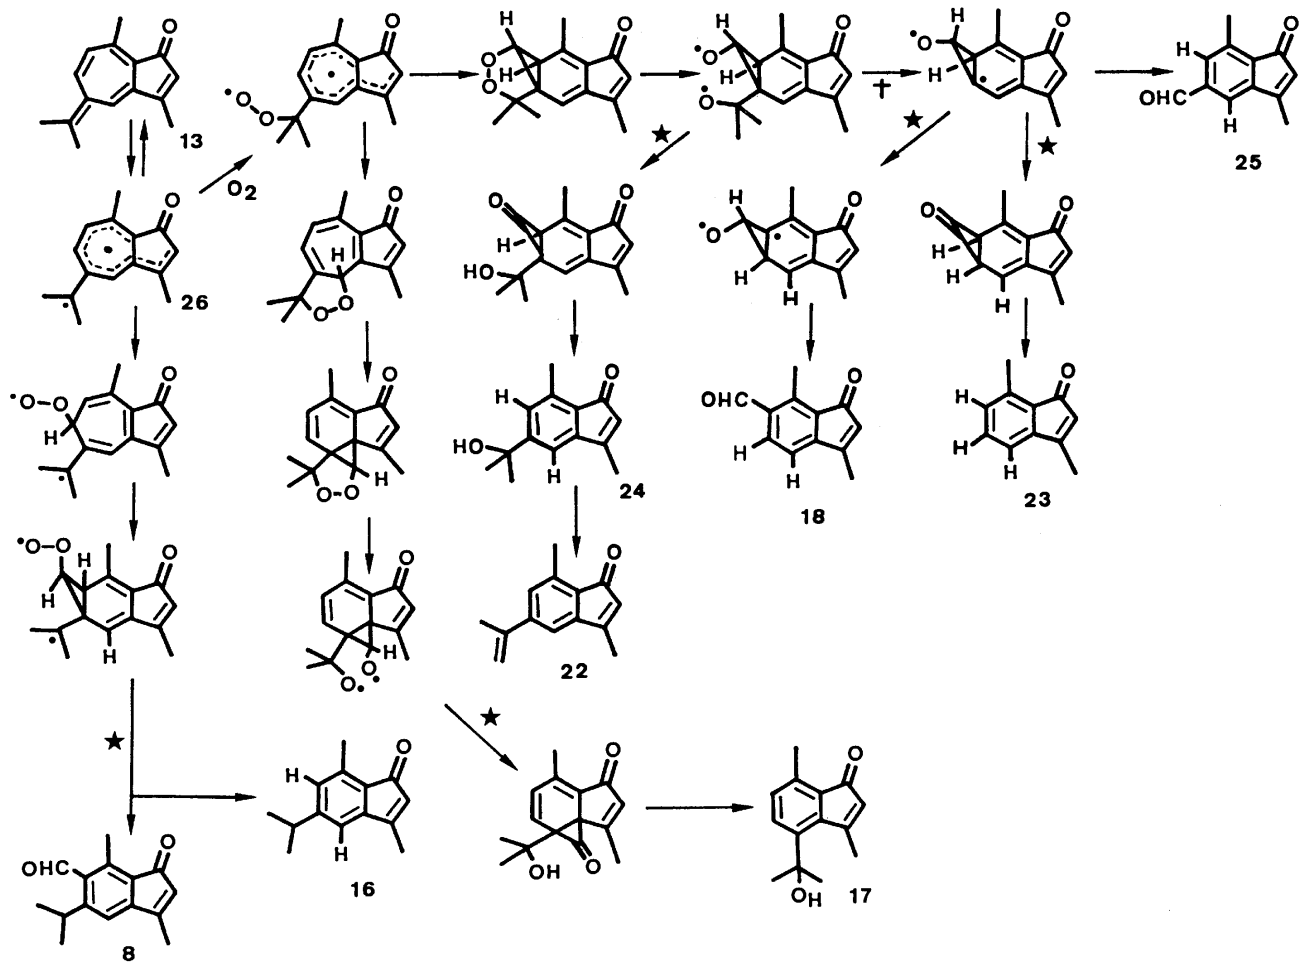
Scheme 3. Reactions of **12**.

The dimer **12** is a pale yellow powder and stable at 25 °C as long as it is kept as a solid. When **12** was, however, dissolved in chloroform and allowed to stand at 25 °C under aerobic conditions, it was found to give many products, a majority of which was obtained by autoxidation of **1** (through path iii). The isolated products were various azulenones [**7**[2,5] (0.4% yield), **13** (30%), **14** (24%), **15** (5%)], indenones [**8**[2,5] (6%), **16**[2,5] (22%), **17** (1%), **18**[11] (2%)], and naphthoquinones [**19**[13] (2%), **20**[2,5] (3%), **21** (5%)] (see Scheme 3). In contrast, when dissolved in degassed chloroform[14] and heated at 60 °C for 1 h under nitrogen, **12** turned out to undergo disruption to afford **13** almost quantitatively.

Compound **13** having a unique structure of quinonemethide is isolable as orange needles but rather unstable. Thus, when dissolved in chloroform and set aside at 25 °C for 1 d in open air, **13** yielded several 1-indenone derivatives **8** (3%), **16** (8%), **17** (1%), **18** (54%), **22** (5%), **23** (1%), **24** (4%), and **25** (1%) (see Scheme 4), some of which had also been produced by autoxidation of **1** (path iii).

The structures of the hitherto unreported compounds **13**—**15**, **17**, and **21**—**25** mentioned above were established by the mass spectrometry and ^{1}H NMR and IR spectroscopy. These spectral data and their assignments are given in the Experimental section. The most probable pathways particularly of the unusual reactions of **13** are then proposed in Scheme 4. It is especially of interest that compounds missing the isopropyl side chain (**18**, **23**) or having an oxidized side chain (**17**, **22**, **24**, **25**) are derived under such extremely mild conditions as those employed presently. This suggests that, at initial stage, **13** is likely to behave like diradical **26** and to react with oxygen competitively at C-6 and the isopropylidene side chain. Then, a series of degradative transformations involving presumably intramolecular hydrogen transfer, acetone cleavage, and decarbonylation proceed to afford various 1-indenones, as illustrated in Scheme 4.

Furthermore, the dimer **12** was shown to react with guaiazulene (**1**) in acetic acid at 25 °C to afford exclusively, at the initial stage, a mixture of **9** (50% yield) and **10** (50%) (Scheme 3). This also provides an important suggestion of a reaction pathway of oxidation of **1**, because both **9** and **10** have been shown[4,11] to give most of the same one-carbon-transfer products as those directly obtained by autoxidation of **1** (see path



Scheme 4. Autoxidation of **13** in chloroform and possible reaction pathways for the products: *Intramolecular H· transfer; †acetone cleavage.

iv in Scheme 1).

These pieces of evidence described so far are indicative of the 3-guaiazulenone dimer **12** (and presumably the dissociated monomeric radical ketone **6**) and 3-azulenone **13** to be very important key intermediates for the two major reaction pathways (iii and iv in Scheme 1) for the autoxidation of guaiazulene (**1**) and apparently other azulenic hydrocarbons as well. Further studies (including theoretical calculation of the reactivities of these compounds) with regard to the exact reaction mechanisms and selective preparations of desired oxidation products are currently under intensive investigation.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. Column chromatography was performed with Wako C-300 silica gel. TLC was conducted on plates precoated with silica gel 60F-254 (0.25 mm, Merck) by using 15:85 AcOEt–hexane as eluant. HPLC was carried out with Hitachi gel #3011 packed in a Pyrex column (ϕ 5 mm, 500 mm length) with 1:9 hexane–MeOH as solvent.

The UV and IR spectra were taken on a Hitachi 323 spectrophotometer and a JASCO IR-A-202 Grating spectrometer, respectively. Mass spectra were taken on a JEOL JMS-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument and are given in terms of *m/z* (rel intensity) compared with the base peak. NMR spectra were recorded in $CDCl_3$ with a JEOL FX-200 (200 MHz for ^1H and 50 MHz for ^{13}C) or JEOL GSX-270 cryospectrometer at 27 °C. The assignments of all signals were made by employing a first-order analysis with the aid of decoupling technique and the parameters were confirmed by a computer-assisted simulation analysis.

Oxidation of Guaiazulene (1). **1**[15] (0.50 g) was added to a stirred solution of peracetic acid [30% aq, 0.64 cm^3, 1.0 mol equiv (for Expt I described in Table 1)] in hexane (20 cm^3). The mixture was stirred at 25 °C for 1 h and then saturated aq sodium carbonate was added. The precipitated solid was filtered off and washed well with water, then with hexane, and finally with ethyl acetate, thus giving pure **12** (105 mg, 71% theoretical yield). The above hexane filtrate and the organic washings were combined, washed thoroughly with water, dried (Na_2SO_4), and evaporated in vacuo. The residue (390 mg) was purified by silica-gel column chromatography first with hexane (to recover unreacted **1**), then with hexane–ethyl acetate (to separate various products), and finally with methanol (to eluate the polar substance) as the eluants. Then, each fraction of the products was further purified by preparative HPLC; when necessary, this chromatographic procedure was repeated.

Expts II and III (Table 1) were conducted under exactly the same procedures as those described above except for using 1.92 and 3.86 cm^3 of 30% peracetic acid in 20 cm^3 of hexane. The yield of each product based on the consumed starting material is summarized in Table 2.

[5,6'-Biguaiazulene]-3,3'(5*H*,6'*H*)-dione (12):[10] A pale yellow powder, mp 138—142 °C (decomp) (lit,[10] 138—142 °C decomp); although some spectral data for this compound were reported[10] the following data to confirm the structure have been obtained in the present study, FAB-MS (matrix, 3-mercapto-1,2-propanediol+NaI) *m/z* 449 (M+23; 3), 427 (M+1; 2), 343 (15), 319 (6), 236 (M/2+23; 20), and 213 (M/2; 100); ^{13}C NMR δ=194.12, 193.57 (C-3, 3'), 162.89, 162.64, 147.90, 147.28, 144.40, 143.66, 141.53, 141.42, 130.29, 129.37, 128.58, 122.87, 122.64, 121.23, 120.35, 45.91, 45.80, 35.55, 22.99, 22.63, 22.45, 22.27, 21.96, 13.73, and 13.69.[16]

5-Isopropylidene-3,8-dimethyl-1(5*H*)-azulenone (13): Orange needles, mp ca. 135 °C (darkened); R_f 0.30; UV λ_{max} (MeOH) 209, 244sh, 265, 300sh, 389, 400sh, and 488sh nm; IR ($CHCl_3$) 1680 cm^{-1} (C=O); EI-MS *m/z* 212 (M$^+$; 100), 197 (95), 183 (5), 169 (17), 153 (12), 141 (14), 128 (9), and 115 (6); ^1H NMR δ=1.89, 1.92 (3 H each, 2 s, Me_2C-5), 2.18 (3 H, d, $J\simeq$1.0 Hz, Me-3), 2.37 (3 H, s, Me-8), 5.62 (1 H, d, J=13.0 Hz, H-7), 6.15 (1 H, qd, $J\simeq$1.0, 0.3 Hz, H-2), 6.43 (1 H, dd, J=13.0, 2.0 Hz, H-6), and 6.52 (1 H, dd, J=2.0,$\simeq$0.3 Hz, H-4). Found: *m/z* 212.1210. Calcd for $C_{15}H_{16}O$: M, 212.1201.

Reactions of 12. A. Under Aerobic Conditions: A solution of **12** (100 mg) in chloroform (10 cm^3) was allowed to stand at 25 °C for 1 d in open air. After evaporation of the solvent and purification of the residue by chromatography, the following products were obtained: **7**[2,5] (0.4% yield), **8**[2,5] (5.7%), **13** (30.4%), **14** (24.1%), **15** (5.1%), **16**[2,5] (21.5%), **17** (1.0%), **18**[11] (1.7%), **19**[13] (2.2%), **20**[2,5] (3.2%), and **21** (4.8%).

3(6*H*)-Guaiazulenone (14): Pale yellow needles; R_f 0.55; EI-MS *m/z* 214 (M$^+$; 100) 199 (46), 184 (6), 172 (80), 171 (80), 156 (28), 143 (62), 129 (37), 128 (34), and 115 (8), the fragmentation pattern closely resembled that of **15** (see below); ^1H NMR, the sample was not stable enough for the measurement of the spectrum.

3(5*H*)-Guaiazulenone (15): Pale yellow needles; R_f 0.55; EI-MS *m/z* 214 (M$^+$; 46), 199 (45), 184 (5), 172 (38), 171 (100), 156 (12), 143 (18), 128 (12), and 115 (5). ^1H NMR δ=1.07 (6 H, d, J=7.0 Hz, Me_2C-7), 2.196 (3 H, d, J=1.5 Hz, Me-1), 2.41 (3 H, s, Me-4), 2.484 (1 H, sept, J=7.0 Hz, CH-7), 2.73 (2 H, d, J=7.0 Hz, H-7), 5.40 (1 H, td, J=7.0, 2.0 Hz, H-6), 5.91 (1 H, q, J=1.5 Hz, H-2), and 6.34 (1 H, d, J=2.0 Hz, H-8). Found: *m/z* 214.1366. Calcd for $C_{15}H_{18}O$: M, 214.1357.

4-(1-Hydroxy-1-methylethyl)-3,7-dimethyl-1*H*-inden-1-one (17): Pale yellow oil; R_f 0.18; IR ($CHCl_3$) 3600—3200 (OH) and 1700^{-1}(C=O); EI-MS 216 (M$^+$; 22), 201 (35), 198 (100), 183 (83), 173 (6), 169 (6), 159 (74), 155 (31), 141 (6), 128 (22), 115 (15), 100 (6), 93 (11), 77 (6), 59 (6), 51 (5), and 43 (34); ^1H NMR δ=1.69 (6 H, s, Me_2C-4), 1.728 [1 H, s, C(OH)-4], 2.51 (3 H, br s, Me-7), 2.61 (3 H, d, J=1.5 Hz, Me-3), 5.75 (1 H, q, J=1.5 Hz, H-2), 6.95 (1 H, br d, J=8.0 Hz, H-6), and 7.216 (1 H, d, J=8.0 Hz, H-5). Found: *m/z* 216.1089. Calcd. for $C_{14}H_{16}O_2$: M, 216.1150.

6-Isopropyl-3,8-dimethyl-1,2-naphthoquinone (21): Pale yellow needles; R_f 0.55; EI-MS *m/z* 228 (M$^+$; 18), 185 (100), 157 (22), and 128 (8); ^1H NMR δ=1.225 (6 H, d, J=7.0 Hz, Me_2C-6), 2.27 (3 H, d, J=1.5 Hz, Me-3), 2.58 (3 H, br s, Me-8), 3.52 (1 H, sept, J=7.0 Hz, CH-6), 5.76 (1 H, q, J=1.5 Hz, H-4), 7.48 (1 H, d, J=2.0 Hz, H-5), and 7.61 (1 H, br d, J=2.0 Hz, H-7). Found: *m/z* 228.1148. Calcd for $C_{15}H_{16}O_2$: M, 228.1150.

B. Under Anaerobic Conditions: A solution of **12** in degassed chloroform was heated at 60 °C for 1 h under nitrogen, followed by the same work-up, giving **13** quatitatively (by TLC and HPLC).

C. In the Presence of 1: A solution of **12** (166 mg) and **1** (300 mg) in acetic acid (15 cm^3) was allowed to stand at 25 °C for 1 h, followed by the same work-up, giving **9**[4] (50% yield)

and **10**[4] (50%).

Reaction of 13. A solution of **13** (100 mg) in chloroform (10 cm^3) was allowed to stand at 25 °C for 1 d in open air, followed by the same work-up as above, giving **8**[2,5] (3.0% yield), **16**[2,5] (7.8%), **17** (1.0%), **18**[11] (53.8%), **22** (5.0%), **23** (1.0%), **24** (4.4%), and **25** (1.0%).

5-Isopropenyl-3,7-dimethyl-1*H*-inden-1-one (22): Pale yellow needles; R_f 0.78; EI-MS *m/z* 198 (M^+; 100), 183 (98), 169 (11), 155 (86), 139 (8), 128 (18), and 115 (13).

3,7-Dimethyl-1*H*-inden-1-one (23): Pale yellow needles, R_f 0.78; EI-MS *m/z* 158 (M^+; 100), 129 (37), and 115 (44).

5-(1-Hydroxy-1-methylethyl)-3,7-dimethyl-1*H*-inden-1-one (24): Pale yellow oil; R_f 0.18; EI-MS *m/z* 198 ($M^+ - H_2O$; 100), 183 (98), 169 (11), 155 (86), 139 (8), 128 (18), and 115 (13).

3,7-Dimethyl-1-oxo-1*H*-indene-5-carbaldehyde (25): Pale yellow needles; R_f 0.49; EI-MS *m/z* 186 (M^+; 100), 157 (20), 143 (3), 129 (30), and 115 (30).

14) On setting aside this solution at room temperature, a well-resolved, hyperfine ESR spectrum became observable, suggesting a splitting of **12** into a certain radical species, probably the monomeric radical **6**, under anaerobic conditions. We are very grateful to Dr. Yozo Miura (Osaka City Univ.) for the measurement of the ESR spectrum. Full analysis of the spectrum for the structural proof is currently in progress and the result will be reported in a future paper.

15) Guaiazulene (**1**) is commercially available from Konan Kako, Co. (Osaka): Blue-violet prisms, mp 31 °C.

16) In addition to these data, we were puzzled to observe optical activity for **12**:$[\alpha]_D^{21}$ −6.98 ($CHCl_3$, *c*=0.5). Details of this unexpected fact is currently being studied and the result will be reported elsewhere.

Note added to Proof. After this paper was accepted for publication, Professor Toyonobu Asao (Tohoku University, Sendai) has kindly informed us that his newly synthesized 3-guaiazulenol gives, on being allowed to stand in ether, an oxidative dimeric product which he considers identical with our specimen **12**. On the basis of 600 MHz ^1H NMR (with 2D mode, in C_6D_6) data, he has assigned the product to be a ca. 10:8 mixture of meso and enantiomers of [5,5′-biguaiazulene]- 3,3′(5*H*,5′*H*)-dione. For the NMR measurement the specimen was dissolved in C_6D_6 (sparingly soluble) by prolonged heating and the IR spectrum (KBr) of his specimen appears to be slightly different from ours. Nevertheless, we are further checking our structure proposed for **12**.

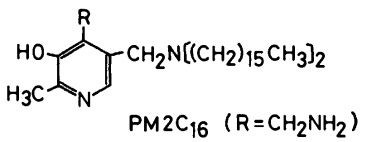
Substrate Selectivity of Artificial Transaminase Constituted with Functionalized Bilayer Membrane†

Yukito MURAKAMI,* Jun-ichi KIKUCHI,§ and Nobuyuki SHIRATORI
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received February 2, 1989)

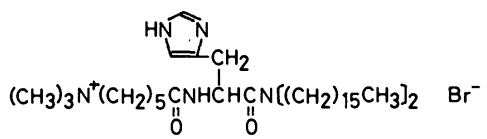
The transamination reactions of α-amino acid derivatives with α-keto acids as catalyzed by an artificial transaminase were examined in aqueous media under mild conditions. The present artificial holoenzyme was constituted with a combination of a cationic peptide lipid having a L-histidyl residue, a hydrophobic pyridoxamine derivative, and copper(II) ions, and found to exercise marked substrate selectivity which came from the molecular recognition in the course of formation of the aldimine Schiff-base chelates composed of the hydrophobic pyridoxal derivative, α-amino acids, and copper(II) ions. The transamination reaction of the hydrophobic β-benzyl L-aspartate with the hydrophilic pyruvate was most effectively catalyzed among 18 combinations of substrate species employed here. Enantioselectivity was observed for the catalytic transamination of phenylalanine with pyruvate.

Biomimetic approaches to constitution of artificial enzymes have been attracting current attention.[1] Nature has adopted α-amino acids as the main building blocks for enzymes and often cofactors, such as coenzymes and metal ions, are incorporated into their catalytic sites. Meanwhile, lipids are major constituents of biomembranes but do not directly participate in enzymatic functions. In our current approaches, we have been using the synthetic lipids having an α-amino acid residue as molecular building blocks for artificial enzymes, and demonstrated that functionalized bilayer membranes formed with the peptide lipids provide appropriate reaction sites for simulation of various enzymatic reactions.[2-4]

When a hydrophobic vitamin B_6 derivative was introduced into the bilayer membrane, the transamination reaction of an α-amino acid with an α-keto acid proceeded catalytically in the presence of copper(II) ions under mild conditions.[5] In a previous study,[6] we have modified the active site of our artificial transaminase by employing various combinations of peptide lipids and hydrophobic vitamin B_6 derivatives and investigated their catalytic performance in the transamination reaction of L-phenylalanine with pyruvate. As a result, the highest catalytic activity has been observed with the bilayer aggregates composed of a peptide lipid having a L-histidyl residue (N^+C_5-His2C_{16}) and a hydrophobic pyridoxamine derivative (PM2C_{16}) in the presence of copper(II) ions. In the present work, we studied on catalytic efficiency of the identical artificial transaminase in detail with primary emphasis on the substrate selectivity.



PM2C_{16} (R=CH_2NH_2)
PL2C_{16} (R=CHO)



N^+C_5His2C_{16}

Experimental

Materials. The following α-amino acids and their derivatives were obtained from commercial sources as guaranteed reagents and used without further purification: DL-2-aminobutanoic acid, DL-norvaline, DL-norleucine, DL-2-aminooctanoic acid, D-phenylalanine, methyl L-phenylalaninate, L- and D-glutamic acid, L-aspartic acid (these were from Nakarai Chemicals), L-phenylalanine, benzyl L-phenylalaninate, γ-benzyl L-glutamate, α,γ-dibenzyl L-glutamate, β-benzyl L-aspartate, and α,β-dibenzyl L-aspartate (these were from Protein Research Foundation). α-Benzyl L-aspartate was prepared by selective hydrolysis of α,β-dibenzyl L-aspartate in a manner similar to that reported previously[7] (Found: C, 58.96; H, 5.91; N, 6.29%. Calcd for $C_{11}H_{13}NO_4$: C, 59.19; H, 5.87; N, 6.27%). Three kinds of α-keto acids which were coupled with the above α-amino acids were commercially available as guaranteed reagents: sodium pyruvate (Wako Pure Chemical Industries), 2-oxobutanoic acid (Nakarai Chemicals), and 3-hydroxypyruvic acid (Sigma Chemical Co., Missouri, U.S.A.). Preparation and characterization of 4-aminomethyl-5-[(dihexadecylamino)methyl]-2-methyl-3-pyridinol (PM2C_{16})[6] and *N*,*N*-dihexadecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-histidinamide bromide (N^+C_5-His2C_{16})[8] have been reported elsewhere. Dansyl chloride [5-(dimethylamino)-1-naphthalenesulfonyl chloride] for fluorescent labeling of amino acids was obtained from Nakarai Chemicals as a guaranteed reagent. Copper(II) perchlorate (Kishida Chemical Co.) was dissolved in deionized water and standardized by conventional chelatometric titration.

Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu Univer-

sity. A Beckman Φ71 pH meter equipped with a Beckman 39505 combined electrode was used for pH measurements after calibration with a combination of appropriate standard aqueous buffers. Single-walled covesicles composed of the peptide lipid and the hydrophobic vitamin B_6 derivative were prepared upon sonication of an aqueous dispersion sample of these species by a probe-type sonicator (W-220F, Heat Systems-Ultrasonics) in a manner similar to that reported previously.[5] Progress of the transamination reaction of an α-amino acid with an α-keto acid, as catalyzed by the vesicular catalyst composed of $N^+C_5His2C_{16}$, $PM2C_{16}$, and copper(II) ions in an aqueous acetate buffer (25 mmol dm^{-3}) at pH 5.0, μ 0.10 with KCl, and 30.0 °C, was monitored by measuring amounts of an amino acid produced. An amino acid derived from the corresponding α-keto acid was dansylated, separated by liquid chromatography on a column of TSK gel ODS-120T (length, 250 mm; internal diameter, 4.6 mm) with a Hitachi 655A high performance liquid chromatograph, and eluting fractions were monitored by a Hitachi F-1000 fluorescence spectrophotometer: flow rate, 1.0 mL min^{-1}; mobile phase, mixtures of Tris buffer (10 mmol dm^{-3}, pH 8.0) and methanol at volume ratios of 2:1, 13:7, and 7:3 for the dansylated alanine, 2-aminobutanoic acid, and serine, respectively. The analytical procedure in detail was similar to that reported elsewhere.[5]

Results and Discussion

On the basis of our current studies on the functionalized bilayer vesicles having vitamin B_6 activity,[5,6,8,9] the reaction cycle for the catalytic transamination of an α-amino acid with an α-keto acid in the $PM2C_{16}$-$N^+C_5His2C_{16}$-Cu^{II} vesicular system is schematically shown in Fig. 1. In order to clarify the mechanistic implication in substrate selectivity exercised by the present artificial transaminase, its catalytic activity for various sets of substrates was examined under comparable kinetic conditions: $PM2C_{16}$, 5.0×10^{-5} mol dm^{-3}; $N^+C_5His2C_{16}$, 1.0×10^{-3} mol dm^{-3}; $Cu(ClO_4)_2$, 5.0×10^{-5} mol dm^{-3}; α-amino acid derivatives, 5.0×10^{-3} mol dm^{-3}; α-keto acids, 5.0×10^{-3} mol dm^{-3}; in an aqueous acetate buffer (25 mmol dm^{-3}) at pH 5.0, μ 0.10 with KCl, and 30.0 °C.

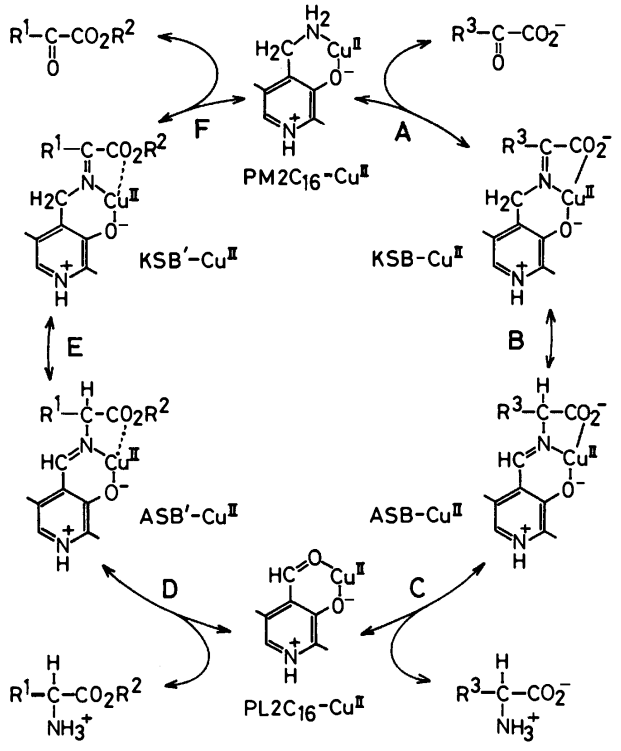

Fig. 1. Schematic representation of transamination cycle with an α-amino acid and an α-keto acid as substrates, as catalyzed by $PM2C_{16}$ and copper(II) ions in functionalized bilayer membrane.

Time courses for the transamination reactions of various DL-α-amino acids, having different normal alkyl side chains, with pyruvate are shown in Fig. 2. The reactivity increased sensitively along with increase in hydrophobicity of the amino acid. Thus, the reaction cycle for the amino group transfer from DL-2-aminooctanoic acid to pyruvate proceeded 47 times faster than that from DL-2-aminobutanoic acid to pyruvate in the present catalytic system (Table 1, Entries 2 and 16, respectively). The transamination reaction of L-phenylalanine (L-Phe) with the hydrophilic pyruvate was also effectively catalyzed by the present vesicular catalyst, as previously reported.[6] However, for a combination of L-Phe and a slightly

more hydrophobic α-keto acid, 2-oxobutanoate, the reactivity was ca. one-third of that for a combination of L-Phe and pyruvate (Fig. 3). Thus, the present vesicular system requires a combination of a hydrophobic α-amino acid and a hydrophilic α-keto acid to achieve high catalytic performance. Such marked substrate selectivity supports our mechanistic concept previously proposed: the overall transamination reaction is controlled by the distribution behavior of substrates between bilayer and bulk aqueous phases and not by the isomerization rate between the aldimine Schiff-base chelate and the ketimine Schiff-base chelate; the former chelate is composed of the hydrophobic pyridoxal derivative ($PL2C_{16}$), an α-amino acid, and the copper(II) ion, while the latter composed of $PM2C_{16}$, an α-keto acid, and the copper(II) ion.[6] In addition, the substrate selectivity evidently comes from the molecular recognition exercised during the course of forming the aldimine Schiff-base chelates (steps C and D in Fig. 1) and the reaction steps for formation of the ketimine Schiff-base chelates (steps A and F in Fig. 1) are not responsible for the selectivity in the overall reaction cycle. On the other hand, the transamination reaction of L-Phe with 3-hydroxypyruvate, a more hydrophilic α-keto acid than pyruvate, did not proceed catalytically (Fig. 3, line C). In this case, the reaction behavior, exhibiting high reactivity in the initial stage followed by gradual inactivation, suggests consumption of the α-keto acid via a certain side reaction because of its labile 3-hydroxyl moiety.

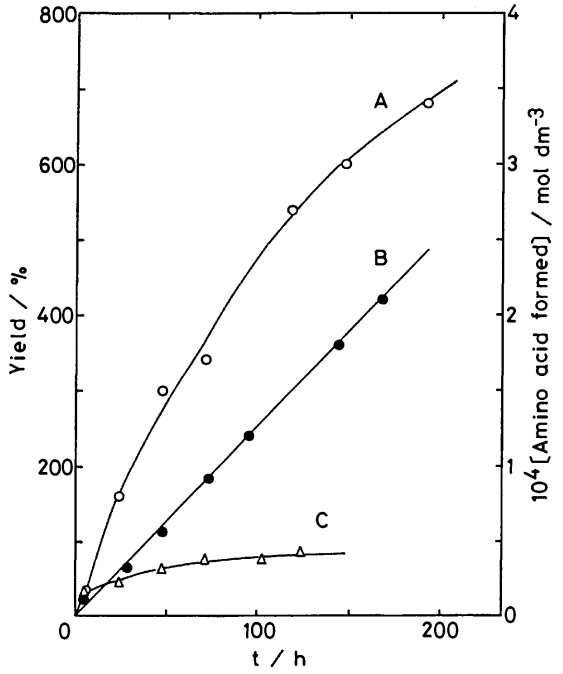

Fig. 3. Time courses for transamination catalyzed by an artificial transaminase formed with $PM2C_{16}$ (5.0×10^{-5} mol dm^{-3}), $N^+C_5His2C_{16}$ (1.0×10^{-3} mol dm^{-3}), and copper(II) ions (5.0×10^{-5} mol dm^{-3}) in an aqueous acetate buffer (25 mmol dm^{-3}) at pH 5.0, μ 0.10 with KCl, and 30.0 °C with combinations of L-Phe and the following α-keto acids (5.0×10^{-3} mol dm^{-3} each): A, pyruvic acid; B, 2-oxobutanoic acid; C, 3-hydroxypyruvic acid.

The substrate selectivity was also much affected by modification of the α-carboxyl moiety of an α-amino acid. As shown in Fig. 4, the transamination reactivity of L-Phe with pyruvate was much depressed upon conversion of the α-carboxylato group into its methyl

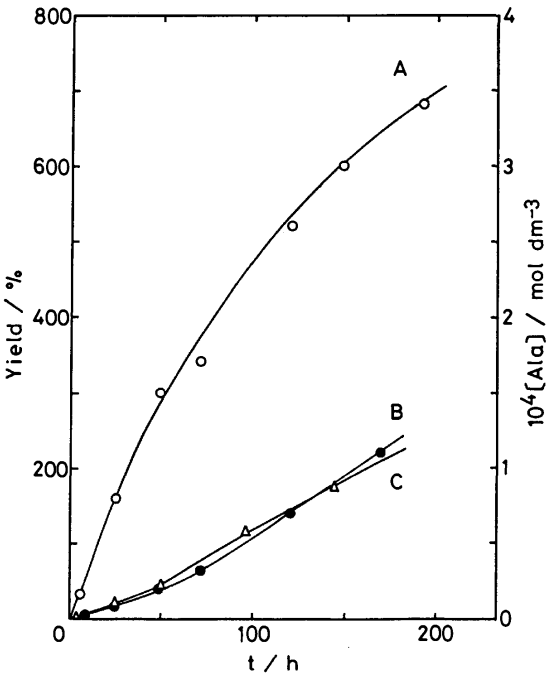

Fig. 4. Time courses for transamination catalyzed by an artificial transaminase formed with $PM2C_{16}$ (5.0×10^{-5} mol dm^{-3}), $N^+C_5His2C_{16}$ (1.0×10^{-3} mol dm^{-3}), and copper(II) ions (5.0×10^{-5} mol dm^{-3}) in an aqueous acetate buffer (25 mmol dm^{-3}) at pH 5.0, μ 0.10 with KCl, and 30.0 °C with combinations of pyruvic acid and the following L-Phe analogs (5.0×10^{-3} mol dm^{-3} each): A, L-Phe; B, methyl L-phenylalaninate; C, benzyl L-phenylalaninate.

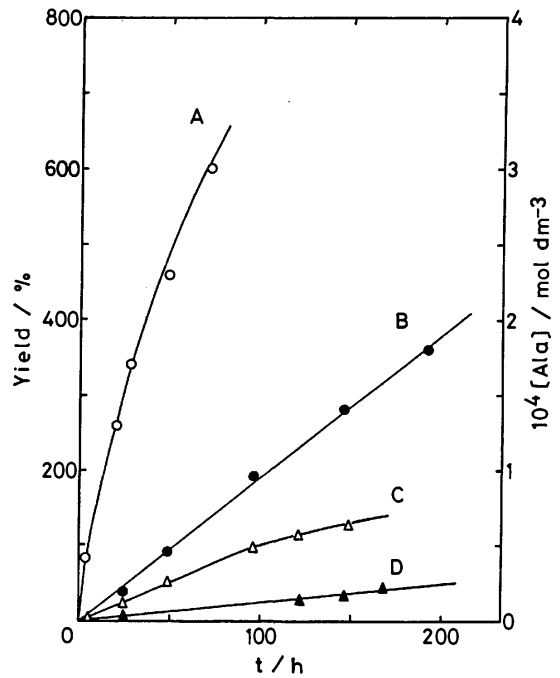

Fig. 5. Time courses for transamination catalyzed by an artificial transaminase formed with $PM2C_{16}$ (5.0×10^{-5} mol dm^{-3}), $N^+C_5His2C_{16}$ (1.0×10^{-3} mol dm^{-3}), and copper(II) ions (5.0×10^{-5} mol dm^{-3}) in an aqueous acetate buffer (25 mmol dm^{-3}) at pH 5.0, μ 0.10 with KCl, and 30.0 °C with combinations of pyruvic acid and the following L-aspartate analogs (5.0×10^{-3} mol dm^{-3} each): A, β-benzyl L-aspartate; B, α,β-dibenzyl L-aspartate; C, L-aspartate; D, α-benzyl L-aspartate.

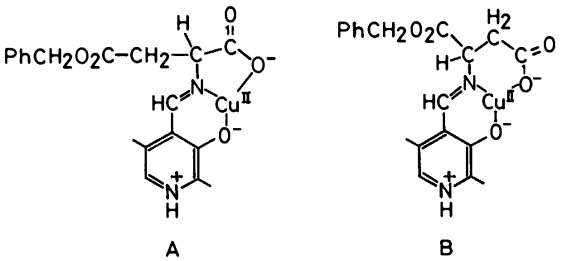
or benzyl ester, in spite of increased hydrophobicity of the α-amino acid species. This seems to reflect the fact that the stability of the copper(II) complex of the terdentate aldimine Schiff-base formed with the former α-amino acid and $PL2C_{16}$ is much enhanced relative to that of the Schiff-base chelate derived from the latter amino acid ester; the alkoxycarbonyl group is a weaker ligand than the carboxylato for copper(II) ions. Consequently, the substrate selectivity is of thermodynamic origin; the higher stability the aldimine Schiff-base chelate attains, the greater overall reactivity is observed.

To confirm this mechanistic implication on the substrate selectivity, the transamination reactions of various L-aspartate and L-glutamate analogs with pyruvate were investigated. Time courses for the transamination of four L-aspartate analogs with pyruvate are shown in Fig. 5. The L-asparate-pyruvate couple is 2.8 times more reactive than the DL-2-aminobutanoate-pyruvate couple (Table 1, Entries 13 and 16, respectively). Although the transamination reactivity was increased by two-fold upon conversion of L-aspartic acid into the corresponding dibenzyl ester due to increased hydrophobicity of the latter substrate, the highest reactivity was observed for the β-benzyl L-aspartate-pyruvate couple among these L-aspartate analogs. In contrast, the α-benzyl L-aspartate-pyruvate couple is markedly less reactive than the β-benzyl L-aspartate-pyruvate couple, even though both α-amino acid derivatives possess comparable hydrophobicity (Table 1, Entries 1 and 17, respectively). This seems to come from the difference in thermodynamic stability between the aldimine Schiff-base chelate composed of β-benzyl L-aspartate, $PL2C_{16}$, and the copper(II) ion (**A**) and the corresponding aldimine chelate of α-benzyl L-aspartate (**B**); the former forms a five-membered chelate ring, while the latter a six-membered one with the carboxylate moiety. Figure 6 shows time courses for the transamination reactions of three L-glutamate analogs with pyruvate. The reaction behavior is analogous to that for combinations of the L-aspartate analogs with pyruvate. Lower reactivity of the L-glutamate analog-pyruvate couples in comparison with the corresponding L-aspartate



A B

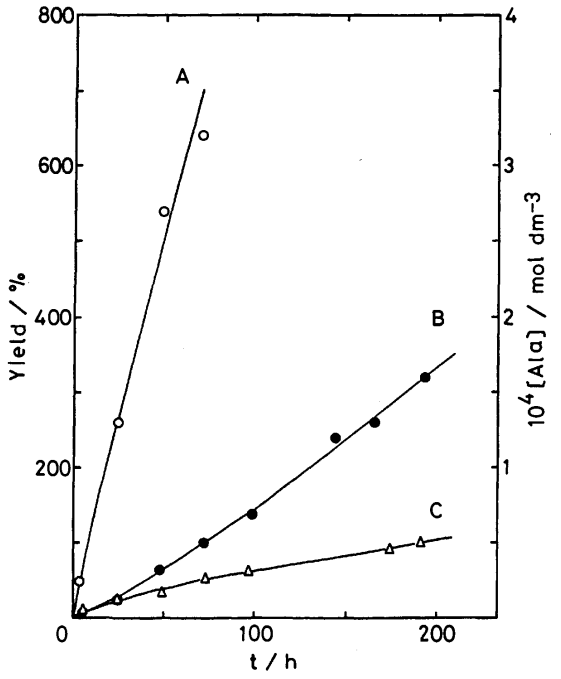


Fig. 6. Time courses for transamination catalyzed by an artificial transaminase formed with $PM2C_{16}$ (5.0×10^{-5} mol dm^{-3}), $N^+C_5His2C_{16}$ (1.0×10^{-3} mol dm^{-3}), and copper(II) ions (5.0×10^{-5} mol dm^{-3}) in an aqueous acetate buffer (25 mmol dm^{-3}) at pH 5.0, μ 0.10 with KCl, and 30.0 °C with combinations of pyruvic acid and the following L-glutamate analogs (5.0×10^{-3} mol dm^{-3} each): A, γ-benzyl L-glutamate; B, α,γ-dibenzyl L-glutamate; C, L-glutamate.

analog-pyruvate couples are also explained primarily from the viewpoint of the chelate effect; the aldimine Schiff-base chelates formed with the former couples are lower in stability relative to those formed with the latter.

As regards the transamination reaction catalyzed by the present vesicular system, the general acid-base catalysis by the imidazolyl group introduced into the peptide lipid is essential to exhibiting the turnover behavior, since the sequential reactions shown in Fig. 1 did not cycle in the vesicle of *N,N*-dihexadecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide in which the L-histidyl residue of $N^+C_5His2C_{16}$ is replaced by the L-alanyl residue.[6] In addition, the reaction site is provided in the hydrogen-belt domain of the highly organized and chiral bilayer membrane.[8] We have previously observed enantioselective catalysis by the chiral L-histidyl moiety of an analogous synthetic peptide lipid in ester hydrolysis.[2] Thus, one can expect to observe enantioselectivity for the transamination reaction catalyzed by the $PM2C_{16}$-$N^+C_5His2C_{16}$-Cu^{II} vesicular system. In fact, we observed that the amino group transfer from D-Phe to pyruvate was accelerated to a 33% extent relative to that from L-Phe to pyruvate (Table 1, Entries 4 and 5, respectively), presumably due to favorable thermodynamic stability of the aldimine Schiff-base chelate of D-Phe. On the other hand, there was no significant difference in transamination reactivity between the L-glutamate-pyruvate and D-glutamate-pyruvate couples (Table 1, Entries 14 and 15, respectively). This seems to arise from the weaker coordination effect by the γ-carboxylato moiety of glutamate for the development of enantioselectivity as discussed above.

In conclusion, it became apparent that the artificial transaminase composed of $PM2C_{16}$, $N^+C_5His2C_{16}$, and copper(II) ions exhibits marked substrate selectivity in the catalytic transamination reactions of α-amino acids with α-keto acids under mild conditions. The substrate recognition exercised in the course of formation of the aldimine Schiff-base chelates in the pseudo-hydrophobic domain of the bilayer membrane is responsible for such selectivity. Although further modification of the present artificial holoenzyme is required for performing high enantioselectivity, it is noteworthy that a simple system composed of three molecular components, a synthetic peptide lipid, a hydrophobic vitamin B_6 derivative, and metal ions, readily undergoes self-organization in aqueous media to form the supramolecular bilayer assembly capable of mimicking the catalytic functions of vitamin B_6-dependent transaminase.

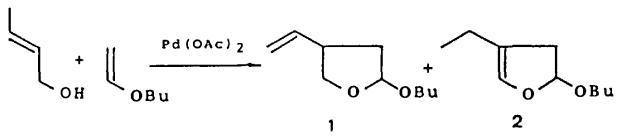
One-Pot Synthesis of Tetrahydrofuran Derivatives from Allylic Alcohols and Vinyl Ethers by Means of Palladium(II) Acetate

Keigo FUGAMI,† Koichiro OSHIMA,* and Kiitiro UTIMOTO*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 12, 1988)

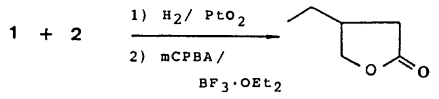
Reaction of allylic alcohol with vinyl ether in the presence of $Pd(OAc)_2$ afforded furan derivatives in good yield. $Pd(OAc)_2$ was essential for the reaction. $PdCl_2$ complex did not afford cyclized product but gave acetal exclusively. Three components were combined at once to produce 4-(3-butenyl)-2-butoxy-4-methyltetrahydrofuran upon treatment of a mixture of 2-methyl-2-propen-1-ol, butyl vinyl ether, and allyl bromide. The reaction could successfully be extended to the synthesis of nitrogen containing heterocycles by use of *N*-tosyl allylic amines in place of allylic alcohols.

We now report here the reaction between allylic alcohols and vinyl ethers promoted by $Pd(OAc)_2$. Treatment of (*E*)-2-buten-1-ol in butyl vinyl ether with $Pd(OAc)_2$ gave unexpected cyclic products **1** and **2** in 74% combined yield (Scheme 1). Hydrogenation



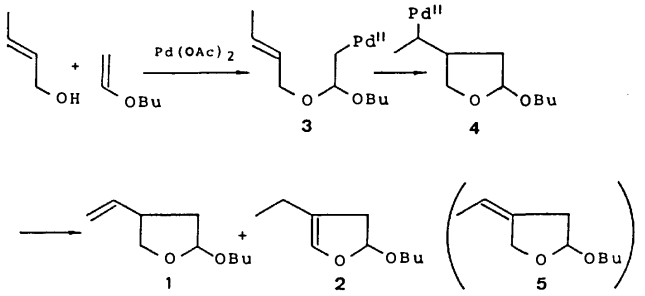
Scheme 1.

of the products **1** and **2** followed by oxidation[1] provided 3-ethyl-γ-butyrolactone which was identical with the authentic sample[2] (Scheme 2).



Scheme 2.

Other results are summarized in Table 1. Five-membered rings were formed in preference to six-membered rings with an exception of the reaction of cinnamyl alcohol which gave a dihydropyran derivative solely (Entries 6 and 7). As shown in Scheme 3, the formation of furan derivatives could be explained by assuming an intermediary palladium compound **3**,



Scheme 3.

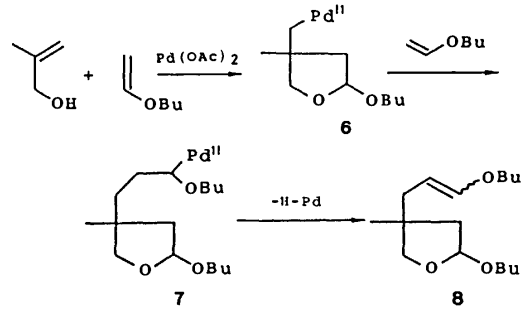
which undergoes intramolecular olefin insertion followed by β-elimination of palladium hydride from palladium complex **4** to afford vinyltetrahydrofuran **1** as a major product along with dihydrofuran derivative **2**. 4-Ethylidenetetrahydrofuran **5** could not be detected in the reaction mixture.

In the reaction of methallyl alcohol, two molar



Scheme 4.

equivalents of butyl vinyl ether were consumed per one 2-methyl-2-propen-1-ol to afford 2-butoxy-4-(3-butoxy-2-propenyl)-4-methyltetrahydrofuran (**8**) (Entry 1 in Table 2).[3] In this case, β-elimination of palladium hydride could not occur from the intermediary palladium complex **6**, then the complex added to the second molecule of butyl vinyl ether to give **7** which was converted into the final product **8** by β-elimination (Scheme 4). It was anticipated that olefins such as vinyl acetate, allyl bromide, and methyl acrylate act as the third component in place of the second butyl vinyl ether. This was indeed the case and these olefins reacted with the complex **6** through the addition-elimination process to give the corresponding coupling products as shown in Table 2. In Entry 3, it was supposed that Pd(II) species would be regenerated in the course of the reaction, but the amount of $Pd(OAc)_2$ could not be reduced.[4] In the case of (*E*)-2-buten-1-ol, the third component such as allyl bromide did not participate in the reaction and the ordinary product **1** was obtained in good yield. Thus, the β-elimination of palladium hydride from the complex **4** took place much faster than the addition of Pd-C bond to the olefinic double bond of allyl bromide.

The reaction of simple allyl alcohol which cannot give vinyltetrahydrofuran derivative resulted in the formation of a complex mixture.

Palladium(II) acetate is essential for the construction of furan or pyran rings. The use of $PdCl_2(CH_3CN)_2$ gave acetal without any contamination by desired cyclized product.[5] It turned out, however, that an addition of an appropriate base to the reaction mixture is effective to give the furan or pyran derivatives. Treatment of a *t*-BuOH solution of 2-methyl-2-propen-1-ol, butyl vinyl ether, and allyl bromide with $PdCl_2(CH_3CN)_2$ in the presence of potassium acetate gave the cyclized product, 4-(3-butenyl)-2-butoxy-4-methyltetrahydrofuran as a single product. The reaction between lithium alkoxide, $PhCH{=}CHCH_2OLi$, and ethyl vinyl ether also enabled us to use $PdCl_2(CH_3CN)_2$ instead of $Pd(OAc)_2$ and provided the corresponding dihydropyran derivative in 99% yield.[6] The $Pd(OAc)_2$-promoted reactions sometimes gave a small amount of noncyclized acetal as a by-product. The extent of the acetal formation seemed to depend on the quality of $Pd(OAc)_2$ employed. In such cases, an addition of one molar equivalent of potassium acetate perfectly suppressed the acetal formation and gave the desired heterocycle exclusively, although the reaction rate was somewhat retarded.

The amount of $Pd(OAc)_2$ could be reduced to 0.3 molar equivalent when $Cu(OAc)_2$ was added as a co-

Table 2. Three Component Combination Reaction[a]

oxidizer.[7] For instance, stirring of an acetonitrile solution of 2-hexen-1-ol (1.0 mmol) and butyl vinyl ether (3.4 mmol) at 25 °C for 20 h under the coexistence of $Pd(OAc)_2$ (0.3 mmol) and $Cu(OAc)_2$ (2.5 mmol) provided 4-(1-butenyl)-2-butoxytetrahydrofuran in 90% yield.

The reaction was successfully extended to the synthesis of pyrrolidine or piperidine derivatives from the corresponding *N*-tosyl allylic amine.[8] The typical results were summarized in Table 3. The presence of tosyl group on nitrogen atom was essential for the successful reaction. Desired heterocycles were not obtained from the reaction of free allylic amines.

Experimental

Distillations of the products were performed by use of Kugelrohr (Büchi), and boiling points are indicated by an air-bath temperature without correction. All melting points were obtained on a Yanaco MP-50929 melting point apparatus and are uncorrected, too. ^1H NMR spectra were taken on a Varian XL-200 spectrometer, $CDCl_3$ was used as solvent, chemical shifts being given in δ with tetramethylsilane as an internal standard. IR spectra were determined on a JASCO IR-810 spectrometer. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran (THF) was freshly distilled from sodium benzophenone ketyl.

Synthesis of *N*-Tosyl Allylic Amines. These compounds were prepared according to a reported procedure.[9,10] Preparation of *N*-geranyl-*p*-toluenesulfonamide is representative. Sodium (0.87 g, 38 mmol) was dissolved in ethanol (20 ml) and ethyl *N*-tosylcarbamate (11 g, 45 mmol) was added at room temperature under an argon atmosphere. After stirring for half an hour, geranyl bromide (5.0 g, 23 mmol) was added to the resulting clear solution. A white precipitate appeared after stirring for an additional hour. Resulting white suspension was stirred over night. White precipitate was filtered off, and the filtrate was poured into aqueous ammonium chloride solution and extracted twice with dichloromethane. Organic layer was dried over anhydrous sodium sulfate and the residue after evaporation of solvent under reduced pressure was submitted to a silica-gel column chromatography to afford 4.0 g (45% yield) of ethyl *N*-geranyl-*N*-tosylcarbamate. A THF solution (10 ml) of *N*-geranyl-*N*-tosylcarbamate (4.0 g, 10 mmol) was added to a 50% aqueous solution of sodium hydroxide (10 ml) and then 10 ml of methanol was added in order to make the reaction mixture homogeneous. After stirring for 12 h, the reaction mixture was poured into aqueous ammonium chloride solution and extracted with dichloromethane. Organic layer was concentrated and purification by silica-gel column chromatography of the residue gave 3.1 g (99% yield) of *N*-geranyl-*p*-toluenesulfonamide: bp 132 °C/2 Torr (1 Torr= 133.322 Pa); IR (neat) 3276, 2920, 2852, 1599, 1496, 1438, 1328, 1160, 1095, 1050, 814, 662 cm^{-1}; ^1H NMR δ=1.54 (br.s, 3H), 1.57 (br.s, 3H), 1.67 (br.s, 3H), 1.9—2.1 (m, 4H), 2.44 (s, 3H), 3.56 (dd, J=6.4, 6.3 Hz, 2H), 4.25 (t, J=6.3 Hz, 1H), 5.0—5.2 (m, 2H), 7.32 (d, J=8.2 Hz, 2H), 7.76 (d, J=8.2 Hz, 2H); Found: C, 66.40; H, 8.16; N, 4.39%. Calcd for $C_{17}H_{25}NO_2S$: C, 66.41; H, 8.20; N, 4.56%.

General Procedure for the Reaction of Allylic Alcohol or *N*-Tosyl Allylic Amine with Vinyl Ether in the Presence of $Pd(OAc)_2$. Typical procedure is as follows. To a solution of (*E*)-2-buten-1-ol (72 mg, 1.0 mmol) in butyl vinyl ether (3 ml, 10 mmol), $Pd(OAc)_2$ (0.23 g, 1.0 mmol) was added and the resulting mixture was stirred at 25 °C for 2 h. The mixture was diluted with hexane (10 ml) and pyridine (0.1 g) was added. After stirring for an additional 10 min, the precipitated palladium residue was filtered off and filtrate was concentrated in vacuo. Purification of the residual oil by silica-gel column chromatography gave 2-butoxy-4-vinyltetrahydrofuran (**1**) (0.13 g, cis:trans=1:1) in 74% yield: bp 75 °C/25 Torr; IR (neat) 2954, 2932, 2869, 1643, 1459, 1347, 1098, 1070, 1032, 1011, 994, 916 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.1 Hz, 3H), 1.3—1.9 (m, 5H), 2.07 (dd, J=12.5, 7.8 Hz, 0.5H), 2.30 (ddd, J=13.4, 9.4, 5.4 Hz, 0.5H), 2.7—3.0 (m, 0.5H), 3.0—3.3 (m, 0.5H), 3.3—3.5 (m, 1H), 3.5—3.8 (m, 2H), 3.95 (t, J=8.0 Hz, 0.5H), 4.07 (t, J=8.1 Hz, 0.5H), 5.0—5.2 (m, 3H), 5.7—6.0 (m, 1H); Found: C, 70.80; H, 10.86%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66%.

2-Butoxy-4-(1-butenyl)tetrahydrofuran (60:40 Mixture of Diastereomers): Bp 104 °C/21 Torr; IR (neat) 2956, 2930, 2870, 1641, 1459, 1443, 1345, 1097, 1069, 1030, 1005, 968, 918 cm^{-1}; ^1H NMR δ=0.8—1.0 (m, 6H), 1.2—2.5 (m, 8H), 2.6—2.9 (m, 0.6H), 2.9—3.2 (m, 0.4H), 3.3—3.8 (m, 4H), 5.0—5.2 (m, 1H), 5.2—5.7 (m, 2H); Found: C, 72.67; H, 11.42%. Calcd for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

2-Butoxy-4-isopropenyltetrahydrofuran (2:1 Mixture of Diastereomers): Bp 74 °C/20 Torr; IR (neat) 2956, 2932, 2870, 1648, 1458, 1378, 1345, 1181, 1103, 1047, 890 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.2 Hz, 3H), 1.2—2.1 (m, 8.67H, including two singlets at 1.69 ppm (1.0H) and 1.72 ppm (2.0H)), 2.2—2.4 (m, 0.33H), 2.7—3.0 (m, 0.33H), 3.0—3.3 (m, 0.67H), 3.3—3.5 (m, 1H), 3.6—3.8 (m, 2H), 3.93 (t, J=8.1 Hz, 0.33H), 4.05 (t, J=8.4 Hz, 0.67H), 4.74 (br.s, 1.33H), 4.76 (br.s, 0.67H), 5.1—5.2 (m, 1H); Found: C, 71.74; H, 11.02%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%.

2-Butoxy-4-isopropyl-2,3-dihydrofuran: Bp 94 °C/20 Torr; IR (neat) 2956, 2930, 2870, 1735, 1656, 1459, 1364, 1283, 1187, 1103, 1056, 939, 852 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.2 Hz, 3H), 1.03 (d, J=6.8 Hz, 3H), 1.05 (d, J=6.8 Hz, 3H), 1.2—1.8 (m, 4H), 2.2—2.5 (m, 2H, including d, at δ=2.36, J=16.3 Hz, 1H), 2.73 (dddd, J=16.3, 7.3, 2.5, 1.2 Hz, 1H), 3.47 (dt, J=9.6, 6.8 Hz, 1H), 3.76 (dt, J=9.6, 6.6 Hz, 1H), 5.48 (dd, J=7.3, 2.8 Hz, 1H), 6.04 (br.s, 1H); Found: C, 71.64; H, 11.11%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%.

2-Butoxy-5-methyl-4-vinyltetrahydrofuran (1:1 Mixture of Diastereomers): Bp 92 °C/21 Torr; IR (neat) 2958, 2930, 2868, 1643, 1459, 1445, 1379, 1095, 996, 936, 915, 658 cm^{-1}. ^1H NMR δ=0.92 (t, J=7.1 Hz, 3H), 1.23 (d, J=6.1 Hz, 1.5H), 1.29 (d, J=6.1 Hz, 1.5H), 1.2—2.8 (m, 7H), 3.3—3.5 (m, 1H, including ddd at δ=3.36, J=13.8, 9.5, 6.5 Hz), 3.6—3.9 (m, 2H, including ddd at δ=3.70, J=16.3, 6.8, 2.1 Hz, and dq at δ=3.82, J=6.1, 3.0 Hz), 5.0—5.3 (m, 3H), 5.67 (ddd, J=17.1, 10.1, 8.1 Hz, 0.5H), 5.74 (ddd, J=17.9, 9.0, 7.6 Hz, 0.5H); Found: C, 71.44; H, 11.23%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%.

2-Butoxy-4-(1-cyclohexenyl)-4-methyltetrahydrofuran (1:1 Mixture of Diastereomers): Bp 130 °C/1 Torr; IR (neat) 3020, 2958, 2928, 2862, 1456, 1437, 1358, 1325, 1122, 1097, 1028, 931, 669, 638 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.3 Hz, 3H), 0.97 (s, 1.5H), 0.98 (s, 1.5H), 1.2—2.3 (m, 14H), 3.3—3.8 (m, 4H), 5.2—5.3 (m, 1H), 5.7—5.8 (m, 1H); Found: C, 75.70; H, 11.17%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99%.

9-Butoxy-8-oxaspiro[5.4]dec-1-ene (Mixture of Diastereomers): bp 120 °C/1 Torr; IR (neat) 3018, 2956, 2928, 2864, 1440, 1347, 1180, 1094, 1031, 931, 731, 656 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.2 Hz, 3H), 1.3—2.2 (m, 12H), 3.3—3.5 (m, 1H), 3.6—3.8 (m, 3H), 5.1—5.2 (m, 1H), 5.5—5.8 (m 2H); Found: C, 74.31; H, 10.82%. Calcd for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54%.

2-Ethoxy-4-phenyl-3,6-dihydro-2*H*-pyran: Bp 105 °C/1 Torr; IR (neat) 2960, 2915, 2855, 1733, 1592, 1486, 1442, 1419, 1339, 1179, 1092, 1043, 1028, 993, 741, 689 cm^{-1}; ^1H NMR δ=1.21 (t, J=7.1 Hz, 3H), 2.71 (dm, J=16.5 Hz, 1H), 2.94 (dm, J=16.5 Hz, 1H), 3.51 (dq, J=9.8, 7.1 Hz, 1H), 3.78 (dq, J=9.8, 7.1 Hz, 1H), 4.69 (d, J=2.2 Hz, 1H), 4.71 (d, J=2.2 Hz, 1H), 5.24 (dd, J=5.0, 0.7 Hz, 1H), 6.4—6.5 (m, 1H), 7.1—7.5 (m, 5H); Found: C, 76.36; H, 7.95%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

2-Butoxy-4-phenyl-3,6-dihydro-2*H*-pyran: Bp 130 °C/2 Torr; IR (neat) 2948, 2922, 2860, 1660, 1594, 1488, 1445, 1420, 1340, 1175, 1095, 1032, 920, 743, 689 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.1 Hz, 3H), 1.2—1.7 (m, 4H), 2.70 (br.d, J=16.4 Hz, 1H), 2.91 (dm, J=16.4 Hz, 1H), 3.43 (dt, J=9.6, 6.7 Hz, 1H), 3.72 (dt, J=9.6, 6.8 Hz, 1H), 4.82 (br.s, 2H), 5.19 (d, J=4.9 Hz, 1H), 6.29 (br.s, 1H), 7.1—7.4 (m, 5H); Found: C, 77.54; H, 8.82%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

2-Methoxy-2-methyl-4-phenyl-3,6-dihydro-2*H*-pyran: Bp 80 °C/2 Torr; IR (neat) 2984, 2938, 2906, 2850, 2824, 1665, 1599, 1492, 1449, 1422, 1381, 1324, 1309, 1203, 1157, 1131, 1061, 1025, 933, 838, 775, 749, 694 cm^{-1}; ^1H NMR δ=1.52 (s, 3H), 2.7—2.9 (m, 2H), 3.26 (s, 3H), 4.65 (ddd, J=13.9, 4.2, 2.3 Hz, 1H), 4.73 (ddd, J=13.9, 4.1, 2.1 Hz, 1H), 6.3—6.4 (m, 1H), 7.1—7.5 (m, 5H); Found: C, 76.53; H, 8.08%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

2-Butoxy-4-(3-butoxy-2-propenyl)-4-methyltetrahydrofuran (*E*:*Z*=1:1): Bp 96 °C/2 Torr; IR (neat) 2956, 2930, 2868, 1664, 1653, 1458, 1376, 1187, 1104, 1030, 928, 737 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.2 Hz, 6H), 1.06 (s, 3H), 1.2—1.8 (m, 9H, including dd, at δ=1.68 J=13.3, 3.4 Hz, 1H), 1.89 (dd, J=13.3, 5.7 Hz, 1H), 2.0—2.2 (m, 1H), 2.2—2.3 (m, 1H), 3.3—3.6 (m, 2H), 3.6—3.8 (m, 4H), 4.9—5.1 (m, 1H), 5.16 (dd, J=5.7, 3.4 Hz, 1H), 5.82 (ddt, J=16.9, 10.3, 5.7 Hz, 1H); Found: C, 71.08; H, 11.45%. Calcd for $C_{16}H_{30}O_3$: C, 71.07; H, 11.18%.

(*Z*)-4-(3-Acetoxy-2-propenyl)-2-butoxy-4-methyltetrahydrofuran (65:35 Mixture of Diastereomers): Bp 130 °C/1 Torr; IR (neat) 2956, 2932, 2870, 1757, 1672, 1459, 1444, 1370, 1215, 1153, 1098, 1032, 934 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.1 Hz, 3H), 1.05 (s, 1.95H), 1.06 (s, 1.05H), 1.3—2.0 (m, 6H), 2.12 (s, 1.95H), 2.15 (s, 1.05H), 2.15 (br.s, 0.65H), 2.19 (br.s, 0.65H), 2.31 (br.s, 0.35H), 2.35 (br.s, 0.35H), 3.3—3.8 (m, 4H), 5.1—5.2 (m, 1H), 5.40 (dt, J=12.4, 8.1 Hz, 1H), 7.11 (dm, J=12.4 Hz, 1H); Found: C, 65.34; H, 9.58%. Calcd for $C_{14}H_{24}O_4$: C, 65.60; H, 9.44%.

4-(3-Butenyl)-2-butoxy-4-methyltetrahydrofuran: Bp 110 °C/2 Torr; IR (neat) 2956, 2930, 2866, 1642, 1459, 1379, 1098, 1032, 911 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.3 Hz, 3H), 1.06 (s, 3H), 1.2—2.2 (m, 10H, including dd, at δ=1.69, J=13.4, 3.3 Hz, 1H, and ddd, at δ=1.88, J=13.4, 5.7, 0.7 Hz, 1H), 3.3—3.8 (m, 4H), 4.9—5.1 (m, 2H), 5.15 (dd, J=5.7, 3.3 Hz, 1H), 5.82 (ddt, J=17.1, 10.2, 6.5 Hz, 1H); Found: C, 73.38; H, 11.52%. Calcd for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39%.

Methyl 4-(4-Butoxy-3-methyltetrahydrofuran-3-yl)-2-butenoate: Bp 105 °C/2 Torr; IR (neat) 2956, 2868, 1727, 1656, 1437, 1341, 1272, 1195, 1096, 1033, 926 cm^{-1}; ^1H NMR δ=0.91 (t, J=7.1 Hz, 3H), 1.08 (s, 3H), 1.2—1.7 (m, 4H), 1.78 (dd, J=13.4, 2.9 Hz, 1H), 1.87 (dd, J=13.4, 5.4 Hz, 1H), 2.3—2.4 (m, 2H), 3.37 (dt, J=9.5, 6.4 Hz, 1H), 3.52 (d, J=8.2 Hz, 1H), 3.6—3.8 (m, 5H, including s at δ=3.74, 3H), 5.15 (dd, J=5.4, 2.9 Hz, 1H), 5.88 (dt, J=15.5, 1.4 Hz, 1H), 6.93 (dt, J=15.5, 7.8 Hz, 1H); Found: C, 65.82; H, 9.69%. Calcd for $C_{14}H_{24}O_4$: C, 65.60; H, 9.44%.

4-(4-Butoxy-3-methyltetrahydrofuran-3-yl)-2-butenyl Acetate: Bp 130 °C/2 Torr; IR (neat) 2956, 2930, 2868, 1742, 1458, 1444, 1380, 1363, 1231, 1196, 1029, 971, 926 cm^{-1}; ^1H NMR δ=0.92 (t, J=7.1 Hz, 3H), 1.05 (s, 3H), 1.2—1.7 (m, 4H), 1.73 (dd, J=13.5, 3.2 Hz, 1H), 1.87 (dd, J=13.5, 5.4 Hz, 1H), 2.07 (s, 3H), 2.22 (br.s, 1H), 2.25 (br.s, 1H), 3.36 (dt, J=9.5, 6.6 Hz, 1H), 3.48 (d, J=8.4 Hz, 1H), 3.6—3.8 (m, 2H, including d at δ=3.68, J=8.4 Hz, 1H), 4.53 (d, J=5.7 Hz, 1H), 5.14 (dd, J=5.4, 3.2 Hz, 1H), 5.5—5.8 (m, 2H); Found: C, 66.55; H, 9.86%. Calcd for $C_{15}H_{26}O_4$: C, 66.64; H, 9.69%.

(*E*)-3,3-Dimethyl-7-phenyl-2,4-dioxahept-6-ene. This compound was obtained by the following procedure. $PdCl_2(CH_3CN)_2$ (26 mg, 0.1 mmol) was added to a benzene solution (2 ml) of cinnamyl alcohol (134 mg, 1.0 mmol) and 2-propenyl methyl ether (0.7 g, 10 mmol) at room temperature under an argon atmosphere. The reaction mixture was stirred for 1 h and diluted with hexane and several drops of pyridine was added. Precipitated palladium species was filtered off and solvent was evaporated. Residual oil was purified by preparative thin-layer chromatography on silica gel to afford (*E*)-3,3-dimethyl-7-phenyl-2,4-dioxahept-6-ene (190 mg) in 95% yield: bp 83 °C/2 Torr; IR (neat) 2988, 2936, 1494, 1459, 1450, 1380, 1368, 1258, 1212, 1184, 1151, 1101, 1072, 1034, 965, 862, 824, 734, 690 cm^{-1}; ^1H NMR δ=1.41 (s, 6H), 3.25 (s, 3H), 4.13 (dd, J=5.8, 1.4 Hz, 2H), 6.30 (dt, J=15.9, 5.8 Hz, 1H), 6.63 (br.d, J=15.9 Hz, 1H), 7.2—7.5 (m, 5H); Found: C, 75.49; H, 8.79%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

The Reaction in the Presence of KOAc. Noncyclized acetal was major by-product in the reaction of allylic alcohol with vinyl ether mediated by $Pd(OAc)_2$. Though the by-product was hardly separable from the desired product, the formation of noncyclized acetal could be completely suppressed by an addition of base such as KOAc to the reaction mixture. Potassium acetate (98 mg, 1.0 mmol) was added to a benzene (2 ml) solution of cinnamyl alcohol (134 mg, 1.0 mmol) and 2-propenyl methyl ether (1.4 g, 19 mmol) and then $Pd(OAc)_2$ (450 mg, 2.0 mmol) was added to this suspension at room temperature under an argon atmosphere. The reaction mixture gradually turned black and was stirred for 15 h. The mixture was diluted with hexane and several drops of pyridine was added. Precipitated solid was filtered off and solvent was removed under reduced pressure. The residual oil was submitted to silica-gel column chromatography to afford 2-methyl-2-methoxy-4-phenyl-3,6-dihydro-2*H*-pyran (108 mg) in 53% yield along with 27% yield of cinnamaldehyde. (*E*)-3,3-Dimethyl-6-phenyl-2,4-dioxahex-5-ene, which was obtained in 27% yield in the experiment without KOAc, was not observed in this case. The rate of reaction was remarkably retarded and yield was usually slightly lower than that without base.

2-Ethoxy-4-isopropenyl-1-tosylpyrrolidine: Bp 135 °C/2 Torr; IR (neat) 2972, 2930, 1649, 1598, 1442, 1343, 1165 1110, 1085, 1064, 986, 897, 814, 707, 670 cm^{-1}; ^1H NMR δ=1.20 (t, J=7.1 Hz, 3H), 1.37 (dd, J=12.6, 5.2 Hz, 1H), 1.56 (s, 3H), 1.91 (dd, J=12.6, 5.8 Hz, 1H), 2.43 (s, 3H), 2.93 (dd, J=10.3,

9.0 Hz, 1H), 3.0—3.3 (m, 1H), 3.4—3.7 (m, 2H), 3.7—4.0 (m, 1H), 4.63 (br.s, 1H), 4.71 (br.s, 1H), 5.2—5.3 (m, 1H), 7.32 (d, J=8.1 Hz, 2H), 7.74 (d, J=8.1 Hz, 2H); Found: C, 62.07; H, 7.61; N, 4.39%. Calcd for $C_{16}H_{23}NO_3S$: C, 62.11; H, 7.49; N, 4.53%.

2-Butoxy-1-tosyl-4-vinylpyrrolidine (75:25 Mixture of Diastereomers): Bp 133 °C/2 Torr; IR (neat) 2956, 2930, 2868, 1644, 1598, 1458, 1347, 1164, 1082, 998, 921, 814, 708, 673 cm^{-1}; ^1H NMR δ=0.91 (t, J=7.2 Hz, 0.75H), 0.92 (t, J=7.2 Hz, 2.25H), 1.22 (dd, J=12.4, 5.0 Hz, 0.75H), 1.2—1.8 (m, 4.25H), 1.94 (dd, J=12.4, 5.9 Hz, 0.75H), 1.9—2.0 (m, 0.25H), 2.44 (s, 3H), 2.87 (dd, J=9.7, 9.6 Hz, 0.75H), 2.9—3.1 (m, 1H), 3.2—3.7 (m, 2.25H), 3.76 (dt, J=9.6, 6.6 Hz, 1H), 4.9—5.2 (m, 2H), 5.18 (d, J=5.0 Hz, 0.75H), 5.29 (dd, J=6.1, 2.7 Hz, 0.25H), 5.50 (ddd, J=17.1, 10.1, 7.4 Hz, 0.75H), 5.78 (ddd, J=17.5, 9.8, 8.1 Hz, 0.25H), 7.32 (d, J=8.4 Hz, 2H), 7.74 (d, J=8.4 Hz, 2H); Found: C, 63.33; H, 7.91; N, 4.30%. Calcd for $C_{17}H_{25}NO_3S$: C, 63.13; H, 7.79; N, 4.33%.

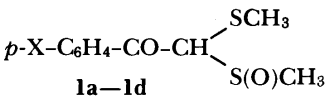
Synopsis. *p*-Substituted α-(methylsulfinyl)-α-(methylthio)-acetophenones (**1**) exhibit, on polarographic reduction, three waves. The two last waves correspond to the reductions of *p*-substituted α-(methylthio)acetophenones (**2**) and *p*-substituted acetophenones respectively. The macroelectrolysis at the first wave potential results in the formation of **2** in good yields in the presence of benzoic acid. The electrolytic reduction of **1** is characterized by the elimination of the methylsulfinyl group rather than by the deoxygenative reduction of the sulfoxide to the sulfide or the reduction of the carbonyl group.

Methylthiomethyl sulfoxide (FAMSO), which is a kind of sulfoxide bearing methylthio group at the α-position, is utilized in a wide variety of organic-synthesis processes. One of the title compounds, α-(methylsulfinyl)-α-(methylthio)acetophenone (**1a**), synthesized with facility from FAMSO and ethyl benzoate, is reduced with sodium tetrahydroborate to afford the corresponding hydroxy compound,[1] while the reaction with copper(II) chloride in 1,2-dimethoxyethane gives PhCOCOSMe.[2]

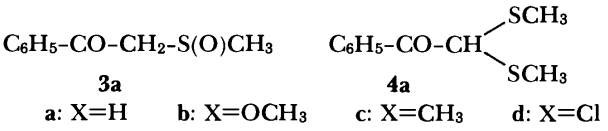
The present paper is concerned with the electrolytic reduction of the title compounds, *p*-substituted α-(methylsulfinyl)-α-(methylthio)acetophenones (**1**) at mercury, platinum, and lead electrodes in acetonitrile (MeCN). The electrolytic reduction of **1** afforded desulfinylated compounds, *p*-substituted α-(methylthio)acetophenones (**2**), in good yields in the presence of an efficient proton donor. A similar desulfinylation occurs in the electrolytic reduction of 1-methylsulfinyl-1-methylthio-2-arylethenes, which are synthesized from FAMSO and the corresponding aldehydes.[3] Phenacyl phenyl sulfide[4] and sulfoxide[5] also favor the cathodic cleavage of the carbon-sulfur bond, whereas the electrolytic reduction of the carbonyl group predominates for the organosulfur compound bearing the COOH group on the carbon adjacent to the carbonyl group ($HOOCCOCH_2SC_2H_5$).[6] Recently, the electrolytic reduction of diphenyl sulfoxide in nonaqueous media has been reported to afford diphenyl sulfide, together with the benzenesulfinate ion.[7] The above examples show that the cathodic cleavage of the carbon-sulfur bond does not necessarily occur for all the organosulfur compounds.

The substrates, **1**, and the related compounds investigated in this work are as follows.



1a—1d

2a—2d



3a **4a**

a: X=H **b**: X=OCH_3 **c**: X=CH_3 **d**: X=Cl

Experimental

The compounds, **1a—1d**, were prepared from FAMSO and ethyl *p*-substituted benzoates according to the published method.[1] The compounds, **1a—1d**, were purified by repeated recrystallizations from a mixture of methanol and water; they showed ^{1}H NMR spectra consistent with the structures assigned.

Polarography and controlled potential macroelectrolysis were carried out, using the experimental set-up and procedure which were reported in a previous paper.[8] All the polarograms were taken in MeCN containing 0.1 (M = mol dm^{-3}) tetrabutylammonium perchlorate (TBAP), the potential being measured against a Ag/0.1 M $AgNO_3$ in MeCN reference electrode (Ag/Ag^+). In the controlled potential macroelectrolysis, tetrabutylammonium tetrafluoroborate (TBAB) were used as the supporting electrolyte, and mercury, platinum, and lead, as the cathode material. After the macroelectrolysis had virtually been completed, the catholyte was carefully concentrated (ca. 3 cm^3), poured into NaCl-saturated water (50 cm^3), and extracted with diethyl ether (3×50 cm^3). After ether-extraction and the usual work-up, the crude mixture and the major product isolated by TLC were subjected to ^{1}H NMR in order to characterize the products.

Results and Discussion

The results of polarography with **1a—1d** are summarized in Table 1. The dc polarogram of **1a** in the absence of proton donors exhibited three waves. In the presence of phenol and benzoic acid, the half-wave potentials ($E_{1/2}$) and wave heights (i_d) of these polarograms were varied, as Table 1 shows. That is, the addition of phenol and benzoic acid caused all the wave heights to increase. On the other hand, the $E_{1/2}$ of the first reduction wave was not changed by adding phenol and benzoic acid, but those of the second and third waves were shifted to more positive potentials. The other substrates, **1b—1d**, exhibited polarographic behavior similar to **1a**. Plots of $E_{1/2}$ vs. the substituent constant sigma gave a good straight line with a slope of 0.50 V for the first reduction wave, indicating that a substrate with a strongly electron-withdrawing group such as Cl is easier to reduce than a substrate with an electron-donating group such as CH_3O.

Controlled potential macroelectrolyses of **1a—1d** at the potential of the first reduction wave were con-

ducted at various cathodes (Hg, Pt, and Pb) in the absence and in the presence of proton donors at room temperature. The substrates, **1a—1d**, were found to undergo the cathodic cleavage of a carbon-sulfur bond to yield *p*-substituted α-(methylthio)acetophenones (**2a—2d**). However, the corresponding hydroxides, *p*-substituted α-(methylsulfinyl)acetophenones (**3**), and *p*-substituted α,α-bis(methylthio)-acetophenones (**4**) were not obtained. Table 2 summarizes the isolated yields of **2a—2d**, along with the coulometric *n*-values (electrons per molecule). The *n*-values were obtained from the amount of the substrate added and the quantity of electricity passed through before the termination of the electrolysis. The yield of **2a** was low in the absence of the proton donor and even in the presence of excess phenol. The addition of benzoic acid caused the yield of **2a** to increase considerably (82%). Therefore, the use of benzoic acid as the proton donor was found to be desirable to improve the yield of **2a**. The kinds of *p*-substituents (X) of the compounds, **1**, and the cathode material (Hg, Pt, and Pb) do not appear to have had a significant influence on the yield of **2**.

Table 3 summarizes the $E_{1/2}$ and i_d values of α-(methylthio)acetophenone (**2a**), α-(methylsulfinyl)acetophenone (**3a**), α,α-bis(methylthio)acetophenone (**4a**), and acetophenone (**5a**) in the presence of proton donors, such as phenol and benzoic acid, together with those of **1a**. If **4a** is an intermediate in the electrolytic reduction of **1a**, the polarographic wave corresponding to the reduction of **4a** must be observed on the polarogram of **1a** because the $E_{1/2}$ value of **4a** is more negative by about 0.17 V than that of **1a**. Such a polarographic wave was not, however, obtained as is shown in Table 3. Furthermore, there was no detectable amount of **4a** in the macroelectrolysis of **1a**. Therefore, it may be concluded that the deoxygenated reduction of the oxygen-sulfur bond in the electrolytic reduction of **1a** does not take place, i.e., the electrolytic redurtion of **1a** does not proceed through **4a**. Similarly, **3a** must also be ruled out as an intermediate in the reductive conversion of **1a** to **2a**, because the polarogram of **1a** did not exhibit the polarographic wave corresponding to the reduction of **3a** and **3a** was not detected in the macroelectrolysis of **1a**. Moreover, Table 3 suggests that the first wave of **1** in the presence of benzoic acid corresponds to a four-electron reduction, since the i_d for the first wave of **1a** was about twice that of **4a** and also, since the i_d for the first wave of **3a**[9] was about twice that of **2a**, when benzoic acid was used as the proton donor.

Tables 2 and 3 indicate that the second and third polarographic waves of **1a** correspond to the reductions of **2a** and **5a** respectively.

On the basis of the above-mentioned results and discussion, it is concluded that the electrolytic reduction of **1** at the potential of the first reduction wave proceeds through neither **3** nor **4**, but through the elimination of the methylsulfinyl group. Also, the reduction of the carbonyl group was found not to occur in the electrolysis of **1**. Furthermore, taking into account the fact that none of the $E_{1/2}$ values of the first reduction wave of **1a—1d** were changed by adding the proton donor, the following scheme may be proposed for the electrolytic reduction of **1** to **2** in the

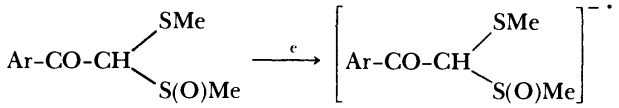
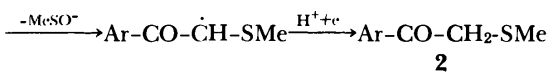
presence of an efficient proton donor:



1



2

It is not clear whether or not the methylsulfinyl anion resulting from the cleavage of the carbon-sulfur bond undergoes further reduction to yield methanethiol, since the formation of methanethiol has not yet been ascertained and since the above mechanism indicates that **1** is reduced in an overall four-electron process (the coulometric n-values obtained were 2.2—2.9 for **1a—1d**, even in the presence of the proton donor). However, the polarographic n-value for the first reduction wave of **1** was 4, suggesting that the reduction of methylsulfinyl anion to methanethiol occurs at the reduction potential of **1**. Furthermore, it has been reported that the electrolytic reduction of 1-methyl-sulfinyl-1-methylthio-2-phenylethene afforded desulfinylated compounds, 1-methylthio-2-phenylethene and methanethiol, with the consumption of 3.6 electrons per molecule.[3] Accordingly, from the evidence that the coulometric n-values were more than 2 in the presence of the proton donor, as is shown in Table 2, together with above considerations, it seems reasonable to conclude that a part of the methylsulfinyl anions are electrochemically reduced to afford methanethiol. The remainder will be converted chemically to methanethiol etc., since methane sulfenic acid, if formed at all, is very unstable.

Photooxidation of Bis[1,2-diphenylethanedithione]nickel(0)-tetrabutylamine with α-Tocopherol

Koe ENMANJI
Materials and Electronic Devices Laboratory, Mitsubishi Electric Co., Tsukaguchi-Honmachi, Amagasaki-shi 661
(Received October 24, 1988)

Synopsis. The photooxidation of a nickel dithiolate complex by α-tocopherol was found for the development of a recording medium which can be used to read by a laser diode. The mechanism was analyzed. As a result, it was found that α-tocopherol produced oxygen adducts by light; the oxygen adducts oxidized bis[1,2-diphenylethanedithione]-nickel(0)tetrabutylamine.

The development of recording medium for a laser diode is desirable since a laser diode is small in size and conventional. Because of the character of high-density recording and rewritability, photon-mode recording was hopeful and the appearence of a recording dye for the laser diode was desired. A Schrauzer complex was one of the dithiolate complexes; it was synthesized in 1962 by Schrauzer and Mayweg.[1] It was reported by them that some complexes have absorption peaks at 700—900 nm,[2] and that the development of a recording medium which can be read by a laser diode is possible if redox reaction can be induced by light. We obtained the reductant (bis[1,2-diphenylethanedithione]nickel(0)tetrabutylamine=BDNH) of bis[1,2-diphenylethanedithione]nickel(0) (BDN) and investigated its properties, finding that BDNH was oxidized by UV light in the presence of α-tocopherol (αT) and produced the BDN. We thus recognized the possibility for developing a photo-recording medium. We now report on our investigation of the effect of various factors on the photooxidation of BDNH to BDN as well as the mechanism.

Experimental

BDNH was purchased from Midori Chem. Co. and used without purification. α-Tocopherol was purchased from Nakarai Chem. Co., and toluene was purchased from Wako Chem. Co.

The monochromatic light was irradiated by a Ushio-500 type super-high-pressure mercury lamp equipped with a Toshiba KL-28 filter. The light intensity was measured by a method described in the literature.[3] The optical absorption spectra were measured by a Shimadzu MPS-5000.

A Hückel molecular orbital calculation was carried out with Otsuka's program[4] by using a Multi 16 computer.

Results and Discussion

BDNH (5.13×10^{-5} mol dm^{-3}) was dissolved into toluene and α-tocopherol (0.100 mol dm^{-3}) was added. The irradiation of this solution made the peak at 975 nm disappear and new peak appeared at 875 nm (Fig. 1). Also, the color changed from brown to green. It was found that BDN was produced. These phenomena were considered by the following mechanism. The oxygen adduct of α-tocopherol was produced by the irradiation of α-tocopherol under aerobic conditions; this adduct substructs a $(C_4H_9)_4N^+$ group from

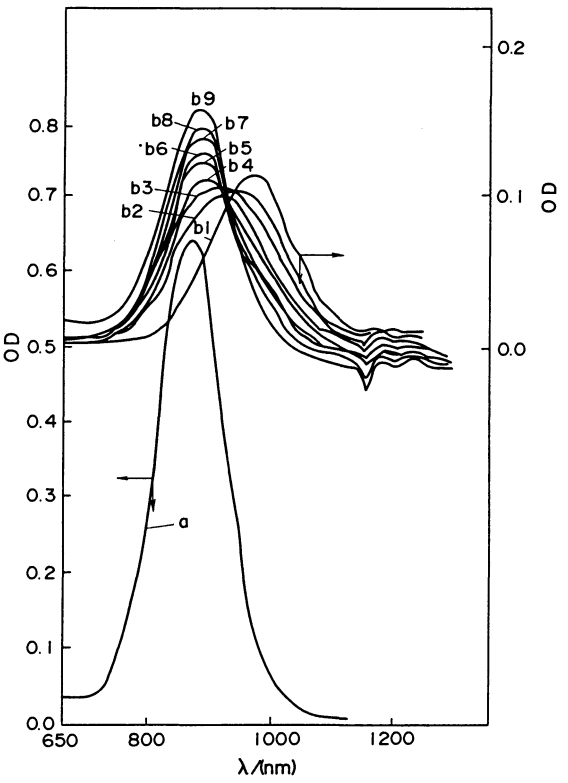

Fig. 1. Change in absorption spectra of BDNH containing α-tocopherol during photo-illumination.
a: BDN, b1: after 0 minutes, b2: 1 min, b3: 2 min, b4 4 min, b5: 9 min, b6: 14 min, b7: 24 min, b8: 34 min, b9: 79 min.
[BDNH]=5.13×10^{-5} mol dm^{-3}, [αT]=0.1 mol dm^{-3}, I=3.24 mol dm^{-3} s^{-1}

BDNH and oxidizes to BDN as the same mechanism as the initiation reaction of the polymerization of methyl methacrylate.[5] The assumed mechanism can be described as in the following equations:

$$\alpha T \xrightarrow{h\nu} \alpha T\cdot, \quad (1)$$

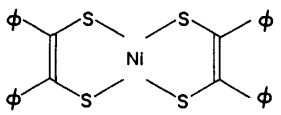
$$\alpha T\cdot + O_2 \xrightarrow{k_i} \alpha TO_2\cdot, \quad (2)$$

$$\alpha TO_2\cdot \xrightarrow{k_q} Q(\alpha T\text{-}O_2\text{-}\alpha T), \quad (3)$$

$$\alpha TO_2\cdot + BDNH \xrightarrow{k_i} \alpha TO_2{=}N(C_4H_9)_4 + BDN \quad (4)$$

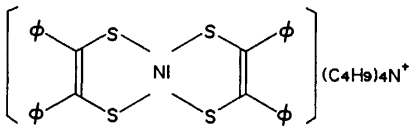
Here, the existence of αT· is assured by the flash-photolysis of an α-tocopherol toluene solution in air.[5] The reaction rate is given by

$$v_i = \frac{k_i C_{BDNH}}{(k_i C_{BDNH}+k_q)} \Phi I[1-10^{-\varepsilon C_{\alpha T} l}]/l, \quad (5)$$



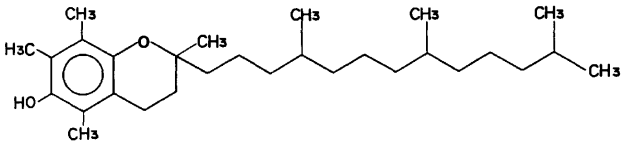
BDN

Scheme 1.



BDNH

Scheme 2.



α-Tocopherol

Scheme 3.

where Φ is the quantum yield for the production of $\alpha T\cdot$, Q is the subproduct, l(cm) is the length of the reaction champer, ε ($1\,mol^{-1}\,cm^{-1}$) is the molecular extinction constant of α-tocopherol, and I (einstein $cm^{-2}s^{-1}$) is the light intensity. When $\varepsilon C_{\alpha T} l$ is sufficiently small, i.e. light is not completely absorbed, $10^{-\varepsilon C}\ \alpha T^{l}$ becomes $1-\varepsilon C_{\alpha T} l$, and Eq. 5 reduces to Eq. 6,

$$v_i = \frac{2.303\ k_i C_{BDNH}}{(k_i C_{BDNH} + k_q)} \Phi I \varepsilon C_{\alpha T}, \qquad (6)$$

if $k_i C_{BDNH} \ll k_q$

$$v_i = \frac{2.303 k_i}{k_q} C_{BDNH}\ \Phi I C_{\alpha T}. \qquad (7)$$

On the contrary, when $\varepsilon C_{\alpha T}$ is sufficiently large, i.e. light is completely absorbed, $10^{-\varepsilon C_{\alpha T} l}$ becomes zero and Eq. 5 can be reduced to Eq. 8.

$$v_i = \frac{2.303\ k_i C_{BDNH}}{(k_i C_{BDNH} + k_q)} \Phi I / l, \qquad (8)$$

If $k_i C_{BDNH} \ll k_q$ holds, Eq. 8 can be reduced to Eq. 9 and the reaction rate is proportional to the first order of the BDNH concentration.

$$v_i = \frac{2.303\ k_i}{k_q} C_{BDNH} \Phi I / l. \qquad (9)$$

Here, for $\varepsilon_{280}=71$ and $C_{\alpha T}>0.02$ mol dm^{-3} Eq. 9 holds and for $C_{\alpha T}<0.001$ mol dm^{-3} Eq. 7 holds. It was found that $k_i\Phi/k_q=\Phi'=0.373$. A plot of logarithm optical density at 975 nm was proportional to the irradiation time. It was found that the reaction is the mechanism of first order of BDNH i.e. $k_i C_{BDNH} \ll k_q$ holds.

The dependence of the concentration of α-tocopherol on the photooxidation of BDNH is shown in Fig. 2. As can be seen in Fig. 2, v_i becomes constant when $C_{\alpha T}$ is larger than 10^{-3} mol dm^{-3}. Consequently, when $C_{\alpha T}$ is larger than 10^{-3} mol dm^{-3} the condition of the $10^{-\varepsilon}\ C_{\alpha T}{}^{l}$ is nearly equal zero holds as well as Eq. 9. The dependence of the light intensity on the photooxidation of BDNH is shown in Fig. 3. As can be seen, since the reaction rate is proportional to the first order of the light intensity, Eq. 5 holds.

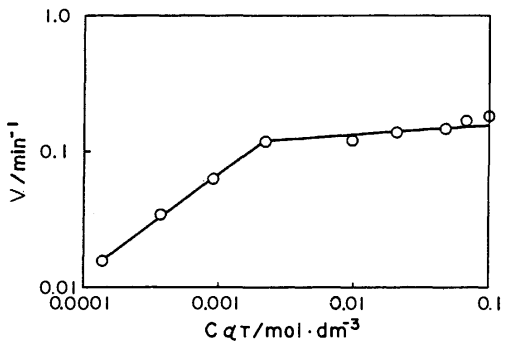


Fig. 2. Dependence of the rate of photooxidation of BDNH on the concentration of α-tocopherol. [BDNH]=5.13×10^{-5} mol dm^{-3}, I=3.24 M s^{-1}

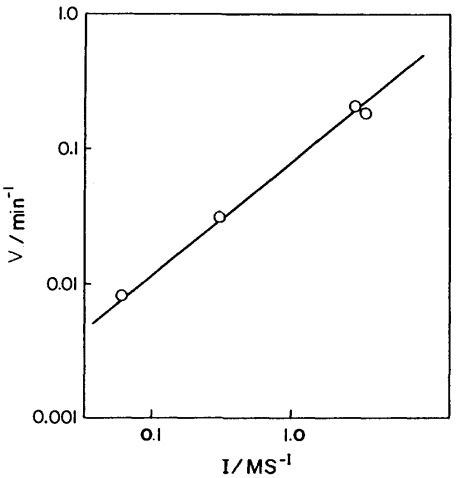

Fig. 3. Dependence of the rate of photooxidation of BDNH on light intensity. [BDNH]=5.13×10^{-5} mol dm^{-3}, [αT]=0.1 mmol dm^{-3}.

Table 1. Effect of Addition of Various Tocopherols on Photo oxidation Rate of BDNH

Tocopherol	v/min^{-1}	$E(E)$ of C_5
α	0.123	3.8985
β	0.146	2.9472
γ	0.351	2.5352
δ	0.904	2.0469

The rates of photooxidation of BDNH are shown in Table 1 under the condition that the concentration of α-tocopherol, β-tocopherol, γ-tocopherol, and δ-tocopherol are 7.74×10^{-3} mol dm^{-3}. As can be seen in Table 1, the photooxidation rate increases according to the order of the action property of vitamine E.[6] Because it was found that tocopherols form a radical at C_5,[7] the delocalization energies of α-tocopherol, β-tocopherol, γ-tocopherol, and δ-

tocopherol to an electrophilic reagent (which are calculated by HMO method) are shown in Table 1. As can be seen, the lower the delocalization energy the larger is the rate of photooxidation of BDNH. The calculation satisfied the experimental results.

The possibility of a photorecording medium was assumed for a BDNH-α-tocopherol system. Increasing the α-tocopherol concentration was not effective for increasing the recording speed, though increasing the light intensity was. In a solid medium this reaction can occur. A device using this reaction will be developed by the present author.

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received November 30, 1988)

Synopsis. A new crown ether spin-labeled by the phenoxyl radical moiety was prepared. Intramolecular odd-π electron delocalization was investigated by means of ENDOR spectroscopy. On the basis of ENDOR spectrometric titration, the equilibrium constant for Na^+-labeled crown-ether-complex formation was evaluated to be $pK_{Na^+}=3.5$ in 2-propanol at −30 °C.

The spin-labeling technique has been applied to obtain information about the molecular structures of both labeled crown ether and its metal complexes. For example, the molecular structure of 2 : 1 sandwich type complexes of labeled crown ethers were characterized on the basis of detailed analyses of the triplet ESR spectra.[1-3] In addition, the dihedral angles of the vibrating crown methylene protons were estimated by means of temperature-dependent ENDOR measurements.[4] In the previous studies, however, the details of the metal-complexation reaction between these labeled crown ethers and metal cations have not been fully compiled. Here, a stable spin-labeled crown ether bearing the phenoxyl radical moiety (CR-O·) was newly prepared and isolated as pure crystals in order to obtain an improved view of the host-guest chemistry relating to this crown ether. The conformational change in the benzylic methylene protons upon metal chelation was investigated in detail by ENDOR. In addition, the equilibrium constants of alkali metal complex formation were also estimated.

Experimental

The spin labeled crown ether CR-O· (Fig. 1) was synthesized by the usual procedures,[3,5] (Found: C, 69.99, H, 8.79%. Calcd for $C_{31}H_{46}O_7$: C, 70.16; H, 8.79%. Mp 135—136 °C). The purity of the CR-O· was estimated to be above 98% by means of magnetic susceptibility measurements at 25 °C. The ENDOR spectra were recorded by a JEOL ES EDX-1 spectrometer in the temperature range from −50 to +10 °C in dry 2-propanol. All the measurements were performed at the Advanced Instrumental Center for Chemical Analysis, Ehime University.

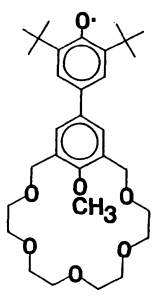

Fig. 1. The molecular structure of the phenoxyl radical crown ether CR-O·.

Results and Discussion

Figure 2 shows the higher half frequency field of the ENDOR spectra observed for metal free CR-O· (1.0 m M†) in 2-propanol. The ENDOR fine structures were safely assigned with reference to the results of previous report[6] as summarized in Table 1. The benzylic methylene protons, H_1 and H_2, revealed a nonequivalence in the magnitude of proton hfcc at −30 °C (Fig. 2-3), as has already been noted for other spin-labeled crown ethers.[4] On raising the temperature, the distance between these two lines began to decrease, finally they collapsed together into a single

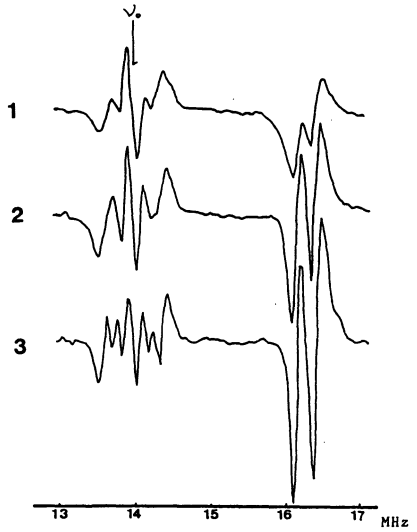

Fig. 2. The higher frequency half of ENDOR spectra observed in the absence of alkaline metal salts at (1) +10 °C, (2) −20 °C, and (3) −30 °C.

Table 1. Observed Proton Hyperfine Coupling Constants (hfcc in mT) of CR-O· and Its Alkaline Metal Complexes

† 1 M=1 mol dm^{-3}.

line above +10 °C (Fig. 2-1). Based on the proton hfcc of the benzylic methylene protons H_1 and H_2 at the maximum separation, the equilibrium dihedral angles were estimated to be 55 ° and 61 ° in terms of the McConnell-Heller equation,[7] as illustrated in Fig. 3. A restricted movement, as demonstrated in the benzylic methylene protons, may be attributed to a steric repulsion occurring between the crown ether chain and the methoxyl group. The activation energy for the vibrating benzylic methylene protons were evaluated to be 14 kJ mol^{-1} after Gutowsky and Holm's treatment.[8]

The ENDOR spectra were measured in the presence of a ten-fold molar equivalent of alkali metal salts: Li^+-, Na^+- and K^+ClO_4. No important ENDOR spectral change was detected, even after the mixing of $LiClO_4$ with the CR-O· (Fig. 4-1), indicating that no complex formation occurs between $LiClO_4$ and the radical crown ether. On the other hand, both Na^+ and K^+ salts showed a drastic variation upon the ENDOR fine structure recorded at −30 °C, as shown in Fig. 4-2 and -3. A nonequivalence in the benzylic-methylene-proton splitting disappeared in the temperature range from −30 °C to +10 °C upon the addition of Na^+ and K^+ salts. This implies that the thermal motion occurring in the benzylic-methylene protons is tightly locked by metal chelation in the crown ether cavity. Interestingly, the ENDOR signal of the metal-free CR-O· was again recorded, after the addition of a 20 molar excess of 18-CR-6, which had a pronounced affinity for Na^+ and K^+ ions. These findings, therefore, indicate that marked conformational changes in the crown ether moiety take place upon the complex formation with Na^+ and K^+ ions.

In order to evaluate the equilibrium constant for Na^+-complex formation, ENDOR spectrometric titration was carried out by changing the initial concentration ratio, R_0=[$NaClO_4$]/[CR-O·$_0$], as is shown in Fig. 5. When a two-fold excess amount of $NaClO_4$ was added to CR-O·, the observed ENDOR spectrum (Fig. 5-2) showed mixed fine structures consisting of the metal-free CR-O· and of the Na^+-CR-O· complex. The ENDOR signal intensity ascribable to Na^+ complex gradually increased, and eventually the ENDOR signals of metal free CR-O· completely disappeared at R_0=6.0 (Fig. 5-4). This ENDOR fine structure recorded during the titration from R_0=0 to 6.0 was adequately simulated by means of the computer superposition of the ENDOR fine structures of CR-O· and its Na^+ complex, as demonstrated in Fig. 5. An excellent agreement was seen between the observed spectra and those simulated, which were obtained after trial-and-error calculations by changing the mixing ratio, R'=[Na^+-CR-O·]/[CR-O·]. In

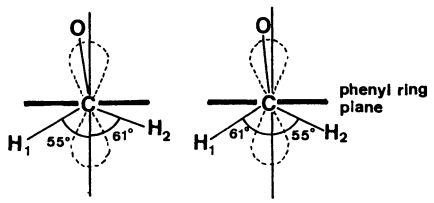

Fig. 3. The equilibrium dihedral angle of the vibrating benzylic methylene protons H_1 and H_2.

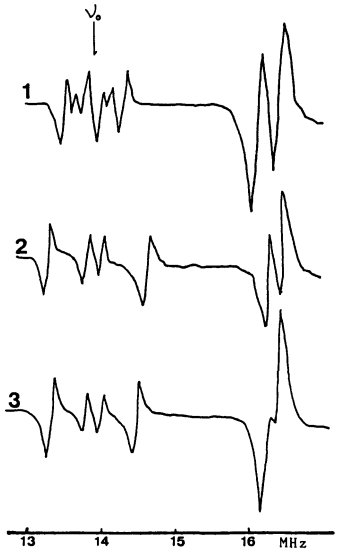

Fig. 4. ENDOR spectra observed at −30 °C in 2-propanol in the presence of ten fold excess amount of (1) $LiClO_4$, (2) $NaClO_4$, and (3) $KClO_4$.

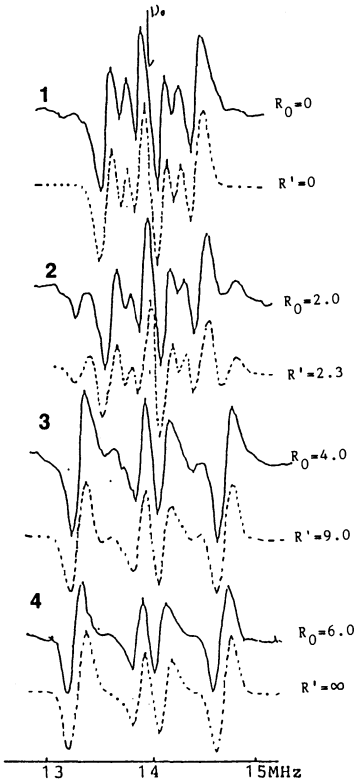

Fig. 5. ENDOR spectral changes observed (solid line) during the $NaClO_4$-titration at −30 °C and the calculated ENDOR fine structure (broken line). R_0 is initial mixing molar ratio [$NaClO_4$]/[CR-O·$_0$] and R' is the estimated molar ratio [Na^+-CR-O·]/[CR-O·] by means of computer superposition using Eq. 1.

terms of the R_0 and R' values, the equilibrium constant $pK_{Na}+$ was calculated using Eq. 1:

$$pK_{Na}+=\log(R'(1+R')/[Na^+_0]+R'[Na^+_0]-R'[CR\text{-}O\cdot_0]) \quad (1)$$

The values of $pK_{Na}+$ at −20 °C and −10 °C were also evaluated to be 3.5 and 3.3 by means of similar procedures. Based on the temperature dependence of the $pK_{Na}+$ values, the thermodynamic parameters of ΔH and ΔS were estimated to be 1.4 kJ mol^{-1} and −1.5 J mol^{-1} deg^{-1}. By a similar ENDOR titration carried out for the K^+-CR-O· system, the $pK_K{}^+$ value was estimated to be above 6.0 at −30 °C. This implies that the labeled crown ether CR-O· possesses a pronounced affinity to the K^+ ion rather than to the Na^+ ion. Further investigations to evaluate the $pK_K{}^+$ value of the K^+-CR-O· complex formation are now in progress.

Metastable Dissociations of $CH_3NO_2^+$ and $CD_3NO_2^+$ Ions. Isotope Effects of the Loss of a Hydroxyl Radical

Ryuichi ARAKAWA
College of Biomedical Technology, Osaka University, 1-1 Machikaneyama-cho, Toyonaka, Osaka 560
(Received December 21, 1988)

Synopsis. A large kinetic isotope effect has been observed for the metastable transitions of $CX_3NO_2^+ \rightarrow CX_2NO^+ + OX$ (X=H, D). The large effect was explained by assuming a rate-determining isomerization to an *aci*-nitromethane ion and the quantum mechanical tunneling of a hydrogen atom.

The dissociation of a nitromethane ion has been studied by a variety of experimental techniques.[1-7] The dissociation mechanism has been discussed in terms of the participation of an *aci*-nitromethane tautomer, $CH_2=N(OH)O^+$, and a methyl nitrite ion, CH_3ONO^+. In particular, isomerization to an *aci*-nitromethane ion, followed by the formation of CH_2NO^+ and OH, has been established by recent studies of the appearance energy and metastable-ion fragmentations using MS/MS and photoionization experiments.[6,7] On the other hand, the NO^+ formation from the nitromethane ion has been explained by its isomerization to the methyl nitrite ion prior to dissociation.[3,4] Moreover, it has been reported that the dissociations of the nitromethane ion at the near threshold are all competing processes.[7] However, no quantitative interpretation accounting for the metastably slow dissociations, including CH_2NO^+ and NO^+ paths, has been presented based on a usual RRKM/QET treatment.

In the system of a methyl nitrite ion, it is of much interest that the dissociation involves non-interconverting excited states or structures. The CH_2OH^+ formation from CH_3ONO^+ appears with a rate constant of $k(E)\approx 10^5$ s^{-1}, while the rate of NO^+ is $k(E)\gg 10^7$ s^{-1}.[3,4] There is no satisfactory interpretation of the slow CH_2OH^+ path. Recently, Ferguson[8] has suggested that a quantum mechanical tunneling for a hydrogen migration is due to the slow dissociation of CH_2OH^+ and has interpreted the large isotope effect of $k_H/k_D\approx 10$, measured previously by Gilman et al.[4] This suggests an alternative reaction path leading to D_2NO^+ for $CD_3NO_2^+$. However, more recent studies,[9,10] have excluded such a proposal.

There is a class of dissociation reactions in which ions dissociate at a rate much slower than that predicted from the RRKM/QET calculation. In such a case, the activation energy is usually less than 1 eV, so that the predicted rates are much greater than 10^7 s^{-1}, while the measured rates are in the 10^5 s^{-1} range. To overcome this difficulty, it has been proposed that the reaction involves isomerization into sufficiently stable isomers or the existence of stable ion-dipole complexes. In addition, tunneling through a potential barrier or a rotational barrier and the participation of an anharmonic interaction potential[11] have been reported to be the origin of the metastable-ion dissociations. The reaction systems of nitromethane and methyl nitrite cations lie within the category discussed above. Below we will present an isotope effect k_H/k_D for the loss of a hydroxyl radical in the nitromethane metastable dissociations. If the isomerization to the *aci*-nitromethane ion is a rate-determining step, tunneling is a probable process for explaining the slow dissociation; thus, the large isotope effect can be expected.

Figure 1 shows the metastable-ion decays for CH_2NO^+ and NO^+ as a function of the ion-storage time, as determined by the use of the ion-trapping

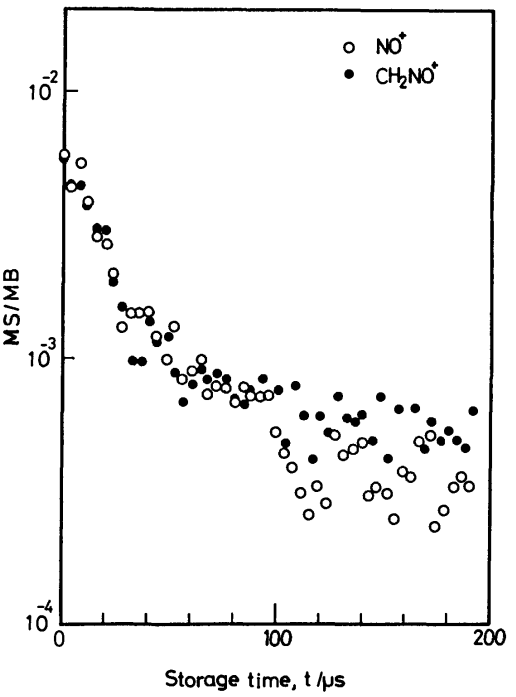

Fig. 1. Metastable-to-main-beam intensity ratio vs. the ion-storage time at the electron-impact energy of 40 eV.

Table 1. Metastable Ion (MI) and Collision-Induced Dissociation (CID) Spectra of Nitromethane Ions

Ion	$CH_3NO_2^+$		$CD_3NO_2^+$

46		42	1±1	37
48				2
60	47	17		
62			55	14

technique[12] utilizing the space charge of an electron beam. It indicates that slow dissociations are measured at $\leqq 10^4$ s^{-1}. The two intensities are almost the same throughout the long storage time. This is consistent with the photoionization result[7] that their appearance energies are nearly equal within the limits of experimental error. The intensities of the metastable ions and of the collision-induced dissociations (CID) at the zero storage time are listed in Table 1. The CID spectra were measured at a 20% decrease in the main beam intensity by raising the He gas pressure in a collision cell. We believed that the CID components in the metastable peaks were negligible, because there was no CID peak of NO_2^+. For $CD_3NO_2^+$ the peak at m/z 46 corresponding to CD_2NO^+ or NO_2^+ was observed with a low intensity. This peak may be CD_2NO^+, because no peak of NO_2^+ was observed for $CH_3NO_2^+$. The metastable observation is actually limited within a narrow rate range, because the present time window in the second-field-free region is between 6.8 and 10.6 μs; it corresponds to the average decay rate of 1.2×10^5 s^{-1}. Thus, the intensity ratio in Table 1 represents the relative rate constant. Consequently, the isotope effect was determined to be $k_H/k_D\approx26$ for the hydroxyl radical loss.

The tunneling correction of the unimolecular rate constants was examined in order to explain the large experimental isotope effect. The correction is given by $k(E)=p(E)k(E_0)$, where $p(E)$ is the tunneling probability and where $k(E_0)$ is the minimum rate at the threshold energy of E_0. The vibrational frequencies for a reactant and a transition state were obtained by a vibrational analysis for the assumed geometries and force fields.[13] The value of k_H/k_D may be independent of the influence of approximate vibrational frequencies resulting from the simple force field. Thus, the rough estimation of vibrational frequencies is sufficient to account for the present isotope effect. The isomerization to the *aci*-nitromethane ion probably involves a hydrogen migration to a oxygen atom prior to the OH loss. A four-center complex was employed as the transition state; the bond orders of C-H and H-O regarding the migrating hydrogen were assumed to be 0.5. The results of the vibrational analysis are shown in Table 2. The activation entropies, ΔS^*, as calculated from a set of frequencies, are $\Delta S^*=-0.20$ (X=H) and -0.63 e.u.(X=D) when $T=1000$ K. In general, rearrangements, followed by molecular elimination, exhibit "tight" transition states and low(or even negative) ΔS^* values, while simple bond cleavages have "loose" transition states and high ΔS^* values.[14] For example, HCN eliminations from pyridine[15] and benzonitrile[16] cations are specified as $\Delta S^*=-2.5$ and 0.4 e.u, respectively. In recent RRKM calculations with reference to the reaction of the methyl nitrite ion to H_2COH^++NO, Baer and Hass[17] have synthesized very tight transition-state frequencies such as -5.6 e.u. Accordingly, the present model represents a reasonable tightness as structural isomerization. Actual RRKM calculations yielded $k(E_0)=3\times10^8$ s^{-1} for $CH_3NO_2^+$, and proved that the chief origin of the large isotope effect is not the $k(E_0)$ rate, but the tunneling probability. The activation energy for CD_2NO^+ was estimated by applying a zero-point energy correction.

Tunneling has been investigated for neutral unimolecular reactions by Miller and his co-workers[18,19] and for metastable-ion dissociations of methane,[20] methanol,[21] and phenol[22] cations. Tunneling through a potential barrier is generally favored for a case of one-step hydrogen-bond cleavage. For isomerization to the aci-nitromethane ion, the barrier heights, as estimated relative to the reactants and the products, are 0.63 and 1.58 eV respectively.[6,7] The $p(E)$ values in Table 3 were calculated with the imaginary frequencies described in Table 2, based on Miller modification[18] using a generalized Eckart potential. The imaginary frequencies used here are nearly equal to those[18] in the isomerization of *trans*-formaldehyde to H_2CO. $p(E)$ depends upon imaginary frequencies and, as may be seen in Table 3, decreases more rapidly for D species than for H with a decrease in the energy. At the energy of 0.35 eV below the threshold, which represents the experimental metastable rate of 10^5 s^{-1}, the ratio of tunneling probabilities is $p_H(E)/p_D(E)\approx30$;

Table 3. The Calculated Tunneling Probabilities

$(E-E_0)$/eV	X=H	X=D
0	5.3×10^{-1}	5.2×10^{-1}
−0.1	1.2×10^{-1}	5.4×10^{-2}
−0.2	1.3×10^{-2}	2.4×10^{-3}
−0.3	1.1×10^{-3}	7.3×10^{-5}
−0.4	6.5×10^{-5}	1.5×10^{-6}
−0.5	2.3×10^{-6}	1.5×10^{-8}

Table 2. Vibrational Frequencies for the Reaction of $CX_3NO_2^+\rightarrow CX_2NO^+$+ OX(X=H,D) as Used in RRKM Calculations

a) The reactant state										
X=H	3080	3080	2960	1650	1560	1480	1330	1060	1060	840
	660	520	380	370	200					
X=D	2300	2290	2140	1640	1440	1140	1060	830	830	780
	560	410	360	350	150					
b) The transition state										
X=H	3470	3080	2980	1720	1330	1130	1090	850	820	660
	520	430	370	190	2450*i*					
X=D	2600	2290	2150	1720	1310	960	870	750	600	590
	430	380	360	140	1770*i*					

thus, it leads to $k_H/k_D \approx 100$. This is in fair agreement with the experimental isotope effect.

Finally, tunneling correction explains the large isotope effect for the hydroxyl-radical loss, assuming that the reaction involves rate-determining isomerization to the *aci*-nitromethane ion prior to dissociation. It is not unusual that an OH or H_2O loss from oxygen containing ions shows intense metastable peaks in the mass spectra in spite of a small activation energy; examples include the H_2O loss from ionized ethyl acetate[23] and the CH_2OH loss from ionized methyl acetate.[24] The reactions involving hydrogen-atom migration generally indicates a complex mechanism in the isomerization/dissociation paths.

(Received December 22, 1988)

Synopsis. The host-guest orientation and the position of the guest *m*-nitrophenol (MNP) in the α-cyclodextrin(α-CD)-MNP complex in aqueous solution have been determined by comparing the complexation-induced ^{13}C NMR chemical shifts of MNP with those predicted by quantum chemical calculation. The results are consistent with the X-ray data of this complex.

α-Cyclodextrins (α-CDs) is a cyclic oligosaccharide composed of six (1—4)-linked α-D-glucosyl residues and admits a variety of guest molecules into its cavity.[1-4] The inclusion of benzene derivatives has been extensively studied in both solution and solid states.[1-4] One of the most interesting phenomena observed in such inclusion complexes is the orientational specificity of the guests in the α-CD cavity. For example, in α-CD-*p*-nitrophenol complex, in both solution[5-8] and solid states[9] the nitro group is located in the cavity and the phenolic hydroxyl group protrudes from the secondary hydroxyl side of α-CD. The determination of the guest orientation is essential for identifying the main driving force stabilizing the inclusion complexes.[10]

For α-CD-*m*-nitrophenol complex, two types of guest orientations have been proposed on the basis of the observation of complexation-induced ^{13}C NMR chemical shifts of the guest MNP. Namely, the first (Fig. 2C or D) is that the nitrophenyl group is located in the cavity and the hydroxyl group is exposed to the aqueous medium.[7] The second (Fig. 2A or B) is the reverse of the first one.[11] In this report, we show that the first is more reasonable, with the aid of the quantum chemical analysis of ^{13}C chemical shift displacements of MNP.

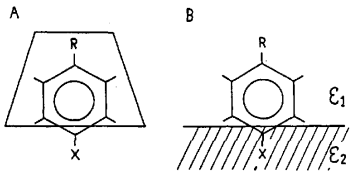

Fig. 1. (A) Schematic representation of α-CD inclusion complexes with benzene derivatives. The CD molecule is represented by bucket-like shape. (B) Double-layer model.

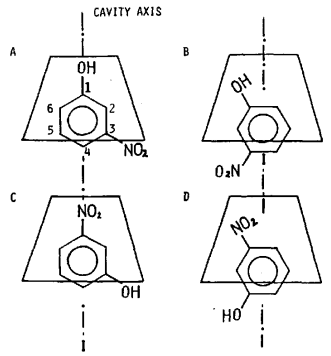

Fig. 2. Possible orientations of the guest MNP relative to the α-CD cavity. Due to the bulkiness of the substituents (NO_2 and OH), only two modes of guest-insertion are possible according to which sustituent is located in the cavity. Furthermore, each of the two is classified into two types of guest-orientations. In the type A and C orientations, the C_3-C_6 axis lies on the cavity one. In type B and D orientations, both the C_4-C_6 and the C_1-C_3 axes are parallel to the cavity axis.

Methods

In the calculation, the "double layer" model developed in a previous paper[12] is used in order to approximate the environment surrounding the guest molecule complexed with α-CD. Namely, it is assumed that a part of the guest molecule is embedded in a low dielectric medium (dielectric constant $\varepsilon_1=2$) and its residual part is exposed to the aqueous medium with higher dielectric constant ($\varepsilon_2=80$) as shown in Fig. 1B. Thus the complexation of the guest with α-CD in aqueous solution corresponds to its transfer from the aqueous medium ($\varepsilon=80$) to the double layer one. The interactions of the guest molecule with the dielectrics are formulated on the basis of Klopman's solvation theory.[13] The molecular wave functions were obtained by means of the CNDO/2 method[14] and subsequently the ^{13}C shielding constants are evaluated using Karplus and Pople's average excitation method.[15]

The geometry of MNP was determined using Pople's standard values for bond lengths and bond angles.[14]

Results and Discussion

According to the preliminary structural analysis using the CPK molecular model, four types of guest

† Previous paper in series is Ref. 10.

†† A part of this paper was presented at the 3rd International Symposium on Cyclodextrin, Lancaster, U. K., July, 1986, and the abstract was issued in *J. Inclusion Phenomena*, **5**, 55 (1987).

††† Present adress: Institute for Molecular Science, Myodaiji, Okazaki 444.

orientations are possible in the α-CD-MNP complex. They are schematically represented in Fig. 2. For each of these orientations, one can draw the borderline dividing the surrounding of the guest into the two layers and express the depth of guest inclusion as the number of atoms included in the layer of ε_1. A series of calculations of ^{13}C shielding was carried out by shifting the borderline. Then, the complexation-induced ^{13}C shift displacements are expressed as the shift changes when the guest MNP is transferred from the medium of ε=80 to the double-layer environments (ε_1=2, ε_2=80). The calculated results are reproduced in Figs. 3 and 4, where the positive and negative signs for ^{13}C displacements indicate low-field and up-field shifts, respectively and the scale in the abscissa indicates the number of the included atoms mentioned above. The observed data (bold lines) were cited from Ref. 7.

In the case of the type A and C orientations, our attention is particularly given to the carbons lying on the cavity axis: namely the C_1 and the C_4 carbons for the type A orientation and the C_3 and the C_6 carbons for the type C one. In the type B and D orientations, the data for only the C_1, C_3, C_4, and C_6 carbons are examined. These carbons are located far from the cavity interior and thus their ^{13}C shieldings are insusceptible to the so-called steric shielding effects,[12] which are not taken into account in the present theoretical model.

As can be seen from Fig. 3 a (for type A), the calculated values for the C_1 carbon deviate from the corresponding observed ones (bold lines) irrespective of the position of the borderline. Therefore it is impossible to reproduce the observed data for both C_1 and C_4 carbons simultaneously by the calculation. Similarly, in the case of the type B orientation (Fig. 3 b), the calculated values for the C_1 and the C_6 carbons always deviate from the corresponding observed data.

On the other hand, in the cases of the reversed-guest insertions with the type C orientation, the calculated values for both C_4 and C_6 carbons are in excellently good agreement with the corresponding observed ones at the position of 10—12 included-atoms (Fig. 4 a). Similarly, on the assumption of the type D orientation, the calculations simultaneously reproduce the observed trends for the C_1, C_3, C_4, and C_6 carbons at the position of 10 included-atoms, although the agreements of the magnitudes of ^{13}C displacements are not always good.

Therefore, for the α-CD-MNP inclusion complex, the observed characteristic ^{13}C displacements are reproduced only when the guest molecule is inserted into the cavity from the nitro group side (Fig. 2C and D). This orientation of the guest molecule is the same as that found in the solid state by X-ray diffraction for the α-CD-MNP complex.[16] Furthermore, it should be noted that the observed trends are reproduced only at the position of the borderline as shown in Fig. 5. If it is assumed that the borderline corresponds to the α-CD wider rim consisting of secondary hydroxyl groups, one or two carbons in the phenyl ring must protrude from the CD cavity. This finding again agrees with that in the solid state.

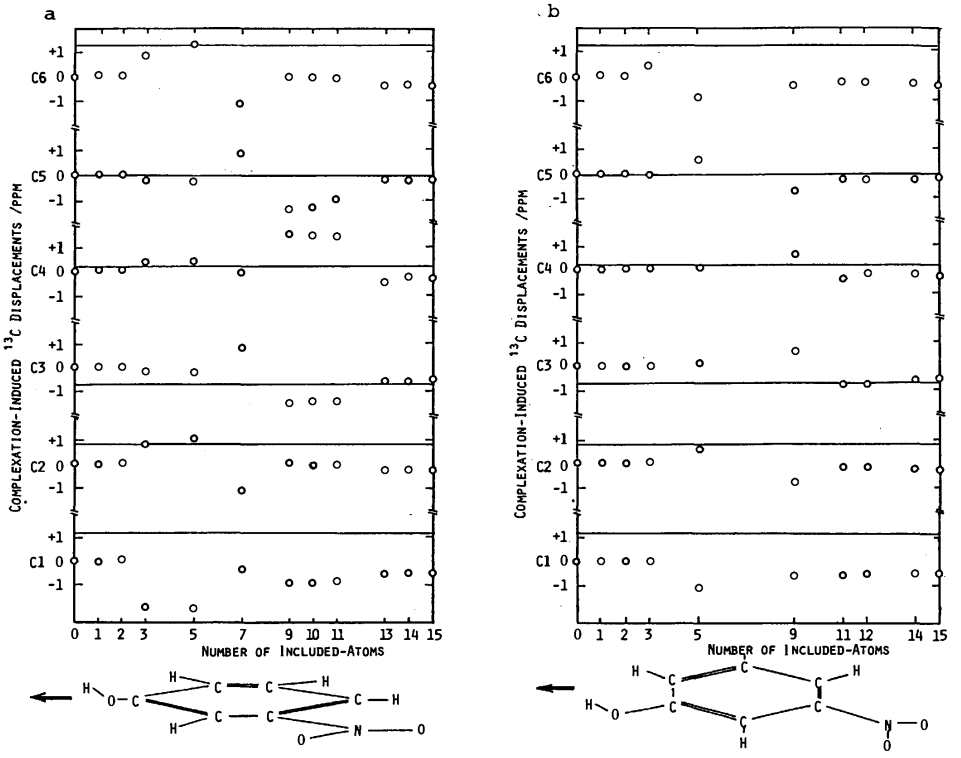

Fig. 3. Dependence of ^{13}C shift displacements of MNP on the position of the borderline. (a) and (b) show the data for the type A and B orientations shown in Fig. 2, respectively. The arrows indicate the direction of guest-insertion.

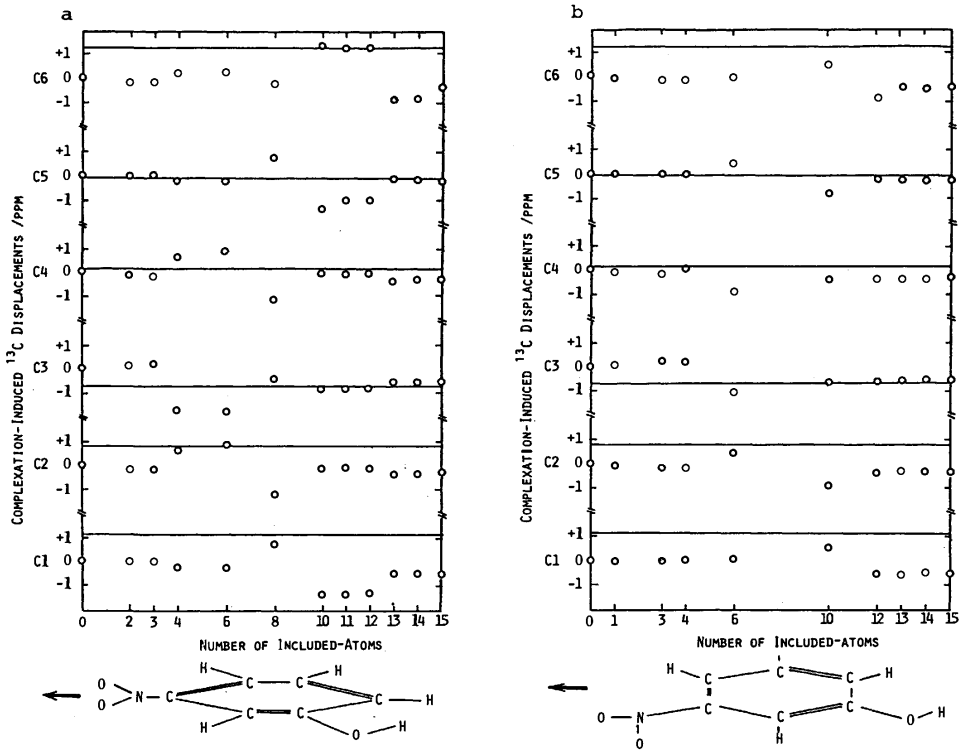

Fig. 4. Dependence of ^{13}C shift displacements of MNP on the position of the borderline. (a) and (b) show the data for the type C and D orientations, respectively.

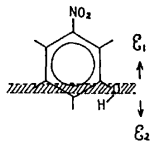

Fig. 5. The position of the borderline (shaded region) where the characteristic ^{13}C displacements are reproduced well by the calculations.

These results are inconsistent with those of Komiyama and Hirai's report.[11] They did not observe the ^{13}C displacements of the tertiary carbons, C_1 and C_3. As described above, these carbons provide decisive information about the orientation of the guest molecule, and thus the lack of these data may be responsible for the discrepancy.

In conclusion, the structure of α-CD-MNP complex in aqueous solution is consistent with that in the solid state.

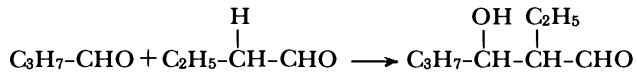
Aldol Addition of Butyraldehyde over Solid Base Catalysts

Geng ZHANG, Hideshi HATTORI,* and Kozo TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 20, 1989)

Synopsis. Aldol addition of butyraldehyde was investigated on alkaline earth oxides, zirconium oxide, and lanthanum oxide to compare the active site and mechanism with those for aldol addition of acetone. It is found that the active site is the surface O^{2-} and the rate-determining step is α-H abstraction.

Aldol type reaction of butyraldehyde as shown below is one of the most important reactions in organic chemistry and has been extensively studied for fundamental understanding.



Many investigations for industrial application of catalysts to aldol addition of ketones and aldehydes were made. Although practical catalysts developed in industry are mostly heterogeneous, the fundamental studies are made primarily in homogeneous system. Recently, we studied aldol addition of acetone over several kinds of solid base catalysts, and found that the active sites for this reaction are surface basic OH groups, and that the rate-determining step is the formation of a new C-C bond between two acetone molecules rather than the abstraction of an α-H^+ ion from acetone.[1-3]

In this work, we studied aldol addition of butyraldehyde over solid base catalysts, and found that the active sites and the rate-determining step for butyraldehyde are different from those for acetone.

Experimental

Catalyst Preparation: Magnesium oxide was prepared from commercial MgO(Merck) as follows. The commercial MgO powder was added into distilled water and stirred at room temperature for 24 h followed by being dried in an oven at 100 °C for 24 h to form hydroxide. Starting material for CaO was $Ca(OH)_2$. Calcium hydroxide was also treated in distilled water in the same way as MgO. The hydroxides of magnesium and calcium were heated at various temperatures in a vacuum to form the oxides before use. Zirconium oxide and La_2O_3 were prepared from aqueous solutions of $ZrOCl_2$ and $La(NO_3)_3$, respectively, by hydrolysis with aqueous ammonia. Strontium oxide was obtained by evacuating $SrCO_3$ at high temperatures.

Reaction Procedures: Reaction was carried out in a H-type batch reactor at 0 °C as described in a previous paper.[1] The two branches were separated by a breakable seal. The catalyst sample was able to be treated in one side and the reactant in another side. One gram of reactant and 50 mg of catalyst were used as a standard procedure. Reactant was admitted to the side of catalyst by breaking the breakable seal and transferring reactant to catalyst side by cooling this side to liquid nitrogen temperature. Reaction was started by rapid melting of the reactant at reaction temperature of 0 °C. In some poisoning experiments, poison was admitted into the reactor before reaction. Products were analyzed by GLC.

Results

The main products were a dimer (namely 2-ethyl-3-hydroxyhexanal) and a trimer. The formation of the trimer was confirmed by field-ionization mass spectrometry, although its exact structure was not clear. Besides dimer and trimer, 2-ethyl-2-hexenal formed by dehydration of dimer was obtained less than 3% of the total products. The activities of several kinds of catalysts for aldol addition of butyraldehyde are summarized in Table 1. Zirconium oxide and La_2O_3 had low activities, while MgO, CaO, and SrO showed high activities. As the specific surface areas were in the order of MgO > CaO ≫ SrO (about a ratio 25 : 10 : 1,[1]) the order for the activities upon unit surface area basis is SrO > CaO > MgO ≫ La_2O_3 > ZrO_2. The activities of La_2O_3 and ZrO_2 for aldol addition of acetone were comparable to that of MgO. Considering the strength of basic site being the order MgO > La_2O_3 > ZrO_2, the activity dependency on the basic strength is higher for butyraldehyde than for acetone.

Relation between the ratio of dimer to trimer and conversion was examined with MgO and CaO by changing the reaction time although the results are not presented. The ratio with MgO declined slightly from 7.1 to 5.0 over the range of conversion from 7.8 to 84.4, while the ratio with CaO kept near an unchanged value of ca. 0.7 over a similar range of conversion as that with MgO. Variations of activity and selectivity with pretreatment temperature of MgO are shown in Fig. 1. Maximum of conversion ap-

Table 1. Activities of Various Catalysts for Aldol Addition of Butyraldehyde

Cat.	Pretreatment temp./°C	Reaction time/h	Conversion /%	Selectivity to 2EHA[a]/%	Dimer/Trimer

SrO	800	1	41.7	1.3	2.2

a) 2EHA: 2-ethyl-2-hexenal.

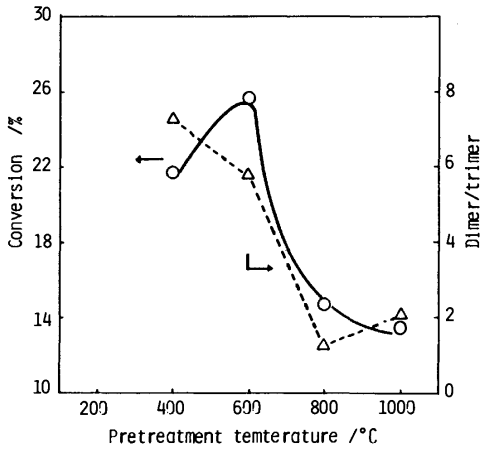

Fig. 1. Pretreatment temperature dependences of activity for aldol addition of butyraldehyde and of ratio of dimer to trimer in the reaction over MgO.

peared around the pretreatment temperature of 600 °C. The ratio of dimer to trimer decreased monotonously as the pretreatment temperature increased.

The results of poisoning experiments with MgO are summarized in Table 2. Ammonia did not poison the active sites, whereas pyridine, carbon dioxide, and water poisoned to considerable extents. Poisoning effect of water in aldol addition of butyraldehyde is in contrast to a marked promoting effect of water in aldol addition of acetone. The ratio of dimer to trimer was increased by water addition. Addition of acetone to butyraldehyde did not affect the reaction of butyraldehyde at all. Neither aldol addition of acetone nor cross aldol addition between butyraldehyde and acetone occurred.

Discussion

A good correspondence of the order of the activity for aldol addition of butyraldehyde to the basic strength of catalyst indicates that the reaction proceeds on the basic sites. Since the activity dependency on the surface basic property is stronger for butyraldehyde than that for acetone, some differences between the constitutions of active sites for aldol addition of acetone and aldehyde are suggested. Two kinds of basic sites, basic OH groups and the surface

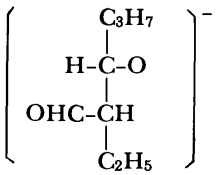
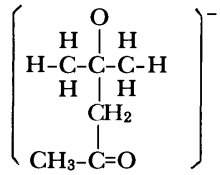
O^{2-}, exist on the surface of solid base catalysts. The results of poisoning experiments in aldol additions of butyraldehyde and acetone suggest the relevant sites for each reaction. The poisoning and promoting effects on the aldol additions of butyraldehyde and acetone are compared in Table 3. Marked difference is observed for the effect of water; considerable promoting effect was observed for acetone while poisoning effect for butyraldehyde. If only surface O^{2-} ions were active sites, water and carbon dioxide would have completely poisoned the active sites. Complete poisoning effect with water and carbon dioxide were observed for many other base-catalyzed reactions such as double bond migration of olefin, hydrogenation of 1,3-butadiene, etc.[4] This is, however, not the observed result for aldol addition of butyraldehyde. The percentage of the activity remaining on addition of water and carbon dioxide is considered to be due to surface OH groups. No promotion effect observed on addition of water is explained by the higher efficiency for the surface O^{2-} ions than for the surface OH groups which may be weaker base than the surface O^{2-}. For aldol addition of acetone, the active sites are the surface OH groups.

Differences in the activity dependency on basic strength and the efficiency of surface O^{2-} and OH groups between aldol addition of butyraldehyde and acetone are considered to be caused by the difference in rate-determining steps for these reactions. Since the aldehyde is stronger acid than ketone, and the surface OH groups can abstract α-H from acetone, it is plausible that the basic strength of the surface OH groups is sufficient to abstract α-H from both butyraldehyde and acetone. The steric hindrance in the C-C bond formation is thought to be larger for acetone than butyraldehyde as shown below.



a) Intermediate for butyraldehyde.



b) Intermediate for acetone.

The rate of C-C bond formation between two butyraldehyde molecules is fast as compared to an α-H abstraction, while the C-C bond formation is slower than an α-H abstraction for acetone. Therefore, the rate-determining step is suggested to be an α-H abstraction for butyraldehyde in contrast to C-C bond formation for acetone. The base strength is directly

associated with the slow step for butyraldehyde, which causes strong dependency of the activity on the basic strength.

It should be noted that the variation of ratio of dimer to trimer with conversion is very small. Nearly constant values of the ratio indicate that the dimer converts to trimer very slowly. Increase of ratio of dimer to trimer owing to the addition of water as shown in Table 2 is ascribed to the conversion of the surface O^{2-} of strong basic sites into the OH groups of weak basic sites. These results indicate that a stronger basic site facilitates the formation of trimer without desorption of dimer. The fact that the ratio of dimer to trimer obtained with MgO is higher than those for CaO and SrO coincides with the result, although a slightly opposite tendency is observed as comparing CaO with SrO.

Effects of Pressure on Hydrolysis of *p*-Nitrophenyl Acetate in Aerosol OT Reversed Micelles

Katsuhiro TAMURA* and Mami YOSHINARI
Department of Chemical Science and Technology, Faculty of Engineering,
The University of Tokushima, Minamijosanjima-cho, Tokushima 770.
(Received January 25, 1989)

Synopsis. Kinetic studies were made on imidazole-catalyzed hydrolysis of *p*-nitrophenyl acetate in Aerosol OT (AOT) reversed micelles (AOT/H_2O/heptane) at high pressure. The rate of the reaction was found to increase with increase in the size of the aqueous core in the reversed micelles and with increase in pressure. Micellar effects on the hydrolysis are discussed in relation with the activation parameters of the reaction.

The hydrolyses of carboxylic acid esters in micelles have often been used as examples of chemical reactions in micellar systems that are similar to enzyme reactions. Studies on micelle catalysts are important because many hydrolyses catalyzed by nucleophiles or enzymes occur in biosystems. Aerosol OT forms stable reversed micelles that can contain large amounts of water as an aqueous core, and these reversed micelles are of biochemical interest because their molecular assembly is similar to that of water pockets in bioaggregates (biomembranes, mitochondria,[1] etc.).

We have studied the effects of pressure on some chemical reactions in micellar systems.[2-6] In the present paper we report the effects of pressure on the hydrolysis of *p*-nitrophenyl acetate in AOT reversed micelles. Micellar effects on the hydrolysis are discussed in relation with activation parameters of the reaction.

Experimental

Sodium salt of bis(2-ethylhexyl) sulfosuccinate (Aerosol OT, AOT) was obtained from Tokyo Kasei. It was dissolved in methanol and filtered, and then the solvent was removed under vacuum. *p*-Nitrophenyl acetate (Tokyo Kasei) was recrystallized twice from ethanol. Imidazole (Wako) was used without further purification.

A high-pressure vessel with quartz optical windows was used to follow the reaction at high pressure directly. Sample solutions were charged into a sliding cell (inner quartz cell) to prevent contamination of the solution by the metal body and packing of the vessel. The high-pressure vessel was set in a Hitachi 100-60 UV-visible spectrophotometer and the reaction product, *p*-nitrophenol, was determined by measuring its absorbance at 400 nm. Pressures were generated by a hand-operated hydraulic pump (Hikari KP-5B) and measured with a Heise Bourdon gauge.

The reaction solution was prepared by mixing 3 wt% AOT in heptane with aqueous 5.0×10^{-2} mol dm^{-3} imidazole solution in various ratios. *p*-Nitrophenyl acetate (8.0×10^{-5} g) was added to 4 cm^3 samples of the AOT/H_2O/imidazole/heptane solutions and the mixtures were stirred for 10 min. Reaction rates in water were used as standards in evaluating micellar effects.

Results and Discussion

Pseudo-first-order rate constants (k) were deter-

mined by the Guggenheim method[7] and are presented in Table 1. Water contents are shown as molar ratios of water to AOT (R=[H_2O]/[AOT]). The hydrolysis of p-nitrophenyl acetate was strongly dependent on the properties of the reaction fields and pressure. For example, the reaction did not occur when the water content was less than 6 ($R<6$). This is because at $R<6$ almost all the water molecules in the reversed micelles are strongly bound to the polar heads of AOT or to sodium ions (counter ions),[8-10] and so hydrolysis does not readily occur. At $R>10$, there is a free water phase and the hydrolysis occurs. Thus we can conclude that the hydrolysis of p-nitrophenyl acetate proceeds only in the presence of free water. The size of the aqueous core also affected the reaction rate: the rate increased with increase in the size of the water pool. Over a range of water contents of $10<R<30$, the rate of p-nitrophenyl acetate hydrolysis was an almost linear function of R ([H_2O]/[AOT]) at both atmospheric and high pressures.

Pressure also promoted the hydrolysis of p-nitrophenyl acetate in AOT reversed micelles. In general, acid- and base-catalyzed hydrolyses of esters are promoted by pressure, because partial electric charges or bonds are formed during the reactions. Apparent activation volumes ($\Delta V^{\neq}_{ap}$) were calculated by the equation:

$$(\partial \ln k/\partial P)_T = -\Delta V^{\neq}_{ap}/RT$$

where R, T, and P are the gas constant, the absolute temperature and the pressure, respectively. The apparent activation volumes of the hydrolysis of p-nitrophenyl acetate are shown in Table 2. These volumes depend greatly on the nature of the reaction field. The large and irregular variations of the values from -3.2 (R=11.2) to -16.0 $cm^3 mol^{-1}$ (R=39.9) suggest that not only the nature of the water pool, but also micellar size are closely related to the effects of pressure on the reaction rate. In particular, the $\Delta V^{\neq}_{ap}$ is found to decrease rapidly at $R\approx30$. Fluorescence polarization studies of AOT reversed micelles at high pressures[11] showed that the micelles aggregated and formed polydisperse syslems at $R\approx30$ and that these changes of micellar size were greatly enhanced by pressure. This aggregation of the micelles can be considered as one reason for the increase in reaction rates with increase in pressure at $R\geqq30$. The activation volume in the aqueous solution (-11.8 cm^3 mol^{-1}) coincided exactly with that at this water content $R\approx30$ (Fig. 1).

b) [Imidazole]=5.0×10^{-4} mol dm^{-3} (aq. soln).

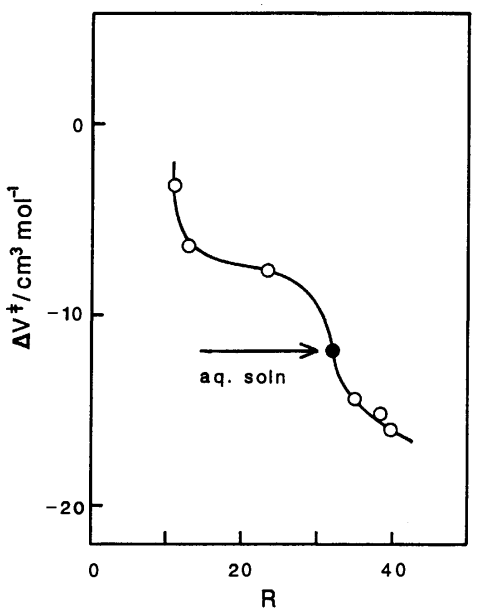

Fig. 1. Activation volumes for the hydrolysis of p-nitrophenyl acetate in AOT reversed micellar systems and aqueous solution at atmospheric pressure and 298.15 K. R=[H_2O]/[AOT].

The base-catalyzed hydrolyses of esters in water usually have activation volumes in the range of -5 to -10 $cm^3 mol^{-1}$.[12] These values are explained as follows. The coordination of OH^- ions to esters should be associated with volume reduction due to formation of new chemical bonds, although loss of electrostriction by dispersion of electric charges may result in some increase in volume. In imidazole-calalyzed hydrolysis of p-nitrophenyl acetate in AOT reversed micelles, the imidazole molecule presumably acts as a nucleophile rather than a general base as in aqueous solutions.[13]

As imidazole is insoluble in dry AOT/heptane solutions, it must be present exclusively in the water pool of AOT/H_2O/heptane reversed micelles. When p-nitrophenyl acetate is added to the AOT/H_2O/imidazole/heptane system, hydrolysis of the ester occurs in the water pool. Therefore, the partition of the ester between the heptane phase and the water phase across the surfactant boundary becomes important.[14] Accordingly, when determining reaction rates at high pressure the effect of pressure on partition coefficients should be considered. The volume change ΔV for the transfer of p-nitrophenyl acetate from the heptane to water phase can be expressed as

$$-RT(\partial \ln K/\partial P)_T = \Delta V = V_W - V_H$$
$$K = x_W/x_H$$

where K is the partition coefficient, V_W and V_H are the partial molar volumes of p-nitrophenyl acetate in the water and heptane phases, and x_W and x_H are the mole fractions in these systems. In general, esters have smaller partial molar volumes in water than in alkanes ($\Delta V<0$). This means that pressure increases

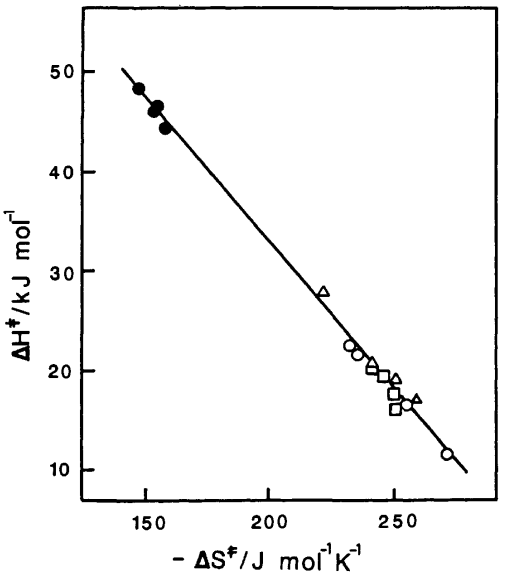

Fig. 2. Linear relationship between activation enthalpies and entropies for the hydrolysis of *p*-nitrophenyl acetate in AOT reversed micellar systems and aqueous solution at atmospheric pressure and 298.15 K.
Water contents (R): △: 12, □: 24, ○: 35, ●: aq. soln.

the partition coefficient and promotes the hydrolysis. This is another reason for acceleration of the reaction by increase in pressure. This effect is more pronounced at higher water contents ($R > 30$).

Figure 2 shows the relationship between the activation enthalpies and entropies of the hydrolysis of *p*-nitrophenyl acetate at 298.15 K. Good compensation effects between the enthalpies and the entropies are observed in the water and AOT systems. Although the activation enthalpies and entropies for the aqueous solution have much larger values than those for AOT systems, the linear relationship is very good.

(Received October 12, 1988)

Synopsis. Through SP-Sephadex ion exchange chromatography $[Ru(Hdpa)_3]^{2+}$ and $[Ru(bpy)_2(Hdpa)]^{2+}$ (Hdpa= di-2-pyridylamine) were resolved by the use of an aqueous sodium *d*-tartrate solution as the eluting agent. *Λ*-$[Ru(Hdpa)_3]^{2+}$ and *Λ*-$[Ru(bpy)_2(Hdpa)]^{2+}$ were eluted in the early fractions. The precipitation of diastereomers with dibenzoyl-*d*-tartrate was also successful in the resolution of $[Ru(Hdpa)_3]^{2+}$ and $[Ru(bpy)(Hdpa)_2]^{2+}$. The absolute configurations of the complexes were assigned by referring to the signs of CD spectra at around 3.2—3.8 μm^{-1}.

Synthetic and spectrochemical studies on a series of complexes $[Ru(bpy)_n(Hdpa)_{3-n}]^{2+}$ (bpy=2,2′-bipyridine, Hdpa=di-2-pyridylamine, n=0—2) have been reported by DeArmond et al.[1,2] The present work describes the resolution of the complexes through SP-Sephadex cation-exchange chromatography and the precipitation of diastereomers with sodium (*R,R*)-dibenzoyltartrate (Na_2dbt). Although $[Ru(bpy)_3]^{2+}$ and $[Ru(phen)_3]^{2+}$ can be resolved through the precipitation of diastereomers with sodium bis(*d*-tartrato)diantimonate ($Na_2Sb_2(tart)_2$),[3,4] this resolving agent failed to give precipitate with the above Hdpa-containing complexes.

Experimental

Preparation of $[Ru(bpy)(Hdpa)_2](ClO_4)_2$. A dilute hydrochloric acid solution (100 cm^3) of $RuCl_3 \cdot 3H_2O$ (Koso Chemicals, 1 g) and Hdpa (Aldrich, 200 mg) was refluxed for 8 h, and filtered. The filtrate was concentrated to about 20 cm^3 while precipitating a green product. This contained *cis*-$[RuCl_2(Hdpa)_2]Cl \cdot H_2O$, the X-ray structural study of which will be reported in a separate paper. The green product was suspended in 200 cm^3 of water with bpy (90 mg) and Hdpa (50 mg), and refluxed for 3 h in the presence of sodium phosphinate (2 g). Upon the addition of $NaClO_4$ to the reaction mixture a brown precipitate was formed. For purification it was charged on the top of an SP-Sephadex column (Na^+ form) and eluted with a 0.3 mol dm^{-3} NaCl solution. Fractions of a brown eluate were collected from which $[Ru(bpy)(Hdpa)_2](ClO_4)_2$ was precipitated. The product was washed with an aqueous solution of 0.1 mol dm^{-3} $NaClO_4$, ethanol/2-methyl-2-propanol (1 : 1 v/v), and ether, successively, and dried at 60 °C. Yield 20% (Found: C, 44.98; H, 3.23; N, 13.98%). Other members of the series $[Ru(bpy)_n(Hdpa)_{3-n}]^{2+}$ which were formed as by-products were separated off by chromatography; complexes with higher n values were eluted faster.

$[Ru(Hdpa)_3](ClO_4)_2$[1] and $[Ru(bpy)_2(Hdpa)](ClO_4)_2$[2] were prepared by methods similar to those reported by DeArmond et al., except that both complexes were purified through the chromatography described above.

Optical Resolution. a) Cation-Exchange Chromatography. $[Ru(Hdpa)_3]^{2+}$ was charged on the top of an SP-Sephadex column (ϕ 6 cm×60 cm), and eluted with 0.15 mol dm^{-3} sodium *d*-tartrate (Na_2*d*-tart) solution. Since one elution gave only partial resolution, the earlier and later fractions were collected separately, and again charged on the column. This procedure was repeated three times. From the early fractions $(+)_{\Delta\varepsilon}$-$[Ru(Hdpa)_3](ClO_4)_2$[5] was isolated. Peaks of CD: $\Delta\varepsilon_{410}$=−36.6, $\Delta\varepsilon_{314}$=207, and $\Delta\varepsilon_{283}$=−177 (cm mol $dm^{-3})^{-1}$.

$[Ru(bpy)_2(Hdpa)]^{2+}$ was also resolved almost in the same way as the above. After elutions were repeated three times $(-)_{\Delta\varepsilon}$-$[Ru(bpy)_2(Hdpa)](ClO_4)_2$ was isolated from the early fractions. Peaks of CD: $\Delta\varepsilon_{355}$=6.83, $\Delta\varepsilon_{292}$=−185, and $\Delta\varepsilon_{275}$=119 (cm mol $dm^{-3})^{-1}$. For $[Ru(bpy)(Hdpa)_2]^{2+}$ the chromatography gave only poor resolution.

b) Precipitation of the Diastereomers with Na_2dbt. Four hundred milligrams of $[Ru(Hdpa)_3](ClO_4)_2$ was converted to the chloride through anion exchange. To a 100 cm^3 chloride solution was added 100 mg of Na_2dbt. The solution was allowed to stand at room temperature for 3—4 days during which $(-)_{\Delta\varepsilon}$-$[Ru(Hdpa)_3](dbt)$ was precipitated. The diastereomer was recrystallized from water. Yield: 130 mg. This was converted to the perchlorate, $(-)_{\Delta\varepsilon}$-$[Ru(Hdpa)_3](ClO_4)_2$. CD: $\Delta\varepsilon_{410}$=36.6 (cm mol $dm^{-3})^{-1}$.

A similar procedure was applied to the resolution of $[Ru(bpy)(Hdpa)_2]^{2+}$. From 400 mg of racemic perchlorate 70 mg of the diastereomer, $(+)_{\Delta\varepsilon}$-$[Ru(bpy)(Hdpa)_2](dbt)$ was obtained. CD peaks of $(+)_{\Delta\varepsilon}$-$[Ru(bpy)(Hdpa)_2](ClO_4)_2$: $\Delta\varepsilon_{408}$=−13.7, $\Delta\varepsilon_{296}$=158, and $\Delta\varepsilon_{279}$=−133 (cm mol $dm^{-3})^{-1}$.

$[Ru(bpy)_2(Hdpa)]^{2+}$ gave no precipitate on addition of Na_2dbt.

Measurements. Electronic spectra were recorded on a Hitachi 340 Spectrophotometer, and CD spectra were on a JASCO J-500A Spectropolarimeter. The solvent was water throughout the measurements.

Results and Discussion

The electronic and CD spectra are shown in Figs. 1 and 2, respectively. The two strong bands at around 3.2—3.8 μm^{-1}, which are common to the four complexes, correspond to the intraligand π-π^* transitions in coordinated pyridine groups. The CD bands

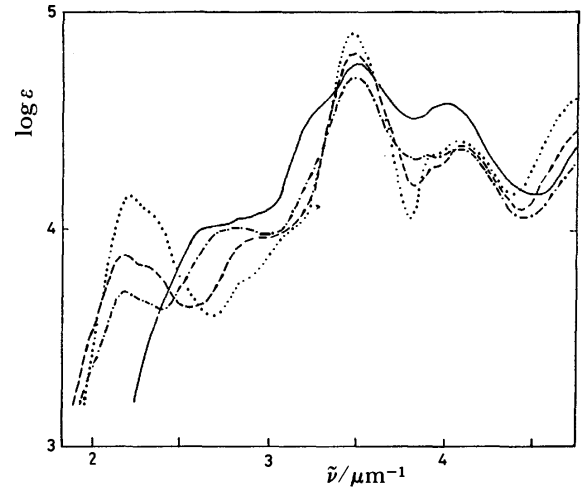

Fig. 1. Electronic spectra of $[Ru(bpy)_n(Hdpa)_{3-n}]^{2+}$. —— $[Ru(Hdpa)_3]^{2+}$;-·-· $[Ru(bpy)(Hdpa)_2]^{2+}$;--- $[Ru(bpy)_2(Hdpa)]^{2+}$; ····· $[Ru(bpy)_3]^{2+}$.

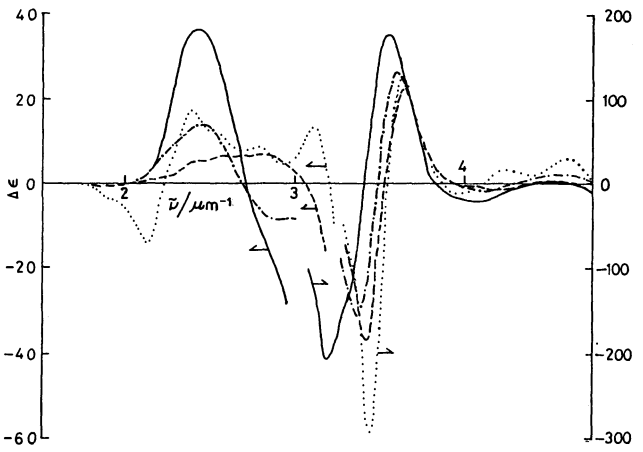

Fig. 2. CD spectra of $(-)_{\Delta\varepsilon}$-$[Ru(bpy)_n(Hdpa)_{3-n}]^{2+}$. The symbols are the same as in Fig. 1.

which are usually observed for tris- and bis(diimine) complexes such as $[M(bpy)_3]^{n+}$, $[M(phen)_3]^{n+}$, and $[M(bpy)_2(py)_2]^{n+}$ are used to assign the absolute configurations of these complexes based on exciton theory;[6-8] that is, an enantiomer whose CD bands corresponding to π-π^* transition show a minus (at lower wavenumbers)-plus (at higher wavenumbers) pattern has a *Δ* configuration. If this rule can be applied to the present system, the CD spectra shown in Fig. 2 are of *Δ* isomers.

The agreement of the absolute values of $\Delta\varepsilon$ of *act*-$[Ru(Hdpa)_3]^{2+}$ resolved by two different methods was sufficiently good to assure complete resolution.

In the precipitation procedure for $[Ru(Hdpa)_3]^{2+}$, when the filtrate after the filtration of $(-)_{\Delta\varepsilon}$-$[Ru(Hdpa)_3](dbt)$ was treated with more Na_2dbt and kept at room temperature for an additional week, often $(+)_{\Delta\varepsilon}$-$[Ru(Hdpa)_3](dbt)$ precipitated, whose optical purity was very good. The perchlorate which was derived from the diastereomer had $\Delta\varepsilon_{410}$ of -36.0 $(cm\,mol\,dm^{-3})^{-1}$. Such "post precipitation" of the other diastereomer was not observed in the resolution of $[Ru(bpy)(Hdpa)_2]^{2+}$.

The enantiomers which form less soluble diastereomers with dbt^{2-} are *Δ*-$[Ru(Hdpa)_3]^{2+}$ and *Λ*-$[Ru(bpy)(Hdpa)_2]^{2+}$. Although the mechanisms of the precipitation and the resolution were not clear, Na_2dbt was found to be a good resolving agent for these two complexes. As described in "Experimental", a single precipitation followed by a recrystallization yielded very pure diastereomers.

Table 1. Enantiomer Which was Eluted in the Early Fractions on the SP-Sephadex Column Chromatography

Complex	Eluting agent		
	Na_2*d*-tart	Na_2Sb_2(*d*-tart)$_2$	NaCl
$[Ru(bpy)_3]^{2+}$	*Δ*	*Δ*	*Δ*
$[Ru(bpy)_2(Hdpa)]^{2+}$	*Δ*	*Δ*	*Δ*
$[Ru(bpy)(Hdpa)_2]^{2+}$	*Δ*	*Δ*	*Δ*
$[Ru(Hdpa)_3]^{2+}$	*Λ*	*Δ*	*Λ*

For chromatographic resolution various reagents were tried. Table 1 shows the enantiomers of each complex which were eluted in the early fractions by three kinds of eluting agents. Among them sodium *d*-tartrate was the most efficient agent in the resolution of $[Ru(Hdpa)_3]^{2+}$ and $[Ru(bpy)(Hdpa)_2]^{2+}$. No definite conclusion could be deduced regarding the mechanism of the resolution from the data.

The optical isomers were inert in aqueous solutions against racemization in the dark. Under irradiation with a xenon lamp, however, they racemized with a very slight decomposition. Preliminary experiments showed that the quantum yield of racemization was in the order $[Ru(Hdpa)_3]^{2+} < [Ru(bpy)_3]^{2+} \approx [Ru(bpy)_2(Hdpa)]^{2+}$.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 61470048 from the Ministry of Education, Science and Culture.

(Received December 7, 1988)

Synopsis. The crystals of the title new lanthanum(III) complex, $LaC_{45}H_{86}N_{11}S_7$, F.W. 1144.59, are orthorhombic, space group $Bm2_1b$, a=17.438(7), b=21.507(9), c=16.616(6) Å, U=6232(4) Å^3, Z=4, D_m=1.21(3), D_x=1.22 g cm^{-3}, and μ(Mo $K\alpha$)=9.63 cm^{-1}. The central lanthanum(III) atom has a unicapped trigonal-prism 7N-hepta-coordination geometry: seven thiocyanato nitrogen atoms are ligated. There are no bridgings between the complexes and/or counter cations. Each benzene molecule is surrounded by the thiocyanate ions and ethyl groups of the cations. Although these crystals lose benzene at about 60 °C, they are stable for more than several weeks at ambient temperature, and can be regarded as a kind of inclusion compound. The isomorphous praseodymium(III) complex was also obtained.

The hexa-coordinated isothiocyanato(SCN) complexes of lanthanoids, $[(C_4H_9)_4N]_3[M(NCS)_6]$ (M=Pr—Yb), reported about 20 years ago,[1] are thought to have a specific structure, since in common complexes of lanthanoids the coordination numbers are in most cases 8, 9 or higher:[2] the SCN does not seem to be as massive as the one which should have a lower coordination number. In cases of the aqua-SCN mixed complexes, their coordination numbers were found to be eight.[3-5] The structures of the anionic thiocyanato complexes of cadmium are different from each other, depending on the kinds of their counter cations.[6,7] We recently found a new hepta-coordinated (in pentagonal bipyramidal form) isothiocyanato complexes of lanthanoids $[(CH_3)_4N]_4[M(NCS)_7]$ (M=Dy—Yb).[5] Therefore, we expected to find other types of new complexes from their tetraethylammonium salts, and obtained the title complexes. From preliminary chemical analyses, we found that they include the metal, SCN ions, and benzene in a mole ratio of 1:7:1, and were expected to have interesting structures. Therefore, their crystal and molecular structures were examined by the single-crystal X-ray diffraction method.

Experimental

Synthesis of Tetraethylammonium Heptakis(isothiocyanato)lanthanate(III)·Benzene (1). Lanthanum and tetraethylammonium thiocyanates were obtained as previously reported.[4] Into a methanolic solution (15 cm^3) containing 1.0 mmol of lanthanum(III) thiocyanate and 0.8 g (4.3 mmol) of tetraethylammonium thiocyanate, 10 cm^3 of an ethanol-benzene mixed solution (1:1=v/v) was added and dried up at about 80 °C using a rotary vacuum evaporator. The sirupy residue was dissolved into 15 cm^3 of dried methanol and was left standing in benzene vapor at ambient temperature. Although no precipitates appeared during several weeks, crystals of the title complex were deposited after several months. Yield: 0.6 g (0.52 mmol, 52%). The praseodymium complex (**2**) was also obtained by almost the same technique, and almost in the same yield. Attempts to synthesize the isomorphous neodymium or the heavier lanthanoid complexes using the same technique have not been successful. Calcd for $MC_{45}H_{86}N_{11}S_7$: M=La (**1**), La, 12.14; C, 47.22; H, 7.57; N, 13.46%; M=Pr (**2**), Pr, 12.29; C, 47.14; H, 7.56; N, 13.44%. Found: **1**, La, 12.02; C, 46.85; H, 7.42; N, 13.45%; **2**, Pr, 12.30; C, 46.91; H, 7.40; N, 13.33%.

Single Crystal X-Ray Structure Analysis. The crystal of **1** was colorless, parallelepiped (0.30×0.25×0.20 mm^3), D_m=1.21(3), and D_x=1.22 g cm^{-3}; and that of **2**, pale green in color, parallelepiped (0.30×0.20×0.12 mm^3), D_m=1.21(3), and D_x=1.23 g cm^{-3}. Intensities in the range $3<2\theta<60°$ were collected on a Rigaku AFC-6A automated 4-circle X-ray diffractometer using graphite monochromated Mo $K\alpha$ radiation (λ=0.71073Å) by means of an ω-2θ scan technique (scan speed (ω), 4° min^{-1}, and scan width (ω), 1.08+0.35 tanθ) for **1** and **2**. The intensities were corrected for Lorentz and polarization factors, but not for absorption and extinction. Of 4970 independent intensities collected, 1571 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination of **1**, while 1874 in 4956 reflections for that of **2**. The crystallographic data of **2** are: a=17.412(7), b=21.468(6), c=16.612(6) Å, U=6209(4) Å^3, μ(Mo $K\alpha$)=10.51 cm^{-1}.

All the calculations were carried out on a HITAC M-682H computer at the Computer Center of the University of Tokyo using a local version of the UNICS program.[8] The scattering factors were taken from Ref. 9.

The structure of **1** was solved by the heavy-atom method (positional and thermal parameters were refined by a block-

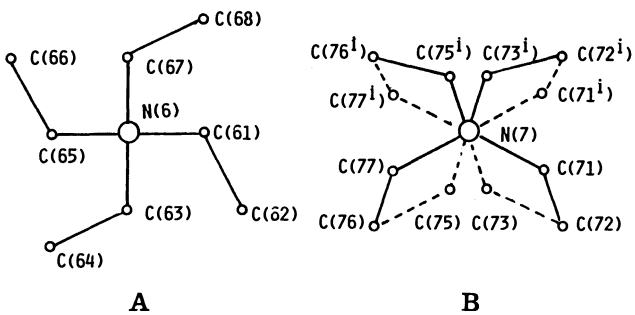

Fig. 1. Schematic presentation of the tetraethylammonium ions with the numbering scheme of the atoms.
A. The ion centered by N(6). **B**. The ion centered by N(7): the bonding and the numbering way are the same as the one centered by the N(8) atom. Key to the symmetry operation: i; $\bar{x}$, y, z.

diagonal least-squares method). No hydrogen atoms were included in the structure factor calculations. The structure of **2** was calculated starting from the final values of **1**. They were also refined. During the final stage of refinements, the movements of the respective parameters were less than one-third of the corresponding standard deviations, except for a few cases. The carbon atoms of the tetraethylammonium ions centered by N(7) and N(8) atoms are disordered, as shown in Fig. 1. The N(7) atom is bonded with four carbon atoms in two ways: with C(71), C(73^{i}), C(75^{i}), and C(77), or with C(71^{i}), C(73), C(75), and C(77^{i}), atoms (i, $-x$, y, z). The occupancy factors of both type structures are 0.5 due to symmetry. The final R and R_w (in parentheses) values[10] are: **1**, 0.091(0.071); **2**, 0.086 (0.070). Since the R and R_w values of the inversed chirality structures were, **1**, 0.093 (0.073); **2**, 0.089 (0.074), the structures were not adopted. Although the thermal parameters of some atoms were found to be large, such phenomena were sometimes found in the lanthanoid complexes, especially for the atoms relatively far from the central metal atom.[11]

The Other Measurements. Thermogravimetric (TG)-differential thermal analysis (DTA) simmultaneous measurement was carried out by the Rigaku "Thermoflex" M-8075 using samples weighing about 10 mg each at heating rate of 10 °C min^{-1} in air, α-alumina as the reference. Infrared spectra were obtained by means of a JASCO A-202 grating infrared spectrophotometer using paraffin oil and hexachloro-1,3-butadiene mull.

Results and Discussion

Selected bond lengths and bond angles are listed in Table 1. A perspective drawing of the anionic complex is shown in Fig. 2, and a projection of the unit cell along b-axis in Fig. 3.[12]

The metal atom is in a unicapped trigonal prism hepta-coordination geometry, as shown by the broken lines in Fig. 2: seven N atoms of SCN ions are ligated. The atoms of the metal and the SCN ions following N(1), N(4), and N(2) (cap position) are on planes parallel to the bc-plane; the other two pairs of the SCN ions (following N(3), and N(3^{i}); and N(5) and N(5^{i})) are at the respective mirror image positions with each other on both sides of the planes. The triangle planes of the prism are approximately parallel to the ac-plane.

The average M-N bond lengths to the three N atoms at the apexes of one bottom triangle are short (**1**, 2.46, and **2**, 2.37Å, on the average), and the other four, to the N atoms at the apexes of the other bottom triangle and at the cap position, are long (**1**, 2.58, and **2**, 2.56Å, on the average). The averages of the M-N-C and N-C-S angles are: **1**, 167 and 172; **2**, 168 and 176°, respectively. These are not much deviated from 180°.

It is an interesting fact that $[Dy(SCN)_7]^{4-}$ ion in tetramethylammonium salt has an approximately pentagonal bipyramidal geometry around its metal atom, while the present $[Pr(SCN)_7]^{4-}$ in tetraethylammonium salt a unicapped trigonal prism.

The centers of cations, N(7) and N(8) atoms, as well as the centers of benzene rings are on planes parallel to the bc-plane. The benzene ring is arranged approximately parallel to the ab-plane and is mirror-symmetrical to the bc-plane. The benzene ring is

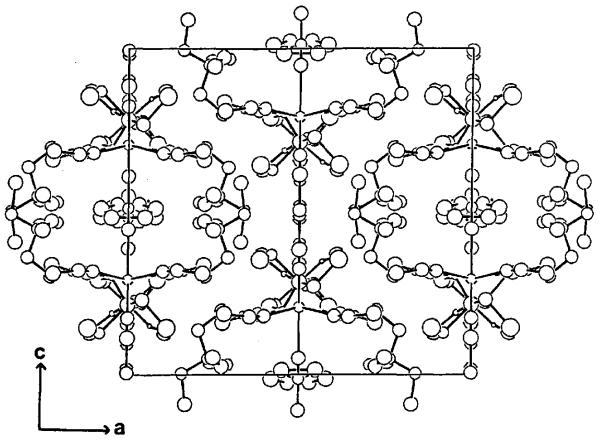

Fig. 3. Projection of the unit-cell along b-axis.

situated between two cations centered by N(7) and N(8) atoms in the c-axis direction. Moreover, on both sides of the ring along b-axis, there are the SCN ions bonded to the cap-positions of the complexes which are neighboring along [011] or [0$\bar{1}$1] axis.

The metal and a center of the cation, N(6), atoms are on planes parallel to the ac-plane intersecting the b-axis at 0 and 0.5, while the benzene molecules and the other cations (centered by N(7) and N(8) atoms) are sandwitched between the former planes: both kinds of layers are arranged alternately along b-axis.

The general feature of the TG and DTA curves of **1** and **2** are approximately the same: they decompose in two steps. At the first step of TG curve (at, **1**, 60; **2**, 103 °C) they lose benzene (corresponding DTA endothermic peaks are at, **1**, 65; **2**, 120 °C). At the second step of TG curve (at, **1**, 264; **2**, 274 °C) they seem to decompose in a one-step reaction into their oxides. However, as the corresponding DTA curve shows an endothermic followed by exothermic peaks, the reaction is likely to consist of several complicated steps.

When **1** and **2** were heated at 110 °C for several hours, they lost only benzene, judging from their mass loss. In the infrared spectra of their heating residue, peaks of SCN were found (ν(CN), 2035; ν(CS), 730(sh); δ(SCN), 482 cm^{-1}) as well as those of the $[(C_2H_5)_4N]^+$ ion (for example, strong peaks at 1490, 1395, 1364, 1170, 997, and 780 cm^{-1}). Those for benzene, found in the spectra of **1** or **2** (for example peaks at 1480, 680 (splitted into two) cm^{-1}), disappeared.

On the other hand, at room temperature, these complexes were stable, and the included benzene was not removed after, at least, several weeks (when they were kept in a stoppered glass bottle in a refrigerator, they were not decomposed even after six months).

Synopsis. The crystal and molecular structure of the new title complex has been determined by means of a single-crystal X-ray diffraction method. It is triclinic with the space group $P\bar{1}$, $Z=2$, $a=15.518(5)$, $b=19.827(7)$, $c=7.493(2)$ Å, $\alpha=100.90(3)$, $\beta=103.94(2)$, $\gamma=82.85(3)°$. Both of the metal atoms have almost the same coordination geometry, pentagonal bipyramidal which coordinates the oxygen atoms of five water molecules (2 axial and 3 equatorial ones) and the two hydroxide ions which bridge the both metal atoms. The Sc(1)···Sc(2) distance is 3.403(2) Å. The average Sc-O(H_2O) bond length is 2.194 Å, which is much longer than that of Sc-O(OH), 2.072 Å. Benzenesulfonate ions and the other water molecules do not coordinate to the metal atoms, though their oxygen atoms as well as those of the coordinated water are connected with each other by a network involving hydrogen bonding.

Although the structures of scandium complexes have not yet been sufficiently clarified, some of them were recently elucidated: most of them are in the octahedral hexa-coordinated geometry,[1-5] and the others are in the octa-coordination.[6-10] Some scandium salts have a layer,[7] a chain[3,4] or a dimeric structure[8] like the lanthanoid complexes.[11-14]

Previously, the authors investigated the structures of several scandium salts,[3-5] and recently were able to obtain the new title complex. Subsequently, its crystal and molecular structure was determined by the single-crystal X-ray diffraction method.

Experimental

Synthesis of Di-μ-hydroxo-bis[pentaaquascandium(III)] Benzenesulfonate Tetrahydrate. Scandium oxide (69 mg, including 1 mmol of Sc) was dissolved into hydrochloric acid (6 mol dm^{-3}, 10 cm^3) after boiling. The solution was dried up on a water bath, and the residue was dissolved into 10 cm^3 of water. To the solution sodium benzenesulfonate hydrate (610 mg, 3.1 mmol) was added, dissolved by warming, and left standing in a desiccator over silica gel at room temperature until one third of the solvent was evaporated; plate-like crystals were deposited. Yield: 92 mg (0.091 mmol as a dimer, 18%) Found: Sc, 9.14; C, 28.67; H, 4.70%. Calcd for $Sc_2C_{24}H_{50}O_{28}S_4$: Sc, 8.95; C, 28.69; H, 5.02%.

X-Ray Structure Analysis. The used crystal was colorless, approximately parallelepiped in shape (0.30×0.25×0.25 mm^3), triclinic, space group $P\bar{1}$, $Z=2$ (including four Sc atoms in a unit cell), $a=15.518(5)$, $b=19.827(7)$, $c=7.493(2)$ Å, $\alpha=100.90(3)$, $\beta=103.94(2)$, $\gamma=82.85(3)°$, $U=2190(1)$ Å, $D_m=1.51(3)$, $D_x=1.52$ g cm^{-3}, μ(Mo $K\alpha$)=5.92 cm^{-1}. The intensities were measured with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å), a ω-2θ scan technique being employed (the scan speed was 4° min^{-1} (ω), scan width, 1.00+0.5 tanθ (ω), and the scan range was 3—55° (2θ)). Of the 10123 independent reflections measured, 5866 reflections of $|F_o|>3\sigma(|F_o|)$ were used for its structure calculation. The intensities were corrected for both Lorentz and polarization factors, but not for absorption and extinction. The structure was solved by the heavy-atom method. The positional and thermal parameters of the atoms were refined by a block-diagonal least-squares method. The positions of the hydrogen atoms of coordinated water molecules and hydroxide ions were obtained from a difference synthesis map; they were included in the structure factor calculations (without fixing); the other hydrogen atoms were excluded from the calculations. During the final stage (in the map) almost no electron clouds could be recognized around the ligated oxygen atoms. The observed H-O bond lengths of the water molecules and the hydroxide ions are 0.91 and 0.90 Å (on the average), respectively (they were a little too short, which may be due to their large temperature factors). The H-O-H bond angles of water, and Sc-O-H of water and hydroxide ions are 110, 122, and 120° (on the average), respectively. The final R value was found to be 0.070 by applying anisotropic temperature factors for all nonhydrogen atoms.[15]

All calculations were carried out on a HITAC M-682H computer at the Computer Center of the University of Tokyo using a local version of the UNICS program system.[16] The atomic scattering factors were taken from Ref. 17.

Results and Discussion

The selected bond lengths and bond angles are shown in Table 1. A perspective drawing of the dimeric complex together with the numbering scheme of the atoms is shown in Fig. 1, and a projection of the unit cell along b-axis, together with the numbering of some metal and other atoms, in Fig. 2.[18]

Both of the scandium(III) atoms, Sc(1) and Sc(2) are approximately in the same coordination geometry, deformed pentagonal bipyramidal. The seven ligating oxygen atoms are five water oxygen atoms (two are axial and three equatorial) and two oxygen atoms of hydroxide ions (equatorial). The two hydroxide ions make bridges between the two metal atoms. The axial Sc-O(H_2O) bonds are shorter than the equatorial ones (the axial bonds are 2.146 Å on the average, and the average equatorial bond length is 2.227 Å), while the Sc-O (hydroxide) bonds are the shortest (2.072 Å on the average). The bond angles of O(hydroxide)-

O(A7)-Sc(1)-O(A3)	76.6(2)	O(A7)-Sc(2)-O(B5)	77.6(2)

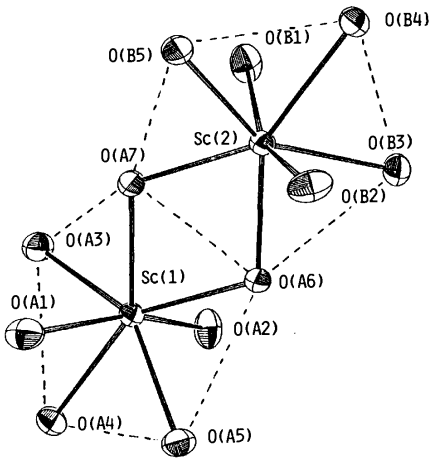

Fig. 1. The perspective drawing of the dimeric complex with the numbering scheme of the atoms: 30% probability thermal ellipsoids are shown for the nonhydrogen atoms of the complex.

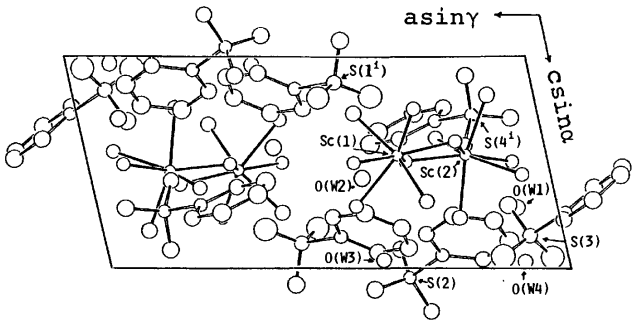

Fig. 2. Projection of the unit cell along b-axis: the numbering scheme of some atoms are also shown (i, x, y, $-1+z$).

Sc-O(hydroxide) and Sc(1)-O(hydroxide)-Sc(2) are, 69.2 and 110.4° (on the average), while the separations of Sc(1)···Sc(2) and O(A6)···O(A7) are 3.403(2) Å and 2.353(6) Å, respectively.

The size and the form of this Sc_2O_2 quadrilateral resemble the corresponding ones of the di-μ-hydroxo bridging found in the dimeric basic nitrate.[8] Moreover, from the difference synthesis map, only one hydrogen atom was found around each O(A6) and O(A7) atom, while two hydrogen atoms were found to exist around the other ligating oxygen atom, respectively. This is further support of our inference that the two bridging oxygen atoms are hydroxide ions.

Three mean-square planes are defined as **A**, **B**, and **C**, including following atoms, respectively: (**A**) Sc(1) and O(A3—A7); (**B**) Sc(1, 2) and O(A6, A7) ; and (**C**), Sc(2) and O(A6, A7, B3—B5). The average positional deviations of the atoms from the respective planes are: **A**, 0.239; **B**, 0.061; and **C**, 0.260 Å. The dihedral angles between them are: **A**-**B**, 147.1; **A**-**C**, 117.8; **B**-**C**, 29.4°, respectively.

The benzenesulfonate ions, as well as crystalline water molecules, are not directly bonded to the metal atoms. Many interatomic distances of 2.6—2.9 Å are observed between the water and sulfonato group oxygen atoms; almost all of them are expected to be hydrogen bondings.[18] Thus, in the crystal the cations, anions, and crystalline water molecules are hydrogen bonded with each other to form a network. However, the O(A6) and O(A7) atoms do not participate in the hydrogen network.

From studies of the solution chemistry of the scandium(III) ion, the existence of a dimeric ion, $[Sc_2(OH)_2]^{4+}$, has already been reported.[19-21] The structure of the present complex may be the same as the species in the above-mentioned solution.

It is an interesting fact that the crystals of scandium benzenesulfonate (**1**), *p*-toluenesulfonate (**2**), and *m*-nitrobenzenesulfonate (**3**), obtained from their aqueous solution under almost the same synthetic conditions, have structures which are much different from each other.[4,5] The very rare coordination number for scandium, 7, was only found in **1**. Moreover, the acid anion does not coordinate only in **1**, in spite of the fact that the acid ion of **1** is the smallest of the three: a minimum mutual steric hindrance is expected for the anion of **1**, even if it coordinates. This fact is also in contradiction to the consideration connecting the inductive effect of the substituents of the benzene rings of their acid anions. Since the methyl group in **2** (in *p*-position) increases, and the nitro group in **3** (in *m*-position) decreases the electron density of the sulfonato group compared with that of **1**, it is unreasonable that only the acid anion of **1** does not coordinate to the scandium atom.

The Fluorometric Determination of Magnesium with 2,2′-Dihydroxy-4,4′-dimethylazobenzene

Izuo AOKI,*,† Atsushi SAITO, and Kunihiro WATANABE
Faculty of Science and Technology, Science University of Tokyo, 2641, Yamazaki, Noda-shi, Chiba 278
†R. & D. Laboratory for Speciality Chemicals, Nippon Soda Co., Ltd., 12-54, Goi-minamikaigan, Ichihara-shi, Chiba 290
(Received December 24, 1988)

Synopsis. In an alkaline medium, magnesium reacts with 2,2′-dihydroxy-4,4′-dimethylazobenzene to emit a strong fluorescence, which is about 5 times as intense as that obtained with its parent compound (2,2′-dihydroxyazobenzene). Nonextraction (water-ethanol-dioxane, a mixed solvent) and extraction (an isopentyl alcohol solvent) procedures for the fluorometric determination of magnesium with this reagent were established. 0.1 μg to 4.0 μg of magnesium can be rapidly determined by the nonextraction procedure. In the extraction procedure, 1000-fold excesses of calcium did not interfere even when no masking agent was used.

Among a large number of 2,2′-dihydroxy azo compounds available for use in colorimetric and fluorometric methods for metal ions, 2,2′-dihydroxyazobenzene (DHAB), which has the most fundamental structure, is an excellent fluorometric reagent for magnesium in the presence of calcium.[1] 8-Quinolinol,[2] methyl salicylate,[3] and calcein[4] give fluorescence reactions with magnesium, but they also react with calcium to emit a strong fluorescence. Dagnall et al.[5] proposed 2,3-bis(salicylideneamino)benzofuran (SABF) as a specific reagent for magnesium without any interference from calcium. Although SABF seems to be more sensitive than DHAB, DHAB is superior to SABF with regard to the stability of its magnesium complex, for SABF gradually hydrolyzes in aqueous methanol solutions.

One of the present authors has previously reported that 2,2′-dihydroxy-4,4′-dimethylazobenzene (4,4′-DDAB) is more sensitive than the parent compound, DHAB, for the fluorometric determination of gallium.[6] In this study, it was found that 4,4′-DDAB reacted quantitatively with magnesium to emit a strong fluorescence in an alkaline medium. The detection limit for magnesium with this reagent was as good as that obtained with SABF. On the other hand, the magnesium-DHAB complex is extractable into isopentyl alcohol; however, the extraction procedure is not so useful for the determination of magnesium because the distribution coefficient of the complex between isopentyl alcohol and water is only about 9.[7] The present authors have, though, found that a remarkable enhancement of the distribution coefficient could be achieved by using 4,4′-DDAB instead of DHAB.

Experimental

Apparatus. The fluorescence spectra and the intensity were measured with a Hitachi Model 204 fluorescence spectrophotometer fitted with a 150 W Xenon lamp. A Shimadzu fluorescence spectrophotometer Model RF-540 (exciting source; 150 W Xenon lamp, photomultiplier; R924F) was used for the measurements of the fluorescence quantum efficiencies.

Reagents. Standard Solution of Magnesium. A stock solution of magnesium was prepared by dissolving 0.5012 g of magnesium (99.9%) with 30 cm^3 of 6 mol dm^{-3} hydrochloric acid and then diluting the mixture to 1 dm^3 with water. The standard solution was prepared by suitable dilution with 0.1 mol dm^{-3} hydrochloric acid from the stock solution.

Synthesis of Azo Compounds. DHAB, 4,4′-DDAB, and 2,2′-dihydroxy-5,5′-dimethylazobenzene (5,5′-DDAB) were synthesized by the conventional method[8] and were identified by means of their melting points and IR spectra. These azo compounds were used as the 1,4-dioxane solution.

Rhodamine B Reference Standard Solution. 0.1 g of rhodamine B was dissolved in ethanol to give a solution containing 10 μg cm^{-3}. This solution was then diluted with water.

All the other reagents and solvents were of an analytical grade and were used without further purification.

Determination Procedure

(A) Nonextraction Procedure (Water-Ethanol-Dioxane, a Mixed Solvent). (a) Preparation of Buffer Solution. Add 20 cm^3 of ethylenediamine (en) and 10 cm^3 of 6 mol dm^{-3} hydrochloric acid to 200 cm^3 of ethanol, and then allow the mixture to cool. Dilute the solution to 500 cm^3 with 1,4-dioxane. **(b) Determination Procedure of Magnesium.** To a sample solution containing from 0.1 μg to 4 μg of magnesium, add 15 cm^3 of the buffer solution and 1 cm^3 of a 0.01% 4,4′-DDAB solution. Dilute the solution to 25 cm^3 with water and allow the mixture to stand for 10 minutes at room temperature. Measure the fluorescence intensity at 560 nm with an excitation wavelength of 465 nm by using a rhodamine B solution as the reference standard.

(B) Extraction Procedure. To a sample solution containing from 0.04 μg to 3 μg of magnesium, add 1 cm^3 of a 0.5 mol dm^{-3} sodium hydrogencarbonate aqueous solution. Adjust the pH to 11.7 with a dilute hydrochloric acid or a dilute sodium hydroxide and then add 1 cm^3 of a 0.02% 4,4′-DDAB solution. Transfer the mixture into a 100 cm^3 separatory funnel and adjust its volume about 50 cm^3 with water. Add 10 cm^3 of isopentyl alcohol to the solution and shake it for 10 minutes. Discard the aqueous layer after the separation of the layers. Centrifuge the organic layer at 2000 rpm for 10 minutes, if necessary. Measure the fluorescence intensity at 560 nm with an excitation wavelength of 480 nm by using a rhodamine B solution as the reference standard.

Results and Discussion

Fluorescence Properties of the Magnesium-4,4′-DDAB Complex. The fluorescence properties of the magnesium-4,4′-DDAB complex in several solvents were investigated and compared with those of magnesium-DHAB and -5,5′-DDAB complexes. The fluorescence properties of these three complexes are listed in Table 1.

The molar extinction coefficients at the maximum absorption wavelength (ε) of the magnesium complexes were affected by the methyl groups in the ligands (azo compounds), while they changed only slightly in different solvents. The ε value of the 4,4′-DDAB complex was the largest among the three complexes. The fluorescence quantum efficiencies (ϕ_f) of the complexes were remarkably affected by both methyl groups and solvents. The ϕ_f values of the 4,4′-DDAB complex in the mixture of water-ethanol-dioxane (volume ratio: 3 : 2 : 3) were about 4 times and 9 times larger than that of the DHAB and 5,5′-DDAB complexes in the same solvent respectively.

The above-mentioned ε and ϕ_f values shown that the absolute sensitivities ($\varepsilon \cdot \phi_f$)[10] of the magnesium-4,4′-DDAB complex in both water-ethanol-dioxane and isopentyl alcohol were about (3—5) times larger than that of the DHAB complex in these solvents.

Structure of the Magnesium-4,4′-DDAB Complex. The mole ratio of magnesium to 4,4′-DDAB in the complex was determined fluorometrically by the continuous variation method to be 1 : 1 in both the mixture of water-ethanol-dioxane and isopentyl alcohol. These results were consistent with those obtained by the equilibrium-shift method.

Knoeck et al.[11] have proposed that the fluorescence enhancement by the addition of alcohols to aqueous magnesium-DHAB complex solutions probably comes from a direct magnesium coordination by the alcohols. The present authors have determined the mole ratio of magnesium to isopentyl alcohol in the extracted 4,4′-DDAB complex by the equilibrium-shift method to be 1 : 2. The complete composition of the magnesium-4,4′-DDAB complex in isopentyl alcohol is, therefore, Mg(4,4′-DDAB)(isopentyl alcohol)$_2$, which is consistent with the five-coordinate structure proposed for the DHAB complex.[11]

Effect of Organic Solvent. In Determination Procedure A (a nonextraction procedure), the effect of adding organic solvents to aqueous solutions on the fluorescence intensity of the magnesium-4,4′-DDAB complex was investigated. A remarkable increase in the fluorescence intensity of the complex was observed upon the addition of ethanol and 1,4-dioxane, while the intensity of the reagent blanks was not changed. The maximum fluorescence intensity of the complex, which was about 5 times as intense as that of its aqueous solution, was obtained with more than 11 cm^3 for dioxane or with 20 cm^3 for ethanol in a final volume of 25 cm^3. Other organic solvents, i.e., acetone, the mixtures of ethanol-methyl isobutyl ketone (MIBK), -ethyl acetate, or -tributyl phosphate (TBP), and the mixtures of ethanol and nonpolar organic solvents, were less effective than ethanol and dioxane. For the determination procedure of magnesium, it was convenient to add these organic solvents as a buffer solution by mixing ethylenediamine (en) and hydrochloric acid. As far as the enhancement ability of the fluorescence intensity of the magnesium complex is concerned, dioxane was superior to ethanol, but dioxane caused a turbidity when en and hydrochloric acid were mixed. A mixture of dioxane and ethanol (3 : 2, v/v) was, therefore, chosen as a solvent of the buffer solution. In consideration of the volume of the sample solution, it was suitable for the determination procedure to add 15 cm^3 of this solution in a final volume of 25 cm^3.

According to Determination Procedure B, the magnesium-4,4′- DDAB complex was extracted with TBP and alcohols, such as isopentyl alcohol, pentyl alcohol, and isobutyl alcohol, but not with MIBK, ethyl acetate, and other nonpolar organic solvents, such as hexane, benzene, and chloroform. Although the extracts with TBP and the alcohols were nearly equal in fluorescence intensity, isopentyl alcohol was chosen for the extraction solvent because it is less soluble in water than the other alcohols and because TBP is inferior to isopentyl alcohol in its separability from water because of its specific gravity (0.97). The extractability of the magnesium-4,4′-DDAB complex was 91.8% (isopentyl alcohol : aqueous phase=1 : 5, v/v), and the distribution coefficient of the complex was 56.3, while the corresponding values of the magnesium-DHAB complex were 66.4% and 9.9 respectively.

Table 1. Fluorescence Properties of Magnesium Complexes with DHAB, 4,4′-DDAB, and 5,5′-DDAB[a]

Ligand	Solvent[b]	$\lambda_{ex(max)}/\lambda_{em(max)}$(nm)		ε	ϕ_f[c]	$\varepsilon \cdot \phi_f$[d]
		Apparent	Corrected	dm^3 mol^{-1} cm^{-1}		dm^3 mol^{-1} cm^{-1}
DHAB	W/E/D	465/565	480/590	1.6×10^4 (480 nm)	0.013	2.1×10^2
	I	475/570	485/595	1.6×10^4 (485 nm)	0.019	3.0×10^2
4,4′-DDAB	W	465/570	480/595	2.2×10^4 (480 nm)	0.013	2.9×10^2
	W/E/D	465/560	480/590	2.2×10^4 (480 nm)	0.049	1.1×10^3
	I	480/560	485/590	2.0×10^4 (485 nm)	0.062	1.2×10^3
5,5′-DDAB	W/E/D	490/575	505/605	1.8×10^4 (505 nm)	0.0055	1.0×10^2

a) The mole ratio of magnesium to ligands is 1 : 1. b) W/E/D: a mixture of water-ethanol-dioxane (3 : 2 : 3, volume ratio); I: isopentyl alcohol; W: water. c) Reference standard solution: 1 μg cm^{-3} rhodamine B ethanol solution (ϕ_f=0.76).[9] d) Absolute sensitivity: $\varepsilon \cdot \phi_f$.

Effect of pH. A maximum fluorescence intensity was obtained at pH values from 10.3 to 11.3 in the mixture of water-ethanol-dioxane (Fig. 1). This pH value can be adequately maintained with the buffer solution described above. In the case of isopentyl alcohol extraction, the magnesium complex showed its maximum fluorescence in the pH range from 11.5 to 12.0. A 0.5 mol dm^{-3} sodium hydrogencarbonate solution was chosen as the buffer because the buffer consisting of en and hydrochloric acid caused an unfavorable separability between isopentyl alcohol and the aqueous phase.

Effect of the 4,4′-DDAB Concentration. The effect of the variation in the 4,4′-DDAB concentration on the fluorescence intensity was also investigated. The maximum intensity was obtained in the range of $(2—4)\times10^{-7}$ mol for 1 μg (4.1×10^{-8} mol) of magnesium in the mixture of water-ethanol-dioxane, where 4×10^{-7} mol corresponded to adding 1 cm^3 of a 0.01% 4,4′-DDAB solution. The addition of 1 cm^3 of a 0.02% 4,4′-DDAB solution was suitable in the isopentyl alcohol-extraction procedure.

Effects of Standing Time and of Shaking Time. The fluorescence of the magnesium complex developed fully within a few minutes after the preparation of the solution in the nonextraction procedure and after shaking in the extraction procedure. The intensity was stable for at least 2 hours.

Calibration Curves. According to Determination Procedure A, magnesium can be determined in the range of (0.1—4.0) μg. Linear relationships are observed between the fluorescence intensity and the magnesium concentration in this range. The coefficient of variation (c.v.) for 1 μg and 0.1 μg of magnesium were 1.2% and 3.2% (n=10) respectively. In Determination Procedure B, the determinable range of magnesium is (0.04—3.0) μg. The c.v. values for 1 μg and 0.04 μg of magnesium were 2.0% and 7.3% (n=10) respectively.

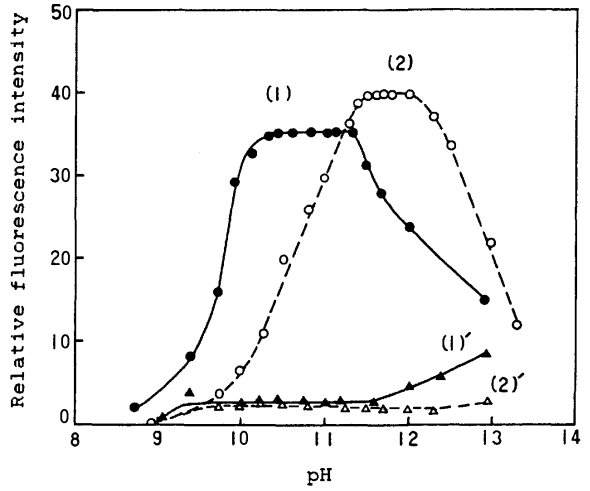

Fig. 1. Effect of pH on fluorescence intensity of magnesium-4,4′-DDAB complex.
(1) *Nonextraction procedure*; solvent: water-ethanol-dioxane (3:2:3, vol. ratio), Mg(II): 1 μg, 0.01% 4,4′-DDAB: 1 cm^3, wavelength: 465 nm/560 nm, 50 div vs. 0.5 μg cm^{-3} rhodamine B (setting 465 nm/560 nm).
(2) *Extraction procedure*; solvent: isopentyl alcohol, Mg(II): 1 μg cm^{-3}, 0.02% 4,4′-DDAB: 1 cm^3, wavelength: 480 nm/560 nm, 80 div vs. 0.5 μg cm^{-3} rhodamine B (setting 480 nm/560 nm).
(1)′ Reagent blank of (1).
(2)′ Reagent blank of (2).

Effect of Diverse Ions. The effects of diverse ions on the fluorescence intensity produced by 1 μg of magnesium were also investigated. In the nonextraction procedure, the following cations in 1000-fold excesses did not interfere: silver(I), arsenic(III), gold(III), barium(II), bismuth(III), cadmium(II), mercury(II), molybdenum(VI), nickel(II), palladium(II), antimony(III), selenium(IV), and thallium(I). Calcium(II), tin(IV), and zinc(II) caused no interference in 100-fold excesses. 1000-fold amounts of chromium(VI), indium(III), and zirconium(IV), 100-fold amounts of iron(II), lanthanum(III), and tungsten(VI), and 10-fold amounts of aluminum(III), cobalt(II), cupper(II), gallium(III), and hafnium(IV) could be tolerated by adding 3 cm^3 of 40% (2.7 mol dm^{-3}) triethanolamine as a masking agent. 1000-fold amounts of cobalt(II) and copper(II), and 500-fold amounts of iron(II) and iron(III) could be tolerated by adding 3 cm^3 of 10% (1.5 mol dm^{-3}) potassium cyanide. In the extraction procedure, 1000-fold excesses of calcium(II), 100-fold excesses of aluminum(III), and 10-fold excesses of chromium(VI), gallium(III), and titanium(IV), did not interfere even when no masking agent was used.

In conclusion, the authors recommend the nonextraction procedure (Determination Procedure A), because it is simple and rapid, and therefore yields highly reproducible results.

(Received January 6, 1989)

Synopsis. A deuterium isotope effect on the rate of acetylacetonate exchange between tetrakis(acetylacetonato)thorium(IV), $Th(acac)_4$, and free acetylacetone in CD_3CN has been examined by means of ^1H NMR technique. The second-order rate constant, k, which is expressed as a function of the observed first-order rate constant, k_{obsd}, and the concentration of acetylacetone in the enol form, $[acetylacetone]_{enol}$, by $k=k_{obsd}/[acetylacetone]_{enol}$ was determined for the reaction of deuterated acetylacetone, Dacac, as well as undeuterated acetylacetone, Hacac. The ratio of second-order rate constants for Hacac and Dacac, k_H/k_D, was approximately 9. This large deuterium isotope effect strongly supports a mechanism proposed in a previous paper that the proton transfer process is the rate determining step of the whole reaction.

Much interest has been concerned with respect to ligand exchange reactions in various acetylacetonato complexes.[1-9] In an earlier paper, we reported the study on the kinetics of acac exchange in $Th(acac)_4$ and proposed a mechanism passing through a nine coordinate intermediate, $Th(acac)_4\cdots$Hacac, where Hacac in the enol form coordinated as a unidentate ligand and a proton transferred from Hacac to one of four acac's at the rate determining step.[2]

This paper presents results of the deuterium isotope effect of the acac exchange in $Th(acac)_4$ in order to clarify the above mechanism.

Experimental

Materials. The complex $Th(acac)_4$ was synthesized by the method reported previously.[2] Acetylacetone was deuterated by the reported method.[7] The deuteration of the methine proton in coordinated acac was carried out by the following procedure: $Th(acac)_4$ (0.2 g) and deuterated acetylacetone Dacac (0.5 g) was dissolved in 2 cm^3 of dichloromethane, and the solvent involving Dacac and Hacac was removed by evaporation under reduced pressure, and then the resulted precipitate was dried in vacuo at 100 °C for one day. Acetonitrile-d_3 (Merck Co., Ltd.) was dried over Molecular Sieves 4A (Wako Pure Chemical Ltd.). Dichloromethane (Wako) was dried over anhydrous calcium chloride (Wako) for one day and distilled. Acetylacetone (Wako) and deuterated acetylacetone were dried over anhydrous calcium sulfate and distilled twice before use.

Kinetic Procedure. $Th(acac)_4$, Dacac, and CD_3CN were weighed, and sealed in a 5 mmϕ NMR sample tube. A JEOL JNM FX-100 FT NMR spectrometer equipped with a JNM-VT-3B temperature controller was used for measurements of ^1H NMR spectra. The water content of the reaction mixture was analyzed by the Karl-Fischer titration. The rate constants of the exchange reaction were determined from the line shape analysis of methine proton signals by using the two-site model.[2]

Results

Deuterium Isotope Effect on the Acac Exchange in $Th(acac)_4$. The ^1H NMR spectra of methine protons for the mixture of $Th(acac)_4$ and Hacac, and their deuterated species in CD_3CN were measured at various temperatures (Fig. 1). The deuterated fraction of acetylacetone was determined to be 86% based on the ratio of peak areas of methine and methyl protons. The signals of coordinated acac (upper field) and that of free $Hacac_{enol}$ (lower field) were observed separately at 0 °C. However, two signals tended to coalesce as the temperature was raised. Though the difference in the chemical shifts of the methine proton signals between Dacac and $Th(acac)_4$ is less than that between Hacac and $Th(acac)_4$, the coalescence temperature of 28 °C was significantly higher than that of 12 °C for the exchange between undeuterated $Th(acac)_4$ and $Hacac_{enol}$.[2] This clearly indicates that the exchange

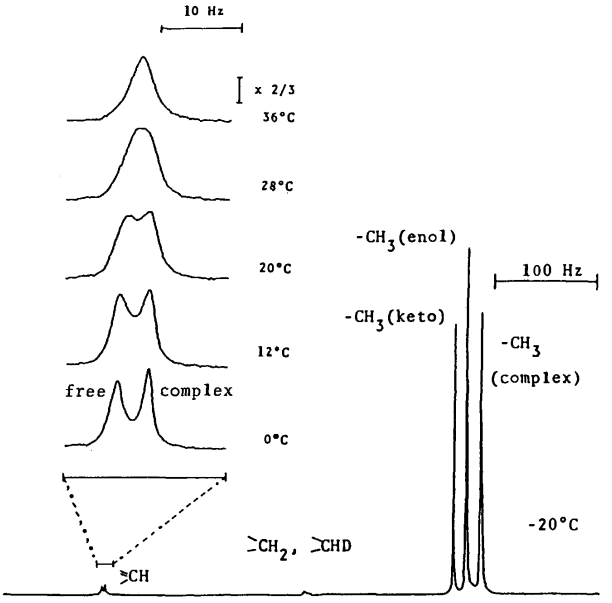

Fig. 1. ^1H NMR spectrum of the mixture of $Th(acac)_4$ and deuterated acetylacetone in CD_3CN, and the change of methine proton signals with temperatures. $[Th(acac)_4]=0.106$ mol kg^{-1}, $[Hacac]_{total}$ (deuterated fraction: 86%)=0.690 mol kg^{-1}, and $[H_2O]=0.08$ mol kg^{-1}. The observed first-order rate constant k_{obsd} was determined at various temperatures as follows.

T/°C	12.0	20.0	28.0	36.0
k_{obsd}/s^{-1}	17.2	24.0	33.4	43.0

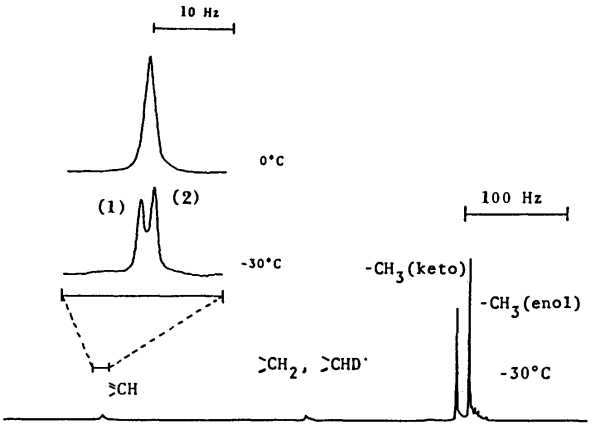

Fig. 2. ^{1}H NMR spectrum of deuterated acetylacetone in CD_3CN at −30 °C. The expanded signals of methine proton at −30 and 0 °C are also shown. $[Hacac]_{total}$ (deuterated fraction: 55%)=0.667 mol kg^{-1} and $[H_2O]$=0.06 mol kg^{-1}.

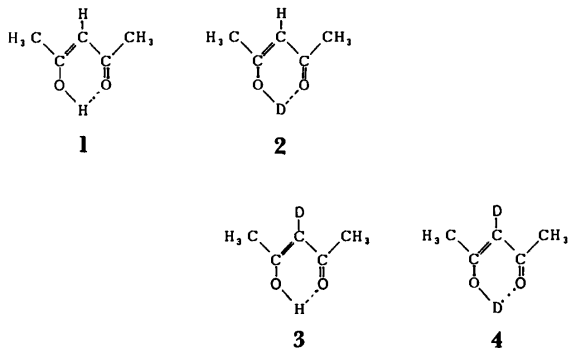
reaction in the deuterated system is much slower than in the undeuterated one.

Acac Exchange between Hacac and Dacac. The NMR spectra of the methine proton of deuterated $Hacac_{enol}$ (deuterated fraction 55%) in the absence of $Th(acac)_4$ are shown in Fig. 2. Two signals, which were observed at −30 °C, coalesced to a single peak at 0 °C. Four types of isotope isomers exist in incompletely deuterated $Hacac_{enol}$ as written below.



1 2

3 4

Among these isomers, only **1** and **2** give the methine proton signals. On the basis of the signal intensity, the peaks in upper and lower fields are assigned as the signals of **2** and **1**, respectively. The exchange rate between **1** and **2** was calculated by use of the two-site model. The reciprocal values of life time for **1**, which correspond to the first-order rate constant for exchange of two methine protons, were determined to be 3.63, 1.97, and 0.82 s^{-1} at 0, −10, and −20 °C, respectively. Because of the very narrow splitting between the signals of **1** and **2**, the singls coalesced at 0 °C, although the exchange rate was comparable with that of acac exchange between $Th(acac)_4$ and $Dacac_{enol}$. The broadening of the methine proton signals due to the exchange between **1** and **2**, however, was taken into account for the calculation of the exchange rates between $Th(acac)_4$ and $Dacac_{enol}$.

Discussion

In the previous paper,[2] the rate of the exchange between $Th(acac)_4$ and free Hacac was found to be first order in both $[Th(acac)_4]$ and $[Hacac]_{enol}$. Since the same rate law is expected for the exchange between $Th(acac)_4$ and Dacac, the observed first-order rate constant, k_{obsd}, is expressed by Eq. 1.

$$k_{obsd}=k[Dacac]_{enol} \quad (1)$$

where k is the second-order rate constant and $Dacac_{enol}$ consists of the four isotope isomers **1**, **2**, **3**, and **4** in the incompletely deuterated system. Therefore, Eq. 1 yields

$$k_{obsd}=k_1[\mathbf{1}]+k_2[\mathbf{2}]+k_3[\mathbf{3}]+k_4[\mathbf{4}] \quad (2)$$

where k_1, k_2, k_3, and k_4 are the second-order rate constants for **1**, **2**, **3**, and **4**, respectively.

It is reasonable to assume that $k_1=k_3(=k_H)$ and $k_2=k_4=(k_D)$, because the primary isotope effects due to O-H and O-D groups are of essential importance for the exchange rate. Then, Eq. 2 is written by

$$k_{obsd}=k_H([\mathbf{1}]+[\mathbf{3}])+k_D([\mathbf{2}]+[\mathbf{4}]). \quad (3)$$

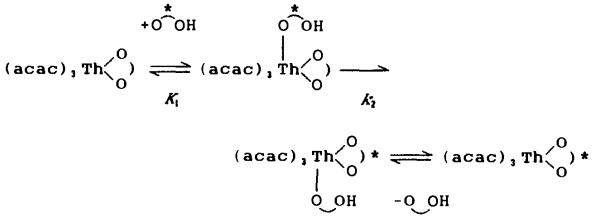
The values of k_H were determined previously[2] and the concentrations [**1**]+[**3**] and [**2**]+[**4**] were calculated from the NMR signal intensity. These data along with Eq. 3 give the values of k_D, which are listed in Table 1. The ratio k_H/k_D is about 9. This value is close to the maximum of the kinetic isotope effect, which is estimated from the difference in the zero-point energy of O-H and O-D bonds in Hacac and Dacac, respectively.[8] The deuterium isotope effects for acac exchange reactions were reported in a variety of complexes, M^{III}=Cr^{III}, Co^{III}, Rh^{III}, Fe^{III}, and V^{III}, and $VO(acac)_2$.[3-7] The small isotope effects observed in these reactions were consistent with mechanisms that the addition of free Hacac to the complexes or the dissociation of acac from the complexes, which preceded the proton transfer step, substantially governed the whole reaction rates. An only exception was recently reported for the acac exchange in $Sc(acac)_3$, which revealed the considerably large isotope effect (k_1^H/k_1^D=5, where k_1 was related to k_{obsd} as $k_{obsd}=k_1[acac]_{enol}$).[8] In the latter case, a role of the proton transfer step was consider to be particular importance for the exchange rate.

In the present study, the deuterium isotope effect is largest of all acac exchange reactions ever studied and k_H/k_D is closed the maximum value. Morever, the rate of acac exchange between $Th(acac)_4$ and Dacac is comparable with that between Hacac and Dacac. These facts strongly supports the following

Table 1. Deuterium Isotope Effect on the Second-Order Rate Constant k for the acac Exchange Reaction in $Th(acac)_4$ in CD_3CN

T/°C	k_H/s^{-1} mol^{-1} kg	k_D/s^{-1} mol^{-1} kg	k_H/k_D
12	184	18.6	9.9
20	246	27.6	8.9
28	351	37.0	9.5

reaction mechanism proposed in the previous paper,[2]



where $\overset{O}{\underset{O}{\frown}}$ and $\overset{O}{\underset{OH}{\frown}}$ represent acac and $Hacac_{enol}$, respectively and proton transfer process (k_2 path) determined the exchange rate.

A similar mechanism was also proposed for the tta (tta=2-thenoyltrifluoroacetonate) exchange in $Th(tta)_4$.[10] In this case, the addition of DMSO (dimethyl sulfoxide) to the complex forming $Th(tta)_4 \cdots$dmso was directly observed by ^1H NMR measurements and the exchange of dmso was found to be extremely fast (10^2 s^{-1} at $-92\,°C$). This fact is consistent with the above mechanism that K_1 path is in fast equilibrium prior to the proton transfer.

Syntheses of 1β-Hydroxyvitamin D_2 and D_3

Yoji TACHIBANA
Central Research Laboratory, Nisshin Flour Milling, Co., Ltd., Tsurugaoka, Ooimachi, Irumagun, Saitama 354
(Received July 30, 1988)

Synopsis. Reduction of 1-oxo-3,5-cyclovitamin D_2 and D_3 was carried out under various conditions. $LiAlH_4$ reduction in ether preferentially afforded 1β-hydroxy-3,5-cyclovitamin D_2 and D_3, which were converted to 1β-hydroxyvitamin D_2 and D_3.

It has been established that the hydroxyl group at C-1 of vitamins D_2 and D_3 plays an important role in eliciting their biological activity.[1] In order to investigate the relationship between the molecular configuration and the physiological activity, DeLuca[2] and Mazur[3] synthesized 1β-hydroxyvitamin D_3 (**2**), the C_1 epimer of 1α-hydroxyvitamin D_3 (**1**), by oxidation of **1** followed by the reduction of the formed 1-oxo-previtamin D_3, and evaluated its biological activity.

DeLuca et al. reported that 1α-hydroxyvitamin D_2 (**3**) is about ten-times less toxic than **1**, but appears to be almost equally potent regarding vitamin D activity.[4] Thus, it is noteworthy to compare the physiological activity of the C_1 epimer of **3** with that of **1**.

In the present paper, the reduction of 1-oxo-3,5-cyclovitamin D_3 (**5**) and D_2 (**6**)[5] under various conditions and the conversion of the formed 1β-hydroxy-cyclovitamin D_3 (**8**) and D_2 (**10**) into the corresponding 1β-hydroxyvitamin D_3 (**2**) and D_2 (**4**), are described.

The 1-oxo-3,5-cyclovitamin D_3 (**5**) and D_2 (**6**) employed for the reduction were prepared from the corresponding 3,5-cyclovitamin D_3 and D_2 by modifying the procedure reported by DeLuca et al.[5] 1-Hydroxycyclovitamin D_3 and D_2 produced in the above mentioned reaction were converted to **5** and **6** by further oxidation with activated manganese oxide.

As indicated in Table 1, the stereochemistry of the reduction of **5** and **6** is highly dependent on the reagent and solvent used.[6,7] The reduction of **5** and **6** with lithium aluminum hydride ($LiAlH_4$) in ether gave 1β-hydroxy isomer (**8** and **10**) and 1α-hydroxy isomer (**7** and **9**) in a ratio of 5/1. On the other hand, the selectivity (**8/7** and **10/9**) was decreased when tetrahydrofuran (THF) was employed as solvent. The reduction with $Na[AlH_2(OCH_2CH_2OCH_3)_2]$ (sodium dihydridobis(2-methoxyethoxy)aluminate) gave similar results. These results may be well explained by assuming the coordination of the methoxyl group (at C-6) and carbonyl group (at C-1) of **5** and **6** to the Al atom of the reagent. Consequently, the approach of the hydride from the α-side of **5** and **6** appears to be hindered due to the chelation described above. Accordingly, the β-side attack of the hydride may be facilitated to yield a higher amount of 1β-hydroxy isomer (**8** and **10**). In contrast, THF may coordinate to the reducing agent, which probably makes the chelation between the Al atom and the oxygen atoms of A ring of vitamin D more difficult compared with the reduction in ether. As a result, this seems to lead to a lower ratio of 1β-hydroxy

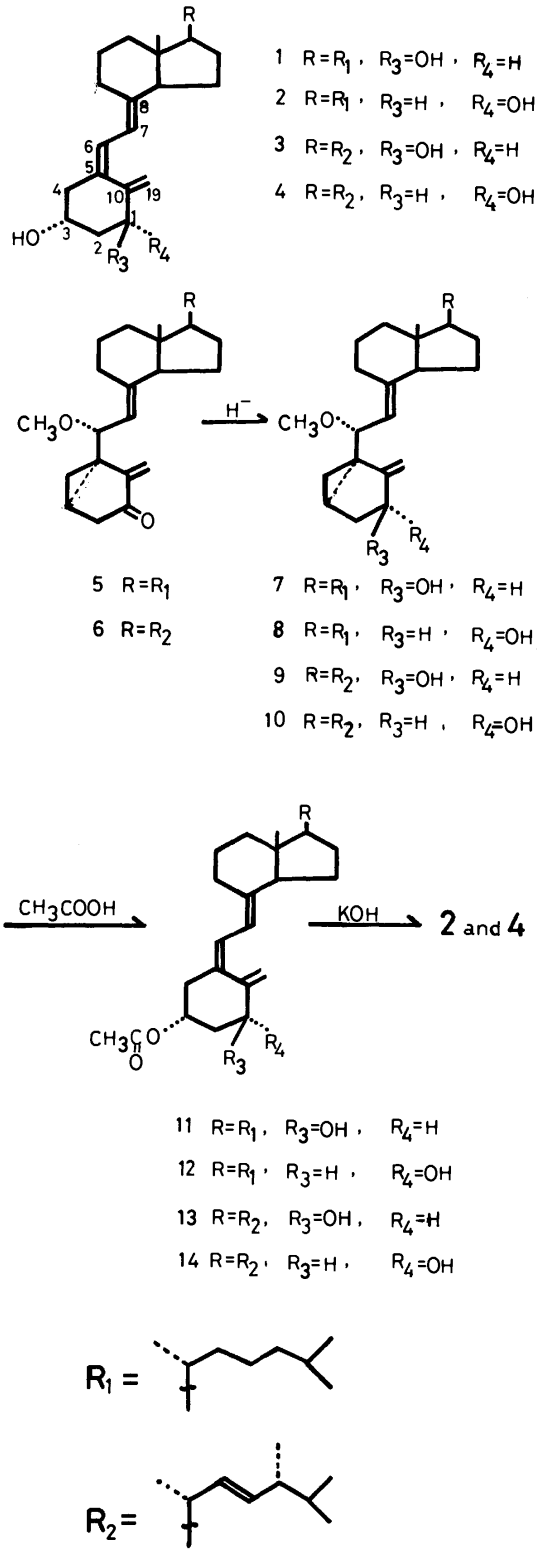
a) Formation ratio was determined by means of high pressure liquid chromatography (HPLC) after 1-hydroxycyclovitamin D_3 and D_3 (**7**—**10**) were converted to corresponding 3β-acetoxy-1-hydroxyvitamin D_3 and D_2 (**11**—**14**). b) rt: room temperature. c) DIBAL solution was added to the solution of 1-oxo-3,5-cyclovitamin D_3 (**5**) and D_2 (**6**).



isomer (**8** and **10**) to 1α-hydroxy isomer (**7** and **9**). The effect of temperature was not relevant to the reduction selectivity.

Other reducing reagents, such as sodium borohydride ($NaBH_4$) and diisobutylaluminum hydride (DIBAL), showed no appreciable stereoselectivity in the reduction of **5** and **6** compared with $LiAlH_4$. It seems that DIBAL may be too bulky to form the chelation with the oxygen atoms of A ring moiety. Especially, the reduction with DIBAL in THF gave almost the same isomer ratio (1β-ol/1α-ol=1). However, this system (DIBAL-THF) can be an effective way to provide radioisotope labeled 1α-hydroxyvitamin D_2 and D_3 at position C-1, which seems to serve as convenient tools for a number of detailed biomedical experiments.[8,9]

Thus, the obtained 1β-hydroxy-3,5-cyclovitamin D_3 (**8**) and D_2 (**10**) were solvolyzed in acetic acid to yield 3β-acetoxy-1β-hydroxyvitamin D_3 (**12**) and D_2 (**14**), which were subsequently hydrolyzed upon treatment with ethanolic potassium hydroxide to produce 1β-hydroxyvitamin D_3 (**2**) and D_2 (**4**), respectively.

The inversion of the hydroxyl group at C-1 of **7** or **9** by a Mitsunobu reaction was not successful.[10] The procedure described here may be applied to the syntheses of other 1β-hydroxyvitamin D derivatives from the corresponding vitamin D derivatives.

Experimental

Melting points were uncorrected. UV spectra were taken on a Hitachi 320 spectrometer. ^1H NMR spectra were recorded in $CDCl_3$ on a JNF-FX200 spectrometer with TMS as an internal standard. Mass spectra were measured on a Hitachi M-80 mass spectrometer. HPLC were performed on a Hitachi 615-11 liquid chromatography equiped with a UV detector (set at 265 nm) and a Hibar column (prepacked column, LiChrosorb Si 60 (5 μm); 4 mm$\times$25 mm) with 20% hexane in dichloromethane as a mobile phase at a flow rate 1.0 ml min^{-1} (pressure: 30 kg cm^{-2}). Solvents were removed under reduced pressure.

1-Oxo-3,5-cyclovitamin D_3 (5) and D_2 (6). To a stirred suspension of SeO_2 (280 mg) in dichloromethane (100 ml), was added 4 ml of 3 M (1 M=1 mol dm^{-3}) 2,2,4-trimethylpentane solution of *t*-BuOOH. After the mixture was stirred for 1 h at room temperature, a dichloromethane solution (100 ml) of 3,5-cyclovitamin D_3[5] (1.0 g) was added dropwise. The mixture was allowed to react for 40 min at room temperature. The solution was washed with a 10% NaOH solution (40 ml). The dichloromethane solution was separated and concentrated to a heavy oil. The residue was extracted with ether, washed with brine, and dried over sodium sulfate. The ether solution was evaporated and the residue was chromatographed on silica gel. Elution with ethyl acetate/hexane (5/95, v/v) gave **5** as oil. 435 mg (42%). λ_{max} 248 nm (ε=4200, EtOH) (lit,[5] ε=3500).

Further elution with ethyl acetate/hexane (1/4, v/v) afforded 1α-hydroxycyclovitamin D_3 (**7**). 312 mg (25%). **7** (312 mg) was dissolved in dichloromethane (30 ml) and allowed to react with (activated) manganese oxide (900 mg) at room temperature for 1 h. The mixture solution was filtered on celite and concentrated. The residue was chromatographed on silica gel. Elution with ethyl acetate/hexane (5/95, v/v) gave **5**. 234 mg (75%).

Treatment of 3,5-cyclovitamin D_2[5] (1.0 g) in a similar way involving the oxidation process of 1α-hydroxycyclovitamin D_2 (**9**) provided 1-oxo-3,5-cyclovitamin D_2 (**6**). 620 mg (60%). λ_{max} 248 nm (ε=4000, EtOH).

1β-Hydroxyvitamin D_3 (2). To an ether solution (20 ml) containing $LiAlH_4$ (200 mg) was added dropwise an ether solution (10 ml) of 1-oxo-3,5-cyclovitamin D_3 (**5**) (400 mg) at room temperature. The mixture was stirred for 30 min. After decomposition of the excess $LiAlH_4$ with H_2O, the ether solution was washed with brine, dried (Na_2SO_4) and evaporated to dryness. The residue was purified by silica

gel chromatography (eluted with hexane/ethyl acetate, 4/1) to give a mixture of 1β- and 1α-hydroxycyclovitamin D_3[5] (**8**/**7**=5.0). 296 mg (74%).

The 1-hydroxycyclovitamin D_3 (296 mg) was dissolved in acetic acid (6 ml) and the mixture was stirred at 55 °C for 20 min. The mixture was extracted with ether, washed with a sat. $NaHCO_3$ solution and brine, dried (Na_2SO_4), and evaporated. The residue was chromatographed on silica gel. Elution with hexane/ethyl acetate (4/1) afforded 3β-acetoxy-1β-hydroxyvitamin D_3 (**12**). 205 mg (65%). λ_{max} 264 nm (ε=17500, EtOH) (lit,[3] ε=18000).

The actate (**12**) (205 mg) was dissolved in ethanolic potassium hydroxide (KOH 150 mg, EtOH 5 ml) and the mixture was stirred for 15 min at room temperature. The ethanol solution was extracted with ether, washed with brine, dried (Na_2SO_4) and concentrated to dryness. The residue was purified by silica gel chromatography (chloroform/ethyl acetate, 9/1) to yield 1β-hydroxyvitamin D_3 as oil. 149 mg (80%). λ_{max} 264 nm (ε=18500, EtOH) (lit,[3] ε=18000).

1β-Hydroxyvitamin D_2 (4). 1-Oxocyclovitamin D_2 (**6**) (400 mg) was reduced with $LiAlH_4$ (200 mg) in ether and treated in a similar manner described above to give 1-hydroxy-3,5-cyclovitamin D_2 (**10**/**9**=5.1). 280 mg (70%). *m/z* 426 (M^+).[5]

1-Hydroxycyclovitamin D_2 (280 mg) was treated with acetic acid (6 ml) at 60 °C for 15 min. After the usual work up, the residue was chromatographed (hexane/ethyl acetate, 4/1) to afford 3β-acetoxy-1β-hydroxyvitamin D_2 (**14**). 182 mg (61%): *m/z* 454 (M^+), 394 (M^+-CH_3COOH); ^1H NMR δ=6.33—6.00 (2H, ABq, *J*=12 Hz, H-6, H-7), 5.37 (1H, m, H-19E), 5.20 (2H, m, H-22, H-23), 5.00 (1H, m, H-19Z), 4.99 (1H, m, H-3), 4.17 (1H, bs, H-1), 2.05 (3H, s, $COCH_3$).

The acetate (**14**) (182 mg) was hydrolyzed in ethanolic potassium hydroxide (KOH 150 mg, EtOH 5 ml) at room temperature for 15 min. The solution was extracted with ether, washed with brine, dried (Na_2SO_4) and evaporated. The residue was chromatographed on silica gel (chloroform/ethyl acetate, 4/1) to produce 1β-hydroxyvitamin D_2 (**4**). 124 mg (75%): Calcd for $C_{28}H_{44}O_2$: M, 412.3339. Found: *m/z* 412.3338; ^1H NMR δ=6.01—6.42 (2H, ABq, *J*=12Hz, H-6, H-7), 5.26 (1H, m, H-19E), 5.17 (2 H, m, H-22, H-23), 4.96 (1H, m, H-19Z), 4.30 (1H, bs, H-1), 4.07 (1H, m, H-3).

1α-Hydroxyvitamin D_2 (3) from 6. A 1 M hexane solution of DIBAL (10 ml) was added to a THF solution (20 ml) of 1-oxo-3,5-cyclovitamin D_2 (**6**) (400 mg) at room temperature and the mixture was stirred for 30 min. The solution was washed with brine and filtered on Celite. The solution was dried over Na_2SO_4 and evaporated. Purification on silica gel (hexane/ethyl acetate, 4/1) gave 1-hydroxycyclovitamin D_2 (**10**/**9**=1). 180 mg (45%).

The 1-hydroxycyclovitamin D_2 (180 mg) was treated with acetic acid (5 ml) at 60 °C for 20 min. The mixture was extracted with ether. The ether solution was washed with sat. $NaHCO_3$ and brine, and concentrated to dryness. The residue was purified by silica-gel chromatography. Elution with hexane/ethyl acetate (9/1) afforded 3β-acetoxy-1β-hydroxyvitamin D_2 (**14**) (60 mg, 31%). Further elution with the same developing solvent gave 3β-acetoxy-1α-hydroxyvitamin D_2 (**13**) (65 mg, 34%).

The acetate (**13**) (65 mg) was hydrolyzed with ethanolic potassium hydroxide (KOH 40 mg, EtOH 5 ml). The solution was extracted with ether, washed with brine and evaporated. Chromatography on silica gel (chloroform/ethyl acetate, 4/1) and crystallization (hexane-ethyl acetate) yielded **3**. 26 mg (44%). mp 140—141 °C (lit, [5] 138—140 °C).

(Received September 1, 1988)

Synopsis. (Eight 9-substituted 9-(2′-bromomethylphenyl)fluorene derivatives) (**1**) were prepared. Their conformational equilibria (*ap* ⇄ *sp*) are discussed on the basis of kinetic data for internal rotation obtained by ^{1}H NMR spectroscopy.

We have recently investigated the conformational equilibria (*ap* ⇄ *sp*) of 9-(2′-substituted phenyl)fluorene derivatives having the 2′-substituents such as methyl-,[2] methoxy-,[3] methylthio-,[4] methylsulfinyl-,[4] dimethylamino-,[5] methoxymethyl-,[6] and methylamino group,[7] on the basis of their DNMR spectra. In the present paper, we wish to report on the preparation of 9-substituted 9-(2′-bromomethylphenyl)fluorene derivatives (**1**) and a study concerning the conformational equilibria of these compounds by comparing their ^{1}H NMR behavior with those of 9-substituted 9-(2′-methylphenyl)fluorene derivatives (**2**).

Results and Discussion

Preparation of 1. Fluorenes **1**, except 9-(2′-bromomethylphenyl)fluorene (**1b**), were prepared by the bromination of the corresponding 9-substituted 9-(2′-methylphenyl)fluorenes **2** with NBS in carbon tetrachloride in the presence of a small amount of BPO. Thus, 9-hydroxy- (**1a**), 9-methoxy- (**1c**), 9-methyl- (**1d**), 9-carboxy- (**1e**), 9-methoxycarbonyl- (**1f**), 9-acetyl- (**1g**), and 9-benzoyl-9-(2′-bromomethyl)fluorene (**1h**) were obtained from 9-hydroxy- (**2a**),[7] 9-methoxy- (**2c**),[8] 9-methyl- (**2d**),[2] 9-carboxy- (**2e**),[2] 9-methoxycarbonyl- (**2f**),[2] 9-acetyl- (**2g**),[2] and 9-benzoyl-9-(2′-methylphenyl)fluorene (**2h**),[2] respectively (Scheme 1). Compound **1b** was obtained by the bromination of 9-(2′-hydroxymethylphenyl)fluorene (**4**), which was prepared by the hydrolysis of 9-(2′-iodomethylphenyl)fluorene (**3**),[6] with dry hydrogen bromide. The results of the preparation of **1** and their partial ^{1}H NMR data are shown in Table 1.

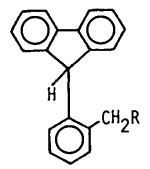
a) Numerals in parentheses are ratios of signal intensities.



1b: R = Br 3: R = I
2b: R = H 4: R = OH

Conformational Equilibria of 1. Signals due to the two rotamers, *ap* and *sp*, of 9-(2′-substituted phenyl)fluorene derivatives were observed in their NMR spectra at room temperature or at low temperature owing to their high barriers for rotation about the C(9)-C(Ar) bond. For example, two singlets due to the bromomethyl group of *ap* and *sp* forms of **1b** were observed at δ 3.44 and 4.96 ($K(ap/sp)$=1/5.5) at room temperature. The geometries of the two rotamers, *ap* and *sp*, of **1b** are shown in Fig. 1.

Since the signal of bromomethyl group of compound **1d** appeared at 3.48 ppm, which was very close to that of the *ap*-form of **1b**, as a sharp singlet even at

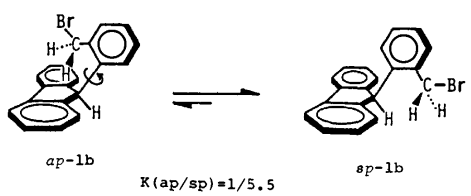


Fig. 1. The two rotamers of **1b**.

low temperature (−50 °C), this compound may exist only as the *ap*-form.

It was, however, difficult to assign the predominant conformers of the other bromomethyl series **1a**, **1c**, **1e**, **1f**, **1g**, and **1h**, by means of their ^{1}H NMR spectra at room temperature. Their DNMR spectra at low temperature (ca. −50 °C) were, therefore, measured by the usual method. The signals of the bromomethyl group in **1a**, **1c**, and **1f** were found to split at low temperature. Although the signal of **1h** broadened (T_c=−45 °C), two isomers of **1h** could not be observed until as low as −50 °C. The DNMR spectra of **1e** and **1g** could not be obtained because of their poor solubilities in $CDCl_3$ at low temperature. The equilibrium constants $K(ap/sp)$ between *ap* and *sp* forms of these compounds at room temperature or at low temperature, together with that of compound **2**,[9] are shown in Table 2. Since each *ap*- and *sp*- bromomethyl signal of **1g** and **1h** could not be observed at low temperature (−50 °C), it was assumed that these chemical shifts were the same values as those of **1b**. Then, K values of **1g** (or **1h**) were estimated from the chemical shifts of the bromomethyl group of *ap*-, and *sp*-**1b** and **1g** (or **1h**).

As shown in Table 2, though the equilibrium of **2a** was onesided in the *ap*-form, two conformers of **1a** existed in equilibrium, $K(ap/sp)$=3.9/1. In order to explain the stabillization of the *sp*-form of **1a**, we assumed the existence of intramolecular hydrogen bonding between the oxygen atom of the 9-hydroxyl group and the hydrogen atom of the 2′-bromomethyl group or the hydrogen atom of the 9-hydroxyl group and the bromine atom of the 2′-bromomethyl group in the *sp*-form (the latter hydrogen bonding has been reported in 2-haloethanol[10]). An intramolecular hydrogen bonding which controlled the equilibrium of **1a** would be influenced by a solvent effect. No expected solvent effects, which were found in the cases of 9-(2′-methoxyphenyl)-9-fluorenol[3] and 9-(2′-dimethylaminophenyl)-9-fluorenol,[5] however, were observed in the ^{1}H NMR spectra of **1a** in several solvents (DMSO-d_6, acetone-d_6, and methanol-d_4). If intermolecular hydrogen bonding between the hydrogen atom of the 9-hydroxyl group and these solvents exists, the equilibrium of **1a** would incline completely to the *ap*-form.

Table 2. Equilibrium Constant and Activation Parameter for Rotation of **1** and **2**[a]

	1			**2**[a]		
	$K(ap/sp)$ (Temp/ °C)	ΔG^*/kcal mol^{-1}		$K(ap/sp)$ (Temp/ °C)	ΔG^*/kcal mol^{-1}	
		ap→*sp*	*sp*→*ap*		*ap*→*sp*	*sp*→*ap*
a	3.9/1(−37)	13.7	12.9	*ap* only		
b	1/5.5(25)	15.5	16.5	1/1.6(25)	16.3	16.6
c	2.6/1(−50)	13.5	12.9	*ap* only

f	1.35/1(−50)	12.9	12.7	1/1.1(−50)	12.4	12.7
g	(1/1)[b,c]			1/2.1(−50)	12.2	12.7
h	(1/2)[c,d]			1/3.5(−65)	11.7	12.4

a) Results taken from Refs. 2 and 12. b) Insoluble in $CDCl_3$ at low temperature. c) K value is estimated from the chemical shifts of the bromomethyl group of *ap*- and *sp*-**1b** and this compound. d) Coalesed at −45 °C.

Compounds **1b** and **1c** also showed a tendency to increase the *sp*-form, compared with 9-(2′-methylphenyl)fluorene (**2b**) and **2c**. Regarding compounds **1a—c**, it can be considered that a repulsive interaction between the π-electron of the fluorene ring and an unshared electron of the bromine atom of 2′-bromomethyl group or a steric repulsion between the fluorene ring and the bromomethyl group may destabilize the *ap*-form. Thus, the *ap*-forms of **1a—c** would be more unstable than those of **2a—c**.

We have already presumed that the stabilization of the *sp*-forms in **2f—h**, which are disadvantageous with respect to the steric effect, may be due to the existence of an attractive interaction between the oxygen atom of the 9-carbonyl group and the 2′-methyl group.[2] However, the *ap*-forms in **1f—h** were found to increase, compared with those of **2f—h**. It can be concluded that the equilibria of **1f—h** are controlled by a balance of the electronic repulsion and/or the steric hindrance between the 2′-bromomethyl group and the 9-carbonyl group or the fluorene ring.

Experimental

All melting points are uncorrected. The ^{1}H NMR spectra were recorded on a JEOL-MH-100 spectrometer with a JEOL model JES-VT-3 variable temperature controller (Solvent, $CDCl_3$; $SiMe_4$). Dynamic NMR spectra were analyzed by using a modified version of the computer program DNMR 3.[11] The IR spectra were measured with a IRA-1 spectrometer as potassium bromide pellets.

Bromination of 2a with NBS. Typical Procedure. To a solution of **2a** (1.0 g, 4 mmol) in CCl_4 (20 ml) was added NBS (0.7 g, 4 mmol) and a small amount of BPO, and the mixture was refluxed for 30 min. After cooling the reaction mixture the obtained succinimide was filtered off; the filtrate was then concentrated. The crude product was washed with water, dried, and recrystallized from petroleum benzine to give 9-(2′-bromomethylphenyl)-9-fluorenol (**1a**) as colorless prisms; yield 1.1 g (85%); mp 146—147 °C; IR (KBr) 3515 cm^{-1} (OH); Found: C, 68.73; H, 4.06%. Calcd for $C_{20}H_{15}OBr$: C, 68.39; H, 4.30%.

9-(2′-Bromomethylphenyl)-9-methoxyfluorene (1c). Yield 49%; colorless prisms; mp 101—103 °C; Found: C, 68.76; H, 4.75%. Calcd for $C_{21}H_{17}OBr$: C, 69.04; H, 4.69%.

9-(2′-Bromomethylphenyl)-9-methylfluorene (1d). Yield 75%; colorless prisms; mp 150—152 °C; Found: C, 72.30; H, 4.85%. Calcd for $C_{21}H_{17}Br$: C, 72.22; H, 4.91%.

9-(2′-Bromomethylphenyl)-9-fluorenecarboxylic Acid (1e). Yield 55%; colorless crystals; mp 163—164 °C; IR (KBr) 1685 cm^{-1} (C=O); Found: C, 66.25; H, 4.02%. Calcd for $C_{21}H_{15}O_2Br$: C, 66.51; H, 3.99%.

9-(2′-Bromomethylphenyl)-9-methoxycarbonylfluorene (1f). Yield 62%; colorless prisms; mp 99—101 °C; IR (KBr) 1730 cm^{-1} (C=O); Found: C, 67.05; H, 4.47%. Calcd for $C_{22}H_{17}O_2Br$: C, 67.19; H, 4.36%.

9-Acetyl-9-(2′-bromomethylphenyl)fluorene (1g). Yield 66%; colorless prisms; mp 103—105 °C; IR (KBr) 1700 cm^{-1} (C=O); Found: C, 70.30; H, 4.28%. Cacld for $C_{22}H_{17}OBr$: C, 70.04; H, 4.54%.

9-Benzoyl-9-(2′-bromomethylphenyl)fluorene (1h). Yield 78%; colorless prisms; mp 131—132 °C; IR (KBr) 1670 cm^{-1} (C=O); Found: C, 73.84; H, 4.45%. Cacld for $C_{27}H_{19}OBr$: C, 73.81; H, 4.36%.

9-(2′-Iodomethylphenyl)fluorene (3). To a solution of **1a** (1 g, 3 mmol) in acetic acid (15 ml) was added hydroiodic acid (57%, 2.1 g, 9 mmol); the mixture was refluxed for 2 h. Upon cooling to room temperature, the reaction mixture was poured into water and extracted with benzene. The benzene solution was washed with a $NaHSO_3$ solution, dried over $MgSO_4$, and concentrated in vacuo. The crude product was recrystallized from petroleum benzine to give **3** as light-yellow crystals; yield 0.52 g (47%); mp 117—119 °C; ^{1}H NMR δ=3.26, 4.75 (0.4H and 1.6H, two s, CH_2I), 4.84, 5.29 (0.8H and 0.2H, two s, 9-H), 6.12—7.78 (12H, m, $H_{arom.}$). Found: C, 62.64; H, 3.76%. Calcd for $C_{20}H_{15}I$: C, 62.84; H, 3.95%.

9-(2′-Hydroxymethylphenyl)fluorene (4). A solution of **3** (0.2 g, 0.5 mmol) in dioxane (10 ml)-water (2 ml) was refluxed for 3 h. Upon cooling to room temperature, the reaction mixture was poured into water; the deposited crude product was filtered, dried, and recrystallized from petroleum benzine to give **4** as colorless needles; yield 0.11 g (80%); mp 135—136 °C; IR (KBr); 3340 cm^{-1} (OH); ^{1}H NMR δ=3.42, 5.03 (0.6H and 1.4H, two s, CH_2OH), 5.04, 5.43 (1H, two s, 9-H), 6.34 (0.7H, d, J=8 Hz, 6′-H), 7.74 (2H, d, J=7.5 Hz, 4- and 5-H), 6.7—7.5 (9.3H, m, $H_{arom.}$). Found: C, 88.18; H, 5.79%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

9-(2′-Bromomethylphenyl)fluorene (1b). Into a solution of **4** (0.5 g, 1.8 mmol) in acetic acid (10 ml) was bubbled dry hydrogen bromide, which was generated by a reaction of tetralin with bromine for 5 min. The reaction mixture was poured into cold water; then, precipitated crystals were filtered, washed, and dried. The product was recrystallized from petroleum benzine to give **1b** as light-yellow needles; yield 0.54 g (88%); mp 87—88 °C; Found: C, 71.82; H, 4.35%. Calcd for $C_{20}H_{15}Br$: C, 71.66; H, 4.51%.

(Received December 15, 1988)

Synopsis. The reaction of arenes with a calculated amount of benzyltrimethylammonium tetrachloroiodate in acetic acid at room temperature or at 70 °C gave nuclear chloro-substituted arenes in fairly good yields.

Direct aromatic chlorination of arenes (**1**) with chlorine has usually been carried out in the presence of a catalyst such as iodine, iron(III) chloride, or an aluminium-mercury couple. As the chlorinating agents which are easier to handle than toxic gaseous chlorine, sulfuryl chloride,[2] iodine trichloride,[3] titanium(IV) chloride,[4] copper(II) chloride,[5] alumina-supported copper(II) chloride,[6] antimony(V) chloride,[7] tellurium(IV) chloride,[8] trichloroisocyanuric acid,[9] and poly(*N*-chloromaleimide),[10] etc. have been used to chlorinate **1**.

As one part of our investigation concerning the halogenation of aromatic compounds with quaternary ammonium polyhalides, we have recently found that a new reagent, benzyltrimethylammonium tetrachloroiodate (BTMA ICl_4), is an effective chlorinating agent.[1,11] In this paper we wish to report on the aromatic chlorination of **1** by the use of BTMA ICl_4.

Results and Discussion

A reaction of **1** with BTMA ICl_4 in acetic acid at room temperature or at 70 °C gave aromatic chloro-substituted arenes (**2**) together with benzyltrimethylammonium dichloroiodate (BTMA ICl_2).[12] Thus, the produced BTMA ICl_2 is easily separable from the reaction mixture, since BTMA ICl_2 is hardly

a) Yield of isolated product. b) Product was obtained as a mixture of 4- and 2-chloro derivatives, and its isomer ratio was determined by GC analysis and / or ^1H NMR spectrum. c) 4-Chloro deriv. / 2-chloro deriv. =3/7. d) 4-Chloro deriv. / 2-chloro deriv. =1/1. e) 4-Chloro deriv. / 2-chloro deriv. =7/3. f) 4-Chloro deriv. / 2-chloro deriv. =2/1.

soluble in acetic acid at room temperature. The results are summarized in Table 1.

The reaction of such polyalkylbenzenes as 1,3,5-trimethylbenzene (**1j**), 1,2,3,4-tetramethylbenzene (**1k**), and 1,2,4,5-tetramethylbenzene (**1l**), with equivalent weights of BTMA ICl_4 gave the desired mono-, di-, or trichloro-substituted arenes selectively. For example, the reactions of **1j** with 1.0, 2.0, and 3.0 equiv of BTMA ICl_4 gave 1-chloro- (**2j-1**), 1,3-dichloro- (**2j-2**), and 1,3,5-trichloro-2,4,6-trimethylbenzene (**2j-3**), in good yields, respectively.

We emphasize that the stable reagent BTMA ICl_4 is an excellent chlorinating agent for **1** since it can be treated safely and quantitatively in comparison with toxic gaseous chlorine. Readily separable by-product BTMA ICl_2 can be easily converted to BTMA ICl_4 by treatment with chlorine in dichloromethane.[24]

However, benzene and isopropylbenzene gave chloro-substituted products in poor yields, respectively, even with a Lewis acid-catalyst such as iron(III) chloride, titanium(IV) chloride, or zinc chloride.

Experimental

1-Chloro-2,4,6-trimethylbenzene (2j-1); General Procedure: To a solution of 1,3,5-trimethylbenzene (**1j**) (0.50 g, 4.16 mmol) in acetic acid (30 ml) was added BTMA ICl_4 (1.74 g, 4.16 mmol). The mixture was stirred for 22 h at room temperature. During the period of stirring BTMA ICl_4, which was only slightly soluble in acetic acid, gradually reacted with **1j** to give a product and a yellow precipitate. The precipitate (BTMA ICl_2, 1.02 g, 2.93 mmol) was filtered off. The filtrate was treated with 5% $NaHSO_3$ (20 ml) and then extracted with hexane (25 ml×4). The hexane solution was washed with 5% $NaHCO_3$ (30 ml) and was purified by column chromatography on alumina. The eluent was concentrated in vacuo to give an oily residue which was distilled, affording **2j-1** as a colorless liquid; yield 0.58 g (90%); bp 205—206 °C/760 mmHg (lit,[17] bp 86—86.8 °C/14 mmHg).

Asymmetric Oxidation of Alkyl Aryl Selenides under Sharpless Oxidation Conditions

Toshio SHIMIZU, Michio KOBAYASHI, and Nobumasa KAMIGATA*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received November 26, 1988)

Synopsis. Optically active alkyl aryl selenoxides were synthesized by the asymmetric oxidation of corresponding selenides under Sharpless oxidation conditions. The absolute configurations of the optically active alkyl aryl selenoxides prepared were estimated by comparisons of their circular dichroism spectra with those of the optically active sulfoxides.

Although optically active sulfoxides were resolved in the early twenties century,[1] there had been no example of an optically active selenoxide for a long time. Recently, though, optically active alkyl aryl and dialkyl selenoxides were obtained by kinetic resolution (5—11% e.e.)[2] or by complexation with optically active diol.[3] We also obtained optically active selenoxides by the optical resolution of racemic selenoxides[4] and the asymmetric oxidation of selenide.[5] Furthermore, we found that chromatographic resolution of racemic selenoxides using an optically active column was effective for preparing optically active diaryl selenoxides.[6] However, alkyl aryl selenoxides could not be separated by this method, and there has been no report on an effective synthetic method for such optically active compounds. Very recently, the asymmetric oxidation of 2-methoxy-2,2-diphenylethyl aryl selenides to corresponding selenoxides (18—40% e.e.) under Sharpless oxidation conditions was reported by Tiecco et al.[7] We have also investigated the asymmetric synthesis of optically active alkyl aryl selenoxides by the asymmetric oxidation of the corresponding selenides under Sharpless oxidation conditions. We report here the results and an estimation of the absolute configurations of the optically active alkyl aryl selenoxides obtained by a comparison of their circular dichroism spectra with those of optically active alkyl aryl sulfoxides.

Results and Discussion

Asymmetric oxidations of methyl 2,4,6-triisopropylphenyl selenide (**1a**) were examined in dichloromethane using titanium tetraisopropoxide and (+)-diethyl tartrate ((+)-DET) under several reaction

1 2

a: R = Methyl. Ar = 2,4,6-Triisopropylphenyl
b: R = Methyl. Ar = 2,4,6-Tri-t-butylphenyl
c: R = Neopentyl, Ar = 2,4,6-Tri-t-butylphenyl
d: R = Benzyl, Ar = 2,4,6-Tri-t-butylphenyl
e: R = o-Methoxybenzyl. Ar = 2,4,6-Tri-t-butylphenyl

temperatures. The highest enantiomeric excess (e.e.) of methyl 2,4,6-triisopropylphenyl selenoxide (+)-**2a** was obtained at −15 °C. The results are summarized in Table 1 (Entries 1—4). When (−)-DET was used in place of (+)-DET, (−)-selenoxide (−)-**2a** was obtained (Entry 5). The reaction conditions of the asymmetric oxidations of **1a** were examined by using some tartrates and Lewis acids (Entries 6—9). However, only a decrease of e.e. was observed. It was observed that the most effective combination of tartrate and Lewis acid was that of diethyl tartrate and titanium tetraisopropoxide. It was reported that the addition of equimolar amounts of water increased the e.e. of optically active sulfoxides in the asymmetric

a) Titanium tetraisopropoxide was used as the Lewis acid. b) DET: diethyl tartrate. c) Optical rotations were taken in chloroform. d) Determined by ^1H NMR by using optically active shift reagent, Eu(hfc)$_3$

oxidation of sulfides.[8] We studied the oxidation of **1a** by adding equimolar amounts of water to our reaction systems. However, the addition of water only decreased the ratio of the enantiomers (Entry 10). The oxidation of **1a** was also carried out in ether or acetonitrile (Entries 11—13). Though the e.e. decreased in both solvents, (+)-selenoxide (+)-**2a** and (−)-selenoxide (−)-**2a** were obtained by the use of (−)-DET and (+)-DET, respectively, in ether (Entries 11 and 12). The absolute configurations of **2a** obtained in ether were opposite to the results found in dichloromethane or acetonitrile. These results suggest that there is an interaction between the Lewis acid and the lone pair of oxygen atoms of solvent ether, which reverses the selectivity of the enantio-face in the oxidation of the selenide.

The asymmetric oxidations of several alkyl 2,4,6-tri-*t*-butylphenyl selenides (**1b—1e**) were carried out using diethyl tartrate and titanium tetraisopropoxide. Methyl, neopentyl, and benzyl groups were chosen as alkyl groups since the existence of β-hydrogen of selenoxide easily caused β-elimination.[9] The results are shown in Table 2. In the oxidation of **1b**, (−)-**2b** was obtained in 33% optical yield in ether using (+)-DET, although the reaction was slow and the chemical yield was 12% after 63 h (Entry 3). Similarly, (+)-**2b** were obtained in 26% optical yield by the oxidation of **1b** using (−)-DET in ether (Entry 4). Asymmetric oxidations of **1c** were also carried out in dichloromethane or ether using (+)-DET (Entries 5 and 6). A higher e.e. of **2c** was obtained in ether than in dichloromethane. However in this case, optically active (+)-selenoxide (+)-**2c** was formed in both solvents.

The solvent effects in the oxidations of **1a—1c** prompted us to study the oxidations of benzyl 2,4,6-tri-*t*-butylphenyl selenide (**1d**) and *o*-methoxybenzyl 2,4,6-tri-*t*-butylphenyl selenide (**1e**) in order to clarify the effect of the oxygen atom of the methoxyl group in **1e**. The oxidations of **1d** and **1e** gave optically active selenoxides (**2d** and **2e**) in 7 and 17% optical yields, respectively (Entries 7 and 8). The ortho methoxyl group in **1e** pretty much increased the e.e. in the oxidation of the selenides. The solvent effect and substrate dependence are very interesting, though the mechanism of the asymmetric oxidation of selenides under these conditions is not clear at the present time.

Davis et al. proposed that the absolute configurations of selenoxides (+)-**2a** and (−)-**2a** are *S* and *R* forms, respectively.[2] However, the optically active selenoxides, **2b—2e**, are new compounds and the absolute configurations are not known. We tried to estimate the optically active alkyl aryl selenoxides **2a—2e** by comparisons of the circular dichroism spectra with those of alkyl aryl sulfoxides. All (+)-selenoxides (+)-**2a—2b** showed positive first Cotton effects in the 258—301 nm region on circular dichroism spectra, as shown in Table 3. On the other hand, alkyl aryl sulfoxides, such as (+)-methyl *p*-tolyl sulfoxide, showed a positive first Cotton effect at 241 nm[10] and (+)-ethyl phenyl sulfoxide also had a positive Cotton effect at 245 nm.[11] Since both (+)-sulfoxides had been determined to be *R*-configuration, the (+)-selenoxides (+)-**2a—2e** were estimated to be of *R* form. These estimations are opposite to those absolute configurations proposed by Davis et al.[2]

Experimental

Materials. **Methyl 2,4,6-triisopropylphenyl selenide (1a)** was prepared by the reaction of 2,4,6-triisopropylphenylmagnesium bromide with dimethyl diselenide,[12] and alkyl 2,4,6-tri-*t*-butylphenyl selenides (**1b—1e**) were prepared by the reaction of 2,4,6-tri-*t*-butylphenyllithium with the corresponding dialkyl diselenides. The physical and spectral data are as follows.

1a: Mp 43—44 °C; IR (KBr) 3000—2800, 1460, 1360, and 880 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23 (18H, d, *J*=7.2 Hz), 2.07 (3H, s), 2.86 (1H, hep., *J*=7.2 Hz), 3.84 (2H, hep., *J*=7.2 Hz), and 6.93 (2H, s); MS (70 eV) *m/z* 298 (M^+)(^{80}Se); Found: *m/z* 298.1230, Calcd for $C_{16}H_{26}{}^{80}Se$: M, 298.1200.

1b: Mp 86.5—87.0 °C; IR(KBr) 3000—2800, 1580, 1465, 1380, 1350, and 870 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28 (9H, s),

General Procedure for the Asymmetric Oxidation of Selenides. A typical manner for the oxidation of **1a** is described below. (+)-Diethyl tartrate (0.34 cm^3, 2.0 mmol) and titanium tetraisopropoxide (0.30 cm^3, 1.0 mmol) were dissolved in 8.0 cm^3 of dichloromethane under nitrogen, and the mixture was stirred for 30 min. Methyl 2,4,6-triisopropylphenyl selenide (**1a**) (297 mg, 1.0 mmol) was added to the mixture and cooled to −15 °C. A solution of *t*-butyl hydroperoxide (1.3 mmol), dried over magnesium sulfate prior to use, in dichloromethane (2.0 cm^3) was added to the cooled solution. Stirring was continued for 18 h at −15 °C. The reaction mixture was subjected to alumina column chromatography without evaporation of the solvent using hexane-ethyl acetate as an eluent to give 182 mg (58%) of methyl 2,4,6-triisopropylphenyl selenoxide (**2a**). $[\alpha]_D^{22}$ + 19.0° (*c* 1.17, chloroform). Enantiomeric excess (e.e.) was determined to be 28.2% by ^1H NMR using optically active shift reagent (Eu(hfc)$_3$).

(*R*)-(+)-2a: Mp 154.0—154.5 °C; $[\alpha]_D^{22}$ +19.0° (*c* 1.17, chloroform); e.e.=28.2%; IR (KBr) 820 (Se=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20, 1.23, and 1.27 (18H, d, J=7.2 Hz, methyl of isopropyl), 2.74 (3H, s), 2.5—3.1 (1H, m), 3.92 (2H, hep.), and 7.03 (2H, s); UV (methanol) 261 (ε 5.03×10^3), 233 (ε 1.09×10^4), and 208 (ε 3.80×10^4) nm; CD (methanol) 258 ([θ] +5.13×10^3) and 228 ([θ] −2.21×10^3) nm; MS (30 eV) m/z 314 (M^+) (^{80}Se); Found m/z 314.1154, Calcd for $C_{16}H_{26}O{}^{80}Se$: M, 314.1149.

Studies on Aromatic Sesquiterpenes. XI.[1] Synthesis of 7-Isopropyl-3,5-dimethyl-1-naphthol

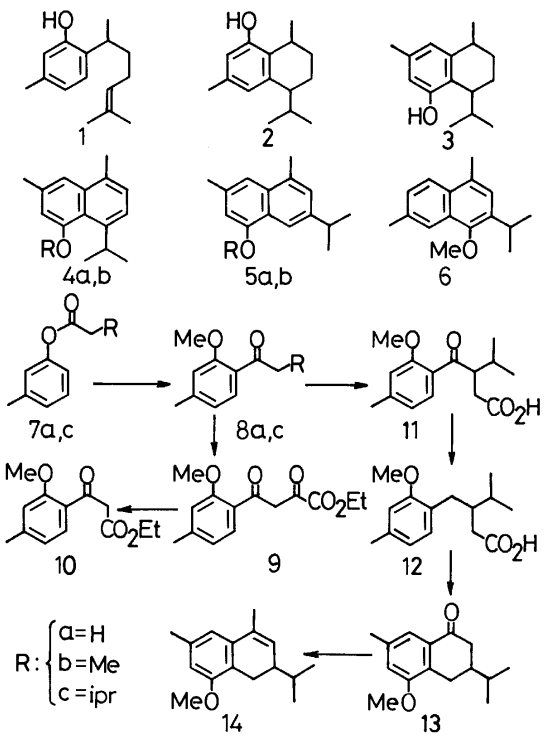
Juichi TANAKA and Kazuo ADACHI*
Osaka Institute of Technology, Omiya, Asahi-ku, Osaka 535
(Received December 7, 1988)

Synopsis. Starting from *m*-cresol, the title new naphthol was synthesized through 4-methyl-3-(2-methoxy-4-methylbenzoyl)pentanoic acid as a key intermediate.

Phenolic sesquiterpene curcuphenol[2] (**1**) was cyclized by treatment with acid catalysts to give 8-hydroxycalamenene (**2**) along with its structural isomer, 5-hydroxyisocalamenene (**3**).[3] The tetrahydronaphthol (**2**) and its methyl ether have been, respectively, isolated from *Dysoxylum* species (Meliaceae) and a horny coral as naturally occurring sesquiterpenes, and their absolute configuration were confirmed by chemical derivation.[4] 5-Methoxydaucalene (**4b**) derived from the methyl ether of **3** afforded 5-hydroxydaucalene (**4a**) by demethylation with BBr_3.[1] However, **4b** was refluxed in a solution of acetic acid with HBr to furnish a new naphthol, which was apparently different from **4a**. 7-Isopropyl-3,5-dimethyl-1-naphthol (**5a**) was proposed as the structure of this new naphthol on the basis of comprehensive spectral studies.[1] 4-Methoxyisocadalene (**6**) has been isolated from *Heterotheca* species (Compositae) and also synthesized.[5] However, the naphthol (**5**), having a related structure with **6**, is an unknown phenolic sesquiterpenoide as a natural product.

In this paper we report on an efficient synthesis of **5**, starting from *m*-cresol through 4-methyl-3-(2-methoxy-4-methylbenzoyl)pentanoic acid (**11**) as a key intermediate. This synthetic fashion is useful for the preparation of 7-isopropyl-1-naphthol derivatives, which are expected to occur as natural products or formation by the conversion of some sesquiterpenes.

In order to prepare the keto acid (**11**), at first the methoxyacetophenone (**8a**) obtained from *m*-tolyl acetate (**7a**) was derived to the diketo ester (**9**). Generally, the diketo esters prepared from a ketone with diethyl oxalate are readily converted into the β-keto esters by decarbonylation with heating,[6] but the pyrolysis of **9** gave a mixture of four components (**8a**, **10**, and the dimerized product including **9**), in which the desired β-keto ester (**10**) was found in low yield (32.8%). Therefore, we next attempted the bromination of isovalerophenone derivative (**8c**) obtained from *m*-tolyl isovalerate (**7c**) and successive condensation of the resulting α-bromo ketone with ethyl cyanoacetate. The crude reaction product was hydrolyzed to give a γ-keto acid (**11**), which showed in its NMR spectrum two methyl proton signals of an isopropyl group at δ=0.73 and 0.97 as a pair of doublets (J=7 Hz) and methylene proton signals as a pair of double doublets at δ=2.35 (J=17 and 4 Hz) and 2.91 (J=17 and 10 Hz). By a Clemmensen reduction the keto acid (**11**) was converted into 4-methyl-3-(2-methoxy-4-methylbenzyl)-pentanoic acid (**12**), which was cyclized with phosphoryl chloride to give the tetralone (**13**). Ketone **13** was allowed to react with methylmagnesium iodide and the dehydration of the resulting alcohol with formic acid afforded 3,4-dihydro-3-isopropyl-5-methoxy-1,7-dimethylnaphthalene (**14**), which was dehydrogenated by heating with 5% Pd-C at 240—250 °C to give 7-isopropyl-1-methoxy-3,5-dimethylnaphthalene (**5b**). 7-Isopropyl-3,5-dimethyl-1-naphthol (**5a**) was obtained by the demethylation of **5b** with HBr in a refluxing acetic acid. The spectra (^1H and ^{13}C NMR, IR and GC) of the synthesized naphthol **5a** were completely coincident with those of the naphthol obtained from the reaction of **4b** with HBr.[1] The IR and NMR spectra of the acetate of **5a** were wholly different from those of the acetate of **4a**.[1]



Experimental

2-Methoxy-4-methylacetophenone (8a) and 2-Methoxy-4-methylisovalerophenone (8c). A mixture of *m*-cresol (0.1 mol), acyl chloride (0.12 mol), Mg (1.2 g), and benzene (25 ml) was refluxed for 1 h to give the corresponding *m*-tolyl esters.[7]

m-Tolyl acetate (**7a**): 78.1%, bp 88 °C/11 mmHg (1 mmHg=133.322 Pa); IR (neat): 1770, 1375, 1210, and 1150 cm^{-1}.

m-Tolyl isovalerate (**7c**): 94.7%, bp 136 °C/22 mmHg; IR (neat): 1755, 1240, 1180, 1140, and 1100 cm^{-1}.

A mixture of the tolyl ester (0.1 mol), $AlCl_3$ (0.12 mol), and carbon disulfide (16 ml) was refluxed for 2 h with stirring. The solvent was removed and the residue heated at 145—150 °C for 4 h. The reaction mixture was decomposed with dil. HCl to give the *o*-hydroxy ketone.

2-Hydroxy-4-methylacetophenone: 84.0%, bp 106—108 °C/9 mmHg; IR (neat): 3600—2300, 1630, 1370, 1325, 1300, 1250, 1230, and 795 cm^{-1}; ^1H NMR ($CDCl_3$): δ=2.30 (s, 3H, CH_3), 2.53 (s, 3H, $COCH_3$), 6.65 (d, 1H, J=8 Hz), 6.71 (broad s, 1H), 7.54 (d, 1H, J=8 Hz), and 12.27 (s, 1H, OH).

2-Hydroxy-4-methylisovalerophenone: 95.3%, bp 151—152 °C/21 mmHg; IR (neat); 3500—2500, 1640, 1360, 1310, 1275, 1210, 1150, and 795 cm^{-1}; ^1H NMR ($CDCl_3$): δ=0.99 (d, 6H, J=6.5 Hz, CH_3×2), 2.26 (m, 1H, J=6.5 Hz, >CH-), 2.31 (s, 3H, CH_3), 2.78 (d, 2H, J=6.5 Hz, CH_2), 6.66 (dd, 1H, J=8, 1.5 Hz), 6.74 (broad s, 1H), 7.60 (d, 1H, J=8 Hz), and 12.50 (s, 1H, OH).

To a mixture of the *o*-hydroxy ketone (0.04 mol) and K_2CO_3 (0.06 mol) in acetone (30 ml) was added dimethyl sulfate (0.05 mol) at room temperature; the mixture was refluxed for 10 h with stirring to yield the *o*-methoxy ketone.

2-Methoxy-4-methylacetophenone (**8a**): 87.9%, bp 125—126 °C/10 mmHg; IR (neat): 1670, 1605, 1290, 1260, 1240, 1170, and 1035 cm^{-1}; ^1H NMR ($CDCl_3$): δ=2.36 (s, 3H, CH_3), 2.57 (s, 3H, $COCH_3$), 3.87 (s, 3H, OCH_3), 6.74 (broad s, 1H), 6.78 (d, 1H, J=8 Hz), and 7.66 (d, 1H, J=8 Hz).

2-Methoxy-4-methylisovalerophenone (**8c**): 96.1%, bp 146 °C/10 mmHg; IR (neat): 1670, 1610, 1470, 1410, 1300, 1280, 1255, 1170, and 1040 cm^{-1}; ^1H NMR ($CDCl_3$): δ=0.94 (d, 6H, J=6.5 Hz, CH_3×2), 2.21 (m, 1H, J=6.5 Hz, >CH-), 2.35 (s, 3H, CH_3), 2.82 (d, 2H, J=6.5 Hz, CH_2), 3.85 (s, 3H, OCH_3), 6.73 (broad s, 1H), 6.77 (d, 1H, J=8 Hz), and 7.56 (d, 1H, J=8 Hz).

Ethyl 3-(2-Methoxy-4-methylphenyl)-3-oxopropionate (10). To a mixture of methoxy ketone **8a** (5.0 g) and Na (0.8g) in ethanol (17 ml) was added diethyl oxalate (5.1 g) with cooling in an ice bath; the mixture was stirred for 3 h. The reaction mixture was decomposed by adding dil. H_2SO_4 under cooling. The precipitate was collected by filtration, (7.8 g, 97.5%) to give ethyl 4-(2-methoxy-4-methylphenyl)-2,4-dioxobutyrate (**9**) as yellow leaves (from petroleum ether), mp 73.0—74.0 °C; IR (KBr): 1745, 1605, 1500, 1295, 1250, 1230, and 1025 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.39 (t, 3H, J=7 Hz, CH_3), 2.40 (s, 3H, CH_3), 3.93 (s, 3H, OCH_3), 4.37 (q, 2H, J=7 Hz, CH_2), 6.79 (s, 1H), 6.84 (d, 1H, J=8 Hz), 7.31 (s, 1H, =CH-), 7.81 (d, 1H, J=8 Hz), and 15.42 (broad s, 1H, enol-OH, disappeared with D_2O). Found: C, 63.63; H, 6.05%. Calcd for $C_{14}H_{16}O_5$: C, 63.62; H, 6.10%.

A mixture of the diketo ester **9** (3.0 g), ground glass (0.3 g), and iron borings (0.03 g) was heated at 150 °C under reduced pressure (16 mmHg). A subsequent distillation of the reaction mixture gave an oily product, bp 157—158 °C/6 mmHg (1.3 g), which was a mixture of **8a** (22.4%), **10** (68.2%), and an unreacted **9** (9.4%) on the basis of the ^1H NMR. The β-keto ester (**10**) was purified by redistillation: (0.8 g, 28.6%), bp 157—158 °C/6 mmHg; IR (neat): 1740, 1670, 1610, 1325, 1260, 1195, and 1035 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.23 (t, 3H, J=7 Hz, CH_3), 2.36 (s, 3H, CH_3), 3.86 (s, 3H, OCH_3), 3.92 (s, 2H, CH_2), 4.17 (q, 2H, J=7 Hz, CH_2), 6.75 (s, 1H), 6.80 (d, 1H, J=8 Hz), and 7.78 (d, 1H, J=8 Hz).

The distillation residue was chromatographed on silica gel and eluted with CH_2Cl_2 to give an unidentified dimerized product (0.4 g) as yellow needles after recrystalization from benzene, mp 213.0—213.5 °C. Found: C, 69.47; H, 5.54%. Calcd for $C_{22}H_{20}O_6$: C, 69.46; H, 5.30%.

4-Methyl-3-(2-methoxy-4-methylbenzoyl)pentanoic Acid (11). The ketone **8c** (8.0 g) in ether (10 ml) was brominated in the presence of $AlCl_3$ (10 mg) with bromine (3.2 g)[8] to give 2-bromo-3-methyl-1-(2-methoxy-4-methylphenyl)-1-butanone as an oil (11.0 g, 99.1%); IR (neat): 1675, 1610, 1460, 1405, 1295, 1280, 1255, 1165, and 1035 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.05 (d, 3H, J=6.5 Hz, CH_3), 1.08 (d, 3H, J=6.5 Hz, CH_3), 2.3 (m, 1H, J=6.5 Hz, >CH-), 2.37 (s, 3H, CH_3), 3.88 (s, 3H, OCH_3), 5.33 (d, 1H, J=6.5 Hz, >CH-), 6.76 (s, 1H), 6.80 (d, 1H, J=8 Hz), and 7.61 (d, 1H, J=8 Hz).

The α-bromo ketone (11.0 g) was added to sodio-cyanoacetate prepared from ethyl cyanoacetate (4.5 g) and Na (0.9 g) in ethanol (20 ml); the mixture was refluxed for 5 h with stirring. The reaction mixture was diluted with water and extracted with benzene to give a crude condensed product (11.0 g), which was refluxed with an aqueous solution of 5% NaOH for 5 h. The solution was acidified with HCl and extracted with benzene. The extract was evaporated and recrystallized from benzene to give **11** as prisms (3.6 g, 35.3%), mp 128.5—129.5 °C; IR (KBr): 1700, 1660, 1610, 1465, 1410, 1290, 1260, 1200, 1035, and 820 cm^{-1}; ^1H NMR ($CDCl_3$): δ=0.73 (d, 3H, J=7 Hz, CH_3), 0.97 (d, 3H, J=7 Hz, CH_3), 2.1 (m, 1H, >CH-), 2.35 (dd, 1H, J=17, 4 Hz, $>C<^{H}_{H}$), 2.36 (s, 3H, CH_3), 2.91 (dd, 1H, J=17, 10 Hz, $>C<^{H}_{H}$), 3.86 (s, 3H, OCH_3), 3.9 (m, 1H, >CH-), 6.74 (broad s, 1H), 6.78 (d, 1H, J=8 Hz), 7.59 (d, 1H, J=8 Hz), and 10.58 (broad s, 1H, CO_2H). Found: C, 67.76; H, 7.87%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

When the above α-bromo ketone was condensed with diethyl malonate in place of ethyl cyanoacetate, the yield of keto acid **11** was only 17.6%.

4-Methyl-3-(2-methoxy-4-methylbenzyl)pentanoic Acid (12). The Clemmensen reduction of keto acid **11** (3.1 g) with amalgamated zinc prepared from Zn (7.6 g) and $HgCl_2$ (0.9 g) for 10 h gave **12** (1.7 g, 58.6%), bp 163—164 °C/5 mmHg, mp 96.5—97.5 °C (from petroleum ether); IR (KBr): 1700, 1610, 1505, 1460, 1450, 1410, 1320, 1300, 1290, 1260, 1155, and 1040 cm^{-1}; ^1H NMR ($CDCl_3$): δ=0.90 (d, 3H, J=6.5 Hz, CH_3), 0.94 (d, 3H, J=6.5 Hz, CH_3), 1.7 (m, 1H, >CH-), 2.2 (m, 3H, CH_2, >CH-), 2.29 (s, 3H, CH_3), 2.5 (m, 2H, CH_2), 3.76 (s, 3H, OCH_3), 6.61 (s, 1H), 6.64 (d, 1H, J=8 Hz), 6.97 (d, 1H, J=8 Hz), and 11.11 (broad s, 1H, CO_2H). Found: C, 71.54; H, 9.16%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

3,4-Dihydro-3-isopropyl-5-methoxy-7-methyl-1(2*H*)-naphthalenone (13). A solution of the carboxylic acid **12** (1.7 g) and $POCl_3$ (0.7 g) in 1,1,2,2-tetrachloroethane (25 ml) was refluxed for 2 h with stirring; the mixture was poured into an ice water. The organic layer was separated and concentrated to afford **13** (1.5 g, 93.8%), bp 165—167 °C/7 mmHg; IR (neat): 1685, 1610, 1465, 1340, 1320, 1300, 1250, 1130, and 1060 cm^{-1}; ^1H NMR ($CDCl_3$): δ=0.98 (d, 6H, J=6 Hz, CH_3×2), 1.7 (m, 1H, J=6 Hz, >CH-), 1.8—2.5 (m, 3H, CH_2, >CH-), 2.35 (s, 3H, CH_3), 2.9 (m, 2H, CH_2), 3.85 (s, 3H, OCH_3), 6.83 (d, 1H, J=1.5 Hz), and 7.44 (broad s, 1H). 2,4-Dinitrophenylhydrazone: Red microcrystals (from benzene), mp 216.0—217.0 °C. Found: C, 61.00; H, 5.70; N, 13.33%. Calcd for $C_{21}H_{24}N_4O_5$: C, 61.15; H, 5.87; N, 13.59%.

3,4-Dihydro-3-isopropyl-5-methoxy-1,7-dimethylnaphthalene (14). A solution of tetralone **13** (1.2 g) in ether (15 ml) was added to a Grignard reagent prepared from methyl iodide (2.3 g) and Mg (0.4 g) in ether (20 ml) with cooling in an ice bath. The reaction mixture was refluxed for 10 h with stirring; the mixture was then decomposed by adding ice and NH_4Cl. The resulting crude alcohol (1.3 g, IR: 3380 cm^{-1}) was dehydrated by stirring with formic acid (2.5 ml) at 80 °C for 2 h. After extraction with benzene, the resulting products were chromatographed on silica gel and eluted with CCl_4 to give **14** as an oil (1.0 g, 83.3%); IR (neat): 1605, 1570, 1460, 1280, 1140, 1060, and 830 cm^{-1}; ^1H NMR ($CDCl_3$): δ=0.93 (d, 6H, J=6 Hz, CH_3×2), 1.69 (m, 1H, J=6 Hz, >CH-), 2.04 (broad s, 3H, $\geq$-CH_3), 2.32 (s, 3H, CH_3), 2.5

(m, 2H, CH_2), 2.9 (m, 1H, >CH-), 3.79 (s, 3H, OCH_3), 5.73 (broad, 1H, =CH-), 6.59 (broad s, 1H), and 6.70 (broad s, 1H).

7-Isopropyl-3,5-dimethyl-1-naphthol (5a). The dihydronaphthalene **14** (1.0 g) was dehydrogenated by heating with 5% Pd-C (0.2 g) at 240—250 °C for 5 h. The resulting products were chromatographed on silica gel and eluted with CCl_4 to give the methoxynaphthalene **5b** as an oil (0.8 g, 80.8%), which was identical in all respects with the specimene[1] derived from **4b**. Picrate: Brown needles (from ethanol), mp 165.0—166.0 °C (lit,[1] mp 165.0—166.0 °C).

A mixture of **5b** (0.7 g) and 48% HBr (7 ml) in glacial acetic acid (7 ml) was refluxed for 2 h. The reaction mixture was diluted with water (20 ml) and extracted with benzene. The extract was evaporated and the residue recrystallized from petroleum ether to give 7-isopropyl-3,5-dimethyl-1-naphthol **5a** (0.6 g, 90.9%) as woolly crystals, mp 86.0—87.0 °C (lit,[1] mp 86.0—87.0 °C). The IR and NMR spectra of this naphthol **5a** were superimposable with those of the specimene[1] obtained from **4b** by refluxing in acetic acid with HBr. Acetate: Prisms (from petroleum ether), mp 67.5—68.5 °C; IR (KBr): 1760, 1610, 1400, 1365, 1200, 1120, 1025, and 870 cm^{-1}; ^1H NMR ($CDCl_3$): δ=1.29 (d, 6H, J=7 Hz, CH_3×2), 2.41 (s, 3H, $COCH_3$), 2.49 (s, 3H, CH_3), 2.62 (s, 3H, CH_3), 2.95 (m, 1H, J=7 Hz, >CH-), 7.04 (d, 1H, J=1.5 Hz), 7.20 (broad s, 1H), 7.43 (broad s, 1H), and 7.58 (broad s, 1H). Found: C, 79.58; H, 7.91%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

Tellurium-Assisted Cyclopropanation and Alkylidenation of α,β-Unsaturated Carbonyl Compounds with Dibromomalonic Esters[1)]

Toshiaki MATSUKI, Nan Xing HU, Yoshio ASO, Tetsuo OTSUBO, and Fumio OGURA*

(Received December 15, 1988)

Synopsis. Dibutyl telluride assists cyclopropanation of α,β-unsaturated ketone, ester, and nitrile with dibromomalonic esters without solvent at room temperature. In addition, it effects alkylidenation of aldehydes including α,β-unsaturated aldehyde with the same reagent.

The dehalogenation of *vic*-dibromide with diphenyl telluride giving the corresponding olefin and diphenyltellurium dibromide is the first reported transformation of an organic molecule using organotellurium compound.[2)] The halophilic nature of the divalent telluride is due to high stability of the resulting tetravalent tellurane. A recent paper has described the cyclopropanation of electron-deficient olefins with dibromomalonic ester with the aid of trialkylstibine, giving polysubstituted cyclopropanes with electron-withdrawing groups,[3)] which are very useful in organic syntheses.[4)] This has prompted us to study the utility of organotellurium species in a similar reaction as one of our interests on organotellurium chemistry. We like to report here tellurium-assisted cyclopropanation of α,β-unsaturated carbonyl compounds as well as alkylidenation of common aldehydes including α,β-unsaturated aldehydes with dibromomalonic esters. The latter provides a novel example of tellurium-based condensation, while a Wittig reaction using telluronium ylides has been already known.[5)]

Dibutyl telluride (**1**), like organostibine, induced cyclopropanation of α,β-unsaturated ester, ketone, or nitrile **3** with dibromomalonic ester **2** (Scheme 1).

Scheme 1.

The termolecular reaction exothermically took place without solvent at room temperature to give the corresponding cyclopropane derivative **5** in moderate to high yields after 1—24 h. The main by-product was dibutyltellurium dibromide (**4**).[6)] A variety of trisubstituted cyclopropanes **5a—k** were thus obtained by appropriate combinations of reactants summarized in Table 1. When benzene or ethanol was used as a solvent, the reaction took longer time. On the other hand, a similar reaction using dibromomalononitrile (**2c**) instead of dibromomalonic ester vigorously occurred, leading to decomposition in most cases. Only from the reaction of **1**, **2c**, and vinyl methyl ketone (**3d**) in ethanol at 0 °C for 3 h, 1-acetyl-2,2-dicyanocyclopropane (**5i**) could be isolated in 85% yield. Bis(*p*-methoxyphenyl) telluride (**6**) instead of dibutyl telluride hardly promoted the reaction even at 150 °C.

a) Reaction conditions: no solvent at RT unless otherwise stated. b) Yield of isolated product. c) Reaction conditions: ethanol solvent at 0 °C.

6

Although organostibine can also induce a similar cyclopropanation of α,β-unsaturated aldehydes, **1** behaves differently. It thus allowed acrylaldehyde (**7a**), crotonaldehyde (**7b**), methacrylaldehyde (**7c**), or *trans*-cinnamaldehyde (**7d**) to react at the aldehyde function with dibromomalonic ester **3**, giving a conjugated olefin **9** (Scheme 2). The optimal reaction required two equiv of **1**, as different from the above cyclopropanation using one equiv of **1**. The formation of **4** as a product from **1** was little detected. On the other hand, dibutylbromotellurium hydroxide (**8**)

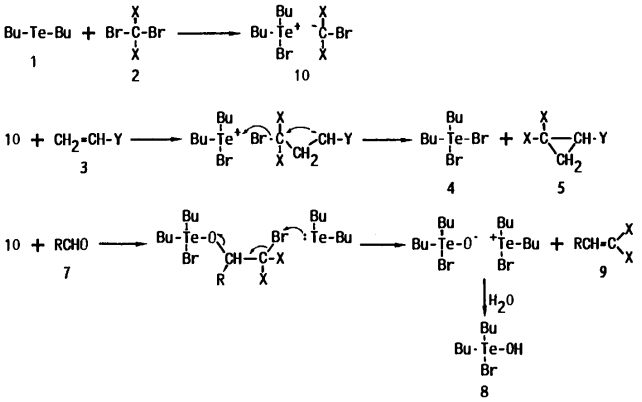
was obtained in an excellent yield after aqueous treatment of the reaction mixture. This alkylidenation is also applicable for common aldehydes such as heptanal (**7e**) and benzaldehyde (**7f**), affording simple condensed products **9** and accordingly useful as a substitute for Knoevenagel condensation of aldehyde and active methylene.[7]

Although the mechanisms are not established, these reactions are likely to proceed through pathways as shown in Scheme 3. The chemoselectivity of cyclo-



Scheme 3.

propanation and alkylidenation of α,β-unsaturated carbonyl compound **3** depends on reactivity of the initial complex **10**. Aldehydes **7** suffer ready 1,2-addition leading to alkylidenation. In contrast, ketones, esters, and nitriles are inert, and accordingly their conjugated olefins can effect Michael type addition leading to cyclopropanation.

Experimental

Melting points are uncorrected. All reactions were carried out under an argon atmosphere. Dibutyl telluride (**1**),[8] dimethyl dibromomalonate (**2a**),[9] diethyl dibromomalonate (**2b**),[9] and dibromomalononitrile (**2c**)[10] were prepared according to the reported methods. Other chemicals are commercially available. IR spectroscopy was run on a Hitachi 260-30 spectrophotometer. NMR spectra were recorded on a JEOL PMX-60 spectrometer (60 MHz) using carbon tetrachloride as a solvent. Mass spectra were measured with a Shimazu QP-1000 spectrometer.

Typical Procedure for Cyclopropanation: 1-Acetyl-2,2-bis(ethoxycarbonyl)cyclopropane (5h). Diethyl dibromomalonate (**2b**; 954 mg, 3 mmol) and methyl vinyl ketone (**3d**; 267 mg, 3.1 mmol) were placed in a 20 mL round-bottomed flask with a septum cap, which was purged with an argon gas. Dibutyl telluride (**1**; 726 mg, 3 mmol, 1 equiv) was added by a syringe and the mixture was stirred at room temperature under an inert gas. The exothermic reaction was complete within 1h. It was then chromatographed on an alumina column (70—230 mesh) with ethyl acetate as eluent to give first dibutyltellurium dibromide (**4**)[6] as a colorless oil, yield 1.012 g (84%); ^{1}H NMR (CCl_4) δ=0.88—1.21 (m, 6H, $2CH_3$), 1.21—2.60 (m, 8H, $4CH_2$), and 3.41—3.80 (m, 4H, $2TeCH_2$).

Further elution gave 1-acetyl-2,2-bis(ethoxycarbonyl)-cyclopropane (**5h**) as a colorless oil, which was further purified by bulb-to-bulb distillation; bp 88—90 °C/11 Pa (lit,[11] bp 92 °C/11 Pa); yield 587 mg (86%).

5a: colorless oil, bp 137—140 °C/15 Pa; IR (neat) 3020, 1755, 1750, 1735, and 885 cm^{-1}; ^{1}H NMR δ=1.55 (dd, 1H, J=5.5 and 8 Hz), 1.83 (dd, 1H, J=4.5 and 7 Hz), 2.46 (dd, 1H, J=7 and 8 Hz), 3.68 (s, 6H), and 3.74 (s, 3H); MS m/z (rel intensity) 216 (M^+, 0.3) and 157 (M^+-CO_2Me, 100). Anal. ($C_9H_{12}O_6$) C, H.

5b: colorless oil, bp 115—116 °C/5 Pa (lit,[12] bp 84—85 °C/1 Pa).

5c: colorless oil, bp 105—107 °C/11 Pa; IR (neat) 3000, 1760, 1750, 1730, and 865 cm^{-1}; ^{1}H NMR δ=1.25 (t, 3H, J=7 Hz), 1.56 (dd, 1H, J=4.5 and 8 Hz), 1.84 (dd, 1H, J=4.5 and 7 Hz), 2.45 (dd, 1H, J=7 and 8 Hz), 3.66 (s, 3H), 3.74 (s, 3H), and 4.10 (q, 2H, J=7 Hz); MS m/z 230 (M^+, 2.1) and 185 (M^+-OEt, 100). Anal. ($C_{10}H_{14}O_6$) C, H.

5d: colorless oil, bp 99—102 °C/8 Pa (lit,[13] bp 76—80 °C/7 Pa).

5e: colorless oil, bp 103—105 °C/11 Pa; IR (neat) 2960, 1760, 1755, 1730, and 885 cm^{-1}; ^{1}H NMR δ=0.8—1.7 (m, 7H), 1.56 (dd, 1H, J=4.5 and 8.5 Hz), 1.85 (dd, 1H, J=4.5 and 7 Hz), 2.49 (dd, 1H, J=4.5 and 8.5 Hz), 3.67 (s, 3H), 3.74 (s, 3H), and 4.07 (bt, 2H, J=6 Hz); MS m/z (rel intensity) 258 (M^+, 13) and 185 (M^+-OBu, 100). Anal. ($C_{12}H_{18}O_6$) C, H.

5f: colorless oil, bp 129—132 °C/11 Pa; IR (neat) 2990, 1755, 1750, 1745, and 860 cm^{-1}; ^{1}H NMR δ=0.8—1.7 (m, 7H), 1.30 (t, 3H, J=7 Hz), 1.33 (t, 3H, J=7 Hz), 1.51 (dd, 1H, J=4.5 and 8.5 Hz), 1.82 (dd, 1H, J=4.5 and 7 Hz), 2.47 (dd, 1H, J=7 and 8.5 Hz), 4.11 (q, 2H, J=7 Hz), 4.19 (q, 2H, J=7 Hz), and 4.31 (t, 2H, J=6 Hz), MS m/z (rel intensity) 286 (M^+, 0.04) and 185 (M^+-CO_2Bu, 100). Anal. ($C_{14}H_{22}O_6$) C, H.

5g: colorless oil, bp 117—120 °C/11 Pa; IR (neat) 3000, 1730, 1708, and 880 cm^{-1}; ^{1}H NMR δ=1.49 (dd, 1H, J=4.5 and 8.5 Hz), 1.88 (dd, 1H, J=4.5 and 7 Hz), 2.33 (s, 3H), 2.77 (dd, 1H, J=7 and 8.5 Hz), 3.62 (s, 3H), and 3.73 (s, 3H); MS m/z (rel intensity) 200 (M^+, 2.3) and 185 (M^+-Me, 100). Anal. ($C_9H_{12}O_5$) C, H.

5i: colorless oil, bp 129—132 °C/11 Pa; IR (neat) 3120, 2255, 1715, and 840 cm^{-1}; ^{1}H NMR δ=2.0—2.4 (m, 2H), 2.40 (s, 3H), and 3.10 (dd, 1H, J=7 and 8.5 Hz); MS m/z (rel intensity) 134 (M^+, 1.4) and 43 (COMe, 100). Anal. ($C_7H_6N_2O$) C, H, N.

5j: colorless oil, bp 121—123 °C/1470 Pa (lit,[14] bp 123—125 °C/1730 Pa).

5k: colorless oil, bp 99—103 °C/15 Pa (lit,[12] bp 98—100 °C/13 Pa).

Typical Procedure for Alkylidenation: Diethyl 2-Propenylidenemalonate (9b). A mixture of diethyl dibromomalonate (**2b**; 477 mg, 1.5 mmol) and acrylaldehyde (87 mg, 1.5 mmol) was treated with dibutyl telluride (**1**; 726 mg, 3 mmol, 2 equiv) as described for the preparation of **5h**. After 30 min, the mixture was taken up with chloroform (30 mL) and washed with water, dried over anhydrous magnesium sulfate, and concentrated in vacuo. The

residue was diluted with hexane (20 mL). The insoluble material was filtered off and the filtrate was chromatographed on silica-gel column (88—125 mesh) with chloroform to give first dibutyltellurium dibromide (**4**) as a colorless oil, yield 30 mg (5%), and then diethyl 2-propenylidenemalonate (**9b**) as a colorless oil, yield 258 mg (87%), which was purified by bulb-to-bulb distillation; bp 63—65 °C/16 Pa; IR (neat) 2990, 1745, 1720, 1590, and 865 cm^{-1}; ^1H NMR δ=1.27 (t, 3H, J=7 Hz), 1.30 (t, 3H, J=7 Hz), 4.18 (q, 2H, J=7 Hz), 4.20 (q, 2H, J=7 Hz), 5.49 (dd, 1H, J=2 and 9.5 Hz), 5.61 (ddd, 1H, J=9.5, 11, and 17 Hz), and 7.14 (d, 1H, J=11 Hz); MS m/z (rel intensity) 198 (M^+, 31) and 153 (M^+—OEt, 100). HRMS Found: m/z 198.0934. Calcd for $C_{10}H_{14}O_4$: M, 198.0892.

Recrystallization of the insoluble material from benzene-hexane gave white scales of dibutylbromotellurium hydroxide (**8**); yield 811 mg (80%); mp 141—142 °C; IR (KBr) 3450 (O-H) and 2970 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.84—1.20 (m, 6H, $2CH_3$), 1.20—2.33 (m, 8H, $4CH_2$), 1.69 (br s, 1H, OH), and 2.70—3.85 (m, 4H, $2TeCH_2$). Anal. ($C_8H_{19}BrOTe$) C, H.

9a: colorless oil, bp 85—87 °C/15 Pa; IR (neat) 3050, 1735, 1720, 1590, and 840 cm^{-1}; ^1H NMR δ=3.74 (s, 3H), 3.77 (s, 3H), 5.54 (dd, 1H, J=2 and 9.5 Hz), 5.67 (dd, 1H, J=2 and 17 Hz), 6.68 (ddd, J=9.5, 11, and 17 Hz), and 7.16 (d, 1H, J=11 Hz); MS m/z (rel intensity) 170 (M^+, 52) and 139 (M^+—OMe, 100). Indirect Electrooxidation by Using Ruthenium Tetraoxide and Chloride Ion as Recycling Mediators. Optimization for the Oxidation of Diisopropylidene-D-glucose to the Ulose

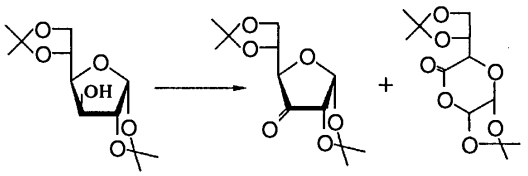
Sigeru TORII,* Tsutomu INOKUCHI, Shigeaki MATSUMOTO, Takeaki SAEKI, and Tsunehei OKI
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Okayama 700
(Received January 5, 1989)

Synopsis. Various factors related to the yield and selectivity for the indirect electrooxidation of diisopropylideneglucose (**1**) to the ulose **2** with ruthenium tetraoxide (RuO_4) and chloride ion are investigated. The following is found to be optimum conditions: pH, ca. 10: solvent system, carbon tetrachloride and *t*-butyl alcohol (ca. 9 : 1); current density, 10—40 mA cm^{-2}; temperature, 20—40 °C; catalyst amount, 2 mol% of $RuO_2 \cdot 2H_2O$ (based on **1**). The optimized electrolysis affords the desired **2** in 90% yield along with a trace of the cleavaged product **3** (0.2%) by an overoxidation.

Ruthenium tetraoxide (RuO_4) has been utilized as a versatile reagent for oxidative transformations[1] since the first example was reported by Djerassi et al.[2] In the preceding paper, we have developed an in situ regeneration of RuO_4 from $RuO_2 \cdot 2H_2O$ or $RuCl_3$ by the electrolysis in a two-phase system consisting of an aqueous sodium chloride and an appropriate organic solvent.[3-5] This electrochemical procedure involves following three reaction steps: (1) oxidation of the substrate by RuO_4, (2) regeneration of RuO_4 from RuO_2 by the action of oxidizing chlorine species, and (3) anodic oxidation of chloride ion to the oxidizing chlorine species. Optimization of the reaction by controlling the electrolysis conditions, however, has not been examined in details. We chose 1,2 : 5,6-di-*O*-isopropylidene-α-D-glucofuranose (diisopropylideneglucose, **1**), prepared from D-glucose by isopropylidenation,[6] as a substrate for the following reasons: (a) synthetic utility of the product as a chiron pool[7] and (b) structural diversity of **1**, bearing acid-labile groups, to know the range of applicability of the



1 2 3

Scheme 1.

method.

The preparation of 1,2 : 5,6-di-*O*-isopropylidene-α-D-ribo-hexofuranos-3-ulose (**2**) by oxidation of diisopropylideneglucose **1** has been carried out by using $CrO_3 \cdot 2Py$ (yield: 6%),[8a] PCC-Molecular Sieves (yield: 85%),[8b] DMSO-Ac_2O (yield: 62%),[9] DMSO-DCC (yield: 0—70%),[10] DMSO-P_2O_5 (yield: 45—65%),[11] DMSO-TFAA (yield: 85%),[12] RuO_4-$NaIO_4$ (yield: 75—95%),[13] photochemical oxidation of pyruvic ester,[14] and others.[15] Most of these oxidizing agents suffer from one of the following disadvantages: high cost of reagents, troublesome workup, and hazardous waste products from the oxidants. In addition, the overoxidation of **2** to the corresponding δ-lactone **3** is a problem to be circumvented.[13] In this study we have investigated the influential factors which are related with the formation of **2** from **1** in the RuO_4-mediated electrochemical process.

Experimental

Material. $RuO_2 \cdot 2H_2O$ purchased from Nippon Engelhard Company was used. The starting compound **1** prepared by the known methods[6] was purified by recrystallization from cyclohexane prior to the use. Chloroform ($CHCl_3$) was washed with water to remove ethanol before use. Aqueous buffer solutions were prepared by dissolving an appropriate phosphate or carbonate in aqueous saturated sodium chloride.

Electrolysis Apparatus. Electrolyses were usually carried out in a simple 30 ml beaker-type cell (2.5 cm diameter and 10 cm height) fitted with a condenser, a stirring bar, a thermometer, and two platinum foil electrodes (3 cm^2) being placed parallel to each other 10 mm apart. The vessel was immersed in a thermostated water bath and approximately maintained at prescribed temperature.

General Procedure for the Electrooxidation of 1. 1,2 : 5,6-Di-*O*-isopropylidene-α-D-glucofuranose (**1**, 400 mg, 1.45 mmol) was dissolved in CCl_4 (5 ml) in an electrolysis vessel and then $RuO_2 \cdot 2H_2O$ (10 mg, 0.06 mmol) and saturated NaCl buffered at pH 9 with 0.03 M $NaHCO_3$ (10 ml) were added to this solution. To the upper aqueous layer of two phase mixture were immersed two platinum electrodes and then the entire mixture was electrolyzed under a constant current of 20 mA cm^{-2} at room temperature with a vigorous stirring. The electrolysis was continued until the organic phase has changed slightly to a yellow solution from greenish black. It required the passage of about 5 F mol^{-1} of electricity based on **1**. The mixture was treated with 2-propanol (0.5 ml) to deactivate the excess ruthenium tetraoxide. The CCl_4 layer was separated and the aqueous layer was extracted with $CHCl_3$. The combined extracts were washed with water, dried over Na_2SO_4, and concentrated in vacuo to give 360 mg of the crude oily products. The product yields were determined with quantitative analysis with gas chromatography. The yields of the ulose **2** and the lactone **3** were 82% and 1.2%, respectively and a small amount of the starting glucofuranose **1** was recovered (7.2%).

Similar electrolysis of 1.20 g (4.62 mmol) of **1** using 0.02 g (0.12 mmol) of $RuO_2 \cdot 2H_2O$ in the mixed solvent of CCl_4 (7 ml), *t*-butyl alcohol (1 ml), and saturated NaCl buffered at pH 10 with 0.03M $NaHCO_3$ and 0.01M Na_2CO_3 (12 ml) as above required 5.1 F mol^{-1} of electricity and then the desired ketone **2**, the lactone **3**, and **1** were obtained in 90%, 0.2%, and 7% yields, respectively.

Analysis. The starting diisopropylideneglucose **1** and the products were analyzed with gas chromatography (1 m, 10% ucone oil 50HB5100/chromosorb W-HP 80/100 mesh). The quantitative analysis was performed in an internal

standard method by gas chromatography (an internal standard: sulfolane).

Results and Discussion

The electrolyses of **1** were carried out in a two-phase system consisted of an organic solvent and an aqueous saturated sodium chloride solution. In order to find a suitable electrolysis solvent system, we first plotted the yields of the diisopropylidene ulose **2** by changing the kind of organic solvents under different pH ranges of an aqueous phase (Fig. 1). Carbon tetrachloride (CCl_4), 4-methyl-2-pentanone, and *t*-butyl alcohol were found to be useful for the present purpose. Of interest to note is that the product yield of the ulose **2** in a halogenated solvent such as carbon tetrachloride (CCl_4) and chloroform ($CHCl_3$) increases at basic pH range. On the other hand, acetone and 4-methyl-2-pentanone were preferable ones in the acidic conditions. The overoxidation of the ulose **2** to the δ-lactone **3** is a major problem to be solved in the present RuO_4-mediated electrooxidation. The formation of **3** can be suppressed to less than 5% by employing CCl_4 or $CHCl_3$.

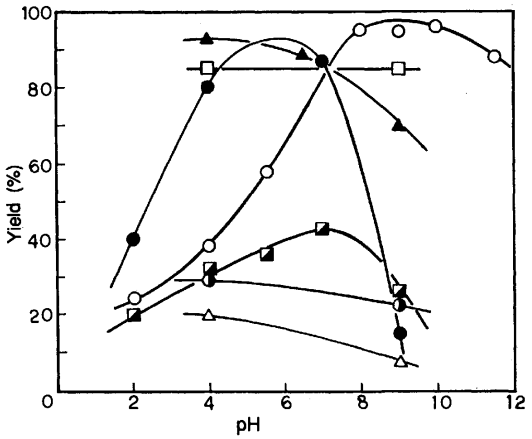


Fig. 1. Effect of pH of the aqueous phase for the formation of **2** in a two phase system consisting of a different sort of organic solvents and saturated NaCl (8 ml/12 ml). Data points of this figure were obtained by electrolysis of **1** (170 mg) in the presence of $RuO_2 \cdot 2H_2O$ (10 mg) at a current of 10 mA cm^{-2} by passing 5 F mol^{-1} of electricty. ○: CCl_4; ◑: diisopropyl ether; ●: acetone; □: *t*-butyl alcohol; ◪: $CHCl_3$; △: CH_3CN; ▲: 4-methyl-2-pentanone.

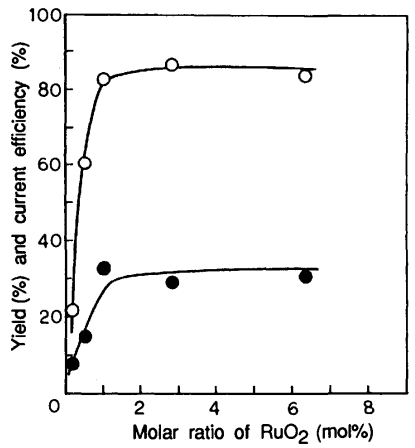

Fig. 2. Effect of molar ratio of $RuO_2 \cdot 2H_2O$ (to **1**) for the formation of **2**. Data points were obtained by electrolysis in CCl_4/saturated NaCl (8 ml/12 ml) by passing 5 F mol^{-1} of electricity. Symbols follows: product yield (○), current efficiency (●).

So far as the effect of current density and temperature is concerned, satisfactory conversion yields were obtained under the conditions of 10—40 mA cm^{-2} at 20—40 °C.

In order to visualize the correlation of the amount of ruthenium reagent for the ulose electrosynthesis, the conversion yields together with the current efficiencies with changing the amount of $RuO_2 \cdot 2H_2O$ are plotted in the Fig. 2. The results show the minimum amount of ruthenium reagent required for the oxidation of **1**. The both conversion yields and current efficiencies reach a plateau under the conditions of more than 1.5 mol% of $RuO_2 \cdot 2H_2O$ (based on the substrate **1**) at a current density of 20 mA cm^{-2}.

In order to clarify the correlation of the amount of ruthenium dioxide toward the current efficiency, the molar ratio of ruthenium dioxide vs. current density was plotted in terms of the conversion yield as well as the current efficiency of the ulose **2** as compiled in Fig. 3. Apparently, both the yields and the current efficiencies increase with increasing the value of RuO_2 amount divided by current density. The maximum points were obtained when the value reached about 0.2×10^{-2} [mol (A cm^{-2})$^{-1}$].

The conversion yields and the current efficiencies in the ulose electrosynthesis are referred to the substrate concentration in the media. The curves in Fig. 4 indicate that the current efficiencies and conversion yields of the ulose **2** decrease in proportion to the increase of the substrate concentration. Carbon tetrachloride can not be used for the large scale operation due to the limited solubility of the substrate **1** (maximum solubility in carbon tetrachloride: 4

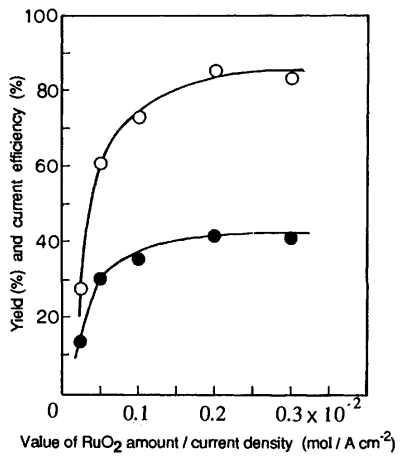

Fig. 3. Effect of value of RuO_2 amount divided by current density for the formation of **2**. Data points were obtained by the electrolysis in CCl_4/saturated NaCl (8 ml/12 ml) at a current of 20 mA cm^{-2} by passing 5 F mol^{-1} of electricity at pH 8—9. Symbols follows: product yield (○), current efficiency (●).

wt%). The co-solvent system may be a choice for the present electrooxidation in order to attain higher concentration of the substrate.

Taking the data in Fig. 1 into the account, we chose *t*-butyl alcohol as an additional solvent to carbon tetrachloride, since *t*-butyl alcohol can maintain almost same current efficiency as carbon tetrachloride. The experimental results are summarized in Fig. 5. The yields of the ulose **2** obtained in various co-solvent ratios and different pH ranges are shown as a form of contour line like as on a map. The horizontal zones are made by binding the points of the same yields. The contour lines summarize the correlation between pH values and co-solvent systems in terms of the conversion yields of the ulose **2**. Of interest to note is that two maximum zones are observed in the region of 90 vol% of carbon tetrachloride (to *t*-butyl alcohol) at about pH 10 and 10 vol% of CCl_4 (to *t*-butyl alcohol) at about pH 4. From a practical point of view, however, it is desirable to choose the electrolysis conditions of slightly basic media to prevent hydrolysis of the acetonide protecting groups.

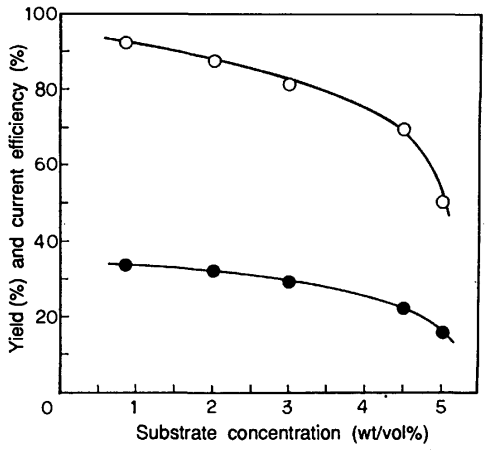

Fig. 4. Effect of substrate concentration for the formation of **2**. Data points were obtained by electrolysis in CCl_4-saturated NaCl (7 ml/14 ml) at a current density of 10 mA cm^{-2} by passing 5.5 F mol^{-1} of electricity at pH 8—9. Symbols follows: product yield (○), current efficiency (●).

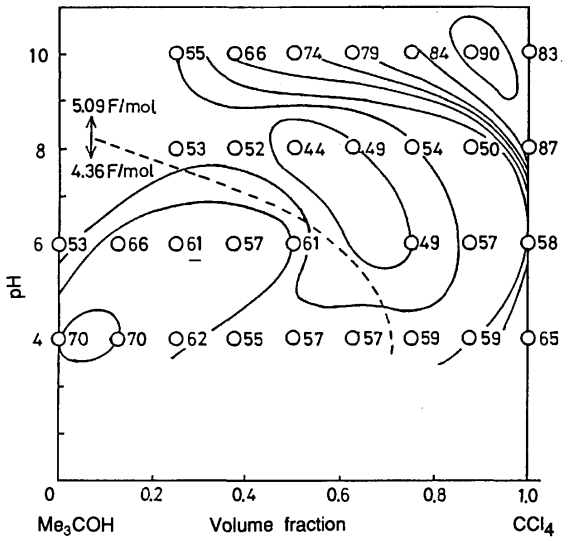

Fig. 5. Correlation between pH and CCl_4/*t*-butyl alcohol ratio for the formation of **2**. The suffix number of data points denotes the yield of **2**. These data were obtained by electrolysis at a current density of 20 mA cm^{-2} by passing 4.36 F mol^{-1} of electricity. The substrate concentration was 6 (wt/vol).

In conclusion, ruthenium tetraoxide has proven to be an efficient mediator as an oxidizing reagent in the present electrolysis system. The constant current electrolysis at 20 mA cm^{-2} of **1** (1.20 g) with 20 mg of $RuO_2 \cdot 2H_2O$ at about pH 10 in CCl_4-Me_3COH (ca. 9 : 1)-saturated NaCl-(Pt) system gives **2** (ratio of **2** to **3**=ca. 450 : 1) in about 90% yields.

The Utility of *t*-Butyldimethylsilane as an Effective Silylation Reagent for the Protection of Functional Groups

Keiji YAMAMOTO* and Makoto TAKEMAE
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro, Tokyo 152
(Received January 11, 1989)

Synopsis. Treatment of compounds containing functional groups, such as alcohols, amines, and carboxylic acids, with *t*-butyldimethylsilane in the presence of a catalytic amount of palladium on carbon is described to provide a new, convenient method for the introduction of a *t*-butyldimethylsilyl (TBDMS) group.

Protection of functional groups via chlorosilanes occupies a prominent place in a variety of protection techniques which are often indispensable for organic syntheses.[1] Corey and Venkateswarlu[2] have invented the use of *t*-butyldimethylsilyl chloride (TBDMSCl) to protect alcohols effectively in *N*,*N*-dimethylformamide (DMF) solution under the catalytic influence of imidazole (Im). The protection with this reagent is most widely used, mainly because of the stability of the corresponding silyl ethers towards certain oxidation, reduction, and mild solvolytic conditions and, moreover, an easy removal of the silyl group from silyl ethers by fluoride ions. Since TBDMSCl/Im/DMF method does not apply well to amines and carboxylic acids, many variations therefrom have been reported.[3]

Hazardous preparation of TBDMSCl using *t*-butyllithium[4] can be avoided on an industrial scale by a sequence of reactions of dimethoxymethylsilane with *t*-butylmagnesium chloride and with methylmagnesium chloride, followed by chlorination of the resulting *t*-butyldimethylsilane.[5] We became aware of the possibility of the selective protection of functional groups with use of the latter compound. Described herein is a convenient method for the protection of certain alcohols, amines, and carboxylic acids, which involves a simple treatment of these compounds with *t*-butyldimethylsilane in the presence of 10% palladium on carbon as a catalyst.

It has previously been documented by Sommer and Lions[6] that the group VIII metal-catalyzed solvolysis of an optically active methyl-1-naphthylphenylsilane with a wide variety of nucleophilic solvents such as alcohols and amines takes place to proceed with inversion of configuration at the silicon center.

Results and Discussion

The group VIII metals and their salts catalyze the cleavage of the silicon-hydrogen bond by certain nucleophiles containing OH and NH functions (Eq. 1). Besides the mechanistic implications of the nucleo-

$$\text{Nu-H} + \text{R}_3\text{SiH} \xrightarrow{\text{metal cat.}} \text{Nu-SiR}_3 + \text{H}_2 \qquad (1)$$

Nu-H=alcohols, amines, and carboxylic acids

philic substitution on the silicon center which is activated by the catalyst, the reaction is experimentally ideal for the selective protection of alcohols, for example, in that only hydrogen is formed as a by-product and the catalyst is easily removed by filtration.

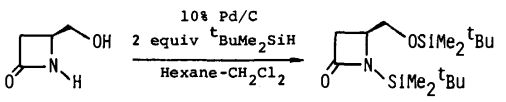
Alcohols: Thus, when *t*-butyldimethylsilane in hexane was treated with 3-phenyl-1-propanol and 10% Pd/C (5 mol% equiv) at room temperature, hydrogen slowly evolved and the silyl ether was obtained in 96% conversion (by GLC) in 2 h. Simple filtration of the reaction mixture through a Celite plug and, if necessary, flash chromatography, provided 3-phenylpropyl *t*-butyldimethylsilyl (TBDMS) ether with satisfactory purity in 72% yield. In the protection of alcohols, rhodium on carbon (10%) worked even better than 10% Pd/C and Ru/C, although it is more expensive. More polar solvents, such as, CH_2Cl_2, THF, and benzene, retarded significantly the rate of reaction, although they are often desirable for solubility purposes.

Several alcohols were examined in this protection procedure under the same conditions (0.3 mol dm^{-3} of the substrate in hexane at 70 °C), and we have found the relative reactivity (percent conversion and reaction time in parentheses) in the order $PhCH_2OH$ (99%, 1 h) > $PhCH_2CH_2CH_2OH$ (96%, 2 h) > $C_6H_{11}OH$ (92%, 7 h) PhCHMeOH (76%, 7 h) ≫ *t*-BuOH (trace, 9 h). The reactivity pattern clearly indicates that a primary alcohol, especially benzyl alcohol, undergoes protection faster than a secondary alcohol, whereas *t*-butyl alcohol hardly reacted under the conditions employed.[4b] Selective protection of primary hydroxyl group in 1,2-propanediol and 1-phenyl-1,2-ethanediol was easily achieved with >96% selectivity. It should be mentioned that no hydrogenolysis at the benzylic position of 1-phenyl-1,2-ethanediol was observed at all under the present conditions. Taking higher reactivity of benzylic alcohols into account, we examined by GLC analysis any competitive formation of $PhCH(OSiMe_2Bu^t)CH_2OH$, an authentic sample of which was prepared separately (see, Experimental). The ratio of primary silylation to secondary silylation was efficiently 96 : 4. The reagent combination of TBDMSCl, 4-(dimethylamino)pyridine, and triethylamine can be employed as well with a pronounced kinetic preference for primary against secondary alcohols.[7]

Protection of allylic alcohols (e.g., cinnamyl alcohol and geraniol) always accompanied partial hydrogenation of the olefin moiety due to the hydrogen which formed as the protection proceeded. Attempted quenching of the by-product hydrogen with excess 1-hexene instead of hexane as a solvent resulted in little improvement. It is worthy of mention that the stoichiometric hydrogenation of certain olefins has previously been reported by employing either ethanol/hydrosilane/Pd-C[8] or methanol/$NaBH_4$/H_2PtCl_6 catalyst[9] system under ambient conditions.

Amines: In the protection of amines, palladium

on carbon was the only choice as a catalyst. Benzene was a better solvent than hexane and CH_2Cl_2. Again benzyl amine reacted faster than morpholine in benzene at 70 °C: $PhCH_2NH_2$ (100%, 1.5 h) > $PhCHMeNH_2$ (82%, 12 h); morpholine (93%, 5 h). In order to exhibit a synthetic usefulness of the procedure, optically active 4-hydroxymethyl-2-azetidinone was subjected to the present protection to provide easily an *N,O*-disilylated derivative (Eq. 2).[10]



(2)

Carboxylic Acids: An expeditious synthesis of *t*-butyldimethylsilyl triflate has been reported by a direct reaction of *t*-butyldimethylsilane with a strong acid.[11] There is another precedent[12] in which $RhCl(PPh_3)_3$-catalyzed reaction of carboxylic acids with $EtMe_2SiH$ or $PhMe_2SiH$ gives the corresponding silyl esters. Hydrocinnamic acid and 2-methylbutanoic acid were reacted with *t*-butyldimethylsilane under the same conditions as those for alcohols described above to afford the silyl esters, respectively, in almost quantitative yields. Since the latter compounds are sensitive to hydrolysis, the present protection procedure is of special advantage due to its easy isolation.

Finally, (1,1,2-trimethylpropyl)dimethylsilane was prepared in a reasonable yield by the reaction of tetramethylethylene and dimethylsilane in the presence of a catalytic amount of $AlCl_3$.[13] All protection procedures presented here are equally applicable to the use of (1,1,2-trimethyl)dimethylsilane. The results will be discussed separately along with the novel mechanistic aspects of the $AlCl_3$-catalyzed hydrosilylation.

In conclusion, we propose the utility of *t*-butyldimethylsilane as an effective silylation reagent for alcohols, amines, and carboxylic acids, the method suffering from a drawback of incompatibility with olefinic functionality.

Experimental

Materials. *t*-$BuMe_2SiH$[4b] is a stable colorless liquid with a low boiling point (80 °C), being provided by Shin-Etsu Chemical Industry, Co., Ltd. and used as received. Group VIII metal catalysts (10% Pd/C, Rh/C, and Ru/C dry type) were obtained from Kawaken Fine Chemicals Co., Ltd. All substrates examined are commercial samples except a 2-azetidinone and mostly purified by distillation before use. Solvents were dried according to the standard procedure. (*S*)-4-Hydroxymethyl-2-azetidinone was prepared starting from pure L-aspartic acid in four steps.[10]

Protection Procedures. Alcohols: In a 20 mL two-necked flask, equipped with a reflux condenser topped with a nitrogen balloon, a rubber septum, and a magnetic stirring bar, were placed an alcohol (1.0 mmol), *t*-$BuMe_2SiH$ (140—174 mg, 1.2—1.5 mmol), 10% Pd/C (53.2 mg, 5 mol%), and dry hexane (3 mL) under a nitrogen atmosphere. The whole mixture was heated at 70 °C for a given time (0.5—9 h). The extent of the reaction was monitored by either GLC or TLC analysis. After the protection was completed (mostly at the conversion > 96% except for *t*-butyl alcohol), the catalyst was filtered through a short Celite plug, and the solvent and excess *t*-$BuMe_2SiH$ were evaporated under reduced pressure. The residue was purified by either column chromatography or by distillation (Kugelrohr), being practically pure for further use.[14] Selective protection of 1,2-propanediol and 1-phenyl-1,2-ethanediol was also carried out using 1.2 equiv amount of *t*-$BuMe_2SiH$ in hexane-CH_2Cl_2 (1 : 1 v/v). In the case of 1-phenyl-1,2-ethanediol, a little phenacyl alcohol was detected as a by-product during the protection. An authentic sample of the secondary silylated product, $PhCH(OSiMe_2Bu^t)CH_2OH$:[15] ^1H NMR (90 MHz, TMS, $CDCl_3$) δ=−0.10 (s, 3H), 0.06 (s, 3H), 0.91 (s, 9H), 3.58 (d, 2H, *J*=6.1 Hz), 4.76 (brt, 1H, *J*=5.9 Hz), and 7.31 (brs, 5H). GLC (Silicone DC-550, 3 m, at 200 °C, H_2 40 mL min^{-1}): T_R=2.4 min. For the primary silylated product, T_R=3.1 min. Table 1 lists ^1H NMR data

Table 1. ^1H NMR (90 MHz, $CDCl_3$, TMS) of TBDMS Derivatives of Alcohols, Amines, and Carboxylic Acids

TBDMS derivative	Chemical shifts (δ)

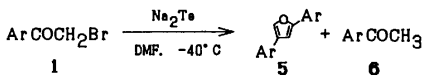
Formation of Furan Derivatives from Phenacyl Bromides and Sodium Telluride; Attempted Extension to Coumarin Synthesis

Seetharamaiyer PADMANABHAN, Takuji OGAWA, and Hitomi SUZUKI*
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received January 14, 1989)

Synopsis. The enolates, generated from phenacyl bromides by sodium telluride, yield 2,4-diarylfurans in addition to the expected dehalogenation products. No 1,4-dicarbonyl compounds could be isolated even in the presence of excess oxidizing agent, copper(II) chloride. Condensation of 2-(methoxymethoxy)arenecarbaldehydes with ethyl bromoacetate in the presence of sodium telluride gave the expected α,β-unsaturated esters which resisted cyclization to yield the desired coumarin derivatives. Attempted intramolecular Reformatsky-type reaction of 2-(bromoacetoxy)-benzaldehyde gave only 6,12-epoxy-6*H*,12*H*-dibenzo[*b*,*f*]-[1,5]dioxocin as the major product.

Sodium telluride, as a reagent for effecting many functional group transformations, has been studied in our laboratory for quite some time. Many heterocyclic compounds containing tellurium as the heteroatom have been synthesized using sodium telluride,[1] while there have been no reports concerning the formation of non-tellurium heterocyclic compounds using sodium telluride. Herein we wish to report the formation of 2,4-diarylfurans (**5**) from the ketone enolates generated from phenacyl bromides (**1**) and the results of our efforts to synthesize coumarins using sodium telluride.

2,4-Diarylfurans. Ketone enolates and ester enolates have been oxidatively coupled to give synthetically important 1,4-diketones employing $CuCl_2$,[2] $FeCl_3$,[3] and $Cu(OTf)_2$.[4] Ketene silyl acetals have also been subjected to similar reaction.[5] Recently, Belletire reported the occurrence of symmetrical dimerizations of carboxylic dianions and β-keto ester dianions using molecular iodine as oxidant.[6] He also reported the C-C coupling at γ-position of the dianions from β-keto sulfones. These results prompted us to investigate whether a coupling at the active methylene of halo ketones could be achieved from the enolate generated by sodium telluride taking advantage of the affinity of telluride anion for the halogens. Such a study would enable us to see the fate of enolates generated by sodium telluride under oxidative coupling conditions.



As a model compound we studied the enolate derived from phenacyl bromide **1** in the presence of iodine. Addition of a solution of **1a** in *N*,*N*-dimethylformamide (DMF) to a suspension of sodium telluride in the same solvent at −40 °C followed by the addition of iodine in DMF resulted in a dark reaction mixture which gave two fractions after chromatography. The first, hexane fraction, showed ^{1}H NMR spectrum which was completely devoid of aliphatic protons. The second one was easily identified as acetophenone (**6a**; 29%). From the elemental analysis and spectral data in combination with comparison of reported melting points of diphenylfuran derivatives, the product isolated from the hexane fraction was identified as 2,4-diphenylfuran (**5a**; 14%). When anhydrous copper(II) chloride was employed in place of iodine the furan was obtained in a slightly better yield (17%). To our surprise no oxidatively coupled product could be isolated from the reaction mixture. Isolation of furan derivative was also possible using iron(III) chloride. Similarly from other substituted phenacyl bromides were obtained 2,4-diarylfurans (**5b—5d**) in varying yields (Table 1).

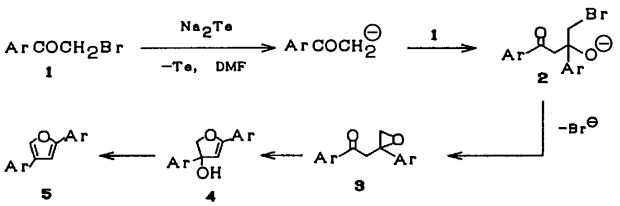
The formation of furan **5** could be attributed to an intermolecular condensation between the enolate generated and the bromo ketone **1** followed by presumably a formation of an epoxide ring which underwent further cyclization (Scheme 1). Synthesis of 2,4-diarylfurans from phenacyl bromides by electrochemical reduction[7] and formation of 2,4-diarylfurans from reactions of phenacyl bromides with nickel carbonyl in DMF[8] and with copper(I) chloride in DMSO[9] have been reported. Formation of furan derivatives during the dehalogenation of halo ketones by magnesium in tetrahydrofuran (THF)[10] has also been observed. Condensation of imino ketones from 1-amino-4,6-diaryl-2-pyridone with phenacyl bromides followed by acid treatment afforded 2,4-diarylfurans having different substituents.[11]

A support for the proposed mechanism was provided by reacting excess of the enolate generated from

Table 1. 2,4-Diarylfuran Derivatives Isolated

	Ar **1**	Mp/ °C **5** (lit,[7] Mp)	Yield/%[a] **5**	 **6**
a	C_6H_5	108—110 (109—110)	17	47
b	4-BrC_6H_4	157—160 (159—160)	36	43
c	4-ClC_6H_4	127—129 (127—128)	19	47
d	4-$C_6H_5C_6H_4$	258—263 (267—268)	2	58

a) Yields refer to the products isolated using an equimolar amount of copper(II) chloride.



Scheme 1.

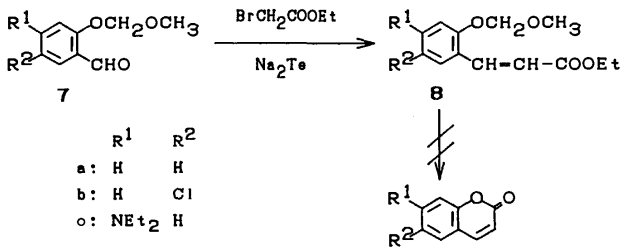
acetophenone by potassium hydride[12] with 4-chlorophenacyl bromide (**1c**) in the presence of copper(II) chloride under the similar conditions. From the reaction mixture the expected 2-phenyl-4-(4-chlorophenyl)furan was obtained in 36% yield. It was found that when the reaction was carried out in the absence of copper(II) chloride or if the formation of enolate was carried out in a short time the yield of furan derivative was considerably low. Attempts to develop an efficient method for synthesizing mixed 2,4-diarylfurans based on the above route did not give encouraging results.

To find the role of the oxidizing agent the reaction was carried out in the absence of copper(II) chloride and also in the presence of potassium iodide. Even in these cases furan derivative **5** was isolated in about 10% yield. This rules out the possibility of additives actually taking part in the reaction, but it is worth mentioning that the presence of copper(II) chloride or iron(III) chloride led to a very clean reaction mixture. In the absence of tellurium species, i.e., only in the presence of sodium hydride, 4-bromophenacyl bromide was recovered intact under similar conditions. With the view to obtain the furans in better yields the reaction was carried out deliberately using a less amount of sodium telluride. Such an attempt was, however, unsuccessful.

Finally in an attempt to isolate the oxidatively coupled product from the ketone enolate, generated from α-bromo ketone by sodium telluride, experiment was carried out using a large excess of copper(II) chloride. No oxidatively coupled product could be isolated from the reaction mixture (Table 2).

It is interesting to note the difference in behavior of both the ester enolate from ethyl bromoacetate and ketone enolates from phenacyl bromide derivatives generated by sodium telluride. In contrast to the ester enolate which has been found to be unreactive towards ketones,[13] the ketone enolates in the present study underwent intermolecular condensation and further cyclization leading to furan derivatives.

Coumarins. Recently we developed a novel route to α,β-unsaturated esters from aldehydes and ethyl bromoacetate using sodium telluride.[13] It was anticipated that extension of this reaction to salicylaldehyde derivatives would lead to coumarin derivatives. Attempted condensation of salicylaldehyde with ethyl bromoacetate resulted only in the recovery of the aldehyde. However, the desired α,β-unsaturated esters (**8a—c**) were obtained from 2-(methoxymethoxy)benzaldehydes (**7a—c**) and ethyl bromoacetate in moderate yields. Attempted cyclization of these unsaturated esters in acetic acid under reflux for 6 h resulted only in the hydrolysis of methoxymethoxy group. Cyclization using sulfuric acid or polyphosphoric acid gave a dark polymeric reaction mixture. Reluctance for cyclization could probably be attributed to the demand of sterically less favorable cis configuration of unsaturated esters for cyclization to occur.



Having met with no success in the above scheme we turned our attention to an intramolecular Reformatsky-type reaction of 2-(bromoacetoxy)benzaldehyde (**9**). Fuson and coworkers observed that the Reformatsky reaction of **9** occurs only in the presence of anhydrous zinc bromide in addition to zinc.[14] The products isolated include salicylaldehyde (65%), coumarin (26%), and *trans-o*-hydroxycinnamic acid (9%). Attempted intramolecular Reformatsky-type reaction of **9** using sodium telluride gave only 6,12-epoxy-6*H*,12*H*-dibenzo[*b*,*f*][1,5]dioxocin (**10**; disalicylaldehyde) (32%) in addition to salicylaldehyde (8%). Compound **10** would result from the self-acetalization of salicylaldehyde, generated from 2-(bromoacetoxy)benzaldehyde by the elimination of ketene. Formation of this compound from reactions using salicylaldehyde has been observed earlier.[15] Thus our attempts to synthesize coumarin derivatives using sodium telluride was entirely unsuccessful.

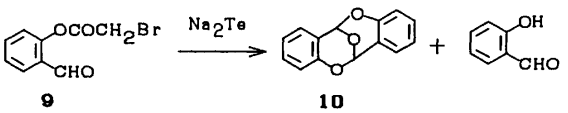


Table 2. Influence of Oxidizing Agents and the Relative Amounts of Halo Carbonyl Compounds, Na_2Te and Oxidant on the Yields of Furan Derivatives **5**

Phenacyl halide	Oxidant	Amounts employed (equiv)			Yield/%

a) Starting material was recovered intact.

Experimental

2-(Methoxymethoxy)arene carbaldehydes (**7a—c**) were prepared following the procedure reported by La Forge for the preparation of **7a**.[16] 2-(Bromoacetoxy)benzaldehyde (**9**) was prepared from salicylaldehyde and bromoacetyl bromide following the method reported.[14]

2,4-Diarylfurans: General Procedure: To sodium telluride (prepared from tellurium (1.0 mmol) and sodium hydride (2.2 mmol; washed with hexane prior to use))[17] in dry DMF (3 ml) at −40 °C was slowly added a solution of halo ketone (**1**: 1.0 mmol) in dry THF (3 ml) followed by the addition of anhydrous copper(II) chloride (1.0 mmol) in DMF (3 ml). Initially the reaction mixture could be stirred, but near the end of complete addition of halo ketone the mixture became very thick. Reaction mixture was kept at that temperature for 2 h and then slowly raised to room temperature. After 1 h the reaction was quenched by adding saturated aqueous ammonium chloride (10 ml) and the organic phase was extracted into benzene. The mixture was freed from insoluble inorganic materials by filtration through a thin layer of Celite. The organic layer was separated and the aqueous layer was extracted with benzene. The combined extracts were washed with 0.5 M† sulfuric acid followed by brine and dried over sodium sulfate. The crude product, obtained after evaporation, was purified by column chromatography over silica gel. Furan derivatives **5** were eluted first using hexane as eluent and then dehalogenated ketone **6** using a mixture of hexane and dichloromethane.

2-Phenyl-4-(4-chlorophenyl)furan: Acetophenone (1.0 mmol) in THF (5 ml) was added to potassium hydride (1.2 mmol; after removal of oil matrix following the procedure and precautions reported by Brown[18]) in THF (35 ml) at 20 °C and after the evolution of hydrogen ceased the reaction mixture was stirred for 24 h. The reaction mixture was cooled to −40 °C and 4-chlorophenacyl bromide (0.6 mmol) in DMF (3 ml) was added followed by the addition of copper(II) chloride (0.6 mmol) in DMF (3 ml). The dark reaction mixture was stirred at this temperature for 30 min and the reaction went to completion during this period. Water (10 ml) was added, THF was removed under vacuum, and the reaction mixture was extracted into benzene. 2-Phenyl-4-(4-chlorophenyl)furan was isolated in 36% yield. Mp 132—134 °C (lit,[11] 130 °C). IR: 1490, 1450, 1155, 1100, 1090, 1010, 930, 910, 835, 805, 770, 690 cm^{-1}; ^1H NMR: δ= 6.79 (s, 1H), 7.0—7.7 (m, 10H).

Preparation of the Unsaturated Esters (8a—c): General Procedure: To sodium telluride (4.0 mmol) in dry DMF (3 ml) at −20 °C was added, 2-(methoxymethoxy)benzaldehyde (**7a—c**) (1.0 mmol) in dry DMF (3 ml) followed by ethyl bromoacetate (4.0 mmol) in DMF (4 ml). Immediate separation of tellurium was observed and the reaction mixture was stirred at this temperature for 1 h and then at room temperature for 1 h. The reaction was quenched by the addition of 0.5 M sulfuric acid (5 ml) and the reaction mixture was extracted with benzene (10 ml). After stirring for 30 min the insolubles were removed by filtration through a bed of Celite and the aqueous layer was extracted with benzene (5 ml). The combined organic layer was washed with water and dried, and the solvent was removed under reduced pressure to give the crude unsaturated ester, which was purified by chromatography on silica gel using hexane as eluent.

Reaction of 2-(Bromoacetoxy)benzaldehyde (9) with Sodium Telluride. To a suspension of sodium telluride (1.0 mmol) in DMF (3 ml) at −40 °C was added a solution of 2-(bromoacetoxy)benzaldehyde (**9**) (1.0 mmol) in DMF (3 ml). The reaction was carried out as in the above case and the crude reaction mixture was purified by chromatography on silica gel. First, 6,12-epoxy-6*H*,12*H*-dibenzo[*b*,*f*][1,5]-dioxocin (**10**) was eluted followed by salicylaldehyde (8%) and only trace of coumarin, detectable on TLC, was eluted. Compound **10**, obtained in 32% yield, was crystallized from hexane. Mp 127—131 °C (lit,[14] 127—130 °C). MS: m/z (rel intensity) 226 (M^+, 100), 197 (24), 181 (22), 180 (10), 121 (12), 121 (67); IR: 1610, 1590, 1480, 1460, 1320, 1270, 1220, 1110, 1060, 1030, 970, 950, 760, 700 cm^{-1}. ^1H NMR: δ=6.22 (s, 2H), 6.7—7.4 (m, 8H). Found: C, 73.84; H, 4.65%. Calcd for $C_{14}H_{10}O_3$: C, 74.33; H, 4.43%.

Tellurodicarbonic Acid Diesters; Preparation and Properties

Hitomi SUZUKI* and Yoshinobu NISHIOKA
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received January 23, 1989)

Synopsis. Title compounds were obtained as reasonably stable to labile oily substances by reacting alkyl carbonochloridates with sodium telluride under phase-transfer conditions at room temperature or in dry *N*,*N*-dimethylformamide under ice-cooling.

Tellurodicarbonic acid (**1**) is one of the tellurium isologues of dicarbonic acid, which has not hitherto been described in the literature. We now report the preparation of dialkyl 2-tellurodicarbonates (**2**) and their unique properties quite different from those of ordinary esters.

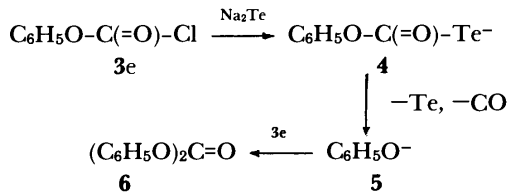
When a solution of alkyl carbonochloridates (**3**) in benzene was added slowly to an aqueous solution of sodium telluride in the presence of tetrabutylammonium bromide at room temperature, the initial reddish violet color gradually faded away and a yellow reaction mixture was obtained together with a small amount of free tellurium. After usual work-up followed by distillation of crude product under reduced pressure, compounds **2** were obtained as a pale yellow oil or low-melting colorless solid which, on standing in open air at room temperature, gradually got colored. Among four diesters **2a—2d** preparerd, diisopropyl ester **2c** is the most stable and can be stored for weeks without any appreciable change in a refrigerator. Dibenzyl ester **2d** is the most labile and begins to decompose within several hours after isolation, finally leading to a black resinous substance. Diesters **2** could be also obtained under aprotic conditions by reacting carbonochloridates **3** with sodium telluride in situ prepared from sodium hydride and tellurium in dry *N*,*N*-dimethylformamide (DMF). The yields of diesters usually ranged from 30 to 60%. Because of the instability of products under basic conditions employed, prolonged reaction time should be avoided.

Attempts to obtain diphenyl tellurodicarbonate (**2e**) under similar conditions were unsuccessful, however. The reaction with phenyl carbonochloridate (**3e**) went on smoothly, but the product isolated was not the expected dicarbonate **2e** but diphenyl carbonate (**6**). The initially formed phenyl tellurocarbonate anion (**4**) would readily collapse into phenolate ion (**5**), carbon monoxide and free tellurium, and the ion **5** thus formed would undergo further reaction with carbonochloridate **3e** to afford **6.**



Diesters **2** possess a characteristic odor not so offensive as that of lower dialkyl tellurides. On contact with skin, they produce black stains after a few hours,

Table 1. Dialkyl Tellurodicarbonates Prepared

Compound **2**	R	Yield/%	Bp (°C/mmHg)[a] [Mp (°C)]	^{1}H NMR/δ	IR/cm^{-1}

a) Boiling points refer to the Kugelrohr bath temperatures. b) Found: C, 19.35; H, 2.49%. Calcd for $C_4H_6O_4Te$: C, 19.55; H, 2.46%. c) Found: C, 31.52; H, 4.70%. Calcd for $C_8H_{14}O_4Te$: C, 31.84; H, 4.68%. d) Not analyzed due to rapid decomposition.

which persist for days. In marked contrast to ordinary esters, compounds **2** resist any further transformations but decomposition. Thus, attempted ester interchange with alcohols in the presence or absence of catalyst only resulted in the decomposition of diesters. Actions of sodium methoxide and diethylamine led to immediate and gradual decompositions of diesters, respectively. Reaction with excess of 4-methylphenylmagnesium bromide afforded bis(4-methylphenyl) ditelluride, which should have been formed by the reaction of the Grignard reagent with tellurium liberated from diester.

Tellurium(II) compounds bearing two carbonyl groups on the tellurium atom are known to be extremely unstable and easily decompose in open air.[1] Acyclic diacyl tellurides such as bis(2-chlorobenzoyl) telluride and di-1-naphthoyl telluride have only recently been isolated and characterized.[2] Thus it is worth mentioning here that diesters **2** in which two ester carbonyl groups attached geminally to the tellurium atom are much more stable toward oxidative degradation than diacyl tellurides.

Reaction of dimethylcarbamoyl chloride with sodium telluride under phase-transfer conditions did not lead to the expected tellurodicarbonic diamide but to bis(dimethylcarbamoyl) ditelluride in a low yield. The ditelluride is most likely to be derived from the oxidative coulpling of tellurocarbamate ion during work-up.[3,4]

Experimental

All melting and boiling points were uncorrected. Infrared spectra were measured as KBr pellets or as neat films between NaCl plates by using a Hitachi 260-10 photospectrometer and only prominent peaks between 2000 and 650 cm^{-1} are recorded. ^1H NMR spectra were determined on a Hitachi R-600 spectrometer using chloroform-*d* as solvent and TMS as internal standard. Mass spectra were obtained on a Hitachi M-80B spectrometer.

Preparation of Dialkyl Tellurodicarbonates: Typical Procedure; Method A: A mixture of tellurium (3.80 g; 30 mmol), Rongalite (9.2 g; 60 mmol) and 1 M (1 M=mol dm^{-3}) sodium hydroxide solution (180 mL) was stirred for 2 h at 60 °C under nitrogen to give sodium telluride as a wine-colored solution. After cooling an aqueous solution (5 mL) of tetrabutylammonium bromide (1.9 g; 6 mmol) followed by a solution of ethyl carbonochloridate (9.1 g; 84 mmol) in benzene (100 mL) was added dropwise with vigorous stirring. The initial color was lost within 15 min and small amounts of tellurium was liberated. The reaction mixture was then passed through a thin bed of Celite to remove the inorganic insolubles, the organic phase was separated, and dried over sodium sulfate. The solvent was evaporated under reduced pressure to leave diester **2b** as a pale yellow oil, which was further purified by Kugelrohr distillation. Bp 89 °C/1.0 mmHg (1 mmHg≈133.322 Pa). Yield, 3.9 g (48%). MS (20 eV): *m/z* (relative intensity) 274 (M^+, 4.4), 232 (7.0), 204 (95.3), 176 (100), 159 (38.7), 130 (71.6), and 73 (20.5). Found: C, 26.21; H, 3.69%. Calcd for $C_6H_{10}O_4Te$: C, 26.31; H, 3.68%.

Method B: A mixture of sodium hydride (53 mg; 2.2 mmol; washed thoroughly with hexane prior to use), tellurium (128 mg; 1 mmol) and dry DMF (1 mL) was heated at 120 ° C for 1 h under nitrogen to give sodium telluride as a pale yellow suspension. After cooling to room temperature, ethyl carbonochloridate (325 mg; 3.0 mmol) in the same solvent (1 mL) was added dropwise. The mixture turned reddish brown under evolution of white fumes. After 15 min the reaction was quenched by the addition of water and the organic phase was extracted with benzene. The extract was washed with water, filtered through a thin bed of Celite, dried over sodium sulfate, and evaporated in vacuo to leave an oil, which was purified by bulb-to-bulb distillation to give diester **2b** in 47% yield.

Reaction of Phenyl Carbonochloridate (3e) with Sodium Telluride: To a wine-colored solution of sodium telluride prepared from tellurium (128 mg; 1.0 mmol), Rongalite (310 mg; 2 mmol) and 1 M sodium hydroxide solution (6 mL) was added an aqueous solution (1 mL) of tetrabutylammonium bromide (64 mg; 0.2 mmol) followed by a solution of phenyl carbonochloridate (330 mg; 2 mmol) in benzene (5 mL) under nitrogen at room temperature. Within 15 min the initial color was lost under the separation of free tellurium. The resulting mixture was passed through a thin bed of Celite to remove the insolubles and the product was extracted with benzene. The extract was dried with sodium sulfate and evaporated under reduced pressure to leave a solid, which was crystallized from hexane to give diphenyl carbonate **6** as white crystals, mp 77—78 °c (lit,[5] 78 °C). Yield, 174 mg (77% based on carbonochloridate).

We are grateful to Professor Shinzi Kato of Gifu University for a gift of bis(2-methoxybenzoyl) ditelluride as a reference compound for spectral inspection. This work was in part supported by a Grant-in-Aid from the Ministry of Education, Science and Culture.

Stereoselective Synthesis of 3′-Deoxy-3′-fluoroadenosine

Yoshitomi MORIZAWA,* Toshiaki NAKAYAMA, Arata YASUDA, and Keiichi UCHIDA
Research Center, Asahi Glass Co., Ltd., Hazawa, Kanagawa-ku, Yokohama 221
(Received January 27, 1989)

Synopsis. A new fluorinated nucleoside, 3′-deoxy-3′-fluoroadenosine(**1**), has been synthesized by a six-step synthesis from methyl 2-*O*-benzyl-5-*O*-*t*-butyldimethylsilyl-β-D-xylofuranoside (**2a**). Activation of O-3 by formation of a triflate followed by nucleophilic displacement allowed introduction of fluoride ion in a stereospecific manner at C-3.

Nucleoside derivatives with a fluorine atom on the sugar moiety are potential antitumor and/or antiviral agents. Extensive studies on the synthesis and biological activity of nucleosides possessing *trans*-fluorohydrin moiety at the C-2′ and C-3′ positions have been reported. Thus, 2′-deoxy-2′-fluoro-β-D-arabinofuranosyl pyrimidines have been found to exhibit selective inhibitory activity against herpes simplex viruses.[1] The synthesis of 3′-fluorinated derivatives, such as 3′-deoxy-3′-fluoro-β-D-xylofuranosyl purines/pyrimidines[2] and 3′-deoxy-3′-fluoro-β-D-arabinofuranosyl purines/pyrimidines have also been reported.[3]

However, there have been only limited reports on the synthesis of nucleosides with a *cis*-fluorohydrin moiety at the C-2′ and C-3′ positions; e.g. 2′-deoxy-2′-fluoroadenosine[4] and -thymidine.[5]

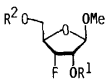
2a : R = H
2b : R = SO_2CF_3



3a : $R^1=R^2=H$
3b : $R^1=CH_2Ph$, $R^2=H$
3c : $R^1=R^2=COPh$

We describe here the novel synthesis of 3′-deoxy-3′-fluoroadenosine, a new class of fluorinated nucleoside. The synthetic plan to reach the fluorinated nucleoside **1** required access to the 3-deoxy-3-fluororibofuranoside **3a**. The latter would be readily available via an appropriately blocked 3-deoxy-3-fluoroarabinofuranoside.[6] However, inversion of configuration at C-2 to give the desired ribo type product did not occur. For example, methyl 3-deoxy-3-fluoro-2-*O*-(methylsulfonyl)arabinofuranoside failed to react with CsOAc[7] and the Mitsunobu reaction[8] ($EtO_2CN=NCO_2Et$-Ph_3P-HCOOH) of methyl 3-deoxy-3-fluoroarabinofuranoside resulted only in recovery of the starting material.[9] Synthesis of the desired deoxyfluoro sugar was finally accomplished by the displacement of the trifluoromethanesulfonate at C-3 of xyloside **2b** with fluoride ion.

The C-2 hydroxyl group of methyl 3,5-*O*-isopropylidene-β-D-xylofuranoside[10] was protected with a benzyl group (100% yield). Hydrolysis of the isopropylidene group with acetic acid-H_2O (8:3) at 50 °C followed by selective protection of the primary hydroxyl group with *t*-butyldimethylsilyl chloride gave methyl 2-*O*-benzyl-5-*O*-*t*-butyldimethylsilyl-β-D-xylofuranoside (**2a**) in 87% yield. Conversion of the free 3-hydroxyl group into the trifluoromethanesulfonate (**2b**) followed by treatment with tetrabutylammonium fluoride in tetrahydrofuran at room temperature gave the desired fluorinated compound **3b** in 58% yield (from **2a**). The stereoisomer, 3-deoxy-3-fluoroxylofuranoside,[2a] could not be detected in the reaction mixture by the examination of the ^{19}F NMR spectra. By contrast, the direct fluorination of the alcohol **2a** with piperidinosulfur trifluoride[11] gave the fluorinated sugar in low yield.

Removal of the benzyl protecting group in compound **3b**, followed by protection of the resulting diol with benzoyl chloride gave the dibenzoate (**3c**) (50% yield). The methyl glycoside was converted into the glycosyl bromide with 30%-HBr-acetic acid and coupled with adenine monobenzoate in the presence of mercury(II) cyanide to give the protected adenosine in 63% yield. Deprotection of the benzoyl group with methanolic sodium methoxide afforded 3′-deoxy-3′-fluoroadenosine **1** in 90% yield.

Experimental

Melting points were determined on a Mettler FP80, the IR spectra on a JASCO IR-810 spectrophotometer, and the NMR spectra on a JEOL JNM-FX-90Q spectrometer. Chemical shifts are given in δ with tetramethylsilane as an internal standard. Ultraviolet spectra were recorded with a Shimadzu MPS-2000 spectrophotometer. Rotatory power at sodium D line was measured with a JASCO DIP-140 polarimeter. Elemental analyses were performed by the microanalytical group of Asahi Glass Co., Ltd. Research Center. Purification of products were carried out with column chromatography on silica gel (Merck, 0.063—0.200 mm or 0.040—0.063 mm).

Methyl 2-*O*-Benzyl-5-*O*-*t*-butyldimethylsilyl-β-D-xylofuranoside (2a). Benzyl bromide (108.7 g, 0.64 mol) was added to a suspension of methyl 3,5-*O*-isopropylidene-β-D-xylofuranoside[10] (63 g, 0.31 mol) and silver oxide (76 g, 0.31 mol) in *N*,*N*-dimethylformamide (DMF) (200 ml) at room temperature over a period of 20 min. After 24 h, the mixture was filtrated on Celite 545 and the solvent was evaporated. Purification by column chromatography (toluene-ethyl acetate=5:1) gave 92 g (100% yield) of benzyl ether: ^1H NMR ($CDCl_3$) δ=1.37 (6H, s), 3.41 (3H, s), 3.9—4.4 (5H, m), 4.59 (2H, s), 4.98 (1H, s), 7.32 (5H, s).

This compound was dissolved in 164 ml of acetic acid and 66 ml of water and the solution was heated in a bath at 50 °C for 1 h. Evaporation to dryness in vacuo and short column chromatography gave crude diol (65.1 g, 92% yield).

To a solution of the diol (53.8 g, 0.21 mol) in DMF (200 ml) was added imidazole (43.4 g, 0.63 mol) and *t*-butyldimethylsilyl chloride (31.9 g, 0.21 mol) at 0 °C. After 3 h, the mixture

was poured into sat. aq. sodium hydrogencarbonate (1000 ml) and the solution was extracted with chloroform. The combined extracts, dried with magnesium sulfate, were evaporated to dryness in vacuo. Purification by column chromatography (toluene-ethyl acetate=5 : 1) gave **2a** (74.4 g, 95% yield) as an oil: ^{1}H NMR ($CDCl_3$) δ=0.10 (6H, s), 0.91 (9H, s), 3.37 (3H, s), 3.9—4.1 (3H, m), 5.2—4.4 (2H, m), 4.61 (2H, s), 4.93 (1H, s), 7.32 (5H, s).

Methyl 2-*O*-Benzyl-3-deoxy-3-fluoro-β-D-ribofuranoside (3b). To a solution of **2a** (74.4 g, 0.20 mol) and 2,6-lutidine (64.6 g, 0.60 mol) in dichloromethane (250 ml) was added trifluoromethanesulfonic anhydride (113.0 g, 0.40 mol) at 0 °C over a period of 1 h. After 2 h, the mixture was washed with sat. aq. copper sulfate (200 ml×3) and purified by short column chromatography to give 106.8 g of a crude triflate (**2b**).

Tetrabutylammonium fluoride (1 M† tetrahydrofuran (THF) solution, 370 ml, 0.37 mol) was added to the solution of the crude triflate in THF (250 ml) at 0 °C. After 7 h, the solvent was evaporated under reduced pressure and the residue was purified by silica-gel column to give **3b** (30.2 g, 58% yield (2 steps)): ^{1}H NMR ($CDCl_3$) δ=3.47 (3H, s), 4.0—4.2 (2H, m), 4.55 (2H, s), 4.5—5.1 (4H, m), 5.27 (1H, s), 7.33 (5H, s); ^{19}F NMR ($CDCl_3$, relative to CCl_3F) −207.1 ppm (ddd, J=13.4, 22.0, 53.7 Hz).

Methyl 2,5-Di-*O*-benzoyl-3-deoxy-3-fluoro-β-D-ribofuranoside (3c). The benzyl ether (**3b**) (30 g, 0.12 mol) dissolved in ethanol (100 ml) was stirred in the presence of 5% palladium on charcoal (20 g) under a hydrogen atmosphere for 24 h. Removal of the catalyst by filtration and concentration gave a diol **3a**.

The diol **3a** was mixed with pyridine (80 ml) and benzoyl chloride (23 g, 0.16 mol), and allowed to react at room temperature for 24 h. All the volatile material was evaporated under reduced pressure and the residue was purified by column chromatography (toluene-ethyl acetate=100 : 1) to give **3c** (16.4 g, 50% yield (2 steps)). Mp 53.8 °C (hexane); ^{1}H NMR($CDCl_3$) δ=3.42 (3H, s), 3.4—4.0 (2H, m), 4.4—5.9 (4H, m), 7.2—8.3 (10H, m); ^{19}F NMR ($CDCl_3$, relative to CCl_3F) −211.6 ppm (ddd, J=4.89, 18.06, 53.22 Hz). Found: C, 63.94; H, 5.23%. Calcd for $C_{20}H_{19}O_6F$: C, 64.17; H, 5.12%.

3′-Deoxy-3′-fluoroadenosine (1). To a solution of **3c** (2.4 g, 6.4 mmol) in acetic acid (12 ml) and acetic anhydride (0.5 ml) was added 30%-hydrogen bromide-acetic acid (36 ml) at room temperature over a period of 20 min. After 4 h, all the volatile was evaporated under reduced pressure and the residue dissolved in nitromethane (20 ml) was added to the solution of 6-benzamidopurine (1.6 g, 6.7 mmol) and mercury(II) cyanide (2.4 g, 9.5 mmol) in nitromethane (80 ml) at 100 °C. The solution was refluxed for 1 h, and evaporated to dryness in vacuo at 50 °C, and the residue was suspended in chloroform (200 ml). After being washed with 30% aqueous potassium iodide (200 ml) and water (200 ml), the solution was dried with magnesium sulfate, evaporated, and purified by column chromatography (toluene-ethyl acetate=1 : 3), giving 6-benzamido-9-(2,5-di-*O*-benzoyl-3-deoxy-3-fluoro-β-D-ribofuranosyl)purine (2.16 g, 63% yield). ^{1}H NMR($CDCl_3$) δ=4.2—5.1 (3H, m), 6.0—6.6 (3H, m), 7.2—8.3 (16H, m), 8.34 (1H, s), 8.64 (1H, s); ^{19}F NMR($CDCl_3$, relative to CCl_3F) −200.0 ppm (ddd, J=18.5, 24.5, 53.0 Hz).

A solution of the protected 3′-deoxy-3′-fluoroadenosine (2.16 g, 3.73 mmol) in methanol (10 ml) and 1 M-methanolic sodium methoxide (3.73 ml, 3.73 mmol) was heated to reflux for 1 h, and then evaporated to dryness in vacuo. The residue was dissolved in water (30 ml) and neutralized with 2 M-acetic acid. Methyl benzoate was removed by washing with chloroform, and the aqueous layer was evaporated to dryness in vacuo. Purification by silica-gel column (ethyl acetate) gave the title compound: 0.91 g (90% yield); UV: λ_{max}^{pH14} 258 nm, λ_{max}^{pH7} 258 nm, λ_{max}^{pH2} 256 nm, λ_{min}^{pH14} 237 nm, λ_{min}^{pH7} 236 nm, λ_{min}^{pH2} 236 nm; mp 206.5 °C (decomp, ethanol); $[\alpha]_D^{25}$ −61.8° (H_2O, c=0.5); ^{1}H NMR (DMSO-d_6) δ=3.6—3.7 (2H, m, H-5′), 4.29 (1H, dt, J=27.6, 3.7 Hz, H-4′), 4.80—5.0 (1H, m, H-2′), 5.09 (1H, dd, J=54.4, 4.2 Hz, H-3′), 5.69 (1H, dd, J=7.3, 4.9 Hz, 5′-OH), 5.89 (1H, d, J=6.3 Hz, H-1′), 5.93 (1H, d, J=8.1 Hz, 2′-OH), 7.39 (1H, s), 8.13 (1H, s), 8.36 (1H, s); ^{19}F NMR (DMSO-d_6, relative to CCl_3F) −19.78 ppm (dt, J=54.4, 27.6 Hz); ^{13}C NMR (DMSO-d_6) δ=61.1 (d, J=12.2 Hz, C-5′), 72.0 (d, J=15.9 Hz, C-2′), 83.9 (d, J=22.0 Hz, C-4′), 86.9 (C-1′), 93.1 (d, J=181.8 Hz, C-3′), 119.4 (C-5), 141.1 (C-8), 149.1 (C-4), 152.4 (C-2), 156.2 (C-6); IR (KBr) 3300, 1650 cm^{-1}; Found: C, 44.61; H, 4.71; N, 25.99%. Calcd for $C_{10}H_{12}O_3N_5F$: C, 44.61; H, 4.49; N, 26.01%.

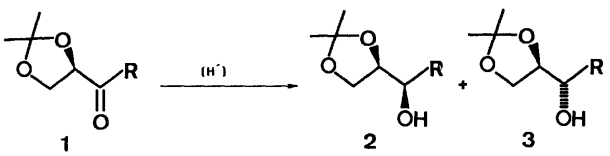
Stereoselective *syn*-Reduction of (*R*)-4-Acyl-2,2-dimethyl-1,3-dioxolanes with Metal Hydride Reagents

Hidenori CHIKASHITA,* Toshiki NIKAYA, Hiromitsu UEMURA, and Kazuyoshi ITOH
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564
(Received January 30, 1989)

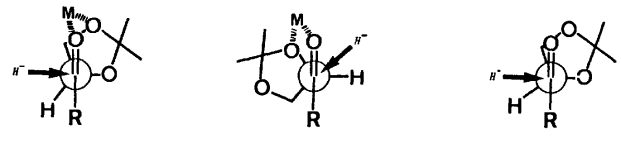
Synopsis. Lithium tri-*s*-butylborohydride and lithium aluminum hydride were found to be efficient reducing agents for the stereoselective preparation of *syn*-glycerol derivatives from (*R*)-4-acyl-2,2-dimethyl-1,3-dioxolanes. The scope and limitation of the stereoselective L-Selectride reduction of (*R*)-4-acyl-2,2-dimethyl-1,3-dioxolanes were also described.

2,3-*O*-Isopropylideneglyceraldehyde is a very useful chiral starting material for the synthesis of a variety of optically active molecules including natural products[1] because of ready availability of both the (*S*)-[2] and (*R*)-forms.[3] Among the methodologies developed in this field, much interest has been concentrated on the diastereoselective addition of C-nucleophiles such as organometallic reagents to the glyceraldehyde. Although the stereochemical course in this reaction has been extensively studied in recent years, the addition of organometallic reagents usually produces *anti*-glycerol derivatives as major products with varying degree of diastereoselectivity depending on the reagents and conditions employed.[4] On the other hand, however, an efficiently controlled method for the preparation of syn-adducts based on this methodology is rare.[5] A different approach to obtain *syn*-glycerol derivatives selectively would be to employ the diastereoselective carbonyl addition of hydride to 4-acyl-2,2-dimethyl-1,3-dioxolanes.[6] We have now examined the diastereofacial selectivity of the reduction of (*R*)-4-acyl-2,2-dimethyl-1,3-dioxolanes (**1**) with a variety of metal hydride reagents and found that lithium tri-*s*-butylborohydride (L-Selectride) and lithium aluminum hydride were excellent candidates as reducing agents for the syn-selective hydride addition to **1** producing *syn*-glycerol derivatives **2**. In this paper, we describe these results including the scope and limitation of the stereoselective L-Selectride reduction of **1**.



Scheme 1.

Reduction of ketone **1a** to the glycerols **2a** and **3a** was initially examined with a variety of metal hydride reagents and the results are presented in Table 1. In all cases of the reducing agents and conditions examined, the reduction proceeded in high yield and provided the syn-diastereomer **2a** as the major product. These results indicate that the β-chelation transition state A which predicts the syn selectivity should be favored over the α-chelation transition state B when chelatable reagents are employed (Entries 1—6). On the other hand, reduction with diisobutylaluminum hydride (DIBAL-H) which is known to have low chelating ability showed very low selectivity (Entry 7). Thus, non-chelation reaction which should predict the syn selectivity according to the Felkin-Ahn transition state model C is regarded to be ineffective for the present type of diastereofacial selection of **1**. Higher diastereoselectivity was obtained in the reaction with a series of lithium metal hydrides (Entries 3—5) with the following order of selectivity: LiBH(*s*-Bu)$_3$>LiAlH$_4$≫LiAlH(O*t*-Bu)$_3$. This shows the high chelation efficiency of the Li^+ counterion in the transition state A rather than the transition state B leading to the formation of the minor anti-addition product **3a**.



Scheme 2.

Although a similar stereochemical outcome of the L-Selectride reduction has been obtained by Macdonald et al. for a model compound,[7] the scope and limitations of the reduction have not been clari-

Table 1. Reduction of **1a** (R=Ph) with Various Metal Hydrides

fied yet. Thus, to establish the generality, we examined the reduction of a variety of (*R*)-4-acyl-2,2-dimethyl-1,3-dioxolanes (**1b—h**). The results are summarized in Table 2. A variety of aromatic (Entries 1—3) and aliphatic (Entries 4,5) ketones were efficiently reduced to the corresponding *syn*-glycerols **2b—e** in high yields with excellent stereoselectivity. Keto ester **1f** and 1,3-dithian-2-yl ketone **1g** were similarly reduced in high yield with excellent syn-selectivity to give the β-hydroxy ester **2f** and the dithianyl alcohol **2g**, respectively. However, the reduction of the 1,3-dithian-2-yl ketone **1h** with L-Selectride did not proceed at all (Entry 8). This result suggests that L-Selectride can not be used for the reduction of highly hindered ketones due to the strong hindrance of the reaction because of the steric bulks of both the reducing agent and the substrate, and shows the limitation of the present L-Selectride reduction. In contrast to this, the reduction of **1h** with $LiAlH_4$, which is the another excellent candidate as shown previously (Table 1), proceeded in high yield to give the syn-product **2h** in good selectivity (Entry 8).

Table 2. Stereoselective Reduction of (*R*)-4-Acyl-2,2-dimethyl-1,3-dioxolanes (**1**) with L-Selectride[a)]

Entry	Substrate	Isolated yield/%	Product ratio[b)] *syn*-**2**:*anti*-**3**
1	 **1a**	83	97: 3

4	 **1d**	67	96: 4
5	 **1e**	33	85:15
6	 **1f**	55	96: 4
7	 **1g**	82	>99: 1
8	 **1h**	No reaction (87)[c)]	(80:20)[c)]

a) All the reactions were carried out with 3 equiv of L-Selectride in THF at −78 °C for 3 h. b) Determined by HPLC analyses (Entries 1—3 and 7), GLC analyses (Entries 4 and 5), and 400 MHz ^{1}H NMR analyses (Entries 6 and 8). c) Reactions with 3 equiv of $LiAlH_4$ in THF at −78 °C for 3 h.

In conclusion, the L-Selectride reduction of (*R*)-4-acyl-2,2-dimethyl-1,3-dioxolanes (**1**) was found to be a fairly general method for the stereoselective preparation of *syn*-glycerol derivatives **2**. On the other hand, $LiAlH_4$ was also found to be useful as another selective reducing agent especially in the case of the reduction of highly hindered substrates.

Experimental

Optical rotations were determined with a Union Digital PM-101 polarimeter. IR spectra were obtained on a JASCO A-202 spectrometer. ^{1}H NMR spectra were measured with a JEOL JNM-GX400 spectrometer at 400 MHz with tetramethylsilane as an internal reference. GLC analyses were carried out on a Yanagimoto Gas chromatograph G2800T using glass columns (3 m) packed with 10% EG-20W on Shimalite-NAW (60/80 mesh). HPLC analyses were carried out on a Yanagimoto high-pressure liquid chromatograph L-5000. Silica gel (Merck silica gel 60, 230—400 mesh ASTM) was used for medium-pressure liquid chromatography (MPLC). TLC were carried out on Merck precoated silica gel plates (Merck silica gel 60 F_{254}).

Materials. Tetrahydrofuran (THF) was freshly distilled over $LiAlH_4$ before use. The other solvents were purified by the usual methods and were freshly distilled before use. Metal hydride reagents were supplied as high grade commercial products and used without further purification. (*R*)-4-Acyl-2,2-dimethyl-1,3-dioxolanes **1a—e** were prepared by the reaction of 1,2-*O*-isopropylidene-D-glyceraldehyde with organolithium or Grignard reagents followed by oxidation of the resulting diastereomeric mixture of glycerol derivatives. The keto ester **1f** and 1,3-dithian-2-yl ketones **1g,h** were similarly prepared by the reaction with the lithium enolate of ethyl acetate[8)] and 2-lithio-1,3-dithiane derivatives and the subsequent PCC and PDC oxidations, respectively.

General Procedure for the Reduction of (*R*)-4-Acyl-2,2-dimethyl-1,3-dioxolanes with L-Selectride. To a 1 M THF solution of L-Selectride (2 ml, 2 mmol) was added dropwise a solution of the (*R*)-4-acyl-2,2-dimethyl-1,3-dioxolanes **1** (1 mmol) in THF (2 ml) under nitrogen with stirring. The mixture was stirred for 3 h at −78 °C and the solution was allowed to warm to room temperature and then quenched by the addition of water (8 ml). The mixture was extracted with ether (30 ml×5) and the extract was washed with water (30 ml×2). The aqueous washings were again extracted with ether and the combined organic layers were dried with $MgSO_4$. The solution was filtered through silica gel (Wakogel C-300) and the filtrate was concentrated under reduced pressure to give a fairly pure (monitored by TLC and ^{1}H NMR) diastereomeric mixture of **2** and **3** as a colorless oil. The β-keto ester **1f** was similarly reduced to a mixture of **2f** and **3f** by the general procedure, except that the reaction time was 5 h and a buffer solution (pH=6.86) was used for quenching in place of water.

Identification of products was performed by spectroscopic (NMR and IR) methods. These spectral data were in satisfactory agreement with those of the corresponding authentic samples.

The relative stereochemistry of major and minor diastereoisomers **2a—f** and **3a—f** was assigned by HPLC, GLC, or ^{1}H NMR comparison with stereochemically defined authentic samples.

The syn and anti diastereoisomers **2g** and **3g** were easily distinguished by ^{1}H NMR on the basis of chemical shift values for the OH protons (δ_{syn}OH>δ_{anti}OH).[9] Full spectroscopic data of the major *syn*-**2g** and the minor *anti*-**3g** which could be separated by MPLC (benzene-ethyl acetate, 20:1 v/v) after conversion into the corresponding benzyl ethers are as follows.

***syn*-2g**: $[\alpha]_D^{24}$+5.00° (*c* 0.95, $CHCl_3$) as a benzyl ether; IR of the benzyl ether (neat) 3030, 2984, 2933, 2896, 1497, 1454, 1422, 1380, 1370, 1248, 1213, 1157, 1069, 1028, 855, 796, 737, and 699 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.39 (s, 3H), 1.46 (s, 3H), 1.94 (m, 1H), 2.11 (m, 1H), 2.68 (d, 1H, *J*=6.0 Hz), 2.81 (m, 2H), 2.92 (m, 2H), 3.75 (ddd, 1H, *J*=6.6, 6.0, 3.9 Hz), 3.93 (dd, 1H, *J*=8.3, 6.6 Hz), 4.10 (d, 1H, *J*=6.6 Hz), 4.12 (dd, 1H, *J*=8.3, 6.6 Hz), and 4.50 (dt, 1H, 3.9, 6.6 Hz).

***anti*-3g**: $[\alpha]_D^{23}$+24.4° (*c* 0.45, $CHCl_3$) as a benzyl ether; IR of the benzyl ether (neat) 3031, 2985, 2933, 2896, 1496, 1454, 1422, 1380, 1370, 1341, 1248, 1213, 1157, 1074, 908, 854, 786, 738, 699, and 681 cm^{-1}: ^{1}H NMR ($CDCl_3$) δ=1.37 (s, 3H), 1.44 (s, 3H), 1.94 (m, 1H), 2.11 (m, 1H) 2.35 (d, 1H, *J*=4.2 Hz), 2.93 (m, 4H), 3.88 (dt, 1H, *J*=6.6, 4.2 Hz), 4.02 (dd, 1H, *J*=8.5, 5.4 Hz), 4.09 (dd, 1H, *J*=8.5, 6.6 Hz), 4.32 (td, 1H, 6.6, 5.4 Hz), and 4.35 (d, 1H, *J*=4.2 Hz).

Reduction of 1,3-Dithian-2-yl Ketone 1h with $LiAlH_4$. To a stirred suspension of lithium aluminum hydride (39 mg, 2 mmol) in dry THF (12 ml) was slowly added the ketone **1h** (375 mg, 1 mmol) in dry THF (2 ml) at −78 °C. After stirring for 3 h at −78 °C, the mixture was quenched by the addition of water (10 ml). The aqueous mixture was extracted with ether and the ether extract was washed with water and then dried with $MgSO_4$. Concentration of the solution under reduced pressure gave the fairly pure (monitored by TLC and ^{1}H NMR) diastereomeric mixture of **2h** and **3h** as a colorless oil (323 mg, 86%).

The relative stereochemistry of the syn and anti diastereoisomers was easily distinguished by ^{1}H NMR on the basis of chemical shift values for the OH protons (δ_{syn}OH >δ_{anti}OH).[9] Full spectroscopic data of the major *syn*-**2h** and the minor *anti*-**3h** separated by MPLC (benzene-ethyl acetate, 4:1 v/v) are as follows.

***syn*-2h**: $[\alpha]_D^{25}$−7.28° (*c* 1.24, $CHCl_3$); IR (neat) 3489, 2925, 2854, 1458, 1423, 1370, 1255, 1218, 1158, 1122, 1065, 965, 909, 869, 797, and 722 cm^{-1}: ^{1}H NMR ($CDCl_3$) δ=0.88 (t, 3H, *J*=6.8 Hz), 1.26 (br, 12H), 1.42 (s, 3H), 1.46 (s, 3H), 1.56 (m, 2H), 1.76 (m, 1H), 1.84—2.06 (m, 3H), 2.71 (m, 2H), 2.89 (ddd, 1H, *J*=14.0, 10.4, 3.6 Hz), 2.95 (ddd, 1H, *J*=14.0, 10.4, 3.6 Hz), 3.02 (d, 1H, *J*=5.3 Hz), 3.83 (dd, 1H, *J*=5.3, 3.9 Hz), 3.87 (t, 1H, *J*=8.0 Hz), 4.17 (dd, 1H, *J*=8.0, 6.3 Hz), and 4.53 (ddd, 1H, *J*=8.0, 6.3, 3.9 Hz). Found: C, 60.53; H, 9.44%. Calcd for $C_{19}H_{36}O_3S_2$: C, 60.60; H, 9.63%.

***anti*-3h**: $[\alpha]_D^{25}$+11.7° (*c* 1.05, $CHCl_3$); IR (neat) 3465, 2922, 2853, 1456, 1423, 1370, 1248, 1213, 1159, 1123, 1058, 908, 856, 799, 758, 722, and 655 cm^{-1}: ^{1}H NMR ($CDCl_3$) δ=0.88 (t, 3H, *J*=7 Hz), 1.26 (br, 12H), 1.38 (s, 3H), 1.46 (s, 3H), 1.55 (m, 2H), 1.87 (m, 3H), 2.02 (m, 1H), 2.71 (m, 2H), 2.75 (d, 1H, *J*=2.2 Hz), 3.00 (ddd, 1H, *J*=3.2, 10.6, 14.1 Hz), 3.08 (ddd, 1H, *J*=3.2, 10.6, 14.1 Hz), 4.02 (dd, 1H, *J*=8.1, 6.8 Hz), 4.12 (dd, 1H, *J*=8.1, 6.8 Hz), 4.25 (dd, 1H, *J*=2.9, 2.2 Hz), and 4.59 (td, 1H, *J*=6.8, 2.9 Hz). Synthesis of Hydroxy Ketones by Chemoselective Alkylation of Keto Aldehydes with Dialkylzincs Catalyzed by Amino Alcohol, Diamine, or Dilithium Salt of Piperazine

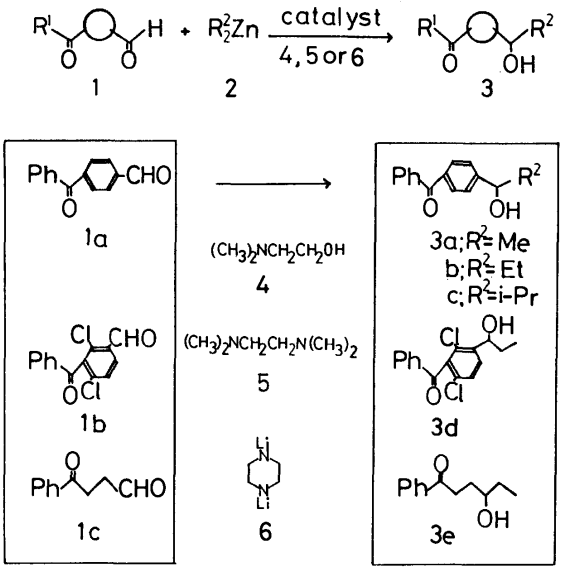
Kenso SOAI,* Masami WATANABE, and Masashi KOYANO
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Shinjuku-ku, Tokyo 162
(Received February 3, 1989)

Synopsis. Hydroxy ketones were obtained in high yields by the chemoselective alkylation of formyl group of keto aldehydes with dialkylzincs in the presence of such catalysts as 2-dimethylaminoethanol, *N,N,N',N'*-tetramethylethylenediamine, or dilithium salt of piperazine.

Chemoselective alkylation of aldehydes in the presence of ketones by organometallic reagents has attracted considerable attention.[1] Organolead,[1a] -lithium, -magnesium (in combination with organoaluminum),[1b] -lanthanoid (and Sc, Y, Nb, Ta),[1c] and -titanium reagents[1d] have been used for the above-mentioned reaction. However, most of the examples reported in these reports are intermolecular competitive experiments between aldehydes and ketones, and there are relatively few example of the chemoselective alkylation of keto aldehydes.

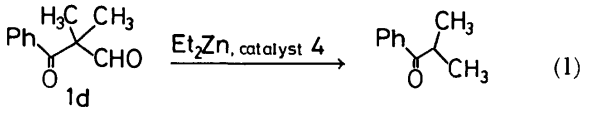
On the other hand, the addition of dialkylzincs to aldehydes without catalyst is very slow.[2] Mukaiyama et al., including one of us (K. S.), reported β-amino alcohol catalyzed addition of diethylzinc to benzaldehyde which affords 1-phenyl-1-propanol in 76%.[3]

To establish the synthetic utility of the aminoalcohol-catalyzed addition of dialkylzincs to aldehydes, we report in this paper the chemoselective alkylation of the formyl group of keto aldehydes with dialkylzincs in the presence of such catalysts as 2-dimethylaminoethanol (**4**) or diamine (Scheme 1). When 4-benzoylbenzaldehyde (**1a**)[4] was treated with dimethyl-, diethyl-, or diisopropylzinc in the presence of 5—20 mol% of **4**, formyl group of **1a** was alkylated (methylation, ethylation, or isopropylation respectively) in chemoselective manner. The results are summarized in Table 1. Isolated yields of the corresponding hydroxy ketones (**3a—c**) were very high (93—100%) (Table 1, Entries 1—3). In a similar manner, chemoselective alkylation of 3-benzoyl-2,4-dichlorobenzaldehyde (**1b**) was performed. The yields of hydroxy ketone (**3d**) were quantitative regardless of the amount of catalyst (Entries 4 and 5). The reaction of 3-benzoylpropanal (**1c**, γ-keto aldehyde)[6] with Et_2Zn using **4** afforded γ-hydroxy ketone (**3e**) in 76% (Entry 8). *N,N,N',N'*-tetramethylethylenediamine (**5**, TMEDA) and dilithium salt of piperazine (**6**)[5] were also found to be effective catalysts (Entries 6 and 7).



Scheme 1.

On the other hand, the reaction of 2-benzoyl-2-methylpropanal (**1d**, β-keto aldehyde)[7] with Et_2Zn using **4** as the catalyst (20 mol%) gave unexpected isopropyl phenyl ketone in 85% (Eq. 1). In addition,



(1)

intermolecular competitive ethylation of a mixture of benzaldehyde and acetophenone using **4** (10 mol%) afforded 1-phenyl-1-propanol (75%)(as a result of the ethylation of benzaldehyde), and acetophenone was recovered (70%).

Experimental

All reactions were carried out under an argon atmosphere. Toluene was distilled from lithium aluminum hydride. 4-Benzoylbenzaldehyde (**1a**),[4] 3-benzoylpropanal (**1c**),[6] and 2-benzoyl-2-methylpropanal (**1d**)[7] were prepared according

to a method described in the literature. 2,4-Dichloro-3-benzoylbenzaldehyde and diethylzinc are commercially available. Diisopropylzinc was prepared according a method from the literature and was purified by distillation.[8] ^{1}H NMR spectra were taken on a JEOL JNM PMX-60 (TMS as the internal reference). The IR spectra were recorded on a Hitachi 260-10 spectrometer. Measurement of mass spectra were carried out on a Hitachi RMU7M spectrometer.

Typical Procedure for Chemoselective Alkylation of Keto Aldehydes with Dialkylzincs Using 2-Dimethylaminoethanol (Table 1, Entry 2): A toluene solution of 2-dimethylaminoethanol (**4**, 0.05 M,† 0.025 mmol) was added to a toluene solution (0.5 ml) of 4- benzoylbenzaldehyde (**1a**, 0.106 g, 0.50 mmol) at 0 °C. After 15 min of stirring, diethylzinc (1.1 ml, 1 M, in hexane solution) was added dropwise. The resulting mixture was stirred at room temperature for 14 h and quenched with 1 M HCl (3 ml), the organic layer was separated, and aqueous layer was extracted with dichloromethane. The combined organic layer was dried over anhydrous Na_2SO_4, then evaporated under reduced pressure. The residue was purified by silica gel TLC [$CHCl_3$: MeOH=50 : 1 v/v as eluent]. 4-(1-Hydroxypropyl)benzophenone (**3b**) was obtained in 93% yield (0.113 g, 0.47 mmol); ^{1}H NMR ($CDCl_3$) δ=0.73—1.16 (t, 3H), 1.50—2.05 (m, 2H), 2.96 (s, 1H), 3.46—4.74 (t, 3H), and 7.12—7.91 (m, 9H); IR (neat) 3430, 2970, and 1660 cm^{-1}; Found: *m/z* 240.1148. Calcd for $C_{16}H_{16}O_2$: M, 240.1151.

According to a similar procedure as that described above, the following hydroxy ketone (**3**) were synthesized from the corresponding **1** and **2** using **4** or **5** as the catalyst.

4-(1-Hydroxyethyl)benzophenone (3a, Table 1, Entry 1): Yield 100%; ^{1}H NMR ($CDCl_3$) δ=1.40—1.67 (d, 3H), 2.76—3.17 (broad, 1H), 4.67—5.01 (m, 1H), and 7.17—7.90 (m, 9H); IR (neat) 3420, 2975, and 1660 cm^{-1}; Found: *m/z* 226.0994. Calcd for $C_{15}H_{14}O_2$: M, 226.0994.

4-(1-Hydroxy-2-methylpropyl)benzophenone (3c, Table 1, Entry 3): Yield 100%; ^{1}H NMR ($CDCl_3$) δ= 0.57—1.30 (m, 6H), 1.67—2.30 (m, 1H), 2.78 (s, 1H), 4.20—4.67 (m, 1H), and 7.03—8.00 (m, 9H); IR (neat) 3450, 2960, and 1650 cm^{-1}; Found: *m/z* 254.1301. Calcd for $C_{17}H_{18}O_2$: M, 254.1307.

2,6-Dichloro-3-(1-hydroxypropyl)benzophenone (3d, Table 1, Entries 4, 5, 6, and 7): Yield 77—100%; ^{1}H NMR ($CDCl_3$) δ=0.83—1.20 (t, 3H), 1.47—2.23 (m, 3H), 4.87—5.33 (m, 1H), and 7.24—8.93 (m, 7H); IR (neat) 3370, 2920, and 1660 cm^{-1}; Found: *m/z* 308.0378. Calcd for $C_{16}H_{14}O_2Cl_2$; M, 308.0372.

† 1 M=1 mol dm^{-3}.

Dilithium salt of piperazine (**6**) was in situ prepared by the treatment of piperazine with 2 equiv of butyllithium (Entry 7).

4-Hydroxy-1-phenyl-1-hexanone (3e, Table 1, Entry 8): Yield 76%; ^{1}H NMR ($CDCl_3$) δ=0.80—1.17 (m, 3H), 1.30—2.13 (m, 5H), 3.00—3.33 (t, 2H), 3.33—3.77 (m, 1H), and 7.20—8.13 (m, 5H); IR (neat) 3450, 2970, and 1685 cm^{-1}; Found: *m/z* 192.1143. Calcd for $C_{12}H_{16}O_2$: M, 192.1151.

Reaction of 1d with Diethylzinc Using 4: The reaction of **1d** (0.174 g, 0.99 mmol) under the same reaction conditions using Et_2Zn instead of diisopropylzinc (Table 1, Entry 3) for 56 h afforded 0.125 g of isopropyl phenyl ketone in 85% yield.

We thank Tomoiki Hayasaka for his contribution during the early stage of this research, and Tri Chemical Laboratory Inc. for a generous gift of dimethylzinc.

The Thermodynamics of Chemical Reactions at High Pressures

Sefton Davidson HAMANN
Division of Chemicals and Polymers, Commonwealth Scientific and Industrial Research Organization, G. P. O. Box 4331, Melbourne, Victoria 3001, Australia
(Received March 24, 1988)

Synopsis. A "thermodynamic" derivation by Jee of a simple proportionality between the effects of pressure on the enthalpy change ΔH and the entropy change ΔS for a chemical reaction in solution, is shown to be erroneous.

In a recent paper,[1] J.-G. Jee has presented a derivation "from the basic thermodynamic equation(s)," of a simple proportional relationship between the influence of pressure on the molar change of enthalpy ΔH for a chemical reaction and its corresponding influence on the molar change of entropy ΔS.

Jee[1] began by applying one of the Maxwell relations to derive the formula

$$(\partial H/\partial p)_T=(T-1/\alpha)(\partial S/\partial p)_T, \quad (1)$$

where p denotes the pressure and T the absolute temperature. This is a standard thermodynamic relation [it is given, for example, by combining Guggenheim's[2] formulae (1.47.4) and (1.48.4)], linking the pressure derivatives of the total enthalpy H and the total entropy S of a closed homogeneous phase in the absence of a chemical reaction: α denotes the coefficient of thermal expansion of the phase,

$$\alpha=(\partial V/\partial T)_p/V, \quad (2)$$

where V is the total volume of the phase.

Jee[1] then assumed that a relation similar to Eq. 1 applies to a chemical equilibrium, with H and S being replaced by ΔH and ΔS, denoting changes of enthalpy and entropy accompanying the reaction. On that basis, and assuming α to be independent of p, he integrated Eq. 1 to obtain his relation (Eq. 12):

$$\Delta H^p-\Delta H^\circ=(T-1/\alpha)(\Delta S^p-\Delta S^\circ), \quad (3)$$

where the superscripts ^{p} and $^\circ$ indicate values at a high pressure and at atmospheric pressure, respectively. He took that formula to mean that there is a "theoretical" linear relationship between $\Delta H^p-\Delta H^\circ$ and $\Delta S^p-\Delta S^\circ$.

If Jee's relation were correct, it might be useful. However, it is not correct.

In dealing with a chemically reacting system we need to consider, not the total quantities H, S, and V for the mixture, but the behavior of the corresponding *partial molar* quantities for the reacting species and for the products. If, for a particular species J, we write these as H_J, S_J, and V_J, then a relation analogous to Eq. 1 holds between the partial molar functions of J in the form

$$(\partial H_J/\partial p)_T=(T-1/\alpha_J)(\partial S_J/\partial p)_T, \quad (4)$$

where α_J is defined[3] as

$$\alpha_J=(\partial V_J/\partial T)_p/V_J. \quad (5)$$

Taking the simple case of a chemical reaction equilibrium,

$$A \rightleftarrows B, \quad (6)$$

between two species A and B in a homogeneous mixture, we have

$$\Delta H=H_B-H_A \quad (7)$$

and

$$\Delta S=S_B-S_A, \quad (8)$$

where ΔH is the difference between the partial molar enthalpy (or standard partial molar enthalpy) of the product and that of the initial species; ΔS is the corresponding difference of entropy.

Combining Eqs. 4, 7, and 8, we obtain

$$(\partial\Delta H/\partial p)_T= (T-1/\alpha_B)(\partial\Delta S/\partial p)_T+(1/\alpha_A-1/\alpha_B)(\partial S_A/\partial p)_T, \quad (9)$$

and if we make an additional (usually unjustified) assumption that α_A and α_B are independent of p, we can integrate Eq. 9 to obtain

$$\Delta H^p-\Delta H^\circ= (T-1/\alpha_B)(\Delta S^p-\Delta S^\circ)+(1/\alpha_A-1/\alpha_B)(S_A^p-S_A^\circ). \quad (10)$$

More complex relations apply if more than two species take part in the reaction.

Unlike the supposed relation (Eq. 3), the correct formula (Eq. 10) does *not* represent a simple proportionality between $\Delta H^p-\Delta H^\circ$ and $\Delta S^p-\Delta S^\circ$. It would do so only if additional conditions were met—namely, either (a) that $\alpha_B=\alpha_A$, which is improbable (particularly so for ionic reactions), or (b) that S_A and S_B have the same functional dependence upon p. These are both *extra*-thermodynamic conditions, and the second resembles El'yanov's[5] assumption of a "linear free energy relation" for the effects of pressure on equilibrium constants, which enabled him to derive an expression similar to Eq. 3

Criticisms analogous to the above apply also to Jee's[1] supposed enthalpy/volume and entropy/volume relations.

Finally, when we come to examine Jee's[1] experimental evidence for linear correlations between ΔH and ΔS, we encounter a difficulty, because it is impossible to reconcile the values of ΔH, ΔS, and ΔV that he has listed in his Table 2 and plotted in Fig. 1, with the experimental values of the equilibrium constants K that he has reported in Table 1. For instance, his listed values of ΔV have both the wrong sign and the wrong magnitude [his formula (Eq. 9) for ΔV is, in any case, incorrect[6] when applied to values of K having volume concentration units ($dm^3\,mol^{-1}$)]. Also, the equilibrium constants yield values of ΔH and ΔS that show large and random scatter, with no indication whatever of the smooth trends suggested in Jee's Table 2.

Admittedly, they give good linear plots of ΔH versus ΔS, with slopes near the experimental temperature, ca. 300 K; but that is precisely the behavior that would arise from random errors in the experimental temperature dependences of the K.

A Mechanistic Study of a Gas-Phase Ion/Molecule Reaction between $CH_2NH_2^+$ and CH_4

Satoshi OKADA,* Yasuo ABE, Setsuo TANIGUCHI, Shinichi YAMABE,† and Tsutomu MINATO††
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai 593

††Institute for Natural Science, Nara University, 1500 Misasagi-cho, Nara 631
(Received October 31, 1988)

A gas-phase ion/molecule reaction starting from (CH_4^+ and N_2O)/(CH_4 and N_2O^+) is studied using a pulsed-discharge high-pressure mass spectrometer and the ab initio MO calculation. Two dominant ions, $C_2H_6N^+$ and $C_3H_8N^+$, are recognized; they are formed by the methylation of CH_4N^+. The $C_2H_6N^+$ is formed via the following two reactions:

$$CH_2NH_2^+ \text{ (or } CH_3NH^+) + CH_4 \longrightarrow (CH_3)_2NH_2^+ \quad (5)$$

$$(CH_3)_2NH_2^+ \longrightarrow CH_3NHCH_2^+ + H_2 \quad (7)$$

The methylation is composed of the heterolytic CH_3^+-H^- addition to the C=N bond of CH_4N^+ and the subsequent H_2 elimination. The growth of the ion by the methylation is largely exothermic, while the H_2 elimination has a large energy barrier on the potential energy surface.

Methane is an inert molecule and does not react in condensed media. However, in the gas phase, some unique reactions[1-3] are observed. Field[1a] and Ausloos[1c] have investigated the ionic reactions, the photolysis, and the radiolysis of CH_4. In those reports, secondary and higher-order reactions of CH_4 with the reactive species (ions, radicals, etc.) generated by these processes have been found. Moreover, Hiraoka[1f] has reported a slow ion/molecule reaction of $C_2H_5^+$ with CH_4. In CH_4/N_2O, Ryan[2] and McAllister[3] have reported the minor formation of CH_4N^+ at a low pressure. In spite of these gas-phase studies, however, the ion structure of CH_4N^+ and the reaction mechanism for the formation of this ion have not yet been made clear.

In this work, a gas-phase ion/molecule reactions in CH_4/N_2O is studied using pulsed-discharge high-pressure mass spectrometry. The time profiles of ions formed at high pressures are extensively analyzed, and these ion species are identified by using, as a labelled compound, CD_4 instead of CH_4. The purpose of this work is to clarify experimentally and theoretically why such simple and small cations as CH_4^+ and N_2O^+ may give larger cationic products in the ion/molecule reaction of (CH_4^+ and N_2O)/(CH_4 and N_2O^+).

Experimental

Apparatus and Reagents. The measurements were done with a pulsed-discharge high-pressure mass spectrometer. The primary ionization of reactant gases in an ion source of chemical ionization[4] and an atmospheric-pressure-ionization mass spectrometer[5] was performed with a Townsend-discharge ion source. In our experiment, the temperature of the ion source is easily controllable in the absence of such filaments as rhenium and tungsten. Then, in the pulsed-discharge ion source, a usual electron trap of a commercially available mass spectrometer was replaced with a discharge electrode.

Figure 1 shows schematic diagrams of the discharge-ion source and pulse circuit. The pulse-timing sequence generated by this circuit and the pulse-counting diagram are shown in the figure. The discharge ion source consists of a tip with a height of 0.1 mm on the flat surface of a stainless steel (3.5 mmϕ×1.6 mm) as the cathode and an 85% transmission gold-clad tungsten screen as the anode, while the potential is that of the ionization chamber. The distance between the cathode and anode was fixed at about 3 mm. The distance from the center of the discharge point to the ion-exit slits was 9 mm; the ion-exit slits, 2×0.01 mm, were made of two stainless steel razor blades. The potential of the

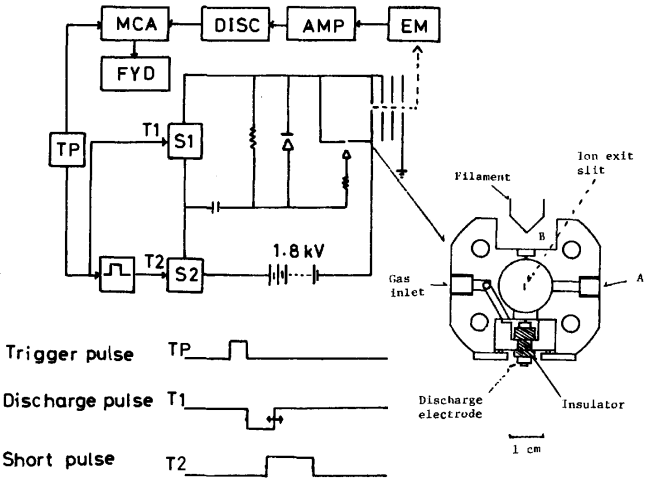

Fig. 1. Schematic diagrams of the discharge ion source and pulse circuit. The pulse timing sequence generated by this pulse circuit and pulse counting diagram are shown. EM: secondary electron multiplier; AMP: amplifier; DISC: discriminator; MCA: multichannel analyzer; FYD: floppy disk drive; TP: trigger pulse; T_1,T_2: discharge and short pulses; S_1,S_2: switching circuits.

first lens with ion-exit slits to prevent field penetration induced by the electric field of the focusing lens was identical with that of the ionization chamber. The pulsed discharge was carried out by two switching circuits (S_1, S_2) using the electric charge and discharge in the capacitor. Since the discharge pulse T_1 tailed for several hundred μs after discharge, the positive pulse T_2 was applied to the discharge electrode to exclude this tailing. In this way, the pulse width of T_1 was decreased to about 30 μs. The discharge-pulse width and the amplitude of T_1 were monitored indirectly with an oscilloscope. Under typical operating conditions, the discharge pulse width, amplitude, and repetition frequency of T_1 were 30 μs, 1.44 kV, and 200 Hz respectively.

The pressures of CH_4 and N_2O in two 10-dm^3 reservoirs were measured with an MKS Baratron model 221 A capacitance manometer. The CH_4/N_2O mixture thus obtained was introduced into the ion source through a Granville-Phillips model-203 manually variable leak. The sample pressure in the ion source was measured with an MKS manometer connected to the gas-inlet line to the ion source. This pressure was corrected with another MKS manometer connected directly to the hole A in Fig. 1 by means of a separate measurement. The correction factor was 0.923. The ion source was heated using an electron-emitting rhenium filament; the maximum temperature obtained was about 453 K. During the present experiments, the holes, A and B, were closed.

In Fig. 1, the time-resolved mass-selected ions formed in the ion source have been accumulated in a multichannel analyzer (Nuclear Data ND 100). Then, the data obtained were transferred to a floppy disk (FYD) and were analyzed with a computer.

The ion-source pressure was in the range from 226.6 to 306.6 Pa, and the flow rate of sample gas was about 0.4 $cm^3\,s^{-1}$. The gases used were methane (Takachiho research grade; 99.95% CH_4), dinitrogen monoxide (Showa Denko, Ltd.; 99.995% N_2O), and methane-d_4 (Merck Sharp and Dohme; 99.5 atom% D). The dinitrogen monoxide was purified by vacuum distillation several times through P_2O_5 chilled with liquid N_2. A trace amount of CO_2 in N_2O was decreased by the use of an Ascarite II trap (20—30 mesh) from Author H. Thomas Co. However, the experimental results obtained were not seriously affected by the Ascarite II. The contents of water and $\geqq C_2$ hydrocarbons in the methane were suppressed by passing the methane through liquid N_2 or Dry Ice-acetone cooled Molecular Sieves. The purities of the methane and dinitrogen monoxide were checked gas-chromatographically using a Pora PLOT Q column of 0.32 mmϕ×10 m at 100 °C. The contents of the $\geqq C_2$ hydrocarbons contained in those samples were less than 1 ppm.

In spite of the general complexity of electrical discharges, the Townsend discharge source[4a] afforded mass spectra that were essentially identical to those obtained with the conventional filament-operated chemical ionization sources. The mass spectra obtained with the Townsend-discharge source have contained only a low abundance of several polymeric reactant ions of a higher mass (m/z>41).

In this study, since the DC discharge was pulsed, it is possible to generate a low current of electricity. Therefore, it seems that the pulsed-discharge ion source suppresses the complexities of the discharge;[6] in fact, the reproducibility of experiments (after six months) could be confirmed.

In the present experiments, the measured total ion current decreased rapidly with a decrease in the temperature of the ion source and the content of CH_4 in the CH_4/N_2O mixture. Headley et al.[7] have reported similar phenomena when oxygen containing molecules such as NO, CO, CO_2, N_2O, and dioxane were used as the reactant gases. Therefore, the experimental conditions are controlled so that the temperature and ratio of the $[CH_4]/[N_2O]$ mixture were kept above 398 K and $\geqq$0.8 respectively. In the text and the **Appendix**,

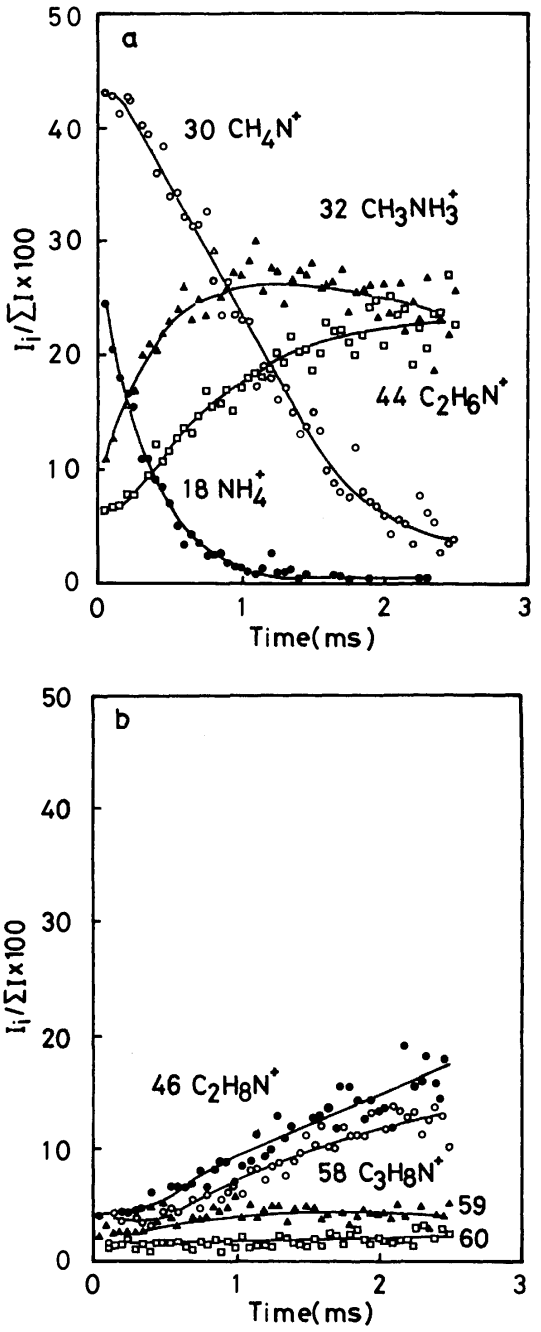

Fig. 2. Normalized ion intensities vs. reaction time observed in CH_4/N_2O mixture at $[CH_4]/[N_2O]$=1.2, T=404 K, P=275.9 Pa. In the figure, mass numbers (m/z) and possible ions are indicated. a is for ions with $m/z\leqq 44$ and b is for $m/z\geqq 46$, respectively.

Reactions (1), (2),···(7) are the major ones, while (A), (B),···(H) are side reactions.

Calculations. The ab initio MO calculation was made using the GAUSSIAN 82 program.[8] The 3-21G basis set was used for the geometry optimization. To obtain accurate energies, the single-point calculation on the 3-21G geometry was made with the third-order Møller-Plesset perturbation of the 6-31+G* basis set (MP3/6-31+G*//RHF(or UHF)/3-21G). For the transition state (**TS**) of the H_2 elimination, the vibrational analysis was performed.

Results and Discussion

Experimental. In Figs. 2 and 3, the time profiles of the relative ion intensities of the major ions observed are exhibited. In Fig. 3, CD_4 was used instead of CH_4. The decay curves in Fig. 2 (Fig. 3) are found for *m/z* 18; NH_4^+(ND_4^+(*m/z* 22)), and *m/z* 30; CH_4N^+(CD_4N^+ (*m/z* 34)). The growth curves are observed for *m/z* 32; $CH_3NH_3^+$($CD_3ND_3^+$(*m/z* 38)), *m/z* 44; $C_2H_6N^+$($C_2D_6N^+$ (*m/z* 50)), *m/z* 46; $C_2H_8N^+$ ($C_2D_8N^+$(*m/z* 54)), *m/z* 58; $C_3H_8N^+$, *m/z* 59 and 60. The reaction mechanism of *m/z* 44 and 46 and the results for the minor ions are given in the **Appendix**.

The major cations except the NH_4^+ and the *m/z* 59 ion are found to appear in three groups; (i), (ii), and (iii):

(i) *m/z* 30 CH_4N^+ and *m/z* 32 $CH_3NH_3^+$
(ii) *m/z* 44 $C_2H_6N^+$ and *m/z* 46 $C_2H_8N^+$
(iii) *m/z* 58 $C_3H_8N^+$ and *m/z* 60 $C_3H_{10}N^+$

In each group, the difference in the mass number is 2

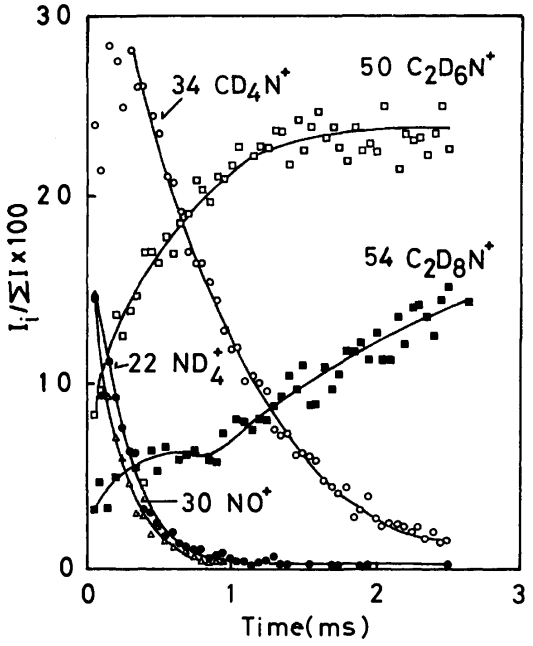

Fig. 3. Normalized ion intensities vs. reaction time observed in CD_4/N_2O mixture at $[CD_4]/[N_2O]$=0.84, *T*=403 K, *P*=295.9 Pa. In the figure, mass numbers (*m/z*) and possible ions are indicated.

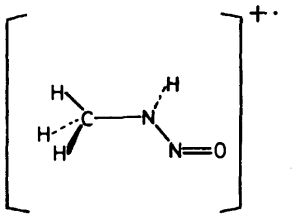
(a hydrogen molecule). The growth of the ion size [(i)→(ii)→(iii)] appears to be by the methylation. The decay curve of *m/z* 30, CH_4N^+, indicates that the ion is the precursor for the methylation.

(i) It has been reported[2,3] that the CH_4N^+ was generated from CH_4^+ (*m/z* 16) and N_2O^+ (*m/z* 44) by Reactions (A) and (B). Although the ion intensity for CH_4N^+ has been reported to be very weak under a low pressure (1.3×10^{-1}—1.3×10^{-2} Pa),[3] the large intensity of CH_4N^+ in the present experiments may be due to the large collisional frequency in Reactions (A) and (B), forming intermediate complexes at high pressures (several hundred Pa):

$$CH_4^+ + N_2O \longrightarrow CH_4N^+ + NO \quad (A)$$

$$N_2O^+ + CH_4 \longrightarrow CH_4N^+ + NO \quad (B)$$

As the ion species of *m/z* 60, the association complex$(CH_4\cdot N_2O)^+$ or an intermediate **1** caused by



1

the insertion of N_2O into methane is likely. However, the $CD_4\cdot N_2O^+$(*m/z* 64) could not be found under our experimental conditions. Thus, the *m/z* 60 ion assigned to $C_3H_{10}N^+$ in Group (iii), to be described below. Two isomers, $CH_2NH_2^+$ (the methaniminium cation) and CH_3NH^+ (the methylimidogenium cation), appear as the CH_4N^+ (*m/z* 30).[1d,9a] The $CH_2NH_2^+$ is more stable than the CH_3NH^+ (the energy difference in the heat of formation between these ions is 121.2 or 138 kJ mol^{-1}).[10] Moreover, it has been reported[1d] that the first electronically excited state of the $CH_2NH_2^+$ is 2 eV above its ground state. The ionic species of CH_4N^+ forming $C_2H_6N^+$ and $C_2H_8N^+$ by the ion/molecule reactions with CH_4 must be the CH_3NH^+ or the electronically excited state of the $CH_2NH_2^+$.[1d]

The overall disappearance-rate constant of CH_4N^+ for CH_4 was estimated to be ca. 1×10^{-14} cm^3/molecule·s at a temperature of 391—403 K, and concentration of $[CH_4]$, from 5.60 to 13.6×10^{16} molecule/cm^3. A similar slow reaction rate constant has been found[10] in the ion/molecule reaction of $C_2H_5^+$ with CH_4 to form *s*-$C_3H_7^+$ and H_2 (*k*=ca. 10^{-14} cm^3/molecule·s at 300 K).

The $CH_3NH_3^+$ may be formed by the reaction between NH_4^+ and CH_4, but the ion is not related to the subsequent methylation. This process will be discussed as Reaction (F) in the **Appendix**.

(ii) Several isomers have been reported[9b,c,11] for

the $C_2H_6N^+$ (m/z 44) and $C_2H_8N^+$ (m/z 46). These ions were generated by the ion/molecule reaction of CH_4N^+ with CH_4. The $C_2H_6N^+$ (m/z 44) may be the $CH_3CHNH_2^+$ (ΔH_f=656.8 kJ mol^{-1})[9b] or $CH_3NHCH_2^+$ (ΔH_f=694.5 kJ mol^{-1}).[9b] As the $C_2H_8N^+$ (m/z 46) ion, the $CH_3CH_2NH_3^+$ (ΔH_f=574.8 kJ mol^{-1})[12,13] or $CH_3NH_2CH_3^+$ (ΔH_f=588.6 kJ mol^{-1})[14] is likely from the enthalpy change in the reactions.

The isomerization from $CH_3CHNH_2^+$ to $CH_3NHCH_2^+$ and that from $CH_3CH_2NH_3^+$ to $CH_3NH_2CH_3^+$ have

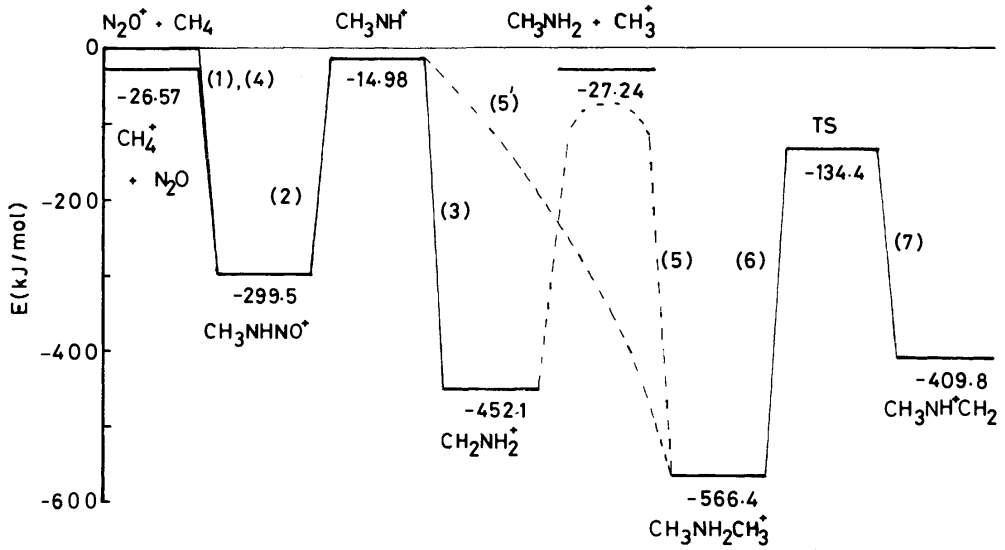


Fig. 4. The energetics of $C_2H_8N_2O^+$ evaluated with the MP3/6-31+G*//HF/3-21G method. The numbers (1)—(7) are defined in charts 1 and 2. The stabilizing energies in kJ mol^{-1} relative to the total energy of (N_2O^++CH_4+CH_4) are shown.

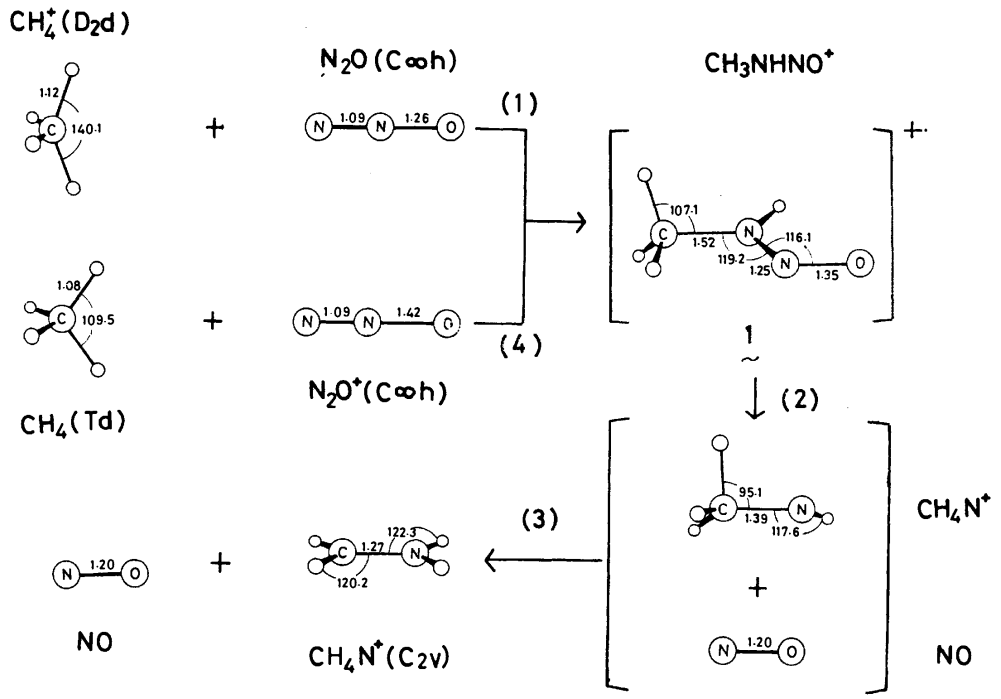

Fig. 5. 3-21G optimized geometries of neutral and cation species involved in reactions (1), (2), (3), and (4). The lengths are in Å and angles in degrees, respectively. The empty circles denote hydrogen atoms.

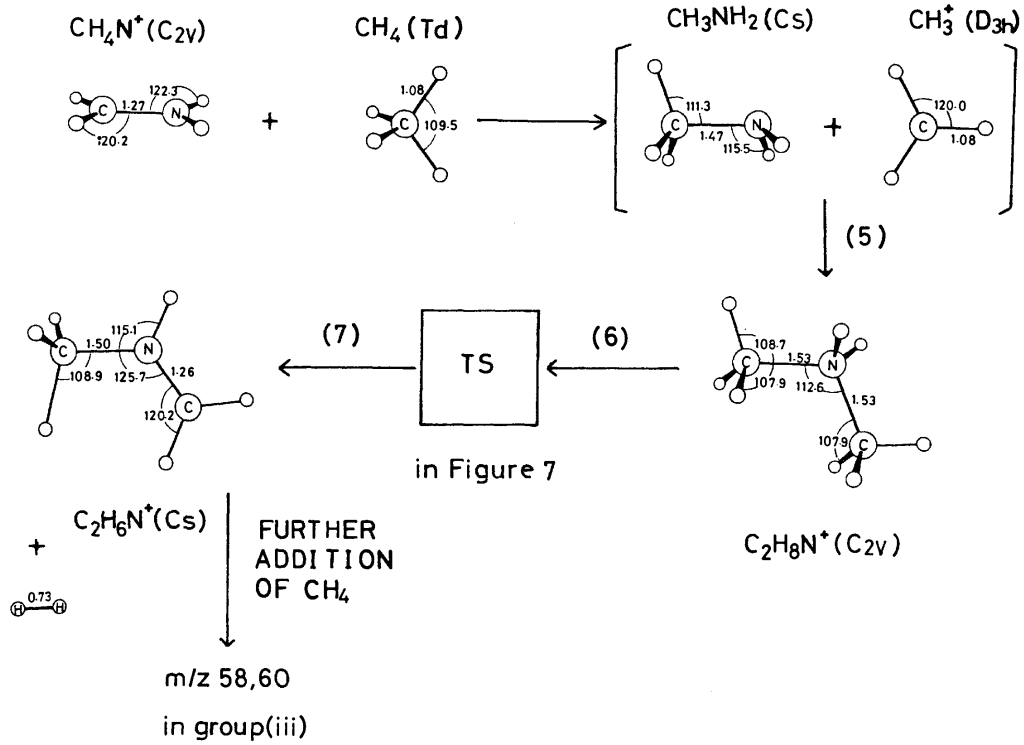

Fig. 6. 3-21G optimized geometries of neutral and cation species involved in reactions (5), (6), and (7).

very high barriers, estimated to be ΔH=ca. 401[11] and >418 kJ mol^{-1}.[15] These isomers, therefore, have been shown to be non-interconvertible under the usual mass-spectrometric conditions.

In the present experiment, the detected ions, *m/z* 30, 44, and 46, may be identified according to Bowers's result.[15] The *m/z* 30 ion is $CH_2NH_2^+$, the *m/z* 46 ion is $CH_3NH_2CH_3^+$ (and partly $CH_3CH_2NH_3^+$), and the *m/z* 44 ion is $CH_3NHCH_2^+$. The detailed discussion of this assignment will be given at the beginning of the **Appendix**.

(iii) For the $C_3H_8N^+$, several isomers have been reported;[9b] $(CH_3)_2CNH_2^+$ (ΔH_f=589.9 kJ mol^{-1}), $CH_3CHNHCH_3^+$ (ΔH_f=615 kJ mol^{-1}), $CH_3CH_2CHNH_2^+$ (ΔH_f=635.9 kJ mol^{-1}), $CH_3CH_2NHCH_2^+$ (ΔH_f=652.7 kJ mol^{-1}), and $(CH_3)_2NCH_2^+$ (ΔH_f=661 kJ mol^{-1}). Among these ions, the most stable isomer is $(CH_3)_2CNH_2^+$. However, the ion species formed by the ion/molecule reaction of $C_2H_6N^+$ with CH_4 is not clear experimentally. The formation and subsequent reactions of these ions must, therefore, be examined theoretically.

Computational. Of the three groups, the ions of (ii) and (iii) seem to be formed by a similar reaction pattern. Since the molecular size of Group (iii) is large, we will restrict ourselves to the cations in Groups (i) and (ii) for the computational analysis.

In Fig. 4, the energy diagram of Charts 1 and 2 is shown. In Figs. 5—7, the geometries of the reactants

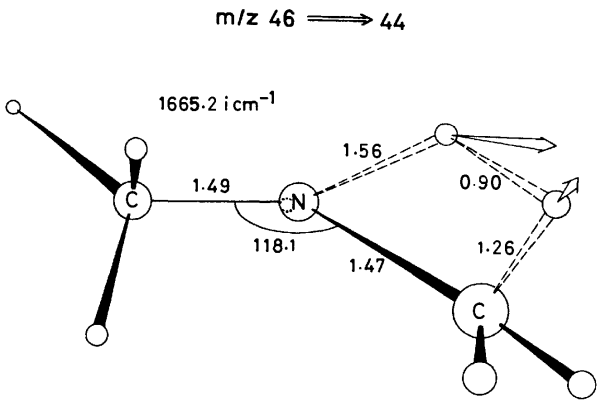

Fig. 7. The transition-state (TS) structure of H_2 elimination in reactions (6) and (7). The reaction coordinate vector corresponding to the sole imaginary frequency 1665.2i cm^{-1} is sketched. Note that a hydrogen atom ((shown by a broken circle)) stays behind the nitrogen atom.

and intermediates are displayed. In Fig. 4, the system of (CH_4^++N_2O) is only 26.56 kJ mol^{-1} more stable than that of (CH_4+N_2O^+). This small energetic difference suggests that both systems are precursors of further reactions. The potential energies vary considerably alnog with the reaction process, which suggests that all the intermediate species are quite "hot" molecules. For instance, the energy level of the transition state of the H_2 elimination is lower than that of the precursor

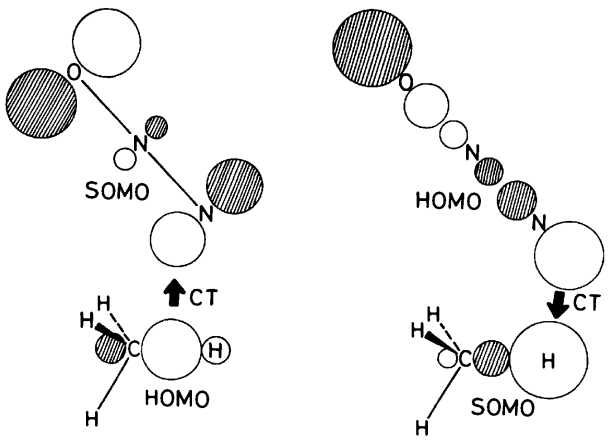
$N_2O^+ + CH_4 \xrightarrow{(4)} [1] \xrightarrow{(2)} CH_3\text{-}NH^+ + NO \xrightarrow{(3)} CH_2NH_2^+ + NO$ (m/z 44 → m/z 30)	−420.2 (−436.9)	−454.8

a) $\Delta H_f(CH_4^+)$=1150 kJ mol^{-1} from Ref. 13a. $\Delta H_f^{298}(CH_2NH_2^+)$=744.7 kJ mol^{-1} from Ref. 9b. $\Delta H_f(N_2O^+)$=1330 kJ mol^{-1} from Ref. 13a. $\Delta H_f^{298}(N_2O)$=82.04 kJ mol^{-1}, $\Delta H_f^{298}(NO)$=90.24 kJ mol^{-1}, and $\Delta H_f^{298}(CH_4)$=−74.80 kJ mol^{-1} from Ref. 13a. The values in parenthesis were estimated using $\Delta H_f^{298}(CH_2NH_2^+)$=728 kJ mol^{-1} from Ref. 9a. b) Computed with the MP3/6-31+G* method.

$CH_4^+ + N_2O$. The sufficient kinetic and vibrational energies accumulated may make the reactions in Charts 1 and 2 likely. In Fig. 4, the energy level of CH_3NH_2 plus CH_3^+ is shown. The level is regarded as the upper boundary of the barrier energy of the hydride-ion shift and the methyl-cation migration. The cooperative mechanism will lower the barrier energy to make Reaction (5) a facile process.

The $(CH_4 \cdot N_2O)^+$ species (m/z 60) **1**, which is ruled out by the experiment using a deuterium compound, is calculated to be stable by 284.5 kJ mol^{-1} relative to CH_3-NH^+ plus NO. Under the present condition (404 K), however, the lifetime of **1** would be too short to be observed in Fig. 2. This is because the hot molecule **1** has enough energy accumulated by insertion to decompose into $CH_4N^+ + NO$.

In Chart 1, four reactions-(1), (2), (3), and (4)- are displayed. Two isomers[1d,9a,d] of CH_4N^+ are considered. One is CH_3-NH^+, while the other is CH_2=NH_2^+. Although a carbene-type form is obtained for CH_3-NH^+, the stability is sensitive to the method of computation.[16] Indeed, the ethylidene CH_3-CH, which is isoelectronic with CH_3-NH^+, has been reported by Pople et al. to be absent.[17] Therefore, CH_3-NH^+ is only a transient species, and CH_2=NH_2^+ (isoelectronic with ethylene) is the sole stable species. In Chart 1, the CH_3NH^+ is shown to be first formed by the insertion of N_2O^+/N_2O into a C-H bond of CH_4/CH_4^+ via **1**. The insertion can be explained by an orbital interaction like the insertion of CH_2 or NH into a C-H bond.[18] For instance, the interaction (in the figure of the frontier orbitals) is effective in the insertion. The charge-transfer (**CT**) interaction from the **HOMO** of the C-H bond to the **SOMO** of N_2O^+ is the driving force of the reaction. In the case of Reaction (1) in Chart 1, the **CT** from the **HOMO** of N_2O to the **SOMO** of CH_4^+ is the driving force. This CH_3-NH^+ isomerizes to CH_2=NH_2^+.



Under the present high pressure (P=275.9 Pa), the transient ion may collide with neutral molecules, H_2 and CH_4, prior to its arrival at CH_2=NH_2^+. If CH_3-NH^+ reacts with H_2, $CH_3NH_3^+$ (m/z 32) in Group (i) may be formed. If CH_3-NH^+ reacts with methane in Chart 2, the protonated dimethylamine (m/z 46) in Group (ii) is produced. The transition-state search for this route was attempted, but we failed to arrive at the energy maximum. Thus, Route (5)′ seems not to include an energy barrier. The reaction of CH_2=NH_2^+ with CH_4 in Route (5) to form the protonated dimethylamine is also likely. The CH_2=NH_2^+ stays at the electronically excited state or at a high vibrational state, as is shown by the large exothermicity in Chart 1. The energy-rich species may cause the hydride-ion shift and the subsequent methyl-cation addition.

The isolation of the methyl cation is unlikely, because the lone-pair electrons on the nitrogen atom capture the cation instantly. Once the $(CH_3)_2NH_2^+$ ion is formed, the dehydrogenation shown in Chart 2 is expected to give m/z 44 in Group (ii). From the protonated dimethylamine, the *N*-methylmethaniminium cation may be produced. The transition state (**TS**)

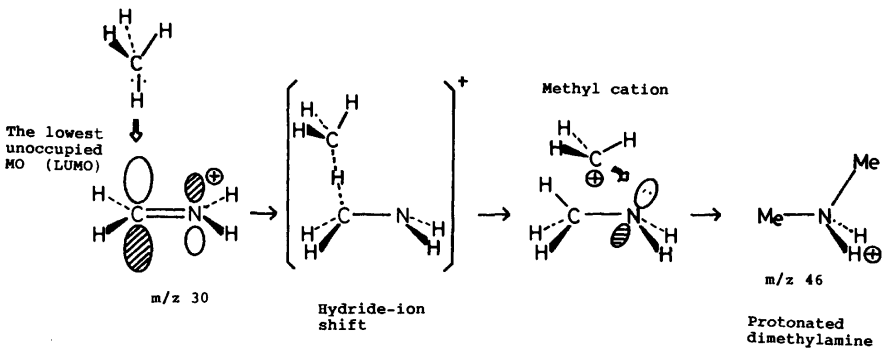
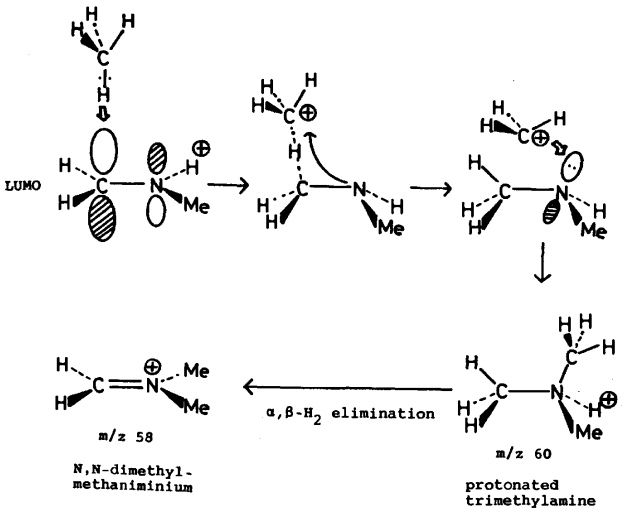
The values in parenthesis were estimated using $\Delta H_f^{298}(CH_2NH_2^+)$=728 kJ mol^{-1} from Ref. 9a. b) Computed with the MP3/6-31+G* method. c) Experimental and calculated ΔH_r for the formation of $CH_3NHCH_2^+$ is calculated from the reaction, $CH_2NH_2^+ + CH_4 \rightarrow CH_3NHCH_2^+ + H_2$.



structure of the dehydrogenation is explicitly determined (It is shown in Fig. 7).

In view of the reaction patterns in Chart 2, the formation of Group (iii) may be deduced. To give the *m/z* 60 species, the H_3C–HN^+=CH_2 should be a precursor for two species in Group (iii):



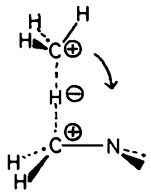
The *m/z* 60 cation is obtained by the methane addition to H_3C–HN^+=CH_2, followed by the H_2 elimination to give *m/z* 58. According to this scheme, the methane addition to CH_2=$N^+(CH_3)_2$ (*m/z* 58) can possibly give CH_3–$N^+(CH_3)_3$ (*m/z* 74), but the formation of *m/z* 72 is unlikely because of the absence of the α,β-H_2 elimination. That is, the *m/z* 74 is the end of the chain reaction of methane addition and H_2 elimination.

Bowers et al.[15] have reported that Reactions (5) and (6) in Chart 2 have the large barriers on the basis of metastable and collision-induced studies of $C_2H_8N^+$. From Fig. 4, the values for these two reactions are estimated to be below 424.9 (−27.24—(−452.2), upper boundary) and 432 (−134.4—(−566.4)) kJ mol^{-1} respectively.

Concluding Remarks

Methane is a rigid, ball-type molecule, and its reaction is improbable in the sense of organic chemistry. However, in the gas phase, specific patterns of chain-type reactions (formally, the methylation) have been observed.[1f,19,20]

The CH_4N^+ ion (*m/z* 30) is the key precursor for the growth of the ion size. The methylation is composed of the heterolytic CH_3^+–H^- addition to the C=N double bond and the subsequent α,β-H_2 elimination. That is, the methane addition is initiated by the hydride ion sharing by two cations. This is followed by the



methyl-cation 1, 2 shift toward the nitrogen lone-pair electrons. The H_2 elimination occurs by a combination of the *N*-protonated hydrogen and the methyl hydrogen. The high vibrational state of the C-H stretching will make the elimination a facile process (cf. Fig. 7). The methylation is terminated when a hydrogen atom connected to the nitrogen atom is not available. That is, $N(CH_3)_4^+$ (*m/z* 74) will be the final product, although no species with this large mass number is detected here.

Thus, the growth of the mass number is the substitution process of protonated amines and imines, primary→secondary→tertiary.

As an important result, the activation energy for the H_2 elimination was quantitatively calculated.

Appendix

***m/z* 46 and 44.** The results by collision-induced dissociation[15] have indicated that, for $CH_3CH_2NH_3^+$ (*m/z* 46), only one metastable dissociation reaction (C) was observed and that there is not a significant barrier in the reverse reaction. Also, it has been shown that, for $CH_3NH_2CH_3^+$, the metastable reactions forming $CH_3NHCH_2^+$ (*m/z* 44) and $CH_2NH_2^+$ (*m/z* 30) were observed, while the reverse reactions of Eqs. (D) and (E) have large activation barriers. (The values were not estimated.)

$$\underset{(m/z\ 46)}{CH_3CH_2NH_3^+} \longrightarrow \underset{(m/z\ 18)}{NH_4^+} + C_2H_4 \qquad (C)$$

$$\underset{(m/z\ 46)}{CH_3NH_2CH_3^+} \longrightarrow \underset{(m/z\ 44)}{CH_3NHCH_2^+} + H_2 \qquad (D)$$

$$\underset{(m/z\ 46)}{CH_3NH_2CH_3^+} \longrightarrow \underset{(m/z\ 30)}{CH_2NH_2^+} + CH_4 \qquad (E)$$

In the present experiments, some ions (*m/z* 30, 44, and 46) are detected. Of these, *m/z* 46 and 44 must be formed by the reverse reaction of (E) and the forward reaction (D) respectively, although the details of these reaction mechanism are unknown.

The Minor Ions. *m/z* 18(NH_4^+). The NH_4^+ (*m/z* 18) in Fig. 2 may be yielded by the following two reactions:

i) The proton transfer from the carbonium ions[12] and hydronium ions, etc., to a trace amount of NH_3, whose ions were found by the ion/molecule reactions in CH_4. The NH_3 is contained in the reaction system as an impurity or is generated by the pulsed discharge in the CH_4/N_2O mixture.

ii) The direct routes forming NH_4^+ by means of ion/molecule reactions.

The decrease in the relative ion intensity of NH_4^+ (*m/z* 18) in the range of reaction times of 0—1 ms may be due to Reaction (F), corresponding to the increase in that of $CH_3NH_3^+$ (*m/z* 32):

$$NH_4^+ + CH_4 \xrightarrow{k} CH_3NH_3^+ + H_2 \qquad (F)$$

The overall disappearance-rate constant of $I_{18}/\sum I$, *k* (the nomalized ion intensity of NH_4^+, where I_{18} denotes the ion intensity of *m/z* 18), was determined to be $(3\pm0.5)\times10^{-14}$ cm^3/molecule·s. This slow rate constant may be due to the endothermicity (ΔH_r=55.22 kJ mol^{-1}) of Reaction (F).

***m/z* 30(NO^+) and *m/z* 46(NO_2^+).** Nitrogen monoxide, NO^+ (*m/z* 30), and NO_2^+ (*m/z* 46) ions are present as other ionic species of *m/z* 30 and 46. However, the results in Fig. 3 show that the relative ion intensity of NO^+ (*m/z* 30) decreased until the reaction time of <0.3 ms. The intensity of NO^+ decreases rapidly, which indicates that the ion reacts with some neutral molecules. A check was made to see whether or not these are higher hydrocarbons as impurities derived in the reagents. In the literature,[9-11] *m/z* and the intensities of the products of reactions between NO^+ and hydrocarbons are available. Fortunately, none of the cited ions were found in our experiment. Thus, the contribution of higher hydrocarbons (as well as ethane) to the reaction with NO^+ may be neglected.

The neutral molecule is expected to be methane, thus giving the following two reactions:

$$NO^+(a^3\Sigma^+) + CH_4 \longrightarrow CH_4^+ + NO \qquad (G)$$

$$NO^+ + CH_4 \longrightarrow \underset{N\text{-hydroxymethaniminium ion}}{CH_2{=}NH(OH)^+} \qquad (H)$$

Eq. (G) is a charge transfer-reaction with a large rate constant (k=ca. 1.0×10^{-9} cm^3/molecule·s). Eq. (H) is an insertion with a large exothermicity (ΔH_r=−180.3 kJ mol^{-1} computed with MP3/6-31+G*//RHF/3-21G). Although the result for NO_2^+ (*m/z* 46) is not shown in the figure, the relative ion intensity of NO_2^+ (*m/z* 46) was very weak (<several%) and independent of the reaction time. Therefore, the contribution of NO^+ and NO_2^+ to the decrease in CH_4N^+ (*m/z* 30) and the formation of $C_2H_8N^+$ (*m/z* 46) could be eliminated by the longer reaction time (>0.3 ms).

***m/z* 59.** The ion species of *m/z* 59 seems to be $C_3H_7O^+$ (oxygen-containing ion)[1a] for the following reasons: i) the relative ion intensity of *m/z* 59 increased with the increase in the content of H_2O in the reaction system; ii) in an experiment using CD_4, *m/z* 66 ($C_3D_7O^+$) was detected as the corresponding ion.

Nitrogen-Containing Molecules besides $C_2H_6N^+$ and $C_2H_8N^+$. If trace amounts of the nitrogen-containing molecules—NH_3, CH_3NH_2, C_2H_7N, etc.— are present in the reaction system as impurities or as products of the pulsed discharge, the formation of CH_4N^+ (*m/z* 30),[1d,e,g,25] $CH_3NH_3^+$ (*m/z* 32), and $C_2N_8N^+$ (*m/z* 46)[25-27] may be, in part, due to the contribution of these molecules. Particularly, the growth curve of $C_2D_8N^+$ (*m/z* 54) in Fig. 3 is somewhat complicated. A part of the increase in $C_2D_8N^+$ may be due to the proton transfer to a trace amount of C_2D_7N. However, the reactions for the formation of $C_2H_6N^+$ (*m/z* 44) are unlikely.[25-27] Munson[26] has reported that the rate of hydride transfer is about one-fifth that of proton transfer, judging from the ratio of the increase in the relative ion

intensities of $(CH_3)_2NCH_2^+$ (m/z 58) and $(CH_3)_3NH^+$ (m/z 60) in $(CH_3)_3N$. The ratio of the increase in the relative ion intensity of these ions in Fig. 2 is different from Munson's result. Our data show that the increase in the relative ion intensity of $C_3H_8N^+$ (m/z 58) is larger than that of $C_3H_{10}N^+$ (m/z 60). This suggests that $C_3H_8N^+$ (m/z 58) and $C_3H_{10}N^+$ (m/z 60) in Fig. 2 were formed by the ion/molecule reaction of $C_2H_6N^+$ with CH_4.

The authors wish to thank the Data Processing Center of Kyoto University for the allotment of the CPU time on the FACOM M-380 Computer. Thanks are also due to the Institute for Molecular Science for the use of the HITAC M-680H computer.

The Addition Effects of Methyl Halides on Ethane Ignition Behind Reflected Shock Waves

Kazuo TAKAHASHI, Tadaaki INOMATA,* Takao MORIWAKI, and Satiko OKAZAKI
Department of Chemistry, Faculty of Science and Technology, Sophia University,
7-1 Kioi-cho, Chiyoda-ku, Tokyo 102
(Received November 29, 1988)

Ignition delay times were measured in C_2H_6–O_2–CH_3X(X:Cl, Br or I) mixtures highly diluted with argon behind reflected shock waves. The measurements covered a temperature range of 1200—1900 K and the pressure range of 1.4—2.9 atm. The times were longer than those without CH_3X, indicating that CH_3X inhibits ethane ignition. This was contrary to the previous results which showed that CH_3X promoted methane ignition. To clarify the addition effects of CH_3X from the viewpoint of the reaction mechanism, computational analyses were performed in C_2H_6–O_2–CH_3Br and CH_4–O_2–CH_3Br mixtures. The analytical results showed that different chain cycles for Br-containing species were formed in the two mixtures. The opposite effects of CH_3Br on ethane and methane ignitions could be interpreted in terms of these different cycles.

For combustion, the effects of additives are generally divided into two types: chemical and physical effects. With respect to the addition of halogen-containing compounds (RX), the former is predominant.[1]

Most RX's decrease the burning velocity when they are added into a flame.[2] Namely, an RX acts as an inhibitor for flame propagation. Rosser et al.[2] and Westbrook[3] have reported that halogen acid (HX) generated by the decomposition of RX captures H atoms in a flame through the following reaction:

$$HX + H = H_2 + X. \quad (X5)$$

Reaction (X5) is competitive with reaction (R76), which is the most important chain-branching reaction in combustion:

$$H + O_2 = OH + O. \quad (R76)$$

However, the addition effect of RX on ignition is not always similar to that on flame propagation. In previous work,[4–6] we have shown that methyl halides (CH_3X) act as promotors for methane ignition, and discussed the promotion effect on the basis of chemical kinetics.

In this study, in order to examine the addition effect of CH_3X on ethane ignition, the ignition delay times were measured in C_2H_6–O_2–CH_3X mixtures by using a shock tube. Moreover, by means of computational analyses, the chain cycle formed in a C_2H_6–O_2–CH_3Br mixture was compared with that in a CH_4–O_2–CH_3Br mixture.

Experimental

All of the experiments were carried out behind reflected shock waves in a 6.2 cm i.d. stainless steel shock tube. The driver and test sections were 1.7 and 3.8 m long, respectively, so that dwell times above 1.5 ms could be obtained in all of the experiments. Other apparatus for measurements of the shock velocity and ignition delay time and associated procedures have already been reported.[4] Ignition delay times, defined as the time interval between the arrival of a shock wave and the onset of ignition, were obtained by rapid increases in pressure and OH emission ($X^2\Pi_i \leftarrow A^2\Sigma^+$ transition, 306.4 nm).

The compositions of test gas mixtures used are shown in Table 1. The accuracy of the composition of mixtures is better than 0.01%. The measurements were carried out over the temperature range 1200—1900 K and the pressure range 1.4—2.9 atm.

Analytical Treatment

To clarify the addition effects of CH_3X from the viewpoint of the reaction mechanism, ignition delay times were calculated in mixtures 1 (C_2H_6–O_2) and 3 (C_2H_6–O_2–CH_3Br), and sensitivity analyses were carried out. Details concerning the calculation were described previously.[5] The reaction mechanism assembled for ethane oxidation consists of the 93 elementary reactions employed in a previous study on methane oxidation (reactions (R1)—(R93)),[5,6] and 18 reactions added in this study (reactions (R94)—(R111) in Table 2). However, with respect to the rate coefficient of reaction (R38),

$$C_2H_5 (+ M) = C_2H_4 + H (+ M), \qquad (R38)$$

an expression given by Warnatz,[18]

$$k_{(R38)}(\text{1st order})/s^{-1}$$

$$= 2.00 \times 10^{14}\exp(-39.67 \text{ kcal mol}^{-1}/RT),$$

was employed in this study instead of the expression in the previous one:

$$k_{(R38)}(\text{2nd order})/\text{mol}^{-1}\,\text{cm}^3\,\text{s}^{-1}$$

$$= 2.00 \times 10^{15}\exp(-30.00 \text{ kcal mol}^{-1}/RT).^{19}$$

To complete the reaction model in the presence of CH_3Br, 9 reactions (Table 3) involving Br-containing species (CH_3Br, Br, Br_2, and HBr) were added to the reactions for ethane oxidation. For a comparison, the ignition delay times in CH_4–O_2 and CH_4–O_2–CH_3Br mixtures were also calculated using the same reaction model.

The reverse rate constants were computed using the forward rate constants and the appropriate equilibrium constants. Most thermochemical and thermodynamic data were taken from Refs. 20 and 21. The data for eight species (C_2H_3, C_2H_5, C_2H_6, CH_3O, CHCO, CH_2CO, H_2O_2, and CH_3Br) were not available, and so were evaluated by a statistical method.[20] Details concerning the calculation procedure and the validity of results were descrived previously.[5]

Three methods were carried out to define calculated ignition delay times. The first of these is the time at which the OH concentration increases rapidly, and the second is the time at which C_2H_6 concentration decreases rapidly. The third is the time at which the gas temperature rises rapidly. All of these times agreed to within 7%. Finally, the calculated ignition delay times were determined from the temperature profile, since the error in reading was least.

Results and Discussion

The ignition delay time (τ) measured in mixtures 1—4 are shown in Fig. 1. The addition of CH_3X lengthens τ, i.e., CH_3X inhibits ethane ignition. This

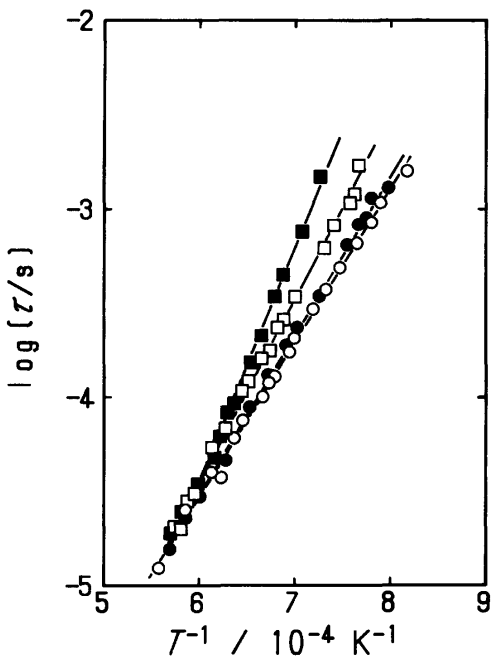

Fig. 1. Measured ignition delay times. O, Mixture 1; ●, Mixture 2; □, Mixture 3; ■, Mixture 4.

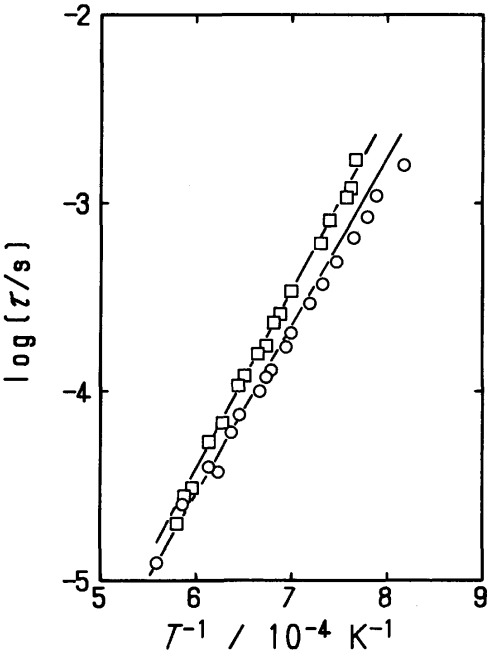

Fig. 2. Comparison between calculated and measured ignition delay times. O, Mixture 1; □, Mixture 3. Straight lines are calculated.

is contrary to the previous results in which CH_3X promoted methane ignition.[5,6] In three CH_3X compounds (CH_3Cl, CH_3Br, and CH_3I), the inhibition effect of CH_3I is the greatest, while that of CH_3Cl is the least. For all mixtures, plots of $\log \tau$ against the reciprocal of the temperature give straight lines. The slope of the line is 0.81 for mixture 1, while the slopes are 0.85, 0.98, and 1.24 for mixtures 2—4, respectively.

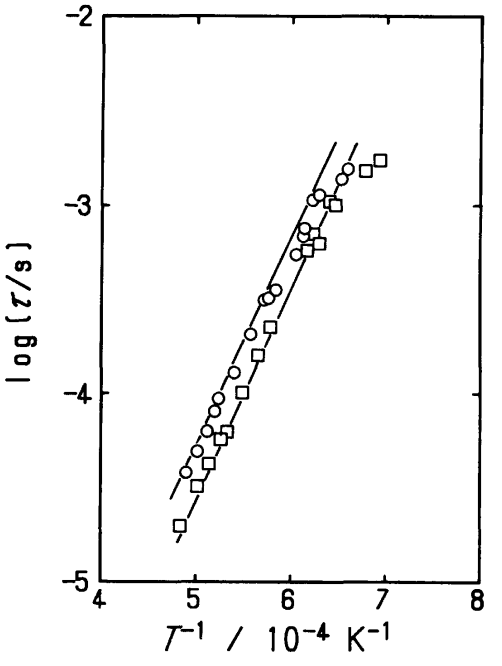

Fig. 3. Comparison between calculated and measured ignition delay times. O, CH_4–O_2 mixture; □, CH_4–O_2–CH_3Br mixture.[5] Straight lines are calculated.

These values indicate that the inhibition effect of CH_3X is remarkable at low temperature.

In Fig. 2, the ignition delay times calculated in mixtures 1 and 3 are compared with the measured ones. Although the temperature dependence of the calculated values in mixture 1 is somewhat large, the calculated ignition delay times are generally in good agreement with the measured values.

Using the same reaction model, the ignition delay times calculated in CH_4–O_2 and CH_4–O_2–CH_3Br mixtures are shown in Fig. 3. Plots in the figure express the measured values which have already been reported.[5] The ignition delay times re-calculated in this study are identical to those found in the previous one, which were calculated by using 93 reactions for methane oxidation and 8 reactions involving Br-containing species.[5] This agreement indicates that the reactions added in this study (Table 2) have no effect for methane ignition.

As is obvious from Figs. 2 and 3, the assembled reaction mechanism can express the experimental results that CH_3Br promotes methane ignition, but inhibits ethane ignition. To clarify the opposite addition effects of CH_3Br on methane and ethane ignitions, sensitivity analyses were performed on 9 reactions involving Br-containing species (Table 3). In a CH_4–O_2–CH_3Br mixture, the ignition delay times calculated by deleting reactions (B1)—(B9), one by one, are shown in Table 4 (1500 K). Similarly, the ignition delay times calculated at 1500 and 1900 K in mixture 3 (C_2H_6–O_2–CH_3Br) are also shown in Table 4.

Table 4. Calculated Ignition Delay Times

Reaction[a]	Ignition delay time/μs		
	CH_4-O_2-CH_3Br	C_2H_6-O_2-CH_3Br	
	1900 K	1500 K	1900 K
None	56.9	161	8.03
(B1) $CH_3Br=CH_3+Br$	119 (+109%)[b]	163 (+1%)	8.35 (+4%)
(B2) $CH_3Br+H=CH_3+HBr$	74.9 (+32%)	107 (−34%)	6.85 (−15%)
(B3) $CH_3Br+Br=CH_3+Br_2$	57.6 (+1%)	161 (0%)	8.09 (+1%)
(B4) $Br+CH_4=CH_3+HBr$	69.5 (+22%)	163 (+2%)	8.01 (0%)
(B5) $HBr+H=H_2+Br$	54.9 (−4%)	139 (−14%)	7.76 (−3%)
(B6) $Br_2+H=HBr+Br$	56.7 (0%)	160 (0%)	8.01 (0%)
(B7) $Br+Br+M=Br_2+M$	56.7 (0%)	160 (0%)	8.09 (+1%)
(B8) $Br+H+M=HBr+M$	57.2 (+1%)	161 (0%)	8.09 (+1%)
(B9) $Br+C_2H_6=C_2H_5+HBr$	57.7 (+1%)	166 (+3%)	8.15 (+1%)

Calculated ignition dely time is 110 μs at 1900 K in CH_4-O_2 mixture; it is 105 μs at 1500 K and 6.69 μs at 1900 K in C_2H_6-O_2 mixture. a) Reaction which is deleted from the complete mechanism. b) Percentage of change to ignition delay time calculated by using complete mechanism.

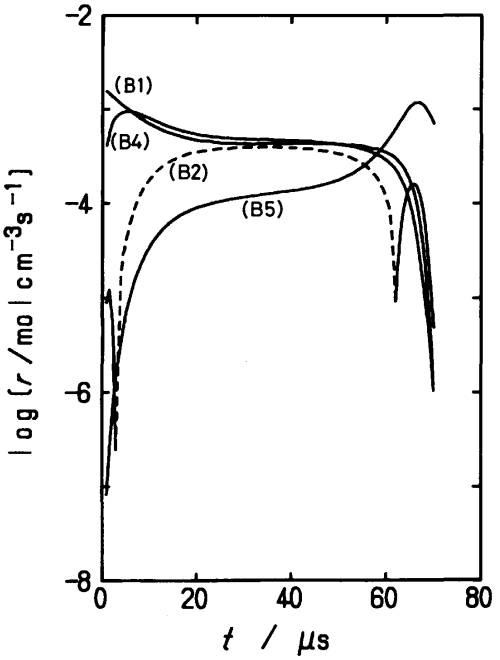

Fig. 4. Net reaction rates of (B1), (B2), (B4), and (B5) at 1900 K in CH_4-O_2 mixture. Calculated ignition delay time is 56.9 μs. t means time after the arrival of reflected shock wave. Solid line: net reaction proceeds in forward direction, dashed line: in reverse direction.

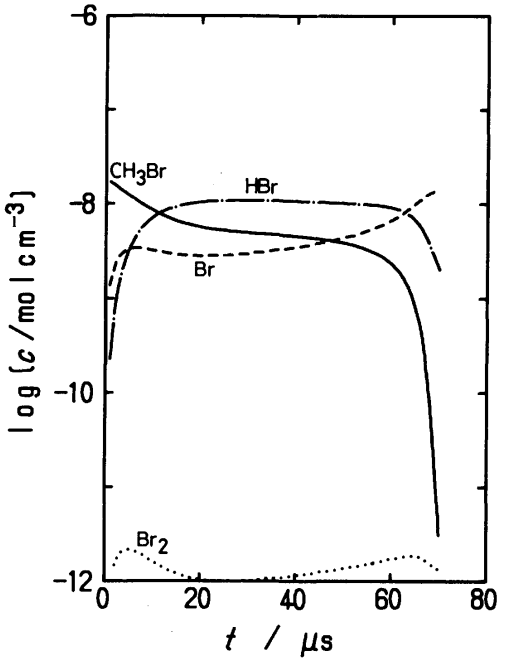

Fig. 5. Calculated concentration profiles of CH_3Br, Br, Br_2, and HBr at 1900 K in CH_4-O_2 mixture.

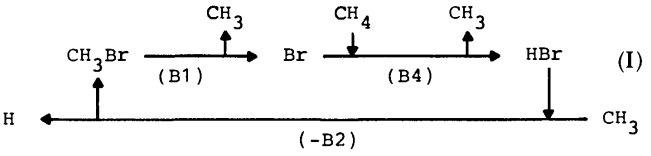
In a CH_4-O_2-CH_3Br mixture, reactions (B1), (B2), and (B4) greatly influence the ignition delay time (Table 4). When each of these reactions is deleted from the complete mechanism, the ignition delay time is longer than that in the complete mechanism, showing that reactions (B1), (B2), and (B4) promote methane ignition. Moreover, considering the reaction rates (Fig. 4) and the concentrations of Br-containing species (Fig. 5), we arrived at the same conclusion as in a previous study.[5] The following cycle is formed among CH_3Br, Br, and HBr:



The net reaction of cycle (I) corresponds to the production of one H atom and one CH_3 radical from methane in each chain, and so methane ignition is promoted.

In mixture 3 (C_2H_6-O_2-CH_3Br), the inhibition effect of CH_3Br is remarkable at low temperature, as has been mentioned. From the calculated results at low

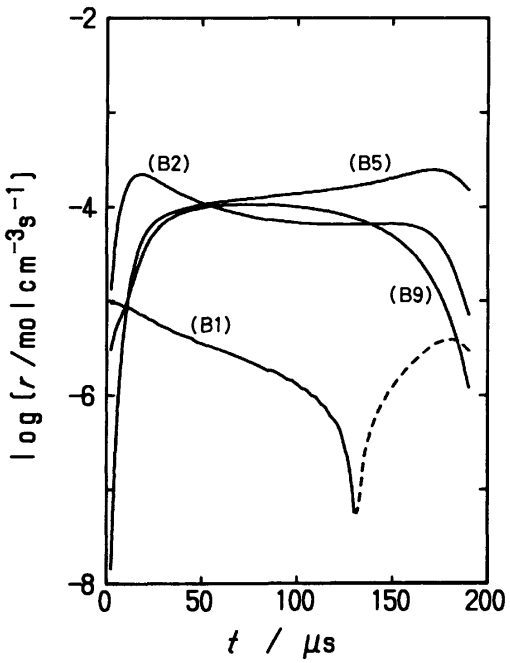


Fig. 6. Net reaction rates of (B1), (B2), (B5), and (B9) at 1500 K in Mixture 3 (C_2H_6-O_2). Calculated ignition delay time is 161 μs.

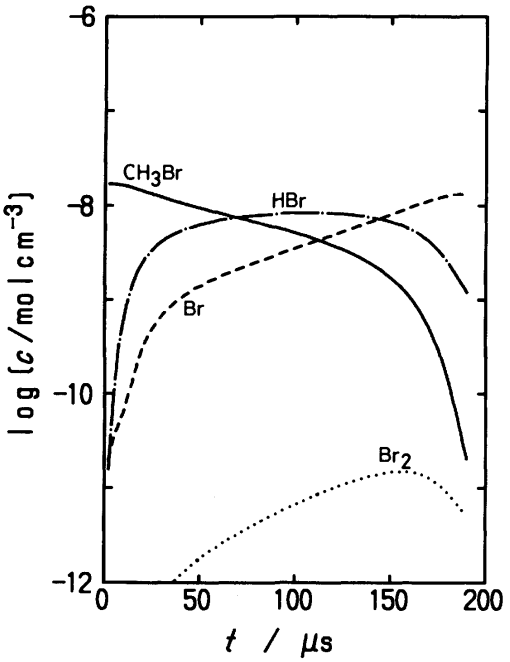

Fig. 7. Calculated concentration profiles of CH_3Br, Br, Br_2, and HBr at 1500 K in Mixture 3 (C_2H_6-O_2).

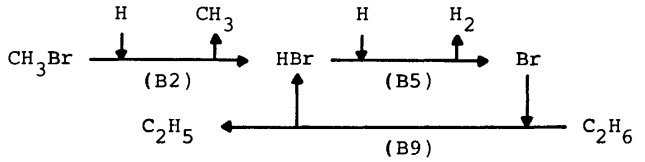
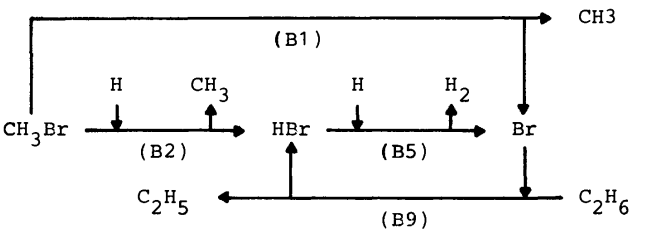
temperature (1500 K), as shown in Table 4, it is obvious that reactions (B2) and (B5) greatly influence the ignition delay time. Both reactions (B2) and (B5) inhibit ethane ignition, because deletion of these reactions makes the ignition delay time shorter. As shown in Fig. 6, the main reaction of CH_3Br consumption at low temperature is not (B1) but, rather, (B2). Reaction (B2) shows a inhibition effect, because the H atom which is the reactant of the most important chain-branching reaction (R76) controlling ignition is simultaneously consumed. Since the product HBr also mainly reacts with the H atom through reaction (B5), ethane ignition is more inhibited. The bromine atoms consume ethane through reaction (B9), and HBr is regenerated. Reaction (B9), itself, seems to show a promotion effect, because ethane is oxidized through reaction (B9). However, as HBr reproduced through reaction (B9) is the reactant of the inhibition reaction (B5), the promotion effect of reaction (B9) is compensated, as shown in Table 4. This consideration suggests that the following cycle is formed at low temperature in a C_2H_6-O_2-CH_3Br mixture:



(II)

The difference between the chain cycle formed in the CH_4-O_2-CH_3Br mixture (I) and that in the C_2H_6-O_2-CH_3Br mixture (II) can also be confirmed in the concentration profiles (Figs. 5 and 7). A bromine atom appears earlier than HBr in the CH_4-O_2-CH_3Br mixture, while HBr appears earlier than Br in the C_2H_6-O_2-CH_3Br mixture.

At high temperature, where the inhibition effect of CH_3Br falls, the other channel of CH_3Br consumption, reaction (B1), is open in the C_2H_6-O_2-CH_3Br mixture. As is obvious in Table 4, the inhibition effects due to reactions (B2) and (B5) decrease at high temperature (1900 K). Instead, reaction (B1) shows a slight promotion effect. These reaction rate profiles at 1900 K are shown in Fig. 8. The rate ratio of reaction (B1) to (B2) at the half time of the induction period, $[r(B1)/r(B2)]_{\tau/2}$, is 0.027 at 1500 K, but 0.25 at 1900 K. The increase in the relative rate of reaction (B1) to (B2) is caused by a difference in activation energy between these reactions. Therefore, the cycle formed at high temperature in the C_2H_6-O_2-CH_3Br mixture is expressed as follows.



(III)

Reaction (B1), which is competitive with reaction (B2) for CH_3Br consumption, shows a promotion

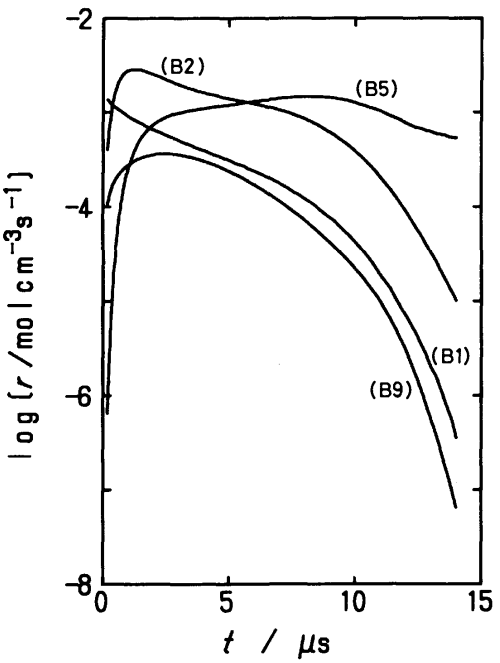


Fig. 8. Net reaction rates of (B1), (B2), (B5), and (B9) at 1900 K in Mixture 3 (C_2H_6-O_2). Calculated ignition delay time is 8.03 μs.

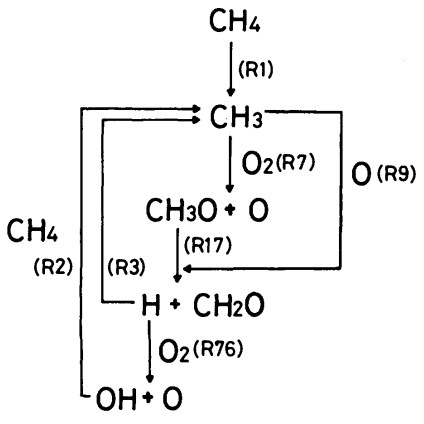
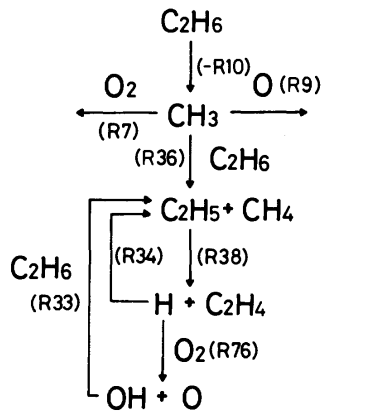


$CH_4 + M = CH_3 + H + M$ (R1)
$CH_3 + O_2 = CH_3O + O$ (R7)
$CH_3O + M = CH_2O + H + M$ (R17)
$CH_3 + O = CH_2O + H$ (R9)
$H + O_2 = OH + O$ (R76)
$CH_4 + OH = CH_3 + H_2O$ (R2)
$CH_4 + H = CH_3 + H_2$ (R3)

Fig. 9. Main process for CH_4 consumption at the early stage of induction period in CH_4-O_2 mixture (1750 K).

effect rather than an inhibition type, as shown in Table 4. The CH_3 radical produced through reaction (B1) accelerates ethane consumption through the path (Fig. 10). Moreover, the relative rates of reactions (B2) and (B5) to the chain-branching reaction (R76) are reduced with temperature, because of the difference in the activation energy between these reactions. The ratios, $[r(B2)/r(R76)]_{\tau/2}$ and $[r(B5)/r(R76)]_{\tau/2}$, are 0.20 and 0.34 at 1500 K, while they are 0.14 and 0.093 at



$C_2H_6 = CH_3 + CH_3$ (-R10)
$CH_3 + O_2 = CH_3O + O$ (R7)
$CH_3 + O = CH_2O + H$ (R9)
$C_2H_6 + CH_3 = C_2H_5 + CH_4$ (R36)
$C_2H_5 = C_2H_4 + H$ (R38)
$H + O_2 = OH + O$ (R76)
$C_2H_6 + OH = C_2H_5 + H_2O$ (R33)
$C_2H_6 + H = C_2H_5 + H_2$ (R34)

Fig. 10. Main process for C_2H_6 consumption at the early stage of induction period in Mixture 1 (C_2H_6-O_2, 1750 K).

1900 K. Therefore, it is concluded that competitive reactions (B1) and (R76) with inhibition reactions (B2) and (B5) lower the inhibition effect at high temperature.

In order to consider why the cycle for Br-containing species in the C_2H_6-O_2-CH_3Br mixture differs from that in the CH_4-O_2-CH_3Br mixture, the reaction rates in two CH_3Br-free mixtures were calculated at 1750 K. The main processes for methane and ethane consumption in the early stage of the induction period are summarized in Figs. 9 and 10. The initiation reaction is reaction (R1) for methane oxidation, while it is reaction (−R10) for ethane oxidation. Although both reactions involve a thermal decomposition of fuels, the initial rate of reaction (−R10) is about 2000-times (1750 K) as fast as that of reaction (R1), because of the difference in the dissociation energy. Then, chain cycles, such as shown in Figs. 9 and 10, are formed while consuming methane or ethane.

In these cycles the difference between the consuming rate of CH_3 and that of C_2H_5 is very important. The C_2H_5 radical is mainly consumed through thermal decomposition (R38), while the CH_3 radical is consumed by being reacted with O_2 (R7) or O atoms (R9). The rate coefficient of reaction (R7) is very small. Although the rate coefficient of reaction (R9) is sufficiently large, its reaction rate is not fast, since few O atoms of the reactant exist during the early stage. The rate ratios of reactions (R7) and (R9) in the CH_4-O_2 mxture to reaction (R38) in the C_2H_6-O_2 mixture at 10% of the time of induction period, $[r(R7)_{Me}/r(R38)_{Et}]_{\tau/10}$ and $[r(R9)_{Me}/r(R38)_{Et}]_{\tau/10}$, are 7.5×10^{-4} and 2.6×10^{-4} at 1750 K, respectively. Therefore, the consuming rate of the CH_3 radical is

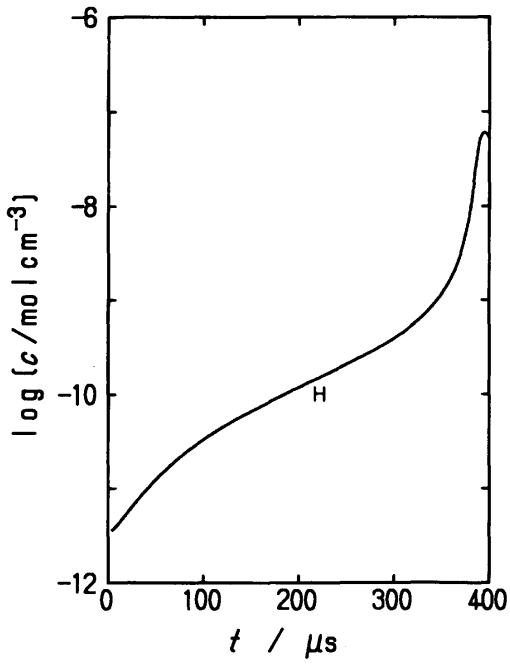


Fig. 11. Calculated concentration profile of H at 1750 K in CH_4–O_2 mixture. Calculated ignition delay time is 360 μs.

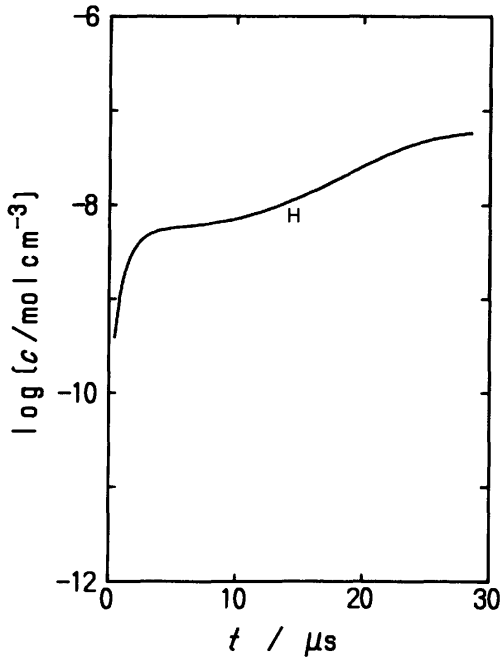

Fig. 12. Calculated concentration profile of H at 1750 K in Mixture 1 (C_2H_6–O_2). Calculated ignition delay time is 16.4 μs.

slower than that of the C_2H_5 radical. This causes a low H concentration during the induction period, as can be seen from a comparison between Figs. 11 and 12. The ratio of the H concentration in the CH_4–O_2 mxture to that in the C_2H_6–O_2 mixture at one half of the induction period, $[[H]_{Me}/[H]_{Et}]_{\tau/2}$, is 0.015 at 1750 K.

From this consideration, we can interpret the opposite effects of CH_3Br on ethane and methane ignitions. With respect to ethane oxidation, since the H concentration is higher during the induction period, reactions (B2) and (B5) are predominant instead of reactions (B1) and (−B2), resulting in an inhibition effect.

The ignition delay times in mixtures 2(C_2H_6–O_2–CH_3Cl) and 4(C_2H_6–O_2–CH_3I) were also calculated using reactions involving Cl- or I-containing species. When the reaction mechanism and the rate coefficients which we had previously used for methane ignition[5,6] were employed, the calculated ignition delay times disagreed with the observed values in both mixtures 2 and 4. The calculation overestimates the ignition delay times in mixture 2, but underestimates them in mixture 4. These disagreements indicate that the assumed reaction mechanism and/or the rate coefficients are impertinent. Thus, more research needs to be carried out in the future.

(Received February 2, 1989)

Dynamics of exciplex formation was studied on cholesteric liquid crystals consisting of cholesteryl 3-(9-ethyl-3-carbazolyl)propanoate (3Cz-2), cholesteryl 5-phenylpentanoate (Ph-4), and cholesteryl methyl terephthalate (CMT) with different amounts of CMT. Transient fluorescence spectrum and the analysis of fluorescence rise and decay curves of the exciplex emission indicated that two types of exciplex are present at low temperatures. Rate constants of exciplex formation were obtained at different temperatures in the cholesteric and isotropic phases. The activation energy for the rate constant was nearly zero in the cholesteric phase, but it was positive (3—6 kcal mol^{-1}) in the isotropic phase. The difference was interpreted in terms of different mechanisms of exciplex formation in the two phases.

Photophysical processes, such as excimer formation and exciplex formation in liquid crystalline mesophases have been studied.[1-8] A primary goal of these studies is to clarify the effect of liquid crystalline order on the photophysical processes, which should depend on the interchromophore distances and orientations. In our previous reports, syntheses of cholesteryl ω-arylalkanoates carrying 1- and 2-naphthyl, 1-pyrenyl, 9-anthryl, and 3- and 9-carbazolyl groups were described.[1-5] The orientations of the aromatic groups in cholesteric liquid crystalline (CLC) phases were determined by circular dichroic (CD) spectroscopy in the ground state and by circularly polarized fluorescence (CPF) spectroscopy in the excited state.[2] Studies on the dynamics of excimer formation of CLC mixtures containing cholesteryl 3-(1-pyrenyl)propanoate (Py-2)[5] revealed that the activation energy of the rate constant for excimer formation was slightly higher in the isotropic phase than in the CLC phase. The activation energy for the excimer dissociation was found to be considerably higher in the isotropic phase than in the CLC mesophase. These data were interpreted in terms of a reduced entropy of the ground state by the cholesteric order and efficient energy migrations before the excimer formation. Weiss and co-workers[7] reported an excimer formation between free pyrene molecules dispersed in a cholesteric mixture. They observed a higher activation energy for the excimer formation in the CLC phase than in the isotropic phase and explained the difference in terms of a higher viscosity of the cholesteric phase. They also observed a higher activation energy in the CLC phase on the exciplex formation in other cholesteric mixtures. The different behaviors of our systems and the Weiss's systems may be ascribed to the differences in the order of chromophore arrangement and their mobility in the CLC phases. In Py-2, the pyrenyl groups are covalently linked to the cholesteryl group and their orientation is highly ordered in the CLC phase. Also their translational diffusion may be highly restricted. Therefore the energy migration process may become more important than the diffusion in CLC phase of our system, for which less activation energy will be needed. One of the purpose of this study is to examine the activation energy for exciplex formation in the CLC mixture and in the isotropic phase containing chromophores covalently linked to cholesteryl groups.

In the present work, a cholesteryl ester carrying covalently linked carbazolyl group, i.e., cholesteryl 3-(9-ethyl-3-carbazolyl)propanoate (3Cz-2, **1**) was used as electron donor and cholesteryl methyl terephthalate (CMT, **2**) was used as an acceptor. Other cholesteryl ω-arylalkanoates carrying phenyl and naphthyl group (Ph-2, **3**; Ph-4, **4**) were used as liquid-crystalline solvents.

A static structure of the exciplex between cholesteryl 3-(9-carbazolyl)propanoate (9Cz-2) and CMT has been studied.[4] Fluorescence spectra showed a presence of a high-energy exciplex in the CLC phase at low temperatures. Thus, it was shown that the orientational constraints by the CLC order can alter the configuration of the exciplex. However, the high-energy exciplex was not detected in the 3Cz-2/CMT system in the stationary-state fluorescence spectrum.

†† Present address: Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227.

The second purpose of this study is to reexamine the exciplex spectra of 3Cz-2/CMT system by using the time-resolved spectroscopy.

Experimental

Preparation of the cholesteryl ω-arylalkanoates has been described.[3] The mixture was placed in an optical cell specially designed to measure surface fluorescence of the liquid crystalline sample under vacuum.[3] Before the fluorescence measurements, the liquid crystalline mixture was mechanically tilted to align the helix axis of the cholesteric texture perpendicular to the cell surface. The perpendicular alignment was confirmed by the appearance of a bright color (blue to red) of the selective reflection.

Fluorescence rise and decay curves were measured on a home-built time-correlated single-photon counting machine, using an air-discharge lamp (half width is about 2.5 ns) as an excitation source. For the measurement of fast processes, a single-photon counting instrument using a picosecond laser pulse was used. The excitation beam was a frequency-doubled laser pulse (314 nm, 13 picosecond, 4 nJ) generated from a synchronously pumped, cavity-dumped dye laser (Spectra Physics 375B dye and Spectra Physics 3000 1W mode-locked YAG lasers). An XP 2020/Q photomultiplier tube was used as a detector. The system was controlled and the data was processed with a PDP-11 minicomputer. The time-resolved fluorescence spectra were obtained by adjusting the time-to-amplitude converter to collect only stop pulses which appeared after a specified time period.

Results and Discussion

Stationary and Transient Spectra. The stationary and the transient fluorescence spectra were measured on a CLC and isotropic mixture of 3Cz-2/Ph-2/CMT (molar ratio: 18/73/9). The mixture of 3Cz-2/Ph-2 (20/80) in the absence of CMT showed little excimer emission in the stationary spectrum, although a weak excimer emission has been observed in a 3Cz-2/Ph-2 (50/50) mixture.[3] Figure 1 compares stationary and transient spectra of the CLC mixture of 3Cz-2/Ph-2/CMT (18/73/9). The transient spectra were measured using a 13 picosecond excitation pulse. The transient spectrum 0.5—1.5 ns after the excitation shows only monomer emission of carbazolyl group. The spectrum around 350 nm is distorted by a self-absorption of carbazolyl groups. The absence of exciplex emission at the early stage indicates the absence of any preformed exciplex site in the CLC mixture. The spectrum 13—18 ns after the excitation shows an exciplex emission centered at 450 nm. (An effect of the selective reflection of the CLC appears as a small trough at 480 nm.) The spectrum profile of the transient exciplex emission is sharper than that of the stationary spectrum and the transient peak locates at shorter wavelength than the stationary one by about 20 nm.

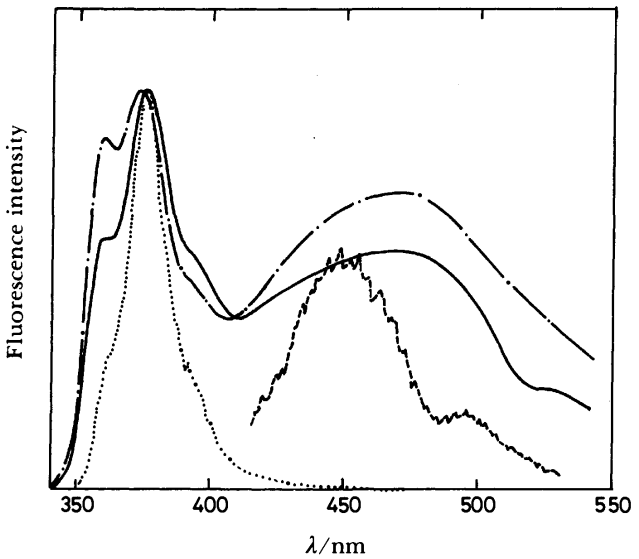

Fig. 1. Stationary and transient fluorescence spectra of 3Cz-2/Ph-4/CMT mixture (molar ratio=18/73/9). Stationary spectra: (——): 70 °C in cholesteric mesophase; (—·—): 130 °C in isotropic phase. λ_{ex}= 333 nm. Transient spectra in cholesteric phase at 76 °C, (--------): 0.5—1.5 ns after excitation; (-----): 13—18 ns after excitation. λ=314 nm. Both the stationary and the transient spectra are uncorrected.

The different profile of the transient spectrum indicates that the configuration of the exciplex at the early stage is different from that of the stationary one.

Rise and Decay Curves of the Exciplex Emission. The rise and decay curves were measured for CLC mixtures of 3Cz-2/Ph-4/CMT having four different molar ratios: (19.5/78/2.4), (19/76.2/4.8), (18.6/74.4/7.0), and (18.1/72.7/9.1). The emissions at longer wavelengths than 500 nm were collected. The curves obtained at lower temperatures than 120 °C were fitted to three component exponential functions (Eq. 1), one for the rise and two for the decay.

$$F(t) = G_1\exp(-t/T_1) + G_2\exp(-t/T_2) + G_3\exp(-t/T_3) \quad (1)$$

The χ^2 values were in most cases less than 1.2. A typical rise and decay curve is shown in Fig. 2. The rise and decay curves at higher temperatures than 120 °C were reasonably fitted to two exponential functions, one for the rise and one for the decay. The rise and decay times (T_1 for rise, T_2 and T_3 for decay) and the ratio of the preexponential factors for the two decay functions (G_2/G_3) are shown in Figs. 3—6.

The longer decay time of the exciplex emission (T_3) shown in Fig. 3 do not depend on the concentration of the acceptor (CMT). As will be discussed later, the longer decay time corresponds to the inverse of the deactivation rate of the exciplex. Therefore, the insensitiveness of the T_3 values to the acceptor concentration can be understood by the independence of the monomolecular process to the acceptor concentration. The activation energy for the deactivation process in cholesteric phase seems to differ slightly

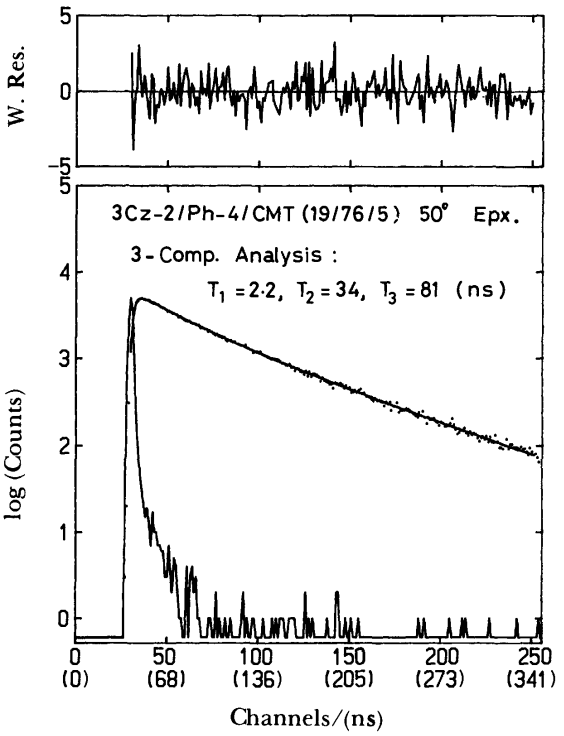

Fig. 2. Rise and decay curve for the exciplex emission from 3Cz-2/Ph-4/CMT (19/76.2/4.8) mixture. $\lambda_{em}>500$ nm. The curve fitting was made with a three-exponential function (Eq. 1), T_1=2.2, T_2=34, T_3=81 (nsec), G_1=−0.38, G_2=−0.23, G_3=0.23, χ^2=1.2.

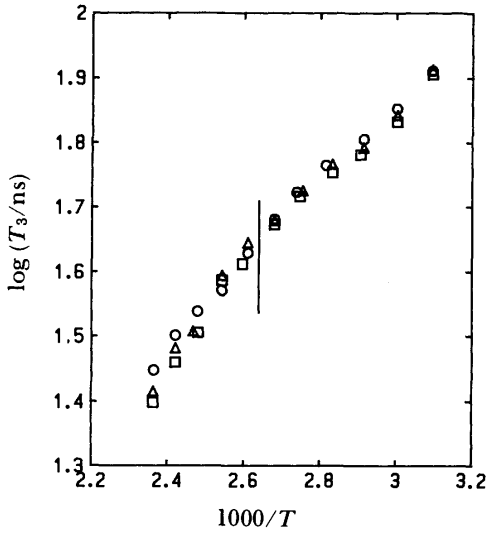

Fig. 3. Temperature dependence of the longer lifetime of the exciplex emission from 3Cz-2/Ph-4/CMT mixtures. Molar ratios are: 19.5/78.0/2.4 (○); 19.0/76.2/4.8 (□); 18.6/74.4/7.0 (△). The vertical bar indicates the cholesteric-isotropic transition point.

from that in isotropic phase.

The shorter decay time of the exciplex (T_2) (Fig. 4) and the G_2/G_3 ratio (Fig. 5) were also insensitive to the acceptor concentration, although the data points

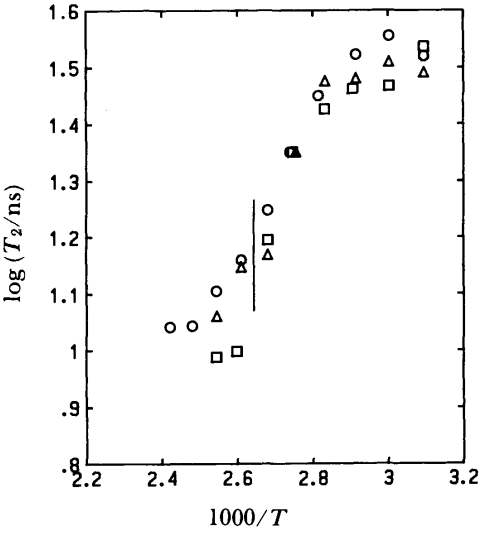

Fig. 4. Temperature dependence of the shorter lifetime of the exciplex emission from 3Cz-2/Ph-4/CMT mixtures. Notations are the same as in Fig. 3.

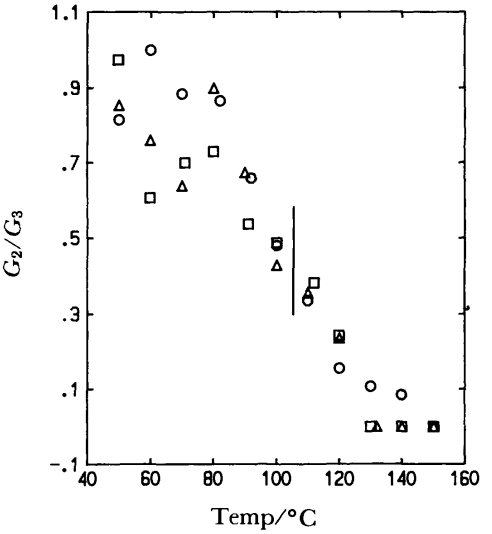

Fig. 5. Temperature dependence of the ratio of preexponential factors for the shorter and the longer lifetime components of the exciplex emission from 3Cz-2/Ph-4/CMT mixtures. Other notations are the same as in Fig. 3.

scatter to somewhat larger extent.

Contrary to other parameters, the rise time of the exciplex (T_1) becomes shorter with the increase of the CMT concentration (Fig. 6). Furthermore, the Arrhenius plot shows a turning point at the cholesteric-isotropic transition point which is shown by vertical bars in the figure.

The decay curves of the monomer emission were also measured. The decay curves consisted of essentially a single fast component with a small contribution of the slow component, which may be ascribed to the exciplex emission overlapped to the monomer emission. The decay times of monomer

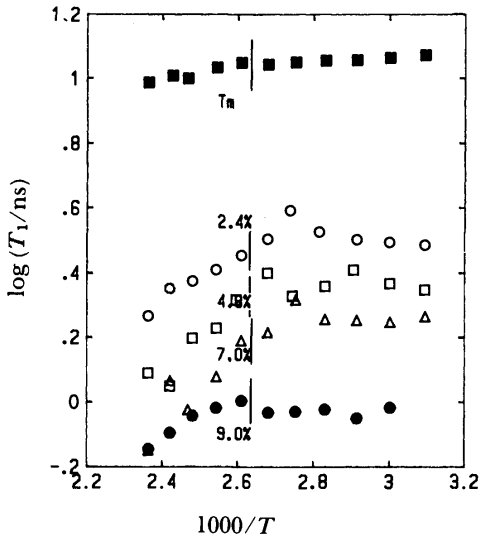

Fig. 6. Temperature dependence of the rise time of the exciplex emission from 3Cz-2/Ph-4/CMT mixtures. Molar ratios of the mixtures are: 19.5/78.0/2.4 (○); 19.0/76.2/4.8 (□); 18.6/74.4/7.0 (△); 18.1/ 72.7/ 9.1 (●). The vertical bars indicate the cholesteric-isotropic transition temperature. The monomer lifetimes observed in the 3Cz-2/Ph-4 (20/80) are also plotted (■).

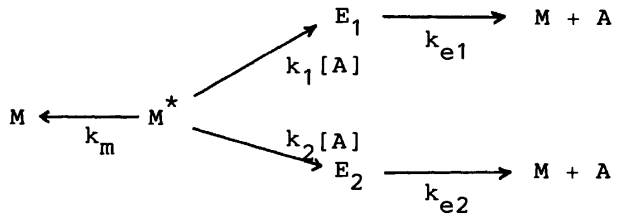
emission were about the same as the corresponding rise times of the exciplex emission. However, since the former data scattered more than the latter, the latter were used in the following discussion. The decay curves of the monomer fluorescence in the absence of CMT [3Cz-2/Ph-4 (20/80)] at different temperatures were fitted to single exponential functions with a typical lifetime of 11.3 ns (80 °C, CLC) or 9.9 ns (132 °C). The lifetimes T_m are plotted in Fig. 6.

Kinetics of Exciplex Formation in the CLC Mixture. The experimental results described above are summarized as follows. (1) There are two types of exciplex, one decaying faster (typically, 30 ns at 80 °C) than the other (60 ns at 80 °C). The faster component disappears at higher temperatures than about 120 °C. (2) The decay times of the two types of exciplex are independent of the concentration of the acceptor, indicating that the decay times are determined only by monomolecular processes of the types of exciplex. (3) The rise time of the exciplex emission is shortened at higher acceptor concentrations, indicating that the rise time is determined by a bimolecular process of the exciplex formation. The rise time is also sensitive to the phase (cholesteric or isotropic) of the mixture. (4) No preformed exciplex site was detected in the in the transient spectrum.

The above results fit the following kinetic scheme which takes two types of exciplex into account. The exciplex formation process was assumed irreversible, since the monomer decay curve showed only marginal



contribution of the decay component of the exciplex emission, which may be ascribed to the insufficient spectral separation. Since only a single rise time was observed in the exciplex emission, the possibility for the successive formation of two types of exciplex, i.e., $M \rightarrow E_1 \rightarrow E_2$, can be excluded. It is not possible to decide only from the kinetic results whether an interconversion between the two types of exciplex is occurring or not. However, since the two types of exciplex can be distinguished in the time scale of a few ten nanosecond, the interconversion, if it exists, should be slower than the time scale.

The relations between the decay times and the rate constants are:

$$k_{e1} = T_2(e)^{-1},\ k_{e2} = T_3(e)^{-1}. \quad (2)$$

The rise time of the exciplex is related to the rate constants for the two exciplex formation processes. Since virtually a single rise time was observed in the exciplex emission, the two rate constants should not be very different to each other. In the following discussion, the apparent rate constant of exciplex formation k_{ap}, calculated using Eq. 3 will be discussed.

$$k_{ap} = T_1(e)^{-1}/[A]. \quad (3)$$

Figure 7 shows the k_{ap} values obtained for the four different concentrations of the acceptor. It is seen that the activation energy in the cholesteric phase is nearly zero, whereas that in the isotropic phase is positive (3—6 kcal mol^{-1}).

Activation Energy for Exciplex Formation. Exciplex formation processes in highly concentrated molecular assemblies are generally governed by the following factors: (1) Diffusion of the donor groups to the acceptor. (2) Energy migration among the donor groups. (3) Population of exciplex-forming sites. (4) Molecular reorientation required for the exciplex formation in the exciplex-forming site. (5) Quenching of the excited state by bimolecular processes, such as an excimer formation, between the excited and the ground-state donor molecules. In the present case, item (5) may be neglected, since only very weak excimer emission was detected in the fluorescence spectrum of 3Cz-2/Ph-4 (20/80) mixture and the decay time of the (20/80) mixture is almost equal to that of the 3Cz-2/Ph-4/Ph-2 (1/33/66) mixture.

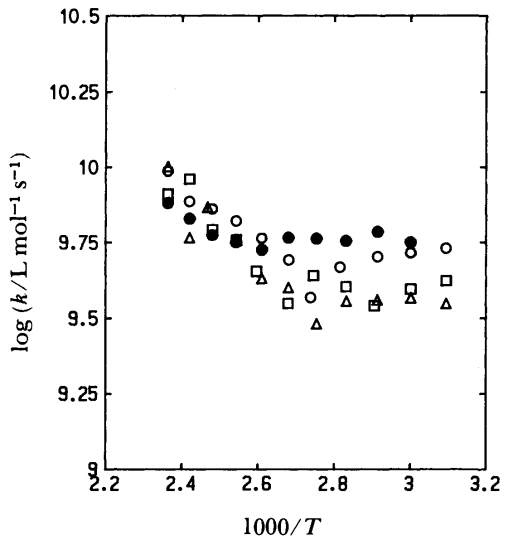


Fig. 7. Arrhenius plot of apparent rate constants for exciplex formation in 3Cz-2/Ph-4/CMT mixtures. Notations are the same as in Fig. 6.

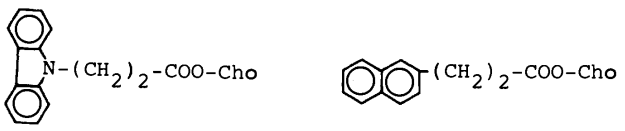
Since cholesteric phase is known to be more viscous than isotropic phase, a higher activation energy for the exciplex formation is expected in the former phase. Actually, Weiss and co-workers reported a higher activation energy of exciplex formation between free pyrene molecules and *N,N*-dimethyl-5α-cholestan-3β-ylamine (CA) in the CLC phase (9.9—11.8 kcal mol^{-1}) than in the isotropic phase (5.3—5.4 kcal mol^{-1}). They observed higher activation energy in the CLC phase also in the excimer formation between pyrene molecules dispersed in the cholesteric mixtures. The Arrhenius plots in Fig. 7 contrast the above expectation and experimental results. The very small activation energy in the CLC phase is remarkable, but the activation energy in the isotropic phase is not mush different from that observed by Weiss and co-workers. Therefore, the low activation energy in the CLC phase cannot be interpreted only by the high concentration of carbazolyl groups in the present system. A possible reason is that the cholesteric order may align the carbazolyl groups in a manner which enhances the energy migration among carbazolyl groups and/or facilitates the exciplex formation in the exciplex-forming site. The lower activation energy in the CLC phase has been observed also in the excimer formation in cholesteric mixtures containing 3—25% of Py-2,[5] although the difference between CLC and isotropic phase is much smaller than the present case.

It was concluded that the exciplex or the excimer formation of Ar-2-type molecules requires less activation energy in the CLC phase than in the isotropic phase. This may be accounted for in terms of the high orientational order in the CLC phase which facilitates the photophysical processes, such as the energy migration and the exciplex formation.

Assignment of the Two Types of Exciplex. Two types of exciplex were suggested from the decay curves of exciplex emission. Furthermore, the exciplex at the early stage after excitation showed a shorter peak wavelength than the stationary spectrum. The early stage component should correspond to the first exciplex component with a shorter decay time. This first component (G_2) disappeared at higher temperatures than about 120 °C (Fig. 5). The second component decays more slowly and, therefore, is a major component in the stationary spectrum. A possible explanation for the first component is that the exciplex in the CLC mesophase cannot take the most stable structure due to constraints by the CLC order. The fact that the first component is still present above the transition point (Fig. 5) can be explained by a local CLC order, which is known to be remaining above the transition temperature.[11]

Similar finding has been observed in a stationary fluorescence spectra of a mixture of cholesteryl 3-(9-carbazolyl)propanoate (9Cz-2, **5**), cholesteryl 3-(2-naphthyl)propanoate (2N-2, **6**), and CMT (9Cz-2/2N-2/CMT=47.6/47.6/4.8).



(**5**) (**6**)

In the cholesteric phase, the mixture showed a high-energy exciplex emission located around 425 nm. At elevated temperatures, the exciplex peak shifted to a longer wavelength. The presence of the high-energy exciplex in the CLC phase has been interpreted in terms of an metastable exciplex structure due to the constraints by the CLC order. The high-energy exciplex could not be found in the stationary spectra of a 3Cz-2/Ph-2/CMT mixture. The present study showed the presence of the metastable exciplex also in the latter mixture at an early stage after excitation. Therefore, it may be commonly stated for these types of CLC mixtures that a CLC order imposes constraints on the structure of exciplex.

Novel porphyrins to which the viologen is linked (*m*-PC*n*V) were synthesized. The linkage methylene chain between the porphyrin and the bipyridine moieties was systematically changed from $(CH_2)_3$ to $(CH_2)_6$. The molecular structure of *m*-PC*n*V was characterized by ^{1}H NMR in some detail. The orientation of the viologen with respect to the porphyrin plane in *m*-PC*n*V was semiquantitatively estimated from the porphyrin ring current induced chemical shift changes on the resonances from the viologen moiety. The NMR conformational analyses on *m*-PC*n*V in dimethyl sulfoxide and acetonitrile clearly revealed the effect of the solvent on its molecular structure.

Porphyrins to which a variety of electron acceptor units are covalently bonded have been investigated intensively to gain insight into the intramolecular electron transfer between the porphyrin and the viologen which results in the generation of a high-energy charge-separated state that has a potential of various applications.[1-7] The intramolecular electron transfer process has been clearly detected in various covalently linked porphyrin–viologen molecules by fluorescence quenching techniques or lifetime measurements[1,5,6] and more directly by resonance Raman spectroscopy.[3] Electron-transfer quenching of the photoexcited porphyrin by the linked viologen was found to depend on solvent and the length of linkage between the porphyrin and viologen.[1] Although the photoinduced electron-transfer process occurs during the lifetime of the excited state of porphyrin which is on nanosecond time scale, it would be of interest to characterize the ground state molecular structure of those porphyrin derivatives and to relate those structures to the rate of the intramolecular electron transfer.

We have synthesized novel porphyrins covalently linked to viologen (*m*-PC*n*V, Fig. 1). The length of the methylene chain ($+CH_2+_n$) between the porphyrin and bipyridine was systematically changed from n=3 to n=6 to investigate the effect of the methylene chain length on the molecular structure which in turn determines the spatial relationship between the porphyrin ring and the bipyridine moiety of the viologen. The solution structure of *m*-PC*n*V was investigated using ^{1}H NMR. The individual resonances have been completely and unambiguously assigned by the combined use of ^{1}H–^{1}H two-dimensional chemical shift correlated spectroscopy (COSY) and two-dimensional nuclear Overhauser effect spectroscopy (NOESY). Based on the porphyrin ring current induced chemical shift,[2,8-11] a spatial relationship between the porphyrin ring and the bipyridine moiety of the viologen in *m*-PC*n*V was semiquantitatively determined. Analyses on the porphyrin ring current induced shifts in terms of the position of a nucleus with respect to the porphyrin plane require appropriate model compound which, ideally, possesses all structure features present in *m*-PC*n*V but the porphyrin ring current, because the induced chemical shift change originates solely from the magnetic anisotropy due to the magnetic dipole arising from the porphyrin ring current. We therefore synthesized the compounds,

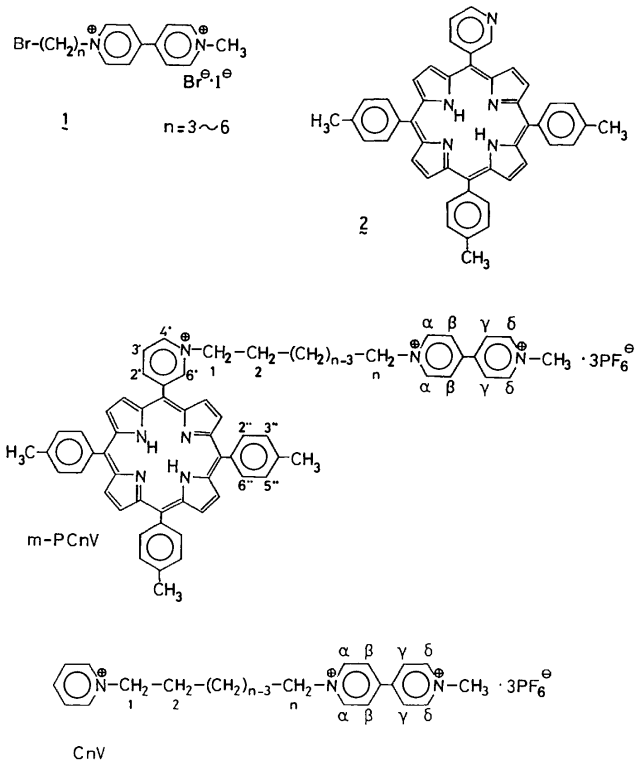

Fig. 1. Molecular structures of 1-methyl-1′-(ω-bromoalkyl)-4,4′-bipyridinium salt (**1**), 5-(3-pyridyl)-10,15,20-tritolylporphyrin (**2**), viologen-linked porphyrin synthesized (*m*-PC*n*V), and model compounds (C*n*V). The numbering systems for *m*-PC*n*V and C*n*V are shown with the structures.

C*n*V, shown in Fig. 1 as models for *m*-PC*n*V. Their NMR spectra were characterized and the difference in the observed chemical shifts between *m*-PC*n*V and C*n*V for the corresponding viologen proton resonances is discussed in terms of the spatial orientation of the viologen moiety with respect to the porphyrin plane in *m*-PC*n*V molecule. Conformational analyses were carried out in two different solvents, i.e., dimethyl sulfoxide and acetonitrile, to investigate the effect of solvent on the molecular structure of *m*-PC*n*V. The difference in conformation of *m*-PC*n*V in different solvents which in turn results in placing the bipyridine moiety of the viologen at spatially different position with respect to the porphyrin plane was clearly reflected in the porphyrin ring current induced shift changes for the viologen proton resonances. Although the linkage methylene chain is flexible, the bipyridine moiety of the viologen does not appear to fold back above the porphyrin plane in *m*-PC*n*V studied here.

Experimental

Materials; All chemicals and solvents were of reagent grade and were obtained from commercial sources.

Syntheses; The viologen-linked porphyrins with a series of methylene chain length (*m*-PC*n*V) were synthesized from the coupling reaction of **1** and **2** (Fig. 1) which were prepared using the literature procedures.[12,13] **1** (0.3 mM; 1 M=1 mol dm^{-3}) and **2** (0.6 mM) were reacted in *N*,*N*-dimethylformamide at 80 °C for 48 hours and then toluene (300 ml) was added to precipitate the product and unreacted **2**. The solids were filtered and then washed with toluene and distilled water. The products were dissolved in MeOH and NH_4PF_6 (0.2 g) was added to replace the counter anion to PF_6^-. The desired products should be insoluble in MeOH with PF_6^-. The precipitate is collected, washed with MeOH, and then dried under vacuum at room temperature for 1 hour. The yield was about 30%. The purity of the products was established from their ^{1}H NMR spectra.

Model compounds, C*n*V, were synthesized using the reaction of **1** with pyridine in MeOH for 8 hours followed by the replacement of the counter anion to PF_6^- using NH_4PF_6. C*n*V was filtered and then washed by MeOH. Solids were dried under vacuum at room temperature.

NMR Measurements; The compounds were dissolved in either dimethyl-d_6 sulfoxide (DMSO-d_6) or acetonitrile-d_3 (MeCN-d_3) for the NMR samples and the concentrations of the samples were 10 and 30 mM for *m*-PC*n*V and C*n*V, respectively. 500 MHz ^{1}H NMR spectra were recorded on a JEOL GSX-500 FT-NMR spectrometer. Typical spectra were recorded with 16 transients, 32 k data points over a 5000 Hz spectral width, and 5.3 μs 90° pulse. Chemical shifts were referenced to the residual solvent peak, which in turn was calibrated against tetramethylsilane, TMS, and are reported in parts per million, ppm, referenced to TMS.

COSY and NOESY spectra were obtained using the standard pulse sequences[14] and data processing procedures. The mixing time of 700 ms was used for NOESY.

Results and Discussion

^{1}H NMR Signal Assignment. 500 MHz ^{1}H NMR spectrum of *m*-PC4V in MeCN-d_3 at 27 °C is illustrated in Fig. 2. The spectrum indicates the purity of the sample prepared. The unambiguous ^{1}H signal assignments are obtained from ^{1}H-^{1}H COSY and NOESY spectra shown in Figs. 3 and 4, respectively. The scalar coupling connectivities in the COSY

spectrum establish most of the assignment but the differentiation of the bipyridine, terminal methylene, or tolyl proton resonances was hampered by the discontinuity of spin-spin coupling network. The dipolar coupling connectivities in NOESY spectrum allow the specific assignment of those resonances. The singlet N-CH_3 resonance at δ 4.14 exhibits a cross-peak with a doublet resonance at δ 8.57 in the NOESY spectrum, indicating the assignment of this resonance to the bipyridine δ proton. The terminal methylene

proton resonances can be differentiated using the connectivities with the pyridine 4′ or/and 6′ and bipyridine α proton resonances and the tolyl proton can be specifically assigned from the NOESY cross-peak with the singlet tolyl CH_3 resonance. The unambiguous assignments of all the resonances for the other *m*-PC*n*V prepared were similarly obtained and the chemical shift values are summarized in Tables 1 and 2. The solvent dependence of the chemical shifts of *m*-PC*n*V ^{1}H resonance is apparent. But, in a given solvent, the shifts of the pyridine resonances as well as the pyrrole N-H proton resonances were found to be essentially independent of the length of the methylene chain of *m*-PC*n*V. The fine structure of the line shape of the resonances arising from the tolyl 2″, 6″ and 3″, 5″ protons was altered by the length of the methylene chain, indicating small deviation in the chemical shift among the resonances from the three tolyl groups on the molecule. The shift values of the tolyl resonances are interpreted in terms of both the orientation of the aromatic ring with respect to the porphyrin plane and the asymmetric nature in electronic structure of the porphyrin ring. Considering that the electronic structure of the porphyrin ring in *m*-PC*n*V is essentially C_2 symmetric, the asymmetry of the porphyrin ring electronic structure does not account for the deviation of the chemical shifts of the resonances from the three tolyl ring protons of *m*-PC*n*V. But no evidence was detected for a direct interaction of those aromatic rings with the bipyridine moiety of the viologen which can be thought to perturb the chemical shifts of the tolyl ring protons.

Analyses of the Porphyrin Ring Current Induced Shift. Spatial relationship between the porphyrin and the viologen can be deduced from the analyses on the porphyrin ring current induced chemical shift changes on the resonances from the viologen.[2,11] The

dipolar field arising from the ring current of the porphyrin ring π-electrons strongly influences the resonance frequencies of the nuclei which are located in the close proximity to the porphyrin and the induced chemical shift change spans up to several ppm depending on the position of the nucleus with respect to the porphyrin ring. The porphyrin ring current induced chemical shift change ($\Delta\delta$) is calculated as the difference in the observed shift between *m*-PC*n*V and appropriate model which, ideally, possesses

all structure features present in *m*-PC*n*V but the porphyrin ring current. Therefore the model compounds, C*n*V, have been synthesized. Their ^{1}H NMR spectra were recorded and the signals were assigned using COSY and NOESY (results not shown). The spectra of *m*-PC*n*V in DMSO-d_6 and MeCN-d_3 are compared with those of the corresponding model C*n*V in Figs. 5 and 6, respectively. The obtained Δδ values, $\Delta\delta=\delta_{m\text{-}PCnV}-\delta_{CnV}$, for corresponding viologen proton resonances are summarized in Table 3. The Δδ values of *m*-PC*n*V in DMSO-d_6 and MeCN-d_3 are compared in Figs. 7 and 8, respectively. Although the patterns of the Δδ plots for both solvents look similar, they are

slightly and subtly different with each other (see below).

Conformational Analyses of *m*-PC*n*V. The $\Delta\delta$ value for 1-CH_2 of *m*-PC*n*V in DMSO-d_6 is about +0.3 ppm, reflecting the strong deshielding effect due to the porphyrin ring current. The $\Delta\delta$ value of methylene proton decreases as ^{1}H nucleus is oriented away from the porphyrin ring along the methylene chain of the viologen and eventually becomes nagative for the resonances from the bipyridine moiety, indicating that the viologen is oriented across the boundary expressed by the equation, $(3\cos^2\theta-1)/r^3=0$, where r is the magnitude of the vector connecting the center of the porphyrin ring and the nucleus and θ is the angle between $\vec{r}$ and the z-axis which is defined normal to the porphyrin plane; in particular, the θ is called the magic angle when θ satisfies the equation $3\cos^2\theta-1=0$, i.e., $\theta=54.7°$. The sign of the $\Delta\delta$ value changes between bipyridyl α and β protons of the viologen, dictating that the part around these nuclei of the viologen moiety is located close to the boundary expressed by $3\cos^2\theta-1=0$. Because of the difficulties arising from nonlinear averaging of the porphyrin ring current induced chemical shift changes in terms of the relative orientation of the nucleus with respect to the porphyrin plane, the flexibility in conformation of the methylene chain, and the uncertainty in the orientation of the pyridine ring with respect to the porphyrin ring, we have not attempted to determine the time averaged conformation of *m*-PC*n*V molecule. The insensitivity of the $\Delta\delta$ values for the length of the methylene chain, however, is consistent with the extended all-anti conformation and the bipyridine moiety being just across the boundary of the magic angle. Since the pyridine ring is neither coplanar nor orthogonal to the porphyrin plane but slightly tilted,[15] the length of the methylene chain linkage does not have a significant effect on the position of the bipyridine moiety of the viologen with repect to the dipolar field arising from the porphyrin ring π-electrons. With the energetically stable all-anti methylene chain conformation,[16] the closest edge-to-edge distance of the π-systems of the porphyrin and bipyridine of *m*-PC*n*V are ca. 6 to ca. 12 Å for n=3 to 6. If there is a direct relationship between that distance and the rate of the intramolecular electron transfer as Gust et al.[2] have suggested, the larger distance for the greater n value is completely consistent with the linkage length dependency of the electron-transfer rate found in viologen-linked zinc porphyrin.[1]

The patterns of the $\Delta\delta$ plots for *m*-PC*n*V in MeCN-d_3 are similar to those in DMSO-d_6, but slightly different features are observed. In the plot illustrated in Fig. 9, the sign of the value changes at bipyridine β proton for *m*-PC3V and *m*-PC4V and between α and 5- or 6-CH_2 resonances for *m*-PC5V and *m*-PC6V, respectively, suggesting either that the dihedral angle between the pyridine and porphyrin planes is closer to orthogonal in MeCN-d_3 than that in DMSO-d_6 or that the direction of the vector connecting pyridyl N and N-CH_3 is directed more toward z axis of the porphyrin ring in MeCN-d_3. These results strongly suggest that the orientations of the viologen with respect to the porphyrin ring of *m*-PC*n*V in DMSO-d_6 and MeCN-d_3 are different and the difference in the spatial relationship between the porphyrin and the viologen in different solvents could explain the solvent dependency of the rate of the intramolecular electron transfer.[1] Similar porphyrin ring current induced shift for 1-CH_2 resonance of *m*-PC*n*V in both solvents indicates that the magnetic anisotropy of the porphyrin ring current is not significantly altered by solvent. As can be seen in the $\Delta\delta$ plots, the difference in conformation between the two solvents is clearly manifested in the difference in the patterns of the $\Delta\delta$ plots. Such difference in conformation between the two solvents appears to be enhanced with the n value. But it is not easy at present to interpret the solvent

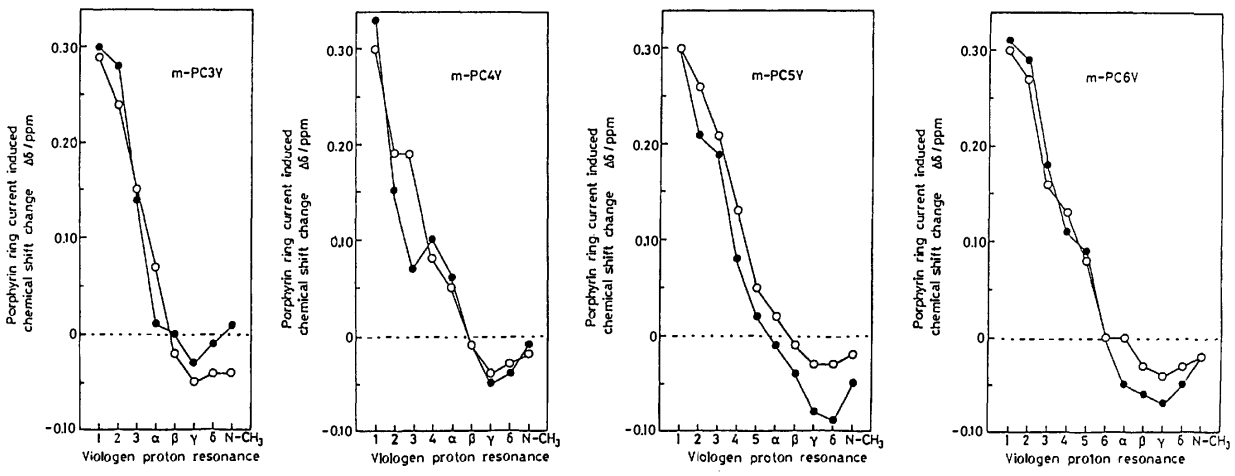

Fig. 9. Plots of the porphyrin ring current induced chemical shift change ($\Delta\delta$) vs. viologen proton resonance of *m*-PC*n*V in DMSO-d_6 (○) and MeCN-d_3 (●).

dependency of *m*-PC*n*V conformation because of the absence of the knowledge of the interaction of *m*-PC*n*V with the surrounding solvent molecules.

Conclusion

Novel porphyrins linked to viologen (*m*-PC*n*V) which are expected to serve as both a photosensitizer and an electron carrier in the same molecule have been synthesized. The flexible methylene chain was used to link the porphyrin ring and the bipyridine and the constituent methylene unit was systematically changed from 3 to 6 to observe the effect of the methylene chain length on the spatial relationship of the bipyridine moiety with respect to the porphyrin. Using the porphyrin ring current induced chemical shift change, the orientation of the viologen with respect to the porphyrin ring in *m*-PC*n*V was semiquantitatively determined and the results suggested that the viologen does not fold back in a way that the bipyridine moiety of the viologen is oriented above the porphyrin plane and that the bipyridine moiety is oriented around the boundary defined by the magic angle where the porphyrin ring current induced shift change vanishes. The conformational analyses of *m*-PC*n*V in DMSO-d_6 and MeCN-d_3 indicated that the spatial orientation of the bipyridine with respect to porphyrin ring is slightly different between the two solvents and such difference in the conformation of *m*-PC*n*V appears to be enhanced with the length of the methylene chain.

With the extended methylene chain conformation, the closest edge-to-edge distance between the π-systems of the porphyrin and the bipyridine increases with the methylene chain length. Therefore the rate of the intramolecular electron transfer of *m*-PC*n*V would be smaller with the longer methylene chain linkage, if there is a direct relationship between the electron transfer rate and the distance of two π-systems.[2] Fluorescence lifetime measurements are currently under way on these *m*-PC*n*V in DMSO and MeCN.

Silica-Supported Heteropoly Acid Catalyst for Liquid-Phase Friedel-Crafts Reactions

Yusuke IZUMI,* Noriko NATSUME, Harumi TAKAMINE, Ikuyo TAMAOKI, and Kazuo URABE
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University,

(Received February 20, 1989)

Silica-supported Keggin-type heteropoly acids such as 12-tungstophosphoric, molybdophosphoric, and tungstosilicic acids efficiently catalyzed Friedel-Crafts alkylation and acylation reactions of aromatic hydrocarbons with 1-octene, benzyl chloride and benzoyl chloride in the liquid phase. The catalytic activity of heteropoly acid was generally enhanced when supported on silica. Silica-supported tungstosilicic acid worked as an insoluble heterogeneous catalyst even to the acylation of *p*-xylene with benzoyl chloride or benzoic anhydride, though deactivation was observed during repeated use. Considering that supported *p*-toluenesulfonic acid, an ordinarily used typical strong protonic acid, was far less active than the supported heteropoly acid, the high catalytic efficiency revealed by heteropoly acid appears to be due to a unique property of heteropoly anion which can stabilize alkyl and acyl cations as the reaction intermediates.

Several types of insoluble heterogeneous acid catalysts have recently been proposed for liquid-phase Friedel-Crafts reactions, in order to replace the conventional homogeneous catalysts such as $AlCl_3$ and sulfuric acid which often pose difficult operational problems of corrosion, removal from products, and requirement of stoichiometric catalyst amount. These heterogeneous catalyst systems include metal ion-exchanged aluminosilicates[1,2] and sulfate-doped metal oxides.[3] Concerning the acylation with acyl halides, however, there have not been developed such heterogeneous catalysts as can endure long-term use, yet.

Keggin-type heteropoly acid, which has been known to catalyze several organic reactions much more effectively than the ordinary protonic acids,[4] has also been explored as a Friedel-Crafts catalyst in the non-supported[5,6] or supported[7] state. The present study aims to inspect the applicability of supported heteropoly acids as heterogeneous catalysts for liquid-phase Friedel-Crafts reactions through the examination on the optimal conditions of catalyst preparation and through the re-examination on a problem of deterioration of heteropoly acid which has previously been pointed out concerning the acylation using acyl halides.[6]

Experimental

Catalyst. Each supported heteropoly acid catalyst was prepared by impregnating a support in the form of powders (115 mesh pass) with an aqueous solution of heteropoly acid followed by drying at 60—70 °C. The catalyst was calcined at a given temperature under reduced pressure (3 kPa) prior to use for the reaction. The Keggin-type heteropoly acids employed were of commercially available purity; tungstophosphoric ($H_3PW_{12}O_{40}\cdot 25H_2O$), molybdophosphoric ($H_3PMo_{12}O_{40}\cdot 9.3H_2O$), and tungstosilicic ($H_4SiW_{12}O_{40}\cdot 23.8H_2O$) acids. Silica A (Fuji Davison B, surface area 585 $m^2\,g^{-1}$, pore volume 0.774 $cm^3\,g^{-1}$), silica B (Fuji Davison ID, 105 $m^2\,g^{-1}$, 1.08 $cm^3\,g^{-1}$), and active carbon (Kraray GC, 1656 $m^2\,g^{-1}$, 0.34 $cm^3\,g^{-1}$) were used as catalyst supports.

Reaction Procedure. The organic reagents used were all purified by distillation. A suspension mixture of liquid organic substrates and solid catalyst granules in a flask was heated under reflux at atmospheric pressure. In the alkylation and acylation reactions using benzyl chloride and benzoyl chloride, the hydrogen chloride evolved during the reaction was removed by a continuous flow of nitrogen.

Analysis. The reaction products were determined by GLC (SE 30 and Unisole 30T columns) using internal standards. After the recation, the structural change of the supported heteropoly acid or of the heteropoly acid dissolved out during the reaction was examined through IR measurement using a Jasco IR-810 spectrophotometer.

Results and Discussion

Alkylation. Among the heteropoly acid catalysts tested, supported tungstophosphoric acid was most active for the alkylation of benzene with 1-octene. Only less than 5 mol% of a by-product dioctylbenzene was formed even at complete conversion of olefin, provided that an excess of benzene was used at a low reaction temperature of 35 °C. The isomers of 3- and 4-phenyloctanes were formed in addition to the major product of 2-phenyloctane (50—80 mol%).

Figure 1 demonstrates a remarkable influence of pretreatment temperature of catalyst on the catalytic activity of silica A-supported tungstophosphoric acid. The maximum conversion of 1-octene was attained when the catalyst was treated at 150 °C. The pretreatment at 100 °C gave only a meager activity. This is probably due to the remains of the crystal water of heteropoly acid which may reduce its acid strength. Indeed, according to the measurement by Hammett indicators, hydrous heteropoly acid ($H_3PW_{12}O_{40}\cdot 25H_2O$) showed an acid strength of $H_0 \geqq -3.0$, but it became more acidic ($H_0 \geqq -8.2$) when dehydrated by calcination at above 150 °C. Since it was confirmed from IR measurement that the Keggin structure of tungstophosphoric acid had still been completely retained even after 300 °C treatment, the reduction in catatytic

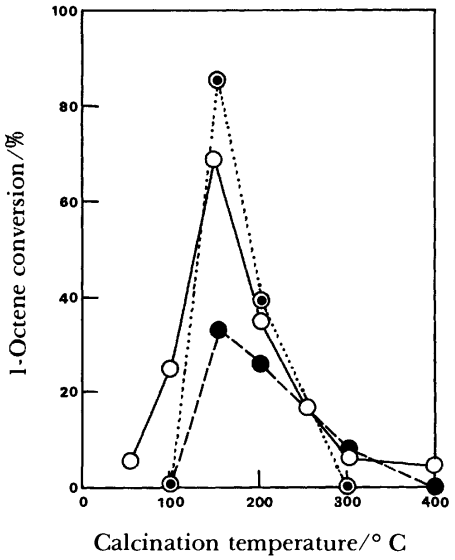

Fig. 1. Alkylation of benzene with 1-octene catalyzed by 12-tungstophosphoric acid (35 °C, 2 h). O: Supported on silica A (15 wt%, 0.01 mmol); ●: supported on silica B (15 wt%, 0.01 mmol); ⊙: non-supported (0.03 mmol); benzene: 30 mmol; 1-octene: 3 mmol.

activity of supported heteropoly acid caused by calcination at 300 °C may be due to decrease in effective surface area of the exposed crystallites of heteropoly acid through aggregation. In this context, it was observed that the surface area of non-supported tungstophosphoric acid was decreased on heating from 8.3 $m^2 g^{-1}$ (150 °C) to 4.2 $m^2 g^{-1}$ (300 °C), though the degree of activity decrease was more drastic (Fig. 1). A similar decrease in surface area on heating has already been pointed out by Misono et al.[8] about non-supported molybdophosphoric acid.

Lower dispersion of heteropoly acid on silica B support which has a relatively small surface area (105 $m^2 g^{-1}$) brought about lower catalytic activity in comparison with high surface area silica A support (585 $m^2 g^{-1}$). Tungstophosphoric acid, even in non-supported state, reasonably catalyzed the reaction, but its efficiency could be enhanced obviously when supported on silica A.

The catalytic activity increased monotonously with the loading of heteropoly acid even beyond high levels of 25 and 30 wt% over silica B and silica A supports, respectively, without any dissolution and deterioration of heteropoly acid (Fig. 2). According to our previous study on the vapor-phase alkylation of benzene with ethene over silica (319 $m^2 g^{-1}$)-supported tungstophosphoric acid catalysts,[4c] a ceiling of activity increase was observed at a lower loading of 15—20 wt% (Fig. 2, a broken line). Since the vapor-phase alkylation proceeded exclusively on the outer surface of the supported heteropoly acid, a loading of more than 15 wt% did not bring about a substantial increase in activity because of crystal growth of supported

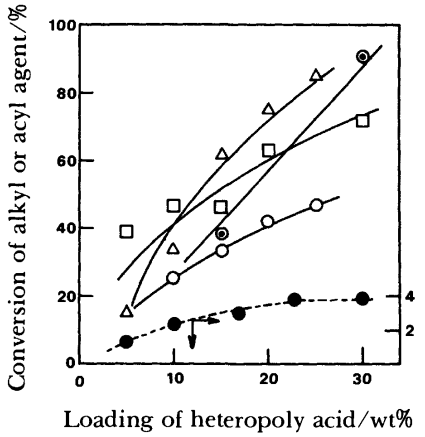

Fig. 2. Effect of loading of heteropoly acid on catalytic activities. O: Alkylation of benzene with 1-octene by 12-tungstophosphoric acid (0.01 mmol) on silica B (35 °C, 2 h); ⊙: alkylation of benzene with 1-octene by 12-tungstophosphoric acid (0.01 mmol) on silica A (35 °C, 1 h); ●: vapor-phase alkylation of benzene with ethene over silica-supported 12-tungstophosphoric acid (200 °C),[4c] △: alkylation of toluene with benzyl chloride by 12-molybdophosphoric acid (0.02 mmol) on silica B (75 °C, 2 h); □: acylation of *p*-xylene with benzoyl chloride by 12-tungstosilicic acid (0.01 mmol) on silica B (138 °C, 1 h).

Table 1. Benzylation of Benzene with Silica-Supported Acid Catalysts (80 °C, 2 h)[a]

Acid	Benzyl chloride conversion/%

$H_3PW_{12}O_{40}$	27.2
$H_4SiW_{12}O_{40}$	17.3
p-$CH_3C_6H_4SO_3H$	0

a) Support: silica B; acid: 0.02 mmol; loading: 15 wt%; pretreatment: 300 °C, 3 h; benzene: 100 mmol; benzyl cloride: 5 mmol.

heteropoly aicd. Therefore, the activity increase beyond 25 wt% loading observed even with a smaller surface area silica B support (105 $m^2 g^{-1}$) in the present liquid-phase alkylation reaction suggests that the reaction may involve a 'bulk-type reaction,' namely, the reaction occurs not only on the surface but also inside the bulk of the crystallites of heteropoly acid on the support.

In contrast to the case of alkylation with olefin, silica B-supported molybdophosphoric acid catalyzed the alkylation of aromatic hydrocarbons with benzyl chloride most efficiently (Table 1). Neither dissolution nor deterioration of the supported heteropoly acid was observed during the reaction. Since the acid strength of molybdophosphoric acid is weaker than that of tungstophosphoric acid,[4d] higher catalytic efficiency of molybdophosphoric acid in this acylation may reflect its stronger affinity to benzyl chloride

compared with other heteropoly acids. *p*-Toluenesulfonic acid, a typical conventional protonic acid, was inactive for this reaction. It is, therefore, suggested that heteropoly acid may exhibit Lewis acid-like catalytic function through an stabilizing effect by heteropoly anion[4d] on the benzyl cation as a reaction intermediate, although heteropoly acid itself is a protonic acid in nature.

Figure 3 illustrates the effect of pretreatment temperature of supported molybdophosphoric acid on the catalytic activity of benzylation of toluene. The maximum conversion appeared when the catalyst was preheated at 300 °C, but deactivation of catalyst occurred at higher pretreatment temperatures above 300 °C mainly because of decomposition of the heteropoly acid.

The benzylation activity increased with increasing loading of heteropoly acid beyond 25 wt% on silica B support without any dissolution and deterioration of heteropoly acid (Fig. 2), indicating that the benzylation involved a bulk-type reaction, also (vide supra). Other active alkyl halides such as bromocyclohexane could be favorably applied as an alkylating agent in the presence of the supported molybdophosphoric acid catalyst, but the catalyst was almost inactive for the alkylation reactions using primary alkyl halides.

Acylation. Figure 4 shows the result of the acylation of *p*-xylene with benzoyl chloride using silica-supported molybdophosphoric acid catalyst which was calcined beforehand at different temperatures. The catalysts which underwent milder thermal pretreatment were active, in particular (a solid line). However, the reaction proceeded still more even when the solid catalyst was removed out of the reaction medium in the course of the reaction (a broken line). In addition, molybdophosphoric acid was found almost decomposed after the reaction. These results unambiguosly indicate that the real active catalyst species was not the heteropoly acid on the support, but any other soluble species which might be formed during the reaction between heteropoly acid and benzoly chloride. Yamaguchi et al.[6] have also reported similar possibility of deterioration of non-supported molybdophosphoric acid when employed as a catalyst in the liquid-phase acylation of chloro-

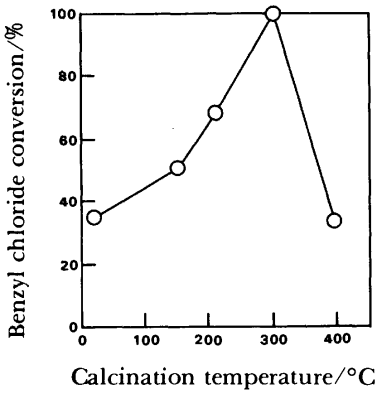

Fig. 3. Alkylation of toluene with benzyl chloride catalyzed by supported 12-molybdophosphoric acid (75 °C, 2 h). Heteropoly acid: 0.02 mmol; support: silica B (15 wt% loading); toluene: 100 mmol; benzyl chloride: 10 mmol.

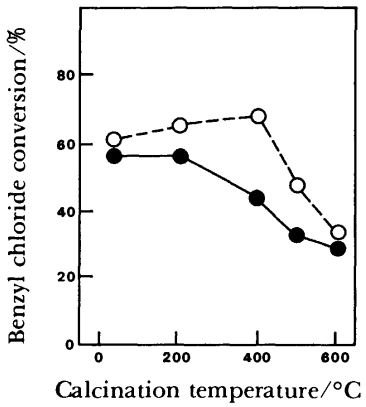

Fig. 4. Acylation of *p*-xylene with benzoyl chloride catalyzed by supported 12-molybdophosphoric acid (138°, 1 h). Heteropoly acid: 0.01 mmol; support: silica B (15 wt% loading); *p*-xylene: 30 mmol; benzoyl chloride: 3 mmol. The broken line denotes the final conversion of the reaction performed for more one hour successively after the catalyst was removed.

benzene with *o*-chlorobenzoyl chloride.

In contrast to molybdophosphoric acid, however, it was found that tungstosilicic acid and tungstophosphoric acid were both hardly soluble and remained unchanged in the reaction medium of the acylation of *p*-xylene with benzoyl chloride, still holding their Keggin structures. Thus the supported tungstosilicic and tungstophosphoric acids proved to effectively catalyze the acylation as heterogeneous and insoluble catalysts, particularly when calcined at between 200—500 °C (Table 2). In these cases, the reaction did not proceed any more if each solid catalyst was filtrated off out of the reaction medium.

The benzoylation activity increased with increasing loading of tungstosilicic acid beyond 30 wt% on silica B support without any dissolution and deterioration of heteropoly acid (Fig. 2), indicating that the benzoylation involved a bulk-type reaction, also.

In a polar reaction medium as met in the acylation of chlorobenzene, however, even silica-supported tungstosilicic acid was gradually migrated and deteriorated in the course of the reaction like as supported molybdophosphoric acid. Thus the silica-supported tungstosilicic acid appears to be effectively applicable as an insoluble acid catalyst for an acylation reaction in which a large excess of less polar aromatic hydrocarbon is applied, as exemplified by a reaction medium which consists of benzene and benzoyl chloride in a mole ratio of between 10:1 and 3:1.

Table 3 represents the deactivation of silica-supported tungstosilicic acid catalyst in the course of the acylation reaction which was repeated several times by separating organic liquid from catalyst followed by the addition of fresh reactants whenever the reaction was performed for 3 h. A rapid decline in catalytic activity was observed from the second repeated run, but the total catalytic turnover was as much as about 300 per mole of heteropoly acid. The deactivation is probably caused by strong adsorption of the product benzophenone onto the catalyst, because it was confirmed from a separate experiment that the acylation was considerably retarded if the reaction was started in the presence of benzophenone. The detailed examination on catalyst deactivation and its regeneration are in progress.

Benzoic anhydride was also favorably employed as an acylating agent over the silica-supported tungstosilicic acid, but the acylation with benzoic acid did not proceed over this catalyst. Active carbon-supported tungstosilicic acid could catalyze the acylation, although its activity was limited to about a half of silica B-supported catalyst because of the reduction in acid strength.

Table 3. Deactivation of Silica-Supported Tungstosilicic Acid in Acylation of *p*-Xylene with Benzoyl Chloride[a)]

a) Support: silica B; loading: 15 wt%; net amount of heteropoly acid: 0.04 mmol; *p*-xylene: 30 mmol; benzoyl chloride: 3 mmol; reaction conditions: 138 °C, 3 h.

p-Toluenesulfonic acid was quite inactive also for this acylation reaction. This fact again indicates a peculiar function of heteropoly anion to be able to stabilize the intermediate acyl cation.

The present work was supported by a Grant-in-Aid for Scientific Research No. 62470075 from the Ministry of Education, Science and Culture.

(Received January 29, 1988)

Several square-planar cobalt(III) complexes of bis(biuretato)-type were synthesized with new quadridentate ligands, alkylenebis(biuret)'s, where alkylene bridging group is (*R,S*)- or (*R*)-propylene, 1,1-dimethylethylene, *cis*-1,2-cyclohexylene, or tetramethylethylene. Faraday parameters for possible CT transitions in the complexes were expressed as functions of MO coefficients and energies. From the examination of the magnetic circular dichroism, the intense absorption band observed at ca. 20×10^3 cm^{-1} was assigned to ligand-to-metal charge-transfer transitions of ligand π (a_u of D_{2h}) to metal d_{yz} and $d_{zx'}$, and the ground state was inferred to be one close to D_{4h} symmetry. The band assignment was also consistent with the resonance Raman spectrum of potassium bis(biuretato)cobaltate(III). Absorption spectra of the complexes occasionally lost intensity with decrease of temperature. Origin of the thermochromism, which was found to be reversible, was also discussed.

Bis(biuretato)cobaltate(III)-type complexes, first reported by Bour and Steggerda, are known to possess a square-planar $Co(N)_4$ coordination geometry.[1-3] Magnetic susceptibility measurements have shown that spin-triplet ground state is retained even below 10 K in crystalline state.[4] The electronic ground state and the coordination mode have been considered to be kept also in solution as judged by observed electronic spectral features. To our knowledge, no detailed investigations have ever been made, however, about the interactions of the complexes with the solvent molecules of weak electron-donor property such as dimethyl sulfoxide (DMSO), ethanol, and water, though some amines have been demonstrated to be coordinated to give usual low-spin six-coordinate cobalt(III) species in ethanol.[4] Consistently potassium bis(3-phenylbiuretato)cobaltate(III) crystallizes with two uncoordinated DMSO molecules as revealed by X-ray analysis.[3]

Furthermore, nature of electronic absorption bands in the complexes have been not so fully investigated. In the present paper, the following main points will be discussed: 1) Assignment of the relatively weak and intense absorption bands observed at 10—16 and ca. 20×10^3 cm^{-1}, respectively. 2) A remarkable thermochromism in water-containing media, which was discovered in the present study.

Scheme 1 displays the ligands used and their abbreviations. The complexes with the last two ligands are known[4] whereas complexes with the other four were newly prepared for the purpose of comparative study of their electronic spectra. Improvement of solubility properties was achieved to some extent by the modification of ligands in the complexes.

Experimental

Materials. *o*-Phenylenebis(biuret) (H_4bbphen) and three new ligands, (*R,S*)-propylene-, 1,1-dimethylethylene-, and *cis*-1,2-cyclohexylene-bis(biuret) (H_4bbpn, H_4bbibn, and H_4*cis*-bbchxn) were prepared in a similar manner as given for H_4bbphen:[4] For the new ligands, mp 201—202, 207—208, 199.5—200.5 °C, respectively. Found for H_4bbpn·2H_2O: C, 29.78; H, 6.52; N, 29.47%. Calcd for $C_7H_{18}N_6O_6$: C, 29.79; H, 6.43; N, 29.77%. Found for H_4bbibn: C, 36.68; H, 6.16; N, 31.82%. Calcd for $C_8H_{16}N_6O_4$: C, 36.92; H, 6.20; N, 32.29%. Found for H_4*cis*-bbchxn·0.5H_2O: C, 40.79; H, 6.42; N, 28.45%. Cacld for $C_{10}H_{19}N_6O_{4.5}$: C, 40.67; H, 6.49; N, 28.46%. (*R*)-Propylenebis(biuret) was similarly derived from (*R*)-propylenediamine. Found for H_4bbpn·2H_2O: C, 29.59; H, 6.60; N, 29.44%.

Tetramethylethylenebis(biuret) (H_4bbtmen) was also obtained by a similar procedure, but we often found that *N,N*-dimethylformamide (DMF) was preferred as solvent for the syntheses of alkylbiurets,[5] especially in this case: mp 210—210.5 °C. Found for H_4bbtmen: C, 41.67; H, 7.00; N, 28.81%. Calcd for $C_{10}H_{20}N_6O_4$: C, 41.66; H, 6.99; N, 29.15%. Yields were generally 30—60% by 0.02—0.1 mole scale preparation for all the ligands.

Apart from isolation and purification procedures, potassium salts of the alkylenebis(biuretato)cobaltate(III) complexes were prepared in a similar method as that employed for the preparation of potassium ethylenebis(biuretato)-cobaltate(III).[4] In some cases active charcoal seems effective in complex formation. All the four complexes newly prepared were reprecipitated from aqueous solutions, whereas the known analogous complexes may be purified, if possible, only with organic solvents. Found for K[Co(*R,S*)-

bbpn]·H_2O: C, 23.49; H, 3.40; N, 23.43% and for the (*R*)-bbpn analog: C, 23.37; H, 3.39; N, 23.34%. Calcd for $C_7H_{12}N_6O_5CoK$: C, 23.47; H, 3.38; N, 23.46%. Found for K[Co(bbibn)]·H_2O: C, 25.89; H, 3.85; N, 22.21%. Calcd for $C_8H_{14}N_6O_5CoK$: C, 25.81; H, 3.79; N, 22.58%. Found for K[Co(*cis*-bbchxn)]·$0.5H_2O$: C, 30.56; H, 3.81; N, 21.02%. Calcd for $C_{10}H_{15}N_6O_{4.5}CoK$: C, 30.85; H, 3.88; N, 21.59%. Found for K[Co(bbtmen)]·$1.5H_2O$: C, 29.16; H, 4.57; N, 19.49%. Calcd for $C_{10}H_{19}N_6O_{5.5}CoK$: C, 29.34; H, 4.68; N, 20.53%. Yields were roughly 50, 45, 20, and 10%, respectively. The two known complexes were prepared according to the literature.[4] Found for K[Co(bbphen)]·H_2O: C, 30.69; H, 2.54; N, 20.95%. Calcd for $C_{10}H_{10}N_6O_5CoK$: C, 30.62; H, 2.57; N, 21.42%. Found for $K[Co(bi)_2]\cdot 0.5H_2O$: C, 15.78; H, 2.42; N, 27.30%. Calcd for $C_4H_7N_6O_{4.5}CoK$: C, 15.54; H, 2.28; N, 27.18%.

Measurements. The visible and ultraviolet absorption and reflectance spectra were recorded by a Hitachi 330 spectrophotometer. The CD and magnetic circular dichroism (MCD) spectra were obtained by a JASCO MOE-1 and a JASCO J-500C spectropolarimeter equipped with a 1.5-T electromagnet.

The low-temperature absorption spectra were measured with a hand-made cell and a glass Dewar provided with a light path. Body of the cell was made of a sheet of aluminum plate, on which polyacrylonitrile windows were mounted. Temperature measurements were carried out with a copper-constantan thermocouple dipped into sample solutions. With those samples that were employed for the low-temperature measurements, ambient-temperature measurements were also made for comparison.

Raman spectra were recorded on a JASCO R-800 laser Raman spectrophotometer. Exciting lines were provided by a Spectra-Physics Model 164 Ar^+ ion laser (514.5, 501.7, 496.5, 488.0, 476.5, 472.7, 465.8, and 457.9 nm) and by a Coherent Radiation Model 599 dye laser employing Rhodamine 6G (588.0 and 567.8 nm). A rotating sample technique was used to minimize thermal decomposition of the sample by laser illumination. Samples were provided by K_2SO_4 disks. Intensities were measured with respect to the 981 cm^{-1} band of K_2SO_4 as internal standard and corrected for instrumental spectral response and the ν^4 law.

Theoretical

Molecular Orbitals. The extended Hückel (EH) molecular orbital calculations with self-consistent charge were carried out on bis(biuretato)cobaltate(III) and three related complex anions: bis(biuretato)-cuprate(II) and -nickelate(II), and tris(biuretato)-cobaltate(III).[6,7] The atomic coordinates from X-ray analyses[3,8] were adapted to fit D_{2h} or D_3 symmetry. The molecular coordinate system adopted is shown in Scheme 2. Double-ζ functions of Richardson et al. for +1 ions were used for metal 3d atomic orbitals (AO),[9] and single-ζ functions of Summerville and Hoffmann for all the other valence AO's including metal 4s and 4p.[10]

Valence orbital ionization potentials (3d-VOIP's) for d^{n-1}s configurations[6b,11] were modified as below to give those results that enable a systematic explanation for the electronic spectra of the above four complexes. First, energy calculations were made for the copper(II) complex using modified *A* and *B* values (*A'* and *B'*) and the original *C*, where $A'=\eta A$, $B'=\eta B$ (η is a scaling factor), and symbols *A*, *B*, and *C* have the usual significance.[6b] A reasonable result was obtained at $\eta=0.4$.[12] Parameters *A'* and *B'* for cobalt or nickel were determined by $A'_M=A_M-0.6A_{Cu}$ and $B'_M=B_M-0.6B_{Cu}$ (M=Co or Ni); i.e., the same amount as in copper was subtracted from the relevant original value regarding each parameter, *A* or *B*. The original values of *A*, *B*, and *C* of d^{n-1}s and d^{n-1}p configurations were used for metal 4s and 4p H_{ii}'s, respectively. Constant Coulomb integrals[10] were employed for hydrogen 1s and second-row-atom 2s and 2p orbitals. The present parametrization may be partly rationalized by intramolecular Madelung energies.[13] Wolfsberg-Helmholz approximation was employed for off-diagonal H_{ij}'s; the value of the interaction constant *k* was 1.75 unless otherwise stated. Open shell configuration with two singly-occupied orbitals was assumed for bis(biuretato)-cobaltate(III) anion.

Figure 1 displays the resulting energy levels for the molecular orbitals (MO) which are largely metal d or ligand π in character. Several MO's of largely oxygen σ were neglected from Fig. 1 for simplicity, though turned out to be located at ca. -112×10^3 cm^{-1} or lower wavenumbers in all the complexes. The present calculation for bis(biuretato)cobaltate(III) ion gave the ground state with $(yz)^1(zx)^1$ configuration in contrast with $(zx)^1(x^2-y^2)^1$ given by Birker et al.,[4] where (yz), (zx), etc. denote the MO's of largely d_{yz}, d_{zx}, etc.

Faraday Parameters for Charge Transfer Transitions. For $^3B_{1g}$ ground state with $(yz)^1(zx)^1$ configuration, such charge-transfer (CT) transitions as shown in Table 1 may be allowed between metal d and ligand π

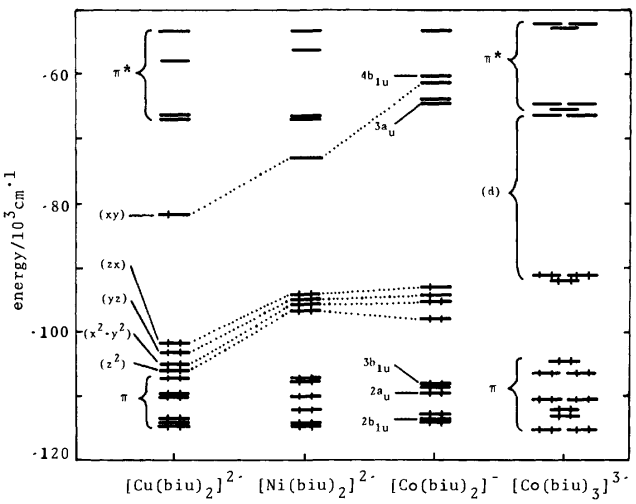

Fig. 1. Molecuar orbital energy diagram of bis-(biuretato)cobaltate(III) and related complexes. Molecular orbitals of largely ligand σ are omitted.

Table 1. Possible Types of Charge-Transfer Transitions in $[Co(bi)_2]^-$ for $^3B_{1g}$ Ground State with $(yz)^1(zx)^1$ Configuration[a)]

Excited states	LMCT	Abbrev.	MLCT	Abbrev.

$^3B_{2u}$	$b_{1u}(\pi_L) \rightarrow (zx)$	J_2	$(zx) \rightarrow b_{1u}(\pi^*_L)$	J_2'
$^3B_{2u}$	$a_u(\pi_L) \rightarrow (yz)$	J_3	$(yz) \rightarrow a_u(\pi^*_L)$	J_3'
$^3B_{3u}$	$a_u(\pi_L) \rightarrow (zx)$	J_4	$(zx) \rightarrow a_u(\pi^*_L)$	J_4'
^3A_u	$a_u(\pi_L) \rightarrow (xy)$	J_5	$(z^2) \rightarrow b_{1u}(\pi^*_L)$	J_5'
^3A_u	——	—	$(x^2-y^2) \rightarrow b_{1u}(\pi^*_L)$	J_6'

a) For example, the abbreviation of ligand MO $b_{1u}(\pi_L)$ represents the $nb_{1u}(\pi_L)$ with n=1, 2, or 3, so J_1 the transition from one of the three MO's.

MO's in bis(biuretato)cobaltate(III) anion. Faraday parameters $\bar{B}_0$ for all the CT transitions can be formulated, as given below, in terms of the MO coefficients and the matrix elements of operator ∇ by the standard procedure:[14)]

$$\bar{B}_0(J_1) = -\bar{B}_0(J_1') = -C(M_1/E_{3b})[M_3/(E_{32}E_{2b}) - \sqrt{3}M_4/(E_{31}E_{1b}) - M_2/(E_{43}E_{4b})], \quad (1)$$

$$\bar{B}_0(J_2) = -\bar{B}_0(J_2') = -C(M_2/E_{4b})[M_3/(E_{42}E_{2b}) + \sqrt{3}M_4/(E_{41}E_{1b}) + M_1/(E_{43}E_{3b})], \quad (2)$$

$$\bar{B}_0(J_3) = -\bar{B}_0(J_4) = C(M_5)^2/(E_{4a}E_{43}E_{3a}), \quad (3)$$

$$\bar{B}_0(J_5) = 2C(M_5M_6/E_{5a})[1/(E_{54}E_{4a}) + 1/(E_{53}E_{3a})], \quad (4)$$

$$\bar{B}_0(J_3') = -\bar{B}_0(J_3) + CM_5M_6/(E_{5a}E_{53}E_{3a}), \quad (5)$$

$$\bar{B}_0(J_4') = -\bar{B}_0(J_4) + CM_5M_6/(E_{5a}E_{54}E_{4a}), \quad (6)$$

$$\bar{B}_0(J_5') = \bar{B}_0(J_6') = 0, \quad (7)$$

where $\bar{B}_0(J)$ refers to a transition J given in Table 1; constant C is equal to 207.35 if MO energy differences E_{ij} are given in 10^3 cm^{-1} and quantities M_k in atomic unit; E_{ij} is defined by $E_i - E_j$; and the i or j values, a, b, and 1—5, denote the MO's, $na_u(\pi_L)$, $nb_{1u}(\pi_L)$ (n: ordinal number), $9a_g=(z^2)$, $10a_g=(x^2-y^2)$, $3b_{3g}=(yz)$, $4b_{2g}=(zx)$, and $8b_{1g}=(xy)$, respectively. Care must be taken especially in the MO symbols a and b, which indicate the π or π^* MO's relevant to the CT transition in question. Thus every equation connecting $\bar{B}_0(J_i)$ for a ligand-to-metal (LM) and $\bar{B}_0(J_i')$ for a metal-to-ligand (ML) CT transition in Eqs. 1, 2, 5, and 6 means only a formal resemblance between the two $\bar{B}_0$'s. In the above formulation, two-center magnetic-transition-moment integrals were ignored and the MO's of mainly metal d character were approximated by pure d orbitals.

The quantities, M_k, can be expressed as:

$$M_1 = -4\sum_{m=1}^{3} c_{bm}[\cos^2\theta_m \langle ZX|\nabla_X|Z\rangle^m + \sin^2\theta_m \langle YZ|\nabla_Y|Z\rangle^m] - 2c_{b4}\langle ZX|\nabla_X|Z\rangle^4, \quad (8)$$

$$M_2 = 4\sum_{m=1}^{3} c_{bm}[\sin^2\theta_m \langle ZX|\nabla_X|Z\rangle^m + \cos^2\theta_m \langle YZ|\nabla_Y|Z\rangle^m] + 2c_{b4}\langle YZ|\nabla_Y|Z\rangle^4, \quad (9)$$

$$M_3 = -4\sum_{m=1}^{3} c_{bm}\cos(2\theta_m)\langle X^2-Y^2|\nabla_Z|Z\rangle^m - 2c_{b4}\langle X^2-Y^2|\nabla_Z|Z\rangle^4, \quad (10)$$

$$M_4 = -4\sum_{m=1}^{3} c_{bm}\langle Z^2|\nabla_Z|Z\rangle^m - 2c_{b4}\langle Z^2|\nabla_Z|Z\rangle^4, \quad (11)$$

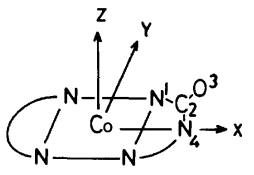
$$M_5 = -2\sum_{m=1}^{3} c_{am}\sin(2\theta_m)[\langle ZX|\nabla_X|Z\rangle^m - \langle YZ|\nabla_Y|Z\rangle^m], \quad (12)$$

$$M_6 = 4\sum_{m=1}^{3} c_{am}\sin(2\theta_m)\langle X^2-Y^2|\nabla_Z|Z\rangle^m, \quad (13)$$

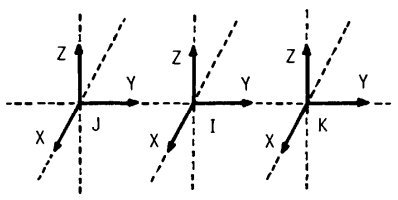
where c_{im} is the amplitude coefficient of $2p_\pi$ AO on atom m in the relevant π-MO i [i=a or b for a_u or b_{1u}; and m=1—4 for N(terminal), C, O, and N(central) atom, respectively, of the N-CO-N group in the first quadrant of the molecular coordinate system (Scheme 2)]. The acute angle θ_m is defined by the x-axis and the position vector of atom m. Two-center integrals $\langle J|\nabla_I|K\rangle^m$, referring to metal $3d_J$ and atom-m $2p_K$ AO's, were defined relative to the local coordinate system shown in Scheme 3 and evaluated by Kral's formulas.[15)] Thus M_k's can be written by

$$M_k = \sum_{m=1}^{4} c_{im}C_{km}, \quad (14)$$

where C_{km}'s, which were evaluated as given in Table 2,



Scheme 2.



Scheme 3.

Table 2. C_{km} Values for $[Co(bi)_2]^-$

k	C_{k1}	C_{k2}	C_{k3}	C_{k4}
1	0.339	0.025	0.00055	0.0010

3	0.0	0.030	0.00028	0.0051
4	0.358	0.042	0.00058	0.0041
5	−0.198	−0.027	−0.00063	0.0
6	−0.339	−0.037	−0.00073	0.0

are dependent only on the given AO set and the molecular geometry.

The above formulation of $\bar{B}_0$ reflects mainly symmetry properties of the system, so it may be applicable to other d^6 planar complexes with a slight modification in M_k's, or Eqs. 8—13. In addition, Eqs. 1—7 need not be revised by a change in the energy order of MO's so long as it takes place within any of the doubly-occupied, the singly-occupied, and the vacant MO's.

The numerical results of $\bar{B}_0$ for several low-energy CT transitions are exemplified together with the calculated dipole strengths $\bar{D}_0$ in Table 3.

Results and Discussion

The absorption, CD, and MCD data obtained in DMSO and in aqueous solution at ambient temperature are shown in Tables 4 and 5 and Figs. 2—5. Abbreviations for intense bands, I—IV, were also denoted in Fig. 2. Spectral features in methanol solution were of intermediate between those in DMSO and aqueous solutions, although related data are not given.

Assignment of the Absorption Bands. An Intense Band at ca. 20×10^3 cm^{-1}: The bis(biuretato)cobaltate(III)-type complexes generally showed an intense absorption band ($\varepsilon\simeq7000$ in DMSO) at ca. 20×10^3 cm^{-1}. This band (band I) may be attributed to CT transitions between metal d and ligand π MO's because of the high intensities and of the relatively low energies. Numerical data of band I have once been given but not discussed at all.[3] From the absorption-band shape and the dispersion pattern of negative A-term type in this region, band I consists of at least two nearly degenerate components.

The band I for the complexes of bis(biuretato)-cobaltate(III) type was observed at much lower energies than the lowest-lying intense bands for the three related complexes.[16] The relative order of the transition energies is in agreement with the EH energy diagrams (Fig. 1) if band I is assigned to the lowest-lying LMCT transitions, whereas a different situation would be expected if it is assigned to MLCT.

Figure 6 shows the Raman spectrum (514.5 nm excitation) of the mother complex, $K[Co(bi)_2]\cdot0.5H_2O$, of the alkylenebis(biuretato) complexes discussed above. Assignment of the observed Raman bands was made based on a close correlation between the peaks in the Raman spectra of $K[Co(bi)_2]\cdot0.5H_2O$ and of $K_2[Cu(bi)_2]$[17] and summarized in Table 6.

It is well known that resonance Raman effects reflect the nature of the resonant electronic transition; that is, if a Raman band showed a strong resonance enhancement near the frequency of an electronic excitation within a certain chromophore, the equilibrium conformation of the chromophore should be considered to be distorted along the normal coordinate for the Raman band.[18] Figure 7 shows the excitation profiles of the Raman bands for which strong enhancements were observed on resonance with band I. Taking the

intensity of each band to be unity at 588.0 nm, the intensities of the bands at 392 and 815 cm^{-1} became ca. 30, those at 548, 1013, and 1625 cm^{-1} ca. 15, and those at 273 and 1362 cm^{-1} ca. 10, at the maximum of band I. The Raman bands arise from the skeletal stretching and deformation vibrations of the chelate ring as shown in Table 6. This observation indicates that the electron which is participating in the transitions of band I should be extensively delocalized over the ligand, being consistent with the assignment given above for band I.

As mentioned before, a marked MCD generally

appears in the region of band I. Its negative A-term pattern is retained among all the planar cobalt(III) complexes investigated. In Eqs. 1—3, so-called pseudo-A terms are found as couples of the B terms, i.e., of $\overline{B}_0(J_3)$ and $\overline{B}_0(J_4)$ and of the third terms in both $\overline{B}_0(J_1)$ and $\overline{B}_0(J_2)$, where each couple refers to a common ligand MO of a_u or b_{1u} symmetry. Such a couple of the B terms can be correlated by the following relation to the A term of a degenerate CT transition in square-planar model complex $[Co(NH_2)_4]^-$ with D_{4h} symmetry:

$$\overline{A}_1(J) = -\overline{B}_0(J')\Delta W = \overline{B}_0(J'')\Delta W, \quad (15)$$

where $\overline{A}_1(J)$ is the Faraday parameter defined for a degenerate transition J, J′ and J″ are the lower and the higher split components in the lower symmetry, and ΔW is the splitting between J′ and J″.[14a] For example, if transitions J_1 and J_2 are chosen as J′ and J″ and the energy difference $\Delta W = E_{43}$ is brought close to zero, the contributions from the first and the second terms of the right-hand sides of Eqs. 1 and 2 become negligible and Eq. 15 comes to hold exactly for J=an $a_{2u}(\pi_L)$-to-$e_g(d_{yz,zx})$ transition. If our $[Co(bi)_2]^-$ model is supposed to be very close to D_{4h}, only the first term $c_{i1}C_{k1}$ must survive in Eq. 14 as inferred from Table 2. Thus the influence of the non-ligating atoms on ligand π MO's disappears. Therefore the pseudo-A terms in the bis(biuretato) complexes can be discussed in terms of the square-planar model complex.

For the A terms of the latter model complex, the following relations are easily shown to hold:

$$\overline{A}_1/\overline{D}_0 = 1 \text{ for transitions between } e_g(d_{yz,zx}) \text{ and } a_{2u}(\pi_L), \quad (16)$$

$$\overline{A}_1/\overline{D}_0 = -1 \text{ for those between } e_g(d_{yz,zx}) \text{ and } b_{1u}(\pi_L), \quad (17)$$

where $\overline{D}_0$ are defined according to the literature.[14a] In addition, Eqs. 16 and 17 hold for various assumed ground states of $^3A_{2g}$ or ^3E_g. It should be noted that the a_{2u} and the b_{1u} MO's of largely ligand π in the square-planar complex correspond to a b_{1u} and an a_u MO's in the D_{2h} complex, respectively. Furthermore, the $^3A_{2g}(D_{4h})$ ground state corresponds to the $^3B_{1g}(D_{2h})$ with $(yz)^1(zx)^1$ configuration, whereas the $^3B_{2g}(D_{2h})$ ground state with $(x^2-y^2)^1(zx)^1$ is considerably different from every state of the D_{4h} model complex, because it has different occupation numbers, i.e., 2 and 1, for (yz) and (zx).

The Gaussian curve fittings were carried out for the band I region of the observed absorption and MCD spectra of the bbpn complex in DMSO (Fig. 8).[19] The $\overline{B}_0$ and $\overline{D}_0$ values were determined as given in Table 7. The $\overline{A}_1/\overline{D}_0$ value was also estimated at ca. −1.5 by use of Eq. 15 and the data in Table 7. By comparison of these results with the calculated values in Table 3 and with

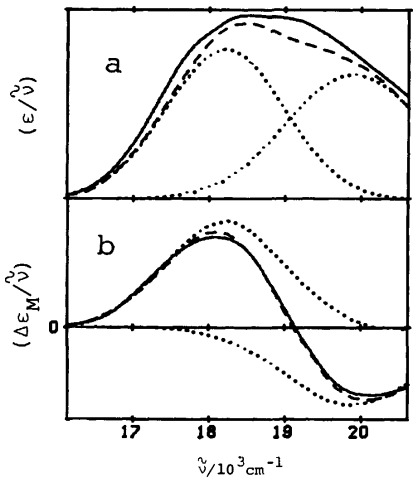

Fig. 8. Gaussian fittings of a) absorption and b) MCD spectra in the region of band I of K[Co(bbpn)] in DMSO: observed (——), calculated (----), and component curves (--------).

Eq. 17, band I may be assigned to the LMCT transitions of $a_u(\pi_L)$ to (yz) and (zx), that is, J_3 and J_4, which are derived from a b_{1u}-to-$e_g(yz,zx)$ transition in $[Co(NH_2)_4]^-$. Such a producibility of dispersion pattern in CT transitions is not specific for the $(yz)^1(zx)^1$ but in common with the $(yz,zx)^3(i)^1$ configuration, where $i=x^2-y^2$ or z^2. It should be noted in this context, however, that the energy difference of (yz) and (zx), ΔW, should be small enough only in the latter configuration, so as to secure essentially equal electron population on themselves, or to make the Boltzmann factor $\exp(-\Delta W/kT)$ unity. The situation is unlikely as in the $(zx)^1(x^2-y^2)^1$ configuration cited before.[4)]

Regarding the transition energies, however, the above band assignment is less satisfactory because in our EHMO results (Fig. 1) $3b_{1u}(\pi_L)$ lies above $2a_u(\pi_L)$ even though the energy difference is small. This point will be mentioned again in the next subsection.

Other Intense Bands: Three other intense absorption bands were generally observed at 23—24 (band II), 27—29 (band III), and ca. $35\times10^3\,cm^{-1}$ (band IV). Although many d-d bands are expected besides LMCT and MLCT bands throughout the wavenumber region, most of the absorption intensities may also be attributed to CT transitions from their high intensities.

Unfortunately, our EHMO calculations could not reproduce the transition energies and MCD intensities of bands I—IV simultaneously; the order of MO energies for k=1.75 (Fig. 1) was not altered by various k values except for the energy of (xy),[20)] and the amplitude coefficients in each MO and the calculated B terms for each CT transition (Table 3) were rather slightly dependent on k. Although any clear-cut assignment of bands II—IV cannot be made in these circumstances, it is supposed that the signs of B terms are usable as the basis for the following discussion but the transition energies are unusable since the difficulty in quantitative determination by MO method is well known.[21)]

Roughly speaking, the MCD of the bands decreases in intensity with increase in transition energies, i.e., in the order of I—IV, in line with the assignment of all these bands to CT and Eqs. 1—6. Since the MO results and Eqs. 1 and 2 predicted a net positive B term for the lowest-lying LMCT of (J_1, J_2) and a net negative one for the lowest-lying MLCT of (J_1', J_2') as seen in Table 3, bands IV and III may be tentatively assigned to the LMCT and the MLCT, respectively. Since band II seemingly resembles band III in the absorption spectra, MLCT may also be assigned to band II. The g value for a relatively strong CD accompanied by band II in the (R)-bbpn complex was one to two orders of magnitude too low for the band to be regarded as magnetically allowed. Since band II of the (R,S)-bbpn complex lost a significant amount of the intensity at liquid nitrogen temperature (Fig. 9b), some d-d character may also be suggested for band II.

Also in the region of bands II—IV the bbphen complex showed a spectral behavior slightly different from that in the other complexes.

Weak Bands in 10—16×10³ cm⁻¹ Region: The complexes of bis(biuretato)cobaltate(III)-type generally exhibited a group of weak absorption bands in this region in both DMSO and aqueous solutions. Two bands were always clearly observed at ca. 11 and $13\times10^3\,cm^{-1}$ and occasionally accompanied by a fine structure consisting of one to several very weak bands. In the region, our data in DMSO solutions nearly reproduced those for the analogous complexes reported by Birker et al.[4)] According to the latter authors the absorption bands measured both in DMSO and in ethanol solution as well as in the solid state of

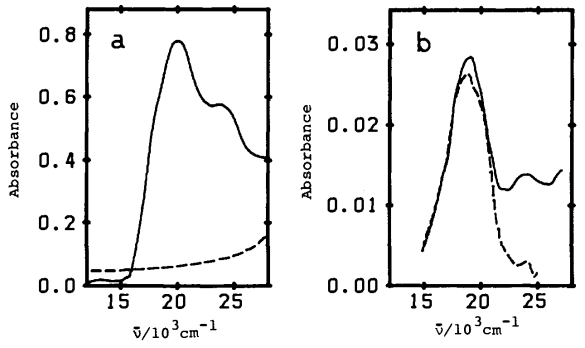

Fig. 9. Absorption spectra of K[Co((*R*,*S*)-bbpn)] at ambient temperature (——) and at 77 K (----): a) in water-glycerol (1/1 volume ratio), and b) in DMF-chloroform (1/1 volume ratio).

potassium bis(3-propylbiuretato)cobaltate(III) were quite the same; so the solvent molecules are not likely to interact with the planar $Co(N)_4$ species. It may be also the case with the complexes investigated in the present work as assumed in the preceding discussion.

The bands under discussion can be assigned to d–d transitions because of the low intensities. Furthermore, the *g* value, $|\Delta\varepsilon|/\varepsilon$, for the (*R*)-bbpn complex was roughly 1×10^{-2} in the region, indicating that the bands are magnetically allowed in agreement with the above assignment. Bour et al. assigned the 11 and $13\times10^3\,cm^{-1}$ bands to the transitions $^3B_{2g}\rightarrow{}^3A_{2g}$ and $^3B_{2g}\rightarrow{}^3E_g$, respectively.[2] This assignment, however, seems to assume an orbital energy too high for (z^2). As seen in Fig. 1, (z^2) may be lowered close to a level of (x^2-y^2), (yz), and (zx) by a configuration interaction involving metal 4s-orbital. Half-value widths of the two main bands are only $1.2—1.6\times10^3\,cm^{-1}$, being considerably narrower than those observed for the spin allowed bands due to transitions from nearly nonbonding d-orbitals[22] to strongly antibonding d_{xy} orbital; e.g., the band widths of planar bis(aminocarboxamidato)-nickel(II) complexes amount to $2.3\times10^3\,cm^{-1}$ or larger.[23] Therefore the weak bands in question would be more appropriately assigned to some transitions among the nonbonding d-orbitals rather than nonbonding d to d_{xy}. The fine structure observed on the d–d bands may reasonably be attributed to some spin-forbidden d–d transitions as judged by an angular overlap model examination of d^6 system.[24]

In agreement with the above discussion, the d–d transitions to d_{xy} orbital are located at $15\times10^3\,cm^{-1}$ or higher wavenumbers even in square-planar cobalt(II) complexes.[25] Exceptionally high intensities of the two bands of the bbphen complex in DMSO (Fig. 4) have been discussed by the previous authors.[4]

Thermochromism. We found a marked thermochromism for the five bis(biuretato)cobaltate(III)-type complexes in water-glycerol (1/1 volume ratio); with the bbphen complex, a small amount of DMSO was added to effect the dissolution. Preliminary measurements were carried out for the absorption spectra of the complexes below ambient temperature. One of the results is shown in Fig. 9a. In general the red color reversibly faded to pale yellow or pale violet when the solutions were cooled to 77 K. The bbtmen complex showed a slightly less pronounced temperature-dependence; its color was changed to bright orange at 77 K.

On the contrary the five complexes did not show any pronounced color change in DMSO or DMF solution, i.e., in nonaqueous media; as an example the temperature dependence of a nonaqueous glassy solution is shown in Fig. 9b. Some, not all, of the solutions changed the colors when a considerable amount of water was added. Red color of those solutions which remarkably faded when cooled to 77 K was darkened when heated. Thus the thermochromism was observed in a rather wide range of temperature. As an example of the detailed behavior, we observed that the decoloration of the bbpn complex was accelerated under −20 °C in the water-glycerol mixture. A hyperchromic effect was also observed when organic solvents such as alcohols and DMSO were added to aqueous solutions. Thus the thermochromism seems to occur only in water-containing media. Seemingly no thermochromism could be detected about the solid samples, however, in agreement with the knowledge that the spin-triplet ground state is retained in potassium bis(3-propylbiuretato)cobaltate(III) dihydrate even at −250 °C;[4] interestingly this substance contains water of crystallization.

While absorption, CD, and MCD spectra of the bis(biuretato)-cobaltate(III)-type complexes were appreciably deformed in aqueous solution, characteristic features exhibitied in DMSO were still retained except for the bbphen complex (Figs. 2 and 3). Dependence of both absorption and MCD spectra upon modification of the ligands was observed more remarkably in aqueous solution than in DMSO. The less the number of out-of-plane substituents are on the bridging group R in Scheme 1, the larger the observed solvent effect became. This fact implies that steric interactions between the bridging groups and water molecules dominate the spectral behavior.

All the above observations may be explained if it is supposed that each complex exists as an equilibrium mixture of the four-coordinate square-planar species and one or more five- or six-coordinate species in aqueous solution, and that any one of the non-planar species comes to dominate with lowering of temperature. This explanation may not be unreasonable in view of the residual ability of coordination in the analogous complexes.[4] Irreversible decomposition of the five complexes containing the bbphen complex seems negligible from the time-dependence of the absorption spectra. The bbpn complex in aqueous solution, for example, varied less than 1% in absorb-

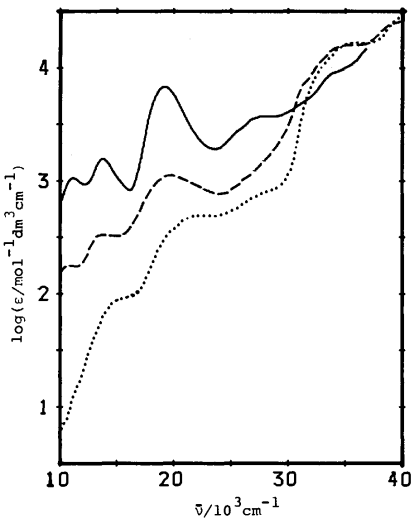

Fig. 10. Absorption spectra of K[Co(bbphen)]: in DMSO (——), in DMSO-water (1/1 volume ratio) (----), and in water (--------). The spectrum in DMSO solution is added for comparison.

ance for 8 h.

The absorption spectrum of the bbphen complex was deformed much more seriously than the other analogous complexes in aqueous solution, as shown in Fig. 10. The spectrum in the region of ca. 30×10^3 cm^{-1} or lower wavenumbers is seemingly dominated by ligand field transitions; accordingly a profound conversion of the planar species is likely to take place to give some usual low-spin cobalt(III) species. The spectral behavior of the bbphen complex should be considered, however, to be not so specific but rather general for all the five complexes since dark brown color of the bbphen complex in aqueous solution instantly turned to bright red, characteristic of the planar species, when a large amount of DMSO was added. Every absorption spectrum given in Fig. 10 obeys Beer's law almost exactly; it showed a negligible time-dependence for a few hours. The observations as a whole rule out the possibility that some associated species might play an important role in the temperature and solvent dependences of absorption spectra of the bis(biuretato)cobaltate(III)-type complexes.

(Received December 26, 1988)

The conductances of mixed nickel(II) chelates, [Ni(acac)(*N,N,N′,N′*-tmen)]X (where acac=2,4-pentanedionato, *N,N,N′,N′*-tmen=*N,N,N′,N′*-tetramethylethylenediamine, and X^-=ClO_4^- or NO_3^-), in alcohols {ethanol (EtOH), 1-propanol (*n*-PrOH), 2-propanol (*i*-PrOH), and 1-butanol (*n*-BuOH)}, ketones {acetone (Me_2CO), methyl ethyl ketone (MEK), and methyl isobutyl ketone (MIBK)}, and nitrobenzene ($PhNO_2$) were measured at 25 °C. The obtained ionic association constants (K_a) of [Ni(acac)(*N,N,N′,N′*-tmen)]ClO_4 which were derived by using the extended Fouss–Hsia function indicated that (1) the perchlorate complex is a normal type of uni-uni-valent electrolyte and (2) it is more dissociated than [Co(acac)$_2$(*N,N,N′,N′*-tmen)]ClO_4 in EtOH, *n*-PrOH, and *n*-BuOH. Walden products of the cations suggest that the nickel(II) chelate cation in the alcohols is present as an octahedral form with the coordination of two solvent molecules. On the other hand, K_a of [Ni(acac)(*N,N,N′,N′*-tmen)]NO_3 are much larger than those of [Ni(acac)(*N,N,N′,N′*-tmen)]ClO_4. This can be ascribed to the coordination of a nitrate ion to the nickel(II) ion. The effect is large and approximately the same in the ketones and $PhNO_2$, though small in EtOH, *n*-PrOH, and *n*-BuOH due to the coordination of solvent molecules.

Since the central metal ion of a quadratic-planar chelate cation is available to interact with solvents and anions, the complex offers interesting information which helps in understanding solute-solvent interactions different from those of octahedral complexes. However, very little attention have been paid to ionic association,[1] although there have been a number of studies concerning axial interaction by solvents with coordinating ability.

In this study, in order to obtain information on the ionic association of quadratic-planar complexes, the conductances of nickel(II) chelates, [Ni(acac)(*N,N,N′,N′*-tmen)]X (acac=2,4-pentanedionato, *N,N,N′,N′*-tmen=*N,N,N′,N′*-tetramethylethylenediamine, and X^-=ClO_4^- or NO_3^-) were measured in some alcohols and ketones as well as nitrobenzene. The conductance measurement is a useful tool for determining the ionic association constant and size of solvated- and coordinated-chelate cations.

It is well known that the color of the mixed nickel(II) chelate, [Ni(acac)(*N,N,N′,N′*-tmen)]ClO_4, which was prepared successfully by Fukuda and Sone,[2] changes abruptly from red to green on varying the solvent basicity. This has been ascribed to an equilibrium between two forms, one quadratic-planar (diamagnetic low-spin) and the other octahedral (paramagnetic hign-spin),

$$\underset{\text{(red)}}{[\text{Ni(acac)}(N,N,N',N'\text{-tmen})]^+} + 2\text{solvent} \rightleftharpoons \underset{\text{(green)}}{[\text{Ni(acac)}(N,N,N',N'\text{-tmen})(\text{solvent})_2]^+}. \quad (1)$$

As for the nitrate complex, on the other hand, the NO_3^- ion acts as a bidentate ligand and a counter anion in non-coordinating and strongly coordinating solvents, respectively.[2]

Since the alcohols and ketones in this study have similar basicities, but different dielectric constants and steric structures, the equilibrium of ionic association may be different from each other. Nitrobenzene, which is an inert solvent in basicity, was selected for a comparison. The obtained conductance parameters were compared in detail with those of an octahedral complex [Co(acac)$_2$(*N,N,N′,N′*-tmen)]ClO_4 in the solvents,[3–5] thus elucidating such solvent effects as solvent basicity, steric factor, and dielectric constant on ionic association.

Experimental

Material. [Ni(acac)(*N,N,N′,N′*-tmen)]ClO_4 was synthesized and recrystallized according to a published procedure,[2] followed by vacuum drying at ca. 50 °C. Calcd. for $NiC_{11}H_{23}N_2ClO_6$: C, 35.38; H, 6.21; N, 7.50%. Found: C, 35.10; H, 6.43; N, 7.67%.

Ni(acac)(*N,N,N′,N′*-tmen)(NO_3) was synthesized according to a published procedure,[2] recrystallized from 2-propanol, and then vacuum dried at ca. 50 °C. Calcd. for $NiC_{11}H_{23}N_3O_5$: C, 39.32; H, 6.90; N, 12.51%. Found: C, 39.54; H, 7.01; N, 12.50%.

Ethanol (EtOH), 1-propanol (*n*-PrOH), 2-propanol (*i*-PrOH), acetone (Me_2CO), methyl ethyl ketone (MEK), methyl isobutyl ketone (MIBK), and nitrobenzene ($PhNO_2$) of reagent grade were purified as described previously.[3–5] 1-Butanol (*n*-BuOH) was refluxed over calcium oxide and fractionally distilled.

Apparatus. The instrumentation and procedure used for the conductance measurements were described previously.[3]

Results

(A)[Ni(acac)(*N,N,N′,N′*-tmen)]ClO_4. The measured molar conductances, Λ (S cm^2 mol^{-1}) and the corresponding concentrations, C (mol dm^{-3}) are given

MIBK	12.8	0.5478	—	—
$PhNO_2$	34.82	1.847	4.4	14.8

in Table 1. In EtOH, a slight increase in conductivity with time (ca. 0.1%/h) was observed. Therefore, a small correction was made by extrapolating to time zero. The data were analyzed by the Fuoss-Hsia function with Fernández-Prini coefficients and $E=E_1\Lambda_0-2E_2$,[6]

$$\Lambda = \gamma(\Lambda_0 - SC^{1/2}\gamma^{1/2} + EC\gamma\log C\gamma + J_1(d)C\gamma + J_2(d)C^{3/2}\gamma^{3/2}), \quad (2)$$

where the symbols have their usual meanings. The ionic association constant K_a can be expressed as

$$K_a = (1-\gamma)/\gamma^2 C f_\pm^2. \quad (3)$$

The mean ionic activity coefficient $f_\pm$ is given by the extended Debye-Hückel equation,

$$-\log f_\pm = AC^{1/2}\gamma^{1/2}/(1 + BdC^{1/2}\gamma^{1/2}). \quad (4)$$

The method for fitting in terms of Λ_0, K_a, and ion-size parameter d was described previously.[3] The standard deviation σ_Λ is defined as

$$\sigma_\Lambda = [\Sigma(\Lambda_{calcd.} - \Lambda_{obsd.})^2/(n-3)]^{1/2}, \quad (5)$$

where n is the number of experimental points. The dielectric constant (ε) and viscosity (η in mPa s) of the solvents[3,5,7-12] used in this study for analyses are given in Table 2, together with the donor number (DN) and acceptor number (AN) as measures of solvent basicity and acidity, respectively.[13] The obtained conductance parameters are given in Table 3. The limiting conductances (λ_0^+/S cm^2 mol^{-1}) and Walden products ($\lambda_0^+\cdot\eta$/S cm^2 mol^{-1} 10^{-1} Pa s) of the nickel(II) chelate cation were obtained from the limiting conductances of the perchlorate ion, λ_0^- (ClO_4^-): in EtOH, 32.04;[5] in *n*-PrOH, 16.42;[7] in *i*-PrOH, 15.24;[8] in *n*-BuOH, 11.22;[9] in Me_2CO, 118.35;[10] in MEK, 93.0;[5] in MIBK, $\lambda_0^-\cdot\eta$=0.34;[5] in $PhNO_2$, 20.9.[12]

(B)[Ni(acac)(N,N,N',N'-tmen)]NO_3. The molar conductivities of [Ni(acac)(N,N,N',N'-tmen)]NO_3 in the alcohols, the ketones, and $PhNO_2$ are given in Fig. 1. Since the conductivities are extremely small, due to a coordination of the nitrate ion to the nickel(II) ion, it is impossible to obtain Λ_0 and, consequently, K_a using the extended Fuoss-Hsia function (Eq. 2).

Thus, only K_a was estimated from Eq. 3, in which the fraction of electrolyte present as ions γ is simply expressed in the form

$$\gamma = \Lambda/(\Lambda_0 - SC^{1/2}\gamma^{1/2}), \quad (6)$$

where Λ_0 of [Ni(acac)(N,N,N',N'-tmen)]NO_3 was obtained from λ_0^+ ([Ni(acac)(N,N,N',N'-tmen)]$^+$) in Table 3 and λ_0^-(NO_3^-) from the literature.[12,14-16] The activity coefficient $f_\pm$ was estimated by using Eq. 4 and

Discussion

(A)[Ni(acac)(*N,N,N',N'*-tmen)]ClO_4. The following classification becomes feasible toward the color change of [Ni(acac)(*N,N,N',N'*-tmen)]ClO_4 in the solvents, as described in Eq. 1:

Class I (Me_2CO, MEK, MIBK, $PhNO_2$, and *i*-PrOH) Red

Class II (EtOH, *n*-PrOH, and *n*-BuOH) Green

This indicates that the nickel(II) chelate ion is mainly present as a quadratic-planar [Ni(acac)(*N,N,N',N'*-tmen)]$^+$ for Class I and an octahedral [Ni(acac)-(*N,N,N',N'*-tmen)(solvent)$_2$]$^+$ for Class II.[2] This can be confirmed from the mobility data shown in Fig. 2. Walden products ($\lambda_0^+ \cdot \eta$) of [Ni(acac)(*N,N,N',N'*-tmen)]$^+$ should be larger than those of [Co(acac)$_2$-(*N,N,N',N'*-tmen)]$^+$ since the molal volume of the former is smaller than that of the latter due to a difference in the number of the ligand acac. This is the case for Class I, except for *i*-PrOH; the difference in $\lambda_0^+ \cdot \eta$ is particularly large in $PhNO_2$. For Class II, on the other hand, the opposite result is observed. In addition, the difference increases in the order EtOH< *n*-PrOH<*n*-BuOH.[17] This can not be explained in terms of coordination by one molecule, supporting

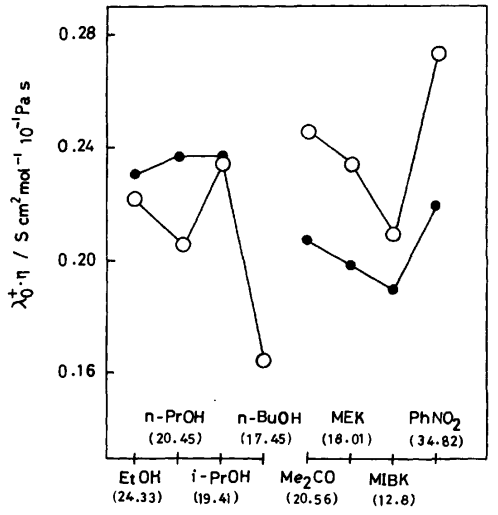

Fig. 2. Walden products of O, [Ni(acac)(*N,N,N',N'*-tmen)]$^+$ and ●, [Co(acac)$_2$(*N,N,N',N'*-tmen)]$^+$ in organic solvents at 25 °C. The values in parentheses are the dielectric constant (ε) of each solvent.

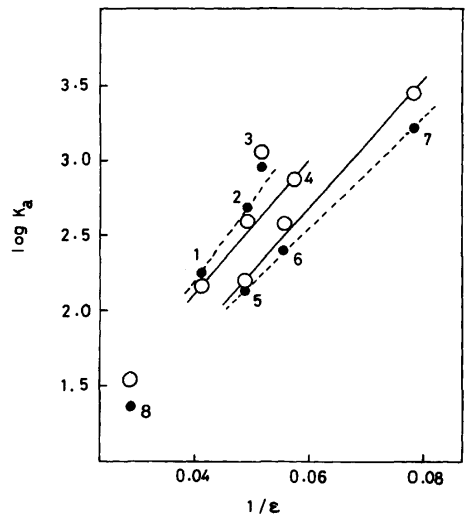

Fig. 3. Plots of $\log K_a$ with $1/\varepsilon$ for O, [Ni(acac)-(*N,N,N',N'*-tmen)]ClO_4 and ●, [Co(acac)$_2$(*N,N,-N',N'*-tmen)]ClO_4 in organic solvents at 25 °C. 1, EtOH; 2, *n*-PrOH; 3, *i*-PrOH; 4, *n*-BuOH; 5, Me_2CO; 6, MEK; 7, MIBK; 8, $PhNO_2$.

coodination by two molecules in Eq. 1.

The transfer of a quadratic-planar [Ni(acac)(*N,N,N',N'*-tmen)]$^+$ to an octahedral [Ni(acac)(*N,N,N',N'*-tmen)-(solvent)$_2$]$^+$ is influenced by solvent basicity.[2] The DN value, which is a measure of the basicity of a solvent, is 20 and 19.6 for EtOH and *n*-PrOH, respectively, suggesting that *i*-PrOH and *n*-BuOH have similar DN values (Table 2). Thus, although the configuration of the nickel(II) chelate cation in these solvents should be equal (Class II), the configuration in *i*-PrOH, which is quadratic-planar, is different from the result regarding primary alcohols. This may be due to a steric hindrance by branched methyl groups: The donor number, which was defined by Gutmann, is obtained from the solvation enthalpy of antimony pentachloride by the donor solvent in 1,2-dichloroethane. Therefore, it indicates the "bulk" donicity of the solvent and does not take into account the structural factor. However, $\lambda_0^+ \cdot \eta$ of the nickel(II) chelate ion in *i*-PrOH is compatible with that of the cobalt(III) chelate ion, suggesting that the solvation of the oxygen atom in acac (the nickel(II) chelate ion) by the OH proton occurs without steric hindrance.

The ketones do not interact with the nickel(II) ion, due to the steric hindrance, in analogy with *i*-PrOH. In addition, they have no solvation site to the nickel(II) chelate ion, resulting in an increase in mobility compared to the cobalt(III) chelate ion. However, the difference in $\lambda_0^+ \cdot \eta$ (Me_2CO=0.038, MEK=0.035, and MIBK=0.02) is small compared to that (0.054) in $PhNO_2$ which is inert in donicity, indicating the presence of a weak interaction between the ketones and the nickel(II) ion.[2] This is also confirmed from the fact that dimethyl sulfoxide (DN=29.8), which is very strong in donicity, coordinates directly to the nickel(II) ion, although the geometry of the solvent is similar to the ketones.

Figure 3 shows that $\log K_a$ of [Ni(acac)(*N,N,N',N'*-tmen)]ClO_4, in analogy with those of octahedral complex [Co(acac)$_2$(*N,N,N',N'*-tmen)]ClO_4, increases with a decrease in the dielectric constant of the solvents (increase in $1/\varepsilon$). This is expected from the coulombic theory of ionic association,[18]

$$\log K_a = e^2/akT \cdot 1/\varepsilon + \log K_a^\circ, \quad (7)$$

where a is the contact distance between the cation and the anion and other symbols (e, k, and T) have their usual meanings. K_a° contains the contribution to K_a for all factors, except for the long-range coulombic interaction. K_a is larger in the alcohols than in the ketones at the same dielectric constant. This larger K_a in the alcohols could be explained in terms of (1) diminution in the dielectric constant due to a breaking of the hydrogen-bonding structure in the vicinity of an ion pair and (2) a multiple-step association process occurring from the solvation of ClO_4^- by the alcohol molecules. This pattern is set up for other uni-uni-valent electrolytes such as [Co(acac)$_2$(en)]ClO_4 (en= ethylenediamine),[3-5] and R_4NClO_4 (R: alkyl group (C=2—4)).[7-9] Moreover, the K_a values of [Ni(acac)-(*N,N,N',N'*-tmen)]ClO_4 are not so much diferent from those of [Co(acac)$_2$(*N,N,N',N'*-tmen)]ClO_4. Thus, it is considered that [Ni(acac)(*N,N,N',N'*-tmen)]ClO_4 in the solvents behaves as a normal-type of uni-uni-valent electrolyte and that the nickel(II) ion does not interact with the ClO_4^- ion.

However, the K_a values of the nickel(II) chelate complex can be classified into two groups as described previously: (1) The K_a values of the nickel(II) complex

are larger than those of the cobalt(III) complex in the ketones, $PhNO_2$, and *i*-PrOH (Class I). (2) The reverse trend is obtained in EtOH, *n*-PrOH, and *n*-BuOH (Class II). Since the nickel(II) ion does not directly interact with the ClO_4^- ion, it seems that the classification can not be only attributed to the difference in the central metal ion {Ni(II) or Co(III)} and the number of the acac. Thus, it may be explained as follows: For Class I, since the nickel(II) chelate ion is present as a quadratic-planar ion, the entity is small compared to $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$. This suggests that K_a of $[Ni(acac)(N,N,N',N'\text{-tmen})]ClO_4$ should be larger than that of $[Co(acac)_2(N,N,N',N'\text{-tmen})]ClO_4$. For Class II, on the other hand, the reverse trend may be obtained due to the large volume of $[Ni(acac)(N,N,N',N'\text{-tmen})(alcohol)_2]^+$ compared with $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ (Fig. 2).

(B)[Ni(acac)(*N,N,N',N'*-tmen)]NO_3. The nitrate ion, as a bidentate ligand, can coordinate directly to $[Ni(acac)(N,N,N',N'\text{-tmen})]^+$ in organic solvents.[2] This behaviour is accounted for by two association processes, outer-sphere ionic association and the formation of an inner-sphere octahedral complex,

$$[Ni(acac)(N,N,N',N'\text{-tmen})]^+ + NO_3^- \overset{K_{a1}}{\rightleftharpoons} [Ni(acac)(N,N,N',N'\text{-tmen})]^+ \cdot NO_3^- \overset{K_{a2}}{\rightleftharpoons} [Ni(acac)(N,N,N',N'\text{-tmen})(NO_3)]. \quad (8)$$

The observed association constant (K_a) can be shown to be equal to

$$K_a = K_{a1} \cdot K_{a2}. \quad (9)$$

Table 4 shows that (1) the K_a values of the nitrate complex are larger than those of the perchlorate complex and (2) may be conveniently classified into two groups; the K_a values in the ketones, $PhNO_2$, and *i*-PrOH are remarkably larger than those in EtOH, *n*-PrOH, and *n*-BuOH. This classification is in good agreement with the classification by the color change of $[Ni(acac)(N,N,N',N'\text{-tmen})]^+$ in each solvent, Classes I and II. For Class I, the nickel(II) chelate ion in Eq. 8 is present as a quadratic-planar chelate ion, resulting in an octahedral complex $[Ni(acac)(N,N,N',N'\text{-tmen})(NO_3)]$. On the other hand, for Class II the nickel(II) chelate ion is present as an octahedral chelate ion $[Ni(acac)(N,N,N',N'\text{-tmen})(alcohol)_2]$, resulting in an octahedral complex $[Ni(acac)(N,N,N',N'\text{-tmen})(NO_3)]$ accompanied by a decoordination of two alcohol molecules from the nickel(II) ion. The coordination of anions is obtained for the copper complex in nitromethane:[1] $[Cu(acac)(N,N,N',N'\text{-tmen})]^+ + X^- \rightleftharpoons [Cu(acac)(N,N,N',N'\text{-tmen})(X)]$ (where $X^- = Cl^-$, Br^-, and SCN^-). The formation constants are large compared to that from the coulombic theory of ionic association.

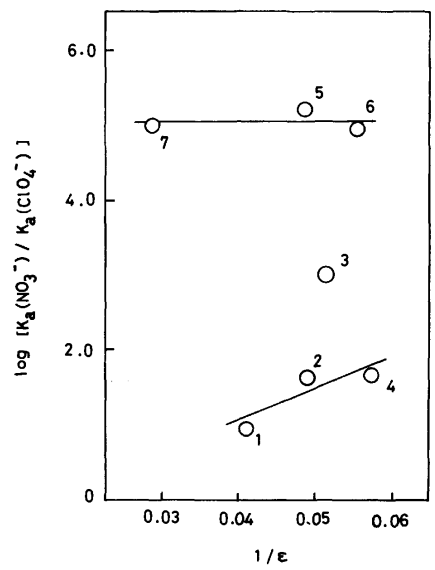

Fig. 4. The ratio of log K_a of $[Ni(acac)(N,N,N',N'\text{-tmen})]NO_3$ to $[Ni(acac)(N,N,N',N'\text{-tmen})]ClO_4$ as a function of $1/\varepsilon$ in organic solvents at 25 °C. 1, EtOH; 2, *n*-PrOH; 3, *i*-PrOH; 4, *n*-BuOH; 5, Me_2CO; 6, MEK; 7, $PhNO_2$.

The K_{a1} value in Eq. 8 seems to be roughly equal to that of the perchlorate complex, since K_a for R_4NNO_3 is similar to that for R_4NClO_4 (from the coulombic theory of ionic association) and the ClO_4^- ion does not interact with the nickel(II) ion. Thus, K_{a2} can be reasonably estimated from Eq. 9. Figure 4 shows plots of $\log K_a(NO_3^-)/K_a(ClO_4^-)$, ($\approx K_{a2}$) vs. $1/\varepsilon$. Similar K_{a2} values are obtained for Class I, indicating that coordination by solvent molecules is very weak for Class I, as discussed in a preceding section. The difference between Classes I and II is ascribed to the energy of decoordination of two alcohol molecules and the desolvation of NO_3^- by the alcohol molecules with high acidities (AN, Table 2). It is considered that the data for *i*-PrOH support the solvation of the acac by 2-propanol melecules, as shown in Fig. 2.

Zone-Melting Separation of Carbazole and Anthracene from Polynuclear Aromatic Compounds Using Biphenyl as a Medium, Followed by the Synchronous Fluorometric Determination

Masaki TACHIBANA* and Motohisa FURUSAWA
Faculty of Engineering, Yamanashi University, Takeda, Kofu 400
(Received January 14, 1989)

Biphenyl is favorable as a zone-melting medium for the selective separation of small amounts of carbazole and anthracene and a subsequent determination. A definite amount (20—100 mg) of an aromatic sample was mixed with 4 g of purified biphenyl. The mixture was zone-melted 20 times. The two analytes were accumulated in the beginning part of the zone-molten ingot, but many others were eliminated from the part. After being dissolved in xylene along with the biphenyl, carbazole and anthracene could be simultaneously determined up to 10 ng ml^{-1} by measuring the synchronous fluorescence intensities at 340 and 384 nm, respectively.

Carbazole and anthracene, widely known as constituents of coal tar, can be easily found as chief impurities in many kinds of polynuclear aromatic chemicals. These two materials may, therefore, serve as significant criteria for the purity and the origin of the products made from tar. However, it is difficult to separate and determine small amounts because of the diversity and complexity of these chemicals. Although conventional chromatographic methods are effective for the general separation of a large number of polynuclear aromatic compounds, a selective and simple method for the separation of carbazole and/or anthracene in such products is of great importance.

In the initial investigation, the authors found that the two materials in dibenzofuran are unusually concentrated in the beginning part of the ingot purified by zone melting, and that they can be selectively separated from many other analogs which are normally accumulated in the end part. Consequently, after zone melting both impurities in dibenzofuran could be simultaneously determined by synchronous fluorescence spectrometry without interference of the concomitants.[1] The advanced technique using dibenzofuran as a zone-melting medium could be applied to the determination of small amounts of anthracene in several chemicals, such as fluoranthene,[2] pyrene, anthraquinone, etc.[3] Carbazole in these chemicals, however, could not be determined because of the spectral interference of a large amount of dibenzofuran.

In the present paper the zone-melting technique was further developed by using biphenyl as an alternative medium. Since biphenyl possesses an unusual zone-melting property similar to that of dibenzofuran, carbazole and anthracene can be separated from the analogs in a similar manner. In addition, biphenyl has no effect on the synchronous measurement of carbazole since it fluoresces in a shorter wavelength region than dibenzofuran. Therefore, the two analytes separated by the zone-melting technique could be simultaneously determined by subsequent synchronous fluorimetry. In terms of the separation efficiency for anthracene, however, the biphenyl medium is not as good as the dibenzofuran medium.

Experimental

Reagents. Biphenyl was purified from commercial chemicals in the same manner as dibenzofuran: the procedure was described in detail in a previous paper.[2] Some polynuclear aromatic compounds were purified in the same way as that employed in the initial investigation.[2,3] The others were either zone-refined or used without purification. Xylene of guaranteed reagent grade was used as a solvent without further purification.

Apparatus. A new-type Shibayama SS-950 high-speed zone refiner was used for any zone-melting procedure. The new-model apparatus is identical, except for the length of the molten zone, in mechanism with the old one.[4] All measurements of the synchronous fluorescence spectra were made on a Hitachi 650-40 fluorescence spectrophotometer equipped with a Hitachi 056 recorder. The excitation and emission spectral bandpasses were always set at 2 nm. A 150-W xenon lamp was used as the excitation light source. Quartz cells of 1.00 cm in path length were used.

Zone-Melting Procedure. A definite amount (20—100 mg) of a sample was mixed with 4 g of the purified biphenyl. The mixture was charged in a glass tube of 4-mm i.d. having a silicone rubber stopper. The tube was then mounted vertically in the zone-melting apparatus. Six molten zones, each approximately 40 mm long, were produced by six ring heaters placed at equal spacings on the charge. The zones were set to travel upward at a speed of 100 mm h^{-1}, and the pass was repeated 20 times. During the travel, the zones were stirred by spinning the tube at 20 s^{-1}, with a reversal of the rotation direction at intervals of 1.0 s.

Synchronous Fluorescence Spectrometry. The zone-molten ingot was cut exactly into quarters. The lower half of the ingot was used for a simultaneous determination, the lowest quarter being for the determination of carbazole alone: the half or the quarter was dissolved in 20 ml or 10 ml of xylene. The synchronous fluorescence spectrum of the solution was measured with a wavelength interval of 6 nm. Carbazole and anthracene were determined from the intensities at 340 and 384 nm, respectively, by using the baseline method. The intensities of the two analytes in a xylene

solution (both 0.200 μg ml^{-1}) were used as the standard. Both calibration curves were prepared from their xylene solutions. The incomplete recovery of anthracene was finally corrected for.

Results and Discussion

Zone-Melting Behavior in Biphenyl. Zone-melting samples for polynuclear aromatic compounds of interest were prepared by uniformly mixing small amounts of the individual compounds with the purified biphenyl. After all these samples were zone-melted under the same conditions, the variation in the concentration of particular compounds was measured for each portion of the ingot cut into segments. The relative concentration, C/C_0, was subsequently calculated from the result, where C_0 and C are the initial and final concentrations in the biphenyl, respectively. In addition, the results of these calculations were embodied in the form of a concentration profile. The resulting profiles for carbazole and anthracene are shown in Fig. 1, and the profiles for 14 different aromatic compounds are shown in Fig. 2 (A)—(N). Figure 1 indicates that carbazole and anthracene are concentrated toward the beginning part of the zone-molten ingot. On the other hand, Fig. 2 shows that all of the analogs, which have large effects on the spectrofluorometric determination of carbazole and/or anthracene, are accumulated in the end part of the ingot, and that the extent of the accumulation is dependent on not only the species but also the content. With regard to these interfering compounds, except 5*H*-benzo[*b*]carbazole (5*H*-BC), roughly speaking, the zone-melting behavior in biphenyl was similar to that in dibenzofuran. Only the accumulation of 5*H*-BC was reversed by this biphenyl medium. The behavior of these substances indicates that the use of biphenyl as the zone-melting medium is suitable, like dibenzofuran, for the selective separation of carbazole and anthracene from the interfering analogs.

Separation of Carbazole and Anthracene from Interfering Compounds. Judging from Figs. 1 and 2, carbazole and anthracene can be separated from 20 to 100 mg of the interfering compounds, except for naphthacene and 5*H*-BC, when 4 g of biphenyl is used as the medium. It is possible to separate the two analytes from less than about 800 μg of naphthacene, but impossible to separate them from 5*H*-BC completely. The recoveries of carbazole and anthracene in the

a) The total amount of anthracene added to the medium was 2.45 μg. b) These values represent relative distances from the beginning of zone-molten ingot. d) The total recovery from the beginning is also shown.

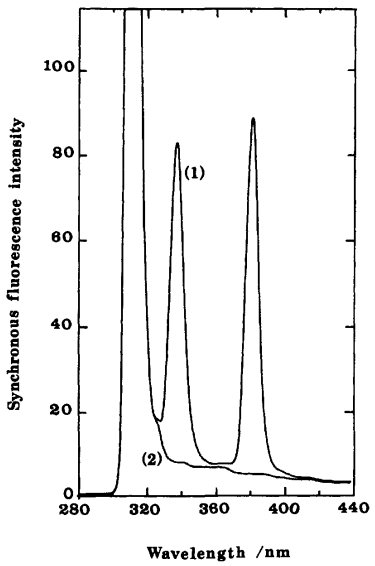

Fig. 3. Synchronous fluorescence spectra of a mixed solution of carbazole, anthracene, and biphenyl and a biphenyl solution.
Wavelength interval ($\Delta\lambda$), 6 nm; solvent, xylene; (1) carbazole (0.2 μg ml^{-1}), anthracene (0.2 μg ml^{-1}), and biphenyl (100 mg ml^{-1}); (2) biphenyl (100 mg ml^{-1}).

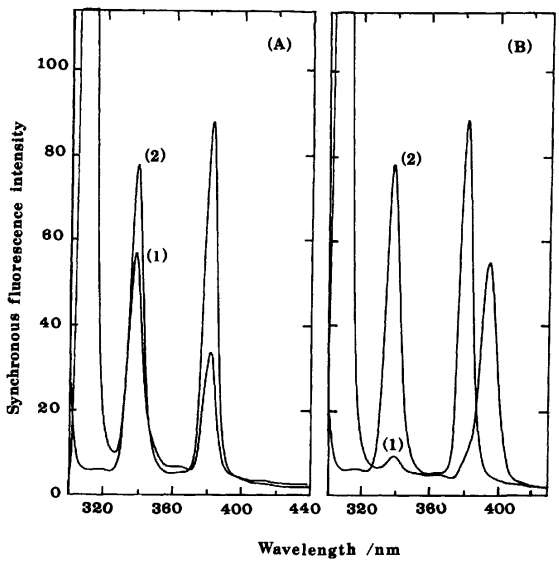

Fig. 4. Synchronous fluorescence spectra of solutions used for the determinations in the practical samples and the standard solution.
Solvent, xylene; $\Delta\lambda$, 6 nm; (A) (1) in the fluoranthene sample; (B) (1) in the chrysene sample; (A) (2) and (B) (2) the standard solution containing both carbazole and anthracene (each 0.200 μg ml^{-1}).

63 to 72% with an average of 67%, 86—91% with that of 88%, and 91—95% with that of 93%, respectively. For the reproducible recovery of anthracene, therefore, it is necessary to use at least the beginning half of the ingot. In the previous dibenzofuran medium, the recovery of anthracene had clearly increased with an increase in the content of other concomitant compounds.[2,3] In this medium, however, such an effect on the recovery could not be definitely observed.

Determinations by Synchronous Fluorescence Spectrometry. Since the simultaneous determination by synchronous fluorimetry has already been reported in the previous papers,[1,5] only the effect of biphenyl on the two analytes was studied. The synchronous fluorescence intensities of carbazole and anthracene gradually increased and decreased, respectively, with an increase in the biphenyl concentration. The variations, however, were so small that the effect of

biphenyl could almost be neglected over the wide concentration range from 0 to 180 mg ml^{-1}. Figure 3 (1) represents the spectrum of a ternary solution of biphenyl (100 mg ml^{-1}), carbazole (0.2 μg ml^{-1}), and anthracene (0.2 μg ml^{-1}). The spectrum has three peaks attributable to these three compounds, and their peaks are well-resolved from one another. Consequently, carbazole and anthracene can be successfully determined even in the presence of biphenyl. Calibration curves were prepared by using xylene solutions containing both analytes (0—0.2 μg ml^{-1}), the 0.2-μg ml^{-1} solution being used as the standard. Each of the resulting curves gave a linear relationship between the intensity and the concentration. Both analytes can be determined up to 10 ng ml^{-1} by using the calibration curves.

Application to Practical Samples. The present method was applied to commercially available fluoranthene and chrysene. The zone-molten ingot obtained by treating the fluoranthene sample (100 mg) was cut in two, and the lower half was dissolved in 20 ml of xylene. The solution was further diluted 4 times with xylene. The synchronous fluorescence spectrum of the dilute solution is illustrated in Fig. 4 (A), as well as the standard solution. The spectrum has peaks at 340 and 384 nm, which agree well with those of the standard solution: each analytical value was 106 and 59 ppm, respectively. Next, the spectrum measured for the determination of carbazole in chrysene is shown in Fig. 4 (B). It was obtained by using 20 mg of chrysene as the sample size, cutting the lowest quarter of the zone-molten ingot away, dissolving it in 10 ml of xylene, and diluting the solution 10 times. No anthracene could be determined because the 5*H*-BC contained as a concomitant impurity was inseparable and influential. For the determination of carbazole, however, the interference of 5*H*-BC could be neglected by using a sufficiently dilute solution of the zone-molten sample: the carbazole content was 40 ppm. The above solutions used for these determinations did not show absorption based on interfering impurities at the characteristic wavelengths to be measured. Therefore, the proposed method in the present paper can be applied to such practical samples.

Spectroscopic and Electrochemical Characterization of 18-Molybdodisulfate(VI)(4−), $S_2Mo_{18}O_{62}^{4-}$

Sadayuki HIMENO,* Toshitaka HORI,† and Atsuyoshi SAITO
Department of Chemistry, College of Liberal Arts, Kobe University, Kobe 657
†Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Kyoto 606
(Received October 13, 1988)

The formation conditions of a yellow Dawson-type $S_2Mo_{18}O_{62}^{4-}$ anion have been investigated as functions of the concentrations of Mo(VI), H_2SO_4, organic solvents, the nature of the organic solvents used, temperature of the solution, and the reaction time. For a 50 mM Mo(VI)/50% (v/v) acetonitrile system, the yellow $S_2Mo_{18}O_{62}^{4-}$ anion formed in 0.2—1.0 M H_2SO_4, while a pale-yellow $Mo_6O_{19}^{2-}$ anion did in 0.04—0.3 M H_2SO_4. The yellow heteropolyanion is electrochemically reduced in six successive steps to mixed-valence heteropoly blues at the glassy carbon electrode. Each of the first four waves corresponds to a reversible two-electron transfer. The mixed-valence blue species were characterized by their inherent visible and infrared (IR) spectra.

The so-called Dawson-type heteropolyanion was first reported for $P_2W_{18}O_{62}^{6-}$ by Dawson and then for $P_2Mo_{18}O_{62}^{6-}$ by Strandberg.[1,2] In addition, $As_2W_{18}O_{62}^{6-}$ and $As_2Mo_{18}O_{62}^{6-}$ anions are known to exist.[3,4] These heteropolyanions have been extensively studied with respect not only to the crystal structures and physical properties in the solid state, but also to the chemical natures in the solution state where they are electroreduced in multi-steps to mixed-valence blue species.[5–7] Nowadays, these behaviors are comprehensively explained in relation to those of the corresponding Keggin-type heteropolyanions.[8] However, there are no previous studies on heteropolyanions with SO_4^{2-} as a central tetrahedron because of the lack of proper examples except for the $S_2V_2W_{16}O_{62}^{6-}$ anion.[9]

In the presence of organic solvents such as acetone and acetonitrile, acidified Mo(VI) solutions become pale-yellow due to the formation of $Mo_6O_{19}^{2-}$.[10–13] When H_2SO_4 was used for the acidification, the yellow color became more intense by heating and the resulting orange-yellow solution changed to blue by chemical and electrochemical reductions. These results show strong promise of the formation of a heteropolymolybdosulfate because the reduction of $Mo_6O_{19}^{2-}$ yields a brown solution.[14] Actually, an orange-yellow heteropolyanion was isolated as tetraalkylammonium salts (R_4N^+ salts, R=CH_3, C_2H_5, and n-C_4H_9) from a Mo(VI)/H_2SO_4/CH_3CN system.[15] Recently, the crystal structural analysis demonstrated the existence of the Dawson-type molybdosulfate anion, $S_2Mo_{18}O_{62}^{4-}$ with SO_4^{2-} anions as central tetrahedra.[16]

The present paper describes the chemical and physicochemical properties of the yellow Dawson-type molybdosulfate anion in solutions, regarding to the optimum formation conditions, ultraviolet(UV)-visible spectroscopic characteristics, and electrochemical behaviors. In addition, mixed-valence blue species are identified by visible and IR spectroscopy.

Experimental

Voltammetric measurements were made on a PARC 174-A polarographic analyzer equipped with a Yokogawa Hokushin Electric 3023 X-Y recorder. A Tokai glassy carbon (GC-30S) with a surface area of 0.071 cm^2 was used as a working electrode. Controlled potential electrolysis (CPE) was carried out with a Hokuto Denko HA-501 potentiostat. A Hokuto Denko HF-202D coulometer was used for coulometric experiments. Glassy carbon fibers (GC-20) were employed as a working electrode. A platinum wire was used as a counter electrode and a saturated calomel electrode (SCE) served as the reference electrode. UV-visible spectra were recorded on a Hitachi 220-A spectrophotometer equipped with a constant temperature housing for the cell. UV-visible spectrophotometric and voltammetric measurements were made at 25±0.1 °C. IR spectra were recorded on a Hitachi 270-30 spectrophotometer as KBr pellets. The TG-DTA measurements were carried out with a Rigaku Denki 8002-SD thermal analyzer.

All reagents were of analytical grade and were used without further purification. Molybdenum(VI) solutions were prepared from $Na_2MoO_4 \cdot 2H_2O$.

The Et_4N^+ and n-Bu_4N^+ salts of the yellow molybdosulfate, $(Et_4N)_4S_2Mo_{18}O_{62}$ and $(n\text{-}Bu_4N)_4S_2Mo_{18}O_{62}$ prepared according to ref. 15 were purified further by recrystallization from neat CH_3CN. As already described,[16] the crystals contain the solvent molecule of CH_3CN as a constituent. The TG-DTA analysis for the crystals showed that they lost the CH_3CN molecule around 130 °C via an endothermic process. The crystals were heated at 130 °C for several hours to let the solvent molecule liberate. The fine powders thus obtained were used for preparing solutions of a given concentration of the heteropolyanion.

Results and Discussion

UV-Visible Spectroscopic Measurements. The R_4N^+ salts of the $S_2Mo_{18}O_{62}^{4-}$ anion are soluble in organic solvents such as acetonitrile, acetone, and dimethyl sulfoxide, giving rise to yellow solutions. Curve a of Fig. 1 shows a UV-visible spectrum of 1.98×10^{-5} M (M=mol dm^{-3}) $S_2Mo_{18}O_{62}^{4-}$ in CH_3CN. The complex anion shows a broad absorption band in

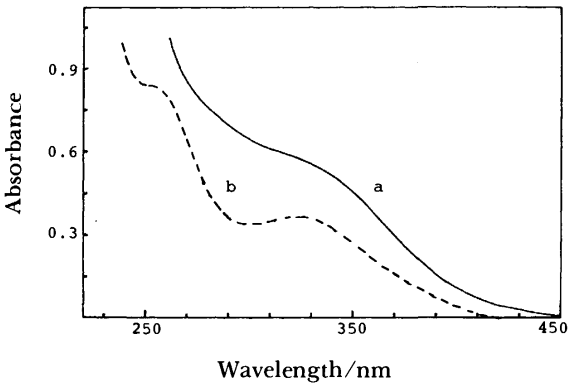

Fig. 1. UV-visible spectra of 1.98×10^{-5} M $S_2Mo_{18}O_{62}^{4-}$ in a, neat CH_3CN and b, 90% (v/v) CH_3CN–water.

the 270—450 nm range. The spectrum in neat CH_3CN was unchanged for at least one month, and conformed to Beer's law in the whole spectral region studied, the molar absorption coefficient at 330 nm being calculated as 2.71×10^3 cm^{-1} M^{-1}.

With the addition of water by more than 5% (v/v), however, the color of the solution changed gradually to pale-yellow. In the presence of 10% (v/v) water, for example, the spectrum was converged in 24 h to that shown in curve b of Fig. 1. The ultimate spectrum with absorption maxima at 257 and 325 nm is attributed not to the reformation of other-type heteropolyanions, but to the hexamolybdate, $Mo_6O_{19}^{2-}$.[11,13] The decomposition was retarded by the presence of 1.0 M $HClO_4$ in the solution, where the spectrum was unchanged for a week. On the basis of these facts, the hydrolytic decomposition of the heteropolyanion proceeds according to the reaction:

$$S_2Mo_{18}O_{62}^{4-} + 3H_2O = 3Mo_6O_{19}^{2-} + 2SO_4^{2-} + 6H^+$$

In the presence of 1.0 M HCl or 1.0 M H_2SO_4 in place of the $HClO_4$, on the other hand, the heteropolyanion decomposed within several hours to give colorless solutions, which is due to the formation of colorless molybdenum(VI)-chloro or molybdenum(VI)-sulfato complexes.[17–19]

Formation of the $S_2Mo_{18}O_{62}^{4-}$ Anion in the Mo(VI)/H_2SO_4/CH_3CN System. In order to confirm the conditions for the formation of the $S_2Mo_{18}O_{62}^{4-}$ anion, absorbance measurements were made for the Mo(VI)/H_2SO_4/CH_3CN system. Firstly, a series of 50 mM Mo(VI) solutions containing 50% (v/v) CH_3CN and various concentrations of H_2SO_4 (0.02—1.2 M) were prepared. When stood for 3 h at 25 °C, the solutions turned to pale-yellow in the H_2SO_4 concentration range 0.04—0.4 M. The absorbances at 410 nm are plotted against the H_2SO_4 concentration and shown in curve a of Fig. 2, where absorbances have a maximum around the H_2SO_4 concentration of 0.06 M. By the addition of R_4NBr to

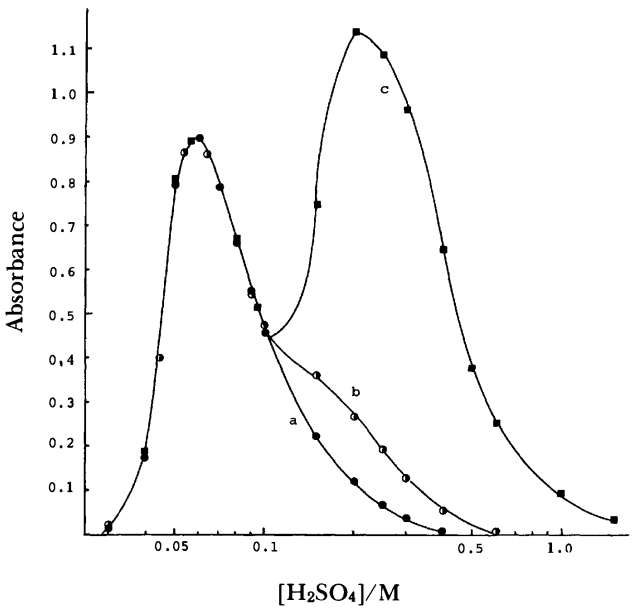

Fig. 2. Absorbances at 410 nm for 50 mM Mo(VI) in 50% (v/v) CH_3CN containing various concentrations of H_2SO_4. Measured after standing a, at 25 °C for 3 h; b, at 25 °C for 24 h; c, at 50 °C for 24 h. Path length, 1 cm.

the solution, pale-yellow precipitates were obtained, being identified as $(R_4N)_2Mo_6O_{19}$ by elemental analysis and IR spectroscopy.[13] When solutions stood for 24 h at 25 °C, absorbances in the H_2SO_4 concentration range >0.2 M were found to increase, while absorbances remained unchanged in the range <0.1 M where $Mo_6O_{19}^{2-}$ was formed. This result, which has been overlooked so far, is well illustrated in curve b. The absorbance grew rather slowly at 25 °C but the absorbance increase was remarkably accelerated by heating of the solution. Curve c shows absorbances after standing at 50 °C for 24 h. Orange-yellow precipitates occurred by the addition of R_4NBr to the yellow solutions in the H_2SO_4 concentration range 0.4—0.8 M. The IR spectrum of the precipitate is in good agreement with that of the authentic $(R_4N)_4S_2Mo_{18}O_{62}$ (vide infra), which indicates that the absorbance increase in the H_2SO_4 concentration range >0.2 M is due to the formation of the yellow $S_2Mo_{18}O_{62}^{4-}$ anion. In conclusion, the $S_2Mo_{18}O_{62}^{4-}$ anion occurs at higher acidities than $Mo_6O_{19}^{2-}$ anion, each anion being distinguishable by the region and condition of formation.

The effect of the Mo(VI) concentration on the complex formation was studied in 50% (v/v) CH_3CN containing 0.4 M H_2SO_4. Absorbances at 400 and 430 nm were measured at 25 °C after standing at 70 °C for 2 h, and plotted against the Mo(VI) concentration in Fig. 3. It was observed that the complex formation became appreciable only at Mo(VI) concentrations >30 mM. Finally, the effect of the CH_3CN concentration (0—80% (v/v)) was investigated. The presence of

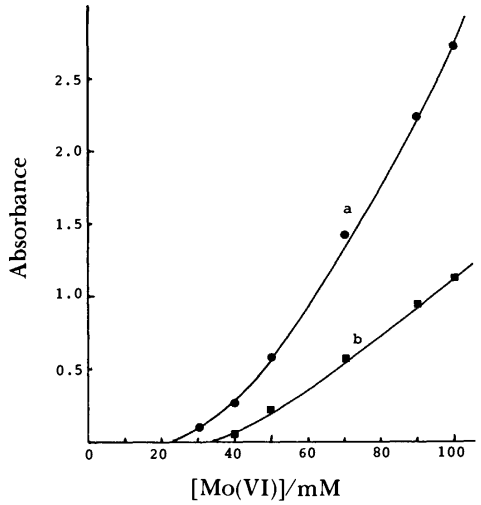

Fig. 3. Effect of Mo(VI) concentrations on absorbances after standing at 70°C for 2 h in 50% (v/v) CH_3CN containing 0.4 M H_2SO_4. Wavelength/nm; a, 400; b, 430. Path length, 1 cm.

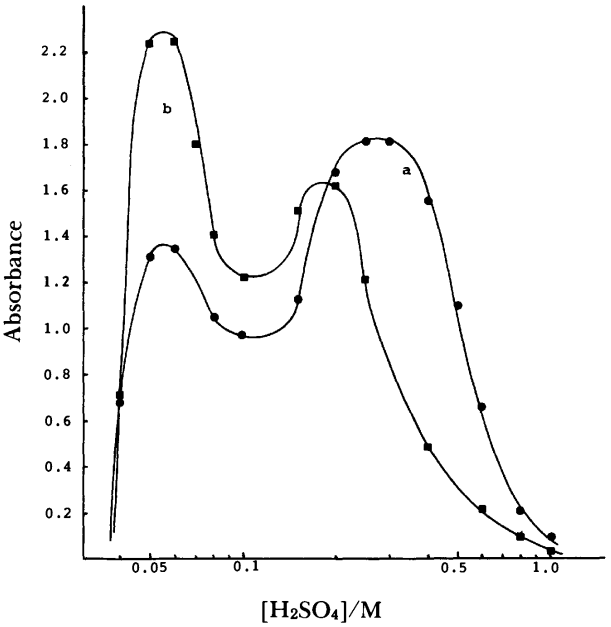

Fig. 4. Absorbances after standing at 50°C for 24 h for 50 mM Mo(VI) in 50% (v/v) a, acetone (400 nm); b, 1,4-dioxane (410 nm) containing various concentrations of H_2SO_4. Path length, a, 2 mm; b, 1 cm.

CH_3CN at concentrations <20% (v/v) had no effect but yellow solutions due to the formation of the $S_2Mo_{18}O_{62}^{4-}$ anion resulted at concentrations >30% (v/v). Adsorbance values increased as the CH_3CN concentration was increased. In the presence of CH_3CN at concentrations >60% (v/v), however, the system separated into two-phases; the $S_2Mo_{18}O_{62}^{4-}$ anion is extracted into the upper layer.

The complex formation is also facilitated in the presence of acetone and 1,4-dioxane. Similar experiments were carried out for the Mo(VI)/H_2SO_4 system containing 50% (v/v) acetone or 1,4-dioxane. The absorbances were measured at 400 nm (for the acetone system) and at 410 nm (for the 1,4-dioxane system) after standing at 50 °C for 24 h. The results are illustrated by curves a and b in Fig. 4. Both curves are similar in shape to curve c of Fig. 2, in that the heteropolyanion is formed at higher acidities than $Mo_6O_{19}^{2-}$; the $S_2Mo_{18}O_{62}^{4-}$ anion can be separated from the $Mo_6O_{19}^{2-}$ anion.

Voltammetric Measurements. Figure 5 shows a typical cyclic voltammogram of 8.33×10^{-5} M $S_2Mo_{18}O_{62}^{4-}$ in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$. The voltammogram consists of six cathodic and six anodic waves under these conditions. The peak potentials (E_p's) for the cathodic waves are: +0.53, +0.43, +0.24, −0.06, −0.20, and −0.24 V. Of these, the fifth cathodic wave is observed as a shoulder and the sixth wave is rather unusual in shape. The anodic peaks occurred at +0.55, +0.45, +0.27, −0.04, and −0.18 V; the sixth anodic wave appeared only as a shoulder. The waves are numbered in the direction of more cathodic potentials. For the first four waves, each peak potential is independent of scan rate, v, and each current function $i_p/v^{1/2}$ is constant, i_p being the

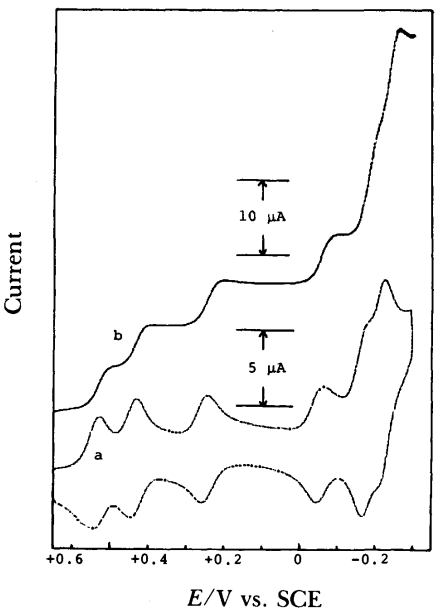

Fig. 5. A cyclic voltammogram (a) and a normal pulse polarogram (b) of 8.33×10^{-5} M $S_2Mo_{18}O_{62}^{4-}$ in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$. Scan rate/mV s^{-1}; a, 100; b, 10.

peak current. The cathodic-to-anodic i_p ratio is one. These results show that each step is diffusion-controlled. The separation of the cathodic and anodic peak potentials for each couple is 28±3 mV, which indicates that these waves are reversible two-electron waves. Coulometric analysis showed that each of the first four reductions consumed two-electrons per the

$S_2Mo_{18}O_{62}^{4-}$ anion. The E_p's shifted to more positive potentials with an increase in the $HClO_4$ concentration. The E_p's for the first four reductions were measured in 95% (v/v) CH_3CN solutions with various concentrations of $HClO_4$ (0.01—0.1 M) which were kept at constant ionic strength of 0.1 with $NaClO_4$. Plots of E_p's against the logarithm of the $HClO_4$ concentration yielded straight lines with a common slope of 60±5 mV, indicating that two protons are consumed for each step of the first four reduction waves.

CPE at each of the first four steps was carried out for 1.0×10^{-4} M $S_2Mo_{18}O_{62}^{4-}$ in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$. Figure 6 shows visible spectra of the solutions obtained. When CPE was made at +0.50 V, a blue solution was obtained, showing a round maximum around 760 nm (curve a). When electrolyzed at +0.35 V, the maximum shifted to 690 nm. As the degree of reduction further proceeded, the blue color became more intense. The spectrum for a 6-electron reduction species was characterized by two maxima around 670 and 790 nm (curve c). Curve d is the spectrum for a 8-electron reduction species, showing a maximum at 570 nm with a round shoulder around 700 nm. Each of 2-, 4-, 6-, and 8-electron reduction species is stable in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$. When reoxidized at +0.80 V, the respective blue species were reverted to the original yellow species, which was identified by IR measurements.

As shown in Fig. 5, the peak separation between the fifth and sixth waves is so small that it is difficult to obtain the visible spectrum for the blue solution by CPE at the fifth step. However, the visible spectrum obtained by CPE at the sixth step (at −0.30 V) was identical in shape with that of the 8-electron reduction species shown in curve d. As CPE at −0.30 V progressed, the spectrum showed a gradual absorbance decrease in the range 450—900 nm. Finally a colorless solution resulted, indicating the decomposition of the heteropolyanion. These observations suggest that the 8-electron reduction species accepts further electrons with the subsequent decomposition.

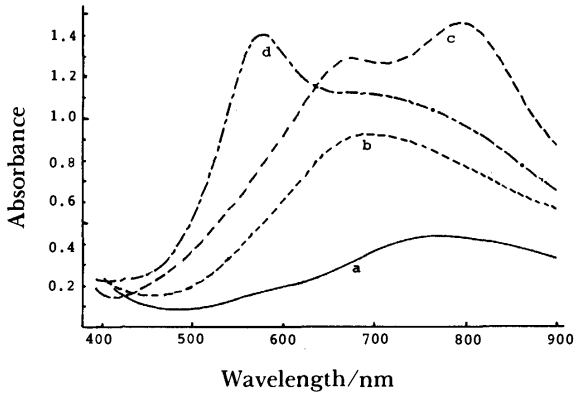

Fig. 6. Visible spectra of the reduced species for 1.0×10^{-4} M $S_2Mo_{18}O_{62}^{4-}$ in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$. a, b, c, d; 2-, 4-, 6-, and 8-electron reduction species, respectively. Path length, 5 mm.

As shown in curve b of Fig. 5, six reduction waves were observed in normal pulse polarography. Their approximate current ratios are 1:1:1:1:2:2, fitting the 2:2:2:2:4:4 electron ratios. In normal pulse polarography, short potential pulses (57 ms) are applied so that the electrode is at its initial potential most of the time. Therefore the effect of the decomposition may not be observed.

The reduction process of $S_2Mo_{18}O_{62}^{4-}$ is summarized as follows:

$$S_2Mo_{18}O_{62}^{4-} + 2H^+ + 2e = H_2S_2Mo^{V}_2Mo^{VI}_{16}O_{62}^{4-}$$

$$H_2S_2Mo^{V}_2Mo^{VI}_{16}O_{62}^{4-} + 4H^+ + 4e = H_6S_2Mo^{V}_6Mo^{VI}_{12}O_{62}^{4-}$$

$$H_6S_2Mo^{V}_6Mo^{VI}_{12}O_{62}^{4-} + 2H^+ + 2e = H_8S_2Mo^{V}_8Mo^{VI}_{10}O_{62}^{4-}$$

$$H_8S_2Mo^{V}_8Mo^{VI}_{10}O_{62}^{4-} + 4e \longrightarrow \text{unstable species}$$

IR Spectroscopic Measurements. Figure 7 shows IR spectra for Et_4N^+ salts of 2- and 4-electron reduction species in addition to the yellow species. As for the yellow species, as reported previously,[15] bands in the range 1500—1350 cm^{-1} are due to the Et_4N^+ unit, and bands at 1170 and 1070 cm^{-1} can be assigned to the asymmetric and symmetric stretches of the S-O bond. In the Mo-O stretching and bending region (<1000 cm^{-1}), the strong band at 960 cm^{-1} can be assigned to $Mo{=}O_{terminal}$ bonds. In addition, a weak band at 880 cm^{-1} and a broad band at 785 cm^{-1} are observed. Thouvenot et al. have made a systematic vibrational study of $XMo_{12}O_{40}^{n-}$ salts related to the Keggin

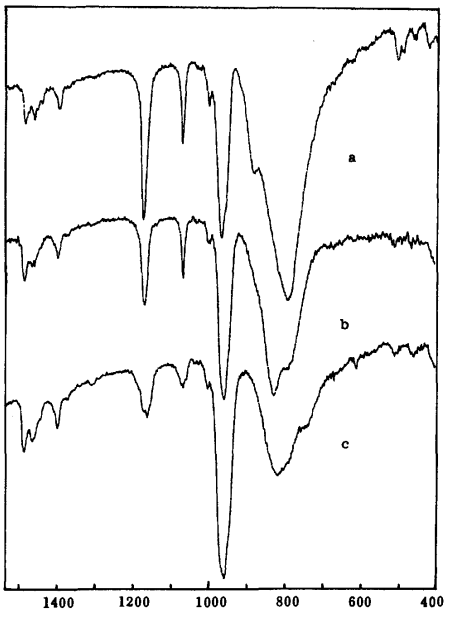

Fig. 7. IR spectra of Et_4N^+ salts of heteropolymolybdosulfates. a, the yellow species; b, 2-electron reduction species; c, 4-electron reduction species.

structure.[20] According to them, bands in the range 890—850 cm^{-1} correspond to inter Mo–O–Mo bridges between corner-sharing octahedra, and bands in the range 800—760 cm^{-1} to intra Mo–O–Mo bridges between edge-sharing octahedra. Both bands at 880 and 785 cm^{-1} are situated within the region predicted by them. In addition to these strong bands, the spectrum contains weak bands at 504, 492, 460, and 420 cm^{-1} to which no assignments can be made.

To obtain the salt of blue species, n-Bu_4N^+ salts of the yellow heteropolyanion were dissolved in 95% (v/v) CH_3CN containing 0.1 M $HClO_4$ and electrolyzed by CPE at +0.50 and +0.35 V. During the electrolysis, the solution was purged with N_2 gas to avoid possible reoxidation by dissolved oxygen. At the end of each electrolysis, Et_4NBr was added to the solution, and the Et_4N-salts of 2- and 4-electron reduction species were obtained. The 4-electron reduction species was also synthesized by CPE of the 0.1 M Mo(VI)/1.5 M H_2SO_4/40% (v/v) CH_3CN system at −0.10 V.[21] As the degree of reduction proceeded, as shown in curves b and c of Fig. 7, both bands due to the S–O bond decreased in intensity with a simultaneous shift to shorter wave numbers. Simultaneously, intensities of bands due to the Mo–O–Mo bridges decreased, while the band due to the $Mo{=}O_{terminal}$ bond remained unchanged. Similar behavior has been reported for the $PMo_{12}O_{40}^{3-}$ salt known as the Keggin structure.[22,23]

Molecular Recognition in the Formation of Conglomerate Crystal. 2. The Role of Arenesulfonic Acid in the Conglomerate Crystals of Amino Acid Salts

Hiroki KIMOTO, Kazuhiko SAIGO,* Yuji OHASHI,† and Masaki HASEGAWA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 9, 1988)

The structures of conglomerate crystals, *p*-chlorobenzenesulfonic acid salt of L-alanine, *p*-toluenesulfonic acid salt of L-serine, and benzenesulfonic acid salt of L-leucine, were determined by X-ray analysis. The crystals are built up of repeating units consisting of two amine components and two acid components to form a helical column by hydrogen bonds. The arrangements of the arenesulfonic acids are found to be similar to each other in these systems. Moreover, the arrangements have similarity to those of cinnamic acid in the crystals of cinnamic acid salts of (*R*)-1-phenylethylamine and of (*R*)-1-(4-isopropylphenyl)ethylamine, which are also conglomerates. These results suggest that our proposed criteria for the choice of an achiral derivatizing agent in the transformation of a racemic compound into a conglomerate crystal is appropriate.

The diastereomeric salt method is the most popular in the optical resolution. But, in the resolution, a stoichiometric amount of an optically pure compound is usually required as a resolving agent, and it is difficult to get both enantiomers from a racemic modification by a simple operation.[1] Although this difficulty can be solved by the preferential crystallization method, this method is applicable to only uncommon conglomerate crystals. They are ascertained by trial-and-error procedure using an achiral derivatizing agent.[1] Then, it is worthy to find the criteria for the choice of an achiral compound in the transformation of a racemic compound into a conglomerate crystal. In the previous paper,[2] we reported the structures of two conglomerate crystals, cinnamic acid salts of α-substituted benzylamine derivatives, and proposed the criteria on the structural requirement for an achiral acid in the transformation of a racemic amine into a conglomerate crystal.

On the other hand, it is already known that the arenesulfonic acid salts of some amino acids are also conglomerate crystals.[3–6] We report here the crystal structures of three conglomerate crystals, *p*-toluenesulfonic acid salt of L-serine (**1**), *p*-chlorobenzenesulfonic acid salt of L-alanine (**2**), and benzenesulfonic acid salt of L-leucine (**3**) to verify our hypotheses for the transformation.

Experimental

Crystal Structure Determination. Colorless plate-like crystals, **1**, **2**, and **3** were grown from saturated aqueous solutions of equimolar mixtures of the amino acids and the arenesulfonic acids, respectively. The specimen used was a fragment of a plate. The space group was determined by

photographs. Data were collected up to $2\theta=125°$ on a Rigaku four-circle diffractometer using graphite-monochromated Cu $K\alpha$ (1.5418 Å) radiation by ω-2θ scan. Standard reflections showed no significant intensity change. Of unique reflections measured, those as observed with $|F_o|>3\sigma(|F_o|)$ were used. The intensities were corrected for Lorentz, polarization, but not for absorption nor extinction. The structure was solved by the direct method (MULTAN 78[7]) and was refined by the full-matrix least-squares (SHELX 76[8]). Crystal data and details of refinement are summarized in Table 1. Scattering factors were taken from "International Tables for X-ray Crystallography".[9] Computations were performed on Hitachi M-680H and M-682H in the Computer Centre of the University of Tokyo.

Results and Discussion

Fractional coordinates for the crystals of **1**, **2**, and **3** are given in Tables 2, 3, and 4, respectively.[10] Labeled

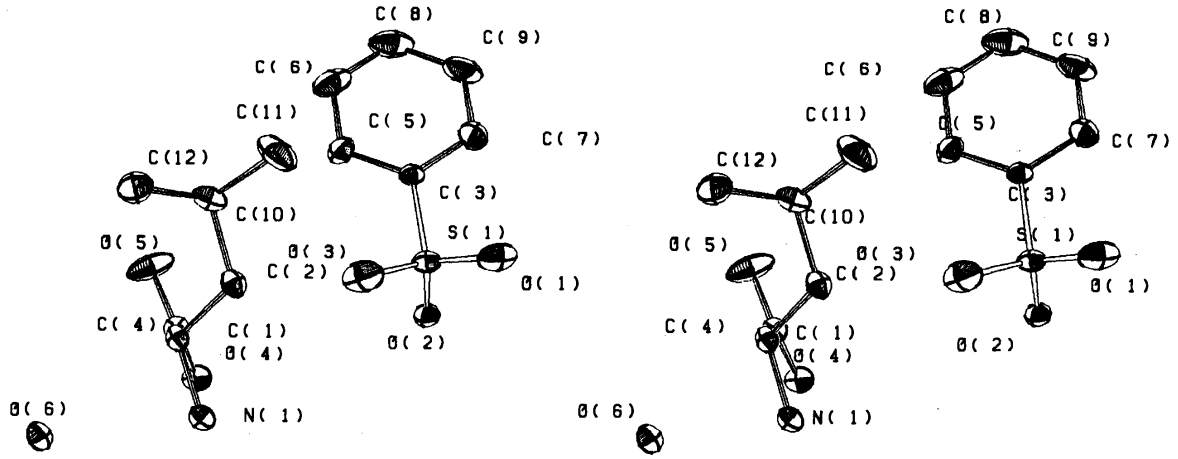

Fig. 3. Labeled stereoscopic drawing of **3**.

stereoscopic drawings of the crystals of **1**, **2**, and **3** are given in Figs. 1, 2, and 3, respectively. Their bond distances and angles are given in Tables 5, 6, and 7, respectively.

In the crystal of **1**, there are three distinct hydrogen bonds, by which two amine components and two acid components form a helical column along the *c* axis (Fig. 4). Moreover, two other hydrogen bonds exist. One links up the hydroxyl group in a molecule of serine with the carboxyl group in the neighboring molecule of serine. They are related by the operation: $x, y, -1+z$. And the other exists between the carboxyl group in serine and the oxygen atom in *p*-toluenesulfonic acid to combine two neighboring columns which are related by the operation: $-1+x, y, -1+z$. The geometries of the hydrogen bonds are listed in Table 8. There is no unusually short contact other than the hydrogen bonds.

In the crystal of **2**, two amine components and two acid components are also arranged to form a helical column by four distinct hydrogen bonds along the *a*

The geometries of the hydrogen bonds are listed in Table 8.

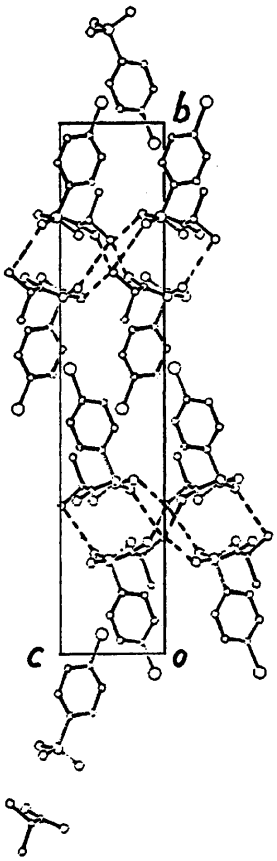

Fig. 5. The crystal structures of **2** viewed along the *a* axis. Hydrogen bonds are shown by dashed lines.

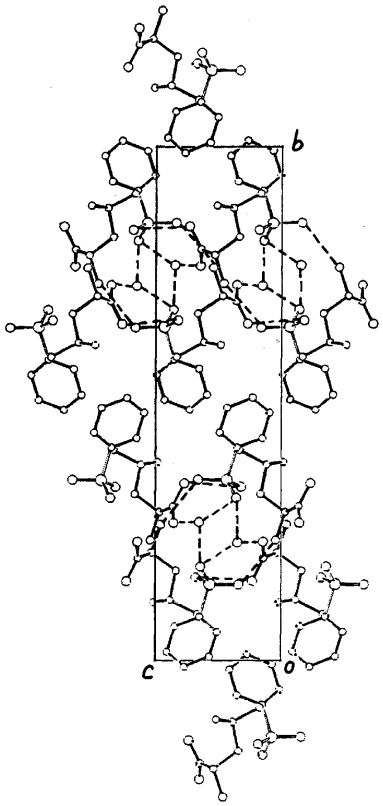

Fig. 6. The crystal structures of **3** viewed along the *a* axis. Hydrogen bonds are shown by dashed lines.

Crystals of **1**, **2**, and **3** are built up, in a similar fashion, by three distinct hydrogen bonds between two amine components and two acid components to form helical columns along the axis. This structural similarity is also observed for the crystals of cinnamic acid salts of (*R*)-1-phenylethylamine (**4**) and of (*R*)-1-(4-isopropylphenyl)ethylamine (**5**).[2] Figure 7 shows the helical columns in **1**, **2**, **3**, **4**, and **5**. Every helical column is found to be supported by repeating helical hydrogen networks.

The crystal of **1** has the same repeating unit as those of the crystals of **4** and **5**, containing one nitrogen in a molecule of the amine component and two oxygens in a molecule of the acid component. The crystal of **1** also has another hydrogen bond, which combines the amine component with the acid component, to fix the column tightly as observed in the crystals of **4** and **5**. Moreover, in the case of the crystal of **1**, one more distinct hydrogen bond exists between the carboxyl group in the amino acid component and the hydroxyl group in the neighboring acid component. They are related by the operation: x, y, $-1+z$. On the other hand, in the crystals of **2** and **3**, the repeating unit includes uniquely a part of amino acids (N-C-C-O). To support the helical hydrogen networks in each column tightly, another distinct hydrogen bond exists between two amino acid components. The repeating units and the supporting hydrogen bonds in each crystal are denoted by dashed and waved lines, respectively, in Fig. 7.

The analyses of these crystals show that conglomerate crystals of amino acid salts include a unique part of the amino acid (N-C-C-O) in the helical column, except for the case like **1** with the hydroxyl group, which can make hydrogen bonds. But, as shown in Fig. 7, the alternate arrangement of the arenesulfonic acid and the amino acid components in the crystals of **1**, **2**, and **3** is essentially the same as those of cinnamic acid and the amine components in the crystals of **4** and **5**. Moreover, arenesulfonic acid is also a rigid molecule like cinnamic acid. The rigidity would prevent the molecule of the amino acid from contacting each other by strong hydrogen bonds.

The appropriate R^1 and R^2 groups tightly pack two neighboring columns, which are related by twofold screw axis. The schematic drawing is shown in Fig. 8. The helical column is denoted by the thick line. Benzene rings in neighboring columns are arranged parallel each other to interact by π-π orbitals. The π-π interaction is denoted by dashed line. Compared with the crystal of **3**, the crystal of **2** has leucine bigger than that of alanine, and benzenesulfonic acid smaller than *p*-chlorobenzenesulfonic acid. The fact suggests that

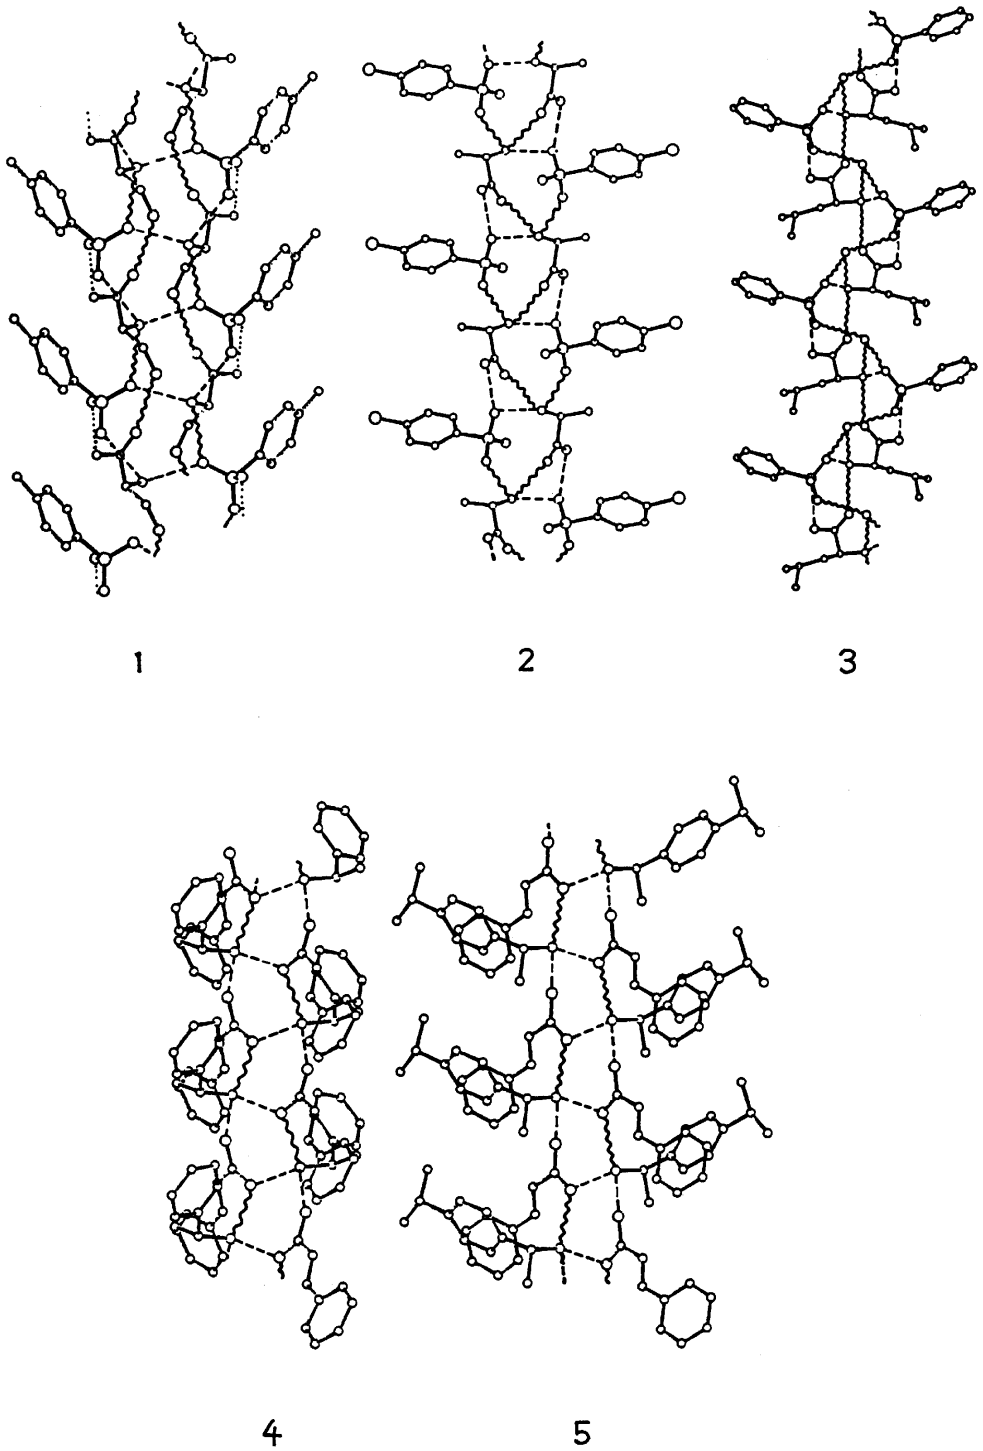

Fig. 7. A helical column in each crystal of **1**, **2**, **3**, **4**, and **5**. Hydrogen bonds are shown by dashed, waved and dotted lines. **1**: *p*-toluenesulfonic acid salt of L-serine, **2**: *p*-chlorobenzenesulfonic acid salt of L-alanine, **3**: benzenesulfonic acid salt of L-leucine, **4**: cinnamic acid salt of 1-phenylethylamine, **5**: cinnamic acid salt of 1-(4-isopropylphenyl)ethylamine.

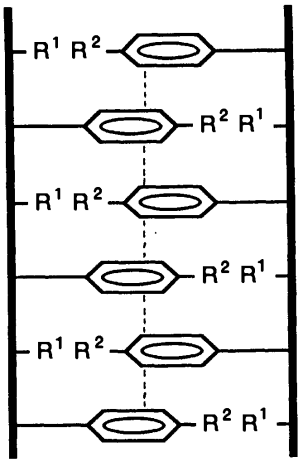

Fig. 8. The schematic drawing of the helical column. **1**: R^1=H and R^2=Me. **2**: R^1=Me and R^2=Cl. **3**: R^1=H and R^2=Pr^i. **4**: R^1=H and R^2=Ph **5**: R^1=H and R^2=$C_6H_4Pr^i$-*p*.

bigger R^1 paired with smaller R^2 makes the crystal packing close by π-π interaction. In the crystal of **1**, R^1 is rather small because hydroxymethyl group is oriented along the column by a hydrogen bond, and paired acid has methyl group bigger than hydrogen as R^2.

These results indicate that the shape of the arenesulfonic acid plays an important role to form a rigid helical arrangement and to offer suitable space for the amino acid molecule. Namely, the following criteria proposed by us are considered to be appropriate for the choice of an achiral derivatizing agent in the transformation of a racemic compound into a conglomerate crystal: (a) The achiral derivatizing agent should be able to form a helical column by hydrogen bonds with the molecule of the racemic compound; (b) The derivatizing agent should be rigid and flat to limit the orientation of the molecules of the racemic compound; (c) The sizes of the derivatizing agent and the molecule of the racemic compound should be complementary to make the crystal packing close.

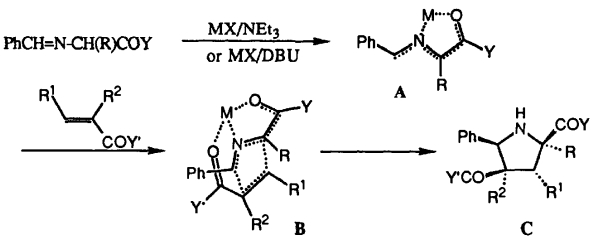
Generation of an *N*-Sodioazomethine Ylide and Its Cycloadditions with α,β-Unsaturated Esters

Shuji KANEMASA,* Manabu YOSHIOKA, and Otohiko TSUGE*
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received December 21, 1988)

Treatment of methyl 2-(benzylideneamino)propanoate with sodium hydride in THF generates an *N*-sodioazomethine ylide, which shows a very poor stereoselectivity in the cycloaddition with methyl acrylate. However, addition of such a base as triethylamine or *t*-butyl alcohol improves the selectivity. Chemical properties of the ylide have been discussed on the basis of the selectivity totally different from that of *N*-lithio analogue.

N-Metalated azomethine ylides **A**, the ylide of new type, can be generated upon treatment of imines [PhCH=NCH(R)COY] of α-amino esters and amides with tertiary amines in the presence of metal halides.[1-3] These ylides show increased reactivity in their cycloadditions and high reliability in stereochemical selectivities. A variety of metals such as lithium, magnesium, zinc, aluminum, and silver can be incorporated; metal-chelated intermediates **B** are responsible for the highly stereoselective cycloadditions with carbonyl-activated olefins [$R^1CH=C(R^2)COY'$] leading to **C**.



In this ylide generation scheme, ylide species **A** are always accompanied by the formation of an equimolar amount of acidic products, trialkylammonium halides, which can act as a quencher of the anionic intermediates involved. Therefore, the ylide generation using tertiary amine is a reversible process, causing the undesired formation of Michael adducts.[2]

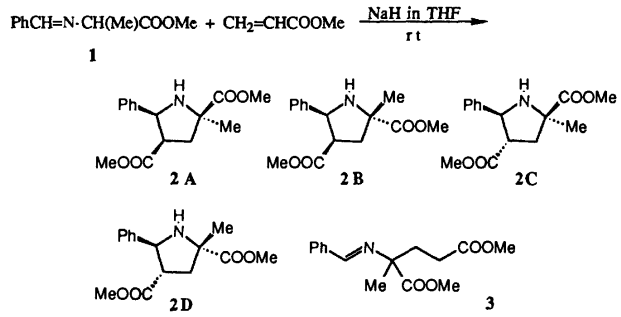
Irreversible ylide generation would be achieved if imines of α-amino esters are treated with metallic bases such as lithium diisopropylamide, butyllithium, and sodium hydride.[4] The ylides generated in high concentration are expected to show a much more enhanced reactivity.

In the present article, reactions of an imine of α-amino ester, methyl 2-(benzylideneamino)propanoate (**1**), with a variety of olefins in the presence of sodium hydride have been examined. Although cycloaddition of the resulting *N*-sodioazomethine ylide with methyl acrylate shows a poor stereoselectivity, addition of triethylamine or *t*-butyl alcohol as a base improves the selectivity. A stepwise cyclization mechanism is proposed since metal chelation is less important. Stereoselectivities are mainly determined at the step of intramolecular nucleophilic imine addition.

Results and Discussion

It was previously reported that treatment of imine **1** with triethylamine and sodium iodide generated the *N*-sodioazomethine ylide.[2] Its reaction with methyl acrylate produced a 1:2.7 mixture of stereoselective cycloadduct **2A** and Michael adduct **3** in a combined yield of 96%, indicating highly ionic character of the transition state rather than a tightly chelated structure.

On the other hand, reaction of imine **1** with methyl acrylate in the presence of sodium hydride, in tetrahydrofuran (THF) at room temperature, gave three isomeric 1:1 cycloadducts **2A—C** in 45, 13, and 6% yields, respectively, along with the Michael adduct **3** (25%, Scheme 1 and Entry 1 in Table 1). These three isomers **2A—C** could be separated from each other through column chromatography over silica gel.



Scheme 1.

Figure 1 shows ^1H NMR spectral data of **2A—C** and the last possible isomeric cycloadduct **2D** whose formation is to be described later. Isomer **2A** is identical with 2,4-*cis*:4,5-*cis*-2,4-pyrrolidinedicarboxylate which was previously obtained as a single isomer in the reaction of **1** with methyl acrylate in the presence of lithium bromide and triethylamine.[1] Isomer **2B** was determined to be a 2,4-trans:4,5-cis structure on the basis of the following spectral data

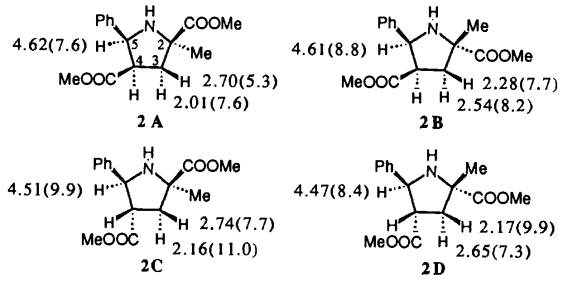


Fig. 1. Structural assignment of isomeric cycloadducts **2A—D** on the basis of ^{1}H NMR spectral data with vicinal coupling constants in Hz in parentheses.

(Fig. 1), and hence the reported 2,4-cis:4,5-cis geometry of **2A** was reconfirmed: 1) The ester methyl at the 4-position (4-COOMe, δ=3.12) is shielded by 5-Ph, 2) the difference of chemical shifts of 3-Hs (2.54−2.28=0.26 ppm) is much smaller than that of **2A** (2.70−2.01=0.69 ppm), and 3) the lower 3-H (2.70) of **2A**, which is cis to 2-COOMe, shows a small trans coupling with 4-H ($J_{3-4(trans)}$=5.3 Hz). The isomer **2B** is most likely to take an envelope conformation with two bulky substituents, 2-Me and 5-Ph, in pseudo equatorial positions. The corresponding envelope conformation of **2A** becomes less stable because the bulkier 2-Me has to occupy a pseudo axial position, the dihedral angle between 3-H (2.70) and 4-H being reduced.

Isomer **2C** has a 2,4-trans:4,5-trans structure on the basis of no shielding of 4-COOMe (δ=3.61), an NOE between one 3-H (2.16) and 2-Me, and an NOE between the other 3-H (2.74) and 4-H. Therefore, the other 4,5-trans isomer **2D** was assigned to be 2,4-cis:4,5-trans structure. Large trans couplings between the higher 3-H (2.16) and 4-H ($J_{3-4(trans)}$=11.0 Hz) and between 4-H and 5-H ($J_{4-5(trans)}$=9.9) are consistent with the assigned geometry of **2C**.

Thus, *N*-sodioazomethine ylides generated from **1** either by treating with sodium hydride or sodium iodide/triethylamine exhibited different stereoselectivities. The only differences anticipated would be 1) higher concentration of the intermediate ylide in the former case, and 2) existence of triethylammonium iodide (or together with triethylamine and sodium iodide) in the latter case.

Therefore, the *N*-sodioazomethine ylide was first generated by using sodium hydride and then treated with triethylamine (1.2 equiv). The resulting species was allowed to react with methyl acrylate. Surprisingly, the pattern of stereoselectivity changed dramatically to produce 2,4-trans:4,5-trans cycloadduct **2C** as major isomer along with 2,4-cis:4,5-trans minor isomer **2D** (Entry 2, **2C**:**2D**=6:1), no formation of either **2A**, **2B** or Michael adduct **3** being detected.

Addition of *t*-butyl alcohol or methanol (1.1—1.2 equiv), instead of triethylamine, resulted in no any deactivation of the reactive intermediate, *N*-sodioazomethine ylide; mixtures of two cycloadducts were similarly obtained (Entries 3 and 4, **2C**:**2D**=7:1). Use of water as an additive, however, furnished **2A** as the sole isomer together with Michael adduct **3** (Entry 5, **2A**:**3**=3:5). Separation of pure **2D** from the mixture with **2C** failed.

These unusual stereoselectivities of the *N*-sodioazomethine ylide in the presence of additives let us investigate further its cycloadditions with other olefinic esters. Triethylamine or *t*-butyl alcohol was employed as additive.

With methyl crotonate and triethylamine, a 7:1 mixture of two stereoisomers was obtained in a total yield of 89% (Scheme 2 and Entry 1 in Table 2). Major isomer **4A** is identical with 2,3-cis:4,5-cis cycloadduct that was previously obtained as the sole product in the lithium bromide/triethylamine-induced reaction of **1** with methyl crotonate.[1] Minor isomer **4C** was assigned to be a 2,3-trans:4,5-trans structure because of no shielding of 4-COOMe (δ=3.64), a large trans coupling of J_{4-5} (10.2 Hz),[5] and lower resonance of 2-Me (21.32, 2-Me of **4A** appears at 20.30). Addition of *t*-butyl alcohol decreased its stereoselectivity, a 2:1 mixture of **4A** and **4C** being obtained (Entry 2).

With methyl methacrylate, the reaction in the presence of triethylamine resulted in a lower isomer ratio (Entry 3, **5A**:**5B**=2.5:1) than that in the presence of *t*-butyl alcohol (Entry 4, **5A** only). The structures of **5A** and **5B** were readily determined as shown in Scheme 2 on the basis of the shielding of 4-COOMe (**5A**: δ=3.24, **5B**: 3.16) and the chemical shifts of 3-Hs (**5A**: 1.77 and 3.04, **5B**: 2.30 and 2.66).

A 1:2 mixture of two regioisomers **6A** and **7** was

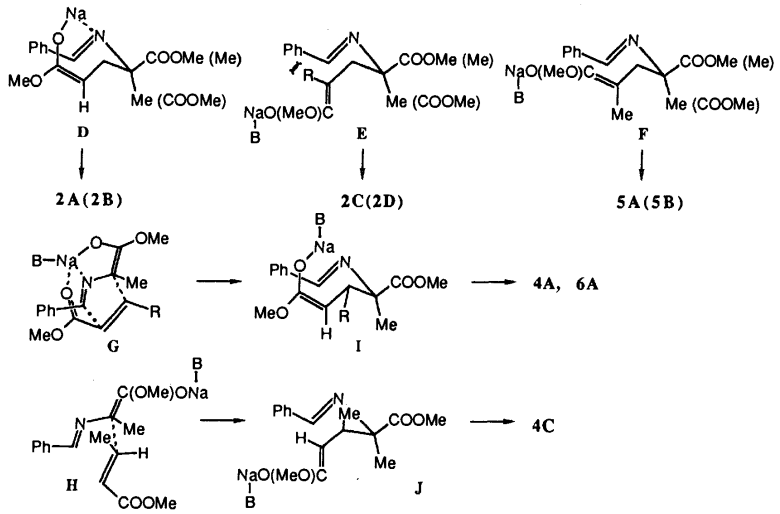

Fig. 2. Stereoselectivity in the cycloadditions of *N*-sodioazomethine ylide with esteric olefins.

obtained in the sodium hydride-induced reaction of **1** with methyl cinnamate (Entry 5). This result resembles a similar reaction induced by lithium bromide and 1,8-diazabicyclo[4.2.0]undec-7-ene (DBU) where a 2:1 mixture of **6A** and **7** was furnished in a total yield of 60%.[2]

Metal enolates containing a metal more electropositive than lithium such as sodium are most likely to undergo stepwise cycloadditions with α,β-unsaturated esters via metal enolate intermediates.[2] A concerted cycloaddition mechanism with a cyclic chelation, e.g. **B**, would be less important in these cases.

Thus, the *N*-sodioazomethine ylide of **1** reacts with methyl acrylate or methacrylate to form sodium enolate intermediates. In the reaction with methyl acrylate in the absence of additive (B), a weak interaction still working between the sodium and the imine nitrogen favors the chelation-controlled cyclization via **D** to give **2A** as major product (Fig. 2),[6] while the presence of an additive, which interacts with the

metal, not only weakens such chelation but also makes the metal bulkier. As a result, cyclization via **E** (R=H) becomes easier, the dramatic change of stereoselectivity having resulted to give **2C** as major product along with **2D**.

In the reaction of the sodium enolate intermediate from methyl methacrylate, cyclization via **E** (R=Me) becomes disfavored because these is a considerable steric repulsion between the phenyl and the methyl moieties. Thus, the cyclization via approach **F** was only observed to give **5A** and **5B**.

The Michael reaction of **1** with methyl crotonate offers an additional stereoselectivity at the newly formed bond, which finally reflects the stereochemistry of cycloadducts **4**. In the presence of a less polar additive such as triethylamine, the endo-selective cycloaddition via approach **G** (R=Me) takes place because there would still remain attractive interactions of the metal sodium to both the imine nitrogen and the ester oxygen atoms. The presence of *t*-butyl alcohol collapses the chelation **G** so that the contribution of linear transition state **H** becomes relatively more important.[7] Stereospecific cyclization of **I** and **J** leads to **4A** and **4C**, respectively.

Poor regioselectivity in the reaction of *N*-lithioazomethine ylide with methyl cinnamate is known.[2] A similar explanation would be enough for the formation of two regioisomers, **6A** and **7**.

In conclusion, 1) *N*-sodioazomethine ylides are characterized more or less as metal enolates, 2) their cycloadditions with α,β-unsaturated esters proceed through a stepwise mechanism via sodium enolate intermediates, 3) a basic additive collapses fragile metal chelations so that the stereoselectivity of cycloadditions is mainly determined by steric factors, 4) *N*-sodio ylides are synthetically complementary to other *N*-metalated ylides.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with JASCO IRA-1 and A-702 spectrometers. ^{1}H and ^{13}C NMR spectra were recorded on JEOL FX-100 (100 MHz for ^{1}H NMR and 25.05 MHz for ^{13}C NMR) and GSX-270 (270 MHz for ^{1}H NMR and 67.94 MHz for ^{13}C NMR) instruments. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra and high-resolution mass spectra (HRMS) were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silica gel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silica gel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph (Yanagimoto) with an ionization flame detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Silicone GE, SE-30, 0.25×50000 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Materials. Dimethyl 2-methyl-*c*-5-phenyl-*r*-2,*c*-4-pyrrolidinedicarboxylate (**2A**),[1] dimethyl 2-(benzylideneamino)-2-methylpentanedioate (**3**),[2] dimethyl 2,*t*-3-dimethyl-*c*-5-phenyl-*r*-2,*c*-4-pyrrolidinedicarboxylate (**4A**),[1] dimethyl 2,*t*-4-dimethyl-*c*-5-phenyl-*r*-2,*c*-4-pyrrolidinedicarboxylate (**5A**),[1] dimethyl 2-methyl-*t*-3,*c*-5-diphenyl-*r*-2,*c*-4-pyrrolidinedicarboxylate (**6A**),[2] and dimethyl 2-methyl-*t*-4,*c*-5-diphenyl-*r*-2,*c*-3-pyrrolidinedicarboxylate (**7**)[2] were all previously prepared.

Reaction of Methyl 2-(Benzylideneamino)propanoate (1) with Sodium Hydride and Cycloaddition with Methyl Acrylate. Sodium hydride (suspension in mineral oil, 60 wt%, 0.06 g, 1.5 mmol) was washed with dry hexane (3 ml×3) and suspended in dry THF under nitrogen. Addition of imine **1** (0.191 g, 1 mmol) was followed by methyl acrylate (0.095 g, 1.1 mmol) after 5 min. The mixture was stirred at room temperature for 1 h, poured into saturated ammonium chloride (10 ml), and extracted with diethyl ether (40 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue (0.261 g) was chromatographed over silica gel by using hexane–ethyl acetate (4:1 to 3:1 v/v) to give **2A** (0.125 g, 45%), **2B** (0.035 g, 13%), and **2C** (0.018 g, 6%). Formation of **3** was confirmed on the basis of ^{1}H NMR spectrum of the crude reaction mixture (25%).

Dimethyl 2-Methyl-*t*-5-phenyl-*r*-2,*t*-4-pyrrolidinedicarboxylate (2B): Colorless liquid; IR (neat) 3270, 1740, and 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.61 (3H, s, 2-Me), 2.28 (1H, dd, J_{gem}=12.8 and J_{3-4}=7.7 Hz, one of 3-H), 2.54 (1H, dd, J_{gem}=12.8 and J_{3-4}=8.2 Hz, the other of 3-H), 2.66 (1H, br, NH), 3.12 (3H, s, 4-COOMe), 3.28 (1H, ddd, J_{4-3}=8.2, 7.7, and J_{4-5}=8.8 Hz, 4-H), 3.75 (3H, s, 2-COOMe), 4.61 (1H, d, J_{5-4}=8.8 Hz, 5-H), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.44 (2-Me), 38.11 (3-C), 49.42 (4-C), 51.13, 52.42 (each COOMe), 63.80 (2-C), 65.73 (5-C), 127.31, 127.43, 127.87, 140.46 (each Ph), 173.01, and 177.75 (each COOMe); MS *m/z* (rel intensity, %) 277 (M^+, 2), 219 (15), 218 (base peak), 158 (30), and 131 (14). Found: C, 64.94; H, 6.94; N, 4.96%. Calcd for $C_{15}H_{19}NO_4$: C, 64.96; H, 6.91; N, 5.05%.

Dimethyl 2-Methyl-*c*-5-phenyl-*r*-2,*t*-4-pyrrolidinedicarboxylate (2C): Colorless liquid; IR (neat) 3270, 1735, and 1725 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.53 (3H, s, 2-Me), 2.16 (1H, dd, J_{gem}=12.8 and J_{3-4}=11.0 Hz, one of 3-H, showing an NOE against 2-Me), 2.58 (1H, br, NH), 2.74 (1H, dd, J_{gem}=12.8 and J_{3-4}=7.7 Hz, the other of 3-H, showing an NOE against 4-H), 2.95 (1H, ddd, J_{4-3}=11.0, 7.7, and J_{4-5}=9.9 Hz, 4-H), 3.61 (3H, s, 4-COOMe), 3.78 (3H, s, 2-COOMe), 4.51 (1H, d, J_{5-4}=9.9 Hz, 5-H), and 7.3—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=26.54 (2-Me), 42.30 (3-C), 51.79, 52.57 (each COOMe), 52.63 (4-C), 65.33 (2-C), 66.06 (5-C), 126.92, 127.76, 128.58, 141.18 (each Ph), 173.44, and 176.98 (each COOMe); MS *m/z* (rel intensity, %) 277 (M^+, 3), 219 (15), 218 (base peak), 177 (15), 158 (32), and 131 (13). Found: C, 64.92; H, 7.01; N, 4.75%. Calcd for $C_{15}H_{19}NO_4$: C, 64.96; H, 6.91; N, 5.05%.

General Procedure for the Reaction of 1 with α,β-Unsaturated Esters in the Presence of Sodium Hydride and Additives. Under nitrogen, sodium hydride (60% in oil,

0.048 g, 1.2 mmol) was washed with dry hexane (3 ml×2) and suspended in dry THF (3 ml). Imine **1** (0.191 g, 1 mmol) was added, and after stirring at room temperature for 15 min was added an additive such as triethylamine (0.121 g, 1.2 mmol), *t*-butyl alcohol (0.082 g, 1.1 mmol), or water (21 mg, 1.2 mmol). After 5 min, an olefin ester (1 mmol) was added. The mixture was stirred at room temperature and then poured into saturated ammonium chloride (10 ml). Extraction with diethyl ether (40 ml×2), evaporation of the dried extract, and chromatography of the residue on silica gel gave **2—7**. The reaction conditions and results are all listed in Tables 1 and 2.

Dimethyl 2-Methyl-*t*-5-phenyl-*r*-2,*c*-4-pyrrolidinedicarboxylate (2D): This isomer could not be isolated in its pure form. Only ^{1}H NMR spectrum was recorded from the spectrum of the mixture with **2C**: ^{1}H NMR ($CDCl_3$) δ=1.50 (3H, s, 2-Me), 2.17 (1H, dd, J_{gem}=13.2 and J_{3-4}=9.9 Hz, one of 3-H), 2.30 (1H, br, NH), 2.65 (1H, dd, J_{gem}=13.2, and J_{3-4}=7.3 Hz, the other of 3-H), 2.90 (1H, ddd, J_{4-3}=9.9, 7.3, and J_{4-5}=8.4 Hz, 4-H), 3.62 (3H, s, 4-COOMe), 3.77 (3H, s, 2-COOMe), 4.47 (1H, d, J_{5-4}=8.4 Hz, 5-H), and 7.3—7.5 (5H, m, Ph).

Dimethyl 2,*c*-3-Dimethyl-*c*-5-phenyl-*r*-2,*t*-4-pyrrolidinedicarboxylate (4C): Isomer **4C** could not be separated in a pure form from the mixture with **4A**. Therefore, mixtures with two different isomer ratios were subjected to ^{1}H and ^{13}C NMR measurements, and spectra of **4C** were assigned as follows: ^{1}H NMR ($CDCl_3$) δ=1.06 (3H, d, J=7.0 Hz, 3-Me), 1.40 (3H, s, 2-Me), 2.7 (1H, br, NH), 3.64 (3H, s, 4-COOMe), 3.81 (3H, s, 2-COOMe), 4.72 (1H, d, J_{5-4}=10.2 Hz, 5-H), and 7.2—7.5 (5H, m, Ph). Both 3-H and 4-H are overlapped with the signals of **4A**. ^{13}C NMR ($CDCl_3$) δ=11.71 (3-Me), 21.32 (2-Me), 43.27 (3-C), 51.56, 52.54 (each COOMe), 56.43 (4-C), 62.33 (2-C), 68.71 (5-C), 127.11, 127.48, 127.58, 142.31 (each Ph), 172.32, and 177.46 (each COOMe).

Dimethyl 2,*c*-4-Dimethyl-*t*-5-phenyl-*r*-2,*t*-4-pyrrolidinedicarboxylate (5B): Colorless liquid; IR (neat) 3430 and 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.33 (3H, s, 4-Me), 1.60 (3H, s, 2-Me), 2.30 (1H, d, J_{gem}=13.6 Hz, one of 3-H), 2.66 (1H, d, J_{gem}=13.6 Hz, the other of 3-H), 2.70 (1H, br, NH), 3.16 (3H, s, 4-COOMe), 3.76 (3H, s, 2-COOMe), 4.06 (1H, s, 5-H), and 7.2—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=23.30 (4-Me), 25.98 (2-Me), 46.62 (3-C), 51.30, 52.38 (each COOMe), 55.09 (4-C), 64.58 (2-C), 72.83 (5-C), 126.98, 127.68, 127.87, 139.22 (each Ph), 175.20, and 178.31 (each COOMe); MS *m/z* (rel intensity, %) 291 (M^+, 5), 290 (18), 233 (17), 192 (12), 191 (89), 172 (23), 131 (64), and 130 (12). Found: C, 65.96; H, 7.54; N, 4.68%. Calcd for $C_{16}H_{21}NO_4$: C, 65.96; H, 7.27; N, 4.81%.

The Polymerization of Toluene and Its Analogs Catalyzed by a Copper(I) Chloride-Aluminum Chloride-Oxygen System

Naoki TOSHIMA,* Keiichi KANAKA, Naoko ISHIYAMA, and Hidefumi HIRAI†
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received December 26, 1988)

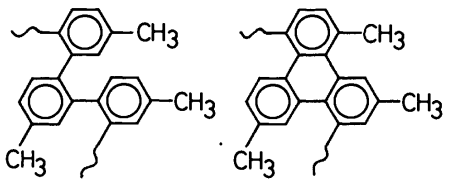
The polymerization of aromatic compounds other than benzene (such as toluene, xylene, ethylbenzene, mesitylene, and biphenyl) was performed by using a copper(I) chloride–aluminum chloride–oxygen system which caused benzene to polymerize. Excess aluminum chloride, with respect to copper(I) chloride, was required for these compounds to polymerize, as was also true for benzene. For example, the treatment of toluene with aluminum chloride and copper(I) chloride (15:3:1 in molar ratio) under 1 atm of oxygen at 50 °C for 24 h gave toluene polymer in 204% yield based on copper(I) chloride. This fact suggests that copper(I) chloride also worked as a catalyst in the case of the polymerization of toluene. The toluene polymer was obtained as both solid and liquid products, both of which were soluble in various organic solvents. The solid product has a complicated, crosslinked and "quinonoid-like" structure. On the other hand, the liquid product has a structure that is nearly identical with that of methylated poly(1,4-phenylene). Other alkylbenzenes gave the only liquid polymerization products, except for *o*-xylene which gave a small amount of solid products. The polymerization of biphenyl gave a low-molecular-weight poly(1,4-phenylene).

It is well-known that the aromatic hydrocarbon polymer is thermally stable[1] and becomes electrically conductive upon doping with various dopants.[2] In particular, an investigation of poly(1,4-phenylene) (PPP), the polymer of benzene, has been intensively carried out while considering synthetic methods and properties.

A number of methods for synthesizing PPP have been invented, such as the electrolytic polymerization of benzene,[3] the dehalogenation from dihalogenated benzene in the presence of nickel complex catalysts,[4] the dehydrogenation from poly(1,3-cyclohexadiene)[5] and so on. On the other hand, for a direct synthesis of PPP from benzene, a well-known procedure is the oxidative cationic polymerization of benzene by a Lewis acid–oxidant system reported by Kovacic et al.[6] In this method, aluminum chloride and copper(II) chloride are used as a Lewis acid and an oxidant, respectively, and are most effectively used for polymerization:[7]

$$n\,C_6H_6 + 2n\,CuCl_2 \xrightarrow{AlCl_3} (C_6H_4)_n + 2n\,CuCl + 2n\,HCl. \quad (1)$$

In this method, however, the polymerization of 1 mol of benzene produces 2 mol of hydrogen chloride. Since the reaction mixtures are occupied by many insoluble metal salts which result in slurried conditions, it is difficult to stir them. Since copper(II) chloride is consumed during the reaction, the yield of PPP based on the oxidant is always less than 100%, i.e., copper(II) chloride does not work as a catalyst. The polymerization of toluene by this method gives a toluene polymer which has mainly a 1,2-phenylene backbone (**1**). Especially, by using carbon disulfide as a solvent, polynuclear polymer (**2**) is obtained which is insoluble in organic solvent.[8] In contrast, by the use of the same reagents, the other group reported that the polymerization reaction also occurs at the benzyl position of toluene molecules.[9] The polymerization of biphenyl by the Kovacic's method was also investigated.[10]



(1) (2)

Recently, the present authors have reported that the polymerization of benzene is possible using copper(I) chloride (a low-valence metal salt), aluminum chloride, and oxygen as an oxidant.[11] In this method the polymerization can be performed under considerably homogeneous conditions as copper(I) chloride becomes soluble in benzene by forming a double salt with aluminum chloride ($AlCuCl_4$);[12] no evolution of a hydrogen chloride gas occurs. Furthermore, it becomes possible to polymerize benzene in over 100% yield based on copper(I) chloride.

Since the PPP obtained in this manner is entirely insoluble in organic solvents and does not melt upon a heat treatment, it is a poor material for processing. It is expected that the introduction of alkyl groups into a highly rigid PPP molecule causes its solubility in an organic solvent to be higher while making the processing of this type polymer easy. As one method to make this kind of modification, we tried to polymerize toluene and its analogs by taking advantage of a copper(I) chloride–aluminum chloride–oxygen system. In the present paper we report on the results of

† Present address: Department of Industrial Chemistry, Faculty of Engineering, The Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162.

the polymerization of toluene and other alkylbenzenes as well as those of biphenyl, which was found to polymerize resulting in a PPP oligomer.

Experimental

Materials. The aluminum chloride (Kishida Chemical Co.) was purified by vacuum sublimation. The copper(I) chloride (Koso Chemical Co.) was reprecipitated from an aqueous hydrochloric acid solution by the addition of distilled water, followed by successive washing with ethanol and diethyl ether. It was then dried in vacuo at 100 °C for 24 h.

The toluene, *o*-xylene, *p*-xylene, ethylbenzene, and mesitylene were distilled over metallic sodium. The biphenyl was purified by recrystallization from petroleum ether.

The oxygen was dried by being passed through columns of Molecular Sieves 3A and diphosphorus pentaoxide before use.

Analysis. The ^{1}H NMR spectrum measurement was carried out with JEOL models FX90Q and GX400 spectrometers at 89.55 and 399.6 MHz, respectively. The infrared absorption spectra were measured with a JASCO model A-3 spectrometer by a KBr disk method. The GPC was recorded on a TOYO SODA model HLC-802UR chromatograph equipped with TSK-GEL G7000H, G5000H, and G3000H columns.

Polymerization of Toluene by a CuCl-AlCl$_3$-O$_2$ System. Copper(I) chloride (0.835 g, 8.43 mmol), aluminum chloride (3.38 g, 25.3 mmol), and toluene (13.5 cm^3, 127 mmol) were placed in a 100 cm^3 Kjeldahl flask, and the mixtures were stirred at room temperature for 2 h under dry nitrogen. During this stage the copper(I) chloride was completely dissolved and a highly homogeneous solution was obtained, leaving some excess aluminum chloride. The polymerization reaction was carried out by replacing the reaction atmosphere with oxygen and stirring the mixtures at 60 °C for 24 h. As the reaction proceeded, the color of the reaction mixtures changed from green to black at the end of the reaction. Polymerization was terminated by adding an 18% hydrochloric acid solution to the reaction mixtures. After the filtration of the reaction mixtures with a membrane filter (Nippon Millipore Kogyo, an SC type, pore size=8.0 μm), the remaining solid was repeatedly washed with a boiling solution of 18% hydrochloric acid and then with boiling water. The subsequent drying of the brownish black solid product at 100 °C for 24 h yielded 0.170 g (44.8% yield based on the charged copper(I) chloride) of the toluene polymer. The toluene solution was also washed several times with an 18% hydrochloric acid solution and water. After the evaporation of the toluene under reduced pressure, followed by drying for 24 h at room temperature, 0.603 g (159% yield based on the charged copper(I) chloride) of a reddish-brown oily product was obtained, which was soluble in toluene. The solid product was insoluble in benzene, acetone, and petroleum ether, though soluble in chloroform, THF, and DMF.

The results of the elemental analysis of the solid product were: C, 87.1; H, 6.3; Cl, 1.3%. Thus, the C/H ratio is 1.42, which is much higher than 1.17, the calculated value of that for $(C_6H_3(CH_3))_n$. The IR spectrum of the solid product showed bands at 810, 860 (C–H out-of-plane bending vibration of a para-disubstituted benzene ring), 1375 (C–H bending vibration of a methyl group), 1510, 1600 (C=C stretching vibration of a benzene ring), and 2920 cm^{-1} (C–H stretching vibration of a methyl group). The ^{1}H NMR spectrum in $CDCl_3$ (Fig. 2) shows peaks at δ 7.0—7.5 (m; aromatic protons), 2.2—2.5 (m; aliphatic protons of a methyl group substituted on a benzene ring), 1.25, 0.88 (m; aliphatic protons) (vide infra).

The results of the elemental analysis of the liquid product were: C, 90.2; H, 7.0; Cl, 0.6%. Thus, the C/H ratio is 1.09, which is nearly identical with the calculated value of that for $H(C_6H_3(CH_3))_4H$, 1.08. The IR spectrum has bands at 700, 730, 770 (C–H out-of-plane bending vibration of a 1,2- and 1,3-disubstituted benzene ring), 810, 890 (C–H out-of-plane bending vibration of the same species and a 1,2,4-trisubstituted benzene ring), 1375 (C–H bending vibration of a methyl group), 1510, 1600 (C=C stretching vibration of a benzene ring), 2860, 2920 (C–H stretching vibration of a methyl group), and 3020 cm^{-1} (C–H stretching vibration of a benzene ring). The ^{1}H NMR spectrum in $CDCl_3$ (Fig. 3) shows the peaks at δ 7.0—7.4 (m; aromatic protons) and 2.2—2.5 (m; aliphatic protons of a methyl group substituted on a benzene ring).

Polymerization of Biphenyl by a CuCl-AlCl$_3$-O$_2$ System. Copper(I) chloride (0.95 g, 9.60 mmol), aluminum chloride (3.85 g, 28.9 mmol), and biphenyl (14.8 g, 96.2 mmol) were placed in a 100 cm^3 Kjeldahl flask, and stirred at 80 °C for 2 h under dry nitrogen, resulting in a reddish-brown solution. Replacing the solution atmosphere with oxygen started the reaction at the same temperature for 24 h. At the end of the reaction, the color of the mixtures was purple. Reaction was terminated by the addition of an 18% hydrochloric acid solution into the reaction mixtures. The obtained solid was repeatedly washed with boiling petroleum ether, an 18% hydrochloric acid solution, and water. It was then dried at 100 °C for 24 h, resulting in 0.501 g (137% yield based on CuCl) of a brown product (poly(1,4-phenylene)).

The results of the elemental analysis for the solid product were: C, 93.1; H, 4.7; Cl, 1.2%. Thus, the C/H ratio is 1.65, while the calculated value of $(C_6H_4)_n$ is 1.50. The IR spectrum showed bands at 815 (C–H out-of-plane bending vibration of a para-disubstituted benzene ring), 1000 (C–H in-plane bending vibration of the same species), and 1480 cm^{-1} (C=C skeletal in-plane vibration).

Results and Discussion

Polymerization of Toluene by the Use of the CuCl-AlCl$_3$-Oxygen System. Table 1 shows the results of the polymerization of toluene by a copper(I) chloride–aluminum chloride–oxygen (CuCl–AlCl$_3$–O$_2$) system using excess $AlCl_3$ with respect to CuCl. Under these conditions, upon replacing the solution atmosphere by oxygen the polymerization of toluene occurred smoothly, and the toluene polymer was obtained. For example, when a threefold quantity of $AlCl_3$ with respect to that of CuCl was used and the polymerization reaction was carried out at 50 °C for 24 h, a solid polymer of toluene and liquid one were obtained in a yield of 44.8 and 159%, respectively, and no evolution of HCl was observed (run 2). In contrast

Table 1. Polymerization of Toluene Catalyzed by Copper(I) Chloride and Aluminum Chloride under Oxygen[a]

Run	Charged molar ratio[b]		Temperature /°C	Yield/%[c]		
	$AlCuCl_4$	Excess $AlCl_3$		Solid	Liquid	Total
1	1.0	2.0	15	19	52	71

5	2.0	4.0	50	31	155	186
6	4.0	8.0	50	86	69	155
7	1.0	2.0+2.5[d]	50	199	287	486

a) Reaction time, 24 h. b) Toluene=15.0. c) Based on CuCl. d) After the reaction with 2.0 excess molar ratio of aluminum chloride for 12 h, then adding further 2.5 excess molar ratio of aluminum chloride, the reaction was continued for further 12 h.

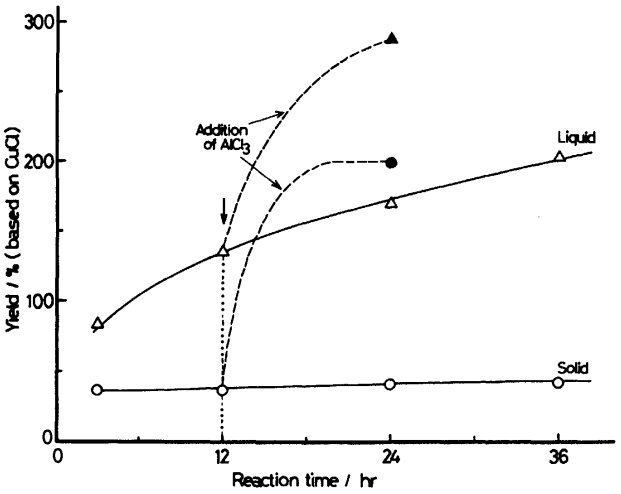

Fig. 1. Changes with the reaction time in the yields of the solid (○) and liquid (△) products of the toluene polymer by a CuCl-$AlCl_3$-O_2 system. The charged molar ratio of CuCl/$AlCl_3$/toluene was 1:3:15 and the reaction temperature was 50°C. Closed circles and triangles show the yields of the toluene polymer in the case of the extra addition of 2.5 excess molar ratio of $AlCl_3$ to CuCl after the reaction for 12 h using 3 fold of $AlCl_3$ to CuCl.

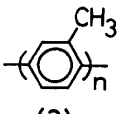
with the Kovacic's method in which $CuCl_2$ works as a reagent, it becomes apparent that toluene polymerizes catalytically with respect to CuCl in the present method.

The yield of the toluene polymer generally increased with the reaction time. The yield of the solid product, however, became saturated within a few hours in contrast with that of the liquid one (Fig. 1). This result indicates that the formation mechanisms of the solid and liquid product are different from each other (vide infra). The yield of the toluene polymer was also influenced by the reaction temperature and the quantity of excess $AlCl_3$. As shown in Table 1, the yield of the toluene polymer became higher upon raising the reaction temperature (run 3) or increasing the quantity of excess $AlCl_3$ (run 4). Furthermore, a drastic increase in the yield could be achieved by an extra addition of $AlCl_3$ in the middle of the reaction and continuous stirring for another 12 h (run 7), as shown by dashed lines in Fig. 1 (the yields of the solid and the liquid products are 199 and 287% respectively at reaction temperature of 50°C). These results indicate that the excess $AlCl_3$ is consumed during the reaction. In fact, when a half molar ratio of water to $AlCl_3$ was added to the reaction system, the polymerization reaction could be suppressed and the yield of the toluene polymer decreased by half. In addition, oxygen was consumed during the polymerization reaction. In a previous paper,[11] we reported on the result of oxygen uptake during the polymerization of benzene. In this case, the uptake of oxygen nearly corresponded to a one-half molar amount of the yield of poly(1,4-phenylene). Therefore, the deactivation of $AlCl_3$ during the reaction is considered to be due to the hydrate formation of $AlCl_3$ with the water generated by the reaction between oxygen and protons which is eliminated from toluene. On the other hand, the polymer yield increases upon rising the reaction temperature.

Structure of Toluene Polymer. Analytical data of the polymers of toluene are shown in Table 2. If the polymerization product has a disubstituted toluene structure in its polymer chain, i.e., an ideal "poly-toluene" structure (**3**), the C/H ratio of the polymer given from elemental analysis should be 1.17.



(3)

The observed value for the solid polymers, however, is about 1.4, which is higher than 1.17. This result suggests that a considerable intramolecular crosslinkage would occur after the addition reaction of toluene, instead of rearomatization by dehydrogenation. This consideration is supported by the results of a ^1H NMR spectral measurement. In the case of the solid product, the areal ratio of peaks of the aromatic protons to those

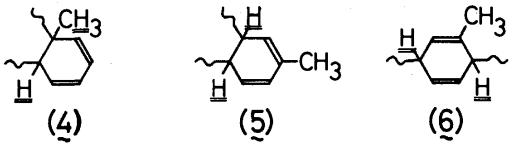
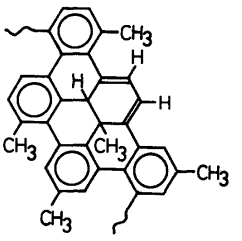
of the methyl protons is 8:15, which fairly deviates from the ideal ratio 1:1. This means that a sufficient amount of aromatic protons isn't included in this polymer structure. Furthermore, as shown in Fig. 2, unexpected peaks from the wholly aromatized toluene polymer structure, such as **1**, **2**, or **3**, were observed at δ 0.88 and 1.24 in the NMR spectra of the toluene polymer. These peaks were not found in the spectra of Kovacic's toluene polymer.[8] Since the peaks at these positions are attributed to aliphatic protons, these observations suggest that the solid polymer obtained in the present investigations arises from a nonaromatized "quinonoid-like" structure like **4**, **5**, and **6**.



(4) (5) (6)

Therefore, the solid product is considered to have the following components in its chemical structure: (a) a highly crosslinked structure between aromatic rings, and (b) a nonaromatized "quinonoid-like" structure. Based on these considerations, an example of the structure **7** which is consistent with the observed analytical data might be depicted in order to estimate the structure of the solid toluene polymer.

On the other hand, the C/H ratio of the liquid product calculated from the elemental analytical data is about 1.1, which is near to the value of the ideal toluene polymer ($(C_6H_3(CH_3))_n$). The peaks at a high



(7)

C/H=1.42
ArH:CH$_3$=8:15

magnetic field in the ^{1}H NMR spectrum, which were observed for the solid polymer, were not found in the liquid polymer (cf. Fig. 3). The areal ratio of the peaks of the aromatic and the methyl protons is almost 1:1. Therefore, the liquid product can be proved to have the ideal "polytoluene" structure (**1** or **3**), in which the framework of toluene is held in the polymer chain. The molecular weight of the toluene polymer was investigated by GPC. In the case of the liquid product, although the peaks of GPC spectrum appeared nearly at the limit of the detection area, the main component could be an oligomer, perhaps a tetramer of toluene.

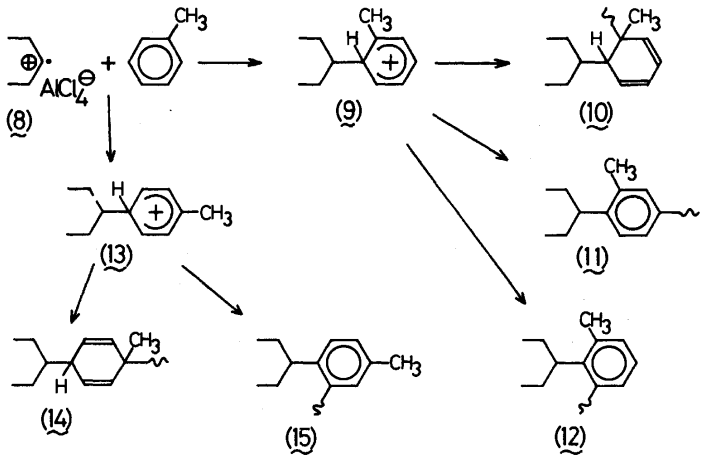
It was reported that, by the use of a Kovacic's method, the polymerization reaction also occurs at the benzyl position of a toluene molecule.[9] In the present method, however, the reaction probably doesn't occur at the benzyl position because neither the liquid product nor the solid product has any peak around δ 4 in the ^{1}H NMR spectrum assigned to methylene

protons connected by two phenylene groups.

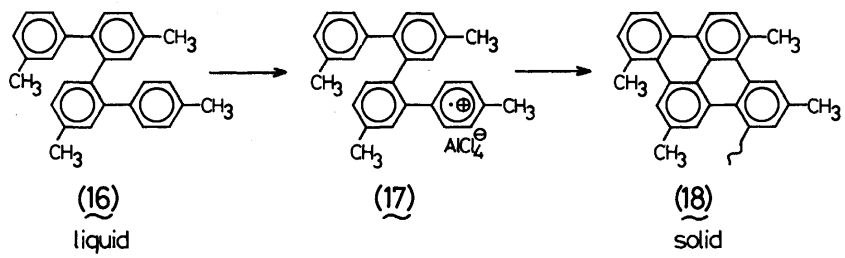
Polymerization Mechanism of Toluene. (a) Formation Mechanism of the Solid Product: The solid polymer of toluene obtained by the CuCl–$AlCl_3$–O_2 system has characteristic aliphatic protons due to a "quinonoid-like" structure. The formation of such protons requires the existence of a ring structure which is connected to another benzene ring of toluene at the carbon atom which substituted by a methyl group. In order to form this kind of structure, a cation radical on a benzene ring of toluene must attack another toluene molecule in an electrophilic way, resulting in cationic polymerization. The possible mechanism is illustrated in Scheme 1. Since the benzene ring of toluene is favorably attacked by electrophiles at the ortho- and para-positions, the toluene molecules attacked by the cation radical of toluene (**8**) would produce species **9** and **13**. When species **9** and **13** are attacked by the next toluene molecule, species **10**, **11**, **12**, **14**, and **15** could be considered to be produced, respectively, on the basis of the orientation of toluene in the substitution reaction. That is to say, the "quinonoid-like" structures (**10** and **14**) are considered to be formed by an extension of the polymer chain from the carbon atoms attached to a methyl group, since the density in positive charge on these carbon atoms is high due to the methyl group.

(b) Formation Mechanism of Liquid Product: In the polymerization of benzene using $CuCl_2$ and $AlCl_3$, Kovacic et al. already proposed a "stair-step" mechanism.[13] That is to say, it now appears the benzene cation radicals serve as the sites for coordination with an appreciable number of benzene nuclei in a propagative manner as stair steps, ranging from straight to spiral. When the chain buildup reaches a certain stage, the radical cation character on the terminal members become too small to induce further propagation. Covalent bond formation and the elimination of protons and electrons then lead to poly(1,4-phenylene). As to the mechanism for the formation of the liquid toluene polymer obtained by the present method, the "stair-step" mechanism is thought to be reasonable. This mechanism is supported by the absence of the peaks at δ 0.88 and 1.24, which appear in the solid product, in the ^1H NMR spectrum of the liquid product. This result is considered to be due to a small possibility for the formation of the aliphatic methyl group on the basis of the "quinonoid-like" structure. This is because it is almost impossible by a steric hindrance upon connecting with the stair steps that a toluene molecule can attack the carbon atom attached to a methyl group.

(c) The Effect of the Addition of Excess $AlCl_3$ in the



Scheme 1. The proposed mechanism for the solid toluene polymer.



Scheme 2. The formation of the solid product from the liquid product of the toluene polymer by the addition of $AlCl_3$.

Course of the Reaction: The extra addition of excess $AlCl_3$ in the course of the reaction and further stirring of the reaction mixtures greatly increased the yield of the toluene polymer based on CuCl. When the reaction was carried out for the same period by adding the excess amount of $AlCl_3$ at once (at the beginning of the reaction), the yield of the polymer was also high. The structure of the latter polymer, however, was different from that of the polymer obtained in the former manner. The intensity of the peaks at δ 0.88 and 1.24 in the ^1H NMR spectrum of the former polymer was lower than that of the latter one. In the former case, the liquid product which formed before the extra addition of $AlCl_3$ is considered to give rise to intramolecular crosslinking and to initiate cationic polymerization again after the extra addition of $AlCl_3$, resulting in the solid product (Scheme 2). In the beginning, the liquid product does not involve the "quinonoid-like" structure. If this liquid product is crosslinked and forms a part of the solid product, the intensity of the ^1H NMR peaks at δ 0.88 and 1.24 would be relatively low in comparison with the solid product directly obtained. In fact, the treatment of the isolated liquid product by $AlCl_3$ in nitrobenzene gave the crosslinked insoluble solid product, indicating that the crosslinking reaction occurred as the result of the extra addition of $AlCl_3$ to the liquid toluene polymer and also that the liquid product had a 1,2-phenylene backbone which could be easily crosslinked (cf. **16** in Scheme 2). As shown in Fig. 1, the yield of the solid product doesn't increase with the reaction time, although the yield of the liquid product does. The reason for this is considered to be due to the deactivation of $AlCl_3$ by hydrate formation with water, since only free $AlCl_3$ could serve as a crosslinking reagent.

Table 3. Polymerization of Various Kinds of Benzene Derivatives Catalyzed by Copper(I) Chloride–Aluminum Chloride under Oxygen[a]

Aromatic compound	Yield/%[b]
o-Xylene	106[c]
p-Xylene	140
Ethylbenzene	91
Mesitylene	81

a) Reaction time, 24 h. Reaction temperature, 50 °C. CuCl : $AlCl_3$: Aromatic compound=1 : 3 : 20. b) Based on the aromatic compound. c) The total yield involving the solid product (5%).

Polymerization of Other Benzene Derivatives. The polymerization of xylenes, ethylbenzene, and mesitylene was attempted by using the present system. Every monomer gave the corresponding polymerization product. The yields of these product are summarized in Table 3. A solid product was obtained only in the case of *o*-xylene. However, no particular difference in the IR spectra was observed between the solid and liquid products of the *o*-xylene polymer. As can be seen in Table 3, the catalytic effectiveness for the present system decreases in the case of polymerizations of xylenes compared with toluene, in spite of the higher solubility of the reaction product. For the polymerization of toluene, the catalytic effectiveness is higher than that for the polymerization of benzene. Thus, the yields of the benzene polymer and the toluene polymer are 65 and 210%, respectively, at a reaction temperature of 50 °C. The decrease in the yield of the xylene polymer is thought to be the result of a steric hindrance of substituted groups. The ^1H NMR spectra showed intense peaks at higher magnetic fields (about δ 1—1.5), suggesting the existence of the "quinonoid-like" structure in these cases as well. These liquid polymerization products are thought to contain both liquid and solid products which correspond to those in the case of the polymerization of toluene, since the other benzene derivatives have many, or long, alkyl groups and the degree of polymerization would be low in these derivatives.

In the case of biphenyl, the polymerization product by the present method exhibited a lighter brown color than that of benzene. The IR spectrum suggested that the polymer involves only mono- and disubstituted benzene rings, not trisubstituted ones. The intensity ratio of the absorption peaks at 700 and 760 cm^{-1}, which were attributable to the C–H vibration of a monosubstituted benzene ring, to that at around 800 cm^{-1} (which was attributable to the C–H vibration of a para-disubstituted benzene ring), was stronger than that of poly(1,4-phenylene). These facts indicate that the polymer obtained from biphenyl is a kind of poly(1,4-phenylene), though its molecular weight is lower than that obtained from benzene. Furthermore,

Table 4. The IR Peak Attributed to the C–H Vibration of a para-Disubstituted Benzene Ring of 1,4-Phenylene Oligomers

p-Phenylene compound	Wavenumber/cm^{-1}	Reference
p-Terphenyl	842	14
p-Quaterphenyl	830	14
p-Quinquephenyl	820	14
p-Sexiphenyl	815	14
Poly(1,4-phenylene)	800	7, 11
Biphenyl-polymer	815	Present work

the peak based on the C–H vibration of a para-disubstituted benzene ring was detected at a higher-wavenumber position (815 cm^{-1}) in this polymer than that in the usual poly(1,4-phenylene) from benzene (800 cm^{-1}). It is reported that the absorption band at this area in poly(1,4-phenylene) shifts to a lower wavenumber by increasing the number of para-disubstituted benzene rings.[14] The absorption band at 815 cm^{-1} is quite similar to that reported for *p*-sexiphenyl (Table 4). Thus, the main part of the biphenyl polymer obtained in the present catalytic system is thought to be a trimer of biphenyl (a hexamer with respect to phenylene unit).

Syntheses of Fluoroalkyl and Fluoroaryl Titanates

Norio YOSHINO,* Junko TOMITA, and Hidefumi HIRAI
Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received January 24, 1989)

Tetrakis(1H,1H-perfluoroethyl) titanate, $Ti(OCH_2CF_3)_4$, tetrakis(1H,1H-perfluoropropyl) titanate, $Ti(OCH_2CF_2CF_3)_4$, tetrakis(2,2,2-trifluoro-1-methylethyl) titanate, $Ti[OCH(CH_3)CF_3]_4$, tetrakis(2,2,2-trifluoro-1,1-dimethylethyl) titanate, $Ti[OC(CH_3)_2CF_3]_4$, tetrakis((1H,1H,3H-perfluoropropyl) titanate, $Ti(OCH_2CF_2CF_2H)_4$, tetrakis(1H,1H,5H-perfluoropentyl) titanate, $Ti[OCH_2(CF_2CF_2)_2H]_4$, tetrakis(1H,1H,7H-perfluoroheptyl) titanate, $Ti[OCH_2(CF_2CF_2)_3H]_4$, and tetrakis(1H,1H,9H-perfluorononyl) titanate, $Ti[OCH_2(CF_2CF_2)_4H]_4$, were prepared by the reaction of titanium tetrachloride with fluoro-substituted alcohols in the presence of ammonia. Tetrakis(pentafluorophenyl) titanate, $Ti(OC_6F_5)_4$ was synthesized by the ester interchange reaction of tetraisopropyl titanate with pentafluorophenyl acetate. These compounds were characterized on the basis of chemical analysis, IR, ^1H NMR, ^{13}C NMR and ^{19}F NMR spectra. Tetrakis(2,2,2-trifluoro-1,1-dimethylethyl) titanate was the monomeric in nitrobenzene, but tetrakis(1H,1H-perfluoroethyl) titanate and tetrakis(1H,1H-perfluoropropyl) titanate were associated in the same solvent, in which the highest association numbers observed were 3.5 and 1.5, respectively. These titanates were very sensitive to moisture and easy to decompose to give titanium oxide and alcohol or phenol.

Metal alkoxides have been the subject of extensive research because of their potential as precursor materials for several applications, such as new-ceramics, adhesives and coupling agents, which are molecular bridges between the interface of an inorganic filler and an organic polymer. Many of alkyl or aryl titanates and their halogenated derivatives were prepared[1] and the reactivities of these titanates towards various types of donors such as amides, amines, ethers, and amino acids have been reported.[2] The number of worldwide commercial applications for coupling agents established using monoalkoxy-type titanates such as titanium isopropoxide tris(2-heptylundecanoyloxide) are now very substantial, as indicated by over one hundred patents.[3-6]

In recent years, dramatic developments have been made in the utilization of organofluoro compounds because of the resulting materials with high performance. However, only a few research reports concerning fluoro-substituted alkoxides of metals have appeared in the literature. Redwood and his co-workers[7,8] have prepared the trifluoromethoxides of heavier alkali metals by the reaction of carbonyl fluoride on a suspension of alkali metal fluoride in acetonitrile. Kapoor et al.[9,10] reported syntheses of 2,2,2-trifluoroethoxides and 2,2,2-trifluoro-1-(trifluoromethyl)-ethoxides of metals, such as germanium, titanium, zirconium, niobium, and tantalum, by the reaction of metal chlorides with the appropriate alcohol. Mazdiyasni et al.[11] reported syntheses of 2,2,2-trifluoro-1-(trifluoromethyl)ethoxides of aluminium, silicon, germanium, titanium, zirconium, and hafnium, through reactions of suitable metal chlorides with sodium 2,2,2-trifluoro-1-(trifluoromethyl)ethoxides. In these reports, the fluoro-substituted alkoxides of metals studied have been limited to only one or two species of low molecular weight or simple structural alcohols, as a starting material. However, the chemical and physical properties of fluoro-substituted alkoxides of metals having a longer $-CF_2-$ bonding or a bulky structure in the alkyl moiety should be important for making new type titanate coupling agents, which possess a dispersing capacity of inorganic particles in a fluorinated organic polymer. Especially, these alkoxides are expected to be stable against moisture, because many compounds having the fluorinated carbon structure possess water repellency.

In this paper, the results of the syntheses and characterizations of fluoro-substituted alkoxides of titanium are reported. The characterizations of these compounds were achieved through chemical analysis, IR, ^1H NMR, ^{13}C NMR, and ^{19}F NMR spectra. Molecular association of these compounds in nitrobenzene has been also determined.

Experimental

Special precautions were adopted to avoid any hydrolysis of the starting materials and products, and all experiments were carried out under an atmosphere of purified nitrogen to preclude oxygen and moisture.

Materials. 1H,1H-Perfluoroethanol, CF_3CH_2OH (bp 74—75 °C) (**1**), 1H,1H-perfluoro-1-propanol, $CF_3CF_2CH_2OH$ (bp 81 °C) (**2**), 1,1,1-trifluoro-2-propanol, $CF_3CH(CH_3)OH$ (bp 75—76 °C) (**3**), 2-trifluoromethyl-2-propanol, $CF_3C(CH_3)_2OH$ (bp 80—81 °C) (**4**) were commercially available. 1H,1H,3H-Perfluoro-1-propanol, $HCF_2CF_2CH_2OH$ (bp 109—110 °C) (**5**), 1H,1H,5H-perfluoro-1-pentanol, $H(CF_2CF_2)_2CH_2OH$ (bp 139—140 °C) (**6**), 1H,1H,7H-perfluoro-1-heptanol, $H(CF_2CF_2)_3CH_2OH$ (bp 169—170 °C) (**7**), and 1H,1H,9H-perfluoro-1-nonanol, $H(CF_2CF_2)_4CH_2OH$ (bp 63 °C/53 Pa) (**8**) were received as gifts from Daikin Industries, Ltd. Pentafluorophenol, C_6F_5OH (bp 143 °C) (**9**) was obtained from PCR Inc. These alcohols, except **8**, were kept over anhydrous magnesium sulfate for a few days and distilled over a small amount of calcium hydride. **8** and **9** were purified by distillation. Titanium tetrachloride (bp

136 °C) and tetraisopropyl titanate (bp 84 °C/133 Pa) were commercially available and purified by distillation. The solvents used were purified by usual methods.

Measurements. IR spectra were measured in a liquid film or by a KBr method with a Hitachi 215 Grating Spectrophotometer. Pulsed Fourier Transform 100-MHz ^{1}H and 25-MHz ^{13}C NMR were run in THF-d_8 with TMS as an internal standard using a JEOL JNR-PX-100 spectrometer at room temperature: ^{1}H NMR spectra (pulse repetition time, 5 s; number of accumulations, 4) and ^{13}C NMR spectra (pulse repetition time, 5 s; number of accumulations, 18500). The resonance peaks of the ^{13}C NMR spectra were assigned by the peak splitting pattern using the method of off-resonance. The FT mode 90-MHz ^{19}F NMR was recorded at 27 °C on a JEOL JNM-FX-90Q in THF with fluorobenzene (−113.6 ppm[12] from $CFCl_3$ in $CDCl_3$) as an external standard: pulse repetition time, 0.5 s; number of accumulations, 20. The assignments of the ^{19}F NMR spectra were referred to in the databook.[12] The molecular association numbers of some fluoro-substituted alkoxides of titanium were measured using the cryoscopic method in nitrobenzene. Gas chromatograms were performed with a Hitachi 063 (PEG-6000 supported Chromosorb A NAW 30/60 mesh 5 m packed column, TCD) or Hitachi G-3000 gas chromatograph (OV-1 25 m Fused capillary column, FID) and these intensities were measured with a Hitachi 834 chromato processor.

Analytical Methods. Titanium was determined gravimetrically as titanium oxide after the hydrolysis of titanium alkoxides. The fluoroalkoxyl group was determined by using gas chromatography after the hydrolysis of titanium alkoxide to alcohol by adding aqueous ammonia.

Synthesis of Tetrakis(1H,1H-perfluoroethyl) Titanate, $Ti(OCH_2CF_3)_4$ (T1). To a stirred 1H,1H-perfluoroethanol **1** 13.8 g (138 mmol), 5.3 g (28 mmol) of titanium tetrachloride was slowly added using a dropping funnel below 5 °C in a two-necked 200-ml flask connected with a dropping funnel and a reflux condenser. The reaction was exothermic. After 30 min, the mixture was allowed to react at 80 °C. The evolution of hydrogen chloride was observed continuously for about 5—8 h. After an addition of 100-ml benzene, dry ammonia gas was slowly introduced to the system for about 3 h at 10 °C; the mixture was reluxed for 30 min. The completion of the substitution reaction was checked by flame testing a clear solution using copper wire. After removing the ammonium chloride formed by filtration, benzene and excess **1** were evaporated using a vacuum-evaporator. A transparent colorless liquid **T1** was obtained by distillation (yield 10.2 g, 82.9%). **T1** gradually transformed into a white waxy solid: bp 114 °C/133 Pa (lit,[9] bp 94 °C/27 Pa) mp 62 °C; IR 2940, 2870, 1450, 1405, 1365, 1280, 1150, 1080, 960, 827, 695, 670 cm^{-1}; ^{1}H NMR δ=4.60 (CH_2, q, J=8.9 Hz); ^{13}C NMR δ=59.7—70.3 (b, m), 124.3 (a, q, J=279.4 Hz) for ($C^aF_3C^bH_2O)_4Ti$; ^{19}F NMR δ=36.0 (m (=multiplet)). Found: Ti, 10.7; RfO (fluoroalkoxyl group), 89.3%. Calcd for $C_8H_8F_{12}O_4Ti$: Ti, 10.8; RfO, 89.2%.

Synthesis of Tetrakis(1H,1H-perfluoropropyl) Titanate, $Ti(OCH_2CF_2CF_3)_4$ (T2). To a stirred 1H,1H-perfluoro-1-propanol **2** (29.5 g, 0.20 mol), titanium tetrachloride (7.5 g, 0.04 mol) was added below 5 °C. After removing hydrogen chloride formed, 100 ml of THF was added and dry ammonia gas was introduced into the solution. The product was purified by distillation to give **T2** (yield 19.5 g, 75.7%): bp 125 °C/1067 Pa, mp 56 °C; IR 2940, 2875, 1350, 1190, 1090, 1008, 948, 926, 800, 730, 688 cm^{-1}; ^{1}H NMR δ=4.81 (CH_2, q, J=15.1 Hz); ^{13}C NMR δ=70.4 (c, m), 114.7 (b, t(=triplet)(q(=quartet)), J=253.6(36.0) Hz), 120.4 (a, q(t), J=286.0(35.7) Hz) for ($C^aF_3C^bF_2C^cH_2O)_4Ti$; ^{19}F NMR δ=28.1 (a, m), −13.3 (b, t, J=13.4 Hz) for ($CF_3^aCF_2^bCH_4O_4$)Ti. Found: Ti, 7.29; RfO, 92.2%. Calcd for $C_{12}H_8F_{20}O_4Ti$: Ti, 7.44; RfO, 92.6%.

Synthesis of Tetrakis(2,2,2-trifluoro-1-methylethyl) Titanate, $Ti[OCH(CH_3)CF_3]_4$ (T3). The synthesis of **T3** was carried out in a similar manner to that of **T1**. The colorless liquid product was purified by distillation to give **T3** (yield 45.5%): bp 59 °C/133 Pa; IR 3000, 2920, 1458, 1385, 1282, 1180, 1130, 1108, 1030, 960, 800, 704 cm^{-1}; ^{1}H NMR δ=1.42 (CH_3, d, J=6.4 Hz), 4.62 (CH, septet, J=6.4 Hz); ^{13}C NMR δ=18.0 (b, d, J=1.5 Hz), 79.5 (c, q, J=32.1 Hz), 126.4 (a, q, J=282.3 Hz) for $[C^aF_3(C^bH_3)C^cHO]_4Ti$; ^{19}F NMR δ=31.4 (d(=doublet), J=7.3 Hz). Found: Ti, 9.73; RfO, 90.2%. Calcd for $C_{12}H_{16}F_{12}O_4Ti$: Ti, 9.58; RfO, 90.4%.

Synthesis of Tetrakis(2,2,2-trifluoro-1,1-dimethylethyl) Titanate, $Ti[OC(CH_3)_2CF_3]_4$ (T4). In a similar manner to that mentioned above, **T4** was synthesized. The white solid product was purified by distillation to give **T4** (yield 79.8%): bp 78 °C/67 Pa, mp 42 °C; IR 2990, 2945, 1460, 1385, 1320, 1155, 1120, 1013, 1000, 900, 775, 670 cm^{-1}; ^{1}H NMR δ=1.44 (CH_3, s); ^{13}C NMR δ=22.8 (b, s(=singlet)), 24.3 (small peak)(b, s), 71.8 (c, q, J=29.3 Hz), 126.5 (small peak)(a, q, J=284.3 Hz), 137.5 (a, q, J=284.3 Hz) for $[C^aF_3(C^bH_3)_2C^cO]_4Ti$; ^{19}F NMR δ=29.1(s). Found: Ti, 8.83; RfO, 91.2%. Calcd for $C_{16}H_{24}F_{12}O_4Ti$: Ti, 8.62; RfO, 91.4%.

Syntheses of Tetrakis(1H,1H,3H-perfluoropropyl) Titanate, $Ti(OCH_2CF_2CF_2H)_4$ (T5), Tetrakis(1H,1H,5H-perfluoropentyl) Titanate, $Ti[OCH_2(CF_2CF_2)_2H]_4$ (T6), Tetrakis(1H,1H,7H-perfluoroheptyl) Titanate, $Ti[OCH_2(CF_2CF_2)_3H]_4$ (T7) and Tetrakis(1H,1H,9H-perfluorononyl) Titanate, $Ti[OCH(CF_2CF_2)_4H]_4$ (T8). These procedures and purification techniques were almost the same as that for the preparation of **T2**.

T5 was colorless liquid (yield 52.4%): bp 131 °C/27 Pa; IR 2945, 2860, 1455, 1405, 1353, 1285, 1240, 1230, 1200, 1100, 1045, 945, 935, 835, 800, 750, 690 cm^{-1}; ^{1}H NMR δ=4.70 (CH_2, t, J=14.7 Hz), 5.43 (HCF_2, t(t), J=52.7(3.7) Hz); ^{13}C NMR δ=70.6 (c, t, J=24.9 Hz), 109.5 (a, t(t), J=249.0 (37.1) Hz), 115.0 (b, t(t), J=249.0(27.3) Hz) for ($HC^aF_2C^bF_2C^cH_2O)_4Ti$; ^{19}F NMR δ=−27.5 (a, d, J=53.2 Hz), −27.6 (a, d, J=53.2 Hz), −15.0 (b, m) for ($HCF_2^aCF_2^bCH_2O)_4Ti$. Found: Ti, 8.31; RfO, 91.4%. Calcd for $C_{12}H_{12}F_{16}O_4Ti$: Ti, 8.38; RfO, 91.6%.

T6; colorless liquid (yield 69.1%): bp 148 °C/27 Pa; IR 2945, 2870, 1450, 1401, 1359, 1285, 1245, 1160, 1140, 1085, 986, 948, 895, 805, 763, 710 cm^{-1}; ^{1}H NMR δ=4.94 (CH_2, t, J=14.7 Hz), 5.38 (HCF_2, t(t), J=51.4(4.0) Hz); ^{13}C NMR δ=76.7 (e, t, J=24.4 Hz), 112.5 (a, t(t), J=255.6(31.7) Hz), 113.7 (b, t(m), J=253.9 Hz), 115.9 (c, t(m), J=266.0 Hz), 120.0 (d, t(t), J=257.1(31.5) Hz) for ($HC^aF_2C^bF_2C^cF_2C^dF_2C^eH_2O)_4Ti$; ^{19}F NMR δ=−25.9 (a, d, J=53.1 Hz), −18.2 (b, s), −13.0 (c, m), −9.1 (d, m) for ($HCF_2^aCF_2^bCF_2^cCF_2^dCH_2O)_4Ti$. Found: Ti, 4.93; RfO, 95.6%. Calcd for $C_{20}H_{12}F_{32}O_4Ti$: Ti, 4.93; RfO, 95.1%.

T7; slightly brown liquid (yield 73.2%): bp 214 °C/400 Pa; IR 2950, 2885, 1455, 1403, 1365, 1290, 1265, 1195, 1140, 1095, 1000, 955, 860, 802, 763, 740, 720, 655 cm^{-1}; ^{1}H NMR δ=4.88 (CH_2, t, J=13.7 Hz), 6.48 (HCF_2, t(t), J=51.8(5.8) Hz);

^{13}C NMR δ=72.9 (g, t, J=24.0 Hz), 109.5 (a, t(t), J=253.0 (31.5) Hz), 111.6 (b, t(x(=no detectable)), J=274.4 Hz), 112.2 (c, t(x), J=272.2 Hz), 112.9 (d, t(x), J=269.8 Hz), 114.3 (e, t(x), J=270.7 Hz), 117.2 (f, t(t), J=257.9(27.8) Hz) for $(HC^aF_2C^b$-$F_2C^cF_2C^dF_2C^eF_2C^fF_2C^gH_2O)_4Ti$; ^{19}F NMR δ=−25.9 (a, d, J=53.1 Hz), −17.4 (b, s), −10.9 (c and d, m), −9.7 (e, m), −8.9 (f, m) for $(HCF_2^aCF_2^bCF_2^cCF_2^dCF_2^eCF_2^fCH_2O)_4Ti$. Found: Ti, 3.45; RfO, 96.6%. Calcd for $C_{28}H_{12}F_{48}O_4Ti$: Ti, 3.49; RfO, 96.5%.

T8; slightly brown waxy solid (yield 56.8%): bp 210 °C/1.3 Pa; IR 2950, 2870, 1455, 1403, 1370, 1352, 1290, 1200, 1140, 1017, 995, 950, 880, 830, 805, 780, 738, 710, 660 cm^{-1}; ^{1}H NMR δ=4,90 (CH_2, t, J=13.9 Hz), 6.32 (HCF_2, t(t), J=50.5(5.4) Hz); ^{13}C NMR δ=71.8 (i, t, J=24.7 Hz), 109.5 (a, t(t), J=253.3(31.7) Hz), 111.6 (b, t(m), J=264.9 Hz), 112.2 (c, t(x=no detectable), J=258.8 Hz), 112.7 (d, t(x), J=262.5 Hz), 112.7 (e, t(x), J=264.9 Hz), 113.6 (f, t(x), J=266.7 Hz), 113.8 (g, t(x), J=271.0 Hz), 117.6 (h, t(t), J=257.9(29.5) Hz) for $(HC^aF_2C^bF_2C^cF_2C^dF_2C^eF_2C^fF_2C^gF_2C^hF_2C^iH_2O)_4Ti$; ^{19}F NMR δ=−25.8 (a, d, J=51.3 Hz), −17.2 (b, s), −10.7 (c and d, m), −9.4 (e to g, m), −9.5 (h, m) for $(HCF_2^aCF_2^bCF_2^cCF_2^dCF_2^eCF_2^fC$-$F_2^gCF_2^hCH_2O)_4Ti$. Found: Ti, 2.59; RfO, 97.6%. Calcd for $C_{36}H_{12}F_{64}O_4Ti$: Ti, 2.70; RfO, 97.3%.

Synthesis of Tetrakis(pentafluorophenyl) Titanate, Ti-(OC_6F_5)$_4$ (T9). **T9** was prepared by a method involving an ester interchange. 18.4 g (0.1 mol) of pentafluorophenol **9** was allowed to react with excess potassium carbonate in 15 ml of water at room temperature. After completion of the reaction, potassium pentafluorophenolate was extracted to tetrahydrofuran (THF). A white solid potassium pentafluorophenolate was obtained after evaporating THF at room temperature under vacuum. A colorless liquid pentafluorophenyl acetate, $C_6F_5OCOCH_3$, (bp 170—172 °C) was obtained by distillation after reacting excess acetyl chloride and potassium pentafluorophenolate at 50 °C. Tetraisopropyl titanate (0.70 g, 2.5 mmol) and pentafluorophenyl acetate (2.88 g, 12.7 mmol) were mixed in a 50-ml distillation flask and heated at 100 °C for 10 h; 0.82 g (yield 42.7% vs. tetraisopropyl titanate) of dark-red solid **T9** (bp 193 °C/0.67 Pa, mp 97—99 °C) was obtained by a fractional distillation i. vac., after removing almost all isopropyl acetate formed and excess pentafluorophenyl acetate by distillation under reduced pressure (2000 Pa) at 80 °C. IR; 1600, 1510, 1487, 1350, 1515, 1190, 1175, 1165, 1090, 1030, 990, 980, 850, 735, 715, 662 cm^{-1}; ^{1}H NMR no proton; ^{13}C NMR δ=140.9 (para, d(t), J=244.7(13.9) Hz), 143.8 (meta, d(m), J=249.1 Hz), 146.1 (ortho, d(m), J=249.1 Hz); ^{19}F NMR δ=120.0 (para, t(m), J=22.0 Hz), 123.6 (meta, t, J=20.2 Hz), 129.8 (ortho, d, J=20.2 Hz). Found: Ti, 6.35%. Calcd for $C_{24}F_{20}O_4Ti$: Ti, 6.14%.

Results and Discussion

These obtained fluoro-substituted titanates were sensitive to moisture and decomposed to give titanium oxide and alcohol or phenol. Considering the hydrolytic nature of these obtained compounds, metal and fluoro-substituted alkoxyl group analyses were in fair agreement with the calculated values.

The NMR spectra of tetrakis(1H,1H,5H-perfluoropentyl) titanate, $Ti[OCH_2(CF_2CF_2)_2H]_4$, **T6** as an example are shown in Figs. 1—3. These spectrum

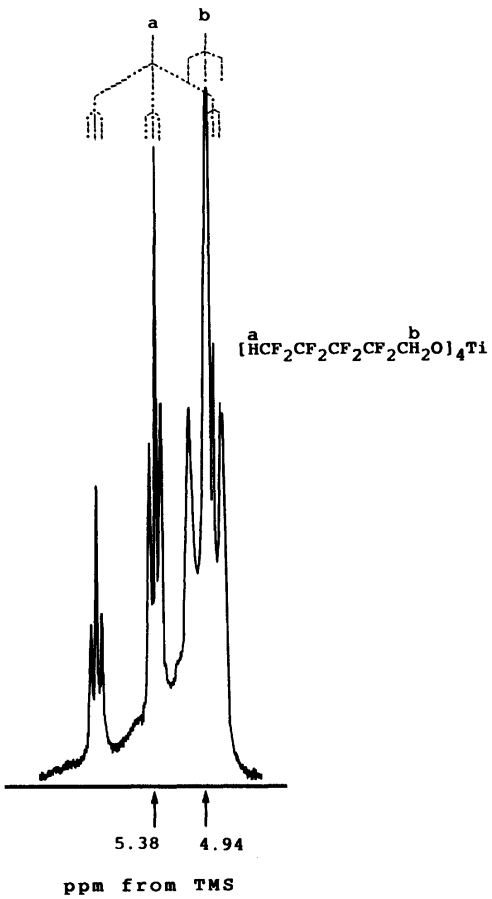

Fig. 1. Pulsed Fourier transform 100 MHz ^{1}H NMR spectrum of **[$HCF_2CF_2CF_2CF_2CH_2O$]$_4$Ti** in THF-d_8 (recorded at r.t.; internal standard, TMS; pulse repetition time, 5 s; number of accumulations, 4).

patterns resembled that of the starting alcohol, except for an absence of the OH group. The ^{13}C NMR spectrum pattern was relatively complicated (see Fig. 2). The resonance peaks of a carbon atom were coupled magnetically with the geminal and vicinal fluorine atoms. In the case of the ^{13}C NMR spectra having a fluorinated carbon atom, it is well-known that the peak intensities of a carbon bonded to a hydrogen atom, such as HCF_2-, H_2CF-, or -HCF-, are stronger than that of a carbon bonded only to fluorine atoms, such as CF_3- or -CF_2-. A group of peaks of the terminal HCF_2- (triplet(triplet)) was observed with the strongest one at 112.5 ppm from TMS in THF-d_8, and the other -CF_2- peaks were weaker and split in a complicated manner.

In ^{19}F NMR, the resonance peaks of -CF_3 of tetrakis(1H,1H-perfluoroethyl) titanate **T1**, were observed as multiplet peaks centered at 36.0 ppm from fluorobenzene in THF. However, the -CF_3 peaks of the starting alcohol, 1H,1H-perfluoroethanol **1**, were triplet at 34.7 ppm. The same difference in the ^{19}F NMR was detected between tetrakis(1H,1H-perfluoropropyl) titanate **T2** and 1H,1H-perfluoro-1-propanol

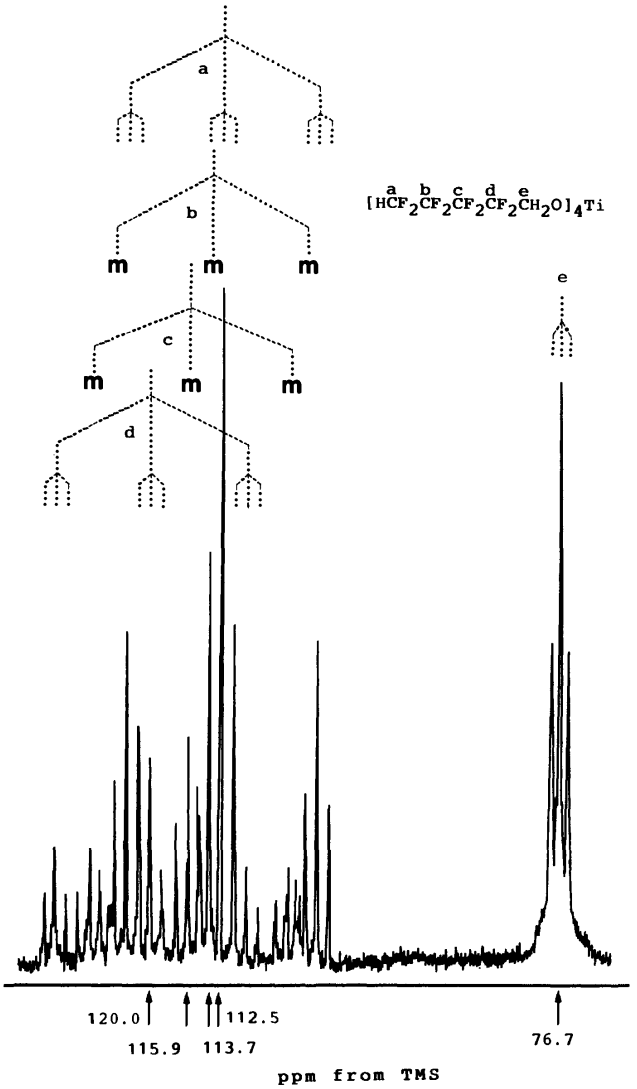

Fig. 2. Pulsed Fourier transform 25 MHz ^{13}C NMR spectrum of $[HCF_2CF_2CF_2CF_2CH_2O]_4Ti$ in THF-d_8 (recorded at r.t.; internal standard, TMS; pulse repetition time, 5 s; number of accumulations, 18500), "m" shows multiplet.

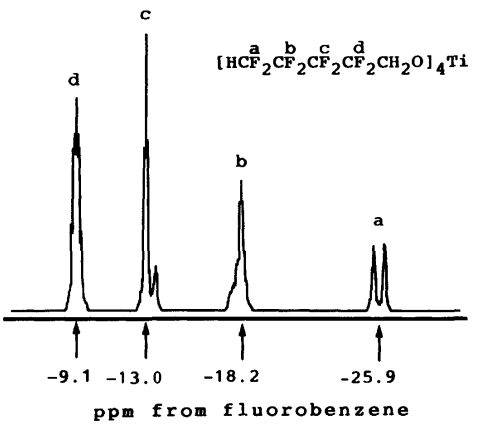

Fig. 3. Pulsed Fourier transform 90 MHz ^{19}F NMR spectrum of $[HCF_2CF_2CF_2CF_2CH_2O]_4Ti$ in THF (recorded at 27°C; external standard, fluorobenzene; rocked with benzene-d_6; pulse repetition time, 0.5 s; number of accumulations, 20).

2, though the observation could not differentiate between tetrakis(2,2,2-trifluoro-1,1-dimethylethyl) titanate **T4** and 2-trifluoromethyl-2-propanol **4**. These results suggest that the magnetic circumstances of the fluorine atoms composed of four $-CF_3$ groups in **T4** are equivalent. On the other hand, the fluorine atoms making four $-CF_3$ groups in **T1** and **T2** form a more complicated magnetic circumstances by molecular association with the mutual titanate molecules in THF. This suggestion was confirmed by measurements of the molecular association number of these three titanates (see later).

Mazdiyasni et al.[11] again tried to synthesize either aluminium or group-IV metal hexafluoro-substituted isopropoxides by an ammonia method described in the literature.[9,10] They found that the only poor yield product obtained was the fluorinated alkoxides of metal having two molecules of ammonia. They also described that the ammonia was apparently bonded strongly enough to prevent its loss during vacuum sublimation or fractional distillation at relatively high temperatures.

The present authors carried out ammonia analyses for a few products by the Kjeldal method. The ammonia contents (0.0025, 0.0127, 0.0023, and 0.0034%) were obtained from **T1**, **T2**, **T4**, and tetrakis(1H,1H,3H-perfluoropropyl) titanate **T5**, respectively. Analytical data showed that either the ammonia molecule did not form ammonia adducts of pure titanates or it dissociated from the ammonia adducts of titanates during vacuum distillation at relatively high temperatures. From these results the ammonia method for these titanate syntheses has been found to be a suitable method, since these analytical values indicate that ammonia contamination only represented one ammonia molecule per ca. 200—1500 titanate molecules.

Molecular Association Numbers of Some Titanates: The molecular association numbers of three titanates, tetrakis(1H,1H-perfluoroethyl) titanate **T1**, tetrakis-(1H,1H-perfluoropropyl) titanate **T2**, and tetrakis-(2,2,2-trifluoro-1,1-dimethylethyl) titanate **T4**, were measured by the cryoscopic method in nitrobenzene. The results are shown in Fig. 4. The bulky **T4**, which has the most bulky fluoro-substituted alkyl groups among the three titanates, shows a monomeric in nitrobenzene. The association number obtained is unity, an independent concentration in the concentration range 0.2—1.8 wt%, as shown by the open squares. The maximum molecular association numbers of **T2** and **T1** were 1.5 (closed circles) and 3.5 (open circles), respectively, and the numbers became larger as the concentration increased within the same concentration range. Considering the electronegativity of the

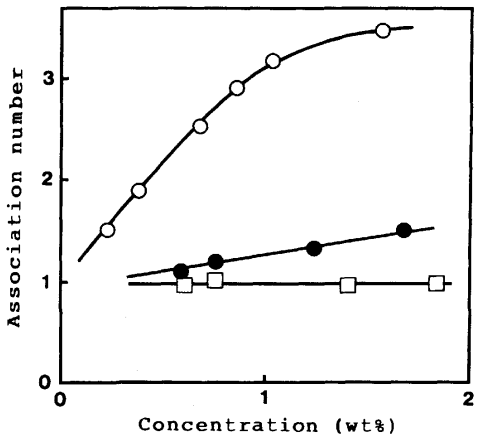

Fig. 4. Association curves of $Ti(OCH_2CF_3)_4$ (**T1**) (○), $Ti(OCH_2CF_2CF_3)_4$ (**T2**) (●), and $Ti[(OC(CH_3)_2CF_3)]_4$ (**T4**) (□): measured by the cryoscopic method in nitrobenzene. The bulky **T4** shows a monomeric in nitrobenzene and the association number is unity being concentration independently in the concentration range 0.2—1.8 wt%. The maximum molecular association numbers of **T2** and **T1** were 1.5 and 3.5, respectively, and the numbers become larger with concentration increase in the same concentration range.

fluorine atom, the partial charge density ($\delta+$) on the titanium atom of these fluoroalkyl titanates should be higher than those of the alkyl titanates. Therefore, the electronegative alkoxyloxygen ($\delta-$) of the fluoroalkyl titanate would be favorable to coordinate to the titanium atom of another fluoroalkyl titanate molecule; in other words, a fluoroalkyl titanate would be subject to form a molecular association. However, the results of the molecular association measurement indicate that the molecular association numbers of these titanates were influenced by a steric effect of the fluoro-substituted alkoxyl groups, rather than their inductive effect. These results also elucidate the difference of the magnetic circumstances of the fluorine atoms in **T1**, **T2**, and **T4** mentioned above, i.e. the magnetic circumstances of the fluorine atoms composed of four $-CF_3$ groups in the monomeric **T4** are equivalent, while the fluorine atoms making four $-CF_3$ groups in the associated **T1** and **T2** form a more complicated magnetic circumstances.

The authors are grateful to Dr. Takeo Konakahara of the Science University of Tokyo for the ^{19}F NMR measurements. We also thank Mr. Noboru Komine, Mr. Yukihide Shiraishi, and Mr. Hideo Terajima for their assistance in carrying out a part of experiment of this study.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 62550618 from the Ministry of Education, Science and Culture, to which the authors are also grateful.

Photoisomerization of Oxime Ethers and Efficiency of Triplet Formation via Exciplexes

Yoshihiko TAKEDA, Hiroaki MISAWA, Hirochika SAKURAGI, and Katsumi TOKUMARU*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received January 28, 1989)

9,10-Dicyanoanthracene(DCA)-sensitized isomerization of (*E*)- and (*Z*)-isomers of an oxime ether of 2-acetylnaphthalene (*E*-**1** and *Z*-**1**, respectively) was investigated in benzene by means of steady irradiation and laser flash photolysis. The excited singlet DCA was effectively quenched by *E*-**1** and *Z*-**1** to afford exciplexes, decay of which gave DCA triplets or **1** triplets. The triplet state of **1** was proposed as the isomerization intermediate and the formation efficiency of **1** triplets was estimated from isomerization quantum yields.

Although photochemical geometrical isomerization of the ethylenic[1] and azo linkage[2] has been well-investigated, little work has been done on photoisomerization of the imine linkage.[3] For many imines, only one geometrical isomer, usually (*E*)-isomer, is stable and the other, usually (*Z*)-isomer, is unstable at room temperature.[4] The (*Z*)-isomers, when formed from irradiation of the (*E*)-isomers, revert quickly to the (*E*)-isomers. This situation made it difficult to work with the imines by the conventional procedures. However, introduction of a methoxyl group on the nitrogen atom of N=C bonds stabilizes effectively configurations of both isomers, enabling one to investigate photochemical geometrical isomerization of oxime ethers, particularly on triplet sensitization.[5]

Recently much effort has been done to investigate photochemical reactions proceeding through electron transfer.[6] During the course of our investigation on photochemical behavior of imines[7] as well as olefins[1c,8] on triplet and electron-transfer sensitization, we found that 9,10-dicyanoanthracene (DCA) sensitizes the isomerization of a pair of oxime ethers of 2-acetylnaphthalene, (*E*)- and (*Z*)-*N*-methoxy-1-(2-naphthyl)ethanimine (*E*-**1** and *Z*-**1**, respectively). In this paper we report in detail isomerization behavior of **1** via exciplexes with DCA.

Experimental

(*E*)- and (*Z*)-*N*-Methoxy-1-(2-naphthyl)ethanimine (*E*-**1** and *Z*-**1**, respectively).[5c] A mixture of 2-acetylnaphthalene (17 g, 0.10 mol) and *O*-methylhydroxyamine hydrochloride (9.3 g, 0.11 mol) was refluxed in ethanol (95%, 210 ml) containing sodium acetate (151 g, 1.85 mol) for 12 h. Usual work-up gave 15 g of a mixture of oxime ethers *E*-**1** and *Z*-**1** (*E*/*Z*=90:10 by GLPC); yield 75%. Crystallization from ethanol afforded pure *E*-**1**; mp 89—90 °C (lit, 89.5—90 °C).[5c]

The mixture of *E*-**1** and *Z*-**1** was dissolved in benzene (1 dm^3), and irradiated under nitrogen with a 400-W high-pressure mercury lamp (>300 nm) for several hours. Evaporation of the solvent left a solid (*E*/*Z*=44:56), which was crystallized from ethanol to give a *Z*-**1** rich filtrate (*E*/*Z*=25:75). This mixture was separated by column chromatography (silica gel, benzene) to afford an oily material, which was distilled twice under vacuum to give pure *Z*-**1**; mp 24.5—26 °C (lit, 25—26 °C).[5c]

DCA was purified by crystallization from ethanol followed by sublimation under vacuum. Benzene was distilled over calcium hydride and acetonitrile was distilled twice over phosphorus pentoxide and then over potassium carbonate.

Fluorescence spectra were obtained on a Hitachi MPF-2A or a Hitachi F-4000 fluorescence spectrophotometer. Fluorescence lifetimes were measured using a single photon counting apparatus, Applied Photophysics Model SP-3X or Horiba NAES 1100.

Laser flash photolyses were performed with 406-nm laser pulses (DPS, 10-nm fwhm) from a XeCl (308 nm) excimer laser (Lambda Physik EMG-101)-pumped dye laser (Lambda Physik FL-3002) and with a pulsed xenon arc (Wacom KXL-151, 150 W) as a monitoring light source. The monitoring light coming from a monochromator (JASCO CT-25C) was amplified by a photomultiplier (Hamamatsu Photonics R928) and stored in a storage scope (Iwatsu TS-8123), and the signals were transferred to a personal computer (NEC PC-9801E) and accumulated for 3—5 times to be averaged. The system was computer-controlled and the decay curves were analyzed by this computer system. Sample solutions containing DCA (1.2×10^{-4} M, M=mol dm^{-3}) and oxime ether *Z*-**1** (0.13 M) were deaerated by bubbling nitrogen for 30 min.

Near-infrared emission from singlet oxygen was observed by a germanium p-n junction detector (Hamamatsu Photonics B2144) with a silicon window. The element was reverse-biased (9 V) and placed in series with a load resistor (1 kΩ). The response time of this system is less than 3 μs.

Redox potentials were measured by cyclic voltammetry with a Hokuto Potentiostat-Galvanostat HA-201 and a Hokuto Function Generator HB-104. The measurements were carried out using a three-electrode cyclic voltammetric cell. The working electrode was a platinum wire and the reference electrode was SCE. Tetraethylammonium perchlorate (0.1 M) was used as a supporting electrolyte. Sample concentrations were ca. 5×10^{-3} M in acetonitrile.

For quantum yield measurements nitrogen-purged solutions of DCA and *E*-**1** or *Z*-**1** were irradiated on a merry-go-round type apparatus with 405- and 436-nm light from a 400-W high-pressure mercury lamp through a Toshiba L-39 glass filter. Light intensities were determined by potassium tris(oxalato)ferrate(III) actinometry. The solutions were analyzed at low conversion (<10%) of the substrate on a Shimadzu GC-4CM-PF gas chromatograph.

Photostationary isomer ratios were measured by irradiating benzene solutions of *Z*-**1** and *E*-**1** in the presence of optically matched concentrations of sensitizers (OD's at

irradiation wavelength=ca. 2).

Results

Quenching of DCA Fluorescene by *E*-1 and *Z*-1. The fluorescence intensity and lifetime of DCA (3×10^{-5} M) were effectively quenched by both *E*-1 (0—0.025 M) and *Z*-1 (0—0.046 M) in deaerated benzene and acetonitrile (Fig. 1 for *Z*-1 in benzene). Stern-Volmer plots are linear over the concentration range investigated. Table 1 lists the quenching rate constants (k_q) calculated from the Stern-Volmer constants ($K_{SV}=k_q\tau_S$) of intensity quenching and fluorescence lifetimes (τ_S), 12.4 ns in benzene and 14.9 ns in acetonitrile, determined by single photon counting. The k_q values are close to the diffusion-controlled rate constant in each solvent.[9]

On quenching of DCA fluorescence by *E*-1 and *Z*-1 in benzene, new weak emissions appeared at the longer wavelength region with their maxima around 520 nm for *E*-1 and 505 nm for *Z*-1. These emissions are reasonably assigned to the exciplexes formed from the excited singlet DCA and the ground-state oximes. Figure 1 indicates the profile of the exciplex emission of *Z*-1. The exciplexes decayed with lifetimes of 22.8 and 28.7 ns for *E*-1 and *Z*-1, respectively, as measured by single photon counting. In acetonitrile no exciplex emission was observed for *E*-1 or *Z*-1.

Photostationary State Isomer Ratio. Oxime ethers *E*-1 and *Z*-1 (5×10^{-3} M) were irradiated in deaerated benzene or acetonitrile solutions containing DCA (1×10^{-3} M) with 405- and 436-nm light. The irradiation resulted in nearly the same photostationary state isomer ratios $([E]/[Z])_{pss}$ around 40/60 starting with either isomer in both solvents. When typical triplet sensitizers like acetophenone and benzophenone (1×10^{-2} M) were used in benzene, similar $([E]/[Z])_{pss}$ values (44/56) were obtained. Direct irradiation of **1** with 313-nm light gave an $([E]/[Z])_{pss}$ value around 60/40. The results are listed in Table 2.

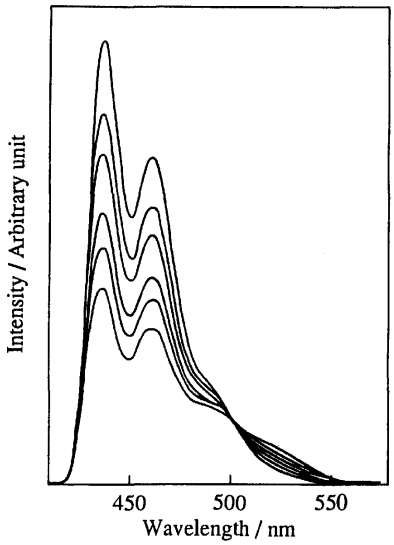

Fig. 1. Quenching of DCA fluorescence by *Z*-1 and exciplex emission in benzene.

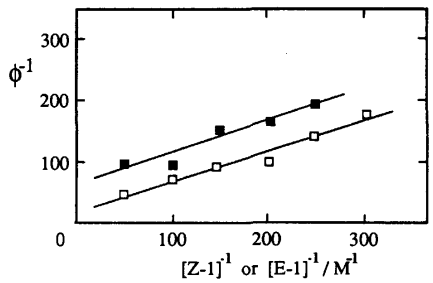

Fig. 2. Stern-Volmer plots of DCA-sensitized isomerization of *E*-1 (■) and *Z*-1 (□) in benzene.

Table 1. Rate Constants for Fluorescence Quenching of DCA by Oxime Ethers in Benzene and Acetonitrile

Oxime ether	In benzene		In acetonitrile	
	$k_q\tau_S$/M^{-1}	k_q/M^{-1} s^{-1}	$k_q\tau_S$/M^{-1}	k_q/M^{-1} s^{-1}
E-1	94	7.8×10^9	270	1.8×10^{10}
Z-1	27	2.2×10^9	420	2.8×10^{10}

Table 2. Photostationary State Isomer Ratios of Oxime Ether **1** on Direct and Sensitized Irradiation in Benzene and Acetonitrile

Sensitizer	Wavelength/nm	Solvent	Isomer ratio	
			Z	*E*
—	313	Benzene	58	42
DCA	405, 436	Benzene	41	59
Benzophenone	366	Benzene	44	56
Acetophenone	313	Benzene	44	56
—	313	MeCN	62	38
DCA	405, 436	MeCN	38	62
Benzophenone	366	MeCN	44	56

Quantum Yields for Isomerization. The quantum yields for DCA(10^{-3} M)-sensitized $E \rightarrow Z$ and $Z \rightarrow E$ isomerization ($\phi_{E \rightarrow Z}$ and $\phi_{Z \rightarrow E}$, respectively) were determined in benzene with varying concentrations (3.3×10^{-3}—2.0×10^{-2} M) of *E*-**1** and *Z*-**1** at their low conversion (<10%). Figure 2 shows Stern-Volmer plots for $E \rightarrow Z$ and $Z \rightarrow E$ isomerization. The reciprocal of the intercept and the ratio of intercept/slope in the plot for $Z \rightarrow E$ isomerization give, respectively, 0.062 as a limiting quantum yield ($\phi_{Z \rightarrow E}^{lim}$) at infinite *Z*-**1** concentration and 32 M^{-1} as a Stern-Volmer constant (K_{SV}). The latter value is in satisfactory agreement with that obtained from the fluorescence quenching, 27 M^{-1}. Similarly the $E \rightarrow Z$ isomerization gives 0.015 as $\phi_{E \rightarrow Z}^{lim}$ and 122 M^{-1} as K_{SV}. This value agrees fairly well with K_{SV} from the fluorescence quenching, 94 M^{-1}. In acetonitrile the isomerization proceeded with much lower efficiencies as estimated from irradiation times needed for accomplishment of the photostationary state.

Triplet Energies of Oxime Ethers. An attempt was done to determine the triplet energies of *E*-**1** and *Z*-**1** by the procedure of Hammond and Saltiel,[10] since *E*-**1** and *Z*-**1** did not emit phosphorescence in rigid glasses. Thus, the photostationary state isomer ratios of **1** were measured in the presence of various sensitizers with triplet energies covering 42—74 kcal mol^{-1} in benzene (Table 3). Figure 3 plots the ratio against the triplet energy of the sensitizer. This plot allows us to estimate the triplet energies of *E*-**1** and *Z*-**1** as ca. 52 and ca. 60 kcal mol^{-1}, respectively.[10]

Laser Flash Photolysis. On laser flash photolysis (LFP) of DCA (1×10^{-4} M) with 406-nm laser pulses from excimer laser (XeCl, 308 nm)-pumped dye laser (DPS) in deaerated benzene in the presence of *Z*-**1** (0.1 M) a transient absorption spectrum was observed in the 400—600 nm region (λ_{max} 442 nm), the lifetime being 9.5 μs as observed at 455 nm (Fig. 4). This spectrum can be attributed to DCA triplets.[11] In the absence of *Z*-**1** the intensity of the absorption was

several times weaker than that observed in its presence.

LEP of DCA with *Z*-**1** in acetonitrile gave a transient absorption spectrum different from that in benzene (Fig. 5). The absorption bands in the 440—750 nm region can be mainly attributed to DCA anion radicals,[12] and the bands in longer wavelengths than 750 nm might be attributed to *Z*-**1** cation radicals since γ-radiolysis of *Z*-**1** in Freon matrix gave absorption bands due to *Z*-**1** cation radicals in the 500—1000 nm region with λ_{max}'s at 650, 810, and 930 nm.[13]

Singlet oxygen luminescence was monitored at 1.27 μm using a germanium photodiode by exciting benzene solutions of DCA (1×10^{-4} M) with 406-nm laser pulses under air in the absence and presence of *Z*-**1**. In the absence of *Z*-**1** the emission was too weak to determine its lifetime; however, in the presence of *Z*-**1** (0.1 M) was exhibited a strong emission with a lifetime of 30 μs.[14]

Discussion

The quenching interaction of singlet excited DCA and the oxime ethers is considered to be accompanied by exciplex formation in benzene as evidenced by the long wavelength emission, and by electron transfer in acetonitrile as shown by transient absorption ascribed to DCA anion radicals and oxime ether cation radicals in laser plash photolysis. The changes of Gibbs' free energy ($\Delta G°$) associated with electron transfer from the DCA excited singlet to the oxime ethers in acetonitrile were estimated as −3.8 and −5.0 kcal mol^{-1} for *E*-**1** and *Z*-**1**, respectively, by Weller's equation (Eq. 1),[15]

$$\Delta G°/\text{kcal mol}^{-1} = 23.06(E_{ox} - E_{red} - e_0^2/a\varepsilon - E_{0,0}) \quad (1)$$

where E_{ox} and E_{red} indicate the oxidation potential of an oxime ether (1.81 V for *E*-**1** and 1.76 V for *Z*-**1** vs. SCE) and the reduction potential of DCA (−0.95 V), respectively, as determined in acetonitrile, $E_{0,0}$ is the singlet excitation energy of DCA (2.87 eV, estimated from its fluorescence spectrum), and $e_0^2/a\varepsilon$ is a Coulombic term (0.06 eV). These values show that the electron transfer can take place as an exothermic process in acetonitrile.

The $([E]/[Z])_{pss}$ ratio in DCA-sensitized irradiation is 1.4 in benzene from Table 1. The ratio is expressed by Eq. 2,

$$([E]/[Z])_{pss} = (k_q^Z/k_q^E)(\phi_{Z\to E}^{lim}/\phi_{E\to Z}^{lim}) \quad (2)$$

where k_q^Z and k_q^E are the rate constants for quenching of DCA excited singlets by *Z*-**1** and *E*-**1**, respectively, and the limiting quantum yields, $\phi_{Z\to E}^{lim}$ and $\phi_{E\to Z}^{lim}$, mean the quantum efficiencies with which the exciplexes give the isomerized derivatives. Combination of the observed ratios of k_q^Z/k_q^E, 0.28, and $\phi_{Z\to E}^{lim}/\phi_{E\to Z}^{lim}$, 4.2, gives $([E]/[Z])_{pss}$ as 1.2, which agrees well with the observed value, 1.4. This fact supports the sensitization with DCA of **1** isomerization.

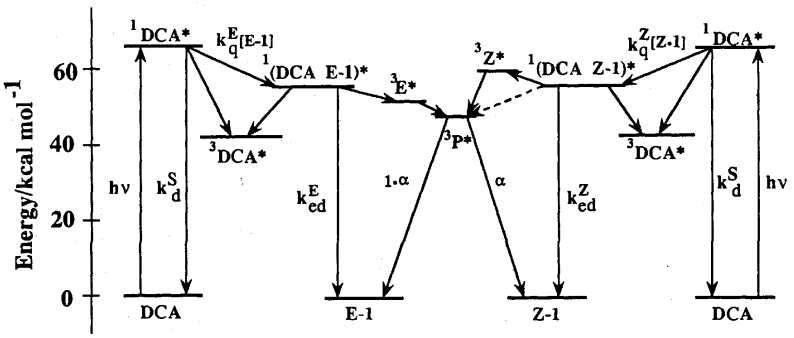
Similarity in the photostationary isomer ratio between DCA and benzophenone sensitization in benzene (Table 2) suggests that the DCA-sensitization generates the triplet state of **1** as the intermediate for isomerization in benzene, as seen in the isomerization of olefins in the presence of electron donors[16] or acceptors[8b,17] in nonpolar solvents where the triplet state of olefins results from the exciplexes.

It is reasonably concluded from energetic considerations and laser flash photolysis study that the triplet state of **1** is the intermediate of isomerization. The Hammond–Saltiel plot (Fig. 3) gave the triplet energies of *E*-**1** and *Z*-**1** as ca. 52 and ca. 60 kcal mol^{-1}, respectively. It is noteworthy that the triplet energy of *Z*-**1** is close to that of naphthalene itself, 61 kcal mol^{-1},[18] indicating that the triplet excitation in *Z*-**1** is nearly localized in the naphthalene moiety which may be twisted around the C–C single bond from the C=N molecular plane. Also, the energies of the exciplexes of DCA with *E*-**1** and *Z*-**1** are estimated around 55 and 56 kcal mol^{-1}, respectively, from their emission maxima.

The energy diagram for DCA-sensitized isomerization of **1** in benzene is depicted in Scheme 1. On excitation of DCA in the presence of *E*-**1**, the resulting singlet excited DCA (66.2 kcal mol^{-1}) interacts with *E*-**1** to give an exciplex, which subsequently either is deactivated to the ground state through nonradiative pathways or exciplex emission, or produces the triplet state of *E*-**1** or DCA (41.5 kcal mol^{-1})[16b] in an exothermic way. In the case of *Z*-**1**, the formation of *Z*-**1** triplets from the exciplex of DCA and *Z*-**1** is nearly 3 kcal mol^{-1} endothermic. However, if the exciplex does not produce directly *Z*-**1** triplets (^{3}Z*) but produces the perpendicular triplet of **1** (^{3}P*) through a nonvertical pathway, it is certainly at least 5 kcal mol^{-1} exothermic, since in the triplet state of stilbene ^{3}P* is nearly the same as, or slightly lower than, ^{3}E* in energy.[1] In any case, ^{3}P* produced either from ^{3}E*, ^{3}Z*, or directly from the exciplexes undergoes deactivation to the ground state *E*-**1** and *Z*-**1** with a certain ratio.

Laser excitation of DCA in deaerated benzene exhibited only a weak transient absorption band due to DCA triplets because of low efficiency of intersystem crossing of DCA excited singlets.[19] It is remarkable that in the presence of *Z*-**1**, laser excitation of DCA afforded the absorption bands of the DCA triplets (λ_{max} 442 nm) with several times stronger intensity than in the absence of *Z*-**1**; however, any transient absorption bands assignable to the triplet states of **1** were not detected. This may be owing to their very short lifetimes, since, even on benzophenone-sensitized laser excitation, only the benzophenone triplet was observed with no detection of **1** triplets.

Likewise, laser excitation of DCA in aerated benzene



Scheme 1.

gave only a very low yield of singlet oxygen, as determined by singlet oxygen luminescene technique. This may be also due to the low quantum yield for intersystem crossing of the DCA excited singlets. However, in the presence of *Z*-**1**, a strong emission from singlet oxygen was detected. This is reasonably attributed to a more efficient production of the DCA triplets under these conditions.

The fact that the DCA triplet is produced from the excitation of DCA in the presence of *Z*-**1** but not in the absence of *Z*-**1** clearly shows that the quenching of DCA singlets by *Z*-**1** gives the DCA triplet and probably also the triplet state of **1**. Therefore, it is reasonable to propose such a mechanism for the isomerization as shown in Scheme 1, where *k*'s are the rate constants for the corresponding processes.

According to this mechanism, the quantum yields for the isomerization can be expressed as follows:

$$\phi_{E\to Z} = \frac{k_q^{E}[E\text{-}\mathbf{1}]}{\tau_s^{-1} + k_q^{E}[E\text{-}\mathbf{1}]} \cdot \phi_T^{E} \cdot (1-\alpha) \quad (3)$$

$$\phi_{Z\to E} = \frac{k_q^{Z}[Z\text{-}\mathbf{1}]}{\tau_s^{-1} + k_q^{Z}[Z\text{-}\mathbf{1}]} \cdot \phi_T^{Z} \cdot \alpha \quad (4)$$

where ϕ_T^E and ϕ_T^Z denote the efficiencies for the production of the triplet state of **1** from the exciplexes. Therefore, the Stern–Volmer equation can be reduced as follows:

$$\frac{1}{\phi_{E\to Z}} = \frac{1}{(1-\alpha)\phi_T^{E}}\left(1 + \frac{1}{k_q^{E}\tau_S[E\text{-}\mathbf{1}]}\right) \quad (5)$$

$$\frac{1}{\phi_{Z\to E}} = \frac{1}{\alpha\phi_T^{Z}}\left(1 + \frac{1}{k_q^{Z}\tau_S[Z\text{-}\mathbf{1}]}\right) \quad (6)$$

The limiting quantum yields at the infinite concentration of *E*-**1** and *Z*-**1**, $\phi_{E\to Z}^{lim}$ and $\phi_{Z\to E}^{lim}$, are written as follows:

$$\phi_{E\to Z}^{lim} = (1-\alpha)\phi_T^{E} \quad (7)$$

$$\phi_{Z\to E}^{lim} = \alpha\phi_T^{Z} \quad (8)$$

The values for α and $1-\alpha$, the ratios of giving *E* and *Z* from the common twisted triplet state of **1**, ^{3}P*, are seen as 0.56 and 0.44, respectively, from the photostationary state isomer ratio arising from sensitizers with sufficiently high triplet energies like acetophenone and benzophenone (Table 1). Substitution of the observed $\phi_{E\to Z}^{lim}$ and $\phi_{Z\to E}^{lim}$ values in Eqs. 7 and 8 affords ϕ_T^Z and ϕ_T^E as 0.14 and 0.027, respectively.

The above values ϕ_T's are nearly comparable or lower than the values for the triplet olefin production from the quenching of the singlet excited state of 2-NaphthylCH=CHBu^t with 1,4-dicyanobenzene in benzene, 0.26[8b] and for the quenching of the singlet excited stilbene with various amines in benzene, 0.09—0.51.[16a] The lower efficiency for the production of triplet **1** in the present reaction can be attributed to the dual courses which the exciplex can take, that is, giving either triplet **1** or triplet DCA; the latter is energetically preferable. Also, the present exciplexes might have higher probability to undergo deactivation than those between the olefins and electron donors or acceptors.

The isomerization efficiency was lower in acetonitrile than in benzene, indicating that the isomerization does not proceed efficiently through cation radicals of **1**. On LFP of DCA with *Z*-**1** in acetonitrile only the ionic species were observed but no triplets were detected. However, the photostationary state isomer ratio of DCA-sensitized isomerization was close to that of benzophenone sensitization in the same solvent (Table 1).

The ion radical pairs *E*-**1**$^+$/DCA$^-$ and *Z*-**1**$^+$/DCA$^-$ are estimated to be 63.5 and 62.4 kcal mol^{-1}, respectively, higher in energy than the neutral species in the ground state from their electrochemical potentials. Back electron transfer in the radical ion pairs can generate the triplet states of DCA and **1**; however, the major role in isomerization of **1** may be played by the **1** triplet thus formed.

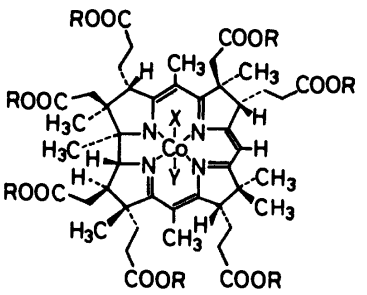
Redox Behavior of Simple Vitamin B_{12} Model Complexes and Electrochemical Catalysis of Carbon-Skeleton Rearrangements†

Yukito MURAKAMI,* Yoshio HISAEDA, Sheng-Di FAN, and Yoshihisa MATSUDA
Department of Organic Synthesis, Faculty of Engineering, Kyushu University,
Hakozaki, Higashi-ku, Fukuoka 812
(Received February 2, 1989)

Various cobalt complexes of 4,10-dipropyl-5,9-diazatrideca-4,9-diene-3,10-dione dioxime, $(C_2C_3)(DOH)_2pn$, were prepared, and redox behavior of them was investigated by means of cyclic voltammetry; Co(II)/Co(I) redox potentials in the range of −0.69 through −0.7 V vs. Ag/AgCl. The monomethylated complex, which has a cobalt-carbon bond at one axial site of the nuclear cobalt, was disproportionated to the dimethylated complex, involving two cobalt-carbon bonds at both axial sites, and the Co^I species by one-electron reduction. The dimethylated complex was inactive for electrochemical reduction, but transformed into the monomethylated complex via cleavage of a cobalt-carbon bond upon electrochemical oxidation. The electrolyses of 1-bromo-2,2-bis(ethoxycarbonyl)propane, 1-bromo-2-cyano-2-ethoxycarbonylpropane, and 2-acetyl-1-bromo-2-ethoxycarbonylpropane in the presence of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2]$ in *N,N*-dimethylformamide did not proceed in a divided cell at −2.0 V vs. Ag/AgCl, since the corresponding dialkylated complexes, inactive for electrochemical reduction, were formed in the course of reaction. When imidazole was added to solutions for the electrolysis, the reaction proceeded efficiently by the trans effect arising from the coordinated axial base and the corresponding carbon-skeleton rearrangement products were obtained. On the other hand, the carbon-skeleton rearrangement proceeded in an undivided cell even in the absence of imidazole; the dialkylated complex was decomposed to give the monoalkylated complex and the reduction and rearrangement products by electrochemical oxidation on the anode.

Vitamin B_{12}-dependent enzymes catalyze various isomerization reactions which result in carbon-skeleton rearrangements: methylmalonyl-SCoA⇌succinyl-SCoA, β-methylaspartate⇌glutamate, and methylitaconate ⇌α-methyleneglutarate.[1] Clarification of these reaction mechanisms is a current research target in bioinorganic chemistry.[2] In this regard, various cobalt complexes have been synthesized as model complexes,[3] and mechanistic studies of various enzyme-mimic reactions have been carried out. One of the most important aspects in designing model complexes is to pay much attention to the redox potentials of the nuclear cobalt in connection with their catalytic activities. The catalytic reactions as mediated by vitamin B_{12} and its model complexes have been carried out by electrochemical means[4,5] in the light of redox behavior of such complexes.[6–8]

We have been dealing with hydrophobic vitamin B_{12} derivatives, which have ester groups in place of the peripheral amide moieties of the naturally occurring vitamin B_{12},[9–14] and found that electrochemical carbon-skeleton rearrangements were catalyzed efficiently by these complexes.[13] In those cases, the reaction takes place with a catalytic cycle shown in Fig. 1: the Co^{II} complex is electrochemically reduced to the Co^I species, and the corresponding alkylated complex is generated by reaction of the supernucleophilic Co^I species with a substrate, a substituted alkyl bromide (RX); the alkylated complex is subsequently decomposed by photolysis or electrolysis to afford the corresponding products, and the cobalt complex acts as a mediator repeatedly. This finding prompted us to develop a simple model complex, which shows redox



Hydrophobic Vitamin B_{12}

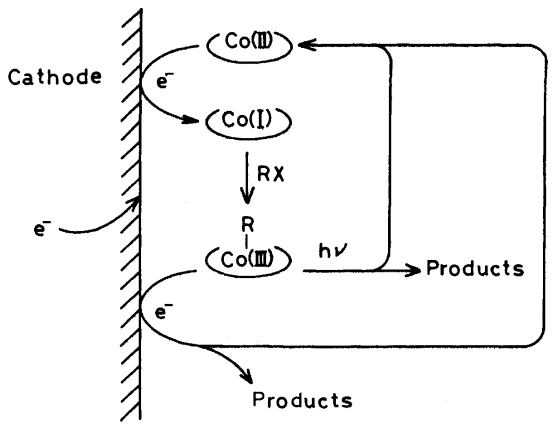


Fig. 1. Schematic representation of electrochemical catalysis.

† Contribution No. 897 from this Department. Preliminary communications; see Refs. 28 and 32.

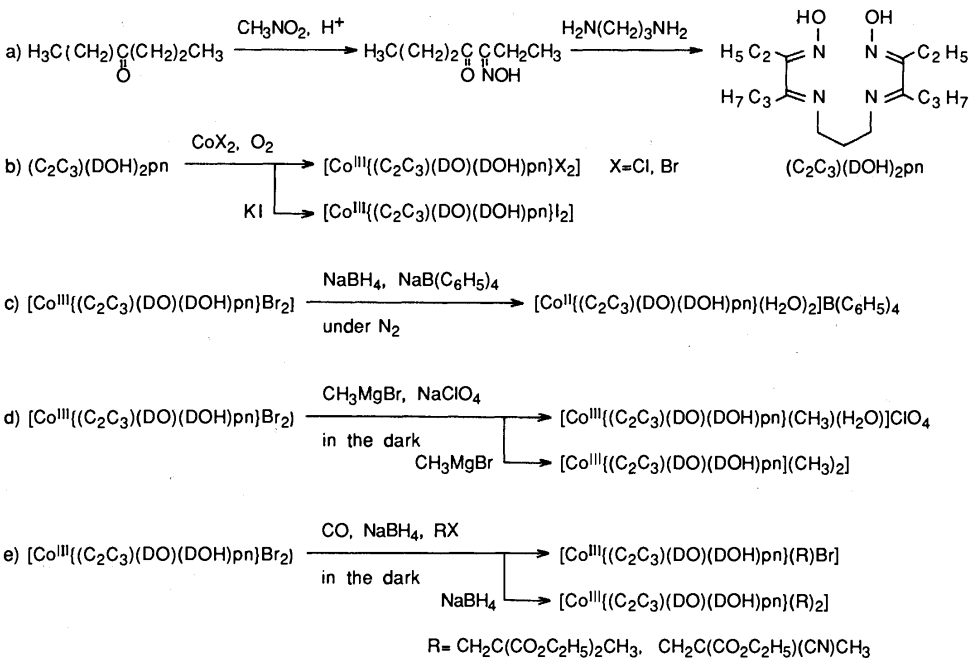
behavior analogous to that of vitamin B_{12} with respect to the nuclear cobalt and catalyzes the isomerization reaction in a similar manner. We report here on the redox behavior of model complexes which are derived from the Costa's complex[15,16] by its modification. Furthermore, the electrochemical carbon-skeleton rearrangements catalyzed by these model complexes was compared with those catalyzed by the hydrophobic vitamin B_{12}.

Experimental

General Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu University. IR spectra were taken on a JASCO IR-810 infrared spectrophotometer, while electronic absorption spectra were recorded on a Hitachi 220A or a Hitachi 340 spectrophotometer. ESR spectra were obtained on a JEOL JES-FElG X-band spectrometer equipped with an Advantest TR-5213 microwave counter and an Echo Electronics EFM-200 NMR field meter. ^1H and ^{13}C NMR spectra were taken on a Hitachi R-24B, a JEOL JNM-EX90, or a JEOL JNM-GSX400 spectrometer installed at the Center of Advanced Instrumental Analysis of Kyushu University. Assignments of NMR signals due to the cobalt complexes were carried out by means of the 2D-NMR technique (H-H and C-H COSY). Cyclic voltammograms were obtained on an apparatus composed of a Hokuto Denko HA-501 potentiostat/galvanostat and a Hokuto Denko HB-104 function generator. An applied potential between the working and reference electrodes in the electrolysis was maintained constant with a Hokuto Denko HA-305 potentiostat/galvanostat and an electrical quantity was recorded on a Hokuto Denko HF-201 coulomb/amperehour meter. GLC analyses were carried out on a Shimadzu GC-4C or a Shimadzu GC-9A apparatus equipped with a Shimadzu C-R3A-FFC chromatopac.

Materials. *N,N*-Dimethylformamide (DMF) was dried and purified just before use according to the standard procedure.[17] Tetrabutylammonium perchlorate (TBAP) was purchased from Nakarai Chemicals and used without further purification. Tetrabutylammonium tetrafluoroborate (TBAF) was prepared after a reported procedure.[18] The substrates such as 1-bromo-2,2-bis(ethoxycarbonyl)propane (**1**), 1-bromo-2-cyano-2-ethoxycarbonylpropane (**2**), and 2-acetyl-1-bromo-2-ethoxycarbonylpropane (**3**) and authentic samples of the corresponding products such as 2,2-bis(ethoxycarbonyl)propane (**A**), 1,2-bis(ethoxycarbonyl)-propane (**B**), 2-cyano-2-ethoxycarbonylpropane (**C**), 1-cyano-2-ethoxycarbonylpropane (**D**), 2-cyano-1-ethoxycarbonyl-propane (**E**), 2-acetyl-2-ethoxycarbonylpropane (**F**), 1-acetyl-2-ethoxycarbonylpropane (**G**), and 2-acetyl-1-ethoxycarbonyl-propane (**H**) were prepared according to the methods described in literature[13] and confirmed to be sufficiently pure by ^1H NMR and GLC. The chelating ligand, 4,10-dipropyl-5,9-diazatrideca-4,9-diene-3,11-dione dioxime, and its cobalt complexes with various axial ligands were prepared by referring to reported procedures[16,19–21] along with some modifications as shown in Scheme 1.

4,10-Dipropyl-5,9-diazatrideca-4,9-diene-3,11-dione Dioxime, $(C_2C_3)(DOH)_2pn$. This ligand was synthesized by the condensation of 3-hydroxyimino-4-heptanone (62.9 g, 0.44 mol), which was prepared from 4-heptanone and methyl nitrate,[22] and 1,3-propanediamine (16.35 g, 0.22 mol): yield 51.0 g (71.4%); IR (KBr) 3200 (OH), 1625 (C=N), 970 cm^{-1} (N–O); ^1H NMR ($CDCl_3$, TMS) δ=0.93 (6H, t, $CH_2CH_2C\underline{H}_3$), 1.03 (6H, t, $CH_2C\underline{H}_3$), 1.45 (4H, m, $CH_2C\underline{H}_2CH_3$), 2.03, (2H, m, $CH_2C\underline{H}_2CH_2$), 2.52 (4H, t, $C\underline{H}_2CH_2CH_3$), 2.91 (4H, q, $C\underline{H}_2CH_3$), 3.60 (4H, t, NCH_2), 6.0 (2H, bs, OH). Found: C, 63.02; H, 9.99; N, 17.08%. Calcd for $C_{17}H_{32}N_4O_2$: C, 62.91; H, 9.96; N, 17.27%.



Scheme 1.

Dibromo(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2]. An acetone solution (10 mL) of (C_2C_3)$(DOH)_2$pn (1.6 g, 5.0×10^{-3} mol) was added dropwise to an aqueous solution (150 mL) of cobalt dibromide hexahydrate (2.0 g, 6.0×10^{-3} mol) while air was bubbled through the latter aqueous solution. After the reaction mixture was stirred for 4 h, precipitates were recovered by filtration and washed with water. The resulting cobalt complex was recrystallized from acetone-water (1:1 v/v) to afford dark green needles: yield 1.6 g (50%), mp 223—224 °C; IR (KBr) 700 cm^{-1} (Co-N); ^1H NMR ($CDCl_3$, TMS) δ=1.09 (6H, t, $CH_2CH_2C\underline{H}_3$), 1.23 (6H, t, $CH_2C\underline{H}_3$), 1.67 (4H, m, $CH_2C\underline{H}_2CH_3$), 2.61 (2H, m, $CH_2C\underline{H}_2CH_3$), 2.91 (4H, t, $C\underline{H}_2CH_2CH_3$), 2.98 (4H, q, $C\underline{H}_2CH_3$), 4.16 (4H, t, NCH_2), 19.37 (1H, s, OH); ^{13}C NMR ($CDCl_3$, TMS) δ=10.2 ($CH_2\underline{C}H_3$), 13.9 ($CH_2CH_2\underline{C}H_3$), 19.9 ($CH_2\underline{C}H_2CH_3$), 21.0 ($\underline{C}H_2CH_3$), 27.9 ($CH_2\underline{C}H_2CH_2$), 32.1 ($\underline{C}H_2CH_2CH_3$), 50.0 (NCH_2), 161.3 (ON=C), 177.7 (C-N=$\underline{C}$). Found: C, 37.72; H, 5.72; N, 10.33%. Calcd for $C_{17}H_{31}Br_2CoN_4O_2$: C, 37.66; H, 5.76; N, 10.33%.

Dichloro(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Cl_2]. This complex was prepared from cobalt dichloride hexahydrate after the method employed for the preparation of [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2], and obtained as dark green needles: yield 53%, mp 236—237 °C. Found: 44.99; H, 6.82; N, 12.32%. Calcd for $C_{17}H_{31}Cl_2CoN_4O_2$: C, 45.04; H, 6.89; N, 12.36%.

Diiodo(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}I_2]. This complex was prepared in the presence of a large excess of potassium iodide by the method employed for the preparation of [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2], and obtained as dark purple prisms: yield 60%, mp 225—226 °C; λ_{max} (CH_2Cl_2) 338 (ε 1.99×10^4), 468 nm (1.02×10^4). Found: 32.12; H, 4.92; N, 8.78%. Calcd for $C_{17}H_{31}I_2CoN_4O_2$: C, 32.09; H, 4.91, N, 8.81%.

Diaqua(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(II) Tetraphenylborate, [Co^{II}\{(C_2C_3)(DO)(DOH)pn\}(H_2O)$_2$]B(C_6H_5)$_4$. This complex was prepared in Schlenk tubes under nitrogen atmosphere. [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2] (0.30 g, 5.53×10^{-4} mol) in methanol-water (10:1 v/v, 50 mL) was treated with a slight excess of sodium tetrahydroborate. The solution turned blue initially, and then purple. After an aqueous solution (20 mL) of sodium tetraphenylborate (0.19 g, 5.53×10^{-4} mol) was added to it, the resulting reddish purple precipitates were recovered by filtration and washed with deaerated water. This product was recrystallized from methanol-water (10:1 v/v) to afford pale brown powder: yield 0.20 g (48%), decomp 86—87 °C. Found: C, 66.63; H, 7.51; N, 7.79%. Calcd for $C_{41}H_{55}BCoN_4O_4$: C, 66.76; H, 7.51; N, 7.60%.

Methylaqua(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III) Perchlorate, [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4. [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2] (2.8 g, 5.2×10^{-3} mol) suspended in dry tetrahydrofuran (40 mL) was treated with methylmagnesium bromide (1.0×10^{-2} mol) at −60 °C under nitrogen atmosphere. After the resulting orange red solution was stirred for 2 h, cold water (10 mL) was added to it. The solution was neutralized with aqueous hydrochloric acid (2 mol dm^{-3}), tetrahydrofuran was removed completely in vacuo, and an excess amount of sodium perchlorate was added to the residue. After the solution was allowed to stand overnight in a refrigerator, a dark red solid was recovered and recrystallized from acetone-water (1:1 v/v) to afford fine red crystals: yield 0.73 g (31%), decomp 121—122 °C; IR (KBr) 1120, 630 cm^{-1} (ClO_4^-); ^1H NMR ($CDCl_3$, TMS) δ=0.61 (3H, s, Co-CH_3), 1.07 (6H, t, $CH_2C\underline{H}_3$), 1.18 (6H, t, $CH_2CH_2C\underline{H}_3$), 1.59 (4H, m, $CH_2C\underline{H}_2CH_3$), 2.23 (2H, m, $CH_2C\underline{H}_2CH_2$), 2.72 (8H, m, $C\underline{H}_2CH_2CH_3$ and $C\underline{H}_2CH_3$), 4.01 (4H, t, N-CH_2), 18.88 (1H, s, OH); λ_{max} (CH_2Cl_2) 468 nm (ε 3.32×10^4). Found: C, 41.96; H, 6.98; N, 10.84%. Calcd for $C_{18}H_{36}ClCoN_4O_7$: C, 41.99; H, 7.05; N, 10.88%.

Dimethyl(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)$_2$]. This compound was prepared in the presence of a large excess of methylmagnesium bromide after the method employed for the preparation of [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4, and obtained as fine red crystals: yield 62%, decomp 118—119 °C; ^1H NMR ($CDCl_3$, TMS) δ=0.05 [6H, s, Co-$(CH_3)_2$], 1.00 (6H, t, $CH_2C\underline{H}_3$), 1.08 (6H, t, $CH_2CH_2C\underline{H}_3$), 1.47 (4H, m, $CH_2C\underline{H}_2CH_3$), 2.10 (2H, m, $CH_2C\underline{H}_2CH_2$), 2.55 (4H, t, $C\underline{H}_2CH_2CH_3$), 2.65 (4H, q, $C\underline{H}_2CH_3$), 3.73 (4H, t, N-CH_2), 19.59 (1H, s, OH); λ_{max} (CH_2Cl_2) 411 nm (ε 4.80×10^4). Found: C, 55.53; H, 9.10; N, 13.44%. Calcd for $C_{19}H_{37}CoN_4O_2$: C, 55.33; H, 9.04; N, 13.58%.

Bromo{2,2-bis(ethoxycarbonyl)propyl}(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{$CH_2C(CO_2C_2H_5)_2CH_3$\}Br]. A methanol solution (200 mL) containing [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2] (500 mg, 9.2×10^{-4} mol) and 1-bromo-2,2-bis(ethoxycarbonyl)propane (1.0 g, 3.7×10^{-3} mol) was stirred while carbon monoxide was introduced into it until saturation was attained. After being stirred for 2 h, the solution turned reddish yellow, indicating formation of the Co^{II} complex. Sodium tetrahydroborate in methanol was added dropwise to the resulting solution until the solution turned deep blue under carbon monoxide atmosphere. The solution changed its color to orange after it was refluxed for 6 h in the dark. The solution was evaporated to dryness, a material insoluble in dichloromethane was removed by filtration, and then the dichloromethane solution was evaporated to dryness. The product was recrystallized from diethyl ether-tetrahydrofuran (1:20 v/v) to afford orange prisms: yield 450 mg (75%); IR (KBr) 1730 cm^{-1} (C=O); λ_{max} (CH_3OH) 474 nm. Found: C, 47.87; H, 7.00; N, 8.53%. Calcd for $C_{26}H_{46}BrCoN_4O_6$: C, 48.08; H, 7.14; N, 8.63%.

Bromo(2-cyano-2-ethoxycarbonylpropyl)(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{$CH_2C(CO_2C_2H_5)(CN)CH_3$\}Br]. This compound was prepared in the presence of 1-bromo-2-cyano-2-ethoxycarbonylpropane after the method for the preparation of [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{$CH_2C(CO_2C_2H_5)_2CH_3$\}Br], and obtained as orange prisms: yield 63%; λ_{max} (CH_3OH) 465 nm. Found: C, 47.55; H, 6.80; N, 11.83%. Calcd for $C_{24}H_{41}BrCoN_5O_4$: C, 47.85; H, 6.86; N, 11.62%.

Bis{2,2-bis(ethoxycarbonyl)propyl}(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{$CH_2C(CO_2C_2H_5)_2CH_3$\}$_2$]. A methanol solution (200 mL) containing [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2] (100 mg, 1.8×10^{-4} mol) and 1-bromo-2,2-bis(ethoxycarbonyl)propane (1.0 g, 3.7×10^{-3} mol), and sodium hydroxide (10 mg, 2.5×10^{-4} mol) was saturated with carbon monoxide by bubbling for 2 h. Sodium tetrahydroborate in

methanol was added dropwise to the resulting solution until the solution turned deep blue. The reaction mixture was then refluxed for 6 h in the dark and turned orange gradually. The mixture was evaporated to dryness, and a material insoluble in dichloromethane was removed by filtration. The dichloromethane solution was evaporated to afford an orange red solid. The product was purified by gel-filtration chromatography on columns of Sephadex LH-20 with methanol and silica gel (Wakogel C-100) with hexane–chloroform (1 : 1 v/v) in this sequence. The solution was evaporated to dryness to afford red powder: yield 74 mg (53%); IR (KBr) 1730 cm^{-1} (C=O); λ_{max} (CH_3OH) 405 nm. Found: C, 55.38; H, 7.96; N, 7.17%. Calcd for $C_{35}H_{61}CoN_4O_{10}$: C, 55.55; H, 8.12; N, 7.40%.

Bis(2-cyano-2-ethoxycarbonylpropyl)(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), [Co^{III}{(C_2C_3)(DO)(DOH)pn}{$CH_2C(CO_2C_2H_5)(CN)CH_3$}$_2$]. This compound was prepared in the presence of 1-bromo-2-cyano-2-ethoxycarbonylpropane after the method for the preparation of [Co^{III}{(C_2C_3)(DO)(DOH)pn}{$CH_2C(CO_2C_2H_5)_2$-CH_3}$_2$], and obtained as red powder: yield 59%; λ_{max} (CH_3OH) 402 nm. Found: C, 56.07; H, 7.75; N, 12.61%. Calcd for $C_{31}H_{51}CoN_6O_6$: C, 56.18; H, 7.76; N, 12.68%.

Cyclic Voltammetry. An electrochemical cell similar to that reported in literature[23] was used and equipped with platinum wire of 0.5-mm diameter as working and auxiliary electrodes. A saturated calomel electrode (SCE) or an Ag/AgCl electrode was served as reference which was separated from a bulk electrolyte solution by a salt bridge prepared with 1,2:4,5-*O*-dibenzylidene-D-glucitol[24] and a DMF solution of TBAP (5.0×10^{-2} mol dm^{-3}); potentials vs. SCE are more cathodic by 30 mV relative to those vs. Ag/AgCl. DMF solutions containing the cobalt complex and TBAP were deaerated prior to each measurement, and the inside of the cell was maintained under argon atmosphere throughout each measurement. All the measurements were carried out at 20±2 °C, and the scan rate was varied in a range from 10 through 200 mV s^{-1}. Half-wave potentials ($E_{1/2}$) and anodic and cathodic currents were evaluated according to the method described previously.[25]

In order to identify the species formed at respective potentials, controlled-potential electrolyses were carried out under various conditions in a three-electrode cell modified for electronic and ESR spectral measurements, as described previously.[25] An applied potential between the working and reference electrodes was maintained constant with a potentiostat.

Catalytic Reactions. The electrolyses of various substrates were carried out upon addition of the cobalt complex in a cylindrical three-electrode cell which was divided into two internal compartments with a single sheet of microporous polypropylene membrane and equipped with platinum meshes as working and auxiliary electrodes.[13] On the other hand, an undivided cell was utilized to perform effective catalytic reactions without additives. A DMF solution of the cobalt complex, a substrate, an additive (if necessary), and TBAF was subjected to electrolysis at an appropriate controlled-potential under argon atmosphere. Then, the reaction mixture was distilled in vacuo and analyzed for products by means of GLC. Identification of the reaction products was performed by coinjection of the distilled sample and the corresponding authentic samples into columns of Silicone DC-550 and Silicone SE-30. A capillary column of Polyethylene Glycol-20M was used for identification of isomers having similar structures. Each product separated by preparative GLC on Silicone DC-550 was identified by means of ^1H NMR spectroscopy.

Results and Discussion

ESR spectra of [Co^{II}{(C_2C_3)(DO)(DOH)pn}$(H_2O)_2$]-$B(C_6H_5)_4$ in base-off and base-on forms are shown in Fig. 2 at 77 K. A typical ESR spectrum of low spin cobalt(II) was observed for the complex in chloroform without a base (A in Fig. 2). When pyridine was added in a two- to ten-fold molar excess over a quantity of the cobalt complex, only one pyridine molecule underwent coordination to the central cobalt at its axial site (B in Fig. 2): a superhyperfine structure due to the interaction between the nitrogen nucleus (I=1) and the cobalt nucleus (I=7/2) was observed in the $g_{\parallel}$ region. In the presence of a large excess of pyridine (ca. 600-fold),

Fig. 2. both axial sites of the central cobalt were occupied by pyridine molecules as confirmed by ESR spectroscopy (C in Fig. 2). The present ESR behavior and the corresponding spin Hamiltonian parameters are comparable to those observed for the hydrophobic vitamin B_{12r} bearing a corrinoid ligand.[9]

Redox Behavior of Simple Vitamin B_{12} Model and Alkylated Derivatives. The redox behavior of the present complexes was investigated in DMF by means of cyclic voltammetry. A cyclic voltammogram of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}I_2]$ is shown in Fig. 3. Three redox pairs were observed at −0.13, −0.70, and −1.45 V vs. Ag/AgCl in the range of 0 through −2.0 V vs. Ag/AgCl. The complex species responsible for these redox potentials were indentified by spectroscopic methods under controlled-potential electrolysis conditions as follows. The species present at +0.3 V vs. Ag/AgCl was ESR-silent, while ESR signals characteristic of Co(II) species were observed at −0.5 V vs. Ag/AgCl. Therefore, the redox potential at −0.13 V vs. Ag/AgCl is assigned to the Co(III)/Co(II) redox couple. The electrochemical reduction at −1.0 vs. Ag/AgCl was followed by electronic spectroscopy. An absorption maximum characteristic of the monomethylated complex was observed at 465 nm in the presence of methyl iodide; formation of the Co(I) species became evident at this potential. Consequently, the potential at −0.70 V vs. Ag/AgCl is assigned to the Co(II)/Co(I) redox couple. The potential at −1.45 V vs. Ag/AgCl is presumably concerned with the redox

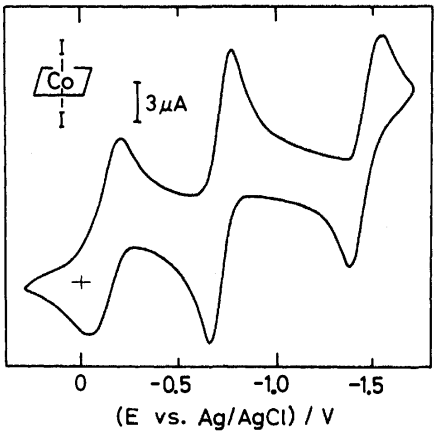

Fig. 3. Cyclic voltammogram of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}I_2]$ (4.5×10^{-3} mol dm^{-3}) containing 0.10 mol dm^{-3} TBAP in DMF at 20±2 °C; scan rate, 100 mV s^{-1}.

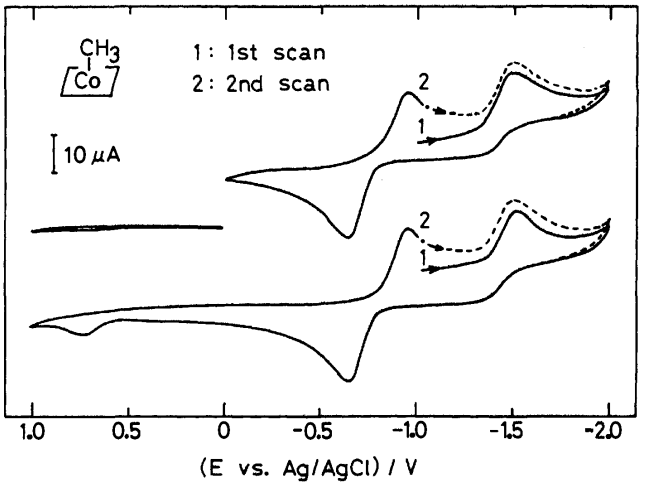

Fig. 4. Cyclic voltammogram of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4$ (4.5×10^{-3} mol dm^{-3}) containing 0.10 mol dm^{-3} TBAP in DMF at 20±2 °C in the dark; scan rate, 100 mV s^{-1}.

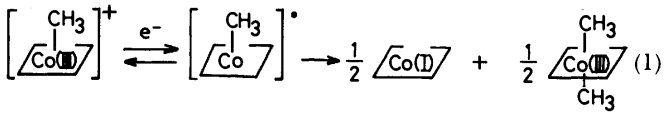
reaction of the equatorial ligand. The complexes with the other halogen ligands, comparable redox potentials were observed: −0.16, −0.70, and −1.43 V vs. Ag/AgCl for $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2]$; −0.27, −0.69, and −1.46 V vs. Ag/AgCl for $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Cl_2]$. As for $[Co^{II}\{(C_2C_3)(DO)(DOH)pn\}(H_2O)_2]B(C_6H_5)_4$, the reversible Co(II)/Co(I) redox couple was also observed at −0.69 V vs. Ag/AgCl. The above redox behavior is identical with that for the Costa's complex.[26,27] These Co(II)/Co(I) redox potentials are close to that observed for the hydrophobic vitamin B_{12};[10] −0.61 V vs. SCE in DMF. The Co(II)/Co(I) redox potential for cobaloxime, a vitamin B_{12} model frequently used, is observed by far in a more cathodic range relative to these values; −1.11 V vs. SCE in acetonitrile.[16]

The redox behavior of the mono- and dimethylated

cobalt complexes, $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4$ and $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)_2]$, respectively, was investigated in DMF.[28] The redox behavior of the Costa's complexes with the cobalt–carbon bond was studied in acetonitrile rather extensively.[16,29] As shown in Fig. 4 for $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4$, a single and irreversible one-electron reduction peak was observed at −1.50 V vs. Ag/AgCl during scanning for the potential range from −1.0 through −2.0 V vs. Ag/AgCl. In the course of scanning for the potential range from −1.0 V vs. Ag/AgCl toward the anodic side, there were observed two oxidation peaks; a reversible Co(I)/Co(II) oxidation peak at −0.65 V vs. Ag/AgCl and another irreversible and small oxidation peak at +0.73 V vs. Ag/AgCl, the latter originating from the one-electron oxidation of the dimethylated complex, $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)_2]$. The latter oxidation peak was not observed when the potential was scanned for the range from 0 through +1.0 V vs. Ag/AgCl.

After the controlled-potential electrolysis of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4$ was completed at −2.0 V vs. Ag/AgCl under anaerobic conditions, the absorption maximum originally observed for $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4$ at 465 nm was shifted to 410 nm when the sample was exposed to air for elimination of the Co^{I} species; the latter band being due to $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)_2]$. This apparently indicates that the monomethylated complex is disproportionated to the dimethylated complex and the Co^{I} species by the electrochemical reduction (Eq. 1). When a large excess of imidazole was added, the



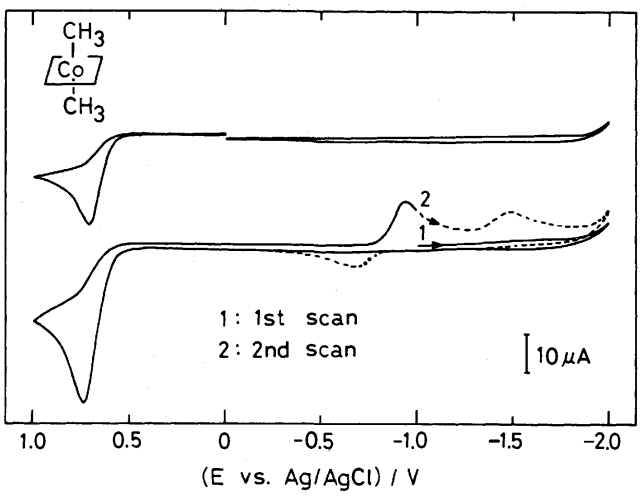


Fig. 5. Cyclic voltammogram of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)_2]$ (4.5×10^{-3} mol dm^{-3}) containing 0.10 mol dm^{-3} TBAP in DMF at 20±2 °C in the dark; scan rate, 100 mV s^{-1}.

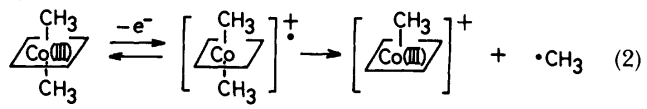
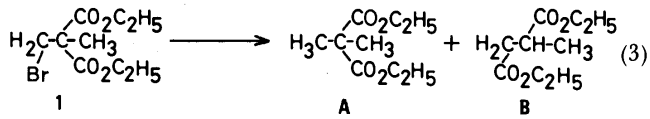
disproportionation reaction did not take place. This behavior is quite different from that observed for the corresponding hydrophobic vitamin B_{12}.[30] The one-electron reduction potential for the present monomethylated complex is close to those for the methylated hydrophobic vitamin B_{12} and methylcobinamide; −1.32 V vs. SCE in DMF[30] and −1.46 V vs. SCE in DMF–1-propanol (1:1 v/v),[31] respectively. On the other hand, the corresponding potential for methylcobaloxime is −2.2 V vs. SCE in acetonitrile at −26 °C,[16] which is by far in a more cathodic range relative to the value for vitamin B_{12} and must arise from the difference in ligand nature; the present and corrinoid ligands are monoanionic, while the cobaloxime ligand is dianionic.

The dimethylated complex is inactive for electrochemical reduction; no peak was observed in the potential range from 0 through −2.0 V vs. Ag/AgCl as shown in Fig. 5. An irreversible oxidation peak was observed at +0.73 V vs. Ag/AgCl. When the potential was sweeped repeatedly in the range of +1.0 through −2.0 V vs. Ag/AgCl, the redox behavior became similar to that of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)(H_2O)]ClO_4$. These facts indicate that the dimethylated complex is cleaved to afford the monomethylated complex and the methyl radical by the electrochemical oxidation (Eq. 2).[29]



Catalytic Reactions under Electrochemical Conditions. On the basis of the above redox behavior, the catalytic function of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2]$ was investigated by using 1-bromo-2,2-bis(ethoxycarbonyl)propane (**1**) as a substrate under electrochemical conditions (refer to Eq. 3).[32] The electrolysis was carried out in a



three-electrode cell, which was divided into two internal compartments with a diaphragm. The following findings were obtained on the basis of the product analyses under various conditions indicated in Table 1. (i) Products **A** and **B** were scarcely detected without imidazole at every potential in the range of −1.0 through −2.0 V vs. Ag/AgCl. (ii) The rearrangement product (**B**) was largely obtained at −1.5, −1.8, and −2.0 V vs. Ag/AgCl in the presence of imidazole. (iii) The rearrangement reaction proceeded more favorably under stronger reduction conditions. When other complexes, such as $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Cl_2]$, $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}I_2]$, and

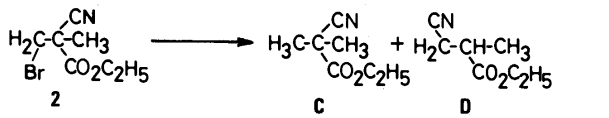
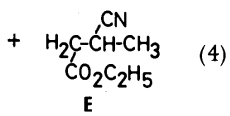
a) Electrolysis was carried out in a two-compartment cell equipped with Pt electrodes at 20±2 °C under argon atmosphere. Starting solutions composed of: [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2], 30 mg (5.5×10^{-5} mol); **2**, 1.0 g (4.5×10^{-3} mol) or **3**, 1.0 g (4.2×10^{-3} mol); imidazole, 100 mg (1.5×10^{-3} mol); 30 mL of DMF containing 0.5 mol dm^{-3} TBAF. b) Refer to Eqs. 4 and 5. c) Electrical charge passed per mol of the substrate. d) Based on an initial amount of the substrate; the rest was the unreacted substrate; analyzed by GLC; refer to Eqs. 4 and 5. e) Unrearranged products were **C** and **F** for substrates **2** and **3**, respectively. f) Rearrangement products were **D** and **E** for **2**, and **G** and **H** for **3**, respectively.

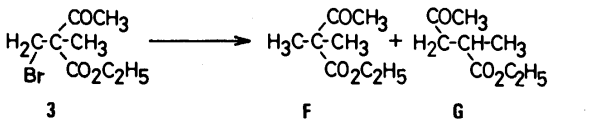
[Co^{II}\{(C_2C_3)(DO)(DOH)pn\}$(H_2O)_2$]$B(C_6H_5)_4$, were used as the catalysts, similar results were obtained.

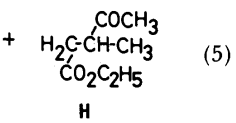
In order to make further qualification of the simple vitamin B_{12} model as the isomerization catalyst, other substrates, such as 1-bromo-2-cyano-2-ethoxycarbonylpropane (**2**) and 2-acetyl-1-bromo-2-ethoxycarbonylpropane (**3**), were also used here. These substrates and the corresponding products are shown in Eqs. 4 and 5, and the product analysis data are shown in Table 2. The 1,2-migration of carboxylic ester, acetyl, and cyano groups proceeds efficiently under these experimental conditions.





(4)





(5)

On careful comparison between the electrochemical carbon-skeleton rearrangement reactions catalyzed by the present simple vitamin B_{12} model and the hydrophobic vitamin B_{12},[33)] some differences are noted between these complexes in their catalytic performance. (i) The hydrophobic vitamin B_{12} does not require an organic base for the catalytic reaction, while a base such as imidazole is essential to the reaction catalyzed by the present complex. Imidazole must be bound to the nuclear cobalt of the alkylated vitamin B_{12} model, so that the cobalt-carbon bond is effectively activated by the trans effect arising from the coordinated axial base. The axial ligation constant (K) of imidazole to the monomethylated cobalt complex is fairly large; $\log K=2.67$ in DMF by means of the spectroscopic

method.[9] When imidazole is not present, the corresponding dialkylated complex, that is inactive for electrochemical reduction, is formed in the course of reaction, and consequently the catalytic reaction does not take place to a detectable extent. (ii) The hydrophobic vitamin B_{12} requires a proton source for the formation of product **B** during the electolysis at −1.5 V vs. Ag/AgCl, while the present model complex affords the products in a significant yield without such an additive under the comparable conditions. The reaction scheme in the divided cell is schematically illustrated in Fig. 6.

In the light of the redox behavior of the dimethylated complex, $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}(CH_3)_2]$, the dialkylated complex is expected to give products, plausibly involving the corresponding isomerization product, by electrochemical oxidation. Therefore, we removed the diaphragm from the divided cell and the electrolysis was carried out in a single-compartment cell under argon atmosphere. Substrates **1**, **2**, and **3** were subjected to electrolysis at −2.0 V vs. Ag/AgCl of the cathode in presence of the cobalt complex in the dark. The products were analyzed by means of GLC, as summarized in Table 3. These results indicate that the rearrangement reactions proceed efficiently in the undivided cell. Under such reaction conditions, the monoalkylated complex and the corresponding dialkylated complexes were formed in a stepwise manner as the intermediates. Reduction of the former complex and oxidation of the latter species must proceed at the cathode and the anode, respectively. In order to clarify the reaction process, the electrolyses of the monoalkylated and dialkylated complexes were carried out at −2.0 V and +1.0 V vs. Ag/AgCl, respectively, in the divided cell.

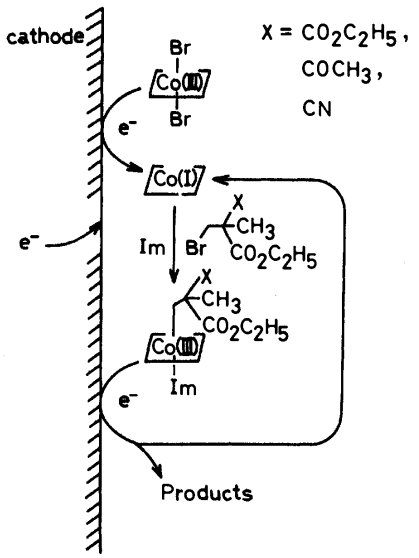


Fig. 6. Schematic representation of electrochemical catalysis in the divided cell.

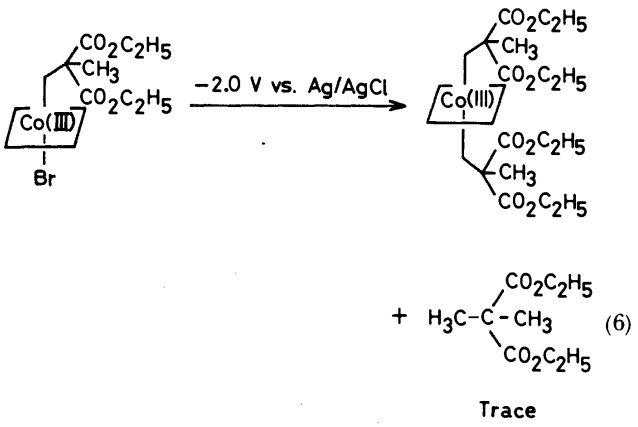
A DMF solution (15 mL) of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{CH_2C(CO_2C_2H_5)_2CH_3\}Br]$ (200 mg, 3.1×10^{-4} mol) and TBAF (2.0 g) was subjected to electrolysis at −2.0 V vs. SCE in the dark for 8 h. The monoalkylated complex was largely converted into the corresponding dialkylated complex as identified by electronic spectroscopy (Eq. 6), even though trace



(6)

amounts of the reduction and rearrangement products were detected by GLC. When $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{CH_2C(CO_2C_2H_5)_2CH_3\}Br]$ was electrolyzed at +1.0 V vs. SCE, the reaction did not proceed to a

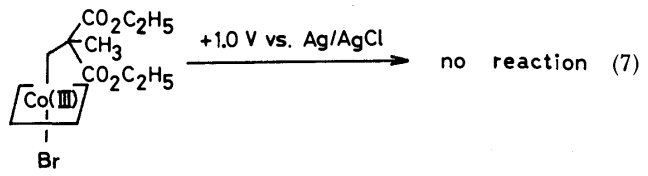
3	1.9	7	3—4	83—85

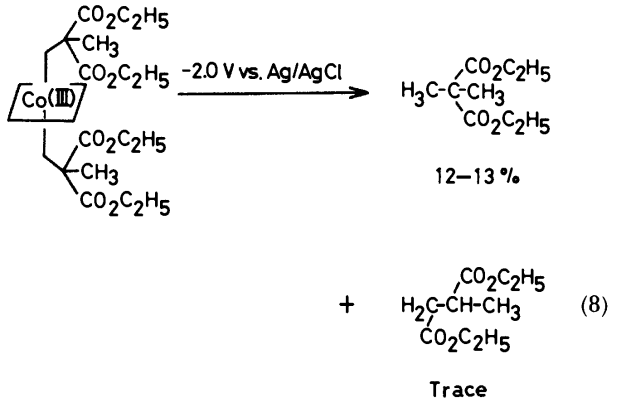
a) Electrolysis was carried out in the undivided cell equipped with Pt electrodes at 20±2 °C under argon atmosphere. Starting solutions composed of: $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2]$, 14 mg ($2.6\times10^{-5}$ mol); **1**, 1.0 g (3.8×10^{-3} mol), **2**, 1.0 g (4.5×10^{-3} mol), or **3**, 1.0 g (4.2×10^{-3} mol); 30 mL of DMF containing 0.5 mol dm^{-3} TBAF. b) Refer to Eqs. 3, 4, and 5. c) Electrical charge passed per mol of the substrate. d) Based on an initial amount of the substrate; the rest was the unreacted substrate; analyzed by GLC; refer to Eqs. 3, 4, and 5. e) Unrearranged products were **A**, **C**, and **F** for substrates **1**, **2**, and **3**, respectively. f) Rearrangement products: **B** for **1**, **D** and **E** for **2**, and **G** and **H** for **3**.

detectable extent as confirmed by electronic spectroscopy and GLC (Eq. 7). A small amount of the product



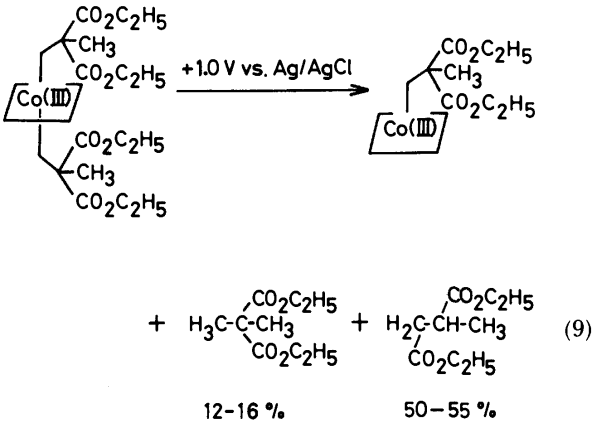
(7)

derived from the cleavage of the cobalt–carbon bond was detected in the electrolysis of $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}\{CH_2C(CO_2C_2H_5)_2CH_3\}_2]$ (200 mg, 2.6×10^{-4} mol) at −2.0 V vs. Ag/AgCl under the identical conditions. However, the rearrangement product was little obtained under such conditions (Eq. 8). On the



(8)

other hand, when the electrolysis was carried out at +1.0 V vs. Ag/AgCl for 6 h, the dialkylated complex was transformed into the monoalkylated one, and the rearrangement product was detected as the major one (Eq. 9).



(9)

In the light of the above results, the electrolysis in the undivided cell plausibly proceeds via the reaction cycle shown in Fig. 7. The tervalent cobalt complex is first converted into the univalent cobalt complex by the electrochemical reduction, and the resulting species is subjected to the electrophilic attack by an alkyl bromide to afford the corresponding monoalkylated complex as the intermediate. This species is subsequently reduced to the one-electron reduction intermediate, which is then disproportionated to the dialkylated complex and the univalent cobalt species. The dialkylated complex is decomposed to give the monoalkylated complex and the products by the electrochemical oxidation on the anode.

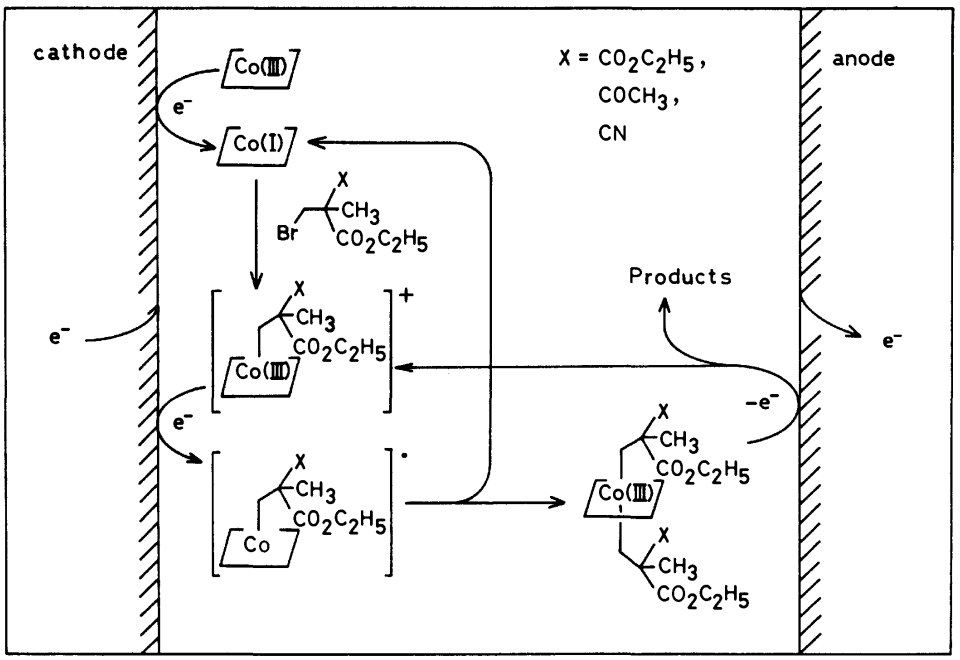


Fig. 7. Schematic representation of electrochemical catalysis in the undivided cell.

Conclusion

We clarified in the present work redox behavior of the simple vitamin B_{12} model as well as that of its alkylated derivatives in connection with the catalytic reactions of the vitamin B_{12} model under electrochemical conditions. A major difference between the simple vitamin B_{12} model complex and the hydrophobic vitamin B_{12} is in alkylation behavior; a dialkylated complex is obtained with the former species. The hydrophobic vitamin B_{12} does not form its dialkylated complex, since the steric hindrance is exercised by the methyl moiety at C(19) position of the corrin ring when an alkyl moiety attacks the nuclear cobalt from the α-face. The simple vitamin B_{12} model does not form its dialkylated complex when an axial base such as imidazole is added to the reaction media, and the electrochemical catalysis proceeds via a mechanism similar to that for the hydrophobic vitamin B_{12}. It became apparent that the coupled electrochemical redox processes facilitate the carbon-skeleton rearrangement via formation of the dialkylated complex as the oxidizable intermediate in the absence of an axial base.

Substituent Effect on the Enantiomer-Differentiating Reaction of Lithiomethyl *p*-Tolyl Sulfoxide with Meta- or Para-Substituted (*R*)-(−)-Menthyl Benzoates

Norio KUNIEDA,* Takeshi NAKANISHI, and Masayoshi KINOSHITA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received February 18, 1989)

Treatment of (*R*)-(−)-menthyl benzoates, which have a variety of meta- or para-substituents, with 2 equivalents of racemic lithiomethyl *p*-tolyl sulfoxide displays the feature of an enantiomer-differentiating reaction, affording the corresponding optically active β-keto sulfoxides. The degree and the direction of enantioselectivity were affected by the nature of the substituent on benzene ring. The electron-releasing substituents trend to increase the %e.e. value. The reversal in the configuration with the variation in the substituent which has a high electron-withdrawing *p*-CN group was also observed. The *R*/*S* values thus obtained gave a good correlation with Hammett's σ values (r=0.975), affording a negative straight line. Based on these observations, a plausible stereochemical course of this reaction has been discussed.

Electronic effects, in addition to steric bulk, have been evaluated experimentally and theoretically as one of the important factor which controls the direction and the extent of the asymmetric induction in certain asymmetric reactions.[1] On the basis of this concept, the investigation of the substituent effect in asymmetric reactions is considered to afford considerably quantitative informations which may help to clarify the stereochemical course of asymmetric reactions. However, up to now, only a few attentions have been focused on this problem.[2]

During the course of our research concerned with the asymmetric induction by chiral sulfinyl group,[3] we have now found that the reaction of lithiomethyl *p*-tolyl sulfoxide, derived from racemic methyl *p*-tolyl sulfoxide and lithium diethylamide, with a limited amount of substituted (*R*)-(−)-menthyl benzoates displays the feature of an enantiomer-differentiating reaction, affording the corresponding optically active β-keto sulfoxides, and the degree of enantioselectivity of this reaction is markedly affected by the nature of the substituent on benzene ring of the chiral benzoates. In this report, we compile substantial amounts of stereochemical data of the enantiomer-differentiating reaction of racemic α-lithiomethyl *p*-tolyl sulfoxide with (*R*)-(−)-menthyl benzoates possessing a variety of meta- or para-substituents and hence would like to discuss the role of the polar effect of the substituents on the enantioselectivity, as an effort to obtain detailed knowledge for the stereochemistry of this reaction.

Results and Discussion

The reaction of racemic lithiomethyl *p*-tolyl sulfoxide (**1**) with meta- or para-substituted (*R*)-(−)-menthyl benzoates (**2**) was carried out according to a procedure similar to that devised for the reaction of α-lithio sulfoxides with chiral sulfinates or chiral carboxylates described in our previous papers.[3c,f,g] When 2 equivalents of **1**, derived from racemic methyl *p*-tolyl sulfoxide and lithium diethylamide, was allowed to react with **2** in tetrahydrofuran (THF) at −78 °C, the corresponding optically active β-keto sulfoxide (**3**) was produced in a good yield (>92%), together with optically active methyl *p*-tolyl sulfoxide which has the opposite configuration to **3** (Eq. 1). The degree of

enantioselectivity of the reaction was estimated by determining the per cent enantiomeric excess (%e.e.) of **3** obtained. That is, the resulting **3** was isolated by a preparative thin-layer chromatography on silica gel and their predominant configuration and the %e.e. value were assigned by direct comparison with the specific rotation of the corresponding authentic (*R*)-(+)-**3**. The authentic (*R*)-(+)-**3** used here was synthesized by the reaction of lithiomethyl *p*-tolyl sulfoxide, derived from optically pure (*R*)-(+)-methyl *p*-tolyl sulfoxide, with the corresponding ethyl benzoates.[3g] Table 1 summarizes the results for the reactions of **1** with nine (*R*)-(−)-menthyl benzoates (**2a—i**) possessing a variety of meta- or para-substituents.

The enantioselectivity of this reaction was sensitive to reaction temperature. The decrease in temperature favored the formation of the predominant enantiomer. The diagram correlating log *R*/*S* against 1/*T* showed

a linear positive slope over 103° temperature range (from 25 °C to −78 °C). The $\Delta\Delta H^*$ and $\Delta\Delta S^*$ values obtained in the reactions for **2c**, **2f**, and **2g** are listed in Table 1. These exhibited small negative values.

Table 1 clearly reveals that the %e.e. value for **3** obtained markedly affected by the nature of the substituent R. The degree of enantioselectivity varies from 1.6% to 24.6%. As gererally observed, the electron-releasing substituents trend to increase the %e.e. value. The best result has been obtained from the reaction of **1** with **2a** (R=*p*-CH_3O), affording (*R*)-(−)-**3a** of a 24.6% optical purity. Furthermore, the reversal in the configuration with the variation in the substituent R is also observed. Namely, the (*R*)-(−)-menthyl benzoates **2a**, **2b**, **2c**, **2d**, **2e**, **2f**, **2g**, and **2h** preferentially reacted with (*R*)-**1** to yield an excess of (*R*)-**3a—h**, while the ester **2i** which has a high electron-withdrawing *p*-CN group preferentially reacted with (*S*)-**1**, affording (*S*)-**3i** in excess.

When the logarithms of the *R*/*S* values thus obtained were plotted against Hammett's σ values,[4] as shown in Fig. 1, a negative straight line was obtained with the correlation coefficient r=0.975. In our previous paper,[3g] we have reported that the reaction of aryl lithiomethyl sulfoxides with (*R*)-(−)-menthyl carboxylates (R'-CO-O-Menthyl) is affected drastically by a steric bulk of the ester moiety R'. However, in the present reaction the demand for the steric effect owing to the substituent R on benzene ring was found to be negligibly small, even where R was bulky *t*-butyl group. Therefore, it can be recognized that the enantioselectivity on the reaction of **1** with **2** should be dependent on the polar effect of the substituent R.

Next the kinetic experiment was conducted on the rate of the reactions using **2a** (R=*p*-CH_3O), **2c** (R=*p*-CH_3), **2f** (R=H), and **2g** (R=*p*-Cl) in THF at −78 °C. The rate was measured by checking the consumption of the starting **1** by means of ^{1}H NMR (see Experimental). The resulting second order rate constants are listed in Table 2, and are found to be in a good correlation with Hammett's σ values[4] with a large positive σ value of +3.40 (r=0.999). The electron-withdrawing substituent on benzene ring of **2** increases the rate of the reaction. It reveals that the degree of enantioselectivity of the reaction decreases with increasing the reaction rate. This σ correlation and the magnitude of the ρ value of the kinetic data also suggest well that the reaction of **1** with **2** takes place through the B_{AC}-2 type mechanism[5] like in the case of the saponification of (−)-menthyl benzoates (ρ=2.628, at 30 °C).[6]

Scheme 1.

As one of the current of stereochemical studies on the electrophilic substitutions of α-lithio sulfoxides, Marquet et al.[7] and Biellmann et al.[8] have proposed that an electrophilic assistance (a chelation) by the lithium cation on the α-lithio sulfoxides towards the electrophiles plays an important role. On the basis of this evidence together with the B_{AC}-2 mechanism and the prefered configuration for the (*R*)-(−)-menthyl carboxylates,[9] we have proposed[3g] that the reaction of aryl lithiomethyl sulfoxides with (*R*)-(−)-menthyl carboxylates proceeds via a six-membered cyclic transition state.[3b,10] Acoording to this prediction, as well as the steric requirements,[12] the reaction of (*R*)-(−)-menthyl benzoates (**2**) with (*R*)-**1** affording (*R*)-**3** takes a transition state **R*** in Scheme 1 preferentially. Most of the results for the direction of enantioselectivity of this reaction agree fairly well with this prediction. However contrary to our expections, the reaction **2i** with **1** afforded (*S*)-**3i** as described above. The change of the degree of enantioselectivity owing to the substituent R on benzene ring and the reversal in configuration from (*R*) to (*S*) in going from **3h** to **3i** may be attributed to the conformational change of the transition state. The two alternative transition states **R*** and **S*** in Scheme 1 may be postulated according to the polar character of the substituent R. There are differences between the two routes in the degree of bonding of both entering and leaving groups on carbonyl carbon atom at the transition state. Actually, it has been reported that the transition-state geometry is affected by the change of substituents.[13]

The reaction of **1** with (*R*)-(−)-menthyl benzoates which have the electron-releasing substituent proceed through the transition state **R*** which exhibits the formation of tight chelation by lithium cation, since the electron-releasing substituent on benzene ring of **2** should contribute to the formation of a rigid transition state. While (*R*)-(−)-menthyl benzoates which have the electron-withdrawing substituent such as *p*-CN show high reactivity toward **1**, and proceed preferentially through the formation of a loose transition state **S*** which does not participate in the chelate formation by lithium cation. This transition state is less sterically hindered than **R***. Incidentally, the lithium cation in the transition state **S*** is perhaps located at the sulfinyl oxigen, since it has been known that the lithiomethyl phenyl sulfoxide is stabilized by an internal chelation between the metalated carbon and the sulfinyl oxygen.[7]

Table 3. Results of the Reactions of **1** with **2f** and **2i** in the Presence of a Lithium Cation Trapping Agent[a]

Benzoates (**2**)		%e.e. of **3f** and **3i**	
		None	Kryptofix 211[b]

2i	**3i**	1.6(S)	4.3(S)

a) In THF, at −78°C. b) 1.1 Equivalents based on **1**. c) Predominant configuration.

That is, a gradual change of the transition state from **R*** to **S*** with the increase of the electron-withdrawing character of the substituent R is posturated. In order to get a clue of this, the reactions of **1** with **2f** and **2i** were carried out in the presence of 4,7,13,18-tetraoxa-1,10-diazabicyclo[8.5.5]eicosane (Kryptofix 211)[14] as a trapping agent of the lithium cation. The results are listed in Table 3. To cite the result, the addition of 1.1 equivalents of Kryptofix 211 to the reaction of **1** with **2f** decreases the %e.e. value of (*R*)-**3f** about 3.5 times.

While the addition of 1.1 equivalents of Kryptofix 211 to the reaction of **1** with **2i** increases the %e.e. value of (*S*)-**3i** about 2.7 times.

Inspection of these data indicates that the transition state of the reaction of **1** with (*R*)-(−)-menthyl benzoates (**2**) markedly affected by the nature of the substituent R on benzene ring. We have now considered that the apparent difference in the mode of the transition states between **R*** and **S*** arises from the polar effect exerted by the substituent R.

Experimental

General. The optical rotations were measured with a Jasco DIP-360 type polarimeter. The ^{1}H NMR spectra were determined by using Jeol PS-100 spectrometer; the chemical shifts are reported in δ units, using tetramethylsilane as the internal reference. All the melting points were obtained with a Yanaco MP apparatus and are uncorrected. The IR spectra were taken on a Jasco A-202 type spectrometer.

Starting Materials. Racemic methyl *p*-tolyl sulfoxide was prepared by the periodate oxidation of methyl *p*-tolyl sulfide;[15] bp 99—100 °C/1.5 Torr (1 Torr=133.322 Pa), mp 43 °C (lit,[16] 42—43 °C). (*R*)-(+)-Methyl *p*-tolyl sulfoxide was prepared from (−)-menthyl (*S*)-*p*-toluenesulfinate, mp 107—107.5 °C, $[\alpha]_D^{25}$ −200° (*c* 0.520, acetone), and methylmagnesium iodide according to the method developed by Andersen;[17] mp 74.5 °C, $[\alpha]_D^{20}$ +146° (*c* 0.460, acetone)[lit,[18] mp 73—74.5 °C, $[\alpha]_D$ +145.5° (acetone)]. (−)-Menthol of commercial grade (Hoei Chemicals, Osaka) was used without further purification. (*R*)-(−)-Menthyl benzoates (**2**) were prepared by treating (−)-menthol with the corresponding substituted benzoic acid chlorides in dry ether in the presence of pyridine. $C_{10}H_{19}$-O-CO-C_6H_4-R; [R, mp or bp, specific rotation (*c*, solvent)], *p*-CH_3O (**2a**); 160—161 °C/1 Torr (lit,[19] 229—230 °C/15 Torr), $[\alpha]_D^{20}$ −79.2° (0.671, C_2H_5OH) (lit,[19] $[\alpha]_D^{20}$ −86.5° (neat)), *p*-*t*-C_4H_9 (**2b**); 171—172 °C/1 Torr, $[\alpha]_D^{20}$ −71.1° (1.56, C_2H_5OH), *p*-CH_3 (**2c**); 138—139 °C/1 Torr (lit,[19] 196—198 °C/11 Torr), $[\alpha]_D^{22}$ −85.3° (1.26, C_2H_5OH) (lit,[19] $[\alpha]_D^{20}$ −89.9° (neat)), *p*-*i*-C_3H_7 (**2d**), 166 °C/1—2 Torr, $[\alpha]_D^{20}$ −75.7° (1.37, C_2H_5OH), *m*-CH_3 (**2e**); 140 °C/2 Torr (lit,[6] 109—110 °C/0.1—0.2 Torr), $[\alpha]_D^{20}$ −85.9° (1.18, C_2H_5OH), $[\alpha]_D^{20}$ −89.6° (1.28, C_6H_5) (lit,[20] $[\alpha]_D$ −88.5° (C_6H_5)), H (**2f**); 54.5 °C (lit,[21] 55 °C), $[\alpha]_D^{20}$ −90.5° (1.53, C_2H_5OH) (lit,[21] $[\alpha]_D^{20}$ −83.5° (C_2H_5OH)), *p*-Cl (**2g**); 146 °C/0.5 Torr (lit,[6] 156 °C/1 Torr), $[\alpha]_D^{20}$ −78.3° (1.09, C_2H_5OH) (lit,[22] −80.6° (neat)), *m*-Cl (**2h**); 146—147 °C/1 Torr (lit,[6] 137 °C/0.5 Torr), $[\alpha]_D^{20}$ −80.0° (1.36, C_2H_5OH) (lit,[22] $[\alpha]_D$ −80.45° (neat)), *p*-CN (**2i**); ca. 150 °C/0.5 Torr (lit,[6] ca. 185 °C/1 Torr), $[\alpha]_D^{20}$ −81.0° (2.10, C_2H_5OH). Tetrahydrofuran (THF) was purified by fresh distillation from a solution of sodium benzophenone ketyl before use in all reactions. Butyllithium was obtained as a 1.56 mol dm^{-3} solution in hexane from Mitsuwa Chemical Co., Ltd. (Osaka). Kryptofix 211 was purchased from MERCK and used without further purification.

Reaction of Racemic α-Lithiomethyl *p*-Tolyl Sulfoxide (1) with Substituted (*R*)-(−)-Menthyl Benzoates (2). Into a 50 cm^3 two-necked, round-bottomed flask equipped with a rubber septum, a magnetic stirring bar, and a nitrogen-inlet tube was placed 15 cm^3 of dry THF, 5 mmol of butyllithium in hexane, and 370 mg (5 mmol) of diethylamine through the septum via a syringe at 0 °C under nitrogen. The flask was cooled to −78 °C, a solution of 5 mmol of racemic methyl *p*-tolyl sulfoxide in 2.5 cm^3 of dry THF was added, and the solution was stirred vigorously for 30 min at 0 °C. A solution of a (*R*)-(−)-menthyl benzoate (2.5 mmol) in 2.5 cm^3 of dry THF was then injected via a syringe, drop by drop, into the solution at −78 °C. After being stirred for an adequate time at −78 °C (the progresses of the reaction was monitored by TLC), the mixture was treated with water (10 cm^3), acidified (ca. pH 3) with 10% hydrochloric acid, and extraced with chloroform (3×10 cm^3). The combined chloroform layers were washed with brine, dried (Na_2SO_4), and evaporated in vacuo. Preparative thin-layer chromatography of the residue on silica gel (MERCK 60PF$_{245}$), using ether as the eluent, gave the analytically pure β-keto sulfoxide (**3**) which was subjected to optical rotation measurement.

Preparation of Authentic (*R*)-(+)-β-Keto Sulfoxides (3). The authentic optically pure meta- or para-substituted (*R*)-(+)-α-(*p*-tolylsulfinyl)acetophenones (**3**) were prepared by the same procedure as described in our previous paper.[3g] The treatment of α-lithiomethyl *p*-tolyl sulfoxide, derived from 1.54 g (10 mmol) of (*R*)-(+)-methyl *p*-tolyl sulfoxide and 11 mol of lithium diethylamide, was treated with 5 mmol of an ethyl benzoate in 25 cm^3 of dry THF at 0 °C. By a work-up similar to that used for the reaction of **1** and **2** described above, the corresponding dextrorotatory β-keto sulfoxide was produced. Recrystallization from ether or ethyl acetate yielded the analytically pure β-keto sulfoxide in satisfactory yield (78—93%). The authentic β-keto sulfoxides (**3**) obtained by this procedure exhibited the following properties. (*R*)-(−)-**3a**: mp 78.5—79 °C. $[\alpha]_D^{25}$ +253° (*c* 0.485, acetone). ^{1}H NMR ($CDCl_3$): δ=2.39 (s, 3H, -CH_3), 3.87 (s, 3H, -O-CH_3), 4.23, 4.49 (dd, *J*=14 Hz, 2H, -CH_2-), 6.85—8.00 (m, 8H, aromatic). Found: C, 67.43; H, 4.60%. Calcd for $C_{16}H_{13}SO_2N$: C, 67.82; H, 4.62%.

The authentic (*R*)-(+)-**3c** and (*R*)-(+)-**3f** have already been prepared in our previous paper.[3g]

Measurement of Enantiomeric Purity. The polarimetric analysis for the mixture of (*R*)- and (*S*)-β-keto sulfoxides (**3**) in acetone indicated that the specific rotation was nicely correlated with the composition of the enantiomeric mixture.[23] A typical experiment using the mixture of optically pure (*R*)-(+)-**3f** and racemic **3f** of various proportions is shown in Fig. 2. Therefore, the per cent enantiomeric excess (%e.e.) for the β-keto sulfoxides (**3**) obtained from the enantiomer-differentiating reaction of **1** and **2** was assigned by direct comparison with the specific rotation of the corresponding authentic **3**, i.e., %e.e.=optical purity=$[\alpha]_{obs}/[\alpha]_{max}\times 100$.[25]

Measurement of the Rate Constant for the Reaction of 1 and 2. The same experimental setup as has been described above was used. A solution of racemic **1** (2 mmol) in 7 cm^3 of dry THF was mixed rapidly with a solution of **2** (1 mmol) in 1 cm^3 of dry THF at −78 °C under nitrogen. From time to time the solution was quenched with water (10 cm^3) to stop the reaction, acidified, and extracted with chloroform (3×30 cm^3). The chloroform layer was washed with brine (3×20 cm^3) and dried (Na_2SO_4). The residue from the organic layer was subjected to the ^{1}H NMR measurement, and the consumption of **1** was measured by checking the methyl proton signal (δ=2.57, $CDCl_3$) of the resulting methyl *p*-tolyl sulfoxide. The second-order rate constant was determined according to the following equation; $kt=1/(C_1-C_2)\cdot\ln C_2(C_1-x)/C_1(C_2-x)$, where C_1 and C_2 represent the molar concentrations of **1** and **2** at time 0, respectively, and x represents the molar concentration that has reacted at time t.

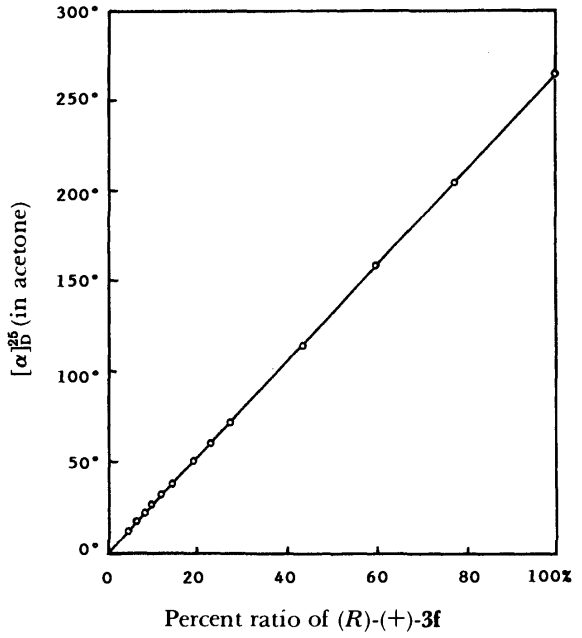

Fig. 2. Relationship between the per cent ratio of (*R*)-(+)-**3f** and the specific rotation.

Mercury-Photosensitized Decomposition of β-Butyrolactone

Shunzo YAMAMOTO,* Rinko GOHDA, Yoshimi SUEISHI, and Norio NISHIMURA
Department of Chemistry, Faculty of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700
(Received November 24, 1988)

The mercury-photosensitized decomposition of β-butyrolactone has been investigated at temperatures between 353 and 393 K and pressures from 450 to 13600 Pa. The products were carbon dioxide, propylene, carbon monoxide, propylene oxide, acetone, and acetaldehyde. The yields of these products increased linearly with reaction time and light internsity, while they were independent of the lactone pressure. Three decomposition processes were proposed to explain the formation of the products. The decrease in the quantum yields of carbon dioxide, carbon monoxide, and acetaldehyde observed in the presence of *cis*-2-butene can be explained by the competitive quenching of the triplet mercury atom by the lactone and *cis*-2-butene (the quenching efficiency of lactone relative to that of *cis*-2-butene was estimated to be 0.61). The decrease in the quantum yields of carbon dioxide, propylene, and acetaldehyde by the addition of oxygen can again be explained only by the competitive quenching of the triplet mercury atoms by lactone and oxygen (k_Q(lactone)/k_Q(oxygen)=1.36). The quantum yields of propylene oxide and acetone, however, decrease more rapidly than predicted for competitive quenching. This indicates the existence of a reaction between oxygen and a biradical, which is a precursor of propylene oxide and acetone.

Recently, we have studied the mercury- and cadmium-photosensitized decompositions of γ-butyrolactone (γ-BL)[1] and β-propiolactone (PL)[2] and found the different kinetic behavior in the two photosensitized reactions. We have concluded that the mercury-photosensitized reaction proceeds through a lactone triplet state, while the cadmium-photosensitized reaction proceeds through an excited complex between an excited cadmium atom and a lactone molecule.

Recently, Frey and Watts[3,4] studied the thermal decomposition of β-butyrolactone (β-BL) and PL and pointed out that the introduction of a methyl group into the 4 position on the lactone ring accelerates the thermal decomposition rate, and that the rate acceleration can be attributed to the stabilization of a positive-charge center (by the methyl group) which develops on C_4 in the compex. We have investigated the mercury-photosensitized decomposition of β-BL in order to compare the results with those of the mercury-photosensitized reaction of PL and to test some of the mechanistic ideas developed for PL.

Experimental

The apparatus and techniques are similar to those used previously.[1,2]

An analysis of the products was performed using simple fractionation at 77 and 190 K, measurements with a gas burette, and gas chromatography. The light intensity absorbed by the mercury atoms at 253.7 nm was determined by *cis*-2-butene actinometry.

β-BL (Tokyo Kasei Ind., GR grade) was used after drying using a Molecular Sieve 5A and several trap-to-trap distillations. Known amounts of liquid lactone were injected into the reaction cell with a microsyringe and were fully degassed after many careful freeze-pump cycles. The pressure of β-BL in the cell was calculated by the perfect-gas equation. *cis*-2-Butene (NihonTokushu Gasu K.K., pure grade), O_2 (Takachiho Shoji, pure grade) were used as supplied.

Results and Discussion

Since the vapor pressure of β-BL is low at room temperature, it is necessary to elevate the reaction temperature in order to obtain sufficient vapor pressure. The mercury-photosensitized reaction was studied at 353, 373, and 393 K. The thermal decomposition at these temperatures and the direct photolysis at 253.7 nm were found to be negligible.

The major products of the mercury-photosensitized decomposition of β-BL were carbon dioxide, propylene, carbon monoxide, propylene oxide, acetone, and acetaldehyde. Yields of these products increased linearly with reaction time and light intensity, showing that they are primary products.

The yields of the products are shown in Fig. 1 as a function of lactone pressure. As Fig. 1 shows, the yields of all products are independent of the lactone pressure. The relative product yields to that of carbon dioxide at 353, 373, and 393 K are shown in Table 1. The ratios of the product yields are independent of temperature. The quantum yields (Φ) of products

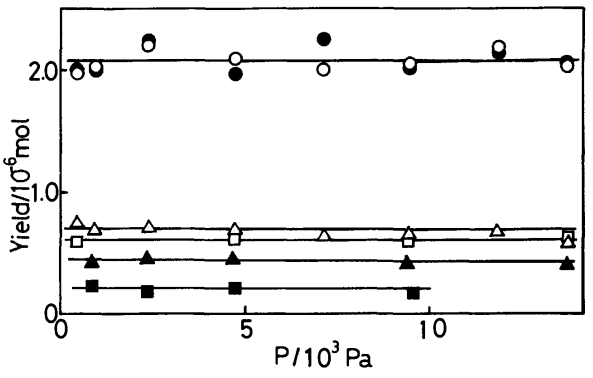

Fig. 1. Pressure dependence of product yields. CO_2 (○), propylene (●), acetaldehyde (□), CO (△), propylene oxide (▲), and acetone (■).

Table 1. Temperature Dependence of Yields of Products Relative to That of CO_2

T/K	C_3H_6	CH_3CHO	CO	C_3H_6O	$(CH_3)_2CO$
353	1.01	0.084	0.086	0.054	0.017
373	1.04	0.078	0.096	0.056	0.013
393	1.04	0.087	0.091	0.051	0.012

Table 2. Quantum Yields of Products in the Mercury-Photosensitized Decomposition of β-BL at 373 K

Products	CO_2	C_3H_6	CH_3CHO	CO	C_3H_6O	$(CH_3)_2CO$
	0.89±0.05	0.90±0.05	0.07±0.01	0.08±0.01	0.05±0.01	0.02±0.01

obtained at 373 K are listed in Table 2. The fact that the prodcut yields are independent of lactone pressure shows that the decomposition of β-BL may occur from the triplet state of the lactone. If the decomposition occurs from the vibrationally excited-electronic ground state which is produced by intersystem crossing, the product yields are expected to be largely pressure-dependent.

In order to explain the experimental results, the following set of reactions is proposed:

$$Hg(^1S_0) + h\nu(253.7\,nm) \rightarrow Hg(^3P_1) \quad (1)$$

$$Hg(^3P_1) \rightarrow Hg(^1S_0) + h\nu(253.7\,nm) \quad (2)$$

$$Hg(^3P_1) + L \rightarrow Hg(^1S_0) + {}^3L \quad (3)$$

$${}^3L \rightarrow CO_2 + CH_3CH{=}CH_2 \quad (4)$$

$${}^3L \rightarrow CO + \alpha CH_3\underline{CHCH_2}O + (1-\alpha)CH_3COCH_3 \quad (5)$$

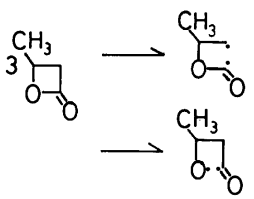
$${}^3L \rightarrow CH_3CHO + CH_2CO \quad (6)$$

Here, ^3L denotes a triplet lactone.

As Table 2 shows, $\Phi(CO_2)+\Phi(CO)+\Phi(CH_3CHO)=1.05\pm0.05$. This shows that the decomposition from the excited triplet state leads to processes (4), (5), and (6).

Recently, Frey and Watts[3,4] investigated the thermal unimolecular decompositions of β-BL and PL and found relatively small energies of activation (163.4 and 180.5 kJ mol^{-1}). They pointed out that a biradical mechanism can be ruled out and a concerted pathway must be involved. Unlike the thermal decomposition, excitation in the mercury-photosensitized reaction undoubtedly provides sufficient energy to produce biradicals, which could then decompose.

If β-BL undergoes Norrish type I cleavage which is common in carbonyl compounds, the following biradicals are formed:

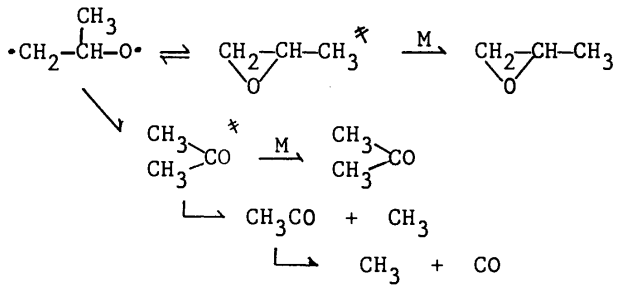


(7)

(8)

Reaction (7) is followed by elimination of carbon dioxide by breakage of the C_4–O bond and produces propylene. The biradical produced by Reaction (8) can either produce carbon monoxide and a biradical, $\cdot CH_2CH(CH_3)O\cdot$, by breakage of the O=C–C_3 bond or produce acetaldehyde and ketene by breakage of the C_3–C_4 bond.

The biradical, $\cdot CH_2CH(CH_3)O\cdot$, can either close to form propylene oxide or isomerize by hydrogen transfer to acetone, as shown by the following scheme:



Scheme 1.

From the large exothermicity of the reactions, β-BL+Hg($^3P_1$)→CO+propylene oxide+Hg($^1S_1$) and β-BL+Hg($^2P_1$)→CO+acetone+Hg($^1S_0$), propylene oxide and acetone will be formed with large excess energy and may dissociate to CO and CH_3 radicals.

As described previously,[2] for the mercury-photosensitized reaction of PL yields of ethylene oxide and acetaldehyde, which are correspond to propylene oxide and acetone in the present case, show pressure dependence at lower pressures. From the pressure dependence of yields of ethylene oxide and acetaldehyde, we have estimated the excess energy of energized ethylene oxide and obtained the value of 272 kJ mol^{-1} which corresponds to about 78% of the enthalpy change for the reaction, PL+Hg(^3P)→ethylene oxide+CO+Hg($^1S_0$).

Here, we assume that almost the same fraction (75—80%) of the enthalpy changes of the following reactions are partitioned to propylene oxide and acetone:

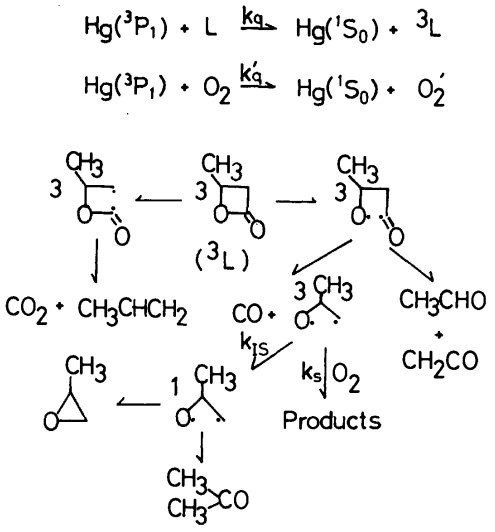
$$Hg(^3P_1) + \beta\text{-BL} \rightarrow Hg(^1S_0) + CO + \underset{\diagdown\,/\,\diagdown}{CH_2CHCH_3\ \ \ \

system suppressed the formation of products. Figure 3 shows the effect of oxygen on the yields of products. As Fig. 3 shows, yields of all products decrease with increasing oxygen pressure. The solid line shows the relative quantum yields calculated using the following relative quenching efficiencies for β-BL and oxygen:

$k_Q(\beta\text{-BL})/k_Q(O_2)=1.36$ (obtained from $k_Q(\beta\text{-BL})/k_Q(cis\text{-2-butene})=0.61$ and $k_Q(O_2)/k_Q(cis\text{-2-butene})=0.45$[8])

The decrease in the quantum yields of carbon dioxide, propylene, and acetaldehyde can be explained by the competitive quenching of the triplet mercury atom by the lactone and oxygen. The decreases in the yields of propylene oxide and acetone, however, are steeper than those of other products. This shows that oxygen has additional effects on the formation of propylene oxide and acetone. As mentioned above, the biradical, $\cdot COCH_2(CH_3)O\cdot$, is a common intermediate for the formation of acetaldehyde and propylene oxide (and acetone). The difference in the effect of oxygen on the formation of acetaldehyde and that of propylene oxide and acetone shows that oxygen does not scavenge this biradical, but may scavenge another intermediate which locates between the biradical and propylene oxide and acetone (the final products).

The effect of oxygen on product yields can be discussed in terms of reactions schematically depicted in Scheme 2.



Scheme 2.

From this mechanism, the following equations can be derived:

$$\frac{\Phi_{CO_2}}{\Phi^\circ_{CO_2}}=\frac{\Phi_{CH_3CHCH_2}}{\Phi^\circ_{CH_3CHCH_2}}=\frac{\Phi_{CH_3CHO}}{\Phi^\circ_{CH_3CHO}}=\frac{k_q[L]}{k_q[L]+k'_q[O_2]} \quad (12)$$

$$\frac{\Phi_{CH_3\underline{CHCH_2O}}}{\Phi^\circ_{CH_3\underline{CHCH_2O}}}=\frac{\Phi_{(CH_3)_2CO}}{\Phi^\circ_{(CH_3)_2CO}}=\frac{k_q[L]}{k_q[L]+k'_q[O_2]}\frac{k_{IS}}{k_{IS}+k_s[O_2]} \quad (13)$$

The relationship between $\Phi_{CO2}/\Phi^\circ_{CO_2}$, $\Phi_{CH_3CH=CH_2}/\Phi^\circ_{CH_3CH=CH_2}$, and $\Phi_{CH_3CHO}/\Phi^\circ_{CH_3CHO}$ vs. oxygen pressure has been already discussed above. The additional effect of oxygen on the yields of propylene oxide and acetone mentioned above is expressed by the term $k_{IS}/(k_{IS}+k_s[O_2])$. The ratio of the rate constants, k_s/k_{IS}, was evaluated by fitting Eq. 13 to the experimental measurements ($k_s/k_{IS}=7.5\times10^{-1}$ Pa). The dashed curve in Fig. 3 shows the calculated values of Φ/Φ° for propylene oxide and acetone. If k_s has a typical value of 1.0×10^{13} cm^3 molecule^{-1} s^{-1} similar to that suggested for the analogous reaction of alkyl monoradicals,[9] then k_{IS} can be calculated to be 3.2×10^6 s^{-1}. This value is in reasonable agreement with that proposed by Montague for intersystem crossing of alkyl biradicals ($3\times10^6<k_{IS}<4.5\times10^8$ s^{-1}).[10]

According to recent kinetic studies[11-14] of the reaction of ethylene with the ground-state oxygen atom(O(^{3}P)), the reaction proceeds via two main channels: one yielding CH_2=CHO·+H (a) and the other, CH_3+HCO (b). The primary process is the addition of the oxygen atom to the C=C double bond to form a triplet biradical, $\cdot CH_2CH_2O\cdot$. Hunziker et al.[11] proposed a schematic potential energy diagram for the O + ethylene reaction and pointed out that the shift of a hydrogen atom in the triplet biradical to give triplet acetaldehyde requires a high activation energy. They also suggested that by collision it can be converted into an isoenergetic singlet biradical which would have low activation energy pathways available to give hot ground state oxide and aldehyde. Koda et al.,[15] however, pointed out that this mechanism cannot explain the pressure independence of the branching ratio over a wide range. They proposed a rapid collision-free intersystem crossing to interpret their experimental results. They assumed that the branching ratio of (b)/(a) is determined by the unimolecular dissociation rate of the triplet intermediate yielding CH_2=CHO·+H compared with the rate of the intersystem crossing to the singlet surface and can interpret the enhancement of the branching ratio by the deuterium substitution of ethylene.

The biradical produced in the mercury-photosensitized reaction of β-BL seems to be a triplet as shown above and to behave similarly to the triplet biradical formed in the oxygen-ethylene reaction and is converted into a singlet biradical by a collision-free intersystem crossing. The fate of the singlet biradical has already been discussed above.

An Oxygen Exchange of Arsenate and Alkylarsonate Ions with Water

Nobuko NIWA, Midori FUSHIMI, Masayasu IIDA, Yuko HORIE, Shinichi YAMABE,† and Akiko OKUMURA*
Department of Chemistry, Faculty of Science, Nara Women's University, Kita-uoya-nishi-machi, Nara 630
†Department of Chemistry, Nara University of Education, Takabatake-cho, Nara 630
(Received December 19, 1988)

The oxygen exchange rates, R's, between the alkylarsonates (methyl- and butyl-) and water were measured over the pH range greater than 9 and at 30 °C. The rates were analyzed in terms of the rate law, $R=k_1[R'\text{-}AsO_3H^-]+k_2[R'\text{-}AsO_3^{2-}]$ (R'-; alkyl-) to obtain k_1 to be 6.64×10^{-4} s^{-1} for methyl- and 4.38×10^{-4} s^{-1} for butylarsonate ions, respectively. The first-order oxygen exchange rate constants, k_1's, on the alkylarsonate univalent anions (methyl and butyl) are almost the same values, which indicates that the steric effect on the rate is absent. The rate constants, k_1's, correlate well with energy levels of the lowest unoccupied molecular orbitals (E_{LUMO}'s) of univalent anions of arsenic, arsenious, and alkylarsonic acids.

The important role of phosphoric acid and its derivatives in biochemical processes is known-well. There are many studies of the hydrolysis of organic phosphates[1] and the oxygen exchange of phosphoric acid with water.[2] The As and P atoms belong to the nonmetal Va group and consequently arsenic and phosphoric acids have similarity in structures and physical properties in solution. On the other hand, the difference of reactivity between them is enormous; the oxoanions of arsenic are reactive, while those of phosphorus are stable and unreactive. Many biochemical effects seem to be due to the ability of arsenic(V) to mimic the analogous phosphates; arsenate may substitute for phosphate as a substrate in certain phosphorylation[3] and some enzymatic arsenolyses.[4] The investigation of the behavior of arsenic(V) is important and is expected to shed light on the reaction mechanism of phosphoric(V) in biological systems.

While the oxygen exchange reactions between the oxoanions of phosphorus and water have been extensively studied, those of oxoanions of arsenic are rather few.[5–7]

The difficulty of the latter measurement by ^{18}O tracer method was mainly in the separation process of the oxoanions from the solution for isotopic oxygen analyses. As stated in a previous paper,[6] on the precipitation of the oxoanions by metal ions, the oxygen exchange of the oxoanions of arsenic is induced. In the case of some alkylarsonates, any precipitant could not separate oxoanions from the solution. NMR instrumentation recently available has alleviated these problems, but there still remains a difficulty in the preparation of ^{17}O-enriched compounds for ^{17}O NMR technique.

However, it is important to study kinetics of the oxygen exchange on As, because it provides information of the microscopic interaction between oxoanion and solvent water and between oxoanions in the solution.[6–10] Furthermore, the detailed kinetic data of the oxygen exchange of arsenate ions may explore the possibility of the use of ^{18}O-labelled arsenate in biochemical tracer work.

Here, we present new rate constants of R'-As(OH)O_2^- ions, where R' is the alkyl group (R'=methyl or butyl). It is of mechanistic interest to know how the alkyl substituent affects the oxygen-exchange rate. The long chain of the butyl would block the nucleophilic attack of a water molecule. After the first-order rate constants are measured, those substituent effects are investigated with the aid of the ab initio molecular orbital (MO) calculation. The relation between the electronic property and the reactivity of arsenate and alkylarsonate ions is sought. In particular, it should be carefully checked what kind of the isomer of the substrate is involved in the oxygen exchange reaction. As atom may have 3, 5, or 7 chemical bonds, and this freedom might be related to the intervention of unexpected isomers and subsequently to the anomalous rate constants. This is a pioneer work which deals with the S_N2 reaction of the As atom systematically.

Experimental and Computational

Materials. Methyl- and butylarsonates were prepared according to Quick.[11] Methylarsonate was recrystallized several times from aqueous ethanol solution (50 vol%). The methylarsonic acid derived from the purified salt has a melting point of 161 °C (161 °C[11]). The C and H contents by elemental analyses are: Found: C, 8.66; H, 3.62%. Calcd for $CH_3AsO_3H_2$: C, 8.58; H, 3.60%. A crude product of butylarsonate was acidified to form arsonic acid, which was purified by the crystallization from water and ethanol. The melting point of the acid are 161 °C (159—160 °C[11]), and elemental analyses gave: Found: C, 26.53; H, 6.12%. Calcd for $C_4H_9AsO_3H_2$: C, 26.40; H, 6.10%.

Rate Measurements. The oxygen-exchange rate of methylarsonate was followed by measuring the decrease in the ^{18}O contents of arsonate upon diluting an isotopically equilibrated solution of $CH_3AsO_3Na_2$ in [^{18}O]water with a large amount of isotopically normal water. A portion of the solution was drawn periodically and the arsonate was recovered by freeze-dry method, its oxygen being converted into carbon dioxide by the guanidinium chloride method.[12] The isotopic analysis of carbon dioxide was made on a Hitachi RMS-I-type mass spectrometer.

The rates of oxygen exchange of butylarsonate were obtained by ^{17}O NMR method. A weighed amount of butylarsonate enriched in ^{17}O was dissolved into 3 ml of water in an ice bath. After pH adjustment, the solution was transferred to a sample tube for running the NMR spectra. In the measurements, both the decrease in the intensity of ^{17}O-signal of the arsonate and the increase in that of water were followed. The rates on both the signals are satisfactorily agreed. ^{17}O NMR spectra were recorded at 36.6 MHz on a FT-NMR spectrometer, JEOL-GX270. The ^{17}O-chemical shift for n-$C_4H_9AsO_3Na_2$ is downfield from water by 130 ppm.

The rate of oxygen exchange, R, was calculated by means of the formulas:

$$R = -\frac{1}{t}\frac{[\text{arsonate}][H_2O]}{3[\text{arsonate}]+[H_2O]}\ln\frac{*O_t - *O_\infty}{*O_0 - *O_\infty}$$

where $*O_0$, $*O_t$, and $*O_\infty$ are ^{18}O (for methylarsonate) or ^{17}O (for butylarsonate) contents at the times 0, t, and infinity, respectively. [arsonate] and [H_2O] are the molar concentrations (mol dm^{-3}) of the arsonates and water, respectively.

The Dissociation Constants of Arsonic Acids. These were determined by the potentiometric titration at 30 °C and I=0.55 mol dm^{-3}. The values of pK_2 are 8.50 for methylarsonic acid and 8.88 for butylarsonic acid.

Ab Initio Molecular-Orbital (MO) Calculation. To compare the reactivity of arsonates for the oxygen exchange with each other, we performed an MO calculation on five substrates with the STO-3G* basis set (STO-3G plus six d orbitals on arsenic). All the electrons are explicitly considered, and the geometries are fully optimized using the GAUSSIAN 82 program.[13]

Results of Kinetics

The exchange rates for the two reactions were measured at 30 °C and over the pH range between 9 and 12 where the dominating ionic species of arsonates are R'-AsO_3^{2-} and R'-AsO_3H^- (R'=CH_3 or n-C_4H_9). The results are shown in Table 1.

The dependence of the rate on the concentration of arsonates was studied at pH 10.6 for methylarsonate (**A**) and pH 10.9 for butylarsonate (**B**). The plots of $\log_{10} R$ against $\log_{10}$[arsonate] give the straight lines with slopes of 0.92 for **A** and 1.07 for **B**, respectively (Fig. 1). The first-order dependence observed in Fig. 1 suggests that the oxygen exchange of arsonates proceeds through two parallel paths:

$$R'\text{-}AsO_3H^- + H_2{*}O \overset{k_1}{\rightleftharpoons} R'\text{-}AsO_2{*}OH^- + H_2O$$

$$R'\text{-}AsO_3^{2-} + H_2{*}O \overset{k_2}{\rightleftharpoons} R'\text{-}AsO_2{*}O^{2-} + H_2O$$

and the exchange rate law may be written as:

$$R = k_1[R'\text{-}AsO_3H^-] + k_2[R'\text{-}AsO_3^{2-}]$$

By the use of this relation, the exchange rates shown in Table 1 were analyzed and the values of k_1 and k_2 are obtained to be 6.64×10^{-4} s^{-1} and 2.69×10^{-4} s^{-1} for methylarsonate and 4.38×10^{-4} s^{-1} and 9.33×10^{-5} s^{-1} for butylarsonate, respectively. Noteworthy is the result that the four rate constants are of the same order, and a noticeable steric or hydrophobic effect of the butyl substituent is not observed.

Table 1. The pH Dependence of the Oxygen Exchange Rates of Methyl- and Butylarsonates (30 °C and I=0.55 mol dm^{-3}. [methylarsonate]=0.1 mol dm^{-3}, [butylarsonate]=0.2 mol dm^{-3})

The rate constants of the oxygen exchange between univalent anoin of arsonate and water, k_1's, thus obtained were used in the following discussion.

Computational Results and Discussion

First, measured exchange-rate constants [$k_1^{(A)}$, $k_1^{(B)}$, $k_1^{(C)}$, $k_1^{(D)}$] are compared with each other. $k_1^{(A)}$ and $k_1^{(B)}$ are presented in the previous section, and $k_1^{(C)}$ [6] and $k_1^{(D)}$ [7] are taken from literatures.

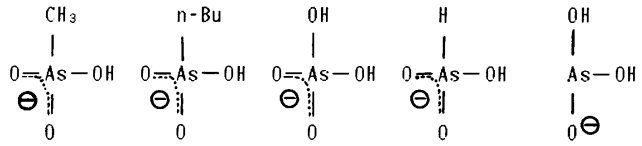
$$CH_3AsO_3H^- + H_2{*}O \longrightarrow CH_3AsO_2{*}OH^- + H_2O \quad \text{(A)}$$
$$k_1^{(A)} = 6.6\times10^{-4}\ \text{s}^{-1}$$

$$n\text{-}C_4H_9AsO_3H^- + H_2{*}O \longrightarrow n\text{-}C_4H_9AsO_2{*}OH^- + H_2O \quad \text{(B)}$$
$$k_1^{(B)} = 4.4\times10^{-4}\ \text{s}^{-1}$$

$$H_2AsO_4^- + H_2{}^*O \longrightarrow H_2AsO_3{}^*O^- + H_2O \quad (C)$$
$$k_1^{(C)} = 1.0\times10^{-4}\ s^{-1}$$

$$H_2AsO_3^- + H_2{}^*O \longrightarrow H_2AsO_2{}^*O^- + H_2O \quad (D)$$
$$k_1^{(D)} = 167\ s^{-1}$$

The relation of $k_1^{(D)} \gg k_1^{(A)} \simeq k_1^{(B)} > k_1^{(C)}$ is recognized. It seems to be curious that the $k_1^{(D)}$ (R′=H) is much larger than $k_1^{(A)}$ (R′=methyl) and $k_1^{(B)}$ (R′=butyl). Some anomalies for the large reactivity of H-AsO_3H^- must be present. To analyze this trend, an MO calculation is made for the following substrates.



For $H_2AsO_3^-$, **D**, **Db** is an isomer of **Da**. The anomalous value of $k_1^{(D)}$ may be related to the isomer. Optimized geometries of **A**, **B**, **C**, **Da**, and **Db** are

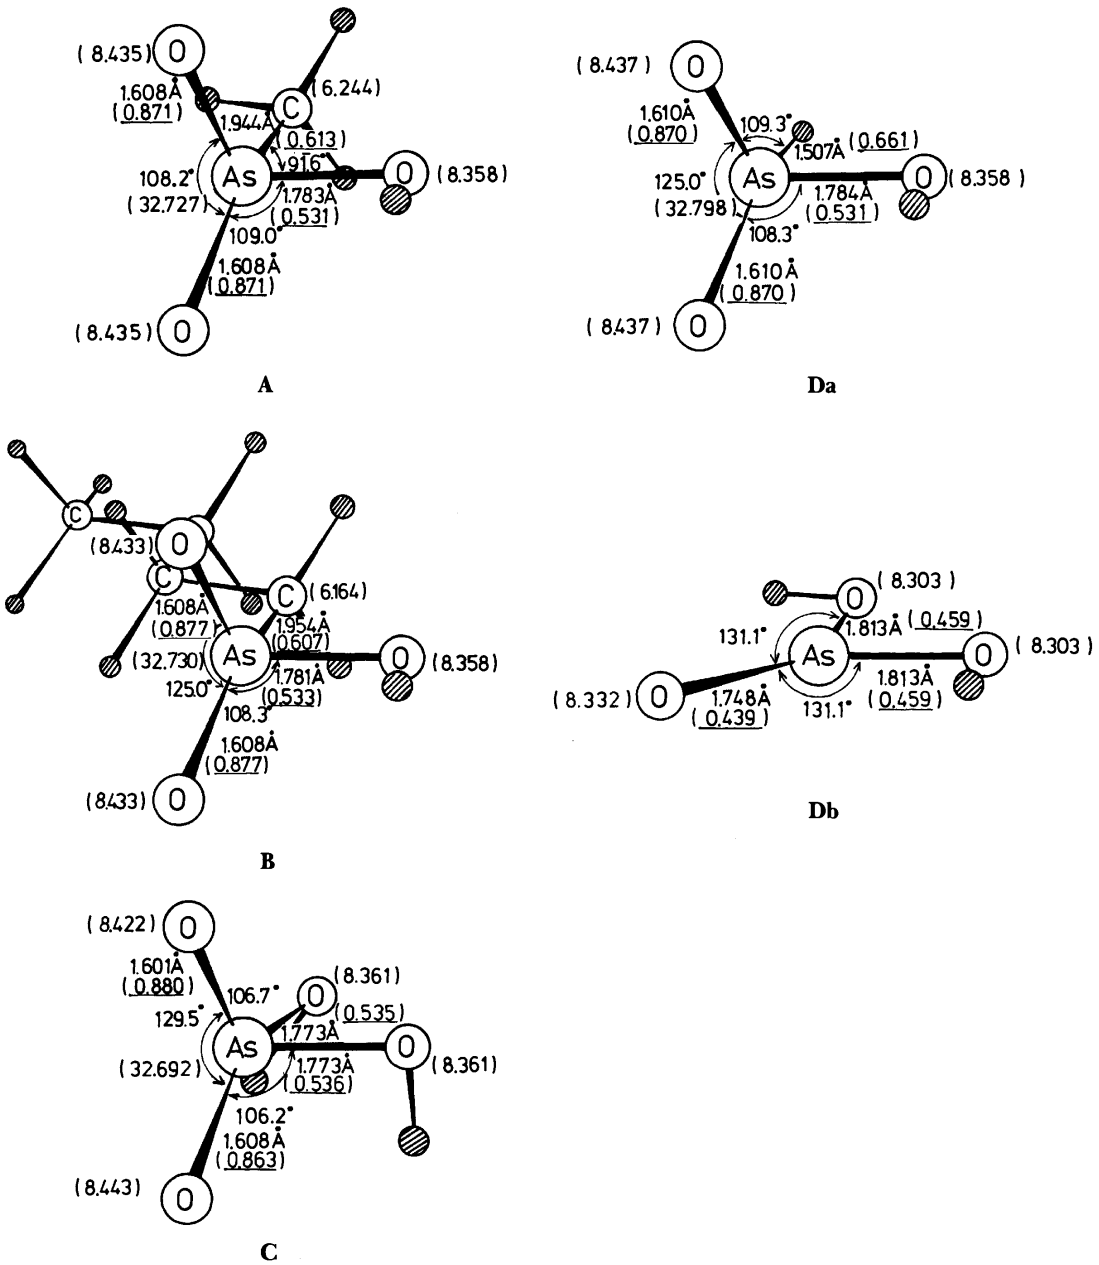


Fig. 2. Geometries of arsenate and alkylarsonate ions optimized with the STO-3G* basis set. Shaded circles denote hydrogen atoms. Values in parentheses stand for the atomic electronic density, and underlined ones do the atom-atom bonding populations.

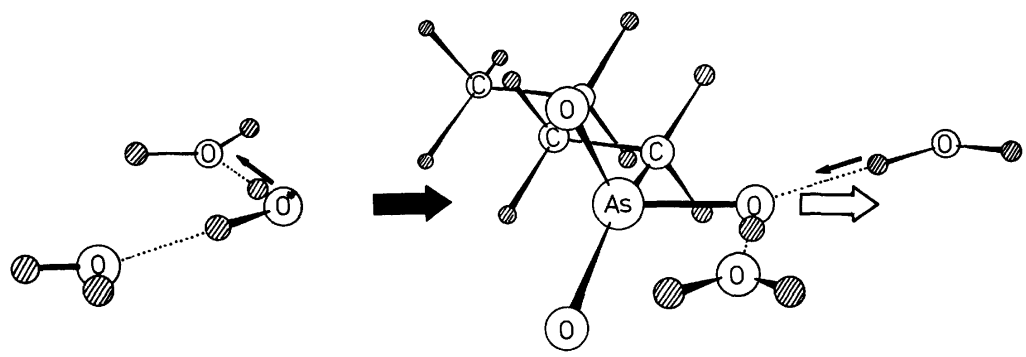
exhibited in Fig. 2. The As-O bond length 1.78 Å of **A** and **B** is comparable to 1.71 Å of the crystal data of propylarsonic acid.[14] Likewise, the As-O 1.61 Å and As-C 1.94 (and 1.95) Å are comparable to 1.65 Å and 1.92 Å, respectively.[14]

First, the presence or the absence of the steric or hydrophobic effect by the butyl group is examind in Fig. 3. The figure shows the lowest unoccupied molecular orbital (LUMO) which undergoes the charge transfer from the nucleophile, water. The orbital extention of LUMO clearly demonstrates that H_2O attacks the back side of the As-OH bond. The butyl chain is distant from the channel of the nucleophilic attack, and the result that the path is not blocked by the alkyl chain is related to $k_1^{(A)} \simeq k_1^{(B)}$ (no steric effect).



Second, the anomalously large value of $k_1^{(D)}$ is interpreted in terms of the computed data, i.e. the energy level of LUMO (E_{LUMO}). E_{LUMO}'s of **A**, **B**, **C**, **Da**, and **Db** vs. rate constants are plotted in Fig. 4. It is found that not E_{LUMO}(**Da**) but E_{LUMO}(**Db**) is in the line. Thus, $H_2AsO_3^-$ is present in the form of $(HO)_2AsO^-$, **Db**, which is consistent with the data of Raman spectra in aqueous solution.[15]

This finding of arsenious acid is the first case in which the structure of the oxoanion in the solution is identified on the basis of the kinetic results of the oxygen exchange. The combined treatment of the kinetic results and MO calculation used in this work seems to be applicable to S_N2 reaction on the heavy atoms other than As.

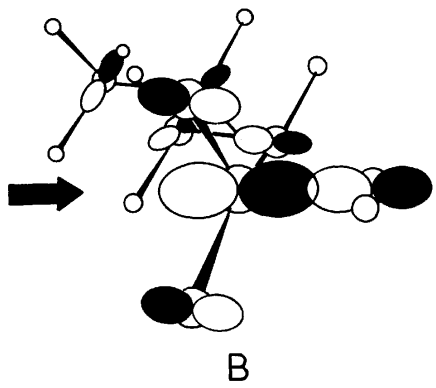


Fig. 3. The sketch of the orbital extension of the frontier orbital, LUMO, of the butylarsonate ion. The bold arrow indicates the direction of the nucleophilic attack of a water molecule.

Concluding Remarks

In this study, rate constants of oxygen exchange of alkylarsonate ions were measured. It is found that the steric effect does not dominate the rates. In the theoretical side, it is confirmed that the alkyl group is apart from the S_N2 path and therefore the rate is insensitive to the size of the alkyl chain. The remarkably large rate constant of the $H_2AsO_3^-$ is ascribed to the low-lying E_{LUMO} of [not $H\text{-}As(OH)O_2^-$] but $(OH)_2AsO^-$.

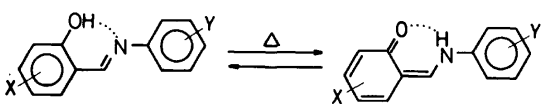
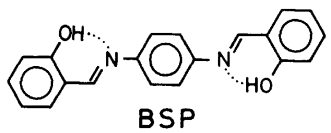
Structure and Optical Properties of a Thermochromic Schiff Base. Low-Temperature Structural Studies of the *N,N'*-Disalicylidene-*p*-phenylenediamine and *N,N'*-Disalicylidene-1,6-pyrenediamine Crystals

Tamotsu INABE,* Naomi HOSHINO,† Tadaoki MITANI, and Yusei MARUYAMA*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received October 24, 1988)

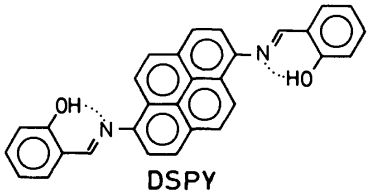
The crystal structure of *N,N'*-disalicylidene-*p*-phenylenediamine (BSP[1]) has been determined at 108 K. This compound shows a thermochromic-type behavior in the crystalline state; this chromism has been interpreted in terms of an intramolecular proton transfer from the hydroxyl oxygen to the imine nitrogen through the O-H···N hydrogen bond. In comparison with the room-temperature structure, no significant differences in the molecular structure and the molecular packing in the lattice have been observed. The room-temperature and low-termperature structures of another *N*-salicylideneaniline derivative, *N,N'*-disalicylidene-1,6-pyrenediamine (DSPY), have also been determined. In contrast to BSP, the absence of a thermal proton-transfer process in DSPY is suggested by optical measurements. Comparative studies of these two compounds indicate that a conjugation system which is not included in a π-electron configurational change by the proton transfer must be coplanar with the hydrogen-bonded chelate ring for the thermal proton transfer.

The room-temperature structure and optical properties of a thermochromic derivative of *N*-salicylideneaniline, BSP, have been reported recently.[2] The thermochromism of *N*-salicylideneanilines in the crystalline state was established to be due to the self-isomerization of a molecule by proton transfer from the hydroxyl oxygen to the imine nitrogen.[3] The temperature dependences of the visible absorption and emission spectra of BSP are consistent with this interpretation. The OH and/or NH vibrational modes in the infrared spectra are supposed to be sensitive to such an isomerization process. The OH stretching mode actually showed a significant change in the peak profile with varying the temperature.[2] However, the change has not completely been interpreted due to its complicated feature.





BSP



DSPY

† Present address: Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060.

Among the other *N*-salicylideneaniline derivatives, DSPY has been found to show no thermochromic behavior, although it has a similar framework to BSP. Thus, a comparison of BSP and DSPY is expected to provide some information about the conditions of the structure and the electronic state required for the proton transfer in *N*-salicylideneanilines. In order to make a clear comparison, it is desirable to employ the structures determined at low temperatures, since the temperature influences not only the thermal motion of atoms but also the thermochromic effects in the case of BSP. In this paper, the room-temperature structure and the optical properties of DSPY as well as the low-temperature structure and that of BSP are presented.

Experimental

Materials. DSPY was prepared by condensation of 1,6-pyrenediamine and salicylaldehyde in the same manner as BSP,[2] and was recrystallized from benzene. 1,6-Pyrenediamine was synthesized following the method reported by Vollman et al.[5]

Optical Measurements. Single-crystal measurements (infrared absorption and visible absorption and emission spectra) were performed by the same methods reported before.[2]

X-Ray Structure Analyses. An automated RIGAKU AFC-5R diffractometer with graphite monochromatized Mo $K\alpha$ radiation was used for data collection of DSPY at room temperature. Thirty-one reflections with $20°<2\theta<30°$ were used to determine the lattice parameters. The crystal data are listed in Table 1. The intensity data were collected in the region $2\theta>50°$ ($-25\leqq h\leqq 25$, $-15\leqq k\leqq 15$, $0\leqq l\leqq 4$) in the θ-2θ mode (scan width, $(1.2+0.5\tan\theta)°$) at a scan rate of $6°\ \mathrm{min}^{-1}$. Background counts at each end were 4—10.5 s. The intensities of the three standards, monitored every 100 data measurements, showed no significant variation. 4360 unique reflections were measured. After reducing the symmetry, 851 independent reflections with $|F_o|>3\sigma(F_o)$ were used for a structure analysis.

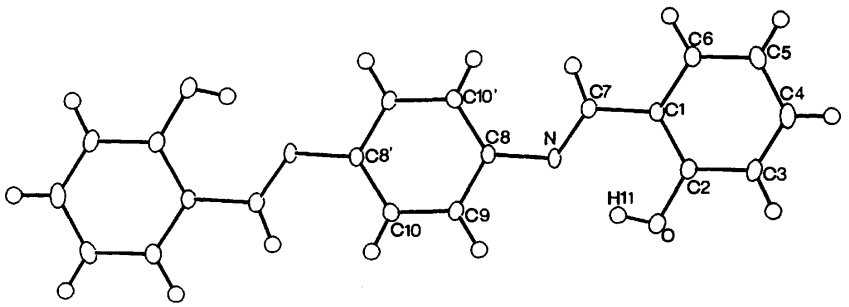

Fig. 1. ORTEP drawing[9] of BSP at 108 K showing the atom numbering scheme.

An automated RIGAKU AFC-5 diffractometer with a cold nitrogen gas flow equipment was used for the low-temperature data collection of BSP and DSPY. Twenty-five reflections for BSP and twenty-one reflections for BSDAP with $20°<2\theta<30°$ were used to determine the lattice parameters. The crystal data are shown in Table 1. The intensity data were collected in the region $2\theta<60°$ for both compounds ($-20\leqq h\leqq 18$, $0\leqq k\leqq 6$, $0\leqq l\leqq 17$ for BSP; $-17\leqq h\leqq 17$, $0\leqq k\leqq 30$, $0\leqq l\leqq 5$ for DSPY) in θ-2θ mode (scan width, $(1.2+0.5\tan\theta)°$) at a scan rate of 3° min^{-1}. Background counts at each end were 8—21.5 s. The intensities of the three standards, monitored every 100 data measurements, remained constant within 1% for both compounds. 2525 unique reflections for BSP and 3529 unique reflections for DSPY were measured. 1050 independent reflections (BSP) and 1160 reflections (DSPY) with $|F_o|>3\sigma(F_o)$ were used for structure analyses.

Crystal structures were solved by a direct method and all hydrogen atoms were determined from difference synthesis maps. A block-diagonal least-squares technique (UNICS III[6]) with anisotropic thermal parameters for nonhydrogen atoms and isotropic for hydrogen atoms (weighting scheme, $1/w=\sigma^2+(0.015|F_o|)^2$) was employed for the structure refinement.

Results and Discussion

BSP. The molecular structure derived at 108 K is shown in Fig. 1; the atomic parameters are listed in Table 2.[7] As can be seen from the thermal parameters, a reduction of the thermal motion by lowering the

temperature was observed in all atoms except for the hydroxyl hydrogen H11. The interatomic distances and bond angles are listed in Table 3 for 108 K and room temperature. At room temperature, an alternation of bond lengths, which is expected when there exists a resonance contribution from the *o*-quinonoid structure, was recognized.[2] This tendency is less pronounced at 108 K. However, an alternation of the bond lengths still remains. From optical measurements, the energy difference between the enol and keto species was evaluated as being ca. 0.1 eV.[2] The thermal energy at 108 K is, thus, low enough to settle more than 99.99% of the molecules into the enol from. Therefore, the partial keto-like contribution seems to already exist in BSP before the color change becomes noticeable. This may be a common feature of thermochromic *N*-salicylideneanilines, since a similar partial contribution from the keto-like structure was observed in *N*-(5-chlorosalicylidene)aniline at 90 K.[4] The largest change in the bond length as a result of temperature appears in the N–C8 bond. The distance is shorter by 0.026 Å at 108 K than at room temperature. The conjugation system is not completely continuous in the limited structure of the proton-transferred species. Thus, the shorter N–C8 distance may indicate that the conjugation system is more extended at low temperatures.

The molecular packing in the lattice is practically the same as that observed at room temperature.[2] The temperature dependence of the lattice parameters are shown in Fig. 2(a). The thermal contraction is most noticeable in the *c** direction, which corresponds to the direction of side-by-side molecular arrangement. The interplanar distance between the mean molecular planes becomes shorter at 108 K (3.26 Å) than at room temperature (3.29 Å). The molecular overlap is shown in Fig. 3. This overlapping mode is convenient for the charge-transfer interaction to operate between the molecules. The azomethine (–CH=N–) groups act as an acceptor relative to the benzene rings in the OH species, and all –CH=N– groups effectively overlap with the benzene rings. When the temperature is

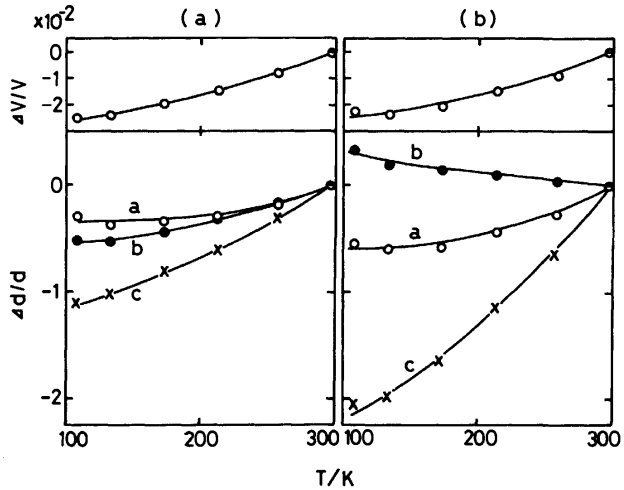

Fig. 2. Temperature dependence of lattice parameters (d and V are the room temperature parameters and volume, respectively, $\Delta d=d(T)-d$, and $\Delta V=V(T)-V$); BSP (a) and DSPY (b).

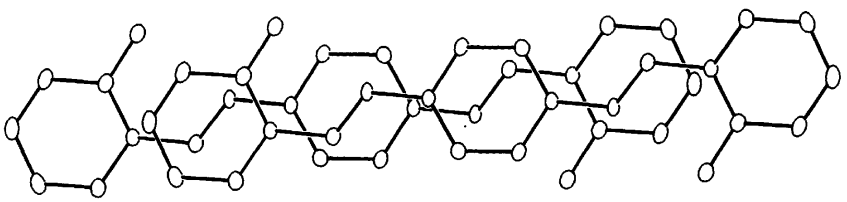

Fig. 3. Molecular overlapping between the BSP molecules.

increased, namely the content of the NH species is increased, the newly formed *p*-phenylenediamine moiety becomes a donor part and the *o*-quinonoid moiety becomes an acceptor part. The thermochromic band is, thus, assigned to the charge-transfer transition between these donor and acceptor portions.[2] Intermolecular charge-transfer interactions between such donor and acceptor portions may operate at higher temperatures.

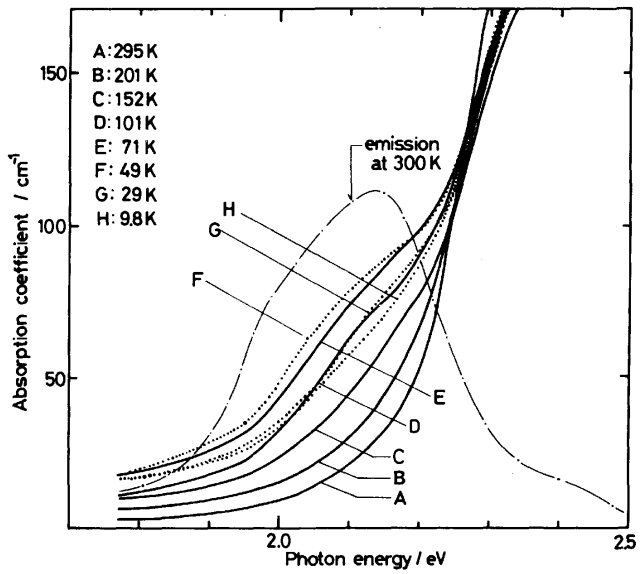

Fig. 4. Single crystal absorption spectral changes with temperature for DSPY.

DSPY. Although the molecule has a common framework with BSP, the optical properties observed for DSPY are significantly different from those observed for BSP. Figure 4 shows the single-crystal visible absorption spectra over a wide temperature range. The spectra change slightly at low temperatures. However, when the temperature is increased, noticeable growth of a new absorption observed in BSP does not occur in DSPY. The emission spectrum obtained at 300 K are also shown in Fig. 4, which corresponds well to the absorption spectra. In BSP the emission spectra show a large Stokes shift, which is a characteristic of the proton-transfer reaction. Judging from the absorption spectra, it can be concluded that the thermal proton-transfer reaction does not occur in the DSPY system.

The existence of a weak absorption band in the lower-energy region at low temperatures is interesting from a different point of view. Since this band diminishes at higher temperatures, it is obviously not related to the thermal proton transfer. In general, such growth of absorption at the lower-energy side by lowering the temperature is unusual, and the origin and mechanism of this growth in DSPY are unknown at the present stage.

The infrared spectra of DSPY were recorded at room temperature and at 6.3 K (Fig. 5). The position of the OH stretching mode shifts slightly with temperature; ca. 2800 cm^{-1} at 6.3 K, ca. 2850 cm^{-1} at room temperature. However, the peak profile does not change essentially. Thus, the results of the infrared spectra also suggests that the thermal proton-transfer process

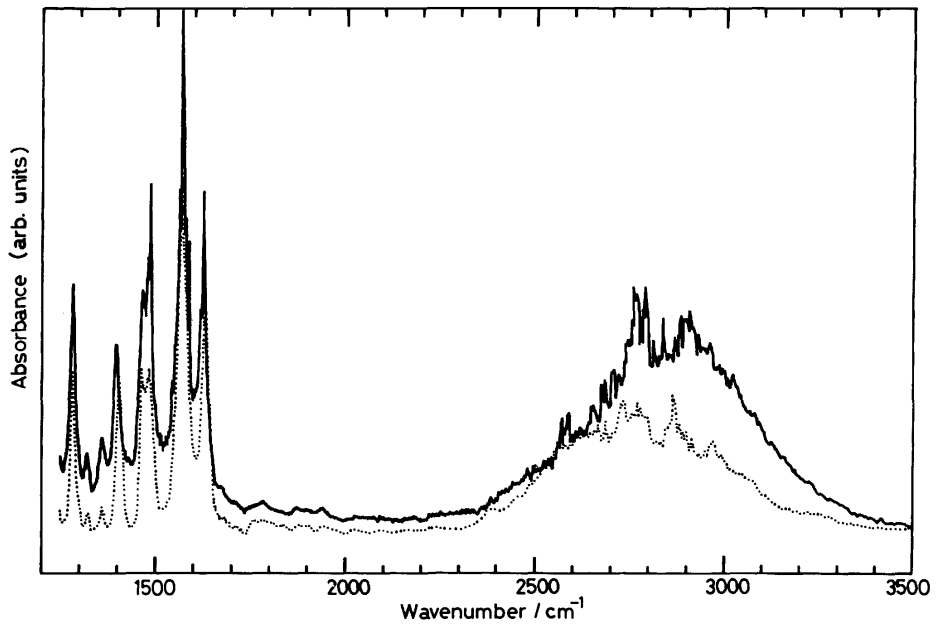

Fig. 5. Single crystal infrared spectra for DSPY at room temperature (solid line) and at 6.3 K (dotted line). The full scale does not coincide with each other because of the difference in the experimental conditions.

is absent in the DSPY system.

As shown in Fig. 6, a significant difference of the molecular structure was found by X-ray analysis. The atomic parameters are listed in Table 4;[7] the bond lengths and angles for both temperatures are listed in Table 5. Two terminal benzene rings are tilted with respect to the central pyrene plane, and the molecule is largely deformed from the planar structure. This tilting angle does not change with temperature: 42.0° at room temperature and 42.4° at 108 K, and no significant changes of the molecular dimensions by temperature have been observed. In DSPY there is no contribution from the quinonoid structure.

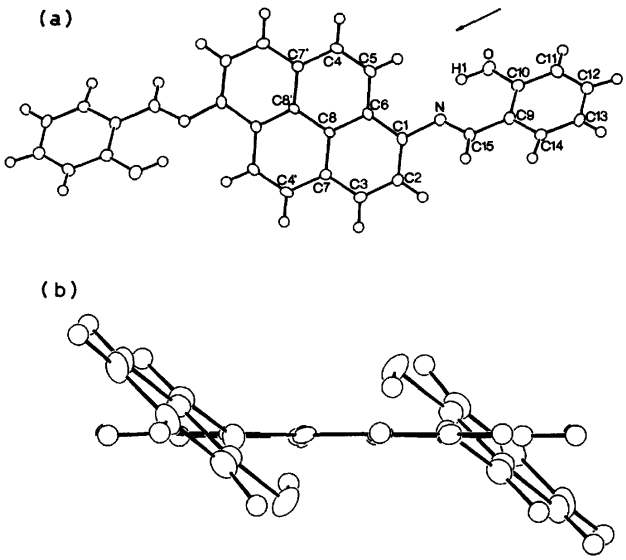

Fig. 6. ORTEP drawing of DSPY at 108 K showing the atom numbering scheme (a) and side view along the arrow indicated (b).

The observed O···N distance is slightly longer than that of BSP. However, the difference is small and it is not likely that the difference in the optical properties arises from it. The observed frequency of the OH stretching mode of DSPY is in good agreement with the value predicted from the Novak's relationship between the position of ν_{OH} and the O···N distance.[8]

The temperature dependence of the lattice parameters are shown in Fig. 2(b), and the crystal structure at 108 K is shown in Fig. 7. By lowering temperature, the length of the *b*-axis is slightly increased, while that of the *c*-axis is decreased. Consequently, the interplanar distance between the pyrene rings is shortened, i.e., 3.43 Å at room temperature and 3.39 Å at 108 K. However, all interatomic distances between the mole-

cules are larger than 3.4 Å, and there is no effective intermolecular interactions.

The results of the optical and structural studies of DSPY and BSP provide important information about the mechanism of the thermal proton transfer in *N*-salicylideneanilines. The geometrical circumstances of the hydroxyl hydrogen in DSPY are the same that in BSP. However, all data indicate no occurrence of thermal proton transfer in DSPY. In the case of BSP, the conjugation system is extended in the whole molecule, since the molecule is planar. Thus, the conjugation system in the central aromatic ring can participate in the stabilization of the partial contribution from the keto-like π-electron distribution. On the other hand, DSPY is not planar; thus, the conjugation system of the central aromatic ring is isolated from the terminal ones. In such a structure, the conjugation

system of the central aromatic group is not able to participate in the stabilization of the keto-like contribution. This seems to be important, since the partial contribution from the keto-like π-electron distribution in BSP is recognized even before the color change has become noticeable. It can therefore be concluded that one of the conditions required for the thermal proton transfer in *N*-salicylideneanilines is that the molecule is planar so that the conjugation system is sufficiently extended to be capable of the corresponding π-electron configuration of the isomer.

Another interesting feature observed in both BSP and DSPY is the large thermal parameters of the hydroxyl hydrogens, even at 108 K. Then, the difference syntheses were calculated by taking the parameters of the hydroxyl hydrogen out of the refined structures; the maps with regard to the hydrogen-bonded chelate rings are shown in Fig. 8. In DSPY, it is clearly seen that there exists only the OH proton at both temperatures. On the other hand, in addition to the OH proton, a contribution from the NH proton in BSP can be seen from the map. Thus, the differences in the optical properties between BSP and DSPY seem to be reflected in these maps. At low temperature, there still remains the contribution from the NH proton in BSP. In general, it is difficult to discuss quantitatively such a hydrogen distribution merely from the X-ray results. The microscopic aspect of the proton behavior in BSP will be clarified by more suitable techniques such as neutron diffractions or nuclear magnetic resonances.

We are grateful to Dr. Koshiro Toriumi of IMS for his helpful discussions about X-ray analysis.

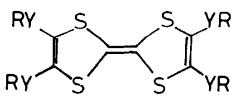
(Received November 28, 1988)

The crystal structure and the electrical property of $TSeC_1$-TTF as well as those of the new complex ($TSeC_1$-TTF)I_3 with two kinds of phases are reported. The crystal structure of $TSeC_1$-TTF was determined to be monoclinic, space group $P2_1/a$, a=7.728(1), b=20.952(4), c=5.315(1) Å, and β=90.57(2)° having a unit cell volume of 860.6(3) Å^3. By an electrochemical method and a diffusion method, $TSeC_1$-TTF gave two forms of single crystals of ($TSeC_1$-TTF)I_3. The crystal data of one form; monoclinic, space group $P2_1/n$, a=24.359(1), b=11.831(3), c=7.842(6) Å, β=96.71(4)°, V=2244(1) Å^3 and those of the other; monoclinic, space group $P2_1/a$, a=23.174(5), b=11.727(3), c=8.960(5) Å, β=110.54(2)°, V=2280(1) Å^3. The former complex has lower resistivity, 4.1×10^4 Ω cm, compared with the latter one 1.1×10^8 Ω cm. The dimerization is more noticeable in the latter complex than in the former one.

For the purpose of developing organic molecules directed toward organic conductors, a family of TYC_n-TTF (Y=S, Se, and Te, n=1—18), shown in Fig. 1, has been prepared and the crystal structures and properties have been widely investigated.[1-3] As a part of the investigation, a variety of the charge-transfer complexes based on the TYC_n-TTF family have also been obtained,[4] and some of them show relatively high conductivities. In this paper the crystal structures and electrical properties of the donor $TSeC_1$-TTF and the new complex ($TSeC_1$-TTF)I_3 with two kinds of phases are presented.

Experimental

The synthesis of $TSeC_1$-TTF compound was reported in the preceding paper.[5] Two kinds of single crystals of $TSeC_1$-TTF were prepared by slow cooling method using different solvents after several days. Dark-red block-like single crystals of ($TSeC_1$-TTF) were grown in hexane solution with higher resistivity 8.5×10^7 Ω cm and higher melting point 106.3 °C, ($TSeC_1$-TTF)(H). On the other hand, red needle-like single crystals ($TSeC_1$-TTF) were grown in a mixed solvent of hexane and benzene with lower resistivity 1.0×10^6 Ω cm and lower melting point 92.5 °C, ($TSeC_1$-TTF)(L). Needle-like single crystals of ($TSeC_1$-TTF)I_3 were obtained by a diffusion method using iodine as an acceptor in a benzene solution after several days, which were black-colored needle-like crystals and the typical size was $0.01\times0.6\times0.01$ mm^3, ($TSeC_1$-TTF)I_3(N). On the other hand,



$R=-C_nH_{2n+1}$

Fig. 1. The molecular structure of TYC_n-TTF (Y= Selenium for $TSeC_n$-TTF, Y=sulfur for TTC_n-TTF and Y=tellurium for $TTeC_n$-TTF).

block-like single crystals of ($TSeC_1$-TTF)I_3 were obtained by an electrochemical method, ($TSeC_1$-TTF)I_3(B). In this method, tetrabutylammonium triiodide ($TBAI_3$) (50 mg) and $TSeC_1$-TTF (14.7 mg) were dissolved in a mixed solvent of THF and acetonitrile with a ratio of 1:10 with gentle heating under an argon atmosphere. Electrochemical oxidation was carried out with a constant current of 1 μA at a constant temperature (25 °C) on a vibration-free table. After 20 days, the anode was covered with a black-colored block-like microcrystalline material. The typical size of the crystals is $0.01\times0.02\times0.02$ mm^3, which is too small for a conductivity measurement.

The X-ray diffraction data collection was carried out with a Rigaku automated four-circle X-ray diffractometer AFC-5R and AFC-5 for the donor molecule ($TSeC_1$-TTF)(H) and the complexes of ($TSeC_1$-TTF)I_3(N) and ($TSeC_1$-TTF)I_3(B), respectively. For the compound of ($TSeC_1$-TTF)(H) the crystal data is: $Se_4S_4C_{10}H_{12}$, F.W. 575.84, monoclinic, space group $P2_1/a$, a=7.728(1), b=20.952(4), c=5.315(1) Å, β=90.57(2)°, V=860.6(3) Å^3, Z=2, D_{calc}=2.22 g cm^{-3} and μ(Mo $K\alpha$) =95.97 cm^{-1}. Intensity data was measured by the θ-2θ scan technique on the diffractometer with graphite monochromatized Mo $K\alpha$ radiation ($2\theta<60°$). 2830 unique reflections were measured. The structure was solved by the direct method using MULTAN 78 program system[6] and refined by the block-diagonal least-squares procedure using 1391 independent reflections with $|F_o|>3\sigma(|F_o|)$. After absorption correction the refinement was converged to a final R value of 0.063. For the complex ($TSeC_1$-TTF)I_3(N) the crystal data is: $Se_4S_4C_{10}H_{12}I_3$, F.W. 956.54, monoclinic, space group $P2_1/a$, a=23.174(5), b=11.727(3), c=8.960(5) Å, β=110.54(2)°, V=2280(1) Å^3, Z=4, D_{calc}=2.788 g cm^{-3} and μ(Mo $K\alpha$)=107.38 cm^{-1}. Intensity data were measured by the θ-2θ scan technique on the diffractometer with graphite monochromatized Mo $K\alpha$ radiation ($2\theta<60°$). 5928 unique reflections were measured. The structure was solved by the direct method using MULTAN 78 program system[6] and refined by the block-diagonal least-squares procedure using 1440 independent reflections with $|F_o|>3\sigma(|F_o|)$. After absorption correction the refinement was converged to a final R value of 0.069. For the complex ($TSeC_1$-TTF)I_3(B), the crystal data is: $Se_4S_4C_{10}H_{12}I_3$, F.W. 956.54, monoclinic, space group $P2_1/n$, a=24.359(7), b=11.831(3), c=7.842(6) Å, β=96.71(4)°, V=

2245(2) Å^3, Z=4, D_{calc}=2.83 g cm^{-3}, and μ(Mo $K\alpha$)=109.09 cm^{-1}. Intensity data was measured by the θ-2θ scan technique on the diffractometer with graphite monochromatized Mo $K\alpha$ radiation ($2\theta<60°$). 6904 unique reflections were measured. The structure was solved according to the Patterson method and refined by the block-diagonal least-squared procedure using 1857 independent reflections ($|F_o|>3\sigma(|F_o|)$). After absorption correction the refinement was converged to a final R value of 0.063. For all these analyses, anisotropic thermal parameters were adopted for all nonhydrogen atoms, and the hydrogen atoms were refined isotropically.[7]

The electrical resistivities were measured by a two probe method. The electrical contacts to the specimen crystals were made with gold paint. Only for ($TSeC_1$-TTF)I_3(B) polycrystalline samples were used, because the single crystal size was too small to measure the resistivity.

Results and Discussion

$TSeC_1$-TTF. The atomic coordinates for ($TSeC_1$-TTF)(H) are listed in Table 1. The molecular and crystal structures are shown in Figs. 2 and 3. Along the c-axis, the $TSeC_1$-TTF molecules are stacked with overlapping as shown in Fig. 3(c), where the distance between the two C_2S_4 molecular planes is 3.481(3) Å. The shortest intermolecular Se-Se contact is 3.670(1) Å which is much shorter than the sum of the van der Waals radii (4.00 Å). The shortest intermolecular S-S contact is 3.663(3) Å, which is still shorter than the sum of the van der Waals radii (3.70 Å). The shortest intermolecular S-Se contact is 3.890(2) Å, which is a little longer than the sum of the van der Waals radii (3.85 Å). The molecule has a special structure which is neither of the chair nor boat form and is of similar to that of $TSeC_4$-TTF's.[2] The four terminal Se-C bonds of a molecule are almost perpendicular to each other. Such kind of molecular shape leads to the electrical resistivities of $7.3\times10^8/4.1\times10^9/8.5\times10^7$ (Ω cm), which is slightly anisotropic.

Table 1. Positional Parameters ($\times10^4$) and Equivalent (Isotropic Thermal Parameters of ($TSeC_1$-TTF)(H)

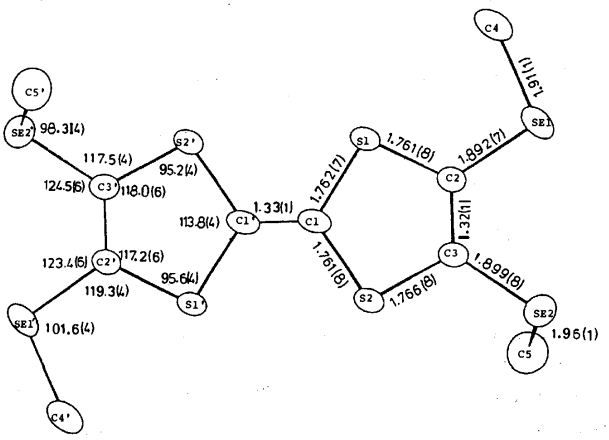

Fig. 2. ORTEP[8] drawing of $TSeC_1$-TTF(H) showing bond lengths and bond angles.

It should be noted here that $TSeC_1$-TTF, by using different solvent, gives two kinds of single crystal with the same chemical composition and the same density but displaying very different physical properties. One is block-like dark red single crystal with higher melting point and higher resistivity [($TSeC_1$-TTF)(H)]; and the other one is needle-like red single crystal with lower melting point and lower resistivity [($TSeC_1$-TTF)(L)]. The difference in resistivity is about 2 orders. The crystal data are still quite different. However, the structure analysis for the single crystal with lower melting point [($TSeC_1$-

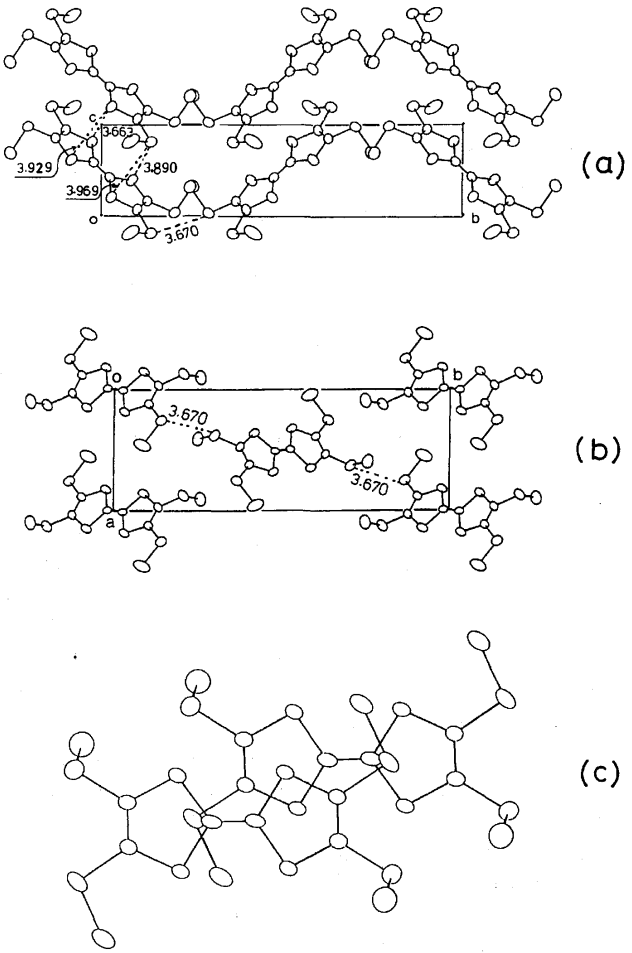

Fig. 3. The crystal structure of $TSeC_1$-TTF(H) projected along the a-axis (a), projected along the c*-axis (b), and the mode of overlapping of $TSeC_1$-TTF (c).

TTF)(L)] is somehow difficult. To elucidate the interesting problem of the donor molecule itself, some more detailed works are going on.

Comparing with TTC_1-TTF and $TTeC_1$-TTF,[9] the magnitude of resistivity of $TSeC_1$-TTF(H) is just in between of them. In TTC_1-TTF the central C_6S_8 moiety is nonplanar and the molecular structure has a boat form. Because of the weak intermolecular interactions between adjacent C_6S_8 moieties and the absence of discernible intermolecular overlaps between adjacent π systems, the resistivity is as high as 2.9×10^{10} Ω cm, which is much higher than that of $TSeC_1$-TTF in high or low phase. For $TTeC_1$-TTF[10] the magnitude of the resistivity, 8.1×10^4 Ω cm, is the lowest in the TYC_1-TTF group (Y=S, Se, and Te). The central $C_6S_4Te_4$ moiety of $TTeC_1$-TTF is planar unlike TTC_1-TTF and $TSeC_1$-TTF. $TTeC_1$-TTF molecules are stacked to form a column structure with the interplanar distance of 3.76 Å. Tellurium atoms between neighboring columns form zigzag chains along the stacking axis of $TTeC_1$-TTF molecules. The distance between those two Te atoms is 3.644(2) Å, which is significantly shorter than the van der Waals distance (4.12 Å).

$(TSeC_1$-TTF$)I_3$(N). The atomic coordinates for the crystal of $(TSeC_1$-TTF$)I_3$(N) are listed in Table 3. The crystal structure is shown in Figs. 4 and 5. Along the c-axis, $TSeC_1$-TTF molecules are stacked in the dimerized form with overlapping as shown in Fig. 5(b). The distances between the two optimal planes of the central C_2S_4 parts of a dimer and between those of two dimers are 3.33 and 4.76 Å, respectively. The shortest intermolecular Se–Se contact within the dimer is 3.845(6) Å (Fig. 4(b)), which is much shorter than the sum of the van der Waals radii (4.00 Å). The shortest

of the van der Waals radii, the electrical conductivity is mainly dominated by the dimerized structure. Therefore, the resistivity appeared as high as $1.1\times10^8\ \Omega$ cm, which is in the same order as that of the donor $TSeC_1$-TTF(H) ($8.5\times10^7\ \Omega$ cm) and higher than that of the donor in another phase (TSeC$_1$-TTF)(L) ($1.0\times10^6\ \Omega$ cm).

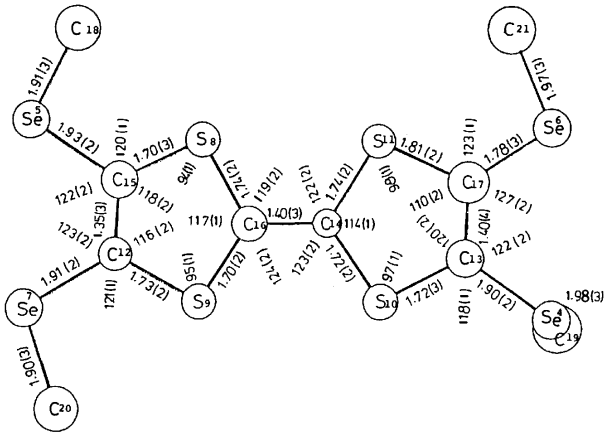

Fig. 9. ORTEP drawing of $TSeC_1$-TTF in the complex $(TSeC_1\text{-}TTF)I_3$(B) showing bond lengths and bond angles.

$(TSeC_1\text{-}TTF)I_3$(B). The atomic coordinates for the single crystal $(TSeC_1\text{-}TTF)I_3$(B) are listed in Table 4. The crystal and molecular structures are shown in Figs. 7, 8, and 9. The donor molecule has a bent structure, and the planes of the two C_2Se_2 parts are slightly bent towards the same direction from the optimal plane of central C_2S_4 part, where the dihedral angles between the optimal plane of the central C_2S_4 part and the planes of the two C_2Se_2 part are 2.0(2) and 4.2(2)°, respectively; and only one Se–C bond is obviously perpendicular to the connected C_2Se_2 part. Along the c-axis, the $TSeC_1$-TTF molecules are stacked in one-dimensional way with overlapping as shown in Figs. 7 and 8, and the distances between the two molecular planes are 3.49(1) and 3.70(2) Å, respectively. The difference between them is not so large as comparing with that of $(TSeC_1\text{-}TTF)I_3$(N). Thus, the degree of dimerization is relatively small. The shortest intermolecular Se–Se contact is 3.637(5) Å which is much shorter than the sum of the van der Waals radii. The shortest intermolecular S–S contact is 3.52(1) Å

which is still much shorter than the sum of the van der Waals radii. Although the shortest interplane distance, 3.49(1) Å, is longer than that of ($TSeC_1$-TTF)I_3(N) (3.33 Å) and the overlapped area (Fig. 8(b)) is smaller than that of ($TSeC_1$-TTF)I_3(N), the resistivity is as low as $4.1\times10^3\,\Omega$ cm even for the polycrystalline samples, because the degree of dimerization of this complex is much smaller than that of the complex ($TSeC_1$-TTF)I_3(N).

Comparing with the iodine complex of TTC_1-TTF, (TTM-TTF)$I_{2.47}$,[11] the resistivities of ($TSeC_1$-TTF)I_3(N) and ($TSeC_1$-TTF)I_3(B) are much higher than that of (TTM-TTF)$I_{2.47}$, $7-10\times10^{-3}\,\Omega$ cm. Anyhow, the relatively high resistivities of ($TSeC_1$-TTF)I_3(N) and ($TSeC_1$-TTF)I_3(B) should also be originated in the simple salt formation.

In summary, we have obtained two kinds single crystals for the donor molecules $TSeC_1$-TTF, ($TSeC_1$-TTF)(H), and ($TSeC_1$-TTF)(L). For the single crystal ($TSeC_1$-TTF)(H), the crystal structure has been analyzed. We have also obtained two kinds of single crystals of a 1:1 triiodide of $TSeC_1$-TTF, ($TSeC_1$-TTF)I_3(N), and ($TSeC_1$-TTF)I_3(B), depending on the preparation methods. Both of the crystal structures have been solved, and we found out some specific factors to understand their properties. We have measured the electrical properties for the complexes of a 1:1 triiodide of $TSeC_1$-TTF in the two different phases. Although the relatively high resistivities of these materials should be originated in the simple salt formation, the degree of dimerization still play a very important role to determine the electrical properties.

Dielectric Relaxation and Intermolecular Association for 1-Decanol. Temperature and Dilution Dependences of Monomer and Three Hydrogen-Bonded Species

Toshiomi SHINOMIYA†
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received December 8, 1988)

The dielectric constants and losses have been measured at frequencies from 1.35 to 4500 MHz for pure 1-decanol at 15—40 °C and for cyclohexane and heptane solutions of 1-decanol at 25°C. The absorption has been resolved into three different Debye-like dispersion regions. The assignments of the three regions were made as follows: the first region being due to a linear hydrogen-bonded chain polymer (C_1), the second one to a chain dimer and trimer (C_2), and the third one to a free monomer (C_3). Four concentrations of these species (C_{1-3}) and a nonpolar cyclic polymer (C_R) were evaluated by applying a modified Kirkwood-Fröhlich equation to each dispersion region. Each of the four concentrations indicates a reasonable behavior regarding the temperature and dilution dependences. The C_1 decreases and, mainly, the C_3 increases as the temperature increases. For cyclohexane and heptane solutions, the C_1 decreases rapidly and the C_R increases correspondingly with decreasing alcohol concentration. The free energies of activation are 23.2 for the first region, 17.3 for the second region, and 11.9 kJ mol^{-1} for the third region.

Many studies[1-3] have reported the co-existence of the alcohol monomer and various hydrogen-bonded species. There is now a general agreement that the alcohol molecule has a tendency to form aggregates in a dilute solution and in the pure liquid state. Wide-range measurements of complex dielectric constants also indicated two or three different dispersion regions. At low temperatures, Cole and Davidson[4] obtained three dispersion regions for 1-propanol. Dannhauser[5] also obtained three dispersion regions for 5-methyl-3-heptanol and 6-methyl-3-heptanol. He assigned the three dispersion regions to a free monomer, OR group in the linear chain structure, and the linear hydrogen-bonded chain species. At room temperatures, Lebrun[6] measured the dielectric constants and losses for higher normal alcohols at a frequency range of 1—9.5×10^3 MHz, obtaining two relaxation times. Garg and Smyth[7] obtained three relaxation times for the ten normal alcohols from propyl through undecyl at 16 wavelengths. They attributed the long relaxation time to the breaking of hydrogen bonds in molecular aggregates followed by ROH rotation, the intermediate relaxation time to a reorientation of a free monomer, and the short relaxation time to a relaxation of the hydroxyl group by rotation around its C–O bond. Glasser et al.[8] obtained two or three relaxation times for heptane solutions of some normal alcohols. In addition to the results of Garg and Smyth, they reported that the intermediate process is related to the reorientation of a free monomer and, possibly, a small multimer or a polymer chain segment.

We are studying hydrogen bonding and intermolecular structures in liquid alcohols. In a previous paper,[9] we proposed a modified Kirkwood-Fröhlich equation for obtaining the concentration of the first dispersion region for 28 linear alcohols. Now we have extended the investigations by performing the assignment of the three dispersion regions and by obtaining the four concentrations of monomer and three hydrogen-bonded species. The concentrations are discussed in terms of changes in the temperature and dilution.

Experimental

Purification of Materials. Commercial heptane was washed with mixed acid, concentrated sulfuric acid, water, 10% potassium hydroxide solution, 1 M potassium permanganate solution (1 M=1 mol dm^{-3}), and again with water. After standing over calcium chloride for 24 hours, it was fractionally distilled. The distillate was dried over calcium hydride and distilled before use. Cyclohexane was purified by the same method as heptane. 1-Decanol was fractionally distilled twice as described before[9] and finally distilled in a grease-free apparatus before use.

Apparatus. The dielectric constants and losses were measured using the following three apparatus over frequencies from 1.35 to 4500 MHz. A Boonton Radio RX meter (Type 250A) was used for measurements at frequencies of 1.35, 6.3, 17, 30, and 45 MHz. Measurements at frequencies 60, 80, 100, 150, 200, 250, 300, 400, and 480 MHz were made with a Hewlett-Packard VHF Bridge (Model 803A). A General Radio Precision Slotted Line (Type 900-LB) was used for measurements at frequencies of 600, 750, 1000, 1400, 2000, 3000, and 4500 MHz. In the measurements of low and high frequency regions, two cells were carefully made of a GR Precision Inner-Conductor Rod, an Outer-Conductor Tube, and a GR 900-BT connector. This equipment was described in detail in a previous paper.[9]

Results and Discussion

Dielectric Relaxation. The Cole–Cole plots are

† Present address: 207-52, Shirahata kami-cho, Kanagawa-ku, Yokohama 221.

shown for pure 1-decanol at 15, 20, 25, 35, and 40 °C in Fig. 1 and for cyclohexane solutions of 1-decanol at 25 °C in Fig. 2. The first dispersion region can be described by a Debye-like semicircular arc, though it is evident that the experimental data can not be satisfactorily fitted by the arc in the high-frequency region of the dispersion. At first glance it looks as if the Cole–Cole plots can be grouped into three dispersion types as pointed out for isomeric decanols in a previous paper.[9] The first type is best described by several overlapping Debye-like semicircular arcs, such as pure 1-decanol at 15 °C in Fig. 1. The second one by a Davidson–Cole skewed arc, such as pure 1-decanol at 40 °C in Fig. 1 and 60 mol% in Fig. 2. The third one by a Cole–Cole depressed-center semicircular arc, such as 30 mol% in Fig. 2. It has usually been considered that the dispersion type was determined by a difference in the measured compounds. However, the shape of the locus of the dispersion is dependent of the temperature and dilution. The shape of the locus for one compound changes from a Debye type to a Davidson–Cole type, as shown in Fig. 1 and from a Davidson–Cole type to a Cole–Cole type, as shown in Fig. 2. This fact indicates that the difference in these dispersion types is determined by a ratio of the magnitudes between the first and other regions calculated. It was, therefore, assumed that dielectric absorption was the sum of several overlapping Debye-like dispersion regions. In this study, the experimental data were analyzed by separation into three different dispersion regions. The dielectric parameters of the three regions were calculated using a least-squares method, as described in a previous paper.[9] The limiting high-frequency dielectric constant, ε_3, of the third region contains experimental errors because of lack of the higher frequencies of the region. Therefore, the ε_3 was assumed to be an average value in all measurements, whose value was calculated using $(\varepsilon_3-1)/(\varepsilon_3+2)=(n_D^2-1)(1+0.19)/(n_D^2+2)$. The calculated dielectric parameters are given in Table 1, together with the refractive indices n_D (measured by the use of a Pulfrich refractometer), densities d, and with viscosities η. The calculated results of the three dispersion regions are also shown by the solid lines in Figs. 1 and 2.

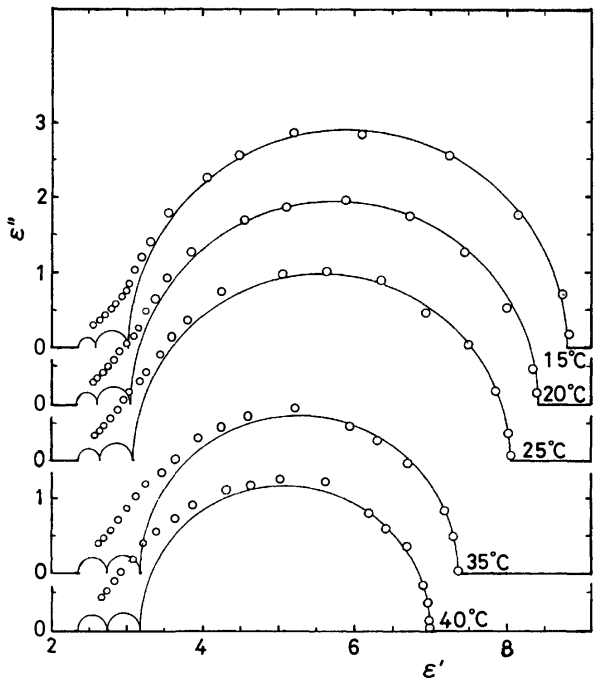

Fig. 1. Cole–Cole plots for pure 1-decanol at 15—40 °C. For clarity, curves have been displaced along the ordinate. Three dispersion regions calculated are shown by solid lines.

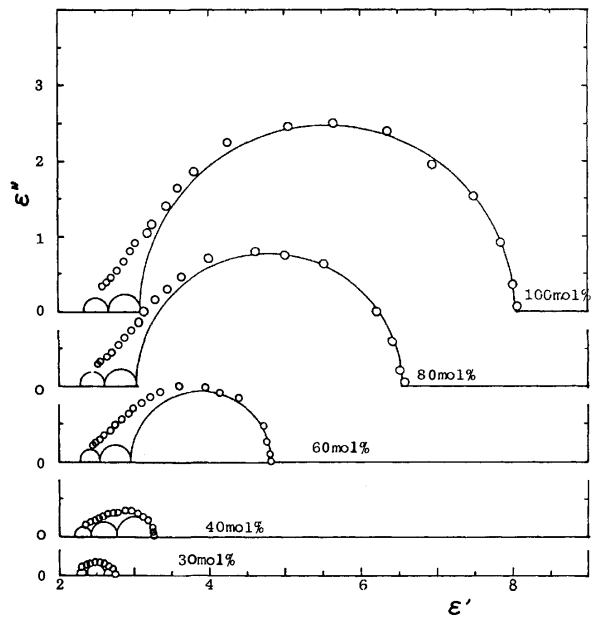

Fig. 2. Cole–Cole plots for cyclohexane solutions of 1-decanol at 25 °C. For clarity, curves have been displaced along the ordinate. Three dispersion regions calculated are shown by solid lines.

The thermodynamic parameters, the free energy of activation ΔF^*, the heat of activation ΔH^*, and the entropy of activation ΔS^*, were obtained by applying the Eyring's equation[9,10] to the three dispersion regions in Table 2.

Assignment of the Three Dispersion Regions. For very dilute cyclohexane solutions (less than 1 mol%) of ethanol, Ibbitson and Moore[11] reported that the near-infrared spectra contained a broad absorption band at 3350 cm^{-1} in addition to two bands at 3520—3540 and 3644—3650 cm^{-1}. From measurements of the dielectric constant and the solute polarization, they attributed the three bands to the presences of a nonpolar cyclic polymer, a linear dimer and trimer, and a free monomer. Meantime, the first dispersion region vanished in the vicinity of 15 mol% of 1-decanol, as shown in Table 1. This observation was in agreement with the results for cyclohexane solutions of 1-hexanol

Table 1. Dielectric Parameters, Refractive Indices, Densities, and Viscosities

Table 2. Thermodynamic Parameters, ΔF^*, ΔH^*, and ΔS^*, for Three Dispersion Regions of 1-Decanol

	ΔF^*[a]	ΔH^*	ΔS^*
	kJ mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}
First region	23.2	39.6	55.1
Second region	17.3	0.72	−55
Third region	11.9	2.2	−33

a) The values of ΔF^* was calculated at 298 K.

measured by Komooka[12] and of ethanol measured by Sagal.[13] From the above consideration, therefore, there are at least a free monomer, a linear dimer and trimer, and a nonpolar cyclic polymer in addition to a higher polar polymer which the first dispersion region originates. These species should correspond to the dielectric dispersion regions observed.

The relaxation times of unassociated liquids were collected from the literature for room-temperature values. Chlorobenzene[14,15] has a relaxation time of 11—14 ps, bromobenzene[14,15] 17—18 ps, 1-bromo-3-methylbutane[15,17] 13—22 ps, 1-chlorooctane[16] 17 ps, 1-bromooctane[15,16] 22—43 ps, 1-iodooctane[16,18] 39—45 ps. In view of these relaxation times, it is considered that the third relaxation time shown in Table 1 is attributed to the reorientation of a free monomer. The free energy of activation ΔF^* is 10.4 kJ mol^{-1} for chlorobenzene and 10.9 kJ mol^{-1} for 1-bromo-3-methylbutane, also corresponding to that of the third region, as shown in Table 2.

The first dispersion region is large, strongly dependent on the temperature (in comparison with the other), and decreases rapidly with dilution. This process is apparently associated with a linear hydrogen-bonded species. It has been reported that this process could be ascribed to the breaking of the hydrogen bonds in molecular aggregates followed by ROH rotation,[7] to a single highly polymer,[1] and to the switching mechanism of the OH moment as one hydrogen bond is broken and another formed.[13] In addition to these models, it may be considered to be due to the existence of an alcohol molecule which forms two hydrogen bonds between an oxygen atom in the molecule and two hydrogen atoms of neighboring molecules, since the magnitude of this region is much greater than the other. Such an alcohol molecule has three hydrogen bonds instead of the four hydrogen bonds of a water molecule in the "flickering cluster model"[19] proposed by Frank and Wen. If such a molecule exists, a more complex polymer can be formed disorderly by joining two linear and cyclic polymers in a three-dimensional spread. The existence of such a molecule, however, has still not been confirmed by experiments. Studies of the X-ray diffraction[20] interpreted this aggregate as a linear hydrogen-bonded chain polymer. It is, therefore, considered that the first dispersion region is attributed to the linear hydrogen-bonded chain polymer. This polymer has various chain lengths which may be dependent on the temperature, dilution, and amount of shielding of the hydroxyl group.

Since the second dispersion region is always small in magnitude, it may be considered to be formed as an intermediate. It becomes difficult to separate the first and second regions as the temperature increases. When the magnitude of the first region decreases, there are some cases in which there is no distinction between the first and second regions. From the above consideration, the second process is due to a short linear chain polymer, such as a chain dimer and trimer.

It is concluded that the first region can be attributed to a linear hydrogen-bonded chain polymer (probably $n \geqq 4$), the second region to a chain dimer and trimer ($n=2$ and 3), and the third region to a free monomer ($n=1$).

The experimental data, inclusive of the three values measured by Garg and Smyth[7] at wavelengths of 3.22, 1.25, and 0.22 cm, have been resolved into four different Debye-like dispersion regions. The four relaxation times obtained are 2490, 179, 27.9, and 3.06 ps at 20 °C and 800, 160, 23.7, and 2.91 ps at 40 °C for pure 1-decanol. The second region could not be found in the Garg and Smyth's analysis because of experimental errors[8] in their measurements at the highest band of the RX meter. The band of the RX meter was not used in our measurements. Meantime, Glasser et al.[8] resolved the dielectric absorption into three dispersion regions at higher concentrations for heptane solutions of some normal alcohols. It is considered that the three regions measured by Glasser et al. correspond to the three higher-frequency regions, except for the lowest-frequency region. The free energies of activation for the four dispersion regions are about 23.2, 17.3, 12.7, and 7.3 kJ mol^{-1}, respectively.

In this study, the highest-frequency region could not be obtained because of the narrow range of the measuring frequencies. This region is attributed to a relaxation of the hydroxyl group by rotation around its C–O bond, as described by Garg and Smyth.[7]

Concentrations of Monomer and Three Hydrogen-Bonded Species. In a previous paper,[9] we proposed a modified Kirkwood-Fröhlich equation as follows:

$$\varepsilon_{i-1} - \varepsilon_i = \frac{3\varepsilon_{i-1}}{2\varepsilon_{i-1} + \varepsilon_i}\left(\frac{\varepsilon_i + 2}{3}\right)^2 \frac{4\pi N_A \mu_0^2}{3 \times 10^3 kT} C_i g_i, \quad (1)$$

$$C_0 = \sum_{i=1}^{k} C_i + C_R, \quad (2)$$

$$g = 1, \text{ if } n = 1 \text{ and } g = 1 + Z\sum_{m=2}^{n} f\left(\cos^2\frac{\theta}{2}\right)^{m-1}, \text{ if } n \geqq 2, \quad (3)$$

$$f = \frac{(\mu_H + \mu_R)(\mu_H + \mu_R \cos\theta)}{\mu_H^2 + \mu_R^2 + 2\mu_H\mu_R \cos\theta}.$$

In this equations, ε_{i-1} and ε_i are the limiting low- and high-frequency dielectric constants of the i-th dispersion, N_A is Avogadro's number, μ_0 the dipole moment of the molecule in vacuum, kT the thermal energy, g_i the Kirwood correlation factor of the i-th dispersion, C_0 the gross stoichiometric concentration in mol dm^{-3} of all alcohol molecules, C_i the alcohol concentration at which the i-th dispersion originates, C_R that of nonpolar cyclic polymer, and Z the coordination number. Additionally, μ_H and μ_R are the components of the dipole moment of alcohol molecule ROH along the O–H and O–R bonds, respectively, θ is the angle between the O–H and O–R bonds, m represents m-th molecule, and n is the number of alcohol molecule in the linear hydrogen-bonded chain polymer. It was assumed in Eqs. 1—3 that $Z=2$, $\mu_H=1.53$ D, $\mu_R=1.20$ D, $\mu_0=1.68$ D, and $\theta=105°$ for linear alcohols such as 1-decanol.

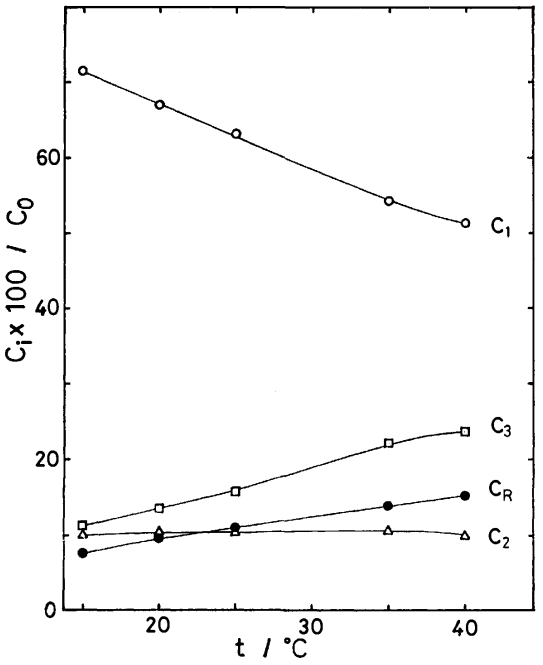

Fig. 3. Percentages of C_i for pure 1-decanol as a function of temperature.

The g factor can be calculated from Eq. 3. The value of the g factor is 1 if $n=1$, 1.87 if $n=2$, 2.19 if $n=3$, 2.31 if $n=4$, 2.36 if $n=5$, and 2.38 if $n \geqq 6$, respectively. According to our assignments, it is assumed that the g_1 is 2.38 for the first region, the g_2 is 2.03 as an average value for the second region, and the g_3 is unity for the third region. The concentrations C_i can be calculated from Eq. 1 by making use of these g_i factors and of the experimental values of ε_{i-1} and ε_i listed in Table 1. The percentages of C_1, C_2, C_3, and C_R against the gross stoichiometric concentration C_0, $C_i \times 100/C_0$, are shown for change of temperature (Fig. 3) and for change of dilution (Fig. 4). For example, the respective percentages of C_1, C_2, C_3, and C_R are 71, 10, 11, and 8% at 15 °C and 52, 10, 24, and 16% at 40 °C for pure 1-decanol. Those for cyclohexane solutions of 1-decanol are 54, 11, 19, and 16% at 80 mol% and 16, 17, 21, and 46% at 40 mol% at 25 °C. Figure 3 shows that the C_1 decreases and both C_3 and C_R increase, as the temperature increases. C_2 does not change in the temperature range 15—40 °C. It is considered that depolymerization occurs for the linear hydrogen-bonded chain polymer. For cyclohexane and heptane solutions of 1-decanol, it is shown in Fig. 4 that the C_1 decreases rapidly and that C_R increases correspondingly, as the concentration of 1-decanol decreases. Both

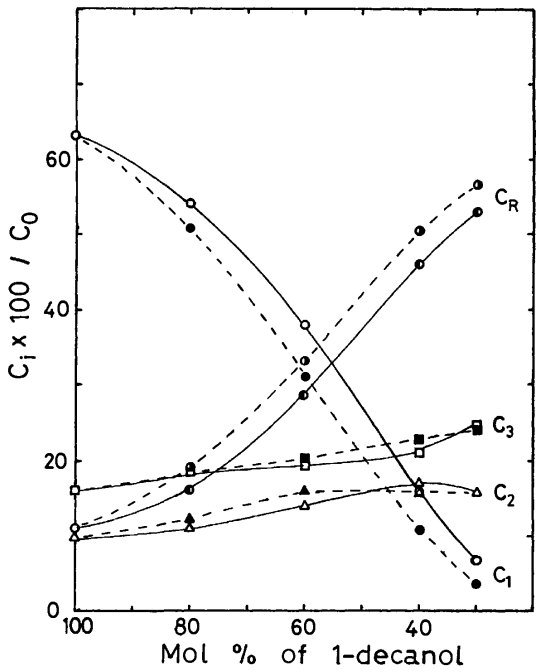

Fig. 4. Percentages of C_i for cyclohexane and heptane solutions of 1-decanol as a function of mol% of 1-decanol. Cyclohexane solutions are shown by solid lines and heptane solutions are shown by dotted lines.

C_2 and C_3 also increase slightly. The length of the linear hydrogen-bonded chain polymer probably becomes short by breaking the hydrogen bonds due to a hindrance of the nonpolar solvent. It is considered from Fig. 4 that the nonpolar cyclic polymer becomes a most stable structure in dilute solutions, although the linear hydrogen-bonded chain polymer is favorable in pure 1-decanol. We can understand the behavior of the four concentrations regarding the changes in temperature and dilution.

^{35}Cl NQR in $SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$

Mitsuo MISHIMA* and Tsutomu OKUDA†
Department of Chemistry, Shimane Medical University, Izumo 693
†Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730
(Received January 21, 1989)

^{35}Cl NQR spectra in $SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$ have been observed. Three crystal modifications of $SnCl_4 \cdot 2Me_2O$ have been found. A cis geometry is suggested for one of them, and a trans geometry for the remainder. A transformation between the cis and trans isomers in the solid state is indicated. The Zeeman effect on single crystals of *cis*-$SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$ has provided detailed information on bond angles and bond character. It is confirmed that the molecular geometry of *cis*-$SnCl_4 \cdot 2Me_2O$ belongs to the C_2 group and that $SnCl_4 \cdot 2Et_2O$ has a trans geometry. The η values of the Cl atoms in *cis*-$SnCl_4 \cdot 2Me_2O$ are negligibly small and those of the Cl atoms in $SnCl_4 \cdot 2Et_2O$ are 0.11. The relatively small η values for the latter are ascribed to π bonding between the Sn and Cl atoms.

Raman and Mössbauer spectroscopies revealed that several octahedral complexes of $SnX_4 \cdot 2L$ (X=Cl, Br; L=Lewis bases) exist in a cis or trans form in the solid state, depending on the conditions of preparation and purification.[1,2] It was demonstrated by Raman[1] and NMR[3-5] measurements that a number of SnX_4 complexes are at cis-trans equilibrium in solution. On the other hand, Davanzo and Gushikem[6] obtained evidence for the cis-trans transformation in the solid state through studies of vibrational spectroscopy, thermal analysis, and X-ray powder diffraction, and reported the transition temperature. For the solid $SnCl_4 \cdot 2Me_2O$, however, the cis geometry was proposed on the basis of Raman spectra.[1]

NQR is a useful method for examining configurations of $SnCl_4$ complexes.[7-9] We examined $SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$ by means of NQR in order to determine their molecular geometries. Furthermore, the Zeeman effect of ^{35}Cl on single crystals of *cis*-$SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$ was examined to obtain information on bond angles and bond characters.

Experimental

The complex $SnCl_4 \cdot 2Me_2O$ was prepared by bubbling a gas of dimethyl ether into a dichloromethane solution of tin(IV) chloride. The crystalline solid was filtered and purified by recrystallization from dichloromethane or chloroform and sublimation. The contents of tin and chlorine were determined gravimetrically.[10] (Found: Sn, 33.8; Cl, 40.4. Calcd: Sn, 33.7; Cl, 40.2%). The complex $SnCl_4 \cdot 2Et_2O$ was prepared by the method described in the literature[11] and identified by measuring its melting point[10,12] and NQR frequencies.[13] Single crystals of the complexes were grown in evacuated sealed tubes by sublimation.

The NQR spectrometer used was a Dean-type superregenerative spectrometer with frequency modulation. The Zeeman effect was examined by means of the zero-splitting cone method. A magnetic field was supplied by means of a Helmholtz coil. Temperature was determined by the use of a copper-constantan thermocouple. Temperature below room temperature in the Zeeman study was controlled by varying the flow of the nitrogen gas from liquid nitrogen.

Results and Discussion

The NQR spectrum for $SnCl_4 \cdot 2Me_2O$ obtained by recrystallization differed from that for the sample obtained by sublimation above 50 °C. The ^{35}Cl resonance frequencies are shown as a function of temperature in Fig. 1. The recrystallized sample gave two NQR lines and the sublimed one only one line. The former is tentatively termed Form-1 and the latter Form-2. The NQR spectrum of Form-2 suggests that the four Sn-Cl bonds of the complex are equivalent. Therefore, the molecule in Form-2 has a trans configuration.[7] Form-1 is assumed to be a cis isomer, judging from the magnitude of the splitting between adjacent NQR lines. This was confirmed by the Zeeman study on a single crystal. In Form-1 the

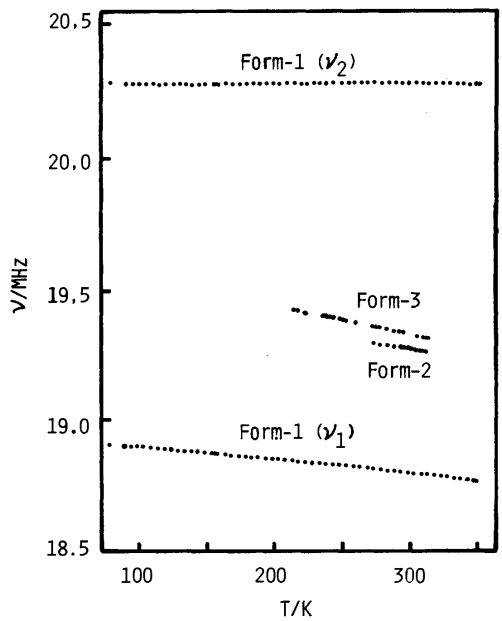

Fig. 1. Temperature dependence of ^{35}Cl resonance frequencies of $SnCl_4 \cdot 2Me_2O$.

frequency of the lower resonance line, ν_1, decreased monotonously with a rise in temperature, whereas the higher resonance line, ν_2, had a very small temperature coefficient and the minimum frequency was 20.278 MHz near 140 K and the maximum one 20.287 MHz near 285 K, suggesting the existence of intermolecular interaction.

Form-2 was unstable at room temperature and, in one night at the longest, changed to another modification (Form-3) which yielded also only one resonance line. When Form-2 was cooled to near 270 K, it changed immediately to Form-3. This transformation became rapid with lowering temperature. When Form-2 was cooled to 77 K, the absorption lines for Form-1 appeared immediately. Form-3 was also unstable and was transformed to Form-1 at room temperature in a day. This transformation also became rapid with lowering temperature, and this change took place immediately at temperature below less than ca. 210 K. The resonance frequencies for Form-2 and Form-3 decreased with a rise in temperature and faded out at 311 K and 314 K, respectively. Both the ν_1 and ν_2 lines in Form-1 disappeared at 350 K without broadening. When the sample was cooled rapidly to room temperature, it gave the same NQR line as did Form-2. Accordingly, this suggests a transition from the cis isomer to the trans one. Although the transition point was reproducible within ±1.5 K, the sample maintained at ca. 340 K for a day gave the same spectrum as did Form-2 at room temperature. Accordingly, the observed transition point seems not to be intrinsic.

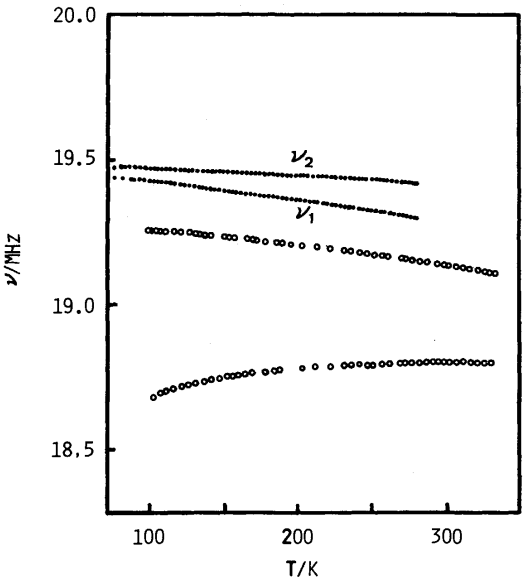

Fig. 2. Temperature dependence of ^{35}Cl resonance frequencies of $SnCl_4 \cdot 2Et_2O$ (●) and $SnCl_4 \cdot 2THF$ (○).

The temperature dependence of the NQR frequencies of $SnCl_4 \cdot 2Et_2O$ is shown in Fig. 2. The resonance lines decreased in frequency with a rise in temperature and disappeared near 280 K. For this complex, a trans geometry was proposed on the basis of the NQR[7] and the vibrational spectra.[11,14] In the trans complex with tetrahydrothiophen $SnCl_4 \cdot 2THT$, the geometry of which was determined by X-ray analysis,[15] no resonance lines were detected at room temperature, although two resonance lines were observed below ca. 210 K.[8,9] The resonance lines of $SnCl_4 \cdot 2THF$, which has a trans geometry in solid,[11] disappeared at 330 K as shown in Fig. 2. The temperature variations of the NQR frequencies of $SnCl_4 \cdot 2THF$ in the range of 100 to 300 K were in good agreement with those of $SnCl_4 \cdot 2THF$ reported by Rupp-Bensadon and Lucken.[9] In some cis-complexes such as $SnCl_4 \cdot 2POCl_3$,[16] $SnCl_4 \cdot 2SeOCl_2$,[16] $SnCl_4 \cdot 2MeCN$, and $SnCl_4 \cdot 2Me_3CCN$ the NQR lines could be detected up to the melting point. It is of interest that in the octahedral complexes of $SnCl_4$ the fade-out phenomenon of the NQR lines is characteristic of the trans geometry.

The Zeeman effect on the ^{35}Cl lines in Form-1 of

Table 1. ^{35}Cl NQR Parameters for $SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$

Compound		Frequency/MHz		η/%	e^2Qqh^{-1}/MHz
$SnCl_4 \cdot 2Me_2O$		77 K	293 K		
Form-1	ν_1	18.906	18.807	4.9	37.600
	ν_2	20.281	20.287	2.7	40.569
Form-2		—	19.279		
Form-3		—	19.340		
$SnCl_4 \cdot 2Et_2O$		77 K	235 K		
	ν_1	19.435	19.341	11.4	38.601
	ν_2	19.474	19.440	11.6	38.793

$SnCl_4 \cdot 2Me_2O$ and $SnCl_4 \cdot 2Et_2O$ was observed at room temperature and at 235 K, respectively. The zero-splitting patterns are shown in Figs. 3 and 4, where z_i indicates the direction of the z axis of the efg tensor at the Cl atom which yields a ν_i resonance line. The observed loci were analyzed by the least squares method to obtain the direction of the efg tensor and the asymmetry parameter (η). The locus is expressed for ^{35}Cl nucleus as follows;

$$\sin^2\theta_0 = 2/(3 - \eta\cos 2\phi_0), \quad (1)$$

where θ_0 and ϕ_0 are the polar and azimuthal angles, respectively. The NQR parameters are listed in Table 1. In $SnCl_4 \cdot 2Me_2O$ a pair of zero-splitting loci were obtained for each resonance line and a twofold axis was determined from the distribution of the Zeeman patterns. The resonance lines of $SnCl_4 \cdot 2Me_2O$ were comparatively weak and each NQR line gave partly overlapped Zeeman patterns. Consequently, the directions of the z axes of the efg tensors and the values of the asymmetry parameters were not so accurate. In $SnCl_4 \cdot 2Et_2O$ the lower resonance line, ν_1, gave only one locus although the two loci were obtained from the higher resonance line, ν_2, as shown in Fig. 4. The reason is because the efg axis of the partner locus is nearly parallel to the rf field. A twofold axis can be determined from the loci for the ν_2 line and the predicted direction of the missing z axis (z_{1B}) is shown in Fig. 4. Therefore, the crystals of these complexes belong to the monoclinic system.

Table 2. Angles between the efg z Axes in $SnCl_4 \cdot 2Me_2O$[a)]

	z_{1A}	z_{1B}	z_{2A}
z_{1B}	92.2°		
z_{2A}	93.5°	91.1°	
z_{2B}	91.1°	93.5°	173.4°

a) Estimated error ±0.3°.

The angles between the Sn–Cl bonds have been deduced, assuming that the principal z axis of the efg tensor is parallel to the Sn–Cl bond. The results for $SnCl_4 \cdot 2Me_2O$ are listed in Table 2. These angles reveal that Form-1 of $SnCl_4 \cdot 2Me_2O$ has a cis geometry. The ν_1 and ν_2 lines can be assigned to the equatorial and the axial chlorine atoms, respectively. The molecular geometry of Form-1 is shown in Fig. 5(a). The molecule possesses a twofold axis, parallel to that of the crystal. The bond angles in this complex are very similar to those of the other cis isomers of the octahedral $SnCl_4$ complexes found by X-ray studies.[17–19] In the monomeric cis-complexes, the angles of $\angle Cl_1SnCl_1$ are greater than 100° and those of $\angle Cl_2$-$SnCl_2$ range from 161.9° to 166.6°. Therefore the molecule in Form-1 of $SnCl_4 \cdot 2Me_2O$ is less distorted.

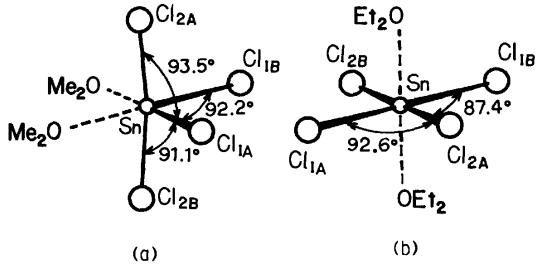

Fig. 5. Molecular shapes of Form-1 of $SnCl_4 \cdot 2Me_2O$ (a) and $SnCl_4 \cdot 2Et_2O$ (b).

Table 3. Angles between the efg Axes and the Crystal Axis in $SnCl_4 \cdot 2Et_2O$[a]

	z_1	x_1	x_2	C_2-axis
z_1				52.34°
z_2	92.58°			78.64°
Plane z_1z_2		86.59°	86.52°	40.59°

a) Estimated error ±0.05°.

It is concluded from the Zeeman analysis that the complex of Et_2O has a trans configuration. This is in agreement with the geometry proposed on the basis of the infrared and Raman spectra.[10,13] As shown in Fig. 4, two of the zero-splitting cones, one from each of the resonance lines, were assigned to each crystal site on the basis of the orientations of the efg axes. The z axes of these cones are nearly at right angles to each other, as can be seen from Table 3. This requires that there are two pairs of chemically equivalent chlorine atoms in a molecule and that the z axes at the chlorine atoms in each pair are collinear. Accordingly, the molecule of $SnCl_4 \cdot 2Et_2O$ has an inversion center at the tin atom and the four Sn–Cl bonds are coplanar. The bond angle $\angle Cl_1SnCl_2$ is close to those in $SnCl_4 \cdot 2Et_3P$ (89.9° and 90.1°).[20] The Sn–Cl_1 and Sn–Cl_2 bonds make angles of 52.3° and 78.6°, respectively, to the twofold axis of the crystal, as is shown in Table 3. The molecule has neither symmetrical plane nor symmetrical axis. The atomic arrangement around the tin atom is very similar to that in $SnCl_4 \cdot 2Et_3P$.[20]

In the Et_2O complex, the Cl_1 atom has almost the same η-value as the Cl_2 atom. These values are somewhat greater than those found in the cis complexes.[16] The x axes of these chlorine atoms are nearly at right angles to the equatorial plane, as can be seen from Table 3. This suggests π interaction between the tin and chlorine atoms. The energy level of the oxygen $2p\pi$ orbital is about 3 eV lower than that of the chlorine $3p\pi$ orbital.[21,22] It is therefore predicted that the chlorine atom donates more charges to the vacant $d\pi$ orbital on the tin atom than the oxygen atom. On the other hand, the oxygen p orbitals do not take part in the π-bonding lying in the equatorial plane. If this is the case, the populations of the p_x orbital on the chlorine atom are more decreased. The difference in population between the p_x and p_y orbitals is estimated to be 0.027 by using the Bersohn's relation.[23] The ionic character of the Sn–Cl bond is calculated to be 57 per cent, assuming that the s character of the bonding orbital of the Cl atom is 0.15.[24]

In the cis isomer of the Me_2O complexes, the η-values are very small. Therefore, the Sn–Cl bonds are almost cylindrically symmetrical. The equatorial Cl atoms are 3 per cent more ionic than the axial ones. This trend is consistent with that in other cis complexes.[16] Since the trans isomers of the Me_2O complex have only one absorption line and the symmetry of the Me_2O moelcule is C_{2v}, the complexes are required to possess at least a twofold axis and a mirror plane. It is therefore considered that the trans complexes have C_{2h}, C_{2v}, or D_{2h} symmetry.

(Received January 20, 1989)

New conducting salts of (phthalocyaninato)platinum (PtPc), $PtPc(ClO_4)_{0.5}$ and $PtPc(AsF_6)_x$, were prepared by electrochemical oxidation. A crystal of $PtPc(ClO_4)_{0.5}$ belongs to a tetragonal system with a space group of $P4/mcc$, the lattice constants being a=14.062(1) Å, c=6.510(1) Å, and Z=2. They are metallic at least down to 120 K, the room-temperature conductivity being $\sigma=10^2$—10^3 S cm^{-1}. XPS indicates that the conduction pathway is located mainly at the ligand chain due to a partial oxidation of the ligand-centered HOMO. ESR experiments have also strongly supported this conclusion. The bandwidth of the ligand-centered conduction band has been estimated to be 1.2 eV from the plasma frequency, $\hbar\omega_p$=0.87 eV, which is obtained by the polarized reflectance spectrum.

Highly conductive iodine salts of metallo-macrocyclic compounds have been extensively studied by groups at Northwestern University.[1-10] These partially oxidized phthalocyanine salts have a stable metallic ground state against Peierls distortion at low temperature, although they have a one-dimensional column structure with a metal-over-metal overlapping mode. On the other hand, the mixed-valent platinum complex, $K_2Pt(CN)_4Br_{1/3}\cdot 3H_2O$ (KCP), has been reported to have a mixed-valent groud state between Pt^{2+} and Pt^{4+},[11,12] which might give rise to a movement of paired electrons.[13] However, it shows a semiconductive behavior at low temperature,[14] because it suffers the Peierls distortion.[15] Therefore it may be interesting to make a partially oxidized platinum chain which is stable against this type distortion, Such materials might possibly be found by searching for the conductive platinum macrocyclic compounds. This was the motivation of the present research. In this paper we report on the preparation and solid-state properties of the partially oxidized salts of (phthalocyaninato)-platinum (PtPc), $PtPc(ClO_4)_{0.5}$ and $PtPc(AsF_6)_x$, which were prepared for the first time in the research described here.

Experimental

PtPc was synthesized from phthalonitrile and $PtCl_2$,[16] and purified several times by a vacuum sublimation. The partially oxidized salts, $PtPc(ClO_4)_{0.5}$ and $PtPc(AsF_6)_x$, were obtained by the electrochemical method in a 1-chloronaphthalene solution using supporting electrolytes of (n-Bu)$_4$NX, (X=ClO_4 and AsF_6). The electrochemical reaction was carried out for about 2 weeks in a galvanostatic mode (1—5 μA) at 120 °C in an Ar or N_2 atmosphere. The concentration of PtPc was ca. 3×10^{-4} mol l^{-1}, and those of the supporting electrolytes were (2×10^{-3}—2×10^{-2}) mol l^{-1}. The crystals were grown along the c-axis, the typical dimensions being $0.01\times0.01\times2$ mm^3. The chemical composition of $PtPc(ClO_4)_{0.5}$ was determined from an X-ray crystal structure analysis.

The intensities of X-ray diffraction were measured at room temperature with a Rigaku AFC-5 automated diffractometer combined with a Rotaflex RU-200, using Cu $K\alpha$ radiation monochromated with a graphite plate. The dimensions of the crystal used in this experiment were $0.03\times0.03\times0.6$ mm^3. The crystal belongs to a tetragonal system with a space group of $P4/mcc$, the cell constants being a=14.062(1) Å, c=6.510(1) Å, and Z=2. We obtained 554 unique reflections, in which 405 reflections with $F_o>3\sigma(F_o)$ were used for the analysis. An absorption correction was made with a program (ACACA) written by C. T. Prewitt. The structure was solved by a heavy-atom method and was refined by a block-diagonal least-squares method with anisotropic temperature factors. The hydrogen atoms were neglected in this analysis. The final R-value was 0.055. The anisotropic temperature factors and F_o-F_c data are deposited as Document No. 8883 at the office of the Editor of Bull. Chem. Soc. Jpn. The computer program used in this analysis was UNICS III system.[17]

The electrical conductivity of a single crystal was measured along the needle axis from 290 K down to 10 K by the use of a four-probe ac method with a frequency of 70 Hz, the constant current being 10 μA. The voltage drop between the inner probes was detected by a lock-in-amplifier (EG & G 5205) which was controlled by a microcomputer. The phase change of the voltage was automatically checked at each temperature. Needle-like crystals were mounted on 10 μm gold wires with carbon paint to obtain electrical contact. The unnested voltage was tolerably small.

XPS was measured by a Kratos XSAM 800 ultrahigh vacuum photoelectron spectrometer using the Mg $K\alpha$ line as

† Present address: Institute for Molecular Science, Myodaiji-cho, Okazaki, Aichi 444.

the excitation source. PtPc was deposited on the copper sample holder through vacuum sublimation. Powdered samples of $PtPc(ClO_4)_{0.5}$ and $PtPc(AsF_6)_x$ were pressed onto the copper holder. No surface treatment was conducted so as to avoid any damage to the sample. Calibration of the spectrometer was performed by Au4f lines and the Au Fermi edge.

The ESR spectra were measured with a JEOL JES-FE1XG and a Varian E-112 using an X-band at temperatures between 290 and 4.2 K. About 80 slim crystals were aligned with silicone grease on a teflon sample holder so that the needle axes were parallel to each other. The crystals were so small that the ambiguity of the alignment was about 10°. The *g*-value was determined by a comparison of the ESR signal of solid Li-TCNQ. The spin susceptibility was calibrated by the integrated intensity of violanthrone, the static magnetic susceptibility of which had been measured. The intensity was obtained from a double integration of the ESR signal.

Polarized reflectance spectra were measured in the spectral range from 4200 to 25000 cm^{-1} with the polarization directions parallel and perpendicular to the *c*-axis at room temperature. The reflectance spectra were measured with a microspectrophotometer. The absolute reflectivity was obtained by comparing with the reflected light from a Si single crystal.

Results and Discussion

Crystal Structure. The atomic parameters of $PtPc(ClO_4)_{0.5}$ are compiled in Table 1. Figure 1 shows side and top views of the molecular column of PtPc in the crystal of $PtPc(ClO_4)_{0.5}$. The space group is the same as those of NiPcI,[1] $NiPc(BF_4)_{0.33}$,[7] $NiPc(ClO_4)_{0.42}$,[9] H_2PcI,[8] CoPcI,[6] and CuPcI.[10] The crystal is composed of molecular columns piled up along the *c*-axis. In this column the phthalocyanine molecules are stacked with a staggered angle of 40.7°. At the same time, the phthalocyanine molecules make molecular layers on the (001) plane. ClO_4^- is located at the interlayer position, as shown in the side view. The site occupancy of ClO_4^- is 0.5, so that the anions are positionally disordered. Since the diameter of ClO_4^- (ca. 5.6 Å)[19] is larger than half the *c*-axis, the anions and voids should be located alternately along the *c*-axis, and these one-dimensionally ordered anions are probably arranged randomly along the *a*- and *b*-axes. Furthermore, the large temperature factors of ClO_4^- indicate that the anion is also rotationally disordered. Table 2 shows a comparison of the average bond distances of PtPc. Since the atomic scattering factor of a platinum atom is much larger than those of carbon and nitrogen atoms, the standard deviations of the bond distances are large: 0.02 Å for Pt–N distance and 0.03—0.04 Å for N–C and C–C bond. In addition, the molecular geometry of the Pc ring is insensitive to the valency.[20] Therefore it is not possible to judge from the molecular geometry whether the ring is oxidized or not. Since the oscillation and Weissenberg photographs of $PtPc(AsF_6)_x$ are essentially the same as those of $PtPc(ClO_4)_{0.5}$, we consider that the former is isostructural to the latter.

Electrical Resistivity. The electrical resistivity of $PtPc(ClO_4)_{0.5}$ along the *c*-axis is 10^{-2}—$10^{-3}\,\Omega$ cm at room temperature. The temperature dependence of the resistivity shown in Fig. 2 is one of the examples in which the cooling and warming rate is 0.5 K min^{-1}. The resistivity decreases at least down to 120 K upon cooling the sample. Below 100 K resistivity jumps take place at various temperatures which are not reproducible; the resistivity gradually increases up to 10^3 times the room-temperature value at 10 K. However, the resistivity recovers the starting value again upon warming the sample to room temperature. This temperature dependence of the resistivity is not reproducible against the heat cycles. The resistivity curve below 50 K cannot be described by a simple exponential function, $\rho(T)/\rho_{RT} \propto \exp(E_a/kT)$, but is well reproduced by the fluctuation-induced tunneling conduction model[21] which is applied to the analysis of the resistivity curves of doped polyacetylene and other inhomogeneous materials. We surmise that the metallic domains still remains at low temperature in $PtPc(ClO_4)_{0.5}$. A more elaborate investigation is necessary for an elucidation of the resistivity in the low-temperature region. Similar electrical properties have also been observed for $PtPc(AsF_6)_x$.

X-Ray Photoelectron Spectra. The X-ray photoelectron spectrum (XPS) has been used to determine the valency of atoms and molecules. For example, XPS played a crucial role in elucidating the mixed-valent state between Pt^{2+} and Pt^{4+} in the KCP crystal.[12] In the present case, however, no difference has been observed among PtPc, $PtPc(ClO_4)_{0.5}$, and $PtPc(AsF_6)_x$ as concerns the line shapes of $Pt4f_{7/2}$ and $Pt4f_{5/2}$, except for a slight increase (0.2 eV) in the linewidth for the oxidized salts. Their binding energies are the same as each other, the values being 73.2 and 76.6 eV for $Pt4f_{7/2}$ and $Pt4f_{5/2}$, respectively. As for the phthalocyanine ring, the line shape of the N1s spectrum is almost exactly the same as each other, and its binding energy is 398.9 eV. In contrast, the line shape of the C1s photoelectron spectra of $PtPc(ClO_4)_{0.5}$ and $PtPc(AsF_6)_x$ is slightly different from that of PtPc. Figure 3 shows a comparison of the line shapes of $PtPc(ClO_4)_{0.5}$ and PtPc. According to the theoretical work of NiPc by Kutzler and Ellis,[22] the highest occupied molecular orbital (HOMO) of NiPc is composed of the $2p_z$ orbitals of carbon atoms and has nodes at the nitrogen atoms and the nickel atom. Since this character of HOMO is also expected in PtPc, the observed result indicates that a partial oxidization occurs mainly in the phthalocyanine ring. The slight chemical shift of the binding energy of C1s is consistent with the ligand-centered oxidation. These XPS results mean that the conduction pathway is not on the Pt chain but, rather, on the Pc rings in contrast to KCP.

Electron Spin Resonance. Figure 4 shows the

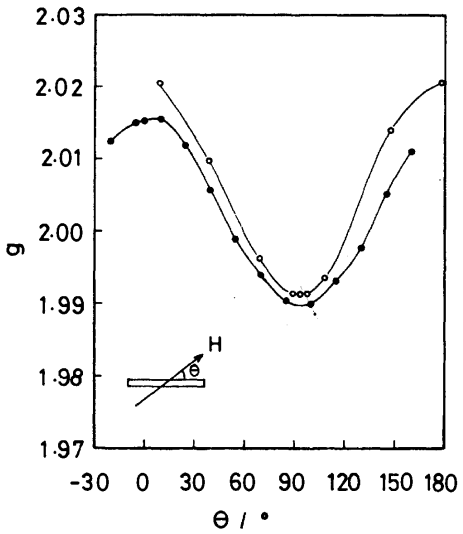

Fig. 4. Angular dependence of the ESR signal of $PtPc(ClO_4)_{0.5}$. The solid and open circles correspond to the room temperature and 4.2 K, respectively.

angular dependence of the g-value of $PtPc(ClO_4)_{0.5}$ at room temperature and 4.2 K. From the tetragonal symmetry of the crystal and molecule, the principal values of the PtPc molecule can be directly determined from this angular dependence. The principal values are given in Table 3, together with the corresponding values of the other related molecules. The symbols, // and ⊥, denote the directions parallel and perpendicular to the normal of the molecular plane. Since the principal values of $PtPc(ClO_4)_{0.5}$ are completely different from the corresponding values of KCP,[23] the unpaired electrons are not in the $5d_{z^2}$ band located at the platinum chain. On the other hand, the g-values are also slightly different from those of the ligand-oxidized cation radical, e.g. $Ni^{2+}Pc^{1-}$.[26] Therefore, the oxidation is mainly ligand-centered, though the unpaired electron also has a slight d-character. This result is similar to that of $NiPc(SbF_6)_{0.5}$.[24,25] However, the relation, $g_{//} > g_{\perp}$, is reverse to that of $NiPc(SbF_6)_{0.5}$,[24,25] in which the d-character of the unpaired electron is interpreted based on the exchange interaction between the conduction electrons on the ligand and the small amount of the localized spins on the $3d_{z^2}$ orbital of nickel atoms. This anisotropy indicates that the $5d_{z^2}$ orbital of Pt is not responsible for the d-character of the unpaired electron, but that the orbital of the unpaired electron has a character of d_{xz} and d_{yz}.[27] It is not reasonable to simply replace the role of $5d_{z^2}$ by $5d_{xz}$ and $5d_{yz}$, because the latters are expected to be strongly hybridized with the π-orbital (e_g) of the ligand in contrast to the former.[22] We thus consider that this molecular orbital with e_g symmetry is mixed to some extent with the ligand-centered HOMO (a_{1u}) in the solid state because the symmetry restriction is released in the general point of the Brillouin zone. However, the contribution of the e_g orbital seems to be very small, because the observed g-value is close to that of the ligand-centered unpaired spin, even at low temperature (as described in the next section). This conjecture is supported by the experimental result of XPS that the oxidation occurs mainly at the ligand part. The different anisotropy of the g-value between PtPc and NiPc is attributed to the electronic structures of their molecules. Unfortunately, details of the electronic structure of PtPc are not known, as compared with that of NiPc.

Figure 5 shows the temperature dependences of the spin susceptibilities, linewidths, and g-values. Upon cooling, $g_{//}$ and $g_{\perp}$ slightly increase from 2.016 and 1.989 to 2.023 and 1.992 at 4.2 K, respectively. This temperature dependence is much weaker than that of $NiPc(SbF_6)_{0.5}$.[25] This slight increase probably sug-

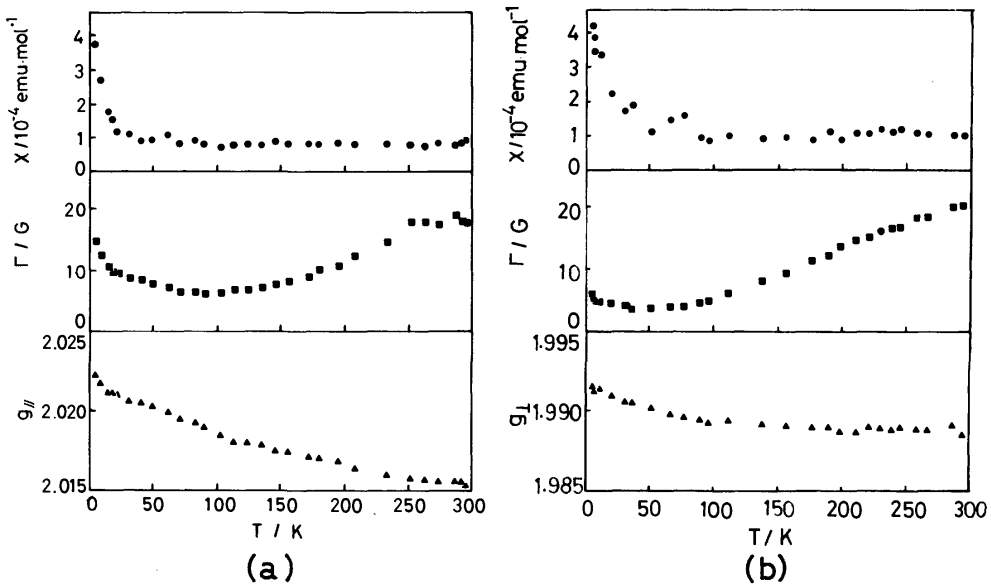

Fig. 5. Temperature dependence of the spin susceptibilities (χ), linewidths (Γ), and g-values (g). (a) $H//c$ and (b) $H \perp c$.

gests a change in the degree of mixing between the e_g and a_{1u} bands. The line shape of the ESR signal is Lorentzian over the whole temperature range. The spin susceptibility, which is obtained by the double integration of the observed signal, remains almost constant down to ca. 20 K. Combining this result with the metallic behavior of the electrical resistivity, the temperature-independent spin susceptibility is attributable to Pauli paramagnetism. The linewidths of organic metals usually decrease upon lowering the temperature, since they are determined mainly by the spin relaxation through the so-called Elliot mechanism.[28] Thus the gradual decrease of the linewidth also supports the view that the origin of the unpaired electrons is conduction electrons. This magnetic result suggests that $PtPc(ClO_4)_{0.5}$ is metallic, at least down to 20 K. Assuming the one-dimensional tight-binding model, we estimated the bandwidth, $4t$, using

$$4t = 4N_A\mu_B^2/(\pi \sin(k_f c)\chi), \quad (1)$$

where N_A is the Avogadro constant, μ_B the Bohr mageton, k_f the Fermi wave vector, c the inter-planar distance between the adjacent PtPc molecules, and χ the spin susceptibility (measured with a unit of emu mol^{-1}). The bandwidth of the ligand-centered band has been estimated to be 0.6—0.8 eV using $\chi=(1.0—0.7)\times10^{-4}$ emu mol^{-1} and $k_fc=(3/4)\pi$. The rise-up of χ in the region of $T<20$ K is attributable to the localized spins, the concentration of which is 4×10^{-3} spins per one $PtPc(ClO_4)_{0.5}$. Since the angular dependence of the g-value of the localized spins is almost the same as that of the conduction electrons (as shown in Fig. 4), the origin of the localized spins is not the magnetic impurity but, rather, a crystal defect. Incidentally, the ESR spectrum of $PtPc(AsF_6)_x$ is essentially the same as that of $PtPc(ClO_4)_{0.5}$, including the temperature dependence.

Polarized Reflectance Spectra. Figure 6 shows the reflectance spectra of $PtPc(ClO_4)_{0.5}$ polarized parallel and perpendicular to the c-axis. The plasma-edge like dispersion is observed only in the $//c$ polarization. This strong anisotropy clearly indicates the presence of a one-dimensional conduction band along the c-axis. We analyzed the $//c$ spectrum based on the Drude model, and obtained the plasma frequency, $\omega_p=7010$ cm^{-1}, the relaxation time of the conduction electrons, $\tau=0.8\times10^{-14}$ s, and the dielectric constant contributed from the electronic excitations in the higher wave number region, $\varepsilon(\text{core})=2.31$. The reflection spectrum calculated from these parameters is drawn by solid lines in Fig. 6. The bandwidth, $4t$, was calculated on the assumption of the one-dimensional tight-binding model using

$$4t = \{V_m(\hbar\omega_p)^2\}/\{4e^2c^2\sin(k_f c)\}, \quad (2)$$

where V_m is the volume of $PtPc(ClO_4)_{0.5}$, e the unit charge of an electron, and k_f and c are the same as those defined in Eq. 1. The bandwidth was estimated to be 1.2 eV, using $V_m=6.437\times10^{-22}$ cm^3, $\hbar\omega_p=0.87$ eV, and $k_fc=(3/4)\pi$. This bandwidth is 1.5—2.0 times larger than that estimated from the spin susceptibility. The difference between them is attributable to the effect of the electron-electron Coulomb interaction.[29] Since the optical spectrum of $PtPc(AsF_6)_x$ is the same as $PtPc(ClO_4)_{0.5}$, we surmise $x\approx0.5$ in $PtPc(AsF_6)_x$, because the position of the plasma edge in the reflection spectrum reflects the concentration of the conduction electrons, which is related to the chemical ratio.

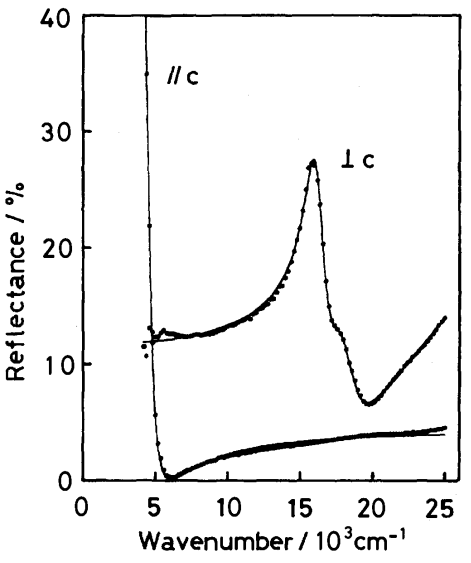

Fig. 6. Polarized reflectance spectrum of the $PtPc(ClO_4)_{0.5}$ single crystal. The circles and the solid lines are respectively the experimental data and the simulated curves based on the Drude model for the $//c$ spectrum and the Lorentz model for the $\perp c$ spectrum.

The $\perp c$ spectrum was simulated by three Lorentz oscillators so as to reproduce the experimental curve. The simulated curve is represented by the solid line in Fig. 6. The resonance frequencies of the Lorentz oscillators in the visible region are 16000 and 17900 cm^{-1}. The 16000 cm^{-1} electronic transition is assigned to the interband transition which corresponds to the Q-band in the free molecule of phthalocyanine. Probably, the shoulder at 17900 cm^{-1} cannot be assigned to the vibrational structure of the Q-band, since the intensity ratio to the main peak at 16000 cm^{-1} and the separation of the excitation energies depend significantly upon the central metals of such salts as $NiPc(SbF_6)_{0.5}$[25] and $CoPc(AsF_6)_x$.[30] The origin of this shoulder is not clear at present. However, it is possibly related to the mixed-valent nature of the phthalocyanine ring, since the monoclinic PbPc crystal[31] exhibits a strong Q-band, the shape of which is a single Lorentzian with a width of 1000 cm^{-1} (FWHM).[32]

We prepared $PtPc(ClO_4)_{0.5}$ and $PtPc(AsF_6)_x$, which were the first oxidized salts of PtPc, in the process of searching for a stable metallic platinum chain with a mixed-valent state. Both PtPc salts are isostructural and have one-dimensional column structures like the iodine complex of NiPc. They are metallic at least down to 120 K and probably to 20 K, or possibly to a temperature lower than that. Contrary to our expectation, however, the conducting pathway is not located on the platinum spine, but mainly on the ligand chain. The solid state properties are almost the same as those of $NiPc(SbF_6)_{0.5}$,[25] but the ESR properties are remarkably different.

31) Since the first singlet excited state of metallo-phthalocyanine is degenerate, the Q-band is split into 4 absorption bands in almost all metallo-phthalocyanine crystals because of the low site symmetry and the exciton effect. However, the exceptional case is found in the monoclinic form of PbPc, in which the arrangement of PbPc is nearly tetragonal like the partially oxidized salts of metallo-phthalocyanine.

Magnetic and Electric Properties of a Cation Radical Salt Tris(decacyclene) Bis(hexafluorophosphate), $(Dc)_3(PF_6)_2$

Tadashi SUGANO and Minoru KINOSHITA*
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received January 26, 1989)

A cation radical salt between a π-electron donor decacyclene and hexafluorophosphate, $(Dc)_3(PF_6)_2$, was prepared by electrochemical synthesis, and conductivity (90—350 K), electron paramagnetic resonance (4—400 K) and static susceptibility (2—300 K) were measured. The salt was found to be semiconductive with the conductivity of ca. 4×10^{-2} S cm^{-1} at room tempertature and the activation energy of 66±3 meV. The magnetic measurements show that this salt is paramagnetic and spin susceptibility is thermally activated with the activation energy of 17 meV resulting from antiferromagnetic intermolecular interaction, although the dication of electron donor might be expected to have triplet spin multiplicity to stabilize ferromagnetic spin alignment in the ground state. The magnetism of $(Dc)_3(PF_6)_2$ is discussed in terms of charge-transfer interaction among donors.

Since McConnell proposed a model for ferromagnetic (FM) spin alignment in purely organic compounds using ionic charge-transfer (CT) complexes in 1967,[1] some its modifications have been suggested for ionic CT complexes and ion radical salts[2-5] and the model has thoroughly been generalized including organometallic complexes.[6] In these models, it is essential that an ionic CT complex or ion radical salt is consisting of molecules which exhibit high spin multiplicity in the CT excited states and/or in the ground state.[1-6]

For the ion radical salts, virtual disproportionation, where an electron on one molecule which has doubly degenerate orbital (d) occupied by one (d^1) or three (d^3) electrons is transferred to an adjacent molecule with the same electronic configuration, could stabilize FM coupling between the molecules.[2,6] This mechanism may further be extended to the case of a crystal consisting of molecules having higher degeneracy.[6] Similarly, one electron transfer between molecular sites with doubly (or multiply) degenerate orbitals with heterospin configurations (e.g., d^1 and d^2; d^2 and d^3) could result in FM or ferrimagnetic (FIM) coupling.[4,6] In contrast to the situations mentioned above, for the CT complexes, antiferromagnetic (AFM) coupling is predicted for virtual backward CT from a d^1 site to a non-degenerate site (s) with single occupancy (s^1) and also for virtual backward CT from d^3 to s^1,[6] whereas the inverse (forward CT) processes could result in FM coupling.[1-3,6] In other words, whether ion radical salts are in a uni or mixed valence state, they would be more appropriate candidates than ionic CT complexes to realize FM spin alignment, since the FM intermolecular coupling could be stabilized regardless of the direction of CT. Such prescription therefore leads us to study an ion radical salt based on an organic molecule with symmetry higher than C_3. Such a molecule is known to possess degeneracy in the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), when it is free.

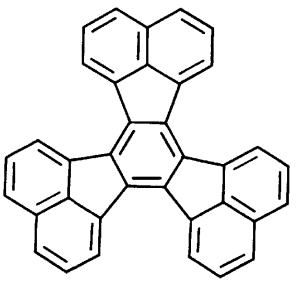

Fig. 1. Molecular structure of decacyclene.

Some aromatic molecules with a three- or six-fold axis of rotation such as decacyclene (diacenaphtho[1,2-*j*:1′,2′-*l*]fluoranthene),[7] 1,3,5-triphenylbenzene,[7,8] hexamethoxytriphenylene,[9] hexachlorobenzene,[10] and hexaazaoctadecahydrocoronene[11] have in fact been shown to have triplet ground state when they were in the dication or dianion state. Therefore, ion radical salts of these aromatic molecules may be a good candidate to establish FM intermolecular coupling in a solid. Cation radical salts of polycyclic aromatic hydrocarbons have been prepared by galvanostatic electrochemical oxidation with an appropriate supporting electrolyte,[12] although some aromatic hydrocarbons such as naphthalene are unstable in atmosphere.[13] We have prepared the cation radical salts of decacyclene (Fig. 1) by the electrochemical oxidation. In this paper, we describe the characterization and investigation of electric and magnetic properties of the cation radical salt with hexafluorophosphate.[14]

Experimental

Decacyclene (Aldrich Chemical Co. Inc.) was recrystallized from a nitrobenzene solution and sublimed twice at 320 °C under 1 Pa. Black single crystals shaped like long needle were prepared by electrochemical oxidation of decacyclene in a dichloromethane solution on a platinum anode under a constant current of 2 μA at 0 °C for 160 hours. Tetrabutyl-

ammonium hexafluorophosphate was used as a supporting electrolyte. The crystals are stable in a dry atmosphere but mechanically unstable and readily decomposed to yield decacyclene when they are ground in an agate mortar.

A preliminary X-ray diffraction analysis shows that this cation radical salt has 3:2 stoichiometry, i.e., tris(decacyclene) bis(hexafluorophosphate), $(Dc)_3(PF_6)_2$. The salt crystallizes in the hexagonal system, space group $P6_322$, with the following cell constants: a=27.896(4) Å, c=10.422(1) Å, V=7024(2) Å^3, Z=4, D_x=1.55 Mg m^{-3} and D_{obs}=1.55 Mg m^{-3}.[15] The crystals were elongated along the crystallographic c-axis with dimensions 2—5 mm in length and 0.05—0.1 mm in width.

Direct current electrical conductivity was measured on a single crystal by means of the four probe technique with silver paste (du Pont No. 4929). Electron paramagnetic resonance (EPR) spectra of a single crystal were recorded on a JEOL JES-FE1X spectrometer at 9 GHz with a cylindrical cavity in the TE_{011} mode. Sample temperature was varied and controlled by using an Oxford ESR900 cryostat of continuous flow type and a DTC-2 temperature controller in the range from 4 to 300 K. A JEOL EXDVT-1 temperature controller was also used in the range from 300 to 400 K. The g factor was determined by comparing the resonance position with that of Li^+TCNQ^- (g=2.0026). The modulation width was always kept much less than one-tenth of the linewidth to prevent line shape from distortion due to overmodulation.

Magnetic susceptibility was measured with a Faraday-type susceptometer over the temperature range from 2 to 300 K on a bundle (1 mg) of the single crystals in a small quartz bucket (ca. 20 mg) at 5 T and on the polycrystalline sample (12 mg) in a quartz bucket (ca. 100 mg) at 3 T. The details of the apparatus were described previously.[16]

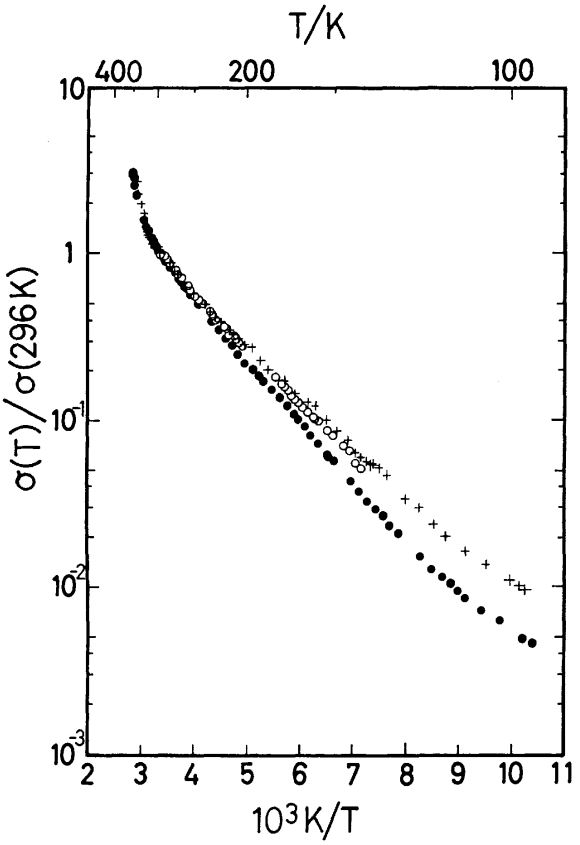

Fig. 2. Temperature dependence of conductivity σ of $(Dc)_3(PF_6)_2$. The conductivities observed for different crystals are normalized at 296 K and represented by crosses, open and closed circles. The conductivity σ follows $\sigma=\sigma_0\exp(-E_c/kT)$ with (2—6)×10^{-2} S cm^{-1} at 296 K and the activation energy E_c=66±3 meV.

Results

Semiconductive behavior with the conductivity (2—6)×10^{-2} S cm^{-1} at 296 K and the activation energy E_c=66±3 meV (1 eV=1.602×10^{-19} J) is observed for $(Dc)_3(PF_6)_2$ in the range from 90 to 300 K as shown in Fig. 2. Three different crystals gave very similar temperature dependence, although the conductivity values varied from sample to sample in the range indicated, probably due to inaccuracy of sample dimensions used in the conductivity calculation. As the temperature increases from room temperature, the conductivity increases more steeply than that in the low temperature region. This phenomenon was reproducible but no indication for phase transitions in the vicinity of room temperature was observed in the magnetic measurements as described below.

The EPR spectra of the single crystal of $(Dc)_3(PF_6)_2$ exhibit a Lorentzian shaped line over the whole temperature range between 4 and 403 K examined here as shown in Fig. 3. The g factor is found to be 2.0025(2) and independent of temperature. This indicates that the unpaired electrons in $(Dc)_3(PF_6)_2$ reside only on the decacyclene molecules. The g factors of aromatic hydrocarbons are given by g=2.00257—(19×10^{-5})λ, where λ is the coefficient of the Hückel MO energy level, $\alpha+\lambda\beta$, occupied by an odd electron.[17] We have calculated MO of decacyclene in the Hückel approximation and found that λ=0.4807 for HOMO which are doubly degenerate and occupied by an odd number of electrons when decacyclene is in the monocation radical state. The g factor is then calculated to be 2.00248 with λ=0.4807. This value is in good agreement with the observed value. It is worth noting that the g factor of PF_5^- radical observed under various conditions is known to be 1.9985(6), 2.00174(2), and 2.0039(2).[18]

The EPR absorption intensity is thermally activated except for the low temperature region below about 40 K where the susceptibility follows the Curie law as shown in Fig. 4. Such activation behavior is reminiscent of the moderately conducting ion radical salts.[19]

The peak-to-peak linewidth B_{pp} observed for the decacyclene cation radical salt is sharp, but not very sharp in comparison with that observed for the following cation radical salts of polycyclic aromatic hydrocarbons having metallic conductivity. The line-

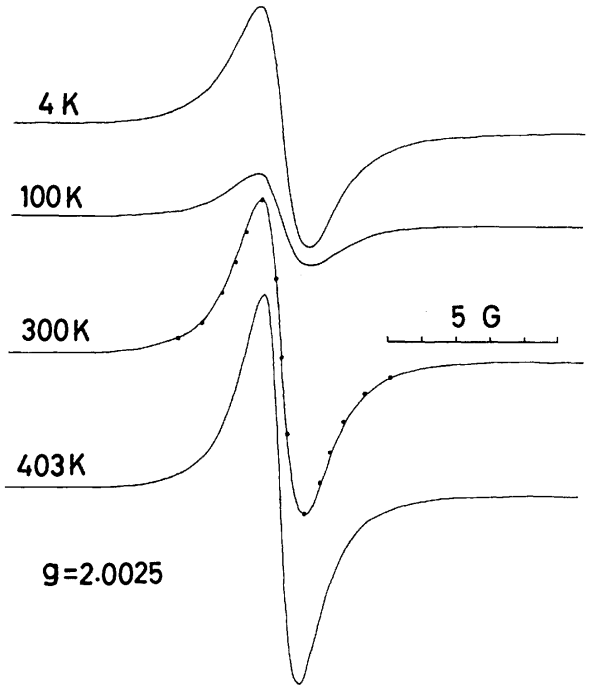

Fig. 3. First derivative curves of EPR spectra of the single crystal of $(Dc)_3(PF_6)_2$ at several temperatures. Closed circles on the 300 K spectrum represent the Lorentzian fit.

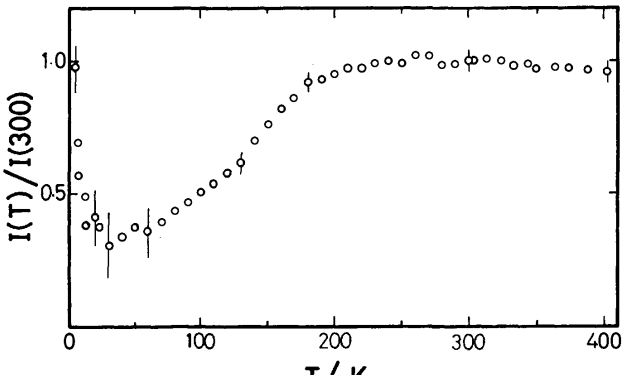

Fig. 4. Temperature dependence of the relative intensity of EPR of $(Dc)_3(PF_6)_2$ normalized at 300 K. Estimated errors are indicated by thin lines. The intensity is thermally activated above 40 K.

width of $(Dc)_3(PF_6)_2$ varies from 155 μT below 60 K down to 117 μT at 403 K as shown in Fig. 5, while the linewidths of the cation radical salts of other hydrocarbons are reported to be 60—80 μT for $(perylene)_2(XF_6)_{1.1}(CH_2Cl_2)_{0.85}$ (X=As or Sb) at 100—300 K,[20] 1.5 μT for $(fluoranthene)_2PF_6$ at 300 K,[21] and 0.25 μT for $(naphthalene)_2AsF_6$ at 300 K.[22] The linewidth of these salts would be ascribed qualitatively to the motional narrowing effect. The conductivity at room temperature is about 0.04 S cm^{-1} for $(Dc)_3(PF_6)_2$ examined here, 160 S cm^{-1} for $(perylene)_2(XF_6)_{1.1}(CH_2Cl_2)_{0.85}$,[20] 1000 S cm^{-1} for $(fluoranthene)_2PF_6$.[23] Since the motional narrowing becomes effective in highly-conducting solid, the linewidth is expected to decrease in the order of $(Dc)_3(PF_6)_2$, the perylene salt, and the fluoranthene salt, as actually observed. The fact that the linewidth of $(Dc)_3(PF_6)_2$ decreases monotonically upon increasing the temperature also supports the motional narrowing effect because the conductivity increases with the increase of temperature. The linewidth is temperature independent below ca. 60 K. Simultaneously, the Curie contribution becomes dominant in the susceptibility. Therefore, the constant linewidth at low temperatures is ascribed to extrinsic origin such as lattice defects.

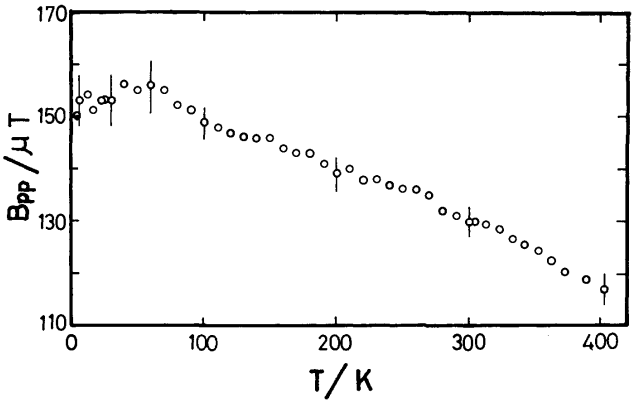

Fig. 5. Temperature dependence of peak-to-peak linewidth of EPR of $(Dc)_3(PF_6)_2$. Estimated errors are indicated by thin lines.

The static susceptibility observed for the bundle of the single crystals of $(Dc)_3(PF_6)_2$ exhibits the temperature dependence similar to that of the EPR absorption intensity obtained for the single crystal as shown in Fig. 6. That is, the paramagnetic susceptibility, which is determined by subtracting the diamagnetic contribution $\chi_d=-8.9\times10^{-4}$ emu mol^{-1} (1 emu mol$^{-1}=4\pi$ cm^3 mol^{-1}) estimated by Pascal's law, is thermally activated except for the low temperature region where the susceptibility follows the Curie law with the Curie constant $C=5.5\times10^{-3}$ emu K mol^{-1} (1 emu K mol$^{-1}=4\pi$ cm^3 K mol^{-1}) corresponding to 0.7% spins with $S=1/2$.

On the contrary, as shown in Fig. 7, the static susceptibility of the polycrystalline sample is very different from that of the single crystals. Substantial increase in the paramagnetism following the Curie-Weiss law is observed. The Curie constant is $C=0.130$ emu K mol^{-1} (17% spins with $S=1/2$) and the Weiss constant is $\theta=-5$ K. The finite Weiss constant of the polycrystalline sample results from the interaction between the Curie spins of high concentration. Since $(Dc)_3(PF_6)_2$ is mechanically unstable, the polycrystalline sample seems to include greater number of defects than the single crystals. Therefore, the large Curie paramagnetism in the polycrystalline sample is

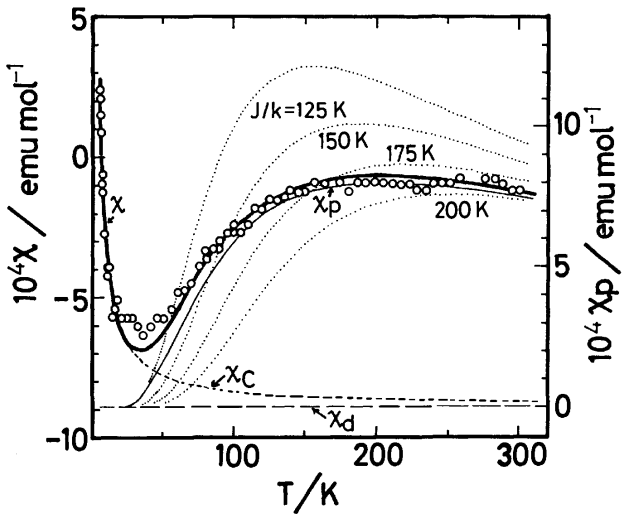

Fig. 6. Temperature dependence of static susceptibility of the bundle of single crystals of $(Dc)_3(PF_6)_2$ is shown by open circles. The diamagnetic (χ_d) and Curie (χ_C) contributions are represented by broken and dashed lines, respectively. The thin line indicates the intrinsic paramagnetic susceptibility (χ_P) calculated by the equation $\chi_P=(C/T)\exp(-E_m/kT)$ with $E_m/k=202$ K. The total susceptibility $\chi=\chi_P+\chi_C+\chi_d$ is shown by the thick line. The dotted lines show the theoretical curves calculated in terms of the single-triplet model with J/k=125, 150, 175, and 200 K.

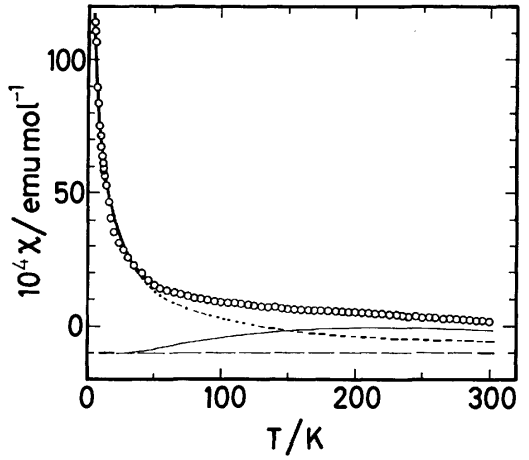

Fig. 7. Temperature dependence of static susceptibility of a polycrystalline sample of $(Dc)_3(PF_6)_2$. The lines represent the same meanings as shown in Fig. 7. It is to be noted that χ_C is about 25 times as large as that of the single crystals, while χ_P and χ_d alter a little.

ascribed to the increase of defects or paramagnetic centers produced by the crystal deterioration. Now it is clear that the Curie contribution observed in the single crystals of $(Dc)_3(PF_6)_2$ is extrinsic in origin and we analyze the paramagnetic susceptibility by subtracting the contribution.

The intrinsic paramagnetic susceptibility χ_P shown by the thin solid line in Fig. 6 is well described by the equation $\chi_P=(C/T)\exp(-E_m/kT)$ with E_m=17.4 meV or E_m/k=202 K. The diamagnetic (χ_d) and Curie (χ_C) contributions are represented by broken and dashed lines, respectively. The total susceptibility χ calculated by summing χ_P, χ_C, and χ_d is shown by the thick solid line in Fig. 6 and it agrees well, as a matter of course, with the observed susceptibility. The magnetic activation energy E_m obtained is about four times as small as the electric activation energy E_c. Such discrepancy is commonly observed for semiconducting organic ion radical solids and interpreted in terms of on-site Coulomb repulsion between itinerant electrons with AFM coupling.[19] The singlet-triplet model $\chi_P=(4C/T)[3+\exp(2J/kT)]^{-1}$ based on AFM coupling between two doublet sites fails to explain the intrinsic paramagnetism of $(Dc)_3(PF_6)_2$. In this case, the exchange coupling constant J/k should vary from 125 K below 50 K to 200 K above room temperature as shown by dotted lines in Fig. 6. Therefore, the AFM interaction among the spin centers residing on the decacyclene molecules seems to be not restricted within the nearest-neighbor spin centers but extended to second- and third-neighbors.

Discussion

The EPR and static susceptibility investigations demonstrate that $(Dc)_3(PF_6)_2$ is paramagnetic over the whole temperature range between 2 and 400 K. The activation behavior of susceptibility suggests the AFM coupling between unpaired electrons on the decacyclene molecules in spite of its capability to cause FM intermolecular interactions.

The decacyclene molecules seem to be stacked face-to-face taking into account their largely planar molecular structure, although the crystal structure of $(Dc)_3(PF_6)_2$ has not yet been solved. Namely, the decacyclene molecules are expected to form a segregated column structure. The 3:2 stoichiometry of the decacyclene salt with the monovalent anion PF_6^- indicates that two of three decacyclene molecules are formally ionized to monocation radicals and one of them remains neutral. The moderate conductivity observed for the salt supports such a mixed valence state. Therefore, $(Dc)_3(PF_6)_2$ can be regarded as a heterospin system consisting of the d^3 (Dc^+) and d^4 (Dc) configurations.

The models proposed by McConnell[1] and other authors[2-6] are based on the CT interaction within molecular dyads. Such a molecular dyad approach, however, could not be applicable to $(Dc)_3(PF_6)_2$ in the mixed valence state, because two different pairs of electronic configurations, i.e., d^3d^4 and d^4d^4, must be considered simultaneously. For the semiconducting cation or anion radical salts with 3:2 or 2:3 stoichiometry such as $(TTF)_3(BF_4)_2$,[24] $Cs_2(TCNQ)_3$,[25] and $Rb_2(TCNQ)_3$,[26] where the number of unpaired

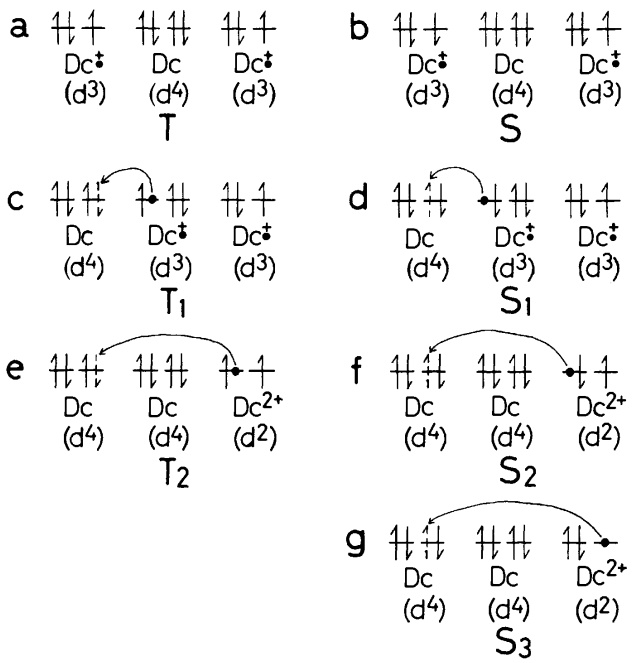

Fig. 8. Ground configurations T and S and excited charge-transfer configurations T_1, T_2, S_1, S_2, and S_3, for an electron transfer among monocation radicals and neutral molecule of decacyclene forming a triad.

electrons per molecule is 2/3 on an average, it is known that molecular triads consisting of the ionized molecules at each terminal and the neutral molecule at the center form an infinite stacking column in the solid. We assume therefore that $(Dc)_3(PF_6)_2$ crystallizes in this type of structure, since it is a semiconductive cation radical salt with 3:2 stoichiometry like $(TTF)_3(BF_4)_2$.

If this is the case, the ground electronic configuration of $(Dc)_3(PF_6)_2$, in the zero-th order approximation, can be described as a heterospin system composed of two d^3 and one d^4 states ($d^3d^4d^3$) as depicted schematically in Fig. 8a for the triplet state (T) and Fig. 8b for the singlet state (S). In terms of this configuration, the interaction is restricted within a triad. However, the discussion on the triad could be generalized to a system of an extended array of triads. Configurations T and S are the no-bond structures and they are nearly degenerate. Strictly speaking, T is slightly more stable than S by the direct exchange interaction represented by the exchange integral. However, such stabilization should be small in the case of intermolecular interaction.

There is a low-lying CT excited configuration ($d^4d^3d^3$ or $d^3d^3d^4$) in each of the triplet (T_1) and singlet (S_1) manifold as shown in Figs. 8c and 8d.[27] These excited configurations T_1 and S_1 admix with the ground configurations, thereby stabilizing T and S, respectively. The magnitude of stabilization is a function of the energy separation (diagonal term) and the magnitudes of the transfer integrals (off-diagonal terms) between the configurations concerned as discussed previously.[28] The diagonal terms in the triplet and singlet manifold would not be very different from each other because the excited configurations consist of two d^3 and one d^4 states as in the ground configurations; only the molecular sites on which the unpaired electrons reside are different. The off-diagonal terms for both manifolds would also not be very different from each other, although numerical calculations of the off-diagonal terms has not been carried out since the crystal structure is not determined yet. Therefore, the ground configurations T and S would be stabilized down to a similar amount by the admixture with the low-lying excited CT configurations T_1 and S_1.

Therefore, we have to consider other excited CT configurations of higher energy. Of these, the configurations T_2, S_2, and S_3 shown in Figs. 8e, 8f, and 8g[29] would contribute considerably to stabilization of the ground configurations T and S. The CT absorption band corresponding to the excitation to the state mainly consisting of S_2 or S_3, as well as that to the state based on S_1, is usually observed in the near-infrared region for most ion radical salts.[30] The diagonal terms for these configurations are, therefore, not too large in spite of on-site Coulomb repulsion on the dication of d^2 configuration. Further, the diagonal term for T_2 must be smaller than that for S_2 and S_3 by the amount of the intramolecular exchange energy. The transfer integral (off-diagonal term) of the salt is expected not to be small, because the transfer integral is known to be large for the cation radical salts of polycyclic hydrocarbons.[31] Therefore, the stabilizations of T and S by admixture of the configurations T_2, S_2, and S_3 are not negligibly small. Since there are two singlet configurations of nearly the same energy, the stabilization of S by admixture of S_2 and S_3 would surpass the stabilization of T, even though the diagonal term for T_2 is more favorable than that for S_2 and S_3. This is a possible reason why $(Dc)_3(PF_6)_2$ does not exhibit FM coupling. There are, of course, many other excited configurations of higher energy and these would also stabilize T and S. However, these would contribute to a similar amount in both manifolds.

Finally, it may be pointed out that there still remain other possibilities of destabilizing ferromagnetically coupled state. For example, there would be Jahn-Teller distortion[32] of a decacyclene molecule removing the orbital degeneracy to increase the diagonal term for the triplet configurations. Although it is known that the dianion of decacyclene has the triplet state as the lowest state in a solution,[7] the electronic structure of its dication is not known. It is therefore of great interest to investigate the molecular and crystal structure of $(Dc)_3(PF_6)_2$ to acquire further insight into the magnetic interaction in this salt.

Conclusion

We have synthesized the cation radical salt between decacyclene and hexafluorophosphate anion with 3:2 stoichiometry. The magnetic and electric properties of the salt were investigated by means of the conductivity, EPR, and static susceptibility measurements. The spin susceptibility of the semiconductive salt is thermally activated with the activation energy of 17 meV, being smaller than that of electrical conduction 66 meV. These results indicate that the unpaired electrons are coupled antiferromagnetically, although the salt apparently meets the requirements of the models for organic ferromagnetism. A possible reason why $(Dc)_3(PF_6)_2$ does not exhibit ferromagnetic intermolecular interaction has been discussed on the basis of the mixed valence state. It is worth noting that magnetic and structural investigations of the salt consisting solely of monovalent decacyclene ions and free from neutral molecules are inevitable to examine the simple and familiar models for ferromagnetic spin alignment based on charge-transfer interaction in organic compounds.

Calabrese, *Science*, **240**, 1185 (1988), shows experimentally that hexaazaoctadecahydrocoronene dication in its tetraflouroborate and hexafluorophosphate salts is distorted by the Jahn-Teller effect to stabilize the singlet ground state in the solids.

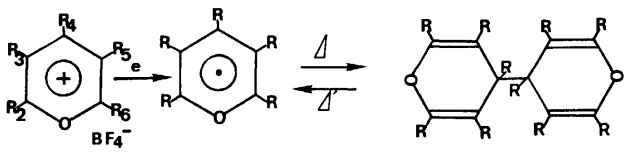
Pyranyl Radicals and Their Dimers

Hiroki KAWATA and Shigeya NIIZUMA*
College of Humanities and Social Sciences, Iwate University, Ueda, Morioka 020
(Received February 6, 1989)

Photochemical and chemical reduction of pyrylium salts in THF solution gave their corresponding radicals which were in equilibrium with dimers. The quantum yields for raidcal formation and the standard enthalpy change ΔH_0 for dimerization decrease with increasing the electron-donating character of the substituting groups in the pyrylium ring. Specially, ΔH_0 for pentaphenylpyranyl and pentaphenylthiopyranyl radicals, in which all carbons in the ring are substituted by phenyl groups, become possitive. The absorption maxima and their molar extinction coefficients of pyranyl radicals, and concurrently the equilibrium constants for the dimerization were determined spectrophotometrically.

Pyranyl radicals are formed by one-electron reduction of the parent pyrylium salts with chemical (organic reducing agent,[1] zinc or other metals,[2] and Grignard reagent[3]), electrochemical[4] and photochemical[5] reactions in the degassed aprotic solvents. They are in equilibrium with their diamagnetic dimers (Scheme 1). This equilibrium lies in favor of the radical at room temperature except the compounds which have a methyl group[1] or a hydrogen atom[2f,6a,c] at 4-position carbon in the pyrylium ring. In such compounds, no equilibrium is observed and the dimer is formed directly at room temperature, so that no ESR signal can be detected. The NMR spectra of the dimers obtained by zinc metal reduction or the reduction with disodiocyclooctatetraene reflected the configuration of the σ bonding between the 4-position carbons of each pyranyl moiety.[1,6c] The equilibrium between pyranyl radicals and their dimers is similar to the case of the dimerization of pyridinyl radicals,[7] where the dimeric intermediate, radical pair, was involved in the dimerization of the radical.

Photoirradiation of 2,4,6-triphenyl-, 2-*t*-butyl-4,6-diphenylpyrylium and 2,4,6-triphenylthiopyrylium tetrafluoroborates in degassed tetrahydrofuran (THF) gave the corresponding radicals by electron transfer from the solvent, THF, itself with relatively high quantum yields.[5] 2,4,6-Triphenylpyranyl radical has a light red color in THF solution and shows the ESR signal with well-resolved hyperfine structure (hfs) at room temperature. With decreasing the temperature, the color fades and at the same time the intensity of the ESR signal decreases because of its dimer formation. In this paper, the investigation of the chemical properties of various kinds of pyranyl radicals formed by the photoreduction or by the zinc metal reduction of pyrylium salts is reported. The dimerization of 2,3,4,5,6-pentaphenylpyranyl and 2,3,4,5,6-pentaphenylthiopyranyl radicals was found to be an endothermic reaction, it being remarkable in comparison with that of other pyranyl radicals.



Scheme 1.

Experimental

The pyrylium salts used are all tetrafluoroborates and were supplied by Prof. Suzuki in this University. They decompose gradually in solution if the solvent contains a small amount of water. The solvents THF and 2-methyl-THF (G.R. of Wako Junyaku) were distilled over calcium hydride and stocked on a sodium-potassium alloy in an ampoule connected to a vacuum line. Triphenylphosphine (G.R. of Kanto Kagaku) was recrystallized twice from ethanol. The degassed sample solution was exposed to a continuous irradiation in a 1×1×4 cm quartz cell. The light source was a Toshiba SHL-100 UV mercury lamp with Toshiba filter system (UVD-35 and L-1A for the 365 nm, P-39B and L-39 for the 406 nm, and V-40 and Y-43 for the 436 nm irradiation). The quantum yield of the photoreaction was determined at 25 °C using potassium tris-oxalatoferrate(III) as an actinometer. The absorption and the ESR spectra were measured with a Hitachi ERI-G3 spectrophotometer and a JEOL PE-1 or RE-2 ESR spectrometer, respectively. The ESR intensity was calculated by a double integration of the first derivative curve with a Graphtec KD-4030 degitizer on-line with a NEC PC-9801 personal computer. The absorption spectra at low tem-

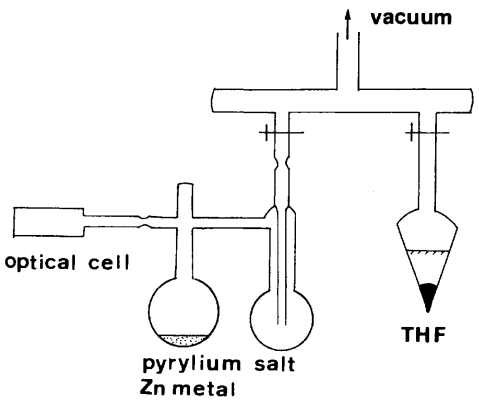


Fig. 1. Apparatus for the preparation of pyranyl radicals and the measurement of the absorption spectra.

perature were measured using a quartz Dewar vessel. The temperature was controlled with Dry Ice-methanol and liquid nitrogen.

The procedure of the preparation of the radical with zinc metal is as follows: Known amounts of pyrylium salt and an excess mole of zinc granular were put together into the reaction vessel connected to the vacuum line (see Fig. 1). After degassing the system, we introduced known amounts of solvent THF to it by distillation. The system was sealed and disconnected from the vacuum line. The solution was stirred with a Teflon-coated magnetic bar until the absorption of the starting material disappeared completely. All the sample solutions were degassed by means of the distillation method. The method of least squares was applied when a straight line was drawn in the analysis of the data.

Results and Discussion

Steady Light Irradiation. Photoirradiation of the degassed THF solution of 3-methyl-2,4,6-triphenyl-, (**1**), 2,3,4,6-tetraphenyl-, (**2**), 2,3,4,5,6-pentaphenyl-, (**3**), 2,4,6-tris(*p*-methoxyphenyl)pyrylium tetrafluoroborate (**4**), and 2,3,4,5,6-pentaphenylthiopyrylium tetrafluoroborate (**5**) gives the corresponding radicals when a reducing agent is added to the solution such as triphenylphosphine or hexamethylbenzene. Without these reductants, the radicals are not formed by the irradiation. Even with the reductants, they are not formed by dark reaction (i.e. by thermal reaction). The photoproducts for **2**, **3**, **4**, and **5** exhibited the strong but broad structureless ESR signals, while that for **1** had a well-resolved hfs. All of those photoproducts are considered to be neutral radicals produced by one-electron reduction. In the case of the photoreduction of 2,4,6-triphenylpyrylium salt, the solvent (THF) itself behaves as a reducing agent.

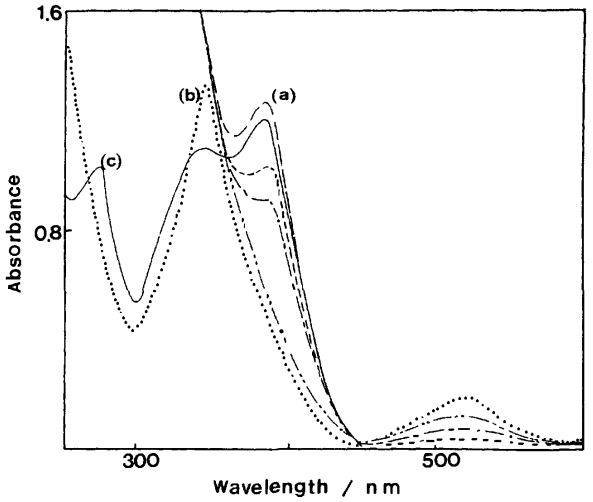

Fig. 2. (a) Spectral change of a solution of **1** containing 1.5×10^{-2} mol dm^{-3} triphenylphosphine on irradiation of 365 nm light with time: ——, 0 min; – – – –, 15 min; — — —, 45 min. (b) ------, Absorption spectrum of the radical for **1** (ca. 1.4×10^{-4} mol dm^{-3}) produced by the zinc metal reduction. (c) —, Absorption spectrum of **1** (1.4×10^{-4} mol dm^{-3}). All the spectra for (a), (b), and (c) were measured using the degassed THF solution and at 25°C.

On the photoirradiation, the concentration of pyrylium salts and triphenylphosphine were fixed to be 1.2×10^{-4} and 1.5×10^{-2} mol dm^{-3}, respectively. The irradiation wavelength was chosen to be 365 nm for **1** and **2**, 406 nm for **3** and **5**, and 436 nm for **4**. The spectral change observed on irradiating of **1** at 365 nm is shown in Fig. 2(a). The absorption of the product at 520 nm increases with the irradiation time at the expense of that of **1** at 385 nm. An isosbestic point appeares at 448 nm. The absorption band shorter than 330 nm could not be measured due to that of triphenylphosphine overlapping there. All the photoproducts have a very weak absorption extending beyond 900 nm. Molar extinction coefficient, ε, is 50—200 dm^3 mol^{-1} cm^{-1} at the wavelength region 600—900 nm. Since both pyrylium salts and the corresponding dimers have no absorption band at the wavelength 480—570 nm, the quantum yields for the formation of radical can be determined photometrically using the second main peak of radicals located in this region (discussed later) if only the extinction coefficient of the radical and the equilibrium constant K_d for the dimer formation are known. On the other hand, the same radicals as those produced by photoreaction were obtained chemically by the reduction with granules of zinc metal in degassed THF solution. The absorption spectrum of the radical produced from **1** obtained in this way is shown in Fig. 2(b). It has the absorption maxima at 342 and 520 nm. Making a comparison between the absorption spectrum of **1** (Fig. 2(c)) and that of the zinc reduction product, we found that **1** was quantitatively converted into the radical by zinc metal reduction. Other pyrylium salts are also reduced completely to the corresponding radicals by zinc metal. The radicals obtained in this way are stable in the degassed THF solution. But they all decompose on introducing air to the solution except for the radical from **4**, which reverts to the starting substance.

In order to know the exact molar extinction coefficients of these radicals, we must refer to the reaction the radical is concerned with. Consider the equilibrium between the radical and its dimer as

$$2\,\text{Radical} \rightleftarrows \text{Dimer}. \qquad (1)$$

The equilibrium constant K_d for the dimer formation is

$$K_d = [D]/[R]^2 = \{C_0 - [R]\}/2[R]^2, \qquad (2)$$

where [D] and [R] are the concentration of the dimer and the radical, respectively, and C_0 is the initial concentration of the pyrylium salt and equals [R]+2[D]. If α is the ratio of [R] to C_0,[8] then K_d is

$$K_d = (1 - \alpha)/2C_0\alpha^2. \qquad (3)$$

Table 1. Absorption Maxima of Radicals, Quantum Yield of Radical Formation, Standard Enthalpy Variation for Dimer Formation, and Equilibrium Constant of Dimer Formation

Compound	Absorption maxima (nm) and ε of radicals[a]	Quantum yield of radicals[b]	ΔH_0/kcal mol^{-1} for 2R ⟶ D	K_d (25 °C)
1	342(10800), 520(1780)	0.022	−14.5[c], −14.2[d]	1690
2	345(13800), 515(3180)	0.029	−12.3[c]	875
3	355(11200), 376(11000) 490(3760)	0.017	+2.36[d]	18700
4	358(34600), 562(3770)	0.014	−15.4[c]	505
5	363(10900), 470(1690)	—	+3.72[d]	1770

a) Obtained by the use of the Eq. 5 in degassed THF solution and ε is in 10^{-3} mol^{-1} cm^2. b) Quantum yield for the radical formation irradiated with the 365 nm for **1** and **2**, the 405 nm for **3** and the 436 nm for **4** at 25 °C. The value for **5** could not be determined since the absorption of the starting **5** was overlapping to that of the radical around 470 nm because of the conjugation of *p*-methoxyphenyl group with pyrylium ring. c) Determined photometrically. d) Determined by the ESR method.

We define the apparent molar extinction coefficient ε at a given wavelength by the following equation.

$$\varepsilon = \alpha\varepsilon_R + (1 - \alpha)\varepsilon_D/2. \quad (4)$$

Here, ε_R and ε_D are the molar extinction coefficients for the radical and its dimer. As the dimer has no absorption at an observing wavelength, we put ε_D as zero. Then, Eq. 3 becomes Eq. 5.

$$\varepsilon = \varepsilon_R - (2K_d/\varepsilon_R)\, C_0\varepsilon^2. \quad (5)$$

We derive respectively ε_R and K_d from the intercept and the slope of the straight line obtained by plotting ε vs. $C_0\varepsilon^2$. The absorption maxima and their molar extinction coefficients for the several kinds of radicals generated by the reduction with the zinc metal are summarized in Table 1 together with the equilibrium constants for the dimerization. The K_d value for **2** was determined to be 875 (at 515 nm) and 915 dm^3 mol^{-1} (at 345 nm) by the method mentioned above. The former is more reliable than the latter in view of the absorption band purity.

The quantum yields listed in Table 1 were calculated as follows: the initial concentration of the radical, $[R]_0$, formed by the irradiation is expressed as $[R]_0=[R]+2[D]$. [R] can be obtained directly from the absorption of the radical and [D] can be calculated from the relation $[D]=K_d[R]^2$. Thus, we can know the true concentration of the radical immediately after irradiation. The quantum yields listed in Table 1 indicate that the compound containing the pyrylium ring substituted by the stronger electron-donating groups has a lower quantum yield. The quantum yields of 2,4,6-triphenylpyranyl and 2,4,6-tris(*p*-methoxyphenyl)pyranyl radical formation are respectively 0.21[5] and 0.014, the latter containing three additional methoxyl groups to the former. The same tendency is seen in the data for **1**, **2**, and **3**. This is explained by the fact that the electron-donating group destabilizes the lowest unoccupied molecular orbital (LUMO) of the pyrylium cation and, as a consequence, destabilizes the highest occupied molecular orbital (HOMO) of the radical. The pyrylium salt substituted by electron-donating group has a higher absolute value of the reduction potential,[2f,9] which is related to the LUMO with the equation of $E_{red}{}^{1/2}= E(\mathrm{LUMO})+C$.[10] Here $E_{red}{}^{1/2}$ is the reversible polarographic half-wave reduction potential and C is a constant including the potential of the reference electrode. All the pyranyl and thiopyranyl radicals prepared so far have the absorption maxima at the wavelength region from 340 to 360 nm, 470 to 560 nm and near IR (weaker compared with the other two bands). These characteristic absorption bands are very useful in identifying the pyranyl or thiopyranyl radicals.

Dimerization of Pyranyl Radicals. Generally the pyranyl radicals are in equilibrium with their corresponding dimers as described above. It is confirmed by measuring the change of the intensity of the ESR signals and/or of the absorbance of the pyranyl radicals with various temperature range. Figure 3 depicts the temperature dependence of the absorption spectra of the radical for **1** in THF. The 520 nm band decreases in intensity with lowering the temperature and almost disappears at −50 °C. It recovers, however, the original intensity through warming back to the room temperature. The equilibrium is favorable for dimer at low temperature. While 2,2′,4,4′,6,6′-hexamethyl-4,4′-bi-4*H*-pyran has a tail of the absorption band at 220 nm in ethanol,[1] 2,2′,3,3′,5,5′,6,6′-octaphenyl-4,4′-bi-4*H*-pyran shows the absorption maxima at 248 nm and the shoulder at 290 nm in degassed THF solution.[6c] 2,2′,4,4′,6,6′-Hexaphenyl-4,4′-bi-4*H*-pyran has an absorption band at 248 nm in degassed cyclohexane.[2a] Thus, we can infer from their structure that the σ-bonding dimers of other radicals may have no absorption band at longer wavelength region.

We can know the concentration of the radicals which come to equilibrium with their dimers by observing the absorbance at 520 nm for the radical from **1**, 515 nm for that from **2**, 490 nm for that from **3**, 562 nm for that from **4**, and 470 nm for that from **5** at a

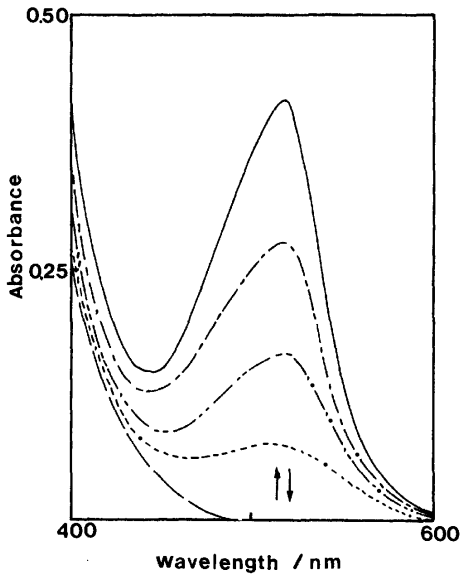

Fig. 3. Temperature effect on the absorption spectrum of the radical for **1**. The concentration of the radical is 2.4×10^{-4} mol dm^{-3}. (a) —, 25 °C; (b) – –, 10 °C; (c) – · –, −5 °C; (d) ·····, −20 °C; (e) – – –, −50 °C. These changes are reversible.

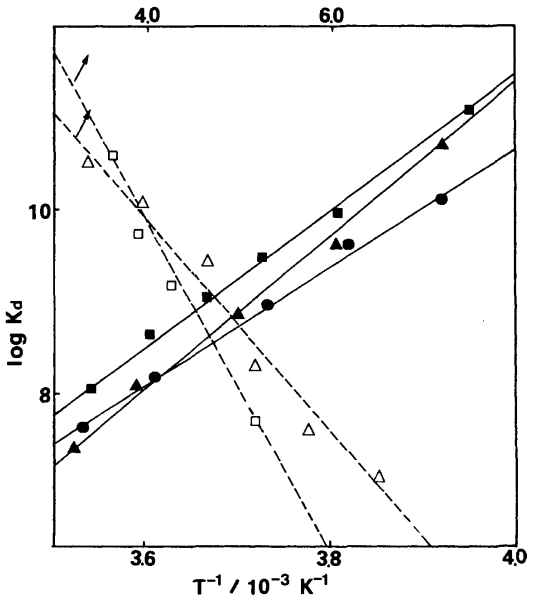

Fig. 4. The plot of $\log K_d$ for the various dimer formations vs. T^{-1}; (■) for **1**, (●) for **2**, (▲) for **4**, (△) for **3**, and (□) for **5**.

given temperature. The plot of $\log K_d$ (from Eq. 2) against T^{-1} gave a good linear correlation for various radicals as shown in Fig. 4. From the possitive slope of these lines, the standard enthalpy change ΔH_0 involved in the dimer formation are calculated to be −14.5, −12.3, and −15.4 kcal mol^{-1} for **1**, **2**, and **4**, respectively, as listed in Table 1. On the contrary to the above cases, the intensity of the absorbance of the radical from **3** at 490 nm increases with lowering the

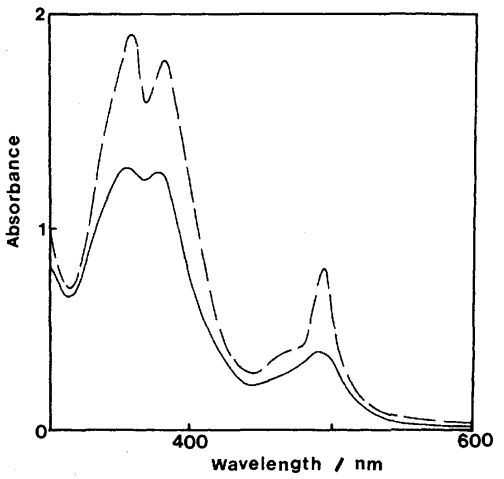

Fig. 5. The absorption spectra of the radical for **3** in the degassed 2-methyl-THF solution: (a) —, 25 °C; (b) – –, 77 K. The concentration of the radical is 1.0×10^{-4} mol dm^{-3}.

temperature and vice versa. Similarly the absorption of the radical from **5** behaves the same temperature dependence as that from **3**.

Figure 5 shows the absorption spectra of the 2-methyl-THF solution of the radical from **3** at room temperature and 77 K, respectively. Indeed the 355, 376 and 490 nm absorbances for the radical increase at 77 K.

The amount of the absorbance change within the temperature range of −40—+30 °C is so small and not enough to determine ΔH_0 for the radicals from **3** and **5**. We took advantage of their ESR signals, which were easily measurable over a wide range of temperature. The equilibrium constant K_d can be calculated by Eq. 6, provided we estimate the signal intensity at an infinite (either plus or minus) temperature, I_∞, by the extraporation.

$$K_d = (I_\infty - I)/I^2. \quad (6)$$

The standard enthalpy change for the dimerization of the radical for **1** obtained by the ESR method is −14.2 kcal mol^{-1}, which is in good agreement with that determined photometrically, −14.5 kcal mol^{-1}. ΔH_0 for **3** and **5** determined by the ESR method are possitive, being 2.36 and 3.72 kcal mol^{-1}, respectively. ΔH_0 of the latter is larger than that of the former. This should be attributed to the difference in the electronegativities between oxygen and sulfur atom in the heterocycles: the oxygen atom enhances the electron-donating charactor of the phenyl groups more than the sulfur atom does. Consequently, the oxygen destabilizes the radical more than the sulfur does. This argument is applicable for the difference in K_d between **3** and **5**. The K_d for the former is larger about one order of magnitude than that for the latter, as similar to the results for 2,4,6-triphenylpyranyl radical and

2,4,6-triphenylthiopyranyl radical.[20] The order of the electron-donating power of the substituents is *p*-methoxyphenyl>methyl>phenyl group. ΔH_0 values for the compounds containing these three groups increases in this order (see Table 1). This may be due to the radical destabilizing character of the electron-donating groups. On the other hand, as the number of phenyl group increases, the values of ΔH_0 of the radicals for **3** and **5** become large, and turn to positive, the equilibrium between radical and its dimer being favorable for radical at low temperature. This abnormality can be explained by the steric hindrance of the phenyl groups with respect to the dimerization (see below).
